Abstract. Mercury was measured onboard the IAGOS-CARIBIC passenger aircraft from May 2005 until February 2016 during near monthly sequences of mostly four inter-continental flights from Germany to destinations in North and South America, Africa and South and East Asia. Most of these mercury data were obtained using an internal default signal integration procedure of the Tekran instrument but since April 2014 more precise and accurate data were obtained using post-flight manual integration of the instrument raw signal. In this paper we use the latter data.

Increased upper tropospheric total mercury (TM) concentrations due to large scale biomass burning were observed in the upper troposphere (UT) at the equator and southern latitudes during the flights to Latin America and South Africa in boreal autumn (SON) and boreal winter (DJF). TM concentrations in the lowermost stratosphere (LMS) decrease with altitude above the thermal tropopause but the gradient is less steep than reported before. Seasonal variation of the vertical TM distribution in the UT and LMS is similar to that of other trace gases with surface sources and stratospheric sinks. Spe-

ciation experiments suggest comparable TM and gaseous elementary mercury (GEM) concentrations at and below the tropopause leaving little space for Hg²⁺ (TM – GEM) being the dominating component of TM here. In the stratosphere significant GEM concentrations were found to exist up to 4 km altitude above the thermal tropopause. Correlations with N₂O as a reference tracer suggest stratospheric lifetimes of 72 ± 37 and 74 ± 27 years for TM and GEM, respectively, comparable to the stratospheric lifetime of COS. This coincidence, combined with pieces of evidence from us and other researchers, corroborates the hypothesis that Hg²⁺ formed by oxidation in the stratosphere attaches to sulfate particles formed mainly by oxidation of COS and is removed with them from the stratosphere by air mass exchange, gravitational sedimentation and cloud scavenging processes.

1 Introduction

Mercury is an element whose high vapor pressure leads to significant emissions into the atmosphere. Measurements of atmospheric mercury show a relatively even distribution over the globe (Sprovieri et al., 2010) with background concentrations varying mostly between $1\text{--}2\text{ ng m}^{-3}$. After oxidation to less volatile and more soluble compounds, mercury is deposited and becomes bioavailable. Its conversion to the highly neurotoxic methyl mercury, which bioaccumulates in the aquatic nutritional chain to concentrations dangerous for humans and animals has motivated intensive research on the biogeochemical cycle of mercury (e.g., Mergler et al., 2007; Scheuhammer et al., 2007; Lindberg et al., 2007; AMAP/UNEP, 2018 and references therein).

Despite decades of research, the atmospheric mercury cycle is still not well understood (Lin et al., 2006; Lindberg et al., 2007; Ariya et al., 2015). Several mechanisms of elemental mercury oxidation in the gas phase have been proposed (Selin et al., 2007; Holmes et al., 2010; Dibble et al., 2012; Horowitz et al., 2017; Travníkov et al., 2017) but their relative importance is still unknown (Lin et al., 2006; Travníkov et al., 2017). Neither have the oxidation products been unequivocally identified so far because of the lack of speciation techniques for individual mercury compounds (Gustin et al., 2015; Ariya et al., 2015). In addition, attempts to constrain the atmospheric mercury cycle using different models had to rely almost exclusively on measurements at the surface in the Northern Hemisphere, which undermined these efforts. Measurements of mercury distribution in the troposphere and stratosphere by research aircraft are expensive and thus usually limited to short-term campaigns covering small regions of the globe (Ebinghaus and Slemr, 2000; Friedli et al., 2001, 2003a, 2004; Banic et al., 2003; Ebinghaus et al., 2007; Radke et al., 2007; Talbot et al., 2007, 2008; Swartzendruber et al., 2008; Slemr et al., 2009, 2014; Lyman and Jaffe, 2012; Brooks et al., 2014; Ambrose et al., 2015; Gratz et al., 2015; Shah et al., 2016; Weigelt et al., 2016a, b). These aircraft measurements have so far provided information about the emissions of mercury from biomass burning (Friedli et al., 2001, 2003a, b; Ebinghaus et al., 2007) and from industrial sources (Friedli et al., 2004; Talbot et al., 2008; Swartzendruber et al., 2008; Slemr et al., 2014; Ambrose et al., 2015; Weigelt et al., 2016b), with sometimes differing information about the vertical distribution of mercury (Ebinghaus and Slemr, 2000; Radke et al., 2007; Talbot et al., 2007, 2008; Slemr et al., 2009; Lyman and Jaffe, 2012; Brooks et al., 2014; Shah et al., 2016; Weigelt et al., 2016a; Bieser et al., 2017). In addition, a pronounced depletion of elemental mercury in air masses influenced by the stratosphere has been reported (Ebinghaus et al., 2007; Radke et al., 2007; Talbot et al., 2007, 2008; Swartzendruber et al., 2008; Slemr et al., 2009; Lyman and Jaffe, 2012). However, because of temporal and spatial limitations resulting from the costs of research aircraft, hardly any information on seasonal varia-

tion of mercury concentrations in the upper troposphere (UT) and lowermost stratosphere (LMS) has been obtained so far.

IAGOS-CARIBIC (In-service Aircraft for a Global Observing System - Civil Aircraft for Regular Investigation of the Atmosphere Based on an Instrumented Container) project offers a possibility of regular large scale sounding of trace constituent distributions in the UT/LMS using an instrumented container flown onboard a passenger aircraft during intercontinental flights (Brenninkmeijer et al., 2007; www.caribic-atmospheric.com, last access: 16 August 2018). From May 2005 until February 2016 mercury was measured with a modified Tekran instrument in combination with a large suite of other trace gases and particles onboard the CARIBIC aircraft (Brenninkmeijer et al., 2007; Slemr et al., 2009, 2014, 2016; GMOS, 2018). Mercury data collected during near monthly sequences of mostly four intercontinental flights from Germany to destinations in North and South America, Africa and East and South Asia represent the largest mercury data set obtained in the UT and LMS so far. Most mercury data were obtained using the Tekran internal default signal integration procedure but since April 2014 we manually integrated the Tekran raw signal. This post-flight integration of the raw signal substantially improved the detection limit and precision of the mercury measurements and removed negative bias of the default integration leading to the occasional occurrence of zero concentrations in the data before April 2014 (Slemr et al., 2016; Ambrose, 2017). Raw signal data are available only since April 2014 and older data cannot be reintegrated. We use the recent, smaller but higher quality dataset here, in an attempt to unravel the behavior of mercury in the UT/LMS.

2 Experimental

The CARIBIC container (Brenninkmeijer et al., 2007; www.caribic-atmospheric.com) onboard an Airbus 340-600 of Lufthansa holds automated analyzers for gaseous mercury, CO, O₃, NO, NO_y, CO₂, CH₄, acetone, acetonitrile, water vapor (total, gaseous, isotope composition) and fine aerosol particles (three counters for particles with lower threshold diameters of 4, 12 and 18 nm, upper cut off about 2.0 μm), as well as an optical particle size spectrometer (OPSS) for particles with diameters > 150 nm. In addition, whole air and aerosol particle samples are taken in flight and subsequently analyzed for greenhouse gases, halocarbons, hydrocarbons and particle elemental composition. The CARIBIC measurement container is usually deployed monthly during a sequence of four intercontinental flights.

The air inlet system and the mercury instrument are described in detail by Brenninkmeijer et al. (2007) and Slemr et al. (2016), respectively. Briefly, the trace gas inlet consists of a trace gas diffuser tube with a flow of more than 2000 volume-L min⁻¹ from which ~ 80 volume-L min⁻¹ is taken at a right angle to a manifold, which supplies the

trace gas analyzers in the container via a temperature controlled PFA lined supply tube. The high air velocity in the trace gas diffuser tube combined with perpendicular sampling at a much smaller velocity discriminates against particles larger than about $1\ \mu\text{m}$ in diameter ($\sim 50\%$ aspiration efficiency, Baron and Willeke, 2001). A modified Tekran instrument (Tekran-Analyzer Model 2537 A, Tekran Inc., Toronto, Canada) samples nominally $0.5\ \text{L (STP) min}^{-1}$ of air from the supply line manifold (heated to $40\ ^\circ\text{C}$) using the $4\ \text{mm ID}$ PFA tubing at about $30\ ^\circ\text{C}$. The major modifications of the instrument were the addition of a second pump supporting the internal Tekran pump and of a computer that communicates with the container's master computer and controls the automatic operation of the instrument. For the period August 2014 until February 2016 a quartz wool scrubber was installed in the instrument to filter out gaseous oxidized mercury (GOM).

To achieve an improved spatial resolution of $\sim 75\ \text{km}$, the instrument was run with a sampling time of only 5 min. Despite an additional pump the nominal flow of $0.5\ \text{L (STP) min}^{-1}$ could not be sustained at the highest flight levels. Limited air flow, the short sampling time and low concentrations resulted in only $\sim 2\ \text{pg}$ of mercury, which is much smaller than $10\ \text{pg}$ considered as minimum for bias-free internal default integration of the signal by the Tekran instrument (Swartzendruber et al., 2009; Slemr et al., 2016; Ambrose, 2017). For this reason, as previously mentioned, the raw analyzer signals were processed post-flight using a manual integration procedure described in detail by Slemr et al. (2016). The detection limit and precision with post-flight processing is estimated to be $\sim 0.05\ \text{ng m}^{-3}$. The instrument is calibrated after every second flight sequence through comparison measurements with a calibrated reference Tekran instrument in the laboratory. All mercury concentrations are reported in $\text{ng Hg m}^{-3}(\text{STP})$.

As discussed in detail by Slemr et al. (2016) we assume that our measurements encompass gaseous elemental mercury (GEM), gaseous oxidized mercury (GOM) and about 70% of particle bound mercury (PBM). Speciation experiments using soda lime (Ca(OH)_2 with NaOH) and KCl coated quartz sand as GOM scrubbers made during several flights demonstrated that GOM does pass through the CARIBIC air sampling system. According to the extrapolation of the reported GOM/PBM (GOM and PBM are both assumed to be Hg^{2+} , i.e., $\text{PBM} + \text{GOM} = \text{Hg}^{2+}$) partitioning equilibria (Rutter and Schauer, 2007; Amos et al., 2012) from ambient temperatures near ground to about $-50\ ^\circ\text{C}$ around the tropopause, most of Hg^{2+} will be attached to particles. Although the CARIBIC trace gas inlet is not optimized to collect particles (see above), we estimated that nevertheless particles with diameter of $<0.5\ \mu\text{m}$ will pass through it, representing $\sim 70\%$ of the aerosol mass. Despite of significant PBM concentrations in the stratosphere reported by Murphy et al. (1998, 2006), we were not able to detect mercury in the aerosol samples collected by the

CARIBIC impactor sampler that uses an inlet optimized for quantitative particle sampling (for a recent publication on aspects of the CARIBIC impactor please see Martinsson et al., 2015). Although not equipped with heaters, the air flow carrying the particles will warm up to $\sim 30\ ^\circ\text{C}$ on the way from the aerosol inlet to the impactor. In view of this, our inability to detect mercury in particle samples thus suggests that Hg^{2+} on particles evaporates when the sample air is heated to $\sim +30\ ^\circ\text{C}$ in the inlet tubing and forms GOM. In summary, we assume that our measurements are close to total mercury ($\text{TM} = \text{GEM} + \text{Hg}^{2+} = \text{GEM} + \text{GOM} + \text{PBM}$) concentration and we refer to them as such.

In order to get information about the GEM fraction, sample air was passed through a quartz wool scrubber for GOM during the outbound flights between August 2014 and February 2016. The method using quartz wool to capture GOM in order to measure GEM, called DOHGS (Detector for Oxidized Hg Species), is described by Lyman and Jaffe (2012) and Ambrose et al. (2013), and the measurements made by this technique have been reported by Lyman and Jaffe (2012), Ambrose et al. (2013, 2015), Gratz et al. (2015) and Shah et al. (2016). The DOHGS took part in the Reno Atmospheric Mercury Intercomparison eXperiment (RAMIX) whose results have been controversially discussed by Gustin et al. (2013), Ambrose et al. (2013) and Hynes et al. (2017). According to Gustin et al. (2013) and Ambrose et al. (2013) GOM measurements by the DOHGS technique agreed well with nylon and cation exchange filters while yielding substantially higher values than the Tekran speciation system. Hynes et al. (2017), on the other hand, found a good agreement of GOM concentrations measured by two-photon laser-induced fluorescence (2P-LIF) with and without a pyrolyzer (the 2P-LIF technique can measure GEM directly without using any filter) and by the Tekran speciation system. According to their interpretation DOHGS overestimated GOM concentrations (underestimated GEM). In summary, the results of RAMIX were inconclusive. As described in supplementary information (SI) our GEM data obtained by using quartz wool traps may have been biased both by the method itself and by the way we used them. The data we obtained using the quartz wool scrubber and presented here as GEM can thus be interpreted only in qualitative terms. We also note that the tracks and altitudes of the outbound and return flights differ sometimes substantially, especially in the case of the flights to North America (the flight tracks from Germany to North America tend to be substantially further north than those of the return flights). This means that the TM and GEM data are not directly comparable even if they were measured on the same day. For half of the (outbound) flights during which the quartz wool scrubber was deployed, GEM concentrations at the beginning of the flight were significantly higher than those of TM during the entire return flight and the differences decreased during the flight indicating contamination that disappeared during the 8–10 h flight. We found that the contamination had started to occur

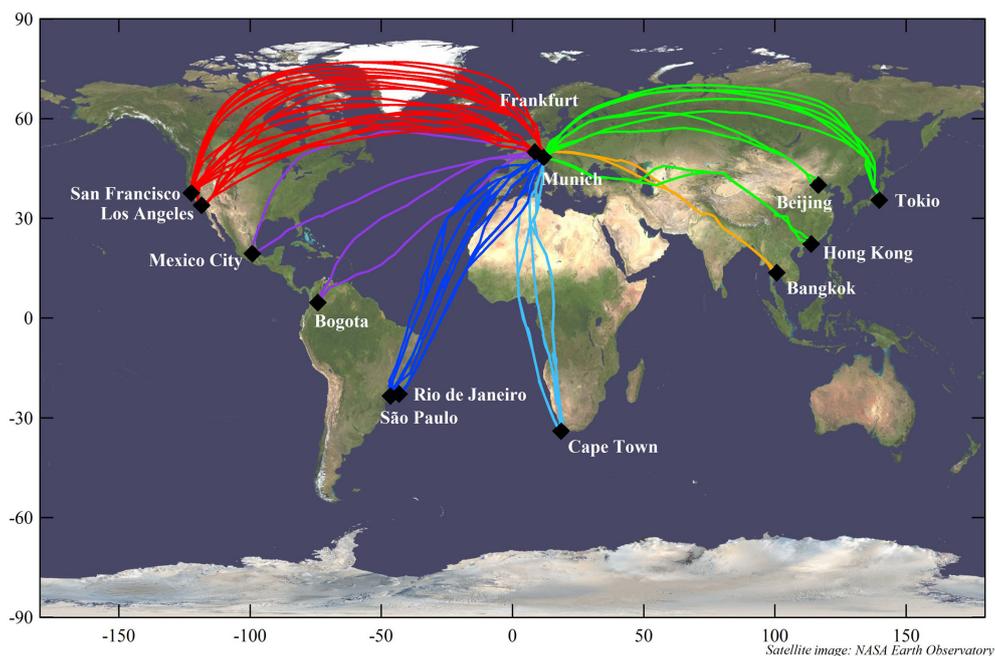

Figure 1. Tracks of the CARIBIC flights made between April 2014 and February 2016 (CARIBIC flights no. 468–536). Mercury data for these flights were obtained by post-flight processing of the Tekran raw signal (Slemr et al., 2016).

after a change of the personnel preparing the instrument and we thus attribute the contamination effect it to this change. These data (half of the outward bound flight results) were eliminated from the data set.

The data we report here were obtained during flights between April 2014 and February 2016 whose tracks are shown in Fig. 1. All but one monthly flight sequences consisted of four individual intercontinental flights. The altitude of these flights varies typically from ~ 9 km at the beginning of the flight to 11–12 km at the end before the final descent. In addition to the meteorological data provided by the aircraft, meteorological parameters along the flight track were calculated from the ECMWF (European Centre for Medium Range Weather Forecasts) data (6-hourly, 60 model levels until February 2006 and 90 model levels thereafter, $1^\circ \times 1^\circ$ horizontal resolution). Eight days backward, 3-D kinematic trajectories were calculated with the KNMI model TRAJKS (Scheele et al., 1996, http://projects.knmi.nl/campaign_support/CARIBIC/, last access: 16 August 2018) at one-minute intervals along the flight path. Consequently, five trajectories were available for each mercury measurement. The data set consists of 33 and 17 individual flights with valid TM and GEM data, respectively.

For the data evaluation, the relevant concomitant meteorological and trace gas data were averaged over the sampling intervals of mercury measurements.

3 Results and discussion

3.1 Latitudinal TM distribution in the upper troposphere

Figure 2 shows latitudinal distribution of TM in the upper troposphere: defined as TM concentrations at potential vorticity (PV) of $-1.5 \leq PV \leq 1.5$ PVU ($1 \text{ PVU} = 10^{-6} \text{ K m}^2 \text{ kg}^{-1} \text{ s}^{-1}$) observed during the flights to South America (Bogota, São Paulo and Rio de Janeiro) in boreal summer (only July and August), fall (September, October, November) and winter (December, January, February). Corresponding latitudinal distributions of acetonitrile (AN, originating almost solely from biomass burning) and of CO and CH₄ with large emissions from biomass burning (Andreae and Merlet, 2001) are also shown. The lowest TM concentrations are observed in the latitude bands of 10–20 and 20–30° S in summer (JA) and the same applies for CO, CH₄ and acetonitrile. The highest TM concentrations in 20–30° S latitude band are observed in fall (SON) and the TM concentrations decrease in winter (DJF) as do the CO and acetonitrile mixing ratios in the 10–20° S latitude band. The highest CO and CH₄ mixing ratios at 20–30° S are observed in winter with mixing ratios in fall somewhat lower. Biomass burning in South America starts in June, peaks in September and ends in December (Duncan et al., 2003). TM concentrations in the southernmost latitude bands follow this seasonal variability as do the acetonitrile, CO and CH₄ mixing ratios at 10–20° S latitude. In the latitude band 20–30° S the CO and CH₄ mixing ratios are higher in boreal

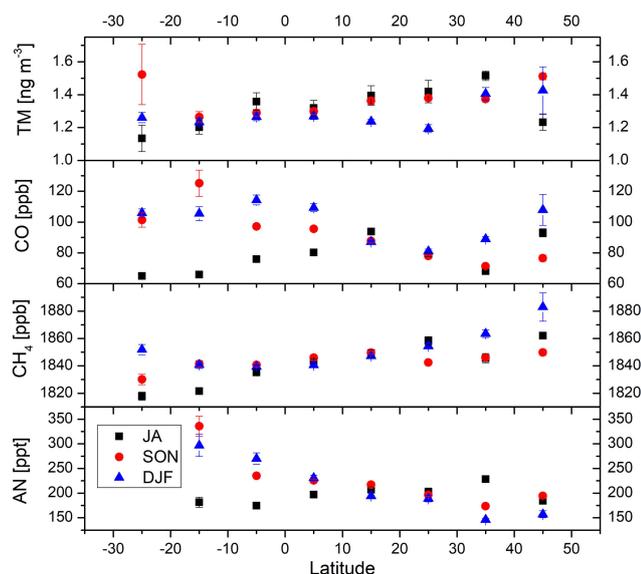

Figure 2. Latitudinal distributions of tropospheric ($PV \leq 1.5$ PVU) TM, CO, CH_4 and acetonitrile (AN) during the flights from Bogotá and São Paulo and Rio de Janeiro to Munich in summer (only July and August, JA), autumn (September, October and November, SON) and winter (December, January and February, DJF). The points represent averages and the vertical bars their standard error. No acetonitrile data were available south of 20° S.

winter than in fall. This might result from larger additional CO and CH_4 sources in boreal winter such as from oxidation of volatile organic compounds and wetlands. It is also worth noting that in boreal fall and winter the acetonitrile and CO mixing ratios in the monitored part of the Southern Hemisphere are higher than in the Northern Hemisphere. In summary, Fig. 2 illustrates the large-scale influence of biomass burning on the latitudinal TM distribution in the upper troposphere of the Southern Hemisphere.

The role of biomass burning is further illustrated by means of Fig. 3, comparing the South America boreal winter profiles of the four trace constituents with those for South Africa (Cape Town). Acetonitrile and CO mixing ratios from flights to South Africa show a pronounced bulge between 30° S and 20° N peaking around the equator. The same applies to results for the flights to South America, be it with somewhat lower values and more southern maximum for acetonitrile. For both flight routes CO and acetonitrile mixing ratios are higher in the southern than in the Northern Hemisphere. Boreal winter (DJF) is an intermediate season between biomass emissions peaking in September in southern Africa and in January in northern Africa (Duncan et al., 2003). The latitudinal pattern of CH_4 is less clear, with wetlands also being a major source. Finally, Fig. 3 shows a similarity between TM and the biomass burning indicators in the tropics at flight altitude.

Biomass burning plumes with enhanced mercury concentrations have been reported before (Brunke et al., 2001;

Friedli et al., 2001, 2003a, b; Ebinghaus et al., 2007; Slemr et al., 2014; among others). Emitting 675 Mg yr^{-1} of mercury, biomass burning is estimated to be the third largest source after emissions from oceans (2682 Mg yr^{-1}) and from fossil-fuel power plants (810 Mg yr^{-1} ; Friedli et al., 2009; Pirrone et al., 2010). Figures 2 and 3 illustrate the influence of biomass burning on the large-scale distribution of TM in the Southern Hemispheric UT.

Acetonitrile mixing ratios in winter (DJF) shown in Fig. 3 are the lowest in the northernmost latitude bands 20 – 50° N. The concomitant elevated TM concentrations and CO and CH_4 mixing ratios are thus mostly due to anthropogenic emissions. An exception is the highest TM concentration observed at 30 – 40° N (Fig. 2) in summer (JA), which coincides with the peak of acetonitrile mixing ratio in the Northern Hemisphere. The respective data originate from the flight no. 475 from São Paulo to Munich on 21 August 2014. Two whole air samples were taken within this latitude band of which sample no. 12 coincides with the peak acetonitrile, acetone, CO and CH_4 mixing ratios. In addition, sample no. 12 contains high ethane and propane mixing ratios (786 and 126 ppt, respectively) as well as somewhat elevated CH_4 and SF_6 mixing ratios. Sample no. 12 was taken over southwestern Spain and its 8 days backward trajectory crosses the Atlantic Ocean, eastern US, Great Lakes up to the Californian Pacific coast. The complex composition of this sample indicates a mixture of anthropogenic pollution with emissions from biomass burning. The latter is additionally supported by fire maps (<https://lance.modaps.eosdis.nasa.gov/imagery/firemaps>, last access: 16 August 2018) reporting individual fire counts along the trajectory in North America and especially a large fire in northern California at the time of trajectory crossing.

3.2 Seasonal variation of the vertical TM distribution in the upper troposphere and lowermost stratosphere

Due to the geographical location of the airport of departure and the CARIBIC destinations it happens to be that about half of the intersected air masses were situated above the tropopause. This allows a fairly representative mapping of measured trace species around the tropopause (see for instance Zahn et al., 2014). Figure 4 shows the seasonal pattern of the average TM concentrations and CO, CH_4 and O_3 mixing ratios relative to the thermal tropopause. The distance relative to the tropopause is based on CARIBIC ozone measurements. Basically, an ozone mixing ratio measured by CARIBIC is compared to representative data from ozone soundings. As these soundings measure both thermal tropopause height and ozone, the distance relative to the tropopause is obtained (Sprung and Zahn, 2010). This value based on the CARIBIC ozone data is considered to be more accurate than PV (calculated from the ECMWF-model) based dynamical tropopause, especially in subtrop-

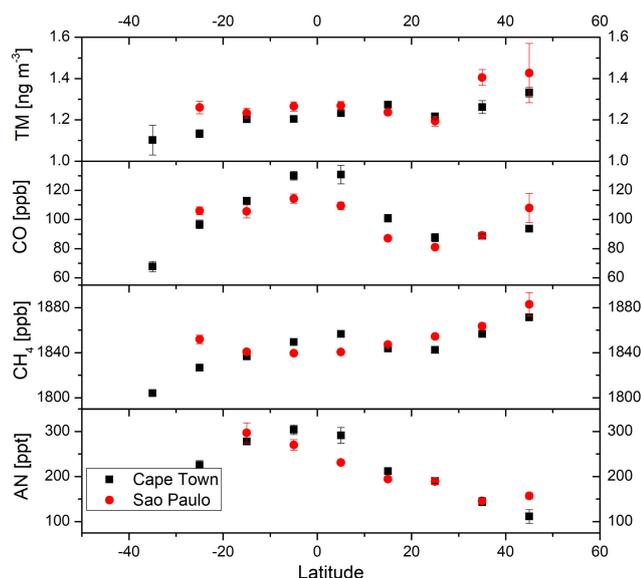

Figure 3. Latitudinal distributions of tropospheric TM, CO, CH₄ and acetonitrile (AN) in winter (December, January and February, DJF) during the flights from Cape Town and São Paulo to Munich. The points represent averages and the vertical bars their standard error. No acetonitrile data are available south of 30 and 20° S for flights to Cape Town and São Paulo, respectively.

ical latitudes where the dynamical tropopause is not well defined by a constant PV threshold value (Kunz et al., 2011). Only measurements north of 20° N were considered for making this plot. The seasonal variation of the vertical distributions of the trace gases and TM reflect their source location and the Brewer-Dobson circulation with a maximum content of stratospheric air in the UT/LMS in spring (Holton et al., 1995; Gettelman et al., 2011). Ozone rich air, depleted in CO, CH₄ and N₂O descends in spring and here the question is what happens to the mercury compounds.

The highest TM concentrations of 1.4–1.7 ng m⁻³ are encountered at 0.5–1.75 km below the thermal tropopause in September/October. Two thirds of these elevated TM data originate from flights from Tokyo to Munich on 30 October 2014, and Beijing to Munich on 31 October 2014, and were observed mostly within ~ 1500 km of Tokyo and Beijing. High TM concentrations are accompanied by elevated CO and CH₄ mixing ratios. Near Tokyo and Beijing elevated SF₆ mixing ratios were also observed. Backward trajectories from these flight segments on 30 and 31 October point to surface contact in Tibet, Bangladesh and northern India. Slightly elevated TM concentrations encountered near Munich on 30 and 31 October are most likely due to emissions located in North America.

The lowest TM concentrations of 0.4–0.6 ng m⁻³ were encountered during the flights Tokyo to Munich (flight no. 502) on 21 April 2015, and Mexico to Munich (flight no. 504) on 22 April 2015. During both flights the lowest TM con-

centrations were accompanied by O₃ and H₂O mixing ratios of >400 ppb and <10 ppm, respectively, characteristic of deeper stratospheric air. No CO data are available for CARIBIC flight no. 502 but CO mixing ratios of <30 ppb for the lowest TM values during the CARIBIC flight no. 504 also point to a relatively deep stratospheric origin of the air, conform extremely low SF₆ and CH₄ mixing ratios in both flights.

3.3 Speciation in the UT and LMS

The reason to show only TM in Fig. 4, without GEM, is that (as mentioned before) about half of the GEM data was lost due to contamination problems attributed to a change of personnel preparing the instrument since October 2015. For analyzing the GEM results, we divide the data set into boreal winter (December–May) and boreal summer (June–November). The upper panel of Fig. 5 shows the vertical distributions of TM and GEM in three different latitude bands for boreal winter, the lower panel shows the vertical distribution of CO measured concurrently with TM or GEM. Likewise, the upper and lower panels of Fig. 6 display the TM, GEM and CO vertical distributions in summer.

In Sect. 3.1 we have shown a close relation between mercury and CO, the latter as a tracer for biomass burning and anthropogenic pollution. Below we use this close relation as a qualitative indicator for comparability of TM and GEM measurements during different flights. Without oxidation of GEM to GOM we expect comparable TM and GEM concentrations when CO(TM) and CO(GEM) are comparable. The data points in Figs. 5 and 6 represent concentration averages and their standard errors. Although extreme individual values were eliminated using the Nalimov outlier test (Kaiser and Gottschalk, 1972), unedited data yield similar plots. We also note that TM and GEM data from all flights were used in these figures, altogether 1528 and 1349 TM measurements in winter and summer, respectively, as well 699 and 916 GEM measurements in winter and summer, respectively.

Winter vertical distribution of CO mixing ratios in Fig. 5 shows, for latitudes 30–60 and >60° N, a steep decrease above the thermal tropopause and essentially identical CO mixing ratios for measurements accompanying TM and GEM measurements in the stratosphere. Stratospheric TM concentrations at 30–60° N latitude shown in Fig. 5 are always substantially higher than those of GEM, and at >60° N latitude mostly so, indicating the presence of larger Hg²⁺ concentrations in the stratosphere. The tropospheric GEM concentrations at 30–60° N latitude tend to be higher than those of TM as do CO(GEM) mixing ratios when compared with those of CO(TM). We thus surmise that the tropospheric differences are mostly due to different degree of pollution in air masses encountered during the forward and return flights. At >60° N latitude there are no tropospheric TM and CO(TM) measurements for comparison with GEM and CO(GEM) because the low altitude of the thermal tropopause

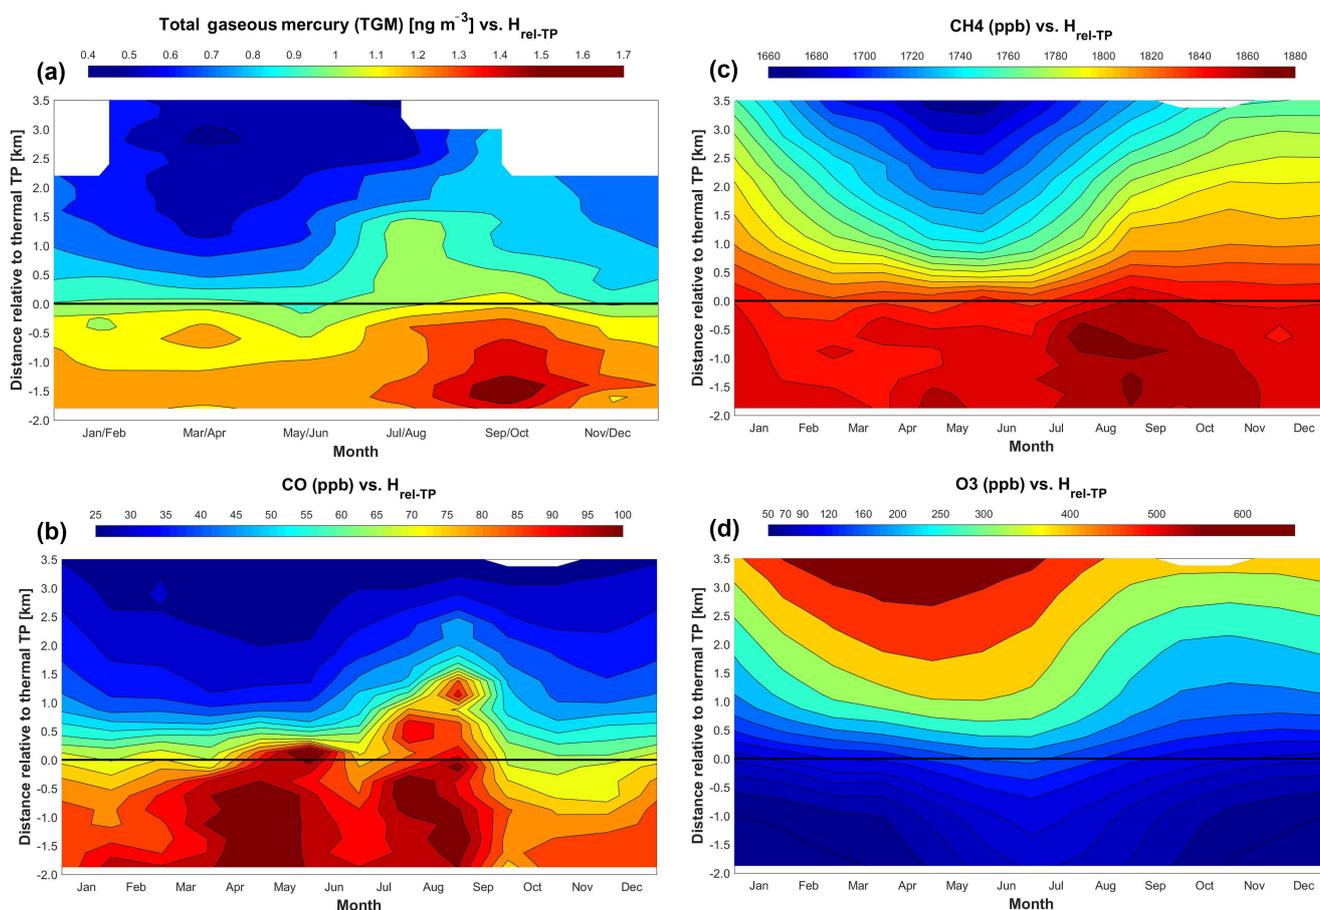

Figure 4. Seasonal variation of mean TM concentrations (a), CO (b), CH₄ (c) and O₃ (d) mixing ratios in distance relative to the thermal tropopause derived from ozone soundings according to Sprung and Zahn (2010). All TM data north of 20° N obtained between April 2014 and February 2016 were considered for this plot (2288 individual data points).

is mostly below the cruise altitude. Conversely, at 30° S–30° N the aircraft generally does not reach the stratosphere. At these latitudes tropospheric TM and GEM concentrations are comparable while CO mixing ratios vary strongly with CO(GEM) mixing ratios, tending to smaller values than those of CO(TM). The interpretation of these data is difficult because of the large influence of biomass burning in some flights (see Sect. 3.1) and possibly because of inter-hemispheric mixing. Comparable TM and GEM concentrations at mostly smaller CO(GEM) than CO(TM) might indicate substantial Hg²⁺ contribution to TM.

In agreement with Fig. 4, TM, GEM and CO (Fig. 6) show less steep gradients at the tropopause in summer. At 30–60° N latitude the stratospheric TM and GEM concentrations follow roughly the mixing ratios of CO(TM) and CO(GEM) suggesting that the TM-GEM difference results more from the degree of pollution than from the Hg²⁺ content. At >60° N latitude in the stratosphere CO(TM) and CO(GEM) mixing ratios are comparable while GEM concentrations tend to be substantially smaller than those of TM, which suggests the presence of substantial Hg²⁺ concentra-

tions. The tropospheric GEM concentrations at latitudes 30–60 and >60° N tend to be higher than those of TM while CO(TM) and CO(GEM) mixing ratios are roughly comparable. In this case, CO as an indicator of air mass pollution does not work and we attribute the difference to difference in air masses. As in winter, roughly comparable TM and GEM concentrations at substantially larger CO(TM) than CO(GEM) mixing ratios at latitudes 30° S–30° N might indicate some Hg²⁺ presence.

In summary, Figs. 5 and 6 show roughly comparable tropospheric GEM and TM concentrations both in winter and in summer at latitudes >30° N. Comparable GEM and TM concentrations leave little scope for Hg²⁺ being the dominant mercury species in the upper troposphere at these latitudes. At 30° S–30° N tropospheric TM and GEM concentrations are roughly comparable in winter and in summer while CO(TM) tend to be substantially larger than CO(GEM) possibly suggesting the presence of substantial Hg²⁺ concentrations. The stratospheric GEM concentrations tend to be smaller than those of TM in winter at latitudes >30° N and in summer at >60° N implying substantial and possibly domi-

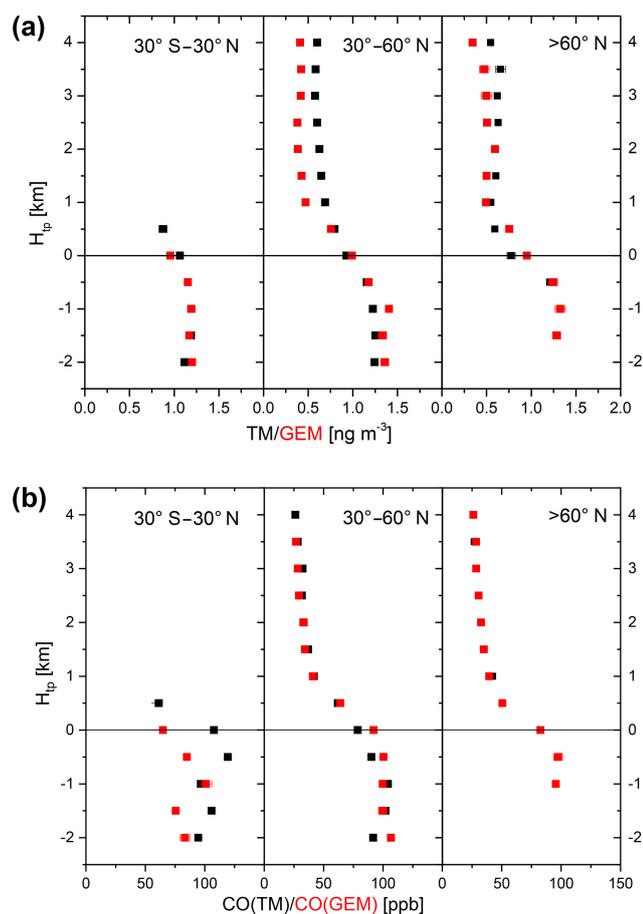

Figure 5. Vertical TM and GEM distribution relative to the thermal tropopause in winter (December–May, **a**). Panel (**b**) shows the vertical distribution of CO measured during the TM and GEM measurements. The data points represent averages and their standard errors, extreme values were eliminated using the Nalimov outlier test (Kaiser and Gottschalk, 1972).

nant Hg^{2+} concentrations. However, not a single GEM measurement out of 1615 was below the detection limit revealing the existence of significant stratospheric GEM concentrations up to 4 km above the thermal tropopause.

Our notion about the behavior and speciation of mercury in the UT/LMS is quite limited and based on a few measurement reports made by either a Tekran speciation system or by DOHGS. Swartzendruber et al. (2006), using a Tekran speciation system, observed at Mount Bachelor higher GOM concentration in downslope air flow than in upslope flow, which implies higher GOM concentrations in the free troposphere than in the planetary boundary layer. Talbot et al. (2007) reported a total depletion of GEM in the UT/LMS. By extrapolation of measurements made by DOHGS in stratospheric intrusions, Lyman and Jaffe (2012) derived an empirical model that predicts a total depletion of GEM at ~ 1 km above the tropopause and of total mercury (including particle bound mercury, PBM) at ~ 2 km above the tropopause.

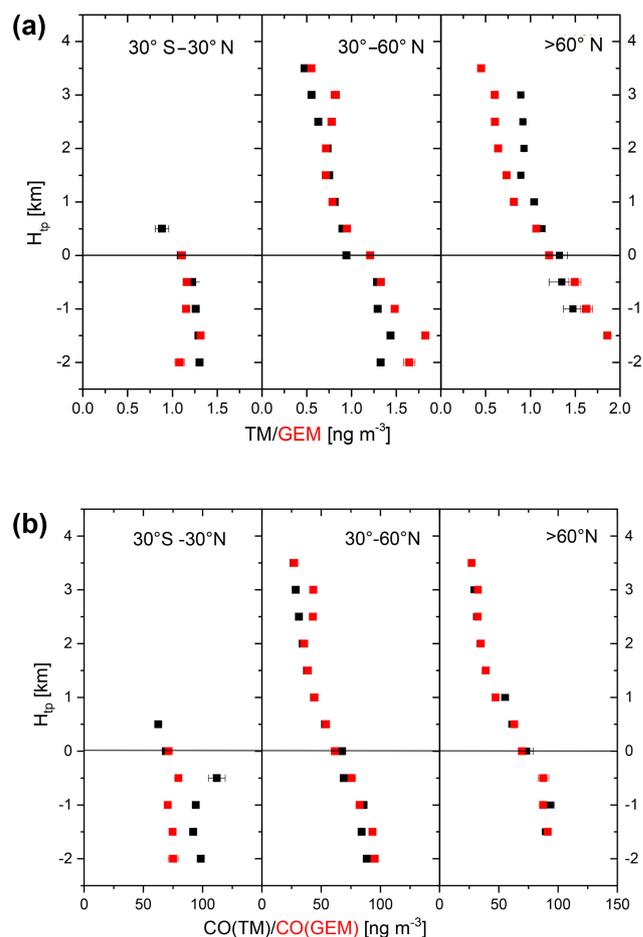

Figure 6. Vertical TM and GEM distribution relative to the thermal tropopause in summer (June–November, **a**). Panel (**b**) shows the vertical distribution of CO measured during the TM and GEM measurements. The data points represent averages and their standard errors, extreme TM and GEM values were eliminated using the Nalimov outlier test (Kaiser and Gottschalk, 1972).

Brooks et al. (2014), using a Tekran speciation system, reported decreasing GOM concentrations above GOM maxima at ~ 4 km altitude above ground. They also found that GEM concentrations are independent of altitude between ground and 6 km altitude for most of the year. Only in April, May and June GEM concentrations decreased with increasing altitude, possibly because of the intensive influx of stratospheric air in this season. Gratz et al. (2015), using DOHGS measurements during the NOMADSS (Nitrogen, Oxidants, Mercury and Aerosol Distributions, Sources and Sinks), observed in June 2013 high GOM concentrations in a tropospheric air mass rich in BrO advected from the subtropical Pacific. Shah et al. (2016), finally, summarized the NOMADSS measurements made by DOHGS in vertical distributions of GOM and TM showing an increase of GOM concentrations from $\sim 0.03 \text{ ng m}^{-3}$ near ground to $\sim 0.2 \text{ ng m}^{-3}$ at an altitude of 7 km. As TM decreased from $\sim 1.6 \text{ ng m}^{-3}$ near ground

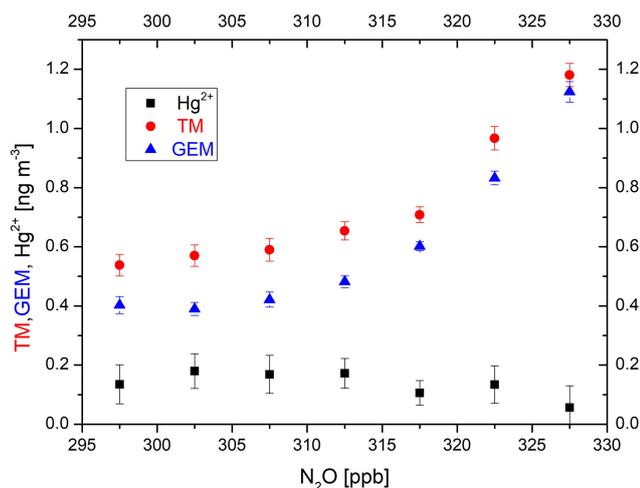

Figure 7. Stratospheric average TM and GEM concentrations in boreal winter (November–April) are binned according to the N₂O mixing ratio. N₂O mixing ratios were detrended using 2015 as a reference year and the N₂O growth rate of 0.844 ppb yr⁻¹ (Assonov et al., 2013). Vertical and horizontal bars represent the standard errors of the averages.

to 1.25 ng m⁻³ at 7 km altitude, Hg²⁺ concentrations represented less than 20 % of TM at 7 km altitude.

Opposite to the total GEM depletion reported by Talbot et al. (2007) our post-flight processed GEM and TM concentrations were never below the detection limit of ~ 0.05 ng m⁻³, even at 4 km altitude above the tropopause. However, when using the default Tekran software, small mercury peaks are occasionally not integrated resulting in erroneous zero concentrations. We thus surmise that the zero GEM concentrations reported by Talbot et al. (2007) were not real but an artifact due to incorrect default integration of the Tekran raw signal (Swartzendruber et al., 2009; Slemr et al., 2016; Ambrose, 2017). We also note that Talbot et al. (2007) reckon their measurements to represent GEM although their inlet system is very similar to that of CARIBIC (Slemr et al., 2014) with proven transmission of GOM. As for CARIBIC, the measurements by Talbot et al. (2007) are thus more likely close to those of TM.

For the UT Lyman and Jaffe (2012) report Hg²⁺ (GOM + PBM = TM – GEM) concentrations varying between zero and ~ 0.25 ng m⁻³ at TM concentration of ~ 1 ng m⁻³. Shah et al. (2016) find in June and July 2013 average Hg²⁺ concentration of ~ 0.2 ng m⁻³ at an altitude of 7 km over USA at TM concentrations of ~ 1.25 ng m⁻³, i.e., representing less than 20 % of TM. Taking into account that we compare TM and GEM measurements from different flights (unlike DOHGS, which measures TM and GEM simultaneously) these findings are roughly consistent with ours.

As pointed out by Lyman and Jaffe (2012), zero TM concentrations at ~ 2 km above the tropopause from their em-

pirical model are not conform to the observations of significant PBM concentrations in the stratosphere up to 8 km above the tropopause by Murphy et al. (1998, 2006). Gaseous Hg²⁺ (GOM) is assumed to be in equilibrium with PBM. An extrapolation of the equilibria observed at ambient air temperatures near ground (Rutter and Schauer, 2007; Amos et al., 2012) to some -50 °C around the tropopause indicates that almost all Hg²⁺ will be attached to particles. Substantial PBM concentrations observed by Murphy et al. (1998, 2006) up to 8 km above the tropopause together with our TM data obtained during some 400 CARIBIC flights made between 2005 and 2016 (including those with default Tekran raw signal integration) thus exclude the possibility that TM disappears at ~ 2 km above the tropopause. We also note that Murphy et al. (1998, 2006) could not detect any PBM in the troposphere at and below 5 km above ground. Non-detectable PBM in equilibrium with GOM at the still low air temperatures at these altitudes is another piece of evidence inconsistent with generally high Hg²⁺ concentrations in the UT.

In summary, it is plausible that our TM data currently provide the most representative picture of its UT/LMS distribution and seasonal variation. Our GEM measurements rely on the questionable performance of the GOM quartz wool traps and the difference between TM and GEM is statistically compromised by not being measured along exactly the same routes and altitudes above the tropopause. Despite this, our TM and GEM observations suggest that Hg²⁺ is not the dominating component of TM in the UT. Our observation of larger contributions of Hg²⁺ to TM in the stratosphere are consistent with the observations of substantial PBM concentrations in UT/LS by Murphy et al. (1998, 2006). As GEM measurements made by us were always above the detection limit, we surmise also the existence of significant GEM concentrations in the stratosphere up to 4 km above the tropopause.

3.4 Stratospheric lifetime of TM and GEM

Stratospheric lifetime of a trace gas is defined as atmospheric burden of a compound divided by its stratospheric sink (SPARC Report, Ko et al., 2013). To determine it for TM and GEM we use here the relative approach (described by Volk et al. (1997) utilizing the CARIBIC N₂O measurements (Assonov et al., 2013) as reference tracer. N₂O, with a lifetime of ~ 120 years is nearly uniformly distributed in the troposphere, with little seasonal variation and is removed in the stratosphere (Nevison et al., 2011). In comparison with SF₆ as chronological tracer, N₂O has the advantage of a much smaller latitudinal gradient in the troposphere and of nearly constant growth rate in the last two decades. Figure 6 shows winter (November–April) average stratospheric TM and GEM concentrations as a function of N₂O mixing ratios. In this plot N₂O mixing ratios were detrended using 2015 as a reference year and the N₂O growth rate of 0.844 ppb yr⁻¹ (Assonov et al., 2013).

TM and GEM concentrations in Fig. 6 start at 1.18 ± 0.27 ($n = 48$) and 1.12 ± 0.21 ($n = 35$) ng m^{-3} , respectively, in the 325–330 ppb bin of N_2O mixing ratios and they drop to 0.59 ± 0.13 ($n = 12$) and 0.42 ± 0.10 ($n = 16$) ng m^{-3} , respectively, in the 305–310 ppb bin. The difference between TM and GEM concentrations is not statistically significant in the 325–330 ppb bin of N_2O mixing ratios, i.e., in the UT as already discussed in Sect. 3.3. However, at lower N_2O mixing ratios, GEM concentrations are systematically smaller than those of TM at the 99 % significance level. The TM–GEM difference (i.e., Hg^{2+} concentration in the gas phase, GOM, and on particles, PBM) is increasing with decreasing N_2O mixing ratios and levels off at $\sim 0.17 \text{ ng m}^{-3}$ at N_2O mixing ratios below 315 ppb representing $\sim 30\%$ of TM concentrations. As mentioned in the experimental section, the CARIBIC trace gas inlet is not designed for collection of particles and, consequently, we presume to measure only Hg^{2+} on 70 % of particles. If all Hg^{2+} (i.e., TM–GEM) were on particles as predicted by extrapolation of Hg^{2+} gas-particle partitioning equilibrium (Rutter and Schauer, 2007; Amos et al., 2012) from ambient temperature to temperatures at the tropopause then the unbiased Hg^{2+} and TM concentrations would be ~ 0.24 and $\sim 0.66 \text{ ng m}^{-3}$, respectively, at N_2O mixing ratios below 310 ppb.

The small decrease of TM and GEM occurring below 315 ppb N_2O points to a long stratospheric lifetime of both TM and GEM. Correlations of all TM and GEM concentrations at N_2O mixing ratios < 315 ppb vs. N_2O yield slopes of $6.30 \pm 2.96 \text{ pg m}^{-3} \text{ ppb}^{-1}$ ($n = 46$, $R = 0.2947$, significance $> 95\%$) and $6.13 \pm 1.82 \text{ pg m}^{-3} \text{ ppb}^{-1}$ ($n = 63$, $R = 0.3909$, significance $> 99\%$), for TM and GEM, respectively. Using a stratospheric N_2O lifetime of 122 ± 24 years (Volk et al., 1997) we arrive at stratospheric TM and GEM lifetimes of 72 ± 37 and 74 ± 27 years, respectively. The uncertainties calculated from the slope uncertainties and the uncertainty of N_2O lifetime are probably lower limits because of the narrow range of encountered N_2O mixing ratios at cruise altitudes of the CARIBIC aircraft (Assonov et al., 2013). We note that our stratospheric TM and GEM lifetimes are not “relatively short” as claimed by Lyman and Jaffe (2012). We think that their TM and GEM concentrations were measured within the region of mixing of stratospheric with tropospheric air. Figure 6 shows that TM and GEM vs. N_2O correlations would result in much shorter lifetimes when data at N_2O mixing ratios larger than 315 ppb were included. With the calculated uncertainties the stratospheric TM lifetime cannot be distinguished from that of GEM. A more precise estimate of TM and GEM stratospheric lifetimes will require measurements with research aircraft capable of flying at higher altitudes.

Data in Fig. 6 allow us to correlate Hg^{2+} (TM – GEM) with GEM as done by Lyman and Jaffe (2012). Hg^{2+} is negatively correlated with GEM with a slope of -0.13 ± 0.04 ($n = 7$, $R^2 = 0.712$) and -0.31 ± 0.04 ($n = 7$, $R^2 = 0.919$) when averages and medians are used, respectively. Chemical conversion of GEM into Hg^{2+} without any Hg^{2+} losses would

yield a slope of -1 and slopes near this value were reported for the free troposphere by Swartzendruber et al. (2006) and for the UT by Lyman and Jaffe (2012). Our slopes in the stratosphere are substantially greater than -1 and somewhat greater than -0.53 reported by Lyman and Jaffe (2012) for stratosphere-influenced air masses. Slopes greater than -1 imply losses of Hg^{2+} (Hg^{2+} yield of GEM oxidation is smaller than the stoichiometry of the reaction) and result in decreasing TM concentrations with increasing Hg^{2+} concentrations in the stratosphere.

A reduction of TM concentration from $\sim 1.2 \text{ ng m}^{-3}$ in tropospheric air to $\sim 0.66 \text{ ng m}^{-3}$ in stratospheric air is too large to be explained by the aerosol bias induced by the incomplete particle sampling mentioned above and requires the presence of an Hg^{2+} removal process. As already proposed by Lyman and Jaffe (2012) such a removal process requires the oxidation of GEM into Hg^{2+} , followed by attachment of Hg^{2+} to stratospheric (mainly sulfate) particles, and their removal by gravitational sedimentation and/or scavenging by clouds (Menzies and Tratt, 1995; Rasch et al., 2008; Wilson et al., 2008). We note that air mass exchange is also taking an important part in removing sulfate particles from the stratosphere but TM concentrations would not change without sedimentation and/or scavenging of Hg^{2+} on particles. The oxidation and subsequent attachment to particles could be a local process in the vicinity of extratropical tropopause layer (exTL) or a non-local process in the tropical upper troposphere (TTL) and during the transport from the TTL to the location of the IAGOS-CARIBIC measurements in the LMS.

If all stratospheric TM were Hg^{2+} and become attached to particles, then the stratospheric lifetime of TM would be given by the stratospheric lifetime of particles of several years (Waugh and Hall, 2002; Friberg et al., 2018). Substantially longer TM and GEM stratospheric lifetimes of ~ 70 years suggest that the stratospheric GEM is oxidized higher up in the stratosphere (Ko et al., 2013). Our TM and GEM stratospheric lifetimes are comparable to COS lifetime of 64 ± 21 years (Barkley et al., 2008) whose oxidation by photolysis and the reaction with $\text{O}(^3\text{P})$ in the stratosphere is a major source of stratospheric sulfate aerosol and is located predominantly in tropics at an altitude of ~ 30 km (Brühl et al., 2012). Long stratospheric lifetimes are governed by the rate of delivery of a substance to its loss region (Ko et al., 2013). Comparable stratospheric lifetimes of TM, GEM and COS thus suggest a similar location of their stratospheric loss regions. At ~ 30 km altitude GEM could be oxidized by Br atoms released by the photolysis of halons and/or by reactions with O atoms (Ko et al., 2013). Collocation of stratospheric loss regions of COS and GEM supports the hypothesis of close relation of stratospheric mercury to stratospheric sulfur (COS + sulfate particles) described by Wilson et al. (2008).

4 Conclusions and outlook

The obvious implication of the long stratospheric TM and GEM lifetimes is that most atmospheric mercury is oxidized in the troposphere. The second direct implication is that if the lifetime of GEM in the stratosphere with its very high O₃ mixing ratios (1 ppm and more) is quite long, then the GEM + O₃ reaction is unlikely to be important in the troposphere with its low O₃ abundance. This implies that either the reaction does not take place or that its primary reaction product is instable. Moreover, with very low stratospheric H₂O mixing ratios below 10 ppm, OH is also an unlikely oxidant for GEM in the stratosphere. The most plausible remaining stratospheric oxidants are Br atoms originating from the decomposition of halons and some halocarbons with a possible contribution of O atoms.

The regular intercontinental IAGOS-CARIBIC flights provide an insight into the large-scale distribution of TM and GEM in the UT/LMS and its seasonal variation. Post-flights processed data with better accuracy and higher precision reveal a seasonal variation of vertical TM distribution in the UT/LMS, which is similar to most of the trace gases with sources in the troposphere, such as CH₄ and CO. Importantly, even at altitudes of up to 4 km above the thermal tropopause TM concentrations are still $\sim 0.5 \text{ ng m}^{-3}$, 1 order of magnitude above the instrumental detection limit. We have never observed zero TM or GEM concentrations and attribute earlier reports about them to an insufficiency in the default signal integration of the Tekran instrument.

Latitudinal TM distribution in the UT during the flights to South America and South Africa were found to be strongly influenced by biomass burning. Although TM and GEM were not measured at the same place and at the same time, the data collectively show that their concentrations in the UT are similar and Hg²⁺ is not a dominating component of TM. Larger Hg²⁺ (TM – GEM) concentrations were observed only in the LMS.

Lower TM concentrations were generally observed in LMS with the pronounced gradient just around the tropopause. We attribute this gradient to mixing of tropospheric air with stratospheric air depleted of mercury. The conservative character of TM measurements implicates thus a loss process by oxidation to Hg²⁺, its attachment to particles and their subsequent removal by gravitational sedimentation and/or scavenging by clouds. Substantial stratospheric PBM concentrations reported by Murphy et al. (1998, 2006) and GOM/PBM equilibria (Rutter and Schauer, 2007; Amos et al., 2012) extrapolated to temperatures in the LMS support this hypothesis.

Correlations of TM and GEM with N₂O as a reference substance show statistically the same TM and GEM concentrations in the UT. In the N₂O range of 330 and 315 ppb TM and GEM concentrations rapidly decrease with decreasing N₂O mixing ratios due to mixing of tropospheric air with stratospheric air depleted of mercury. Below 315 ppb

until 295 ppb of N₂O, TM and GEM concentrations hardly change. TM and GEM lifetimes of 72 ± 37 and 74 ± 27 years, respectively, were calculated from correlations of TM and GEM vs. N₂O below 315 ppb, albeit with large uncertainties caused by our limited altitude range and the resulting narrow range of N₂O mixing ratios between 315 and 295 ppb. Measurements of TM, GEM and N₂O to higher altitudes above the tropopause (i.e., to N₂O mixing ratios substantially below 290 ppb) are needed to better constrain the stratospheric TM and GEM lifetimes.

Stratospheric lifetimes of TM and GEM are comparable to the COS stratospheric lifetime of 64 ± 21 years (Barkley et al., 2008), which is, in volcanically quiet periods, the major precursor of sulfate particles in the stratosphere (Wilson et al., 2008). Comparable COS and GEM stratospheric lifetimes suggest collocation of their loss regions. This coincidence corroborates the hypothesis of Hg²⁺ attachment to sulfate particles and their removal by gravitational sedimentation and scavenging by clouds. This hypothesis, first proposed by Lyman and Jaffe (2012), could be directly tested in future by quantitative measurements of Hg/S ratios on stratospheric particles. Such measurements would also better constrain the mercury fluxes across the tropopause.

Mercury measurements onboard IAGOS-CARIBIC were stopped in March 2016 and the space of the mercury instrument is now occupied by other instruments. The reason for the termination of the mercury measurements was the feeling that, with the present instrumentation, we will only reproduce the existing data. An improved instrumentation including reliable speciation technique is needed to gain new insights. Any institution capable of providing and maintaining such an instrument is welcomed to participate in future IAGOS-CARIBIC measurements. For details please consult the CARIBIC coordinator Andreas Zahn.

Data availability. The data are stored at the GMOS data bank and can be obtained under http://sdi.iaa.cnr.it/geoint/publicpage/GMOS/gmos_aircraft.zul (GMOS, 2018).

The Supplement related to this article is available online at <https://doi.org/10.5194/acp-18-12329-2018-supplement>.

Author contributions. All authors except JB are members of the CARIBIC team and as such carried out the measurements and provided the chemical (mercury by AW and RE, CH₄, N₂O, CO, NMHC by CAMB and AR-S, particles by MH and BGM, acetonitrile, O₃, H₂O by MN, AZ and HB, NO and NO_y by HZ) and the meteorological (model and trajectories by PvV) data on which the analysis is based. FS processed the data and prepared the manuscript. All authors contributed to discussions of the analysis and the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We thank Lufthansa Airlines and Lufthansa Technik for their commitment and support. We also thank Jan Boedewadt from HZG for modifying the Tekran instrument for deployment in the CARIBIC container. The development and operation of the CARIBIC system has been financially supported by the German Ministry of Education and Science (AFO 2000, IAGOS-D), by the European Commission's DGXII Environment RTD 4th and 5th Framework programs, by grants from the Max Planck Society and from Frankfurt Airport.
