Highlights

- Pesting resistance is obtained at 800 °C for Cr-13.5Si-32.2Mo (at.%)
- Monolithic σ phase in Cr-Si-Mo system decomposes into A2 solid solution and A15 intermetallic
- Outstanding oxidation at 800 °C and reasonable oxidation resistance up to 1200 °C is obtained for 100 h
- Protective Cr_2O_3 scales form, no nitridation or spallation occurs at 800 - 1200 °C up to 100 h

Abstract

1 Cr-13.5Si-32.2Mo (at.%) solidifies as metastable σ-phase with a dendritic microstructure during arc
2 melting. Heat treatment leads to a decomposition into a fine-lamellar microstructure of $(Cr,Mo)_{ss}$ and
3 $(Cr,Mo)_3Si$. A protective Cr_2O_3 layer with low growth rates was formed upon cyclic oxidation at 800,
4 1100 and 1200 °C for up to 100 h. In addition to the Cr_2O_3 layer, the formation of an internal silicon
5 oxide layer is found for 1200 °C. Oxidation scales show parabolic growth rates at 1100 and 1200 °C.
6 Up to 100 h, the oxidation occurred remarkably free of nitridation, spallation or pesting.

Cr-Si-Mo, Cyclic Oxidation, Pesting Resistance, Silicides, σ Phase

1 Introduction

7 To further improve the efficiency of turbines, it is inevitable to develop new high temperature structural
8 materials, which can exceed the operation temperatures of currently used Ni-based alloys. Hence,

9   refractory metals and alloys have come into focus of research due to their high melting points. However,
10 refractory metal alloys usually suffer from poor oxidation resistance at elevated temperatures [1] [1].
11 Significant progress with respect to the oxidation resistance was made in the development of oxidation-
12 resistant Mo-Si-Ti alloys [2–4]. Unlike other Mo-Si-based alloys with volume fractions of the solid
13 solution around or beyond 50 %, some eutectic and eutectic-eutectoid Mo-Si-Ti alloys were found to
14 withstand catastrophic failure in the so-called pesting regime around 800 °C, when the formation of
15 volatile MoO_3 becomes dominant and therefore detrimental to the material. Those pesting-resistant Mo-
16 Si-Ti alloys form protective scales consisting of a mixture of TiO_2 and SiO_2 [2,4], despite the expected
17 non-protective nature of TiO_2 at high temperatures [5–7].

In Ref. [3] it was shown, that pesting resistance in Mo-Si-Ti alloys is mainly determined by the Ti
content. A minimum Ti content of 34 at.% in the solid solution and 43 at.% in the nominal alloy
composition is required. However, even in pesting resistant Mo-Si-Ti alloys, phase specific oxidation
of the Ti containing Mo solid solution is observed. At the transition between pesting and pesting-
resistant compositions, the microstructural dimensions also influence pesting resistance. These fine-
lamellar, two-phase microstructures consist of a body centered cubic (bcc) solid solution
(Strukturbericht A2, W prototype, space group no. 229) and hexagonal or tetragonal silicides ($D8_8$,
Mn_5Si_3, no. 193 or $D8_m$, W_5Si_3, no. 140), respectively. Hence, they may profit from the high temperature
strength and oxidation resistance of the intermetallic phases, while the high amount of bcc solid solution
promises processing capability. Therefore, future alloy design should focus also on other fine-lamellar
microstructures consisting of a solid solution and an intermetallic compound. New alloy strategies need
to address the question, how similar microstructural features compare to the Mo-Si-Ti alloys with
respect to the oxidation resistance in the pesting regime and if selective oxidation of the solid solution
phase can be minimized or avoided through a homogeneous distribution of the passivating elements
between the solid solution and intermetallic phases.

As the large amount of Ti leads to an unexpectedly protective oxide scale, similar or even superior
results might be achieved through alloying with elements, which are considered passivating such as Cr.
Alloying with Cr (instead of Ti) to produce a protective Cr_2O_3 scale is promising for several reasons: (i)
There is a complete solubility in the binary Mo-Cr system similar to the Mo-Ti at high temperatures [8].
(ii) With 1907 °C, the melting point of Cr is higher than that of Ti and the solid solution strengthening
in binary $(Cr,Mo)_{ss}$ (A2, W, no. 229) is stronger than in Mo-Ti [9]. These two aspects indicate even
better high temperature mechanical properties than of the eutectic Mo-Si-Ti alloy [2]. Regarding the
intermetallic phase, desired by the alloy strategy, $(Cr,Mo)_3Si$ (A15, Cr_3Si, no. 223) is obtained [10] with
a complete solubility between Mo_3Si and Cr_3Si. The $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ notations are used
throughout the manuscript to emphasize that Mo is in solution in both phases, substituting Cr sites. Due
to the complete solubility of both constituting phases, a ternary, two-phase alloy consisting of $(Cr,Mo)_{ss}$
and $(Cr,Mo)_3Si$ might, thus, enable the homogenous formation of a Cr_2O_3 scale and protect the Mo-rich
solid solution from pesting.

Although the oxidation behavior of pure Cr, Cr-Si alloys as well as Mo-Si alloys, have been studied in
literature already, there is not much data on the oxidation behavior of Cr-Mo solid solutions, nor Cr-
Mo-Si for Si contents of < 24 at.% with high amounts of Mo-rich solid solution. For an overview on the
challenges in developing high temperature alloys in both alloy systems, the reader may be referred to
Refs. [1,11,12]. For pure Cr, it is known at elevated temperatures not only Cr_2O_3 is formed, but volatile
CrO_3 as well [13]. At temperatures above 1000 °C, the rate of CrO_3 evaporation becomes faster than the
rate of Cr diffusion through the oxide to react with oxygen so that the oxide layer loses its protectiveness
[13]. Apart from this, a large volume misfit between Cr and its oxide and differences in thermal

54 expansion, were claimed responsible for the deterioration of the adhesion between oxide and substrate,
55 leading to massive spallation [14]. Additionally, the inward diffusion of N led to the formation of a
56 nitride layer below the outer Cr_2O_3 scale [15]. Alloying Cr with Si and/or Mo improves the oxidation
57 and nitridation resistance [16]. The majority of oxidation experiments with relevance to the Cr-Si-Mo
58 system have however been carried out with compositions either in or close to the binary Cr-Si system
59 [11,17,18] or with high Si contents in the ternary system [19–21], thus avoiding the occurrence of large
60 amounts of a Mo-containing solid solution.

61 Rudy and Nowotny [22] revealed that in the ternary Cr-Si-Mo system a σ phase ($D8_b$, Cr_6Fe_7, no. 136)
62 forms under non-equilibrium, fast cooling conditions in the composition range from 57Cr-29Mo-14Si
63 to 39Cr-47Mo-14Si (unless stated otherwise at.% are used throughout the article). Heat treatments above
64 1150 °C lead to a decomposition of the σ phase solid state reaction, forming a fine-lamellar
65 microstructure of $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ [22].

66 Hence, with respect to the Cr-Si-Mo system, the aforementioned research questions are refined to

67 i.   How do fine-lamellar Mo-Si-Cr alloys compare to similar Mo-Si-Ti or Cr-based alloys with
68   respect to oxidation resistance, especially in the pesting regime at about 800 °C with potential
69   MoO_3 evaporation [23,24] and beyond 1000 °C where CrO_3 starts to evaporate [11,25]?
70 ii. How does solute partitioning of Cr in Mo-Si-Cr compare to Ti in Mo-Si-Ti in view of the
71   continuous phase fields of $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ and does a homogeneous distribution of Cr
72   lead to a uniform oxidation of both phases?

2 Experimental and materials

2.1 Material synthesis

73 The Cr-13.5Si-32.2Mo alloy was identified as composed of σ phase only in preliminary work and,
74 therefore, synthesized from pure Mo foils (EVOCHEM, 99.95 %) Si pieces (ChemPur, 99.99 %) and Cr
75 granules (ChemPur 99.99%) by arc melting. Arc melting was performed using an AM/0,5 Arc Melter
76 (Edmund Bühler GmbH), equipped with a water-cooled Cu crucible for ingot casting. The chamber was
77 evacuated and flooded with Ar of > 99.998 % purity at least three times. In the last evacuation cycle,
78 the chamber was pumped down to less than $1·10^{-4}$ mbar. Subsequently the chamber was vented with Ar
79 to a base pressure of 600 mbar for arc melting. The ingots were flipped and remelted five times to ensure
80 homogeneity. To evaluate the as-cast microstructure, samples were taken for microstructural analyses.
81 Prior to all oxidation experiments, the ingots were heat treated for 100 h at 1200 °C in a protective Ar
82 atmosphere (> 99,998 % purity). For heat treatments, a HTRH 70-600/18 resistance tube furnace
83 (Carbolite GeroGmbH & Co. KG) was used. To protect the ingots from impurities in the Ar atmosphere
84 Ti sponge was used as getter material in the tube furnace. No O uptake was detected.

2.2 Microstructure analysis

85 Samples for microstructural analysis in the as-cast (AC), heat-treated (HT) and oxidized condition were
86 cold mounted in VariKem 200 resin, ground to grit P2500 with SiC grinding paper followed by 3 and
87 1 μm diamond polishing steps. Surface finish was achieved using a colloidal OP-S suspension (Buehler
88 ITW). Backscattered electron contrast imaging (BSE) micrographs of AC and HT as well as the oxide
89 scales were taken at 20 kV on a LEO Gemini 1530 (Carl Zeiss AG) scanning electron microscope
90 (SEM). Volume fractions of solid solution and silicide phase in the HT condition were determined from
91 BSE micrographs using the open source image processing software ImageJ (version 1.53c) [26]. SEM-
92 based energy-dispersive X-ray spectroscopy (SEM-EDS) was performed on an Auriga 60 (Carl Zeiss

93　AG) SEM equipped with an Octane Super EDS detector. For EDS analysis the SEM was operated at 14
94　kV acceleration voltage.

95　The phases present in the bulk material, as well as the phases formed during cyclic oxidation were
96　investigated through X-ray diffraction (XRD) using a D2 Phaser (Bruker). The XRD device is equipped
97　with a LynxEye line detector and the Cu tube was operated at 30 kV and 10 mA. The scans were
98　performed at a step size of $0.01°$ in 2Θ. The cubic lattice parameters of the $(Cr,Mo)_{ss}$ and the $(Cr,Mo)_3Si$
99　were determined by extrapolating towards $\Theta = 90°$, using the weight function $\frac{1}{2}(\cot^2\Theta + \cot\Theta\cos\Theta)$
100　similar to Nelson and Riley (NR) [27]. In addition, the chemical composition/Cr/Mo ratio was
101　determined by back calculations. For microstructure and NR analysis of the AC and HT condition, XRD
102　was performed on bulk cross sections, which were ground to grit P2500. Oxide scale XRD analysis was
103　performed on the as-oxidized sample surface without any further metallographic preparation.

104　Energy dispersive X-ray spectroscopy (EDS) using a transmission electron microscope (TEM) was used
105　to determine the local chemical composition of the individual phases in the non-oxidized HT condition
106　and to analyze the oxide scale after cyclic oxidation at 800 °C for 100 h. A TEM lamella was prepared
107　using a FEI Strata 400S Focused Ion Beam with a Ga Ion source. EDS was performed on a FEI Osiris
108　TEM in high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM)
109　mode with an acceleration voltage of 200 kV. The EDS spectra are quantified in an automatic manner
110　using standard procedure implemented in the Bruker Esprit 2.3 software employing thin film
111　approximation of the TEM lamella with theoretical Cliff-Lorimer parameters.

2.3 Cyclic oxidation

112　Prior to oxidation in air, cuboidal samples of $(5 \times 5 \times 5)$ mm^3 in dimensions were cut from HT material
113　by electrical discharge machining. All sides of the cuboids were ground to grit P2500 after machining
114　in order to avoid any influence by the prior treatment of the material. Before oxidation, the sample
115　surface area was obtained through area measurements using the software Olympus Stream Enterprise
116　1.7 (Olympus) and a Wild-Heerbrugg M420 optical macroscope. For cyclic oxidation HT material was
117　used exclusively. Cyclic oxidation was performed at 800 (pesting regime), 1100 (potential limit of
118　operation of the present alloy), and 1200 °C (significant evaporation of chromia is expected) in
119　laboratory air using muffle furnaces (Gero and Nabertherm). The duration and sequence of oxidation
120　cycles was performed according to the scheme described in Ref. [28]. Mass changes of the oxidation
121　samples were tracked after each oxidation cycle using a Sartorius precision balance with an accuracy of
122　1 µg up to a total duration of 100 h. Oxide scale thicknesses were determined by processing BSE
123　micrographs of sample cross sections using ImageJ

3 Results

3.1 Microstructure and chemical composition

124　The overall chemical composition of the arc-melted ingot was analyzed through EDS analysis to be
125　(55.0 ± 0.2)Cr-(13.3 ± 0.1)Si-(31.7 ± 0.3)Mo. The deviation from the nominal composition is considered
126　to lie well within the limits of EDS measurements. Figs. 1a and b show BSE micrographs of the alloy
127　in the AC and HT condition with an overview in the upper part of the image and magnifications below.
128　The corresponding XRD patterns are shown in Figs. 1c and d. In the AC condition, a dendritic
129　microstructure for Cr-13.5Si-32.2Mo is obtained as seen in Fig. 1a. The dendritic and interdendritic
130　regions exhibit continuous transitions in BSE (atomic number Z) contrast. Results from SEM-EDS point
131　analysis of the bright and dark regions in the BSE micrographs are presented in Tab. 1. At least three

measurements were taken and averaged in each region. The Si content varies by only 3 at.% between the two regions, whereas the Cr and Mo content vary by roughly 10 at.%. XRD analysis reveals a monolithic tetragonal σ phase, represented by green triangles in Fig. 1c, in agreement with Rudy and Nowotny [22] for a similar composition range in the Mo-Si-Cr system. The difference in Cr and Mo content between the apparently brighter and darker regions (in BSE) do not significantly affect the lattice parameters.

Figs. 1b and d prove the solid state decomposition of the σ phase during a heat treatment in protective Ar atmosphere at 1200 °C for 100 h. In the HT condition, no σ phase is detected anymore. The HT material consists of $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ with (44 ± 2) and (56 ± 2) vol.%, respectively, as determined by binarization and pixel analysis of BSE micrographs. The STEM HAADF inlet in Fig. 1b represents a cross section through the lamellar microstructure. The pattern in the light grey $(Cr,Mo)_{ss}$ lamellae is an artefact from FIB sample preparation. With the NR analysis of the XRD pattern, the cubic lattice parameters a for $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ were determined. Fig. 2 depicts the literature lattice parameters of binary $(Cr,Mo)_{ss}$ (Fig. 2a) and quasi-binary $(Cr,Mo)_3Si$ intermetallic solutions (Fig. 2b) as a function of the dissolved Cr content in the respective phase as black lines. The lattice parameter of pure Mo marks the left axis of Fig 1a. By alloying Cr to Mo, Mo sites in the solid solution are substituted by Cr atoms, hence decreasing the lattice parameter. A similar trend applies to the quasi-binary intermetallic solution in Fig. 2b with the left and right axis marking the lattice parameter of Mo_3Si and Cr_3Si, respectively. The progression of a was used to estimate the chemical composition of each phase in HT Cr-13.5Si-32.2Mo. The points in Figs. 2a and b indicate the determined lattice parameters of the two phases present in Cr-13.5Si-32.2Mo, e.g. 3.006 Å for $(Cr,Mo)_{ss}$ and 4.696 Å for $(Cr,Mo)_3Si$. These are in good agreement with Ref. [22], reporting a to lie between 2.98–3.02 Å for $(Cr,Mo)_{ss}$ and 4.69–4.71 Å for $(Cr,Mo)_3Si$ for phases within a similar composition range. The corresponding ranges of Cr contents of constituting phases in the present alloy are marked by blue and red shaded regions on the composition axis. These were recalculated considering a conservative error of lattice parameter determination of ± 0.005 Å, not further resolving the inhomogeneous Cr concentrations by the dendritic microstructure that are *not* homogenized during the heat treatment (see Fig. 1a). The change in lattice parameter by Si is small and therefore neglected in the present analysis [29,30]. The arrows show the nominal Cr content in the alloy for comparison. Furthermore, the results for the alloy's chemical composition obtained through SEM-EDS, TEM-EDS and NR analysis of $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ phase are listed in Tab. 1.
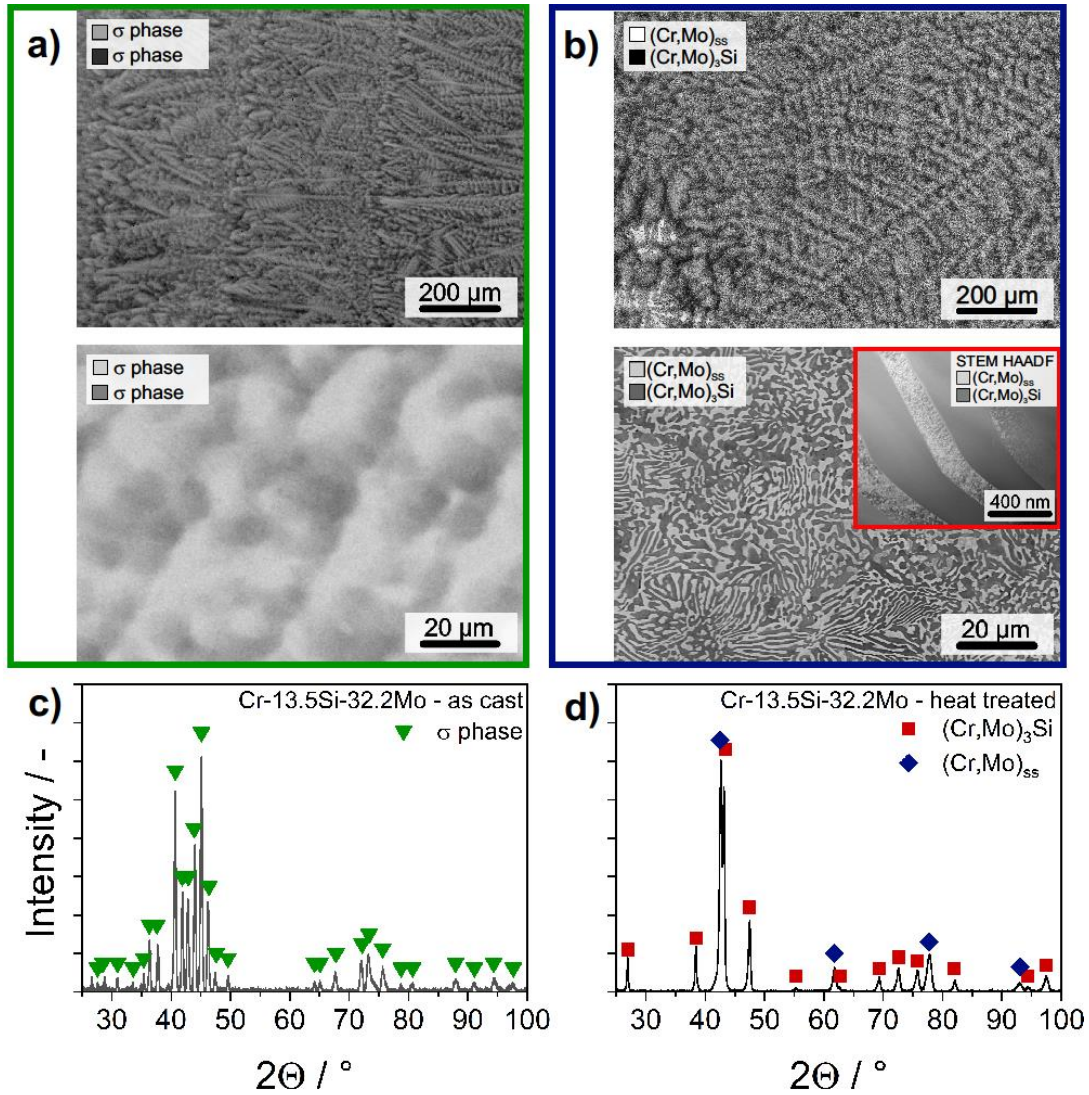

Fig. 1: BSE micrographs, overview and magnifications of a) the AC microstructure (almost monolithic σ phase with dendritic microstructure) and b) HT microstructure (fine-lamellar, two-phase microstructure). The inset in b) shows a STEM HAADF image of the lamellar regions. c) and d) show corresponding XRD patterns with peak positions of the identified phases.

Tab. 1: Chemical composition of the alloy and compositions of the constituting phases in the AC and HT condition according to SEM-EDS, STEM-EDS and back calculation from XRD. Errors noted for SEM- and STEM-EDS represent the standard deviations of at least three individual measurements.

|	Phase/Region	Method	Mo / at.%	Si / at.%	Cr / at.%	Mo/Cr ratio
Desired composition	Total	–	32.2	13.5	54.3	0.59
Experimental composition		SEM-EDS	31.7 ± 0.3	13.3 ± 0.1	55.0 ± 0.2	0.58
AC	σ, light grey	SEM-EDS	37.0 ± 0.7	12.1 ± 0.1	50.9 ± 0.6	0.73
	σ, dark grey		24.4 ± 1.0	15.3 ± 0.2	60.3 ± 0.8	0.40

		XRD		–		0.55
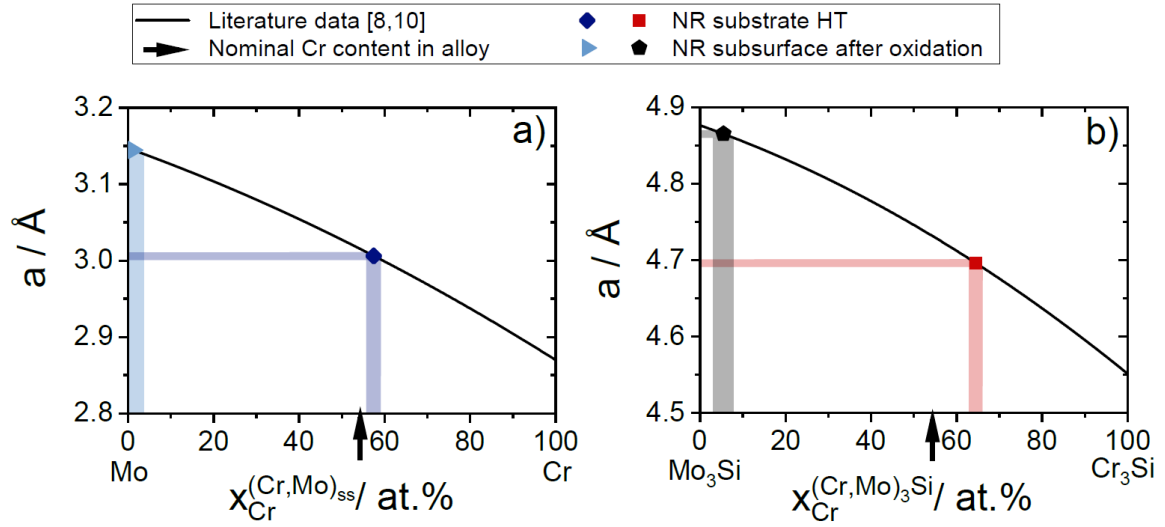

Fig. 2: Lattice parameters a in the binary $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ solutions. Black lines represent literature data from Refs. [8,10]. Lattice parameters a of the respective phases in Cr-13.5Si-32.2Mo, determined from XRD patterns by NR analysis are projected to the literature reference with an error of ± 0.005 Å as highlighted by horizontal bars. This corresponds to a range of Cr content, indicated by the vertical columns. The arrows indicate the nominal overall Cr content in the alloy. The light blue and black symbols on the Mo-rich sides, belong to surface-near solid solution and silicide seen in oxidized samples that are significantly depleted in Cr due to the oxidation process.
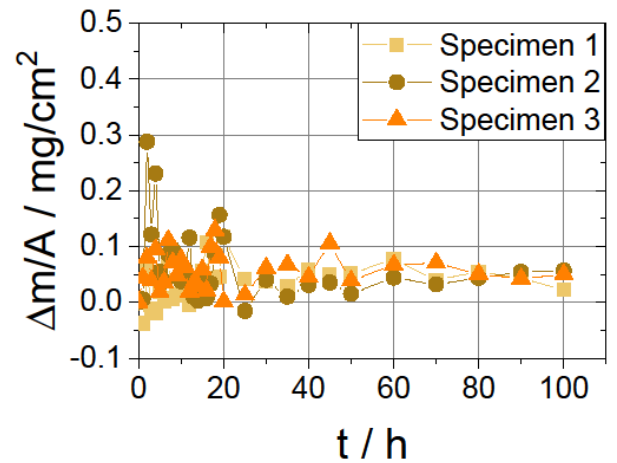

3.2 Cyclic oxidation

163   Fig. 3a displays a selection of oxidation samples after oxidation for 100 h for the temperatures tested.
164   Figs. 3b-d show the specific mass change as a function of time during cyclic oxidation at 800 (pesting
165   regime), 1100 (potential limit of operation of the present alloy), and 1200 °C (significant evaporation of
166   chromia is expected) for three samples tested at each temperature. Figs. 4a-d shows BSE images of cross
167   sections of oxidized specimen after various oxidation times. STEM-EDS and SEM-EDS mappings of
168   the oxidation scales forming at 800, 1100 and 1200 °C are shown in Figs. 4e, f and g. The diffraction
169   patterns obtained for the oxidized Cr-Si-Mo samples after 100 h of cyclic oxidation are given in Fig. 5.
170   As indicated by the orange circles in Fig. 5, α-Cr_2O_3 chromia (corundum prototype, no. 167) was
171   identified to form as a top layer at all temperatures.
Fig. 3: a) Macroscopic sample images after 100 h at 800, 1100, 1200 °C and specific mass change for cyclic oxidation in laboratory air up to 100 h at b) 800, c) 1100 and d) 1200 °C. Note the different scaling of the diagram for 800 °C in c.
Fig. 4: BSE micrographs of the oxide scales forming during 100 hours of cyclic oxidation at a) 800, b) 1100 and 1200 °C as well as after c) 10 and d) 100 h. Subscale porosity is seen in b)-d). e) STEM-EDS mapping of the oxide scales after 100 h cyclic oxidation at 800 °C. ZAF quantified SEM-EDS element mappings of the oxide scales after 100 h at f) 1100 and g) 1200 °C. Continuous white lines indicate the borders of the oxide scale, the dashed lines below indicate the Cr depleted region. In g), a dashed line is added to mark the internal corrosion.

Oxidation experiments at 800 °C reveal that the sample surface still appears metallic with a green tinge after 100 h. The mass gain of the three samples is very small and remains below 0.1 mg/cm^2 (Fig. 3b) after this period of time. Oxidation at 800 °C leads to an extremely thin continuous surface layer of less than 1 μm in thickness after 100 h (see Fig. 4a). There is no indication of internal oxidation. In the XRD analysis in Fig. 5a, not only α-Cr$_2$O$_3$ is identified but also (Cr,Mo)$_{ss}$ and (Cr,Mo)$_3$Si. The Bragg peaks of either phase are marked with dark blue diamonds (Cr,Mo)$_{ss}$ and red sqares (Cr,Mo)$_3$Si in the diffraction pattern in Fig. 5a. Additionally, a second solid solution (Cr,Mo)$_{ss}$ with a lattice parameter a of 3.144 Å is identified. It is indicated by light blue triangles in the diffraction pattern. The recalculated Cr concentration of this Mo-rich subsurface solid solution is added to Fig. 2a. STEM-EDS element maps confirm a Mo-rich, Cr-depleted, subsurface layer. Additionally, an extremely thin Si oxide layer formation is observed at the interface between bulk material and Cr$_2$O$_3$. The former homogeneous solid solution obviously decomposes into a Mo-rich and Cr-rich solid solution with a lamellar or stripe-like microstructure. This was observed in TEM close to the surface but also for regions deeper in the substrate (not shown here) after cyclic oxidation at 800 °C.

186   At 1100 °C, the sample surface appears dark and rough after 100 h, as seen in Fig. 3a but no spallation
187   of the oxide scale is observed. Mass gain of all three samples tested is in the same order of magnitude.
188   It is less than 1.5 mg/cm^2 after 100 h. From the BSE micrograph in Fig. 4b, it can be concluded that a
189   continuous surface layer of about (4.8 ± 1.4) µm is formed. Furthermore, the formation of pores below
190   the outer scale is observed but there is still no indication of internal oxidation similar to oxidation at
191   800 °C. The presence of α-Cr_2O_3, a solid solution $(Cr,Mo)_{ss}$ with $a = 3.144$ Å and a silicide phase
192   $(Cr,Mo)_3Si$ with $a = 4.865$ Å is obtained from XRD. The oxide scale formed at 1100 °C consists solely
193   of Cr and O. Mo and Si are detected predominantly in the substrate's microstructure with a sharp
194   boundary to the oxide regions. A significant Cr depletion below the outer oxide scale is obtained. Mo
195   and Si are enriched in this region. The partitioning of Si to solid solution and silicide vanishes and Si is
196   distributed homogeneously in the Cr-depleted region.

197   Samples, which were oxidized for 100 h at 1200 °C, present a dark rough surface with a similar
198   macroscopic appearance as for 1100 °C. Again, no spallation is observed up to 100 h of oxidation. As
199   shown in Fig. 3d, mass gain is observed until 50 h of oxidation time, followed by a mass loss for the
200   next 30 h, succeeded by only very small overall mass changes are measured after 80 h until 100 h of
201   oxidation time. Figs. 4c and d show BSE images of the scales forming at 1200 °C after 10 h and 100 h,
202   respectively. After 10 h, there is a continuous oxide scale of uniform thickness of (3.4 ± 0.9) µm. After
203   100 h, pronounced internal corrosion appears below the surface layer. The surface layer has a thickness
204   of (7.9 ± 2.0) µm. As shown in Fig. 4d, the depth of the internal corrosion varies strongly with a median
205   thickness of (6.6 ± 2.8) µm. Below the internal corrosion region the two-phase microstructure disappears
206   and pores have formed. The only phase identified by XRD is α-Cr_2O_3. The SEM-EDS mappings
207   depicted in Fig. 4f show the distinct difference between the chemical composition of the outer oxide
208   layer and the region of internal corrosion. The specimen surface and the boundary between the scale and
209   the substrate are indicated with continuous white lines. The dashed white lines in the scale mark the
210   boundary between the chromia scale and the Si-enriched oxide region, potentially being an internal
211   corrosion region. Again, the outer chromia scale contains neither Mo nor Si and the XRD analysis (see
212   Fig. 5c) confirms the formation of Cr_2O_3. No other crystal structures are detected.

Fig. 5: Diffraction patterns of the oxide scales formed on the samples after 100 h of cyclic oxidation.

4 Discussion

4.1 Synthesis and microstructure

Analysis of the AC and HT microstructures showed that it is possible to synthesize monolithic σ phase via arc melting. A full decomposition into $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ is achieved through a heat treatment, despite the dendritic AC microstructure. In the HT microstructure, there is no pronounced difference of Cr contents in the two phases. According to STEM-EDS analysis, the difference in Cr contents between the A2 and A15 phase in HT condition are only about 5 at.%. Therefore, Cr is equally available for the formation of a chromia layer from both phases and can prevent site-specific oxidation

11

of the Mo containing A2 phase in cyclic oxidation at 800 °C. In this respect, the situation is different from pesting-resistant Mo-Si-Ti alloys which exhibit significant difference in Ti and Si content and oxidize to TiO_2 and SiO_2 mixed oxide scales.

There are only incomplete assessments of the ternary Cr-Mo-Si phase diagram available in literature, for example in Ref. [31]. Information on the σ phase therein is limited basically to the report by Rudy and Nowotny [22]. Based on the reported solubility and stability ranges of binary $(Cr,Si)_{ss}$ (6.7 at.% Si [32]) and $(Mo,Si)_{ss}$ (0.3 at.% Si [33]) as well as Mo_3Si (~24 at.% [34]) and Cr_3Si (22.9 to 25.6 at.% [32]) at 1200 °C, Fig. 6 was constructed using data from the present study and the literature data. The binary limits at 1200 °C were linearly interpolated although Ref. [31] suggests a slightly concave shape at least for the solid solution at 1300 °C. Note that the present results extend the reported information on the σ phase from Ref. [22] with respect to: (i) slightly higher possible Cr contents (than for the suggested stability range at 1500 °C of Cr-(47-29)Mo-14Si in Ref. [22][1]), (ii) larger stability range of Si contents (ditto) and (iii) most importantly, the formation of the σ phase from the liquid in the Mo-Si-Cr system (as unknown so far [31], since Ref. [22] only reported on microstructures after long-term annealing treatments). The compositions of the solid solution and silicide phase after complete decomposition at 1200 °C are included as well. There is a slight deviation of the experimentally obtained composition ranges and the tie line connecting the phase compositions of $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ across the nominal composition of the alloy after long-term annealing (expected to be an almost vertical tie line in Fig. 6). This might be probably due to an underestimation of the Cr content in the solid solution by the applied methods in this study and the still inhomogeneous Cr distribution following the dendritic solidification of the σ phase that was not removed by the 1200 °C annealing.

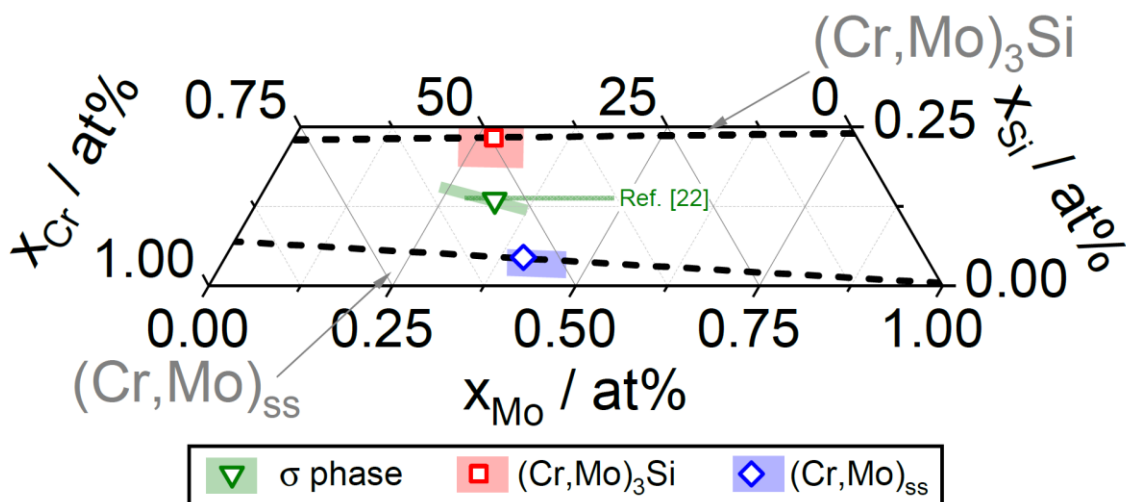

Fig. 6: Summary of the gained phase stability information. A monolithic σ phase is obtained for the nominal composition indicated by the triangle. The green shaded region indicates the range of compositions obtained in the dendritic AC microstructure. The proposed stability range of the σ phase at 1500 °C taken from Ref. [22] is included for comparison. The two-phase microstructure of $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ is obtained after prolonged annealing at 1200 °C. The shaded regions indicate the composition ranges summarized in Tab. 1. Phase compositions of $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ at 1200 °C were obtained by linear interpolation of the binary limits reported in literature.

---

[1] Note the wrong transfer of the reported stability range of the σ phase by Rudy and Nowotny [22] to Ref. [31].

242 The chemical compositions obtained by SEM and STEM-EDS analysis in general, listed in Tab. 1,
243 deviate from the re-calculated Cr and Mo content via NR analysis. In case of SEM-EDS, the discrepancy
244 originates from the fine-lamellar microstructure and comparably large probe size. It is likely that the
245 probe volume includes both phases. The lamella for STEM-EDS however, only represents a very small,
246 selected sample volume. As seen in Figs. 1a and b, the dendritic microstructure from AC is still present
247 in the HT condition. The dendrites can still be obtained in the overview micrograph of the HT state and,
248 thus, the STEM-EDS result represents information from the Cr depleted regions.

249 Apart from the successful synthesis of the desired fine-scaled, two-phase microstructure, two major
250 issues are identified with respect to sample manufacturing and conditioning, that are:

251 (i)   Incomplete decomposition of the σ phase during the heat treatment might be obtained
252   depending on the dendrite size. In case of increased ingot size for the alloy, longer heat
253   treatment durations might be needed to ensure complete decomposition (progressing from
254   interdendritic regions into the dendrite centers) of widely spaced dendrites which result
255   from slower cooling rates.
256 (ii)   Pronounced cracking occurs in the σ phase already in the AC bulk material, which will
257   affect mechanical properties and oxidation resistance upon cycling of large batches.

4.2 Oxide scales

258 The very small mass changes in Fig. 3b indicate a very good oxidation resistance at 800 °C. The origin
259 of the initial mass changes up until 20 h of cyclic oxidation has yet to be determined. In the presence of
260 Mo, low mass change might also result from a superposition of mass gain and simultaneous evaporation
261 of MoO_3, which is usually formed at temperatures above 500 °C and potentially leads to the so-called
262 pesting phenomenon. However, the scale thickness of less than 1 µm after 100 h at 800 °C is comparably
263 low, which is consistent with the low mass gain and further indicates the absence of any evaporation.
264 For pesting-resistant Mo-Si-Ti alloys, layer thicknesses of 2.3-5 µm are reported for those conditions
265 [28,35]. Scale thicknesses of pure Cr, Cr-10Ni (wt.%) and Cr-10Fe (wt.%) have been reported to lie
266 between 2-3 µm after only 10 h of cyclic oxidation at 800 °C [36].

267 From the XRD analysis of the oxide scale after 100 h at 800 °C, shown in Fig. 5a, Bragg peaks of the
268 substrate phases are still obtained due to the thin oxide scale. It is found that two different A2 as well as
269 A15 phases exist in the subsurface region after oxidation (compare different lattice parameters shown
270 in Fig. 2). In these regions, Cr and Mo concentrations were determined using XRD in combination with
271 NR and set into ratio. A Mo:Cr ratio of 99:1 was found for the A2 phase formed during oxidation while
272 the phase has a ratio of 44:56 in the HT condition. This can be explained by an outward diffusion of Cr
273 towards the surface to form the Cr_2O_3 layer and hereby leading to a Mo enrichment in the subsurface
274 zone. Due to the verification of Mo enrichment, an evaporation of MoO_3 can be excluded. The Mo
275 enrichment appears to be more pronounced at the interface between $(Cr,Mo)_{ss}$ and Cr_2O_3 layer, than
276 between $(Cr,Mo)_3Si$ and Cr_2O_3. Si oxide formation however, is more pronounced on top of $(Cr,Mo)_3Si$,
277 due to the availability of Si from that phase. Our observations agree with the suggestions made in
278 Ref. [16], that Si oxide acts as a barrier for Cr outward diffusion and reduces the driving force for inward
279 diffusion of O through the scale due to the higher O content of SiO_2 compared to Cr_2O_3. Elemental maps
280 of Mo and Cr show a lamellar structure in $(Cr,Mo)_{ss}$ in the transition region to the Cr depletion due to
281 the miscibility gap suggested in binary Cr-Mo and the prolonged duration of cycling between room
282 temperature and 800 °C [37,38]. It is concluded that a thin, protective chromia scale forms on Cr-13.5Si-
283 32.2Mo at 800 °C, which makes the alloy pesting-resistant. A schematic scale mockup is depicted in
284 Fig. 7a.

Fig. 7: Schematic of the scale mockup and oxidation mechanisms during long-term oxidation obtained from the present investigation: a) 800, b) 1100 and c) 1200 °C.

At 1100 °C, layer thicknesses are again lower than in pesting-resistant Mo-Si-Ti alloys with 0.5, 3 and 5 μm (Cr-13.5Si-32.2Mo) versus 5, 13, 26 μm (Mo-20Si-52.8Ti) for 1, 10 and 100 h of oxidation time, respectively, under the same oxidation conditions. For Ni-32.6Cr, a 12.5 μm chromia scale is reported after 50 h of isothermal oxidation in Ref. [39], whereas Ref. [36] reports 17 and 20 μm scale thicknesses after 10 h of cyclic oxidation of Cr and Cr-10Fe (wt.%) at 1100 °C, respectively. The Cr_2O_3 scale and the elemental distribution below the oxide scale are indicative of Cr outward diffusion and formation of a protective scale, effectively suppressing evaporation of MoO_3. Subsurface A2 and A15, still detected in the XRD patterns through the oxide scales, are both significantly depleted in Cr in agreement with the SEM-EDS maps. Taking the low solubility of Si in $(Cr,Mo)_{ss}$ (1100 °C up to 5 at.% in equilibrium) into account, the SEM-EDS maps reveal that the increasing Si content in the subsurface region leads to a decreasing, partially even disappearing, volume fraction of the solid solution phase, in favor of a A15 subsurface region. The transformation from the dual-phase initial microstructure to the A15 subsurface region results in the formation of significant porosity in that region. The compositions and lattice parameters of the constituting phases in Tab. 1 and Fig. 2, respectively, indicate crystallographic densities in the initial condition of 8.7 and 7.8 g/cm³ for $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$, respectively. Hence, the alloy exhibits a density of approximately 8.2 g/cm³ given the volume fractions of the constituting phases. The monolithic A15 subsurface region instead would yield a significantly increased density of 9.0 g/cm³ considering its lattice parameters and composition. Hence, a significant amount of free volume is needed to compensate this difference in densities. In conclusion, a scale mockup as schematically depicted in Fig. 7b is proposed which is dominated by the Cr depletion due to the Cr formation in the subsurface region.

14

306 Despite the mass loss after 50 h of cyclic oxidation, the samples oxidized at 1200 °C do not exhibit
307 significant spallation. The layer thickness of 15 μm after 100 h is in the same range as oxide scales
308 measured in Ref. [16] for Cr-Si alloys. 15-22 μm thick scales were formed on Cr-7Si-2X (X=Ge, Pt,
309 Mo) after 100 h in these isothermal oxidation experiments at 1200 °C under synthetic air. Since no
310 crystal structures other than α-Cr_2O_3 chromia were the detected, Si-enriched oxide regions might be
311 oxidized to amorphous SiO_2.

312 A significant Cr depletion zone is detected below the scale. This is indicated by the dashed line within
313 the substrate in Fig. 4f. From the BSE image in Fig. 4c (larger magnification on the right side), it can be
314 concluded that no internal corrosion is present after 10 h. In contrast, significant internal corrosion takes
315 place between 10 and 100 h of oxidation at 1200 °C. Hence, the initial protection by chromia formation
316 gets lost. Paths through the oxide scale can be seen in the chromia scale in Fig. 4d, which can allow O
317 inward diffusion. The progression of the mass change indicate, that up until 50 h Cr_2O_3 formation is
318 dominant in mass change kinetics. After 50 h, evaporation becomes dominant over scale formation,
319 leading to net mass losses. It is reasonable that Cr_2O_3 is the evaporating species rather than MoO_3. In the
320 surface layer, no Mo was detected (see Fig. 4f) and low O partial pressure in the Cr depleted region of
321 the bulk makes the formation of MoO_3 unlikely. The very low mass changes after 80 h suggest, that
322 evaporation processes terminated or got balanced to equal extent. The progress of oxidation after the
323 transient stage might be visualized as shown in Fig. 7c. The situation is dominated by the evaporation
324 of the volatile species and the significant internal corrosion.

325 During all oxidation experiments performed in this study, no nitride formation is found in any of the
326 investigated specimens. The formation of brittle Cr_2N during exposure needs to be considered the most
327 important challenges for development of oxidation-resistant, Cr-based alloys [11,40–42]. In terms of
328 mass gain and the determination of mass gain kinetics the formation of Cr_2N results in even thicker
329 scales and therefore higher mass gains in comparison to the oxide formation [43]. For example, after
330 isothermal oxidation of pure Cr at 1200 °C in synthetic air, a Cr_2O_3 scale thickness of 66 μm was
331 measured in comparison to an additional 352 μm of Cr_2N [16]. Alloying Cr with Si improves its
332 resistance as the A15 phase is intrinsically resistant against nitridation which was proven by
333 thermodynamic calculations as well as experiments [14]. Cr-Si alloys, consisting of both A2 solid
334 solution as well as A15 silicide phase, only show Cr_2N formation in the regions of former Cr_{ss} which is
335 detrimental for mechanical properties [44]. Nitride formation was recently attributed to Cr_2O_3 scale
336 failure and oxide scale cracking rather than atomic diffusion though the oxide scale [45]. The present
337 results on Cr-13.5Si-32.2Mo might be rationalized by the changes of the subsurface microstructure as
338 depicted in Figs. 4e and f. The Cr depletion as well as Mo and Si enrichment leads to an almost single-
339 phase A15 silicide region which might prevent and shield the two-phase substrate material from
340 nitridation. As reported in Ref. [46], additions of Mo to $(Cr,Mo)_{ss}$ – the threshold is expected between
341 5–8 at.% – further increase the resistance of the A2 phase towards nitridation [46]. This is in agreement
342 with the present observations as the investigated alloy contains around 32 at.% Mo without distinct
343 portioning to the individual phases.

344 To summarize, the alloy Cr-13.5Si-32.2Mo behaves differently at each of the temperatures tested.
345 Whereas 800 °C lies comfortably below critical temperatures for the formation of volatile Cr species,
346 1100 °C is already critical for many Cr rich alloys due to evaporation and nitridation. Inward diffusion
347 of N was *not* found at any temperature in the present study. For this temperature, mass gain and scale
348 thickness both point towards a parabolic oxidation rate and the formation of protective chromia. At
349 1200 °C, the alloy suffers from internal corrosion for longer periods of exposure.

4.3 Oxidation kinetics

350   For the dependence of the oxide scale thickness d over the exposure time t, the power law function

$$d^n = k_{d,n} \cdot t \qquad (1)$$

351   was applied. $k_{d,n}$ is the growth rate constant related to the scale thickness. The exponent n was once
352   adjusted individually to achieve optimum fit quality as indicated by the dashed lines in Fig. 8. For scale
353   measurement a conservative error estimation was used. For 1200 °C, the double layer was considered
354   for scale measurement. Statistical fluctuations are taken into account in the fits. For further calculations
355   error propagation was considered.

356   For 800 °C and 1100 °C, $k_{d,n}$ was additionally calculated with n being fixed to 2, which corresponds
357   to a (true) parabolic growth law [47]. The calculated values for $k_{d,n}$ with variable and fixed n are listed
358   in Tab. 2 including the fit quality R^2_{adj}.

Fig. 8: Oxide scale thicknesses d of Cr-13.5Si-32.2Mo with growth exponent n fitted according to Eq. (1) For samples oxidized 800 °C, and 1100 °C the scale was considered to solely consist of the Cr_2O_3 layer observed in BSE and EDS. At 1200 °C additionally the internal oxidation was considered.

359 However, often the oxidation progress is obtained from mass gain over time [48]:

$$\left(\frac{\Delta m}{A}\right)^n = k_{m,n} \cdot t \tag{2}$$

360 with the mass change Δm, the specimen surface area A and the oxidation rate constant $k_{m,n}$. To conclude
361 parabolic oxidation from a mass change curves, additional information on the oxide scale needs to be
362 obtained. For parabolic oxidation, the substrate degradation is slowed down over time by the formation
363 of a protective scale. Since the weight change could be influenced by evaporating species, mass changes
364 could appear to be parabolic but scale growth might not, due to an equilibrium of formation and
365 evaporation.

Tab. 2. Growth or oxidation rate constants $k_{d,n}$ or $k_{m,n}$ for 800, 1100 and 1200 °C. Note that for fitting data of one sample in Fig. 3c, a constant offset was assumed for the determination of the parabolic fit of mass gain. $k_{d,n}^*$ marked with * was converted from the averaged oxidation constant $k_{m,n}$ using Eq. (4).

T / °C	fit for	constant	unit	n / 1	value of k	R_{adj}^2 / 1
800	thickness	$k_{d,n}$	cm^n s^{-1}	3.96	$1.43 \cdot 10^{-24}$	0.81
				4	$1.01 \cdot 10^{-24}$	0.91
1100	thickness	$k_{d,n}$	cm^n s^{-1}	2.11	$4.19 \cdot 10^{-13}$	0.71
				2	$1.08 \cdot 10^{-12}$	0.85
	thickness*	$k_{d,n}^*$	cm^n s^{-1}	2	$1.09 \cdot 10^{-12}$	–
	mass change	$k_{m,n}$	g^n cm^{-2n} s^{-1}	2.30–5.37	–	> 0.99
				2	$2.97 \cdot 10^{-12}$	0.82–0.98
1200	thickness	$k_{d,n}$	cm^n s^{-1}	1.88	$1.11 \cdot 10^{-11}$	0.94
				2	$4.55 \cdot 10^{-12}$	0.96

366 For 800 °C, $k_{d,n}$ yields a quartic growth with $n = 4$ with reasonable R_{adj}^2. For 1100 and 1200 °C, fits to
367 the progression of the scale thickness resulted in n values close to 2. Therefore, the scale thicknesses at
368 1100 and 1200 °C follow parabolic growth laws with very good fit quality. However, considering the
369 mass changes (see Figs. 3b-d), only the oxidation behavior at 1100 °C might actually qualify as parabolic
370 since significant mass loss occurs beyond 50 h at 1200 °C indicative of evaporation.

371 In Fig. 9, parabolic growth constants $k_{d,n=2}$ and mass change constants $k_{m,n=2}$ of several chromia
372 forming materials from literature [14,16,36,39,49] as well as the Mo-20Si-52.8Ti reference alloy [35]
373 are plotted for oxidation temperatures between 800 and 1300 °C in an Arrhenius-type diagram. The
374 dashed lines solely connect $k_{d,n=2}$ data points from one and the same study and only serve as guides to
375 the eye. Parabolic growth rates $k_{d,n=2}$ of Cr-13.5Si-32.2Mo were obtained for 1100 and 1200 °C and
376 included in Fig. 9. Data for 800 °C is omitted due to the quartic growth law. Filled symbols represent
377 studies with direct scale thickness measurements. Data with half-filled symbols are taken from studies
378 where $k_{m,n=2}$ were determined by mass gain measurements. $k_{d,n}^*$ values were approximated assuming
379 that mass change is caused exclusively by inwards diffusion of O forming solid, monolithic Cr$_2$O$_3$ and
380 no species were evaporating. Combining Eqs. (1) and (2) under these conditions yields:

$$k_{d,n}^* = k_{m,n}\left(\frac{d \cdot A}{\Delta m}\right)^n \tag{3}$$

381 The mass gain Δm by solid oxide formation, using the amount of substance n and molar masses M, is
382 $\Delta m = n_{O \text{ in } Cr_2O_3} M_O = 3\, n_{Cr_2O_3} M_O = 3\frac{M_O}{M_{Cr_2O_3}} m_{Cr_2O_3}$. The mass of Cr$_2O_3$ $m_{Cr_2O_3}$ is obtained from

17

383   its density $\rho_{Cr_2O_3}$ and estimated using its thickness d and the surface area of the specimen A as $m_{Cr_2O_3} =$

384    $\rho_{Cr_2O_3} \cdot V_{Cr_2O_3} \approx \rho_{Cr_2O_3} \cdot d \cdot A$, with $V_{Cr_2O_3}$ being the volume of the chromia scale. Hence, the

385   following relationship is obtained:

$$k_{d,n}^* = k_{m,n} \left(\frac{M_{Cr_2O_3}}{\rho_{Cr_2O_3} \cdot 3\, M_O} \right)^n \qquad (4)$$

386   The parabolic growth constants $k_{d,n=2}^*$, plotted in Fig. 9a were recalculated the with $M_{Cr_2O_3} =$

387   152 g/mol, $M_O = 16$ g/mol and $\rho_{Cr_2O_3} = 5.2$ g/cm^3. The green semi-filled symbols in Fig. 9 are

388   representative of an oxidation study where the Si content was systematically varied between pure Cr

389   and Cr-25Si [14]. The positive influence of increasing Si on the oxidation and growth rates is obvious

390   from the diagram. The calculated growth constants of pure Cr from Refs. [14] and [16] at 1200 °C are

391   rather high as compared to an extrapolation of experimental $k_{d,n=2}$ values from Ref. [36]. However,

392   these $k_{d,n=2}^*$ values obtained from literature by conversion of $k_{m,n=2}$ might still underestimate the

393   progression of the oxidation, since evaporation effects are neglected in the calculation. It should also be

394   noticed that the calculated $k_{d,n=2}^*$ of pure Cr from Ref. [14] lies more than one order of magnitude above

395   the calculated $k_{d,n=2}^*$ of Cr-Si alloys of the same study, showing the positive influence of Si. Spallation,

396   evaporation and nitridation of Cr$_2$O$_3$ scales at high temperatures complicates the determination of $k_{m,n}$.

397   In isothermal experiments as e.g. in Ref. [16], the parabolic rate constants are often obtained until the

398   first rapid mass gain, before scale spallation. If scale spallation is observed, $k_{m,n=2}$ would likely be

399   much higher than directly obtained $k_{d,n=2}$. This must be especially considered when comparing results

400   from isothermal oxidation to cyclic oxidation as in Fig. 9. Among the chosen chromia-forming alloys,

401    $k_{d,n=2}$ roughly lies at about 10^{-10} cm^2 s^{-1}. Cr-13.5Si-32.2Mo with $k_{d,n=2}$ of $1.08 \cdot 10^{-12}$ and $4.55 \cdot 10^{-}$

402   ^{12} cm^2 s^{-1} for 1100 and 1200 °C, respectively, comfortably lies more than one order of magnitude below

403   that. An almost perfect agreement of the conversion from $k_{m,n=2}$ to $k_{d,n=2}^* = 1.09 \cdot 10^{-12}$ cm^2 s^{-1} and the

404   directly obtained $k_{d,n=2}$ is obtained for 1100 °C. This is considered proof, that there is no significant

405   evaporation, internal oxidation or nitridation. The oxidation scale appears to be solely formed of solid

406   Cr$_2$O$_3$ on Cr-13.5Si-32.2Mo at 1100 °C. A direct comparison of the experimentally determined mass

407   change and hypothetic mass changes based on the formation of solid, monolithic Cr$_2$O$_3$ from the

408   thickness measurements is included in the Supplementary material Fig. S1 for all temperatures tested.

409   A positive influence of small Mo additions to Cr-Si alloys regarding the decrease in the formation of

410   volatile species was observed by Ulrich et al. [16] for Cr-7Si-2Mo. The results for Cr-13.5Si-32.2Mo

411   support these observations and extend the statement to much higher Mo contents. Up to 100 h of

412   oxidation, the novel Cr-13.5Si-32.2Mo alloy overall possesses excellent oxidation behavior compared

413   to a variety of chromia formers and – due to their pesting failure – to most Mo alloys containing large

414   amount of Mo-rich solid solution.

Fig. 9: a) Oxidation rate constants $k_{d,n=2}$ for parabolic scale growth of several Cr_2O_3 formers [14,16,36,39,49] reported in literature and of the eutectic Mo-Si-Ti reference alloy from Ref. [35]. Data obtained by mass gain (indicated by semi-filled symbols) were converted using Eq. (4). b) Mass change constants $k_{m,n=2}$ for parabolic scale growth of several Cr_2O_3 formers [14,16,39,49] reported in literature. All direct $k_{d,n=2}$ are obtained from cyclic oxidation experiments. Re-calculated $k^*_{d,n=2}$ as well as $k_{m,n=2}$ are obtained from isothermal oxidation experiments unless otherwise indicated by (cyc.).

415 In order to benefit from the oxidation resistance of Cr-13.5Si-32.2Mo in a potential application, the
416 manufacturing is presently limited due to the presence of the σ phase during synthesis. This might be
417 avoided by the application of a bottom-up processing of mechanically alloyed powders and the direct
418 synthesis of the two-phase microstructure from a super-saturated condition. Another approach might
419 envisage alloys free of or lean in σ phase as Cr, the major element contributing to the oxidation
420 resistance, is rather homogeneously distributed across the solid solution and silicide. Hence, lower Si
421 contents might also lead to outstanding oxidation resistance but also to much larger fractions of
422 potentially ductile solid solution.

5 Conclusions

423 The following conclusions can be drawn from the present study and the discussion of its results:

424 - A metastable, monolithic σ phase in the Mo-Si-Cr system is obtained for Cr-13.5Si-32.2Mo
425 (at.%) from the liquid. It fully decomposes into a fine-lamellar microstructure of solid solution
426 $(Cr,Mo)_{ss}$ and $(Cr,Mo)_3Si$ (Cr_3Si prototype) through a solid state reaction with only marginally
427 difference in Cr contents.
428 - Cyclic oxidation in laboratory air shows outstanding oxidation resistance by the formation of
429 chromia scales with small mass gain at 800 and 1100 °C for up to 100 h. Chromia formation
430 leads to Mo and Si enrichment in the subsurface region and the formation of a Mo-rich
431 $(Cr,Mo)_3Si$ region that prevents the material from nitridation.
432 - Good oxidation behavior is noted at 1200 °C. However, internal oxidation and evaporation of
433 Cr_2O_3 is obtained at this temperature beyond 50 h.
434 - No scale spallation occurred for any of the temperatures tested.
435 - Oxidation rate constants associated with quartic and parabolic rate laws at 800 and 1100 °C,
436 respectively, are very low compared to other Cr_2O_3 formers.
