Composition and Electronic Structure of Mn_3O_4 and Co_3O_4 Cathodes in Zinc−Air Batteries: A DFT Study

Fernanda Juarez, Hui Yin, and Axel Groß*

ABSTRACT: The surface structures of promising cathode materials for zinc−air batteries, Mn_3O_4 and Co_3O_4, have been systematically studied under operating conditions by density functional theory calculations. The environment has been taken into account using grand canonical schemes for both gas-phase and electrochemical conditions. By analyzing the structures appearing in the calculated phase diagrams and Pourbaix diagrams in detail, we derive the factors underlying their stability in the gas phase and under electrochemical conditions. Changes in charge, oxidation states, and spin states of the metal cations on the surface are discussed, and their feasibility as active centers for the oxygen evolution and reduction reaction is thoroughly analyzed.
INTRODUCTION

In the search for concepts to develop the next generation of batteries with performances comparable to or even superior than those of existing devices, zinc−air batteries (ZABs) belong to the most promising approaches.[1−3] However, in spite of the many advantageous features, one of the basic problems for their use is the slow kinetics of the oxygen evolution reaction and oxygen reduction reaction (OER and ORR) on air cathodes.[1] In recent years, many efforts have been devoted to solve this problem by finding new electrocatalysts with sufficiently high activities to promote both reactions.[2,4−9] Manganese and cobalt oxides are natural candidates to enhance the OER and ORR because of their role in water oxidation in many biological systems and their multiple oxidation states, natural abundance, and inexpensive costs.[6,10−14] Besides, as in the case of other transition metal oxides,[15] their catalytic activity can be enhanced by doping or by introducing oxygen vacancies.

In recent studies of OER mechanisms on cobalt oxides, surface Co ions have been proposed as the active site for the OER.[16−18] According to these proposals, the oxidation state of cobalt increases during the OER. As a result, the density and oxidation state of surface cobalt ions are critical for OER/ORR activity. When these reactions are catalyzed by manganese or cobalt oxides or (oxy)hydroxides, the catalysis involves oxidation states from +2 to +4, with the cation species M^{3+} being the main active center.[17−19] In bulk oxides, the coordination geometry of manganese and cobalt ions is usually tetrahedral (T_d) or octahedral (O_h), resulting in a high-spin state for both Co^{2+} and Mn^{2+} ions (with magnetic moments M_S of 3 and 5 μ_B, respectively). In contrast, for Co^{3+}, three different spin states are possible, i.e., low spin $(M_S = 0\ \mu_B)$, high spin $(M_S = 4\ \mu_B)$, and intermediate spin $(M_S = 2\ \mu_B)$. In this case, the spin state is very sensitive to changes in the coordination geometry, e.g., Co−O length or Co−O−Co angle. Different to the cobalt in cobalt oxides, in manganese oxides, Mn^{3+} always remains in the high-spin state $(M_S = 4\ \mu_B)$.[20]

In many transition metal oxides, when Co^{3+} is in the intermediate-spin state, it has the electronic configuration $t_{2g}^5 e_g^1$, whereas Mn^{3+} is in the $t_{2g}^3 e_g^1$ state.[20−22] Constructing catalysts with moderate binding strength between the active sites and reactants/intermediates, by optimizing the electronic configuration, is an effective strategy to improve their electrocatalytic OER/ORR performance. The presence of a single electron in the antibonding e_g orbital is expected to yield just the appropriate strength of interaction between O_2 and the catalyst required for high OER and ORR activity, and it is therefore considered to play a crucial role in the catalytic properties of the oxides.[20−22]

Nevertheless, the reductive capacity of the metal ions in the oxide is not completely determined by the oxidation and spin states; the local geometry and coordination also play an important role.[23] It is well-known that there are significant differences in catalytic activities between tetrahedrally and octahedrally coordinated sites.[24] In the work of Wang et al.,[25] it was demonstrated that not only do the $Co_{O_h}^{3+}$ species act as the active sites, but also, the $Co_{O_h}^{2+}$ sites exhibit a high catalytic activity due to the fact that they are easily oxidized to active Co^{3+} species. On the contrary, the $Co_{T_d}^{2+}$ species shows poor catalytic activity.

Recent studies have confirmed that controlling the surface morphology is a promising way to improve OER and ORR activities on transition metal oxides.[26−28] For example, it has been shown that Co_3O_4 (111) surfaces exhibit higher activities than other surface terminations, probably as a consequence of their higher Co ion density and higher reactivity toward water dissociation.[26] In another work, the addition of nanocrystalline CeO_2 to Co_3O_4 modified the local geometry and therefore the electronic structure of the Co^{3+} surface species so that they can be more easily oxidized into the Co^{4+} state.[29] The presence of defects has also been used to enhance the electrocatalytic performance of oxides for the OER.[17] For example, Gong's group designed core−shell $Mn_3O_4@Mn_xCo_{3-x}O_4$ oxide catalysts that were terminated with abundant edge sites which, due to their unsaturated coordination, facilitated the adsorption of OH in basic conditions.[30]

The surface Co−OH groups are the starting point of the water oxidation cycle, and they can be transformed into Co^{4+} oxo sites and subsequently form hydroperoxide and other intermediates.[31] In recent publications, it was found that the preferred structural motifs under OER conditions consist of di-μ-oxo-bridged $Co_{O_h}^{3+/4+}$ ions with a contracted CoO_6 bonding environment, where μ_2−OH bridges are created between two electronically coupled high-spin cobalt ions.[31−33] The formation of these motifs is independent of the initial cobalt coordination and oxidation state, explaining the higher catalytic activity of surfaces in which they are already formed before the OER.

There have been several theoretical studies addressing the properties of manganese and cobalt oxide surfaces and their OER and ORR activities.[19,34−38] However, to the best of our knowledge, there are hardly any systematic studies addressing the thermodynamically stable surface structures of these oxides under operating conditions except for ref 39. Therefore, in this work, we will determine the most stable structures of Mn_3O_4 and Co_3O_4 (111) surfaces both in the gas phase and under electrochemical conditions. This study is motivated by the notion that such an investigation is in principle mandatory,[40−42] as the most active catalyst will be useless if it is not stable under operating conditions. The operating conditions will be taken into account employing grand canonical approaches.[43] Based on the concepts of ab initio thermodynamics[44] and the computational hydrogen electrode (CHE),[45] we will obtain the equilibrium structures as a function either of the chemical potentials of oxygen and hydrogen or of the electrode potential and pH. We will also analyze the changes in charge, oxidation, and spin states of metal cations on the surface and their feasibility as the active center for the OER and ORR.

METHODS

Ab initio calculations were performed with the periodic density functional theory (DFT) code Vienna ab initio simulation package (VASP).[46] The exchange and correlation energy was calculated within the generalized gradient approximation (GGA) using the Perdew−Burke−Ernzerhof (PBE) functional.[47] To include van der Waals forces, we added the D3 correction as implemented by Grimme et al.[48−50] The electron−core interaction was described with the projector augmented wave (PAW) method.[51]

The electronic wave functions were expanded using a plane wave basis set with an energy cutoff of 500 and 600 eV for Co_3O_4 and Mn_3O_4, respectively. The DFT+U approach was introduced to treat the highly localized Co and Mn 3d states in Co_3O_4 and

Mn_3O_4, using parameters of $U - J = 2.5$ and 3.0 eV, respectively. These parameters were obtained based on extensive testing by optimizing the description of pure Co and Mn as well as those of different types of bulk oxides, as described in refs 38, 52, and 53. In some DFT+U studies, larger U values have been used,[54,55] but other studies also arrived at similarly low U values for Co^{2+}/Co^{3+} (usually between 3 and 3.7 eV), in particular when determining it by fitting experimental results.[36,39,55−57] Furthermore, note that the combination of dispersion corrections with the +U approach can yield improved structural properties of an oxide material already at low U values and also a slightly improved band gap.[58]

All structures were relaxed until the residual forces on the free atoms were smaller than 0.02 eV/Å. The bulk Co_3O_4 and Mn_3O_4 oxides were optimized using k-point meshes of $7 \times 7 \times 7$ and $6 \times 6 \times 4$, respectively, yielding lattice constants of $a = b = c$ = 8.16 Å for Co_3O_4 and $a = b = 5.87$ Å and $c = 9.60$ Å for Mn_3O_4. The most stable magnetic structure found by us for each oxide was in accordance with previous studies.[59,60]

The Co_3O_4 (111) surfaces were represented using (2×2) slabs $(11.54 \times 11.54 \text{ Å}^2)$ consisting of 11 layers, where the bottom 7 layers were kept fixed during the relaxations. The Mn_3O_4 (111) surfaces were constructed using (1×1) slabs $(8.30 \times 11.25 \text{ Å}^2)$ with a thickness of 16 layers, keeping the bottom 8 layers fixed during the geometry optimizations. For the slab calculations of cobalt and manganese oxides, k-point meshes of $6 \times 6 \times 1$ and $5 \times 5 \times 1$ were used, respectively. In all of the cases, 15 to 20 Å of a vacuum was added in the z-direction, and dipole corrections were applied for the asymmetric slabs.

To simulate the effect of water in the electrochemical interface, we used an implicit solvent model[61−63] and the permittivity of clean water $\left(80 \frac{\text{A s}}{\text{V m}}\right)$. Local electronic charges were derived using the Bader charge partition scheme[64] for both of the spin components. The spin magnetic moment M_S (also known as magnetization) was calculated as the difference between the number of valence electrons at each spin state. It is important not to confuse this magnetic moment with the effective spin-only magnetic moment that can be measured experimentally.

To derive the thermodynamically stable surface structures under operating conditions, grand canonical approaches[43,65] have been employed which have been shown to reliably reproduce experimentally determined surface structures.[41,66] The stability of the surfaces in the gas phase was examined by calculating the Gibbs energy of formation $\Delta\gamma^{GAS}$, according to the ab initio thermodynamics formalism.[44] To simulate the effect of the electrode potential U and pH in the solid/liquid interface, the Gibbs energy of formation in solution $\Delta\gamma^{AQ}$ was computed using the computational hydrogen electrode (CHE) method[45] and following the same methodology successfully used in refs 67 and 68. All details and definitions concerning the energies of formation $\Delta G_{form}^{GAS/AQ}$ are given in the Supporting Information (SI).

RESULTS AND DISCUSSION

Formation Energy of (111) Surfaces in the Gas Phase. Although Co_3O_4 and Mn_3O_4 oxides have many similarities, the geometry of their (111) surfaces differs considerably. Both oxides are normal spinels with divalent and trivalent cations, located in tetrahedral and octahedral sites ($M_{T_d}^{2+}$ and $M_{O_h}^{3+}$), respectively. However, whereas the cobalt oxide (II, III) has a cubic spinel structure, the manganese oxide (II, III) adopts a
Figure 1. Side view of Co_3O_4 and Mn_3O_4 (111) surfaces. The first row (a−c) represents the stoichiometric slab of manganese oxide, and the second and third rows (d−f and g−i) correspond to the nonstoichiometric and stoichiometric slabs of cobalt oxide, respectively. In the first column (a, d, g), the metal atoms were colored according to their magnetic moment: green corresponding to spin up, yellow to spin down, and white to nearly zero. In the second column (b, e, h), the metal atoms were colored in accordance with their coordination, where blue and purple correspond to M_{O_h} and M_{T_d}, respectively. In the last column (c, f, i), all of the atoms were drawn in correspondence with their charge and using the color scale on the side of the panels.

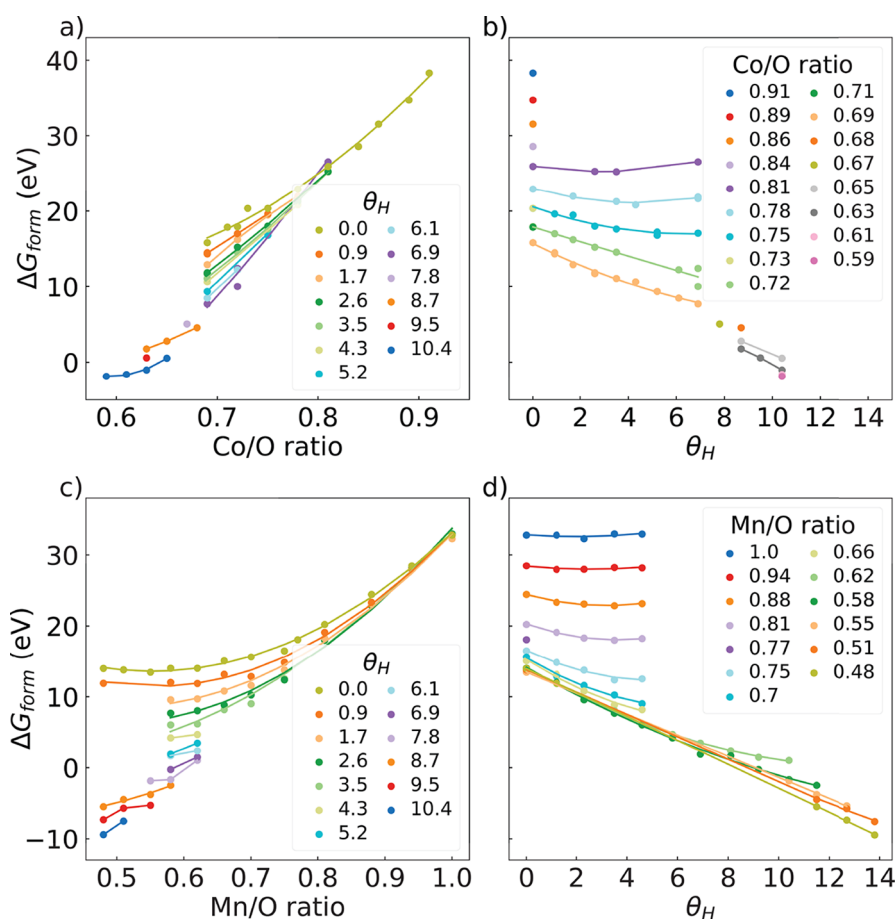

Figure 2. Formation energy (ΔG_{form}^{GAS}) in the gas phase of (a, b) Co_3O_4 and (c, d) Mn_3O_4 (111) surfaces. The energies are plotted as a function of (a, c) the metal/oxygen ratio n_M/n_O and (b, d) the amount of H per surface area θ_H.

tetragonally distorted spinel structure known as hausmannite. This deformation along the [001] direction is the consequence of the Jahn−Teller effect on the coordination octahedron around the Mn^{3+} ions. The side views of the resulting (111) slabs are shown in Figure 1.

The first row in Figure 1 depicts the asymmetric slab of the (111) surface of manganese oxide. This face has many possible terminations. To the best of our knowledge, it has not been systematically studied yet, so the most stable structures have not been determined yet. Because of its asymmetric form, it is possible to cleave the bulk oxide in order to obtain stoichiometric slabs, as shown in Figure 1. The resulting surface exposes many different types of Mn ions, with varying coordination and number of dangling bonds. Most of the ions on the surface of the slab belong to octahedral sites, but a few tetrahedral ions are also accessible from the top. With the purpose of considering different Mn/O proportions on the surface, we added manganese and/or oxygen atoms to this initial structure. The newly added atoms were placed in positions that maximize the number of Mn−O bonds and reduce the number of dangling bonds.

The bulk Co_3O_4 oxide can be cleaved through six different planes in order to create unreconstructed (111) surfaces, two of which are terminated by oxygen atoms, and the rest of them expose different types of Co atoms.[36] However, none of the symmetric (1 × 1) slabs recovers the stoichiometry of the bulk oxide. Previous studies, not including H adsorption, have shown that the most stable surface has a metal/oxygen ratio n_{Co}/n_O close to 0.75, and it is terminated by divalent cations $Co^{2+}_{T_d}$ (see Figure 1d−f).[37] These cobalt ions are surrounded by three O atoms having one dangling bond. Starting from this O-rich surface, it is possible to obtain a stoichiometric slab by partially covering it with Co ions. These cations occupy octahedral sites and are bound to the O atoms in the second layer, being less saturated than the Co ions in the first layer (see Figure 1g−i). The stoichiometric termination of this surface is also an important structure that can be predominant when the chemical potential of the species is modified. Together with the nonstoichiometric O-rich terminations, they are the prevalent structures under experimental conditions, without considering the presence of hydrogen.[37]

We started our study by first analyzing the stability of different slab terminations in the gas phase using the formation energy ΔG^{GAS}_{form}. Figure 2 shows this energy as a function of the proportion between metal and oxygen atoms n_M/n_O and the amount of H per surface area θ_H. As far as Mn_3O_4 is concerned (see Figure 2b), for low hydrogen content, the minimum of the formation energy is close to the stoichiometric ratio $n_M/n_O = 0.75$. Increasing the amount of oxygen, i.e., going to lower Mn/O ratios, does not significantly modify the energy values, as this situation corresponds to the saturation of the initial dangling bonds of the metal ions. On the other hand, increasing the amount of metal ions leads to higher energies because, despite creating new M−O bonds, new dangling bonds are being formed on the surface.

The relationship between the formation energy and the amount of hydrogen on the surface depends on the n_M/n_O ratio (see Figure 2b,d). In general, a smooth transition between two limiting situations can be observed. On one hand, the energy remains practically constant upon the addition of hydrogen to the surface when the n_M/n_O ratio is high. This is due to a competition between the metal ions and the hydrogen atoms for

the most reactive oxygen sites. In some cases, the coordination of the metal ions on the top is being reduced in order to form new O−H bonds. On the other hand, the formation energy decreases almost linearly with the amount of H when the surface has a higher content of oxygen.

As we already pointed out, the structure of the (111) surface of manganese oxide is very different to that of cobalt oxide. In the former case, it is possible to saturate each oxygen atom exposed at the surface with one hydrogen atom without increasing the energy of the slab. On the cobalt oxide surface, only half of the oxygen atoms that belong to the second layer of the original slab (Figure 1d−f) can be bound to hydrogen. In the presence of a solvent, the repulsion between hydrogen atoms that are adsorbed on first-neighbor oxygen ions and separated by 2.08 Å rises from 0.2 to 1.0 eV upon increasing the number of first neighbors from one to two. Nevertheless, all of the newly adsorbed O atoms can be saturated with H atoms to create hydroxyl groups.

Phase Diagrams in the Gas Phase. In spite of having found that fully hydroxylated surfaces have the lowest Gibbs energy of formation, the chemical composition of the (111) surfaces depends on the external conditions to which they are exposed, e.g., temperature, partial pressure of oxygen, hydrogen, etc. The most stable systems are shown in Figures 3 and 4 for

Figure 3. Phase diagram in gas phase of the (111) surface of Co_3O_4. The dashed black line indicates the dissolution of the bulk oxide, hence the lower limit of μ_O.

[a] Pictures are included in the SI, Figures S1−S6.

The system labels in the phase diagrams are organized as follows. Surface terminations without any hydrogen are plotted with shades of gray, and they are numbered starting from **1** on both phase diagrams. The O-rich and the stoichiometric Co$_3$O$_4$ (111) surfaces are, respectively, labeled as **1a** and **1c** in Figure 3. All of the systems labeled with **1** have a higher metal to oxygen ratio as $\Delta\mu_O$ decreases. The stoichiometric surface of the manganese oxide corresponds to system **1a** in Figure 4.

As for manganese oxide, the systems that contain hydrogen are predominantly numbered according to the ratio n_{Mn}/n_O; for instance, systems **5a** and **5b** have the same amount of Mn and O, but they differ in the content of H. Increasing numbers were used to indicate a higher proportion of oxygen on the surface. The surfaces denoted by **7** require special attention. They correspond to surfaces with varying low metal to oxygen ratios and a maximum number of adsorbed H on the O atoms.

The cobalt oxide surfaces containing H atoms are mainly organized according to the number of metal ions on top of the slab n_{Co}. Systems starting with **2** and **3** have the same amount of metal and oxygen as system **1a**. The family of systems **3** was created by adding more OH groups to system **2d**. Finally, the group of slabs labeled by **4**−**6** have an increasing amount of cobalt ions.

With the addition of hydrogen atoms to the surface, the stable systems shown in the phase diagram of Co$_3$O$_4$ have a chemical composition that becomes closer to the one of bulk oxide. The ratio n_{Co}/n_O is slightly lower than 0.75 but still between 0.69 and 0.72. The group of systems labeled with **2** represents the initial stages of the hydrogenation of the O-rich surface labeled as **1a**. All of the other stable terminations have higher amounts of metal atoms which are being compensated by the addition of oxygen and hydrogen atoms forming OH groups.

In general, we find that there is a good agreement between the results shown in Figure 3 and those presented in ref 39. The same structures are present at low H and O chemical potentials; however, the results differ at higher potentials because, in ref 39, the adsorption of water molecules was also considered. Another minor source for variation is the difference in the reference energy of the O$_2$ molecule which we derived from the formation energy of water.

Phase Diagrams in the Presence of an Aqueous Electrolyte. Figures 5 and 6 show the phase diagrams of the Co$_3$O$_4$ and Mn$_3$O$_4$ (111) surfaces in the presence of an aqueous electrolyte, plotted as a function of the electrochemical potentials of the hydrogen and metal ions, $\tilde{\mu}_{H^+}$ and $\tilde{\mu}_M$, respectively. Here, we have also added different lines that represent the limits of the stability of the resources. For hydrogen, the stability window is given by the dissolution of water to form O$_2$ or H$_2$ molecules (black dashed lines). In the potential region that we have studied for these systems, the bulk oxide can be dissolved into the acidic or the alkaline form of the M^{2+} ion, leading to the upper limit of its electrochemical potential. Before going further, we want to stress the fact that all of our results are only strictly valid for thermodynamic equilibrium conditions; kinetic effects are not taken into account which might of course alter the results. This particularly concerns the stability of the phases at a boundary between two phases.

It also needs to be noted that some regions in the phase diagram are not reachable because the pH is beyond experimental conditions. Note, first, that the electrochemical potentials of the protons and of the metal cations M^{2+} are not independent of each other (see eq S6). Furthermore, by combining the expressions for these electrochemical potentials, eqs S5 and S8, we can eliminate the electrode potential in the relation between $\Delta\tilde{\mu}_{M^{2+}}$ and $\Delta\tilde{\mu}_{H^+}$ (see eq S8), which allows us to determine the range of feasible alkaline pH values between 7 and 14 which are included as two black lines in Figures 5a and 6a. In order to understand the chemistry of the surfaces, we extended the plots beyond all of the proposed limits. Again, the parameters characterizing the stable systems are given in Table 1, and side and top views of the atomistic structures of the phases can be found in the SI (Figures S1−S6). Furthermore, the degree of oxidation of the surface as a function of the electrode potential and pH is shown in Figure 7, where additional top views of the most important terminations in or close to the stability regions are also provided.

To better read the phase diagrams of Co$_3$O$_4$ and Mn$_3$O$_4$ in the presence of an aqueous electrolyte, we emphasize certain
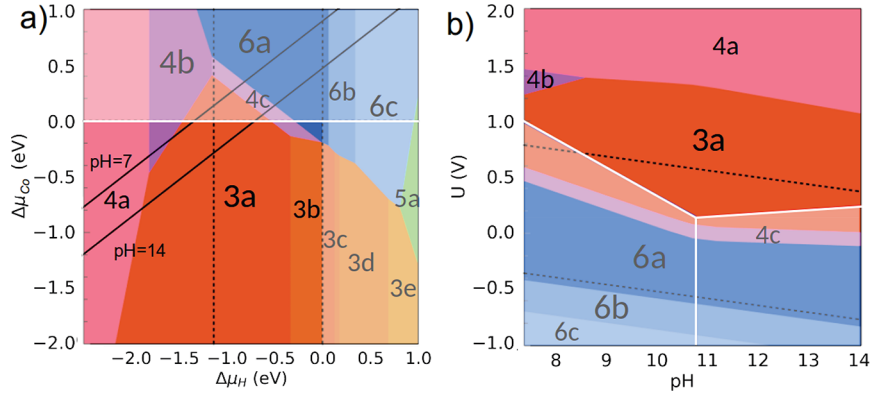

Figure 5. (a) Phase and (b) Pourbaix diagrams of the Co_3O_4 (111) surface in solution. The dashed black lines indicate the evolution of O_2 and H_2 from water, therefore, the lower and upper limits of μ_H, respectively. The white lines indicate the regions of stability of the metal ions in their acidic and alkaline forms. The black lines on the left plot correspond to constant pH values of 7 and 14. The Pourbaix diagrams were calculated for room temperature ($T = 298.15K$) and a molar Co concentration $[M] = 10^{-6}$ M in the aqueous electrolyte.

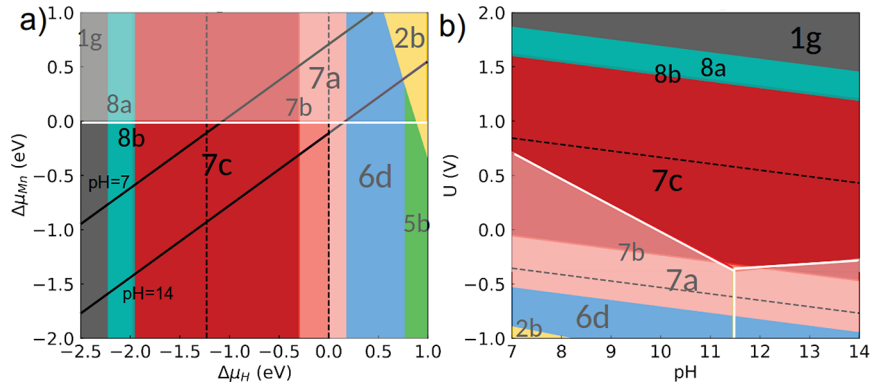

Figure 6. (a) Phase and (b) Pourbaix diagrams of the Mn_3O_4 (111) surface in solution. The dashed black lines indicate the evolution of O_2 and H_2 from water, therefore the lower and upper limits of μ_H, respectively. The white lines indicate the regions of stability of the metal ions in their acidic and alkaline forms. The black lines on the left plot correspond to constant pH values of 7 and 14. The Pourbaix diagrams were calculated for room temperature ($T = 298.15$ K) and a molar Mn concentration $[M] = 10^{-6}$ M in the aqueous electrolyte.

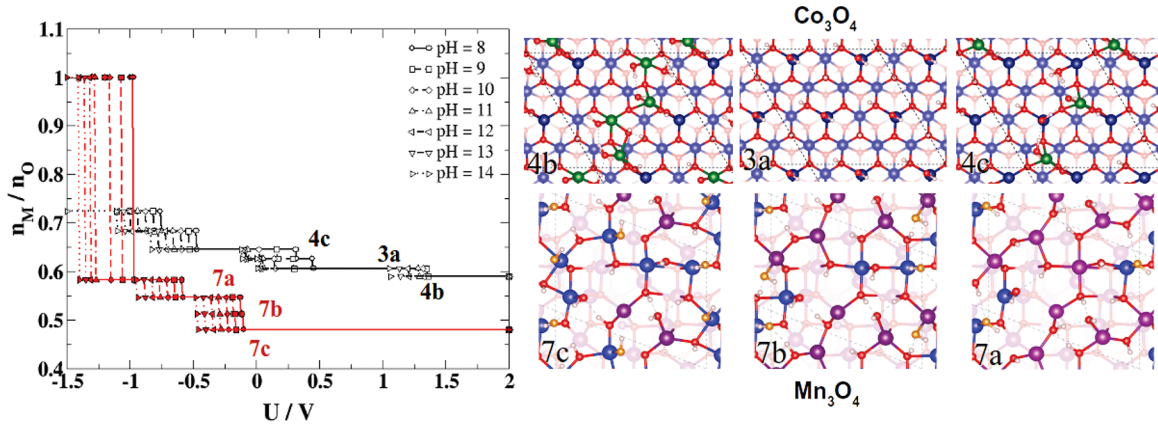

Figure 7. Ratio of the number of metal to oxygen atoms n_M/n_O in the (111) surfaces of Mn_3O_4 (red symbols) and Co_3O_4 (black symbols) as a function of the electrode potential U and the pH. Additional top views of the most important surface terminations were added on the side. The supercells of Co_3O_4 and Mn_3O_4 have an area of 11.54×11.54 and 8.30×11.25 Å^2, respectively. Mn^{2+}, Mn^{3+}, Co^{2+}, Co^{3+}, O, and H are represented as purple, blue, navy blue, green, red, and white spheres, respectively.

characteristics related to the arrangement of the stable phases which can all be derived from the particular expressions of the electrochemical potentials given in the SI. Note that systems that have the same number of metal ions per surface area are separated by a vertical line, parallel to the $\Delta\tilde{\mu}_M$ axis. A negative slope of the line that separates two systems indicates that the slab

on the right side has a higher concentration of metal ions than the other one. The second related feature is that surfaces that are stable in regions of higher $\Delta\tilde{\mu}_M$ values have a higher content of metal ions. Furthermore, stable systems are arranged in order of increasing n_M/n_O ratio as $\Delta\tilde{\mu}_H^+$ becomes more positive. In the particular cases when several surfaces have the same n_M/n_O ratio,

the slabs with a higher amount of H are situated in regions of higher $\Delta\tilde{\mu}_{H^+}$.

In contrast to the gas phase, at the electrolyte/electrode interface, it is very unlikely to have any termination of the Co_3O_4 or Mn_3O_4 (111) surfaces in the absence of any amount of adsorbed hydrogen. Actually, most of the systems are highly hydrogenated (see Figures S1–S6).

As Figure 7 indicates, the variation of the n_M/n_O ratio is rather small, with a higher oxidation of the metal ions in the manganese oxide surfaces. This plot also demonstrates that our model correctly reproduces the increasing oxidation of the surface as the electrode potential U increases. It can also be noticed that the most stable systems (**3a** for Co_3O_4 and **7c** for Mn_3O_4, respectively) are the result of the tendency to maximize the hydroxylation of the surface. These stable systems have the lowest possible n_M/n_O proportion that allows them to have the maximum amount of adsorbed hydrogen and, if possible, the lowest number of metal ions exposed on the surface (see the minimum in Figure S7c).

Geometry and Electronic Structure of the Mn_3O_4 (111) Surface in Solution. The Pourbaix diagrams illustrate the change in the stability of different surface terminations as a function of electrochemical control parameters. At the same time, their structures also determine the catalytic processes that can occur on them. However, a deeper analysis is required to understand how, locally, any reactions can proceed. It is beyond the scope of the present paper to perform a detailed study of OER and ORR mechanisms by calculating the energies of reaction intermediates and deriving reaction paths. Still, we want to assess the potential catalytic activity of the resulting surface structures by analyzing their geometric and electronic properties in some detail. On the Mn_3O_4 (111) surface, we have analyzed the metal ions of the four systems **6d**, **7a**, **7b**, and **7c** that belonged to the topmost layer in the unrelaxed and non-hydrogenated surface structures. Note that these four considered systems are the stable phases in the Pourbaix diagram (Figure 6) arranged according to increasing electrode potentials. The last three structures **7a**, **7b**, and **7c** are the most stable ones in the region of thermodynamic stability; the first one is a more reduced surface termination, according to our phase diagrams (Figure 6). Figure 8 collects the magnetic moment, charge, and coordination of these atoms.

Typically, in the bulk Mn_3O_4 oxide, there are only two types of metal ions: tetrahedrally coordinated Mn^{2+} ions and Mn^{3+} cations with octahedral coordination. According to our calculations and in very good agreement with previous DFT results,[69] the charge and magnetic moment in the bulk are $+1.51e/4.5$ μ_B and $+1.64e/3.8$ μ_B for Mn^{2+} and Mn^{3+}, respectively. In Figure 8, it can be clearly observed that the oxidation state of several atoms changes from +2 to +3 as the electrode potential increases, i.e., for more oxidizing conditions, whereas the coordination oscillates between tetrahedral and octahedral geometries. There is a good correlation between the magnetic moment and the charge in these atoms (see Figure 9) with a charge value of $+1.55e$ separating oxidation states +2 and +3. From both figures, it is evident that the magnetic moment is a better indicator of the oxidation state of the ions than the Bader charge.

According to Figure 8, the feasibility of oxidizing the metal ions on the surface is as follows: $5 > 3 > 2 > 4, 7 > 1, 6$. Atom 5 always stays in oxidation state III, and atoms 1 and 6 remain as Mn^{2+}, even in structure **7c**, i.e., at high potentials.

Figure 8. Calculated properties of the topmost metal atoms on the most stable (111) surfaces of Mn_3O_4: (a) magnetic moment, (b) charge, and (c) coordination. (d) Top view of the surface structure **7c** indicating the labeling of the surface atoms in panels a−c.

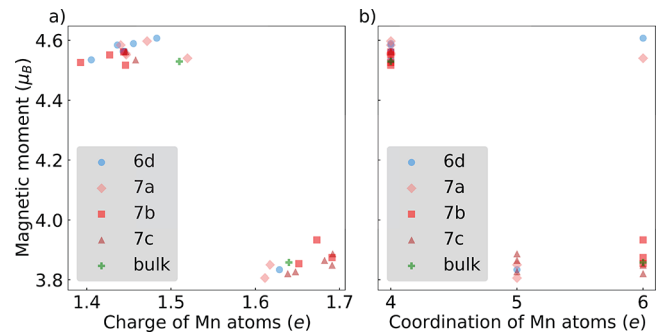

Figure 9. Magnetic moment of the topmost metal atoms on the most stable Mn_3O_4 (111) surfaces as a function of their (a) charge and (b) coordination.

From the seven selected ions, atom number 1 is the deepest one, and it is the only one that, even in the stoichiometric clean surface, is completely coordinated. In the cases that we analyzed, this atom changes neither its oxidation state (+2) nor its tetrahedral coordination, probably because of steric hindrance. Similarly, atom 6 always remains in oxidation state +2, coordinated by four neighbors. This atom is more exposed to the surface than atom 1, but as a result of the surface cleavage, it is contracted inward, creating stronger bonds and becoming more inactive to oxidation.

Atom 2 corresponds to an interesting case. In most cases, the oxidation is a consequence of the adsorption of new O atoms (or OH groups). Upon increased oxidation, this atom never changes the number of neighbors, having always an octahedral coordination. Nevertheless its oxidation state goes from +2 to +3 because the charge in the ion locally changes as the result of the oxidation of its neighbor (atom 3).

Among the considered atoms, atoms 4 and 7 are probably the most active toward the OER. As stated in the Introduction, these atoms fulfill two of the criteria for a good catalyst for this reaction: an oxidation state +3 and an incomplete coordination

sphere. Because both of them are in the topmost position and not completely coordinated, they are easier to access by any reactant approaching the surface. Furthermore, atoms 4 and 7 are connected through a μ_2-OH bridge, making this H atom the most acidic site and likely to be deprotonated.

Another descriptor that it is extensively used in the field of electrocatalysis is the position of the center of the d-band.[23,70] In Figure 10, the positions of the d-band centers for the most stable

Figure 10. Center of the d-band of the topmost metal atoms on the most stable (111) surfaces of Mn_3O_4.

(111) surface terminations of Mn_3O_4 are plotted; the whole projected density of states is shown in Figure S9. No direct correlation between the position of the d-band center and the magnetic moment of the manganese ions can be deduced from this figure. In addition, the order of the energetic position of the d-band centers varies from atom to atom; there is no systematic trend. Note that the formation energy and thus the stability of oxides have been related to the d-band filling[71] and thus also to the position of the center of the d-band. The higher the filling, i.e., the lower the d-band center, the lower the stability of the oxides,[71] i.e., the weaker the metal−oxygen bonds. In fact, it can be deduced from Figure 10 that those metal atoms that are highly oxidized by surface oxygen atoms such as atom 2 have the lowest d-band centers which means that they are supposed to be less reactive. Note that this is consistent with the notion that the number of excess electrons which depend on the oxidation state of the metal can be used as a descriptor for the reactivity of metal oxide surfaces.[72] In the most stable surface (**7c**), only atoms 1 and 7 have d electrons closer to the Fermi level and are therefore supposedly more reactive. However, because of the reasons mentioned before, atom 7 can be easily reached and oxidized by any adsorbent whereas atom 1 can only be indirectly oxidized.

Geometry and Electronic Structure of the Co_3O_4 (111) Surface in Solution. The amount of metal ions on the surfaces of the most stable terminations of Co_3O_4 (111) is different. The most reduced systems, **6b** and **6a**, have a higher amount of ions on the surface, whereas the more oxidized surface, **3a**, has a lower amount. Hence, the oxidation states cannot be followed atom by atom.

The magnetic moment and the Bader charges of all of the atoms on the stable systems, **4b**, **3a**, and **4c**, and on the more reduced surfaces, **6a** and **6b**, are collected in Figure 11. Two

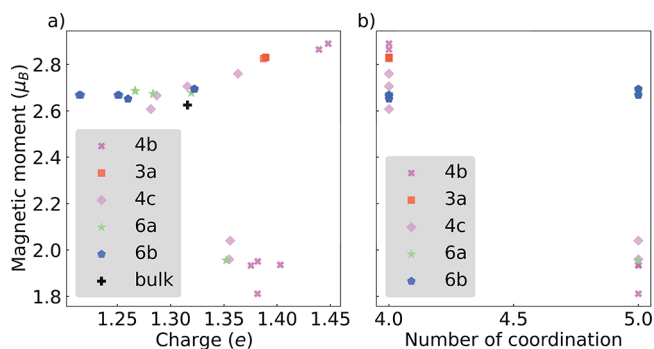

Figure 11. Magnetic moment of the topmost metal atoms on the most stable Co_3O_4 (111) surfaces as a function of its (a) charge and (b) coordination.

magnetic moments can be clearly distinguished. The state with a higher magnetic moment of approximately 2.7 μ_B, increases its value as the surface is increasingly oxidized, and it is in accordance with an oxidation state of +2 and high-spin configuration. The other magnetic moment observed is around 1.9 μ_B, in agreement with the presence of Co^{3+} in an intermediate-spin state. In general, the charge on the metal ions follows the degree of oxidation of the surfaces. Moreover, the charge of the Co^{3+} ion is at least higher than or equal to the charge of the same ion in the bulk: +1.36e.

Unexpectedly, the oxidation state is not completely correlated with the charge, but it is more in agreement with the coordination of the ion. Most of the Co^{2+} ions have a coordination number of 4 in a tetrahedral geometry whereas all of the metal ions in oxidation state +3 are pentacoordinated forming trigonal bipyramidal or square pyramidal structures. On the bulk oxide, where all of the trivalent ions are octahedrally coordinated, the Co^{3+} is in the low state. As we mentioned before, the spin state of these ions is strongly dependent on the coordination geometry, being easily modified by temperature or pressure changes.[73]

Some of the metal ions of system **6b** also have a coordination number of 5 in a distorted square pyramidal geometry. However, in this case and because the amount of oxygen atoms is low, the charge on the ions is lower than +1.35e, and they remain in oxidation state +2. As is usual for many divalent ions, they are in a high-spin state (with a magnetic moment around 3 μ_B), even when the geometry of coordination is no longer tetrahedral.[74]

The system **3a**, which is the predominant surface in the Pourbaix diagrams, has the lowest amount of metal ions of the systems analyzed in this section. It is also the flattest surface with all of its Co ions tetrahedrally coordinated in oxidation state +2. In spite of the oxidation state, the ion charge of +1.39e is higher than the charge of the Co^{3+} ion in the bulk. The position of the center of its d-band (shown in Figure 12) is more in agreement with the charge than with the oxidation state due to the magnetic moment.

The position of the d-band centers of the analyzed metal ions moves to more negative values as the charge on the ions increases, and it becomes more oxidized. There are no significant differences between the values of the spin-up band of the oxidation states +2 and +3; however, the spin-down pDOS is closer to the Fermi level when the metal ions are more reduced.

Analyses of the Bader charges and magnetic moments have shown that, in the most stable surface (**3a**), the metal ions are in an oxidation state and spin state most likely to be inactive. In
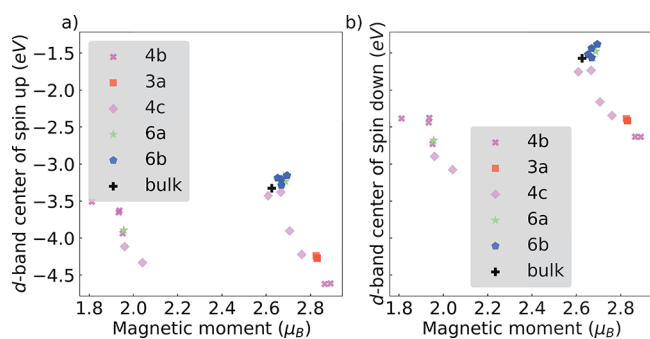

Figure 12. Center of the d-band of the topmost metal atoms on the most stable (111) surfaces of Co_3O_4 as a function of its magnetic moment for its (a) spin-up and (b) spin-down component.

addition, it can be seen in Figure 7 that the distance between the cobalt ions on the surface is too large to make possible the formation of μ-oxo bridges. Nevertheless, there is another system that is close to the region of thermodynamic stability: surface **4c**. Here, again, Figure 7 shows the presence of some Co^{3+} ions (green spheres) connected to neighbor cobalt ions through μ_2-OH bonds. Both characteristics make metal ions on surface **4c** promising active centers for OER/ORR catalysis.

Undoubtedly, surface termination **3a** is thermodynamically more stable than system **4c** in the experimental conditions simulated in this work, when the solvent is only included as a continuum polarizable medium. Thus, we would predict that this surface termination should be present under operating conditions. However, experimental results have shown that the (111) surface of the Co_3O_4 oxide is an active OER/ORR catalyst because of the presence of Co^{3+} ions on the surface[26,28,75−81] and/or the formation of μ_2-oxo bridges between adjacent metal ions.[31,33,82] However, because of the lack of those characteristics, system **3a** is very likely to be inactive, so it is not consistent with the experiments mentioned above that this system should be the thermodynamically most stable structure under operating conditions. This discrepancy might be a consequence of the lack of explicitly considered water molecules in our study.[83] Preliminary DFT calculations appear to confirm that system **4c** becomes the most stable one when water molecules are included explicitly and forming the first solvation layer. Water molecules added to the surface will not only modify the stability of the surfaces but also change the charge of the metal ions and the acidity of the adsorbed H atoms. A change in the coordination number of the metal can also modify the oxidation state having a significant impact on its oxidizing properties. The role of explicit water molecules for the structure and catalytic activity is the subject of a forthcoming study.

CONCLUSION

The thermodynamically stable phases of Mn_3O_4 and Co_3O_4 (111) surfaces have been systematically studied under operating conditions in a grand canonical approach based on density functional theory calculations. These materials are promising candidates for bifunctional oxygen evolution and oxygen reduction reaction catalysts at the cathode of zinc−air batteries. By considering a broad variety of stoichiometric and non-stoichiometric surface terminations, we have derived surface phase diagrams both for gas-phase and electrochemical conditions. Due to the complexity of the underlying spinel structures, no simple rules for the factors determining the stability of the surface structures can be derived. We find that

stoichiometric surface terminations are among the stable structures; however, lowering the metal to oxygen ratio does not significantly modify the energies as this lowering is accompanied by the saturation of initially dangling bonds of the metal ions. By analyzing the charge, coordination, and magnetic moment of the metal atoms, we identify possible surface terminations that could be catalytically active with respect to the oxygen evolution reaction. We find that such structures, however, do not belong to the thermodynamically stable phases which might be due to the neglect of the explicit consideration of water molecules in the first-principles total energy calculations.
