doi: 10.1111/nph.16471

**Key words:** carbon balance, drought, elevated CO<sub>2</sub>, heat, photosynthesis, primary metabolites, protein, respiration.

- Trees are increasingly exposed to hot droughts due to CO<sub>2</sub>-induced climate change. However, the direct role of [CO<sub>2</sub>] in altering tree physiological responses to drought and heat stress remains ambiguous.
- *Pinus halepensis* (Aleppo pine) trees were grown from seed under ambient (421 ppm) or elevated (867 ppm) [CO<sub>2</sub>]. The 1.5-yr-old trees, either well watered or drought treated for 1 month, were transferred to separate gas-exchange chambers and the temperature gradually increased from 25°C to 40°C over a 10 d period. Continuous whole-tree shoot and root gas-exchange measurements were supplemented by primary metabolite analysis.
- Elevated [CO<sub>2</sub>] reduced tree water loss, reflected in lower stomatal conductance, resulting in a higher water-use efficiency throughout amplifying heat stress. Net carbon uptake declined strongly, driven by increases in respiration peaking earlier in the well-watered (31–32°C) than drought (33–34°C) treatments unaffected by growth [CO<sub>2</sub>]. Further, drought altered the primary metabolome, whereas the metabolic response to [CO<sub>2</sub>] was subtle and mainly reflected in enhanced root protein stability.
- The impact of elevated [CO<sub>2</sub>] on tree stress responses was modest and largely vanished with progressing heat and drought. We therefore conclude that increases in atmospheric [CO<sub>2</sub>] cannot counterbalance the impacts of hot drought extremes in Aleppo pine.

## Introduction

Forests are exposed to a rapidly changing climate world-wide, and extreme weather events such as heatwaves and drought spells are predicted to increase in frequency and severity as atmospheric [CO<sub>2</sub>] a[CO<sub>2</sub>] is rising (Coumou & Rahmstorf, 2012; Baldwin *et al.*, 2019; Pfliegerer *et al.*, 2019). This has pronounced impacts on forest carbon (C) and water (H<sub>2</sub>O) cycling (Williams *et al.*, 2013), particularly in already H<sub>2</sub>O-limited ecosystems (Choat *et al.*, 2018). Yet, the interacting effects of elevated [CO<sub>2</sub>] (e[CO<sub>2</sub>]) with extreme environmental conditions (such as drought, heat stress, and the combination of both) on tree stress resistance are far from clear.

Heatwaves during extended drought periods can be a main cause of forest decline (Anderegg *et al.*, 2013). Hot droughts are particularly stressful because evaporative demand is high, while H<sub>2</sub>O availability is low and trees need to tightly regulate H<sub>2</sub>O loss (Ameye *et al.*, 2012; Ruehr *et al.*, 2016; Birami *et al.*, 2018). This typically induces stomatal closure to maintain the integrity of the H<sub>2</sub>O transporting system (Tyree & Zimmermann, 2002). Simultaneously, C assimilation rates decline while C is needed to

support osmoregulation and cellular maintenance (Hsiao, 1973; Huang *et al.*, 2012; Hartmann & Trumbore, 2016). Therefore, a C imbalance can arise under progressing stress, which triggers a cascade of metabolic adjustments.

A driving force of metabolic activity in plants is respiration. Typically, *c.* 30–80% of the daily photosynthetic C gain is released back to the atmosphere (Atkin & Tjoelker, 2003). During stressful conditions, the amount of respiration to assimilation can change dramatically and trees can become a net source of CO<sub>2</sub>. It has been shown that the C loss in trees subjected to higher temperatures and increasing drought is larger and occurs earlier than under cooler conditions. This was due to respiration continuing at relatively high rates whereas assimilation started to decline earlier in drought-treated trees grown under 35°C compared with 25°C (Zhao *et al.*, 2013). Other work has shown that respiration can strongly increase under rapid warming, even in combination with drought, until rates drop at very high temperatures (Gauthier *et al.*, 2014). By contrast, if trees are exposed to elevated growth temperatures, respiration typically acclimates, nearly offsetting the effect of the warming (Reich *et al.*, 2016; Drake *et al.*, 2019). Although much research has focused on the

temperature relationship of respiration, we have little mechanistic understanding to predict how respiration will respond to day-long heatwaves, let alone in combination with drought and/or changes in  $[\text{CO}_2]$ .

Increasing  $a[\text{CO}_2]$  may affect tree stress responses through a variety of plant physiological processes. For instance,  $e[\text{CO}_2]$  often suppresses photorespiration and dark respiration (Drake *et al.*, 1999; Dusenge *et al.*, 2019), whereas it stimulates C assimilation and productivity under nonstressful conditions (Ainsworth & Long, 2005; Ainsworth & Rogers, 2007; Ameye *et al.*, 2012; Simón *et al.*, 2018; Zinta *et al.*, 2018). Alongside increases in C uptake, stomatal conductance  $g_s$  typically declines (Eamus, 1991). This reduction in  $g_s$  corresponds with a larger leaf-intercellular  $[\text{CO}_2]$   $C_i$ , stimulated photosynthesis, and increased plant  $\text{H}_2\text{O}$ -use efficiency (WUE) – the ratio of C uptake via assimilation per unit  $\text{H}_2\text{O}$  loss from transpiration (Lavergne *et al.*, 2019). Increases in WUE under  $e[\text{CO}_2]$  have been observed in many studies (Eamus, 1991), particularly in  $\text{H}_2\text{O}$ -limiting environments (Wullschleger *et al.*, 2002). However, the combined effects of  $e[\text{CO}_2]$  stress responses during extreme heat and/or drought stress have rarely been investigated, and results remain inconclusive. For instance,  $e[\text{CO}_2]$  could not mitigate extreme drought stress (withholding  $\text{H}_2\text{O}$  until mortality occurred) in *Pinus radiata* and *Callitris rhomboidea* (Duan *et al.*, 2015) or in *Eucalyptus globulus* when +240 ppm  $\text{CO}_2$  was combined with a constant +4°C warming (Duan *et al.*, 2014), whereas it alleviated extreme heat stress in *Pinus taeda* and *Quercus rubra* (Ameye *et al.*, 2012; +320 ppm, +12°C heatwave) and *Larrea tridentata* (Hamerlyncx *et al.*, 2000; +340 ppm  $\text{CO}_2$ , +8°C heatwave).

A more comprehensive picture on the interacting effects of  $e[\text{CO}_2]$  on plant stress performance could be gained through a whole-tree C perspective – integrating sink and source responses (Dusenge *et al.*, 2019; Ryan & Asao, 2019). Moreover, investigating changes in the primary metabolism could allow identification of some of the underlying mechanisms (Xu *et al.*, 2015; Mohanta *et al.*, 2017). For instance,  $e[\text{CO}_2]$  can increase sugar and starch concentrations, which might buffer plant C losses during drought via enhanced C supply and/or improved osmoregulation (Ainsworth & Long, 2005; Ainsworth & Rogers, 2007) as well as may reduce oxidative stress (Zinta *et al.*, 2014). However,  $e[\text{CO}_2]$  may also affect the C : nitrogen (N) stoichiometry and N dilution, as has been observed, resulting in decreased protein and amino acid concentrations (Poorter *et al.*, 1997; Johnson & Pregitzer, 2007). A decrease in protein content may affect assimilation and respiration rates (Drake *et al.*, 1999; Xu *et al.*, 2015; Dusenge *et al.*, 2019), could dampen stress-induced upregulation of amino acids important for osmoregulation (Zinta *et al.*, 2018), and may affect the abundance of heat-shock proteins, and therefore plant thermotolerance (Coleman *et al.*, 1991; Huang *et al.*, 2012; Zhang *et al.*, 2018). Hence,  $e[\text{CO}_2]$  can trigger metabolic processes that may directly interact with tree drought and heat stress responses. Yet, results remain inconclusive because we miss an integrated understanding of the interactive effects of  $e[\text{CO}_2]$  and stress on the C balance and primary metabolism of trees.

Here, we provide novel insights into the impacts of  $e[\text{CO}_2]$  on whole-tree shoot and root stress responses in Aleppo pine saplings

originating from a semi-arid forest at the arid timberline (Grünzweig *et al.*, 2009). To elucidate the effects of  $[\text{CO}_2]$  in combination with drought and heat stress on physiological responses, we combined measurements of whole-tree C balance, WUE, and primary metabolites. More specifically, our hypotheses were as follows: first, that  $e[\text{CO}_2]$  increases photosynthesis, which results in a larger net C uptake maintained during heat stress; second, that WUE increases proportionally with  $a[\text{CO}_2]$  and that this increase can be maintained during heat stress but not during hot drought, when stomata are closed; and third, the tree metabolic response to temperature is suppressed under  $e[\text{CO}_2]$ , which is reflected in a concurrent change in respiratory activity and primary metabolites.

## Materials and Methods

### Plant material

*Pinus halepensis* (Miller) saplings were grown from seeds for 18 months under ambient  $\text{CO}_2$  (*c.* 420 ppm) or  $e[\text{CO}_2]$  (*c.* 870 ppm, within the range of representative concentration pathway 8.5 for 2100; IPCC, 2014) in a scientific glasshouse facility in Garmisch-Partenkirchen, Germany (732 m asl, 47°28'32.87"N, 11°3'44.03"E) with highly UV-transmissive glass (70%). The origin of the seed material is a 50-yr-old Aleppo pine plantation in Israel (Yatir Forest). Cones of trees were sampled growing in close proximity to a meteorological station and flux tower (IL-Yat, 650 m asl, 31°20'49.2"N, 35°03'07.2"E).

In the following, the experimental design of the study is explained in detail from the germination of the seedlings until the 18-month-old saplings were transferred into separate tree gas-exchange chambers (see Fig. 1). Seeds germinated on vermiculite in two transparent growth chambers either under ambient  $[\text{CO}_2]$  or  $e[\text{CO}_2]$ . About 10 wk after germination, in July 2016, the seedlings were transferred to pots ( $5 \times 5 \times 5 \text{ cm}^3$ , 0.125 l) containing a C-free potting mixture of 1 : 1 : 0.5 quartz sand (0.7 mm and 1–2 mm), vermiculite (*c.* 3 mm), and quartz sand (Dorsolit 4–6 mm) with 1 cm of expanded clay (8–16 mm) as a drainage. Seedlings were fertilized with 2 g of slow-release fertilizer (Osmocote® Exact 3-4M 16-9-12 + 2MgO+TE; ICL Specialty Fertilizers, Heerlen, the Netherlands) supplemented by liquid fertilizer (Manna® Wuxal Super; Wilhelm Haug GmbH & Co. KG, Ammerbuch, Germany). Placement of the seedlings within the two growth chambers was randomized every second week; and to overcome a possible chamber effect, the  $\text{CO}_2$  treatments were moved at monthly intervals between the chambers (Fig. 1). After the saplings were 7 months old they were placed in two glasshouse compartments referring either to  $a[\text{CO}_2]$  and  $e[\text{CO}_2]$  conditions and 10-month-old seedlings were individually transferred to larger pots (4.5 l) for a second time. The potting mixture was again a C-free substrate of 1 : 1 : 2 vermiculite (3–6 mm), coarse (4–6 mm), and fine quartz sand (2–3 mm) with 1 cm of expanded clay (8–16 mm) as a drainage. Slow-release fertilizer (5 g, Osmocote® Exact Standard 5-6M 15-9-12+2MgO+TE; ICL Specialty Fertilizers) was added to the mixture and supplemented by liquid fertilizer, phosphate, and

**Fig. 1** Experimental timeline from seedling (*Pinus halepensis*) germination until two heat experiments (each 10 d) were conducted 18 months later. The initiation of the CO<sub>2</sub> (elevated [CO<sub>2</sub>] (e[CO<sub>2</sub>]): dark blue; atmospheric [CO<sub>2</sub>] (a[CO<sub>2</sub>]): light blue) and drought treatments (orange) is also shown. Seedlings of the four treatments (a[CO<sub>2</sub>]W, e[CO<sub>2</sub>]W, a[CO<sub>2</sub>]D, e[CO<sub>2</sub>]D; D, drought; W, well-watered) were randomly selected and transferred to the gas-exchange chambers where temperature was increased stepwise (25°C, 30°C, 35°C, 38°C, 40°C) and above and belowground gas-exchange measured. The heat experiment was repeated with a new set of seedlings to increase number of replicates to eight per treatment. Note that one gas-exchange chamber per treatment was left blank to serve as a quality control. The yellow dotted lines depict iteration of the CO<sub>2</sub> treatments between two growth chambers or two glasshouse bays.

magnesium addition once. Incoming light from outside was supplemented with plant growth-lamps (T-agro 400 W; Philips, Hamburg, Germany) and the saplings were irrigated regularly to saturation. A possible effect of the placement within the glasshouse was again overcome by iterating the CO<sub>2</sub> treatments between the two glasshouse bays four times before the start of the heat stress experiment in September 2017 (Fig. 1).

Atmospheric CO<sub>2</sub> differed greatly between the glasshouse compartments (421 ± 105 ppm in a[CO<sub>2</sub>] and 867 ± 157 ppm in e[CO<sub>2</sub>] on average, increase in [CO<sub>2</sub>] of 106% during growth period), whereas all other growth conditions were kept similar (see Supporting Information Fig. S1). Moisture sensors (10HS; Decagon Devices Inc., Pullman, WA, USA; calibrated to potting substrate) and an automated drip irrigation system were installed (Rain Bird, Azusa, CA, USA) when seedlings were 15 months old. The irrigation was adapted to result in a relative substrate H<sub>2</sub>O content (RSWC) of 50% (Fig. S2) close to the soil H<sub>2</sub>O content in the Yatir Forest during spring conditions. RSWC was calculated as follows:

$$RSWC = 100 \times \frac{SWC_{\text{sample}} - SWC_{\text{min}}}{SWC_{\text{max}} - SWC_{\text{min}}} \quad \text{Eqn 1}$$

(SWC<sub>max</sub> (g g<sup>-1</sup>), maximum amount of H<sub>2</sub>O held by the substrate (e.g. field capacity); SWC<sub>min</sub> (g g<sup>-1</sup>), minimum amount of H<sub>2</sub>O held by the substrate, set to zero; SWC<sub>sample</sub>, measured substrate H<sub>2</sub>O content, derived from the calibrated moisture sensors).

When seedlings were about 17 months old, half of the seedlings from each CO<sub>2</sub> treatment were randomly selected and assigned to a drought treatment (D). In the drought trees, irrigation was slowly reduced to maintain daily-averaged RSWC at c. 10%, whereas RSWC in the well-watered trees (W) was maintained at 50%, leading to a pronounced decrease in H<sub>2</sub>O potential. Two sets of seedlings from each of the four treatments (a[CO<sub>2</sub>]W, e[CO<sub>2</sub>]W, a[CO<sub>2</sub>]D, e[CO<sub>2</sub>]D) were randomly

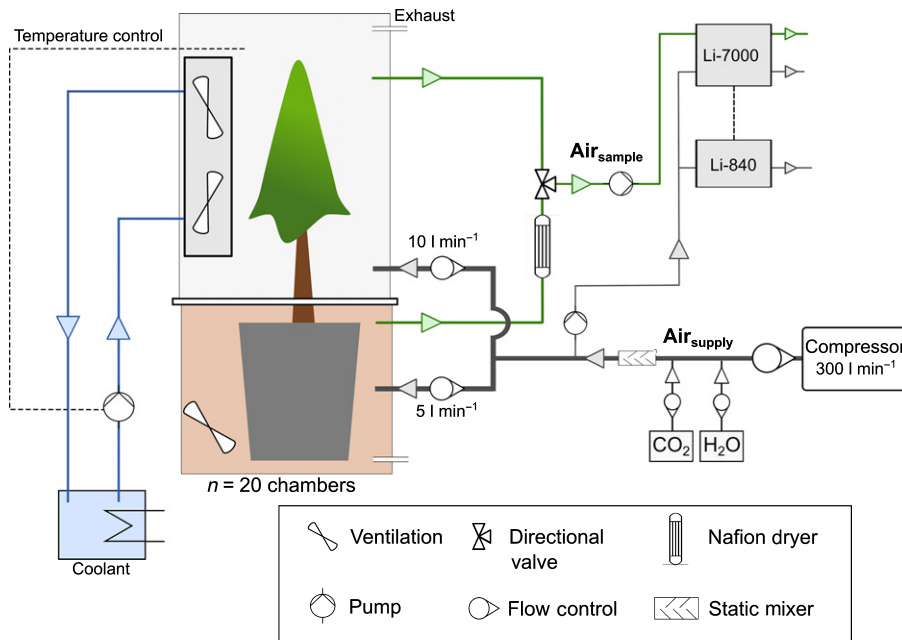

selected 40 d and 50 d after drought had been initiated (Fig. 1), transferred to custom-built separate tree gas-exchange chambers (see section Chamber system) and exposed to increasing heat stress (n = 4 per treatment) for a period of 10 d.

### Tree gas-exchange chambers

**Chamber system** We developed a tree gas-exchange system with 20 separate chambers divided into above and belowground compartments to continuously measure the exchange of H<sub>2</sub>O and CO<sub>2</sub>. Each of the 20 aboveground compartments were individually temperature-controlled (Fig. 2). The aboveground and belowground compartments were separated and gas tightness between the above- and belowground compartment was ensured after enclosing the tree stem. For details on the set-up and constant air supply of the tree gas-exchange system, see S1.

The chamber system was installed in the glasshouse and outside light was supplemented with plant growth lamps (T-agro 400 W; Philips, Hamburg, Germany). Canopy light conditions inside each chamber were measured automatically with a photodiode (G1118; Hamamatsu Photonics, Hamamatsu, Japan), which had been cross-calibrated with a high-precision photosynthetic active radiation (PAR) sensor (PQS 1; Kipp & Zonen, Delft, the Netherlands). Root-zone conditions were monitored with temperature sensors (TS 107; Campbell Scientific Inc., Logan, UT, USA) and moisture sensors (10HS; Decagon Devices Inc.). These data were logged half-hourly (CR1000; Campbell Scientific Inc.).

**Gas-exchange measurements** The gas-exchange chambers were constantly supplied with an air stream (Air<sub>supply</sub>) of either 408 ppm or 896 ppm CO<sub>2</sub>. Sample air (Air<sub>sample</sub>) was drawn at a rate of 500 ml min<sup>-1</sup>, and each seedling was measured once every 80 min using differential gas analysis. We used two gas analyzers: the analyzer measuring absolute [CO<sub>2</sub>] and [H<sub>2</sub>O] (LI-840; Licor, Lincoln, NE, USA) was connected to a differential gas

**Fig. 2** Whole-tree gas-exchange system separated in an above and belowground compartment, shown exemplified for one chamber ( $n = 20$  in total). The arrows indicate the direction of flow. The air supply to the chambers is given in black ( $Air_{supply}$ ), and the sample air is given in green ( $Air_{sample}$ ). The Li-840 measured absolute  $[CO_2]$  and  $[H_2O]$  connected to an Li-7000 to measure differences between  $Air_{supply}$  and  $Air_{sample}$ . Note that trees (*Pinus halepensis*) were potted in carbon-free substrate and the belowground  $CO_2$  efflux is therefore interpreted as root respiration.

analyzer (Li-7000; Li-Cor) quantifying  $[CO_2]$  and  $[H_2O]$  differences between  $Air_{supply}$  and  $Air_{sample}$ . The data were logged at 10 s intervals. The gas analyzers were calibrated following the manufacturer's recommendations.

To eliminate any offset between  $Air_{supply}$  and  $Air_{sample}$  not caused by plant gas-exchange, empty aboveground and belowground compartments ( $n = 1$  per treatment, four in total) containing C-free potting substrate only, were measured and offsets (on average  $+0.33 \pm 1.2$  ppm  $CO_2$  and  $0.02 \pm 0.05$  ppt  $H_2O$  in the aboveground compartments) removed accordingly. Differences in  $CO_2$  were slightly larger in the belowground compartments ( $c. +2$  ppm on average) and may be due to some microbial activity in the potting substrate.

Gas-exchange fluxes of  $CO_2$  and  $H_2O$  were calculated from the concentration differences between  $Air_{supply}$  and  $Air_{sample}$ . Plant  $H_2O$  loss via transpiration  $E$  ( $mol\ s^{-1}$ ) was calculated as follows:

$$E = \frac{\dot{m}(W_{sample} - W_{supply})}{1 - W_{sample}} \quad \text{Eqn 2}$$

( $\dot{m}$ , air mass flow ( $mol\ s^{-1}$ ) into the chamber compartment;  $W_{sample}$ ,  $H_2O$  vapor concentration of  $Air_{sample}$  ( $mol\ mol^{-1}$ );  $W_{supply}$ ,  $H_2O$  vapor concentration of  $Air_{supply}$  ( $mol\ mol^{-1}$ )).

From daytime  $E$  and  $H_2O$  vapor concentrations we determined stomatal conductance  $g_s$  ( $mol\ s^{-1}$ ) as follows:

$$g_s = \frac{E \left( 1000 - \frac{W_{leaf} + W_{sample}}{2} \right)}{W_{leaf} - W_{sample}} \quad \text{Eqn 3}$$

( $W_{leaf}$  ( $mol\ mol^{-1}$ ), leaf  $H_2O$  vapor concentration, derived from the ratio of saturation vapor pressure (kPa) at a given air temperature ( $^{\circ}C$ ) and atmospheric pressure). This

approach, which neglects boundary-layer conductance, is suitable under well-coupled conditions, as confirmed by negligible temperature differences between chamber and tree canopy ( $< 1^{\circ}C$ ; see Table S1).

$CO_2$  gas exchange ( $mol\ s^{-1}$ ) – that is, net photosynthesis  $A_{Net}$ , shoot respiration  $R_{shoot}$ , and root respiration  $R_{root}$  – was calculated as follows:

$$CO_2 \text{ flux} = -\dot{m}(C_{sample} - C_{supply}) - (EC_{sample}) \quad \text{Eqn 4}$$

( $C_{sample}$ ,  $[CO_2]$  of  $Air_{sample}$  ( $mol\ mol^{-1}$ );  $C_{supply}$ ,  $[CO_2]$  of  $Air_{supply}$  ( $mol\ mol^{-1}$ );  $E$ , used to correct for dilution through transpiration ( $mol\ s^{-1}$ )). In the case of  $R_{root}$  (where sample air was dried), the  $H_2O$  vapor dilution term became negative. The daily net C uptake (mg) per tree was calculated based on daily-averaged  $A_{Net}$  and respiration as follows:

$$C_{Net} = A_{Net} - (R_{shoot} + R_{root}) \quad \text{Eqn 5}$$

In order to determine changes in whole-tree WUE, apparent WUE was derived as follows:

$$WUE_a = \frac{A_{net}}{E_{day}} \quad \text{Eqn 6}$$

To allow comparison of tissue gas-exchange activity between treatments and because root surface area was not available, we calculated gas-exchange rates per shoot (i.e. needle and woody tissues) or root DW, if not stated otherwise. The percentage share of soluble C from tissue biomass was small ( $< 4\%$ ; Table S2), hence we refrained from taking normalization to soluble C into account. Tree biomass was determined at the end of the experiment and separated into needles, roots, and woody tissues before drying at  $60^{\circ}C$  for 48 h (Table 1).

## Heat stress experiment

Responses of shoot and root gas-exchange with increasing temperature and evaporative demand were assessed continuously using the tree gas-exchange system described in the Tree gas-exchange chambers section and Notes S1. In brief, randomly selected seedlings were placed into separate gas-exchange chambers ( $n = 4$  per treatment, Fig. 1). The chambers containing one tree each were positioned next to each other in a randomized block design. The heat stress experiment was repeated in order to double the numbers of replicates per treatment. Each heat experiment lasted 10 d, and after the initial 2 d at 25°C (20°C nighttime) the temperature was increased stepwise every second day to the following daytime temperatures: 25, 35, 38, and 40°C (Fig. 3a). We refrained from temperatures above 40°C as tree mortality has been found to strongly increase in Aleppo pine seedlings above this threshold, particularly in combination with drought (Birami *et al.*, 2018). As during a typical heatwave in the Yatir Forest (Tatarinov *et al.*, 2016), vapor pressure deficit (VPD) increased alongside increasing temperature, and this increase was slightly greater in the drought-treated saplings due to low  $E$  (Fig. 3c). PAR was kept relatively constant between gas-exchange chambers, and daily averages were  $456 \pm 140 \mu\text{mol m}^{-2} \text{s}^{-1}$ . To overcome some of the light limitations (saturating PAR for photosynthesis was at  $1200 \mu\text{mol m}^{-2} \text{s}^{-1}$ ) daytime length was set to 16 h, well above the average summer day length in Yatir Forest. Irrigation was controlled to maintain the RSWC of well-watered trees at *c.* 50% and of drought-treated trees at *c.* 10% (Fig. 3). The irrigation amount did not differ between the  $[\text{CO}_2]$  treatments (a $[\text{CO}_2]$ W and e $[\text{CO}_2]$ W:  $300 \text{ ml d}^{-1}$ ; a $[\text{CO}_2]$ D and e $[\text{CO}_2]$ D:  $50 \text{ ml d}^{-1}$ ) and drought-treated seedlings reached a midday needle  $\text{H}_2\text{O}$  potential  $\psi_{\text{midday}}$  indicating stomatal closure (Fig. S3; Table 2).

## Sample preparation

We sampled needle tissue for analysis of primary metabolites on the last day of the following temperature levels: 25, 35, 38 and 40°C. To avoid disturbance of belowground fluxes, root biomass was only sampled at 25°C (additional set of saplings, not used for the experiments) and at 40°C. Sampling took place in the

afternoon between 15:00 h and 16:00 h; samples were immediately frozen in liquid  $\text{N}_2$  and then stored at  $-80^\circ\text{C}$  until ground to fine powder in liquid  $\text{N}_2$  before freeze-drying for 72 h with cooling aggregate at  $-80^\circ\text{C}$  and sample temperature at  $-30^\circ\text{C}$  (Alpha 24 LSC; Martin Christ Gefriertrocknungsanlagen GmbH, Osterode am Harz, Germany). The freeze-dried samples were stored in the dark in closed vials at room temperature, and analyses of primary metabolites were completed within 2 months (Fürtauer *et al.*, 2019). For details on analysis of primary metabolites via gas chromatography coupled with time-of-flight mass spectrometry (Fürtauer *et al.*, 2016; Weiszmann *et al.*, 2018) and protein content via Bradford assay (Fürtauer *et al.*, 2018), please see Notes S2.

## Statistical data analysis

Data processing, analysis, and statistics were carried out using R v.3.5.2 (R Core Team, 2018). Gas-exchange measurements of each chamber were carefully inspected before analyses, and day or nighttime fluxes outside 1.5 times the interquartile range (above the upper quartile and below the lower quartile) per temperature were considered outliers. This removed, on average, 3.8% of  $\text{CO}_2$  and 5.7% of  $\text{H}_2\text{O}$  gas-exchange data.

Primary metabolites were scaled to SD before treatment effects in needles and roots at 25°C were visualized by hierarchical clustering, utilizing R packages GGPlot2 (Wickham, 2016) and CLUSTER (Maechler *et al.*, 2018). Further, the overall changes in the primary metabolome depending on tissue, treatment, and temperature were analyzed after centering of the scaled data via principal components analysis.

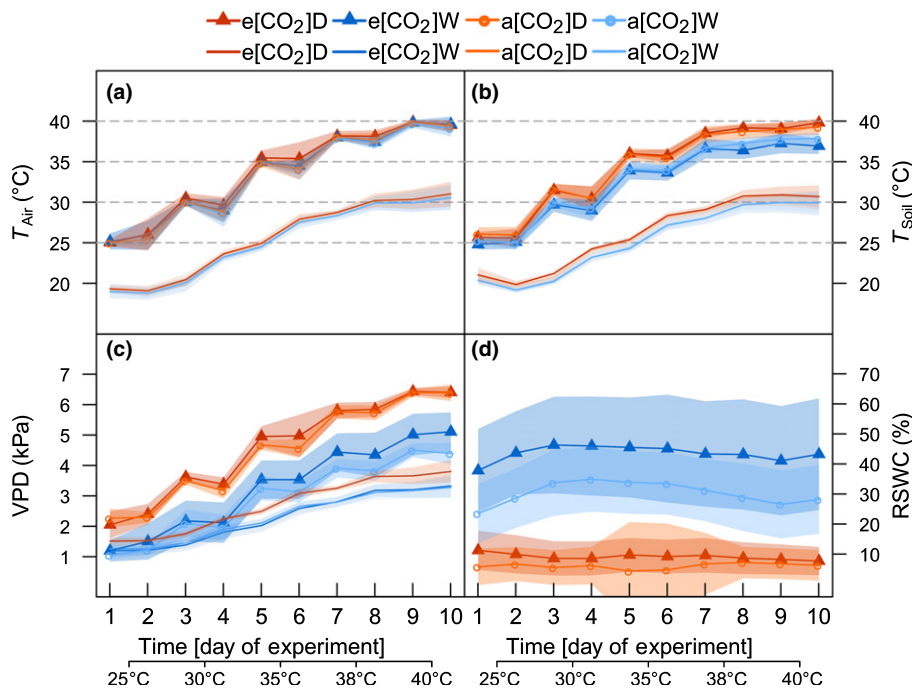

Treatment effects on biomass, gas-exchange rates, and metabolites at specific temperature levels were tested using ANOVA, and differences between treatments were revealed by post hoc analysis (Tukey honestly significant difference (HSD)). Treatment and temperature dependencies of gas-exchange fluxes and metabolites (fixed effects) were checked by implementing a linear mixed effects model (LMERTEST; Kuznetsova *et al.*, 2017). In order to account for temporal autocorrelation, tree was accounted as a random factor. Using the reduced sample size Akaike information criteria (Akaike, 1974; Giraud, 2015), the most parsimonious model was selected with or without tree as random factor,

**Table 1** Needle, shoot, root, total tree biomass, needle area, and total soluble carbon (C, calculated as C equivalents of all measured metabolites) for 1.5-year-old *Pinus halepensis* seedlings are given as treatment averages  $\pm 1$  SE ( $n = 16$  per treatment) at the end of the experiment (post-stress).

Treatment	Biomass (g DW)				Needle area (cm <sup>2</sup> )	Soluble C ( $\mu\text{mol g}^{-1}$ DW)
	Needle	Root	Wood	Total		
a $[\text{CO}_2]$ W	33.4 $\pm$ 1.0 A	51.1 $\pm$ 1.4 B	15.4 $\pm$ 0.6 A	99.9 $\pm$ 2.1 A	1296 $\pm$ 38 A	1090 $\pm$ 209 A

D, drought; W, water treated; a, atmospheric; e, elevated.

$E$ , transpiration;  $g_s$ , stomatal conductance;  $A_{Net}$ , net photosynthesis;  $R_{dark}$ , dark respiration;  $C_i$ , leaf-intercellular [CO<sub>2</sub>]; WUE, water-use efficiency;  $\psi_{midday}$ , midday needle water potential.

Tree net C uptake is the sum of photosynthesis  $A_{Net}$  minus respiration  $R$ .  $\psi_{midday}$  is given and was measured at the time of tissue sampling for metabolite analysis. Significant differences between treatments were derived from ANOVA followed by Tukey's honestly significant difference and are given in upper-case letters ( $P < 0.05$ ).

and the treatment and temperature effects included with and without interaction. We report a pseudo- $R^2$  ( $pR^2$ ) for the selected model (MUMIN; Barton, 2019). Homoscedasticity and normality of residuals were checked and, if applicable,  $\log_e$  transformation applied.

To analyze differences in the temperature relationship of  $A_{Net}$  we applied an exponential decay function ( $y = e^{-bx}$ ); in the case of respiration  $R$ , we fitted a second-order polynomial function following (Gauthier *et al.*, 2014):

$$R = e^{a+bT+cT^2}$$

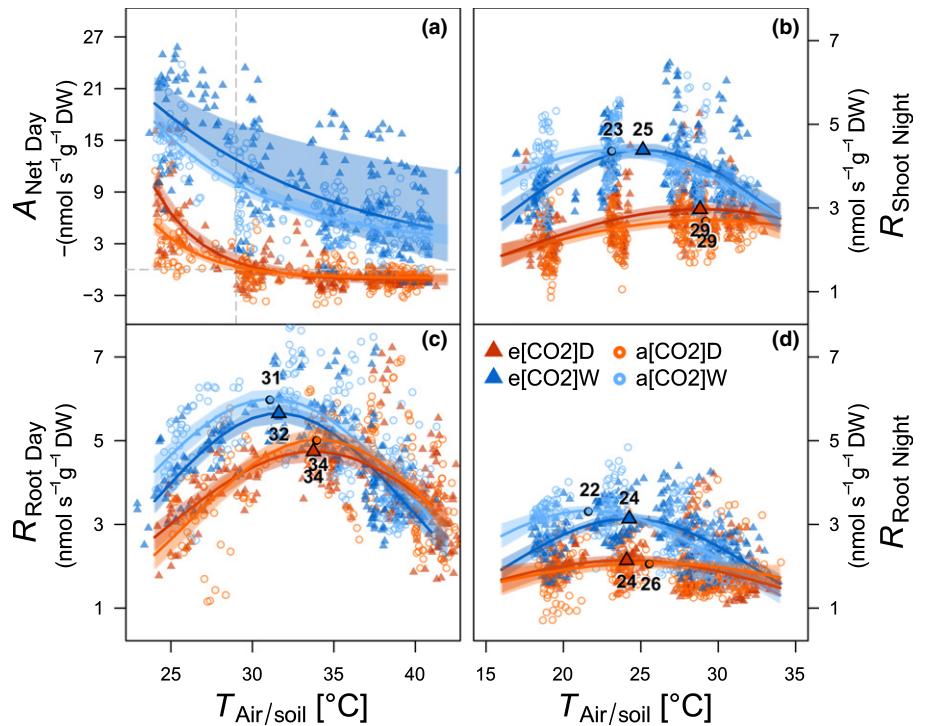

The uncertainties of all fitted functions are given as 95% confidence intervals derived from first-order Taylor expansion using the PROPAGATE package (Spiess, 2018).

## Results

### Tree biomass

Differences in above and belowground biomass were distinct after growing *P. halepensis* seedlings for more than 1 yr under a [CO<sub>2</sub>] of 421 ppm or e[CO<sub>2</sub>] of 867 ppm (Table 1). A doubling of atmospheric [CO<sub>2</sub>] increased total tree biomass by 35%. This increase was particularly pronounced in woody tissues (stem and twigs, +47%) and to a lesser extent in needles (+26%). The 1-month drought period had no obvious effect on aboveground biomass, but reduced belowground biomass under ambient (−15%) and e[CO<sub>2</sub>] (−11%). The amount of nonstructural carbohydrates in total biomass varied between 1.5 and 3.5% and

**Fig. 4** Gas-exchange dynamics with increasing heat stress under ambient or elevated  $[\text{CO}_2]$  in drought or well-watered *Pinus halepensis* trees. Shown are hourly averages per tree and treatment of (a) net photosynthesis  $A_{\text{Net}}$ , (b) shoot dark respiration  $R_{\text{Shoot}}$ , and (c) daytime (10:00 h to 18:00 h) and (d) nighttime (23:00 h to 04:00 h) root respiration  $R_{\text{Root}}$ . The temperature response of  $A_{\text{Net}}$  was fitted with an exponential decay function and respiration data fitted to a second-order polynomial function (see Eqn 6). The temperature at the respiratory peak is highlighted. The shaded areas depict the 95% confidence intervals of the fitted functions. Note that gas-exchange data are expressed per DW shoot or root tissue.

was slightly larger under drought with no clear trend of  $[\text{CO}_2]$  (Table S2).

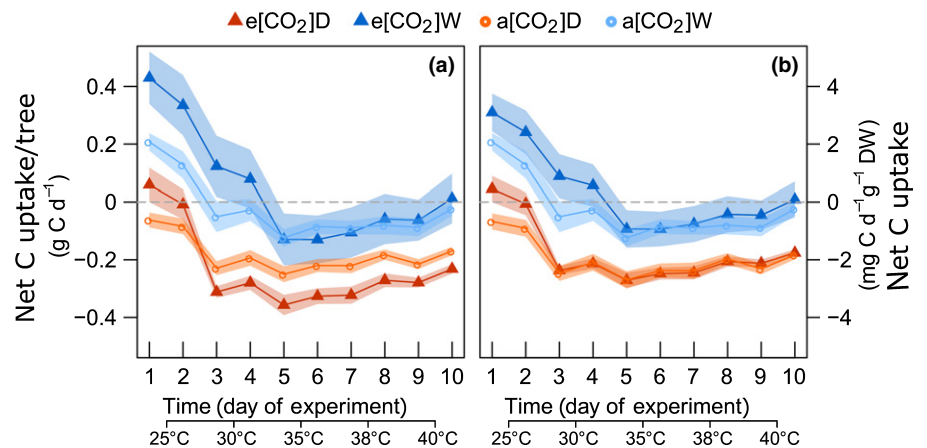

### Tree gas-exchange

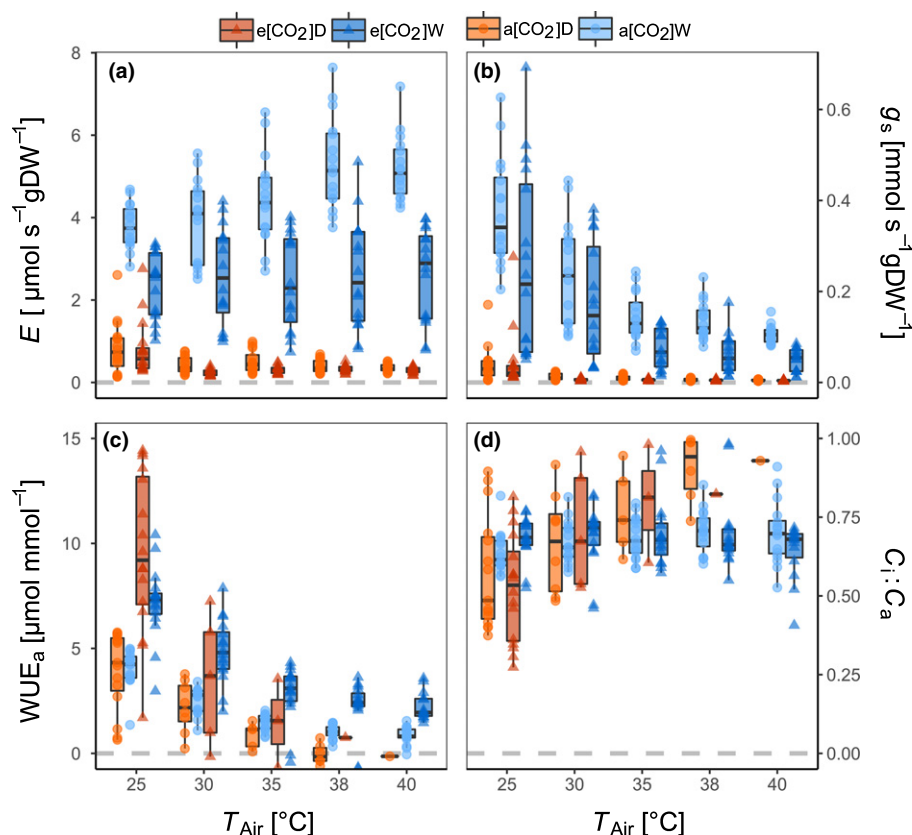

**Impacts of  $[\text{CO}_2]$  and drought** Elevated  $[\text{CO}_2]$  affected gas-exchange rates expressed per tissue DW (Table 2; see also Fig. 4). Under well-watered conditions and at ambient temperature ( $25^\circ\text{C}$ ),  $R$  was lower in  $e[\text{CO}_2]\text{W}$  trees than in  $a[\text{CO}_2]\text{W}$  trees. In addition,  $e[\text{CO}_2]$  reduced  $g_s$  and  $E$ , which resulted in an increase of WUE (Table 2), whereas  $A_{\text{Net}}$  was largely unaffected (Table 2). Under drought, the effect of  $[\text{CO}_2]$  on WUE was pronounced, with  $C_i$  being increased near stomatal closure, allowing for a higher  $A_{\text{Net}}$  (Table 2). The positive effect of  $e[\text{CO}_2]$  on biomass,  $C_i$ , and WUE was also reflected in daily net C uptake (i.e. tree C balance), but the degree did depend on  $\text{H}_2\text{O}$  supply.

Whereas in the well-watered trees the net C uptake tended to double under  $e[\text{CO}_2]$ , drought trees were able to maintain a small C sink if grown under  $e[\text{CO}_2]$  (Table 2).

**Heat stress responses altered by  $[\text{CO}_2]$  and drought** Increasing temperatures affected VPD accordingly (Fig. 3c), and we found pronounced responses in gas exchange of the well-watered seedlings.  $A_{\text{Net}}$  declined with temperature irrespective of the  $[\text{CO}_2]$  (Fig. 4a). This was contrasted by initially increasing C loss via  $R_{\text{Root}}$  and  $R_{\text{Shoot}}$  until a respiratory peak has been reached and respiration rates began to decline (Fig. 4b,c). This respiratory peak was reached  $2\text{--}4^\circ\text{C}$  later and at lower rates in the drought-treated saplings. The trees' net C uptake reacted accordingly with a sharp initial decrease, which then leveled off at increasing heat stress ( $30\text{--}35^\circ\text{C}$ ; Fig. 5). The effects of  $e[\text{CO}_2]$  were not distinct, but data showed a tendency of whole-tree net C losses to be

**Fig. 5** Temperature responses of the whole-tree carbon (C) balance (i.e. net C uptake) in *Pinus halepensis* seedlings (a) per tree and (b) DW biomass. Shown are daily averages per treatment ( $a[\text{CO}_2]\text{W}$ ,  $e[\text{CO}_2]\text{W}$ ,  $a[\text{CO}_2]\text{D}$ ,  $e[\text{CO}_2]\text{D}$ ;  $a[\text{CO}_2]$ , atmospheric  $[\text{CO}_2]$ ;  $e[\text{CO}_2]$ , elevated  $[\text{CO}_2]$ ; D, drought; W, well-watered). Whole-tree net C uptake was derived from hourly photosynthesis and respiration data per seedling (Eqn 5). Note that positive numbers reflect a daily net C gain, and negative numbers are a net C loss. The shaded areas are  $\pm 1$  SE ( $n = 8$ ).

**Fig. 6** Treatment responses of (a) transpiration  $E$ , (b) stomatal conductance  $g_s$ , (c) apparent water use efficiency ( $WUE_a$ ), and (d) the ratio of intercellular to ambient  $[CO_2]$  ( $C_i : C_a$ ) of *Pinus halepensis* seedlings with increasing temperature. Data points are daily-averaged values per temperature level and tree (between 10:00 h and 16:00 h).  $WUE_a$  and  $C_i : C_a$  are given for  $C_i \leq C_a$ . The relationships of hourly  $WUE$  and  $g_s$  with temperature are given in Supporting Information Fig. S4.

observed at slightly higher temperatures under both well-watered and drought conditions.

A pronounced interaction of  $e[CO_2]$  with heat stress became clear in a constantly lower  $E$  (lme:  $pR^2 = 0.89$ ; Tukey HSD,  $P < 0.05$ ) but higher  $WUE$  (lme:  $pR^2 = 0.81$ ; Tukey HSD,  $P < 0.05$ ) with increasing temperatures under well-watered conditions. This was due to a tight stomatal control in the  $e[CO_2]W$  trees (Fig. 6a,b; Table S3). The picture changed dramatically when heat stress was combined with drought; the  $H_2O$ -saving effect of  $e[CO_2]$  quickly subsided at temperatures  $> 30^\circ C$ , coinciding with stomatal closure. Interestingly, the  $C_i$  to ambient  $[CO_2]$  ( $C_a$ ) ratio seemed largely unaffected by the  $[CO_2]$  and remained almost constant throughout the experiment (Fig. 6d, excluding  $C_i > C_a$ ).

### Primary metabolites

**Impacts of  $[CO_2]$  and drought** The primary metabolism in roots and needles was clearly distinct, irrespective of treatment (Fig. 7; metabolite profile at  $25^\circ C$ ). We found inositol pathway intermediates (e.g. *myo*-inositol, pinitol), polyamines, and aromatic amino acids to dominate in needle tissues, whereas monosaccharides, TCA intermediates (e.g. malate), and amino acids of the glutamate and aspartate family were higher concentrated in roots.

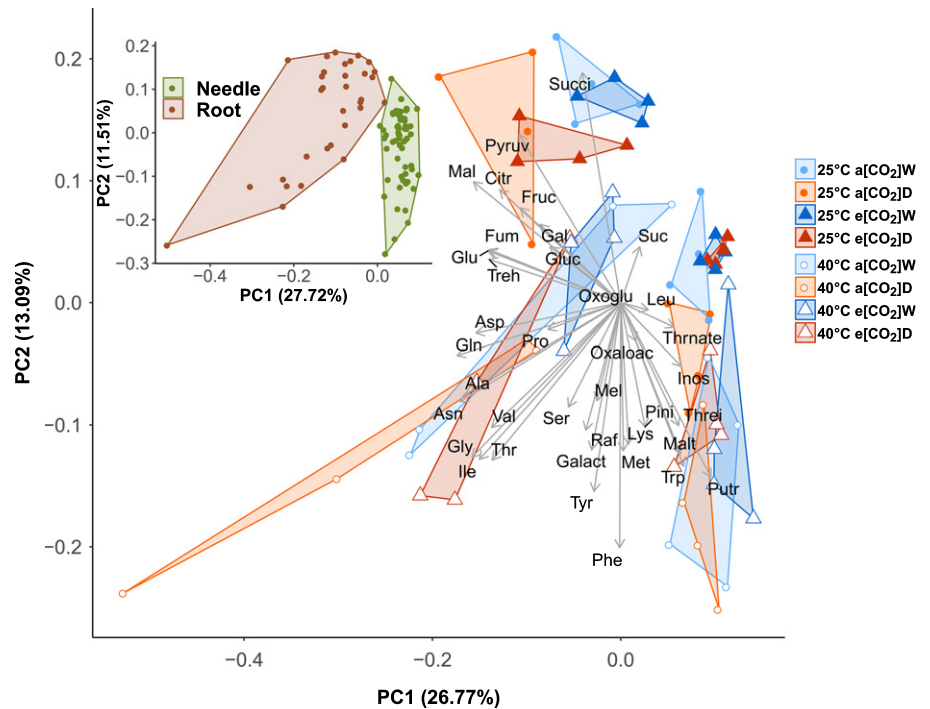

In addition, we found the metabolic responses to drought larger than the  $[CO_2]$  effect, as reflected in the clustering (Fig. S5). For instance, monosaccharides (lme:  $pR^2 = 0.74$ ) and

sucrose (lme:  $pR^2 = 0.43$ ) were clearly enhanced under drought, accompanied by increased levels of proline in both needles (lme:  $pR^2 = 0.47$ ; Tukey HSD,  $P < 0.05$ ) and roots (lme:  $pR^2 = 0.69$ ; Tukey HSD,  $P < 0.05$ ). Further, increased levels of branched-chain amino acids and amino acids of the glutamate and aspartate families were found in drought treatments (e.g. glutamine – needle lme:  $pR^2 = 0.59$ ; root lme:  $pR^2 = 0.77$ ; Tukey HSD,  $P < 0.05$ ). A distinct response of the primary metabolome to  $e[CO_2]$  under drought was remarkably absent in roots, whereas  $e[CO_2]$  showed a tendency to mitigate metabolic responses to drought in needle tissues.

**Heat stress responses affected by  $[CO_2]$  and drought** The temperature increase from  $25^\circ C$  to  $40^\circ C$  affected the primary metabolome in needles and roots differently (Fig. 7). A general trend in needle tissues was the decrease of carboxylic acids (lme:  $pR^2 = 0.47$ ) and an increase of sugar alcohols (e.g. pinitol, lme:  $pR^2 = 0.65$ ; and galactinol, lme:  $pR^2 = 0.59$ ), whereas *myo*-inositol decreased (lme:  $pR^2 = 0.25$ ; Tukey HSD,  $P < 0.05$ ). Secondary metabolite precursors such as putrescine (lme:  $pR^2 = 0.37$ ), tyrosine, and phenylalanine also increased with temperature (lme:  $pR^2 = 0.6–0.84$ ) relatively uniformly among treatments. Responses to increasing temperatures became most obvious in the root tissues (Fig. 7), where we found amino acids (glutamine, asparagine, alanine, serine, threonine, valine, and isoleucine) to accumulate with rising temperatures (lme:  $pR^2 = 0.6–0.8$ ). This increase was marked under  $a[CO_2]$  in both drought and well-watered trees along with a decline in root

**Fig. 7** Principal components analysis of all quantified 38 primary metabolites in shoot and root tissues (*Pinus halepensis*) at 25°C (closed symbols) and at 40°C (open symbols) per treatment. Polygons indicate treatment clustering. Inset: visualization of overall changes in root (brown symbols) and needle (green symbols) tissues irrespective of treatment and temperature. Note that all metabolite data were scaled to SD (see the Materials and Methods section). Metabolite abbreviations: Gluc, glucose; Fruc, fructose; Gal, galactose; Suc, sucrose; Treh, trehalose; Malt, maltose; Mel, melibiose; Raf, raffinose; Inos, *myo*-inositol; Pini, pinitol; Galact, galactinol; Threi, threitol; Oxoglu, 2-oxoglutarate; Oxaloac, oxaloacetate; Citr, citrate; Mal, malate; Succ, succinate; Fum, fumarate; Pyruv, pyruvate; Thrnat, threonate; Glu, glutamate; Gln, glutamine; Asp, aspartate; Asn, asparagine; Gly, glycine; Ala, alanine; Ser, serine; Ile, isoleucine; Leu, leucine; Val, valine; Thr, threonine; Pro, proline; Lys, lysine; Met, methionine; Tyr, tyrosine; Phe, phenylalanine; Trp, tryptophane; Putr, putrescine.

protein (lme:  $pR^2 = 0.38$ ; Fig. 8t). By contrast, needle protein increased above 35°C in all treatments (Fig. 8t), particularly under e[CO<sub>2</sub>]D (lme:  $pR^2 = 0.23$ ; Tukey HSD,  $P < 0.05$ ). In addition, treatment-specific responses to temperature were found in monosaccharides (lme:  $pR^2 = 0.74$ ), where drought resulted in an accumulation of monosaccharides in needles (Tukey HSD,  $P < 0.05$ ; Fig. 8a,b). In the well-watered treatments, we found monosaccharides to decline in roots (Fig. 8c,d; lme:  $pR^2 = 0.70$ ; Tukey HSD,  $P < 0.05$ ). This decline tended to be greater in trees grown under a[CO<sub>2</sub>].

## Discussion

### Tree C balance under e[CO<sub>2</sub>]

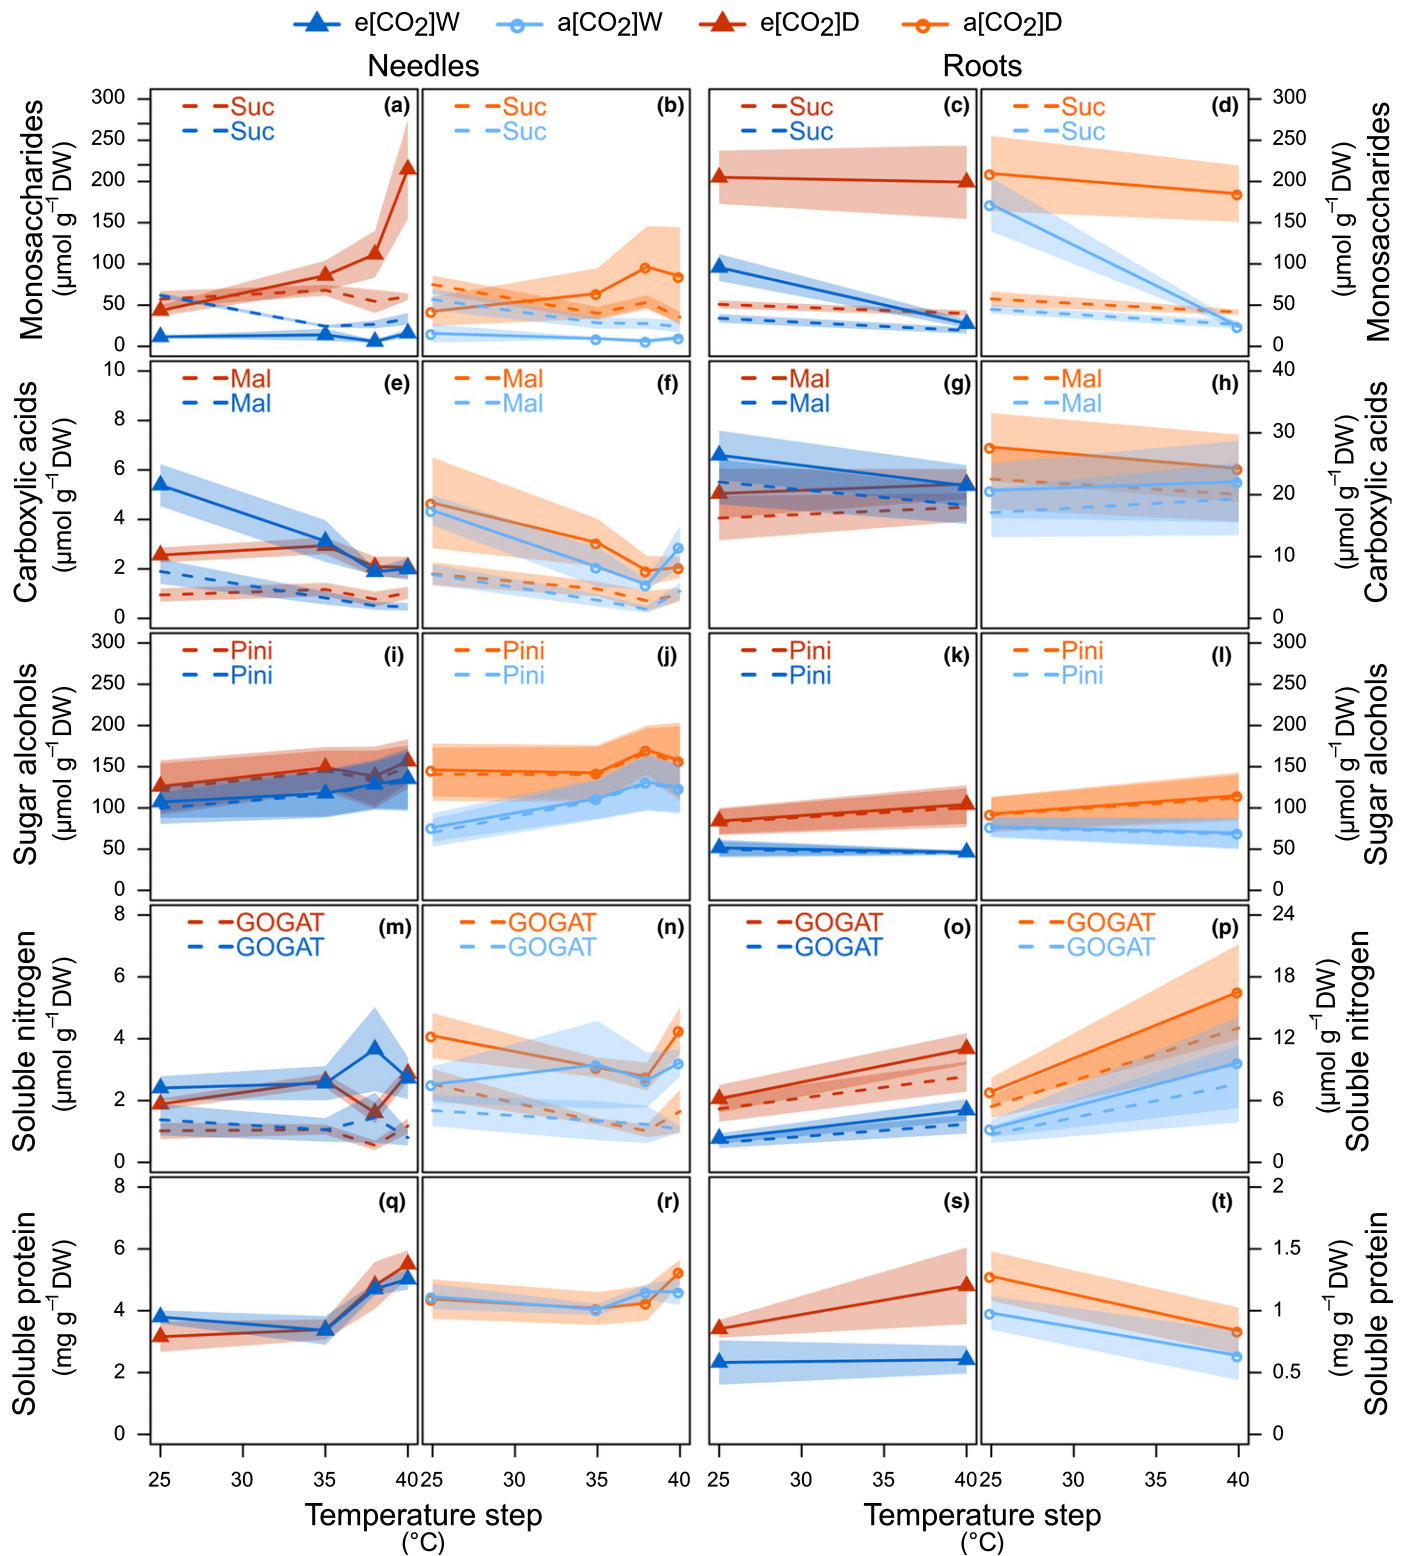

Aleppo pine trees grown for 1.5 yr under e[CO<sub>2</sub>] exhibited a larger biomass than trees grown under a[CO<sub>2</sub>]. We cannot exclude limiting effects on growth due to the size of the pots, which were lower than what has been previously recommended (Poorter *et al.*, 2012). Nevertheless, we found clear differences in root biomass and e[CO<sub>2</sub>] to stimulate root growth, in agreement with many other studies (for a meta-analysis of free-air CO<sub>2</sub> enrichment studies, see Nie *et al.*, 2013). The observed overall larger biomass of e[CO<sub>2</sub>] trees in our study tended to result in a larger net C gain (i.e. net photosynthesis minus respiration; on average, +120% per tree). To exclude the CO<sub>2</sub>-induced biomass stimulation on these results, we expressed gas-exchange rates per tissue DW. Based thereon, we did not find e[CO<sub>2</sub>] to increase C-fixation rates, as  $A_{Net}$  was quite similar between the two [CO<sub>2</sub>] treatments (Table 2), and carboxylation efficiency was unchanged (data not shown). Hence, the stimulation of the seedlings' net C gain in the e[CO<sub>2</sub>]W treatment was not driven by increased photosynthesis but due to an apparent reduction of  $R_{Shoot}$  and  $R_{Root}$

under e[CO<sub>2</sub>] (−23% on average). It is noteworthy that, under drought conditions, [CO<sub>2</sub>] did not affect respiration rates.

The responses of respiration to e[CO<sub>2</sub>] can be highly variable (Dusenge, 2019). Some studies find respiration to be insensitive to [CO<sub>2</sub>], whereas others find it to either increase or decrease (Drake *et al.*, 1999; Gonzalez-Meler *et al.*, 2004; Ainsworth & Long, 2005; Gauthier *et al.*, 2014; Xu *et al.*, 2015; Aspinwall *et al.*, 2017; Dusenge *et al.*, 2019). Our study adds new evidence that e[CO<sub>2</sub>] reduces  $R_{Shoot}$  or  $R_{Root}$  per tissue DW (day and nighttime) during nonstressful conditions. Correspondingly, we also did not find an upregulation of respiratory substrates such as sugars in response to e[CO<sub>2</sub>]. A likely explanation for reduced dark respiration in response to rising [CO<sub>2</sub>] may involve lower protein turnover due to N dilution from increases in nonstructural carbohydrates or other organic compounds (Xu *et al.*, 2015); yet, in our study, the C : N ratio at 25°C derived from the sum of primary metabolites did not differ (Table S2). However, we found evidence that e[CO<sub>2</sub>] reduced protein content in needle and root tissues at the control temperature. Indeed, the CO<sub>2</sub> effect (at 25°C) disappeared when expressing  $R_{Shoot}$  per protein content. Because protein turnover is highly energy demanding, a lower protein content of plants under e[CO<sub>2</sub>] could reduce the respiratory costs of tissue maintenance (Drake *et al.*, 1999) and may contribute to increased net C uptake under well-watered conditions.

### Temperature acclimation of respiration affects tree C balance and is modulated by drought and [CO<sub>2</sub>]

The response of respiration to slowly increasing temperatures and VPD did not follow temperature kinetics of a single enzyme, which is exponential in a physiological temperature range (Bond-Lamberty *et al.*, 2004; Michaletz, 2018). By contrast, we found

**Fig. 8** Heat stress responses of selected primary metabolites and protein content in leaves and roots of *Pinus halepensis* seedlings. Shown are treatment averages of (a–d) sucrose and the sum of monosaccharides (glucose, fructose, and galactose), (e–h) malate and the sum of carboxylic acids (citrate, malate, fumarate, succinate, oxoglutarate, oxaloacetate), (i–l) pinitol and the sum of sugar alcohols (*myo*-inositol, pinitol, threitol, galactinol), (m–t) glutamate synthase amino acids (GOGAT) and the sum of (m–p) all measured amino acids including putrescine and (q–t) protein content. The shaded areas are ± 1 SE ( $n=8$ ).

respiration to acclimate to several days of heat stress. Moreover, we found that daytime respiration at 40°C was close to the initial rates at 25°C. This is in stark contrast to studies conducting fast temperature curves, which typically find respiratory peaks to occur at much higher temperatures (e.g. Gauthier *et al.*, 2014). However, an acclimation of leaf respiration to elevated growth temperatures has been reported in many instances (Reich *et al.*, 2016; Drake *et al.*, 2019), and  $R_{\text{Shoot}}$  has been shown to decline during consecutive heatwaves (Birami *et al.*, 2018). Likely explanations for the early downregulation of  $R_{\text{Shoot}}$  and  $R_{\text{Root}}$  that we have found in response to heat stress are: first, reduced respiratory demand due to downregulation of growth and maintenance respiration; second, adenylate restriction caused by ATP turnover decline; and/or third, reduced C availability (O'Leary *et al.*, 2019). Though our study cannot support respiration to be limited by reduced C availability as, for instance, carboxylic acids did not decrease in root tissues, we can clearly show that Aleppo pine trees are able to regulate respiratory losses to maintain a new equilibrium between C loss and uptake (Fig. 4). This was reflected in the whole-tree C balance stabilizing at an almost constant rate between 35°C and 40°C, with larger net C loss under drought conditions. An homeostatic linkage between photosynthesis and respiration to temperature has been suggested by a recent synthesis on a large number of studies (Dusenge *et al.*, 2019).

The impacts of  $e[\text{CO}_2]$  on respiration vanished with increasing heat stress in the well-watered trees; and after the respiratory peaks were reached, on average 1–2°C later under  $e[\text{CO}_2]$ , respiration did not differ between the  $[\text{CO}_2]$  treatments anymore. However, the effect of drought delaying the timing of the respiratory peak was more pronounced. Respiration was initially lower under drought until maximum rates were reached *c.* 2–6°C later than in the well-watered trees. The subsequent decline in respiration under drought was less pronounced, so that respiration of the drought and well-watered treatments converged. A similar delay of the respiratory peak in response to drought (although at much higher temperatures) has been found during rapid warming of eucalypt leaves (Gauthier *et al.*, 2014). In accordance with Gauthier *et al.* (2014), we found a declining ratio of  $A_{\text{Net}}$  to respiration but no indications for C depletion. In summary, this indicated that treatment differences (e.g. drought or  $[\text{CO}_2]$ ) in respiration were distinct at 25°C, but quickly subsided after maximum temperatures were surpassed. The underlying reasons are not clear; but strikingly, the trees maintained a new equilibrium between  $A_{\text{Net}}$  and respiration, and whole-tree net C loss in the well-watered treatments was  $< 0.1\% \text{ DW d}^{-1}$  and in the drought treatments  $< 0.2\% \text{ DW d}^{-1}$ , independent of the  $[\text{CO}_2]$ .

### Responses of WUE to elevated $[\text{CO}_2]$ , heat, and drought stress

The apparent lack of a  $[\text{CO}_2]$  effect on net C uptake under stress was counterbalanced by a very consistent  $\text{H}_2\text{O}$ -saving strategy, largely maintained throughout all temperature steps (Table S3). In the well-watered  $e[\text{CO}_2]$  trees,  $E$  remained constant with

increasing VPD and temperature. This was reflected in an improved WUE under  $e[\text{CO}_2]$ , which increased proportionally with  $a[\text{CO}_2]$  under well-watered conditions. Moreover, this increase in WUE was not only maintained but apparently increased with rising temperatures (on average, +77% at 25°C, 94% at 30°C, 95% at 35°C, and 133% at 40°C) and, therefore, agrees with our second hypothesis. Several strategies are reported to control WUE in plants (Lavergne *et al.*, 2019); and under rising  $C_a$ , three scenarios are typically proposed in which leaves maintain either constant  $C_i$ , constant  $C_a - C_i$ , or constant  $C_i : C_a$  (Saurer *et al.*, 2004). A variety of studies have reported constant  $C_i : C_a$  as a response to  $e[\text{CO}_2]$  during drought or other abiotic stresses (Ainsworth & Long, 2005; Kauwe *et al.*, 2013; Gimeno *et al.*, 2016). This agrees with our study, where  $C_i : C_a$  remained almost constant over the entire experimental temperature gradient in the well-watered seedlings. Constant  $C_i : C_a$  could indicate a feedback control on  $g_s$  from photosynthetic activity, for instance via temperature-induced downregulation of Rubisco (Crafts-Brandner & Salvucci, 2000). We observed similar  $C_i : C_a$  patterns in the drought treatments, with a tendency for a larger increase in WUE at 25°C. This  $\text{H}_2\text{O}$ -saving effect naturally disappeared when stomata closed almost fully at 30°C. Thus, hot drought quickly diminishes any  $\text{H}_2\text{O}$ -saving effect of  $e[\text{CO}_2]$ .

### Plant stress responses affected by elevated $[\text{CO}_2]$

Whole-tree gas-exchange of  $\text{H}_2\text{O}$  and  $\text{CO}_2$  revealed some interacting  $[\text{CO}_2]$  responses during drought and heat stress, most pronouncedly reflected in increased WUE. However, we found the benefits of  $e[\text{CO}_2]$  to vanish under more extreme heat or combined heat–drought stress. Recently, it has been shown that extreme drought can counterbalance any beneficial  $[\text{CO}_2]$  effects on C dynamics and  $\text{H}_2\text{O}$  relations (Duan *et al.*, 2013, 2015). In addition, more detrimental effects and larger leaf senescence in trees grown under  $e[\text{CO}_2]$  compared with  $a[\text{CO}_2]$  have been found during a hot drought event occurring naturally (Warren *et al.*, 2011). The underlying mechanisms are not yet understood, but excessive leaf-temperature stress under  $e[\text{CO}_2]$  due to lower  $g_s$  (and lower  $E$ ) are thought to be a possible explanation, increasing thermal stress (Bassow *et al.*, 1994; Warren *et al.*, 2011). As the well-mixed conditions inside the tree chambers in our study omitted large differences in surface needle temperatures (Table S1), we can exclude additional heating of  $e[\text{CO}_2]$  trees affecting metabolic stress responses.

Underlying mechanisms for the rather modest effect of  $[\text{CO}_2]$  on tree stress performance might be reflected in metabolic adjustments in needles and roots. Generally, we found the primary metabolome of roots and shoots to differ, which can be explained by the presence or absence of chemical pathways in specialized tissues like plastids (Li *et al.*, 2016). Elevated  $[\text{CO}_2]$  tended to mitigate the drought response at 25°C in needle tissues, which fits well to overall  $\text{H}_2\text{O}$ -saving strategy (e.g. WUE; see Table 2). However, the response to heat stress was distinct but not altered by  $e[\text{CO}_2]$ . For instance, we found *myo*-inositol to decline as a typical precursor of osmotic active substances like pinitol and galactinol (Nishizawa *et al.*, 2008). Together with proline, these

metabolites contribute to thermostability of membranes and proteins (Nishizawa *et al.*, 2008; Zinta *et al.*, 2018). In contrast to needles, root metabolites showed distinct responses to stress, as seen in highly elevated levels of soluble sugars and amino acid increase with heat and drought stress. The apparently greater drought sensitivity of roots was also reflected by a lower root biomass but higher overall metabolite C content than in the well-watered trees (Table 1), indicating that root growth halted during drought and that available C was mainly invested into osmoregulation. Possible explanations may involve reduced C transport from source to sink tissues (Ruehr *et al.*, 2016; Brauner *et al.*, 2018) and a larger hydraulic vulnerability of roots (Johnson *et al.*, 2016).

We found some indications for e[CO<sub>2</sub>] to potentially mitigate stress-induced metabolic responses, in agreement with others (Zinta *et al.*, 2014, 2018). In particular, e[CO<sub>2</sub>] seemed to lessen the heat-induced changes in monosaccharides and amino acids in roots. Similarly, Zinta *et al.* (2018) reported a dampened response of sugars and amino acids to combined heat–drought stress in *Arabidopsis thaliana* grown under e[CO<sub>2</sub>]. Hence, the larger increase in amino acid concentrations in roots from trees grown under a[CO<sub>2</sub>] in our study could be triggered by protein degradation, which was suggested by a decline in protein content while asparagine accumulated (Brouquisse *et al.*, 1992). Heat stress has been found to decrease root protein content, as protein degradation rates at high temperatures typically exceed protein synthesis (Huang *et al.*, 2012). A greater protein stability is assumed to improve the thermotolerance of plants but may come at the cost of increased maintenance. Interestingly, we found a greater stability of root protein content under e[CO<sub>2</sub>] with heat stress, but the average root protein content as well as  $R_{\text{root}}$  at 40°C did not differ between a[CO<sub>2</sub>]W and e[CO<sub>2</sub>]W. This may indicate an active downregulation of protein turnover in a[CO<sub>2</sub>] trees to reduce the C cost of maintenance respiration. Counterintuitively, we found protein content in needle tissues to increase at temperatures  $\geq 35^\circ\text{C}$  in all treatments. It is noteworthy that e[CO<sub>2</sub>] trees, which had a lower protein content at 25°C, exhibited a relatively greater increase in protein content with heat stress. This increase in soluble protein might be due to an upregulation of heat-shock proteins (Aspinwall *et al.*, 2019) to prevent failure of the photosynthetic apparatus (Escandón *et al.*, 2017) or could be caused by N remobilization for Rubisco, which can explain up to 30% of changes in total protein (Warren & Adams, 2001). In summary, we found the stress response of the primary metabolome to be highly tissue specific and to be largely independent of growth [CO<sub>2</sub>] in contrast to our third hypothesis. However, we detected some indications for a slightly enhanced thermotolerance under e[CO<sub>2</sub>] reflected in a larger upregulation of needle proteins and improved stability of root proteins, at the expense of lower amino acid accumulation.

## Conclusion

Growing Aleppo pines for 18 months under e[CO<sub>2</sub>] of *c.* 870 ppm had a stimulating effect on tree biomass (+40%), but did not result in larger tree H<sub>2</sub>O loss due to reductions in

stomatal conductance reflected in a nearly proportional increase in WUE maintained throughout a 10 d heatwave (25°C, 30°C, 35°C, 38°C, 40°C). Drought stress initially amplified the e[CO<sub>2</sub>] effect on WUE until stomata closed at higher temperatures. Considering the tree C balance, we found a stimulation of the net C uptake under e[CO<sub>2</sub>] largely due to reduced tissue respiration alongside lower protein content. Nevertheless, respiration responded independent of [CO<sub>2</sub>] to heat stress with an initial increase followed by a decline above 31–34°C. Photosynthesis decreased simultaneously, and the trees started to lose C above 30°C, irrespective of [CO<sub>2</sub>]. Elevated [CO<sub>2</sub>] had only a modest effect on the stress response of the primary metabolome, which differed among tissues. Interactive effects between [CO<sub>2</sub>] and heat stress became visible via lower protein degradation in roots under e[CO<sub>2</sub>], indicating an improved thermotolerance. In summary, we could show that a doubling of atmospheric [CO<sub>2</sub>] has little influence on Aleppo pine seedling responses to heat, drought, or hot drought stress. Though our study is restricted to physiological responses of seedlings, the results have implications for model development, which are two-fold: the effect of atmospheric [CO<sub>2</sub>] on tree physiological responses decreases with stress intensity, such as hot drought; and respiration acclimates to heat stress within days and the relationship with temperature is independent of [CO<sub>2</sub>] but altered by drought. In order to more accurately assess mitigating effects of e[CO<sub>2</sub>] on drought stress responses of Mediterranean-type forests, e[CO<sub>2</sub>]-induced changes of whole tree C allocation affecting tree H<sub>2</sub>O uptake and H<sub>2</sub>O loss need to be considered.

## Acknowledgements

We would like to thank Andrea-Livia Jakab, Lisa Fürtauer, and Romy Rehschuh for assistance with the experimental set-up and lab work and Daniel Nadal-Sala for help with statistical analyses. We are also grateful to Dan Yakir and his team members for access to the Yatir research site and fruitful scientific discussions. Further, we would like to thank Wolfram Weckwerth and the Department of Molecular Systems Biology (University of Vienna, Austria) who provided us with the expertise and the infrastructure to conduct the metabolome analysis. This work was supported by the German Research Foundation through its German–Israeli project cooperation program (SCHM 2736/2-1 and YA 274/1-1) and by the German Federal Ministry of Education and Research, through the Helmholtz Association and its research program ATMO. BB received additional support from the Graduate School for Climate and Environment, and NKR acknowledges support from the German Research Foundation through its Emmy Noether Program (RU 1657/2-1).

## Author contributions

AA, BB and NKR designed the study. BB conducted the experiment and analyzed the data with support from AG, MG, TN, YP and NKR. BB and NKR wrote the paper with contributions from all co-authors.

## Data availability statement

The gas-exchange data have been made available through PANGAEA® Data Publisher for Earth & Environmental Science: <https://doi.pangaea.de/10.1594/PANGAEA.910582>. Metabolite data will be made available upon request.

## About *New Phytologist*

- *New Phytologist* is an electronic (online-only) journal owned by the New Phytologist Trust, a **not-for-profit organization** dedicated to the promotion of plant science, facilitating projects from symposia to free access for our Tansley reviews and Tansley insights.
- Regular papers, Letters, Research reviews, Rapid reports and both Modelling/Theory and Methods papers are encouraged. We are committed to rapid processing, from online submission through to publication 'as ready' via *Early View* – our average time to decision is <26 days. There are **no page or colour charges** and a PDF version will be provided for each article.
- The journal is available online at Wiley Online Library. Visit **www.newphytologist.com** to search the articles and register for table of contents email alerts.
- If you have any questions, do get in touch with Central Office (np-centraloffice@lancaster.ac.uk) or, if it is more convenient, our USA Office (np-usaoffice@lancaster.ac.uk)
- For submission instructions, subscription and all the latest information visit **www.newphytologist.com**
