Abstract

The mechanical properties of BaTiO₃ filled HDPE nanocomposites are studied by experimental and numerical approaches. First, the viscoelastic behavior of neat HDPE is highlighted experimentally in tensile and relaxation tests. A method is then proposed to define a constitutive viscoelastic law representative of this behavior at different tensile crosshead speeds at room temperature. Afterward, this law is implemented in a finite-element-based micromechanical model representing the BaTiO₃ filled HDPE nanocomposites with different filler amounts. The experimental and numerical results are further compared. Both the experiments and numerical simulations confirm the viscoelastic behavior of the polymer nanocomposite. For nanocomposites with filler concentrations up to 20%, the error between the experimental and numerical findings remains less than 8%, confirming that the model represents well the composite behavior for low and moderate filler amounts. The proposed strategy can be applied to other polymer composites in order to predict the complete mechanical behavior of viscoelastic composite materials. Introduction

Industries demand more and more performant parts fulfilling simultaneously several tasks. These custom-made parts are often manufactured by multifunctional materials. Composites are one of the promising material families which can satisfy such attempt. However, their development is a scientific challenge since there are several parameters affecting their performance, where the role of each constituent has to be determined. Among these composites, the particulate filled polymer composites are of interest. The final properties of these nanocomposites can be adapted to each application by choosing the appropriate parameters, such as the nature of the parent materials (matrix and particles), their proportions, the shape and the distribution of fillers.

The use of Barium titanate (BaTiO₃) filled High Density Polyethylene (HDPE) nanocomposites can meet these requirements. HDPE is one of the largely used thermoplastic polymers by industry due to its simple chemistry, low cost and ease to process. BaTiO₃ is frequently employed due to its inherent dielectric/piezoelectric properties [1], [2], [3], [4]. Nevertheless, there are a few research on the BaTiO₃ filled HDPE nanocomposites and they have mainly focused on the permittivity, electrical and thermal properties [5], [6], [7], [8], [9]. Mechanical properties are fundamental characteristics of materials, since they must support mechanical loads during their use. However, there are few investigations on mechanical characterization of BaTiO₃ filled HDPE nanocomposites in the literature [7], [8], [10].

Mechanical properties of composites, and particularly Young's modulus, can be measured experimentally. However, it may be useful to have a predictive model able to calculate these properties as a function of its parent components. These predictive models can be developed using either an analytical or numerical approaches. Analytical approach using a Hashin-Strikman model [11], [12] as well as numerical approaches have been employed in several research studies [13], [14] [15], [16]. Concerning HDPE filled BaTiO₃ nanocomposites, their mechanical properties were studied experimentally and numerically in our recent work [10]. In this investigation, it was attempted to predict the Young's moduli of BaTiO₃ filled HDPE nanocomposites with different filler fraction by developing a micromechanical model. The influence of different BaTiO₃ particle distribution was underlined. However, the experimental Young's moduli determined from tensile tests have been found different, to some extent, to the ones predicted by the numerical model. Several reasons were proposed to explain the origin of this disparity: shape of the particles considered spherical in the micromechanical model, influence of particle percolation, the modification of polymer properties surrounding filler particles. The later effect i.e. the influence of interphase formed between particles and polymer in polymer composites has been widely studied [17], [18], [19]. Another reason of the discrepancy between the experimental and numerical results could be the viscoelastic behavior of polymers. The behavior of HDPE in the micromechanical model developed in this previous work was supposed to be isotropic linear elastic, but the results of tensile tests carried out at different crosshead speeds have clearly shown the influence of strain rate on the measured stiffness, indicating a viscoelastic behavior [10]. ies [5], [6], [7], [8], [9]. Mechanical properties are fundamely must support mechanical loads during their use. He
echanical characterization of BaTiO₃ filled HDPE nanocom
ties of composites, and particularly Young's m

The characterization of the viscoelastic behavior of polymer nanocomposites has been the subject of numerous experimental research [20], [21], [22]. However, concerning the numerical approach, relatively little work has been done, to the authors' knowledge. For instance, a viscoelastic constitutive law was implemented in a micromechanical model to characterize creep behavior of silica-polyimide nanocomposites [23] or to predict the frequency response of particulate filled polymer [24].

This brief literature review shows that research concerning the mechanical behavior of the BaTiO3- HDPE nanocomposite has been limited to either experimental testing or to numerical modeling assuming linear elastic behavior for the polymer. It also reveals that the mechanical response of the nanocomposite is influenced by the strain rate. In this context, a constitutive model for the polymer, incorporating a time component, is required to better capture the overall mechanical behavior of both neat HDPE and BaTiO3-HDPE composites. Therefore, the aim of the present work is to implement a viscoelastic law in a micromechanical model representing BaTiO₃ filled HDPE nanocomposites in order to determine their tensile stiffness for different strain rates. The following approach was used. First, a viscoelastic constitutive law of neat HDPE was defined from experimental tensile and relaxation tests at room temperature for different strain rates. The representativeness of this law was

validated by implementing it in a finite element model of neat HDPE and comparing numerical and experimental results. Then, this general constitutive law was implemented into the micromechanical model of BaTiO₃ filled HDPE nanocomposites. Finally, numerical results were compared with the experimental ones obtained from tensile tests carried out on this nanocomposite. The approach presented in this paper can be applied to all particulate incorporated polymer nanocomposites.

Fundamentals of viscoelasticity

2.1. Viscoelastic behavior

The viscoelastic behavior which is well known on polymers has effects on both short-term and longterm mechanical behavior.

The short-term effects of this viscosity can be seen, for example, on the stress-strain curve in a uniaxial tensile test. Due to viscoelasticity, this curve differs from a straight line: viscoelasticity induces a non-linear behavior. Moreover, the stress-strain curves depend on the strain rate and the temperature. The increase in strain rate leads to an increase in material stiffness; this particular behavior has been highlighted in polyethylene [25], [26]. Concerning the effect of temperature, tensile tests on HDPE carried out by Amjadi and Fatemi [27] have shown the influence of temperature and strain rate on Young's modulus and yield stress. r behavior. Moreover, the stress-strain curves depend on
orcease in strain rate leads to an increase in material s
highlighted in polyethylene [25], [26]. Concerning the
highlighted in polyethylene [25], [26]. Concerning

In the long term, the viscoelasticity results in relaxation or creep phenomena. Relaxation refers to the fact that stress decreases in a specimen subjected to constant strain. Conversely, creep refers to the fact that strain increases in a specimen subjected to constant stress. Examples of creep curves for HDPE can be found in [28], [29] and relaxation curves in [30].

2.2. Constitutive law and characterization methods

For a linear viscoelastic behavior, using the Boltzmann superposition principle, the stress can be expressed from the strain history through the following integral formulation [\(Equation 1](#page-4-0) and [31] and [32]).

$$
\sigma(t) = \int_0^t E_{relax}(t-\tau) \ \dot{\varepsilon}(\tau) \ d\tau
$$
 Equation 1

where $E_{relax}(t)$ is the relaxation modulus, and $\dot{\varepsilon}(t) = d\varepsilon(t)/dt$ is the strain rate.

In order to characterize the viscoelastic behavior of materials, the relaxation modulus $E_{relax}(t)$ has to be determined by experimental tests. One of the widely employed experimental approaches to characterize the viscoelastic behavior of a material is in the time domain. In this method, the relaxation modulus $E_{relax}(t)$ can be determined directly from a relaxation test. This method was used for example by Elleuch and Taktak [33] and well suited to characterize the long-term behavior of a viscoelastic material. When we are interested in short-term behavior, as is the case in this work, some corrections must be made at the start of the relaxation phase [34]. This point will be developed and discussed in the next section.

2.3. Viscoelastic models

Two rheological models are commonly proposed to represent the viscoelasticity of polymers: Kelvin and Maxwell models. Kelvin model is generally used to study the creep phenomenon and Maxwell model is applied for relaxation experience [35] [36]. In these models, springs and dashpots are used to represent the stiffness and viscous behavior of materials, respectively. A Kelvin element consists of a spring which is in parallel with a dashpot, whereas in Maxwell model, an element contains a spring and a dashpot in series.

A generalized Maxwell model is used in this work to represent the viscoelastic behavior. It contains several Maxwell elements in parallel **(**[Figure 1\)](#page-5-0).

Figure 1: generalized Maxwell model

This model is described by a Prony series representing the relaxation modulus ([Equation 2](#page-5-1)).

$$
E_{relax}(t) = E_{\infty} + \sum_{i=1}^{n} E_i e^{-\frac{t}{\tau_i}}
$$
 Equation 2

where $\boldsymbol{E}_{\boldsymbol{i}}$ is the stiffness of the ith component and $\boldsymbol{\tau}_{\boldsymbol{i}}=\boldsymbol{\eta}_{\boldsymbol{i}}$ $\sqrt{E_{t}}$ is its relaxation time, η_{i} being the viscosity.

Materials and methods

The aim of this work is to define a viscoelastic constitutive law of neat HDPE through experiments, and then introduce this law in a micromechanical model of HDPE filled by BaTiO₃ nanoparticles.

3.1. Materials

The sample preparation and characterization methods have already been detailed in our previous work $[10]$. Briefly, the nanocomposite samples were prepared by mixing BaTiO₃ nanoparticles (mean size 500 nm) and HDPE in a blender at 170°C-180°C. In addition to the neat HDPE, the nanocomposite blends with four different BaTiO₃ amounts were prepared: 10 v%, 20 v%, 30 v% and 40 v%. Then, the blends were shaped in an injection mold. The thermal, structural and mechanical characterizations of nanocomposites have been performed by Thermo Gravimetric Analysis (TGA), Differential Scanning Calorimetry (DSC), Fourier Transformed Infrared Spectroscopy (FTIR), X-Ray Diffraction (XRD), Scanning Electron Microscopy (SEM) and tensile tests. The density measurements were done by using a double weighing method and the difference between the theoretical and experimental densities was less than 2%. This observation would indicate that the composite samples have a homogenous composition and exclude the excessive amount of porosity [10]. In addition to the previously structural characterization, samples extracted from the neat HDPE and the BaTiO₃ filled HDPE nanocomposites were scanned using the lab-based nanotomography (nanoCT Xradia 810 Ultra). Through the data reconstruction it is possible to observe the filler particle distribution on the samples as an example for neat, 10v% and 40v% BaTiO₃ filled HDPE [\(Figure 2\)](#page-6-0). Small samples were cut off with a blade from the tensile test sample and glued in a needle using an UV-curing glue. The nanoCT data was acquired with pixel size of 63.6 nm (sample 40v%) and 127.2 nm (sample neat and 10v%) with acquisition time per projection varying from 20 to 50 s, depending on the sample, and 901 projections were acquired over 180° within a field of view of 65 µm. Neat sample was scanned using Zernike phase contrast mode, while the samples with BaTiO₃ particles were characterized using absorption contrast. The nanoCT data was reconstructed using the proprietary software from Zeiss 'Scout and Scan Reconstructor', which is based on the filtered back projection algorithm. $E_{relax}(t) = E_{\infty} + \sum_{i=1}^{n} E_i e^{-\frac{t}{\tau_i}}$ Equation 2

A commercial software, *ANSYS 2021R1* is used for the numerical approach.

3.2. From experimental characterization to a viscoelastic model

In this section, the approach used to define a viscoelastic model from experimental data is presented.

It should be noted that the results presented in this section correspond to a single test at a single crosshead speed carried out on a sample of neat HDPE at room temperature. These results are intended to illustrate the method. Experimental characterization

The experimental tensile tests consist of two steps:

- a) Step 1 (loading step): a uniaxial load is applied to the sample for a given crosshead speed. The maximum load of 120 N is employed, which corresponds to a normal axial tensile stress around 6 MPa. The maximum tensile stress is assumed to be below to the yield stress of the samples. The time at the end of this step is noted t_1 .
- b) Step 2 (relaxation step): subsequently the crosshead is held in its position until time t_2 . t_2 time has been set to 600 seconds.

Experimental results are illustrated in [Figure 3.](#page-7-0) The evolution of strain with time is represented in [Figure 3a](#page-7-0). During step 1, the tensile test speed imposed on the crosshead results to a nearly constant strain rate: $\dot{\varepsilon}_1$. A zoom at the beginning of the tensile test is shown in [Figure 3b](#page-7-0). During step 2, strain looks like almost constant in time and the strain rate ε_2 can be considered as zero. At step 2, a very slight variation of the strain in time appears probably due to sliding of the sample in the grips. The change of stress with time is represented in [Figure 3c](#page-7-0). A zoom at the beginning of the relaxation test is shown in [Figure 3d](#page-7-0). The effect of viscoelasticity appears in the nonlinear behavior during step 1 and in the relaxation of stress during step 2 as clearly seen on [Figure 3d](#page-7-0).

Figure 3: Tensile and relaxation tests on neat HDPE sample

From experimental data to the definition of a relaxation modulus

In a uniaxial tensile test, if the mechanical behavior of the material is perfectly linear elastic, the stress-strain curve is a straight line and the Young's modulus is defined as its slope. For a viscoelastic material like HDPE, the mechanical behavior is nonlinear and the stress strain curve is not a straight line (Figure 4). Using ISO527-1 Standard, an equivalent Young Modulus is defined as the slope of a straight line between 0.0005 and 0.0025 strain points. It should be noted that this strain range could be used for neat HDPE, but not for HDPE-BaTiO₃ nanocomposites which are the main objective of this work. The reason of this inconvenience comes from the fact that BaTiO₃ nanocomposites exhibit very small deformation compared to neat HDPE, especially at high BaTiO₃ nanocomposites concentrations, such that the resulting strains remain below the strain range used for neat HDPE. In order to focus on the influence of strain rate, as well as the amount of BaTiO₃ particles, on mechanical behavior, we determined an equivalent Young Modulus (noted E_{cavity}) defined as the slope of the straight line between 1 and 5 MPa stress points [\(Figure 4](#page-8-0) and [Equation](#page-7-1) [3\)](#page-7-1) on stress-strain curves. $\varepsilon_{\sigma=5 \text{ MPa}}$ and $\varepsilon_{\sigma=1 \text{ MPa}}$ are the strains corresponding to 1 MPa and 5 MPa stress points. t_2

 $\frac{1}{100}$
 $\frac{1}{$

$$
E_{equiv} = \frac{5 MPa - 1MPa}{\varepsilon_{\sigma=5 MPa} - \varepsilon_{\sigma=1 MPa}}
$$
 Equation 3

This definition of E_{equiv} is based on stress rather than strain, in order to avoid the aforementioned problem of the low strains encountered with $BaTiO₃$ filled composites. In addition, the values of stress (1 and 5 MPa) are selected specifically to encompass most of the loading phase.

Journal Pre-proo

Figure 4: Experimental stress-strain curve (black line) and definition of Young's moduli

The viscoelastic behavior is defined by the relaxation modulus $E_{relax}(t)$ [\(Equation 1\)](#page-4-0). This relaxation modulus is usually determined from a relaxation test, but it can also be extracted from a uniaxial loading stress-strain curve as follows.

During the loading step, the relaxation modulus corresponds to the tangent modulus [\(Equation 4\)](#page-8-1) which is the slope of the stress-strain curve (Figure 4) [37].

$$
E_{tangent}(t) = \frac{d\sigma(t)}{d\varepsilon(t)}
$$
 Equation 4

During the relaxation step, the secant modulus (Figure 4) should be used as the relaxation modulus $E_{relax}(t)$ [\(Equation 5\)](#page-8-2)

$$
E_{secant}(t) = \frac{\sigma(t)}{\varepsilon(t)}
$$
 Equation 5

However, the secant modulus corresponds strictly to the relaxation modulus only in the ideal case where the load is applied suddenly [38], [37]. If the load is not applied instantaneously, which is the real case, the secant modulus differs from the relaxation modulus for the short time of the relaxation step. This point will be illustrated and discussed later.

During the relaxation step, the numerical value of the secant modulus can be determined directly from the stress and strain measured for each time step. However, the numerical value of the tangent modulus cannot be evaluated directly from experimental data due to the noises in stress and strain measurements, since a small variation in stress or strain can result in a big change in derivative. In order to transform an experimental noisy curve, the stress-strain curve is first fitted with a high degree polynomial. Then the tangent modulus is computed from the high degree polynomial approximation of experimental curves $\sigma(t)$ and $\varepsilon(t)$. An example of relaxation modulus determined from tests on neat HDPE is given in [Figure 5.](#page-9-0)

Figure 5: Relaxation modulus determined from experimental stress-strain curve on neat HDPE

A discontinuity is observed between the two steps at instant t_1 , due to the way of calculation of E_{relax} . In particular, this discontinuity arises because the relaxation modulus would correspond to the secant modulus of step 2 only if the load were applied suddenly, which is not the case here.

From relaxation modulus to viscoelastic model

The curve fitting tool included in the commercial software ANSYS is used to determine the parameters of Prony series from experimental relaxation modulus $E_{relax}(t)$. Some points are extracted from the experimental curve to achieve the curve fitting calculations. In order to highlight the influence of the point selection for curve fitting, two models (Model1 and Model2) are computed from two different sets of experimental points (Figure 6). In Model1, the points are selected close to t_1 in loading step and far from t_1 in the relaxation step, while in Model2, the selected points are far from t_1 in loading step and closer to t_1 in relaxation step. bserved between the two steps at instant t_1 , due to the

ion modulus to viscoelastic model
ool includ

(b) Relaxation modulus: zoom at the beginning of curve (a)

Figure 6: Experimental relaxation modulus with the points selected for curve fitting with two different models

In order to represent the evolution of the relaxation modulus as accurately as possible over the whole duration of experiments, a generalized Maxwell model with three terms in Prony series ([Equation 2](#page-5-1)) is used. The parameters extracted by using curve fitting tool in ANSYS are listed in [Table 1.](#page-10-1)

Table 1: The parameters of Prony series obtained by curve fitting for two models

The relaxation modulus computed [\(Equation 2\)](#page-5-1) with these parameters [\(Table 1\)](#page-10-1) is also represented in [Figure 6](#page-10-0) for two models (dotted curves). It is clear that the relaxation modulus calculated from these two models corresponds well to experimental points selected for curve fitting.

Validation: numerical simulation of the tensile test

In order to validate these models and quantify the influence of point selection for curve fitting, these models are then implemented in a 2D plane stress finite element model corresponding to the experimental tests. As an example, a neat HDPE sample studied experimentally is shown in [Figure](#page-11-0) [7a](#page-11-0). The geometry of the numerical model is a rectangular surface [\(Figure 7b](#page-11-0)) representing the central part of the sample in [Figure 7a](#page-11-0). A displacement δ is applied during a first load step (Figure [7c](#page-11-0)), then kept constant during a second one [\(Figure 7d](#page-11-0)). The value of the imposed displacement δ is chosen so that the experimentally measured strain at the end of the loading step is obtained.

Experimental tensile test specimen of neat HDPE (a), 2D finite element model (b), deformation of the sample under load (c) and applied displacement in two steps (tensile and relaxation) loading (d)

Numerical stress computed with these two models are compared to the experimental results (solid black curve) in [Figure 8a](#page-12-0). It is remarked that Model2 gives a better correlation with experimental data at the start of the relaxation step.

(b) Evolution of relaxation modulus over time for experimental and two numerical models plotted by using the parameters of two Prony series

Figure 8: Comparison of the experimental and numerical results for two models

A tangent modulus (loading step) and a secant modulus (relaxation step) can also be computed from these numerical results, in the same way as they were determined from experimental data. [Figure](#page-12-0) [8b](#page-12-0) provides a comparison of the various relaxation moduli calculated from numerical results of the two models (solid red and purple lines), experiments (solid black line), and Prony series-based theoretical results for the two models (dotted curves). These outcomes confirm that the relaxation modulus defined by the Prony series is equal to the tangent modulus during the loading step and to the secant modulus during relaxation step, except for the short time at the beginning of the relaxation step.

The choice of points used for the curve fitting of Model1 results from this property: during the first step, the tangent modulus is strictly equal to the relaxation modulus and curve fitting points are selected along the entire curve up to time $t₁$; the first point of the relaxation step is then chosen so that a decreasing modulus over time is obtained. The stress calculated with this model corresponds perfectly to that measured during the loading step but shows a slight difference at the start of the relaxation step (just after t_1).

To obtain a better correlation at the start of the relaxation step, a second model was calculated using a new set of curve fitting points. For the relaxation step, the points closer to time t_1 were added, which led to remove the last points close to t_1 in step 1 in order to maintain a decreasing modulus [\(Figure 6b](#page-10-0)). Concerning the correlation between numerical and experimental stresses, this second model results in an improvement during step 2 without an important influence during step 1. The stress is less dependent on the relaxation modulus during the loading step than during the relaxation step, since during the loading step, the relaxation modulus is determined from the derivative of stress i.e. $d\sigma(t)/d\varepsilon(t)$ [\(Equation 4\)](#page-8-1), whereas during the relaxation step, it is directly proportional to the stress i.e. $\sigma(t)/\epsilon(t)$ [\(Equation 5\)](#page-8-2). It is therefore more difficult to determine the tangent modulus accurately: a small change in the measurements can result in a large change in its derivative.

To conclude, the approach described in this section was successfully validated: the relaxation modulus determined from the experimental data (tangent modulus for the loading step, secant modulus for the relaxation step) can then be used to describe an effective representative model for viscoelastic behavior of HDPE. Since Model2 led to a better overall correlation, the points at the transition zone between two steps around time t_1 were excluded for curve fitting.

3.3. Overall approach

The method used to define a viscoelastic model from an experimental characterization was described in the previous section, at a fixed crosshead speed. The aim of the work presented in this paper is to introduce a viscoelastic behavior of HDPE into a micromechanical model of BaTiO₃ filled HDPE nanocomposites representative of the behavior of HDPE at all strain rates. The overall approach used to meet this objective is illustrated in Figure 9. oach

Journal Pre-proo

Figure 9: Approach used to define and validate a viscoelastic model (a) , (c) and (d) on neat HDPE (b) and (e) on BaTiO³ filled HDPE nanocomposites

The first step [\(Figure 9a](#page-14-0) and Figure 9b) concerns the experimental mechanical characterization of neat HDPE and BaTiO₃ incorporated HDPE nanocomposites (0 v%, 10 v%, 20 v%, 30 v% and 40 v% in BaTiO₃). All tests were performed at room temperature. For each material i.e., 0 v%, 10 v%, 20 v%, 30 v% and 40 v% BaTiO₃ filled HDPE, three different samples were characterized at different tensile crosshead speeds, and for each speed, the test was repeated thrice. Finally, an average curve was computed from these nine experimental curves for each speed. An example is given in [Figure 10](#page-15-0) for a tensile crosshead speed of 1 mm/min on neat HDPE. The equivalent Young Modulus E_{equiv} defined in [Equation 3](#page-7-1) is then extracted from the average stress strain curve $\sigma(\varepsilon)$. For neat HDPE, an average relaxation modulus $E_{relax}(t)$ is also computed for each speed.

(a) Complete curve

(b) Zoom at the beginning of experiments

Figure 10: Example of an average curve obtained from nine stress-time curves with a 1 mm/min crosshead speed on neat HDPE (each color (blue, green and red) corresponds to a sample and three tests are performed on each sample)

The second step (Figure 9c) consists of defining a viscoelastic model representative of neat HDPE which takes into account all crosshead speeds. To do so, an average relaxation modulus is calculated from the various relaxation moduli obtained for each speed. A viscoelastic model is then defined from this global average relaxation modulus, as explained in the previous section. tests are performed on each sample)
igure 9c) consists of defining a viscoelastic model represeccount all crosshead speeds. To do so, an average
various relaxation moduli obtained for each speed. A viscobal average relaxa

In order to estimate the correctness of this generalized viscoelastic model to effectively represent the behavior of neat HDPE, numerical stress strain curves $\sigma(\varepsilon)$ and equivalent Young's modulus (E_{cavity}) are computed with this model [\(Figure](#page-14-0) 9c) and compared to the experimental results (Figure [9d](#page-14-0)).

Finally, the generalized viscoelastic model obtained on neat HDPE is applied to the micromechanical model on BaTiO₃ filled HDPE nanocomposites (Figure 9e), and numerical results are compared with experimental results for different crosshead speeds. This strategy can be justified, since the viscosity is mainly induced by polymer rather than the ceramic fillers.

Results and discussion

4.1. Neat HDPE: Characterization and definition of a general viscoelastic model

Characterization of the relaxation modulus

Using the approach described in the previous section, experimental relaxation modulus $E_{relax}(t)$ is evaluated for the following crosshead speeds: 0.5, 1, 2, 5, 10, 50 and 100 mm/min. The results are presented in [Figure 11.](#page-16-0)

The modulus determined in the relaxation step is almost independent of the crosshead speed used in the loading step. The dispersion of the different curves is greater for $E_{relax}(t)$ determined from the tangent modulus of the loading step. For relatively fast crosshead speeds i.e. 50 and 100 mm/min, only the relaxation step is considered. In fact, during the loading step, load is applied very fast which makes it difficult to determine accurately the slope.

Viscoelastic model for neat HDPE

In order to select a set of points for curve fitting, an average relaxation modulus curve is calculated from the curves obtained for different crosshead speeds. It should be noted that for each speed, values just before and just after time t_1 are excluded from the calculation of the average value, in the same way as the points used to define Model2 [\(Figure 6\)](#page-10-0). The set of points selected on the average curve for curve fitting are represented in [Figure 11:](#page-16-0) the whole experimental span [\(Figure 11a](#page-16-0)) and

Figure 11: Relaxation modulus for different crosshead speeds (continuous lines) and set of points (0) used for curve fitting (a) the whole experimental span, (b) zoom at the beginning of experiments. The thick black curve is the relaxation modulus plotted by using the Prony parameters in Table 2

The parameters of the Prony series resulting from the curve fitting process in ANSYS are given on [Table 2.](#page-16-1) The relaxation modulus curve plotted by using these Prony parameters are also represented in [Figure 11](#page-16-0) (thick black curve).

Table 2: Prony series parameters final model

Validation of the model on neat HDPE

In order to check the viscoelastic final model previously defined [\(Table 2\)](#page-16-1) representing the behavior of the neat HDPE, the numerical approach defined in [Figure 7](#page-11-0) is used for the four lowest crosshead speeds (0.1, 1, 2 and 5 mm/min).

The change of stress with time for experimental results and numerical calculations is illustrated for different crosshead speeds in [Figure 12.](#page-18-0) The curves over entire experimental time span are presented in [Figure 12a](#page-18-0), and the initial parts of these curves are shown in [Figure 12b](#page-18-0). The continuous lines are the experimental curves with different crosshead speeds and the dotted lines are the numerical ones obtained from the general viscoelastic model by using the Prony parameters in Table 2. A very good agreement is observed between numerical results and experimental data for these crosshead speed on neat HDPE.

Journal Pre-proof

Figure 12: Experimental (continous lines) and numerical (dotted lines) results for different crosshead speeds on neat HDPE: stress-time curves over the entire time span (a), zoom at the beginning (b) and stress - strain curves (c)

The experimental and numerical stress-strain curves are then plotted [\(Figure 12c](#page-18-0)). The average strain rate corresponding to each crosshead speed and the equivalent Young's moduli are summarized in the table in the inset of [Figure 12c](#page-18-0).

These curves clearly confirm the viscoelastic behavior of HDPE: stress-strain curves are not straight lines, and the stiffness depends on the loading speed. In fact, when the crosshead speed increases, the equivalent Young's modulus increases. We also remark that the strain rate is almost directly proportional to the crosshead speed.

A good agreement is observed between experimental and numerical results. The difference between numerical and experimental Young's moduli seems to increase with increasing crosshead speed but still remains negligible. To conclude, the model proposed previously represents well the viscoelastic behavior of neat HDPE.

4.2. BaTiO³ filled HDPE nanocomposites: characterization and micromechanical modeling

The viscoelastic constitutive law of neat HDPE is then implemented into a micromechanical model for determining the behavior of BaTiO₃ filled HDPE nanocomposites. Numerical results obtained using this law are compared with experimental results.

The experimental approach described in the previous section is applied to the nanocomposite samples, but only the first step, i.e., loading step, was performed. Samples with different amount of BaTiO₃ filler are tested: 10 v%, 20 v%, 30 v% and 40 v%. The tests were performed using the following crosshead speeds: 0.5, 1, 2 and 5 mm/min. As for neat HDPE, three different samples are tested for each crosshead speed and the test is repeated at least thrice on each sample for a given speed. Finally, an average curve is computed and plotted.

Micromechanical model

The *Material Designer* application of ANSYS is used to generate a 3D geometry of the Representative Volume Element (RVE) of nanocomposites. The distribution of BaTiO₃ particles (considered spherical) is chosen as random with a mean particle diameter of 0.5 µm and a standard deviation of 0.15 µm, as determined by using SEM in our previous work [10]. The random particle distribution for the amounts of 10 v% and 40 v% are shown as examples in [Figure 13a](#page-20-0) and [Figure](#page-20-0) [13b](#page-20-0), respectively. For random particle distribution, the size of this RVE must be large enough that the macroscopic results should be independent of particle distribution. For each amount of BaTiO₃ filler, the RVE size was adjusted in a way that the standard deviation of macroscopic Young's modulus with 10 different random distributions remains less than 1%. A more detailed description of the creation of the RVE can be found in [10]. nstitutive law of neat HDPE is then implemented into a m
behavior of BaTiO₃ filled HDPE nanocomposites. Nume
ompared with experimental results.
approach described in the previous section is applied the first step, i.e.,

This geometry of the RVE is then transferred in the *Mechanical* application tool (finite element software) of ANSYS. The Boundary Conditions (BC) representing a macroscopic uniaxial test are applied. A displacement δx is imposed in x direction and displacements in y (δy) and z (δz) directions are let free but imposed constant [\(Figure 13c](#page-20-0)).

Journal Pre-proo

(c) u^x deformation (mm) represent on deformed shape with initial geometry and BC

Figure 13: RVE of randomly distributed BaTiO₃ particles in HDPE matrix with different filler amount (a) 10 v%, (b) 40 v%, (c) boundary conditions and results for 40 v% filler when a uniaxial displacement (δx) is applied in x direction

The macroscopic normal strain is defined from the imposed displacement [\(Equation 6\)](#page-20-1), and macroscopic normal stress is computed from reaction force (Equation 7).

$$
\varepsilon_{macro}(t) = \frac{\delta_x(t)}{a}
$$
 Equation 6

$$
\sigma_{macro}(t) = \frac{F_x(t)}{a^2}
$$
Equation 7

where $\varepsilon_{macro}(t), \, \delta_x(t),$ a, $\sigma_{macro}(t),$ $F_x(t)$ are the macroscopic strain, the imposed displacement in x direction, the length of cube edge of RVE, macroscopic normal stress and applied force in x direction, respectively.

For each amount of BaTiO₃ filler and each crosshead speed, the imposed displacement $\delta_{x}(t)$ is calculated so that the macroscopic strain corresponds to the experimentally measured strain.

The material properties used for the calculations are shown in [Table 3.](#page-20-3) The mechanical behavior of HDPE is simulated by the viscoelastic model found in the previous sections. BaTiO₃ particles are supposed to have a linear elastic isotropic behavior.

Table 3: material properties of HDPE matrix and BaTiO₃ filler used in the micromechanical model

Results

The experimental and numerical stress-strain curves are obtained for each composition of nanocomposites with different crosshead speed. As an example, the experimental stress-strain curves (continuous lines) and numerical (dotted lines) ones are illustrated for 20 $v\%$ BaTiO₃-filled HDPE composite [\(Figure 14a](#page-21-0)) for different crosshead speeds.

As for neat HDPE, the viscoelastic behavior clearly appears for nanocomposites: an increase in the tensile crosshead speed leads to an increase in the stiffness of the nanocomposites. The equivalent Young's Modulus strongly depends on the strain rate as summarized on the table of the inset on [Figure 14a](#page-21-0).

Figure 14: Experimental (continuous lines) and numerical (dotted lines) results for BaTiO₃ filled HDPE stress-strain curves for HDPE filled by 20 $v\%$ BaTiO₃ with different tensile crosshead speeds (a) equivalent Young's moduli against strain rate for all the HDPE-BaTiO₃ nanocomposite samples (b)

The experimental and numerical results for all filler amounts and all crosshead speeds are summarized on [Table 4](#page-22-0) and represented in [Figure 14b](#page-21-0). [Figure 14b](#page-21-0) shows the evolution of the experimental (continuous lines) and numerical (dotted lines) equivalent Young's moduli as a function of the strain rates.

Table 4: The experimental and numerical equivalent Young's moduli for all the samples and all crosshead speeds

The deviation in experimental results remains below 8%, indicating the reliability of results. As seen on Table 4 and on [Figure 14b](#page-21-0), the results confirm the influence of the amount of filler particles on the stiffness of nanocomposites. In fact, the experimental and numerical equivalent Young's moduli (E_{equiv}) increase with increasing BaTiO₃ filler amount. The stiffness is increased up to 320-400% (depending on the strain rate) when polymer is filled by 40 v % BaTiO₃ compared to neat HDPE. These results also confirm the viscoelastic behavior of the nanocomposite: stiffness increases with increasing strain rate for all samples.

A very good agreement between experimental and numerical results is observed for neat HDPE, 10 $v\%$ and 20 $v\%$ BaTiO₃ filled HDPE indicating that the proposed micromechanical model is representative. For example, for nanoparticle concentration of 20%, a difference of 4.5% is found between experimental and numerical results for a crosshead speed of 1mm/min. For comparison, when a linear elastic model was employed for the polymer [10], this difference reached to 25% for the same crosshead speed. These observations confirm the effectiveness of the viscoelastic model to better reproduce the behavior of the polymer in the nanocomposite compared to simple linear elastic one.

The discrepancy between experimental and numerical results for higher filler amounts can be attributed to the following potential reasons:

- The filler shape and filler particle distribution play an important role in the mechanical behavior of the composite [39]. In the numerical model, spherical particles are distributed randomly in the polymer matrix without any agglomeration. In our previous work [10], we have demonstrated that the

filler distribution modifies the stiffness especially for high filler amount (30 y%). Experimentally, the formation of filler agglomerates cannot be excluded, since no specific surface modification process was performed on filler particles. Indeed, the X-ray nanotomography in [Figure](#page-6-0) [2](#page-6-0) shows that the filler particles agglomerate in the samples, mainly for high particle concentrations. For 10v% filled HDPE, the individual particles are unambiguously distinguished with a very small number of agglomerates formed by a few filler particles. But the For 40v% filled HDPE sample, there are less visible individual particles and more agglomerates compared to the 10v%. Numerical simulation has shown that for a given amount of spherical filler, the agglomeration of filler results in a higher stiffness as found by numerical simulation compared to the random distribution [10]. In a similar way, the filler percolation at high filler amount can result in a different experimental stress pathway.

- The interaction between filler particles and polymer matrix is of great consequence on the mechanical properties of nanocomposites. In fact, when a stress is applied to the nanocomposites, the stress should be transmitted from polymer to the stiffer filler particles. In the numerical model, the interaction between particles and polymer matrix is considered as "perfect contact" without any interphase region. In the literature, the role of an interphase between filler and polymer matrix, with modified polymer properties, has been extensively pointed out [17], [18], [19]. In fact, the polymer properties are modified in the interphase. But in our numerical model, it is very difficult to take into account the interphase since its properties (thickness, viscoelastic properties…) are unknown and should be considered separately from the polymer matrix. An additional difficulty In addition, it is difficult to design manually the interphase around each particle for each random particle distribution. As indicated previously, the aim of this work was to develop a micromechanical model including a viscoelastic behavior. so that Thus, an interphase region was not considered to simplify the analysis and keep it focused on the viscoelasticity effects. For the interact was been extensively pointed into the section of the liferature, the role of an interphase between filler and properties, has been extensively pointed out [17], [18], [18] fied in the interphase. But in o

- From a chemical point of view, the mechanical properties of polymers are in relation with the mobility of chains. In filled polymers, the presence of rigid filler particles can decrease the polymer chain mobility especially for high filler amount where the interparticular distance decreases.

Conclusion

The aim of this work was to develop a numerical model able to predict the mechanical behavior of nanocomposites from that of its constituents. Previous research on the subject has shown the limits of model based solely on the elastic behavior of polymers. This work therefore focused on the implementation of a viscoelastic constitutive law in a micromechanical model developed previously. The study was divided into two steps: The first step consisted in defining a viscoelastic model of the neat HDPE based on experimental data. In the second step, this model was implemented into a numerical micromechanical model of the nanocomposite. Particular attention was paid to the correlation between numerical and experimental results.

Tensile tests confirmed viscoelastic behavior of neat HDPE and HDPE filled BaTiO₃ nanocomposites: stiffness characterized by the equivalent Young Modulus depends strongly on strain rate. These tests ascertained that a pure elastic model does not permit to accurately simulate the mechanical behavior of this type of material as it does not take into account the time dependence of the mechanical response.

Regarding the determination of the relaxation modulus, the work carried out here has confirmed the impossibility to use only the modulus obtained from a relaxation test: if the load is not applied instantaneously, the measured modulus does not correspond exactly to the relaxation modulus. An approach based on a two-step test has been proposed combining the results of tensile and relaxation tests. Several experiments with different crosshead speeds were performed to determine a master curve of this relaxation modulus. The curve fitting process allowed to define the parameters of a viscoelastic constitutive law based on the generalized Maxwell model. Simulations performed with this model show that it is representative of the mechanical behavior of neat HDPE for different tensile crosshead speeds.

Finally, the implementation of this viscoelastic model in a numerical micromechanical approach showed that it is possible to predict the mechanical behavior of a nanocomposite with a good accuracy for small and intermediate amounts of filler. In particular, it was found that the discrepancy between the numerical and experimental equivalent Young's modulus remains less than 7% for nanoparticle concentration up to 20%. For higher amount of filler, further considerations must be taken into account to understand the origin of the differences between experimental and numerical results and improve the model and make it more representative.

In conclusion, this work has highlighted the viscoelastic behavior of neat HDPE and BaTiO₃ filled HDPE nanocomposites. The introduction of this viscoelastic behavior into the developed model has greatly improved its representativeness even if some points still need to be further investigated. The strategy developed in this work can be extended to other filled polymers.

Highlights:

- The viscoelasticity of polymer nanocomposites is highlighted.
- The master curve of HDPE relaxation modulus is experimentally obtained.
- A constitutive law based on the generalized Maxwell model is established for HDPE.
- Mechanical properties of nanocomposites are predicted using a micromechanical model.
