Abstract

The mid-infrared FTIR-limb-sounder Michelson Interferometer for Passive Atmospheric Sounding – STRatospheric aircraft (MIPAS-STR) was deployed onboard the stratospheric aircraft M55 Geophysica during the RECONCILE campaign in the arctic winter/spring 2010. From the MIPAS-STR measurements, vertical profiles and 2-dimensional vertical cross-sections of temperature and trace gases are retrieved. Detailed mesoscale structures of polar vortex air, extra vortex air and vortex filaments are identified in the results at a typical vertical resolution of 1 to 2 km and typical horizontal sampling density of 45 or 25 km, depending on the sampling programme. Results are shown for the RECONCILE flight 11 on 2 March 2010 and are validated with collocated in-situ measurements of temperature, O₃, CFC-11, CFC-12 and H₂O. Exceptional agreement is found for the in-situ comparisons of temperature and O₃, with mean differences (vertical profile/along flight track) of 0.2/–0.2 K for temperature and –0.01/0.05 ppmv for O₃ and corresponding sample standard deviations of the mean differences of 0.7/0.6 K and 0.1/0.3 ppmv. The comparison of the retrieved vertical cross-sections of HNO₃ from MIPAS-STR and the infrared limb-sounder Cryogenic Infrared Spectrometers and Telescopes for the Atmosphere – New Frontiers (CRISTA-NF) indicates comprehensive agreement. We discuss MIPAS-STR in its current configuration, the spectral and radiometric calibration of the measurements and the retrieval of atmospheric parameters from the spectra. The MIPAS-STR measurements are significantly affected by continuum-like contributions, which are attributed to background aerosol and broad spectral signatures from interfering trace gases and are important for mid-infrared limb-sounding measurements in the Upper Troposphere/Lower Stratosphere (UTLS) region. Considering for continuum-like effects, we present a scheme suitable for accurate retrievals of temperature and an extended set of trace gases, including the correction of a systematic line-of-sight offset.

1 Introduction

Airborne and balloon-borne remote-sensing measurements are filling the gap between in-situ-measurements and satellite-borne remote sensing measurements in terms of spatial coverage and spatial resolution. While classical in-situ measurements from aircraft or balloon platforms allow for measurements with high absolute accuracy constrained to the flight track, satellite remote measurements allow for maximal vertical sampling range, global coverage and extended time series, but often with higher uncertainties. In contrast to comparable satellite techniques, remote-sensing measurements from aircraft and balloon platforms focus on limited atmospheric areas, but with a much higher sampling density. The proximity of the sampled air-masses results in lower uncertainties in the retrievals, since errors through pointing stability and precision, non-local thermodynamic equilibrium effects in the spectra and extended horizontal trace gas gradients are less severe. Further advantages of airborne high-altitude remote-sensing measurements are that flight scenarios can be adapted to scientific objectives individually and specific atmospheric structures can be targeted flexibly.

The cryogenic FTIR spectrometer MIPAS-STR (Piesch et al., 1996) onboard the high altitude aircraft M55 Geophysica is the airborne version of the series of MIPAS-instruments (Fischer and Oelhaf, 1996), including also balloon-borne (Friedl-Vallon et al., 2004) and satellite-borne techniques (Fischer et al., 2008). From the limb-emission measurements of MIPAS-STR, vertical profiles and two-dimensional cross-sections of atmospheric temperature and trace gases (HNO₃, O₃, CFCs, ClONO₂, H₂O and several other species) are derived, allowing for the reconstruction “snapshots” of the chemical and dynamical atmospheric situation along the flight-track.

MIPAS-STR was first deployed during the Antarctic campaign APE-GAIA in 1999 (Höpfner et al., 2000). In the following years, MIPAS-STR was operated in several other scientific campaigns and was applied for the validation of MIPAS-ENVISAT (Blom et al., 2004; Keim et al., 2004; Cortesi et al., 2007; Höpfner et al., 2007; Wang et al., 2007) and the microwave limb sounder MARSCHALS (Dinelli et al., 2009). The vertical

7038

The effective optical path difference of the double pendulum interferometer (Fischer and Oelhaf, 1996) is ± 13.9 cm. Two-sided interferograms are recorded, resulting in spectra with an unapodized spectral resolution of 0.036 cm^{-1} . After applying the Norton-Beer strong apodization (Norton and Beer, 1976), an effective spectral resolution of 0.058 cm^{-1} is obtained. The effects of vibrations, which are typical for an aircraft platform like the Geophysica, on the interferometer of MIPAS-STR have been investigated by Kimmig (2001). A dedicated time-equidistant sampling method introduced by Brault (1996) was adapted for the recording of interferograms, such that perturbations in the spectra resulting from vibrations are minimized.

In order to minimize instrumental background radiation, the instrument is dry ice-cooled to about 210 K and the different reflective optics are coated with gold, protected gold or Silflex MK2TM, respectively. The detector is cooled by liquid helium to about 4 K. Incoming infrared radiation is entering the detector dewar via an anti-reflectance coated ZnSe-window. Inside the detector dewar, the radiation is split up into four parts by dichroics and is directed via filters and blockers to the Si:As back-illuminated band-impurity detectors of the four channels. In this context, results from the spectral channel 1 (725 to 990 cm^{-1}) are discussed. For this channel, a typical plot of the apodized noise equivalent spectral radiance (NESR) under flight conditions is shown in Fig. 2. In the spectral range between 820 and 970 cm^{-1} , an optimal mean NESR of about $8 \times 10^{-9} \text{ W}/(\text{cm}^2 \text{ sr cm}^{-1})$ is obtained, and at lower and higher wave-numbers, the NESR is still mainly around 1 to $2 \times 10^{-8} \text{ W}/(\text{cm}^2 \text{ sr cm}^{-1})$.

The electronics module consists of a hierarchic system with intelligent and independent subsystems, realized by a transputer-network. The top system is a PC-based computer running a real-time operating system. Subsystems are the interferometer electronics, the line-of-sight (LOS) electronics and the housekeeping/auxiliary electronics. The system is designed for fully automatic operation during flight. On ground, the system can be accessed and commanded via Ethernet and during flight via an Iridium satellite link (see <http://www.iridium.com/default.aspx>).

7041

Since the recording of a single interferogram takes about 9.5 s and the measurements are performed at fixed tangent altitudes, a reliable and accurate line-of-sight (LOS) stabilization is required for compensating roll-variations of the aircraft in order to minimize uncertainties in the trace gas retrievals. The development and verification of the LOS stabilization of MIPAS-STR is described by Keim (2002). The LOS elevation stabilization is realized by the scan-mirror control loop. The angle of the scan-mirror is measured by a 19-bit encoder and stabilized by a motor with reference to the attitude information provided by the Attitude and Heading Reference System (AHRS), which is part of the instrument. The AHRS is a Schuler-adapted, north-seeking strapdown inertial navigation system with embedded GPS and a 10 states Kalman-filter. The AHRS provides attitude angles at a data rate of 128 Hz and low data age, allowing for a near real-time LOS stabilization. After flight, the LOS data is refined by a dedicated post-processing procedure, compensating for drifts in the AHRS data.

Under flight conditions, a slight misalignment of the optical axis of the instrument with respect to the coordinate system of the AHRS can happen. The observed misalignment is mainly attributed to the exposure of the instruments housing to the large temperature difference between ground and stratosphere (in the order of 50 K). For the compensation of this effect, the offset of the LOS with reference to the AHRS coordinate system is quantified by LOS retrievals (see Sect. 5). The retrieved LOS offset is found to be approximately stable under the relatively constant flight-conditions in the stratosphere for individual flights. For each flight, one single LOS offset-parameter is determined and considered for the subsequent retrievals of temperature and trace gases. Including the uncertainties inherent to the AHRS, the accuracy of the scan-mirror adjustment and the uncertainties resulting from the LOS retrieval, a total pointing accuracy of 0.78 arcmin (1σ) is estimated. This value corresponds to about 3% of the instrumental FOV or about 100 m at the lowest tangent altitude.

The sampling programme of MIPAS-STR includes atmospheric measurements and calibration measurements. The atmospheric measurements with negative elevation angles, which are characterized by their tangent altitude, allow for the retrieval of ver-

7042

tically resolved profiles of atmospheric temperature and trace gases below flight altitude. Measurements with positive elevation angles allow for the retrieval of the column amounts of these parameters above the flight path and also contain limited information on the vertical distributions directly above flight altitude. In Fig. 3, the sampling scheme of the standard limb sequence is illustrated. The atmospheric measurements are enclosed by blackbody and deep space (zenith view) calibration measurements. Since the limb scans are aligned in a mirrored pattern, two full scans are shown. The standard sequence includes limb-viewing geometries with tangent altitudes between 5 km and the flight altitude (with a vertical spacing of 1 km above and 1.5 km below 8 km), an additional limb observation with an elevation angle of -0.3° in order to sample the area directly below the flight altitude, and comprehensive upward sampling. For a typical flight altitude of 18 km, one full limb scan of the standard limb sequence (including calibration measurements) takes about 3.8 min, corresponding to a flight path of approximately 45 km. The horizontal distances of the tangent points from the aircraft position increase from about 33 km for the highest geometry (tangent altitude 17.9 km, corresponding to an elevation angle of -0.30°) to about 400 km for the lowest geometry (tangent altitude 5 km, corresponding to an elevation angle of -3.54°). The vertical FOV diameter at the tangent point increases for the respective geometries from about 0.3 km to 3.0 km. Taking into account the vertical FOV angle of 0.44° , an oversampling with a factor of 2–3 is obtained for the limb-viewing geometries.

In the presence of opaque tropospheric clouds or in case of the requirement for an increased horizontal sampling density at higher altitudes, a modified measurement scenario is applied. Tangent altitudes below 9 km are omitted and upward-scanning is performed less frequently, resulting in a total time of about 2.4 min for one full limb scan, corresponding to a horizontal sampling of approximately 25 km.

7043

3 Spectral and radiometric calibration

The spectral and radiometric calibration procedure is described in Höpfner et al. (2000) and Keim (2002) and is in many aspects similar to the procedure for the balloon-borne instrument MIPAS-B2 (Friedl-Vallon et al., 2004). In this context, a summary of the full calibration cycle specific to MIPAS-STR is given.

For the conversion of the atmospheric raw interferograms into radiometric calibrated spectra, basically four characteristic key-quantities have to be determined:

- The nonlinearity in the detector response
- The instrumental phase needed for the statistical phase correction within the Fast-Fourier-Transformation of the atmospheric interferograms into spectra
- The radiometric offset resulting from instrumental background radiation
- The gain-function for the radiometric calibration of the spectra

After the determination of these parameters, the atmospheric interferograms are transformed into spectra and are radiometrically calibrated according to the two-point calibration:

$$S(\nu) = \frac{A(\nu) - U(\nu)}{c(\nu)} \quad (1)$$

whereas ν stands for the spectral position, $A(\nu)$ for the atmospheric raw spectrum, $U(\nu)$ for the instrumental background spectrum, $c(\nu)$ for the radiometric gain function and $S(\nu)$ for the calibrated atmospheric spectrum. A schematic representation of the full calibration cycle is shown in Fig. 4 and the key-steps are described in the following sections in more detail.

For the correction of the detector nonlinearity, dedicated measurement phases are carried out during each flight, and the detector nonlinearity is considered to be approximately constant during an individual flight. After determination, the detector nonlin-

7044

earity correction is applied to all interferograms of a flight prior to the other calibration steps.

For the subsequent steps phase correction, determination of instrumental offset, and radiometric calibration, an individual flight is separated into parts, where (i) the instrumental phase is sufficiently stable and (ii) the instrumental offset and (iii) the radiometric gain function show only approximately linear variations, since the instrumental phase is averaged and the latter two quantities are fitted linearly in time for the atmospheric measurements. Furthermore, the mentioned parameters are determined separately for each interferometer scan direction (forward/backward sweep are carried out alternately), and the atmospheric interferograms are calibrated separately for the different interferometer scan directions, since the data-acquisition is slightly different.

3.1 Detector nonlinearity correction

The Si:As back-illuminated band impurity detectors show a significantly nonlinear response at increasing photon fluxes, resulting in a distortion of the interferograms and artefacts in the associated spectra.

The quantification of the detector nonlinearity for the balloon-borne instrument MIPAS-B2 is described in Kleinert (2006) and is carried out analogously for MIPAS-STR. Accordingly, a measured nonlinear interferogram can be approximated by a polynomial function of linear interferograms. Hence, the corresponding uncorrected spectrum can be described as a convolution of the undisturbed spectrum with itself and shows higher order artefacts. The effects of nonlinearity can be deduced and corrected from the artefacts in blackbody spectra from interferograms without digital filtering data reduction as a function of the corresponding DC-level measured at the detector.

In the case of MIPAS-STR, during each flight at least one phase for the recording of interferograms without digital filtering data reduction is carried out. Depending on the availability of measurements of sufficient quality, between 15 and 30 interferograms are averaged typically for each interferometer scan direction and converted into spectra. The resulting two spectra are averaged again and from the final resulting spectrum,

7045

the nonlinearity is quantified by the minimization of the corresponding artefacts according to Kleinert (2006). In the case of the channel 1 spectra of MIPAS-STR, the quadratic and cubic artefacts are clearly apparent and are minimized in the spectral interval from 30 to 280 cm^{-1} for the quadratic and in the interval from 2150 to 2900 cm^{-1} for the cubic artefacts. No signs of higher artefacts are found. Although the quadratic artefacts are outside channel 1 and a cubic artefact shows only weak influence in this spectral region, the difference in the detector responses between deep space spectra (low photon flux) and blackbody spectra (high photon flux) has to be considered to keep the two-point calibration valid. For RECONCILE flight 11 on 2 March 2010 discussed in this context, an 18 % lower response is found for a typical blackbody spectrum compared to a deep space spectrum.

3.2 Phase correction of the interferograms

Since different contributions of radiation arise from the atmosphere and the different optical components inside the instrument, complex spectra with a natural phase are resulting from the interferograms after the Fast-Fourier-Transformation (see Friedl-Vallon et al., 2004). Basically, atmospheric radiation and radiation resulting from the instruments optical components between the beamsplitter of the interferometer and the detector contribute to the real part of the spectrum, while the self-emission of the beamsplitter contributes mainly to the imaginary part. Due to the frequency-dependent signal propagation in time in the optical dispersive elements and the electronic components, as well as sampling shifts relative to the interferogram peak, phase errors are resulting. Since the beamsplitter emission gives rise to significant contributions in the atmospheric measurements, the standard method described by Forman et al. (1966) cannot be applied here. A dedicated approach suited for the phase correction for MIPAS instruments has been developed by Trieschmann et al. (1999). A characteristic instrumental phase is determined using blackbody calibration measurements and is then used as initial phase for a statistical phase correction of the atmospheric interferograms (see Fig. 4).

7046

Following this approach, in the first step an initial mean instrumental phase is determined from the blackbody measurements of the corresponding flight part according to Forman et al. (1966). This step is applicable, since for the blackbody measurements the contribution of the beamsplitter emission is comparably weak. The resulting preliminary instrumental phase is then applied for the phase correction of the 5°/8°/10°-measurements (elevation angles depending on the sampling sequence), which show only weak atmospheric signatures and allow for the extraction of the beamsplitter emission in the imaginary part. The resulting imaginary spectra, which are characterized by the beamsplitter emission pattern, are then averaged and smoothed in order to reduce the noise level without affecting the broad signatures resulting from the beamsplitter emission. In the next step, the improved final instrumental mean phase is determined from the blackbody measurements according to Forman et al. (1966), taking into account the beamsplitter emission derived in the previous step. The resulting instrumental phase serves as starting point for the statistical phase correction of the deep-space and atmospheric interferograms. In the statistical phase correction (Trieschmann et al., 1999), (i) the correlations between the real and imaginary parts of the spectra are minimized, since these parts are theoretically absolute independent from each other and (ii) the variances in the imaginary parts are minimized, since no sharp line features are expected here.

After the phase correction, the real parts of the atmospheric spectra (negative and positive elevation angles), which are containing the atmospheric signatures of interest, and the deep space spectra, allowing for the extraction of the instrumental background radiation, are further processed in order to obtain finally calibrated atmospheric spectra.

3.3 Determination of instrumental offset and radiometric calibration

The instrumental offset in the real parts of the spectra is determined from the deep space spectra following the iterative scheme developed by Höpfner et al. (2000). Since the deep space spectra are obtained from zenith view observation geometries towards

7047

cold space, only weak atmospheric rest-signatures are apparent, and further remaining contributions represent the instrumental background radiation. In order to reproduce the instrumental background with maximal accuracy, the remaining atmospheric rest-signatures are removed by a radiative transfer step with KOPRA/KOPRAFIT (see Sect. 5.1). For this step, calibrated deep space spectra are required and therefore, a preliminary calibration is applied. The atmospheric rest-signatures in the deep space spectra are removed by a line fitting step without radiative transfer, allowing for the determination of a preliminary instrumental offset. Using the preliminary instrumental offset, a preliminary radiometric gain function is determined from the blackbody measurements, allowing for the calibration of the deep space spectra. For the determination of the preliminary gain function, as well for the final gain function, the blackbody measurements are used at a reduced resolution of 0.5 cm⁻¹, in order to reduce the noise level without affecting the filter function.

In the radiative transfer step, the remaining weak signatures of CO₂, O₃, HNO₃ and H₂O are retrieved and then subtracted from the measured deep space spectra, resulting in the desired instrumental offset spectra.

With the knowledge of the instrumental offset, the final radiative gain function is determined from the blackbody measurements according to Eq. (2):

$$c(\nu) = \frac{BB(\nu) - U(\nu)}{B(\nu, T) \cdot e(\nu)} \quad (2)$$

whereas $c(\nu)$ represents the final radiative gain function, $BB(\nu)$ the blackbody spectrum, $U(\nu)$ the instrumental offset spectrum, $B(\nu, T)$ the Planck function of the temperature T and $e(\nu)$ the emissivity of the blackbody. With the knowledge of the precise instrumental offset and the radiative gain function, the atmospheric spectra are calibrated according to Eq. (1).

In Fig. 5, examples of calibrated atmospheric spectra are shown together with a calibrated deep space spectrum. The deep space spectrum and the spectra with high elevation angles indicate a flat baseline and show no signs of any significant radiometric

Crutzen, 1997). Different types of particles also can result from or nucleate on meteoritic material (e.g. Curtius et al., 2005). Polar Stratospheric Cloud (PSC) particles are formed during winter at high latitudes (e.g. Peter, 1997) and significantly affect mid-infrared limb-emission spectra. Typical spectral signatures of PSC constituents allow for the classification of PSC types (e.g. Höpfner et al., 2006). Also cirrus cloud particles affect mid-infrared limb-emission spectra (e.g. Spang et al., 2002) and the corresponding effects can be taken into account by dedicated radiative transfer models (Ewen et al., 2005). Further types of stratospheric aerosol-particles were measured by in-situ instruments, whereas the sources for some particle types remain unclear (e.g. Murphy et al., 1998). So in summary, there can be different aerosol-families present in the UTLS region under nominal cloud-free conditions, which are capable of affecting the MIPAS-STR observations.

Regarding the second point, continuum-like signatures on the scales of retrieval microwindows (typically several cm^{-1}) also result from large molecules with characteristic broad signatures in the spectra, which are not or inaccurately covered by radiative transfer modelling. Here, the availabilities of suitable climatological profiles, as well as accurate spectral line-data and cross-sections represent limiting factors. For example, the mixing ratios of the family of the halocarbons increase with decreasing altitude in the UTLS (e.g. Fabian and Borchers, 1981) and the comparably large molecules exhibit broad spectral signatures, whereas the variable vertical profiles and the available spectral data for radiative transfer modelling are uncertain in several cases. Further candidates with poorly known profiles are the broad family of aliphatic and aromatic hydrocarbons. Several species have already been identified by infrared remote-sensing instruments (e.g. Coheur et al., 2007; Razavi et al., 2011). For many further species there are also large uncertainties in the knowledge of the vertical profiles and the spectral line and cross-section data. Although many species alone give rise to only weak signatures below or close to the NESR of MIPAS-STR, the net-effect accumulated by many different species can significantly affect the observations. Therefore, continuum-like contributions have to be expected on scales of retrieval microwindows as a conse-

7053

quence of incomplete radiative transfer modelling of broad trace gas signatures, especially towards lower observation geometries.

The third aspect results from the fact that in the considered altitude range in the UTLS significantly increasing pressure broadening of the spectral lines is observed with decreasing altitude. As a consequence of the increasing Lorentzian character of the spectral lines and the overall increase of many spectral signatures towards lower observation geometries, the overlap of adjacent spectral signatures increases. For the consideration of the effects of overlapping line wings, spectral signatures in an extended wavenumber-range of 25 cm^{-1} around the selected microwindows are taken into account in the retrievals discussed here. Influences of the extreme line-wings of very strong distant CO_2 -lines and the non-Lorentzian behaviour of H_2O -lines are considered by dedicated continuum models included in KOPRA (Stiller et al., 2000). However, remaining broad continuum-like spectral signatures resulting from the incomplete modelling of overlapping spectral signatures cannot be ruled out. Virtually continuum-like contributions on the spectral baseline within a microwindow might also result from imperfect spectral modelling of adjacent spectral signatures using the Voigt model, since it does not always allow for a sufficient reconstruction of the observed spectral line shapes (e.g. Ciurylo, 1998; Boone et al., 2007; Schneider et al., 2011). However, we clarify that the retrieval of background-continuum does not correct imperfect spectral modelling of line shapes, but rather might partially compensate net-effects resulting from incorrectly modelled line-wings of adjacent spectral signatures.

Furthermore we mention, that also stray-light effects resulting from impurities on the instruments scanning mirror might result in spectral contributions possibly interpreted as continuum-like contributions. Although no explicit signs for significant stray-light contributions could be identified in the MIPAS-STR spectra discussed here, however, stray-light contributions cannot be excluded completely.

So in summary, different superimposed so-called continuum-like contributions play a role in UTLS mid-infrared limb-emission FTIR spectra, with increased importance towards lower altitudes. The sources for continuum-like effects are variable with altitude

7054

and for different spectral regions, whereas a clear and quantitative separation is complicated. Therefore, the net-effect of continuum-like contributions in the measurements analysed here is quantified by the retrieval of a wave number-independent background continuum, allowing for a reliable reconstruction of the main target parameters. Of course it has to be considered, that the main retrieval target has to show a signature sufficiently differing from continuum-like behaviour in the spectral microwindow(s) chosen for the retrieval. Taking this into account, we show that the simultaneous reconstruction of wave number-independent background continuum is necessary in the discussed retrievals for achieving agreement between the measurements and the retrieved spectra, and that the retrieval results of the main targets are ascertained by in-situ measurements (Sect. 6).

In Fig. 9a, a measured spectrum with a tangent altitude of 12 km is shown, where significant continuum-like effects are apparent. Also shown are the corresponding retrieved spectra with and without continuum-retrieval. The retrieval without consideration of background continuum results in poor agreement between measurement and retrieval result, while the retrieved spectrum with simultaneous reconstruction of background continuum reproduces the measured spectrum well. Remaining differences in the residual exceeding the NESR-level are attributed to signatures of weakly interfering trace gases, which are not identified or incorrectly modelled using climatological profiles. Such effects of weakly interfering gases increase towards lower altitudes, but compared to the chosen signatures of the target gas, the resulting uncertainties are small and allow for a reliable reconstruction of the target profile, at least at stratospheric altitudes. In Fig. 9b, the retrieved continuum profile from the corresponding full limb scan is shown for this microwindow and retrieval.

5.3 Retrieval approach

The full retrieval chain applied for the subsequent reconstruction of the LOS offset, temperature profiles and trace gas profiles is summarized in Fig. 10. As pointed out in Sect. 2, for MIPAS-STR the relative pointing information is known with high precision

7055

due to the high accuracy of the attitude angles provided by the AHRS. Only a small constant absolute offset between the reference system of the AHRS and the instruments LOS has to be quantified by retrievals. Therefore, the first step in the applied retrieval chain is the determination of the LOS offset using strong isolated CO₂-lines in the spectra. For each sequence of a flight, an individual LOS offset parameter is retrieved, and the average of all retrieved LOS offset parameters is used as LOS correction, resulting in one single parameter per flight. Thereby, the following assumptions are made: (i) the temperature and pressure profiles used for the LOS retrieval, which are interpolated from the ECMWF T106 grid-point analysis, are correct on average during a flight. (ii) The applied CO₂-profile and spectral line data for the modelling of the CO₂-lines are also sufficiently accurate. (iii) Further significant errors e.g. resulting from uncertainties in the relative LOS-information (due to the limited accuracy of the AHRS data) or radiometric calibration show no significant systematic behaviour during a flight. (iv) The LOS offset is approximately constant during a flight.

Since an extended set of typically 50 to 70 limb sequences is available for a single flight and different air-masses along hundreds of kilometres are sampled, the effects of the uncertainties of the temperature and pressure profiles interpolated from ECMWF and of the CO₂-profile are expected to compensate for the average LOS offset. The atmospheric profile of CO₂ is well known, and weak variations in the low percent range have only small impacts on the LOS retrieval. Further errors resulting from the limited accuracy of the spectral line data, the relative LOS knowledge and the radiometric calibration are also expected to compensate on the timescale of flight, whereas remaining systematic contributions cannot be ruled out fully. However, severe systematic errors propagated into the LOS offset correction are expected to result in significant systematic errors in the majority of the subsequent trace retrievals and would alter the agreement with in-situ measurements, which is not observed (see Sect. 6). An approximately constant behaviour of the LOS offset under flight conditions is plausible, since the instrument is exposed to relatively constant temperatures during flight in the stratosphere.

7056

In the next step indicated in Fig. 10, temperature is retrieved for all limb sequences, using the same spectral signatures with strong isolated CO₂-lines as for the LOS retrieval. The lines fulfil the requirements/advantages for a temperature retrieval of (i) strong intensity, (ii) being clearly separable from other spectral signatures, (iii) different opacity and (iv) different temperature-dependence. It has to be noted, that the absolute situation (i.e. position in altitude) of the retrieved temperature profiles is clearly affected by the previously determined LOS correction relying on interpolated temperature profiles from ECMWF and making use of the same spectral signatures as the temperature retrieval. But on the other hand, only one single constant LOS correction is applied for all limb sequences of a flight, and no vertical information within the profile is retrieved from the CO₂-signatures in the determination of the LOS correction. In contrast, mainly the information on vertical variability of the profile is derived from the CO₂-signatures in the temperature retrieval. In Sect. 6 we show that the retrieved temperatures represent an improvement compared to the interpolated ECMWF temperatures.

According to Fig. 10, the different trace gases are retrieved subsequently in the following steps. First, target gases with dominant signatures and low spectral interference with other species are retrieved; then, with the optimised knowledge of the profiles of these gases, the corresponding spectral signatures are modelled for the retrieval of further trace gases with signatures influenced by the previously retrieved gases. Using previously fitted fixed profiles of significantly interfering species rather than climatological profiles allows for an improved modelling, since atmospheric variability is taken into account. This is especially important, when spectra of air-masses from different origin (e.g. vortex and extra-vortex air) within single limb scans are retrieved. If possible, the simultaneous reconstruction of interfering gases is avoided, since the total number of fit-parameters is increased and the simultaneous reconstructed parameters can potentially compensate each other to a certain extend (depending on the shapes of the individual signatures and the selected microwindows), especially in the context of the continuum-retrieval. Hence, the previous accurate retrieval of the interfering species

7057

making use of strong separate signatures and keeping the corresponding profiles fixed in subsequent retrievals is preferred. For weakly interfering gases (with signatures close to the noise-level of the spectra), climatological profiles are applied for spectral modelling.

Following this approach (compare Fig. 10), first HNO₃ is retrieved, for which strong isolated signatures are available, characterised by only very weak known interference with other trace gases. Under consideration of the retrieved HNO₃-profiles, O₃ and CFC-12 are retrieved in the next stage. The retrieved HNO₃- and O₃-profiles are then considered for the retrievals of CFC-11 and ClONO₂. Finally, H₂O is retrieved under consideration of the retrieved HNO₃-, O₃- and ClONO₂-profiles. The vertical profile of H₂O shows a strong tropospheric gradient in contrast to the only weakly varying stratospheric mixing ratios. Therefore, logarithmic inversion is applied, resulting in more reasonable results in this particular case than the linear inversion applied for the other retrievals. It has to be mentioned, that for the other retrieval target parameters microwindows with no significant spectral interference with H₂O signatures are used, since several signatures of H₂O strongly increase towards tropospheric altitudes and complicate retrievals of other parameters.

5.4 Retrieval setup

For the retrievals, a grid between 0–100 km with a spacing of 0.5 km below 30 km and increasing spacing above is applied. Regularization is needed, since the applied retrieval grid in the vertical range of interest (spacing of 0.5 km) is finer than measurement grid (mainly spacing of 1 km) and the vertical FOV of the instrument. However, considering the complex combination of (i) the increase of the vertical FOV diameter with decreasing tangent altitude, (ii) oversampling, (iii) the non-strictly conducted 1 km-sampling grid in the specific limb programs, (iv) the corrected LOS variations quantified in the AHRs-post-processing altering the sampling grid, and (v) the effects of the inhomogeneous vertical FOV, the combination of a 0.5 km retrieval grid with an optimized regularization is found to allow for a comprehensive use of the vertical information in-

7058

cluded in the spectra. The regularization strength is adjusted as small as possible to make maximal use of the information in the spectra and simultaneously avoiding oscillations in the retrieved vertical profiles.

The utilized spectral microwindows for the retrievals and the most prominent target signatures are summarized in Table 2. Spectral line parameters and cross-sections for the retrievals are taken from the MIPAS database (Flaud et al., 2002, 2006). Only for ClONO₂, cross-section data is taken from a study of Wagner and Birk (2003). Depending on the availability of suited microwindows with sufficiently strong target signatures and low spectral interference with other gases, each 1 or 2 microwindows are selected for the individual retrievals, allowing for manageable and efficient optimization of the regularization parameters and fast computation. Retrieval parameters are (i) the target quantity (LOS offset/temperature/trace gases), (ii) wave number independent background continuum for each microwindow and (iii) spectral shift of the microwindows. As mentioned before, the simultaneous reconstruction of further trace gases beside the target quantity is avoided, if possible. From the cases discussed here, only in the retrieval of the LOS correction and in the temperature retrieval O₃ is reconstructed as additional parameter. However, the corresponding signatures are clearly separable from the target-signatures of CO₂, allowing for a reliable reconstruction of the main target parameter (the results for O₃ with comparably low accuracy and vertical resolution are discarded subsequently). Regularization is applied to the retrieval parameters temperature, trace gases and background continuum.

In the individual retrievals, the first step is the optimization of the background continuum regularization strength for high vertical resolution, keeping the regularization of other retrieved quantities (trace gases/temperature) at a conservatively chosen fixed strength. In the next step, the optimized regularization strength for the background continuum is kept fixed and the regularization strength for the target quantity is optimized for high vertical resolution. Regularization parameters are optimized for a representative limb sequence and are subsequently kept constant for all limb sequences of a flight.

7059

Pressure profiles for all retrievals are interpolated from the ECMWF analysis at T106 resolution. Since the retrieval of the LOS correction is carried out prior to the temperature retrieval, temperature profiles for the LOS retrieval are also interpolated from the ECMWF T106 analysis. For the subsequent trace gas retrievals, the retrieved temperature profiles are taken into account.

In all discussed retrievals, initial guess and a priori profiles are identical for an individual retrieval parameter. For the temperature retrievals, the interpolated profiles from ECMWF are used as initial guess/a priori profiles. For the trace gas retrievals, the initial guess/a priori profiles are taken from the Polar Winter Profiles for MIPAS V3.1 of Remedios et al. (2007), slightly modified for the conditions of the Polar Winter 2009/2010 (i.e. CO₂ mixing ratios updated). For the reconstruction of background continuum, the initial guess/a priori is set to zero, starting the retrieval with the assumption of no continuum. Signatures of weakly interfering trace gases which are not retrieved are considered by their climatological profiles from Remedios et al. (2007).

5.5 Retrieval result characterization

The retrieval results are characterized by the following quantifiers: (i) estimated error, (ii) vertical resolution and (iii) degrees of freedom. Different error-sources inherent to the measurement technique and the retrieval method are divided into two groups. The dominating errors, assigned as “primary errors”, are resulting from:

- uncertainties in the spectroscopic line data
- uncertainties of the applied temperature profiles
- uncertainties of the LOS-information
- radiometric calibration errors
- spectral noise

Further errors sources referred as “secondary errors” are

7060

- uncertainties in the applied pressure profiles
- uncertainties resulting from horizontal inhomogeneities in the atmosphere
- uncertainties in the retrieved/climatological trace gas profiles used for forward-modelling of interfering species
- 5 – uncertainties of trace gas profiles above the flight path
- errors due to non-local thermodynamic equilibrium at high altitudes
- line-mixing of spectral signatures
- errors in the characterization of the FOV
- deviations of the real ILS from the theoretical model
- 10 – errors resulting from the limited knowledge of the aircraft altitude (GPS)
- errors resulting from stray-light in the instrument
- further errors resulting from the electronic data acquisition chain

The primary errors are considered in the error estimation, while the secondary errors are expected to be of minor importance in most cases and are not included in the error-budget. Uncertainties of the interpolated pressure profiles are expected to have low impact as a consequence of the high quality of the ECMWF data. Errors due to the non-consideration of horizontal gradients of atmospheric parameters along the line-of-sight are expected to be less important compared to the balloon-borne and satellite-borne MIPAS instruments as a consequence of shorter light paths through the atmosphere. However, in the presence of strong horizontal gradients and contrasts of trace gas mixing ratios, significant uncertainties in the retrievals cannot be excluded, since in the retrieval constant atmospheric conditions are assumed for single limb scans. On the other side, to limited extent, the effects of horizontal gradients in the retrievals can

7061

also be interpreted as a characteristic of the sampled air-mass as a whole rather than an error. Further uncertainties can arise from horizontal inhomogeneities along flight track, since spectral contributions from a certain altitude regime can change within the recording of a limb sequence, but significantly affect different measurement geometries of the same sequence.

Errors resulting from potentially inaccurate modelling of interfering signatures using retrieved and climatological profiles are expected to be of minor importance, since spectral microwindows with dominating signatures of the target gas and weak signatures from known interfering gases are utilized. Furthermore, errors in the modelling of broad and weakly structured interfering signatures are at least partially compensated by the retrieval of background-continuum.

The limited knowledge of the profiles of atmospheric constituents above the flight path represents a relevant error source in principle, especially in the case of trace gases where the maximum of the profile is located above the flight altitude. However, this uncertainty is reduced by considering the upward-viewing geometries included in the limb sequences, allowing for the reconstruction of column information above the flight path and to a limited extent also vertical information.

Errors resulting from non-local thermodynamic equilibrium are expected to be practically insignificant for the measurement geometries of MIPAS-STR, since these effects are mainly important high above the flight altitude (e.g. Manuilova et al., 1998; von Clarmann, 2003). Possible errors resulting from line-mixing (e.g. Funke et al., 1998) are minimized by choosing microwindows without significant Q-branches. The minor importance of FOV and ILS related uncertainties is discussed in Sect. 2.

It has to be noted, that the error resulting from the knowledge of the flight altitude can become important especially in ascent and descent phases, since the aircraft changes the flight altitude with several meters per second, and the GPS altitude information (which is also uncertain within several tens of meters) has to be interpolated to the mean time of an interferogram. Stray-light related errors were investigated by Keim (2002) for flights with strong particle contamination on the scan mirror of MIPAS-

7062

STR. During the RECONCILE campaign, no strong particle contamination of the scan mirror was observed and stray-light related effects were not identified. However, weak stray light contributions cannot be fully excluded. Significant errors resulting from the electronic data acquisition chain are not identified.

5 As described in Rodgers (2000), another relevant error in principle is the smoothing error, indicating the uncertainties resulting from the limited vertical resolution of the retrieval result. In case of Tikhonov-Philipps regularization, the smoothing error expresses the retrieval error due to smoothing as a consequence of regularization (e.g. von Clarmann, 2003). Following Rodgers (2000), no smoothing error is estimated
10 for the shown MIPAS-STR results, since in most cases no estimate of the true ensemble covariance of suited accuracy (i.e. a climatological covariance matrix) needed for the calculation is available. Especially in the discussed flight, structured and overlapping air-masses from different origin are covered by the measurements of MIPAS-STR, and the estimation of a representative climatological covariance matrix is practically not
15 possible. Following Rodgers (2000), the retrieval result is considered as an estimate of the smoothed version of the state rather than an estimate of the complete state, which has to be kept in mind when interpreting the retrieval results.

For the retrieval of the LOS correction, in principle all errors listed above under “primary errors” are relevant for the determination of the individual LOS offsets. But since
20 the LOS offset is estimated as the average of a large number of limb sequences (61 for RECONCILE flight 11), the different errors are expected to compensate each other. In Fig. 11, the retrieval results for the individual LOS offsets are shown for the whole flight. The values are scattering well around a mean LOS offset of 5.45 arcmin with a
25 1σ -uncertainty of 0.19 arcmin. Outliers can be caused by the availability of low numbers of quality-filtered observation geometries, and/or different combinations of the individual error sources listed above. The outliers associated to the first sequence and the last sequences belong to ascent and descent phases, where the flight altitude is changing fast, resulting in additional uncertainties of the sampling geometries. As can be seen in Fig. 11, the found LOS offset is approximately constant during the flight,

7063

and using the average LOS offset as correction for all limb sequences seems to be appropriate. The uncertainty of the corrected LOS is calculated taking into account the
5 1σ -uncertainties resulting from (i) the attitude information from the AHRS after postprocessing of 0.75 arcmin, (ii) errors resulting from the scan-mirror control of 0.09 arcmin and (iii) the 1σ -uncertainty of the derived mean LOS correction of 0.19 arcmin. The uncertainties are combined by the root of the square sum, resulting in an estimated
10 LOS-uncertainty of 0.78 arcmin. Hence, the LOS-uncertainty, which is used for the estimation of the LOS-associated uncertainties in the following retrievals, is dominated by the accuracy of the post-processed attitude information provided by the AHRS.

10 The error of to the temperature retrieval is estimated according to Wetzel et al. (2002) for the balloon-borne MIPAS instrument. The effects of spectroscopic line data errors and uncertainties of the applied CO₂-profile are estimated by retrievals with a shifted CO₂-profile (5 %). LOS-related errors are estimated by retrievals taking into account of the LOS-uncertainty (0.78 arcmin), and radiometric calibration errors are considered by
15 retrievals with modified gain (2 %). The corresponding errors for retrieved temperature profiles are calculated as the differences between the retrieval results with the modified quantity and the initial retrieval results according to

$$\Delta \mathbf{x}_j = \begin{pmatrix} \Delta x_{1,j} \\ \Delta x_{2,j} \\ \vdots \\ \Delta x_{n_{\max},j} \end{pmatrix} = (\mathbf{K}^T \mathbf{S}_y^{-1} \mathbf{K} + \gamma \mathbf{L}^T \mathbf{L})^{-1} \mathbf{K}^T \mathbf{S}_y^{-1} (\mathbf{y}_{\text{error},j} - \mathbf{y}_{\text{result}}), \quad (4)$$

whereas $\Delta \mathbf{x}_j$ represents the vertical error profile resulting from the modified quantity
20 j , $\Delta x_{n,j}$ the errors at the altitude levels n , $\mathbf{y}_{\text{error},j}$ the calculated spectrum with the modified quantity and $\mathbf{y}_{\text{result}}$ the calculated spectrum of the initial retrieval result (von Clarmann, 2003). Together with the spectral noise error, the resulting error vectors are combined to the estimated 1σ -uncertainty for temperature by the root of the square-sum according to:

$$\Delta \mathbf{x}_T = \sqrt{\Delta \mathbf{x}_{\text{prof,spec}}^2 + \Delta \mathbf{x}_{\text{los}}^2 + \Delta \mathbf{x}_{\text{cal}}^2 + \Delta \mathbf{x}_{\text{noise}}^2}, \quad (5)$$

7064

the uncertainty of the spectroscopic data, followed by the errors resulting from the radiometric calibration and the uncertainties of the retrieved temperature profiles. The LOS error is variable with altitude, and is together with the spectral noise error of minor importance. For sequences with more extended vertical coverage, all estimated errors
5 except of the assumed spectroscopic line data error significantly increase towards the lower observation geometries, and the LOS error and the spectral noise error can become the dominating errors.

For the shown result, the estimated error is between 9 to 12 % in the altitude range between flight altitude and the lowest tangent point. Above flight altitude, the absolute numbers of all errors except of the spectroscopic error still decrease virtually, but
10 this has to be interpreted in context of the vertical resolution indicated in the right panel. For the measurement geometries between flight altitude and the lowest tangent point, a high vertical resolution of mainly between 1 and 1.5 km is achieved due to the availability of comprehensive vertical information included in the spectra with negative
15 elevation angles. Therefore, the estimated error is representative in this altitude range in the context of the vertical resolution. From the geometries with positive elevation angles, mainly column information is obtained for the atmosphere above the aircraft, and the vertical resolution rapidly decreases. Hence, for the parts of the retrieved profiles above the aircraft, the absolute numbers of the errors still decrease, but the vertical
20 information is “smeared” over a broader vertical range. Practically only column information is obtained above 17.5 km and the errors become physically meaningless. At altitudes below approximately 8.5 km, which are not covered by the measurements, no vertical information is obtained, as indicated by the vertical resolution tending to infinity.

For the HNO_3 -profile shown in Fig. 12, 8.7 DOF are obtained, which have to be
25 interpreted in the context of the 9 tangent altitudes in the vertical range between 8.9 and 16.7 km plus two upward scanning geometries carried out in the modified limb sequence, indicating weak influence of the regularization. For higher flight altitudes, resulting in scans with more tangent altitudes, and scans with increased vertical coverage (as in the standard sequence), the numbers of DOF increase. The shown profile

7067

represents the result for HNO_3 for an individual limb scan, and the corresponding errors are varying from scan to scan, depending on the atmospheric situation, the vertical distribution of the target species, and the sampling geometries. Whereas in most cases, the spectroscopic error represents the dominating error, the relative importance of the
5 different error contributions can vary depending on the retrieval target.

6 Results

6.1 Approach for comparison of MIPAS-STR results and in situ measurements

Several in-situ instruments were deployed onboard the Geophysica during the RECONCILE campaign, allowing for comparisons with the MIPAS-STR results (Table 3). High
10 precision ambient temperature measurements were obtained from the Thermodynamic Complex (TDC). Ozone measurements were taken by the Fast-Response Chemiluminescent Airborne Ozone Analyzer (FOZAN). CFC-11 and CFC-12 measurements were provided by the High Altitude Gas AnalyzeR (HAGAR). Gas-phase water vapour measurements were obtained by the Fluorescent Lyman-alpha Stratospheric Hygrometer
15 for Aircraft (FLASH-A), which is a recent modification of the previously utilized FLASH instrument on board of the Geophysica aircraft (Sitnikov et al., 2007).

For the discussed flight, MIPAS-STR measurements of high spatial coincidence with the in-situ measurements related to the ascent phase of the Geophysica are available (Fig. 13). The lowest tangent point of the selected scan 02_01788 is located at an
20 altitude 8.9 km and the flight altitude is 16.7 km, whereas 9 limb-viewing and 2 upward-viewing geometries were carried out. The two tangent points located spatially closest to the flight path during ascent correspond to tangent altitudes of 14.0 and 15.1 km. For comparisons, it has to be considered that the airvolume sampled by MIPAS-STR during one limb sequence (duration typically a few minutes) covers horizontally several
25 tens of kilometres along flight track and several hundreds of kilometres along the viewing direction (see Sect. 2) and the vertical resolution is limited compared to in-situ

7068

situ comparisons here.

In Fig. 14e, the results for H₂O from MIPAS-STR and FLASH-A are shown, and the instruments agree within the uncertainties. Slightly increasing differences below 10 km are attributed to the decreasing spatial overlap of the measurements and the tropospheric variability of H₂O. The retrieved profile of ClONO₂ is shown in Fig. 14f, where no in-situ measurements suited for comparisons are available. The retrieved profile indicates high ClONO₂-mixing ratios in the upper part of the profile, characteristic for the chlorine-deactivated air in the late vortex. Virtually negative mixing ratios below 10 km are a consequence of lowest mixing ratios of ClONO₂ in the troposphere and can result from predominantly additive combination of the discussed error sources. For gases with such weak signatures compared to the overall spectral background at tropospheric observation geometries, especially spectral interference with other trace gases not or incorrectly considered by climatological profiles can become important. However, we mention that the applied retrieval method does not constrain the result to positive values in order to avoid biases in statistics (von Clarmann, 2003). The corresponding retrieved profile for HNO₃ (for which also no in-situ comparison is performed) is discussed in Sect. 5.4 (Fig. 12).

For the shown retrieved profiles of the discussed scan, the estimated 1σ-errors are typically about 10–15%. Typical vertical resolutions of 1 to 2 km are achieved in the altitude range of the tangent points. Between 6.4 and 8.7 DOF are obtained from the 9 limb-viewing and 2 upward-viewing geometries, indicating comprehensive vertical information in the measurements. For the continuum retrievals (not shown here) carried out for each microwindow simultaneously together with the target parameters, typically about 7 DOF are obtained for this scan. The shown retrieval results are nearly insensitive on the initial guess/a priori information as a consequence of the high signal-to-noise ratios of the measurements and the applied weak regularization.

The comparison of the retrieval results and the in-situ measurements along the flight track is shown in Fig. 15a–e. The retrieval results of MIPAS-STR for temperature are in very good agreement with the results of TDC (Fig. 15a) and the agreement is improved

7071

compared to the interpolated ECMWF temperatures. As can be seen in Fig. 15b, for O₃ also reasonable agreement is found between MIPAS-STR and FOZAN.

The results of MIPAS-STR for CFC-11 and CFC-12 along the flight track are also in principle in agreement with the measurements of HAGAR (Fig. 15c and d), often already within one sigma of the errors. As in the case of the profile comparisons, higher mixing ratios of the CFCs are found in the first flight part for the MIPAS-STR results at flight altitude and are attributed to spectral contributions from outside of the polar vortex. The strong contrasts of the mixing ratios of the CFCs at the vortex edge can be seen consistently in the MIPAS-STR and HAGAR results in Fig. 15c and d. The vortex edge shows up in the HAGAR measurements sharply between 11:14 and 11:21 UTC by strong increases of the mixing ratios of CFC-11 and CFC-12 of 80 pptv and 180 pptv, respectively. In the case of MIPAS-STR, the corresponding structures appear more smoothly between 11:00 and 11:25 as a consequence of the different sampling characteristics. For comparison, the differences between vortex and extra-vortex air are less pronounced in the case of O₃ along the flight track, as consistently indicated by the results of MIPAS-STR and FOZAN (Fig. 15b). For CFC-11 and CFC-12, noticeable differences between the results of MIPAS-STR and HAGAR are found also especially in the last flight part (12:15–12:45) (Fig. 15c and d). The lower mixing ratios in the results of MIPAS-STR are explained by the fact that filaments of vortex air with lower mixing ratios of the CFCs were located along the instruments viewing direction in this particular flight part (compare Sect. 6.3), contributing to the spectra of MIPAS-STR. As can be seen in Fig. 15e, for H₂O reasonable agreement is found between the results of MIPAS-STR and FLASH-A.

The mean differences and the sample standard deviations of the mean differences between the results of MIPAS-STR and the in-situ measurements for the shown profile comparisons and comparisons along the flight track are summarized in Table 4. While the mean differences indicate systematic differences between the MIPAS-STR and the in-situ results, the sample standard deviations of the mean differences indicate the qualitative agreement for single retrieval-grid points. Both quantities together indicate

7072

the quantitative agreement. In the case of the profile comparisons, these quantities are calculated taking into account the smoothed in-situ results at the retrieval-grid altitudes. For the comparisons along flight track, the unsmoothed in-situ results are interpolated in time for the MIPAS-STR retrieval results.

5 With mean differences of $+0.2/-0.2$ K for the profile and along-flight-track comparison, and respective sample standard deviations of about 0.7/0.6 K, the retrieved temperatures of MIPAS-STR agree very well with the TDC measurements within the uncertainties of the involved instruments. Also for O_3 excellent agreement is found between MIPAS-STR and FOZAN. The absolute mean differences between MIPAS-STR and
10 HAGAR for CFC-11 and CFC-12 in the range of 8–21 pptv are also small. However, all mean differences calculated for the CFCs are positive, which is attributed to the extended first flight part with the MIPAS-STR measurements significantly biased by extra-vortex air. The corresponding percentages of the sample standard deviations of the mean differences (see Table 4) reflect the fact that the strong horizontal contrasts
15 in the mixing ratios of the CFCs alter the comparability of the MIPAS-STR and HAGAR measurements. These comparably high values are mainly driven by the differences at high profile altitudes with very low absolute mixing ratios of the CFCs. However, this is masking the fact that the absolute mean differences and sample standard deviations for the CFCs are in the low ppt-range, indicating considerable agreement at higher mixing
20 ratios of the CFCs (i.e. at lower profile altitudes). For the profile/along-flight-track comparisons for H_2O , the mean differences and corresponding sample standard deviations indicate agreement between the involved instruments.

To overcome the complications of the limited spatial overlap of the MIPAS-STR and HAGAR results in the context of the strong horizontal contrasts of the mixing ratios
25 of the CFCs, in Fig. 16 the correlations of CFC-11 and CFC-12 derived from MIPAS-STR and HAGAR are shown. Collocated pairs of CFC-11 and CFC-12 measurements of the individual instruments are considered, whereas no spatial coincidence between the measurements of the two instruments is necessary. The resulting correlations show comprehensive agreement within the variability of the results of MIPAS-STR and the

7073

associated uncertainties. Only for mixing ratios of CFC-11 between 30 and 150 pptv, slightly higher mixing ratios of CFC-12 are found for HAGAR, but the corresponding results are still within the variability of the MIPAS-STR results.

6.3 Two dimensional trace gas distributions

5 The retrieved vertical trace gas profiles obtained from the MIPAS-STR measurements are combined to 2-dimensional vertical cross-sections of the corresponding species along the flight track. In the upper panel of Fig. 17, the resulting vertical cross-section for HNO_3 is shown. In the first flight part between 10:00 and 11:15, at altitudes above 14.5 km, air of the late vortex edge can be clearly identified. A weak renitrification
10 remnant is found with a HNO_3 -maximum at 15.5 km and mixing ratios of about 8 ppbv, indicating between 2 to 3 ppbv higher mixing ratios compared to the layers above and below. The resolved vertical thickness of the layer is about 1 km, which is close to the vertical resolution limit of MIPAS-STR. Above, denitrified air characterised by low HNO_3 -mixing ratios is found.

15 Between 11:35 and 12:00, a structure of extra vortex air can be identified, which is characterized by low HNO_3 -mixing ratios below 16 km and shows no de-/renitrification-structure. The structure is diagonally linked to further structures of extra-vortex air in the last flight section with low HNO_3 -mixing ratios, characteristic for extra-vortex air. In the last flight part, between 12:05 and 12:45, two prominent structures with strongly
20 enhanced HNO_3 -mixing ratios are apparent, which can be assigned to filaments of the polar vortex with renitrified air. HNO_3 mixing ratios of up to 10 ppbv are found for the lower structure centred at 14.5 km with a vertical extension of about 3 km, whereas the mixing ratio is about 5 ppbv increased compared to the surrounding air. The tiny upper structure located around 17.5 km with a vertical extension of about 1.5 km also shows
25 significantly enhanced HNO_3 mixing ratios of up to 9 ppbv.

In Fig. 18, the corresponding vertical cross-section of HNO_3 derived from CRISTA-NF measurements is shown. CRISTA-NF is capable of the measurement of limb-emission spectra in a comparable spectral region like MIPAS-STR and is pointing

7074

approximately into the same direction. The characteristics of CRISTA-NF are briefly summarized in Table 5 (e.g. Spang et al., 2008; Ungermann et al., 2011). While MIPAS-STR with its comparable high spectral resolution is able to separate weak trace gas signatures not resolved by CRISTA-NF, the advantage of CRISTA-NF is the higher vertical and horizontal sampling density allowing for the identification of atmospheric fine-structures not resolved by MIPAS-STR.

HNO_3 is retrieved from the CRISTA-NF measurements in the same spectral region as for MIPAS-STR and a typical vertical resolution of 0.5 km is obtained. For details concerning the CRISTA-NF retrieval, see Ungermann et al. (2011). As can be seen in Figs. 17 and 18, the retrieved vertical cross-sections of HNO_3 from the two instruments agree very well. All major structures observed in the MIPAS-STR result are also identified for CRISTA-NF: the de- and renitrification layers in the first part of the flight, the structure with extra-vortex air in the middle of the flight, and the vortex filaments in the last part of the flight. Several smaller substructures can also be identified in both results. It has to be noted, that the range of the colour-coding for CRISTA-NF in Fig. 18 is slightly higher than for MIPAS-STR in Fig. 17. Higher peak values observed in the CRISTA-NF result are consistent with atmospheric fine-structures with enhanced HNO_3 -mixing ratios spatially higher resolved by CRISTA-NF. However, we emphasize that the measurements of the two limb-sounding instruments using different techniques and processed with different forward and inversion models are resulting in cross-sections with considerable agreement.

The vertical cross-section of CFC-11 from MIPAS-STR in Fig. 19 shows a complementary picture to the HNO_3 cross-sections: vortex air in the first flight part and vortex filaments at the end of the flight are characterised by low mixing ratios of CFC-11, while extra vortex air is indicated by increased mixing ratios of CFC-11 at stratospheric altitudes.

Some of the structures visible in the cross-sections of HNO_3 and CFC-11 are horizontally largely extended (like the renitrification remnant in the beginning, with an extension along flight track of about 500 km between the turning point and the vortex

7075

edge) or show diagonally linked patterns and further fine-structures.

7 Conclusions

In the work in hand, we present the FTIR limb-sounder MIPAS-STR deployed on the high altitude aircraft M55 Geophysica in its current performance. The applied calibration scheme from the measured data towards radiometrically calibrated spectra is discussed. A comprehensive bottom-up retrieval scheme for the reconstruction of temperature, HNO_3 , O_3 , CFC-11, CFC-12, ClONO_2 and H_2O is introduced, including the correction of a systematic line-of-sight offset. The significant influences of continuum-like effects on limb-emission mid-infrared spectra in the UTLS region and their treatment by the retrieval of wavenumber-independent background continuum on the scale of retrieval microwindows are discussed. Retrieval results are shown exemplary for RECONCILE flight 11 on 2 March 2010.

The estimated overall 1σ -errors of the retrieval results are below 1 K for temperature and typically between 10 and 15 % for the trace gases in the vertical range spanned by the tangent points. The vertical resolutions for the different target parameters are typically between 1 to 2 km in the vertical range of the tangent points and slightly above the flight path, allowing for the identification of narrow vertical structures. Depending on the sampling programme, typical horizontal sampling densities of 45 or 25 km are obtained, respectively. Between 6.4 and 8.7 degrees of freedom are obtained for the different target-parameters for a limb sequence with 9 limb-viewing and 2 upward-viewing observation geometries, indicating comprehensive vertical information included in the spectra.

The retrieval results are validated against available in-situ measurements carried out onboard the Geophysica during the same flight. The profile comparisons show a high degree of consistency between MIPAS-STR and the in-situ instruments, taking into account the errors of MIPAS-STR and the in-situ results, the vertical and horizontal resolution of the MIPAS-STR results, atmospheric inhomogeneities and the geograph-

7076

ical and time-mismatch between the MIPAS-STR and in-situ measurements. For temperature and O_3 the results show very good agreement within the estimated errors of the involved instruments. For CFC-11 and CFC-12, higher discrepancies are apparent around flight altitude and are attributed to the observed strong contrasts in the mixing ratios of the CFCs between vortex and extra-vortex air. The comparison of the correlation of CFC-11 and CFC-12 derived from the MIPAS-STR and HAGAR measurements, respectively, overcomes the complication of limited spatial coincidence between in-situ and remote-sensing measurements and indicates enhanced agreement between the two instruments. For the in-situ comparison of H_2O , also comprehensive agreement is found.

In the retrieved vertical cross-sections of HNO_3 and CFC-11, detailed mesoscale structures are identified, which are attributed to vortex air, vortex filaments and extra-vortex air. Small-scale structures with vertical extensions down to 1 km are resolved. The vertical cross-sections of HNO_3 from MIPAS-STR and the infrared limb sounder CRISTA-NF, which were simultaneously deployed onboard the Geophysica during RECONCILE, are in very good agreement, taking into account the different characteristics of the two instruments.

The presented results give insights into the properties of the arctic UTLS in the early year 2010 and demonstrate the suitability of MIPAS-STR for quantitative studies of the chemistry and dynamics of the UTLS region with rather high spatial resolution. This allows for further studies with MIPAS-STR data on mesoscale structures, denitrification processes and chlorine activation.

Acknowledgements. We dedicate this paper to C. E. Blom, who greatly contributed to the success of MIPAS-STR onboard the M55 Geophysica over many years. This work was supported by the EU under the grant number RECONCILE-226365-FP7-ENV-2008-1. We thank the RECONCILE coordination team, Myasishchev Design Bureau and Enviscope for making the RECONCILE field campaign a success. ECMWF data for the MIPAS-STR retrievals were obtained via NILU's NADIR database. W. Woiwode thanks A. Kleinert and G. Wetzel from IMK-ASF, Karlsruhe Institute for Technology, for helpful discussions, and M. von Hobe from IEK-7, Research Centre Jülich, as representative for the RECONCILE team for especially supporting

7077

young scientists.

Table 1. Characteristics of MIPAS-STR in the current configuration.

Telescope	
Field of view (full cone)	0.44°
Etendue	$2.6 \times 10^{-3} \text{ sr cm}^2$
Interferometer	
Effective optical path difference	$\pm 13.9 \text{ cm}$
Scan time per interferogram	$\sim 9.5 \text{ sec}$
Sampling frequency	48.8 kHz
Signal frequency	2.1–6.1 kHz
Unapodized/apodized spectral resolution	$0.036 \text{ cm}^{-1}/0.058 \text{ cm}^{-1}$
Detectors	
Si:As – BIB	
NESR (single apodized spectrum, in-flight)	
Channel 1 (725–990 cm^{-1})	$1 \times 10^{-8} \text{ W}/(\text{cm}^2 \text{ sr cm}^{-1})$
Channel 2 (1150–1360 cm^{-1})	$8 \times 10^{-9} \text{ W}/(\text{cm}^2 \text{ sr cm}^{-1})$
Channel 3 (1560–1710 cm^{-1})	$5 \times 10^{-9} \text{ W}/(\text{cm}^2 \text{ sr cm}^{-1})$
Channel 4 (1810–2100 cm^{-1})	$5 \times 10^{-9} \text{ W}/(\text{cm}^2 \text{ sr cm}^{-1})$
Pointing	
Pitch/roll accuracy (AHRS)	0.5 arcmin (1σ)
Yaw accuracy (AHRS)	0.3° (1σ)
Estimated LOS-elevation accuracy	0.78 arcmin (1σ)
Dimensions	
Optics module	$135 \times 75 \times 75 \text{ cm}^3$
Electronics module	$50 \times 50 \times 50 \text{ cm}^3$
Total mass	$\sim 200 \text{ kg}$
Power consumption	$\sim 300 \text{ W}$ (28 V DC)

7085

Table 2. Microwindows and target signatures selected for the retrievals. Spectral positions of the most prominent target signatures are listed. For cross-section gases, the spectral signatures are relevant in the whole range of the microwindow.

Retrieval target	Microwindow [cm^{-1}]	Target signature	Spectral position [cm^{-1}]
LOS/temperature (CO ₂ signatures)	810.1–813.1	R24e (11101←10002)	810.93
		R26e (11101←10002)	812.48
	955.6–958.5	P6e (00011←10001)	956.19
		P4e (00011←10001)	957.80
HNO ₃	866.0–870.0	v5/2v9 bands	9 prominent lines (v5-band)
O ₃	780.6–781.7	v2-band	780.80 781.13 781.18 781.52
	787.0–788.0	v2-band	787.13 787.46 787.86
CFC-11	842.5–848.0	v4-band	cross-section
CFC-12	918.9–920.6	v6-band	cross-section
	921.0–922.8	v6-band	cross-section
ClONO ₂	779.8–780.5	v4-band	cross-section
	805.1–805.5	v3-band	cross-section
H ₂ O	795.7–796.1	pure rotation	795.89

7086

Table 3. In-situ instruments onboard the Geophysica used for comparisons with MIPAS-STR.

Instrument	Target	Time resolution	Accuracy	Reference
TDC	Temperature	1 s	0.5 K	Shur et al. (2007)
FOZAN	O ₃	2 s	< 10 %	Ulanovsky et al. (2001)
HAGAR	CFC-11	90 s	0.5–5 ppt (1.4–5.6 %)	Riediger et al. (2000) Werner et al. (2010)
HAGAR	CFC-12	90 s	2–8 ppt (1.2–1.7 %)	Riediger et al. (2000) Werner et al. (2010)
FLASH-A	H ₂ O (gas)	4 s	10 %	see text

7087

Table 4. Mean differences and sample standard deviations (1σ , in parentheses) of the mean differences between MIPAS-STR and in-situ results for profile comparison and comparison along flight track.

Target	Vertical profile		Flight track	
Temperature	0.21 (0.73) K		–0.19 (0.64) K	
O ₃	–0.01 (0.12) ppmv	–3 (14) %	0.05 (0.26) ppmv	2 (9) %
CFC-11	17 (9) pptv	14 (13) %	8 (24) pptv	21 (40) %
CFC-12	21(19) pptv	5 (5) %	14 (42) pptv	8 (16) %
H ₂ O	1.16 (1.91) ppmv	8 (14) %	0.29 (0.36) ppmv	6 (7) %

7088

Table 5. Characteristics of CRISTA-NF. The spectral resolution is given for the low resolution spectrometer (LRS) which is capable of the detection of HNO_3 .

CRISTA-NF	
Spectrometer type	2 Ebert-Fastie Grating Spectrometers
Spectral range	667–2500 cm^{-1}
Spectral resolution	1.6 cm^{-1} (LRS)
FOV (vertical x horizontal)	3 × 300 arcmin
Vertical/horizontal sampling density	0.25/15 km
Time per spectrum/limb scan	~1.2/70 sec

7089

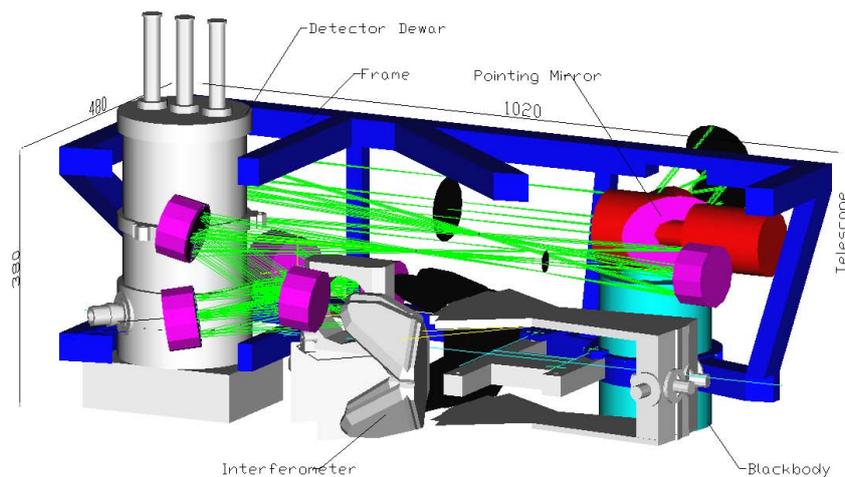

Fig. 1. Schematic representation of the optics module of MIPAS-STR (taken from Blom et al., 1998). Mirrors are shown in pink and the light path along scan-mirror, telescope and interferometer towards the detector dewar is indicated by green lines.

7090

RECONCILE Flight 11 (March 2nd 2010) - Inflight NESR Channel 1

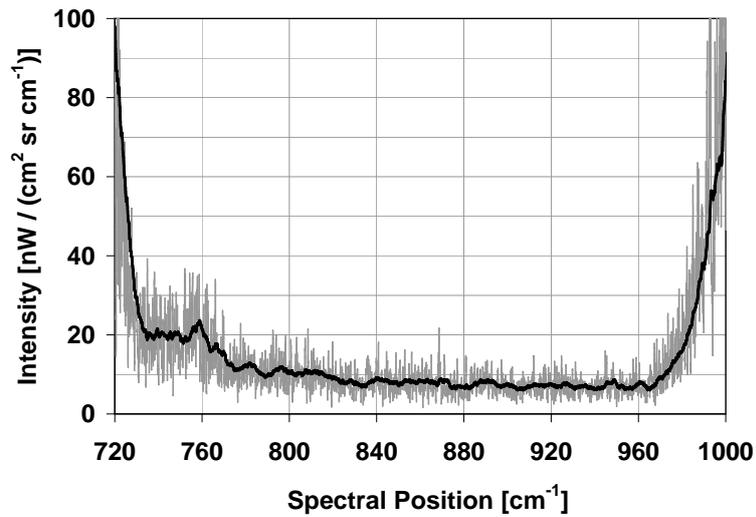

Fig. 2. Typical NESR of a single channel 1 spectrum under flight conditions (grey curve) and moving average (black curve).

7091

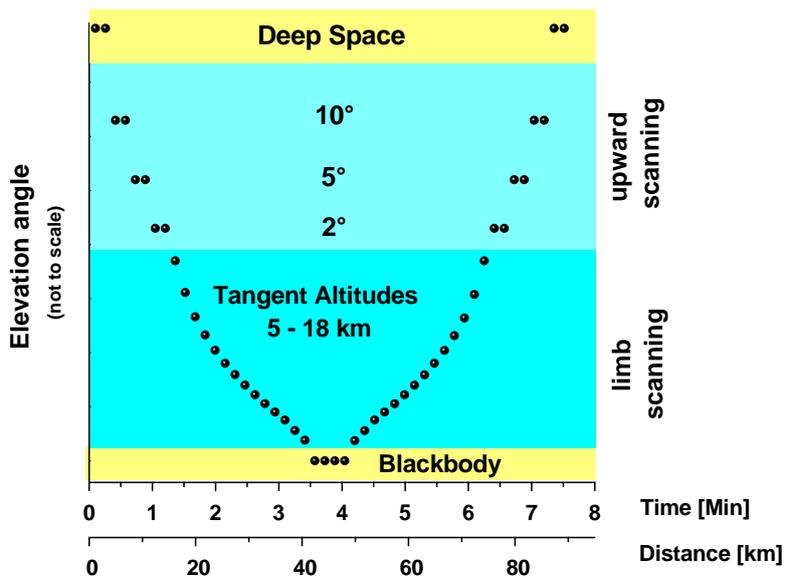

Fig. 3. Schematic representation of the standard sampling programme of MIPAS-STR, including atmospheric measurements (cyan) and calibration measurements (yellow). Two full limb scans are shown.

7092

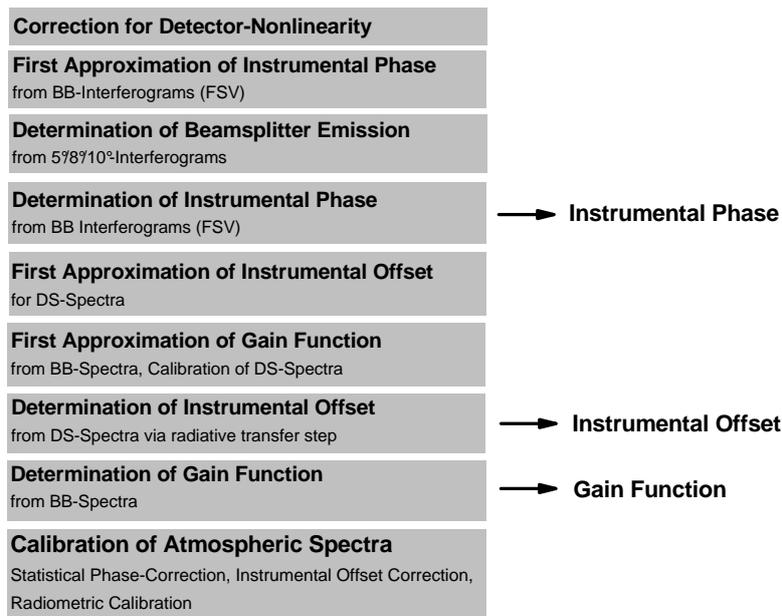

Fig. 4. Schematic representation of the full calibration cycle for MIPAS-STR measurements, including the determination of the detector non-linearity, instrumental phase, instrumental offset and radiometric gain function (BB = blackbody measurements, DS = “deep space” measurements (zenith view), FSV = phase correction according to Forman, Steel and Vanasse, for details see text).

7093

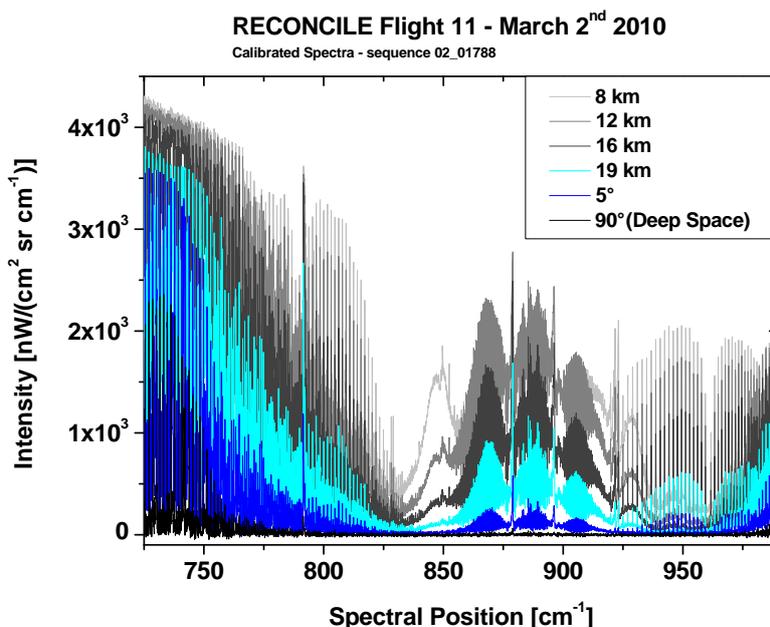

Fig. 5. Examples for single calibrated spectra from RECONICLE flight 11 on 2 March 2010. In the box in the upper right side, the corresponding tangent altitudes/elevation angles of the spectra are listed (0° elevation corresponds to horizontal view).

7094

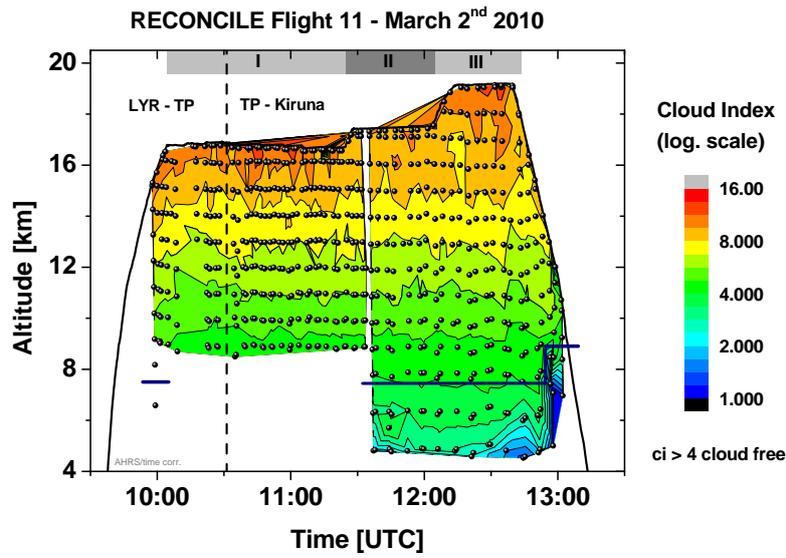

Fig. 6. Vertical distribution of tangent points (points) and interpolated cloud index (ci, contour). Flight altitude of the Geophysica (solid black line) along flight track from Longyearbyen (LYR) via the turning point (TP, dashed black line) to Kiruna. The horizontal blue lines represent the approximate threshold for cloud index 4.

7095

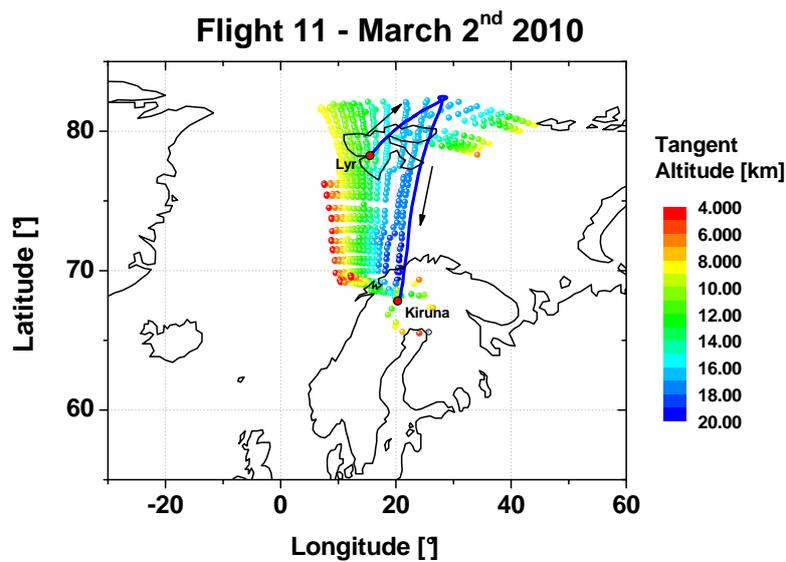

Fig. 7. Flight track of the Geophysica for RECONCILE flight 11 (solid blue line) and distribution of tangent points of the MIPAS-STR observations, colour-coded with reference to the tangent altitude.

7096

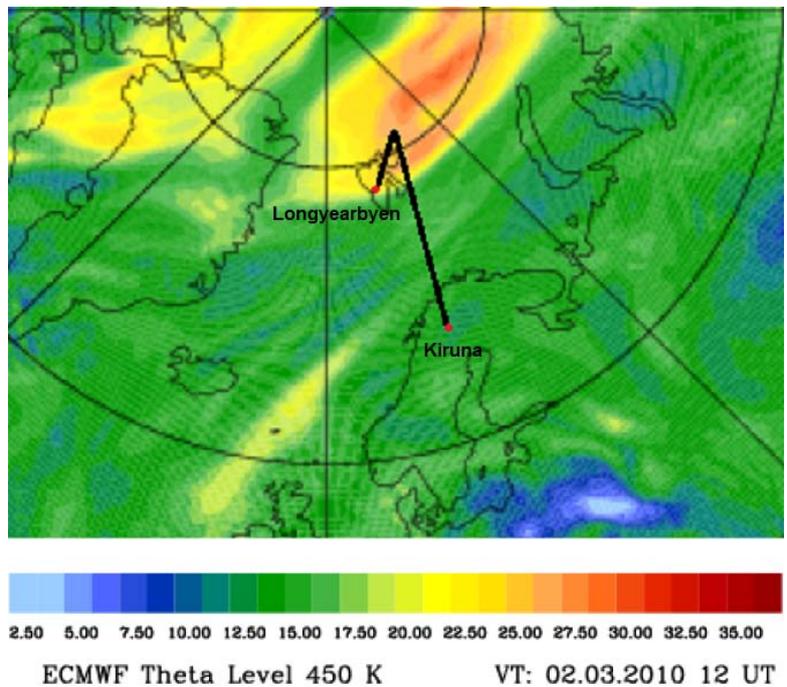

Fig. 8. Meteorological situation during RECONCILE Flight 11. The colour-coding of the map shows the potential vorticity at the 450 K-level (approximately 17 km altitude). A late vortex remnant, coming from Canada and reaching from Spitsbergen to Siberia, can be identified clearly. The flight path of the Geophysica is indicated schematically.

7097

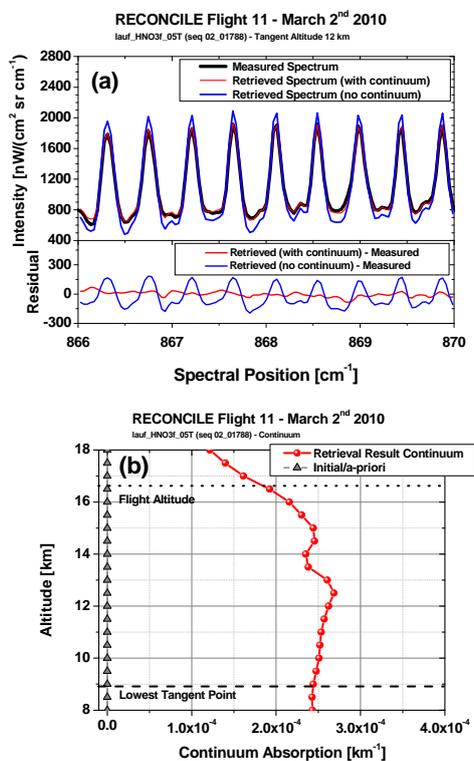

Fig. 9. (a) Measured spectrum (black) and retrieved spectra with (red) and without (blue) background continuum retrieval for a flight altitude of 16.7 km and a tangent altitude of 12 km for the HNO₃-retrieval and residuals. **(b)** Associated retrieval result for continuum absorption of the corresponding full limb sequence.

7098

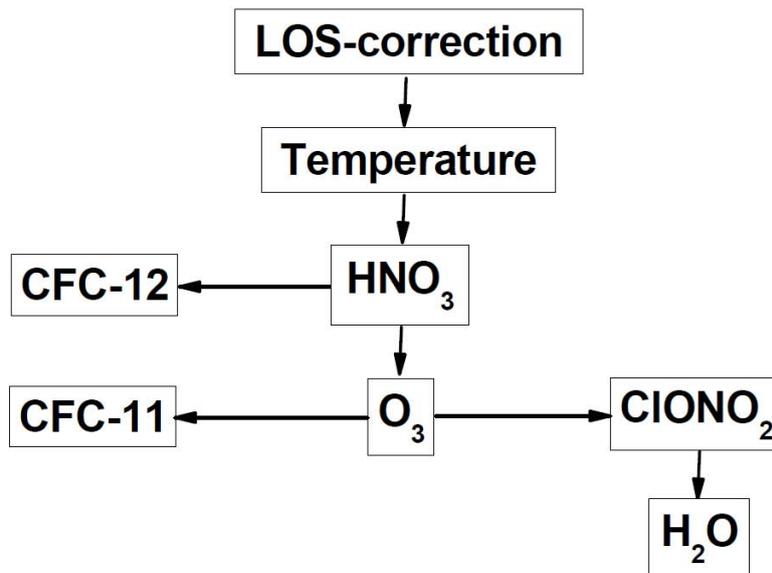

Fig. 10. Schematic representation of the subsequent retrievals of LOS correction, temperature and the discussed trace gases from MIPAS-STR channel 1 spectra. For each target parameter, all other parameters prior in the scheme are determined previously.

7099

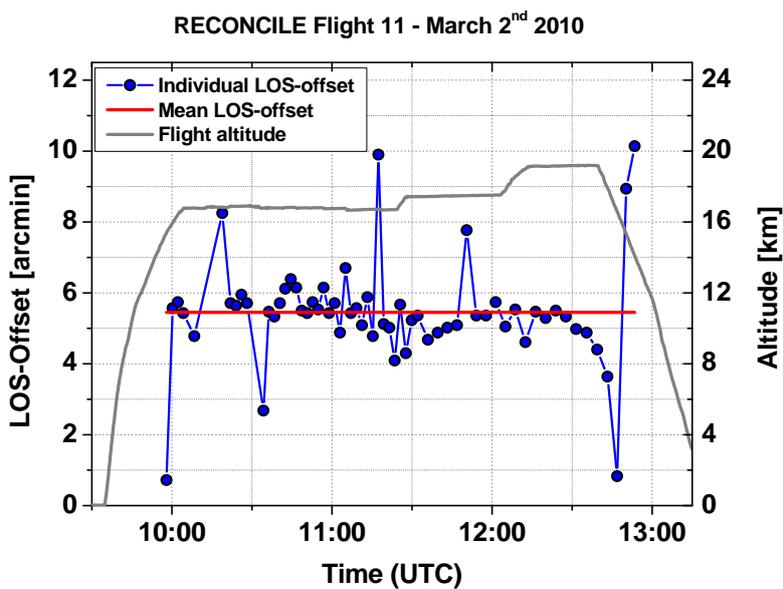

Fig. 11. Retrieved LOS offsets from the individual limb sequences and mean LOS offset used as LOS correction.

7100

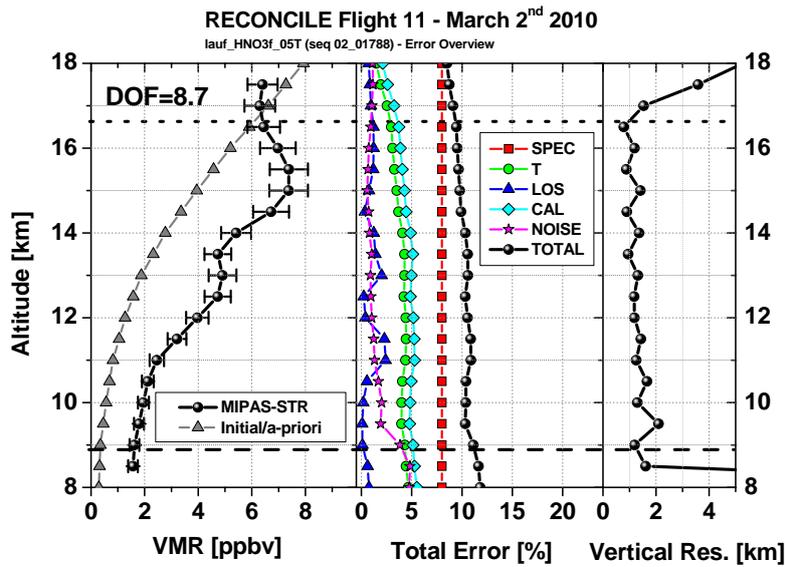

Fig. 12. Left side: retrieved vertical profile of HNO₃ with estimated error and initial guess/a priori profile (DOF = degrees of freedom). Middle: Different error contributions and estimated error in percent (SPEC = spectroscopic data, T = temperature, LOS = line-of-sight, CAL = radiometric calibration, NOISE = spectral noise, TOTAL = estimated 1 σ -error). Right side: Vertical resolution of the retrieval result. The dotted horizontal line indicates the flight altitude of the Geophysica and the dashed horizontal line the lowest tangent point of the scan.

7101

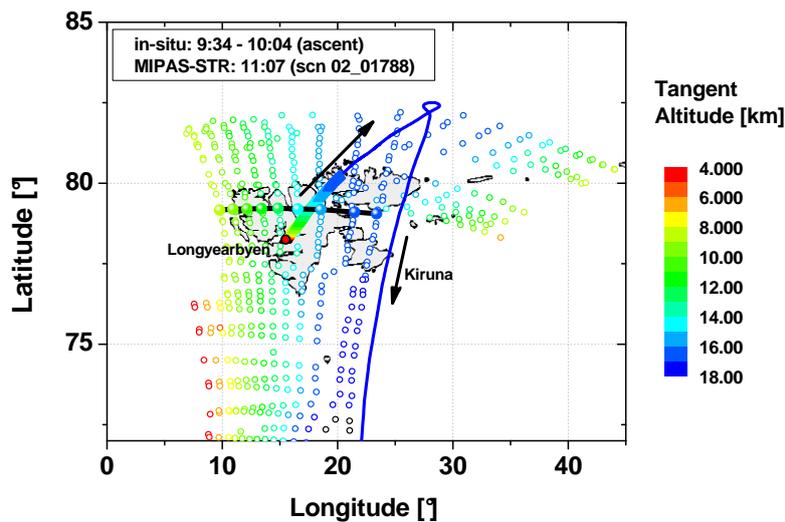

Fig. 13. Limb scan of MIPAS-STR selected for comparisons with in-situ profiles. The distribution of the tangent points of MIPAS-STR (circles) along the flight path (blue line) is indicated colour-coded with reference to the tangent altitude. The selected scan 02_01788 for the comparisons is indicated by filled circles. The flight altitude of the Geophysica is plotted colour-coded with altitude for the ascent phase.

7102

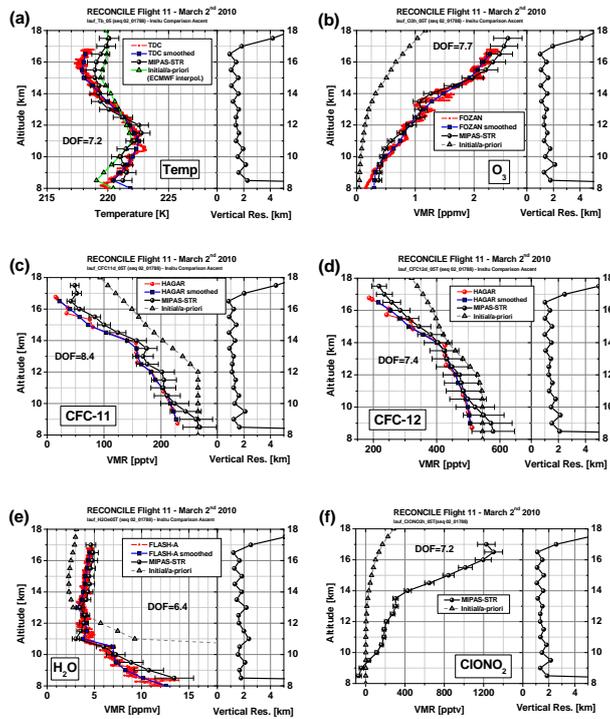

Fig. 14. (a–f): Retrieved profiles of temperature, O_3 , CFC-11, CFC-12, H_2O and $ClONO_2$ with estimated error and comparison with in-situ measurements (left panels in the plots). Initial-guess/a priori profiles for the retrievals and DOF of the results are also indicated. Vertical resolutions of the retrieval results (right panels in the plots).

7103

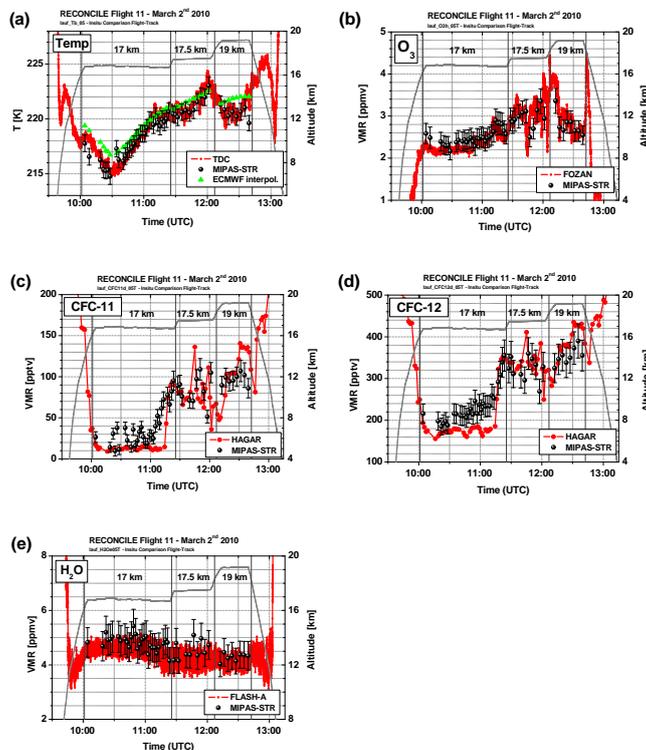

Fig. 15. (a–e): Comparison of the retrieval results inclusive estimated error for temperature, O_3 , CFC-11, CFC-12 and H_2O with in-situ measurements along flight track. Retrieval results are shown for the indicated retrieval-grid altitudes.

7104

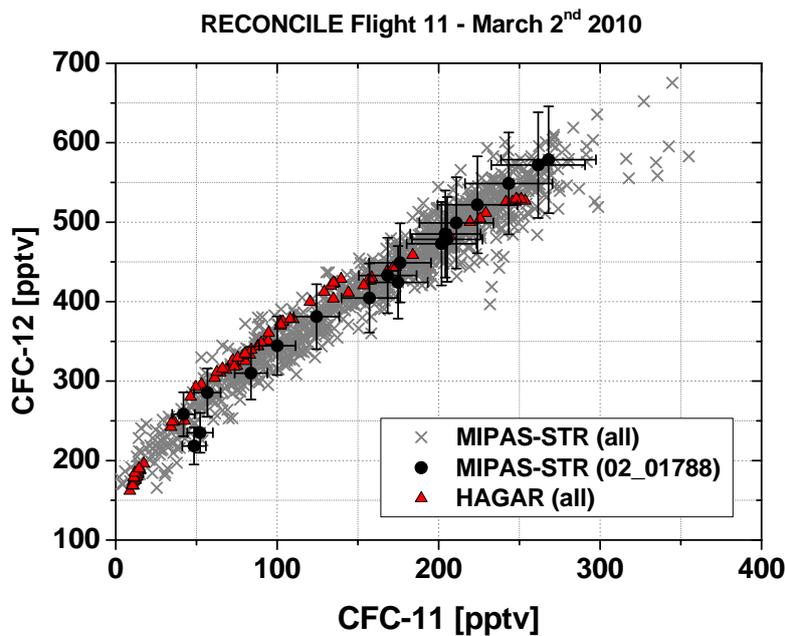

Fig. 16. Correlation of CFC-11 and CFC-12 derived from the MIPAS-STR and HAGAR measurements for RECONCILE flight 11. For MIPAS-STR, all retrieved profile points with a vertical resolution better than 5 km are shown. The points associated to sequence 02_01788 of MIPAS-STR, for which the in-situ profile-comparisons are carried out, are shown together with the corresponding estimated 1σ -errors.

7105

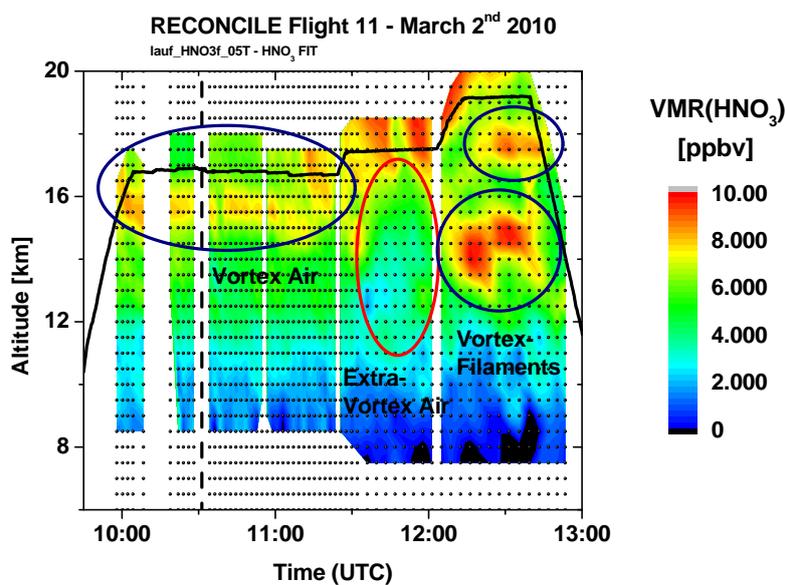

Fig. 17. Vertical cross-section of HNO_3 along flight track derived from MIPAS-STR measurements. The turn between the north-eastern flight leg (from Longyearbyen) to the southward flight leg (towards Kiruna) is indicated by the dashed vertical line. Retrieved HNO_3 -mixing ratios are linearly interpolated between the retrieval grid points (black dots) and are shown colour-coded. Interpolation is performed between grid points with vertical resolutions of the result of better than 5 km.

7106

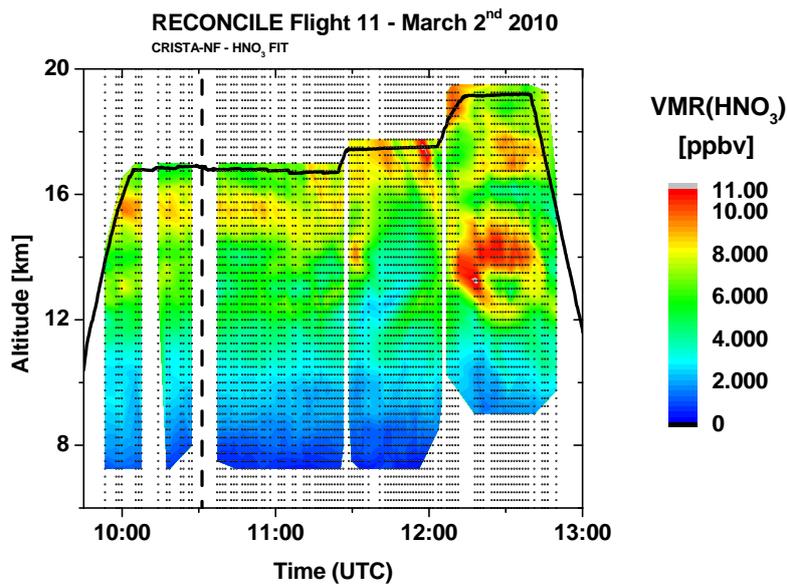

Fig. 18. Vertical cross-section of HNO₃ along flight track derived from CRISTA-NF measurements (compare Fig. 17).

7107

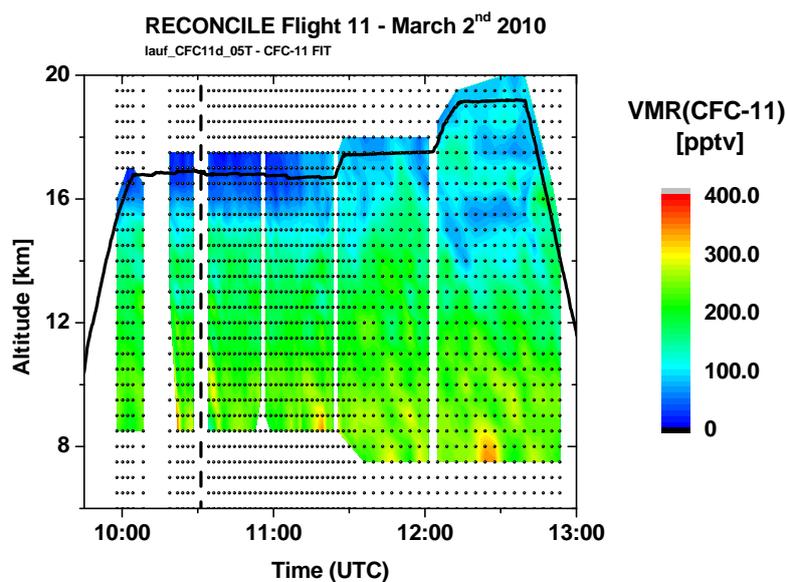

Fig. 19. Vertical cross-section of CFC-11 along flight track derived from MIPAS-STR measurements (compare Fig. 17).
