## **Abstract**

This work focuses on the deactivation and in-situ regeneration effects of a commercial PdO/Al<sub>2</sub>O<sub>3</sub> catalyst for removal of oxygen by oxidation of CH<sub>4</sub> at low O<sub>2</sub>:CH<sub>4</sub> ratios when hydrogen sulfide and sulfur dioxide are applied. The experimental work is carried out at an operating temperature range of 200 °C < T < 300 °C, atmospheric pressures and H<sub>2</sub>S contents of < 50 ppmv.

SO<sub>2</sub> and H<sub>2</sub>S show a different behavior in the examined range of operating conditions. Due to the low operating temperatures and low oxygen contents applied in this work, it was possible to identify an intermediate species, presumably PdSO<sub>3</sub>, with an increased activity for the oxidation of methane. This stands in contrast to the literature, where SO<sub>2</sub> typically causes catalyst deactivation. Based on the experimental results, a reaction scheme was derived and kinetic measurements for each of the participating reactions were carried out separately.

Furthermore, a deactivation model was derived and validated by experimental data with low contents of H<sub>2</sub>S, showing that residual activities, observed by some authors, are a result of rate-equality of deactivation and in-situ regeneration process on the surface of the catalyst.

Nomenclature		
$\Theta$	surface coverage	-
A-D	kinetic constants	-
a	activity	-
d	deactivation order	-
$E_A$	activation energy	kJ/mol
$\Delta_R H^\ominus$	standard enthalpy of reaction	kJ/mol
$\Delta_{ads} H^\ominus$	standard enthalpy of adsorption	kJ/mol
k	reaction rate constant (mass specific)	mol/(s·g·bar <sup>B</sup> )
K	equilibrium constant	bar <sup>-C</sup>
$K\beta'/K\beta_{1,3}$	XRF intensity ratio	-
$2\theta$	Bragg-diffraction angle. (Angle between primary and secondary beam after diffraction at a crystal)	°
$m_{ac}$	mass of active compound	g
m, n	reaction order	-
$N_i$	amount of species i	mol
$p_i$	(partial) pressure (of i)	bar
$\Psi$	deactivation function	as needed
$\phi_i$	ratio i of total active sites	-
$r_i$	mass specific reaction rate	mol/(s·g·bar <sup>B</sup> )
R	universal gas constant	8,314 kJ/(kmol·K)
t	time	s
$T_R$	reaction temperature	K

XS55	Synthetic W-Si multilayer crystal (lattice distance $2d = 55 \text{ \AA}$ ; long wavelength)	

# 1 Introduction

In order to prevent damage to the natural gas infrastructure (e. g. corrosion [1]), the maximum oxygen concentration is limited to 10 ppmv for transportation pipelines connected to underground storages and/or cross border transmission [2–4]. One option for the removal of oxygen from biomethane (or other fuel gas streams) is the implementation of the heterogeneously catalyzed oxidation reaction of methane (eq. 1), catalyzed by PdO/Al<sub>2</sub>O<sub>3</sub>

Typically, the catalytic oxidation reaction of methane is applied in lean-gas treatment, in terms of reduction of CH<sub>4</sub> emissions from (oxygen-rich) off-gas streams [5] and in catalytic burning systems for increased combustion efficiencies [6–8]. In contrast to these applications, catalytic removal of oxygen from fuel gas streams is carried out at oxygen-understoichiometric conditions and consequently at lower reaction temperatures [8–10].

As no hydrogen or hydrocarbons are present in biomethane, the utilization of CH<sub>4</sub> brings in economic benefits in comparison with state-of-the-art technologies for oxygen removal, as no additional reducing agent has to be supplied, stored and added to the gas separately. Besides, the utilization of biomethane for removal of oxygen is a more sustainable option than using fuels from fossil sources [11,12].

Recently, kinetic data for the catalytic removal of oxygen by combustion of CH<sub>4</sub> for very low O<sub>2</sub>:CH<sub>4</sub> ratios was determined for a set of reference catalysts on noble metal basis (platinum and palladium on Al<sub>2</sub>O<sub>3</sub> support) [41].

Furthermore, the effects of trace compounds of biomethane on catalyst durability are of interest, e. g. sulfur components, siloxanes [13], ammonia [8], BTEX [14] and halogenated hydrocarbons [15]. This work focuses on sulfur compounds, as they represent the major part of contaminants of biomethane [16].

In the majority of available literature, the influence of H<sub>2</sub>S and SO<sub>2</sub> [17–19] on the activity of noble metal catalysts for catalytic combustion of methane is studied. Deactivation by SO<sub>2</sub> or H<sub>2</sub>S are usually not treated separately [20], since under typical reaction conditions of methane combustion (T > 350 °C, oxygen excess) hydrogen sulfide is oxidized to SO<sub>2</sub> [21]. When mercaptanes [10] or THT (Tetrahydrothiophene) [22] are examined, typically a complete conversion to H<sub>2</sub>O, CO<sub>2</sub> and SO<sub>2</sub> is assumed, since C-S bonds are not stable at high temperatures [23,24]. The deactivation mechanism is thus treated as of SO<sub>2</sub>.

Despite extensive research on the deactivation and regeneration mechanism of sulfur compounds on noble catalysts [18,19,25,26], the details of the catalytic surface processes do not seem to be fully understood yet (see section 2). Due to the lack of data on the influence

of sulfur contaminants on catalyst activity at low  $O_2:CH_4$  ratios, detailed examinations on sulfur poisoning of a  $Pd/Al_2O_3$  catalyst under oxygen removal conditions have been carried out in this work.

## 2 Literature Overview

In literature, there is general agreement, that sulfur compounds cause significant loss of catalyst activity, when noble metals on  $Al_2O_3$  are applied. Deactivation of the catalyst is initiated by adsorption of the sulfur-containing compound on the catalyst surface, followed by a chemical reaction with the active compound. Due to the chemisorption reaction, sulfur forms chemical bonds with the active sites hindering desorption at typical operating conditions. Gradually, the catalyst is poisoned [17,25].

In some cases [17,20,25,26], residual activities of fully poisoned  $PdO/Al_2O_3$  catalysts are observed. Two explanations can be found for this effect:

- The sulfur covered active compound ( $PdSO_x$ ) itself features some catalytic activity for methane oxidation [17,26] or
- a continuous regeneration of the active sites takes place, caused by storage of sulfur in the catalyst support under formation of  $Al_2(SO_4)_3$  [25].

Ordonez et al. [26] examined the influence of  $SO_2$  on the catalytic activity of  $PdO/Al_2O_3$ . As feed gas, 5000 ppmv of methane in an air stream was used. The reaction was operated in a temperature range of 350 °C to 550 °C. Ordonez et al. found that high sulfur concentrations lead to an increase in deactivation rate, whereas the residual activity of the catalyst remains constant. Further, an increase of reaction temperature had a positive effect on the residual activities in Ordonez's case. Unfortunately, Ordonez et al. did not commit to one of the two aforementioned explanations for their observations. For modelling, the authors assumed  $PdSO_4$  to cause the residual activities.

Besides the active compound, the catalyst support plays an important role for the deactivation of noble metal catalysts. Hoyos et al. [17] showed that the deactivation rate of  $PdO$  on an  $Al_2O_3$  support is significantly lower than on  $SiO_2$ , which is a consequence of the sulfate forming ability of the support material.  $Al_2O_3$  is able to store sulfur as  $Al_2(SO_4)_3$  and therefore acts as a sulfur sink, causing a decrease in deactivation rate. Hoyos et al. proved the existence of sulfate by infrared-spectroscopy. In contrary,  $SiO_2$  was not able to form sulfate. Escandón et al. [27] confirmed these results.

Yu et al. [18] also examined the deactivation of a  $PdO/Al_2O_3$  with  $H_2S$  in excess of oxygen. From their own results and from literature data the authors proposed a deactivation

mechanism of three consecutive reaction steps – the formation of sulfide (eq. 2), its oxidation to sulfite (eq. 3) and finally the storage of sulfur as sulfate in the catalyst support (eq. 4):

The authors found that at 200 °C the oxidation of sulfide to sulfite (eq. 3) is kinetically inhibited. As a consequence, PdS remains on the catalytic surface at low temperatures. At higher temperatures (400 °C) and in presence of oxygen, the oxidation of sulfide to sulfite occurs. Thereafter, aluminum sulfate is formed and the active compound of the catalyst (PdO) is restored (eq. 4). Yu et al. carried out infrared spectroscopy measurements and did not observe any formation of PdSO<sub>4</sub>. Yu et al. further claimed physical blockage of the active sites by Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> and a decrease of surface area (BET) responsible for the short-term deactivation of the catalyst at high temperatures.

Other research groups [17,19,25] do not share this view and rather explain the short-term deactivation by transformation of PdO to any PdSO<sub>x</sub> species with less activity. Ordonez et al. [28] investigated the deactivation and regeneration of PdO/Al<sub>2</sub>O<sub>3</sub>-catalysts after SO<sub>2</sub>-poisoning by performing desorption experiments under inert atmosphere at high temperatures (600 °C). Under these conditions, both, O<sub>2</sub> and SO<sub>2</sub> can be detected in the off-gas in various ratios. This indicates for the presence of SO<sub>x</sub>-groups on the active sites of the catalyst, as PdSO<sub>4</sub> decomposes to SO<sub>2</sub> and O<sub>2</sub> (eq. 10) at high temperatures. After high temperature deactivation experiments, an increasing amount of oxygen is released due to a higher degree of sulfate formation (eq. 6). As a conclusion, Ordonez et al. assumed that both, sulfate and sulfite groups, are present on the catalyst surface and proposed the mechanism eq. 5 - 12.

Furthermore, Ordonez et al. examined different gases and gas mixtures for their ability to regenerate a poisoned Pd catalyst. A catalyst, which afore was deactivated with SO<sub>2</sub>, was regenerated at 550 °C with hydrogen, dry air, humid air, nitrogen and under vacuum for 20 h. Exclusively with hydrogen a complete recovery of catalyst activity was achieved. For the other gases, only 80 - 90 % of the original activity was reached.

### 3 Experimental Set-up and Procedure

An extensive description of the lab-scale test rig used in this work is given in [41]. The palladium catalyst used in this work is a commercially available product. As active compound 0.5 wt% of PdO are dispersed on the spherical catalyst support of Al<sub>2</sub>O<sub>3</sub> with an outer diameter of 1 - 1.2 mm. The catalyst features a specific surface area of 173 m<sup>2</sup>/g (BET). During the measurements, the catalyst was diluted with glass-spheres of similar diameter by a ratio of 1:10. The glass-spheres are chemically inert with respect to chemical adsorption of sulfur compounds. Information on the applied experimental procedures is given in relevant subsections. *Table 1* gives an overview over the applied gases. For gas analysis an appropriate  $\mu$ GC system was used. Additionally, representative catalyst samples were prepared under relevant test conditions and analyzed ex-situ via XRF (details on XRF methodology are given in section 3.1.1). The kinetic parameters and reaction orders were determined by numeric fit via minimization of least squares of integral experimental and calculated oxygen conversion. The catalytic reactor was modelled as a PFR (Bo > 100). MS Excel was used for computation.

*Table 1: Gases used with information on respective purities and suppliers*

Compound	Purity
Methane	3.5 (99.95 vol%)
Synthetic air (20.5 vol% O <sub>2</sub> in N <sub>2</sub> )	20.5 vol% O <sub>2</sub> in N <sub>2</sub> 5.0
Nitrogen	5.0 (99.999 vol%)
Hydrogen	5.0 (99.999 vol%)
Hydrogen sulfide in methane	300 ppmv in CH <sub>4</sub> 5.0
Sulfur dioxide in nitrogen	1370 ppmv in N <sub>2</sub> 5.0

#### 3.1.1 XRF-Analysis

Principles of X-ray fluorescence analysis are described in [29,30]. The determination of sulfur species on the catalyst surface was carried out by K $\beta$ -X-ray fluorescence with representative samples, taken subsequently to the measurements in the catalytic test rig. The intensity ratio of K $\beta$ '/K $\beta$ <sub>1,3</sub> varies depending on the binding form of S and can be used for speciation analysis [31–34]. At the K $\alpha$ -line a small energy shift in dependence of the

binding form can be observed when spectrometers with an extremely good angle resolution are used [35].

The measurements were carried out, using an S4 Explorer (Bruker AXS, acc.: 0.05 % F.S.) equipped with Rh-tube, and the crystals LiF200 ( $2d = 4.028 \text{ \AA}$ ), PET ( $2d = 8.74 \text{ \AA}$ ) and XS55 ( $2d = 55 \text{ \AA}$ ). The PET was used for the determination of the sulfur speciation. The  $K\beta$ -region was scanned from  $69.5^\circ$  to  $71^\circ 29'$  equivalent to  $2.4851 - 2.4396 \text{ keV}$  (step size  $\sim 0.73 \text{ eV}$ ) to determine the  $K\beta'/K\beta_{1,3}$  intensity ratio. For noise reduction the scans were smoothed using a moving 13 point polynomial approximation [36]. The samples were prepared in spectro cups, covered with  $6 \mu\text{m}$  mylar film as bulk powder samples. For calibration of the peak position and the  $K\beta'/K\beta_{1,3}$  intensity ratios the following sulfur species were measured: elemental sulfur,  $\text{FeS}_2$ ,  $\text{MoS}$ ,  $\text{Na}_2\text{SO}_3$ ,  $\text{CaSO}_4 \times 2 \text{ H}_2\text{O}$ ,  $\text{CuSO}_4$ ,  $\text{SrSO}_4$ , and  $\text{BaSO}_4$ . The  $K\beta$  scans of these compounds are shown in *Figure 1*.

*Figure 1: Energy scan across the  $K\beta_{1,3}$  and  $K\beta'$ -lines of elementary sulfur, sulfide, sulfite and different sulfates. The spectra are normalized to the maximum intensity point and shifted for clarity.*

With elementary sulfur and sulfides the  $K\beta'$ -line is not present. With increasing oxidation state of sulfur the  $K\beta'/K\beta_{1,3}$  intensity ratio increases. The observed energy difference between the  $K\beta'$  and the  $K\beta_{1,3}$ -line is  $\sim 15 \text{ eV}$ . This is in agreement with the data of [31]. *Table 2* compiles the  $K\beta'/K\beta_{1,3}$  intensity ratio for the different compounds.

Table 2:  $K\beta'/K\beta_{1,3}$  intensity ratio for sulfides, sulfites and sulfates. The intensity ratio of elementary sulfur at the  $K\beta'$  position to the  $K\beta_{1,3}$  intensity was set as zero point.

Compound	$K\beta'/K\beta_{1,3}$ intensity ratio
S	--
FeS <sub>2</sub>	0.03
MoS	0.023
Na <sub>2</sub> SO <sub>3</sub>	0.143
CaSO <sub>4</sub>	0.276
CuSO <sub>4</sub>	0.268
SrSO <sub>4</sub>	0.269
BaSO <sub>4</sub>	0.242

## 4 Results and Discussion

In order to determine whether one of the aforementioned deactivation mechanisms is applicable to the reaction conditions applied in this work (low  $O_2:CH_4$  ratios), preliminary measurements on each of the involved reaction steps have been carried out (4.1.1 - 4.1.4). Based on these findings, a reaction scheme is proposed (4.2) and a deactivation / reactivation model is applied (4.3).

### 4.1 Examinations on reaction mechanism

#### 4.1.1 Deactivation of PdO/Al<sub>2</sub>O<sub>3</sub> by Hydrogen Sulfide and Sulfur Dioxide

Figure 2 shows two deactivation experiments with H<sub>2</sub>S in the feed at different temperatures (250 °C and 300 °C). For comparison, the actual oxygen conversion  $X_{O_2}$  is normalized to the conversion of the fresh catalyst  $X_{O_2,0}$ . While the catalyst shows activity for methane oxidation, no H<sub>2</sub>S is detected at the reactor outlet.

During both experiments a decrease of oxygen conversion can be observed due to formation of palladium sulfide [18], as confirmed by XRF measurements (see 4.1.3).

Furthermore, it is obvious that the catalyst deactivates faster at 250 °C than at 300 °C. At 250 °C, after 3.5 h no carbon dioxide is detected in the off-gas anymore - methane conversion is stopped completely. The residual oxygen conversion ( $X_{O_2,res}$ ) probably is a result of oxidation of hydrogen sulfide to water and surface sulphur species and some beginning of regeneration of blocked active sites (PdS → PdO;  $X_{O_2,0}(T = 250\text{ °C}) = 0.2 \rightarrow X_{O_2,res} = 0,015 \rightarrow$  oxygen consumption: 61 ppmv  $\rightarrow n_{H_2S}:n_{O_2} \approx 1:1$ ). After approximately three hours, a slight breakthrough of H<sub>2</sub>S occurs in the off-gas ( $y_{H_2S,out} = 10$  ppmv) at  $T = 250\text{ °C}$ .

Figure 2: Preliminary examinations on the deactivation of PdO/Al<sub>2</sub>O<sub>3</sub> by hydrogen sulfide ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 960$  mbar, GHSV:  $45,000$  h<sup>-1</sup>,  $p_{total} = 1.013$  bar,  $y_{O_2,0} = 4100$  ppmv,  $y_{H_2S,0} = 50$  ppmv, balance: N<sub>2</sub>):  $T = 250$  °C ( $\Delta$ );  $T = 300$  °C ( $\square$ )

In contrast, when the deactivation experiment is carried out at 300 °C, a minor methane conversion still takes place even after 10 h. In addition, the decrease of activity is delayed for approximately 2 h, which is equivalent to the moment when a breakthrough of SO<sub>2</sub> of approximately 20 ppmv occurs in the off-gas. Until then, the complete amount of sulfur in the feed remains on the catalyst surface.

Examinations with an empty reactor (under the same operating conditions) indicate for some conversion of H<sub>2</sub>S to SO<sub>2</sub> at higher temperatures, very likely catalyzed by the reactor itself ( $X_{H_2S \rightarrow SO_2}$  (300 °C) = 40 %). At 250 °C, however, no formation of SO<sub>2</sub> is observed.

Deactivation experiments in literature (under excess oxygen conditions) usually come to the conclusion that deactivation by H<sub>2</sub>S or by SO<sub>2</sub> is equivalent for reasons already mentioned. Since this is not the case under this works operating conditions, the influences of both gases on catalyst deactivation have been examined separately.

#### 4.1.2 Influence of Sulfur Dioxide on Catalytic Activity

Under typical excess oxygen conditions SO<sub>2</sub> leads to the formation of PdSO<sub>x</sub>-species with no or only minor residual activity for methane oxidation [17,18]. To eliminate any influences of the applied reaction system, examinations under literature conditions (1500 ppmv CH<sub>4</sub> in excess of O<sub>2</sub>) have been carried out. A plot of  $X_{CH_4}$  vs. time is included in the supplementary

data section. In accordance to literature, under suchlike operating conditions  $\text{SO}_2$  leads to a decrease in methane conversion. Additionally, a minor residual activity is confirmed [26].

Figure 3 again shows the influence of  $\text{SO}_2$  addition, but under oxygen removal conditions (= lower temperatures and methane in excess). Unexpectedly, under these conditions  $\text{SO}_2$  leads to an increase of oxygen conversion, which is in average about 1.6 times higher compared to the standard degree of conversion ( $X_{\text{O}_2,0}$ ) of a fresh catalyst. It appears as if any stable  $\text{PdSO}_x$ -intermediate with a higher activity than original  $\text{PdO}$  is formed. Furthermore, no deactivation at all is observed, even after 20 h TOS with 100 ppmv  $\text{SO}_2$  in the feed gas.

Figure 3: Influence of sulfur dioxide on oxygen conversion at different temperatures ( $\dot{V} = 100 \text{ l/h (STP)}$ ,  $p_{\text{CH}_4,0} = 960 \text{ mbar}$ ,  $\text{GHSV}: 45,000 \text{ h}^{-1}$ ,  $p_{\text{total}} = 1.013 \text{ bar}$ , balance:  $\text{N}_2$ ):  $T = 240 \text{ }^\circ\text{C}$ ,  $y_{\text{O}_2,0} = 1025 \text{ ppmv}$ ,  $X_{\text{O}_2,0}(240 \text{ }^\circ\text{C}) = 0.6$ ; ( $\square$ );  $T = 290 \text{ }^\circ\text{C}$ ,  $y_{\text{O}_2,0} = 4100 \text{ ppmv}$  ( $\Delta$ ),  $X_{\text{O}_2,0}(290 \text{ }^\circ\text{C}) = 0.67$ ;  $y_{\text{SO}_2,0}$  at  $T = 240 \text{ }^\circ\text{C}$  (...);  $y_{\text{SO}_2,0}$  at  $T = 290 \text{ }^\circ\text{C}$ : (---)

For a reasonable explanation of the observed phenomena, the original reaction of oxygen with methane on  $\text{PdO}$  has to be taken into consideration. The catalytic conversion of oxygen on noble metal catalysts can be described by the Eley-Rideal-mechanism [37,38]. Eley-Rideal presumes oxygen to be present in excess at the active sites of the catalyst at any time. Validity of this mechanism was confirmed in [41] for very low oxygen partial pressures as used in this work. Thus the partial pressure of oxygen shows no influence on the rate of reaction ( $r_{\text{CH}_4} \sim p_{\text{O}_2}^0$ ). Eley-Rideal further presumes methane to take part in the reaction directly from the gas phase or from a short-term adsorbed state on the catalytic surface.

Hence, at moderate pressures, the oxidation reaction is usually modelled first order in methane ( $r_{\text{CH}_4} \sim p_{\text{CH}_4}^1$ ).

This implicates any  $\text{PdSO}_x$  species to have a positive effect on rather the activity of the catalyst itself or on the adsorption of methane on the catalyst surface. Further it seems that the reactive intermediate is not stable at high temperatures or/and when high contents of oxygen are present in the feed gas (see *Figure 3*), indicating why suchlike results have not been published yet.

Obviously, the catalyst behaves different after  $\text{SO}_2$ -feed is terminated. At  $T = 240 \text{ }^\circ\text{C}$  and  $y_{\text{O}_2,0} = 1025 \text{ ppmv}$  the  $\text{PdSO}_x$ -intermediate is stable. The slight increase of conversion probably occurs as some physisorbed  $\text{SO}_2$ , inhibiting the oxidation reaction of methane, is desorbed from the catalyst.

A totally different behavior is observed at  $T = 290 \text{ }^\circ\text{C}$  and  $y_{\text{O}_2,0} = 4100 \text{ ppmv}$ . Under these conditions the catalytic activity decreases to its original level (of  $\text{PdO}$ ) after termination of the  $\text{SO}_2$  feed. During the entire experiment, no  $\text{SO}_2$  is detected in the off gas, indicating storage of sulfur in the support of the catalyst as aluminum sulfate and subsequent transformation of the active sites back to  $\text{PdO}$ . This process probably also takes place during  $\text{SO}_2$  feed, but the formation of the  $\text{PdSO}_x$  intermediate however seems to be dominant at the reaction conditions applied.

#### 4.1.3 Identification of Reactive Intermediate Species

According to the literature, it is likely that the species with increased activity are either  $\text{PdSO}_3$  [18] and/or  $\text{PdSO}_4$  [17]. For further identification, the effect of oxygen on the formation of the  $\text{PdSO}_x$ -intermediate and its subsequent transformation to  $\text{PdO}$  was examined in detail. In order to confirm the experimental findings, X-ray fluorescence analysis (XRF) was also used.

Aforementioned examinations revealed that the active compound is stable at  $240 \text{ }^\circ\text{C}$  and an oxygen inlet concentration of about  $1000 \text{ ppmv}$ . Consequently, these conditions were used to examine the formation of the intermediate compound. Thus, the catalyst was exposed to  $\text{SO}_2$  in an oxygen-free atmosphere where formation of palladium sulfite is expected (see eq. 5).

In order to prevent any inhibition of the combustion reaction (eq. 1) by adsorbed  $\text{SO}_2$ , the catalyst was flushed with pure methane for approximately one hour after the formation segment. Thereafter, oxygen was added to the feed gas – and an increased activity was apparent immediately. Consequently, it can be stated that oxygen is not necessary to form the active  $\text{PdSO}_x$ -intermediate, when  $\text{SO}_2$  is applied. This finding indicates palladium sulfite ( $\text{PdSO}_3$ ) or any compound with an equal Pd:O ratio to be the active intermediate. *Figure 4* illustrates the applied experimental procedure and the results.

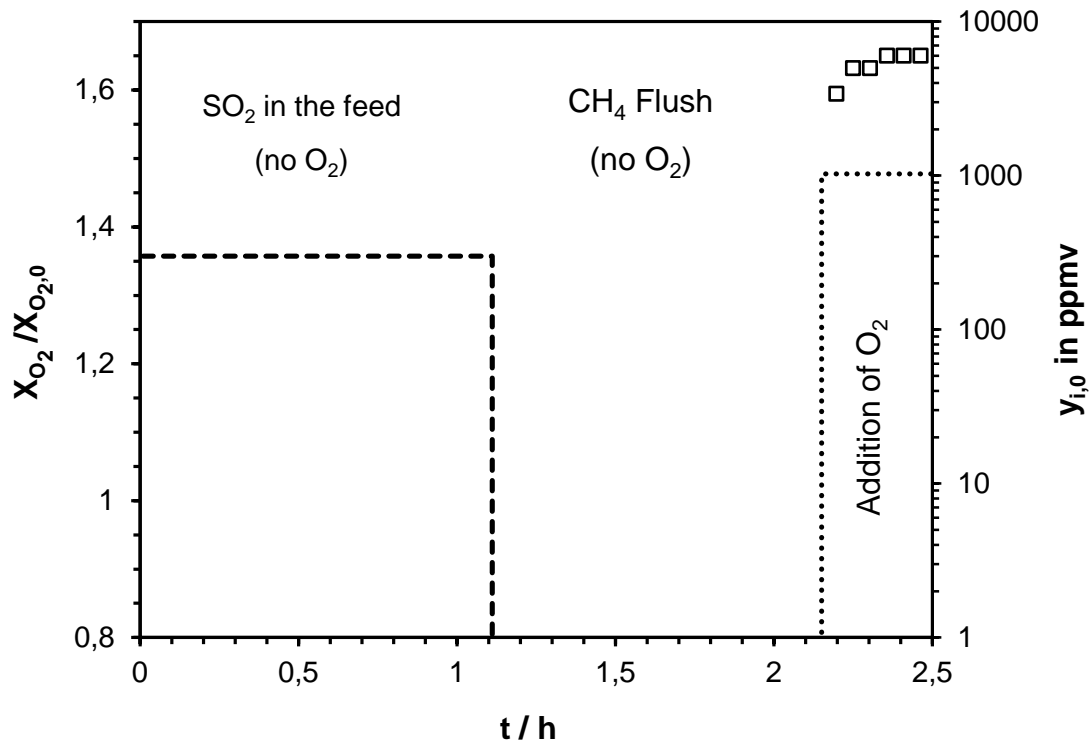

Figure 4: Influence of oxygen on formation reaction of the  $PdSO_x$ -intermediate ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 960$  mbar, GHSV:  $45,000$   $h^{-1}$ ,  $p_{total} = 1.013$  bar,  $T = 240$  °C, balance:  $N_2$ ):  $X_{O_2}/X_{O_2,0}$  ( $\square$ );  $y_{O_2,0}$  (.....);  $y_{SO_2,0}$  (---)

To verify  $PdSO_3$  as the active intermediate, the influence of oxygen during recovery of PdO was examined additionally. In contrast to  $PdSO_4$ ,  $PdSO_3$  requires oxygen to form  $Al_2(SO_4)_3$  and restore PdO (eq. 13).

Upon this second attempt the  $PdSO_x$  species was formed in a methane / sulfur dioxide (100 ppmv) / oxygen (4100 ppmv) atmosphere at higher temperature. Figure 5 shows the procedure. After terminating both, the  $SO_2$  and  $O_2$  feed, the reactor was again passed through an isothermal flush cycle at 290 °C for approximately 1.5 h. After resumption of oxygen supply, the conversion is apparent immediately, but a fast decrease of activity - back the original activity level of PdO - occurs. It can be therefore stated, that not only high temperatures but oxygen is needed for completing the regeneration cycle of the active compound. This again indicates for  $PdSO_3$  as the active intermediate species.

Figure 5: Influence of oxygen on formation of PdO ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 910$  mbar, GHSV:  $45,000$  h<sup>-1</sup>,  $p_{total} = 1.013$  bar,  $T = 290$  °C, balance: N<sub>2</sub>):  $X_{O_2}/X_{O_{2,0}}$  ( $\Delta$ );  $y_{O_{2,0}}$  (.....);  $y_{SO_{2,0}}$  (---)

### Results of XRF Species Analysis

For XRF analysis, three catalyst samples were prepared by applying different gaseous sulfur compounds and reaction temperatures: H<sub>2</sub>S at 220 °C (→ PdS), SO<sub>2</sub> at 220 °C (→ PdSO<sub>3</sub>) and one Pd-sample on Al<sub>2</sub>O<sub>3</sub> carrier after exposure to SO<sub>2</sub> first at 300 °C followed by 220 °C (→ PdSO<sub>3</sub>+Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>). Figure 6 shows the resulting scans across the Kβ' and Kβ<sub>1,3</sub>-lines.

The Kβ'/ Kβ<sub>1,3</sub> intensity ratio increases from 0.077 for the reaction with H<sub>2</sub>S at 220 °C to 0.242 for the reaction with SO<sub>2</sub> starting at 300 °C and then decreasing to 220 °C. The ratio for the reaction with SO<sub>2</sub> at 220 °C is slightly lower but with 0.223 clearly higher than 0.143, the ratio of Na<sub>2</sub>SO<sub>3</sub>. Even after the reaction with H<sub>2</sub>S a small Kβ'-peak is visible and the ratio (0.077) is slightly higher than that of MoS (0.023). A comparison of the Kβ'/ Kβ<sub>1,3</sub> intensity ratios is given in Table 3.

Figure 6:  $K\beta'$ ,  $K\beta_{1,3}$ –scan of  $\text{Pd-Al}_2\text{O}_3$  catalyst spheres after reaction with  $\text{H}_2\text{S}$  at 220 °C,  $\text{SO}_2$  at 220 °C and  $\text{SO}_2$  at 300 °C/220 °C. MoS, Gypsum and  $\text{Na}_2\text{SO}_3$  are given for comparison.

Table 3:  $K\beta'/K\beta_{1,3}$  intensity ratio for the catalyst material after reaction with  $\text{H}_2\text{S}$  and  $\text{SO}_2$  at different temperatures forming sulfides, sulfites and sulfates. The intensity ratio of S at the  $K\beta'$  position to the  $K\beta_{1,3}$  intensity was set as zero point

Preparation of catalyst samples for XRT / Compounds	$K\beta'/K\beta_{1,3}$ intensity ratio
Deactivation with 50 ppmv of $\text{H}_2\text{S}$ at T = 220 °C	0.067
Application of 50 ppmv $\text{SO}_2$ at T = 220 °C	0.223
50 ppmv of $\text{SO}_2$ at 300 °C; $\text{SO}_2$ at 220 °C; $\text{SO}_2$ while cooling to RT	0.242
$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	0.278
$\text{Na}_2\text{SO}_3$	0.143
MoS	0.023
$\text{SrSO}_4$	0.269

The  $K\beta'/K\beta_{1,3}$  intensity ratios imply, that after reaction with  $\text{H}_2\text{S}$  the sulfur is mainly bound as PdS. A small part seems to be present as  $\text{PdSO}_3$  or  $\text{PdSO}_4$ . This may be caused by oxidation with  $\text{O}_2$  from the air after the  $\text{H}_2\text{S}$ -reaction. This is supported by the fact, that the ratio increases if the same samples are measured after considerably longer contact with air (Figure 7).

Figure 7: Time dependency of the  $K\beta'/K\beta_{1,3}$ -ratio for the sample after reaction with  $H_2S$  at  $220^\circ C$

The  $K\beta'/K\beta_{1,3}$  ratio of  $SO_2$  at  $220^\circ C$  is higher than the ratio of  $Na_2SO_3$  and slightly lower than the  $SrSO_4$  ratio. This implies that a small part is present as  $PdSO_3$  and the major part as  $SO_4^{2-}$  – but probably as  $Al_2(SO_4)_3$ . It seems as if oxidation of  $PdSO_3$  to  $Al_2(SO_4)_3$  occurs even at  $220^\circ C$ , but formation of  $PdSO_3$  is probably faster than the consecutive reaction of  $PdSO_3$  to  $Al_2(SO_4)_3$ . The  $K\beta'/K\beta_{1,3}$  ratio for the reaction with  $SO_2$  at  $300^\circ C$  followed by  $220^\circ C$  is higher than for the reaction at  $220^\circ C$ , but still slightly lower than that of  $SrSO_4$ . This clearly shows, that the major part of sulfur is bound as  $SO_4^{2-}$ , most likely as  $Al_2(SO_4)_3$ . A small part still is present as  $PdSO_3$ . As the applied catalyst exhibits only 0.5 ma.-% of PdO, consequently the determined amount of  $PdSO_3$  is smaller than that of  $SO_4$ -species for all relevant samples.

The results of this work correlate with the proposed mechanism by Yu et al. [18]. The formation of  $PdSO_4$ , as suggested by other authors [19,26], was not confirmed under the operating conditions applied in this work (see Figure 4 and Figure 5). However, deviations concerning catalytic activity of the  $PdSO_x$ -species between this work and literature observations occurred (see supplementary data, Fig. B vs. Figure 3 - Figure 5). One possible explanation could be that  $PdSO_4$  (with low activity for oxidation of methane) might be formed when high oxygen contents are applied, whereas formation of the reactive  $PdSO_3$ -intermediate occurs when only little oxygen is available in the gas phase.

The influence of  $\text{SO}_2$  on the catalytic activity is furthermore able to account for the initially described delay in conversion decrease at 300 °C (see *Figure 2*). The formation of  $\text{PdSO}_3$  is probably able to compensate the loss of activity by formation of  $\text{PdS}$ . The  $\text{SO}_2$  breakthrough occurs due to competing adsorption of  $\text{H}_2\text{S}$  and  $\text{SO}_2$ . At high sulfur loadings of the surface,  $\text{SO}_2$  adsorption decreases, therefore the deactivation of the catalyst by  $\text{H}_2\text{S}$  dominates.

#### 4.1.4 In-situ Regeneration of the Catalyst

Finally, the regeneration of the deactivated catalyst was examined. *Figure 8* shows a characteristic regeneration curve after the  $\text{H}_2\text{S}$  exposure to the catalyst is terminated. Typically all samples for regeneration measurements were pre-treated with 100 ppmv of  $\text{H}_2\text{S}$  until residual activity for methane oxidation = 0.

*Figure 8: In-situ regeneration of a deactivated  $\text{PdO}/\text{Al}_2\text{O}_3$  catalyst after termination of  $\text{H}_2\text{S}$ -feed (  $\dot{V} = 100 \text{ l/h (STP)}$ ,  $p_{\text{CH}_4,0} = 960 \text{ mbar}$ ,  $y_{\text{O}_2,0} = 4100 \text{ ppmv}$ ,  $\text{GHSV: } 45,000 \text{ h}^{-1}$ ,  $p_{\text{total}} = 1.013 \text{ bar}$ ,  $T = 296 \text{ °C}$ , balance:  $\text{N}_2$ )*

Equivalent to the termination of the deactivation measurements, no  $\text{CO}_2$  is detected at the beginning of the catalyst regeneration phase. After a delay of approximately one hour (in this case), the activity recovers in the course of the measurement back to its original level. No sulfur compounds are detected in the off-gas, indicating for storage of the complete sulfur loading in the catalyst support. Therefore it is very likely that palladium sulfide is oxidized to sulfite, followed by formation of  $\text{Al}_2(\text{SO}_4)_3$  and recovery of  $\text{PdO}$ , equivalent to the measurements with  $\text{SO}_2$ .

The delay in regeneration is a consequence of excess of H<sub>2</sub>S on the catalyst surface, which was adsorbed on the support during deactivation experiment. Under the assumption that the complete amount of palladium on the catalyst surface is accessible for H<sub>2</sub>S and a 1:1 stoichiometry is valid for deactivation, only 1/11 of the amount of H<sub>2</sub>S which is necessary to completely deactivate the catalyst reacts with the active compound. The rest is adsorbed on the support material (see section 4.4.3, *Figure 17*). This excess of sulfur on the catalyst surface is very likely to re-cover the active sites after they are regenerated. After degradation of this sulfur reservoir, recovery of methane conversion becomes visible. In contrary to Ordonez et al. [28], a complete in-situ recovery of the catalytic activity under reaction conditions is possible, as the original activity of the fresh catalyst is reached. The experimental findings lead to the conclusion that the active compound is regenerated to PdO and that Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> neither physically blocks active sites nor significantly narrows pores at conditions applied in this work, which would lead to a mass transfer limitation of the methane oxidation. However, how many deactivation and regeneration cycles are possible with one catalyst has not been determined in this work, as for all experiments, a fresh catalyst was used.

## 4.2 Reaction Scheme

When high partial pressures of H<sub>2</sub>S ( $\geq 20$  ppmv) are used for the deactivation experiments, the in-situ regeneration reactions are obviously too slow for achieving a stationary state on the catalyst surface. But, when low partial pressures of the catalyst poison are applied, e.g. in the case where the reaction is used for oxygen removal from fuel gas streams, an equilibrium state between deactivation and regeneration is expected, probably leading to the residual activities observed by some authors [8,25,26]. In such a case, different states of the active compound (Pd) are likely to be present on the catalyst surface, whereby the ratios of PdO, PdS and PdSO<sub>3</sub> depend on the applied reaction conditions (T, p<sub>i</sub>).

In order to verify this assumption, measurements with low partial pressures of hydrogen sulfide were carried out. The reaction temperature was chosen as high as possible for fast in-situ regeneration of the catalyst, but low enough for minor H<sub>2</sub>S conversion to SO<sub>2</sub>. The results for four different partial pressures of H<sub>2</sub>S at 280 °C are shown in *Figure 9*.

As can be seen, constant and comparably high residual activities are achieved for each of the examined partial pressures. An increase of H<sub>2</sub>S content leads to lower residual activities due to intensification of deactivation. These results are in contrast to Ordonez et al. [26], who observed one single residual activity, which was independent of the partial pressure of the catalyst poison.

It could be that the regeneration of PdO from PdSO<sub>4</sub> (presumed to be present at high oxygen contents) is slower than the regeneration from PdSO<sub>3</sub> to PdO (at low oxygen contents), leading to a high fraction of PdSO<sub>4</sub> on the catalytic surface under typical literature operating conditions. This may cause the single constant residual activity, observed by Ordóñez et al. [26] even for different concentrations of H<sub>2</sub>S. For deeper insights, additional experiments and sample analysis are necessary.

Figure 9: Influence of low  $p_{H_2S,0}$  on the oxygen conversion ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 960$  mbar,  $y_{O_2,0} = 4100$  ppmv, GHSV:  $45,000$  h<sup>-1</sup>,  $p_{total} = 1.013$  bar,  $T = 280$  °C, balance: N<sub>2</sub>):  $y_{H_2S,0} = 4$  ppmv ( $\Delta$ );  $y_{H_2S,0} = 8$  ppmv ( $\square$ );  $y_{H_2S,0} = 10$  ppmv ( $\circ$ );  $y_{H_2S,0} = 14$  ppmv ( $\diamond$ )

Based on the presented experimental findings, Figure 10 gives a summary of the proposed reaction scheme for deactivation and regeneration of the PdO/Al<sub>2</sub>O<sub>3</sub> catalyst, when low ratios of O<sub>2</sub>:CH<sub>4</sub> are applied.

Figure 10: Proposed deactivation and regeneration scheme of the PdO/Al<sub>2</sub>O<sub>3</sub> catalyst for low O<sub>2</sub>:CH<sub>4</sub> ratios

### 4.3 Surface Species Modelling

In order to describe temporal changes of catalyst activity Levenspiel [39] proposed an empirical model consisting of a deactivation function  $\Psi$ , depending on the temperature and the partial pressure of the catalyst poison  $p_i$  and a deactivation order  $d$  on the original catalyst activity  $a$  (eq. 17).

$$-\frac{da}{dt} = \Psi(p_i, T) * a^d \quad (17)$$

In an advanced version, the model was adapted to account for residual activities  $a_s$  (eq. 18).

$$-\frac{da}{dt} = \Psi(p_i, T) * (a - a_s(p_i, T))^d \quad (18)$$

Based on the approach of Froment [40], Ordonez et al. [26] proposed a different model for the catalytic oxidation of methane by PdO and the deactivation by sulfur which takes into account surface phenomena on the catalyst. Ordonez et al. assume that an active site of the catalyst can be present as palladium oxide (PdO) or as palladium sulfate (PdSO<sub>4</sub>).  $\phi_{PdSO_4}$  represents the coverage fraction of PdSO<sub>4</sub> of all active sites. On the fresh catalyst, only PdO is present ( $\phi_{PdSO_4} = 0$ ), whereby only PdSO<sub>4</sub> is existent on the completely deactivated catalyst ( $\phi_{PdSO_4} = 1$ ). Eq. 19 shows Ordonez' reaction rate approach.  $k_1$  is the reaction constant of PdO,  $k_2$  of PdSO<sub>4</sub>.

$$-r_{O_2} = k_1 * (1 - \phi_{PdSO_4}) * p_{CH_4} + k_2 * \phi_{PdSO_4} * p_{CH_4} \quad (19)$$

The fraction of deactivated active sites can be described by eq. 20, whereby  $k_s$  represents the deactivation constant and  $p_s$  the partial pressure of the catalyst poison.

$$\frac{d\phi}{dt} = k_s(T) * (1 - \phi_{PdSO_4})^n * p_s^m \quad (20)$$

With this approach, Ordonez et al. [26] were able to describe the catalyst deactivation for different temperatures and partial pressures of SO<sub>2</sub>.

The surface species model proposed in this work is based on the approach of Ordonez et al. According to the experimental results at low O<sub>2</sub> partial pressures, the states of the active sites of the catalyst can rather be PdO, PdS or PdSO<sub>3</sub> (eq. 21).

$$\Phi_{PdO} + \Phi_{PdS} + \Phi_{PdSO_3} = 1 \quad (21)$$

The rate of total oxygen conversion is a result of the respective activity of the three possible states of the active compound (eq. 22).

$$-r_{O_2} = \Phi_{PdO} * r_{O_2,PdO} + \Phi_{PdS} * r_{O_2,PdS} + \Phi_{PdSO_3} * r_{O_2,PdSO_3} \quad (22)$$

If possible, the reaction rates are related to the original reaction rate equation for methane oxidation taken from [41] with kinetic parameters for PdO ( $k_{0,CH_4-ox} = 1.1 \cdot 10^8$ ;  $E_A = 87.8$  kJ/mol;  $A = 0$ ;  $B = 1,3$ ;  $C = 2.5$ ;  $D = 0.5$ ;  $K_{CO_2} = 1 \text{ bar}^{-1}$ ;  $K_{H_2O,0} = 1.17 \cdot 10^{-5} \text{ bar}^{-0.5}$ ;  $\Delta_{ads}H_{H_2O} = 58.4$  kJ/mol).

$$r_{O_2,i} = a_i * r_{O_2,PdO} = k_{O_2}(T) \cdot p_{CH_4}^B \cdot \frac{1}{(1 + K_{CO_2} p_{CO_2}^{2.5} + K_{H_2O}(T) \cdot p_{H_2O}^{0.5})} \quad (23)$$

The calculations are carried out by a time discretized numerical method. The ratio  $\Phi_{i,j}$  of the surface species i at time j are calculated on basis of the ratio  $\Phi_{i,j-1}$  of the previous time step and its time discrete change (eq. 24).

$$\Phi_{i,j} = \Phi_{i,j-1} + \Delta t * \frac{d\Phi_{i,j-1}}{dt} \quad (24)$$

This leads to the calculation rules eq. 25-27 for the three possible states of the active compound palladium:

$$\Phi_{PdS,j} = \Phi_{PdS,j-1} + \Delta t * \left( \left( \frac{d\Phi_{PdS,j-1}}{dt} \right)_{PdO \rightarrow PdS} - \left( \frac{d\Phi_{PdS,j-1}}{dt} \right)_{PdS \rightarrow PdSO_3} \right) \quad (25)$$

$$\Phi_{PdSO_3,j} = \Phi_{PdSO_3,j-1} + \Delta t * \left( \left( \frac{d\Phi_{PdSO_3,j-1}}{dt} \right)_{PdS \rightarrow PdSO_3} - \left( \frac{d\Phi_{PdSO_3,j-1}}{dt} \right)_{PdSO_3 \rightarrow PdO} \right) \quad (26)$$

$$\Phi_{PdO,j} = \Phi_{PdO,j-1} + \Delta t * \left( \left( \frac{d\Phi_{PdO,j-1}}{dt} \right)_{PdSO_3 \rightarrow PdO} - \left( \frac{d\Phi_{PdO,j-1}}{dt} \right)_{PdO \rightarrow PdS} \right) \quad (27)$$

The formation of PdO out of PdS is described by rate eq. 28. An oxygen dependency is considered, see eq. 16.

$$\frac{d\Phi_{PdO}}{dt} = k_{PdO}(T) * \Phi_{PdSO_3}^{n_{PdO}} * p_{O_2}^{m_{PdO}} \quad (28)$$

A similar approach is used to describe the formation of PdSO<sub>3</sub> by oxidation of PdS (eq. 29).

$$\frac{d\Phi_{PdSO_3}}{dt} = k_{PdSO_3}(T) * \Phi_{PdS}^{n_{PdSO_3}} * p_{O_2}^{m_{PdSO_3}} \quad (29)$$

Again, oxygen partial pressure is taken into consideration, see eq. 14.

As already mentioned, the formation of PdS from PdO and H<sub>2</sub>S occurs by two different routes and thus a different modelling approach must be applied. With a fresh catalyst, for the first minutes of the deactivation experiment, the formation of PdS mainly results from direct adsorption of H<sub>2</sub>S from the gas phase on the active sites, followed by the deactivation reaction (eq. 2). But H<sub>2</sub>S also adsorbs on the catalyst support, leading to an increase of sulfur loading of the Al<sub>2</sub>O<sub>3</sub> surface during the experiment (see *Figure 11*). As already shown during regeneration measurements, this sulfur sink is not inert throughout the reaction cycle. During deactivation measurements it additionally re-occupies free and/or already regenerated active sites. Therefore, some assumptions for modelling of the deactivation process have to be applied.

*Figure 11: PdS formation scheme*

This leads to the following approach to describe the formation of PdS from PdO (eq. 30):

$$\left(\frac{d\Phi_{PdS}}{dt}\right)_{PdO \rightarrow PdS} = \left(\frac{d\Phi_{PdS}}{dt}\right)_{from\ gas\ phase} + \left(\frac{d\Phi_{PdS}}{dt}\right)_{from\ support} \quad (30)$$

The formation of PdS directly from the gas phase shows a dependency of partial pressure of H<sub>2</sub>S and of PdO-ratio. For modelling of the reaction a rate constant k<sub>PdS</sub> is applied (eq. 31).

$$\left(\frac{d\Phi_{PdS}}{dt}\right)_{gas\ phase} = k_{PdS} * p_{H_2S}^{m_{PdS}} * \Phi_{PdO}^{n_{PdS}} \quad (31)$$

The formation of PdS from surface H<sub>2</sub>S is modelled by a sulfur surface diffusion term, incorporating the fraction of PdO and the sulfur coverage  $\Theta$  of the support, representing the driving force for mass transfer (eq. 32).

$$\left(\frac{d\Phi_{PdS}}{dt}\right)_{support} = k_{\theta} * \Theta * \Phi_{PdO}^{n_{\theta}} \quad (32)$$

The sulfur coverage  $\Theta$  of the support is defined by the ratio of the accumulated sulfur loading  $N_S(t)$  and the maximum possible sulfur loading  $N_{S,max}$  (eq. 33).

$$\Theta = \frac{N_S(t)}{N_{S,max}} \quad (33)$$

Since  $N_{S,max}$  is not easily accessible, a new rate constant  $k'$  is defined (eq. 34):

$$k' = \frac{k_\Theta}{N_{S,max}} \quad (34)$$

The change in sulfur loading is defined by the remaining amount of  $H_2S$  that is stored in the packing less the PdS formation reactions (eq. 35).

$$\left(\frac{dN_{s,j-1}}{dt}\right) = \dot{N}_{H_2S,in} - \dot{N}_{H_2S,out} - N_{PdO} * \left( \left(\frac{d\Phi_{PdS,j-1}}{dt}\right)_{gas\ phase} + \left(\frac{d\Phi_{PdS,j-1}}{dt}\right)_{support} \right) \quad (35)$$

In the context of this work, it is assumed that all PdO atoms are accessible on the catalyst surface and that each PdO reacts with one  $H_2S$  molecule.

## 4.4 Examinations on Reaction Kinetics

*As any  $PdSO_3$  or equivalent component is metastable under at least some of the applied reaction conditions, it was possible to carry out separate kinetic studies on the most important reactions of the proposed reaction scheme (4.4.1 - 4.4.3).*

### 4.4.1 Regeneration of PdO from $PdSO_3$

The experimental procedure for determination of regeneration kinetics of PdO is similar to the procedure applied in *Figure 5*.  $PdSO_3$  was formed under an  $SO_2$  and  $O_2$  containing atmosphere and afterwards the catalyst was flushed with methane. The conversion of oxygen was monitored after oxygen feed was re-enabled after the flush cycle. Despite the high reaction rates ( $r_{O_2,PdSO_3} = 1.6 r_{O_2,PdO}$ ), it was possible to determine the influences of oxygen partial pressure and temperature on the reaction  $PdSO_3 \rightarrow PdO$  (eq. 16). As can be seen in *Figure 12* and *Figure 13* an increase of oxygen partial pressure and temperature both result in faster PdO formation, which is typical for an oxidation reaction.

The regeneration reaction of PdO from  $PdSO_3$  can be divided into three consecutive steps:

- Oxidation of  $SO_2$ , which is chemically bound on PdO, to  $(PdO-)SO_3$
- Transport (by surface diffusion) of  $SO_3$  to the surrounding  $Al_2O_3$  surface
- Storage of  $SO_3$  as  $Al_2(SO_4)_3$  in the catalyst support

The positive effect on the regeneration rate by an increase of oxygen content in the feed gas leads to the conclusion that step a) is the rate-determining step, as the consecutive transport step should exhibit no oxygen dependency.

Figure 12: Influence of  $p_{O_2}$  on the regeneration reaction of PdO from PdSO<sub>3</sub> ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 910$  mbar,  $T = 250$  °C, GHSV: 45,000 h<sup>-1</sup>,  $p_{total} = 1.013$  bar, balance: N<sub>2</sub>):  $X_{O_2}$  at  $y_{O_2,0} = 2050$  ppmv exp ( $\diamond$ ) calc (.....),  $y_{O_2,0} = 3075$  ppmv exp ( $\Delta$ ) calc (---),  $y_{O_2,0} = 4100$  ppmv exp ( $\square$ ) calc (— .)

Figure 13: Influence of temperature on the regeneration reaction of PdO from PdSO<sub>3</sub> ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 910$  mbar,  $y_{O_2,0} = 4100$  ppmv, GHSV: 45,000 h<sup>-1</sup>,  $p_{total} = 1.013$  bar, balance: N<sub>2</sub>):  $X_{O_2}$  at  $T = 240$  °C exp ( $\diamond$ ) calc (.....),  $T = 250$  °C exp ( $\Delta$ ) calc (---),  $T = 265$  °C exp ( $\square$ ) calc (— .)

Finally the kinetic parameters for this reaction were evaluated. For the measurements, it was assumed, that at the beginning of the experiment the active sites are present exclusively as  $\text{PdSO}_3$  ( $\phi_{\text{PdSO}_3} = 1$ ) and at the end of regeneration, total conversion to  $\text{PdO}$  ( $\phi_{\text{PdO}} = 1$ ) has occurred. *Figure 12* shows furthermore a comparison of the experimental data and the calculation results for different partial pressures of oxygen. Both, the temperature and oxygen dependence can be described satisfactorily with the parameters in *Table 4*.

Further, it can be assumed that when high surface coverage of the support material with e.g.  $\text{H}_2\text{S}$  or water occurs, the oxidation reaction of  $\text{PdSO}_3$  and furthermore the surface diffusion process could be inhibited [19]. However, such conditions were not applied in this study.

#### 4.4.2 Formation of PdO from PdS

As the kinetics of the  $\text{PdSO}_3 \rightarrow \text{PdO}$  reaction are established, it is possible to access the kinetic parameters of the previous formation reaction of  $\text{PdSO}_3$  from  $\text{PdS}$ . *Figure 14* shows the normalized oxygen conversion progression of a completely deactivated catalyst, some time period after the termination of the  $\text{H}_2\text{S}$  pretreatment (100 ppmv of  $\text{H}_2\text{S}$  until residual activity for methane oxidation = 0) for three different reaction temperatures. As can be seen, an increase of temperature promotes the regeneration of the catalyst.

*Figure 14: Temperature influence on the PdO-formation from PdS and comparison of experimental results and calculated conversion for the formation of PdO from PdS at different temperatures ( $\dot{V} = 100 \text{ l/h (STP)}$ ,  $p_{\text{CH}_4,0} = 960 \text{ mbar}$ ,  $y_{\text{O}_2,0} = 4100 \text{ ppmv}$ ,  $\text{GHSV: } 45,000 \text{ h}^{-1}$ ,*

$p_{total} = 1.013 \text{ bar}$ , balance:  $N_2$ ):  $X_{O_2}$  at  $T = 277 \text{ }^\circ\text{C}$  exp ( $\diamond$ ) calc (.....),  $T = 288 \text{ }^\circ\text{C}$  exp( $\Delta$ ) calc (---),  $T = 296 \text{ }^\circ\text{C}$  exp ( $\square$ ) calc (— .)

For analysis of the regeneration curves, an idle time segment at the beginning of the experiments (see *Figure 8*) is neglected, as the elimination of surface sulfur does not cause an increase in oxygen conversion (due to re-coverage of active sites). Only when the amount of active sulfur on the surface is fairly eliminated, the regeneration of the catalyst gets visible by an increase of oxygen conversion (due to oxidation of methane at the regenerated PdO sites).

As already noted, the regeneration of PdS consists of two reaction steps, the oxidation of PdS to PdSO<sub>3</sub> and the consecutive recovery of PdO under formation of Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>. Comparison of the time scale of both reactions (*Figure 12* and *Figure 14*) leads to the conclusion that the oxidation of PdS is the rate-determining step in the reaction scheme. PdSO<sub>3</sub> is a metastable intermediate species - at temperatures above 250 °C its retention time on the catalyst surface is short, therefore the ratio of PdSO<sub>3</sub> on the surface tends to be fairly small ( $\phi_{PdSO_3} \rightarrow 0$ ).

*Figure 15: Influence of  $p_{O_2}$  on the formation of PdO from PdS ( $\dot{V} = 100 \text{ l/h (STP)}$ ,  $p_{CH_4,0} = 960 \text{ mbar}$ ,  $T = 277 \text{ }^\circ\text{C}$ ,  $GHSV: 45,000 \text{ h}^{-1}$ ,  $p_{total} = 1.013 \text{ bar}$ , balance:  $N_2$ ):  $\Delta p_{O_2}$  at  $p_{O_2,0} = 4 \text{ mbar}$  ( $\square$ ),  $3 \text{ mbar}$  ( $\Delta$ ) and  $2 \text{ mbar}$  ( $\diamond$ )*

Furthermore, the influence of the oxygen partial pressure was examined. As can be seen, in the first hour of measurements, regeneration rates equal each other. Therefore, it seems as if the partial pressure of oxygen had no influence on the regeneration of active sites (when at

least 2000 ppmv of oxygen are applied to the feedgas). After approximately one hour a decrease of reaction rate occurs with the lowest of the applied inlet concentrations of oxygen. Most likely, the active sites in the upper part of the catalyst bed are then regenerated. As a consequence a depletion of oxygen occurs in the lower region of the bed due to recovery of methane combustion in the upper part. Thus  $p_{O_2}$  decreases in the lower part of the bed, resulting in an inhibition of the regeneration reaction. Nevertheless, in a technical application the strongest sulfur loading is expected at the top part of the catalyst bed, especially in continuous operation mode. Simultaneously, this is where the oxygen content is highest. Thus an influence of oxygen on the regeneration of deactivated palladium sites is neglected. Finally the kinetic parameters for the oxidation of PdS to PdSO<sub>3</sub> (eq. 31) were determined (see *Table 4*). The results of the fits are shown in *Figure 14*. As can be seen, the calculated conversion rates are in good agreement with the experimental results.

#### 4.4.3 Deactivation of PdO by Formation of PdS

*Figure 16* shows the decrease of oxygen conversion with different concentrations of hydrogen sulfide (GHSV of 45,000 h<sup>-1</sup>) with a constant temperature and besides H<sub>2</sub>S an equal gas composition. It is apparent that an increase of partial pressure of H<sub>2</sub>S results in an intensification of catalyst deactivation.

Furthermore, *Figure 17* shows the oxygen conversion as a function of accumulation of H<sub>2</sub>S ( $n_{H_2S,total}/n_{PdO,catalyst}$ ) on the catalyst surface. Since the amount of H<sub>2</sub>S for a complete deactivation of the catalyst is almost equal for different partial pressures of H<sub>2</sub>S, the total injected quantity of H<sub>2</sub>S, not its partial pressure, is the most important factor for the deactivation of the catalyst.

Besides, if sulfur deposited at the active sites primarily, a complete deactivation of the catalyst would occur at a specific amount of H<sub>2</sub>S of one (under the assumption that all PdO molecules are accessible on the catalyst surface and that one PdO site reacts with one single H<sub>2</sub>S molecule). However, the experimental results indicate that the major part of H<sub>2</sub>S adsorbs on the support, not at the active sites. Still, no sulfur desorption occurs after terminating the H<sub>2</sub>S feed, indicating for an additional strong chemisorption of H<sub>2</sub>S on the catalyst support.

Figure 16: Comparison between experimental and calculated data for the deactivation at different partial pressures of  $H_2S$  ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 960$  mbar, GHSV:  $45,000$  h $^{-1}$ ,  $p_{total} = 1.013$  bar,  $y_{O_2,0} = 2050$  ppmv,  $T = 250$  °C, balance:  $N_2$ ):  $y_{H_2S,0} = 50$  ppmv: exp. ( $\diamond$ ), calc. without support-sulfur ( $- \cdot \cdot$ ), calc. with support-sulfur ( $- \cdot \cdot \cdot$ );  $y_{H_2S,0} = 30$  ppmv: exp. ( $\Delta$ ), calc. without support-sulfur ( $- - -$ ), calc. with support-sulfur ( $\cdot \cdot \cdot \cdot$ )

Figure 17: Influence of  $p_{H_2S}$  as a function of the specific amount of  $H_2S$  ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 960$  mbar, GHSV:  $45,000$  h $^{-1}$ ,  $p_{total} = 1.013$  bar,  $y_{O_2,0} = 2050$  ppmv,  $T = 250$  °C, balance:  $N_2$ ):  $y_{H_2S,0} = 100$  ppmv ( $\Delta$ );  $50$  ppmv ( $\square$ );  $30$  ppmv ( $\diamond$ )

Figure 18 shows the influence of  $p_{O_2}$  on the formation of PdS from PdO. The deactivation rates do not deviate significantly in the first (two) hours of the experiments. Thereafter, the conversion of oxygen at 1025 ppmv decreases faster. This is probably an effect of pore-narrowing leading to a mass transfer limitation of the methane oxidation and/or the regeneration reaction of PdS, caused by depletion of oxygen at the inner active sites. Indeed, this phenomenon does not occur at higher partial pressures of oxygen. Thus, as expected from reaction stoichiometry, it is assumed that  $p_{O_2}$  has no significant influence on the formation of PdS.

Furthermore the influence of temperature was examined. The applicable temperature range for the measurements is limited by  $SO_2$  formation (280 °C) and by the minimum temperature for oxygen conversion (235 °C). A temperature effect on deactivation reaction is not visible within these boundaries. In literature, adsorption of sulfur, not the consecutive reaction with the active compound is considered to be the rate-determining reaction step [17,25]. Probably due to the small variation range, changes of temperature show no effect on sulfur adsorption. At the end of the experiments no activity for methane oxidation is observed anymore ( $r_{O_2, PdS} = 0$ ), additionally a minor  $H_2S$  breakthrough appears. Higher reaction temperatures result in a slight increase of residual activities, which is not due to higher activity for oxidation of methane but due to an increase of regeneration rate.

Figure 18: Influence of  $p_{O_2}$  on the formation of PdS from PdO ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 960$  mbar, GHSV:  $45,000$   $h^{-1}$ ,  $p_{total} = 1.013$  bar,  $y_{H_2S,0} = 50$  ppmv,  $T = 250$  °C, balance:  $N_2$ ):  $y_{O_2,0} = 1025$  ppmv ( $\Delta$ ); 2050 ppmv ( $\square$ ); 4100 ppmv ( $\diamond$ )

Finally, the kinetic parameters for the formation of PdS were derived. As already addressed, the formation of PdS occurs directly by H<sub>2</sub>S adsorption on the active sites but additionally by surface diffusion of sulfur molecules, adsorbed on the catalyst support. The deactivation directly from the gas phase was adapted to the initial degradation rate (slope of the deactivation curves within the first minutes of measurements), as it is assumed that the amount of sulfur on the support (and therefore the formation of PdS from support-sulfur) is low in this time period. As deactivation progresses, more and more support-sulfur takes part and additionally covers the active sites. The kinetic parameters of this term are predominantly fitted to the end of the deactivation measurements. The derived parameters are summarized in *Table 4*. *Figure 16* shows the experimental results and calculated conversion rates for 30 ppmv and 50 ppmv of H<sub>2</sub>S at low temperatures. For demonstration, the conversion rates are calculated with and without PdS-formation from support-sulfur.

To summarize the results, *Figure 19* shows the measurements at low feed concentrations of H<sub>2</sub>S, which result in residual activities, as deactivation and regeneration rates equal each other. As can be seen, it is possible to calculate the residual activities, when the kinetic parameters of the involved reactions are incorporated, which were derived from separate experimental studies on each reaction. *Figure 20* shows a parity plot of all experimental vs. calculated data.

*Figure 19: Comparison between experimental and calculated data for catalyst deactivation at different partial pressures of H<sub>2</sub>S ( $\dot{V} = 100$  l/h (STP),  $p_{CH_4,0} = 960$  mbar, GHSV:  $45,000$  h<sup>-1</sup>,  $p_{total} = 1.013$  bar,  $y_{O_2,0} = 4100$  ppmv,  $T = 280$  °C, balance: N<sub>2</sub>):  $y_{H_2S,0} = 14$  ppmv: exp. ## 5 Summary and Conclusion

As sulfur compounds are an important kind of gas contaminants, this work focuses on the effect of sulfur-containing gas components on the durability of a commercial  $PdO/Al_2O_3$  catalyst for removal of oxygen by oxidation of  $CH_4$  at low  $O_2:CH_4$  ratios, an operating temperature range of  $200\text{ °C} < T < 300\text{ °C}$  and low  $H_2S$  contents.

As  $SO_2$  and  $H_2S$  show a different behavior in the examined range of operating conditions, the influences of both were determined separately in course of preliminary examinations on catalyst deactivation and consecutive in-situ regeneration. Due to the low operating temperatures and low oxygen contents applied in this work, it was possible to identify an

intermediate species, presumably PdSO<sub>3</sub>, with an increased activity for the oxidation of methane. This stands in contrast to the literature, where SO<sub>2</sub> typically causes catalyst deactivation. As a conclusion it can be drawn, that oxygen content in the gas phase may have an influence on oxidation stage of the PdSO<sub>x</sub> component spectrum on the catalyst surface. Based on the experimental results, a reaction scheme was derived and kinetic measurements for each of the participating reactions were carried out separately.

Furthermore, the derived deactivation model was validated by experimental data with low contents of H<sub>2</sub>S, showing that the residual activities, observed by some authors, are a result of rate-equality of deactivation and in-situ regeneration process on the catalytic surface.

In further investigations more detailed information on catalyst surface species can be obtained by using extended X-ray absorption spectroscopy (EXAFS) at an adequate synchrotron beamline. EXAFS enables the determination of the atomic environment as well of the Pd-atoms as of the sulfur atoms.

The results of this work are useful in particular when low contents of H<sub>2</sub>S or SO<sub>2</sub> (< 1-2 ppmv) are applied to the catalyst, e.g. in terms of oxygen removal with in-situ fine purification of the gas. Further on, first long-term deactivation measurements with high amounts of H<sub>2</sub>S (which were not part of this work) reveal, that a steady decline of conversion takes place after a certain TOS (depending on total H<sub>2</sub>S amount applied to the catalyst). Whether the pores of the catalyst are physically blocked by surface sulfur, swelling of the support by storage of sulfate or other mechanisms take place has to be examined further, but passing through this type of deactivation is again fully reversible for the first few cycles. However, in order to deal with high H<sub>2</sub>S amounts, it needs to be further examined how the long-term stability evolves, how many deactivation and regeneration cycles are possible until the catalyst support is completely saturated and irreversible deactivation takes place, respectively.
