## ABSTRACT

Populations of farmland butterflies have been suffering from substantial population declines in recent decades. These declines have been correlated with neonicotinoid usage both in Europe and North America but experimental evidence linking these correlations is lacking. The potential for non-target butterflies to be exposed to trace levels of neonicotinoids is high, due to the widespread contamination of agricultural soils and wild plants in field margins. Here we provide experimental evidence that field realistic, sub-lethal exposure to the neonicotinoid imidacloprid negatively impacts the development of the common farmland butterfly *Pieris brassicae*. Cabbage plants were watered with either 0, 1, 10, 100 or 200 parts per billion imidacloprid, to represent field margin plants growing in contaminated agricultural soils and these were fed to *P. brassicae* larvae. The approximate digestibility (AD) of the cabbage as well as behavioural responses by the larvae to simulated predator attacks were measured but neither were affected by neonicotinoid treatment. However, the duration of pupation and the size of the adult butterflies were both significantly reduced in the exposed butterflies compared to the controls, suggesting that adult fitness is compromised through exposure to this neonicotinoid.

## INTRODUCTION

The use of neonicotinoids has been implicated in the global decline of pollinators and this has caused much debate and controversy (*Goulson, 2013; Stokstad, 2013*). Since their introduction in the early 1990s they have become the most widely used insecticides in the world. Their success is partly due to their systemic nature, which allows them to be applied in a variety of ways, such as seed dressings, foliar sprays and soil drenches (*Jeschke et al., 2011*). After application, the chemicals are able to spread throughout the plant tissues, hence protecting the whole plant from pests.

However, the impact of neonicotinoids extends beyond the crop plants and the target pest species and this has brought their widespread use into question (*Goulson, 2013; Van der Sluijs et al., 2015*). For example, beneficial insects can be exposed to these insecticides when

they forage on flowering crops, as trace levels have been detected in the pollen and nectar of treated plants (Blacquièrè *et al.*, 2012; David *et al.*, 2016). Non-target invertebrates are also exposed to neonicotinoids when they forage on non-crop plants growing in agricultural lands (Krupke *et al.*, 2012; Botías *et al.*, 2016). Such contamination of non-target plants can occur from the dust produced during the drilling of treated seeds, which drifts onto surrounding vegetation and has been shown to contain high concentrations of neonicotinoids (Krupke *et al.*, 2012; Girolami *et al.*, 2013; Limay-Rios *et al.*, 2016).

A debatably more serious route of contamination is through the soil; when used as seed dressings, only 1.6 to 20% of the active ingredient of neonicotinoids is taken up by the crop and the remainder stays in the soil (Sur & Stork, 2003). The half-lives of neonicotinoids in soils can exceed 1,000 days and so they can accumulate when used repeatedly (Bonmatin *et al.*, 2015). This persistence, combined with a high potential for lateral movement and leaching, can cause widespread contamination of agricultural areas (Sánchez-Bayo *et al.*, 2007; Gupta, Gajbhiye & Gupta, 2008; Kurwadkar *et al.*, 2014). A study of conventionally managed farmland in France found that 65% of soil samples contained >1 ppb imidacloprid (despite only 15% of sites having been planted with treated seeds in the same year), 14% of samples contained between 10 and 100 ppb and 4% contained over 100 ppb (Bonmatin *et al.*, 2005). In a study in Eastern England, clothianidin, thiamethoxam and imidacloprid were all detected in fields where no treatment had been applied in the previous three years—imidacloprid at levels up to 10.7 ppb (Jones, Harrington & Turnbull, 2014). Botías *et al.* (2015) sampled agricultural soils and found both the soil directly beneath the treated crop and also the soils in the field margins to be highly contaminated with neonicotinoids, again even when none of the detected chemical had been applied in the previous three years. This soil contamination can lead to uptake into field margin plants and, indeed, neonicotinoid residues have been found in 52% of foliage samples collected from wild plants in oil seed rape field margins (Botías *et al.*, 2016). This demonstrates that non-target insects in field margins are likely to be chronically exposed to highly variable concentrations of neonicotinoids in plant tissues.

To date, much of the work on the effect of neonicotinoids on non-target invertebrates has focused on honeybees and species of bumblebee. Exposure to field realistic concentrations has been shown to have substantial sub-lethal effects, such as reduced foraging efficiency (Gill, Ramos-Rodriguez & Raine, 2012; Feltham, Park & Goulson, 2014), impaired navigation (Henry *et al.*, 2012), a reduction in learning and memory (Stanley, Smith & Raine, 2015), reduced ovary development (Baron, Raine & Brown, 2017) and reduced reproductive success (Whitehorn *et al.*, 2012; Baron *et al.*, 2017b). Such sub-lethal effects can have substantial negative impacts at the population level (Rundlöf *et al.*, 2015; Woodcock *et al.*, 2016) and neonicotinoids have been implicated as a contributory factor in the global decline of pollinators (Van der Sluijs *et al.*, 2015). However, little research has investigated the impact on other non-target invertebrate taxa, such as butterflies (Pisa *et al.*, 2015). Farmland butterflies in England declined by 56% between 2002 and 2009, despite large investments in the management of areas for biodiversity conservation during this time (Brereton *et al.*, 2011). The declines have also occurred despite predictions that

moderate climate change will benefit UK butterflies due to warmer summer temperatures (Roy *et al.*, 2001).

The possibility that the recent declines in butterfly numbers may have been driven by the increasing usage of neonicotinoids has been modelled by Gilburn *et al.* (2015). This paper extended previous models of the UK population indices of 17 species of widespread farmland butterflies (Roy *et al.*, 2001) with the additional explanatory variable of neonicotinoid pesticides usage. These models found a strong negative association between 15 of the 17 butterfly species population indices and the number of hectares of farmland treated with neonicotinoids the previous year. These population declines have also primarily occurred in England where neonicotinoid usage is at its highest; in contrast in Scotland, where neonicotinoid usage is much lower, butterfly numbers are stable. Similar negative associations between butterfly populations and neonicotinoid application have been observed in California, particularly after 1997 when imidacloprid started to be used in this state (Forister *et al.*, 2016). Despite these compelling correlations, there is little experimental evidence demonstrating the effects of trace levels of neonicotinoids on non-target butterfly species. It has been found that doses as low as 1 ppb of clothianidin have sub-lethal impacts on Monarch butterflies (*Danaus plexippus*) and contamination of the larval foodplant, milkweed, may be contributing to the mortality of neonates (Pecenka & Lundgren, 2015). In this paper we seek to further address this knowledge gap by investigating the sub-lethal effects of the neonicotinoid imidacloprid on the large white butterfly (*Pieris brassicae*). This butterfly is a widespread species and its larvae feed on wild or cultivated species of the Brassicaceae family (Feltwell, 1982). It was chosen as a study species due to ease of handling in laboratory and because it currently has a stable population in the UK, but it is declining at some sites, particularly in the more agricultural south and east of the country (UKBMS), where neonicotinoid usage is high.

## MATERIALS & METHODS

Cabbage plants (*Brassica oleracea* var. *capitata* L.) were grown from seed purchased from an organic supplier (Laura's Organics Ltd., Wigan, UK). Pure imidacloprid (Sigma-Aldrich, UK) was dissolved in a known volume of distilled water and used to dose the cabbage plants. Each time the plants were watered they received either 0 (control), 1, 10, 100 or 200 parts per billion (ppb) imidacloprid to create five treatment groups of cabbage plants. The treated water was added directly to the soil beneath the plants to avoid additional residue contamination on the leaves. These levels were chosen to fall within the range of concentrations of neonicotinoids that have been found in agricultural soils (Bonmatin *et al.*, 2005; Botías *et al.*, 2015). It is known that imidacloprid has a high xylem mobility through cabbage plants (Buchholz & Nauen, 2002) and the cabbage plants therefore represented agricultural field margin vegetation grown in contaminated conditions.

*Pieris brassicae* eggs were sourced from a butterfly breeder (M. Hoare, Knoles butterflies) and consisted of one sibling group, originating from one female. When the larvae hatched they were split into five treatment groups and placed in ventilated plastic boxes in a controlled environment cabinet under a 16 h L/ 8 h D regime at 20 °C (see Table 1 for

**Table 1** Sample sizes across the treatments and larval survival.

Neonic treatment	Sample size	Predator treatment	Sample size	No. survived to adulthood
Control	32	P	15	14
		NP	17	14
1 ppb	31	P	15	14
		NP	16	15
10 ppb	32	P	15	14

200 ppb	31	P	15	13
		NP	16	16

sample sizes). Each of the five boxes were provided with cabbage leaves from one of the imidacloprid treatment groups *ad libitum*. When the majority of the caterpillars were heavier than 30 mg (range of initial mass 19–124 mg, mean 55.7 mg), they were weighed and placed individually in boxes. Solitary conditions have been previously shown to not impact the development of this normally gregarious species ([Higginson et al., 2011](#)). The solitary caterpillars continued to feed on the cabbage treatment they had originally received and this was refreshed three times, every third or fourth day. The weight of cabbage placed into each box, the weight of cabbage removed and the weight of frass produced was recorded each time, allowing the ‘Approximate Digestibility (AD)’ to be calculated ([Waldbauer, 1968](#)) at the three time points.

$$AD = \text{Food ingested} - \text{Frass produced} / \text{Food ingested}.$$

In order to investigate whether any impacts of neonicotinoids are amplified by additional stress, the individually housed caterpillars were then randomly allocated to a predator attack treatment. Half of each cabbage treatment group were subjected to a simulated predator attack, and the other half were left undisturbed. We simulated a predator attack by lightly pinching the caterpillars’ abdomen three times, using soft forceps (Storkbill fine blunt forceps; NHBS, Totnes, UK). The caterpillar’s immediate response to the attack was recorded, including whether it regurgitated, moved its head or tail or dropped from the leaf. These behaviours were not mutually exclusive and caterpillars often displayed more than one response. The predator attacks occurred a total of three times and were carried out once every second or third day. The date that the caterpillar pupated was recorded and the pupae were allowed to eclose in the individual boxes.

Once the butterflies had eclosed, they were transferred to flight cages measuring 60 × 40 × 60 cm (width × depth × height), located in an unheated polytunnel on the Stirling University campus. Butterflies were individually marked on their hind wings and kept in their treatment groups, meaning there were a total of ten flight cages (1 ppb predator; 1 ppb no predator; 10 ppb predator; 10 ppb no predator; 100 ppb predator; 100 ppb no predator; 200 ppb predator; 200 ppb no predator; control predator; control

no predator; [Table 1](#)). After death of the adults the forewings of each individual were measured, a standard indicator of overall size in butterflies ([Gage, 1994](#)).

## STATISTICAL ANALYSIS

Data were analysed in R, version 3.4.1 ([R Core Team, 2017](#)). Binomial generalized linear mixed effect models were used to analyse determinants of the Approximate Digestibility (AD) of the cabbage leaves by the larvae. Neonicotinoid treatment (0, 1, 10, 100, 200 ppb) and predator treatment (Predator (P) or no predator (NP)) were entered as factors, the initial larval weight and the time point (1, 2, 3) were entered as co-variates and the individual larval ID was entered as a random effect. Binomial generalized linear mixed effect models were also used to analyse the behaviour of the subset of larvae that underwent simulated predator attacks. Separate (binomial glmer) models analysed the probabilities of larvae reacting, regurgitating, moving their head, moving their tail and, finally, dropping from the leaf. Additionally, a generalized linear mixed effect model with Poisson distribution was used to analyse the total number of behaviours performed. In all behaviour models the neonicotinoid treatment (0, 1, 10, 100, 200 ppb) was entered as a factor, the initial larval weight and the time point (1, 2, 3) were entered as co-variates and the individual larval ID was entered as a random effect. In all models, fit was assessed using chi-square tests on the log-likelihood values to compare different models. Visual inspection of residual plots did not reveal any deviations from normality.

Pupation length, measured in days, was compared across firstly the neonicotinoid treatment groups and secondly across the predator treatment groups with Kruskal-Wallis tests, due to its non-normal distribution. Post hoc Wilcoxon tests were used to test pairwise comparisons and these were Bonferroni corrected for multiple comparisons. Finally, adult forewing length was analysed with a general linear model, with neonicotinoid treatment, predator treatment and sex entered as factors and the initial larval weight as a co-variate. Visual inspection of residual plots did not reveal any deviations from normality.

## RESULTS

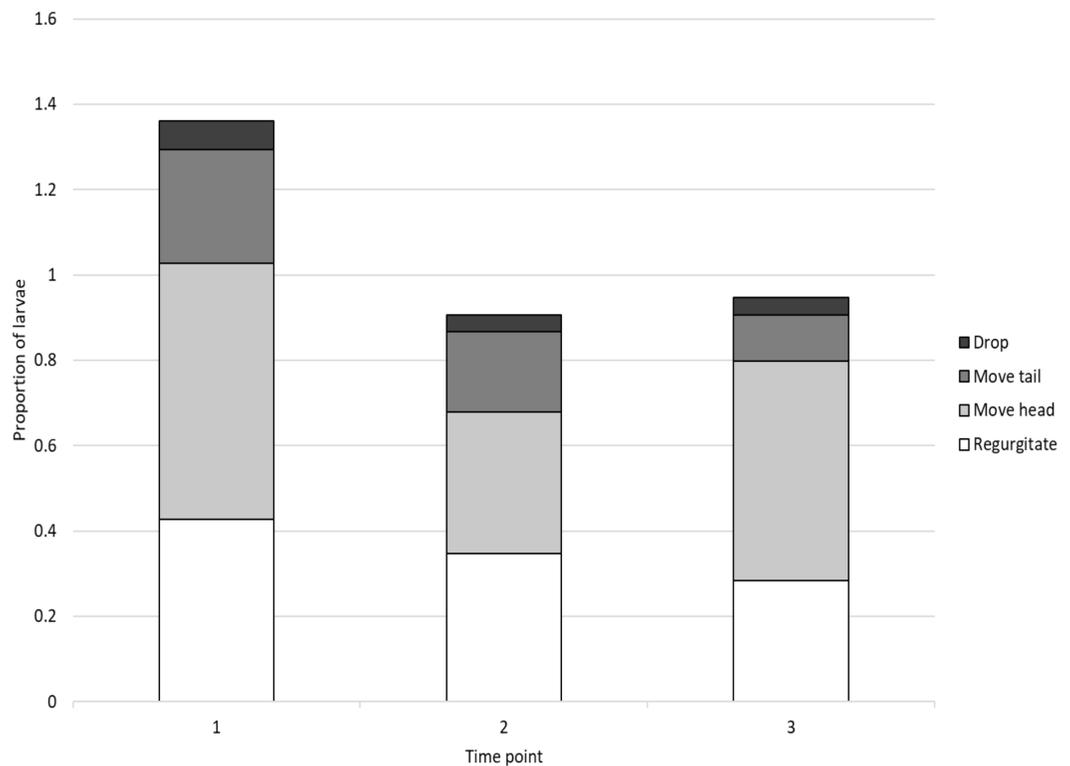

A total of 158 larvae were split across the five neonicotinoid treatment groups and 143 of these survived until adulthood (mortality was less than 10% of the initial number of larvae), with no difference among treatments in larval survival ([Table 1](#)).

### Approximate Digestibility (AD)

The mean Approximate Digestibility (AD) across all larvae was 51.95% (range 38.37 – 81.23%). Approximate Digestibility was not affected by either the neonicotinoid treatment, the simulated predator treatment or initial weight of the larvae ( $\chi^2 = 3.87$ ,  $df = 4$ ,  $p = 0.424$ ;  $\chi^2 = 0.964$ ,  $df = 1$ ,  $P = 0.326$  and  $\chi^2 = 0.293$ ,  $df = 1$ ,  $P = 0.588$  respectively). However, AD declined significantly over time ( $\chi^2 = 21.63$ ,  $df = 1$ ,  $P < 0.001$ ) ([Table 2](#)).

### Anti-predator behaviour

More than half (58.5%) of larvae reacted when subjected to a simulated predator attack but the probability of a larvae reacting or not was not affected by neonicotinoid treatment,

**Figure 1** The proportion of larvae reacting with the four behaviours at each time point.

**Table 2** Parameter estimates and 95% CIs from the generalised linear mixed effect models for Approximate Digestibility (AD). The parameter estimates shown here are with reference to the control neonicotinoid treatment and the non-predator treatment group.

		Parameter estimate	Lower 95% CI	Upper 95% CI
Intercept		1.052	0.346	1.758
Neonic Treatment	1 ppb	-0.124	-0.584	0.336
	10 ppb	0.116	-0.337	0.569
	100 ppb	0.302	-0.152	0.755
	200 ppb	-0.048	-0.493	0.397
Predator treatment	P	0.144	-0.138	0.425
Initial larval weight		1.592	-4.173	7.356
Time		-0.506	-0.726	-6.285

initial larval weight or the time point ( $\chi^2 = 2.65$ ,  $p = 0.617$ ;  $\chi^2 = 0.730$ ,  $P = 0.393$  and  $\chi^2 = 0.556$ ,  $P = 0.456$  respectively). The most common responses were head movements and regurgitation (48.2% and 35.3% reactions, respectively). Tail movements and dropping from the leaf were less commonly observed (18.8% and 4.9% reactions). Behaviours were not mutually exclusive and larvae often displayed more than one response (see Fig. 1 for the breakdown of behaviours at the three time points).

The neonicotinoid treatment had no impact on the number of total behaviours performed ( $\chi^2 = 2.18$ ,  $df = 4$ ,  $p = 0.703$ ) or on the probability of a larvae responding with a particular behaviour (regurgitation:  $\chi^2 = 1.64$ ,  $df = 4$ ,  $p = 0.802$ ; move head:  $\chi^2 = 2.30$ ,  $df = 4$ ,  $p = 0.681$ ; move tail:  $\chi^2 = 2.40$ ,  $df = 4$ ,  $p = 0.662$ ; drop:  $\chi^2 = 2.36$ ,  $df = 4$ ,  $p = 0.669$ , see [Table 3](#) for parameter estimates and 95% CIs from the generalised linear mixed effect models). However, the number of total behaviours performed declined over time and decreased with increasing initial larval weight ( $\chi^2 = 6.42$ ,  $df = 1$ ,  $p = 0.011$  and  $\chi^2 = 4.74$ ,  $df = 1$ ,  $p = 0.029$  respectively, [Table 3](#)). No variable predicted the probability of larvae moving their head or dropping from the leaf ([Table 3](#)) but the probability of a larvae regurgitating was lower for larvae that had a greater initial weight ( $\chi^2 = 6.19$ ,  $df = 1$ ,  $p = 0.013$ , [Table 3](#)) and the probability of responding with a tail movement declined over time ( $\chi^2 = 6.31$ ,  $df = 1$ ,  $p = 0.012$ , [Table 3](#)).

### Pupation

The mean duration of pupation was 12.76 ( $\pm 0.145$ ) days and this was impacted by neonicotinoid treatment ( $H(4) = 21.88$ ,  $p < 0.001$ ) with the control larvae pupating for a significantly longer time than any of the treated groups ([Fig. 2](#)). Pupation length was not impacted by predator treatment ( $H(1) = 0.137$ ,  $p = 0.712$ ).

### Adult forewing length

Butterflies in the neonicotinoid treatment groups had significantly smaller forewings compared to control butterflies (1 ppb,  $t(4) = -3.74$ ,  $p < 0.001$ ; 10 ppb,  $t(4) = -4.71$ ,  $p < 0.001$ ; 100 ppb,  $t(4) = -4.94$ ,  $p < 0.001$ ; 200 ppb,  $t(4) = -4.36$ ,  $p < 0.001$ , [Fig. 3A](#)). Additionally, male butterflies had smaller forewings than females, as expected for this species ( $t(1) = -3.73$ ,  $p < 0.001$ , [Fig. 3C](#)) and forewing length declined with increasing initial larval weight ( $t(1) = -3.45$ ,  $p < 0.001$ , [Fig. 3B](#)). The predator treatment had no impact on the forewing length of adults ( $t(1) = -1.21$ ,  $p = 0.228$ ).

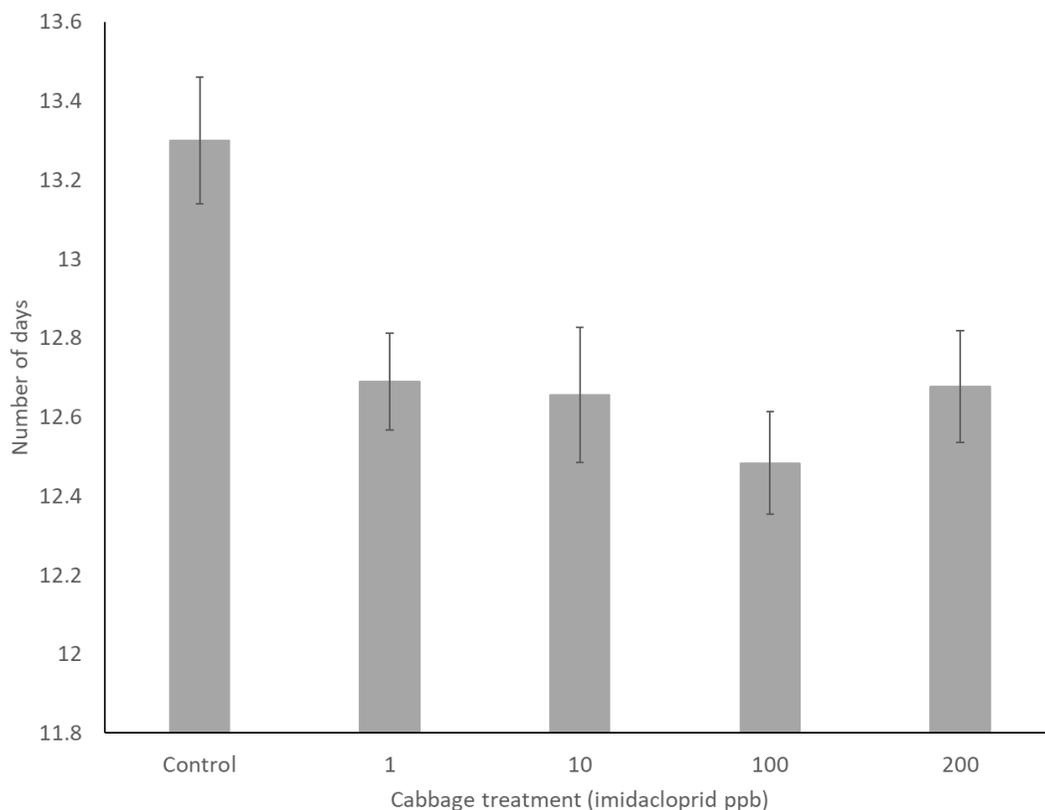

## DISCUSSION

We have shown that when larvae of the common farmland butterfly *Pieris brassicae* are exposed to sub-lethal doses of the neonicotinoid imidacloprid, they have a shorter pupation period and the adult butterflies emerge significantly smaller. This effect was observed across all neonicotinoid doses, with exposure from 1 ppb up to 200 ppb having the same impact ([Fig. 3](#)). In Lepidoptera, there is a strong positive relationship between body size and fitness, with larger individuals having greater reproductive success ([Bauerfeind & Fischer, 2008](#); [Higginson et al., 2011](#)), as well as a better flight ability and endurance ([Shirai, 1995](#)). Therefore, the results of this study provide support for the hypothesis that the recent negative population trends observed in farmland butterflies might be a consequence of increasing neonicotinoid usage ([Gilburn et al., 2015](#); [Forister et al., 2016](#)).

The neonicotinoid treatment did not appear to affect the assimilation of nutrients from the cabbage leaves by the larvae as the approximate digestibility (AD) was not different among the treatments. AD did, however, decline with the age of the larvae, which is expected as smaller larvae tend to select the parts of the leaf they eat, avoiding the less

digestible leaf veins, whilst larger larvae are less discriminating ([Panizzi & Parra, 2012](#)). It is possible that the neonicotinoid impacted the efficiency of conversion of the digested food into biomass and it would be interesting to explore this mechanism in a future study.

Our study found that it is the adult stage of this species that is impacted by neonicotinoid exposure as a larva and it would be worthwhile to further investigate the impacts of these chemicals on the behaviour and reproductive success of adults. Neonicotinoids impact the ability of bees to effectively navigate and forage (e.g., [Henry et al., 2012](#); [Feltham, Park & Goulson, 2014](#)) and it is possible that similar impacts in butterflies would decrease their ability to find suitable forage flowers and hence impact their survival in the field. Additionally, as *P. brassicae* is a migratory species, small impacts on navigation could have profound impacts when moving over hundreds of kilometres. Sub-lethal doses of neonicotinoids are also known to impact the reproductive success of bumblebees (e.g., [Whitehorn et al., 2012](#); [Baron, Raine & Brown, 2017](#)), and a similar impact on the fecundity of adult butterflies would explain the dramatic population declines that have been observed in agricultural regions. It has been found that imidacloprid can reduce the development time of pupae as well as the fecundity and survival of the pest moth species *Helicoverpa armigera* ([Ahmad, Ansari & Ahmad, 2013](#)), so it would be beneficial to investigate whether

**Figure 3** Variables predicting the forewing length of adult butterflies. (A) Adult forewing length was significantly greater in the control butterflies compared to those exposed to imidacloprid (compared to control: 1 ppb  $t_{(4)} = -3.74$ ,  $p < 0.001$ ; 10 ppb  $t_{(4)} = -4.71$ ,  $p < 0.001$ ; 100 ppb  $t_{(4)} = -4.94$ ,  $p < 0.001$ ; 200 ppb  $t_{(4)} = -4.36$ ,  $p < 0.001$ ). (B) Initial larval weight had a significant negative correlation with adult forewing length ( $t_{(1)} = -3.45$ ,  $p < 0.001$ ). (C) Adult females had significantly larger forewings than adult males ( $t_{(1)} = -3.73$ ,  $p < 0.001$ ).

Full-size DOI: [10.7717/peerj.4772/fig-3](https://doi.org/10.7717/peerj.4772/fig-3)

these impacts extend to non-target Lepidoptera species, where such effects would not be advantageous.

Interestingly, the simulated predator attacks had no impact on either larval development or adult body size of *P. brassicae* in this experiment. This is contrary to the findings of [Higginson et al. \(2011\)](#), who found that there was a growth and survival cost to predator attacks in *P. brassicae*. However, their study induced the larvae to defensively regurgitate in each simulated predator attack and so the later costs were a consequence of the regurgitation (through loss of body fluids and nutrients), rather than the attack itself. Although regurgitation was a commonly observed defensive behaviour in our experiment,

it comprised only 35% of the observed reactions and therefore possibly did not occur frequently enough to cause observable negative effects on the developing larvae. We did observe that the larvae that had a greater initial weight were less likely to regurgitate and performed fewer defensive behaviours overall. This could be linked to the trade-offs between growth and defensive behaviours, with the larger larvae on a pathway to optimise growth at the expense of anti-predator strategies (*Higginson et al., 2011*). We also observed that the amount of behaviours performed and specifically the propensity to move their tails, declined over time as the larvae aged. This could be linked to the fact that the larvae became less active as they prepared to pupate (P Whitehorn, pers. obs., 2014).

## CONCLUSIONS

In conclusion, this study provides some initial experimental evidence for the sub-lethal impacts of neonicotinoids on a common butterfly species. We find that exposure to levels as low as 1 ppb have negative consequences for the size of adult butterflies, a strong indicator of fitness in butterflies. Further research is needed to investigate how such exposure might impact the behaviour and reproductive success of this and other butterfly species.

## ACKNOWLEDGEMENTS

We would like to thank James Weir and Calum Brown for their help in the laboratory, and the IUCN Task Force on Systemic Pesticides for its support and encouragement.

## ADDITIONAL INFORMATION AND DECLARATIONS

### Funding

Penelope R. Whitehorn was funded by an Impact Research Fellowship held at the University of Stirling. This work was also supported by grants from the Triodos Foundation, Zeist (Netherlands) and the Gravin van Bylandt Stichting, The Hague, (Netherlands). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

### Grant Disclosures

The following grant information was disclosed by the authors:

Impact Research Fellowship.

Triodos Foundation, Zeist (Netherlands).

Gravin van Bylandt Stichting, The Hague, (Netherlands).

### Competing Interests

The authors declare there are no competing interests.

### Author Contributions

- Penelope R. Whitehorn conceived and designed the experiments, performed the experiments, analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the paper, approved the final draft.

- George Norville performed the experiments, approved the final draft.
- Andre Gilburn and Dave Goulson conceived and designed the experiments, authored or reviewed drafts of the paper, approved the final draft.

### Data Availability

The following information was supplied regarding data availability:

Whitehorn, Penelope (2018): Data for\_Larval exposure to the imidacloprid impacts adult size in *Pieris brassicae*.xlsx. figshare. Dataset. <https://doi.org/10.6084/m9.figshare.5769360>.
