Abstract. Centrality indices are widely used analytic measures for the importance of nodes in a network. Closeness centrality is very popular among these measures. For a single node $v$, it takes the sum of the distances of $v$ to all other nodes into account. The currently best algorithms in practical applications for computing the closeness for all nodes exactly in unweighted graphs are based on breadth-first search (BFS) from every node. Thus, even for sparse graphs, these algorithms require quadratic running time in the worst case, which is prohibitive for large networks.

In many relevant applications, however, it is unnecessary to compute closeness values for all nodes. Instead, one requires only the $k$ nodes with the highest closeness values in descending order. Thus, we present a new algorithm for computing this top-$k$ ranking in unweighted graphs. Following the rationale of previous work, our algorithm significantly reduces the number of traversed edges. It does so by computing upper bounds on the closeness and stopping the current BFS search when $k$ nodes already have higher closeness than the bounds computed for the other nodes.

In our experiments with real-world and synthetic instances of various types, one of these new bounds is good for small-world graphs with low diameter (such as social networks), while the other one excels for graphs with high diameter (such as road networks). Combining them yields an algorithm that is faster than the state of the art for top-$k$ computations for all test instances, by a wide margin for high-diameter graphs.

1 Introduction

Finding a graph's most central nodes is a fundamental problem in network analysis. Intuitively, the centrality of nodes represents their structural importance within the domain under consideration. Depending on the definition, the most central nodes can be for example those that are traversed by a large fraction of shortest paths, those that can quickly reach the rest of the graph or the ones that recur more often in random walks [14, Chap. 7]. In this work, we focus on closeness centrality, a widely-used centrality measure which is defined as the inverse of the average shortest-path distance. In other words, a node with high closeness represents an individual or an entity that is close, on average, to all the other entities of the domain. The identification of the nodes with highest closeness finds its application in a plethora of research areas. Examples include facility location [10], marketing strategies [9] and identification of key infrastructure nodes as well as disease propagation control and crime prevention [3]. Unfortunately, computing the closeness of all nodes in a graph can be very expensive. The currently best algorithm solves an all-pairs shortest paths (APSP) problem to compute the distance between each pair of nodes. For an unweighted graph $G = (V, E)$ with $n$ nodes and $m$ edges, this can be done in $O(n^{2.373})$ using fast matrix multiplication [23] or in $O(nm)$ running a BFS from each node. Since real-world networks are often sparse and since the first approach contains large hidden constants, BFS-based approaches are predominant in practice (also see Section 2.2). Nevertheless, this running time becomes prohibitive already for networks with a few million nodes, restricting the exact computation of closeness to a small fraction of real applications. Moreover, since closeness values tend to be close together [14, p. 182], resorting to approximations [8,16] for accelerating the computation may lead to undesirable errors in the nodes' ranking w.r.t. closeness.

The problem we therefore target in this paper is the identification of the top- $k$ nodes with highest closeness, and doing so faster than computing it for all nodes. As mentioned above, many research areas are indeed interested in the most central nodes of the network, rather than in the closeness value of each single node. For example, somebody willing to open a store might be interested in knowing one or a few locations that are close, on average, to many potential customers and not in the closeness of each possible location. To the best of our knowledge, only two methods that improve on exhaustive computation (= computing closeness for all nodes) have been proposed so far [16,4]. Both are quite recent; only the slightly older one [16] can handle (nonnegative) edge weights.

Contribution. In this paper, we propose an algorithm for unweighted graphs that, compared to [16,4], further reduces the number of traversed edges to find the top- $k$ nodes w.r.t. closeness centrality. The basic idea is to find, for each node, an upper bound on its closeness and stop the computation when $k$ nodes are found whose closeness is higher than the upper bounds for the other nodes. We present two techniques for computing upper bounds, each effective on a different class of graphs.

In the worst case, our algorithms are not guaranteed to be faster than computing closeness for all nodes. This is not surprising, since it was proven that the complexity of finding the node with highest closeness is equivalent (under subcubic reductions) to the APSP problem [1]. Nonetheless, by combining our two bounds, we achieve significant speedups (between one and four orders of magnitude) on exhaustive computation, both on street networks and complex networks. Compared to the best previous algorithm for unweighted networks [4], we improve the running time in all experiments. Intriguingly, there is a clear distinction between networks with high diameter (such as street networks) and low diameter (complex networks): While the acceleration by our algorithm is only 1.7 on average (but also up to a factor of 18) for complex networks, our algorithm outperforms the previous algorithm [4] by two orders of magnitude on networks with high diameter.
2 Preliminaries

2.1 Notation

Let $G = (V, E)$ be a (strongly) connected unweighted graph with $n = |V|$ nodes and $m = |E|$ edges. We say node $u$ and $v$ are at distance $k$ if the length of the shortest path between $u$ and $v$ is $k$. We refer to the distance from $u$ to $v$ as $d(u, v)$. Then, we define the total distance $S(v)$ of node $v$ as the sum of the distances from $v$ to all the other nodes, i.e. $S(v) = \sum_{w \in V} d(v, w)$. The closeness centrality for node $v$, $c(v)$, is defined as

$$c(v) = \frac{n - 1}{S(v)} . \quad (1)$$

We define the diameter of $G$, $\text{diam}(G)$, as the maximum distance between any two nodes in $G$. Also, we define the neighborhood $N(v)$ of a node $v$ as the set of nodes $w$ such that $(v, w) \in E$ (or $\{v, w\} \in E$, for undirected graphs). The degree of $v$, $\text{deg}(v)$, is the size of $v$’s neighborhood.

Some extensions of closeness centrality have been proposed also for disconnected graphs [17,7]. However, since there is no clear generalization of closeness that can be applied to all contexts, we restrict ourselves to connected undirected graphs and strongly-connected directed graphs. We believe this is not a major limitation, since one could just apply our algorithm to the largest (strongly) connected component or to each component separately.

2.2 Related Work

The closeness of all nodes in unweighted graphs can be computed by solving the APSP problem. For this problem, there is no solution that is always better than running a BFS from each node. This requires $O(n(n + m))$ time (for sparse graphs this is faster than approaches based on fast matrix multiplication). Since this running time is prohibitive for large networks, attention has been devoted to approximation algorithms. For graphs with bounded diameter, Eppstein and Wang [8] proposed an algorithm that computes the closeness of all nodes within an additive error $\epsilon$ with high probability. The method basically samples a set of source nodes, runs a BFS from them and uses the computed distances to extrapolate the closeness of the other nodes. Subsequently, Brandes and Pich [5] conducted an experimental evaluation of this approximation algorithm, also considering different ways of sampling the source nodes. A more refined approximation algorithm with better practical performance has recently been published [6]. Although the approximation algorithms can often provide scores that are close to the real ones, they may fail at preserving the ranking, in particular for nodes with similar closeness. For this reason, the problem of accurately computing the ranking of the top-$k$ nodes with highest closeness has been considered, both exactly [16], with high probability [15] and with heuristics [13,12]. Although the algorithms can actually save time compared to the exhaustive computation of closeness for all nodes, it was shown [4] that on many instances their running time is very close to that of APSP. Only very recently a new method that efficiently computes the top-$k$ closeness values in unweighted graphs has been proposed [4] and shown to outperform the existing approaches on several real-world networks. We will refer to this method as BCM. For each node $v$, BCM runs a BFS that keeps track of the sum of the distances of the visited nodes and of a lower bound on the distances of the unvisited nodes. In particular, assuming that all the nodes up to distance $j$ have been visited in the BFS, the sum of the distances of the unvisited nodes is bounded by $j + 2$ minus the sum of the degrees of nodes at distance $j$. When this sum (plus the lower bound) becomes larger than that of the $k$-th node with maximum closeness discovered so far, the BFS is interrupted, avoiding to visit the remaining edges. Clearly, for the approach to work
well, the nodes with maximum closeness must be considered as early as possible. In the worst case, if nodes are considered in order of increasing closeness, the approach would be as bad as running a complete BFS for each node. Since in real-world networks there is often a correlation between degree and closeness, the authors propose to consider the nodes in order of decreasing degree.

3 Computing top-k closeness centrality

In this section we describe our new approach for computing the top \( k \) nodes with maximum closeness. The basic idea of the algorithm is to keep track of a lower bound on the total distance of each node (and therefore an upper bound on the closeness). Let \( S(v) \) be the total distance of node \( v \) and let \( \tilde{S}(v) \) be the lower bound. Then, if \( S(v) \leq \tilde{S}(w) \forall w \in V \), it is also true that \( S(v) \leq S(w) \forall w \in V \). Thus, \( v \) is (one of) the node(s) with maximum closeness. This simple observation allows us to skip the computation of the exact value of \( S(w) \) for all the remaining nodes.

The idea sketched above is implemented as Algorithm 1. First, we compute the lower bounds \( \tilde{S} \) (Line 1) and insert all the nodes into a priority queue \( Q \), ordered by increasing \( \tilde{S}(v) \). Then, we extract the nodes from \( Q \) one after another (Line 10). If the priority \( S^* \) of the extracted node \( v^* \) is exactly the total distance of \( v^* \) (\( \text{exact}[v] = \text{true} \)), then the closeness centrality of \( v^* \) is smaller than the closeness centrality of all the other nodes in \( Q \). Therefore we can append \( v^* \) to the list of the most central nodes. Otherwise (i.e. \( S^* \) is only a lower bound on \( S(v^*) \)), we compute the exact total distance of \( v^* \) (Line 16), we re-enqueue \( v^* \) with priority \( S(v^*) \) and, possibly, we update the lower bounds on the other nodes using the information obtained while computing \( S(v^*) \). Clearly, the tightness of the bounds \( \tilde{S} \) can influence the algorithm’s performance dramatically. If the bounds are close to the exact values, only a few iterations will be enough to find the \( k \) most central nodes, allowing us to skip the computation of \( S(v) \) for a large portion of nodes. In Sections 3.1 and 3.2, we propose two different techniques for computing and updating the lower bounds \( \tilde{S} \). Unlike BCM [4], our algorithm computes lower bounds in the initialization phase, i.e. before computing the closeness of any node. This allows us to skip completely all the remaining nodes, once we find \( k \) nodes whose exact \( S(v) \) is smaller than the lower bounds of the other vertices. On the contrary, BCM does not compute any initial bound and starts a BFS from each node \( v \in V \), interrupting it if the lower bound on \( S(v) \) becomes larger than the current \( k \)-th smallest value of \( S \) (see Section 2.2 for more details). Since the lower bound is computed and updated during the BFS, this often requires to visit several edges before the bound becomes large enough to interrupt the BFS, in particular if the diameter is relatively large.

3.1 Level-based lower bound

Let \( G \) be an undirected graph and let us consider a BFS traversal from a source node \( s \). We refer to the distances \( d(s,v) \) between \( s \) and all the nodes \( v \in V \) as levels: node \( v \) is at level \( i \) if and only if the distance between \( s \) and \( v \) is \( i \), and we write \( l_s(v) = i \) (or simply as \( l(v) = i \) if \( s \) is clear from the context or if the particular \( s \) is irrelevant). Let \( i \) and \( j \) be two levels, \( i \leq j \). Then, the distance between any two nodes \( v \) at level \( i \) and \( w \) at level \( j \) must be at least \( j - i \). Indeed, if \( d(v, w) \) was smaller than \( j - i \), \( w \) would be at level \( i + d(v, w) < j \), which contradicts our assumption. It follows directly that \( \sum_{w \in V} |l_s(w) - l_s(v)| \) is a lower bound on \( S(v) \), for all \( v, s \in V \):

**Lemma 1.** \( \tilde{S}(v) := \sum_{w \in V} |l_s(w) - l_s(v)| \leq S(v) \quad \forall v, s \in V. \)

To improve the approximation, we notice that the number of nodes at distance 1 from \( v \) is exactly the degree of \( v \). Therefore, all the other nodes \( w \) such that \( |l(v) - l(w)| \leq 1 \) must be at least at
Proposition 1. Computing the lower bound $\tilde{S}^{(un)}_L(v)$ takes $O(diam(G) + n + m)$ time.
Notice that many real-world networks (e.g., social networks) exhibit the small world phenomenon \cite{1998v2}, i.e., their diameter is \(O(\log n)\). Therefore, for these networks and large enough \(n\), the computation of the lower bound is linear in the number of edges.

For directed graphs, the result does not hold for nodes \(w\) whose level is smaller than \(l(v)\), since there might be a directed edge or a shortcut from \(v\) to \(w\). Yet, for nodes \(w\) such that \(l(w) > l(v)\), it is still true that \(d(v, w) \geq l(w) - l(v)\). For the remaining nodes (apart from the outgoing neighbors of \(v\)), we can only say that the distance must be at least 2. The upper bound for directed graphs can therefore be written as:

\[
\tilde{S}_L^{(\text{dir})}(v) = 2 \cdot \#\{w \in V : l(w) - l(v) \leq 1\} + \sum_{w \in V \atop l(w) - l(v) > 1} (l(w) - l(v)) - \deg(v) - 2 \quad (3)
\]

The computation of \(\tilde{S}_L^{(\text{dir})}\) for directed graphs is analogous to the one described in Algorithm 3. The particular choice of the source node \(s\) does not influence the correctness of the bounds; however, it can determine how close they are to \(S\). A node \(s\) with large eccentricity (i.e., maximum distance) is preferable, since the presence of more level allows for a major differentiation in the lower bounds of the different nodes. For this reason, in \texttt{seedNode()} in Algorithm 3, first we pick a node \(v\) at random and then we choose as \(s\) the node with maximum distance from \(v\).

### 3.2 Neighborhood-based lower bound

In a tree we can compute the closeness centrality of all nodes faster than running a BFS from each node. We exploit this by providing an exact bound for trees which translates into a lower bound in general unweighted graphs later on.

Let us consider a node \(s\) for which we want to compute \(S(s)\). The number of nodes at level 1 in the BFS tree from \(s\) is clearly the degree of \(s\). What about level 2? Since there are no loops, all the neighbors of the nodes in \(N(s)\) are nodes at level 2 for \(s\), with the only exception of \(s\) itself. Therefore, naming \(L_k[s]\) the set of nodes at level \(k\) from \(s\) and \(#L_k[s]\) the number of these nodes, we can write \(#L_3[s] = \sum_{w \in N(s)} #L_1[w] - \deg(s)\). In general, we can always relate the number of nodes in each level \(k\) of \(s\) to the number of nodes at level \(k - 1\) in the BFS trees of the neighbors of \(s\). Let us now consider \(#L_k[s]\), for \(k > 2\).

Figure shows an example where \(s\) has three neighbors \(w_1, w_2\) and \(w_3\). Suppose we want to compute \(#L_4[s]\) using information from \(w_1, w_2\) and \(w_3\). Clearly, \(L_4[s] \subset L_3[w_1] \cup L_3[w_2] \cup L_3[w_3]\); however, there are also other nodes in the union that are not in \(L_4[s]\). Let us consider \(w_1\): the nodes in \(L_3[w_1]\) (red nodes in the leftmost tree) are of two types: nodes in \(L_4[s]\) (the ones in the subtree of \(w_1\)) and nodes in \(L_2[s]\) (the ones in the subtrees of \(w_2\) and \(w_3\)). An

![Fig. 1. Relation between nodes at level 4 for \(s\) and the neighbors of \(s\). The red nodes represent the nodes at level 3 for \(w_1\) (left), for \(w_2\) (center) and for \(w_3\) (right).](image-url)
analogous behavior can be observed for $w_2$ and $w_3$ (central and rightmost trees). If we simply sum all the nodes in $\#L_3[w_1]$, $\#L_3[w_2]$ and $\#L_3[w_3]$, we would be counting each node at level 2 twice, i.e. once for each node in $N(s)$ minus one. In general, for $k > 2$, we can write

$$\#L_k^{(u)}[s] = \sum_{w \in N(s)} \#L_{k-1}[w] - \#L_{k-2}[s] \cdot (\deg(s) - 1).$$  (4)

From this observation, we define a new method to compute the total distance of all nodes, described in Algorithm 4 in Appendix A. Instead of computing the BFS tree of each node one by one, at each step we compute the number $\#L_k[v]$ of nodes at level $k$ for all nodes $v$. First (Lines 1 - 4), we compute $\#L_1[v]$ for each node (and add that to $S(v)$). Then (Lines 7 - 27), we consider all the other levels $k$ one by one. For each $k$, we use $\#L_{k-1}[w]$ of the neighbors $w$ of $v$ and $\#L_{k-2}[v]$ to compute $\#L_k[v]$ (Lines 10 and 13). If, for some $k$, $\#L_k[v] = 0$, all the nodes have been added to $S(v)$. Therefore, we can stop the algorithm when $\#L_k[v] = 0 \ \forall v \in V$.

**Proposition 2.** Algorithm 4 requires $O(\text{diam}(T) \cdot m)$ operations to compute the closeness centrality of all nodes in a tree $T$. (Proof in Appendix A)

For cyclic graphs, Eq. (4) is not true anymore – but a related lower bound on $\#L_k[\cdot]$ will still be useful. Indeed, there could be nodes $x$ for which there are multiple paths between $s$ and $x$ and that are therefore contained in the subtrees of more than one neighbor of $s$. This means that we would count $x$ multiple times when considering its level $k$, overestimating the number of nodes at level $k$. However, what we know for sure is that at level $k$ there cannot be more nodes than in Eq. (4). If, for each node $v$, we assume that the number of nodes at level $k$ that is that of Eq. (4) and we stop the computation when the sum of the numbers of nodes at levels $i \leq k$ is equal to $n$, we get a lower bound $\tilde{S}_N(v)$ on $S(v)$. In fact, since $\#L_k[v] \geq \#\{w \in V | d(v, w) = k\}$, the sum of the levels of the first $n$ nodes found by our algorithm is always smaller than or equal to the sum of the actual distances of the $n$ nodes. The procedure is described in Algorithm 2. The computation of $\tilde{S}_N$ works basically like Algorithm 4, with the difference that here we keep track of the number of the nodes found in all the levels up to $k$ (nVisited) and stop the computation when nVisited becomes equal to $n$ (if it becomes larger, in the last level we consider only $n - \text{nVisited}$ nodes, see Lines [28]-[33]).

**Proposition 3.** For an unweighted graph $G$, computing the lower bound $\tilde{S}_N$ described in Algorithm 2 takes $O(\text{diam}(G) \cdot m)$ time. (Proof in Appendix A)

In directed graphs, we can simply consider the out-neighbors, without subtracting the number of nodes discovered in the subtrees of the other neighbors in Eq. (4). The lower bound is obtained by replacing Eq. (4) with the following in Lines 12 and 15 of Algorithm 2

$$\#L_k^{(dir)}[k] = \sum_{w \in N(s)} \#L_w[k - 1].$$  (5)

### 3.3 Additional engineering

The two lower bounds that we described in the previous sections cover the first line of Algorithm 1. One could either compute only one of them or both of them, taking for each node the maximum among the the two. Having a lower bound that is close to the exact total sum of a node is crucial. For example, if all the lower bounds were smaller than the minimum value of $S(v)$, our algorithm would be as bad as computing closeness for each node. On the other hand, if the actual values of $S(v)$ of the first $k$ nodes were smaller than the lower bounds of the remaining nodes, we could find the top $k$ nodes with a constant number of BFSs. For this reason, after the initialization, we try
to further improve the bounds of the nodes also while computing the exact closeness of a node \(v\) in Line \(16\). In the case of the level-based lower bound, we can keep track of the nodes in each level of the BFS from \(v\) and recompute \(\tilde{S}_L\) using \(v\) as source. If, for some node, the new bound is larger than its current one, we can update it. Also, to additionally reduce the number of visited edges, we can stop the BFS beforehand when we discover that the closeness of \(v\) cannot be larger than that of the current \(k\)-th top node, similarly to BCM \[4\] (see Section 2.2 and \[4\] for more details).

Algorithm 2: Neighborhood-based lower bound

Input: A graph \(G = (V, E)\)  
Output: Lower bounds \(\tilde{S}_N(v)\) of each node \(v \in V\)

1. foreach \(s \in V\) do
2.   \(\#L_{k-1}[s] \leftarrow \deg(s)\);
3.   \(\tilde{S}_N[s] \leftarrow \deg(s)\);
4.   \(\text{nVisited}[s] \leftarrow \deg(s) + 1\);
5.   \(\text{finished}[s] \leftarrow \text{false}\);
6. end

7. \(k \leftarrow 2\);
8. nFinished \(\leftarrow 0\);
9. while nFinished < \(n\) do
10.   foreach \(s \in V\) do
11.      if \(k = 2\) then
12.         \(\#L_k[s] \leftarrow \sum_{w \in N_G(s)} \#L_{k-1}[w] - \deg(s)\);
13.      end
14.      else
15.         \(\#L_k[s] \leftarrow \sum_{w \in N_G(s)} \#L_{k-1}[w] - \#L_{k-2}[s](\deg(s) - 1)\);
16.      end
17.   end
18.   foreach \(s \in V\) do
19.      if finished[\(v\)] then
20.         continue;
21.      end
22.      \(\#L_{k-2}[s] \leftarrow \#L_{k-1}[s]\);
23.      \(\#L_{k-1}[s] \leftarrow \#L_k[s]\);
24.      if \(n - \text{nVisited}[s] > \#L_{k-1}[s]\) then
25.         \(\tilde{S}_N[s] \leftarrow \tilde{S}_N[s] + k \cdot \#L_{k-1}[s]\);
26.      end
27. else
28.      \(\tilde{S}_N[s] \leftarrow \tilde{S}_N[s] + k(n - \text{nVisited}[s])\);
29. end
30.\(\text{nVisited}[s] \leftarrow n\);
31. nFinished \(\leftarrow \text{nFinished} + 1\);
32. finished[s] \(\leftarrow \text{true}\);
33. end
34. \(k \leftarrow k + 1\);
35. end
36. return \(\tilde{S}_N\)

4 Experiments

Implementation and Settings. For the experimental evaluation, we implemented three versions of our algorithm: one based on the level-based lower bound (BM\(_L\)), one that uses the neighborhood-based lower bound (BM\(_N\)) and one that combines both (BM), i.e. takes the maximum among the two bounds. For a comparison with the state of the art, we also implemented the algorithm presented
by Borassi et al. [4] (BCM) as baseline. This algorithm was shown to outperform the other existing algorithms for exact and approximate top-$k$ closeness centrality [4]. We implemented all algorithms in C++, building on the open-source NetworKit framework [18]. The machine used has 2 x 8 Intel(R) Xeon(R) E5-2680 cores at 2.7 GHz, of which we use only one, and 256 GB RAM. All computations are sequential to make the comparison to previous work more meaningful.

**Methodology.** We test the algorithms on a large collection of real-world networks. Tests on synthetic networks are added in order to examine the scaling behavior of the algorithms. The real networks are taken from SNAP (snap.stanford.edu), KONECT (konect.uni-koblenz.de) and the 10th DIMACS Implementation Challenge [2]. In case of disconnected networks, we always extract the largest (strongly) connected component first. In all the tests we adopt as a measure of performance the performance ratio, introduced by Borassi et al. [4]. Naming $|E_{vis}|$ the number of edges visited by a top-$k$ algorithm, the performance ratio is defined as $|E_{vis}|$ divided by the number of edges that the exhaustive algorithm (running a BFS for all nodes) would use, i.e. $\frac{|E_{vis}|}{n \cdot m}$. This measure does not depend on the particular implementation of the algorithms, but only on the actual number of operations performed. Moreover, it allows an assessment independent of computer architectures. In the measure we do not consider the initialization phases of any of the algorithms, since the times they require are negligible. We refer to the inverse of the performance ratio as speedup and evaluate the algorithms mainly by comparing their speedups.

**Results.** Our results show that our two lower bounds perform differently depending on the nature of the network. In particular, BM$_L$ performs very well on street networks (where closeness has a straightforward interpretation) and on networks with similar properties, i.e. a relatively large diameter and small variance in the degree distribution. The presence of several “levels” with relatively few vertices allows for a differentiation in the lower bounds of the different nodes. This leads to a fast identification of the most central nodes. On the other hand, BM$_N$ and the baseline BCM perform relatively poorly on this kind of networks, because their assumption is that closeness centrality is strongly correlated with the degrees. For example, to find the top node with highest closeness on the street network of Luxembourg, BM$_L$ (as well as the combined version BM) has a speedup of more than 400, whereas BM$_N$ and BCM have speedups of 3.2 and 2.6, respectively. Since BCM does not scale well to large street networks (for networks with millions of nodes, it does not finish the computation in two days), we tested only BM on a set of street networks, also taken from [2]. The results are shown in Table 1. Using BM, we are able to find the top 100 nodes with highest closeness in the whole European street network in minutes (where the exhaustive algorithm would take years).

To examine the scaling on graphs with properties similar to those of street networks, we compared the algorithms on synthetic Delaunay graphs of increasing sizes, taken from [2]. Figure 2 (left) shows the speedups of BM and those of BCM, with $k$ (the number of nodes with highest closeness computed) equal to 1 and 10. The results obtained using only BM$_N$ are extremely similar and therefore omitted. Since we use a log-log scale, it is quite apparent that the speedup of BM increases exponentially with the size of the graph, reaching values of more than $10^3$ for graphs with $2^{20}$ nodes. The speedup of BM, in turn, is basically constant and always smaller than 10.

Very different is the behavior of the algorithms on complex networks (e.g. social networks, communication networks), characterized by a strongly varying degree distribution and a very small diameter. Here BM$_L$ cannot perform well, because very similar lower bounds are computed for many nodes, due to the small number of levels in the BFS trees. On the other hand, the structure of complex networks allows BM$_N$ to compute lower bounds that are close to the the actual closeness values, quickly identifying the top-$k$ nodes. Also BCM performs very well on complex networks, since here the degree is often related to the closeness of nodes and the small diameter makes it possible to
quickly discard nodes that cannot be in the top-$k$ list. Figure 2 (right) shows the speedups of BM and BCM on synthetic complex networks of increasing sizes, created with an efficient generator 20 according to an hyperbolic geometry-based model 11. This model was shown to reproduce many properties of real complex networks (such as low diameter and power-law degree distribution, see 21 and the references therein). The picture shows that the speedups of both algorithms increase with the size of the graph, with $BM$ reaching values larger than $10^4$. The speedups of $BM$ are always larger than those of $BCM$ and the gap between the two seems to increase with the size of the graphs.

It is also interesting to note that the gap between the number of operations required to find the top node and the top $k$ nodes is often much larger in complex networks than in street networks. Table 2 summarizes the speedups of BM and BCM on complex undirected networks. We do not report the results of $BM_L$ and $BM_N$ because the first one does not perform well on complex networks so it would have been too expensive to compute for many of the tested networks and because those of $BM_N$ are basically the same as those of the combined algorithm $BM$. The table shows that $BM$ is always faster than $BCM$. The speedups vary considerably depending on the properties of the networks, but they tend to increase with the size of the network and to be larger in networks with small diameters. Table 3 contains the results on directed networks. Also here $BM$ is always faster than $BCM$, although the difference between the two is often relatively small.

To summarize, our results show that our combined version $BM$ performs very similarly to $BM_L$ on street networks and to $BM_N$ in complex networks, i.e. it always performs like the fastest of the two methods on the network it is applied to. Also, $BM$ is always faster than the currently best existing method $BCM$, several orders of magnitude in street networks and up to a factor 18 in complex networks, where $BCM$ already performs well. In these networks, we are on average 1.7 times faster than $BCM$ (geometric mean).

5 Conclusions

In this paper we have presented new methods for finding the $k$ nodes with highest closeness centrality in a network, a problem of high practical relevance in network analysis. By finding lower bounds on the inverse closeness of each node, we limit the exact computation to a small fraction of vertices. More precisely, we propose two lower bounds, one that has shown to work better on networks with relatively large diameter and degree distribution with small variance (e.g., street networks) and one that is more performant on complex networks. The combination of the two approaches into one method is orders of magnitude faster than computing closeness for all nodes in our experiments, on every tested network. Compared with the state of the art, our combined approach is always faster than the currently best algorithm for top-$k$ closeness centrality [4]. Thanks to our new approach, we are able to find the top-10 nodes with highest closeness in the whole European street network (with 54 millions edges) in minutes (where exhaustive computation would take years).

Future work may include the extension of our technique and of those presented in [4] to weighted graphs, for which the computation of a lower bound is the only obstacle. Also, it would be interesting to investigate whether our concepts can be extended to other centrality measures, such as betweenness, and whether they can be used to compute a fast approximation of closeness in very large networks. We also plan to run our code in parallel to further accelerate the computations. Our implementation will be made publicly available as part of a future release of the network analysis tool suite NetworKit [18].

Acknowledgements. The authors would like to thank Michele Borassi for helpful discussions regarding the code described in [4]. Furthermore, we would like to thank Moritz von Looz for providing the hyperbolic random graphs used in our experiments.

A.1 Pseudocode of Algorithm 3

**Algorithm 3: Level-based lower bound**

Input: A graph $G = (V, E)$
Output: Lower bounds $\tilde{S}_L(v)$ of each node $v \in V$

1. $s \leftarrow$ seedNode();
2. $d \leftarrow$ BFSfrom($s$);
3. $\text{maxL} \leftarrow \max_{v \in V} d(s, v)$;
4. for $i = 1, 2, ..., \text{maxL}$ do
   5. $L[i] = \{w \in V : d(s, w) = i\}$;
   6. $nL[i] = \#L[i]$;
5. end
6. for $i = 1, 2, ..., \text{maxL}$ do
   7. $\text{sum} \leftarrow 0$;
   8. for $j = 1, 2, ..., \text{maxL}$ do
      9. if $|j - i| \leq 1$ then
         10. $\text{sum} \leftarrow \text{sum} + 2nL[j]$;
      11. else
         12. $\text{sum} \leftarrow \text{sum} + |j - i| \cdot nL[j]$;
      13. end
   14. end
   15. for $v \in L[i]$ do
      16. $\tilde{S}_L(v) \leftarrow \text{sum} - \deg(v) - 2$;
   17. end
5. end
6. return $\tilde{S}_L$

A.2 Proof of Proposition 2

**Proof.** The for loop in Lines 1 - 4 of Algorithm 4 clearly takes $O(n)$ time. For each level of the while loop of Lines 7 - 27, each node scans its neighbors in Line 10 or Line 13. In total, this leads to $O(m)$ operations per level. Since the maximum number of levels that a node can have is equal to the diameter, the algorithm requires $O(\text{diam}(T) \cdot m)$ operations. \qed

A.3 Proof of Proposition 3

**Proof.** Like in Algorithm 4, the number of operations performed by Algorithm 2 at each level of the while loop is $O(m)$. At each level $i$, all the nodes at distance $i$ are accounted for (possibly multiple times) in Lines 12 and 15. Therefore, at each level, the variable $n\text{Visited}$ is always greater than or equal to the number of nodes $v$ at distance $d(v) \leq i$. Since $d(v) \leq \text{diam}(G)$ for all nodes $v$, the maximum number of levels scanned in the while loop cannot be larger than $\text{diam}(G)$, therefore the total complexity is $O(\text{diam}(G) \cdot m)$. \qed
A.4 Pseudocode of Algorithm 4

Algorithm 4: Closeness centrality in trees

Input: A tree $T = (V, E)$

Output: Closeness centralities $c(v)$ of each node $v \in V$

foreach $s \in V$ do
  $\#L_{k-1}[s] \leftarrow \text{deg}(s)$;
  $S[s] \leftarrow \text{deg}(s)$;
end

$k \leftarrow 2$;
nFinished $\leftarrow 0$;
while nFinished $< n$ do
  foreach $s \in V$ do
    if $k = 2$ then
      $\#L_k[s] \leftarrow \sum_{w \in N(s)} \#L_{k-1}[w] - \text{deg}(s)$;
    end
    else
      $\#L_k[s] \leftarrow \sum_{w \in N(s)} \#L_{k-1}[w] - \#L_{k-2}[s](\text{deg}(s) - 1)$;
    end
  end
  $\#L_{k-2}[s] \leftarrow \#L_{k-1}[s]$;
  $\#L_{k-1}[s] \leftarrow \#L_k[s]$;
  if $\#L_{k-1}[s] > 0$ then
    $S[s] \leftarrow S[s] + k \cdot \#L_{k-1}[s]$;
  end
  else
    nFinished $\leftarrow$ nFinished $+ 1$;
  end
  $k \leftarrow k + 1$;
end

foreach $s \in V$ do
  $c(v) \leftarrow (n - 1) / S[v]$;
end

return $c$
