Zusammenfassung

Das Experiment QUENCH-16 mit Lufteinbruch wurde im Juli 2011 in der QUENCH-Anlage mit einem elektrisch beheizten 21-Stab Bündel durchgeführt. Der Versuch fand im Rahmen des von der EU gesponserten LACOMECON Programms statt; er wurde von AEKI Budapest vorgeschlagen und in Kooperation mit weiteren Institutionen (PSI, EdF, GRS) geplant.

QUENCH-16 war der zweite Versuch mit Lufteinbruchphase im Rahmen des QUENCH Programms. Im Unterschied zu QUENCH-10 waren bei QUENCH-16 1) die während der Voroxidationsphase in Dampf gebildete Oxidschicht deutlich geringer, 2) die Sauerstoffmangelphase während des Lufteinbruchs signifikant länger und 3) die Temperatur bei der Initiierung des Flutens geringer. Trotzdem wurde während des Flutens signifikante Temperatureskalation gemessen, verbunden mit der Freisetzung von deutlich größeren Mengen an Wasserstoff, verglichen mit der Quench-Phase des QUENCH-10-Tests.

In metallographischen Nachuntersuchungen des Bündels, und insbesondere auch der während des Versuchs gezogenen Eckstäbe, wurde die Bildung von Zirkoniumnitrid über weite Bündelbereiche beobachtet. Diese ZrN Phasen wurden vorzugsweise während der Sauerstoffmangelphase gebildet. Während des Flutens des Bündels wurde ein Großteil der Nitride wieder oxidiert, was zur Bildung von extrem porösen und somit nicht-schützenden Oxidschichten geführt hat. Die erhöhte Wasserstoffproduktion während des Flutens hängt ursächlich mit dem Lufteinbruch zusammen und wurde verursacht durch 1) die schnelle Oxidation von ZrN, 2) die Reaktion von Zirkonium mit Dampf, der durch die nichtschützende poröse Oxidschicht zum Metall gelangt und 3) die Oxidation von Metallschmelze.

Abstract

The out-of-pile bundle experiment QUENCH-16 on air ingress was conducted in the electrically heated 21-rod QUENCH facility at KIT in July 2011. It was proposed by AEKI Budapest and performed in the framework of the EC supported LACOME program. The test scenario was based on coordinated planning analyses by PSI, EdF and GRS.

The primary aims were to examine the oxidation of the Zircaloy-4 claddings in air following a limited pre-oxidation in steam, and to achieve a long period of oxygen starvation to promote interaction with the nitrogen. QUENCH-16 was thus a companion test to the earlier air ingress experiment, QUENCH-10, which was performed with strongly pre-oxidized bundle. Unlike QUENCH-10, significant temperature escalation and intensive hydrogen release were observed during the reflood phase.

Post-test investigations of bundle cross sections reveal many residual nitride traces at various elevations. The nitrides were formed during the oxygen starvation stage of air ingress. The upper oxide scales above nitrides have a porous structure due to re-oxidation of nitrides during reflood. Under this outer scale the relative thick oxide layer was formed during reflood. At lower bundle elevations frozen partially oxidized melt was detected, relocated from upper elevations. Three contributors for intensive hydrogen production during reflood were identified: 1) re-oxidation of nitrides, 2) secondary oxidation of cladding metal by steam penetrated through the porous re-oxidized scales and 3) melt oxidation.

Introduction

Air ingress issues have received considerable attention in recent years in view of the likely acceleration of the cladding oxidation, fuel rod degradation, and the release of some fission products, most notable ruthenium. The Paks NPP cleaning tank incident and the accident at Fukushima Daiichi drew attention to the possibility of overheated fuel assemblies becoming exposed to air outside of the reactor.

Experimental and analytical works on air ingress were performed within the EC 4th and 6th Framework Programs [1, 2]. Numerous single effect tests on cladding oxidation in air were performed at ANL [3] (temperatures 300-900°C; alloys Zircaloy-4, ZIRLO, M5), AEKI [4] (temperatures 600-1500°C), IRSN [5] and KIT [6, 7] (temperatures 700-1600°C). The recent OECD/NEA project SFP investigated the performance of full-scale 17x17 PWR assemblies in air with special emphasis on thermal-hydraulic and ignition phenomena [8]. A number of previous out-of-pile bundle air ingress tests have been performed under a range of configurations and oxidizing conditions, namely CODEX AIT-1, AIT-2 with small 9-rod bundles [9], QUENCH-10 with 21-rod strong pre-oxidized bundle [10, 11] and PARAMETER-SF4 with finally molten 19-rod bundle [12]. The accumulated data have demonstrated that air oxidation of cladding is a quite complicated phenomenon governed by numerous processes whose role can depend on the oxidizing conditions, the oxidation history and the details of the cladding material specification. The models for air oxidation do not yet cover the whole range of representative conditions. The main aims of new bundle tests should be the investigation of areas where data were mostly missing.

The QUENCH-16 bundle test was proposed by AEKI (MTA EK / Hungary) in the framework of the EC-sponsored LACOMECON program [13] as part of the collective investigation of air ingress into overheated nuclear fuel assemblies. The experiment focused specifically on the following phenomena:

- air oxidation after rather moderate pre-oxidation in steam;
- slow oxidation and nitriding of cladding in high heated air and transition to rapid oxidation and temperature excursion;
- role of nitrogen under oxygen-starved conditions,
- formation of oxide and nitride layers on the surface of cladding;
- release of hydrogen from oxidized zirconium during air ingress scenario;
- reflooding of the oxidized and nitrated bundle by water, release of nitrogen.

The proposal included a target scenario characterized by:

- a long period of oxygen starvation to promote the occurrence of the above phenomena;
- reflood quench initiated at temperatures well below the melting point of the cladding to provide the opportunity of avoiding a major oxidation, to facilitate post-test inspection of the bundle.

Concerning the second objective, it was realized that avoiding such an excursion could not be guaranteed, especially in the light of previous experiments such as PARAMETER-SF4 which showed clearly how a starvation period can promote an excursion. The outcome would in any case yield valuable data on this phenomenon.

QUENCH-16 was successfully performed on 27 July 2011 in the QUENCH facility at KIT. The facility is well qualified for such kind of large-scale bundle experiments and was approved during long period of operation, during which a lot of experiments with different test parameters were conducted (Table 1). The QUENCH-16 experiment was performed according to a test protocol following the outcome of discussions among the participants and based on coordinated planning analyses by GRS, EDF and PSI using independent simulation tools.

1 Test facility

The main components of the QUENCH test facility are presented in [Fig. 1](#). The test section is enclosed by a safety containment with a wall thickness of 5.6 mm and an inner diameter of 801.8 mm. The facility can be operated in two modes: a forced-convection mode depicted in the flow diagram of [Fig. 2](#) and a boil-off mode. In the forced-convection mode (relevant for QUENCH-16) superheated steam from the steam generator and superheater together with argon as a carrier gas enter the test bundle at the bottom ([Figs. 3 and 4](#)). The system pressure in the test section is around 0.2 MPa. The quenching water is injected through a separate line marked “bottom quenching” in [Fig. 3](#).

The argon, the steam and air not consumed, and the hydrogen produced in the zirconium-steam reaction flow from the bundle outlet at the top through a temperature-controlled off-gas pipe to the condenser where the steam is separated from the non-condensable gases. The water cooling circuits for bundle head and off-gas pipe are temperature-controlled to guarantee that the steam/gas temperature is high enough so that condensation at test section outlet and inside the off-gas pipe can be avoided. The temperature at the bundle head is kept at 348 K, and the flow rate of the cooling water is 250 g/s.

The off-gas pipe system ([Fig. 14](#)) contains a water-cooled outer jacket with a water flow rate of 370 g/s. The water inlet temperature for the jacket is controlled at 393 K. Between the inner off-gas pipe and inner tube of the cooling jacket there is stagnant off-gas (yellow gap in [Fig. 14](#)). The main dimensions of the tubes that make up the off-gas pipe are:

Inner pipe: outer diameter 139.7 mm, wall thickness 4.5 mm, total length 3256 mm, material: stainless steel.

Inner tube of cooling jacket: outer diameter 154 mm, wall thickness 2 mm, material: stainless steel.

Outer tube of cooling jacket: outer diameter 168.3 mm, wall thickness 5 mm; material: stainless steel.

The design characteristics of the test bundle are given in [Table 2](#). The test bundle is made up of 21 fuel rod simulators, each with a length of approximately 2.5 m, and of four corner rods (see cross section in [Fig. 5](#)). The fuel rod simulators ([Figs. 6 and 7](#)) are held in their positions by five grid spacers, four of Zircaloy-4, and one of Inconel 718 in the lower bundle zone. All test rods, excluding the rod in the bundle center, are heated electrically with tungsten heaters over a length of 1024 mm and are filled with Kr at a pressure of approx. 0.22 MPa. The heated rods ([Fig. 6](#)) were connected to a controlled feeding system that compensated minor gas losses and allowed observation of a first cladding failure as well as a progression of rod failure. The rod cladding of the heated and unheated fuel rod simulator is Zircaloy-4 with 10.75 mm outside diameter and 0.725 mm wall thickness (see also [Table 2](#)).

Tungsten heating elements of 6 mm diameter are installed in the center of the heated rods and are surrounded by annular ZrO₂ pellets. The physical properties of the ZrO₂ pellets are described in [Table 3](#). The tungsten heaters (chemically clean tungsten) are connected to electrodes made of molybdenum (chemically clean molybdenum) and copper (material 2.1293 with Cr 0.8, Zr 0.08 and rest Cu) at each end of the heater. The molybdenum and copper electrodes are joined by high-frequency/high-temperature brazing under vacuum (2×10^{-3} mbar) using an AuNi 18 powder (particle size <105 μm). The electrical resistance of

internal rod heating system, combined from W heater and Mo-copper electrodes, was measured before (at the end of bundle assembling) and after the test ([Table 4](#)). The measured electric resistance of a single heater (W+Mo+Cu sections) is 3.4 mΩ at room temperature. This value increases significantly with temperature. The additional resistance of the external electric circuit between the axial end of the single heater and the connection to the generator (sliding contacts, cables, and bolts) is 1.46 mΩ + 0.22 mΩ = 1.68 mΩ. This value can be taken as constant because the external electric circuit remains at ambient temperature throughout the experiment.

For electrical insulation the surfaces of both types of electrodes are plasma-coated with 0.2 mm ZrO₂. To protect the copper electrodes and the O-ring-sealed wall penetrations against excessive heat they are water-cooled (lower and upper cooling chambers filled with demineralized water). The copper electrodes are connected to the DC electric power supply by means of special sliding contacts at the top and bottom. The maximum total heating power available is 70 kW. The distribution of the electric power within the two groups is as follows: about 40 % of the power is released into the inner rod circuit consisting of eight fuel rod simulators (in parallel connection) and 60 % in the outer rod circuit (12 fuel rod simulators in parallel connection).

The lower boundary for the lower cooling chamber is a sealing plate made of stainless steel with plastic inlays for electrical insulation, sealed toward the system by O-shaped rings. The upper boundary of the lower cooling chamber is a sealing plate of stainless steel. An insulation plate made of plastic (PEEK) forms the top of the upper cooling chamber, and a sealing plate of Al₂O₃, functioning as a heat-protection shield, is the lower boundary of the upper cooling chamber (see [Fig. 6](#)).

In the region below the upper Al₂O₃ plate the copper electrode is connected firmly to the cladding. This is done by rotary swaging the cladding onto the electrode. In the swaging region a sleeve of boron nitride is put between electrode and cladding for electrical insulation. The axial position of the fuel rod simulator in the test bundle is fixed by a groove and a locking ring in the top Cu electrodes. Referred to the test bundle the fixing point of the fuel rod simulators is located directly above the upper edge of the upper insulation plate. So, during operation the fuel rod simulators are allowed to expand downwards. Clearance for expansion of the test rods is provided in the region of the lower sealing plate. Also in this region, relative movement between cladding and internal heater/electrode can take place.

The test bundle is surrounded by a 3.05 mm thick shroud (82.8 mm ID) made of Zr 702 with a 34 mm thick ZrO₂ fiber insulation (physical properties are given in [Table 5](#)) and an annular cooling jacket made of Inconel 600 (inner tube) and stainless steel (outer tube); see [Fig. 5](#). The annulus between shroud and cooling jacket was filled (after several cycles of degasing) with stagnant argon of 0.22 MPa and was connected to a flow-controlled argon feeding system in order to prevent steam access to the annulus after shroud failure. The 6.7 mm annulus of the cooling jacket is cooled by an argon flow. Above the heated zone, i.e. above the 1024 mm elevation there is no ZrO₂ fiber insulation to allow for higher radial heat losses. This region of the cooling jacket is cooled by a water flow ([Figs. 3 and 4](#)). Both the lack of ZrO₂ insulation above the heated region and the water cooling force the axial temperature maximum downward.

Insertion of four corner rods avoids an atypically large flow cross section at the outer positions and hence helps to obtain a rather uniform radial temperature profile. There are four corner rods installed in the bundle. Two of them, i.e. rods “A” and “C” are made of a Zircaloy-4 solid rod \varnothing 6 mm at the top and a Zircaloy-4 tube (outer \varnothing 6 mm, inner \varnothing 4.2 mm) at the bottom and are used for thermocouple instrumentation. The other two rods, i.e. rods “B” and “D” (solid Zircaloy-4 rods of 6 mm diameter) are particularly determined to be withdrawn from the bundle to check the degree of oxidation and hydrogen uptake at specific times. In QUENCH-16 three corner rods were used for analysis of the oxide layer thickness. Rod B was pulled out of the bundle before air ingress, rod D before quenching and rod A was removed after test termination.

2 Instrumentation and data acquisition

For **temperature** measurements the test bundle, shroud, and cooling jackets are equipped with thermocouples at orientations and elevations as illustrated in [Fig. 8](#) and [Fig. 9](#) correspondingly, and listed in [Table 6](#). An overview of the positions of the bundle thermocouples is given in [Table 7](#). There are 40 high-temperature (W/Re) thermocouples in the upper hot bundle region (bundle and shroud thermocouples between elevations 650 and 1350 mm) and 32 low-temperature (NiCr/Ni) thermocouples in the lower “cold” bundle region (bundle and shroud thermocouples between -250 and 550 mm).

The dimensions of the thermocouple components are provided in [Table 8](#), some properties of the thermocouple insulator in [Table 9](#). The thermocouples attached to the outer surface of the rod cladding at elevations between -250 and 1350 mm are designated “TFS” for all heated rods.

In the lower bundle region, i.e. up to 550 mm elevation, NiCr/Ni thermocouples with stainless steel sheath/MgO insulation and an outside diameter of 1.0 mm are used for measurements of the rod cladding and shroud temperatures. The thermocouples in the hot zone and above are high-temperature thermocouples with W5Re/W26Re wires, HfO₂ insulation, and a duplex sheath of tantalum (inside) and Zircaloy (outside) with an outside diameter of about 2.2-2.3 mm ([Fig. 10](#)).

The thermocouple attachment technique for the surface-mounted high-temperature TCs is shown in [Fig. 11](#) and [Fig. 15](#). The TC tip is held in place by two clamps of zirconium (0.2 mm thick). As these clamps are prone to oxidation and embrittlement in a steam environment an Ir-Rh wire of 0.25 mm diameter is additionally used in test QUENCH-16. The leads of the thermocouples from the -250 mm to the 850 mm level leave the test section at the bottom whereas the TCs above 850 mm are routed to the top avoiding to route TC cables through the hot zone (see [Fig. 9](#)).

Additionally, the cables of shroud thermocouples (designated TSH xx/x “I”) were routed toward outside the shroud insulation to avoid heat transfer from the shroud into the TC cable, apart from the TC junction. The shroud thermocouples are mounted at the outer surface between -250 mm and 1250 mm.

The thermocouples that are installed inside the Zircaloy instrumentation rods at the two corner positions of the bundle (positions A, and C) are designated “TIT” (see [Fig. 12](#)). All “TIT” thermocouples are of the high-temperature type. The thermocouples of the cooling jacket (TCI and TCO) are 1 mm NiCr/Ni thermocouples with stainless steel sheath for all levels. The thermocouples of the cooling jacket are installed inside the wall of the inner cooling tube (from -250 mm to 1150 mm, designation “TCI”) and at the outer surface of the outer cooling tube (from -250 mm to 950 mm, designation “TCO”) as illustrated in [Fig. 8](#).

The thermocouples which failed during the experiment are listed in [Table 10](#).

The off-gas including Ar, H₂, O₂, N₂ and steam is analysed by a state-of-the-art mass spectrometer “Balzers GAM300” ([Fig. 13](#)) whose sampling tube is connected with the off-gas pipe. The mass spectrometer allows also indicating the failure of rod simulators by detection of Kr release.

The **mass spectrometer** “BALZERS GAM 300” is a completely computer-controlled quadrupole MS with an 8 mm rod system which allows accurate quantitative measurement of gas concentrations down to about 10 ppm. For the MS measurement a sampling tube is inserted in the off-gas pipe located approx. 2.7 m downstream from the test section outlet (see [Fig. 2](#) and [4](#)). It has several holes at different elevations to guarantee that the sampling of the gas to be analyzed is representative ([Fig. 14](#)). To avoid steam condensation in the gas pipes between the sampling position and the MS the temperature of the gas at the MS inlet is controlled by heating tapes to be between 110 and 150 °C (the upper operating temperature of the MS inlet valves). This allows the MS to analyze the steam production rate. Besides, the concentrations of the following species were continuously measured by the mass spectrometer during all test phases: argon, hydrogen, steam, nitrogen, oxygen, and krypton. The fuel rod simulators are filled with krypton which can be used as an indicator for a cladding failure. Additionally, the MS is used to control the atmosphere in the facility, e.g., to monitor the gas composition at the beginning of the test.

The temperature and pressure of the analyzed gas are measured near the inlet valve of the MS. The MS is calibrated for hydrogen, oxygen and nitrogen with well-defined argon/gas mixtures and for steam with mixtures of argon and steam supplied by a Bronkhorst controlled evaporator mixing (CEM) device. The MS off-gas is released into the atmosphere because the amount of hydrogen taken out of the system is negligible. A heated measuring gas pump was used to ensure a continuous flow of the steam-gas mixture from the off-gas pipe to the mass spectrometer.

For the MS device the mass flow rates of the gases of interest are calculated by referring the measured concentrations to the known argon mass flow rate according to equation (1):

$$\dot{m}_i = \frac{M_i}{M_{Ar}} \cdot \frac{C_i}{C_{Ar}} \cdot \dot{m}_{Ar} \quad (1)$$

with M representing the molecular masses, i the index of the gas, C the concentrations in vol-% and \dot{m} the mass flow rates of the corresponding gases. Instead of argon other gas with known flow rate can be used (e.g. steam, as applied for the quench phase of the QUENCH-16 test due to switch-off the argon as carrier gas).

The data of the main **data acquisition** system and of the mass spectrometer were stored on different computers. All computers were synchronized against each other. The data of the main acquisition system as well as those of the mass spectrometer data were stored at a frequency of 1 Hz, the ones with the MS with approximately 1.1 Hz. The latter were interpolated to 1 Hz for further data processing.

3 Test performance

3.1 Test conduct and results of on-line measurements

The test was performed with a bundle similar to that used in the QUENCH-10. The experience of the QUENCH-10 test provided very valuable information for test preparation and for this reason the QUENCH-16 scenario was specified with the modification of QUENCH-10 scenario. Two important changes were considered in the QUENCH-16 scenario:

- The pre-oxidation period was shortened compared to QUENCH-10 to produce thinner oxide scale on the cladding (100-200 μm instead of 500 μm). The oxidation temperature and power were kept similar to QUENCH-10.
- The air ingress phase lasted longer and the maximum temperature was lower than in QUENCH-10. During the specification of the test conditions it was emphasized that oxygen starvation should be established in the upper part of the bundle. To reach such conditions the electrical power, the air and argon flow rates were reduced. It was proposed to have an average heat-up rate in this phase between 0.1-0.2 K/s.

In summary the QUENCH-16 test was conducted with the following tests phases:

Preparation	Heat-up in a flow of 3.4 g/s superheated steam and 3 g/s argon to peak cladding temperature $T_{\text{pct}} = 873 \text{ K}$.
Phase I	Stabilization in a flow of 3.4 g/s superheated steam and 3 g/s argon at 873 K; facility checks.
Phase II	Heat-up in a flow of 3.4 g/s superheated steam and 3 g/s argon with 0.1-0.4 K/s to 1300 K during 2300 s
Phase III	Pre-oxidation of the test bundle in a flow of 3.4 g/s superheated steam and 3 g/s argon during 4000 s at temperatures increasing from 1300 K to 1430 K
Phase IV	Intermediate cooling from 1430 K to 1000 K during 1000 s in the same flow of steam and argon.
Phase V	Air ingress and transient heat-up from 1000 K to 1873 K with slow heating rate of 0.2 K/s in a flow of 0.2 g/s of air and 1 g/s argon for 4040 s. Total oxygen consumption during 835 s before end of this phase.
Phase VI	Quenching of the bundle by a flow of 53 g/s of water; argon was switched off. Temperature escalation to 2420 K with intensive hydrogen release.

The detailed sequence of the test events is described in [Table 11](#). [Fig. 16](#) illustrates the phases of test performance. The readings of all cladding and shroud thermocouples are presented in [Figs. 17 – 33](#) separately for each elevation.

In the pre-oxidation phase and following slow cooling phase the claddings were oxidized in superheated steam (3.4 g/s). The maximal ZrO_2 thickness measured at corner rod B withdrawn after phase IV was 130 μm ([Fig. 50](#)). In the subsequent air ingress phase, which lasted 4035 s, the steam flow was replaced by 0.2 g/s of air. [Fig. 34](#) presents an overview of thermocouple readings during the end of this and the beginning of quench phases. The change in flow conditions had the immediate effect of reducing the heat transfer so that the temperatures began to rise again. The generally limited rate of temperature increase was the result of a rather low air flow rate, probably not untypical for reactor or spent fuel pool conditions. The faster temperature increase was most marked at the mid elevations of the bundle ([Fig. 16](#) and [Fig. 34](#)). As result, the axial temperature maximum was shifted from elevation 950 to 550...750 mm ([Figs. 35 – 36](#)). After some time measurements demonstrated gradually an increasing consumption of oxygen, accompanied by acceleration of the temperature increase at certain locations.

Oxygen was completely consumed at about 3200 s after beginning of air ingress ([Fig. 37](#)). Shortly before that time, partial consumption of the nitrogen was first observed, indicating local oxygen starvation which promoted the onset of nitriding. Following this, the temperature continued to increase until water injection was initiated when the maximum observed temperature was about 1873 K. Thus there was a period of about 835 s complete oxygen consumption and hence starvation in upper part of the bundle. During this time period the residual steam has reacted with bundle materials, resulting in negligible release of hydrogen ([Fig. 38](#)). The total hydrogen release measured before reflood initiation was about 16 g. The total uptakes of oxygen and nitrogen were about **58** and **29 g**, respectively.

Reflood was initiated by injecting 53 g/s of water ([Fig. 39](#)). The quench initiation was indicated also with system pressure oscillations ([Fig. 40](#)) and sharp increase of condensed water ([Fig. 41](#)). Almost immediately after the start of reflood there was a **temperature excursion** in the mid to upper regions of the bundle (500 to 1400 mm, see [Figs. 26 – 34](#)), leading to maximum measured temperatures of about 2420 K. Cooling was established at the hottest location ca. 70 s after the start of injection, but was delayed further at other locations. Reflood progressed rather slowly, perhaps due to the high temperatures and partial degradation, and final quench was achieved after about 500 s. Thereafter the water supply was terminated. The water balance for the whole test is presented in [Table 12](#).

In line with the temperature escalations, a significant quantity of **hydrogen (128 g)** was generated during the reflood. [Fig. 43](#) shows two curves for hydrogen release, calculated on the basis of 1) steam flow rate measured by the L701 device, and 2) argon flow rate (measured by the Fm406 gauge) into the bundle through the shroud which failed 40 s after the reflood initiation. There are also indications of *nitrogen release* during the quench phase: **24 g** from 29 g consumed during oxygen starvation period were released again due to the oxidation of nitrides ([Fig. 37](#)).

3.2 Corner rods withdrawn from the bundle

Three corner rods were withdrawn from the bundle to investigate the degree of oxidation for different phases of the experiment (Fig. 44). Rod B was extracted before air ingress. Its surface has a dark smoothly oxidized structure typical for relative thin dense oxide layers (Figs. 45 – 46).

Rod D withdrawn at the end of the air ingress phase exhibits gray or white oxide scale at elevations between 300 and 900 mm (Figs. 47 – 48). The white scales were spalled in the region between 350 and 650 mm, the lower sublayer has a yellow-brown color typical for zirconium nitride. The estimated content of nitrogen in this sublayer defined by EDX analysis was between 30 and 40 at% (with about 50 at% zirconium and between 20 and 10 at% oxygen).

Similar spalling nitrated surface structure was observed for the corner rod A partially withdrawn after the test (upper part of the rod remained in the bundle). However, only some spots of the sublayer under spalled oxide scales have yellow-brown color (Fig. 49). The largest area of this sublayer has a dark-grey color, typical for zirconium oxide. This oxide was formed by re-oxidation of nitrides during the reflood.

3.3 Neutron radiography examinations of corner rods

Neutron radiography was successfully applied for the post-test examination in former QUENCH tests. In the system steam - zirconium the concentration of absorbed hydrogen can be quantitatively and non-destructively determined with a spatial resolution of about 25 μm . The method was applied to the post test examinations of the QUENCH-16 test too. Neutron radiographs of the corner rods A, B and D were taken. The system of this test is more difficult than those of former tests. During oxidation in wet air we have to deal with zirconium, hydrogen, oxygen and additionally nitrogen which has a significant higher neutron cross section than oxygen. Therefore, the total macroscopic neutron cross section Σ_{total} of specimens withdrawn from the QUENCH-16 test after initiation of the air ingress has to be described by:

$$\Sigma_{\text{total}}(x, y) = \frac{-\ln(T(x, y))}{s(x, y)} \quad (2)$$

$$= \sum_i \sigma_i \cdot N_i \quad (3)$$

$$= \underbrace{N_{\text{Zr}}(x, y) \overline{\sigma_{\text{Zr}}}}_{\Sigma_{\text{sample as received}}} + N_{\text{O}}(x, y) \sigma_{\text{O}} + N_{\text{H}}(x, y) \sigma_{\text{H}} + N_{\text{N}}(x, y) \sigma_{\text{N}} \quad (4)$$

where T is the neutron transmission, x and y the pixel positions, s the path length through the sample, i the isotope number, σ the microscopic total neutron cross section of the isotope and N the number density of the isotope.

From these radiography measurements a separation of the contributions of oxygen, hydrogen and nitrogen is not possible. Therefore, no concentrations can be determined.

Rod B withdrawn before air ingress was initiated shows homogeneous neutron attenuation over the whole length. [Fig. 54](#) gives a typical radiograph taken from this rod. The total macroscopic neutron cross section varies between 0.2098 and 0.2219 cm⁻¹, indicating that no significant amount of hydrogen was absorbed in the pre-oxidation phase in steam.

Rod D was withdrawn at the end of the air oxidation phase before quenching. The neutron radiograph given in [Fig. 55](#) shows a laminar breakaway of the oxide/nitride layer. Small differences in the total macroscopic neutron cross section were determined for various elongations. The highest values of about 0.25 cm⁻¹ were found for the axial positions between 550 and 640 mm. At the upper (910 < z < 1030 mm) and lower end (0 < z < 250 mm) values of $\Sigma_{total} \approx 0.21$ cm were calculated. It can be assumed that the differences in the total macroscopic neutron cross section are caused by differences in the oxidation and nitriding level at these positions. In contrast to rod A (below), no small dark spots are obvious in the radiographs of rod D.

Unfortunately, in rod A withdrawn after the test the thermocouple and inner surface of the rod is welded with the rod because of melt formation ([Fig. 53](#)). It could not be removed. Between z = 450 and 510 mm the rod is completely filled with relocated melt. An example is given in [Fig. 56d](#). Radial cracks in this melt are visible. In [Fig. 56c](#) a large hole is visible indicating the brittleness of the remaining tube walls. At lower elongations z the oxide layer is very porous (see [Fig. 56b](#)). At elongations z ~ 230 mm a lot of small darker spots of different dimensions are visible in [Fig. 56a](#). It cannot be excluded that these spots are hydrogen enriched. Possibly, steam has reached the remaining metal through the porous oxide/nitride layer at these positions during the quench phase. The “hydrogen pump effect” occurring in zirconium alloys covered by oxide layers containing a large amount of open cracks [14] would result in very local hydrogen enrichments. However, the larger neutron attenuation of these spot can also be explained by the formation of dense nitride accumulations.

4 Posttest investigations

4.1 Metallographic examination of corner rods

A maximum oxide layer thickness of 135 μm was determined for rod B at bundle elevation of 950 mm ([Fig. 50](#)) with direct metallographic measurements ([Fig. 51](#)). Due to partial scale spalling the axial distribution of the oxide layer thickness for rods D and A was calculated on the basis of measurements of residual metal diameter.

Metallographic investigations of corner rod D, withdrawn before reflood initiation, showed formation of porous nitrides inside the oxide layer as well as on the interface between oxide layer and α-Zr(O)-layer ([Fig. 52](#)). The nitrides were formed at elevations above 300 mm under local or full oxygen starvation conditions. If the gas phase in the gas channel does not contain oxygen, the oxygen of the oxide layer is transported into the metal cladding part not only from the ZrO₂/metal boundary, but also from the oxide bulk. As a result, the formation of α-Zr(O) clusters in the oxide layer is observed [15]. The nitrogen diffused from the gas phase through the oxide scales and reacted with α-Zr(O), resulting in the formation of zirconium nitride clusters. No nitride formation was observed at and above elevation 950 mm with saturated α-Zr(O) layer. Due to the higher density of ZrN in comparison to ZrO₂ density

(about 25% difference), the structure of the formed nitrides is very porous. The stresses induced during formation of nitrides cause formation of cracks going through the cladding. Indeed, the first rod failures were detected about 80 s after beginning of full oxygen starvation and the corresponding formation of nitrides ([Fig. 42](#)).

The investigation of the corner rod A withdrawn from the bundle after the test showed that nitrides were re-oxidized during the reflood with the formation of porous outer oxide sublayer at elevations 300 – 800 mm and growth of thick secondary inner oxide sublayer, formed due to steam penetration through the outer porous structure ([Fig. 53](#)). Due to the strong temperature escalation during reflood a part of the corner rod A was molten and relocated to lower positions (melt inside the corner rod at 450 mm in [Fig. 53](#)).

4.2 Videoscope inspection

The videoscope inspection at positions of withdrawn corner rods B ([Figs. 57 – 59](#)) and D ([Figs. 60 – 62](#)) showed an intensive degradation of the oxide layer with partial spalling at bundle elevations between 450 and 850 mm. The oxide layers between 250 and 750 mm have a white color – typical for the porous oxide structure. Yellowish oxide scales at the outer surface of claddings were observed at elevations between 750 and 1050 mm. The yellow coloring of the cladding surfaces can be caused by 1) small nitride traces inside the oxide and 2) oxidized tantalum particles from destroyed high-temperature thermocouples installed at elevations above 650 mm (such phenomenon with formation of yellow Ta_2O_5 spots was observed also for the QUENCH-15 bundle).

The status of grid spacers was checked in details. Only some remnants of the grid spacer #3 (originally installed at 550 mm) were observed at lower elevations ([Fig. 60](#), 450 mm), whereas the significantly oxidized grid #4 was geometrically stable and not relocated ([Fig. 57](#), 1050 mm and [Fig. 59](#), 1050 mm).

The axial movement of the camera inside the bundle allows to achieve the imagination of 3D melt distribution. Frozen melt droplets and rivulets with oxidized surface were observed between rods at lower elevations between -60 and 420 mm.

4.3 Metallographic examination of bundle cross sections

After videoscope investigations the bundle (together with shroud and heat insulation) was extracted from the facility ([Figs. 63, 64](#)), dismantled from heat insulation ([Figs. 65, 66](#)) and filled with the epoxy resin, which was hardened during two weeks. Then the bundle was cut at different elevations. The cross sections were ground and polished ([Table 13](#)). Metallographic investigation of cross sections ([Figs. 67 – 71](#)) showed the formation of pools of partially oxidized frozen melt between 300 and 500 mm relocated from upper elevations 500 – 800 mm.

The melting of Zr cladding of high-temperature thermocouples, relocation and oxidation of the corresponding melt at different elevations is depicted in [Fig. 72](#). The TC cladding melting took place at elevations above 500 mm. The melt inside the central pellet hole was

significantly oxidized at elevations above 600 mm by steam penetrated into the rod simulator through the failed cladding tube.

All 21 claddings at *elevation 250 mm* were not damaged (Figs. 73 – 76). The cladding surface is only insignificantly oxidized and reveals traces of metallic melt relocated from upper elevations (Fig. 77). The presence of Hf in the shroud (alloy Zr 702) allows the identification of the contributions of different bundle elements to the formation of the melt relocated to elevation 250 mm. Results of EDX analysis depicted in Fig. 78 show that the metallic melt pools consist of more than 50% of shroud melt. Similar EDX results were found for elevation 350 mm (Fig. 88).

Some claddings at *elevations 350 and 450 mm* have through-going cracks (Figs. 79 – 82 and Figs. 89 – 92). The oxide layers at the outer surfaces of most of the claddings reveal typical two-sublayer-structure: 1) the outer porous oxide formed during the pre-oxidation, nitrated during the oxygen starvation stage at the end of air ingress and re-oxidized during reflood; 2) the secondary internal dense oxide formed during the reflood due to the steam penetration through the porous outer sublayer (Figs. 83 – 85 and Fig. 93). Some nitrides formed relatively deep inside the prior α -Zr(O) layer did not react with steam and are surrounded by secondary oxide layer growth during reflood (e.g. rod 5 in Fig. 84). The surface of few claddings, intensively oxidized at the beginning of reflood, was blocked later by melt relocated downwards along the cladding. In such cases of local steam starvation the oxygen was partially transported from the oxide layer to adjacent α -Zr(O) layer and melt. As a result, metallic α -Zr(O) precipitates inside the oxide layer were formed (rod 6 in Fig. 84) according to mechanism described in [15].

The concave inner surface of shroud shows the presence of only relatively thin outer porous scales (Figs. 86, 94). It can be supposed that a part of the porous outer layer was spalled under larger compressive stresses at the concave inner shroud surface in comparison to stresses at the convex outer cladding surface. Relatively thin porous oxide scales without residual nitride traces were observed also at higher elevations.

The molten pools between 230 and 530 mm were formed by melt relocated from *elevations 550, 650 and 750 mm*. The metallographic observations reveal the formation of corresponding voids below the residual oxide layer (Figs. 96 – 99, Figs. 101 – 104 and Figs. 106 – 109). Relative thick inner oxide layers were formed at inner cladding surface between melt and pellet at these elevations (Figs. 100, 105, 110). These layers were developed as the result of the reaction with steam penetrated under the cladding after its failure (some claddings failed yet before reflood – see chapter 3). No remains of grid spacer were detected at elevation 550 mm. The spacer was partially oxidized, partially melted and relocated to lower elevations.

At *elevation 850 mm* only few claddings were locally molten (Fig. 111 - 114). However all claddings at this elevation were significantly damaged due to nitriding, re-oxidation of outer oxide layer and formation of thick secondary oxide layer formed during quench (Fig. 115).

No melt was formed at *elevation 950 and 1050 mm* (Figs. 116 – 119 and Figs. 121 – 124). The oxide structure at these elevations is typical for cladding oxidation in steam without

intermediate air oxidation (Figs. 120, 125). No reaction with nitrogen took place at elevations above 900 mm. Two factors prevented nitrogen attack at these elevations: 1) relative thick oxide layer formed during preoxidation (Fig. 50), and 2) relative low temperatures during the oxygen starvation phase (compare e.g. Figs. 29 and 28). The grid spacer at elevation 1050 mm was markedly oxidized but not destroyed, and kept the intact geometry at original position.

5 Estimation of hydrogen release by different oxidation mechanisms

5.1 Melt oxidation

The melt was formed due to strong temperature escalation during the reflow. Its oxidation contributed significantly to the hydrogen production during this test phase. The image analysis of frozen melt structures (Figs. 87, 95) allows defining the degree of oxidation of the melt on the basis of the correlation between relative area of ceramic precipitations and content of oxygen transported into the melt [16]. The average oxygen content of the melt at elevation 350 mm was measured to be about 8 wt% (corresponding relative ceramic area 10%), at elevation 450 mm about 11 wt% (corresponding relative ceramic area 25%).

The measurement of melt areas of molten pools at elevations 350 and 450 mm and extrapolation of these data to axial region 300 – 500 mm allows estimating the mass of hydrogen produced by bulk oxidation of pools to be 3 g. According to the EDX measurements, the pools contain 50% shroud material. Therefore the oxidation of the cladding part inside melts gives 1.5 g hydrogen. Oxide scale development at the melt surface gives additionally 3 g (1.5 g from cladding melt and 1.5 g from shroud melt). The oxidation of melt located inside claddings at elevations between 450 and 950 mm gives 16 g released hydrogen.

The similar estimation procedure for the hydrogen release during the oxidation of the shroud melt located radially outside bundle and axially between elevations 430 and 550 mm gives the hydrogen mass of 11 g. Therefore, the total hydrogen production by melt oxidation is about 33 g (**19 g from claddings** and 14 g from shroud).

5.2 Oxidation of solid metal cladding

Measurements of the thicknesses of α - and prior β -layers as well as of oxide scales of the cladding are made at four points of each simulator rod with an azimuth interval of 90° and at each elevation according to Tables 14 and 16. Table 16 includes separately two types of oxide layers: 1) oxide layer at the outer cladding surface formed during the whole test, and 2) oxide layer at inner cladding surface formed mostly at higher elevations between melt and pellet (marked by red color). Fig. 126 to Fig. 147 illustrate the results of the layer thickness measurements for the respective bundle elevations. All these figures indicate scatter in the data due to the radial temperature gradient from the center of bundle to its periphery.

Averaged results of these measurements are summarized in Table 15 and Table 17. Again the thicknesses of the inner oxide layers between melt and pellet are marked with red color

in Table 17. Fig. 148 shows the corresponding axial distribution of final cladding oxidation. The maximum of oxidation lies at 550 mm. According to metallographic investigations the oxide layer at the outer cladding surface for elevations between 300 and 900 mm has a clear double structure: 1) porous outer sublayer formed before reflood and 2) dense and relative thick secondary sublayer formed during the reflood due to steam penetration through the outer porous sublayer.

The total mass of cladding outer sublayer corresponds approximately 9 g hydrogen released during the bundle pre-oxidation phase. Additionally about 4 g hydrogen was released during this test phase due to oxidation of shroud and corner rods (the estimation is based on the fact that the total surface of shroud and four corner rods corresponds effectively to surface of ten claddings). According to the mass spectrometer measurement, 16 g hydrogen were released before reflood. The difference of $16 - 9 - 4 = 3$ g hydrogen should be connected with formation of the α -Zr(O) layer and oxidation of other construction elements (grid spacers, thermocouples, heaters).

On the basis of data for thicknesses of the *secondary oxide sublayer* formed at the rod simulator claddings during the quench phase between elevations 300 and 900 mm (Table 18), the corresponding hydrogen release was estimated to be **46 g** (considering combined α -Zr(O) layer). Additionally 6 g hydrogen were released during the quench phase by steam oxidation of the inner surface of ruptured claddings (corresponding layer thicknesses are marked in Table 16 in red color). A similar estimation for the oxidation of the solid part of the shroud between 300 and 900 mm during reflood gives 26 g hydrogen. The consideration of the oxidation at elevations above 900 mm gives 5 g hydrogen released from bundle and 1 g from shroud.

5.3 Oxidation of nitrides during reflood

A very intensive nitride formation was observed at elevations 350 – 850 mm. The upper oxide scales above nitrides have a porous structure due to re-oxidation of nitrides during reflood:

Only some nitride traces at the boundary between the inner dense and the spalled outer porous oxide scales were observed. On the basis of measured nitrogen release during the quench phase (24 g) and according to formula (5), the mass of hydrogen released during *nitride re-oxidation* was about **7 g**. Because the surface of shroud and the remaining corner rods is equivalent to about nine cladding surfaces, the mass of hydrogen released due to cladding nitride oxidation should be about 5 g.

Hence, a significant part of the hydrogen release during the quench phase was produced by intensive oxidation of the rod cladding and shroud metal (with formation of dense oxide sublayer as shown in Fig. 85) by steam penetrated through the outer porous scale formed during the air ingress phase at the beginning of reflood.

6 Summary

The QUENCH-16 bundle test with Zry-4 claddings was performed with three typical features before initiation of reflood: moderate pre-oxidation to maximal 135 μm of oxide layer (instead ca. 500 μm for QUENCH-10), a long period of oxygen starvation during the air ingress phase (about 800 s instead 80 s for QUENCH-10), and reflood initiation at temperatures significantly below the melting point of the cladding (about 1800 K instead of 2200 K for QUENCH-10).

The change in flow conditions during the air ingress phase in comparison to the pre-oxidation phase had the immediate effect of reducing the heat transfer so that the temperatures began to rise and the axial temperature maximum was shifted from elevation 950 to 550...750 mm. A total oxygen starvation during 800 s before reflood initiation was observed at bundle elevations above 300 mm. The corresponding total oxygen uptake at the lower bundle elevations during that phase was 58 g.

A partial consumption of nitrogen during the oxygen starvation, accompanied by acceleration of the temperature increase at mid bundle elevations, caused the formation of zirconium nitrides inside the oxide layer at bundle elevations between 350 and 850 mm. Due to a noticeable difference between zirconium nitride and zirconium oxide densities, the structure of formed nitride containing clusters is very porous.

Immediate temperature escalations after reflood initiation, leading to maximum measured temperatures of about 2420 K, were caused by massive steam penetration through the porous oxide/nitride scales and intensive reaction with nitrides and especially with metallic cladding. Very thick oxide sub-layers up to 400 μm developed during the reflood phase. The cooling phase up to the final quench lasted ca. 500 s after achievement of peak temperatures.

A relatively high concentration of residual nitrides was observed mostly at elevations 350 - 550 mm. Spalled oxide scales with a re-oxidized porous structure were observed at elevations between 350 and 850 mm.

24 g nitrogen from 29 g, consumed during oxygen starvation period, were released during the quench phase. This quantity of released nitrogen corresponds to 7 g hydrogen produced during re-oxidation of nitrides (5 g bundle + 2 g shroud).

Metallographic investigation of cross sections between 300 and 500 mm showed partially oxidized frozen melt, relocated from upper elevations 500 – 800 mm. Image analysis of frozen Zr-O melt regions allows estimating the hydrogen release due to melt oxidation to be 33 g (19 g bundle + 16 g shroud).

A significant part of hydrogen released during reflood of the QUENCH-16 bundle was generated due to oxidation of the cladding metal by steam penetrated through the porous oxide layer formed due to re-oxidation of ZrN. Estimation made on the basis of corresponding layer thicknesses between elevations 300 and 900 mm gives 46 g hydrogen generated by oxidation of bundle and 26 g by shroud. The damaging of claddings by

through-going cracks caused the steam penetration under cladding with oxidation of inner cladding surface; the corresponding hydrogen release was estimated to be 6 g. Oxidation of non-nitrided surfaces of claddings and shroud at elevations above 900 mm causes hydrogen production of about 5 and 1 g correspondingly. [Table 19](#) summarizes contributions of different oxidation mechanisms in the hydrogen production.

According to measurements by mass spectrometer, the total hydrogen production during QUENCH-16 was higher compared to QUENCH-10, i.e., 144 g (QUENCH-10: 53 g), 128 g of which were released during reflood (QUENCH-10: 5 g). The estimated contribution of claddings oxidation in the hydrogen release during reflood is 81 g.

Acknowledgements

The LACOMECON program is performed by KIT with financial support from the HGF Program NUKLEAR and the European Commission. The authors thank all colleagues involved in the investigations, particularly J. Moch and C. Rössger for bundle preparation, U. Stegmaier and U. Peters for metallographic analysis, J. Laier for data processing, M. Heck for very detailed draft review and corrections. Furthermore the very valuable support of the test planning by pre-test calculations performed at PSI, GRS, and EdF is strongly acknowledged.

Table 11: QUENCH-16; Sequence of events

Time [s]	Event
0 (10:41:35h)	Start data recording, T_{\max} =TFS 6/14=871 K, el. power switched from 4.3 to 9.7 kW. Start of pre-oxidation phase in gas mixture of overheated steam (Fm 205 = 3.4 g/s) and argon (Fm 401B = 3 g/s).
2291	El. power switched from 9.8 to 10.8 kW. T_{\max} = TFS 4/13 = 1306 K.
3002	El. power switched from 10.8 to 11.3 kW. T_{\max} = TFS 4/13 = 1360 K.
6301 (12:26:34h)	Start of cooling phase . Reduction of el. power from 11.3 to 3.9 kW. T_{\max} = TFS 4/13 = 1428 K.
7249	Corner rod B withdrawn.
7307 (12:43:22h)	Start of air ingress phase . Turn on the air flow with flow rate 0.2 g/s. Switch of argon flow from 3 g/s to 1 g/s. Switch-off of steam supply (0 g/s at 7319 s). T_{\max} = TFS 6/14 = 998 K.
7321	First indication of air at mass spectrometer.
10270... ...10400	Accelerated temperature increase at bundle elevation 9 (550 mm). TCR 9 increased from 1445 to 1620 K.
10300... ...10800	Accelerated temperature increase at bundle elevation 8 (450 mm). TFS 4/8 increased from 1290 to 1700 K.
10350... ...10650	Transition to <i>complete oxygen starvation</i> and to <i>partial nitrogen consumption</i> . Decrease of nitrogen flow rate through the off-gas pipe from 0.16 to 0.13 g/s.
10500... 11120	Accelerated temperature increase at bundle elevation 7 (350 mm). TCR 7 increased from 1205 to 1700 K.
10587	First <u>rod failure</u> : Kr indication at mass spectrometer.
10900... ...11341	Accelerated temperature increase at bundle elevation 6 (250 mm). TFS 15/6 increased from 1115 to 1400 K.
11330	Corner rod D withdrawn. Maximal bundle temperature TCR 12 = TFS 18/11 = TFS 2/10 = 1870 K
11341	Initiation of fast water injection. <u>Stop of overheated gas and argon</u> supply (closing of the V 302 valve). Reaction of the T511 bundle inlet thermocouple.
11350... 11413	Initiation of quench water supply (Fm 104 increased from 0 to 53 g/s).
11352... ...11560	<i>Release of hydrogen and nitrogen.</i>
11380	<u>Shroud failure</u> : flow of argon from the shroud annulus into the bundle (Fm 406 increase).
11395... ...11530	Intensive water boiling in bundle (evaporation rate ca. 53 g/s); indication by increased off-gas flow rate (F 601); constant collapsed water level at elevation L 501 = 530 mm.
11530... ...11780	Constant evaporation rate ca. 47.3 g/s (according to coolant channel of 33.65 cm ²). Increase of collapsed water level from elevation L 501 = 570 mm to L 501 = 995 mm.
11830	Thermocouples TFS 13/17 and T 512 at bundle elevation 1350 mm wetted with double-phase fluid. Collapsed water level at elevation L 501 = 1194 mm.
12047... ...12080	Shut down of the quench pump (Fm 104 decreased from 53 to 0 g/s).
14625	Shut down of electrical power supply (power reduction from 3.6 to 0 kW).
14640 (14:45:36h)	End of data recording. Stop of Ar flow into shroud annulus. Bundle T_{\max} = TFS 10/12 = 390 K; shroud T_{\max} = TSH 16/180 = 405 K. L 501 = 1020 mm. Total collected condensed water 33602 g (according to summarised L 701 = 2350 mm).
(28.07.11)	L 501 = 654 mm – corresponding water mass inside bundle is 6590 g (measured after bundle dismounting). Water mass inside shroud annulus: 7264 g. Increase of L 701 = 1103 mm.

Table 12: QUENCH-16; Water/steam balance

Accumulated mass of water [g]	
Total steam injected (Fm 205)	24853
Total quench water injected (F 104)	36691
Quench water from fast injection system	4000
Total used water	65544
<hr/>	
Condensed water collected (L 701 = 2350+1103 = 3453 mm)*	49378
Water/steam consumed by metal oxidation (144 g released H ₂)	1296
Water found posttest in the test bundle (L501 = +654 mm)	6590
Water found posttest retained in the ZrO ₂ fiber insulation**	7264
Water found posttest in the annulus of the upper plenum	450
Total posttest water	64978

*) water column of 1 mm corresponds to 14.3 g

**) post-test insulation weight (between -300 mm and 1000 mm): 13614 g; weight of the dry insulation (10 annuli): 10 x 900 g = 9000 g; 2650 g collected as water

Table 13: Cross sections of the QUENCH-16 test bundle for metallographic examination

Sample	Sample length (mm)	Axial position (mm)		Remarks

Table 19: Estimated contribution mechanisms for hydrogen release

Mechanism	H ₂ mass, g
Oxidation of claddings before reflood initiation	9
Oxidation of shroud and 4 corner rods before reflood initiation	4
Total hydrogen production before reflood initiation measured by mass spectrometer	16
Hydrogen release during reflood	
Re-oxidation of nitrides inside claddings	5
Oxidation of melt relocated from claddings	3
Oxidation of melt inside claddings	16
Oxidation of solid cladding metal by steam penetrated through the porous re-oxidized layer at elevations 300 – 900 mm (secondary oxidation of outer cladding surface)	46
Oxidation of inner surface of cladding by steam penetrated through damaged cladding	6
Oxidation of not nitrated claddings at elevation above 900 mm	5
Total contribution of claddings during reflood	81
<i>Re-oxidation of nitrides inside shroud and 2 corner rods</i>	<i>2</i>
<i>Oxidation of melt relocated from shroud</i>	<i>3</i>
<i>Oxidation of shroud melt outside bundle</i>	<i>11</i>
<i>Oxidation of shroud and 2 corner rods metal by steam penetrated through the porous re-oxidized layer at elevations 300 – 900 mm</i>	<i>26</i>
<i>Oxidation of not nitrated shroud at elevation above 900 mm</i>	<i>1</i>
Total contribution of shroud and corner rods during reflood	43
Total hydrogen production during reflood: by metallography / by mass spectrometer	124 (81+43) / 128

Air ingress issues have received considerable attention in recent years in view of the likely acceleration of the cladding oxidation, fuel rod degradation, and the release of some fission products, most notable ruthenium. The accident at Fukushima Daiichi drew attention to the possibility of overheated fuel assemblies becoming exposed to air outside of the reactor.

Experimental and analytical works on air ingress were performed within the EC 4th and 6th Framework Programs. A number of previous out-of-pile bundle air ingress tests have been performed under a range of configurations and oxidizing conditions, namely CODEX AIT-1, AIT-2 with small 9-rod bundles, QUENCH-10 with 21-rod strong preoxidized bundle and PARAMETER-SF4 with finally molten 19-rod bundle. The accumulated data have demonstrated that air oxidation of cladding is a quite complicated phenomenon governed by numerous processes whose role can depend on the oxidizing conditions, the oxidation history and the details of the cladding material specification. The models for air oxidation do not yet cover the whole range of representative conditions.

The out-of-pile bundle experiment QUENCH-16 on air ingress was conducted in the electrically heated 21-rod QUENCH facility at KIT in July 2011. It was performed in the framework of the EC supported LACOMECON program. The primary aims were to examine the oxidation of the Zircaloy-4 claddings in air following a limited pre-oxidation in steam, and to achieve a long period of oxygen starvation to promote interaction with the nitrogen. QUENCH-16 was thus a companion test to the earlier air ingress experiment, QUENCH-10, which was performed with strongly pre-oxidized bundle. Unlike QUENCH-10, significant temperature escalation and intensive hydrogen release were observed during the reflood phase. Three contributors for intensive hydrogen production during reflood were identified: (i) re-oxidation of nitrides, (ii) secondary oxidation of cladding metal by steam penetrated through the porous re-oxidized scales and (iii) melt oxidation.
