*Keywords:* Gluconate Formate C–S–H phases AFm phases Ettringite Portland cement Uptake

## ABSTRACT

Editorial Handling by: Erich Wieland The uptake of formate and gluconate by C–S–H, AFm phases, ettringite and hydrated Portland cement (PC) was studied at pH 13 by batch sorption experiments. The formation of gluconate and formate-AFm phases was observed in pure systems, but not in hydrated cement. Gluconate sorbs more strongly on AFm phases and ettringite than formate. Higher calcium concentrations increase the gluconate sorption on C–S–H and hydrated Portland cements due the formation of Ca-gluconate surface complexes on C–S–H. Measured  $R_d$  values for gluconate sorption on C–S–H increase from 2.0 dm<sup>3</sup>·kg<sup>-1</sup> for C–S–H with Ca/Si = 0.8 to 34 dm<sup>3</sup>·kg<sup>-1</sup> for Ca/Si = 1.4 at pH 13. They are a factor 5 to 10 higher at lower pH values, and higher Ca-concentrations. Calcium concentration does not significantly affect the uptake of formate by C–S–H. Formate sorbs on hydrated PC with  $R_d$  values in the range of 3–33 dm<sup>3</sup>·kg<sup>-1</sup>.

## **1. Introduction**

Organic additives are widely used to control and adjust the workability, durability and strength of cementitious materials. The added amount [\(Ma et al., 2015;](#page-11-0) [Perez, 2007](#page-11-0)) and the order of addition of cement additives may alter the properties of cement [\(von Daake and](#page-11-0)  [Stephan, 2017\)](#page-11-0).

Sodium gluconate (Na( $C_6H_{12}O_7$ ), Na-GLU) is commonly used as a retarder ([Nafee et al., 2023;](#page-11-0) [Perez, 2007](#page-11-0); [Singh, 1976;](#page-11-0) [Zhang et al.,](#page-11-0)  [2017\)](#page-11-0) and can, when combined with a superplasticizer, alter the fluidity of the cement paste ([Li et al., 2012;](#page-10-0) [Zou et al., 2017](#page-11-0)) and the setting time ([Li et al., 2018\)](#page-10-0). [Singh \(1976\)](#page-11-0) suggested that gluconate poisons the hydrates nuclei on the surface of  $C_3S$  grains, but as soon as gluconate is completely adsorbed and the fresh nuclei are formed, the hydration process accelerates again. [\(Perez, 2007](#page-11-0)) showed that gluconate sorbs specifically on alite  $(C_3S)$  and gluconate uptake depends on the dosage. At low gluconate dosages (0.09 wt%), gluconate sorbs weakly on aluminate-sulfate phases (responsible for the formation of AFm phases and ettringite) and has a small effect on the congruent dissolution of alite. At higher dosage (*>* 0.13 wt%), gluconate can also adsorb on alite surface, thus inhibiting the initial C–S–H formation and increasing the induction period. High gluconate dosage inhibits also slightly the hydration of the aluminates. [\(Ma et al., 2015\)](#page-11-0) showed the delayed formation of ettringite and inhibition of gypsum dissolution for a gluconate dosage higher than 0.05% dry cement.

Formate (HCOO<sup>−</sup> , FOR) is a known cement accelerator and is also used as antifreezing additive for concretes ([Hartmann et al., 2014](#page-10-0); [Vdovin and Stroganov, 2020\)](#page-11-0). [Hewlet \(1998\)](#page-10-0) compared the calcium salts of chloride, nitrite and formate, and related their accelerating efficiency to the mobility of the anions within the silicate particles, concluding that the anion size is a major factor. Due to its larger size (0.45 nm), formate is less suitable as accelerator than anions with smaller size such as nitrite (0.34 nm) or chloride (0.27 nm) [\(Hewlet,](#page-10-0)  [1998\)](#page-10-0). It was observed that the presence of formate accelerates the precipitation of  $Ca(OH)_2$  as well as the reaction of  $C_3S$  and  $C_2S$  (Heikal,  $2004$ ). Calcium formate Ca(HCOO)<sub>2</sub> has a relatively low solubility in water (approx.  $16g/100 g H<sub>2</sub>O$  at room temperature), such that it must be added to concrete or cement mixture in solid form. Sodium formate, which has also accelerating properties ([Gebler, 1983\)](#page-10-0), is approximately 3 times more soluble in water, but it leads to the increase of alkali content to the mixture, which can contribute to the formation of alkali silica products responsible for expansion and cracking of concrete ([Lindgård et al., 2012\)](#page-10-0).

In the context of cement-based repositories for the disposal of low and intermediate level radioactive waste (L/ILW), the presence of low molecular weight organics such as gluconate, α-isosaccharinate or formate needs to be taken into account in the evaluation of the long-term safety of the repository. The presence of low molecular weight organics may alter the solubility and sorption properties of radionuclides in the cement matrix, possibly influencing the migration of these

<span id="page-1-0"></span>radionuclides. Low molecular weight organics are found in the repository either as a component in the cement formulations (e.g., cement additives), as part of the emplaced waste (e.g., decontaminating agents such as EDTA, NTA or citrate), as degradation products of complex organic materials (e.g., cellulosic materials), or present as  $^{14}$ C containing organic compounds in core structural material and reactor coolant waste streams [\(Ochs et al., 2016](#page-11-0); [Wieland and Hummel, 2015\)](#page-11-0).

Only a few studies have previously investigated the uptake of formate by hardened cement paste (HCP) [\(Kaneko et al., 2002](#page-10-0); [Wieland](#page-11-0)  [et al., 2016](#page-11-0)). Wieland et al. (2016) investigated the sorption of several 14C labelled small organic molecules (i.e. formic acid, acetic acid, acetaldehyde, formaldehyde, ethanol, methanol) on HCP ( $S/L = 333$  g· dm<sup>-3</sup>) and AFm phases, such as monosulphate (Ms), hemicarbonate (Hc), monocarbonate (Mc) and ettringite. The authors observed that the strength of the uptake for the investigated organics followed the sequence alcohol *<* aldehyde *<* carboxylate and that the uptake of formate was stronger than of acetate. At a contact time of 90 days, formate sorbed on hydrated cement phases in the following order:  $C-S-H > Hc > Ms \sim AFt > Mc$ . The partition coefficient  $(R_d)$  of the investigated organic molecules on HCP and individual cement phases ranged from 0.01 to 1  $\rm{d}m^{3}\cdot kg^{-1}$ . This is also in agreement with a recent investigation on Portland cement (PC), where only a weak to moderate uptake of formate by hydrated cement was observed ([Nedyalkova et al.,](#page-11-0)  [2021\)](#page-11-0).

The uptake of GLU and  $\alpha$ -ISA ( $\alpha$ -isosaccharinate, a main degradation product of cellulose and chemical analogue of GLU) by cement and C–S–H phases has been extensively investigated in the last 30 years. ([Glaus et al., 2006](#page-10-0)) investigated the uptake of GLU and α-ISA by HCP using an artificial cement pore water corresponding to the first degradation stage of cement (ACW,  $pH = 13.4$ , Na = 114 mM, K = 180 mM,  $Ca = 2$  mM). Sorption data were interpreted using a two-site Langmuir isotherm, which postulates the presence of two (strong and weak) sorption sites. The uptake of gluconate was slightly stronger than the uptake of  $\alpha$ -ISA and distribution ratios of R<sub>d</sub>  $\approx$  3–4·10<sup>3</sup> dm<sup>3</sup>·kg<sup>-1</sup>for [GLU]<sub>tot</sub> =  $10^{-7}$ – $10^{-4}$  M were observed. Desorption of sorbed gluconate species was found to be strongly kinetically inhibited due to the strong interaction with active sites of cement (and C–S–H phases).

([Androniuk et al., 2017\)](#page-10-0) investigated the sorption of gluconate on C–S–H phases by combining wet-chemistry sorption studies and molecular dynamics simulations and reported  $\rm R_d$  values of 4.5, 27, 217 dm $^{3} \cdot$  $kg^{-1}$  for the uptake by C–S–H with Ca/Si of 0.83, 1.0 and 1.4, respectively. A fast sorption kinetics was observed and interpreted in terms of surface sorption rather than incorporation into the C–S–H structure. Based on molecular dynamics calculations, Androniuk and co-workers proposed that the sorption of gluconate is triggered by the formation of Ca-gluconate surface complexes on C–S–H. These results evidence the key role of Ca in the gluconate retention process, in line with experimental sorption trends reported for the uptake by C–S–H phases with increasing Ca/Si ratio [\(Androniuk et al., 2017](#page-10-0); [Nalet and Nonat, 2016](#page-11-0)). C–S–H phases with high Ca/Si ratios (Ca/Si *>* 1), have a positive apparent surface charge due to  $Ca^{2+}$  uptake, which overcompensates the negative surface charge of C–S–H caused by deprotonated silanol groups ([Haas and Nonat, 2015;](#page-10-0) [Labbez et al., 2011\)](#page-10-0). Therefore, [\(Nalet and](#page-11-0)  [Nonat, 2016\)](#page-11-0) interpreted the gluconate sorption to occur through interaction with Ca ions at the surface of the C–S–H particles. Speciation calculations showed that the increase of Ca/Si in C–S–H also leads to the formation of polynuclear aqueous Ca-gluconate complexes such as CaGLUOH<sup>0</sup>, Ca<sub>3</sub>GLU<sub>2</sub>(OH)<sup>0</sup><sub>4</sub> or Ca<sub>2</sub>GLU<sub>2</sub>(OH)<sup>2</sup><sub>4</sub><sup>-</sup>, which lower the fraction of free  $Ca^{2+}$  at higher gluconate concentrations (Bouzouaid et al., [2021, 2022; Kutus et al., 2020\)](#page-10-0). Due to the formation of strong aqueous Ca-gluconate complexes, the total concentration of Ca in the aqueous phase increases with the increase of the gluconate concentration. Depending on the experimental conditions, the formation of aqueous Ca-GLU complexes can lead to the desorption of calcium ions from the C–S–H surface, thus resulting in a decalcification of the C–S–H phases and accordingly in a weaker uptake of gluconate. In the aqueous phase,

([Bouzouaid et al., 2022](#page-10-0)) proposed also the formation of the quaternary complex  $Ca_3Glu_2(H_3SiO_4)_2(OH)_2^0$ , which becomes relevant in the pore water of C–S–H systems with 0.9 *<* Ca/Si *<* 1.2 and prevailing over other Si-complexes (H<sub>4</sub>SiO<sub>4</sub>, H<sub>4</sub>SiO<sub>4</sub>, H<sub>2</sub>SiO<sub>4</sub><sup>2</sup>–). The consideration of such complexes is important for the accurate description of the solution chemistry in cementitious systems containing gluconate.

This study aims at quantitatively characterizing the uptake of gluconate and formate by cement hydrates (C–S–H, monocarbonate, hemicarbonate, monosulfate, ettringite) and PC, comparing the retention of both organic ligands, as well as providing new insights into the retention mechanism and the impact of these organic ligands on the structure and composition of the investigated cement phases. Following a similar approach as reported in [\(Guidone et al., 2024\)](#page-10-0) for citrate, the uptake of formate and gluconate was investigated by characterizing both solid and liquid phases. Thermodynamic modelling was considered to derive solubility constants of formate and gluconate AFm-phases and to assess the aqueous speciation of formate and gluconate in the investigated systems.

## **2. Materials and method**

## *2.1. Materials*

Sulfate-ettringite (labelled as SO4-AFt), AFm phases, monosulfate (Ms), monocarbonate (Mc) and hemicarbonate (Hc), and C–S–H phases were synthesized by the co-precipitation method.  $C_3A$  (3CaO Al<sub>2</sub>O<sub>3</sub>) was used as reactive precursor for the AFm phases. The  $C_3A$  and  $CA$  $(CaAl<sub>2</sub>O<sub>4</sub>)$  were prepared from  $CaCO<sub>3</sub>$  (Merck Millipore,  $> 98.5$ ) and Al<sub>2</sub>O<sub>3</sub> (Sigma-Aldrich,  $> 99.0\%$ ) mixed for 1 day at a 3:1 or 1:1 M ratio and heated for 1 h at 800 ◦C, 4 h at 1000 ◦C and 24 h at 1425 ◦C ([Nedyalkova et al., 2019](#page-11-0)). CaO was obtained by heating CaCO<sub>3</sub> (Merck, Supelco,  $\geq$  99.0%) at 1000 °C for 12 h and cooling it down in a closed desiccator to minimise the CO<sub>2</sub> uptake. Freshly prepared CaO was used for the synthesis of Hc and C–S–H phases. Ms, Mc, Hc, SO4-AFt and C–S–H phases were synthesized with a solid to liquid, S/L, ratio of 44, 46, 44, 42 and 55  $\text{g}\cdot\text{dm}^{-3}$ , respectively.

Ms was prepared by mixing CaSO<sub>4</sub>·2H<sub>2</sub>O (Sigma-Aldrich,  $\geq$  97.0%) and C3A with a stoichiometric ratio 1:1. Mc and Hc was synthesized by mixing C<sub>3</sub>A, CaCO<sub>3</sub> and CaO with 1:1:0 and  $1:^{1}/_{2}:^{1}/_{2}$  stoichiometric ratio. SO<sub>4</sub>-AFt was synthesized by mixing CaO and  $\text{Al}_2\text{SO}_4$ -16.3H<sub>2</sub>O (Sigma-Aldrich,  $\geq 60.0\%$ ) at a molar ratio of 6:1 in Milli-Q water. C–S–H phases were synthesized by mixing CaO and  $SiO<sub>2</sub>$  (Areosil 200, Evonik) in stoichiometric amounts with Milli-Q water, in order to achieve Ca/Si ratios of 0.8, 1,0, 1.2 and 1.4. All sample manipulations were performed under N<sub>2</sub> atmosphere in a glovebox. Ultra-pure water (Millipore, 18.2) MΩ) was used for both solution preparation and synthesis of cement phases.

Gluconate-AFm ( $S/L = 76.3$  g⋅dm<sup>-3</sup>) and gluconate-AFt ( $S/L =$ 104.8  $\text{g}\cdot\text{dm}^{-3}$ ) were synthesized by mixing C<sub>3</sub>A, CaO and Na-gluconate (NaC<sub>6</sub>H<sub>11</sub>O<sub>7</sub>, Sigma-Aldrich,  $> 98.0\%$ ) at a stoichiometric ratio of 1:1:2 and 1:3:6. The synthesis of formate-AFm  $(S/L = 46.2 \text{ g} \cdot \text{dm}^{-3})$  and formate-AFt  $(S/L = 50.8 \text{ g} \cdot \text{dm}^{-3})$  was carried out by mixing C<sub>3</sub>A, CaO and Na-formate (NaCHO<sub>2</sub>, Sigma-Aldrich,  $\geq$  99.0%) with a stoichiometric ratio of 1:1:4 and 1:3:6, respectively. An additional formate containing AFm phase (FOR-AFm\_2) was prepared by mixing 1.26 g of CA, 1.79 g of CaO and 0.68 g of Na-formate ( $S/L = 83$  g⋅dm<sup>-3</sup>). Formate-AFm\_2 was equilibrated for 84 days, gluconate-AFm, gluconate-AFt, formate-AFm, and formate-AFt for 60 days.

Ms, Mc, Hc, SO<sub>4</sub>-AFt and C–S–H phases were equilibrated in a climatic room at 20 ◦C for 1 month under continuous shaking at 100 rpm, while gluconate(formate)-AFm and gluconate(formate)-AFt phases were equilibrated for 2 months. Phase separation was achieved through vacuum filtration using 0.45 μm nylon filters. Afterwards, the AFm phases and SO<sub>4</sub>-AFt were dried over a saturated CaCl<sub>2</sub> solution at  $\sim$  37 % relative humidity as detailed in [\(Guidone et al., 2024;](#page-10-0) [Nedyalkova et al.,](#page-11-0)  [2019\)](#page-11-0). Sorption experiments in the gluconate-containing systems resulted in the formation of a gel-like phase (most likely made of Ca-gluconate complexes). The gel-like phase hindered phase separation, preventing in some cases the collection of sufficient volume for the quantification of the sorbed gluconate. C–S–H phases were dried under liquid nitrogen in a freeze dryer for 7 days following the procedure established by L'Hôpital et al. to minimise  $CO<sub>2</sub>$  uptake (L'Hôpital et al.,  $2015$ ). The resulting dry solids were stored over saturated CaCl<sub>2</sub> solutions before further analysis.

Hydrated Portland cement (PC, CEM 42.5 N) was prepared by mixing 1 kg of dry cement with 400 g of Milli-Q water resulting in a water to cement ratio (w/c) of 0.4. The paste was hydrated for 28 days at 20  $\degree$ C in closed polyethylene (PE) bottles. A part of the hydrated paste was ground by hand with an agate mortar to  $\leq 63$  µm without hydration stoppage to avoid contamination by organics, and used for sorption experiments with Na-formate and Na-gluconate. Further details about the composition and quantitative analysis of PC used in this study are reported in [\(Guidone et al., 2024\)](#page-10-0).

## *2.2. Kinetic sorption experiments*

The sorption kinetics of gluconate on cement hydrates was investigated between 1 day and 14 days. Kinetic studies were carried out by adding to the pre-synthesized phases suspensions 0.218 g of Nagluconate, 9 cm<sup>3</sup> of NaOH solution ([NaOH] = 1 M) and 1 cm<sup>3</sup> of Milli-Q water. The addition of solution to suspensions avoided any drying of the synthesized solids before the sorption studies. This resulted in a total initial gluconate concentration of  $[GLU]_{tot,in} = 21$  mM, a total initial Na concentration of [Na]<sub>tot,in</sub> = 0.2 M and a total volume of 50 cm<sup>3</sup>. Following the same approach, 10 cm<sup>3</sup> of 1 M Na-formate solution was added on the pre-equilibrated hydrate or cement suspensions targeting a total initial formate concentration of  $[FOR]_{tot,in} = 221$  mM.

Suspensions were shaken continuously (100 rpm) at 20 °C, and sampled after selected contact times ( $t_{eq}$  (days) = 1, 2, 4, 7, 14). The solid and liquid phase were separated following the methodology reported in section  $2.1$ . AFm phases and SO<sub>4</sub>-ettringite were dried in a desiccator over saturated CaCl<sub>2</sub> solution ( $\sim$ 35% relative humidity) at room temperature for 4 weeks. The C–S–H phases were freeze-dried using liquid nitrogen to minimise carbonation and kept under vacuum for 7 days to remove free water. Afterwards, C–S–H phases were also placed in a desiccator over saturated CaCl<sub>2</sub> solution and stored before further analysis.

#### *2.3. Sorption experiments*

Sorption experiments were carried out on pre-synthesized suspensions of cement phases and hydrated cements ( $d_{\text{particle}} \leq 63 \, \mu \text{m}$ ) by adding different volumes (0.05–2.5  $\text{cm}^3$ ) of 1 M of Na-gluconate or 0.02–0.22 g of Na-gluconate corresponding to gluconate concentrations of 2.0⋅10<sup>-5</sup> M < [GLU]<sub>tot,in</sub> < 2.1⋅10<sup>-2</sup> M. In addition, 1 M NaOH solution was added to obtain in all cases a total sodium concentration [Na]<sub>tot</sub> = 0.2 M and a pH = 13.3 and to be able to compare the sorption at comparable pH values. The uptake of formate was investigated in the concentration range of 2.0⋅10<sup>-4</sup> M < [FOR]<sub>tot,in</sub> < 2.2⋅10<sup>-1</sup> M by adding a total volume of 10  $\text{cm}^3$  containing various amounts of 1 M of Naformate and 1 M of NaOH solutions to obtain a total sodium concentration of  $[Na]_{tot} = 0.2$  M. The addition of the above-mentioned solutions led to an increased aqueous volume, thus resulting in suspensions of monosulfate, monocarbonate, hemicarbonate, sulfate-ettringite and C–S–H phase with a final S/L ratio of 44 g⋅dm<sup>-3</sup>, 37 g⋅dm<sup>-3</sup>, 35 g⋅dm<sup>-3</sup>, 32 g⋅dm<sup>-3</sup> and 44 g⋅dm<sup>-3</sup>, respectively. In the case of sorption experiments with PC, 40 cm $^3$  of Milli-Q was added to 2.5 g of hydrated cement to achieve a S/L ratio of 50  $\rm g\cdot dm^{-3}.$ 

The samples were equilibrated at 20 ◦C on horizontal shakers (100 rpm) for 7 days. Relatively short contacting times were chosen to minimise possible re-crystallization and precipitation processes as done previously by ([Guidone et al., 2024](#page-10-0); [Nedyalkova et al., 2022\)](#page-11-0). Phase

separation was achieved by vacuum filtration through 0.45 μm nylon filters under inert atmosphere  $(N_2)$ . Filtration was carried out without any washing steps to preserve the integrity of the solid phase. Drying was performed as described in section [2.1.](#page-1-0)

The uptake of gluconate and formate on the pre-synthesized cement phases was quantified in terms of the distribution coefficient,  $R_d$ , by using the following equation (Eq. 1):

$$
R_d = \frac{C_{i,0} - C_{i,eq}}{C_{i,eq}} \frac{V}{m} \left[ d m^3 \cdot kg^{-1} \right]
$$
 (1)

Where  $C_{i,eq}$  represents the equilibrium concentration [mol·dm<sup>-3</sup>] of gluconate or formate,  $C_{i,0}$  the initial concentration [mol·dm<sup>-3</sup>] added to the system, *m* is the mass [kg] of sorbent (e.g. PC, C–S–H phases, AFm phases) and  $V$  is the total volume  $[dm<sup>3</sup>]$  of solution.

## *2.4. Solid phase characterization*

After drying, solid samples were characterized by X-ray powder diffraction (XRD), thermogravimetric analysis (TGA) and infrared spectrometry (FT-IR). XRD analyses of AFm phases, sulfate-ettringite and PC were performed with a Panalytical X'Pert Pro MPD diffractometer with θ-θ geometry, using CuKα ( $\lambda = 1.54184$  Å) radiation obtained using a Ge (111) Johansson monochromator and equipped with a solid state X-Celerator detector. XRD patterns were recorded at room temperature at a step size of 0.017◦ 2θ and a total measurement time of 45 min in the interval 5◦ *<* 2θ *<* 70◦. The XRD patterns of the C–S–H phases, were analyzed with a CuKα1.2 radiation and the PIXcel detector was used. A 2θ interval of 5◦–70◦, a step size of 0.013◦ 2θ and a total measurement time of 1 h were applied at room temperature.

Infrared spectroscopy (FT-IR) analysis was carried out on Bruker Tensor 27 FT-IR spectrometer. Spectra were recorded in the wavelength range 4000  $\text{cm}^{-1}$  - 400  $\text{cm}^{-1}$  with a resolution of 4  $\text{cm}^{-1}$ . This analysis was performed on powder samples in order to evaluate the possible incorporation or uptake of gluconate or formate.

TGA measurements were carried out on a Mettler Toledo TGA/SDTA 851 instrument (Mettler Toledo, Switzerland) to determine the amount of water bound and the amount of portlandite. Measurements were performed with  $\sim$  30 mg of sample using a heating rate of 20 °C/min and a temperature range between 30  $\degree$ C and 980  $\degree$ C under N<sub>2</sub> atmosphere. Portlandite (CH) was quantified based on the weight loss in the temperature range 400–500 ◦C using the tangential method as detailed in ([Lothenbach et al., 2016\)](#page-10-0). The water losses and the amount of CH was expressed relative to the mass of the samples at 600 ◦C.

## *2.5. Liquid phase characterization*

An aliquot of the supernatant solution was used for the pH determination. The pH measurement was performed using a Knick pH-meter with a SE 100 pH/Pt 1000 electrode at room temperature. The instrument was calibrated with NaOH solution of known concentrations (0.1, 0.2, 0.5 and 1 M) to minimise the alkali error [\(Traynor et al., 2020](#page-11-0)).

The characterization of the aqueous phase was performed by inductively coupled plasma-optical emission spectroscopy (ICP-OES) analysis. Total concentrations of Al, Ca, Na, Si and S were measured on an Agilent 5110 ICP-OES apparatus equipped with Agilent SPS 4 autosampler. Prior to each series, the instrument was calibrated using elemental standards at 5 different concentrations in the range 0.5–50 ppm. Ar is used as inert carrier gas. All samples were diluted in 2 wt% HNO3 with dilution factors of 10, 100 and 1000.

The total organic concentration was measured using a Sievers 5310 C total organic carbon (TOC) analyser using potassium hydrogen phthalate standards with 5 different concentrations in the range 1–50 ppm. Samples with expected low organic concentration were diluted by a factor of 5 with 0.1 M HCl solution, while samples with higher gluconate concentrations were diluted by a factor of 10, 100 and 1000 with 0.01 M <span id="page-3-0"></span>HCl solution. Results were given after subtracting the background concentrations measured in blank solutions. The electroneutrality of the solution has been checked for all system investigated considering the measured concentrations and pH values. In general, the values were in the expected ranges, although on average a 10% surplus of cations was observed, which was assigned to the uncertainties associated with the alkali concentration, the measured organic concentration as well as on the uncertainty associated to the pH measurement.

## *2.6. Thermodynamic calculations*

Solubility products of the formate-AFm(AFt) and gluconate-AFm (AFt) solid phased synthesized in this work were determined on the basis of the measured total ion concentrations. The thermodynamic modelling program GEM-Selektor (GEMS) ([Wagner et al., 2012\)](#page-11-0) was used to calculate the activity of aqueous species, which takes into account chemical interactions involving solids, solid solutions, metal ions, and aqueous electrolyte at once. General thermodynamic data were taken from the PSI Nagra database, data for cement hydrates from the Cemdata18 database ([Lothenbach et al., 2019\)](#page-10-0). The CSHQ model ([Kulik,](#page-10-0)  [2011;](#page-10-0) [Lothenbach et al., 2019\)](#page-10-0) was used to describe the alkali uptake and the composition of C–S–H. In addition, the complexation of formate

<sup>a</sup> Values extrapolated to 0 M ionic strength using the WATEQ Debye-Hückel equation from those reported in [\(Kutus et al., 2020](#page-10-0); [Pallagi et al., 2010](#page-11-0)) by [\(Bouzouaid et al., 2021](#page-10-0)).

<sup>b</sup> [\(Lumsden, 1902](#page-11-0)) reports a high solubility of Ca(HCOO)<sub>2</sub> of 166 g⋅dm<sup>-3</sup> at  $20 °C$ .

and gluconate with the different cations was considered using different complex formation constants as detailed in Table 1.

Activity coefficients of the aqueous species were calculated with the built-in extended Debye-Hückel equation (Eq. 2) and NaOH as a background electrolyte:

$$
\log \gamma_i = \frac{-A_y z_i^2 \sqrt{I}}{1 + B_y a \sqrt{I}} + bI \tag{2}
$$

zi is the charge of species *i*, I the effective molal ionic strength, *a*  corresponds to 3.31, and *b* to 0.98 for NaOH electrolyte [\(Helgeson et al.,](#page-10-0)  [1981;](#page-10-0) [Kulik et al., 2013](#page-10-0)). *Ay* and *By* are *P,T*-dependent Debye-Hückel solvent parameters.

The solubility products and saturation indices were calculated from the activity of the species  $Ca^{2+}$ , Al(OH)<sub>4</sub><sup>,</sup> OH<sup>-</sup>, SO<sub>4</sub><sup>2</sup><sup>-</sup>, CO<sub>3</sub><sup>2</sup><sup>-</sup>, CHO<sub>2</sub><sup>-</sup>,  $C_6H_{11}O_7^-$  and H<sub>2</sub>O, obtained using GEMS and the measured total concentrations.

## **3. Results and discussions**

#### *3.1. Uptake of formate and gluconate by AFm and AFt phases*

# *3.1.1. Synthesis of formate and gluconate AFm and AFt phases*

AFm phases consist of positively charged main layers with a general composition  $[Ca_4Al_2(OH)_{12}]^{2+}$ , and anions and water present in the interlayer region  $[X_x \cdot nH_2O]^{2-}$ . The interlayer can contain either two monovalent (2X<sup>-</sup>) or one bivalent (X<sup>2-</sup>) anion, while the amount of water  $(nH<sub>2</sub>O)$  depends on the type of anion, temperature, and relative humidity [\(Buttler et al., 1959;](#page-10-0) [Taylor, 1973](#page-11-0)). AFm phases form hexagonal or pseudo hexagonal crystals: monosulfate (Ms) and hemicarbonate (Hc) have a trigonal geometry (Kuzel and Pöllmann, 1991; Pöllmann [et al., 1997](#page-11-0)), while monocarbonate (Mc) has a triclinic symmetry ([François et al., 1998](#page-10-0)). The spectra of the ligand-free phases indicate the formation of Ca<sub>4</sub>Al<sub>2</sub>(SO<sub>4</sub>)(OH)<sub>12</sub>⋅6H<sub>2</sub>O (C<sub>4</sub>AsH<sub>12</sub>) and traces of C<sub>4</sub>AsH<sub>14</sub>  $(Ca_4Al_2(SO_4)(OH)_{12}·8H_2O)$  for the Ms samples, of hemicarbonate:  $Ca_4Al_2(CO_3)_0.5(OH)_{13}.5.5H_2O(C_4Ac_{0.5}H_{12})$  as well as of some carbonated hemicarbonate,  $C_4Ac_{0.8}H_{10.2}$  for the Hc sample and of monocarbonate: Ca<sub>4</sub>Al<sub>2</sub>CO<sub>3</sub>(OH)<sub>12</sub>⋅5H<sub>2</sub>O (C<sub>4</sub>AcH<sub>11</sub>)) as detailed in (Guidone [et al., 2024\)](#page-10-0). The XRD spectra of gluconate and formate containing AFm phases are shown in [Fig. 1.](#page-4-0) Interestingly, both formate and gluconate-–AFm are relatively well crystalline, in contrast to citrate–AFm  $(Ca_4Al_2(C_6H_5O_7)_{0.67}(OH)_{12}·6H_2O)$ , which showed a relatively broad basal spacing ([Guidone et al., 2024](#page-10-0)).

The XRD of FOR-AFm ([Fig. 1](#page-4-0)a) indicates the formation of a wellcrystalline layered structure with high intensity bands at 10.9◦ and at 21.8◦ 2θ corresponding to the interlayer distances (003) and (006), respectively. In agreement with the study of  $(P<sub>o</sub>llman, 1989)$  a d-spacing of 8.1 Å was obtained for formate-AFm,  $Ca<sub>4</sub>Al<sub>2</sub>(HCO<sub>2</sub>)<sub>2</sub>(OH)<sub>12</sub>·5H<sub>2</sub>O$ . A main layer reflection (110) at 31.0◦ 2θ is observed as characteristic for AFm-phases with trigonal geometry such as Ms or Hc ([Allmann, 1977](#page-10-0)). In addition, traces of portlandite were detected (reflection at  $\approx 18^\circ$  2θ). The shoulder observed at 11.2 $^{\circ}$  2 $\theta$  (7.9 Å) indicates the presence of a second formate AFm, possible with less water. The two peaks are better resolved at 21.8° 2 $\theta$  (4.07 Å) and at 22.4° 2 $\theta$  (3.97 Å).

The XRD of GLU-AFm, shown in [Fig. 1b](#page-4-0), also indicates the formation of typical layered structures of AFm phases. The main reflection at  $\approx$ 8.5◦ 2θ indicates a larger basal distance of 10.3 Å for GLU-AFm than observed for FOR-AFm, in agreement with the larger size of gluconate ( $H_{11}C_6O_7^-$ ) than formate (HCO<sub>2</sub>). An increase of the interlayer distance can be expected for larger anions, as previously observed for different organic-containing AFm and LDH phases ([Meyn et al., 1990; Okoronkwo](#page-11-0)  [et al., 2018](#page-11-0); [Von Hoessle et al., 2015](#page-11-0); [Wang et al., 2018](#page-11-0)). The corresponding 006 reflection of GLU-AFm at  $\approx 17.1^{\circ}$  2 $\theta$  (d<sub>spacing</sub> = 5.1 Å) partially overlaps with the main reflection of katoite  $(Ca_3Al_2(OH)_{12})$ , which is present in minor quantities. The broad signal at  $\approx 32^{\circ}$  20 corresponds to the main layer, 110, reflection of AFm phases. The presence

<span id="page-4-0"></span>

**Fig. 1.** XRD diffraction patterns of the synthesized samples: a) formate-AFm and formate-AFt, and b) gluconate-AFm and gluconate-AFt after 2 months of equilibration time. C: calcite; FOR-AFm: formate-AFm; GLU-AFm: gluconate-AFm; K: katoite  $(Ca_3Al_2(OH)_{12})$ ; P: portlandite  $(Ca(OH)_2)$ .

of katoite indicates a low stability of gluconate AFm phase. In addition to the main gluconate-AFm (GLU-AFm) signal, also two additional, smaller, signals at  $6.3° 2\theta (13.9 \text{ Å})$  and  $12.1° 2\theta (7.3 \text{ Å})$  are visible. Based on their narrow shape and their positions it was assumed that they correspond to the basal distance (labelled as  $d_{003}$ ) of gluconate AFm phases with more (GLU-AFm-a) and less water (GLU-AFm-b). Many of the AFm phases have the tendency to show several basal spacing depending on drying and the activity of water as discussed in detail in ([Baquerizo et al., 2015](#page-10-0)). The corresponding  $d_{006}$  signals are visible at 12.7 $\degree$  20 (6.9 Å) and at 24.1 $\degree$  20 (3.68 Å), respectively, which agrees with the assignment of those smaller peaks to AFm phases. The FT-IR spectra of those synthesis are summarised in ESM (Section [1 and 2\)](#page-0-0).

The XRD (in Fig. 1a) and FT-IR data (shown in ESM) of the sample FOR-AFt sample is characterized by the same signals as detected for formate-AFm, which indicates that no formate-containing ettringite was formed but only formate-containing AFm phases. This is in agreement with observation for other monovalent anions such as chloride or iodide ([Aimoz et al., 2012](#page-10-0); [Balonis et al., 2010\)](#page-10-0), where also only AFm phases form, while the formation of ettringite is mainly observed for bi- and trivalent anions such as sulfate, chromate, selenite or citrate ([Baur and](#page-10-0)  [Johnson, 2003](#page-10-0); [Guidone et al., 2024](#page-10-0); [Leisinger et al., 2010](#page-10-0); [Perkins and](#page-11-0)  [Palmer, 2000\)](#page-11-0). In contrast to a previous study by ([Dalconi et al., 2021](#page-10-0)), no M-phase  $(Ca_6(AI(OH)_6)_2(HCOO)_6(OH)_{12})$  was observed in this work for formate. The authors reported the main diffraction peaks of this phase at d-spacings of 6.87 Å, 5.19 Å, 4.86 Å and 4.14 Å, which converted to Cu-anode, corresponds to =  $12.9°$ ,  $17.1°$ ,  $18.2°$  and  $21.4°$   $20.$ 

The XRD spectra of the sample GLU-AFt (Fig. 1b) indicates the absence of a gluconate-containing ettringite phase, the presence of an amorphous phase and traces of calcite.

The total concentrations measured for the different elements in the aqueous solution (see Table 2) were used to calculate the ion activity products (IAP) for formate- and gluconate-AFm. The calculated IAP of formate-AFm reported in Tables 2 and is comparable to the solubility product of chloride  $(-27.3)$  or nitrate  $(-28.7)$  containing AFm phases ([Balonis et al., 2010,](#page-10-0) [2011;](#page-10-0) [Lothenbach et al., 2019\)](#page-10-0). The solubility product calculated for gluconate-AFm is higher than that of formate-AFm, as also evidenced by the high calcium and aluminium concentrations and the presence of some katoite.

## *3.2. Sorption experiments*

# *3.2.1. Uptake kinetic of formate and gluconate on monocarbonate, hemicarbonate, monosulfate and ettringite*

The uptake kinetics of formate and gluconate sorption on presynthesized monocarbonate, hemicarbonate, monosulfate and ettringite was investigated by adding a total formate concentration of 221 mM or a gluconate concentration of 21 mM, while the total sodium concentration was kept at 200 mM. The addition of gluconate lowered the pH value by about 0.1–0.3 pH units (see Tables S1–S4, in the Electronic Supplementary Material, ESM). Most of the formate added remained in solution, such that a decrease by 4 pH units was observed for ettringite (Table S13, ESM), by 2 pH units for Mc (Table S11, ESM) and  $\approx$ 1 pH unit for Ms and Hc (Table S10 and S12, ESM). Note that the decrease of pH is directly related with the decreasing volume of NaOH solution added with increasing formate concentration to have in all suspensions a  $[Na]_{tot} = 0.2$  M.

The uptake of formate and gluconate occurred mainly during the first day and increased only moderately between 1 and 7 days, to remain approximately constants afterwards. The solution compositions, reported in the electronic supplementary material (ESM), in Tables S1 and S<sub>2</sub> for gluconate, and Tables S<sub>10</sub> and S<sub>11</sub> for formate, show that the

# *3.2.2. Aqueous concentrations in equilibrium with AFm phases and ettringite*

The sorption experiments with increasing concentrations of gluconate show that gluconate increases the calcium and sulfate concentrations in the presence of monosulfate and ettringite, while the pH is somewhat lowered. The increase of the sulfate concentration in the presence of gluconate indicates a partial replacement of sulfate by gluconate, similarly to the observations obtained for citrate ([Guidone et al.,](#page-10-0)  [2024\)](#page-10-0). Gluconate also lowers the pH and increases the calcium concentration in solution, which is related to the formation of stable calcium gluconate complexes. Thermodynamic modelling using the data summarised in [Table 1](#page-3-0) indicates that aqueous Ca speciation at pH values above 12 is dominated by the ternary CaGluOH $^0$  and Ca $_3\mathrm{Glu}_2(\mathrm{OH})^0_4$ complexes. This is in agreement with the findings previously reported by ([Bouzouaid et al., 2022](#page-10-0)).

In the case of formate (see Tables S29–S31 in ESM), pH values and sulfate concentrations remain constant at formate additions below 100 mM, indicating a very low replacement of sulfate by formate. Also, the calcium concentrations do not vary significantly, which agrees with the weak complexation between  $Ca^{2+}$  and formate (see [Table 1](#page-3-0)). This is further confirmed by thermodynamic scoping calculations, which showed that  $Ca^{2+}$  and  $CaOH<sup>+</sup>$  were the major aqueous Ca-species in solution below 100 mM formate. Calcium formate complexes, CaFor<sup>+</sup> and  $Ca(For)_2^0$ , become only important at formate concentrations well above 100 mM. For higher formate concentrations, the experimentally determined Ca concentrations increased, while the pH values decreased due to the high concentration of formate in solution indicating an only weak formate uptake.

Recent studies have shown that iodide, selenite, and selenite are sorbed in the inner and outer surface sites of hemicarbonate and monosulfate, while citrate is sorbed only in the case of hemicarbonate in both the inner and outer surface area [\(Guidone et al., 2024; Lothenbach et al.,](#page-10-0)  [2024;](#page-10-0) [Nedyalkova et al., 2022\)](#page-11-0). The sorption on monocarbonate was observed to be much lower and to occur on the outer surface area only, as interlayer sorption was suppressed by the rigid structure and narrow interlayer distance of monocarbonate ([Guidone et al., 2024; Lothenbach](#page-10-0)  [et al., 2024](#page-10-0); [Nedyalkova et al., 2022](#page-11-0)). The total sorption capacity of AFm phases, i.e. the sum of surface and interlayer anion sorption sites, corresponds for single charged anions to 3.7 mol⋅kg<sup>-1</sup> Mc, 3.2 mol⋅kg<sup>-1</sup> Ms and 4.8 mol⋅kg<sup>-1</sup> ettringite. The uptake of organics on the external surfaces of AFm phases has been observed to be approximately 200 times lower ([Guidone et al., 2024\)](#page-10-0), corresponding to  $\approx 0.02$  mol per kg solid.

Sorption isotherms for the uptake of gluconate and formate by AFm phases and ettringite are shown in Fig. 2. In the case of gluconate, only concentrations above 0.1 mM gluconate equilibrium concentration could be measured, and thus only limited sorption data are available for this system. Fig. 2a shows that gluconate sorbs moderately on hemicarbonate and ettringite, and weaker on monosulfate, which agrees with the sequence observed in previous sorption experiments ([Lothenbach](#page-10-0)  [et al., 2024](#page-10-0); [Nedyalkova et al., 2022\)](#page-11-0). The limited amount of sorption data for gluconate makes the interpretation difficult. However, the data tentatively indicate an uptake of gluconate in both outer surface and interlayer sites for hemicarbonate, while for monosulfate the uptake is potentially limited to the outer surface sites, as previously observed for citrate ([Guidone et al., 2024\)](#page-10-0). For ettringite, no steps at around 0.02 mol‧  $kg^{-1}$  are visible, indicating potentially an uptake on both out surface sites as well as within the water containing channels of ettringite. For the uptake of gluconate an R<sub>d</sub> value of (119  $\pm$  75) dm $^3$ ·kg $^{-1}$  was determined for Hc, a tentative value of (1.27  $\pm$  0.72) dm<sup>3.</sup>kg<sup>-1</sup> for Mc bases on the kinetic experiments, of  $(30 \pm 11)$  dm<sup>3</sup>·kg<sup>-1</sup> for Ms and  $(38 \pm 38)$  $dm^3 \tcdot kg^{-1}$  for ettringite.

The uptake of formate by Mc, Hc and AFt is expectedly weak ( $R_d \sim$ 1–3  $\text{dm}^3$ ·kg<sup>-1</sup>) ([Wieland et al., 2016](#page-11-0)) due to the electrostatic forces occurring between cement phases and formate (Fig. 2b).  $R_d$  values of 1.5  $\pm$  0.1 dm<sup>3</sup>·kg<sup>-1</sup>, 93  $\pm$  93 dm<sup>3</sup>·kg<sup>-1</sup>, 2.3  $\pm$  0.9 dm<sup>3</sup>·kg<sup>-1</sup> and 2.9  $\pm$  1.4  $dm<sup>3</sup>$ ·kg<sup>-1</sup> were derived for Mc, Ms, Hc and ettringite, respectively, for low formate solution concentrations *<*2 mM. Except for the high values associated with a very high uncertainty observed for Ms, the  $R_d$  values for formate are comparable to the values reported by [Wieland et al.](#page-11-0)   $(2016)$ : R<sub>d (Ms)</sub>  $\approx 2 \text{ dm}^3 \cdot \text{kg}^{-1}$ , R<sub>d (Mc)</sub>  $\approx 0.3 \text{ dm}^3 \cdot \text{kg}^{-1}$ , R<sub>d (AFt)</sub>  $\approx 1 \text{ dm}^3$ .  $\text{kg}^{-1}$  and  $\text{R}_{\text{d (HC)}}$   $\approx$  20  $\text{dm}^3\text{-kg}^{-1}$  at  $\approx$  3 mM formate and lower pH values of ≈12. The comparable values also seem to indicate that in the case of ettringite and AFm phases, where anions compensate the positive charge of the main layer, the pH has a minor effect on the  $R_d$  values, with the exception of Hc, where formate competes with OH<sup>−</sup> and a clearly lower uptake was observed in the present study at pH 13.2 than by Wieland et al. at pH  $\approx$  12.

## *3.2.3. Solid AFm phases and ettringite*

A slight variation of the main basal spacing of Hc values is observed in the presence of gluconate and formate [\(Fig. 3](#page-6-0)). The interlayer

**Fig. 2.** Experimental a) gluconate and b) formate sorption isotherm for monosulfate (Ms), monocarbonate (Mc), hemicarbonate (Hc) and ettringite (AFt) after an equilibration time of 7 days. The upper and lower horizontal lines indicate the overall potential anion uptake and the uptake on the outer surface (1:200) ([Guidone](#page-10-0)  [et al., 2024](#page-10-0)) of Ms, Mc and Hc, respectively.

<span id="page-6-0"></span>

**Fig. 3.** XRD patterns of hemicarbonate after sorption of a) gluconate and b) formate (contacting time  $t = 7$  days). Effect of gluconate/formate on the basal spacing of Hc (hemicarbonate) and cHc (carbonated hemicarbonate).

distances of both hemicarbonate (Hc) and carbonated hemicarbonate (cHc, C<sub>4</sub>Ac<sub>0.8</sub>H<sub>10.2</sub> (Runčevski et al., 2012)) shift to higher 2 $\theta$ <sup>°</sup> values, indicating a small decrease in basal spacing with gluconate (Fig. 3). At low initial formate concentrations, no significant effect was observed. At intermediate formate concentration the relative intensity of the Hc signal decreases. At  $[FOR]_{tot,in} > 111$  mM, only the reflection of cHc is present but shifted towards lower 2θ◦ values, while the signal of Hc is no longer visible, indicating a destabilisation of Hc. Furthermore, the decrease of the relative peak intensity with increasing gluconate and formate concentration may indicate a decrease in ordering of the stacking and/or a more variable interlayer distance. Note that the main layer signal at  $\approx 31^\circ$  20, related to the 110 plane, did not broaden or decrease in intensity.

The XRD spectra (see Figs. S3, S4, S8 and S9 in the ESM), indicate a strong broadening of the main basal signal mainly for Ms, and to a lower extent for Mc, indicating again a disordering effect of gluconate on AFm phase and possibly fewer stacking layers in the c direction. The apparent slight shift of the basal spacing to lower 2θ° values is probably mainly related to the reduced number stacking layers in the c direction leading to an apparent shift of the basal reflection lower angles as discussed in detail in the literature [\(Grangeon et al., 2013](#page-10-0); [Mesecke et al., 2022](#page-11-0)). These findings are in agreement with the results obtained for the kinetic experiments series, where a broadening of the basal reflection was observed for Hc, but not for Mc, which is also in agreement with observations of Nedyalkova and co-workers ([Nedyalkova et al., 2019](#page-11-0)). The ettringite phases (Figure S5 and S10, ESM) showed no significant changes.

The presence of gluconate increases the concentration of sulfate in solution for Ms and ettringite (see Table S18 and S21, ESM), which agrees with the observed uptake of gluconate on outer surface sites as suggested by [\(Ma et al., 2017\)](#page-11-0) for monosulfate. The weak increase in sulfate concentration has been observed upon formate addition in the presence of ettringite (Table S32, ESM), while in the case of Ms, the sulfate concentration and the pH values decreased at higher formate concentrations.

#### *3.3. Uptake of formate and gluconate by C*–*S*–*H phases*

## *3.3.1. Uptakes kinetic of gluconate and formate on C*–*S*–*H phases*

The uptake kinetics of both gluconate and formate on presynthesized C–S–H phases with  $Ca/Si = 0.8$ , 1.0, 1.2, and 1.4 as detailed in ([Guidone et al., 2024](#page-10-0)), was investigated for equilibration times  $1 \le t_{eq}$  (days)  $\le 14$ . Total gluconate concentrations of up to 21 mM and formate concentrations of up to 221 mM were added to the C–S–H suspensions and the samples were further equilibrated under continuous

shaking, prior to separation and analysis. The pH values remained almost constant for all gluconate samples (Tables S5–S8, in the ESM), but was lowered by  $\approx 1$  pH unit (Ca/Si > 1.0) and up to of 3 pH units for C–S–H with a Ca/Si of 0.8 in the case of formate as less NaOH is added with the increase of formate concentration (see Tables S14–S17, in the ESM). The presence of high gluconate and formate concentrations clearly destabilizes the portlandite initially present in the C–S–H phases with  $Ca/Si = 1.2$  and 1.4. The destabilisation of portlandite is related, in the case of gluconate, mainly due to the formation of the aqueous species  $Ca-glu\text{concate}$  complexes,  $CaGluOH<sup>0</sup>$ ,  $Ca_2(Glu)_2(OH)_4^{2-}$ and  $Ca_3(Glu)_2(OH)_4^0$ , as shown also in the study of [\(Bouzouaid et al., 2022](#page-10-0)). In the case of formate, where the complex formation between Ca and formate is weak (see [Table 1](#page-3-0)), little effect on the calcium concentration is observed, except for those samples with very high formate additions (111 and 221 mM), where the hydroxide concentration and thus the pH is lowered, resulting in higher calcium concentration in equilibrium with C–S–H [\(Yan et al., 2022\)](#page-11-0) as well as in the destabilisation of portlandite (see Table S35 and S36, ESM).

In general, gluconate and formate solution concentrations decrease mainly during the first day, and show only moderate variations afterwards, indicating that again an equilibration time of 1 week is sufficient to investigate sorption.

## *3.3.2. Effect of gluconate and formate on C*–*S*–*H*

A significant increase of Ca concentration takes place for all C–S–H phases with increasing gluconate concentration, in agreement with the observations reported in ([Bouzouaid et al., 2022](#page-10-0)). The increase is particularly distinct for C–S–H with a Ca/Si = 1.0, where Ca concentrations increased from 0.2 mM in the absence of gluconate to 1.1 mM in the presence of 21 mM of gluconate, and less strong at higher Ca/Si as detailed in Tables S22–S25 (see ESM). The stronger increase of Ca at lower Ca/Si is related to the stronger decrease in pH observed with increasing gluconate concentration and the common ion effect of Ca, Si and hydroxide for C–S–H. The lower Na concentrations at low Ca/Si ratios indicate a strong uptake of Na<sup>+</sup> on the ion exchange sites of C–S–H phases as reported also e.g. by ([Yan et al., 2022](#page-11-0)), as well as a lower sorption of gluconate, resulting in lower OH<sup>−</sup> concentration in solution. This effect is less pronounced with the increase of Ca/Si ratio.

In the case of formate, a strong increase of Ca concentration is observed, in particular at lower Ca/Si, where the pH decreased strongly at higher formate concentrations (see Tables S33-S36, ESM). The strong effect of pH is in agreement with the trends reported in literature, where lower pH result in more Ca and less Si in solution as well as in a decalcification of C–S–H (L'Hôpital [et al., 2015;](#page-10-0) [Liu et al., 2021;](#page-10-0) Yan [et al., 2022\)](#page-11-0). The decrease of pH value is more pronounced for formate <span id="page-7-0"></span>than for gluconate (see Tables S33-S36, ESM).

Mass balance calculations indicate that only a slight decrease of the Ca content in C–S–H takes place at high gluconate and formate concentrations (see Tables S27 and S38 in the ESM), although the aqueous Ca concentration increased and any portlandite originally present at Ca/  $Si = 1.2$  and 1.4 was dissolved. The presence of gluconate or formate has a negligible effect on the interplanar distance for C–S–H phases, although a peak broadening is observed in particular at higher Ca/Si, probably related to a decrease in the number of layers stacked in c-direction ([Grangeon et al., 2013](#page-10-0); [Mesecke et al., 2022\)](#page-11-0). The apparent decrease in basal spacing can be explained by the decrease in the number of stacked layers.

## *3.3.3. Gluconate and formate uptake by C*–*S*–*H*

Fig. 4 shows the sorption isotherms for the uptake of gluconate and formate by C–S–H phases and PC. The quantification of C–S–H weight, calculated by combining mass balance calculation and water content obtained from TGA analysis, is reported in Table S26 and S37 (see the ESM file). For all C–S–H phases investigated, the uptake of gluconate shows a linear increase with increasing gluconate concentration in the aqueous phase. Gluconate sorbs relatively weakly on C–S–H phases with a Ca/Si = 0.8 and 1.0 with average R<sub>d</sub> values of (1.9  $\pm$  1.3) dm<sup>3.</sup>kg<sup>-1</sup> and (7.0  $\pm$  3.0) dm<sup>3</sup>·kg<sup>-1</sup>. For Ca/Si = 1.2 and 1.4 the sorption of gluconate is visibly stronger with average R<sub>d</sub> values of (15.6  $\pm$  2.5) dm $^3$ ·kg $^{-1}$  and (33.9  $\pm$  17.5) dm $^3$ ·kg $^{-1}$ , respectively.

The strong increase of uptake of gluconate at higher Ca/Si confirms earlier observations of ([Androniuk et al., 2017](#page-10-0); [Bouzouaid et al., 2022](#page-10-0); [Nalet and Nonat, 2016\)](#page-11-0), who reported that the uptake of gluconate is mediated by complexation with calcium at the surface of C–S–H phases. The R<sub>d</sub> values measured here at pH of  $\approx$  13, are roughly a factor 10 lower than the R<sub>d</sub> values of 4.5 dm<sup>3</sup>·kg<sup>-1</sup> (Ca/Si = 0.83), 40 dm<sup>3</sup>·kg<sup>-1</sup> (Ca/Si = 1) and 285 dm<sup>3</sup>·kg<sup>-1</sup> (Ca/Si = 1.4) measured at pH values of 10.5–12.3 ([Androniuk et al., 2017](#page-10-0)). The lower pH values in the exper-iments of ([Androniuk et al., 2017\)](#page-10-0) resulted in higher calcium concentrations of 1, 2 and 12 mM for  $Ca/Si = 0.83$ , 1.0 and 1.4, than observed here with 0.1, 0.2, 3 mM Ca for Ca/Si = 0.8, 1.0 and 1.4 at pH  $\approx$  13, underlining the important role of calcium (and thus indirectly of pH) on the ability of C–S–H to take up gluconate. It should be noted that the presence of 200 mM Na in all experiments presented here influences the formation of calcium gluconate complexes [\(Bouzouaid et al., 2021](#page-10-0)), the surface charge of  $C-S-H$  (L'Hôpital [et al., 2015\)](#page-10-0) and thus gluconate uptake by C–S–H.

Based on molecular dynamic calculations, ([Androniuk et al., 2017\)](#page-10-0) proposed the formation of Ca-gluconate surface complexes on C–S–H.

Fig. 4b shows the sorption isotherms calculated for the uptake of formate by C–S–H phases. Due to the small difference between the initial and the measured formate concentration, no uptake could be quantified for  $[FOR]_{tot,in} = 11$  mM for C–S–H phases with a Ca/Si = 0.8, 1.0 and for  $[FOR]_{\text{tot,in}} = 4.4 \text{ mM}$  for Ca/Si = 1.2 and 1.4. At low formate concentrations  $[FOR]_{eq} < \sim 10^{-3}$  M, the uptake occurs on all C–S–H phases, increases linearly with the increase of formate concentration and is independent of the Ca/Si ratio of the C–S–H, in contrast to the observation for gluconate. This indicates that the uptake of formate by C–S–H is not related to calcium present at the surface of C–S–H, in agreement with the weak character of the Ca-formate complexes forming in the aqueous phase ([Shock, 1995;](#page-11-0) [Shock and Koretsky, 1995](#page-11-0); [Shock et al., 1997](#page-11-0); [Wieland, 2014](#page-11-0)) ([Table 1](#page-3-0)). At  $[FOR]_{eq} > \sim 10^{-2}$  M, due to the weak interaction of formate with C–S–H phases, no quantification of sorbed formate could be derived.

At formate concentration lower than 2 mM, average distribution coefficient R<sub>d</sub> values of (25.6 ± 15.6) dm<sup>3</sup>·kg<sup>-1</sup>, (12.3 ± 5.0) dm<sup>3</sup>·kg<sup>-1</sup>,  $(12.5 \pm 8.3)$  dm<sup>3</sup>·kg<sup>-1</sup> and  $(34.4 \pm 16.6)$  dm<sup>3</sup>·kg<sup>-1</sup> for Ca/Si of 0.8, 1.0, 1.2 and 1.4 respectively were determined, which is considerably lower than the  $R_d$  values of 190 and 102  $dm^3 \cdot kg^{-1}$  determined by (Wieland [et al., 2016\)](#page-11-0) for low and high Ca/Si ratio, respectively. The lower uptake observed in the present study is probably related to the higher pH values present in our experiments (pH *>* 13), which increases the negative charge on C–S–H (L'Hôpital [et al., 2015](#page-10-0)) and thus decreases anion sorption, compared to the experiments of ([Wieland et al., 2016](#page-11-0)) at pH 10.5 to 12.5, where no additional NaOH had been added.

## *3.4. Gluconate and formate sorption on Portland cement*

The uptake of gluconate by hydrated Portland cement paste increases linearly with the increase of gluconate concentration as shown in Fig. 4a; solution composition is detailed in Table S28, in the ESM file. The measured uptake of gluconate on Portland cement is with an average R<sub>d</sub> of (131  $\pm$  10) dm<sup>3</sup>⋅kg<sup>-1</sup> significantly higher than the sorption on C–S–H, monosulphate and ettringite measured here at pH 13, but in the same range as the 285 dm<sup>3</sup>⋅kg<sup>-1</sup> measured at pH values of 12.3 for  $Ca/Si = 1.4$  [\(Androniuk et al., 2017](#page-10-0)) as illustrated in [Fig. 5.](#page-8-0) The strong increase of gluconate uptake on C–S–H with the calcium concentration in solution explains the relatively high sorption measured on PC (and that gluconate sorbs strongly on C–S–H phases with high Ca/Si). Gluconate also sorbs on portlandite with an average  $R_d \sim 22 \, \text{dm}^3 \cdot \text{kg}^{-1}$  at pH 12.5 calculated from the sorption measurements reported by ([Nalet and](#page-11-0)  [Nonat 2016\)](#page-11-0). Thus, the uptake on high Ca/Si C–S–H contributes significantly to the gluconate uptake on PC together with the uptake on

**Fig. 4.** Sorption isotherms calculated as moles of a) gluconate and b) formate, expressed per kg of solid phase, for C–S–H phases with a ratio of 0.8 ≤ Ca/Si ≤ 1.4 and Portland cement (PC) after 7 days of contacting time. The lines are intended as eye guide only.

<span id="page-8-0"></span>

**Fig. 5.** Comparison of average R<sub>d</sub> values for the uptake of gluconate (half-filled symbols) and α-ISA (empty symbols) on C–S–H phases, portlandite and PC, as a function of the Ca equilibrium concentration.

Hc and ettringite, while the contribution of portlandite is less important. Based on the strong dependency, a decrease of gluconate sorption at lower calcium concentrations was observed in Fig. 5, a somewhat lower  $R_d$  than measured here can be expected for hydrated Portland cements, where pH values of  $\approx$ 13.5 and Ca concentrations in the range of 1–3 mM are generally observed (Vollpracht et al.,  $2016$ ), while the R<sub>d</sub> values might be higher in leached cements characterized by higher Ca concentrations in the pore solution.

Glaus and co-authors investigated the uptake of sodium gluconate  $([GLU]_{tot,in} = 10^{-7}$ -10<sup>-4</sup> M) on hydrated cement equilibrated with artificial cement pore water ([Ca] $_{\text{tot}}$  = 1.6⋅10<sup>−3</sup> M), corresponding to a  $R_d \sim 1 \;{\rm dm^3 \cdot kg^{-1}}$  and  $R_d \sim 10^5 \;{\rm dm^3 \cdot kg^{-1}}$  for the lowest ([GLU]<sub>tot,in</sub> =  $10^{-7}$  M) and the highest ([GLU]<sub>tot,in</sub> =  $10^{-4}$  M) total initial gluconate concentration, respectively [\(Glaus et al., 2006\)](#page-10-0). The decrease in the  $R_d$ value with increasing GLU concentration, as observed by [\(Glaus et al.,](#page-10-0)  [2006\)](#page-10-0), indicated non-linear sorption of GLU in the given concentration range.

Gluconic acid has chemically a strong similarity with  $\alpha$ -isosaccharinic acid ( $\alpha$ -ISA). R<sub>d</sub> values determined in this work for gluconate are comparable with those reported in the literature for α-ISA. A  $R_d \approx$ 120 dm<sup>3</sup>⋅kg<sup>-1</sup> was reported for the uptake of α-ISA ([α-ISA]<sub>tot</sub> = 8.5⋅10<sup>-4</sup> M) by degraded hardened cement paste (pH = 12.4, [Ca]<sub>tot</sub>  $\approx$ 10<sup>-2</sup> M) over an equilibration time of 200 days [\(Pointeau et al., 2008](#page-11-0)). The authors observed a strong dependency between Ca concentration (and pH) with the uptake of  $\alpha$ -ISA by cement. Hence, an increase of R<sub>d</sub> from 4 dm<sup>3</sup>⋅kg<sup>-1</sup> to 100 dm<sup>3</sup>⋅kg<sup>-1</sup> was observed when the pH dropped from 13 to 12.5, with the consequent increase in Ca concentration by one order of magnitude. Given the fast equilibrium conditions reached within 3 days, Pointeau and co-workers proposed that α-ISA uptake is likely controlled mainly by surface complexation mechanism, mainly involving C–S–H phases [\(Pointeau et al., 2008](#page-11-0)).

García and co-workers studied the uptake of α-ISA by C–S–H phases with Ca/Si =  $0.8$  and 1.2 (pH = 10.5-12.1) as well as on hydrated cement (pH = 13.3) ([García et al., 2020](#page-10-0)) again indicating a non-linear sorption of α-ISA in the given concentration range. Sorption data show the correlation between sorbed gluconate and Ca concentration in the aqueous phase. The higher α-ISA uptake on C–S–H 1.2 was interpreted in terms of Ca-α-ISA complex formation at the surface of C–S–H phase. Data were satisfactorily modelled using one-site Langumir isotherm. However, the same approach did not properly explain the sorption behaviour in the PC-α-ISA system. Sorption experiments conducted on hydrated cement resulted in an average R<sub>d</sub> value of  $\approx$ 40 dm<sup>3</sup>⋅kg<sup>-1</sup> at [Ca]<sub>eq</sub>  $\approx$  $2.0·10^{-3}$  M.

A strong dependency of  $R_d$  values with the concentration of  $\alpha$ -ISA  $(R_d \approx 400 \text{ dm}^3 \cdot \text{kg}^{-1}$  for [ $\alpha$ -ISA]<sub>tot</sub> =  $10^{-5}$  M and  $R_d \approx 1 \text{ dm}^3 \cdot \text{kg}^{-1}$  for  $[\alpha$ -ISA]<sub>in</sub> = 0.3 M) was observed by Van Loon and Glaus at pH 13.3 and  $[Ca]_{tot} = 3$  mM [\(Van Loon and Glaus, 1998\)](#page-11-0). Similar trend were observed in the study of [\(Jo et al., 2022\)](#page-10-0) conducted on hydrated cement (S/L = 1 g⋅dm<sup>-3</sup>) in the α-ISA concentration range  $10^{-5}$  M < [α-ISA]<sub>tot</sub><  $10^{-2}$  M. The authors interpreted the uptake of α-ISA on hydrated cement using a one-site Langumir isotherm.

Tasi and co-workers investigated the uptake of α-ISA by PC in the degradation stage II (pH = 12.5,  $[Ca]_{tot} = 21$  mM), and reported R<sub>d</sub> values ranging from  $\approx 200 \text{ dm}^3 \cdot \text{kg}^{-1}$  (at S/L = 2 g⋅dm<sup>-3</sup>) to  $\approx 1600$ dm<sup>3</sup>⋅kg<sup>-1</sup> (at S/L = 50 g⋅dm<sup>-3</sup>) ([Tasi et al., 2021](#page-11-0)). The strong uptake was interpreted in terms of affinity with  $Ca^{2+}$  ions on cement.

Fig. 5 underpins the evident correlation between the uptake of GLU/ ISA (expressed in terms of  $R<sub>d</sub>$  values) and the Ca concentration in the pore solution of the investigated PC or C–S–H system.

The uptake of formate on hydrated Portland cement paste increases linearly with the increase of formate concentration. For a formate equilibrium concentration below  $\approx 10^{-3}$  M, the same uptake was observed as for the C–S–H phases as visible in [Fig. 4b](#page-7-0). The R<sub>d</sub> of (8.6  $\pm$ 2.6) dm<sup>3</sup>⋅kg<sup>-1</sup> observed here on hydrated cement paste (pH  $\approx$  13.3), is somewhat higher than the R<sub>d</sub> values of  $\approx 1 \text{ dm}^3 \cdot \text{kg}^{-1}$  determined by ([Wieland et al., 2016\)](#page-11-0) for hydrated cement pastes at a pH of 12.9. The lower R<sub>d</sub> value observed by [\(Wieland et al., 2016\)](#page-11-0) might be related to the higher S/L ratio used (i.e.  $8622$  g⋅dm<sup>-3</sup>) compared to the S/L ratio of 50 g⋅dm<sup>-3</sup> used in this study. Another possible reason for the discrepancy of the  $R_d$  values is the experimental set-up: cement samples were mixed with a solution containing the aimed formate concentration, samples were let equilibrate at different times ( $t = 1$  h, 28 d, 390 d), and the

aqueous formate concentration was measured in the squeezed solution ([Wieland et al., 2016](#page-11-0)). It is worth of mentioning that [\(Wieland et al.,](#page-11-0)   $2016$ ) were not able to quantify the uptake of <sup>14</sup>C-formate in the sorption batch experiments carried out on hydrated cement (S/L = 333 g⋅dm<sup>-3</sup>). In agreement with ([Wieland et al., 2016\)](#page-11-0), [Nedyalkova et al. \(2021\)](#page-11-0) obtained an R<sub>d</sub> value of 0.9 dm<sup>3.</sup>kg<sup>−1</sup> on aged hydrated cement (S/L = 130 g⋅dm<sup>-3</sup>) at pH = 13.4, which lower value can be due to the lower fraction of C–S–H phases estimated in the cement composition analysis.

## *3.5. Sorption of gluconate and formate in comparison with other organics*

Gluconate, formate as well as citrate [\(Guidone et al., 2024\)](#page-10-0) have been observed to sorb relatively strongly on hemicarbonate, while the uptake by monosulfate and monocarbonate was limited and occurred on outer-surfaces site mainly, as shown by the sorption isotherms for formate and gluconate in [Fig. 2.](#page-5-0) Fig. 6 compares the  $R<sub>d</sub>$  values for the uptake of formate, citrate and gluconate on AFm phases (Ms, Hc), AFt and PC. The uptake of gluconate and citrate on Hc is approximately 2 orders of magnitude higher than the uptake of formate, the same preference for gluconate over citrate and over formate was observed for ettringite. Conversely, Ms shows a higher affinity towards citrate uptake ([Guidone et al., 2024](#page-10-0)), followed by formate and gluconate. The higher distribution ratio quantified for the Ms-FOR system might not be representative of the studied system, as it is based on a limited number of experimental data and a high error. If compared to the citrate and gluconate systems, no significant difference of the distribution coefficient can be observed for the uptake of formate by Hc and AFt. The uptake of gluconate and citrate by PC is comparable to each other, indicating a cumulative effect on the different phases present in PC in addition to a strong effect of Ca-concentration as discussed above and in ([Guidone et al., 2024\)](#page-10-0).

In the case of C–S–H phases, the uptake of gluconate and citrate is mediated by a Ca complex at the C–S–H surface ([Androniuk et al., 2017](#page-10-0); [Guidone et al., 2024](#page-10-0)) and therefore is dependent on the Ca/Si of the solid phase (Fig. 7). For the strongly complexing ligands gluconate and citrate the uptake on C–S–H phases is increased in the presence of more calcium in solution as shown in [Fig. 5](#page-8-0) for gluconate and in ([Guidone](#page-10-0)  [et al., 2024\)](#page-10-0) for citrate. Thus, for both gluconate and citrate the sorption increases with the Ca/Si ratio of C–S–H and is even higher for PC, as shown in Fig. 7. Since the uptake of citrate and gluconate is increased in the presence of more calcium, the higher retention of gluconate and

*Applied Geochemistry 175 (2024) 106145*

**Fig. 7.** Comparison of average  $R_d$  values collected for the uptake of formate (squares), citrate ([Guidone et al., 2024\)](#page-10-0) (circles), and gluconate (triangles) on C–S–H phases with a Ca/Si ratio of 0.8–1.4 and PC at pH 13 and for a contacting time of 7 days.

citrate on hydrated PC is mainly related to the higher availability of calcium in PC, where the presence of portlandite results in the formation of C–S–H with a Ca/Si in the range of 1.6–1.8 [\(Taylor et al., 2010\)](#page-11-0) as well as in higher calcium concentration in solution (see [Fig. 5](#page-8-0) and sections 5.2, 5.3, 6.2 and 6.3 in ESM). In addition, not only C–S–H is present in hydrated PC, but also ettringite and AFm phases, which also contribute to the observed high uptake in hydrated PC.

This trend is not observed in the case of formate (Figs. 6 and 7), where the formation of Ca-formate complexes is weak and does not contribute significantly to the sorption on C–S–H phases. Formate shows a comparable sorption on all solids investigated.

## **4. Conclusions**

This study provides key insights on the uptake of formate and gluconate by C–S–H, AFm phases, ettringite and hydrated cement (PC).

- The formation of formate(gluconate)-AFm phases has been investigated and characterized. A well crystalline layered structure has been observed for FOR-AFm. In agreement with the study of (Pöllman, 1989) a trigonal geometry has been assigned. The analysis of the GLU-AFm structure indicated the formation of a main AFm phase with a d-spacing  $= 10.3$  Å due to the partial intercalation of gluconate in the interlayer region. Two further GLU-AFm phases with different water content have been also observed. The synthesis of formate or gluconate containing ettringite did not result in the formation of ettringite-like phases.
- Gluconate sorbs more strongly on AFm phases and ettringite than formate without affecting significantly the crystalline structure. The weaker uptake of formate depends mainly on the weak electrostatic interactions occurring between the positively charged surface sites of AFm and ettringite and the negatively charged formate.
- Ca plays a key role in gluconate sorption mechanism on C–S–H. Higher calcium concentration increases the gluconate sorption on C–S–H and hydrated Portland cements due the formation of Cagluconate surface complexes on C–S–H. An increase in sorption on C–S–H phases mediated by the formation of calcium surface complexes has also been reported for citrate [\(Guidone et al., 2024](#page-10-0)) and α-ISA ([Pointeau et al., 2008](#page-11-0)). The chemical similarities of gluconate

**Fig. 6.** Comparison of average  $R_d$  values collected for the uptake of formate (squares), citrate [\(Guidone et al., 2024\)](#page-10-0) (circles) and gluconate (triangles) on AFm phases (Ms, Hc) and AFt at pH 13 and for a contacting time of 7 days.

<span id="page-10-0"></span>and α-ISA result in a comparable and strong uptake on cement phases and PC.

- In contrast, calcium plays no significant role for the uptake of formate by C–S–H. Generally, formate sorbs relatively weak on C–S–H and hydrated PC, with  $R_d$  values in the range of 4–9 dm<sup>3</sup>·kg<sup>-1</sup>.
- The observed difference between formate, citrate and gluconate, as well as the similarity in the uptake of  $\alpha$ -ISA and gluconate, illustrate the strong effect of the functional groups and their structural arrangement of the organic ligand on the sorption affinity.
