Abstract. Ammonia (NH₃) is the major alkaline species in the atmosphere and plays an important role in aerosol formation, which affects local air quality and the radiation budget. NH₃ in the Upper Troposphere and Lower Stratosphere (UTLS) is difficult to detect and only limited observations are available. We present two dimensional trace gas measurements of NH₃ obtained by the airborne infrared imaging limb sounder GLORIA (Gimballed Limb Observer for Radiance Imaging of the Atmosphere) that has been operated onboard the research aircraft Geophysica within the Asian Monsoon during the StratoClim campaign (July 2017) and onboard HALO (High Altitude and Long Range Research Aircraft) above the South Atlantic during the SouthTRAC campaign (September-November 2019). We compare these GLORIA measurements in the UTLS with results of the CAMS (Copernicus Atmosphere Monitoring Service) reanalysis and forecast model. The GLORIA observations reveal large enhancements of NH₃ of more than 1 ppbv in the Asian Monsoon upper troposphere, but no clear indication of NH₃ in biomass burning plumes in the upper troposphere above the South Atlantic above the instrument's detection limit of around 20 pptv. In contrast, CAMS reanalysis and forecast simulation results indicate strong enhancements of NH₃ in both measured scenarios. Comparisons of other retrieved pollution gases, such as peroxyacetyl nitrate (PAN) show the ability of CAMS models to reproduce the biomass burning plumes above the South Atlantic in general. However, NH₃ concentrations are largely overestimated by the CAMS models within these plumes. We suggest that emission strengths used by CAMS models are of different accuracy for biomass burning and agricultural sources in the Asian Monsoon. Further, we suggest that loss processes of NH₃ during transport to the upper troposphere may be underestimated for the biomass burning cases above the South Atlantic. Since NH₃ is strongly undersampled, in particular at higher altitudes, we hope for regular vertically resolved measurements of NH₃ from the proposed CAIRT mission to strengthen our understanding of this important trace gas in the atmosphere.

20 1 Introduction

Ammonia (NH_3) is the major alkaline trace gas of the atmosphere and part of total reactive nitrogen. Sources of atmospheric NH_3 are livestock and fertilizer in agriculture, but also industry and combustion processes (e.g., Bouwman et al., 1997). Further, NH_3 has been measured in biomass burning plumes in vicinity of fires (e.g., Hegg et al., 1988; Coheur et al., 2007; Tomsche et al., 2023). It is expected that total emissions of ammonia rise strongly (Szopa et al., 2021). Atmospheric sinks of NH_3 are wash-out due to the high water solubility of NH_3 , and formation of aerosols, like ammonium sulfate (in presence of sulfuric acid) or ammonium nitrate (in presence of nitric acid). The importance of ammonia in the atmosphere for the initial formation of new particles has been corroborated by various studies (e.g., Kirkby et al., 2023, and references therein). As aerosols are of importance for local air quality, and for climate through their direct and indirect radiative impact (e.g., Szopa et al., 2021), it is necessary to observe and understand the distribution of NH_3 in the atmosphere from the boundary layer up to the lower stratosphere.

In situ measurements of NH_3 are, however, challenging due to the wide range of ambient levels (5 pptv to 500 ppbv) and the interaction of ammonia with surfaces of the instrument (“sticky”) (e.g., von Bobruzki et al., 2010). Still, there are various in-situ measurements at boundary layer altitudes, but only very few in the free troposphere and quasi none in the upper troposphere (e.g., Ziereis and Arnold, 1986; Nowak et al., 2010; Tomsche et al., 2023).

Due to its specific spectral lines in the thermal infrared region, remote sounding spectrometers are suited to quantify NH_3 in a “contact-free” manner. In that way, NH_3 has been observed by infrared sounders from satellite and aircraft in nadir and limb geometry. From satellite instruments measuring in nadir, such as TES (Tropospheric Emission Spectrometer), IASI (Infrared Atmospheric Sounding Interferometer), CrIS (Cross-track Infrared Sounder), or AIRS (Atmospheric Infrared Sounder) global observations of NH_3 in the lower troposphere are available (e.g., Beer et al., 2008; Clarisse et al., 2010; van Damme et al., 2015; Shephard and Cady-Pereira, 2015; Warner et al., 2016). First observations of NH_3 in the upper troposphere (in particular of the Asian summer monsoon) have been achieved by the MIPAS (Michelson Interferometer for Passive Atmospheric Sounding) instrument from the Envisat satellite (Höpfner et al., 2016), and by the GLORIA (Gimballed Limb Observer for Radiance Imaging of the Atmosphere) instrument onboard the Geophysica research aircraft (Höpfner et al., 2019). The connection of large amounts of NH_3 reaching the upper troposphere through convection with the formation of solid ammonium nitrate particles as secondary aerosols was also shown during these flights (Höpfner et al., 2019; Wagner et al., 2020; Appel et al., 2022).

In the present work we utilize observations of mid- to upper tropospheric NH_3 obtained within two aircraft campaigns of the GLORIA instrument to analyse the performance of the CAMS atmospheric model to describe the distribution of NH_3 under different situations: within the Asian summer monsoon and within biomass burning plumes.

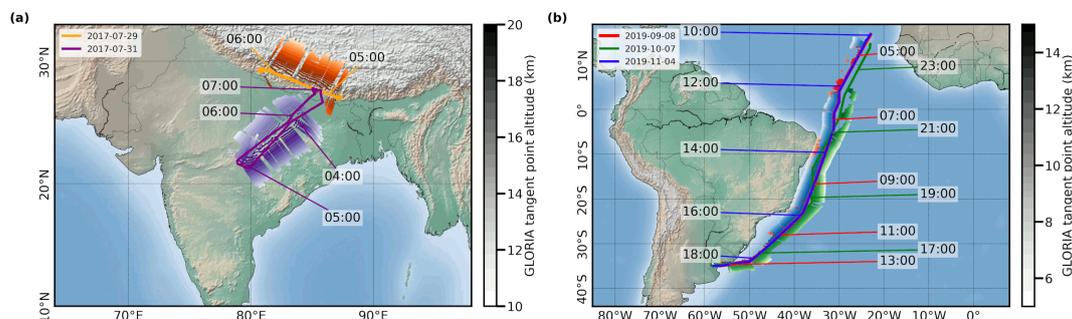

Figure 1. Flight paths and locations of GLORIA tangent points for discussed flights of (a) the StratoClim campaign and (b) the SouthTRAC campaign. Tangent points affected by clouds are not used in the retrieval process and result in gaps in the plotted geolocations. Note different color bar ranges and map scales for each panel. The flight path of the flight on 8 September 2019 is identical to the flight path of the flight on 4 November 2019, which hides large parts of the earlier flight.

50 2 Observations and atmospheric model simulations

2.1 GLORIA measurements

The GLORIA instrument has been deployed on various airborne campaigns with the M55 Geophysica and the HALO research aircraft. In this study, GLORIA measurements from the M55 Geophysica StratoClim campaign (July/August 2017, base in Kathmandu, Nepal), and from the HALO SouthTRAC campaign (September-November 2019 with bases in Oberpfaffenhofen, Germany and Rio Grande, Argentina) are discussed. Flight paths and the location of GLORIA tangent points are summarized in Fig. 1. For this study, StratoClim flights on 29 July 2017 and 31 July 2017 have been selected because of measured high NH_3 (Höpfner et al., 2019), while SouthTRAC flights on 8 September 2019, 7 October 2019, and 4 November 2019 are chosen because of measured large pollution plumes above the South Atlantic (Johansson et al., 2022). Both StratoClim flights were conducted from and to Kathmandu, Nepal, and the three selected SouthTRAC flights were directed from Sal, Cape Verde, to Buenos Aires, Argentina, and vice versa, as part of the transfer flights between Germany and Argentina.

The GLORIA instrument (Friedl-Vallon et al., 2014; Riese et al., 2014) combines an imaging detector working in the thermal infrared with a Fourier-Transform-Spectrometer in an actively controlled gimbal frame. This combination allows for simultaneous observations of 128×48 (vertical \times horizontal) atmospheric spectra, high spectral sampling up to 0.0625 cm^{-1} , and compensation of aircraft movements and active targeted line-of-sight control. Further, two external black bodies are used for in-flight radiometric calibration measurements, together with upward looking atmospheric “deep space” observations. For the measurements discussed in this work, mostly interferograms which were obtained with a maximum optical path difference (MOPD) of 8.0 cm (spectral sampling of 0.0625 cm^{-1}) are used. Only during the StratoClim flight on 29 July 2017, due to operational restrictions, interferograms with 2.5 cm MOPD were recorded, resulting in a spectral sampling of 0.2 cm^{-1} . Within GLORIA level 1 processing, the interferograms are Fourier-Transformed and radiometrically and spectrally calibrated. The resulting calibrated spectra at each detector pixel are screened, filtered, and finally horizontally binned into 127 spectra per

recorded measurement sampled in the vertical direction (with one horizontal line of spectra being disregarded completely due to detector artifacts; Kleinert et al., 2014; Ungermann et al., 2022). All GLORIA retrievals in this study are based on version v03.02 of GLORIA level 1 data (calibrated spectral radiances).

Based on these binned calibrated spectra, profiles of atmospheric temperature and trace gases are retrieved perpendicular to the flight track (Johansson et al., 2018). The retrieval uses a nonlinear least-squares fit with Tikhonov regularization of the retrieval software KOPRAFIT together with the radiative transfer model KOPRA (Stiller, 2000). For NH_3 , the overall retrieval strategy from Höpfner et al. (2019) is applied, while for PAN, retrievals as described by Johansson et al. (2020, 2022) are utilized. Due to the reduced spectral sampling on the flight of 29 July 2017, spectral windows and regularization have been adjusted slightly. For NH_3 retrievals of StratoClim flights, vertical resolutions between 0.8 and 1.3 km, and estimated errors between 10 and 50 pptv have been achieved, for SouthTRAC flights discussed in this work, vertical resolutions between 0.5 and 0.7 km, and estimated errors between 6 and 12 pptv (10,90 percentile ranges, each).

2.2 CAMS global atmospheric composition model configurations

As part of the Copernicus Atmosphere Monitoring Service (CAMS), two data products are publicly available: First, the ECMWF (European Centre for Medium-Range Weather Forecast) Atmospheric Composition Reanalysis version 4 (EAC4; Flemming et al., 2015; Inness et al., 2019), and second, the CAMS global atmospheric composition operational near-real time forecasts. Both atmospheric model configurations use the ECMWF Integrated Forecast System (IFS) model, and assimilate multiple observations of atmospheric state and composition. In this study, CAMS model output is linearly interpolated in space and time onto GLORIA measurement geolocations to ensure optimal comparisons between observation and model output.

2.2.1 CAMS reanalysis

The CAMS reanalysis is currently available between 2003 and 2021, and uses 60 vertical levels between 0.1 and 1000 hPa, and a horizontal resolution of $0.75^\circ \times 0.75^\circ$ latitude \times longitude. Data is provided every 3 h and includes meteorological parameters, concentrations of chemical trace gases, as well as aerosols. It is based on IFS cycle 42r1, and employs data assimilation of trace gases O_3 , CO, and NO_2 , along with aerosol optical depth (Inness et al., 2019). Chemistry is handled by a module named IFS(CB05) (Flemming et al., 2015), with its tropospheric chemistry as inherited from the TM5 model (Huijnen et al., 2010), and aerosols are treated as described by Morcrette et al. (2009). Anthropogenic emissions are prescribed from MACCity (MACC/CityZEN; Granier et al., 2011), biogenic emissions from MEGAN2.1 (Model of Emissions of Gases and Aerosols from Nature; Guenther et al., 2012), and biomass burning emissions from GFAS v1.2 (Global Fire Assimilation System; Kaiser et al., 2012). CAMS reanalysis has been evaluated by various aircraft measurements: Wang et al. (2020) compared tropospheric trace gas profiles over the Arctic, North America, and Hawaii to CAMS reanalysis and show that simulated PAN is in agreement with observations. Further, Johansson et al. (2020, 2022), and Wetzel et al. (2021) compared GLORIA PAN and other pollution trace gases to CAMS reanalysis data in the upper troposphere above the Asian Monsoon, the North Atlantic, and the South Atlantic, respectively. They found an overall agreement for the measured plume structures and for biomass burning

plumes above the South Atlantic (including SouthTRAC flights that are discussed in this study). In these plumes especially the trace gas PAN was even in quantitative terms described well by the model.

105 2.2.2 CAMS forecast

The CAMS global atmospheric composition near-real time forecast is operationally available since 2015, and in contrast to the reanalysis, this data product receives a version upgrade approximately once a year. For this reason, the CAMS forecast data for StratoClim measurements in 2017 (cycle 43r1) are different to those for SouthTRAC measurements in 2019 (cycle 46r1). Both forecast model results are based on a newer model version compared to CAMS reanalysis (cycle 42r1). The model
110 utilizes 60 vertical levels for simulations for 2017, and 137 model levels for 2019, and in both cases a horizontal resolution of $0.4^\circ \times 0.4^\circ$ latitude \times longitude. New forecasts are started every day at 0:00 UTC and 12:00 UTC, and output is provided every 3 h for vertically resolved parameters. In this work, model output of shortest possible lead times of 0, 3, 6, and 9 h are used for interpolation as mentioned above.

Besides changes in resolution, CAMS forecast for the measurements in 2017 differs compared to CAMS reanalysis, among
115 other things in the following aspects: Additional observational data sets are considered for assimilation (e.g., vertical ozone profiles of the Ozone Mapping and Profiler Suite). Further, a new source scheme for Secondary Organic Aerosols, which is based on scaled CO emissions, is introduced (Eskes et al., 2016). Additionally, CAMS forecasts for the measurements in 2019 differs among other things in these aspects: Now, CAMS makes use of CAMS_GLOB_ANT v2.1 anthropogenic and CAMS_GLOB_BIO v1.1 biogenic emissions. Biomass burning plume injection height from GFAS is introduced, along with
120 a diurnal cycle in its emissions. Further, separate ammonium and nitrate aerosol species are introduced, interaction between chemistry and aerosol schemes are established, which implied a change in the modelled ammonia life cycle. Also a selection of chemical reaction rates are updated (Eskes et al., 2017, 2018; Basart et al., 2019).

3 Ammonia measurements and comparisons

In this section, GLORIA measurements of NH_3 are presented and compared to CAMS reanalysis and forecast simulation
125 results. In addition, as indicator for the pollution plumes, GLORIA measurements of PAN are shown. First, the two flights from the StratoClim campaign within the Asian monsoon air are presented, followed by three SouthTRAC flights concentrating on biomass-burning situations.

3.1 Asian Monsoon

From space-borne infrared nadir and limb-observations it is known that elevated concentrations of NH_3 are present in the
130 atmosphere above the Indian subcontinent at lower levels (van Damme et al., 2015) and even in the upper troposphere during the time of the Asian Monsoon (Höpfner et al., 2016). For the GLORIA airborne measurements on 31 July 2017, strongly enhanced abundances of NH_3 of up to about 1000 pptv were reported (Höpfner et al., 2019). The current analysis of the flight on 29 July 2017 above Nepal shows even higher concentrations of up to 1500 pptv, as presented in Fig. 2a. This maximum

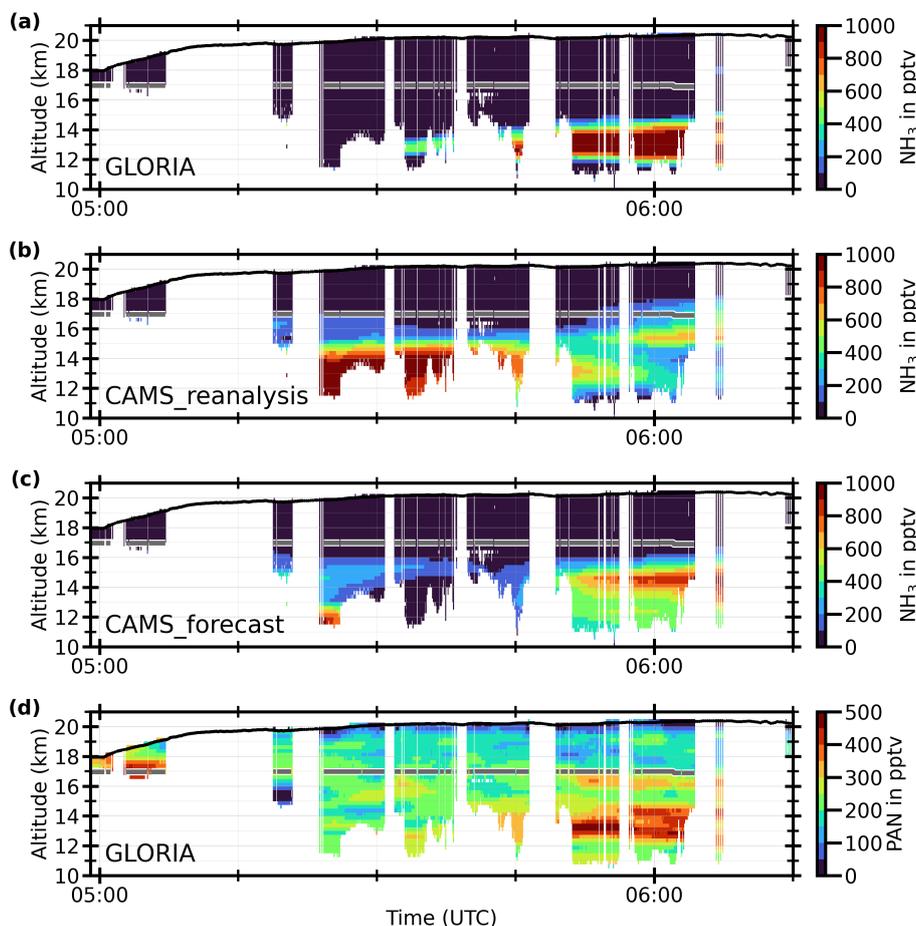

Figure 2. StratoClim flight on 29 July 2017: GLORIA time/altitude cross sections of (a) NH_3 and (d) PAN together with CAMS reanalysis (b) and CAMS forecast (c) simulation results, interpolated onto GLORIA geolocations. GLORIA data is horizontally averaged to match lower horizontal resolutions of CAMS forecast of ≈ 44 km. The black line indicates flight altitudes, the gray line shows the ECMWF analysis 380 K potential temperature as indication of the tropopause location in the Asian Monsoon. Blank spaces indicate regions of high cloud tops, calibration measurements, or aircraft movements (like curves).

is part of a larger horizontal structure between 5:30 UTC and 6:15 UTC and 12 km to 14 km altitude. Peak values of NH_3 VMRs coincide with maximum PAN VMRs (Fig. 2d). CAMS reanalysis (Fig. 2b) indicates a similar NH_3 enhancement at the same altitude range, but shifted to earlier measurement times (eastwards). In addition, a thin maximum up to 700 pptv NH_3 is present at 15 km altitude, which is at a similar location as a second, smaller observed PAN maximum (see Fig. 2d), but does not correspond to a measured NH_3 maximum. CAMS forecast also shows two plumes, but spatially shifted and of different intensity. This model indicates a major NH_3 maximum around 6:00 UTC peaking at approximately 14 km altitude. Maximum VMRs are up to 900 pptv and thus smaller than observed, which may be caused by too fast NH_4^+ production in the model.

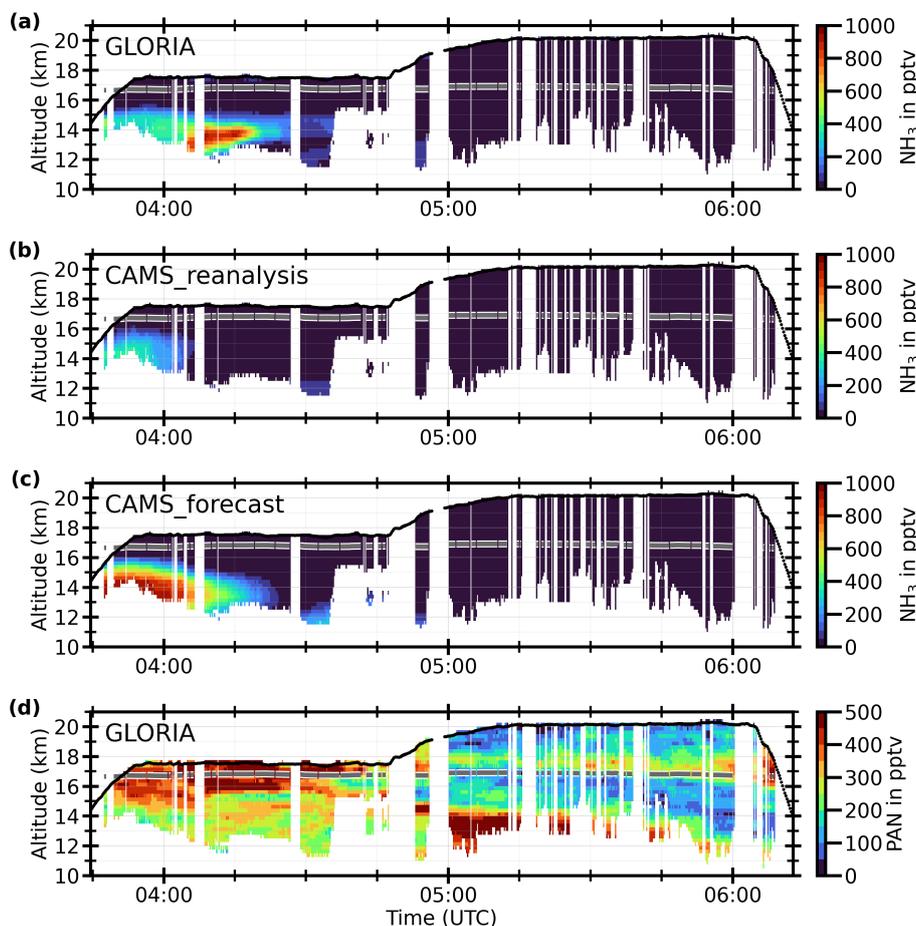

Figure 3. Same as Fig. 2, but for flight on 31 July 2017.

Another maximum is forecasted at approximately 05:30 UTC and 12 to 16 km altitude with maximum VMRs up to 1000 pptv at 12 km altitude.

The StratoClim flight on 31 July 2017 reveals one large enhancement of NH₃, peaking at 4:15 UTC and 14 km altitude with VMRs up to 1000 pptv (Fig. 3a). A second, faint maximum (4:30-4:50 UTC, 12 km altitude) indicates lower VMRs up to 100 pptv. For the second part of the flight (later than 5:00 UTC), GLORIA measurements show no enhanced NH₃. This is remarkable, since the flight region is very similar to the first part of the flight and mainly the viewing direction of GLORIA has changed (see Fig. 1a). However, PAN observations indicate polluted air masses also for this second part of the flight. These PAN pollution plumes in the second part of the flight are reproduced by CAMS reanalysis and forecast (see Johansson et al., 2020 and supplementary figures 1-2). CAMS reanalysis and forecast successfully reproduce the approximate position of the observed NH₃ plumes, as well as the absence of NH₃ plumes in the second part of the flight (see Fig. 3b,c). However, CAMS reanalysis does not simulate the major plume later than 4:10 UTC, and also maximum VMRs are simulated below 400 pptv,

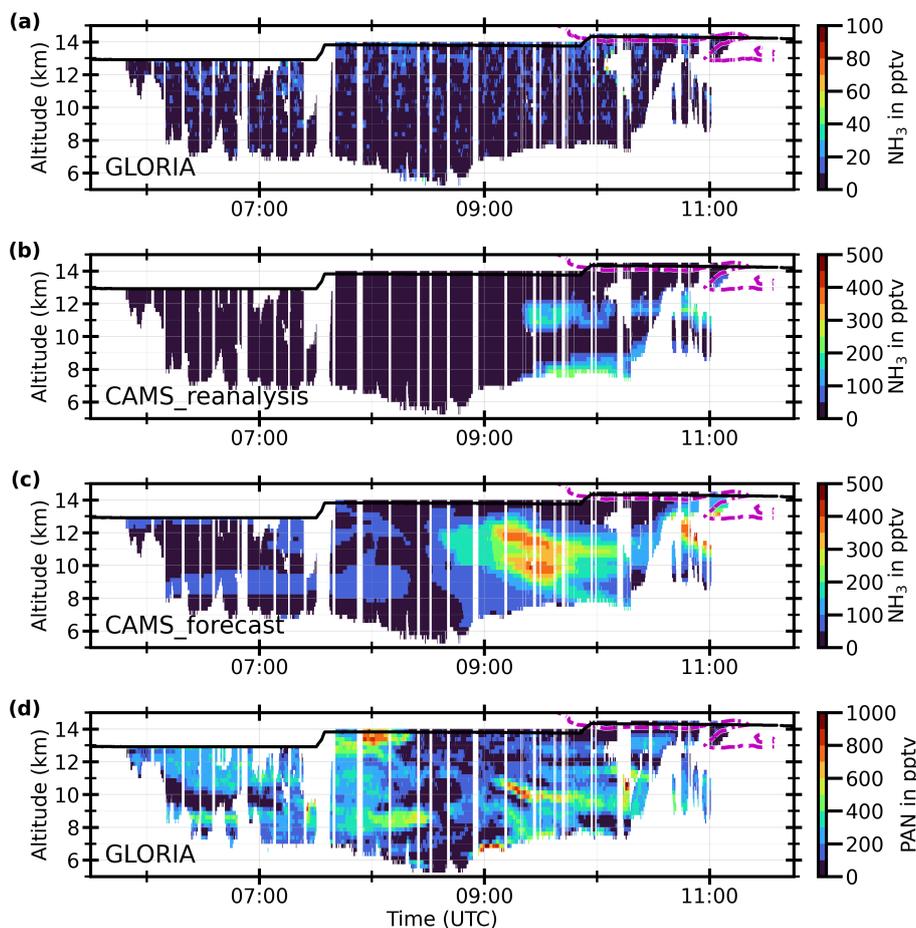

Figure 4. SouthTRAC flight on 8 September 2019: GLORIA time/altitude cross sections of (a) NH_3 and (d) PAN together with CAMS reanalysis (b) and CAMS forecast (c) simulation results, interpolated onto GLORIA geolocations. GLORIA data is horizontally averaged to match lower horizontal resolutions of CAMS forecast of ≈ 44 km. The black line indicates flight altitudes, the dashed magenta line shows the ECMWF $\pm 2,4$ PVU isolines as indication of the tropopause. Blank spaces indicate regions of high cloud tops, calibration measurements, or aircraft movements. Note that color bars for NH_3 change between GLORIA measurements (a) and both CAMS simulation results (b-c). Further, color bars have been adjusted to generally lower NH_3 VMRs compared to Figs. 2-3.

and thus considerably lower than the measured ones. CAMS forecast also simulates the largest VMRs of the major plume earlier than measured, but maximum VMRs are comparable to the GLORIA measurements.

3.2 Biomass burning plumes above the South Atlantic

155 All three of the transfer flights between Sal, Cape Verde, and Buenos Aires, Argentina, and vice versa, have been influenced by pollution plumes, originating from biomass burning events (Johansson et al., 2022). In the following we will discuss the observations of NH_3 by GLORIA within these plumes in comparison to both CAMS reanalysis and forecast model configurations.

For SouthTRAC flight on 8 September 2019 (Fig. 4a), GLORIA measured less than 20 pptv NH_3 over large parts of the flight, despite clear biomass burning plume structures observed in PAN (Fig. 4d). Very small enhancements below 60 pptv are indicated at approximately 10:15 UTC and 13 km altitude, surrounding the filtered air masses, where no retrieval has been possible due to cloud or aerosol contamination. In such close proximity, the cloud or aerosol feature, however, could have affected the NH_3 retrieval quality. CAMS reanalysis (Fig. 4b) and forecast (Fig. 4c) simulate enhanced concentrations of NH_3 within extended areas, which are correlated with the PAN biomass burning plumes. CAMS reanalysis shows two horizontal plumes with VMRs up to 250 pptv, between 9:30 and 11:00 UTC and at 8 and 11 km altitude. This structure corresponds to the measured biomass burning plumes. Using backward trajectories, it has been shown that these air masses likely entered the upper troposphere above central South America (see Fig. 3 of Johansson et al., 2022). Further, GLORIA measured C_2H_4 (upper tropospheric life time of ≈ 1.2 d) exclusively at these spots, which indicates a young age of these air masses (see Fig. 1 of Johansson et al., 2022). Similarly, CAMS forecast indicates maximum VMRs up to 400 pptv for these plumes. In addition, CAMS forecast also simulates enhancements of lower VMRs up to 100 pptv for air masses associated with PAN plumes in the first part of the flight (e.g., 6:15 to 8:30 UTC and 9 km altitude, and 8:00 UTC and 12 km altitude). No similar enhancements of NH_3 are visible in the GLORIA observations.

The SouthTRAC flight on 7 October 2019 was characterized by a large, nose-like plume of PAN (and other pollution species) with high VMRs up to 1000 pptv (17:30 to 20:15 UTC, and 8 to 12 km altitude; Fig. 5d). This plume is reproduced by both CAMS model configurations, and trajectories indicate central South America as source of these air masses (see Johansson et al., 2022 and supplementary figures). Further, background PAN VMRs between 19:00 and 21:00 UTC are up to 350 pptv and thus considerably larger than tropospheric background concentrations in the beginning of the flight, which indicates further pollution outside the major PAN plume. NH_3 as measured by GLORIA (Fig. 5a) instead, does not show any plume-like structure, but background VMRs below 30 pptv. Again, close to a possible aerosol or cloud contamination at 21:00 UTC and 13 km altitude, larger NH_3 VMRs up to 70 pptv are observed. As mentioned for measurements of SouthTRAC flight on 8 September 2019, this NH_3 enhancement might be an artifact due to the challenging conditions for the retrieval in the presence of clouds and aerosols.

In contrast to the observations, the CAMS reanalysis simulates large amounts of NH_3 of more than 1500 pptv. Parts of the simulated NH_3 plume resemble the large nose-like PAN plume, as measured by GLORIA. Other parts of the plume include the air masses of the elevated background PAN VMRs, and also the region of enhanced measured NH_3 , but more than an order of magnitude higher than observed. The CAMS forecast does not simulate as high NH_3 VMRs as the reanalysis, but still maximum VMRs up to 150 pptv, which is considerably more than measured by GLORIA. The structure of maximum simulated NH_3 VMRs coincides with measured PAN maxima and thus indicates that the CAMS forecast also simulates large NH_3 VMRs within biomass burning plumes.

Similar to both presented SouthTRAC flights, the GLORIA observations on 4 November 2019 do not show enhanced NH_3 concentrations, despite PAN plumes measured in these air masses (see Fig. 6a,d). Between 14:30 and 16:00 UTC, small enhancements of NH_3 are observed at 13 km altitude, just below flight altitude. Otherwise, NH_3 VMRs are below 20 pptv. Again, CAMS reanalysis and forecast largely overestimate NH_3 for this flight: CAMS reanalysis (Figs 6b) simulates up to

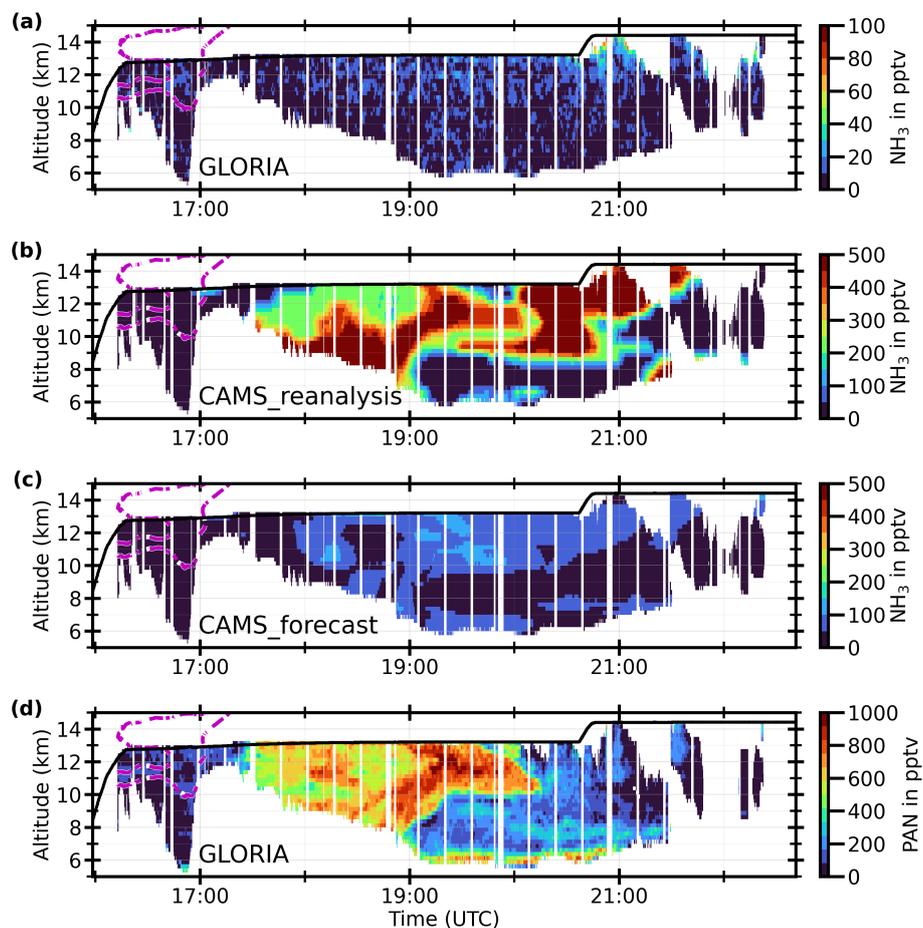

Figure 5. Same as Fig. 4, but for flight on 7 October 2019.

400 pptv of NH_3 at measurement times with enhanced PAN observations. However, simulated NH_3 structures are not directly comparable to the observed PAN distributions. Still, simulated PAN patterns, in particular at 15:00 UTC, are similar to this
195 NH_3 distribution (see supplementary Fig. S5). This indicates an overall displacement of the simulated plumes, compared to the GLORIA observations. CAMS forecast (Fig. 6c) again shows lower NH_3 concentrations compared to the reanalysis, but still values of up to 150 pptv. In this case, simulated NH_3 patterns resemble more the structures observed in PAN.

3.3 Discussion

The GLORIA NH_3 observations show a very different situation for the atmosphere above the Asian Monsoon and above
200 the South Atlantic. While GLORIA measured plumes of strongly enhanced NH_3 VMRs in the upper troposphere within the Asian summer Monsoon, biomass burning plumes above the South Atlantic do not show detectable enhancements of ammonia. Comparisons with both CAMS models for the StratoClim measurements during the Asian monsoon show reasonable agreement

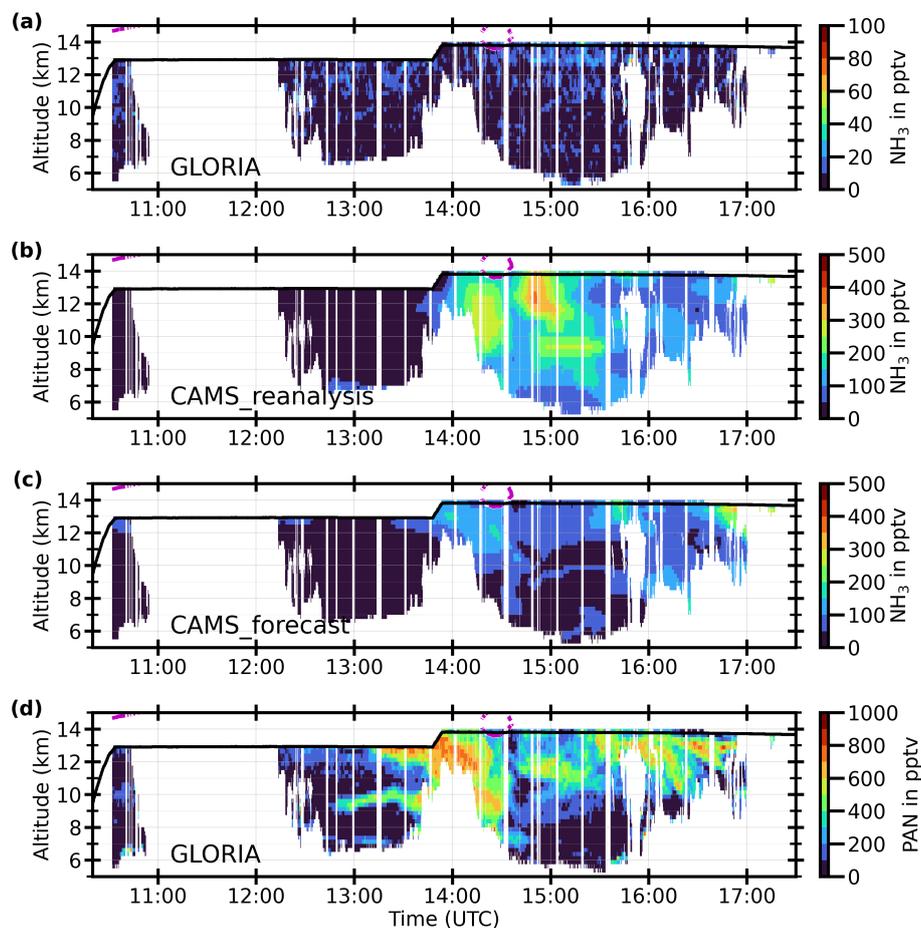

Figure 6. Same as Fig. 4, but for flight on 4 November 2019.

in quantitative terms as well as in the location of the plumes (within the expected performance of the model). In particular the better representation of the major plume during the flight on 31 July 2017 in the CAMS forecast (compared to the CAMS
205 reanalysis) may be due to the higher horizontal resolution and upgraded model properties of the forecast (see Sec. 2.2.2).

For the SouthTRAC flights above the South Atlantic, CAMS reanalysis and forecast both simulate NH₃ plumes of several hundred pptv, which are correlated with biomass burning plumes, but which are not observed by GLORIA. The simulated biomass burning plumes (in particular the PAN plumes) show reasonable agreement with the GLORIA PAN measurements, which excludes a mismatch of the plume locations between model and observation as reason for the disagreement in NH₃.

210 This difference in the ability of CAMS models to reproduce measured NH₃ VMRs may have various reasons: Sources for NH₃ may be of different quality for different regions on Earth and also for different emission types. While the enhancements of NH₃ measured in the Asian Monsoon on 31 July 2017 likely stem from anthropogenic (agricultural) activities (see Supplementary figures 10-11 of Höpfner et al., 2019), plumes above the South Atlantic, in which CAMS models show enhanced

NH₃, are likely to come from biomass burning events (Johansson et al., 2022). These two types of emissions, anthropogenic
215 and biomass burning, are prescribed by different emission data sets in CAMS model simulations (see Sec. 2.2), and both data
sets may vary in their accuracy and precision regarding NH₃.

When comparing the amount of NH₃ in the lower atmosphere near the surface (Supplementary figures S6-S7), the CAMS
reanalysis dataset shows comparable values in the order of 10 ppbv in the Asian Monsoon over Northern India/Pakistan by
end of July 2017 as well as over the burning regions in the Amazonian in October 2019. The concentrations in the Monsoon
220 region are in broad agreement with the total column amounts of NH₃ as observed by IASI (Clarisse et al., 2023). Regarding the
biomass-burning cases, the near-surface concentrations of the model appears consistent with observations of NH₃ within fire
plumes of tens to few hundreds of ppbv (Tomsche et al., 2023). However, IASI total column amounts in the region of the South
American plume-origin in autumn 2019 are by a factor of around 5 less abundant compared to the ones inside the monsoon.
This would indicate an overestimation of the model with respect to the Amazonian fire sources.

225 Further, atmospheric sinks, such as wet deposition or formation of ammonium (NH₄⁺)-containing aerosols, may be underes-
timated by CAMS model configurations within biomass burning plumes above the South Atlantic. In addition, it is still under
discussion, how NH₃ is efficiently transported into the upper troposphere in the Asian Monsoon without being washed-out
by the strong precipitation within thunderstorms. For example, Ge et al. (2018) explain large NH₃ VMRs by deep convective
vertical transport of NH₃ being dissolved in liquid cloud droplets, from which NH₃ would be released during the freezing
230 process of the cloud particles. However, this transport mechanism may be imitated by the CAMS models by a lower wash-out,
which is helpful for the Asian Monsoon, but not for biomass burning above the South Atlantic.

4 Conclusions

In this work, we have tested different CAMS model configurations with respect to their capability to simulate NH₃ mixing
ratios in the upper troposphere. Knowledge about NH₃ in the atmosphere is important due to the influence of ammonia on
235 aerosol formation in an altitude region strongly influencing Earth's radiative budget.

We have selected two general scenarios, where enhanced concentrations of NH₃ can be expected to be transported from
ground sources to high altitudes: the Asian monsoon, and strong biomass burning in South America and Africa. In both cases,
the CAMS model configurations simulated elevated amounts of NH₃ in the upper troposphere.

240 Comparing these model data with observation of NH₃ obtained by the GLORIA infrared remote sounding instrument during
two aircraft measurement campaigns reveals that the model configurations reproduce broadly well the observations of elevated
NH₃ concentrations within the Asian summer monsoon. However, they strongly overestimate NH₃ within the biomass burning
plumes in the mid-upper tropical troposphere, where no clear enhancement is visible in our measurements.

245 Clarifying the reason for this model overestimation is beyond the scope our analysis. There are, however, hints that the
emission of NH₃ through biomass burning might be overestimated. Still there exist large uncertainties about the losses of NH₃
through different processes like particle formation and wash-out on its way from its source region to the measurement location
in the upper troposphere.

In terms of measurements, NH_3 is strongly undersampled especially at higher altitudes of our atmosphere, which means that there is a need for more vertically resolved observations. Here we have shown, that by using vertically high resolved observation from spectroscopic infrared limb-observations, it is possible to judge on the skills of atmospheric models to describe this trace gas correctly. With hopefully upcoming satellite missions, like ESA's Earth explorer 11 candidate CAIRT (Changing-
250 Atmosphere Infra-Red Tomography Explorer; Sinnhuber et al., 2023), it will be possible to get daily global and altitude-resolved vertical distribution of NH_3 from the mid-troposphere to the lower stratosphere. In combination with infrared nadir sounders, like IASI, it will be possible to gain much more insight in the processes governing the distribution of ammonia in our atmosphere.

255 *Data availability.* GLORIA measurements are available in the database HALO-DB (<https://halo-db.pa.op.dlr.de/mission/101> and <https://halo-db.pa.op.dlr.de/mission/116>) and will be available on the KITopen repository. The CAMS model data is available from the Copernicus Atmosphere Data Store (<https://ads.atmosphere.copernicus.eu>). IASI NH_3 v4 columns are available online: <https://iasi.aeris-data.fr/NH3/>

Author contributions. SJ initiated the study, performed the analyses, and wrote the manuscript together with MH. GW, MH, JU, AK, NG, PP, and SJ performed the GLORIA data processing. FFV, EK, TG, CP, GM, HN, TN and coworkers operated GLORIA during the StratoClim
260 and SouthTRAC campaigns. MH, MR, JU, BMS, WW and SJ participated in scientific flight planning during the campaigns. VH provided insights into the CAMS simulations. All authors commented on and improved the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We gratefully thank the SouthTRAC coordination team, in particular DLR-FX for successfully conducting the field campaign, and local support from Argentina and Chile. For the successful campaign from Kathmandu, we thank the StratoClim coordination
265 team as well as the Geophysica team, and local support from Nepal. The results are based on the efforts of all members of the GLORIA team, including the technology institutes ZEA-1 and ZEA-2 at Forschungszentrum Jülich and the Institute for Data Processing and Electronics at the Karlsruhe Institute of Technology. The StratoClim campaign was supported by the European Community's Seventh Framework Programme (FP7/2007–2013) under grant no. 603557. The SouthTRAC measurement campaign was supported by the German Science Foundation (Deutsche Forschungsgemeinschaft, DFG) under the Priority Program HALO SPP 1294. Within the HALO SPP this work was
270 supported by project grant HO 4120/4-1. In addition the participating Helmholtz institutes contributed to the HALO operation costs based on their programme-oriented funding We thank ECMWF for providing CAMS data. Contains Copernicus Atmosphere Monitoring Service Information 2023. Neither the European Commission nor ECMWF is responsible for any use that may be made of the information it contains. We thank AERIS for providing IASI NH_3 data, and we particularly appreciate helpful comments from Lieven Clarisse. We acknowledge support by the KIT-Publication Fund of the Karlsruhe Institute of Technology.
