I. INTRODUCTION

There is considerable interest in improving the precision for the direct CP violation $\phi_3/\gamma$ phase $\gamma = \arg(-V_{ub}V_{cb}^*/V_{cd}V_{cb}^*)$ in the $b \to d$ unitarity triangle of the Cabibbo-Kobayashi-Maskawa flavor mixing matrix of quarks [1,2]. This angle connects the sides for decay contributions of penguin—rare decays—and box—mixing—diagrams.

The most precise result from a single analysis at the LHCb experiment is [3] $\gamma = (65.4^{+12.8}_{-12.6})^{\circ}$. It uses the Giri-Grossman-Soffer-Zupan method [4] for $B^\pm \to DK^\mp$ with the choice of $D \to K_SK^+\pi^-$, $D \to K_SK^+K^-$ three-body decays. In charged $B$ decays, the observation of CP violation (CPV) needs [5] the interference of two amplitudes with different weak phases—changing sign from particles to antiparticles—and strong phases—invariant under CP. This mismatch is what originates a CP-violating asymmetry in the corresponding decay rates for $B^+$ and $B^-$. In this case $D$ represents a $D^0$ or $\bar{D}^0$ meson reconstructed from a final state that is common to both, $D^0$ and $\bar{D}^0$ being produced, respectively, by $b \to c\bar{s}u$ and $b \to u\bar{c}s$ tree-level diagrams. The parameters of their mixing have been simultaneously determined in the analysis in Ref. [3].

The amplitude of the decay $B^- \to DK^-$, $D \to K_sh^+h^-$ can be written as a sum of $B^- \to D^0K^-$ and $B^- \to \bar{D}^0K^-$ contributions as

$$A_B(m_2,m_3) = A_D(m_2,m_3) + r_B e^{i(\delta_b - \gamma)} \tilde{A}_D(m_2,m_3),$$

where $m_\pm$ are the squared invariant masses of the $K_sh^+$ particle combinations that define the position of the decay in the Dalitz plot. The parameter $r_B$ is the ratio of the magnitudes of the $B^- \to D^0K^-$ and $B^- \to \bar{D}^0K^-$ amplitudes, $\delta_b$ being their strong relative phase. Neglecting CP violation in charm decays, the charge-conjugated amplitudes for $B^+$ decay satisfy $\tilde{A}_D = A_D$. The sensitivity to $\gamma$ is obtained by comparing the distributions in the Dalitz plots of $D$ decays from $B^+$ and $B^-$ mesons. As a consequence, the variation of the strong phase within the Dalitz plot is needed. Complementary information from measurements performed by CLEO [6] and BESIII [7-9] is available. Alternative methods [10-12] correspond to different choices for the decay channels of the $D$'s.

In this paper, we discuss an ideal conceptual experiment for $\gamma$ by exploiting the $B_0^0 - \bar{B}^0$ Einstein-Podolsky-Rosen (EPR) entanglement [13]. The use of the EPR correlation was proposed in Refs. [14-17] for several decay channels in the $B$ factories. Entanglement has been instrumental in the past for the observation of time-reversal violation by the BABAR Collaboration [18] using the concept and method given in Refs. [19-21] and with far-reaching information [22-24]. The method for $\gamma$ consists in the observation of the coherent double decay to flavor-nonspecific products. In it, the extraction of the $\gamma$ phase is free from the essential strong phases contamination needed in charged $B$ decays. The necessary interference between amplitudes containing the

\( V_{ca}V_{cb}^{*} \) and \( V_{ud}V_{ub}^{*} \) sides of the unitarity triangle is automatic from the two terms of the entangled \( B^0 - B^0 \) system. The double ratio intensity to the \((f, g)\) and \((g, f)\) pairs of \(CP\)-eigenstate decay products, with \( f = J/\psi K_S, J/\psi K_L \) and \( g = \pi^+\pi^-, \pi^0\rho^0, \rho_1^0 \rho_2^0, \rho_2^0 \rho_2^0 \), will do the job from \(CP\)-conserving and \(CP\)-violating transitions, as we demonstrate below. The measurement of the time-ordered intensities for these \(16 = 2(f) \times 4(g) \times 2\) (time ordering) combined processes is rich in physics and consistencies, leading to the relative phase \(\gamma\) responsible of direct \(CP\) violation. The Belle-II experiment at the upgraded KEK facility would have the opportunity to perform the analysis presented here if enough integrated luminosity is accumulated in the coming years.

II. TIME-ORDERED DOUBLE-DECAY INTENSITIES

The choice of the \(\rho_L\rho_L\) channels together with \(\pi\pi\) channels is motivated by their common \(CP\) properties, as seen in the change of basis [25] from the two-particle states with definite helicity to \(L - S\) coupling

\[
\langle JM; LS|JM; \lambda_1\lambda_2 \rangle = \sqrt{2L+1 \over 2J+1} C(LSJ|\lambda) \times C(s_1s_2S|\lambda_1 - \lambda_2). 
\]

(2)

In particular, for helicities \(\lambda_1 = \lambda_2 = 0\), the \(pp\) system from \(B\) decay is in states with \(L = S = 0.2\), so it has definite symmetry properties under \(C = +\), \(P = +\), and \(CP = +\). Therefore, we may use a unified theoretical framework for the discussion of the time-ordered intensities associated to the double decays \((f, g)\) and \((g, f)\) with decay times \(t_1\) and \(t_2\) such that \(\Delta t \equiv t_2 - t_1 > 0\). For any \(g\) decay products, the choice of \(f = J/\psi K_S\) defines for the \(\Delta t\) living partner a \(CP\)-forbidden transition, whereas \(f = J/\psi K_L\) corresponds to a \(CP\)-allowed transition.

Taking the transition amplitude from the \(C = -\)entangled \(B^0 - \bar{B}^0\) state to the time-ordered decay products \(f\) and \(g\), its square and integration over the initial decay time at fixed \(\Delta t \equiv t\) leads to the double-decay intensity [24]

\[
I(f, g; t) = e^{-\Gamma|t|} \left| {\Gamma g \over \Gamma f} \right|^2 e^{i\Delta M t / 2} A_H^f A_L^g - e^{-i\Delta M t / 2} A_H^g A_L^f \right|^2, 
\]

(3)

with \(\Gamma\) the common decay width of the eigenstates \(B_H = pB^0 + q\bar{B}^0\) and \(B_L = p\bar{B}^0 - qB^0\) with definite time evolution, \(\Delta M = M_H - M_L\) their mass difference, and \(A_{H,L}^g = \langle f, g|T|B_{H,L}\rangle\) their decay amplitudes. In the absence of \(CP\) violation in the mixing for this system, \(|p|/|q| = 1\). As anticipated, this intensity presents interference terms between \(f\) and \(g\), either direct or through mixing. With \(\Delta \Gamma = 0\) for \(B_L\) decays, there are time-independent and oscillatory terms in \(t\) with different physics. Because of the definite (anti)symmetry of the \(C = -\)entangled state, Eq. (3) satisfies the following expected symmetry property: The combined transformation \(t \rightarrow -t\) and \(f \leftrightarrow g\) is the identity, hence the interest in the separate measurements of \(I(f, g; t) + I(g, f; t)\) and \(I(f, g; t) - I(g, f; t)\) in order to separate even and odd terms in \(t\). As a consequence, we find it convenient to express Eq. (3) in the basis \(\{\cos^2(\Delta M t / 2), \sin^2(\Delta M t / 2), \sin(\Delta M t)\}\) of time dependences as

\[
\bar{I}(f, g; t) = {\Gamma \over \Gamma_f} e^{i\gamma t} I(f, g; t) \\
= T_d^f \cos^2(\Delta M t / 2) + T_m^f \sin^2(\Delta M t / 2) \\
+ T_d^f \sin(\Delta M t),
\]

(4)

where \(\Gamma_f\) is the average decay probability to \(f\) from \(B^0\) and \(\bar{B}^0\). \(\bar{I}(f, g; t)\) is a reduced intensity, with \(T_d^f = T_d^g\), \(T_m^f = T_m^g\), and \(T_d^f = -T_d^g\) the “intensity parameters” for each decay pair. The \(T_d\) parameter shows up since the \(t = 0\) separation between the two decays for each \(f, g\) pair, so it is the signal for a direct correlation between the decay amplitudes.

We introduce the usual mixing \(\propto\) decay interference \(\lambda = {\lambda \over \lambda f} \) from \(B^0\) and \(\bar{B}^0\) via \(\bar{I}(f, g; t)\) is a reduced intensity, with \(T_d^f = T_d^g\), \(T_m^f = T_m^g\), and \(T_d^f = -T_d^g\) the “intensity parameters” for each decay pair. The \(T_d\) parameter shows up since the \(t = 0\) separation between the two decays for each \(f, g\) pair, so it is the signal for a direct correlation between the decay amplitudes.

III. DECAY AMPLITUDES—ISOSPIN ANALYSIS

The decay channels \(f = J/\psi K_L, J/\psi K_S\) are known to be well described by their tree-level amplitudes, which satisfy \(\lambda_f = 1\), i.e., \(C_f = 0\). As an important consequence of Eq. (6), a nonvanishing \(T_d\) intensity parameter is trapping penguin amplitudes through their modulus.
contribution $C_g \neq 0$ ($\lambda_g \neq 0$) for any decay channel $g$. The phase of $\lambda_f$ is to a great accuracy the mixing phase $q/p = e^{-2i\phi_u}$, with $\phi_u = \beta$ in the SM. Assuming also $\Delta F = \Delta Q$, that is, no wrong sign decays, we have

$$\lambda_S = -\lambda_L = -e^{-2i\phi_M}$$

imposed by the two opposite CP eigenvalues for the decay products $J/\psi K_L$ and $J/\psi K_S$. The surviving terms in Eq. (6) are linear in $\lambda_f$, implying consistency relations for the absolute and relative normalizations of the intensity parameters:

$$I^{Lg}_d + I^{Sg}_d = 1, \quad I^{Lg}_m + I^{Sg}_m = 1, \quad I^{Lg}_{od} + I^{Sg}_{od} = 0, \quad \forall \ g.$$  

leading, in turn, to consistencies for the double-decay time-dependent reduced intensities

$$\hat{I}(L, g; t) + \hat{I}(S, g; t) = 1, \quad \forall \ g, \ \forall \ t.$$  

Using the exchange symmetry properties, Eqs. (8) and (9) are also valid for the time-ordered $(g; L, S)$ decays. They provide a controlled connection between the CP-forbidden and CP-allowed time-dependent transitions for any of the four decay products $g$.

The $\lambda_g$ amplitudes ($g = \pi\pi, \rho_L \rho_L$) can be parametrized as

$$\lambda_g = \rho_g e^{-i2\phi_M + i\phi_g},$$

where $\phi_g$ is a weak phase in the decay $b \to u \bar{u} d$ and both $\rho_g \neq 1$ and $\phi_g \neq \gamma$ are due to the penguin contributions. At tree level, all $g$ states considered here would have $\phi_g = \gamma$. Notice that the $(R_f R_g + S_f S_g)$ combination appearing in the $I^{Lg}_d$ intensity parameter is blind to the phase of $q/p$ and it directly probes

$$\lambda_S^2 + \lambda_L^2 = \pm \rho_g e^{i2\phi_g},$$

where the $\pm$ corresponds to $f = L, S$, respectively. As anticipated, no mediation of the mixing is present in the $I_d$ parameter of the intensity. Thus, the determination of this direct correlation between the two decay products in Eq. (4) for these processes becomes

$$I^{Lg}_d = \frac{1}{2} \left[ 1 \mp \frac{2\rho_g}{1 + \rho_g^2} \cos(2\phi_g) \right],$$

where clearly the mixing is not present. If penguin contributions were not relevant, we would have at tree level

$$I^{Lg}_d = \sin^2 \gamma \quad \text{for all CP-forbidden transitions,}$$

$$I^{Sg}_d = \cos^2 \gamma \quad \text{for all CP-allowed transitions.}$$

With the expected $g$-dependent penguin contributions through both $\rho_g$ and $\gamma - \phi_g \equiv \epsilon_g$, to be discussed below, Eq. (12) provides a powerful consistency from the four $g$'s and the two $f$'s for the extraction of the CPV $\gamma$ phase.

Let us focus now on the different information to be accessed by the measurement of the other intensity parameters. In the case of $I_{od}$, the combination in Eq. (6) involves the $\lambda_S / \lambda_L$ product, which connects the $f, g$ decay amplitudes through the mixing. The use of Eqs. (7) and (10) leads to

$$I^{Sg}_{od} + I^{Lg}_{od} = 1 \quad \forall \ g,$n  

The result (14) depends on the phase $2\phi_M + \phi_g$, indicating explicitly that the $I_{od}$ parameter denotes a correlation between the two $f$ and $g$ decay channels induced through the mixing. As already advertised, $I^{Sg}_{od} + I^{Lg}_{od} = 1 \quad \forall \ g$, as for the other term even in time. The two $(f, g)$ time-even intensity parameters combine in the observable sum of intensities for the time-ordered exchange of decay products $f \leftrightarrow g$. We obtain the result

$$\hat{I}(f, g; t) + \hat{I}(g, f; t)$$

$$\begin{aligned}
&= 2[I^{Lg}_d \cos^2(\Delta M t/2) + I^{Lg}_m \sin^2(\Delta M t/2)] \\
&= \frac{1}{2} \left[ \frac{2\rho_g}{1 + \rho_g^2} \left( \cos(2\phi_g) \cos^2(\Delta M t/2) \\
&\quad + \cos(4\phi_M + 2\phi_g) \sin^2(\Delta M t/2) \right) \right],
\end{aligned}$$

for $f = L, S$ correspondingly. As seen, the contributions of the direct CPV phase $\phi_g$ and the mixing-induced CPV phase $2\phi_M + \phi_g$ separate in two different time-dependent behaviors, the second naturally needing a time slice to become apparent. For any of the two $f$ channels and the four $g$ channels, these two terms are separately apparent when

$$\frac{\Delta M t}{2} = n\pi, \quad \frac{\Delta M t}{2} = (2n + 1) \frac{\pi}{2},$$

with $n = 0, 1, 2, \ldots$.

The third intensity parameter $I_{od}$ can be separated out from the difference of the two time-ordered intensities:

$$I(f, g; t) - I(g, f; t) = 2I^{Lg}_{od} \sin(\Delta M t)$$

$$\begin{aligned}
&= \mp \left[ \frac{1 - \rho_g^2}{1 + \rho_g^2} \sin(2\phi_M) \right] \sin(\Delta M t),
\end{aligned}$$

where $I^{Lg}_{od} + I^{Sg}_{od} = 0 \quad \forall \ g$ in this case. It is worth remarking that this intensity parameter would vanish if the penguin contribution were absent in the $g$ decay channels. As the CPV mixing $\sin 2\phi_M$ ($\sin 2\beta$ in the
SM) is the best measured parameter in this field, Eq. (17) can be used to measure the deviation of $\rho_g$ in each of the four $g$ channels from 1, induced by the penguin amplitude, and check its prediction from the isospin analysis given below. Consistently, the measurement of observable (17) for both $f = L$ and $f = S$ has to reproduce a change of sign, providing, in particular, the relative normalization of events in these two decay channels.

Besides the factor depending on $\rho_g$, the observables are also affected by the penguin amplitudes in a departure of the phase $\phi_g$ from a common $\gamma/\phi_3$ through

$$e_g = \gamma - \phi_g,$$

(18)
to be extracted from a dedicated isospin analysis. The procedure follows the original ideas of Gronau and London along the path described in Refs. [26,27]. The neutral and charged $B$-meson decays differ in the presence versus absence, respectively, of the penguin contribution to the amplitudes for each final $h = \pi, \rho_L$ system. The charged decay amplitudes $A^{+0} = A(B^+ \rightarrow h^+ h^0)$ and $\bar{A}^{+0} = A(B^- \rightarrow h^- h^0)$ have a final $(h^+ h^0)$ isospin-2 state and, therefore, only the $\Delta I = 3/2$ tree-level amplitude contributes with the weak phase $\gamma$. It is convenient to define, with the same notation for both neutral decay channels $\pi\pi$ and $\rho_L\rho_L$ and using $g = \pm$ or 00 for the corresponding decay charges:

$$a_g = \frac{A_g}{A_{+0}}; \quad \bar{a}_g = \frac{\bar{A}_g}{\bar{A}_{+0}},$$

(19)
in such a way that the double ratio gives

$$\rho_g e^{2i\epsilon_g} = \frac{\bar{a}_g}{a_g}.$$  

(20)

The isospin triangular relations with these complex ratios are

$$1 = a_{00}; \quad \frac{1}{\sqrt{2}} a_{+0} = 1 = \bar{a}_{00}.$$  

(21)

Equations (21) allow one to get $a_g$ and $\bar{a}_g$ by using all the branching ratios of the processes $B^{\pm} \rightarrow h^\pm h^0$; $B^0$, $\bar{B}^0 \rightarrow h^+ h^-$, $h^0 h^0$. In Table I, we give the summary of our isospin analysis with the present Particle Data Group data [28]. Taking into account that the $\rho_L^+\rho_L^0$ channel is the one with larger branching ratio, we must conclude that the error in $e_{\rho_L^+\rho_L^0}$, $\delta e_{\rho_L^+\rho_L^0} = 0.091 = 5.2^{+2.4}_{-1.0}$, gives us an estimate of the uncertainty due to the present knowledge of the penguin pollution in the determination of $\gamma/\phi_3$. An important improvement in the branching ratios entering in the isospin analysis is expected as an outcome of Belle-II and LHC experiments that will reduce this error significantly.

IV. RESULTS FOR THE EXTRACTION OF $\gamma$

The intrinsic accuracy of the method proposed in this paper is controlled by our ability to extract $\phi_g$. In order to estimate the expected uncertainty in that extraction, we proceed as follows (further details are provided in the Appendix). First, we fix input values of $\phi_g$ and $\gamma$. For each decay channel $g = \rho_L^+\rho_L^0, \rho_L^0\rho_L^0, \pi^+\pi^-, \pi^0\pi^0$, we also fix input values of $\rho_g$ and $e_g$, which fix $\phi_g = \gamma - e_g$, following the three different benchmark cases in Table II. Next, considering the decay channels $f = L, S$, we compute the six coefficients $I_{d,m,od}^{S_g}$ and $I_{d,m,od}^{L_g}$, which control the four time-dependent decay channels $(f, g), (g, f)$, for each $g$. Then, for each $g$, a given number of events is generated according to the four double-decay intensities. The procedure is repeated in order to produce our simulated data, from which $I_{d,m,od}^{S_g}$ are extracted including uncertainties and $I_{d,m,od}^{L_g}$ are given by Eq. (8). Finally $\rho_g, \phi_g$ and $\phi_M$ are obtained with a simple fit. Notice that the intensity parameters $I_{d,m,od}$ depend, respectively, on $\phi_g, \phi_M + \phi_g$, and $\phi_M$ phases. Therefore, the inclusion of the $I_{d,m,od}$ term together with $I_{d,m}$ in the fit allows one to avoid the discrete degeneracy $\phi_g \rightarrow \phi_g + \pi$, with the information of the quadrant for $\phi_M$.

We show the results of our analysis in two scenarios A and B taking into account the Belle-II projected luminosity [29–31] and the corresponding branching ratios: Scenario A assumes 1000 $\rho_L^+\rho_L^0$ events of type $B_{pp}$, 50 $\rho_L^0\rho_L^0$ events of type $B_{pp}$, 200 $\pi^+\pi^-$ events of type $B_{\pi\pi}$, and 50 $\pi^0\pi^0$ events of type $B_{\pi\pi}$. Scenario B assumes 500 $\rho_L^+\rho_L^0$ events of type $B_{pp}$, and 100 $\pi^+\pi^-$ events of type $B_{\pi\pi}$. The results of the fit to the generated $I_{d,m,od}^{S_g}$ in both scenarios are given in Table III. From the results in scenario A, we conclude that, since $\gamma = \phi_g + e_g$, the error $\delta \phi_g = 0.201 = 1.1^{+1.2}_{-1.1}$ gives an idea of the intrinsic statistical limiting error we would expect in the determination of $\gamma$ for the assumed number of events. Combining $\phi_g$ with $e_g$, the error $\delta e_g = 0.008 \pm 0.091$ would bring the error in $\gamma$ to the present error in $e_{\rho_L^+\rho_L^0}$, hence the importance of its improvement, as already mentioned.

Even before these improvements, we can do better and fit the three $T^{(g)}_{d,mod}$ for all channels in terms of $\gamma$, $\epsilon_\rho$, and $\rho_\rho$ including all the information of the isospin analysis. In this case, the result is $\gamma = 1.222 \pm 0.080 = (70.0 \pm 4.6)^\circ$. Note that the error on $\gamma$ is smaller than the error in $\epsilon_\rho$, due to a unique $\gamma$ in all channels, which presents a quantitative conclusion: The present proposal could provide a measurement of $\gamma$ below the $1^\circ$ error if the errors in the isospin analysis can be reduced to the level of $\delta \rho^+_L \rho^-_L \approx 1^\circ$. For the more conservative scenario B, we get an intrinsic error $\delta \rho^+_L \rho^-_L = 1.8^\circ$. Again, using all the information used in the isospin analysis and $\phi_M$, we estimate $\gamma = 1.221 \pm 0.085 = (70.0 \pm 4.9)^\circ$, which reinforces the idea that, with this method, it could be statistically possible to go below $1^\circ$ of precision in the determination of $\gamma$, thanks to the expected improvements in the data entering in the isospin analysis.

From the theoretical side, the inclusion of penguin pollution in the reference channels $J/\psi K_{S,L}$ is done with the phase substitutions $\phi_M \to \phi_M = \phi_M - \Delta \phi / 2$ and $\phi_\rho \to \phi_\rho = \phi_\rho + \Delta \phi / 2$, where $|\Delta \phi / 2| \leq 0.34^\circ$ has been estimated in Ref. [32] and comfortably below the statistical $1^\circ$. The corresponding moduli corrections to the right-hand sides in Eqs. (8) are below $10^{-2}$. For the most important channel $\rho^+_L \rho^-_L$, these equations remain valid up to corrections of the order of $10^{-3}$ due to additional suppression factors like $(1 - \rho^2) / (1 + \rho^2_\rho)$ and $\sin(2(\phi_\rho + \phi_M))$. Effects from the corrections to the leading $(q/p)_{B,K}$ values are below the considered penguin pollution.

V. OUTLOOK

In conclusion, with $B^0 - \bar{B}^0$ entanglement, we consider the double-decay rate intensity to flavor-nonspecific channels governed by the $c$ and $u$ quarks. It offers a conceptual alternative to the decay of single $B^\pm$ mesons for the extraction of the direct CPV $\gamma/\phi_M$ phase. The needed interference between two decay amplitudes is provided by the exchanged terms of the entangled state, and no strong phases appear as essential ingredients. The eight time-symmetric $(f, g)$ intensities with $f = J/\psi K_L$, $J/\psi K_S$, $g = (\pi \pi)^0$, $(\rho_1 \rho_3)^0$ have a tree-level common $\gamma$ phase, $g = \rho^+_L \rho^-_L$ being the benchmark channel. Several constraining consistencies among the different intensities appear. We find that an intrinsic accuracy of the order of $1^\circ$ could be achievable for the relative phase of the $f$ and $g$ amplitudes. The present limitation of $\pm 5^\circ$, to be improved by the existing experimental facilities, comes from the phase of the penguin contribution in the $g$ amplitude, extracted from an isospin analysis to neutral and charged $B$ decays.

APPENDIX: SIMULATION

As discussed in the main text, the intrinsic limitation of the method is controlled by our ability to extract $\phi_M$. The procedure to estimate the expected uncertainty in that extraction is the following.

1. We fix input values of $\phi_M = \beta = 0.384$ and $\gamma = 1.222$, and, for each decay channel $g = \rho^+_L \rho^-_L$, $\rho^+_L \rho^-_L$, $\pi^+ \pi^-$, $\rho^0 \pi^0$, we also fix input values of $\rho_\rho$ and $\epsilon_\rho$, which fix $\phi_\rho = \gamma - \epsilon_\rho$. We consider the three different benchmark cases in Table II.

2. Considering the decay channels $f = L, S$, the six coefficients $T^{(g)}_{d,mod}$, $I^{(g)}_{d,mod}$ are computed: They control the four time-dependent combinations $(f, g)$, $(g, f)$, for each $g$.

3. For each $g$, we generate values of $t$, the events, distributed according to the four double-decay intensities. In order to incorporate the effect of experimental time resolution, each $t$ is randomly displaced following a normal distribution with zero mean and $\sigma = 1$ ps. Additional experimental effects such as efficiencies are not included. Generation proceeds until a chosen number of events $N_g$ with $|t| \leq 5 \sigma_{\rho\rho}$ has been obtained with the four $(f, g)$, $(g, f)$ combinations altogether. These $N_g$ events are binned.

4. The procedure is repeated in order to obtain mean values and standard deviations in each bin: These constitute our simulated data, as illustrated in Fig. 1, which corresponds to $g = \rho^+_L \rho^-_L$ (benchmark $B_g$ in Table II), $N_g = 1000$ events and 20 bins in $[0; 5 \sigma_{\rho\rho}]$. The black dots with bars are the mean values and significant differences if one considers, for example, 15 or ten bins.
From the simulated data, one can obtain $I(S, \rho^+\rho^-; t) = 0.1170 \pm 0.0138$, $I(m, \rho^+\rho^-; t) = 0.1658 \pm 0.0456$, and $I_{od}(\rho^+\rho^-; t) = 0.000 \pm 0.0198$, with $I_{d,m,od}(\rho^+\rho^-; t)$ given by Eq. (8), and similarly for decay channels $\rho^0\rho^0$, $\pi^+\pi^-$, $\pi^0\pi^0$ according to the different benchmarks $B_{pp}$ and $B_{xx}$ in Table II.

Finally, we extract $\rho_g, \phi_g$, and $\phi_M$, with a simple fit to the $T_{d,m,od}^S$. Concerning the number of events, with the Belle-II design luminosity [29] and the branching ratios $BR(g)$ and $BR(f)$, we assume that it would be possible to collect 1000 events for $g = \rho^0\rho^0$, 200 events for $g = \pi^+\pi^-$, and 50 events for both $g = \rho^0\rho^0$ and $g = \pi^0\pi^0$ channels. We show the results of our analyses for two scenarios.

(i) Scenario A assumes 1000 $\rho^0\rho^0$, 50 $\rho^0\rho^0$, 200 $\pi^+\pi^-$, and 50 $\pi^0\pi^0$ events for both $B_{pp}$ and $B_{xx}$.

(ii) In scenario B, we assume 500 $\rho^0\rho^0$ and 100 $\pi^+\pi^-$ events of type $B_{pp}$ and 100 $\pi^+\pi^-$ events of type $B_{xx}$.
