Ⓢ *Supporting Information*

ABSTRACT: A comprehensive molecular analysis of a simple aqueous complexing system—U(VI) acetate—selected to be independently investigated by various spectroscopic (vibrational, luminescence, X-ray absorption, and nuclear magnetic resonance spectroscopy) and quantum chemical methods was achieved by an international round-robin test (RRT). Twenty laboratories from six different countries with a focus on actinide or geochemical research participated and contributed to this scientific endeavor. The outcomes of this RRT were considered on two levels of complexity: first, within each technical discipline, conformities as well as discrepancies of the results and their sources were evaluated. The raw data from the different experimental approaches were found to be generally consistent. In particular, for complex setups such as accelerator-based X-ray absorption spectroscopy, the agreement between the raw data was high. By contrast, luminescence spectroscopic data turned out to be strongly related to the chosen acquisition parameters. Second, the potentials and limitations of coupling various spectroscopic and theoretical approaches for the comprehensive study of actinide molecular complexes were assessed. Previous spectroscopic data from the literature were revised and the benchmark data on the U(VI) acetate system provided an unambiguous molecular interpretation based on the correlation of spectroscopic and theoretical results. The multimethodologic approach and the conclusions drawn address not only important aspects of actinide spectroscopy but particularly general aspects of modern molecular analytical chemistry.
1. INTRODUCTION

Exploring the migration pathways of contaminants in the ecosphere is a major field in the environmental sciences. In the past few decades, particular attention was paid to the migration behavior of radioactive heavy metals because of their chemo- and radiotoxicity in humans.[1] The dispersion of these elements in soils and rocks is mainly governed by their chemical speciation in the pore water and accordingly by the chemical reactions occurring at mineral–liquid interfaces.[2,3] Among the radionuclides, the high abundance of uranium (U) at sites considered for remediation activities and its relevance to the long-term safety assessment of nuclear waste repositories have led to numerous studies on the hydrolysis reactions of the hexavalent, highly soluble uranyl cation UO_2^{2+} and its complexing reactions with ubiquitous inorganic and organic ligands.[4–7] Additionally, waste forms from other parts of the nuclear fuel cycle are of concern such as remedies of the uranium mining, milling, and enrichment industries, or uranium from other industrial processes, for example geothermal energy generation or phosphate fertilizer production.[8]

Previously, the thermodynamic data of such complex species were primarily derived from macroscopic approaches, such as potentiometric and extraction experiments.[6] However, the assignment of species to distinct molecular complexes with empirical formulas was mainly accomplished without structural information. In fact, the existence of most of the postulated species and their contributions to the multifaceted aqueous chemistry of the UO_2^{2+} ion still await unequivocal evidence from spectroscopic or theoretical approaches. In recent years, progress in the advancement not only of spectroscopic techniques but also of quantum chemical (QC) approaches has provided an increasing amount of spectral data related to the aqueous speciation of U(VI). However, the state of knowledge still appears partially contradictory and unclear.[9–12]

The idea of a multimethodological round-robin test (RRT) on the aqueous speciation of an actinide system was born in the aftermath of the closing round table discussion at the first Workshop on Advanced Techniques in Actinide Spectroscopy (ATAS) held in November 2012 at Dresden, Germany. During this discussion, scientists working in experimental or theoretical disciplines of actinide research shared their perspectives on the contributions from the other discipline and their expectations associated therewith. It became obvious that the current knowledge is inconsistent because of the multitudinous data

provided by various spectroscopic and theoretical approaches, the meaning and interpretability of which are often hard to convey to the highly specialized scientists in different disciplines. Hence, this interdisciplinary test on a relatively simple actinide complex system was intended to elucidate the collection of knowledge from data acquisition to the resulting interpretational approaches. Consistencies and discrepancies in the results and in the way of best practice obtained by each single spectroscopic or theoretical technique applied in various laboratories and their sources should be disclosed to elaborate the potentials and limitations of each single technique. Furthermore, the benefit of multimethodical approaches for the molecular study of a selected complex system was to be assessed (cf. Figure S1).

The selection of the chemical system to be investigated and of the analytical techniques to be applied by the participants was mainly based on experience within the actinide geochemistry community as well as the feasibility of performing experiments encompassing the broad array of techniques available in leading laboratories in the field of geochemical sciences. After extensive discussions between potential participants, the aqueous U(VI) acetate system appeared to be the most implementable system in terms of experimental effort, radiation safety, sample preparation, and applicability to sophisticated spectroscopic techniques, namely, vibrational, luminescence, X-ray absorption, and nuclear magnetic resonance (NMR) spectroscopy. For several reasons (e.g., organizational aspects, few number of participants, etc.), techniques, such as UV–vis absorption spectroscopy or mass spectrometry that may also provide high information value on species distribution, were not considered.

The U(VI) acetate system has been examined since the 1950s. Mainly thermodynamic data on the complexing species and recently structural information by the application of spectroscopy and quantum chemistry have been derived. Up to now, the presence of four species for this complexing system is discussed in the acidic pH range (pH ≤ 4): $UO_2(H_2O)_5^{2+}$, $UO_2CH_3COO^+$, $UO_2(CH_3COO)_2$, and $UO_2(CH_3COO)_3^-$, denoted below as the (1,0), (1,1), (1,2), and (1,3) species, respectively (cf. Figure S2).[13] A more recent study takes fewer species into account.[14] Because of the formation of insoluble hydrolyzed U(VI) solid phases, for example, schoepite, the pH range considered in this RRT was restricted to a maximum value of 3.5. The details of the RRT organization are provided in the following section and in the Supporting Information (Sections S1–S4).

More than 40 scientists from 20 institutions joined the RRT. According to the technique applied, the results were initially collected by nominated scientists acting as cluster speakers for a single technique applied in several laboratories. During a special session of the second ATAS workshop held in November 2014, preliminary summary reports were presented and discussed extensively. This work represents the outcome of this RRT. First, a survey of the experimental and theoretical data obtained is given for each technique. Second, the results are combined into a discussion focusing on the consequences for the knowledge on the U(VI) acetate speciation. Finally, general conclusions and perspectives of the RRT are provided. We believe that the methodology as well as the outcome of this RRT appeals to a broad community of inorganic chemists, actinide chemists, analytical chemists, geochemists, and environmental engineers.

2. ORGANIZATION OF THE RRT

The RRT was initiated in late 2013 at the Helmholtz-Zentrum Dresden−Rossendorf (HZDR). After the approval of the participating institutions, five clusters were formed according to the spectroscopic and theoretical techniques, namely, vibrational spectroscopy (VIB, five institutions), laser-induced luminescence spectroscopy (LUM, nine institutions), NMR spectroscopy (five institutions), X-ray absorption spectroscopy (XAS, three laboratories located at three different European synchrotron sources), and QC calculations (QCC, six institutions) (cf. Figure S1). An overview of the clusters and the respective participating institutions is given in Table S1. For each cluster, a representative speaker was nominated.

For each analytical method, participants received four samples, denoted U1−U4, and respective reference samples, denoted B1−B4 (see Table S2). Those samples were uniformly prepared at HZDR. The participants received detailed information on sample preparation as it is given in the Supporting Information (Section S3). Apart from the requirement of measuring the samples as received, no further restrictions or guidelines were given to the participants to avoid significant impact on the specific approaches of the participants. The performance of the measurements and analysis of the raw data (e.g., data transformations, background subtraction, smoothing, deconvolution, etc.), as well as data interpretation, were entirely at the responsibility of each single operator or operating team. The Supporting Information (Section S4) provides detailed information on each cluster, describes experimental procedures, and lists all relevant setting parameters of the participants for each analytical method and quantum chemistry.

The period for active participation was from January to August 2014. Each participant submitted the raw data obtained, a detailed description of settings, the data analysis procedures applied, and the interpretational approaches of the derived molecular structures to the respective cluster speaker who in turn provided a summary report of the cluster to the organizers of the RRT.

3. RESULTS AND DISCUSSION

3.1. Results from the Clusters. All clusters delivered substantial data sets for intercomparison to determine consistencies and discrepancies within the applied analytical methods. For the sake of brevity, only a summary of the most important aspects can be given here. But, a description and

interpretation of the whole data and its discussion with up-to-date literature as well as of different interpretative approaches of the participants are given in detail in the Supporting Information (Section S5). Furthermore, the original data from each participant are given in Section S6.

3.1.1. Vibrational Spectroscopy. All vibrational spectra of the samples U1−U4 obtained by IR and Raman spectroscopy are shown in Figure 1. The focus is set on the spectral region of the asymmetric ($\nu_3(UO_2)$) and symmetric ($\nu_1(UO_2)$) stretching modes for clarity (Figure 1A,B). All other features observed in the spectra of the different samples mainly reflect the modes of the acetate molecule, which do not show a change in frequency but in intensity (Figures S9 and S10). The spectra provided by the single contributors are given in different colors. A detailed description of the spectroscopic features and their interpretation is given in the Supporting Information (Section S5.1).

The vibrational spectroscopic data of this RRT provided by five independent participants are in excellent agreement for all samples (cf. Table S8). For IR spectroscopy, the interpretation of IR data by all participants is consistent, and four different species could be spectrally identified. Generally, all species found in the IR spectra should be intrinsically observed in the

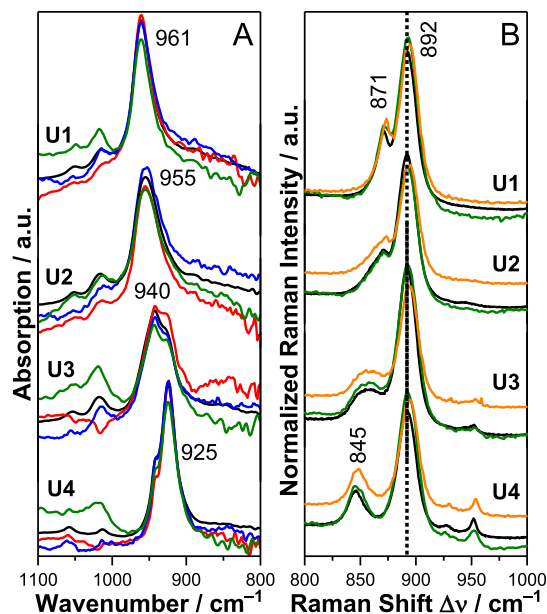

Figure 1. Vibrational spectra of samples U1−U4. Different colors correspond to different participants. Only the spectral regions of the $\nu_3(UO_2)$ mode from IR (A) and of the $\nu_1(UO_2)$ mode from Raman spectroscopy (B) are shown. Values are given in cm^{-1}.

Raman spectra as well. However, Raman spectra of the U(VI) acetate complexes are more difficult to interpret because of the strongly interfering bands of the symmetric stretching mode $\nu_1(UO_2)$ of the different species and a vibrational mode of the acetate ligand. Consequently, the results of this cluster demonstrate that IR and Raman spectroscopy are strongly complementary techniques for the aqueous speciation of actinyl complexes.

3.1.2. Luminescence Spectroscopy. A survey of the time-resolved emission spectra revealed significantly different sets of acquisition parameters, resulting in a large time gate that ranged from a few nanoseconds to 100 ms (Figure 2A). Beside the gate width, parameters such as the initial time delay and the number and size of the gate steps strongly varied between the data sets

provided by the participants (cf. Table S5 in the Supporting Information). However, general analysis of the time-resolved spectra from each participant suggested multi-exponential decay behavior, indicating the presence of at least two distinct species showing characteristic peak positions and luminescence lifetimes regardless of the variation in the spectral parameter applied (cf. Figures S11−S19 in the Supporting Information).

For a detailed analysis of the spectral data, the reader is referred to the Supporting Information. In summary, the strongly varying acquisition parameters applied by the participants of the LUM cluster required additional global data analysis prior to an adequate data evaluation (Figure 2B,C).

Figure 2. Time regimes applied by all participants of the LUM cluster during the acquisition of the luminescence spectra (A). Emission spectra of sample U1 as measured (B) and after calibration (C) using the peak maximum at 490 nm as an internal standard. Only spectra of four participants could be used for calibration (for details, see Supporting Information 5.2).

After an internal referencing of selected spectra, the relative peak positions show only marginal deviations, demonstrating the applicability of luminescence spectroscopy to the investigation of U(VI) speciation and the identification of single species. However, among the results of all participants, the obtained luminescence lifetimes displayed a broad distribution range. These discrepancies likely arose from the use of significantly differing experimental setups and algorithms for the spectral analysis. These aspects were already addressed during the first interlaboratory RRT on aqueous solutions of U(VI) studied by LUM.[15]

3.1.3. X-ray Absorption Spectroscopy. The discussion of the XAS results will be focused on samples U1 (pH 1) and U4 (pH 3.5), which were analyzed by all groups (cf. Figure S20). As demonstrated in a recent comprehensive study, samples U2 (pH 2) and U3 (pH 2.5) are known to contain species mixtures that

are impossible to be unequivocally resolved by XAFS analysis based on four data points, that is, U(VI) acetate under four different pH conditions.[13] A detailed discussion of the curve-fitting results and their interpretation is given in the Supporting Information (Section S5.3). To sum up most important findings (Table 1), we can conclude that

- The data sets for samples U1 and U4 obtained at different beamlines are consistent.
- U1: the presence of the (1,0) species was unambiguously confirmed by all three teams, and the structure reported in the literature was reproduced better than within typical extended X-ray absorption fine structure (EXAFS) error margins.
- U2 and U3: complex mixtures of all the species considered cannot be differentiated using EXAFS through measurements of only four data points, but a clear spectral trend is discernible from the EXAFS measurements of participants XAS-2 and -3.
- U4: the dominant presence of the (1,3) species was confirmed by all the cluster's participants. However, uncertainties in CN determination might cause different interpretations of the coordination schemes for the same data set.

The final point underpins the general importance of a priori speciation information that might be necessary for obtaining a conclusive picture from EXAFS curve fit analysis. Conversely, any EXAFS shell fitting analysis will be prone to be biased by such a priori knowledge.

3.1.4. NMR Spectroscopy. The NMR data are remarkably consistent and show little variation among the five independent groups. A detailed discussion of both ^1H and ^{13}C spectra is given in the Supporting Information (Section S5.4). The use of an internal standard as well as the reliability of modern NMR spectrometers allows excellent and reproducible results. Based on the control samples, the impact of the pH on the acetate spectra was found to be negligible. Hence, the speciation of the acetate molecule does not significantly change in this pH range. Conversely, systematic changes are observed in the spectra of the U(VI) acetate samples with increasing pH. This effect is most dramatic in the ^{13}C spectra (Figure 3), where the signal representing the carboxyl group considerably with pH. This line broadening is attributed to the exchange between free and bound acetate groups, which is in the range of the relaxation time of the resonance signal. NMR spectroscopy can be used to examine high exchange rates of such molecular complexes in solution and has successfully been applied to binary and ternary U(VI) complexes.[16] The observation of only one averaged peak per position in the ^1H and ^{13}C spectra of the U(VI) acetate complex system even at the higher field clearly indicates a fast exchange rate. The differences observed in the line widths of the signals measured at the same field (at 400 MHz) are mainly due to the variations in the homogeneity of the magnetic field, that is, due to the differences in the shimming procedure. At higher fields, the chemical shifts differ more (in Hz) between the exchanging sites (free acetate and complexes), and the exchange-averaged signals are broader compared to those in the 400 MHz spectra.

As neither the chemical shifts of the individual exchanging species nor their relative population are known, simulation of the spectra via a matrix formalism cannot be applied to extract kinetic information. Adequate results can be achieved only by running experiments at lower temperatures, but these are far

beyond the scope of this RRT. Nevertheless, the observations of increased linewidths and chemical shifts in the current data set are consistent with earlier findings, suggesting a correlation of the linewidths with the concentration of the U(VI) acetate species.[16]

3.1.5. Theory/QCC. DFT is the most widely used method for calculations of uranyl(VI) complexes because U(VI) formally exhibits a 5f⁰ electronic configuration, and thus a single-configurational approach is appropriate. The effect of the spin−orbit coupling is only marginal for most of the properties considered here, and therefore, it was neglected. We tested various DFT functionals and a wave function method (MP2). The structural and spectroscopic properties of the two most relevant species, that is, the complexes (1,0) and (1,3), and the energy of ligand replacement, that is from (1,0) to (1,3), were calculated. The results are given in Tables S13 and S14 (Supporting Information). The detailed discussion in the Supporting Information (Section S5.5) focuses on the results obtained with the same basis set for various methods (Programs Gaussian, TURBOMOLE, and ParaGauss), as summarized in Tables S10 and 2, together with ADF results in solution for comparison.

The results suggest that the calculated spectroscopic parameters depend considerably on the optimized structures. Generally, all methods satisfactorily reproduce the U−O$_{ax}$ distances, whereas the U−O$_{eq}$ distances are generally overestimated compared to experimental data. To fully evaluate the calculated results, they must be compared with the experimental results, which will be done in the next section.

3.2. Molecular Aspects of the U(VI) Speciation Derived from Each Cluster's Results. In this section, the results and interpretational approaches obtained from each cluster are analyzed with respect to the aqueous U(VI) acetate speciation. As a synopsis, Table 3 displays the consistency of the data obtained and the results of interpretational approaches. The predominant U(VI) species in samples U1 and U4 are expected to be the (1,0) and (1,3) species, respectively. At variance, for samples U2 and U3, the presence of several species is expected where the predominance of uranyl complexes with an increasing number of ligands increases with pH. Thus, to evaluate the data across all clusters, the (1,0) and (1,3) species are discussed first.

The unequivocal data provided by the spectroscopic clusters for sample U1 facilitate the assignment of the spectral features observed to the predominant aqueous (1,0) species. This conclusion is explicitly supported by the VIB and XAS clusters.
Figure 3. ^{13}C NMR spectroscopic data of the methyl (left) and carboxyl regions (right). Comparison of the chemical shifts (top) and linewidths (below) for samples U1−U4 obtained by different RRT participants. Note that for better comparison the same line broadening factor (lb) was applied to the raw data (see Tables S11 and S12).

All participants performing Raman and infrared spectroscopy concordantly assigned the spectral data showing the symmetric ($\nu_1(UO_2)$) and asymmetric ($\nu_3(UO_2)$) stretching vibrational modes to the fully hydrated uranyl ion. Furthermore, the structure of the aqueous uranyl complex, in which the UO_2^{2+} moiety is coordinated by 5 water molecules in the equatorial plane, is unambiguously reproduced by EXAFS shell fitting by all

three participating beamline groups. However, regarding the results of the U1 sample from the LUM cluster, the assignment of the predominant species as the (1,0) species is mainly based on the prevailing conditions.

The (1,3) species is unequivocally identified by all participants in the VIB and XAS clusters. Based on the highly consistent spectral data, the interpretational approaches used by the participants differ only slightly. Most participants interpreted the spectral data in terms of the predominance of the (1,3) species with a structure, in which all three acetate ligands are bidentately coordinated to the uranyl moiety. From the VIB data, only one set of Raman spectra was not assigned to the (1,3) species, while in one set of IR spectra, the presence of an even higher coordinated U(VI) acetate complex, the (1,4) species, was discussed but was subsequently considered to be unlikely because of steric considerations. Moreover, according to one set of XAS data, the (1,3) species was considered to exhibit a mixed type of coordination of the ligands, that is, two bidentately and one monodentately bound ligand.

In contrast, the assignment of spectral features to the (1,1) and (1,2) species is generally less clear. Only the vibrational spectra exhibit a spectral feature, namely the frequency of the $\nu(UO_2)$ modes, that directly correlates with the formation of each species and thus allows the unambiguous assignment of four distinct species. However, even the interpretation of vibrational data is hampered by overlapping signals, and the assignment of these species is not completely consistent in case of the Raman spectra. Note, however, that the Raman spectroscopy results of this RRT convincingly revise previous literature data.[17] For the XAS and LUM clusters, identifying these species is not possible for various reasons. For EXAFS spectroscopy, this is mainly due to the number of samples being too small, as shown previously.[13] Moreover, it has been

LUM	−/−[e]			
QCC	+/−[f]	N/A	N/A	+/+

[a]+/+: high consistency of data and interpretation between the participants; +/−: high consistency of data and ambiguous interpretation between the participants; −/−: low consistency of data and interpretation if available; N/A: not available. [b]Deviation in assignment & interpretation. [c]Unequivocal identification not feasible. [d]Deviation in interpretation of structure. [e]Due to low sample number nearly no interpretation approaches; global equilibration procedure required. [f]Variation due to weakly bound H_2O-ligands.

demonstrated that the spectrum of the (1,2) species intrinsically cannot be derived from EXAFS data.[13] Indeed, the LUM data from all contributors demonstrate that each sample shows its characteristic spectral fingerprint; however, specific species can be extracted only when an extensive parametric analysis of a larger data set is available than the one generated within this RRT.

NMR spectroscopy is a non-optical spectroscopic technique that exclusively provides signals reflecting changes of the energy differences in nuclear spin states in hydrogen and carbon atoms of the ligand, which differentiates this technique from the other spectroscopic methods used in this RRT. On the one hand, the slight shifts observed in the ^1H and ^{13}C spectra nicely represent the ongoing complexation of the uranyl moiety by acetate molecules as the pH increases. On the other hand, an assignment of the signals observed to distinct species is not possible. As already stated in Section 3.1.4, a more detailed analysis yielding speciation information can be obtained only by conducting much more extensive experiments, which are beyond the scope of this RRT.

A principal concern of this RRT was the juxtaposition of the results obtained from the experimental and theoretical approaches. For the sake of simplicity, the calculations focused on the (1,0) and (1,3) species assuming the penta−aquo complex $UO_2(H_2O)_5{}^{2+}$ for the (1,0) species and the exclusively bidentate complex $UO_2(CH_3COO)_3{}^-$ for the (1,3) species.

In general, the accuracy of the calculated values of the interatomic distances and the vibrational frequencies agree well with experimental results but the quality of the results depends slightly on the method applied (Table 2). Compared to the structures in the gas phase (Table S10), the calculations including solvation effects provide slightly longer U−O_ax distances and slightly shorter U−O_eq distances (Tables S10 and 2). Solvation effects slightly improve the agreement with EXAFS results for U−O_eq and in some cases also for U−O_ax distances. As an example, the solvation calculations of both the (1,0) and (1,3) species at the MP2 level gave bond distances that are all within 0.02 Å of the values from the EXAFS data (Table 2). At the DFT level, the deviations are slightly larger. Depending on the type of functional, the deviations from the experimental bond distances can be as large as 0.1 Å (Table S14). For all methods, a trend to overestimating the lengths of U−O bonds to the ligands has to be noted, by 0.06 Å for (1,0) and by 0.03 Å for (1,3) on average. The geometry differences between the species (1,0) and (1,3) are qualitatively reproduced by all methods. The increase of U−O_ax by about 0.01 Å und the increase of U−O_eq by about 0.05 Å due to complexation, as observed by EXAFS, are overestimated for U−O_ax and

underestimated for U−O_eq by about 0.02 Å in all calculations (Table 2). In general, calculated differences of properties should be more accurate than absolute values due to favorable error cancelation. On the other hand, the observed deviations from experiment are not unexpected due to limitations of the solvation modeling in the calculations and due to some contributions from species with less than three acetate ligands in probe U4 in the experiment (see Figure S2).

The calculated harmonic vibrational frequencies of the ν_1 and $\nu_3(UO_2)$ modes are consistent with the experimental values. Not surprisingly, the better the agreement between the experimental and theoretical bond distances, the better tends to be the agreement in vibrational frequencies (irrespective of gas phase or aqueous phase calculations). For instance, the calculations at the MP2 level, which coincide well with the experimental bond distances, provide an average deviation of only 17 cm^{-1} (max. 27 cm^{-1}) between the theoretical and experimental $\nu_1/\nu_3(UO_2)$ frequencies (Table 2). The results obtained with the M06L functional with ParaGauss are only slightly less accurate. In line with the overestimation of the increase of the U−O_ax bond due to acetate complexation in the calculations, the red shift of the uranyl stretching vibrations as a result of acetate complexation, which amounts to about 30 cm^{-1} in experiment, is overestimated by all methods by at least 30 cm^{-1} (Table 2). The difference between ν_3 and ν_1 is well reproduced by MP2 (Table 2, overestimated for (1,0) = 2 cm^{-1}, for (1,3) = 13 cm^{-1}), but underestimated by DFT by 40 cm^{-1} for (1,0) and 30 cm^{-1} for (1,3) on average (Table 2). These findings of systematic deviations support the assumption of differences between experiment and theory due to model aspects in the calculations and additional species in the experimental probes (see above).

Besides, it should be noted that there are three essential sources of errors in computations: the model choice, the electronic structure method, including the particular (relativistic) treatment of the core electrons, and the solvation treatment. Commonly some error cancelation may be expected. One may therefore always argue that good agreement with experiments may simply be a coincidence and computational results always warrant a critical evaluation.

This RRT demonstrates that the basic molecular parameters of small actinide complexes obtained using QCC are accurate with respect to the experimental findings. In particular, the interatomic distances are obviously predicted with higher accuracy than vibrational frequencies (for which rescaling is a rather common practice). Deviations of calculated parameters from the experimental values, averaged over all methods applied, amount to 1−2.5% for bond lengths and to 4−6% for the uranyl stretching vibrations. For well-defined systems and with a proper

choice of the method, an even better agreement with experiment is achievable. Small systematic deviations, especially of differences of properties, point to limitations of the models used in the calculations and uncertainties of speciation in the experimental probes: thus, such differences are of special interest and are helpful for improving calculations as well as the interpretation of experiments.

4. CONCLUSIONS AND PERSPECTIVES

4.1. Evaluation of the RRT. The concept of this RRT based on the contributions of a broad array of spectroscopic techniques and QC approaches to the aqueous U(VI) speciation exemplified for the U(VI) acetate system. This project intended to collect results from as many laboratories with dedicated expertise in the molecular analysis of actinides as possible. Hence, for the sake of practicability, the scale of the RRT had to be restricted to a relatively small number of samples, which can hardly be considered as adequate for a thorough investigation of an aqueous speciation as complex as the U(VI) acetate system. In consequence, a conclusive evaluation of the RRT shall be restricted to some general, yet still-instructive aspects. Table 4 summarizes the major findings of the applied techniques as well as their strengths and limitations concerning the U-acetate complex system.

The generally high consistency of the data, obtained within each cluster, reflects the accuracy and suitability of the techniques applied for the exploration of the uranyl complex system. In particular, those techniques conducted on commercial instruments provided highly consistent data, as shown by the results of the VIB and NMR clusters. Despite having worked on different beamlines and individually adapted setups, even accelerator-driven XAS provided highly consistent raw data. Regarding the characteristic specifications of the single facilities, one of the merits of this RRT is explicitly demonstrating the reproducibility of the performance of the three participating synchrotron beamlines.

A distinct comparison of the luminescence spectral data was only feasible after performing a correction routine for wavelength calibration, as described in Sections 3.1.2 and S5.2. At first, the consistency of luminescence data appeared to be quite low. This inconsistency might raise questions about the comparability of the spectral analysis, which was performed based on only simple spectral fingerprinting published previously. Conversely, when the spectra were referenced internally to the spectral distances of the peaks, the data within the LUM cluster demonstrated high reproducibility. However, considering the data of the luminescence decay curves provided by the respective participants, a comparison of the spectral data is hardly possible, as described in Section S5.2. In fact, these aspects were already addressed in a previous RRT in 2003.[15]

Multimethodological approaches to the analysis of molecular complexes are expected to benefit from the acquisition of complementary information. Potentially, this advantage might be derived from IR and Raman spectroscopy because of the intrinsic selection rules of the vibrational modes observed in the respective spectra. In fact, four prevailing species and the interacting functional groups in the molecular complexes could be evidently derived from the vibrational spectra (see Sections 3.1.1 and S5.1). This information was nicely reflected by the results in the NMR cluster, which provided evidence for the increasing degree of complexation of the uranyl moiety with increasing pH (see Sections 3.1.4 and S5.4). As the results from the LUM and XAS cluster indicated the presence of only three

Table 4. Summary of Strengths and Limitations of Applied Analytical Tools and Their Relevance to the U(VI) Acetate System

method	type of transitions	direct molecular/specific information	major findings	for U–Ac complex system	
				strengths	limitations
VIB	molecular vibrations	vibrational modes, molecular symmetry	identification and characterization of species (1,0), (1,1), (1,2) and (1,3)	easily accessible through commercial instruments	concentrations required generally higher than environmentally relevant
XAS	core electrons	oxidation state, coordination number, bond length	identification of species (1,0) and (1,3)	derivation of molecular structure by coordination number and bond distances	synchrotron facility required, concentrations required generally higher than environmentally relevant
NMR	nuclear spin	coordination of functional groups	correlation of complexation and pH	identification of functional groups and protonation states	concentrations required generally higher than environmentally relevant
LUM	valence electrons	transition energy, luminescence lifetime, number of species	identification of species (1,0), (1,2) and (1,3), non-luminescent species (1,1)	analysis of multicomponent systems, very low detection limit	sophisticated user configuration settings
QCC		molecular and electronic structures, chemical bonds, nature of electronic transitions	molecular characterization of species (1,0) and (1,3)	no lab access required, complementary to experiments, independent verifications of properties	ambiguity due to solvation models
other methods considered: UV–vis absorption spectr.	valence electrons	transition energy and selection rules	identification of 4 species	easily accessible through commercial instruments	relatively high concentrations required
mass spectrometry		mass-to-charge ratios of species	concentrations too high	direct confirmation of species	neutral species invisible, not suitable for high concentrations, and high ionic strengths

species, the missing complementarity of these techniques with the former ones must be discussed in more detail.

Due to the intrinsic properties of the EXAFS spectra, the (1,2) species cannot be differentiated from the other species which is largely due to symmetry reasons as already mentioned above (see Sections 3.1.3 and S5.3). Hence, such intrinsic limitations, which might not be obvious even to advanced spectroscopists, must be understood prior to performing extensive series of experiments. The intrinsic luminescence properties of the species might also be responsible for the lower number of species observed using LUM. One of the species—most likely the (1,1) species—was assumed to be not luminescent. Although an ultimate verification is still lacking, this explanation would clearly elucidate why comprehensive complementary information was not obtained from the LUM cluster. However, it has to be emphasized that the number of samples was certainly insufficient for a thorough investigation of the speciation, particularly in the case of luminescent spectroscopy.

Consequently, to gain maximum benefit from a multi-methodological approach exploring the U(VI) acetate speciation, the techniques must be carefully selected, which requires a detailed knowledge of their capabilities and restrictions. Even then, experienced users might suffer from unexplored details of intrinsic properties of the molecules under investigation. At this point, theoretical calculations, as they represent an independent and thus complementary approach to molecular properties, appear particularly valuable. As shown in this RRT, results from various QC codes are very consistent when the same stationary points of the species under study are considered. Bond distances are well reproduced with the MP2 and a number of DFT approaches, while vibrational frequencies show slightly larger deviations, but are still useful for the assignment of the spectral findings to distinct molecular structures. Nevertheless, the general trends of geometry and vibrational parameters of the U(VI) acetate system are calculated in agreement with the experiment. Small systematic deviations from the experimental results, which are independent of the detailed method applied, are of special interest, as they point to weaknesses of the models applied and/or the need for a more detailed understanding of the system considered in the experiments. DFT calculations predict chemical shifts of NMR signals quite precisely. In the future, the development of algorithms providing reliable calculations of luminescent spectra is desired.

In summary, this RRT was very successful in terms of the high number of participants throughout the community and their acceptance to share their expertise and experimental (unpublished) data. Furthermore, the cooperation and willingness of the participants to contribute to the discussions during the compilation process of the RRT illustrate the profound interest in improving the performance of the various techniques and in continuing the knowledge transfer among scientists from various analytical disciplines to obtain a deeper understanding of basic molecular complexes in actinide chemistry.

4.2. Scope and Perspectives.
In the past decades, significant progress in laser technology, microfluidics, digital signal processing, and the development of novel light detectors has contributed to dramatic efficiency enhancements of spectroscopic methods in terms of significantly reduced accumulation times and increase in quality of spectra. Consequently, due to improved signal-to-noise ratios in the spectra, the extraction of further molecular information by numerical analysis has gained importance in spectroscopic investigations. Apart from classical analysis methods, such as curve decomposition or factor analysis, which have been applied intensively ever since, various statistical methods—chemometrics in particular—have been developed for processing these data and extracting essential information. However, only the accurate application of such statistical methods prohibits from misinterpretation of the results, which might lead to erroneous understanding otherwise.[18] This particularly refers to well-established fitting procedures, which often appear to be poorly documented in scientific articles. Hence, the provision of comprehensive numerical information necessary for the reproduction of such an analysis is indispensable. Moreover, we felt confident through this RRT that it is necessary to establish a method utilizing chemometrics as a routine tool for characterization of molecular structures. In the future, further development of dimension reduction and feature extraction methods such as self-organizing maps is foreseen to contribute further to molecular spectroscopy.

A key concern of this RRT was the elicitation of the mutual promotion of QC calculations and spectroscopic approaches. The results presented provide a widely consistent molecular understanding of the (1,0) and (1,3) uranyl acetate species, even though theoretical predictions and experimental findings showed some discrepancies to a different extent with respect to the different spectroscopic techniques. Hence, the development or improvement of algorithms explicitly considering the intrinsic properties of specific spectroscopic techniques is expected to enhance the concordance of theoretical and experimental approaches and appears therefore necessary. If an intense communicative exchange of theoreticians and experimentalists generates a mutual understanding of their operational modes and mindsets, future work might proceed in extracting specific information from complex experimental data and vice versa in verifying theoretical investigations by experimental findings.

On a technical level of instrumentation, this RRT demonstrated the importance of the availability of experimental parameters. Only detailed sets of relevant instrumental parameters strengthen the sustainability of the data presented and might provide the basis for future technical improvements. In this context, it was shown that a commonly accepted and applied calibration routine for LUM is mandatory though hard to be implemented throughout worldwide researchers. Nevertheless, we suggest a suitable calibration approach in the Supporting Information (cf. Figure S21). This approach follows the procedure already described earlier using the emission line of a conventional Hg lamp.[19] In the future, it is eligible to represent luminescence spectra on an energy scale (wavenumber units) instead of a wavelength scale. This would facilitate the comparability of spectral features observed under different experimental setups, thereby data interpretation by various researchers becoming more perspicuous and comprehensible.
