5. SEVERE ACCIDENT MANAGEMENT TRAINING ACTIVITIES

Tecnatom and Westinghouse develop training plans and material and teach courses with different scopes on phenomenology and management of severe accidents for, among others, the following objectives:

- Initial training for operation and TSC personnel prior to the entry into force of each revision of the plant-specific SAMGs, including follow-up exercises of the guidelines on predefined scenarios.
- Continuous retraining of operating personnel and TSCs involved in the use of SAMGs, including exercises to follow the guidelines.
- Training in severe accidents and SAMGs for all Emergency Response Organization (ERO) personnel.
- Preparation training for ROs and SROs license examination.
- Preparation of exercises and drills.

6. DEVELOPMENT OF SEVERE ACCIDENT MANAGEMENT AIDING TOOLS

The PROMOCAT application is a computer tool, developed by Tecnatom, and implemented since 2013 at the Vandellós and Ascó power plants, to support the TSC in the overall management of an emergency and provide training during the preparedness phase:

- following and evaluating plant parameters in real time
- allowing source term calculation
- including specific modules for all the different TSC and ERO groups, which incorporates all the necessary actions to be performed during the emergency

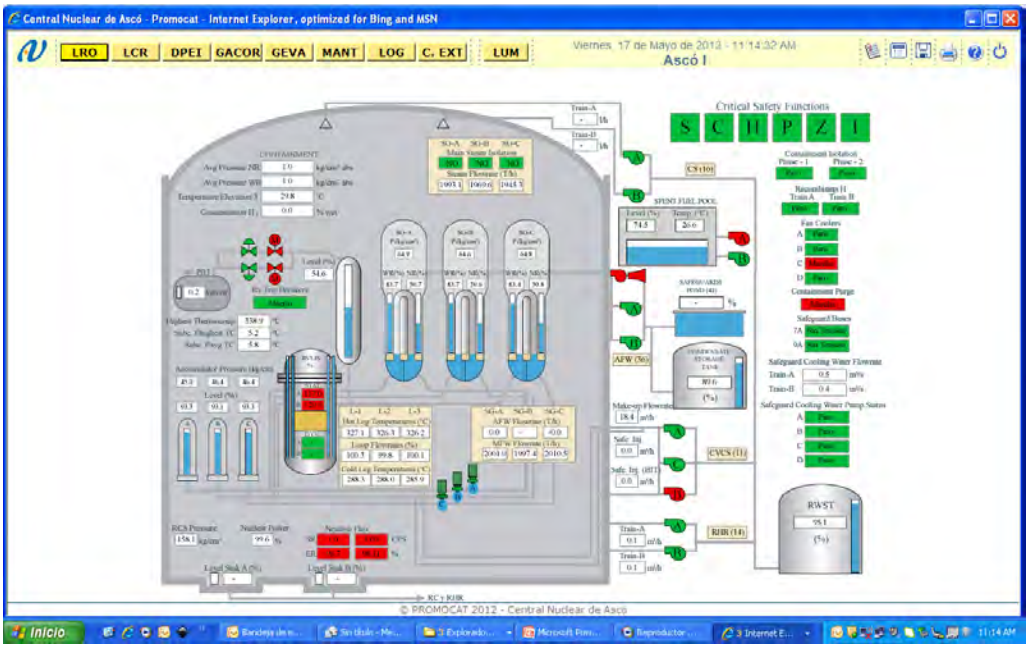

Figure 6. PROMOCAT Operation Screen.

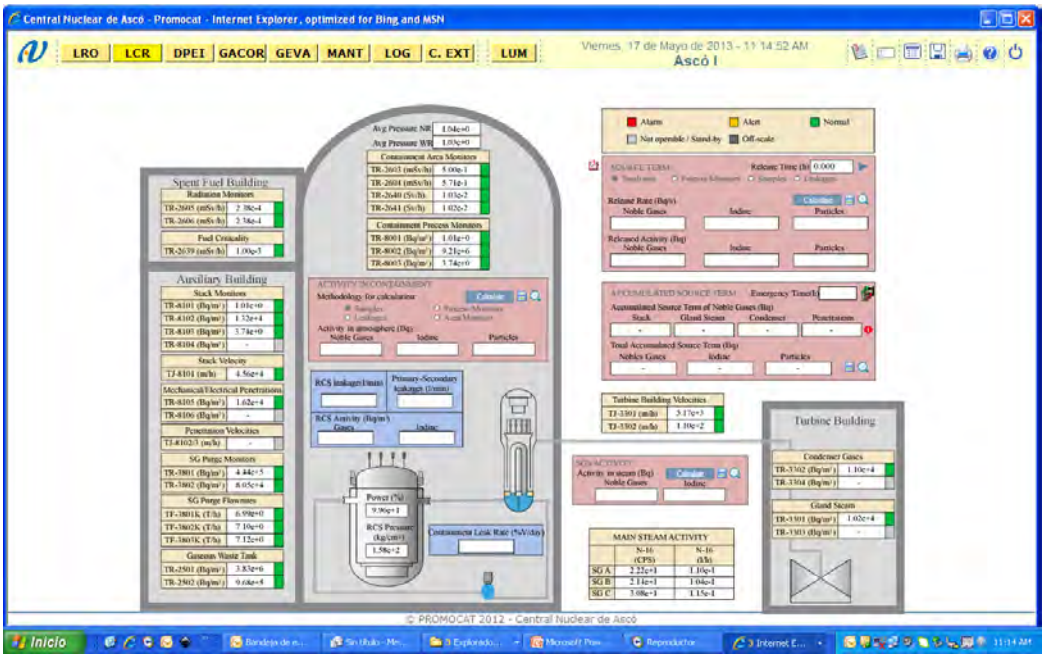

Figure 7. PROMOCAT Radiological Control Group Screen

To this end, it has different screens to help the different TSC groups in carrying out their functions, as well as facilitating the integration of these functions:

- Evaluation Group (Figure 6)
- Radiological Control Group (Figure 7)
- Emergency Director Guide
- Administration Module, that allows the management and administration of the different parameters and process of the Application.
- Historical Module, which gathers all the main actions performed during the Application session.
- Drill Module, that allows running a specific predefine simulation

The PROMOCAT application has two operating modes: REAL and DRILL. Once one of them has been chosen, the way of operation between the modules of the application will be the same, except for the origin of the parameters and variables data in the management of the emergency.

In this way, if the REAL mode is selected, the values of the monitored variables are obtained from the Safety Parameter Display System (SPDS), i.e. from the databank of the parameters measured in the plant. If the DRILL mode is selected, the data will be obtained from an Excel file containing the information of the variables and equipment for different times, which allows its use for exercises and drills.

After the implementation of Vandellós and Ascó specific SAMGs Revision 0, their new structure, based on the DPG made it necessary to modify the PROMOCAT SAMG module in depth.

First phase of the development of the new SAMG module, already implemented in the plants and used in the latest annual drills, provides access to the Revision 0 documents of the plant-specific SAMGs and facilitates the continuous and automatic acquisition of the values of the parameters required by the DPG to determine the level of threat to the barriers against the release of fission products, and consequently, select the priority guide to be implemented at all times depending on the conditions of the plant.

In addition, it provides an estimate of the trends of the values of these parameters, automatically selects the preferable instrumentation from which to obtain the data when there are alternative measurements, allows the automation of certain calculations such as those of correction factors of the levels of the steam generators, allows the manual entry of the values by the user when the instrumentation is lost or is not reliable, facilitates the monitoring of the accident through the ability to graph the parameters and activates the display of certain alarms.

7. CONCLUSIONS

Tecnatom, currently integrated in Westinghouse, has played a leading role in the development, revision and updating of the Severe Accident Management Guidelines (SAMG) for the Spanish Nuclear Sector since 2001. In this way, it has accumulated extensive experience and knowledge in the field of phenomenology and management of this type of accidents which, in addition to promoting the continuous improvement of the capacities of the plants for the prevention and mitigation of these through the successive revisions of the specific guidelines, has contributed to advancing in other related developments and activities, such as the training of personnel involved in emergencies and the design and development of support systems for their management and SAMGs use.

Following the integration into Westinghouse, the activities described in relation to Severe Accident Management continue and are expanded internationally.

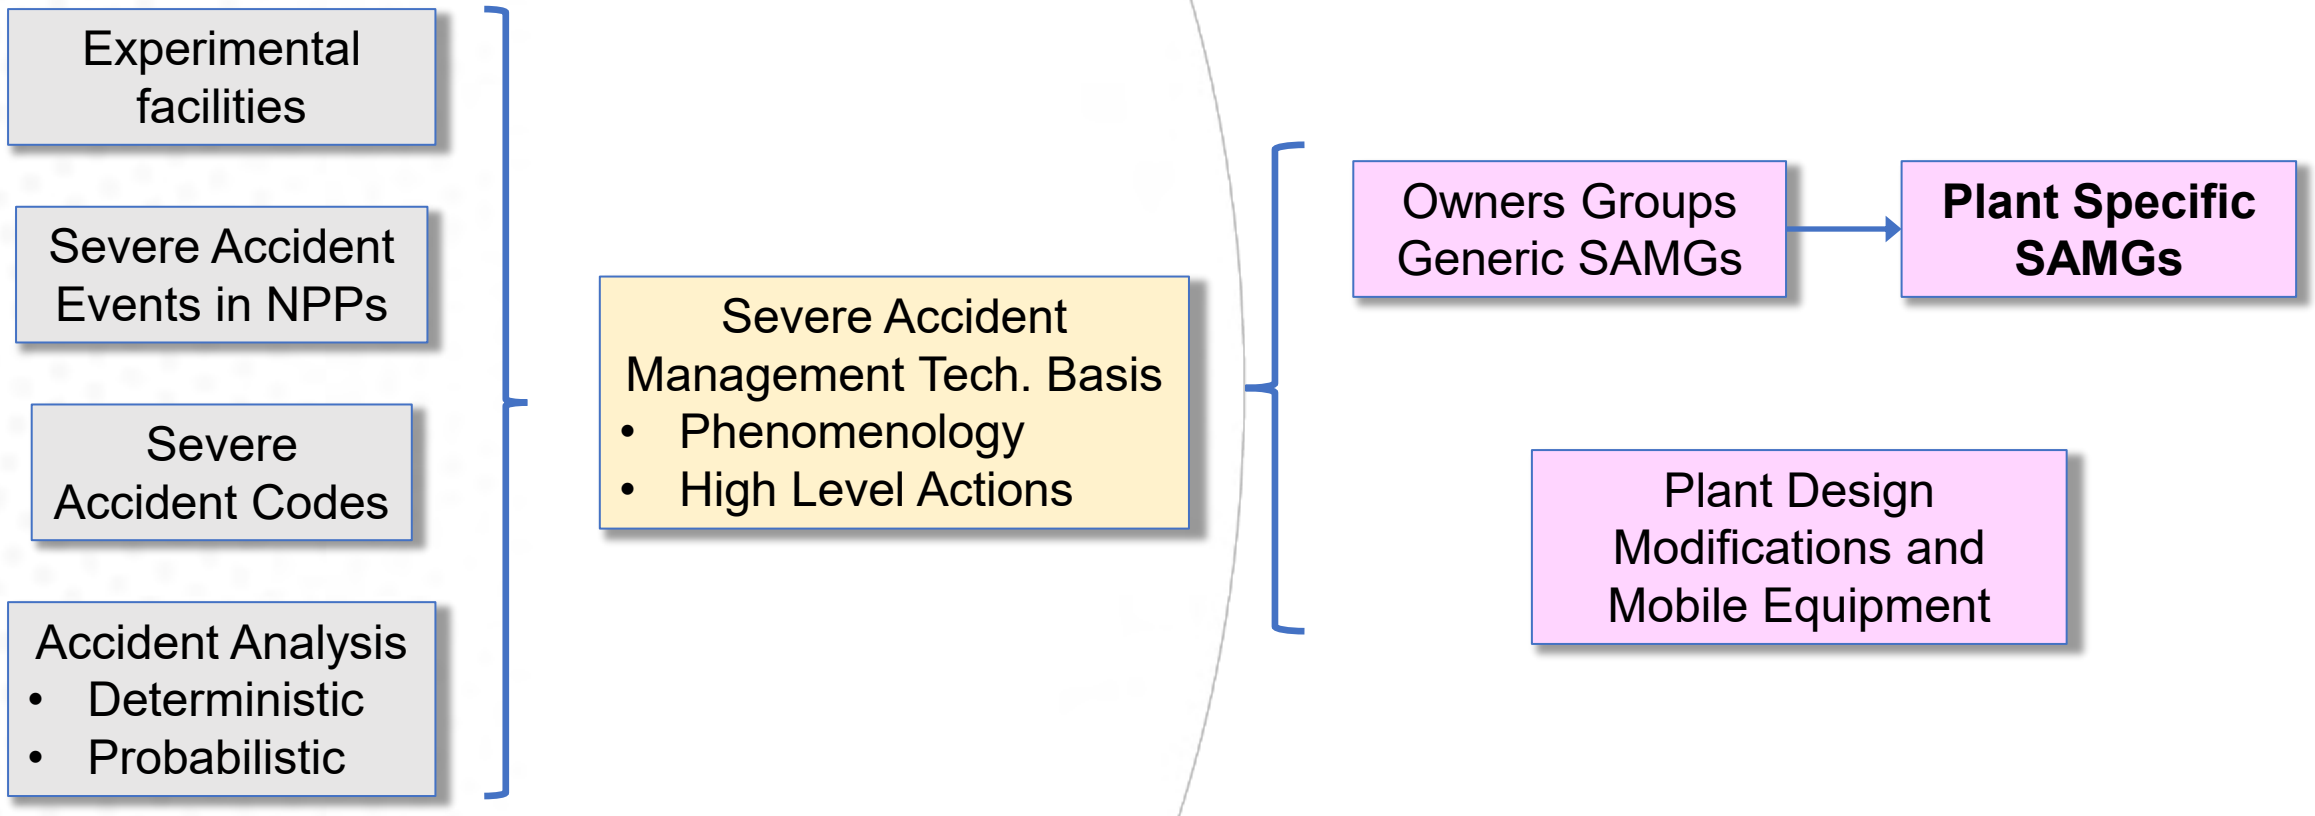
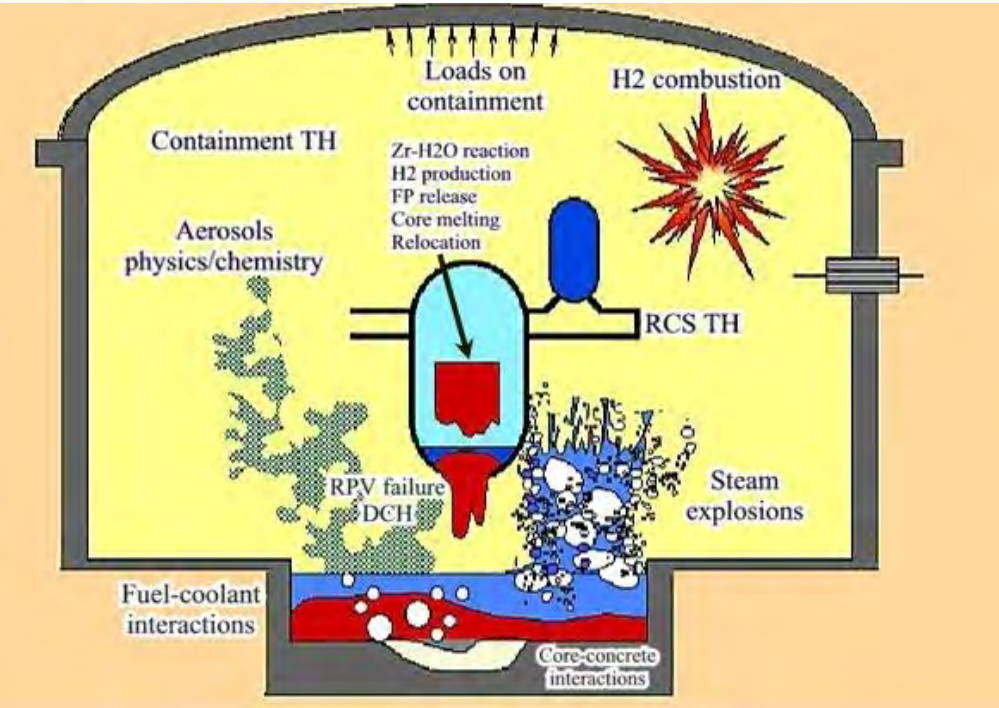
Severe Accidents in NPPs Research and Application



Severe Accident Management Guidelines (SAMGs)

Severe Accident specific (phenomenological / operational) conditions

Very different from those postulated in Design Basis Accidents (DBA) ⇒ analysis of severe accidents requires considering additional involved mechanisms and plant operability conditions:

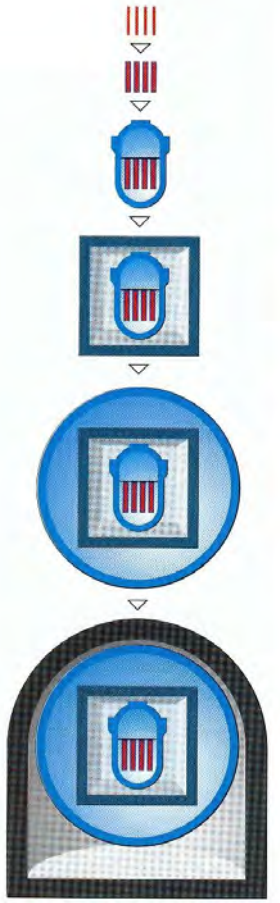


- ✓ chemical reactions at high temperatures
- ✓ additional heat sources
- ✓ geometry changes
- ✓ materials strength and interactions
- ✓ potential radioactive releases to the environment
- ✓ containment conditions and phenomena
- ✓ systems availability
- ✓ alternative systems
- ✓ ……

Severe Accident Management Guidelines (SAMGs)

Severe Accident Management Guidelines (SAMGs) provide guidance to operators and Emergency Response Organization staff for use if accident conditions progress beyond the prevention capabilities described in Emergency Operating Procedures (EOPs).

- SAMGs are needed because responding to a Severe Accident requires new strategies and priorities that are not adequately addressed by other operating procedures
- SAMGs are designed to fill the void beyond the EOPs and other accident response procedures for responding to an accident which progresses beyond limited core or spent fuel overheating due to inadequate core cooling (i.e., a Severe Accident).
- These guidelines employ strategies intended to
  - ✓ arrest the progression of fuel damage
  - ✓ maintain the capability of the containment as long as possible, and
  - ✓ minimize radiological releases



Severe Accident Management Guidelines (SAMGs)

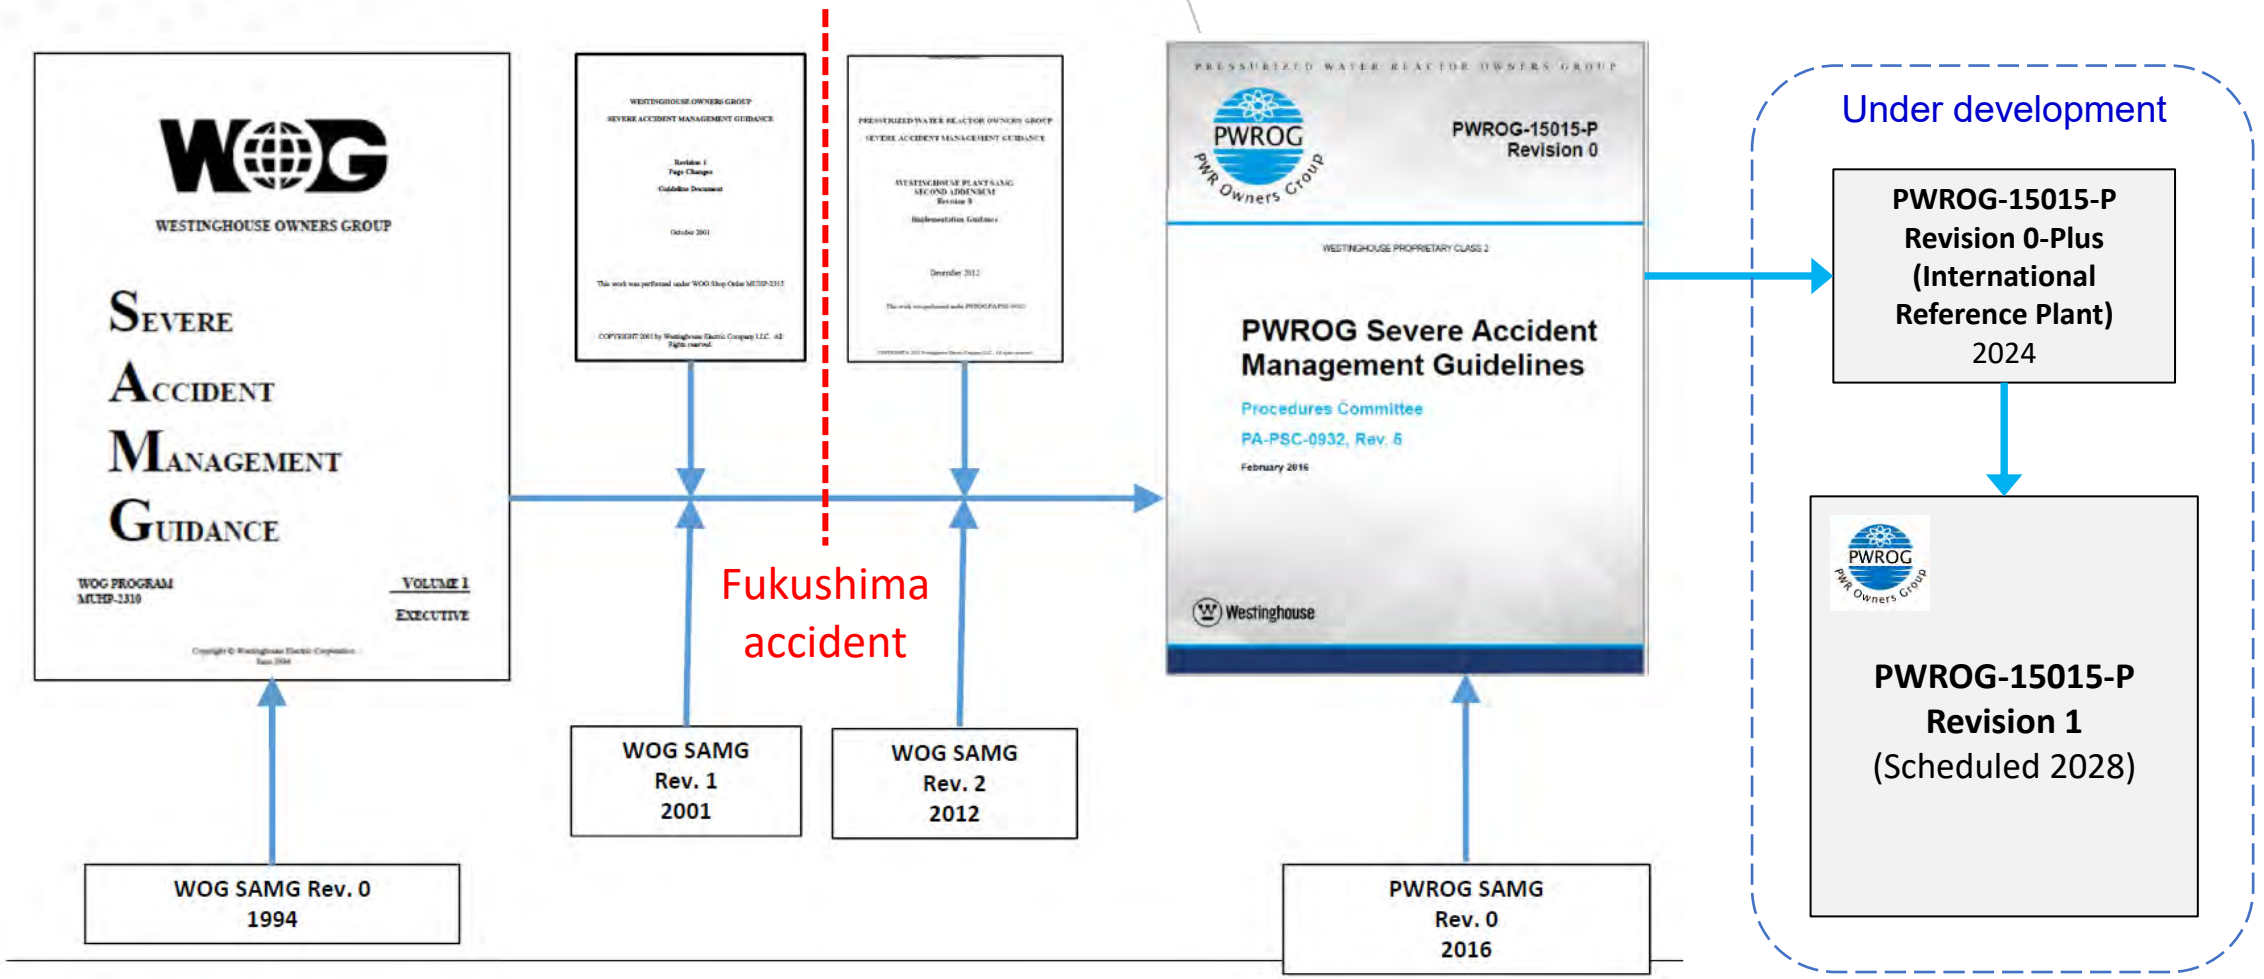
Accident Management (AM) → encompasses those actions and strategies taken during the course of an accident aimed to :

1. Prevent or delay the escalation of the event (DBE) into a severe accident (core damage)	Emergency Operating Procedures (EOPs)
2. Mitigate Severe Accident consequences : • terminating the progress of core damage once it has started and retain the core within the reactor vessel • maintaining containment integrity as long as possible • minimizing on-site/off-site radioactive releases • achieving a long-term safe and stable condition	Severe Accident Management Guidelines (SAMGs)
3. Protect the safety and health of workers and general public	Emergency Plan (EP)

Severe Accident Management Guidelines (SAMGs)

EOPs	SAMGs
• Designed primarily for **Design Basis Accidents**	• Applied when core damage has occurred → provide management strategies for **Severe Accidents**
• Objective : core damage **PREVENTION**	• Objective : core damage consequences **MITIGATION** → to protect remaining fission product boundaries (RCS, containment), arrest severe damage progression and prevent / mitigate / delay radioactivity releases.
• Priority → **maintaining fuel integrity** and restoring core cooling	• Priority → **protecting fission product barriers** and minimizing releases
• Used by the **Control Room (CR) staff**	• Used by the **Control Room (CR) and Technical Support Center (TSC) staff**
• 'Rule based' procedures → no positive and negative effects balance evaluation; **verbatim compliance** required	• 'Knowledge-based' guidelines → identify potential strategies and associated positive/negative effects to support a **decision making process**
• Sympton based	• Sympton based

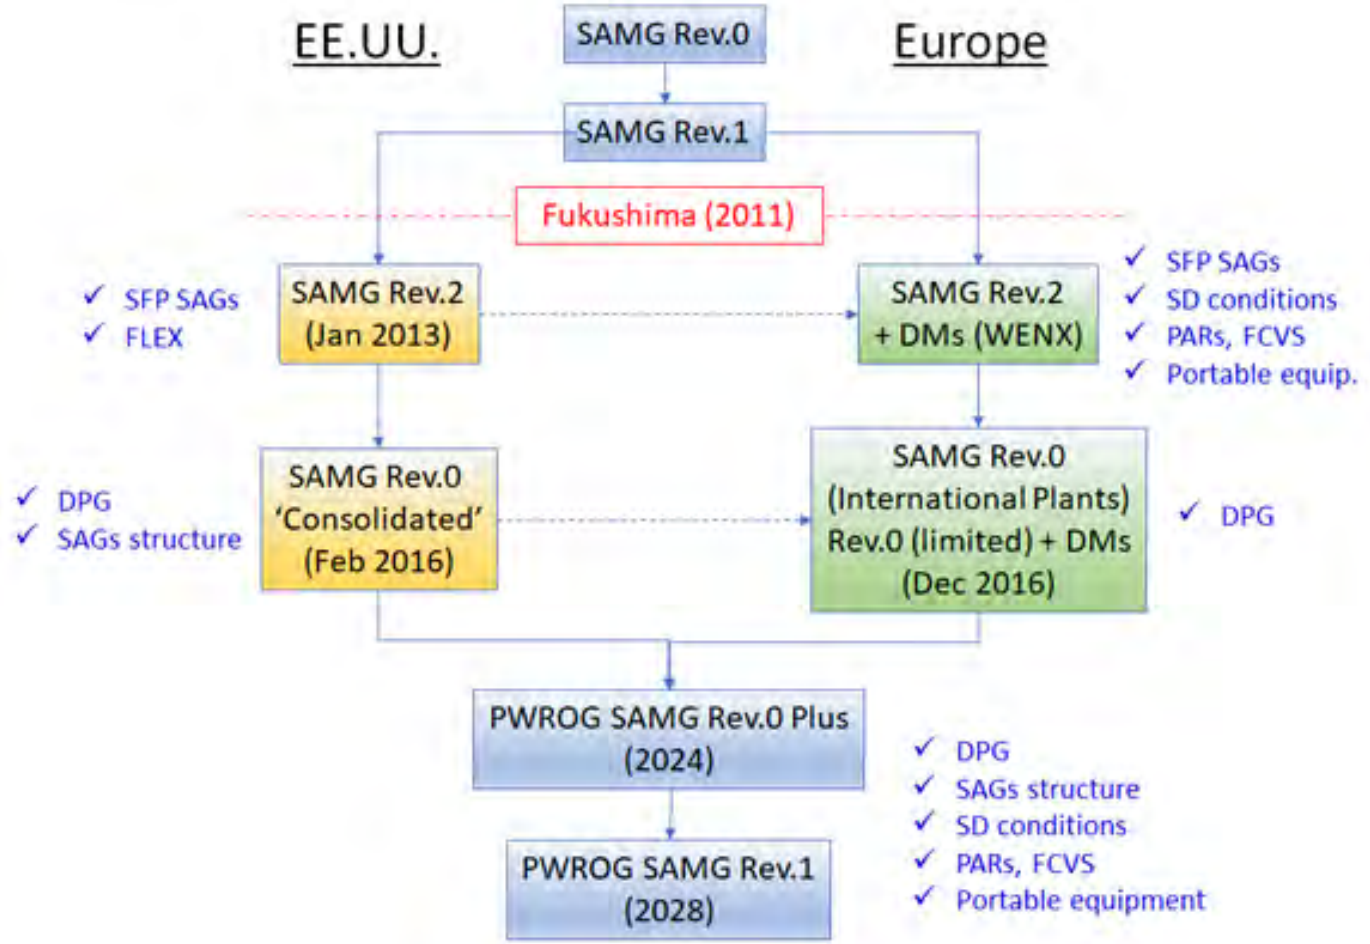
Development of the WOG/PWROG Generic SAMGs



Development of the WOG/PWROG Generic SAMGs

- In March 2021, the PWROG initiated an effort to integrate an International Reference Plant (IRP) design into the generic PWROG-15015-P SAMGs for US plants. The resulting generic SAMGs revision will increase access to the latest PWROG SAMG features for additional PWROG member plant designs with Passive Autocatalytic Recombiners (PARs) and Filtered Containment Venting System (FCVS) and will address severe accidents arising from shutdown initial conditions.
- A preliminary version of the PWROG-15015-P SAMGs with the changes approved prior to January 1, 2022 to integrate the IRP features has been developed and validated in 2024 with the name PWROG-15015-P Revision 0-Plus.
- The official updated revision will be referred to as PWROG SAMG Revision 1 and is scheduled to be published in April 2028.

Development of the WOG/PWROG Generic SAMGs



Development of Plant Specific SAMGs

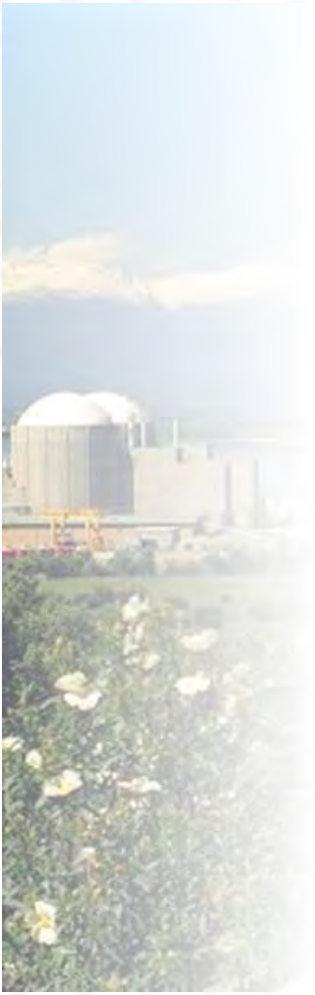
Implementation of the Plant Specific SAMG Programs

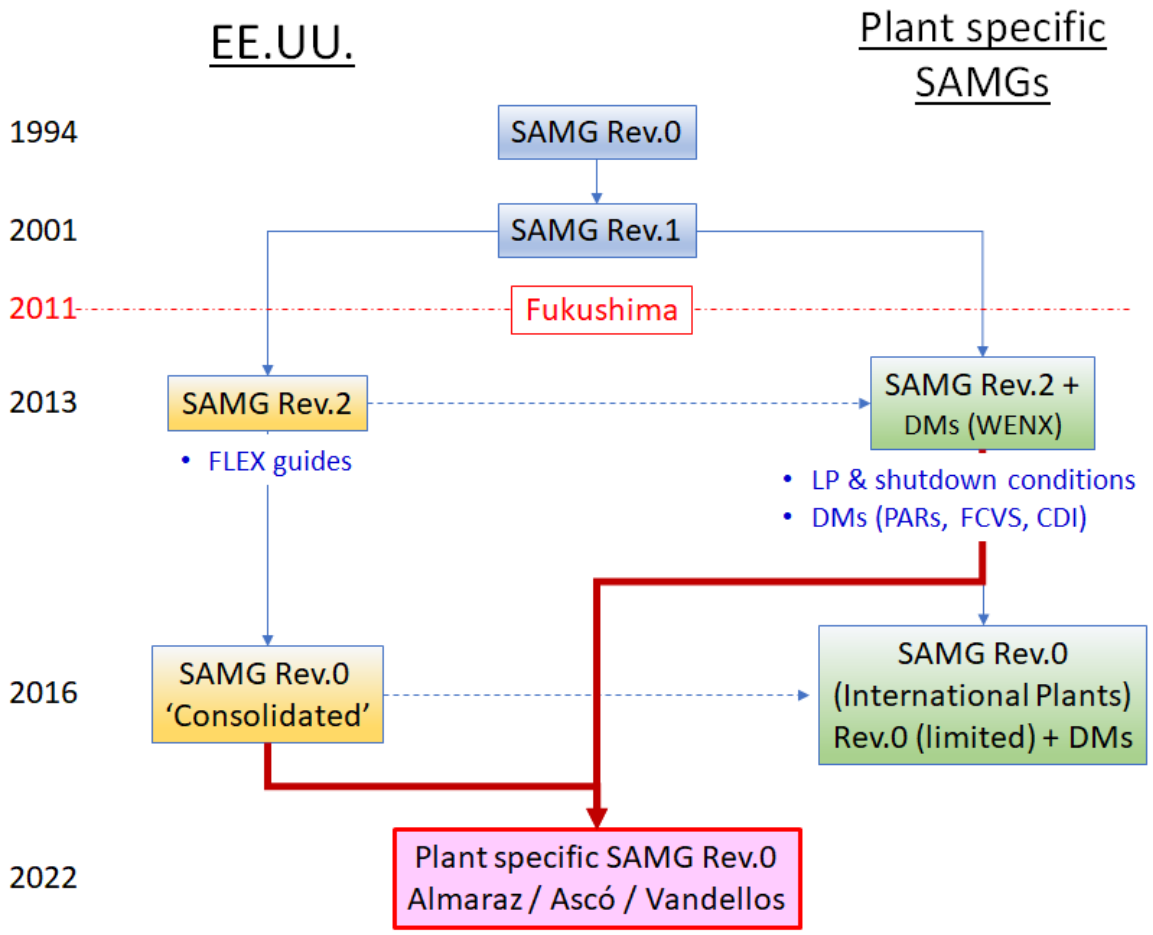
- Applicability analysis of the WOG/PWROG generic guides, customization to the specific plant and reference documentation generation, including :
  - plant specific setpoints
  - specific computational aids
  - plant systems performance
  - equipment identification
  - specific alignments
  - instrumentation capacities
  - SAMGs interface with EOPs and E-Plan
- Organizational and procedural changes
- SAMGs Writing, according to “WOG/PWROG Writer Guide” and “EOP Writing Guidelines” and the specific methodology developed in the documentation process.
- SAMGs Verification and Validation → to evaluate standards and criteria to be accomplished. and check the SAMGs ease of use by CR and TSC staff

Tecnatom / Westinghouse activities in SAMGs

- Since 2001, Tecnatom has participated in the development and validation of the specific SAMGs for Almaraz, Ascó and Vandellós Westinghouse design NPPs, based on the different revisions of the generic guidelines of the Westinghouse Owners' Group (WOG), currently PWR Owners' Group, (PWROG).
- Following the integration of Tecnatom into Westinghouse, the scope of action in the SAMGs field has extended to other countries, as the currently underway development of the plant specific SAMGs for Framatome design Koeberg NPP in South Africa.
- Westinghouse has also participated in the development projects or post-Fukushima updating of Ringhals (Sweden) or Sizewell B (UK) specific SAMGs, using the generic PWROG SAMGs as reference,
- In addition, Westinghouse actively participates from its formation in PWROG activities for the development and maintenance of both the generic Emergency Response Guidelines (ERGs), reference of the plant-specific EOPs, and the generic SAMGs, reference of the plant-specific guidelines.

Tecnatom / Westinghouse activities in SAMGs





Tecnatom / Westinghouse activities in SAMGs

Koeberg NPP specific SAMGs update project

In November 2024, Eskom and Westinghouse signed a contract to enhance a wide range of Koeberg NPP procedures to deal with an Extended Loss of Alternating Current Power (ELAP) respond in the event of an external hazard and manage severe accidents.

The project, currently under development, is divided into four Work Packages (WPs) that will cover the required procedures and document updates and developments. Westinghouse provides the qualified and competent resources to support the scope of all four WPs.

WP4, “Updates to the Severe Accident Management Guidelines (SAMGs)”, consists in the revision and adaptation of the SAMGs currently in force in Koeberg to the structure and contents of the generic PWROG-15015-P Revision 0-Plus SAMGs

The base scope of the ongoing project will develop an updated set of plant specific SAMGs in compliance with generic PWROG-15015-P Revision 0-Plus.

Tecnatom / Westinghouse activities in SAMGs

Other activities associated with Severe Accident Management (SAM)

- Design of training plans and delivery of courses on phenomenology and management of severe accidents for operation crews and Emergency Response Organization (ERO) personnel in Spanish NPPs and abroad (United Arab Emirates, China, etc.)
- Development of Technical Support Center (TSC) computer aiding tools for using SAMGs in real or simulated severe accident scenarios.
- Implementation of severe accident codes (MAAP) into Full Scope Replica Simulators (Laguna Verde NPP, Mexico) and Interactive Graphic Simulators (Almaraz NPP, Spain)
- Development of severe accident simulation tools based on IA surrogate models. The company is currently involved in the ASSAS (Artificial intelligence for Simulation of Severe Accidents) European Union project, presented in another paper within this meeting and in the visit to Westinghouse headquarters in Madrid.

ABSTRACT

The accident in Unit-2 of the nuclear power plant Three Mile Island has been extensively investigated in the scientific community for decades. The knowledge gathered from the accident investigations have been used for code developments and validations. TMI-2 accident simulation is also part of the validation matrix for the AC^2/ATHLET-CD system code. However, due to the internal structure of the code, it was not possible to reproduce the asymmetrical characteristics of the accident.

Recent improvements to the AC^2/ATHLET-CD system code have enabled azimuthal nodalization within the core region. This allows the adequate representation of local effects also during a severe accident.

Firstly, the paper presents briefly the necessary model developments to consider local conditions during a severe accident. Due to departing from the mandatory ring-shaped nodalization of the core region, models that took advantage of the classically cylindrical nodalization of the core region had to be refactored or developed anew. This applies in particular to the thermal radiation and to the horizontal melt relocation models.

Secondly, the new nodalization option including the newly developed models are used to reproduce the asymmetrical characteristics of the TMI-2 accident with AC^2/ATHLET-CD, and the reasons for this behaviour are discussed. The paper also provides an overview of the potential future applications of the non-ring-shaped nodalization option of AC^2/ATHLET-CD.

1. INTRODUCTION

In order to ensure and further improve the safety of existing and new-built nuclear reactors, computer codes have been developed that can simulate the response of the entire nuclear power plant to an initiating event. The simulations of potential scenarios have the capacity to identify vulnerabilities in the design of power

plants, thus enabling the implementation of countermeasures. Historically, the development and utilization of these system codes was primarily focused on the analysis of design basis accidents. However severe accidents like TMI-2, Chernobyl and Fukushima Daiichi highlighted the importance of the investigation of severe accidents. Existing codes were extended, and new codes were developed that could take into account the phenomena that predominantly or exclusively occur during a severe accident, including hydrogen production, melting processes, lower plenum phenomena and fission product release and transport.

In order to achieve the most accurate representation of the actual evolution of the accident, it would be ideal to investigate every structure within the cooling circuit and of the core separately. However, it is important to note that modelling and simulating each fuel pin individually would result in a substantial increase in the computational costs of the simulation. This is particularly relevant when considering that the development of the relevant codes (AC^2/ATHLET-CD, RELAD/SCADAP, MELCOR, etc.) [3, 8], [1] started multiple decades ago, at a time when the capabilities of computers were significantly more limited than they are today, but high-resolution reactor level analyses of a whole accident are still prohibitively numerically expensive and not suitable for uncertainty analyses as well.
The construction of reactors is such that the core parameters are as close to uniformity and symmetry as possible. This is done in order to ensure reliable, safe (with the greatest margin to safety criteria) and economic operation of the nuclear power plant. This reactor core characteristics led to one of the main assumptions of the most relevant severe accident codes: instead of modelling and nodalizing each fuel pin individually, they are grouped together horizontally in concentric rings and axially into multiple axial nodes. An example of a typical core nodalization is shown in Figure 1.

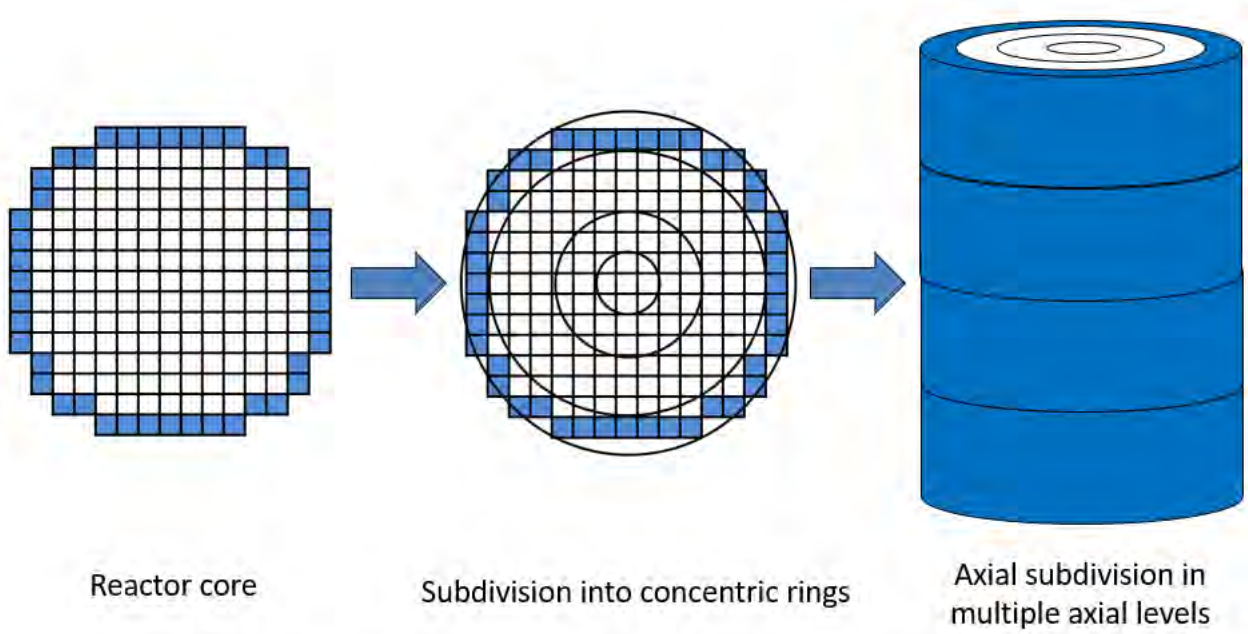

Figure 1. Example for a typical core nodalization in severe accident codes [7]

Each ring consist of multiple fuel rods (typically multiple thousands [6]). Ring shaped nodes are used and enforced, because it is assumed that the core configuration and the boundary conditions are cylindrically symmetrical. All the fuel rods defined within a ring are assumed to behave identically, meaning all the intensive parameters are the same, the extensive parameters are summed up within a ring. With this method, the required computational times for the simulations can be reduced significantly. Instead of simulating ~50000 fuel rods divided into multiple axial segments, these codes usually use 4-6 axially subdivided rings [10, 14].

The method briefly described above is widely used and accepted. It has some drawbacks, however. It adequately represents accidents with symmetrical initial and boundary conditions that progress symmetrically, but due to the enforced ring shaped nodalization, the simulations cannot differentiate azimuthal differences within the core region. If the accident has some local effects (local blockages, control rod ejection), asymmetrical characteristics (differently cooled core regions) or even minor deviances from an ideally symmetrical condition, then these asymmetrical effects can impact the accident evolution significantly. Such spontaneous symmetry breaking is expected in realistic scenarios. The analysis of such kinds of accidents is not adequately possible with the standard ring-shaped nodalization method. This created a motivation for model development in AC^2/ATHLET-CD.

In order to be able to simulate and analyse severe accidents with strongly asymmetrical characteristics, a new core nodalization method was implemented into AC^2/ATHLET-CD, that allows the azimuthal discretization of the ring-shaped nodes, allowing a more adequate consideration of local and asymmetrical effects during a severe accident. The departure from the obligatory ring-shaped nodalization inherently increases the required computational time for the analyses, but the increase is compensated for by the significant advancement of the IT capabilities. The new nodalization method required significant changes to the code, as the models that took advantage of the cylindrically symmetrical nodalization had to be either adjusted, refactored or newly developed.

This paper discusses the required model changes and demonstrates their usability on the TMI-2 accident, which had an asymmetrical characteristic. So far, the TMI-2 accident has mainly been analyzed under symmetrical conditions. This paper analyses the simulation of the accident by taking local effects also into account by using an azimuthally subdivided core. A potential explanation for the asymmetrical accident evolution is also provided.

2. REQUIRED MODEL DEVELOPMENTS TO ALLOW AZIMUTHAL NODALIZATION IN THE CORE REGION

The difficulty of considering local effects during an accident using a severe accident code can be summarized with the help of Figure 2. The upper part visualizes the issues mentioned in the introduction. The core has to be nodalized horizontally into concentric rings. If there is a local effect in the core (regardless of the origin of the local effect), its impact has to be averaged over the whole ring, as the main assumption of severe accident codes is that all the fuel rods within a core node behave identically. This leads to the redistribution of the local effect over the whole ring, thus losing its local impact. This generalization can impact the whole accident evolution. Let's assume a hypothetical scenario, where the cooling of a certain region in the core is limited, for example due to a local blockage.

- Real case: the local reduction of the cooling can lead to film boiling and local fuel degradation, eventually.
- Modelled case with the standard ring-shaped nodes: The impact of the cooling reduction has to be distributed along the whole ring, thus the cooling reduction per fuel rod is lower than if it were only considered locally. This could lead to a situation, where the reduced cooling is still sufficient to cool the core and prevent melting.

This hypothetical example shows that the evolution of the accident can strongly depend on the type of nodalization and highlights the potential drawbacks of using the mandatory, standard ring-shaped nodalization.

The solution to these issues is to allow the azimuthal discretization of the core rings. With this, a node can be defined around the local effect. The effect is still redistributed along the node, but as the node is smaller

and defined around the local effect, the impact of the redistribution is smaller. This is depicted in the bottom part of Figure 2.

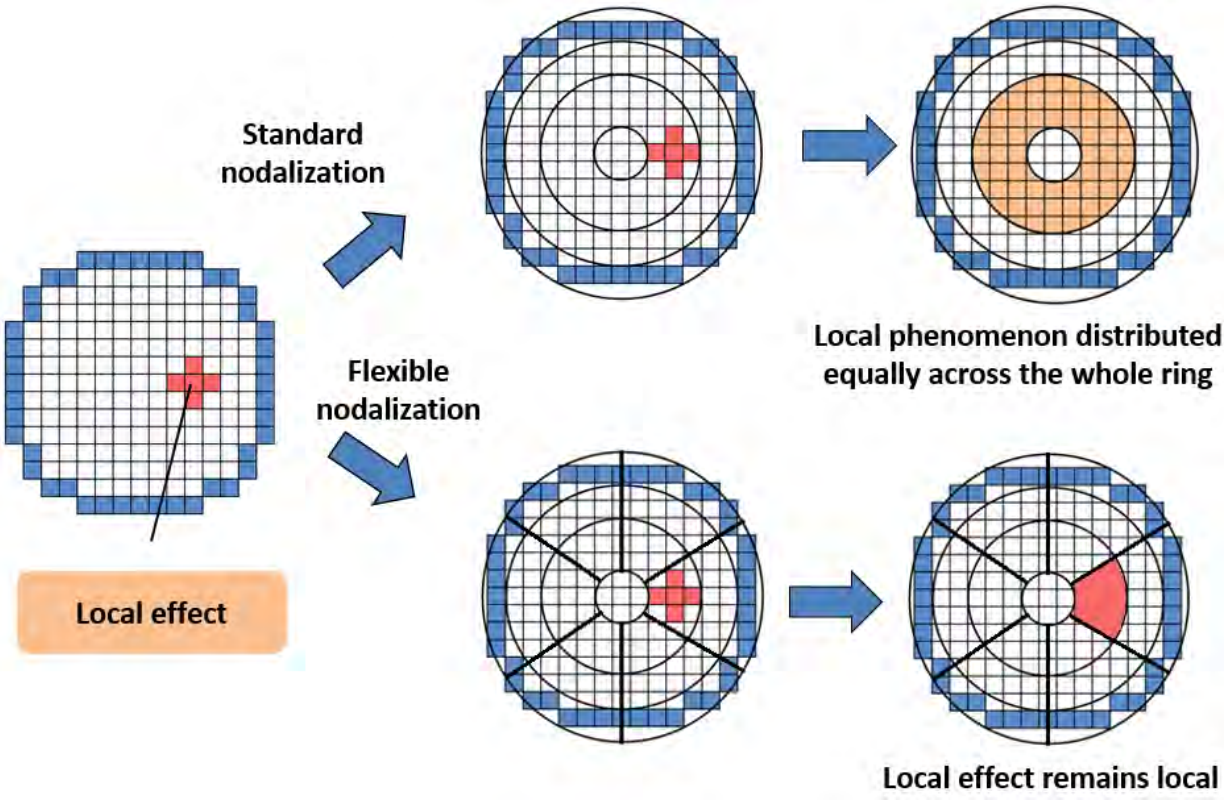

Figure 2. Consideration of local effects depending on the nodalization type [7]

As the ring-shaped nodalization was hardcoded into AC²/ATHLET-CD, internal changes to the code were necessary to allow a user-defined number of azimuthal sectors. This required model changes and their verification, validation. These are presented in the following chapters.

2.1. Model Developments

Due to the departure from the ring-shaped nodalization it had to be checked whether any of the existing models is impacted by this change and whether these models took advantage of the assumption that the boundary conditions are cylindrically symmetrical. After a detailed review of the code base, the following conclusions were made [13]:

- Most of the simulated phenomena are calculated for a single fuel pin (regardless of the node shape and size):
  - Heat generation, conduction, convection, oxidation, cladding failure, fission product release, axial melt relocation.
  - Results of the single rod calculation are multiplied by the number of rods in a node.
  - No model changes are needed.
- The modelling of fluid flow is already flexibly definable:
  - No model changes are needed.
- Heat radiation between nodes:
  - Model changes are needed, standard model is based on cylindrically symmetrical assumptions
- Radial relocation of melt:

- Model changes are needed, standard model is based on cylindrically symmetrical assumptions

The last two points will be introduced briefly below.
The change of the shape of the nodalization has no impact on the heat radiation processes within a cell. Changes had to be made in the modelling of heat radiation towards neighbouring cells. In the standard, ring-shaped nodalization scheme, horizontal heat radiation is only considered from a ring towards its inner and/or outer neighbour. If a neighbouring node is molten, then the next neighbouring node is taken. This is illustrated on the left side of Figure 3. The calculation of the required view factors between the ring shaped nodes is calculated via means of analytical correlations [9]. Importantly, due to the nature of the nodalization no shadowing effects can occur.
This is no longer true for the nodalization scheme where azimuthal discretization is made possible. During the core degradation process configurations can form, which create a total or partial shadowing effect between two free surfaces for heat radiation rays. Right side of Figure 3 shows a possible configuration with shadowing effects. Red areas indicate molten nodes. Heat radiation from side "2" towards side "5" is unblocked, but heat radiation rays from side "8" towards side "5" are partially blocked by the still intact surfaces of "6" and "7". This effect has to be taken into account in the adjusted heat radiation model. Unfortunately, due to shadowing effects, analytical solutions for the determination of view factors are not applicable.

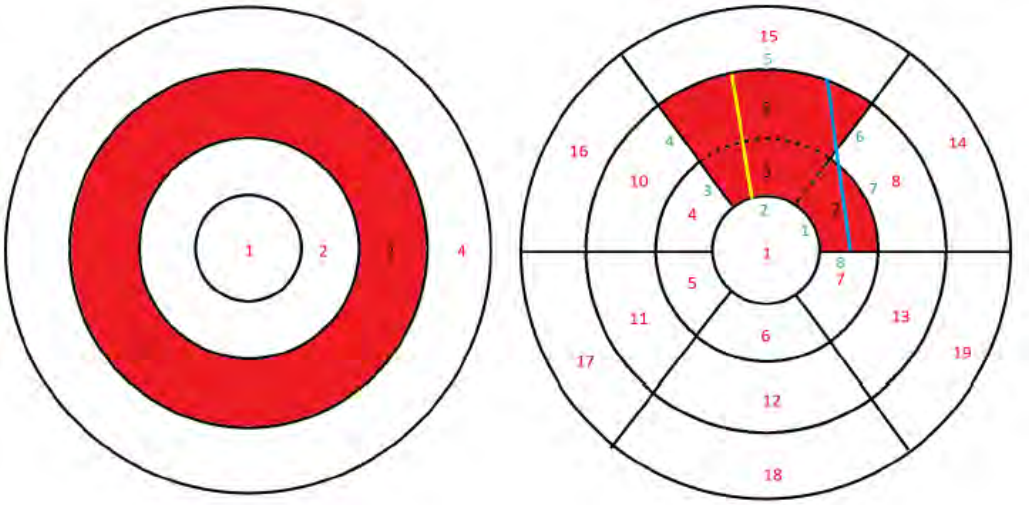

Figure 3. Left: no shadowing effects possible. Right: possible shadowing effects [7]

To solve the issues of the standard heat radiation model with the neighbour identification and shadowing effects, the following code changes were made:

- Creation of an algorithm that identifies the surfaces that exchange radiative heat with each other, both in intact and degraded states of the core.
- In the areas, where the core is intact, the old heat radiation model is used, however, it is modified, so that it is able to consider heat radiation also in azimuthal direction.
- For the areas, where core nodes have relocated and a cavity was formed, a numerical method was implemented to determine the required view factors for the heat radiation, including shadowing effects.

Due to length limitations, a detailed introduction to the developed model and its verification and validation is omitted here. It is described in detail, including its verification and validation in [7] and is summarized in [11, 12, 17].

The model developments for the consideration of the horizontal melt relocation also in an azimuthally subdivided core required less effort than the consideration of the heat radiation in a 3D cavity. The physical model was left unchanged, the relocating mass is still dependent on the melt height differences in the neighbouring nodes, as described in detail in [9]. The only adjustment to the model was the adequate identification of the target nodes for the horizontal melt relocation. In a ring-shaped nodalization, the melt could only relocate to an inner or outer neighbouring ring, while in a three-dimensionally nodalized core, the melt can also relocate azimuthally. The identification process for the correct neighbouring target node is the same as for the heat radiation between intact nodes.

3. TMI-2 ACCIDENT

The accident in the unit 2 of Three Mile Island nuclear power plant is one of the few, if not the only accident, that happened in a light water reactor, that is well documented, and where the accident progression has a definite asymmetrical characteristic. The accident started with the opening of the pilot operated relief valve (PORV) that stuck open, which remained undetected long enough and which caused significant loss of coolant. The ensuing core uncovery then led to fuel degradation, melt formation and relocation. The melt relocated to the lower plenum in one segment of the core, on the outer side. The accident is described in detail in numerous literature like [2, 15, 16] to name a few. The final state of the core is illustrated on the left side of Figure 4. The right side of the figure shows the assumed location of the relocation, which is close to loop-B.

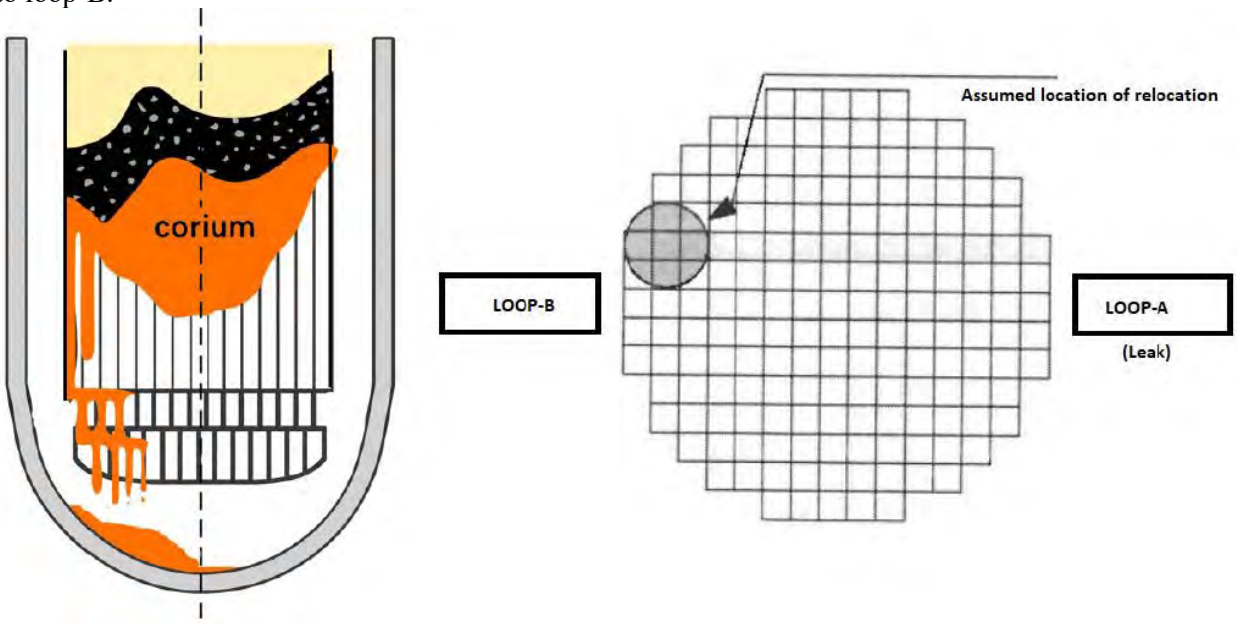

Figure 4. Left: Sideways relocation of melt (vertical cut), Right: assumed location of relocation (horizontal cut) [7]

The figure shows the clear asymmetrical characteristics of the accident, which for reasons described in the previous chapters, could not be adequately represented in severe accident codes using standard ring-shaped core nodes.
The following chapter will demonstrate that the newly developed nodalization method and models allow the consideration of the asymmetrical characteristics when the rings are subdivided azimuthally. The results are also used to partially validate the newly developed method and provides a possible explanation for the reason of the asymmetrical behaviour of the accident.

3.1. TMI-2 input decks

The TMI-2 accident has been used for validation of ATHLET-CD for many decades; therefore an input deck was already available. This input deck includes all the major components of the primary circuit and defines the actual events during the accident, like the timings of the operator actions, as boundary and initial conditions. This input deck nodalizes the core region axially into multiple levels and horizontally into concentric rings, therefore it cannot address the asymmetry of the accident leading to a one-sided melt relocation by definition. The core nodes are connected to one upper plenum volume that distributes the coolant into loop A and loop B. The two loops are modelled separately, including the steam generators, pumps and in loop A the pressurizer with the PORV. The two cold legs per loop enter a common ring-shaped downcomer node that leads the coolant to the lower plenum. From lower plenum volume, that is only axially subdivided, the fluid is distributed to the four core ring nodes and to the core bypass. A detailed description of the standard TMI-2 input deck can be found in [4].
This input deck was used as basis for the creation of the input deck with azimuthal nodalization. The azimuthal subdivision of the core into four sectors results in more cells, which leads to an increase in computational needs. The subdivision of the core region into four azimuthal segments was chosen to reflect the potential impact of the mass flows of the 2 hot legs and 4 cold legs. A higher number of subdivisions would have been possible, but to keep the increase in the computational time at a minimum, the subdivision was not increased above 4. Future investigations might repeat this analysis with higher subdivision. We know from the literature that the relocation of melt to the lower plenum happened closer to loop B (right side of Figure 4). By subdividing the rings into four azimuthal segments like shown in Figure 5, the local impact can be taken into account. The effect is still averaged over the node (right side of Figure 5) but allows the qualitative representation of the accident progression.

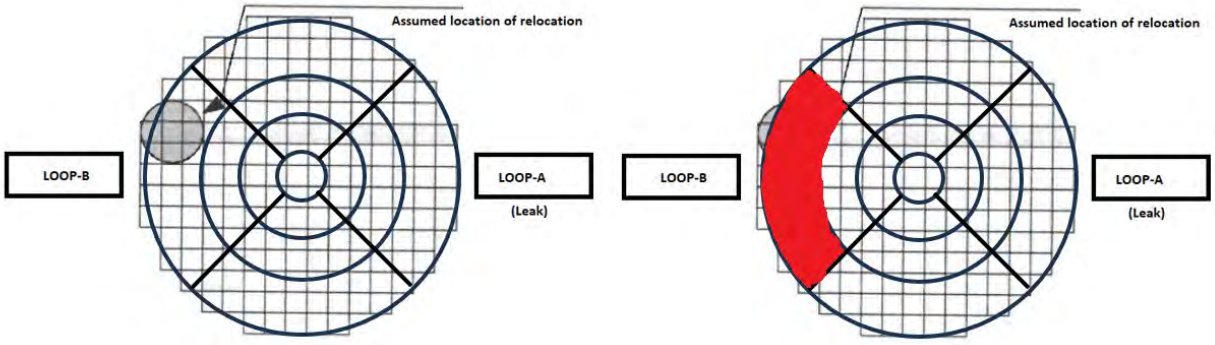

Figure 5. Left: Core nodalization to represent local effects during TMI-2 accident. Right: averaging effect of the azimuthal nodalization [7]

The azimuthal subdivision alone does not create an asymmetrical behaviour. In order to achieve an asymmetrical behaviour some kind of asymmetrical effect had to be implemented into the input deck. After literature review, the followings conclusions were made what effects could have influenced the accident asymmetrically:

- Besides minor differences in local parameters, the core can be considered as cylindrically symmetrical. Thus, the origin of the asymmetrical behaviour is from the outside of the core region. The core parameters were defined symmetrically.
- The leak through the PORV in the pressurizer was located in loop-A, which could have an asymmetrical impact on core cooling. Therefore, a thermohydraulical nodalization was implemented in the input deck that can reflect this behaviour.
- The heat removal from the two steam generators were different due to the different secondary side pressures and feedwater supply [2]. These could also asymmetrically influence the core cooling and requires the same type of nodalization to take into account as in the previous point.
- Different operation of the main coolant pumps in loop A and B.

Based on these findings, subdividing only the core region azimuthally should not lead to an asymmetrical accident evolution, besides smaller numerical effects [5], as all the core nodes receive symmetrical conditions, because the impacts of the two different loops are averaged out in the only axially subdivided upper and lower plenum volumes. To allow physical phenomena-based 3D effects to take place, the whole pressure vessel had to be subdivided azimuthally and had to be connected to each. This led to the final nodalization of the pressure vessel shown in Figure 6 as a cross-sectional cut from the top.

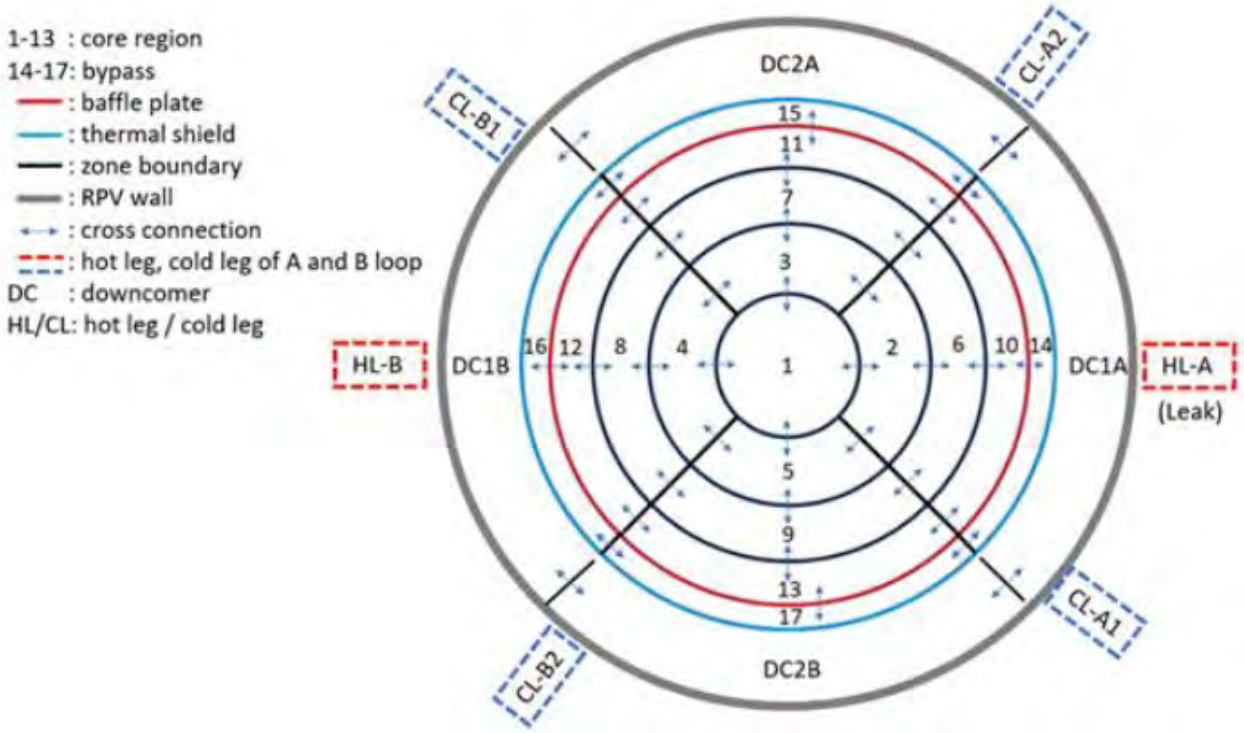

Figure 6. Top view of the 3D nodalization of the inside of the reactor pressure vessel [7]

The accident scenario of TMI-2 was simulated using an input deck with an azimuthally subdivided reactor pressure vessel. The goal of these calculations is to demonstrate the impact of the nodalization on the accident progression, partially verify/validate the new models using the available TMI-2 data and to explain the reason for the asymmetrical tendence observed during the accident. The main findings are presented and summarized in the following chapter.

3.2. Analysis of the simulation results using azimuthally subdivided core

It is well documented in [4] that using a ring-shaped nodalization for the core, AC^2/ATHLET-CD is capable, with some exceptions, of capturing the integral evolution of the accident. It is important that this is also true for the case where the core is azimuthally subdivided. Figure 7 is a useful indicator of whether this criterion is met. It shows the pressure evolution measured in TMI-2, as well as the results of simulations with ring-shaped and 3D core nodalization, starting 100 minutes after the accident sequence began. The first 100 minutes of the accident sequence is omitted, because there are no significant differences between the simulated and measured data. The first differences start to occur after the PORV is closed. The pressure starts to increase, however, in case of the 3D nodalization the pressure increases more rapidly, but the difference to the measured value is still not too large. The difference could be attributed to different temperature distributions in the core, which will be discussed later. Larger differences occur after the main coolant pump in loop B is activated, which delivers water into the already partially degraded core. This results in a large increase in pressure, but both simulations overestimate the pressure increase. It is a known

issue that AC²/ATHLET-CD can overestimate the heat transfer and thus the pressure increase in some cases during the quenching process. As both calculations show the same behaviour, it is not caused by the new model developments or by the azimuthal nodalization, therefore it is not discussed further in this paper. Both simulations fall back approximately to the measured pressure values after the peak, but keep increasing faster than in the real case, indicating again an overestimation of the heat transfer from the hot structures/melt to the water. The pressure evolution then follows the real trend, although the case with the 3D nodalization shows some delay. Larger qualitative difference occurs at around 224 minutes into the accident sequence. When the molten material from the core relocates to the lower plenum, it gets into contact with water and fragments. The resulting large surface area intensifies the heat transfer from the melt/debris to the water, leading to a pressure peak as visible in Figure 7. The relocation of the melt is initiated in the simulations also at T=224 minutes, but AC²/ATHLET-CD lacks fragmentation modelling. Therefore, it cannot reproduce the resulting pressure peak. This modelling gap is, however, not in connection with the topic of this paper.

Looking at the overall accident evolution based on the pressure data, we can conclude that both simulations can qualitatively describe the accident scenario. The larger differences can be explained by gaps in the AC²/ATHLET-CD modelling base, that is not the topic of this paper. Notably, the differences between measured and simulated values were slightly larger for the input deck with the detailed nodalization, for which some explanation is given below.

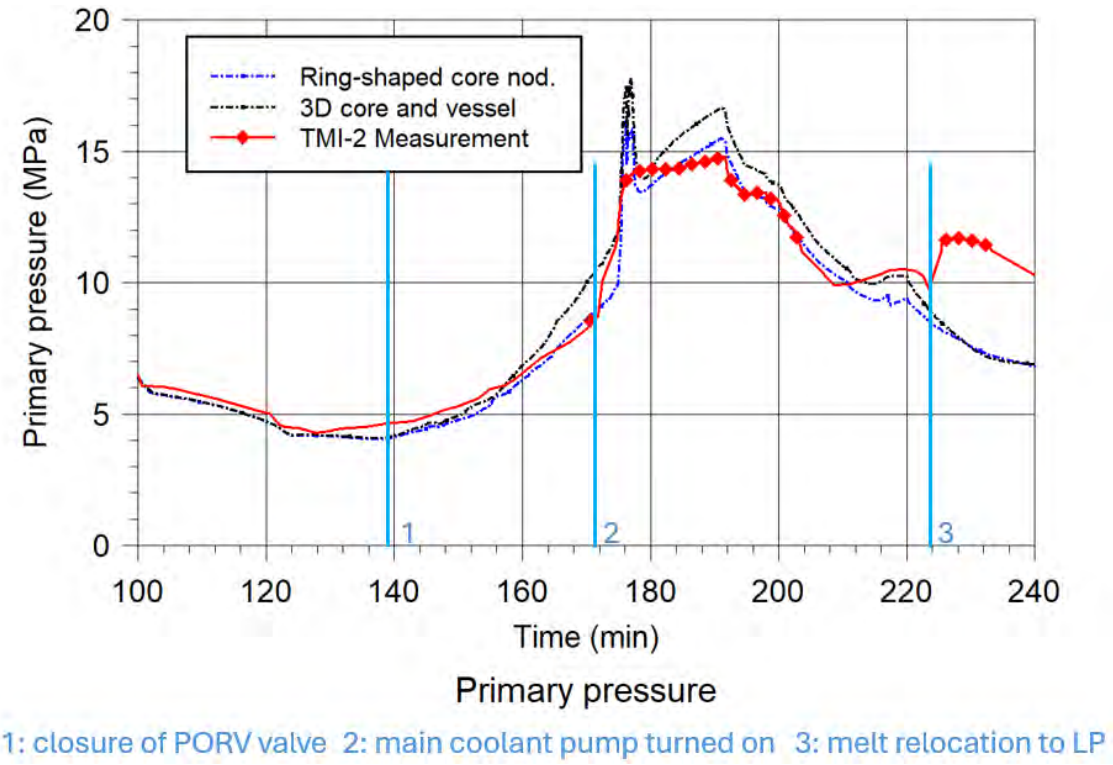

Figure 7. Evolution of the primary pressure during the accident in TMI-2. Simulated and measured values

Following the previous summary of the overall accident evolution, the objective of this paper is addressed. As already mentioned previously, the main goal of this paper is to demonstrate the capability of AC²/ATHLET-CD to reproduce the asymmetrical characteristics of the accident and give an explanation on the origin of the asymmetrical effect.

Figure 8 shows the side view of the state of the core at the end of the simulation. As the created nodalization is three-dimensional, a cross-sectional cut view from one direction is insufficient to represent the 3D state of the core. Consequently, the left and right sides of the figure show the same reactor at the same time, viewed from the direction indicated by the arrow in the graph. The figure depicts the reactor vessel, fuel and control rods, as well as the melt in the lower plenum. The colours of the structures indicate their temperatures. For easier orientation, the node numbers of Figure 6 are also shown in Figure 8.
It is clearly visible that a cavity was formed during the core degradation process. However, it is also apparent that the form of the created cavity is not cylindrically symmetrical. Segment "2" is not molten, which is located on the opposite side of the assumed location of the material relocation to the lower plenum (see Figure 4). Alternatively, this can be expressed as follows: the core is more degraded in the direction of loop-B. There are two important conclusions to be drawn from this fact. Firstly, the calculation managed to create a cylindrically asymmetrical core degradation. Secondly, the resulting asymmetrical core degradation is shifting in a direction closer to loop-B, like in the real accident. There is also a slight local effect in direction of loop-A in the segment “6”, where a node also melted. This can be attributed to the fact, that due to the creation of the cavity, segment “2” can radiate its energy (using the newly developed heat radiation model for the 3D cavity) to colder areas and more coolant can get to the hot surfaces of segment “2”, thus intensifying its cooling. Segment “6” doesn’t have this extra cooling effect, thus melts. The first objective of this analysis was reached, as it was demonstrated that with the 3D nodalization of the core, the asymmetrical characteristics of the accident could be reproduced on a qualitative level.

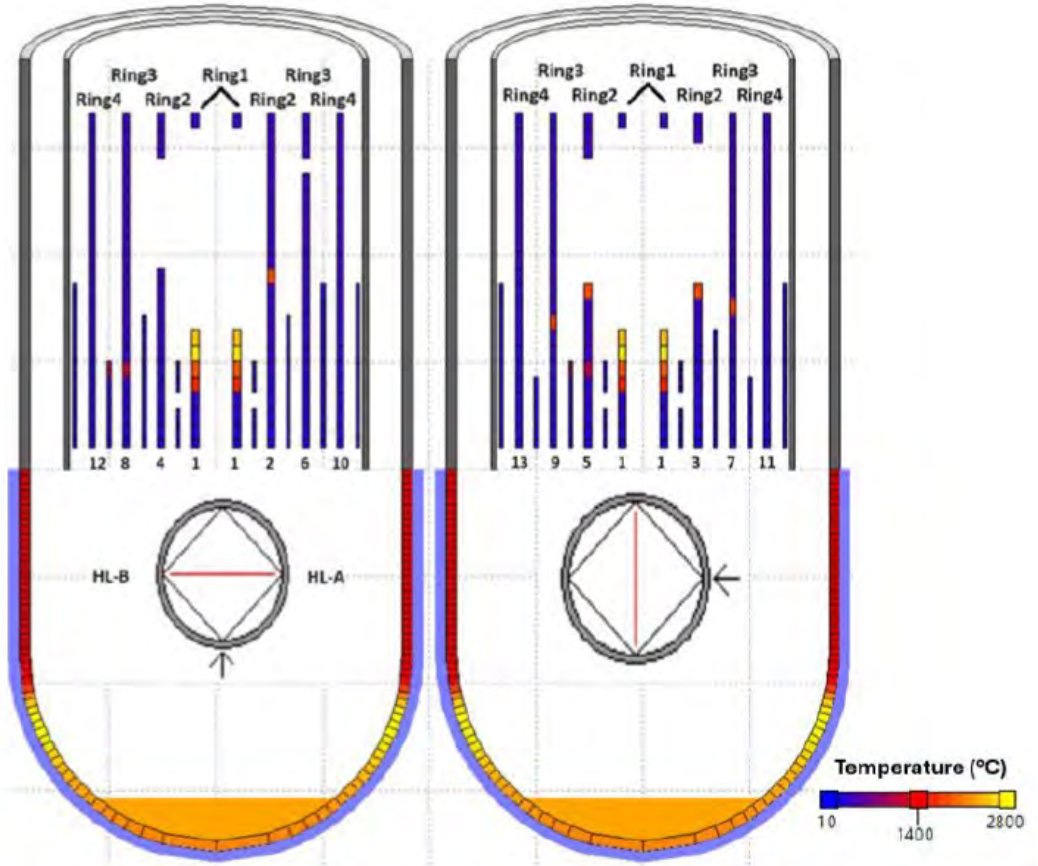

Figure 8. Cross sectional cut of the reactor vessel from the direction of the indicated arrow, using the detailed nodalization. [7]

The second objective of this analysis is to find an explanation for the reason of the asymmetrical accident evolution. For this a deeper and more local analysis is needed. We know based on Figure 8 that the side

closer to loop-B degraded more than the side of the reactor closer to loop-A. The temperature evolution of these two sides were compared, specifically the fuel temperatures at the axial elevation of 3.4 m (axial node 18) of rod group “12” and “10”. This is depicted in the top right corner of Figure 9. Up until the core is covered with water, i.e. up until around 6500 seconds after the start of the accident, the temperature differences between the two sides are negligible. They start to deviate from each other slightly, but a larger and significant difference occurs at around 7200 seconds, where the auxiliary feedwater injection into the steam generator in loop-A was increased, then shortly afterwards stopped. This results in a larger heat removal from loop-A, leading to an increased mass flow rate in loop-A that results in a short-term flow reversal in loop-B, too. This can be seen in the bottom graph of the right side of Figure 9. As a result of this flow reversal, colder fluid is falling onto the upper segments of rods closer to loop-B, which results in a temporary cooling of those fuel rods. After the feedwater injection to steam generator-A stopped, the mass flows returned to their previous directions. At this stage of the accident, contrary to the expected results, the region closer to loop-B is colder than the region of the core, that remained intact at the end of the accident.

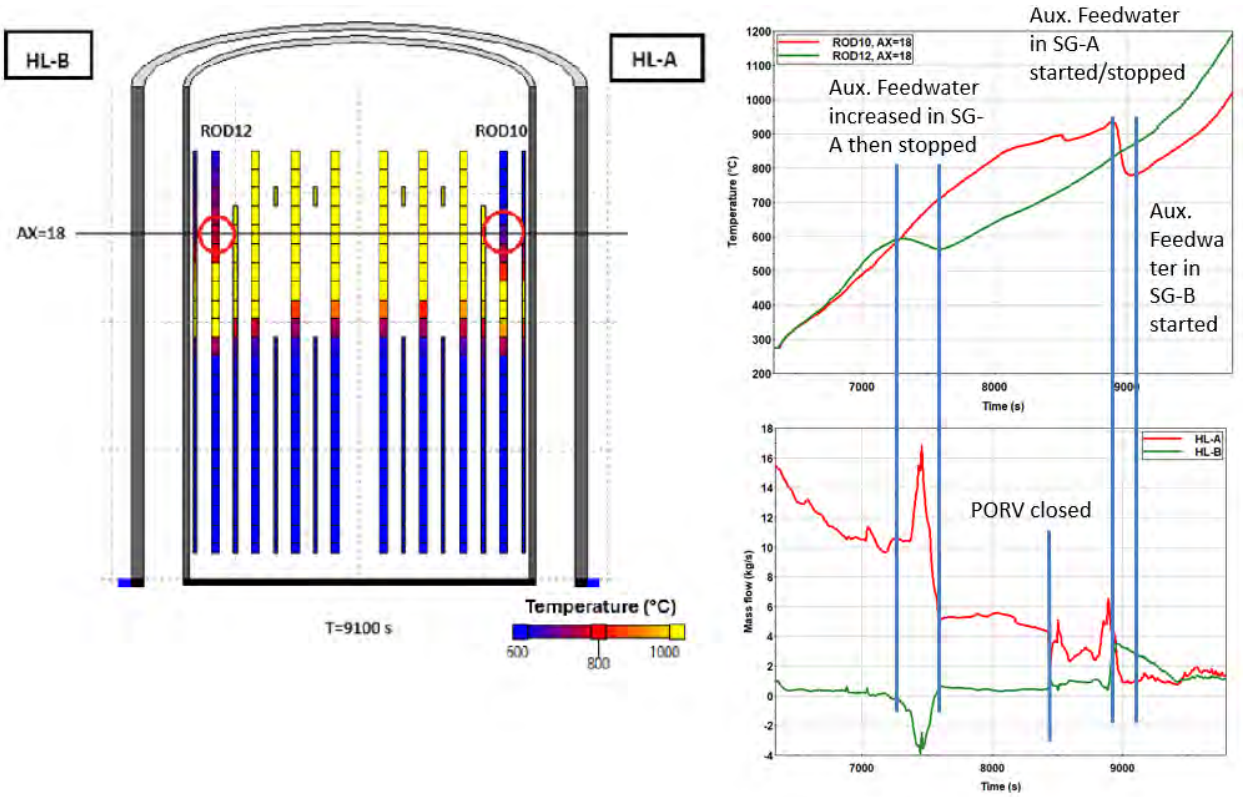

Figure 9. Evolution of fuel temperatures on two opposite sides of the core [7]

Rod group “12” remained colder for about 1500 seconds. The leak through the pressurizer was detected at approximately 8500 seconds into the accident and was closed. However, this had only a minor impact on the mass flows and thus on the temperature evolution of the investigated fuel rods, as can be seen in Figure 9. At around 9000 seconds, the operators started the feedwater injections in steam generators A and B, but then turned it off in loop A again, influencing the heat removal from the reactor. These actions caused large mass flow changes, again within the core as well. The local mass flow changes caused rod group “10” to cool down, as seen in the top right graph of Figure 9. From this time on, the side of the reactor closer to loop-A remained colder during the entire accident evolution, up until core reflooding. Left side of Figure 9 depicts at T=9100 seconds into the accident the location of the fuel rods that were compared and shows that the left side of the reactor is about 100 °C warmer than the right side. Thus this region reaches onset of the

extensive oxidation earlier, causing an earlier rapid heat-up and eventually an earlier core degradation, leading to the cavity formation as can be seen in Figure 8.

Using the azimuthally subdivided core nodalization it was possible with AC²/ATHLET-CD to reproduce qualitatively the asymmetrical core degradation of the TMI-2 accident and to give a hypothesis why the accident evolved non symmetrically. The location of the leak in only one of the loops appears to have exerted a minor asymmetrical effect on the accident evolution, contrary to the author's expectations. However, the different heat removal from the primary system through the steam generators impacted the accident scenario more significantly according to the presented AC²/ATHLET-CD simulation.
The simulation results are promising and plausible, but the asymmetrical tendency of the accident evolution is predominantly captured qualitatively, quantitative improvements are still possible. The lack of quantitative accuracy can be traced back to two things.
Firstly, the AC²/ATHLET-CD models lack some key phenomena (such as fuel fragmentation and relocation outside of the core) or consider them in a simplified way (e.g.: quenching process). These limitations are not associated with the newly developed models, but the finer nodalization enhances their impact on the overall calculation.
Secondly, the input deck parameters have a certain degree of uncertainty. Some of these uncertainties come from the accident itself, for example the exact temperature when the fuel started to relocate. Some of them are caused by the finer, azimuthal nodalization of the pressure vessel. The exact geometry gets a larger importance, if the nodalization is finer, and some of the form loss factors and exact dimensions were not known to the user at the time of the input deck creation. Changing these values can have a significant impact on the quantitative results of the simulation.
For these reasons, future works will focus on improving the model basis of AC²/ATHLET-CD and on further enhancing the TMI-2 input deck. Also uncertainty analyses are planned to identify the factors that influenced the accident the most. Related changes can allow the code to reproduce the real accident evolution more realistically and accurately.

4. SUMMARY AND OUTLOOK

This paper presents an option implemented in AC²/ATHLET-CD that allows users to depart from the mandatory ring-shaped core nodalization in most severe accident codes, thus enabling local effects to be taken into account. This required the refactoring or newly developing of the models that took advantage of the symmetrical boundary conditions of the mandatory ring-shaped nodalization. Most notably the models of heat radiation and horizontal melt relocation were refactored/newly developed. Using this new nodalization option, including the newly developed and refactored models, the TMI-2 accident was simulated. It was chosen to be analyzed because the accident evolution has a proven, well documented asymmetrical characteristic. This was reflected by creating an azimuthally subdivided core. The results obtained show the asymmetrical behaviour, although with some quantitative differences to the actual measurements. These differences and future improvement options were discussed. A possible explanation was also found and analysed why the accident evolved asymmetrically.

In the future, the departure from the mandatory ring-shaped nodalization allows the investigation of design extension condition scenarios, where a strong local impact is expected, like, for example, accident scenarios with control rod ejection or partial core reflooding from the top. The power distribution of spent fuel pools are usually not cylindrically symmetrical, this approach can be applied there, too, as was already demonstrated in [12]. It also allows to investigate if minor deviations from an ideally symmetrical condition can lead to a larger asymmetrical progression, which is not unlikely for such non-linear processes and the numerical schemes used in AC²/ATHLET-CD. This option does not make the standard ring-shaped nodalization obsolete but enables the future investigation of scenarios with strong local effects.

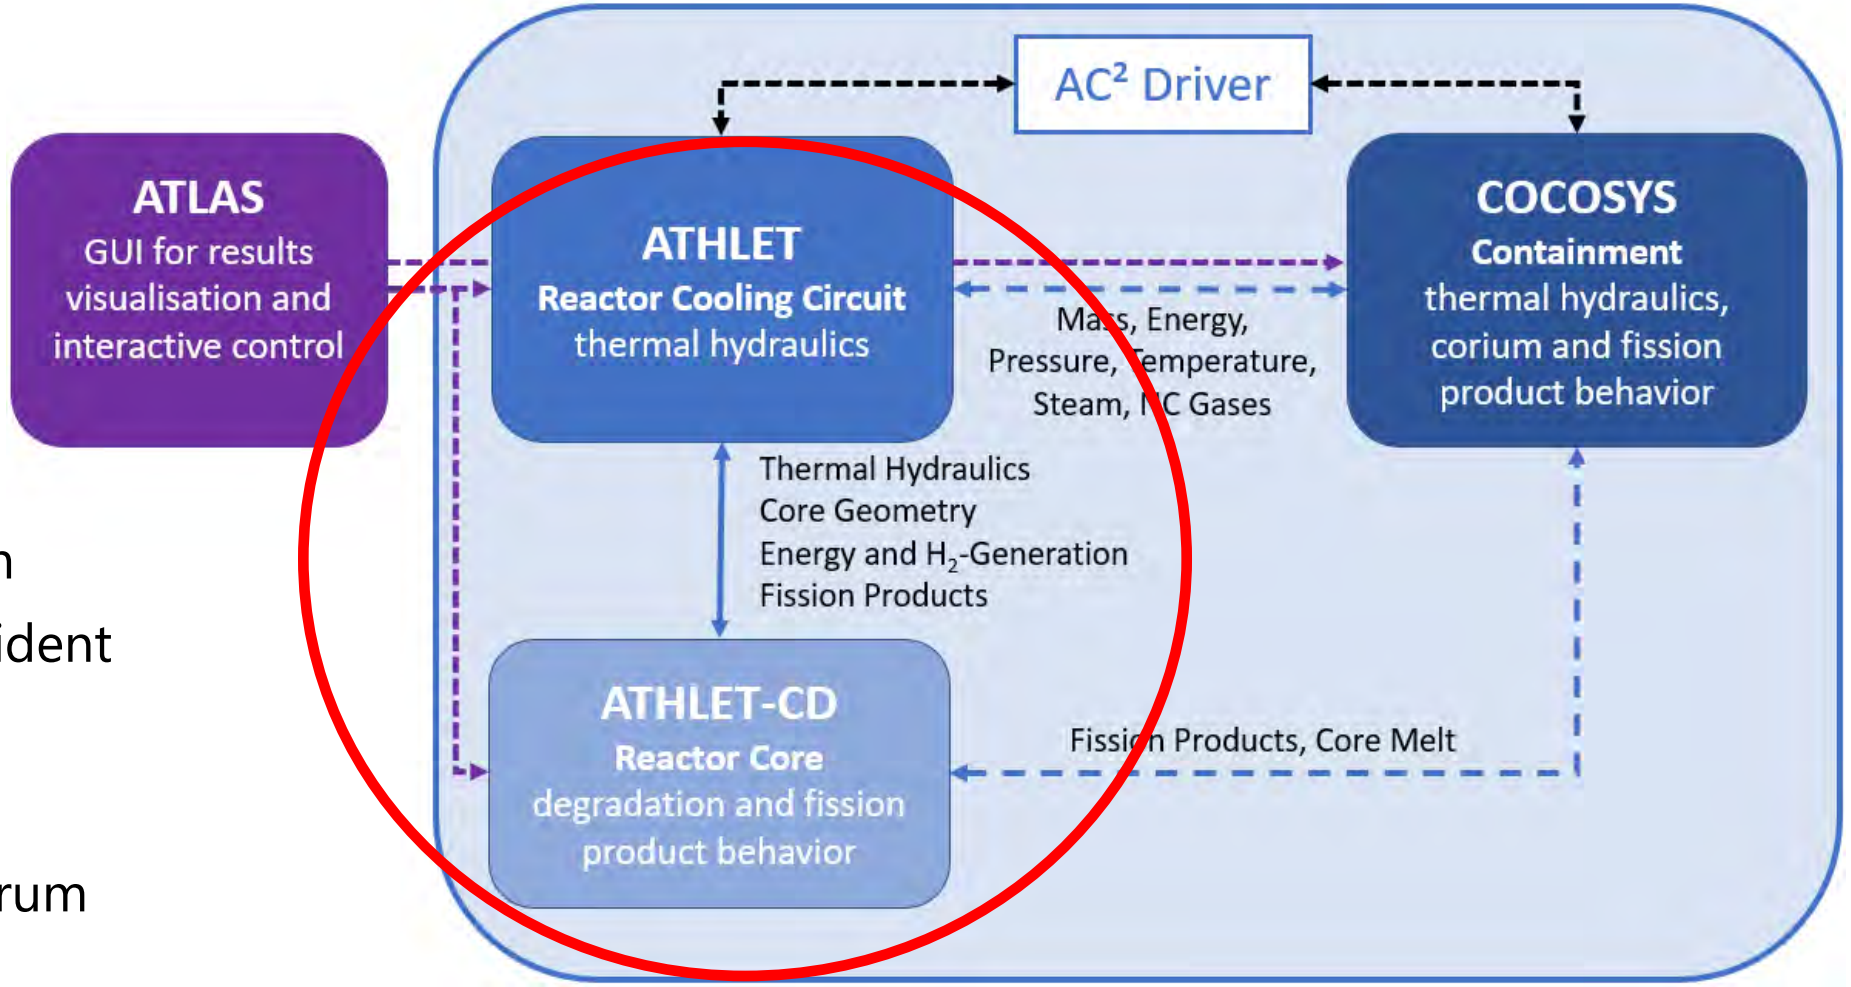
ERMSAR 2026 - The 12th European Review Meeting on Severe Accidents Research, Madrid, Spain, 18-22.05.2026

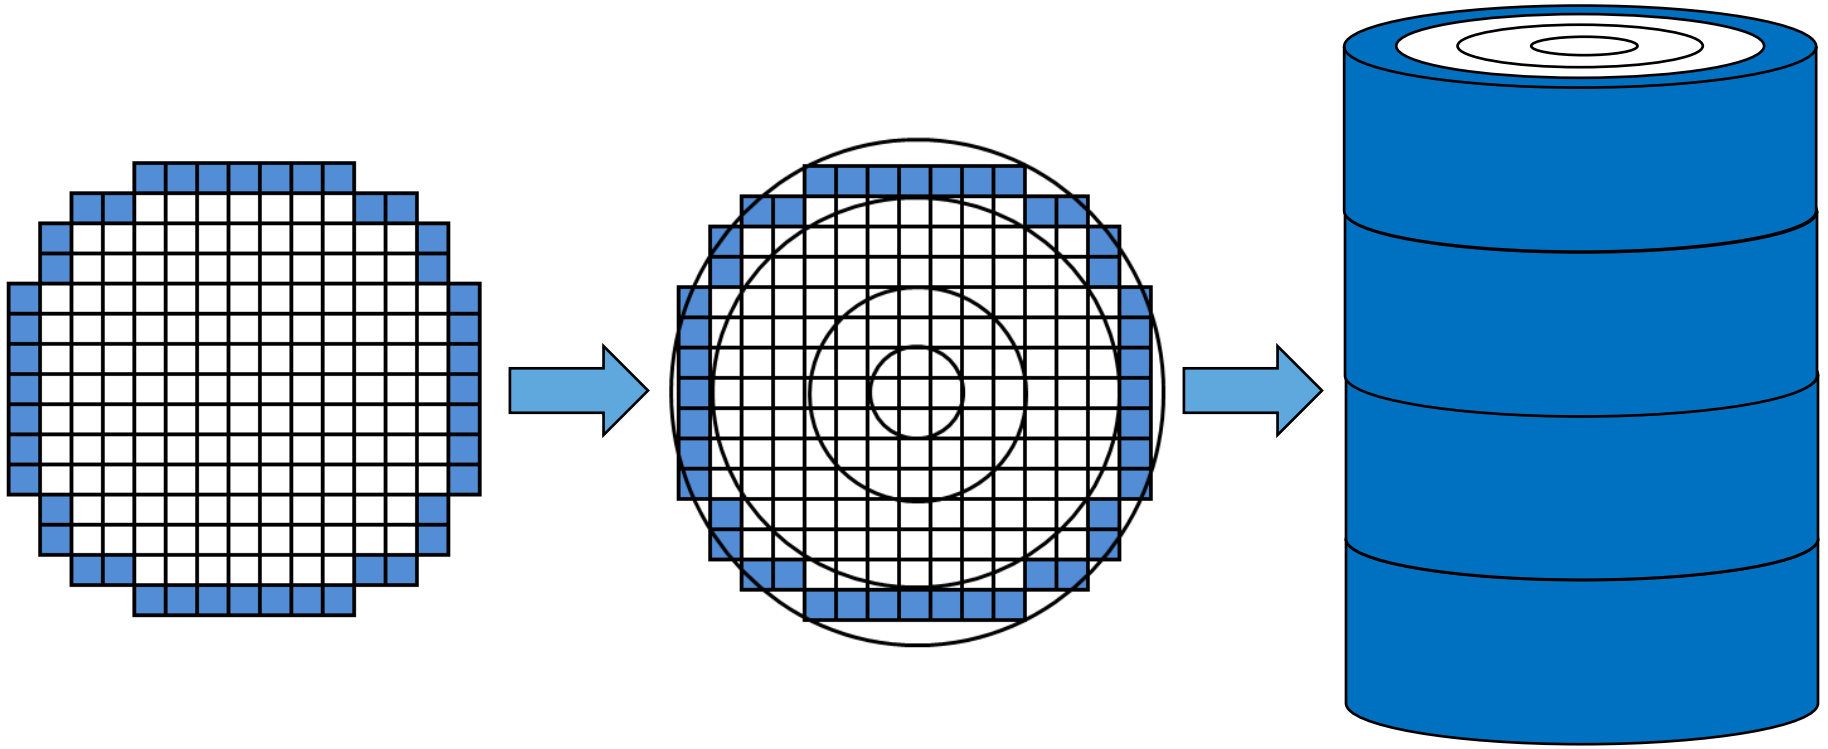
What is AC²?

- **AC²**:
  - **A**THLET
  - ATHLET-**C**D
  - **C**OCOSYS
- Deterministic system code system for accident analysis
- Covers a wide spectrum of phenomena



© Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) gGmbH

Core representation



Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted.* PSS.

Reactor core

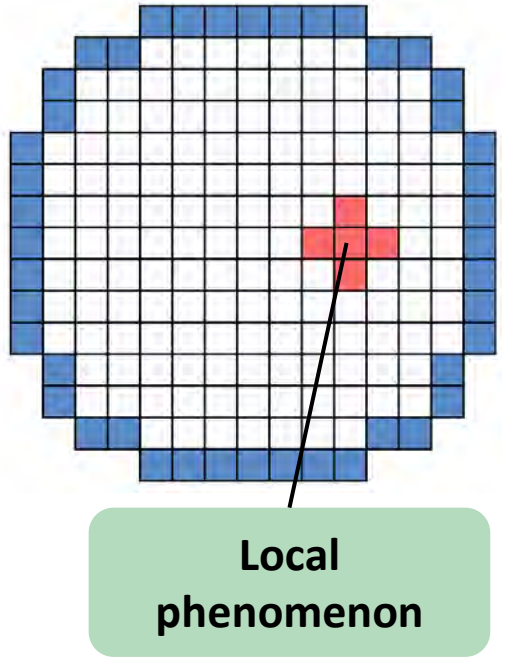
Subdivision into concentric rings

Axial subdivision in multiple axial levels

- All fuel rods/structures within an axially/radially defined node behave identically
- Good applicability in symmetric conditions

Accidents with asymmetrical characteristics

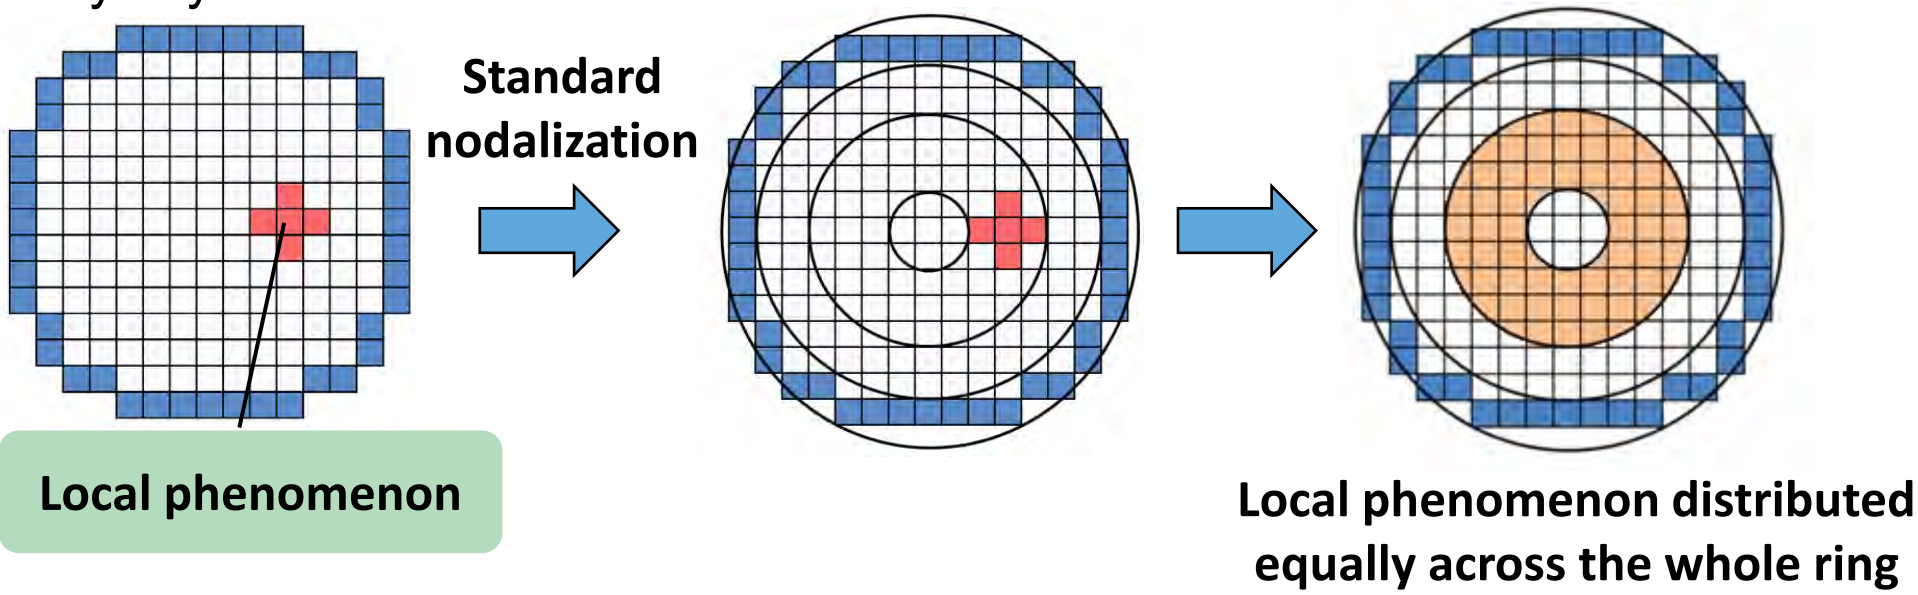
- Control rod ejection
- Asymmetric reflooding from above
- Non-uniform power distribution
- Small local deviations from ideally symmetric conditions can lead to extended asymmetric characteristics



Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted.* PSS.

Ring nodalization vs local effects

- Ring-like nodalization might lead to incorrect and unrealistic results if there are azimuthally asymmetric effects

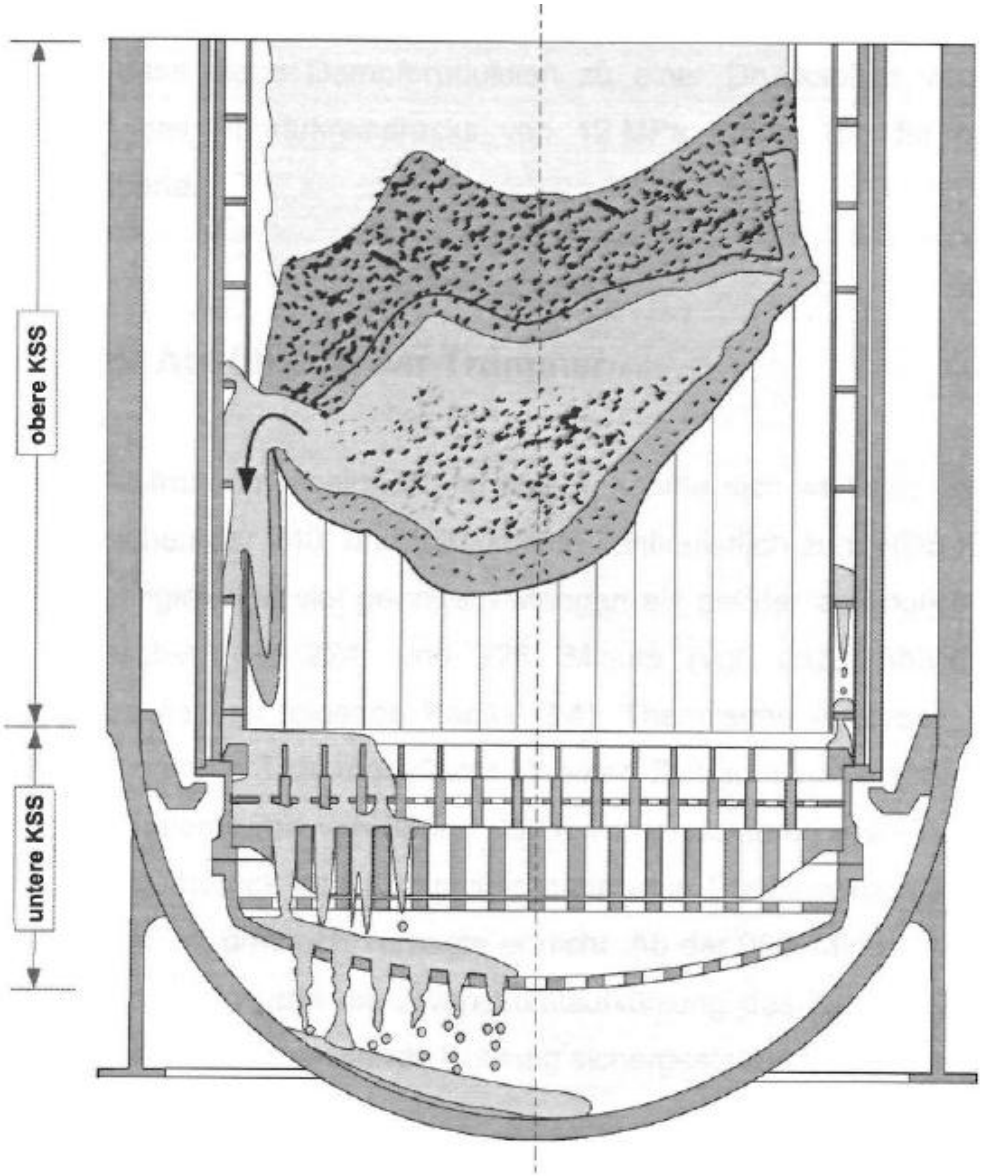


- Possible consequences (example):
  - Local power peak → enough to degrade and melt the core locally
  - Distributed, averaged power peak → not enough to degrade the core, all safety standards are met
- The nature of the core nodalization influences the simulation results

Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted.* PSS.

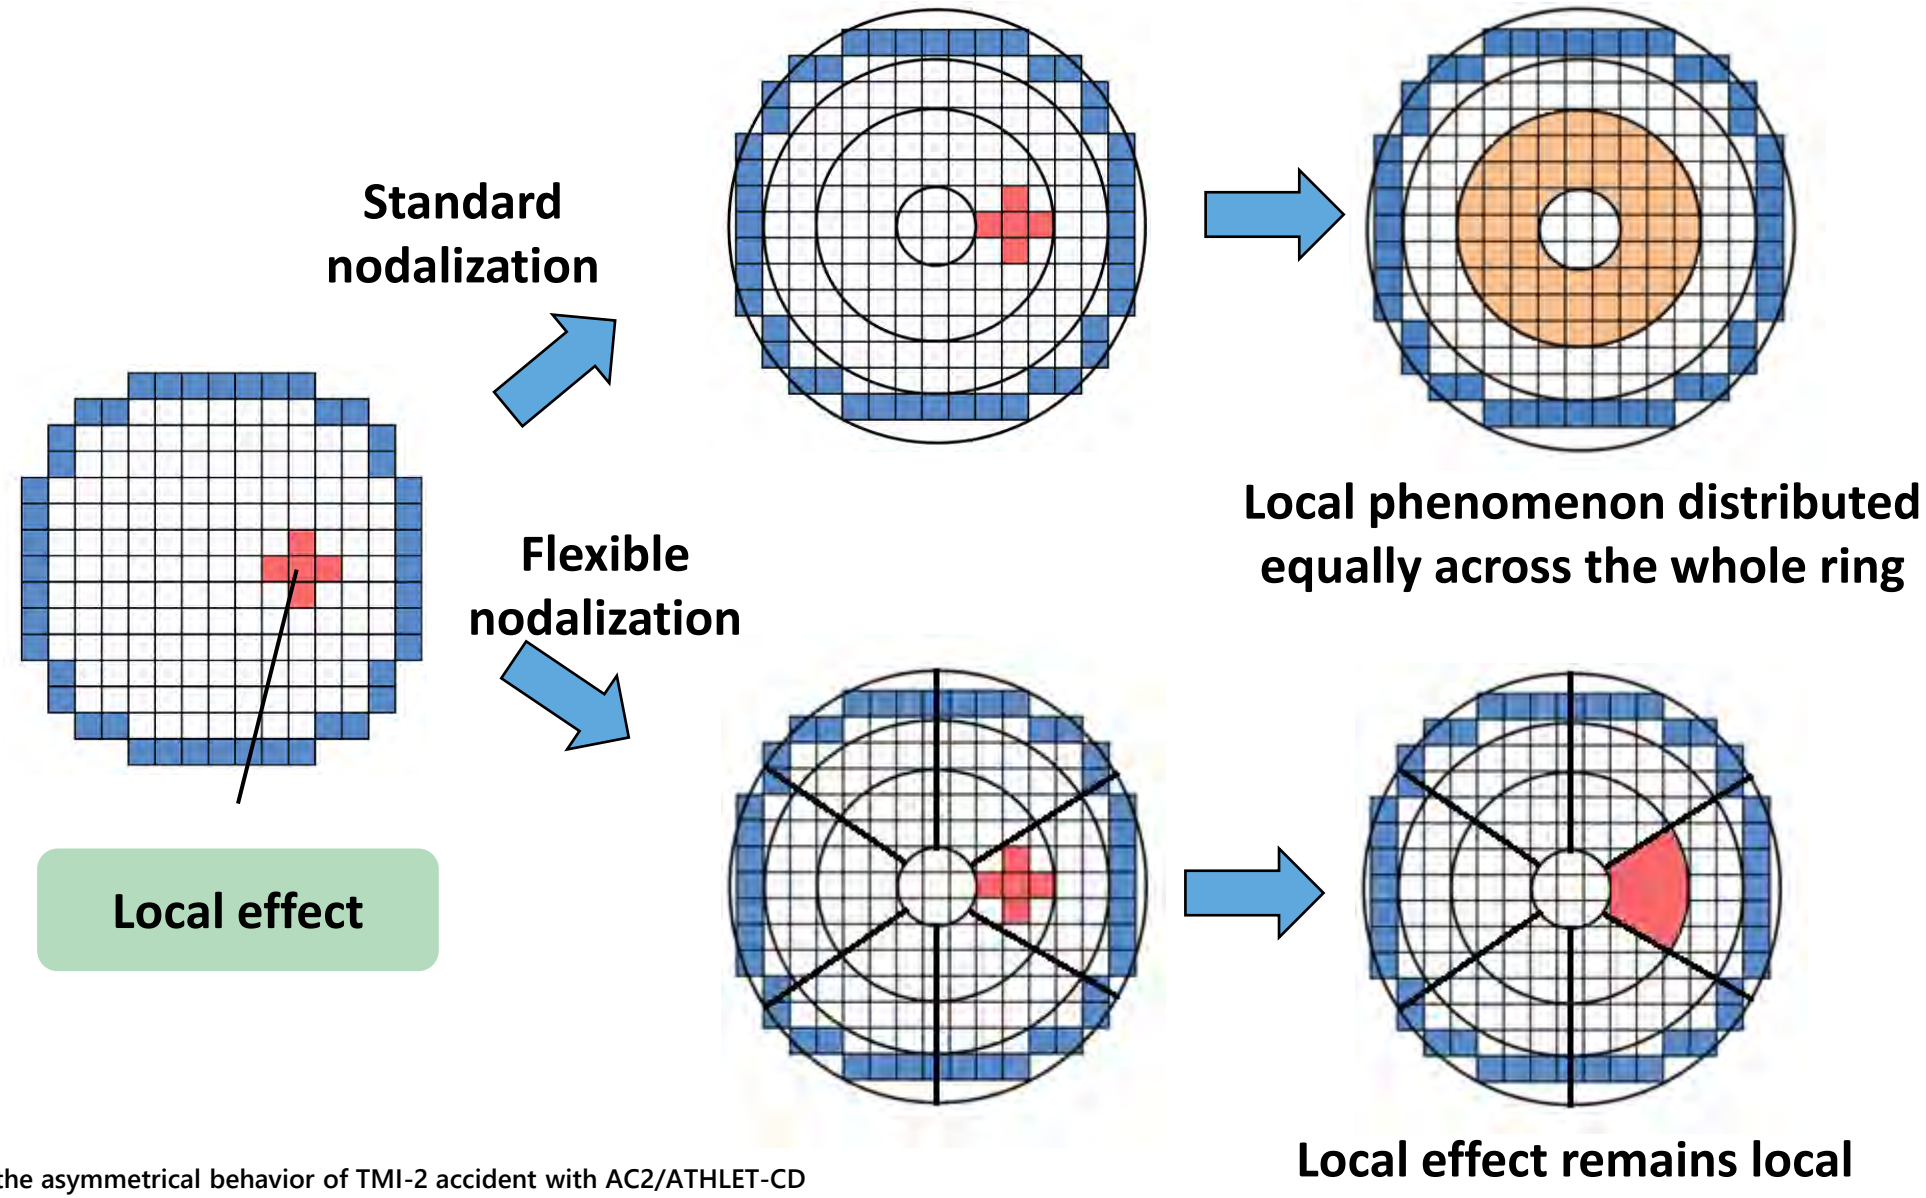
Real life example for asymmetric accident evolution

- TMI-2 accident
- Melt relocation to the lower plenum happened though one quadrant of the core
- Motivation:
  - Reproduce the asymmetric characteristics of the accident evolution



Source: T. Drath, et al.: Simulation des TMI-2 Unfalls mit dem Programmsystem ATHLET-CD (Teil 1), RUB-LEE, BMWi 150 1241, 12.2004

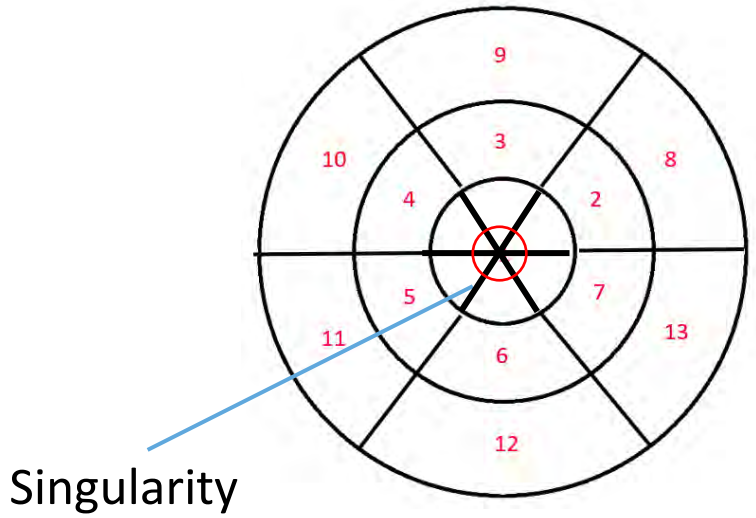
Flexible nodalization: think globally, nodalize locally



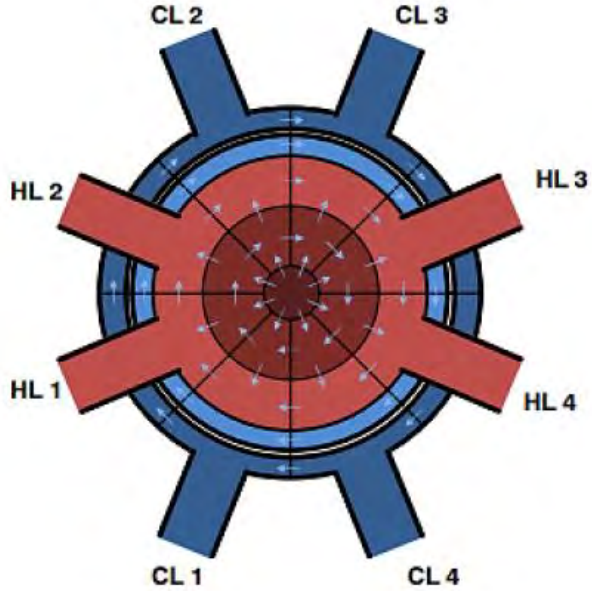
Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted.* PSS.

Change of mandatory nodalization

- Azimuthal subdivision of the rings
  - User-dependent amount of subdivision
  - Required data derived from other geometrical data
  - Innermost “ring” not subdivided
    - Avoid singularity problem



- Similar/same nodalization as in ATHLET for 3D core nodalization
    - Used for DBA



Source: P. Schöffel et. al.: ATHLET3.4.0 Users's Manual, nov. 2023

Required model changes due to nodalization change

- Most of the simulated phenomena are calculated for a single fuel pin (regardless of the node shape and size):
  - Results multiplied by the number of rods in a node
  - No model changes needed ✓

- Thermohydraulics (ATHLET) are flexibly definable
  - No model changes needed ✓

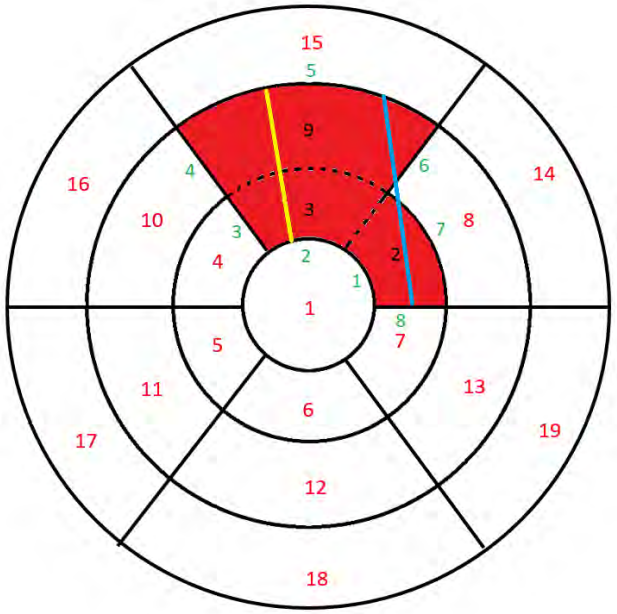
- Heat radiation between nodes, horizontal relocation of melt
  - Model changes needed, standard model is based on cylindrically symmetrical assumptions

- Additional model changes due to newly discovered bugs, minor, unrelated improvements

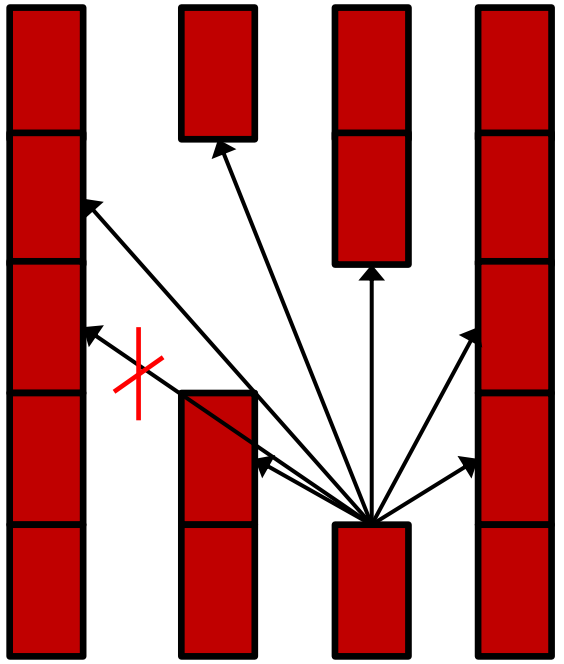
Heat radiation – degraded geometry (flexible nodalization)

- Identification of target areas complex
- Shadowing effects (3D)
- No cylinder-cylinder radiation

} Numerical determination of view factors



Cross section - reactor



Longitudinal cut - reactor

Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted.* PSS.

Heat radiation – flexible nodalization - logic

- Old heat radiation model between neighbouring intact nodes
  - Slight adjustments regarding directions and partners
- After a cavity is created, free surfaces are formed
  - New view factors are calculated numerically between all the surfaces, including shadowing effects
- Heat exchanged via heat radiation calculated:
  - Pure axially
  - Pure horizontally
  - Diagonally
- View factors remain constant until further node melts
- Exchanged power added to energy equation of the structures

Application: TMI-2 accident

- 2 – loop PWR
- LOCA due to stuck open PORV valve
- Severe accident

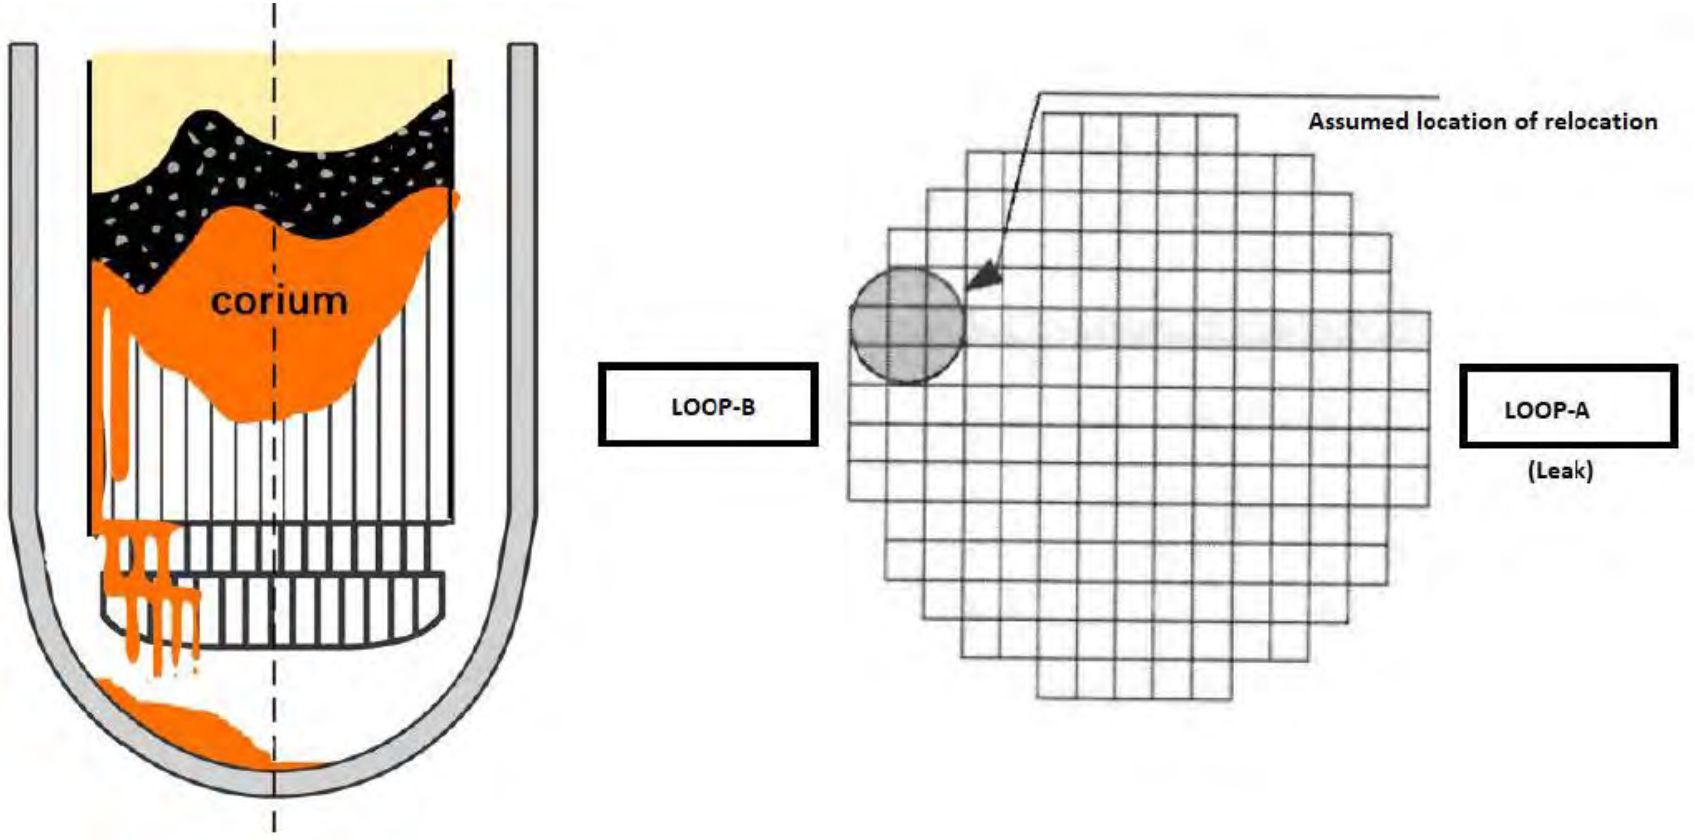
TMI-2 asymmetric behaviour

- Proven asymmetric behaviour

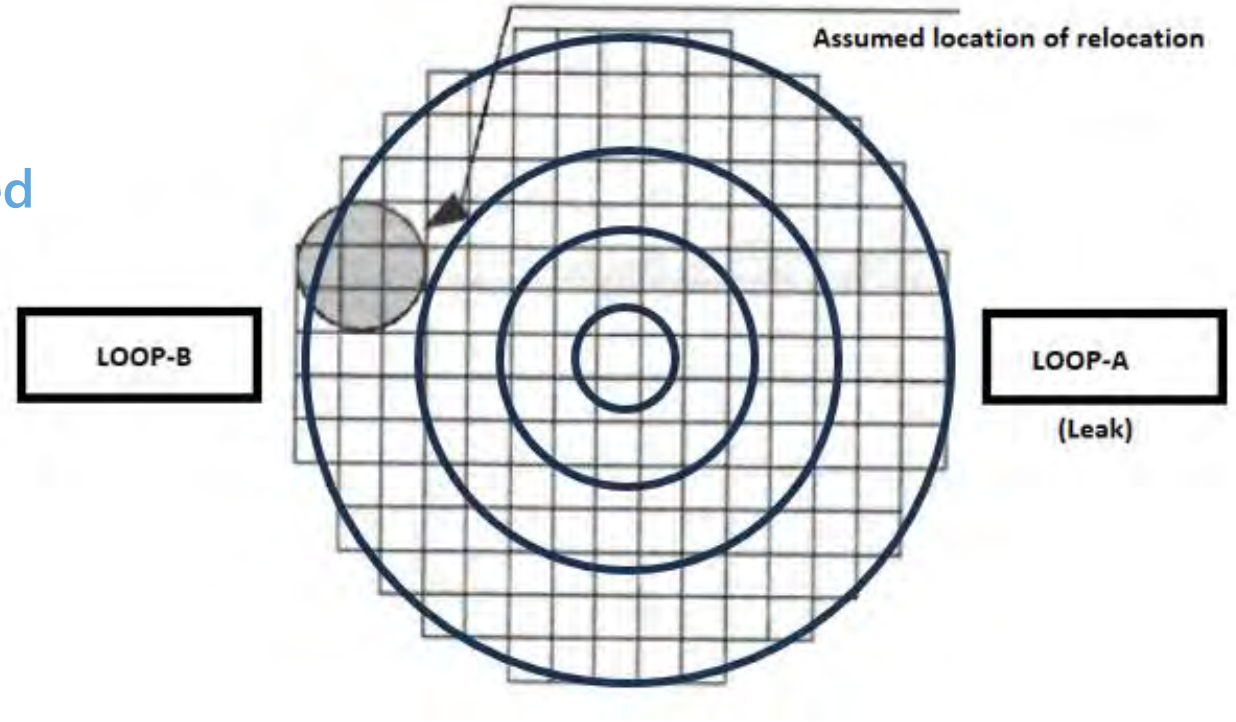


Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics*. *Dissertation - submitted*. PSS.

TMI-2 accident: old method

- Core nodalization
  - Rings

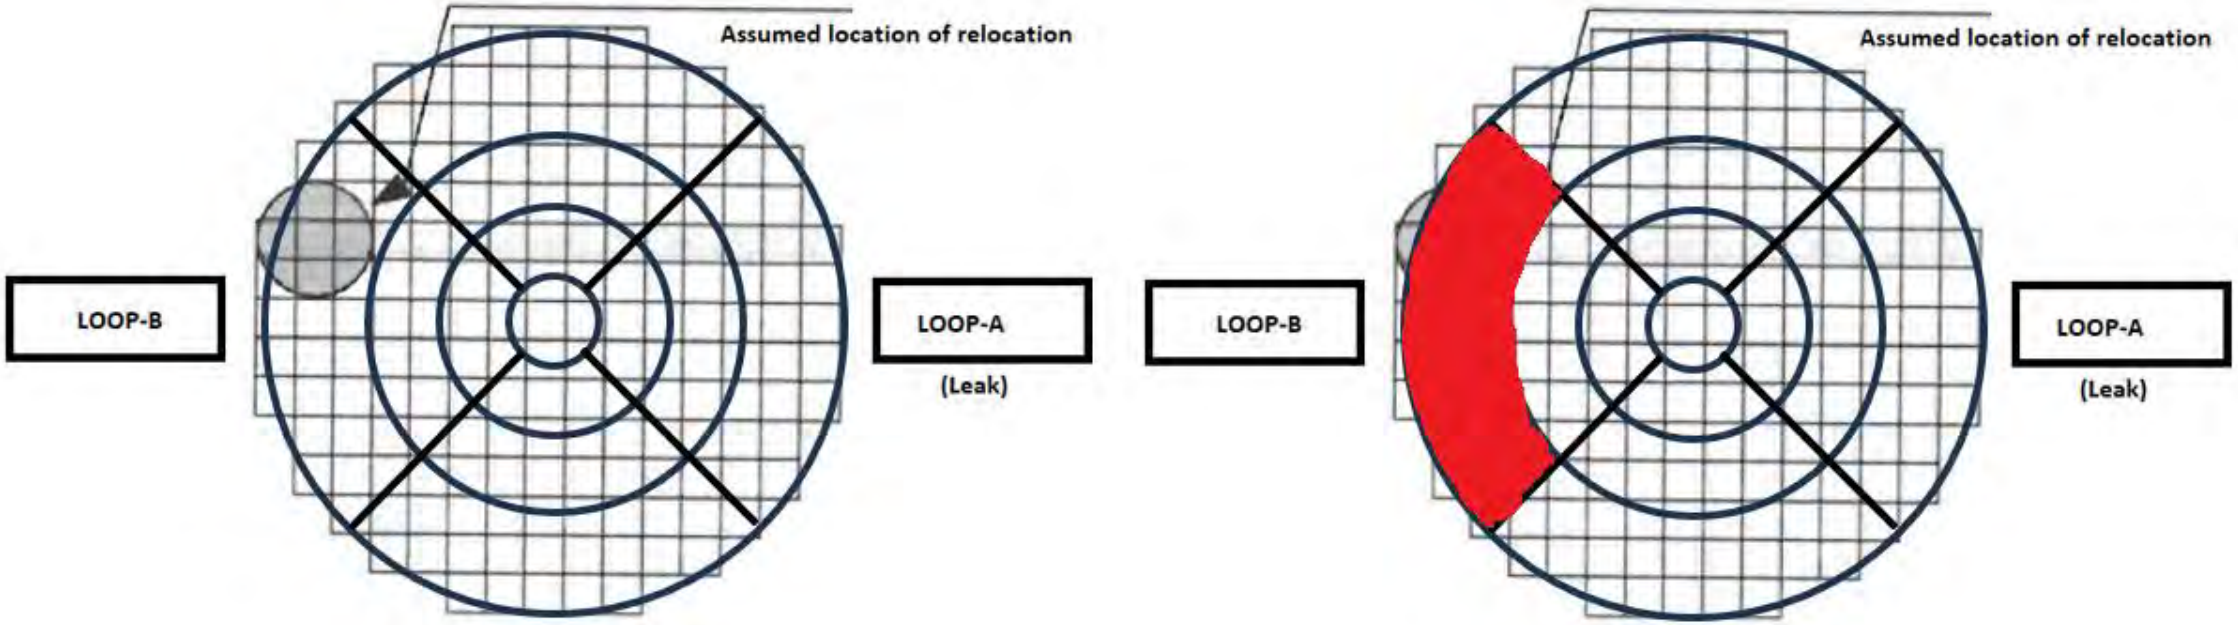
- Local impact can not be considered
  - Rings create an average



Source: T. Drath, et al.: Simulation des TMI-2 Unfalls mit dem Programmsystem ATHLET-CD (Teil 1), RUB-LEE, BMWi 150 1241, 12.2004

TMI-2 accident: new method

- Azimuthally subdivided core nodalization
  - Local impact remains local



Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted.* PSS.

TMI-2 accident: new method

- Symmetrical boundaries → symmetrical simulation

- Asymmetric impacts had to be defined
  - Leak in one leg (hot leg A)
  - Different heat removal from steam generators due to different feedwater supply
  - Main coolant pumps operated differently

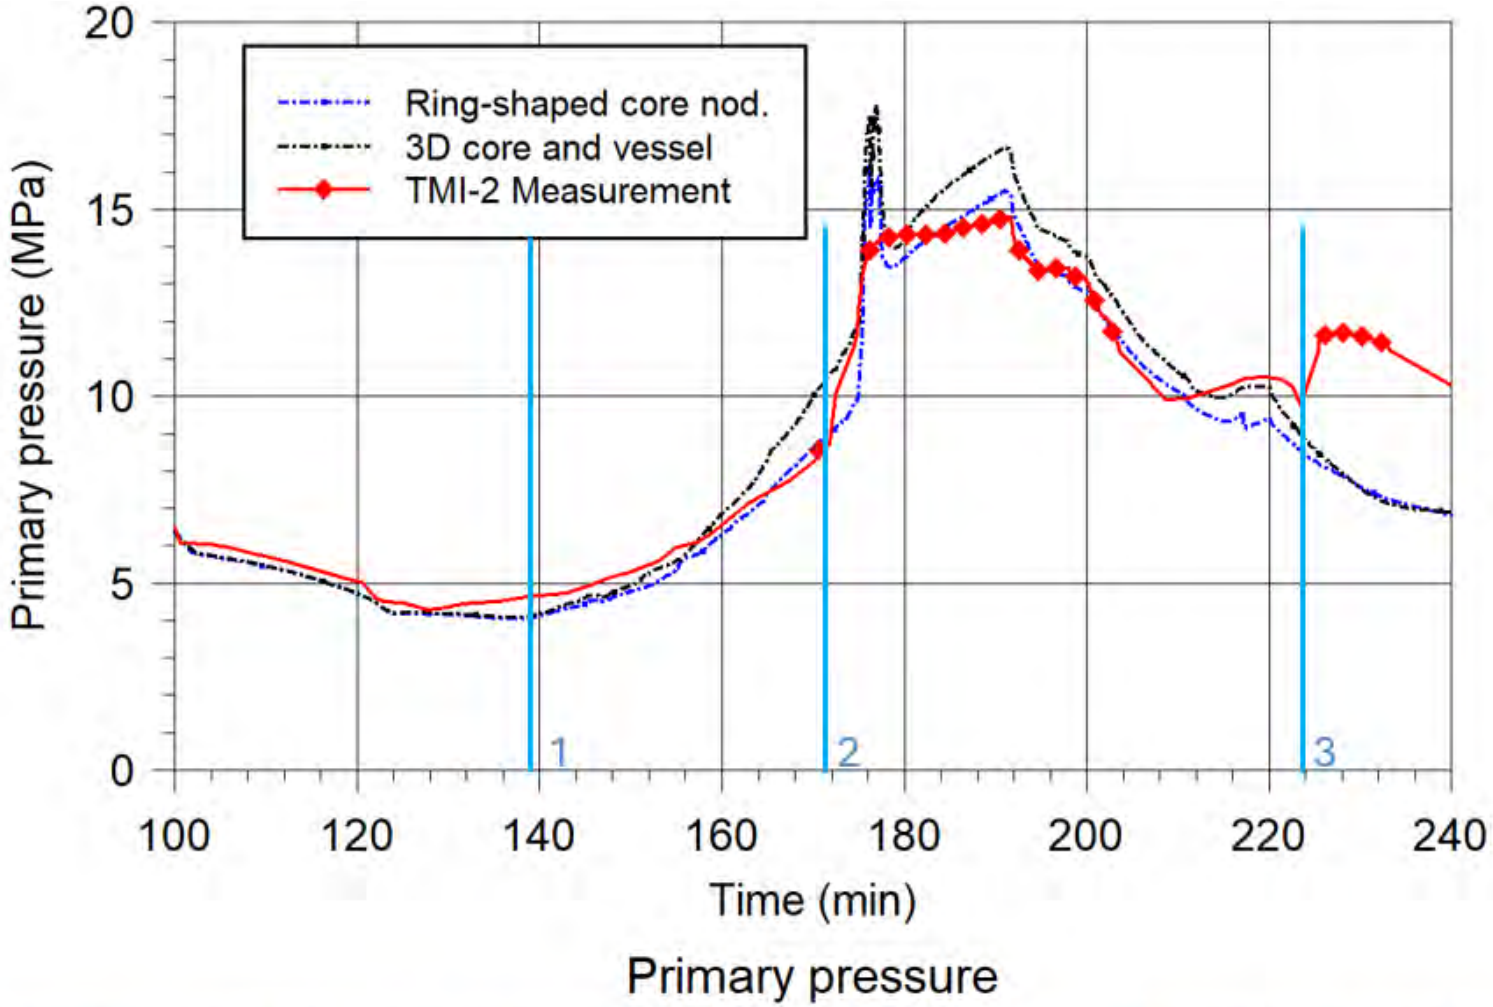
- Everything else → symmetrically defined

- Nodalization
  - Each element has its own structure, element, no artificial grouping and simplifications
  - Practically a 3-D nodalization of RPV, separate modelling of the loops

TMI-2 simulation: integral results

- **Evolution of pressure:**
  - Good indicator about the accident evolution
  - Similar progression
  - Small deviations from the real measurements
  - Qualitatively fairly good agreement for both calculations
  - Some missing models:
    - No fragmentation→ No pressure peak during melt relocation to LP

- **Overall accident evolution similar**



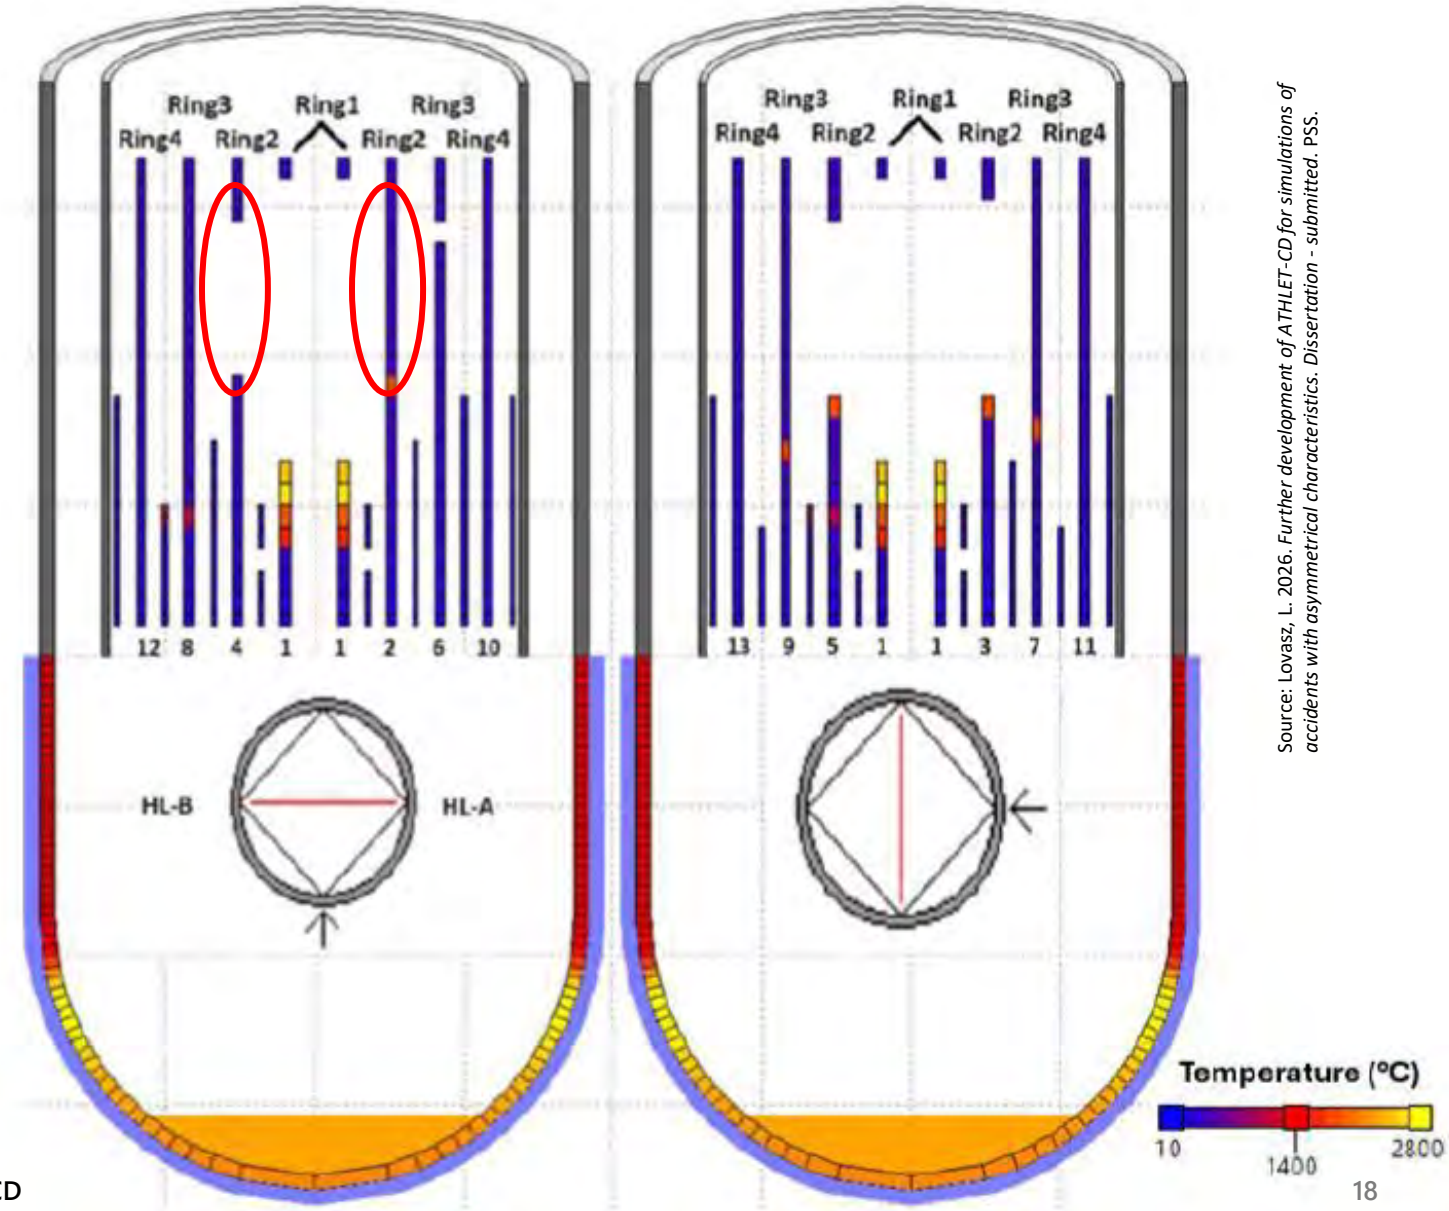
Primary pressure

1: closure of PORV valve 2: main coolant pump turned on 3: melt relocation to LP

TMI-2 simulation: local results

- Clearly asymmetric characteristics in RING 2

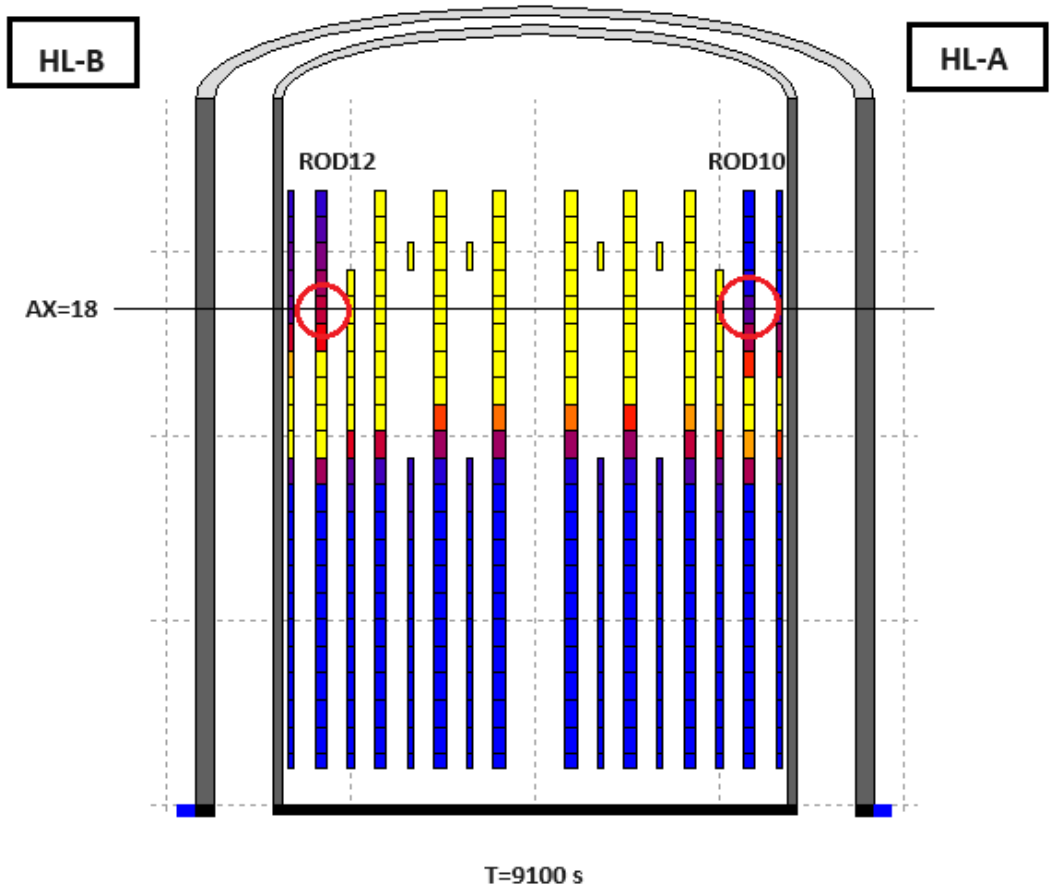
- Closer to HL-B
  - As expected
  - As in real plant

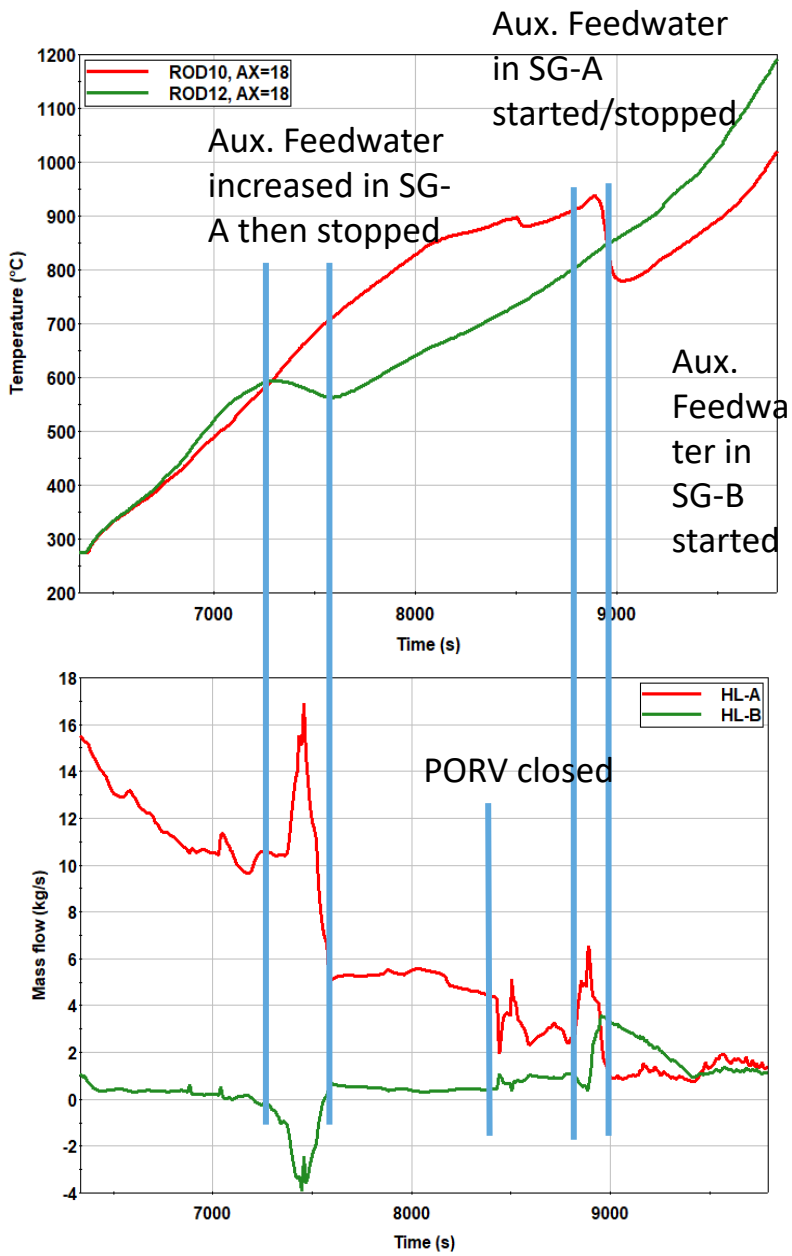


Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted.* PSS.

TMI-2 simulation: reason for asymmetry

- Different feedwater supply to SG-s
- One sided leak (PORV) minor impact





Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted*. PSS.

Conclusions and outlook

- ATHLET-CD core nodalization changed
  - Azimuthal subdivision possible
  - Models adjusted / newly developed

- TMI-2 was simulated using the new nodalization
  - Asymmetric behaviour reproduced
  - Possible explanation found

- Future improvements needed:
  - Input deck
  - Models: melt relocation, fragmentation, debris bed, etc.

- Theoretical option created to consider local effects during a severe accident

ABSTRACT

Simulators for Nuclear Power Plants are essential tools for training plant operators [1]. Nevertheless, most existing simulators worldwide are limited to Design Basis Accidents and do not address the management of Severe Accidents [2]. The importance of realistic training for such scenarios has grown significantly following the implementation of post-Fukushima safety enhancements, which introduced measures to better mitigate severe accident conditions [3].

The European project ASSAS (Artificial Intelligence for Simulation of Severe Accidents) seeks to bridge this gap by developing a proof-of-concept severe accident simulator. This prototype will incorporate a generic Pressurized Water Reactor based on fundamental principles, with its Graphical User Interface designed by Westinghouse.

Beyond serving as a demonstrator for future industrial-grade simulators, this basic-principles simulator is intended to support educational and training activities focused on severe accident phenomenology. Achieving this goal required balancing several challenges: representing the complexity of severe accidents without overwhelming users, covering a broad range of phenomena and operational situations with a limited set of systems and scenarios, and ensuring accurate real-time simulation performance.

This paper presents the work carried out by Westinghouse, in charge of the development of the simulator within the ASSAS project. It details the development of simulator specifications and interfaces, the selection of systems and scenarios, and the design of the Graphical User Interface, along with the main criteria adopted to meet the project objectives.

KEYWORDS
Simulator, Training, TEAMSUITE®, ASTEC, Graphical User Interface

1. INTRODUCTION

The European project **ASSAS (Artificial Intelligence for Simulation of Severe Accidents**) was initiated in 2022 with the objective of developing a proof-of-concept simulator for Nuclear Power Plant (NPP) Severe Accidents (SA), primarily for educational and training purposes. The simulator integrates the ASTEC (Accident Source Term Evaluation Code) [1], developed by ASNR (France), within a commercial simulation environment based on TEAM_SUITE®, Westinghouse's modeling and simulation platform.

The prototype aims to illustrate the key phenomena associated with severe accidents and to serve as a training tool for a broad audience, including students, nuclear professionals (operators, TSOs, regulators, emergency responders), and non-specialists such as decision-makers and civil society. To fulfill these objectives, the simulator incorporates:

- An intuitive graphical interface for scenario control and evolution.
- Clear visualization of critical severe accident phenomena.
- Real-time or accelerated execution without significant loss of accuracy.

To enable real-time operation, ASTEC has been adapted to maintain acceptable fidelity while ensuring seamless interaction with the industrial simulation environment TEAM_SUITE®. The prototype employs non-sensitive data from a generic 4-loop, 1,300 MWe PWR model, with scalability to other reactor designs, including BWRs. Ultimately, the project seeks to demonstrate the feasibility of integrating severe accident capabilities into full-scope simulators, which are currently limited to design-basis scenarios.

A distinctive feature of ASSAS is the investigation of Artificial Intelligence (AI) techniques to develop surrogate models for selected physical models or plant systems [2]. Users will have the option to select between native ASTEC physics-based models and data-driven surrogates. Machine learning approaches are being explored to create fast, efficient models that significantly enhance computational performance. Unlike first-principles models, AI-based models learn correlations from training data, offering substantial speed advantages. However, their complexity increases with the number of input/output variables—a challenge commonly referred to as the "curse of dimensionality." To mitigate this, the simulator limits the number of available actions while preserving sufficient flexibility to illustrate key severe accident phenomena. Adding new systems, actions, and malfunctions remains technically feasible when relying exclusively on physics-based ASTEC models.

This paper presents the design process of the simulator, including interface development, ASTEC integration, scenario selection, and validation methodology.

2. A GRAPHICAL USER INTERFACE (GUI) SERVING OUR PEDAGOGICAL OBJECTIVES

The data presented to the user is selected to support operation of the defined scenarios and to provide a clear understanding of severe accident behavior. The GUI design follows a minimalist philosophy aimed at decision-making in critical situations, emphasizing clarity and cognitive efficiency. Key principles include:

- **Reducing cognitive load:** Display only essential information to avoid overwhelming the user and enable focus on critical system states.
- **Visual hierarchy:** Highlight key parameters while relegating secondary data to less prominent levels or making them accessible on demand.
- **Context and clarity:** Ensure each data point serves a clear purpose in understanding accident progression and supporting safe, timely decisions.
- **Progressive interaction:** Allow deeper exploration of details only when necessary (for example through pop-up windows), preventing screen overload.

The selected data is categorized into three groups according to the accident phase: (i) typical instrumentation for nominal operation and transients, (ii) variables associated with Design Basis Accidents (DBA), and (iii) parameters and flags related to the severe accident phase.

To complement this approach, the interface includes a selector that enables users to switch between two visualization modes: one displaying all variables available in the Human-Machine Interface (HMI) and another limiting the view to those typically present in a real Main Control Room (MCR). For example, the concentration of combustible gases in the containment will be hidden in the MCR view. When a Station Blackout (SBO) malfunction is active, transmitters not battery-backed are lost. This feature combines flexibility for comprehensive analysis with operational realism for training and assessment.

1.1 Summarizing severe accident data efficiently

The simulator interface is structured as a hierarchical display tree, comprising five main views: Home display, Overview display, Systems display, Severe Accident display, Alarm display.

The Home display provides a comprehensive representation of the Nuclear Power Plant layout, enabling navigation to individual system views by selecting the corresponding system icons.

The second level, referred to as the Overview display, consolidates and presents the most critical parameters for each system in a single interface.

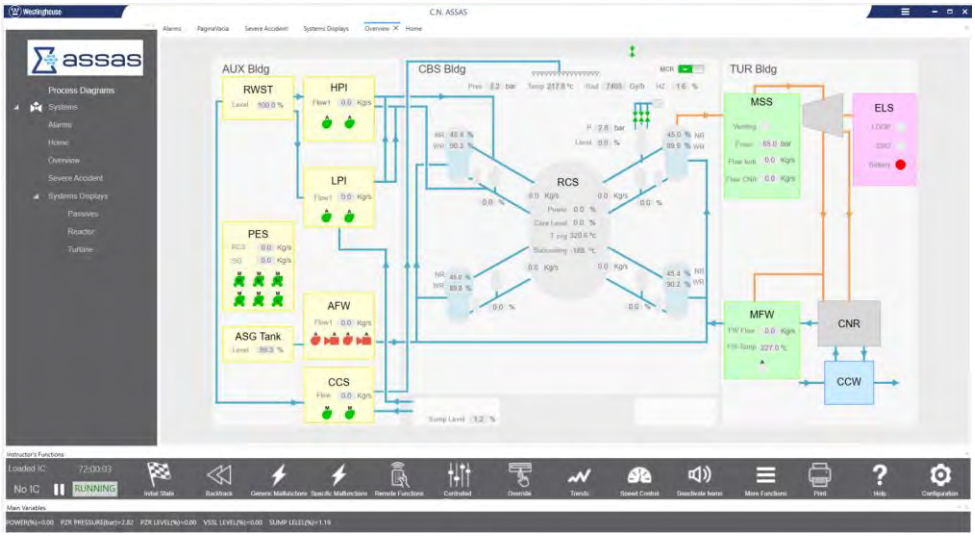

Figure 1. Overview Display.

The third level, the Systems display, offers an extensive view encompassing all plant systems. Users can explore this display through scrolling functionality. As the simulator is designed for conceptual understanding rather than operator training in a realistic environment, this structure facilitates a clearer comprehension of plant operations and system interdependencies.

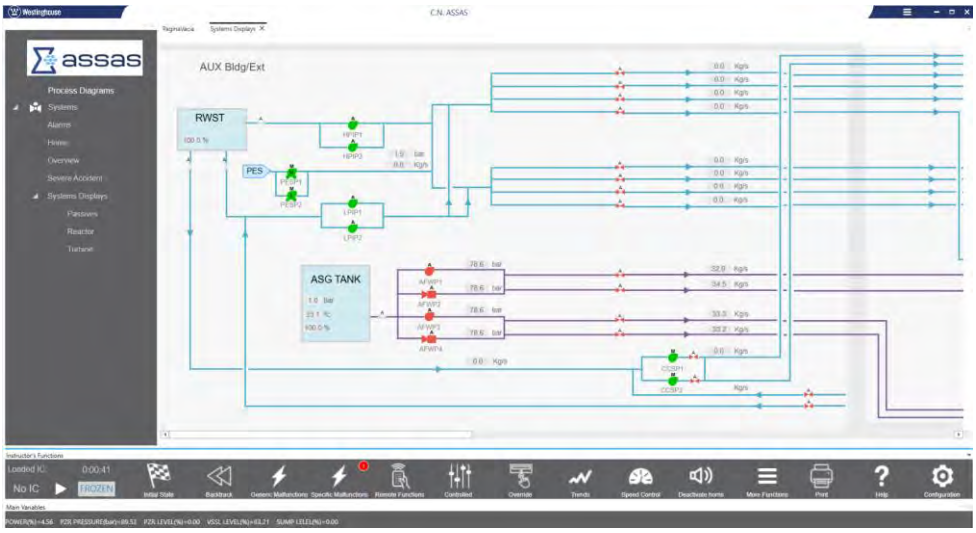

Figure 2 System Display 1

The alarm display shows, for each system, the alarms that appear during the scenario. For didactic purposes, these alarms have been grouped into three categories: (i) alarms associated with normal operation, (ii) alarms triggered by the progression of a Design Basis Accident (DBA), and (iii) alarms related to the severe accident phase.

The Severe Accident display provides advanced functionalities designed to support detailed monitoring and analysis during severe accident scenarios. Key features include:

- A Shapiro diagram illustrating hydrogen (H_2) and carbon monoxide (CO) flammability conditions, associated to a pop-up window giving the detailed steam-gas mixture composition inside the containment (hydrogen, carbon monoxide, steam, oxygen, carbon dioxide).
- Interactive buttons adjacent to activity indicators, enabling pop-up windows that display isotopic compositions within the containment and those released to the environment. These include specific radionuclides representative of a chemical family, to show their different behavior during the accident [6]:
    - Xe-133 (representing Noble gases)
    - I-131 and I132 separated in organic, inorganic, and aerosol forms (representative of Halogens)
    - Cs-134, 136 and 137 (representative of Alkali metals)
    - Te-132 (for the Tellurium group)
    - Sr-90 (representative of Barium and Strontium)
    - Ru-103 (representative of Noble metals)
    - La-140 and Cm-242 (for Lanthanides and Actinides)
    - Pu-241 (for the Cerium group)
    - Mo-99 (for Early transition elements)
    - Sb-127 (for Highly volatile metals)
- A summary of corium formation in the core region, the vessel lower plenum and the reactor pit, associated with a pop-up window giving the mass of magma and debris in 38 different meshes.
- In the safeguard component area, the current alignment of each safety system is clearly identified by highlighting in black the labels corresponding to its active suction source and discharge point.

The display also includes a **Fission Product Barrier Threats** table, which identifies potential challenges based on plant parameters exceeding predefined thresholds. This table supports decision-making regarding

applicable mitigation strategies and is complemented by a graph showing the time evolution of selected variables.

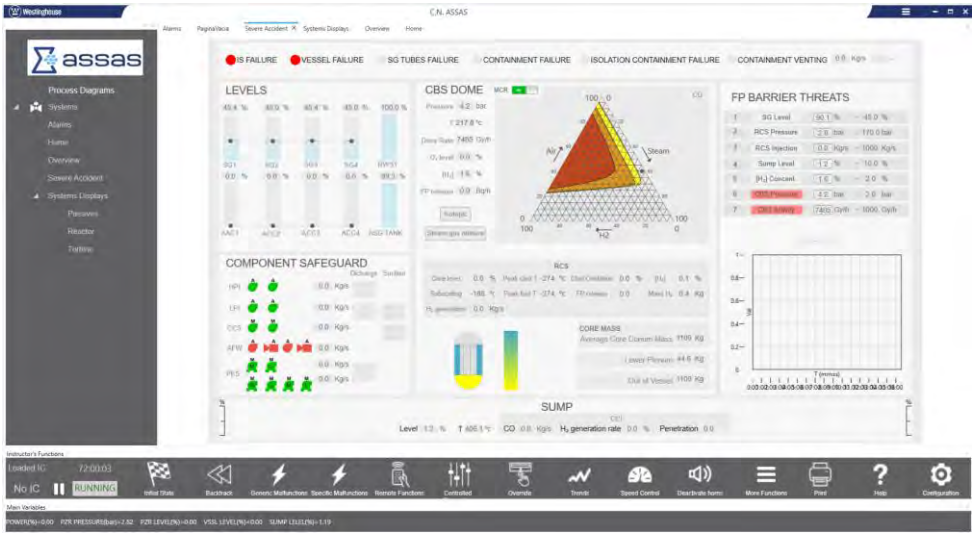

Figure 3 Severe Accident Display

1.2 An interactive tool

The Instructor Station (IS) is the application responsible for providing the instructor, or any other user of the Simulator, with the control and supervision capabilities of a simulation session of the ASSAS Simulator.

The Instructor Station (IS) provides the capability to reset the simulator to a selected initial condition, enabling the user to initiate the simulation from a steady-state configuration, immediately following the onset of an accident, or at any point within the accident sequence. Furthermore, the IS allows the recording of snapshots at any stage of the simulation for subsequent analysis. These snapshots include complete ASTEC savings with all physical variables used for computation.

An additional functionality of the Instructor Station is the ability to introduce predefined malfunctions during the simulation, such as Loss of Coolant Accident (LOCA), Station Blackout (SBO), or Steam Generator Tube Rupture (SGTR) with fixed rupture severities.

The Instructor Station provides real-time monitoring of simulation performance by displaying the current time-step value and CPU utilization. This functionality enables the identification of potential numerical convergence issues and deviations from real-time execution, ensuring the stability and reliability of the simulation process.

Interactive functionality allows users to operate components by selecting active elements such as valves and pumps. Additionally, any displayed variable can be plotted by clicking on its corresponding readout. Visual indicators are employed to denote component status: active pumps and open valves are displayed in red, whereas inactive components appear in green.

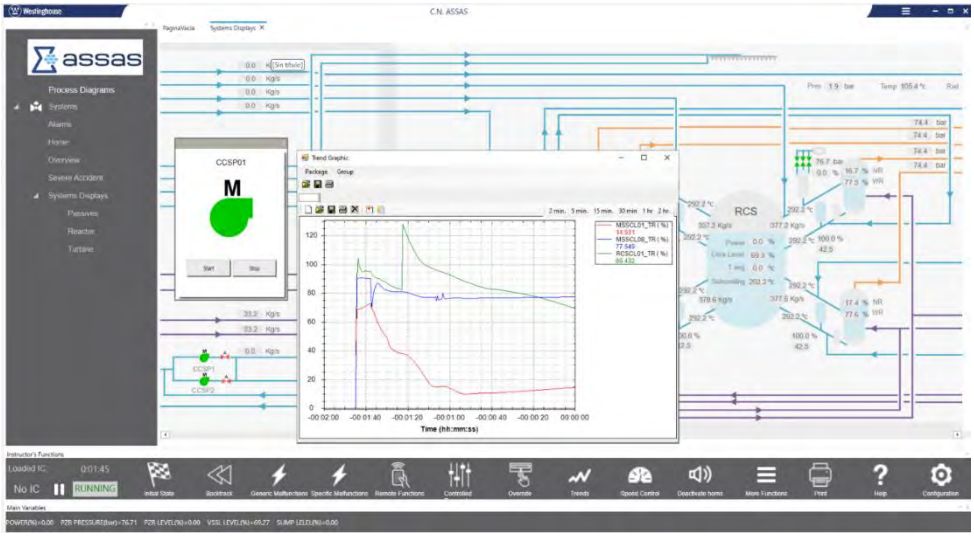

Figure 4 Plots and Controls

1.3 Virtual reality

The objective of this tool is to provide 3D animated and interactive visualizations of key components of a four-loop PWR nuclear power plant—such as the reactor core, vessel, coolant system, steam generators, and containment building—to offer users additional insight into system behavior during severe accident scenarios. Designed for didactic purposes, the interface aims to help users understand the progression of severe accidents in an integrated environment. It provides a qualitative rather than quantitative representation of plant conditions, since the physical phenomena are not known with the level of details presented in the display. A disclaimer will make it clear to the user.

The main functionalities include visualization through Virtual Reality (VR) images of critical physical parameters—such as temperature, void fraction, pressure, hydrogen concentration, core degradation, and water level—based on data provided by the Human-Machine Interface (HMI). The magnitude of the value will be indicated by a color scale in all components, interpolating from the value in each ASTEC control volume. These visualizations cover the containment area, the primary circuit, and different sections of the reactor core, enabling an immersive and intuitive understanding of accident evolution.

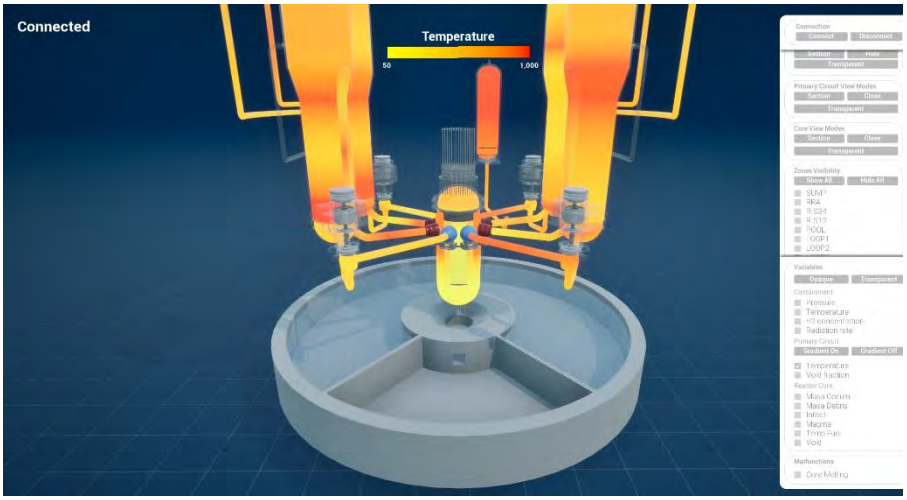

Figure 5 VR image

3. A REACTOR MODEL SHOWING THE MAIN PHENOMENA OF A SEVERE ACCIDENT

Two scenarios have been considered in the specifications of the simulator:
- SBO with Auxiliary Feedwater (AFW) Turbine Driven Pump (TDP) failure,
- LOCA with Safety injection and Containment spray systems failure.

These scenarios have been chosen, one with high pressure and the other with low pressure, to try to cover as much phenomenology as possible [7]. In real life, these are the scenarios that are used to validate the severe accident management guidelines because they go through most of the guideline strategies.

These scenarios define:
- The operator actions that must be modelled by ASTEC or the data-driven surrogate models.
- The transmitters that the final user must monitor at least.
- The involved phenomena.

The specific evolution will depend on the automatic actions, instructor and operator actions taken by the user. The simulator can be used in a discovery mode, for which all actions are allowed for the trainee. In the training mode, malfunctions are triggered by the instructor from his own station, limiting the possibilities for the trainee to operator actions. The additional malfunctions include the induced steam generator tube rupture and the delay to recover some active safety systems.

Due to the presence of Passive Autocatalytic Recombiners (PARs) and other modelling choices, calculation results show that combustion and explosion risks can be avoided. Therefore, the combustion model of ASTEC is not used.

3.1 Scope of the simulator

The ASSAS simulator scope covers just the Design Basis Accident (DBA) and the Severe Accident (SA), excluding the normal operation. So, Turbine, Condenser, Condensate, Circulating water, Reactor Heat Removal and Chemical and Volumetric control systems are out of scope.

The systems that are presented to be operated or monitored by the GUI are:
- Auxiliary Feedwater System (AFW).
- Reactor Coolant System (RCS) including PORVs (Pressure Operated Relief Valve), RCP (Reactor Coolant Pumps) and safety valves.
- Main Steam Supply System (MSS) including SGs.
- Containment Cooling Sprays (CCS). It is assumed to fail but it can be recovered in the LOCA sequence (instructor action).
- High- and Low-Pressure Injection System (HPI), assumed unavailable in both sequences
- Accumulator Injection System (ACI).
- Portable Equipment System (PES), with a deployment delay fixed by the instructor.
- Filtered Containment Venting System (FCVS), based on a sand bed filter.

AFW and PES have been removed from ASTEC input deck to be developed by Team_SUITE® tools (Team_Flow for thermohydraulics and Team_Logic for logics). The objective was to show the interoperability of both tools, illustrating how data could be imported from an existing DBA simulator to extend it to severe accidents.

3.1.1 Portable Equipment System (PES) scope

It has been decided to include PES in the simulator, to show the user important mitigation actions for the considered scenarios, in line with the strategy deployed by many operators. To show the effect of early and late involvement of PES, the instructor can impose a delay between 20 minutes and 24 hours to connect them. The PES consists of external pumps installed at certain plant locations to supply cold water, enabling the removal of accumulated latent heat from the coolant and structural materials, which results from residual heat generation after a reactor trip.

It is considered that the system has a limited number of portable pumps that can be used in the simulator: three medium-pressure (21bar) and three low-pressure (12bar) pumps. Each type of pump can be connected to a pair of Steam generators, or to the RCS. In this latter case, cold water is injected into the cold legs and hot legs simultaneously, through the safety injection lines. The volume injected in the RCS is limited to avoid an overfilling of the sumps and the flooding of the reactor cavity, in line with the ex-vessel melt retention strategy. In addition, the input deck used in the simulator does not include a model for the external cooling of the vessel and for the water-coolant interaction in case of vessel rupture with a flooded cavity. As far as the Steam generators are concerned, it is assumed that the PES will be regulated not to exceed 44% of the narrow range level, in line with the regulation of the AFW system.

These types of pumps comply with the requirements of the system in both situations: In the need of high-pressure water injection and in the other case where a high flow of water is needed to avoid an induced SGTR on hot and dry SGs.

3.1.2 Game Over Flags and simulation end

The simulator includes specific “game over” flags to indicate when the scenario exceeds its intended scope. They correspond to situations that are challenging or even impossible to model with ASTEC, and that relate to a failure of the severe accident mitigation strategy. These conditions are:

- **High-pressure vessel rupture (above 20 bar):** The simulator displays the message *“Simulator out of scope: high-pressure vessel rupture possibly leading to direct containment heating and containment threat.”* Such situations can be modelled by ASTEC, but with a high computational cost, probably not compatible with real-time execution. They were expected to be difficult to capture with machine learning models as well. So, they were excluded from the scope of the simulator for simplicity.
- **High-pressure containment failure (above 6 bar):** The message *“Simulator out of scope: probable containment failure due to overpressure”* is shown. Anyway, ASTEC does not include a mechanical model of the containment, making the modelling of such transient impossible with the current implementation of the simulator.
- **Basemat melt-through:** The message *“Simulator out of scope: containment failure due to basemat melt-through”* is displayed. ASTEC cannot model the evolution of the accident after the complete failure of the basemat.

The maximal simulation time is fixed at 5 days, considering that the emergency response would switch to a different organization and time scale after this duration, with more external support to the site. It is also considered that catastrophic containment failure is less likely after this delay.

3.2 Scenario 1: LOCA with Safety injection and Containment spray systems failure scenario

The phenomena considered in the simulation cover two main phases: the Design Basis Accident (DBA) phase and the Severe Accident phase.

During the DBA phase, the initiating event is a 6-inch cold leg LB-LOCA (Large Break LOCA) combined with the failure of the active Safety Injection (SI) systems (LPI and HPI) and containment spray systems. The CSS can be recovered during the simulation with a delay fixed by the instructor varying from 1 to 24 hours after the LOCA initiation. This leads to rapid RCS depressurization, reactor and turbine trip on low pressure, SI signal activation (with SI failure), and containment pressurization. Additional phenomena include extensive Departure from Nucleate Boiling (DNB), core blowdown, RCP coastdown, ineffective accumulator discharge due to core bypass, and loss of safeguard systems. Fuel overheating occurs, and fission products—mainly from the fuel gap—are released into the RCS. The user may have the possibility to inject water from the Portable Equipment System to mitigate the accident, with a delay fixed by the instructor.

The Severe Accident phase involves high cladding temperatures promoting oxidation, extensive cladding failures, and further fission product release into the RCS. Hot gas circulation within the RCS occurs, accompanied by hydrogen generation and discharge of steam and hydrogen into the containment through the broken leg. Autocatalytic recombiners are assumed available to mitigate hydrogen (and later CO) accumulation and prevent explosions.

As the accident progresses, increased fission product release to containment occurs, followed by core melting and relocation, corium slump into the reactor vessel lower plenum, and potential lower head failure according to ASTEC model criteria. Subsequent phenomena include corium discharge into containment, corium-concrete interaction, ex-vessel hydrogen and CO generation, recombination by autocatalytic devices, containment basemat ablation, and containment pressurization. Long-term risks include containment overpressure failure, and eventual filtered venting of fission products.

Several actions are proposed to the trainee to mitigate the accident progression. The PORVs of the pressurizer and the steam generators can be opened, with little expected effect due to the RCS depressurization. Since the AFW is assumed available, PES can only be used to inject water into the RCS. The CSS can be actuated manually once it has been recovered. The FCVS can be operated when the pressure exceeds 5bar, in line with typical depressurization strategies.

3.3 Scenario 2: SBO with AFW failure scenario

The simulated phenomena are divided into two main phases: the Design Basis Accident (DBA) phase and the Severe Accident phase.

In the DBA phase, the initiating event is a Station Blackout (SBO) combined with the failure of the Auxiliary Feedwater Turbine-Driven Pump (AFW-TDP). This leads to RCP coastdown, reactor trip, and unavailability of turbine bypass. Active safeguard systems fail, including HP and LP safety injection (except passive accumulators) and auxiliary feedwater. Steam generators dry out, degrading the RCS heat sink, while pressure rises until safety and relief valves cycle. The pressurizer PORV/SRV opens as RCS pressurization continues, subcooling is lost, and natural circulation is impaired due to AFW loss and steam presence in SG tubes. Ultimately, the core becomes uncovered and overheats.

The Severe Accident phase includes globally the same phenomena as the scenario 1 (the discharge of hot gases into the containment occurs through the pressurizer valves or an induced primary breach). In addition, the instructor can trigger a creep failure of SG tubes. The simulator also includes a possible creep failure of the primary circuit due to the circulation of superheated steam at high pressure, based on a physical model of ASTEC.

The actions proposed to the trainee to mitigate the accident slightly differ from the LOCA sequence. The PORVs of the pressurizer and the steam generators can be opened like in the LOCA sequence, thanks to their battery back-up. In this sequence, PES can only be connected both to the RCS and the Steam generators. They will start to operate when the concerned circuit's pressure will have decreased to their maximal counterpressure. The CSS is assumed unavailable during the whole sequence, due to the loss of electric power. The conditions for the opening of the FCVS are the same as for the LOCA sequence, since the main valve of the system is manual.

4. TECHNICAL CHALLENGES OF THE SIMULATOR DEVELOPMENT

4.1 Interface between the simulator and ASTEC

The integration of ASTEC within Westinghouse's Team-K environment has been made using a dll (dynamic link library) supplied by ASNR. This dll is loaded from an interface to parse the commands from Team-K to ASTEC, and also to connect Simulator's variables with the Odessa database (ASNR's proprietary hierarchical database format used by ASTEC), thus permitting writing and reading values in both directions.

The following image shows the top level ASSAS simulator Architecture, in which ASTEC is one of the possible simulation modules.

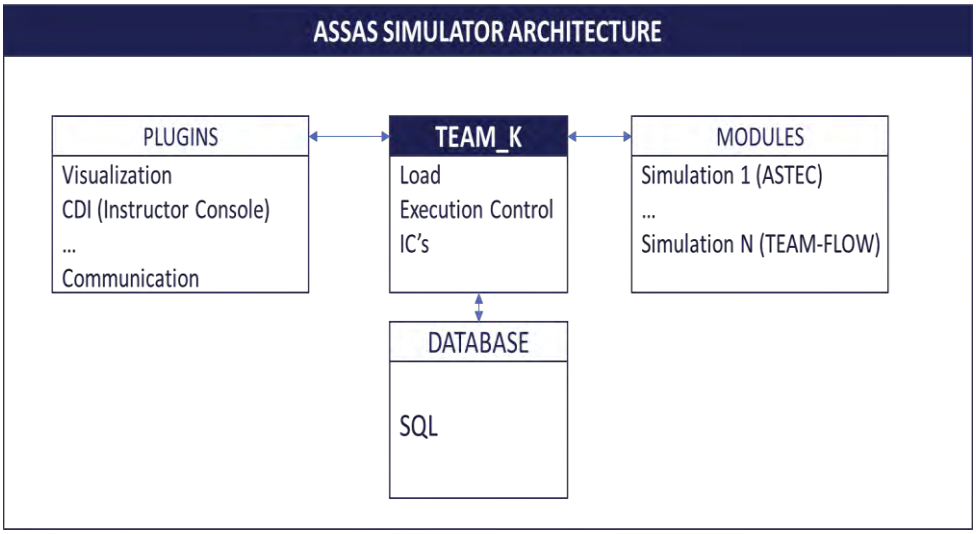

Figure 6 TEAM_K and ASTEC integration

After the integration, the resulting simulator supports the following functions:

- Start, Run, Pause, Stop from the GUI.
- Plot graphs of the calculated variables.
- Saving and Loading Initial Conditions.
- Interaction with ASTEC Simulation with GUI interactive commands.
- The integration of machine learning models is transparent for the simulator. The models can be called by ASTEC directly, or they will read and write in the Odessa database, through which they will interact with the simulator.
- Team-K can call other Team-Suite® models to include additional engineering systems, logic controllers, or a physical interface for example.

4.2 Performance tests

The results of the CPU-time consumption tests show that the simulator achieves expected performances. For the first 200 seconds of the simulation, ASTEC uses a reduced time step (0.1s) to limit calculation uncertainties. In this phase, the simulator is in average twice slower than real time. When the ASTEC time step reaches its nominal value of 1s, the simulator runs 2 to 3 times faster than real time, until it reaches the core degradation phase. For that complex phase of the accident, the acceleration factor is close to one. After the vessel rupture, the phenomena in the primary and secondary circuits are no longer computed, limiting the simulation to the containment models. This allows the simulator to run an order of magnitude faster than real time. The GUI and external models don't have significant impact on execution time.

4.3 Validation

The ASSAS project plans three distinct implementations of ASTEC:

1. The reference ASTEC version (physics-based model).
2. The reference ASTEC integrated with TEAM_SUITE®.
3. An optimized ASTEC version incorporating surrogate models (ASSAS version) integrated with TEAM_SUITE®.

The integration of ASTEC with TEAM_SUITE® is expected to introduce virtually no regression, as most physical models remain under ASTEC's control. Simulator performance will be assessed by comparing user-displayed data across the different ASTEC versions, using the reference model as the benchmark. Specific validation methods will be proposed for the integration of machine learning surrogate models.

5 CONCLUSION: SUMMARY OF THE ACHIEVEMENTS AND PERSPECTIVE ABOUT FUTURE TASKS

In the frame of ASSAS, the reference severe accident code ASTEC has been coupled with the commercial simulation platform TEAM_SUITE® to build a basic-principles severe accident simulator. This simulator benefits from the advanced functionalities offered by TEAM_SUITE®: ergonomic and customizable GUI, interactive simulation, easy data plotting and analysis, management of real time execution, easy navigation between various pre-saved initial conditions, etc. Improvements of ASTEC and of the reactor input deck made it possible to run the simulation in real time, offering realistic training conditions.

Efforts have been dedicated to the pedagogical relevance of the simulator. Severe accidents scenarios have been selected to show the main phenomena in various conditions and the effect of accident mitigation strategies. The interface was designed to be intuitive, attractive and synthetic, while offering the possibility to dive in specific details. This makes the simulator a powerful tool to spread severe accident knowledge to a broader audience.

Even if the simulator appears simple at first sight, with only a few operator actions, it can be adapted to industrial needs with limited efforts. New features can be added to the ASTEC input deck or directly in TEAM_SUITE®, thanks to the bidirectional interface between both systems. It can include additional accidental scenarios, more engineering systems, more automatisms, etc. The GUI can also be easily replaced by a full replica of a control room. The impact of such modifications on calculation time would probably be negligible.

The next step of ASSAS will consist in developing, interfacing and evaluating data-driven surrogate models, to check their impact on the accuracy and performance of calculations. Since machine learning models will

be trained on data generated with a specific design, their ability to generalize to new designs remains an open question.

ABSTRACT

In the 1990s, the importance of understanding the chemical phenomena that occur during a nuclear accident has been recognized. This led to the development of two non-ideal thermodynamic databases using CALPHAD method: NUCLEA is mainly devoted to the study of in and ex-vessel corium progression whereas Mephista is dedicated to fuel degradation and release of fission products. The NUCLEA database contains 20 atoms. U, O and Zr represent the corium, Fe, Ni and Cr describe the steel of the vessel and structures whereas Ag, In, B and C depict the control rods. It also contains the main non-volatile fission products: Ba, La, Ru and Sr as well as the main elements of concrete: Al, Ca, Mg and Si. Finally, Ar and H are considered in the gas phase. The Mephista database contains 16 atoms, 12 of which (U-Zr-O-Fe-Si-C-Ba-La-Ru-Sr-Ar-H) are shared with NUCLEA. It also includes Pu to account for MOX fuels, along with the following additional fission products: Cs, Mo, and Ce. The modeling of common systems is performed identically. The merging of these databases, which began in 2023, has just been completed. As a result, NUCLEA-26 is now able to address the issues of fuel degradation, fission product release as well as those of the overall corium progression. The database will continue to be improved by considering experimental and ab initio calculations-based data that will be produced. This article provides a general overview of the models used in the database and the different systems assessed. Finally, application cases involving multicomponent systems are considered in the context of corium–concrete interaction studies.

Corium, Thermodynamic Database, NUCLEA, Ex-Vessel

1. INTRODUCTION

In the field of nuclear safety, the importance of a good understanding of chemical phenomena that could occur during a possible severe accident in Light Water Reactors (LWR) was identified from the end of the 1980s. At the same time, the use of the CALPHAD method developed in 1970 [1] was increasing due to the improvement of computers capabilities. This method, which consists in a critical assessment of experimental data, a definition of a simple physical model for the Gibbs energy of the phase and an

optimization procedure to define the values of the model parameters, allows to use all available thermochemical and phase diagram data in a consistent way [2].

The main objective of the Euratom ENTHALPY project (European Nuclear Thermodynamic Database for in- and ex-vessel applications) (2000-2003) was to merge the 2 non-ideal corium-oriented thermodynamic databases existing in Europe, TDBCR and MTDATA respectively developed by THERMODATA and AEA-T, in one European commonly agreed database and to extend it to key in- and ex-vessel elements [3]. This project led to the first version of the NUCLEA database in 2003. Since then, this database was continuously improved by THERMODATA until 2014 and then by ASNR with the technical support of the CNRS SIMAP laboratory (Grenoble Alpes University) and the financial support of EDF and CEA [4], [5].

The NUCLEA-23 database, released in 2023, contained 20 atoms. U, O and Zr represent the corium, Fe, Ni and Cr describe the steel of the vessel and structures whereas Ag, In, B and C depict the control rods. It also contains the main non-volatile fission products: Ba, La, Ru and Sr as well as the main elements of concrete: Al, Ca, Mg and Si. Finally, Ar and H are considered in the gas phase.

In parallel, another database, the Mephista database also developed by THERMODATA and then ASNR, contained 16 atoms. 12 of which (U-Zr-O-Fe-Si-C-Ba-La-Ru-Sr-Ar-H) are shared with NUCLEA. It also includes Pu to account for MOX fuels, along with the following additional fission products: Cs, Mo, and Ce. The common systems were modeled identically, avoiding consistency issues between the two databases. As a result, merging them mainly consisted of modeling the many missing systems. This merger, which began in 2023, has just been completed. As a result, NUCLEA-26 is now able to address the issues of fuel degradation, fission product release, as well as those of the overall corium progression.

As it developed, the database was applied to multi-component systems representative of the reactor case. Calculations were performed and compared with experimental results in systems involving numerous chemical elements. They pointed out systems to be improved and sometimes lead to experimental programs dedicated to key systems. The experimental data produced in more than 30 years in the field of corium thermodynamics is reviewed in [6].

Thus, even if the number of atoms in the database should not change in the next future, the database will continue to be improved by considering experimental and theoretical chemistry-based data that will be produced or by modeling key ternary systems not yet modeled.
This article provides a general overview of the models used in the database and the different systems assessed. Finally, application cases involving multicomponent systems are considered in the context of corium–concrete interaction studies.

2. NUCLEA DATABASE DESCRIPTION AND ASSESSED SYSTEMS

The NUCLEA-26 database contains 24 elements:

- O, U, Pu, Zr (fuel modeling),
- Ag, In, B, C (control rods),
- Fe, Cr, Ni (vessel),
- Ba, Ce, Cs, La, Mo, Ru, Sr (fission products),
- Al, Ca, Mg, Si (concrete) and
- Ar, H (atmosphere, solely included in the gaseous phase).

The NUCLEA database is built with the compound energy formalism (CEF) [7], [8] which allows to describe the thermodynamic properties of phases with sublattices and the modeling use, in particular, the associated model [9] [A,A_aB_b,B] which is a special case of a CEF model with only one sublattice and three

constituents whose one, the associate, is a stoichiometric compound formed from the other two. A maximum of 3 sublattices is considered in the solutions modeling. The excess Gibbs energy terms are expressed with Redlich-Kister polynomials [10] and the extrapolation in the ternary is the Muggianu's extrapolation model [11]. All unaries data are taken from SGTE unary database[1] if they exist and updated according to SGTE unary database evolution. Few ternary interactions, almost all in the liquid phase, are assessed and no reciprocal interaction is considered. Magnetism is considered in magnetic species and in BCC_A2 (body-centered cubic phase) and FCC_A1 (face-centered cubic phase) solutions with few excess terms.

A pragmatic approach has been adopted to answer nuclear safety issues related to severe accident management and, if the thermodynamic database is defined in the 298.15-3500K temperature range, a more specific attention is paid to the 1200-3500K temperature range. Thus, all solutions are considered to be disordered (no short-range order in solution is modeled) and low non-stoichiometry of compounds are not considered (compounds are considered to be stoichiometric in this case). This simplification may reduce the accuracy of solid-phase modeling, particularly at low temperatures, but, we are particularly interested in the liquid phase and modeling non-stoichiometry and ordering requires adding parameters, and the more parameters there are, the more extrapolation problems can occur.

For corium applications in particular (e.g. in-vessel corium retention), NUCLEA must cover all compositions ranging from the metallic to the oxidic state. It is developed following the CALPHAD methodology and includes the modeling of all 231 binary systems, as well as all pseudo-binary systems. Pseudo-binary systems refer to binary systems involving two of the following oxides: Al_2O_3, B_2O_3, BaO, CaO, Ce_2O_3, CeO_2, Cr_2O_3, Cs_2O, CsO_2, FeO, Fe_2O_3, In_2O_3, La_2O_3, MgO, MoO_2, MoO_3, NiO, Pu_2O_3, PuO_2, SiO_2, SrO, UO_2, and ZrO_2. When no experimental data are available for a given system, the thermodynamic description is based on estimates. In addition, 44 ternary systems are fully modeled, and their list is presented in Table I. Furthermore, 27 sections derived from quaternary systems, listed in Table II, as well as the $BaMoO_3$-$BaUO_3$-$BaZrO_3$ section of the quinary Ba-Mo-O-U-Zr system, are also modeled.

Table I. Assessed ternary systems

Ag-Mo-O	B-C-Fe	B-C-U	B-C-Zr	B-Fe-U	B-Fe-Zr	C-Cr-Fe
C-Cr-Mo	C-Cr-Ni	C-Fe-Mo	C-Fe-Ni	C-O-Pu	C-O-U	C-O-Zr
C-Pu-U	C-U-Zr	Ca-Mo-O	Ce-Cs-O	Ce-Fe-O	Ce-O-Pu	Ce-O-U
Cr-Cs-O	Cr-Fe-O	Cr-Fe-Ni	Cr-Fe-Zr	Cr-Mo-O	Cr-Ni-O	Cr-Ni-Zr
Cr-O-Zr	Cs-Mo-O	Fe-Mo-O	Fe-Ni-O	Fe-Ni-Zr	Fe-O-Pu	Fe-O-U
Fe-O-Zr	Fe-Pu-U	Fe-Pu-Zr	Fe-U-Zr	Mo-O-U	O-Pu-U	O-Pu-Zr
O-U-Zr	Pu-U-Zr					

[1] Database initially based on Dinsdale's data [12] and still improved by the Scientific Group Thermodata Europe (SGTE)

O-Si-U-Zr	SiO_2 -UO_2 -ZrO_2		

In NUCLEA-26, 710 solid stoichiometric phases, 31 liquid stoichiometric phases, 100 solid solution phases, one liquid solution phase and one gaseous phase (composed of 258 species) are modeled.

3. EXAMPLE OF VALIDATION OF NUCLEA DATABASE IN THE CONTEXT OF CORIUM-CONCRETE INTERACTIONS

In parallel with its development, the NUCLEA database was applied to various application cases. This made it possible to identify the systems to be improved and to validate the database. An example is presented to illustrate the capabilities of the database. Calculations performed with the NUCLEA-26 database and NucleaToolbox 4.6 [13] are compared with experimental results obtained in the Euratom ENTHALPY project [14] devoted to the investigation of corium-concrete chemistry.

3.1. Problem Statement

If the corium cannot be stabilized in the reactor vessel, the mixture of molten materials resulting from the fuel, cladding and structural elements degradation could melt through the reactor vessel and relocate on the concrete basemat of the reactor cavity. The concrete is mainly composed of SiO_2, $CaCO_3$ and H_2O and decomposes in presence of corium in condensed species (SiO_2 and CaO) and gaseous species (H_2O and CO_2). Thus, the core-concrete mixture is composed of heavy oxides (UO_2 and ZrO_2), light oxides (mainly SiO_2 and CaO), metals (Fe, Ni, Cr and Zr) and low volatile fission products stirred by gases generated from concrete decomposition. When oxides and metals species mix, oxidation reactions can occur and

generate gaseous species such as H_2, CO and SiO. The core-concrete mixture is a multi-component, multiphasic (gas, liquid, solid) melt whose composition changes progressively during the molten core concrete interaction (MCCI). MCCI is characterized by the coupling of several phenomena: high temperature concrete decomposition, bubbling corium pool thermohydraulics and physicochemistry of corium melts. Different modelings of MCCI exist but they generally rely on the liquidus and/or the solidus temperatures of the pool or a temperature based on a threshold in the volumetric liquid fraction of the pool.

During the Euratom ENTHALPY project, primarily dedicated to the creation of the NUCLEA database, ten liquidus and solidus temperatures of key subsystems of the overall system UO_2-ZrO_2-SiO_2-FeO_x-CaO-Al_2O_3-Cr_2O_3 relevant to severe accidents were measured [14]. They were first determined by Visual Polythermal Analysis (VPA) in an Induction Melting Cold Crucible (IMCC) furnace. The melt was superheated in order to homogenize it and melt down all the charge materials. A melt sample was taken at temperature for effective composition determination. The power introduced into the melt was decreased until films and crusts started appearing at the melt surface during the molten pool cooling. The melt surface temperature was measured by a spectral ratio pyrometer. The arithmetic mean between the maximum film and the minimum melt temperatures is assumed to be the liquidus temperature. In its turn, the solidus temperature is assumed to be the arithmetic mean between the maximum crust and the minimum film temperatures. Then, the solidified bulk was used for liquidus temperature determination by VPA in the Galakhov's microfurnace and for solidus temperature determination by Differential Thermal Analysis (DTA). In the Galakhov's microfurnace, the liquidus temperature is defined as the temperature at the moment the sample spreads across the tungsten holder surface. The solidus temperature is determined as the initiation of the endothermic effect at heating the sample and of the exothermic effect at its cooling. If these temperatures are different, the value obtained when heating the sample was regarded as the more credible one. All measurements were carried out under inert atmosphere. The determination of sample chemical composition and microstructure were determined by means of Scanning Electron Microscopy with Energy Dispersive X-ray spectroscopy (SEM/EDX). Based on these temperature measurements, performed using different experimental techniques and for compositions that may slightly vary, the authors recommend a solidus temperature and a liquidus temperature associated with a given composition. Compositions of urania-zirconia samples mixed with steel oxides without concrete (MC_WC series), limestone concrete (MC_LC series), limestone-common sand concrete (MC_LCSC), concrete and steel oxide (MC_CSO series) and a zirconia sample (without urania) mixed with concrete and steel oxides (MC_WU) as well as the recommended solidus and liquidus temperatures, if any, are presented in Table III.

Table III. Compositions, in weight-%, and measured solidus and liquidus temperatures, if any, of the ten ENTHALPY tests [14].

	UO_2	ZrO_2	FeO	Cr_2O_3	SiO_2	CaO	Al_2O_3	solidus (K)	liquidus (K)
MC_WC_1	41.7	16.4	41.5	0	0	0	0.4	1623	2073-2133
MC_WC_2	43.3	17.8	28.9	10.0	0	0	0	-	1983-2033
MC_LC_1	61.9	14.9	0	0	0	23.2	0	2133-2143	2163-2253
MC_LC_2	33.6	13.5	0	0	0	26.4	26.5	1613	2043
MC_LCSC	31.5	9.5	0	0	25.5	33.5	0	1733-1793	2073-2133

MC_CSO_1	33.8	14.5	30.1	7.5	14.1	0	0	1633-1673	1873-1913
MC_CSO_2	24.2	7.9	9.1	0	25.0	33.8	0	1513-1633	*2073-2153*[a]
MC_CSO_3	37.9	13.5	16.9	12.0	12.1	7.6	0	1663-1673	1933-1973
MC_CSO_4	41.4	15.5	12.0	4.2	13.6	6.3	7.0	1523	2073-2133
MC_WU	0.3	39.5	28.8	3.6	12.0	2.7	13.1	1593	2073-2153

[a] this recommended value seems erroneous because it is significantly higher than the values measured by the three methods.

3.2. Results and Discussion

The comparison between measured and computed solidus and liquidus temperatures for corium-concrete mixture is presented in Table IV.

Table IV. Comparison between measured and computed solidus and liquidus temperatures for corium-concrete mixture.

	solidus (K)			liquidus (K)		
	experimental	computed	ΔT	experimental	computed	ΔT
MC_WC_1	1623	1552.0	-71.0	2073-2133	2050.0	-23
MC_WC_2	-	1566.0	-	1983-2033	2090.0	57
MC_LC_1	2133-2143	2064.0	-69.0	2163-2253	2309.0	56
MC_LC_2	1613	1728.0	115.0	2043	1993.0	-50
MC_LCSC	1733-1793	1686.0	-47.0	2073-2133	2129.0	ok
MC_CSO_1	1633-1673	1443.0	-190.0	1873-1913	1981.0	68
MC_CSO_2	1513-1633	1486.0	-27.0	*2073-2153*	1954.0	*-119*
MC_CSO_3	1663-1673	1401.0	-262.0	1933-1973	2033.0	60
MC_CSO_4	1523	1349.0	-174.0	2073-2133	2151.0	18
MC_WU	1593	1340.0	-253.0	2073-2153	2197.0	44

ΔT is the difference between computed and experimental values. When the experimental temperature is given as an interval, and the calculated value lies outside this range, the difference is computed as the calculated temperature minus the closest bound of the experimental interval.
Liquidus temperatures are well reproduced: the difference does not exceed 70 K except for test MC_CSO_2 for which the reported recommended value seems to be wrong. Indeed, for this test, the liquidus temperature measured by VPA is 1882 ± 46 K in the IMCC furnace, 1684–1765 K in Galakhov's furnace, and 1823 K by DTA, whereas the recommended range is 2073–2153 K. If, as for the other tests,

the liquidus temperature recommended is assumed to be the one measured by VPA in IMCC furnace, the discrepancy is reduced to only 26 K.

Solidus temperatures are less accurately reproduced, with differences of up to 260 K. However, experimental results should be interpreted with caution. Except for MC_LC_2 test, the computed solidus temperature is always lower than the experimental one.

For this specific test, the evolution of the enthalpy derivative with respect to temperature (ΔH/ΔT) and the phase weight fractions are plotted as a function of temperature in Figure 1. Boettinger [15] has shown that when this apparent heat capacity curve is inverted and expanded along the horizontal axis, it provides an approximate representation of the shape of the DTA signal during melting. Calculated solidus and liquidus temperatures are plotted in black, while experimental ones are plotted in green and blue, respectively.

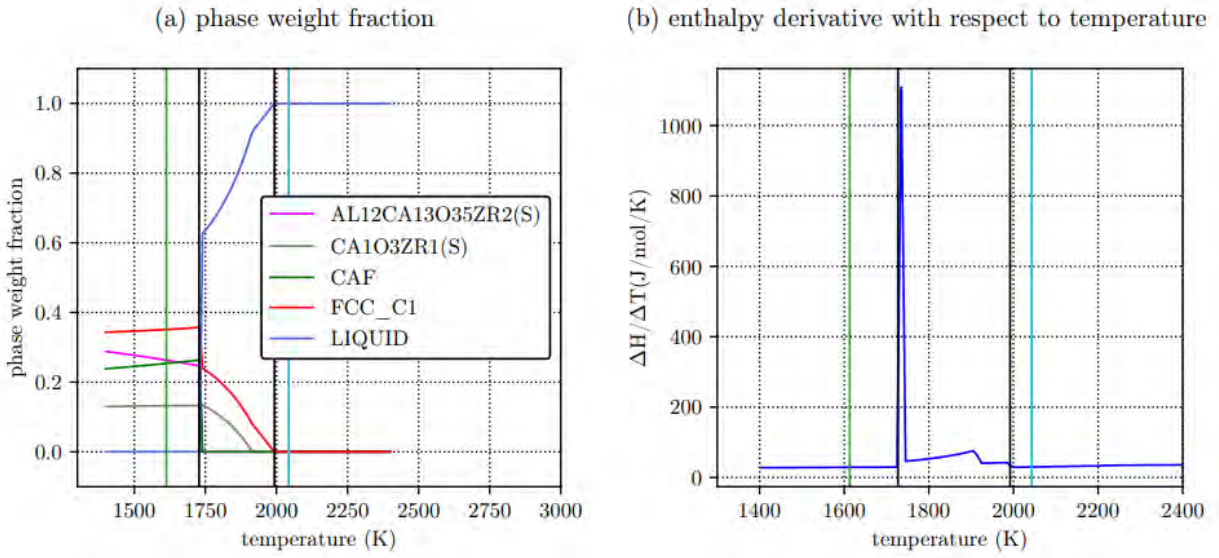

Figure 1. Evolution of the calculated phase weight fractions (a) and enthalpy derivative with respect to temperature (b) as a function of temperature for the MC_LC_2 test.

The solidus temperature calculated with NUCLEA corresponds to the solidification at 1728 K of the 62 w-% liquid phase into 26 w-% of the Al_2CaO_4 compound (the only compound in the CAF phase which is the solution due to the extension of this compound to $CaFe_2O_4$ in the Al-Ca-Fe-O system), 25 w-% of the $Al_{12}Ca_{13}Zr_2O_{35}$ compound, and an additional 11 w-% of the FCC_C_1 phase. It is important to note that the detection of such an invariant reaction during heating requires the presence of the quaternary compound in the initial sample. This compound may be challenging to form without subjecting the sample to annealing for a considerable duration before the DTA measurement at heating.

For the most frequent cases where the calculations do not match the experimental data, it should be kept in mind that peaks in the DTA signal may appear whenever a phase transformation occurs. As a result, the determination of the solidus temperature can be confused with another phase transformation (this misinterpretation is all the more common as the complexity of the system increases), even though a liquid phase is present. For instance, for the MC_CSO_3 test, the evolution of the enthalpy derivative with respect to temperature (ΔH/ΔT) and the phase weight fractions plotted as a function of temperature in Figure 2 indicate that the reported solidus temperature may actually correspond to the transformation of the TET_OXIDE phase (stable phase of ZrO_2 in which 20 w-% of UO_2 are dissolved) into an FCC_C1

phase (solution of fluorite structure rich in UO_2 and ZrO_2) rich in ZrO_2 in this case. Calculated solidus and liquidus temperatures are plotted in black, while the experimental solidus and liquidus temperature ranges are plotted in green and blue, respectively.

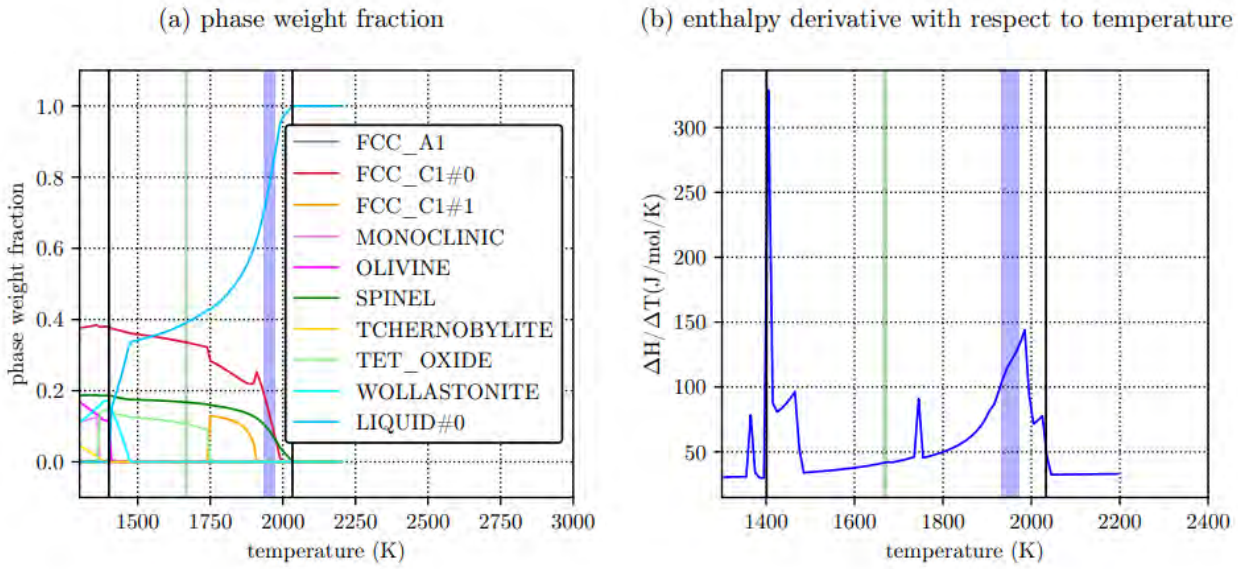

Figure 2. Evolution of the calculated phase weight fractions (a) and enthalpy derivative with respect to temperature (b) as a function of temperature for the MC_CSO_3 test.

4. CONCLUSIONS

The NUCLEA thermodynamic database, developed using the CALPHAD method, comprises 24 elements. It covers both metallic and oxide composition domains and enables the modeling of material evolution during a potential severe accident, from fuel degradation to in-vessel corium interactions and ex-vessel corium–concrete interactions.

The database validation example, chosen in the domain of corium-concrete interactions, highlights the difficulty of performing high-temperature experimental measurements in multiphase mixtures and, consequently, the limited amount of experimental data available to support the database assessment. Nevertheless, the NUCLEA results are satisfactory, particularly with respect to the calculation of the liquidus temperature.

The database will continue to be improved as new experimental data become available.

NUCLEA database
a European Nuclear Thermodynamic Database for severe accident phenomenology

ERMSAR 2026 - 12th European Review Meeting on Severe Accident Research Conference

B. Michel, B. Piar, M. Barrachin, E. Fischer

May 18-22, 2026

NUCLEA: A thermodynamic database developed since the 1990s

Keys thermodynamic systems for severe accident applications

Keys systems for corium applications

- **for the fuel degradation**: O-U-Zr for UO_2 fuel and U-Pu-O-Zr for MOX fuel,
- **for in-vessel corium**: Fe-O-U-Zr for UO_2 fuel and Fe-U-Pu-O-Zr for MOX fuel,
- **for fissions products (FPs) contributing to residual power**: UO_2-FPs
- **for ex-vessel corium**: Fe-O-U-Zr + Ca and Si.

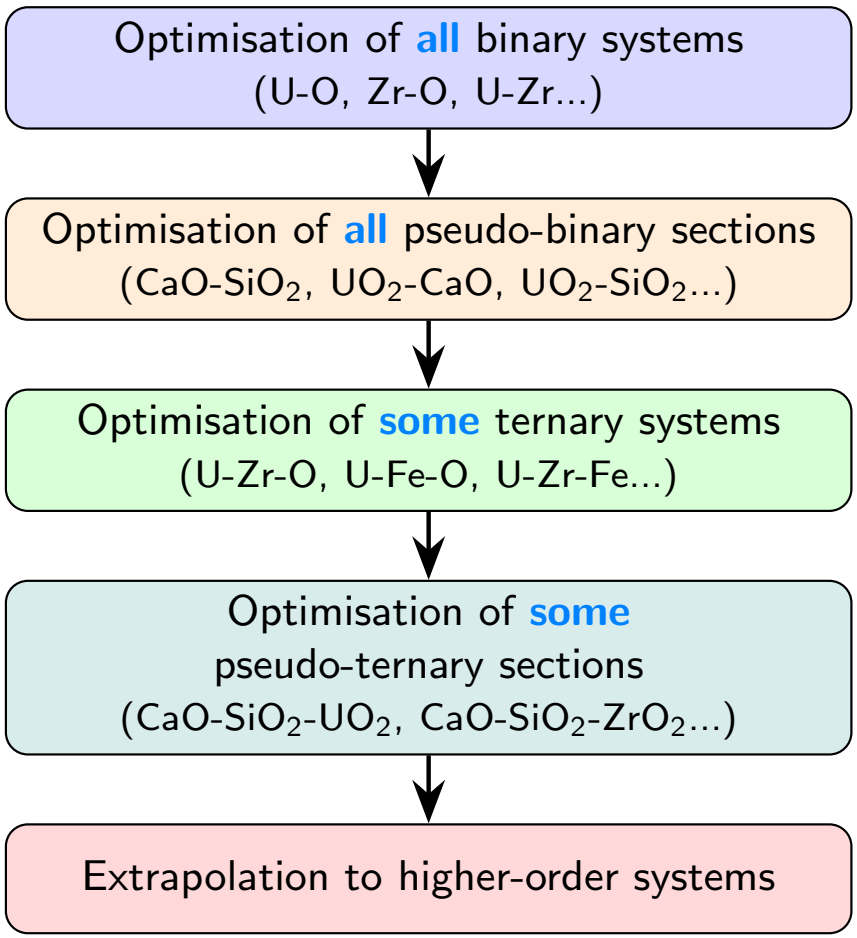
Impact of 'minor' elements

- **Ni and Cr**: for steels for in-vessel corium phenomenology,
- **B, C, Ag and In**: for the impact of control rods on the degradation,
- **Al and Mg**: for concretes for ex-vessel phenomenology.

Development of NUCLEA, a non-ideal solution database, by THERMODATA:

- first version released in 2003 as part of the EC ENTHALPY program,
- owned by ASNR since 2014,
- coupled with the ASNR ASTEC code.

NUCLEA database developed using the CALPHAD approach



Database models for Gibbs energy

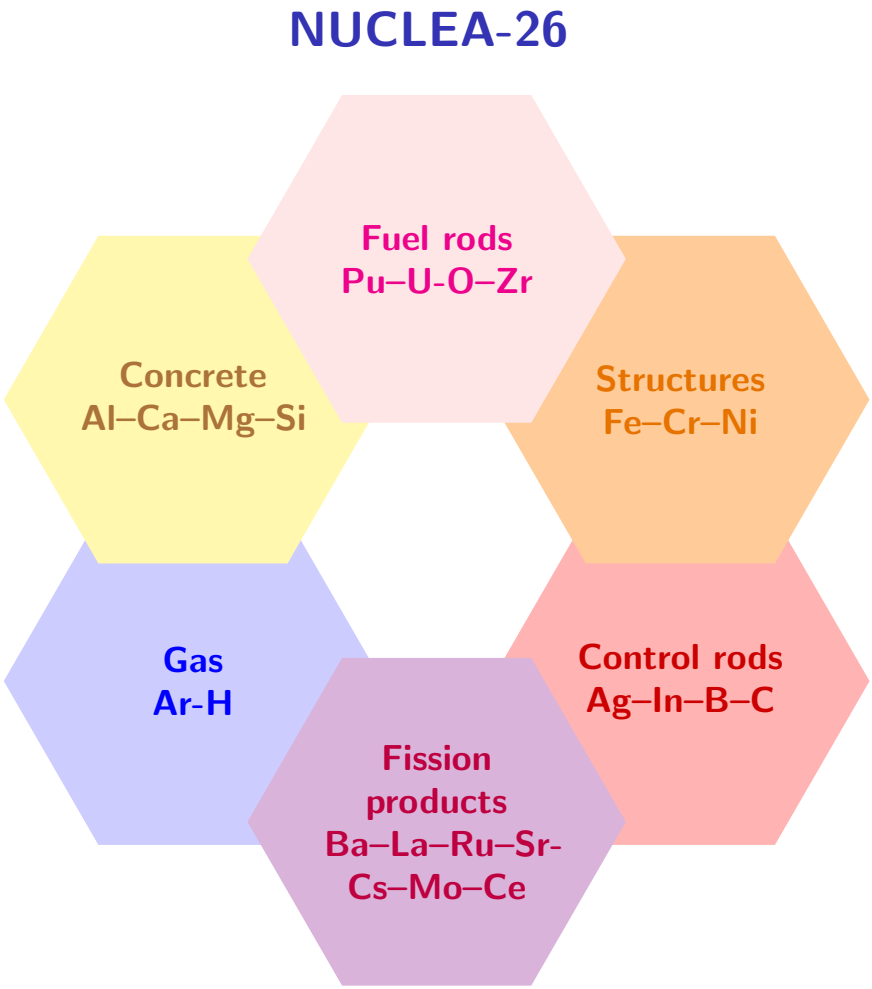
- Pure element Gibbs energy functions derived from the SGTE unary database.
- Solution modeling uses the compound energy formalism (CEF) (including the associated model)

Need for thermodynamic and phase diagram reliable data

- Few thousands publications analysed since 1990 to select data
- Dedicated projects to produce key data for corium and FPs applications
- Continuous work

The database covers all compositions ranging from the metallic to the oxidic state

NUCLEA database: the 2026 version



Since 2014:

- Development of an ASNR software, **NucleaToolbox**, to compute phase equilibria and manage the database development and analysis,
- Merger between NUCLEA and Mephista, an ASNR database dedicated to fuel degradation,
  ⇒ **adding of Cs, Ce, Mo and Pu to NUCLEA.**

The database contains 24 chemical elements and is now able to address the issues of fuel degradation, fission product release, and corium progression

NUCLEA database: the results of numerous research programs

Dedicated programs:

- either for obtaining data in certain binary or ternary systems in order to directly improve their modeling,
- or for obtaining data in systems involving numerous elements in order to qualify the database.

ASNR has been extensively involved in all these programs

Impact of these research programs on NUCLEA development

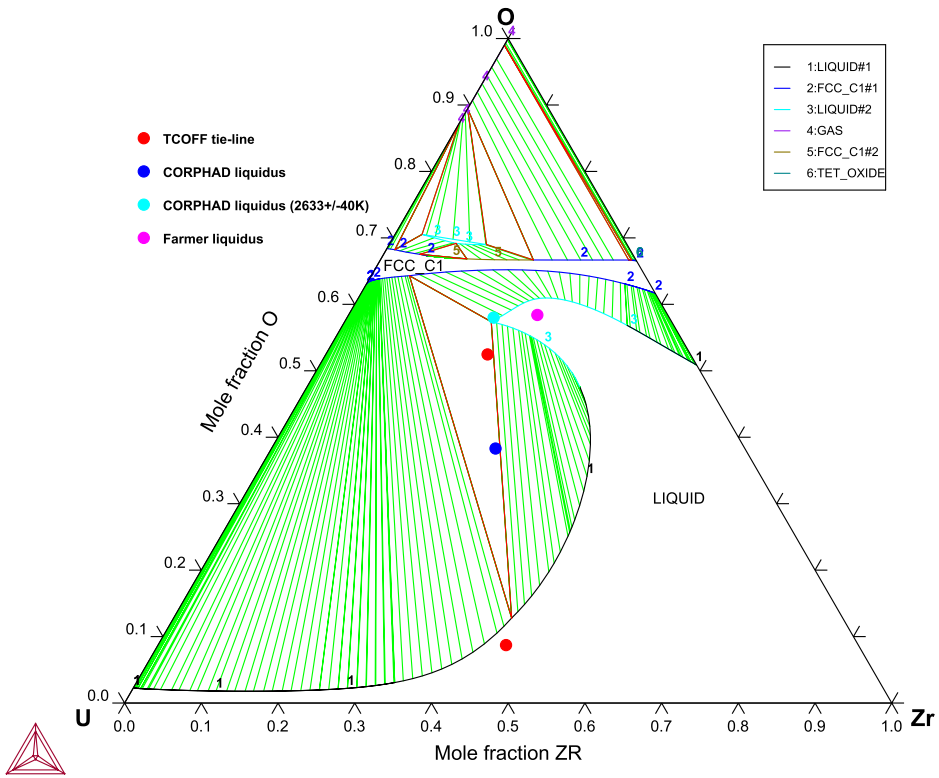
Acquisition of high-temperature thermodynamic data is challenging, particularly for uranium-containing samples, and few data are available.

$\Rightarrow$ acquisition of **thermodynamic** data in the following systems:

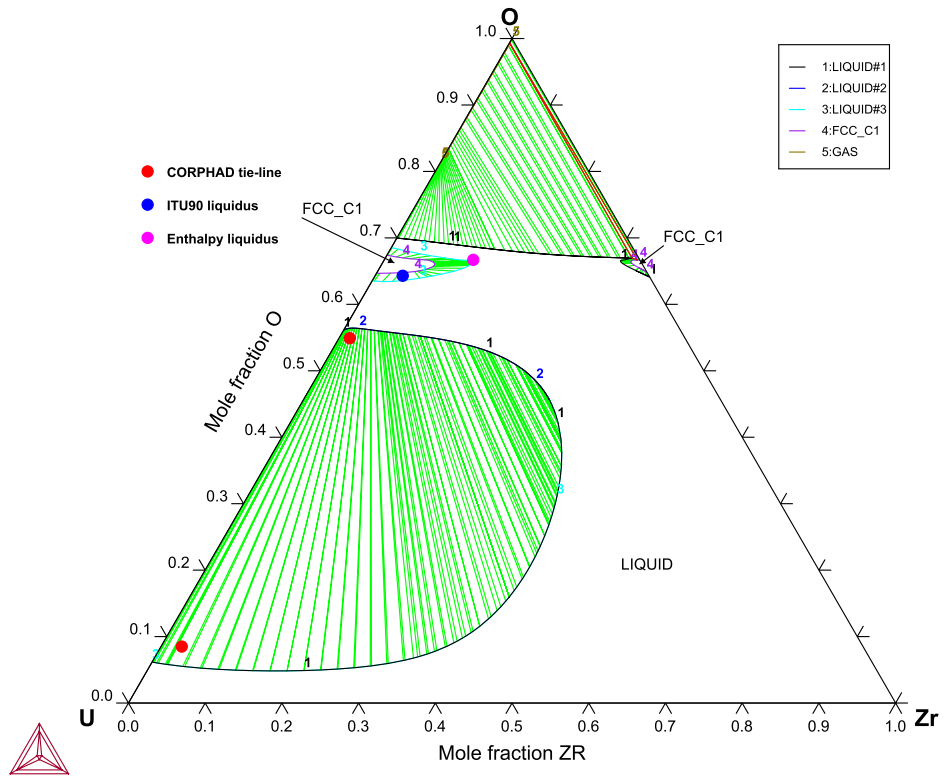
- U-O, U-O-Zr, U-O-Fe...
- UO_2-CaO, UO_2-SiO_2, UO_2-FeO...

Database development: U-Zr-O phase diagram

2600K

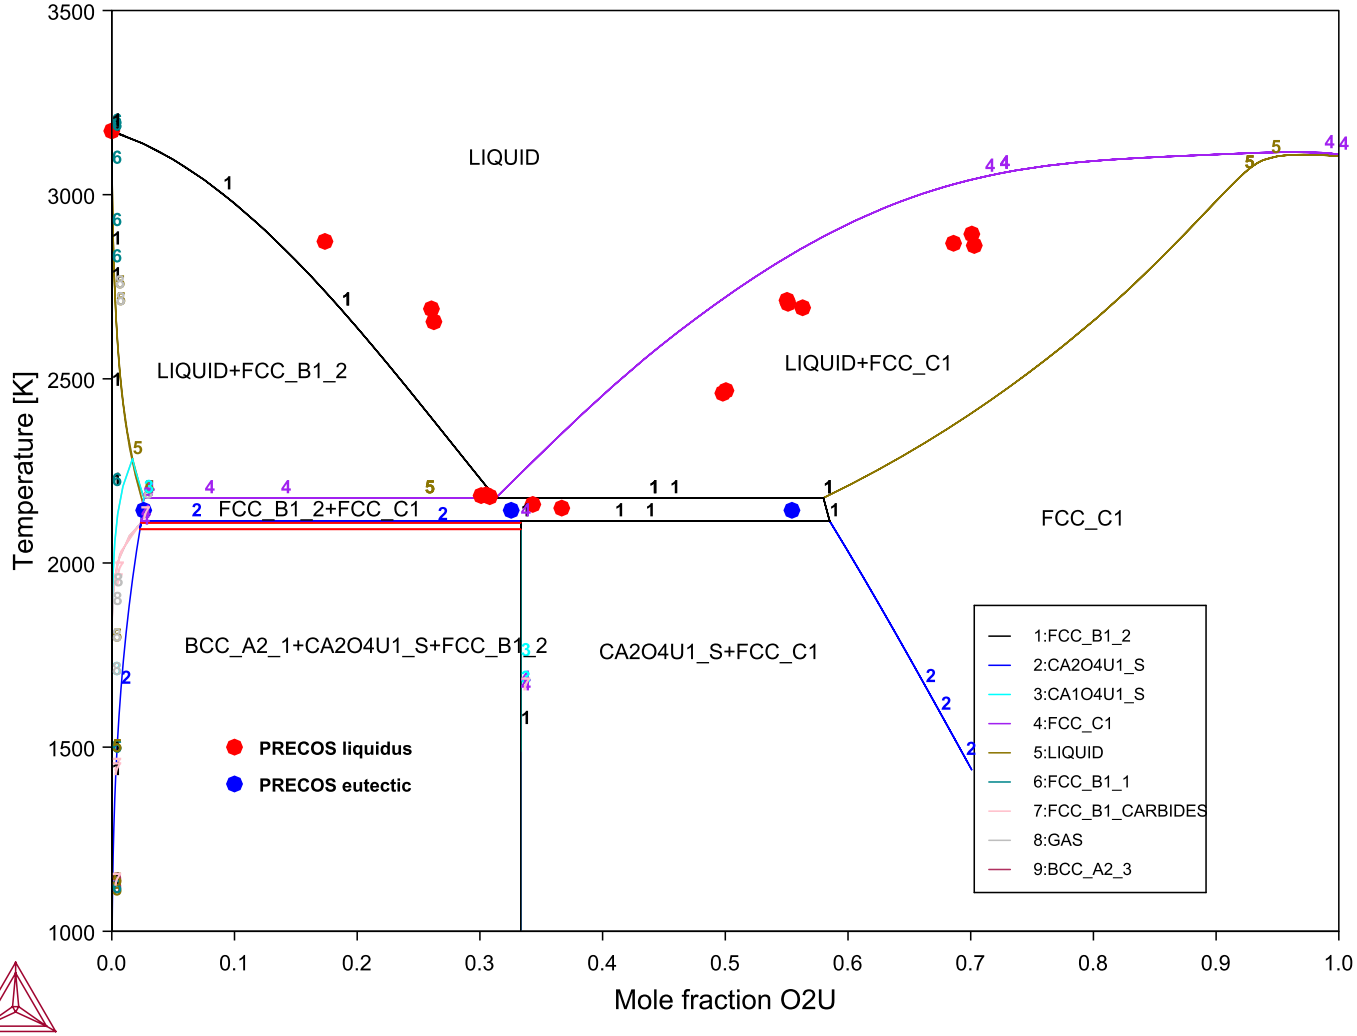


2950K



Good agreement but still few data at these temperatures

Database development: UO_2-CaO section



Good agreement for the eutectic but difficulties in reproducing the liquidus curves.

Impact of research programs for In-Vessel Issues

Due to the low solubility of the metal in the corium, 2 liquids of different density can form and the determination of the position and the thickness of the metallic layer is crucial for a possible focussing effect.

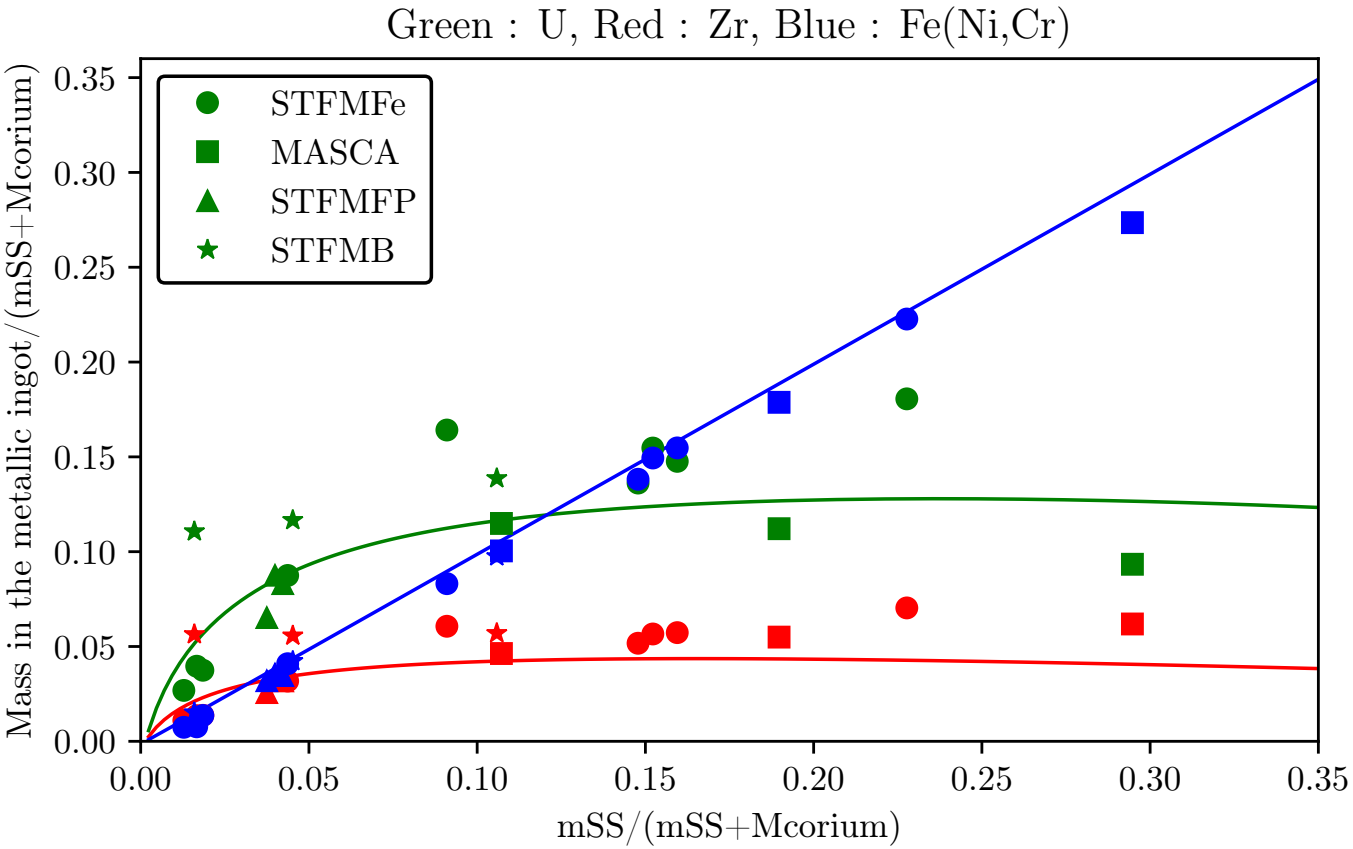
Keys parameters are:

- the zirconium oxidation degree of the corium, C_n,
- the U/Zr ratio,
- the metallic fraction in the melt.

$\Rightarrow$ 38 tests were carried out in MASCA and MASCA2 projects to deal with liquids demixing, 31 in a small device (STFM series) and 7 in a larger one (MA series)

In-Vessel Validation: Composition of the metallic ingot

Comparison betwwen experimental and calculated compositions of the metallic ingot versus metallic fraction in the melt for C_{32}, U/Zr = 1.2 at 2900K (18 tests)

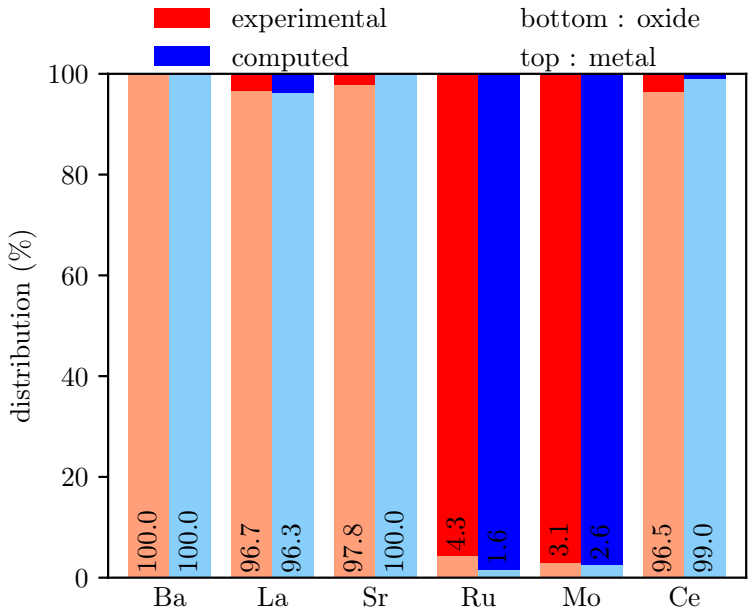


U increases in the metallic phase up to 10% and then remains constant.

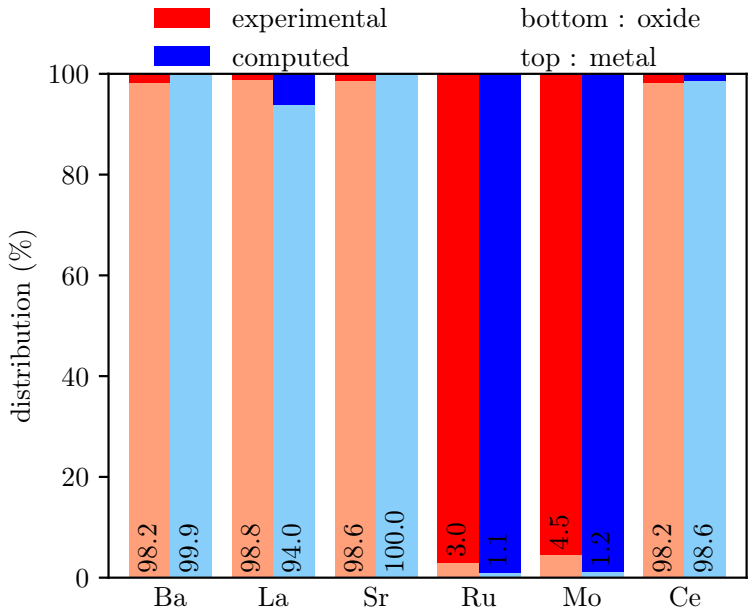
⇒ Trends are satisfactorily reproduced.

In-Vessel Validation: Fission Products Partition

MASCA MA3 Test



MASCA MA4 Test



- Ba, La, Sr, and Ce $\Rightarrow$ oxide phase,
- Mo and Ru $\Rightarrow$ metallic phase.

Good agreement between the calculated and experimental FPs partitioning

Impact of research programs for Ex-Vessel Issues

Ex-vessel issues are an even greater challenge because the impact of the concrete components, CaO, SiO_2 (and MgO and Al_2O_3) must be included.
Modeling involves multiple temperatures (concrete ablation, pool solidification) and possibly the liquid fraction (xliq).

⇒ Databases are generally validated by comparing liquidus and solidus temperatures.

Remarks on solidus temperature determination

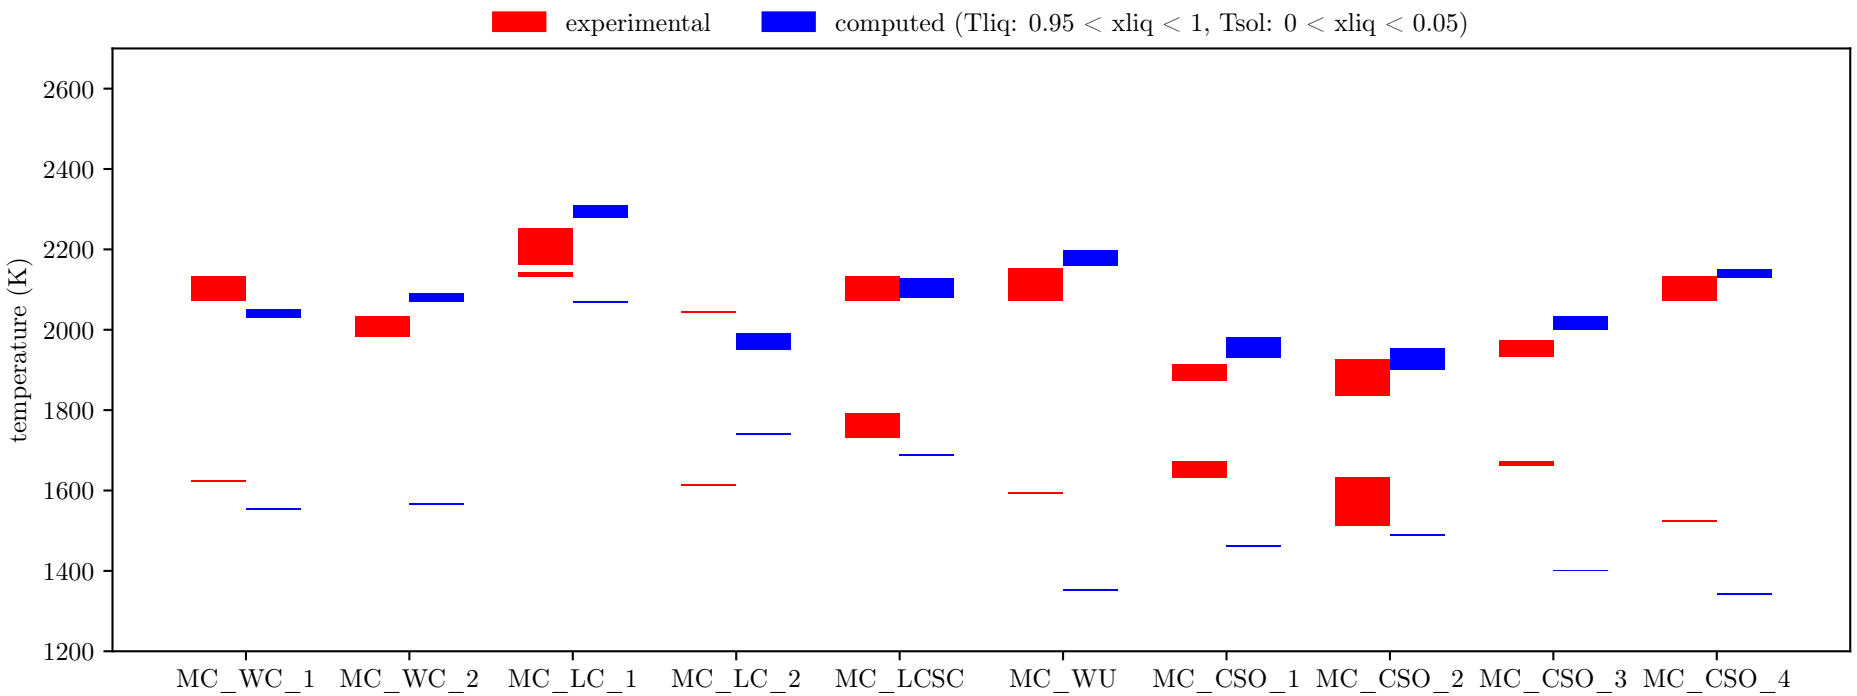
Most of these programs follow a three-stage experimental procedure:

- First, Visual Polythermal Analysis (VPA) in an Induction Melting Cold Crucible (IMCC) furnace measured the **liquidus temperature**, samples were taken from the molten pool.
- Then, melt samples were analysed to determine the **effective composition** of the molten pool (segregation due to temperature gradient).
- Finally, the **solidus temperature** was measured by Differential Thermal Analysis (DTA) by heating one of these samples.

⇒ Samples may not be in thermodynamic equilibrium (rapid cooling)

Ex-Vessel Validation: Solidus and Liquidus Determination

ENTHALPY Program



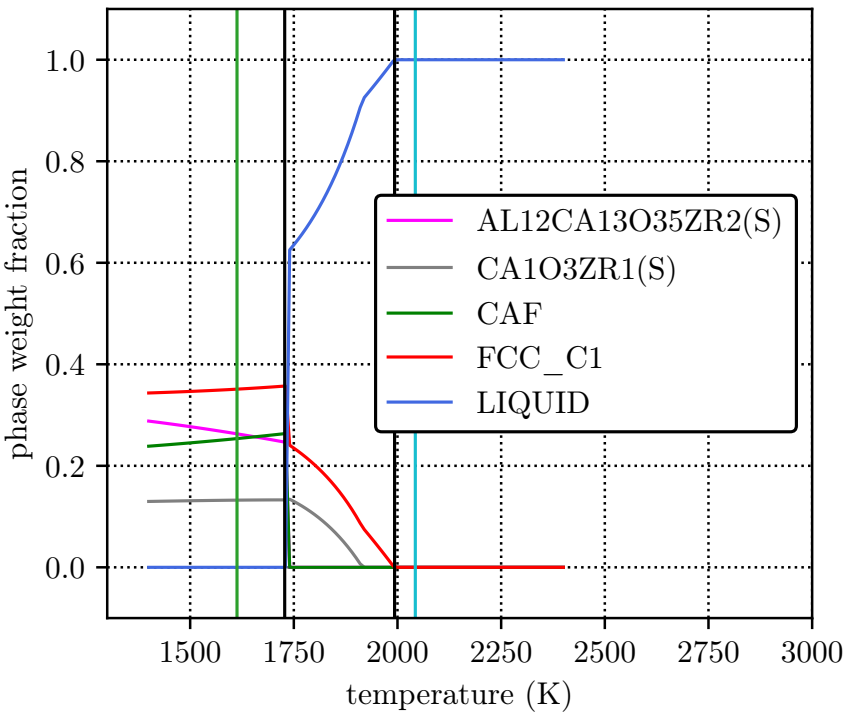
Liquidus temperatures: good agreement (<70K)

Solidus temperatures: poor agreement (up to 260K)

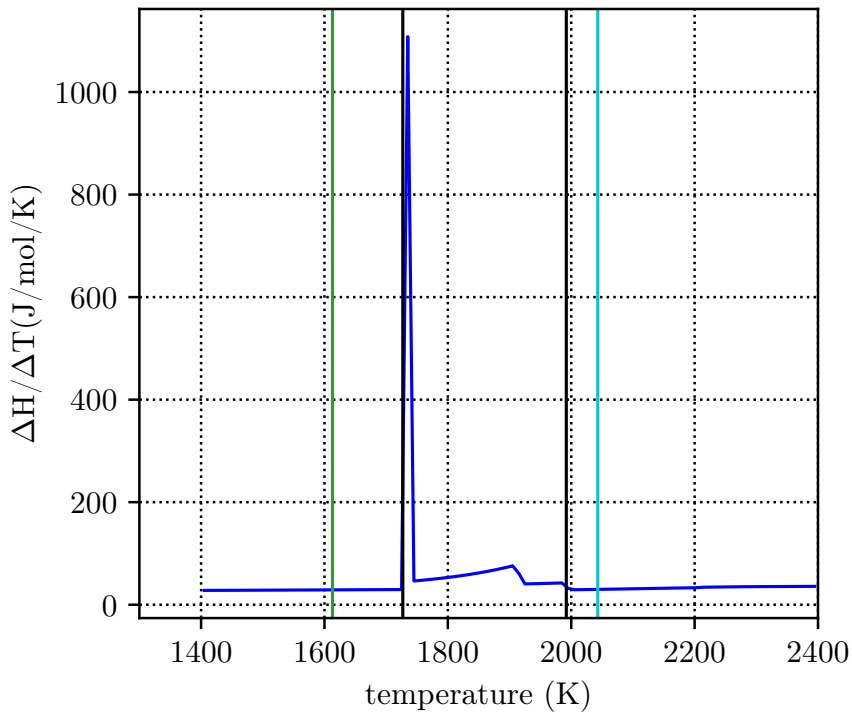
Issues in Solidus Determination 1/2

MC_LC_2	UO_2	ZrO_2	CaO	Al_2O_3
w-%	33.6	13.5	26.4	26.5

Phase weight fraction



Derivative of enthalpy versus temperature

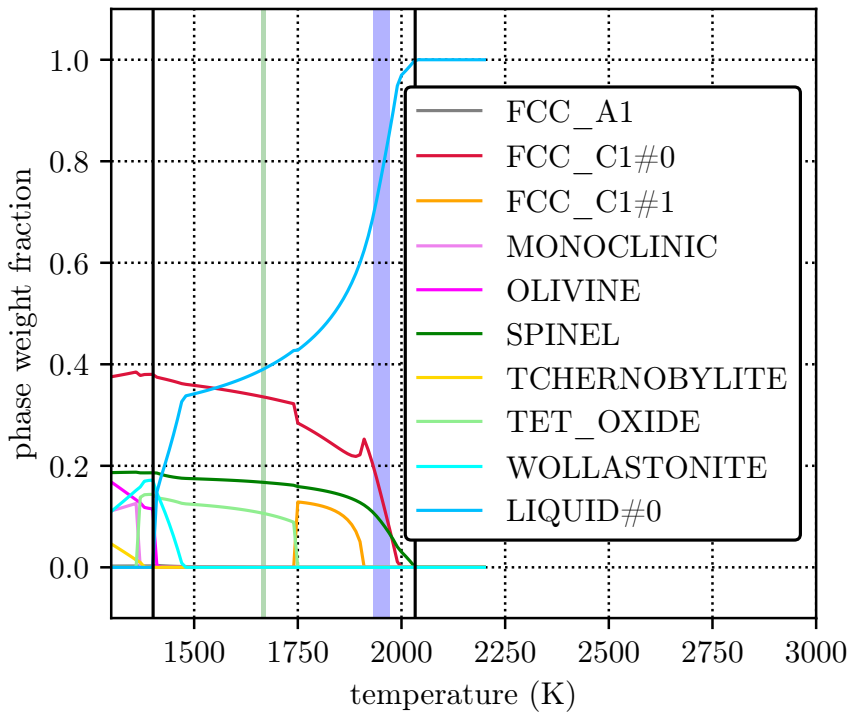


Quinary system ⇒ expected reliable extrapolation but Tsolidus overestimated by 110K
Tsolidus linked to the melting of $(Al_2O_3)_6(CaO)_{13}(ZrO_2)_2$ ⇒ possibly not formed during cooling

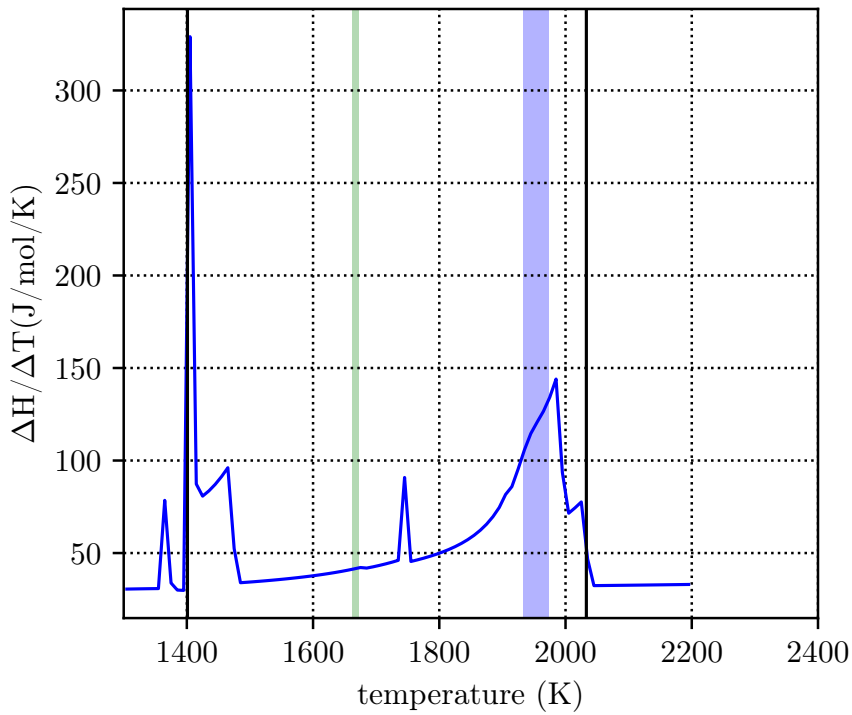
Issues in Solidus Determination 2/2

MC_CSO_3	UO_2	ZrO_2	FeO	Cr_2O_3	SiO_2	CaO
w-%	37.9	13.5	16.9	12	12.1	7.6

Phase weight fraction



Derivative of enthalpy versus temperature



several thermal arrests in multi-component system ⇒ difficult to assign one to Tsolidus
Tsolidus linked to the melting of olivine, $(Ca,Fe)_2SiO_4$ ⇒ possibly not formed during cooling

Conclusion

- NUCLEA-26 database is able to address the issues of fuel degradation, fission product release, and corium progression.
- Validation of NUCLEA for in-vessel conditions: good agreement for U–Zr evolution in the metallic ingot and fission product partitioning between oxide and metal.
- For ex-vessel conditions: good agreement for the liquidus temperature, but determining the solidus temperature is more challenging.
- Coupling of NUCLEA with ASTEC/ICARE for IVR studies and with ASTEC/MEDICIS for ex-vessel applications.

Future developments

new data integration, possible ternary extensions, no additional elements planned

Publications

- article on NUCLEA validation recently submitted to Annals of Nuclear Energy (*NUCLEA: A thermodynamic database validated for severe accident codes*)
- article on NUCLEA modeling and NucleaToolbox software currently being written

ABSTRACT

Stable corium cooling in ex-vessel regions is a critical issue during severe accidents in light water reactors. The dry cavity strategy is an effective mitigation approach that involves spreading molten debris in a core catcher before water injection. For this strategy to be effective, the molten debris must spread uniformly to ensure efficient cooling. Physical properties such as apparent viscosity, which evolves during solidification, play a crucial role in melt spreading. These properties are strongly influenced by the boundary conditions, particularly the initial temperature and mass flow rate of the molten debris released into a core catcher. This study used the THERMOS code system to simulate molten debris spreading behavior in an european pressure reactors type core catcher under dry cavity conditions. Sensitivity analyses were performed, focusing on molten debris temperature and mass flow rate. The results reveal that the shape and distribution of the debris bed vary significantly depending on these parameters. Differences in the release mass flow rate substantially affect the melt circulation and oxide distribution in the core catcher. At high mass flow rates, mixing between the low-temperature circulating melt and the high-temperature melt descending from the slope reduced the overall molten debris temperature. At low mass flow rates, weak circulation from low inertia led to early solidification and the formation of dams on the slope. These results indicate that thermal and hydrodynamic conditions govern spreading and highlight the need for accurate viscosity-evolution and oxide-effect models. The findings are applicable to the evaluation of the dry cavity strategy in severe accident management.

1. INTRODUCTION

During severe accidents in light water reactors, failure of the lower head of the reactor pressure vessel (RPV) may result in molten debris migrating into the cavity (referred to as the pedestal in boiling water reactors, BWRs) within the containment vessel (CV) [1]. To mitigate molten corium-concrete interaction (MCCI) and prevent basemat failure, either a wet cavity strategy or dry cavity strategy is adopted to maintain the

debris bed within the cavity in a stable cooling state [2-5]. The wet cavity strategy involves preflooding the cavity before RPV failure, thereby promoting jet fragmentation and enhancing cooling effectiveness. Conversely, the dry cavity strategy involves the installation of a core catcher, etc., to effectively spread molten debris within the dry cavity, which is then stabilized using water injection or a cooling system. The dry cavity strategy has garnered considerable attention because of its advantages, such as a practical elimination of steam explosion risk, and has already been implemented in reactors such as european pressu re reactors (EPRs) [4],[5].

Regarding debris bed formation under dry conditions, data have been obtained from experimental programs, such as COMAS [6], RIT [7], KATS [8],[9], ECOKATS [10], and VULCANO [11]. Analysis results of debris bed formation behavior under dry conditions within the core catcher using CORFLOW code [12], THEMA code [13], and MPS code [14] were reported. However, these analyses did not account for the initial conditions of the released debris or the temporal evolution of high-resolution physical properties.

To reduce uncertainties in the molten debris spreading behavior, simulations were conducted using the THERMOS code system [15], considering high-resolution time-dependent variations in material properties. Stable molten debris cooling in the dry cavity strategy requires that the debris be widely spread within a core catcher. The objective of this study is to determine whether the THERMOS analysis method, previously applied in representative Japanese BWR analyses [15], can be extended to dry cavity strategies such as debris spreading within a core catcher. This paper presents the results of analyses conducted using THERMOS, focusing on the molten debris temperature and release mass flow rate.

2. OVERVIEW OF THERMOS CODE SYSTEM

THERMOS code system [15] comprises modules such as JBREAK [2], MSPREAD [18],[19], and THEMAT [15]. JBREAK [2] solves the hydrodynamics of molten jets, including release from the RPV, interaction with coolant, impingement on obstacles, and impact on the floor. JBREAK has been validated [2] based on the DEFOR-A experiments [16],[17], focusing on molten jet breakup and droplet behavior under wet conditions. MSPREAD models molten debris deformation and cooling after reaching the floor surface, specifically its spreading, solidification due to cooling, and transition into stationary debris as apparent viscosity increases [18],[19]. The floor-surface irregularities (e.g., sumps and weirs) is considered in the melt spreading process. MSPREAD has been validated [19],[20] using dry-condition melt spreading experiments (KATS-12 [9], ECOKATS-1 [10], and VULCANO-VEU7 [11]) and wet-condition experiments (PULiMS E10 [16]). THERMAT calculates physical properties based on the temperature of different material mixtures and the mass fraction of each component. The density of molten debris is evaluated as a mass-fraction-weighted average. The Da Andrade exponential function [21] is applied to compute the viscosity for each composition, and the apparent viscosity of molten debris is evaluated using the Ramacciotti model [22].

These modules interact through two-way interfaces at each time step and computational cell to handle complex molten debris behavior. Coupled analysis of ex-vessel molten debris behavior within the CV of a representative Japanese BWR has been conducted using the THERMOS – JBREAK / MSPREAD / THERMAT) system [15].

3. ANALYSIS CONDITIONS FOR DEBRIS BED FORMATION IN A CORE CATCHER

Figure 1 shows the core catcher geometry considered in this study. The dimensions (17.6-m wide and 11.0-m deep) are based on AREVA's EPR design [4],[5]. Molten debris released from the RPV falls as a molten jet onto a 7.2-m sloped surface inclined at 2°, subsequently spreading within the core catcher [4],[5].

The molten jet fall and floor impingement are calculated using JBREAK, whereas the melt spreading and cooling on the floor are computed using MSPREAD. The interface between JBREAK and MSPREAD employed the method described in the BWR analysis [15]. The computational mesh size is consistent with that employed in the VULCANO-VEU7 validation [19] and BWR analyses [15]. Based on these studies,

the contact thermal resistance between the floor and molten debris is set to 0.00012 $m^2 \cdot K/W$ and the Ramacciotti model's coefficient is set to 6.3.

This analysis focuses exclusively on metallic molten debris behavior within the core catcher, neglecting the effects of UO_2 and concrete. The composition of molten debris released from the RPV is derived from the s tation brack out (SBO) scenario of a representative Japanese BWR, as applied in previous THERMOS analyses [15]. The debris comprises Zr, Fe, Cr, Ni, Fe_2O_3, Cr_2O_3, and NiO, with a time-dependent release history [15]. This history indicated a consistently metal-rich composition across all time periods. Approximately 57 s after the molten debris was released, a small quantity of oxides appeared, constituting approximately 5% of the molten debris.

Eight cases were analyzed (Table I) to investigate the influence of release velocity and temperature. In an EPR, a holding zone (port) is located outside the RPV; a 0.36-m diameter (equivalent to 0.1 m^2) is employed in this study because the port failure area is typically ≥ 0.1 m^2. From this failure area, molten debris was released at either 1.52 m/s (corresponding to 1,000 kg/s) or 0.66 m/s (corresponding to 333 kg/s, respectively), with a total mass of up to 100 tons. The initial debris temperatures corresponding to the initial superheats of 11 K, 111 K, 511 K, and 911 K were 1,900 K, 2,000 K, 2,400 K, and 2,800 K, respectively. Concrete mixing within the port and core catcher was neglected, and static water injection into the core catcher was not considered.

Figure 1. Spatial Modeling of the EPR Core Catcher.

Table I. Analysis Conditions

	Molten jet diameter [m]	Initial release velocity [m/s] (release mass flow rate [kg/s])	Initial melt temperature [K] (initial superheat [K])
Case 1-L	0.36	0.60 (333)	1900 (11)
Case 2-L	0.36	0.60 (333)	2000 (111)
Case 3-L	0.36	0.60 (333)	2400 (511)
Case 4-L	0.36	0.60 (333)	2800 (911)
Case 1-H	0.36	1.52 (1000)	1900 (11)
Case 2-H	0.36	1.52 (1000)	2000 (111)
Case 3-H	0.36	1.52 (1000)	2400 (511)
Case 4-H	0.36	1.52 (1000)	2800 (911)

4. ANALYSIS OF RESULTS

4.1. Influence of Thermal and Hydrodynamic Conditions on Melt Spreading Behavior

Case 2-H represents a scenario with a high molten jet release velocity and a molten debris superheat of 111 K, indicating high fluidity. Figure 2 shows the molten jet in yellow and the spreading debris on the floor surface in red. After impinging on the sloped surface, the molten jet flows into the core catcher and subsequently spreads throughout the entire core catcher after colliding with the wall opposite the slope. These results demonstrate that the THERMOS analysis system can qualitatively capture high-resolution spreading behavior of molten debris within the core catcher.

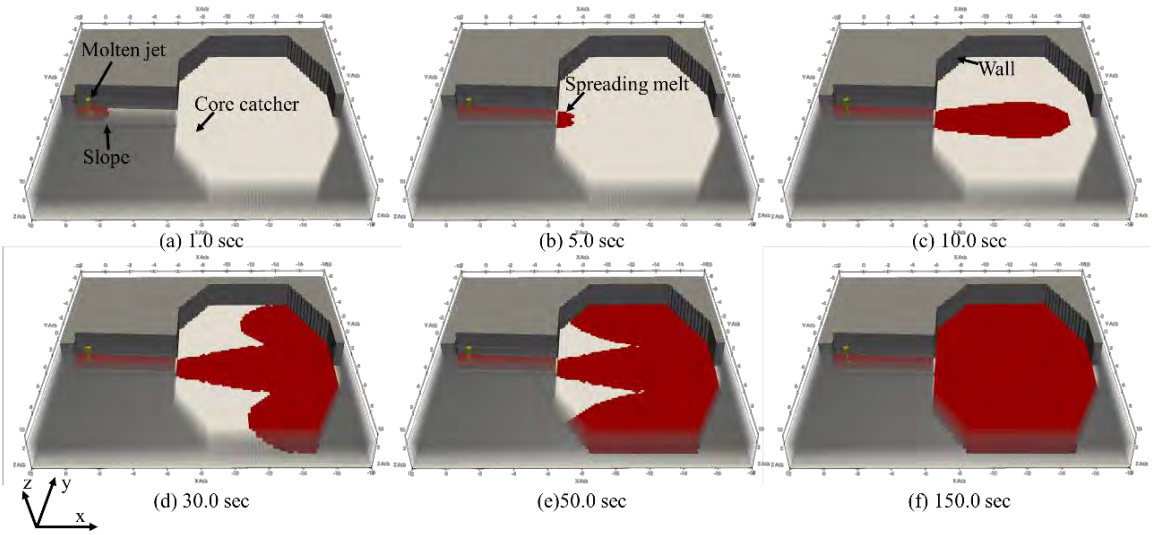

Figure 2. Spreading Behavior of Molten Debris within the Core Catcher for Case 2-H.

Figure 3 shows the time history of the molten debris spreading area for all analysis cases, divided into (a) t he initial short period (0–50 s) and (b) the extended period (0–350 s) until spreading cessation. Colored plo ts represent high-mass-flow-rate cases, whereas white plots indicate low-mass-flow-rate cases. Molten deb ris temperatures of 1900 K, 2000 K, 2400 K, and 2800 K are shown in blue, purple, green, and red, respect ively. As marked in Fig. 3(a), the spreading behavior exhibits three characteristic inflection points:

(I) molten debris flows from the sloped surface into the core catcher;
(II) molten debris impacts the core catcher wall and transitions to circulating flow; and
(III) molten debris spreads across the entire core catcher and terminates.

The results clearly indicate that spreading across the entire core catcher occurs more rapidly at higher molten jet mass flow rates or higher initial debris temperatures. As shown in Fig. 3(b), complete spreading is achieved within approximately 100 s for high-mass-flow-rate cases, regardless of temperature. Conversely, at low mass flow rates, complete spreading does not occur when the molten debris temperature is relatively low (e.g., 1900 K or 2000 K). These observations highlight the combined effect of thermal and hydrodynamic conditions on debris spreading behavior. Specifically, higher temperatures reduce apparent viscosity, promoting lateral flow, whereas higher mass flow rates increase momentum, accelerating melt spreading on the catcher floor. This interplay is critical for evaluating the effectiveness of the dry cavity strategy, as insufficient spreading may lead to localized overheating and structural failure. A more detailed quantitative analysis of these factors is provided in the following sections.

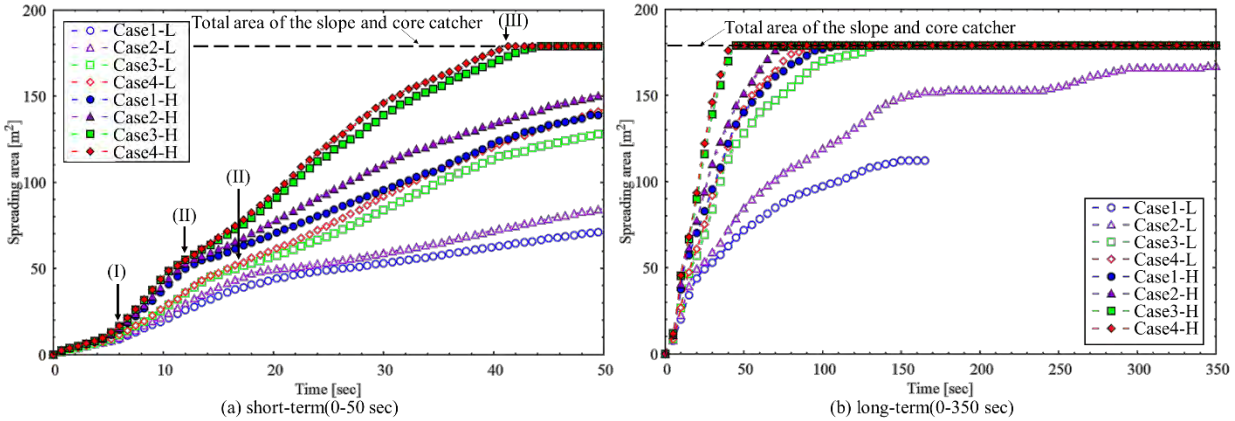

Figure 3. Time History of Molten Debris Spread Area for All Analysis Cases.

4.2. Detailed Analysis

4.2.1. Effect of the Released Molten Debris Temperature

Figure 4 shows apparent viscosity contours and the time evolution of velocity vectors during molten debris spreading for low-mass-flow-rate cases, focusing on the influence of initial debris temperature. Solidified melt is shown in gray. In all cases, the molten jet accelerates along the sloped surface before entering the core catcher and spreading across the floor. Subsequently, the flow impacts the wall opposite the slope exit and circulates along the core catcher wall. In cases with initial temperatures exceeding 2400 K (Figs. 4(c) and 4(d)), a stable circulation flow develops within the core catcher, indicating extremely high fluidity.

Figure 5 compares temperature, superheat, apparent viscosity, and spreading velocity along the E–W cross-section (Fig. 1) at 100 s and 150 s, where notable differences among cases are observed. As shown in Figs. 4(b-5), (c-4), and (d-4), the cooled circulating melt mixes with the incoming debris at the slope exit. Consequently, as shown in Figs. 5(a-1), (a-2), (b-1), and (b-2), a sharp decrease in melt temperature and superheat occurs at the slope exit after the circulating flow reaches this region (at 150 and 100 s for Cases 3-L and 4-L, respectively). Nevertheless, for high-superheat cases, such as Cases 3-L and 4-L, solidification does not occur because the superheat remains positive and no notable increase in apparent viscosity is observed (Figs. 5(a-3) and (b-3)). As a result, molten debris continues to spread rapidly within the core catcher, with only a slight reduction in velocity at the mixing point (Figs. 5(a-4) and (b-4)).

In contrast, in low-superheat cases (case 1-L and case 2-L; Figs. 4(a) and (b)), the initial apparent viscosity is high and solidification occurs during circulation. Insufficient circulation prevents complete spreading across the core catcher. At 150 s, the molten debris exhibits negative superheat and flows in a partially solidified, highly viscous state (Figs. 5(a-1), (a-2), (b-1), and (b-2)). Particularly, the temperature approaches the solidus (≈1895 K) in Case 1-L, resulting in extremely high apparent viscosity that halts spreading.

The above results demonstrate that high initial temperature promotes stable circulation flow and enhances fluidity, making temperature a dominant factor governing spreading behavior. This finding underscores the importance of accurately modeling thermal properties and apparent viscosity evolution when evaluating dry cavity strategies for severe accident mitigation.

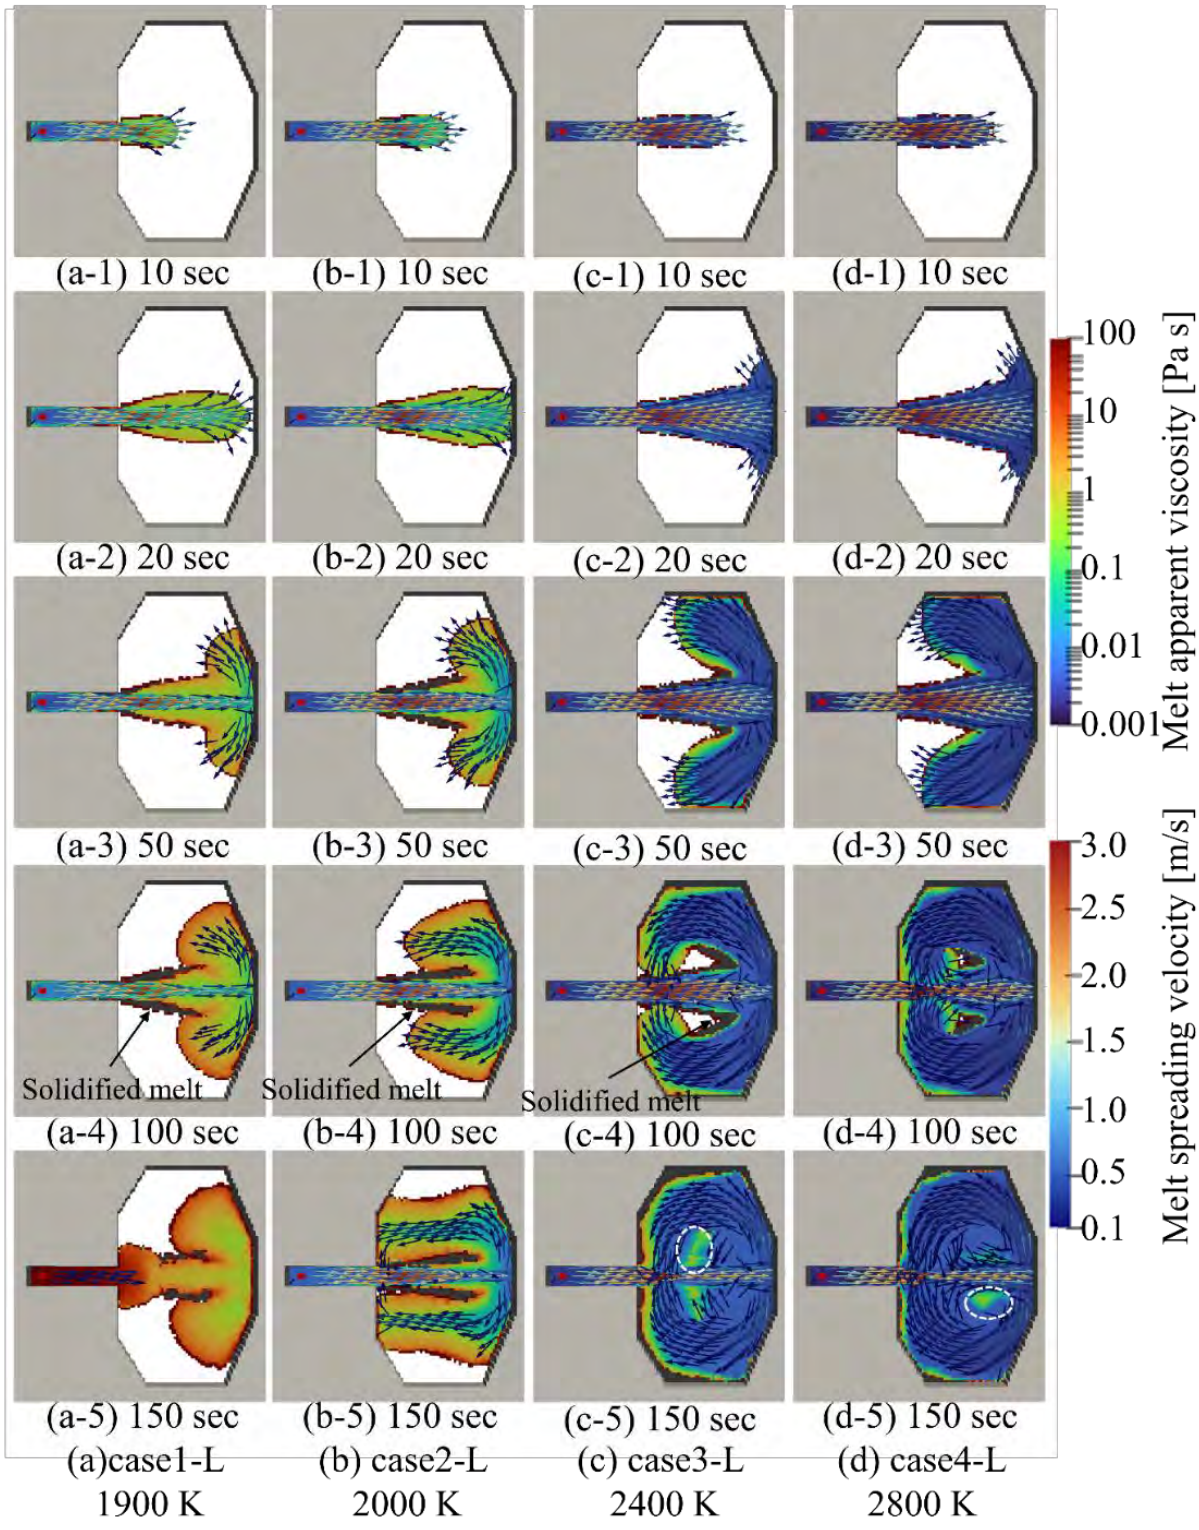

Figure 4. Time Progression of Apparent Viscosity Contours and Velocity Vector during Melt Spreading.

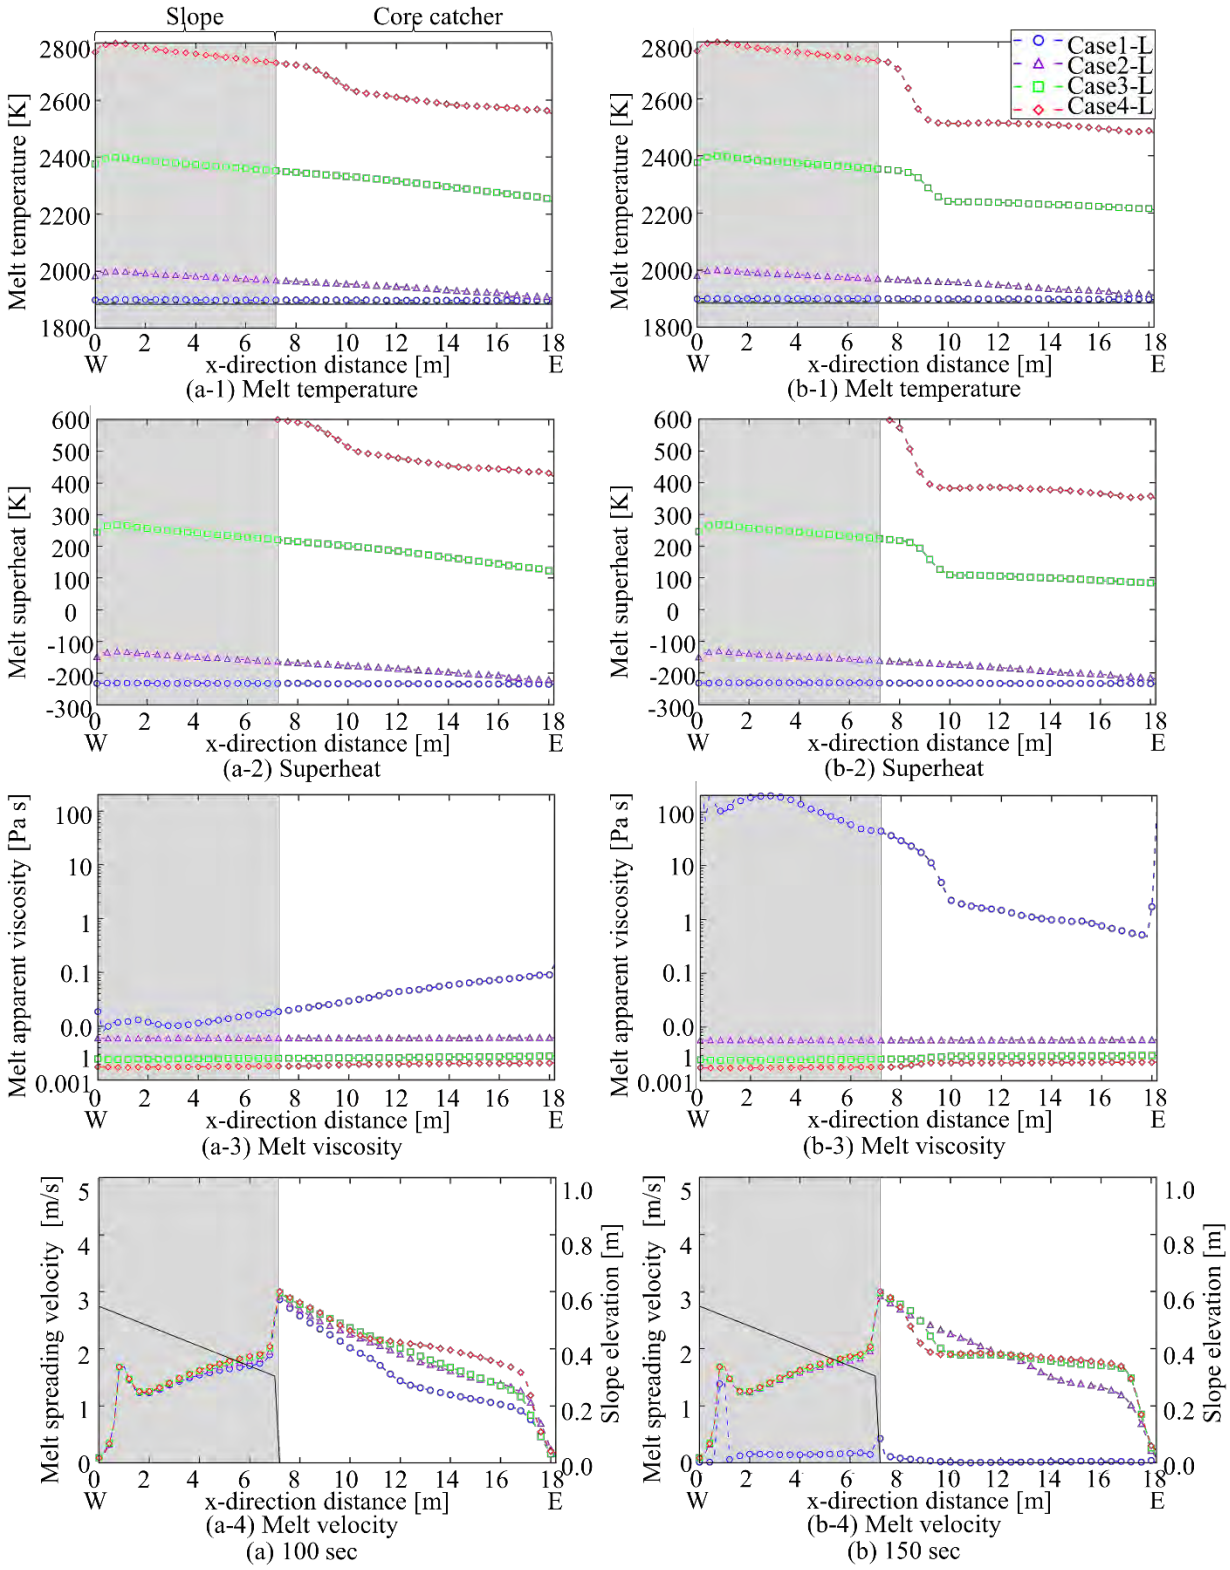

Figure 5. Comparison of Melt Temperature, Superheat, Apparent Viscosity, and Velocity Distribution in the E–W Cross-Section for Low-Mass-Flow-Rate Cases.

4.2.2. Effect of Released Mass Flow Rate Under Low-Temperature Conditions

As mentioned in Section 4.2.1, the melt spreading stopped midway in Case 1 at low mass flow rates and low temperature (1900 K). Meanwhile, as shown in Fig. 3, the melt spreading did not stop at high mass flow rates, even at low temperature (1900 K). Therefore, this section presents the analysis results focusing on the differences between the low- and high-mass-flow-rate cases at 1900 K.

Figure 6 shows the temporal evolution of apparent viscosity contours and velocity vectors during debris spreading for Case 1 at 1900 K, emphasizing the effect of release velocity. For high and low-mass-flow-rat e cases, the melt spreading across the floor-surface impinges on the wall opposite the slope exit, resulting in momentum loss after wall impingement towing to diminished inertial forces. For high-mass-flow-rate ca ses, the large inertial force of the molten debris generates a strong circulating flow even after wall impact, enabling the debris to spread across the entire core catcher. In contrast, the initial inertia is small for low-mass-flow-rate cases, and the momentum necessary to establish sufficient circulating flow is lost through wall impingement. Consequently, circulating flow fails to develop and melt spreading ceases.

Figure 7 shows the oxide-fraction distribution within the molten debris. The THERMOS analysis results apply the debris composition released during the SBO scenario of a representative Japanese BWR, as calculated by MELCOR. Oxides begin to appear approximately 50 s after release. Compared to the low-mass-flow-rate condition, the high-mass-flow-rate condition exhibits a higher oxide fraction over a wider area. The oxide fraction considerably influences the solidus/liquidus temperatures and, consequently, the physical properties of the molten debris.

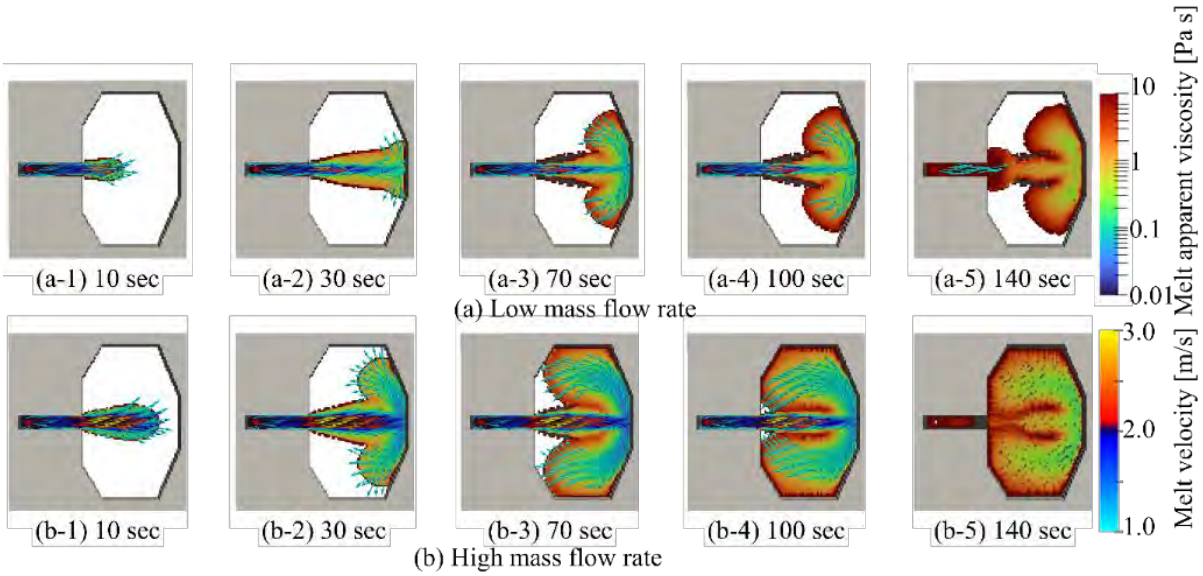

Figure 6. Progression of Debris Bed Apparent Viscosity and Velocity Distribution Based on Mass Release.

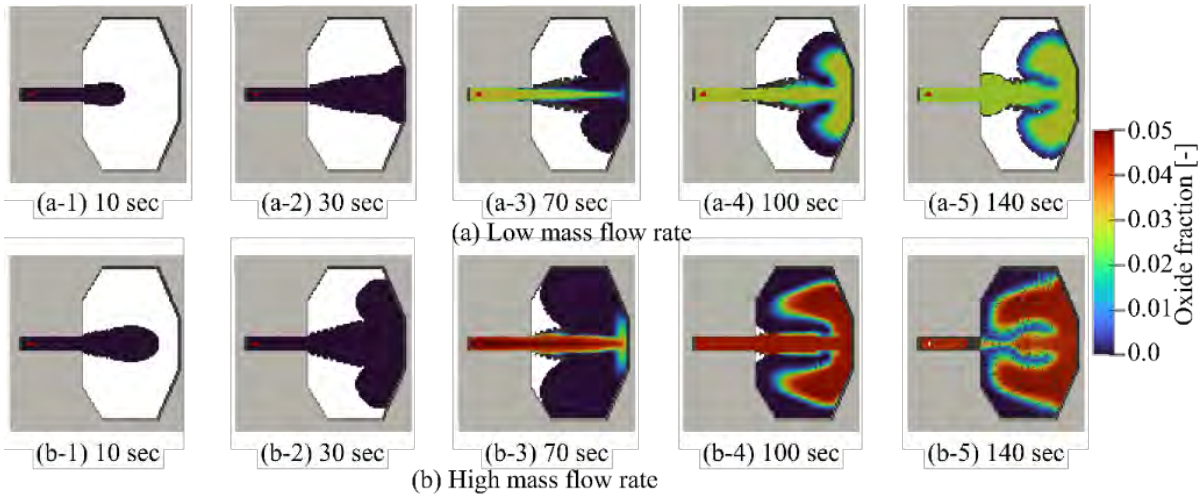

Figure 7. Progression of Oxide Mass Fraction in Debris Bed Due to Mass Release.

Figure 8 summarizes the distributions of molten debris temperature, superheat, spreading velocity, apparen t viscosity, and debris bed thickness along the E–W cross-section, divided into (a) short-term (10, 20, and 5 0 s) and (b) long-term (100, 120, and 140 s) intervals. Analysis results are shown with blue outlines and re d fills for low- and high-mass-flow-rate cases, respectively.

From the short-term perspective (10–50 s after release; Fig. 8(a-1)), the molten jet fell and spread along the slope, causing the melt temperature to decrease by approximately 10 K. As noted earlier, oxide-rich molte n debris began to appear around 50 s, raising the debris liquidus and solidus temperatures (Fig. 8(a-2)). Co nsequently, the melt superheat became negative by about 250 K and apparent viscosity increased over time (Fig. 8(a-3). Nevertheless, continuous jet release drove further molten debris spreading, resulting in debris beds of roughly uniform height under low- and high-mass-flow-rate conditions.

From the long-term perspective (100–140 s after release; Fig. 8(b-1)), sufficient circulation flow developed under high-mass-flow-rate conditions, promoting molten debris mixing at the slope exit and causing a temperature decrease. In contrast, circulation flow was absent at low mass flow rates, resulting in a nearly uniform temperature distribution. The molten debris solidus temperature increased after approximately 50 s due to oxide supply. Notably, the solidus temperature was only about 5 K lower for the high-mass-flow-rate cases than for the low-mass-flow-rate cases. Because these cases involved negative superheat, this slight difference in solidus temperature significantly affected the apparent viscosity. Although the melt temperature was lower at high mass flow rates, the oxide-mixing effect reduced the solidus temperature. Consequently, the apparent viscosity was lower at higher mass flow rates. As a result, the high-mass-flow-rate cases maintained higher momentum and achieved complete spreading across the core catcher. After 120 s, the spreading slowed dramatically in both cases and eventually ceased due to extremely high apparent viscosity. For the low-mass-flow-rate cases, jet discharge had stopped, causing debris to accumulate and form a slope-like dam (Fig. 8(b-5)).

The difference in discharge mass flow rate influenced the circulating melt flow formation within the core catcher and the oxidized material distribution within the molten debris. For the high-mass-flow-rate cases, the melt temperature decreased due to mixing between the circulating low-temperature melt and high-temperature melt from the slope exit. However, the oxide fraction lowered the solidus temperature, maintaining low-apparent viscosity and ensuring fluidity, which allowed the melt to spread throughout the entire core catcher. Meanwhile, for the low-mass-flow-rate cases, insufficient circulation developed due to low inertia, causing the melt to solidify before achieving full spreading. The released melt solidified on the slope, resulting in dam formation. These results demonstrate that the release velocity of molten debris strongly influences its spreading behavior within the core catcher.

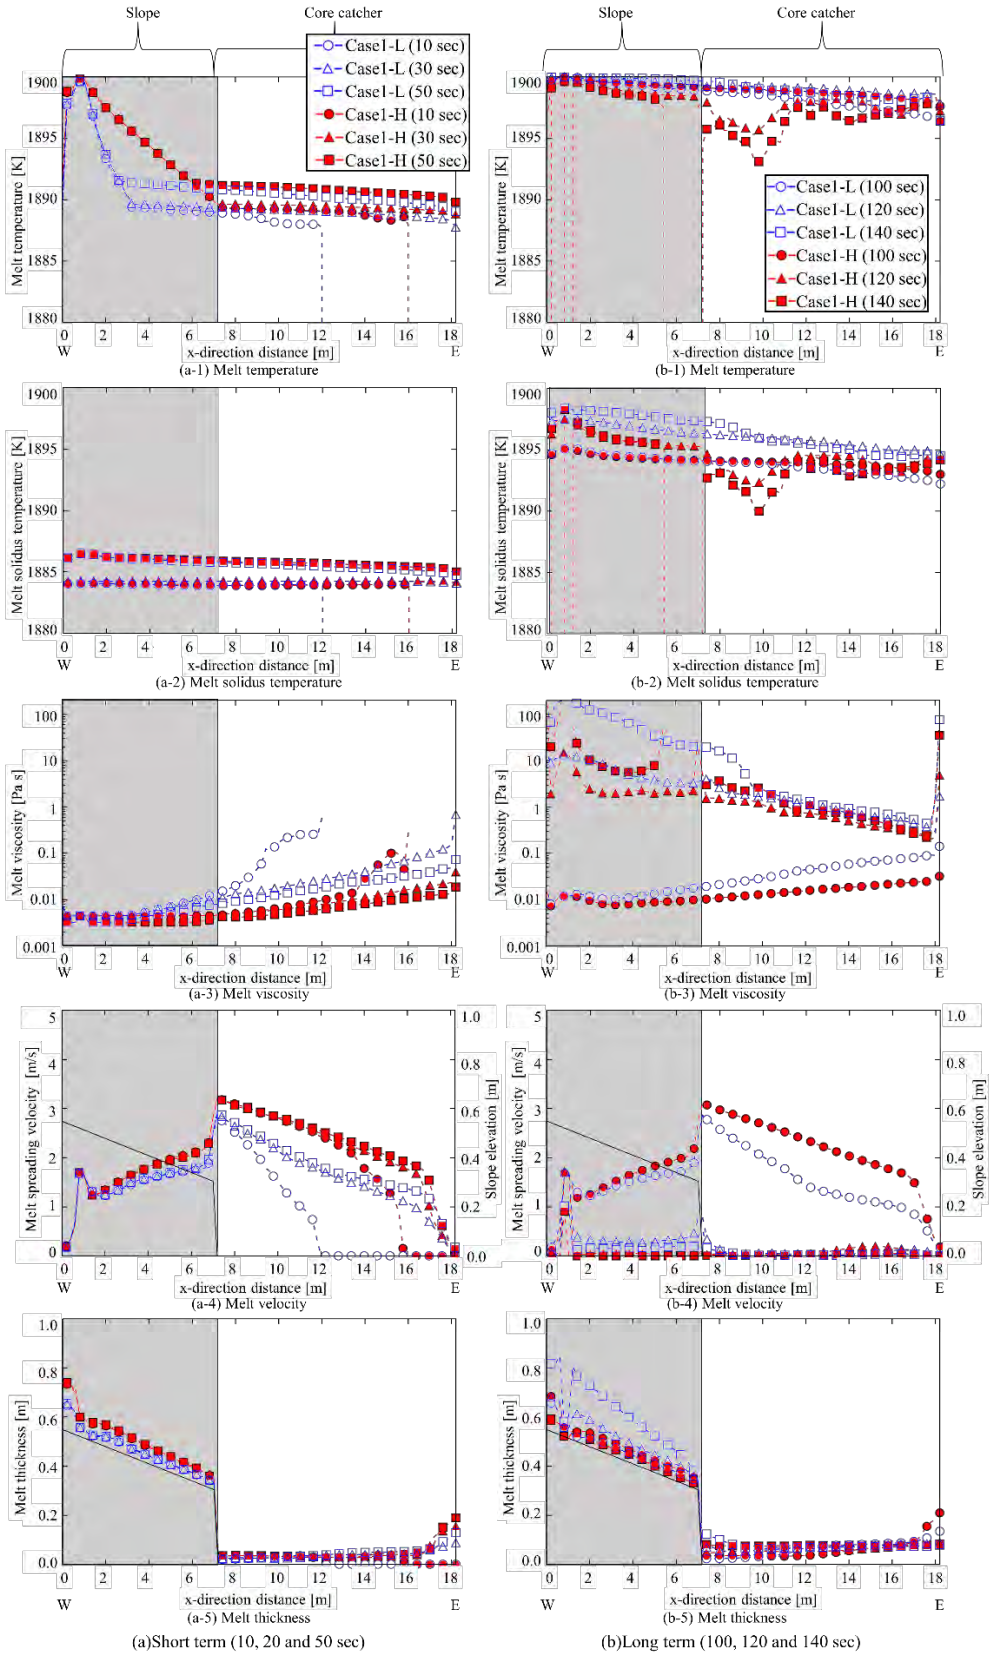

Figure 8. Effects of Mass Flow Rate on Various Parameters in the E–W Cross-Section.

5. CONCLUSIONS

The THERMOS analysis system was applied to a core catcher system representative of the dry cavity strategy. A sensitivity analysis focusing on the molten debris temperature and release rate was conducted to evaluate the debris bed formation process within an EPR-type core catcher under dry conditions. The THERMOS analysis system enabled high-resolution simulation of the apparent viscosity evolution during melt spreading and the convective behavior of molten debris within the core catcher.
The sensitivity analysis results indicated that the temperature of the released molten debris strongly influences its apparent viscosity, which governed fluidity, and was a dominant factor affecting spreading behavior within the core catcher. Furthermore, differences in the released mass considerably impacted the formation of melt circulation flow and the distribution of oxides within the core catcher. At high mass flow rates, the melt temperature decreased due to mixing between the circulating low-temperature melt and high-temperature melt flowing from the slope exit. However, the oxide fraction lowered the solidus temperature, thereby maintaining low-apparent viscosity and enabling complete spreading across the core catcher. Meanwhile, at low mass flow rates, insufficient circulation developed due to low inertia, causing the melt to solidify before full spreading occurred and resulting in the formation of a dam on the slope.
Debris bed formation is a complex, three-dimensional, transient phenomenon that cannot be accurately evaluated using simplified one-dimensional correlations. The THERMOS analysis system demonstrated its capability to address these complexities through coupled modeling of molten jet, melt spreading, and thermophysical property evolution. This study, based on MELCOR analysis results for a representative BWR SBO scenario, assumed a molten debris composition that was predominantly metal-rich with limited oxide content. Future work will include analyses considering the reduction of solidus temperature due to concrete incorporation under conditions dominated by UO_2-rich molten debris.

Background and objectives

Background

- In Japan, the dry cavity strategy utilizing a core catcher is planned for the SRZ-1200 to prevent containment vessel failure caused by a molten core in the event of a severe accident.
- In France, the European Pressurized Reactor (EPR) has begun operation using a dry cavity strategy that incorporates a core catcher.

Objectives

- To investigate debris bed behavior in an EPR core catcher under dry cavity conditions using the **debris bed formation and cooling analysis code :THERMOS developed by the NRA** in Japan.

Overview of THERMOS

MELCOR2

● **Debris release history from the lower head.**

MELTHER

MELCOR2-THERMOS interface soft

- Mapping from the R-Z to the 3D cartesian coordinate system
- Conversion of the multi-phase & multi-material compositions in MELCOR2 to the molten and particle phases of metals and oxides in JBREAK.

Applied in this analysis

: THERMOS modules

THERMOS

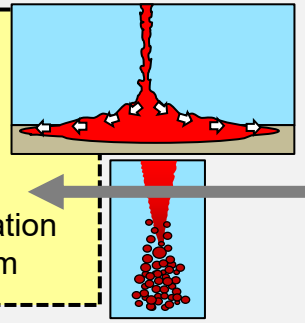
THERMAT

Material libraries

JBREAK

Molten jet falling based on the 3D VOF and particle debris settlement based on Lagrangian method.

- Momentum & energy interaction with the ambient fluids based on the multi-fluid VOF method
- Jet impingement onto the floor considering liquid - solid phase separation
- Settlement in air/water : Particle debris based on the free fall algorithm



Two-way coupling

- Momentum and energy source terms.
- The flow field.

Filtration of the molten jet into the debris bed.

DPCOOL

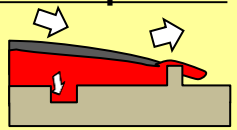
Underwater debris bed cooling.

Local re-melting and solidification in the debris bed.

MSPREAD

Molten debris spreading behavior based on the horizontal 2D shallow water equation

- Molten debris spreading and **solidification** based on the multi-layer models
- Sump / Pedestal slit weir



REMELT

Material interactions and liquid phase filtration in the particle bed.

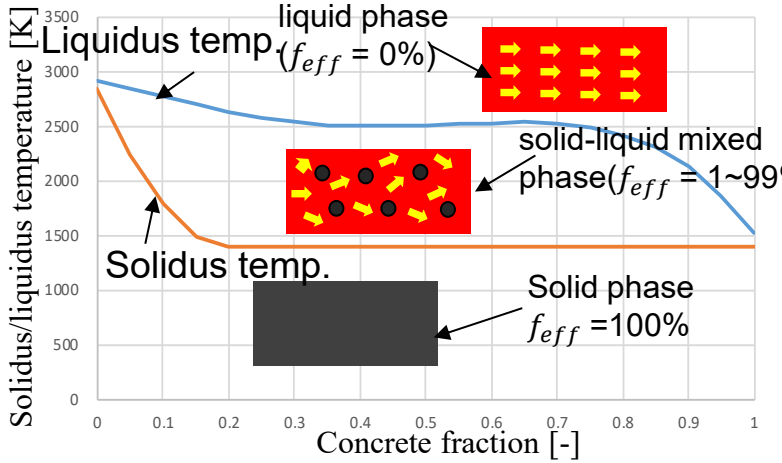
Viscosity model for solidification melt

◆ **Viscosity of liquid phase**

✓ Averaged based on melt composition using Da Andrade model (If melts of UO_2, Zr, etc.)

$$\mu_{liq,m} = 6.12\times 10^{-5}\sqrt{T_{sol,m}}F_{\mu,c}(T)exp\left[\frac{1.8033T_{sol,m}^{1.348}}{R}\left(\frac{1}{T}-\frac{1}{T_{sol,m}}\right)\right]$$

$F_{\mu,c}$: Ratio of gram atomic weight 1/2 to molar volume 2/3
T : melt temp



◆ **Debris apparent viscosity of solid-liquid mixed phase**

As the debris temperature decreases between the liquidus and solidus temperature, a partially solidified dispersed phase is formed and contributes to the increase in viscosity using Ramacciotti model.

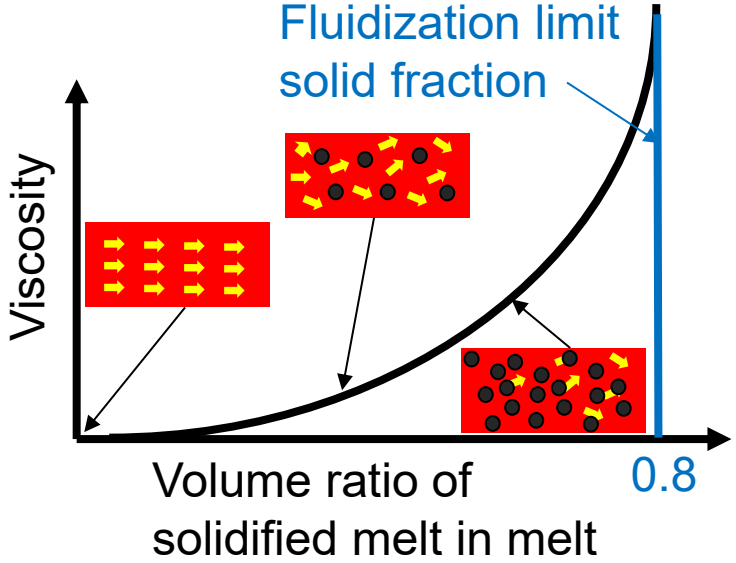
✓ Debris apparent viscosity :μ_{eff}

Ramacciotti coefficient (Sensitivity parameters in this study)

Viscosity liquid phase

$$\mu_{eff} = \mu_{liq,ave}\cdot\exp\left(2.5\cdot C_R\cdot f_{eff}\right)$$

Volume ratio of solidified melt in melt



✓ **Melt spreading terminates** when the volume ratio of solidified melt exceeds Fluidization limit solid fraction (=0.8 in this study).

THERMOS validation results based on dry condition tests

THERMOS (MSPREAD) was in **good agreement with the melt spreading behavior** measured in the dry condition tests such as KATS-12,VULCANO-VEU7, ECOKATS-1 and ECOKATS-2.

Analysis conditions for geometry

- The geometry for THERMOS was modeled based on the publicly available EPR geometry.
- The slope angle was set to 2 degrees.
- It was assumed that the melt jet freely falls the distance of 1.2 m between the melt plug and the slope.
- In these analyses, the sacrificial concrete placed in a core catcher was not considered.

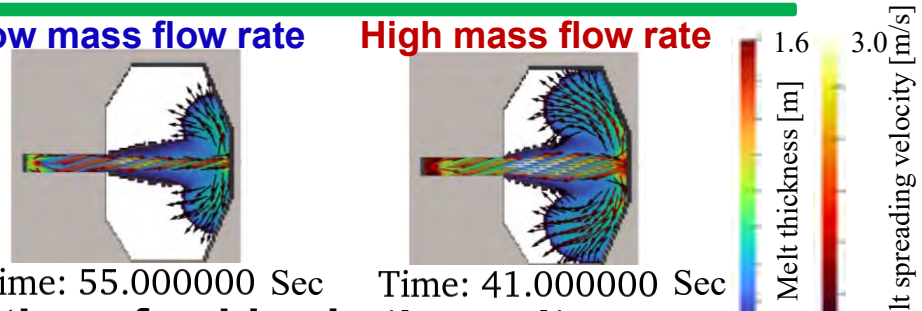
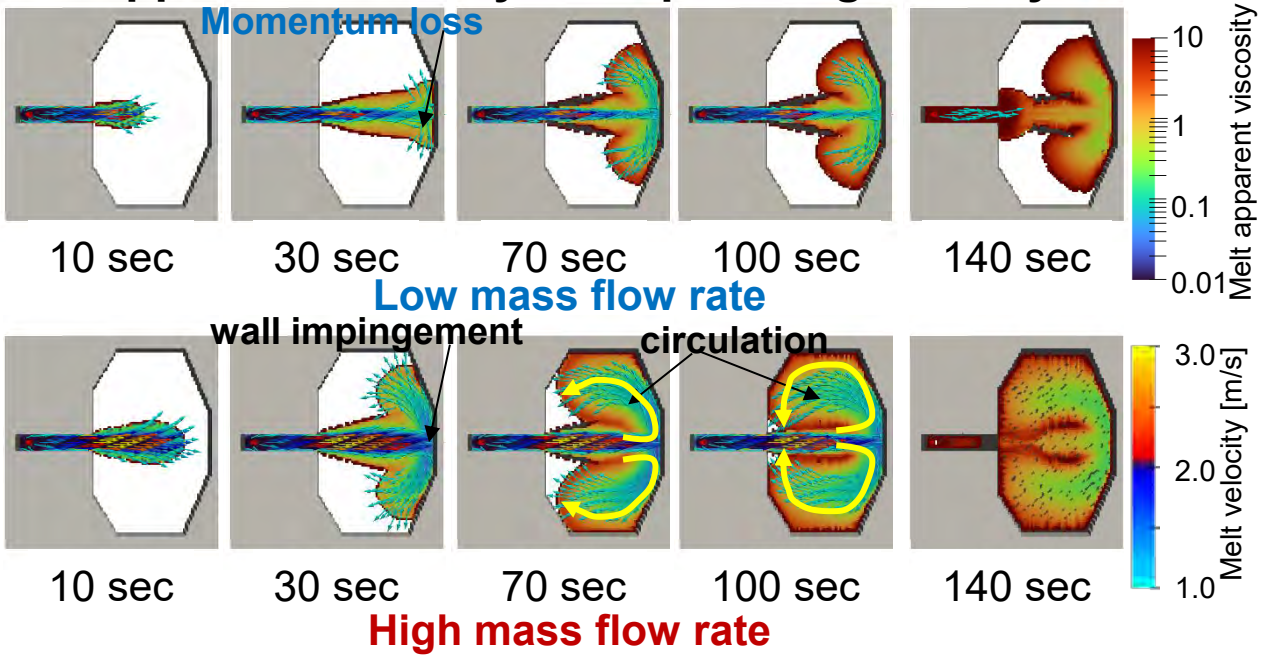
  - ✓**Effect of release flow rate on spreading behavior**
  - ✓Re number evaluation
- ◆Conclusion

Effect of release mass flow rate on spreading behavior under low-temp. conditions

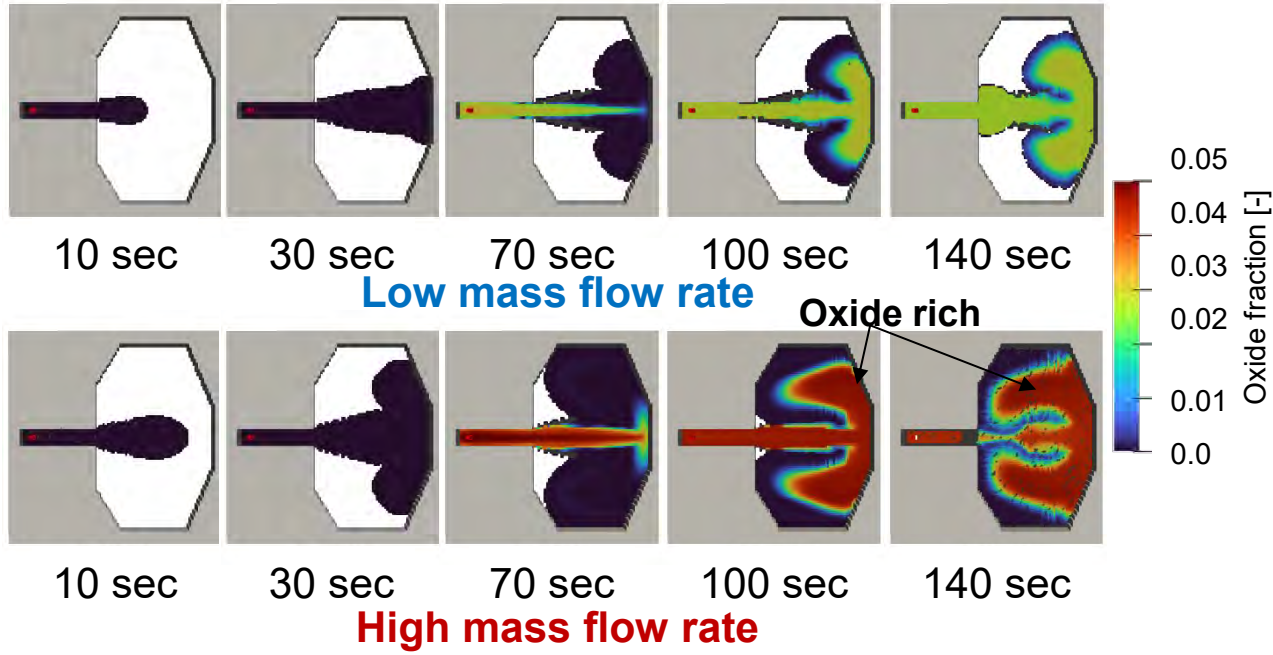
- **At low mass flow rates, melt spreading terminated** under lowest-temperature conditions (1900 K/ 11 K).
- **At high mass flow rates, melt spreading continued** even under the same condition of lowest-temperature (1900 K/ 11 K).



Apparent viscosity and spreading velocity



Mass fraction of oxides in the melt



- **Low mass flow rates:** The combination of **insufficient inertia** and **momentum loss due to wall impingement** suppressed **circulation**, causing **spreading to terminate.**
- **High mass flow rates:** The **large inertia** of the molten debris generated **strong circulation** after wall impingement, enabling **spreading throughout a core catcher**.
  Debris composition also affected spreading: **oxides released after approximately 50 s** were distributed more widely and influenced the **solidus temperatures**.

Experimental study on the interaction between molten corium simulant and Sacrificial Materials

Nan Li, Li Zhang, Erhui Chen, Hongliang Wang, Yidan Yuan*
CNNC Key Laboratory for Severe Accident Research in Nuclear Power Safety,china Nuclear Power Engineering Co., Ltd.
Beijing, 100048, China

ABSTRACT

The ex-vessel retention(EVR) strategy serves as a critical method for the safe containment of molten corium during severe nuclear accidents. Within core catchers, high-temperature molten corium are interacted with sacrificial material, thereby reducing its temperature while promoting the oxidation of reactive metals which helps suppress hydrogen gas generation. This interaction not only increases the overall volume of the molten mixture but also enhances the contact area with the catcher wall, which effectively reduce heat flux on the cooling surface. A new experiment platform called COLOR has been established to carry out experiments on the interaction of molten corium. Pre-experiments were carried out using Fe_2O_3-ZrO_2 mixture as molten corium. The erosion rate of Fe_2O_3-ZrO_2 system was 0.2mm/s which was the same in the ablation front. Furthermore, a simplified heat transfer model was established to evaluate the thermal flux and crust thickness at the crucible wall and the computational results show good agreement with the experimental observations.

KETWORDS

Ex-vessel Retention; Sacrificial materials; Interaction between sacrificial materials and melt

1. Introduction

Severe accident, also termed design-beyond-accident or design-extended accident, refers to a reactor experiencing large-scale melting[1]. To ensure nuclear power plant safety, the design incorporates a defense-in-depth system with three barriers against radioactive leakage: fuel elements, primary circuit pressure boundaries, and containment vessels. The occurrence of such an accident may cause failure of these barriers, leading to the release of molten materials and radioactive substances, which would have the most significant impact on the environment and public health. Therefore, appropriate measures must be implemented to prevent and mitigate such accidents.

The Ex-vessel melt Retention (EVR) Strategy is a critical measure to ensure the core melt is cooled and retained within the containment vessel, thereby maintaining its integrity and preventing the leakage of both the molten material and radioactive byproducts. Sacrificial materials are used in the design of Core Cather to cope with the various needs during melt relocation[2], such as: avoiding transient thermal shocks, lowering melt temperature, diluting volumetric power density, increasing melt mobility, and protecting the cooling channel. The selection of sacrificial materials and verification of their performance is one of the key technologies in the development of Core Catcher.

The selection of sacrificial materials is closely related to their function, which is to interact physicochemically and chemically with the core melt to change the melt pool characteristics and structure. Sacrificial materials include: Sacrificial Metal Sacrificial Material (SSM) and Oxide Sacrificial Material (OSM). The main function of SSM is to reduce the temperature of the mixed system. OSM is the main component of sacrificial materials, usually consisting of oxides of light metals, whose main function is: 1) to oxidize the active metals in the melt so as to minimize the production of hydrogen. 2) to reduce the density of the melt until inversion occurs (metal layer below, oxide above) to avoid thermal focusing effects. 3) to reduce the temperature of the melt and the liquid phase line temperature after mixing with it. 4) to minimize the production of the non-condensable gases 5) to prevent the re-criticality of the melt.[3-5]

During a typical severe accident of VVER[6], when the pressure vessel sidewall is broken, the molten corium fall into the CC, interacting with the sacrificial material. The oxides in the sacrificial material melt rapidly, increasing the volume of the melt and effectively reducing its heat release rate. Meanwhile，active metal in corium (such as Zr,Cr) are oxidized and rise to the surface of the melt to form solid crust. Through corium-sacrificial material interaction, the density of the oxide melt is reduced and finally lower than that of the metal. The inversion of the metallic layer and oxide layer occurs[7-8].

The interaction experiments between sacrificial materials and molten materials have been extensively researched[9-11]. The properties of mixtures of U-Zr-O-Fe have been studied and the phase diagram of mixture system has been redrawn by Bechta. S.M. An [12]conducted experiments to investigate the erosion characteristics of zirconia melt on various materials and derived the corresponding calculation formulas.A model of interaction has been developed based on the experiment SACR-8 and SACR-9[13]. This model assumes the chemical reaction and generation of heat happens in a reaction layer adjacent to the SM surface. In addition, according to the results of the experiments, the velocity of interaction front is approximately constant. It does not depend on the concentration of Zr if the

concentration of Zr is higher than 5 mass%. VESTA was used for the jet impingement experiments, which verify the convective heat transfer model that estimates the ablation rate of special concrete more reasonably even though some water content in the material may result in a radiation heat transfer through the suddenly created steam layer[14].KAERI also set up an experiment to research the ablation characteristics of the concrete[15].

In order to study the interaction process between the molten material and the sacrificial material, the interaction experimental platform—COLOR platform was built. The simulation experiments of the interaction between the molten material and the sacrificial material were carried out on the COLOR platform, and the molten erosion rate were obtained. Furthermore, a simplified heat transfer model was established to evaluate the thermal flux and crust thickness at the crucible wall and the computational results show good agreement with the experimental observations.

2. New experiment platform—COLOR

The platform can melt 20kg molten corium and conduct melt-sacrificial interaction test, molten pool temperature and ablation rate measurement. The schematic of experiment facility is shown in Figure 2.1. The platform consists of a furnace vessel, a cold crucible, a corium heating system including a high-frequency power supply, an induction coil and an inverter, a temperature measurement system, and a control system, a cooling system for removing the heat generated in the cold crucible, the induction coil, and the high-frequency power supply.

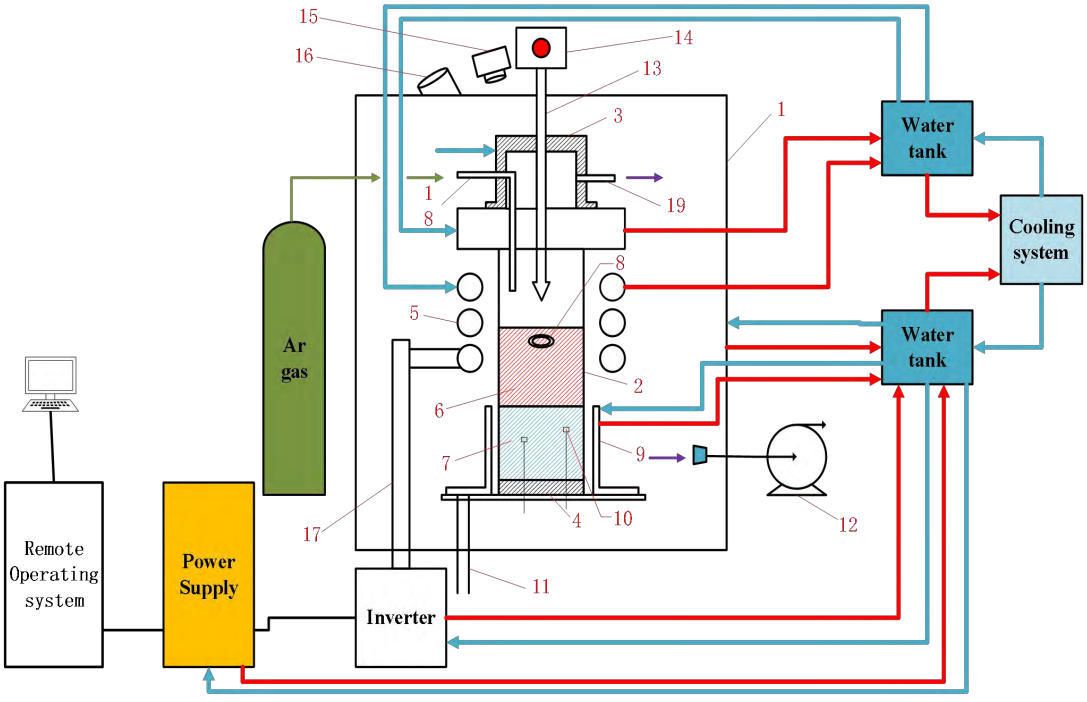

Figure 2.1 A schematic of COLOR facility.
1-furnace vessel; 2-cold crucible; 3-crucible lid; 4- water cooled bottom; 5-induction coil; 6-molten corium; 7-sacrificial material; 8-metal ring; 9-shielding; 10- thermocouples; 11-lifter; 12-vacuum pump; 13-thermometer tube; 14-infrared pyrometer; 15-camera; 16-window; 17-coaxial electrodes; 18-inlet; 19-outlet

The furnace vessel uses double-layer stainless steel structure with cooling water, which protect the cold crucible and guarantee high vacuum environment and structural stability. Observation windows and video cameras are provided to observe the situation in the cold crucible during the experiment. The cold crucible has dimensions of 160 mm in diameter and 600 mm in height, which is made by copper pipe (Figure 2.2). Cold water is allowed to flow into each tube to cool down the interface between the melt and tube to maintain a solid boundary surrounding the melt. The crucible wall can be divided into two half so that the material could be discharged easily after the test. Crucible water jacket collects the multi-channel cooling water of the crucible wall and connects to the cooling water system through the main channel.

The high-frequency power supply is designed to have a capacity of 200kW and 150kHz in frequency, melting temperature can reach more than 2800°C. Induction coil can move up and down to heat different areas, ensuring that the material is fully melted. The shielding device is located in the lower part of the crucible to prevent sacrificial materials from being heated by induction as well as electromagnetic interference to the thermocouples.

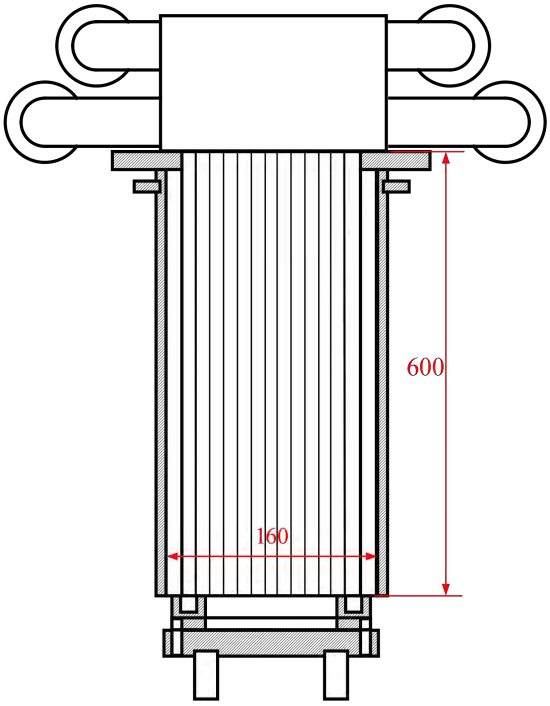

Figure 2.2 The structure of cold crucible

The melt temperature is monitored by infrared thermometer and it has a temperature range of 1000-3200 ℃ within ±0.5% error. A thermometer tube whose head is made by tungsten is arranged above the crucible and extends into the furnace through a vacuum seal to measure the temperature of the molten pool. Tungsten head is used to break up the hard shell that may exist on the surface of the molten material in order to measure the temperature of the molten pool. The velocity of ablation are obtained by thermocouples embedded in the SM[1,13]. The specific assumptions are as follows: firstly, set a point (x0,y0,z0) and a moment (t0) that the interaction begins,Secondly, record the position of the i-th thermocouple (xi, yi, zi) and the moment of corrosion(ti) when its temperature has a sharp increase.

The ablation rate W can be calculated using the following formula:

$$W = \frac{\sqrt{(x_i - x_0)^2 + (y_i - y_0)^2 + (z_i - z_0)^2}}{t_i - t_0} \quad (1)$$

The primary component of molten corium is ZrO_2. Since ZrO_2 is non-conductive at room temperature, electromagnetic induction heating is not feasible. Therefore, a conductive circuit is formed by embedding metal ring into ZrO_2. The metal is first heated by a high-frequency power source. At high temperatures, the oxidation of the metal generates heat, raising the temperature of the surrounding oxide to the conduction temperature.

3. Pre-experiment on the interaction between molten corium simulant and Sacrificial Materials

3.1 Pre-experiment of ZrO_2 -Fe_2O_3

The pre-experiment uses Fe_2O_3 powder as SM and ZrO_2 powder as the molten corium. Fe_2O_3 powder was loaded at a height of 22.5cm for the lower layer, while ZrO_2 was loaded in both lump and powder forms at a height of 20cm for the upper layer. The middle of the induction coil is arranged as high as the top surface of ZrO_2 and it was gradually moved down to heat up the ZrO_2.The initial position of shielding device is at the upper surface of Fe2O3 layer. In order to calculate the ablation rate, Type K thermocouples are arranged at different locations in the sacrificial material. The specific scheme is shown in Figure 3.1.

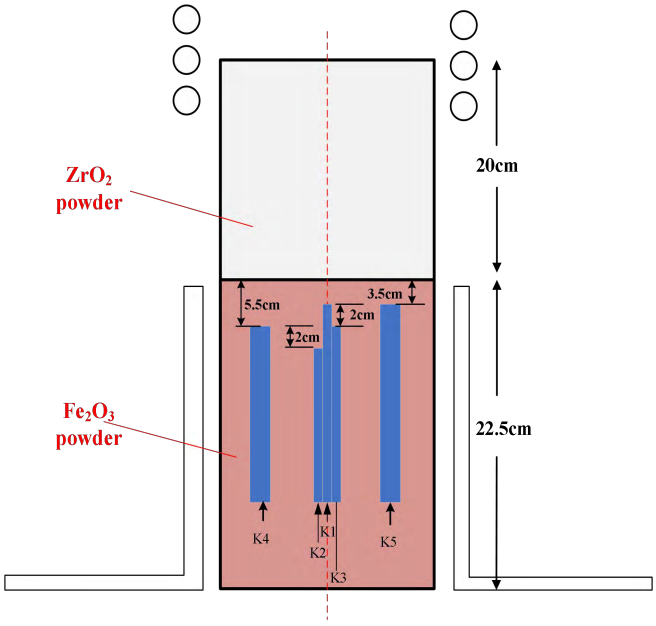

Figure 3.1 The distribution of material and facilities in the Preliminary experiments of ZrO_2 -Fe_2O_3

The experiment lasted approximately 30 minutes. Initially, the heating power was incrementally increased in a stepwise manner to monitor the melting process of the molten material. The coil is moved down by 4cm at 800s and 1160s; the shielding moves down and the ablation starts at 1600s.

After the experiment, open the crucible and analyse the ingot. The result are shown in Figure 3.2, which also gives the initial position of the Fe_2O_3 layer and the ZrO_2 layer. The corrosion depth of

Fe_2O_3 is 9cm and the ablation front is almost flat which proves the axial ablation rate is the same in the ablation front. Iron oxide powder remains unmelted at the bottom of the crucible. Figure 3.3 proposes the internal structure of the test section. A cavity is formed above the oxide ingot. Since ZrO_2 powder is used in the experiments, there are a large number of pores within the ZrO_2 layer. ZrO_2 increases in density during heating. Both of these points lead to the decrease in volume of the material. In addition, the ablation of ZrO_2 and Fe2O3 also leads to the decrease the volume of the material. So the large cavity is formed. In the melting process, the melt is cooled by the crucible sidewall and oxide crust is formed. The main components of oxide ingots are ZrO_2 and $Fe2O_3$. It indicates that ZrO_2 has been melted and has corroded with Fe_2O_3.

Figure 3.2 The results of Fe_2O_3-ZrO_2 test section
1-initial position of the top surface of ZrO_2 layer;2-initial position of the top surface of Fe_2O_3 layer;
3-ablation front; 4-unmelted Fe_2O_3

Figure 3.3 The internal structure of the test section
1-oxide crust; 2-cavity; 3-oxide ingot; 4-ablation front

Type K thermocouples are used in the experiment and the highest measured temperature are 1300°C which would be recorded as the arrival of the ablation. All thermocouples are damaged. The thermocouples readings during the experiment are shown in Figure 3.4. The temperature of thermocouples is about 100°C before shielding device is moved down. Correspondingly, the temperature of the thermocouples begin to rise until the thermocouples are damaged.

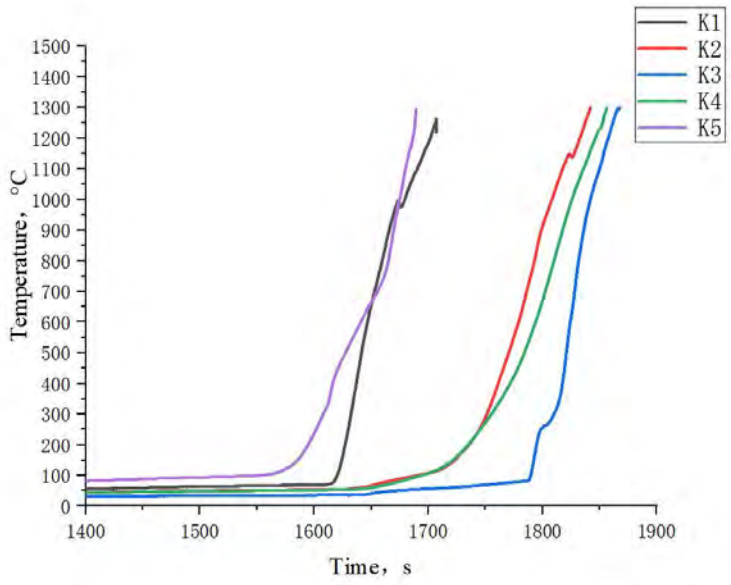

Figure 3.4 Temperatures measured by thermocouples during the pre-experiment

Damage time of the thermocouples are planned to calculate the ablation rate W. However different types of thermocouples have the different time for damage process, heat-up time which means the time when the thermocouples start to heat up are used to calculate the ablation rate W. All of them are shown in Table 1. The average ablation rate is 0.19mm/s

Table 1 Damage time and Heat-up time of the thermocouples

Thermocouples	Damage time /s	Time for Damage process /s	Heat-up time /s	Distance to the top of Fe_2O_3 layer /mm
K1	1707	87	1620	35
K2	1842	127	1715	55
K3	1867	80	1787	75
K4	1856	146	1710	55
K5	1689	111	1578	35

The changes of current and heat power in the test are shown in the Figure 3.5. At the start of the test, the power is increased in steps to 75kW. At 400~800s, the current drops which means the ZrO_2 powder begins to melt. Because the conductivity of the melt increases after melting, a magnetic field in the opposite direction of magnetic fields generated by high-frequency power sources is generated in the melt (Lenz's Law). Figure 3.6 shows the heat power and heat loss during the heating process over time. The total heat loss includes the heat loss from the crucible wall, crucible base, power supply, and coil.

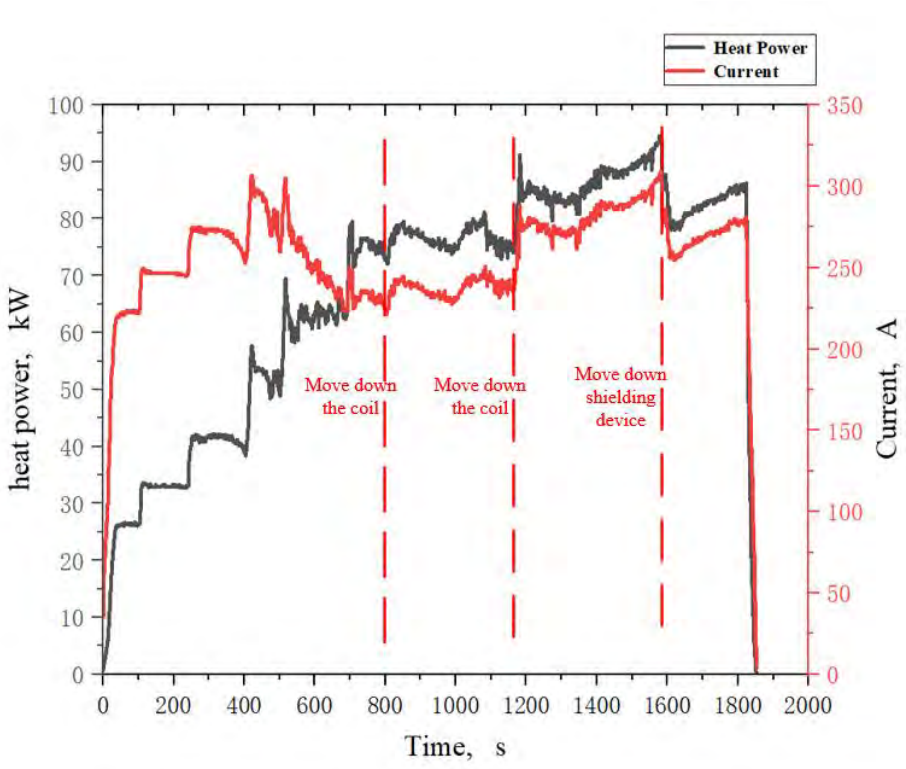

Figure 3.5 The profile of current and heat power during the heat process

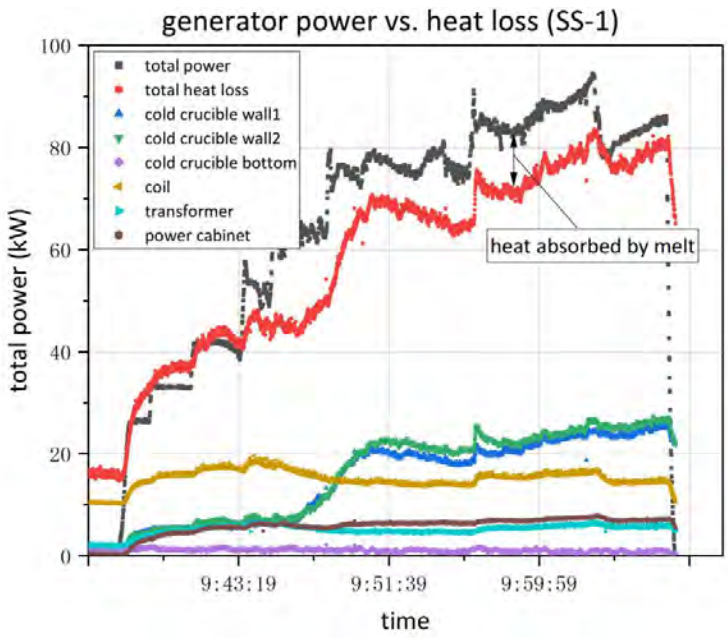

Figure 3.6 heat power and heat loss during the heating process

3.2 Pre-experiment of ZrO_2 and Sacrificial Materials

After completing the pre-experiment with Fe_2O_3 and ZrO_2, the experiments with ZrO_2 and sacrificial materials commenced. The composition of the sacrificial material placed in the lower layer is Fe_2O_3-Fe_3O_4-Al_2O_3. A layer of 3cm thick zirconia powder is laid on the bottom of the sacrificial material to prevent the molten material from flowing out of the crucible through the gap between the sacrificial material and the crucible. The upper layer is filled with 20cm high zirconia powder, and the total mass is 10.2 kg. The setting of material and facilities is shown in Figure 3.7.

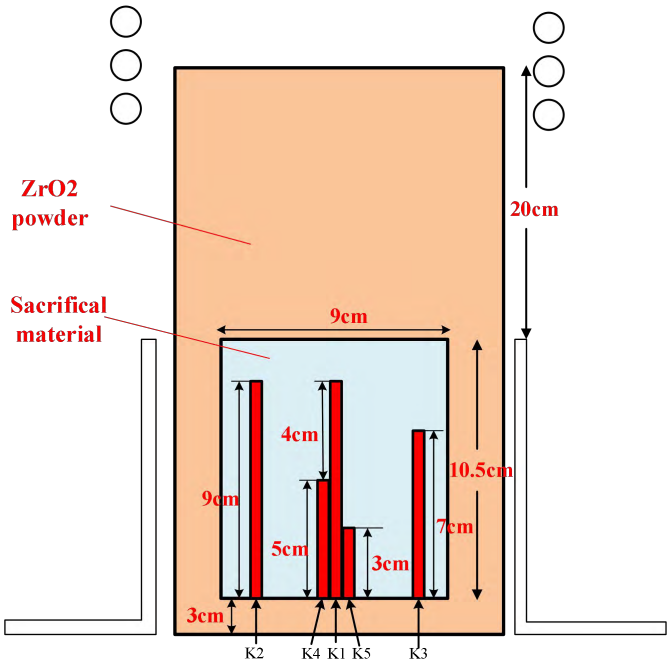

Figure 3.7 The setting of material and facilities in the pre-experiment of ZrO_2 and SM

The experiment results after disassembly and drying are shown in Figure 3.8. The erosion depth of ZrO_2 on the sacrificial material is 6 cm, the cavity is formed on the top of the ingot, and 2 cm crust is formed on the inner wall of the crucible.

Figure 3.8 Results of ZrO_2-sacrificial material experiment
1-initial height of ZrO_2 layer, 2-initial height of SM, 3-ablation front, 4-unmelted SM, 5-cavity, 6-crust

Based on experimental data, a simplified heat transfer model for the molten pool-crust-cooling water system was established (Figure 3.9), with the following assumptions:

1) The cooling water flow rate is the same for each copper tube.
2) Only the molten region is in contact with the external environment during the heating process.
3) The heat transfer between the crust and the cooling water is turbulent forced convection.

The thickness of the crust is calculated with formula (2),(3),(4). The thickness of the crust is 1.92cm, which is 4% different from the actual measurement.

$$q=h(T_w-T_0) \tag{2}$$

$$Nu=0.023Re^{0.8}Pr^{0.4} \tag{3}$$

$$q=k(T_m-T_w)/d \tag{4}$$

where q is the heat flux from the hard shell of crucible wall to coolant, h is the convective heat transfer coefficient, T_w is the temperature of the outer wall of hard shell, T_0 is the temperature of coolant, Nu is the Nusselt number, Re is the Reynolds number, Pr is the Prandtl number, k is the thermal conductivity of hard shell, d is the thickness of hard crust, T_m is the temperature of inner wall of hard crust.

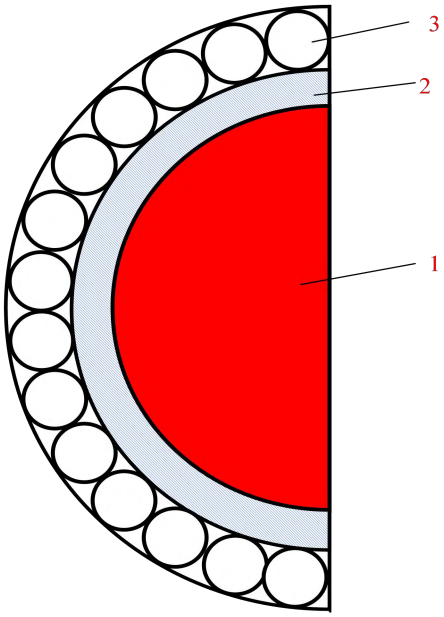

Figure 3.9 Heat transfer model for the molten pool-crust-cooling water system
1-molten pool, 2-crust, 3-water flow path

4.Conclusion

This paper introduces the new platform built COLOR for the melt interaction with sacrificial material.Two sets of preliminary experiments were completed on this experimental bench. The erosion rate of Fe_2O_3-ZrO_2 interaction was 0.2 mm/s. A simple heat transfer model of molten material, hard shell and cooling water was established, and the theoretical calculation value of the edge wall hard shell was obtained, which was 4% different from the experimental results.

Further experiments will be conducted to investigate the interaction between molten materials and sacrificial materials. Based on experimental data and conclusions, a model for molten-sacrificial material interactions will be developed. This model will be utilized in specialized analysis programs for severe accidents to simulate molten material behavior and the interaction processes within the core catcher.

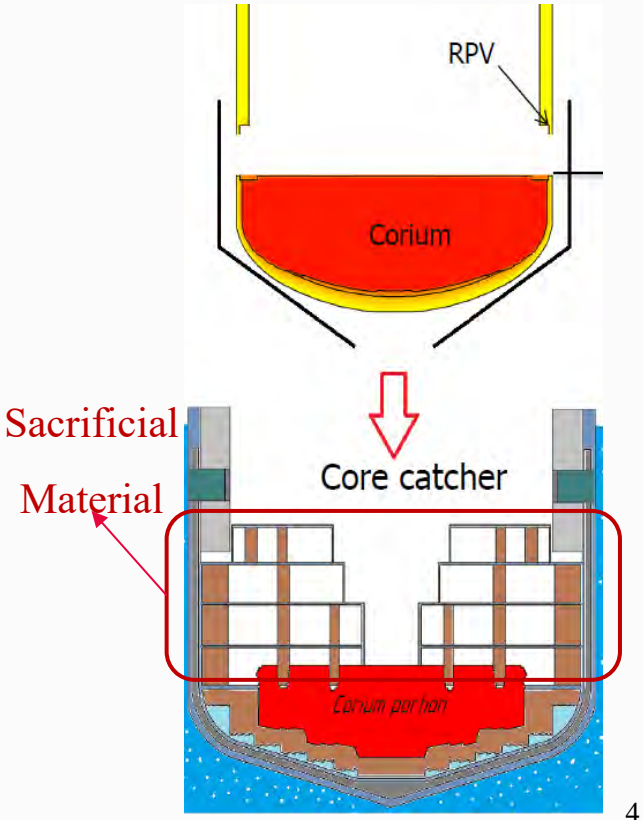
1.Background

- Ex-vessel retention
  - Use core catcher (CC) to cool and retain core melt when the pressure vessel fails in a serious accident
- Sacrificial material (SM)
  - High-temperature (2800℃) core melt would cause threat to the CC and containment through MCCI
  - Arranged Sacrificial material to change status of the core melt to keep integrity of the CC
  - SM plays an important role in stabilization and long-term cooling of the core melt for the CC



1.Background

Primary functions of SM

dilution of the core melt

- to decease the temperature and volumetric power density of the core melt

lower the liquidus temperature of the molten pool (melt-sacrificial material mixture)

- to ensure chemistry reaction and convection mobility

ensuring the metallic phase underneath the oxide

- to avoid heat flux focusing and hydrogen generation

oxidize as much active metals (U、Zr、Cr) as possible

- to prevent possible hydrogen generation when encountering with water

reducing concentration of fission products and ensuring subcritical of the melt

Objective

In order to test the properties of the Specifically designed sacrificial material and investigate interaction mechanisms between corium and sacrificial material.

Test ID	PT-1	PT-2	PT-3	PT-4	PT-5
Atmosphere	Air		Argon		
SM composition	Fe_2O_3	Fe_2O_3, Al_2O_3	Fe_2O_3, Al_2O_3	Fe_2O_3, CaO	Fe_2O_3, SrO

COLOR facility

2. COLOR facility

COLOR（COLd crucible for cOrium behavior Research）

Induction-melting facility for prototypic oxidic melts up to 2800° C

Examples of application

- Interaction of corium - concrete / sacrificial material
- Selection of concrete / sacrificial material
- Transient tests for metallic / oxidic melts

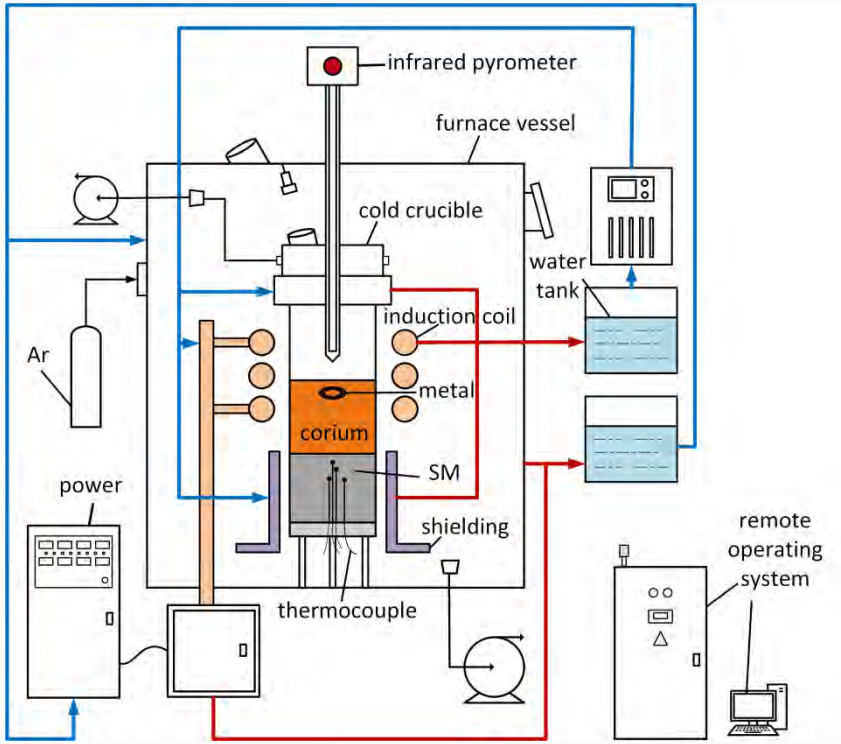
Principle

- Cold crucible, high frequency induction heating

Technical parameter

temperature:	up to 2800° C
melt mass:	1 - 20 kg
frequency range:	1 – 150kHz
maximum power:	200 kW

2. COLOR facility



Main data
- **Temperature of melt**
- **Ablation rate**

1. vacuum chamber: provide environment

Conclusion and Future works

4. Conclusion and Future works

- A platform COLOR has been built for studying the core melt behavior. It enables the melting of a 20 kg melt, with temperature over 2800° C.
- Pre-test on the interaction between simulant and Sacrificial Material have been completed and the ablation rate of PT-1 is 0.19 mm/s.。
- More experiments will be conducted to investigate the interaction between prototype melt and new sacrificial materials.

ABSTRACT

The molten corium interaction with the coolant in the reactor cavity may produce a violent steam explosion thus this can be an additional risk of containment failure in pre-flooding strategy during a nuclear reactor severe accident. The amount of corium jet breakup in a pre-flooded reactor cavity is affected by the depth of water pool. As a correlation approach in estimating the amount of jet breakup, two jet breakup length models of Saito et al. and Epstein & Fauske were assessed for selected FARO test data and found that both models significantly overpredicted the debris mass. A new model for jet breakup length has been proposed based on the Kelvin-Helmholtz instability for melt-steam-water interfaces. The prediction of debris mass of FARO tests was significantly improved by the new model. From the analysis of pre-flooded PWR cavity using the new jet breakup length model, it was found that for 30 cm diameter jet, the fraction of debris mass was less than 40% in a 4 m deep pool. The rate of jet breakup and the particle size are greatly influenced by the vapor film thickness between the hot melt and the coolant water. An analytical model for estimating the vapor film thickness on vertical plate encompassing subcooled liquid has been developed based on the assumption of laminar boundary layer flow. The solution of the model revealed various film boiling parameters such vapor film thickness, vapor velocity profile and heat transfer rate from the hot surface as well as to the subcooled liquid. For high superheat of 2000 K case, the laminar assumption seemed not valid due to high vapor velocity. To overcome the shortcoming, a turbulent model is to be developed in the future.

KEYWORDS
Severe accident, Steam explosion, FCI, Jet breakup, Film boiling

1. INTRODUCTION

In light water reactors (LWRs) if the coolant supply in the reactor coolant system becomes insufficient or even stops, the reactor fuel overheats, melts, and then relocates into the lower plenum of reactor vessel. The molten core in the reactor vessel lower head may threaten the vessel integrity and when the vessel lower head fails the molten corium can be released and accumulated on the concrete floor of the reactor cavity. If the cavity is dry, the molten corium ablates the concrete floor, so-called an MCCI (Molten Core Concrete Interaction) occurs and there is a potential risk of concrete base mat penetration.

There has been a study that has proposed that water addition on the corium pool in the cavity can enhance the cooling of the corium, thus reduce the risk of MCCI significantly [1]. This post-flooding strategy, however, relies on the complex mechanism of water ingression through the cracks in the solidified crust, thus the success probability of corium cooling can be marginal.

One other option is to flood the reactor cavity before the reactor vessel fails. In this case, the released molten corium jet interacts with water coolant in the cavity and breaks up into small particles, then forms particle debris bed on the cavity floor. The risk of MCCI in this case is speculated lower than that of a dry cavity, although this cannot be completely assured due to remaining uncertainties in the ex-vessel FCI and debris bed coolability. Besides, the molten corium interaction with the coolant in the cavity may produce a violent steam explosion thus this can be an additional risk of containment failure in this pre-flooding strategy.

One of the important lessons learned from the past severe accidents (Fukushina-1, Chernobyl) is that the maintaining the reactor containment integrity is a crucial aim during a severe accident to protect the public from radiation hazard. Despite the MCCI can be a cause of containment failure in a long-term phase, the steam explosion can be a cause of early containment failure when the amount of fission product source term inside the containment is relatively high. This may imply that an early containment failure must be prevented and a severe accident management action should be focused on preventing the early containment failure. In this respect, the timing of water addition is important in the severe accident management perspective.

When the pre-flooding strategy is chosen for severe accident management action, the risk of an energetic Fuel-Coolant Interaction (FCI) should be assessed. An FCI is a highly complex, multi-physics process involving molten fuel jet and droplet breakup, as well as heat and mass transfer among the hot molten fuel, liquid coolant, and coolant vapor. It is sometimes referred to as a "thermal explosion," driven by the rapid transfer of thermal energy from the molten fuel to the coolant, leading to the instantaneous vaporization of the liquid coolant. The resulting high pressure propagates through fuel-coolant mixture, causing fine fragmentation of molten fuel droplets into particles smaller than 0.1 mm [2]. This drastic increase of heat transfer surface area is considered the primary driving force for explosion propagation through the fuel-coolant mixture. The elevated pressure then expands against surrounding structures, potentially causing damage depending on the explosion's intensity.

In the OECD/NEA international program SERENA, FCI has been studied with a particular focus on evaluating the capabilities of computational codes to predict FCI-induced dynamic loads on reactor structures. In the first phase of the SERENA project [3], predictions from various FCI codes were compared against experimental data. The comparison revealed that the codes were still unable to reproduce all observed attributes with the same level of accuracy and also that a large uncertainty exists in the prediction of coolant void fraction and corium jet breakup.

The prediction of melt jet breakup is important not only because the rate of jet breakup and resulting droplet size affect significantly the energetics of steam explosion, but also because the amount of fragmented melt mass and the drop size affect the coolability of debris bed on the concrete floor. The physical mechanisms of melt jet breakup include the Rayleigh-Taylor instability, boundary layer stripping, and the Kelvin-Helmholtz instability, as depicted in Fig. 1 [4]. It is noted that the left hand-sided figure for boundary layer stripping in Fig. 1 shows only the leading edge and broken drops of a cylindrical jet from the post-processing of a CFD result. Most FCI codes [5-8] have its own modeling approach on jet breakup, but those models tend to involve a complex numerical algorithm or to assume a continuous process for the cyclic nature of jet breakup process.

One of the simple, but semi-empirical models is called jet breakup length model. The distance of melt jet traveling to a point of complete breakup is called ‘jet breakup length’ and there have been a few studies on building a semi-empirical relation of the jet breakup length: Saito et al [9], Epstein and Fauske [10]. An

Figure 1. Illustration of jet breakup at leading edge by boundary layer stripping (left) and at lateral surface by Kelvin-Helmholtz instability (right)

experimental work by Bang et al. [11] using cold Woods metal reported that the Epstein and Fauske correlation is more suitable than Saito's for the high-temperature corium jet breakup.

In this paper, the level of accuracy of the existing jet breakup length models are evaluated for some selected FARO tests [12]. Also, an advanced, theoretically-based model for jet breakup length is proposed and evaluated using the experimental data. Based on the new jet breakup length model, the mixing limit of corium jet pouring into pre-flooded reactor cavity is discussed. Finally, a numerical model for predicting vapor film thickness is presented.

2. JET BREAKUP LENGTH

2.1. Evaluation of Existing Models for Jet Breakup Length

As introduced in the previous section, there are two major models for jet breakup length: Saito et al. [9] and Epstein & Fauske [10]. Saito et al. conducted experiments using 90°C water jet injected into Freon-11 pool at temperature ranging from 2 to 23.2 °C, or alternatively, a 10 to 19 °C water jet injected into a liquid-nitrogen pool at −195.8 °C. The water jet diameter was in the range of 5 to 40 mm and jet velocity was in the range of 2.5 to 15 m/s. They confirmed that instabilities were generated due to the vapor flow occurring between the jet and the cooling liquid. As a result, the jet was fragmented and the vapor-enshrouded jet penetrated further into the coolant. They observed that the jet penetration length increased with increasing jet velocity, jet diameter, and the density ratio between the jet and the coolant. Based on the energy balance between the two fluids, an experimental correlation for the jet penetration length was developed as a function of jet diameter, density ratio of jet and coolant, and Froude number of the jet.

$$\frac{L_{brk}}{D_j} = 2.1\left(\frac{\rho_j}{\rho_c}\right)^{0.5} Fr^{0.5},\ Fr = \frac{V_j^2}{gD_j} \tag{1}$$

Epstein and Fauske examined the mean entrainment velocity at the leading edge of a turbulent flow based on Taylor's earlier hydrodynamic study of a hot turbulent gas plume rising in air. Taylor assumed that the entrainment velocity is proportional to the time-averaged cross-sectional velocity of the turbulent flow. This proportionality constant was experimentally defined as the entrainment coefficient and was assumed to have a value of 0.1. Epstein and Fauske assumed that the amount of fragment stripped from the jet into the surrounding fluid along the jet side surface is constant, and they considered the rate of fragment mass reduction to be proportional to the difference between the velocity of the flow field and the instantaneous accelerated velocity of the fragments. Under this assumption, the jet breakup time can be derived from a

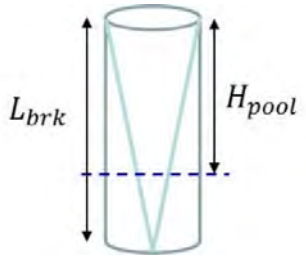
[Note] (1) Melt composition: UO_2+ZrO_2 (80%+20%), (2) Based on melt density=7300 kg/m^3

force balance between the kinetic energy of the fragments undergoing breakup and the kinetic energy of the surrounding fluid. Using this jet breakup time, the relationship of jet breakup length was developed.

$$\frac{L_{brk}}{D_j} = \frac{1}{2E_o}\left(\frac{\rho_j}{\rho_c}\right)^{0.5} \tag{2}$$

The constant ranging from 0.05 to 0.1 was recommended for E_o. It is noted that the Epstein & Fauske correlation is independent of jet velocity, but a function of density ratio of water and corium. This model is based on the entrainment concept caused by the Kelvin-Helmholtz instability and it does not account for the condition of hot melt undergoing film boiling at the melt-coolant interface.

In order to assess the validity of these two models for hot corium-water interactions, selected FARO test data [12] were applied to the correlations. The jet breakup process is assumed to have a conical shape, as shown in Fig. 2. If the water pool depth is smaller than the estimated jet breakup length, the fraction of melt that remains as an unbroken "cake" can be approximated as the ratio of the cross-sectional area of the unbroken portion of the jet to that of the initial jet at the cavity floor level. The relationship between the debris mass fraction, water pool depth, and jet breakup length is given in Fig. 2.



$$\alpha_{debris} = 1 - \left(\frac{D_o}{D_j}\right)^2 = 1 - \left(1 - \frac{H_{pool}}{L_{brk}}\right)^2$$

Figure 2. Relation for fraction of debris mass broken from conical jet

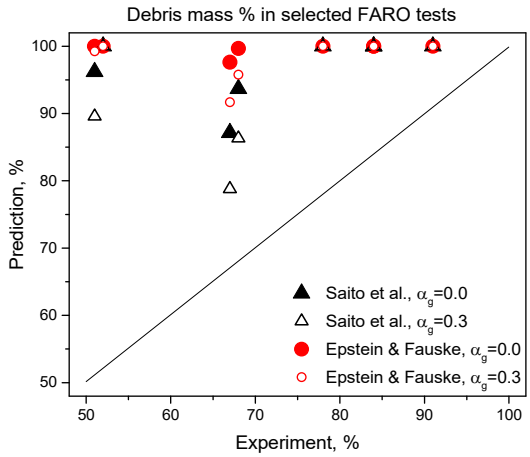


Figure 3. Comparison between the prediction of jet breakup length model and experimental data

The major experimental conditions and the calculation results of selected FARO tests are summarized in Table 1. The comparison of the prediction and the experimental data for the fraction of debris mass is shown in Fig. 3. In the FARO tests, the fraction of debris out of the total corium mass ranged from 51% to 92%. But, as shown in Fig. 3, both the two correlations of jet breakup length greatly overpredicted the debris mass and in more than half the test cases the predictions indicate 100% jet breakup.

The effect of void in coolant pool was also examined by assuming 30% void. This could be the case when melt pouring time was longer so that the melt jet continued to pour after the coolant became a two-phase pool by coolant boiling. As for the tests L-28 and L-33, larger mass of corium with smaller jet diameter results in melt jet length much longer than the coolant pool depth: 1.44 m coolant pool depth v.s. 12.2 m melt jet length in L-28 test. The estimated melt jet lengths are given in Table 1 for comparison purpose. The mean density of liquid and vapor was replaced for the coolant density and the results are listed in Table 1 and also marked by open symbols in Fig. 3. The void fraction of 30% can lower the coolant density to 70% of pure liquid and this level of reduction in liquid density does not alter the jet breakup length by a significant amount.

It is noted that the present estimation of debris mess using the jet breakup length model did not account for re-melting or agglomeration of particles. Re-melting of particles can occur if the solid particles are surrounded by highly superheated melt or the decay heat is higher than the heat loss rate from the particle. The later case of decay heat is not relevant in FARO tests, but the re-melting by contacting superheated melt could occur. Unfortunately, however, this can not be identified since only the posttest data are available.

2.2. Theory of Advanced Jet Breakup Length Model

Epstein and Fauske [13] also proposed a formulation of Kelvin-Helmholtz instability for melt-steam-water system which may represent the hot melt undergoing film boiling. However, the solution of the dispersion equation involves complex numbers so that an analytical expression of the fastest growing wave number could not be obtained. They were able to show only the two limiting cases where analytic solutions can be obtained; thin film and thick film. The fastest growing wave number and the associated maximum growth constant for these two limiting cases are:

For thin film:

$$k_{D,o} = \frac{2\,\rho_j\,\rho_l\,(V_l - V_j)^2}{3(\rho_j+\rho_l)(\sigma_j+\sigma_l)} \tag{3}$$

$$n_{D,o}^2 = \frac{\rho_j\,\rho_l k_{D,o}^2\,(V_l - V_j)^2}{(\rho_j+\rho_l)^2} - \frac{(\sigma_j+\sigma_l)k_{D,o}^3}{(\rho_j+\rho_l)} \tag{4}$$

For thick film:

$$k_{D,\infty} = \frac{2\,\rho_j\,\rho_g\,(V_g - V_j)^2}{3(\rho_j+\rho_g)\sigma_j} \tag{5}$$

$$n_{D,\infty}^2 = \frac{\rho_j\,\rho_g k_{D,\infty}^2\,(V_g - V_j)^2}{(\rho_j+\rho_g)^2} - \frac{\sigma_j k_{D,\infty}^3}{(\rho_j+\rho_g)} \tag{6}$$

Based on the formulation of Kelvin-Helmholtz instability for melt-steam-water system by Epstein & Fauske, Bang et al. [14] obtained a numerical solution of the complex-variable dispersion equation of the Kelvin-Helmholtz instability in melt-steam-water system for various relative velocity and film thickness. The solutions were then fitted into the correlations of the fastest growing wave number and the maximum growth constant as follow.

Fastest growing wave length:

$$\frac{k_D}{k_{D,\infty}} = 1 + \frac{1}{\frac{k_{D,\infty}}{k_{D,o}} + 25(V_g - V_j)^{1.5}\delta + (k_{D,\infty}\delta)^2} \tag{7}$$

Growth constant at k_D:

$$\frac{n_D}{n_{D,\infty}} = 1 + \frac{1}{\frac{n_{D,\infty}}{n_{D,o}} + 5(V_g - V_j)^{1.5}\delta + 100(n_{D,\infty}\delta)^2} \tag{8}$$

Now, following the entrainment concept proposed by Epstein and Fauske, the new formulation of the jet breakup length which accounts for film boiling has been developed. The jet breakup length can be ideally defined as the distance which the jet leading edge travels for the time period for which the entrainment front reaches the center of the jet from the jet surface, i.e., the completion of jet breakup. The entrainment velocity is formulated from the Kelvin-Helmholtz instability by Epstein and Fauske [10] as

$$v_{en} \sim \frac{\pi}{16}\left(\frac{\lambda_D}{\tau}\right) \tag{9}$$

where λ_D is the fastest growing wave length and τ is the time scale of the growth and is basically $1/n_D$. The jet breakup length is then the jet velocity multiplied by the time of jet breakup completion.

$$L_{brk} = V_j \cdot (\frac{D_j}{2})/v_{en} \tag{10}$$

Combining Eqs. (9) and (10) and adjusting the constant for the consistency between the KHI and the entrainment concept [10], the proposed jet breakup length is

$$\frac{L_{brk}}{D_j} = \frac{1}{2\sqrt{3}E_o} V_j \left(\frac{k_D}{n_D}\right) \tag{11}$$

The fastest growing wave number, k_D, and the maximum growth constant, n_D, are calculated using Eqs. (7) and (8). The recommended value for the constant Eo is 0.1.

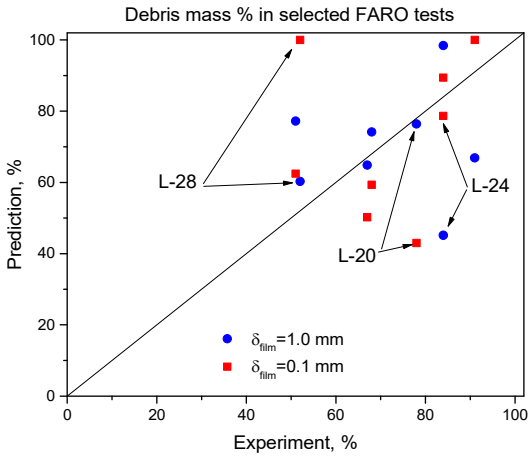

Figure 4. Comparison of debris mass between the prediction of the advanced jet breakup length model and experimental data

The proposed new jet breakup length correlation was assessed using the selected FARO tests and the results are shown in Fig. 4. In general, the debris mass prediction by the proposed jet breakup length model is greatly improved. The important shortcoming of the new model, however, is that the vapor film thickness is not known and be assumed. When thin vapor film of 0.1 mm is assumed, the test L-20 is underpredicted and the test L-28 is overpredicted by greater degree. But it is good to observe that when the vapor film of 1 mm thickness is assumed, the predictions of both L-20 and L-28 tests are greatly improved, as illustrated using arrows in Fig. 4. On the contrary, thinner vapor film of 0.1 mm gives better prediction that 1 mm vapor film in test L-24. Nonetheless, the vapor film thickness at the time of instability initiation must be known. There is no experimental data of vapor film thickness reported for such high temperature corium and water. An analytical modeling of film boiling can be an informative approach for finding the vapor film thickness. In the following section 3, laminar boundary layer modeling of film boiling on a vertical plate is presented.

2.3. Application of Advanced Jet Breakup Length Model to Reactor Conditions

The jet breakup length predicted by Eq. (11) for a typical PWR corium-water FCI condition is shown in Fig. 5. In case of no film boiling, the dimensionless jet breakup length is around 15 and independent of jet entry speed as same as Epstein-Fauske model. However, if there is vapor film between the melt and water, the dimensionless jet breakup length jumps to over 40 even though the vapor film thickness is assumed unpractically thin, 0.01 mm.

For pre-flooding strategy of a PWR cavity in which coolant is filled prior to the breach of reactor pressure vessel, the fraction of corium jet breakup into particle debris is an interesting subject. If the jet breakup length is shorter than the depth of coolant pool in the cavity, the corium is completely broken up and it forms a debris bed on the cavity floor. However, the jet breakup length is longer than the coolant pool depth, a fraction of corium remains as a cake (i.e., unbroken mass) on the cavity floor and the coolability remains as a concern depending on the size of such a cake.

The fraction of the debris mass (α_{debris}) can be estimated using the jet breakup length formulation of Eq. 11. For 30 cm diameter corium jet, the fraction of debris is calculated for the pool depth of 4 m and 7 m and shown in Fig. 5. If no vapor film (isothermal case), most of the jet is broken up since the jet breakup length is shorter than 4 m. However, in hot corium case in which vapor film exists, although the vapor film thickness is not known precisely, the jet breakup length becomes much longer, thus the fraction of debris

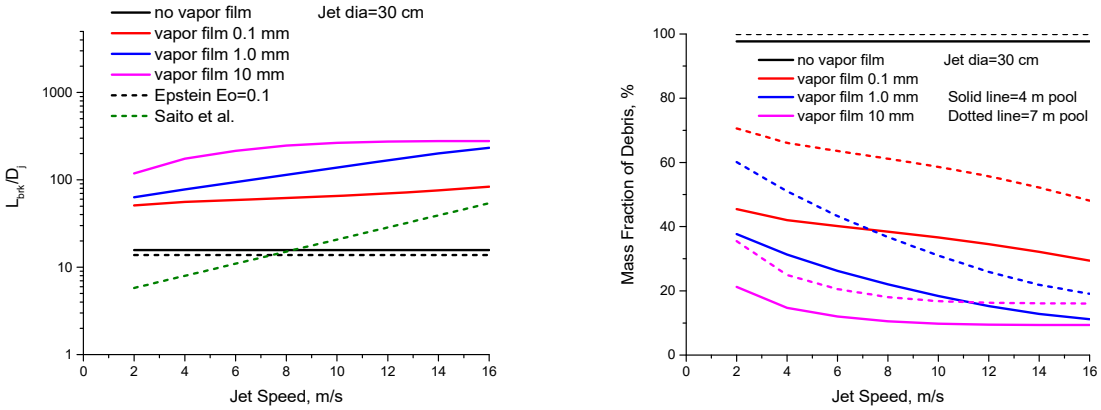

Figure 5. Jet breakup length (left) and mass fraction of debris (right) predicted by the proposed jet breakup length model

becomes smaller, less than 40% in 4 m deep pool. This implies that the coolant pool depth is an important parameter in the view of ex-vessel debris coolability. The experimental data of jet breakup length is scarce due to the explosive nature of FCI experiments as well as poor availability of good measurement technique. This makes it difficult to better validate the applicability of the proposed relation of jet breakup length.

3. ANALYTICAL MODELING OF FILM BOILING ON VERTICAL PLATE

It is observed that the proposed jet breakup length model is strongly influenced by the vapor film thickness. Although the film boiling is one of common boiling modes, the information on the vapor film thickness on vertical plate is scarce in the literature. Bromley [15] is the first who proposed film boiling model for vertical plate, but it is limited to saturated film boiling and the interfacial shear at the interface is not matched. Thus, in this study, an analytical film boiling model has been developed under the assumption of laminar boundary layer. Laminar boundary layer modeling for film boiling over a sphere was developed by Bang [16] and the present modeling is an extension to a vertical plate. Both velocity fields of vapor and liquid are computed and the energy equations of both vapor and liquid are also solved to include subcooled film boiling as shown in Fig. 6.

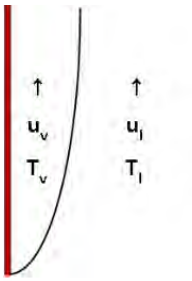

Figure 6. Film boiling on vertical plate

The boundary layer equations for vapor and liquid in film boiling on vertical plate can be written as below.

For vapor:

$$u\left(\frac{\partial u}{\partial x}\right)+v\left(\frac{\partial u}{\partial y}\right)=\nu_v\left(\frac{\partial^2 u}{\partial y^2}\right)+g_0\frac{\rho_l-\rho_v}{\rho_v} \quad (12)$$

$$u\left(\frac{\partial T}{\partial x}\right) + v\left(\frac{\partial T}{\partial y}\right) = \alpha_T\left(\frac{\partial^2 T}{\partial y^2}\right) \tag{13}$$

For liquid:

$$u\left(\frac{\partial u}{\partial x}\right) + v\left(\frac{\partial u}{\partial y}\right) = \nu_l\left(\frac{\partial^2 u}{\partial y^2}\right) \tag{14}$$

$$u\left(\frac{\partial T}{\partial x}\right) + v\left(\frac{\partial T}{\partial y}\right) = \alpha_T\left(\frac{\partial^2 T}{\partial y^2}\right) \tag{15}$$

These equations can be reduced to ordinary differential equations by similarity transformation.

For vapor:

$$f''' + \left[\frac{1}{2}\right] f f'' = \left[-\left(\frac{Gr_x}{Re_x^2}\right)_{vap}\right] \tag{16}$$

$$\theta'' + Pr_v\left[\left(\frac{1}{2}\right)\right] f\,\theta' = 0 \tag{17}$$

For liquid:

$$F''' + \left[\frac{1}{2}\right] F F'' = [0] \tag{18}$$

$$\Theta'' + Pr\left[[0] + \left[\left(\frac{1}{2}\right)\right] F\right]\Theta' = [0] \tag{19}$$

At the interface of vapor and liquid, the velocity and tangential shear must be matched and these interfacial relations are

$$F'(0) = f'(\eta_\delta) \tag{20}$$

$$F''(0) = \sqrt{\frac{\rho_v \mu_v}{\rho_l \mu_l}} f''(\eta_\delta) \tag{21}$$

$$F(0) = \sqrt{\frac{\rho_v \mu_v}{\rho_l \mu_l}} f(\eta_\delta) \tag{22}$$

The relation between the energy balance at the interface and the evaporation rate can be written as

$$\frac{Ja_v}{Pr_v}[-\theta'] - \frac{Ja_l}{Pr_l}[-\Theta']\sqrt{\left(\frac{\rho_l \mu_l}{\rho_v \mu_v}\right)} + \frac{[Nu_r]}{\sqrt{([Re_v])}}\left(\frac{Ja_v}{Pr_v}\right) = \left[x\frac{\partial \eta_\delta}{\partial x}\right] f' + \frac{1}{2} f \tag{23}$$

These set of equations with the boundary and interfacial conditions were numerically solved. The solution of the model revealed various film boiling parameters such vapor film thickness, vapor velocity profiles and heat transfer rate from the hot surface as well as to the subcooled liquid. First, a set of solutions obtained for a moderate wall temperature, the superheat temperature of 400 K in the atmospheric pressure. The water subcooling was varied from the saturation condition to 50 K subcooling. Fig. 7 shows the vapor film thickness for different liquid subcooling and it is observed the vapor film thickness can be smaller than 1 mm in high subcooling of water.

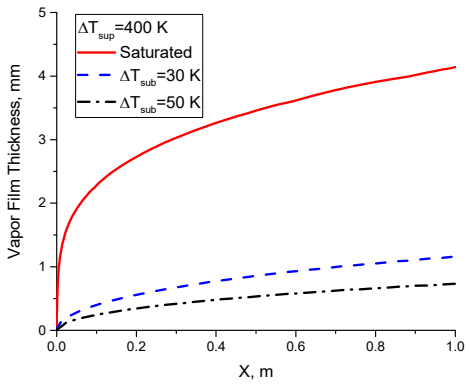

Figure 7. Effect of subcooling on film thickness (400 K superheat)

The calculated local heat transfer coefficient is compared with the Bromley model in Fig. 8 and it is found that the Bromley model seems to overpredict. The vapor velocity profiles in the film are illustrated in Fig. 9 and the ratio of the average vapor velocity to free stream liquid velocity is also given in Fig. 9. In saturated film boiling, the average vapor velocity is ten times as large as the free-stream liquid velocity.

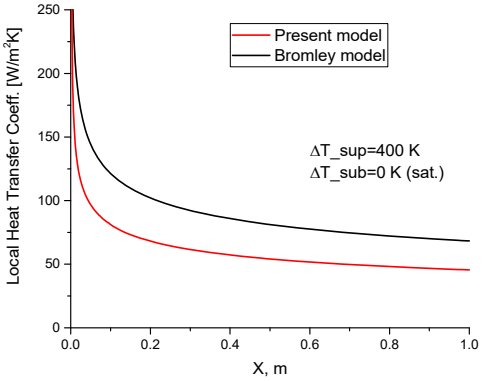

Figure 8. Comparison of heat transfer coefficient with Bromley model (400 K superheat)

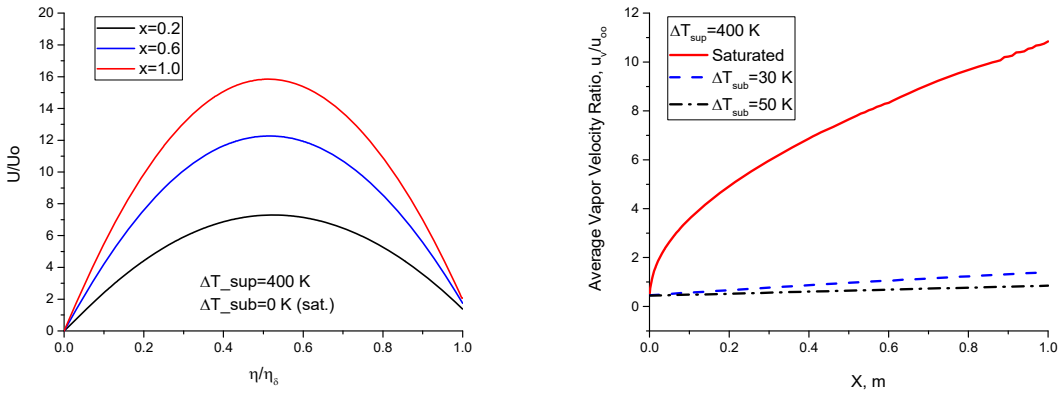

Figure 9. Vapor velocity profile (left) and average vapor velocity (right) for 400 K superheat

In fuel-coolant interaction during a severe accident, the molten fuel temperature is as high as 3000 K. Although the physical realm of the state in which water contacts such a high temperature surface can be very complex, it is assumed that film boiling develops between the hot surface and liquid. For superheat of 2000 K, the solution was hardly obtained except for the first few tens of centimeters. This problem could be caused by the assumption of laminar flow since the vapor flow becomes very high and the vapor film develops very thicker even for high subcooling of liquid. Fig. 10 shows the vapor film thickness and the average vapor velocity for 2000 K superheat. For better solutions for high temperature corium, turbulent model is to be developed in the future.

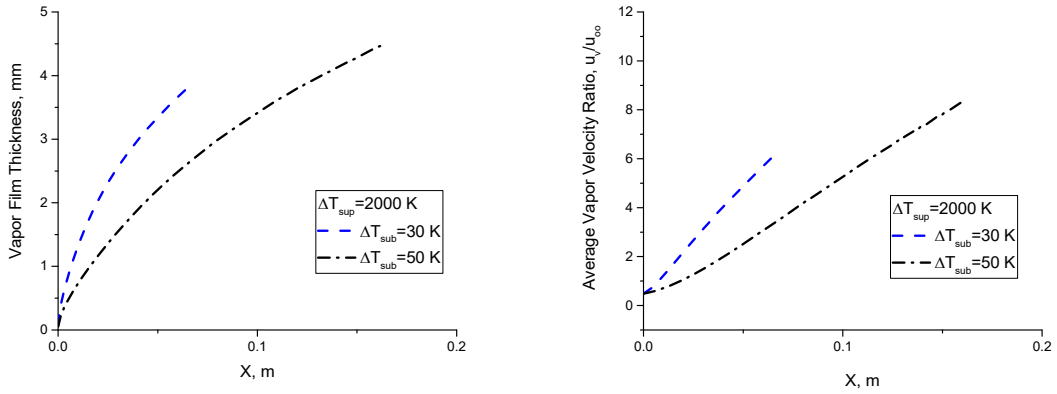

Figure 10. Vapor film thickness (left) and average vapor velocity (right) for 2000 K superheat

4. CONCLUSIONS

The molten corium interaction with the coolant in the cavity may produce a violent steam explosion thus this can be an additional risk of containment failure in pre-flooding strategy. The amount of corium jet breakup in a pre-flooded reactor cavity is affected by the depth of water pool. As a correlation approach in estimating the amount of jet breakup, two jet breakup length models of Saito et al. and Epstein & Fauske were assessed for selected FARO test data and found that both models significantly overpredicted the debris mass.

A new model for jet breakup length has been proposed based on the Kelvin-Helmholtz instability for melt-steam-water interfaces. The prediction of debris mass of FARO tests was significantly improved by the new model. From the analysis of pre-flooded PWR cavity using the new jet breakup length model, it was found that for 30 cm diameter jet, the fraction of debris mass was less than 40% in a 4 m deep pool.

It was found that the rate of jet breakup and the particle size are greatly influenced by the vapor film thickness between the hot melt and the coolant water. An analytical model for estimating the vapor film thickness on vertical plate encompassing subcooled liquid has been developed based on the assumption of laminar boundary layer flow. The solution of the model revealed various film boiling parameters such vapor film thickness, vapor velocity profiles and heat transfer rate from the hot surface as well as to the subcooled liquid. For high superheat of 2000 K case, the laminar assumption seemed not valid due to high vapor velocity. To overcome the shortcoming, a turbulent model is to be developed in the future.

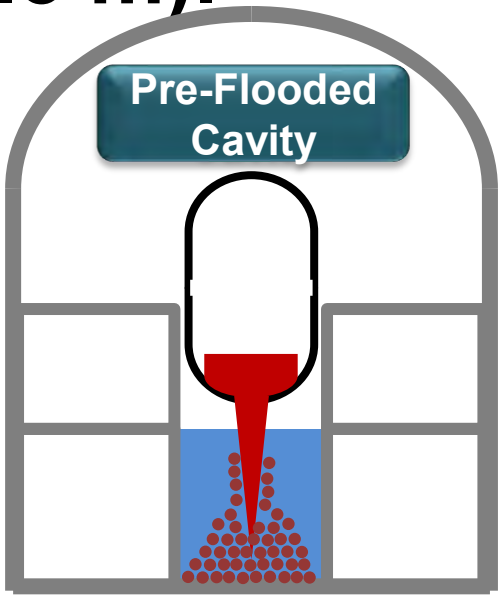
Debris bed	Less FCI risk	No MCCI	No E.V. risk
FCI risk	MCCI	High cost	Success?

Pre-Flooding & FCI

- Corium jet breaks up into particles in pre-flooded cavity.
- Debris bed of particles larger than 3 mm is likely coolable if the bed height is low (<~0.3 m).
- Steam explosion may occur,

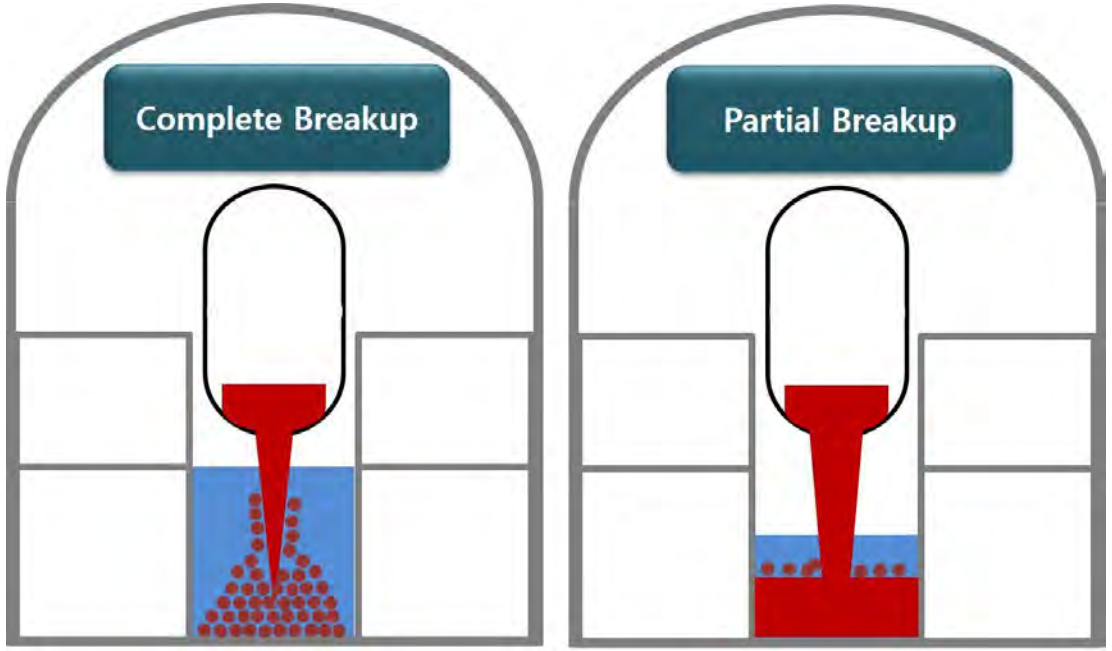
  but the impulse must be low

  enough not to fail cavity.



Ex-Vessel Corium Jet

- **Amount of corium jet breakup has been a key to ex-vessel coolability as well as steam explosion intensity.**
- **Spreading, particle size, and debris bed geometry are also concern.**



Research Objectives

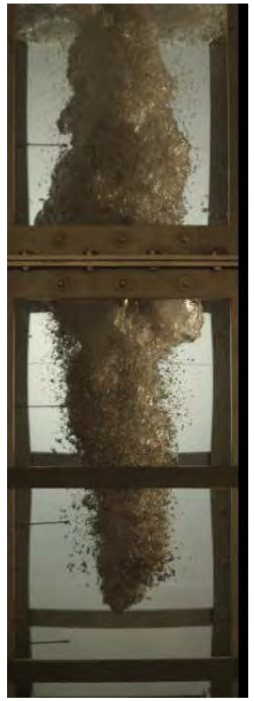
- Evaluate the performance of jet breakup length models
- Develop a jet breakup length model with account of vapor film between melt and coolant
- Numerical calculation of vapor film thickness

Melt Jet Breakup Study

- **A number of experimental studies on melt jet breakup worldwide**

Corium, ~2900°C
(TROI, KAERI)

Oxides, ~1100°C
(DEFOR, KTH)



Sn-Bi, ~300°C

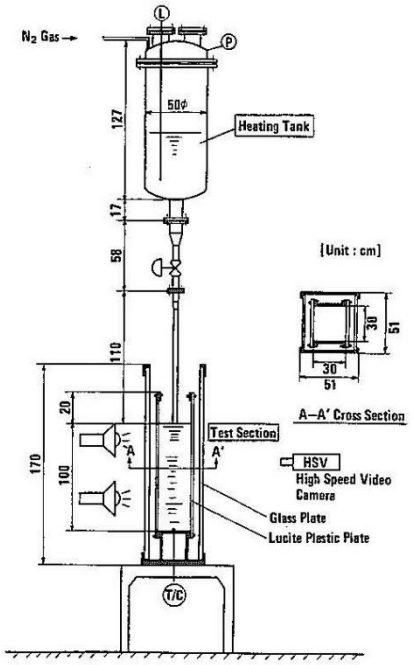
Jet Breakup Modeling

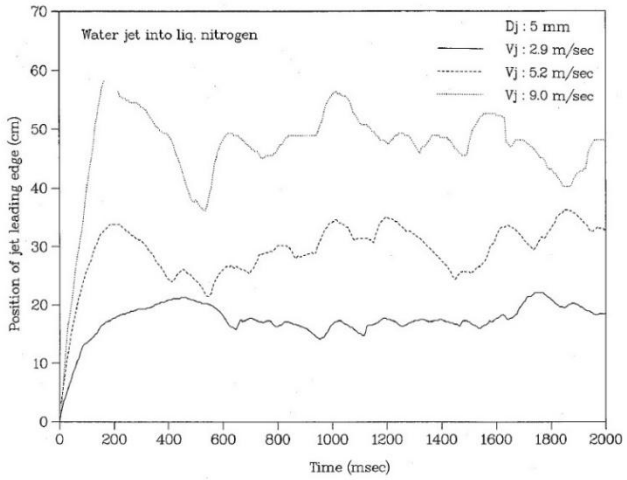
- Jet breakup length correlation
  - Saito et al.
  - Epstein and Fauske
  - Simple, but semi-empirical
- Physics-based modeling
  - Viscous stress induced: boundary layer stripping
  - Instability induced: Rayleigh-Taylor, Kelvin-Helmholtz
  - Inertia exchange: drop breakup
  - FCI codes have their own modeling approach
  - Complex transient phenomenon involving boiling

Saito et al. Model

- Study jet penetration for water/R-11 and water/LN2
- R-11: ρ~1476 kg/m^3, T_B=23.8°C, D_j=5~40 mm
- LN2: ρ~806 kg/m^3, T_B=-196°C, D_j=5 mm
- Propose a '**penetration length**' correlation



$$L_{brk}/D_j = 2.1\left(\frac{\rho_j}{\rho_\infty}\right)^{1/2}\frac{u_j}{\sqrt{gD_j}}$$



Epstein & Fauske Model

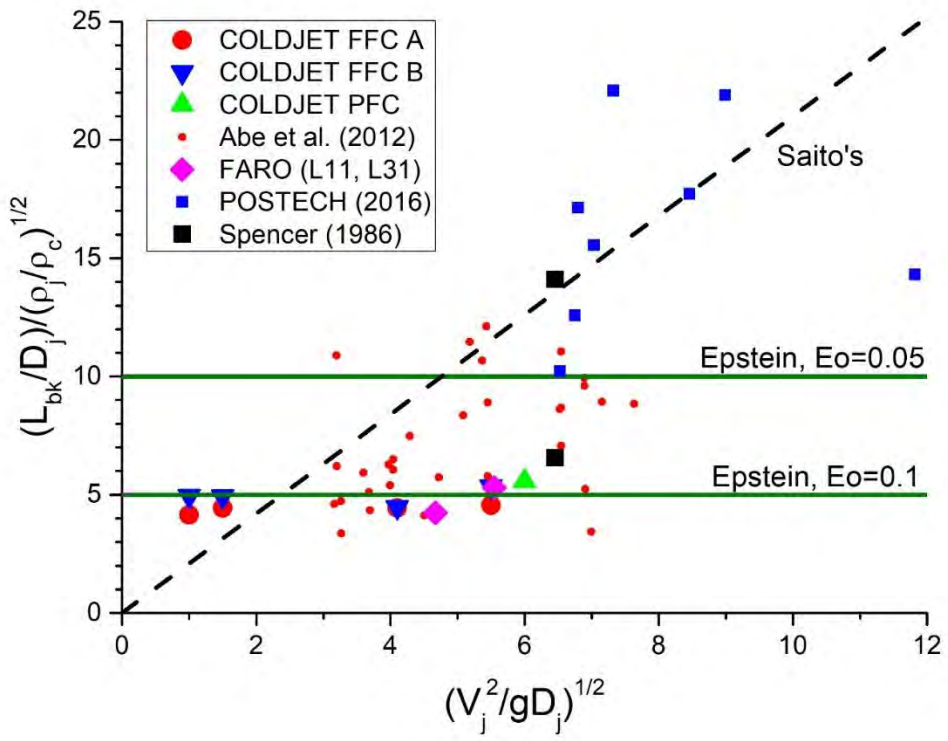
- Turbulent entrainment of hot gas in air (Taylor, 1945)
- Ricou & Spalding (1961) added density ratio.
- Kelvin-Helmholtz instability theory

$$v_{en} \sim \frac{\pi^2}{8\sqrt{3}} \left(\frac{\rho_\infty}{\rho_j}\right)^{1/2} u$$

- Tests of high speed (~100 m/s) water jet in air (1~40 bars) showed that jet velocity has little effect on jet breakup length.

$$L_{brk} = t_{brk} u = \frac{D_j/2}{v_{en}} u = \frac{D_j/2}{E_o \left(\frac{\rho_\infty}{\rho_j}\right)^{1/2} u} u = \frac{1}{2E_o} D_j \left(\frac{\rho_j}{\rho_\infty}\right)^{1/2}, E_o = 0.05\sim0.1 \; from \; data$$

Comparison of Two Models



Saito's

$$\frac{L_{brk}}{D_j} = 2.1\left(\frac{\rho_j}{\rho_c}\right)^{1/2}\left(\frac{V_0}{gD_j}\right)^{1/2}$$

Epstein's

$$\frac{L_{brk}}{D_j} = \frac{1}{2E_0}\left(\frac{\rho_j}{\rho_c}\right)^{1/2}$$

- **It appears that Epstein model is good for high temperature corium (film boiling) or cold melt (no boiling), while Saito model is good for moderate temperature melts (probably nucleate boiling).**

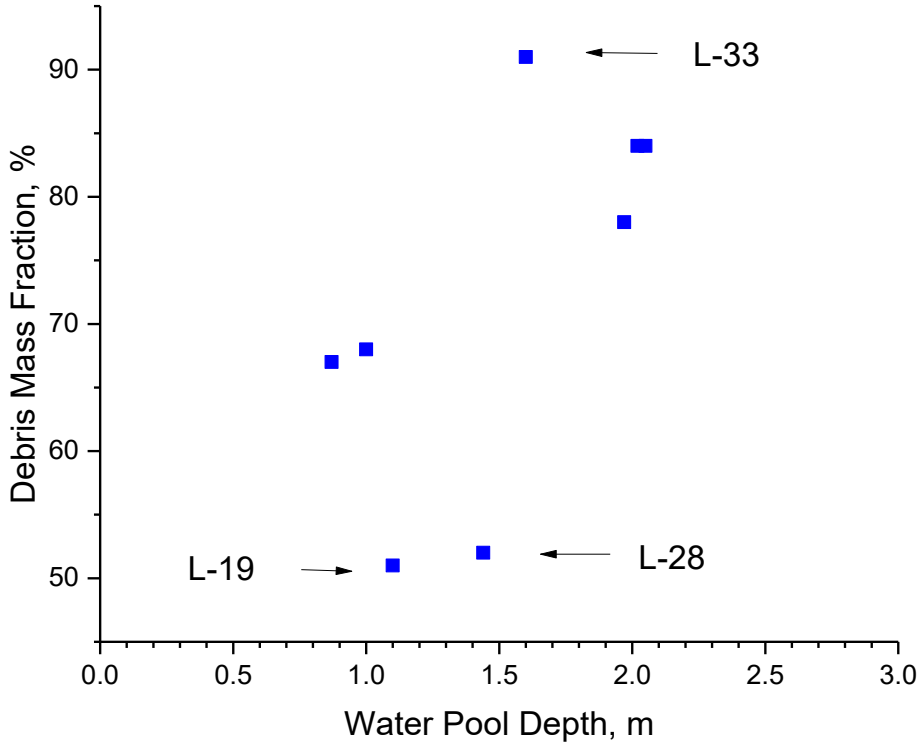
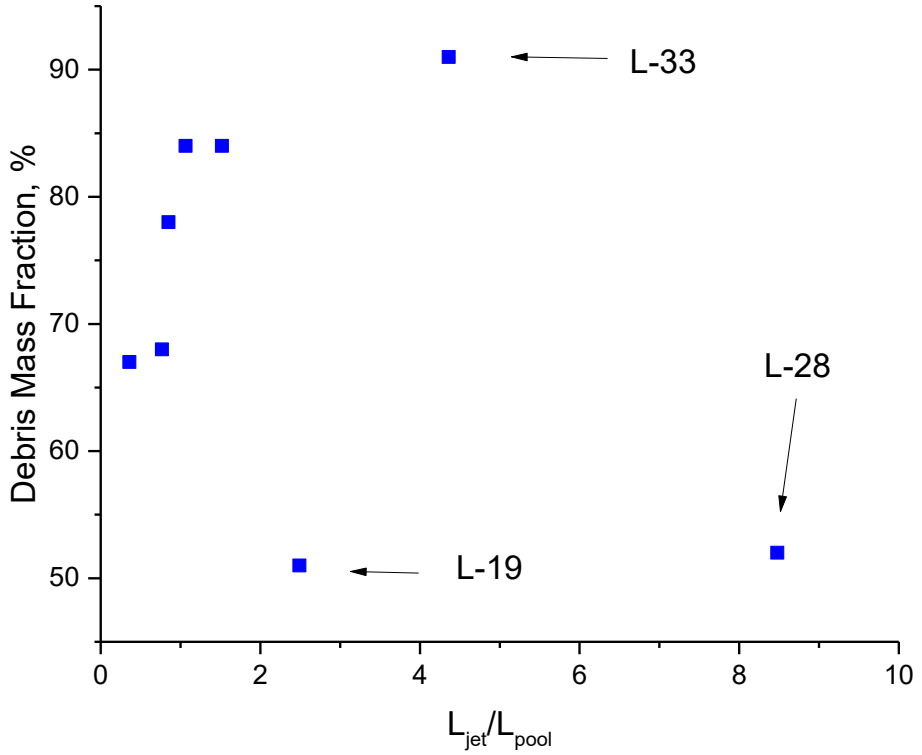
void fraction = 0.3	92	96	100	99	100	100	100	100

Note: Kudinov et al. (NED, 2013) considered "cake" as "agglomerated mass."

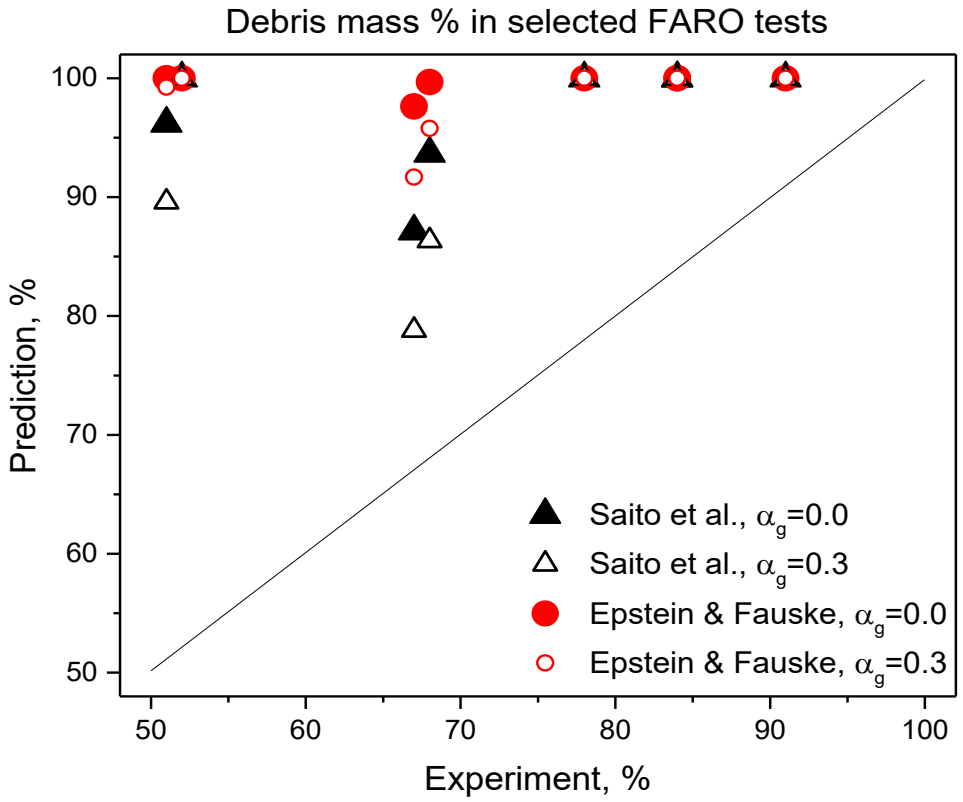
Pool Depth vs. Jet Length

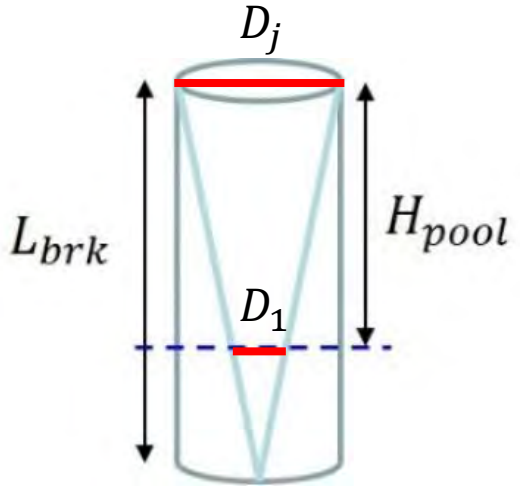




L-19: Longer free fall in low pool depth
L-28: Long melt pouring time (~5 s) by reduced jet diameter (10 cm → 5 cm)
L-33: Triggered explosion when 25% melt entered.

Prediction of FARO Debris Mass



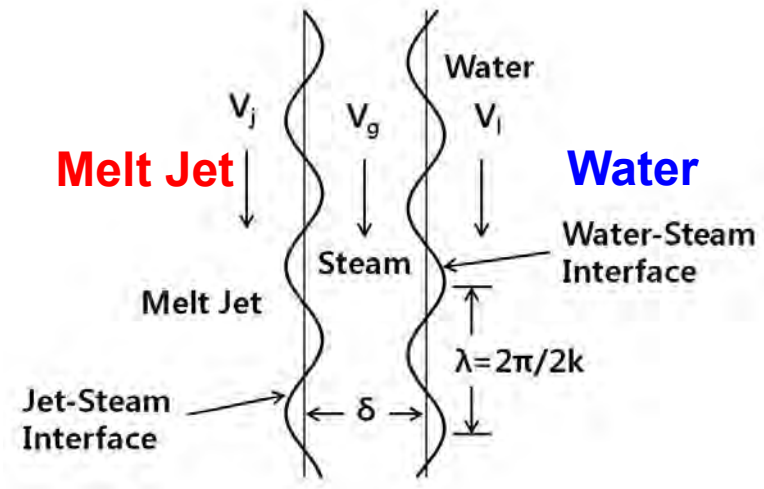


$$\alpha_{debris} = 1 - \left(\frac{D_1}{D_j}\right)^2 = 1 - \left(1 - \frac{H_{pool}}{L_{brk}}\right)^2$$

Note: re-melting or agglomeration could occur in FARO, but these are not accounted for in this analysis, nor clearly identified in FARO posttest debris.

Account of Vapor Film

- **Epstein & Fauske proposed melt-vapor-water KHI model (1985)**
- **Complex dispersion equation: unable to obtain analytic solution for k_D and n_D**



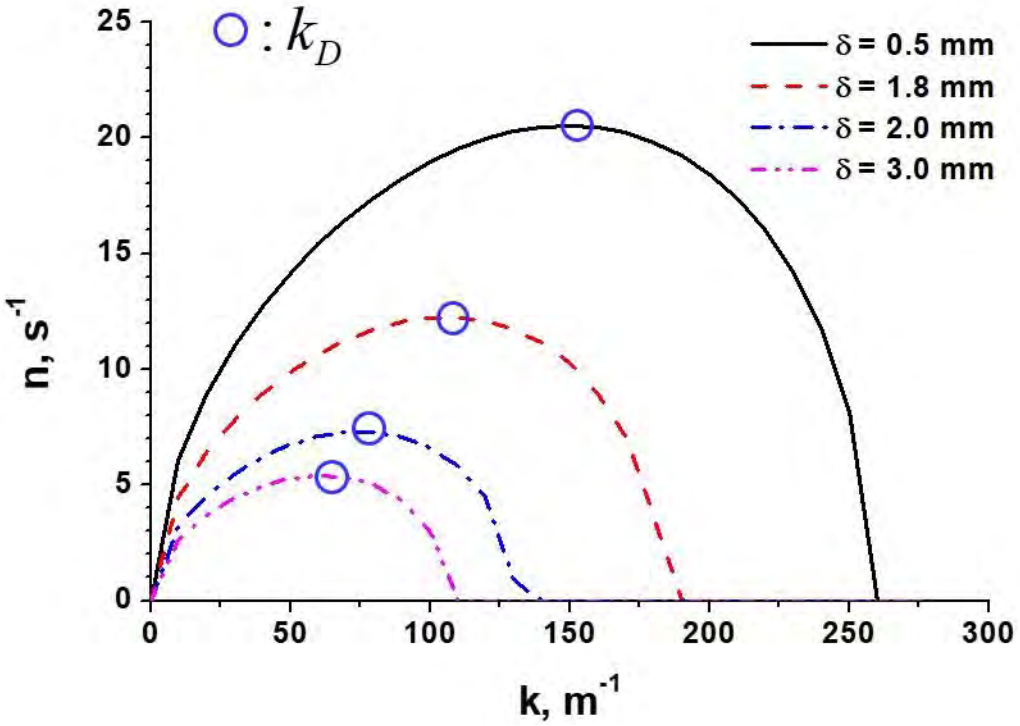
$$\eta \sim e^{ikx+nt}$$

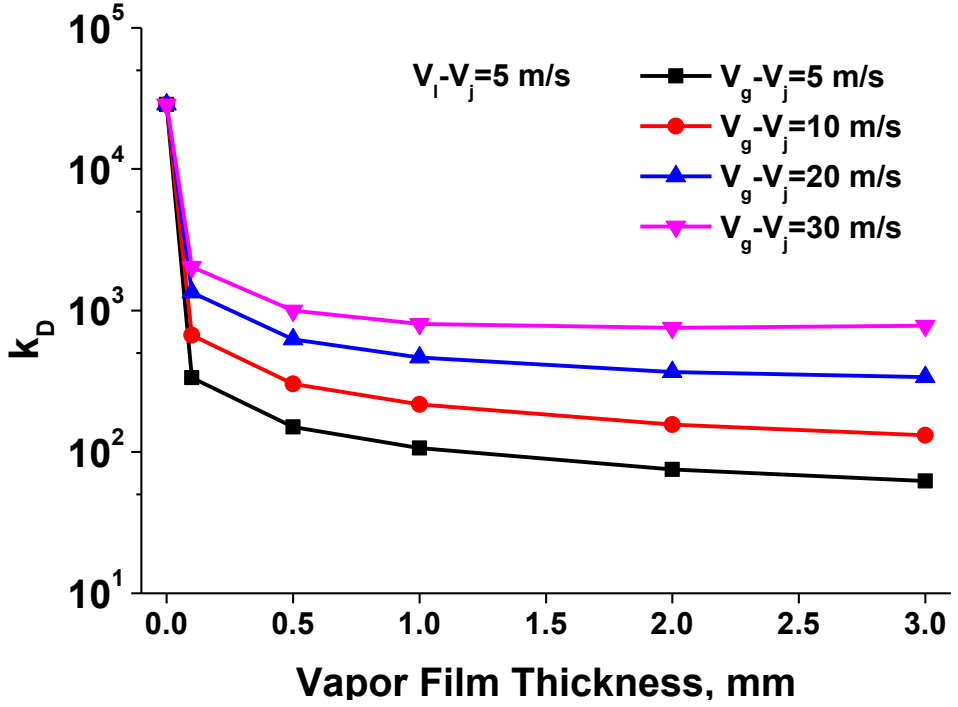
$$[\rho_g(n+ikV_g)^2+\{\rho_l(n+ikV_l)^2+\sigma_l k^3\}$$
$$\cdot\tanh(k\delta)]\cdot[\rho_j(n+ikV_j)^2+\sigma_j k^3]$$
$$+\rho_g^2(n+ikV_g)^4\tanh(k\delta)$$
$$+\rho_g(n+ikV_g)^2[\rho_l(n+ikV_l)^2+\sigma_l k^3]=0$$

Numerical Solutions for k_D, n_D

k_D: Fastest growing wave number

n_D: Growth constant corresponding to k_D





(Bang et al., NED, 2014)

Correlated Numerical Solutions

$$\frac{k_D}{k_{D,\infty}} = 1 + \frac{1}{\frac{k_{D,\infty}}{k_{D,o}} + 25\left(V_g - V_j\right)^{1.5}\delta + \left(k_{D,\infty}\delta\right)^2}$$

$$\frac{n_D}{n_{D,\infty}} = 1 + \frac{1}{\frac{n_{D,\infty}}{n_{D,o}} + 5\left(V_g - V_j\right)^{1.5}\delta + 100\left(n_{D,\infty}\delta\right)^2}$$

Thin vapor film: (kδ→0)

$$k_{D,o} = \frac{2\,\rho_j\,\rho_l\left(V_l - V_j\right)^2}{3\left(\rho_j + \rho_l\right)\left(\sigma_j + \sigma_l\right)}$$

$$n_{D,o}^2 = \frac{\rho_j\,\rho_l k_{D,o}^2\left(V_l - V_j\right)^2}{\left(\rho_j + \rho_l\right)^2} - \frac{\left(\sigma_j + \sigma_l\right)k_{D,o}^3}{\left(\rho_j + \rho_l\right)}$$

Thick vapor film: (kδ→∞)

$$k_{D,\infty} = \frac{2\,\rho_j\,\rho_g\left(V_g - V_j\right)^2}{3\left(\rho_j + \rho_g\right)\sigma_j}$$

$$n_{D,\infty}^2 = \frac{\rho_j\,\rho_g k_{D,\infty}^2\left(V_g - V_j\right)^2}{\left(\rho_j + \rho_g\right)^2} - \frac{\sigma_j k_{D,\infty}^3}{\left(\rho_j + \rho_g\right)}$$

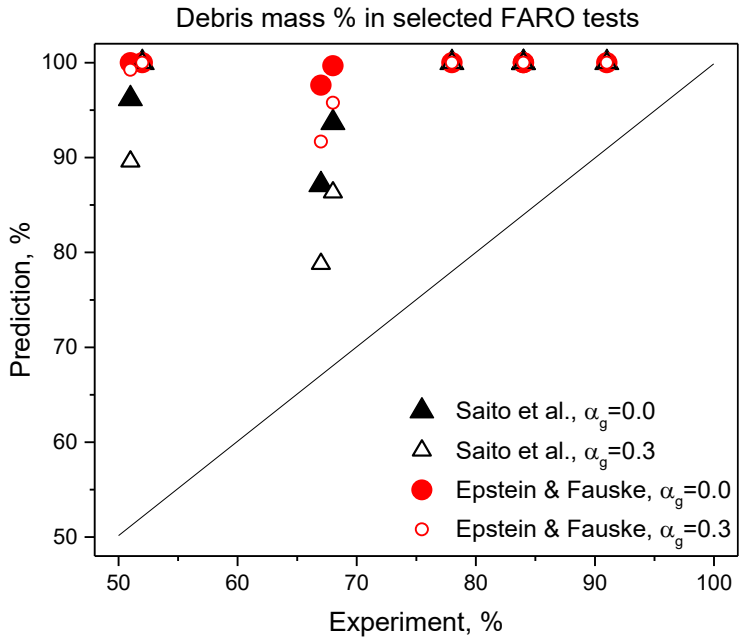
Jet Breakup Length with δ_{film}

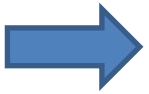
- **Beginning from Epstein & Fauske model, a new jet breakup length model has been developed with account of vapor film thickness.**
- **Yet, it requires the information on vapor film thickness.**

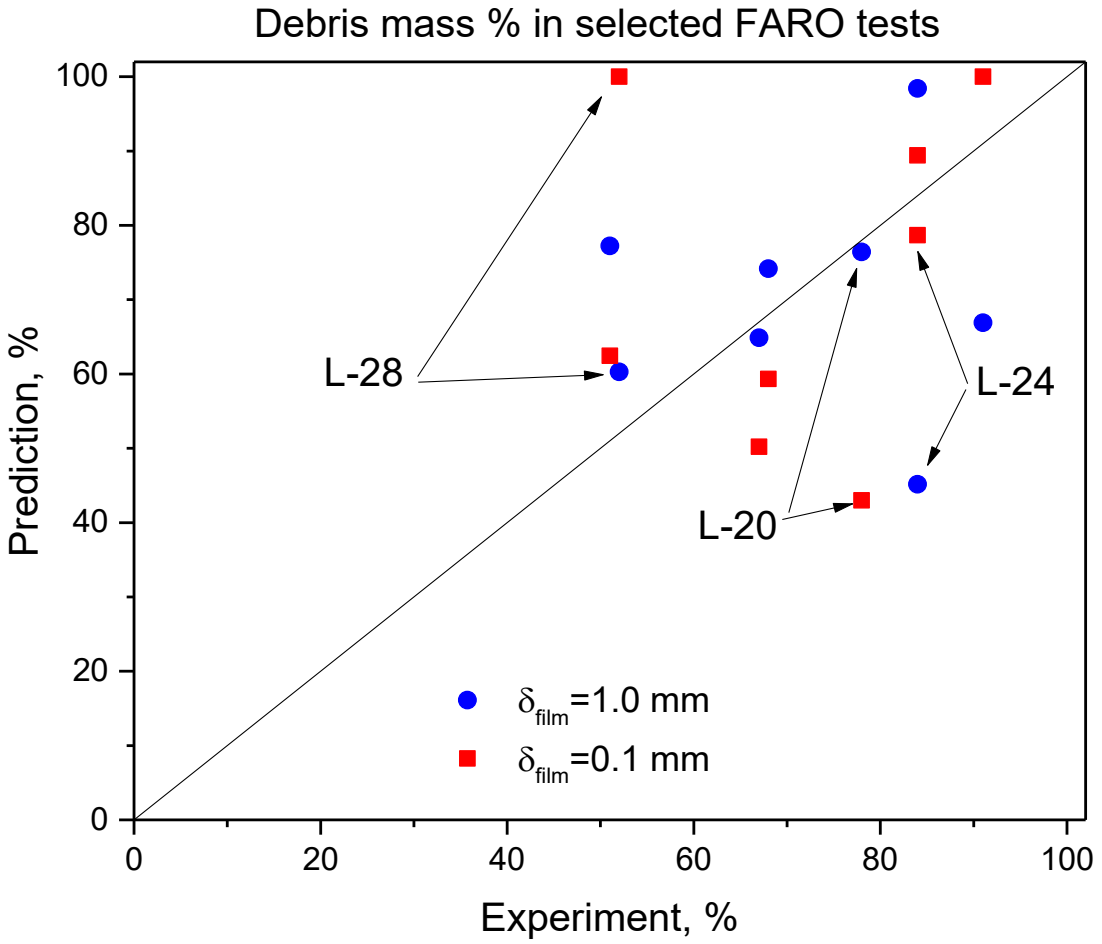
$$v_{en} \sim \frac{\pi}{16}\left(\frac{\lambda_D}{\tau}\right) \qquad \tau \sim \frac{1}{n_D} \qquad \lambda_D = \frac{2\pi}{k_D}$$

$$L_{brk} = V_j \cdot \left(\frac{D_j}{2}\right) / v_{en} \quad \rightarrow \quad \frac{L_{brk}}{D_j} = \frac{1}{2\sqrt{3}E_o} V_j \left(\frac{k_D}{n_D}\right)$$

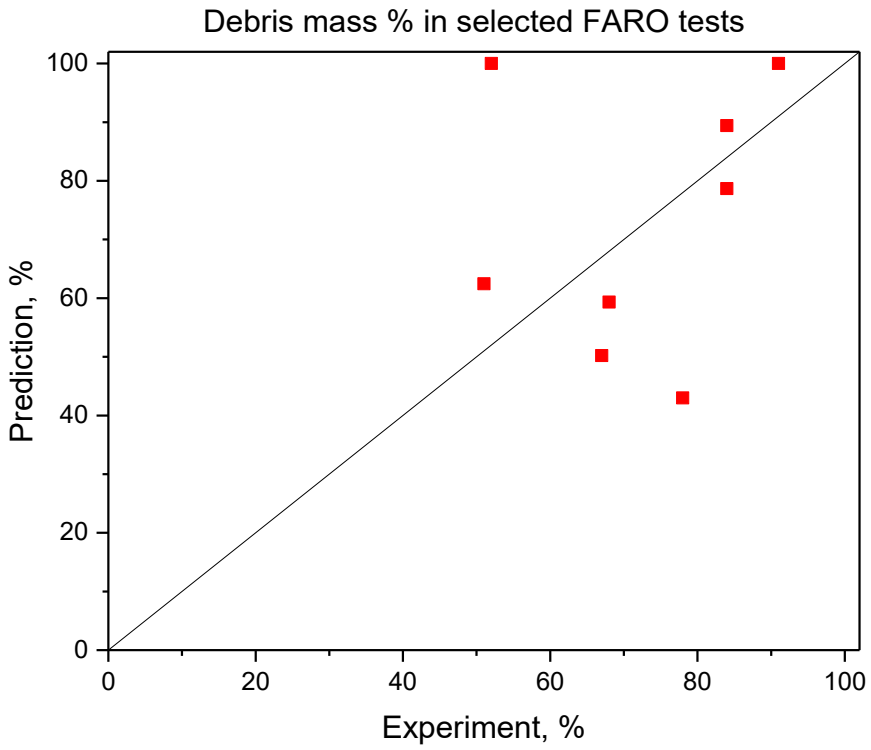
Prediction of FARO Data



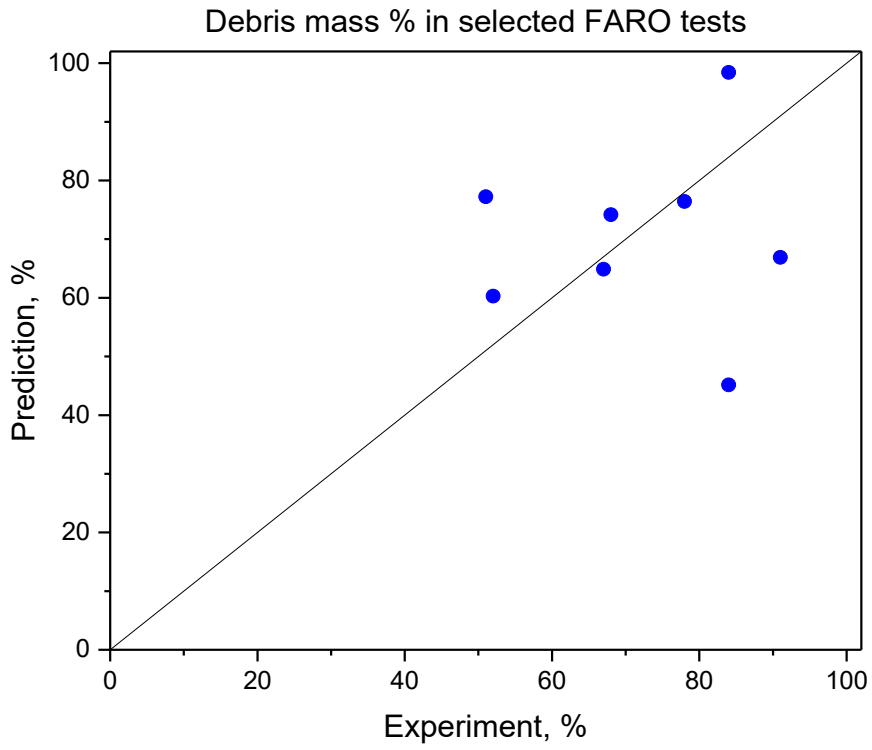




δ_{film} Effect

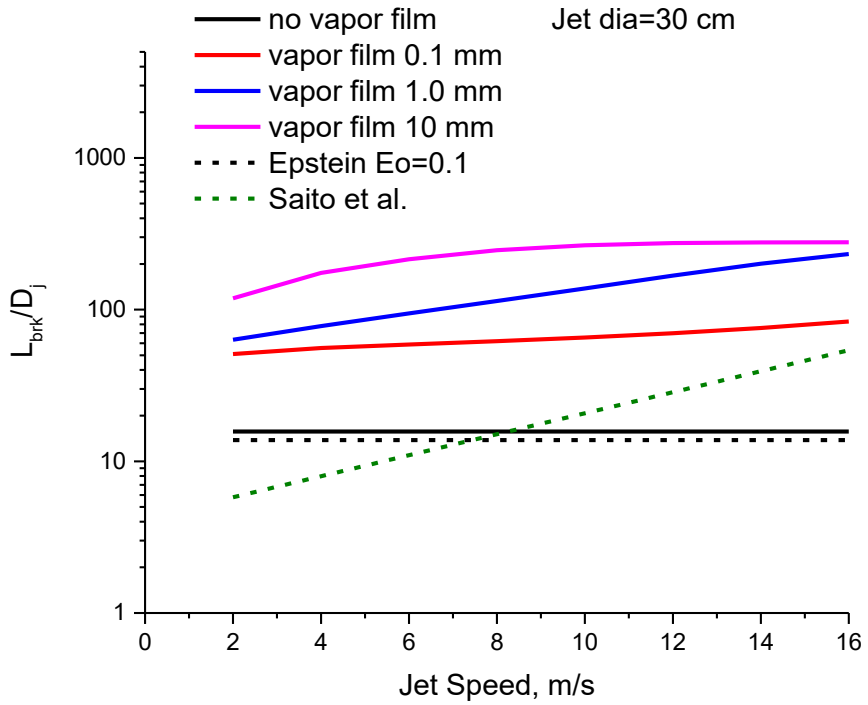


δ_{film}=0.1 mm

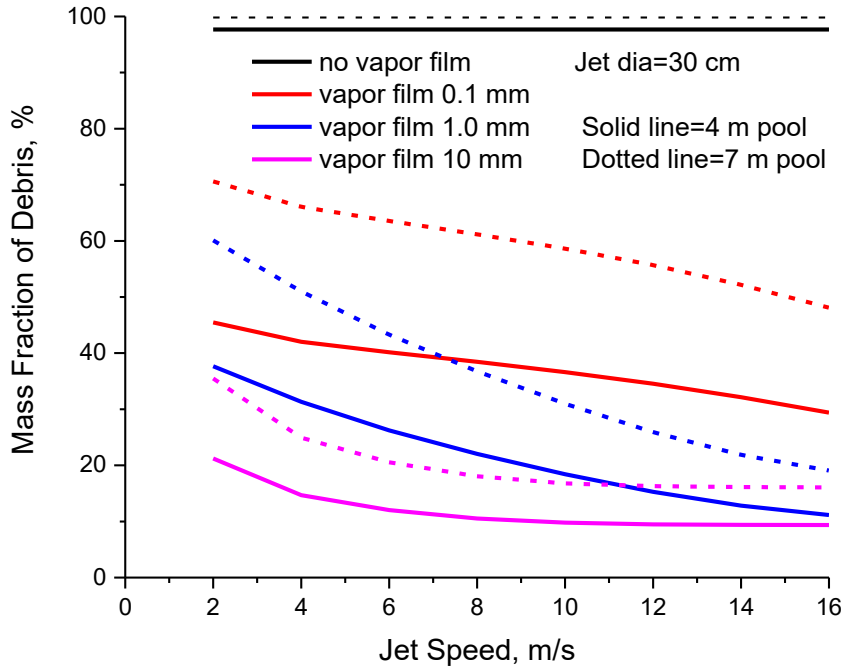


δ_{film}=1.0 mm

Estimation of Reactor Case



Jet Breakup Length



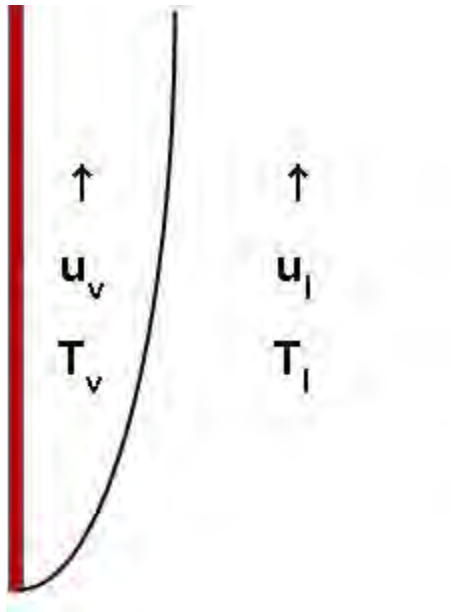
Debris Mass

With just 1.0 mm thick vapor film, the jet breakup length is longer than 50 times the jet diameter: 15 m for 0.3 m dia. Jet.

Vapor film thickness and vapor velocity are important parameters.

Film Boiling Model

- **Jet diameter >> vapor film thickness : vertical flat surface approx.**
- **Since Bromley analysis (1950) for saturated liquid, information on vapor film thickness is scares.**



Vapor

$$u\left(\frac{\partial u}{\partial x}\right)+v\left(\frac{\partial u}{\partial y}\right)=\nu_v\left(\frac{\partial^2 u}{\partial y^2}\right)+g_0\frac{\rho_l-\rho_v}{\rho_v}$$

$$u\left(\frac{\partial T}{\partial x}\right)+v\left(\frac{\partial T}{\partial y}\right)=\alpha_T\left(\frac{\partial^2 T}{\partial y^2}\right)$$

Liquid

$$u\left(\frac{\partial u}{\partial x}\right)+v\left(\frac{\partial u}{\partial y}\right)=\nu_l\left(\frac{\partial^2 u}{\partial y^2}\right)$$

$$u\left(\frac{\partial T}{\partial x}\right)+v\left(\frac{\partial T}{\partial y}\right)=\alpha_T\left(\frac{\partial^2 T}{\partial y^2}\right)$$

Major assumptions:

- **Boundary layer flow**
- **Laminar flow**
- **Smooth interface**

Similarity Transformation

$$f''' + \left[\frac{1}{2}\right] f f'' = \left[-\left(\frac{Gr_x}{Re_x^2}\right)_{vap} \right]$$

$$\theta'' + Pr_v \left[\left(\frac{1}{2}\right)\right] f\ \theta' = 0$$

$$F''' + \left[\frac{1}{2}\right] F F'' = [0]$$

$$\Theta'' + Pr \left[[0] + \left[\left(\frac{1}{2}\right)\right] F \right] \Theta' = [0]$$

Interfacial Conditions

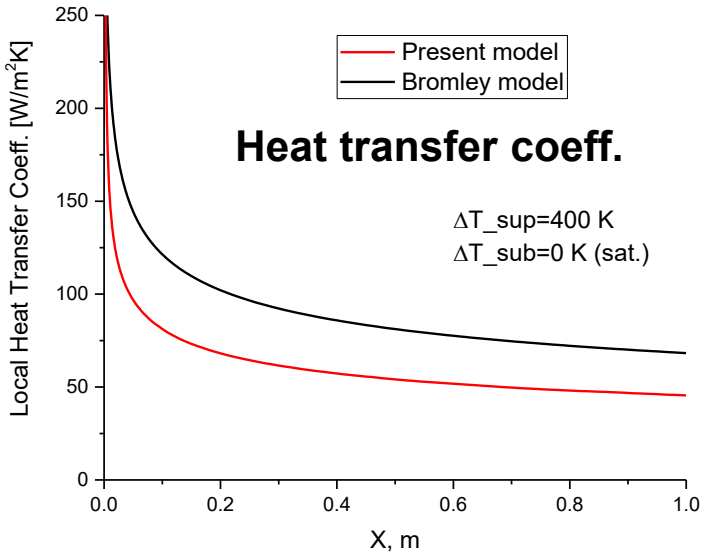
$$F'(0) = f'(\eta_\delta)$$

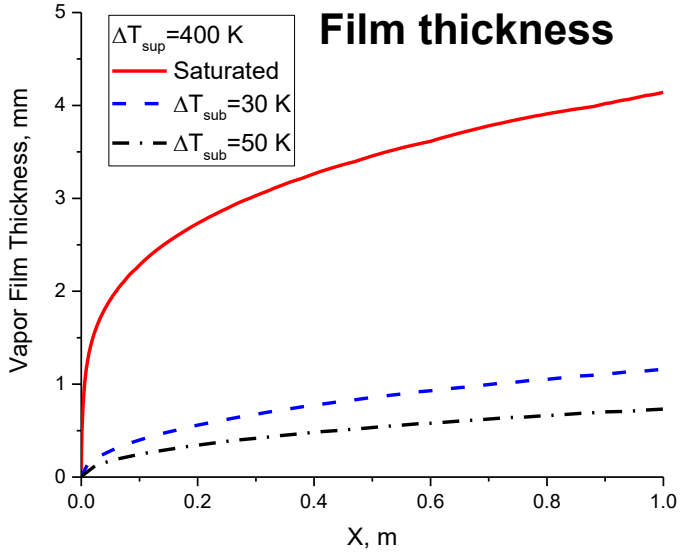
$$F''(0) = \sqrt{\frac{\rho_v \mu_v}{\rho_l \mu_l}}\, f''(\eta_\delta)$$

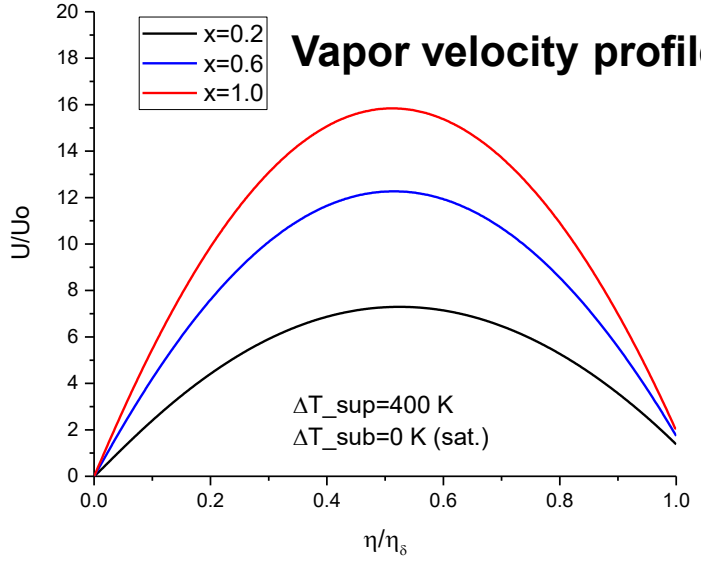
$$F(0) = \sqrt{\frac{\rho_v \mu_v}{\rho_l \mu_l}}\, f(\eta_\delta)$$

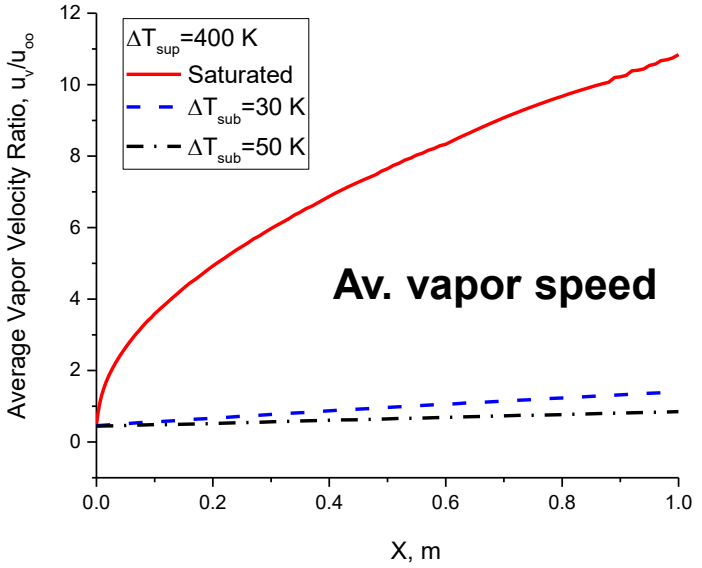
$$\frac{Ja_v}{Pr_v}[-\theta'] - \frac{Ja_l}{Pr_l}[-\Theta'] \sqrt{\left(\frac{\rho_l \mu_l}{\rho_v \mu_v}\right)} + \frac{[Nu_r]}{\sqrt{([Re_v])}} \left(\frac{Ja_v}{Pr_v}\right) = \left[x \frac{\partial \eta_\delta}{\partial x} \right] f' + \frac{1}{2} f$$

Solution for T_s=500°C, V_j=4 m/s

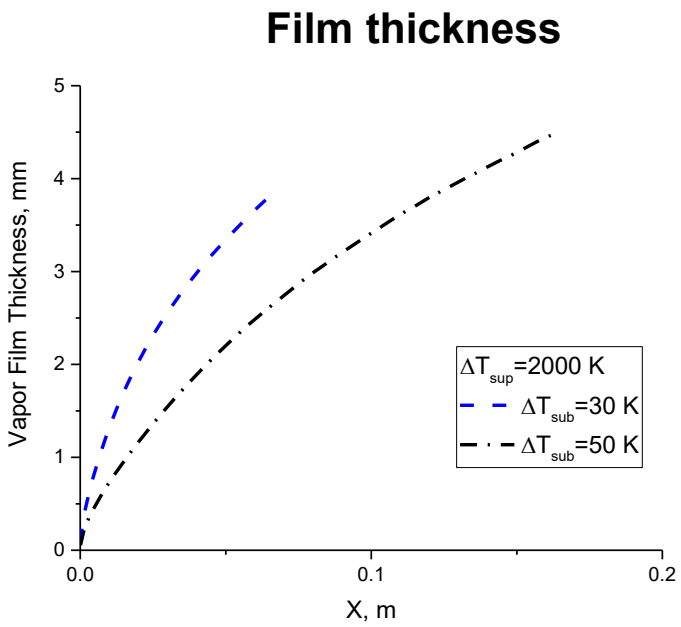


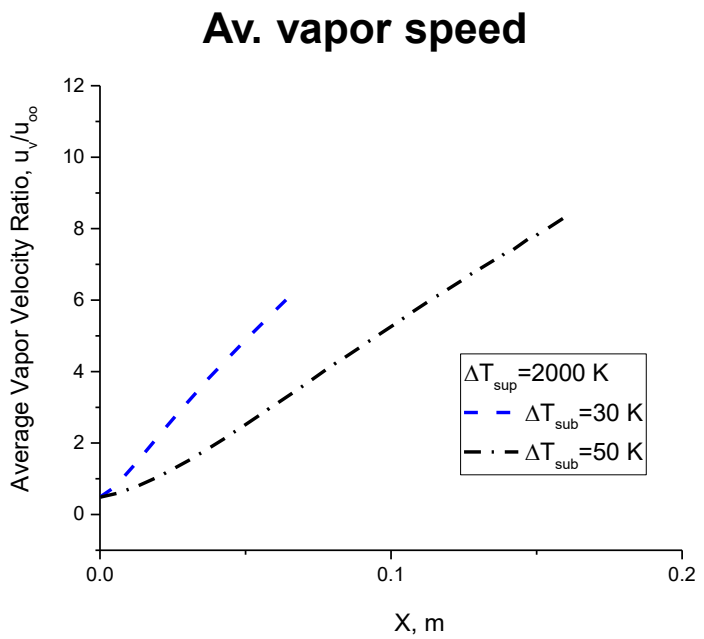






Solution for T_s=2100°C, V_j=4 m/s





- For high temperature surface, vapor film grows much thicker and numerical convergence failed, possibly due to the assumption of laminar flow.
- If jet breakup discontinues vapor film flow, the vapor film thickness on the first short length (~0.1 m) would be relevant.

Conclusions

- Amount of corium jet breakup in ex-vessel is a key to corium coolability and MCCI as well as steam explosion intensity.
- Existing jet breakup length models tend to overpredict debris mass of FARO data.
- A new formulation of jet breakup length is proposed by taking account of vapor film.
- Existence of vapor film on the corium jet surface increases significantly the jet breakup length.
- Film boiling on vertical plate has been modeled and solved for vapor film thickness.

COCOSYS simulation of CsI decomposition under irradiation and the formation of organic iodide in the containment

ABSTRACT

Iodine is one of the most hazardous fission products (FP) released to the containment of a nuclear power plant during a severe accident. The metallic iodide aerosol CsI is one of the main airborne iodine species in the containment and the CsI decomposition with formation of gaseous iodine species is a primary concern in nuclear accident scenarios. The thermal and radiolytic decomposition of CsI generates molecular iodine, which can further react with organic compound and form the organic iodide. In this paper the AC^2/COCOSYS code is applied to simulate and analyze the CsI decomposition and related iodine aerosol transport in the containment of LOCOV tests. The LOCOV experiment in the French EPICUR facility studied the decomposition of deposited CsI aerosol and the reactivity of I_2(g) with methane to quantify the organic iodide formation rate in the presence of volatile organic compounds (VOC) [1]. The COCOSYS simulation investigates the decomposition of CsI aerosol, the organic iodide formation and the distribution of the different iodine species across the coupon, the atmosphere, the vessel walls and the filter. The simulation results of LOCOV model show that the thermal decomposition of CsI is very slow, but a fast decomposition of CsI is observed under irradiation. The injected methane reacts with I_2 and organic iodide is generated, while the oxidation of I_2 with ozone produces iodine oxide aerosol IO_x. The gas phase I_2 in vessel deposits on the surfaces of vessel wall. With the time going on, the deposited I_2 reacts with Fe. Higher dose rates caused higher CsI decomposition and RI generation rates. The comparisons between simulation results and measurements show the modelling capabilities of organic iodide formation with COCOSYS in two LOCOV tests.

KEYWORDS
CsI decomposition, organic iodide, aerosol, irradiation

1. INTRODUCTION

Iodine is one of the most hazardous fission products (FP) released to the containment during a severe nuclear reactor accident. The evolution of volatile iodine concentration is determined by a balance between formation and deposition processes [2-4]. Volatile molecular iodine (I_2) can be produced from the iodine deposited on painted surfaces or from suspended aerosols [2-5]. The organic iodide compounds (RI) can be produced from iodine deposited on painted surfaces or reaction between iodine and organic gas, like methane [1-12]. The low-molecular-weight RI is harder to trap for the filter, making it more likely to be released into the environment. It makes the studies of volatile molecular iodine release and RI formation very important in the severe accident management.

The metallic iodide aerosol CsI is one of the main airborne iodine species in the containment and the CsI decomposition with formation of gaseous iodine species is a primary concern in nuclear accident scenarios [1, 7, 13]. The CsI decomposition process can be affected by many parameters. The AER-CsI test series in

the STEM-EPICUR program studies the behavior of CsI aerosols deposited on different surfaces of the containment and the ability to produce volatile iodine species [1]. The effects of various experimental parameters on the iodine species releases were evaluated: initial CsI concentration on the coupon, relative humidity, temperature, dose rate and nature of the coupon surface (stainless steel, quartz or EPOXY paint). The extensive experiment program STEM-EPICUR has been performed to obtain data concerning iodine volatilizations.

STEM-EPICUR program also investigated the formation of organic iodide from the painted surface in the containment atmosphere under various conditions [4, 6]. The initial concentration of iodine deposited on the painted coupon and the relative humidity were found to have significant impacts on the volatilization of organic iodide [6]. The ESTER-EPICUR tests investigated the iodine chemistry within the containment, focusing on the RI formation pathways not involving paints [14]. Specifically, the LOCOV tests examined reactivity under gamma irradiation on metal surfaces, such as electropolished stainless and galvanized steel, within an oxygen-depleted atmosphere containing organic gases (CH_4). The effects of methane, ethylene, surface, species and dose rate are checked through different tests.

The advanced iodine model (AIM), part of the AFP2 module in the AC^2-COCOSYS containment code, was developed to simulate aerosols, fission products and iodine chemistry [15-17]. Within AFP2, the CsI decomposition rate is calculated based on the dose rate, available CsI mass and a 'damage term' that accumulates proportionally to radioactivity, and a model dependent recovery rate. The recovery rate serves to buffer both the acceleration and deceleration of the decomposition process. In this study, COCOSYS is utilized to simulate CsI decomposition, RI formation, and the resulting distribution of iodine species across the coupons, atmosphere, vessel walls, and filters as investigated in the LOCOV and LOCOV2 tests.

2. Model Setup

The LOCOV and LOCOV2 tests utilized steel coupons as substrates for CsI deposits within a containment vessel. While the LOCOV test employed electropolished stainless steel with an initial iodine concentration of 1.86×10^{-4} mol/m^2, the LOCOV2 test used galvanized steel with a concentration of 1.60×10^{-4} mol/m^2 (see Table 1).

Table I. Experimental setups of LOCOV and LOCOV2

Test	LOCOV	LOCOV2
Coupon	Electropolished stainless steel	Galvanized steel
Aerosol	CsI	CsI
CsI concentration (mol/m^2)	$1.86\text{x}10^{-4}$	$1.60\text{x}10^{-4}$
Temperature (°C)	120	120
Pressure (bars)	3.5	3.5
Pre-irradiation	1 hour with dry air	1 hour with dry air 3 hours with wet air 50% R.H.
Irradiation	43 hours with Air (3% O_2) + 2% CH_4 + 50% R.H.	
Post-irradiation	1 hour with dry air (3% O_2) + 2% CH_4	
Dose rate (kGy/h)	1.2	6.9

Compared with LOCOV test, LOCOV2 test was performed with higher dose rate. The experiment is performed with continuous air flow that is directed through the vessel and released over a filter line in which the released chemical iodine components are trapped and analyzed according to the chemical compositions

that are separated in the different stages of the used May-pack filters. The air temperature in vessel is 25 °C and the pressure is 3.5 bar; both stay constant during the experiments LOCOV and LOCOV2. There is 1-hour pre-irradiation sweeping phase and 1-hour post-irradiation sweeping phase with 8.72×10^{-6} kg/s dry air (3% O_2 + 2% CH_4) for LOCOV test. LOCOV2 has extra 3 hours of pre-irradiation wet air sweeping period after the one-hour dry air sweeping phase. The irradiation phase duration is about 44.3 hours with 50% R.H. air (3% O_2 + 2% CH_4), in which the air gas injection rate is 6.25×10^{-6} kg/s and water injection rate is 1.54×10^{-6} kg/s. The different volatile iodine species (I_2, IO_x, RI) released during the test are transferred to the May-pack device and trapped on the different filters. The conceptual setup of the tests is shown in Fig.1.

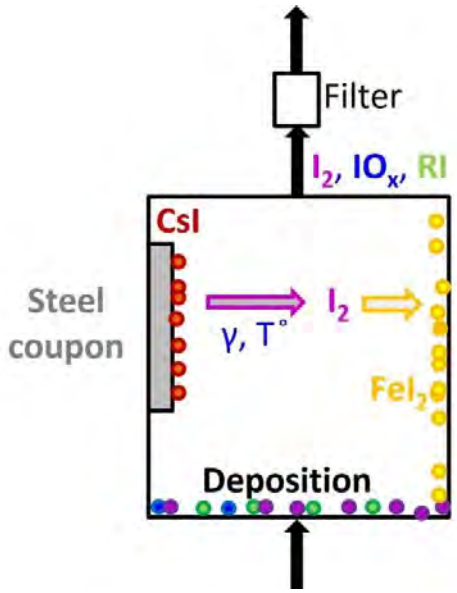

Figure 1. Conceptual model of LOCOV and LOCOV2 tests.

The principal reactions related to the CsI decomposition, RI formation and related iodine chemistry are shown in Fig. 2. In the iodine model AIM the decomposition of deposited CsI(dep) at the surface of coupon is simulated with two reactions that take place under irradiation: a faster reaction under irradiation with the production of I_2 and a slower reaction with the production of IO_x.

$$2\mathrm{CsI(dep)} + 2\mathrm{H_2O(g)} \xrightarrow{\gamma} \mathrm{I_2(g)} + 2\mathrm{CsOH(dep)} + 2\mathrm{H^+} \quad (1)$$

$$\mathrm{CsI(dep)} + \frac{1}{2}\mathrm{H_2O(g)} + \frac{x+0.5}{3}\mathrm{O_3(g)} \xrightarrow{\gamma} \mathrm{CsOH(dep)} + \mathrm{IO_x(g)} \quad (2)$$

A new conceptual model with a damage term is implemented for the CsI reaction under irradiation (Eq. 3). The idea behind the new model is to model the typical time dependent behavior of a delayed decomposition of CsI by introducing a damage term H (H for harm and to distinguish it from the dose D) in the reaction mechanism. The damage term accumulates proportional to the deposited mass, a model dependent recovery rate and the reaction rate of CsI:

$$\frac{dH}{dt} = m_{CsI} D_{gas} - H f_{rec} - \frac{\dot{r}}{m_{CsI}} H \quad (3)$$

The new CsI decomposition rate is then simply described as:

$$\frac{d[\mathrm{CsI}]}{dt} = -k_r^{\gamma} H \quad (4)$$

Where:

H	Damage term [kg·kGy/h]
m_{CsI}	Available CsI mass [kg]
D_{gas}	Dose rate [kGy/h]
f_{rec}	Recovery factor, which is a function of decomposition rate [1/s]
$\dot{r}$	Reaction rate of CsI [kg/s]
[CsI]	CsI concentration at the coupon surface [kg/ m^2]
k_r^{γ}	Radiolytic reaction coefficient [1/(m^2·kGy)]

Generally, the decomposition rate is high when there is more available CsI mass and the dose rate is high. At the beginning, there is more CsI available for reaction, so the decomposition rate will be high. As irradiation consumes more CsI, the amount available for reaction diminishes, leading to a decrease in the decomposition rate. However, the recovery factor f_{rec} also declines alongside the decomposition rate, effectively buffering the overall rate reduction.

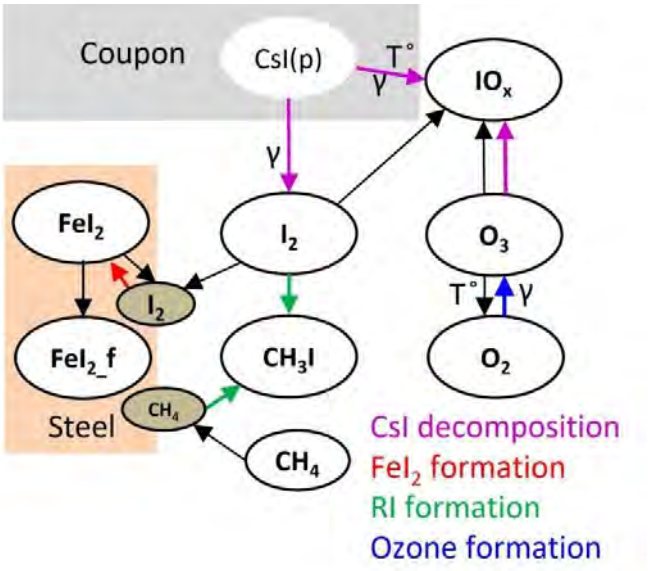

Figure 2. Schematic modelling of CsI destruction and RI formation.

Depending on the dose rate, ozone is formed from the oxygen in the air. Radiolytically produced ozone can react with gaseous I_2 to form IO_x aerosols, which exhibit distinct behavior compared to gaseous I_2. The backward conversion of IO_x to I_2 is also possible under accident typical gas temperatures. Deposition of I_2 onto steel surface and the subsequent chemical reaction with steel is an unwanted removal process for volatile iodine from the gas phase e.g. in iodine tests. The reaction of gaseous iodine (I_2) with dry stainless-steel surfaces can be described as the sequence of two processes: an initial, fast and reversible physisorption process, followed by a slower chemical reaction of the physical sorbed I_2 with the steel producing chemisorbed, non-volatile metal iodides (represented by FeI_2). FeI_2 can be further oxidized forming strongly bound iron-iodide-oxides FeI_2_f, which is a permanent iodine sink, and no iodine can be released from it into the gas phase again. Organic iodine formation occurs through a reaction of deposited methane with gaseous I_2, which was considered as the best model through comparing the different RI generation mechanisms models results with test measurements.

3. Simulation Results

3.1. LOCOV test simulation

The measurement showed that there is 30.7% missing mass balance at the end of LOCOV test [14]. Therefore, the LOCOV model simulated with COCOSYS focuses on the released iodine mass evolution in filter, the mismatch of iodine mass on coupon at the end is ignored.

Methane is injected into the vessel during the whole test process, so in the first 1 hour, the concentration of methane in the vessel increases quickly. When the irradiation starts, the radiolysis of the air/steam atmosphere produces ozone immediately (Fig. 3). The radioactive decomposition of CsI releases I_2. The oxidation of I_2 by ozone produces IO_x; simultaneously, the thermal production of IO_x also consumes ozone. Due to these ozone-consuming reactions, the ozone concentration decreases slightly and then maintains a constant level until the end of irradiation. Due to the extremely slow thermal decomposition of CsI, the IO_x concentration remains negligible and therefore omitted from the figure. Injected methane reacts with I_2 to generate organic iodine; however, the generation rate declines as the I_2 concentration is depleted. Once the irradiation stops, the production of both ozone and I_2 from CsI decomposition also ends. The remaining ozone and I_2 react rapidly, consuming both reactants in a short timeframe. Consequently, the concentration of methane begins to recover, while the concentration of organic iodine decreases sharply.

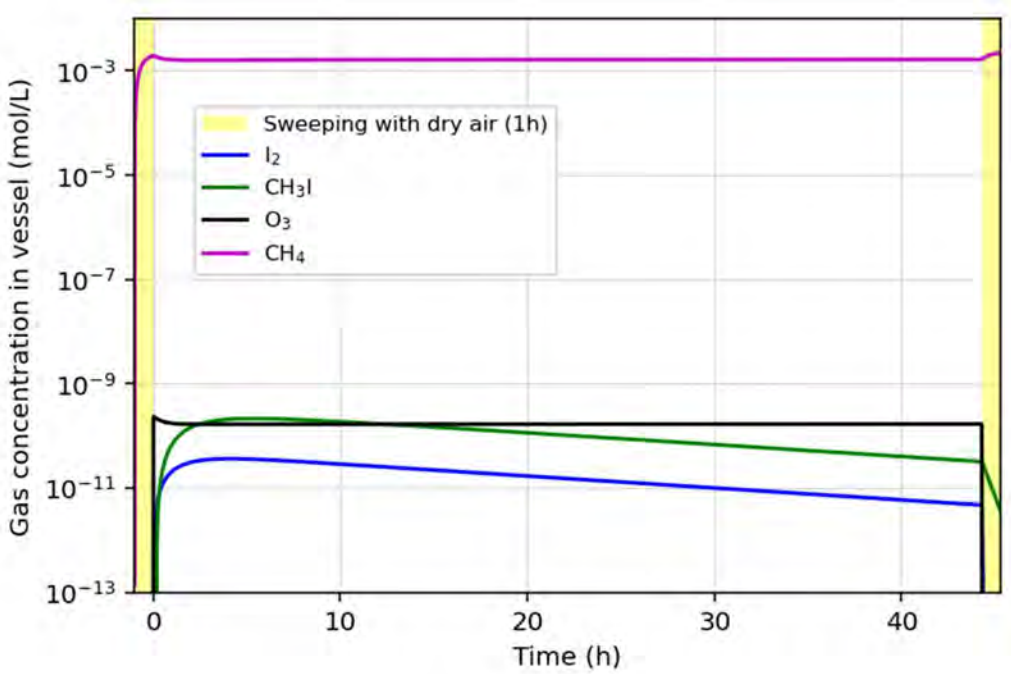

Figure 3. Evolution of gas phase species concentration in the containment for LOCOV model.

Fig. 4 illustrates the overall iodine balance across the hosts coupon, vessel atmosphere, vessel structures, and filter. At the end of simulation, there is totally 74.9% iodine deposited at the steel surface, 14.5% iodine in filter, 10.6% iodine on coupon. Due to the continuous flow design of the experiment, only a small fraction is present in the vessel atmosphere during the whole experimental sequence. The released gas phase I_2 from CsI decomposition in vessel deposits on the surfaces of the vessel walls. With the time going on, the deposited I_2 reacts with Fe and the FeI_2 is produced. FeI_2 can be further oxidized forming strongly bound iron-iodide-oxides, so the deposited iodine mass in form of FeI_2 continues increasing (Fig. 5). On the other hand, the deposited I_2 starts decreasing 10 hours after the irradiation. Because of the low concentration of

airborne IO_x, the deposited iodine in form of IO_x can be ignored. At the end of simulation, 95% of steel surface deposited iodine are FeI_2, only 5% are in form of I_2. Characterizing the spatial and chemical distribution of iodine is essential for understanding the system's behavior. This approach ensures the model can be accurately calibrated as more detailed experimental data becomes available.

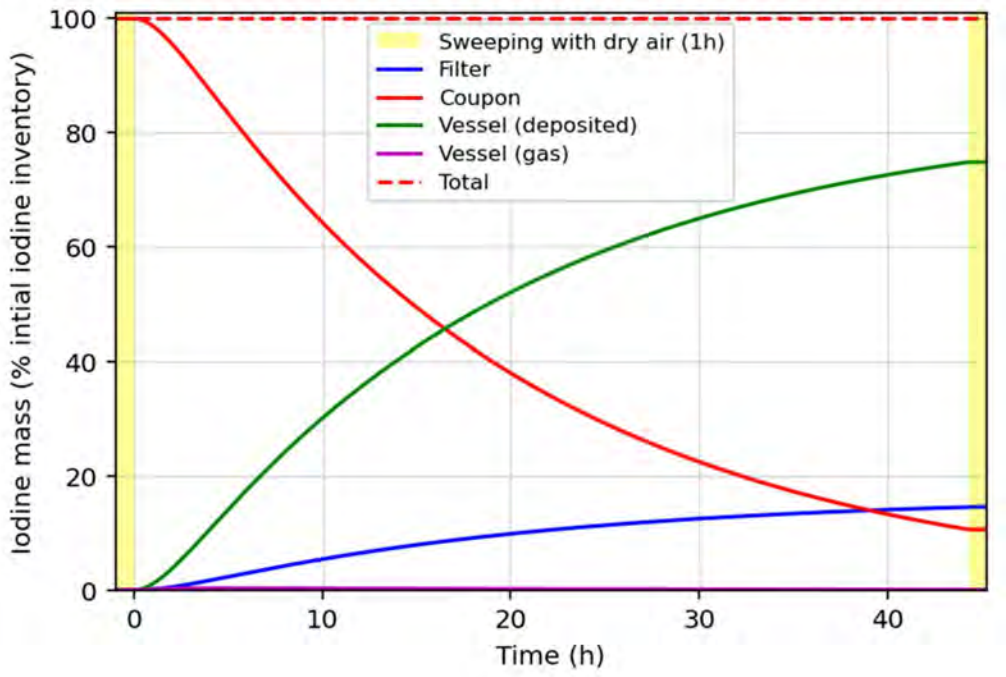

Figure 4. Evolution of iodine mass distribution for LOCOV model.

The simulated iodine mass in the filter is compared with experimental measurements from the LOCOV test in Fig. 6. The simulation indicates that the I_2 generation and subsequent organic iodine production rates are lower during the initial irradiation phase, resulting in a more gradual increase in the filter load. Generally, the simulation accurately captures the observed evolution of organic iodine. For the molecular iodine on the filter, there is 3.5% deposition at the end of simulation, which is a little bit lower than the measured data. The linear gradient trend in the measured data suggests a quasi-constant gas I_2 concentration within the vessel. However, during the final one-hour dry air weeping phase, after irradiation stopped, a sudden release of molecular iodine was detected on the filter. The mechanism behind this release remains unclear and requires more detailed observation. The simulation shows no more molecular iodine released from the system in the last hour. Same as the test observation, the concentration of IO_x is very low and can be ignored. The radioactive decomposition dominates the CsI release.

Within the COCOSYS calculation a large part of iodine is trapped on the steel walls of the vessel. This is a possible explanation for the large balance error observed in the experiment. However, the iodine-steel model of COCOSYS is derived from the specifics of the THAI vessel operated by Becker Technologies in Germany [18]. The steel inside the EPICUR facility is different and assumed to be inert to iodine deposition and reaction to a great extent. Therefore, the actual iodine sink remains unknown, though the piping utilized during the experiment may also account for the large balance error.

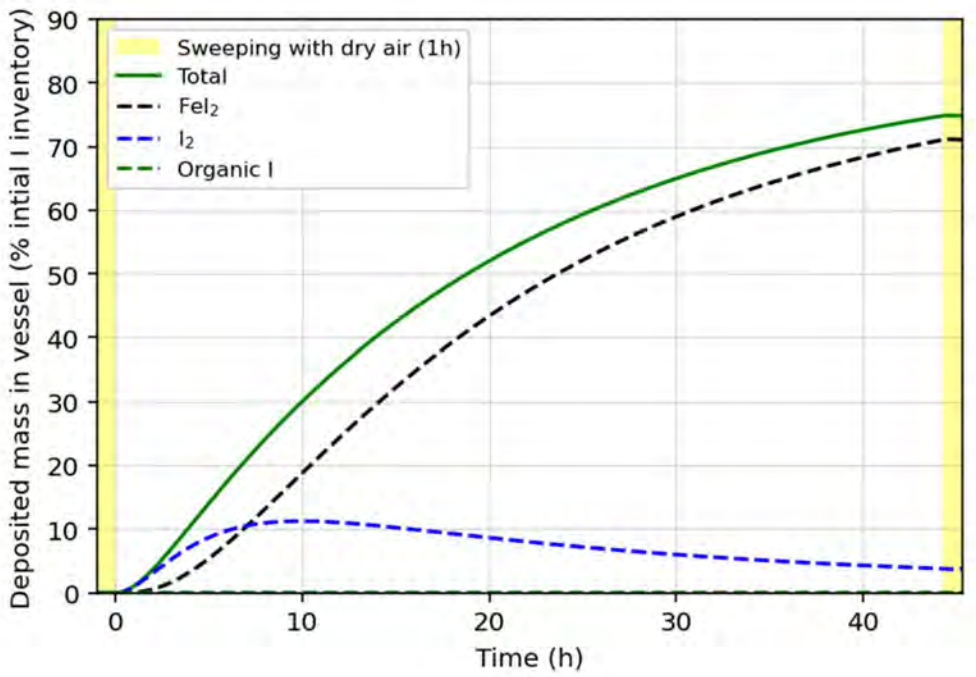

Figure 5. Evolution of deposited iodine at the steel surface for LOCOV model.

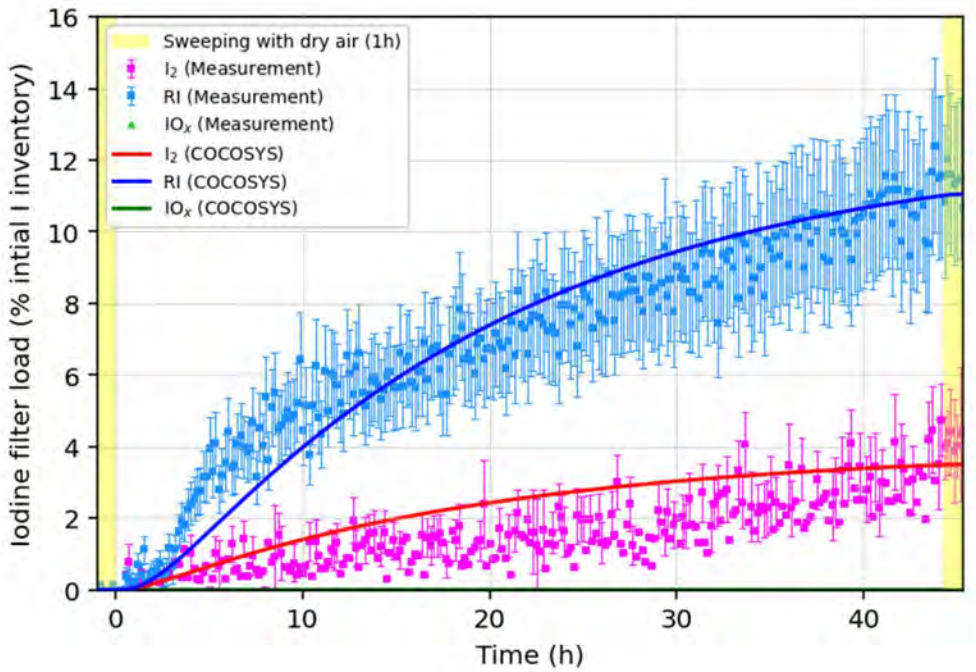

Figure 6. Comparison of measured and simulated iodine activity in filter for LOCOV test.

3.2. LOCOV2 test simulation

The chemical model implemented in COCOSYS as depicted in Fig.2 has been developed on LOCOV results. To estimate the general validity of this model and check the sensitivity of dose rate on CsI

decomposition and RI generation, also the experiment LOCOV2 has been simulated. Different from LOCOV test, LOCOV2 used galvanized steel as the coupon surface material and higher dose rate. Because of the higher dose rate in LOCOV2, which is 6.9 kGy/h compared to only 1.2 kGy/h in LOCOV test, the decomposition rate of CsI on coupon and the ozone generation rate are higher in LOCOV2 simulation. Therefore, the molecular iodine I_2 concentration in the containment increases quickly when the irradiation starts, and the concentration of ozone is much higher compared with LOCOV model (Fig. 7). Consequently, the generation rate of RI is higher, too. These higher concentrations of I_2 and RI cause more iodine mass transport out of the vessel and into the filter (Fig. 8). This fast mass flow-out limits the deposition of iodine on the steel wall surfaces. At the end of simulation, there is almost 54% iodine mass in the filter, and there is still 46% iodine mass on the coupon (Fig. 8). The iodine deposition at the containment wall surface can be ignored.

At the end of experiment LOCOV2 there is 0.3% IO_x, 29.1% I_2 and 23.0% RI deposition on the filters compared to the initial inventory. Compared to the LOCOV test, higher rates of CsI decomposition of RI formation resulted in a greater release of molecular and organic iodine. Generally, the simulated organic iodine on the filter shows good agreement with the measured RI evolution (Fig. 9). Regarding the molecular iodine on the filter, the simulation shows a slower release rate in the first 20 hours compared to experimental results. The damage term implemented in COCOSYS buffers the high CsI decomposition rate when both the dose rate and available CsI mass are elevated. This likely explains why the model underestimates the initial rapid release of molecular iodine; However, the simulation successfully captures the overall release trends.

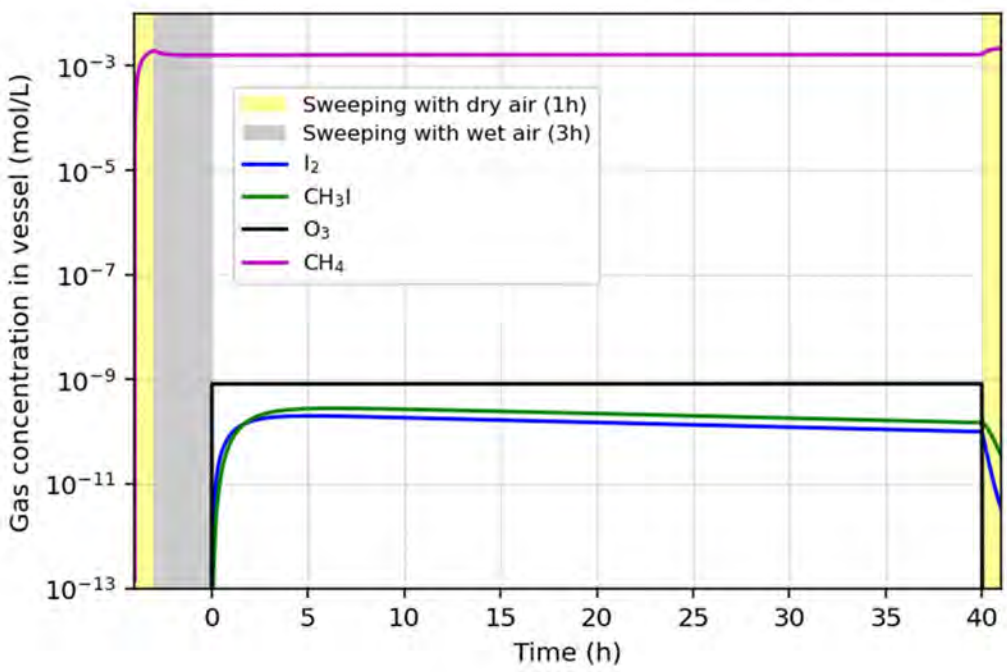

Figure 7. Evolution of gas phase species concentration in the containment for LOCOV2 model.

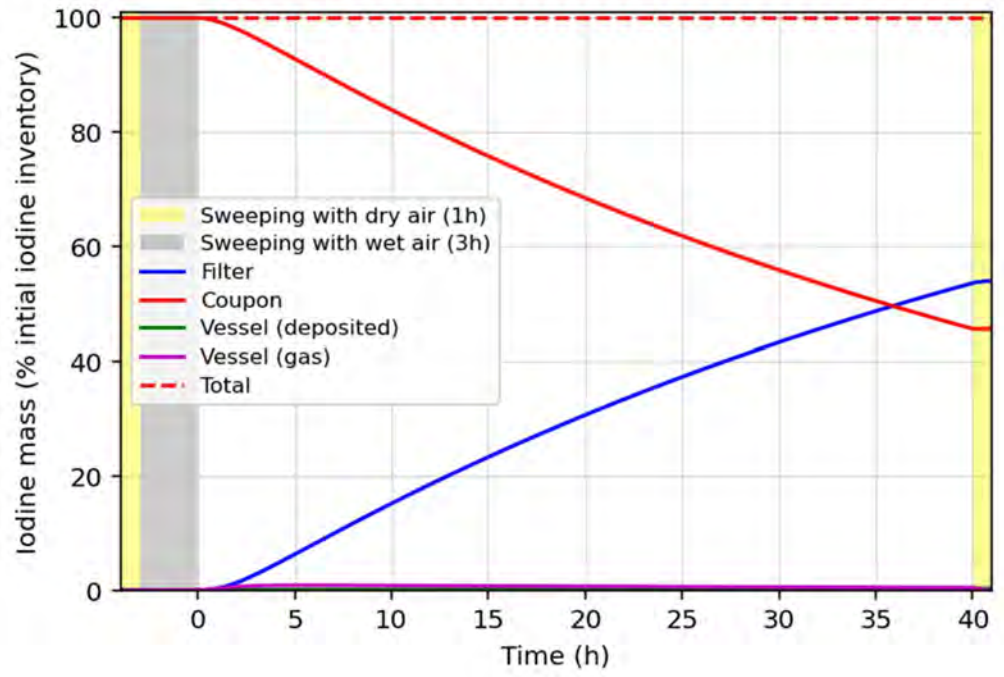

Figure 8. Evolution of iodine mass distribution for LOCOV2 model.

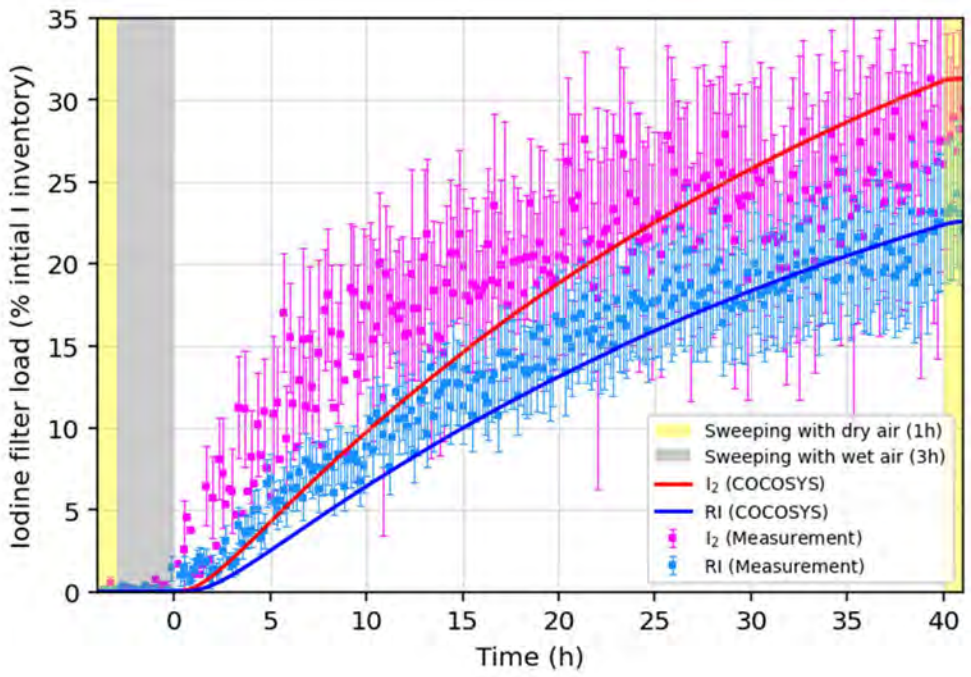

Figure 9. Comparison of measured and simulated iodine activity in filter for LOCOV2 test.

4. CONCLUSIONS

The LOCOV and LOCOV2 tests, which investigate CsI decomposition and RI generation, were simulated using the AFP2 module in COCOSYS. The models show that irradiation significantly accelerates CsI decomposition compared to thermal processes. Injected methane reacts with I_2 to generate organic iodine, while the oxidation of I_2 by ozone produces IO_x aerosols. Additionally, gaseous I_2 deposits onto the steel vessel walls, where the model predicts a subsequent reaction with iron to form FeI_2. While higher dose rates increased CsI decomposition, the lower I_2 deposition rate on the steel wall in LOCOV2 may be attributed to relatively high humidity, a phenomenon warranting further study. Overall, the agreement between simulation and experimental data demonstrates the robust capabilities of COCOSYS in modelling organic iodide formation.

In these experiments, a specific fraction of iodine reacts with volatile organic compounds (VOC). While these species may form directly at the steel surfaces, the underlying mechanisms remain unidentified. Additionally, mass balances are often incomplete across various tests. COCOSYS simulations indicate this may be due to the trapping of iodine species on the EPICUR vessel walls or within the external piping. To further clarify the generation processes of organic and molecular iodine, additional measurement data on the coupon and steel structure surfaces are required.

Simulation of melt spreading in CoSMUS experiments using the MPS method

Lu Zhao, Weimin Ma, Andrei Komlev, Sevostian Bechta

KTH Royal Institute of Technology
Stockholm, Sweden
20/05/2026

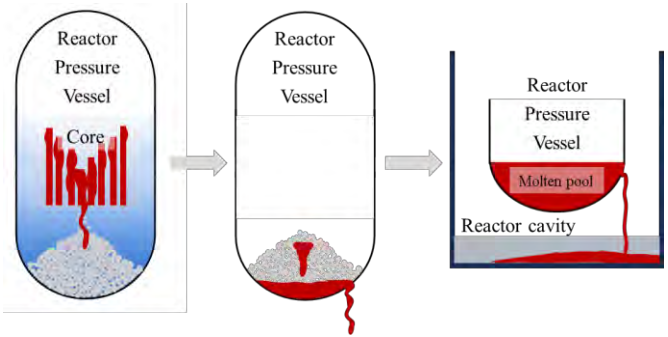
Outline

- Introduction
- Modelling approach
- Simulation of oxidic melt dry spreading
- Concluding remarks & Outlook

Introduction

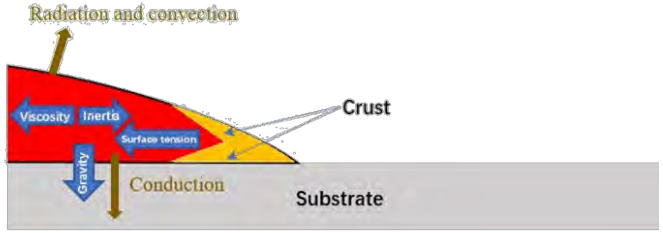
❑ Significance

- ➢ Following vessel failure, corium (molten core material) will pour onto the containment floor and likely spread.
- ➢ Spreading extent influences melt coolability (i.e., deeper melt are difficult to cool).
- ➢ Spreading melt can lead to thermal attack on important structures (i.e., concrete) and threaten containment integrity.



❑ Phenomenology

- ➢ Hydrodynamic motion: gravitational, viscous, inertial and surface forces
- ➢ Heat transfer with liquid-solid phase change
- ➢ Additional phenomena: concrete ablation, gas generation, melt eruption, etc.

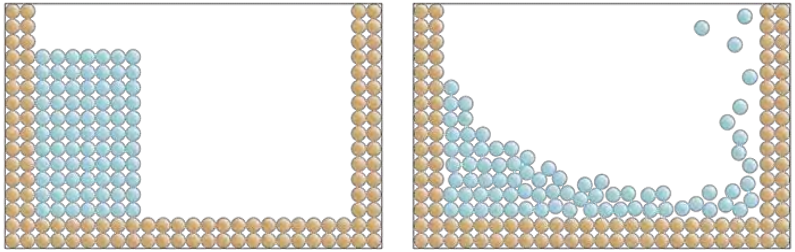


❑ Objectives

- ➢ Further validate the capability of MPS code for dry spreading analysis.
- ➢ Deepen the understanding of melt dry spreading mechanisms.

MPS modelling approach

- Moving particle semi-implicit (MPS) method is employed



Example: water column collapse

- <u>What is MPS method?</u>

✓ Lagrangian approach for incompressible free surface flow.

✓ The computation domain is represented by particles.

✓ Pressure term is calculated implicitly.

- <u>Why choose MPS method here?</u>

✓ Allows large deformation of interfaces.

✓ No numerical diffusion.

✓ Easier to generate particle configuration.

Main equations

- **Mass conservation**

$$\frac{D\rho}{Dt} + \rho\nabla \cdot \mathbf{u} = 0$$

- **Momentum conservation**

$$\frac{D\boldsymbol{u}}{Dt} = -\frac{1}{\rho}\nabla P + \nu\nabla^2\mathbf{u} + \boldsymbol{g} + \frac{\boldsymbol{F}}{\rho}$$

Weight function

$$\omega(r) = \begin{cases} \frac{r_e}{r} - 1 & (0 < r < r_e) \\ 0 & (r_e \le r) \end{cases}$$

Particle number density

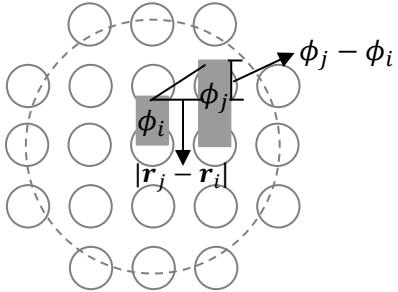
$$n_i = \sum_{j \neq i} \omega(|\boldsymbol{r}_j - \boldsymbol{r}_i|)$$

Free surface detection

$$\langle n \rangle_i^* < \beta n^0, \beta<1$$

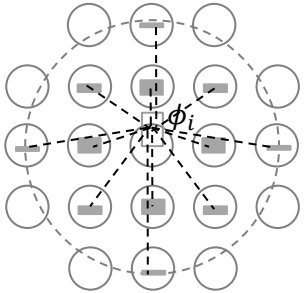
Gradient discretization

$$\langle \nabla\phi \rangle_i = \frac{d}{n^0}\sum_{j \neq i}\left[\frac{\phi_j - \phi_i}{|\boldsymbol{r}_j - \boldsymbol{r}_i|^2}(\boldsymbol{r}_j - \boldsymbol{r}_i)\omega(|\boldsymbol{r}_j - \boldsymbol{r}_i|)\right]$$



Laplacian discretization

$$\langle \nabla^2\phi \rangle_i = \frac{2d}{\lambda n^0}\sum_{j \neq i}\left[(\phi_j - \phi_i)\omega(|\boldsymbol{r}_j - \boldsymbol{r}_i|)\right]$$



Additional models (1)

- **Heat transfer model**

$$\frac{DH}{Dt} = k\nabla^2 T + S_Q$$

$$H_i^{k+1} = H_i^k + k\Delta t \cdot \frac{2d}{\lambda n^0} \sum_{j \neq i} \left(T_j^k - T_i^k\right) \omega\left(\left|\boldsymbol{r_j} - \boldsymbol{r_i}\right|\right) + S_Q \Delta t$$

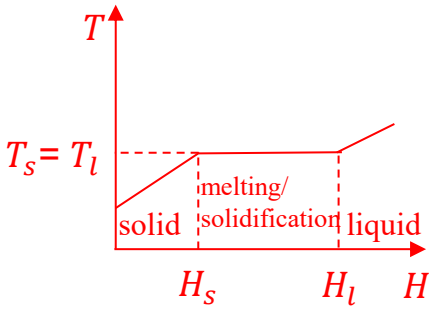
$$T = \begin{cases} T_s + \dfrac{H - H_s}{\rho C_{p,s}} & H < H_s \\ T_s + \dfrac{(H - H_s)(T_l - T_s)}{H_l - H_s} & H_s \leq H \leq H_l \\ T_l + \dfrac{H - H_l}{\rho C_{p,l}} & H > H_l \end{cases}$$

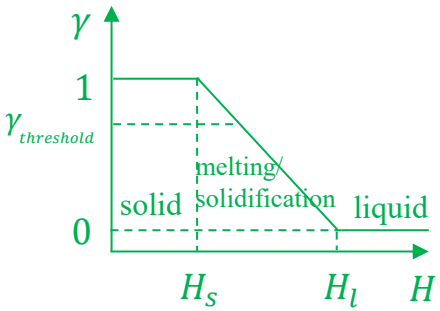
T_s and T_l are the solidus and liquidus temperature; H_s and H_l are the enthalpies at the liquid and solid state.

- **Phase change model**

$\gamma \geq \gamma_{threshold}$ *particle is solid*
$\gamma < \gamma_{threshold}$ *particle is liquid*

$$\gamma = \begin{cases} 1 & H < H_s \\ \dfrac{H_l - H}{H_l - H_s} & H_s \leq H \leq H_l \\ 0 & H > H_l \end{cases}$$





Additional models (2)

➢ Surface tension model

- Interparticle potential: $p(r) = \begin{cases} \frac{1}{3} C_f \left(r - \frac{3}{2} l_0 + \frac{1}{2} r_e\right)(r - r_e)^2 & r < r_e \\ 0 & r \geq r_e \end{cases}$

- Force: $\boldsymbol{F}_{st} = -\frac{\partial p(r)}{\partial \boldsymbol{r}} = -C(r - l_0)(r - r_e)\frac{\boldsymbol{r}}{r}$

  C_f: the potential force coefficient between fluid particles, $C_f = \frac{6\sigma l_0^2}{\sum\left(r - \frac{3}{2} l_0 + \frac{1}{2} r_e\right)(r - r_e)^2}$

➢ Wettability (contact angle)

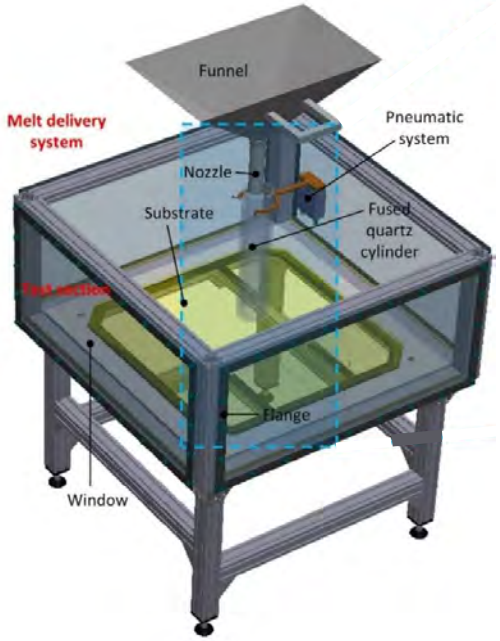
- Based on contact angle: $C_{fs} = \frac{C_f}{2}(1 + \cos\theta)$

  C_{fs}: the potential force coefficient between fluid and solid particles

  θ: the contact angle

Description of CoSMUS experiment

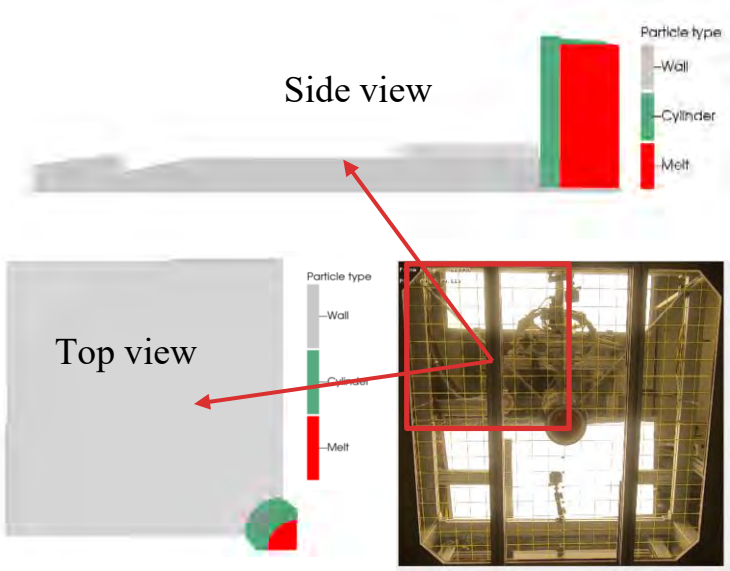
- The "dam break" melt supply method is employed to eliminate jet-coolant interaction and fragmentation, while minimize heat loss and ensure symmetrical melt delivery.
- The facility is composed of melt delivery system, and the test section.



CoSMUS test matrix							
Expt.	**Melt type**	**Cavity condition**	**Composition**	**Melt volume (l)**	**Melt superheat (°C)**	**Water subcooling (°C)**	**Gap for melt flow (mm)**
CoSMUS 01a_DM	**Metal**	**Dry**	**Zn**	**0.81**	**11**	**-**	**10**
CoSMUS 01b_DM				**0.96**	**75**	**-**	**10**
CoSMUS 01c_DM				**0.97**	**90**	**-**	**10**
CoSMUS 02_WM		**Wet**		**0.99**	**71**	**4±1**	**10**
CoSMUS 03_DO	**Oxide**	**Dry**	**Eutectic Bi_2O_3-WO_3 mixture**	**0.82**	**66**	**-**	**10**
CoSMUS 04_WO		**Wet**		**0.86**	**36**	**5±1**	**10**
CoSMUS 05_WO				**0.75**	**10**	**4±1**	**60**

Simulation of oxidic melt dry spreading

- Using eutectic WO_3-Bi_2O_3 mixture as an oxidic corium simulant, the CoSMUS03_DO test was conducted with the superheat of 66 °C.
- A quarter-section of the test is simulated to reduce computational time as the high-speed camera indicates symmetrical spreading.

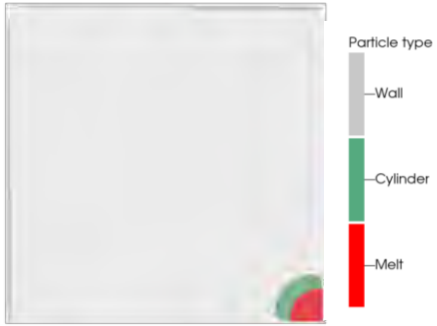


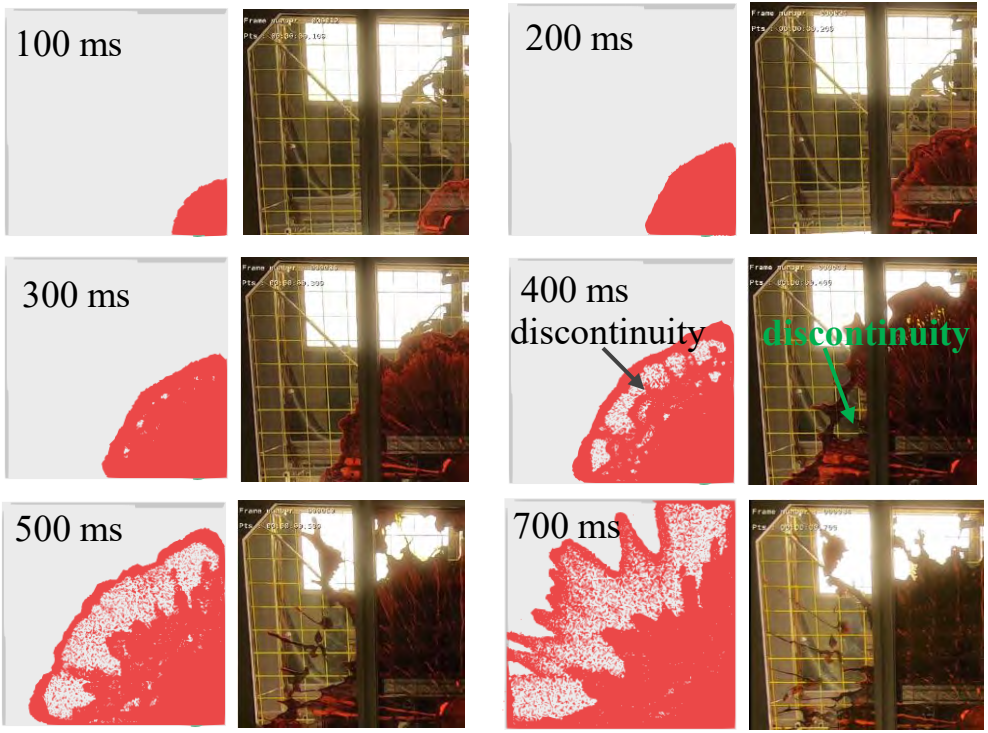
Thermophysical properties and initial conditions for CoSMUS03_DO

Parameter	Melt	Substrate
Material	Eutectic WO3-Bi2O3	Quartz
Density, kg/m^3	6724	2650
Specific heat, J/(kg·K)	501	690
Thermal conductivity, W/m/K	1.6	1.4
Emissivity	0.85	-
Viscosity, pa·s	0.003	-
Latent heat, kJ/kg	196.606	-
Surface tension, N/m	0.3-0.4	-
Melting point, K	1148	-
Initial temperature, K	1214	293

Results of CoSMUS03_DO test (1)

Melt spreading process

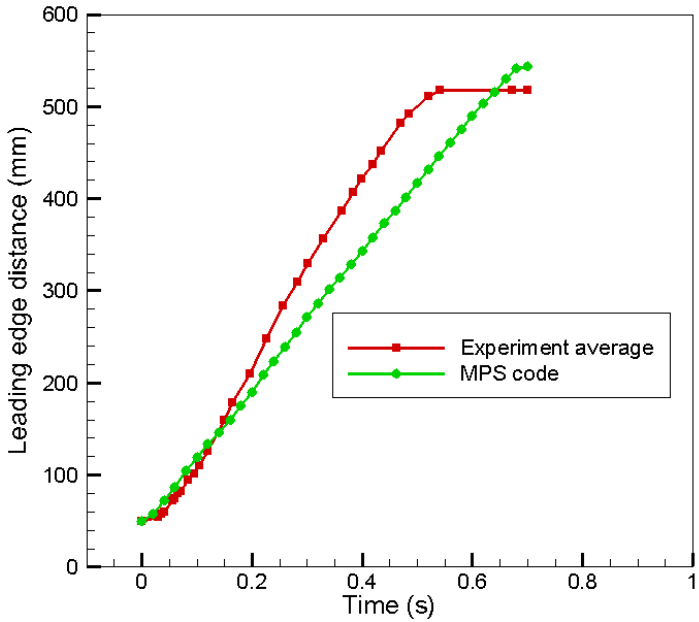




- Before 300 ms, both the experiment and simulation show a rapid spreading with a symmetrical shape and smooth edge.
- After 300 ms, melt discontinuity is observed at melt front due to low surface tension. As melt spreads further, the melt front becomes highly irregular, forming finger-like structures due to instabilities.
- Fingers appear earlier and are narrower in the experiment.

Results of CoSMUS03_DO test (2)

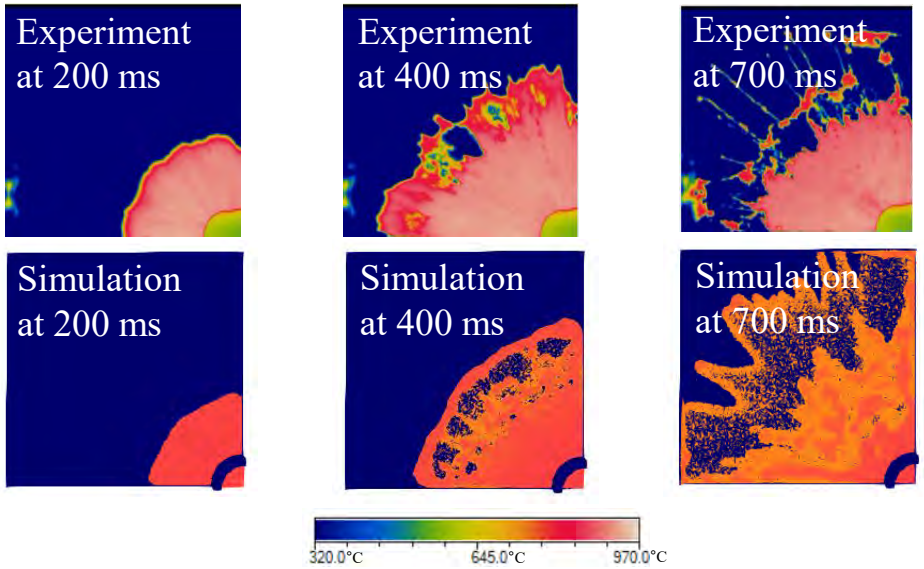
Evolution of melt leading edge

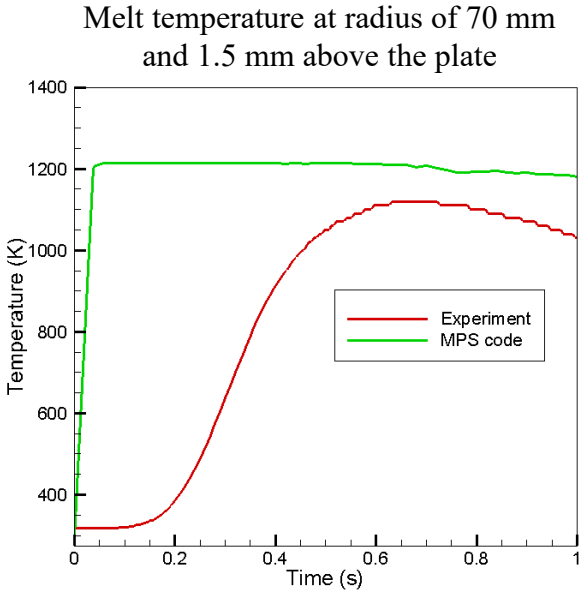


- Both the experimental and numerical data show a nearly constant velocity of melt leading edge over time, followed by a termination phase.
- The simulation predicts a lower spreading rate and larger edge distance. These discrepancies may arise from uncertainties in the estimation of key physical parameters (e.g., surface tension, wettability).

Results of CoSMUS03_DO test (3)

Melt top surface temperature field





- With melt spreading further and reaching a large area, the temperature at the top of the melt decreases with time.
- Experiment shows a higher melt top surface temperature, which may be caused by the uncertainty in the IR camera emissivity setting.
- The simulation predicts a rapid temperature rise, while experimental data exhibit a more gradual temperature rise.
- After reaching the peak temperature, the experiment shows a gradual decline, likely due to the incomplete contact between thermocouples and the melt & the crust formation around TC junctions.

Concluding remarks & Outlook

Concluding remarks

- Melt discontinuity and fingers are observed from the periphery of oxidic melt.
- The simulation predicts a rapid temperature rise, while the experimental data shows a more gradual temperature increase at a given position.
- Uncertainties in the estimation of key physical parameters (surface tension, wettability) can cause discrepancies between the simulation and experimental results.

Outlook

- Sensitivity analysis of key parameters will be conducted to better quantify their influences.
- Apply the code in reactor-scale safety analysis.

ABSTRACT

A realistic assessment of the probabilities of containment-failure modes (e.g., leaks and ruptures) is essential for improving the quality and credibility of Level 2 probabilistic safety assessments (PSAs) for nuclear power plants (NPPs). The paper presents the technical background on the impact of two representative scenarios—slow- and fast-pressurizations—characterized by different containment-pressurization rates and commonly used in severe-accident risk analyses and Level 2 PSAs. Both approaches fundamentally rely on probabilistic-fragility curves that are developed independently for two distinct failure modes—leaks and ruptures of predefined nominal size. In some cases, smaller leakage modes—below the nominal leak size—may be explicitly included to enable a more realistic evaluation of probabilistic-safety goals concerning a release of 100-TBq Cs-137. Findings from relevant case studies are presented together with key insights on their implications for Level 2 safety and performance goals, including Large Early Release Frequency (LERF) and the Cs-137 release risk.

1. INTRODUCTION

In nuclear power plants (NPPs), Level 2 Probabilistic Safety Assessment (PSA) evaluates containment performance and characterizes the associated severe-accident risk by considering a range of severe-accident progressions that arise from various core-damage sequences [1]. Many countries establish their own probabilistic safety goals for severe-accident risk [2]—for example, Large Early Release Frequency (LERF), Large Release Frequency (LRF) (defined in some jurisdictions as the 100-TBq Cs-137 release frequency), and Containment Failure Frequency (CFF), as shown in Table I. The LERF is employed as a surrogate risk indicator for severe accident-induced early fatalities, thereby embodying a quantitative health objective (QHO) [3, 4]. The LRF serves as a surrogate indicator for severe accident-induced long-term public health effects and land-contamination risk. By contrast, the frequency of 100-TBq Cs-137 releases specifically quantifies the severe accident-induced long-term land-contamination risk.

Various factors—modeling assumptions, data gaps, and scenario variability—introduce conservatism and uncertainty into the assessment of these Level 2 risk indicators. This paper concentrates on potential containment failure modes and their impact on the severe accident risk, emphasizing the need for a more robust technical basis to estimate the associated risk indicators.

Within the LERF assessment, many Level 2 PSAs evaluate the probabilities of two distinct containment failure modes—leak and rupture. Some Level 2 PSAs explicitly consider two pressure-load types that may be imposed on the containment during a severe-accident progression [5]: (a) slow pressure loads; (b) fast

pressure loads. The slow load denotes a pressure increase that is slower than the time required for a breach to depressurize the containment, typically arising from the gradual generation of steam and non-condensable gases. Although thermodynamically rapid, this load is slow relative to the structural response. The fast/rapid load, by contrast, describes a pressure rise that exceeds the depressurization time through a breach. Rapid pressure loads may arise from high-pressure melt ejection, detonation or deflagration of combustible gases, and steam spikes generated by ex-vessel fuel–coolant interactions. From this viewpoint, we first present case studies that examine how these two pressure-load types affect leak and rupture failure probabilities.

Certain cases require the explicit consideration of a leakage mode that is smaller than the conventional leak size, whose nominal size is typically equivalent to the containment-design leakage rate, in order to evaluate more accurately the potential release of Cs-137 to the environment, in addition to the conventionally applied leak and rupture modes. This is because such a small-leakage mode in a Level 2 PSA can alter both the amount and the rate of radioactive material released, and consequently the environmental impact. If the probabilities of the three failure modes (small-leakage, leak, and rupture) are not distinguished in the fission-product source-term evaluation, the Level 2-related risk and the resulting probabilistic consequence-analysis can be underestimated, potentially leading to inadequate emergency-response measures or off-site risk. In this context, an additional case study is presented to provide a technical basis for assessing how the inclusion of a small-leakage mode could affect a 100-TBq Cs-137 release risk.

This paper primarily focuses on structural failure or damage of the containment that may occur during severe accidents; bypass-containment events, although recognized as another contributors to Level 2 risk, are excluded from the analysis.

Table I. Level 1 and 2 related safety goals defined in several countries

Country	Level 1 risk	Level 2 risk	Objects/Remarks
Canada (Regulator)	CDF < 10^{-5} /ry	SRF (1000-TBq I-131) < 10^{-5} /ry LRF (100-TBq Cs-137) < 10^{-6} /ry	New plants
Czechia (Licensee)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	LERF (> 1 % Cs-137, up to 10 h from fuel damage) < 10^{-5} /ry LERF: practically eliminated	Existing plants (incl. SFP) New plants (incl. SFP)
Finland (Regulator)	CDF < 10^{-5} /ry	LRF (100-TBq Cs-137) < 5.0×10^{-7} /ry	All plants (incl. new)
France (Regulator)	CDF < 10^{-5} /ry CDF < 10^{-6} /ry	LRF: practically eliminated (not quantitatively specified)	New plants (all modes/hazards) New plants (internal events)
Hungary (Regulator)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	L(E)RF < 10^{-5} /ry L(E)RF < 10^{-6} /ry	Existing plants New plants
Japan (Regulator)	CDF < 10^{-4} /ry	CFF < 10^{-5} /ry 100-TBq Cs-137 < 10^{-6} /ry	All plants (incl. new)
R. Korea (Regulator)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	LERF < 10^{-5} /ry LERF < 10^{-6} /ry 100-TBq Cs-137 < 10^{-6} /ry	Existing plants APR1400 follow-up All plants (incl. new reactors)
Sweden (Licensee)	CDF > 10^{-5} /ry < 10^{-4} /ry	L(E)RF (> 0.1 % of core inventory) < 10^{-7} /ry	All plants
USA (Regulator)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	LERF < 10^{-5} /ry LERF < 10^{-6} /ry	Existing plants New plants
IAEA	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	LERF < 10^{-5} /ry LERF < 10^{-6} /ry	Existing plants New plants

CDF = core damage frequency, SRF = small release frequency, SFP = spent fuel pool, ry = reactor year

2. DEFINITION OF THE PROBLEM AND RELEVANT CASE STUDIES

According to internationally recognized guidelines—e.g., NUREG-1150 [5] and the EPRI PSA Application Guide [6]—the two containment-failure modes employed in Level 2 PSA, leak and rupture are defined for a large, dry, pre-stressed, reinforced-concrete containment that has a cylindrical body with a hemispherical dome, as follows:

- Leak: *a containment breach that halts a gradual pressure buildup and requires 2 h or more to depressurize the large dry containment*. A typical example of this failure mode is the failure of the equipment hatch ring or the tearing of the containment liner plate, with nominal opening sizes ranging from 0.04 to 0.1 ft² (approximately 0.0037—0.0093 m²).
- Rupture: *a containment breach that depressurizes the containment within 2 h*. A typical example of this failure mode is hoop failure of the containment due to membrane stresses in the cylindrical wall. Such a rupture is typically characterized by a break greater than 1.0 ft², with nominal opening sizes ranging from 1.0 ft² (0.0929 m²) to 2.0 ft² (0.1858 m²).

As applied in the Level 2 PSA for the reference PWR [7], the probability density function (PDF) and the cumulative distribution function (CDF)—for the two failure modes are shown in Table II and Fig. 1. The modes are estimated independently for the cylindrical wall, each mode characterized by nominal break sizes of 0.1 ft² and 1.0 ft², respectively.

Table II. Containment fragility curves of the reference plant

Failure Modes	Lognormal PDF as a Function of Pressure Load (p)	Median Pressure (p_m, *psig*[1])	Logarithmic Standard Deviation (β)
Leak	$f(p) = \frac{1}{\beta\sqrt{2\pi}p}\exp\left[-\frac{(\ln(p)-\ln(p_m))^2}{2\beta}\right]$	162	0.14
Rupture		189	0.21

[1] 1 psig = 0.006894757 MPa

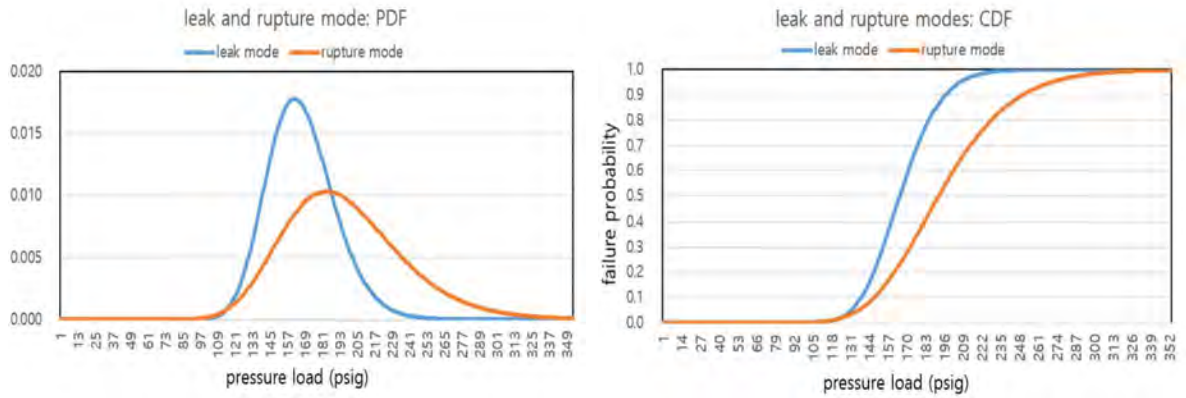

Figure 1. Containment fragility curves of the reference plant: PDF and CDF.

The Level 2 risk indicator, LERF (Large Early Release Frequency) is defined as the aggregate frequency of all accident scenarios that cause large, unmitigated releases from the containment to the environment prior to an effective evacuation of the surrounding population, thereby creating the potential for early health effects. The accident scenarios encompassed by LERF involve (a) unscrubbed, unfiltered releases of radioactive material resulting from containment isolation failures; (b) containment-bypass events such as interfacing-system loss-of-coolant accidents (ISLOCA) and induced-steam-generator tube ruptures (I-SGTR); and (c) any scenario that causes containment damage or failure that is equivalent to the "large" release defined above. These releases occur at, or shortly after, the reactor vessel breach—generally within 4 h of the breach in a pressurized-water reactor (PWR). As is the case in many countries, the Korean Level

2 PSAs also adopt the definition of LERF given above.

Regarding the 100-TBq Cs-137 release risk, some countries (e.g., Canada and Finland) embed this requirement in the Large Release Frequency (LRF) requirement, as shown in Table I. In the Level 2 context, LRF is defined as the aggregate frequency of all accident scenarios that could lead to any release to the environment (a) requiring long-term relocation of the population or (b) exceeding100-TBq Cs-137. In contrast, other countries—most notably Korea and Hungary—treat the criterion as a separate metric. The Korean Level 2 PSA defines the overall release frequency as the sum of the LERF and the Large Late Release Frequency (LLRF). LLRF represents a late-phase containment failure that is triggered by excessive pressurization and can release airborne fission products during the 72-h mission window assumed in a Level 2 PSA. Both LERF and LLRF are derived from Level 2 PSA Source Term Category (STC) event tree, as illustrated in Fig. 2.

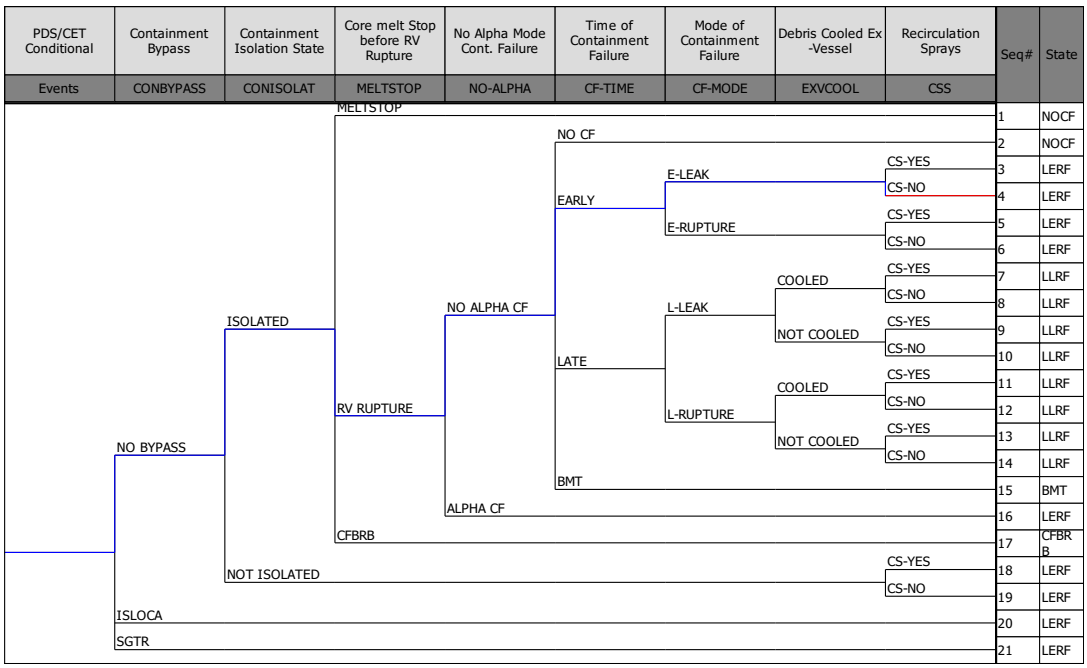

Figure 2. STC classification event tree of the reference plant.

The following sections illustrate how the two different containment pressurization scenarios—slow and fast—affect the relevant containment failure mode probabilities, the associated STC frequencies and LERF values, and the provisional impact of small leakage size on the assessment of a 100 TBq Cs-137 release risk.

2.1. Influence of containment pressurization scenarios to relevant failure probabilities

2.1.1. Case 1: scenarios involving slow pressurization

For slow pressurization, it is generally assumed that a leak occurs first at a given pressure, and rupture follows only in a subset of cases without considering a transition between leak and rupture [5, 8]. Under slow pressurization, we further assume that containment failure is governed by the failure mode that occurs at the lowest pressure, with each probability distribution estimated independently. In such case, both leak and rupture probabilities at a given pressure—$P_l(p)$ and $P_r(p)$, respectively—are evaluated using the following expressions:

$$P_l(p) = \int_0^p f_l\,(p')[1 - F_r(p')]dp' \quad (1a)$$
$$P_r(p) = \int_0^p f_r\,(p')[1 - F_l(p')]dp' \quad (1b)$$
$$P_{no}(p) = 1 - [P_l(p) + P_r(p)]dp' \quad (1c)$$

Where:
$f_l(p), f_r(p)$: PDFs of the leak and rupture, respectively, with respect to the pressure p,
$F_l(p), F_r(p)$: CDFs of the leak and rupture, respectively, with respect to the pressure p,
$P_l(p), P_r(p), P_{no}(p)$: Leak, rupture, and no failure probabilities at the pressure p, respectively.

According to Equation (1), the cumulative probabilities of a containment leak and rupture up to pressure p account for the conditional probabilities that leak and rupture have not occurred at or below that pressure, respectively. Based on the fragility curves shown in Table II, the leak and rupture probabilities evaluated for this case are presented in Fig. 3.

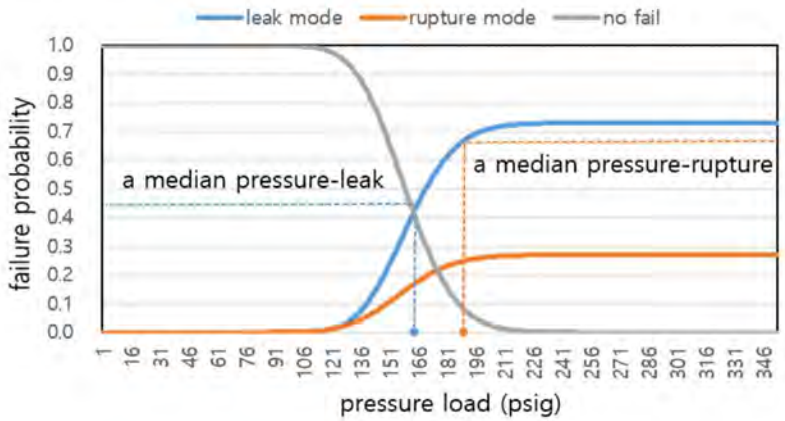

Figure. 3. Estimated probabilities for each failure mode: Case 1.

According to Fig. 3, up to approximately 75 psig, there is no difference between the rupture and leak probabilities, as both are nearly zero. However, from that point up to approximately 189 psig—where the rupture probability reaches its median—the probability of leak increases at a faster rate than that of rupture, resulting in a significantly higher leak probability. Beyond this point, the rate of increase for both probabilities declines markedly. For example, the probabilities of leak and rupture at the median pressure of the leak mode are 0.44050 and 0.17529, respectively, whereas they are 0.67868 and 0.25367 at the median pressure of the rupture mode. Unlike in Case 1, the leak probability does not decrease to zero but instead remains consistently near its maximum value of approximately 0.73. Similarly, the rupture probability does not increase to 1.0 but remains consistently at its maximum value of approximately 0.27.

2.1.2. Case 2: scenarios involving fast pressurization

In the presence of fast pressurization, the pressure will continue to rise if the failure mode is a leak, and thus a rupture failure may occur even though the initial failure at the pressure p was a leak [5, 8]. This is based on the belief that a leak does not arrest pressurization, and therefore, rupture following a leak remains possible. In this case, the leak probability is reduced by an amount proportional to the fraction of cases that transition to rupture. Then, under fast pressurization, both leak and rupture probabilities, $P_l(p)$ and $P_r(p)$, are expressed as follows [8–10]:

$$P_l(p) = F_l(p)[1 - F_r(p)] \quad (2a)$$
$$P_r(p) = \int_0^p f_r\,(p')dp' = F_r(p) \quad (2b)$$
$$P_{no}(p) = 1 - [P_l(p) + P_r(p)]dp' \quad (2c)$$

According to Equation (2a), the cumulative probability of a containment leak up to pressure p accounts for the conditional probability that rupture has not occurred at or below that pressure. Fig. 4 and Table III show the leak and rupture probabilities for Case 1, and their comparison with Case 2, respectively, evaluated using the fragility curves provided in Table II.

According to the figure and table, Cases 1 and 2 exhibit similar trends up to approximately 120 psig. However, beyond this point, Case 2 shows a much higher rupture probability than Case 1. For example, in Case 1, the probabilities of leak and rupture at the median pressure of the leak mode are 0.44050 and 0.17529, respectively, whereas in Case 2, they are 0.38427 and 0.23146. Similarly, at the median pressure of the rupture mode, the probabilities of leak and rupture are 0.67868 and 0.25367 in Case 1, and 0.43228 and 0.5 in Case 2, respectively. This difference can be attributed to a portion of the leak probability transitioning into rupture probability under fast pressurization as the pressure increases or a simultaneous occurre3nce of both failure modes. From this perspective, Case 2 represents a more conservative scenario than Case 2. Fig. 5 illustrates, for reference, how leak-induced rupture progressively influences the corresponding rupture probability as pressure increases, particularly when both leak and rupture occur concurrently.

Overall, Cases 1 and 2 demonstrate that, despite the two different pressurization scenarios employed, the sum of the leak and rupture probabilities at a given pressure load remains conserved and thus does not affect their contribution to the LERF (or LRF) under a given pressure.

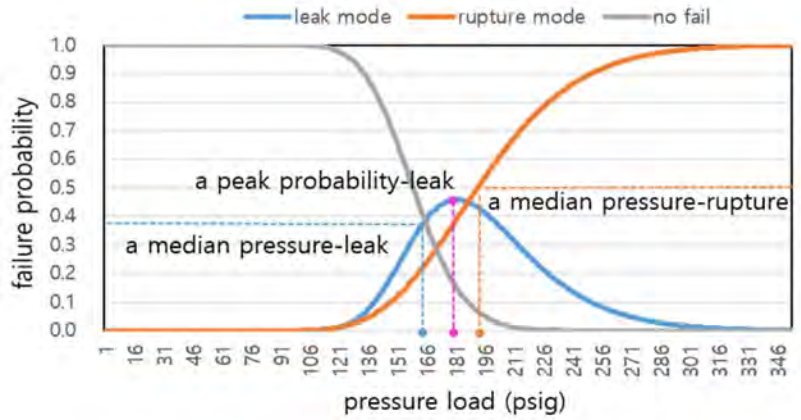

Figure 4. Estimated probabilities for each failure mode: Case 2.

Table III. Failure mode probabilities evaluated in Cases 1 and 2

Figure 5. Transition in failure probability from leak to rupture: Case 2.

2.2. Case 3: Influence of small leakages on the 100-TBq Cs-137 risk indicator

As shown in Table I, several countries set a regulatory threshold of 100-TBq for the Cs-137 release. The corresponding mass of this radionuclide is derived as follows.

$$\mathrm{A} = \lambda \cdot \mathrm{N} = \lambda \cdot (\frac{\mathrm{m}}{\mathrm{M}})\mathrm{N}_A \tag{3a}$$

$$\mathrm{m} = \frac{\mathrm{A}\cdot\mathrm{M}}{\lambda\cdot\mathrm{N}_A} = 31.25\ \mathrm{g}\ /100\ TBq \tag{3b}$$

Here, A (activity in Bq) = 100 TBq = 1.0×10^{14} Bq, λ (decay constant) = $\ln 2/t_{1/2}$ = 0.693/ (30.17 y) = 7.28×10^{-10}/s, $t_{1/2}$ (half-life) = 30.17 y, M (molar mass) = 137 g/mol, and N_A (Avogadro constant) = 6.023×10^{23}/mol.

For the reference plant [11], the design requirement specifies that the leakage of radioactive material must not exceed 0.2 % (or, under the more stringent condition, 0.1%) of the free containment volume within the first 24 h at a design leakage pressure of 57 psig (≈0.49 MPa), and thereafter must be limited to ≤ 0.1 % of the containment volume per day. A conservative severe-accident analysis of the station-blackout (SBO) scenario [12] shows that, in the absence of any structural failure of the containment, up to 20 g of airborne Cs-137 can be released during the first 24 h (10 g if the 0.1 % leakage limit is applied). Within the 72-h mission window used for the Level 2 PSA, the cumulative release could reach 40 g (≈30 g for the 0.1 % limit). These releases exceed the Cs-137 release threshold of 100 TBq (≈31 g), except when the 0.1 % leakage limit is imposed, in that case the release remains below the threshold even though the containment has not suffered structural damage.

Other accident scenarios may exhibit trends comparable to those of the SBO case, yet the design-pressure threshold can still be exceeded under any of the following conditions: (a) the containment is pressurized beyond its design pressure without structural degradation; (b) minor structural degradation occurs as a result of the pressurization—although the degradation size is considerably smaller than that assumed for nominal leak modes typically considered in Level 2 PSA (e.g., a 0.1 ft² opening in the reference plant); or (c) relevant uncertainties are introduced into the analysis [13, 14].

Consequently, relying exclusively on the nominal leak and rupture failure modes used in Level 2 PSAs—traditionally the basis for estimating the Cs-137 release threshold of 100 TBq—may underestimate the total release potential, especially in multi-unit incidents where the cumulative effect of minor leaks from each unit can be substantial.

The minor leakage pathways described above—those that can exceed the Cs-137 release threshold of 100-TBq—are expected to lie just above the design containment-leakage limit but still below the nominal leak threshold. Under the newly introduced *small-leakage* mode, certain accident scenarios considered in Level 2 PSAs, in which fission products (including Cs-137) are released into the containment without producing a measurable leak or rupture, may be re-classified as surpassing the Cs-137 release limit of 100-TBq. In these cases the probabilities of leak and rupture are recalibrated by applying the transition probability from the no-containment-failure condition to the small-leakage mode.

Once the small leakage mode—capable of producing an environmental release of Cs-137 that exceeds 100-TBq—is identified and its probability distribution is characterized, the probability of this mode, together with the probabilities of the conventional leak and rupture modes, are re-evaluated by extending the formulations of Cases 1 and 2 to cover all three failure modes [8, 10].

2.2.1. Scenarios involving slow pressurization

$$P_1(p) = \int_0^p f_1(p')[1 - F_2(p')][1 - F_3(p')]dp' \quad (4a)$$
$$P_2(p) = \int_0^p f_2(p')[1 - F_1(p')][1 - F_3(p')]dp' \quad (4b)$$
$$P_3(p) = \int_0^p f_3(p')[1 - F_1(p')][1 - F_2(p')]dp' \quad (4c)$$
$$P_{no}(p) = 1 - \sum_1^3 P_i(p) = \prod_i^3 [1 - F_i(p)] \quad (4d)$$

Here, subscripts i = 1, 2, and 3 denote the small leakage, leak, and rupture modes, respectively, and $P_i(p)$ and $F_i(p)$ represent the corresponding failure probabilities and CDFs at the pressure p.

2.2.2. Scenarios involving fast pressurization

$$P_1(p) = F_1(p) \prod_{i=2}^3 [1 - F_i(p)] \quad (5a)$$
$$P_2(p) = \int_0^p f_2(p')[1 - F_3(p')]dp' \quad (5b)$$
$$P_3(p) = \int_0^p f_3(p')[1 - F_2(p')]dp' \quad (5c)$$
$$P_{no}(p) = 1 - \sum_1^3 P_i(p) = \prod_i^3 [1 - F_i(p)] \quad (5d)$$

3. CONCLUSIONS

In the first part of this paper, two case studies were performed to assess the impact of relevant pressurization scenarios on the leak- and rupture-probability estimates for Level 2 PSAs under slow and fast conditions. The second part emphasizes the need to consider small-leakage modes that can affect Cs-137 releases.

The following summarizes the key findings of these case studies.

(1) **Containment pressurization-condition effect on relevant risk indicators** – In the two case studies, Case 1 assumes a slow pressurization while Case 2 assumes a fast pressurization
- For a given pressure the combined leak- and rupture-probability is conserved; consequently the contribution of the combined probability to the LERF/LRF does not change.
- However, the individual leak- and rupture-probabilities differ between the two approaches. The fast-pressurization scenario (Case 2) yields higher individual probabilities than the slow-pressurization scenario (Case 1). From this viewpoint, Case 2 is the more conservative of the two.
- Implications for the downstream STC analysis – These pressurization-condition differences can temporarily affect the results of the subsequent STC scenario-based probabilistic consequence analysis. This is because the STC analysis explicitly uses the source-term results and the associated probabilities (or frequencies) for each leak and rupture mode; therefore any shift in the individual probabilities feeds through to the final consequence estimates.

(2) Provisional influence of small leakage modes on relevant risk indicator
- As highlighted in Case 3, restricting containment-failure modes to the conventional leak and rupture categories employed in traditional Level 2 PSAs may underestimate the potential release of Cs-137—particularly in multi-unit accident scenarios, where small-leakage modes could contribute substantially to the total release.
- Accordingly, both the nominal range of these small-leakage modes (which spans from slightly above the design leakage level to just below the nominal leak mode) and their impact on relevant risk indicator associated with the environmental release of 100-TBq Cs-137 must be systematically evaluated to enable a more realistic assessment.

1. Motivation & context

- **Level 2 PSA:** Evaluates containment performance and severe accident risk following core damage sequences, and relevant key risk indicators are characterized as LERF, LRF (100-TBq Cs-137), CFF.
  - **LERF** (Large Early Release Frequency) – a surrogate indicator of early fatalities, expected during the early stage of a severe accident or at the moment of a RPV breach.
  - **LRF** (Large Release Frequency) or **Cs-137 release limit** – an indicator of long-term health effects (latent-cancer fatality) and land contamination. Korea, Japan, Canada, Finland adopt a 100-TBq Cs-137 release threshold, limiting the combined frequency of the relevant scenarios to $< 1.0 \times 10^{-6}$/ry.
  - **CFF** (Containment Failure Frequency) – the frequency of structural damage to the containment building and of bypass events (e.g., ISLOCA, spontaneous/induced SGTR).
- **Underlying problem:** A realistic assessment of containment failure modes (leak and rupture) is essential for credible safety evaluations; however, modeling assumptions and scenario variations introduce uncertainties into Level 2–relevant risk indicators.
- **The present study:** Investigate the impact of pressurization rates (slow vs. fast) and the role of “minor leakage” modes in achieving Level 2–relevant safety goals.

1. Motivation & context

Level 2-relevant risk targets defined in several countries

Country	Level 1 risk	Level 2 risk	Remarks
Canada (Regulator)	CDF < 10^{-5} /ry	SRF (1000-TBq I-131) < 10^{-5} /ry LRF (100-TBq Cs-137) < 10^{-6} /ry	New plants
Czechia (Licensee)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	LERF (> 1 % Cs-137, up to 10 h from fuel damage) < 10^{-5} /ry LERF: practically eliminated	Existing plants (incl. SFP) New plants (incl. SFP)
Finland (Regulator)	CDF < 10^{-5} /ry	LRF (100-TBq Cs-137) < 5.0×10^{-7} /ry	All plants (incl. new)
France (Regulator)	CDF < 10^{-5} /ry CDF < 10^{-6} /ry	LRF: practically eliminated (not quantitatively specified)	New plants (all modes/hazards) New plants (internal events)
Hungary (Regulator)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	L(E)RF < 10^{-5} /ry L(E)RF < 10^{-6} /ry	Existing plants New plants
Japan (Regulator)	CDF < 10^{-4} /ry	CFF < 10^{-5} /ry; 100-TBq Cs-137 < 10^{-6} /ry	All plants (incl. new)
Korea (Regulator)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	LERF < 10^{-5} /ry LERF < 10^{-6} /ry 100-TBq Cs-137 < 10^{-6} /ry	Existing plants APR1400 follow-up All plants (incl. new reactors)
Sweden (Licensee)	CDF < 10^{-4} /ry	L(E)RF (> 0.1 % of core inventory) < 10^{-7} /ry	All plants
USA (Regulator)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	LERF < 10^{-5} /ry LERF < 10^{-6} /ry	Existing plants New plants
IAEA (Recommend)	CDF < 10^{-4} /ry CDF < 10^{-5} /ry	LERF < 10^{-5} /ry LERF < 10^{-6} /ry	Existing plants New plants

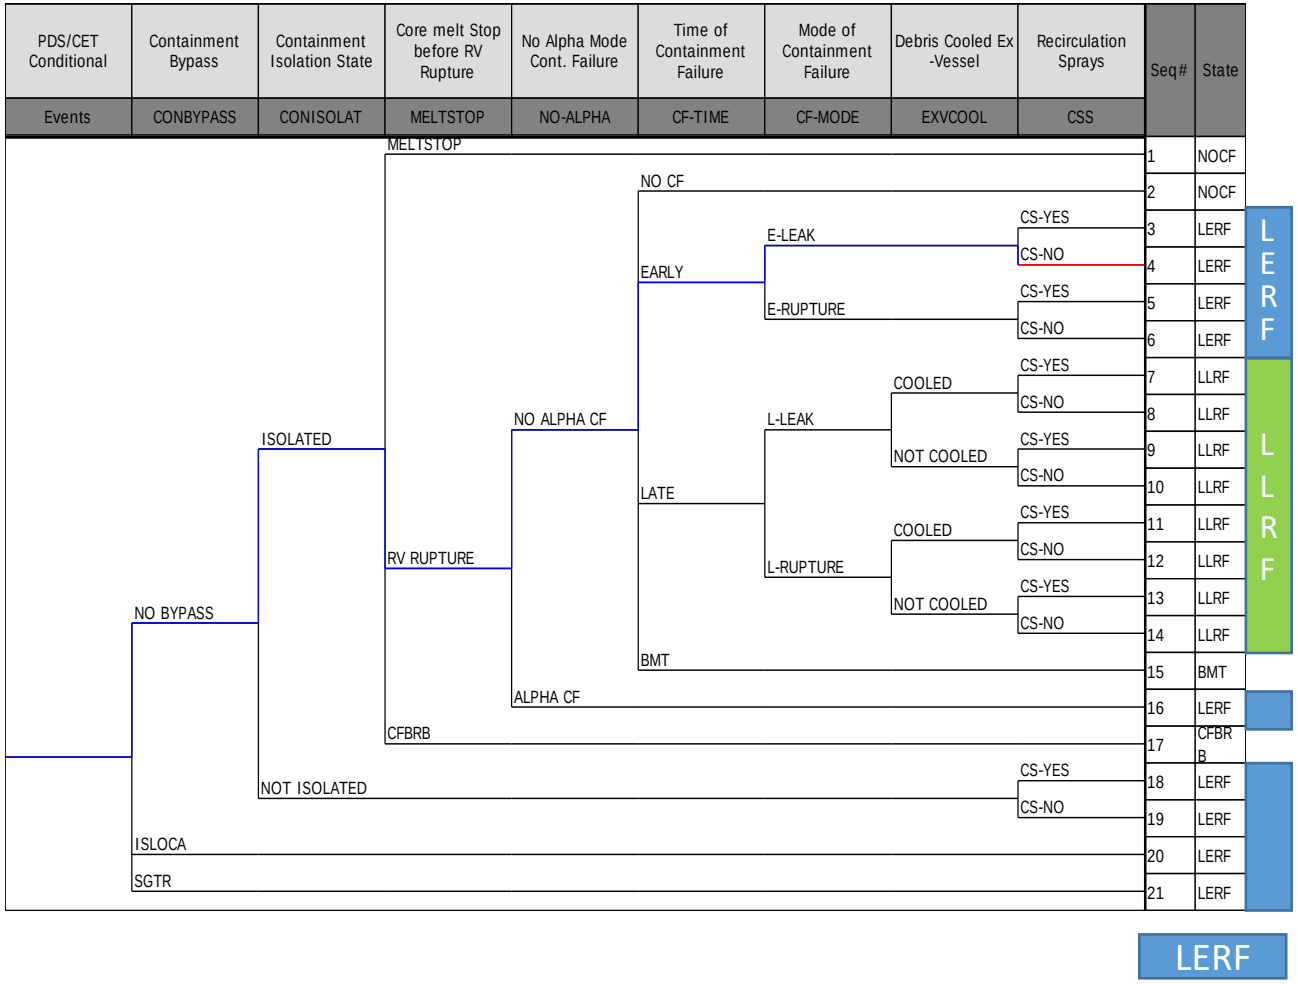
2. Problem statement

- **Influence of pressurization rate on leak & rupture probabilities**
  - Leak & rupture as the two dominant containment failure modes considered in Level 2 PSA.
  - Pressurization rate determining whether a leak can stop a further build-up of cont. pressure.
- **Containment failure modes** (structural), for a large/dry PWR (pre-stressed, reinforced-concrete containment having a cylindrical body with a hemispherical dome)**:**
  - **Leak**: A breach that halts gradual pressure buildup and requires ≥ 2 hours to depressurize.
    - Nominal size: 0.04–0.1 ft²
    - A typical failure mode: a failure of the equipment hatch ring or the tearing of the containment liner plate
  - **Rupture**: A breach that depressurizes the containment within 2 hours. Nominal size: > 1.0 ft².
  - Relevant fragility curves of the reference PWR: typically estimated using lognormal PDFs
    - Median Pressure : 162 psig for a leak mode; 189 psig for a rupture mode.

Failure Modes	Lognormal PDF as a Function of Pressure Load (p)	Median Pressure (p_m, psig)	Logarithmic Standard Deviation (β)
Leak	$f(p) = \frac{1}{\beta\sqrt{2\pi}p}\exp\left[-\frac{(\ln(p)-\ln(p_m))^2}{2\beta}\right]$	162	0.14
Rupture		189	0.21

2. Problem statement

(1) ST release sequences leading to LERF/LRF

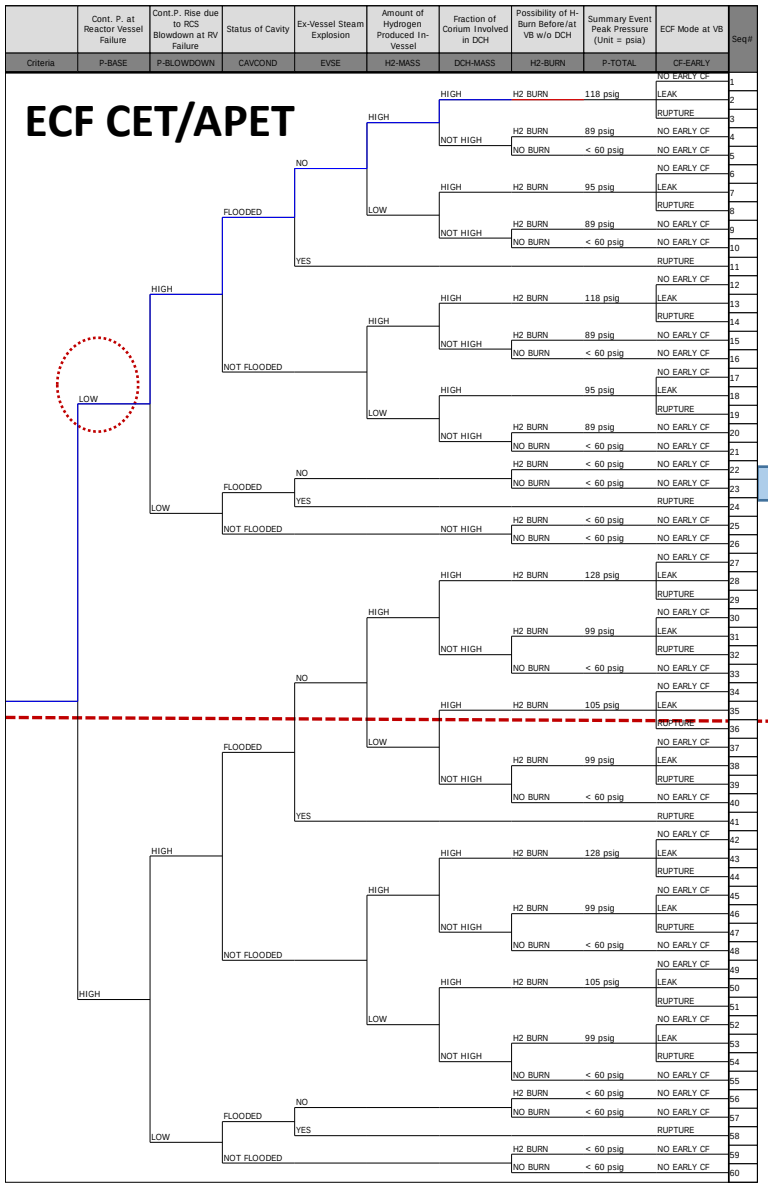


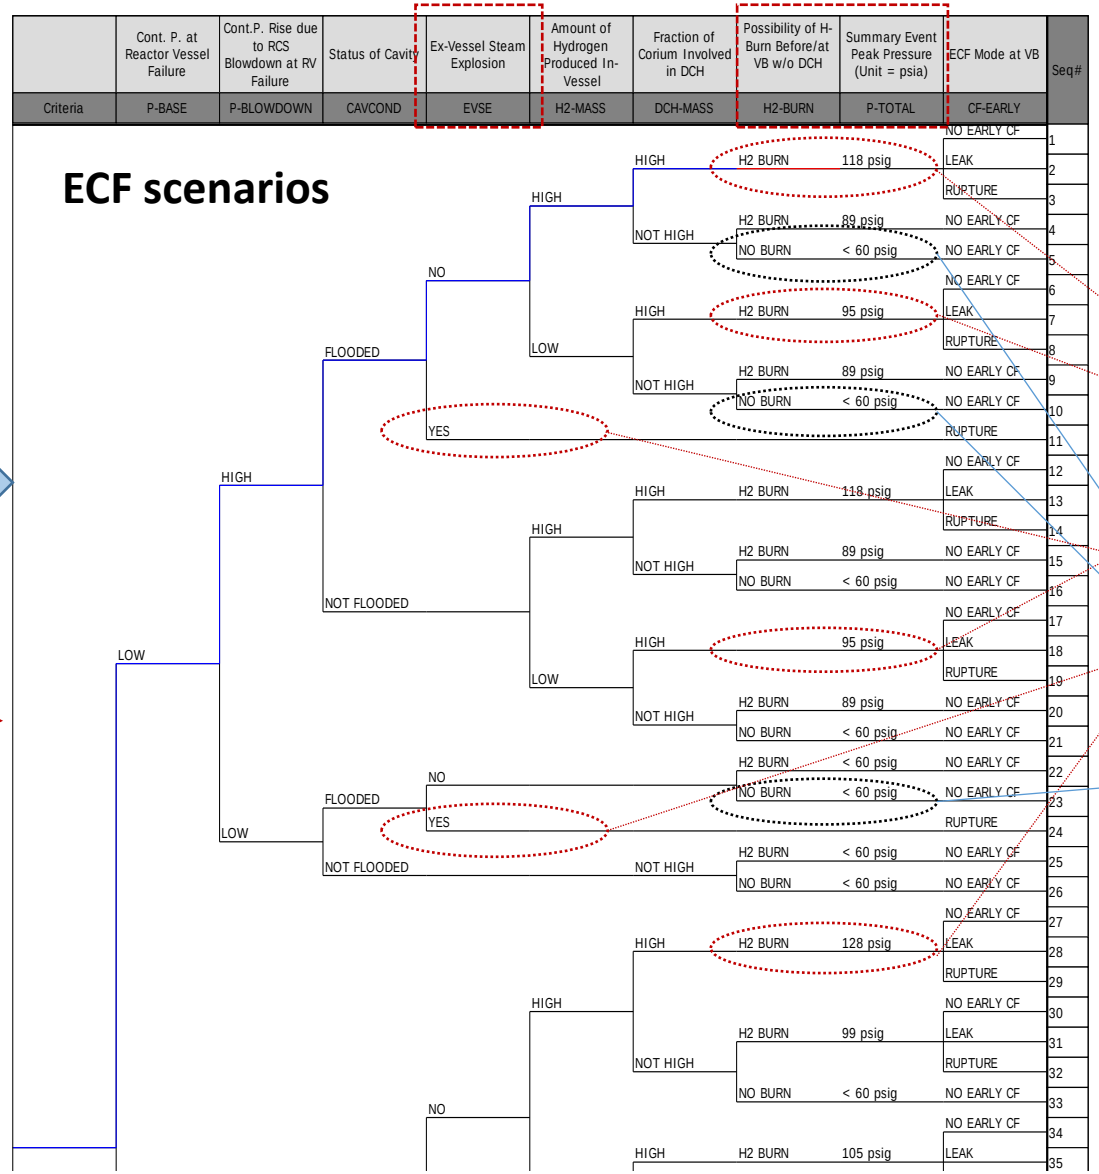
STC defined in the reference Level 2 PSA (derived from APET)

- **LERF**: the aggregate frequency of all accident scenarios, causing **large**, unmitigated releases **prior to** an effective evacuation of the surrounding population **(early)**.
  - Relevant accident scenarios: (a) unscrubbed releases of radioactive material resulting from cont. isolation failures; (b) cont.-bypass events such as ISLOCA & I-SGTR; and (c) any scenario causing cont. damage or failure that is equivalent to the above “large” release.
  - Relevant time window: at, or shortly after, the RPV breach—generally within 4 h of the breach in PWR.
- **LLRF** (Large Late Release Frequency): includes **late-phase** containment failure scenarios, causing **large**, unmitigated releases of airborne FPs during the **72-h mission time** assumed in a Level 2 PSA
- **LRF** (in the Korean Level 2 PSA)**: LERF + LLRF**;
  ***Cs-137 release limit** – an indicator for land contamination risk

2. Problem statement

(2) Fast/slow pressurization scenarios defined in the reference Level 2 PSA





Classification of ECF scenarios

- Dynamic (H-Burn)
- Dynamic (Ex-S/E)
- Slow-p (No Burn)

3. Case studies (pressurization rate)

❑ Case 1 - Slow pressurization scenarios

- Pressure Dynamics: The pressure increase is slower than the **system's** depressurization capacity (e.g., gradual steam over-pressurization, non-condensable gas generation from MCCI).
- Failure Logic: The lowest-pressure failure mode governs the outcome; once a leak occurs, it relieves the pressure, preventing further buildup.
- **Failure-Path: Leak (**or **rupture) →** *(if pressure continues)* **→ Leak-only (**or **rupture–only) (no other failure mode)**

❑ Case 2 - Fast pressurization scenarios

- Pressure Dynamics: Pressure rise exceeds the depressurization capacity (HPME, Ex-S/E, H-combustion/detonation).
- Failure Logic: A leak does not arrest pressurization; Rupture can follow the leak, giving much higher rupture probabilities than in Case 1.
- **Failure-Path: Leak → *(if pressure continues)* → additional leak or rupture; Rupture terminates pressure rise → no further failures. If pressure stops after the first leak, the event ends as a *leak-only* failure.**

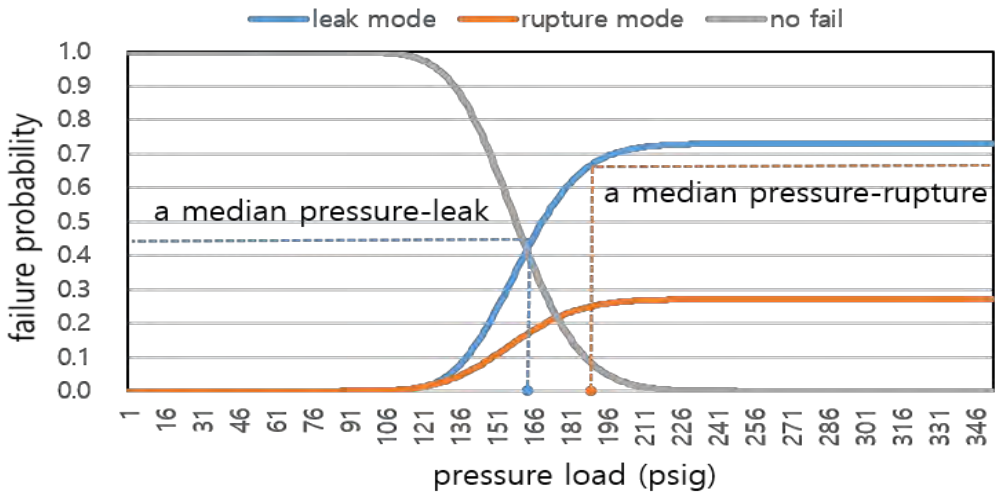
❑ Probabilistic formulation for failure modes (*f* = PDF, *F*=CDF, *p*= pressure load)

Case	Leak prob. (P_l)	Rupture prob. (P_r)	No Fail (P_{no})
Case 1 (slow-p)	$P_l(p) = \int_0^p f_l(p')[1 - F_r(p')]dp'$	$P_r(p) = \int_0^p f_r(p')[1 - F_l(p')]dp'$	$P_{no}(p) = 1 - [P_l(p) + P_r(p)]dp'$
Case 2 (fast-p)	$P_l(p) = F_l(p)[1 - F_r(p)]$	$P_r(p) = \int_0^p f_r(p')dp' = F_r(p)$	

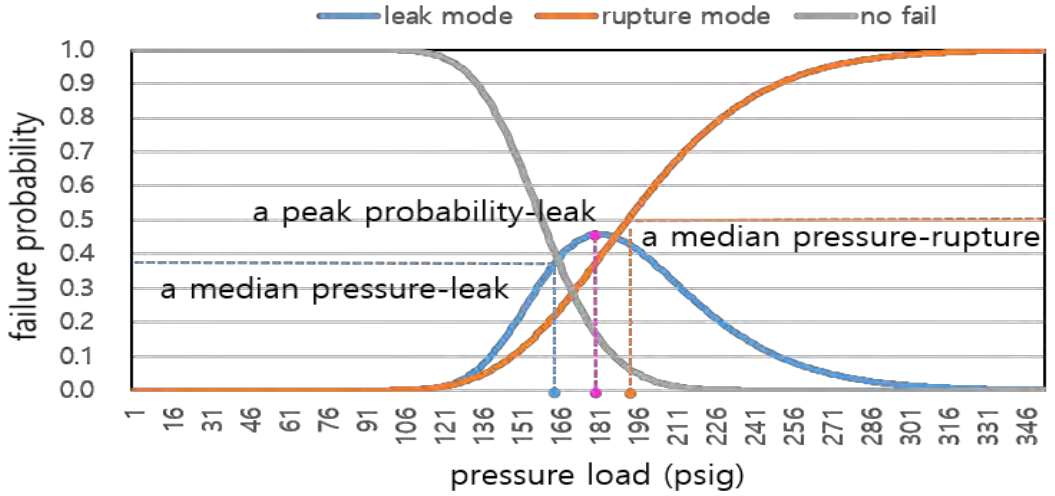
3. Case studies (pressurization rate)

❑ Results for the reference plant:

- **Case 1 (slow)**
  - Up to approximately 189 psig—where the pressure reaches its median of the rupture mode, the leak probability increases at a faster rate than that of rupture, resulting in a significantly higher leak probability.
  - Beyond this point, the rate of increase for both probabilities declines markedly. Beyond 200 psig, the leak probability stabilizes at ~0.73, while the rupture probability stabilizes at ~0.27.
- **Case 2 (fast)**
  - At 181 psig, the leak probability reaches its maximum (~0.46), but the rupture probability continuously increases
  - For the fast case, rupture can follow the leak, thereby shifting a portion of the leak probability to rupture mode.



Case 1: Estimated probabilities for each failure mode



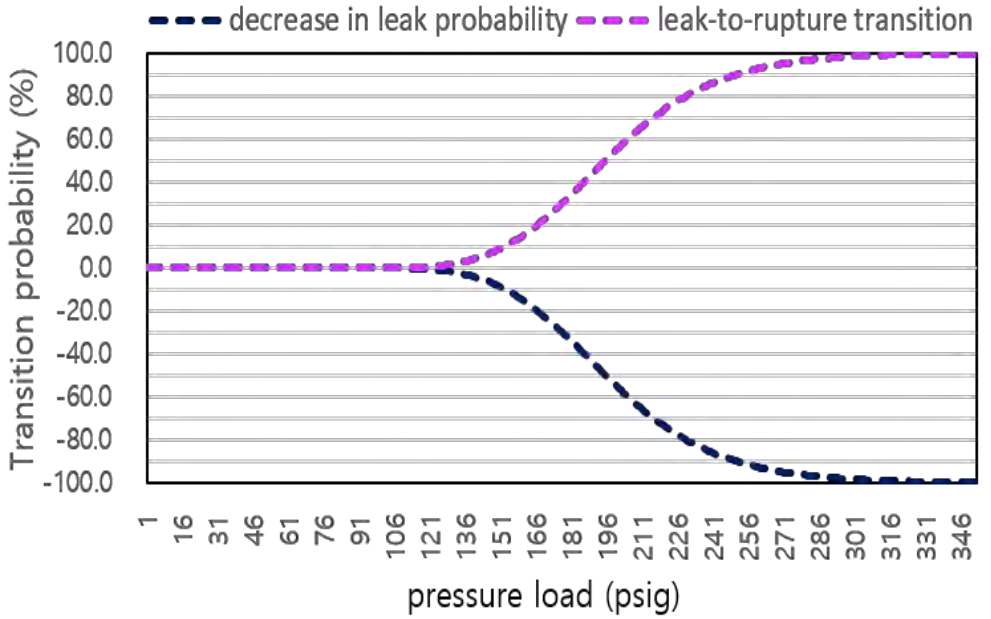
Case 2: Estimated probabilities for each failure mode

3. Case studies (pressurization rate)

❑ Comparison of pressurization influence:

- **The sum of leak and rupture probabilities remains conserved across both scenarios.**
  - For any pressure, P_{leak} + $P_{rupture}$ remains constant between Cases 1 & 2.
  - Consequently, the combined contribution to LERF/LRF does not change. Only the individual leak and rupture probabilities differ.
- **Changes in individual probabilities influence STC analysis because source-term calculations use separate leak and rupture frequencies.**
  - Shift in individual probabilities → temporary change in probabilistic consequence estimates.
  - Fast-pressurization scenario yields higher rupture frequencies → larger estimated consequences.

Case 2: Transition from leak to rupture mode



Transition probability (%) = $100 \times [F_l(p)F_r(p)]/[1 - P_{no}(p)]$

For fast pressure, leaks converted into additional leaks or *ruptures as the pressure continues to rise*

3. Case studies (pressurization rate)

- **Failure mode probabilities evaluated at specified pressures:**

Pressure (p, psig)	Cases	P_l	P_r	P_{no}
75	Case 1	0.0	0.00001	1.0
	Case 2	0.0	0.00001	
100	Case 1	0.00038	0.00122	0.999
	Case 2	0.00028	0.00122	
120	Case 1	0.01600	0.01518	0.969
	Case 2	0.01579	0.01527	
162[1]	Case 1	0.44050	0.17529	0.384
	Case 2	0.38427	0.23146	
178	Case 1	0.61419	0.23243	0.153
	Case 2	0.45895	0.38762	
189[2]	Case 1	0.67868	0.25367	0.068
	Case 2	0.43228	0.5	
200	Case 1	0.70995	0.26407	0.026
	Case 2	0.36777	0.60618	
250	Case 1	0.72935	0.27065	0.0
	Case 2	0.09135	0.90857	

[1] *a median pressure of the leak mode ($p_{m,\ leak}$),* [2] *a median pressure of the rupture mode ($p_{m,\ rupt}$).*

3. Case studies (minor leakage)

❑ Cs-137 risk relevant issue:

- Threshold for 100-TBq Cs-137: ≈ 31.25 g (achievable without structural failure of the containment).
  - Design leakage limit of reference plant: ≤ 0.2% (or stricter 0.1%) of containment free volume at 57 psig
  - Problem: For a SBO scenario analysis, the cumulative release could reach 40 g within 72 h mission time, exceeding the threshold even without structural failure unless the stricter 0.1% leakage limit is applied.
  - Risk impact: Relying solely on nominal leakage sizes may underestimate release potential, particularly in multi-unit incidents, where cumulative minor leaks can push the total release above the 100-TBq threshold.
  - Traditional Level-2 PSA (limiting to only leak + rupture) could underestimate total Cs-137 release.

❑ Re-evaluating the Cs-137 risk:

- Minor leakage definition: a leakage pathways or minor structural degradation exceeding the design leakage limits but remaining below the nominal leak threshold (e.g., 0.1 ft^2).
- Classification: Containment scenarios previously categorized as “no failure” may be reclassified as exceeding the 100-TBq release limit.
- Proposed approach: Extend the Cases 1 & 2 formulations to include a third failure mode (minor-leakage), enabling probability recalibration.

3. Case studies (minor leakage)

- **Probabilistic formulation of three failure modes** (*f* = PDF, *F*=CDF, *p*= pressure load)

Case	Minor leakage (P_1)	Leak (P_2)	Rupture (P_3)	No Fail (P_{no})
Slow-p	$P_1(p) = \int_0^p f_1(p')[1-F_2(p')][1-F_3(p')]dp'$	$P_2(p) = \int_0^p f_2(p')[1-F_1(p')][1-F_3(p')]dp'$	$P_3(p) = \int_0^p f_3(p')[1-F_1(p')][1-F_2(p')]dp'$	$P_{no}(p) = 1 - \sum_1^3 P_i(p) = \prod_i^3 [1-F_i(p)]$
Fast-p	$P_1(p) = F_1(p)\prod_{i=2}^3 [1-F_i(p)]$	$P_2(p) = \int_0^p f_2(p')[1-F_3(p')]dp'$	$P_3(p) = \int_0^p f_3(p')[1-F_2(p')]dp'$	

4. Summary & take-away

- **Pressurization influence on the Level 2-relevant risk:**
  - Combined (leak + rupture) probability is conserved for a given pressure → no change in overall LERF/LRF contribution.
  - Fast pressurization (Case 2) leads to higher rupture probabilities → more conservative one.
  - These differences can affect source-term and offsite consequence analyses.
- **Minor-leakage influence on the Cs-137 release risk:**
  - Excluding minor-leakage modes may underestimate Cs-137 release potential, especially in multi-unit scenarios.
  - Minor-leakage openings may lie between the design leakage limit and the nominal leak threshold.
  - Incorporating them provides a more realistic assessment of the 100-TBq Cs-137 risk indicator.
- **Moving forward:**
  - **Integrate the identified issues into the conventional Level-2 PSA framework**
  - **Feed the relevant results into downstream safety-critical STC & risk analyses**

ABSTRACT

In large containments, atmospheric counter-current flows can occur during design-basis accidents (DBAs) and severe accidents, particularly within and between compartments and their openings (e.g. in the pressure reduction system of an RBMK 1000). These flows have been observed in containment test facilities, such as the THAI TH-27 benchmark, and predicted by computational fluid dynamics (CFD) codes, notably in analyses in the vicinity of the steam generators of the German KONVOI design. Studies have shown that strong shear flows and significant density differences in the gas could cause changes in the local flow direction, which could ultimately lead to counter-current flows. Experimental investigations of counter-current flows in liquids and two-phase mixtures in the primary circuit have also been used successfully to develop and validate models for accident analysis codes.

This work involved the validation and benchmarking of models that predict atmospheric counter-current flows based on experiments conducted in the THAI facility. The test configuration consisted of the THAI test vessel (TTV) without the inner cylinder and the parallel attachable drum (PAD). The TTV and the PAD were connected by the lower connecting pipe. Two tests, TH-35 and TH-36, were conducted to generate counter-current flow data across a range of Reynolds numbers, capturing the transition from laminar to turbulent flow regime. The counter-current flow was induced by injecting hot air and steam into the TTV and extracting gas from the top of the PAD. The difference in gas density between the two vessels caused the hot gases to flow into the PAD, where they descended as a plume. Simultaneously, colder air and steam flowed backwards from the PAD into the TTV, through the lower half of the connecting pipe. In both tests, three steady state subphases were defined, in which the gas injection mass flows were kept constant. Vessel pressure had to be regulated by injecting gas into the TTV and releasing gas from the PAD.

The test data was recorded with high spatial and temporal resolution for validating semi-empirical modeling approaches used in LP and CFD. This paper reports on the experimental findings and the results of the benchmark, which reveal the complexity of the flow phenomena and the necessity of making adequate assumptions about heat transfer and boundary conditions in the simulation models.

1. INTRODUCTION

Atmospheric counter-current flows can occur in design-basis accidents (DBA) and severe accidents (SA) in large containments, especially in small compartments and in flow openings (e.g. in the pressure reduction system of an RBMK 1000) between individual compartments. Such flows have also been detected in containment test facilities, e.g. in the TH-27 benchmark **[Fre18]** and were predicted for containments by CFD analyses in the vicinity of the steam generators of German KONVOI plants **[Roy00]**, **[Rud15]**.

The Counter-current flow itself is represented by a special case of a strong shear flow, where the flow direction changes its flow direction locally due to density differences in the gas. Experimental investigations on counter-current flows in liquids and two-phase mixtures in the primary circuit **[Pra12]**, **[Ste92]** have already been successfully used to develop and validate suitable models in AC^2 (ATHLET) **[Ler19]**. For a correct prediction of atmospheric counter-current flows, a model extension based on a semi-empirical approach that accounts for turbulent effects has been implemented, e.g. in the COCOSYS module **[Ili19]**. The corresponding model parameters were calibrated using experimental data from the SETH project **[Set12]** and validated using the TH-35 benchmark.

The objective of test TH-35 and its benchmark was to investigate the strength and intensity of a counter-current flow in a range of Reynolds numbers, representing the transition between laminar and turbulent flows. The $THAI^+$ facility consisting of the THAI test vessel (TTV) without inner cylinder and the parallel attachable drum (PAD) connected by the lower connecting pipe was used in test TH-35. The counter-current flow was forced to occur by injecting hot gases into the TTV and removing a gas mixture from the top of the PAD. The different gas densities in the two vessels allowed for hot gases flowing to the cold PAD where the hot gas ascended as a plume. At the same time, cold fluid was flowing backwards from the colder PAD into the hotter TTV, along the lower half of the connecting pipe.

Three steady-state sub-phases were defined, in which the gas injections were kept constant. It was mandatory to regulate the vessel pressure in sliding pressure mode, by injecting gas into the larger TTV and releasing gas from the PAD. The test data allows for validating semi-empirical modelling approaches of LP codes and CFD models. Specific features of the test data which can be used for validation purposes are:

- stationary hot temperature inside a large volume
- steady-state vessel pressure regulation during the three gas injection phases
- several measurements capturing the flow distribution in the lower connecting pipe
- dense temperature measurements in both compartments connected to the lower connecting pipe
- record of the steam condensation rates in both large volumes.

1. TEST CONFIGURATION

The basic configuration of the $THAI^+$ facility and the most important dimensions, Figure 1, are given in **[Fre16]**. The $THAI^+$ configuration consists of the THAI test vessel (TTV) and the smaller parallel attachable drum (PAD) which are connected in test TH-35 by one pipe segment of DN 500 installed at the level of the sump compartments. It is to be noticed that for test TH-35 the inner cylinder and all condensate trays are removed from the THAI test vessel.

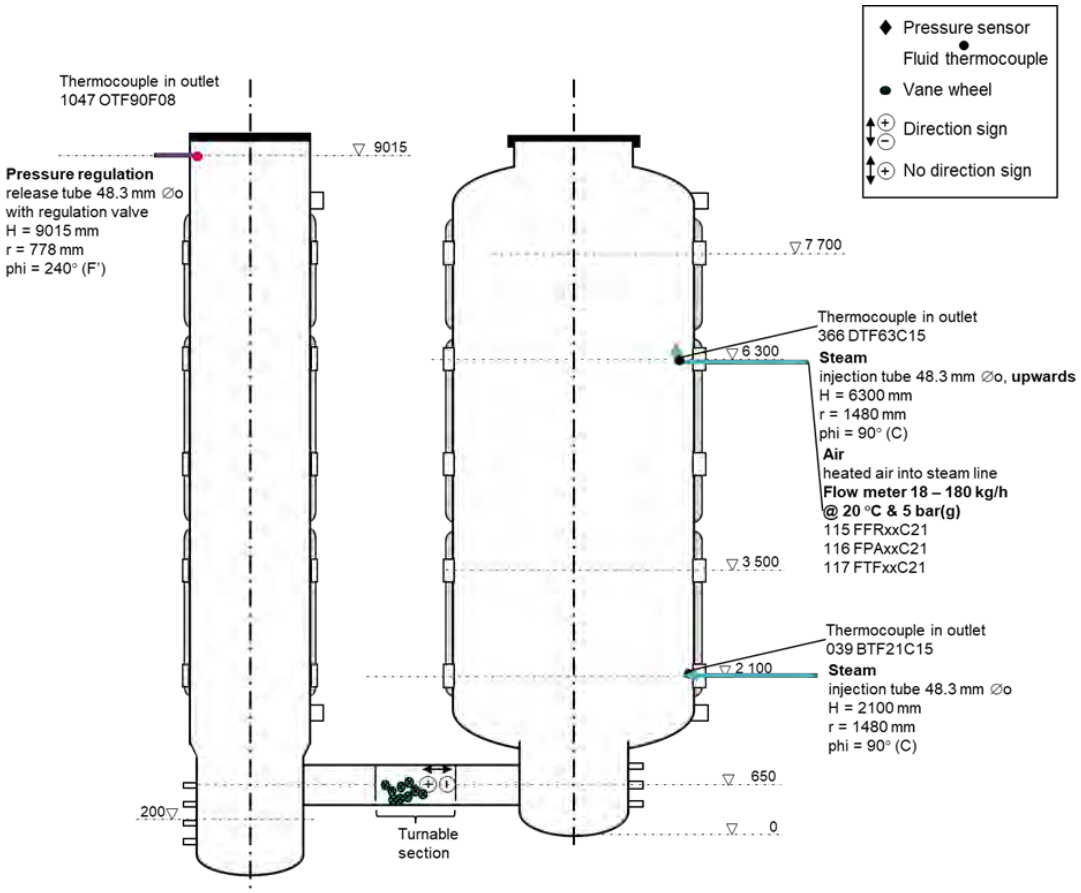

Figure 1. Configuration of the THAI+ vessels

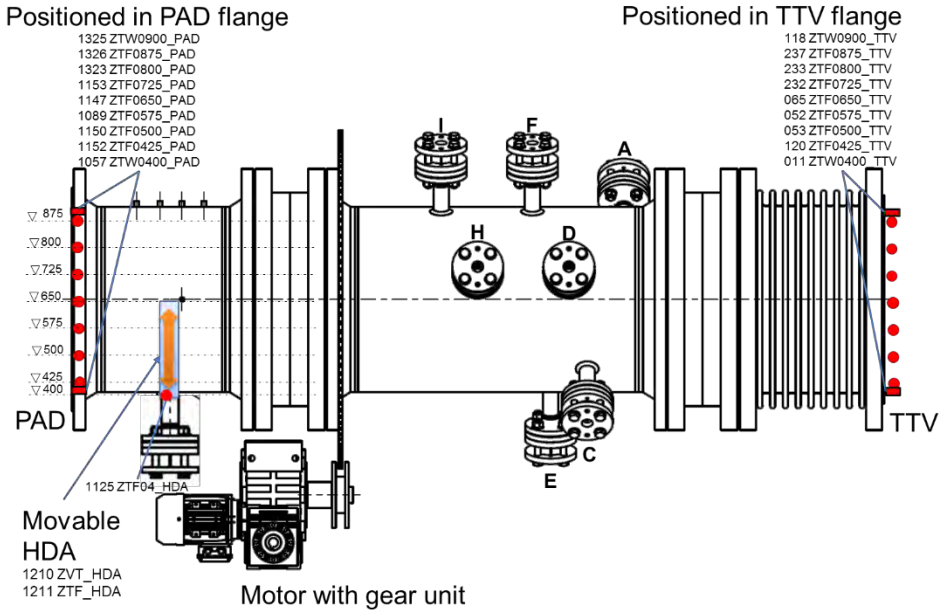

Figure 2. Lower connecting pipe including METUSA, HWA-probe and t/c installed at flanges to PAD and TTV sump compartment (gas and wall)

In contrast to the standard THAI$^+$ configuration, the METUSA flow measurement system was installed in the lower connecting pipe, see Figure 2. METUSA consists of two rotatable flanges which envelope an 885 mm long DN 500 pipe section into which 9 vane wheels were installed. Each of the 24 mm ∅ vane wheels was installed at a different pipe radius between centerline and outer wall surface. Additionally, 6 of the vane wheels had been installed at different angles and axially in distance of 50 or 100 mm in order to minimize the flow disturbance. By turning the pipe section by 360°, each of the vane wheels runs along a circular path. The summation of the six circular paths, each being 24 mm thick, allows to calculate the velocity distribution inside the pipe accurately. Negative velocity values indicate a flow direction from TTV to PAD vessel and positive vice versa. Beside the METUSA, a hot wire anemometer (HWA) probe was installed in the lower connecting pipe to record the backward flow along the pipe radius. Pre-heated air was injected vertically upwards at an elevation of 6.3 m, r = 1.48 m, angle C, injection tube (Figure 1) into the TTV using a pipe exit diameter of 43.1 mm $\varnothing_i$.

2. TEST PROCEDURE

The test transient for TH-35 consisted of a preconditioning phase followed by a main test phase, the latter subdivided into three quasi steady-state phases:

t = −74640 s	All three thermal oil mantels of TTV activated in heating mode, flow direction downwards, primary oil temperature set to 142 °C.
t = −74280 s	The TTV's lower and upper vessel shoulder and the vessel lid were heated electrically with target temperature of 140 °C. The TTV vessel columns were heated with target temperature of 140 °C. The TTV sump compartment was not heated.
t = 0 s	Start of pre-heated air flow injection with 10.1 g/s (temperature 91.8 °C) into TTV vessel at H = 6.3 m; stabilization of pressure by regulating PAD's uppermost exhaust valve at H = 9.015 m
t = 5 820 s	Increase of pre-heated air flow rate to 20 g/s (temperature 117.3 °C), and vessel pressure regulated
t = 11 760 s	Increase of pre-heated air flow rate to 29.9 g/s (temperature 124.3 °C), and vessel pressure regulated
t= 17520 s	Air injection stopped

The initial test conditions, measured at t= 0 as being the time of starting the air injection are listed in Table I. The temperature distribution of the vessel walls and the fluid temperature was provided with the resolution of Table II. To the benchmark participants. The fluid temperature distribution at t = 0 s still includes some temperature fluctuations, especially due to the very different wall temperatures inside the TTV and PAD sump. The pressure regulation was executed very precisely, i.e. pressure fluctuations occurred within less than 2 mbar during the test.

Table I. Measured initial test conditions for tests TH-35

Conditions	TH-35
Vessel total pressure (MPa)	0.1304
TTV wall temperatures (°C)	139
PAD wall temperatures (°C)	22.4
TTV steam concentration (%)	<0.5 vol%

Table II. Inside vessel wall and fluid temperatures before air injection at t = 0 s

Avg. wall temperatures	TTV wall temp >8.17 m	°C	140.5	Avg. fluid temperatures	TTV Section "D"	°C	136.1
	TTV oil mantles 1.82-8.17	°C	137.9		TTV Section "A+C"	°C	135.8
	TTV Lower Section 1.82- 1.2	°C	138.5		TTV Section "B"	°C	135.0
	TTV Sump <1.2 m	°C	73.9		TTV Sump	°C	53.7
	PAD wall temp >8.17 m	°C	22.1		PAD Section "O"	°C	24.8
	PAD oil mantles 1.82-8.17	°C	22.4		PAD Section "M"	°C	25.7
					PAD Section "L"	°C	25.5
	PAD Sump <1.1 m	°C	21.6		PAD Sump (gas)	°C	22.2
	Lower Pipe	°C	33.3		Lower Pipe	°C	36.1

Figure 3 depicts the air injection rate and the air injection temperature measured at the pipe exit. The air flow rate is stabilized within less than 2 min after starting or increasing the air injection mass flow. The temperature of the injected air did not reach equilibrium with the inner vessel temperature, but the injected air is easily heated up and mixed by the hot gas atmosphere inside the TTV.

The thermal oil mantles and the electrical heaters of the TTV were started at t = −74640 s and operated in heating mode until end of the test. The vessel temperatures have been stabilized long before starting the main phase of the experiment. The injected heating power beyond the initial heating phase balanced the thermal losses of the vessel's insulation. Averages of thermal oil and electrical heating power are given in Table III for the three phases.

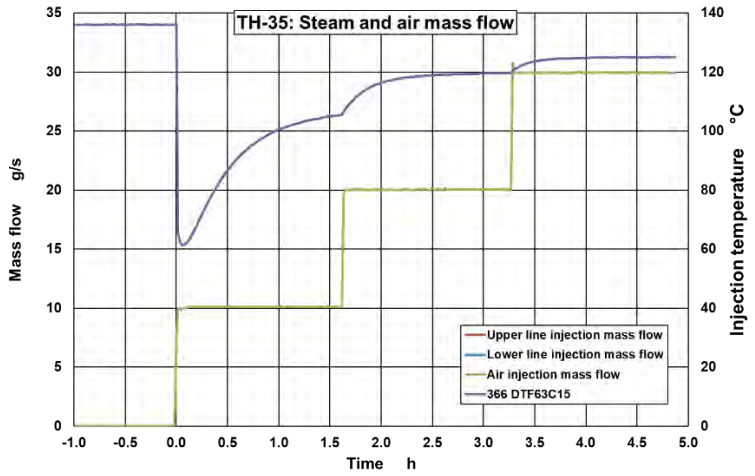

Figure 3. TH-35 air mass flow rate and temperature at air release location

Table III. Average of thermal oil and electrical heating power

	Phase 1	Phase2	Phase3
Start time (s)	0	5820	11760
End time (s)	5820	11760	17520
Upper mantle (kW)	2.20	2.22	2.17
Middle mantle (kW)	3.24	3.26	3.21
Lower mantle (kW)	3.59	3.59	3.55
Upper elect. heat (kW)	2.60	3.23	3.00
Lower elect. heat (kW)	1.74	1.59	1.57

3. TEST RESULTS

The temperature distribution at the vessels' sumps and the lower connecting pipe is depicted in Figure 4 for phase 1. The temperature data were taken from the temporal center of the phase and averaged over 10 minutes. The colour map reveals that hot gases are transported in a very small layer at the top of the pipe from TTV to PAD, while the gas temperature at the center of the pipe and at the lower half is much colder. The velocity measurement data of HWA and METUSA provide a velocity profile along the vertical axis of the pipe, Figure 5. The reverse flow is stable while the forward flow increases with increasing air injection rate. Comparison of the temperature distribution inside the lower connecting pipe (Figure 4) with the velocity profile shows that cold gases are transported backwards from PAD to TTV in the lower half of the pipe. The forward flow from TTV to PAD at the upper half of the pipe transports a small layer of hot gases at the upper pipe wall together with colder gas at pipe center. This indicates that the recirculated gases are mixed within the TTV sump compartment without ascending into the plenum of the TTV and transported back to the PAD immediately.

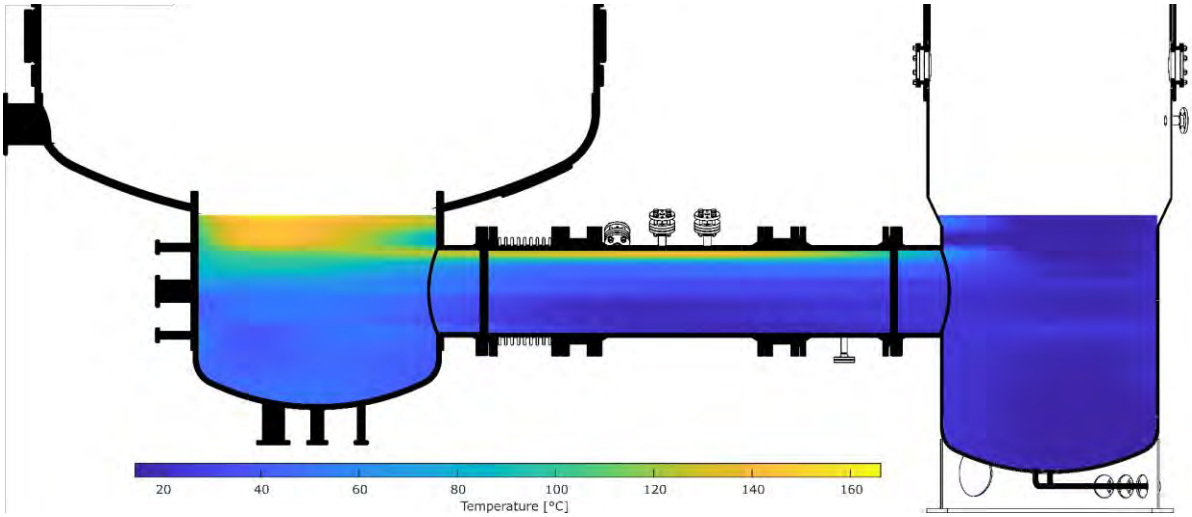

Figure 4. TH-35 gas temperature distribution at the vessels' sumps and the connecting pipe for phase 1, data averaged between t = 45 and 55 min

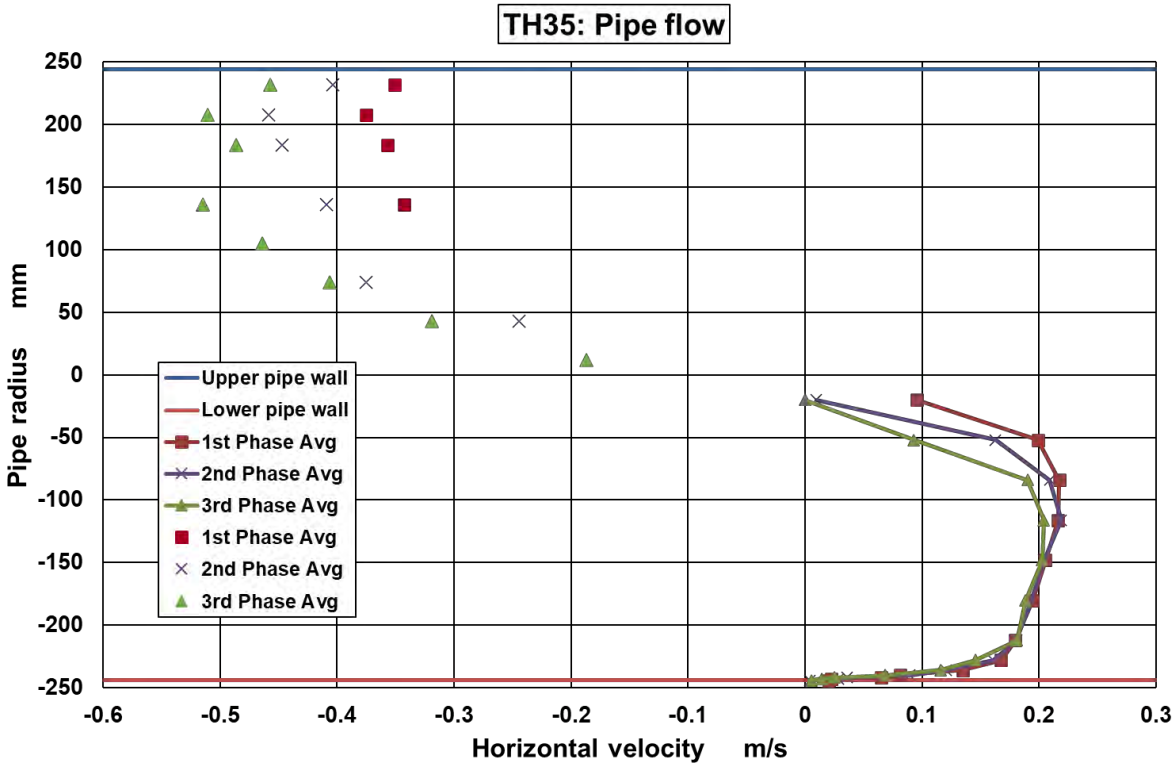

Figure 5. TH-35 averaged flow velocities along the vertical axis of the connection pipe, comparison of all three phases

4. SIMULATION MODELS

Benchmark simulations were performed by CNL using the CFD type GOTHIC code [Rah12] [Got18] and GRS submitted results using the lumped-parameter code COCOSYS (AC^2) [Kle17] [Arn21]. The following provide insights into the model set-ups.

GRS-COCOSYS-B

The nodalization used for the TH-35 benchmark is presented in Figure 6. The nodalization consists of 67 zones for the TTV, 66 zones for the PAD and 4 zones for the lower connecting pipe totalling 137 zones for the THAI$^+$ facility. In addition to those zones, 7 environmental zones and 3 heating mantle zones were used. The walls of the TTV, PAD and the connecting pipe were modelled with a total of 134 structures. A plume was used to model the rising of the hot air that was being injected during the experimental phases.

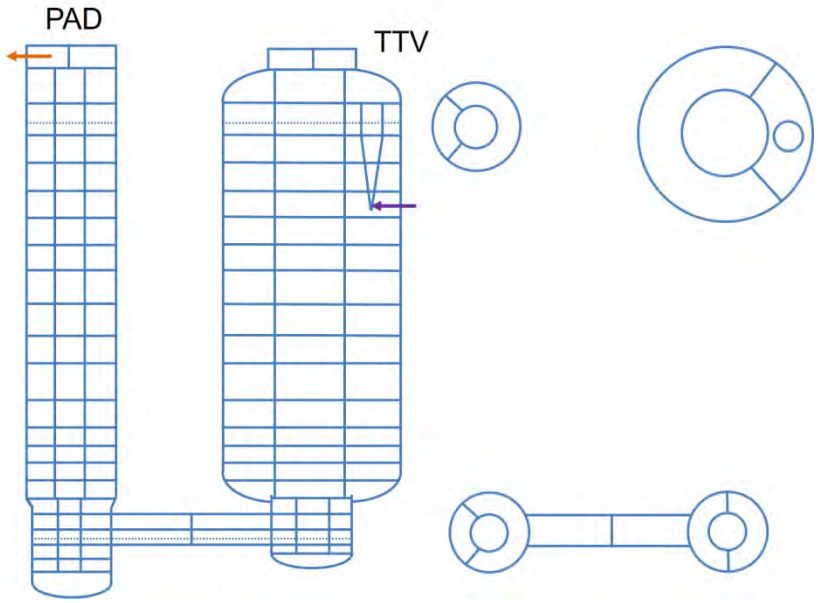

Figure 6. COCOSYS nodalization of the THAI+: side view (left) and cross-section view (right) at two levels

COCOSYS is a lumped parameter code and the mass flow in the junctions between zones are modelled according to [Arn21]. The modelling strategy representation of the counter current is documented in [Ili19]. A stepwise linear shape of the turbulence flow loss coefficient is assumed for Reynolds number in the transition regime. For TH-35 a maximal pressure loss coefficient of $\zeta_{max}^{turb} = 0.25$ was used. This value is based on previous numerical experiments comparing simulations performed with COCOSYS and simulations performed with the commercial CFD program ANSYS CFX [CFX16].

CNL-GOTHIC-B and CNL-GOTHIC-R

The GOTHIC model representation of the THAI$^+$ facility is shown in Figure 7. The test facility was represented by five GOTHIC control volumes (Vol. 1 for the TTV sump, Vol. 2 for the main region of the TTV, Vol. 3 for the PAD sump, Vol. 4 for the main region of the PAD, and Vol. 5 for the lower connection pipe). The control volumes were subdivided on a 3D Cartesian grid and connected to one another with 3D connectors. The average grid spacings in the nodalization of the control volumes are given in Table IV. The grid spacing was not always made uniform in the control volumes when aligning them with natural geometric features of the system was more practical. Only half of the facility was modeled because of the symmetrical geometry.

Table IV. GOTHIC model control volume nodalization

Control Volume	Average Grid Spacing			Number of Cells
	x	y	z	
1	0.228 m	0.228 m	0.285 m	72

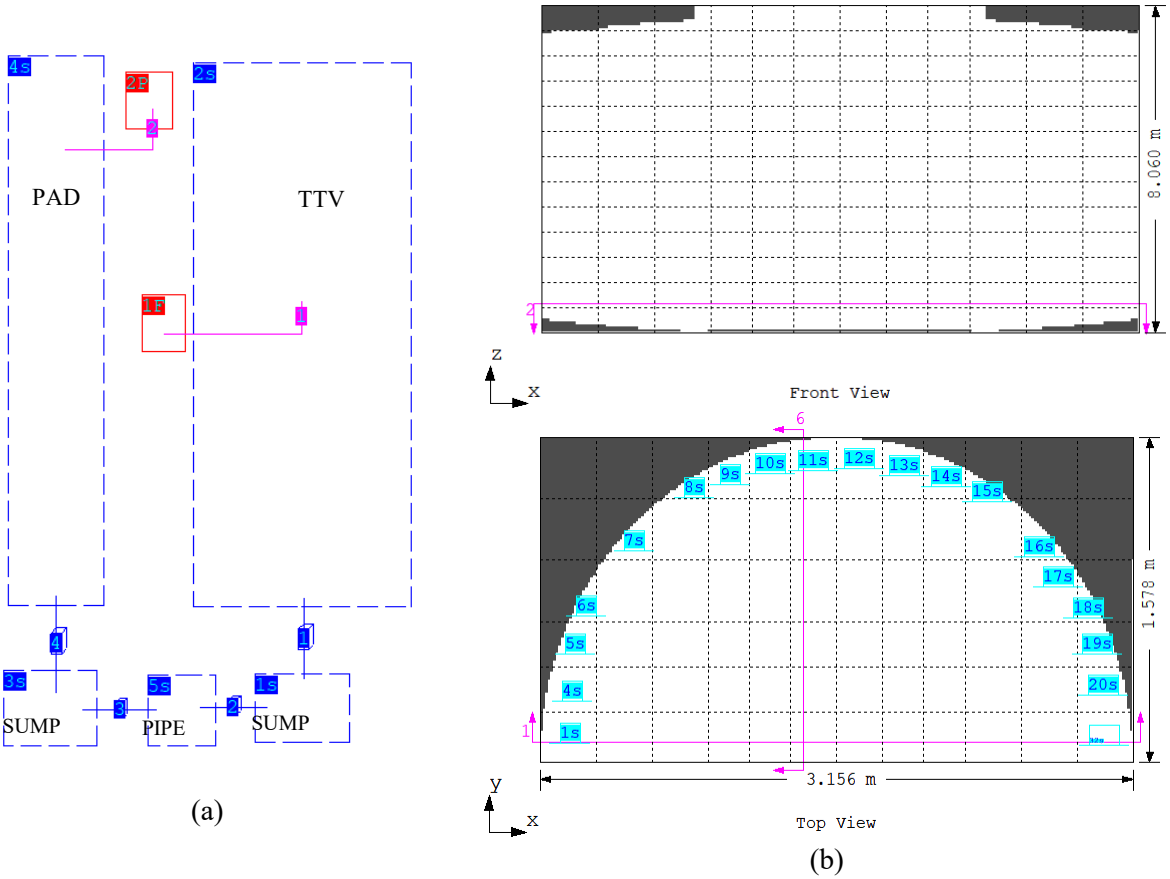

Figure 7. CNL-GOTHIC control volume layout (a) and 3D nodalization for TTV main vessel (b) for the blind simulation of TH-35

Thermal conductors were used to model heat transfer to internal structures. The conduction was modeled as 1D and perpendicular to the structure surface, and involved the combination of stainless steel, insulation, and aluminum. Only the stainless-steel vessel wall layer was modeled in the jacketed regions of the TTV and PAD, where an external temperature boundary condition corresponding to the mantle oil temperature (138 °C) was applied. The gas release through the PAD's relief valve was modelled by a pressure boundary (2P) to maintain the constant vessel pressure. Air injection was modelled by a flow boundary (1F).

5. SIMULATION EXERCISE

By heating the THAI vessel and injecting hot air into the TTV, gas is transferred to the PAD vessel through the DN500 connecting pipe at sump compartment level. The test facility was operated at constant pressure by removing gas mixture from the top of the second vessel (PAD). The different gas densities in the two vessels let hot gases flow to the cold PAD where the hot gas rose as a plume. At the same time, cold fluid was flowing backwards from the PAD into the hotter TTV, along the lower half of the connecting pipe. Velocity measurement data was evaluated along the vertical axis of the pipe circumferentially extrapolated, beyond availability of measurement data. This provided an estimate of the forward and backward volumetric flow in the pipe for the three test phases. The forward flow based on the interpreted test data would be 0.031 m^3/s in phase 1, 0.038 m^3/s in phase 2 and 0.046 m^3/s in phase 3, Figure 8. The forward flow in GRS-

COCOSYS-B agrees well with the test data. The backward flow based on the interpreted test data would be 0.023 m^3/s in phase 1, 0.022 m^3/s in phase 2 and 0.021 m^3/s in phase 3, Figure 9. The backward flow in the COSOSYS simulation is slightly below the test data.

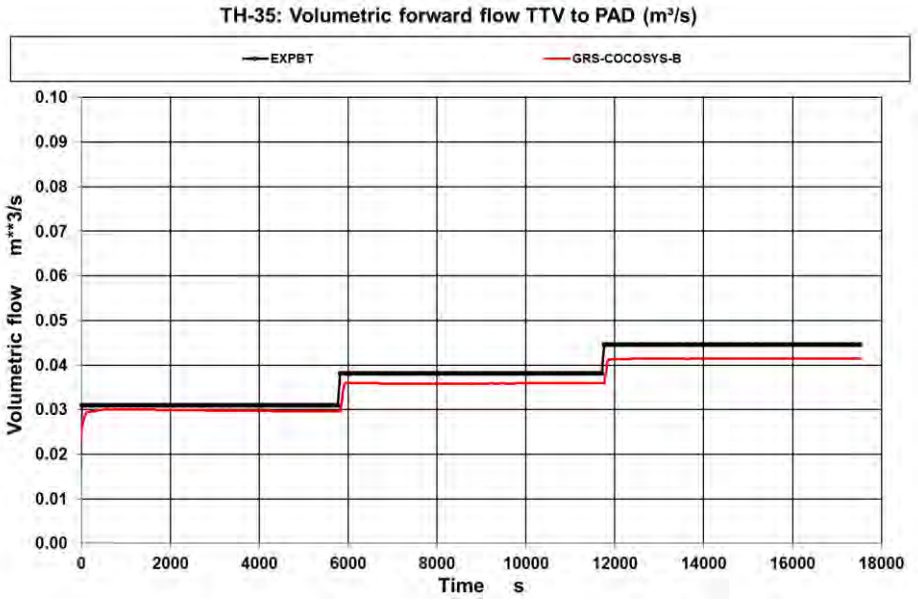

Figure 8. Gas flow through lower connection pipe in forward flow direction, i.e., TTV to PAD

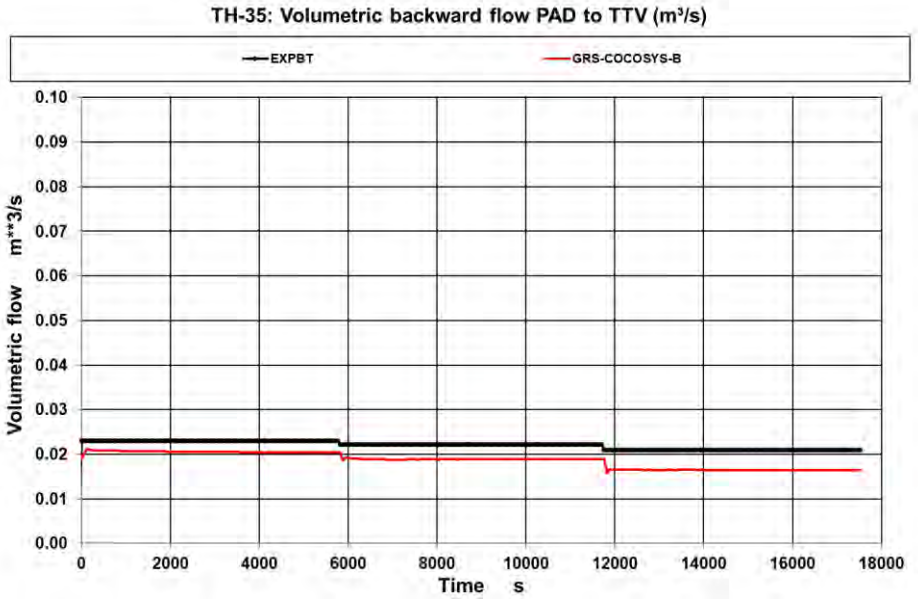

Figure 9. Gas flow through lower connection pipe in backward flow direction, i.e., PAD to TTV

6. SUMMARY

Two experiments investigating counter-current gas flows between two compartments were carried out at the THAI test facility. Data of test TH-35 were used for a simulation exercise. The simulations were conducted based on a specification report that provided participants with the geometric details as well as the initial and boundary conditions of test TH-35 but did not include the actual experimental results.

The forward and reverse flows in the connecting pipe were assessed using local velocity measurements. Overall, the comparison between simulation outcomes and experimental data is encouraging, particularly with respect to both flow directions, the net forward flow, and the ratio of forward to reverse flow.

In a second experiment, the heated TTV vessel was filled with an air–steam mixture, and additional steam and air were injected to initiate both flow and counter-current flow. The findings showed that steam entering the cooler PAD vessel caused rapid heating of its walls due to steam condensation. This heating effect decreased the temperature difference between the two vessels, thereby weakening the driving force for counter-current flow. As a result, forward flow velocities remained nearly constant throughout the three phases, while reverse flow velocities decreased significantly during the transient phase of the experiment.

ACKNOWLEDGMENTS

The project was supported with funds from the Federal Ministry for the Environment, Nature Conservation, Nuclear Safety and Consumer Protection (BMUV) under grant number 1501630.

The development and validation of COCOSYS are funded by the Federal Ministry for the Environment, Climate Action, Nature Conservation and Nuclear Safety (BMUKN).

Outline

- Motivation
- THAI+ test setup and procedure
- Experimental Results
- Benchmark Setup and Results
- Conclusion

Motivation

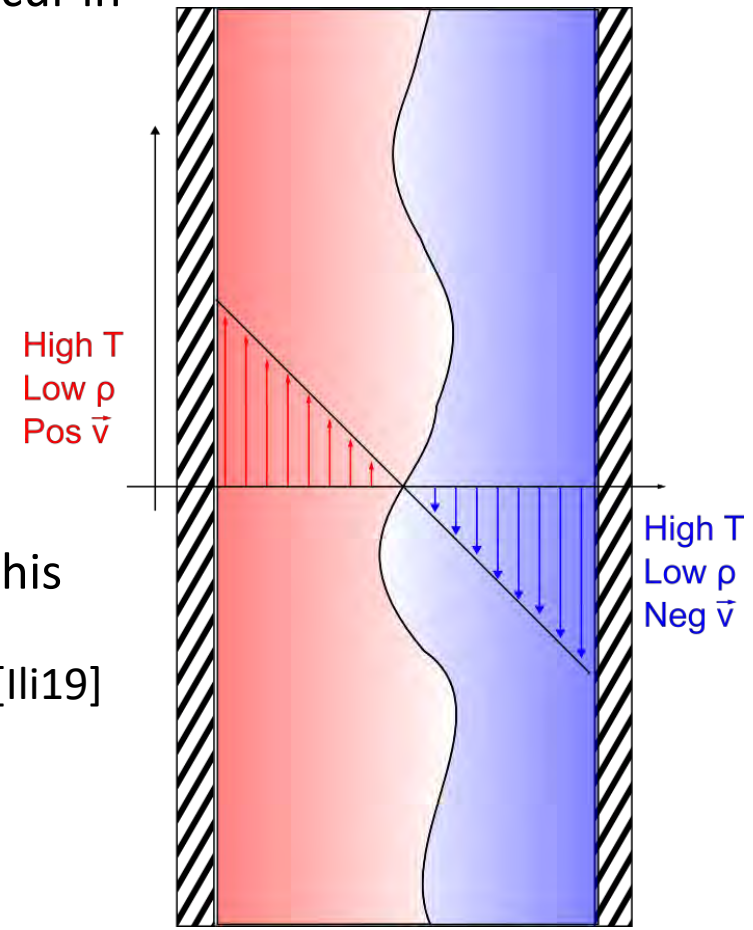
Motivation

- Counter current flow phenomena are observed in experiments or can occur in multi-compartment containments
  - THAI TH-27 [Fre18]
  - CFD of KONVOI steam generator towers [Roy00]

- Governing physics:
  - Local differences in T and ρ
  - Reversal of flow direction
  - Strong shear and enhanced turbulence

- Simulation codes need high spatial nodalization or modelling to predict this behaviour
  - E.g. COCOSYS countercurrent flow model for gaseous flows based on TH-27 [Ili19]

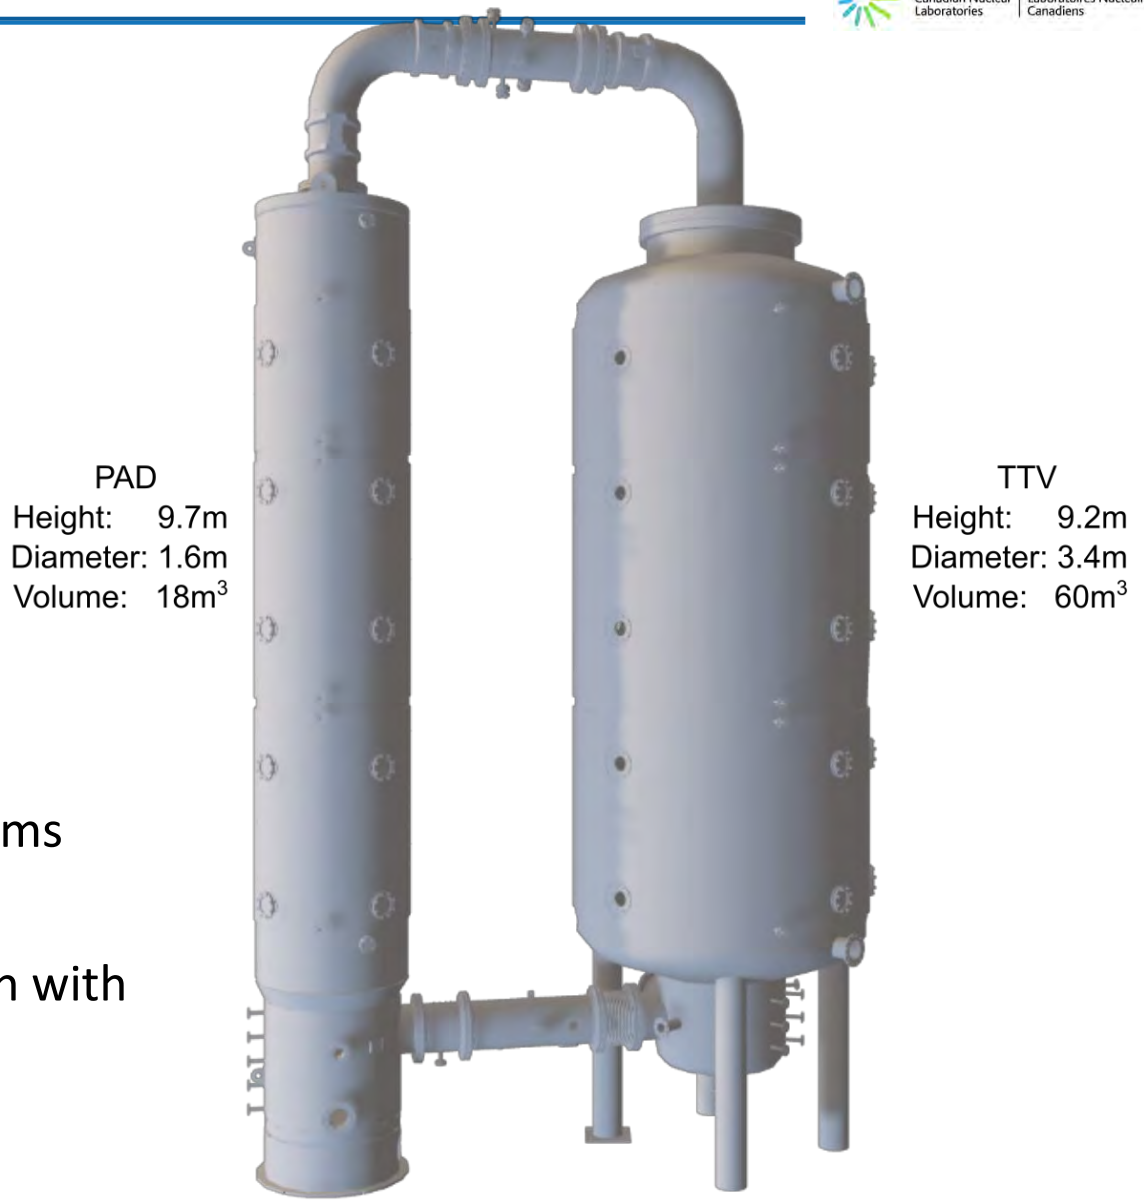
- Benchmark initiated in THAI-research framework:
  - Provide high resolution experimental results of counter current flows (TH-35, TH-36)
  - Blind Benchmark with participation by CNL and GRS for code validation



THAI+ test setup

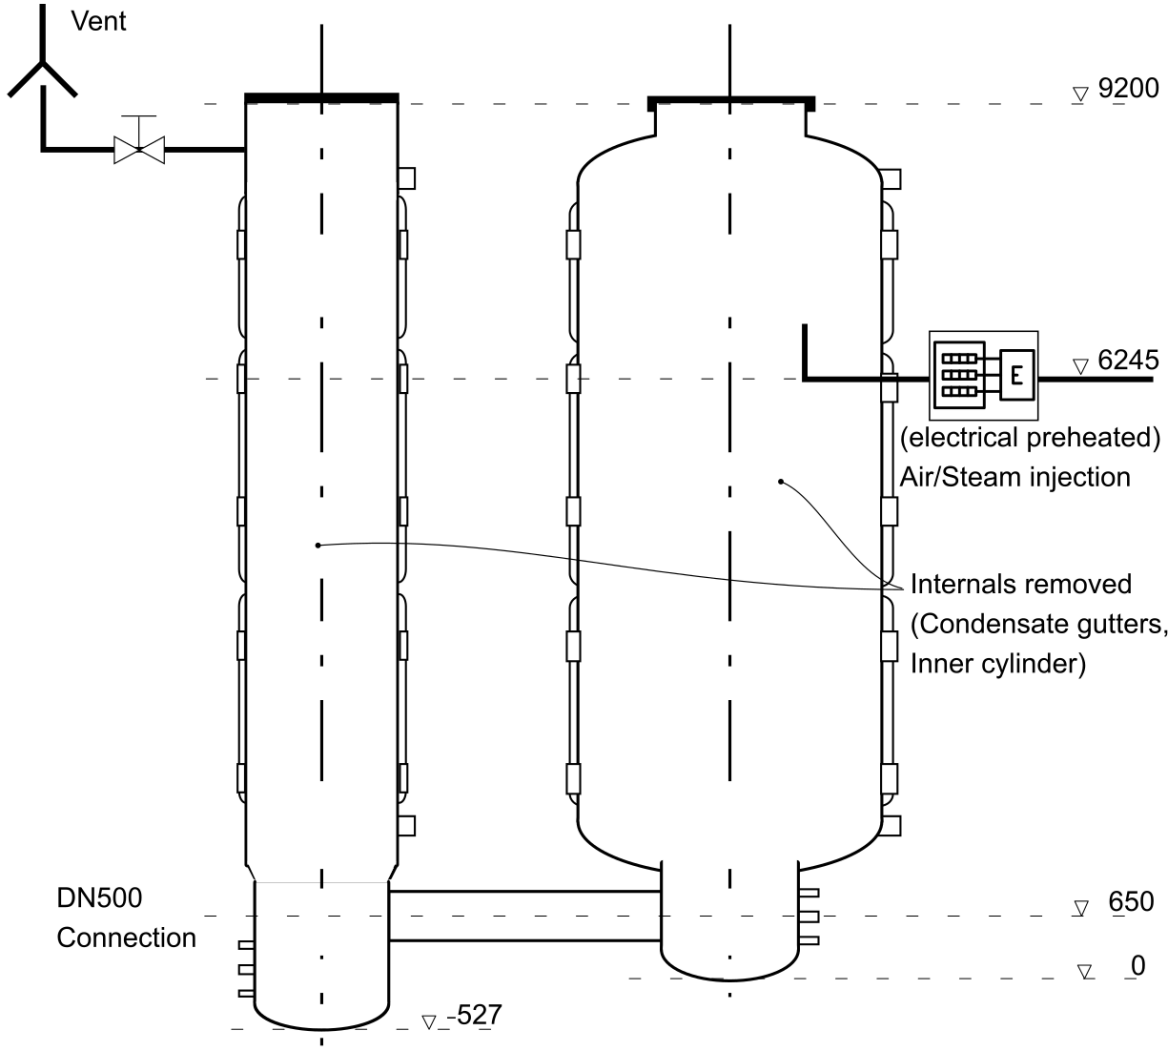
THAI+ Facility

- THAI+: Multi-compartment Test facility for **T**hermal-hydraulics, **H**ydrogen, **A**erosols, **I**odine
- 2 vessel configuration (14 bar at 180 °C)
  - THAI test vessel (TTV)
  - Parallel Attachable Drum (PAD)
- System can be heated or cooled independently via three thermal oil mantles (accuracy +/- 1 °C)
- Access trough flanges for (optical) measurement systems
- Approved for H_2, CO and radiolabeled I_2 in combination with deflagrations



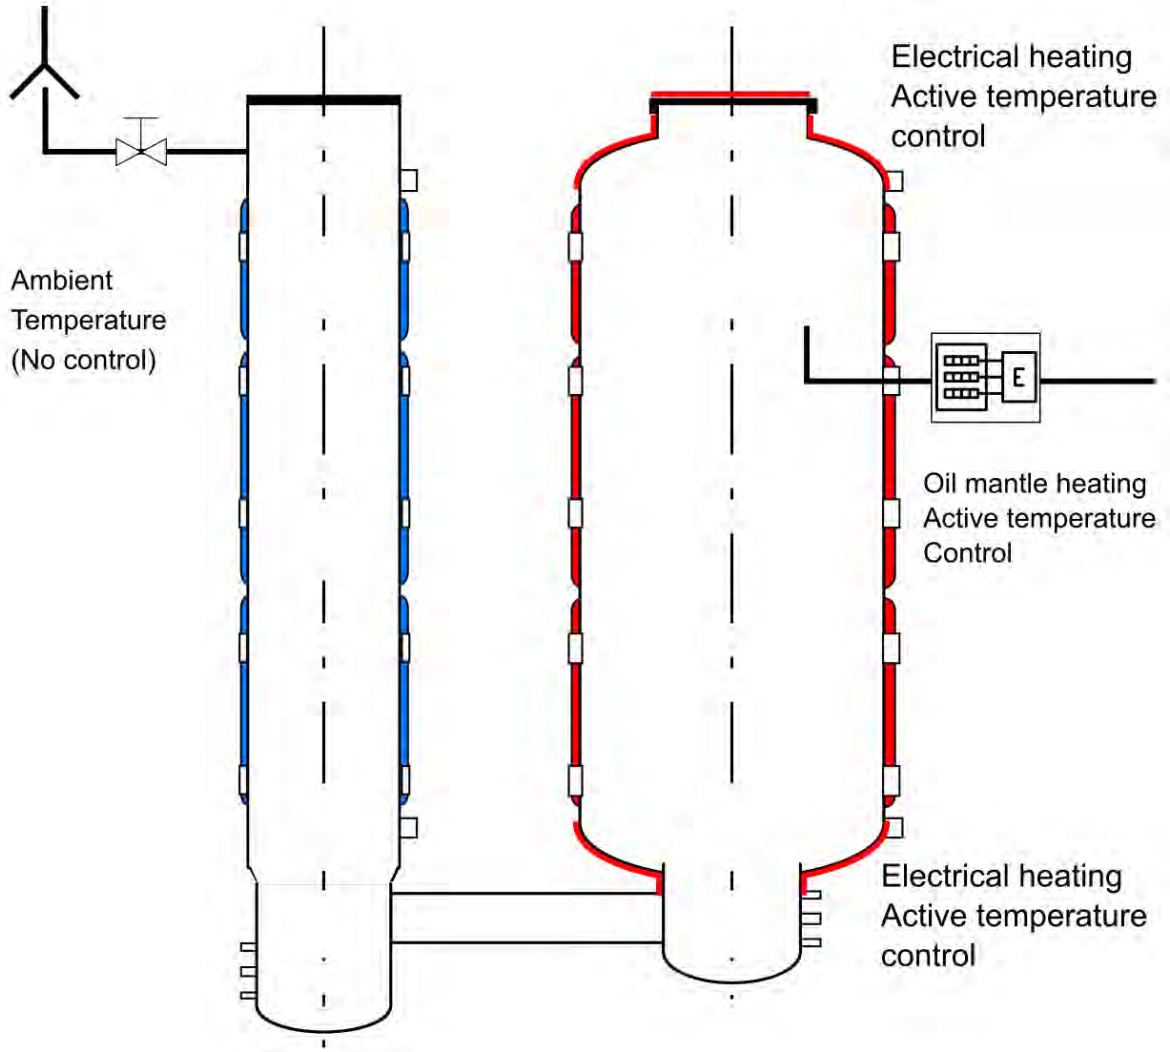
Test Setup

- Internal components removed
- Vessels connected at 0.65m with DN500 pipe.
  No top connection
- Injection of preheated air into TTV at 6.3m
- Venting of PAD vessel for pressure control at top lid
- Oil mantle heating for vessel preconditioning
  - TTV: Controlled heating
  - PAD: No active heating (Ambient Temperature)
- Electronic heating of lid and sump area for TTV



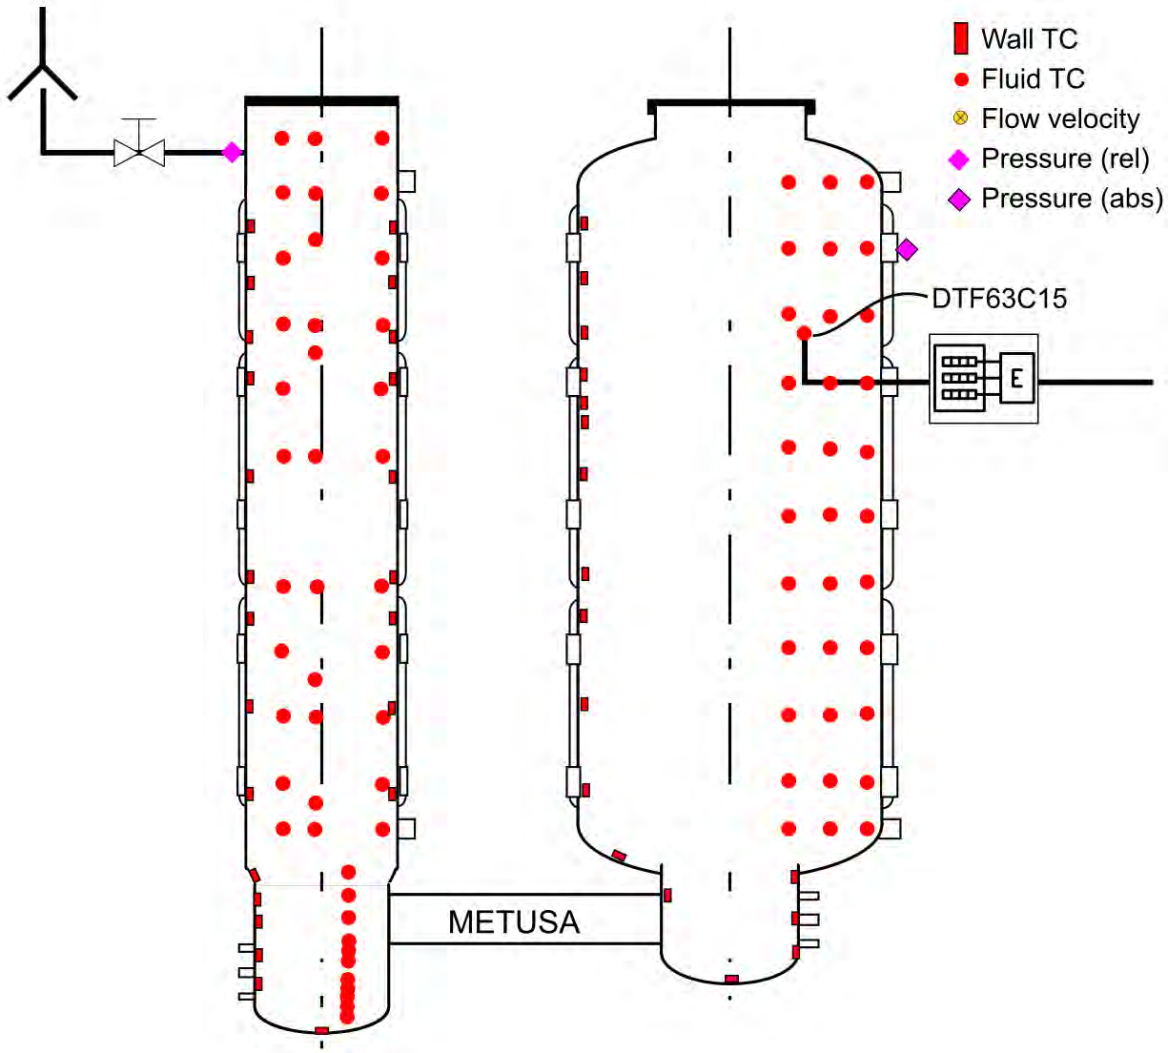
Test Setup

- Internal components removed
- Vessels connected at 0.65m with DN500 pipe.
  No top connection
- Injection of preheated air into TTV at 6.3m
- Venting of PAD vessel for pressure control at top lid
- Oil mantle heating for vessel preconditioning
  - TTV: Controlled heating
  - PAD: No active heating (Ambient Temperature)
- Electronic heating of lid and sump area for TTV



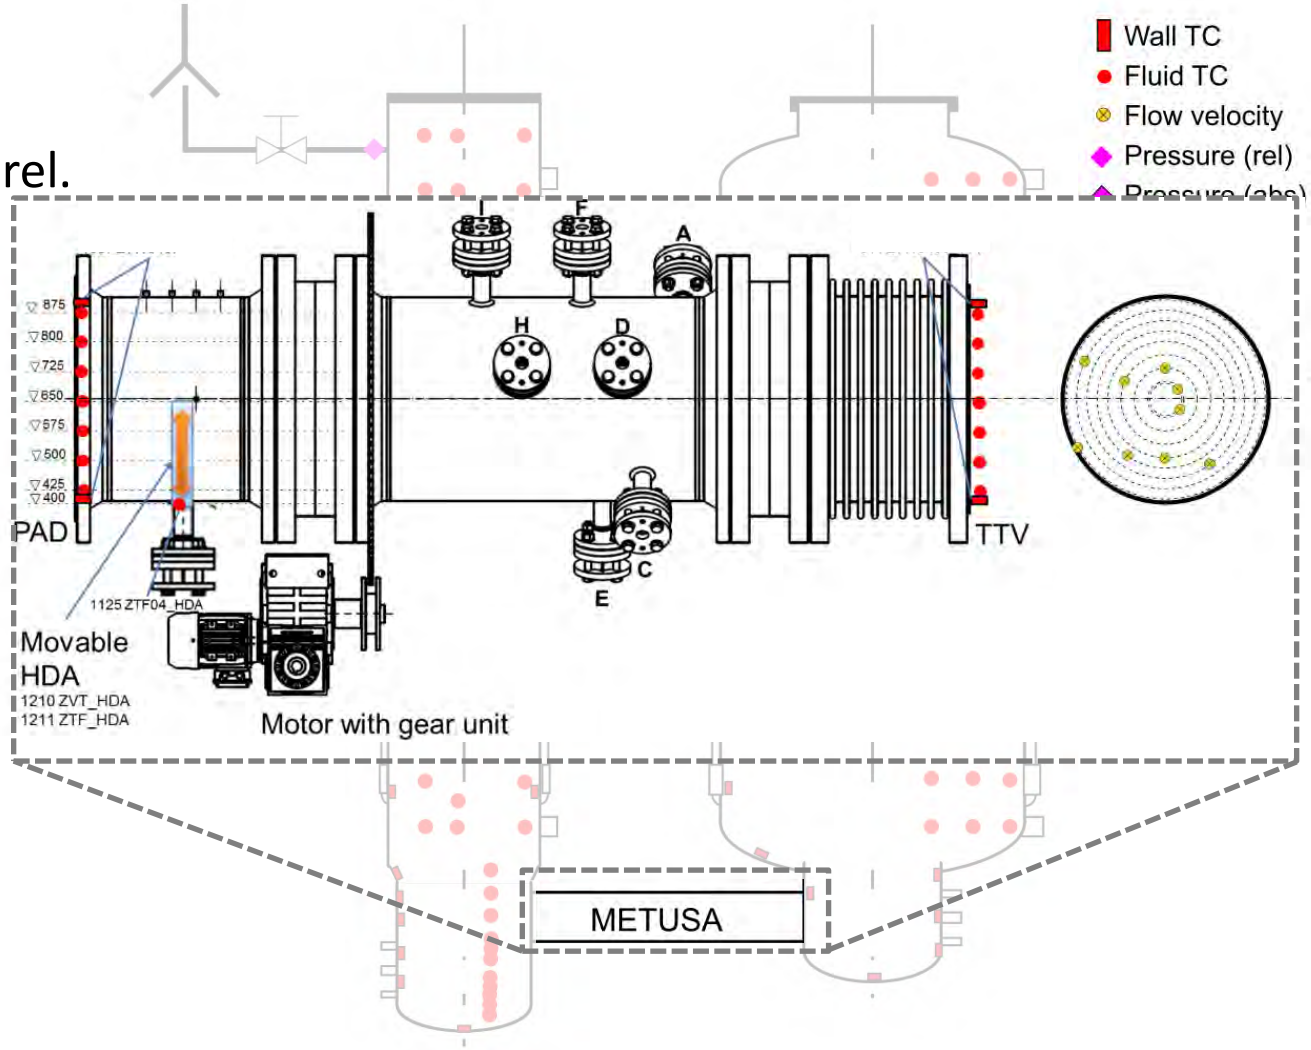
Test Instrumentation

- High resolution wall and fluid temperature instrumentation (Type- K thermocouples) in both vessels
- Piezo resistive pressure transducer for abs. and rel. vessel pressure (both)
- METUSA interconnection pipe
  - Fluid and wall temperature profile
  - Rotating vane wheel anemometer for volume flow rate
  - Traversable Hot-Wire-Anemometer for high-res velocity profile



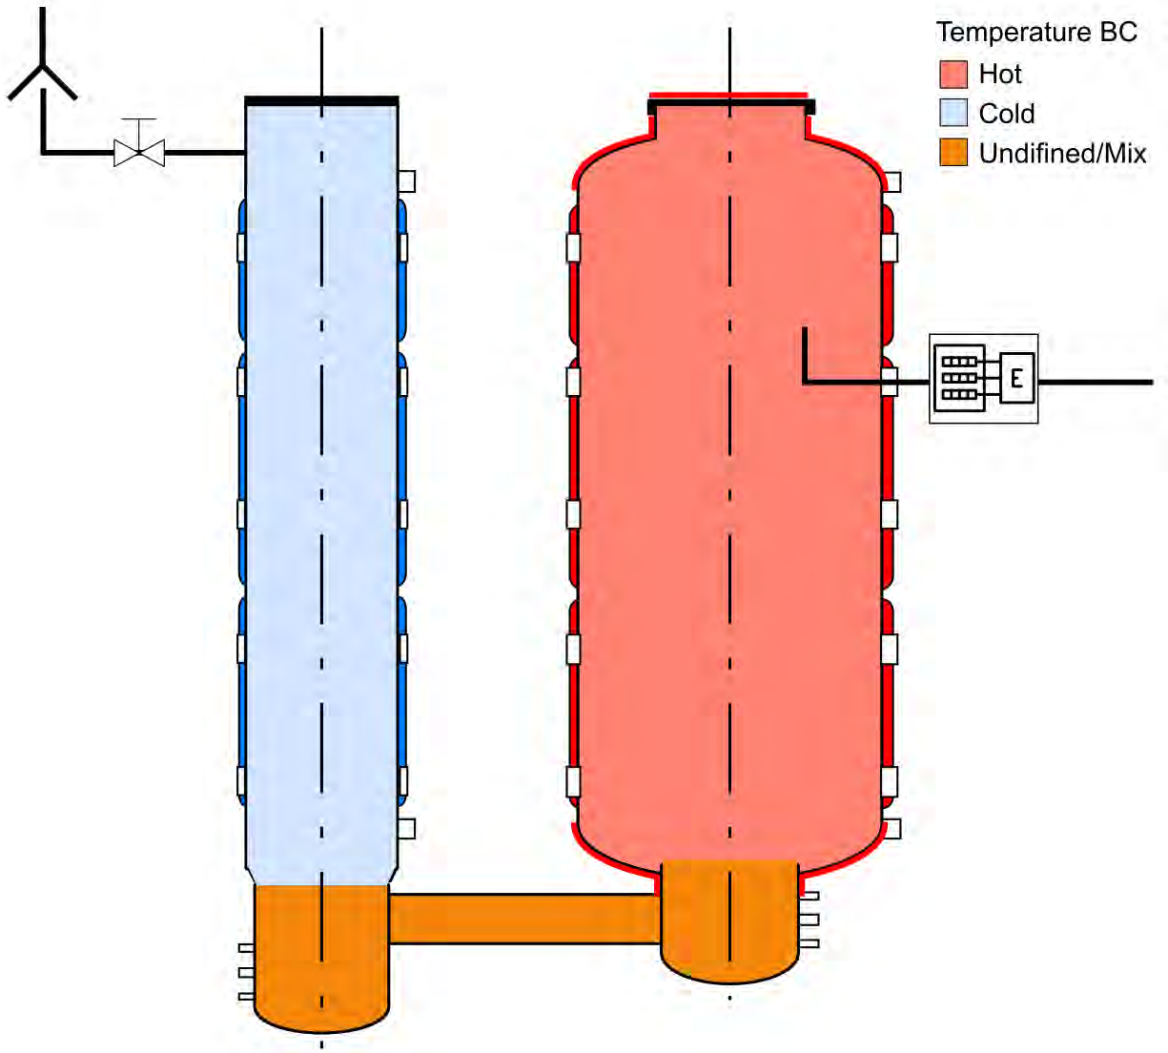
Test Instrumentation

- High resolution wall and fluid temperature Type- K Thermocouples in both vessels
- Piezo resistive pressure transducer for abs. and rel. vessel pressure (both)
- METUSA interconnection pipe
  - Fluid and wall temperature profile
  - Rotating vane wheel anemometer for volume flow rate
  - Traversable Hot-Wire-Anemometer for high-res velocity profile



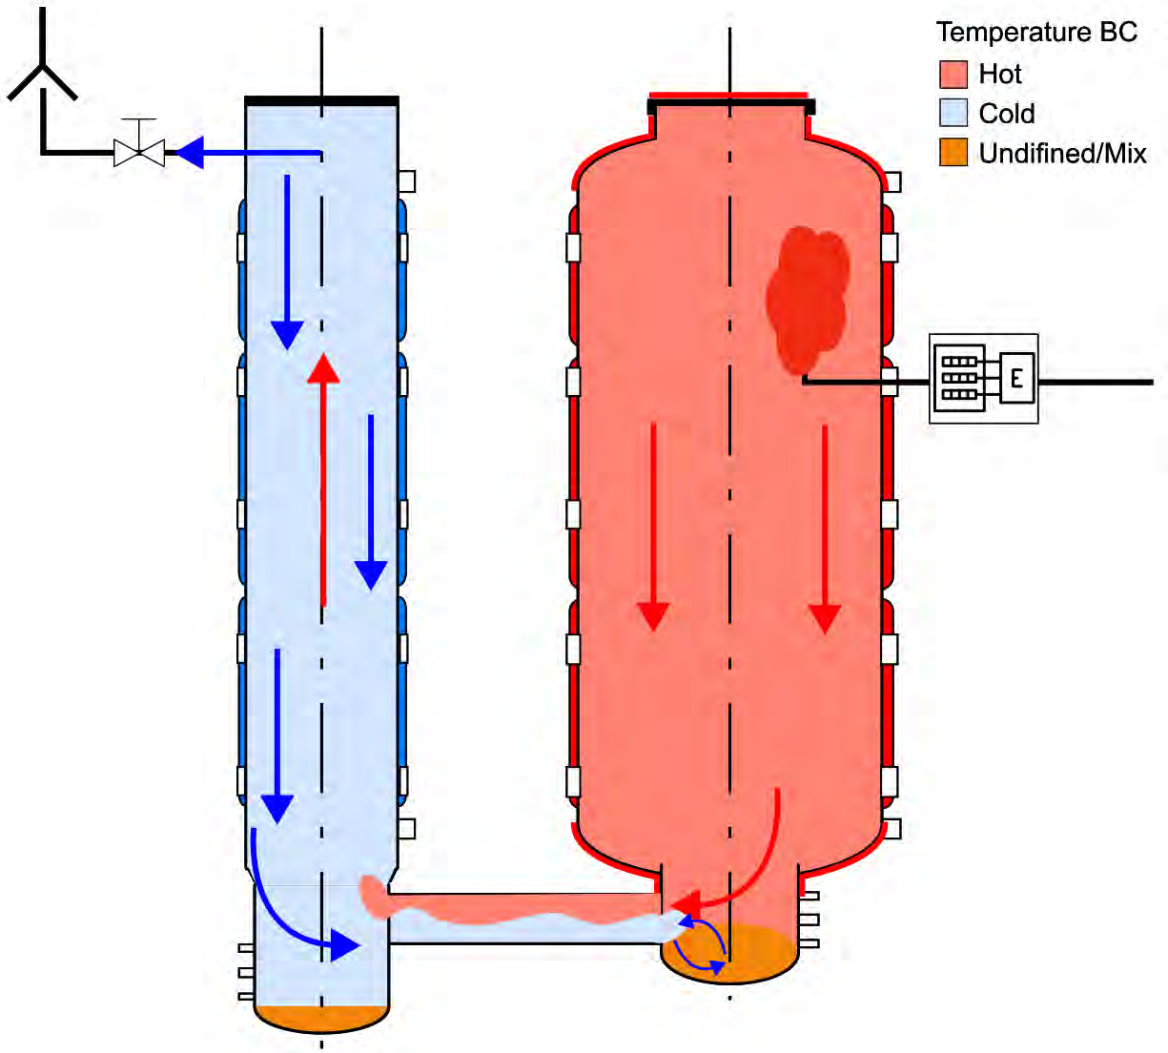
Test Procedere TH-35

- Preconditioning Phase (-21 h to T_0):
  - Initial atmosphere: Air, 1bar (a)
  - Heating up vessel from ambient conditions using oil mantel and electrical heating
    - TTV: 140°C
    - PAD: no heating, ~ 25°C
    - METUSA: no heating, but gas exchange due to therm expansion of the heated TTV gases
- 1st Test Phase (T_0)
  - Injection of preheated Air to TTV (10 g/s)
  - Hot Air will be forced through intersection pipe
  - Hot plumes ascend in PAD
  - Cold air descends in PAD
  - Counter-current flow develops in intersection
- 2nd Test Phase (T_0+1.5h)
  - Increase of air mass flow to 20 g/s
- 3rd Test Phase (T_0+3.0h)
  - Increase of air mass flow to 30 g/s



Test Procedere TH-35

- Preconditioning Phase (-21 h to T_0):
  - Initial atmosphere: Air, 1bar (a)
  - Heating up vessel from ambient conditions using oil mantel and electrical heating
    - TTV: 140°C
    - PAD: no heating, ~ 25°C
    - METUSA: no heating, but gas exchange due to therm expansion of the heated TTV gases
- 1st Test Phase (T_0)
  - Injection of preheated Air to TTV (10 g/s)
  - Hot Air will be forced through intersection pipe
  - Hot plumes ascend in PAD
  - Cold air descends in PAD
  - Counter-current flow develops in intersection
- 2nd Test Phase (T_0+1.5h)
  - Increase of air mass flow to 20 g/s
- 3rd Test Phase (T_0+3.0h)
  - Increase of air mass flow to 30 g/s



Experimental Results

Experimental Results

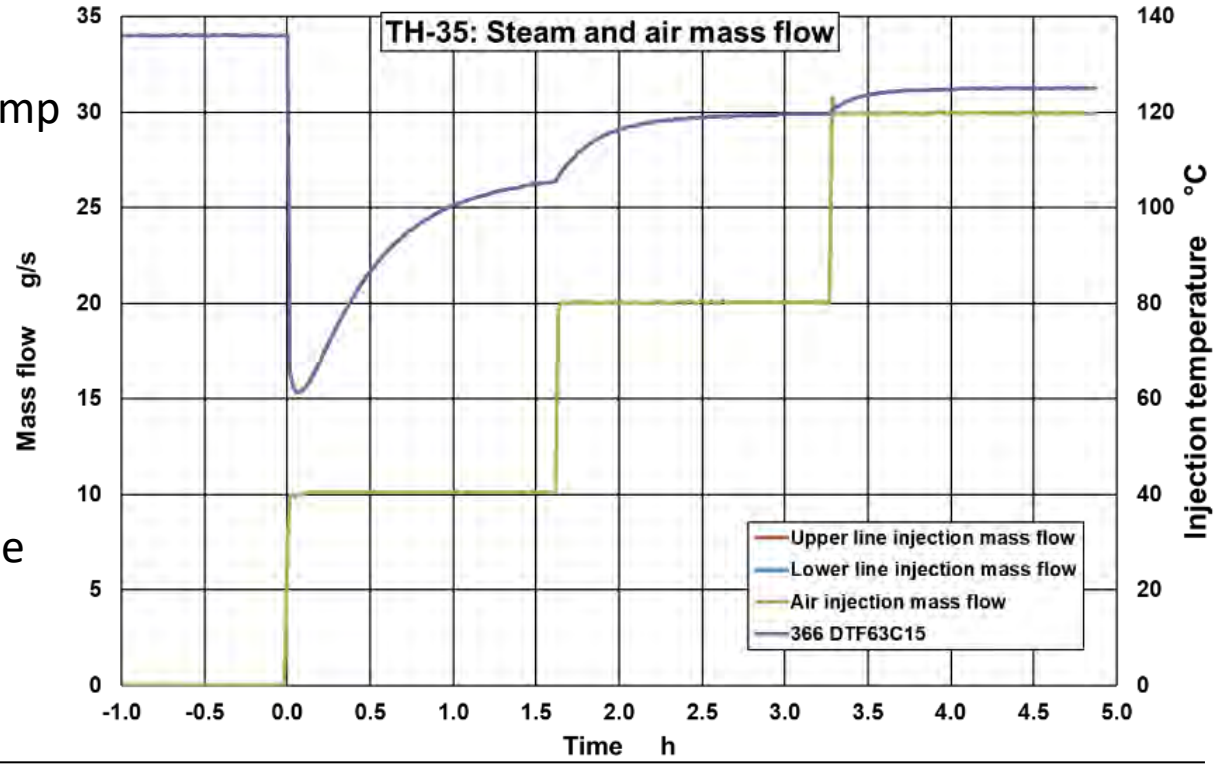
- Boundary conditions before test start (T_0 =0 h):
  - Heating started 21h prior to T_0
  - Stable conditions held for >1.5h
  - Target Temperature and humidity met at T_0

- 1st Test Phase (T_0)
  - Adjustment of target air flow <30s
  - Injected air temperature slightly below vessel fluid temp
  - No overall temperature decrease due to wall heating
  - Pressure regulation with fluctuation <2mbar during test

- 2nd and 3rd Test Phase:
  - Target mass flow rates reached within few seconds
  - Air temperature reaches steady state ~1h after change of injection rate

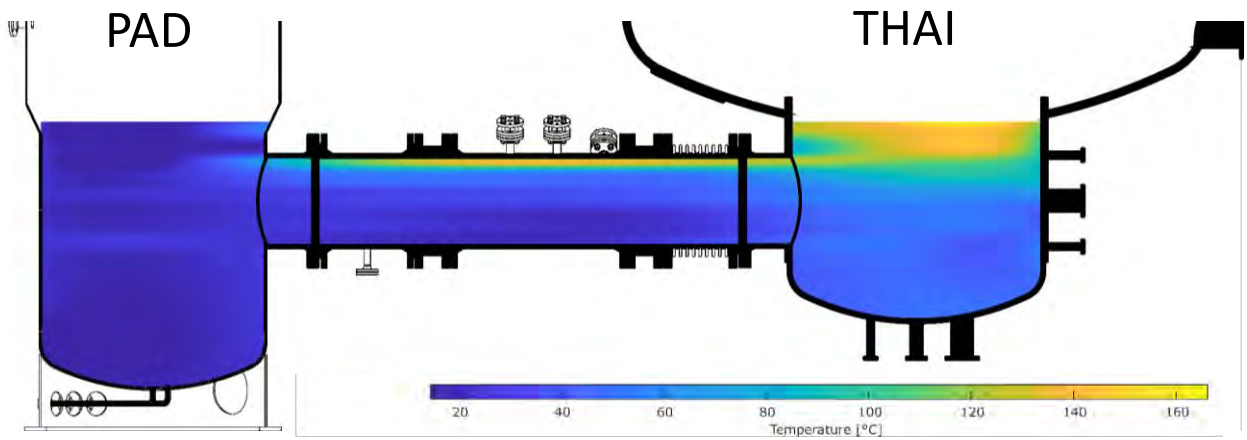
- No steam injection in TH-35 (Conducted in TH-36)

Avg. wall temperatures				Avg. fluid temperatures			
TTV wall temp >8.17 m	**°C**	**140.5**		**TTV Section "D"**	**°C**	**136.1**
TTV oil mantles 1.82-8.17	°C	137.9		TTV Section "A+C"	°C	135.8
TTV Lower Section 1.82- 1.2	°C	138.5		TTV Section "B"	°C	135.0
TTV Sump <1.2 m	°C	73.9		TTV Sump	°C	53.7
				PAD Section "O"	°C	24.8
PAD wall temp >8.17 m	°C	22.1		PAD Section "M"	°C	25.7
PAD oil mantles 1.82-8.17	°C	22.4		PAD Section "L"	°C	25.5
PAD Sump <1.1 m	°C	21.6		PAD Sump (gas)	°C	22.2
Lower Pipe	°C	33.3		Lower Pipe	°C	36.1

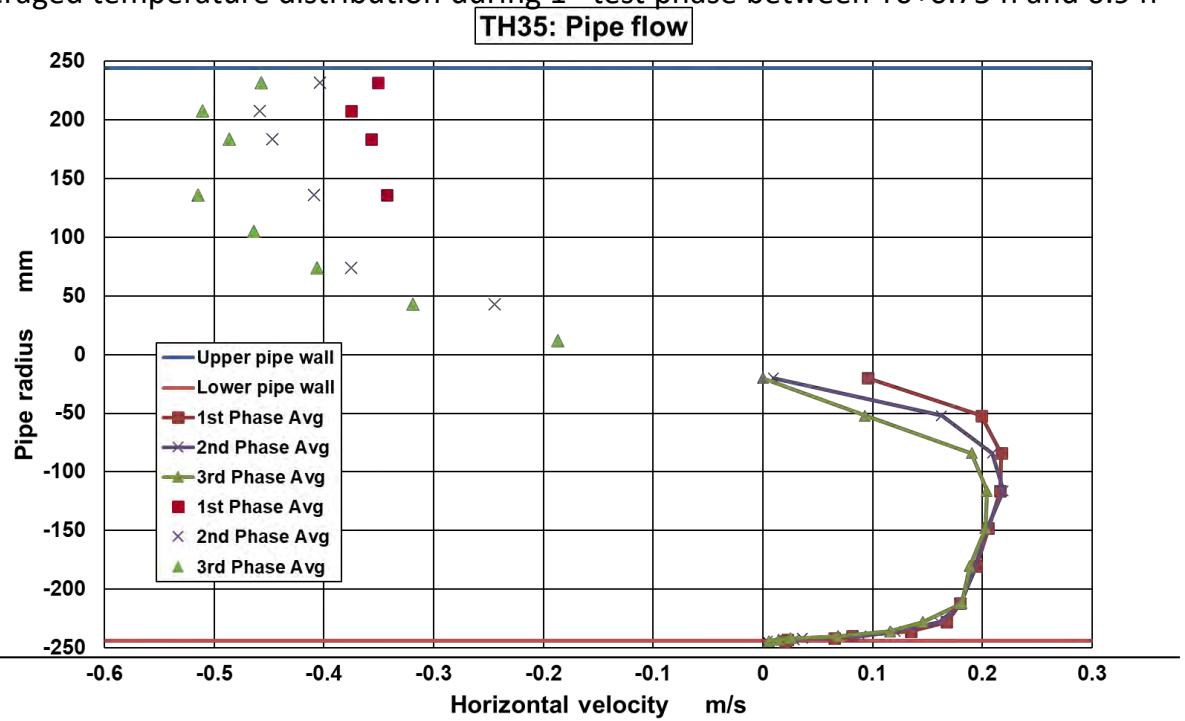


Experimental Results

- Expected temperature distribution in pipe section:
  - Temperature increase in upper part of pipe
  - Indication for mass transfer in upper segment
  - Steep temperature gradient 100°C / 200 mm
- Developed countercurrent flow established in intersection
  - Negative velocity: Flow from THAI to PAD
  - Pos. velocity: Flow from PAD to THAI
- 1st test phase:
  - Centreline velocity <0.1m/s (below vane wheel detection threshold)
  - Noticeable flow of “COLD” fluid from TTV sump compartment to PAD
- 2nd + 3rd test phase:
  - Magnitude and spatial dimension of neg. velocity (forward flow) increase with mass flow
  - No change in cold return flow at lower pipe wall



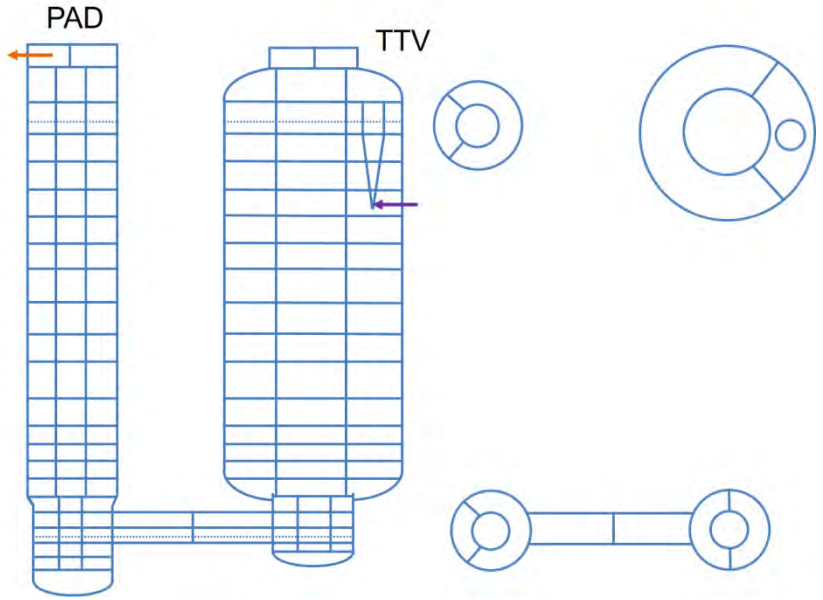
Averaged temperature distribution during 1st test phase between T0+0.75 h and 0.9 h



Benchmark Setup and Results

Numerical Setup

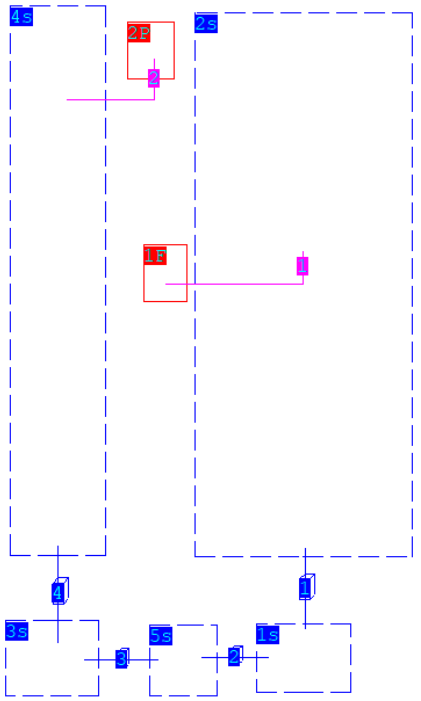
- GSR COCOSYS*

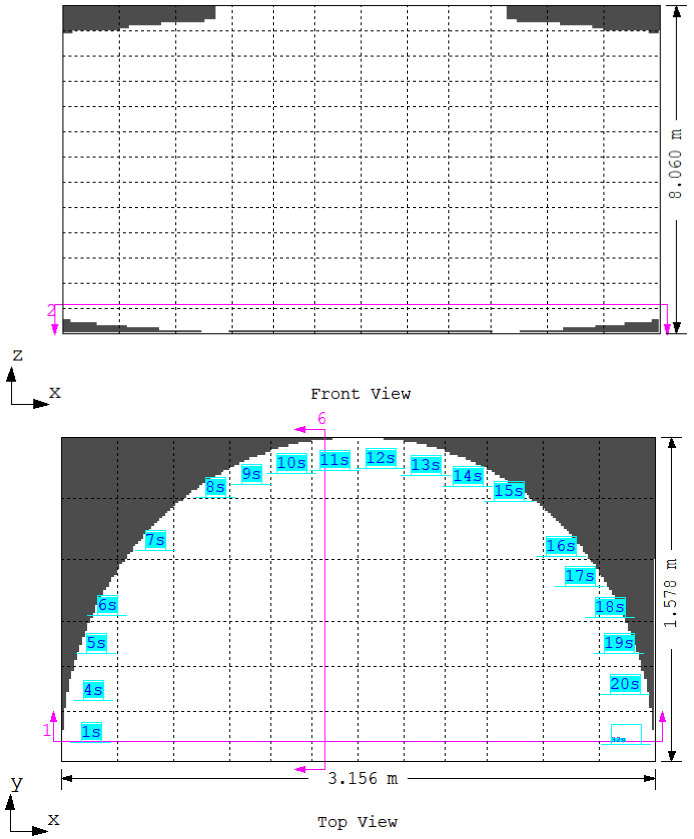


- 137 zones for vessel (67 TTV, 66 Pad, 4 Interconnection)
- Separate node for plume
- Turbulence flow loss coefficient is assumed for Reynolds number in the transition regime
- A maximal pressure loss coefficient of $\zeta_{max}^{turb} = 0.25$ was used

*Corresponding Author: **D. Iliev, GRS**

- CNL GOTHIC**





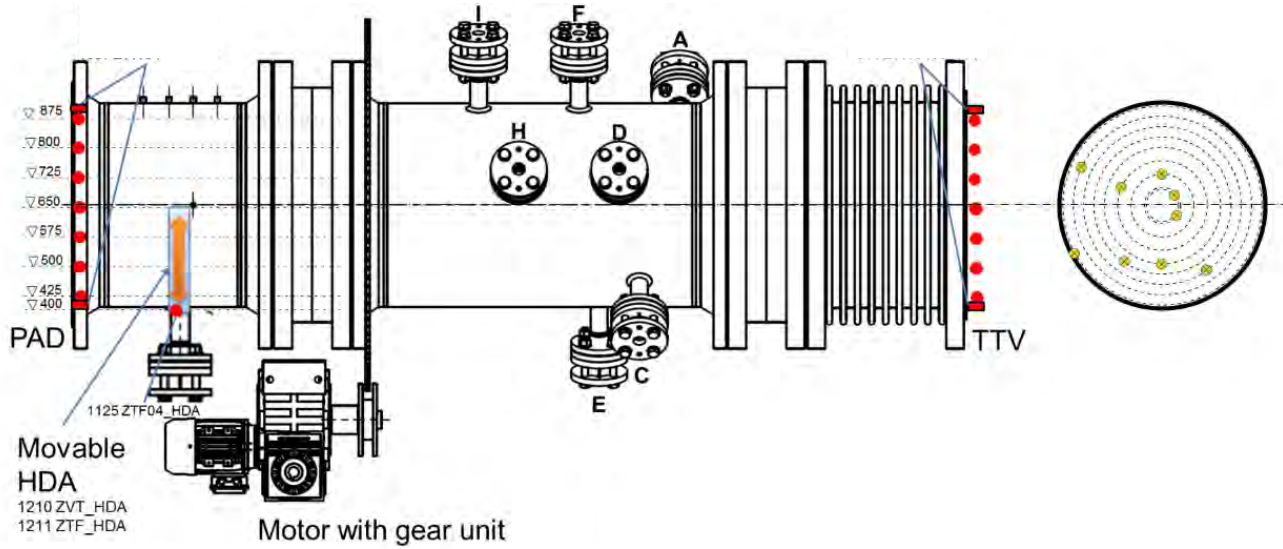
- Five control volumes (TTV, PAD, Pipe TTV Sump, PAD Sump)
- Each control volumes subdivided on a 3D Cartesian grid
- Use of symmetry boundary conditions
- Heat transfer to stainless steel liner modelled, const T in oil mantle as boundary conditions

** Corresponding Author: **Z. Liang, CNL**

Benchmark Results

- Evaluation method
  - Integration spatially resolved flow measurement from experiment
  - Comparison between exported volume flow from simulation
- Forward flow: From heated TTV to PAD
- Backward flow: From PAD to heated TTV

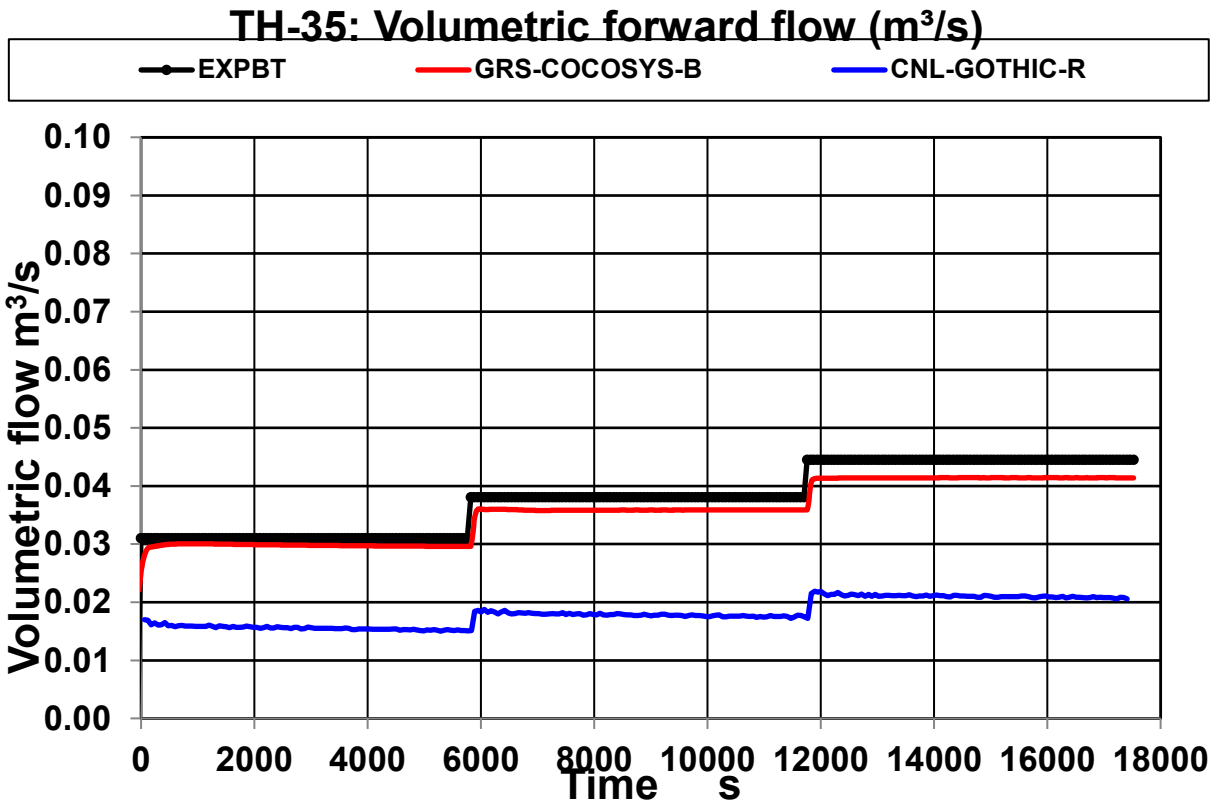
Backward Flow

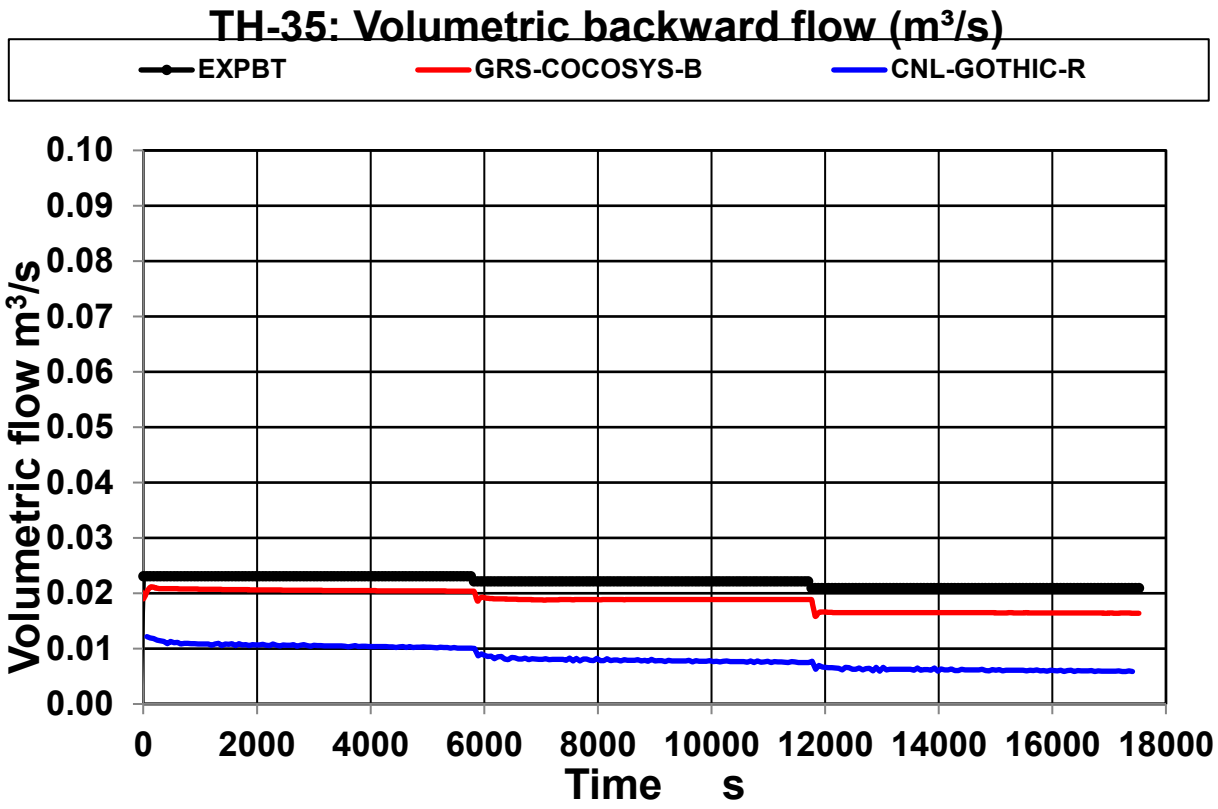


Forward Flow

Benchmark Results

- Comparison of exp. and simulation results





- Phenomenologically both codes capture countercurrent flow
- Prediction of COCOSYS in very good agreement
- Higher injection rates increase forward flow significantly, but backward flow only slightly

Summary and conclusions

Summary and conclusions

- THAI+ facility used for experimental investigation of countercurrent flows

- Successful test campaign with parametric studies on turbulence and gas composition
- Main findings:
  - Forward flow scales with mass injection rate
  - Forward flow is thermally stratified!
  - Backward flow is quasi constant if thermal gradient is steady-state
  - Mixing of backward flow within the TTV sump compartment, no ascend into TTV vessel
- Benchmark using simulation codes COCOSYS (GRS), GOTHIC (CNL)
  - Countercurrent flow captured by both tools
  - Prediction of COCOSYS in good accordance with experimental results

- High resolution data available for code benchmarking
  - TH35: Countercurrent Flows in Air Atmosphere
  - TH36: Countercurrent Flows in Steam-Air Atmosphere

ABSTRACT

The actuation of the spray safety system is known to have a significant impact on the evolution of the hydrogen combustion risk inside the containment building of PWR reactors. Its actuation decreases the quantity of steam in the containment, while its mixing effect homogenises the containment atmosphere, avoiding local accumulations of hydrogen that could otherwise be the main contribution to the hydrogen risk. While the steam content in the containment tends to a steady value that can be estimated by a simpler heat and mass balance, the local distribution of hydrogen depends on complex 3D flows. This works recognises the need of studying this issue using 3D models, addresses the complexities and numerical cost of its numerical modelling, and proposes a systematic evaluation of the positive/negative impact of the spray system actuation on the hydrogen risk.

The systematic analysis, performed under the CSN/UPM-GOMERES and UE-AMHYCO projects, includes the selection of a bounding sequence in terms of H2 risk, different postulations of the main safety system actuations (PAR and spray), and a postprocessing strategy to extract adequate safety relevant figures of merit to compare the cases. All the scenarios postulated in this work, based on a Station Black Out (SBO) accident releasing ~850 kg of hydrogen to the containment building, concluded that the cooling effect of the spray has a more significant impact than the mixing. Therefore, the late recovery of the spray induced more severe conditions. Last, since all the scenarios without PARs lead to non-acceptable hydrogen risks with the current postulations, an alternative strategy for the late recovery of the spray for designs without PARs is proposed.

KEYWORDS
Hydrogen, Containment, GOTHIC, Spray, PARs

1. INTRODUCTION

Containment spray systems are implemented in most containment designs [1] because they provide a highly effective means to cool down and depressurise the containment. Indeed, they were originally designed and sized against criteria dominated by pressure/temperature control and source-term reduction via the wash-down of aerosols [2]. Nevertheless, although the spray was not conceived as a hydrogen-mitigation device, its actuation can have a major impact on the severe-accident hydrogen risk by simultaneously (i) enforcing a strong cooling/condensation sink that removes steam; (ii) driving large-scale mixing that reshapes the 3D distribution of hydrogen and steam in the containment [3]. In the compartmentalised geometry of a containment the assessment of the spray mixing is not trivial, because the hydrogen risk characterisation (slow deflagrations versus mixtures with flame-acceleration potential) is governed by local heterogeneities rather than by a single global average [4]. Consequently, the fast-changing conditions induced by the spray

actuation and the complex flow structures of the containment make a 3D assessment with sufficient thermal-hydraulic resolution particularly necessary to evaluate the combustion risk.

The need to go beyond the well-established Lumped Parameter (LP) approach for topics such as hydrogen risk is aligned with the conclusions of the systematic review published by Zhao et al. [5], which concluded that the use of more detailed models is a central factor in improving the Severe Accident Management Guidelines (SAMGs). In this context, spray actuation and/or recovery are among the most complex SAMG decisions, because they couple multiple –and potentially competing– objectives (containment depressurisation, aerosol wash-down, and hydrogen risk management), for which the net effect may be beneficial or adverse depending on the scenario. Therefore, while analytical tools are essential to inform SAMGs in such conditions, any safety-relevant contribution must assess spray operation systematically across different postulations and quantify its interactions with other mitigation systems, such as Passive Autocatalytic Recombiners (PARs), ignitors, fan coolers, or Filtered Containment Venting Systems (FCVS)).

Following these two requirements –detailed 3D modelling and a systematic assessment of spray actuation across postulations– a search in the open literature yields only a small number of journal publications addressing hydrogen risk with 3D tools [6–11], summarised in Table I. The reduced size of the list is explained by the level of complexity of the issue –3D modelling of a multi-phase, multi-scale, multi-component fluid domain, with strong fluid-solid interactions, engineering systems, and long transients– and its associated computational cost. Furthermore, based on the authors' evaluation, none of the listed references meets the combined scope and depth needed to be labelled as a detailed and systematic 3D analysis of spray actuation, for the reasons highlighted in red in Table I. Therefore, this work intents to contribute to the state of the art by improving the scope –in terms of number of cases and the use of a systematic approach– and the thermal-hydraulic resolution –in terms of accuracy and number of cells– of the comparable studies available in the open literature. This objective can be achieved only by acknowledging that, in order to maintain affordable computational costs, selective simplifications of the physics of the problem must be implemented.

*An advanced implementation requires: thermal & mechanical non-equilibrium when modelling gas and droplets interactions, evaporation of the liquid reaching the walls, and to use the real number of nozzles when modelling the spray safety system

To close the Introduction –and precisely in line with this balance between thermal-hydraulic resolution and computational affordability– all simulations have been performed with GOTHIC8.3(QA). The features of the code are extensively described in previous publications [12] but, in a few words, it could be described as a "Hybrid System Level and Coarse Grid CFD Tool [13]", meaning that the code allows combining the LP and CFD resolutions in the same model. Indeed, in the open spaces of the containment, GOTHIC solves the Reynolds-Average Navier Stokes equations in a similar fit as the commercial CFD codes, and close to the walls, it uses heat and mass transfer correlations like the nuclear legacy system codes. This hybrid approach enables the use of relatively coarse 3D meshes because the correlations close the equations without modelling the fluid boundary layer, saving tens of thousands of cells.

1. A SYSTEMATIC APPROACH TOWARDS COMBUSTION RISK EVALUATION

The systematic approach used to quantify the influence of the spray actuation on the hydrogen combustion risk, whose results are summarized in this work, are part of a PhD Thesis developed under the framework of CSN/UPM-GOMERES and UE-AMHYCO projects [4]. The blocks in Figure 1 summarise the different work lines deemed necessary to label the current research as a systematic evaluation. Nevertheless, for the sake of brevity, this section will simply provide a brief summary of some of the blocks with the necessary references to more detailed information. This paper will cover the blocks in different tones of blue in Figure 1, with subsections 2.1, 2.2, and 2.3 describing the sequence selection criteria, the figures of merit for the combustion risk evaluation, and the systematic exploration of different activation criteria for the spray. Later, section 3 will describe the results of the simulation with and without PARs.

The contribution to the state of the art ambitioned in Table I—including spray and other safety systems, with a 3D model at containment scale, for up to 24 distinct transients with 9 h of simulated time—can only be achieved by accepting, at every stage of the work, that affordable computational costs require selective simplifications of the underlying physics. This immediately rules out the most detailed gas-to-droplet interaction approaches, such as Euler–Lagrangian schemes, spray atomisation, internal droplet temperature gradients, and droplet–droplet interactions (break-up, coalescence, etc.) Alternatively, this work adopts a relatively coarse mesh and a monodispersed representation of the droplet field, accounts for thermal and mechanical non-equilibrium in the gas–droplet coupling, includes evaporation of the liquid reaching the walls, and preserves the real number of nozzles when representing the spray rings of a generic PWR-W.

To evaluate whether the proposed approach retains the critical physics needed to assess the *global* impact of spray operation in terms of containment cooling and hydrogen mixing, it has been validated against six PANDA experiments, selected to span a range of representative conditions and phenomena for the intended plant-scale application. Two of these experiments (one of them including a spray ring) were performed within the OECD/NEA HYMERES-2 Project and were comprehensively discussed in [14], while the corresponding results for the remaining four tests are available in [4]. Overall, the validation exercise showed a solid qualitative agreement with the experimental measurements for the six simulated experiments; in quantitative terms, however, the simulations exhibited a consistent overestimation of the spray cooling effect. Since such quantitative deviations observed at the PANDA scale may directly affect the quantification of the hydrogen risk when extrapolated to the containment analysis, the present systematic evaluation will include a set of parametric cases to consider the impact of equivalent deviations before extracting any safety-relevant conclusion.

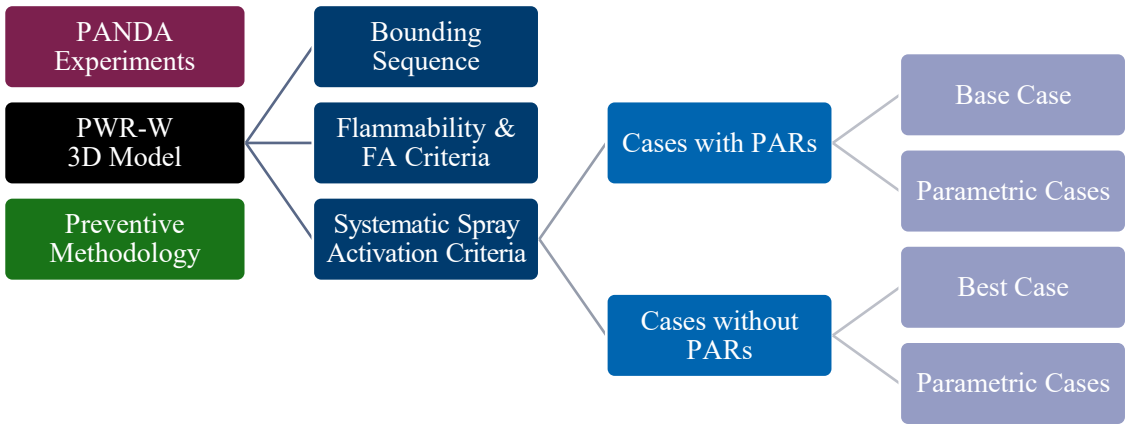

Figure 1. Flowchart of the systematic approach on evaluating the impact of the spray on the H_2 risk

In addition to the lessons learnt from the PANDA validation, the 3D PWR-W containment model used for the calculations was developed following the "Preventive Methodology" described in detail in [12], which provides a practical framework to optimise the computational cost of GOTHIC models through a geometry definition strategy tailored to the porous-media approach. This methodology introduces targeted geometric simplifications that remove the root causes of numerical issues associated with particular cell configurations —especially when targeting fine meshes on the order of 1 m³ per cell— observed in previous UPM GOTHIC models, which often led to unaffordable computational costs. As demonstrated in [12], the 3D PWR-W model used in this work achieved a reduction of the computational cost by a factor of about 40 when compared with models using an even coarser cells (1.5 m³ per cell vs. 1.95 m³ of the previous finest model).

1.1. Bounding Sequence Selection

The next step of the systematic approach to estimate the impact of the spray actuation on the hydrogen combustion risk was the selection of a bounding accident sequence combining: (i) severity in terms of combustion potential; and (ii) an a priori expectation of high sensitivity to spray operation. In this work, the transient was selected from the sequences made available within the EU AMHYCO Project [15], which were screened by the project partners to maximise the expected combustion risk based on expert judgement, rather than targeting the most probable sequences from a full Level 2 probabilistic risk assessment.

A detailed description of AMHYCO's selection criteria is provided in [15]. In brief, the screening using LP Severe Accident (SA) codes considered peak combustible gas molar fractions in the containment, total combustible gas mass, maximum release rates, and containment pressure levels, complemented by an overall qualitative assessment. In the present application, the selected sequence particularly prioritised the combination of a high total hydrogen mass and high containment pressures, since this pairing is expected to maximise the potential cooling effect of spray actuation (or recovery).

The transient selected in this work is a Station Black-Out (SBO) calculated by IRSN with ASTEC within AMHYCO [15], and implemented as time-dependent mass and energy sources for the containment model. Figure 2 summarises the releases: an initial two-phase intermittent discharge followed by steam releases, all originating from the Pressuriser Relief Tank (PRT). Later, once core degradation is ongoing, the pressurizer relief valves lock open progressively depressurising the primary circuit. The slow steam–core interaction yields up to 848 kg of hydrogen by the end of the in-vessel phase. These work simulations' are stopped at the time of the reactor vessel failure. The main milestones of the sequence are summarised in Table 2. In the absence of spray actuation, the containment pressure remains between 3.5 and 4.5 bar most of the transient, so any postulated spray recovery is expected to significantly affect the containment thermal-hydraulic conditions.

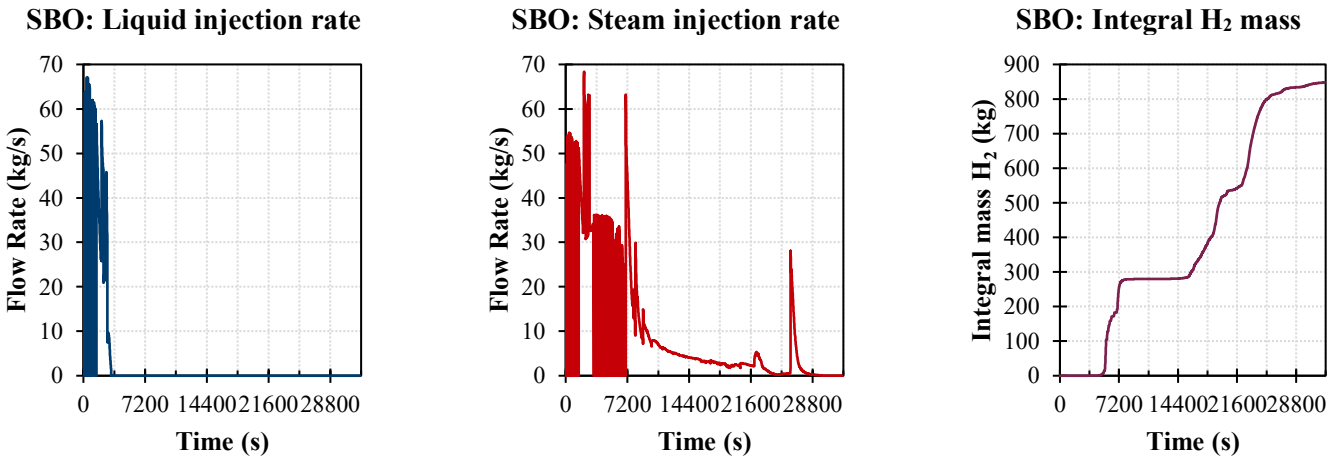

Figure 2. Boundary conditions for the containment analyses calculated by IRSN using ASTEC [15]

Table 2. On the left, main milestones of the simulated SBO. On the right, postulated spray recoveries

	Time in GOTHIC
Loss of all offsite power	- 2 h 37 min
Rupture of PRT (Pressure relief Tank) disks	-11 min
Pressuriser valves locked opened (SAMG action)	1 h 56 min
Accumulator tank discharge	2 h 9 min
RPV failure	8 h 58 min

Case IDs	Spray On	Spray Off
v010	**No Spray**	**No Spray**
v011	**7200 s**	**14400 s**
v012	**10800 s**	**18000 s**
v013	**14400 s**	**21600 s**
v014	**18000 s**	**25200 s**
v015	**21600 s**	**28800 s**
v016	**25200 s**	**32400 s**

1.2. Systematic Spray Activation Criteria

To label the assessment of spray operation as systematic, the analysis must postulate alternative recovery logics and timings rather than a single best-estimate actuation time. This is particularly relevant for the present SBO, in which sprays are unavailable by definition. Hence, the analysed cases represent postulated spray recoveries framed as candidate SAMG actions after core degradation has started. As summarised in Table 2, the time window for these recoveries happens just after the SAMG action of IRSN calculation, triggered by a high core-temperature signal and leading operators to keep the pressuriser valves open to depressurise the primary circuit, and avoid a potential early containment failure by direct containment heating.

On this basis, the spray "activation criteria" are defined as discrete recovery times starting after the SAMG entry, which occurs at approximately 2 h in the present GOTHIC calculations (Table 2). The spray is then recovered once per hour from 2 h to 7 h, including a reference case without spray, and each recovery is modelled as a 2 h direct spray phase. This duration is consistent with the assumed water availability, since the spray is postulated as the only system drawing from the Reactor Water Storage Tank and the available inventory supports approximately 2 h of direct injection at the nominal flow rate. Moreover, the transition to the recirculation phase is postulated as failed in the base cases, and is only explored within the parametric cases. These postulations are not intended to reproduce any plant-specific SAMG logic, but to illustrate how an analytical tool can screen candidate high-level mitigation actions by comparing alternative timings and boundary conditions. The same recovery windows are analysed with and without PARs, yielding 14 base cases, which are complemented by 10 parametric cases exploring spray actuation parameters, PAR efficiencies, recirculation availability, and selected material properties.

Finally, the boundary conditions associated with the spray safety system correspond to a generic PWR-W for which the spray is the only dedicated containment heat-removal system (i.e., no fan coolers are modelled). The nominal liquid flow rate is 208 kg/s per train, and the present work postulates the operation of a single train. The system consists of three spray rings (104, 64, and 48 nozzles), and each nozzle injects 1 kg/s of droplets with an SMD of 1000 μm, at 30 °C, and with a full cone angle of 60°.

1.3. Flammability and Flame Acceleration (FA) Criteria

A systematic analysis requires a well-defined figure of merit to enable consistent comparisons between cases. In the context of hydrogen combustion, previous methodologies [16,17] typically differentiate between slow deflagrations, conditions with the potential to promote Flame Acceleration (FA), or, in more extreme cases, a deflagration-to-detonation transition (DDT). While slow deflagration remains a relevant safety concern for the containment –since it may challenge systems and instrumentation needed for accident

management– the containment structure is generally expected to withstand such slow regimes, but not the much higher dynamic pressures associated with FA or DDT [3]. Moreover, hydrogen combustion cannot be halted once initiated. Thus, the emphasis of the present evaluation is placed on preventing conditions that could lead to FA. Accordingly, the primary safety criterion adopted in this work is to avert FA conditions, and whenever they are identified, the parametric analysis will explore mitigation alternatives.

The FA assessment is based on the σ criterion, which builds on the dimensionless analysis proposed by Dorofeev et al. [18] from a broad experimental database. The σ criterion evaluates the expansion ratio between burned and unburned mixtures and compares it to a critical value (σ_c) that depends on the initial conditions and mixture composition. In this work, the computation of the σ followed the guidelines given in [16]. Accordingly, the hydrogen risk is quantified here through a cell-by-cell post-processing of the 3D simulation results. Specifically, the computed pressure, temperature and gas composition of each cell. Each cell is first tested for flammability, and only flammable cells are subsequently evaluated for FA potential. The flammability limits account for the effect of mixture temperature and, in addition to the limits given in [16], implement a lower oxygen concentration threshold to account for hydrogen starvation conditions potentially induced by the PARs. For each flammable cell, σ is divided by the critical value σ_c to obtain the σ-index (σ_i), and cells with $\sigma_i \geq 0.92$ are labelled as FA-prone, where the threshold accounts for the ±8% uncertainty reported by [18]. The resulting σ field is retained cell-by-cell, both to compute the integral FA hydrogen mass and to enable 3D visualisations of FA potential in different containment regions.

Finally, the figure of merit to compare the different cases will be the temporal evolution of the total hydrogen mass in the containment with the potential to undergo FA, obtained by summing the hydrogen mass of all the cells where $\bar{\sigma} \geq 0.92$. It is important to note that combustion processes are out-of-scope of the present simulations. Therefore, hydrogen is accumulated inside the containment without considering partial combustions processes triggered by spurious ignition sources. Also, since the simulations are stopped before entering in the ex-vessel phase, CO is not included in these analyses.

2. SBO WITHOUT PARs AND SPRAY RECOVERY

This section will present the unmitigated cases, i.e., the different spray activation windows simulated in the model without PARs. Although these unmitigated SBO cases will also serve as a reference to quantify the role of PARs and their interaction with spray recovery, their relevance goes beyond a purely comparative purpose. For PWR-W containments in the United States, the need for PARs has been repeatedly discussed across licensing and post-event reviews (TMI-2, the AP600 design, and post-Fukushima), with the recurring conclusion that PAR installation is not required provided that pre-established hydrogen-control requirements are correctly implemented. Consequently, the "without PARs" configuration remains representative existing plant conditions and is therefore analysed here with an equivalent scope as the mitigated cases.

The unmitigated cases will be presented in two sub-sections. Section 3.1 presents selected results of the different spray recovery windows to: (i) understand the impact of spray recovery by comparing spray vs no-spray cases; and (ii) evaluate the relevance of local conditions on the global combustion risk metrics. Section 3.2 then summarises the parametric cases used to challenge the base-case conclusions, also showing a spray operation strategy aiming to reduce the combustion risk for PWR-W without PARs. All simulations were performed on a single desktop computer (Intel i7-8700, 3.2 GHz) using six MPI ranks: the reference case without spray required 91.3 h, whereas the corresponding case with spray required 118.9 h, with the increase attributed to the higher velocities induced by droplet injection.

2.1. Spray activation windows

The global evolution of the containment thermal hydraulics and the hydrogen combustion risk for the different spray recoveries are summarised in Figure 3 (containment pressure) and Figure 4 (total FA mass).

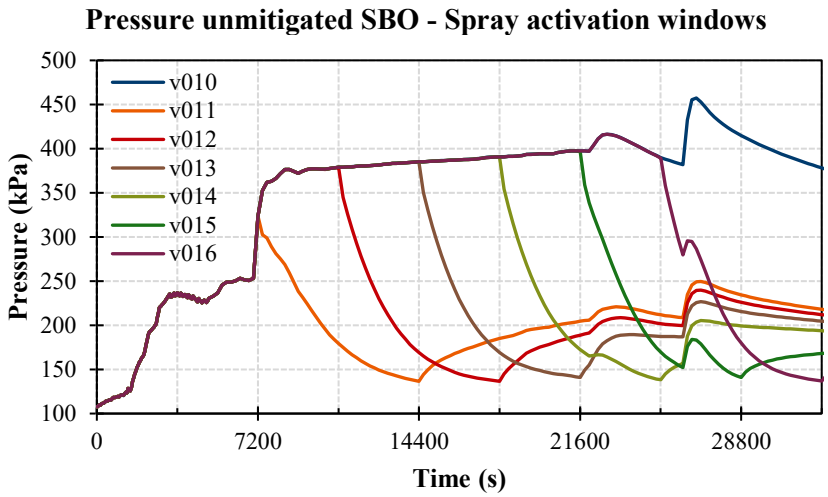

Figure 3. Unmitigated SBO containment pressure evolution for different spray activation windows

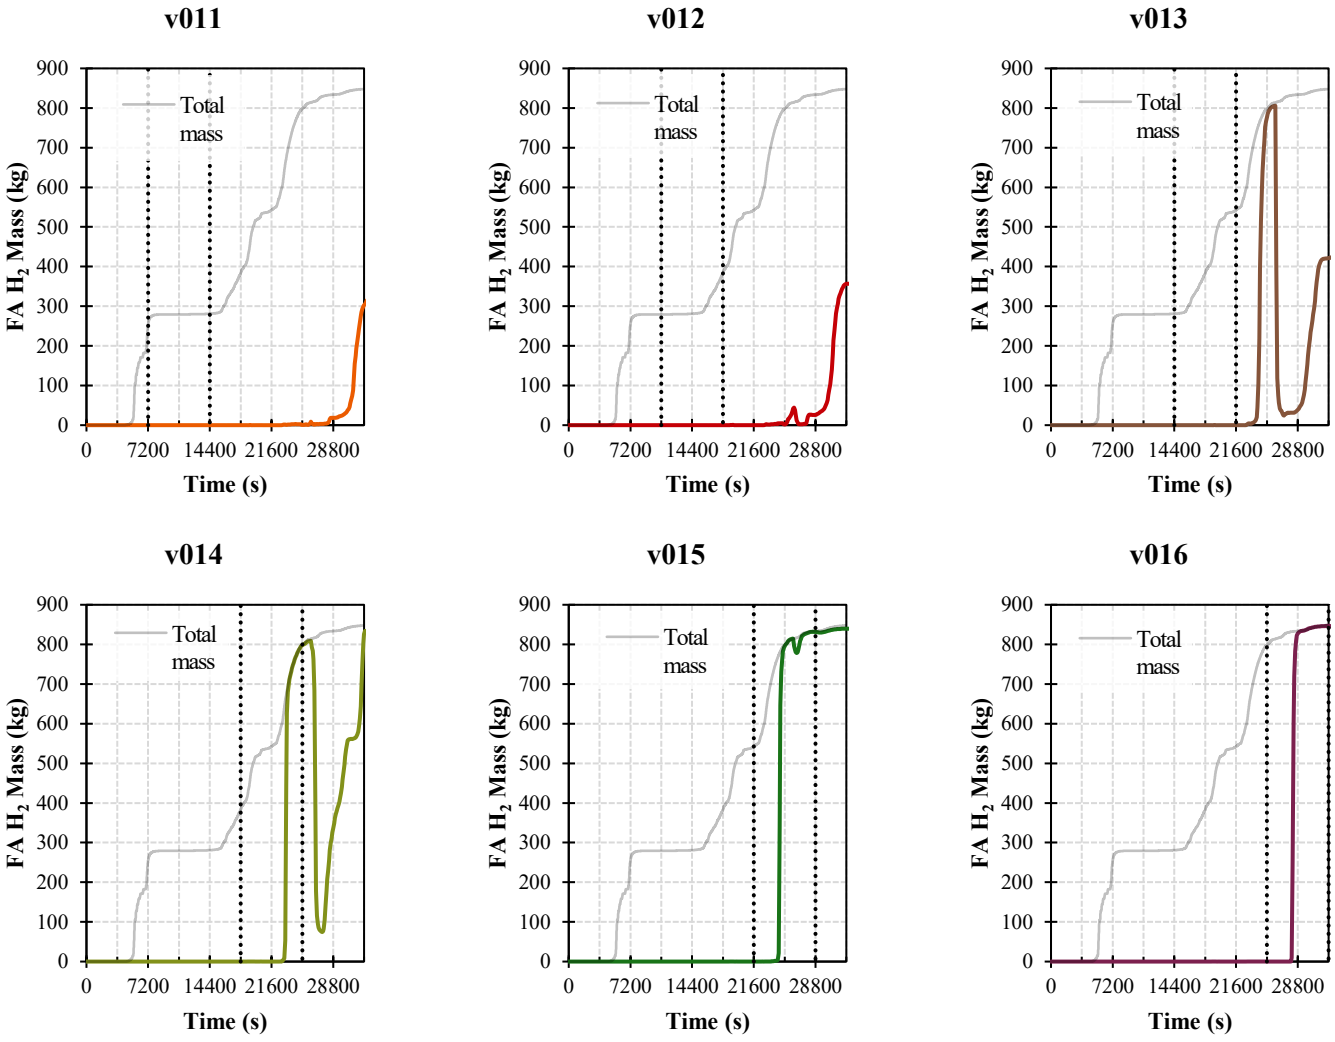

Figure 4. Mass of hydrogen with FA potential ($\sigma_i > 0.92$) for different spray activation windows
Each graph shows the evolution of the flammable H2 for the spray activation windows indicated with dotted lines. The thin grey line is used to guide the eye for comparing the FA mass with the total H_2 mass released to the containment

The containment pressure response in Figure 3 shows two radically different containment conditions in cases with and without spray recovery. Generally, the pressure increase is driven by the time-dependent mass and energy injections (see Figure 2), with intermittent releases during the early phase (before 7200 s) and, later, a sharp increase when the primary circuit is depressurized. In the case without spray, wall condensation partly mitigates the pressure rise but cannot compensate for the continuous steam and hydrogen inflows. By contrast, all spray-recovery cases exhibit the same characteristic response: the 2 h direct spray phase produces an abrupt pressure reduction, followed by a pressure rebound once droplet injection is stopped, as steam and hydrogen injections continue and the containment is warm-up again. The impact of the spray on pressure increases with later recoveries: for identical droplet flow rate and injection temperature, the pressure drop grows from about 190 kPa for activation at 2 h to about 250 kPa for activation at 7 h, consistent with the larger temperature difference between the droplets and the vapour phase at later times.

Figure 4 reports with colours matching the former pressure lines the figure of merit introduced in section 1.3, i.e., the total hydrogen mass with potential to produce a FA ($\sigma_i \geq 0.92$), for the different spray recovery windows (v010 is not included because the FA mass remains zero without spray). The grey line provides the total hydrogen injected to the containment to facilitate the interpretation of the results. The main trend is that later spray recoveries –linked with the lowest containment pressures and, therefore, steam concentrations– lead to higher FA masses as the atmosphere becomes less inerted. Indeed, in the latest recoveries (v015–v016), the FA mass matches the total injected hydrogen. In earlier recoveries, the FA curves frequently lie below the grey line, indicating phases in which only part of the hydrogen inventory is in FA conditions while the remainder is not. This behaviour already implies that local conditions, not only global averages, affect the integral FA mass.

The relevance of the local concentration of hydrogen is illustrated in Figure 5 (right). First, the figure on the left show that without spray the σ_i field remains well below the 0.92 threshold, consistent with the null FA mass in v010. When the spray is recovered, the FA condition may appear in regions with relatively small heterogeneities. Generally, the local H_2 maximums occur in the lower elevations of the containment rather than in the dome. This non-trivial phenomenon is explained by a complex combination of the hydrogen release point, the containment compartments, small density-driven flows, and the heterogeneous wall condensation, which once the spray has stopped, is concentrated in the concrete walls located at the lower elevations. Indeed, and as shown in Figure 5 (right), the mass of hydrogen with FA potential ($\sigma_i \geq 0.92$) in case v011is concentrated in the lower compartments. Since the local heterogeneities are driven by 3D flows, and even when the global thermohydraulic trends are well captured by LP codes, the identification of the worst combustion risk condition may require a 3D evaluation.

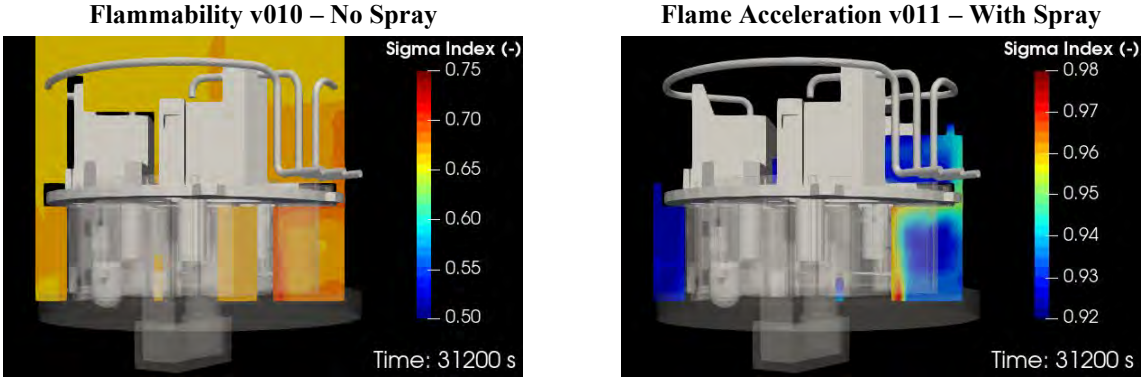

Figure 5. 2D slice of $\bar{\sigma}$ at the location of the hydrogen injection with thresholds for flammability and FA
On the left, all the cells within the flammability limits ($\bar{\sigma} > 0$) are coloured, and on the right the threshold value is $\bar{\sigma} > 0.92$ and therefore the coloured cells may have a FA regime

2.2. Parametric cases

The conclusions extracted from section 2.1 are systematically challenged with dedicated parametric cases, both to probe robustness and to cover known modelling uncertainties/inaccuracies linked to the necessary simplifications of the physics to perform these calculations with acceptable computational cost (see section 1). For the unmitigated SBO, the parametric cases included: (i) alternative hypotheses for spray recirculation availability, (ii) spray injection temperature, (iii) concrete thermal conductivity, and (iv) spray mass flow rate. For the sake of brevity, only one subset is illustrated here, with the remaining ones available in [4]. As an example of the "challenge" logic, the worst recovery window (v015) was repeated with a reduced spray flow rate (75% of nominal, based on the validation of our modelling approach) to obtain less severe (more steam-inerted) conditions. Since the total H_2 mass under FA conditions remained significant, it is re-stated that this scenario has the potential to induce non-acceptable combustion risks for PWR-W without PARs.

A second objective of the parametric analysis is to explore mitigation-oriented operating alternatives. The spray operation cannot always be treated as a discretionary hydrogen-mitigation action (it may be demanded for pressure control before SAMG actions). Therefore, rather than concluding that "spray recovery should be avoided", [4] evaluates whether modifying spray *operating conditions* can combine pressure control while retaining enough steam inertisation to suppress FA. In the most penalising window (v015), the direct spray phase is repeated with warmer droplets (80 °C, v015b). Instead of showing this case, which removed the FA risk, Figure 6 directly show the parametric case used to challenge its robustness. Specifically, v015c combined the warmer droplets with an increase of the concrete thermal conductivity up to 2.25 W/m·K.

Figure 6 shows that the postulated higher concrete conductivity reduces the pressure already before spray recovery (from ~400 kPa in v015 to ~300 kPa in v015c by the 6th hour), implying a lower steam content and, therefore, potentially worse hydrogen conditions. During spray operation, the hotter spray temperature limits the pressure drop (≈250 kPa in v015 and ≈70 kPa in v015c), i.e., it avoids excessive steam removal while still providing depressurisation. Consistently, Figure 6 (right) shows that FA conditions are suppressed in v015c (even though mixtures remain flammable), indicating that warmer spray injection – even when maximising the steam removed by wall condensation– provides a practical balance between containment pressure control and hydrogen-risk mitigation for PWR-W designs without PARs.

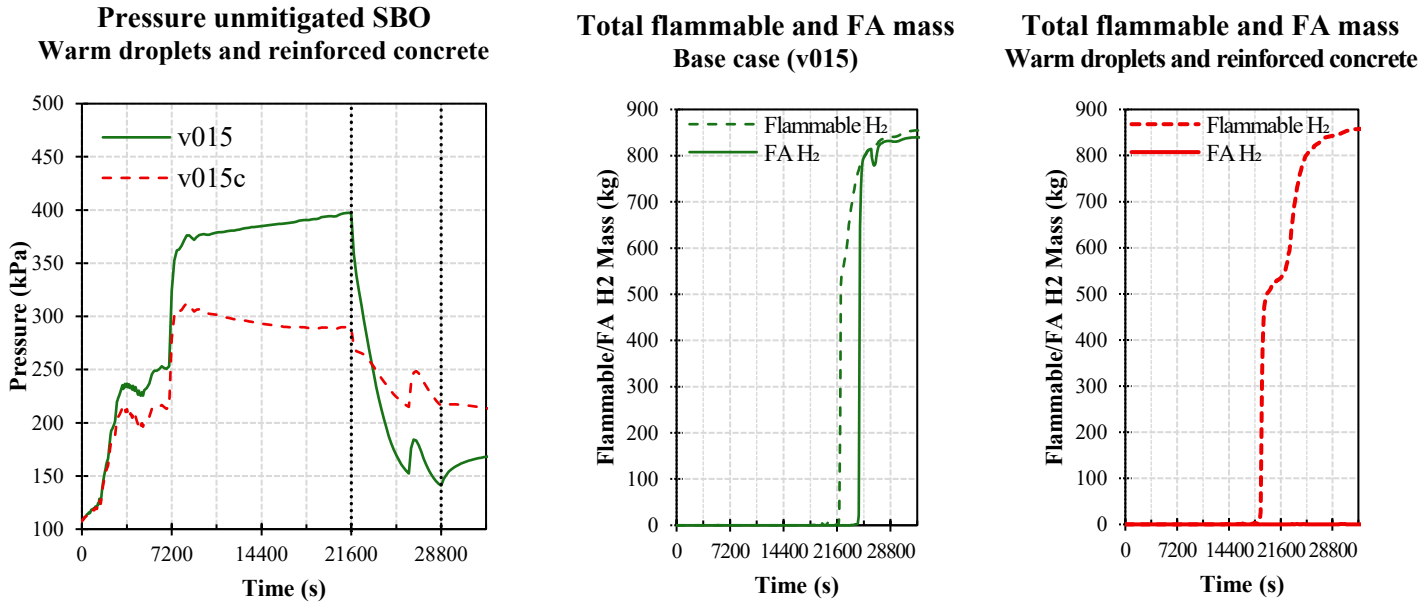

Figure 6. Illustration of the combustion risk limitation by increasing spray injection temperature

3. SBO WITH PARs AND SPRAY RECOVERY

PARs constitute the standard hydrogen control and mitigation system in the European Union, and the comparison in Figure 7 illustrates their effect under the present SBO conditions. The 'generic' PAR sizing and layout adopted in the present model are documented in [12]. Since all cases including PARs remain far from FA conditions, the results are discussed in terms of compartment-averaged H_2 volume fractions rather than the FA criterion. Each line in Figure 7 represents the volume average of a separated compartment, with the matching between lines and zones given in the caption. The comparison shows three representative spray windows for direct reference: "no spray", "early spray", and "late spray", shown without PARs in the top row (v010, v011, v015) and with PARs in the bottom row (v110, v111, v115). The results show that PAR actuation markedly reduces the containment-average H_2 levels across all spray timings: whereas the unmitigated cases reach room-averaged peaks of the order of 10.5–13.5%, the cases mitigated with PARs remain within roughly 4.5–6.5%. The dominant concentration peak is consistently associated with the main release phase between the 6th and 7th hour (see Figure 2), when PARs cannot fully offset the large injection rates.

As in the previous section, the conclusion that PARs suppress FA is challenged through parametric variations, including (i) reduced PAR recombination efficiency down to 40% of nominal, and (ii) an increased concrete thermal conductivity to intensify wall condensation and decrease steam inertisation. Even under these penalising assumptions, the predicted FA mass remains negligible and no significant FA conditions are obtained for any sequence mitigated with PARs.

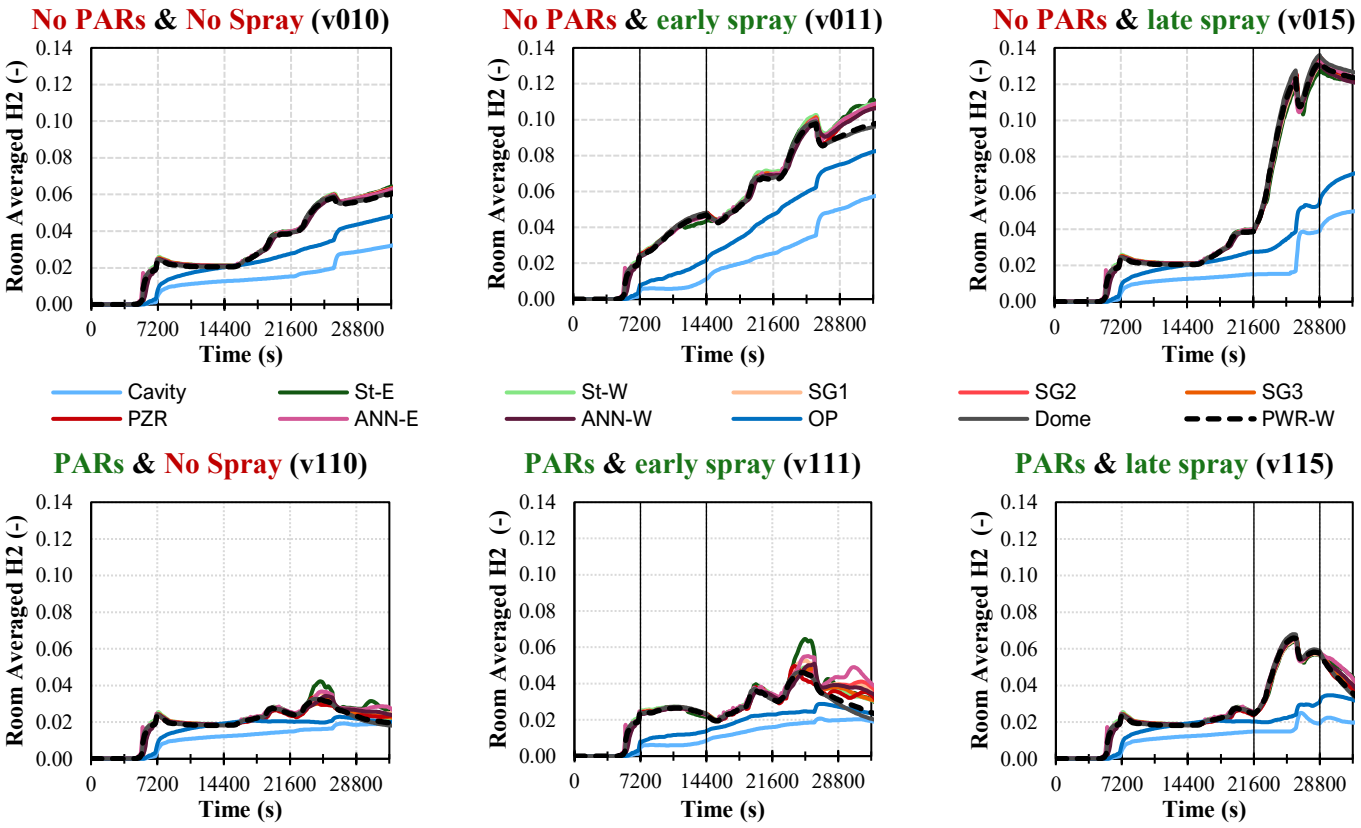

Figure 7. Averaged H2 fractions without (top) and with PARs (bottom) and different spray actuation
Each line of the graph represents an averaged volume fraction for different compartments of the containment. The dashed line "PWR-W" is an average for the full containment. The "SG" and "PZR" labels refer to the different steam generators and pressuriser compartments. "OP" is the outage pool, the "ANN" lines are the open spaces outside the secondary shielding, and St-E" and "St-W" stands for the closed spaces of the containment stairs

4. CONCLUSIONS

This work aimed to improve both the scope (systematic evaluation) and the thermal-hydraulic resolution (plant-scale 3D modelling) of the limited set of comparable studies in the open literature evaluating the influence of the spray activation on the hydrogen risk. Across all scenarios simulated in this research and in alignment with the findings from most prior studies in the open literature, the initiation of the spray system resulted in worsened conditions in relation to hydrogen risk. Research on the spray system in the nuclear industry used to open the articles discussing the "compensating effects" of the spray actuation, with steam removal as a negative factor and containment homogenisation as a positive factor. For the sequence simulated in this work –added to complementary calculations with other available transients– the role of steam removal is significantly more relevant. It should not be discarded that the spray activation may positively impact the hydrogen risk for very particular conditions with low steam release in the containment and a strong hydrogen stratification within the containment. Nevertheless, the simulations performed in this article suggest that steam removal must be the main issue to consider in the SAMGs before activating the spray during a severe accident.

A key element of the systematic approach is that safety-relevant statements are challenged with dedicated parametric cases . Indeed, the two main conclusions of this research, at the bullet points below, are challenged as follows:

- "All the spray activation windows for the sequences without PARs induced conditions with the potential to create fast hydrogen combustion". This statement is reinforced by a parametric case designed to create the conditions minimising the combustion risk (reduced spray flow rate, lower bound of concrete thermal conductivity, and tightened fast flame criteria). The identification of fast flame conditions in the enveloping case highlights the high risk associated with a late operation of the spray during a severe accident in designs without PARs.
- "The PARs system impeded the formation of mixture with potential to create fast hydrogen combustions". The conservativeness of this statement is proved by a parametric case designed to create the conditions maximising the combustion risk (up to a 60% decrease of the recombination efficiency and a lower bound of concrete thermal conductivity). There was no FA risk associated with the enveloping case, reinforcing the statement on the efficiency of PARs.

Lastly, this article has proposed an alternative to reduce the risk of flame acceleration in cases without PARs. Typically, the spray activation prioritises containment pressure signals –in several cases, it will be initiated before the hydrogen generation phase– so the recommendation cannot be limited to "do not activate the spray". Therefore, the alternative would be to make compatible the primary role of the spray, the cooling of the containment, while keeping enough steam in the containment to avoid the most severe hydrogen risk conditions. Specifically, it would consist of setting a higher injection temperature for the sprayed droplets for both the direct and recirculation phases of the spray injection.

These conclusions remain conditional on the adopted modelling scope: no explicit combustion modelling (such as PAR-induced ignitions) or simulations limited to the in-vessel phase. Future works could include: (i) extend the analysed sequences into the ex-vessel phase and asses more sequences; (ii) improve calculation of PARs efficiency and spray modelling; (iii) include additional safety devices as filtered venting or fan coolers; and (iv) evolve from selected parametric case to a comprehensive best-estimate-plus-uncertainty framework.

ABSTRACT

Combustible gases in light-water reactor containments is a central element of severe-accident management. Within the EU-AMHYCO project, the "generic containment" methodology, developed within the SARNET project, was adopted to enable consistent comparisons of mitigation strategies across organizations and codes by prescribing both boundary conditions and nodalization. This paper investigates key modelling options when applying such methodology by investigating their effect on the analysis of a large-break LOCA sequence in a 3-loop Westinghouse PWR containment with MELCOR 2.2. Through sensitivity studies, the results obtained highlight how relevant is making the right modelling decisions when setting the "generic containment" scenario. Otherwise, the methodology might mislead proper accident management decisions. A large-break LOCA sequence is simulated with MELCOR v2.2 using a full-plant model to generate time-dependent mass and energy releases into the containment. These releases are then imposed as external sources in the stand-alone containment model. The results support the use of the stand-alone generic containments for benchmarking and sensitivity studies, while highlighting the need for previous assessment steps.

KEYWORDS
Severe accidents; Containment; Combustible gases; Stand-alone model; MELCOR

1. INTRODUCTION

During a severe accident, steam reacts with hot claddings to produce hydrogen (H_2) and release thermal energy, the latter resulting in an even faster core degradation. Oxidation of other in-vessel metals, like steel, also contribute to H_2 generation, though to a lesser extent. Moreover, in case of Reactor Pressure Vessel (RPV) failure, the molten material falling into the cavity decomposes concrete and, eventually, result in further generation of H_2, but also large amounts of carbon monoxide (CO), which is also combustible. The resulting H_2/CO-air-steam mixture can form a flammable cloud that, if it ignites, might threaten the integrity of components and safety systems and even containment. Such energetic phenomena happened in the containment of TMI-2 [1] and in the reactor buildings of Units 1, 3 and 4 at the Fukushima-Daiichi Nuclear Power Plant [2]. The management of combustible gases in light-water reactor containments is a cornerstone of accident management.

The present paper is a sequel of some of the activities conducted within the EC AMHYCO project [3], funded by the European Union. Various mitigation strategies were explored using a generic stand-alone containment model [4]. CIEMAT focused on a 3-loop Westinghouse analysis undergoing a SBO and LB-LOCA accidents. This paper investigates the potential effect of some of the key hypotheses made when applying the generic-containment approach to gain insights into combustible gases management. To do so, MELCOR 2.2 has been used to simulate a LB-LOCA accident.

2. APPROACH AND METHODOLOGY

The European SARNET-II project (2009-2013) developed a methodology to define a "Generic-containment Model" for a German-KWU plant [5]. The reason for defining such a generic stand-alone containment model was to enable its use by all participants in a multi-step benchmark on containment thermal-hydraulics. Thereby, the nodalization effect and influences from other simulation domains were eliminated or at least minimized in the conclusions of the comparison results.

This methodology was further used in the NUGENIA-SAMHYCO-Net project (2017-2020) and, more recently, in the EU-AMHYCO project (2020-2025) [3], which extended it to Western PWR (PWR-W) and to VVER reactors. Figure 1 shows the different steps of the methodology, including results assessment. Since this paper's scope is limited to the PWR-W, the only model described below is this one. To meet the objectives of the AMHYCO project, the generic-containment model must be built up from publicly available data [6] and the boundary conditions and nodalization must be precisely determined.

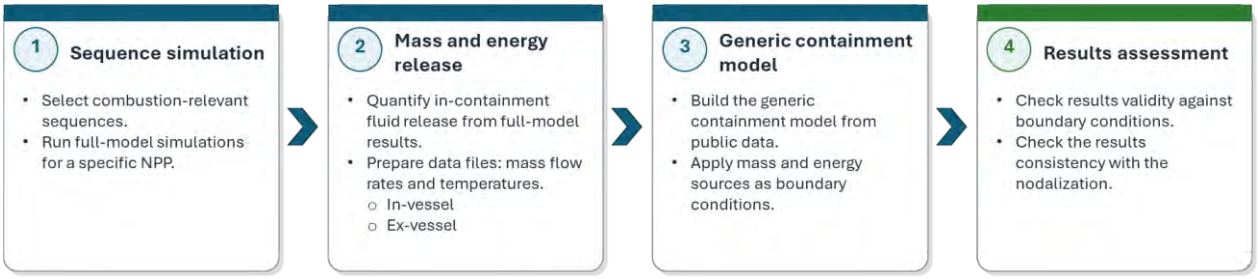

Figure 1. Flowchart with methodology steps.

2.1. Sequence and full-plant model

Among the sequences simulated in AMHYCO, a LBLOCA was selected to perform a detailed assessment as presented in this paper. This sequence is defined as a double-ended guillotine break in the hot leg in the pressurizer loop. This sequence is characterized by a rapid release of hot water into the containment and subsequent vaporization. The initial containment pressure rise is mitigated by the automatic activation of sprays at 2.6 bar setpoint, and when the Refueling Water Storage Tank (RWST) empties, the spray system changes to recirculation mode (i.e., pumping water from the containment sump). The LBLOCA evolves with a relatively low steam concentration in the containment and, consequently, the pressure is low, while the fraction of combustible gases is significant. Table I collects the main event chronology of the sequence.

Table I. Chronology of main events in the LBLOCA sequence

Event	Time
Fluid release	0.003 s
Sprays activation	4.1 s
First H2 release	0.32 h
Total core uncovering	1.2 h
Sprays on recirculation mode	2.1 h
RPV failure	2.4 h
Onset of MCCI gas generation	2.6 h

The MELCOR v2.2 code [7] is used to simulate the LBLOCA sequence in a 3-loop Westinghouse PWR 1000 MWe with a large and dry containment. All the systems and components of the plant: core, primary

circuit, steam generators and secondary circuits, cavity, and containment are modelled. The core and the Reactor Coolant System (RCS) are modelled in accordance with the recommendations of the SOARCA project [8]. Each loop is modelled individually with 29 control volumes (including the accumulators). The core consists of 5 channels in 5 axial nodes, plus the bypass. The vessel is completed with the downcomer, the lower plenum, and four nodes for the upper plenum. A total of 138 nodes defines the primary and the secondary circuits. In addition to the 82.6·tons of fuel (UO_2), in the core region, there are a total of 23.2 tons of zirconium in the fuel cladding and about 44.8 tons of stainless steel in other metallic structures, which are available for oxidizing with steam to generate hydrogen.

2.1.1. Approximations and hypotheses

Water injection safety systems in the primary system, other than hydro-accumulators, are assumed to be unavailable. Each accumulator injects 24.3 m^3 through a valve-controlled flow-path as primary pressure drops below 46 bar.

As for combustible gas modelling two major assumptions are made in the simulation:
- The BURN package of MELCOR, devoted to simulating the gases deflagrations, is not activated.
- PARs are not considered.

The reason underneath both assumptions is to maximize the combustible gas accumulation in containment as much as feasible.

The pedestal region plays a key role in the combustible gas generation ex-vessel. Modelling of the MCCI relies on two additional assumptions in CORCON-Mod3 module of MELCOR [7]:
- A single-cavity region.
- A single-layer approach for the molten pool. Namely, the materials in corium are fully mixed.

Interesting to note that a generic limestone concrete type has been selected for the concrete slab in the cavity [9], with no additional iron mass for the reinforcing bars (no specific data available).

The in-containment spray system model has been set according to plant specifications:
- Constant flowrate of 0.208 m3/s at 293.15 K (from the RWST), injected at the dome compartment.
- Activation setpoint 2.6 bar containment pressure.
- Once RWST empties, the water source is switched to the containment sump.

2.1.2. Containment nodalization

The containment model consists of 19 nodes connected by a flow path (Figure 2). The annular regions surrounding the SGs and PRZ compartments are physically divided into two levels by a slab. Therefore, two flow paths must be defined for those compartments to each of the annular compartment levels. Similarly, for the connections between the different SGs and PRZ compartments, the same division into levels has been kept. Some equipment compartments or stairwells also connect the different levels of the containment vertically.

A total of 41 flow paths are defined from center to center of the connected volumes, following the guidelines in MELCOR's [7]. Finally, the model accounts for 168 heat structures, including steel and/or concrete, providing surfaces for in-containment heat transfer and condensation.

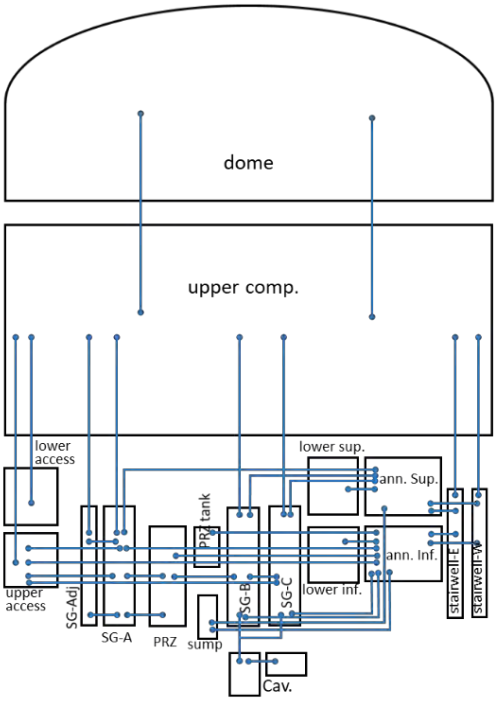

Figure 2. Containment nodalization scheme for the full model.

2.2. Stand-alone model

2.2.1. Boundary conditions

Based on the generic containment defined in the AMHYCO project [6], CIEMAT built up the input deck for MELCOR v2.2, in which mass and energy sources associated with gas releases from the primary circuit are derived from the previous full-model simulations (Figure 3) and given as external sources by *ad hoc* MELCOR control functions.

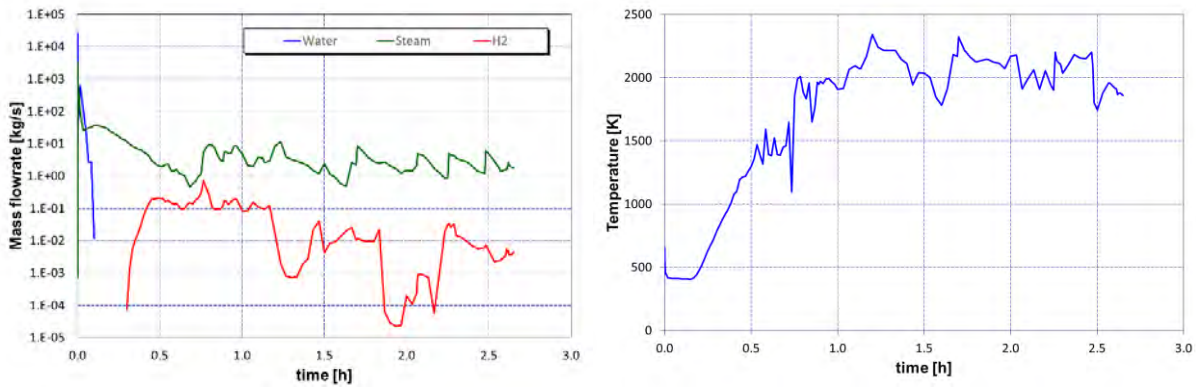

Figure 3. Fluid sources in the in-vessel phase: mass flow rates (left) and temperature (right).

A similar approach is used for the ex-vessel gas sources (Figure 4), although in this case gases are supposed to be released at thermal equilibrium with the corium in the cavity.

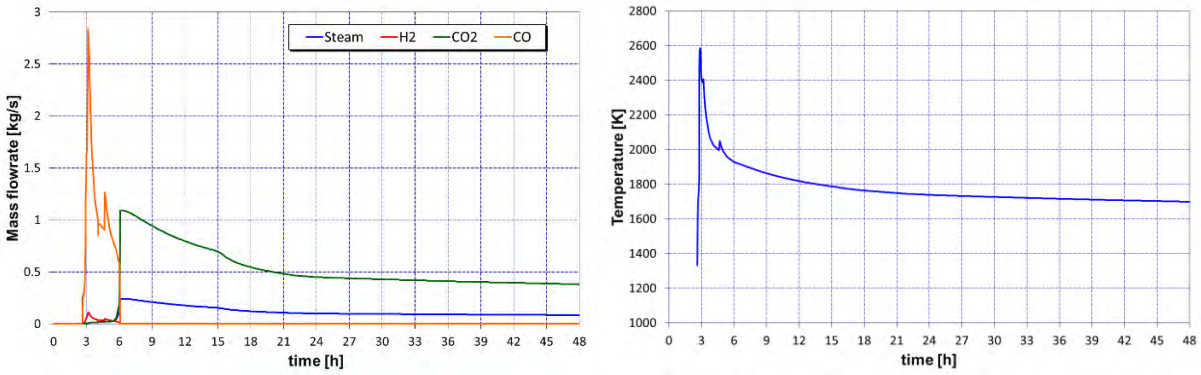

Figure 4. Fluid sources in the ex-vessel phase: mass flow rates (left) and temperature (right).

Two approaches are considered for modelling heat transfer from the molten corium in the cavity pit to the cavity atmosphere:

- A direct heat source in the cavity atmosphere of the stand-alone model. Convective and radiative losses from the corium surface, as estimated by MELCOR in the full-model calculation are included.
- A "fabricated" horizontal heat structure (HS) is set in the cavity with the full cavity cross-section as surface area. This HS is modelled with the bottom surface temperature set to the corium temperature from the full-model simulation, whereas the upper surface exchanges the heat to the atmosphere above it (a high thermal conductivity along with a very thin thickness guarantee the same temperature at both surfaces). Results of both approaches are compared in the sections below.

2.2.2. Containment nodalization

The total internal free volume is represented by 11 control volumes (Figure 5). A large dome volume is defined, covering the upper and dome compartments of the full model. In contrast with the full mode, the annular region is divided into two lateral volumes to capture possible asymmetries of the scenario. Table II summarizes the main characteristics of the containment model and compares the full and generic models.

A total of 32 flow paths are defined to model the gas flows between these volumes. Flow path lengths are defined as the center-to-center distances between volumes. Moreover, 71 heat structures provide the heat transfer and condensation areas for all concrete and steel containment surfaces.

The same safety system definition is used in the generic-containment model, so that no differences in simulation arise from modelling the safety systems within the containment.

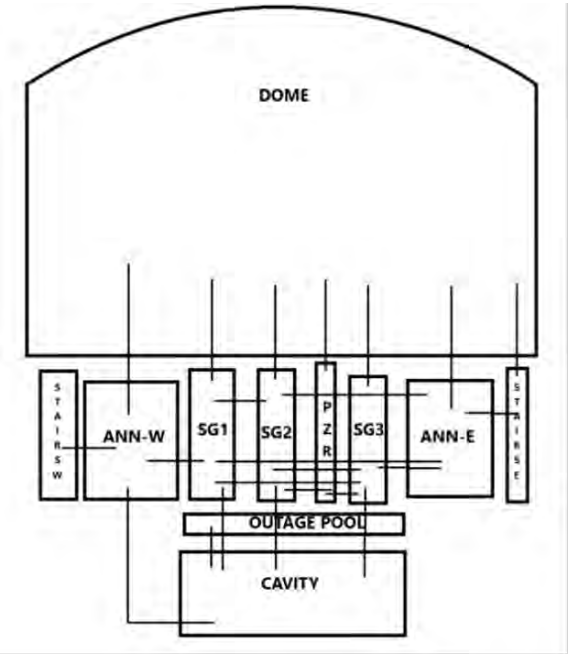

Figure 5. Containment nodalization scheme for the generic-containment model.

Table II. Main Characteristics of the containment models and correspondence between the full model and the generic model

3. Methodology review

3.1. Fluid mass and energy sources into the containment

The main concern in applying the methodology is the correct definition of the fluid and energy sources to make sure the stand-alone model reproduces the full-model containment scenario along the entire sequence. Therefore, a first step is to confirm that fluids delivery (mass and energy associated) is properly captured in the tables set-up from the full-plant model (Figure 3 and Figure 4). To do so, the full-plant deck is simplified by removing all the MELCOR packages not directly involved in the containment simulation (i.e., core, primary and secondary loops, etc.) and leaving just those essential for containment and its associated safety systems. Note that setting all key flow paths (i.e., from the cavity to the SG room where the LOCA break is located) is essential and should be carefully conducted. In other words, no difference other than fluid sources set as boundary conditions of the stand-alone can feed any discrepancy between full and stand-alone models.

Two different approaches are considered:

a) Heat-source approach

Corium heat losses are directly modelled as a source in the cavity atmosphere. When doing so, the pressure shows a very similar evolution to that in the full-model approach, with negligible differences observed in the in-vessel phase (Figure 6). However, in the ex-vessel phase, the heat-source approach slightly overpredicts pressure, and the deviation grows until 21 h. This discrepancy is less than 8% at the end of the calculation, which is not a substantial difference but might anticipate the actuation of the FCVS in a few hours (~ 3 h) with respect to the full-model estimates. Given the limited effect of the thermal difference (< 2%), temperature differences can support just part of the pressure difference noted; in other words, such as approached more steam remains airborne in the stand-alone calculation (Figure 7). This might be associated to different reasons: slight differences in the sources due to the integration time steps, slightly higher water temperature that gets higher saturation pressure, and/or even to different inter-compartment flows that might yield less steam condensation. Confirming these edges is beyond the scope of this paper, given the size of the discrepancies found. However, it is worth noting how such differences might affect the gas cloud flammability (Figure 8). Although the deflagration potential of CO is known to be significantly lower than that of H_2, the concentrations of both gases are shown together in the figures below for simplicity. Interestingly, a slight overestimation of the steam molar fraction has a visible but not drastic consequence in the combustion risk.

b) Heat-structure (HS) approach

Using an HS to estimate the heat losses from the corium in the cavity yields a similar in-containment trend to that of the heat-source approach, although the pressure and temperature overestimation is even higher (Figure 6). This discrepancy between the two approaches is noticeable between 3 and ~21 h.

This study highlights that splitting the containment model and setting representative boundary conditions for the heat and mass transfer is not a straightforward task. The two approaches intended resulted in visible discrepancies with the full-scope model, the biggest ones reported when using the HS approach: between 15 and 25% overprediction during some time periods (4-9 h) in terms of pressure and a bit less than 10% underestimate in steam molar fraction (same time period). In other words, any of the approaches attempted, particularly the HS one, leads to more steam content in the cavity atmosphere and to lower combustion risk (Figure 7 and Figure 8).

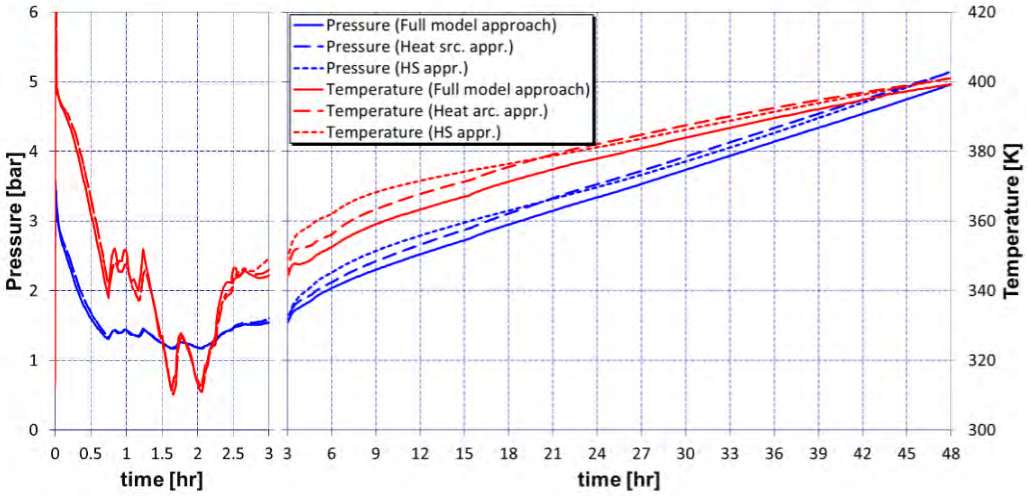

Figure 6. Evolution of pressure and temperature in the dome. Assessment of source definition.

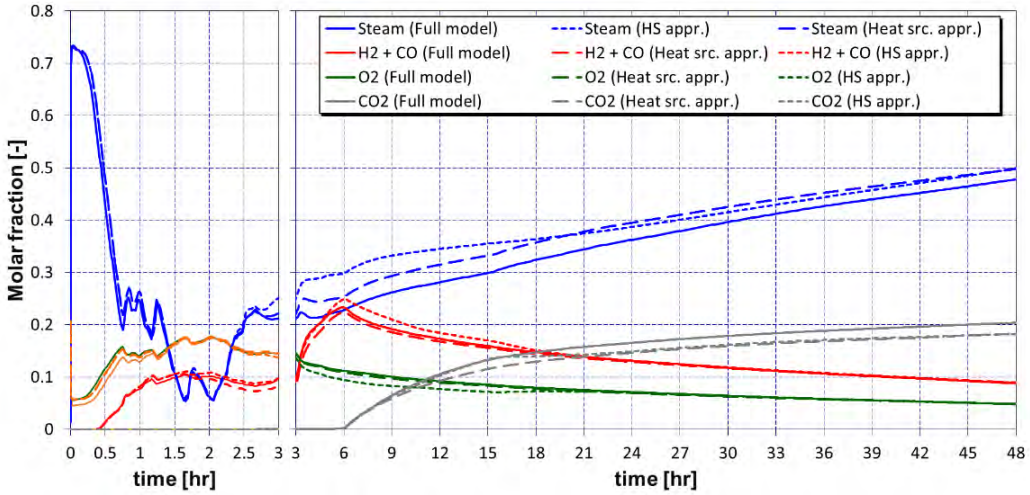

Figure 7. Atmosphere composition in the upper compartment. Assessment of source definition.

In summary, the verification of the stand-alone boundary conditions resulted in a negligible effect when sources and sprays are high (in-vessel phase). However, when mass flow and their momentum are low (ex-vessel phase), the stand-alone approach introduces significant deviations that are not straightforward to identify.

3.2. Nodalization effect

Defining compartments and their connections (flow paths) is a key task when building a simulation model with lumped-parameter codes. This is even further emphasized when the focus is on local gas composition. Therefore, when applying this methodology, which entails using a generic-containment nodalization, the effects must be checked and quantified. Thus, the results of the following simulations have been compared: The containment stand-alone model with the external sources. This model uses the same containment nodalization as the full model (Figure 2), with external sources and the heat source approach in the cavity. The generic-containment model as defined in AMHYCO (Figure 5) with the same external sources as the previous simulation.

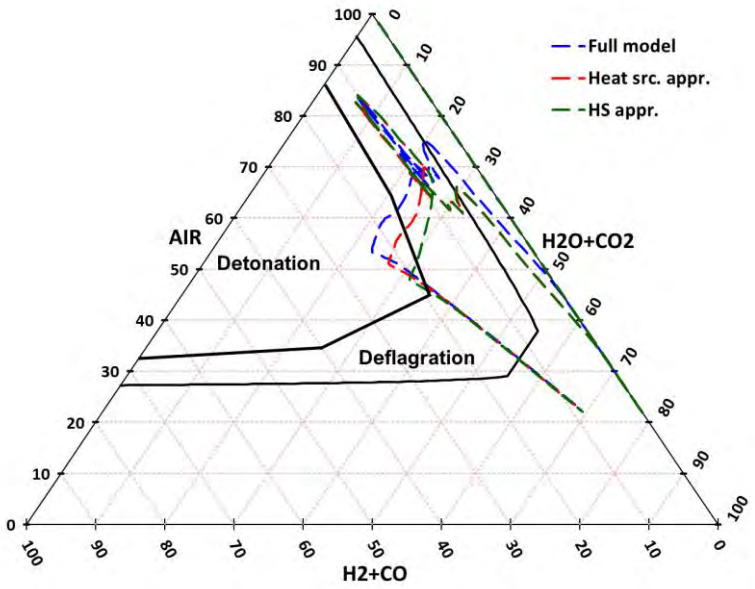

Figure 8. Shapiro diagram in the upper compartment. Assessment of source definition.

Figure 9 shows the comparison of the pressure and dome temperature evolution for simulations. The full-model approach is kept in figures for comparison. During the in-vessel phase, evolution is primarily governed by the intense mass source into the containment and by condensation on cold surfaces or on sprayed droplets. As a consequence, the effect of the containment nodalization is secondary in this phase of the accident. The effect is higher during the ex-vessel phase as gas sources momentum is smaller than during the in-vessel phase, and the distribution from the cavity to other compartments is more meshing-dependent. The generic-containment model notably underpredicts pressure (more than 12% with respect to the full-scope model). As observed, most of this difference does not come from the thermal discrepancy, but from the steam remaining airborne in the case of the generic containment. Given that the same mass and energy flows were set, the reason behind this difference should be evaporation/condensation in both models. Through Figure 10 and Figure 11, it is noted that despite the combustible gas compositions are not that different, when bringing them into the Shapiro diagram, there is a visible discrepancy in the flammability of both gas mixtures.

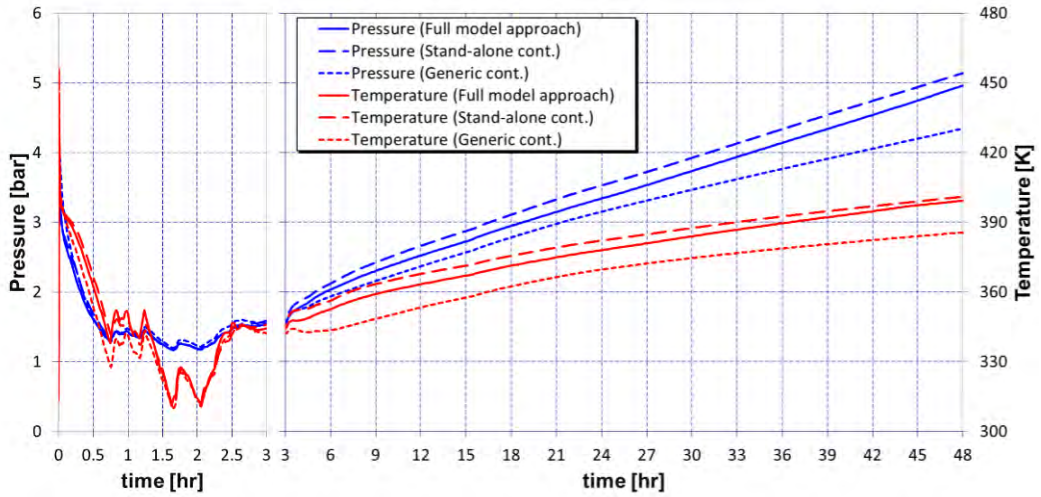

Figure 9. Evolution of pressure and dome temperature. Assessment of the nodalization effect.

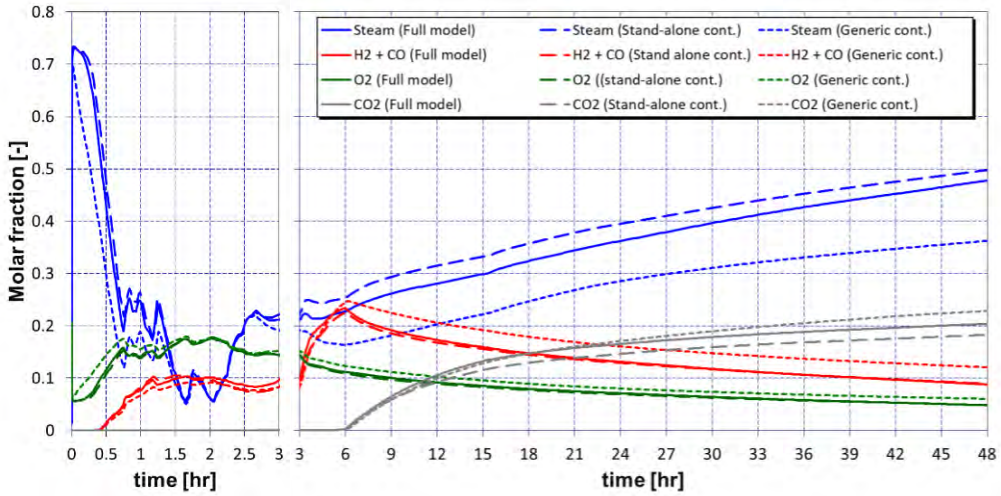

Figure 10. Atmosphere composition in the dome compartment. Assessment of the nodalization effect.

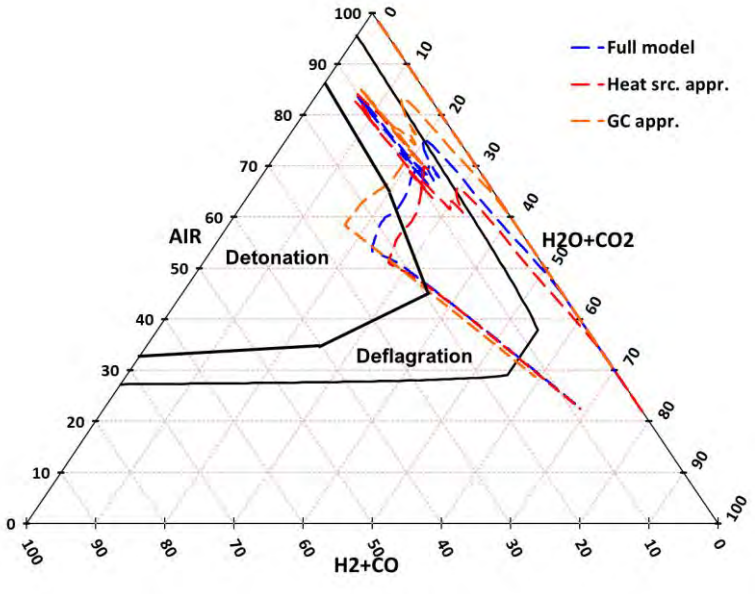

Figure 11. Shapiro diagram in the dome compartment. Assessment of the nodalization effect.

Again, in the in-vessel phase of the accident, the slight discrepancies introduced by the nodalization are attenuated as the accident progresses. During the ex-vessel phase, however, the energy distribution from the cavity to the other containment compartments is more mesh-dependent, leading to significant effects on the local evaporation–condensation balance and, consequently, on the containment pressure and atmospheric composition.

4. CONCLUSIONS

The generic stand-alone containment approach, as developed in SARNET and adopted in the AMHYCO project, is a valuable approach for comparing mitigation strategies, particularly for combustion risk. Nonetheless, its application should carefully consider three main aspects:

- Mass and heat sources definition. Translating the information resulting from the full-plant model, requires a thorough understanding of the mass and energy management in the code (MELCOR 2.2). The external boundary conditions set in the input deck should mimic such management as tight as possible, which given the huge complexity of SA codes, is far from being trivial.
- Ex-vessel onset. As a result of the RPV breach, major energy and mass transfer happen into the cavity and capturing them all is very challenging and is subject to approximations. The two more straightforward options tested in this work have been the direct injection of energy into the cavity atmosphere and the inclusion of an "fabricated" structure representing high-temperature corium. According to what observed in previous sections, a direct injection is preferable even if moderate deviations noted with respect to the full-scale model in the case of MELCOR 2.2.
- Nodalization effect. When changing containment meshing gas atmosphere flammability will likely change. Even if same sources used, the different compartment volumes and flow-paths result into changing balances like evaporation/condensation that eventually end up in different atmosphere compositions and, hence, gas mixture flammability. Such an effect is more pronounced during the ex-vessel phase.

The results shown in this work are specific for a LB-LOCA in a large Western PWR when using MELCOR 2.2. However, the conclusions withdrawn above do have a generic nature, except when referring to the code used.

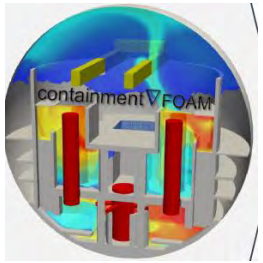
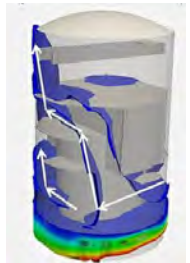
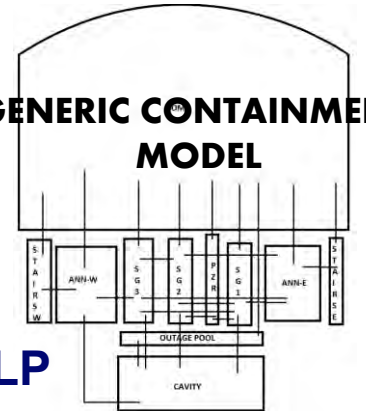
CFD





GOTHIC

LP



GC methodology

Methodology's steps

1 Sequence simulation

- Select combustion-relevant sequences.
- Run full-model simulations for a specific NPP.

2 Mass and energy release

- Quantify in-containment fluid release from full-model results.
- Prepare data files: mass flow rates and energy rates.
  - o In-vessel
  - o Ex-vessel

3 GC model

- Build the generic containment model from public data.
- **Propose a simplified nodalization.**
- **Apply mass and energy releases as boundary conditions (sources).**

4 Results assessment

- **Check results validity against boundary conditions.**
- **Check the results consistency with the nodalization.**

The "Generic Containment" harmonizes containment modeling and reduces simulation computation time while maintaining the representativeness of the scenario.

FINAL REMARKS

Final remarks

- **The “Generic Containment” methodology is a valuable approach for comparing mitigation strategies and combustion risk.**
- **Three main aspects must be carefully assessed when applying this methodology:**
  - Mass and energy sources definition is not a straightforward task and requires a thorough understanding of mass and energy management in the code. Boundary conditions must keep the representativeness of the full plant model.
  - **Ex-vessel onset** is a key event. Large energy and fluid sources and small momentum poses a challenge for the “Generic Containment” application in the ex-vessel phase.
  - Meshing is fundamental to the evaporization/condensation balance, and it might end up significantly affecting the flammability of the cloud.
- **Any discussion of the results of the “Generic Containment” application must take into account the deviations from the initial full model.**

This work is a sequel to the AMHYCO project.

ABSTRACT

After suffering from a severe nuclear accident, lots of technical issues and engineering concerns were generated for the safe and effective decommissioning of Fukushima Daiichi nuclear power plant. During the decommissioning of the Fukushima Daiichi nuclear power plant, aerosols generated during fuel debris retrieval can accumulate on internal structures of the primary containment vessel and alter contamination pathways under ventilation. Understanding how aerosol generation intensity influences surface deposition under such low-velocity venting conditions is therefore important for radiological safety and decontamination planning. This study experimentally investigates aerosol deposition onto a cubic obstacle

* Corresponding and presenting author.

placed in a vertical ventilation column using zirconia aerosols as simulants. Aerosol injection rates from 0.24 to 1.8 g/h and deposition durations of 6 and 12 hours were examined in the UTAD[2] facility under laminar flow representative of PCV conditions. Deposited mass measurements were combined with surface morphology observations. Results show that both higher aerosol injection rates and longer exposure times lead to significantly increased surface deposition. The increase is not only due to greater particle supply but also to the progressive evolution of the deposited layer. Surface morphologies reveal a transition from discrete particles to dense agglomerated structures, which enhance the surface's ability to retain subsequent injecting aerosols. This behavior explains the strong dependence of contamination on aerosol generation rate. These findings provide insight for identifying hotspot contamination regions and for optimizing ventilation and operational strategies during Fukushima Daiichi decommissioning.

1. INTRODUCTION

Severe nuclear accidents can lead to extensive core damage and fuel debris formation, accompanied by the release of radioactive aerosols inside the primary containment vessel (PCV) [1–5]. During the ongoing decommissioning of the Fukushima Daiichi Nuclear Power Station (1F-NPP), aerosol generation, transport, and surface contamination have become major concerns for radiological protection and operational safety [6–8]. Many internal structures within the damaged PCV exhibit high radiation levels and require decontamination prior to debris retrieval, while fuel debris must often be segmented into smaller pieces using remote cutting technologies, which further promotes aerosol production [9–11].

High-power laser techniques have recently been proposed as effective tools for surface decontamination and debris cutting in such environments [9,12–16]. However, these processes are known to generate large quantities of submicron aerosols, particularly within the Greenfield gap size range (0.1–1 μm), which are difficult to remove using conventional spray systems due to low mechanical collection efficiencies [17–20]. To address this limitation, lots of recent studies focused on enhanced spray-based mitigation approaches, including pre-injection of water mist and electrically charged mist and spray droplets, which significantly improve aerosol capture through intensified agglomeration and electrostatic interactions [21–30].

Despite the demonstrated efficiency of these spray-based technologies in controlled experiments, their practical deployment inside the highly complex geometry of the damaged PCV remains challenging. Certain regions are inaccessible to sprays, and in such areas ventilation systems become an alternative means of aerosol control by maintaining negative pressure and directing airflow toward filtration units [31, 32]. However, ventilation itself may unintentionally promote aerosol dispersion and surface deposition on internal structures, resulting in secondary contamination and increased decontamination workload [33].

Aerosol deposition and transport have been extensively studied under turbulent flow conditions in environmental, industrial, and nuclear applications [34–36]. Within the nuclear field, large experimental programs (e.g., FALCON, MARVIKEN, PHEBUS) and severe accident analysis codes have provided substantial understanding of particle transport and surface contamination in turbulent regimes [7,37–39]. More recent studies also investigated aerosol generation and transport during cutting of debris simulants and activated materials [40–42]. However, predicting aerosol deposition remains difficult due to re-entrainment, surface conditions, and complex particle–flow interactions [43].

The ventilation conditions expected during 1F decommissioning differ fundamentally from these turbulent scenarios. Engineering assessments indicate that gas velocities inside the PCV drywell may be as low as 0.01–0.1 m/s, corresponding to laminar flow regimes under normal ventilation and thermal convection conditions [45]. Under laminar flow, deposition is governed primarily by gravitational settling and

Brownian diffusion rather than turbulence-induced impaction [46]. In addition, the presence of structural obstacles can locally disturb the flow field, creating stagnation zones and recirculation regions that strongly influence particle trajectories and deposition behavior. These effects remain insufficiently understood under decommissioning conditions.

Therefore, simplified and well-controlled experimental studies are essential to isolate the fundamental mechanisms governing aerosol deposition near obstacles. The present work conducts such an investigation using the UTAD^2 (the University of Tokyo, Aerosol Dispersion & Deposition) facility. It is noted that the aerosol generation rates may vary by using different laser operation conditions during decommissioning. Therefore, by introducing a representative cubic obstacle into a low-velocity venting flow with different aerosol feed rates, this study examines how effect of aerosol generation rates affects aerosol transport and surface contamination. The findings aim to improve the understanding of aerosol deposition under laminar ventilation, provide insight into potential contamination hotspots inside the PCV, and support the development of predictive tools and mitigation strategies for Fukushima Daiichi decommissioning.

2. EXPERIMENTAL FACILITY AND SETUP

2.1. Test section and obstacle configuration

Experiments were conducted in the UTAD^2 facility, consisting of a transparent vertical polycarbonate pipe 3.2 m in height and 11.4 cm in inner diameter. Figure 1 shows the experimental facility. A ventilation fan controlled by a variable frequency drive is installed at the top of the column, together with a high-efficiency filter to remove exhausted aerosols. During deposition experiments, the fan was operated at 2.0 Hz, generating a bulk flow velocity of approximately 0.08 m/s, representative of low-flow ventilation expected during 1F decommissioning. The lower end of the pipe serves as the air inlet. Aerosols are injected near the bottom of the test section and transported upward by the ventilation flow. A detachable 20-cm-high section is located at mid-height, where a cubic aluminum obstacle (6 cm side) is installed. Figure 2 illustrates the details of the obstacle. Aerosols transported by the flow interact with this obstacle and deposit on its surfaces. As shown in Figure 1, there are two locations, P1 and P2, which are considered for pressure, velocity and aerosol measurements.

2.2. Aerosol generation

Zirconium dioxide (ZrO_2) aerosol was used to simulate aerosols generated during debris cutting and laser processing. This material choice is based on previous studies showing similar particle characteristics during laser cutting of debris simulants [8, 16]. A Palas RBG-1000 powder disperser was employed to generate stable aerosol injection. The device uses a piston-brush feeding mechanism and compressed air dispersion to produce reproducible airborne particles. The generator was operated at different feed rates with a gas flow of 27–28 L/min for different experimental runs, producing the adjustable aerosol supply rate of 0.24–1.8 g/h.

Because particle agglomeration occurs during dispersion, the actual airborne size distribution inside the test section was measured independently, rather than assumed from powder properties. A Dekati HR-ELPI+ (High-Resolution Electrical Low-Pressure Impactor) was used to measure aerosol number concentration and size distribution at the upstream location (i.e., P1 shown in Figure 1). Aerosols were sampled through a sampling tube with 10 L/min flow rate. The HR-ELPI+ classifies particles by inertial impaction and measures concentration via electrical current after corona charging, allowing real-time size-resolved measurements from 6 nm to 10 μm. Figure 3 shows the aerosol concentration measurement results at the P1 location. As shown in Figure 2, the aerosol size distribution is larger than the manufacturer's data (a mass median diameter of 0.15 μm), indicating aerosol agglomeration during injection and dispersion.

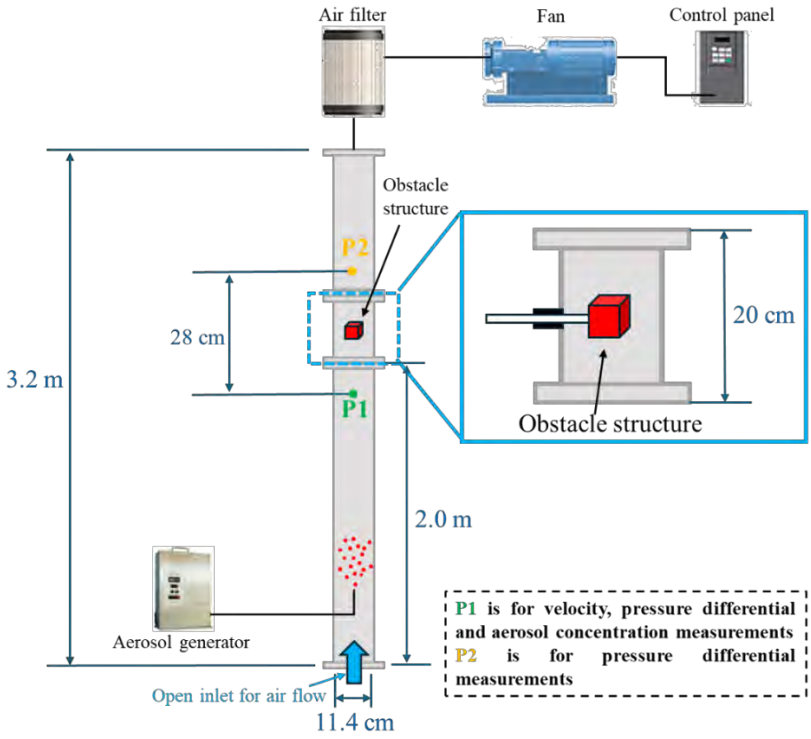

Figure 1. The UTAD[2] experimental facility.

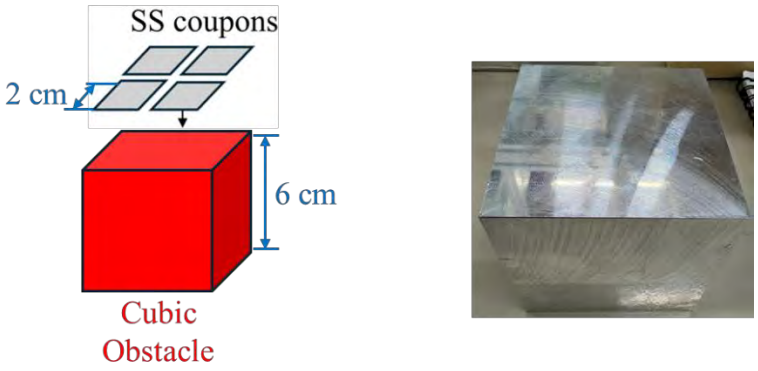

Figure 2. Illustration of the obstacle structure.

2.3. Deposition quantification

To quantify deposited mass, as shown in Figure 2, four stainless steel (SS) square coupons (≈2 cm) were attached to the top surface of the obstacle. These coupons represent typical reactor structural materials and allow high-precision weighing. Before and after each experiment, coupons were weighed using an A&D BM-22 microbalance with 1 μg resolution. Deposited mass was determined from the mass difference. The uncertainty of the gravimetric deposition measurement was mainly associated with the microbalance resolution, coupon handling, ambient humidity, and possible coupon-to-coupon variability. Although complete run-to-run repetition was limited due to the long duration of each deposition experiment, all coupons were weighed before and after the tests using the same microbalance, and the same cleaning, mounting, removal, and weighing procedures were applied to all cases. Surface morphology of deposited particles was examined using a Keyence VHX-X1 digital microscope with 2D/3D imaging capability and sub-micron resolution, enabling visualization of particle coverage and agglomeration.

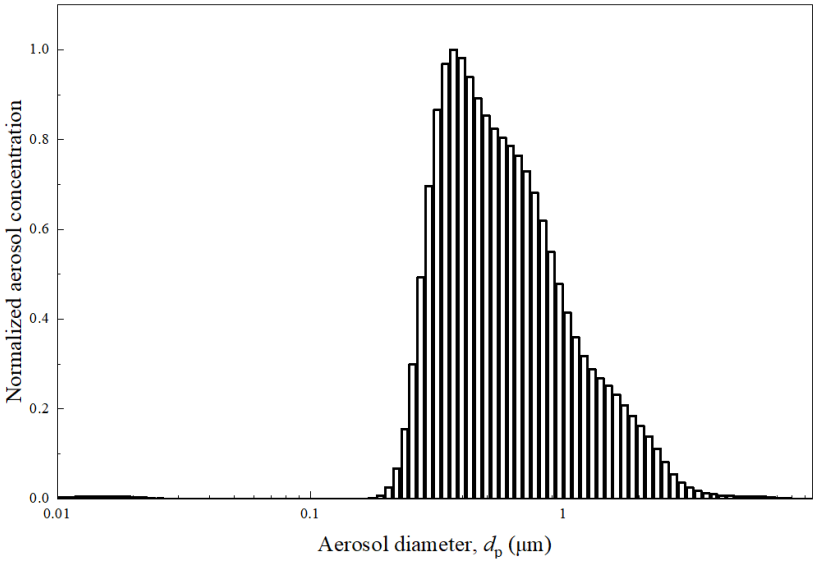

Figure 3. Aerosol size distribution.

2.4. Experimental procedures

Figure 4 shows the general experimental procedures. Prior to each run, the coupon was cleaned, weighed, and mounted on the obstacle. The obstacle was installed in the test section, followed by aerosol injection and simultaneous ventilation. Experiments were conducted under ambient laboratory conditions with continuous ventilation, preventing temperature gradients and minimizing thermophoretic effects. Deposition durations (t_{dep}) were fixed at 6 and 12 hours. After each test, the obstacle was removed, the coupons were re-weighed, and surface imaging was performed. All surfaces were cleaned before subsequent runs to ensure consistent initial conditions. Table I lists the conditions for experimental cases. To minimize possible disturbance of deposited aerosols during post-experimental handling, a fixed handling protocol was applied for all tests. After aerosol injection and ventilation were stopped, the detachable test section was carefully opened only after allowing the internal flow to fully cease. The obstacle was then removed slowly while maintaining its original orientation, and the coupons were not directly touched during transportation. The coupons were transferred to the balance using clean tweezers by gripping only the coupon edges. No brushing, wiping, or air blowing was applied before weighing. The transportation distance between the test section and the microbalance was kept short, and the post-test weighing was performed immediately after removal. Since the same procedure was applied to all experimental cases, possible handling-induced losses were minimized and treated as part of the measurement uncertainty. In addition, visual inspection before and after transportation did not show obvious particle detachment or redistribution on the coupon surfaces.

3. RESULTS AND DISCUSSION

3.1. Characterization of flow resistance

Before performing aerosol deposition experiments, it is necessary to understand the baseline ventilation behavior of the UTAD[2] facility and to quantify how the presence of the obstacle influences the flow field under different operating conditions. Such characterization ensures that the deposition experiments are conducted under well-defined and reproducible flow regimes and provides a physical basis for interpreting subsequent aerosol deposition behavior. To achieve this, flow velocity and pressure drop measurements were conducted in the absence of aerosol injection. This not only avoids contamination of the measuring probes but also allows an accurate assessment of the intrinsic ventilation characteristics of the system. The ventilation fan frequency varied over a wide range to examine both laminar and turbulent regimes.

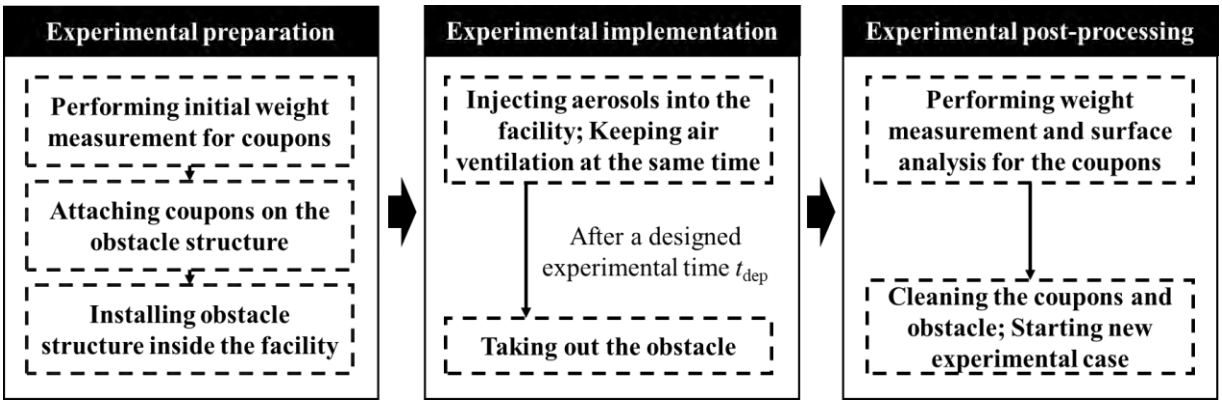

Figure. 4. Experimental procedures.

Table I. Experimental cases.

Case	Aerosol type	Deposition time, t_{dep} [h]	Aerosol injection rate, $\dot{m}_p$ [g/h]
1	ZrO_2	6	0.24
2	ZrO_2	6	0.60
3	ZrO_2	6	1.20
4	ZrO_2	6	1.80
5	ZrO_2	12	0.24
6	ZrO_2	12	0.60
7	ZrO_2	12	1.20
8	ZrO_2	12	1.80

The local flow velocity at the upstream measurement position (P1) was measured using a hot-wire anemometer, while the pressure difference between the upstream and downstream locations (P1 and P2) was recorded using a high-precision differential pressure transmitter. To quantitatively evaluate the effect of the obstacle, the dimensionless loss coefficient K was calculated:

$$K = \frac{2\Delta P}{\rho_{air} v_{flow}^2} \quad (1)$$

where ΔP indicates the pressure differences, ρ_{air} represents the air density, and v_{flow} is the flow velocity. The flow velocity used in Eq. (1) was measured at the pipe centerline at the upstream position P1. Therefore, the calculated K should be regarded as an apparent loss coefficient based on the local velocity rather than a strict cross-section-averaged value. Since the same measurement position and procedure were applied to both the obstacle and no-obstacle cases, the relative comparison of flow resistance remains meaningful, although the non-uniform laminar velocity profile may affect the absolute value of K.

Fig. 5 presents the variation of the loss coefficient as a function of Reynolds number $Re = \frac{\rho_{air} v_{flow} D}{\mu_{air}}$, where μ_{air} means the air viscosity and D denotes the inner diameter of the test section. A clear distinction between laminar and turbulent regimes can be observed. In the laminar region, the values of K for the cases with and without the obstacle remain nearly identical. This indicates that, under low Reynolds number conditions, the overall flow resistance is governed primarily by viscous shear along the pipe wall rather than by form drag induced by the obstacle. In contrast, as the Reynolds number increases and the flow approaches turbulent conditions, the loss coefficient for the obstacle case becomes significantly larger than that of the unobstructed pipe. This behavior reflects the increasing contribution of flow separation, vortex shedding, and form drag around the obstacle under turbulent conditions. These results have important implications for the deposition study. Under the lowest fan frequency used in the aerosol experiments that indicate lowest

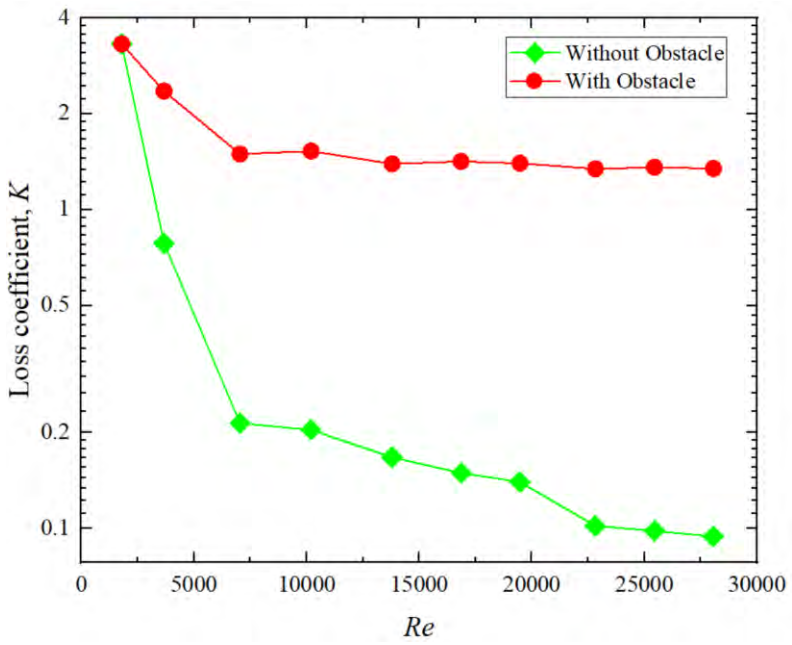

Figure 5. Variation of the loss coefficient under different Reynolds numbers.

flow velocity and lowest Reynolds number, the flow falls well within the laminar regime. Therefore, the obstacle has minimal influence on the global flow resistance but may still locally disturb the flow field, creating stagnation and recirculation regions without introducing turbulence, which is representative of the expected flow environment inside the Fukushima PCV during decommissioning operations.

3.2. Deposition mass variation

Figure 6 illustrates the evolution of aerosol deposition mass under different aerosol injection rates and deposition durations. Two clear trends can be identified. First, for a fixed deposition time, the deposited mass increases as the aerosol injection rate increases. Second, for a fixed injection rate, the deposited mass continuously increases with longer deposition time. These two tendencies suggest that surface contamination is affected by both particle supply and the evolution of surface condition during prolonged deposition, although the present gravimetric data alone cannot fully decouple these two effects. On the one hand, the influence of injection rate can be understood beyond a simple increase in particle supply. On the other hand, as demonstrated by the surface morphology observations in Figure 7, deposition initially occurs in the form of discrete particles, which gradually transform into clusters and interconnected agglomerated layers. When the injection rate is higher, this transformation takes place more rapidly. The surface therefore reaches a state characterized by significant roughness and three-dimensional particle accumulation at an earlier stage. Once such agglomerated structures are formed, the deposited layer itself acts as an efficient collector for incoming aerosols by providing numerous attachment sites and enhancing particle–particle interactions. Consequently, higher injection rates accelerate the transition of the surface into a condition that favors further particle retention. However, this effect is not expected to be pronounced at the early stage when the surface coverage is still limited. It becomes more evident after a sufficient deposited layer has formed, because the rough and agglomerated layer provides additional attachment sites for incoming aerosols.

The effect of deposition time shows a similar enhancing characteristic in Figure 6. At the shorter deposition (e.g., 6 hours), deposition is mainly controlled by the attachment of individual particles onto a relatively smooth surface. As time progresses, the continuous accumulation of particles modifies the surface morphology, increasing its effective roughness and its ability to trap additional aerosols. This explains why

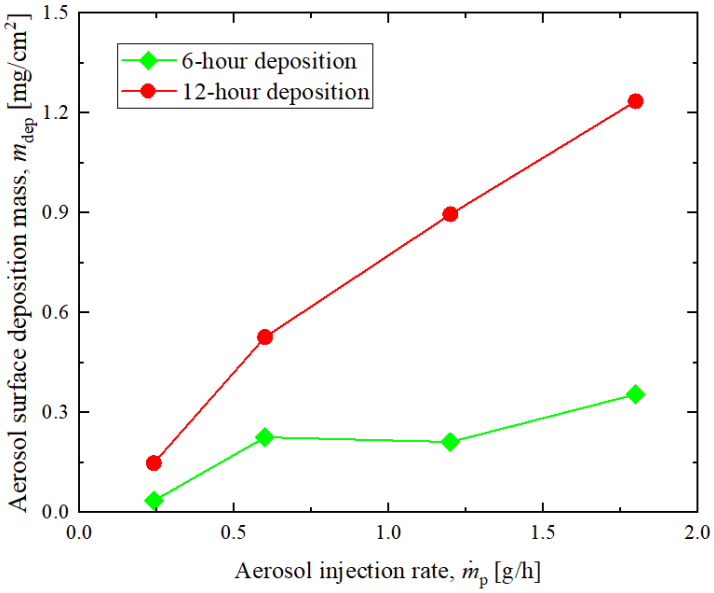

Figure 6. Variation of deposition mass with increase of aerosol injection rate.

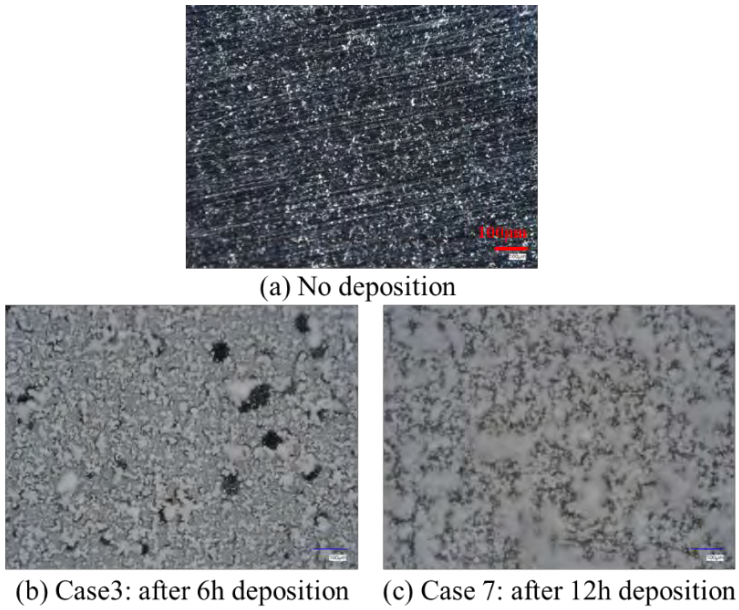

Figure 7. Aerosol deposition morphologies after different deposition times ($\dot{m}_p$=1.20 g/h).

the growth of deposited mass does not simply follow a constant rate, but becomes more evident at longer deposition times, as illuminated in Figure 6. The surface gradually evolves for receiving particles and promoting further accumulation. The combined influence of injection rate and deposition time indicates that aerosol surface deposition is strongly affected by the dynamic evolution of the deposited layer itself. A higher particle supply and longer deposition both contribute to faster development of agglomerated surface structures, which in turn enhance subsequent deposition. Therefore, the trends observed in Figure 6 reflect a progressive deposition process rather than a purely transport-limited phenomenon. In addition, a simple comparison between the 12 h and 6 h cases shown in Figure 6 further supports this interpretation. If deposition were controlled only by exposure time, the 12 h/6 h deposited-mass ratio would be expected to be approximately 2.0. The observed ratio becomes larger at higher aerosol injection rates, suggesting that the effect of prolonged exposure is strengthened when the particle supply is high. This behavior is consistent

with the formation of a rough and agglomerated deposited layer, which provides additional attachment sites for incoming aerosols.

From a practical engineering decommissioning viewpoint, these findings imply that during operations associated with high aerosol generation rates, such as debris cutting or surface decontamination, structural surfaces inside the containment environment may become rapidly contaminated if exposure is sustained. Controlling the instantaneous aerosol release rate and limiting prolonged exposure under such conditions can be effective strategies to mitigate progressive surface contamination during decommissioning activities. While it should be noted that the present measurements were limited to the top surface of the cubic obstacle. Therefore, the obtained deposition mass represents the local deposition behavior on the top-facing coupons rather than the complete spatial distribution over the whole obstacle. Since the front, side, top, and wake regions may experience different local flow conditions, face-resolved deposition measurements will be needed in future work to quantify the spatial variability around the obstacle. Furthermore, it should be noted that the present dataset is still limited to selected injection rates and deposition durations; therefore, additional intermediate data points and repeated tests will be required in future work to further confirm the quantitative trend.

4. CONCLUSION

This study experimentally investigated aerosol deposition onto a representative obstacle structure under low-velocity venting decontamination conditions relevant to the Fukushima Daiichi decommissioning scenarios. Using controlled zirconia aerosol injection in the UTAD[2] facility, the influence of aerosol generation rate and deposition duration on surface contamination behavior was systematically examined. The results demonstrate that surface deposition is not governed solely by particle supply, but strongly influenced by the dynamic evolution of the deposited layer itself. Higher aerosol injection rates and longer deposition times both accelerate the transformation of the surface from discrete particle coverage to agglomerated and interconnected structures. These morphological changes significantly enhance the surface's ability to retain subsequently arriving particles, leading to a progressive deposition process. The findings indicate that obstacle structural surfaces located within ventilation paths are particularly susceptible to rapid contamination when aerosol generation is sustained. From an engineering perspective, controlling instantaneous aerosol release rates and limiting prolonged exposure under high-generation conditions can be effective strategies to mitigate progressive surface contamination during debris retrieval and decommissioning operations. This work provides fundamental understanding and practical insight into aerosol deposition behavior under laminar venting conditions, contributing to the identification of contamination-prone regions and the optimization of decontamination and ventilation strategies inside the Fukushima Daiichi PCV.

ACKNOWLEDGMENTS

The authors acknowledge the financial support and valuable technical insights from Tokyo Electric Power Company (TEPCO) that are of great importance to the completeness of this study.

Radioactivity Source Term (US DOE: DOE-HDBK-3010-94)

Source Term=MAR×DR×ARF×RF×LPF

- MAR (Material-at-Risk): The total quantity of radioactive material subjected to physical stress, measured in grams or curies.
- DR (Damage Ratio): The fraction of the MAR that is impacted by the accident conditions.
- ARF (Airborne Release Fraction): The proportion of radioactive material that becomes aerosolized and suspended in the air due to accident-induced stress.
- RF (Respirable Fraction): The fraction of airborne radioactive material that can be inhaled by humans.
- **LPF (Leak-Path Factor): The proportion of radioactive material that escapes after passing through various filtration or deposition mechanisms.**

① Transition of cutting aerosols to the gas phase
② Transition of cutting aerosols to the liquid phase
③ Collection by the local aerosol collection system
④ Transition from the pedestal to the PCV
⑤ Sedimentation and deposition inside the PCV/exhaust system
⑥ Dispersion & migration within the PCV
⑦ Transition to the PCV exhaust system
⑧ Leakage from the PCV to the building

1. Background

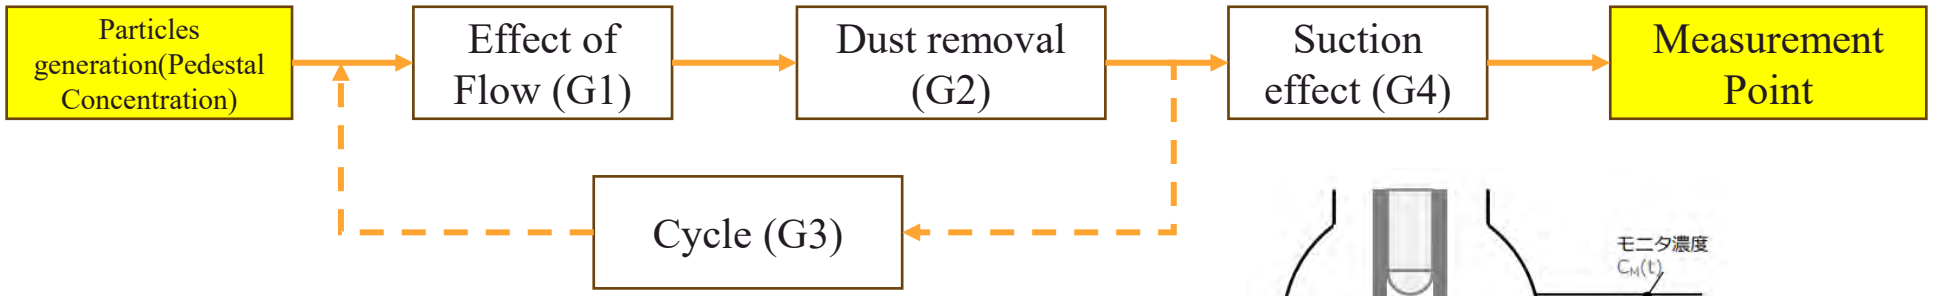
- It is considered that the PCV ventilation system flow rate will be a maximum of approximately 1000m^3/h.
- Based on rough estimation by considering the volume of gas/cross-sectional area of the drywell and the possible influence of debris decay heat and application of abrasive water jet, this may lead to approximate **0.01~0.1 m/s** gas velocity and an expected **laminar flow** inside the overall PCV.
- In laminar flows, **aerosol deposition** is governed by mechanisms such as gravitational settling, Brownian diffusion, thermophoresis and inertial impaction.
- However, **the presence of structural obstacles** and induced suction flows can introduce significant flow field perturbations, altering particle trajectories and deposition patterns in ways that are not yet well characterized.
- Understanding these effects is particularly relevant for the design of aerosol mitigation strategies inside the PCV and around debris retrieval points, where both physical obstructions and air extraction devices are routinely employed.

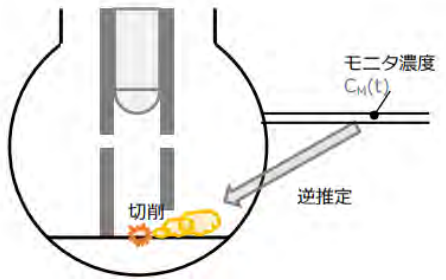
[1]MHI report

1. Background

Objective:

- Evaluating the LPF in 1F decommissioning by studying the aerosol deposition





Study on the aerosol deposition behaviors

- To study flow resistance and dust adhesion behavior caused by equipment inside the PCV
- To support analysis of aerosol source & sink terms in 1F decommissioning

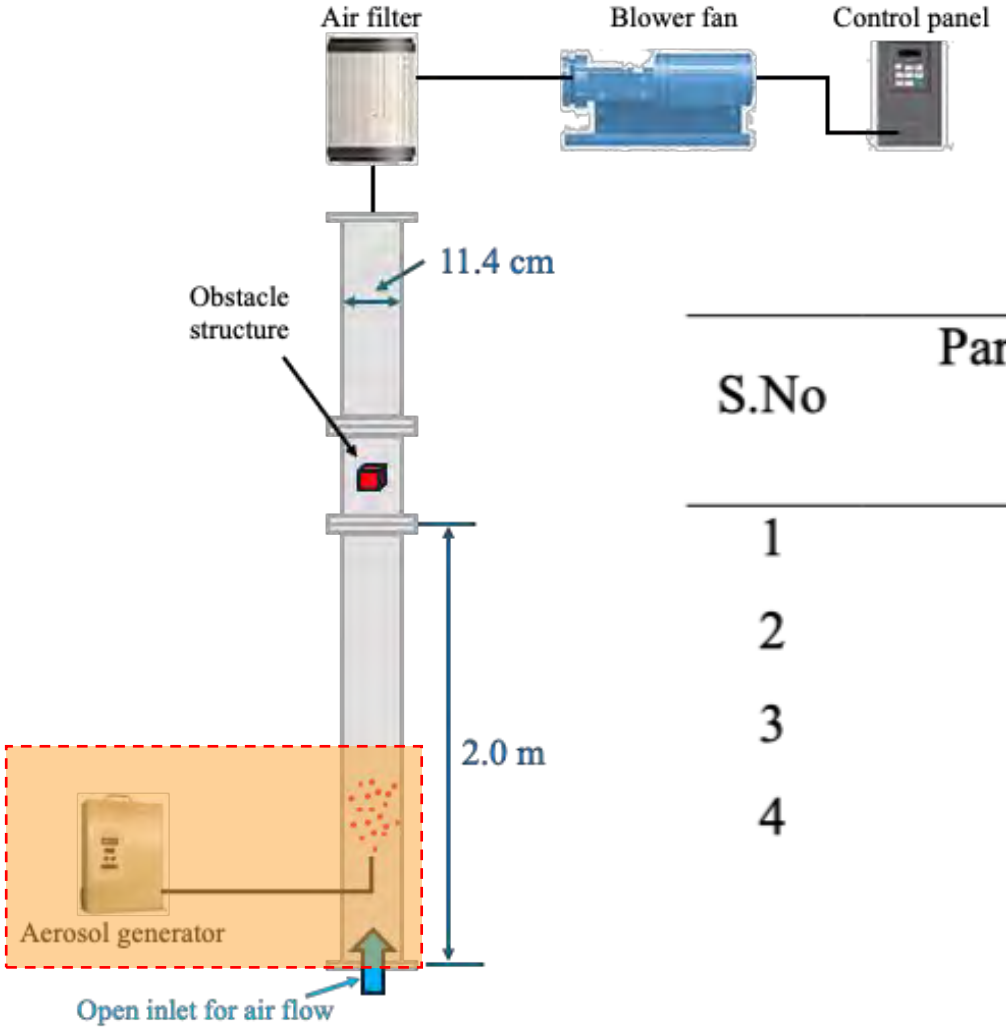
Parameters for Aerosol Injection by the RBG 1000 Generator

Generator model	RBG 1000
Gas volume flow (L/min)	27 to 28
Type of aerosol particles	ZrO_2
Feed rate (mm/h)	**2 to 15**
Aerosol injection mass rate (g/h)	**0.24 to 1.80**
Reservoir inner diameter (mm)	14
Aerosol outlet dispersion cover, Φ (mm)	$\Phi_{inside} = 3.6$; $\Phi_{outside} = 6.0$

2. Experimental condition

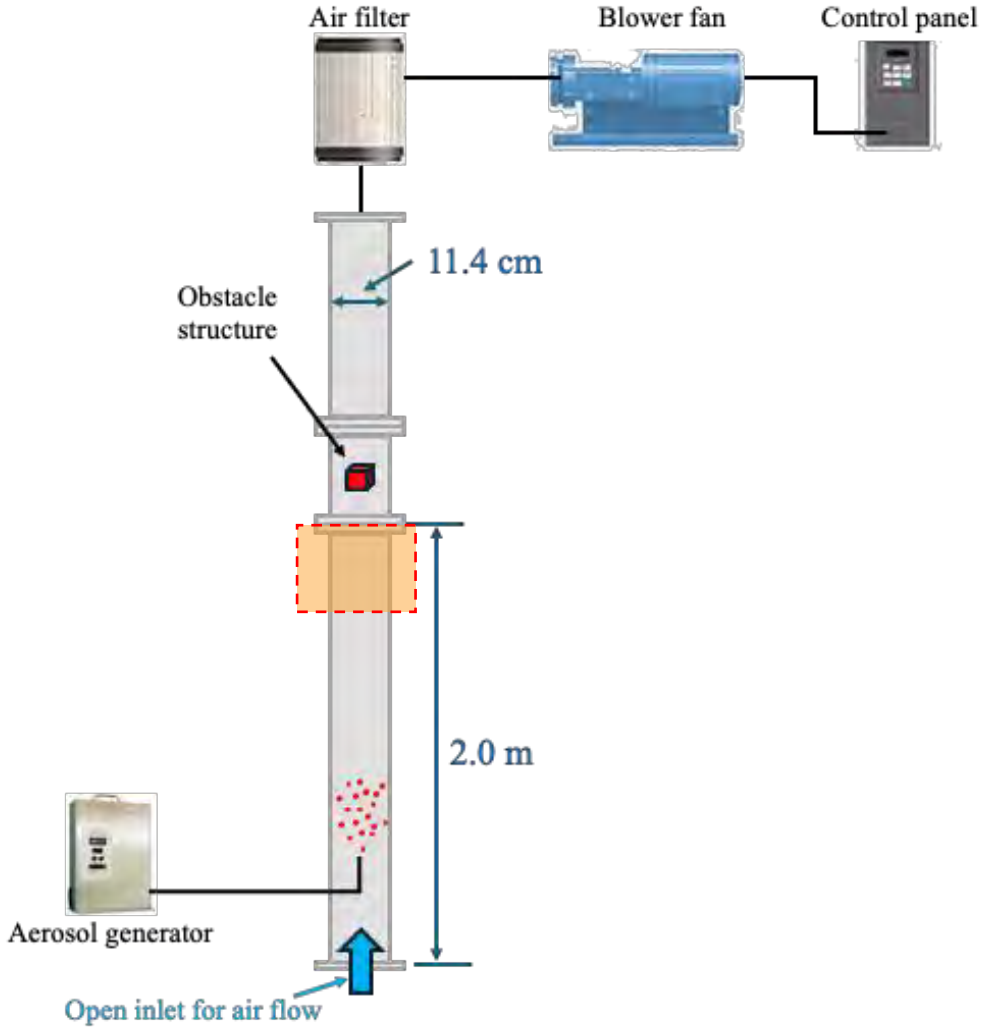
- **Aerosol generation**

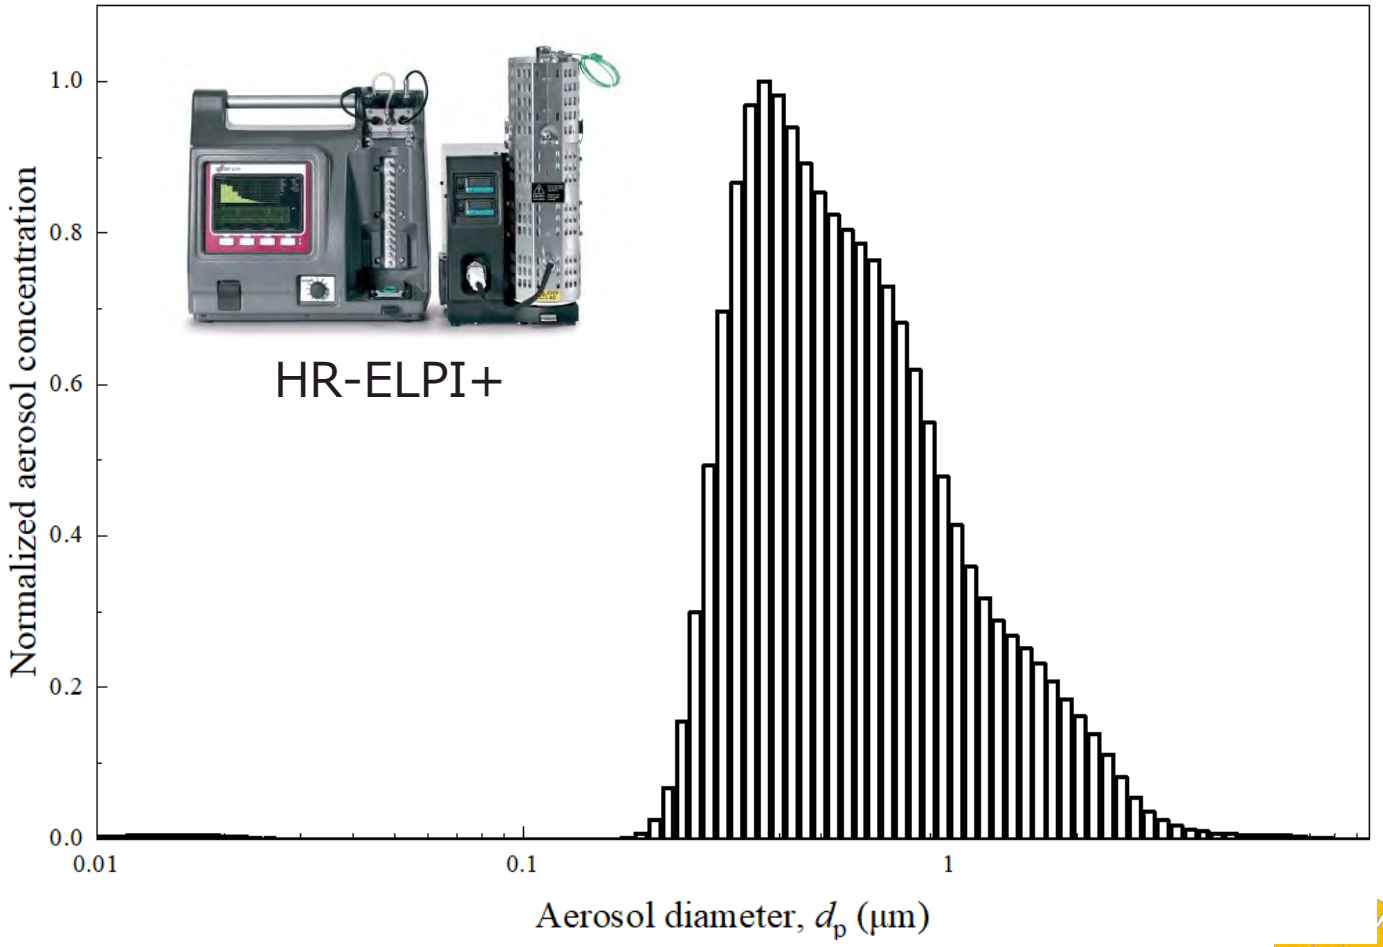


S.No	Particle feed rate (g/h)	Air velocity (m/s)	Concentration (P/cm^3)
1	0.24	0.09±0.01	45,000±2,000
2	0.60	0.09±0.01	1,20,000±5,000
3	1.20	0.09±0.01	3,50,000±10,000
4	1.80	0.09±0.01	6,20,000±7,000

2. Experimental condition

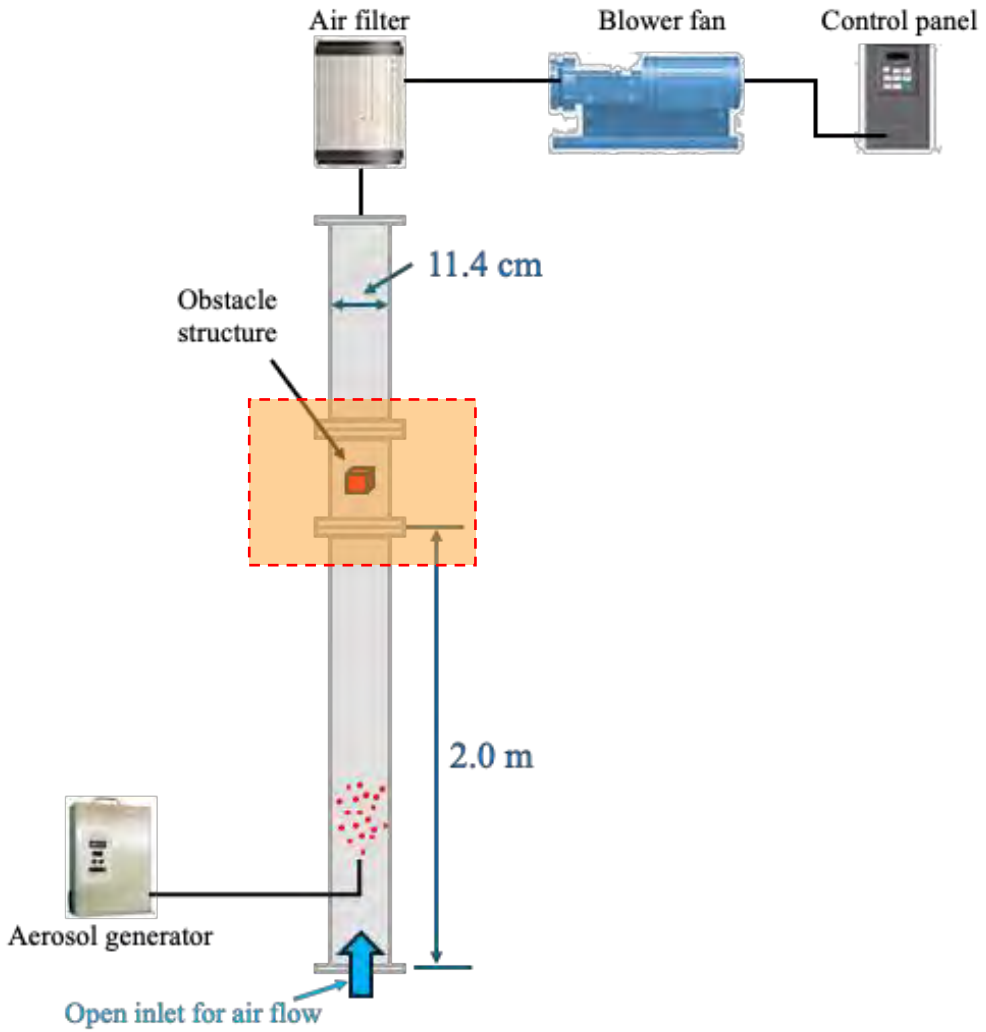
- **Aerosol generation**

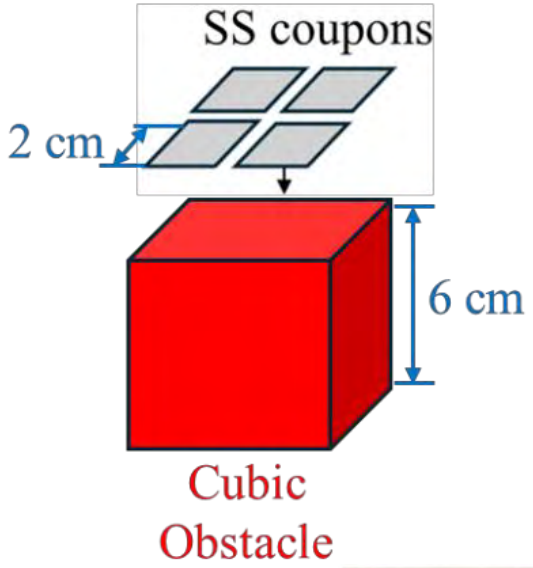


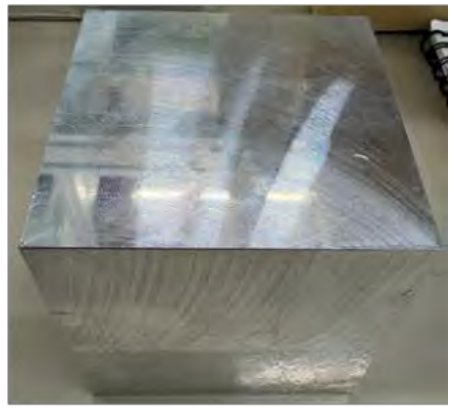


2. Experimental condition

- **Obstacle structure**

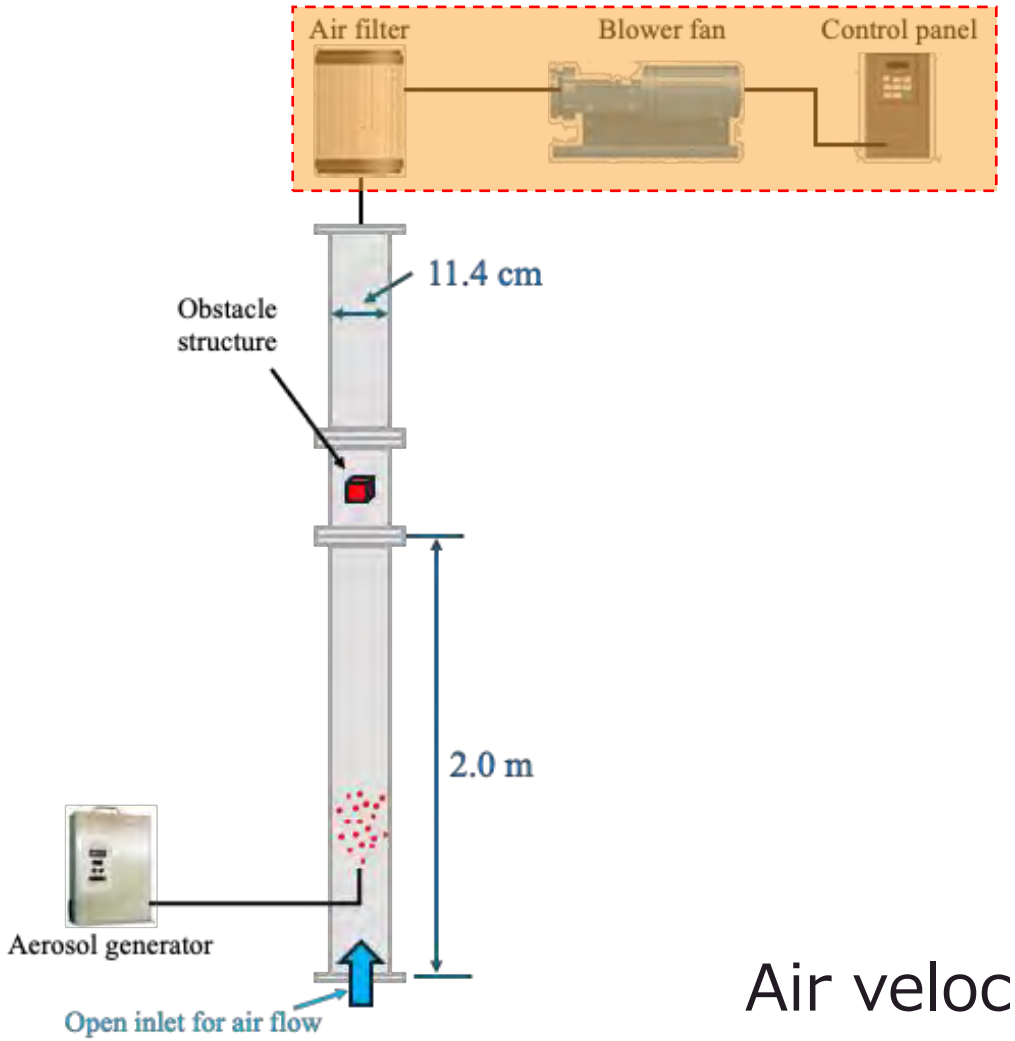


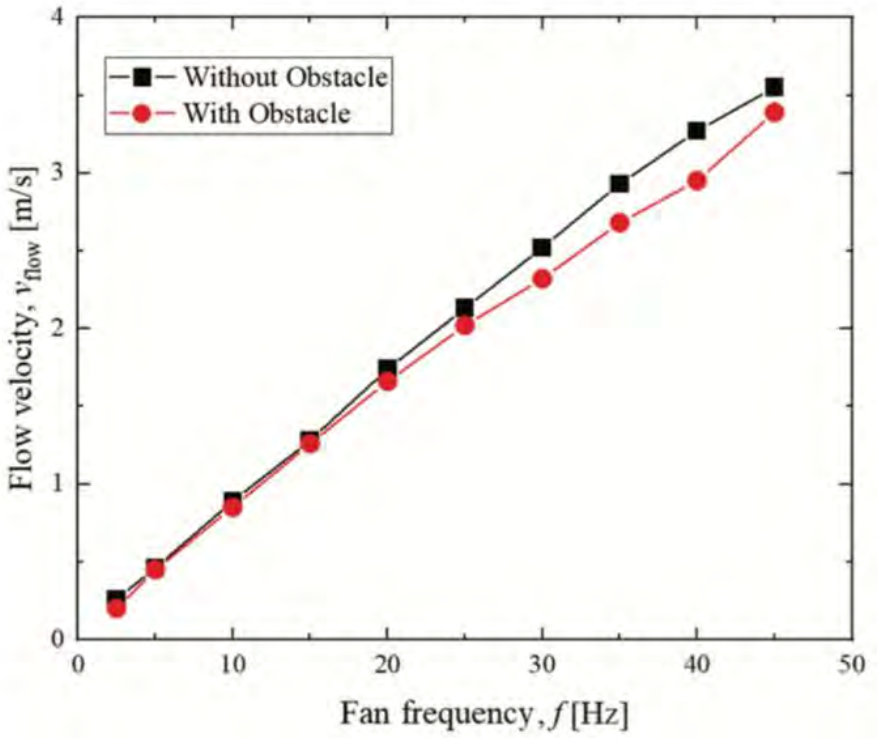




2. Experimental condition

- **Venting condition**



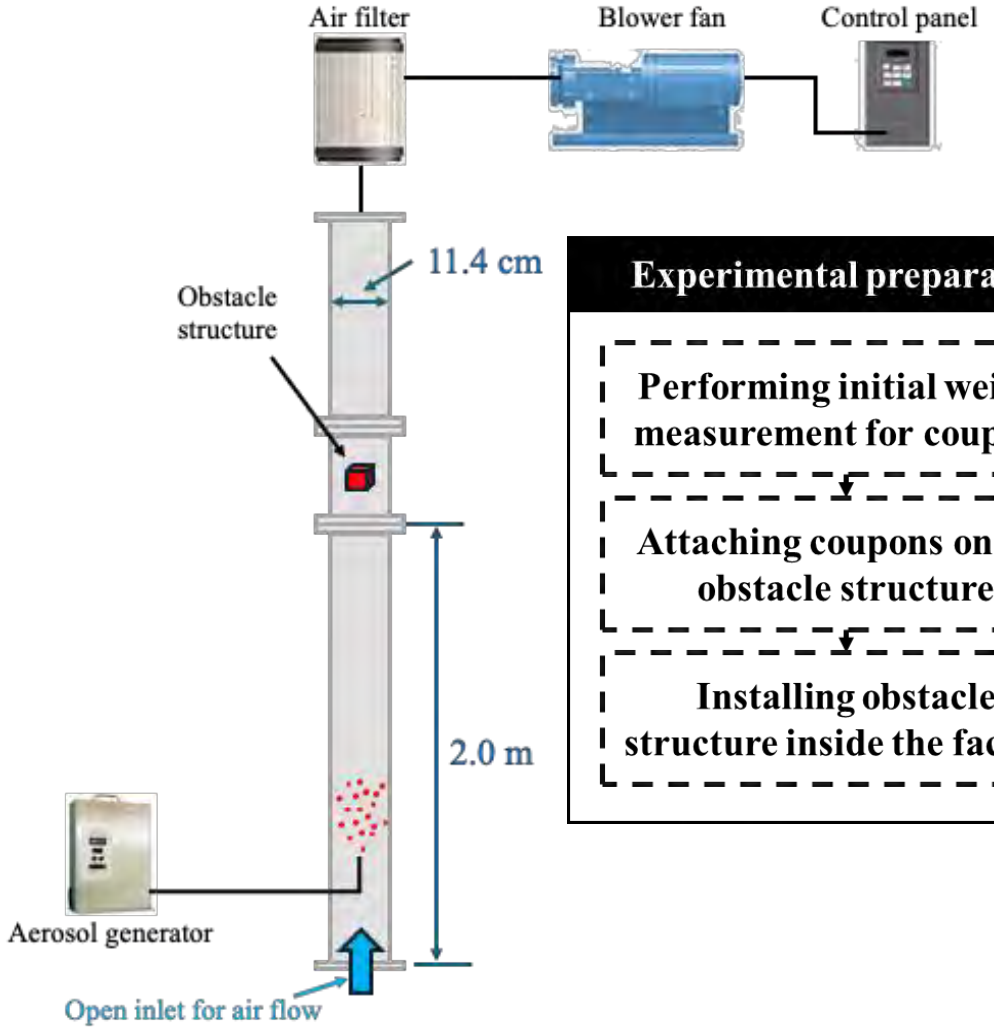


Blower frequency: **2Hz**

Air velocity inside the facility: **0.08～0.10m/s**

2. Experimental condition

- **Experimental procedure**



Experimental preparation

- Performing initial weight measurement for coupons
- Attaching coupons on the obstacle structure
- Installing obstacle structure inside the facility

Experimental implementation

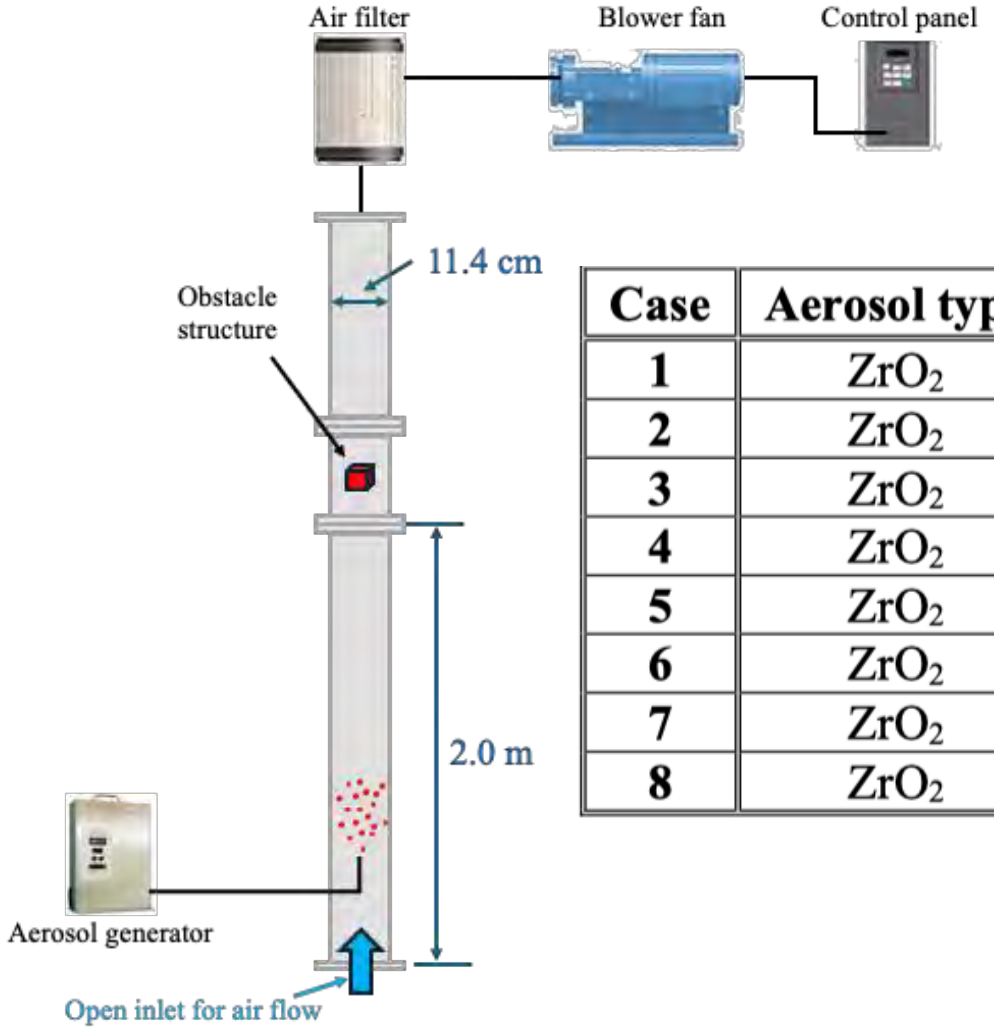
- Injecting aerosols into the facility; Keeping air ventilation at the same time
- After a designed experimental time t_{dep}
- Taking out the obstacle

Experimental post-processing

- Performing weight measurement and surface analysis for the coupons
- Cleaning the coupons and obstacle; Starting new experimental case

2. Experimental condition

- **Experimental cases**



Case	Aerosol type	Deposition time, t_{dep} [h]	Aerosol injection rate, $\dot{m}_p$ [g/h]
1	ZrO_2	6	0.24
2	ZrO_2	6	0.60
3	ZrO_2	6	1.20
4	ZrO_2	6	1.80
5	ZrO_2	12	0.24
6	ZrO_2	12	0.60
7	ZrO_2	12	1.20
8	ZrO_2	12	1.80

Outline

- Background
- Experimental condition
- Results and discussion
- Summary

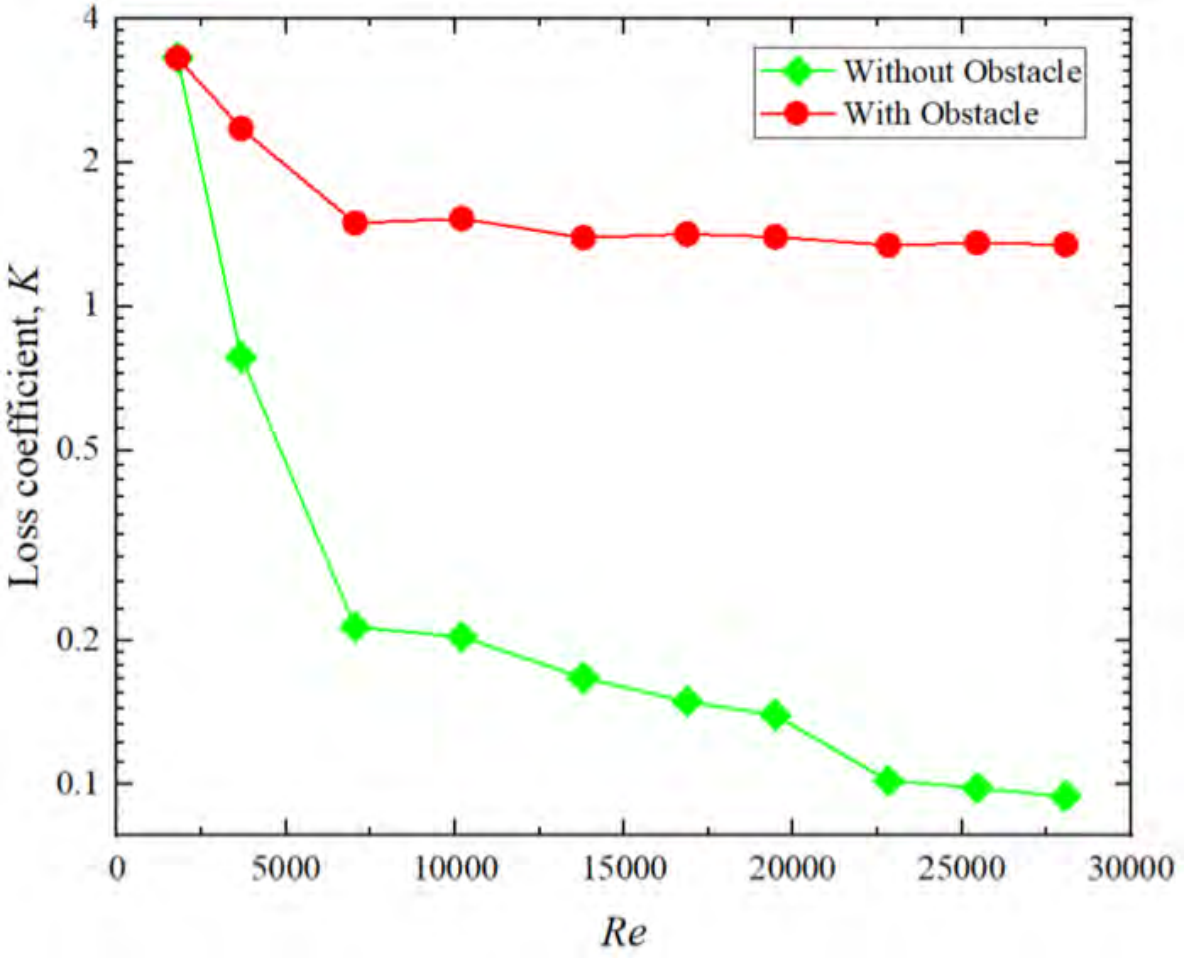
3. Results and discussion

- **Flow resistance evaluation for the obstacle**

Loss coefficient: $K = \frac{\Delta p}{\frac{1}{2}\rho V^2}$

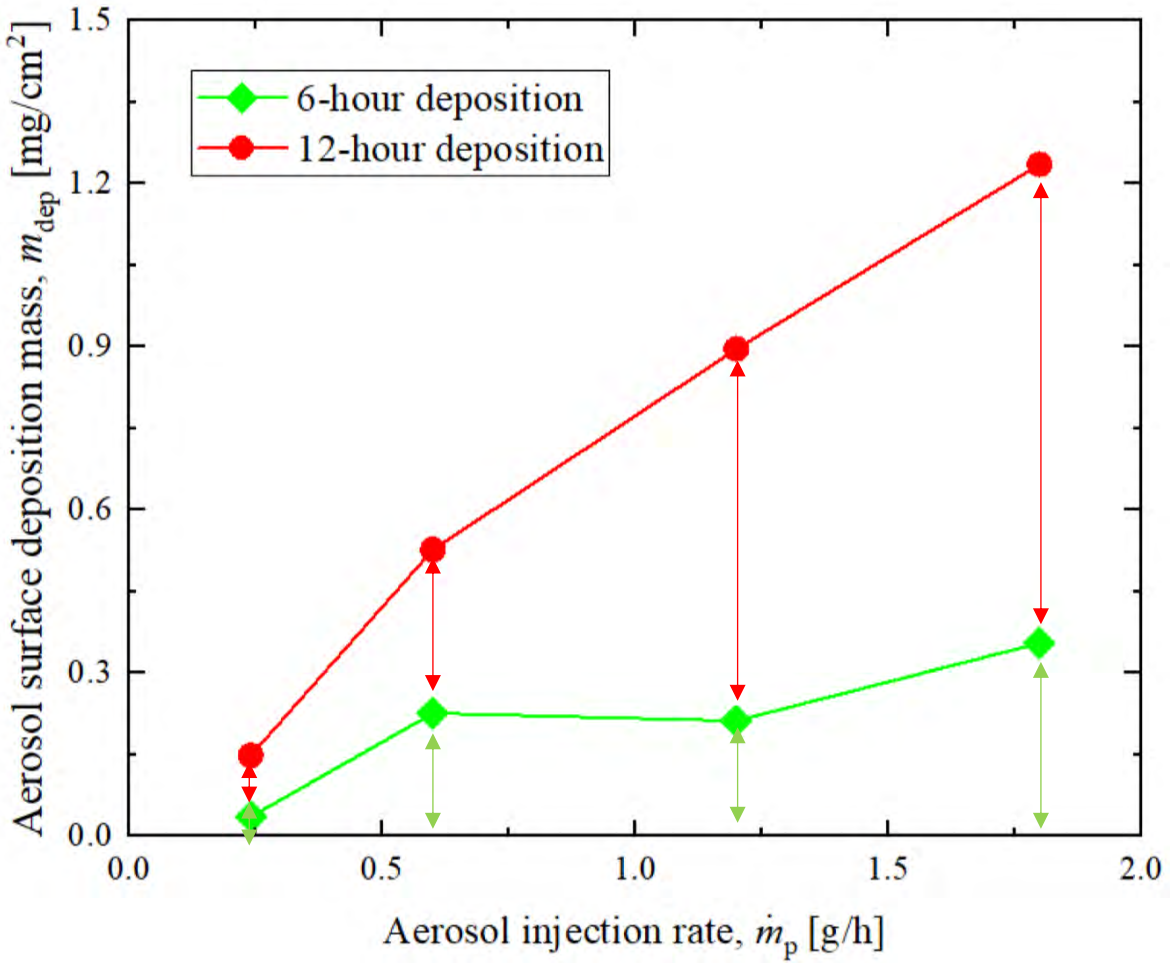
- Under low Reynolds number conditions, the overall flow resistance is governed primarily by viscous shear along the pipe wall rather than by form drag induced by the obstacle.

- As the Reynolds number increases and the flow approaches turbulent conditions, the loss coefficient for the obstacle case becomes significantly larger than that of the unobstructed pipe, reflecting the increasing contribution of flow separation, vortex shedding, and form drag around the obstacle under turbulent conditions.



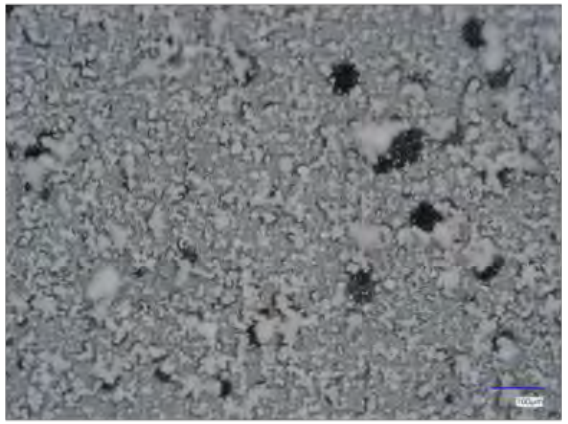
3. Results and discussion

- For a fixed deposition time, the deposited mass increases as the aerosol injection rate increases.
- For a fixed injection rate, the deposited mass continuously increases with longer deposition time.
- The mass gains from the later 6-hour deposition (↔) are generally higher than the first 6-hour deposition (↔).
- This may be caused by surface condition changes during the deposition procedures.

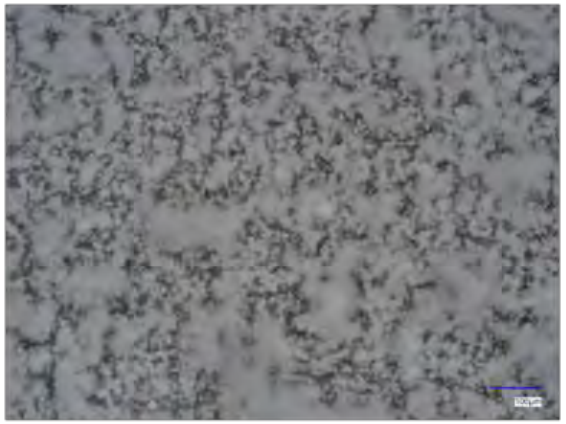


3. Results and discussion

(a) No deposition



(b) Case3: after 6h deposition



(c) Case 7: after 12h deposition

- **LIBS results show an increase in aerosol particle number density and agglomeration on both horizontal upward-facing and vertical surfaces.**

Net deposition → deposition + agglomeration

- During operations associated with high aerosol generation rates, structural surfaces inside the containment environment may become rapidly contaminated if exposure is sustained.
- Controlling the instantaneous aerosol release rate and limiting prolonged exposure under such conditions can be effective strategies to mitigate progressive surface contamination during decommissioning activities.

Outline

- Background
- Experimental condition
- Results and discussion
- Summary

4. Summary

- Investigated aerosol deposition onto a representative obstacle under low-velocity venting conditions relevant to Fukushima Daiichi decommissioning.
- Using ZrO_2 aerosol in the UTAD[2] facility, we examined how injection rate and deposition time affect surface contamination.
- Deposition is driven not only by particle supply, but also by the evolving morphology of the deposited layer itself.
- Higher injection rates and longer times shift the surface from discrete particles to agglomerated, interconnected structures, which capture incoming particles more efficiently and drive progressive deposition.
- Obstacle surfaces along ventilation paths are highly vulnerable to rapid contamination under sustained aerosol generation.
- Limiting peak release rates and prolonged exposure can effectively mitigate progressive contamination during debris retrieval and decommissioning.

Following the Fukushima accident, enhancing the safety of existing nuclear facilities became essential to ensure adequate safety margins during incidental and accidental situations. Developing new accident-tolerant nuclear fuels should offer better performance during normal operation, transient conditions, and Design Basis Accident (DBA) scenarios than the current UO_2/Zr alloy. To this end, chromium-based Advanced Technical Fuel (ATF) concepts are being developed.

The most advanced concept is chromium coating of the fuel cladding which should limit hydrogen production and be beneficial for accident management. However, the impact of this type of fuel on the source term remains unknown. In case of severe accident, significant quantities of chromium could be released. The airborne chromium could then:

- i) be released in a toxic oxidation state (Cr^{VI}),
- ii) interact with other volatile fission products (Cs, I, Mo) and modify the source term.

To study these phenomena, an experimental line has been developed at ASNR[a]. This line enables $Cr_2O_{3(s)}$ to be heated to 1550°C, leading to the chromium vaporization with gaseous Mo and Cs species, in a controlled atmosphere (H_2O, O_2, N_2) to simulate primary circuit transport in severe accident conditions.

The various chromium species volatilized and redeposited are analysed by XRD, ICP-OES/MS, UV-Visible, IR and XPS. Cr^{VI} transport downstream of the bench has been observed. Some tests are ongoing to investigate experimental parameters.

The goal is to refine/validate the ASTEC (Accident Source Term Evaluation Code) simulation tool developed by ASNR, to assess potential outside releases mainly of Cs and Cr concerned by this kind of ATF fuel.

KEYWORDS: chromium, LOCA, ATF, transport, source term

1. Introduction

New concepts of advanced fuel design concepts (ATF) are currently in development phase [1]. The main purpose of these fuels is to get more robust fuel performance and economic benefits for Pressurized Water Reactor (PWR). The safety must be ensured in nominal conditions and in the case of accidental situation like Loss Of Coolant Accident (LOCA). This last situation is taken into account during the design of PWR reactors.

Various ATF-concepts are being developed to mitigate issues related to LOCA-type accidents. Three chromium containing ATF are being considered:

- Chromium coating of the fuel cladding [2-3]. The aim is to form a protective chromium oxide layer. This layer decreases the cladding oxidation by steam, thus reducing the formation of dihydrogen gas. This layer also improves the mechanical resistance of the cladding against swelling and therefore delays its rupture when the temperature rises. This concept is being studied as part of the OECD Quench ATF project.
- Incorporation of Cr_2O_3 into the fuel pellet [4-6] (ANR BENEFICIA). This method increases the size of the uranium dioxide grains. The enlargement of the grains increases the transfer time of fission products (FP) to the grain boundaries, lengthening the average travel distance. However, this approach also modifies the diffusion rate coefficient of the fission products.
- Incorporation of chromium inside the fuel cladding (Fe-Cr-Al alloys) [1].

The most advanced chromium containing ATF concept is the metal chromium coating on the fuel cladding [2-3]. This coating can decrease the kinetic of steam oxidation by two orders of magnitude in nominal or LOCA conditions [7] (Figure 1).

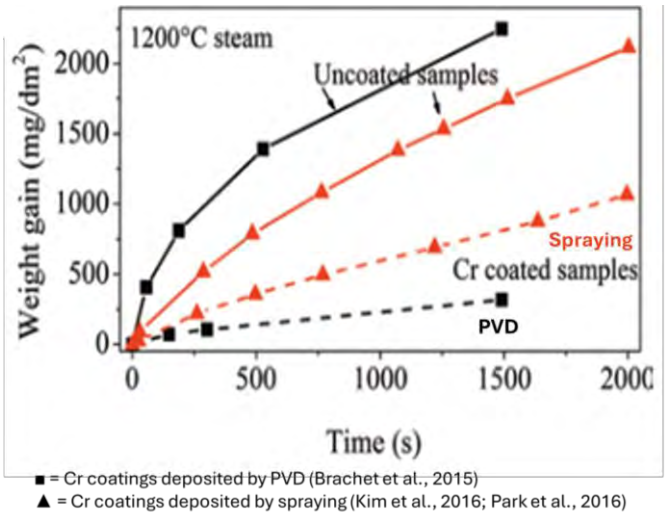

Figure 1 : Comparison of corrosion rate of uncoated and Cr-coated Zr-based alloys, fabricated by different processes (PVD and spraying), in a high-temperature steam atmosphere representative of LOCA conditions. [7]

Nevertheless, international assessments have identified significant knowledge gaps concerning the chromium behavior under severe accident conditions. The main purpose of the previously mentioned projects (BENEFICIA, Quench, FORESEEN) is to address these gaps and improve the understanding of chromium behavior. This PhD work also contributes to this objective.

The amount of chromium in an ATF core can be significant considering either the incorporation of chromium inside the pellet or as a coating. For PWR, it can represent up to several hundred kilograms of chromium [2-3; 7-8]. This large quantity of chromium can be volatilized in case of severe accident [9-10] in oxidizing conditions. Airborne chromium could then: i) be released in a toxic oxidation state (Cr^{VI}); ii) or interact with volatile fission products (Cs, I, Mo) that may also be released.

Chromium has a strong affinity for cesium (cesium chromites [11]) and molybdenum (chromium molybdates [12]). It is therefore necessary to study the behavior of chromium in interaction with these PFs under severe accident conditions to get a better assessment of potential releases. These elements are

vaporized at high temperature (≈ 1550°C) and transported in the primary circuit which has a decreasing thermal gradient (down to 150°C). The transporting atmosphere is mainly composed of steam. In such conditions, several physico-chemical processes may change species states and form. The vaporized species can then [8]: i) adsorb and condense on surfaces; ii) nucleate to form aerosols and agglomerates; iii) or remain in a gaseous state.

The transported species are referenced to the aerosols and gaseous species which could be released into the confinement vessel, or even into the environment depending on the severe accident scenario.

The goal of this study is then to get a better understanding of the transport of chromium in the primary circuit in such accidental conditions through experiments. Analyses will be carried out to identify the different species involving chromium deposited and transported. These experiments will enable the creation of an experimental database to validate the ASTEC calculation code [13]. SOPHAEROS module will be enhanced by the addition of chromium reactivity in accident situations.

The experimental procedure for chromium vaporization will be presented in the first chapter along with the analytical procedure. Modelling using SOPHAEROS will also be described in this chapter. The experimental results of chromium vaporization tests in an atmosphere mainly composed of steam will be presented in the second chapter. The third chapter will be dedicated to modelling results. A discussion based on the comparison of modeling and experiments, as well as improvements needed, will then be held. In conclusion, the different chromium reactions occurring in these accident scenarios will be summarized.

2. Materials and Methods

2.A. Experimental facility (ACCrAS)

The ACCrAS (Analysis of Chromium behavior in case of Severe Accidents) experimental bench simulates the chemical transport of chromium in a thermal gradient between 1550 and 150°C with controlled flow and atmosphere. As shown in Figure 2, the ACCrAS bench is divided into three parts:

- Main circuit: high-temperature tubular furnace capable of heating up to 1550°C. The chromium precursor ($Cr_2O_{3(s)}$) is deposited in an yttria-stabilized zirconia (Zr8Y) crucible (1 cm^2) inside of the alumina tube (ϕ = 30 mm, L = 1 m). Transport mainly takes place from the center of the furnace (1550°C) to the downstream filter (150°C). Linings (Zr8Y, ϕ = 30 mm, L = 10 cm) and coupons (Zr8Y, L = 5 cm, l = 1 cm) are used to recover the deposits.

- Upstream of the furnace: steam generation, injection of the incoming gas flow (atmosphere), and pressure monitoring.

- Downstream of the furnace: separation of the flow into different lines named “By-Pass”, “Main line” and “Kinetic line”. The main and bypass lines are designed to separate transported aerosols from the gas. The aerosols are recovered on a quartz filter, and condensable gases are recovered in acid bubblers. The kinetic line enables real-time measurements of the transported chromium (gas + aerosols).

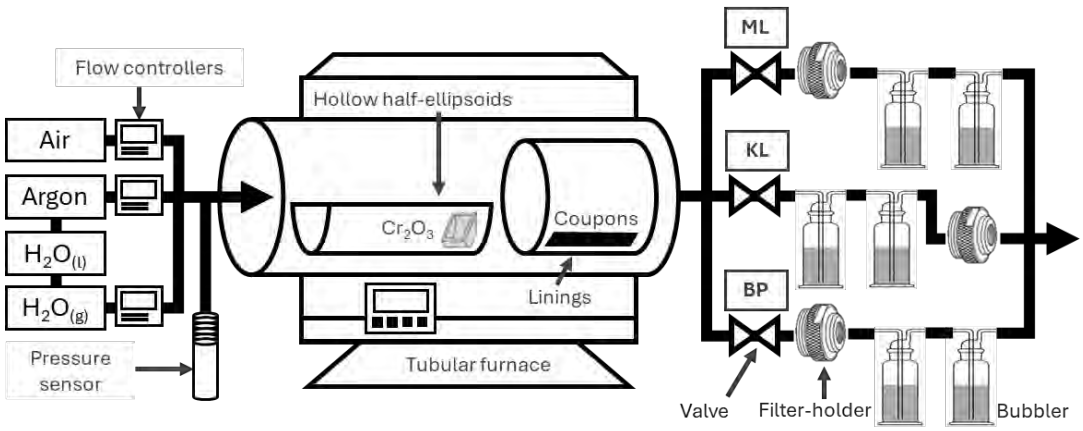

Figure 2 : Diagram of the ACCrAS experimental bench. ML = Main Line, KL = Kinetic Line, BP = By-Pass

Thermal maps (Figure 3) allow to define the collection temperature of the deposits by relating temperature and position in the ACCrAS bench. The impact of flow rate on temperature is negligible between 0.5 and 1.0 NL.min^{-1}. Downstream the vaporization zone (furnace's center), the ACCrAS bench shows a strong decreasing thermal gradient over the first 30 cm (-40°C.cm^{-1} on average).

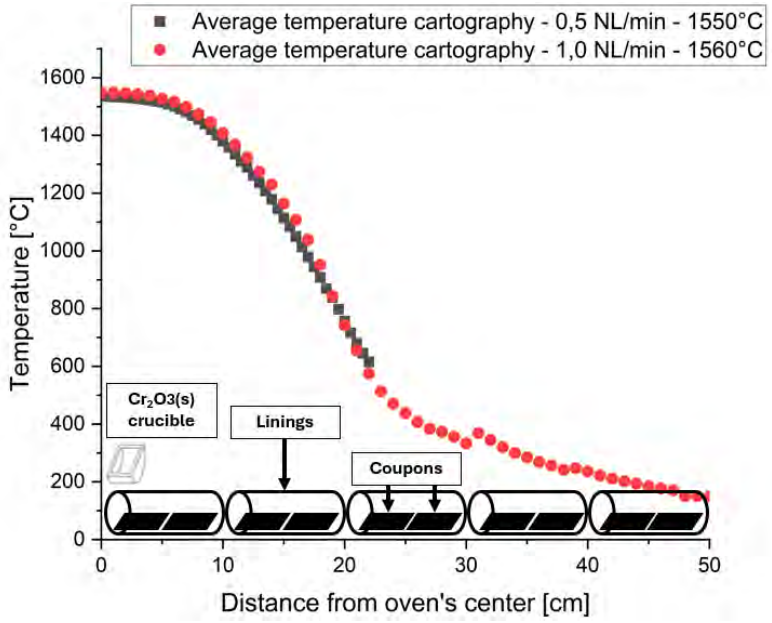

Figure 3 : Thermal maps carried out on the ACCrAS test bench taken at 1550°C for 0.5 NL.min^{-1} and 1560°C for 1.0 NL.min^{-1}. 0 cm = furnace's center, 50 cm = downstream flange.

A test consists of three distinct stages:

i) the heating ramp: the gas flow (0.1 NL.min^{-1} of argon) is directed downstream into the By-Pass line during this stage;
ii) the 4-hour temperature plateau at 1550°C: the gas flow is directed into the main line;
iii) and the cooling ramp: the gas flow (0.1 NL.min^{-1} of argon) is directed downstream into the By-Pass line.

During the temperature plateau, the gas flow is composed of 80% (v/v) water vapor and 20% (v/v) air. The experimental setup is maintained at 150°C outside the furnace using heating sleeves and coils to prevent condensation of water vapor.

A preliminary test has been conducted to determine the vaporized chromium quantity during heating and cooling ramp. Less than 6 µg of chromium were recovered into the bench. This mass is negligible compared to the one vaporized during ACCrAS tests.

Thermal maps can then discriminate a temperature area for each lining and coupon and are also useful to determine the residence time of the particles. The residence time is calculated over a distance (Δx) based on pressure (P), temperature (T), pipe volume (cross-section "S" and length "Δx"), and molar flow rate (N) according to Equation 1. For a total carrier gas flow rate of 0.5 NL.min^{-1} at atmospheric pressure: the residence time between the center of the furnace and the filter is 16 seconds.

Equation 1 : Residence time of a particle as a function of volume, pressure, temperature, volume, and flow rate.

$$Residence\ time\ (s) = \frac{P\ (Pa) \times S\ (m^2) \times\ \Delta x(m)}{R\ (J.K^{-1}.mol^{-1} \times N\ (mol.s^{-1}) \times T\ (K)}$$

2.B. Post-test analyses and characterization

Post-test analyses aim to determine the elementary distribution of chromium in the deposits, aerosols and gas, as well as the nature of the chemical species. The first step consists of performing non-destructive surface analyses on the coupons: XRD, FTIR, Raman, SEM, EDX, XPS and TOF-SIMS.

The second step is to wash every ACCrAS bench pieces (liners, cradles, filters, alumina tube, and PFA tubing) with nitric acid (0,15 M), to recover soluble chromium species, expected to be Cr^{VI} species.

It is then necessary to dissolve the refractory deposits of chromium-containing species that have formed on the coupons and linings, expected to be Cr^{III} species. The chromium (III) oxide is known to be highly resistant to dissolution [14-16]. Two dissolution procedures were specifically developed for this work.

The nitric acid solutions can be analyzed using UV-Visible spectroscopy to determine the presence of chromium (VI) which presents characteristic absorption bands at 278 and 350 nm [17]. This method is less sensitive (detection limit = 2,5 ppm) than ICP-OES. Finally, all dissolved samples can be analyzed by Inductively Coupled Plasma (ICP) techniques for the quantitative determination of chromium.

ICP-OES (Optical Emission Spectroscopy) method can quantify the chromium between 25 and 100 pbb at the 205.560 and 267.716 nm wavelengths in pure nitric matrix with an uncertainty of +/- 10% at 95% confidence level. Matrix effects related to the presence of diluted chlorine increased the uncertainty up to 40% in the worst case.

2.C. Modelling method (SOPHAEROS)

The ASTEC (Accident Source Term Evaluation Code) [13] software is developed to predict the source term in the event of an accident. The SOPHAEROS module can simulate the chemistry and transport of FPs and other elements in a primary circuit or in experimental benches. Input parameters are the chemical system (species and concentration), the geometrical description of the line (subdivided in volumes), thermal conditions, atmosphere composition and flow. The SOPHAEROS module determines the chemical speciation in each volume using predefined chemical paths (kinetically controlled).

The objective of the ACCrAS device is to provide validation data on the reactivity of chromium under accident conditions for comparison with SOPHAEROS software simulations. The ACCrAS test bench is modeled in SOPHAEROS with 36 volumes as shown in Figure 4. The temperature within each volume is assumed to be isothermal and is determined using a polynomial fit of the thermal maps shown previously. The pression is set at 1 atm in the modelling and the total flow is set at 0,4 $NL.min^{-1}$ of water and 0,1 $NL.min^{-1}$ of argon or N_2/O_2 mix (80%/20%).

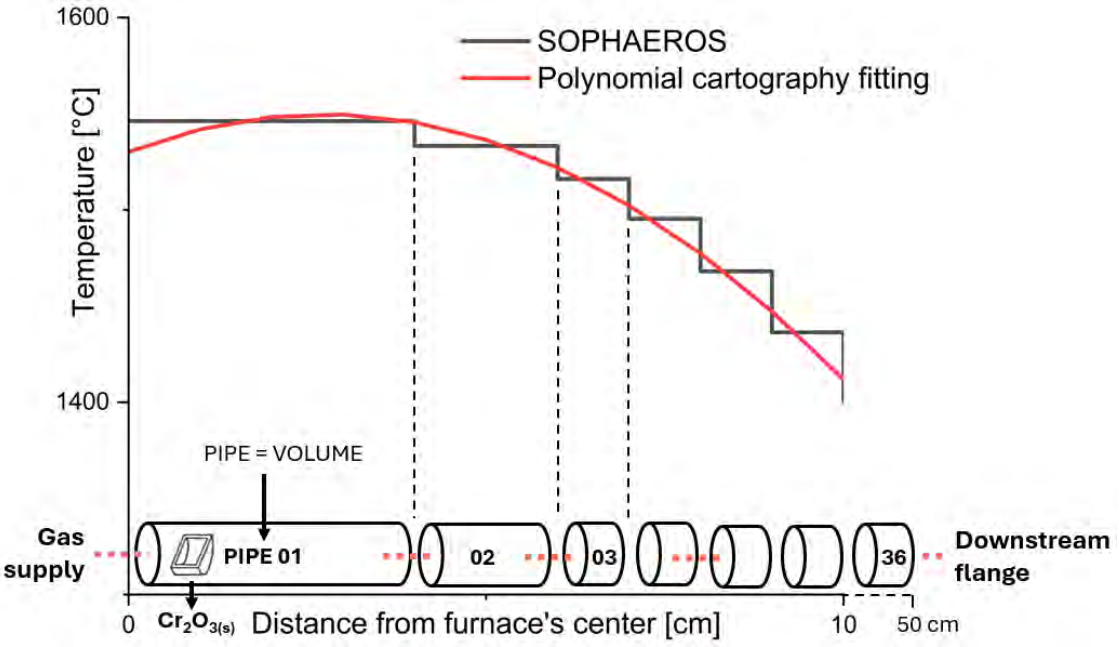

Figure 4 : Diagram showing how the SOPHAEROS module works and representing the 10 first centimeters of the ACCrAS bench in this module. The volumes represented in SOPHAEROS are isothermal and are compared with the polynomial fit of the thermal maps realized at 1 NL.min^{-1} and 1560 °C presented in Figure 3.

For each relevant species of severe accident situation, the MDB database [13] developed by ASNR provides a set of thermodynamic data (enthalpy, entropy, heat capacity, …) and physicochemical data

(particle size, density, conductivity, …). Chromium oxides and hydroxides are present in the SOPHAEROS database (MDB) but this one does not currently contain mixed species with chromium in interaction with cesium and molybdenum.

For chromium oxides, several types of chemical reactions are encoded: the volatilization/condensation reactions of Cr_2O_3(s) at different surface states, as well as chemical reactions in the gas phase. It is necessary to define the stability of the Cr_2O_3(s) surface according to its state in order to correctly formulate the condensation and vaporization reactions of Cr_2O_3(s). DFT calculations were performed [18] to determine the relative energy of the different surface states of $Cr_2O_{3(s)}$ and are summarized in Figure 5. Note that the surface area of a Cr_2O_3 unit cell is 21.23 Å^2 [18].

Termination	Stoichiometry	N[O_2]	ΔE (meV/Å^2)	
From Cr-O–Cr	Cr-O_3–Cr (*I*)	$Cr_{12}O_{18}$	0	00
	Cr-O_2–Cr (*V*)	$Cr_{12}O_{16}$	–1	202
	Cr-O_3–Cr-O_1 (*II*)	$Cr_{12}O_{20}$	1	–50
	Cr-O_3–Cr-O_2 (*III*)	$Cr_{12}O_{22}$	2	–27
	Cr-O_3–Cr-O_3 (*IV*)	$Cr_{12}O_{24}$	3	–32
	Cr-Cr-$O_{3/2}$ (*VI*)	$Cr_{12}O_{18}$	0	80
From Cr2-$O_{3/2}$	Cr-Cr *VII*)	$Cr_{12}O_{15}$	–3/2	321
	Cr-Cr-O_1 (*VIII*)	$Cr_{12}O_{17}$	–1/2	135
	Cr-Cr-O_2 (*IX*)	$Cr_{12}O_{19}$	1/2	21
	Cr-Cr-O_3 (*X*)	$Cr_{12}O_{21}$	3/2	–20

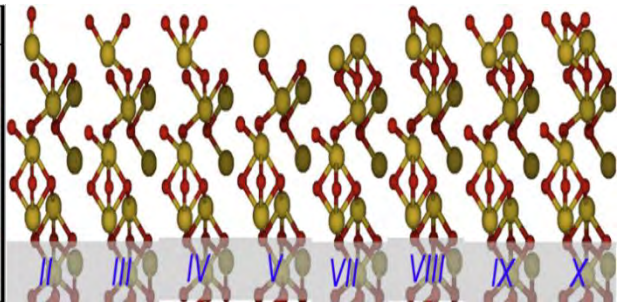

Figure 5 : Stoichiometry, energy and O_2 difference of different $Cr_2O_{3(s)}$) surfaces compared to a hexagonal lattice of surface (I) (left) and representation of the termination of these surfaces (right). Yellow : Cr, red : O. [18]

The different surface states of $Cr_2O_{3(s)}$ are labelled with roman numerals ranging from (I) to (X). The hydrogenated and hydrated surface states described in the publication of S. Souvi et Al. (2017) [18] have also been incorporated into the MDB database. It is then possible to define condensation and volatilization reactions.

The chromium condensation following the $CrO_{3(g)}$ deposit on the surface X can be schematized as in the Figure 6. This figure also represents the vaporization of $CrO_{3(g)}$ from $Cr_2O_{3(s)}$.

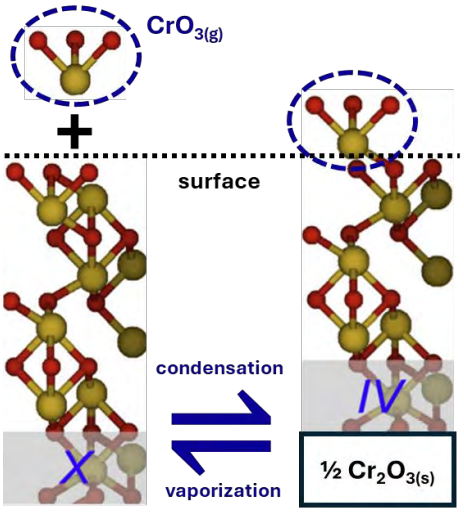

Figure 6 : Schematic representation of chromium condensation by deposition of $CrO_{3(g)}$ on mcrCrO_3 (X).

The condensation of a new layer of Cr_2O_3(s) after the deposition of CrO_3(g) as schematized previously is described following Equation 2.

Equation 2 : Condensation of chromium by deposition of $CrO_{3(g)}$ on Cr-Cr-O_3 surface, labelled X.

$$\frac{1}{2}Cr_{12}O_{21}(\mathrm{X}) + \mathrm{CrO_{3(g)}} \rightarrow \frac{1}{2}Cr_{12}O_{24}(\mathrm{IV}) + \frac{1}{2}\mathrm{Cr_2O_{3(s)}}$$

Following the previous equation and the ones described in the S. Souvi et Al. (2017) publication [18], the calculation of the free enthalpy of the reaction can then be written according to Equation 3:

Equation 3 : Free enthalpy of the chromium condensation reaction by deposition of $CrO_{3(g)}$ on surface X.

$$\Delta rG°(X \rightarrow IV, T) = \frac{1}{2} \times G°(Cr_2O_{3(s)}, T) - G°(CrO_{3(g)}, T) + 21,23\ [Å^2] \times \Delta E \left[\frac{J}{mol.Å^2}\right] + \frac{Nb(O_2)}{2} \times G°(O_{2(g)}, 0K)$$

All reactions leading to a change in the state of the $Cr_2O_{3(s)}$ surface from molecules comprising H, O, and Cr were added into the database. The surfaces "-Cr-O_3-H_x-Cr-O_y" are renamed "mcrH_xO_y" and the surfaces "-Cr-Cr-O_y-H_x" are renamed "mcrCrH_xO_y" in SOPHAEROS. Gas molecules considered in the simulation are $O_{[1-3]}$, $H_{[1-2]}$, $H_{[1-2]}O_{[1-2]}$, $Cr_{[1-2]}O_{[0-3]}$, $CrHO_{[1-3]}$, $CrH_2O_{[2-4]}$, $CrH_3O_{[3-4]}$ and $CrH_4O_{[4-5]}$.

The dimerization and decomposition reactions of atmospheric elements (O, O_2, H_2O, H_2O_2, HO_2, H) as well as the gas phase reactions of chromium-containing molecules are also taken into account. The SOPHAEROS module then allows the chemical speciation to be visualized for each moment (with a defined time step) of the simulation in the condensed, sorbed, gas, and aerosols phases.

3. Experimental results

Several chromium transport tests were carried out under various conditions in the experimental bench. The conditions that can vary include the atmosphere (water vapor, air, or argon) and the presence of cesium and molybdenum precursors. Only the tests involving the vaporization of chromium alone in air and steam will be presented (Table I) and discussed here.

Table I : Summary table of ACCrAS tests performed, objectives and specifications.

Test name	Objective	Note
ACCrAS-Cr-1	Transport test in steam and air atmosphere	Only 2h30 of steam during plateau Cracked and crumbled filter
ACCrAS-Cr-2	Kinetic of chromium transport (gas + aerosols) downstream at 150°C	No filter on the main line Bubbler not cooled
ACCrAS-Cr-3	Reproducibility test of ACCrAS-Cr-1	Only 2h30 of steam during plateau Slightly cracked filter

During these tests, 20 mg of $Cr_2O_{3(s)}$ (i.e., 263.2 µmol of Cr) are placed in a Zr8Y crucible in the center of the furnace. The chromium is vaporized under a flow of 0.4 NL.min^{-1} of $H_2O(g)$ and 0.1 NL.min^{-1} of synthetic air (80% $N_{2(g)}$ + 20% $O_{2(g)}$) during the 4-hour step period at 1550°C. Photographs of the collection coupons, filters and bubblers after these tests are shown in Figure 7.

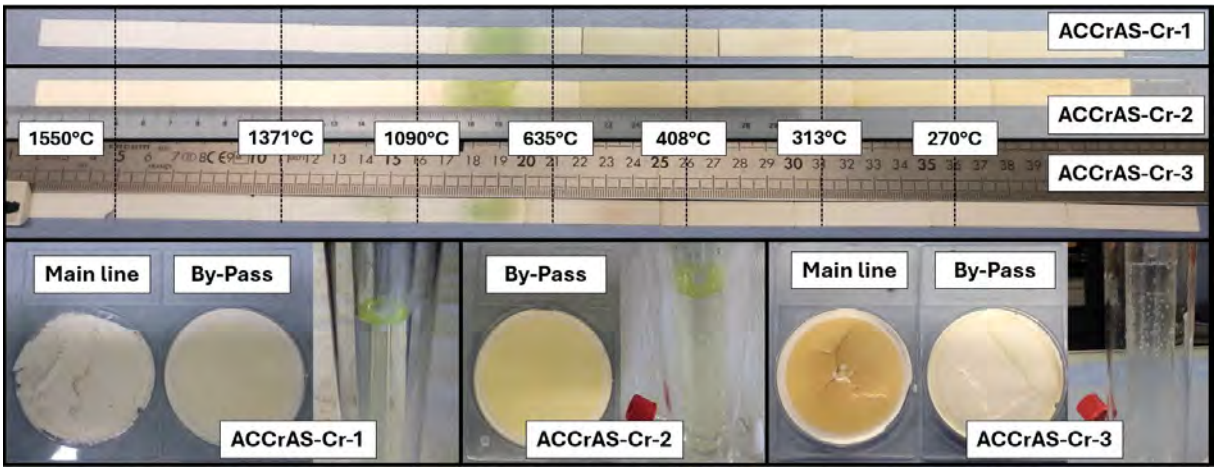

Figure 7 : Photographs of collected coupons, filters (main line and/or bypass) and bubblers (main line) from the ACCrAS-Cr-(1 to 3) tests.

A green deposit can be observed between 770°C and 1015°C on the coupons for all these tests. A second green deposit is also observable at around 1175°C only in the third test. Small brown deposits also appear at lower temperatures below 635°C. Even though the main line filter in the ACCrAS-Cr-3 test cracked

slightly, a yellowish deposit can be observed on it. Slight yellow deposits are also visible on the bypass filters in the ACCrAS-Cr-(1 and 2) tests. The main line bubblers show a yellowish coloration when the filter is crumbled (ACCrAS-Cr-1) or when there is no filter (ACCrAS-Cr-2).

Indeed, no further oxidation of the Cr_2O_3 precursor was observed after several hours under an oxidizing atmosphere (steam/air) at 1550 °C, as confirmed by XRD and IR characterization [19]. A quantitative dissolution of the remaining mass of Cr_2O_3 precursor is difficult to achieve due to grain growth. The amount of chromium vaporized is then determined by the difference in mass of the crucible containing the chromium (III) oxide before and after the test. Quantitative ICP-OES analyses were used to determine the distribution of chromium deposited throughout the experimental setup following dissolution of the deposits (Figure 8).

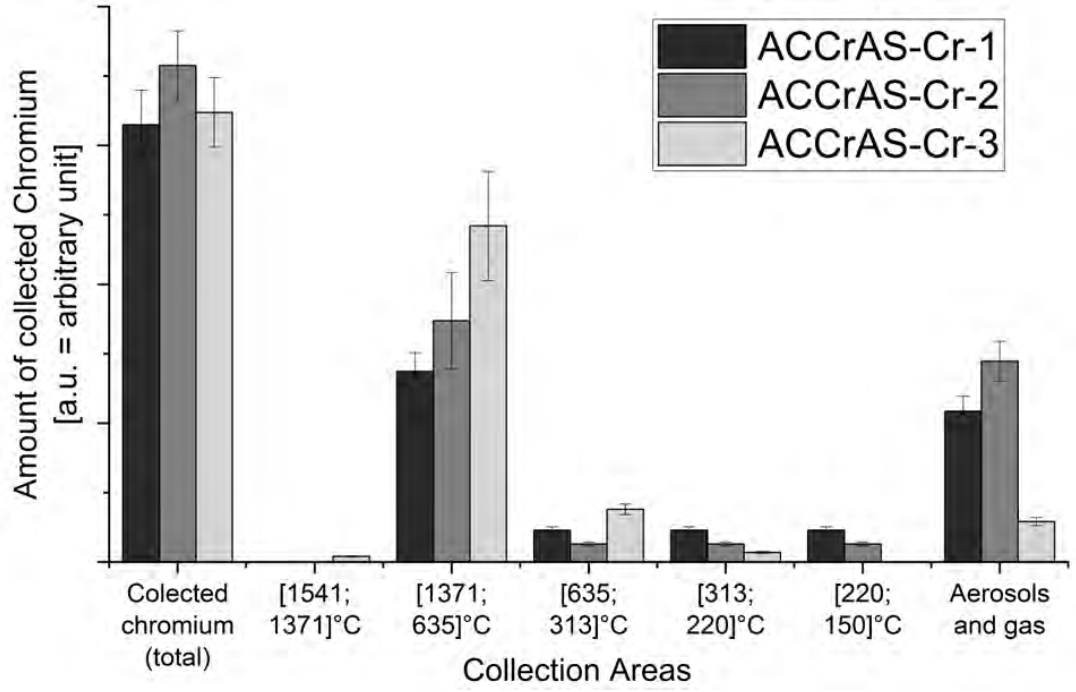

Figure 8 : Histogram showing the distribution of chromium in the ACCrAS-Cr-(1 to 3) tests. Chromium vaporization for 4 hours at 1550°C under 80% water vapor and 20% air. The y-axis shows the proportion of chromium recovered as a function of vaporized chromium amount during the test.

The fractions of chromium vaporized during these tests ranged from 15 to 20 %. The lower chromium vaporization level observed in the ACCrAS-Cr-(1 and 3) tests can be attributed to the shorter exposure to a steam-containing atmosphere during these tests. The most reliable value is that of the ACCrAS-Cr-2 test, since there were no malfunctions affecting the atmosphere during this test.

The chromium mass balance (first column in Figure 8) was calculated as the ratio between the mass of chromium collected and the mass loss of the Cr_2O_3 precursor from the crucible. The mass balance in these tests ranges from 60 to 70%, which is perfectible. Unrecovered fractions are attributed to the underestimation of the deposits with the experimental matrix in ICP-OES. Especially in the ACCrAS-Cr-3 test, despite its much more intense yellowish color, the mass of chromium measured on the filter of the main line of this test (2.4 µg Cr) is as low as that of the filter of the bypass line of the ACCrAS-Cr-2 test (2.6 µg Cr).

The amount of chromium deposited is between 60 and 65% of the mass vaporized during the ACCrAS-Cr-(1 and 2) tests. The green deposits were identified as Cr(III) species by Raman spectroscopy, XPS and XRD. The amount of chromium transported downstream of the bench therefore represents between 35 and 40% of that collected in these first two tests and are identified as Cr(VI) species.

These deposits on the filters appear to be Cr^{VI} aerosols, as they are both yellowish and highly soluble in nitric acid (0.7%). Unfortunately, the presence of Cr(VI) species could not be confirmed by UV-Visible

spectroscopy since these species appear to be unstable over time in nitric acid solution. The main hypothesis is the possible reduction of Cr^{VI} in nitric solution.

The amount of chromium dissolved in the bubblers is minor (< 10%) compared to that present on the filters in the ACCrAS-Cr-3 test. It is therefore possible to assume that chromium is mainly transported downstream of the bench as aerosols. The ACCrAS-Cr-2 test is used to determine the kinetics of chromium transported (aerosols + gas) to the downstream bubbler. In the first approach, chromium transport kinetic can be interpolated by a linear model (Figure 9) with a delay of approximately 40 minutes.

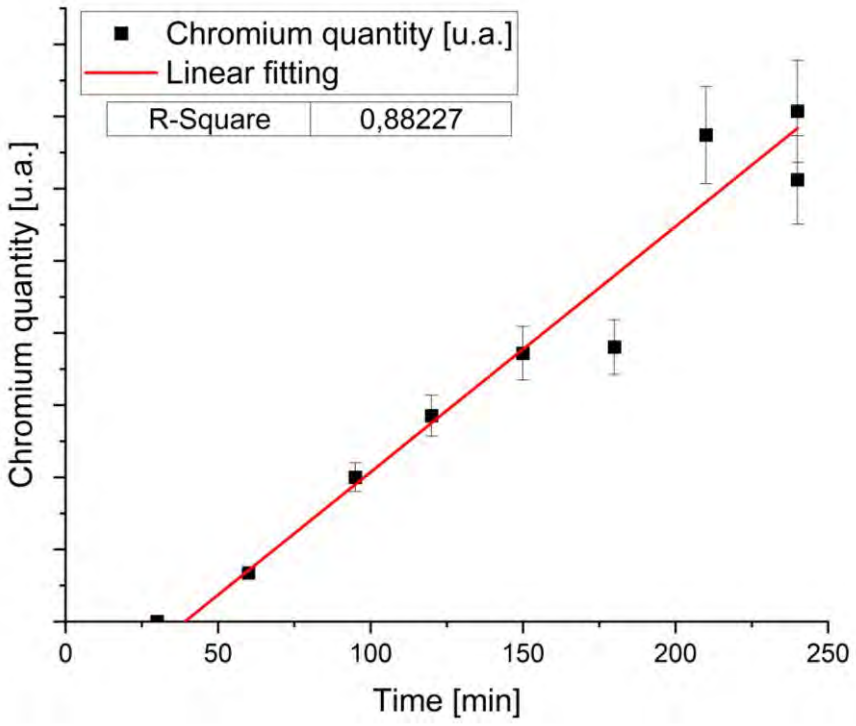

Figure 9 : Transport kinetics of chromium in terms of mass [µmol] as a function of time [minutes] from the start of the step at 1550°C during the ACCrAS-Cr-2 test.

The transport delay cannot be explained by the residence time (16 seconds) of the carrier gas down to the bubbler. Additional measurements should be performed at the early stage of chromium vaporization to enable further investigation. However, the most plausible explanation is that transport is initially limited due to preferential condensation on the bare surface but becomes more favorable in a second stage once chromium-containing sites are present.

4. Modeling results

SOPHAEROS model was used to simulate the distribution of different chromium species in gaseous, condensed, and sorbed phases in the ACCrAS experimental bench. It is then possible to compare the simulation results with the experimental tests based on the following information: i) the mass of vaporized chromium (III) oxide; ii) the mass distribution and speciation of deposited chromium as a function of temperature; iii) the quantity and oxidation state of chromium transported in aerosol form trapped on the filter; iv) As well as the amount and oxidation state of gaseous chromium transported and solubilized in the bubbler.

The input parameters of the experiment described in the code are as follows: 4-hour step at 1550°C with $Q(O_2)$ = 0.02 $NL.min^{-1}$, $Q(N_2)$ = 0.08 $NL.min^{-1}$ and $Q(H_2O)$ = 20 $g.h^{-1}$ under a pressure of 1 atm with initially 20 mg of $Cr_2O_{3(s)}$. To enable comparison between SOPHAEROS outputs and the experimental results, the powder specific surface area was adjusted in the simulation. The experimentally measured mass of vaporized chromium was then used as a reference.

The gaseous chromium simulation shows that $Cr^{III}_2O_{3(s)}$ vaporizes mainly into $Cr^{VI}O_{3(g)}$ and in a less extent $Cr^{IV}O_{2(g)}$, which quickly reach kinetic equilibrium with $Cr^{V}HO_3(g)$. From t = 5 seconds, and at around 770°C (20 cm), the formation of $Cr^{VI}H_2O_{4(g)}$ is calculated coming mainly from $Cr^{VI}O_{3(g)}$ as well as the formation of $Cr^{III}H_3O_{3(g)}$ from $Cr^{V}HO_{3(g)}$. A steady state appears to be reached as early as t = 75 seconds. Simulations (Figure 10) predict the deposition of $Cr^{III}_2O_{3(s)}$ at high temperatures between 875 and 1395°C (10.4 and 18.8 cm). This $Cr^{III}_2O_{3(s)}$ deposit represents 7% of the vaporized chromium. The chromium is transported downstream of the circuit mainly in the form of $Cr^{VI}H_2O_4(g)$ and $Cr^{III}H_3O_3(g)$ in low fraction. Adsorption (sorbed phase) of chromium at low temperature is also simulated.

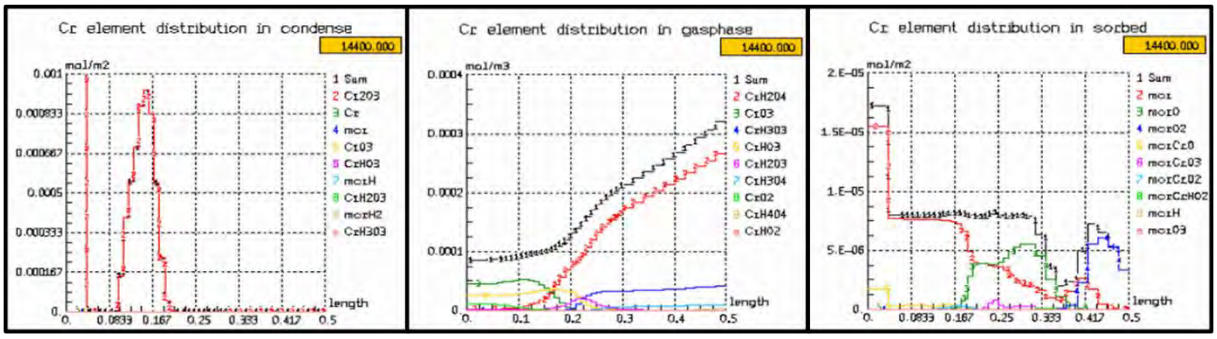

Figure 10 : SOPHAEROS simulation of chromium distribution (mol/m³ in volume or mol/m² on surfaces) at t_{final} = 4 h as a function of distance from the center of the furnace. Left) condensed phase; center) gas phase; right) sorbed surface states.

At 1550 °C, gaseous chromium species (Figure 10) are predominantly $CrO_{3(g)}$ (55 mol%), followed by $CrHO_{3(g)}$ (31 mol%) and $CrO_{2(g)}$ (14 mol%). Numerous reactional pathways lead to the deposition of $Cr_2O_{3(s)}$. The major part (> 99%) of these pathways involves reactions with $CrO_{3(g)}$ and $CrO_{2(g)}$.

Simulations show that $CrH_2O_{4(g)}$ comes from the decomposition of $CrO_{3(g)}$ and $CrHO_{3(g)}$ at high temperature. $CrH_2O_{4(g)}$ would then mainly come from the intermediate hydroxides $CrH_4O_{4(g)}$ and $CrH_4O_{5(g)}$ at low temperature. $CrHO_{3(g)}$ also leads to the formation of $CrH_3O_{3(g)}$ under 635°C.

5. Discussion

Despite the experimental difficulties encountered (loss of integrity of the downstream filter and the instability of Cr(VI) in solution), these experiments show good reproducibility in terms of chromium vaporized, deposited, and transported. The results of these experiments can then be compared with the SOPHAEROS modeling in Table II.

Table II : Comparative table between ACCrAS experiments and SOPHAEROS modeling. Chromium deposition and transport in a gradient temperature from 1550°C and 150°C after the vaporization of $Cr_2O_{3(s)}$ at 1550°C in an atmosphere composed of water (0.4 NL.min⁻¹) and air (0.1 NL.min⁻¹).

Areas of interest	ACCrAS experimental results	SOPHAEROS simulations
"High temperature" deposits	$Cr_2O_{3(s)}$ – [770 ; 1015]°C	$Cr_2O_{3(s)}$ – [875 ; 1395]°C strongly underestimated
"Low temperature" deposits	$Cr^{III}H_3O_{3(s)}$? - < 635°C	Condensation not calculated (surface adsorption observed)
Gas and Aerosols transported (150°C)	Cr^{VI} (Mainly aerosols)	$Cr^{VI}H_2O_{4(g)}$ + $Cr^{III}H_3O_{3(g)}$ strongly over estimated

This comparison shows similarities in position (+/- 5 cm) of high-temperature chromium deposits (> 635°C), as well as the transport of chromium (+VI) downstream of the bench. However, the fraction of chromium deposited is significantly underestimated by the model, even though the chemical form (Cr_2O_3) is similar.

Low-temperature deposits (< 635°C) are observable in experiments but are not predicted by the simulations. Raman analyses currently being processed suggest that these deposits may be amorphous chromium (III) hydroxide (CrH_3O_3). Deposition of chromium (III) hydroxide cannot be modeled because this species is not currently referenced in the SOPHAEROS thermodynamic databases in either crystalline or amorphous form. This may explain the discrepancy between modelling and experiments.

The proportion of gas and aerosols transported downstream of the bench is overestimated in the modeling compared to the experiments. Nevertheless, modelling predicts Cr transport in the Cr(VI) form ($CrH_2O_{4(g)}$) consistently with Cr(VI) mainly found at the experimental line outlet (very soluble and yellow aerosols).

Efforts must therefore be made in both experiments and modeling concerning the vaporization of chromium alone. The prospects for experimental improvements are to refine the thermal profile of the deposits using narrower parts and to verify the chemical structure of the deposits at low temperatures. The future works for computational improvements would then be: i) the addition of aerosol formation simulation; ii) the addition of thermodynamic data associated with the crystalline and amorphous states of $Cr(OH)_3$; iii) and the addition of condensation reactions with other solid species.

6. Conclusion

The results of experimental tests show that chromium (III) oxide vaporizes significantly at 1550°C in an atmosphere containing water vapor (0.4 $NL.min^{-1}$) and air (0.1 $NL.min^{-1}$). The vaporization rate of chromium under these conditions is around 800 $\mu g.h^{-1}$. Chromium vaporization in a pure argon atmosphere is three orders of magnitude lower than in an atmosphere containing water vapor.

Chromium deposition in the thermal gradient (1550-150°C) is reproducible in the tests conducted under these conditions. According to the experiments, most of the vaporized chromium is condensed in the form of $Cr_2O_{3(s)}$ between 770 and 1015°C on an yttria-stabilized zirconia surface. According to the modeling, only 7% of the vaporized chromium would be condensed in the form of chromium (III) oxide between 875 and 1395°C. Most of this $Cr_2O_{3(s)}$ deposit would result from reactions involving $CrO_{2(g)}$ and $CrO_{3(g)}$. According to experiments, chromium is then transported downstream of the bench at 150°C in the form of aerosols of Cr^{VI}, representing almost 40% of the amount of vaporized chromium. A linear kinetics of Cr^{VI} transport downstream is measured after a delay of several dozen minutes.

According to the model, 93% of the vaporized chromium is transported in the form of $Cr^{VI}O_2(OH)_{2(g)}$ (majority) and $Cr^{III}H_3O_{3(g)}$ (minority). The transported chromium $Cr^{VI}O_2(OH)_{2(g)}$ would come from the decomposition of $CrO_{3(g)}$ and $CrHO_{3(g)}$ at high temperature, then would mainly come from the intermediates $CrH_4O_{4(g)}$ and $CrH_4O_{5(g)}$ at low temperature. The transported chromium (III) hydroxide $CrH_3O_{3(g)}$ is thought to originate mainly from the decomposition of $CrHO_{3(g)}$ at high temperatures.

The modeling can be improved given the differences in transport/deposit proportions observed with experiments. However, the results are generally consistent regarding the species deposited and formed.

Tests on the vaporization of chromium in interaction with Cs and Mo fission products were also carried out later on in atmospheres composed of water vapor with argon or air.

ABSTRACT

Interfacial gas mass transfer in two-phase gas-liquid flows plays a key role in the retention of radioactive gases in pool scrubbing. A comparative fundamental analysis is provided between high-resolution measurements with a Wire-mesh sensor and a Volume-of-Fluids Direct Numerical Simulation code for gas-liquid water co-current upward bubbly flow at atmospheric conditions with CO_2 injection as a gas simulant. The Wire-mesh sensor measurements provide 2D plane time-resolved visualizations and quantitative data on the void fraction and dissolved CO_2 concentration. The computational simulations include an irregular stencil formulation at the interface to compute the mass transfer. There is a good correlation between experiments and simulations in the evolution of the hydrodynamics and mass transfer in terms of the axial rising distance and gas flow rate. Discrepancies are observed in the bubble fragmentation due to unresolved interaction between the gas-liquid interface and turbulence in the simulations. The non-instantaneous dissociation of the dissolved CO_2 introduces a time delay in the experimental evaluation of the mass transfer. Such comparative studies among experimental and computational methods provide a valuable assessment of the capabilities of the state-of-the-art techniques and contribute to an improved understanding and further optimization of gas-liquid flow nuclear safety systems.

1. INTRODUCTION

In a severe accident scenario in a nuclear power plant light-water reactor with core degradation, pool scrubbing is an essential process, among other retention strategies, to capture harmful radioactive particles and gaseous species [1]. Modelling and evaluation of pool scrubbing is performed analytically with the use of well-established lumped parameter codes such as SPARC-90 [2] and BUSCA [3] whose development and validation have been based on integral tests of radioactive species retention [4]. With the continuous development of computational capabilities, in addition to the existing lumped parameter codes, advanced analytical methods such as Computational Fluid Dynamics (CFD) have been acknowledged to play a more relevant role in the nuclear safety domain [5]. In the context of pool scrubbing, CFD activities have been developed in the IPRESCA [6] project to assess its use in the simulation of two-phase gas-liquid flows in reactor systems. Namely, the first attempts have performed code-to-code comparison of flow bubble hydrodynamics in low-momentum flows [7]. Volume-of-Fluids (VOF) [8] and Euler-Euler [9] methods have been used to reproduce higher gas injection flows in the liquid pool experiments from [10]. As pointed out in [8], variables such as time-averaged void fraction or gas velocity are available in the current experiments and can be captured with the current CFD methods. However, there is a larger uncertainty in pool scrubbing-related computational studies for evaluating local quantities, such as bubble sizes, shapes, or interfacial area density, for which more recent studies have performed dedicated investigations [11], [12]. These are fundamental to extending the use and validation of CFD codes for computing the end goal transport of species, whether particles or gases, through the gas-liquid interface.

This study aims to support the analysis of gas mass transfer in gas-liquid flows and the extension of CFD codes to more complex flow applications, such as chemical reactors or pool scrubbing processes, by a comparative analysis of high-resolution experiments and simulations of a dissolvable gas (CO_2)-liquid co-current upward bubbly flow under atmospheric conditions. The experimental data is obtained with a Wire-mesh sensor (WMS) based technique developed in [13] from which the hydrodynamics and mass transfer via the void fraction and concentration field of the dissolved gas can be fully resolved. Additionally, a quantitative evaluation of the bubble size, velocity, interfacial area density, and mass transfer fluxes is also provided. From the computational simulations side, the in-house DNS code PSI-BOIL [14] is employed to compute the gas-liquid co-current upward bubbly flow with mass transfer. This CFD code is based on a VOF method to capture the gas-liquid interface and uses the sharp-interface phase-change approach to compute the mass transfer. It has been recently adapted for the single bubble mass transfer of CO_2 [15]. During the experiments, HSC imaging will be used to provide additional qualitative information and validation on the gas-liquid flow dynamics.

This research is conceived as an evaluation study in which both WMS and CFD results will be compared at the same relevant flow scales and variables. The ultimate goal is to assess the current capabilities of two state-of-the-art experimental and computational techniques under non-ideal flow conditions and to provide further guidance for improving and extending the applications of these methods to flows of industrial interest, such as pool scrubbing.

2. INSTRUMENTATION AND METHODS

2.1. Experimental and computational models

The WMS measurements were presented in a previous study by the author's [13] whose simplified description, in consideration of the follow-up CFD parametric model, is included here. The experiments were conducted in a $l_{ch} = 50\,mm$ square cross-section, upward gas-liquid co-current flow channel at the ARAGO facility of the Paul Scherrer Institute (**Figure 1a**). The gas flow Q_g of 100% CO_2 was injected upwards via a $d_{inj} = 6\,mm$ inner and $d_{inj,out} = 8\,mm$ outer diameter orifice at an adjustable distance h from 42 to $540\,mm$ (every $50\,mm$) to the WMS measurement plane. Three gas flow rates were used,

leading to the following gas superficial velocities $j_g = 0.4 \cdot 10^{-2}, 1.4 \cdot 10^{-2}$, and $5.7 \cdot 10^{-2}\ m/s \pm 1\ \%$. The liquid flow to compensate for the WMS grid intrusiveness on the bubble gas motion was set to Q_l with a corresponding associated liquid superficial velocity $j_l = 0.39\ m/s \pm 5\ \%$. The three-layer WMS was installed at $M1$ and $M2$ axial locations, and results of the combination of two measurement planes, i.e., *Receiver 1-Transmitter* and *Receiver 2-Transmitter* with an axial resolution or pitch of $\Delta z = 1\ mm$. The radial pitch or distance between neighboring $0.05\ mm$ diameter wires in the measurement plane is $\Delta x = \Delta y = 1\ mm$, with an acquisition frequency of $f = 3200\ Hz$. Each experimental point has a measurement time of $t_{meas,WMS} = 10\ s$ which is repeated three times. The uncertainty in the WMS results indicates the standard deviation $\pm\sigma$ between test repetitions.

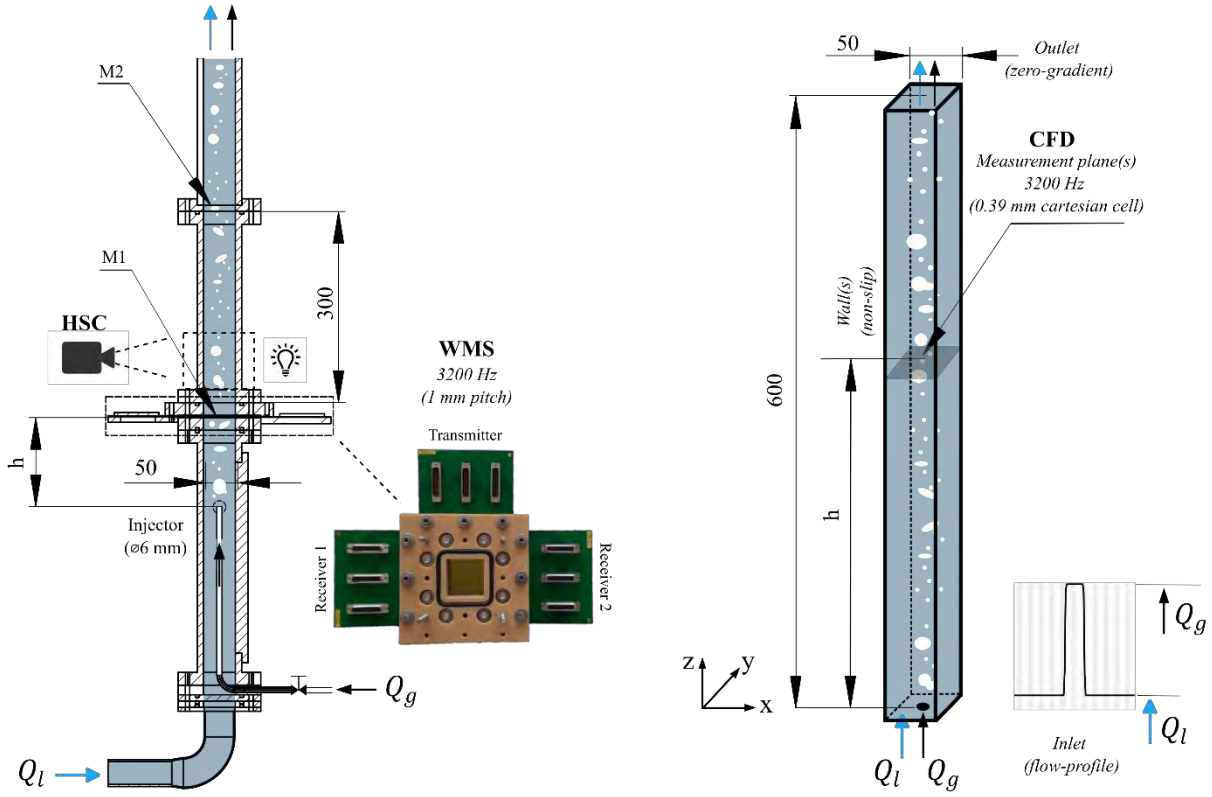

Figure 1. Scheme of the ARAGO set-up for the WMS and HSC experiments (a), and computational domain used for the CFD simulations (b).

The CFD model employed in the gas-liquid upward co-current flow mass transfer is a 3D DNS simulation with a Finite Volume Method (FVM) discretization, which uses the Volume-of-Fluids (VOF) approach to solve for the gas-liquid interface, and a sharp-interface phase-change model to account for the mass transfer of dissolved species at the interface. The models are integrated into the in-house open-source CFD code PSI-BOIL [14] and have been modified and applied by the authors to the modelling of the absorption of gas bubbles in a liquid [15]. The inlet velocity condition is a flat profile as a function of the flow rates Q_g (at the injector) and Q_l (in the liquid bulk) with a smooth transition between both regions (**Figure 1b**). The validity of such an imposed and assumed profile to capture the experimentally measured bubble formation and initial size distribution is discussed in the following Section 3.1. The computational domain of the gas-liquid mass transfer experiments in the column (**Figure 1b**) is discretized using a Cartesian mesh of resolution $\Delta x_{CFD} = 0.39\ mm$ in a cross-sectional size 50 x 50 mm (128 x 128 cells) with a total height of $H = 600\ mm$ (1536 cells) leading to a total number of $25 \cdot 10^6$ cells. The used spatial resolution is largely

limited by the computational cost of the simulations, which is 34 days at $j_g = 5.7 \cdot 10^{-2}\ m/s$ using 128 cores in the Merlin 6 cluster at the Paul Scherrer Institute, and it is acknowledged to be a relevant limitation of the CFD results. The effects of the mesh resolution in the CFD results for the different gas injection conditions are discussed in the following Section 3. For the sake of comparison with the WMS measurements, a series of axial planes are located at a distance h where the void fraction ε, the dissolved CO_2 concentration c_l, and the axial velocity w are recorded with a frequency f. The simulations were conducted for $t = 2.0\ s$ of physical time where only the range $t_{meas,CFD} = [1.0, 2.0]\ s$, under assumed steady-state conditions, is used for comparison with the WMS results.

2.2 Data post-processing methods

The development of the WMS for the study of gas-liquid flows in the last couple of decades has led to a wide set of methods and validation studies from which systematic review of the methodology can be found in [16]. The goal of the present study is not the further development of WMS post-processing techniques, but rather to provide a common framework for analyzing WMS and CFD data based on the author's previous work and methodologies for interfacial mass transfer in gas-liquid flows [13]. In this regard, and for the sake of the reader's understanding, the basis of the WMS and CFD post-processing framework are briefly described below.

The raw data WMS measurements of conductivity $u_{i,j,k}$ at the crossing point $[i, j]$, at location $[x, y]$ in the measurement plane, for the frame $[k]$ are calibrated to obtain the void fraction $\varepsilon_{i,j,k}$ and the concentration of dissolved CO_2 in the liquid $c_{l_{i.j.k}}$. For the void fraction $\varepsilon_{i,j,k}$, the so-called Maxwell expression is used in the regions where the gas is present, i.e., the normalized conductivity with respect to the single-liquid phase $g_{i,j,k} < 1.0$. In the liquid phase, i.e., wherever $g_{i,j,k} \geq 1.0$, the concentration $c_{l_{i.j.k}}$ is calculated [13]. For the CFD, the recorded void fraction at the grid nodes of the measurement planes $\varepsilon_{i,j,k}$ is a direct result; thus, no further processing is required. The liquid region where the CFD values of $c_{l_{i.j.k}}$ are calculated is defined as $\varepsilon_{i,j,k} < 0.5$. Respectively, for the gas region $\varepsilon_{i,j,k} \geq 0.5$. The three-layer WMS data of the void fraction and dissolved CO_2 in the liquid can be used to compute the average axial velocity of the gas $\langle w_g \rangle_{i,j}$ and liquid $\langle w_l \rangle_{i,j}$ phase respectively. This operation is performed through cross-correlation of the bottom and top WMS transmitter-receiver pairs planes, where a specific time delay, for a fixed known distance, is observed between the measurements [17]. Together with the time-averaged values of $\langle \varepsilon \rangle_{i,j}$ and $\langle c_l \rangle_{i.j}$, it is possible to estimate the time-averaged mass flux of dissolved species $\langle \dot{m}_l \rangle_{i,j}$ through the WMS plane:

$$\langle \dot{m}_l \rangle_{i,j} \cong \langle w_l \rangle_{i,j} \langle c_l \rangle_{i.j} (1 - \langle \varepsilon \rangle_{i,j}) \tag{1}$$

A similar operation can be performed with the CFD results, but in this case, both fluxes can be calculated instantaneously, as the axial velocity $w_{i,j,k}$ is resolved in time, and no prior time-averaging is required, so that:

$$\dot{m}_{l_{i,j,k}} = w_{i,j,k} c_{l_{i.j.k}} \tag{2}$$

A posteriori time-averaging is possible for (2), to obtain $\langle \dot{m}_l \rangle_{i,j}$, and evaluate the validity of the formulation used in (1). By integration on the cross-section of the total mass flux of dissolved species, $\langle \dot{M}_l \rangle$ can be obtained. The associated interfacial area density $a_{g_{i,j,k}}$ can be approximated from the norm of the gradient of the void fraction as formulated by [18]. Finally, both for the WMS and CFD data, the bubble sizes are characterized by identifying interconnected volumes where $\varepsilon_{i,j,k} \geq \varepsilon_{th} = 0.1$, and using the bubble velocity W_b as the average of the measured gas velocities w_g inside each identified bubble.

3. RESULTS AND DISCUSSION

3.1. Flow hydrodynamics

The flow hydrodynamics of the co-current gas-liquid flow in the column ranges from single individual ellipsoid bubbles rising at the channel center at $j_g = 0.4 \cdot 10^{-2}\ m/s$ to a complex heterogeneous distribution of bubble sizes covering the entire cross-section for $j_g = 5.7 \cdot 10^{-2}\ m/s$ (**Figure 2**).

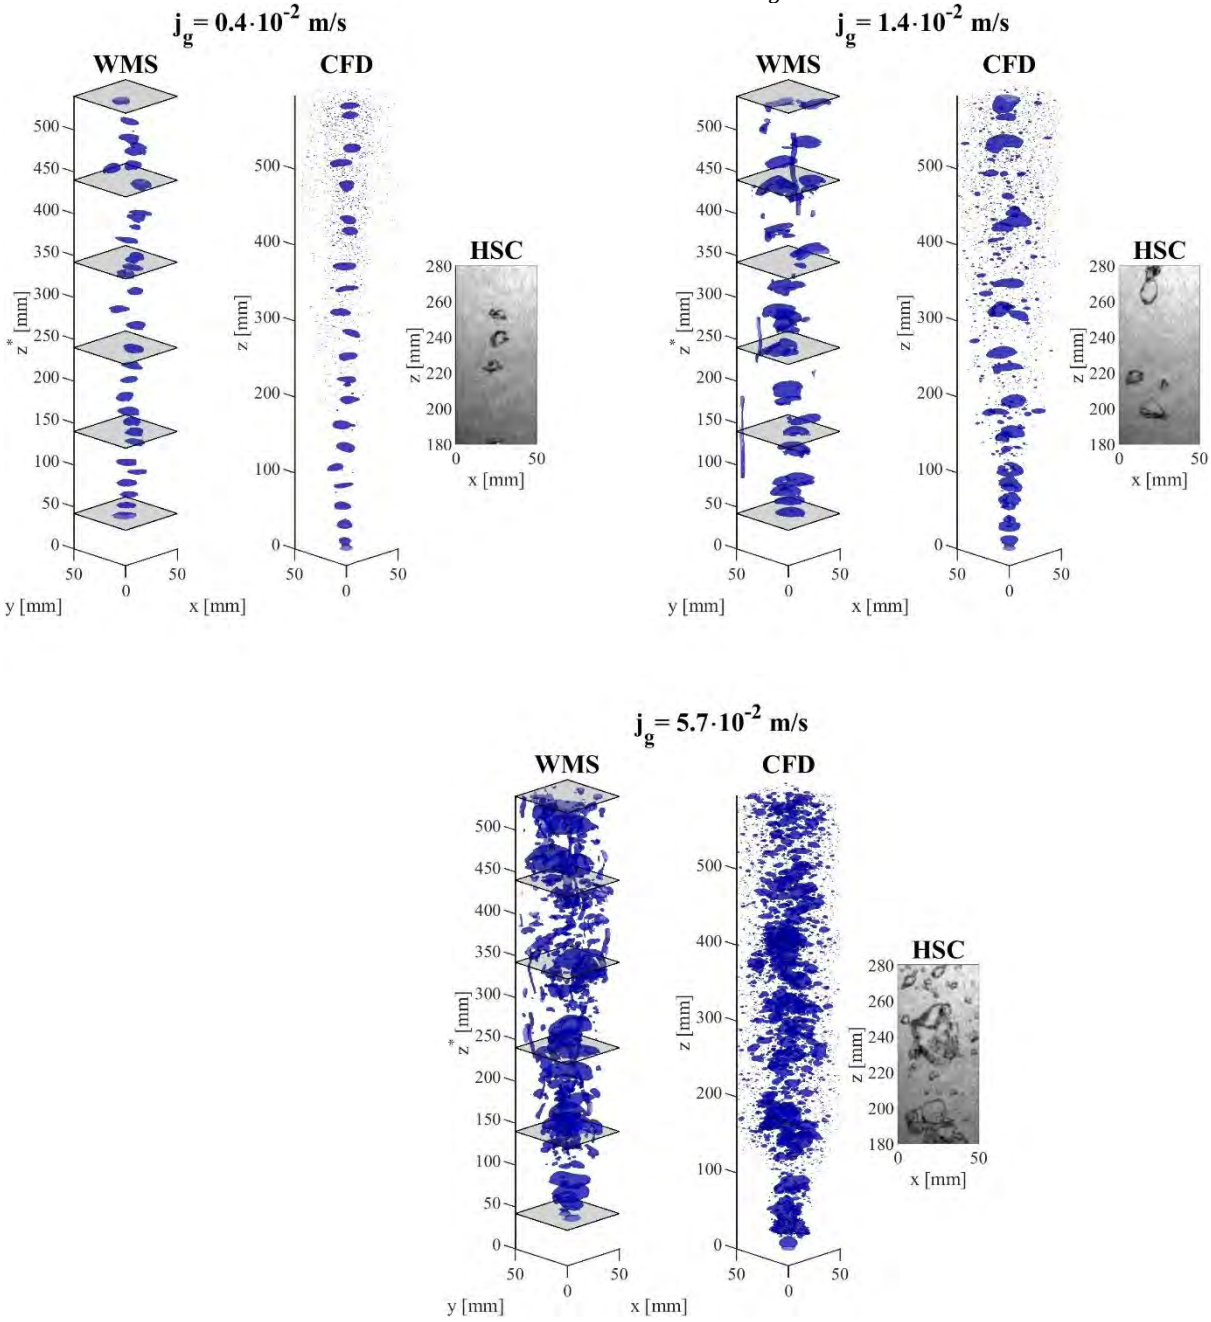

Figure 2. Void fraction contours at $\varepsilon = 0.1$ for the CFD and WMS for different gas superficial velocities j_g, where the WMS data is reconstructed from the plane measurements (gray planes) at $h = 42, 140, 240, 342, 440$ and $540\ mm$, and the vertical axis is converted from WMS time frames k to distance z^* using the average gas velocity W_g. The HSC shows the side imaging of the flow for the window $h = [180, 280]\ mm$.

In terms of the axial evolution from the injection to the top of the column, the bubble rising process is characterized by a radial dispersion of the gas flow and an enhanced interaction between neighboring bubbles. This interaction leads to the formation of larger caps or slugs, as well as the fragmentation into smaller spherical bubbles, which spreads the initial monodisperse bubble size into a broader and polydisperse distribution. As pointed out in the previous study by the authors [13], such dispersion and bubble interaction behavior is enhanced with the increase in the gas superficial velocity. It is also associated with higher turbulence, mixing levels, and shorter rising lengths from the initial injection to the fully developed gas-liquid flow conditions [19]. From a qualitative point of view in **Figure 2**, the WMS and CFD results, as well as the HSC data in the measurement window in the vicinity of the injector, show the described and similar bubble shape, size, and axial evolution.

At the highest gas superficial velocity $j_g = 5.7 \cdot 10^{-2}\ m/s$, the CFD results show a clear overprediction of the bubble fragmentation and do not reproduce the presence of the large slugs, which are instead captured both by the WMS and HSC measurements. It is hypothesized that the overprediction of the CFD bubble fragmentation is due to the unresolved interaction between the gas-liquid interface and the turbulence levels at the current mesh resolution. The imposed velocity profile at the inlet boundary condition, instead of the simulation of the flow process with the injector walls, can also contribute to the earlier fragmentation of the globules at the largest gas flow injection velocity. The presence of this artifact is also visible in the CFD results in the form of small spherical bubbles detaching from the ellipsoids at $j_g = 0.4 \cdot 10^{-2}$ and $1.4 \cdot 10^{-2}\ m/s$. However, over-fragmentation becomes more critical with the increase in gas flow, and thus in turbulence, and on the finer mesh requirements to capture the entire spectrum of turbulent scales.

The intrusiveness of the WMS in terms of the bubble velocity and fragmentation is a known limitation [20] of this experimental technique. Near the mesh grid, bubbles not only decelerate due to the inertial, buoyant, and surface tension forces balance, but can also experience shape deformation. While similar bubble volumes are observed between the WMS and CFD results at $j_g = 1.4 \cdot 10^{-2}\ m/s$, in the case of the WMS data, the ellipsoids are flattened and show a larger major axis length.

The volumetric bubble size distribution provides a quantitative evaluation of the hydrodynamics of the gas-liquid co-current flow (**Figure 3**). At the injector's vicinity ($h = 42\ mm$), the monodisperse peak at $d_b \approx 9.0\ mm$ for $j_g = 0.4 \cdot 10^{-2}\ m/s$ and at $d_b \approx 12.0\ mm$ for $j_g = 1.4 \cdot 10^{-2}\ m/s$ are in good agreement between the WMS and CFD results. This shows that the computational model and the used Inlet boundary condition can adequately characterize the injection and bubble formation process. The wider dispersion and higher values of the right distribution tail (larger bubble sizes) for $j_g = 5.7 \cdot 10^{-2}\ m/s$ shows that over-fragmentation at the largest gas velocity is already a computational issue at the injection location. The results close to the injection show that the computational model and the used Inlet boundary condition can adequately characterize the injection and bubble formation process for gas velocities up to $j_g = 1.4 \cdot 10^{-2}\ m/s$, whereas over-fragmentation appears at the injector for larger gas flow rates and more turbulent flows. The increase in the average bubble volume and the spreading of the calculated size distribution with the rising distance ($h = 540\ mm$) are also well captured by the CFD. The most remarkable discrepancies appear, as expected, at the highest superficial velocity $j_g = 5.4 \cdot 10^{-2}\ m/s$ where the overestimation of the bubble breakup and fragmentation leads to the formation of a smaller bubble size tail in the distribution, evident at $h = 540\ mm$.

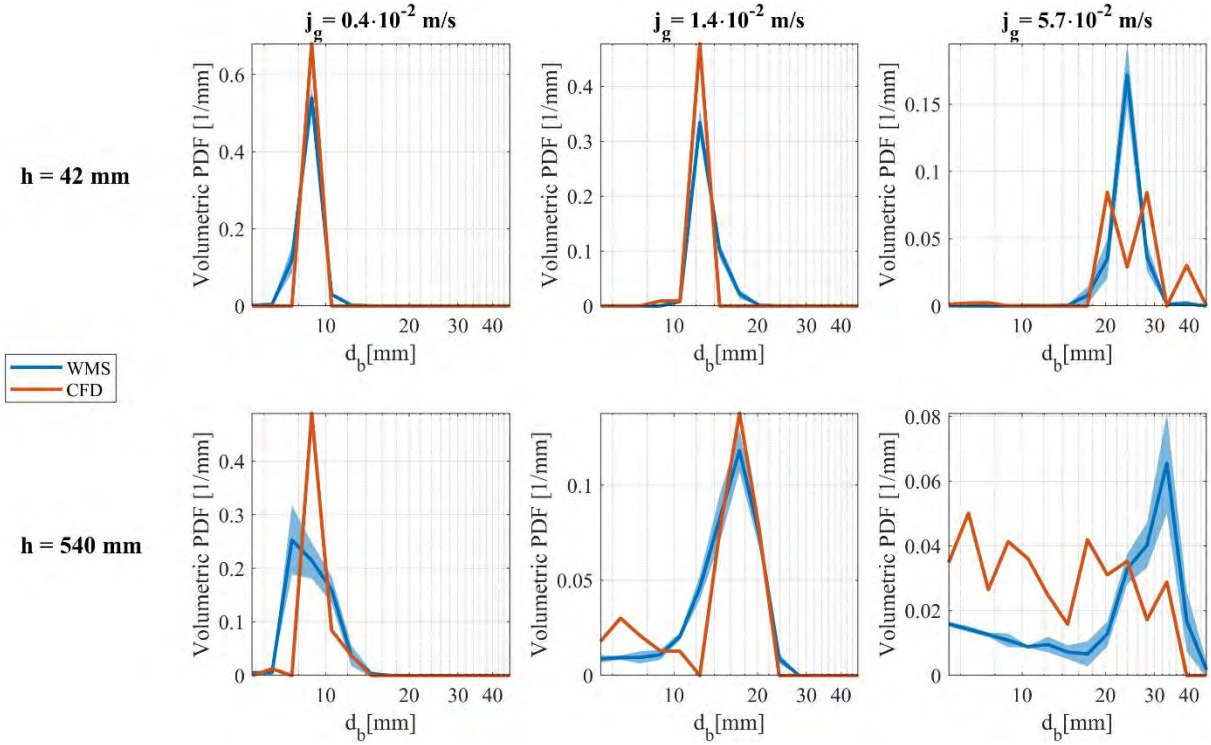

Figure 3. Volumetric Probability Density Function (PDF) of the bubble size d_b for the WMS and CFD as a function of the gas superficial velocity j_g, height $h = 42\ mm$ (top) and $h = 540\ mm$ (bottom). The *shaded* regions indicate the standard deviation $\pm\sigma$ between test repetitions.

In gas-liquid mass transfer processes, the liquid side mass transfer coefficient k_l and the interfacial area density a_g are the most relevant variables in the study of the mass transfer flux $\dot{m}_g$, whose standard formulation scales as $\dot{m}_g \propto k_l a_g$. According to the WMS results in **Figure 4**, for the gas superficial velocities $j_g = 0.4 \cdot 10^{-2}\ m/s$ and $j_g = 1.4 \cdot 10^{-2}\ m/s$, the integrated time-averaged value of the interfacial area density $\int \langle a_g \rangle dS_{ch}$ decreases in height. This is because of the observed coalescence in **Figure 3** which increases the average bubble volume and thus decreases the surface to volume ratio which scales as $\propto 1/d_b$.

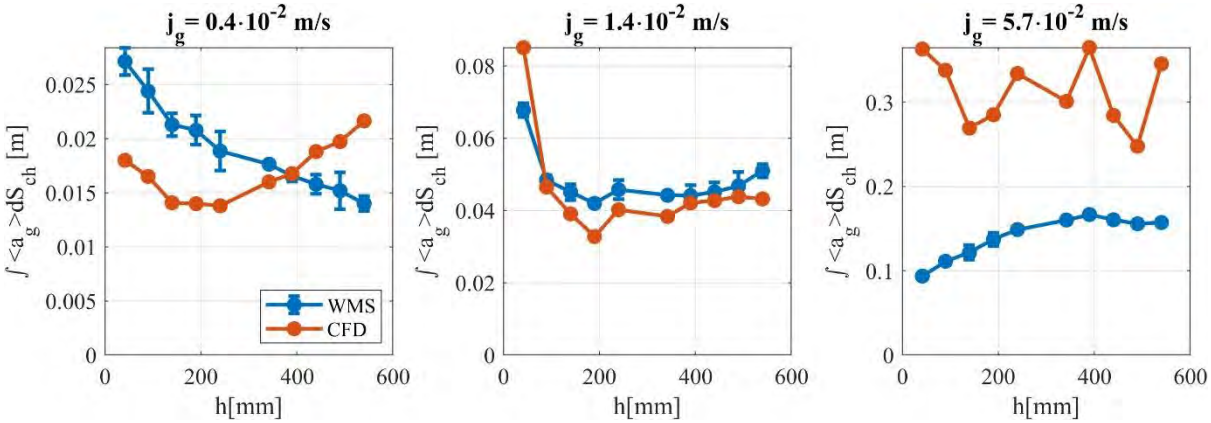

Figure 4. Integration of the time-average interfacial area density $\int \langle a_g \rangle dS_{ch}$ for the WMS and CFD as a function of the gas superficial velocity j_g and height h.

The CFD results in **Figure 4** effectively capture the mentioned evolution for $j_g = 1.4 \cdot 10^{-2}\ m/s$, while in the case of $j_g = 0.4 \cdot 10^{-2}\ m/s$, the increase of the predicted bubble fragmentation in height leads to a simultaneous increase in the interfacial area density, which is not observed in the experiments. As expected, the most significant discrepancy appears at $j_g = 5.7 \cdot 10^{-2}\ m/s$ where the over-fragmentation of bubbles in the CFD results due to the increase of turbulence levels leads to a value of the interfacial surface that doubles the value of the WMS measurements. The observed WMS and CFD differences in the interfacial area density are not the only, but one of the main reasons for subsequent discrepancies in the total mass transferred between the phases. The lack of extensive statistical data, i.e., physical simulation time under steady-state conditions, in the CFD results also leads to some oscillations of the interfacial area density values at the highest gas flow conditions of $j_g = 5.7 \cdot 10^{-2}\ m/s$.

3.2. Interfacial mass transfer

The flow hydrodynamics and mass concentration in the liquid field in **Figure 5** is based on the reconstructed plane results from the WMS and the fully resolved CFD. This visualization provides a comparison between experiments and simulations on the same scale for an entire complex flow process. In line with the aims of this work, it provides a more detailed insight into the mesoscale flow characteristics and CFD model validation. Both for the WMS and CFD results, the rising of the bubbles in the column leads to a cumulative increase in the dissolved concentration c_l in the liquid bulk. The mass transfer at the gas-liquid interface is governed, at these gas-liquid turbulent flow conditions (liquid flow associated Reynolds $Re_l \approx 10^4$) by the unsteady eddy renewal of the thin concentration layer on the liquid side of the gas-liquid interface [21]. Downstream of each bubble, a recirculation or wake region forms, where the advected high-concentration volume of dissolved species accumulates. This is particularly visible at the near-injector region of the CFD results. As the gas flow develops in height and dispersion and turbulence levels increase, the turbulent diffusive transport between the downstream wakes and the liquid bulk is enhanced, leading to more vigorous mixing and a homogeneous increase in the overall concentration of dissolved species in the liquid phase.

From a qualitative point of view, there is an overall agreement between the WMS and CFD on the axial evolution and radial dispersion of the concentration in the liquid (**Figure 5**). Still, remarkably larger concentration gradients are reported close to the injector in the CFD results. Given the low associated rising time at these axial locations, it is suggested that the discrepancy originates from the presence of a non-negligible dissociation time of CO_2 in the water [22]. Therefore, a time or rising distance delay appears between the absorption of $CO_2(aq)$ as modeled by the CFD, and the signal conductivity from the ions HCO_3^- and H^+as measured by the WMS from the equilibrium reactions $CO_2(aq) + H_2O \rightleftarrows H_2CO_3 \rightleftarrows HCO_3^- + H^+$. The time delay possibly resulting from the kinetic limitations of dissociation of CO_2 in the water and CFD outlines the importance of considering chemical kinetics in mass transfer processes in gas-liquid non-ideal flows, where the targeted time scales can be within the range of absorption and dissociation chemical reactions.

The gas-liquid mass transfer can be quantitatively evaluated from the mass flux of dissolved species $\dot{m}_l$, respectively $\langle \dot{M}_l \rangle$ when integrated in the cross-section plane. The mass flux of dissolved species represents the total dissolved CO_2 transported by the liquid, and thus the cumulative amount of mass transferred from the gas to the liquid at a certain rising distance h (**Figure 6**). From the CFD results, both the approximation $\langle \dot{m}_l \rangle \cong \langle w \rangle \langle c_l \rangle (1 - \langle \varepsilon \rangle)$ in (1) and the time-averaging of the instantaneous mass flux $\langle \dot{m}_l \rangle = \langle w c_l \rangle$ in (2) can be computed. The agreement between the two approaches, as shown in **Figure 6**, proves the validity of the approximation (1) to evaluate the total mass transfer, and to compare the CFD and WMS data.

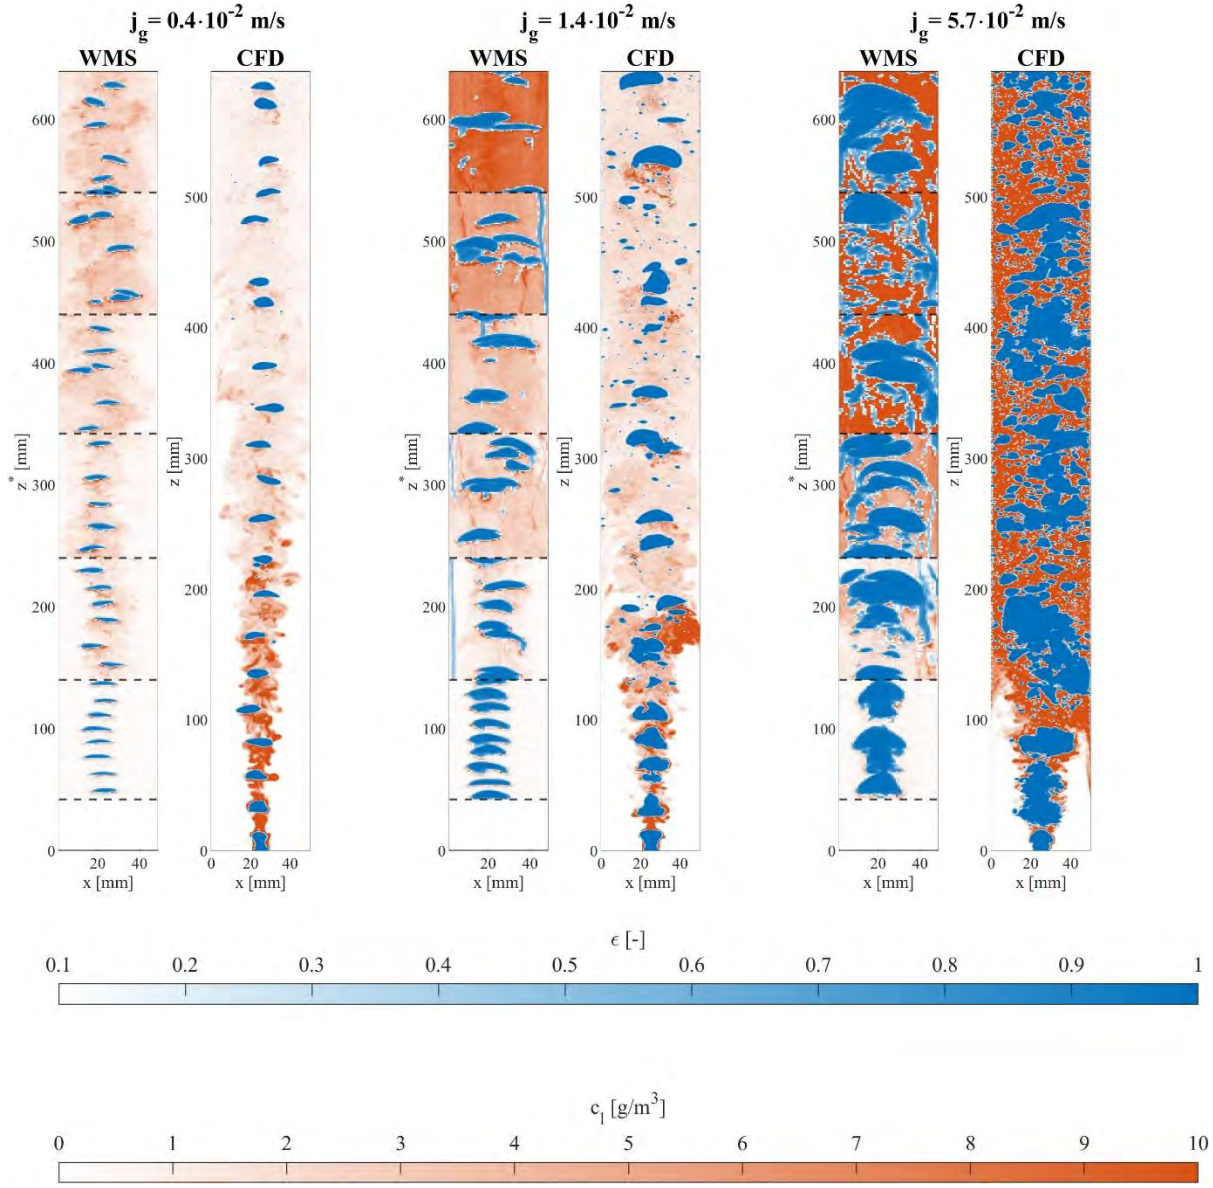

Figure 5. Concentration c_l and void fraction ε projection with threshold $\varepsilon_{th} = 0.1$ for the CFD and WMS for different gas superficial velocities j_g, where the WMS data is reconstructed from the plane measurements (dashed lines --) at $h = 42,\ 140, 240, 342, 440$ and $540\ mm$, and the vertical axis is converted from WMS time frames k to distance z^* using the average gas velocity W_g.

At the lowest and intermediate superficial velocities $j_g = 0.4 \cdot 10^{-2}\ m/s$ and $j_g = 1.4 \cdot 10^{-2}\ m/s$, the experimental and computational results show a similar evolution of the mass transfer flux in the studied height range of the column. This agreement is concurrent with the captured evolution of the interfacial area density, as shown in **Figure 4**. The underestimation of the expected high concentration gradients by the WMS close to the injector is reflected in **Figure 6** as a lower measured mass transfer by the WMS when $h < 240\ mm$. As the transferred and dissolved CO_2 dissociates into ions with the rising distance h, the concentration measured by the WMS increases, and thus the measured mass flux of dissolved species increases. At the highest measurement points, namely $h > 390\ mm$, the trend is inverted, and the CFD underestimates the mass transfer compared to the WMS results.

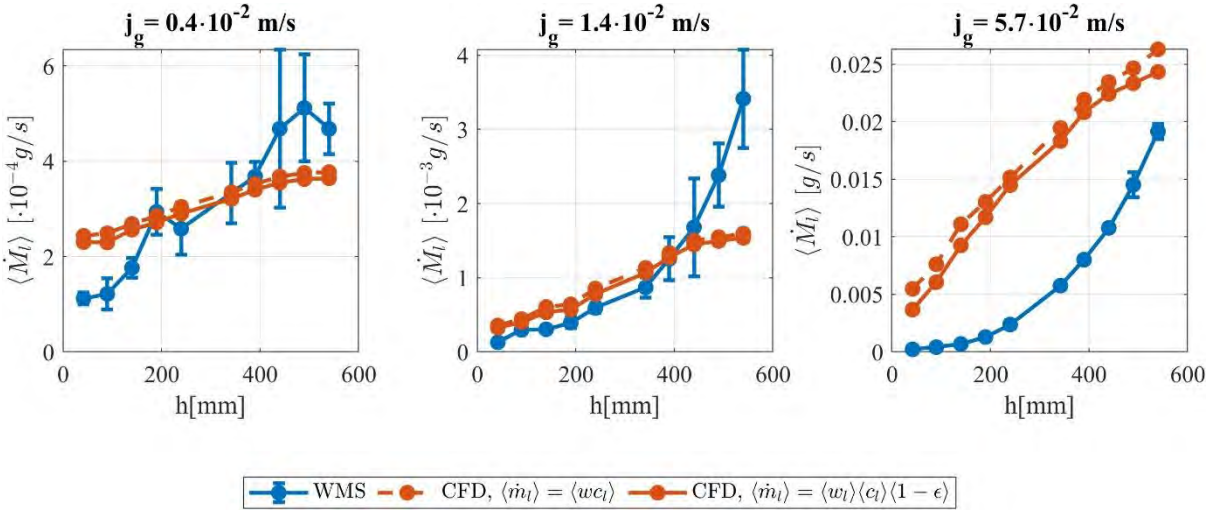

Figure 6. Total time-averaged mass flux of dissolved species $\langle \dot{M}_l \rangle$ for the WMS and CFD as a function of the gas superficial velocity j_g and height h.

In the current CFD model [15], the interfacial mass transfer, being computed as the gradient of the concentration in the liquid phase normal $\vec{n}$ to the gas-liquid surface $\dot{m}_g \propto D(\nabla c_l) \cdot \vec{n}$, is underestimated for coarse mesh sizes, as the resolution $\Delta x_{CFD} = 0.39\, mm$ is used in the current simulations. A convergence study of the model for a single bubble case [15] has reported that the mass transfer results do not lie in the convergence asymptotic regime for the current resolution, with a larger discrepancy in the mass transfer coefficient. In contrast, in our more practical application in this study, a reasonable agreement is found at the superficial velocities $j_g = 0.4 \cdot 10^{-2}\, m/s$ and $j_g = 1.4 \cdot 10^{-2}\, m/s$. While a further refinement and convergence analysis might be desirable, at the current computational cost, this is not feasible, and such systematic bias in the evaluation of the concentration gradient must be acknowledged.

For the largest superficial velocity of $j_g = 5.7 \cdot 10^{-2}\, m/s$, the discrepancy between the experimental and simulation results is primarily dominated by the previously discussed significant overestimation of the interfacial area density. The larger turbulence levels at these conditions lead to a wider range of turbulent scales to solve, and the finer mesh requirements not being fulfilled result in a more significant impact of the unresolved gas-liquid stresses at the interface, thus bubble fragmentation, interfacial area density overestimation, and the resulting mass transfer are also not being properly reproduced.

4. CONCLUSIONS

A fundamental comparative study of mass transfer in gas-liquid flows with a high-resolution WMS and the DNS CFD code PSI-BOIL for gas-liquid flows has been performed in this study. The primary objective was to cross-evaluate the current capabilities of state-of-the-art experimental and computational techniques for studying multiphase flow applications with mass transfer in nuclear safety, such as in pool scrubbing processes.

The first part of the evaluation considered the most relevant variables in the analysis of the gas-liquid flow hydrodynamics, namely the bubble size distribution, gas phase velocity, and interfacial area density. In this regard, there is a general agreement between the WMS and CFD results up to a gas superficial velocity of around $10^{-2}\, m/s$ with single point injection. Above this range, the increase in turbulence levels of the gas-liquid flow mixture leads to a significant over-fragmentation of the ellipsoid and cap bubbles in the

calculations. At the largest gas flow rate and turbulence levels, the initial bubble size formation and distribution are also affected by the over-fragmentation with the currently imposed inlet velocity profile. Measurements with an HSC support this observation. This over-fragmentation bias in the CFD results directly affects the calculation of the interfacial area density and, therefore, is reported to be the most relevant limitation that needs to be resolved in the CFD model to characterize the mass transfer for superficial velocities larger than $10^{-2}\,m/s$. A bubble deformation is also acknowledged in the WMS results. The following evaluation of the mass transfer has pointed out the limitations of the WMS and CFD mesoscale comparison of the concentration field of dissolved CO_2 when assuming chemical equilibrium conditions. For non-ideal flows, the chemical process and time scales of the hydration and dissociation of CO_2 should be taken into consideration for both CFD modelling and WMS post-processing, as they may fall within the range of the relevant turbulent time scales. Overall, the CFD predictions on mass transfer agree with the WMS experimental results for the superficial velocities below $10^{-2}\,m/s$. It is also acknowledged here that the employment of coarse structured meshes, restricted by the computational cost, is an important limitation of this study, which leads to a systematic underestimation of the fluxes as a function of the concentration gradients. Furthermore, as the gas flow rate and turbulence levels increase, so do the mesh refinement requirements to capture the entire range of turbulence scales and thus the reported issues of unresolved stresses at the gas-liquid interface. The extension of subgrid modelling and unstructured meshes in PSI-BOIL is considered in the future to solve the over-fragmentation and gradient underestimation in the CFD results.

ABSTRACT

In this work, we present the impact of the new chemical modelling, implemented in the ASTEC code, dedicated to the source term evaluation during a severe nuclear accident. This new modelling approach is based on three major developments: (i) The removal of the thermodynamic equilibrium assumption in the gas phase, replaced by a generalized chemical kinetics model, relying on the systematic generation of reaction pathways and the approximation of kinetic rate constants. (ii) The introduction of surface reactivity, including non-congruent condensation and evaporation processes, allowing a more accurate representation of the chemistry of previously challenging species, such as $CsHMoO_4$(g) and RuO_4(g). (iii)The enrichment of the thermodynamic database, with the inclusion of new species in the condensed, adsorbed, and gaseous phases. This paper details the scientific motivations and the physical foundations of these developments. Their impacts on source term evaluation will be illustrated through comparisons with experimental results from the GAEC, CHIP, and CHIP+ programs. A particular focus will be placed on the speciation of iodine at the outlet, in both gaseous (I_2, HI, IOH, …) and aerosol forms (CsI, AgI, CdI_2, …).

1. INTRODUCTION

In the context of a severe accident (SA) in a nuclear power plant (NPP), the release of fission products (FPs) can result in extensive contamination, posing significant risks to both human health and to the environment. In case of atmospheric releases into the environment following early containment venting procedure or containment failure, iodine can account for a large part of the radiological consequences owing to its volatility and substantial radiotoxicity. The amount of iodine source term (ST) is strongly linked to the physico-chemical forms of the released radioisotopes, especially the fraction present in gaseous or aerosol form in the containment.

In the early 1990s, it was generally assumed that iodine enters the containment predominantly in aerosol form. Thus, NUREG/CR-5732 [1] stated -based on thermodynamic calculations- that the chemical forms of iodine entering the containment from the RCS can reasonably be characterized as at least 95% caesium iodide (CsI), with the remaining 5% present as gaseous I_2 and HI. For caesium, the main prevailing assumption was that the CsOH is in large excess [2]. However, it later became apparent that the situation is more complex. In particular, the large scale Phébus FP test series showed that several condensable iodide forms not associated to caesium may exist in the RCS [3]. Moreover, a significant amount of iodine under a gaseous form was found in the containment early during the bundle transient phase, implying that this gas originates from the circuit [4-6]. Both shortcomings in thermochemical properties and the equilibrium assumption in the circuit gas phase have been put forward to account for the differences between the theoretical and the experimental results [7-8; 3].

To enhance the understanding of the key chemical processes involving released FPs and control rod materials in the RCS during a severe accident, as well as to develop an experimental database, the ISTP-CHIP (2005–2012) and the follow-up CHIP+ (2012–2018) experimental programs were launched at IRSN [9]. Chemical systems involving iodine, main released FPs which can interfere with iodine (Cs and Mo) and control rod material (B, Cd, Ag and In) were considered. Experiments conducted on the I–O–H system revealed kinetic limitations in the reactivity of gas phase iodine [10]. In contrast, no significant kinetic limitations were observed when Cs is added in quite large excess relative to iodine, enabling the principal caesium species (CsI, CsOH) to be accurately described using the thermodynamic equilibrium assumption [11]. The formation of caesium molybdates can be clearly evidenced when both Mo and Cs are considered [11], whereas results obtained from the B-Cs-I-O-H system tend to show that the formation of caesium borates is less favourable [12]. Finally, when silver, indium, or cadmium (SIC) is introduced into the Mo-Cs-I-O-H chemical system, numerous metallic molybdates involving SIC components are formed [13]. These species compete with Cs-molybdate formation and may diminish the scavenging effect of Mo towards Cs.

At the same time, significant effort was devoted to developing a kinetic scheme for iodine transport through the RCS, with the objective of improving the ASTEC software (Accident Source Term Evaluation Code). A kinetic model for iodine, oxygen, and hydrogen, comprising 33 reactions was developed by Xerri et al. [14], building upon the scheme originally proposed in Wren's report [7]. This model was applied to re-interpret the FPT1 experimental data- with a notable improvement- although similar progress was not achieved for FPT3 [15]. The model was further applied to reproduce experimental observations for both the I–O–H system [10] and the Cs–Mo–I–O–H system [11]. The model provides a good reproduction of the experimental trends observed in the two CHIP PL tests involving Mo, Cs, I, O, and H under both oxidizing and reducing conditions. In particular, the formation of gaseous iodine (I_2) in oxidizing carrier gases, driven by the formation of Cs_2MoO_4, is well captured by the model—whether using the thermodynamic equilibrium assumption or incorporating iodine kinetic reactions. However, the caesium-molybdate deposition profile is not accurately captured, as the model overpredicts deposition in the high-temperature region of the tube.

To improve the agreement with the CHIP experimental results, especially the deposition profiles in the high- and low-temperature sections, several improvements have been implemented in ASTEC:

1. The kinetic model for the gas phase, initially developed for the I-O-H system (Xerri et al., 2012), is generalized to all elements. It relies on the systematic generation of reaction pathways and the approximation of kinetic rate constants. It thus eliminates the need for the thermodynamic equilibrium assumption in the gas phase.
2. The introduction of surface reactivity, including non-congruent condensation and evaporation processes, allowing a more accurate representation of the chemistry of previously challenging species, such as $CsHMoO_4$(g), H_2MoO_4(g) and RuO_4(g).
3. The enrichment of the thermodynamic database, with the inclusion of new species in the condensed, adsorbed, and gaseous phases.

This paper details in section 2 the improvements implemented in the ASTEC code. Experiments (GAEC IOH and CHIP PL tests) are then simulated and the capability of the code to reproduce the experimental data is discussed in Section 3.
In the following sections the different models are distinguished as follows:

- Th_Eq: Thermodynamic equilibrium.
- Kin_v0: I-O-H kinetic model used in publications [10], [11] and [15].
- Kin_v0-Eq: I-O-H kinetic model used in [10] with (H-O) subsystem at equilibrium
- Kin_v1: Generalized kinetic model with the enriched database described in this paper

2. NEW DEVELOPMENTS IN ASTEC

The French *Autorité de Sûreté Nucléaire et de Radioprotection* (ASNR) is developing the ASTEC code, which aims at simulating an entire SA sequence from the initiating event up to the release of radioactive elements in the environment. The SOPHAEROS module of ASTEC is responsible for the transport of FPs, the physics of aerosols and the chemistry of FPs and structural materials in both the primary circuit and the containment. Given the variety of chemical elements that may be involved (and consequently the large number of species to be considered), reliable modeling of this chemistry requires kinetic data covering several thousand reaction pathways (homogeneous and heterogeneous) over a wide temperature range, often exceeding 2000 °C.

2.1. Generalization of kinetic control

The kinetic data available in the database associated with ASTEC does not cover the chemistry of all species already identified from a thermodynamic standpoint. Moreover, databases continue to grow much faster in thermodynamic data than in kinetic data, mainly thanks to ab initio methods. It should be noted that it is far easier to compute the thermodynamic properties of a species than to evaluate the kinetics of its formation or destruction. This situation raises a fundamental question: how can one best model a system for which complete thermodynamic data are available but kinetic data are only partially known? In other words, how can the evolution of the kinetically controlled part of the system be combined with the spontaneous adaptation of the other part at thermodynamic equilibrium? To address this challenge, the simplest approach is to replace thermodynamic equilibrium—for the part of the system for which only thermodynamic data are available—with a fast kinetic process. This yields a system entirely governed by kinetics: one part following real reaction rates, the other governed by artificially accelerated rates. The question then shifts to the very definition of "fastness": how can one assign to each reaction pathway a rate constant that is both sufficiently high—not to impose an artificial dynamic constraint—and proportional to thermodynamic reality, i.e., to the relative stability of products and reactants? In other words, can we define a maximum or an upper bound for chemical rate constant?

The maximum rate constant has been evaluated for A+B→AB type reactions by adopting collision theory formalism, expressing the reaction rate as the product of a collision frequency, noted $Freq_{A\&B}$, and a reactivity probability P^{REACT}:

$$v_d = Freq_{\mathrm{A\&B}} \times P^{REACT} \tag{1}$$

Then, the reactivity probability has been evaluated at molecular energy states level, and the following upper bound expression has been determined:

$$v_d^{\mathrm{UB}} = K_d^{\mathrm{UP}}[A][B] \tag{2}$$

$$k_d^{\mathrm{UB}} = \sigma Av \sqrt{\left(\frac{8k_BT}{\pi\mu_{\mathrm{AB}}}\right)}\, Q\left(\frac{3}{2}(N_{\mathrm{AB}}-1), \frac{E_{EF}}{k_BT}\right)\frac{P}{P^{\circ}} exp\left(\frac{-\Delta_r G^o(T)}{RT}\right) \tag{3}$$

$$k_r^{\mathrm{UB}} = \sigma Av \sqrt{\left(\frac{8k_BT}{\pi\mu_{\mathrm{AB}}}\right)}\, Q\left(\frac{3}{2}(N_{\mathrm{AB}}-1), \frac{E_{EF}}{k_BT}\right)\frac{P}{RT} \tag{4}$$

where v_d^{UB}, k_d^{UB} and k_r^{UB} stand for upper bound for forward rate, forward rate constant and backward rate constant, respectively. σ is the collision cross section, μ_{AB} is the reduced mass of fragments A and B, Av is Avogadro number, k_B is Boltzmann constant, T is the temperature, P is the pressure, $P°$ is standard pressure, R is the perfect gas constant ($R = Av \times k_B$) and N_{AB} the number of atoms in the molecule AB. E_{EF} is efficient energy, defined as the larger of the dissociation energy at 0 K and the activation energy: $E_{EF} = \max(D_0, E_a)$.. Q is regularized upper incomplete gamma function:

$$Q(a,x) = \frac{\Gamma(a,x)}{\Gamma(a)} \tag{5}$$

Thus, if the activation energy E_a is not known, $E_{EF}$is assigned a default value equal to D_0, which ensures a physically meaningful limiting rate. The present work will highlight the impact of this generalized kinetic on the source term evaluation.

2.2. Surface reactivity

Unlike reactivity in the gas or condensed (homogeneous) phases, surface reactivity is inherently heterogeneous. It involves an adsorbed phase and enables mass transfer between two other phases through the interface. The first step in introducing surface reactivity into SOPHAEROS consisted in accounting for the adsorbed phase within the thermodynamic database associated with ASTEC. The main difficulty of this step lies in the lack of thermodynamic data related to the adsorbed phase, particularly the absence of standard Gibbs free energy of formation in this phase, i.e., no ΔG°f(ads). In contrast to the gas and condensed phases, for which ΔG°f(g) and ΔG°f(c) are intrinsic properties of each species, ΔG°f(ads) depends both on the species under consideration and on the nature of the adsorption sites (substrate), as well as on the state of coverage of adsorption sites, due to changes in the local environment of these sites during adsorption. As a result, at this stage, such reactivity can mainly be addressed for species (or systems) for which ΔG°f(ads) values have been evaluated using *ab initio* calculations. Examples include the adsorption and decomposition of **CsHMoO₄** and **H₂MoO₄** on **MoO₃** surface (non-congruent condensation) [19] and [20], the adsorption and decomposition of **RuO₄** on a **RuO₂** surface, as well as the impact of **NOx** on the non-congruent condensation of **RuO₄** [16] and [20]. Given the difficulty of performing such calculations for all systems of interest, generic approximations for these data are proposed. The details and the relevance of these approximations will be discussed in a dedicated paper. It was then necessary to introduce the concept of reactive sites, after which surface chemistry could be described through a set of elementary reactions of the type:

$$\mathrm{A(g) + site \rightarrow A(ads)} \quad \text{or} \quad \mathrm{A(g) + B(ads) \rightarrow AB(ads)} \tag{6}$$

The kinetic modeling must account for both transport effects, to properly describe the diffusion of species toward reactive sites (so-called “physical” limitations), and chemical effects that come into play once the species is in the vicinity of the reactive site (energy barriers associated with the formation or breaking of chemical bonds). Accordingly, the forward (K_d) rate constant can be expressed in the following form:

$$K_d = K^{phys.} K^{chim.} \tag{7}$$

Physical limitations ($K^{phys.}$) are evaluated using correlations that are widely accepted in the literature, such as the Chilton–Colburn analogy leading to:

$$K^{phys.} = \frac{\tau^A \sigma_A}{S_{TOT}} \tag{8}$$

Where τ^A the Chilton–Colburn analogy condensation/vaporization flux, S_{TOT} is the total surface area, and σ_A is the specific surface area of the adsorption sites.
As for chemical limitations ($K^{chim.}$), ab initio calculations remain the most appropriate approach to characterize them. The associated rate constant takes the following general form:

$$K^{chem.} = k_0(T)exp\left(\frac{E_a}{RT}\right) \quad (9)$$

However, these chemical limitations are expected to be less significant at high temperatures, as is the case in the primary circuit. Therefore, by default, the value of $K^{chem.}$ is assigned to one. To determine backward rate constant (K_r), we use the relation between equilibrium constant (K_c^{eq}) and kinetic constants:

$$K_r = \frac{K_d}{K_c^{eq}} \quad (10)$$

For a reaction such as A(g) + B(ads) → AB(ads):

$$K_c^{eq} = \frac{\theta_{AB}^{eq}}{[A]^{eq}\theta_B^{eq}} = \frac{RT}{P^\circ}exp\left(\frac{-\Delta_r G^\circ}{RT}\right) \quad (11)$$

And thus:

$$K_r = K_d\frac{P^\circ}{RT}exp\left(\frac{\Delta_r G}{RT}\right) \quad (12)$$

Where $[A]^{eq}$, θ_{AB}^{eq}, and θ_B^{eq}stand for the equilibrium gas concentration of A and the equilibrium surface fractions occupied by AB and B, respectively.

2.3. Enrichment of the thermodynamic database

In addition to the data related to the adsorbed phase required to address surface chemistry, particularly non-congruent condensation, the main effort was devoted to enriching the thermodynamic database with gaseous species. Indeed, extending the kinetic approach instead of relying on thermodynamic equilibrium requires the inclusion of specific intermediate species that ensure connectivity within reaction pathways. Most of these intermediates had no influence under thermodynamic equilibrium assumptions and were therefore not previously considered in the database. The list of the main species for which Gibbs free energies of formation have been calculated and incorporated into the database is given below:
Condensed phase: H_2MoO_4, Cs_2MoO_4, $Cs_2Mo_2O_7$
Adsorbed phase (MoO_3 surface): H_2MoO_4, Cs_2MoO_4, $Cs_2Mo_2O_7$
Adsorbed phase (RuO_2 surface): RuO_4, H_2O, O_2, NO, NO_2, HNO_3
Gas phase:
Ag–Mo–O system: $AgMoO_2$, Ag_2MoO_2, $AgMoO_3$, Ag_2MoO_3, $AgMoO_4$, $AgHMoO_4$, Ag_2MoO_4, $Ag_2Mo_2O_7$
Cs–Mo–O system: $CsMoO_3$, Cs_2MoO_3, $CsMoO_4$, $CsHMoO_4$, Cs_2MoO_4, $Cs_2Mo_2O_7$
Cd–Mo–O system: $CdMoO_3$, $CdMoO_4$, $CdMo_2O_7$

3. MODEL–EXPERIMENT COMPARISON

This section aims to highlight the improvements achieved by the new model in predicting iodine chemistry using data from two distinct experimental series. Thus, to validate the developments described in the preceding section, the following experimental tests have been simulated with the ASTEC/SOPHAEROS code:

- The first experimental series (IOH GAEC tests) consists of tests carried out in an open-flow reactor in which molecular iodine was injected at high temperature (>1440 K) under either reducing or oxidizing atmosphere. These tests were performed on a small-scale test facility initially developed by Lacoué-Nègre [17] and Gouello et al. [18] within the framework of the CHIP program. The objective of these experiments was to determine iodine gas-phase speciation at 423 K following recombination across a strong temperature gradient, under conditions representative of those encountered during severe accident (SA) scenarios. The main experimental parameters were the atmospheric composition and the iodine concentration. The tests used for the validation are the first two performed in reducing conditions (IOH-1 and IOH-2) and the two performed in oxidizing conditions (IOH-4 and IOH-5) [10]

- The second experimental series (CHIP PL tests) was conducted in the CHIP facility, which was designed to detect and quantify gaseous iodine at the circuit outlet as a function of several parameters, including residence time, temperature gradient, carrier gas composition ($H_2O/H_2/Ar$), and the nature and concentration of elements injected into the line. The separate injection of elements in the CHIP PL configuration makes it possible to achieve both an excess of Mo relative to Cs and an excess of Cs relative to I, as observed in the Phébus experiments. The tests used for the validation are those involving Mo, Cs, I, O, and H (PL_MoCsI_3 and PL_MoCsI_2 tests[11], and those involving Mo, Cs, I, O, H plus one element representative of the SIC control rod ([Cd + MoCsI] and [Ag + MoCsI] tests) [13].

3.1. Simulation of the IOH GAEC tests

The IOH GAEC experiments [10]were conducted in a high-temperature tubular furnace equipped with an alumina tube (30 mm inner diameter, 1 m in length). The carrier gas was supplied at the inlet of the test line and consisted of either a steam/argon mixture or a hydrogen/argon mixture (with H_2 concentrations up to 3 vol.%). Gaseous iodine was generated by sublimation of molecular iodine pellets and transported by a low argon flow before being directly injected into the high-temperature zone at 1810 K. The reactants were then cooled in the reaction zone, characterized by a strong temperature gradient (from 1810 K down to 423 K) and a residence time of a few seconds. Downstream of the reaction zone, the transport line ended in four independent sampling lines, each equipped with two gas scrubbers connected in series and an aerosol filter, enabling the collection and characterization of chemical species.

3.1.1. Reducing conditions

Table I. impact of model evolution on its ability to reproduce the measurements of iodin speciation (GAEC tests IOH-1 & IOH-2)

	IOH-1	IOH-2
Carrier Gas composition (v/v%)	Ar/H_2 (97.3/2.7)	Ar/H_2 (99/1)
Measured deposits in the main line (%)	35.6 ± 2.8	26 ± 1.8
Measured Iodine released at 423 K (%)	64.4 ± 3.5	74 ± 5.2
HI and HOI **(%)**		
Measurement	**85.9 ± 2**	**79.5 ± 1**
Th_Eq	100	100
Kin_v0	5.2	3.2
Kin_v0-Eq	90.5	78.4
Kin_v1	92	82

Under reducing conditions (absence of oxygen), ASTEC/SOPHAEROS calculations assuming thermodynamic equilibrium predict exclusively HI at the outlet, whereas a quantity of I_2 were observed

experimentally [10]. It puts in evidence that the {I, O, H} system undergoes some kinetic limitations in reducing conditions, for residence time of several seconds and for the H/I molar ratio used in these tests (9.9 10^3 for IOH-1 and 3.2 10^3 for IOH-2). The previous kinetic model (Kin_v0) predicts that a great amount of the iodine at the outlet (from approx. 75 to 90%) remains as I_2, in disagreement with the experimental data. In Kin_v0-Eq version, this discrepancy was addressed by assuming a partial thermodynamic equilibrium for {O, H} subsystem. Using the new modelling (Kin_v1) the agreement with the experimental measurements is satisfactory without any equilibrium assumption.

3.1.2. Oxidizing conditions

Under oxidizing conditions, the thermodynamic equilibrium assumption (Th_Eq) predict exclusively I_2 at the outlet, whereas measurable amounts of iodine were detected in the aqueous phase of scrubber (9.1±6% for the IOH-5 test and 3.8±1% for the IOH-4 test), attributed to HI [10].The previous modeling (Kin_v0) predicts that between 65% (IOH-4) and 80% (IOH-5) of iodine is released as molecular iodine, which is lower than the experimental values, see table II. Again, this discrepancy was addressed by assuming equilibrium for the subsystem (H-O). The generalized kinetic model (Kin_v1) yields values in good agreement with experimental measurements. At this stage, the primary strength of the new modelling (Kin_v1) lies in its improved internal consistency, as it can treat the full I–O–H chemical system, including the H-O sub-system, without relying on assumptions of partial thermodynamic equilibrium.

Table II. Impact of model evolution on its ability to reproduce the measurements of iodin speciation (GAEC tests IOH-4 & IOH-5)

	IOH-4	IOH-5
Carrier Gas composition (v/v%)	H_2O/Ar (50/50)	H_2O/Ar (50/50)
Measured deposits in the main line (%)	17.5 ± 1.4	33 ± 2.9
Measured Iodine released at 423 K (%)	82.5 ± 4.8	67 ± 4
I_2 (%)		
Measurement	**96.2 ± 1**	**90.9 ± 6**
Th_Eq	100	100
Kin_v0	65	80.1
Kin_v0-Eq	92.4	96.2
Kin_v1	96	98

3.2. Simulation of the CHIP PL tests

The CHIP PL experiments were conducted in the CHIP test line [11]. The test line (3.5 m in length and 60 mm in inner diameter) consists of two tubes connected by a specific junction: an alumina tube (2 m long) located in the high-temperature zone, and a stainless-steel tube (1.5 m long) forming the transport zone, which simulated the reactor coolant system (RCS) piping. The thermal profile along the test line is achieved using a high-temperature oven together with heated upstream and downstream sections. It consists of three zones: (i) a preheating zone extending from the inlet flange (800 °C) to the high-temperature oven; (ii) a high-temperature zone maintained at 1600 °C; and (iii) a “transport zone” in which the temperature decreases from 1600 °C to 150 °C, producing a steep temperature gradient. The steam/carrier gas mixture is directly supplied at the inlet of the high-temperature alumina tube. Except for silver (which is directly deposited in the main line as silver powder), the reagents of interest are vaporised in external generators connected to the main line. Gaseous iodine is obtained by sublimation of molecular iodine pellets. Caesium, molybdenum and cadmium vapours are produced by vaporization of respectively caesium hydroxide, molybdenum trioxide and metallic cadmium. The vaporised reagents (i.e. I2, CsOH, MoO3 and Cd) are then transported in separate lines with an increasing temperature gradient up to the HT zone where they are mixed. The residence time from the high-temperature zone to the outlet (10–11 s) is representative of a

severe accident scenario involving a break in the cold leg of the RCS. The test line terminates with an integral quartz aerosol filter followed by gas scrubbers filled with a sodium hydroxide solution to trap gaseous iodine species. Just upstream of this final filter is the connection to the sampling lines, which allow the measurement of iodine speciation between gaseous I_2 and other forms of Iodine, including aerosols.

3.2.1 PL_MoCsI_2 and PL_MoCsI_3 tests

The results are displayed in Table III. They show that the progression from full equilibrium model (Th_Eq) though the partially equilibrium based (Kin_v0-Eq) to the new modelling (Kin_v1) leads to a significant reduction in the discrepancy between calculations and measurements.

Table III. impact of model evolution on its ability to reproduce the measurements of iodine speciation (CHIP: PL_MoCsI_2 & PL_MoCsI_3)

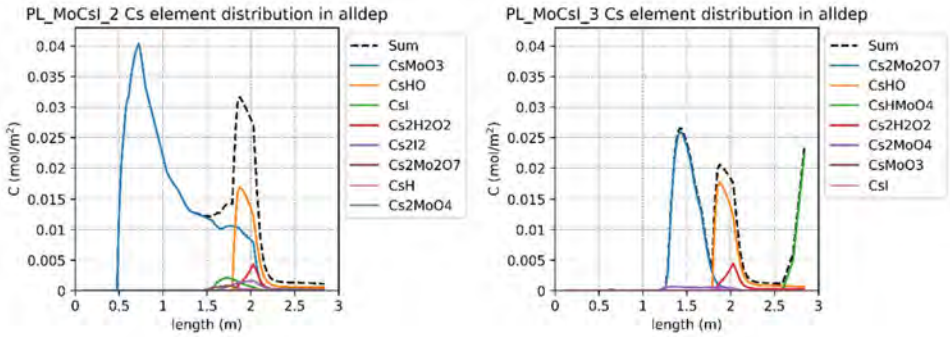

Figure 1. Deposition profiles of Cs species along the tube (PL_MoCsI_2 & PL_MoCsI_3)

For PL_MoCsI_2, the new modelling provides a very good estimate of the measured transport of iodine (60% vs 62±3.1% measured) as well as that of caesium (45% vs 48±3% measured). However, the transport of molybdenum remains slightly underestimated (25% calculated vs 33±5% measured). All transported iodine is predicted to be in aerosol form (CsI), see Table III, in good agreement with measurements. The new modelling reproduces the deposition profiles reasonably well, those of iodine, for which deposition on both tubes, alumina (high temperature) and steel (low temperature), is very well captured. It's worth highlighting the good agreement obtained for caesium and molybdenum deposition on both tubes. One can notice that the tendency of the new modelling to underestimate the transport is in conjunction with an overestimation of deposit at low temperature, zone where the deposit is more governed by aerosols deposition rather than gas condensation. In other words, chemistry modeling is not necessarily the one to blame for this difference. This overall improvement in deposition is mainly attributed to the introduction of new species containing reduced molybdenum Mo(V), such as $CsMoO_3$, Mo_2O_8, etc., see Figure 1. In addition, the formation of different oxidation states of molybdenum (IV, V, and VI) was experimentally evidenced in this test [18].
For PL_MoCsI_3, the new modelling reproduces the overall experimental trends and provides a satisfactory prediction of deposition and transport phenomena, including the gaseous iodine fraction (82% compared with 88.3±6.4% measured). It should be emphasized that, within the present modeling framework, only the main tube is considered; consequently, the calculated gaseous fraction corresponds to the iodine fraction at the outlet of this tube. The recent model developments have a limited impact on iodine transport, which is only slightly reduced. In contrast, they significantly affect the transport behavior of caesium (Cs) and molybdenum (Mo), leading to a markedly improved agreement between calculated results and experimental observations. This improvement mainly arises from the enrichment of the thermochemical database, particularly through the introduction of $CsHMoO_4$. This addition strongly limits the formation of Cs_2MoO_4 and, as a result, substantially reduces high-temperature deposition of both Cs and Mo. Under oxidizing conditions and at high temperatures, caesium is therefore predominantly distributed between two gaseous species: CsOH (the injected species) and $CsHMoO_4$. As temperature decreases, two additional gaseous species (CsI and Cs_2MoO_4) appear only in trace amounts at intermediate temperatures, at the expense of CsOH, which nevertheless remains present until aerosol formation occurs at low temperatures.

3.2.2 CHIP+: PL_MoCsI_Cd and PL_MoCsI_Ag tests

Since both experiments (Cd and Ag) were designed to address the same questions, namely whether these control-rod elements can form iodides (CdI or AgI) and molybdates ($CdMoO_4$ and $AgMoO_4$), a direct comparison of their main outcomes is proposed below.

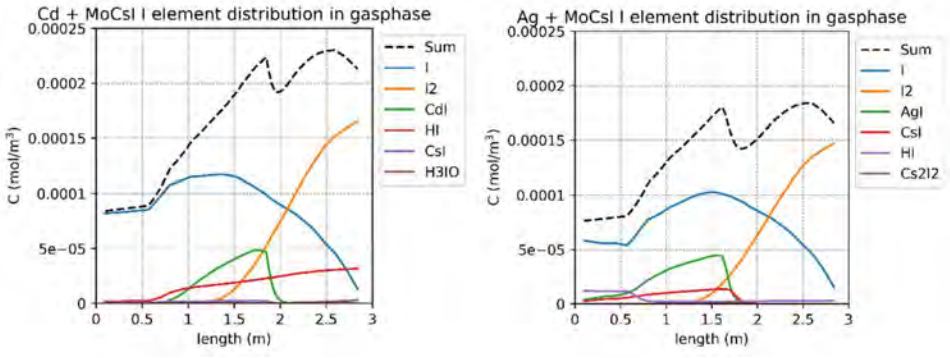

Figure 2: gaseous profiles of I along the tube for PL_MoCsI_Cd (left) & PL_MoCsI_Ag (right) tests

Although the modeling predicts quantitatively comparable results for the two experiments, few qualitative differences are observed particularly concerning gaseous iodine speciation (I_2/HI), aerosol speciation (AgI/CsI or CdI/CsI), Figure 2. At high temperature, iodine speciation is not similar in both experiments,

for *PL_MoCsI_Cd* , the atomic form of iodine is the only species present at the outlet of the furnace whereas, for the *PL_MoCsI_Ag* test, AgI, I, CsI and HI are formed in the very central part of the furnace. This difference highlights the impact of H_2 injected, in the Ag test, in stabilizing Cs atomic at high temperature, and consequently promoting the CsI formation, as observed previously in PL_MoCsI_2 test. On the other hand, CdI is formed further downstream, i.e., at a later stage, due to the thermodynamic stability of Cd atomic compared to silver.

Table IV. Impact of model evolution on its ability to reproduce the measurements of iodin speciation (CHIP+: PL_MoCsI_Cd & PL_MoCsI_Ag)

		PL_MoCsI_Cd H_2O / He / Ar = 49.4 / 42.8 / 7.8			**PL_MoCsI_Ag H_2O / Ar / H_2 = 49.6 / 48.6 / 1.8**		
		Exp.	Kin_v1	Th_Eq	Exp.	Kin_v1	Th_Eq

Cd or Ag	Released	56	66.7	42.09	37	41	32
	Deposited	44	33.3	57.91	63	59	68
	HT / LT	3±0.3 / 41±4	2.7 / 30.6	1.09 / 56.8	57±5 / 6±1	49 / 9	52 / 16

As regards the comparison with measurements, Table IV reveals that iodine (I), caesium (Cs), and molybdenum (Mo) exhibit the same trends as those observed in the previous tests, with a satisfactory agreement for both transport and deposition on the two tubes. The gaseous I_2 fraction is well predicted for the Cd test but is overestimated for the Ag test.

The reaction mechanisms of the I–Ag–Cs–O–H system are currently under re-evaluation in order to better assess transport phenomena, in particular through the reassessment of certain thermo-kinetic data. Nevertheless, it should be emphasized that the experiment involving silver (Ag) presented several challenges and unexpected behaviors from a data analysis perspective. Consequently, it cannot be excluded that the associated uncertainty margins are larger than those initially estimated.

At this stage, silver appears to exhibit a higher capacity to trap molybdenum than cadmium, as it forms two molybdenum-bearing compounds ($AgMoO_3$ and Ag_2MoO_4), whereas only one such compound is formed with cadmium ($CdMoO_4$; see Figure 3). In particular, $AgMoO_3$ plays a key role, since its formation from the injected species Ag and MoO_3 proceeds via a barrierless reaction. As a consequence, a smaller fraction of molybdenum remains available to react with caesium and form $CsMoO_3$, $CsHMoO_4$, or Cs_2MoO_4 in the silver experiment. This, in turn, increases the availability of caesium to form CsI, at the expense of AgI formation.

The injection of hydrogen in the Ag experiment, at a flow rate comparable to that of molybdenum, does not promote the formation of $CsMoO_3$, in contrast to what was observed for the PL_MoCsI_2 test under reducing conditions. Instead, its impact on molybdenum is primarily associated with the formation of Mo_3O_8 species.

4. CONCLUSIONS

In this paper, we present an overview of the recent developments in chemistry modeling implemented in the ASTEC code. The main advances include the replacement of the thermodynamic equilibrium assumption with a generalized kinetically controlled model, the introduction of surface reactivity, and the enrichment of the thermokinetic database associated to ASTEC code. The improved capability of the code to predict experimental observations has been assessed on the GAEC, CHIP, and CHIP+ test series. For the GAEC experiments, we demonstrate that this new approach is more consistent, as it no longer requires assuming partial thermodynamic equilibrium for specific subsystems, as was the case in the previous version (where improved results were obtained when the H–O subsystem was assumed to be at equilibrium). The robustness of the model is further evaluated using the CHIP tests, for which the simulations reproduce the experimental measurements very well, including the transport of the different elements, the gaseous I_2 fraction, and the deposition profiles. Similar trends are also obtained for the CHIP+ experiments (MoCsI+Cd and MoCsI+Ag).

According to the results, both silver and cadmium exhibit a high reactivity toward molybdenum. This reactivity reduces the availability of molybdenum to interact with caesium, thereby increasing the capability of caesium to partially trap iodine. In addition, both elements are capable of directly trapping a fraction of iodine through the formation of AgI or CdI. Nevertheless, these effects remain partial, as a fraction of gaseous iodine is still measured in the sampling lines in both experiments, highlighting a chemistry governed by complex kinetic limitations that warrant further investigation. In particular, the differences observed in the transported I_2 fraction call for a reassessment of the thermokinetic behavior of silver system.

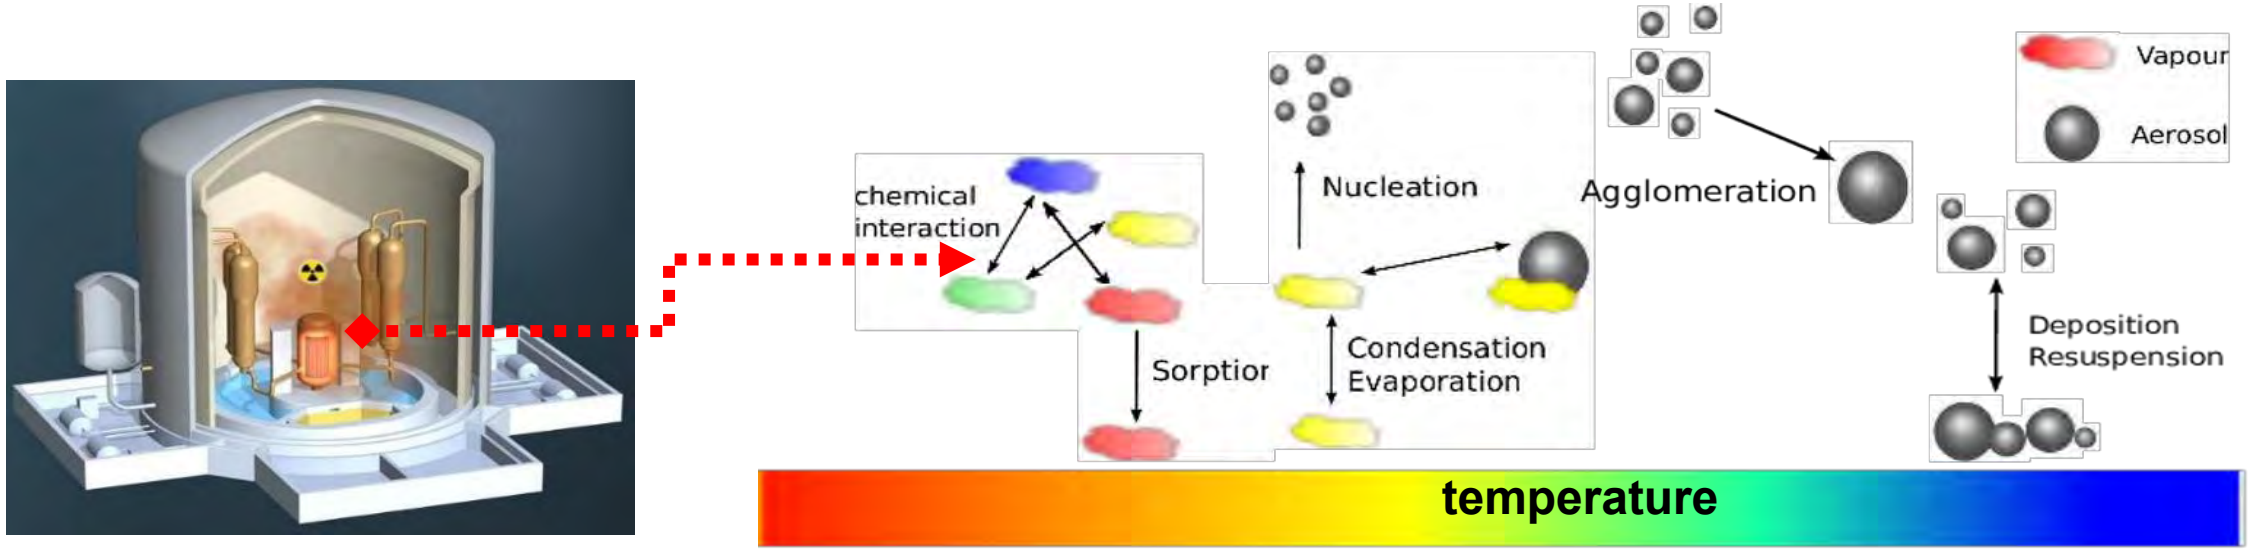
INTRODUCTION

LIMITS OF THERMODYNAMIC EQUILIBRIUM



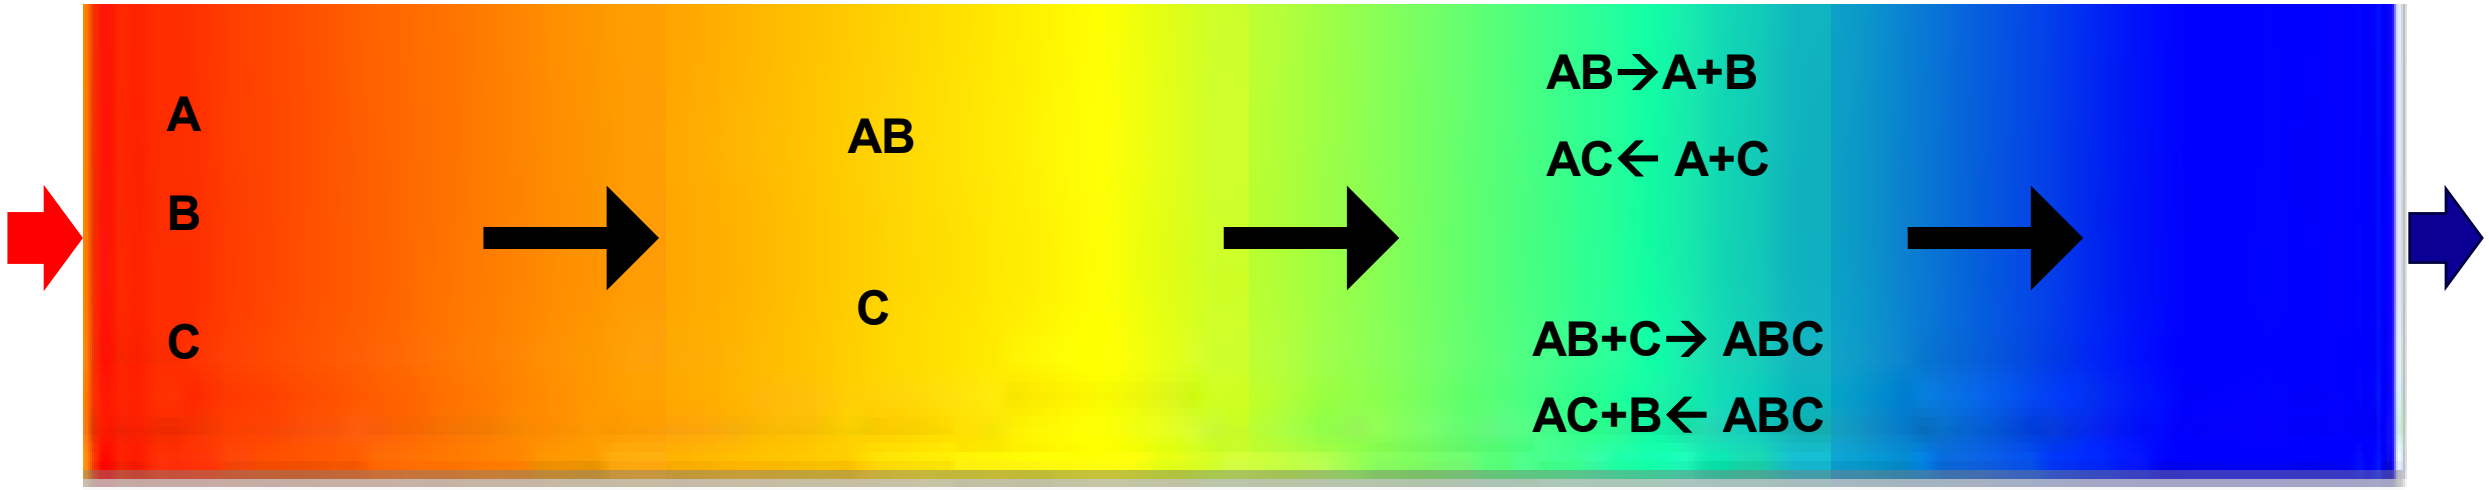
- **Previous assumption:** Thermodynamic equilibrium (Th. Eq.) for speciation in the gas phase**.**
- **Experimental feedback:** Th. Eq. does not hold (e.g., I–O–H system).
  - Need to generalize the **kinetic** & to consider the **surface chemistry**.
- **The Paradox:**
  - Thermodynamic data ($\Delta_f G$) are abundant and easy to compute (ab initio).
  - Kinetic data (E_a, rate constants) are scarce and complex to evaluate.
- **How can thermodynamic data be used to estimate missing kinetic parameters?**

02

GASEOUS PHASE: NEW KINETIC MODELING

FROM THERMODYNAMIC DATA TO KINETIC DATA

- **Molecules try to agglomerate!**
- **Temperature tends to separate them.**

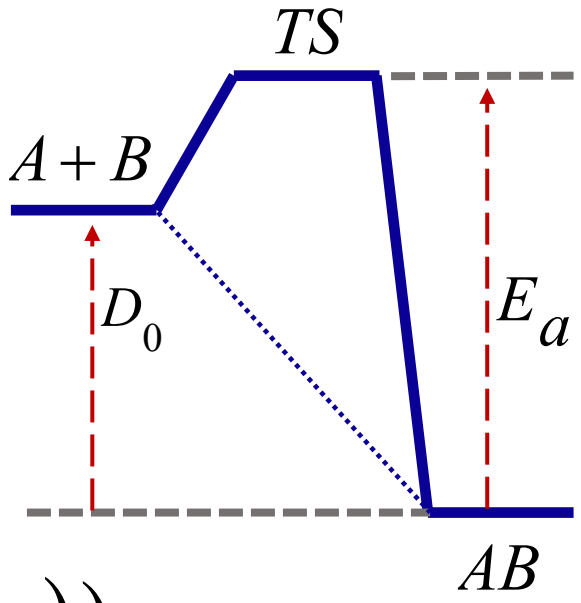


- **Objectif:** consider the impact of the unstable intermediate on the kinetics.

REHABILITATION OF COLLISION THEORY

- **Reaction rate expressed as a product:** $v_f = Freq_{A\&B} \times P^{REACT}$

- **Reactivity Probability (P^{REACT}):** Evaluated at the molecular energy states level:



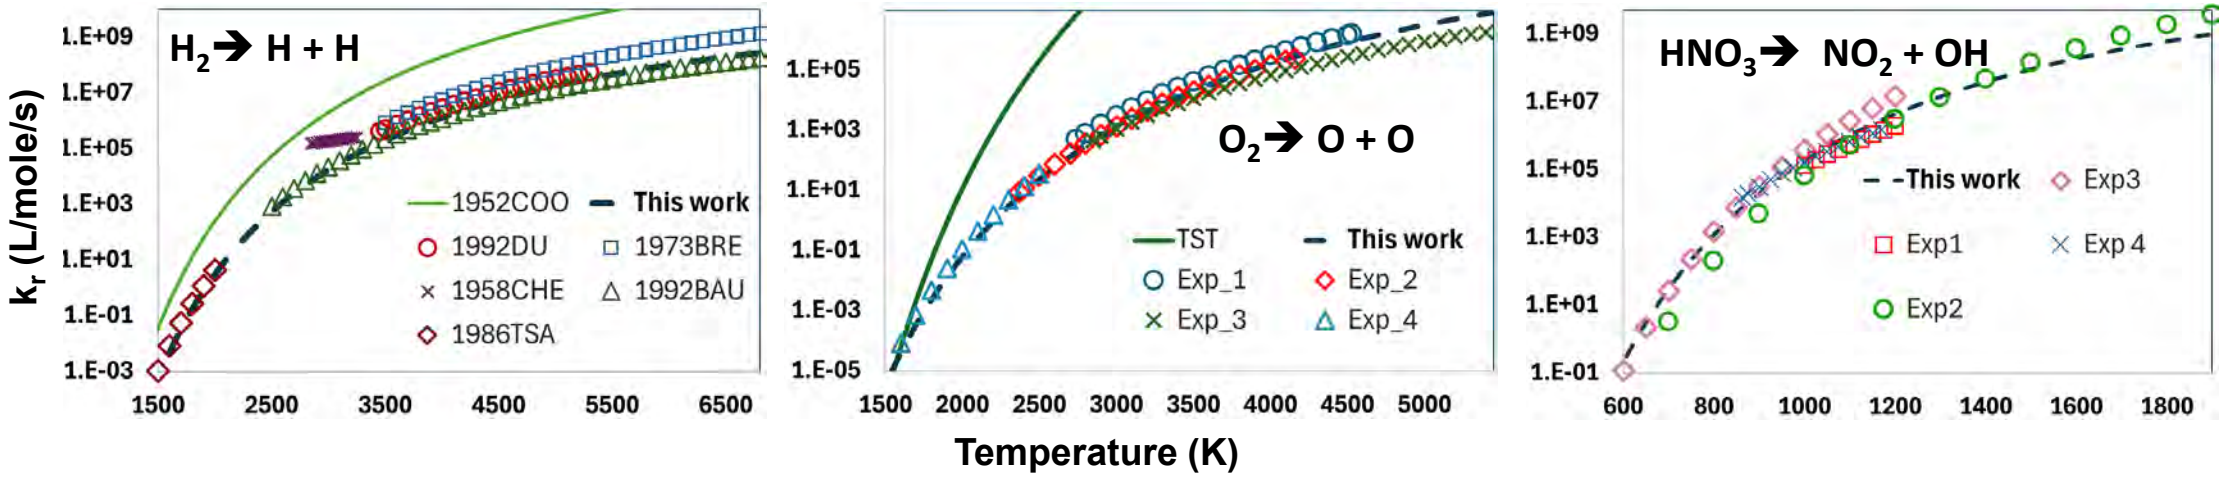
- **The Upper-Bound Formula:**
  - Relies strictly on macroscopic thermodynamic properties ($\Delta_r G°$).
  - Uses fundamental dissociation energy (D_0) at 0 K when activation energy (E_a) is unknown.

$$v_d^{\mathrm{UB}} = Freq_{A\&B} \times P_{A+B \mapsto AB}^{REACT}\left(\Delta_r G; \max\left(E_a, D_0\right)\right)$$

- **Result:** A physically meaningful maximum rate, proportional to the relative stability of products and reactants.

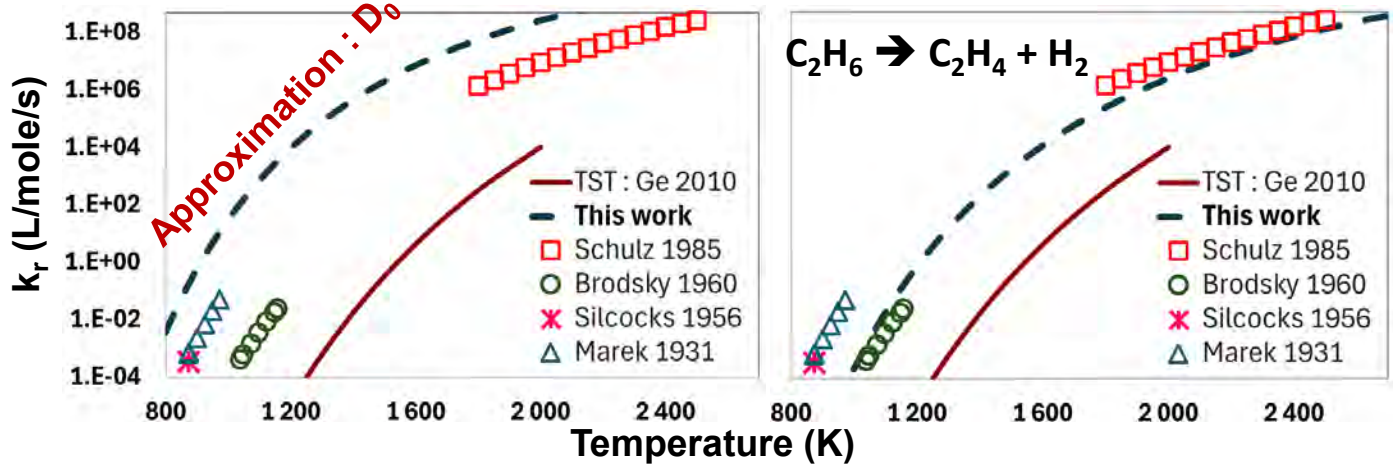
COMPARISON WITH LITERATURE DATA (NIST)

- **Barrierless reactions:** The approach perfectly reproduces experimental observations and temperature dependence.

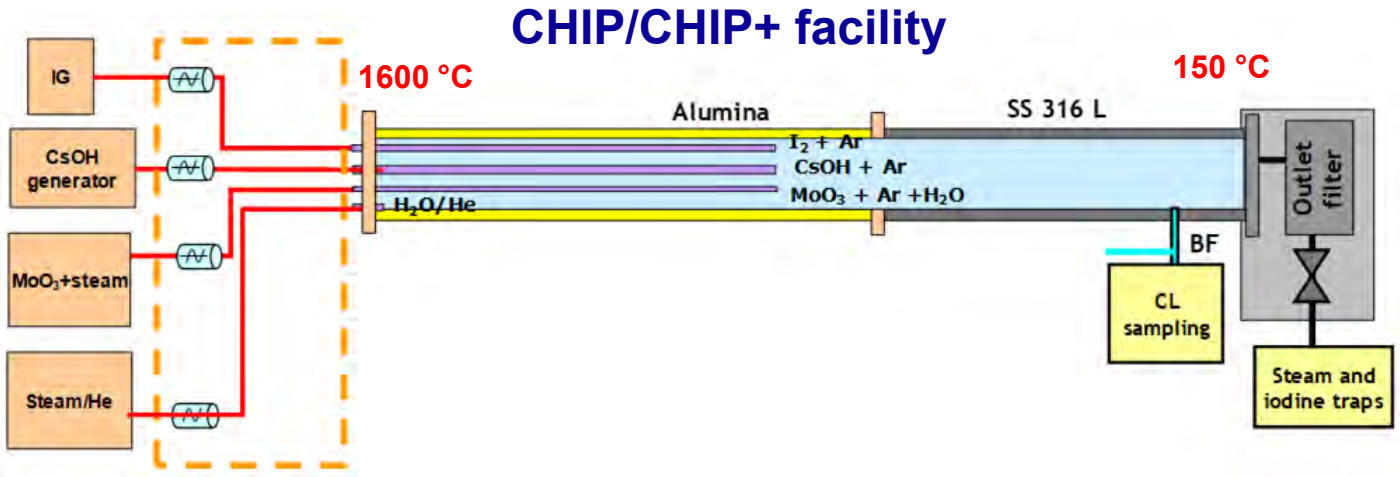


- **Reactions with energy barrier:** Replacing D_0 with an ab initio calculated E_a provides highly promising results.

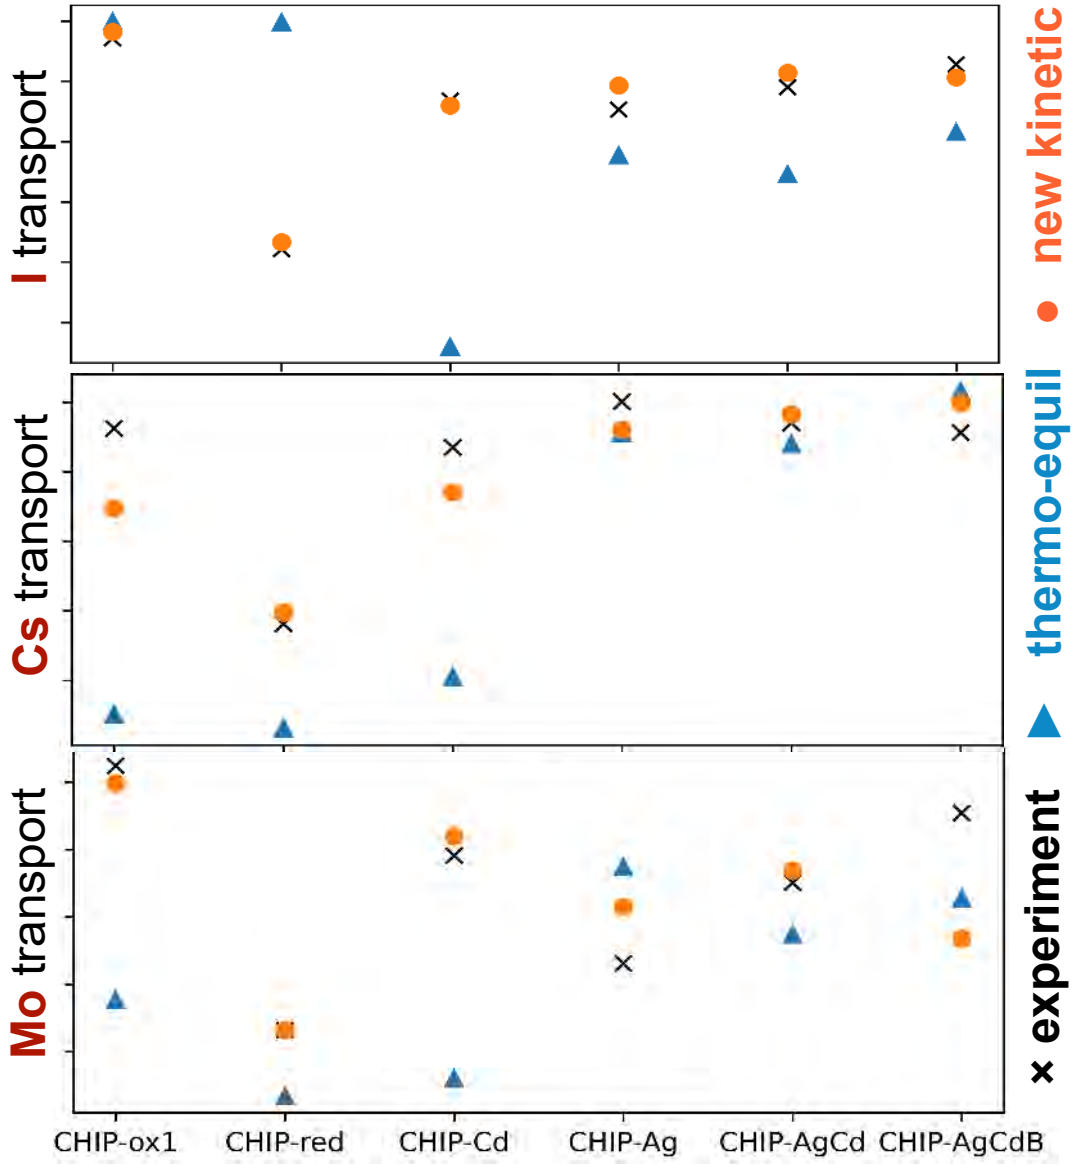
- **Advantage:** Allows discrimination between different measured kinetics using only basic thermodynamic data.



ANALYTICAL TESTS - CS-I-MO SYSTEM



- 6 tests with different compositions.
- Both calculation, performed with :
  - Database enriched with data for Mo, Cs, Cd, and Ag.
  - Including surface decomposition of $CsHMoO_4$, H_2MoO_4.
- New model: upper bound of kinetics rates reproduces better the experimental transport.



03

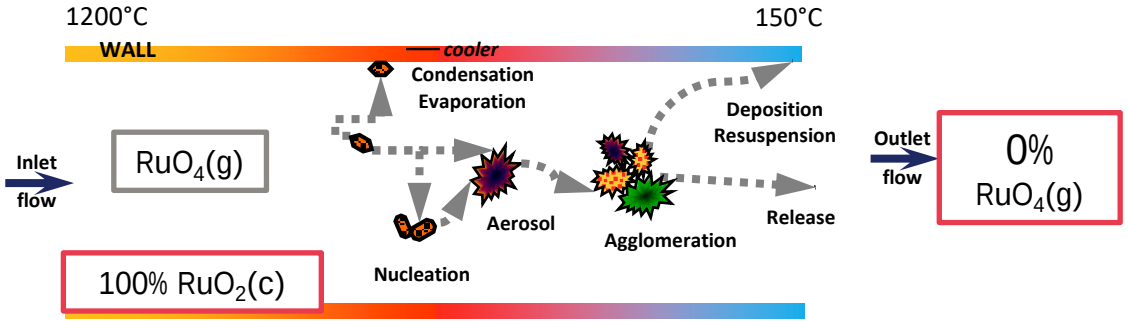
ADSORBED PHASE: SURFACE REACTIVITY

SURFACE REACTIVITY

- **Motivation:** the no-congruent evaporation/condensation of **RuO_3** and **RuO_4**

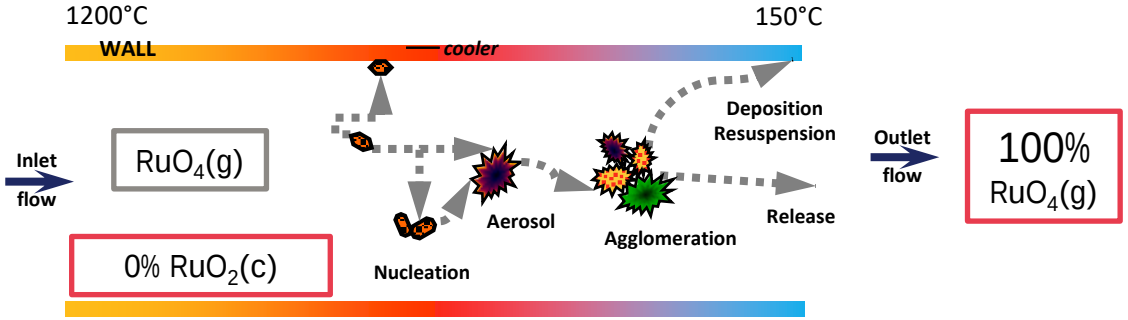
- **Full thermodynamic equilibrium**

➔No transport of Ru.



- **Thermodynamic equilibrium in gas phase + congruent condensation.**

➔Full transport of Ru.



- **Experiments (ASNR facility)➔ transport : 1% to 50%.**

- **Surface decomposition of RuO_4 & RuO_3 must be considered.**

INTRODUCING SURFACE CHEMISTRY

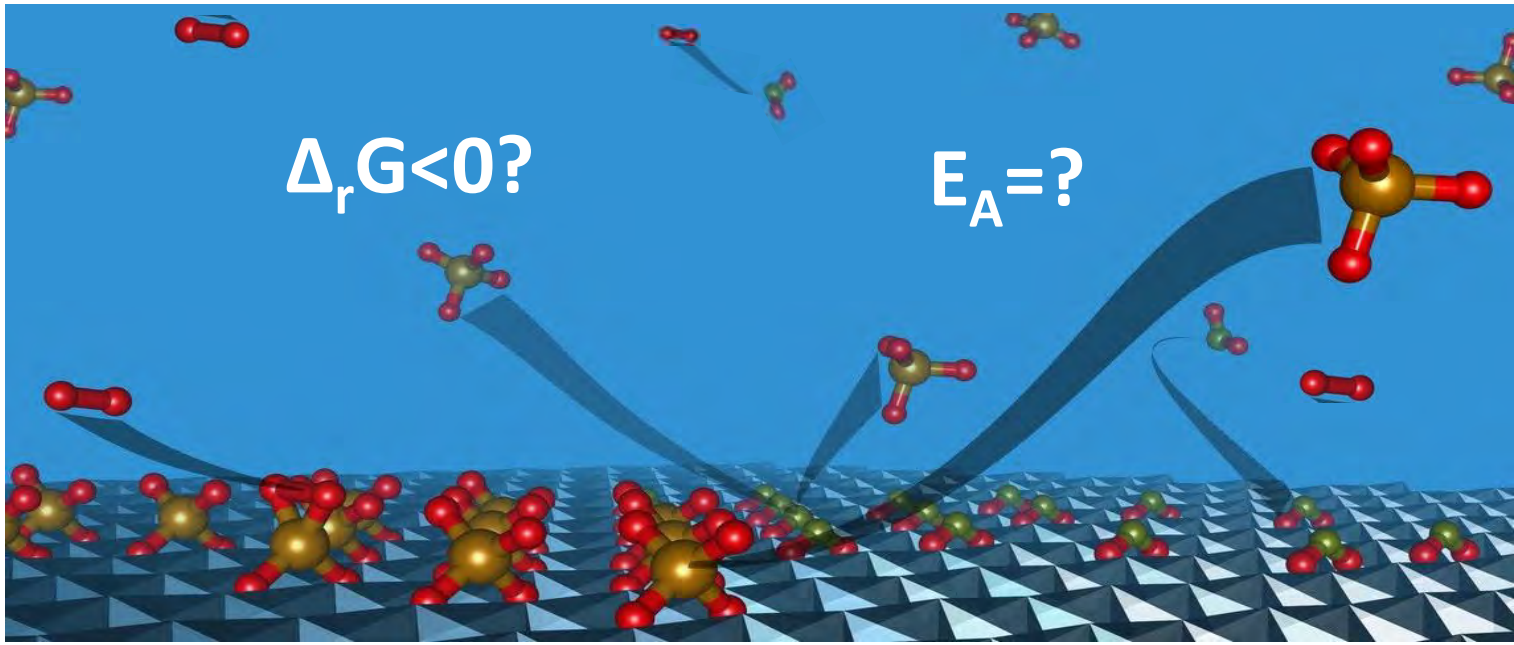
Concept:

- Introduction of "**active sites**"

  Single adsorption: $A_g + S_0 \rightleftharpoons A_s$

  Multiple adsorption: $B_g + A_s \leftrightarrow AB_s$

- Considering **Adsorbed phase** in the MDB



Data: Adsorption Gibbs energies

- Calculated via ab initio (e.g., RuO4, CsHMoO4).
- approximated generically from existing MDB

Kinetic Laws:

- Controlled by diffusion toward the surface (Physical limitation: Chilton-Colburn analogy).
- Controlled by adsorption/desorption energy barriers (Chemical limitation).

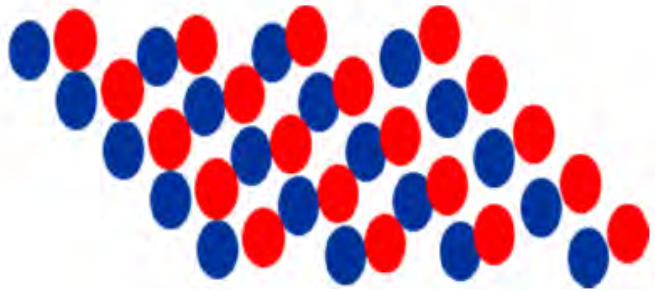
SURFACE REACTIVITY

- **Approximated data:** via Mean Field Approximation (MFA); boundary conditions are approximated

$G^{o}_{(ad)}(\theta,T)$ = $(1-\theta)\times G^{o}_{(ad)}(0,T)$ + $\theta\times G^{o}_{(ad)}(1,T)$

Intermediate coverage

Isolated adsorption

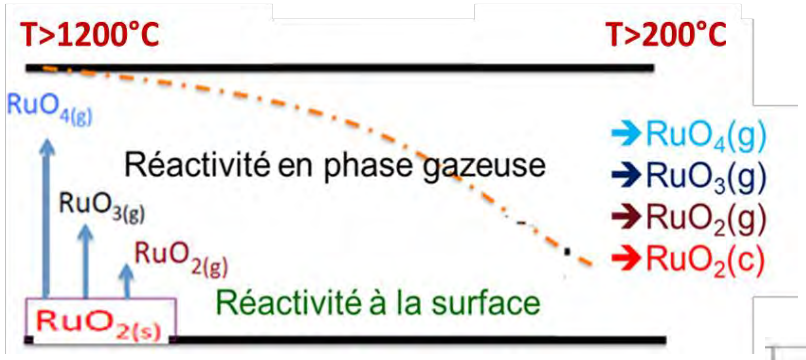


Full monolayer coverage

- **Generic approximations are made based on thermodynamic data of gaseous & condensed species (in MDB)**

ANALYTICAL TESTS – RU SYSTEM

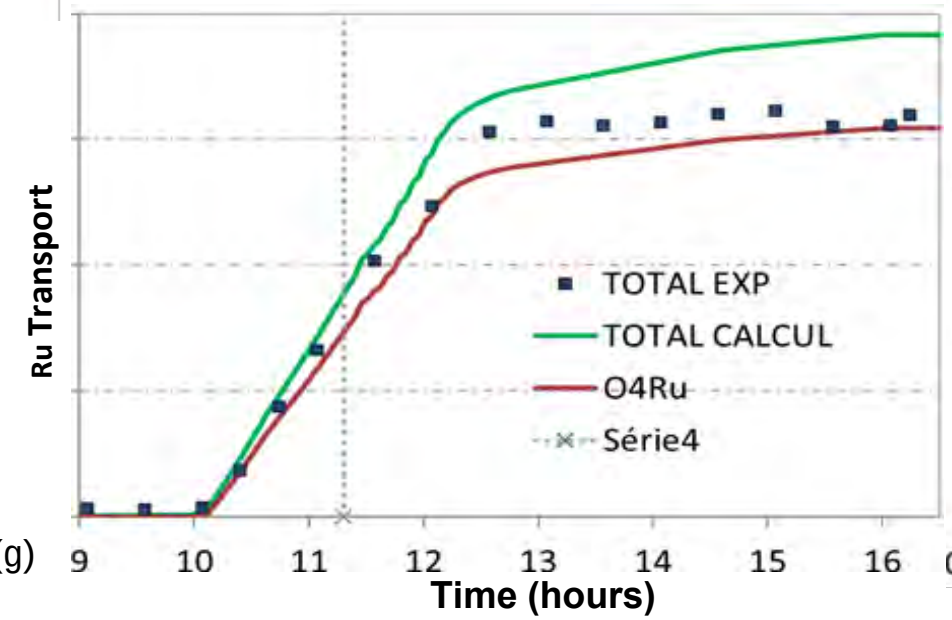
- **Challenges:** the no-congruent evaporation/condensation of **RuO_3** and **RuO_4**

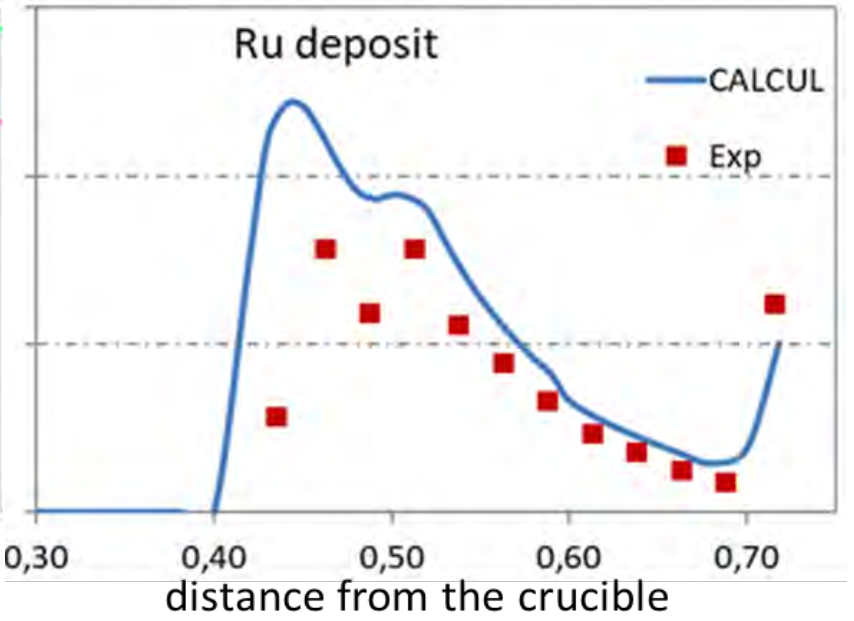


- RuO_4 (g) ↔ RuO_4 adsorb)
- RuO_4(adsorb) ↔ RuO_2(c) + O_2(g)

- RuO_3 (g) ↔ RuO_3 adsorb)
- RuO_3(adsorb) ↔ RuO_2(c) + O (g)
- 2xRuO_3(adsorb) ↔ 2xRuO_2(c) + O_2(g)

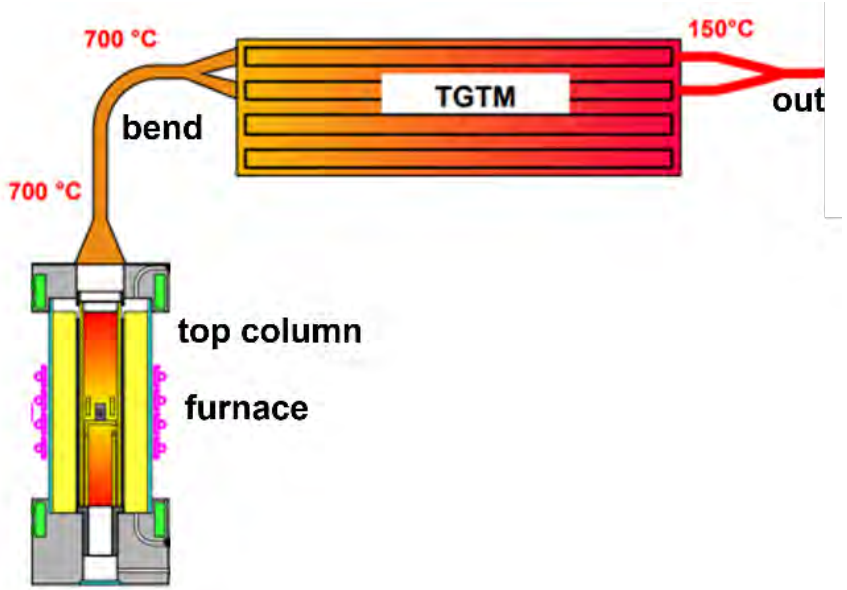
- **ASTEC vs experiment (START test :quartz tub and low flowrate)**





- **ASTEC reproduces the experimental observations**

INTEGRAL TEST – RU SYSTEM



Ru	ASTEC	EXP
out	32.92%	30.81%

04

CONCLUSION

TAKE HOME MESSAGES

- **New trajectory for chemistry modeling is under implementation in the ASTEC/SOPHAEROS module.**
  - **Gas phase:** the thermodynamic assumption could be replaced by a generic chemical pathway.
  - **Surface reactivity** can now be considered.
  - All parameters (Gibbs energies of adsorption and rate constants) can be **generically approximated from the existing thermodynamic database (MDB)**.
- **Requirement:** Continue improving the MDB with **adsorption Gibbs energies** and accurate rate constants (including **activation energies**).
- **Surface reactivity** plays a key role in understanding and reproducing **Ruthenium**, **Cesium** and **Molybdenum** chemistry and transport.
- The **validity of these models holds for large temperature range** (from 2200 °C to 150 °C).

Analytical ab initio-Based Modeling of the Adsorption Isotherm

Ankita Jadon, Nathalie Girault, Bruno Piar, Denis Petitprez, and Sidi M. O. Souvi*

Access Through Your Institution | Other Access Options | Supporting Information (1)

Abstract

An analytical ab initio-based model for adsorption isotherm is presented. As input data, this model takes the adsorption Gibbs free energies of different possible coverages within a reasonably large unit cell. In this way, the lateral interactions between adsorbates and their dependence on temperature are included. The self-dependence of surface coverage is taken into account via the introduction of heterogeneity of adsorption and the use of an appropriate configurational partition function. The model reproduces the isotherm and selectivity (for binary gas mixtures) of ab initio-based grand-canonical Monte Carlo simulations. The presented isotherm has a moderated dependence on the width of the chosen ab initio unit cell, particularly for high surface loading. This isotherm seems to be a very good approximation for the grand-canonical solution, depending on the accuracy and completeness of the ab initio data.

Ab Initio Insight into $CsHMoO_4$ and H_2MoO_4 Complexes on MoO_3 Surfaces

Mariam Saab, Sidi M. O. Souvi*, Jean Denis, François Virot, and Monica Calatayud*

Access Through Your Institution | Other Access Options | Supporting Information (1)

Abstract

Solid surfaces play a crucial role in many processes, yet their impact on nuclear safety is not well understood. This study investigates how solid surfaces affect the behavior of radioactive gaseous species, focusing on the interaction of fission product complexes formed under nuclear accident conditions. Specifically, we examine the condensation and decomposition of Cs–Mo complexes, $CsHMoO_4$ and H_2MoO_4, when interacting with MoO_3 deposits in a reactor cooling system, considering two surface terminations: O and Mo. Using density functional theory (DFT), we calculate the Gibbs free energy for these reactions on MoO_3 surfaces at temperatures ranging from 300 to 1800 K. $CsHMoO_4$ condenses below 850 K and dissociates between 300 and 650 K on O-MoO_3 and 650–1250 K on Mo-MoO_3, forming Cs_2MoO_4 and MoO_3, along with steam release. H_2MoO_4 condenses below 500 K and decomposes between 600 and 800 K, but only on Mo-terminated surfaces. These findings improve the accuracy of nuclear simulations, helping to predict species composition and transport within the reactor cooling system during accidents.

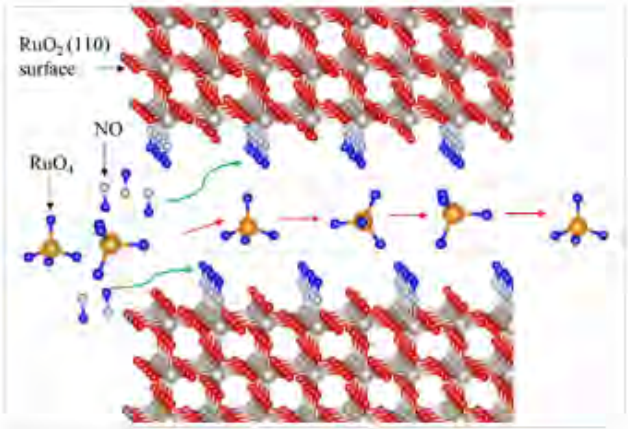
Ab Initio Investigation of the Competitive Adsorption of RuO_4 and NO_X on a RuO_2 Surface: Assessment of RuO_4 Release in a Severe Nuclear Accident

Etienne P. Hessou, François Virot, Monica Calatayud*, and Sidi M. O. Souvi*

Access Through Your Institution | Other Access Options | Supporting Information (1)

Abstract



Nuclear safety has recently become a central issue in the context of the current energy and geopolitical crises. Accurate estimates of the nature and extent of radioactive species potentially released from nuclear facilities are essential for assessing and optimizing safety plans. Computational techniques appear as a powerful tool to understand the formation and transport of such species and to quantify their amount. This study focuses on the decomposition of gaseous ruthenium tetroxide (RuO_4), a fission product likely to be released into the emergency ventilation ducts in the event of an accident at a fuel reprocessing plant. RuO_4(g) is expected to decompose during its transport on the available surfaces into solid RuO_2 (c) and amorphous O_2(g). However, other species like NO_X present in the environment might interact with the surfaces of the growing deposit (RuO_2), poisoning the reactive sites vis-à-vis the RuO_4 adsorption/decomposition and favoring its transport in the gas phase to the environment. To understand this poisoning effect on RuO_2 surfaces, we carried out periodic density functional theory calculations at the PBE level. The impact of dispersion corrections (PBE+D level) is presented in the Supporting Information. RuO_4, NO, and NO_2 molecules at different coverages are computed on the RuO_2 (110) surface. We provide adsorption Gibbs free energies, isotherms, and the poisoning effect in the conditions of an accident. Our results show that the NO_X seems to have a noticeable poisoning impact on the RuO_2 (110) surface, reducing the adsorption of RuO_4(g), the first step of the condensation mechanism. Our calculations show that this impact increases with NO_X partial pressure and decreases with temperature. The results of the study will also be of interest in other fields like heterogeneous catalysis, where RuO_x surfaces are involved.

ABSTRACT

This paper outlines ongoing research activities in a national-funded joint project that uses machine learning (ML) methods to predict late-phase phenomena observed in severe accidents. The focus is on the long-term coolability of debris beds in the lower plenum, their melting and possible discharge into the cavity as a debris bed outside the reactor pressure vessel. Due to the complexity of the phenomena that can occur during this process, system codes may require high computing capacities.
The aim of the work described in this paper is to develop a ML model capable of quickly predicting the coolability of water-saturated debris beds, thereby significantly accelerating calculations within system codes. Therefore, a Gaussian Process Regression (GPR) combined with an artificial neural network (ANN) was developed, resulting in several advantages. Firstly, GPR models can extrapolate beyond the limits of the training data more effectively, since not all possible parameter combinations can be included in the training data. Secondly, they provide uncertainty in the prediction, which is important for the interpretability of the results. Combined with the ability of ANN to learn even complex relationships, this approach is well suited for the planned model development, as first results already confirm. The model is therefore able to predict the target variables with sufficient accuracy even under initial conditions that have not been trained previously.

KEYWORDS
Machine learning, artificial neural network, severe accident, coolability, debris bed

1. INTRODUCTION

The safety of nuclear reactors is a critical factor in preventing postulated accidents and minimizing their consequences. If a serious accident occur in which the fuel rods are damaged due to insufficient cooling, and a debris bed forms in the reactor pressure vessel (RPV), successful long-term cooling of the debris bed is essential to prevent remelting and impairment of the RPV's integrity. In the worst case, failure of the RPV can lead to the release of melt into the containment, and an ex-vessel debris bed might form that must also be cooled over the long term to prevent interactions between the debris-bed material and the reinforced concrete. It is essential to understand and predict the sequence of events in order to minimise the consequences. As part of international reactor safety research, extensive efforts are made [1, 2].
System codes are frequently used for this purpose, such as the AC² program package developed by the German Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) gGmbH. This code enables the simulation of the reactor's thermohydraulic behavior during normal operation, disturbances, and accident scenarios [3]. To enhance the accuracy of these simulations, the underlying model basis is continuously improved. Because many phenomena during a severe accident are highly complex, realistic simulation requires

substantial numerical effort. Detail codes such as COCOMO (Corium Coolability Model) only focus therefore on the simulation of debris bed cooling using mechanistic models [4]. The coolability of the debris bed is a key aspect of accident mitigation and depends on many different parameters, e.g., particle size and shape as well as porosity and geometry. Over time, the structure can also change, and local melt pools or dryouts can form [5–7]. Because COCOMO performs detailed calculations for multi-flow phenomena, the results are very accurate, but the computation time exceeds real elapsed time during an accident. For the simulations used in this study, COCOMO required an average of one hour of processing time. If incorporated into a system code, the computation time would compound and thus be inefficient. To significantly reduce this computation time without losing too much information, a joint research project is pursuing an approach that involves the development of a machine learning (ML) model. For this purpose, COCOMO is used to generate training data, enabling a machine learning model to learn from the detailed simulations and replicate their behaviour. The aim is to develop a model that can capture the essential physical phenomena represented by COCOMO and integrate it into a PSS in-house version of the AC² system code. This would make a high level of detail available within a fast-running system code while significantly reducing computational effort. Over the course of the project, several ML model approaches have already been developed and investigated [8, 9], with a focus on the development of artificial neural networks.

Machine learning is a branch of artificial intelligence that enables software to learn from examples and experience without being explicitly programmed. There are three main learning mechanisms: supervised learning, unsupervised learning, and reinforcement learning. In supervised learning, which is of particular interest in this paper, labelled data are used to train ML models, where both input variables and desired outcomes are known [10-14]. Another approach to machine learning is artificial neural networks (ANNs), which consist of neurons connected by nodes, typically organized in layers. The input data are read in by the input layer and then passed to one or more hidden layers, where the information is processed. The output is finally generated in the output layer. The information from the individual nodes is multiplied by weights, which are adjusted during the training process. At the end of each layer, the information is summed up and passed on to an activation function, which influences its transfer to the next layer. The general structure of an ANN is shown in Figure 1. By using ML and ANNs, complex relationships between input and output data can be identified and corresponding rules can be derived. This enables the creation of powerful models that can learn from data and make predictions or decisions [15, 16].

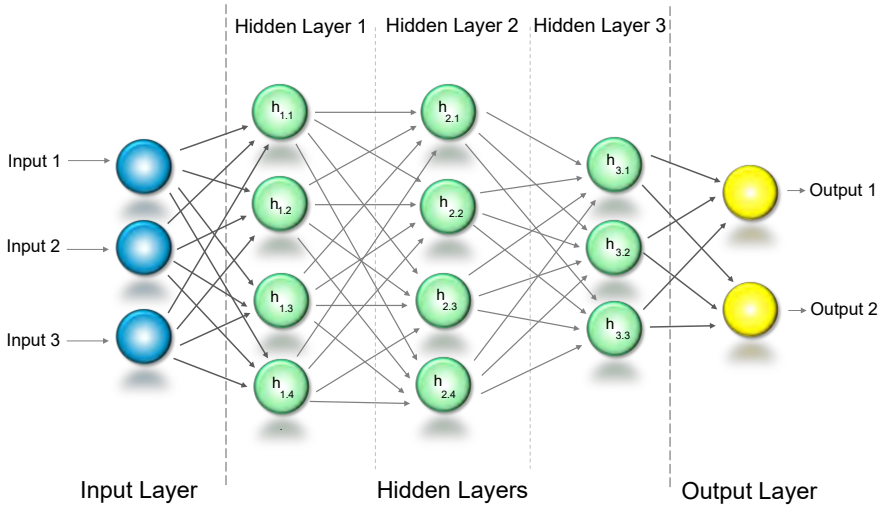

Figure 1: Generic artificial neural network.

In addition, a Gaussian Process Regression (GPR) model was developed [9]. GPR is a machine learning technique that employs a non-parametric approach to predict and model complex, non-linear data, typically assuming a zero-mean prior. The model generates a distribution over a large number of functions for the training data, which are considered a sample. This distribution is characterized by a mean function, representing the expected value, and a covariance function (kernel), representing the dependency between points. An example of a covariance function is the radial basis function [17, 18].

This paper describes the further development of an ANN that is enhanced through combination with a GPR model, a technique known as Deep Kernel Learning (DKL). This combination leverages the advantages of both structures to predict relevant parameters during the cooling of a debris bed in the containment within a very short time. The results of this work aim to reduce the computation time for simulating nuclear reactor accidents and to improve the safety of nuclear reactors.

2. TRAINING DATA

For the creation of the training data basis, the dryout experiments at the DEBRIS test facility [19] at IKE were used as a foundation. The system comprises a debris bed located in a pressure vessel, fully submerged in water, a water buffer tank to keep the water level constant, and the connecting piping. The test pressures were 1, 3, and 5 bar. Specifically, the debris bed is placed in a PTFE (polytetrafluoroethylene) crucible (height = 870 mm, internal diameter = 125 mm) inside a glass cylinder with an induction coil; a high-frequency generator inductively heats the particles as a substitute for decay heat. Above a ceramic base layer (~60 mm), the test particles consist of pre-oxidized steel spheres (2, 3, 6 mm) with a layer thickness of 640 mm. Water is supplied from the top (Top Flooding) or from the bottom (Bottom Flooding). [20]

The training dataset was generated using the detailed code COCOMO and originates from numerical simulations based on an input file provided by IKE and validated against the DEBRIS experiments described above, with a cylindrical, axisymmetric geometry and a mesh of 1,400 cells (see Figure 2). To generate as many input files as possible, the porosity, particle diameter, and the system pressure are varied and combined within physical limits. These parameters also serve as ML features, including the saturation temperature; the parameters used and their data ranges are shown in Table I. The target quantity is the dryout heating power. This is determined in COCOMO via interval nesting: first, a coarse search is performed in 100 W/kg steps between 200 and 2,200 W/kg, starting from the maximum value, with the dryout criterion checked to narrow the range. Subsequently, within the interval, the midpoint of the currently tightest bounding power pair is iteratively simulated until the interval width is below 1 W/kg. The reported mean yields the dryout heating power with an accuracy of ±0.5 W/kg; the simulation accuracy is not included.

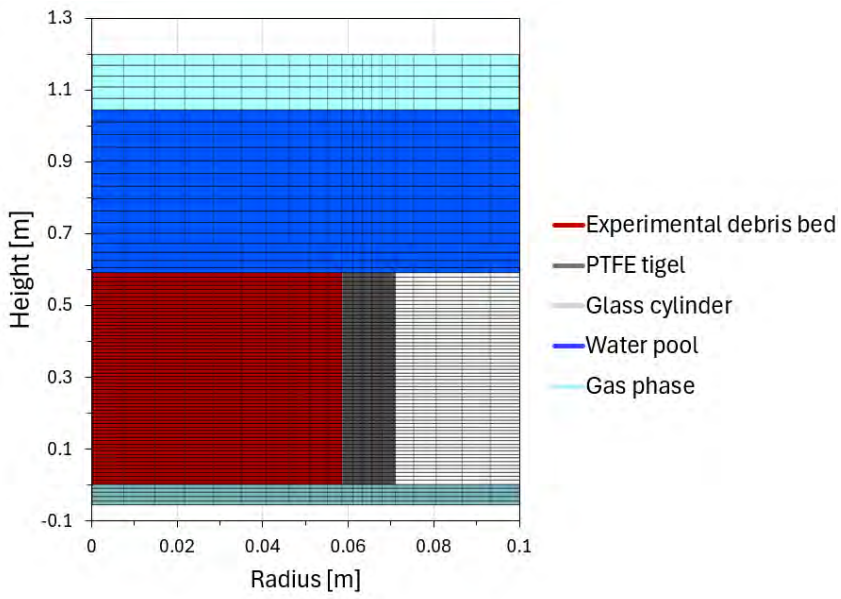

Figure 2: Geometry of the input files used for training data generation with COCOMO.

The dataset created using this method consists of a total of 250 data points. It is divided into training and test data, with 80% randomly selected for training. The remaining 20% serve as test data. Since the overarching aim of this project is to integrate the developed ML model into a severe accident code to significantly accelerate predictions, user influence is a non-negligible factor. Consequently, the model may be provided with parameter ranges and material compositions that were not covered in the training data. As it is not feasible to include the virtually infinite combinations in the training dataset, knowledge of the prediction deviation when the ML model is forced to extrapolate is indispensable. Recognizing that ML models achieve their best performance only within the bounds of the training data, an additional validation dataset of 100 data points was therefore generated, featuring a different material composition than the DEBRIS training data. In addition, the parameter ranges were slightly adjusted. The exact data domains are provided in Table I.

Table I. Varied parameters and data rooms

Parameter	Pressure [MPa]	Porosity [-]	Particle diameter [m]	Saturation temperature [K]	Dryout heating power [W/kg]
DEBRIS set	0.1 – 0.5	0.27 – 0.47	0.0025 – 0.0061	373 – 425	150 - 860
Validation set	0.1 – 0.5	0.37 – 0.51	0.0005 – 0.0040	373 – 425	220 - 2090

3. MODEL DEVELOPMENT

All models presented here were developed in Python using the PyTorch framework and trained via supervised learning. The dataset based on the DEBRIS experiments was divided into training data (80%) and test data (20%). In addition, a separate validation set was employed to assess the model configuration independently of the test data. As the initial model architecture, a multilayer neural network (NN) with four layers was chosen, consisting of an input layer, two hidden layers, and an output layer. The hidden layers

used the ReLU activation function to capture nonlinear relationships and improve training dynamics. To select the final model parameters and structure, a systematic hyperparameter analysis was conducted, in which different configurations were evaluated and compared based on their performance on the validation set. The final assessment of generalization capability was performed on the validation set.

A GPR with a special kernel is utilised. The kernel in the model is a combination of a constant kernel and a Radial Basis Function kernel. The constant kernel adds a constant component to the model, while the RBF kernel determines the smoothness of the predicted function. The initial values and ranges for both kernel components are specified to initialise and optimise the model parameters. The code initialises the GPR with the defined kernel and sets the noise level of the observations to 0.01. The noise level refers to the variance of the noise that is added to account for uncertainties such as measurement errors. The model is then trained with the training data. The next step is to predict the target values for the test dataset, also calculating the standard deviations to quantify the uncertainties of the predictions

To leverage the strengths of both previous models to improve the prediction of the validation data, Deep Kernel Learning is used. The GPR model is particularly well suited for data extrapolation, while the NN model can better capture complex relationships between variables. The DKL model is trained as follows: first, the training data are fed into an NN and the network is trained. Next, the outputs of the NN's last hidden layer are passed to an GPR model and used to train it. This is done because the GPR learns more effectively when it is provided with multiple data inputs. The NN consists of five layers and uses the activation functions ReLU, tanh, and sigmoid. The GPR model uses a Matérn kernel, scaled by an additional parameter. Through this combination of NN and GPR, the model can exploit the advantages of both approaches and thus, in principle, provide improved predictions on the validation data.

4. RESULTS AND METRICS

The evaluation of machine learning models is of critical importance, with the primary objective being to ensure robust and accurate predictions on previously unseen data, thereby validating the model's generalizability and the efficacy of the training process. In the context of supervised learning, the discrepancy between the prediction of the model and the actual value of the simulation in the entire data set is calculated. A significant discrepancy signifies inadequate performance of the machine learning model, while a negligible discrepancy indicates optimal performance. There exist numerous methods for calculating this discrepancy through the utilisation of so-called loss functions. One such approach involves the calculation of the mean absolute error (MAE). This approach is susceptible to outliers, which can be mitigated by employing as an alternative loss function. In this case, the mean value is calculated using the deviation between the predicted and actual values of the entire data set [21]. Another option is to use the R^2 value, which is a measure of the quality of the predictions of the ML model. The value can be between 0 and 1, where 1 corresponds to a prediction of 100% [22]. Another parameter of interest is the maximum error (MAX). These three metrics were selected as the evaluation guidelines for this work.

In relation to simulating real accidents or even generic scenarios with a system code, there is a nearly infinite number of parameter combinations, which can also change during the process. The influence of users should not be underestimated either. It is therefore possible that the models have to work with boundary conditions that were not covered by the training data. For this reason, the focus should be on a suitable selection of samples. Especially for different material compositions, as these can change during the process and are difficult to estimate in reality. For this reason, it is important to know where the limits of the models are and what the deviations are for data outside the trained parameter ranges in order to be able to interpret the results appropriately. Furthermore, the aim is of course to minimise these deviations. Therefore, all models were tested on two different data sets and the results were compared.

The results of the NN and the GPR model for the test data, based on the DEBRIS experiments, are shown in Figure 3. Here, the models' predictions are plotted against the actual simulation data. In the case of perfect agreement, the points lie on the trend line. Both models exhibit good performance, which is reflected not only in the graphical representations but also in the metrics. The R^2 scores of all models exceed 0.9, indicating strong predictive capability. The R^2 score refers to the 20% test data drawn from the DEBRIS dataset. In this comparison, the NN performs worst with 0.969, while the GPR model achieves the best score at 0.997. Considering the MAE and the maximum error as well, the GPR model (5.55 and 16.92 W/kg) delivers the best performance in predicting the dryout heating power for the test data. Conversely, the NN (19.09 and 79.19 W/kg) performs worst on these metrics. For test data that reflects the trained range, these two models are therefore very well suited for predicting dryout heating power.

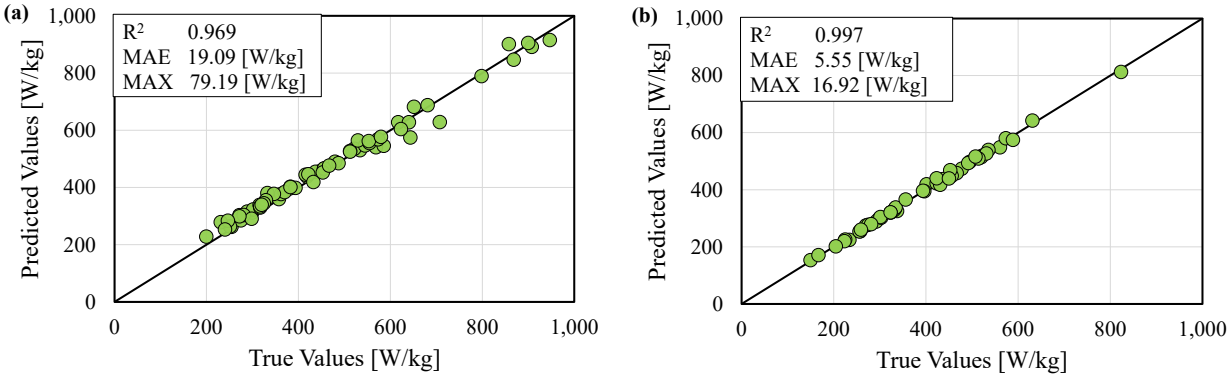

Figure 3. Prediction of NN (a) and GPR (b) for the DEBRIS test data.

When the models are provided with validation data featuring a different material composition, a very different picture emerges. Here, both models perform significantly worse. The MAE of the neural network and the GPR model are above 100 W/kg. Although the maximum error is considerably higher for the GPR model, at 505.20 W/kg, than for the NN (296.80 W/kg), the majority of its predictions are closer to the true value. Compared with GPR, the NN substantially underestimates most of the test data. Nevertheless, the predictions of both models are unsatisfactory when they are forced to extrapolate due to the different material composition and slightly differing parameter ranges. This outcome was to be expected; however, given the aim of integrating the ML model into a system code and the associated user influence, it cannot be guaranteed that only material and parameter combinations encountered during training will occur in practice, so at least an improvement of these validation results is required.

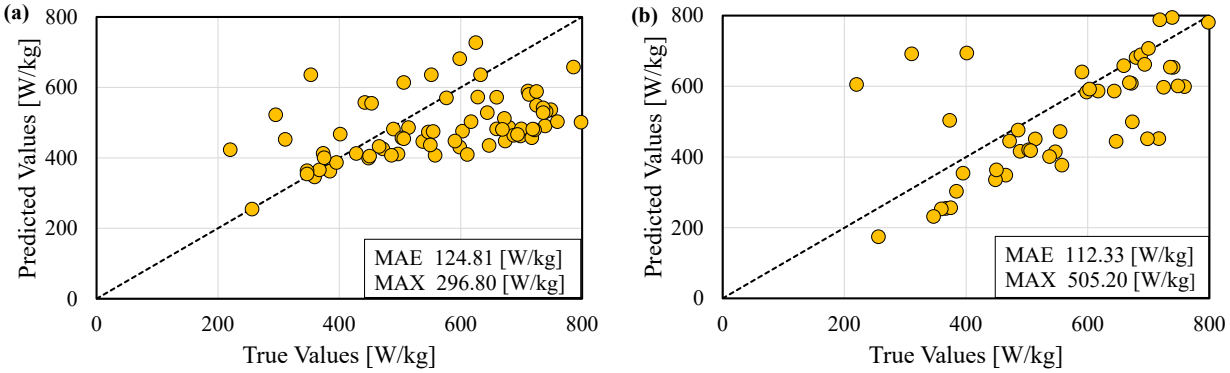

Figure 4. Prediction of NN (a) and GPR (b) for the validation data.

To combine the strengths of both ML models, the development of a combined model was pursued. The hypothesis is that a combined model will demonstrate excellent predictions for both the DEBRIS test data and the validation data, which differs from the training data. As illustrated in Figure 5, the outcomes for both data sets are presented, with the green dots representing the predictions for the DEBRIS data and the yellow dots denoting those for the validation data. Firstly, it is evident that the combined model exhibits inferior performance in comparison to NN and GPR on the DEBRIS test data. The R^2 score remains above 0.9, however, all three metrics have deteriorated. In the context of the problem under consideration and the training data employed, the combined model does not appear to be the optimal choice. However, given that the objective of this study is to enhance the prediction accuracy for entirely unseen validation data, the combined model is evaluated using precisely this data. As demonstrated in Figure 5, a substantial enhancement is observed in direct comparison with the other two models. Naturally, deviations from the true value are still observable, but the MAE is almost halved relative to the NN. The maximum error can also be improved somewhat. Moreover, the dryout heating power is no longer underestimated in most cases; instead, a distinctly more balanced picture emerges. In general, most predictions lie within the 20% margin. The hypothesis that predictions would improve for data deviating from the domain on which the model was trained has been confirmed.

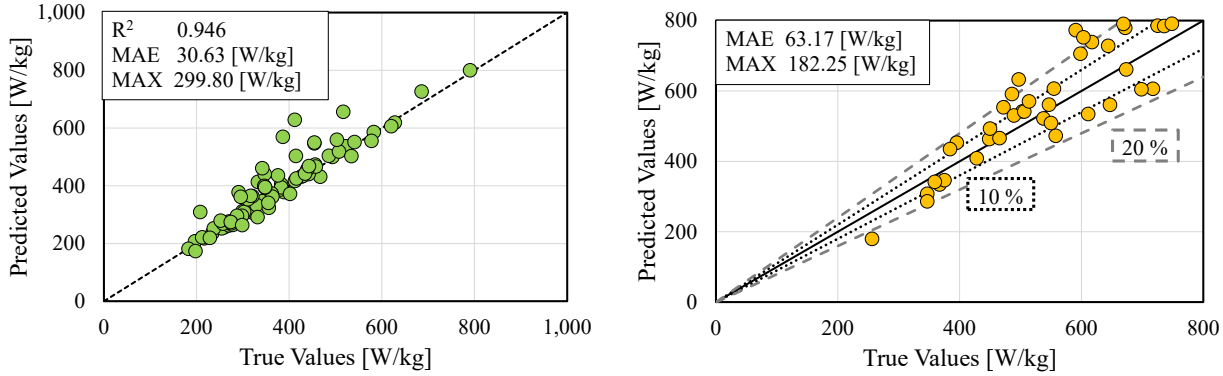

Figure 5. Prediction of the combined model for the DEBRIS test data (left) and the validation data (right).

5. CONCLUSIONS

In case of a postulated severe accident scenario involving ex-vessel debris bed formation, long-term cooling is a key factor in accident mitigation. The phenomena occurring during this process can be modelled with severe accident codes. Due to their complexity, however, these codes require substantial computational effort and long computing times. The work presented in this paper aims to significantly reduce these computation times using machine learning models, without losing too many details.

More specifically, this paper describes the further development of a machine learning model for predicting the dryout heating power of a debris bed. The initial model architecture was a multilayer neural network with four layers: an input layer, two hidden layers, and an output layer. The hidden layers used the ReLU activation function to capture nonlinear relationships and improve training dynamics. A systematic hyperparameter analysis was conducted to select the final model parameters and structure. A Gaussian Process Regressor with a special kernel was also used. The kernel in the model is a combination of a constant kernel and a radial basis function kernel. The third model is a hybrid version of an artificial neural network

and a Gaussian Process Regression model. The idea behind this combination is to leverage the strengths of both models to improve predictions for validation data that differ from the training data in terms of material composition. Since the ML model is to be integrated into a system code, it is not possible to cover all possible parameter combinations in the training data. The model is therefore forced to extrapolate. Even though the performance of an ML model degrades significantly under extrapolation, the predictions should remain within a reasonable range so as not to overly affect the subsequent calculations of the system code.

The R^2 value for the combined model is around 0.95, which is slightly lower than for the individual models but still very good. The results for the validation data show that the combined model provides improved predictions. The mean absolute error is reduced from over 100 W/kg to 63 W/kg, representing an improvement of about 40%. Most predictions fall within a 20% band, indicating a satisfactory agreement between predictions and actual values. The individual models tend to underestimate the validation data. In this regard, the combined model yields more balanced predictions. The results of the work thus confirm the assumption that combining the capabilities of neural networks and Gaussian process regression models improves predictions outside the trained range.

INTRODUCTION

- In the case of a severe accident, debris beds may form as a result of insufficient cooling
- After successful quenching, long-term cooling is essential to prevent renewed melting of the debris bed
- Highly complex and numerically demanding processes
- In reactor safety research severe accident codes are used to simulate accident scenarios and therefore the coolability of debris beds

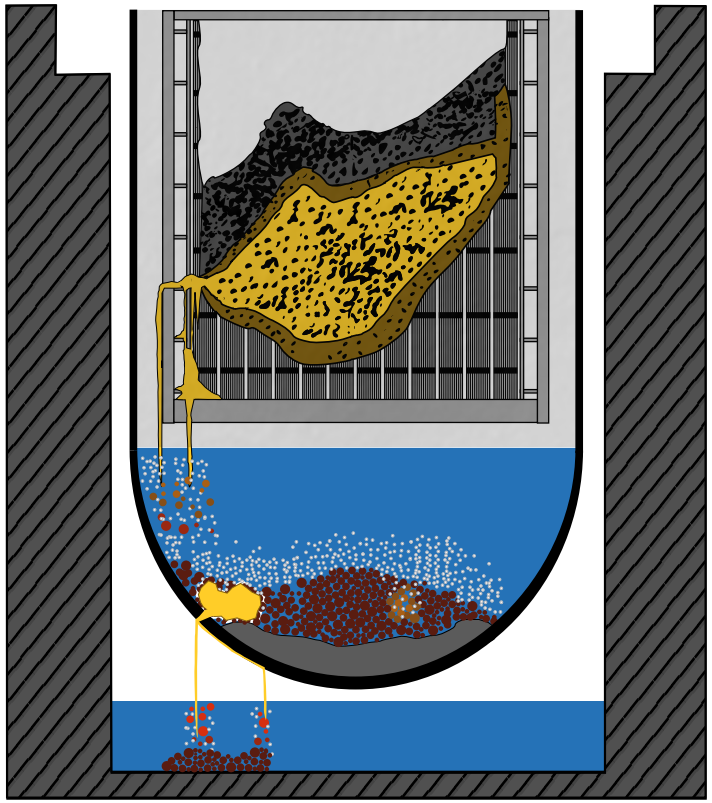

Figure: Peschel, 2024

INTRODUCTION

- Long-term cooling is critical for safety
  - Prevents remelting of debris bed due to decay heat
  - Maintains integrity of RPV and containment
  - Insufficient cooling leads to localised drying out
- Key parameter: Dryout heat flux
  - Determines maximum heat flux before dryout
  - Essential for predicting long-term cooling capability
- System codes accurate but computationally intensive

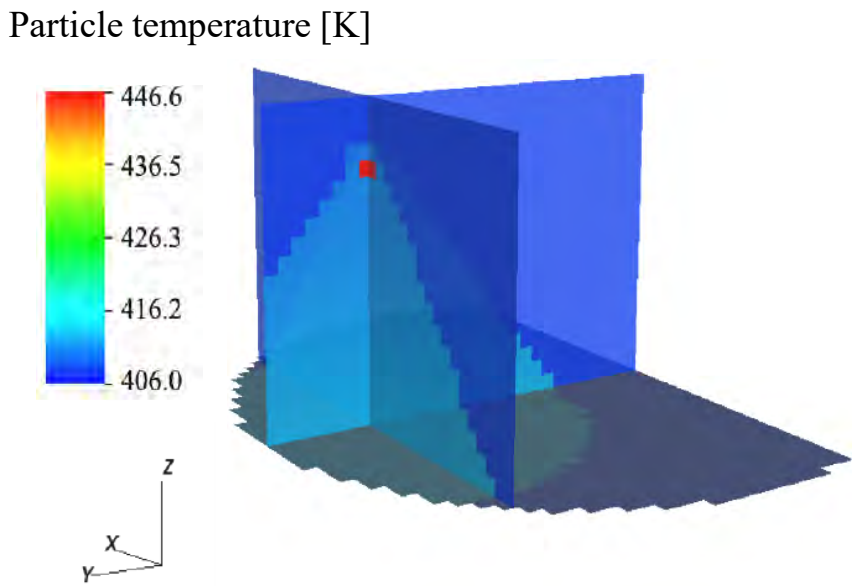

Figure: Hartmann, 2020

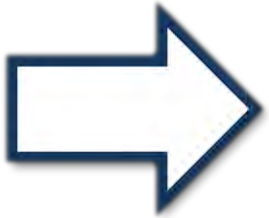
INTRODUCTION

Problem

- Due to the complexity of some phenomena
  - High numerical effort
  - Long computing times



Aim

- Reduction of computing time
- Minimal loss of detail

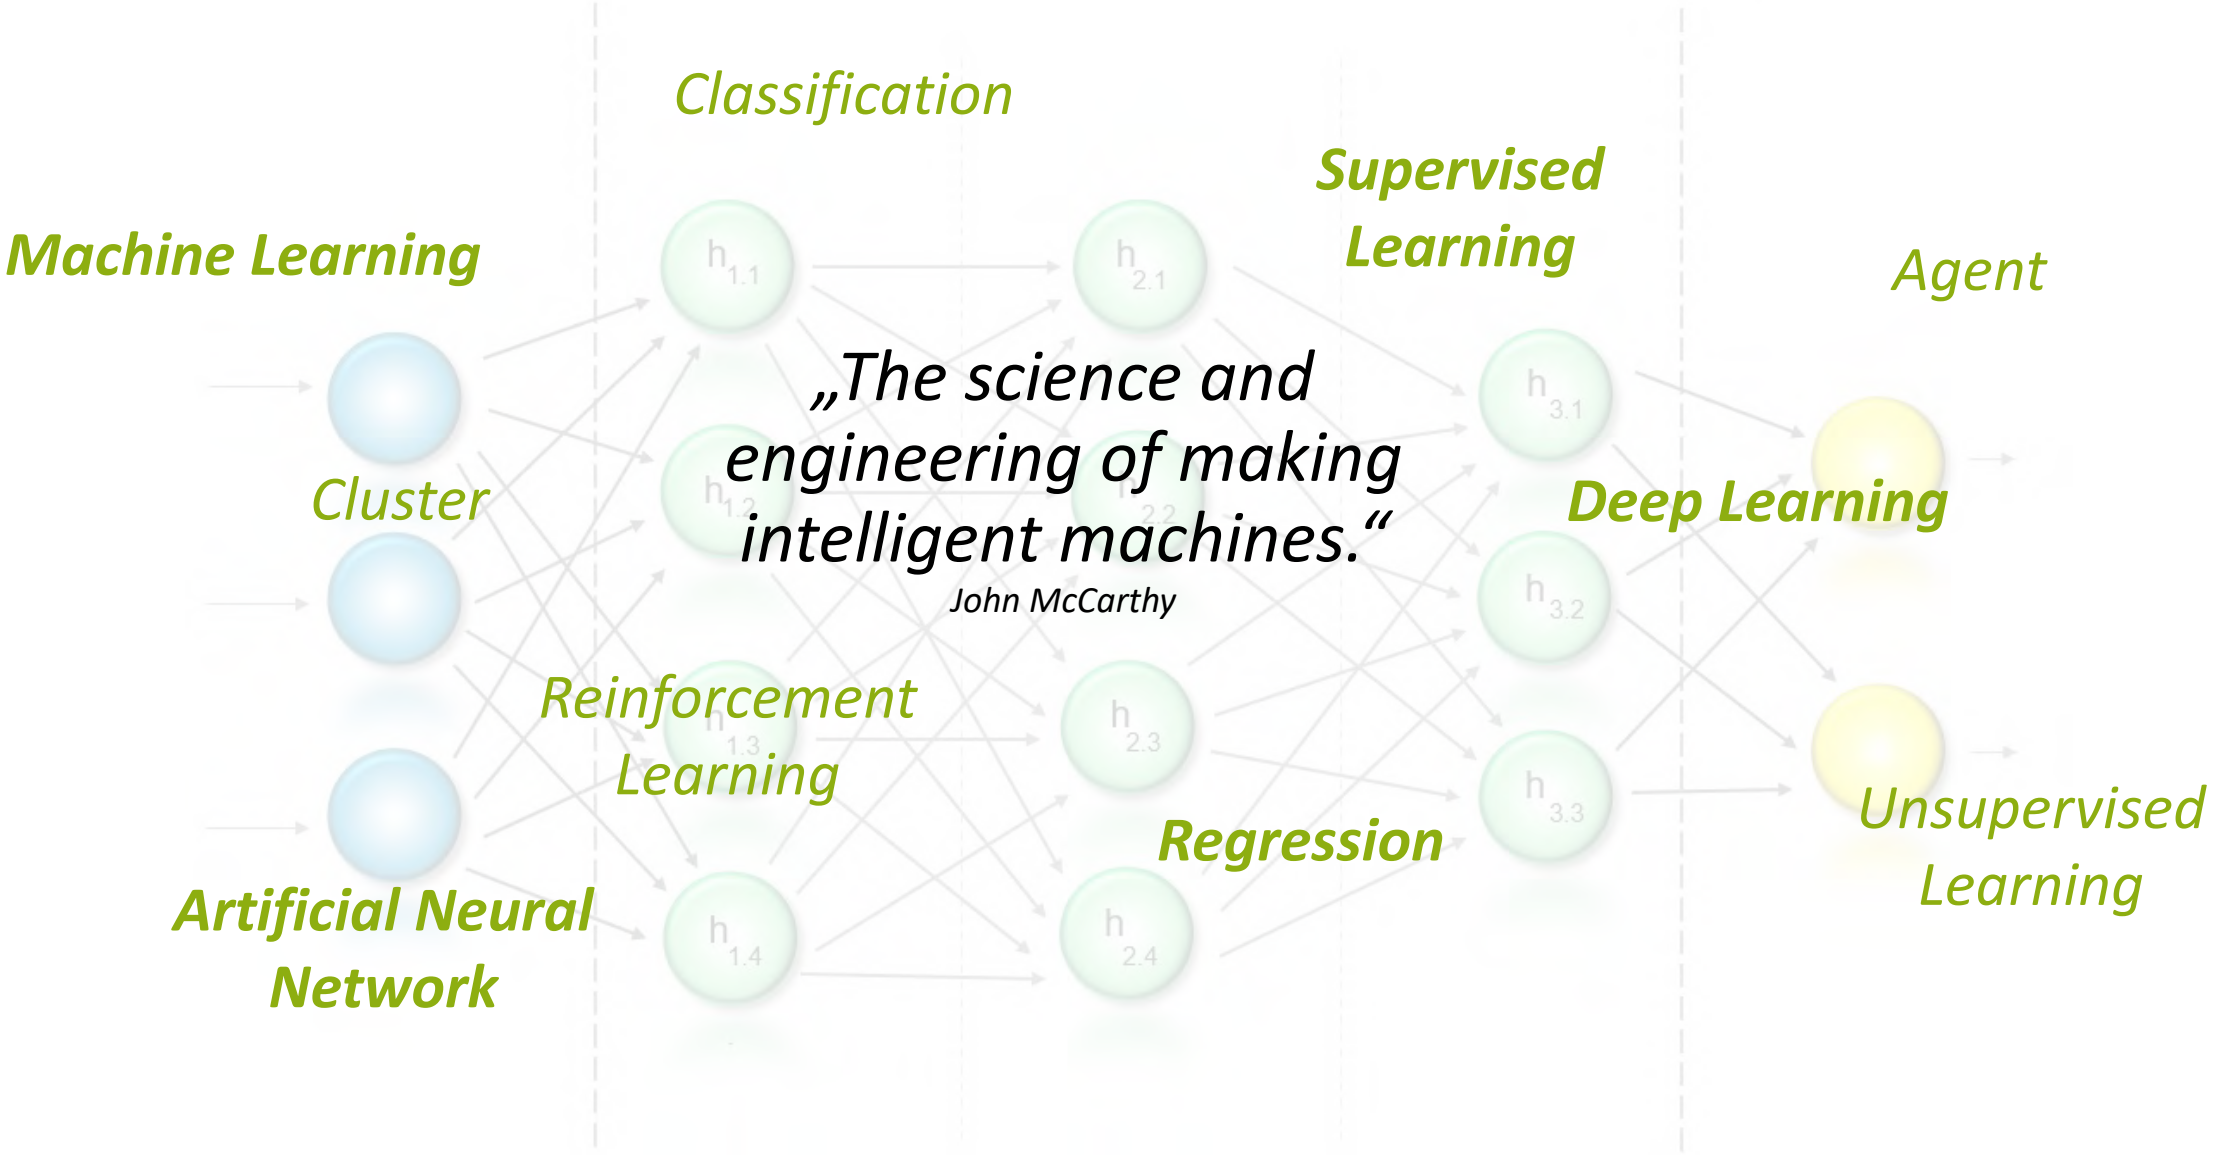
Concept

Use of machine learning model to predict the coolability of debris beds

Integration into the severe accident code AC²

Basics of Machine learning

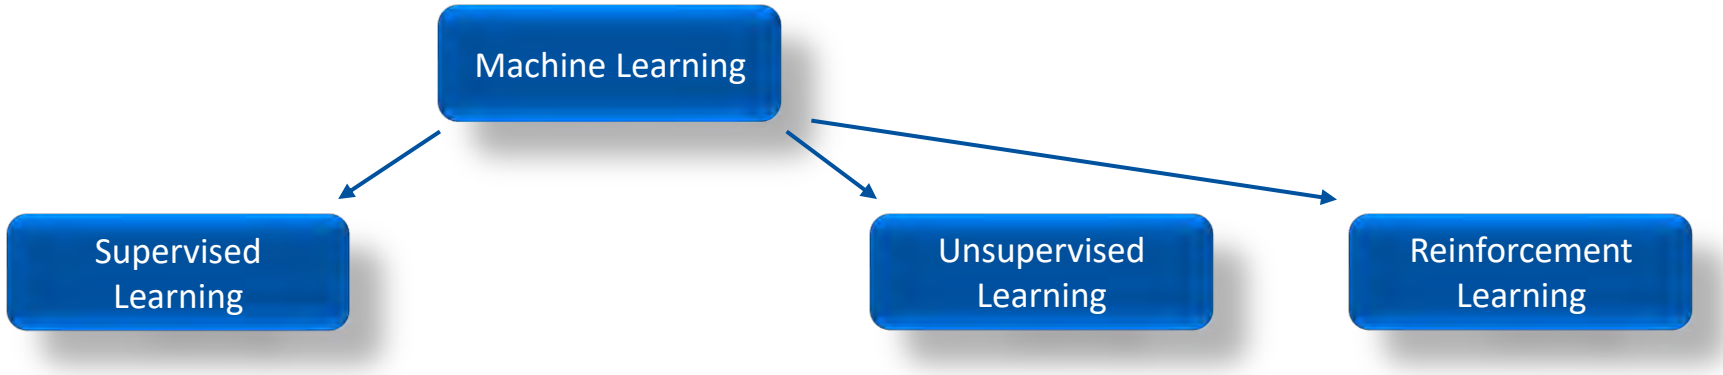
Artificial Intelligence



Basics of Machine learning

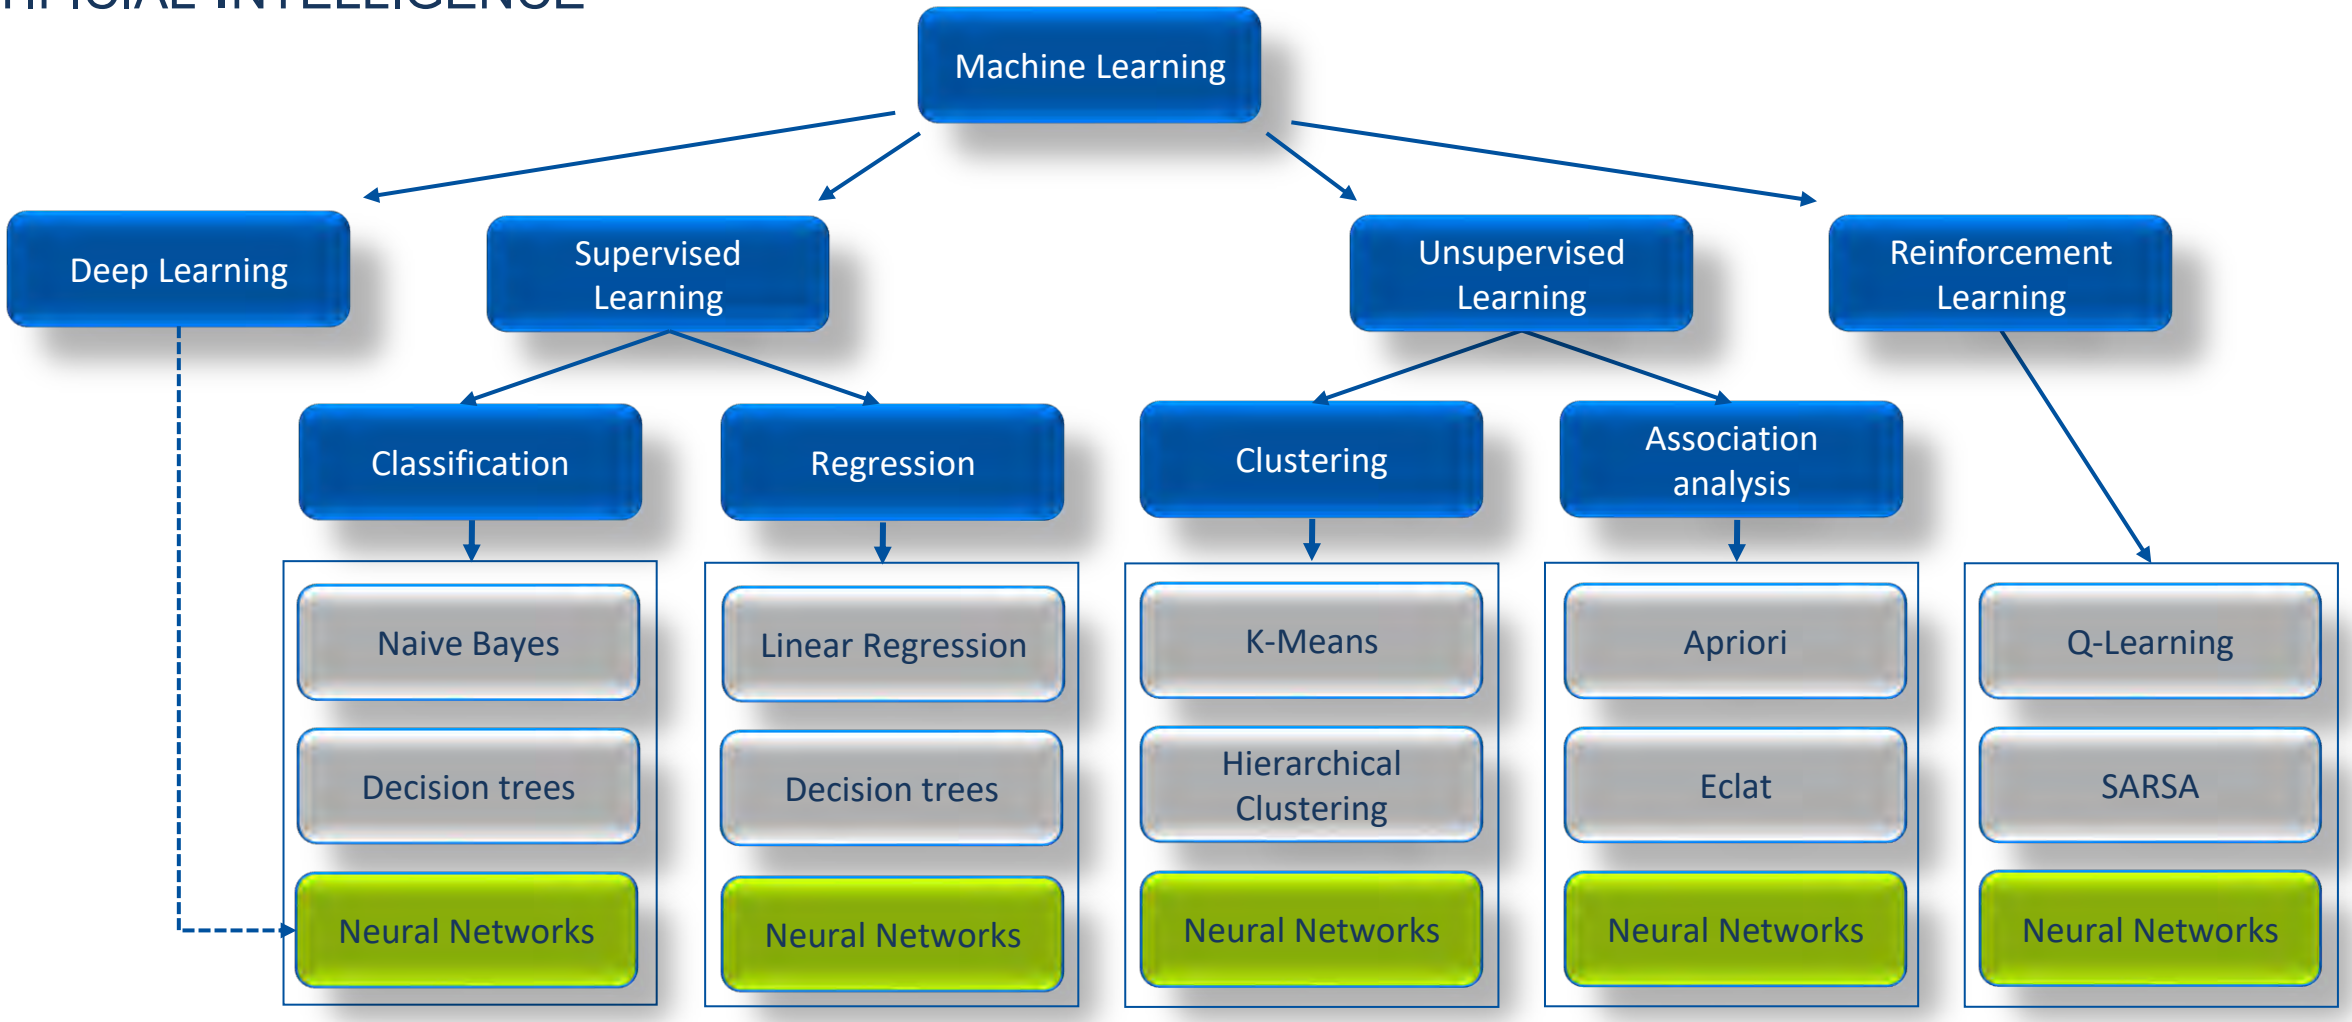
Artificial Intelligence

The purpose of machine learning models and algorithms is to identify meaningful correlations in input data and derive rules based on these correlations.



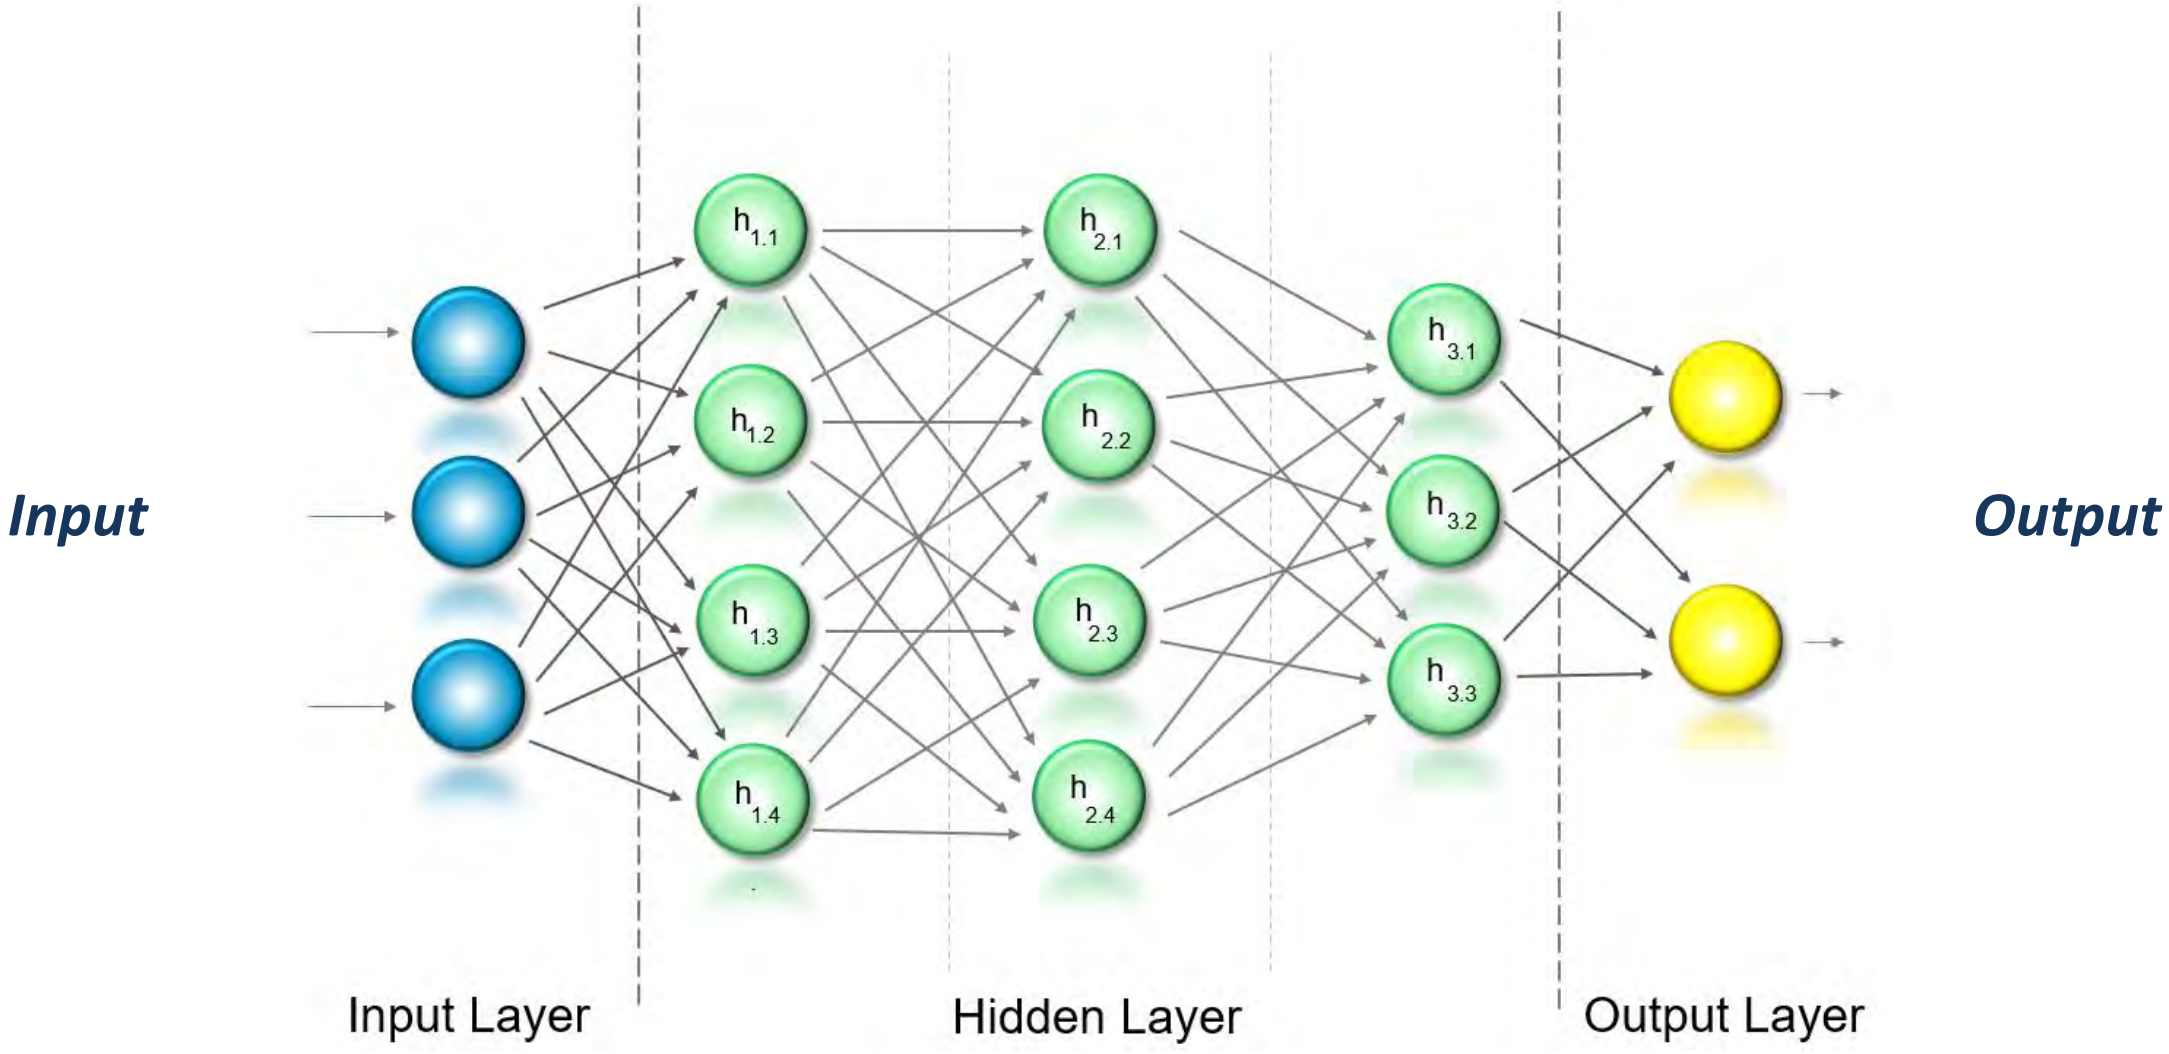
Basics of Machine learning

Artificial Intelligence



BASICS OF MACHINE LEARNING

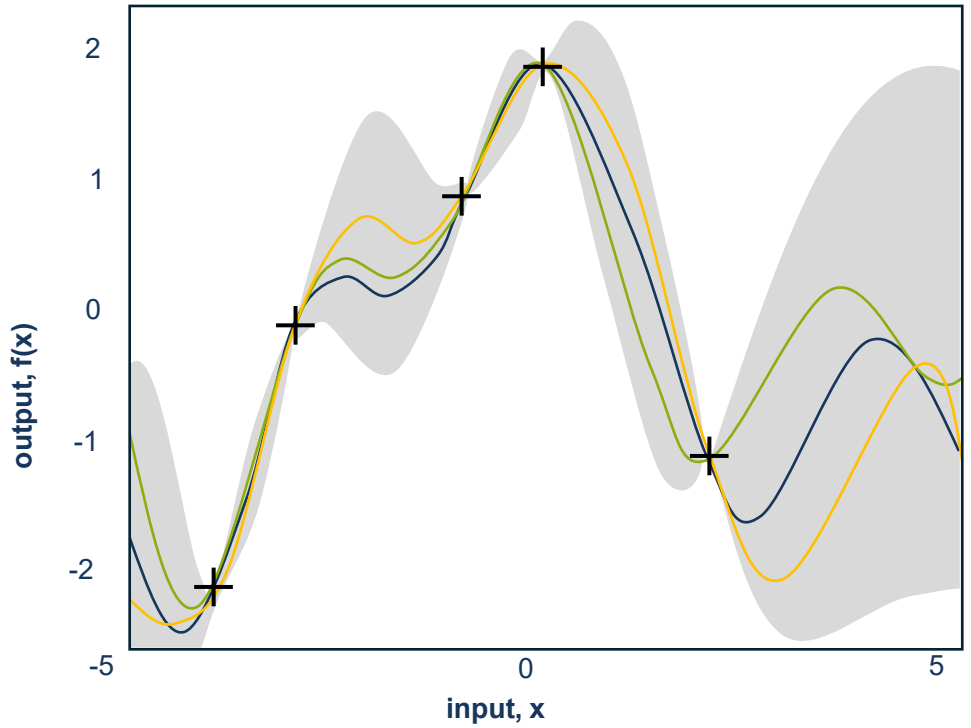
ARTIFICIAL NEURAL NETWORKS



Basics of Machine learning

Gaussian Process Regression (GPR)

- Non-parametric method used to predict and model complex data.
  - Distribution of the training data across all possible functions that describe this data.
  - This distribution is characterised by a mean function and a covariance function, or `kernel´
  - In this model: Radial Basis Function
- Not only outputs individual data points, but also provides a probability distribution
- Training data is regarded as a „sample“



Training Data

- Creation of an initial database with the detail code COCOMO
- Basis: DEBRIS dryout tests of the IKE
- Parameter variation:
  - Input parameters: *system pressure, particle diameter, porosity, saturation temperature*
  - Output parameters: *dryout heating power*

	System Pressure [MPa]	Particle Diameter [m]	Porosity [-]	Saturation Temperature [K]
Range	**0.1 – 0.5**	**0.0024 – 0.006**	**0.27 – 0.46**	**373 - 425**

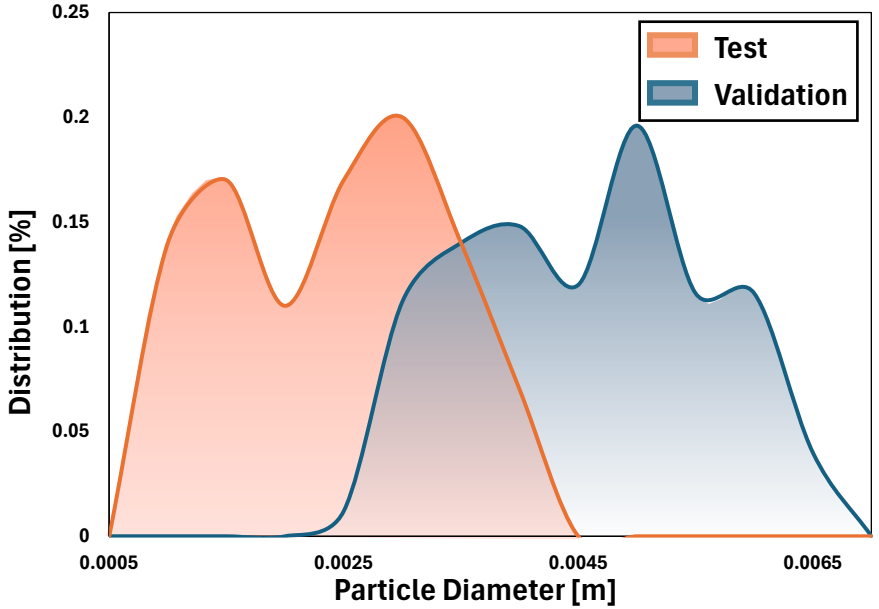
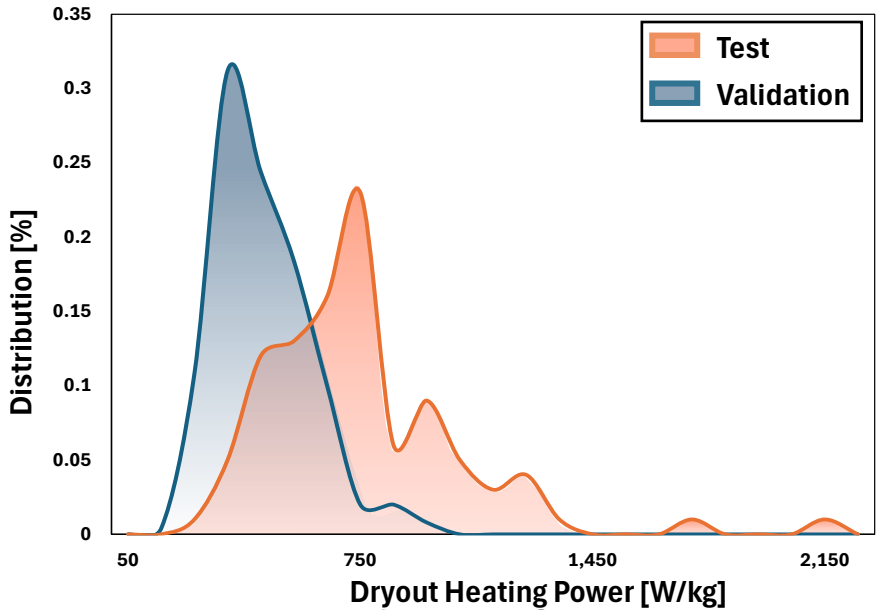
Validation Data Set

- Data set with different material data
- Hypothetical corium parameter outside the trained range
- COCOMO simulation data

- ‘Blind test’
- Investigate limits of the models
- Training set cannot cover all possible combinations

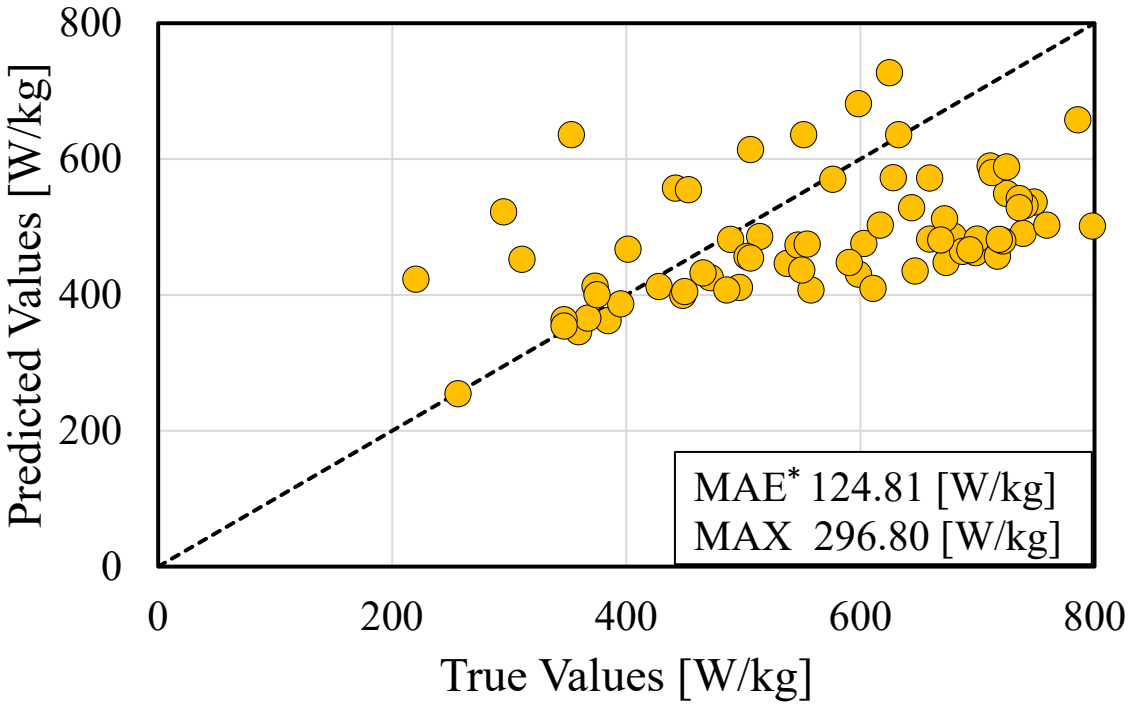




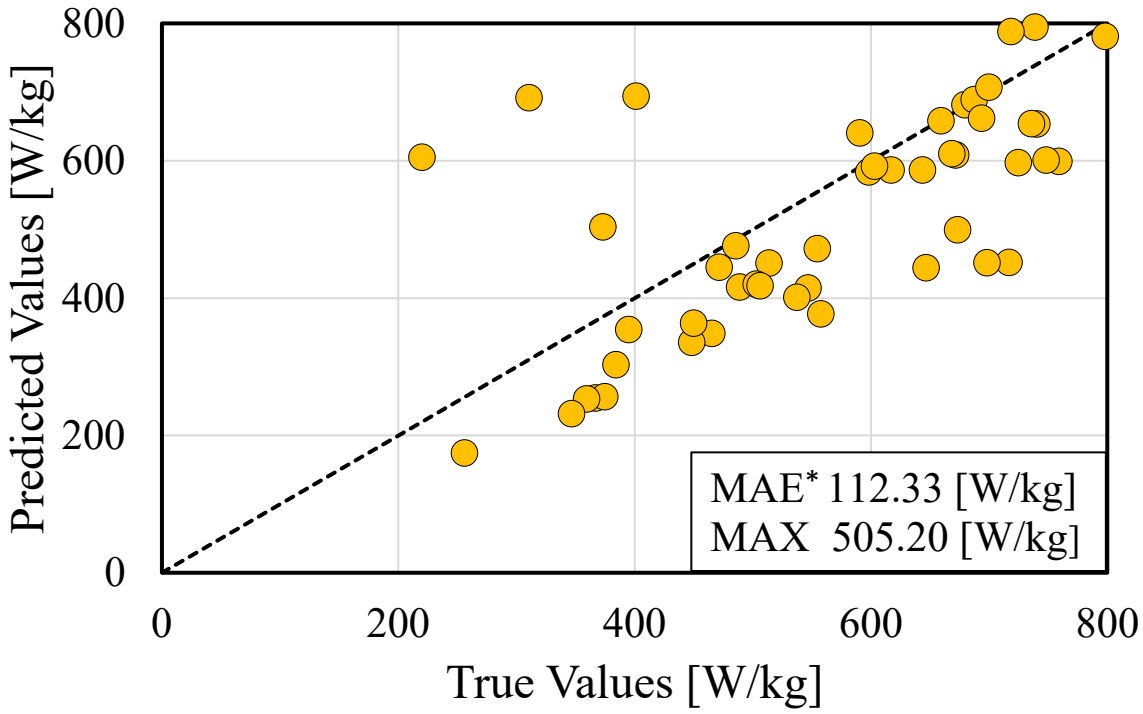
Preliminary Results

Validation Data

Neural Network



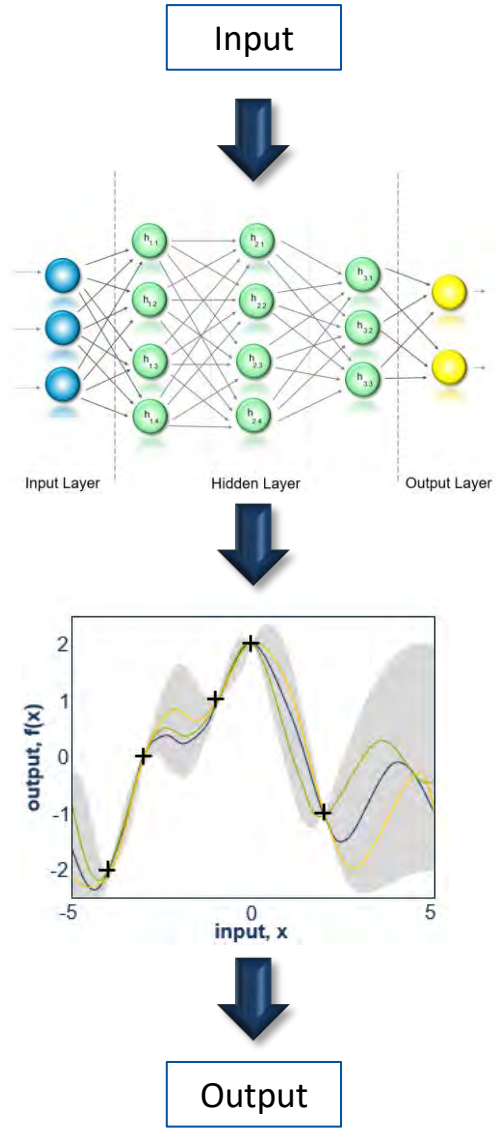
GPR model



*Mean absolute Error

Coupling of Neural Network and GPR

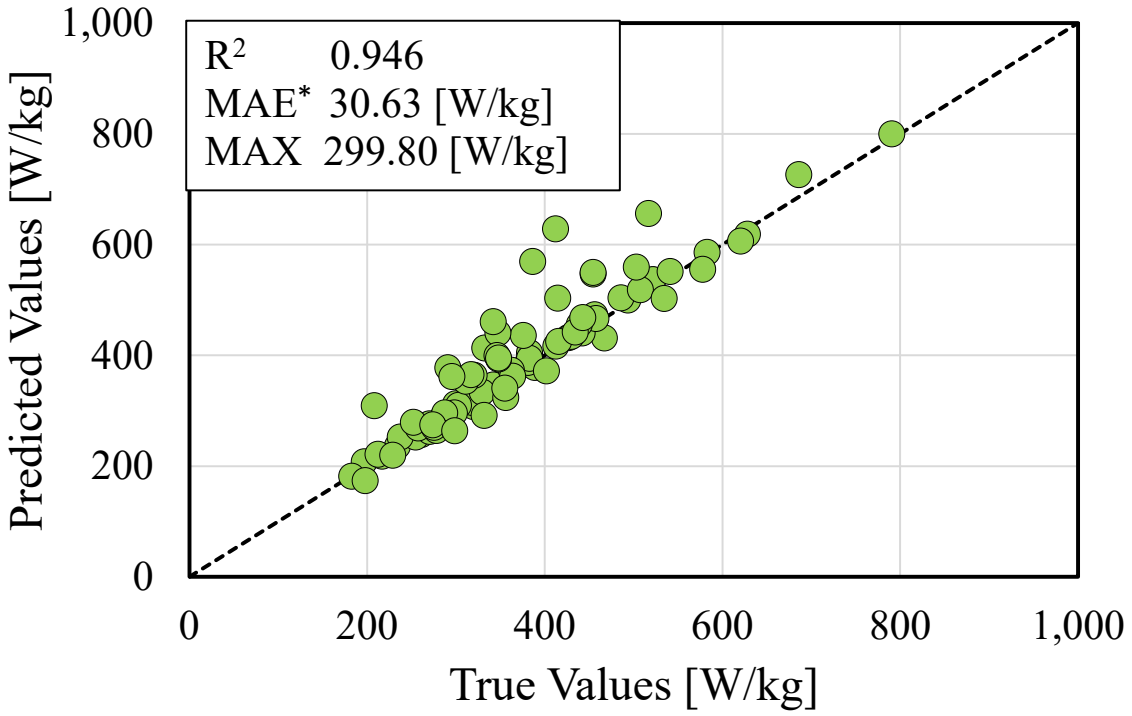
- Idea: Coupling Neural Network and GPR to improve prediction of the validation data set
  - GPR is capable of better extrapolation
  - Neural Network performs better complex relationships
- Training data first read into Neural Network and trained, then results of the last hidden layer of the Neural Network passed on to GPR and trained with it
- Neural Network consists of 5 layers and uses ReLU, tanh and Sigmoid activation functions
- GPR has a Matern kernel, scaled with an additional parameter



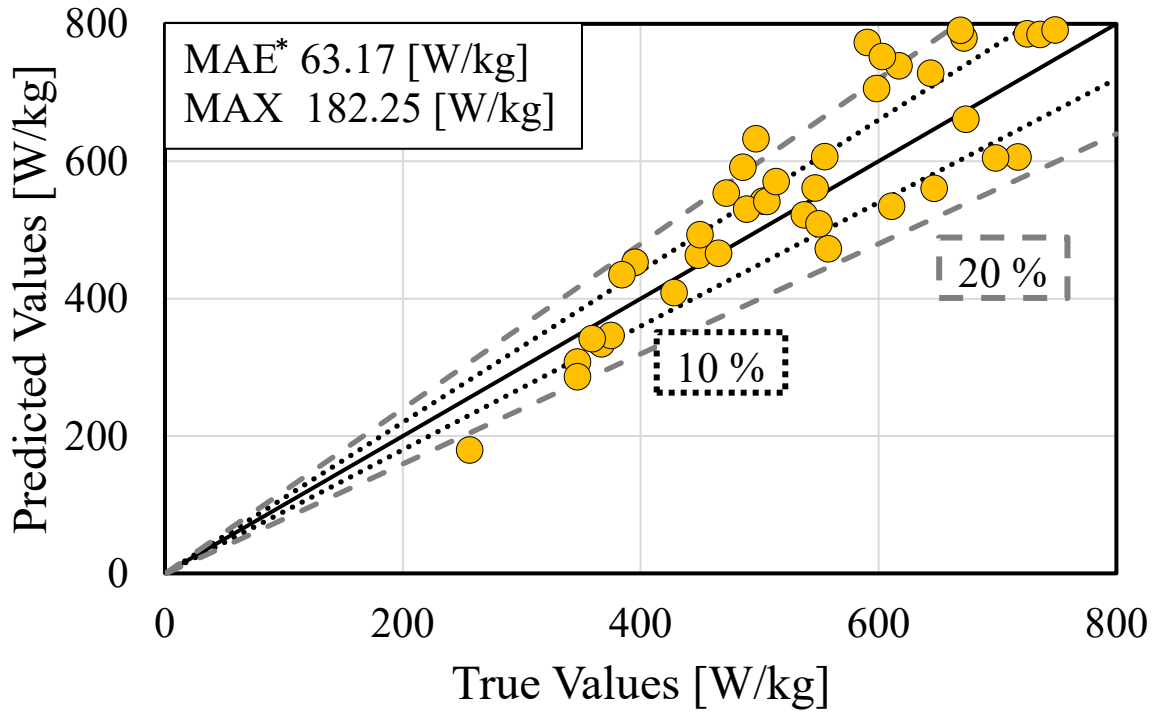
Preliminary Results

Coupling Model

Test data



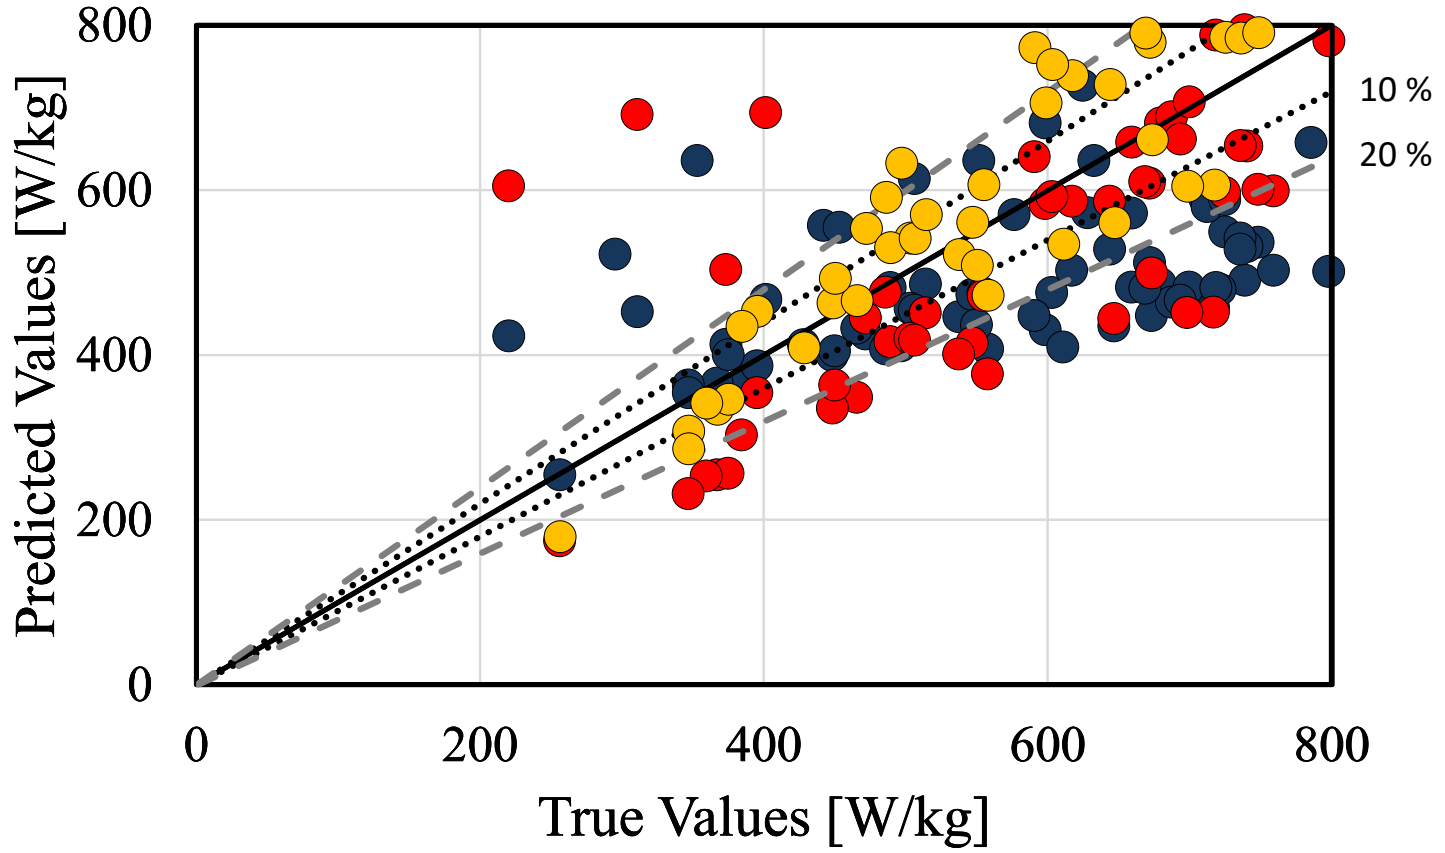
Validation data



*Mean absolute Error

Preliminary Results

Validation Data



Conclusion

- Successful creation of an initial database
- Development of promising machine learning approaches
- Recognition of the limits
  - Very accurate predictions within the trained range
  - Significant deviations in predictions for data outside the valid range
- Development of initial Neural Network and GPR combining model

↳ Improved performance for data outside the defined limits (extrapolation)

Outlook

- Improve the quality of the networks / Modification
- Focus on coupling with AC²
  - Align models with the system code requirements
  - Time dependent
  - Adjustment of parameters

  ↳ Generate new datasets

- Integration into the AC² system code
- Application to power plants

AI-DRIVEN ESTIMATION OF CORIUM THERMOPHYSICAL PROPERTIES FOR EX-VESSEL CORIUM STABILIZATION SIMULATIONS

Raphaël Monod, Charlaine Bouillet and Jean Baccou

ABSTRACT

The management of severe accidents in some second- and third-generation reactors is based on stabilizing the corium outside the vessel by spreading and pouring water onto the upper crust. The coolability of the melt is estimated using different models, including water ingression, which depends on thermodynamic properties such as the mass liquid fraction or volumetric liquid fraction of corium. However, corium is a highly complex mixture that may contain a large number of chemical elements, and the accurate calculation of its properties is both difficult and computationally expensive.

In the ASTEC software, the traditional strategy relies on preliminary calculations performed with a thermodynamic equilibrium code. For a given corium composition at vessel failure and a given concrete composition, the properties are obtained by interpolating a two-dimensional table in temperature and composition derived from these preliminary calculations, allowing the evolution of the mixture during corium–concrete interaction to be tracked.

This approach is satisfactory when the corium composition evolves solely due to the addition of concrete of constant composition, but it loses validity in the presence of phenomena such as gas release, secondary flow of corium from the vessel to the cavity, or interaction with basemat made of concretes of different types.

To overcome these limitations, a new approach has been developed based on machine learning. Two neural networks were trained on Gibbs minimizer NucleaToolbox calculations with the NUCLEA thermodynamic database to directly estimate the mass liquid fraction and volumetric liquid fraction of corium from temperature and effective atomic compositions, regardless of the actual corium–concrete mixture composition.

The aim of the paper is first to present the methodology used to develop these neural networks, and then to highlight the impact of using them to account for the real composition of the corium–concrete mixture in a severe accident simulation code such as ASTEC.

1. INTRODUCTION

In the event of a severe accident involving the core melt in a nuclear power plant, two management strategies can be considered. The first involves attempting to cool the reactor vessel from the outside to preserve its integrity and keep the corium inside the vessel. The second accepts a potential vessel failure and allows the corium to spread outside the vessel so that it can be cooled and stabilized. Whether the corium is retained in-vessel or ex-vessel, its physical and thermodynamic properties play a major role in the stabilization process. In the case of ex-vessel corium stabilization however, the corium composition is more complex and varies significantly with time due to its interaction with the basemat concrete.

The Accident Source Term Evaluation Code (ASTEC) is a software tool developed by ASNR [1] that allows the modelling of a nuclear accident from its initiation to the release of the source term into the environment; In particular, ASTEC has dedicated models to evaluate the two severe accident-management strategies: in-vessel corium retention [2] and ex-vessel corium retention [3]. This paper discusses new developments that have been carried out for ex-vessel retention strategy evaluation with the MEDICIS module of ASTEC that handles molten corium-concrete interaction (MCCI).

In MEDICIS, the corium may contain up to 12 elements after its interaction with the concrete: Al, C, Ca, Cr, Fe, H, Ni, Mg, O, Si, U, and Zr. The resulting mixture has complex thermodynamic properties. One of the most important properties, regarding the evaluation of the corium stabilization is its liquid fraction. In MEDICIS, the mass liquid fraction and the volumetric liquid fraction are particularly employed. Mass liquid fraction is defined as the total mass of the liquid phases divided by the total mass of all solid or liquid phases at thermodynamic equilibrium. Volumetric liquid fraction is defined as the total volume of the liquid phases divided by the total volume of all solid or liquid phases at thermodynamic equilibrium.

The computation time for a single equilibrium point of such a mixture using a Gibbs energy minimizer such as NucleaToolbox and the NUCLEA thermodynamic database, though relatively modest (typically a few seconds to a minute per calculation), is not compatible with a direct, on-the-fly call during an ASTEC run. Traditionally, ASTEC therefore relies on pre-computed tables for compositions that are approximately close to the actual mixture of the simulation. In the best-case scenario, when the vessel fails, the composition of the corium that falls into the cavity can be saved and the calculation can be halted. The tables are then generated for a range of mixing ratios between that corium and the concrete that forms the cavity. These calculations can be time-consuming, the operation is manual, and this approach does not fully account for all phenomena that might produce a corium-concrete mixture composition different from a simple mass-weighted average of the initial corium and the cavity concrete. Such phenomena include secondary pouring from the vessel with compositions differing from the first corium slump, gas emission, or compositions formed from multiple concrete sources.

To overcome this limitation, we propose in this work a new fast-to-evaluate surrogate model that can accurately predict the volumetric and mass liquid fractions of a mixture at a specified temperature. Pressure is not treated as a variable and is fixed at 1 bar. The difficulty in building this model stems from the nature of the data to be computed, which exhibit various behaviours depending on the mixture composition. Indeed, the disappearance or appearance of certain phases as a function of temperature can have a large impact on the simulated quantity, producing data with steep gradients or even discontinuities (Fig. 1, from [4]). Classical regression models consequently lose significant accuracy in these regions. To capture this specificity, the model construction relies on a machine-learning approach that employs a bagging ensemble of neural networks.

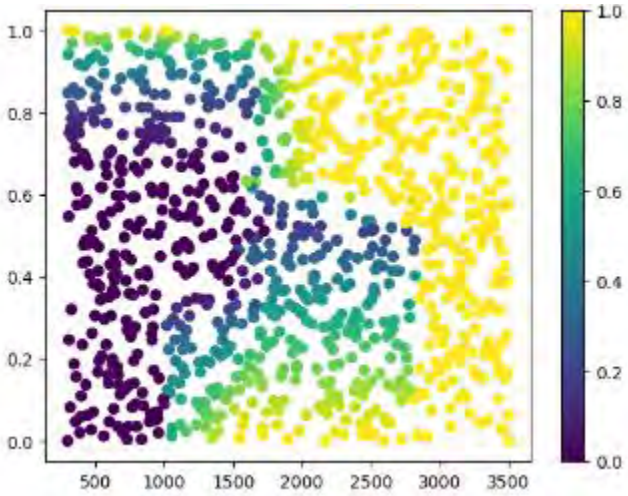

Figure 1. Mass liquid fraction of corium (colour) as a function of temperature (abscissa) and oxygen proportion (ordinate).

The paper is organized as follows. Section 2 presents the construction of the model. The model is then employed in the ASTEC Section 3, replacing the pre-computed tables, within the corium-concrete interaction module. Then the Section 4 is dedicated to the conclusion.

2. CONSTRUCTION OF THE SURROGATE MODEL

The construction of the model rests on two essential ingredients, which are detailed in the following three subsections. The first ingredient is the generation of a representative database for the problem of interest, which will be used for training, validation, and testing of the model. A key aspect of this generation is the removal of potentially aberrant simulated values caused by incorrect thermodynamic equilibria. The second ingredient is the choice of the modelling family that will be used to represent the model.

2.1. Generation of the Training Database

The training database was assembled by blending standard corium with the various concretes used in French nuclear power plants, in several different proportions. Each of these mixtures was partitioned into three phases: an oxidized phase, a metallic phase, and a gaseous phase, using an extremely simple atom-recombination algorithm based on an empirical affinity of atoms to assemble into molecules. From these three phases, four distinct compositional mixtures were constructed: the oxidized composition, the metallic composition, the fully purified gas composition, and the total composition. All molar fractions were subsequently rounded to the nearest multiple of 1/256, to limit the over-representation of certain regions and to guarantee a bijective mapping between the ASCII values of the data sets and the binary values used by the codes, thereby simplifying the construction of the calculation database.
In total, 6129 different compositions were generated. For each of these compositions, a temperature-dependent table of length 225 was produced, yielding 1379025 thermodynamic equilibrium calculations. Of these, 472 failed to converge and were therefore excluded from the training database.

2.1.1. Deleting of non-global equilibria

It can happen that an energy-minimisation software converges to a local, rather than the global, minimum. In such cases the Gibbs free energy G(T) may exhibit discontinuities, as can the mass or volumetric liquid

fractions as functions of temperature. Because these solutions are not the ones sought and they lead to discontinuities, it is essential to detect and exclude them from the training database.

For a homogeneous phase (i.e., with a fixed number of moles n) and at a fixed pressure P, the constant-pressure heat capacity is

$$C_p = -T \left.\frac{\partial^2 G}{\partial T^2}\right|_{n,P} \tag{1}$$

At the temperatures considered (above 500 K), where quantum effects are negligible, the system is in equilibrium and the pressure is atmospheric, we can assume that heat capacities are strictly positive, i.e.

$$-T \left.\frac{\partial^2 G}{\partial T^2}\right|_{n,P} > 0 \tag{2}$$

Because of linearity, for several homogeneous phases whose individual compositions remain fixed, the average heat capacity is simply the mass-weighted mean of the elemental heat capacities. Consequently, the above relation remains valid for any collection of homogeneous phases with fixed individual compositions. Now let us consider a region where the individual phase compositions change (appearance, disappearance, or evolution). Take three temperatures $T_1 < T_2 < T_3$ that are infinitesimally close to each other. If the phase compositions did not evolve, and letting $G_k = G(n, T_k, P)$, we would have

$$-T \left.\frac{\partial^2 G}{\partial T^2}\right|_{n,P} = -T_2 \frac{2}{T_3 - T_1}\left(\frac{G_3 - G_2}{T_3 - T_2} - \frac{G_2 - G_1}{T_2 - T_1}\right) \tag{3}$$

Suppose now that at T_3, a change in composition occurs because a more stable equilibrium exists. Denote by $G'_3 = G'(n,T_3,P)$ the new Gibbs-energy value. The more stable equilibrium satisfies $G'_3(n,T_3,P) < G3(n,T_3,P)$. Hence

$$\frac{G'_3 - G_2}{T_3 - T_2} - \frac{G_2 - G_1}{T_2 - T_1} < \frac{G_3 - G_2}{T_3 - T_2} - \frac{G_2 - G_1}{T_2 - T_1} \tag{4}$$

and therefore

$$-T_2 \frac{2}{T_3 - T_1}\left(\frac{G'_3 - G_2}{T_3 - T_2} - \frac{G_2 - G_1}{T_2 - T_1}\right) > -T_2 \frac{2}{T_3 - T_1}\left(\frac{G_3 - G_2}{T_3 - T_2} - \frac{G_2 - G_1}{T_2 - T_1}\right) > 0 \tag{5}$$

Thus, for the global Gibbs energy G_{global} of the system, which can switch from one phase arrangement to another as a function of temperature, we obtain

$$-T_2 \frac{2}{T_3 - T_1}\left(\frac{G_{global3} - G_{global2}}{T_3 - T_2} - \frac{G_{global2} - G_{global1}}{T_2 - T_1}\right) > 0 \tag{6}$$

So

$$\frac{2}{T_3 - T_1}\left(\frac{G_{global3} - G_{global2}}{T_3 - T_2} - \frac{G_{global2} - G_{global1}}{T_2 - T_1}\right) < 0 \tag{7}$$

In other words, whether the individual phase compositions remain fixed or change with temperature, the global Gibbs-energy function is concave. Any point where it would be convex would imply that the equilibrium calculated at T_1 or T_3 is not the global minimum (obtaining a more stable equilibrium at T_2 would not alter the concavity). In such cases, the arbitrary choice is to exclude from the training database the point between T_1 and T_3 that exhibits the lowest second derivative.

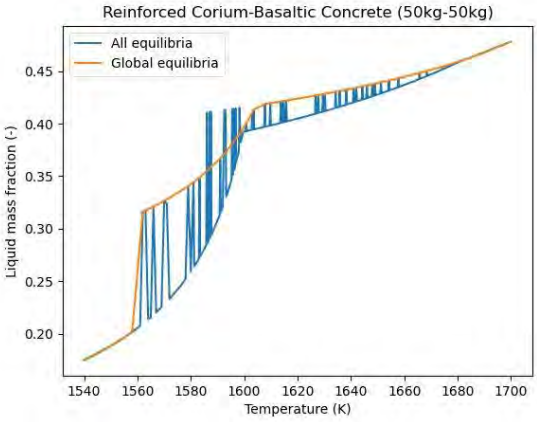

Figure 2. Liquid mass fraction as a function of temperature. The blue curve represents all points, while the yellow curve has been filtered to remove points that lie on non-global equilibrium.

Fig. 2 shows the volumetric liquid fraction in a region that is particularly problematic because of the high concentration of non-global equilibria. It is evident that removing the points with the algorithm described above produces a far smoother, more regular curve.

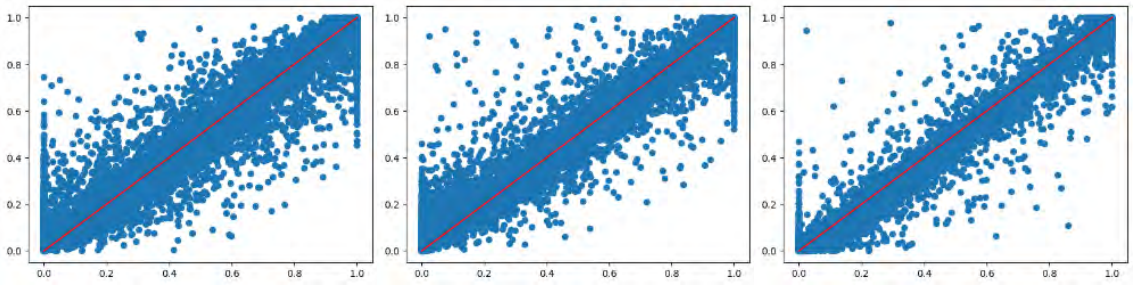
2.1.2. Final training database

From the algorithm outlined in section 2.1, we obtained 1378553 converged calculations. Among them, 14121 were detected as non-global equilibria, which accounts for about 1 % of the calculations, and were removed from the training database. Consequently, 1364432 points could be used.

2.2. Choice of the Modelling Family

A preliminary study [4] was conducted using a reduced database that consisted of mixtures with a small set of elements (Fe, O, U, Zr). The goal was to compare different model families – namely k-nearest neighbours, random forests, and multi-layer perceptrons. For the first two families the hyper-parameters (6 neighbours, 400 trees) were tuned by cross-validation. The architecture of the multi-layer perceptron was also optimized via grid search and comprises: an input layer of 5 neurons (temperature plus the 4 atomic fractions), three fully-connected hidden layers with 100 neurons each, using ReLU activation, a single-output neuron with a sigmoid activation.
Choosing the model type and its hyper-parameters is beyond the scope of this paper; all details can be found in [4]. Only a few results are shown here because they guided the choice of model structure for the study that follows, which uses the 12-element database described earlier. The models' performance for the mass liquid fraction and for the volumetric liquid fraction is comparable. Consequently, only the results for the mass liquid fraction are presented in the following.

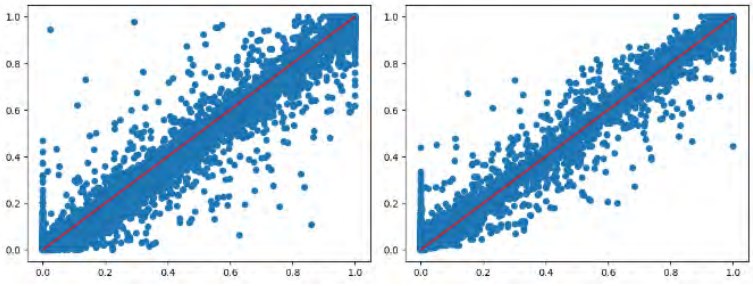
Fig. 3 illustrates the performance of the three modelling families by plotting the predicted mass-liquid fraction against the exact values over the test set (25 % of the database). The mean-squared error (MSE) is also reported.



a) (b) (c)

Figure 3. Prediction of the mass liquid fraction. Predicted values as a function of true values for the k-nearest neighbors (a), random forests (b), and multilayer perceptron (c) models.

The multi-layer perceptron modelling produced the most accurate predictions, and therefore it was selected for the subsequent study. To increase stability and precision—particularly in regions with discontinuities—a bagging ensemble of ten multilayer perceptrons was employed. In this approach, several perceptrons sharing the same architecture as the one described earlier were trained, each using a bootstrap sample drawn from the entire training set. The final model's prediction is the average of the ten individual predictions. This ensemble method yields better results than a single perceptron (see Fig. 4).



(a) MSE=0.54e-3 **(b) MSE=0.37e-3**

Figure 4. Prediction of the mass liquid fraction. Predicted values as a function of true values for the multilayer perceptron (a) and the bagging ensemble of 10 multilayer perceptrons (b) models.

2.3. Retain Model For 12 Atoms Compositions

For the main study presented in this paper, we adopt a bagging ensemble of ten multilayer perceptrons. Each perceptron shares the same architecture as described earlier, except that the input layer now contains 13 neurons (temperature plus the 12 atomic fractions). Thus, each network consists of an input layer with 13 neurons (temperature + 12 compositional components), three fully-connected hidden layers of 100 neurons each, using ReLU activation, a single-output neuron with a sigmoid activation.

With the inclusion of biases, each perceptron has 21 701 trainable parameters. These parameters are learned from the detailed database described in Section 2.1. It is worth noting that, in addition to improving predictive accuracy, the bagging procedure yields a standard deviation associated with the predictions, providing an estimate of the uncertainty in the predicted quantity. This uncertainty information can be leveraged to add new simulations (active learning), as explained in [4]. Figure 5 displays the performance of the bagging model on a test set drawn from the database. The root-mean-square error (RMSE) is 0.014, and the correlation coefficient exceeds 0.99.

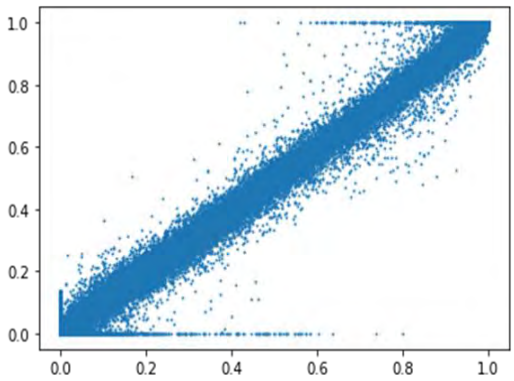


Figure 5. Predicted values of the liquid mass fraction as a function of true values using the bagging ensemble of 10 multilayer perceptrons in the case of 12 atoms.

For use of this model in ASTEC studies, additional non-trainable layers are added upstream of the network to convert the inputs into mole fractions and to handle the nondimensionalisation used during training. This makes the model easier to use by the client code and, more importantly, ensures that its inputs and outputs match those of the legacy models.

3. RESULTS

3.1. Models applied to specific compositions

The models were used to compare corium–concrete mixing results for a typical corium and three typical concretes of empirical composition that were not used to build the training dataset. These three concretes are of different types: siliceous concrete, limestone concrete, and basaltic concrete. The mass compositions of the corium are given in Table I, and the mass compositions of the concretes are given in Table II. Note that the concrete compositions include reinforcing steel.

Table I. Typical corium composition

Species	Mass fraction (%)
UO2	52
ZrO2	13
Zr	2

Fe	22
Cr	7
Ni	4

Table II. Typical concretes compositions

Species	Reinforced siliceous concrete mass fraction (%)	Reinforced limestone concrete mass fraction (%)	Reinforced basaltic concrete mass fraction (%)
Al2O3	2.5	2	14
CO2	0.5	24	-
CaO	12	35	12
Fe	5	9	4
H2O	5	5	4
SiO2	75	24	60
MgO	-	1	-
Fe2O3	-	-	6

For each concrete, a composition consisting of 50 kg of corium and 50 kg of concrete is considered. After rounding to 1/256 quanta, the compositions of the resulting mixtures are given in Table III.

Table III. Composition of three typical mixtures

Species	Reinforced siliceous concrete mole fraction (/256)	Reinforced limestone concrete mole fraction (/256)	Reinforced basaltic concrete mole fraction (/256)
Al	2	1	11
C	0	21	0
Ca	8	24	8
Cr	5	5	5
Fe	18	21	21
H	21	21	17
Ni	2	2	2
Mg	0	1	0
O	141	133	140
Si	47	15	39
U	7	7	8
Zr	5	5	5

For each of these compositions, the surrogate model results for the mass liquid fraction are compared with those provided by the minimization code. Fig. 6a shows the results for the mixture using siliceous concrete, Fig. 6b for the mixture using limestone concrete, and Fig. 6c for the mixture using basaltic concrete. In each case, the results obtained with the surrogate model are compared with those obtained using the NucleaToolbox thermodynamic minimizer. We observe that, for all three concrete families, the results provided by the surrogate model are in good agreement with the reference results.

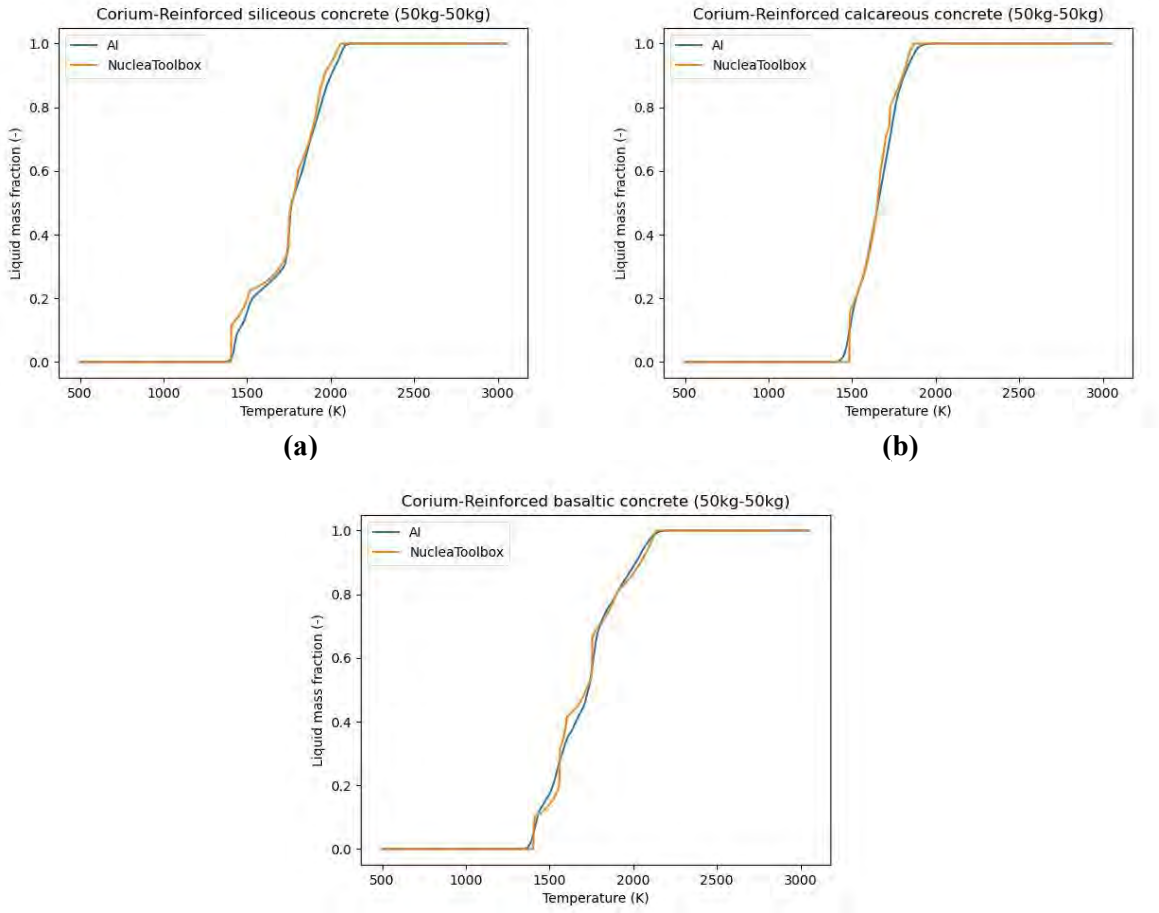

Figure 6. Mass liquid fraction as a function of temperature computed by AI (in blue) and by NucleaToolbox (in yellow) for mixture with 50% in mass of siliceous concrete (a), limestone concrete (b) and basaltic concrete (c).

3.2. Usage in an ASTEC computation

In this paragraph, calculations are performed with the MEDICS module of the ASTEC code and correspond to a reactor case. For the comparison with the surrogate model, it is assumed that all the corium is relocated at the reactor vessel failure, with the spreading of the corium in the reactor cavity. There is no secondary flow of corium from the reactor vessel to the reactor cavity after the reactor vessel rupture. The basemat is made of a single concrete.

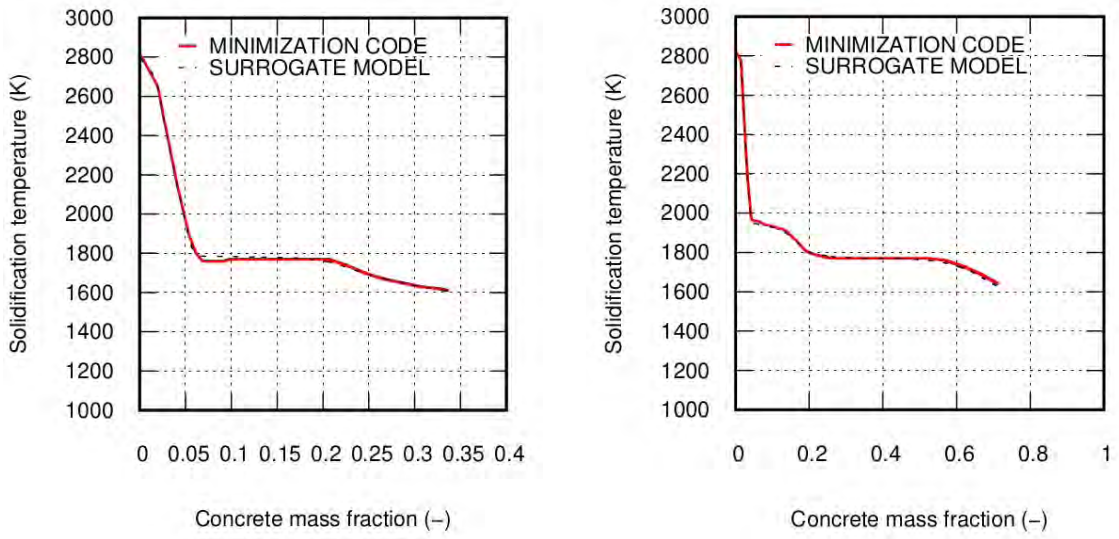
The initial corium mass corresponds to the melting of the entire core and of the lower plenum hemisphere, the lower plenum internals, and the baffle. The initial temperature of the corium is taken equal to 3000 K. Two types of concrete are used for the comparison, a Limestone/Common Sand (LCS) concrete and a siliceous concrete, which both are part of the model's learning base.

It is assumed that the reactor vessel failure is supposed to occur three hours after the automatic shutdown of the reactor. The residual power is calculated by the ISODOP module of ASTEC, based on an isotopic inventory. The corium reflooding starts at the beginning of the MCCI.

For each type of concrete, two calculations are performed:

- In the first case, the evolution of the mass liquid fraction and the volumetric liquid fraction of the corium versus temperature are evaluated according to the quantity of concrete incorporated in the corium by using pre-calculated tables from NucleaToolbox Gibbs minimizer and NUCLEA database developed at ASNR;
- In the second case, the evolution of the mass liquid mass fraction and the volumetric liquid fraction of the corium versus temperature are evaluated during the calculation according to the composition of the corium by using the surrogate model.

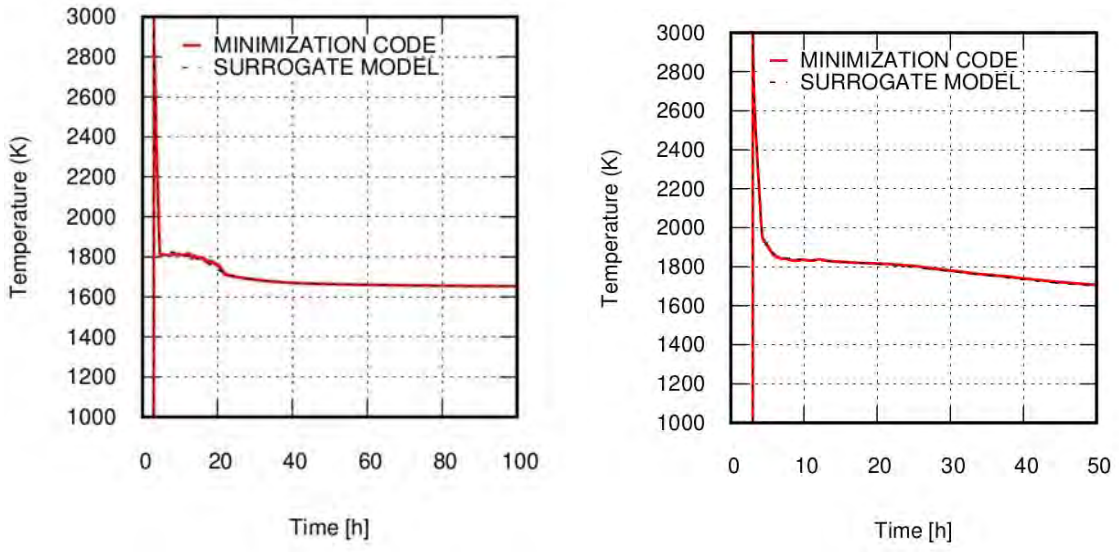
The solidification temperature is another material parameter used by the MEDICIS models. It is evaluated from the volumetric liquid fraction. Fig. 7 shows a comparison of the solidification temperature evolution according to the concrete mass incorporated in the corium during the calculations. For each type of concrete, the values provided by the substitution model are very similar to those calculated by NucleaToolbox.



LCS concrete *siliceous concrete*

Figure 7. Evolution of the solidification temperature versus concrete mass fraction.

The evolution of the corium temperature versus time is presented in Fig. 8. The figure shows that using the surrogate model provides the same results as using pre-calculated tables from NucleaToolbox. The same holds for the other characteristic quantities of the calculations, including the ablation profiles.



LCS concrete *siliceous concrete*

Figure 8. Evolution of the corium temperature versus time.

4. CONCLUSIONS

Surrogate models for the computation of the mass liquid fraction and the volumetric liquid fraction were developed using neural networks, based on a bagging ensemble of multilayer perceptrons. These models yield good results, both on standalone test cases and when integrated into a more complex code such as ASTEC. Although these models have not yet been optimized, they presently add a CPU overhead that makes an ASTEC run roughly 20–25 times slower when it relies solely on MEDICIS. Up to this point, we have considered only the physical outcome, and no optimization—trivial or otherwise—has been implemented. Profiling is underway, and we are exploring further optimisations, including the possibility of delegating network inference to a GPU.

The main difficulty lies in building a training dataset that covers a domain as wide as possible without over-representation, while keeping its size reasonable. A reduction method was tested and proved to be effective. Further works deal with improvement of the database using dataset enrichment strategies that refer to the large literature of active learning. Moreover, the work presented here was applied to ex-vessel compositions and could be extended to in-vessel compositions.

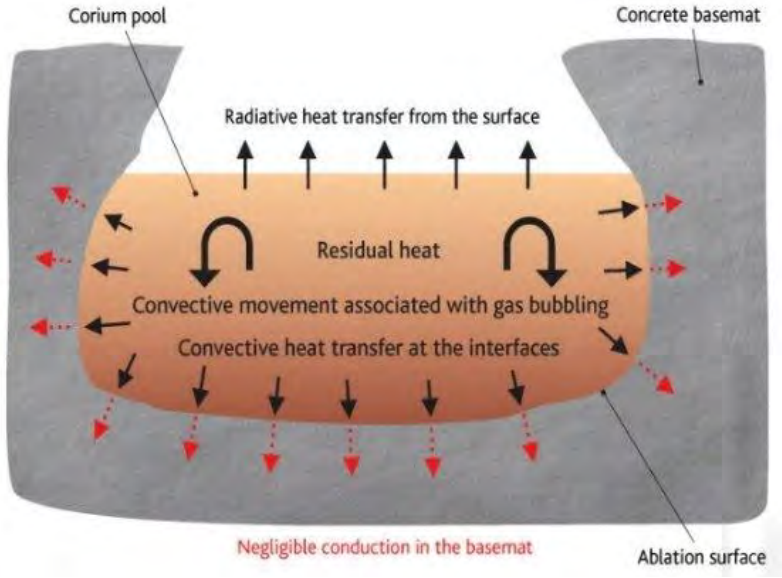
AI-DRIVEN ESTIMATION OF CORIUM THERMOPHYSICAL PROPERTIES FOR EX-VESSEL CORIUM STABILIZATION SIMULATIONS

INTRODUCTION AND CONTEXT



- Obtaining better estimates of material properties contributes to more relevant simulation results for nuclear transient accidents.

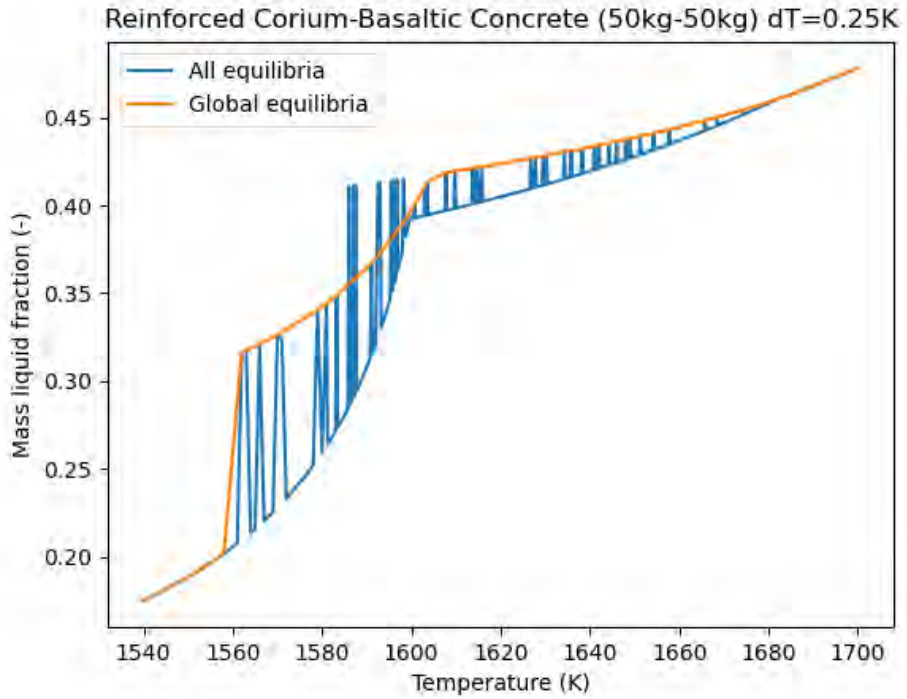
- One step of an accident can be the Molten Corium Concrete Interaction (MCCI). In simulations, the mixture can be typically composed of 12 atoms (Al, C, Ca, Cr, Fe, H, Ni, Mg, O, Si, U, Zr)

- For an accurate simulation of corium ex-vessel stabilization, codes like ASTEC (Accident Source Term Evaluation Code) require the following properties of the corium–concrete mixture:
  - o the mass liquid fraction (as a function of temperature),
  - o the volumetric liquid fraction (as a function of temperature),
  - o the solidus temperature (the temperature at which the volumetric liquid fraction is 1%),
  - o the solidification temperature (the temperature at which the volumetric liquid fraction is 50%, for example),
  - o the liquidus temperature (the temperature at which the volumetric liquid fraction is 99%).

- These properties are partly obtained using a thermochemical code capable of calculating the different phases of a complex mixture. The present work is based on NucleaToolbox, developed by ASNR.

SURROGATE MODEL OBJECTIVES

- Drawbacks of a direct link with a thermochemical code:
  - What should be done in **case of non-convergence**?
  - How can we detect points that have converged to a local **(non-global) minimum**, and how should they be handled?
  - The **CPU cost** of a call to a thermochemical software can be high, even prohibitive, especially if it must be used to invert a function within an iterative algorithm (for instance, finding the temperature corresponding to a given liquid fraction).
  - **Access** to a thermochemical software and material databases is required



- Solution: Create a surrogate model of the thermochemical code.

[Mass/Volumetric]LiquidFraction = f(Temperature,Composition)

- Main difficulty: Presence of high gradients and discontinuities

SPECIFICATION OF THE SURROGATE MODEL

[Mass/Volumetric]LiquidFraction = f(Temperature,Composition)

- 13 inputs (1 temperature and 12 atomic molar compositions whose sum equals one)
  - Temperature: float between 500.K and 3050.K, multiple of 1/64=0.015625
  - Compositions: float between 0. and 1., multiple of 1/256=0.00390625
- 1 output (mass liquid fraction or volumetric liquid fraction)
  - Float between 0. and 1.
- Training dataset cardinality
  - 1.127.772 entries before cleaning
  - 1.119.732 entries after cleaning (after removing non global equilibria)

DETECTING AND REMOVING NON GLOBAL EQUILIBRIA (1/3)

- Minimizer looks for a minimum value of the Gibbs energy G

- The second derivative of G versus T (at phases composition and pressure fixed) is linked to the thermal capacity, which is positive

$$C_p = -T \left.\frac{\partial^2 G}{\partial T^2}\right|_{PhasesComposition,P} > 0$$

$$-T_2 \frac{(G_1 - 2G_2 + G_3)}{T_3 - T1} > 0$$

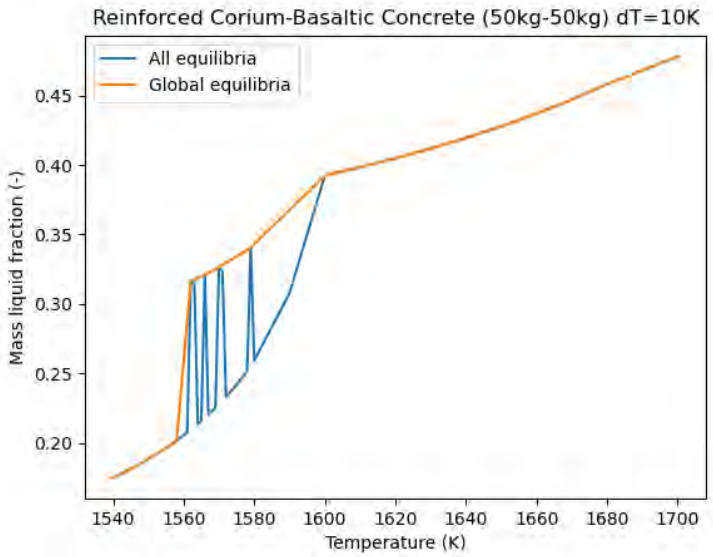
$$G_3' < G_3$$

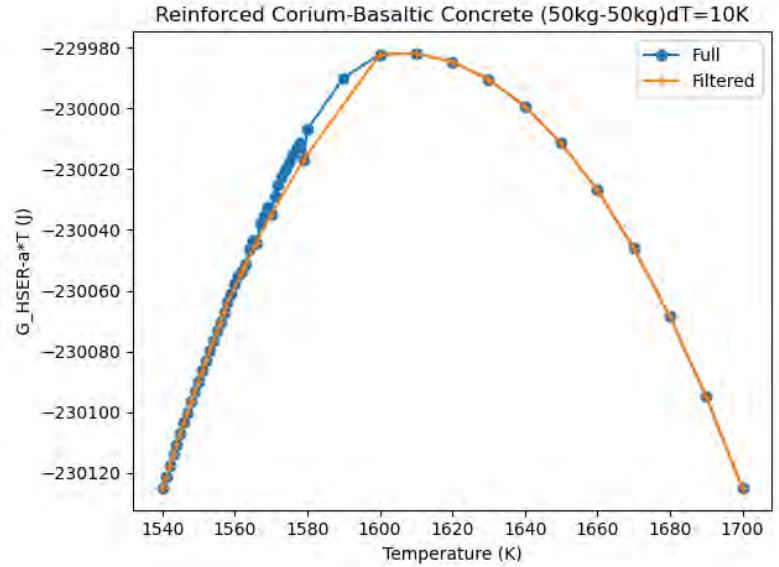
$$-T_2 \frac{(G_1 - 2G_2 + G_3')}{T_3 - T1} > -T_2 \frac{(G_1 - 2G_2 + G_3)}{T_3 - T1} = C_p > 0$$

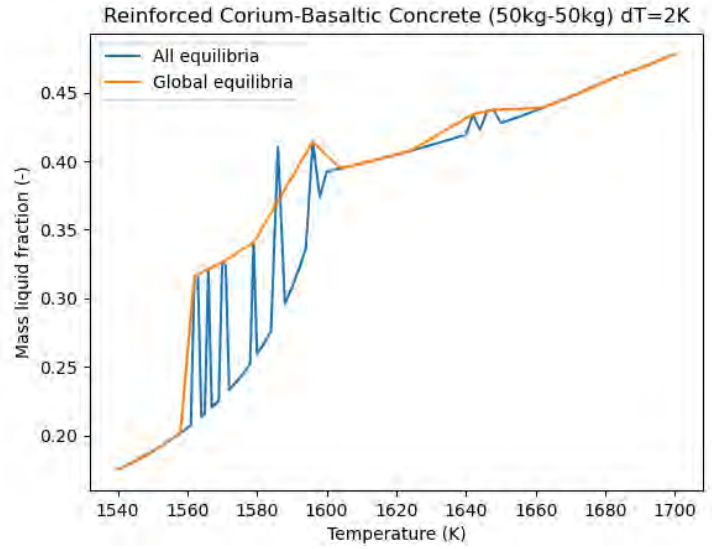
$$\frac{\partial^2 G}{\partial T^2} < 0$$

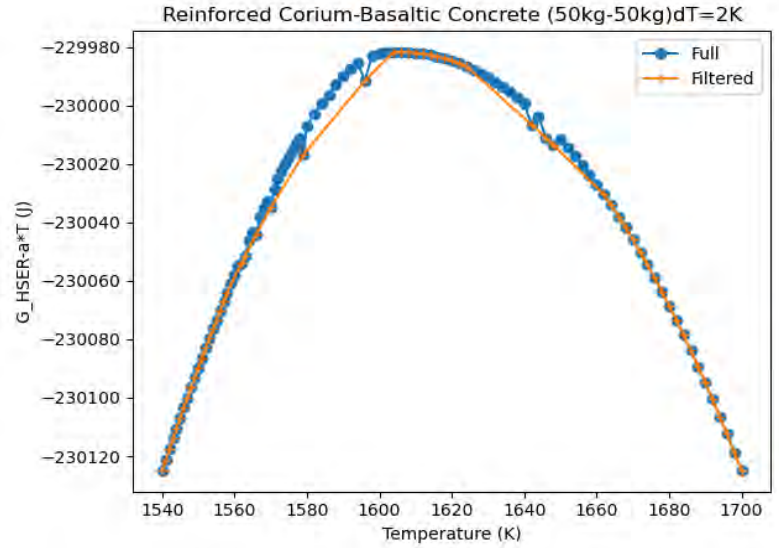
- But... it may be necessary to have a sufficiently fine temperature resolution to obtain enough good points...

DETECTING AND REMOVING NON GLOBAL EQUILIBRIA (2/3)

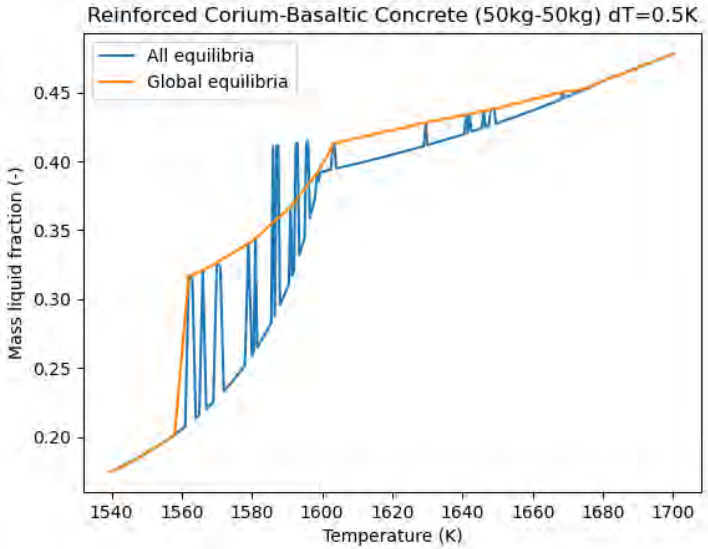


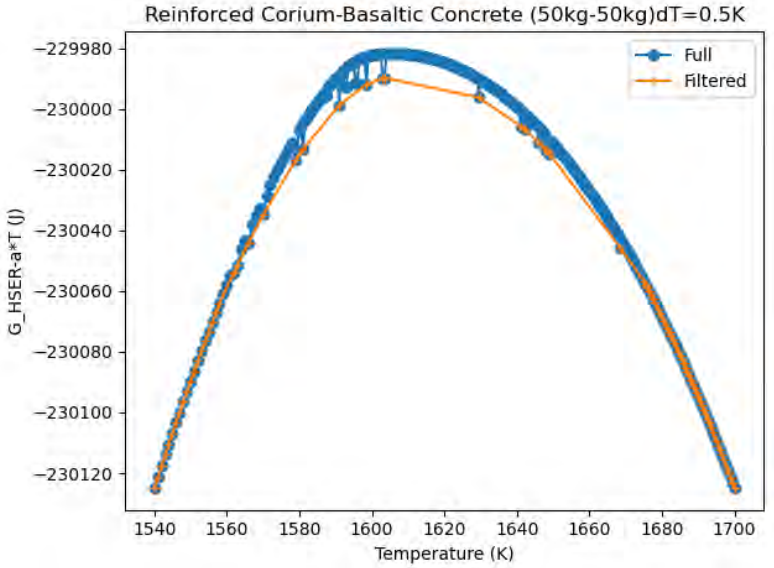


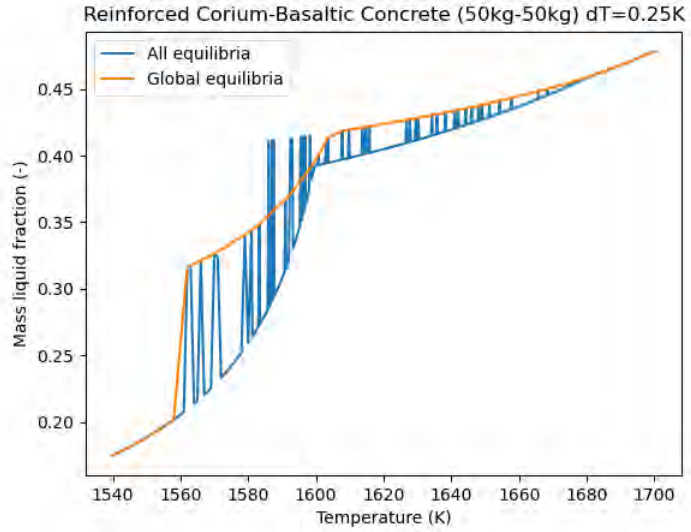


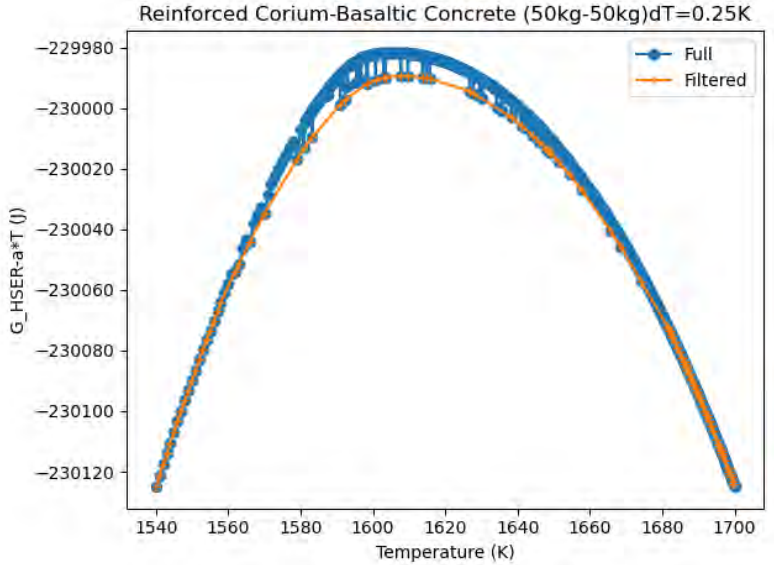


DETECTING AND REMOVING NON GLOBAL EQUILIBRIA (3/3)







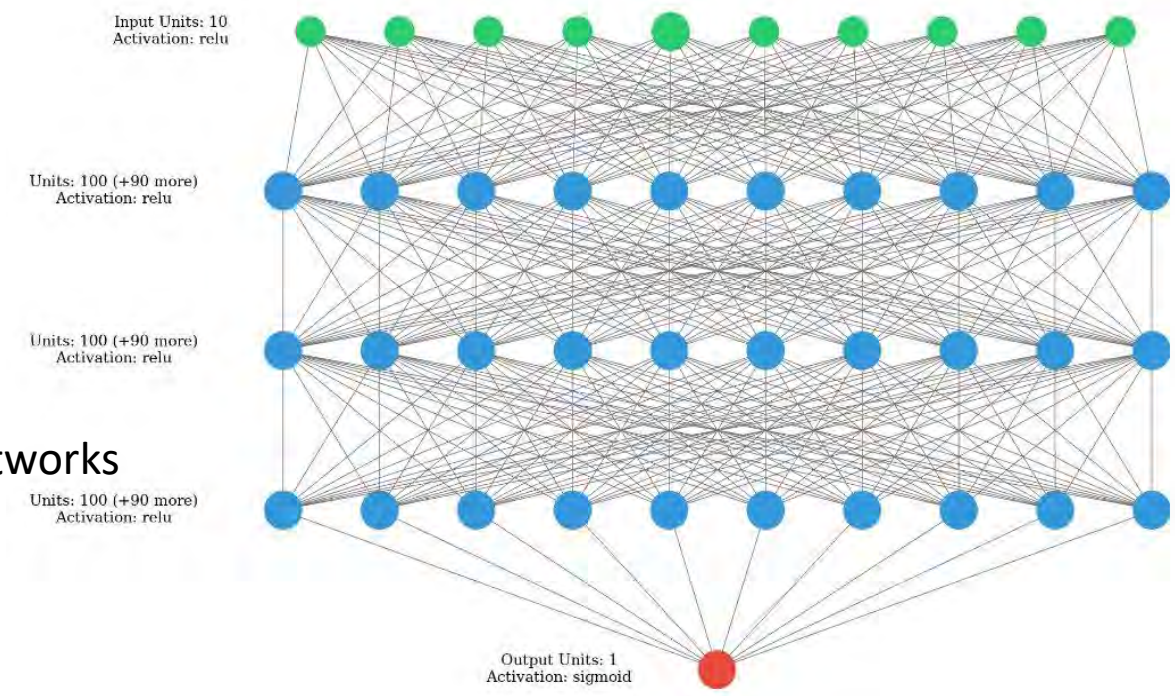


TESTED MODELS

- First work had objective to compare different models (KNN, Random Forest, Gaussian Process, Multi Layers Perceptron, Baggings of MLP, etc.) and hyper parameters

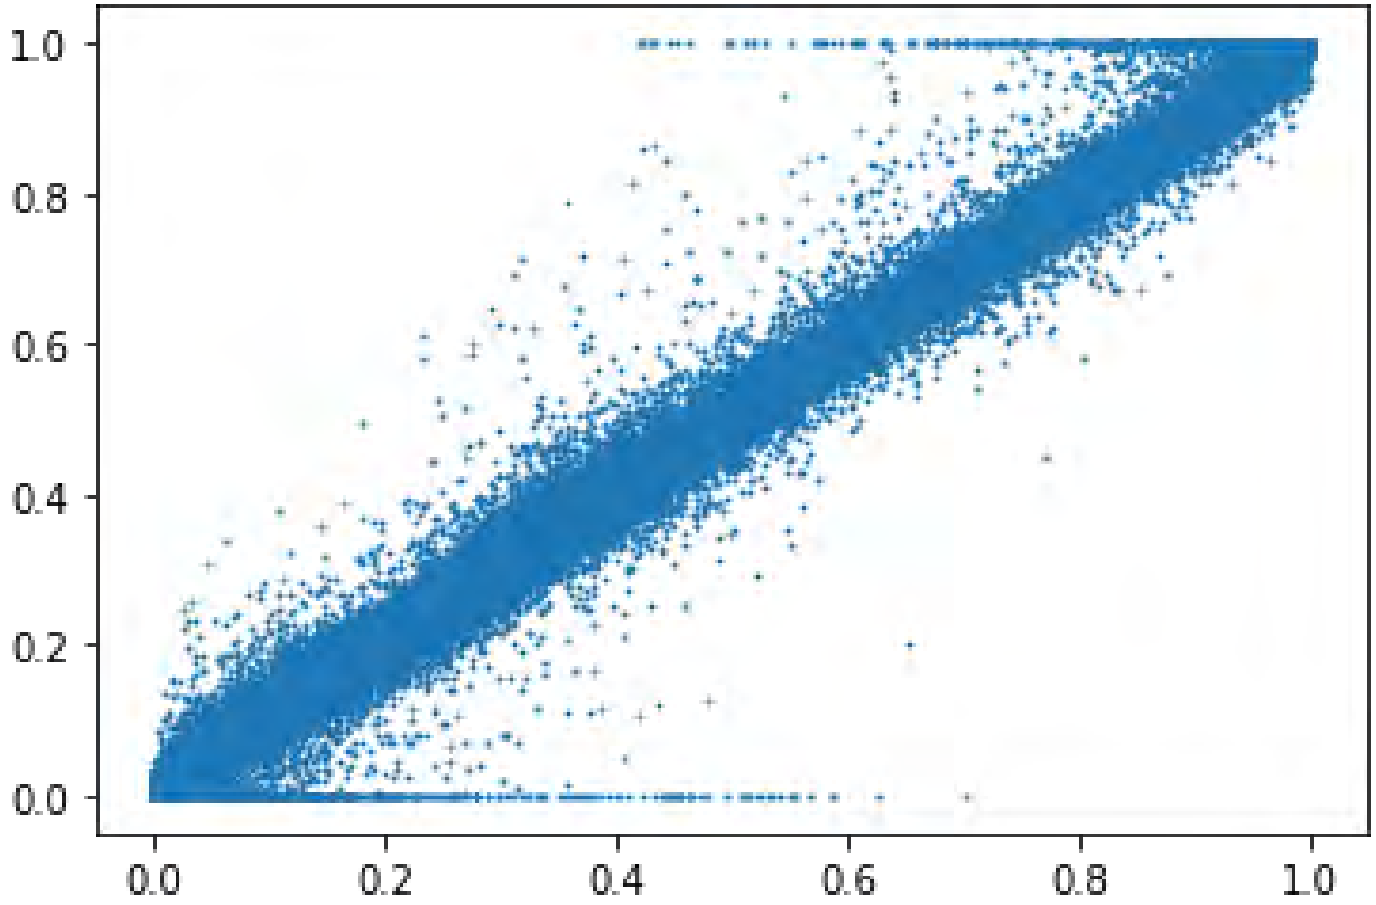
- Bagging of 10 MLP retained:
  - 3 hidden layers with RELU
  - 1 output layer with sigmoid
  - 21701 parameters
  - Additional non-trained layer placed right after the input layer to manage the scaling

- Thanks to bagging:
  - Better accuracy using the mean over networks
  - Error estimation using the standard deviation over networks
  - Estimator to add new entries in the training database (Query by bagging)
  - How removing entries ?



FINAL MODEL STATISTICS

- Split 50% train / 50% test
- Bagging of 10 MLP
- RMSE (Root Mean Square Error): 0.014
- Correlation coefficient: 0.99



Predicted values versus exact values for test points

EXAMPLES

- A typical corium

Species (Corium)	Masses fraction (%)
UO2	52.3
ZrO2	13.2
Zr	02.4
Fe	22.2
Cr	06.4
Ni	03.5

- Three typical reinforced concretes: a siliceous concrete, a limestone concrete, and a basaltic concrete.

Species	Reinforced siliceous concrete masses fraction (%)	Reinforced limestone concrete masses fraction (%)	Reinforced basaltic concrete masses fraction (%)
Al2O3	2.5	2	14
CO2	0.5	24	-
CaO	12	35	12
Fe	5	9	4
H2O	5	5	4
SiO2	75	24	60
MgO	-	1	-
Fe2O3	-	-	6

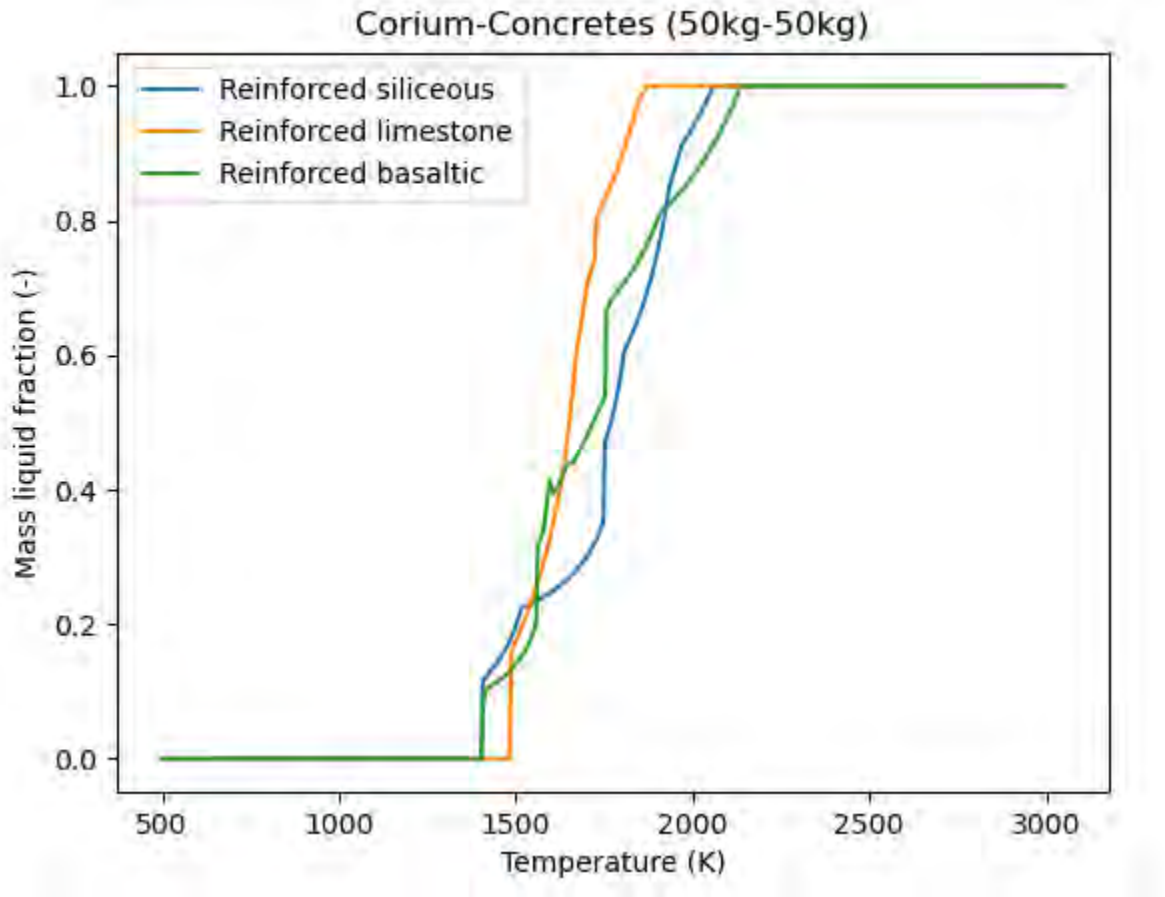
EXAMPLES

- For each concrete, we study the liquid mass fraction of a mixture consisting of 50 kg of corium and 50 kg of concrete.

Species	Corium - Reinforced siliceous concrete mol fraction (/256)	Corium - Reinforced limestone concrete mol fraction (/256)	Corium - Reinforced basaltic concrete mol fraction (/256)
Al	2	1	11
C	0	21	0
Ca	8	24	8
Cr	5	5	5
Fe	18	21	21
H	21	21	17
Ni	2	2	2
Mg	0	1	0
O	141	133	140
Si	47	15	39
U	7	7	8
Zr	5	5	5

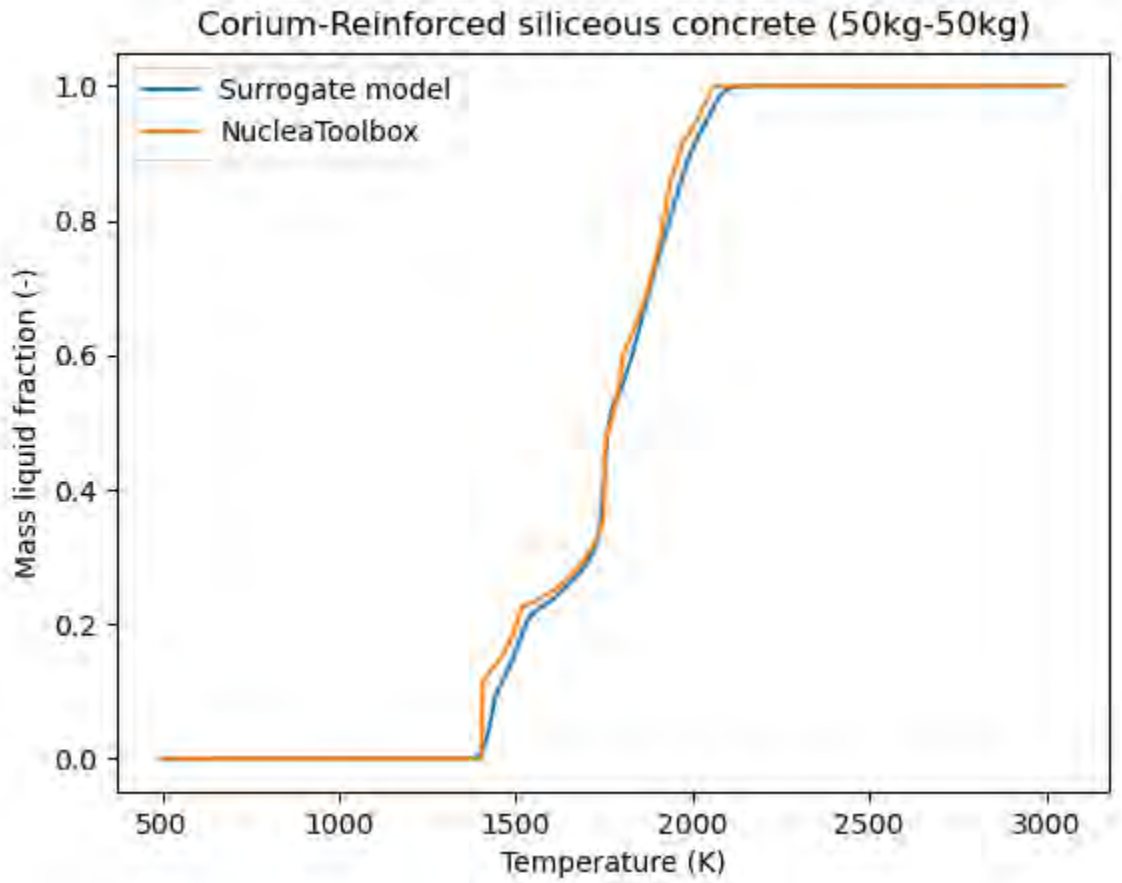
RESULTS (SILICEOUS VS LIMESTONE VS BASALTIC)

- Mass liquid fraction for the three mixtures as a function of temperature.



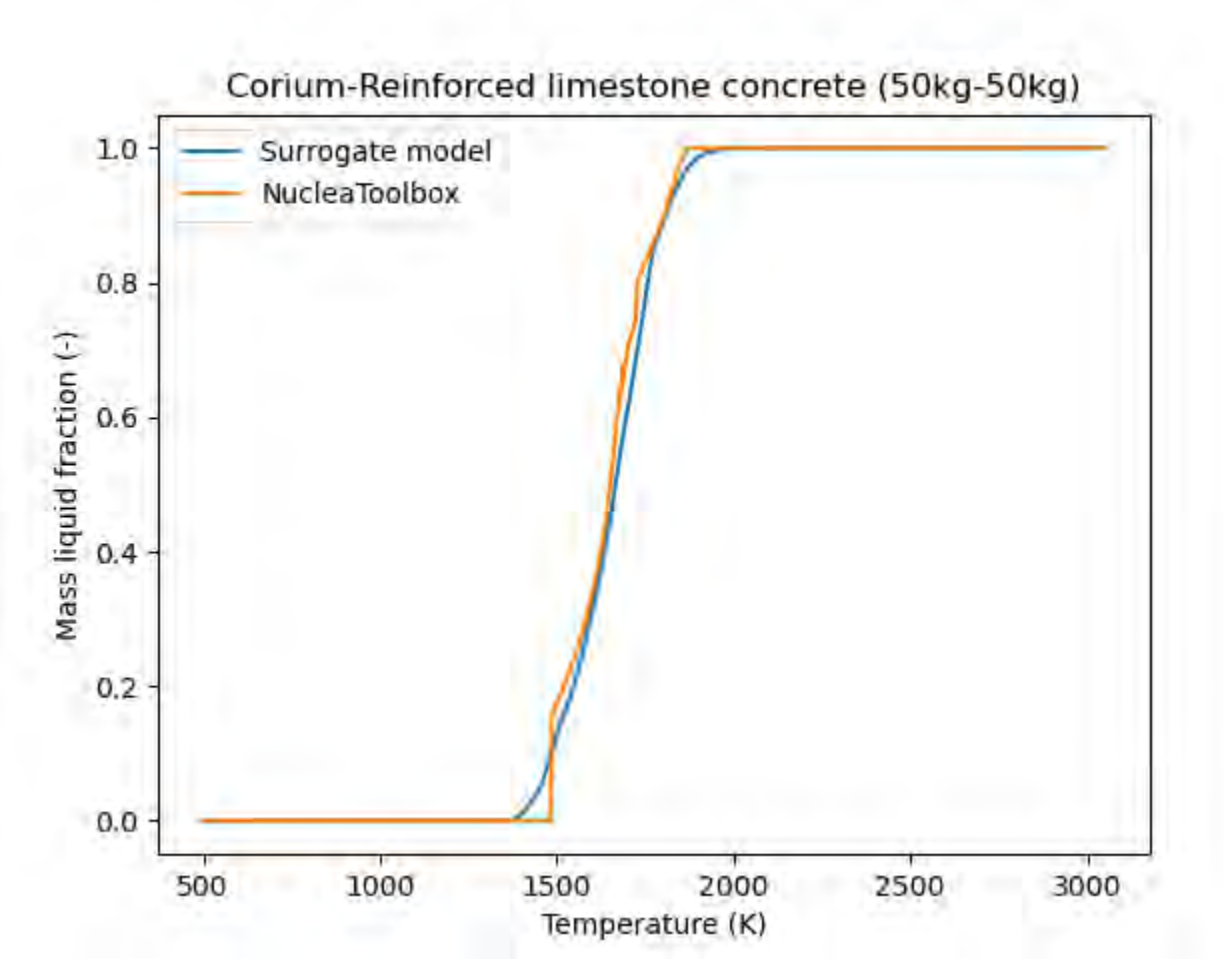
RESULTS (SILICEOUS CASE)

- Mass liquid fraction for corium-reinforced siliceous concrete, NucleaToolbox vs surrogate model



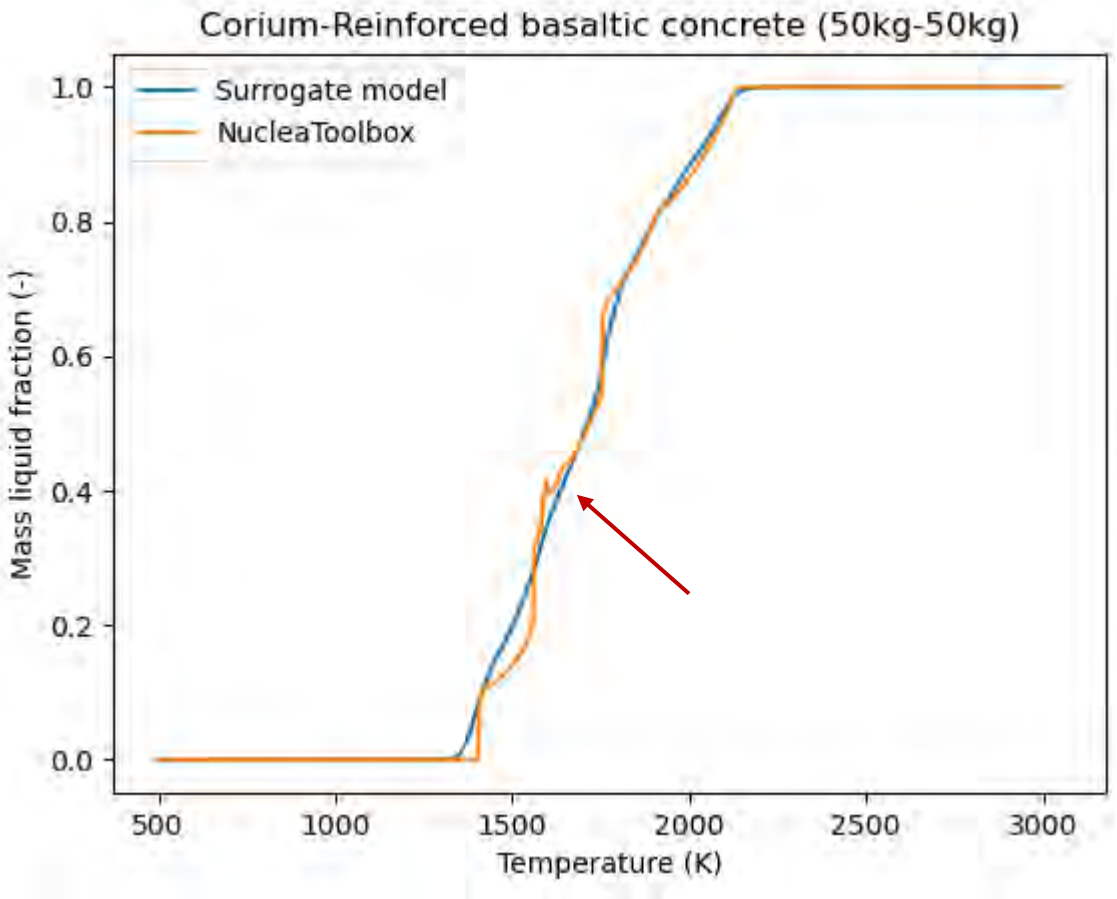
RESULTS (LIMESTONE CASE)

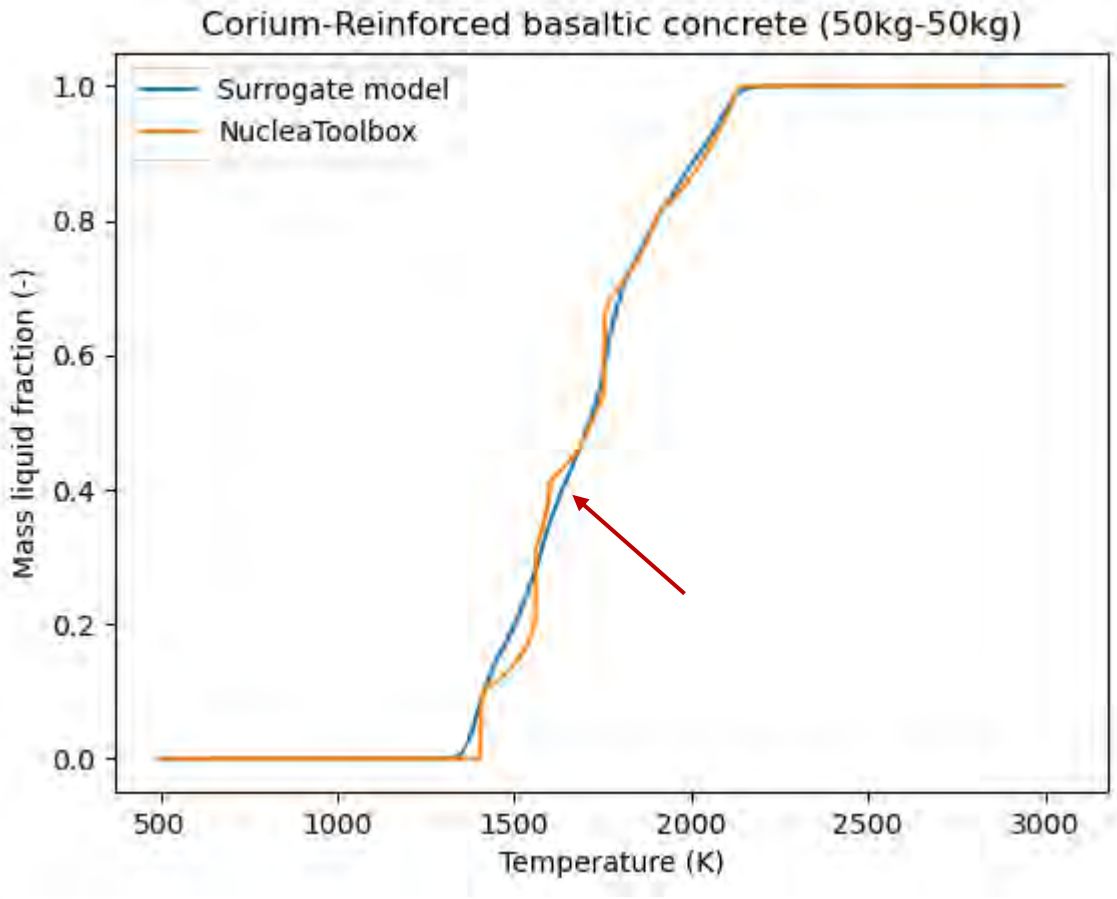
- Mass liquid fraction for corium-reinforced limestone concrete, NucleaToolbox vs surrogate model



RESULTS (BASALTIC CASE)

- Mass liquid fraction for corium-reinforced basaltic concrete, NucleaToolbox vs surrogate model (with different discretizations to remove local equilibria pointed on the figures)



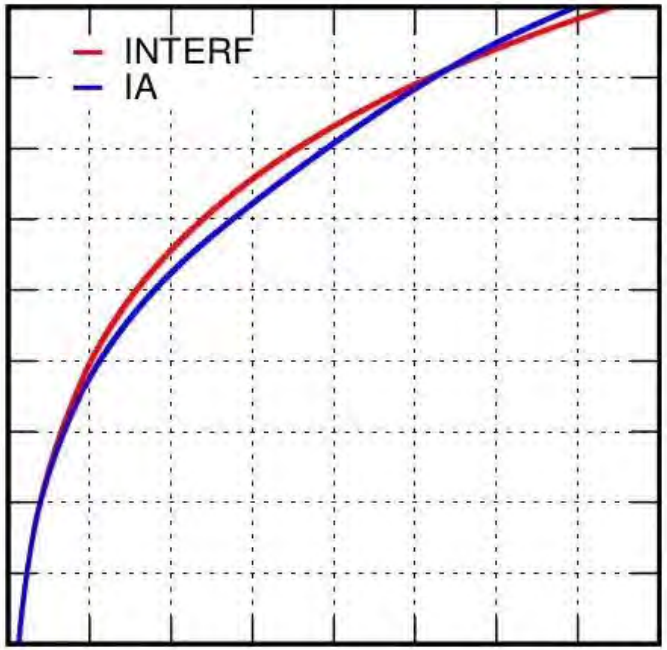


APPLICATION TO ASTEC

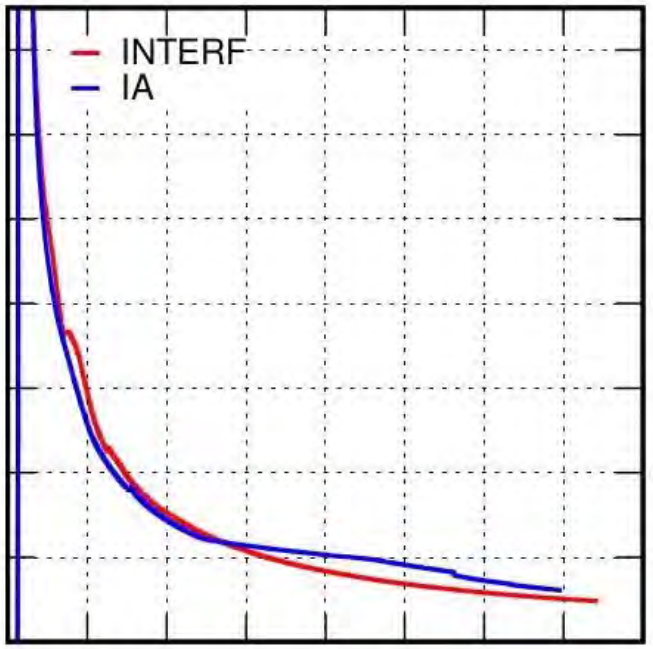
- Remember of used properties:
  - the mass liquid fraction => [Bagging of 10] Neural Network[s]
  - the volumetric liquid fraction => [Bagging of 10] Neural Network[s]
  - the solidus temperature => inversion of volumetric liquid fraction with a Brent algorithm
  - the solidification temperature => inversion of volumetric liquid fraction with a Brent algorithm
  - the liquidus temperature => inversion of volumetric liquid fraction with a Brent algorithm

APPLICATION TO ASTEC, SINGLE CONCRETE CASE

Axial Erosion vs Time



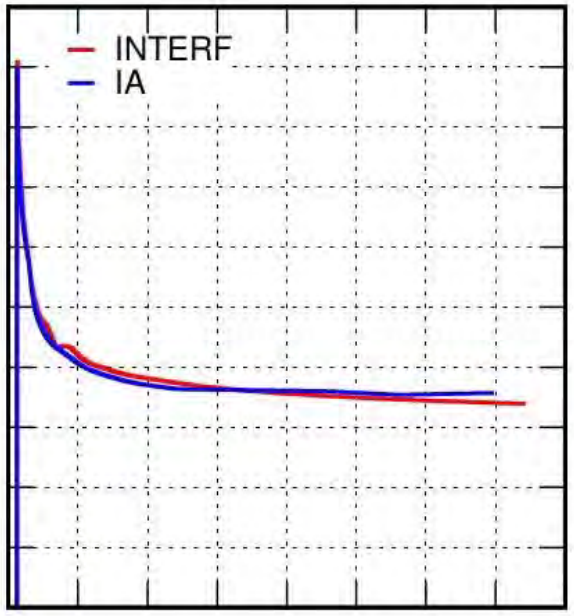
Thermal flux to concrete vs Time



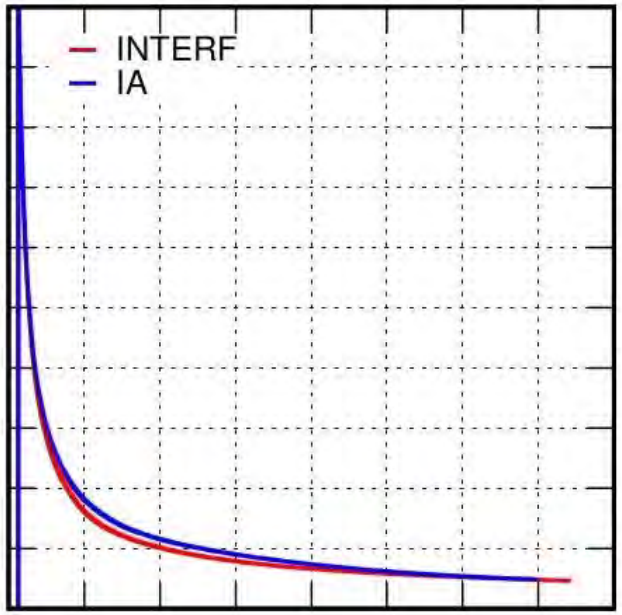
Note: INTERF is the current tool used by ASNR to compute mass and volumetric liquid fractions.

APPLICATION TO ASTEC, SINGLE CONCRETE CASE

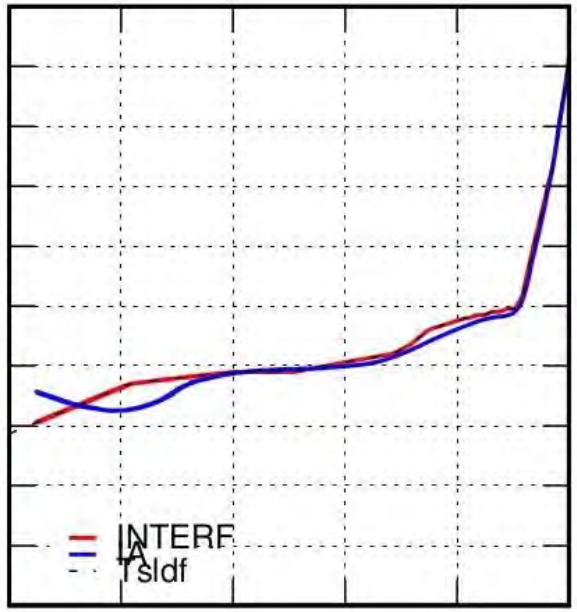
Oxide layer temperature vs Time



Corium mass fraction versus time

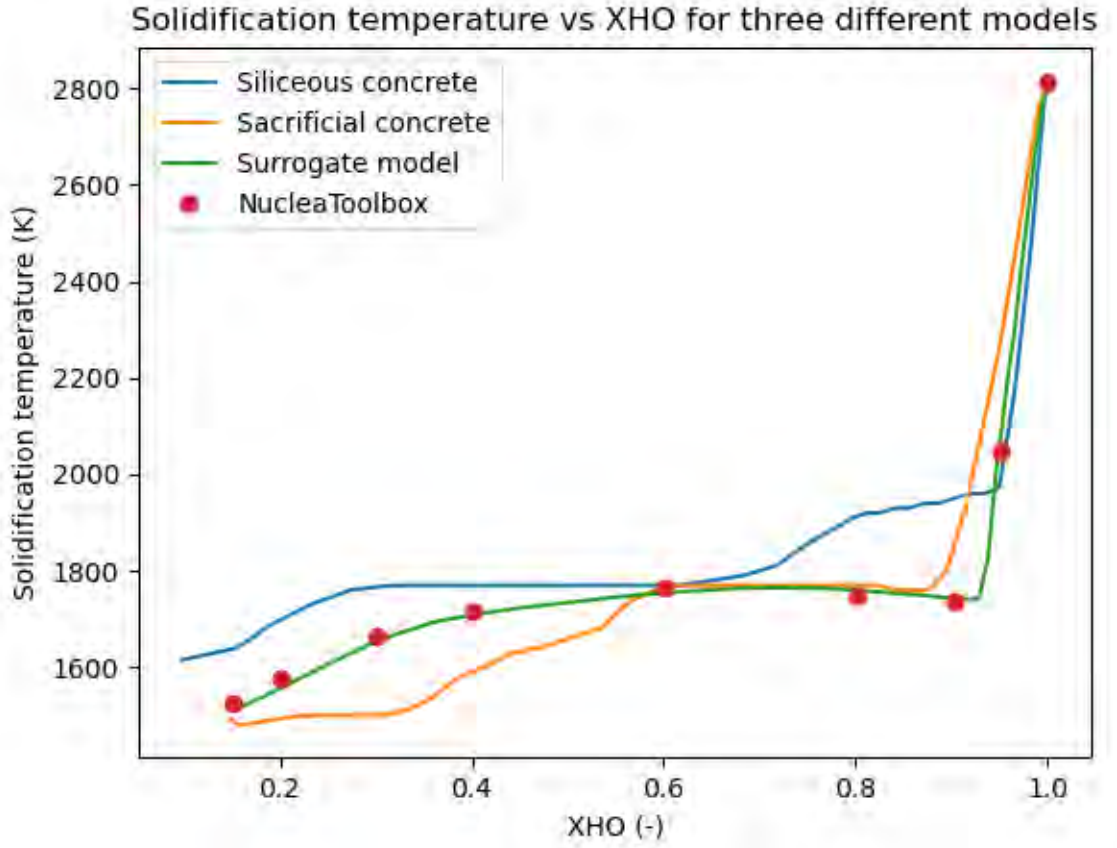


Solidification temperature versus corium mass fraction



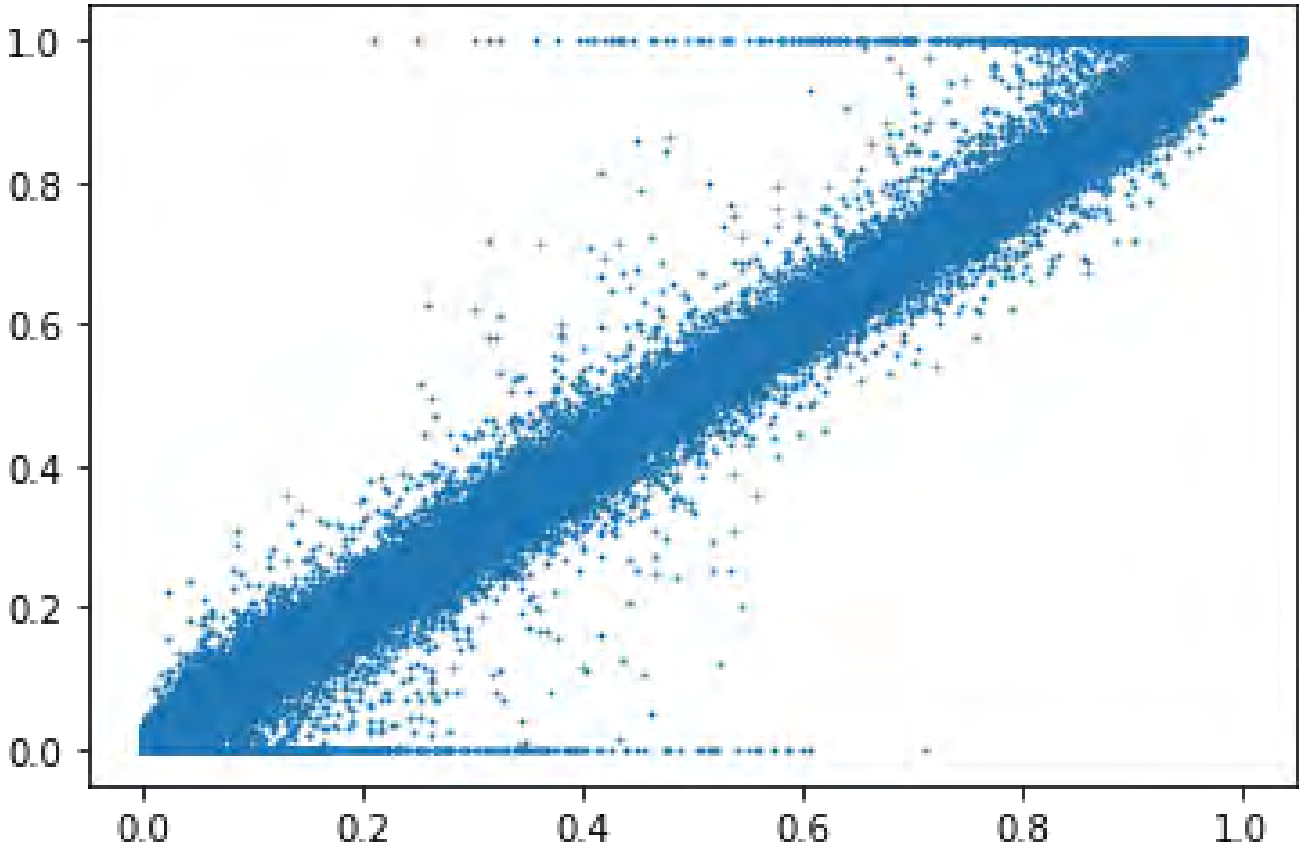
APPLICATION TO ASTEC, TWO CONCRETES CASE

- For nuclear power plants whose basemat concrete is highly siliceous, EDF is considering thickening the basemat with a sacrificial concrete layer.
- This two-layer configuration with different concrete types is not handled well by ASTEC.
- Estimating the corium-concrete mixture properties using those of the highly siliceous concrete is overly conservative, while using the properties of the sacrificial concrete is not bounding.
- The AI model is particularly useful in this case. It was compared against NucleaToolbox calculations at several operating points.
- Note: XHO is an estimator of the corium fraction in the mixture.



BEFORE CONCLUSION, TRY TO REDUCE TRAINING DATABASE

- Remove point if liquid mass fraction is inside a segment of 0 or 1
- 421.198 entries instead of 1.119.732 (37.6%)
- Bagging of 10 MLP
- RMSE (Root Mean Square Error): 0.015 (instead of 0.014)
- Correlation coefficient: 0.99 (not changed)



Predicted values versus exact values for test points

CONCLUSION AND PERSPECTIVES

- Goods result of the AI model in test examples
- Goods results applied to ASTEC computation
- Optimization is coming to reduce CPU time cost
- The biggest difficulty is to have a learning database covering all cases
- Some solutions to expand the training dataset have been investigated (but not here)
- A first solution to reduce the training dataset has also been investigated

ABSTRACT

Internal investigations of the Fukushima Daiichi Unit-1 Primary Containment Vessel (PCV) revealed distinct debris signatures including a shelf-like deposit inside the pedestal above intact exposed rebars, and extensive spreading in the Drywell annulus without thermal damage to metallic structures. These observations suggest that concrete ablation and melt transport occurred at moderate temperatures, contrasting with the high-temperature conditions (>1500 °C) typical of classic MCCI experiments.

These features may be explained by a hypothesized melt spreading scenario where the initial high-temperature corium interacts with concrete and structural materials within the pedestal, generating a subsequent melt that later relocates or redistributes in the PCV, herein termed a "MCCI-derived secondary product".

This paper numerically investigates the spreading behavior of such a MCCI-derived secondary product. A two-dimensional geometry was established with scaled inflow conditions based on an estimate of 1F Unit-1. Using the Lagrangian Moving Particle Semi-implicit (MPS) method, the melt spreading dynamics and associated crust formation behavior were analyzed to identify the potential rheological properties and solidification criteria of the melt that can explain the observed deposit distribution and morphology in the D/W annulus of Unit-1. The results provide plausible insights into the late-phase accident progression and melt transport behavior of Unit-1.

KEYWORDS

Fukushima Daiichi Nuclear Power Plant Unit-1, melt spreading, severe accident, MPS method

1. INTRODUCTION

The decommissioning of the Fukushima Daiichi Nuclear Power Station requires improved understanding of fuel debris relocation and deposition inside the Primary Containment Vessel (PCV) to facilitate retrieval planning and operations. Recent internal investigations of the Unit-1 PCV have revealed widespread deposits in the Drywell (D/W) annulus. A distinct feature of these deposits is their non-uniform morphology characterized by a pronounced gradient in deposit height above the floor, decreasing with distance from the pedestal opening [1,2]. A schematic summary of the key Unit-1 observations motivating this study is

provided in Figure 1, including the widespread D/W deposits, the decreasing deposit-height trend from the pedestal opening, and the exposed standing rebars near the pedestal opening.

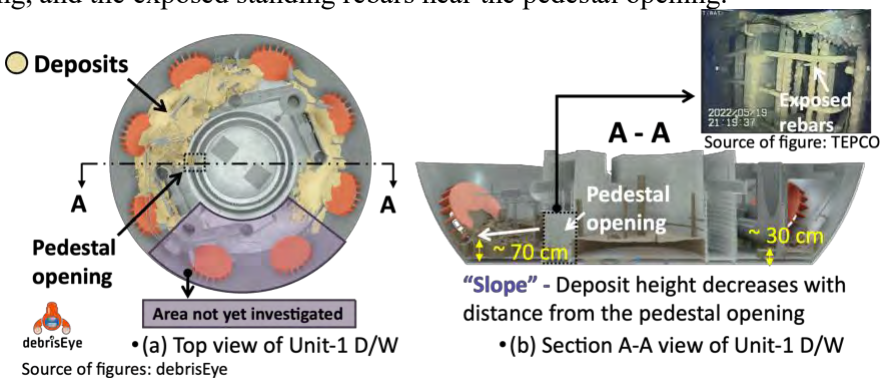

Figure 1. Schematic of key observations from Unit-1 PCV internal investigation

These observations, especially the absence of clear high-temperature melt traces on jet deflectors and metallic structures, are not readily explained by direct relocation of high-temperature corium alone. One plausible interpretation is that the initial high-temperature corium was largely retained inside the pedestal by crust formation, local debris-bed blockage, or limited discharge pathways, while prolonged concrete ablation under decay heat later generated a more concrete-rich, lower-temperature melt capable of relocating into the D/W through locally reopened or overflowed pathways. This subsequent material is herein termed a "MCCI-derived secondary product (MCCI-DSP)", defined as an MCCI-originated product that subsequently relocates, redistributes, or forms away from the primary reaction zone. For Unit-1, the MCCI-DSP is assumed to be a concrete-rich melt with possible Fe-bearing oxide contributions. Existing deposit analyses indicate that the U content is less than 1 wt% in the sampled deposits from the Unit-1 D/W annulus, suggesting that fuel-bearing components could be minor [3]. However, limited entrainment of such species cannot be excluded.

The Unit-1 observations motivate renewed attention to cooling-controlled spreading, where free surface heat loss and crust formation can strongly influence both spreading kinetics and final deposit morphology. However, the severe accident database for ex-vessel spreading has largely been built around single-release experiments where spreading and freezing occur over relatively short durations (typically in the order of tens of seconds), such as VULCANO and ECOKATS series [4,5]. These experiments generally represent gravity–viscous spreading regimes and target the maximum spreading distance governed by gravity-driven flow, viscous resistance, and bulk solidification. Although dedicated spreading codes such as MELTSPREAD and THEMA have been benchmarked against the extensive database of spreading experiments, they are based on the shallow-water approximation which does not explicitly resolve vertical variations in velocity, temperature, and phase [6–8]. Additionally, they are primarily only validated against spreading length for short durations. Consequently, the spreading dynamics under conditions of continued inflow and extended timescales, with a focus on the spreading morphology associated with the front / leading-edge crust behavior, remain insufficiently understood in the nuclear severe accident field.

To address this gap, this study utilizes the Moving Particle Semi-implicit (MPS) method [9,10], a Lagrangian particle framework suited for capturing free surface topological changes accompanied by phase changes. Building upon past successful applications of MPS method to melt spreading analyses [11–13], this study aims to clarify the mechanisms of (i) wide-area spreading under continuous inflow and (ii) sustained slope formation consistent with the Unit-1 deposits. A two-dimensional simulation geometry was established to simulate the spreading of MCCI-derived secondary product melt in a representative circumferential slice of the Unit-1 D/W annulus. Radiative / convective cooling from the free surface is considered and a temperature-dependent viscosity model for the mushy zone, with a high viscosity assigned

to near-solid material (crust) was employed. The roles of bulk viscosity and crust rigidity were discussed with sensitivity cases.

2. NUMERICAL METHOD

2.1. Governing Equations and Discretization of MPS Method

The governing equations of the MPS method for incompressible flows are described as conservation of mass, momentum, and energy as follows:

$$\frac{D\rho}{Dt} = -\rho\nabla.\mathbf{u} = 0 \tag{1}$$

$$\frac{D\mathbf{u}}{Dt} = -\frac{1}{\rho}\nabla P + \frac{1}{\rho}\nabla\cdot(\mu\nabla\mathbf{u}) + \mathbf{g} + \frac{\mathbf{F_s}}{\rho} \tag{2}$$

$$\rho\frac{Dh}{Dt} = k\nabla^2 T + Q \tag{3}$$

where ρ is the density, $\mathbf{u}$ is the velocity, P is the pressure, μ is the dynamic viscosity, $\mathbf{g}$ is the gravitational acceleration, $\mathbf{F_s}$ represents external forces except gravity, such as surface tension. h is the specific enthalpy, T is the temperature, k is the thermal conductivity, and Q is the external volumetric heat source or sink.

In order to reduce the discretization error and improve the numerical accuracy, the original particle interaction models have been modified using the second-order corrective matrix developed by Duan et al. [9,10]. The discretization models for the gradient, divergence, and Laplacian operators are shown in Eqs. (4) – (6):

$$\langle\nabla\phi\rangle_i = \frac{1}{n_0}\sum_{j\neq i}\left\{w_{ij}\frac{\phi_j-\phi_i}{r_{ij}}\left(\begin{bmatrix}\mathbf{C}_1\\ \mathbf{C}_2\\ \mathbf{C}_3\end{bmatrix}P\right)\right\} \tag{4}$$

$$\langle\nabla\cdot\mathbf{u}\rangle_i = \frac{1}{n_0}\sum_{j\neq i}\left\{w_{ij}\frac{\mathbf{u}_j-\mathbf{u}_i}{r_{ij}}\left(\begin{bmatrix}\mathbf{C}_1\\ \mathbf{C}_2\\ \mathbf{C}_3\end{bmatrix}P\right)\right\} \tag{5}$$

$$\langle\nabla^2\phi\rangle_i = \frac{1}{n_0}\sum_{j\neq i}\left\{w_{ij}(\phi_j-\phi_i)\frac{[\mathbf{C}_4+\mathbf{C}_5+\mathbf{C}_6]P}{l_0 r_{ij}}\right\} \tag{6}$$

where ϕ is a scalar variable; $\mathbf{C}_1$ to $\mathbf{C}_6$ are the first to sixth rows of the corrective matrix $\mathbf{C}$ defined in [10], respectively; r_{ij} is the distance between particle i and particle j; l_0 is the constant initial particle size.

The weight function (between the reference particle i and its neighbor particle j) w_{ij} and particle number density n_i are defined as:

$$w(r) = \begin{cases}\left(\frac{r_{ij}}{r_e}-1\right)^2, & 0\le r_{ij} < r_e\\ 0, & r_e \le r_{ij}\end{cases} \tag{7}$$

$$n_i = \sum_{j\neq i} w(|\mathbf{r_i}-\mathbf{r_j}|) \tag{8}$$

The particle shifting technique is implemented by relocating the particles from the particle-dense region to the particle-dilute region. The particles in a particle-dense region are moved by the position vector as:

$$\delta\mathbf{r_i} = -\frac{l_0\Delta r_i}{n_0}\sum_{j\neq i}\frac{w_{ij}}{r_{ij}^2}\mathbf{r_{ij}} \tag{9}$$

More details on the particle shifting technique for the internal and surface particles can be found in [14].

2.2. Temperature, Phase Change, and Viscosity Models

The following specific enthalpy - temperature relationship is adopted in the current MPS method to evaluate the thermal state and phase change of each particle, and the temperature is updated through the enthalpy-based energy equation.

$$h(T) = \begin{cases} C_{p,s}T, & T \le T_s \\ h_s + (h_l - h_s)\frac{T-T_s}{T_l-T_s}, & T_s < T < T_l \\ C_{p,l}T + L, & T \ge T_l \end{cases} \quad (10)$$

$$h_s = C_{p,s}T_s \quad (11)$$

$$h_l = C_{p,l}T_l + L \quad (12)$$

where $C_{p,s}$, $C_{p,l}$ are specific heat of the material for its solid and liquid state, respectively; T_s is the solidus temperature; T_l is the liquidus temperature; h_s and h_l are the specific enthalpies at the solidus and liquidus temperature, respectively; L is latent heat. Note that a single, constant latent heat (L) is assigned to the MCCI-DSP melt as an effective property. This is a simplified treatment of a multicomponent melt. Species-dependent latent heats and detailed solidification sequences, as may occur for example in corium–concrete mixtures, are not explicitly resolved.

The viscosity model utilized in the current MPS method is temperature-dependent and is associated with the solid fraction γ of the melt:

$$\mu = \begin{cases} \mu_l, & \gamma = 0 \\ \mu_l exp(2.5C\gamma), & 0 < \gamma < \gamma_{th} \\ \mu_{solid}, & \gamma \ge \gamma_{th} \end{cases} \quad (13)$$

The solid fraction γ is defined to change linearly between solidus T_s and liquidus temperature T_l as:

$$\gamma = \begin{cases} 0, & T \ge T_l \\ \dfrac{T_l - T}{T_l - T_s} & T_s < T < T_l \\ 1 & T \le T_s \end{cases} \quad (14)$$

where C is an empirical parameter between 4 and 8, and the current study uses 6, μ_l is the liquid viscosity of the melt at the liquidus temperature. Similarly, Eq. (14) approximates the solid fraction as a linear function of temperature over the solidification range. This treatment assumes an effective mixture behavior and does not explicitly account for species-dependent phase fractions, densities, or latent heats. The viscosity remains as the liquid viscosity of the melt at the liquidus temperature when $\gamma = 0$. The viscosity changes exponentially with solid fraction between 0 and a defined threshold solid fraction γ_{th}, following the correlation developed by Ramacciotti et al. [15]. When the solid fraction of a melt particle increased beyond γ_{th}, it is deemed as solidified (namely, a crust particle) and its viscosity is increased to the solid viscosity μ_{solid}, which is set as 10^5 Pa·s in the current study.

2.3. Radiative heat loss and convective cooling from the free surface

In the present MPS framework, heat transfer within the condensed phases is explicitly resolved by heat conduction via the particle interaction model, while convection is naturally captured by the Lagrangian motion of particles. However, since the ambient gas phase is not explicitly modeled, simplified heat transfer models are adopted to define the boundary cooling conditions at the free surface. Specifically, both the radiative and convective heat loss from the free surface is considered as heat sink of a particle represented by Q in Eq. (3). The radiative heat flux $q_{radiative}$ removed from the free surface is evaluated based on Stefan-Boltzmann law as:

$$q_{radiative} = \sigma\varepsilon(T^4 - T_{background}^4) \quad (15)$$

where σ is Stefan-Boltzmann constant, ε is the emissivity, and $T_{background}$ is the background temperature for the thermal radiation.

Similarly, the convective heat flux $q_{convective}$ removed from the free surface is evaluated using Newton's cooling law as:

$$q_{convective} = h_c(T - T_{envioronment}) \quad (16)$$

where h_c is the convective heat transfer coefficient and $T_{envioroment}$ is the environment temperature.

Additionally, once the melt spreads onto the concrete substrate, heat transfer at the melt–concrete interface is resolved by conductive heat transfer between neighboring particles. Subscale heat-transfer processes at the interface are not explicitly modeled, and no additional thermal contact resistance is imposed in the present model, such as that inferred in the VULCANO tests [4]. Therefore, the interface treatment corresponds to ideal thermal contact and may overestimate heat loss to the substrate if an effective contact resistance develops.

3. SIMULATION GEOMETRY, CONDITIONS, AND THERMO-PHYSICAL PROPERTIES

The simulation geometry is depicted in Figure 2. The current two-dimensional MPS simulation represents a circumferential slice of the Unit-1 D/W annulus. A buffer pool is arranged beneath the injection inlet to mitigate potential numerical instabilities that may arise from melt impingement on the floor and subsequently affect the spreading process. The concrete substrate connected to the buffer pool is 2.0 m long with a thickness of 0.06 m. A constant-velocity inflow boundary on the left side supplies the MCCI-derived secondary product melt (hereafter referred to as "the melt") at 0.016 m/s, corresponding to a mass flow rate of 2 kg/s for the modeled half D/W annulus (i.e., 4 kg/s for the full annulus). This rate is a scaling estimate derived from an equilibrium energy balance that the decay power is depleted by the generation of the melt, using an early high decay-power level (roughly 7 MW) and an assumed concrete decomposition enthalpy (1779 kJ/kg **[16]**). While subject to uncertainties, this value is adopted as an order-of-magnitude boundary condition to characterize the hydrodynamics of the active spreading phase of the melt in the D/W annulus.

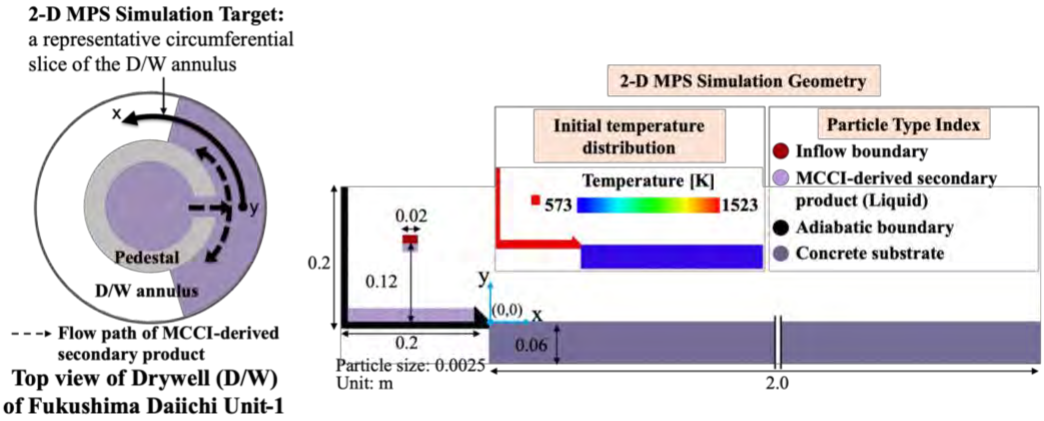

Figure 2. MPS simulation target and geometry

Regarding the boundary conditions, the melt within the buffer pool boundary is treated as adiabatic. Once the melt spreads onto the concrete substrate, heat transfer is considered, including the conductive heat loss to the concrete substrate and convective and radiative heat loss to the atmosphere (see Eq. (15) and (16)). In the current study, h_c is set as 10 W/m^2/K, which is in the order of general natural convection of gas. $T_{background}$ and $T_{envioronment}$ are both set as a constant 573 K. The feedback on the environment temperature and background temperature due to the radiative and convective heat loss from the melt is neglected.

The thermophysical properties used in this study are listed in Table I. The thermophysical properties of the MCCI-derived secondary product are primarily taken from those of basaltic concrete [17]. Regarding the phase change temperatures, recent heating tests on Unit-1 aggregate surrogates (basalt, andesite, and sandstone) confirmed that all aggregate types are fully melted by 1473 K [18]. Since the specific phase change behavior of the secondary product is not uniquely constrained, the liquidus temperature is set to 1523 K as a representative value that is modestly above the beforementioned fully melted temperature 1473

K. Solidification of MCCI-derived secondary product melt is modeled in terms of solid fraction γ that increases from 0 to 1 between the liquidus (1523 K) and solidus temperature (1350 K) (see Eq. 14). The transition to the solid viscosity μ_{solid} is fundamentally defined by the immobilization temperature of 1473 K. For implementation in the Ramacciotti viscosity model, this temperature is converted to the corresponding solid fraction, γ_{th} (0.289). This value is lower than the solid fractions of approximately 50 vol% often associated with spreading termination in corium experiments, such as VULCANO VE-U7 [19], because it is not used here as a universal rheological immobilization criterion. Instead, it is a phenomenological, temperature-based threshold for the onset of effectively rigid crust formation for the Unit-1 MCCI-DSP.

Table I. Thermo-physical properties used in the current study

Thermo-physical properties	MCCI-derived secondary product	Basaltic concrete
Density (kg/m^3)	2240.0	2240.0
Specific heat (J/kg/K)	1250.0	1250.0
Heat conductivity (W/m/K)	2.5	2.5
Viscosity at liquidus temperature (Pa·s)	Low viscosity case: 5.00×10^{-3}	2.70 x10^{-3}
	High viscosity case: 22.36	
Solidus temperature (K)	1350	1350
Liquidus temperature (K)	1523	1650
Fusion heat (kJ/kg)	442.5	442.5

Two reference liquid viscosities are considered, i.e., a low-viscosity case with $\mu_l = 5.00\times10^{-3}$ Pa·s and a high-viscosity case with $\mu_l = 22.36$ Pa·s, which is the viscosity of basalt. These two bounding viscosities are intended to examine bulk melts with initially high and low contrast with respect to the crust viscosity μ_{solid}, respectively. In addition to the temperature-dependent viscosity increase associated with solidification (see Eq. (13) and (14)), an optional freezing criterion is introduced to represent an effectively rigid crust at the leading edge. Specifically, when a crust particle (i.e. the temperature drops below the immobilization temperature of 1473 K) and its velocity magnitude falls below 10^{-4} m/s, the particle coordinates are fixed in space until remelting. In the present model, mechanical failure (e.g., cracking or fracture-driven breaching) is not considered.

To investigate the respective influences of bulk viscosity and effectively rigid crust on slope formation and persistence, three sensitivity cases are considered as listed in Table II.

Table II. Sensitivity case conditions

Case ID		μ_l(Pa·s)	Freezing criterion
1	**Low Viscosity - Freezing (LV-F)**	5.00×10^{-3}	On
2	**Low Viscosity - No Freezing (LV-NF)**	5.00×10^{-3}	Off
3	**High Viscosity - Freezing (HV-F)**	22.36	On

4. RESULTS AND DISCUSSION

4.1. Overview of Spreading Length and Behavior

The spreading length histories of the MPS simulation cases are depicted in Figure 3. The two low-viscosity cases show intermittent spreading advances characterized by “stop-and-go” cycles and stagnation plateaus, while the high-viscosity case exhibits continuous advance.

In the early phase (time < 50 s), the two low-viscosity curves almost overlap despite the short plateaus, which indicates temporary stagnation of the melt front advance due to crust formation. As spreading progressed, the effect of cooling became more prominent, leading to more significant crust formation, especially at the melt front. As a result, the spreading length and behavior start to diverge. In the current study, such front crust behavior dominates not only the spreading behavior, i.e., "stop-and-go" or continuous creeping, but also the melt deposit morphology, which will be detailed in the following sections.

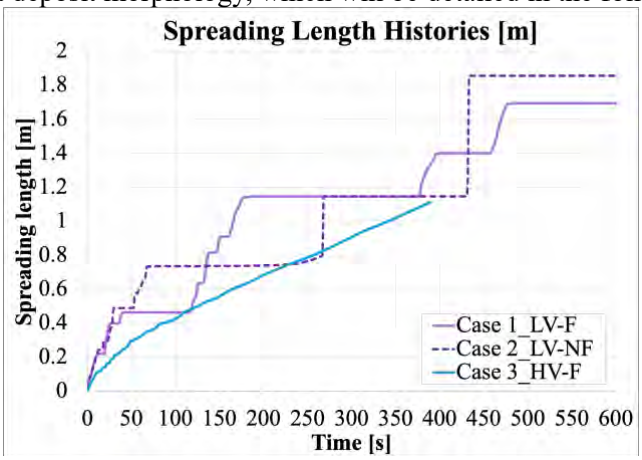

Figure 3. Spreading length histories of MPS simulation cases

4.2. Spreading behavior of Low-viscosity cases: morphology evolution and slope formation

4.2.1. Phase I: early rapid advance with transient crust effects

Figure 3 summarizes the early spreading behavior of the low-viscosity cases with (LV-F) and without (LV-NF) the freezing criterion. Up to approximately 12 s, the two cases exhibit nearly identical spreading length histories and a relatively thin layer of melt with nearly uniform thickness along the spreading direction, indicating that the initial advance is governed primarily by viscous-gravity spreading under continuous inflow and that the effect of crust treatment remains insignificant at this stage.

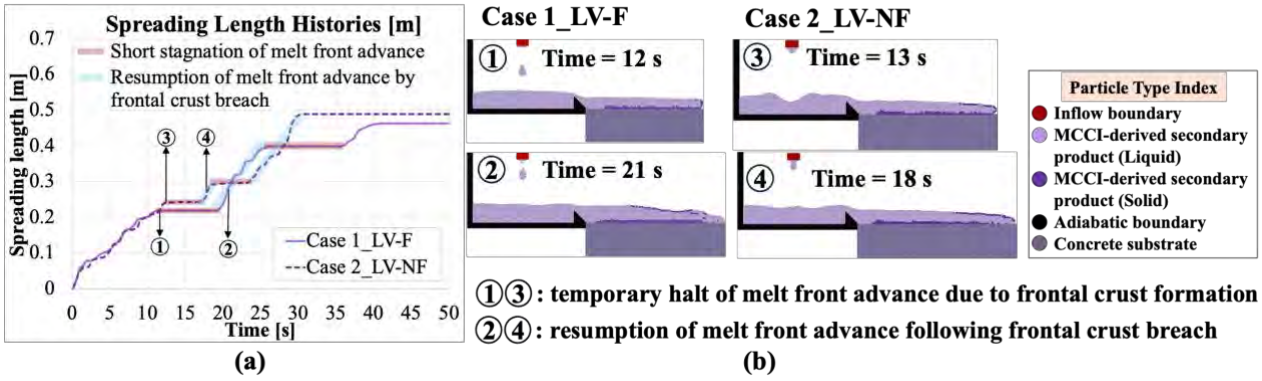

Figure 4. (a) Spreading length history for Phase I (b) Snapshots of representative moments of MPS simulations in LV-F and LV-NF cases (Phase I)

After 12 s, both curves start to exhibit short plateaus resulting in intermittent increases of spreading length. These short stagnations are highlighted in .
Figure **4** (a) and are interpreted as temporary halts of melt front advance induced by frontal crust formation, which was later breached (thermally but not mechanically) to allow for resumption of melt front advance. Such transient behavior of crust breach and resumption of melt advance is detailed in the Snapshots 1 to 4 in .
Figure **4** (b), and the corresponding temperature / solid fraction distribution of melt are shown in Figure 5.

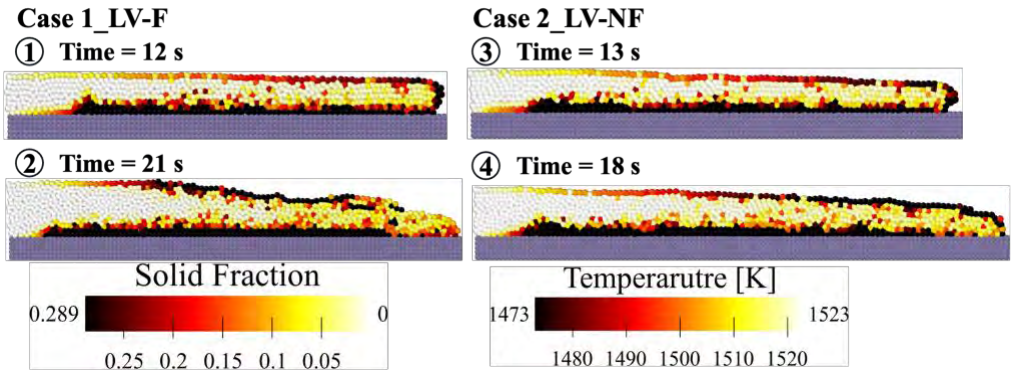

Figure 5 Temperature / solid fraction distribution of melt for representative moments of MPS simulations in LV-F and LV-NF cases

Snapshots 1 and 3 correspond to the onset of such short plateaus for the LV-F (t =12 s) and LV-NF (t = 13 s) cases, respectively. In both cases, a high-solid-fraction thin layer developed near the free surface and concentrated at the melt front due to radiative and convective heat loss to the environment. Through the viscosity model dependent on solid fraction, the frontal crust locally increased the effective viscosity and reduced the front mobility, leading to an apparent halt of the melt front advance, producing the short plateaus in the spreading length histories shown in Figure 4 (a).

Snapshots 2 (LV-F, t = 21 s) and 4 (LV-NF, t = 18 s) illustrate the subsequent resumption of melt front advance. As the inflow continued, the melt from the hot interior reached the front and led to the frontal crust breach. It should be noted that, in the present modeling, "crust breach" refers to recover of advance through either (i) thermal remelting of immobilized crust or (ii) hydrostatically driven viscous creep / advection of the highly viscous crust. When the freezing criterion is activated and crust particles are fixed in space, mechanism (ii) is no longer available. Thus, in the LV-F case a crust fixed in space can be "breached" only by thermal remelting. While in LV–NF, crust particles are not artificially fixed in space, so both (i) and (ii) can apply, allowing for front advance even when crust remains at the melt front. This can explain why some crust particles can still be observed at the melt front when melt front advance resumed in Snapshot 4 for the LV-NF case, while the melt front appears completely crust free in Snapshot 2 for the LV-F case.

Overall, Phase I shows that while global spreading histories remain comparable, frontal crust formation already strongly affects the instantaneous advance of the melt front. High bulk thermal energy prevents the crust from becoming a durable barrier, allowing repeated breaches through remelting (LV-F) or viscous deformation (LV-NF). Consequently, both cases exhibit "stop-and-go" cycles driven by the competition between rapid surface cooling and advective heat supply from the hot interior. Notably, the dynamics observed in most spreading experiments generally correspond to this phase. These short stagnations foreshadow the Phase II divergence, where crust persistence ultimately controls the transition to sustained crust anchoring and slope formation.

4.2.2 Phase II: Long stagnation

Following the initial "stop and go" cycles of Phase I, both cases transition into Phase II characterized by extended plateaus ("long stagnation") in the spreading length (e.g., t≈ 42–114 s for LV-F and t≈ 68 – 225 s for LV-NF in Figure 6 (a)), despite the continuous inflow. This indicates that the global kinematics in Phase II are no longer controlled by the supply rate alone, but by the frontal crust development under cooling. Considering mass conservation, because the spreading length remains unchanged while inflow persists, the injected melt mass must be accommodated by an increase in the melt thickness in 2-D. The key difference between LV–F and LV–NF is how this melt thickening is redistributed along the spreading direction.

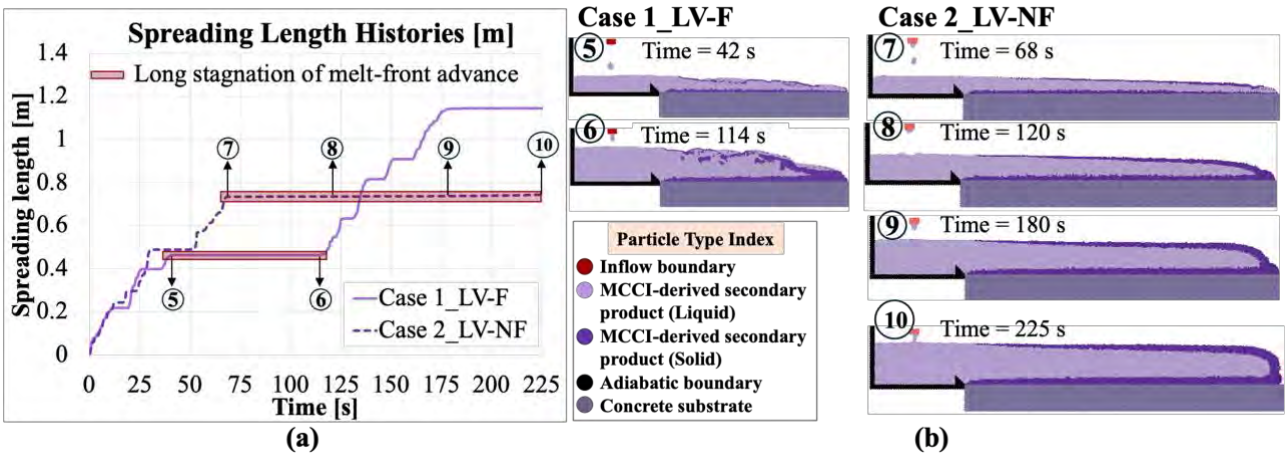

Figure 6 (a) spreading length histories with Phase II highlighted (b) Snapshots of representative moments of MPS simulations in LV-F and LV-NF cases (Phase II)

In the LV-F case, once the freezing criterion immobilizes the crust particles and fixes them in space, the frontal crust behaves as an effectively rigid obstruction at the melt front. Forward melt transport through the front is strongly suppressed, and continued inflow produces damming and upstream accumulation, generating a pronounced thickness gradient ("slope") behind the stalled front (see Snapshots 5-6 in Figure 6(b)). In other words, during Phase II the LV–F system converts sustained inflow into a vertical thickening pool against a fixed rigid front, establishing a persistent slope in the subsequent evolution. This process suggests the kinematic anchoring of the crust could be the direct origin of the persistent slope observed in the Fukushima Unit-1 deposits.

In contrast, the LV-NF case maintains a relatively uniform thickness, characterized instead by pronounced morphological evolution of the "nose". Because the frontal crust remains by assumption a mobile Newtonian fluid, hydrostatic pressure gradients drive slow viscous creep, progressively transforming the front from a sharp wedge into a rounded "bullet-nose" (Snapshots 7 – 10). This reshaping reflects the fundamental tendency of viscous gravity currents to level out to minimize potential energy. Although high viscosity of the frontal region suppresses rapid extension, internal viscous relaxation continues to smooth sharp thickness gradients.

The comparison between LV-F and LV-NF cases reveals that macroscopic stagnation arises from two fundamentally different physical states. In LV-F, long stagnation is due to the effectively rigid frontal crust working as a rigid dam to support a persistent slope. In LV-NF, stagnation is a state of creep-limited flow, where the crust resists rapid extension but continues to viscously relax and flatten under hydrostatic load. This contrast is essential for the subsequent interpretation of slope persistence, namely the frontal crust needs to sustain a hydrostatic head without creeping (LV-F) so that a thickness gradient in the deposited profile can be produced and sustained. It should also be noted that sustained slopes may be produced by other rheological mechanisms, such as non-Newtonian or yield-stress behavior. In the present study, the freezing criterion is used as a simplified kinematic representation of an effectively load-bearing frontal crust, rather than as the only possible physical mechanism for slope preservation [20].

4.2.3 Phase III: Resumption of melt front advance by overriding

Figure 7 compares the late stage spreading length histories following the Phase II stagnation. Both cases exhibit intermittent resumption of melt front advance, manifested as stepwise increases in the spreading lengths, herein defined as Phase III. These stepwise increases in spreading length occur at t ≈ 118, 375, 450 s for LV-F and t≈ 260, 430 s for LV-NF. Such spreading length increases are driven by overriding, where

a new flow path bypasses the previously stagnated front. However, the significantly higher spreading rate observed in the LV-NF events reflects a fundamental mechanism divergence between the two cases.

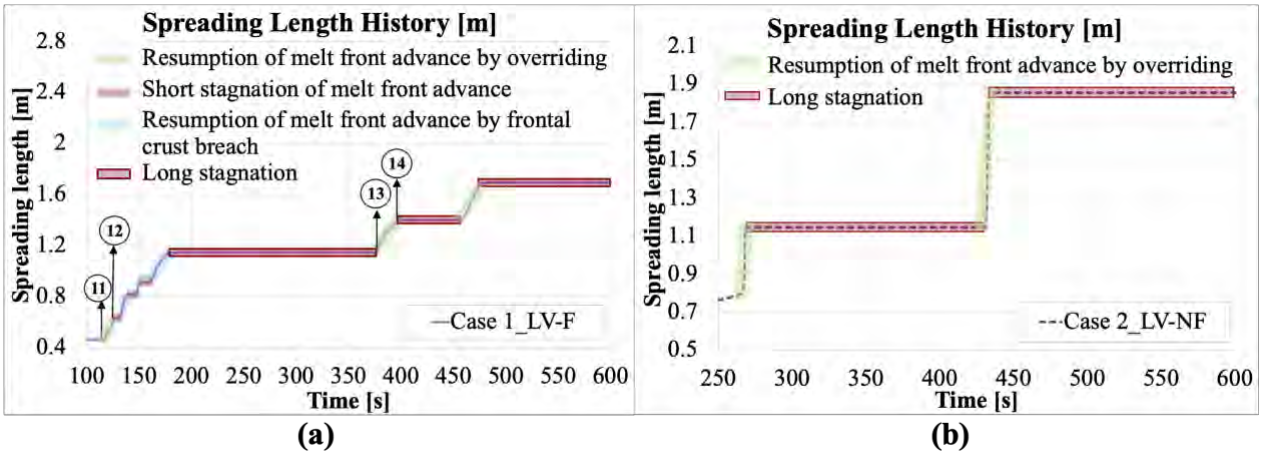

Figure 7 (a) Spreading length histories of LV-F case (b) Spreading length histories of LV-NF case

I. LV–F: overriding via hot-melt bypass over an immobilized frontal crust

Figure 8 (a) shows representative snapshots illustrating the overriding mechanisms in the LV–F case. During the preceding stagnation, the frontal crust developed into an effectively rigid barrier. Continuous inflow led to the accumulation of upstream melt until a preferential flow path was established that overrode this barrier. These overriding events are illustrated by Snapshots 11 (t = 118 s) and 13 (t = 378 s) in Figure 8 (a), where a thin, rapidly advancing interior melt layer overrode the immobilized nose (arrows indicate the dominant melt flow paths). Because the newly advancing layer was thin, it was cooled efficiently and rapidly developed a new frontal crust which temporarily halted the renewed advance until it locally remelted again (see Snapshots 12 (t = 126 s) and 14 (t = 395 s) in Figure 8(a)). These short "stop-and-go" episodes similar to those in Phase I are visible in the late-time spreading history (e.g., t≈126–175 s in Figure 7 (a)), indicating that overriding events can be followed by rapid re-establishment of frontal crust and short stagnations.

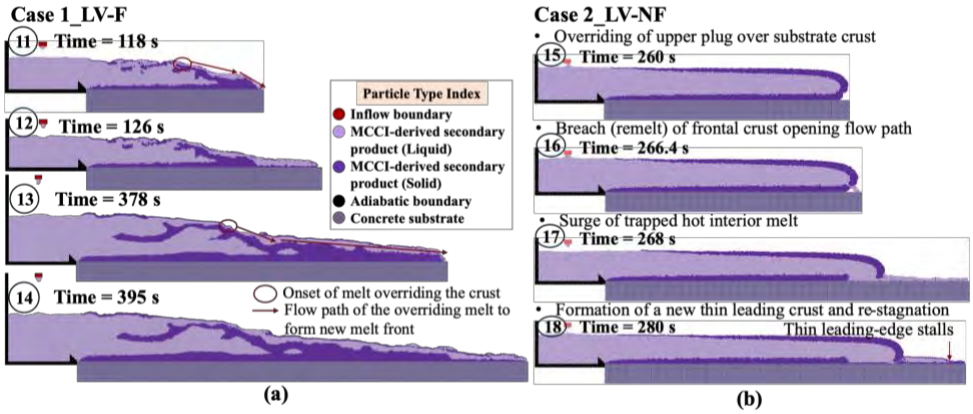

Figure 8 Snapshots of representative moments of MPS simulations for (a) LV-F and (b) LV-NF cases (Phase III)

II. LV–NF: overriding initiated by plug creep triggering interior melt discharge

In LV-NF, the frontal region remained a highly viscous but mobile Newtonian plug. Phase III occurred when this slow evolution enabled the bulk melt to override the cooled substrate / basal crust and open a flow

path for the hot interior melt. As shown in Figure 8 (b), the plug crept forward under hydrostatic load until the frontal crust confinement breached (Snapshot 16). Once breached, the low-viscosity interior discharged rapidly, surging along the floor as a thin melt layer (Snapshots 17-18). Unlike the controlled bypass over the readily formed crust structure in LV-F, such discharge dispersed the accumulated potential energy of melt in a sudden surge, producing a sharp step increase in spreading length in Figure 7 (b).

Overall, Phase III in LV-F can be interpreted as a thermal bypass of the frontal crust region, rather than remobilizing the originally anchored front through remelting, while in LV–NF the overriding event can be interpreted as a two-stage process: (i) gradual plug reconfiguration by viscous creep / advection, followed by (ii) rapid discharge and spreading of hot interior melt once the constraining crust is sufficiently weakened. In both cases, Phase III can be short-lived, and the spreading kinetics quickly transitioned back to intermittent advance punctuated by short stagnations as in Phase I or long stagnations in Phase II.

4.3 High-viscosity case (HV–F): continuous advance and uniform deposition tendency

Figure 9 presents the spreading behavior for the high-viscosity case (HV-F). In contrast to the intermittent "stop-and-go" dynamics of the low-viscosity cases, the HV-F case exhibits continuous advancement characterized by a rounded nose (Snapshots 19-20). This behavior stems from the high viscosity of the bulk melt, which facilitates efficient momentum diffusion from the interior to the leading edge.

As shown by the solid fraction and velocity distribution in Figure 9 (b), the viscous interior physically dragged the developing crust forward, maintaining frontal velocities well above the freezing threshold ($|u| < 10^{-4}$ m/s). Consequently, although the freezing criterion was active in the simulation, it was practically never triggered. As a result, the melt advanced predominantly by continuous creep, resulting in a relatively uniform thickness profile, in contrast to the pronounced upstream accumulation and slope formation mechanism observed in the LV-F case.

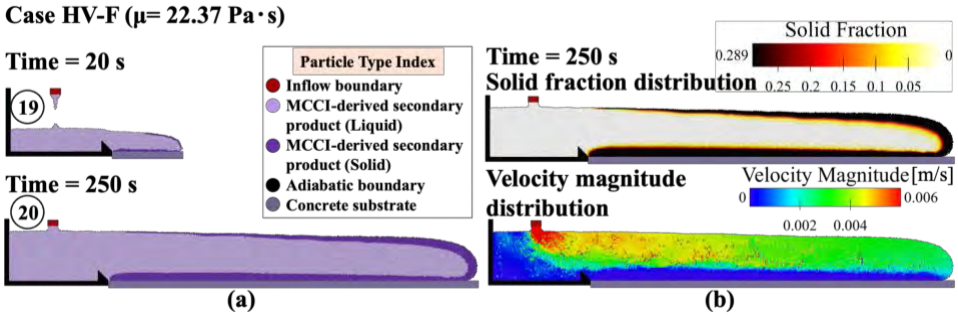

Figure 9 Snapshots of representative moments of MPS simulations for high-viscosity case

4.4 Implications for interpreting Unit-1 PCV deposits

Post-accident investigations of Unit-1 PCV reveal two key requirements for a mechanistic explanation of melt transport in the D/W annulus, i.e., (a) sufficient mobility to spread broadly in the D/W annulus and (b) capability to retain a decreasing-height trend with travel distance (the "slope"). Within the present MPS framework, i.e., treating the melt as a Newtonian fluid with temperature-dependent viscosity and an optional kinematic immobilization rule ("freezing criterion"), the simulations suggest that reproducing these features is facilitated by two rheological attributes:

1. Front crust rigidity to suppress long-term gravitational relaxation. The simulation results show that high viscosity alone is insufficient to maintain a slope over extended timescales. When the frontal region remains a mobile Newtonian layer, thickness gradients progressively relax through creep driven primarily by hydrostatic pressure. A sustained shelf-like morphology therefore requires the frontal region to behave effectively as a mechanically supportive structure, which is represented here by the freezing criterion that allows the front to sustain a hydrostatic head without long-term deformation.

2. Sufficient viscosity contrast between the bulk melt and the crust to enable frontal anchoring. Slope formation is favored when the bulk melt remains sufficiently less viscous relative to the crust. This allows the interior melt to flow without generating enough viscous drag to mobilize the frontal crust, permitting the leading edge to slow down and anchor while the inflow piles up upstream. Conversely, a relatively high-viscosity interior exerts strong drag on the crust, physically pulling the frontal region forward and maintaining a continuous creep regime to disrupt stable slope formation.

These findings imply that one plausible scenario for the observed Unit-1 deposit morphology is that the MCCI-derived secondary product initially possessed high flowability during relocation, but upon cooling developed a locally rigid frontal structure that effectively anchored the deposit geometry against gravitational leveling.

5. CONCLUSIONS

A 2-D model with free-surface radiative / convective cooling and temperature-dependent viscosity was applied to simulate the spreading of a hypothesized MCCI-derived secondary product using the MPS method, to clarify the mechanisms of the sloped deposits in the Fukushima Daiichi Unit-1 D/W annulus. Three sensitivity cases were used to separate the effects of bulk viscosity and frontal crust behavior. The comparative results support the following interpretation.

The simulations indicate that reproducing slope formation requires a kinematic anchoring mechanism (modeled here via a freezing criterion) that acts as an effective rigidity, allowing the frontal crust to sustain a hydrostatic head without long-term deformation. Another key finding is that a large bulk-crust viscosity contrast promotes the conditions for front anchoring, facilitating slope formation.

Although the present modeling employs a simplified representation of crust rigidity through a kinematic immobilization criterion, this interpretation provides a physically consistent basis for relating the observed deposit morphology to melt mobility and frontal anchoring behavior and potentially offers a useful framework for future studies incorporating more detailed descriptions of the rheological properties of debris deposits in the Unit-1 PCV. A potential future step is to identify the in-pedestal processes capable of generating an MCCI-DSP with such rheological attributes, including coupled interactions among concrete, steel / iron oxides, and possible chemical modifiers, supported by dedicated material-property measurements.

ACKNOWLEDGMENTS

This study has been performed by the funds from Japanese Ministry of Economy, Trade, and Industry as The Subsidy Program “Project of Decommissioning, Contaminated Water and Treated Water Management (Development of Analysis and Estimation Technologies for Characterization of Fuel Debris)” starting FY2025.

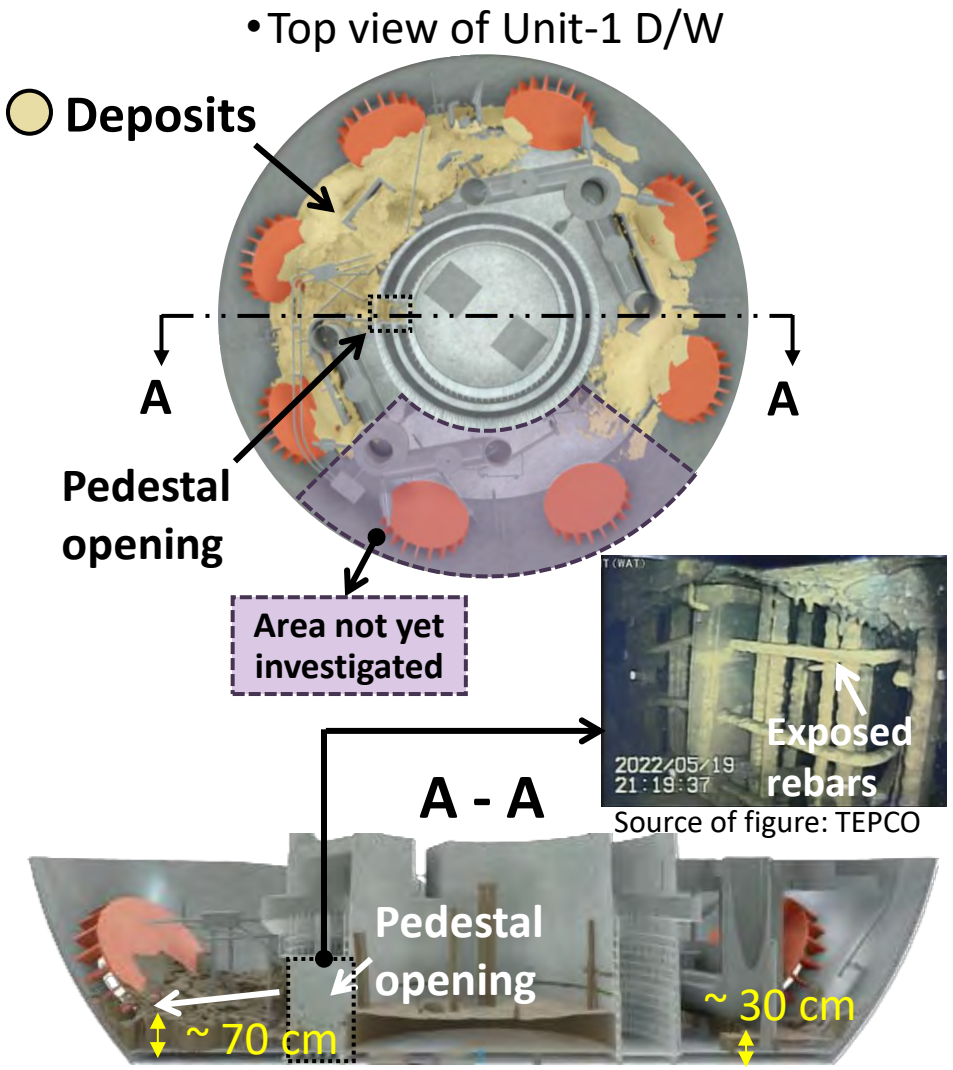
Investigation on the Melt Transport Behavior in the Drywell of Fukushima Daiichi Nuclear Power Station Unit-1 with MPS Method

*Xin Li[1], Akifumi Yamaji[2], Ikken Sato[2], Takuya Yamashita[1]

1. Japan Atomic Energy Agency
2. Waseda University

Background - Distinctive Deposits Observed in Unit-1 D/W

Findings from PCV Internal Investigations of Fukushima Daiichi Unit-1



Source of figure: TEPCO

"Slope" - Deposit height decreases with distance from the pedestal opening

Source of figures: debrisEye

1. Widespread deposits in the D/W annulus
Deposits extending far beyond the pedestal opening to cover a large area of the D/W annulus

2. Sloped Deposit Morphology
Deposit height decreases with distance from the pedestal opening — a Unit-1-specific feature.

3. No melt traces on jet deflectors
Difficult to reconcile with direct high-temperature fuel-debris spreading.

4. Exposed & Standing rebars near pedestal opening
Suggests low-to-moderate temperature transport & ablation of concrete, instead of classical MCCI

These features are difficult to explain with simple high-temperature corium spreading.

From Unit-1 Evidence to a Non-Classical MCCI Interpretation

Classical high-temperature spreading

- Thermal damage on metallic structures expected (not observed in Unit-1).
- Spreading often treated as short-duration release (experimental limitation).
- Post test slope not evident, except a few cases (e.g., FARO L-26S), mechanism unclear.

Conflicts with Unit-1 observations.

Unit-1 accident progression

- No effective cooling by water injection.
- Sustained concrete interaction under moderate decay power.
- Corium crust likely suppressed mixing of fuel-rich corium and molten concrete.

MCCI remains the source, BUT relocated material to outside pedestal likely NOT classical corium–concrete mixture.

Moderate-temperature transport
+ Continuous melt generation

Interpretation proposed in this study

MCCI-Derived Secondary Product (MCCI-DSP)

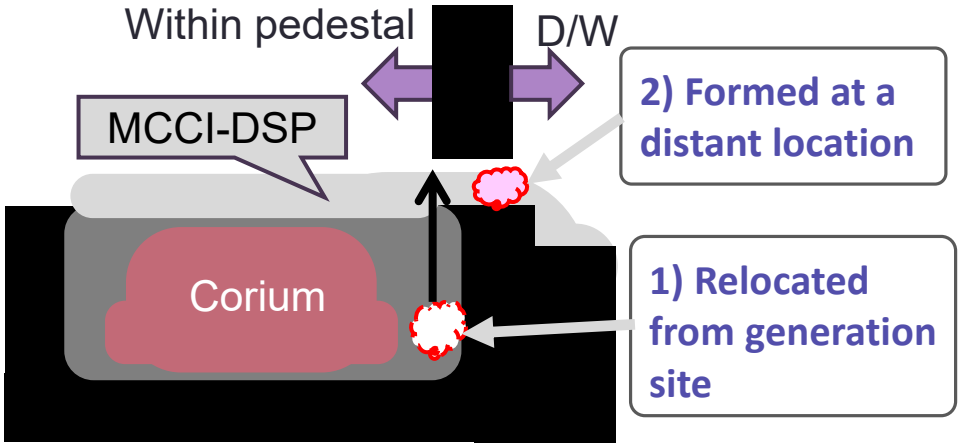
Generated by pedestal MCCI product, then relocated into the D/W annulus at moderate temperature.

Proposed interpretation: MCCI-Derived Secondary Product

Definition adopted in this study

Products originating from MCCI but encompassing a broader **spatial and temporal scope** than conventional experiments. They could differ in macroscopic composition and properties from typical residues from MCCI tests, defined as material that has either:

1) **relocated from the vicinity of the primary MCCI region**, or
2) **formed at a location away from the primary MCCI region through concrete melting**



Conceptual schematic

The concept extends the spatial and temporal scope of MCCI:

Not only the initial high-temperature corium, but also materials that evolve, relocate, or re-generate after corium–concrete interaction are considered.

Primary MCCI in pedestal
High-T corium + concrete

→ **Secondary product forms**
composition / properties evolve

→ **Relocation into D/W annulus**
moderate-temperature transport

→ **D/W spreading**
cooling + crust formation

→ **Sloped deposit**

- In the context of 1F Unit-1, this MCCI-DSP is considered to be a concrete-rich melt.

Knowledge Gaps in Past Studies

- Past severe-accident spreading studies have established a strong foundation, **but key features of the Unit-1 deposition scenario remain outside their scope.**

1 Experimental scope is limited

- VULCANO, ECOKATS: **single-release, short-duration** tests
- Focus on **maximum spreading length** — not long-time morphology

2 Existing spreading codes lack vertical resolution

- MELTSPREAD / THEMA rely on the **shallow-water approximation**
- Cannot resolve vertical **velocity, temperature, or phase** profiles

3 Frontal crust dynamics are unresolved

- Crust under **continuous inflow** + **extended timescales** not well addressed

  → ***the regime that governs Unit-1 deposits***

Research focus and objectives

Research focus

What flow and solidification mechanism produces the observed thickness gradient of Unit-1 D/W deposits?

Assumptions from Unit-1 PCV Internal Investigations

- **Origin**

  Deposit interpreted as an **MCCI-DSP** that **originated inside the pedestal** and relocated / solidified in the D/W annulus.

+

- **Material Properties**

  Thermal physical properties close to molten concrete (composition not yet uniquely constrained).

↓ Based on these assumptions, the deposit mechanism is investigated

Research objectives

Clarify the **frontal crust dynamics** under **continuous inflow** + extended timescales

Moving Particle Semi-implicit (MPS) Method

Basics of MPS method : Lagrangian particle method

No mesh; Fluid treated as a set of particles; Each particle carries mass, momentum, and enthalpy.

Discretization by particle interaction

Gradient, divergence, and Laplacian operators approximated using neighbor particles within an influence radius (r_e) , weighted by ***w(r)***.

Fit for free-surface, large-deformation flows

Handles solid–liquid phase change accompanied by flow heat transfer

Multiphase MPS with corrective matrix (Duan et al. 2019) — stable & accurate at high viscosity, suitable for crust formation.

Governing Equations

Mass

$$\frac{D\rho}{Dt} = -\rho\nabla.\mathbf{u} = 0$$

Navier-Stokes

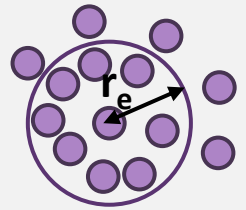
$$\rho\frac{D\mathbf{u}}{Dt} = -\nabla P + \mu\nabla^2\mathbf{u} + \rho\boldsymbol{g} + \boldsymbol{f}$$

Energy

$$\rho\frac{Dh}{Dt} = k\nabla^2 T + Q$$

Weight Function

$$w(r) = \begin{cases} \left(\frac{r_{ij}}{r_e} - 1\right)^2, & 0 \le r_{ij} < r_e \\ 0, & r_e \le r_{ij} \end{cases}$$



Particle Interaction Models

Gradient:

$$\langle\nabla\phi\rangle_i = \frac{1}{n_0}\sum_{\mathbf{j}\neq i}\left\{w_{ij}\frac{\phi_j - \phi_i}{r_{ij}}\left(\begin{bmatrix}\mathbf{C}_1\\ \mathbf{C}_2\\ \mathbf{C}_3\end{bmatrix}P\right)\right\}$$

Laplacian:

$$\langle\nabla^2\phi\rangle_i = \frac{1}{n_0}\sum_{\mathbf{j}\neq i}\left\{w_{ij}(\phi_j - \phi_i)\frac{[\mathbf{C}_4 + \mathbf{C}_5 + \mathbf{C}_6]P}{l_0 r_{ij}}\right\}$$

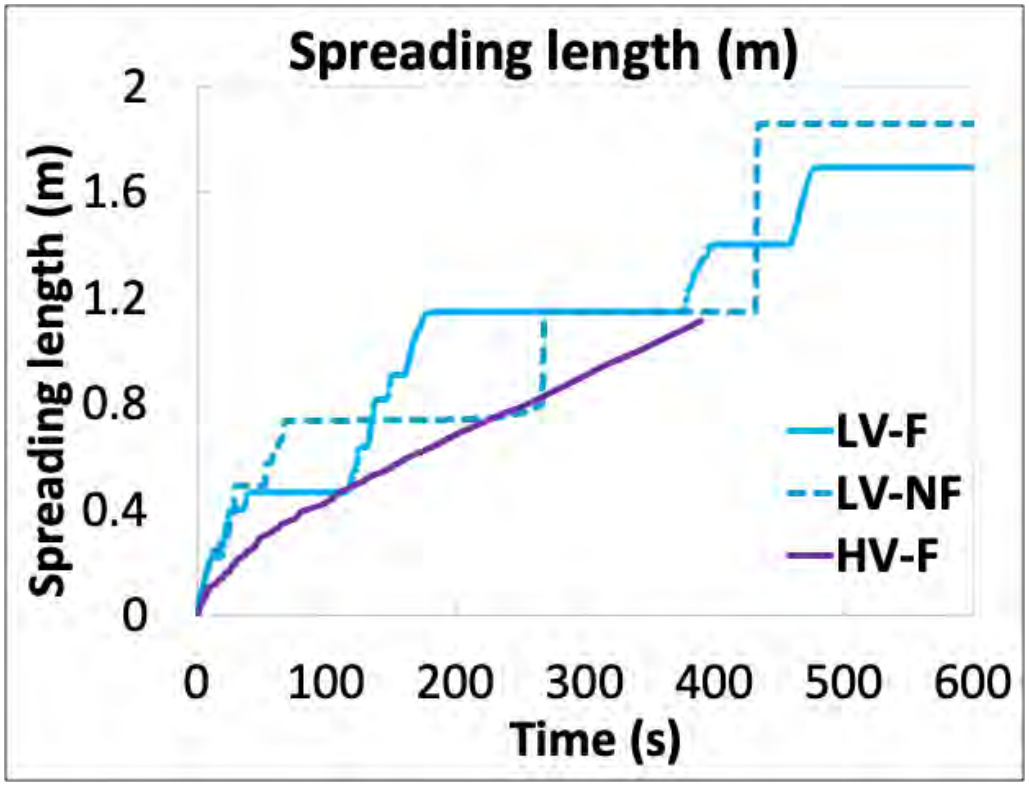
Results – Spreading Length Histories

Cases ID		Liquid bulk viscosity μ_l (Pa·s)	Crust Freezing Criterion
LV-F	Low Viscosity – Freezing	5×10^{-3}	ON
LV-NF	Low Viscosity – No Freezing	5×10^{-3}	OFF
HV-F	High Viscosity –Freezing	22.4	ON



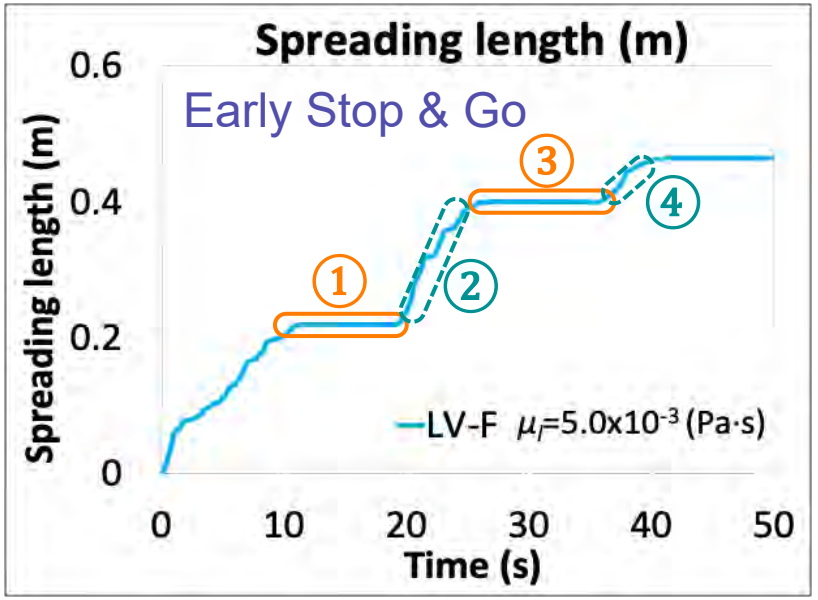
History of the leading-edge position of MCCI-DSP spreading: low and high viscosity cases.

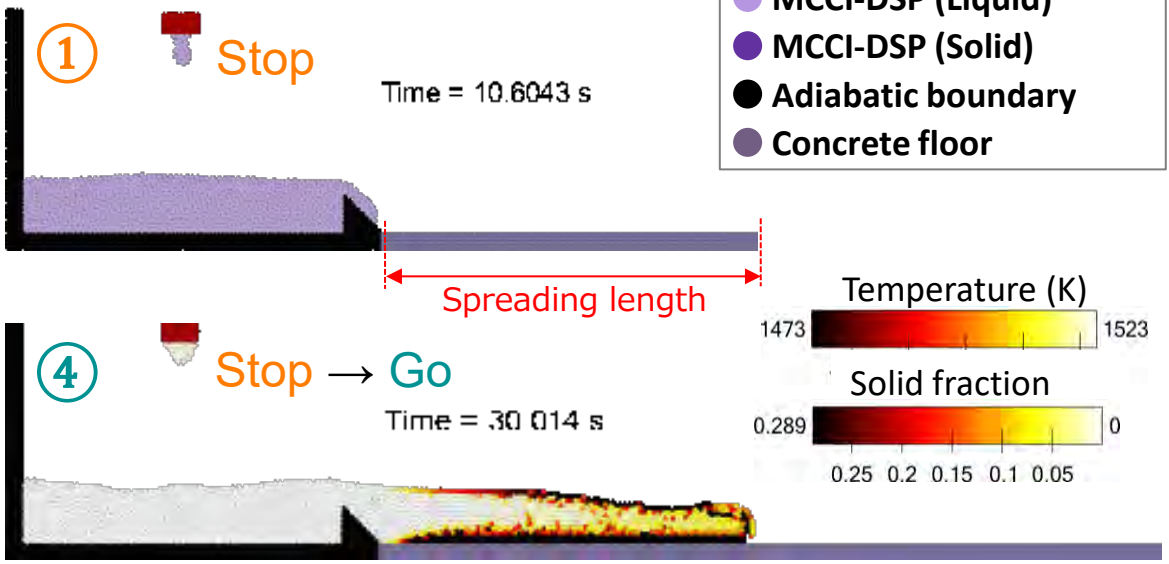
- **Low-Viscosity Cases**
  - **Intermittent Advance ("Stop-and-Go")**
  - Thin melt is temporarily blocked by frontal crust, then resumes via overriding or pushing through.
- **High-Viscosity Case**
  - **Continuous Advance (No stagnation)**
  - The thicker spreading melt is not blocked by the crust.
- **Impact of Time Evolution & Crust Anchoring (LV cases)**
  - **Early Phase (< 50 s)**: **Negligible effect**; crust is underdeveloped.
  - **Later Phase (> 50 s)**: **Significant effect**; developed crust and its anchoring strongly influence the results.

LV-F: Early Stop & Go Cycles (0 – 50 s)

Cases ID		Liquid bulk viscosity μ_l (Pa·s)	Crust Freezing Criterion
LV-F	Low Viscosity – Freezing	5 x 10^{-3}	ON

- **Early phase: Frontal-crust formation (Stop) and Remelting (Go)**





Stop **Temporary halts of melt front advance (①③ in above figure)**

Melt front advance is obstructed by **thin frontal crust formation**.

Go **Resumption of melt front advance (②④ in above figure)**

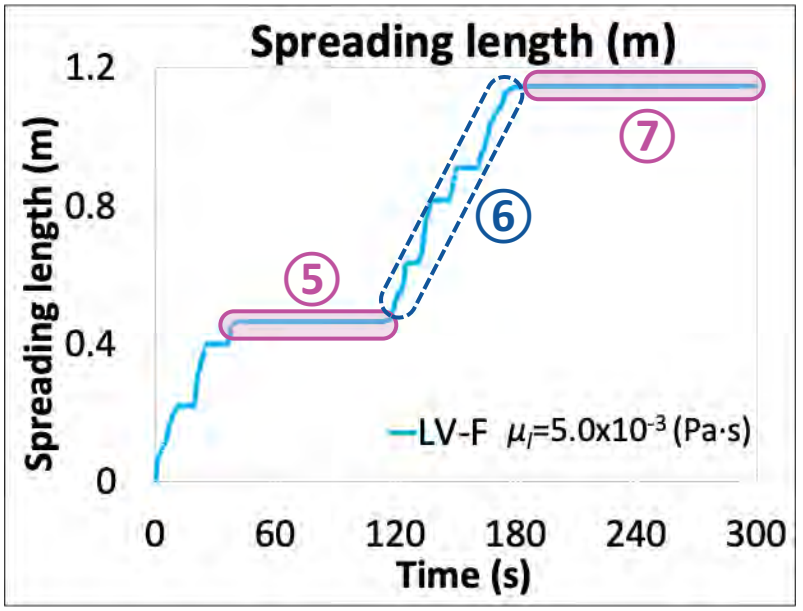
Melt front advance resumes via **crust remelting** driven by upstream heat.

Mechanism

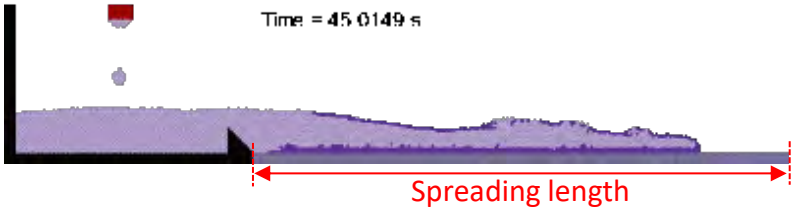
- Insulating upper crust sustains high-temperature bulk flow.
- Stop-and-go advance of the leading edge driven by crust formation/remelting.

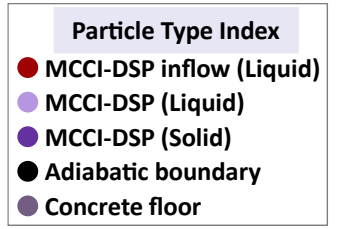
LV-F: Slope Formation & Overriding (> 50 s)

Later phase: Persistent slope forms → Rigid crust supports the hydrostatic head without deformation.



⑤ Stop-2 **Long stagnation & Slope formation**





⑥ Go-2 **Flow resumption by overriding**

→ Melt flow path

Slope-formation mechanism

Frontal crust develops & fixed in space → effectively rigid "dam"

↓

Continued inflow piles up behind the dam → thickness gradient grows

↓

Hot interior melt eventually overrides the immobilized front → new advance, new crust

Cycle repeats → leaves a persistent thickness gradient profile (slope)

Stop-2 **Long stagnation & Slope formation (⑤⑦ in above figure)**

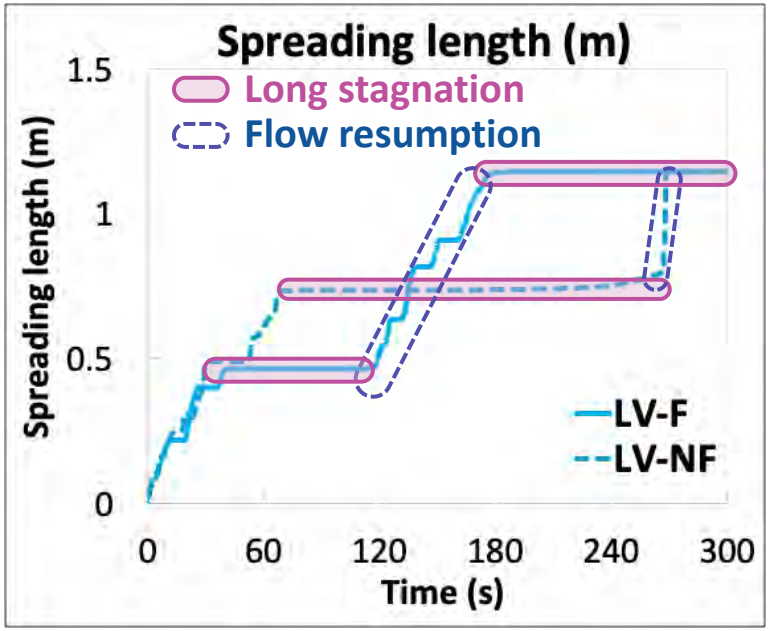
Slope grows via continuous inflow during front stagnation.

Go-2 **Resumption of melt front advance by overriding (⑥ in above figure)**

Melt overrides the sloped crust, advancing as a thin layer.

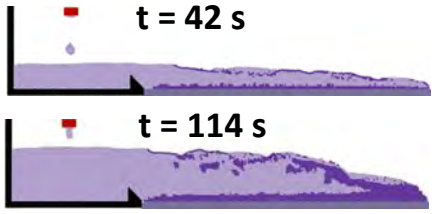
LV-F vs. LV-NF: Crusts Fixed in space vs. Not Fixed

Cases ID		Liquid bulk viscosity μ_l (Pa·s)	Crust Freezing Criterion
LV-F	Low Viscosity – Freezing	5×10^{-3}	ON
LV-NF	Low Viscosity – No Freezing	5×10^{-3}	OFF

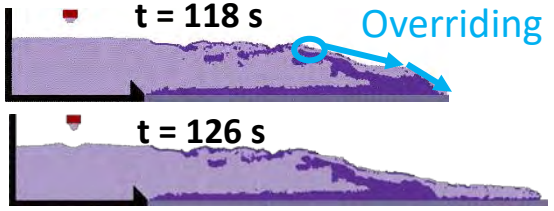


LV-F: Crust fixed in space

Long stagnation → Slope forms



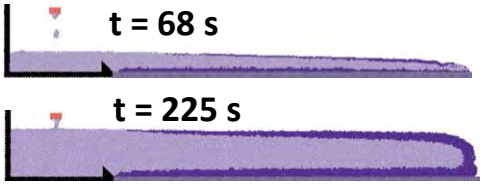
Flow resumes → Persistent slope



Slope forms & persists

LV-NF: Crust Not Fixed in space

Long stagnation → crust creeps, slope relaxes



Flow resumes → No slope

Advance resumes by pushing the frontal crust

Slope flattens — not sustained

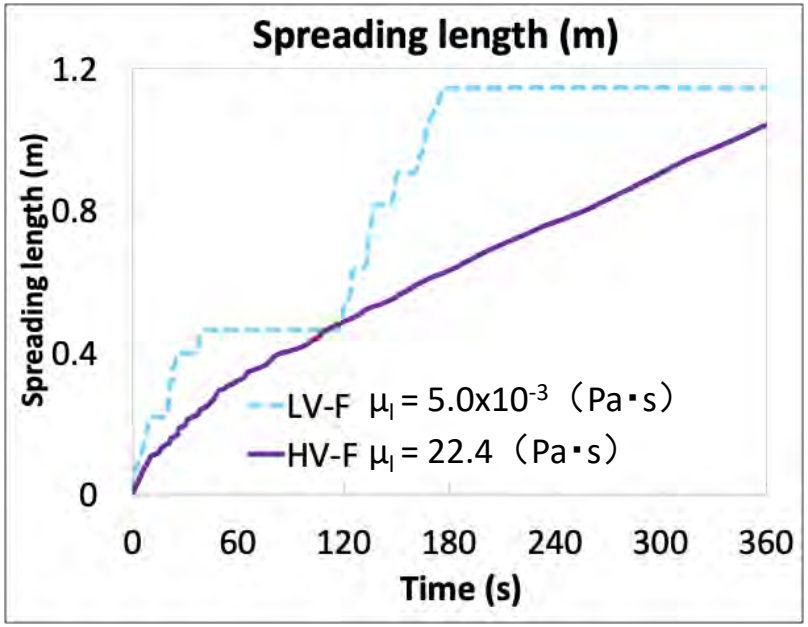
Particle Type Index
- MCCI-DSP inflow (Liquid)
- MCCI-DSP (Liquid)
- MCCI-DSP (Solid)
- Adiabatic boundary
- Concrete floor

LV-F (Crust fixed in space): Immobilized frontal crust acts as a rigid barrier to the continuous inflow, building and preserving the slope during overriding.

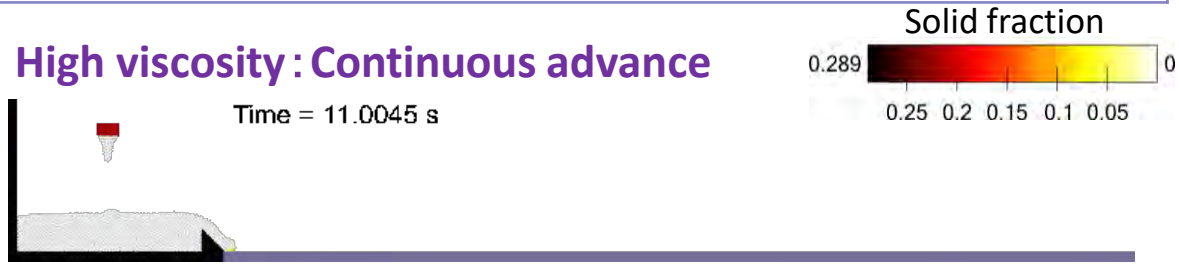
LV-NF (Crust Not Fixed in space): Crust is a highly viscous but mobile Newtonian fluid; Hydrostatic pressure drives slow creep, flattening the slope.

HV-F: High Liquid Bulk Viscosity, Freezing ON

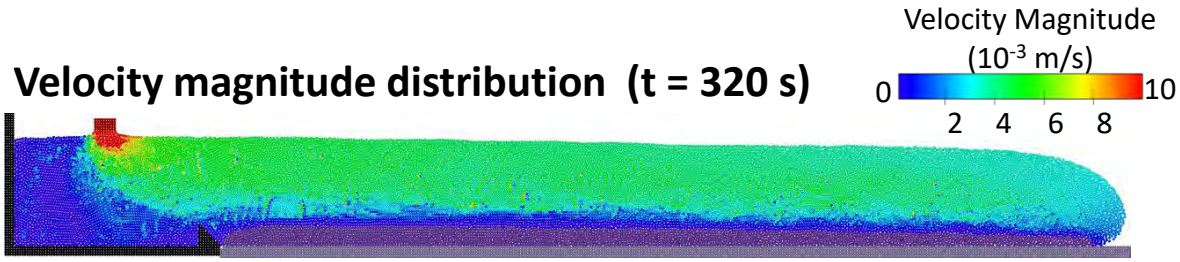
Cases ID		Liquid bulk viscosity μ_l (Pa·s)	Crust Freezing Criterion
LV-F	Low Viscosity – Freezing	5×10^{-3}	ON
HV-F	High Viscosity – Freezing	22.4	ON



High viscosity : Continuous advance



Velocity magnitude distribution (t = 320 s)



Efficient momentum diffusion with low velocity gradient

→ **Crust moves together with the bulk melt**

→ **Relative uniform thickness**

High viscosity case characteristics

- **High bulk viscosity** (μ_l = 22.4 Pa·s) enables efficient momentum diffusion from interior to front.
- **Viscous interior physically drags the forming crust forward**, keeping its velocity above the freezing threshold $|u| < 10^{-4}$ m/s.
- Although **the crust freezing criterion** is active in the simulation, it is **essentially never triggered**.

Continuous creep, uniform thickness → ✕ No slope formation

Conclusion: MPS Findings & Implication to Unit-1

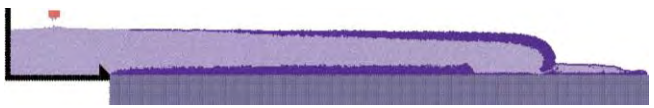
MPS simulation results — which case reproduces the observed slope?

LV-F *Low μ + crust anchoring* ✓

Sustained slope by Stop & Go

✓ *Matches Unit-1*

LV-NF *Low μ + mobile crust* ✗



Creep flattens the slope

X Cannot sustain slope

HV-F *High μ → crust drags* ✗

Continuous, uniform spreading

X No slope formation

Three Requirements for Sustained Slope Formation

1 Viscosity contrast

$\mu_{bulk} \ll \mu_{crust}$

Sufficient viscosity contrast prevents the interior melt from dragging the frontal crust, allowing it to anchor.

2 Crust anchoring

non-creeping front

Crust anchors to the floor and sustains a hydrostatic head — no creep relaxation under gravity.

3 Continuous Inflow

1F-specific

Sustained supply during stagnation drives upstream thickness build-up — unlike short spreading tests.

Implication for Unit-1 D/W deposits

- **Possible Unit-1 Deposit Formation Process:**

  Highly fluid MCCI-DSP ➔ Cooling ➔ Rigid frontal crust formation ➔ crust anchoring against gravitational leveling ➔ sustained slope

ABSTRACT

Ex-vessel corium spreading is one of the most critical phenomena in nuclear safety. Because large-scale experiments are difficult to conduct, numerical simulations—particularly those based on the Lagrangian particle method—are widely employed, as this approach is well suited for phenomena involving large deformations. However, conventional corium spreading simulations remain highly computationally expensive, as they rely on implicit algorithms to stabilize the viscosity term and to solve the pressure Poisson equation (PPE) in the momentum equation. Consequently, even with parallel computation, simulating the entire process requires considerable computational time.
To overcome these limitations and achieve significant acceleration of corium spreading simulations, this study proposes an advanced graph neural network (GNN)-assisted particle method. Instead of explicitly computing mathematical operators such as gradients, divergences, and Laplacians through neighbor particle interactions, the Lagrangian particle coordinates are reorganized into graph structures, enabling efficient learning-based approximations of particle interactions. The GNN is trained to learn and reproduce these graph structures using datasets generated by our in-house moving particle hydrodynamics (MPH) code.
To validate the proposed method, the dam-break problem—one of the representative benchmark cases—was simulated using the GNN-particle method in both 2D and 3D. The results show that the total RMSE was on the order of 1×10^{-4}, demonstrating that the GNN-particle method can accurately reproduce the results of the conventional particle method. Furthermore, in terms of computational performance, the GNN-particle method achieved nearly a 40-fold speed-up compared to OpenMP parallel computation and even outperformed OpenACC GPU computing. These findings indicate that the proposed method provides substantial computational efficiency, paving the way toward real-time simulation in the near future.

1. INTRODUCTION

Corium spreading is a crucial phenomenon during severe accidents because it governs the initial distribution of molten material and strongly influences subsequent processes such as molten core–concrete interaction (MCCI) [1]. Although several prototype experiments have been conducted [2], numerical simulation remains essential for deepening mechanistic understanding, as it enables visualization of transient flow behavior and quantitative evaluation of key metrics (e.g., run-out distance, thickness evolution, and thermal–hydraulic loads). In particular, Lagrangian particle methods have been widely applied to corium spreading because they naturally capture large deformation and free-surface flows [3]. However, applying Lagrangian methods to highly viscous corium spreading is computationally demanding. Severe time-step restrictions imposed by the Courant–Friedrichs–Lewy (CFL) condition and viscous diffusion constraints often necessitate fully implicit treatments for both the pressure field and the viscous term, resulting in prohibitively high computational cost and limiting applicability to real-scale analyses.

*

In parallel, machine-learning-based surrogate modeling has attracted considerable attention as a promising strategy to reduce the computational cost of conventional CFD. Most existing work has focused on Eulerian, grid-based solvers, where convolutional neural networks (CNNs) and related architectures are used to learn flow-field mappings, predict temporal evolution, or accelerate key sub-solvers such as the pressure Poisson equation (PPE) . For example, Guo et al. applied CNNs to infer velocity fields around vehicle geometries [4]. Tompson et al. proposed a hybrid pipeline that alternates the pressure projection step with a CNN-based surrogate to accelerate incompressible flow simulations [5]. Kim et al. employed generative models to reconstruct high-resolution flow fields from coarse CFD results [6].

More recently, surrogate modeling for Lagrangian particle simulations has progressed rapidly with the emergence of graph-based architectures. Graph neural networks (GNNs) can learn particle interactions from trajectory data by representing particles as nodes, neighbor relations as edges, and updating latent states through message passing [7]. Sanchez-Gonzalez et al. (2020) introduced the Graph Network–based Simulator (GNS), which learns fluid-particle dynamics from SPH trajectories [7]. Nevertheless, most prior learned simulators are largely data-driven, and their internal representations are not readily interpretable in terms of the governing equations, which can limit robustness and generalization. In addition, existing studies have predominantly targeted low-viscosity flows, whereas surrogate modeling for highly viscous Newtonian fluids—central to corium spreading—remains largely unexplored.

In this study, we propose a physics-informed GNS that explicitly incorporates discretized governing equations within the graph network to improve robustness and extrapolation capability. Training datasets are generated using a moving particle hydrodynamics (MPH) solver [8,9] for multiple scenarios, including dam-break, box drop, a static water column, and flows over complex geometries. We first present the baseline GNN architecture and then introduce a momentum-equation-constrained, physics-informed formulation on particle graphs. The proposed model is evaluated by comparing predicted run-out distance, pressure histories, and root mean squared error (RMSE) against the reference MPH simulations. Finally, we assess extrapolative performance by predicting cases beyond the training distribution using the trained model.

2. CFD model

The governing equation of the MPH method is consisting of momentum equation

$$\frac{\mathrm{D}\mathbf{u}}{\mathrm{Dt}} = -\frac{1}{\rho_0}\nabla p + \nu\nabla^2\mathbf{u} + \mathbf{g}, \tag{1}$$

and pressure equation for incompressible control

$$p = -\lambda\nabla\cdot\mathbf{u} + \kappa\frac{\Delta\rho}{\rho_0}, \tag{2}$$

where ρ_0, u, p , ν, g, λ, and κ, correspond to the density, pressure, kinematic viscosity, gravity acceleratio n, bulk viscosity, and bulk modulus, respectively.

The MPH method proposes the following interaction models between particles i and j for the discretizatio n of the gradient, divergence, and Laplacian operators, respectively.

$$\nabla\phi = \sum_j (\phi_j + \phi_i) r_{ij} \frac{w'_{ij}}{|r_{ij}|}, \tag{3}$$

$$\nabla \cdot \mathbf{\Pi} = \sum_j \left(\mathbf{\Pi}_j - \mathbf{\Pi}_i\right) \cdot r_{ij} \frac{w'_{ij}}{|r_{ij}|}, \tag{4}$$

$$\nabla^2 \phi = 2 \sum_j \left(\phi_j - \phi_i\right) \frac{w'_{ij}}{|r_{ij}|}, \tag{5}$$

where the terms ϕ and Π are an arbitrary scalar parameter and an arbitrary vector, respectively. The term w'_{ij} represents the derivative of the normalized weight function w_{ij}, which are defined as:

$$w_{ij} = \frac{W_{ij}}{\sum_j W_{ij}}, \tag{6}$$

$$W_{ij} = \begin{cases} (r_e - r_{ij})^2 \ ; \ (r_{ij} < r_e) \\ 0; (r_{ij} > r_e) \end{cases}, \tag{7}$$

$$w'_{ij} = -\frac{\partial w(r)}{\partial r}, \tag{8}$$

where W_{ij} , r_e, and r_{ij} are weight function, the effective radius and the distance between particles *i* and *j*, r espectively. The governing equations (Eqs. (1)-(2)) are discretized with the particle interaction models (Eq s.(3) - (5)) as

$$\frac{\mathrm{D}\mathbf{u}}{\mathrm{Dt}} = -\frac{1}{\rho_0} \sum_j \left(p_j + p_i\right) \frac{r_{ij}}{|r_{ij}|} w'_{ij} + 2\nu \sum_j \left(\mathbf{u}_j - \mathbf{u}_i\right) \frac{w'_{ij}}{|r_{ij}|} + \mathbf{g}, \tag{9}$$

$$p_i = -\lambda \sum_j \left(\mathbf{u}_j - \mathbf{u}_i\right) \cdot \frac{r_{ij}}{|r_{ij}|} w'_{ij} + \kappa(n_i - n_0). \tag{10}$$

However, the discretized momentum equation (Eq.(9)) does not conserve the angular momentum. In order to conserve the angular momentum, Eq.(9) is modified as

$$\frac{\mathrm{Du}}{\mathrm{Dt}} = -\frac{1}{\rho_0} \sum_j \left(p_j + p_i\right) \frac{r_{ij}}{|r_{ij}|} w'_{ij} + 2\nu(d+2) \sum_j \left(\frac{\mathbf{u}_j - \mathbf{u}_i}{|r_{ij}|} \cdot \frac{r_{ij}}{|r_{ij}|} \right) \frac{r_{ij}}{|r_{ij}|} w'_{ij} + \mathbf{g}. \tag{11}$$

Here, d is the dimension of the calculation geometry.

In this study, the 1st order explicit Euler time integration is applied to estimate the acceleration of the each particle. First, the pressure is estimated as

$$p_i^k = -\lambda \sum_j \left(\mathbf{u}_j^k - \mathbf{u}_i^k\right) \cdot \frac{r_{ij}}{|r_{ij}|} w'_{ij} + \kappa(n_i - n_0). \tag{12}$$

By substituting (12) into Eq.(11), the acceleration $\frac{\mathrm{Du}}{\mathrm{Dt}} \sim \mathbf{a}_{data}$ is obtained.

$$\mathbf{a}_{data} \sim \frac{\mathrm{D}\mathbf{u}_i^k}{\mathrm{Dt}} = -\frac{1}{\rho_0}\sum_j \left(p_j^k + p_i^k\right)\frac{r_{ij}}{|r_{ij}|}w_{ij}' + 2\nu(d+2)\sum_j \left(\frac{\mathbf{u}_j^k - \mathbf{u}_i^k}{|r_{ij}|}\cdot\frac{r_{ij}}{|r_{ij}|}\right)\frac{r_{ij}}{|r_{ij}|}w_{ij}' + \mathbf{g}. \quad (13)$$

3. Deep Learning

3.1. Fundamental Graph Neural Networks based simulation

Figure 1 provides an overview of the fundamental GNN framework. In the encoder, the particle system is mapped to a graph representation. Node features consist of scalar and vector quantities associated with each particle, such as velocity and the material property while edge features characterize the interaction between neighboring particles, including the relative displacement and/or distance between particles i and j. Thus, the graph representation explicitly stores both the physical state of each particle and the strength/geometry of its interactions with neighboring particles.

The node feature of particle i at time step k is defined as

$$\mathbf{h}_i^k \equiv \left[\tilde{\mathbf{u}}_i^k, \tilde{\mathbf{u}}_i^{k-1}, \tilde{\mathbf{u}}_i^{k-2}, \tilde{\mathbf{u}}_i^{k-3}, \tilde{\mathbf{u}}_i^{k-4}, \tilde{\Delta}_{wall}^k\right], \quad (14)$$

where $\tilde{\mathbf{u}}_i^k$ is the normalized velocity vector defined as

$$\tilde{\mathbf{u}}_i^k \equiv \frac{\mathbf{u}_i^k}{U} = \left[\frac{\mathrm{u}_i^k}{U}, \frac{\mathrm{v}_i^k}{U}, \frac{\mathrm{w}_i^k}{U}\right]. \quad (15)$$

Here, U is a representative velocity scale. Following prior work, the current and previous four-time steps are included to provide a short velocity history. To encode wall effects, we additionally use the normalized distances to the nearest wall,

$$\tilde{\Delta}_{wall}^k \equiv \left[clip\left(\frac{\Delta x_{i,wall}^k}{R}, 0,1\right), clip\left(\frac{\Delta y_{i,wall}^k}{R}, 0,1\right), clip\left(\frac{\Delta z_{i,wall}^k}{R}, 0,1\right)\right], \quad (16)$$

$\Delta x_{i,wall}^k$, $\Delta y_{i,wall}^k$, and $\Delta z_{i,wall}^k$ denote the x-directional, y-directional and z-directional distances toward the nearest wall, which are normalized with the connectivity radius R and then clipped within the range [0,1].

The edge feature between nodes i and j at time step k is defined as

$$\boldsymbol{e}_{ij}^k \equiv \left[\frac{x_j^k - x_i^k}{R}, \frac{y_j^k - y_i^k}{R}, \frac{z_j^k - z_i^k}{R}, \frac{r_{ij}}{R}\right], \quad (17)$$

where x_i^k, y_i^k, and z_i^k are the coordinate of the node. r_{ij} is the distance between the nodes i and j defined as

$$r_{ij} = \sqrt{(x_j^k - x_i^k)^2 + (y_j^k - y_i^k)^2 + (z_j^k - z_i^k)^2}. \quad (18)$$

Following the encoding, which is the graph construction, the GNN updates the dynamical states through message passing, in which information is exchanged along edges and aggregated at each node to represent neighbor interactions. Specifically, for each edge $\boldsymbol{e}_{ij}$, an edge message is computed from the sender and receiver node features and the edge features, and the incoming messages to node i are aggregated to obtain a neighborhood representation. The node state is then updated using this aggregated message, yielding an updated latent feature for each.

The message passing consists of three stages. An edge message is computed from the receiver and sender node features and the edge attributes:

$$\mathbf{m}_{i,j}^k = \phi_e\left(\mathbf{h}_i^k, \mathbf{h}_j^k, \mathbf{e}_{ij}^k\right). \quad (19)$$

Incoming messages are aggregated to form a neighborhood representation:

$$\bar{\mathbf{m}}_i^k = \sum_{j \in N(i)} \mathbf{m}_{i,j}^k. \quad (20)$$

The node state is then updated with a residual form:

$$\mathbf{h}_i^{k+1} = \mathbf{h}_i^k + \phi_h\left(\mathbf{h}_i^k, \sum_{j\in N(i)} \phi_e(\mathbf{h}_i^k, \mathbf{h}_j^k, \mathbf{e}_{ij}^k)\right), \tag{21}$$

The edge message function ϕ_e learns how information is exchanged between neighboring particles. It takes as input the receiver-node features $\mathbf{h}_i^k$, the sender-node features $\mathbf{h}_j^k$, and the edge attributes $\mathbf{e}_{ij}^k$, and outputs a latent message $\mathbf{m}_{i,j}^k$ that encodes the influence of particle j on particle i. In practice, ϕ_e is commonly implemented as a shared multilayer perceptron (MLP) applied to every edge, which ensures permutation equivariance with respect to node ordering and enforces a consistent interaction rule across all particle pairs.

The aggregation step in Eq. (20) then combines the incoming messages to node (i) into a single neighborhood representation $\bar{\mathbf{m}}_i^k$. Summation is widely used because it is permutation-invariant to the ordering of neighbors and naturally reflects the additive structure of many particle interactions. Depending on the targeted behavior, other aggregators such as mean or max pooling may also be employed.

Finally, the node update function ϕ_h integrates the aggregated neighborhood information with the previous node state $\mathbf{h}_i^k$ to produce the updated node feature $\mathbf{h}_i^{k+1}$ in Eq. (21). Similar to ϕ_e, ϕ_h is typically parameterized as a shared MLP (often augmented with residual connections and normalization) and applied identically to all nodes. This message-passing procedure is repeated for M steps to progressively refine the latent particle states.

The updated node features $\mathbf{h}_i^{k+1}$ are then passed to a decoder that maps the latent representation back to physical quantities of interest, such as the acceleration $\mathbf{a}$. These predicted quantities are subsequently used to advance the particle system in time through symplectic Euler scheme as

$$\mathbf{u}_i^{k+1} = \mathbf{u}_i^k + \mathbf{a}_i^k * \Delta t, \tag{22}$$

and

$$\mathbf{x}_i^{k+1} = \mathbf{x}_i^k + \mathbf{u}_i^{k+1} * \Delta t. \tag{23}$$

All the process is conducted to minimize the following the loss function as

$$\mathcal{L}^{data} \equiv \frac{1}{N}\sum_i^N \|\mathbf{r}\|^2 = \frac{1}{N}\sum_i^N \left\|\tilde{\mathbf{a}}_{i,predict}^k - \tilde{\mathbf{a}}_{i,data}^k\right\|^2, \tag{24}$$

where N, $\tilde{\mathbf{a}}_{i,data}^k$ and $\tilde{\mathbf{a}}_{i,predict}^k$ denote all the nodes, the ground truth data on the acceleration, and the predicted acceleration data, respectively.

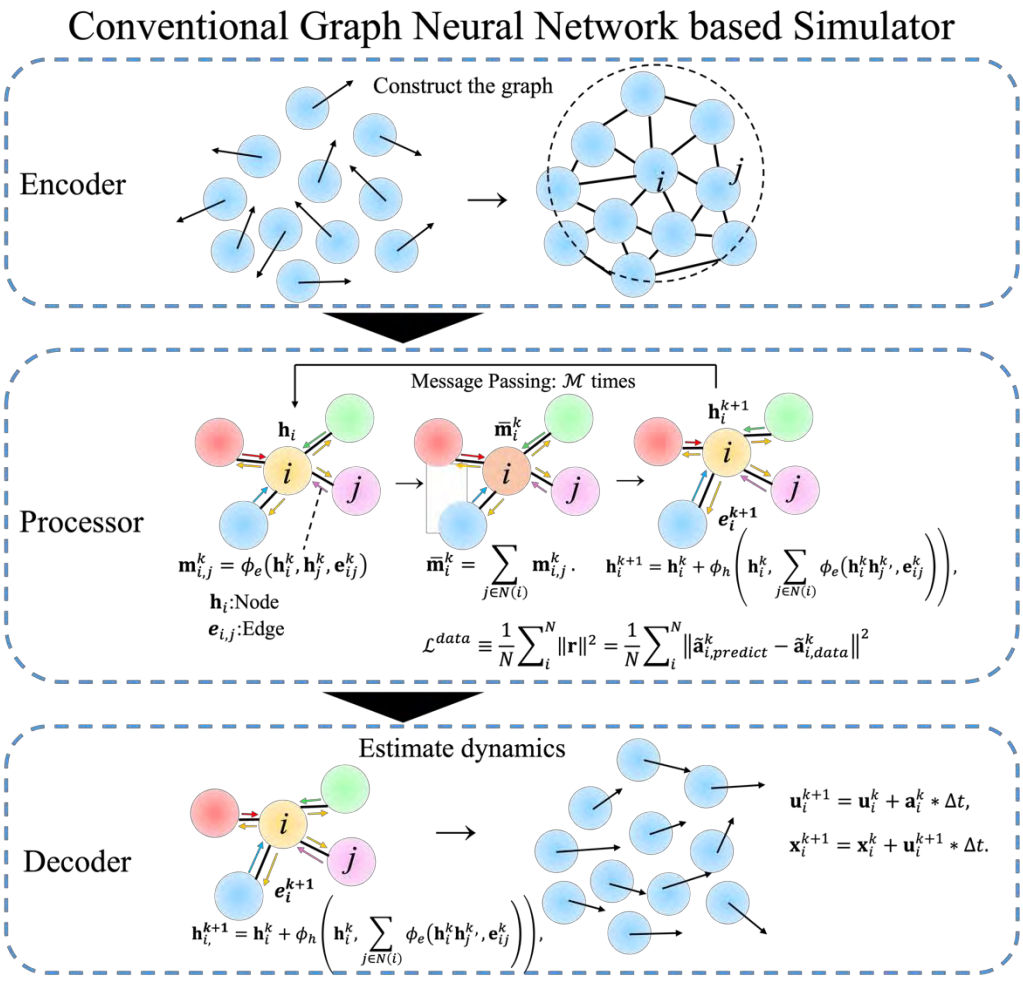

Figure 1 Schematic illustration of the fundamental Graph Neural Networks

3.2. Discretized Momentum-Equation-Constrained Physics-Informed Neural Networks

Since Eq.(1) does not include the pressure as the feature and viscosity which are essential to solve the Navier-Stokes equations, following node features are applied

$$\mathbf{h}_i^k \equiv \left[\tilde{\mathbf{u}}_i^k, \tilde{\mathbf{u}}_i^{k-1}, \tilde{\mathbf{u}}_i^{k-2}, \tilde{\mathbf{u}}_i^{k-3}, \tilde{\mathbf{u}}_i^{k-4}, \tilde{p}_i^k, \tilde{p}_i^{k-1}, \tilde{p}_i^{k-2}, \tilde{p}_i^{k-3}, \tilde{p}_i^{k-4}, \tilde{\Delta}_{wall}^k, \nu_i\right], \tag{25}$$

where $\tilde{p}_i^k$ is the normalized the pressure defined as

$$\tilde{p}_i^k \equiv \frac{p_i^k}{P}, \tag{26}$$

with p_i^k denoting the pressure at node i and time step k, and P a representative pressure scale. The pressure head is trained by minimizing the mean-squared error between the predicted and reference increments:

$$\mathcal{L}^{pressure} \equiv \frac{1}{N}\sum_i^N \|\mathbf{r}\|^2 = \frac{1}{N}\sum_i^N \left\|\Delta\tilde{p}_{i,predict}^{k+1} - \Delta\tilde{p}_{i,data}^{k+1}\right\|^2. \tag{27}$$

In the meantime, we inspire the particle-based discretization models. First, We adopt a smooth radial kernel with connectivity radius R and Eq.(28):

$$n_{ij}^k = exp^{-\left(\frac{(r_{ij}^k)^2}{R^2}\right)}, \tag{28}$$

the normalized graph weight

$$w_{ij}^k = \frac{n_{ij}^k}{\sum_{j\in N(i)} n_{ij}^k}, \tag{29}$$

From the normalized the graph weight, we can compute the graph-based node interaction models. First, we approximate the graph-based gradient operator as:

$$\nabla\phi_i^k = \sum_{j\in N(i)} \left(\phi_j^k - \phi_i^k\right) \frac{\mathbf{r}_{ij}}{(r_{ij})^2} w_{ij}^k . \tag{30}$$

With a similar way, the Laplacian operator is approximated as:

$$\nabla^2\phi_i^k = 2\sum_{j\in N(i)} \left(\phi_j^k - \phi_i^k\right) \frac{w_{ij}}{(r_{ij})^2}. \tag{31}$$

We can define a physics-based estimate of the nodal acceleration as the result of neighbor interactions. For incompressible flow, we write

$$\tilde{\mathbf{a}}_{i,physic}^k = \mathbf{g} + \nu\nabla^2\mathbf{u}_i^k - \frac{1}{\rho_0}\nabla p_i^k. \tag{32}$$

By substituting Eqs. (30) and (31) into Eq.(32),

$$\tilde{\mathbf{a}}_{i,physic}^k = \mathbf{g} + 2\nu\sum_{j\in N(i)} \left(\tilde{\mathbf{u}}_j^k - \tilde{\mathbf{u}}_i^k\right) \frac{w_{ij}}{(r_{ij})^2} - \frac{1}{\rho}\sum_{j\in N(i)} \left(p_j^k - p_i^k\right) \frac{\mathbf{r}_{ij}}{(r_{ij})^2} w_{ij}. \tag{33}$$

Here, $\tilde{\mathbf{u}}^k$ and $\tilde{p}^k$ denote the predicted velocity and pressure used to compute the physics term (i.e., before applying the physics loss). Similar to message passing, the GNN produces predicted states (and thus predicted acceleration) through M processor layers. We impose a physics-consistency loss by minimizing the discrepancy between the model-predicted acceleration and the physics-based acceleration estimate:

$$\mathcal{L}^{Physics} = \frac{1}{N}\sum_i^N \|\mathbf{r}\|^2 = \frac{1}{N}\sum_i^N \left\|\tilde{\mathbf{a}}_{i,predict}^k - \tilde{\mathbf{a}}_{i,physics}^k\right\|^2 . \tag{34}$$

4. Prediction of CFD results with PI-GNN

Figure 2 and Table I. summarize the simulation cases considered in this study: (i) a fundamental dam-break configuration and (ii) a case with a more complex geometry. Training data were generated using our Moving Particle Hydrodynamics (MPH) solver, and the developed GNS was trained on these MPH datasets. Each simulation involved approximately 8,600 particles, with a time step of $\Delta t = 1.0 \times 10^{-5}$ s. Table II is the PI-GNN training conditions.

Figure 3 presents representative snapshots of the dam-break simulation (MPH) and the corresponding PI-GNN predictions. The dynamic viscosity was set to 1.0×10^3 Pa·s and 1.0×10^2 Pa·s, and the color contour indicates the velocity magnitude. For $\mu = 1.0 \times 10^3$ Pa·s, the highly viscous fluid exhibits only limited spreading, as evidenced by both the snapshots and the low velocity levels; the square-shaped fluid body shows little deformation even after $t = 0.6$ s. In contrast, for $\mu = 1.0 \times 10^2$ Pa·s, the spreading behavior is clearly more pronounced than in the $\mu = 1.0 \times 10^3$ Pa·s case. The PI-GNN reproduces the same trend across both viscosities and closely matches the MPH results overall. The RMSE of the acceleration is 1.27×10^{-5} for $\mu = 1.0 \times 10^3$ Pa·s and 6.31×10^{-5} for $\mu = 1.0 \times 10^2$ Pa·s, indicating that the PI-GNN predicts the dam-break dynamics with good accuracy.

Figure 4 shows representative snapshots of the box-drop simulation with a complex geometry and the corresponding PI-GNN predictions. Overall, the PI-GNN captures the main features of the MPH solution. However, for $\mu = 1.0 \times 10^3$ Pa·s, an evident discrepancy appears at $t = 0.6$ s: the MPH simulation shows a relatively low velocity for the small falling object, whereas the PI-GNN predicts a higher velocity. The acceleration RMSE is 6.32×10^{-6} for $\mu = 1.0 \times 10^3$ Pa·s and 1.78×10^{-6} for $\mu = 1.0 \times 10^2$ Pa·s, suggesting that the PI-GNN achieves high predictive accuracy overall despite this localized mismatch.

Figure 5 shows the time histories of the mean displacement, mean velocity, and mean pressure of the dam-breaking fluid body. The PI-GNN reproduces the MPH simulation results well for all three quantities. In th e velocity profile, a small oscillatory behavior appears around $t = 0.6$ s in the PI-GNN prediction, which i s not observed in the simulation.

Figure 6 shows the mean displacement, mean velocity, and mean pressure of the large square box in the co mplicated-geometry case. While the PI-GNN predictions of displacement and velocity remain in good agre ement with the MPH results, the pressure prediction exhibits a noticeable discrepancy compared with the d am-break case.

Table III compares the computational cost of the conventional MPH simulation and the proposed PI-GNN inference, both evaluated on an NVIDIA A100 GPU. A substantial speedup is achieved by the PI-GNN acr oss all tested cases. In particular, the high-viscosity simulations ($\mu = 1.0 \times 10^3$ Pa·s) require very small-ti me steps, leading to long runtimes of 2321.3 s and 1436.8 s on the GPU. In contrast, the PI-GNN performs the full prediction in only 6.54 s and 3.97 s for the corresponding cases, respectively, which corresponds t o an acceleration of nearly 350×. These results highlight the strong potential of the PI-GNN framework for enabling prompt surrogate simulations of highly viscous free-surface flows, and ultimately for acceleratin g practical corium spreading analyses.

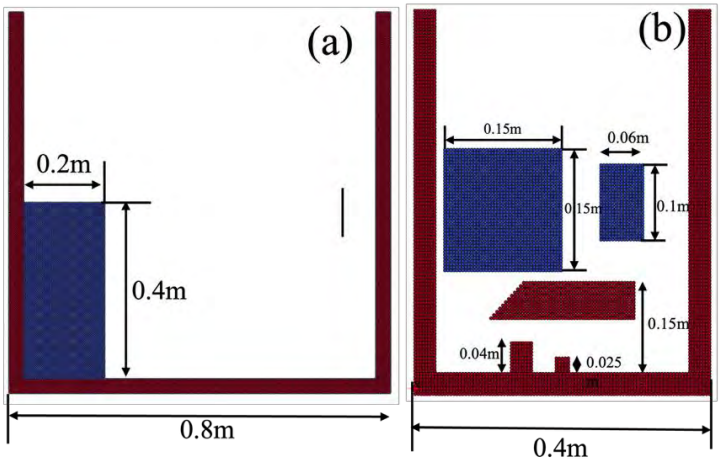

Figure 2 Simulation and PI-GNN prediction geometry

Table I. Simulation conditions

	(a) Dam-break	(b) Box Drop

Table III. Calculation time

	CPU	GPU	PI-GNN	Speed-up
Dam-break (1×10^3 Pa.s)	14948.8s	2321.3s	6.543s	354.8 times
Dam-break (1×10^2 Pa.s)	2772.5	469.2s	6.631s	70.8 times
complex geometry (1×10^3 Pa.s)	10149.5s	1436.8s	3.97s	361.9 times
complex geometry (1×10^2 Pa.s)	1078.7s	295.2s	4.046s	73.0 times

5. CONCLUSIONS

This study proposed a physics-informed graph neural network (PI-GNN) surrogate for Lagrangian particle simulations and validated its performance on (i) a fundamental dam-break problem and (ii) a box-drop problem with complicated geometry. By embedding physics-consistent constraints into the message-passing framework, the PI-GNN accurately reproduced the main transient dynamics predicted by the Moving Particle Hydrodynamics (MPH) solver over a wide viscosity range, including highly viscous conditions representative of corium spreading.

For the dam-break case, the PI-GNN captured the viscosity-dependent spreading behavior for $\mu = 1.0 \times 10^3$ Pa·s and $\mu = 1.0 \times 10^2$ Pa·s, showing close agreement with MPH snapshots and low acceleration-based RMSE. In the complicated-geometry case, the PI-GNN similarly reproduced the dominant flow and object motion, although a localized discrepancy was observed around $t = 0.6$ s in the high-viscosity condition, where the velocity of a small falling object was overestimated. Time-history comparisons further indicated that mean displacement and velocity were generally well predicted, while pressure remained more challenging—especially in the complicated-geometry scenario—suggesting that improving pressure robustness is a key remaining issue.

A major outcome is the significant computational acceleration enabled by the PI-GNN. The runtime comparison on an NVIDIA A100 GPU demonstrated that cases requiring extremely small time steps in MPH (e.g., $\mu = 1.0 \times 10^3$ Pa·s) can be predicted in a few seconds by the PI-GNN, achieving nearly $O(10^2$–$10^3)$ speedups (approximately 350× in the present tests). These results demonstrate the strong potential of PI-GNNs to provide prompt, high-fidelity surrogate predictions for highly viscous free-surface flows, and to support practical, large-scale corium spreading assessments.

Future work will focus on improving pressure prediction and rollout stability under complex interactions (e.g., enhanced loss balancing, better boundary/geometry encoding, and multi-step consistency constraints), and extending the framework to more realistic severe-accident conditions, including broader geometries, non-Newtonian behavior, multiphase effects, and phase change.

ERMSAR 2026

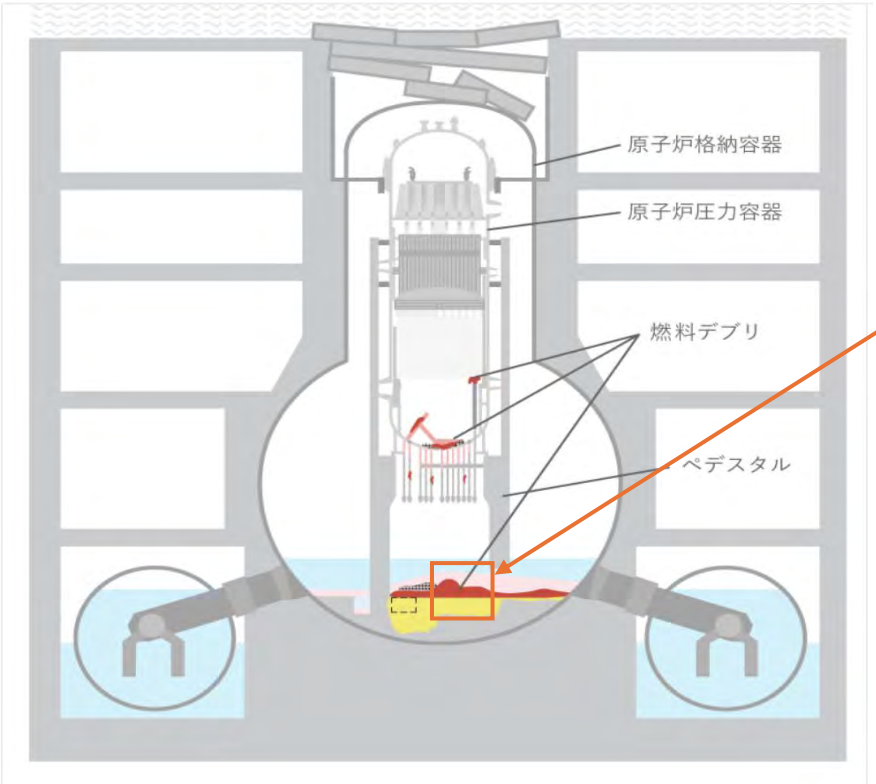
An advanced graph neural network application to highly viscous newtonian fluid flow towards the rapid corium spreading simulation

THE UNIVERSITY OF TOKYO

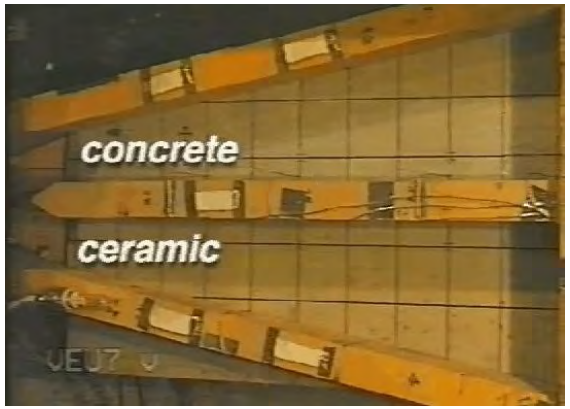
***Hiroki Asatsuma**, Ryo Yokoyama

Background

Understanding the behavior of highly viscous fluids in severe accidents is critically important.



Fukushima Daiichi Unit 1[1]



Numerical Simulation is useful

- The problem involves phase change
- Experimental approaches are difficult and limited in scale
- Highly viscous flows involve free surfaces and large deformation

→ **Particle methods** are suitable for this problem

[1] https://www.tepco.co.jp/decommission/progress/retrieval/unit1/index-j.html

Challenges in High-Viscosity CFD

Explicit Euler:

- Constraint imposed by the viscous diffusion condition
- Extremely small Δt for high viscosity

$$\Delta t < \frac{x^2}{8\nu}$$

Implicit Euler:

- Requires solving large sparse matrices
- The iteration count to convergence depends on the problem size.

$$\rho_0 \frac{\mathbf{u}^{k+1}}{\Delta t} = -2\mu(dim+2)\sum_j \left(\frac{\mathbf{u}_j^{k+1} - \mathbf{u}_i^{k+1}}{|\boldsymbol{r}_{ij}|} \cdot \mathbf{e}_{ij}\right)\mathbf{e}_{ij}w'_{ij} -$$

$$\sum_j \left(\lambda \sum_j (\mathbf{u}_{ji}^{k+1} - \mathbf{u}_{ij}^{k+1}) \cdot \mathbf{e}_{ij}w'_{ij} + \lambda \sum_i (\mathbf{u}_{ij}^{k+1} - \mathbf{u}_{ji}^{k+1}) \cdot \mathbf{e}_{ij}w'_{ij}\right)\mathbf{e}_{ij}w'_{ij}$$

$$= \rho_0 \frac{\mathbf{u}^k}{\Delta t} - \kappa \sum_j \left((n_j - n_0) + (n_i - n_0)\right)\mathbf{e}_{ij}w'_{ij} + \rho_0 \mathbf{g}$$

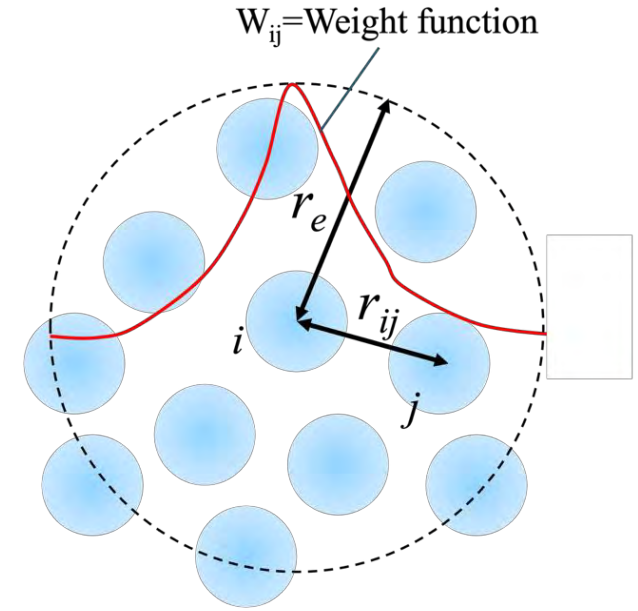
High computational cost is unavoidable, regardless of the method.

→ Acceleration methods are required.

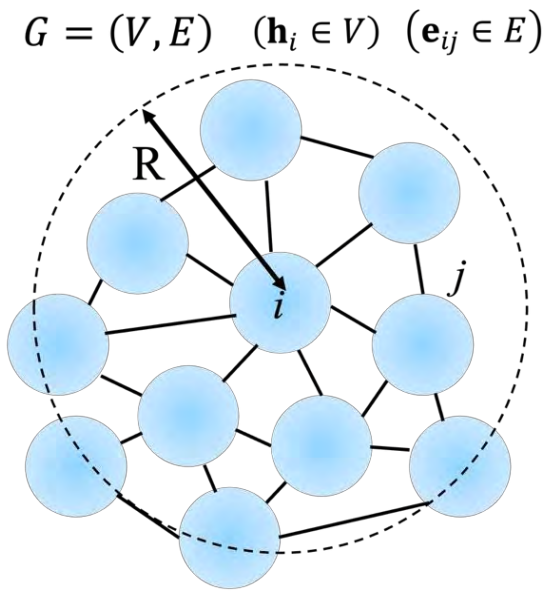
AI-based Surrogate model

Graph Neural Networks (GNNs)

A neural network that constructs a graph structure based on relationships between nodes and edges and learns those relationships.



Concept of Particle Simulation (e.g. MPS)

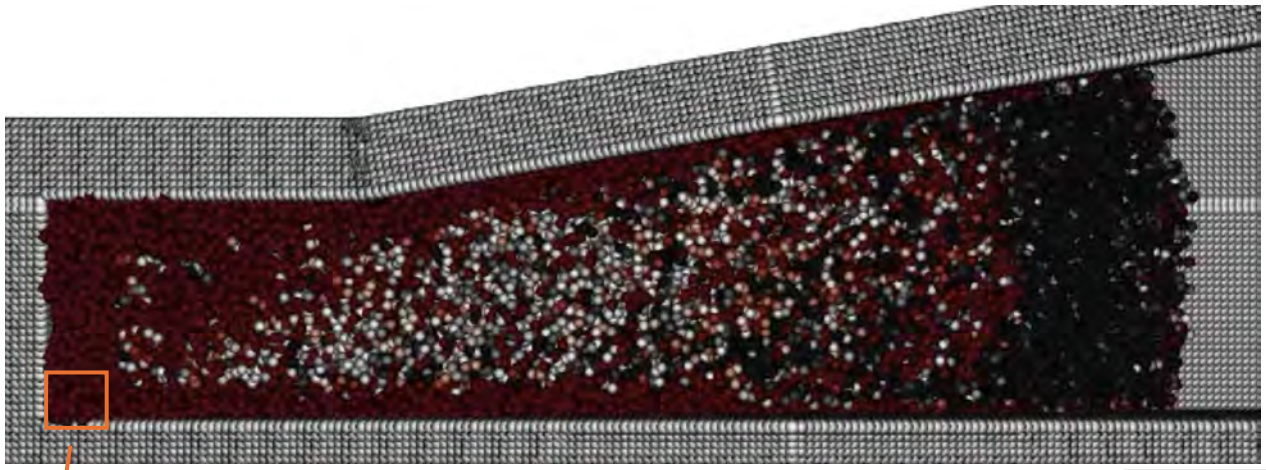


Concept of GNN

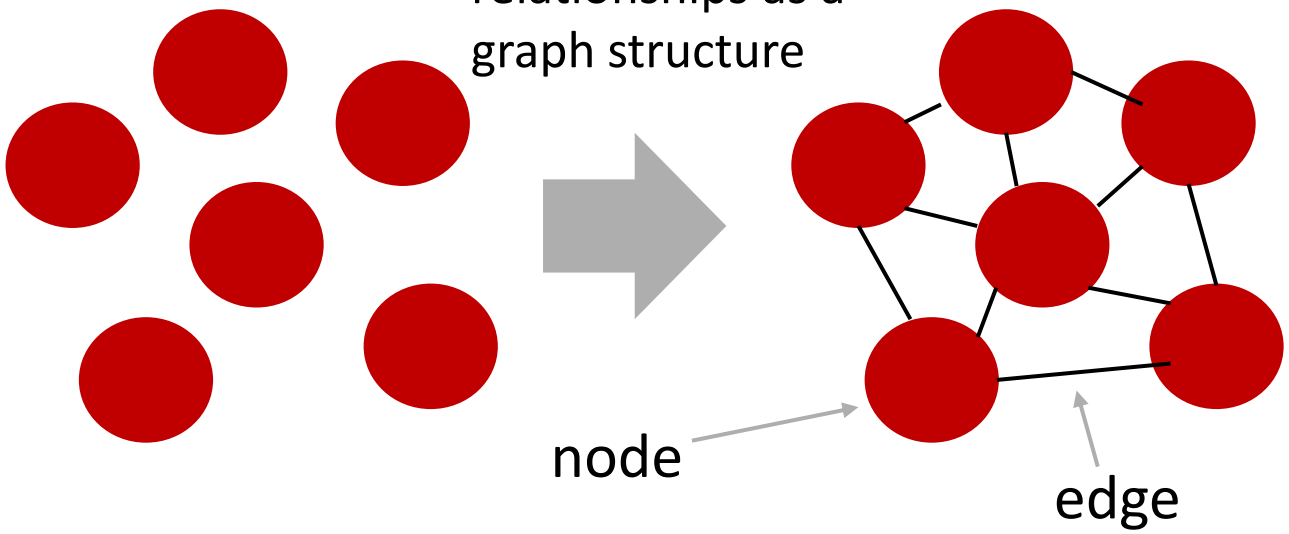
GNNs can effectively handle irregular structures such as unstructured meshes.

suitable surrogate models for particle methods

Concept of GNS (Graph Network-based Simulators)



Representing particle relationships as a graph structure



Deep learning of graph structures and temporal relationships

↓

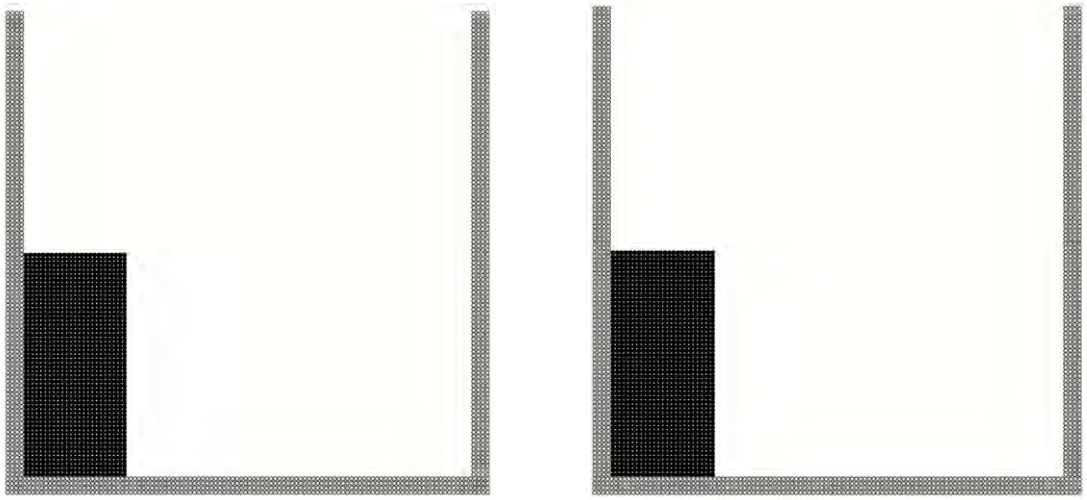
No need to solve matrix equations or discretized equations

↓

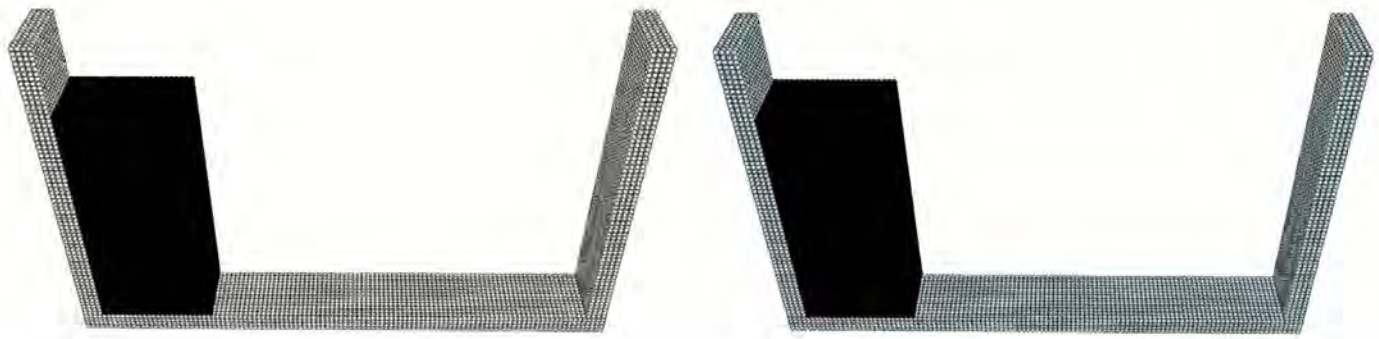
Significantly reduces computational cost

Performance of conventional GNS

Viscosity= 1.0×10^{1} (Pa.s)



CFD GNS(1200 epochs)



CFD GNS(1000 epochs)

	CFD (CPU)	GNS	Speed-up
2D-Dam-break	99.17s	5.87s	16.9 times
3D-Dam-break	686.90s	38.03s	18.1 times

Conventional GNS achieved more than 15× speed-up in both cases.

Limitations of conventional GNS

- **Only position, velocity, and acceleration can be predicted**

  pressure estimation is also important in fluid simulations.
- **Fully data-driven and limited in scalability**

  Prediction accuracy drops sharply even with slight changes

  in geometry or a small increase in the number of particles.
- **Low interpretability**

  It is difficult to understand how the model learns internally.
- **Long training time**

  Achieving highly accurate results requires many training epochs.
  (More than 1000 epochs)

Objective of this study

Develop a graph neural network with embedded discretized equations to enable rapid severe-accident simulation and improve extrapolation performance

Key Evaluation Points

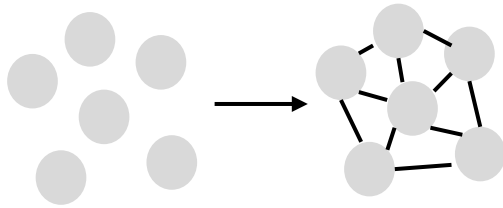
- the model's extrapolation capability under untrained conditions
- Number of training epoch compared with conventional GNS
- How much the computational time can be reduced compared with CFD

Conventional GNS (Graph Network-based Simulators)

- **Encoder**

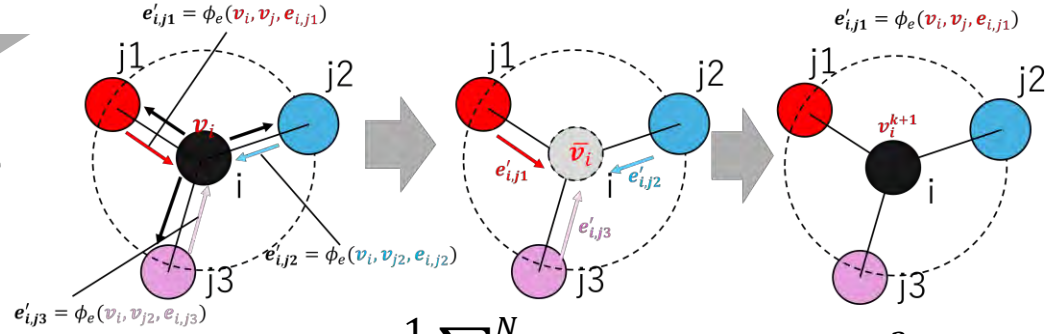
  Converts particle data into a graph structure that can be processed by the GNN

  - Nodes: velocity history, distance to boundaries $\mathbf{h}_i^k \equiv \left[\tilde{\mathbf{u}}_i^k, \tilde{\mathbf{u}}_i^{k-1}, \tilde{\mathbf{u}}_i^{k-2}, \tilde{\mathbf{u}}_i^{k-3}, \tilde{\mathbf{u}}_i^{k-4}, \tilde{\Delta}_{wall}^k\right]$
  - Edges: relative distance between particles $\boldsymbol{e}_{ij}^k \equiv \left[\frac{x_j^k - x_i^k}{R}, \frac{y_j^k - y_i^k}{R}, \frac{z_j^k - z_i^k}{R}, \frac{r_{ij}}{R}\right]$



- **Processor**

  Node features are updated through message passing to reflect inter-particle interactions.



$$\mathcal{L}^{data} = \frac{1}{N}\sum_i^N \left\|\tilde{\mathbf{a}}_{i,predict}^k - \tilde{\mathbf{a}}_{i,data}^k\right\|^2$$

- **Decoder&Rollout**

  Converts learned features into physical quantities and updates velocity and position from the predicted acceleration using Euler integration

$$u_i^{t+1} = u_i^t + y_i^t \Delta t$$

$$x_i^{t+1} = x_i^t + u_i^{t+1} \Delta t$$

Improvement of conventional GNS

(1) Modifications to Feature amount

$$\mathbf{h}_i^k \equiv \left[\tilde{\mathbf{u}}_i^k, \tilde{\mathbf{u}}_i^{k-1}, \tilde{\mathbf{u}}_i^{k-2}, \tilde{\mathbf{u}}_i^{k-3}, \tilde{\mathbf{u}}_i^{k-4}, \tilde{\Delta}_{wall}^k\right]$$

$$\mathbf{h}_i^k \equiv \left[\tilde{\mathbf{u}}_i^k, \ldots, \tilde{\mathbf{u}}_i^{k-4}, \tilde{p}_i^k, \ldots, \tilde{p}_i^{k-4}, \tilde{\Delta}_{wall}^k, \nu_i\right]$$

- Add pressure information from five time steps to the features.
- Include kinematic viscosity to enhance the representation of viscosity–flow behavior.

(2) Training the GNS to learn pressure

$$\Delta\tilde{p}_i^{k+1} = \tilde{p}_i^{k+1} - \tilde{p}_i^k$$

$$\mathcal{L}^{pressure} \equiv \frac{1}{N}\sum_i^N \|\mathbf{r}\|^2 = \frac{1}{N}\sum_i^N \left\|\Delta\tilde{p}_{i,predict}^{k+1} - \Delta\tilde{p}_{i,data}^{k+1}\right\|^2$$

Train the GNS to learn the pressure increment.

- Learning absolute pressure would restrict the range of pressures that can be handled.
- Enable the model to handle larger pressures so it remains applicable when the scale increases.

Discretized Momentum-Equation-Constrained Physics-Informed Graph Neural Networks

Hypothesis: Discretization is possible within the graph connectivity radius, and the acceleration of node can be calculated based on the discretized Navier–Stokes equation.

$$\tilde{\mathbf{a}}_{i,physic}^{k} = \mathbf{g} + \nu\nabla^2\mathbf{u}_i^k - \frac{1}{\rho_0}\nabla p_i^k$$

$$= \mathbf{g} + 2\nu\sum_{j\in N(i)}\left(\tilde{\mathbf{u}}_j^k - \tilde{\mathbf{u}}_i^k\right)\frac{w_{ij}}{(r_{ij})^2} - \frac{1}{\rho_0}\sum_{j\in N(i)}\left(p_j^k - p_i^k\right)\frac{\mathbf{r}_{ij}}{(r_{ij})^2}w_{ij}$$

estimates the "theoretical" acceleration from the momentum equation, which is spatially discretized in the graph.

Based on the discretization model used in SPH

$$\nabla^2\mathbf{u}_i^k = \sum_{j\in N(i)}\left(\tilde{\mathbf{u}}_j^k - \tilde{\mathbf{u}}_i^k\right)\frac{w_{ij}}{(r_{ij})^2}$$

$$\nabla p_i^k = \sum_{j\in N(i)}\left(p_j^k - p_i^k\right)\frac{\mathbf{r}_{ij}}{(r_{ij})^2}w_{ij}^k$$

$$\mathcal{L}^{Physics} = \frac{1}{N}\sum_i^N \|\mathbf{r}\|^2 = \frac{1}{N}\sum_i^N \left\|\tilde{\mathbf{a}}_{i,predict}^k - \tilde{\mathbf{a}}_{i,physics}^k\right\|^2$$

We define a loss function based on the acceleration obtained from the discretized equation and the acceleration estimated by GNS, and correct the GNS-predicted acceleration to be physically consistent.

Discretized Momentum-Equation-Constrained Physics-Informed Graph Neural Networks

Loss function for the entire processor

$$\mathcal{L}^{total} = \mathcal{L}^{data} + w_{phys}\mathcal{L}^{physics} + w_p\mathcal{L}^{pressure}$$

w_p and w_{phys} are weighting coefficients.

$$\mathcal{L}^{data} = \frac{1}{N}\sum_i^N \left\|\tilde{\mathbf{a}}^k_{i,predict} - \tilde{\mathbf{a}}^k_{i,data}\right\|^2$$

In conventional GNS, this was the only loss function used for training.

$$\mathcal{L}^{Physics} = \frac{1}{N}\sum_i^N \left\|\tilde{\mathbf{a}}^k_{i,predict} - \tilde{\mathbf{a}}^k_{i,physics}\right\|^2$$

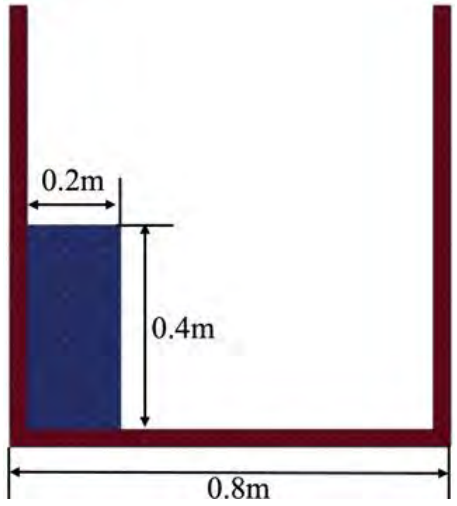
$$\mathcal{L}^{pressure} = \frac{1}{N}\sum_i^N \left\|\Delta\tilde{p}^{k+1}_{i,predict} - \Delta\tilde{p}^{k+1}_{i,data}\right\|^2$$

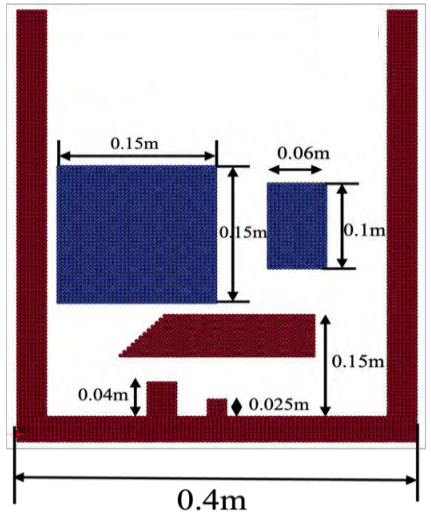
The physics-based correction is not reliable in the early stage of training.

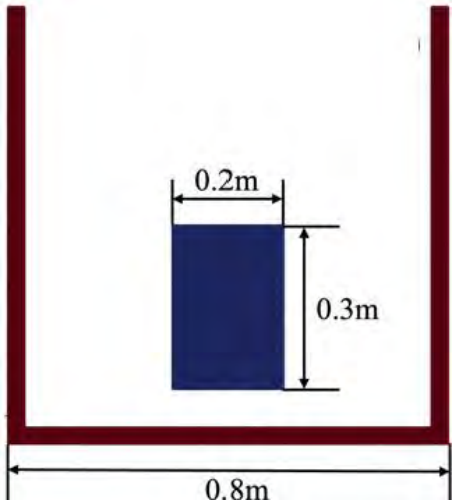
The loss weight is automatically adjusted through backpropagation: the data term is emphasized in the early stage, while the physics-informed term is emphasized in the later stage.

Making datasets

Make three datasets with different initial conditions







Extract data every 1.0×10^{-3}s from 2.0 s simulations
→ 2000 data samples

Calculation Conditions common to All Cases

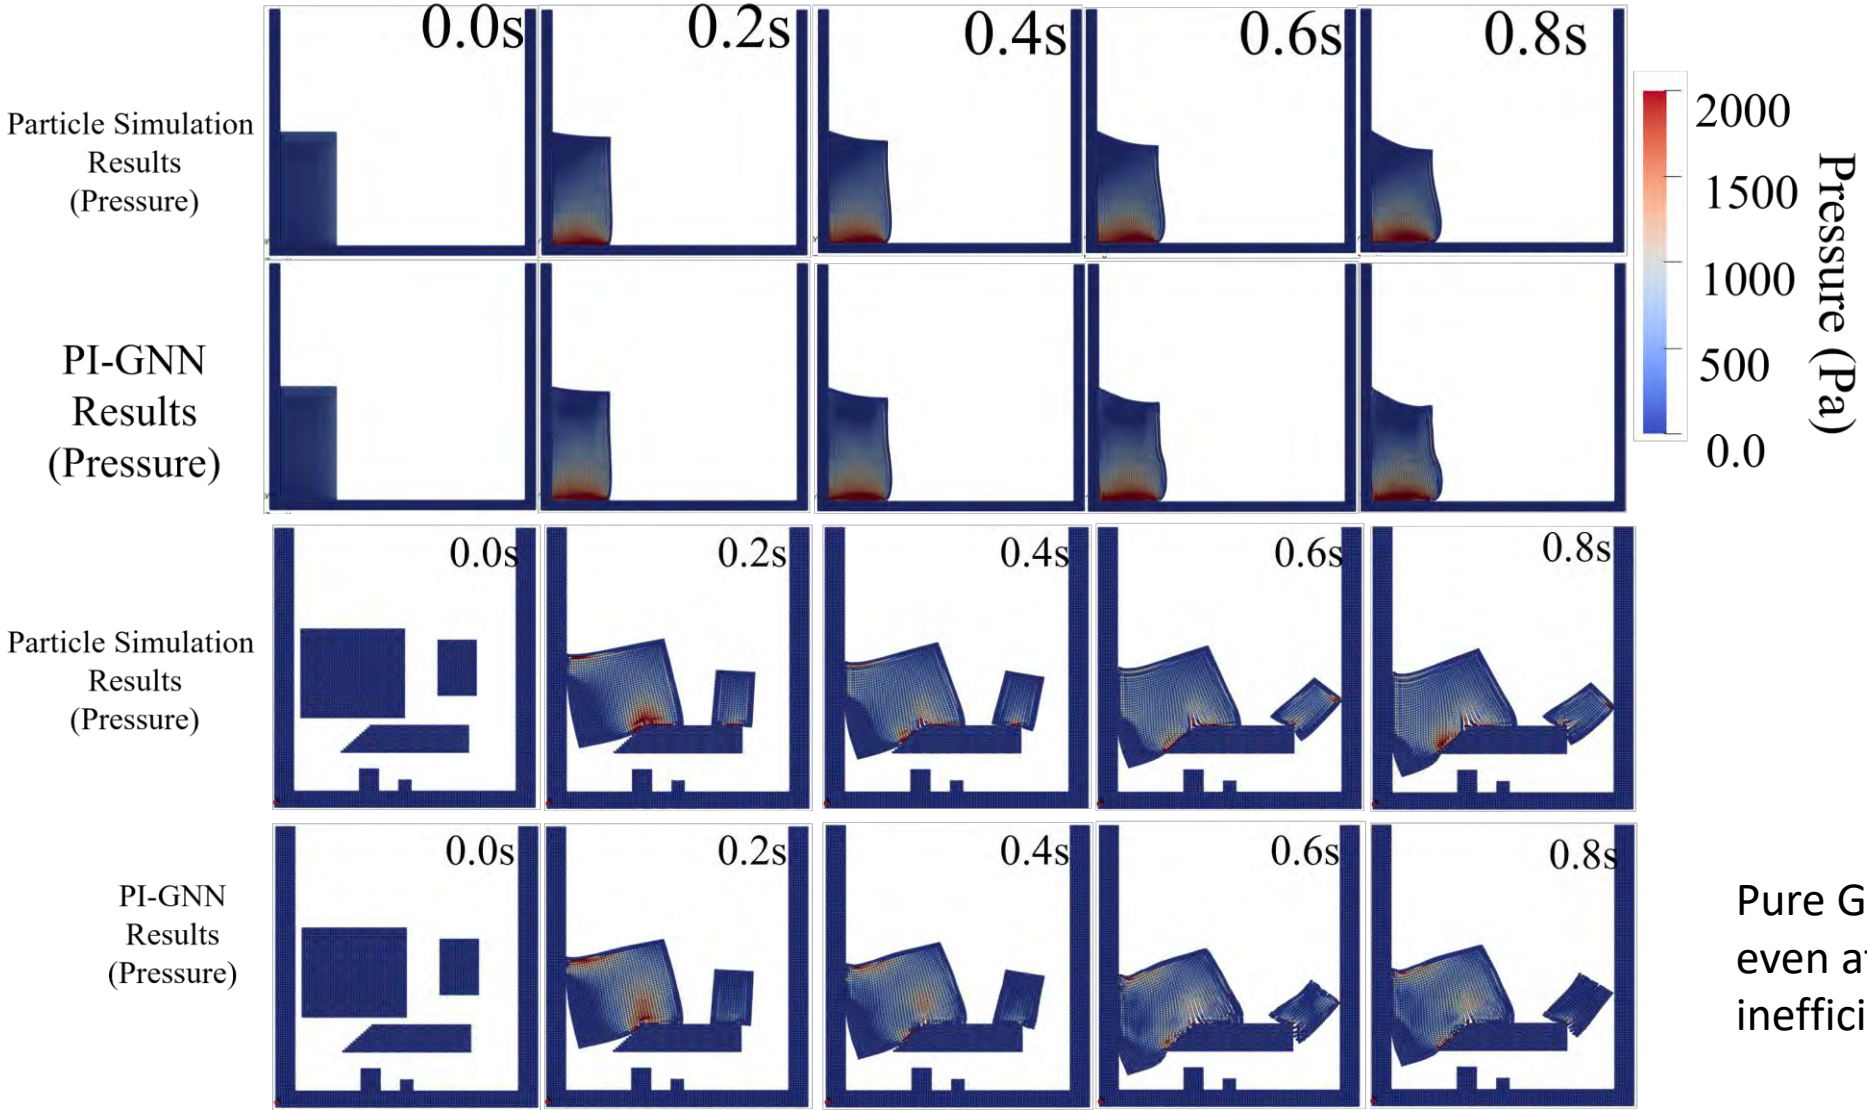
	Value
Particle Size	0.004m
Effective Radius	0.010m
Bulk Modulus	1.0×10^{6} (Pa)
Viscosity	1.0×10^{3}(Pa.s), 1.0×10^{2}(Pa.s), 1.0×10^{1}(Pa.s), 1.0×10^{0} (Pa.s)
Δt	1.0×10^{-5} (s) for 1.0×10^{3} (Pa.s), 1.0×10^{-4} (s) for 1.0×10^{2} (Pa.s)

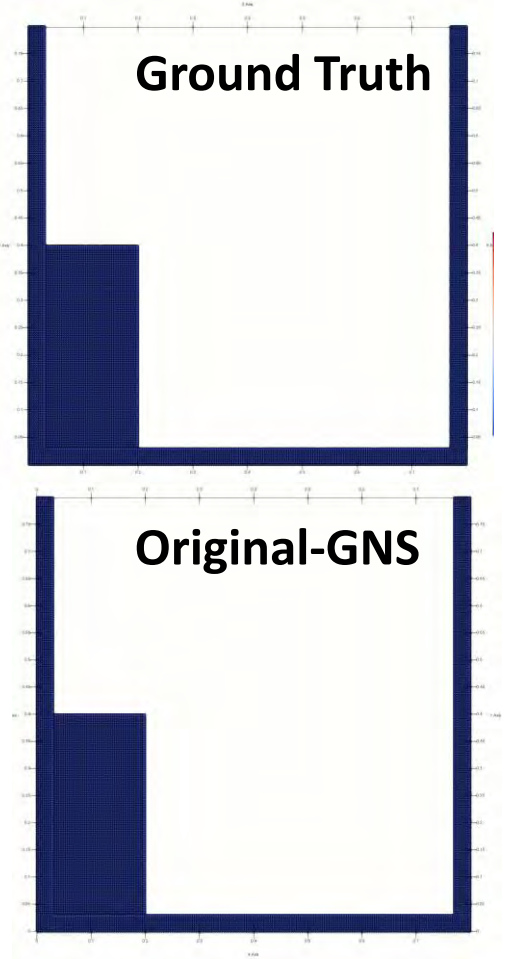
PI-GNS Hyperparameters

	Value
Batch size	2
Noise	6.7×10^{-4}
MLP layers	128
Graph Radius	0.012m

Results(Representative Example)

Pressure Field Prediction $\mu = 1.0 \times 10^3$ Pa · s, Epoch 600

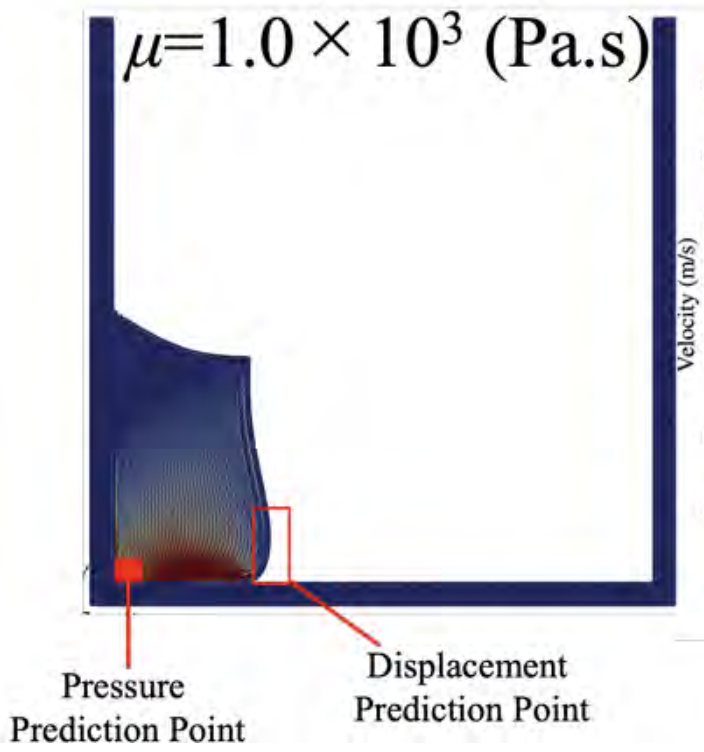


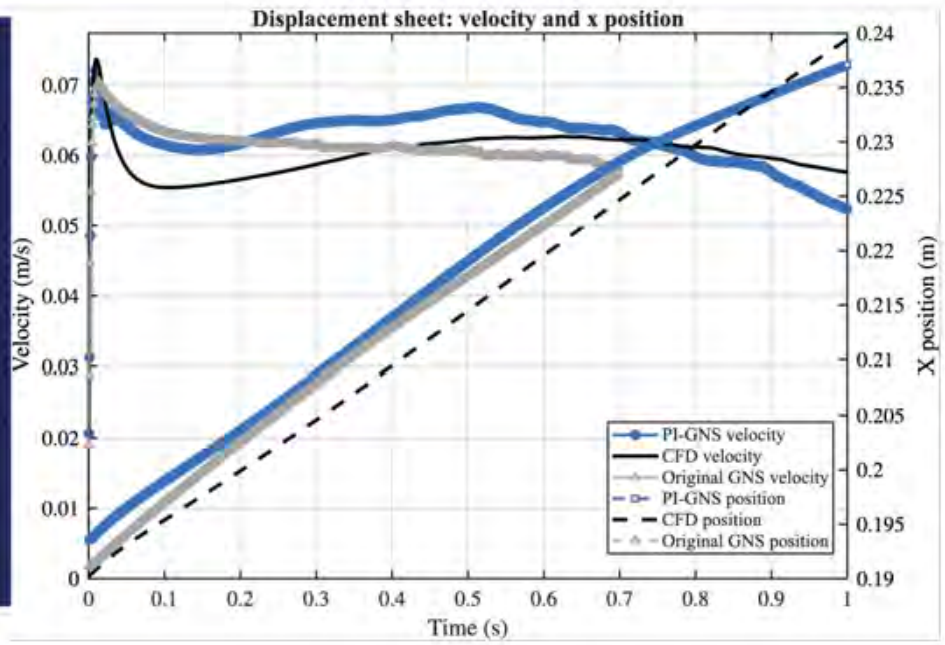


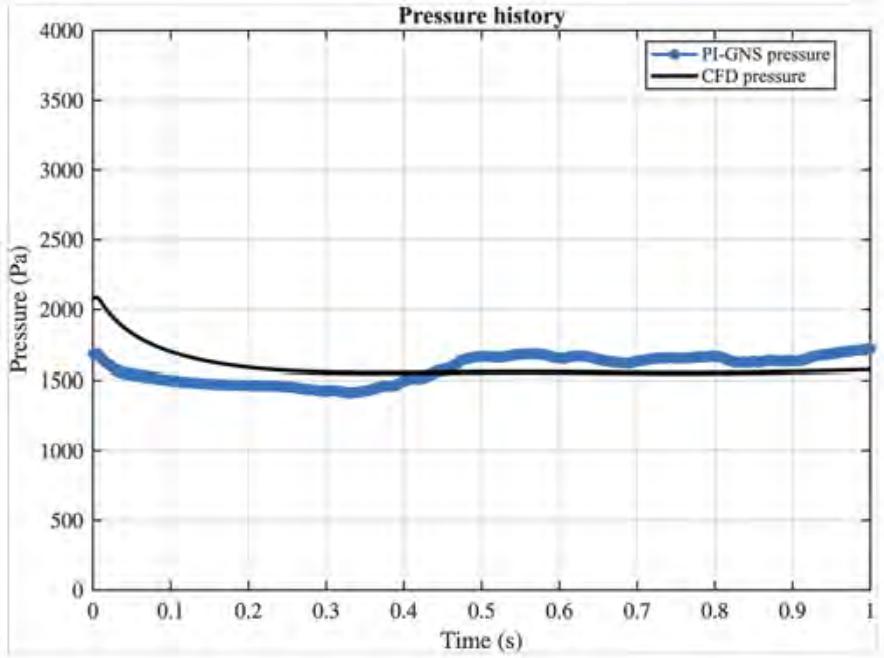
Pure GNN shows poor reproducibility even after 1000 epochs, indicating inefficient training.

Results

Quantitative Comparison of Displacement, Velocity, and Pressure in the Dam-Break Case







Comparison of Computational Time

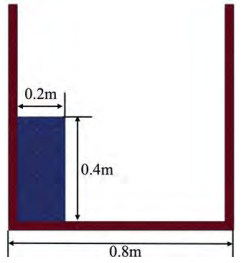
	CFD (CPU/ OpenMP)	CFD (GPU)	PI-GNS	Speed-up (CPU)	Speed-up (GPU)
Dam-break (1×10^3 Pa.s)	14948.8s	2321.3s	6.543s	2285 times	354.8 times
Dam-break (1×10^2 Pa.s)	2772.5s	469.2s	6.631s	418.1 times	70.8 times
complex geometry (1×10^3 Pa.s)	10149.5s	1436.8s	3.97s	2556.5 times	361.9 times
complex geometry (1×10^2 Pa.s)	1078.7s	295.2s	4.046s	266.6 times	73.0 times

- PI-GNS achieved a 2285× speed-up compared with CPU-based CFD and a 354× speed-up compared with GPU-based CFD.
- As viscosity increases, CFD becomes more time-consuming, while the computational time of GNS remains almost constant.

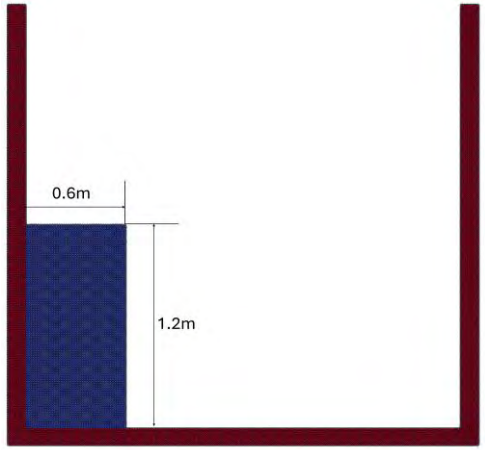
→This method is particularly advantageous for highly viscous flows.

Prediction of Geometrically Similar Dam-Break Cases

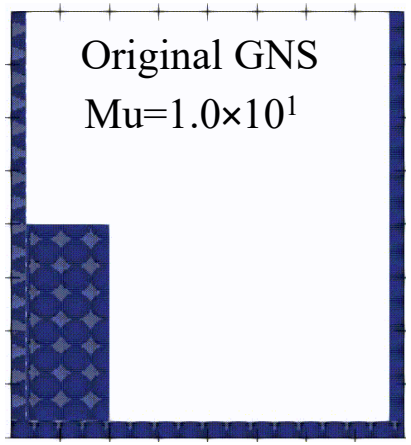
We made PI-GNS predict a 3× scaled geometrically similar system.



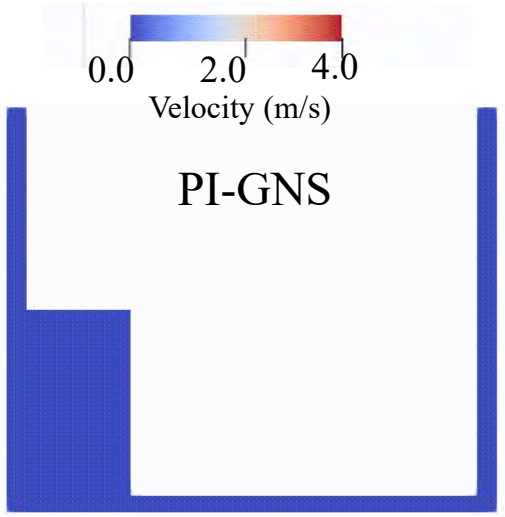
the geometry used for training

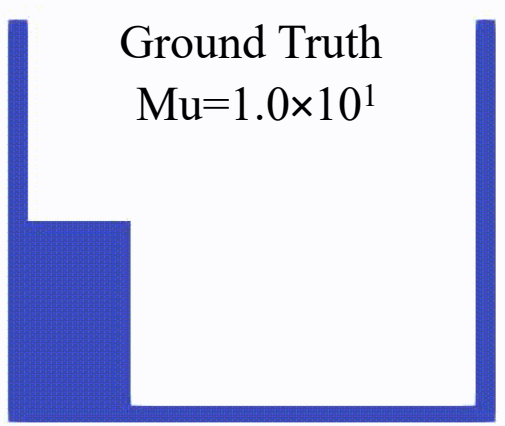


predicted geometry



When the pure GNS predicts a 2× scaled geometrically similar system, the prediction becomes highly unstable and crashes.





PI-GNS greatly improved prediction accuracy.

This suggests that large-scale behavior may be predicted from small-scale training data, which is difficult with conventional GNS.

Conclusion

- Introduced **pressure** and **kinematic viscosity** as additional features into the conventional GNN framework
- Developed an **inter-node spatial discretization model**, assuming that particle-method-like discretization can be applied within the graph
- PI-GNS reproduced flow behavior more accurately than conventional GNS with fewer training epochs
- PI-GNS significantly improved accuracy for scaled-up particle systems, which was difficult for conventional GNS

ADVANCING NUCLEAR SAFETY TECHNOLOGY

A Modernized Architecture for MELCOR

Generalized core damage progression, multi-physics coupling, and the dynamics of an evolving component network

David L. Luxat · Lucas Albright · Brad Beeny · Troy Haskin · Dallin Keesling
Dept. 8852 · Nuclear Energy Safety Technologies · Sandia National Laboratories

SAND2026-XXXXP

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

This is not a new code

MELCOR remains MELCOR. A modernized physics layer runs alongside it through a named, auditable external bridge — no edits to MELCOR source are required to add new physics.

What is new

- The validated MELCOR is preserved, with 30+ years of regulatory pedigree intact; every historical input deck still runs.
- The modernized layer makes it possible to introduce new ways of representing physics more readily — core damage progression is treated as an evolving network of components, with inter-component transport rates carried as state variables and advanced by the same integrator as the components.
- The same component-network describes a fuel rod, a debris bed, a corium pool, core components in an external vessel, or a heat-pipe reactor block — resolution and geometry are deck-level choices, not code-level constraints.

What this talk covers

- The two-layer architecture and the external bridge between original code and modernized layer
- The generalized dynamical form — state and the couplings between state, on one integrator
- Thermal structures with moving-boundary ablation; heat pipes as a sub-network behind a boundary closure
- Coated-particle fuel in a heat-pipe reactor — a non-light-water-reactor application of the same framework
- Lower-head retention and drain into an external vessel under two failure modes

Purpose. Preserve the validation basis; extend the code beyond what the original physics packages can represent.

PART 1

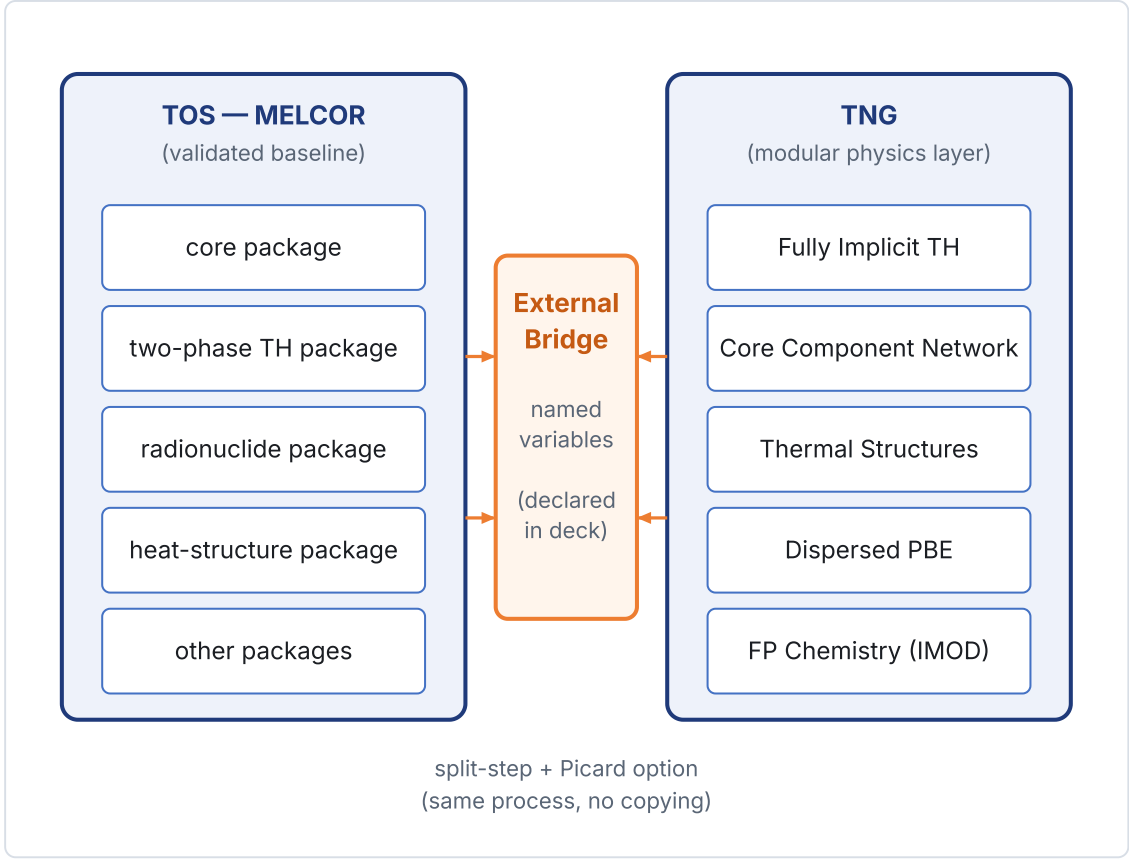
External Bridge and Numerics

The External Bridge — how the original code and the modernized layer compose

By design, the original code and the new physics layer share no internal state directly. They communicate only through the bridge.

- The original code runs its full step first, package by package, using its own numerics.
- The bridge extracts the end-of-step state from the original code and writes it to named exchange variables on the new physics side.
- The new physics layer advances the same time interval with that state held as a fixed boundary condition, then stages its outputs as source terms for the next step in the original code.
- Every exchanged quantity is declared in the input deck — a reviewer can audit the coupling without reading source code.

Consequence. A new submodel is developed, tested, and validated **without running MELCOR at all**. The bridge connection is added only when the submodel is ready to integrate.



Separating numerics from physics

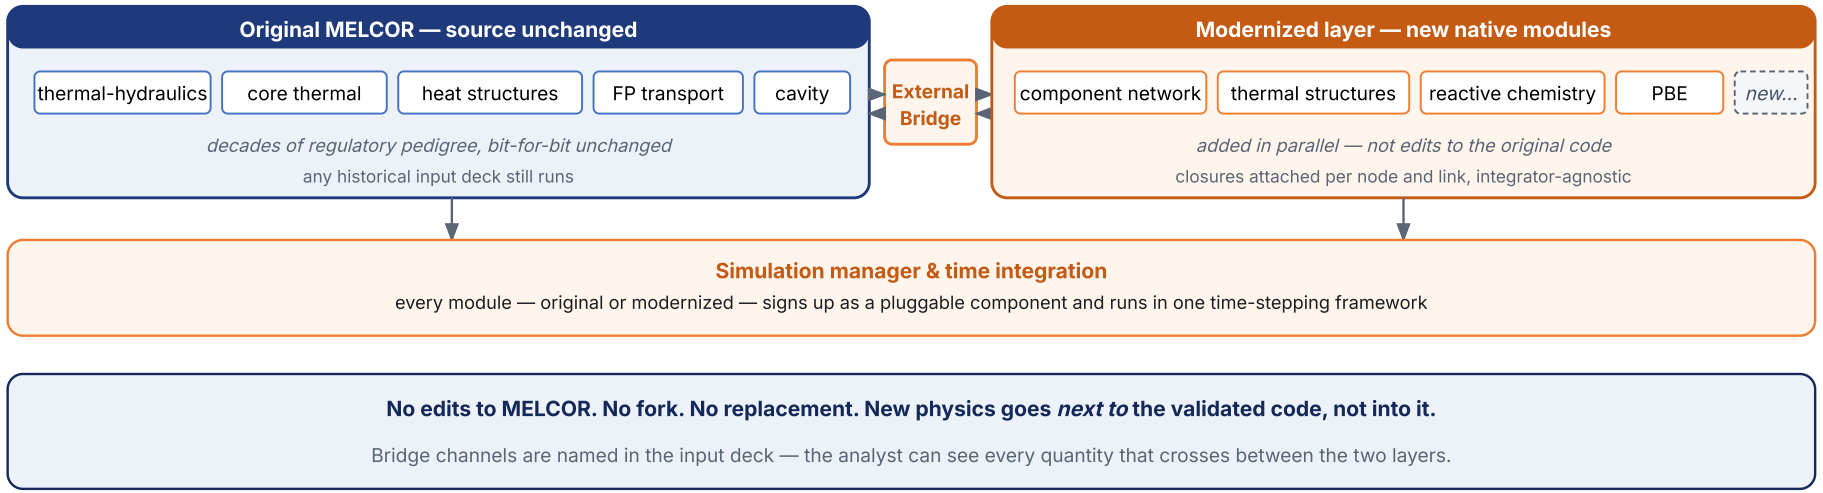
Physics submodels describe what equations to solve. Numerics describe how to advance them in time. They meet through a defined interface, not through shared internals.

- **Physics submodel** — carries its state variables, its residual equations, and the closures that act on it. Independent of the integrator.
- **Shared exchange variables** — every quantity that crosses between submodels has a name. All inputs and outputs are referenced by name; the references are stable for the whole run.
- **Integration interface** — a common interface between a physics submodel and a time integrator. Lets the same submodel run under fully-implicit Newton, IDA, or Runge–Kutta methods without changes to the physics submodel.
- **Common access pattern** — the integrator reads and writes

Why this matters for core damage

- Adding a new closure (e.g. eutectic dissolution) is a self-contained activity. The closure attaches to a node type, and the integrator does not need to change.
- A stiff transient (oxidation + phase change + reactive heat) can be re-routed onto a fully-implicit Newton solver with one entry in the input deck — same physics submodel.
- The Jacobian is built automatically from the residual — no hand-coded derivatives.

The result. Numerics improvements (better linear solvers, preconditioning, graphics-processor offload) and physics improvements (new closures) evolve on independent schedules. Neither blocks the other.



PART 2

Generalized Dynamical Form

State dynamics and coupling dynamics

Classical formulation: state variables on a fixed network topology.

CLASSICAL (STATIC TOPOLOGY)

$d\mathbf{x}/dt = \mathbf{f}(\mathbf{x}; \mathbf{A})$ — adjacency $\mathbf{A}$ is prescribed

Generalized formulation: the network itself is dynamical, with the couplings carried as state variables.

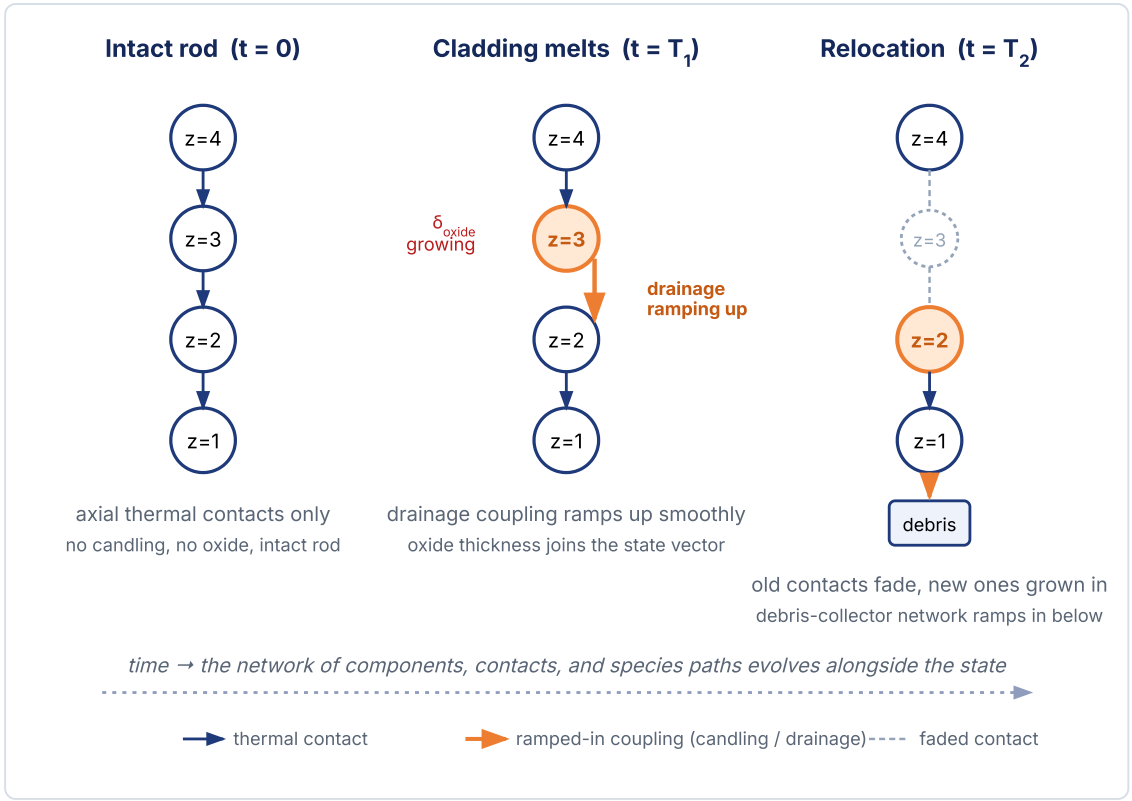
GENERALIZED (EVOLVING TOPOLOGY)

$d\mathbf{x}/dt = \mathbf{f}(\mathbf{x}, \mathbf{c})$ — component state

$d\mathbf{c}/dt = \mathbf{g}(\mathbf{x}, \mathbf{c})$ — couplings between components

What's in c: per-link drainage strength, per-node oxide thickness, per-face boiling-regime weights, eutectic progress fraction, cladding-failure fraction. Each entry evolves continuously through g; no on/off switching.

The same fuel column at three snapshots — the network of contacts evolves with the state:



Panel 1
$d\mathbf{x}/dt = \mathbf{f}(\mathbf{x}, \mathbf{c})$; $d\mathbf{c}/dt = 0$

Panel 2
$d\mathbf{c}/dt = \mathbf{g}(\mathbf{x}, \mathbf{c})$ — coupling ramps up smoothly

Panel 3
$\mathbf{c}$ has evolved — $\mathbf{f}$ now lives on a different network

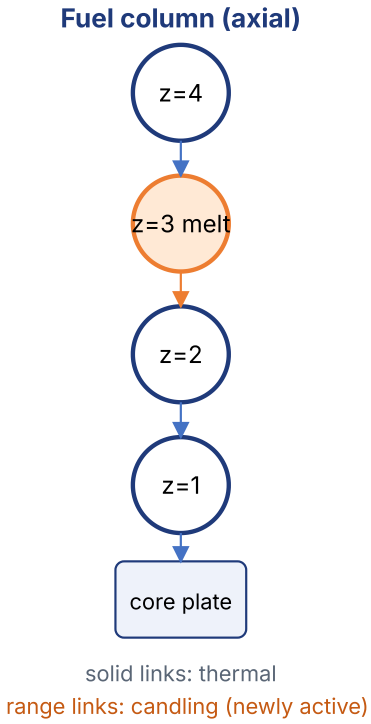
Take-away. In the original code, component types and inter-component transport laws are hard-coded. Here both are input, advanced by the same integrator as the state.

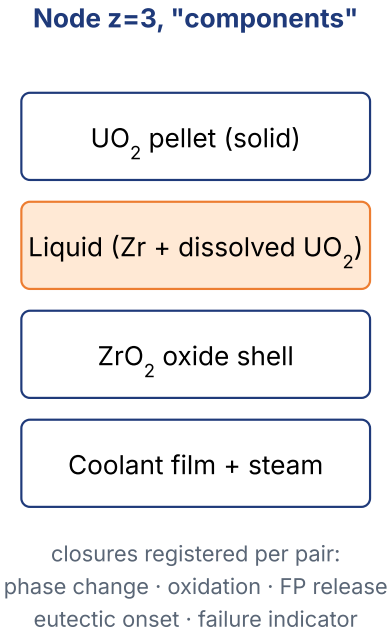
Component network — the flow-network pattern, generalized

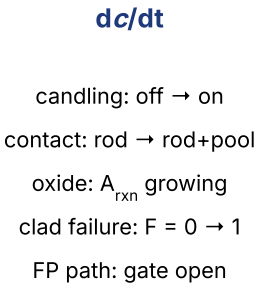
A familiar pattern. Classical flow networks placed the state inside control volumes and let flow paths transport between them. The component network reuses that idea for solids and condensed phases.

- **Node** — a spatial location that holds state. An axial slice of a fuel rod, a debris box, a coated-particle compact, one lump of a relocated pool.
- **Node-component pair** — a material at a node. The same node holds many: fuel pellet, cladding, oxide layer, dissolved liquid, gas gap.
- **Link** — a typed exchange between nodes. Thermal contact, melt drainage, fission-product transport, mechanical contact. **Mass and energy transport rates between components are the couplings**.

> **Why the analogy matters.** In a thermal-hydraulic flow network, junctions are static; the topology is fixed by piping. Here the network is **dynamic** — links open as cladding melts and pours; new networks appear when material relocates into a receiving vessel.





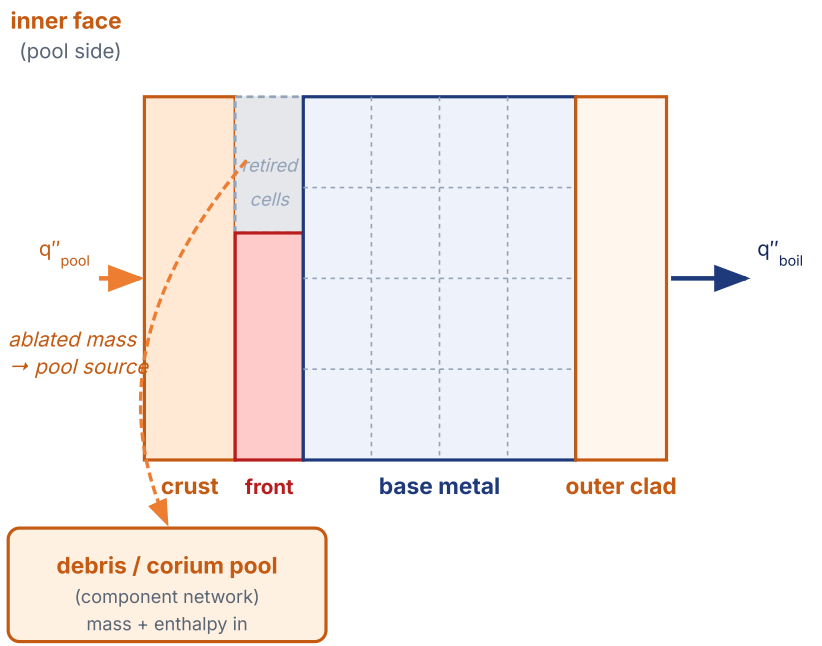


Thermal structures — meshed solids with moving-boundary ablation

A thermal structure is the second building block of the modernized layer. Where the component network resolves components at a node, a thermal structure resolves a meshed solid — cladding, lower head, calandria wall, debris-bed crucible — cell by cell.

- **Multi-region mesh.** A wall can carry stacked regions — crust, oxide, base metal, outer cladding — each with its own material card and its own per-cell state.
- **Named faces.** Inner, outer, top, bottom, side. Each face carries its own boundary closure (radiation, pool convection, external boiling, contact to a neighbouring network).
- **Moving-boundary ablation.** When the surface cell exceeds wall solidus while corium is in contact, a Stefan front advances into the wall. The integrated melt enthalpy comes out of the incoming heat flux; the ablation depth is a continuously evolving state variable per face cell.
- **Boundary topology is dynamic.** As a cell ablates fully, the moving-boundary manager retires it and exposes the next cell behind it as the new surface — the per-face boundary closure picks up the new geometry automatically.
- **Coupling back to the network.** Ablated mass and its enthalpy are sourced into the receiving network node (a debris bed, a relocating pool) — the same cross-network mass and energy balance that holds for every other link.

A lower-head wall slice — multi-region, multi-face



Per-face state: $\delta_{remaining}$, $T_{surface}$, ε_{creep}

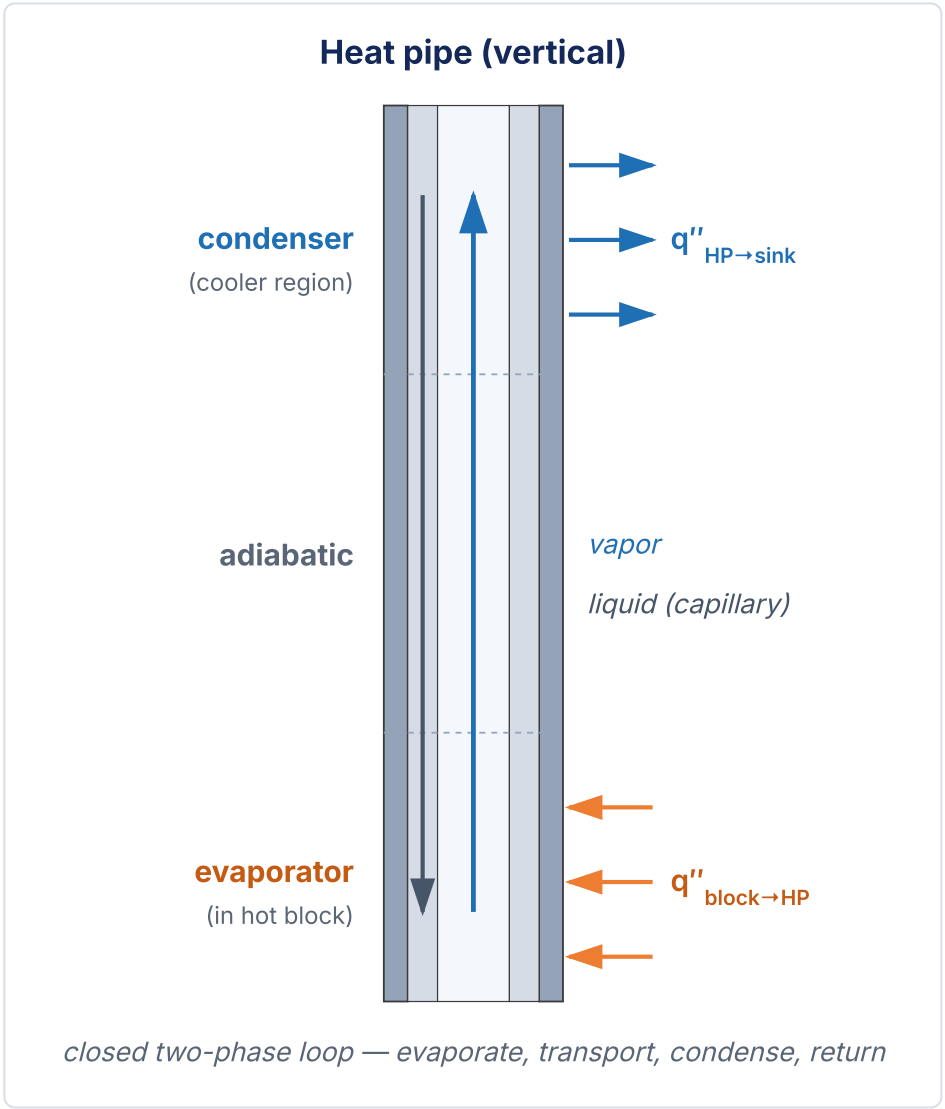
Breach event: $\delta_{remaining} < \delta_{min}$ or $\varepsilon_{creep} > \varepsilon_{crit}$ — hands off to the orifice closure.

Heat pipes — a sub-network behind a boundary closure

A heat pipe is a closed two-phase device. Working fluid evaporates at the hot end, vapor flows to the cold end, condensate returns through a wick by capillary force. Effective conductance is tens to hundreds of times higher than a solid bar of the same size — but only inside an operating envelope.

- **Inside the heat pipe**: its own small network — evaporator, wick, vapor space, condenser — each carrying state, exchanging mass and energy through internal couplings.
- **Outside**: a boundary closure on the host node. Heat extraction follows a prescribed axial profile with an effective conductance $G_{HP}(T_{block}, T_{HP})$ attached to the affected cell faces.
- **Operating limits live in c**: capillary, entrainment, sonic, and boiling margins — each a continuously evolving distance-to-dryout, not a binary flag.
- **Failure is a closure swap, not an event**: as a margin crosses zero, the boundary path smoothly degrades from full HP transport to thermal-resistance-only. Integrator sees a continuous transition; the deck names the margin.

> The HPR result later shows this directly — the "central-HP-failed" case is the same model with one pipe's closure swapped.

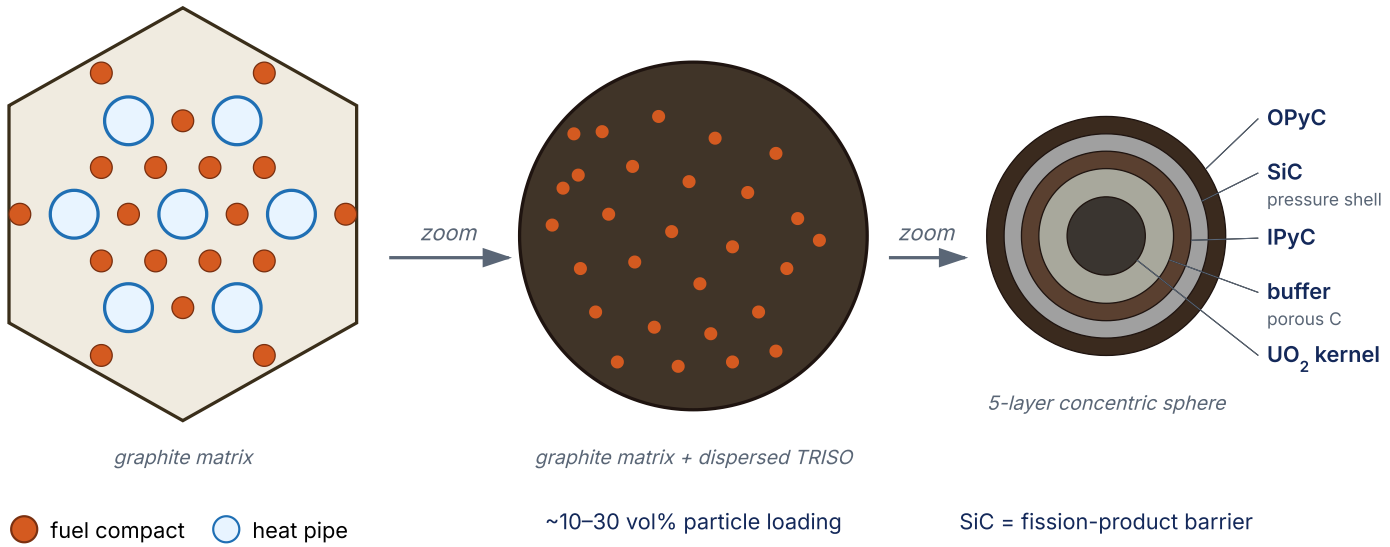


PART 3

Illustrative examples

What the HPR model represents — block, heat pipes, compacts, particles

A coated micro-particle fuel form composes into the same generalized network used throughout the deck. Only the closures attached to the nodes and links change.



What lives where

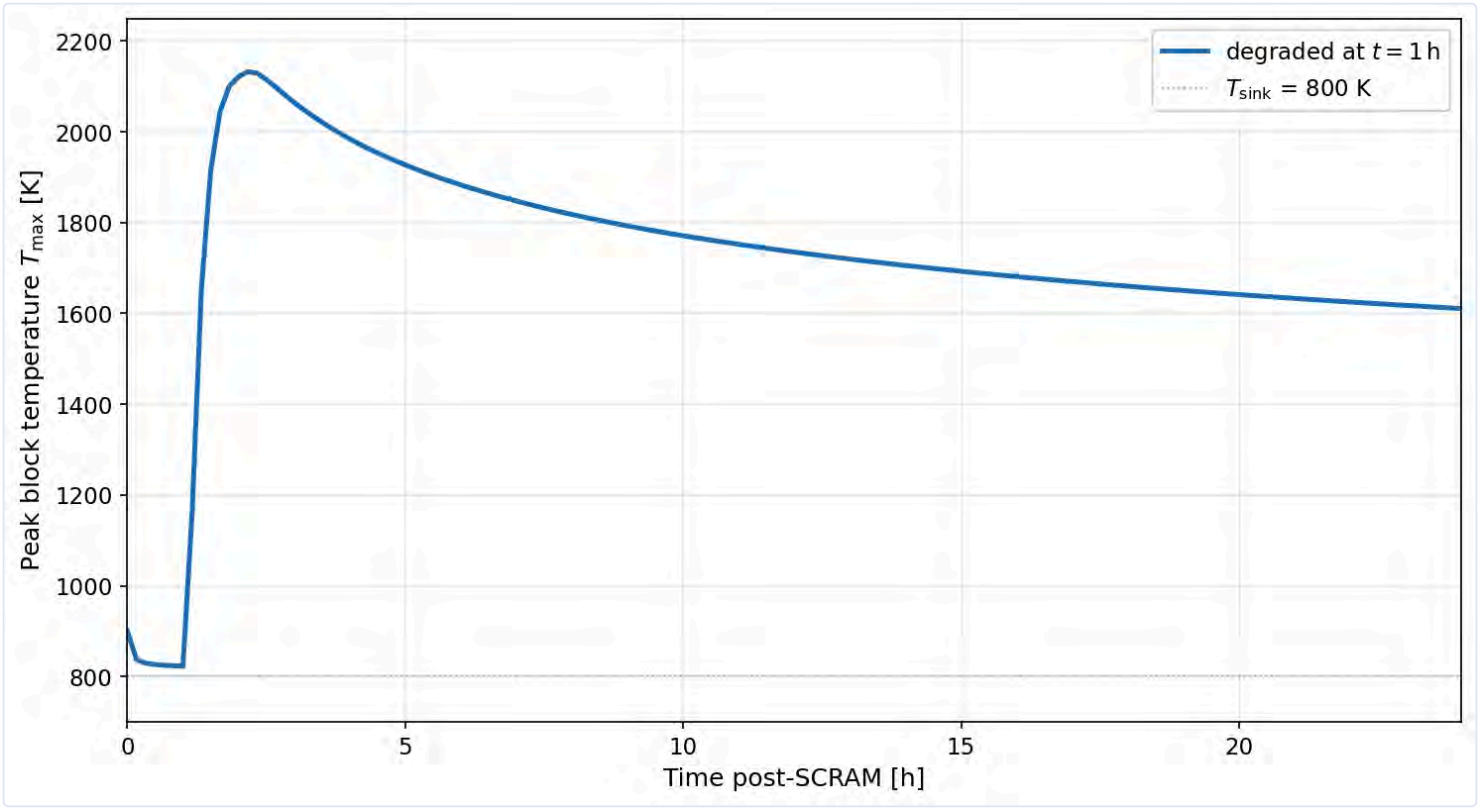
- **Block** → meshed node, radial + axial
- **Compacts** → effective **k** closure (ME / ZBS / Bruggeman)
- **Heat pipe** → boundary closure; HP failure = closure swap
- **TRISO particle** → one analytical 5-layer submodel; Weibull SiC failure

The zoom is conceptual. Millions of particles are not tracked individually. The block carries a homogenized k_{eff}; one analytical particle stands in for the population and carries the Weibull failure statistic plus the species transport path.

Matrix is an input, not a hard-coded assumption. The compact matrix shown here is graphite, but the framework treats matrix material as a property of the node — SiC, ZrC, or any other matrix can be selected by changing the material assignment in the input deck. The same homogenization closures and the same analytical-particle submodel apply.

TRISO HPR result — block T under degraded cooling at t = 1 h

Block holds at ~830 K while cooling works. At t = 1 h cooling degrades; block peaks at 2133 K at 2.2 h and cools back to 1611 K by 24 h as Q‴(t) falls.



Block temperature, degraded cooling at t = 1 h. T_{sink} (800 K) shown as a reference.

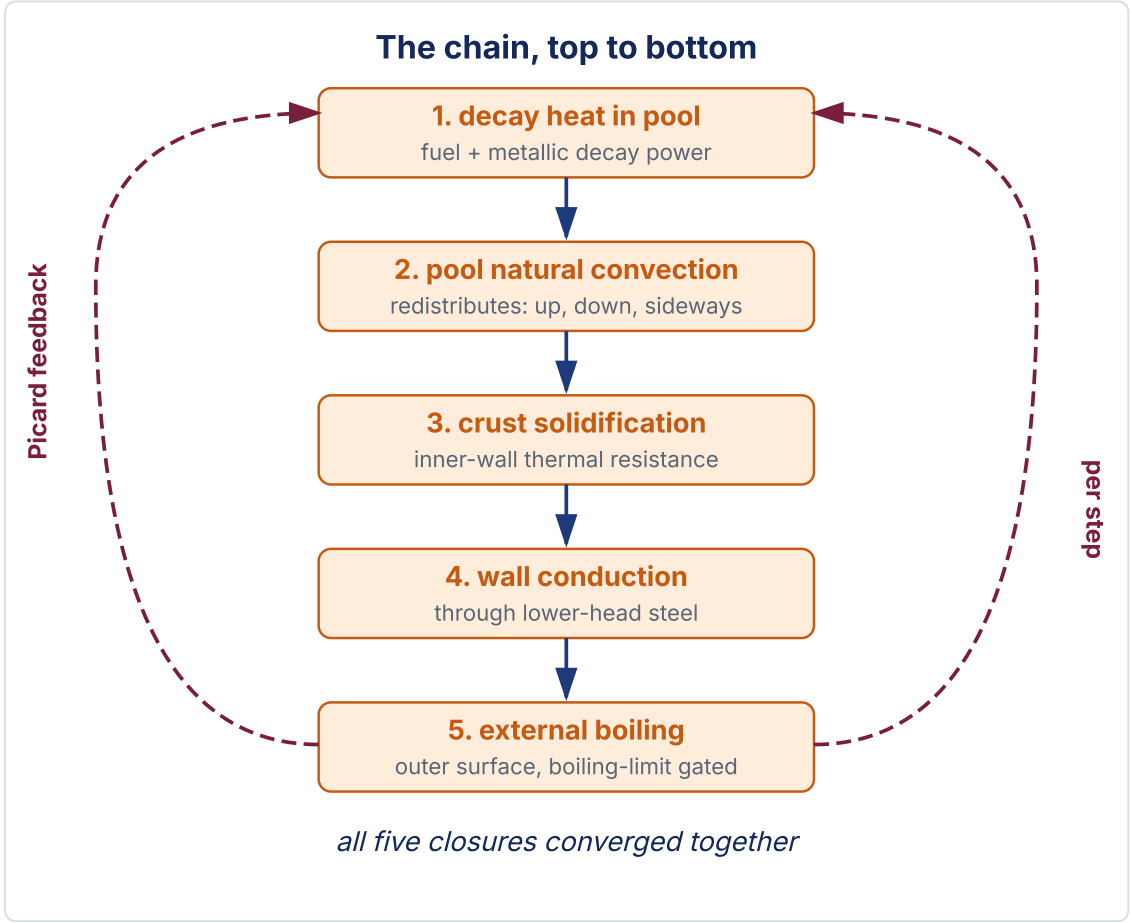
One hour of working cooling lets Q‴(t) fall enough that the system recovers once cooling degrades.

In-vessel retention — five-step coupled solve

A relocated corium pool sits inside the lower head; operator action floods the outer vessel surface. Whether the wall survives depends on five physics steps running together, not in sequence.

1. **Decay heat** deposited in the pool from relocated fuel and metallic inventory
2. **Pool natural convection** redistributes the heat — up to the free surface, down and out to the curved wall, sideways into a metallic layer if one exists
3. **Crust solidification** on the inner wall sets a thermal resistance and protects the steel from direct contact with molten material
4. **Wall conduction** through the lower-head steel mesh, per angular zone
5. **External boiling** on the outer surface removes the heat — subject to a boiling-limit set by geometry and surface coverage

A change in pool convection shifts the angular flux distribution; the changed flux shifts crust thickness; the changed crust shifts wall temperature; the changed wall temperature shifts the boiling regime. All five reach a self-consistent solution in **one** Picard iteration per time step — not lagged across steps.



Lower-head ablation and cross-network melt pour

Ablation dynamics are central. When the pool is hotter than wall solidus, a Stefan front advances into the steel face by face. When remaining thickness drops below a threshold, the breach event fires.

- **Per-face Stefan front.** Each angular zone tracks its own remaining wall thickness; partial breaches (a single failed band) are the natural outcome.
- **Two failure paths watched together.** Creep damage accumulates under sustained stress at sub-solidus temperatures; ablation thins the wall at solidus contact. Whichever crosses its threshold first fires the breach.
- **Breach hands off to a gravity-drainage closure.** Drain rate is set by the breach area and the hydrostatic head above the breach — a single-phase orifice law, no flashing, no critical-flow regime relevant for this type of melt drainage.
- **Driving head** is gravity ($\rho\, g\, h_{pool}$) plus any system overpressure between donor and outer vessel.

Mass and energy balance across the boundary

Four named quantities cross every cross-network link, summing to machine zero each step:

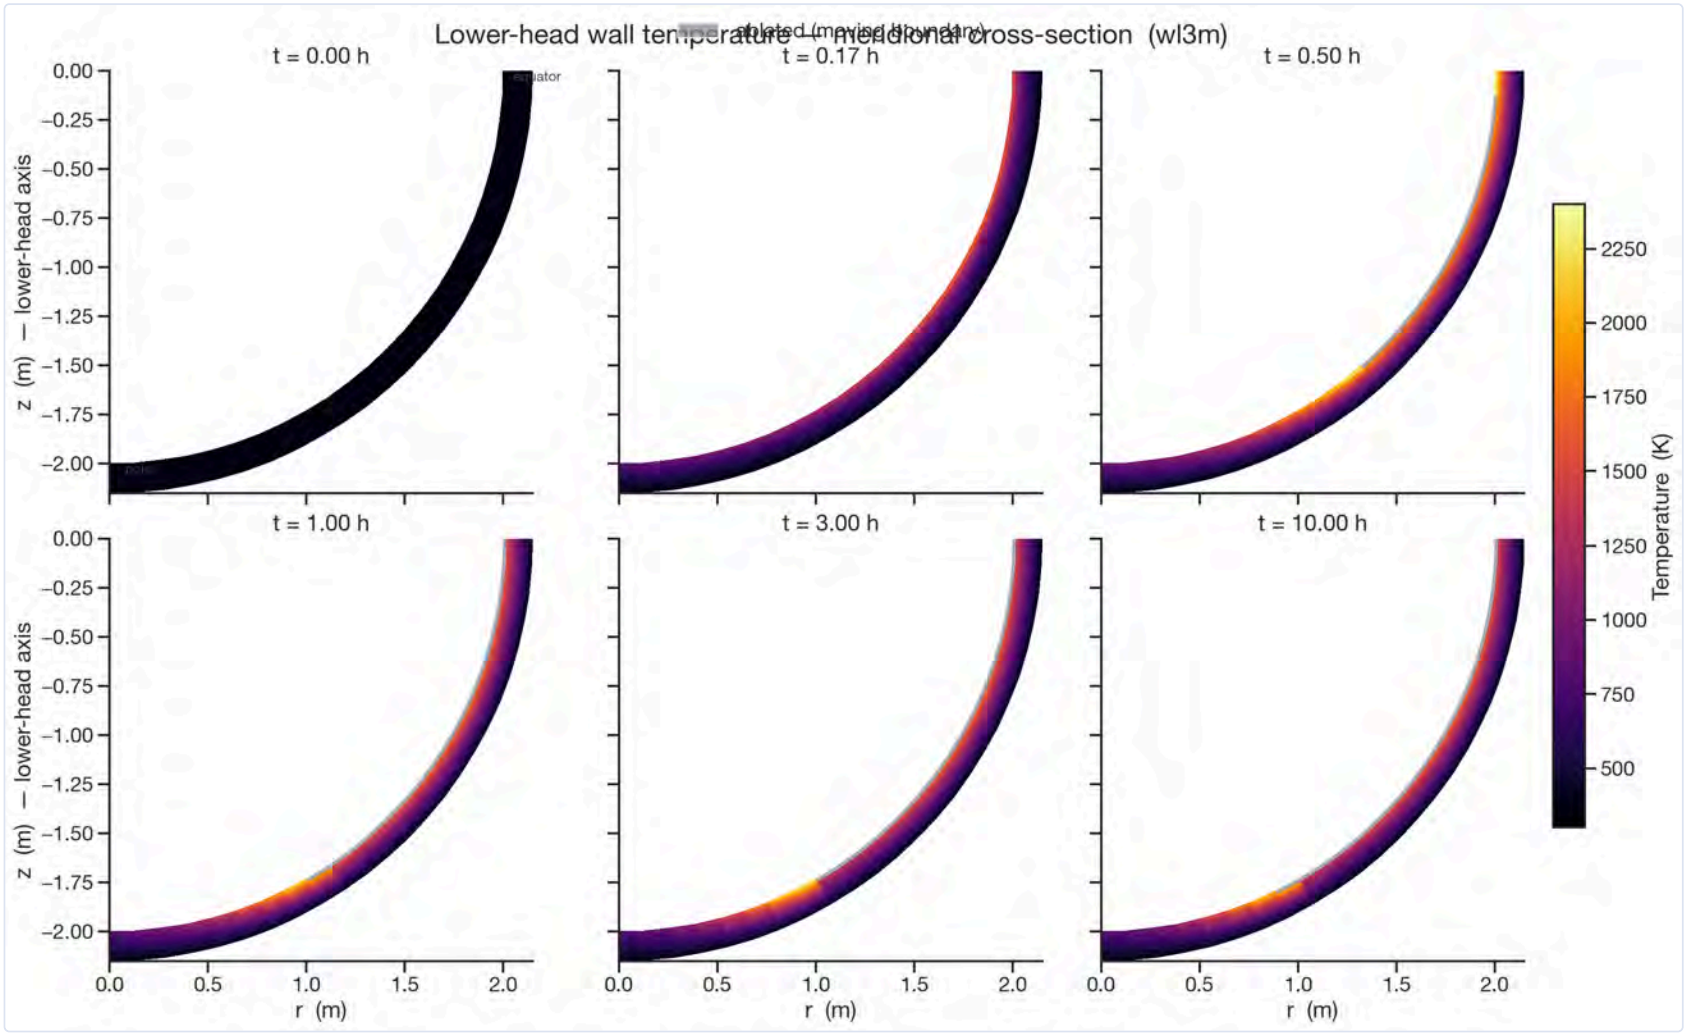
- **Mass per species** — donor decremented, outer vessel incremented, by the same per-species amount
- **Enthalpy** — jet specific enthalpy is the donor-side value; no flash losses, no artificial mixing
- **Decay-heat carry-along** — each transferred kilogram brings its decay-power generation rate with it
- **Full composition vector** — every tracked species follows the mass; the outer vessel composition is mass-weighted by the arriving stream

The same balance applies to **every** cross-network link: rod region to lower plenum, lower plenum to ex-vessel cavity, lower plenum to an external vessel.

Result — lower-head wall under nominal ex-vessel cooling

- Large-PWR hemispherical lower head, full-submergence outer cooling
- Same mesh and closures as Part 2
- Equator at **z = 0**, pole at **z = −R**
- Gray cells: retired by the moving-boundary manager

> Ablation self-limits to a one-cell band at the peak-flux polar angle. Wall survives 10 h.

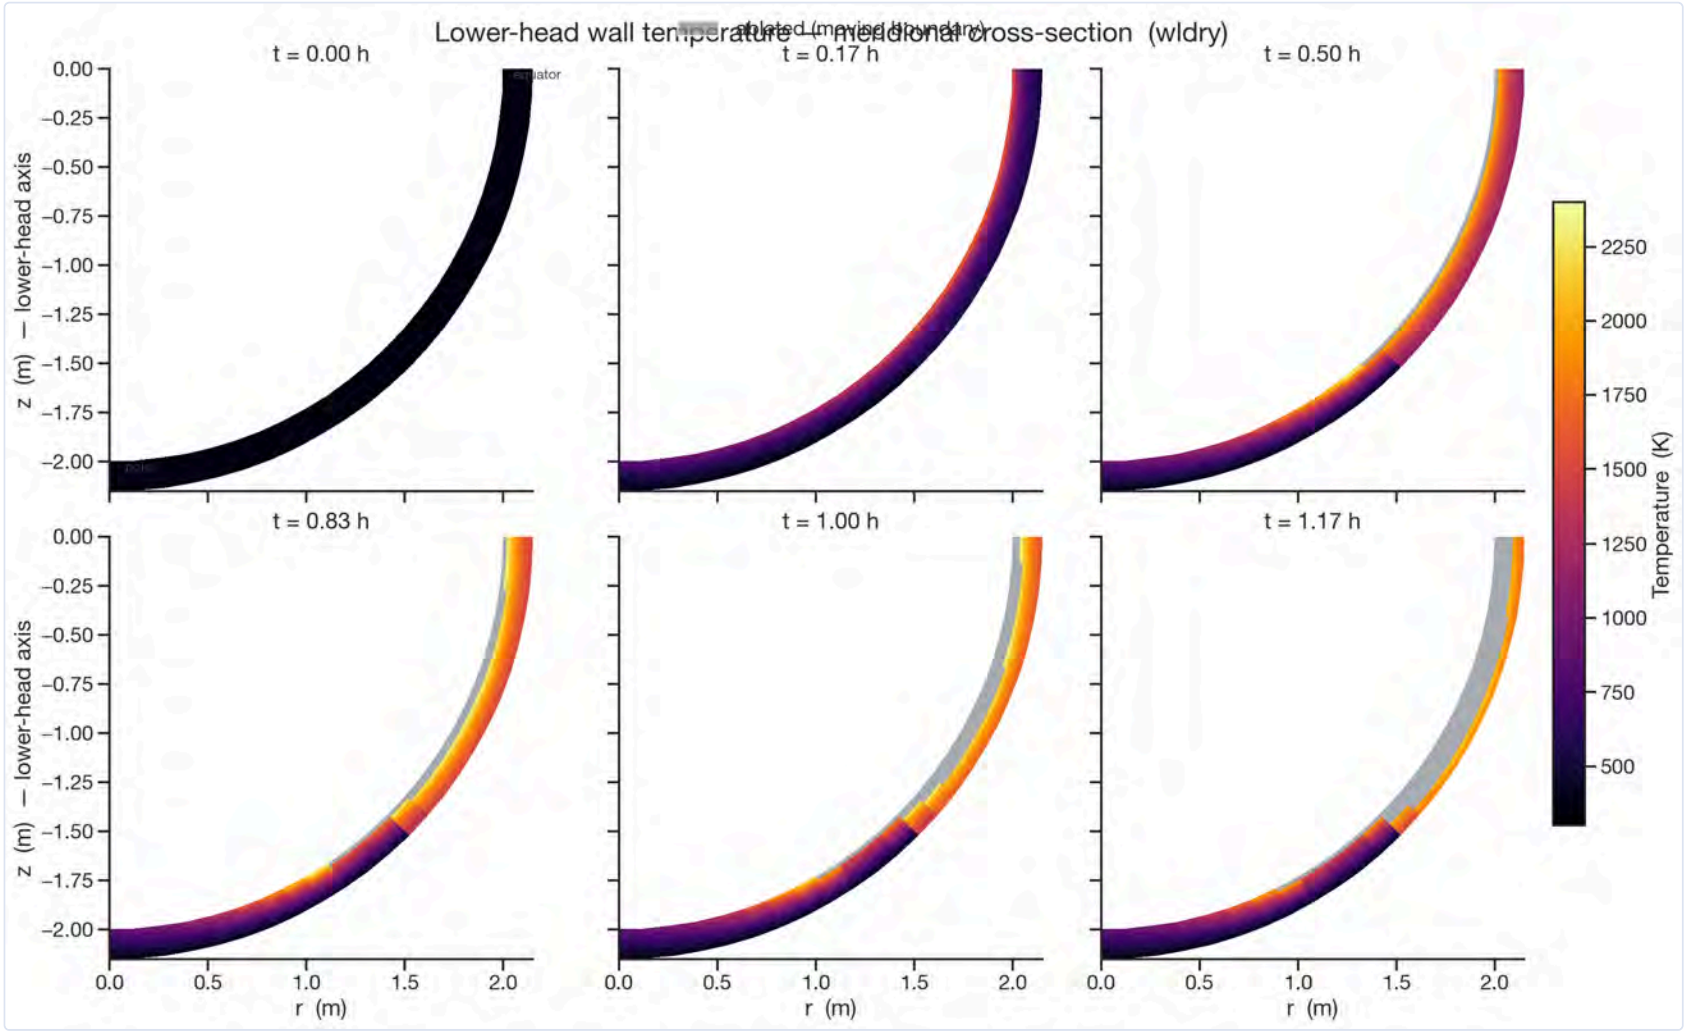


Wall temperature, six snapshots over 10 h.

Result — same model, degraded outer cooling, breach at 77 min

- Same mesh, same closures, same integrator
- Outer water dropped: upper hemisphere on radiation only ($h_{dry} \approx 100$ W/m²·K)
- Per-face breach fires at **t ≈ 77 min** when $\delta_{remaining} < \delta_{min}$

> Only the outer face closure changed. Front cascades; wall breaches.



Same six-snapshot format. Run halts at t ≈ 1.28 h on outer-ring breach.

Core components in external vessels

The component-network building block does not care which vessel a component sits in. Each vessel is its own connected component graph; cross-network links transport mass and energy between them under the same audited balance.

- **Integrated small modular reactors.** Designs like NuScale place the reactor pressure vessel inside an outer containment vessel submerged in pool water. If the RPV breaches, relocated material drains into that containment vessel — an external vessel that the framework now represents as a separate network on the receiving end of the cross-network link.
- **Heavy-water designs.** The shield tank in the 900 MWe-class CANDUs built in Ontario (Bruce, Darlington) is a large water-filled vessel surrounding the calandria. In late-phase progression, relocated core material is retained in the shield-tank water inventory — a network of its own, populated by the same kinds of nodes and links.

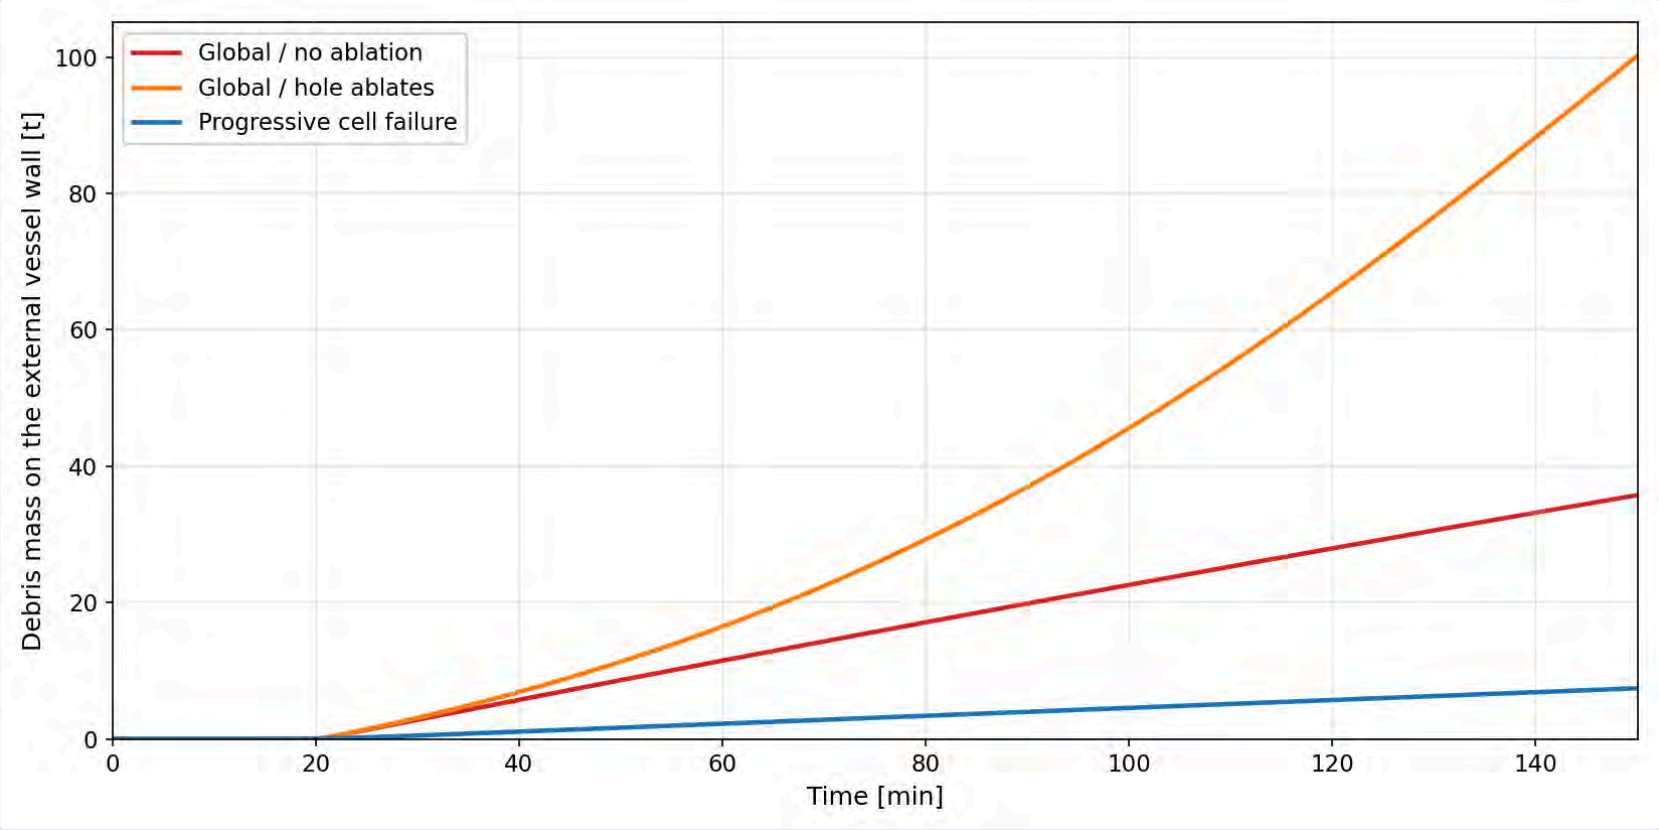
Why this matters at the engineering level

- No new closures need to be written to extend physics into an external vessel — the same melt drainage, the same heat-transfer correlations, the same failure indicators all apply the same way
- The run log lists each vessel as a named network with its own component inventory — the analyst sees exactly which vessels contain what, when
- The cross-network conservation balance is checked independently for every vessel-to-vessel link — an automatic check on every run, not a tolerance band

The pattern is general. If a new advanced design places core components in a vessel the original code never modelled, those components are represented in the existing framework as another network. No changes to MELCOR itself; the existing validated physics is undisturbed.

Debris accumulation in the external vessel

Global / hole ablates: ~100 t debris by 150 min — the breach widens as the orifice erodes. **Global / no ablation**: ~40 t at fixed orifice. **Progressive cell failure**: ~5 t debris — a much slower per-zone failure mode.



Debris mass on the external-vessel wall, three failure-mode scenarios.

Looking forward — where this can go

The component-network representation does not prescribe geometry or resolution. Heat transfer, mass transfer, and species transport between any set of nodes follow the same form. What the analyst chooses to declare in the input deck is what gets simulated.

Any network, any resolution

- Lumped region, one assembly, every rod — resolution is a modeling choice, not a code constraint
- Heat-transfer, mass-drainage, species-transport links coexist on the same network
- New components are added by declaring new node types and the closures attached to them

3D-resolved core, if the question asks for it

- Every fuel assembly meshed independently in a true 3D arrangement
- Every rod within an assembly resolved separately when intra-bundle behavior matters
- Cross-assembly thermal coupling, in-bundle melt drainage, intra-rod failure all in one framework

Beyond the reactor vessel

- A spent-fuel pool with rod-by-rod inventory under loss-of-cooling scenarios
- Heat-pipe reactors, fluoride-salt designs, micro-reactors, integrated SMRs
- Any external vessel that receives core material — calandria shield tanks, ex-vessel cavities, dedicated catchers

ADVANCING NUCLEAR SAFETY TECHNOLOGY

ABSTRACT

Small modular reactor (SMR) and advanced reactor (AR) designs see increased interest in new markets for nuclear energy to combat climate change. Canadian Nuclear Laboratories' (CNL) reactor safety research supports safe deployment with a flexible technical program supporting regulatory and industry stakeholder needs. SMR/ARs for remote (off-grid) locations and grid-level applications using various technologies are being explored based on the deployment landscape in Canada. Severe accident research is a key component focused on potential scenarios, progression, and prediction of radionuclide source terms, which informs design, regulation, and emergency response. CNL has developed competencies and is building additional capabilities in reactor safety research of technologies being deployed in Canada and has a base understanding of other designs of interest. Major technologies include water-cooled (primarily small boiling water reactors, BWRs), high temperature gas reactors (HTGR), and micro-reactors (micro-HTGR and heat-pipe designs). Baseline capabilities and early research are being developed for sodium fast reactors and molten salt designs. CNL is constructing experimental apparatus and conducting tests to generate knowledge and data regarding important phenomena where gaps have been identified. Modelling efforts are focused on experimental benchmarks and the development of generic integral analysis models for these different technologies, both in severe accidents and containment. Recent developments in experiments include passive containment cooling experiments for small BWR containments, and the commissioning of early tests/results of an onset of natural circulation experiment for HTGR, as well as a self-heated pebble bed core experiment. Integral accident analysis models and uncertainty and sensitivity investigations have been conducted for small BWR and HTGR models in MELCOR, and CNL is participating in the SASPAM-SA project. In micro-reactor space heat pipe experiments, ongoing and new agreements for custom heat pipe designs will enhance CNL capabilities. There is also an evaluation of historic AECL designs, including the SLOWPOKE and Nuclear Battery, as well as the development of a microreactor framework to support deployment in Canada.

KEYWORDS
Small Modular Reactors, source term, high temperature gas cooled reactors (HTGR), small BWR, heat pipes

1. INTRODUCTION

The resurgence in nuclear energy worldwide continues, and the deployment of new nuclear is growing closer in many markets. Planned deployments include new large builds, small modular reactors (SMR), advanced reactors (AR), and micro-reactor designs. There is interest in the deployment of all these classes of reactors in Canada to contribute to clean energy generation and meet the needs of government and industry.

The most recent developments in Canada have been related to the GE-Hitachi BWRX-300, a small boiling water reactor (BWR), deployment at the Ontario Power Generation (OPG) Darlington site, where the construction license for the first of four units was approved by the Canadian Nuclear Safety Commission (CNSC) in 2025 April. The nuclear construction at the site is now underway, and the licensing process is moving on to the next stage, where the objective will be a license to operate. OPG is targeting the end of 2029 for the commissioning and connection to the grid of the first BWRX-300 unit at Darlington. There are also advancing plans for deployment in Saskatchewan with SaskPower selecting the BWRX-300 as their technology of choice and moving forward with siting plans in the southern part of the province, with deployment timed for the mid-2030's. AR development is continuing with the ARC sodium fast reactor and MOLTEX molten salt reactor designs in New Brunswick, with these companies incrementally pushing forward with the various aspects of their technologies.

In terms of new large builds, major announcements include 4800 MW of new nuclear at Bruce Power's "C" site and up to an additional 10 reactor units planned for OPG's new Wesleyville site east of Toronto. These commitments to large new builds are tied to the recent success of the Darlington refurbishment project, which was delivered ahead of schedule and under budget, with the fourth unit completing its refurbishment and returning to power operations with CNSC approved initial power testing starting in 2026 February [1]. In addition, the major component refurbishment of the Bruce Power plant continues to proceed well, and the refurbishment of OPG's Pickering B plant was recently announced (definition and planning in 2026-2027 and refurbishment beginning in the end of 2028, the end of the current license to operate), which is expected to complete in the mid-2030s [2], solidifying further the long-term supply of nuclear energy for Ontario.

The micro-reactor deployment picture has evolved with Global First Power changing hands (Ultra Safe Nuclear Corporation (USNC) went bankrupt and was bought out by Nano Nuclear) and now realigning its potential siting of the micro-modular high temperature gas cooled reactor (HTGR) design, now known as Kronos, at the AECL (Atomic Energy of Canada Limited) Chalk River Laboratory Site. The Westinghouse e-Vinci effort has also refocused on defense opportunities and paused civil deployment, which puts on hold former agreements with the Saskatchewan Research Council for deployment of an e-Vinci in Saskatchewan. There is also renewed interest in AECL historic intellectual properties, such as the SLOWPOKE district heating reactor and AECL Nuclear Battery, with a request for expression of interest call in early 2025 [3], as well as a developing framework for microreactor deployment undertaken by AECL/CNL and the government of Canada. Additionally, the Canadian Department of National Defence is exploring the potential for integrating nuclear power into its plans for expanded operations in the north of Canada as part of increased efforts to meet North Atlantic Treaty Organization (NATO) commitments. All in, this shows a significant push towards microreactor development and deployment in Canada.

Canadian Nuclear Laboratories (CNL) maintains its role of supporting current nuclear fleet operations and the deployment of the future fleet and is expanding its research efforts in reactor safety to support interest in new nuclear deployment in Canada. The reactor safety research program has significant ongoing efforts, primarily under AECL federal nuclear science and technology funding. Reactor safety encompasses neutronics, fuel safety, thermalhydraulics, containment, and severe accidents and covers both the current fleet of reactors and the expansion to come, regardless of size or technology. This research program includes experiments and modelling and has the robustness and adaptability to support the needs of both industry and government stakeholders. There are key efforts throughout this program to support safe new nuclear deployment based on the current landscape and interests in Canada. The specific focus of this paper is the research efforts related to severe accidents in the context of SMR and advanced reactor deployment. This paper builds on previous overviews of CNL severe accident research related to SMR/ARs [4] [5] to provide an update on the severe accident research efforts at CNL in this area and to showcase new developments in experiments, modelling, and analysis.

Before discussing the severe accident research in detail, it is worth mentioning the evolving research and future strategy at CNL regarding new nuclear deployment. AECL/CNL has more than 80 years of experience in nuclear research and is the pioneering organization in Canada. The design, development, deployment and operation of the fleet of CANDU reactors in Canada and abroad is the major source of CNL experience, but over the last 10 years, CNL has developed capabilities and competencies that expand its knowledge into SMR/AR designs that are moving towards deployment. Over these ten years of focus on SMR/AR research development, the strategic outlook for reactor safety has evolved. Initial approaches focused on a technology agnostic view with a drive to develop tools and methods that could be applied across multiple potential technologies/designs. The development of a good set of tools and capabilities has led to more focused research related to specific technologies and phenomena, led by the deployment landscape in Canada and other countries, as well as the technology readiness level (TRL). The reactor safety program builds a base of knowledge commensurate with the TRL, deployment landscape and ongoing research worldwide to ensure Canada has the tools necessary to support safe deployment and make unique, more in-depth research contributions to technologies of interest that align with CNL skills and capabilities. In this way, CNL can develop and maintain the necessary knowledge and contribute complementary research important to Canada and to the international community. The major technologies of interest for CNL are i) water-cooled SMRs, specifically small BWRs and related passive cooling; ii) high-temperature gas reactors, including both SMR and micro-reactors; iii) microreactor focused phenomena and technologies such as heat pipes; and iv) select areas of interest for other advanced designs, such as SFRs and MSRs, commensurate with the development of capabilities that may be needed in the future when TRLs and deployment of these technologies advance. The primary areas of severe accident research align with these and are discussed in depth in the previous review papers [4] [5] and updated with the most recent developments herein.

The method for selecting important research areas and major goals for the reactor safety, and consequently the severe accident, research program has remained consistent as previously discussed [4] [5]. Phenomena Identification and Ranking Table (PIRT) efforts, conducted by CNL or others, highlight the important gaps in knowledge. CNL's experience in developing and evaluating PIRTs related to SMRs/ARs is key to this step. The PIRT results/evaluations identify gaps that need to be addressed, and CNL sets targeted research priorities based on needs and capabilities. Gaps are addressed with experiments/modelling to investigate important phenomena, generate valuable data, develop models, and conduct benchmarking, qualification, and validation of the analysis codes, leading towards the closure of the research gaps.

The final piece of the CNL reactor safety/severe accident strategy is participation in the international research community, which allows CNL to leverage its own efforts to benefit from the valuable work of others and make its own unique contributions. CNL connects to academia, other research laboratories bilaterally and international organizations such as the Organization for Economic Cooperation and Development Nuclear Energy Agency (OECD-NEA), International Atomic Energy Agency (IAEA), Generation IV International Forum (GIF) and European Commission EURATOM. As mentioned previously [4] [5], CNL has taken on leadership positions in expert groups and working groups in these organizations as well as in joint projects under their purview. This is commensurate with the advanced interest in Canada for SMR/AR deployment. Major SMR/AR severe accident interactions include the US Nuclear Regulatory Commission Cooperative Severe Accident Research Project (CSARP) and MELCOR Code Assessment Project (MCAP), the SNETP (Sustainable Nuclear Energy Technology Partnership)/EURATOM initiatives such as SASPAM-SA, SEAKNOT and the ERMSAR Conference, as well as NEA and IAEA joint projects.

The approach builds knowledge and experimental/modelling capabilities to support development and assessment of SMR/AR regulatory/licensing requirements, and emergency planning and response. Considering the above strategy and international engagement, CNL can ensure its knowledge and capabilities meet the needs of its stakeholders (both industry and government) and can support the safe deployment of SMR/ARs in Canada. This paper updates previous overviews of CNL severe accident research on SMRs/ARs, [4] [5], discussing both experimental efforts, Section 2, and modelling, Section 3.

2. EXPERIMENTAL EFFORTS SUPPORTING SMR SAFETY

The experimental campaigns discussed in the previous overviews, [4] [5], have continued to progress and are focusing on a few major areas as identified in PIRTs. For water-cooled SMRs, it is the containment behaviour in integrated pressurized water reactors (iPWRs) and small BWRs, including passive systems. In the case of HTGRs, the focus continues to be on the potential for air ingress, as well as new investigations into pebble bed core heat transfer in accident conditions. Efforts with microreactors, especially heat pipes, are now progressing towards accident analysis. Finally, there are some minor continued efforts in fission product release and the self-heating behaviour in molten salts.

2.1. Water Cooled Reactor Experiments

Research on water-cooled SMRs focuses increasingly on passive safety features. CNL has examined containment behaviour, passive-system reliability, and the conditions that govern their success or failure. Earlier reviews summarized iPWR work [4] [5], which the latest experiments extend to small-BWR containment behaviour. Passive emergency-cooling loops rely on steam condensation on major heat sinks, with condensate returning by gravity. Condensation is most effective at high temperatures and low non-condensable content. Hydrogen produced during fuel-sheath oxidation, and air ingress both reduce heat-transfer coefficients and degrade passive-system performance.

These effects were studied in the Strong Condensation Containment Apparatus (SCCA) program [4][5]. Phase 1 (2021) investigated steam injection and wall heating in an iPWR-like vented annulus; Phase 2 (2022) added helium to simulate hydrogen-rich severe-accident conditions, with results reported in [6][7][8]. Phase 3 (2025) reconfigured the facility for a small-BWR passive containment cooling system (PCCS), using a heat-exchanger analog instead of a chilled wall. Both forced and natural PCCS modes were tested; passive cooling showed lower performance, but all tests produced the same characteristic stratified structure of a hot upper layer over a cooler under-layer. Data from all phases support the SASPAM-SA (Safety Analysis of SMR with Passive Mitigation Strategies – Severe Accident) collaboration on passive-system behaviour in water-cooled SMRs.

The most important thermalhydraulics observation for all three phases of the SCCA experiments (covering both iPWR and small BWR containment analogies) is the strong thermalhydraulic stratification seen with multi-gas mixtures, resulting in a hot upper layer and cooler under layer. The hot upper layer is strongly condensing, and the transition to the cooler layer is a sharp temperature gradient. The cooling capacity exceeds the energy input from the steam, and the condensation enhances the heat transfer coefficients (HTCs) significantly compared to natural convection. Heat transfer primarily occurs in the hot upper layer, the thickness of which is dictated by the energy balance of the steam injection and condensation. Phase 3 results confirmed this interpretation for the PCCS configuration. HTCs followed Dehbi-type correlations (Figure 1), increasing with steam concentration and decreasing with helium, with values ranging from ~600 W/m²·K in high-steam down to ~100 W/m²·K at high helium fractions. The HTCs for forced and natural PCCS modes are comparable, though natural circulation produced slightly higher gas temperatures.

When a light non-condensable gas like helium (or, in a reactor accident, hydrogen) is introduced, it does not separate from steam in the upper layer because of its buoyancy and instead dilutes the upper layer, reducing its effective heat-transfer coefficient and causing the layer to swell. The light gas also diffuses into the lower layer, where it can reach concentrations of 10–30%, which would have combustibility implications if it were hydrogen. The Phase 3 experiments confirmed these behaviours: helium accumulated strongly in the upper layer, reaching dry concentrations above 90% (nearly pure steam–He). The steam also migrated downward by diffusion and interface mixing, achieving wet concentrations of 10%-60% at the highest injection rates.

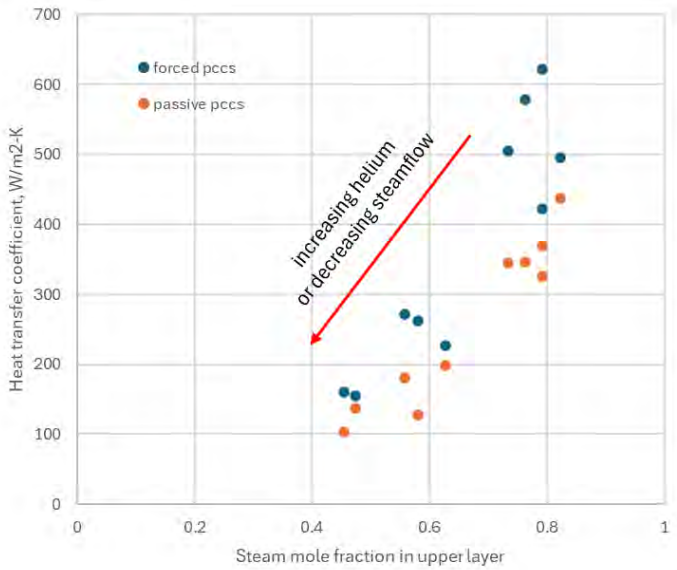

Figure 1. Experimental HTCs as a function of steam concentration in the hot upper layer, under both natural and forced convective flow conditions in PCCS. Results are preliminary

Aerosol transport is primarily diffusiophoresis, driven by steam condensation and turbulent impaction, both concentrated in the hot upper layer. Stratification limits aerosol deposition area and creates an evaporative barrier promoting re-entrainment of aerosols back into the hot upper layer, keeping concentrations in this region high. Phase 3 measurements of turbulence and droplet characteristics supported this picture, where the steam–gas interface remained stable at 2–2.6 m elevation, with suppressed vertical velocity and minimal turbulent kinetic energy (TKE). Above the interface, TKE was much higher, and the droplet size distribution (GSD) was broader, consistent with the vigorous condensation-cloud region observed in all phases.

The next stage, SCCA testing, Phase 4, will continue to explore the PCCS configuration for a small BWR, but will shift perspective upward in containment to look at a bottom injection of steam with a cold heat structure at the top of the volume, along with the PCCS heat exchanger on the side wall. This configuration is commensurate with the top section of a small BWR containment where the containment upper head is cooled by the PCCS pool. In addition, accompanying benchmark modelling of these Phase 3 and 4 PCCS tests will be conducted with CFD, containment (GOTHIC) and severe accident (MELCOR) codes.

With the completion of the four SCCA experimental phases covering both iPWR and small BWR containment configurations, and the accompanying modelling and benchmarking activities, the next stage of the program will shift towards the investigation of the passive Isolation Condenser System (ICS) of a small BWR. This work will extend the experimental foundation established in the SCCA campaigns by examining heat transfer, condensation behaviour, and non-condensable gas effects within a tube-bank configuration directly analogous to the ICS. The SCCA derived experiments may also be paired with other experimental apparatus focused on different aspects of the ICS to provide additional dimensions of investigation and data to better understand the phenomena related to ICS operation.

Regarding late stages of severe accidents, CNL's Cold Crucible Induction Furnace (CCIF) enables high temperature synthesis and rapid quenching of corium materials, supporting studies of phase behaviour, melt miscibility, stratification, and chemical interactions with structural materials [9]. Designed for ~2 kg charges containing depleted or natural uranium, the facility can reach temperatures above 2,300 °C and produces resolidified corium samples suitable for the determination of mechanical properties and developing and validating thermodynamic databases such as TAF-ID. While the CCIF has been extensively applied to

CANDU corium, recent work has produced the first corium representative of Accident Tolerant Fuel (ATF) concepts using FeCrAl cladding—an important development for SMR and advanced reactor safety. Thermodynamic analysis indicates that FeCrAl must be partially oxidized for significant interaction with UO_2 to occur, including dissolution and formation of eutectic phases; therefore, the experiment required a high oxidation ratio, using FeCrAl that was 70% oxidized. This charge was successfully melted, reaching 2,417 °C and yielding high quality in vessel UO_2–FeCrAl corium. Pictures of the charge before and after melting are presented in Figure 2. Currently under characterisation, these pioneering samples will support validation of ATF thermodynamic models and open the door to future experimental programs on melt stratification, vessel material interactions, and even ex-vessel systems such as UO_2–FeCrAl–concrete.

Figure 2: FeCrAl-UO_2 in-vessel corium produced at CNL's CCIF (right), and samples recovered after test (left). Stratification of a metallic phase was observed.

2.2. High Temperature Gas Reactor Experiments

The focus of HTGR experiments at CNL for severe accidents is on the behaviour of the heat transport system under accident conditions and investigations into the heat transfer behaviour of a pebble bed core. Regarding the heat transport system, investigation has been focused on the transition from stagnant flow conditions to bulk natural circulation of air within the core after a break of the helium pressure boundary. It is difficult to reliably predict the timing of this transition, referred to as the onset of natural convection (ONC), and the potential for air interacting with hot graphite (resulting in graphite oxidation) makes this an important event. This ONC phenomenon and its potential impact of air flow on the graphite oxidation rate was studied in the Helium-Air Natural Convection (HANC) experiment. The HANC experimental apparatus geometry resembles an inverted letter "U" that models the coolant flow path within the pressure vessel of a modular HTGR. This shape/configuration is consistent with other apparatus used to study air ingress phenomena found in literature. HANC is set apart from previous studies as it is the full core height of some small modular HTGR concepts (3 m) and was designed to go up to typical operating temperature (700°C).

The structure of the HANC apparatus was primarily 3" Schedule 40 316 stainless steel pipe with welded elbows to create the "U" shape. The principal regions of the HANC apparatus (Figure 3) were: (i) hot leg – the side of the inverted "U" that operated at the highest temperature, (ii) cold leg – the side of the inverted "U" that operated at the lowest temperature, (iii) upper plenum – the section of pipe that connected the hot and cold legs, (iv) lower head – connected the cold leg to the environment through openings with removable seals, and (v) lower plenum – connected the hot leg to the environment also through openings with removable seals. The upper plenum, lower head, and lower plenum were named after the corresponding regions of a modular HTGR that they represented. The pipe forming the inverted "U" was electrically heated with clamp-on band heaters. Custom-formed tubular heaters were also placed inside the lower head and lower plenum. The primary measurements were of surface and gas temperatures.

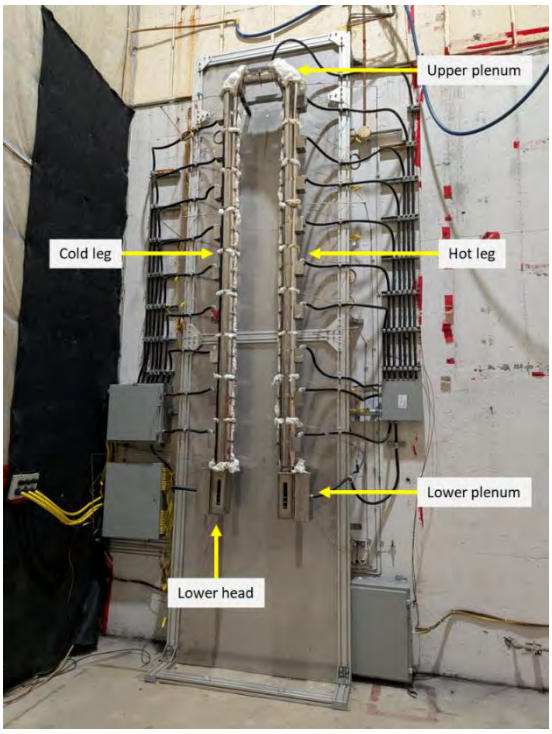

Figure 3. Annotated photograph of the HANC apparatus.

The first HANC test series (HANC-1) was completed in December 2025/January 2026, where ONC was measured in a range of test conditions (200°C to 300°C on the cold leg and 400°C to 700°C on the hot leg). Also studied were variable opening orientations (horizontal and vertical) in the lower head and lower plenum to represent different gas duct and break orientations in modular HTGRs. The measurement data will be used for future model benchmarking with computer codes like RELAP5, GOTHIC, and MELCOR. Refinements to the HANC apparatus are being considered for a second test series (HANC-2) in future years.

The second experimental program at CNL focused on HTGR, which relates to experiments on heat transfer and flow in a Pebble Bed (PB) core, under normal operation and accident conditions (natural convection). The PB-HTGR typically utilizes a discrete bed of fuel elements (pebbles) reactor core, where the pebbles are ~6 cm spheres of pyrolytic graphite matrix comprising thousands of tristructural-isotropic (TRISO) fuel (^{235}U) particles coated with silicon carbide. These pebbles continuously move (flow) through the reactor core, and spent fuel is continuously replenished. The modes of heat transfer in HTGR cores involve convection to the coolant gas (typically helium), radiation between the pebbles and to the gas, and conduction between contacting pebbles. In a molten salt cooled PB reactor, the primary mode of heat transfer is only convection to the salt and conduction between the pebbles. The present work focuses on PB-HTGR cores, while the results are generally extensible to other PB reactor cores.

The current iteration of the Pebble Bed Experiments for Analysis of Core Heat transfer (PebbleBEACH) facility at CNL considers stationary pebbles for the purposes of generating steady state data for model development and code validation. Photographs of the PebbleBEACH facility are shown in Figure 4. These experiments are similar to the SANA [10] experiments performed in Germany in the mid 1990's (which involved stationary graphite pebbles heated by 5 cylindrical graphite heaters placed vertically inside the core), with additional measures to evaluate the individual contributions of surface radiation, convection, contact conductance, and the impact of internal heat generation (as opposed to external heating) in the pebbles, on core heat transfer. Individual contributions of radiation, convection and contact conductance are

correlated using different pebble materials and surface emissivities, while internal heat generation is simulated using pebbles with impregnated heaters. Other experiments, such as those at UC Berkley [11], had considered inductively heated spheres at smaller scales for simulating internal heat generation. The pebbles considered for the first series of experiments performed at CNL in 2025, shown in Figure 4, are polished stainless steel with an emissivity <0.1. These experiments involved external heating, reactor scale pebble sizes, and dimensionless properties for the coolant and flow consistent with normal operations.

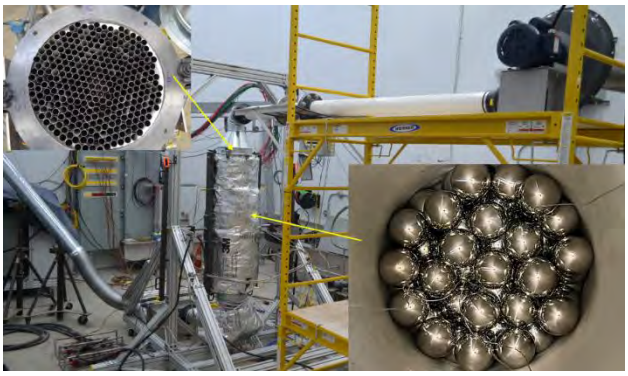

Figure 4: Photograph of the PebbleBEACH facility at CNL

The third component of the HTGR experiments relates to the characterization of dust generation for graphite pebbles in PB-HTGR. Due to the numerous interactions and friction resulting from the continuous movement of pebbles through the core and contact with each other and the reactor internals, PB-HTGRs are expected to produce a significant amount of graphite dust during operation. This is an important source term for safety evaluations as well as a phenomenon critical for evaluating accidents due to the pyrophoric nature of fine graphite under sufficiently small particle sizes. The Pebble bed Aerosol Generation Experiments (PAGE) at CNL will involve accelerated frictional deterioration of the reactor scale pebbles, resulting in dust production and characterization. This facility is currently under the conceptualization stage.

2.3. Heat Pipe Experiments

A newer area of interest based on the deployment landscape is that of microreactors, and in terms of severe accidents, there are interesting research areas being explored. In a general sense, the extent of analysis needs is being evaluated as the size, and potential source terms of these designs are much different from a large reactor or SMR. A microreactor related technology of interest that is being explored for normal operations and accident conditions is a heat pipe cooled reactor design.

Heat pipe reactors (HPR) are commonly configured as a core block with numerous fuel channels interspersed with many coolant channels, not dissimilar to the core block of a HTGR. However, the coolant channels in HPRs comprise heat pipes that passively remove heat from the core block through natural circulation of the sealed alkali metal working fluid within the tube. Thus far, heat pipe reactors are microreactor concepts often targeted for remote deployment with fully- or semiautonomous operating modes. In these scenarios, complete failure of 5% of the heat pipes is a credible failure ratio based on probabilistic safety assessments for a design basis scenario [12]. Heat pipe experiments have been operated at CNL to study alkali-metal heat pipe behaviour under startup, operational transients, and off-normal transients for nuclear reactors. Building upon a series of fundamental studies conducted at CNL using the AHPAT single heat pipe testing apparatus with sodium and potassium as the working fluid [13][14], a multi-heat pipe array AHPAT testing system was developed with five parallel sodium heat pipes operating in vertical orientation and rated at 50 kW, resembling a reactor core block configuration. This apparatus has

been used to look at scenarios beyond the design basis with the potential to progress into severe accidents, where a 20 to 60 % failure rate of heat pipes (simultaneous failure) was investigated with simultaneous delay of activation of shutdown systems (i.e. full power maintained) [14]. The tests were performed with a nominal heat pipe operating temperature of 550°C and an average core-block temperature of 750°C, and the delay in the activation of shutdown systems was 1 hour. For the case with 60% heat pipe failure, the temperature of the failed heat pipes quickly increases to match the core-block temperature within 5 minutes (i.e. 200°C temperature increase). The core temperature remains relatively constant for ~35 minutes and then increases at a rate of up to 250°C/hr over the rest of the transient before activation of shutdown systems is simulated by reducing the power. Future studies with the AHPAT multiple heat pipe scenarios include extension of scenarios identified in MELCOR assessments on accident progression in HPRs [15], such as reactivity insertion during normal operation but with a high failure rate of heat pipes and a 1-hour delay in shutdown rod insertion. CNL is also in the process of scaling up the AHPAT multiple heat pipe apparatus to higher power with more heat pipes to improve the correlation of experimental results to postulated reactor scenarios.

2.4. Molten Salt Reactor Related Experiments

CNL has conducted experimental work focused on molten salt characterization, production capabilities, and on fission product release under severe accident conditions, as discussed in the previous overviews [4] [5], as well as associated molecular dynamics modelling to study fission product behaviour in molten salts. These efforts position CNL well to address MSR related issues that emerge as the deployment of this technology advances. In terms of severe accident research, recent efforts have focused on completing confirmatory experiments on the conversion of UO_2 to a UF-based fluoride/fluoride-chloride molten salt, using depleted uranium, to provide further data to augment the results and conclusions of the previously conducted fission product release experiments [4]. When these confirmatory studies are completed, CNL molten salt severe accident research related to fission product behaviour will reach an appropriate baseline, and further efforts will be paused until emerging research needs are identified by stakeholders.

One other area of MSR related research that is being explored is the volumetric heat generation in core, which includes the development of ‘scalable’ experimental capability for self heating fluids for use in natural circulation loops to simulate MSR cores. Several natural convection loops are available at both CNL and at external laboratories, including Massachusetts Institute of Technology (MIT) and Centrum výzkumu Řež (CVR), for the simulation of molten salt flow and heat transfer in MSR cores. Experimental facilities involving forced circulation of molten salt are not common, due to challenges in identifying pumps and other flow control components that are compatible with molten salts at high temperatures, which are notoriously corrosive. Molten salt loops at CNL and other organizations typically employ heating of the channels through which the salt flows (i.e., indirect heating of the salt). In fuel salt MSR cores, however, heat is generated volumetrically inside the coolant. The molten FLiBe or FLiNaK type salt carries uranium fuel in the form of UF_4, which fissions when it passes through the moderated portion of the core loop. Temperature distributions and associated flow could be distorted due to indirect heating techniques, especially during natural circulation.

Several techniques for introducing volumetric heat generation in molten salts have been considered in the past. These include induction heating with salt simulants with added dopants, microwave heating and Joule heating. While both microwaves and induction can heat volumetrically, the scalability of these techniques beyond just one or a few channels is not practical due to the loss in penetration depth of the induction or microwave fields. Additionally, the introduction of heating in moderator region (usually a graphite block) close to the fuel channel is non-trivial. After critically examining various strategies for a potential scalable apparatus, introduction of volumetric heating of salts using the Joule heating technique was determined to be most practical. However, challenges related to electrolysis (due to application of high voltages), corrosion and the presence of electrically live fluid in the loop, and non-conductive materials suitable for high

temperature operation, will need to be resolved. The test apparatus used for ongoing experiments for joule heating of simulant molten salts is shown in Figure 5. These experiments are intended towards the investigation and mitigation of corrosion and electrolysis (by applying suitable voltage waveforms), material compatibility (high temperature plastics suitable for use with FLiBe and FLiNaK loops) and alternative (to thermocouple) local temperature measurement instrumentation, and their scalability for the development of larger loops.

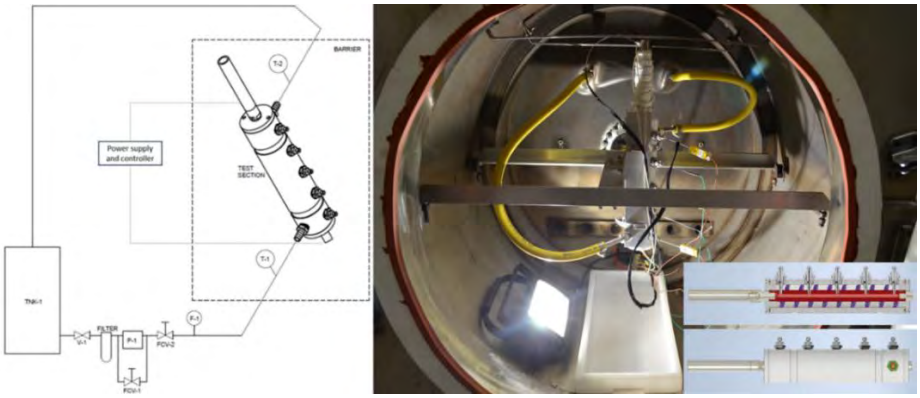

Figure 5: Depiction of the joule heating apparatus for MSR core heat transfer experiments

3. SEVERE ACCIDENT MODELLING AND ANALYSIS EFFORTS FOR SMR

CNL is conducting both full reactor and experimental apparatus benchmarking, modelling and analysis efforts to increase knowledge and expand capabilities for integrated severe accident analysis and source term calculations for a variety of SMR/AR designs. Experimental benchmarking is focused on the SCCA experiments for iPWR containment configurations, but will be extended to new experiments for small BWR PCCS and for HTGR air ingress (HANC) configurations. Integrated reactor analysis is being conducted for several SMR designs using the MELCOR code, including generic iPWR, small BWR, pebble bed HTGR, and SFR. These analyses do not contribute to licensing yet, but focus on building capability and exploring the important phenomena and systems involved in severe accidents in each reactor technology.

3.1. Water Cooled Reactor Analysis

CNL efforts in modelling of water cooled SMRs have focused on iPWR and small BWR, which represent the major designs being deployed. Given the strong reliance of these designs on passive safety systems, the overall focus of these models has been on quantifying the impact that disruptions of passive safety systems have on severe accident progression and source term generation. The primary tool for this has been MELCOR, and as introduced previously [4] [5], CNL has developed reference models for both a generic iPWR design and a generic small BWR design. These efforts are part of CNL's contributions in the EU SASPAM-SA project, including MELCOR analysis of both iPWR (SASPAM-SA design 2) and a generic small BWR (design 3). CNL is contributing a generic small BWR model to SASPAM-SA to support analysis by the other participants and eventual benchmarking to CNL results.

The recent developments of CNL water cooled SMR analysis have been captured in publications in the recent NUTHOS-14 Conference (2024 August) for iPWR [16] [17] and small BWR [18]. The finalized models for iPWR and small BWR are now being used in more detailed studies to assess the performance/impacts of passive systems and understand accident behaviour over a variety of conditions. The iPWR studies were extended across many scenarios to build the understanding needed to support

emergency planning and operation intervention levels [5] [16] [17]. The generic small BWR MELCOR model, introduced in [5], was completed, and analysis of common accident scenarios was conducted, including station blackout accidents (SBO) and loss-of-coolant accidents (LOCA) involving ICS and/or PCCS impairment to varying degrees. The analysis indicated that in the SBO case, significant impairments (e.g., 100% losses in ICS and/or PCCS) were required for any fuel damage to occur [18]. For the SBLOCA cases, the small break was placed 2.5 m below the top of the active fuel to determine the impact of fuel failures on passive safety performance. The results showed that non-condensable gases, such as hydrogen generated through oxidation of hot cladding material, would migrate into the passive ICS, cause a blockage in flow, and diminish the heat removal capability, causing a positive feedback loop of fuel degradation [18].

Another important recent effort was a phenomena identification and ranking table (PIRT) for design extension conditions in the BWRX-300 small modular reactor, which was delivered to the CNSC. With one licensing assessment already underway for the Darlington New Nuclear Project, and the prospect of several more to be initiated in the near future, the CNSC requested expert support and consultation from CNL. Design extension conditions are a subset of beyond-design basis accidents considered in the design of a facility that could include some severe accidents. Using only open-literature information, a panel of CNL subject matter experts from across the Science & Technology organization developed the PIRT to identify knowledge gaps that could be used as the basis for planning a future research & development program supporting BWRX-300 safety and licensing. The generic small BWR MELCOR model was also used to conduct an analysis that supported this PIRT effort.

Continued efforts in severe accident uncertainty and sensitivity (U&S) analysis included using the generic small BWR MELCOR model in a MELCOR-DAKOTA coupled code analysis, implementing the Wilks method [19]. The analysis explored 19 input parameters with 124 simulations and tracked hydrogen generation (Figure 6) and radionuclide releases for the same SBLOCA case performed in the previous best-estimate simulations [18]. The uncertainty analysis modelling framework builds on the foundation for CNL's small BWR severe accident uncertainty analysis knowledge and expertise and will be used to support future severe accident uncertainty and sensitivity analyses.

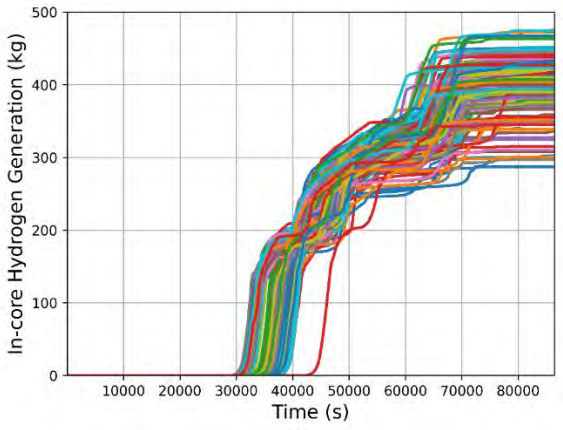

Figure 6: Generic Small BWR Uncertainty Analysis Total H2 Generation over the Transient

In addition to the full reactor modelling and analyses, benchmarking studies of the SCCA experiments, discussed in Section 2.1, for passive safety systems have been performed using MELCOR and the more detailed thermal-hydraulic code GOTHIC to ensure that phenomena are appropriately captured [20]. Benchmarking of the SCCA Phase 1 and 2 iPWR focused experiments with MELCOR and GOTHIC showed that accurately reproducing this stratification was essential. The MELCOR 3×3 model matched the

experimental profiles reasonably well at intermediate injection rates (6–10 g/s) but performed less accurately at low and high flow rates. The finer 6×3 nodalization did not consistently improve results and often underestimated the steam-layer thickness. GOTHIC, using 30 vertical zones, more reliably captured the two-layer structure and demonstrated the importance of sufficiently detailed vertical nodalization; treating the SCCA as a lumped or overly coarse volume could not reproduce the experimental behaviour. This stratification also governed aerosol transport. Buoyancy suppressed vertical mixing, confining droplets to the steam-rich upper layer, an effect captured in both codes. Deposition occurred primarily in this region, making leak-path elevation important for source-term assessment. Diffusiophoresis was identified experimentally as the dominant deposition mechanism, with turbulence providing a secondary contribution. At higher steam injection rates, discrepancies between experiments and GOTHIC predictions grew due to limitations in its turbulence modelling, while MELCOR's restriction of the steam layer to only the top control volumes led to underprediction of its thickness.

Overall, the SCCA Phase 1 and 2 tests and associated modelling provided valuable insight into thermalhydraulic and aerosol behaviour in submerged containments relevant to iPWR. The benchmarking exercises showed that MELCOR and GOTHIC can capture many key behaviours but also highlighted limitations related to nodalization, stratification, turbulence, and particle transport. These findings support the need for complementary CFD analyses incorporating advanced turbulence and droplet-transport models to better reproduce the complex flow patterns observed in the tests. A more detailed CFD analysis of the Phase 1 and 2 tests is upcoming, as well as future benchmarking of MELCOR and GOTHIC against the updated SCCA Phase 3 and 4 tests focused on small BWR PCCS operation.

3.2. HTGR Analysis

The CNL MELCOR model of a 200 MWth pebble bed HTGR, discussed in [5], has been used to simulate a severe air-ingress accident (also referred to as the depressurized loss of forced circulation, DLOFC) by imposing a simultaneous guillotine break of the co-axial inlet/outlet pipe that connects to the RPV [21]. A detailed nodalization was developed to better capture air-ingress into the vessel, and the results indicated a relatively short air-ingress period on the order of 4 hours and elucidated the role of the onset of natural circulation on the graphite oxidation during the accident. These simulations reinforced the importance of the onset of natural circulation phenomena and the need for experimental analysis with the HANC apparatus, as discussed in Section 2.2. The HTGR severe accident model has also been used in uncertainty and sensitivity analysis using the MELCOR-DAKOTA coupling and implementing the Wilks method. The simulations explored the impact of 11 uncertain input parameters on key figures of merit during the DLOFC transient scenario, such as peak fuel temperature (to determine the margin to TRISO fuel failure limits), ONC timing (to determine the onset of significant graphite oxidation), and radionuclide release over 124 simulations. The analysis and results are complete and submitted for publication.

3.3. SFR Analysis

As part of developing baseline capabilities for SFR analysis and considering the planned deployment of the ARC-100 SFR in New Brunswick, CNL is exploring SFR related severe accidents and source terms analysis. A generic SFR model was developed in MELCOR using a literature review of past and present SFR designs to simulate the unprotected loss of flow accident (ULOFA) and unprotected transient overpower accident (UTOPA) for a generic 250 MWth pool-type SFR. The best-estimate analysis was carried out for each scenario (an example output is shown in Figure 7, left), with an uncertainty and sensitivity analysis carried out by simulating 60 input decks for the ULOFA scenario, with the reactivity coefficients used as uncertain input parameters tracking FOMs of coolant boiling margin, clad melting temperature margin, and fuel melting temperature margin (an example output for fuel melting margin under a ULOFA is shown in Figure 7, right). With this baseline model developed and the initial analysis accomplished, further efforts will be considered based on the deployment landscape of this technology in Canada.

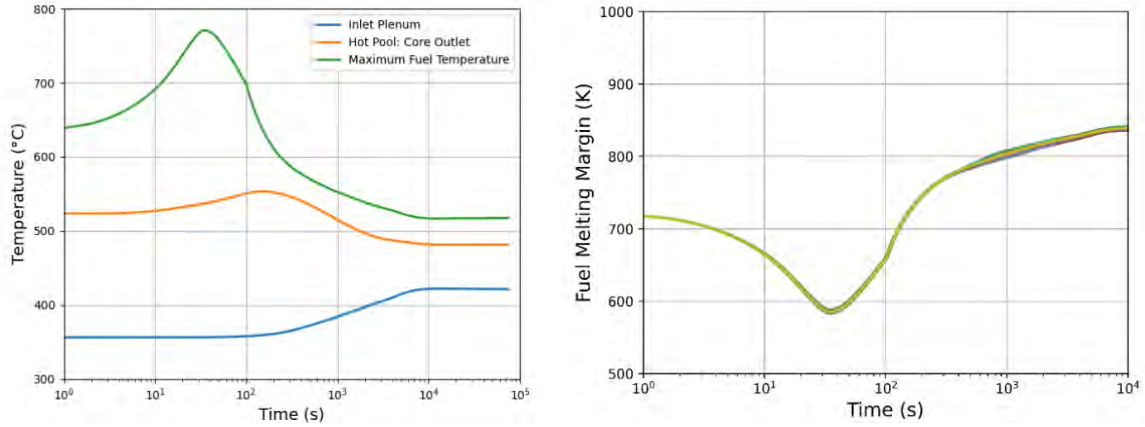

Figure 7: Temperature transient behavior during a best-estimate ULOFA simulation (left) and horsetail plot of fuel melting margin under a ULOFA for 60 simulations.

3.5. Severe Accident Uncertainty and Sensitivity Capabilities

CNL is, and has been, developing capabilities in severe accident uncertainty and sensitivity (U&S) analysis, as discussed in [4] [5]. CNL's participation in the IAEA Coordinated Research Project (CRP) I31033 – "Advancing the State-of-Practice in Uncertainty and Sensitivity Methodologies for Severe Accident Analysis in Water-Cooled Reactors" (2019-2023) [22], went well and focused on MAAP-CANDU severe accident and SUSA uncertainty analysis for CANDU severe accident U&S [23]. This analysis is captured in a paper to the Journal of Nuclear Technology and will be published soon [24]. The analysis methods and knowledge developed during the CRP have been leveraged to perform other uncertainty analyses on other CANDU severe accident variations, as well as non-CANDU type reactors, including SMRs. CNL also seeks to build on the international collaboration under the IAEA CRP through exploring, in more detail, the results from the CANDU portion of the CRP—particularly hydrogen releases—and aims to organize a form of international workshop between the CANDU focused CRP participants (namely CNL, KAERI, and UPB) to identify and potentially improve computer code models for CANDU severe accidents.

Parallel to the MAAP-CANDU and SUSA uncertainty analysis, developments have been made with the MELCOR severe accident code and the DAKOTA uncertainty analysis package. These developments include the development of a Python-based coupling of the two codes and deployment on the CNL ATHENA high-speed computing cluster. This framework has been applied to several small modular reactor severe accident analysis models, including the small BWR, pebble bed HTGR, and the SFR model, as discussed in the previous sections. The MELCOR/DAKOTA coupling is currently the preferred tool for non-CANDU analysis, but the applicability of SUSA will be explored in the future. In previous analysis, the MELCOR-DAKOTA uncertainty analysis framework used the Wilks method, but it has recently been expanded to use other methods, including variable importance measurement through the Morris method, as well as applying correlational structures (as opposed to only simple independent random sampling) using the Iman-Conover method. This has been accomplished through custom Python scripts combined with the DAKOTA uncertainty analysis package. Python analysis scripts have also been developed to better elucidate data patterns and facilitate simpler and more robust data analysis by providing scatterplots of raw data, as well as the residual plots that determine the partial correlation coefficients and simple regression coefficients. The capabilities developed at CNL, and efforts to assess the U&S for severe accident calculations for several reactor technologies, position CNL well to make significant contributions to international efforts and identify improvements for severe accident computer code modelling.

3.6. Emergency Planning Zones

CNL is building on previous work in emergency planning zones (EPZs), discussed in [4] [5], including participation in the IAEA CRP on SMR EPZs and the associated technical document, as well as CNL's own studies on challenges related to SMR EPZs and a framework for EPZ sizing. CNL is at the forefront of using high-fidelity computational fluid dynamics (CFD) simulations to study atmospheric dispersion of radionuclides in complex semi-urban environments [25]. As SMRs are expected to be deployed closer to end users in urban settings, CNL has advocated incorporating CFD into the existing suite of Gaussian and Lagrangian particle dispersion models to reduce excessive conservatism in EPZ sizing [26]. CNL is also supporting the ongoing development of EPZs for iPWR designs in the SASPAM-SA collaboration.

4. CONCLUSIONS

New nuclear deployment in Canada is accelerating to meet clean energy goals, and CNL is supporting safe deployment through robust reactor safety research. CNL capabilities and knowledge are developed to align with the SMR/AR deployment landscape in Canada and support both industry and regulatory stakeholders. Reactor safety and severe accident research, in particular, has and is further developing base capabilities for the range of popular SMR/AR technologies and pursuing deeper expertise for the key technologies nearing deployment. This flexible program allows research gaps to be identified and addressed through experiments and modelling to provide knowledge and data that are needed to support safety analysis reports and licensing reviews.

Severe accident research at CNL is focused primarily on water cooled SMR containment behaviour, especially for small BWRs, passive system reliability and performance in severe accident conditions and integral accident analysis to compute potential radionuclide source terms. HTGRs are another near deployment technology of interest, and CNL has developed experiments in core heat transfer, heat transport system onset of natural circulation, and is working towards confinement phenomena. Integral severe accident analysis, along with uncertainty and sensitivity assessments provide insight on HTGR accident behaviour and helps to refine experiments. An area of active research development moving beyond normal operations into accident conditions is heat pipe reactor cooling systems utilized in microreactors. The baseline capabilities in SFR integral analysis, and understanding molten salt reactor designs, especially focused on fission product behaviour and simulating self heated cores, positions CNL to move deeper with ease should the deployment of these technologies accelerate. CNL's research program is enhanced through international participation in joint projects under NEA, IAEA and EU, as well as with the GIF working groups. It is also enhanced through knowledge sharing in major conferences, especially ERMSAR. The reactor safety and severe accident research program continually evolves to address identified gaps, generate knowledge to address regulatory and industry stakeholder needs and support safe deployment of new nuclear in Canada.

ACKNOWLEDGMENTS

Much of the work discussed herein and CNL participation in various international working groups, projects and initiatives is funded through the Atomic Energy of Canada Limited (AECL) Federal Nuclear Science and Technology Program.

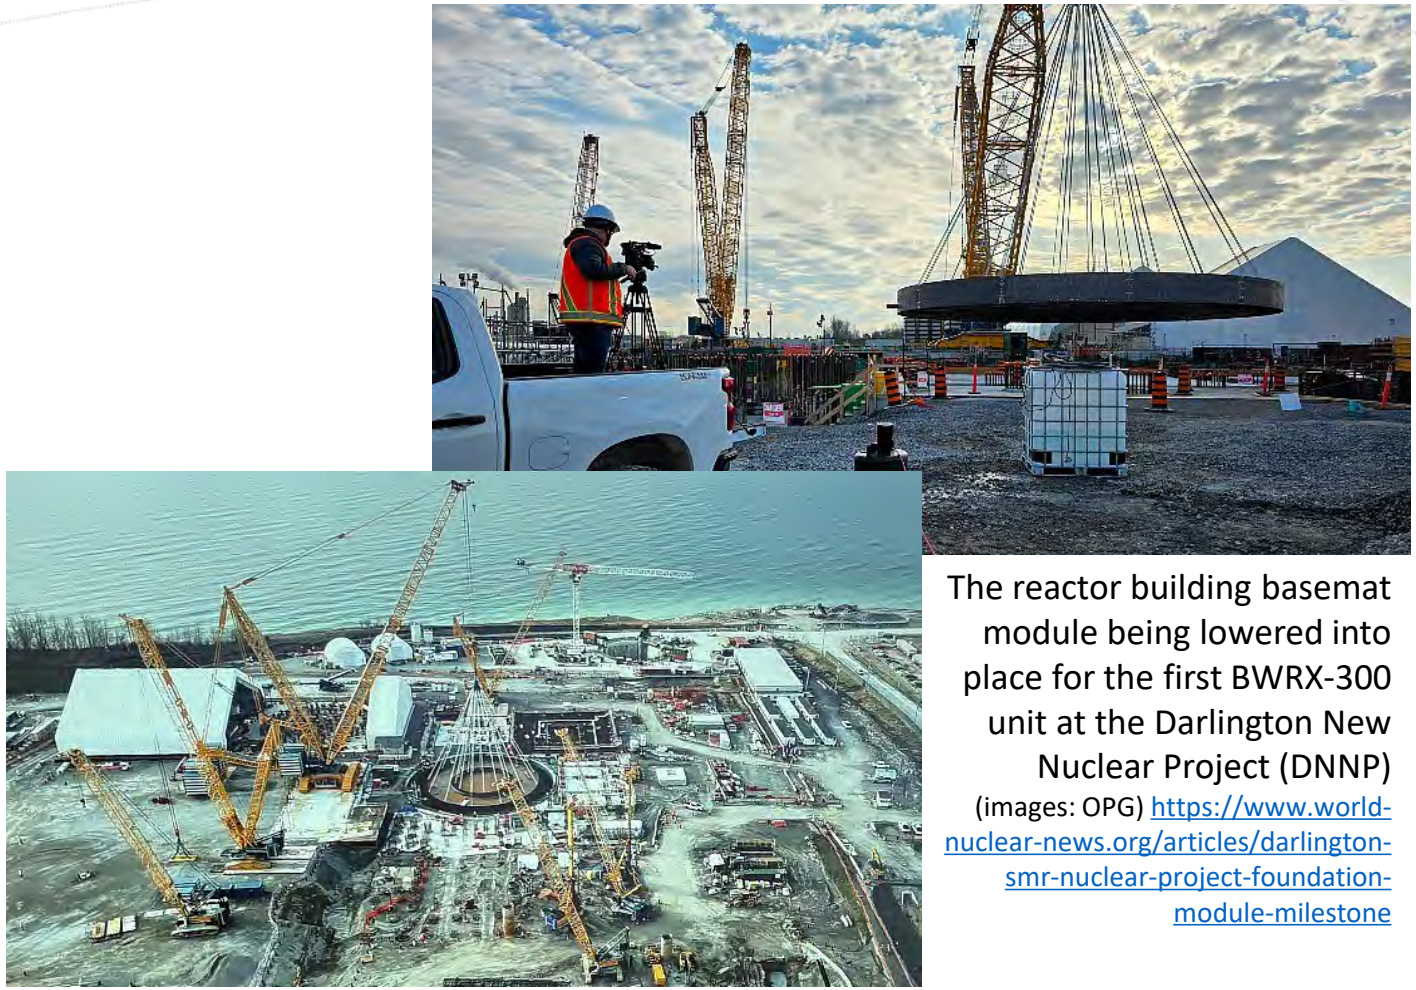
CNL Severe Accident Analysis Research to Support Safe Deployment of Small Modular and Advanced Reactors

Andrew C. Morreale*, Garik Patterson, Luke S. Lebel, David W. Hummel, Chuk Azih, Eric D. Jia, Abishek Sridhar, Ernesto Geiger.

Canadian Nuclear Laboratories (CNL)



The reactor building basemat module being lowered into place for the first BWRX-300 unit at the Darlington New Nuclear Project (DNNP) (images: OPG) https://www.world-nuclear-news.org/articles/darlington-smr-nuclear-project-foundation-module-milestone

The 12th European Review Meeting on Severe Accident Research (ERMSAR-2026), Madrid, Spain, May 18-22, 2026

Outline

- Introduction
  - Updates on SMR and large reactor deployment in Canada
  - CNL Reactor Safety/Severe Accidents Research Program and Strategy
- Experimental Efforts
  - Small BWR PCCS experiments
  - Corium production in the CCIF
  - HTGR Experiments: Helium-Air Natural Convection, and Pebble Bed Core
  - Heat Pipes
  - Molten salt experiments
- Modelling Analysis
  - Water cooled reactor analysis
  - Advanced reactors (HTGR and SFR)
  - Severe accident Uncertainty and Sensitivity
- Conclusion

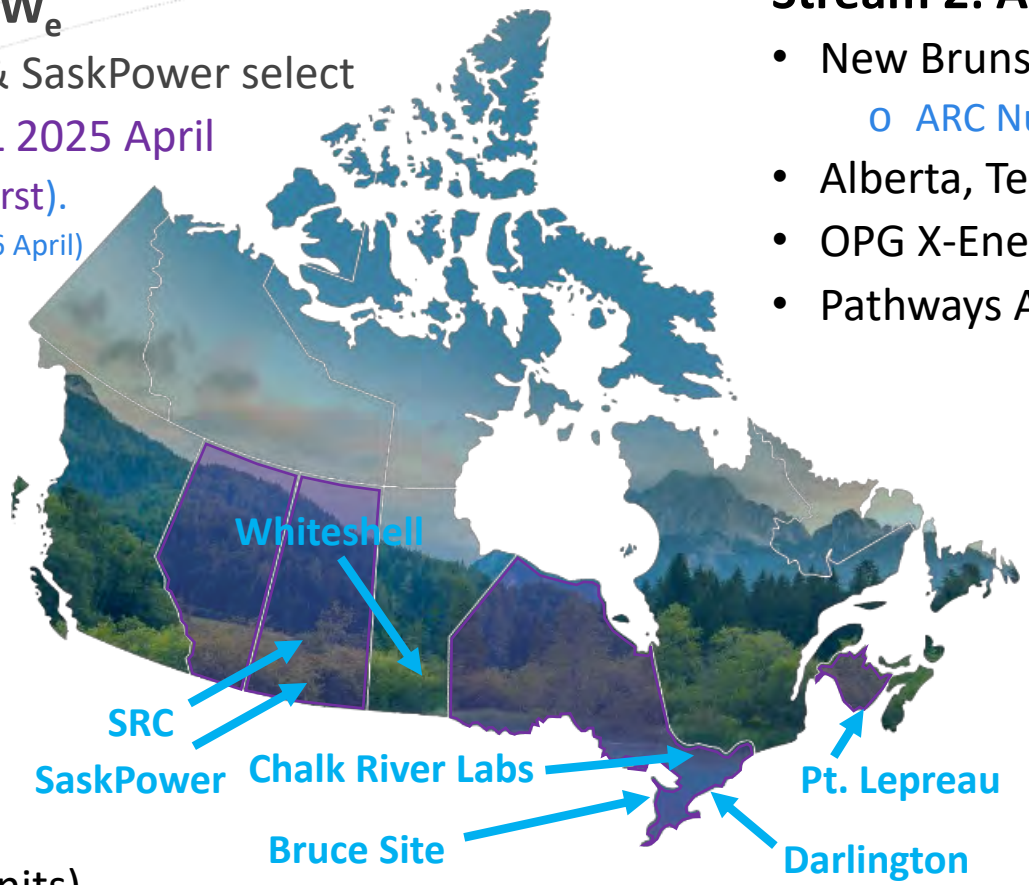
New Nuclear Deployment Landscape in Canada

Stream 1: On-Grid, ~300 MW_e

- Ontario Power Generation & SaskPower select GE-Hitachi BWRX-300: 1st CL 2025 April
  - Darlington 4 units (2029 first).
    - U1 containment base (2026 April)
  - SK 4 units (2034-2042)
- Alberta
  - SMART MOU
  - OPG & Capital Power

Large Nuclear

- Refurbishments:
  - Darlington complete;
  - Bruce MCR going well
  - Pickering B (planed 2028)
- Bruce "C" = 4800MWe
- OPG Wesleyville siting (10 units)
- AtkinsRéalis 1,000 MW CANDU® MONARK™



Stream 2: Advanced Reactors

- New Brunswick Power, Point Lepreau
  - ARC Nuclear ARC-100, LTPS submitted; Moltex SSR-W
- Alberta, Terrestrial Energy MOU
- OPG X-Energy framework agreement
- Pathways Alliance

Stream 3: Off-Grid, <15 MW_e

- Canadian Nuclear Laboratories
  - Global First Power (NANO Nuclear)
- McMaster University/GFP MOU
- Saskatchewan Research Council (SRC) searching for options instead of eVinci
- AECL Nuclear Battery/SLOWPOKE RFEOI
- DND/DRDC Microreactor interest for nuclear in the north

Government efforts:

- Federal SMR Roadmap/Action Plan; AECL/CNL microreactor framework (in progress)
- Canadian Nuclear Safety Commission (CNSC) pre-licensing vendor design review
  - 11 SMRs; 3 large reactors

Canadian Nuclear Laboratories | Laboratoires Nucléaires Canadiens

CNL Reactor Safety Overview

- CNL is Canada's premier nuclear science and technology organization
  - Supporting government research priorities, regulatory and industry stakeholders, and representing Canada (with CNSC and NRCan) in the international community.
  - Flexible technical research program supports new reactor deployment and stakeholder needs
- Reactor safety = support current fleet + build capabilities/analysis for future fleet
  - Develop understanding of phenomena/technologies and build/expand modelling and experimental analysis capabilities. *Evolving research guided by Canadian deployment (interest, builds, CNSC VDRs).*
- SMRs and Advanced Reactors
  - Canadian SMR deployment landscape
  - Coolants: water, gas, sodium, molten salts (f/c) + micro-reactors (heat pipes)
  - Continually evolving research program
    - Initial base knowledge is expanded as technologies move towards deployment
- Current Fleet and New Large Builds
  - Large builds in Canada (selecting technologies)
  - R&D to explore emerging issues
  - R&D for current and future fleet
    - Focus on severe accidents to better understand accident progression, source term consequence and impact on emergency response.

CNL research is leveraged by international (NEA, IAEA, GIF) & bilateral cooperation + industry/vendor work

Reactor Safety and Severe Accidents

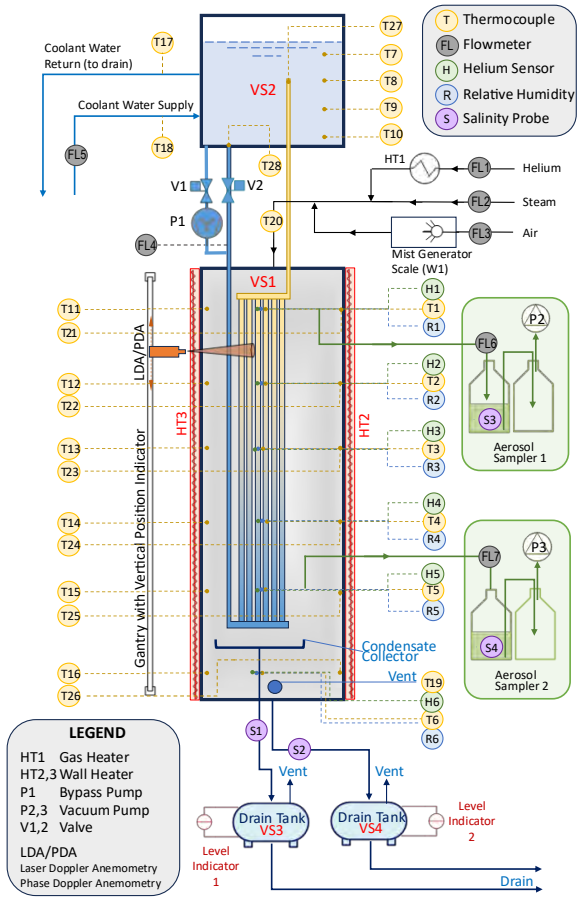
- Robust technical program supports SMR research, development, and deployment
  - Built upon decades of CANDU experience and recent efforts in SMR and Advanced Reactor analysis driven and refined by the Canadian deployment landscape as well as technology readiness level.
  - Advancing development of tools for multiple designs + focused research on near term deployment
- Severe accidents are a significant part of the reactor safety program
  - Phenomena Identification and Ranking Table (PIRT) activities: highlight knowledge gaps, set research
    - CNL experience in conducting and evaluating PIRTs related to SMR/AR
  - Experiments and modelling investigate gaps and better understand phenomena including special focus on severe accident scenarios, phenomena, progression and source term
    - Containment phenomena, fission product behaviour, passive safety features, integral assessment of generic SMR designs to evaluate systems/design features and impacts on source term and emergency response.
- International collaborations are key to reactor safety/severe accidents
  - IAEA CRPs (IVMR, Ex-Vessel, SA Uncertainty); US NRC's CSARP/MCAP
  - NEA joint projects (FACE, TCOFF-2, ROSAU, COPS, THEMIS, PANDA, WGAMA-CCVM, TAF-ID)
  - EURATOM/SNETP (key projects: SEAKNOT, IPRESCA, AMHYCO, SASPAM-SA, and ERMSAR conference)

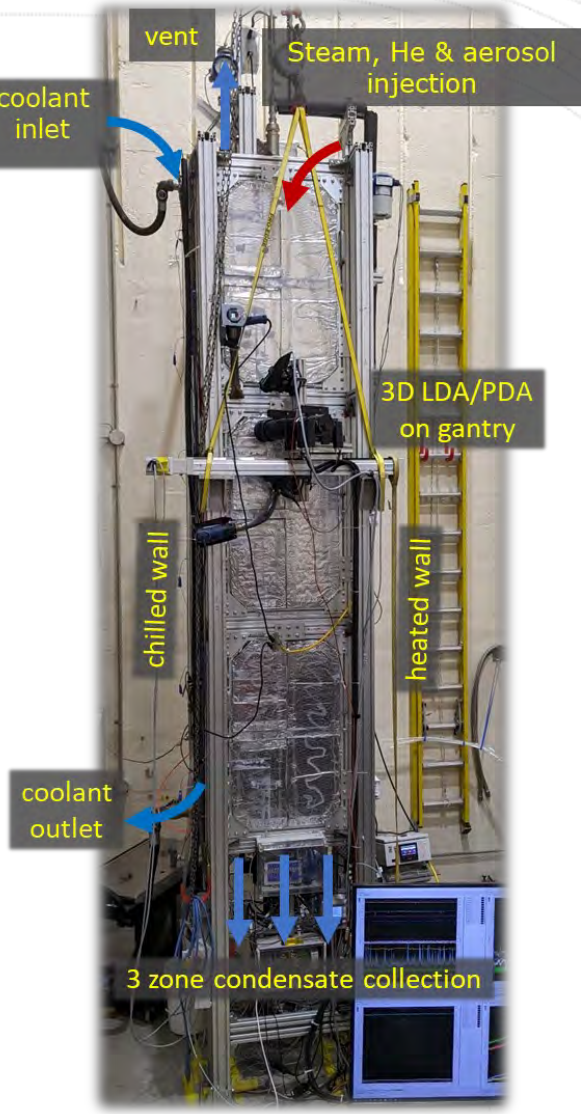
Experimental Campaigns

- Progression of tailored experiments to address research gaps, paired with benchmarking
  - PIRTs and previous campaigns have focused research in certain areas.
- **Water cooled SMRs:** pathways disrupting passive safety systems + source term impact
  - Natural circulation + effects of small and/or integrated containment on gas mixing and FPs
  - Benchmarking of the iPWR containment passive cooling experiments (condensation, leakage/air ingress) and the new small-BWR passive containment cooling system (PCCS) experiments
  - Late-stage severe accident investigation of corium materials in the cold crucible induction furnace
- **High temperature gas reactors:**
  - Air ingress and potential for graphite oxidation: **1st experiment on onset of natural circulation**
  - New investigations into pebble bed heat transfer in accident conditions
- **Heat pipes:** Progress in HP microreactor efforts to benchmarks and accident behavior
- **Molten salt designs:** some progression in fission product (FP) behaviour/retention in molten salts and new efforts in self heating experiments

SCCA Experiments: iPWR & small BWR Containment

- Experiments using the **Strong Condensation Containment Apparatus** (SCCA) aim to study detailed containment thermal-hydraulic and aerosol phenomena within a prototypical containment section.
  - Dimensions: 3.6 m high × 0.75 m wide × 0.40 m deep.
  - Operating Conditions (iPWR): 2 kW heated wall, ~10°C chilled wall, steam injection rates 2 to 15 g/s, and helium injection from 0-40%.
  - Aerosol Measurements: NaCl solution droplet aerosols tracked and collected at multiple locations to quantify aerosol transport.
  - Optical Diagnostics: 3D LDA/PDA employed to measure near-wall aerosol size and velocity distributions.
- **iPWR Phase 1** (March 2021): Investigated the influence of steam injection and wall heating in a vented vessel configuration.
- **iPWR Phase 2** (June 2022): Examined effects of He injection, relevant to the core damage phase where H_2 and radionuclides are co-released.
- **Small BWR PCCS Phase 1** (June 2025): New test using a passive containment cooling system (PCCS) heat exchanger (forced or natural circulation flows) similar to BWR containment (instead of chilled wall).
- **Small BWR PCCS Phase 2** (2026 planned): different location in containment (top of containment with cooled dome upper surface)





iPWR Experiments in the SCCA (2021 and 2022)

- **SCCA iPWR Experiments:** Combined thermalhydraulics and aerosol transport experiments for an immersed containment iPWR configuration
  - Experiments analogous to loss-of-containment isolation accident; LDA/PDA + salinity
  - Two distinct layers (hot upper layer and cooler under-layer) formed, whose thickness depends on steam injection rate and He, with suppression of HTC
  - Accumulation of hydrogen analog (He) in under-layer, forming flammable mixtures
  - Dense fog formation (deposition dominated by diffusiophoresis & turbulence)
  - 'evaporative barrier' forms between layers (traps aerosols in upper layer; effectively shuts off gravitational settling)
  - Tests run March 2021 (team injection and wall heating) and June 2022 (influence of non-condensables)

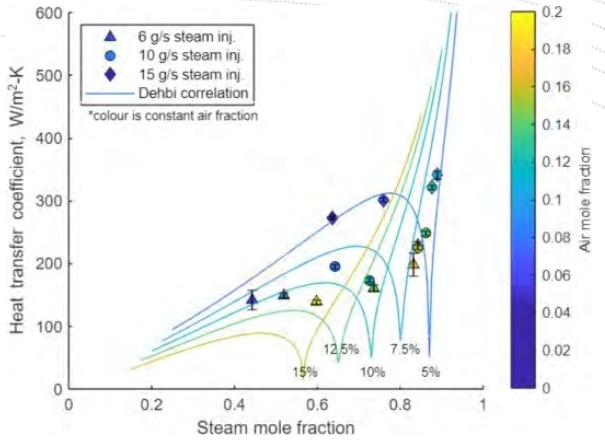


Figure: *Experimental HTC as a function of steam concentration in the hot upper layer, compared to Dehbi [1] correlation (air and helium [3].*

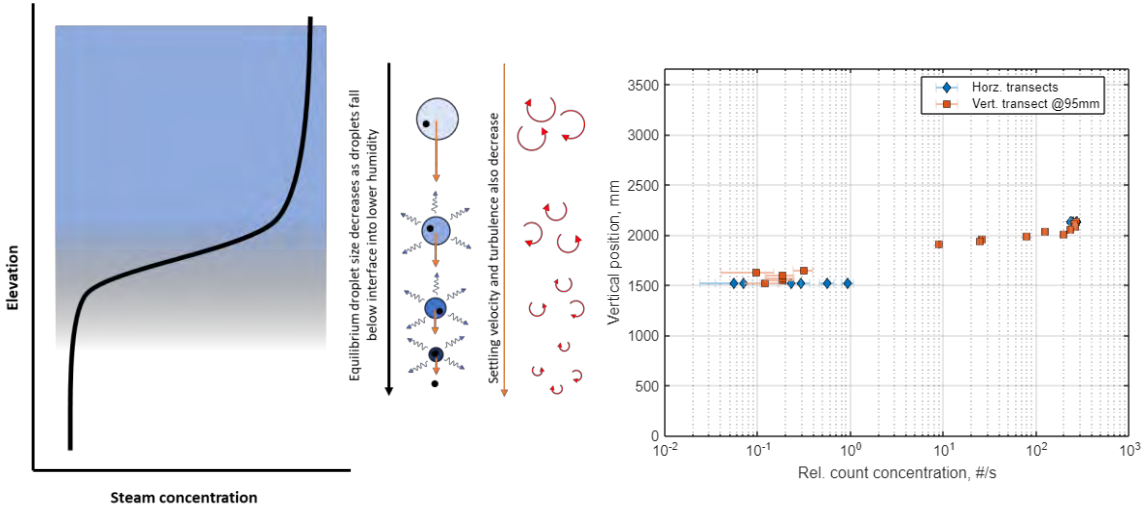
[1] Dehbi, A., A generalized correlation for steam condensation rates in the presence of air under turbulent free convection. Int. J. Heat Mass Transfer, 86, 2015



Evidence for "evaporative barrier" that traps fission products in upper layer of volume

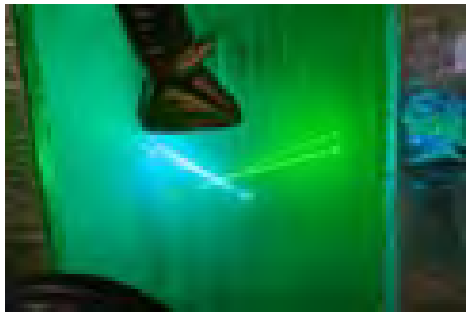
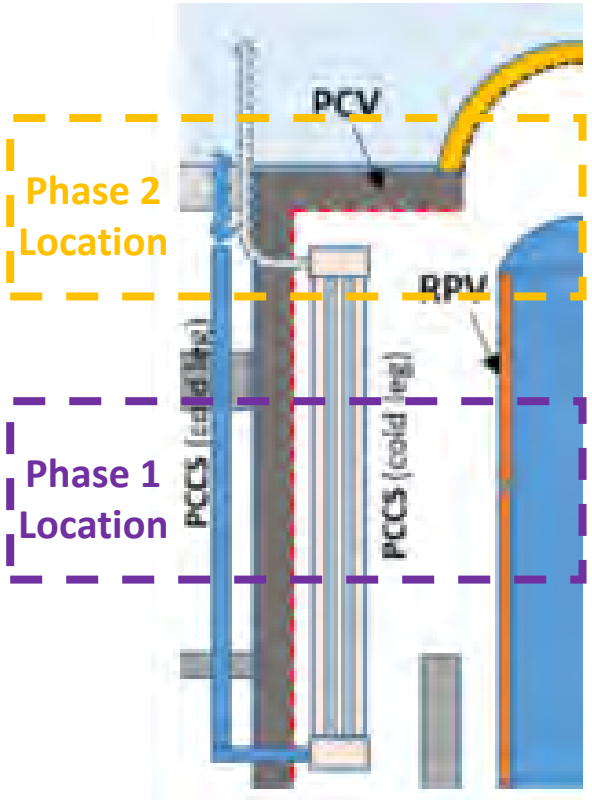
SCCA Conversion to Study PCCS in Small BWR

- Small BWR utilizes tube bank heat exchangers for passive containment cooling system (PCCS)
  - Natural-circulation driven (or forced) with tube bank suspended in the containment
    - Similar to GDCS (gravity driven cooling system) in Economic Simplified BWR (ESBWR) design
    - Condensate falls directly to bottom of containment
- SCCA modified with a tube bank (PCCS simulant)
  - Investigate impact of non-condensable gases on heat transfer on containment side
    - Study deposition patterns, aerosol properties, and flow dynamics, and stratification phenomena
    - Change “chilled wall” to tube bank + water reservoir
  - Phase 1 tests 2025 July (mid-containment; steam injection from above), Phase 2 summer 2026 (top containment)
  - Benchmarks planned: MELCOR (underway), CFD and GOTHIC (coming soon)



L: New configuration of SCCA for PCCS tests
R: LDA/PDA measurements
B: diagram of small BWR containment



PCCS Experiments – Key Takeaways

1) Gas Stratification and Heat Transfer
   - Active (forced convection) and passive (natural convection) cooling modes tested. NC tests had lower heat transfer rates.
   - Two distinct layers (hot upper layer and cooler under-layer) with thickness dependent on steam injection rate (equilibrium of heat in from steam injection and heat out from condensation).
   - Condensation occurs primarily in hot upper layer due to strong dependence of heat transfer on local steam concentration.
   - He co-injection cools upper layer (according to Antoine's equation), expanding it to increase surface area and maintain equilibrium.
2) He Dilution Impacts on Heat Transfer Coefficient
   - HTCs track Dehbi's correlations: ↑ with steam, ↓ with helium, and trends are consistent with Dehbi except near the unstable density transition zone.
   - Upper-layer HTCs for forced flow vs natural circulation PCCS: Natural mode has slightly higher gas T, but comparable HTC to forced.
   - More He (or less steam) drops HTC from ~600 to ~100 W/m²·K.

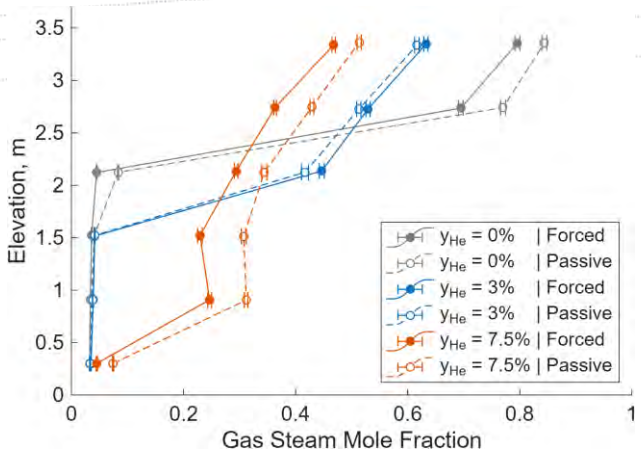


Figure: *Steam stratification and layer separation, under both natural and forced convection conditions, with 10g/s steam.*

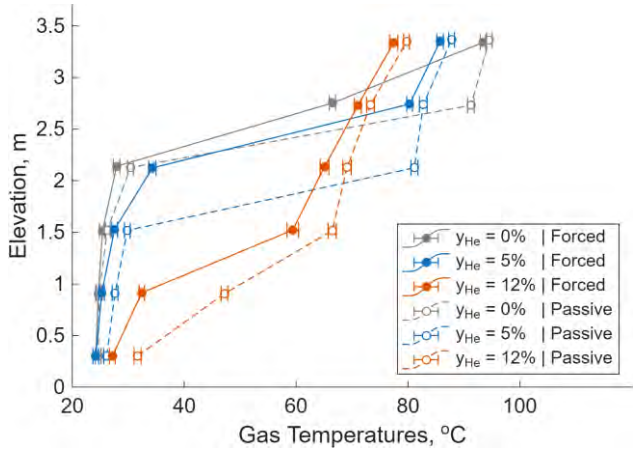
Figure: *Inflation (and lower temperature) as a result of helium co-injection with 6g/s steam, under natural and forced convection conditions.*



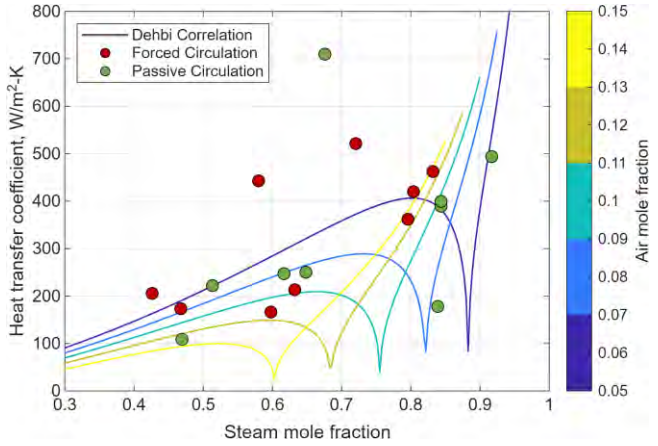


Figure: *Experimental heat transfer coefficients as a function of steam concentration in the hot upper layer, under both natural and forced convective flow conditions in PCCS, compared to Dehbi's correlation [1].*

[1] Dehbi, A., A generalized correlation for steam condensation rates in the presence of air under turbulent free convection. Int. J. Heat Mass Transfer, 86, 2015

Key Takeaways Helium (H_2 analog) and Aerosols

- **He accumulates in upper layer:** localized steam condensation, mass-transfer barrier (He rich; >90% dry) just above interface
- **He downward Migration & Mixing:** He diffuses across interface into under-layer (10-60% wet) and smooths the vessel's vertical temperature gradient.
- Aerosol concentrations drop 1-2 orders of magnitude at interface: evaporative barrier traps the bulk inventory in upper layer.
- Unlike heated iPWR tests, unheated PCCS under-layer droplets can re-condense and form fog after shrinking through barrier.
- LDA/PDA (10-30 um particle sizes) were mostly fog (can't discern NaCl droplets)
- Broader size distribution in steam layer and particles in cool underlayer below detection

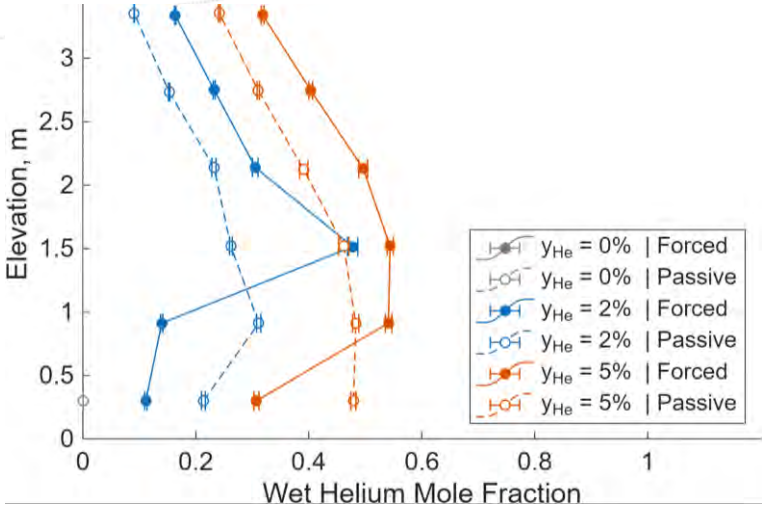

Figure: *Wet helium concentration under both natural and forced convection conditions, with 6 g/s steam.*

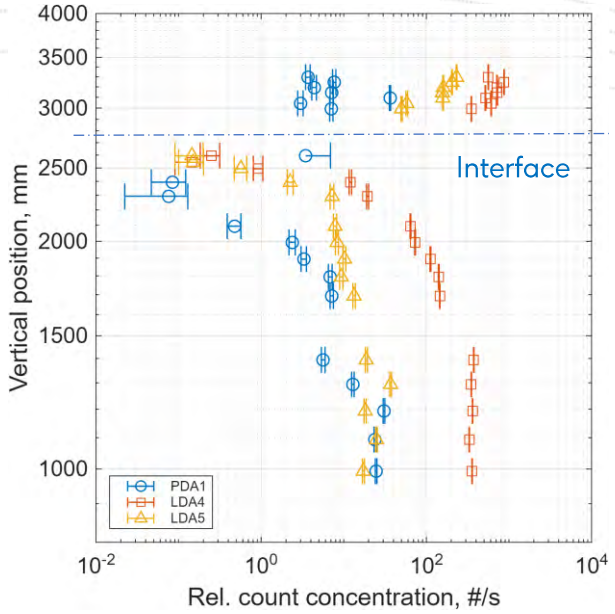

Figure: *Relative droplet count concentrations for 0% He and 10 g/s steam under natural circulation.*

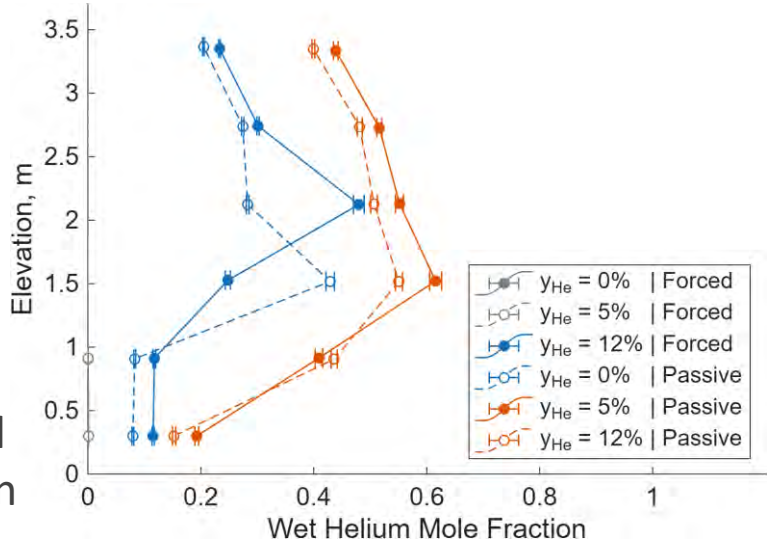

Figure: *Wet helium concentration under both natural and forced convection conditions, with 15 g/s steam.*

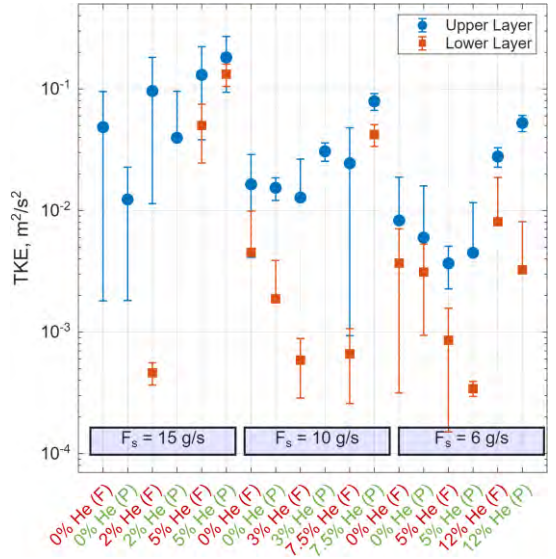

Figure: *TKE at different test conditions.*

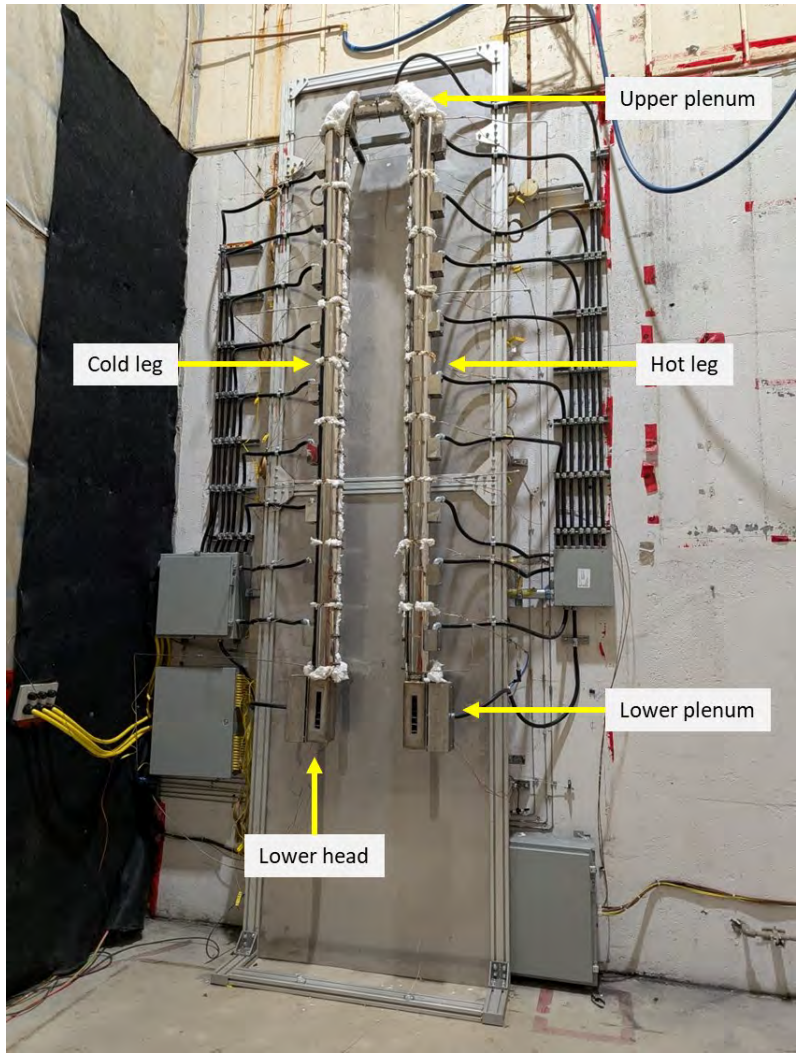
Late-stage Severe Accidents:

- CNL's Cold Crucible Induction Furnace (CCIF)
  - High temperature synthesis & rapid quenching of corium
  - Studies phase behaviour, melt miscibility, stratification, and chemical interactions with structural materials
  - Up to 2 kg charges with DU or NU; temperature = ~2300°C
  - Resolidified corium samples suitable for mechanical properties testing and database (TAF-ID) validation.
- Extensive experiments with CANDU corium and recent new tests with Accident Tolerant Fuel (ATF) - FeCrAl
  - Partial oxidation of FeCrAl (~70% in tests) required for UO_2 interaction (dissolution; eutectic phase formation)
  - Charge reached 2417°C = high quality UO_2–FeCrAl corium
  - Characterisation is underway to produce data to support validation of ATF thermodynamic models
  - Future experiments planned for melt stratification, vessel material interactions, & ex-vessel (UO_2–FeCrAl–concrete)

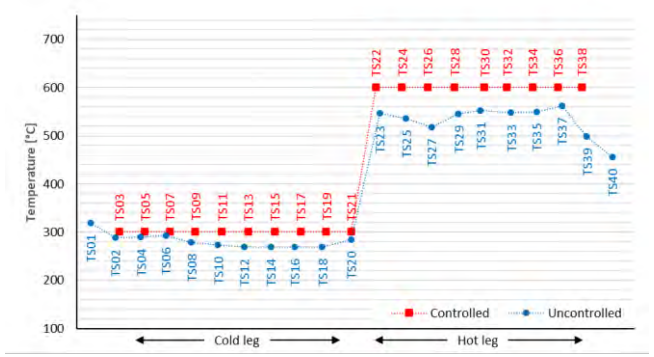
Above: CCIF producing FeCrAl corium
Left: FeCrAl corium samples post-test

Helium-Air Natural Convection (HANC) Experiment Studying Air Ingress

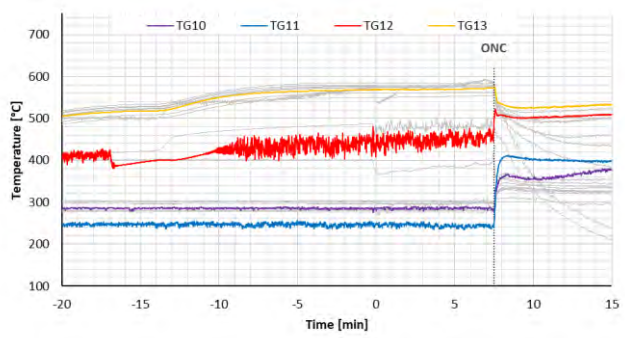
- PIRT exercise for DLOFC accident in HTGR
  - Phenomena of forced-to-natural circulation transition found highly important to accident source, but poorly understood
- HANC is designed to measure the time to the onset of natural convection (ONC)
  - conditions resembling guillotine break of coaxial inlet/outlet duct in an inverted “U” type geometry.
  - Initially filled with He and electrically heated up to 700°C. Each test initiated by opening seals on the lower head / plenum (boxes).
- First test series (HANC-1) completed January 2026. Test reports to be completed by mid 2026.
- Apparatus design improvements and new test series (HANC-2) to start planning in late 2026.



Annotated photograph of the completed HANC apparatus showing the represented regions of a HTGR.



Example steady temperature profile before ONC (300°C / 600°C cold leg / hot leg).



Example measured gas temperature transient including clear evidence of ONC.

Planned benchmarks with RELAP5, GOTHIC, & MELCOR

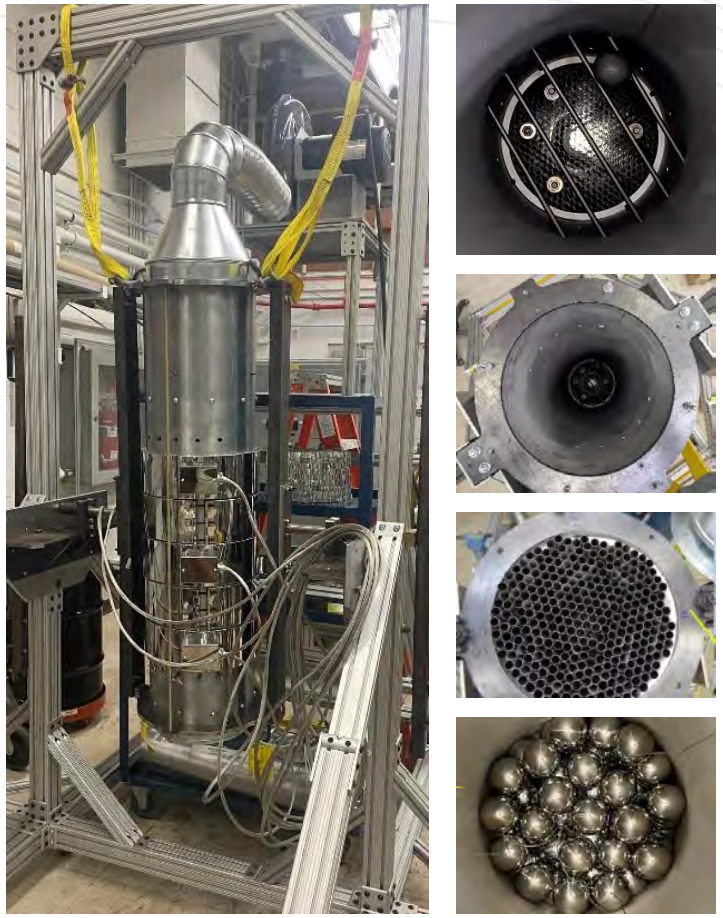
HTGR Core Heat Transfer Experiments

Pebble Bed Experiments for Analysis of Core Heat transfer (PebbleBEACH):

- Both forced (upward/downward) and natural convection (+radiation), with externally/internally (coming soon) heated pebbles;
- Measuring contributions of surface radiation, contact conductance, & convection to heat transfer (using pebbles with different materials and emissivity)
- In pebble cartridge heaters will be installed to study impact of internal heat generation (as opposed to external heating) in the pebbles, on core heat transfer
- First Pebble Beach tests conducted in 2025 December:
  - Pebbles are polished stainless steel with an emissivity <0.1
  - External heating, reactor scale pebble sizes, and dimensionless properties for the coolant and flow consistent with normal operations.

Pebble Bed Aerosol Generation Experiments (PAGE) – *concept design*

- Focused on characterization of graphite dust generation for PB-HTGR cores
  - An important potential source term in safety evaluations, and due to the pyrophoric nature of the dust may have implications on accident behaviour/progression
  - Experiments will involve accelerated frictional deterioration of the reactor scale pebbles, resulting in dust production and characterization.



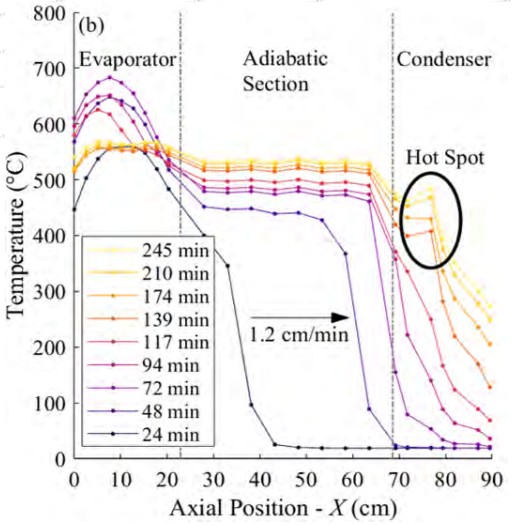
Pebble BEACH apparatus

Measures T and HTCs for normal operation (forced convection) & accident (natural circulation)

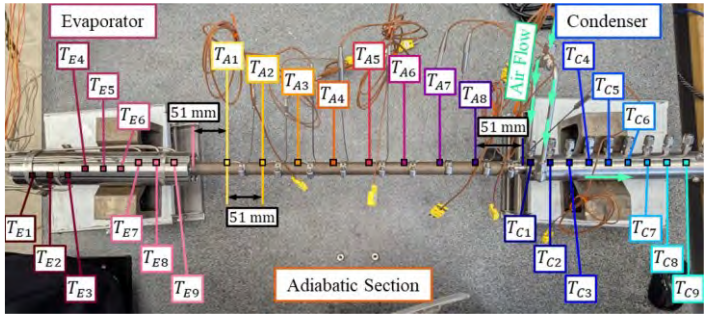
Future: aerosols (from pebble movement) and flow reversal and instability investigations.

Heat Pipe (HP) Experiments

- Heat pipe array (Na working fluid) setup.
- 5 parallel HPs at 50kw
- Scaling up array: more HPs and higher power

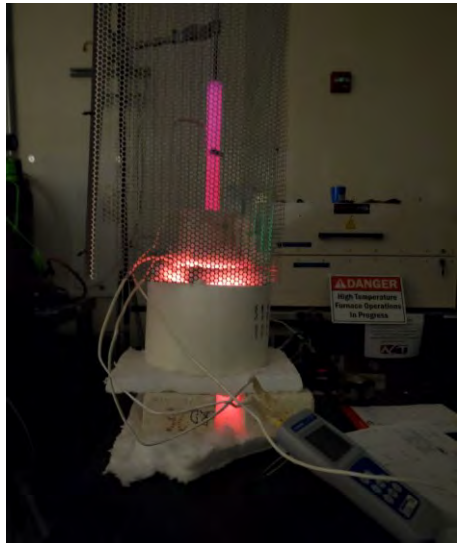


- Example test results of start up transient for a single heat pipe.



- Set up of a single heat pipe with sodium working fluid.

- Evaluating heat transfer and thermalhydraulics of sodium and potassium HPs for start-up, steady state, cyclical, and shutdown
- Severe accident scenarios using HP array (20-60% HP failure rate) with HP at 550˚ C & block at 750˚C (shutdown system delay 1H)
  - 60% failure case: 1) core increases to block temp in 5 min; constant for 35 mins; then increases by 250˚C/hr until shutdown simulated



- QA testing of a 0.5m potassium heat pipe
- TH and heat transfer experiments now underway

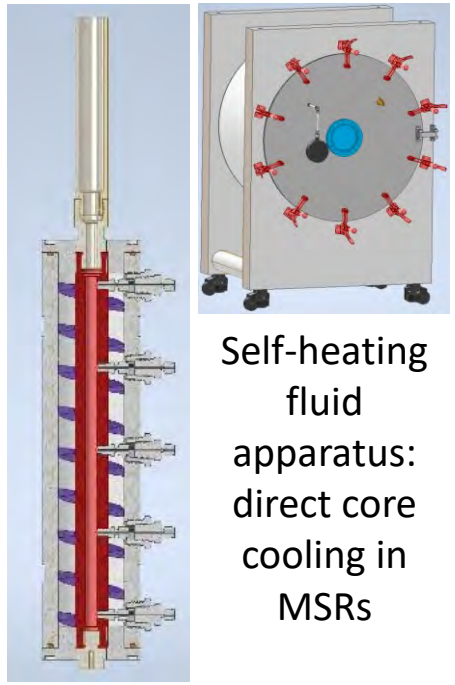
Experiments + Modelling

- Na HPs (up to 1000˚C) including single and multiple rupture; Single potassium heat pipe tests.
- Working with partners (UW-Madison) on design and building of custom heat pipes.
- Heat pipe modelling using both CFD (STAR-CCM+) and system-TH (ARIANT) codes

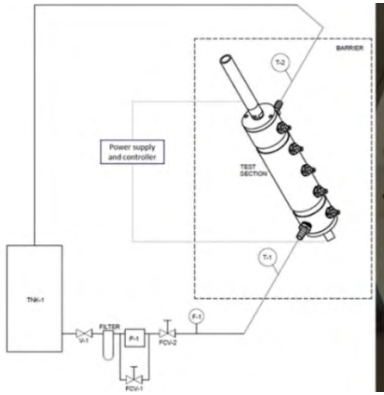
Molten Salt Reactor (MSR) Related Experiments

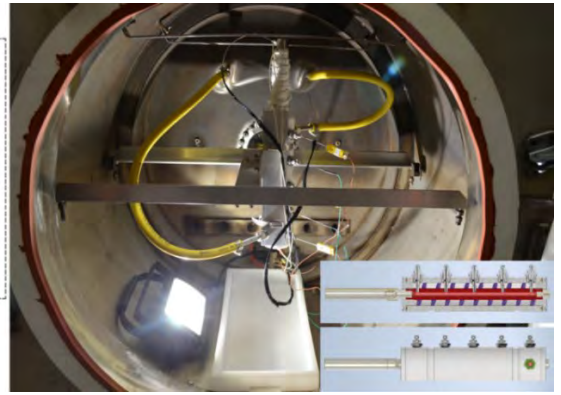
- Molten salt characterization, production, & FP release under accident conditions
- Molecular dynamics modelling of fission product behaviour in molten salts.
- **Recent FP efforts:** confirmatory experiments on conversion of UO_2 to a UF-based fluoride/fluoride-chloride molten salt, using depleted uranium.
  - Data to augment results/conclusions of previous FP release experiments
- **Volumetric heat generation in core:**, development of 'scalable' experimental capability for self heating fluids for natural circulation loops to simulate MSR.
  - Focused on a joule heating technique with simulant molten salts
  - Investigate and mitigate corrosion and electrolysis, material compatibility and local temperature measurements.
- Application of voltage waveforms
- High temperature plastics suitable for use with FLiBe and FLiNaK loops)
- Alternatives to thermocouples for local temperature measurement
- Scalability for developing larger loops.

Molten Salt Volumetric Heating



Self-heating fluid apparatus: direct core cooling in MSRs

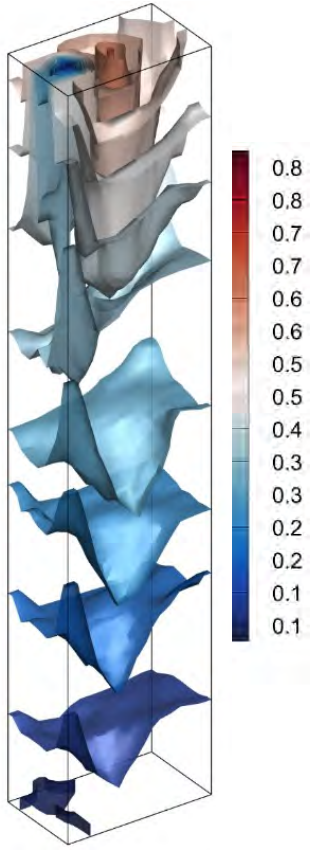




Benchtop Joule Heated Salt Experiment: Dynalene 450 simulant salt (~120 °C MP); steady state water jacket cooling; extendable to fluoride salts

Severe Accident Modelling and Analysis – Water Cooled efforts

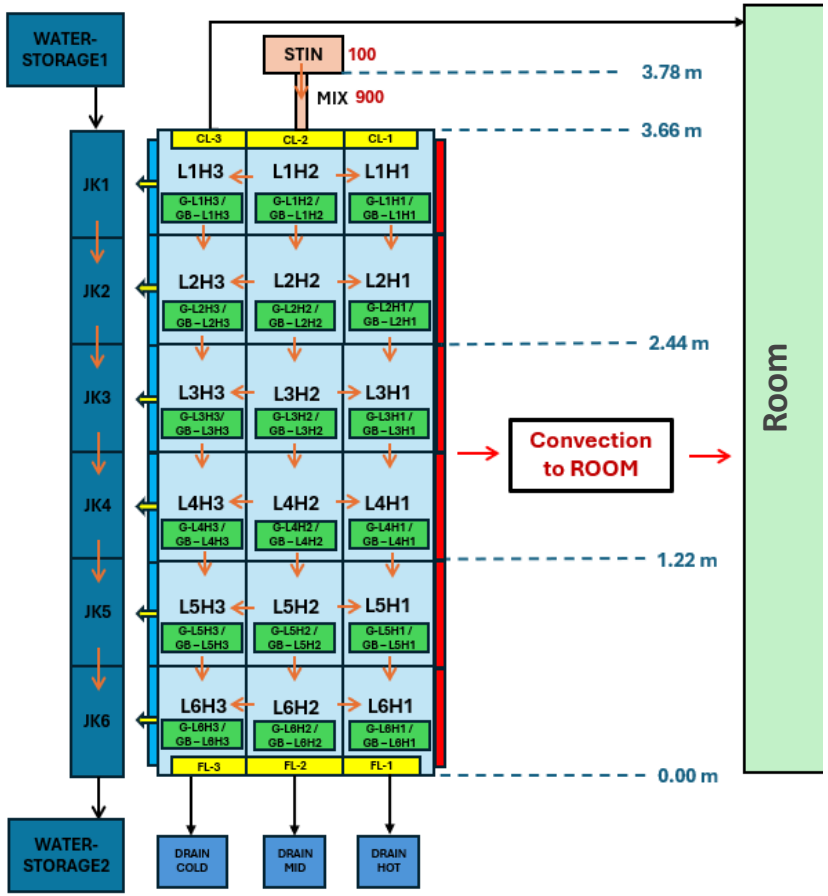
- Completion of the benchmarking of SCCA Experiments
  - **Benchmarking:** MELCOR (Phase 1); GOTHIC (Phase 1 & 2); CFD (Phase 1 refining, Phase 2 coming)
  - Jia, D. E., Lebel, L., Morreale, A., & Zhou, F. (2024). GOTHIC and MELCOR benchmarking of the CNL strong condensation containment apparatus experiments. Nuc. Eng. and Des., 427, 113440.
- iPWR Severe Accident Modelling and Emergency Response:
  - J. Cui, L. Lebel, A. Morreale and D. Hummel, "MELCOR Model of iPWR and Application to Emergency Planning Zone Study", Nuclear Engineering and Design, Vol. 442, October 2025.
- Experiments and benchmarking of SCCA small BWR PCCS experiments Phase 1 (2025 June)
  - MELCOR Benchmarking of Phase 1 in progress; planned GOTHIC Benchmarking to start in spring 2026 and CFD Benchmarking of BWR PCCS experiments planned following iPWR benchmarks.
- Integrated severe accident analysis with MELCOR to evaluate passive systems
  - Assessing impacts of passive system failures (including failure modes) for iPWRs and small BWRs.
- Participation in the EU SASPAM-SA Project – Water Cooled SMR Severe Accidents
  - SASPAM-SA (Safety Analysis of SMR with Passive Mitigation Strategies – Severe Accident)
  - CNL contributing data/experience from SCCA iPWR and small-BWR experiments, benchmarking and integral severe accident analysis for iPWR and small BWR + emergency response methodologies.

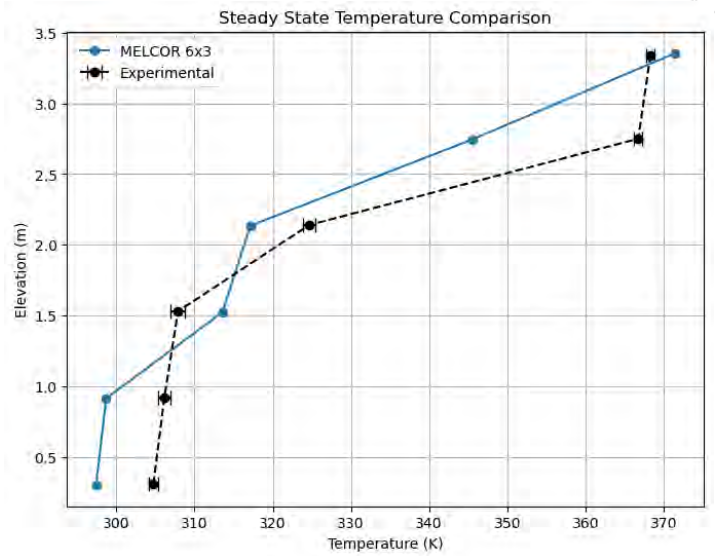


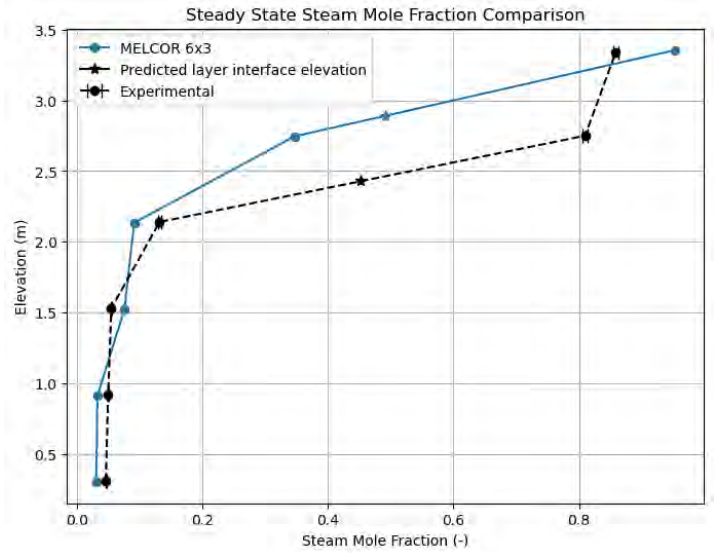
GOTHIC modelling of the SCCA (steam fractions)

MELCOR Benchmarking of small BWR PCCS Tests

- Benchmarking PCCS Phase 1 (2025 June) experiments with MELCOR
  - Using a 6x3 nodalization to track the natural convection with 6x1 PCCS heat exchanger
  - Initial challenges with radiation modelling corrected improving temperature predictions for the bottom layer
  - Steam layer can cross CVH volumes
- Future Benchmarking to include:
  - MELCOR analysis of Phase 1 PCCS tests nearly complete; eventual benchmarking of Phase 2 test (test to be conducted in 2026-2027)
  - GOTHIC & CFD modelling of PCCS Phase 1 & 2 planned to start 26-27.







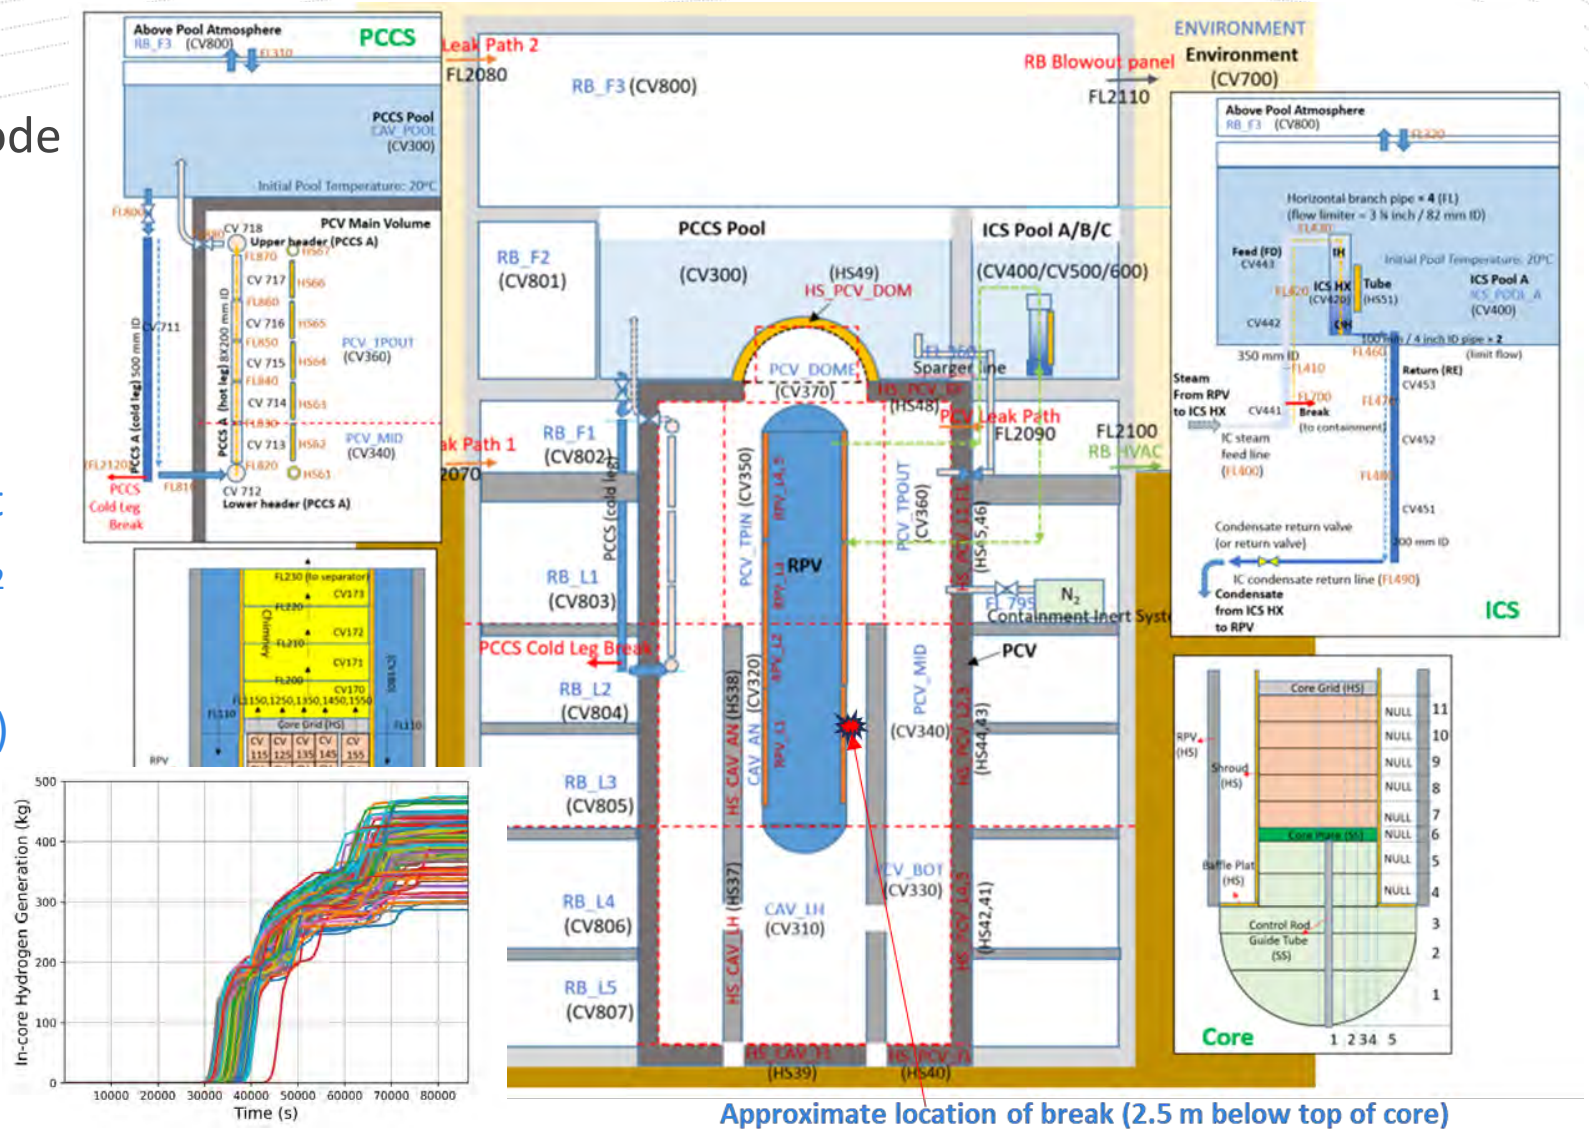
Above: MELCOR nodalization for PCCS tests.

Right Top: Steady State Temperature Comparison

Right Bottom: Steady State Steam Mole Fraction Comparison

Small BWR Severe Accidents

- MELCOR Severe Accident Analysis Code
- Generic small-BWR MELCOR model
  - Natural circulation driven primary coolant and safety systems
- Initial analysis of SBO and SBLOCA cases to explore core degradation
  - SBO w/ varied ICS/PCCS impairment
  - SBLOCA (on 1'' instrument line) – H_2 (NCG) impact on ICS performance
  - ICS condensate return into chimney region (early studies to downcomer)
- Modelling and analysis of small BWR passive system phenomena
- Modelling support for DEC PIRT
- MELCOR + DAKOTA Uncertainty Analysis focused SBLOCA cases to explore core degradation



F. Zhou, A. C. Morreale, L. Lebel, J. Cui, and G. Patterson, "Severe accident analysis of a generic small boiling water reactor", submitted to NUTHOS-14, Vancouver, Aug 25-28, 2024

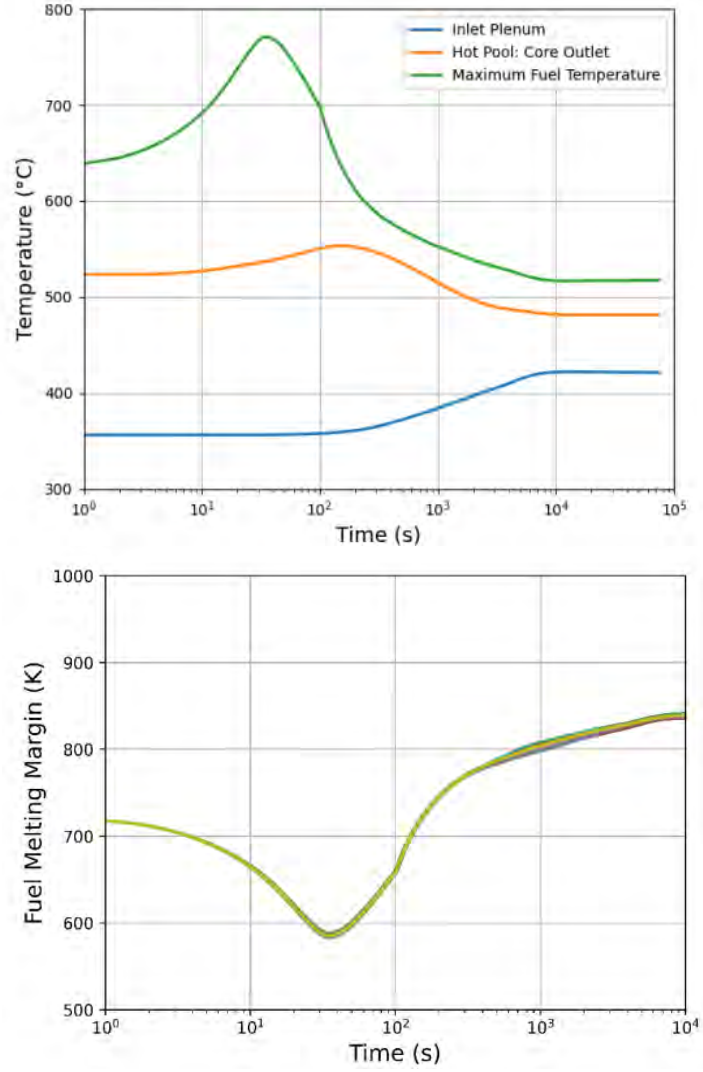
HTGR and SFR Reactor Analysis UPDATE

HTGR (High Temperature Gas Reactor):

- Further analysis of 200 MWth pebble bed HTGR: onset of natural circulation/air ingress and DLOFC, as well as uncertainty/sensitivity using MELCOR-DAKOTA with Wilks method
  - Air ingress period seen to be ~4H; **U/S analysis:** impact of 11 uncertain inputs on key figures of merit during DLOFC (peak fuel temperature, ONC timing, and radionuclide release) over 124 simulations.
- Preparing to benchmark recent HANC tests (MELCOR model dev.)

SFR (Sodium Fast Reactor):

- Generic 250 MWth SFR MELCOR analysis for unprotected loss of flow accident (ULOFA) & unprotected transient overpower accident (UTOPA)
  - Best-estimate analysis (below), and U/S analysis of ULOFA (60 input decks for the ULOFA scenario, with the reactivity coefficients used as uncertain input parameters tracking FOMs of coolant boiling margin, clad melting temperature margin, and fuel melting temperature margin.

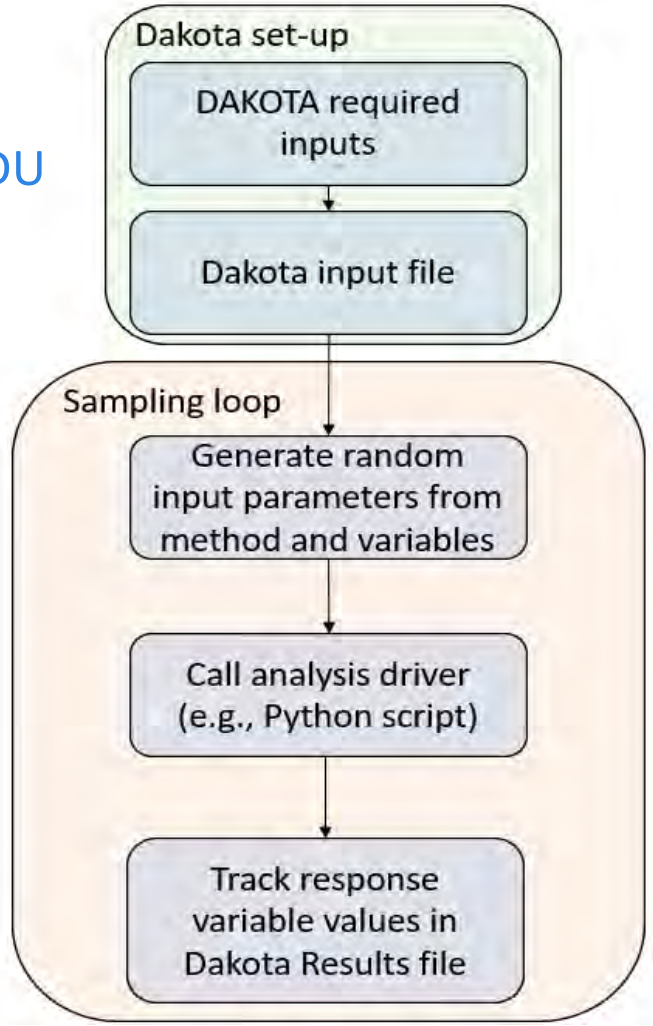


Top: ULOFA Temperature transient
Bottom: horsetail plot of fuel melting margin under a ULOFA for 60 simulations

Sensitivity and Uncertainty Analysis

- Building on previous participation in IAEA CRP
  - Further efforts in CANDU focused on hydrogen releases (international workshop with CRP CANDU partners: CNL, KAERI, and UPB)
  - MAAP-CANDU + SUSA toolset for S/U analysis
- MELCOR + DAKOTA coupling using Python developed and applied to
  - Small BWR model
  - Sodium fast reactor model
  - High temperature gas reactor model
- Initial efforts using Wilks method
- Implementation of Morris method and Iman-Conover method via DAKOTA and Python scripts

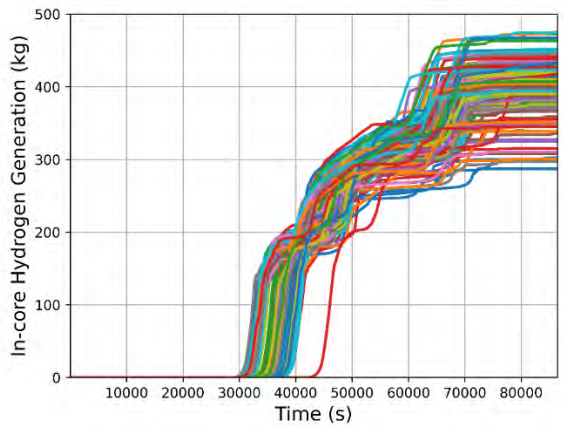
MELCOR + DAKOTA Coupled Uncertainty and Sensitivity Analysis



Morris Method

Wilks Method

Iman-Conover Input Correlations



Generic Small BWR Uncertainty Analysis Total H2 Generation over the Transient

Conclusions

- New nuclear deployment, including Small Modular and Advanced Reactor, interest in Canada and abroad to achieve clean energy goals and Canadian government support for nuclear energy
- CNL operates a flexible research program, guided by the SMR/AR deployment landscape in Canada
  - Develops and maintains capabilities and knowledge to support industry and regulatory stakeholders
  - Reactor safety and severe accident research further developing base capabilities for range of SMR/AR technologies and pursuing deeper expertise for key technologies closer to deployment.

- Severe accident research focus on WC designs (especially small BWRs) and HTGRs as near term.
  - Experiments (core heat transfer, heat transport system, natural circulation, and containment)
  - Integral severe accident analysis, along with uncertainty and sensitivity assessments.
- Other focuses include heat pipe cooling systems, SFRs and molten salt FP behaviour
  - Baseline capabilities/understanding positions CNL to move deeper should deployment accelerate
  - Experiments (core heat transfer, heat transport system, natural circulation, and containment)
- CNL research enhanced by international involvement (NEA, IAEA, EU, GIF) + ERMSAR especially

Thank you. Merci.

ACKNOWLEDGMENTS

The work discussed herein and CNL participation in various international working groups, projects and initiatives is primarily funded through the Atomic Energy of Canada Limited (AECL) Federal Nuclear Science and Technology Program.

Introduction

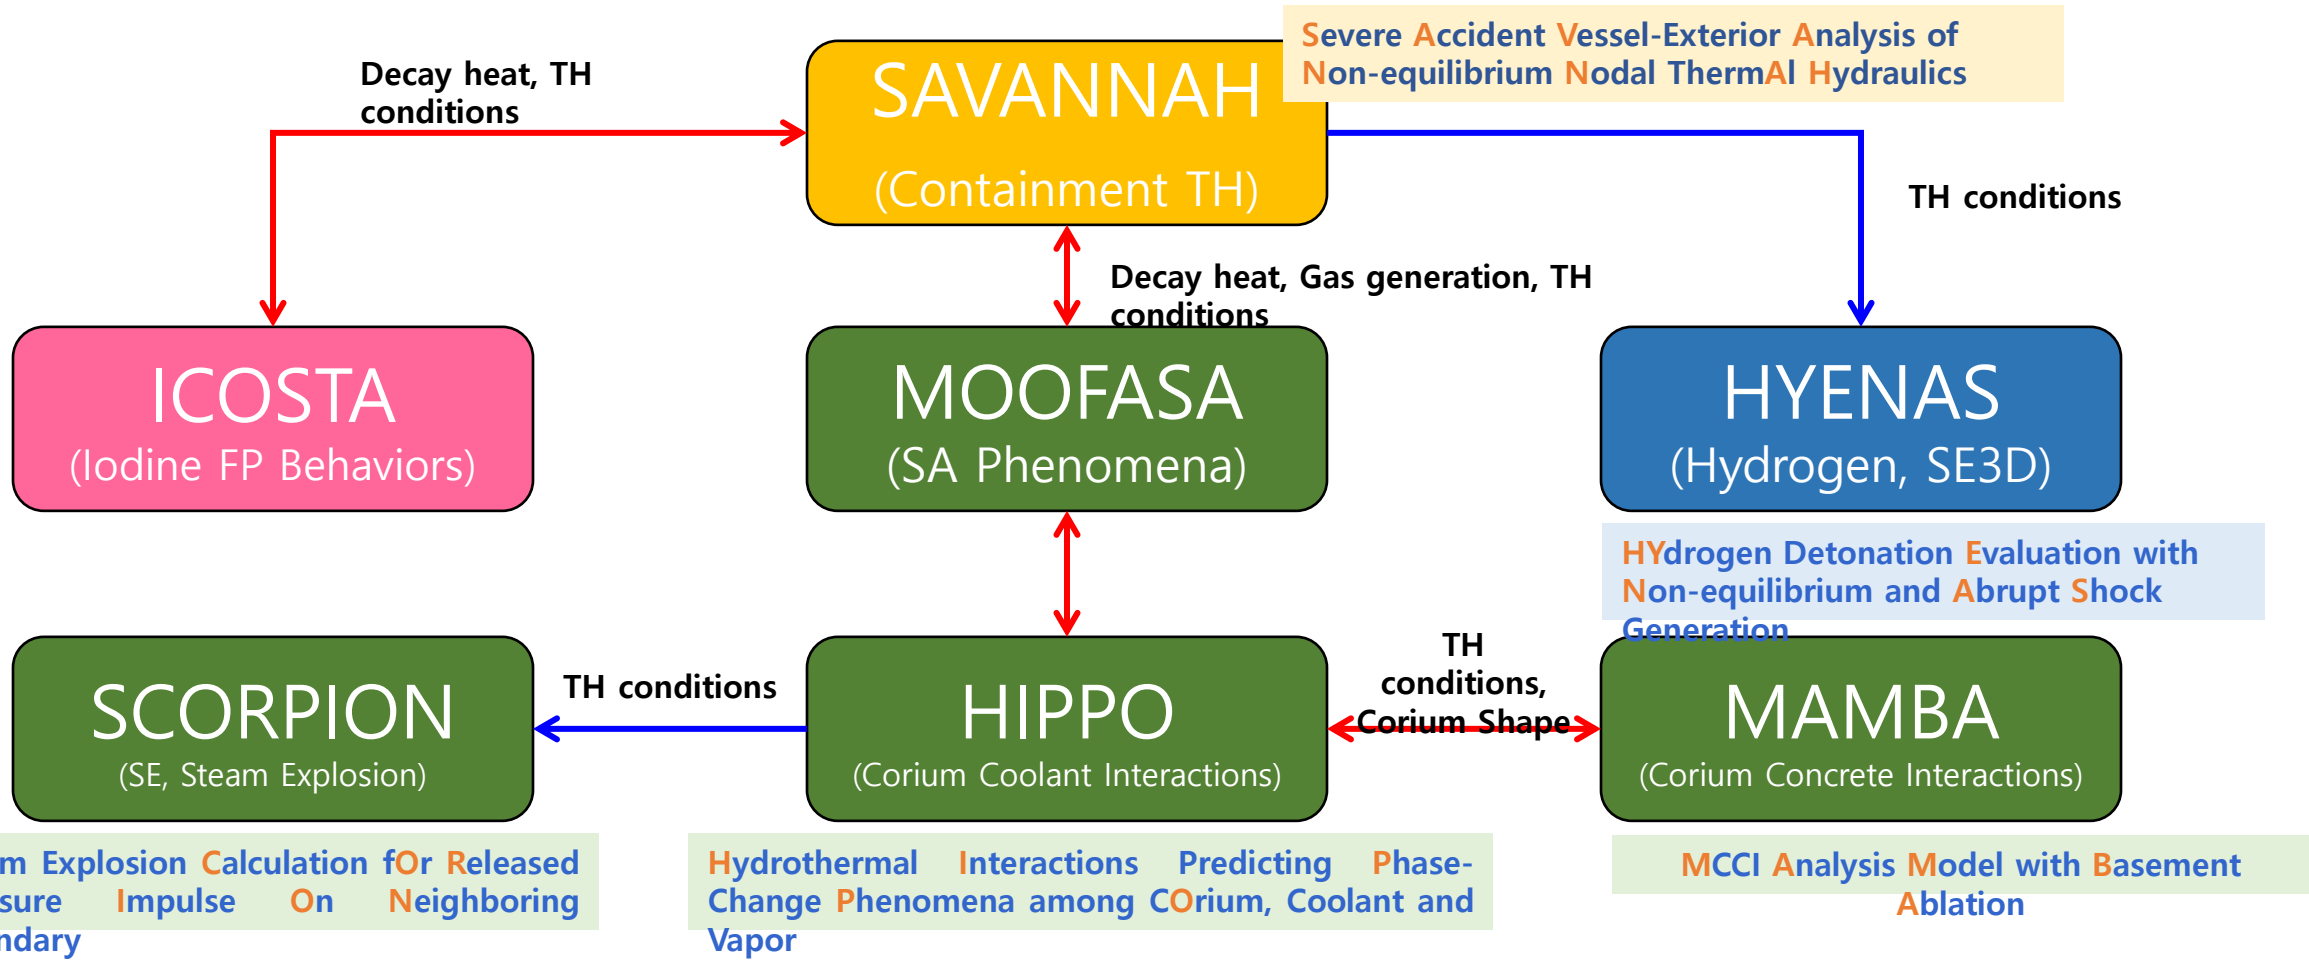
- **Heavy Dependence on Foreign Codes**: South Korea has depended entirely on international codes like MELCOR for severe accident safety analysis.

- **Source Code Access Restrictions**: Recent US NRC restrictions on source code access make it difficult to modify software for Korea's specific reactor features or to respond quickly to local regulatory needs.

- **Objective of Development**: To achieve technological independence by creating a domestic severe accident analysis code (SAFARI) tailored to Korea’s regulatory and management environment.
  - SAFARI Framework: The main, integrated system for severe accident analysis.
  - SAVANNAH Module: A specialized module dedicated to simulating ex-vessel containment behavior and thermal-hydraulics.

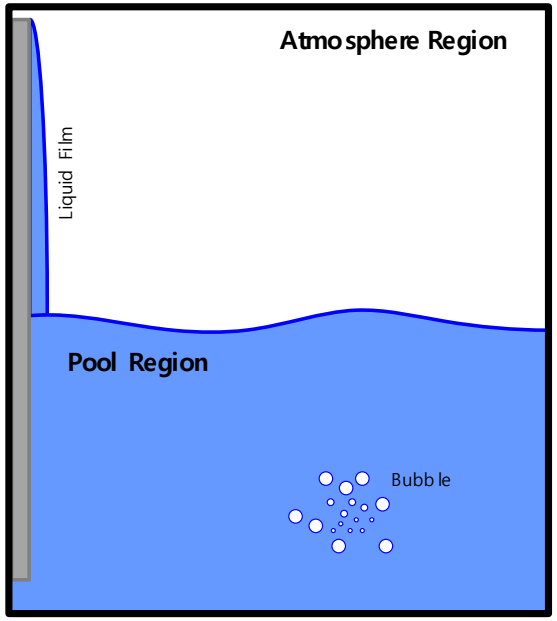
FNC Technology Co., Ltd.

SAFARI (Safety Analysis Code For Severe Accident Risk Identification)

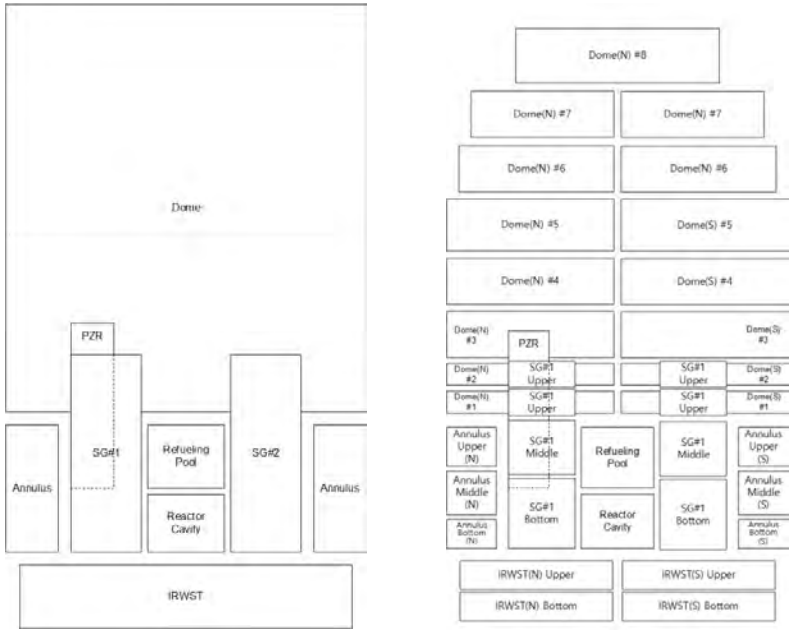


Concept & Nodalization

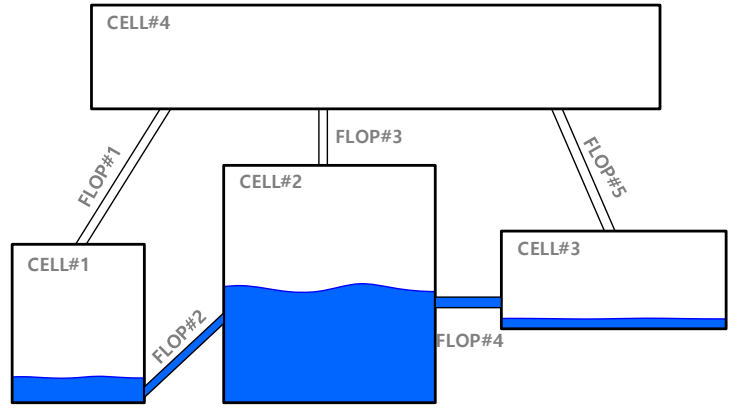
- Lumped-parameter model
- Compartment-based nodalization
  - CELL: containment Compartment
  - FLOP: inter-compartment flow path
- Non-equilibrium treatment:
  - **Pool** region (Liquid Water + Steam)
  - **Atmosphere** region (Steam, Non-condensable gases)



[Concept of Cell]



[Containment Nodalization]



[Example connections between Cell and Flow path]

Governing Equations

Mass Conservation Equation (**Each Material**)

$$M_{i,m}^{n} - M_{i,m}^{n} = \sum_{j} \underbrace{\sigma_{ij}\alpha_{j,\phi}^{n}\rho_{j,m}^{d}v_{j,\phi}^{n}A_{j}\Delta t}_{\text{Convection Term}} + \underbrace{\delta M_{i,m}}_{\text{Source Term}}$$

Energy Conservation Equation (**Each Phase**)

$$E_{i,\phi}^{n} - E_{i,\phi}^{n} = \sum_{j} \underbrace{\sigma_{ij}\alpha_{j,\phi}^{n}(\rho_{j,m}^{d}h_{j,m}^{d})v_{j,\phi}^{n}A_{j}\Delta t}_{\text{Convection Term}} + \underbrace{\delta E_{i,\phi}}_{\text{Source Term}}$$

Momentum Conservation Equation (Each Phase)

$$v_{j,\phi}^{n} = v_{j,\phi}^{o} + \frac{\Delta t}{\rho_{j,\phi}L_{j}}\Bigg[\underbrace{P_{i}^{\tilde{n}} + \Delta P_{pp} - P_{k}^{\tilde{n}}}_{\text{Pressure Difference}} + \underbrace{(\rho g \Delta z)_{j,\phi}^{\tilde{n}}}_{\text{Elevation Change}} \underbrace{- \left(f\frac{L_{j}}{D} + \sum K\right)\frac{\rho_{j,\phi}}{2}\left(|v_{j,\phi}^{n-1} + v_{j,\phi}^{n-2}|v_{j,\phi}^{n} - |v_{j,\phi}^{n-2}|v_{j,\phi}^{n-1}\right)}_{\text{Frictional Term}}\Bigg]$$

Primary Unknown Variables

- Each material mass: $M_{i,m}^{n}$[kg]
- Each phase internal energy: $E_{i,\phi}^{n}$[J]
- Each phase velocity: $v_{j,\phi}^{n}$ [m/s]

[Super script]
n: new variable
o: old variable

[Sub script]
i: cell index
k: cell index 2
j: flowpath index
m: material index
ϕ: phase index
pp: pump

[Variable]
M: material mass [kg]
E: phase internal energy [J]
P: Pressure
σ: connectivity [-]
α: volume fraction [-]
ρ: density [kg/m^3]
h: specific enthalpy [J/kg]
v: velocity
t: time
g: gravitational constant [m/s^2]
f: frictional coefficient
K: form loss coefficient

Numerical Solution Scheme [1/2]

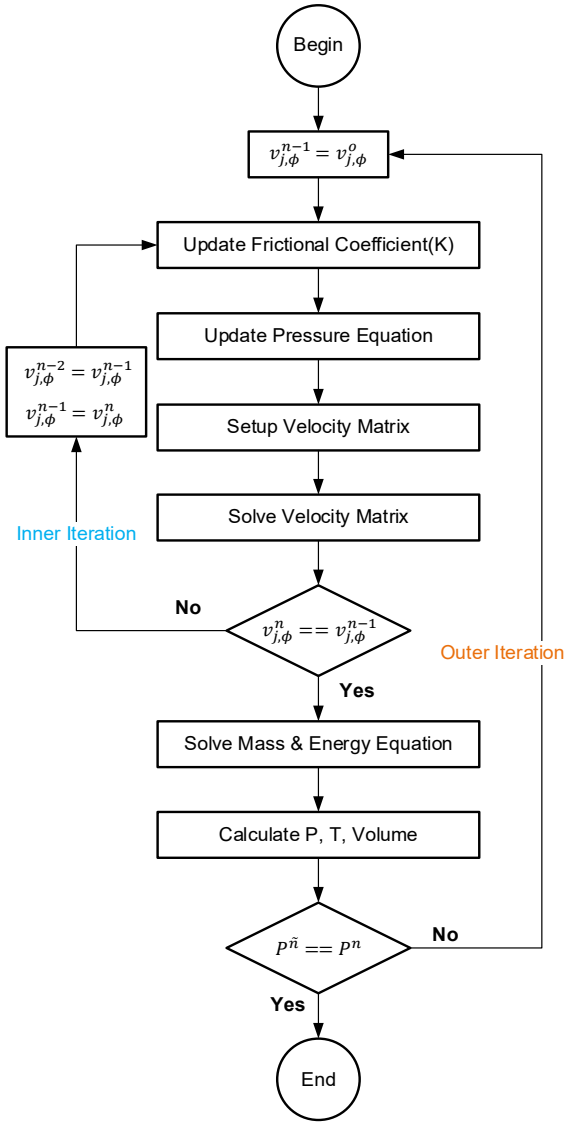
- Step 1. Update Frictional Coefficient (f, K)
- Step 2. Update Pressure Equation: **Pressure-Velocity Coupling**

$$P_i^{\tilde{n}} = P_i^{o+} + \sum_{m=1}^{M}[(\frac{\partial P}{\partial M})\Delta M]_m + (\frac{\partial P}{\partial E})_{pool}\Delta E_{pool} + (\frac{\partial P}{\partial E})_{atm}\Delta E_{atm}$$

- Step 3. Setup Velocity Matrix

$$\begin{vmatrix} a_{P,1}+c_{P,1.1} & c_{P,1.2} & \cdots & c_{P,1.J} & b_{P,1}+d_{P,1.1} & d_{P,1.2} & \cdots & d_{P,1.J} \\ c_{P,2.1} & a_{P,2}+c_{P,2.2} & \cdots & c_{P,2.J} & d_{P,2.1} & b_{P,2}+d_{P,2.2} & \cdots & d_{P,2.J} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ c_{P,J.1} & c_{P,J.2} & \cdots & a_{P,J}+c_{P,J.J} & d_{P,J.1} & d_{P,J.2} & \cdots & b_{P,J}+d_{P,J.J} \\ a_{A,1}+c_{A,1.1} & c_{A,1.2} & \cdots & c_{A,1.J} & b_{A,1}+d_{A,1.1} & d_{A,1.2} & \cdots & d_{A,1.J} \\ c_{A,2.1} & a_{A,2}+c_{A,2.2} & \cdots & c_{A,2.J} & d_{A,2.1} & b_{A,2}+d_{A,2.2} & \cdots & d_{A,2.J} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ c_{A,J.1} & c_{A,J.2} & \cdots & a_{A,J}+c_{A,J.J} & d_{A,J.1} & d_{A,J.2} & \cdots & b_{A,J}+d_{A,J.J} \end{vmatrix} \begin{vmatrix} v_{1,P}^n \\ v_{2,P}^n \\ \vdots \\ v_{J,P}^n \\ v_{1,A}^n \\ v_{2,A}^n \\ \vdots \\ v_{J,A}^n \end{vmatrix} = \begin{vmatrix} e_{P,1} \\ e_{P,2} \\ \vdots \\ e_{P,J} \\ e_{A,1} \\ e_{A,2} \\ \vdots \\ e_{A,J} \end{vmatrix}$$

- Step 4. Solve Velocity Matrix
- Step 5. Solve Mass & Energy Equation
  - Determination of cell mass [kg] and energy [J]
  - Once the velocity field is resolved, the final mass and phase energies are determined
- Step 6. Calculate P, T, and Phase Volume



Numerical Solution Scheme [2/2]

- Step 6. Calculate P, T, and Phase Volume: EOS (Equation Of State)
- 1. Find Pool TH State
  - Find properties using **assumed pressure** and **pool energy**
- 2. Calculate Phase Volume
  - After calculating the pool volume, remaining volume is assumed to be the atmosphere volume
- 3. Find Atmosphere TH State
  - Find properties using **each material density** and **phase internal energy**

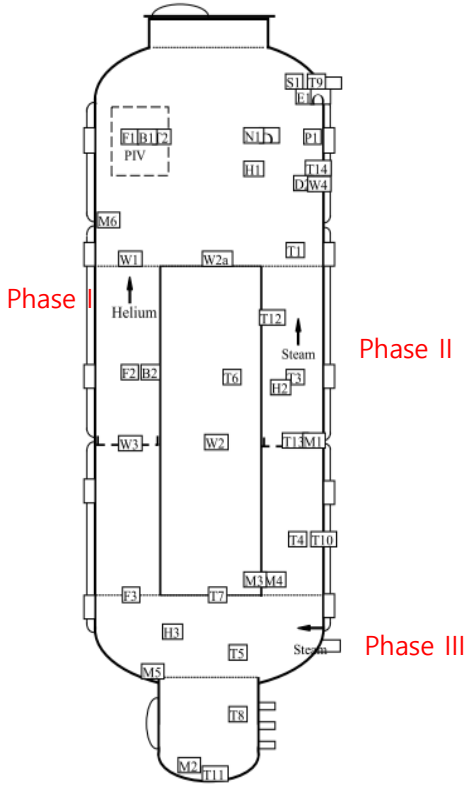
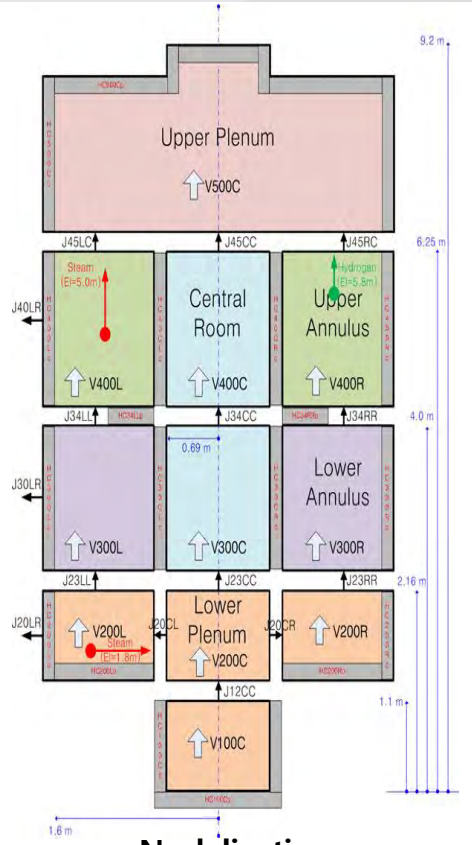
Verification Results

Validation – ThAI [1/2]

- Target Physics
  - Helium Distribution, Condensation
- Geometry
  - Total Height: 9.2 m
  - Diameter: 3.2 m
  - Total Volume: 60.0 m^3
  - Material: Carbon Steel
- Initial Condition
  - 1.0 bar / 295.15 K / 70% Humidity
- Test Condition
  - 0.0 – 2,700 sec: Helium Injection (0.6 g/s)
  - 2,700 – 4,700 sec: Steam Injection (35 g/s)
    - Injection Location: Annulus
  - 4,700 – 5,700 sec: Steam Injection (35 g/s)
    - Injection Location: Lower Plenum



Schematic Diagram



Nodalization

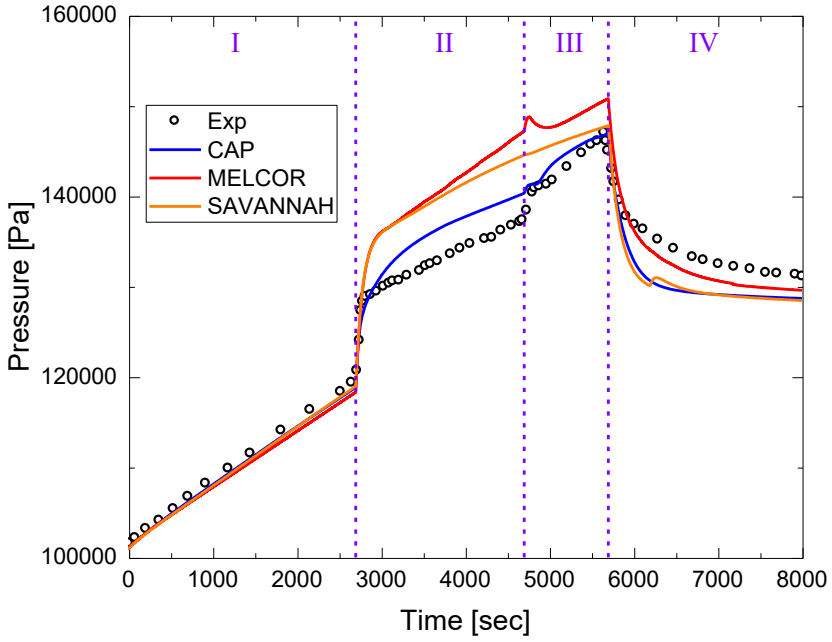
Table 2. **ThAI test sequence**

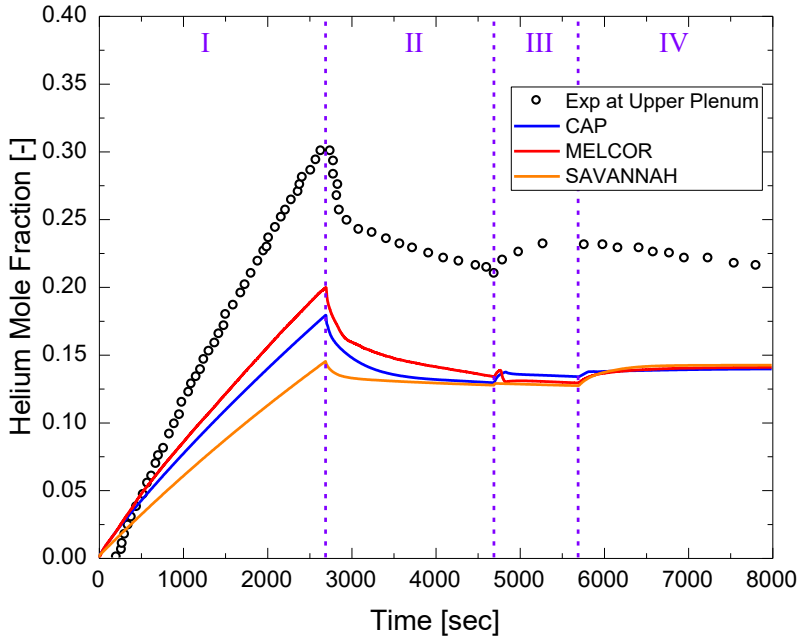
Phase	Time (s)	Activity
I	0 - 2700	Vertical helium jet injection.
II	2 700 - 4 700	Vertical steam jet injection at the upper injection nozzle.
III	4 700 - 5 700	Horizontal steam plume injection at the lower injection nozzle.
IV	5 700 - 7 700	No injection, passive cool-down of the facility.

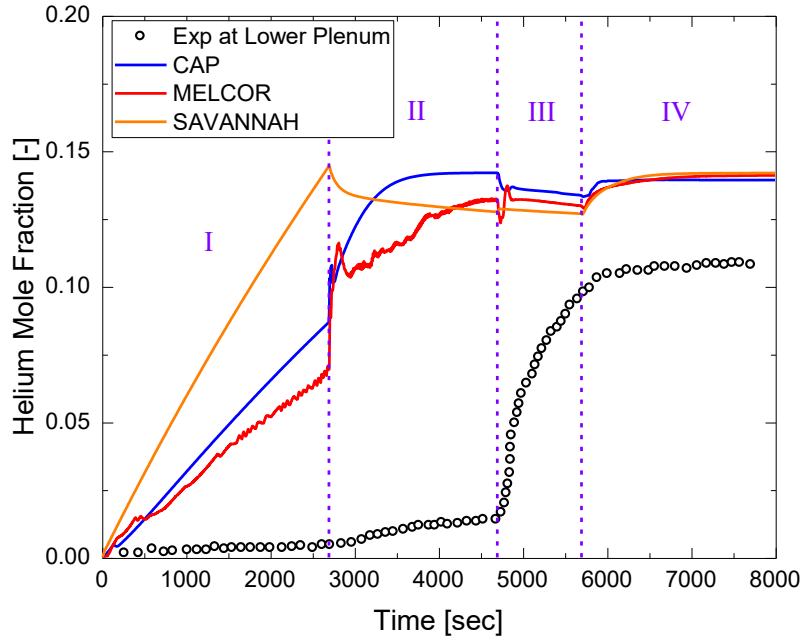
Validation – ThAI [2/2]

Key Findings

- SAVANNAH predicts containment pressure reasonably well
- Lumped-parameter approach shows limited spatial stratification prediction
- Helium Distribution
  - SAVANNAH: Predicts a uniform distribution
  - CAP & MELCOR: Predict slight spatial variations depending on the location.







Validation – HDR V44 [1/2]

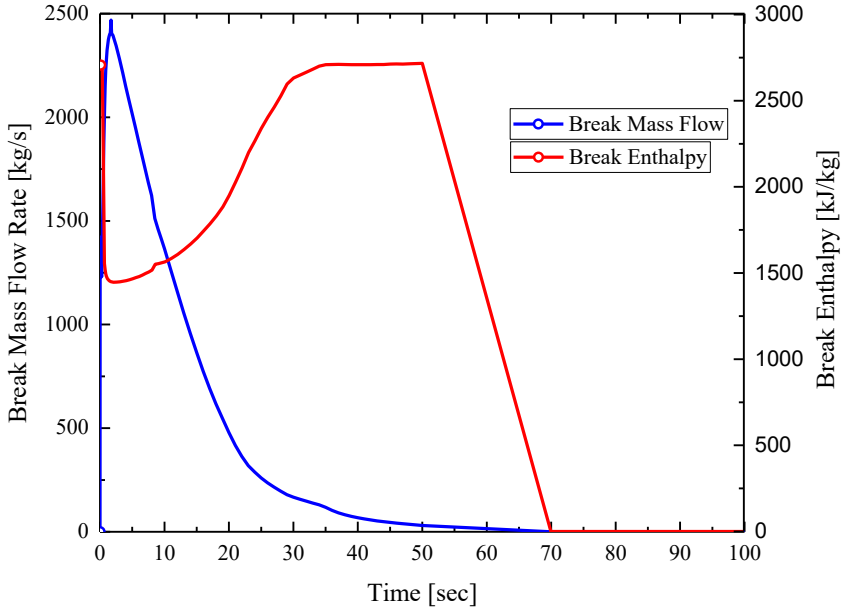
Target Physics

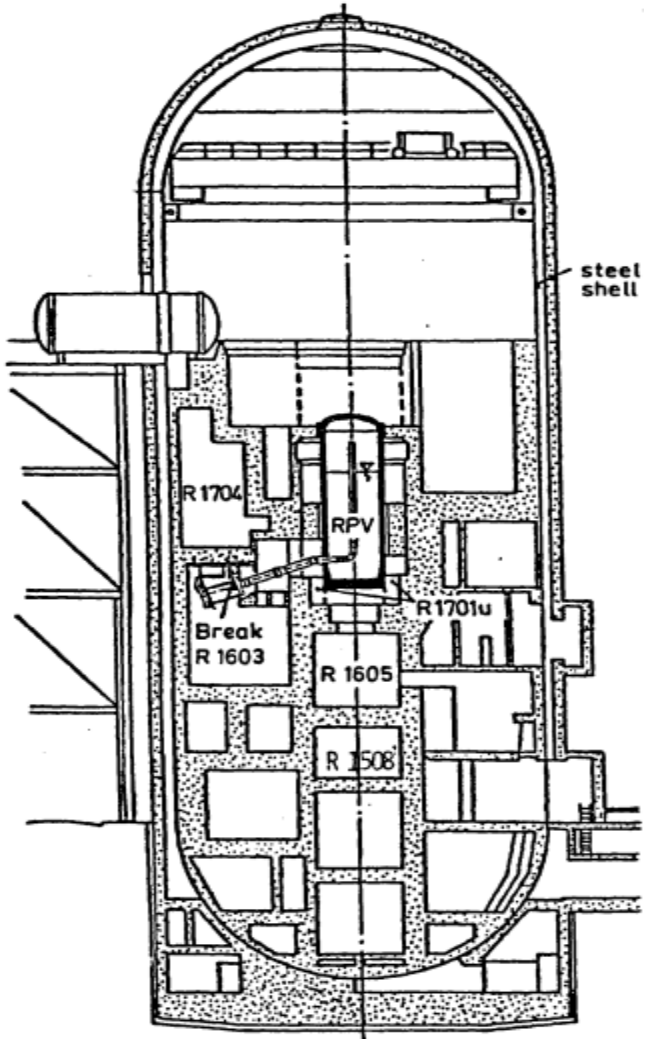
- Steam/Water Blowdown, Condensation

Geometry

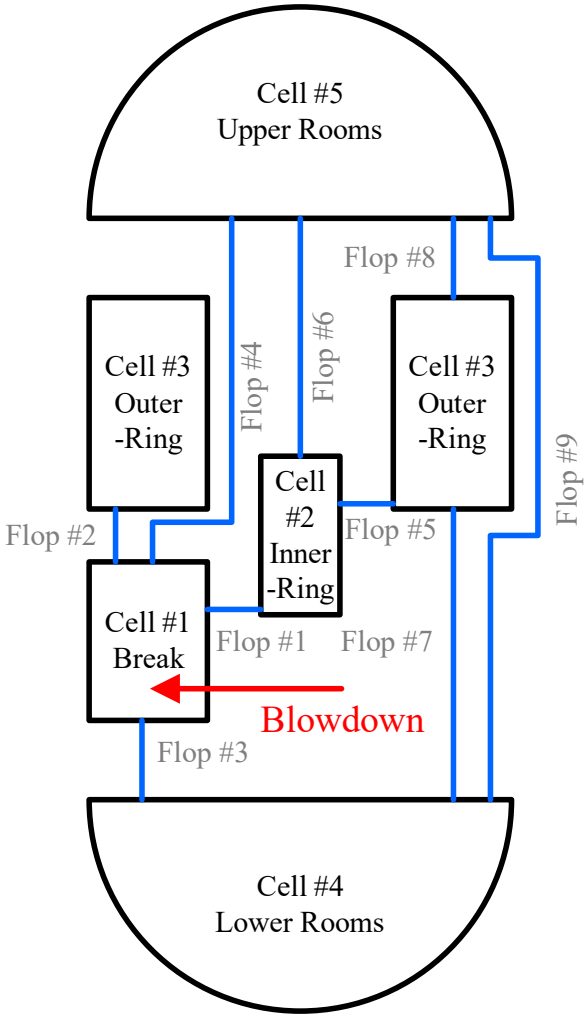
- Total Height: 60 m
- Diameter: 20 m
- Total Volume: 11,300 m^3

Blowdown Condition





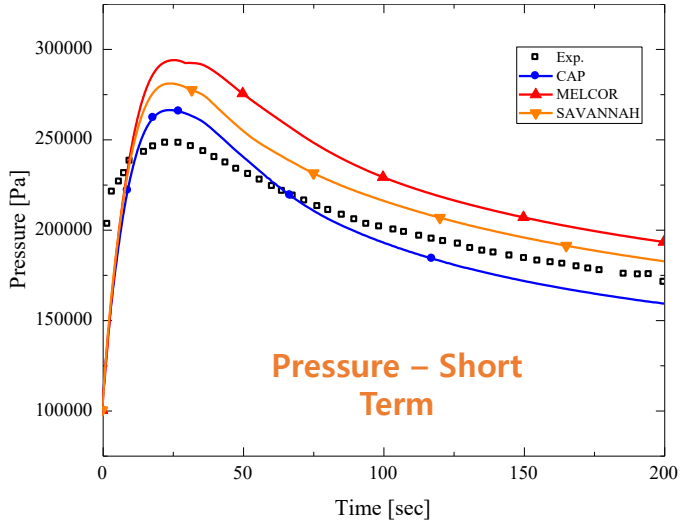
Schematic Diagram

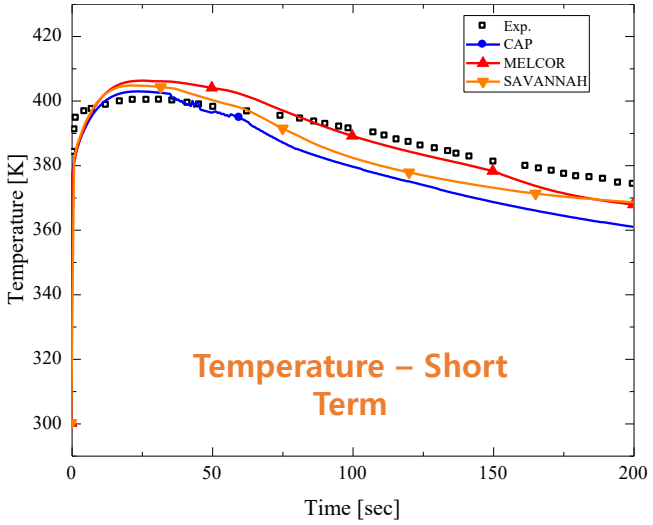


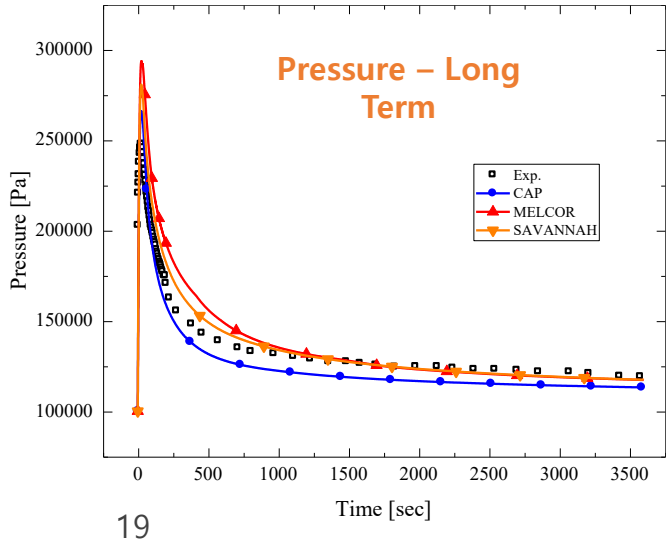
Nodalization

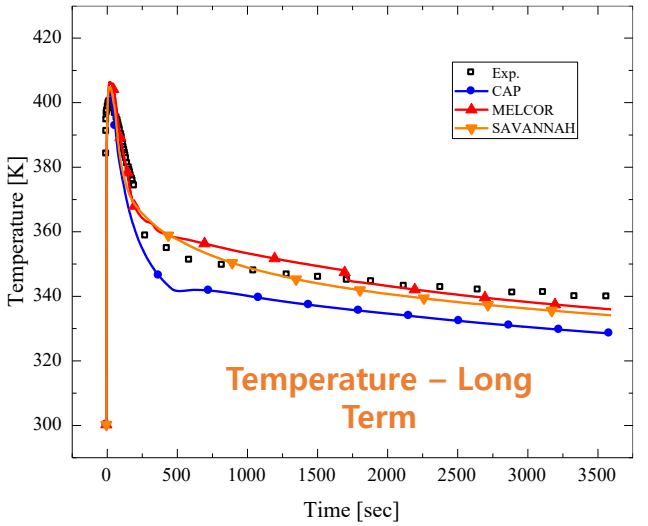
Validation – HDR V44 [2/2]

- Peak pressure slightly over-predicted by all codes
- SAVANNAH shows similar long-term behavior to MELCOR
- CAP predicts pressure and temperature lower than other codes









5 Conclusion & Future Work

Conclusions

- SAVANNAH was developed as a containment thermal-hydraulic analysis module within the SAFARI framework
- The governing equations for TH is similar with MELCOR
- Verification results showed good agreement with analytic solutions
- Validation tests demonstrated that SAVANNAH can reasonably predict:
  - Blowdown behavior
  - Pressure response
  - Condensation trends in containment thermal-hydraulic response

Future Work

- Integrate SAVANNAH with other SAFARI modules for coupled analysis.
- Advanced code refinement to improve prediction accuracy under highly transient and multi-dimensional convective conditions

$$b_{\phi,j} = -\frac{\alpha_{j,-\phi} f_2 L_2 \Delta t}{\rho_{j,\phi} L_j}$$

$$c_{\phi,j} = -\frac{\Delta t}{\rho_{j,\phi} L_j}\left\{\sum_j F_j A_j \Delta t \sum_m \rho_{j,m}^d \alpha_{j,P}^n \left[\sigma_{ij}\left(\frac{\partial P^*}{\partial M_{i,P}} + \frac{\partial P^*}{\partial E_{i,P}} h_{j,m}^d\right) - \sigma_{kj}\left(\frac{\partial P^*}{\partial M_{k,P}} + \frac{\partial P^*}{\partial E_{k,P}} h_{j,m}^d\right)\right]\right\}$$

$$d_{\phi,j} = -\frac{\Delta t}{\rho_{j,\phi} L_j}\left\{\sum_j F_j A_j \Delta t \sum_m \rho_{j,m}^d \alpha_{j,A}^n \left[\sigma_{ij}\left(\frac{\partial P^*}{\partial M_{i,m}} + \frac{\partial P^*}{\partial E_{i,A}} h_{j,m}^d\right) - \sigma_{kj}\left(\frac{\partial P^*}{\partial M_{k,m}} + \frac{\partial P^*}{\partial E_{k,A}} h_{j,m}^d\right)\right]\right\}$$

$$e_{\phi,j} = v_{j,\phi}^{o+} + \frac{\Delta t}{\rho_{j,\phi} L_j}\left\{\widehat{P}_i + \Delta P_j - \widehat{P}_k + (\rho g \Delta z)_{j,\phi}^o + \frac{\partial (\rho g \Delta z)_{j,\phi}}{\partial M_{i,P}}(\widehat{M}_{i,P}^o - M_{i,P}^{o+}) + \frac{\partial (\rho g \Delta z)_{j,\phi}}{\partial M_{k,P}}(\widehat{M}_{k,P}^o - M_{k,P}^{o+}) + v_{j,\phi}^o (\rho \Delta v)_{j,\phi}^o\right\} + \frac{K^* \Delta t}{2L_j}|v_{j,\phi}^{n-2}| v_{j,\phi}^{n-1}$$

Condensation Heat Transfer Model

- While CAP adopts the Uchida model, SAVANNAH and MELCOR employ the Heat and Mass Transfer Analogy(HMTA) model under non-condensable gas conditions;

- Condensation Model
  - CAP: $h = 450(\frac{\rho_{ncg}}{\rho_{steam}})^{-0.8}$
  - MELCOR: $h = Sh\frac{D}{L_c}$

    $Sh = NuSc^{1/3}Pr^{-1/3}$
  - SAVANNAH: $h = \frac{\Gamma_d'' h_{fg}}{T_g - T_w}$

    $\Gamma_d'' = \frac{\rho_{stm} ShD_{sg}}{L_c} ln[\frac{max(P_{tot} - P_w, 0.1)}{P_{ncg}}]$

    $Sh = NuSc^{1/3}Pr^{-1/3}$

ABSTRACT

Pool scrubbing is a process for the mitigation of the source term in many Severe Accident (SA) scenarios, regardless of reactor technology. Naturally set and/or *ad-hoc* included in some safety systems, its efficiency depends on thermal-hydraulic and physicochemical variables, whose variability ranges are extremely broad. As a result, estimating accurate and reliable predictions poses a big challenge for SA system and stand-alone codes. This work presents a broad and systematic evaluation of SPARC90, which is the basis of the pool scrubbing module in MELCOR and ASTEC, against a credited database of more than 100 tests, which encompasses prevailing boundary conditions of any scenario in which pool scrubbing might play a role. The results indicate that SPARC90 generally follows, but underestimate data, with a mean signed relative error of -21%. Nonetheless, the code systematically misses data points representing specific scenarios, like Steam Generator Tube Rupture (SGTR) or Filtered Containment Venting System (FCVS) experiments, consistently with its modeling capabilities. Conditions representative of Molten Core Concrete Interaction (MCCI) are also explored through selected surrogate tests, suggesting that a reasonable predictive capability might still be achievable. The discussion of these findings provides a rational basis to orient future developments in pool scrubbing modelling.

KEYWORDS
Pool scrubbing, SPARC90, model validation, source term.

1. INTRODUCTION

Pool scrubbing is an efficient source term mitigation process during Severe Accidents (SA). It refers to the set of mass transfer phenomena responsible for particulates and vapors absorption by a continuous liquid body when a gaseous disperse phase moves across it. Pool scrubbing is not a reactor-specific process, but it might occur in several safety relevant scenarios of water-cooled reactors. Some examples are: Boiling Water Reactors (BWR), such as Fukushima [1], Pressurized Water Reactors, particularly in Steam Generator Tube Rupture (SGTR) accidents [2], Small Modular Reactors [3], Filtered Containment Venting Systems (FCVS) [4], and Molten Core Concrete Interaction (MCCI) [5]. This scenario diversity results in broad ranges of boundary conditions that may even change over time, from sub-cooled to saturated pools, high to low injection velocities, or deep to shallow pools. As a consequence, a large and sound database is of utmost importance to thoroughly characterize pool scrubbing and to benchmark dedicated codes.

The efficiency of pool scrubbing is indeed determined by a wide range of parameters, which are generally categorized according to the physical phase they influence on. Factors related to the carrier gas include its

composition, temperature, and flow velocity; those associated with Fission Products (FP) involve their physical state (aerosol or vapor), particle size distribution, and composition; while the pool parameters encompass its thermal condition, its size, submergence, and the configuration and type of injectors. Over the past several decades, these aspects have been the subject of extensive experimental and analytical research ([6], [7], [8]). Notably, the intensive programs conducted during the 1980s and 1990s produced several standalone computational models, such as BUSCA ([9]), SUPRA ([10]), and SPARC90 [11], that were later integrated into integral system codes like MELCOR ([12], [13]) or ASTEC [14]. However, as other studies have already shown, pool scrubbing models need enhancements and/or extensions [15].

In this direction, the long-term objective of this research is to establish a modelling framework capable of simulating pool scrubbing in a flexible and consistent way across the different reactor types and accident scenarios in which this process may occur. As a necessary first step toward such a framework, SPARC90 has been selected to be systematically assessed to quantify its predictive capabilities, identify its main limitations, and thereby provide a rational basis for any subsequent model development or extension.
To this end, a unique and high-quality experimental database has been built, gathering information from more than 900 tests performed in nearly 50 independent programs [16]. A subset of "Qualified for Validation" (QfV) experiments, selected through an adequacy analysis [17], is then simulated in SPARC90, with the goal of systematically assessing its capabilities in simulating a broad and diverse dataset. While earlier assessments have typically relied on limited subsets of experiments, the availability of a broader and rigorously characterized dataset enables a comprehensive and homogeneous understanding of the SPARC90 predictive performance over a wide spectrum of conditions. The work provides indeed an in-depth understanding of the similarities and discrepancies between numerical predictions and experimental evidence. Beyond a global evaluation of the code accuracy, the analysis further addresses safety-relevant configurations, including SGTR, FCVS, and MCCI scenarios, with the objective of identifying priorities and directions for subsequent model improvement.

The variable adopted as reference metric to assess SPARC90 is the Decontamination Factor (DF), defined as the ratio of the incoming over the outgoing mass of aerosols in the pool. The present study is restricted to aerosol scrubbing, so that FP vapors are beyond scope.

2. METHODS

2.1. SPARC90

SPARC90 is a semi-empirical simulation tool developed at the Pacific Northwest Laboratory to evaluate FP retention in BWRs pressure suppression pools during SA [11]. The code models the complex thermal-hydraulic and physicochemical interactions between gas-aerosol mixtures discharged through submerged vents and the pool, providing estimates of aerosol and iodine scrubbing efficiencies. The code's formulation and validation rely predominantly on experimental programs from the 1980s and 1990s, which were largely conducted under BWR conditions and reflect vent geometries typical of suppression-pool designs.

SPARC90 represents the suppression pool as a system of interacting zones: the vent exit region, the unstable globule breakup region, the rising bubble swarm, and the pool surface. The code, however, explicitly calculates aerosol removal only in two regions: the vent-exit region, where inertial impaction and condensation driven deposition dominate, and the rising bubble swarm region, where centrifugal deposition, gravitational settling, and Brownian diffusion govern particle capture. The unstable globule breakup region is not modeled for scrubbing; instead, the breakup length determines the starting point of the swarm. The pool surface region is assigned a unit decontamination factor (DF = 1), because scoping calculations suggested that any additional retention associated with bubble bursting or surface condensation is negligible under expected BWRs SA conditions [11].

SPARC90 also simulates the effects of bubble coalescence and cooling during rise, incorporating coupled heat and mass transfer between the gas phase and the surrounding liquid. These processes produce supersaturated vapor conditions that promote aerosol hygroscopic growth, treated by both mechanistic (Mason-type) and thermodynamic-limit models. The code also features additional subroutines for volatile iodine species.

SPARC90 can represent different vent or injector geometries, such as downcomers, horizontal vents, and multi-hole "T" or "X" quenchers, through specific correlations for globule formation, breakup length, and vent Weber number. Input parameters define the pool geometry, vent configuration, aerosol size distribution, and gas composition, while output includes DFs for each particle size class and overall system performance. Figure 1 illustrates the SPARC90 flow chart [11].

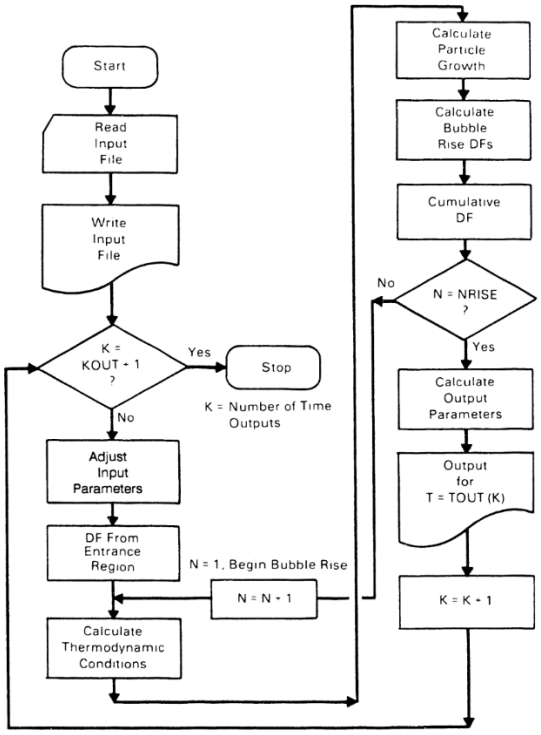

Figure 1. SPARC90 flow chart [11]**.**

2.2. Database

The global pool scrubbing database retrieved from the open literature for this ongoing research consists of more than 908 experiments belonging to 48 experimental programs carried out from the 1960s to 2025. After compiling it with available information, a database adequacy analysis was carried out to achieve the highest quality standard feasible for code validation [17], [18]. This methodology allows a systematic evaluation of representativeness and completeness of a database. The resulting validation matrix collects 106 QfV experiments which address a wide range of conditions of the key variables affecting pool scrubbing, like particle size distribution, gas and aerosol flow rates and compositions, pool depth and thermal state, and injection configurations. Table I collects the most relevant information of this validation matrix, whereas more details are provided in [16].

Table I. Pool scrubbing validation matrix [16].

Several researchers, such as ([10], [15], [19]) have discussed the limitations of current pool scrubbing predictions, particularly in relation to SPARC90. However, a broad and comprehensive evaluation of this code is still lacking in the literature, as most previous modeling efforts have relied on relatively small subsets of experiments. Therefore, assessing SPARC90 against a broad and diverse database such as the one shown in Table I is of primary importance for a comprehensive analysis of its capabilities. Most of these experiments consist of injecting gases into a bare pool as it happens in multiple pool scrubbing scenarios, like suppression pools, quench tanks or even auxiliary buildings in V-sequences. Notably, however, few SGTR experiments are available among the QfV ones, which could provide meaningful information as for the SPARC90 specific capabilities in this scenario. Considering instead FCVS, available experiments such as [20], are not considered QfV for different reasons [16], but labeled Useful for Understanding (UfU), and usable to study FCVS pool scrubbing performance. MCCI, on the other hand, does not feature dedicated experiments, yet some QfV tests share relevant boundary conditions with MCCI, making them suitable to assess SPARC90 capabilities in this scenario.
Furthermore, most QfV experiments (82/106) were conducted under jet injection regime. However, SPARC90 hydrodynamics models only consider bubble regime. Assessing the code against these experiments may therefore highlight deficiencies and indicate specific directions for improvement.

Finally, when performing code validation, it is mandatory to assess the validity range of the validation exercise. In this context, Table II summarizes the ranges of the most relevant boundary conditions covered by the pool scrubbing validation matrix (Table I). These ranges describe the experimental conditions included in the database and set the limits of the present benchmark.

Table II. Boundary conditions covered by the pool scrubbing validation matrix.

Boundary Conditions		
Particle Characteristics	Composition	CsOH,MnO,CsI, DOP, Ni, SnO_2, TiO_2, Nanophase TiO_2, SiO_2

	AMMD (μm)	0.2-7.2
Carrier Gas	Composition	Air, Air+Steam, N2+Steam
	Mass Flow Rate (kg/s)	1.04E-04 to 1.09E-01
	Weber number	6.93E+01 to 9.49E+06
	Steam Mass Fraction (%)	0 to 98
Thermal Hydraulics	Pool Temperature (K)	293.0 to 399.5
	Pool Pressure (Pa)	1.23E+05 to 4E+05

	Injector Diameter (m)	5E-03 to 2E-01
	Submergence (m)	0 to 4.61

3. RESULTS AND DISCUSSION

3.1. Global Behavior

Figure 2 illustrates the simulation results: experimental DF with error bands, and SPARC90 DF values are plotted for QfV experiment. As noted, SPARC90 generally underestimates measurements: a Mean Signed Relative Error (MSRE) of -21% is calculated between predictions and experimental values. The MSRE, defined as $MSRE = \frac{1}{N}\sum\left(\frac{prediction-experiment}{experiment}\right) * 100$, is a performance metric used to evaluate how much a model's predictions differ from the actual values. A MSRE closer to zero indicates a global higher accuracy, while its sign represents the direction of the error.

Despite this reasonable global agreement, SPARC90 shows a markedly different behavior depending on the magnitude of the experimental DF, as highlighted in Figure 2. For this reason, three DF ranges are considered to cluster the experiments: DF lower than 20, DF between 20 and 100, and DF higher than 100.

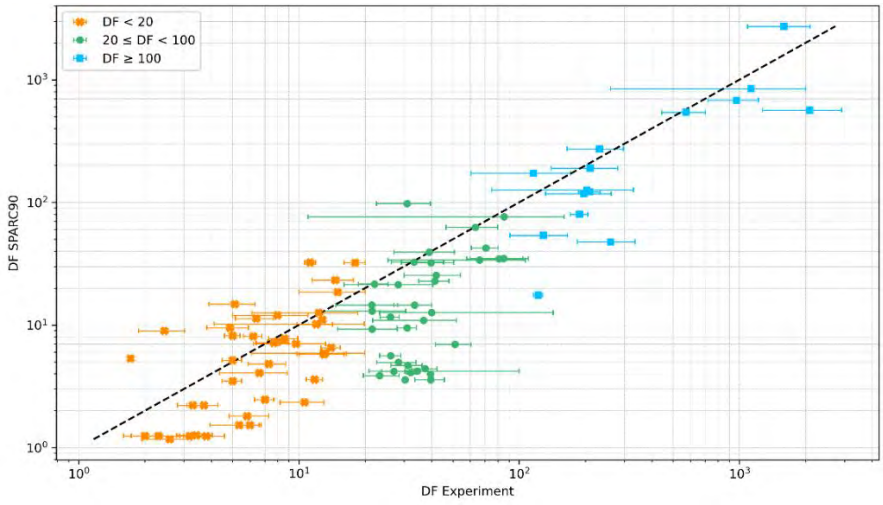

Figure 2. SPARC90 vs experimental DF.

In the low-DF range (DF < 20), which includes 42 experimental points, the MSRE is approximately +2%, indicating a slight overestimation of the experimental values and an overall very good agreement. In the intermediate range (20 < DF < 100), the MSRE decreases significantly to -47%. This range includes 34 experiments, providing sufficient statistical robustness to confirm a systematic underestimation by the code. Finally, in the high-DF range (DF > 100), only 15 experimental points are available, but an MSRE of -27%

is still observed, confirming the general tendency of SPARC90 to underestimate experimental DF values. In this region, a Root Mean Square Error (RMSE) of 509 indicates that the MSRE is dominated by a few experiments characterized by very high DF values.

At this point, it must be stressed that a global MSRE of -21% might be within the expected accuracy for pool scrubbing analytical tools, considering the intrinsic uncertainties of the experimental measurements. The determination of the DF relies on the ratio of two distinct mass measurements: the incoming and the outgoing aerosol mass. While the incoming mass is typically measured in a well-defined injector geometry with controlled isokinetic sampling, measuring the outgoing mass is significantly more challenging.
The aerosol exiting the pool spreads across a broad cross-section, where the hydrodynamic complexity of the bubble swarm, characterized by continuous coalescence, break-ups, and interfacial exchanges, generates radial concentration gradients [21]. Achieving a perfectly representative sample in such conditions is technically demanding, and even minor deviations in sampling representativeness can propagate into the calculated DF. In fact, the impact of these experimental challenges is reflected in the magnitude of the error bars observed in the experimental data points, as visible in Figure 2.
Therefore, the global SPARC90 MSRE seems consistent with the order of magnitude of the inherent experimental uncertainty. This comparison, however, does not intend to overlook the physical deficiencies of SPARC90, but it suggests that the code's predictions are reliable enough to capture the dominant features of the decontamination process within the limits of experimental data.

It is also worth recalling that DF is the parameter most commonly adopted in pool scrubbing analyses. However, from a nuclear safety perspective, the truly relevant quantity is the actual mass of radionuclides leaving the pool, as it directly contributes to the source term. For this reason, Figure 3 compares SPARC90 predictions and experimental data in terms of outgoing aerosol mass.

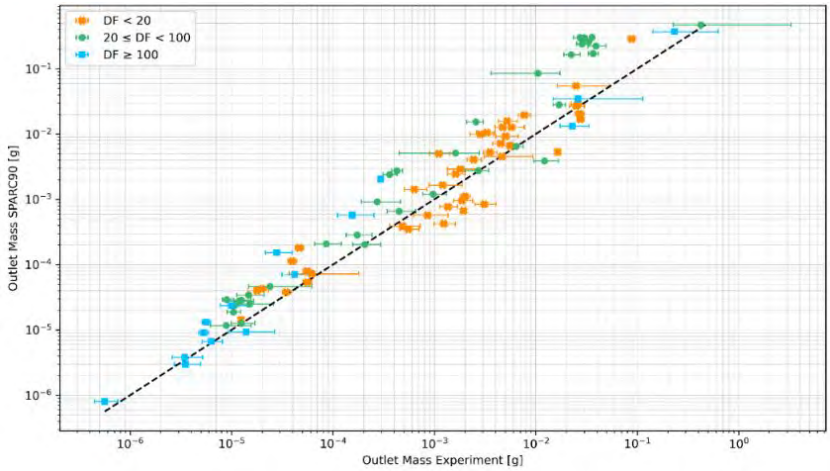

Figure 3. SPARC90 vs experimental outgoing mass from the pool.

Notably, absolute mass values are strongly dependent on the specific facility and experimental protocol, which makes direct comparison between different experiments less straightforward. Therefore, the three DF ranges previously defined are considered again in order to consistently analyze SPARC90 behavior.

Furthermore, pool scrubbing experiments are often conducted in small-scale facilities, where tiny aerosol masses are injected and measured. As a consequence, even a small absolute difference between simulated and experimental outgoing mass can result in a large relative error. Indeed, MSRE values computed in terms of outgoing mass are significantly larger than those obtained for DF: a global MSRE of 155% is obtained, with values of 63% for DF < 20, 284% for the intermediate DF range, and 119% for DF > 100. Although larger in magnitude, these trends are consistent with those observed for DF. In most cases, SPARC90 yields

conservative results by overestimating the outgoing mass, while showing better accuracy at low DF and larger discrepancies at higher DF.

Overall, these results are partially in contrast with previous SPARC assessments, such as ([8], [22]), which showed much larger discrepancies between experiments and calculations, particularly at high DF and under jet injection. The difference between the present assessment and previous ones is likely attributable to the different datasets employed. As stated earlier, in the current work the validation relies on a wider and more rigorously characterized set of experiments, selected through a systematic approach (i.e., adequacy analysis). This ensures that the comparison between model and data relies on measurements with well-understood conditions and quantified experimental errors. This said, specific insights on SPARC90 accuracy will be further discussed below.

3.2. High-velocity injection regime

As said above, a good number of data points in the database fall in what is known as jet-injection regime (i.e., We $\geq 10^5$). As shown in Fig. 4, SPARC90 can predict DF values from jet experiments with reasonable accuracy. Jet experiments exhibit a larger scatter, with both under- and over-predictions, and with calculated DF values up to an order of magnitude lower than measured and other times 3 times higher than measured. Anyway, when expressed in terms of MSRE is -23% (7 points over the globule's one, -16%). Therefore, it is important to bear in mind the limitations of MSRE itself for a full characterization of analytical estimates. The largest deviations span indeed from a -91% to a +267% MSRE.

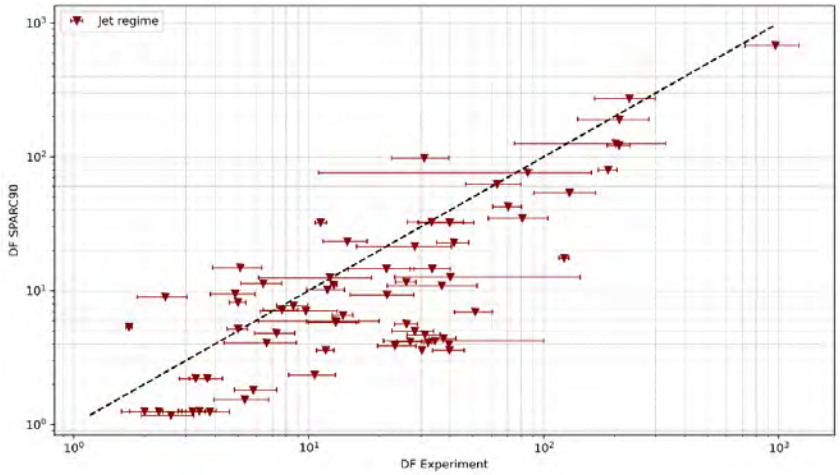

Figure 4. SPARC90 vs experimental DF highlighting jet and bubble experiments.

Beyond what said in the paragraph above, the most interesting observation is the fact that SPARC90 estimates under jet-injection regime do not rely on any analytical model, either empiric or mechanistic, of the jet injection regime. As highlighted by [23], a mathematical algorithm of any kind is missing in the SPARC90 source code. And yet, SPARC90 seems to be able to capture this effect. A deeper look into the estimates allows finding that what is happening is closely related to the integral nature of DF. In jet-injection scenarios, SPARC90 cannot remove particles due to inertial deposition nearby the injection spot. However, other removal mechanisms acting on the way the gas reaches the pool surface makes the job (aerosol removal processes are proportional to in-bubble airborne concentration). Therefore, those accurate SPARC90 estimates happen just due to an error compensation [22].

3.3. SGTR scenario

SGTR experiments are systematically underpredicted, as shown in Figure 5. Slightly smaller deviations are observed when steam is present in the carrier gas, supported by a MSRE of -74% in steam experiments, versus -93% for the others. Condensation is a fast thermal phenomenon that likely occurs nearby injection, so that it is responsible for an early decontamination of the carrier gas. For this reason, whenever present, it fades off the influence of the huge surface exposed to the tight pack of inverted U-tubes, which foster in-pool particle absorption.
Since SPARC90 currently lacks models for submerged structures, this assessment is not intended as a validation of the code for SGTR conditions. Rather, it serves to identify its present limitations and to support future model development. Previous studies ([24] [25]) show that SGTR scenarios exhibit enhanced in-pool retention because the U-tube bundle increases gas fragmentation and turbulence. These mechanisms are not represented in SPARC90, which explains its discrepancy under SGTR conditions.

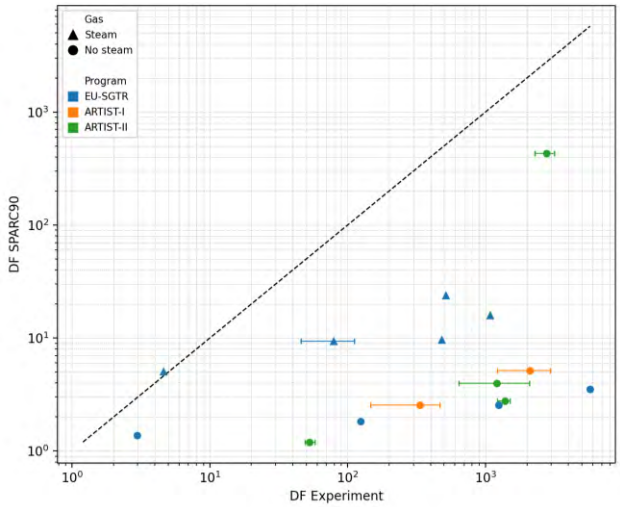

Figure 5. SPARC90 vs experimental DF for SGTR experiments.

3.4. FCVS scenario with Venturi injector

Experiments employing a venturi-scrubber injector represent some wet FCVS designs. As expected, given the lack of an *ad-hoc* venturi model in SPARC90, the results (Figure 6) confirm that SPARC90 is unable to accurately reproduce these data causing a systematic underprediction. Similarly to the SGTR case, this assessment aims at quantifying performance discrepancies arising from missing FCVS physics rather than validating current code capabilities.
It is worth noting, though, that the venturi tests conducted by [20] were not included among the QfV experiments listed in Table I. However, they were classified as UfU with respect to venturi behavior [16].

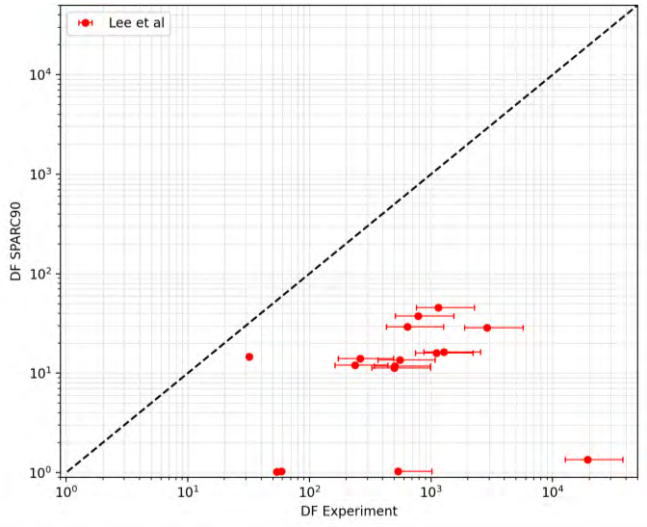

Figure 6. SPARC90 vs experimental DF for VENTURI experiments.

3.5. MCCI scenario

Pool scrubbing during the ex-vessel phase of an accident scenario would occur whenever a water layer covers the corium melt. Concrete thermal decomposition generates H_2O_v and CO_2, which going through the melt oxidize remaining metals and turn into CO and H_2. As a result, those gases contaminated by FPs absorbed when moving across the corium reach the corium interface and bubble in the water phase. Even though few studies have specifically addressed this scenario [26], some of the experiments in the database might be considered partially representative, by comparing the most relevant boundary conditions:

- Water temperature. Given the hot temperatures of corium melt, it is reasonable to assume that water will be near or at saturation soon after the interaction onset.
- Particle size. Several experimental programs investigated the features or aerosols emitted from MCCI processes ([5], [26], [27]), indicating a 0.1-4 μm AMMD range for MCCI aerosols.
- Gas flow rate and composition. At MCCI beginning, metals are still present within the corium and are oxidized by the MCCI gases, resulting in a gas mixture predominantly composed of CO and H_2. Since the molecular weight of CO is close to that of air (28 vs 29 g/mol), and CO would dominate the mixture by mass, it is reasonable to approximate MCCI pool scrubbing using air experiments.
- Multiple-hole injection. Gas and FPs injections would be distributed across multiple openings at the interface between the corium crust and the water.

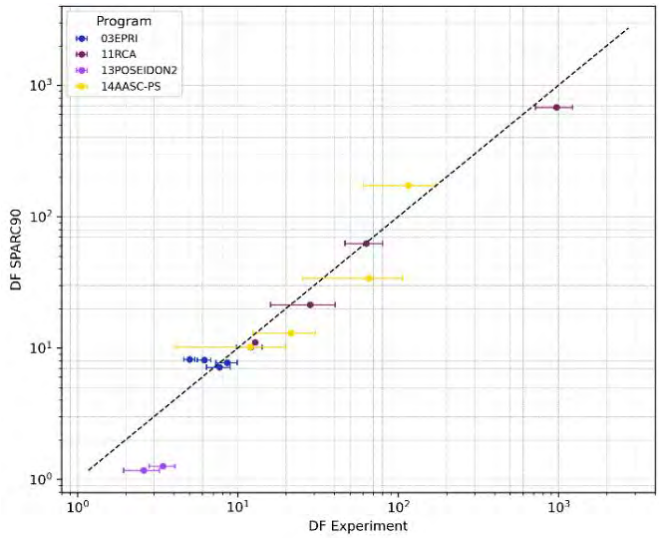

Figure 7. SPARC90 vs experimental DF for MCCI-like experiments.

In sight of these conditions, no condensing tests with air injection meeting the rest of requirements above might be adopted as MCCI-like tests. Among the QfV experiments, 15 of them meet these criteria, although none employ a multi-hole injector, which is a decontamination enhancer.
Data-SPARC90 comparison is displayed in Figure 7. Agreement of estimates and data is visible. In other words, the analysis suggests that SPARC90 is capable of simulating MCCI pool scrubbing. Dedicated experiments under anticipated prevailing conditions, though, would help to further validate this observation.

4. CONCLUSIONS

This paper presents a rigorous and systematic assessment of SPARC90 against a broad and QfV database. Three major takeaways can be highlighted:

- Broadly speaking, SPARC90 demonstrates a good predictive capability when compared against more than 100 data, showing a DF MSRE deviation a bit higher than 20% in absolute terms. A closer look to the SPARC90-data comparisons highlight the fact this deviation falls down to the range of 2% for scenarios with limited retention efficiencies (≤95%). For higher retention efficiencies (i.e., less contamination going out of the pool), MSRE are higher but with a dominant bias to underpredict.
- When compared to MCCI-representative data, SPARC90 displays a remarkable agreement with data, which highlights its ability to address those scenarios, even if not initially considered in the code conception.
- On the contrary, according to the results shown and discussions held in previous sections, SPARC90 use in scenarios with any high injection gas velocities, venturi scrubbers (FCVS) or submerged structures (SGTR) is not credited. Even in cases where estimates might be considered acceptable (high injection regime), SPARC90 does not feature the proper physical models at the pool injection zone; in other words, numerical consistency comes from the wrong reasons. In the other two scenarios, the configuration makes some of SPARC90 hypotheses not to be valid anymore. Addressing those scenarios would entail a substantial extension of SPARC90 formulation.

Further analyses are planned to enhance the understanding of SPARC90 behavior and to support targeted improvements of the model. In the short run, the authors aim to:

- Quantitatively test the assumptions currently adopted in SPARC90 for the inlet region (globule breakup transition) and the pool surface, which were originally validated for BWR conditions, and assess their impact on the overall DF in a wider range of accident scenarios.
- Extend the physics of SPARC90 to explicitly address the jet injection regime by implementing a physically consistent jet model, thereby ensuring that current satisfactory DF predictions are supported by sound physical grounds, thus improving the overall robustness of the code.

  - air injection only.
  - hot pool experiments.

04

Main Insights

WRAP-UP

General Reliability

- SPARC90 demonstrated **reasonable predictive accuracy** across 100+ experiments, with a global MSRE of -21%.
- Remarkable **agreement with MCCI**-representative data, despite being a non-native scenario for SPARC90.

Modeling Gaps

- SPARC90 **misses FCVS and SGTR predictions**, consistently with the models it features.
- SPARC90 predicts with **reasonable accuracy jet-injection** DF despite lacking specific models: **right results for the wrong reasons**.

NEXT STEPS

- The **transition region** during globule breakup is only partially treated in SPARC90.
- The pool **surface region** is not presently simulated in SPARC90 (DF = 1 in this zone).
- **New physics**: jet, FCVS and SGTR physics must be included in SPARC90 to ensure long-term consistency.

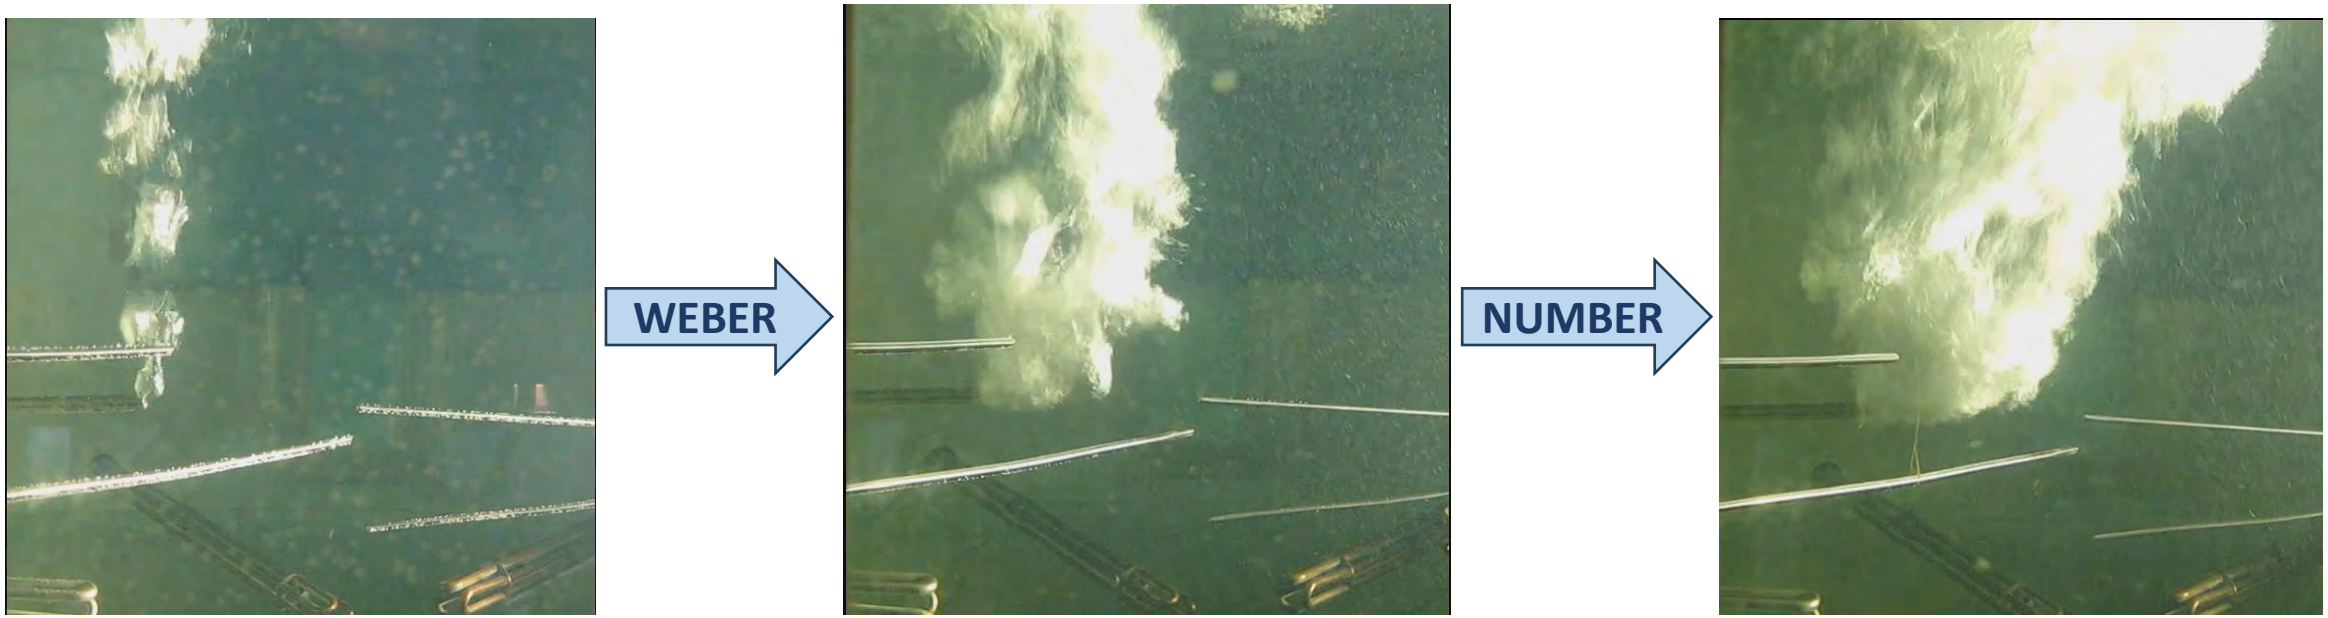
- Possibly, identify some phenomena to be included into SPARC as a **new correlation** (paper).



POOL SCRUBBING IN WATER COOLED SMRs: SCENARIOS, PECULIARITIES AND CHALLENGES

L.E. Herranz, M. Garcia, T. Lugo
CIEMAT
Avenida Complutense 40, 28040 Madrid (Spain)

ABSTRACT

Pool scrubbing might be an add-on to the built-in passive systems used in most WC-SMRs, strengthening even further the passive nature of accident management. This work investigates potential pool scrubbing scenarios in a generic 300 MWe integral Pressurized Water Reactor. By using MELCOR 2.2 accident scenarios in which pool scrubbing might play a role in mitigating any potential source term to the environment have been identified and thoroughly analyzed. The results indicate that some water-filled components potentially playing a role in cleaning-up the contaminated gases entering containment are by-passed due to reverse flow caused by an earlier containment failure. In other scenarios, though, components like the pressurizer quench tank provided an effective filtering of the radioactive gas (up to 70% of the mass entering), even under unfavorable conditions for the scrubbing process. The present paper, framed within the Euratom SASPAM project, will thoroughly discuss these finding.

KEYWORDS
Source Term, Severe Accident, Pool Scrubbing, WC-SMRs

1. INTRODUCTION

Fission products retention in water ponds, hereafter pool scrubbing, is known to be an efficient way to mitigate potential source term to the environment in case of a SA in nuclear power plants. When hot, contaminated gas gets into a water pond, thermal and hydraulic interactions between gas and water are the origin of a set of phenomena (including steam condensation, droplet entrainment or internal gas circulation) that foster aerosol and vapour depletion mechanisms (diffusiophoresis, inertial impaction or centrifugal deposition among others) causing the transport of radioactive material to the gas-water interface and, finally, their absorption into the pool. The efficiency of these processes is dependent on prevailing conditions in the carrier gas, radioactive material properties and thermal state of the pool. A vast investigation has been conducted over decades to thoroughly understand the multi-physics that govern these complex processes [1], [2], [3], [4], [5], [6].

Given the huge amount of water bodies in WC-SMRs**,** and particularly in iPWR designs, the potential of pool scrubbing is relevant. Many iPWR concepts incorporate a submerged containment or water pools that could act as a passive scrubbing barrier during a SA, enhancing defense-in-depth by increasing retention of fission products before they could reach the environment. Few studies [7] have specifically addressed pool scrubbing in iPWRs so far, but traditional source term analysis methods are being tested in frameworks like EU SASPAM [8].

Within the framework of the Horizon Euratom SASPAM project [8], CIEMAT has investigated postulated SA scenarios in a generic 300 MWe iPWR design. Beyond identifying those scenarios and thoroughly

characterize them, the focus of such analyses was to assess the role of pool scrubbing in mitigating source term. In this work the analytical tool used is MELCOR 2.2 [9], [10].

2. STUDY APPROACH

A generic 300 MWe iPWR characterized by a dry spherical containment and the use of several passive systems is the focus of the present study. During normal operation, the reactor functions with forced circulation, while in the event of accidental transients, it relies on a passive safety strategy. The design features an integral RPV that houses the core, a compact SG, the CRDM, the primary pumps, and the PRZ located in the upper section, which is separated from the riser by a perforated plate. Heated water exiting the core rises through a circular riser up to the primary pumps suction [11]. The use of passive SSs offers improvements in plant simplification, safety, reliability, and investment protection compared to conventional plant designs [12]. A sketch of the plant and the passive SSs configuration is shown in Fig. 1 and includes:

- The EHRS consists of 4 independent loops operating in natural circulation. Each loop includes a horizontal U-tube heat exchanger connected to a separate SG feed/steam line. The heat exchangers are located in the RWST (two units) outside the containment. Its functions are both core cooling and containment depressurization.
- Two full-system pressure EBTs to provide borated water to the RPV by gravity for reactor shutdown.
- The ADS assists the EHRS in depressurizing the RPV when/if the RPV coolant inventory drops below a specific level by releasing steam in the pool of the QT located in the DW (ADS st-1) and allows the pressure equalization between containment and RPV atmospheres (ADS st-2).
- The containment PSS consists of two tanks connected to the DW through a vent pipe to condense the steam released into the containment following a LOCA or steam/feed line break accident, thereby limiting containment pressurization. Additionally, the PSS provides an elevated water source for gravity injection into the RPV in the event of a LOCA accident.
- The LGMS consists of two large tanks located in the DW and connected to the DVI lines.

The modeling and the analysis of the sequences included in this study were conducted using the MELCOR 2.2 code [9], [10].

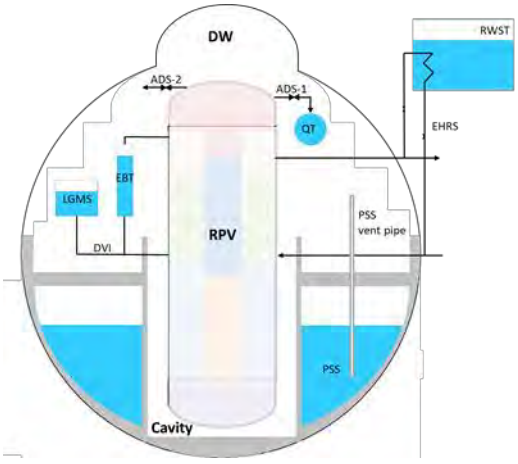

Figure 1. Passive SSs sketch (for simplicity, only one line is reported for redundant systems).

In case of a SA initiated by a small break ($4.28 \cdot 10^{-2}$ m diameter) in the DVI pipe connecting RPV and LGMS and EBT, pool scrubbing might happen in two specific locations: the PSPs, when FPs reaching the DW from the reactor core are carried through the connecting pipe into PSP; the QT, when FPs released from the core find their way through the ADS st-1 system (activated by low RCS pressure) to the aqueous phase in the QT and, from there, to the containment DW atmosphere.

Four scenarios have been considered in this analysis, based on the work conducted under the WP2 frame of the SASPAM project. Table II shows the safety systems assumed operative during the accident unfolding. It is worth noting that triggering a SA requires failure of EHRS.

2.1. Modeling Overview

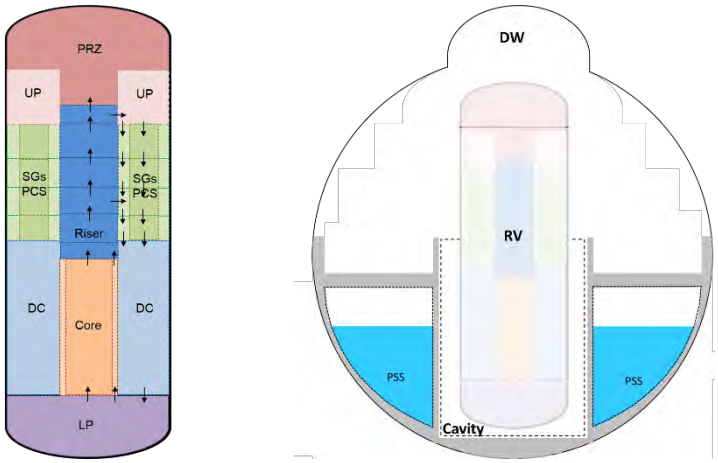
MELCOR requires two types of nodalization within RPV: one is specifically devoted to tracking fuel along the accident, i.e., fuel degradation through the COR package; the other is used for THs calculation through the CVH package [9], [10].

The reactor core is located inside the integral RPV and features internal structures and assembly configurations similar to the Westinghouse 17x17 XL fuel assembly design [13]. For modeling fuel degradation through the COR package, the core is segmented into 6 radial zones (rings) and 16 axial levels (Fig. 2a). The 89 FAs are distributed from ring 1 to 4. The FAs are divided into 16 axial core levels being the active part of the reactor core from axial level 7 to 14. Cells belonging to fifth and sixth rings correspond, respectively, to the LP zone under the DC and the core-bypass.

The reactor core is represented by a single CV and is connected to the LP and riser through FLs. Similarly, the core-bypass, also represented by 1 CV, establishes connections with the LP and the riser. The LP consists of one CV divided into 5 segments to represent its geometric form and is connected through FLs to the cavity (for vessel breach simulation), DC, core, and core-bypass. The DC is represented by 1 CV, which is connected through FLs to the DVI line, the first CV of the SG primary side, and the first CV of the SGs-bypass. The riser is represented by 6 CVs, with FLs allowing flow movement among them. Additionally, FLs connect the riser to the core, core-bypass, PRZ, UP, and SGs-bypass. The SGs PCS is defined by 4 CVs with FLs for interconnection among them; besides SGs PCS is connected to the DC, UP, and SGs-bypass through FLs. Likewise, the SGs-bypass consists of 4 CVs connected to each other and to the DC, UP, riser, and SGs PCS. The UP is defined by 1 CV connected to the SGs PCS and SGs-bypass, and it is also connected to the EBTs (A/B) and to the riser. Finally, the PRZ is represented by 1 CV divided into 5 segments. Two FLs from the PRZ represent the ADS st-1 and st-2 lines, and the PRZ is also connected to the riser (see Fig. 2a).

The spherical containment is divided in two parts: one CV that represents the DW in the upper part of the containment with a total volume of 3237 m^3, and 1 CV to define the cavity volume (450 m^3) (Fig. 2b). The

containment is filled with N_2 to reduce the combustion risk and it is thermodynamically coupled with the primary system through FLs connecting it to the RPV and cooling systems. Each PSS tank is connected to the DW atmosphere through vent pipes to control containment pressure and LGMS water supply system into the RPV when its internal pressure approaches containment one via the ADS st-2 line. Besides, the DW is connected to the QT through the ADS st-1 line. A leak due to overpressure to the environment is also modelled as a FL. The cavity, located below the DW, collects liquid break flow and condensates from the containment to ensure cooling of the lower vessel part in case of SA.



a) RPV b) Containment

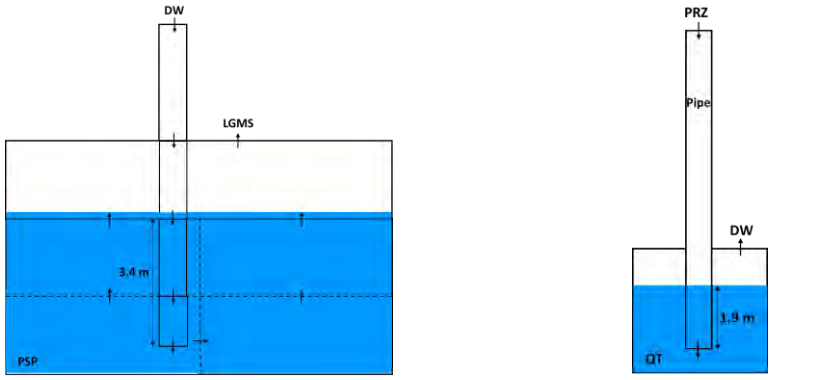
Figure 2. TH nodalization.

According to the characteristics of the iPWR analyzed, pool scrubbing might happen during a SA sequence in two specific locations into the containment: the PSPs and the QT.

The PSS was conceived to prevent containment overpressure in case of a LOCA or steam/feed line break accident. It consists of two tanks connected to the DW through a vertical vent pipe. Steam entering the sub-cooled aqueous phase of PSP condenses, thereby limiting containment pressurization. Additionally, the PSP provides an elevated water source for gravity injection into the RPV in the event of a LOCA accident.

Each PSP is modeled through 5 CVs with a total volume of 459 m^3 and interconnected horizontally and vertically by FLs to differentiate specific regions (Fig. 3a). Top and bottom regions and near- and far-field regions, result in a pool split into 4 zones. The gas phase of PSP is the fifth node (see Fig. 3a). By doing so, it is intended to provide MELCOR model the chance to simulate natural circulation, despite the inherent difficulties to do so in a lumped parameter code. In-pool injection is defined as a horizontal vent (0.06283 m^2) with an initial submergence of 3.41 m.

The pressurizer quench system consists of a vent pipe and a QT. The QT is modeled as a single open volume (33.6 m^3), connected to the PRZ through the quench vent pipe. At low PRZ pressure (<11.7 MPa), ADS st-1 is activated and the quench vent discharges steam from PRZ to the QT through a FL defined as a multi-hole sparger (800 holes with a hydraulic diameter of 0.01 m for each hole) with an initial submergence of 1.94 m (Fig. 3b). The quench vent pipe is modeled as 1 CV (10.7 m^3) connected to the PRZ and the QT through FLs.



a) PSP-TH nodalization b) QT-TH nodalization

Figure 3. TH nodalization.

3. RESULTS

A steady-state analysis preceded the analysis presented in this section, which extends over 2 days.

3.1. Scenario Analysis

The key events during the sequences analyzed are shown in Table II.

Table II. Summary of the relevant phenomenological events time-table.

Key Event (h)	SA1	SA2	SA3	SA2*
Start of the transient	0	0	0	0
Scram time	0.01	0.01	0.01	0.01
RI-DC valves opening	0.03	0.03	0.03	0.03
EHRS	-	-	-	-
EBT actuation	0.04	-	0.04	-
ADS-st1 activation	-	-	0.05	0.05

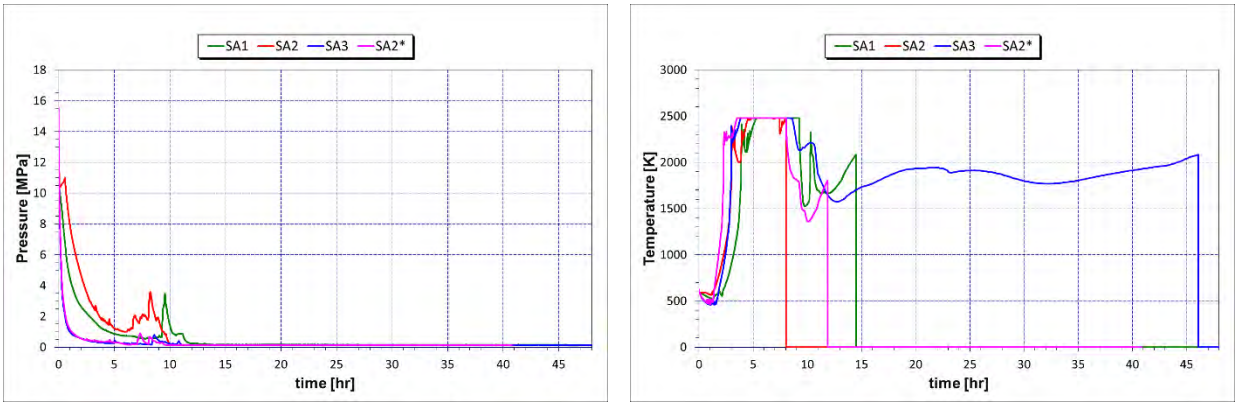
Liquid collapsed level at DVI level	0.33	0.60	0.05	0.05
Containment failure	1.29	1.69	0.50	0.48
Reverse flow from the PSP	1.29-1.59	1.69-1.89	0.55-0.84	0.48-0.85
Time of H_2 production onset	3.50	2.61	2.56	1.91
Gap release	3.50	2.60	2.62	1.97
Core completely uncovered	6.66	5.52	6.12	5.56
Time of vessel failure	-	-	-	-

As shown in Fig. 4, all sequences unfolding is similar in broad terms, the availability of SSs impacting the key events timing, but not the major trends of key variables like RPV pressure (a) and peak clad temperature (b). After the scram, due to the DVI break, a rapid RPV depressurization, partially dumped by the secondary system isolation occurs in all the sequences (Fig. 4a). Independently on the availability of SSs this depressurization of RPV is fast and if the ADS-st1 is available (SA3, SA2*), this rapid depressurization allows its activation, which makes the QT an efficient sink of the decay heat. In all the sequences, when the water level at the DC reaches the DVI line breach (7.9 m high with respect to) it can be observed an exponential pressure decay. In all the cases, the slight pressure oscillations correspond to fluctuations experienced during core degradation and the higher-pressure peaks result from pieces of core slumping in the partially water-filled RPV bottom.

The decrease of cooling rate and the eventual exposure of fuel to steam being produced in RPV, leads to core heat up to temperatures over 2000 K causing the onset of in-vessel FP and H_2 release. As expected, cladding temperature sharply rise up from roughly 1500 K due to oxidation enthalpy released from the Zr-steam interaction (Fig. 4b). During the temperature excursion, temperatures at the upper levels of the FAs (ring 1 in all the sequences) reach about 2500 K and triggers the loss of core integrity until its complete relocation into the LP.

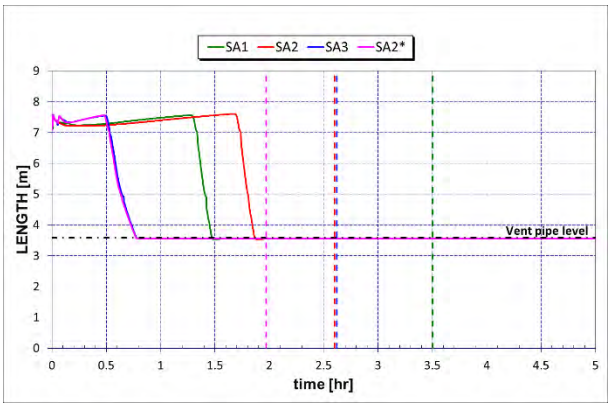


a) RPV pressure b) Max. cladding temperature

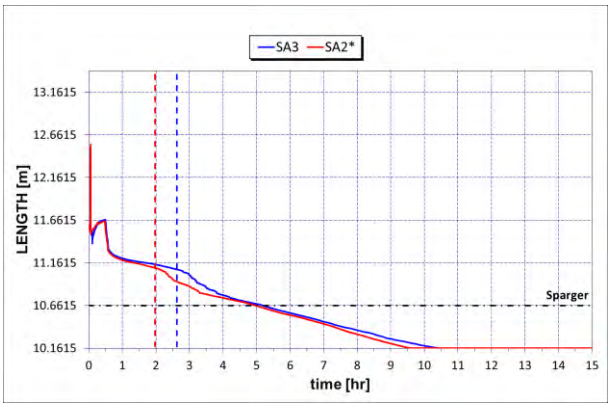
Figure 4. Sequences evolution.

In all the analyzed sequences, DW pressure reaches the containment failure threshold (P_{DW} > 1.5 MPa) and the prompt depressurization of DW makes it decreasing faster than in PSP, causing an inverse pressure gradient between DW and PSP ("reverse flow"). Namely, pressure difference sucks water from PSP into the DW atmosphere. In all the cases, such a water injection in the DW from PSP causes its level in the PSP to fall right below the pipe injection spot before FP release onset, as shown in Fig. 5a (dotted line). Therefore, no pool scrubbing is predicted to occur in the PSP. In other words, the filter potential of PSP is lost in the SA sequences analyzed. For the same reason, no significant amount of radioactivity is dragged by the "flow reversal" into the containment atmosphere.

Actuation of the ADS st-1 in SA3 and SA2*, opens an alternative path to the steam produced in RPV. A fraction of steam flows from PRZ to the QT, where it gets condensed and water temperature rises. In both cases, at the time FPs reach the QT, water get close to or at saturation and the continuous water evaporation eventually results in the quencher uncovery (Fig. 5b). Therefore, in both sequences FPs get scrubbed for some time in the QT (2.62 h - 5.18 h, in SA3; 1.96 h - 4.94 h, in SA2*). The vertical dotted lines mark the onset of FP injection in the QT in each sequence.



a) PSP water level



b) QT water level

Figure 5. Water level in PSP&QT.

3.2. Pool Scrubbing Results

Pool scrubbing phenomena can play a role on the source term decontamination in the QT whenever the ADS st-1 system is available. How effective it is in each sequence is the matter for discussion in next sub-sections.

3.2.1. Boundary conditions

The thermal-hydraulic conditions in the QT during the period of interest for pool scrubbing in both sequences (SA3, SA2*) are shown in the next figures (Fig. 6).

The prevailing boundary conditions are very similar in both sequences. After the activation of the ADS st-1 (0.05 h in both cases) steam starts to flow down the QT line from the PRZ, where it gets condensed and water temperature rises (Fig. 6a, 6b): while QT pressure remains above atmospheric pressure (a bit lower in SA3 due to the performance of additional cooling systems), the pool temperature rises. Water is close to or at saturation most time during FP arrival. Consequently, condensation of steam within the aqueous pond is not anticipated to play any major role on FP retention. The carrier gas is composed mainly by steam and, at some time intervals, H_2 concentration shows a peaky structure, but just occasionally, it goes over 30% of the mole fraction (Fig. 6c, 6d). According to the Weber non-dimensional number at the sparger (Fig. 6e, 6f), jet regime dominates gas injection all the time, showing values more than 3 orders of magnitude over the jet threshold ($We \geq 10^6$).

3.2.2. Source term

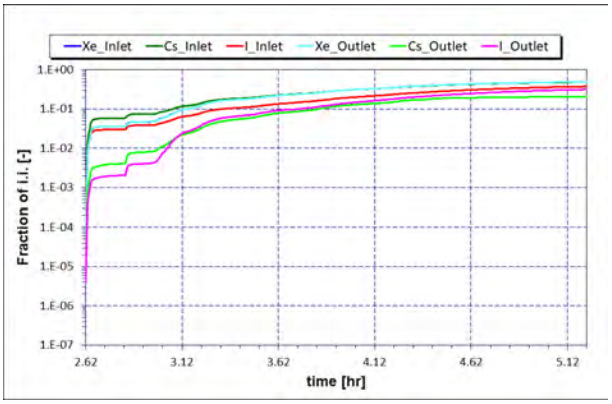
The initial fuel inventory, according to WP2, has been estimated with an ORIGEN calculation in MELCOR default model, scaled down properly from a 3410 MWth Westinghouse PWR at the end of the cycle with different burnups per region and a three-year refueling cycle [13]. Most FPs, except NG and a minor fraction of iodine, turns into aerosols and their behavior is modeled through the radionuclide package [9]. As in NUREG-1465 [14], radionuclides are grouped in 14 classes of elements with similar chemical properties; other classes have been introduced "ad-hoc" according to the code developers' recommendations, representing CsI and Cs_2MoO_4. The FPs reported in this section are xenon (Xe), as a representative of NG, and cesium (Cs) and iodine (I) as the most volatile and radiologically significant.

The aerosols (mix of FPs, fuel, structural and control rod material) are assumed to have a density of 4500 kg/m^3 and their size distribution is assumed to be a lognormal function with lower and upper bounds of 0.1 μm and 20 μm, respectively. Particles are assumed to be spherical.

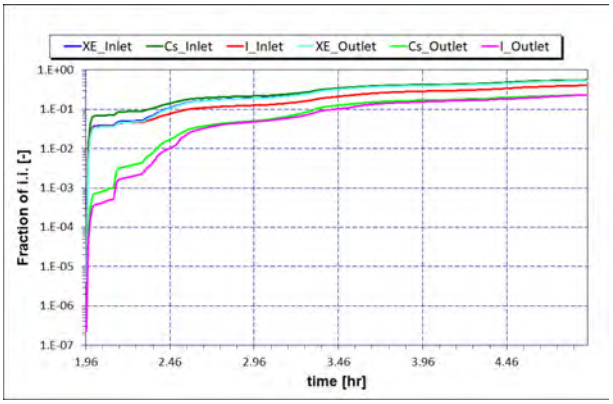
Pool scrubbing is modeled in MELCOR through an adaptation of the SPARC-90 code [15]. The models include the effect of steam condensation at the pool entrance and aerosol deposition by Brownian diffusion, gravitational settling and inertial impaction during bubble rise. The injection in the QT through a multi-hole sparger (800 holes with a hydraulic diameter of 0.01 m each) enhances particle deposition at the injection zone.

MELCOR calculates the accumulated mass of FPs and other materials leaving the core and transported through the NPP systems. The following figures show the FPs fraction (initial inventory, i.i.) entering and

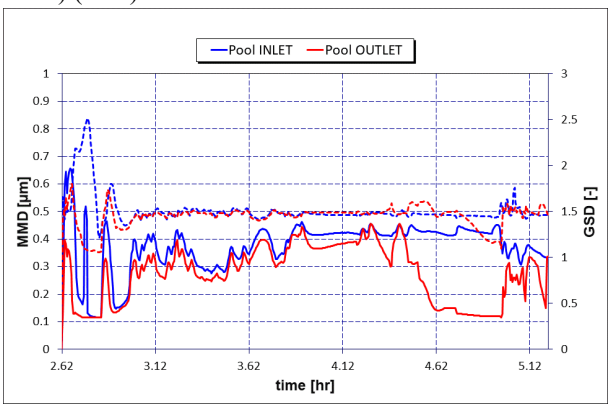
leaving the QT-pool for both sequences (Fig. 7a, 7b) from the time of their arrival. As expected, Xe, as a noble gas, is immediately transported through one volume to another (nearly 100% of the Xe is released to the environment at the end of the calculation). As it can be observed from the figure, the fraction of Cs and I absorbed in the pool reduces more than one order of magnitude the entering fraction of both elements. Regarding aerosol size, Figs. 7c and 7d show the aerosol size reduction (MMD) caused by the QT pool retention. The pool scrubbing effect is noticeable at both the beginning and end of the time interval. At the beginning, high We numbers foster inertial effects at the inlet of the pool (jet impaction) despite the small absolute size of particles; whereas at the end of the interval, the close-to-zero non-condensable fraction extends the bubbles residence time and enlarges the bubble exchange surface, which results in a visible decrease of the concentration leaving the water surface (i.e., a higher decontamination) mostly due to centrifugal deposition. This latter effect makes particles size outgoing the pool visibly smaller (around a factor of 4.0 compare to the incoming ones).



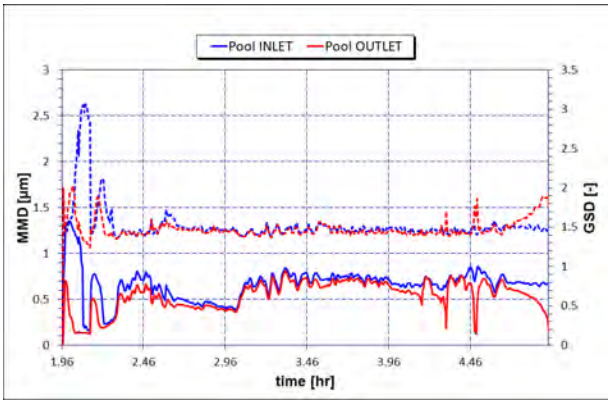
a) FPs fraction entering & leaving the QT-pool (fraction of i.i.) (SA3)



b) FPs fraction entering & leaving the QT-pool (fraction of i.i.) (SA2*)



c) Inlet and outlet aerosol MMD in/from the QT (SA3)



d) Inlet and outlet aerosol MMD in/from the QT (SA2*)

Figure 7. Effect of pool scrubbing on aerosols entering the QT-pool.

As shown in Figs. 8a and 8b, in both sequences the ADS st-1 via for fission products and aerosols to enter the DW is the dominant (98%) when compared to the DVI line one (2%). According to the sequence's evolution, the QT scrubbing effect affects roughly 45% of the total mass potentially entering the DW (almost 70 kg arrived once QT scrubbing was not effective anymore because water level falls below the injection point). As derived from the retention efficiency shown in Figs. 8c and 8d, in-QT pond absorbs around 70% of the incoming mass during the pool scrubbing period (roughly 55/60 kg arriving during that time). In other words, pool scrubbing affects less than half of the mass entering the DW.

4. CONCLUSIONS

The effect of pool scrubbing on the potential source term to the environment has been investigated with the MELCOR code. The analysis of several postulated scenarios indicates that scrubbing in water ponds might visibly affect the eventual source term coming to the environment, although its quantitative effect is not massive (a reduction factor less than a factor 2.0).

Some specific conclusions might be withdrawn from the study:

- MELCOR 2.2 modelling capability can cope with the conditions addressed in the scenarios studied, although some missing models in the code (i.e., jet injection regime) might exacerbate the code deviations in the scenarios analyzed.
- The FPs bypass of the PSP in SA3 and SA2* is highly dependent on the reactor design (flow reversal). Different pressure settings for containment performance might turn the system in an efficient FP trap; this might be also so if a FCVS was installed.
- A high-pressure scenario, SA3 and SA2*, entails FP scrubbing in the QT of the reactor pressurizer. Despite unfavorable thermal conditions for pool scrubbing in the QT, in-QT pool scrubbing is estimated to substantially reduce the mass entering the DW from the PZR. All in all, in-QT scrubbing results in a mild impact on the source term to the environment (a reduction of about 30%).
- Given the containment early failure, FPs would have the chance to escape into the environment after little more than 2 h.

- In terms of particle sizes, though, the submicron particles predicted to be released to the environment would not show any major change.

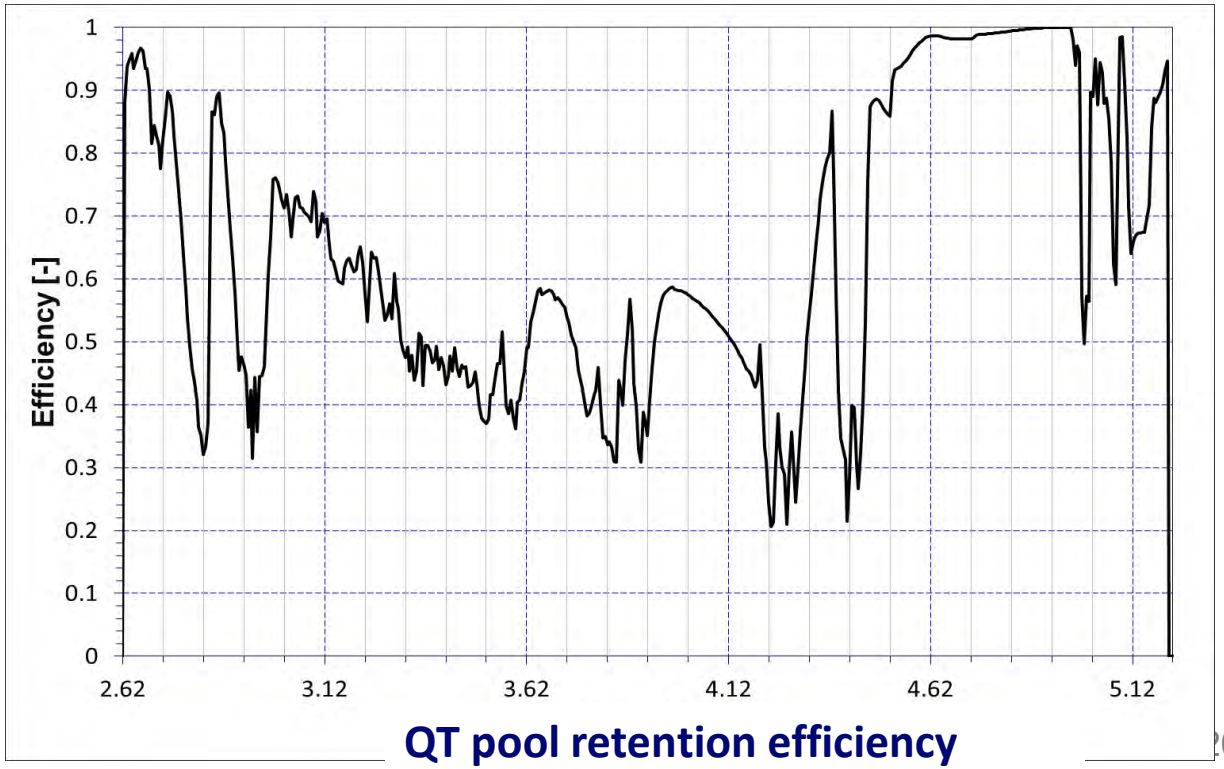
- In-QT pool absorbs ~ 70% of the incoming mass.



QT pool retention efficiency

04

Conclusions

Main Insights

- MELCOR 2.2 can simulate accident scenarios in iPWRs.
- In the analysed sequences, FPs bypassed the PSP pool due to flow reversal (direct connection to containment design).
- High pressure scenarios with ADS-st1 activated involves significant scrubbing in the quench tank.
- In terms of Source Term to the environment, in-QT scrubbing might mean a reduction of up to 30%.

ABSTRACT

Accurate predictions of aerosol removal via pool scrubbing is critical for evaluating source term behavior during severe accident analysis in light water reactors. Sequences such as BWR suppression pool scrubbing, filtered containment venting systems (FCVS), and PWR steam generator tube rupture (SGTR), inject fission product laden gas into water pools. Aerosol particles are removed in the pool via inertial impaction, condensation driven capture, and bubble rise deposition.

This work presents recent development and benchmarking of the pool scrubbing model implemented in the MAAP6 severe accident code. The model calculates the overall decontamination factor (DF) as the product of three independent contributions: (1) injection zone scrubbing, which includes jet entrainment and orifice driven capture, (2) condensation zone scrubbing, based on diffusiophoresis, and (3) bubble rise zone scrubbing, accounting for Brownian motion, gravitational settling, and bubble breakup dynamics.

The MAAP6 model implementation has been compared and validated against experimental results, from tests spanning jet injection and bubble rise regimes. Results demonstrate the MAAP6 pool scrubbing model captures observed DF trends across multiple flow conditions, providing improvements over previous empirical formulations.

Suppression pool scrubbing, aerosol decontamination factor, bubble rise, gas jetting, MAAP6

1.0 INTRODUCTION

The Modular Accident Analysis Program version 6 (MAAP6) is a severe accident systems code being developed by the Electric Power Research Institute (EPRI). This paper describes a new model developed to calculate pool scrubbing of aerosols. The new model replaces simplified aerosol scrubbing calculations in previous versions of the MAAP code which were based on lookup tables based on the results calculated by the SUPRA code.

The decontamination capability of a pool depends mainly on the behavior of the fission-product-containing-gas bubbles as they form at and detach from multihole spargers, downcomer pipes or side vents and rise

through the pool. The expressions derived here for the decontamination factors (DF's) of the gaseous fission products and the fission product aerosols are based on modeling that results in explicit, algebraic forms. The fission products are carried by a mixture of steam and noncondensible gas of known molecular weight. The components of the noncondensible gas may include hydrogen, carbon dioxide, carbon monoxide, and/or nitrogen.

In developing the models for the fission product DF's, it is convenient to divide the pool into three zones. These zones are (including the key modeling assumptions):

1. Injection Zone: At low gas discharge rates single bubbles grow and detach periodically from the discharge orifice. During bubble growth aerosol particles deposit on the bubble surface by centrifugal force and inertia. All other mechanisms of deposition are neglected. At high gas discharge rates, gas jets are formed at the orifice, and the principal mechanism of aerosol depletion is aerosol inertial deposition upon entrained liquid drops.

2. Condensation Zone: Particle removal by steam condensation, diffusiophoresis and thermophoresis is assumed to occur immediately after the bubble detaches from the orifice (or jet) and before it breaks up until a stable bubble size is reached. Therefore, the thickness of the condensation zone is small on the scale of the pool depth. The stable size bubble is assumed to be in thermodynamic equilibrium with the surrounding pool. Heat and mass transfer analogies are used to estimate particle removal by diffusiophoresis and thermophoresis during the bubble's approach to equilibrium. The experimental conditions presented in this paper have low steam content in the carrier gas such that the contributions of the condensation zone are relatively small. Thus, overall aerosol removal tends to be dominated by injection/jetting and bubble rise regimes. However, follow on work is planned to analyze experiments with higher steam content.

3. Bubble Rise Zone: Following injection and initial gas cooling and condensation near the pool surface, gas bubbles detach and rise through the surrounding liquid as a buoyant plume. The plume buoyancy is due only to the noncondensible gas contained in the bubbles. The large detachment bubble is mechanically unstable and undergoes breakup until a stable distribution of many smaller bubbles is reached some distance above the discharge orifice. Fission product scrubbing is assumed to be negligible in the bubble breakup zone and is therefore not treated as a separate suppression pool zone. The small bubbles generated above the discharge orifice continue to rise through the pool. Removal of gaseous fission products from the bubbles occurs by in-series gas-side and liquid-side-controlled convective diffusion, while aerosol particle scrubbing within the rising bubbles occurs by sedimentation, centrifugal force, and Brownian motion. In hot pools there is a significant increase in the size of a rising bubble because of the reduction in the hydrostatic pressure and concomitant water evaporation into the bubble. The bubble grows beyond its largest stable size and breaks up. During breakup a portion of the bubble is converted into many small bubbles, thereby dividing the pool into two bubble rise zones: a lower zone with relatively large bubbles and an upper zone with smaller bubbles. The model to predict the break-up bubble size in the upper zone uses a critical Weber number and a characteristic velocity that is proportional to the turbulent energy dissipation rate generated by the rising bubble plume.

2.0 MODELING APPROACH

MAAP6 implements a regime dependent injection decontamination factor (DF) such that the discharge is treated as either bubble plume formation or jet discharge, based on a critical velocity comparison. The critical discharge of orifice gas velocity for jet formation is computed and compared to the actual orifice velocity obtained from continuity. Zhao and Irons [1] derived the semi-empirical expression for the critical discharge orifice gas velocity $u_{o,cr}$ for the formation of a gas jet, Eq. (1), where σ_f and ρ_f are the water pool surface tension and density, respectively, and d_o is the diameter of the orifice. From here, the model

determines if conditions correspond to a bubble plume path or if conditions correspond to a jet discharge path.

$$u_{o,cr} = 3.24 \left(\frac{\rho_f}{\rho_{g,o}}\right)^{1/4} \left(\frac{\sigma_f}{\rho_{g,o} d_o}\right)^{1/2} \quad (1)$$

If the actual orifice velocity is less than or equal to the critical velocity, the discharge is treated as a bubble plume. If the actual velocity exceeds the critical value, the discharge is treated as a gas jet.

2.1 Injection Zone Decontamination Factor

For a bubble plume path, the model calculates Stokes number from Eq. (2), where C is the aerosol particle slip correction factor, ρ_a density of dry aerosol material, d_a is the diameter of dry aerosol particle, g is gravity, $\dot{Q}_{g,o}$ is volumetric flow of gas mixture at discharge orifice and $\mu_{g,o}$ is the viscosity of gas mixture at discharge orifice.

$$St = 0.685 \frac{C\rho_a d_a^2 (g^2 \dot{Q}_{g,o})^{1/5}}{\mu_{g,o} d_o} \quad (2)$$

Then the efficiency of particle capture is calculated from Eq. (3) and the dimensionless parameter χ_o from Eq. (4). The position of the ε versus St curve for jet Reynolds number above 100 is relatively constant. Therefore, for practical applications just one efficiency curve may be considered to represent all efficiency curves. A typical circular jet impactor efficiency curve is shown in Figure 1 [2].

$$\varepsilon = 1 - \frac{1}{1 + \exp\left[\frac{St^{1/2} - 0.447}{0.0453}\right]} \quad (3)$$

Aerosol mass conservation in the forming bubble states that the rate of change of aerosol mass in the bubble is due to the inlet mass flow rate of aerosol minus the mass rates of aerosol deposition on the bubble surface due to inertial impaction and centrifugal force.

$$\chi_o = \frac{19.67\, C\rho_a d_a^2 (\dot{Q}_{g,o}^3 g)^{1/5}}{d_o^2 \mu_{g,o}} \quad (4)$$

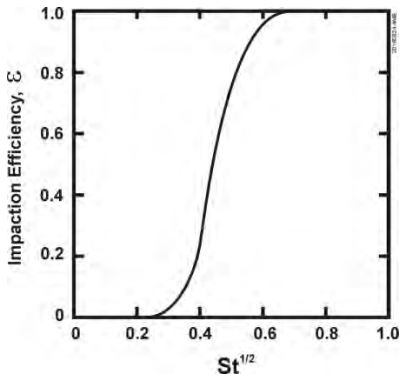

Figure 1 Jet Impactor Efficiency Curve

In MAAP6, this bubble plume injection calculation is implemented directly through the fitted efficiency expression and the closed form DF_{fb} expression using St, ε, and χ_o, with particle slip correction included

through C. The resulting expression for the bubble decontamination factor at detachment is shown in Eq. (5).

$$DF_{fb} = \frac{\chi_o^3}{3(1-\varepsilon)[\chi_o^2 - 2\chi_o + 2(1-e^{-\chi_o})]} \quad (5)$$

As mentioned previously, above a critical injector gas velocity there is a transition from the bubbly flow regime to the gas jetting regime. MAAP6 model implements compressible discharge handling using stagnation pressure logic and critical stagnation pressure check. When choked or under expanded flow conditions occur, the model is solved for expansion region outlet conditions using momentum and mass conservation, which yields an effective jet velocity and an effective jet diameter prior to aerosol removal calculations.

The entrainment and atomization of the liquid within the jet is postulated to be complete when the jet velocity u falls below the gas velocity required for droplet formation from capillary wave growth on the liquid surface. The available experimental data on air flowing over a horizontal liquid surface, [4], shows that a minimum gas velocity is required for atomization of the liquid by the gas flow. A constant drop size is selected based on the pneumatic atomization of the entrained liquid in the immediate vicinity of the injector. Finally, the in-jet aerosol decontamination factor DF_j is calculated using Eq. (6).

$$DF_j = \exp\left[\beta\left(\frac{1}{S} + \frac{1}{S^2}\ln\frac{S+\frac{u_{atm}}{u_o}}{\frac{(1+S)\,u_{atm}}{u_o}} - \frac{1+S}{S\left(S+\frac{u_{atm}}{u_o}\right)}\right)\right] \quad (6)$$

Where S is an inverse Stokes number, β is defined by Eq. (7), u_{atm} is the gas velocity above which liquid (water) atomization occurs, and u_o is the gas mixture velocity at discharge orifice. Though, before Eq. (6) can be used, expressions are needed to estimate the effective droplet velocity lag constant, f, and the effective droplet diameter d_f. In MAAP6, f is either treated as a constant or solved iteratively depending on user input settings.

$$\beta = \frac{3fd_o}{8E_o(1-f)d_f}\left(\frac{\rho_{g,o}}{\rho_f}\right)^{3/2} \quad (7)$$

Where ρ_f is density of pool water and E_o is the empirical entrainment coefficient (0.08 for jet; 0.12 for bubble plume).

2.2 Condensation Zone Decontamination Factor

MAAP6 implemented the condensation zone DF to account for steam condensation and resulting gas composition changes as the plume rises.

Thermophoretic transport coefficient, K_T, is determined including mean free path and slip effects. The model then computes equilibrium inert fraction and two alternate condensation DFs, bubble volume reduction and bubble mass reduction, then conservatively selects the smaller. Though, diffusiophoresis has a modifying effect on the condensation induced particle deposition velocity and DF_{con} must be adjusted to account for this. Therefore, DF_{cz}, total condensation zone DF, is determined with the dimensionless diffusiophoretic particle transport coefficient, K_D, fluid Prandtl number, and temperature ratio effects. In MAAP6 the fluid Prandtl number used for DF_{cz} is evaluated using the gas properties at pool temperature.

$$DF_{cz} = (DF_{con})^{K_D} \left[\frac{1 - (K_T Pr)^{\frac{1.25 T_0}{T_f}}}{1 - (K_T Pr)^{1.25}} \right] \quad (8)$$

2.3 Bubble Rise Zone Decontamination Factor

The MAAP6 model also calculates the decontamination factor in the bubble rise zone with explicit capture mechanisms during rise, including inertial capture, gravitational settling, and Brownian diffusion. The model first determines bubble rise velocities and transition behavior using the terminal velocity and bubble rise absolute velocity that depend on the volumetric inert gas discharge rate.

In this zone, the aerosol deposition mechanisms are centrifugal force v_{cf}, sedimentation v_{sed} and Brownian diffusion v_B. The major assumptions made in quantitatively dealing with these deposition mechanisms are that they are uncoupled from one another and additive, and that all the particles are of the same size and uniformly distributed. For constant average bubble diameter, from $z = z_{br}$ where $c_a = c_{a,br}$ to the top of the pool at $z = H$ where $c_a = c_a(H)$ results in the desired formula for the aerosol removal during bubble ascent is expressed by the bubble rise decontamination factor Eq. (9) [9, 10, 11, 12, 13]

$$DF_{rise} = \frac{c_{a,br}}{c_a(H)} = \exp\left[\frac{6(H - z_{br})}{U_b \bar{D}_b} \left(v_{cf} + \frac{1}{4} v_{sed} + v_B \right) \right] \quad (9)$$

MAAP6 computes z_{br} as a breakup distance based on the broken-up bubble diameter. If the discharge inert gas flow is below the transition value then z_{br} is set to 0. MAAP6 also computes an average bubble diameter for rise capture and uses that average bubble diameter in the rise deposition velocities and DF_{rise} expression.

If the suppression pool is hot enough for secondary bubble breakup to occur in the upper portion of the pool, then, a pool threshold temperature split is evoked and the two segment treatment for superheated conditions is applied, with separate rise DFs for lower and upper regions.

$$DF_{rise,1} = \exp\left[\frac{6(z_{br,2} - z_{br})}{U_b \bar{D}_{b,1}} \left(v_{cf} + \frac{1}{4} v_{sed} + v_B \right) \right] \quad (10)$$

$$DF_{rise,2} = \exp\left[\frac{6(H - z_{br,2})}{U_b \bar{D}_{b,2}} \left(v_{cf} + \frac{1}{4} v_{sed} + v_B \right) \right] \quad (11)$$

Hygroscopic particle growth effects are available in the model formulation. In MAAP6, soluble aerosol behavior is implemented through a soluble particle growth diameter calculation, and the slip correction factor is recalculated using the resulting soluble particle diameter.

2.4 Total Weighted Decontamination Factor

The overall pool scrubbing DF is then formed as a product which ensures stable behavior and prevents nonphysical DF values below 1. In MAAP6, each zone DF is bounded to be at least 1.0 prior to multiplication.

$$DF_{pool} = \begin{cases} (DF_{fb})(DF_{cz})(DF_{rise}); \text{ gas bubbling at injector} \\ (DF_j)(DF_{cz})(DF_{rise}); \text{ gas jetting at injector} \end{cases} \quad (12)$$

3.0 BENCHMARK CONFIGURATIONS
3.1 CRIEPI Experimental Setup

To validate the MAAP6 model, data provided by the Central Research Institute of Electric Power Industry (CRIEPI), Tokyo, Japan, were used to perform benchmark the MAAP6 aerosol scrubbing model. Two sets of experiments were considered: one focusing on aerosol removal dominated by bubble rise mechanisms [5] and the other focusing on the jetting and impaction regime [6].

3.1.1 Bubble Rise Regime

The CRIEPI bubble rise experiments were performed to investigate aerosol removal under conditions dominated by discrete bubble formation and buoyant rise in a water pool. Air was used as the carrier gas and was injected through a multi-hole orifice plate consisting of 100 circular holes, each with an inner diameter of 5 mm. This configuration distributed the gas uniformly and limited the gas exit velocity, thereby suppressing jet formation and inertial impaction near the injection point.

The volumetric air flow rate varied between approximately 1000 and 2500 L/min, corresponding to gas velocities at the orifice exit of approximately 8.5 to 21 m/s. The pool submergence depth varied from 1.5 m to 3.5 m in increments of 0.25 m. All experiments were conducted at ambient pressure and temperature under stagnant air water conditions. Insoluble barium sulfate ($BaSO_4$) particles were used as the aerosol simulant, with geometric mean particle diameters ranging from approximately 0.2 to 1.2 μm.

In the MAAP6 benchmark model, the bubble rise configuration was represented using a fixed submergence depth of 1.5 m. The carrier gas temperature and pool temperature were both set to 293.15 K, and the steam mass fraction was set to zero. Aerosol particle diameters were varied within the experimental range to evaluate particle size effects on removal efficiency.

The model calculated decontamination factors were compared to CRIEPI experimental values and to the empirical correlation proposed by CRIEPI for the bubble rise regime. CRIEPI DF_{BR} empirical formula was expressed by the function of the $BaSO_4$ aerosol diameter ($D_{p,GEO}$) and submergence depth (x). This correlation was used as an additional reference for trend comparison in the results plot and can be seen demonstrated as the red dashed line (DFBR(x, Dp.GEO)) in Figure 2, though, the primary benchmark assessment focused on agreement between MAAP6 predictions and measured decontamination factors.

3.1.2 Jetting Regime

The CRIEPI jetting experiments were conducted to characterize aerosol removal under high velocity gas injection conditions where a submerged jet forms and aerosol removal is dominated by inertial impaction and turbulent mixing. From these experiments, MAAP6 modeled air injected through a single circular orifice with an inner diameter of 13 mm.

The volumetric gas flow rate ranged from 756 to 2789 L/min, corresponding to gas exit velocities of approximately 95 to 350 m/s. Additionally, all experiments were performed at ambient pressure (1.013×10^5 Pa) and room temperature, with stagnant pool conditions. Based on the reported flow conditions, the experiments fall entirely within the jetting regime, as the CRIEPI Weber numbers (Jet regime, We number $>> 10^5$) exceed both the experimental regime transition threshold and the corresponding MAAP6 critical discharge velocity criterion for jet formation.

For the MAAP6 benchmark implementation, cases implemented consist of three particle size sets, each containing 17 flow conditions. The first set used an aerodynamic mass median diameter (AMMD) of 0.2

μm (2.0×10^{-7} m), the second set used an AMMD of 0.3 μm (3.0×10^{-7} m), and the third set used an AMMD of 0.5 μm (5.0×10^{-7} m). For each particle size, the same sequence of volumetric flow rates was applied.

Experimental volumetric flow rates provided by CRIEPI were interpreted as normal volumetric flow rates and converted to gas mass flow rates using the ideal gas relationship consistent with CRIEPI's formulation of Q_{G1} (the volumetric flow rate of the gas). A constant ambient pressure (1.013×10^5 Pa) and temperature (293.15 K) were assumed for all cases, with air properties used to evaluate gas density. The resulting gas mass flow rates ranged from ~ 0.0163 kg/s to 0.0601 kg/s and were supplied directly to the MAAP6 model. The steam mass fraction is set to zero for all cases and the gas and pool surface temperature were assumed to be ambient. The pool submergence depth was set to 2.125 m for all jetting cases, consistent with the experimental configuration provided by CRIEPI for the selected dataset. A single representative Weber number within the jetting regime was applied uniformly across all benchmark cases to isolate the effects of particle size and gas flow rate on decontamination factor predictions.

CRIEPI experimental decontamination factors for the jetting regime were provided directly and were mapped one to one to the corresponding MAAP6 cases. These values were used as the reference data for evaluating MAAP6 predictions of aerosol removal in the jetting and impaction regime.

In addition to comparison with experimental decontamination factors, the empirical jetting correlation developed by CRIEPI was also evaluated and added to the results comparison as seen through the red dashed line (DFJET(vG, Dp.GEO)), in Figure 3, Figure 4, and Figure 5. CRIEPI's empirical correlation captures the exponential increase in DF_{JET} with inlet gas velocity and the increasing sensitivity of DF_{JET} with particle size. This expression was evaluated alongside the MAAP6 predictions and CRIEPI experimental data for the jetting benchmark cases.

3.2 UW Madison Experimental Setup

In addition to the CRIEPI experimental benchmarks, MAAP6 was evaluated against experimental data generated by the University of Wisconsin Madison to examine aerosol removal behavior over a wider particle size range than that available in the CRIEPI dataset. The UW Madison experiments investigated extensive parametric effects, including bubble size, aerosol size, aerosol density, aerosol concentration, pool depth, system temperature, and bubble swarm behavior [7]. Accordingly, the MAAP6 comparison is limited to the UW Madison aluminum aerosol tests that vary particle size and pool depth, with bubble swarm and multi-material datasets excluded from the benchmark dataset.

For comparison with MAAP6, experimental data was taken from tests using powdered aluminum aerosols with particle sizes ranging from approximately 0.01 to 18 μm and pool heights of 1.8 m and 0.9 m. Aluminum particles were selected to hold aerosol material properties constant while varying pool depth. For consistency with the MAAP6 input definition, the UW Madison aerosol sizes reported as aerodynamic diameters were converted to equivalent physical diameters assuming spherical aluminum particles with a density of 2.7 g/cm³, using the standard aerodynamic diameter relationship, with no shape factor or agglomeration correction applied.

Pool height influences both local pressure and bubble residence time during ascent. Specifically, bubble residence time determines the duration of aerosol liquid interaction during bubble rise and directly affects overall decontamination performance. To isolate the effect of pool height, UW Madison experiments were performed using two pool depths (1.8 m and 0.9 m) at a temperature of 200 °C, with a fixed bubble diameter of approximately 3.63 cm. Although the UW Madison experiments were conducted in a liquid sodium pool at elevated temperatures, they are still used here for qualitative trend comparison as the current MAAP6 model evaluates pool scrubbing using water properties rather than liquid metal properties, which may effect bubble hydrodynamics and residence time.

The experimental results show that decontamination performance decreases with increasing aerosol size in the submicron regime and increases again for larger particles as dominant removal mechanisms transition from Brownian diffusion to inertial impaction and gravitational settling. These trends provide a complementary benchmark to the CRIEPI data by extending the evaluation of MAAP6 across multiple aerosol removal regimes.

4.0 MAAP6 RESULTS

4.1 CRIEPI Benchmark Comparison

4.1.1 Bubble Rise Regime

The purpose of these benchmark comparisons was to examine and validate the MAAP6 pool scrubbing model with data provided by the jetting and bubble rise experiments conducted by CRIEPI.

CRIEPI's water scrubber experiments developed an empirical framework describing bubble rise decontamination as a function of aerosol diameter and submergence depth. For direct comparison, submergence depth was held constant in the MAAP6 bubble rise simulations while particle size was varied. Results from the MAAP6 model, CRIEPI experimental data, and the CRIEPI empirical correlation data (shown in the red dashed line in Figure 2) consistently indicate that larger particles are removed more efficiently than smaller particles, and that bubble rise decontamination factors increase strongly with particle size. This behavior is evident in Figure 2, where agreement is strongest at smaller particle sizes and decontamination factors increase rapidly as particle diameter approaches 1 μm.

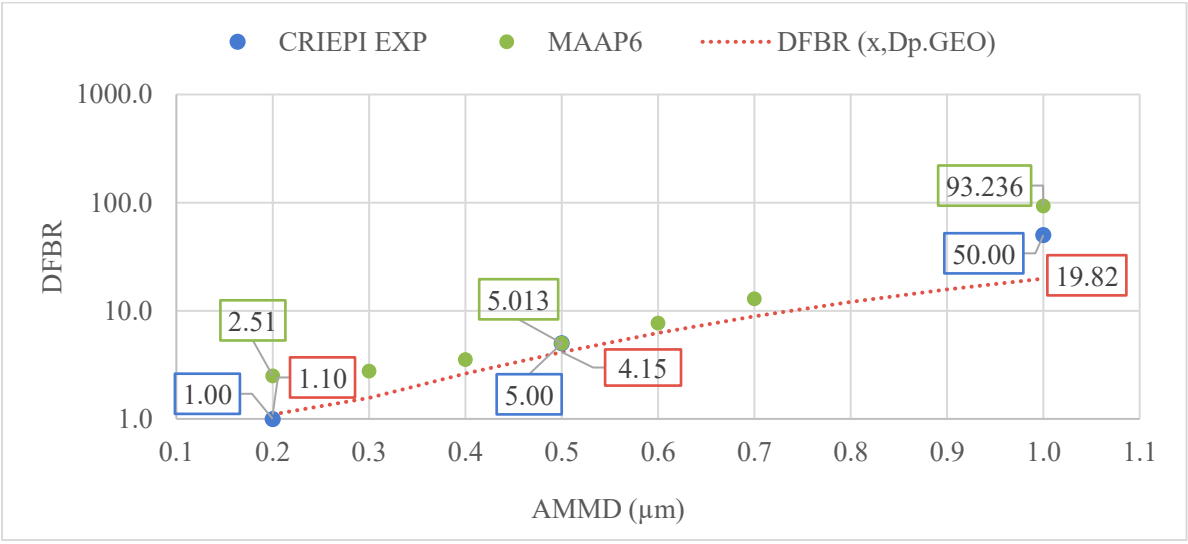

Figure 2 DFBR experimental data, model output and empirical correlation for ranging particle sizes

4.1.2 Jetting Regime

In addition to the bubble rise benchmarks, the MAAP6 model was evaluated against CRIEPI jetting experiments and the CRIEPI empirical jetting correlation, seen as the red dashed line DFJET(vG, Dp.GEO). In these cases, pool submergence depth was held constant while particle size was varied across 0.2μm, 0.3μm, and 0.5μm. For each particle size, comparisons show that decontamination factors generally increase with increasing inlet gas velocity, and that larger particles exhibit greater sensitivity to velocity, consistent with CRIEPI observations. While experimental data exhibits scatter and nonmonotonic behavior at

individual conditions, MAAP6 reproduces the overall scaling trends with velocity and particle size observed in the jetting regime, seen in Figure 3, Figure 4, and Figure 5.

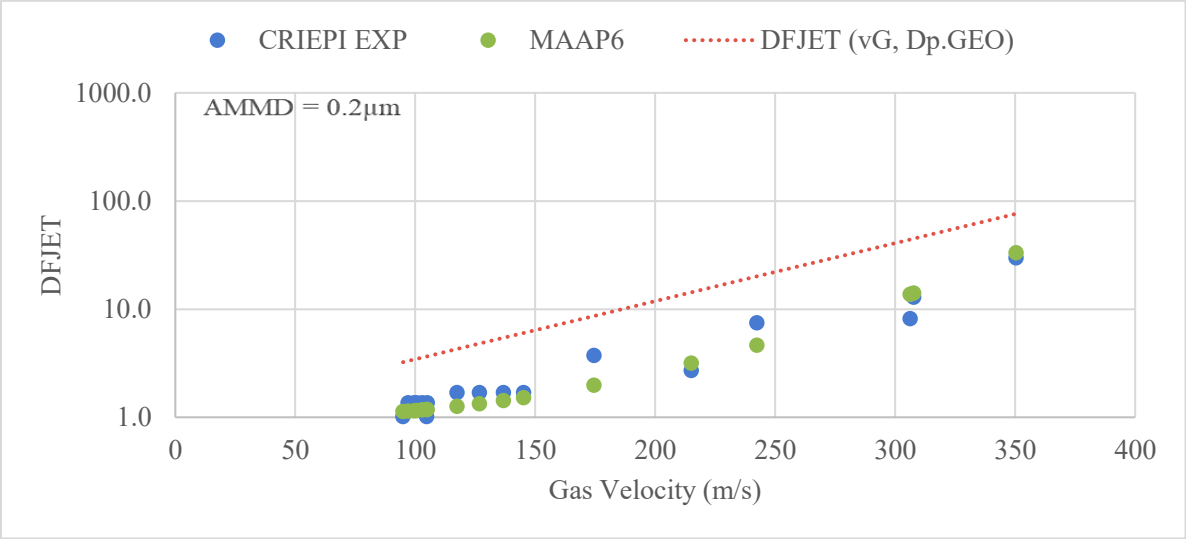

Figure 3 DFJET experimental data, MAAP6 model output and empirical correlation curves for 0.2 µm aerosols as a function of inlet gas velocity(vG)

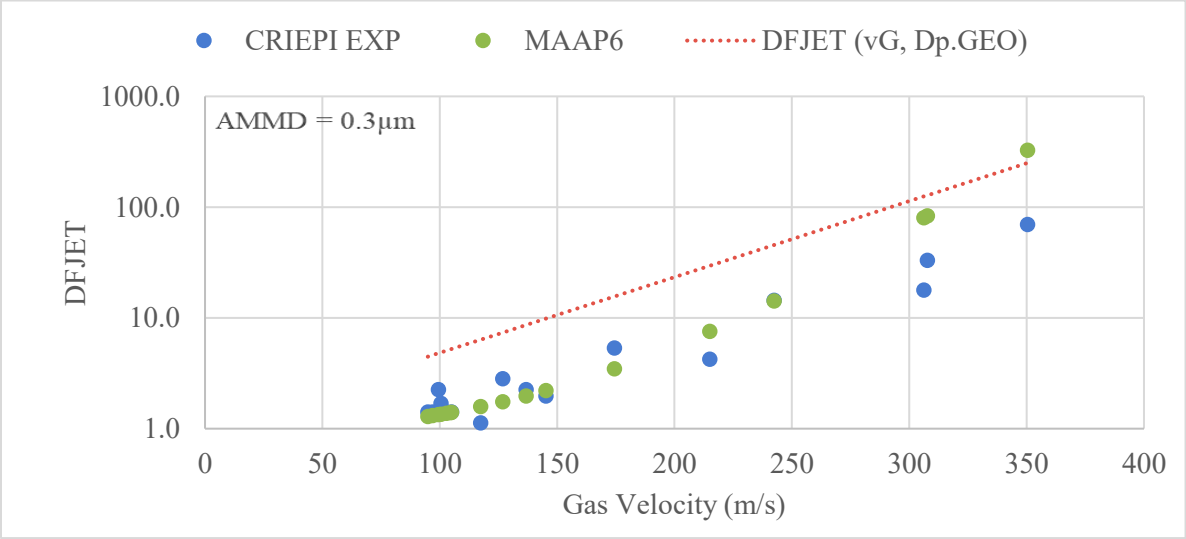

Figure 4 DFJET experimental data, MAAP6 model output and empirical correlation curves for 0.3 µm aerosols as a function of inlet gas velocity(vG)

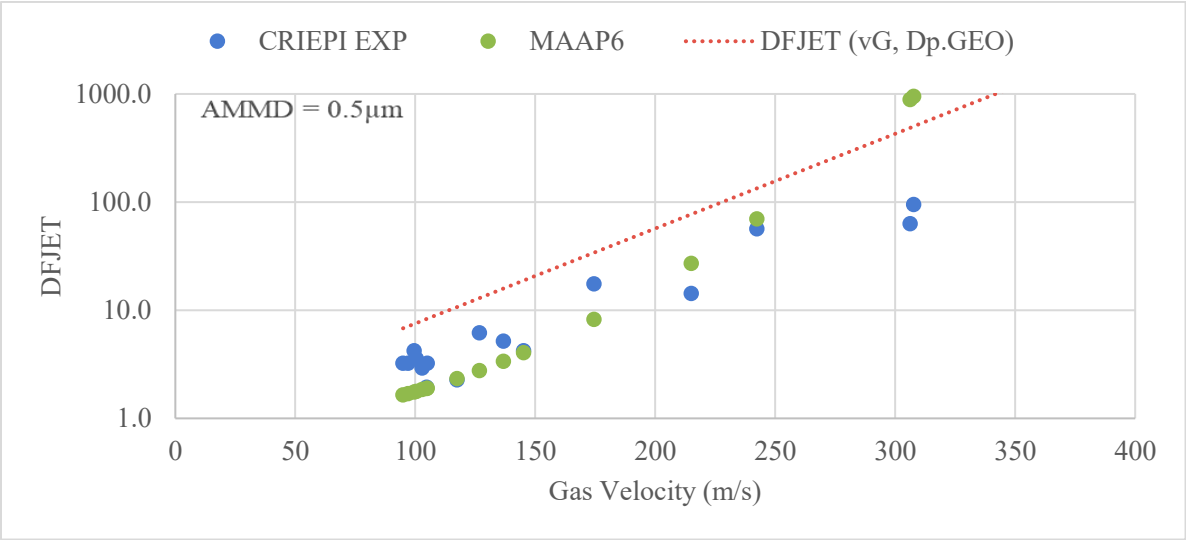

Figure 5 DFJET experimental data, MAAP6 model output and empirical correlation curves for 0.5 µm aerosols as a function of inlet gas velocity(vG)

4.2 UW Madison Benchmark Comparison

University of Wisconsin Madison data was incorporated into the MAAP6 benchmarks to extend model evaluation to a broader aerosol size range and additional dominant removal mechanisms. The UW Madison experiments demonstrate that total decontamination factors are relatively high at very small aerosol diameters, decrease in the intermediate size range, and increase again for larger particles as inertial and gravitational mechanisms become dominant.

These trends are observed across multiple pool depths, with higher decontamination factors reported for the deeper 1.8 m pool compared to the 0.9 m pool, reflecting increased bubble rise time. MAAP6 predictions are consistent with these trends and reproduce the qualitative dependence of decontamination factor on aerosol size and pool depth observed in the UW Madison experiments.

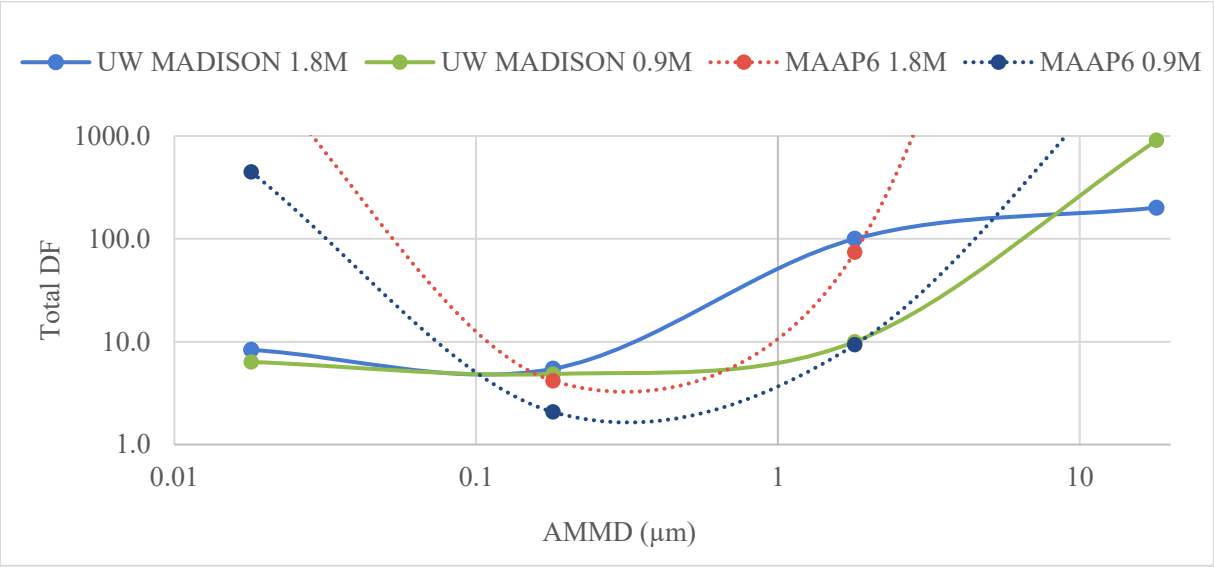

Figure 6 Comparison of DF by pool depth between experimental data and model output

5.0 CONCLUSIONS

This study benchmarked the MAAP6 suppression pool aerosol scrubbing model against experimental data from to examine model behavior across bubble rise and jetting dominated regimes. The benchmark comparisons focused on aerosol size dependence, gas injection conditions, and pool depth effects on decontamination factors.

The MAAP6 model predictions reproduce the primary trends observed in the experimental datasets. In the bubble rise regime, decontamination factors increase with particle size and submergence depth, consistent with CRIEPI benchmark observations. In the jetting regime, MAAP6 captures the dependence of decontamination factor on inlet gas velocity and the increasing sensitivity with particle size. Comparison with UW Madison aluminum aerosol data extends the evaluation to a broader particle size range and shows consistent qualitative dependence on aerosol size and pool depth.

Overall, the benchmark results indicate that the MAAP6 suppression pool scrubbing model provides a reasonable representation of dominant aerosol removal trends across the experimental conditions considered. It is noted that experiments investigated in this paper are limited subset of the available experimental data [8]. Further evaluation is planned to assess model behavior for higher steam fractions, additional aerosol materials, alternative pool conditions, and hygroscopic aerosols.

NOMENCLATURE (IF NEEDED)

c_a aerosol volume concentration (m^3 aerosol per m^3 spatial volume)
$c_{a,br}$ aerosol volume concentration in broken-up bubbles, above condensation zone

C aerosol particle slip correction factor
d_a diameter of dry aerosol particle
d_o discharge orifice diameter or effective diameter of gas mixture jet discharge
d_f effective average diameter of entrained drops (water) in jet
$\overline{D}_b$ average diameter of bubble in bubble rise zone
DF decontamination factor
DF_{con} decontamination factor due to steam condensation in bubble
DF_{cz} total aerosol decontamination factor for the condensation zone
DF_{fb} aerosol decontamination factor for forming bubble at discharge orifice
DF_j aerosol decontamination factor for jet at discharge orifice
DF_{rise} aerosol decontamination factor for bubble rise zone
E_o empirical entrainment coefficient (0.08 for jet; 0.12 for bubble plume)
f drop velocity lag coefficient in jet
g gravitational constant
H depth of submerged discharge orifice
K_T thermophoretic transport coefficient
Pr fluid Prandtl number: kinematic viscosity divided by thermal diffusivity
$\dot{Q}_{g,o}$ volumetric flow of gas mixture at discharge orifice
S inverse Stokes number parameter
T_f temperature of suppression pool
T_o temperature of gas mixture at discharge orifice or effective gas mixture jet discharge temperature
u_{atm} gas velocity above which liquid (water) atomization occurs
$u_{o,cr}$ critical discharge orifice gas mixture velocity above which jetting occurs
U_b absolute bubble rise velocity
u_o gas mixture velocity at discharge orifice or effective gas mixture jet discharge velocity
v_B aerosol particle deposition velocity due to Brownian diffusion
v_{cf} aerosol particle deposition velocity due to centrifugal force
v_{sed} aerosol particle deposition velocity due to sedimentation
z_{br} bubble breakup distance above discharge orifice
$z_{br,2}$ elevation in hot pool above which secondary bubble breakup is possible
β dimensionless parameter
ε efficiency of particle capture by bubble surface or entrained drops
μ_g viscosity of gas mixture
λ mean free path of gas mixture
ρ_a density of dry aerosol material
ρ_f density of pool water
$\rho_{g,o}$ gas mixture density at discharge orifice or effective gas mixture discharge density
σ_f surface tension of pool water
χ_o dimensionless parameter

Subscripts
atm refers to end of atomization zone in jet
o refers to conditions at discharge orifice exit plane when flow is subsonic or effective discharge conditions in jet when discharge is choked
1 refers to lower bubble rise zone in hot pool
2 refers to upper bubble breakup zone in hot pool when secondary bubble breakup occurs

ACKNOWLEDGMENTS

The authors gratefully acknowledge the Central Research Institute of Electric Power Industry (CRIEPI) and the University of Wisconsin Madison for providing experimental data and technical clarification that supported benchmarking and implementation of the MAAP6 suppression pool aerosol scrubbing model.

MAAP6 Suppression Pool Aerosol Scrubbing Model

- Historical motivation for model development:
  - A concern was raised that the decontamination factor (DF) calculated by MAAP for a sparger injection release geometry was not monotonically increasing with pool depth

Mass fraction of steam	DF calculated by MAAP	
	4 m pool	6 m pool
0.0	2,218	561
0.5	106.7	106.7
0.9	19.5	19.5
0.99	25.6	55.7

- MAAP6 now implements a mechanistic pool scrubbing model that replaces prior simplified empirical lookup table treatment and was benchmarked against bubble rise and jetting data

© 2026 Electric Power Research Institute, Inc. All rights reserved.

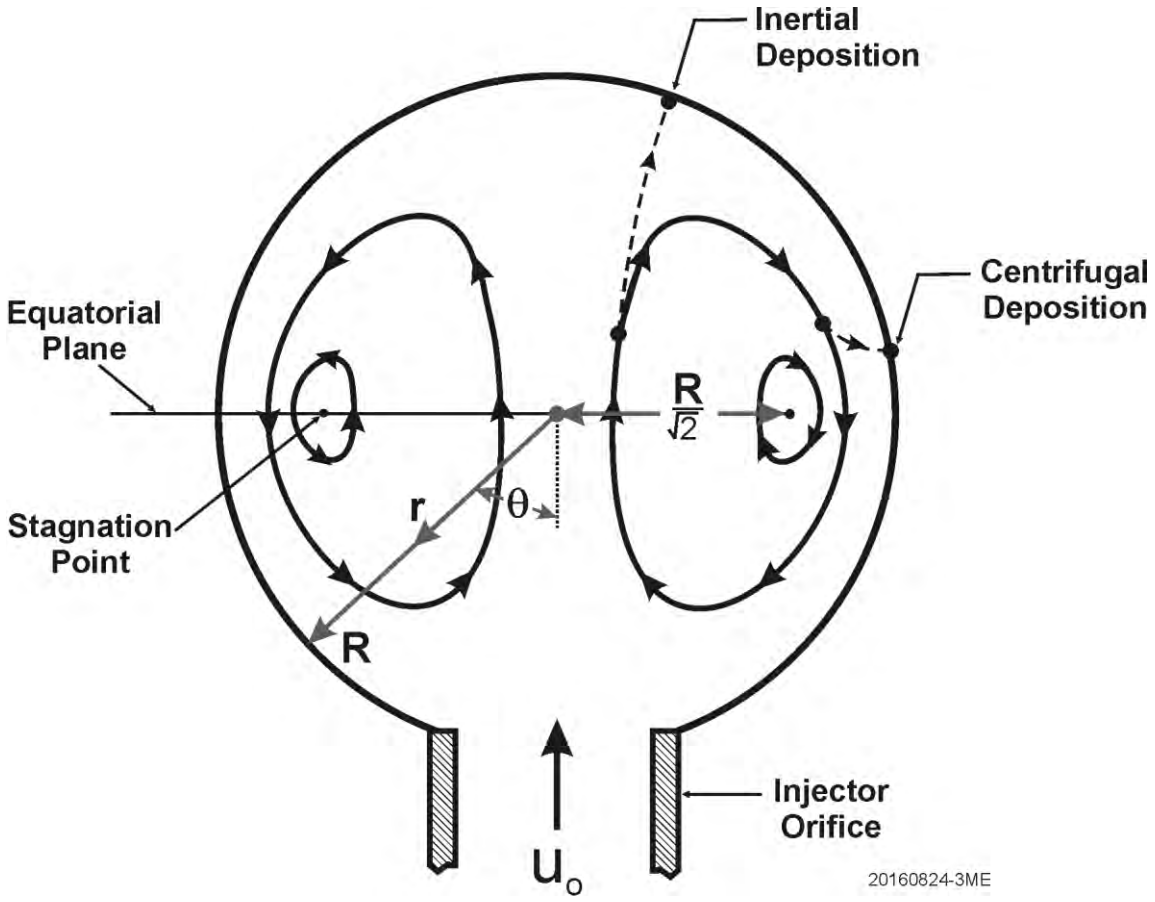
Mechanistic Pool Scrubbing Model-Pool Scrubbing Zones

- Overall DF is calculated as the product of injection, condensation, and bubble rise zone contributions.
- Injection Zone:
  - The gas can leave the discharge location as bubbles or by forming a jet, depending on the discharge volume to flow area ratio.
- Condensation Zone
  - After the flow has developed the plume will rise and any steam will condense if conditions allow.
- Bubble Rise Zone
  - The mechanism for decontamination changes once the rising plume is in thermal equilibrium with the surrounding pool

© 2026 Electric Power Research Institute, Inc. All rights reserved.

Mechanistic Pool Scrubbing Model-Bubble Plume Path DF_{bf}

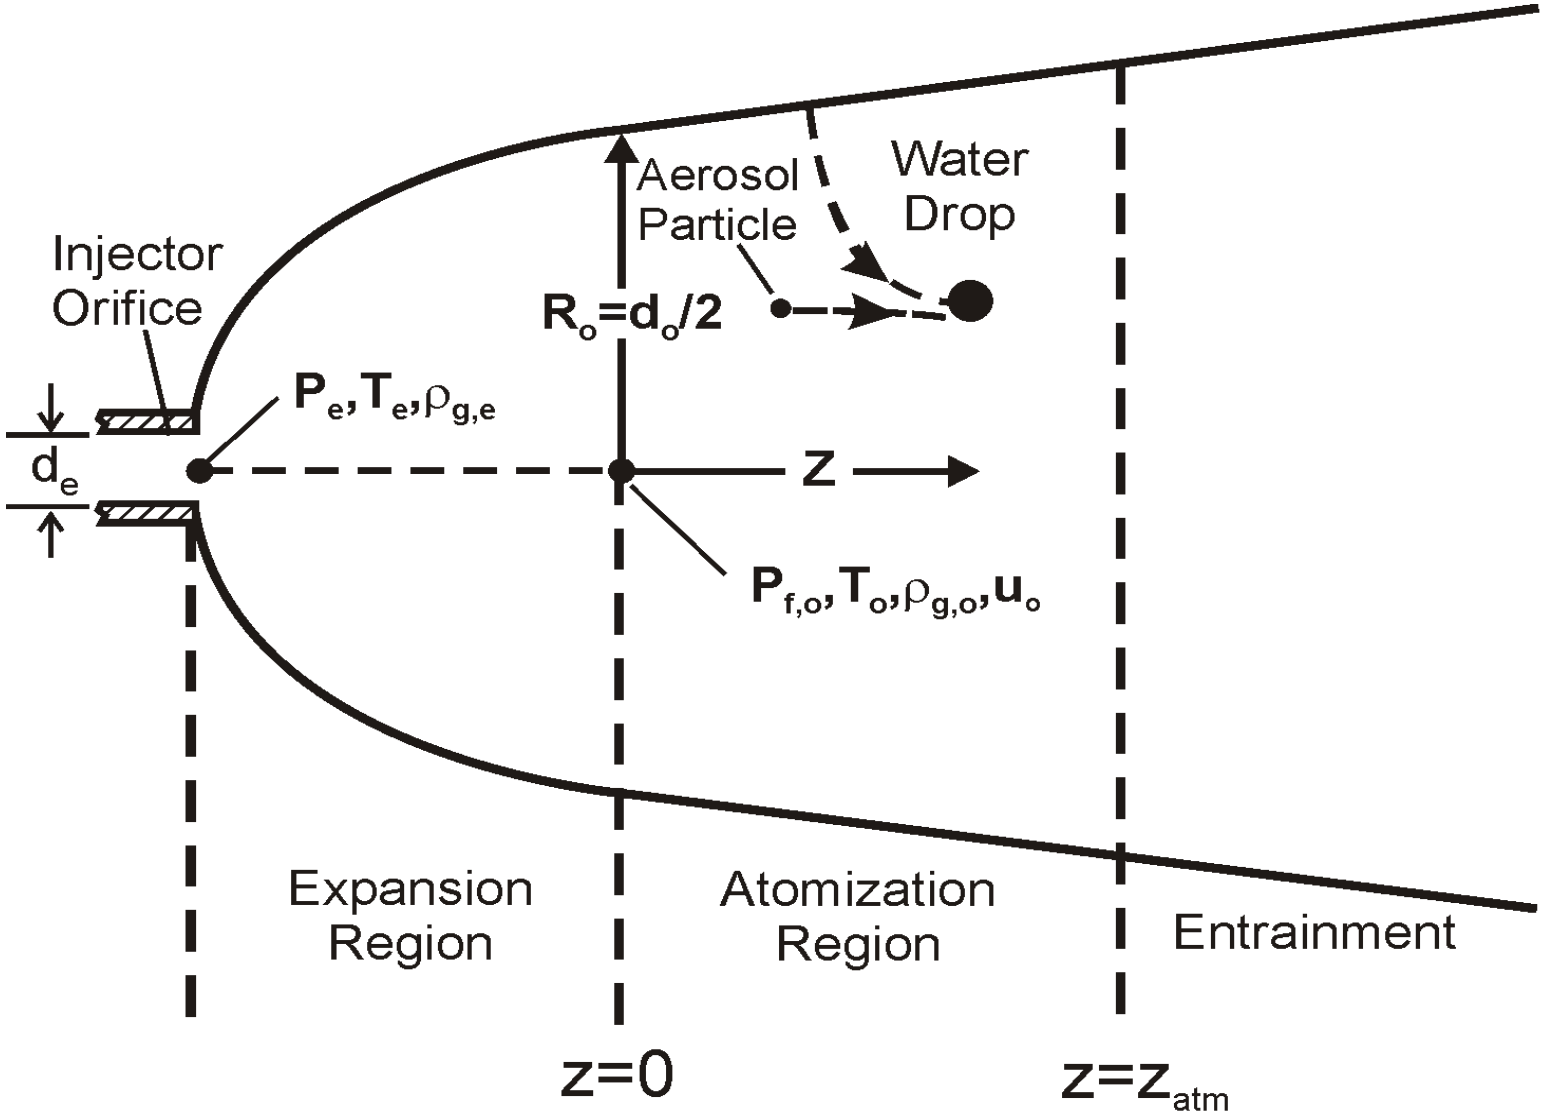
- At low gas discharge rates single bubbles grow and detach periodically from the discharge orifice.
- During bubble growth aerosol particles deposit on the bubble surface by centrifugal force and inertia.
- All other mechanisms of deposition are neglected.



© 2026 Electric Power Research Institute, Inc. All rights reserved.

Mechanistic Pool Scrubbing Model-Gas Jet Region DF_j

- At high gas discharge rates gas jets are formed at the orifice
- The principal mechanism of aerosol depletion is aerosol inertial deposition upon entrained liquid drops.
- MAAP6 applies compressible discharge handling and calculates an effective jet velocity and diameter prior to evaluating in-jet aerosol capture.



© 2026 Electric Power Research Institute, Inc. All rights reserved.

Mechanistic Pool Scrubbing Model-Condensation Zone DF_{cond}

- Particle removal by steam condensation, diffusiophoresis and thermophoresis is assumed to occur immediately after the bubble detaches from the orifice (or jet) and before it breaks up until a stable bubble size is reached.
- The thickness of the condensation zone is small on the scale of the pool depth.
- The stable size bubble is assumed to be in thermodynamic equilibrium with the surrounding pool.
- Heat and mass transfer analogies are used to estimate particle removal by diffusiophoresis and thermophoresis during the bubble's approach to equilibrium.
- In practice, its contribution is relatively small for the cases studied, with overall DF tending to be dominated by injection/jetting and bubble rise.

© 2026 Electric Power Research Institute, Inc. All rights reserved.

Mechanistic Pool Scrubbing Model-Bubble Rise Zone DF_{rise}

- The removal of the gaseous fission products from the bubbles occurs by in-series gas-side and liquid-side-controlled convective diffusion.
- Aerosol particle scrubbing within the rising bubbles occurs by sedimentation, centrifugal force, and Brownian motion.
- MAAP6 computes breakup distance and average bubble diameter explicitly for rise-zone capture and can apply a two-segment rise treatment for hot pool conditions.

$$DF_{rise} = exp\left[\frac{6(H - z_{br})}{U_b \bar{D}_b}(v_{cf} + 0.25v_{sed} + v_B)\right]$$

  - D_b (the average bubble break-up diameter) is a function of the Weber number.
  - H is the pool height
  - Z_{br} is the top of the break-up zone
  - U_b is the bubble rise velocity
  - v_{cf},v_{sed},v_B are the centrifugal force, sedimentation and Brownian motion deposition velocities, respectively.

MAAP6 MODEL VALIDATION

Validating MAAP6 Pool Scrubbing Model

- Mechanistic model was implemented to the MAAP6 code framework and benchmarked against experimental data.
  - Data from CRIEPI allowed for comparison on MAAP6 Bubble rise regime and Jetting regime. MAAP6 outputs are examined against experimental data and against CRIEPI's developed empirical model
  - University of Wisconsin Madison (UW Madison) also provided data to benchmark total DF aerosol removal behavior over a wider particle size range and removal mechanisms.

CRIEPI BENCHMARK

CRIEPI Benchmark Configuration-MAAP6 Model Evaluation

- Objective
  - Evaluate MAAP6 prediction of aerosol removal in the (1) jetting regime and in (2) bubble rise regimes
  - Benchmark MAAP6 DF trends against CRIEPI experimental data and their developed empirical correlations (DFJET, DFBR)

© 2026 Electric Power Research Institute, Inc. All rights reserved.

CRIEPI Benchmark Configuration-MAAP6 Model Evaluation

- Methodology

Bubble Rise Configuration:

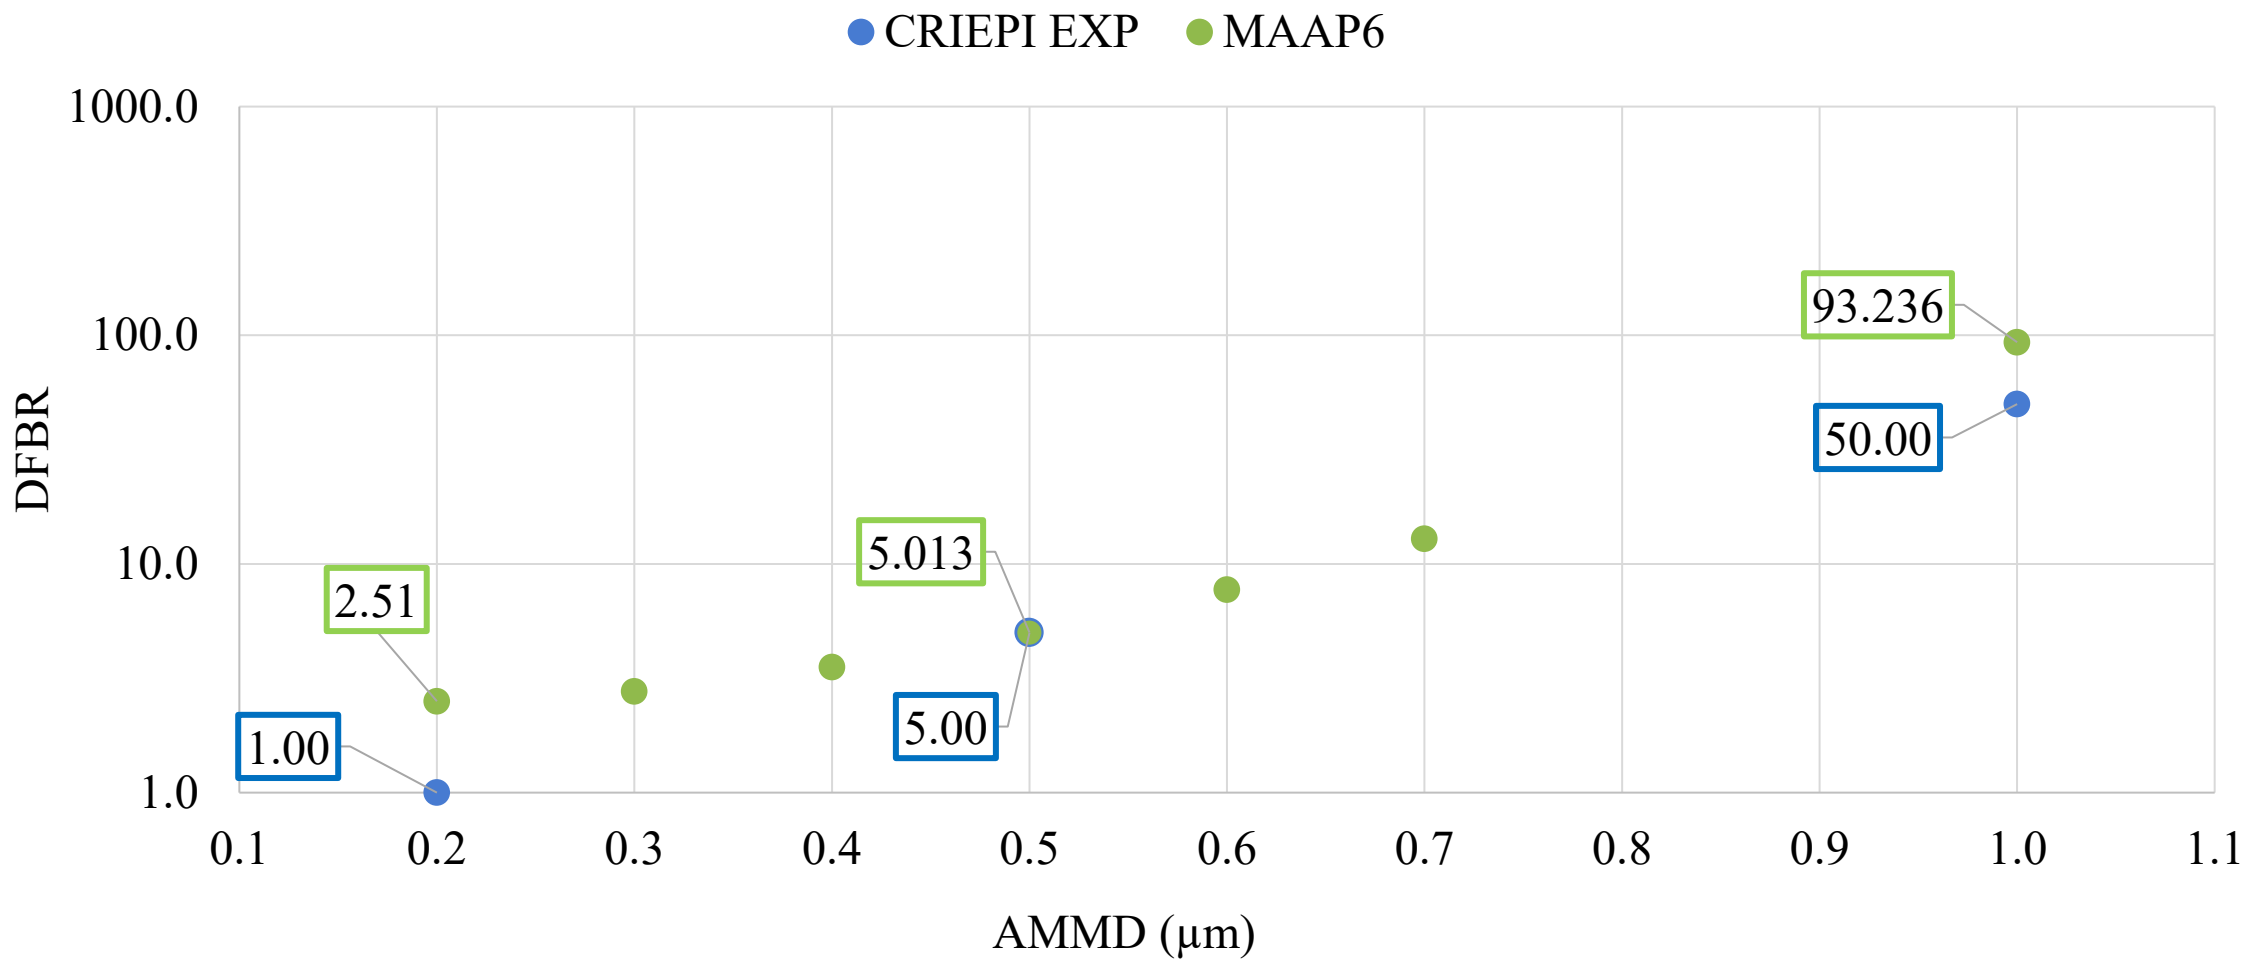
- Represent CRIEPI multi-hole injection (100 holes, 5 mm diameter) to suppress jetting
- Fix submergence depth at 1.5 m and vary particle size (0.2 to 1.2 µm)
- Use ambient air conditions with no steam contribution

Jetting Configuration:

- Implement CRIEPI jetting test conditions directly (single 13 mm orifice, ambient air, stagnant pool)
- Apply 17 flow conditions per particle size at constant submergence depth (2.125 m)
- Evaluate three particle sizes: 0.2 µm, 0.3 µm, 0.5 µm

© 2026 Electric Power Research Institute, Inc. All rights reserved.

CRIEPI Benchmark Results ~ Bubble Rise Regime



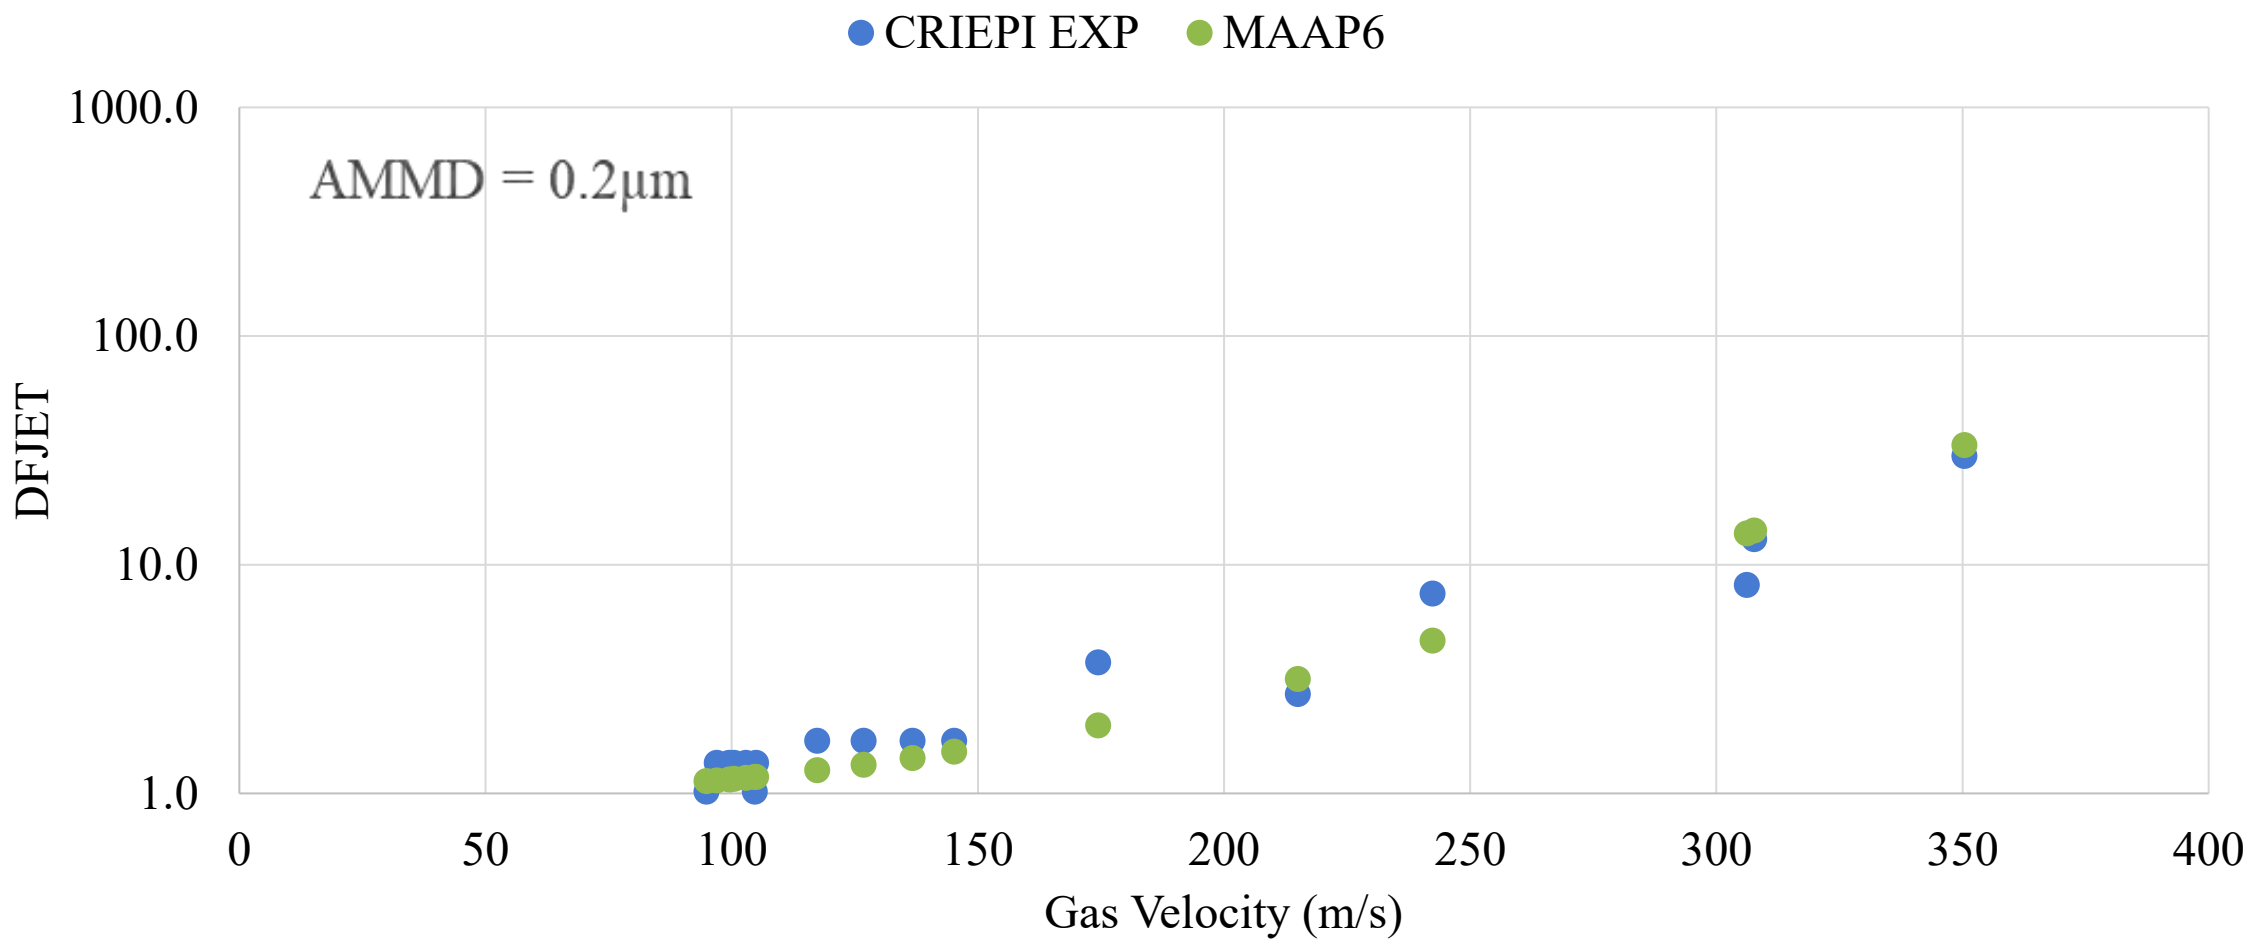
© 2026 Electric Power Research Institute, Inc. All rights reserved.

CRIEPI Benchmark Results ~ Bubble Rise Regime (Key Trends)

- DF increases strongly with particle size
- Larger particles are removed more efficiently than smaller particles
- MAAP6 shows strongest agreement at smaller particle sizes
- Rapid increase in DF observed as particle size approaches ~1 µm

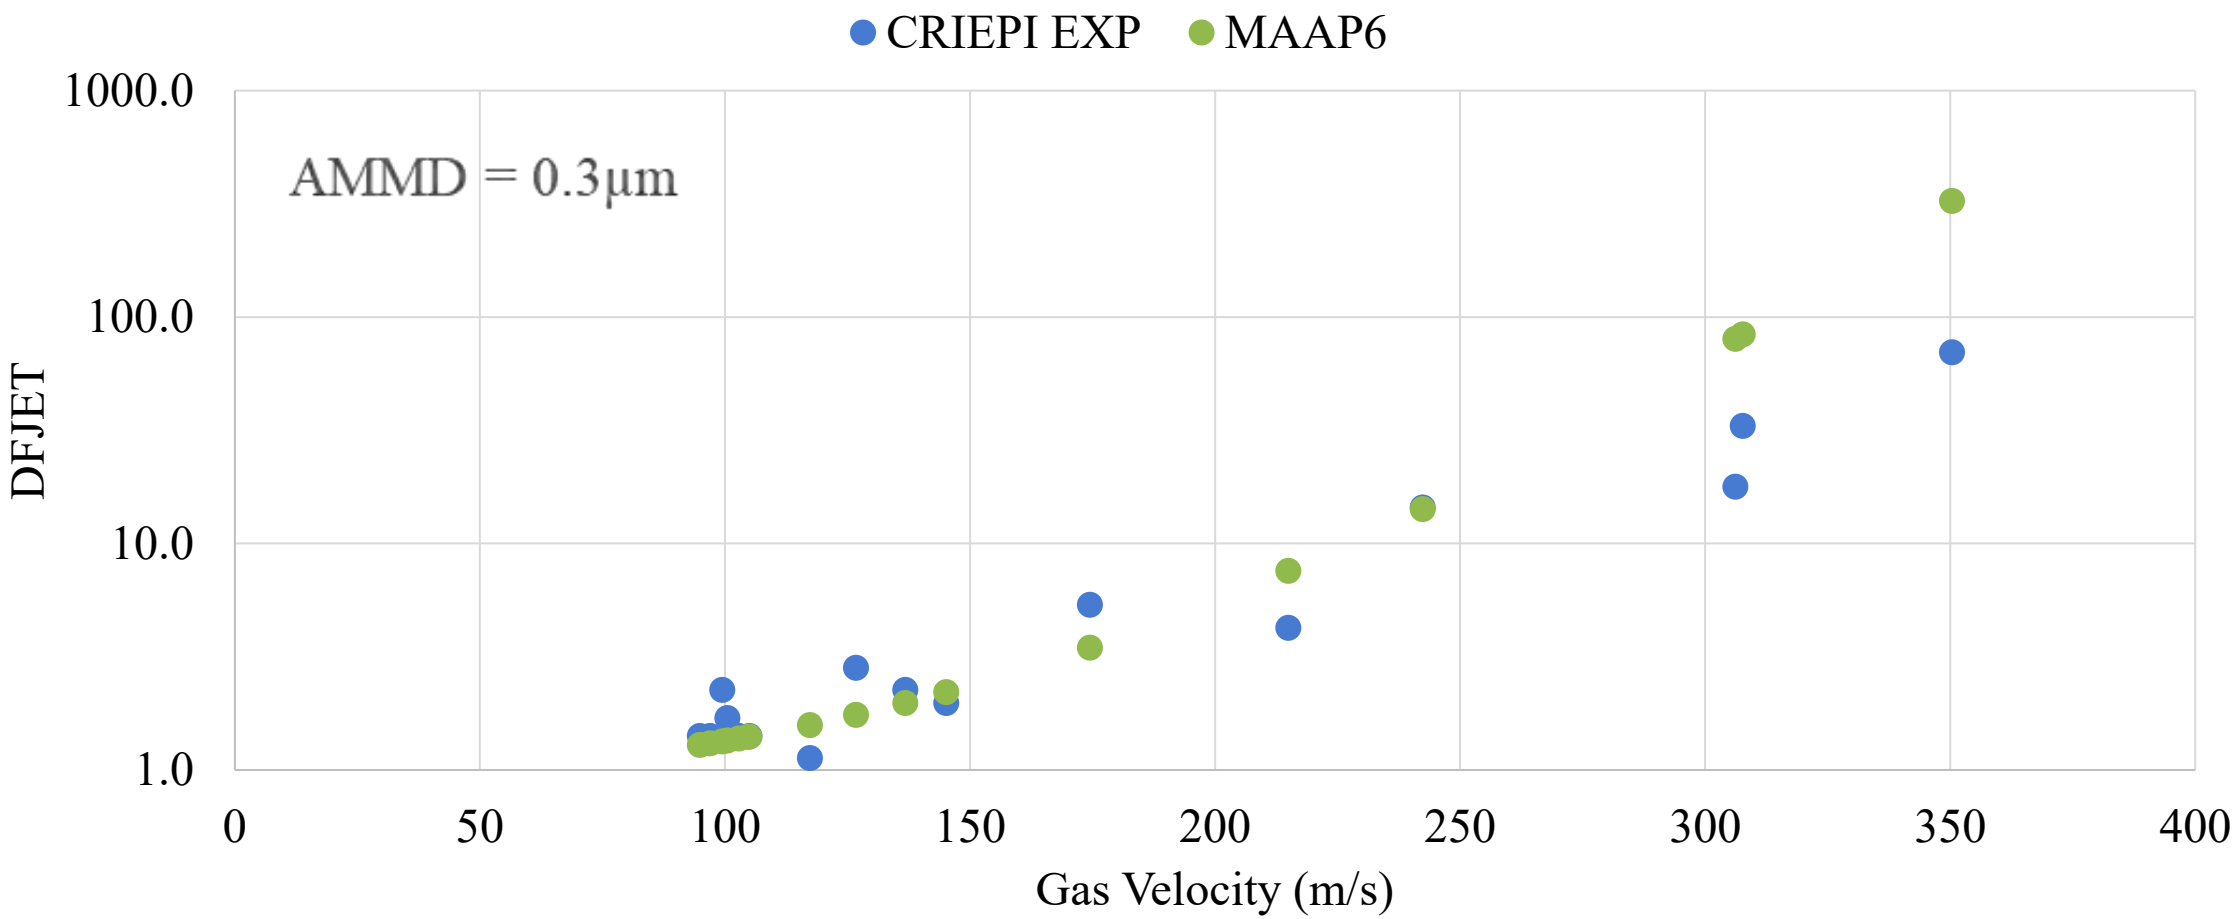
© 2026 Electric Power Research Institute, Inc. All rights reserved.

CRIEPI Benchmark Results ~ Jetting Regime 0.2 µm



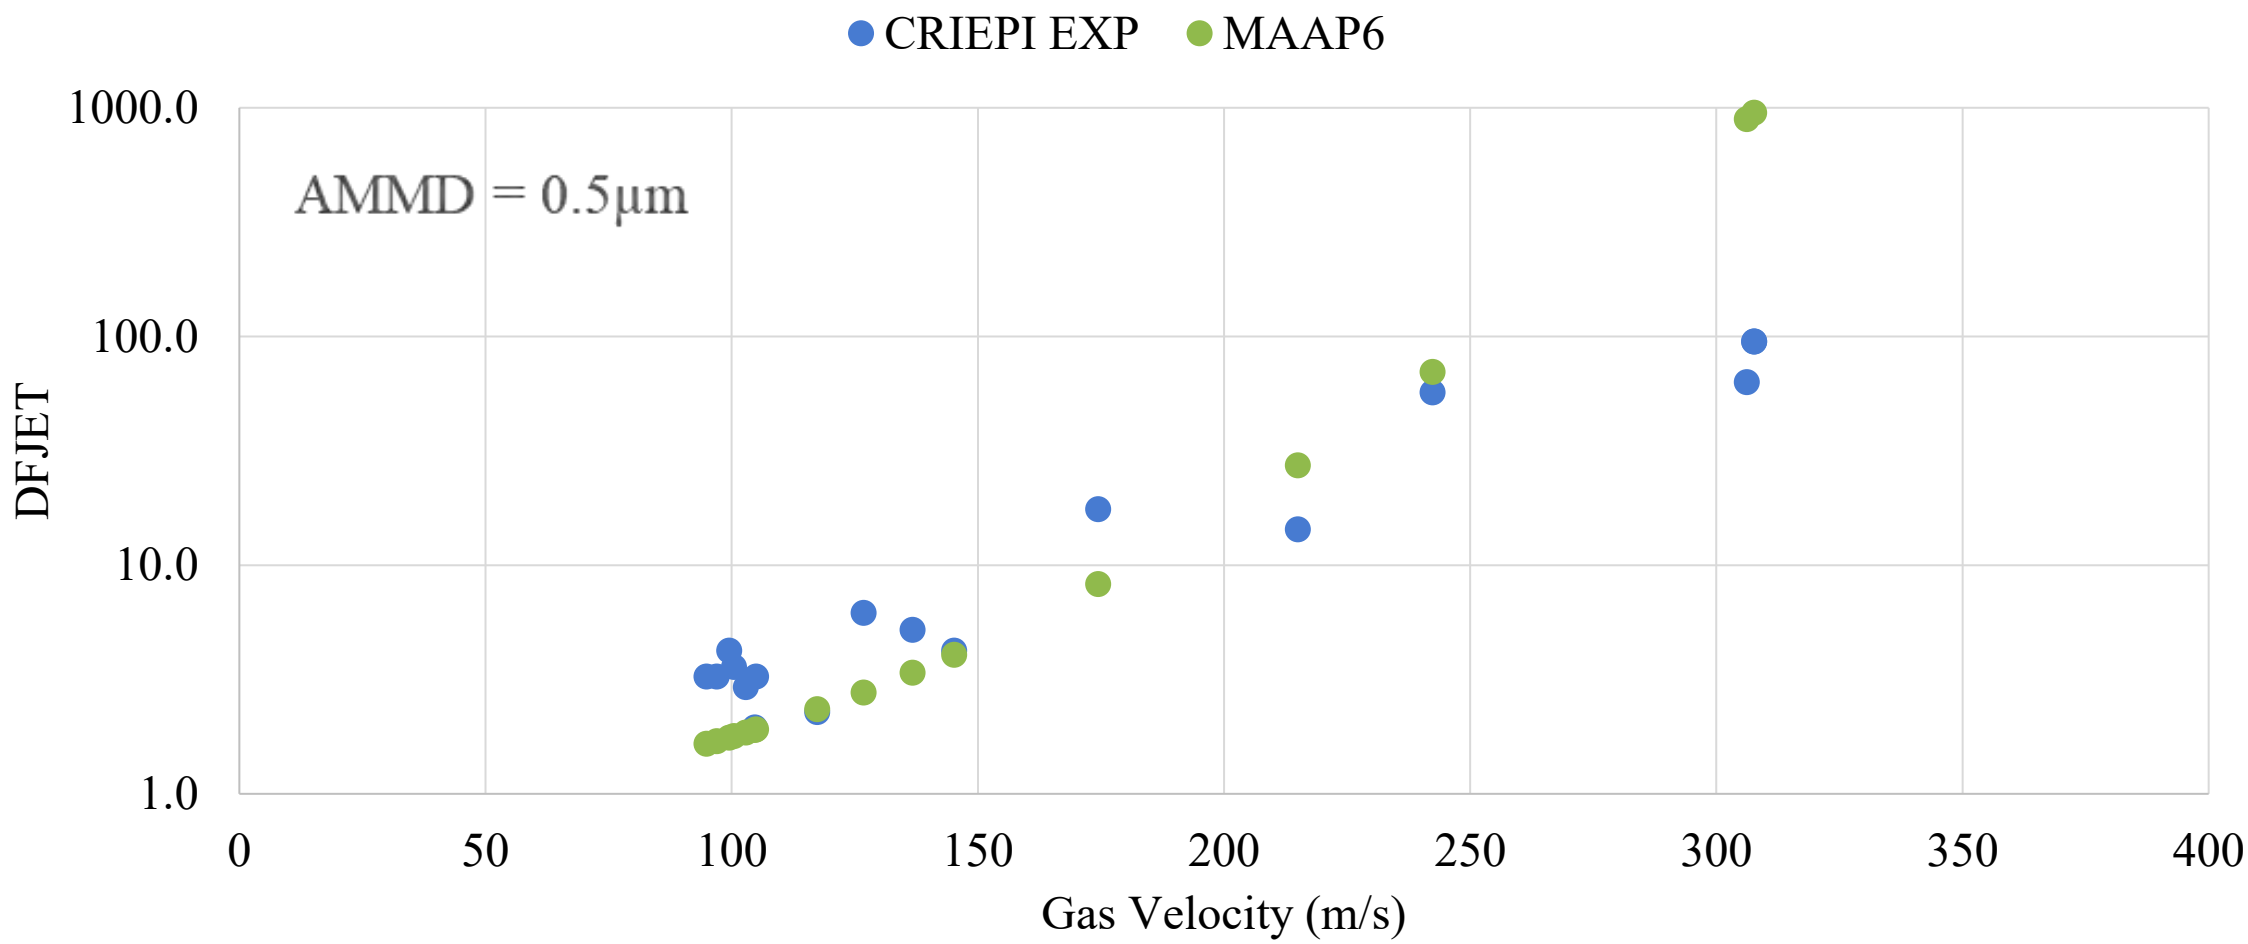
© 2026 Electric Power Research Institute, Inc. All rights reserved.

CRIEPI Benchmark Results ~ Jetting Regime 0.3 µm



© 2026 Electric Power Research Institute, Inc. All rights reserved.

CRIEPI Benchmark Results ~ Jetting Regime 0.5 µm



© 2026 Electric Power Research Institute, Inc. All rights reserved.

CRIEPI Benchmark Results ~ Jetting Regime (Key Trends)

- DF increases with increasing gas velocity across all particle sizes
- Larger particles show stronger sensitivity to velocity (inertial effects dominate)
- MAAP6 captures overall scaling with velocity and particle size

© 2026 Electric Power Research Institute, Inc. All rights reserved.

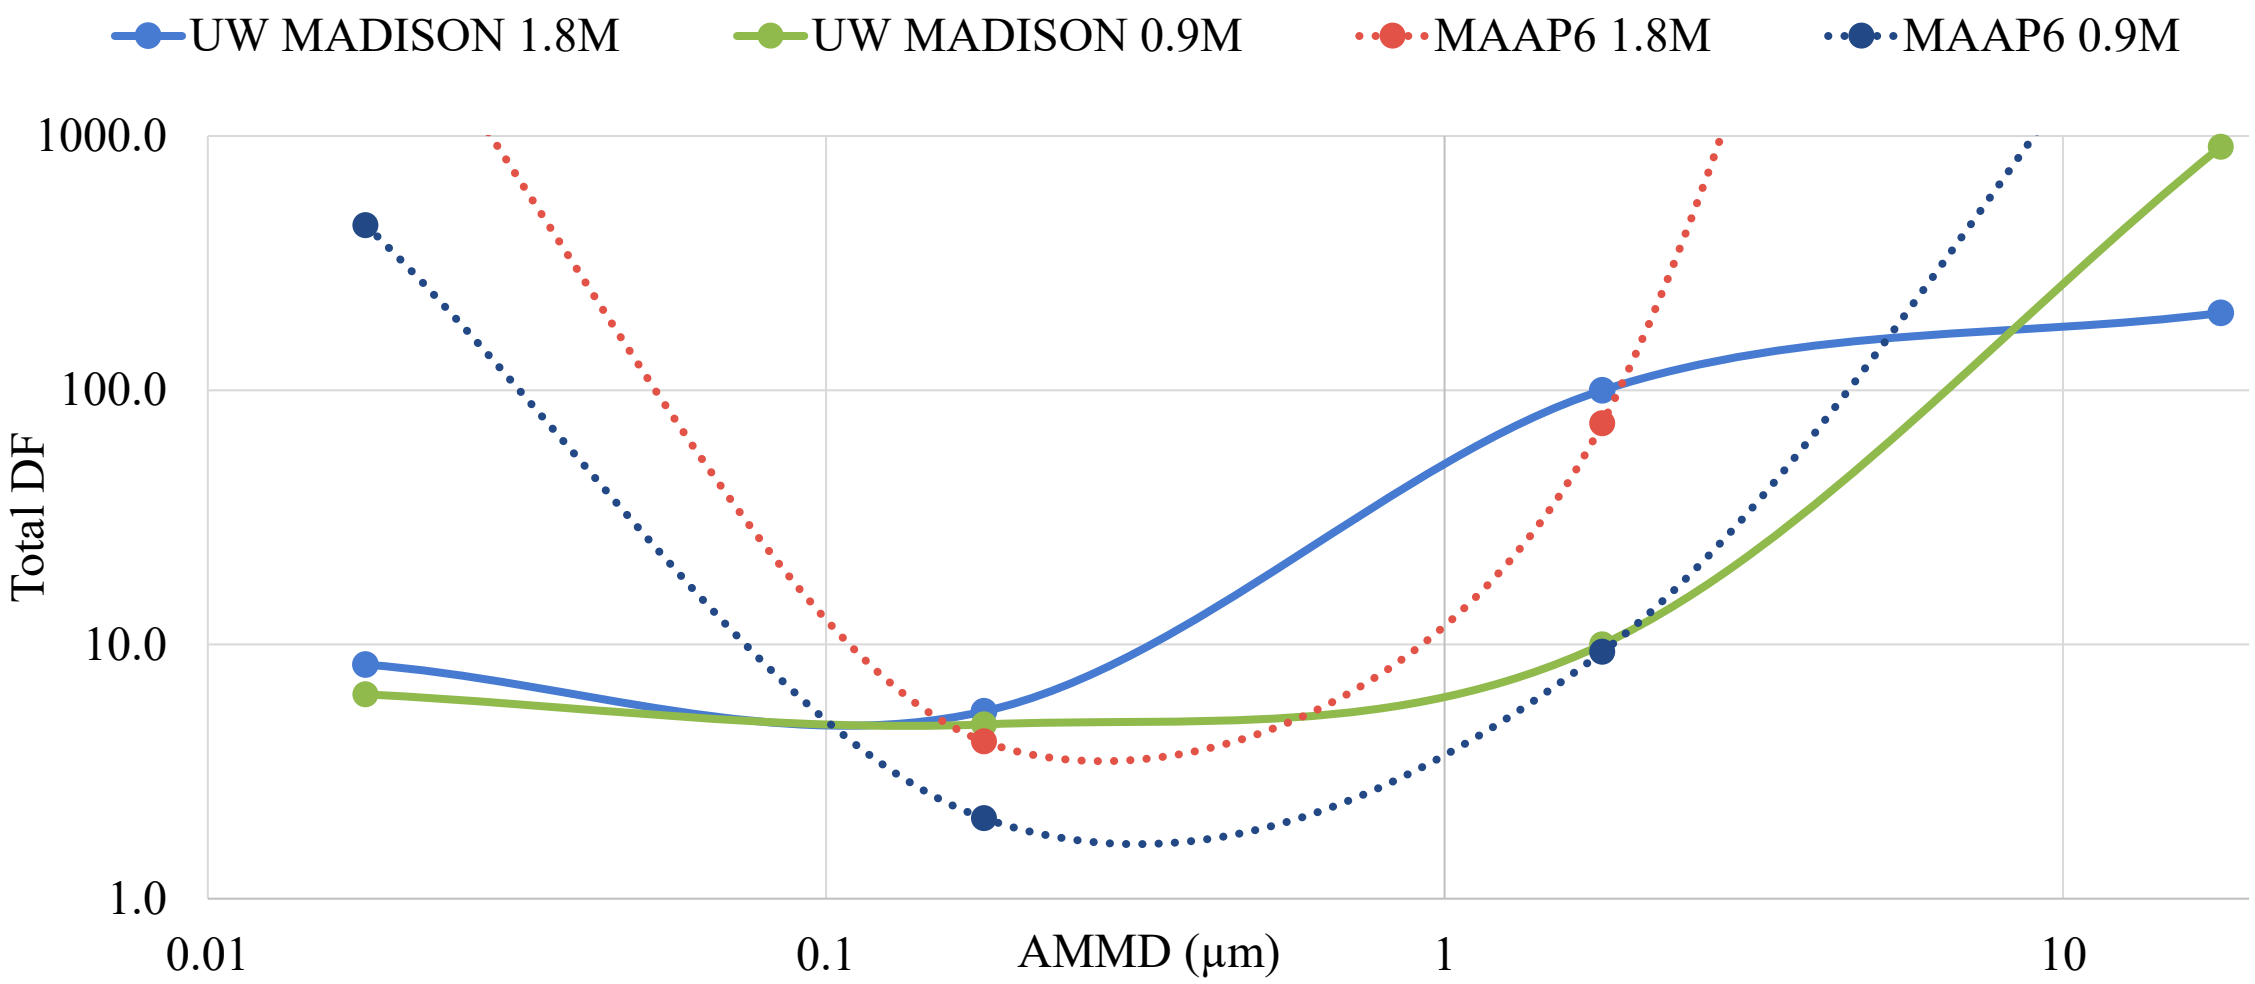
UW MADISON BENCHMARK

UW Madison Benchmark Configuration – MAAP6 Model Evaluation

- Objective
  - Extend MAAP6 validation to a broader aerosol size range and additional removal mechanisms
  - Evaluate model behavior across regimes transitioning from diffusion, impaction, and gravitational settling
- Methodology
  - Use UW Madison aluminum aerosol experiments with particle sizes ~0.01 to 18 µm
  - Convert reported aerodynamic diameters to physical diameters assuming spherical particles ($\rho = 2.7\ g/cm^3$)
  - Evaluate two pool depths: 0.9 m and 1.8 m to assess residence time effects
  - Maintain consistent material properties and isolate effects of particle size and pool depth
  - Results are used for qualitative trend comparison due to water vs sodium pool

© 2026 Electric Power Research Institute, Inc. All rights reserved.

UW Madison Benchmark Results



© 2026 Electric Power Research Institute, Inc. All rights reserved.

UW Madison Benchmark Results (Key Trends)

- DF is high at very small particle sizes, decreases in the intermediate range, then increases again for larger particles
- Trend reflects transition from diffusion-dominated to impaction to also gravitational settling mechanisms
- Deeper pool (1.8 m) results in higher DF due to increased bubble residence time
- MAAP6 reproduces the qualitative dependence of DF on particle size and pool depth
- Provides complementary validation beyond CRIEPI by covering multiple removal regimes

© 2026 Electric Power Research Institute, Inc. All rights reserved.

Conclusions and Future Work

- MAAP6 now includes a mechanistic pool scrubbing model with separate injection, condensation, and bubble rise zone contributions
- Benchmarking against CRIEPI data showed the model captures key DF trends in both bubble rise and jetting regimes
- Comparison with UW Madison data extended evaluation across a broader aerosol size range and multiple dominant removal mechanisms
- Overall, MAAP6 reproduced the primary trends observed across experimental datasets

- Looking Forward
  - Continue evaluation against additional aerosol materials and pool conditions

ABSTRACT

Iodine is one of the most hazardous fission products (FP) released to the containment of a nuclear power plant during a severe accident. The metallic iodide aerosol CsI is one of the main airborne iodine species in the containment and the CsI decomposition with formation of gaseous iodine species is a primary concern in nuclear accident scenarios. The thermal and radiolytic decomposition of CsI generates molecular iodine, which can further react with organic compound and form the organic iodide. In this paper the AC^2/COCOSYS code is applied to simulate and analyze the CsI decomposition and related iodine aerosol transport in the containment of LOCOV tests. The LOCOV experiment in the French EPICUR facility studied the decomposition of deposited CsI aerosol and the reactivity of I_2(g) with methane to quantify the organic iodide formation rate in the presence of volatile organic compounds (VOC) [1]. The COCOSYS simulation investigates the decomposition of CsI aerosol, the organic iodide formation and the distribution of the different iodine species across the coupon, the atmosphere, the vessel walls and the filter. The simulation results of LOCOV model show that the thermal decomposition of CsI is very slow, but a fast decomposition of CsI is observed under irradiation. The injected methane reacts with I_2 and organic iodide is generated, while the oxidation of I_2 with ozone produces iodine oxide aerosol IO_x. The gas phase I_2 in vessel deposits on the surfaces of vessel wall. With the time going on, the deposited I_2 reacts with Fe. Higher dose rates caused higher CsI decomposition and RI generation rates. The comparisons between simulation results and measurements show the modelling capabilities of organic iodide formation with COCOSYS in two LOCOV tests.

KEYWORDS
CsI decomposition, organic iodide, aerosol, irradiation

1. INTRODUCTION

Iodine is one of the most hazardous fission products (FP) released to the containment during a severe nuclear reactor accident. The evolution of volatile iodine concentration is determined by a balance between formation and deposition processes [2-4]. Volatile molecular iodine (I_2) can be produced from the iodine deposited on painted surfaces or from suspended aerosols [2-5]. The organic iodide compounds (RI) can be produced from iodine deposited on painted surfaces or reaction between iodine and organic gas, like methane [1-12]. The low-molecular-weight RI is harder to trap for the filter, making it more likely to be released into the environment. It makes the studies of volatile molecular iodine release and RI formation very important in the severe accident management.

The metallic iodide aerosol CsI is one of the main airborne iodine species in the containment and the CsI decomposition with formation of gaseous iodine species is a primary concern in nuclear accident scenarios [1, 7, 13]. The CsI decomposition process can be affected by many parameters. The AER-CsI test series in

the STEM-EPICUR program studies the behavior of CsI aerosols deposited on different surfaces of the containment and the ability to produce volatile iodine species [1]. The effects of various experimental parameters on the iodine species releases were evaluated: initial CsI concentration on the coupon, relative humidity, temperature, dose rate and nature of the coupon surface (stainless steel, quartz or EPOXY paint). The extensive experiment program STEM-EPICUR has been performed to obtain data concerning iodine volatilizations.

STEM-EPICUR program also investigated the formation of organic iodide from the painted surface in the containment atmosphere under various conditions [4, 6]. The initial concentration of iodine deposited on the painted coupon and the relative humidity were found to have significant impacts on the volatilization of organic iodide [6]. The ESTER-EPICUR tests investigated the iodine chemistry within the containment, focusing on the RI formation pathways not involving paints [14]. Specifically, the LOCOV tests examined reactivity under gamma irradiation on metal surfaces, such as electropolished stainless and galvanized steel, within an oxygen-depleted atmosphere containing organic gases (CH_4). The effects of methane, ethylene, surface, species and dose rate are checked through different tests.

The advanced iodine model (AIM), part of the AFP2 module in the AC^2-COCOSYS containment code, was developed to simulate aerosols, fission products and iodine chemistry [15-17]. Within AFP2, the CsI decomposition rate is calculated based on the dose rate, available CsI mass and a 'damage term' that accumulates proportionally to radioactivity, and a model dependent recovery rate. The recovery rate serves to buffer both the acceleration and deceleration of the decomposition process. In this study, COCOSYS is utilized to simulate CsI decomposition, RI formation, and the resulting distribution of iodine species across the coupons, atmosphere, vessel walls, and filters as investigated in the LOCOV and LOCOV2 tests.

2. Model Setup

The LOCOV and LOCOV2 tests utilized steel coupons as substrates for CsI deposits within a containment vessel. While the LOCOV test employed electropolished stainless steel with an initial iodine concentration of 1.86×10^{-4} mol/m^2, the LOCOV2 test used galvanized steel with a concentration of 1.60×10^{-4} mol/m^2 (see Table 1).

Table I. Experimental setups of LOCOV and LOCOV2

Test	LOCOV	LOCOV2
Coupon	Electropolished stainless steel	Galvanized steel
Aerosol	CsI	CsI
CsI concentration (mol/m^2)	$1.86\text{x}10^{-4}$	$1.60\text{x}10^{-4}$
Temperature (°C)	120	120
Pressure (bars)	3.5	3.5
Pre-irradiation	1 hour with dry air	1 hour with dry air 3 hours with wet air 50% R.H.
Irradiation	43 hours with Air (3% O_2) + 2% CH_4 + 50% R.H.	
Post-irradiation	1 hour with dry air (3% O_2) + 2% CH_4	
Dose rate (kGy/h)	1.2	6.9

Compared with LOCOV test, LOCOV2 test was performed with higher dose rate. The experiment is performed with continuous air flow that is directed through the vessel and released over a filter line in which the released chemical iodine components are trapped and analyzed according to the chemical compositions

that are separated in the different stages of the used May-pack filters. The air temperature in vessel is 25 °C and the pressure is 3.5 bar; both stay constant during the experiments LOCOV and LOCOV2. There is 1-hour pre-irradiation sweeping phase and 1-hour post-irradiation sweeping phase with 8.72×10^{-6} kg/s dry air (3% O_2 + 2% CH_4) for LOCOV test. LOCOV2 has extra 3 hours of pre-irradiation wet air sweeping period after the one-hour dry air sweeping phase. The irradiation phase duration is about 44.3 hours with 50% R.H. air (3% O_2 + 2% CH_4), in which the air gas injection rate is 6.25×10^{-6} kg/s and water injection rate is 1.54×10^{-6} kg/s. The different volatile iodine species (I_2, IO_x, RI) released during the test are transferred to the May-pack device and trapped on the different filters. The conceptual setup of the tests is shown in Fig.1.

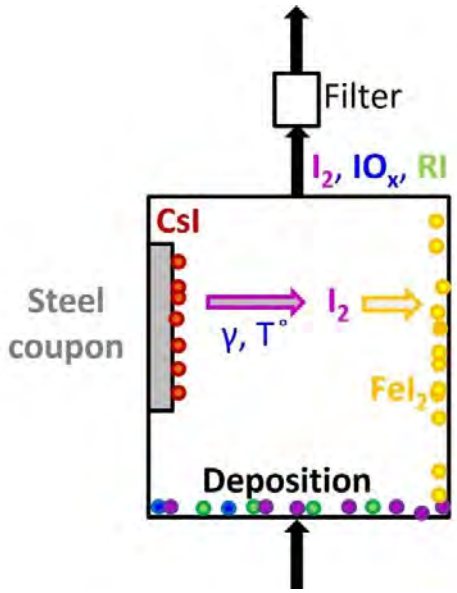

Figure 1. Conceptual model of LOCOV and LOCOV2 tests.

The principal reactions related to the CsI decomposition, RI formation and related iodine chemistry are shown in Fig. 2. In the iodine model AIM the decomposition of deposited CsI(dep) at the surface of coupon is simulated with two reactions that take place under irradiation: a faster reaction under irradiation with the production of I_2 and a slower reaction with the production of IO_x.

$$2\mathrm{CsI(dep)} + 2\mathrm{H_2O(g)} \xrightarrow{\gamma} \mathrm{I_2(g)} + 2\mathrm{CsOH(dep)} + 2\mathrm{H^+} \quad (1)$$

$$\mathrm{CsI(dep)} + \frac{1}{2}\mathrm{H_2O(g)} + \frac{x+0.5}{3}\mathrm{O_3(g)} \xrightarrow{\gamma} \mathrm{CsOH(dep)} + \mathrm{IO_x(g)} \quad (2)$$

A new conceptual model with a damage term is implemented for the CsI reaction under irradiation (Eq. 3). The idea behind the new model is to model the typical time dependent behavior of a delayed decomposition of CsI by introducing a damage term H (H for harm and to distinguish it from the dose D) in the reaction mechanism. The damage term accumulates proportional to the deposited mass, a model dependent recovery rate and the reaction rate of CsI:

$$\frac{dH}{dt} = m_{CsI} D_{gas} - H f_{rec} - \frac{\dot{r}}{m_{CsI}} H \quad (3)$$

The new CsI decomposition rate is then simply described as:

$$\frac{d[\mathrm{CsI}]}{dt} = -k_r^{\gamma} H \quad (4)$$

Where:

H	Damage term [kg·kGy/h]
m_{CsI}	Available CsI mass [kg]
D_{gas}	Dose rate [kGy/h]
f_{rec}	Recovery factor, which is a function of decomposition rate [1/s]
$\dot{r}$	Reaction rate of CsI [kg/s]
[CsI]	CsI concentration at the coupon surface [kg/ m^2]
k_r^{γ}	Radiolytic reaction coefficient [1/(m^2·kGy)]

Generally, the decomposition rate is high when there is more available CsI mass and the dose rate is high. At the beginning, there is more CsI available for reaction, so the decomposition rate will be high. As irradiation consumes more CsI, the amount available for reaction diminishes, leading to a decrease in the decomposition rate. However, the recovery factor f_{rec} also declines alongside the decomposition rate, effectively buffering the overall rate reduction.

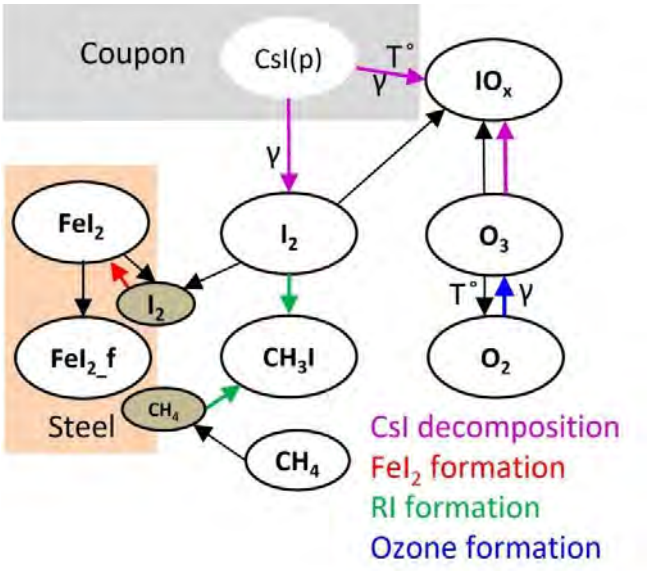

Figure 2. Schematic modelling of CsI destruction and RI formation.

Depending on the dose rate, ozone is formed from the oxygen in the air. Radiolytically produced ozone can react with gaseous I_2 to form IO_x aerosols, which exhibit distinct behavior compared to gaseous I_2. The backward conversion of IO_x to I_2 is also possible under accident typical gas temperatures. Deposition of I_2 onto steel surface and the subsequent chemical reaction with steel is an unwanted removal process for volatile iodine from the gas phase e.g. in iodine tests. The reaction of gaseous iodine (I_2) with dry stainless-steel surfaces can be described as the sequence of two processes: an initial, fast and reversible physisorption process, followed by a slower chemical reaction of the physical sorbed I_2 with the steel producing chemisorbed, non-volatile metal iodides (represented by FeI_2). FeI_2 can be further oxidized forming strongly bound iron-iodide-oxides FeI_2_f, which is a permanent iodine sink, and no iodine can be released from it into the gas phase again. Organic iodine formation occurs through a reaction of deposited methane with gaseous I_2, which was considered as the best model through comparing the different RI generation mechanisms models results with test measurements.

3. Simulation Results

3.1. LOCOV test simulation

The measurement showed that there is 30.7% missing mass balance at the end of LOCOV test [14]. Therefore, the LOCOV model simulated with COCOSYS focuses on the released iodine mass evolution in filter, the mismatch of iodine mass on coupon at the end is ignored.

Methane is injected into the vessel during the whole test process, so in the first 1 hour, the concentration of methane in the vessel increases quickly. When the irradiation starts, the radiolysis of the air/steam atmosphere produces ozone immediately (Fig. 3). The radioactive decomposition of CsI releases I_2. The oxidation of I_2 by ozone produces IO_x; simultaneously, the thermal production of IO_x also consumes ozone. Due to these ozone-consuming reactions, the ozone concentration decreases slightly and then maintains a constant level until the end of irradiation. Due to the extremely slow thermal decomposition of CsI, the IO_x concentration remains negligible and therefore omitted from the figure. Injected methane reacts with I_2 to generate organic iodine; however, the generation rate declines as the I_2 concentration is depleted. Once the irradiation stops, the production of both ozone and I_2 from CsI decomposition also ends. The remaining ozone and I_2 react rapidly, consuming both reactants in a short timeframe. Consequently, the concentration of methane begins to recover, while the concentration of organic iodine decreases sharply.

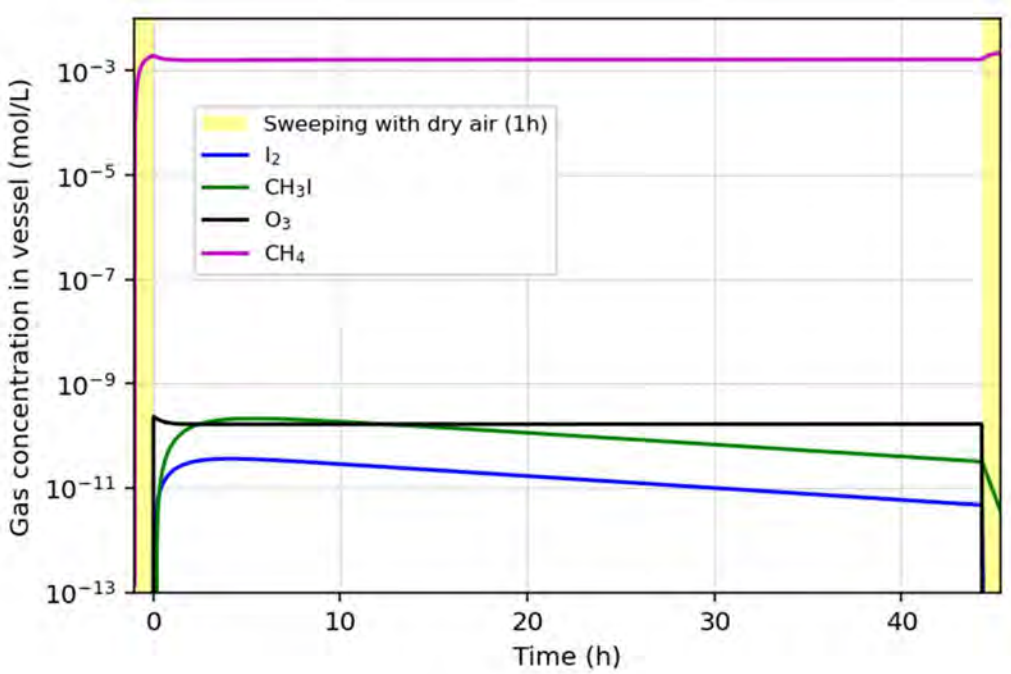

Figure 3. Evolution of gas phase species concentration in the containment for LOCOV model.

Fig. 4 illustrates the overall iodine balance across the hosts coupon, vessel atmosphere, vessel structures, and filter. At the end of simulation, there is totally 74.9% iodine deposited at the steel surface, 14.5% iodine in filter, 10.6% iodine on coupon. Due to the continuous flow design of the experiment, only a small fraction is present in the vessel atmosphere during the whole experimental sequence. The released gas phase I_2 from CsI decomposition in vessel deposits on the surfaces of the vessel walls. With the time going on, the deposited I_2 reacts with Fe and the FeI_2 is produced. FeI_2 can be further oxidized forming strongly bound iron-iodide-oxides, so the deposited iodine mass in form of FeI_2 continues increasing (Fig. 5). On the other hand, the deposited I_2 starts decreasing 10 hours after the irradiation. Because of the low concentration of

airborne IO_x, the deposited iodine in form of IO_x can be ignored. At the end of simulation, 95% of steel surface deposited iodine are FeI_2, only 5% are in form of I_2. Characterizing the spatial and chemical distribution of iodine is essential for understanding the system's behavior. This approach ensures the model can be accurately calibrated as more detailed experimental data becomes available.

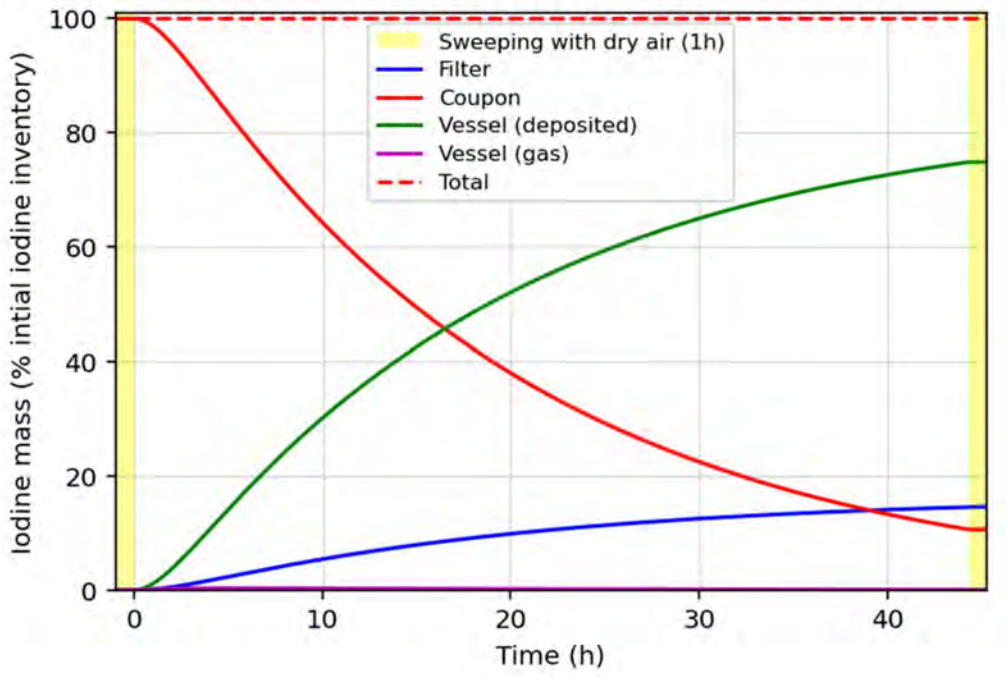

Figure 4. Evolution of iodine mass distribution for LOCOV model.

The simulated iodine mass in the filter is compared with experimental measurements from the LOCOV test in Fig. 6. The simulation indicates that the I_2 generation and subsequent organic iodine production rates are lower during the initial irradiation phase, resulting in a more gradual increase in the filter load. Generally, the simulation accurately captures the observed evolution of organic iodine. For the molecular iodine on the filter, there is 3.5% deposition at the end of simulation, which is a little bit lower than the measured data. The linear gradient trend in the measured data suggests a quasi-constant gas I_2 concentration within the vessel. However, during the final one-hour dry air weeping phase, after irradiation stopped, a sudden release of molecular iodine was detected on the filter. The mechanism behind this release remains unclear and requires more detailed observation. The simulation shows no more molecular iodine released from the system in the last hour. Same as the test observation, the concentration of IO_x is very low and can be ignored. The radioactive decomposition dominates the CsI release.

Within the COCOSYS calculation a large part of iodine is trapped on the steel walls of the vessel. This is a possible explanation for the large balance error observed in the experiment. However, the iodine-steel model of COCOSYS is derived from the specifics of the THAI vessel operated by Becker Technologies in Germany [18]. The steel inside the EPICUR facility is different and assumed to be inert to iodine deposition and reaction to a great extent. Therefore, the actual iodine sink remains unknown, though the piping utilized during the experiment may also account for the large balance error.

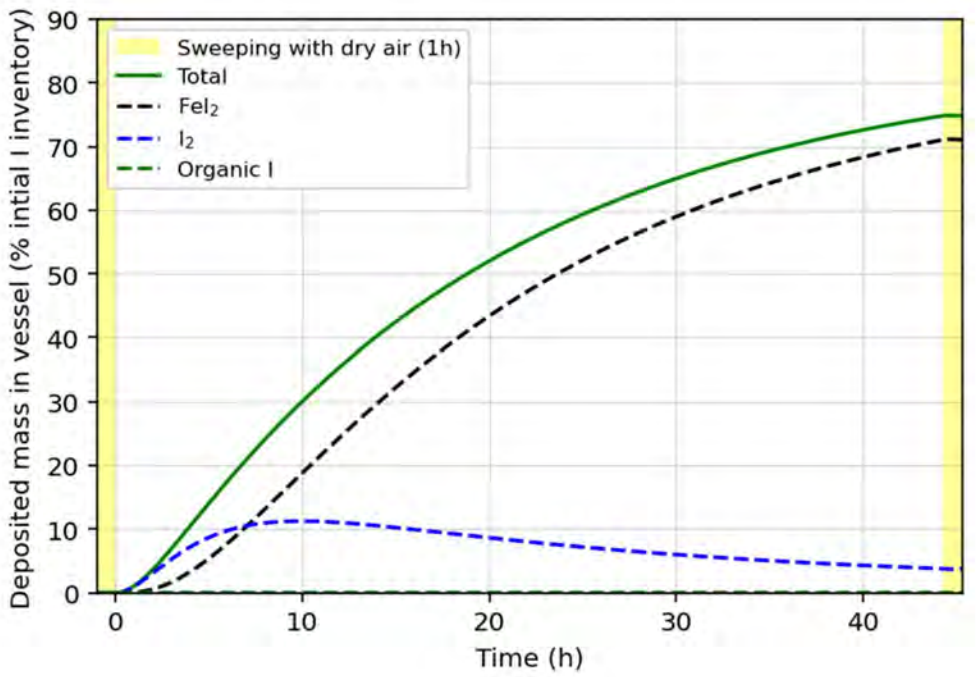

Figure 5. Evolution of deposited iodine at the steel surface for LOCOV model.

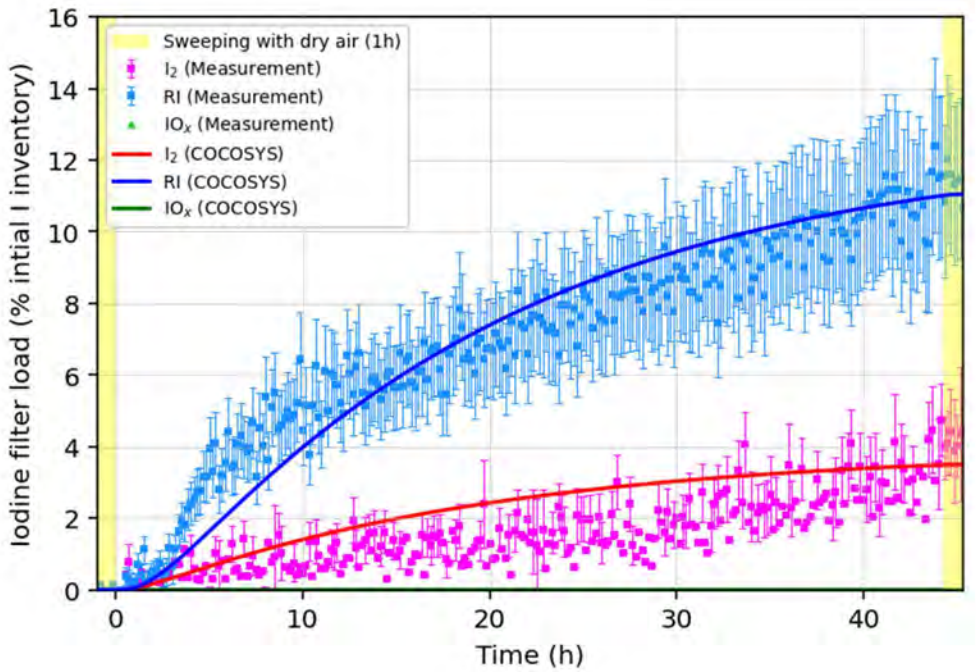

Figure 6. Comparison of measured and simulated iodine activity in filter for LOCOV test.

3.2. LOCOV2 test simulation

The chemical model implemented in COCOSYS as depicted in Fig.2 has been developed on LOCOV results. To estimate the general validity of this model and check the sensitivity of dose rate on CsI

decomposition and RI generation, also the experiment LOCOV2 has been simulated. Different from LOCOV test, LOCOV2 used galvanized steel as the coupon surface material and higher dose rate. Because of the higher dose rate in LOCOV2, which is 6.9 kGy/h compared to only 1.2 kGy/h in LOCOV test, the decomposition rate of CsI on coupon and the ozone generation rate are higher in LOCOV2 simulation. Therefore, the molecular iodine I_2 concentration in the containment increases quickly when the irradiation starts, and the concentration of ozone is much higher compared with LOCOV model (Fig. 7). Consequently, the generation rate of RI is higher, too. These higher concentrations of I_2 and RI cause more iodine mass transport out of the vessel and into the filter (Fig. 8). This fast mass flow-out limits the deposition of iodine on the steel wall surfaces. At the end of simulation, there is almost 54% iodine mass in the filter, and there is still 46% iodine mass on the coupon (Fig. 8). The iodine deposition at the containment wall surface can be ignored.

At the end of experiment LOCOV2 there is 0.3% IO_x, 29.1% I_2 and 23.0% RI deposition on the filters compared to the initial inventory. Compared to the LOCOV test, higher rates of CsI decomposition of RI formation resulted in a greater release of molecular and organic iodine. Generally, the simulated organic iodine on the filter shows good agreement with the measured RI evolution (Fig. 9). Regarding the molecular iodine on the filter, the simulation shows a slower release rate in the first 20 hours compared to experimental results. The damage term implemented in COCOSYS buffers the high CsI decomposition rate when both the dose rate and available CsI mass are elevated. This likely explains why the model underestimates the initial rapid release of molecular iodine; However, the simulation successfully captures the overall release trends.

4. CONCLUSIONS

The LOCOV and LOCOV2 tests, which investigate CsI decomposition and RI generation, were simulated using the AFP2 module in COCOSYS. The models show that irradiation significantly accelerates CsI decomposition compared to thermal processes. Injected methane reacts with I_2 to generate organic iodine, while the oxidation of I_2 by ozone produces IO_x aerosols. Additionally, gaseous I_2 deposits onto the steel vessel walls, where the model predicts a subsequent reaction with iron to form FeI_2. While higher dose rates increased CsI decomposition, the lower I_2 deposition rate on the steel wall in LOCOV2 may be attributed to relatively high humidity, a phenomenon warranting further study. Overall, the agreement between simulation and experimental data demonstrates the robust capabilities of COCOSYS in modelling organic iodide formation.

In these experiments, a specific fraction of iodine reacts with volatile organic compounds (VOC). While these species may form directly at the steel surfaces, the underlying mechanisms remain unidentified. Additionally, mass balances are often incomplete across various tests. COCOSYS simulations indicate this may be due to the trapping of iodine species on the EPICUR vessel walls or within the external piping. To further clarify the generation processes of organic and molecular iodine, additional measurement data on the coupon and steel structure surfaces are required.

COCOSYS simulation of CsI decomposition under irradiation and organic iodide formation

ERMSAR 2026, Madrid, **Chuanhe Lu**, Holger Nowack 20.05.2026

Contents

- New CsI decomposition and organic iodide formation model
- Simulation model set-up
- Simulation results
- Summary

Key factors for CsI decomposition

Experimental results (EPICUR AER-CsI, ESTER-EPICUR organic iodides experiments):

- **CsI concentration on the coupon**
- **Dose rate**
- Temperature
- Relative humidity
- Nature of the coupon

Updated AFP2 module in AC²-COCOSYS: aerosols, fission products and iodine chemistry

New CsI decomposition mechanism

- Simplified CsI decomposition process: no sensitive fraction

$$2CsI(dep) + 2H_2O(g) \xrightarrow{\gamma} I_2(g) + 2CsOH(dep) + 2H^+$$

$$CsI(dep) + \frac{1}{2}H_2O(g) + \frac{x+0.5}{3}O_3 \xrightarrow{\gamma,T} CsOH(dep) + IO_x(g)$$

- Delayed CsI decomposition (new terms are introduced into the reaction mechanism)

$$\frac{dH}{dt} = m_{CsI}D_{gas} - Hf_{rec} - \frac{\dot{r}}{m_{CsI}}H$$

$$\frac{d[CsI]}{dt} = -k_r^{\gamma}H$$

- New recovery factor:
  - buffers the decomposition rate decreases process

H	Damage term [kg·kGy/h]
m_{CsI}	Available CsI mass [kg]
D_{gas}	Dose rate [kGy/h]
f_{rec}	Recovery factor, which is a function of decomposition rate [1/s]
$\dot{r}$	Reaction rate of CsI [kg/s]
[CsI]	CsI concentration at the coupon surface [kg/ m^2]
k_r^{γ}	Radiolytic reaction coefficient [1/(m^2·kGy)]

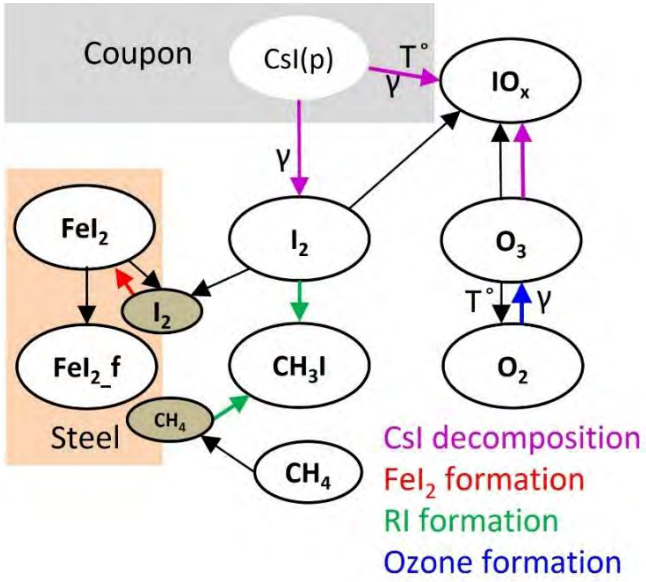
New organic iodide generation model

LOCOV test:

- check if organic iodide also occurs at the surface of steel directly with volatile organic compounds (VOC)

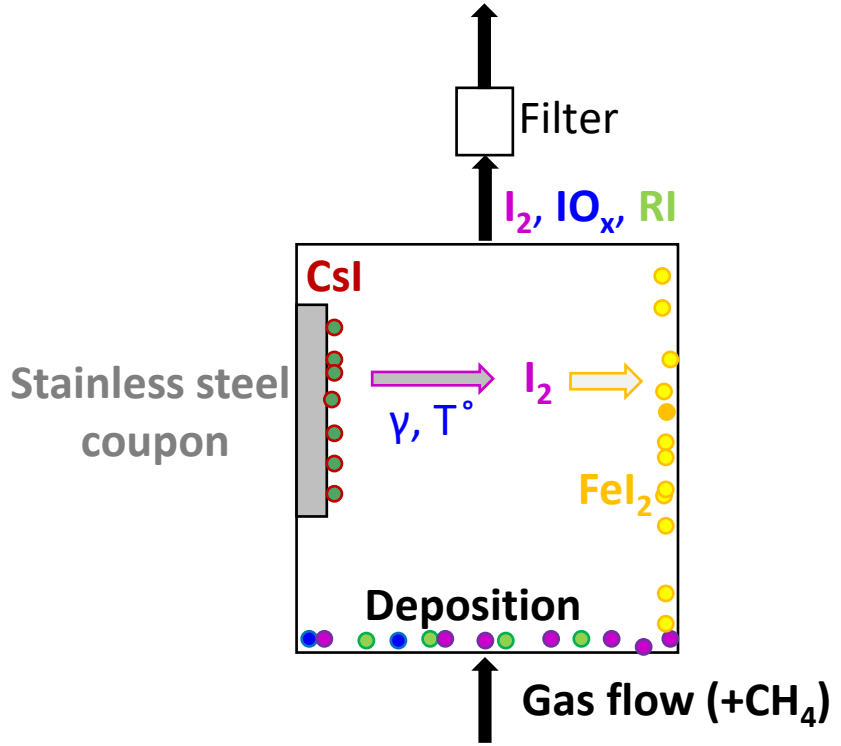
$$I_2(g) + 2R(dep) \rightarrow 2RI(g)$$

- CsI decays under irradiation (γ)
- CsI builds I_2 in the gas phase under γ
- I_2 adsorbs on steel and forms Fe-species
- Methane is also sorbed on the steel surface
- Reaction on the steel surface between CH_4 and **I_2 in the gas phase**
- Production of organic iodine in the gas phase



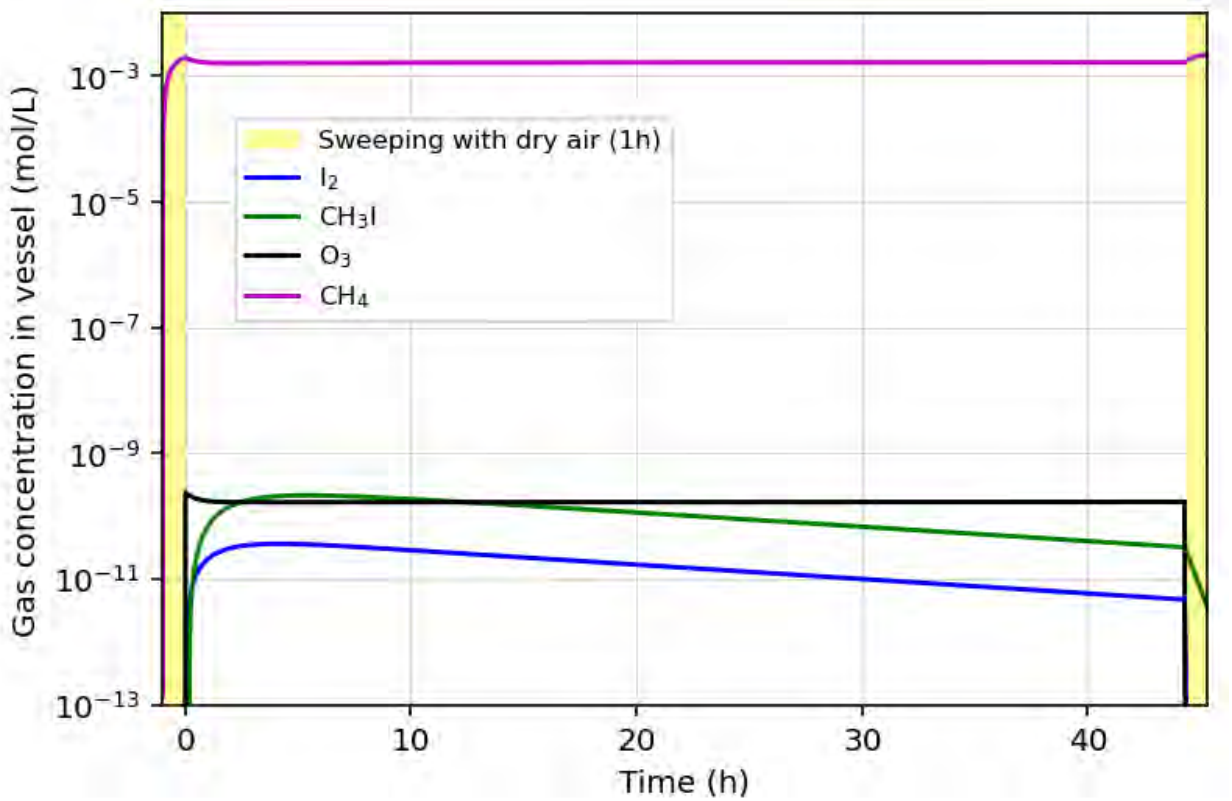
LOCOV tests

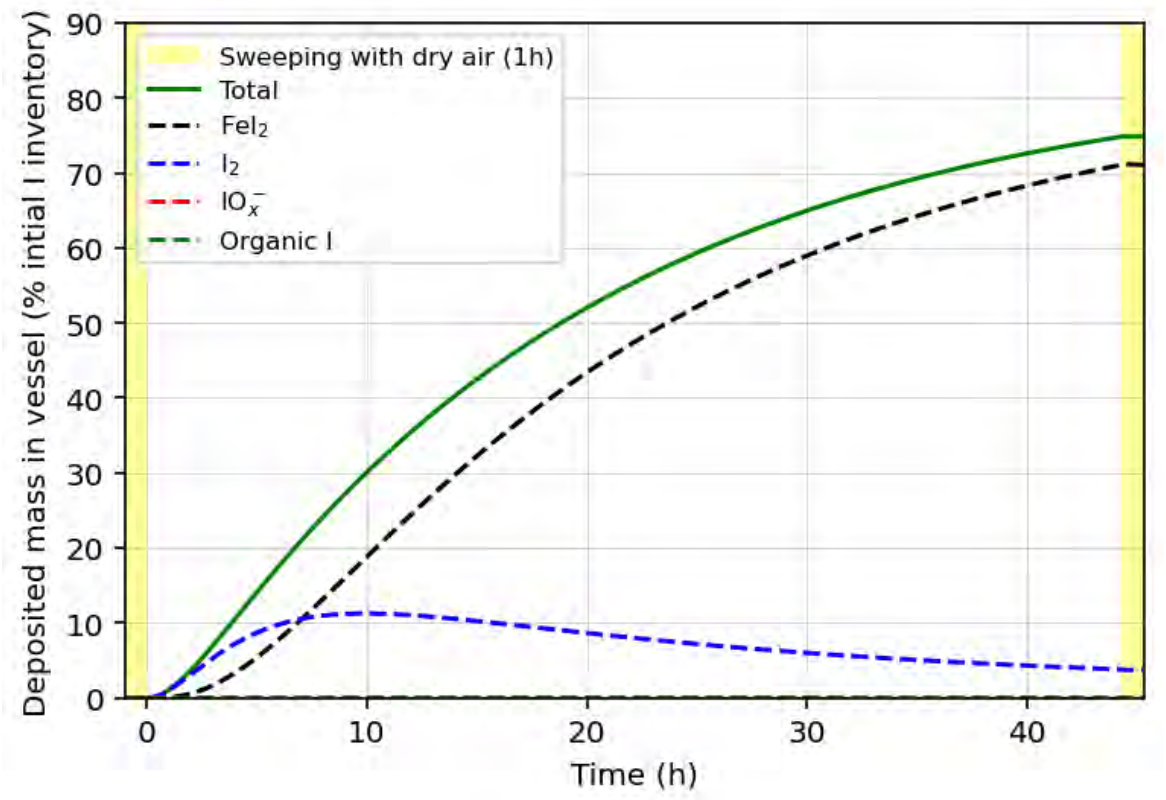
Test	LOCOV	LOCOV-2
Objectives	Surface Effect	
Sample	Stainless steel	Galvanized steel
Aerosol	CsI	CsI
Concentration ([I] in mol/m^2)	1.86×10^{-4}	1.60×10^{-4}
Temperature(°C)	120	
Pressure (bar)	3.5	
Gas	Air(3% O_2) + 2%CH_4 + 50% R.H.	
DR(kGy/h)	1.2	6.9
Pre-irradiation	1h with dry air	1h with dry air then 3 h with Air-50% R.H.



- Calculation with AFP2 module in AC^2-COCOSYS V3.2

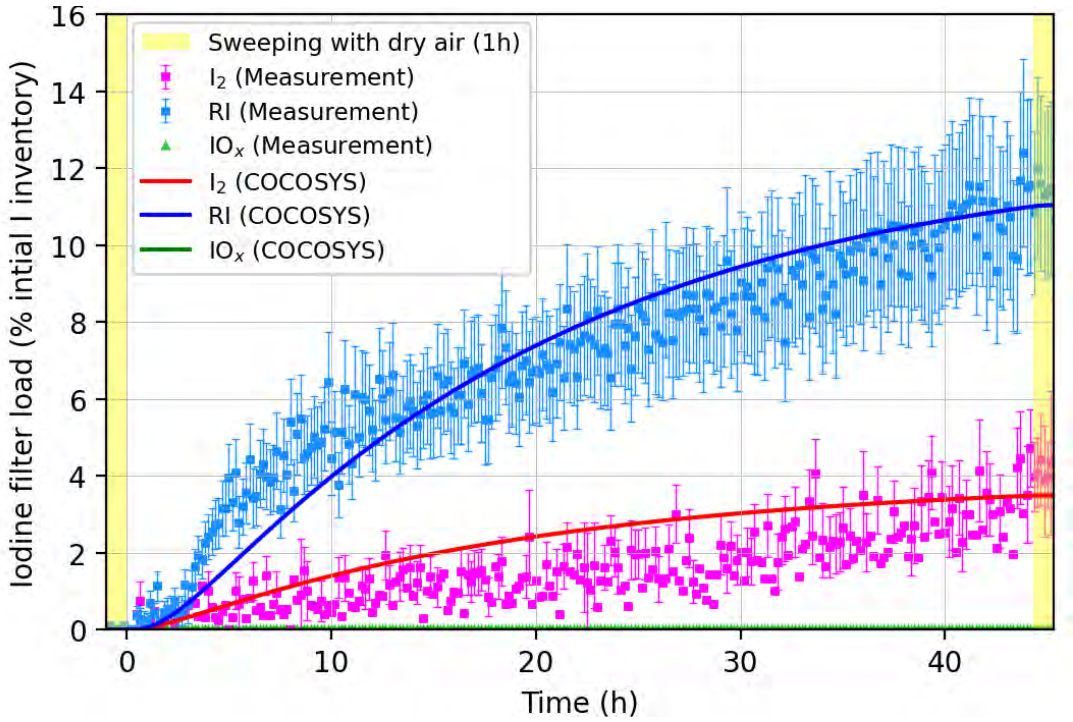
LOCOV simulation results

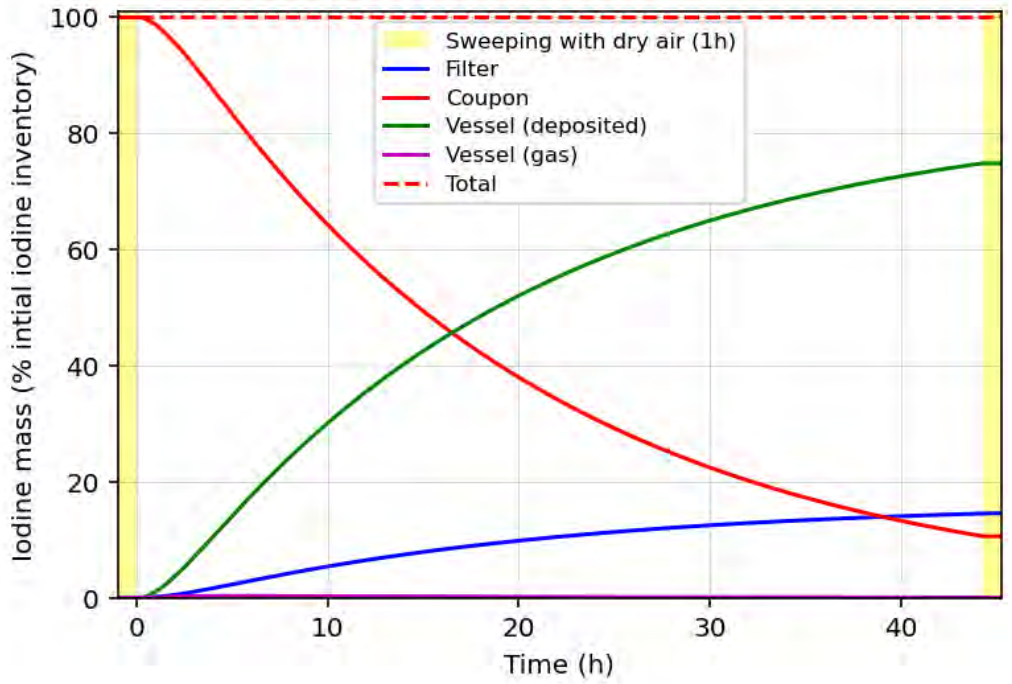




- There is more gas phase organic iodide than gas phase I_2 in the containment
- Most of Iodine mass on the steel surface is in form of FeI_2

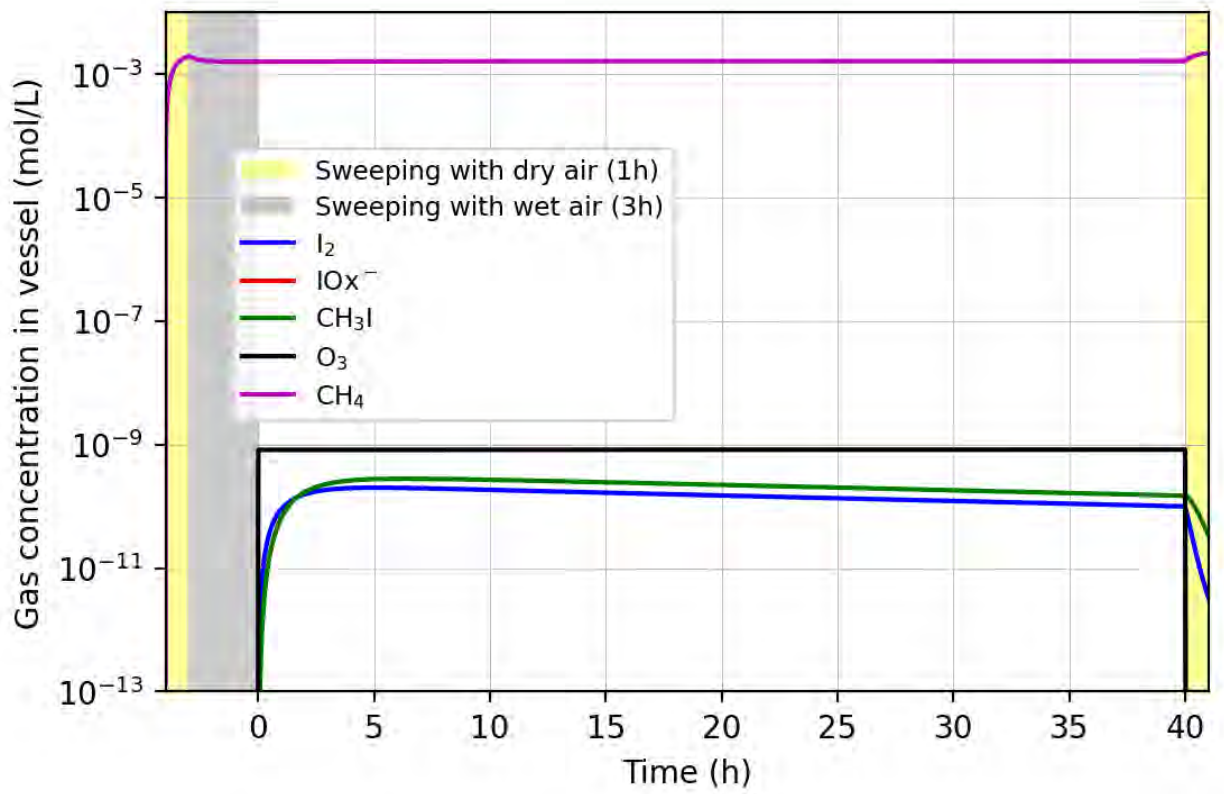
LOCOV simulation results





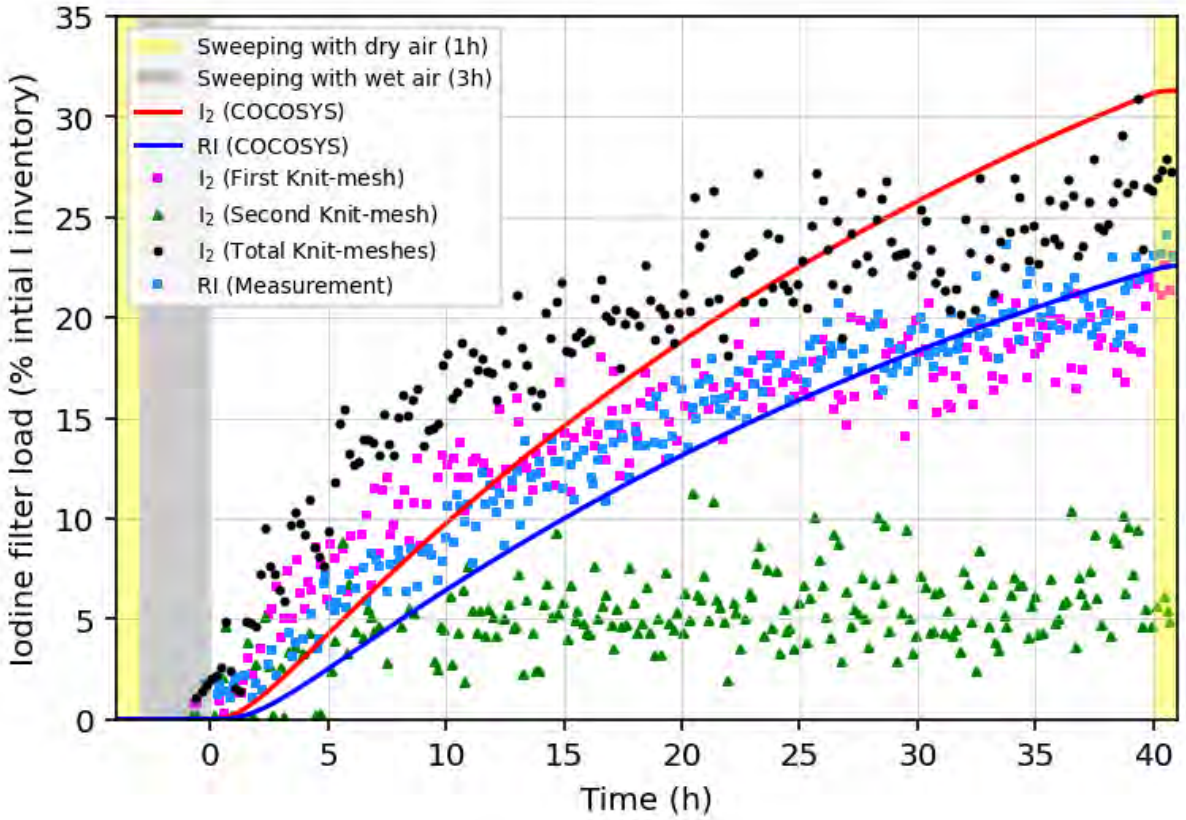
- More organic iodide than molecular iodine in filter
- Most of iodine mass is deposited at the steel surface

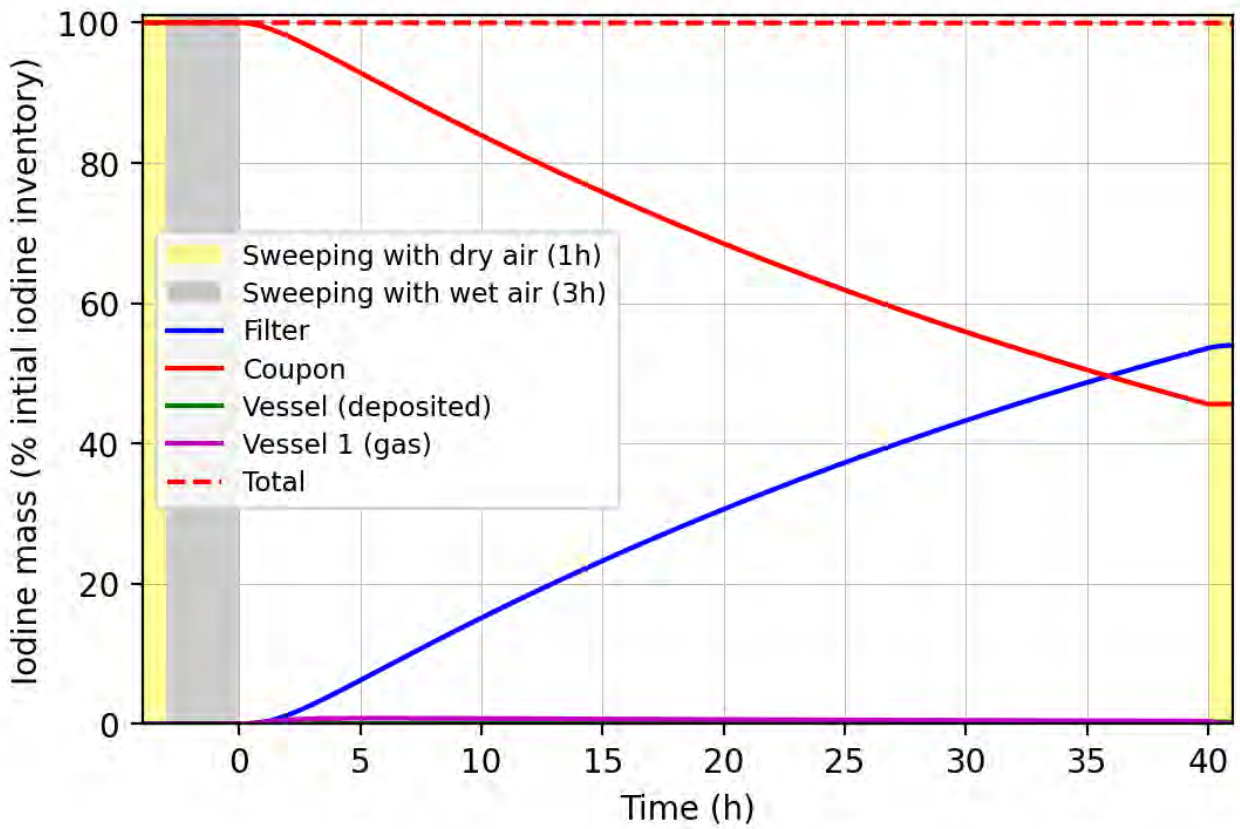
LOCOV2 simulation results



- Higher gas phase I_2 concentration in the containment compared with LOCOV.

LOCOV2 simulation results





- More molecular iodine in filter
- Most of iodine mass is transported into filter
- There is still many iodine mass on the coupon
- Almost no iodine deposited at the steel surface

Conclusion

- Simulation with new CsI decomposition and RI production has similar results as the findings of experiment.
- The new CsI decomposition function and RI generation are properly implemented.
- Controlling process for fast iodine release at the early period of irradiation needs to be discussed.
- Iodine sorption on steel surface requires more detailed study.

ABSTRACT

The European AMHYCO project (Euratom 2019–2020, GA No 945057) investigated the risk of H_2/CO combustion within nuclear power plant containments during the ex-vessel phase of a severe accident (SA), with the objective of supporting the enhancement of the Severe Accident Management Guidelines (SAMGs). In this framework, a detailed model of a generic PWR-KWU containment was created with the 3D code GOTHIC 8.3(QA). For a selected Total Loss of AC Power (TLAP) scenario, more than ten hours in the ex-vessel progression were simulated.. This represents a novel achievement, as the GOTHIC code was not specifically designed for ex-vessel phenomenology. The results proved the capability of the code to reproduce relevant footprints of the accident at a reasonable computational cost using a desktop PC.
A robust and efficient 3D containment model was established in the GOTHIC code, using the Preventive Methodology (as developed by UPM). For the mass & energy input into the containment model, a procedure was created to adapt selected ex-vessel outputs from integral codes such as MELCOR. This was implemented through a Lumped Parameter (LP) cavity control volume in GOTHIC, configured with thermal structures and injection sources, and embedded in the 3D mesh. This allows GOTHIC to handle the large mass and energy releases coming from the reactor vessel at the time of its failure, including heat and combustible gas inputs.
Comparisons with MELCOR calculations of the same TLAP sequence during AMHYCO´s Work Package 4 showed consistent trends in containment temperature and gas concentration evolution across the main regions driving natural circulation. Furthermore, GOTHIC provided enhanced spatial resolution of H_2 stratification and local ex-vessel effects, visualized through post-processing of cell-averaged values. The results support cross-code benchmarking and contribute to strengthening the methodological basis for containment performance and combustion risk assessment under SA conditions.

1. INTRODUCTION

Severe accidents (SAs) in light water reactors can lead to the in-core generation and subsequent in-containment accumulation of combustible gases, primarily hydrogen (H_2) and — during the ex-vessel phase — also carbon monoxide (CO). If these gases are transported to regions of the containment prone to accumulation, they can form flammable clouds whose combustion could threaten containment integrity and the safety systems availability [1]. Therefore, when analyzing SAs, one of the main concerns is to simulate adequately the spatial distribution of those gases. During long SA sequences, the containment atmosphere is shaped by buoyancy-driven circulation, condensation patterns, and geometry-driven recirculation loops that may sustain stratification and localized accumulation pockets [2]. In highly compartmentalized designs, such as the PWR-KWU containment, non-intuitive concentration gradients can develop across elevations and rooms, challenging the well-mixed conditions assumption and making the assessment of combustion risk strongly dependent on spatial resolution [3]. After the Fukushima Daiichi accident, many European utilities and regulators implemented a broad set of hardware upgrades, including the installation of passive autocatalytic recombiners (PARs) and filtered containment venting systems. These, together with updated insights from experiments and modelling, have driven the revision and strengthening of Severe Accident Management Guidelines (SAMGs). In European pressurized water reactors (PWRs), PARs are a key mitigation measure, but their effectiveness depends on the local availability of combustible gases and oxygen (O_2). In the late accident phase, the situation is further complicated by the presence of additional non-condensable gases (NCGs), potential O_2 depletion, and instrumentation limitations, in particular for CO monitoring [4].

The AMHYCO project (Euratom 2019–2020, GA No 945057) specifically targeted the ex-vessel phase, combining experiments, models, and containment simulations to translate academic advances into SAMG-oriented guidance [5]. From the simulation standpoint, AMHYCO provided a shared geometrical database for lumped parameter (LP), 3D, and computational fluid dynamics (CFD) analyses of representative PWR containments (Western, KWU, VVER). The aim was to enable consistent cross-code comparisons and targeted investigations of phenomena that LP approaches may lack due to inherent spatial averaging. This follows in the footsteps of mature methodologies which recommend a hierarchical and systematic approach towards SA phenomenology and H_2 risk studies [6]. Integral/system codes such as MELCOR can simulate the most relevant phenomenology surrounding core degradation and ex-vessel phenomena over many hours [7]. However, the LP approach of these codes allow only limited spatial resolution of the containment atmosphere. Conversely, 3D containment tools can resolve circulation and stratification patterns from the compartment or room scales down to cell-averaged fields [8]. Yet, some of these codes, e.g. GOTHIC, do not mechanistically compute ex-vessel melt evolution and must rely on externally prescribed source terms for molten corium-concrete interaction (MCCI) related mass and energy (M&E) releases. This creates a key methodological challenge: ensuring that long-term ex-vessel source terms extracted from an integral code are translated into numerically robust, physically coherent, and reproducible boundary conditions (BCs) for 3D containment simulations — while ensuring mass and energy conservation, avoiding artificial discontinuities [9].

This work focuses on the PWR-KWU case and addresses one specific gap: extending a detailed 3D GOTHIC 8.3(QA) containment model beyond the in-vessel phase and into the ex-vessel progression of a SA sequence, at computational costs acceptable when using a desktop PC. The paper is structured as follows. Section 2 summarizes the 3D containment model creation under a common database. Section 3 presents the hybrid cavity concept and a proposed MELCOR-to-GOTHIC BC translation workflow. Section 4 discusses the main results of an unmitigated Total Loss of AC Power with late depressurization (TLAP) sequence simulated with GOTHIC 8.3(QA). Results are compared with MELCOR calculations that used the same containment database and in/ex-vessel BCs. Section 5 closes with conclusions and recommendations for cross-code benchmarking and for extended 3D containment analyses supporting late-phase SAMG assessment.

2. PWR-KWU CONTAINMENT DATABASE, MELCOR AND GOTHIC 3D MODELS

2.1. From the Plant Layouts to a Generic Containment Database

The modelled PWR-KWU containment corresponds to a 1300-MWe KONVOI-type plant. The reactor building consists of a spherical steel containment (UJA) surrounded by a reinforced-concrete airplane-crash shell (UJB). The UJA layout is highly compartmentalized, separating accessible rooms (during power operation) from equipment rooms hosting the reactor coolant system, and with additional internal structures (e.g., shrapnel protection and large steel components such as walking grids and the polar crane). The CAD model was built from containment layouts that were publicly available [10]. The main walls, floors, and internal partitions were reconstructed by a bottom-to-top extrusion process level by level, producing a geometrically traceable 3D "generic containment" representation. As several geometric details were incomplete, the CAD reconstruction followed an iterative refinement process, including internal reviews by partners with prior modelling experience on the PWR-KWU design to confirm key architectural features (e.g., overlaps, missing openings, or unrealistic compartment separations). Once the 3D CAD model captured the relevant compartmentalization and major internal connections, the information needed for containment simulations was extracted into a generic database provided as structured tables [11] (Table I gathers the main structural characteristics of the containment). The main objective was to formalize the containment subdivision and connectivity in a way that can be shared by LP and 3D users, while maximizing code-to-code comparability under a shared geometric basis. In turn, spaces expected to behave similarly under accident conditions were grouped into regions, which are defined by their free volume and total heat transfer surfaces (namely, concrete and steel). For UJA, ten regions were defined, and an additional one for the UJB to capture dominant long-term heat losses.

2.2. PWR-KWU MELCOR Model Overview

The PWR-KWU MELCOR (LP) containment model was developed by FRAMATOME GmbH following the AMHYCO generic containment database. The UJA regions are depicted in Figure 1 (except the spent fuel pool, SFP) along with 19 of the 24 junctions used to connect the spaces. To ensure internal consistency with MELCOR modelling practices while preserving the global inventory of the generic database, minor practical adjustments were introduced (e.g., selected junction loss characterization and limited geometric/elevation refinements affecting the lumped heat structures). Additional flow resistances were applied in some inter-compartment connections to avoid unrealistically weak circulation and over-mixing through nominally "open" pathways. Overall, the objective of this LP model was a transparent mapping between where M&E are released and how they are transported across the main containment regions, later used as a baseline for comparison against the 3D GOTHIC results.

2.3. PWR-KWU 3D GOTHIC Model Overview

GOTHIC is an integrated, coarse-grid CFD, multi-physics code that solves the conservation equations of mass, momentum and energy for multi-component, multi-phase flows and can be applied using lumped-parameter (LP), 3D, or hybrid LP–3D domains [12]. Geometry is represented on a user-defined Cartesian mesh through a porous-media approach, where volumetric and surface porosities are assigned to cells and faces to model blockages and hydraulic separations. Heat transfer to structures is handled through nodalized thermal conductors, which solve 1D heat diffusion in solids and apply user-selected heat-transfer correlations at fluid interfaces; for condensation in the presence of NCGs, the diffusion layer model is typically used. LP and 3D models share the same governing equations but differ in spatial resolution and numerical treatment. LP volumes are fully mixed with average state variables and momentum conservation only across 1D junctions, with closure correlations applied globally. In 3D, the domain is discretized into

structured cells where local balances are solved, enabling gradients, flow directionality and spatially resolved application of closure relations. In this work, 3D turbulence effects are represented using the standard k–ε model. GOTHIC 8.3(QA) [13] was employed, consistent with AMHYCO activities.

The PWR-KWU GOTHIC 3D containment model was developed by translating the AMHYCO generic containment database into a numerically robust 3D representation [14]. The model has ~25200 active cells (from a total of ~60000, adding up the blocked cells) and a mesh size range of 1-8 m^3. The overarching aim was not to reproduce the CAD geometry in a body-fitted sense, but to preserve the compartment free volumes, hydraulic separation paths, and main structure inventories. To achieve this at practical computational cost, the model construction follows the Preventive Methodology, developed at Universidad Politécnica de Madrid (UPM), which aims to avoid mesh-induced solver pathologies and to enable long transient runs with stable timesteps at practical resolution [15]. As sketched in Figure 2, the detailed CAD is simplified with the target homogeneous Cartesian mesh in mind: compartments are shaped to remain hydraulically independent while avoiding cell configurations prone to solver failures (e.g., low-porosity or obstructed cells). The simplified geometry is then transferred to GOTHIC through an automated CAD-to-GOTHIC pipeline, where coordinates are transferred to GOTHIC via dedicated Python scripts, minimizing manual editing and improving reproducibility. Beyond the standard workflow, the PWR-KWU implementation incorporates refinements, facilitating long SA calculations.

Table I. PWR-KWU containment parameters

Structural Parameters	
UJA containment free volume (m^3)	73945
UJB containment free volume (m^3)	49255
Steel shell diameter (m)	56.00
Steel shell thickness (mm)	38.00
Shrapnel cylinder outer diameter (m); thickness	41.20; 0.80
Lower cup average concrete thickness (m)	2.90
Concrete thickness: cavity floor to foundations (m)	7.30
Heat Structures (UJA+UJB)	
Area of concrete surfaces exposed to the fluid (m^2)	66571
Volume of concrete structures (m^3)	54277
Area of steel surfaces exposed to the fluid (m^2)	40030

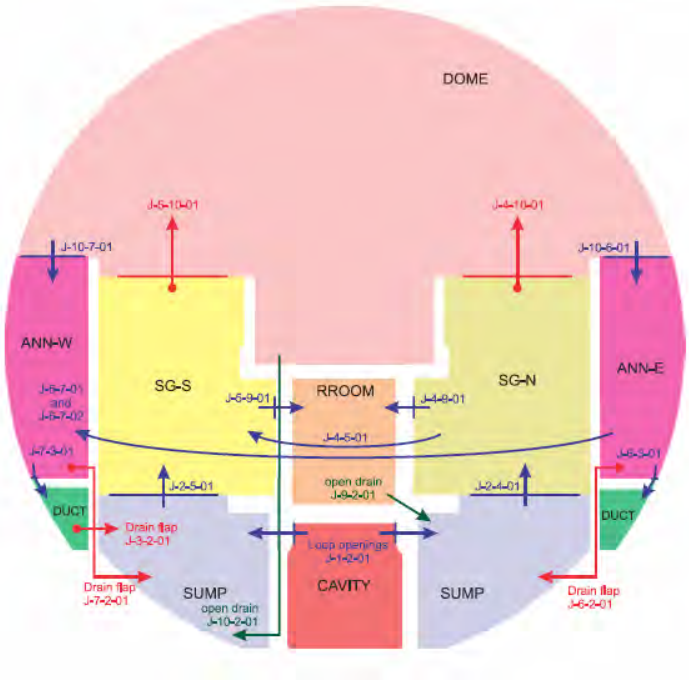

Figure 1. PWR-KWU containment UJA LP regions.

First, the containment is intentionally built as a hybrid LP–3D representation, with UJB, the SFP and the reactor cavity represented as LP CVs, while the open gas spaces governing natural circulation and stratification are resolved in 3D with locally adapted mesh resolutions. Second, the model is pre-configured for localized high M&E releases by performing a study of structures before geometry simplification, so that locations likely subjected to high-velocity jets can be as unblocked as possible. This should improve stability

and reduce solver failures in demanding phases. Third, specific attention is paid to curved, porosity-generating structures characteristic of the PWR-KWU (e.g., dome/liner and missile shield). Early mesh subdivision choices and local geometry adaptations are supported by automated parsing of solver-error outputs to guide iterative CAD corrections. Then, the number of persistent low-porosity cells is reduced, a process that otherwise would require time-consuming cell-by-cell correction. Moreover, heat-transfer realism is maintained by selecting thermal conduction settings consistent with the chosen mesh; in particular, thresholds are defined so that wall-to-fluid heat transfer is properly partitioned between vapor and liquid as pool heights evolve during the transient. Finally, the agreement of integrated free volumes, flow areas and structure surfaces was checked to be acceptable (below maximum 3% relative differences). Thus, subsequent LP–3D differences can be interpreted as code-induced, either from different models, e.g., convective heat transfer, or directly due to the higher spatially resolution of the 3D model.

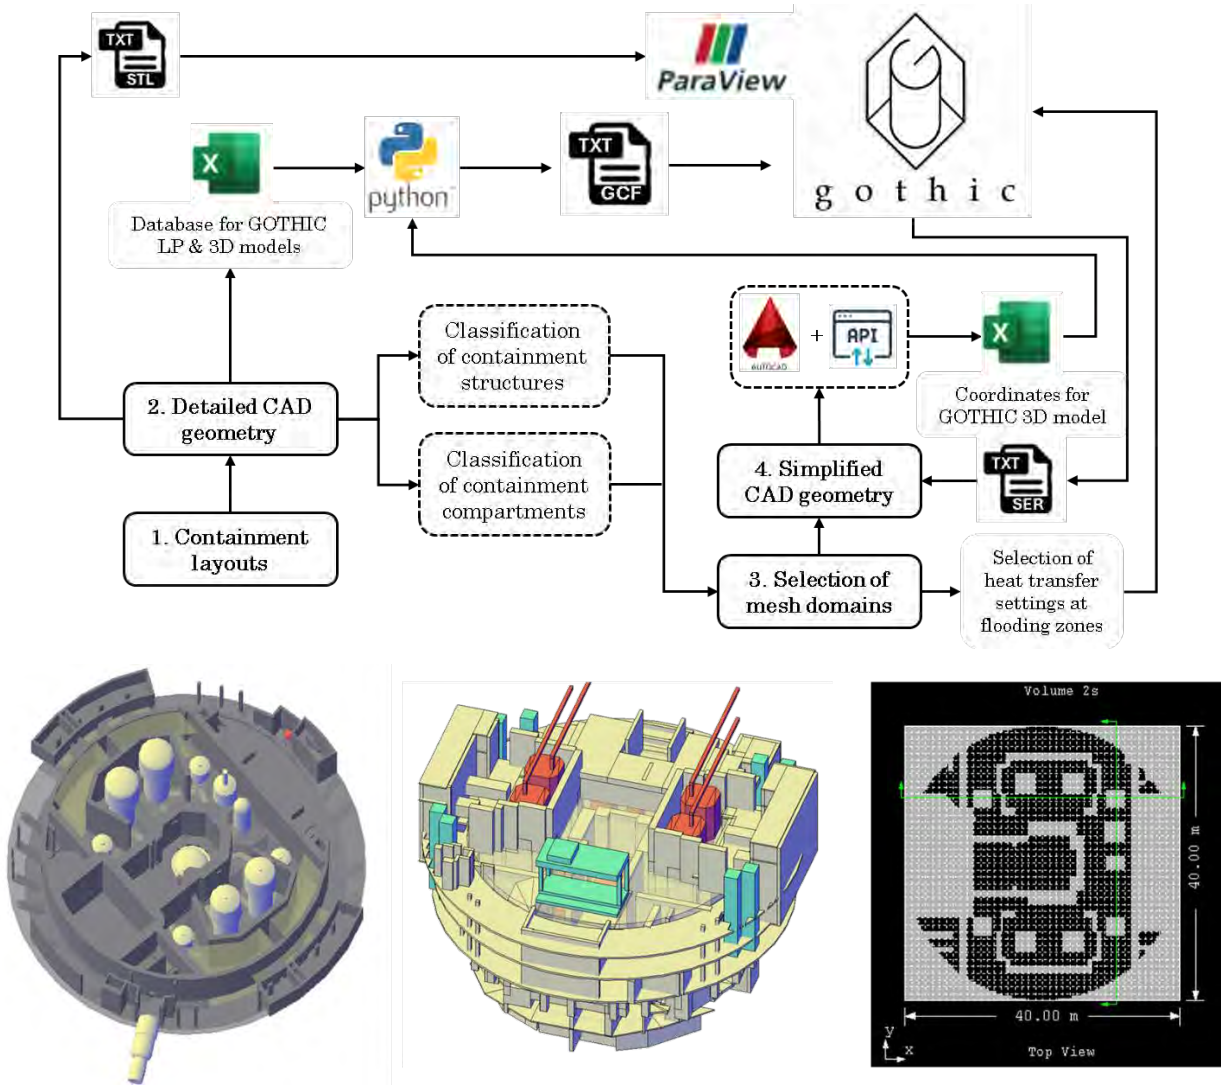

Figure 2. Scheme of the pre-processing steps and tools of the Preventive Methodology (up); detailed CAD, simplified adaptation, and GOTHIC model (bottom, from left to right).

3. METHODOLOGY: EXTENDING GOTHIC TO EX-VESSEL SIMULATIONS

GOTHIC is well-suited to resolve containment thermal-hydraulics and gas transport at LP and 3D scales, but it is not a mechanistic ex-vessel code: it does not explicitly simulate corium thermochemistry, MCCI kinetics, melt pool evolution, fuel-coolant interaction, or the detailed cavity flooding/quenching processes that govern late-phase M&E releases after RPV failure. However, for containment-scale purposes, the key requirement is not resolving the corium physics itself but reproducing the impact onto the containment, i.e., the time-dependent injection of steam, NCGs and the associated thermal loads that drive pressurization, circulation and stratification. To bridge this gap, ex-vessel source terms predicted by MELCOR are imposed in GOTHIC through an embedded LP cavity control volume (CV) coupled to a mesh-optimized 3D containment domain. The cavity CV acts as a numerically robust interface that absorbs demanding ex-vessel M&E releases and transfers their effects to the surrounding in 3D modelled containment through controlled junctions, enabling a single GOTHIC setup to cover the in-vessel phase and several hours of ex-vessel accident progression.

This work formalizes a phenomenon-oriented selection of MELCOR ex-vessel outputs that must be preserved, and a traceable output-to-input translation into GOTHIC. As summarized in Figure 3, the procedure extracts a limited set of time histories from MELCOR cavity/CVH results that define the source term driving containment response: (i) cavity pressure and the thermodynamic state and composition of released gases (steam and NCGs, including H_2/CO), (ii) component mass release rates, and (iii) thermal power terms associated with melt-surface heat transfer to the cavity atmosphere and structures, including heat losses through cavity walls. Dry-cavity and flooded-cavity configurations are represented consistently; in the flooded case, once biological shield breach enables sump-to-cavity water ingress, MCCI gases are cooled, and additional steam generation is reflected in the source histories. These series are then mapped to GOTHIC flow-type BCs (mass flow with composition and temperature/enthalpy) applied to the cavity LP CV. Built-in heater components are used to inject energy into the vapor or liquid phase. Also, heat transfer coefficients are imposed on the corresponding GOTHIC thermal conductors to reproduce evolving convective regimes in the cavity. The geometric and hydraulic descriptors of the connections between cavity and containment (elevation, area, hydraulic diameter, and loss coefficients) are taken from the generic database, ensuring physical consistency of the interfaces rather than treating them as “outputs”. Finally, because integral-code outputs may contain sharp transients and non-uniform sampling that would enforce restrictive timesteps in GOTHIC, time series are pre-processed using conservative smoothing/resampling (e.g., moving averages or piecewise interpolation) under the constraint that time-integrated injected mass (per species) and injected energy/enthalpy are preserved.

Within this framework, the cavity LP CV functions as a composite boundary-condition-generator embedded in the subdivided containment domain: it does not attempt to model the cavity mechanistically, but it imposes their containment-scale consequences at physically consistent temperatures and gas compositions and transfers them to the 3D regions through controlled junctions. The cavity-as-interface concept was verified through MELCOR–GOTHIC test cases that exercise the main ex-vessel loading modes and the associated mapping logic (Figure 4), where GOTHIC reproduces the reference evolution of cavity CVs pressure and gas phase temperature over a 28-hour dry-cavity transient with good agreement.

4. APPLICATION CASE AND BENCHMARK COMPARISON

The TLAP sequence considered in this paper originates from AMHYCO WP2, where bounding accident scenarios in which the combustible gases cause a risk for containment integrity were simulated with integral codes [16]. The reference accident progression was first produced with a detailed MELCOR model to define a consistent timeline and to provide the in-vessel and ex-vessel release histories used by project partners.

Thus, in AMHYCO WP4, the TLAP was simulated using the shared generic containment database. This paper reports on UPM's GOTHIC 8.3(QA) calculations and compares them to the corresponding MELCOR v2.2.15254 calculation performed by FRAMATOME GmbH, under the cross-code benchmark database shared during the project. GOTHIC 3D output was averaged per region, using UPM´s ProTON code, considering an equivalent free volume by extracting coherent coordinates from the mesh and ensuring comparability. The focus of the results is put on temperatures and gas concentrations across the key circulation regions outside the cavity, which is treated as an interface to impose ex-vessel source terms rather than as a target region for benchmarking. The case was simulated in 15 days CPU time, with only 2 core CPUs (i7-9700@3.0 GHz) and a maximum time step of 0.04 s, maintaining solver stability.

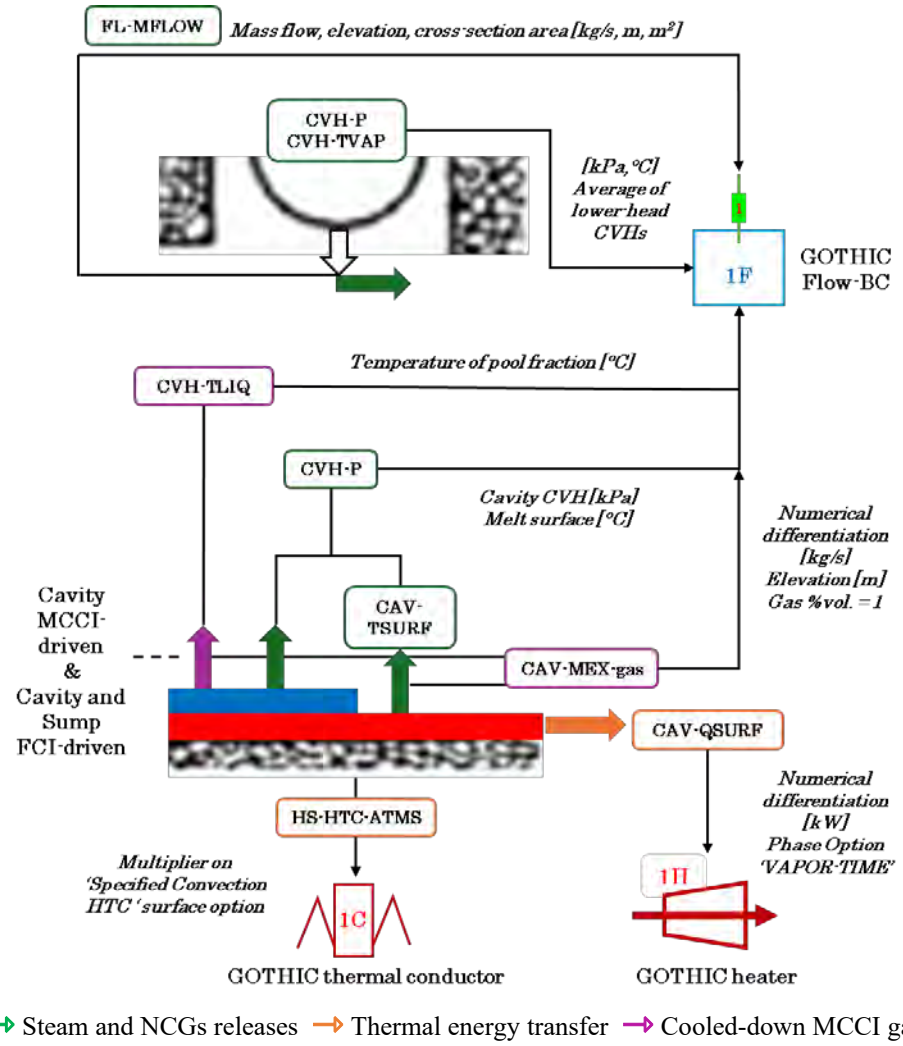

Figure 3. Conceptual mapping of MELCOR ex-vessel outputs into GOTHIC inputs.

Regarding the TLAP scenario, a complete loss of AC power is assumed. Following reactor trip, decay heat is initially removed by the steam generators (SG), which discharge steam to the environment until SG dryout (≈1 h). Thereafter, primary pressure increases and steam is released to containment through pressurizer safety valves, while the remaining primary inventory keeps the core covered for roughly one additional hour. As the core uncovers, temperatures rise and a depressurization action is initiated at 3 h 11 min (650°C signal at 2 h 41 min plus 30 min delay), producing a short, intense release of steam and H_2 to the containment. Accumulators then inject and delay degradation, but core damage progresses and the reactor pressure vessel fails at 9 h 44 min, marking the start of the ex-vessel phase. Corium relocation to the cavity

initiates MCCI and sustained M&E releases, and at 14 h 49 min biological shield penetration leads to sump-to-cavity water ingress, partial melt submergence, and melt relocation towards the sump. The released gases mass flows and temperature histories for twenty hours of the accident can be found in [9], [14].

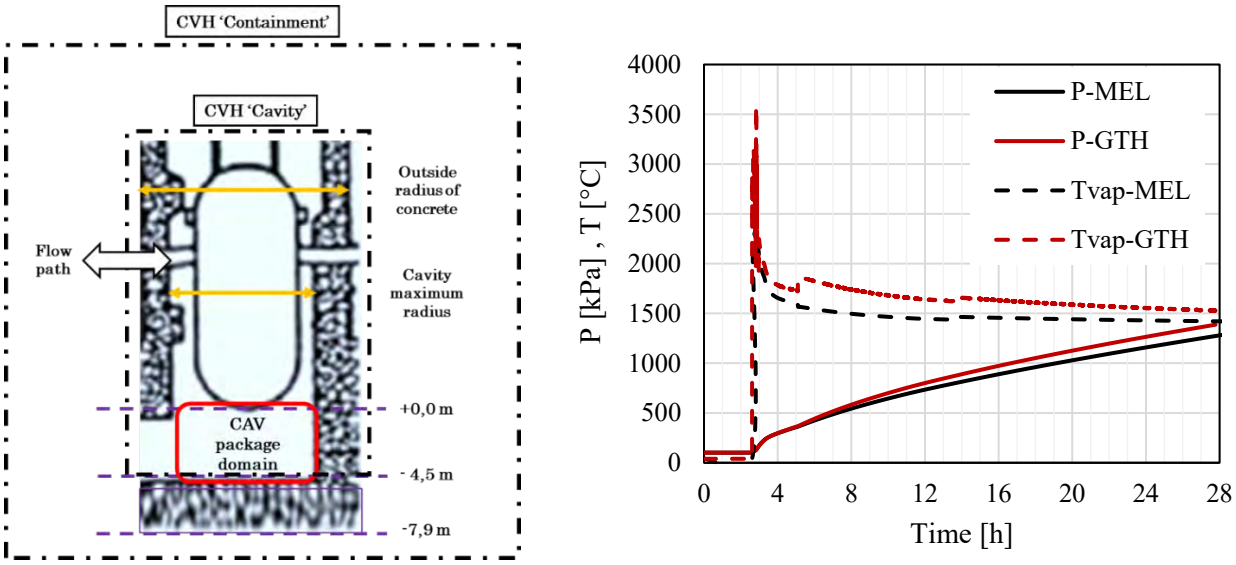

Figure 4. Conceptual representation of MELCOR test case model (left), comparison of cavity CV pressure and temperature during a 28-hour dry cavity scenario (flooded scenario not shown here).

4.1 Comparison of MELCOR vs GOTHIC 3D Global Gas Distribution

The pressure, temperature and volumetric fractions are compared in the generic-database regions that govern containment-scale circulation and accumulation, namely SUMP, SG-N, DUCT and DOME (Figure 5 and Figure 6). For the in-vessel phase (0-9 h), both codes reproduce the expected containment response driven by steam releases and the primary depressurization sequence (detailed differences are discussed in [9]). The main pressure peak occurs at around 4 h, with GOTHIC predicting a systematically higher value (maximum deviation reaches ~+0.61 bar). This offset should not be interpreted as a direct consequence of different gas homogeneity alone. Rather, it is more plausibly linked to differences in the treatment of condensation, wall heat transfer, and effective heat-storage capacity between the MELCOR and GOTHIC models, which control the net steam removal from the containment atmosphere. The use of a shared generic database ensures comparable geometry and source-term basis, but not identical thermal-hydraulic closure behavior or structure-to-fluid heat exchange in both codes. Regional gas temperatures show consistent trends, while differences in steam redistribution are observed across the circulation path: compared to GOTHIC, MELCOR tends to predict stronger steam removal in the SG-N, DUCT and DOME regions, and higher steam retention in the SUMP. In addition, MELCOR predicts a 50% higher H_2 peak in the SG-N region at the time of release from the primary circuit. In the ex-vessel phase (9-20 h), the bulk containment regions remain steam-dominated, and both codes capture the long-term evolution of H_2 and CO across the main circulation pathway. Overall, the benchmark indicates consistent global trends in the key accumulation regions. However, GOTHIC maintains a higher pressurization level during the whole phase. A plausible contributor is the different net steam removal and redistribution driven by condensation/heat-transfer treatment between codes. Regarding gas composition and temperature, differences are most evident in the DUCT, where GOTHIC systematically predicts a warmer and more combustible-gas-enriched corridor than

MELCOR. In contrast, the DOME shows closer agreement and smoother trends, with GOTHIC typically slightly leaner in combustible gases and slightly lower in steam. Finally, UJB temperatures show close agreement between MELCOR and GOTHIC, supporting that the global heat-loss pathway at containment scale is consistently represented.

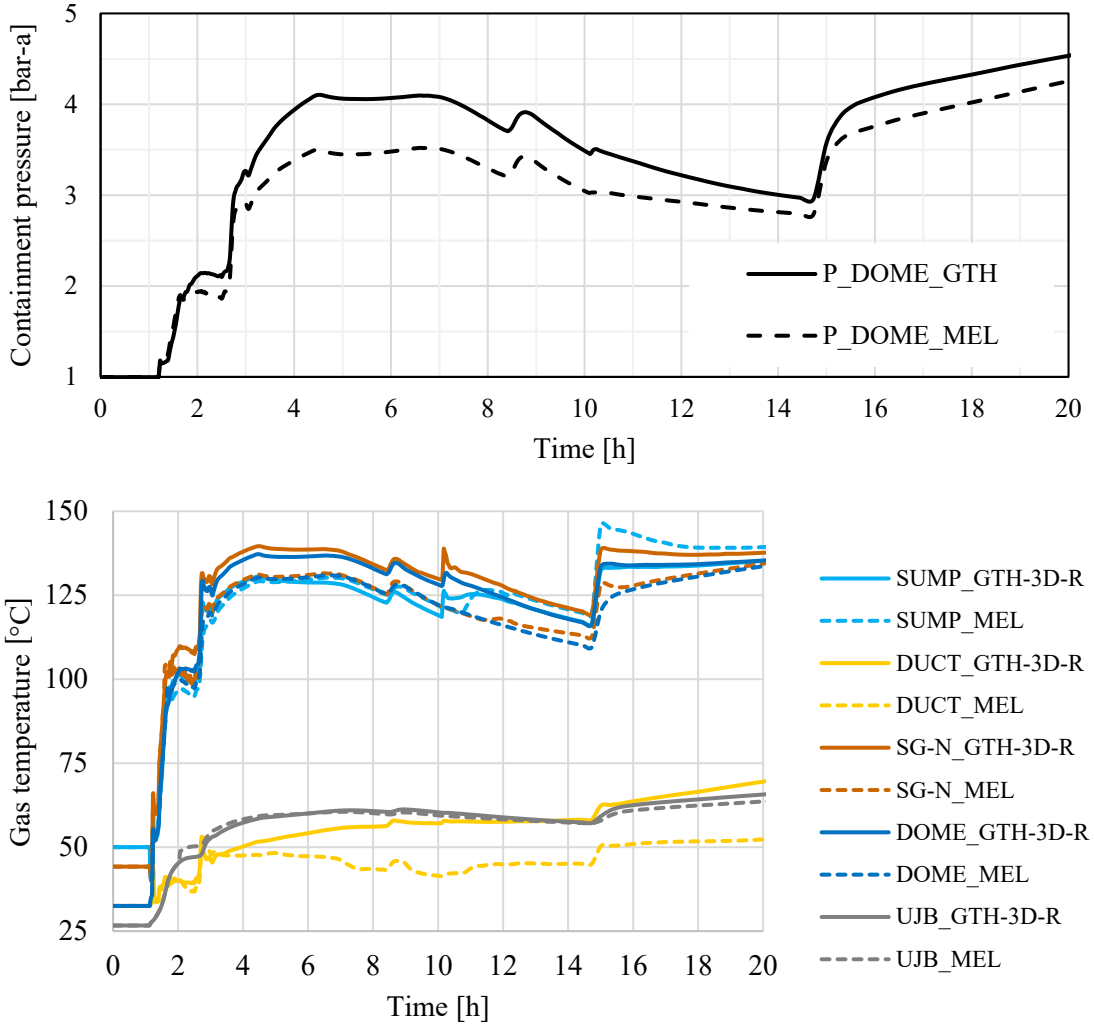

Figure 5. TLAP gas phase pressure (up) and temperature (bottom).

4.2 3D hydrogen stratification footprints along the TLAP progression

The regional differences motivate a closer look at the 3D spatial resolution to interpret circulation and stratification beyond LP trends. Figure 7 illustrates how the GOTHIC 3D model resolves containment-scale H_2 distribution by capturing the imprint of phenomena such as buoyancy-driven transport and enrichment of light gases driven by steam condensation and limited mixing. At 4.5 h, H_2 appears highly non-uniform. Enriched layers develop in the lower sump level, indicating that condensation is substantially higher in that region due to the accumulated water pool. As seen in Figure 6, MELCOR did not capture that accumulation and yielded lower concentration values. Also, GOTHIC predicts H_2 gradients in the operational floor due to perhaps an inverse stratification pattern due to condensation at the DOME liner. This indicates that the early H_2 release has limited immediate homogenization across the full containment height. At 14.5 h, the picture changes qualitatively. The overall H_2 level is higher and the containment exhibits a large-scale stratified

structure, with smoother gradients across wide volumes. This reflects the combined effect of sustained ex-vessel gas generation and thermal driving, which strengthens natural circulation loops and progressively fills larger regions, while still preserving vertical gradients. Also, structures are hotter and condensation is less present. However, for instance MELCOR did not capture the same accumulation in the DUCT region, being slightly higher in GOTHIC. Finally, these 3D fields translate directly into combustion-risk relevance by revealing stratified layers and local pockets where flammability conditions may exist despite possible benign region-averaged values.

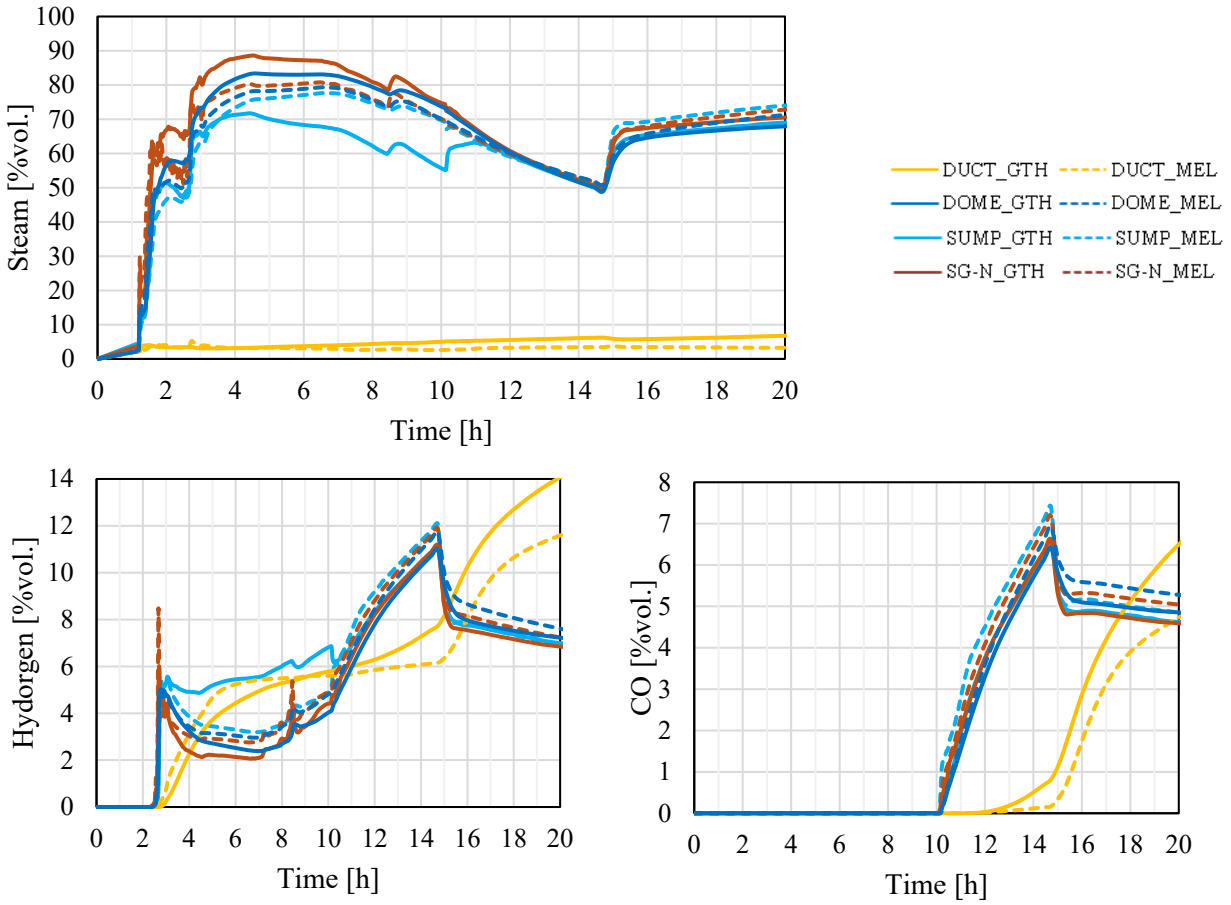

Figure 6. TLAP gas components concentrations: steam (up), H_2 and CO (bottom).

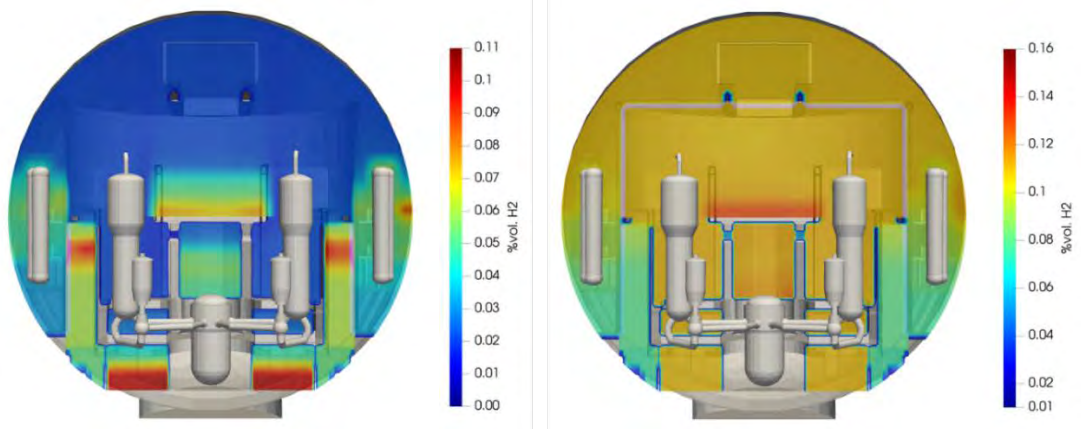

Figure 7. GOTHIC 3D hydrogen concentration at 4.5 h (left) and 14.5 h (right).

5. CONCLUSIONS AND OUTLOOK

This paper shows that GOTHIC 8.3(QA) can be extended to late-phase severe accident containment simulations by introducing relevant ex-vessel releases through a reproducible MELCOR-to-GOTHIC boundary condition translation. This is achieved by using an embedded GOTHIC LP cavity acting as an interface to the GOTHIC 3D domain. Using the AMHYCO database, GOTHIC 3D and MELCOR LP results can display coherent trends, showing consistent global pressure and temperature trends, and the evolution of steam, H_2 and CO compositions in the main circulation regions. This has been achieved with moderate systematic pressure differences that could be explained due to the different heat/mass-transfer and mixing treatments between the codes, which are affected by the inherently different level of spatial resolution.

Beyond trend benchmarking, the 3D calculation provided an added value by resolving stratification and localized accumulation footprints (e.g., the distinct H_2 layering patterns between the in-vessel and ex-vessel phases) that can be masked by the LP well-mixed control volume assumptions. The approach has clear modelling limits. The ex-vessel phase is condensed into an LP cavity, so melt pool hydrodynamics, detailed flooding/quenching and local condensation phenomena are not resolved explicitly, and the 3D containment response depends on the fidelity of the imposed source terms. Also, as the ex-vessel phase is driven by prescribed source terms, the largest modelling sensitivity is expected to be confined to the short interval immediately after RPV failure (order of minutes to tens of minutes), while longer-term containment trends remain robust; an exception would be highly energetic short-time phenomena (e.g., steam explosions and fuel-coolant interactions), which are outside the scope of the present approach.

Nonetheless, the workflow is largely transferable: the database-driven LP/3D consistency, the preventive CAD-to-mesh strategy, the automated geometry import, and the cavity-interface concept can be applied to other containments and sequences provided that the plant-specific subdivision and flow paths are defined coherently. The next steps include sensitivity studies (mesh strategy, junction losses, heat-transfer options and source-term preprocessing), extension to additional scenarios and mitigation configurations, and — where relevant — coupling or upgrading combustible-gas treatment (including consistent H_2/CO mitigation/combustion capabilities) to bridge the gap of SAMG monitoring limitations.

4. Extending GOTHIC to ex-vessel simulations

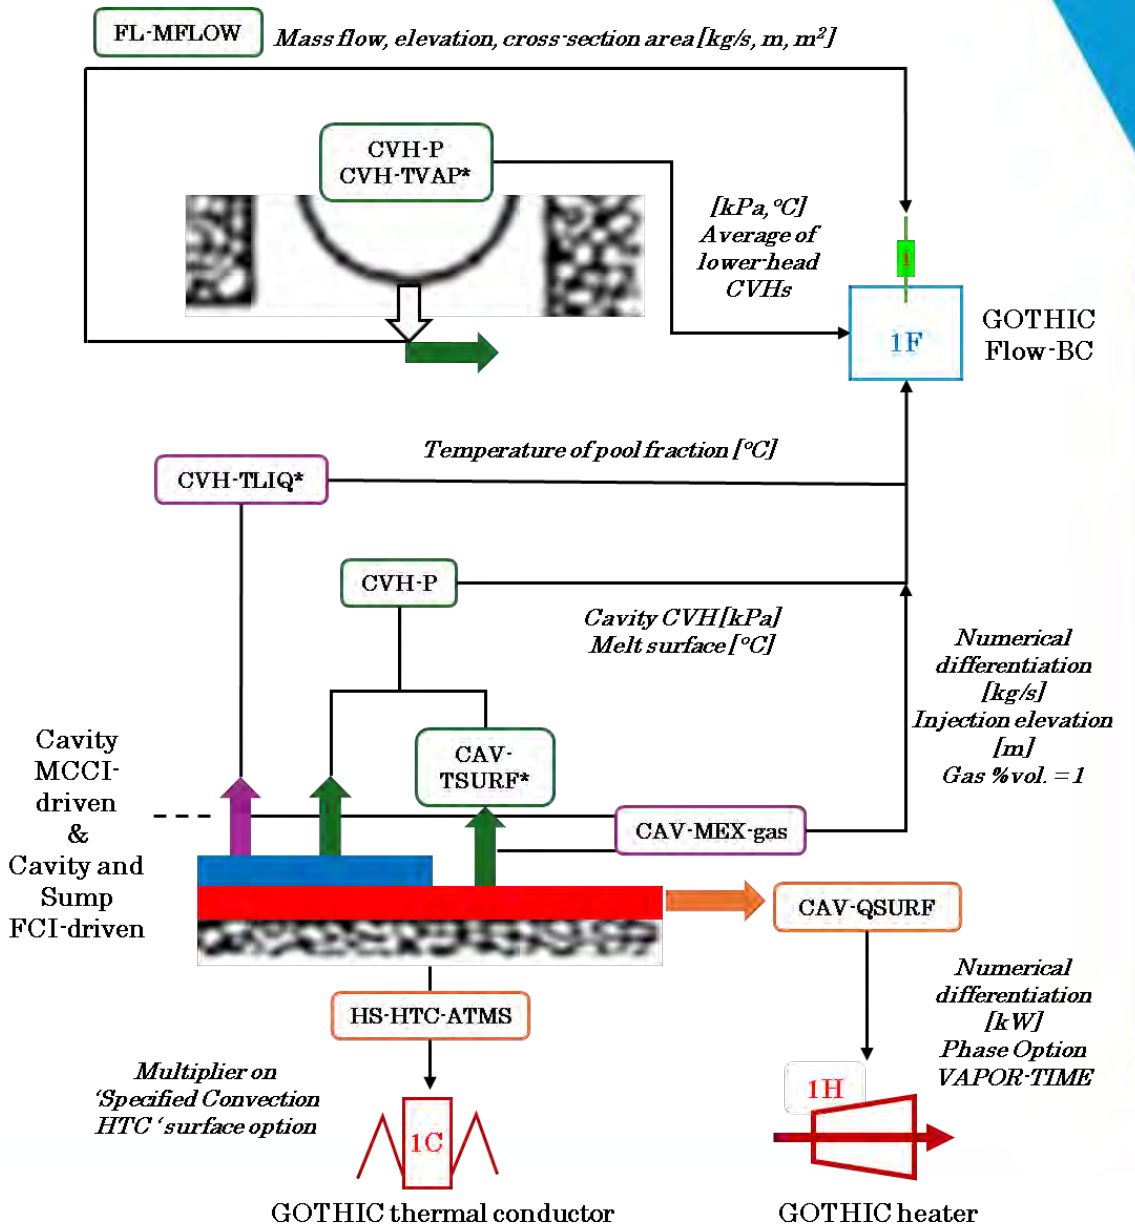
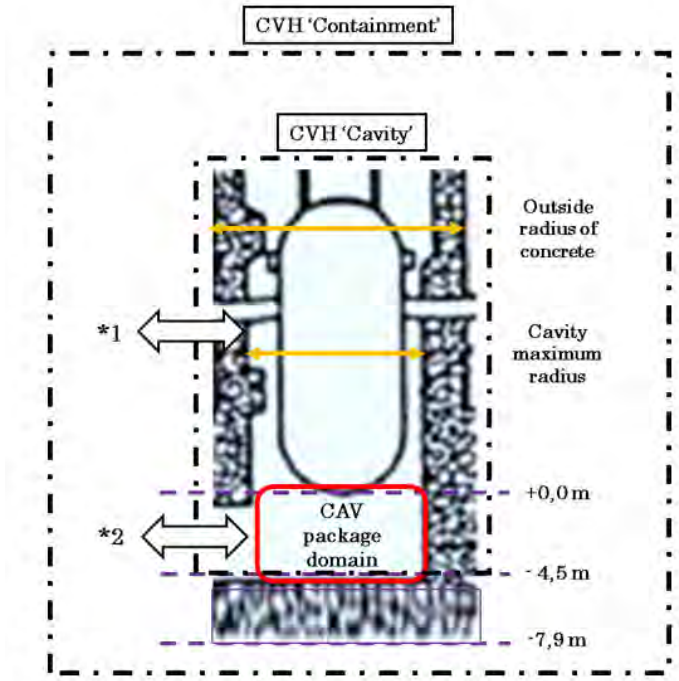
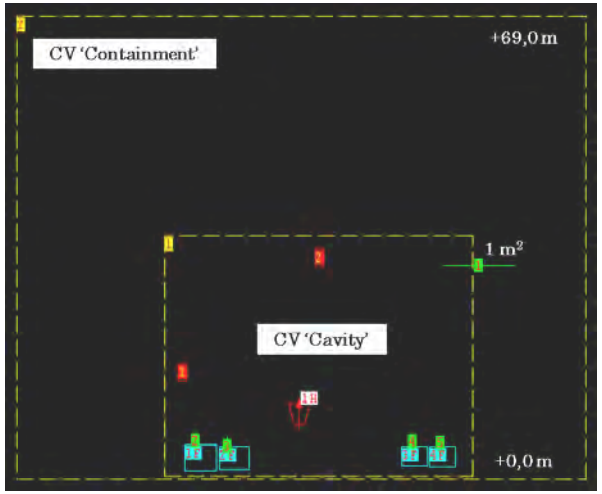
- GOTHIC doesn´t mechanistically simulate melt phenomena.
- MELCOR provides the ex-vessel mass and energy source terms.
- An embedded LP cavity should be used as a robust interface to the 3D containment.
- Selected MELCOR outputs are translated traceably into GOTHIC inputs (BCs).
- This enables one single GOTHIC model to cover in-vessel and long ex-vessel progression.

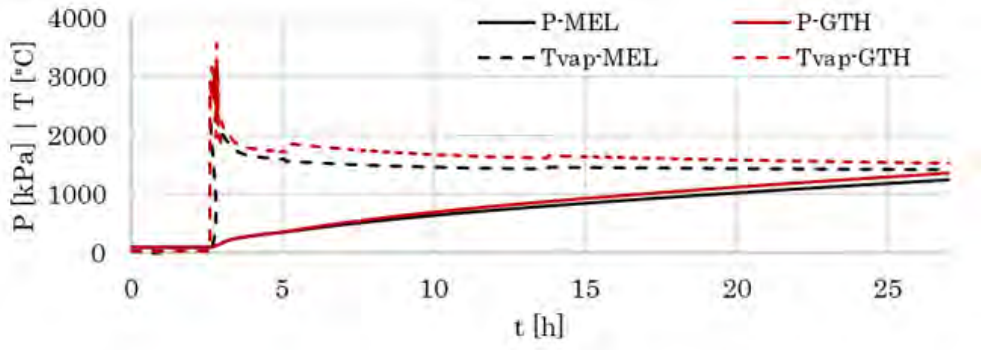


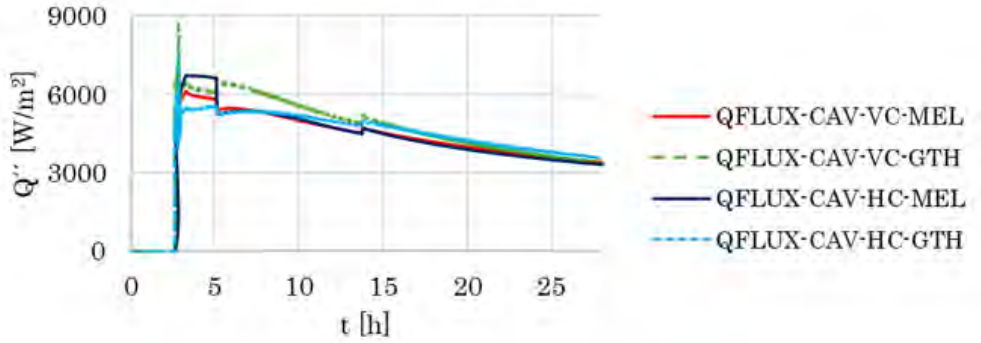
4. Extending GOTHIC to ex-vessel simulations

MELCOR-to-GOTHIC test configuration (dry cavity)









** 1. Flow path connection between cavity and containment control volumes.*
** 2. Flow path connection for water ingress into the cavity control volume.*

** VC stands for Vertical Concrete, HC stands for Horizontal Concrete*

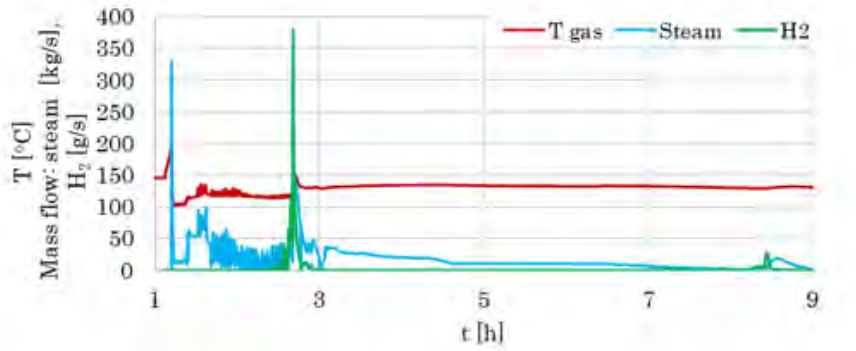
Several test cases verified the MELCOR-to-GOTHIC approach and showed that a sufficiently-complex GOTHIC boundary condition can successfully reproduce the cavity releases to the adjacent volumes without compromising computational effort

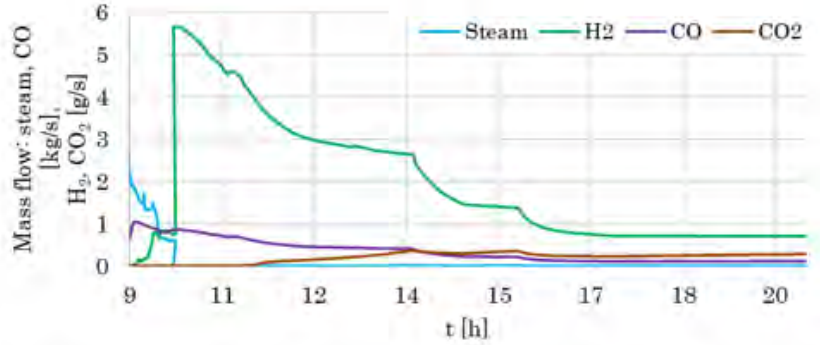
5. MELCOR vs GOTHIC application case

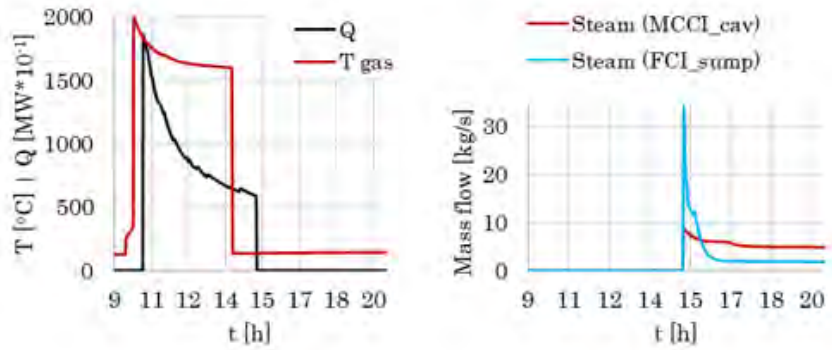
TLAP scenario (complete loss of AC power) + late depressurization

AMHYCO D2.2 – Identification and analysis of accident sequences with posing high H_2/CO combustion risk

- Short, intense release of steam and H_2 to the containment (in-vessel, 0.7 ton).
- RPV fails at ~9 h. then, sustained M&E releases from MCCI at the cavity floor (1.62 ton H_2 + 13.9 ton CO).
- Biological shield penetration leads to sump-to-cavity water ingress, partial melt submergence, and melt relocation towards the sump.
- Total simulation window: 9 h (in-vessel) + 11 h (ex-vessel).

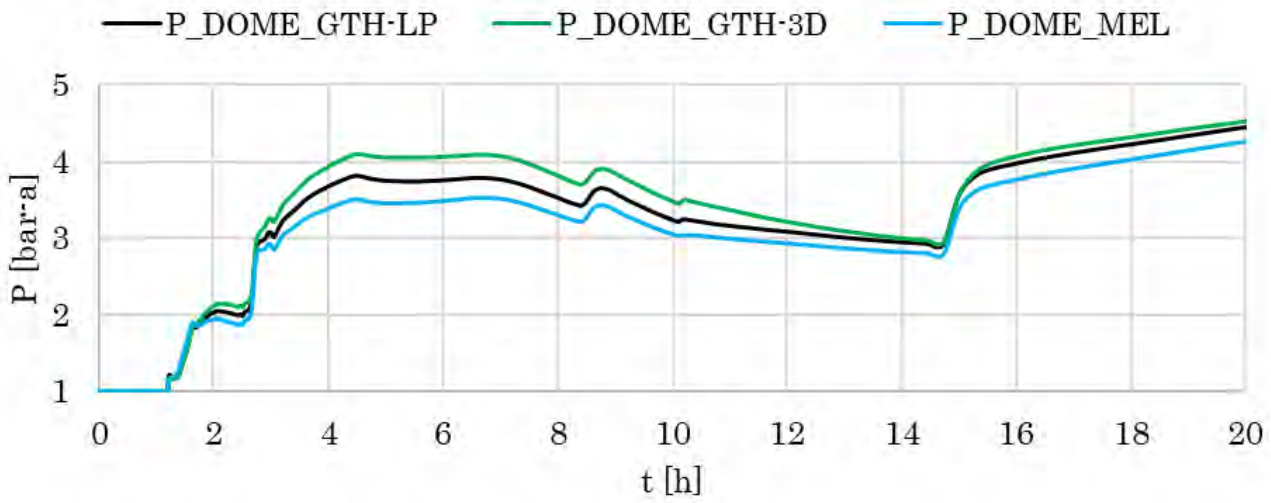






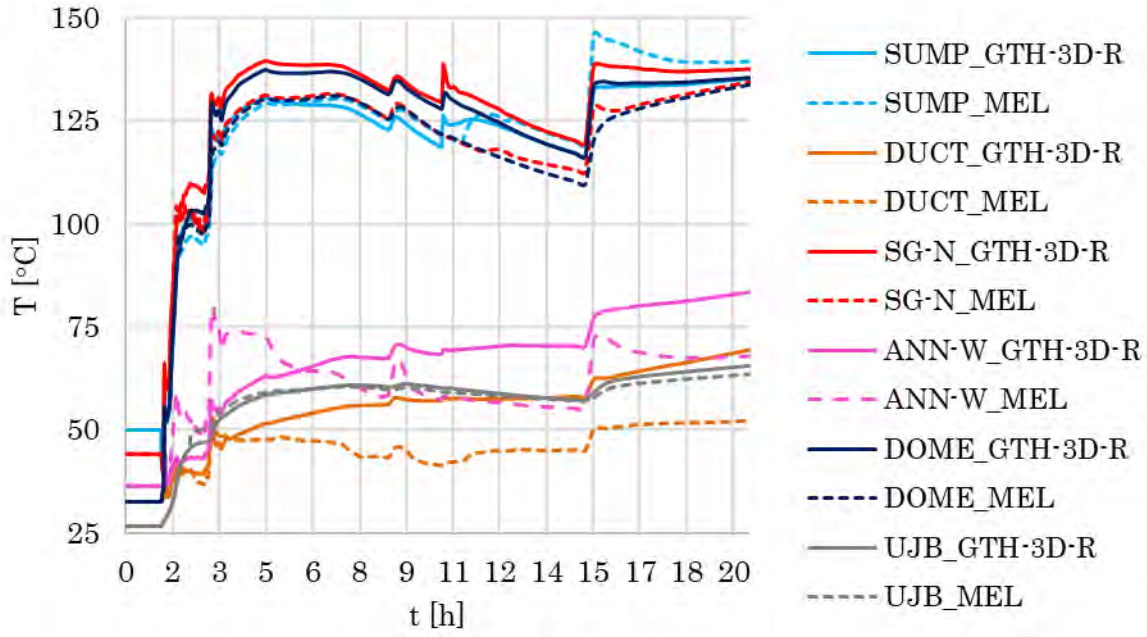
5. MELCOR vs GOTHIC LP/3D application case

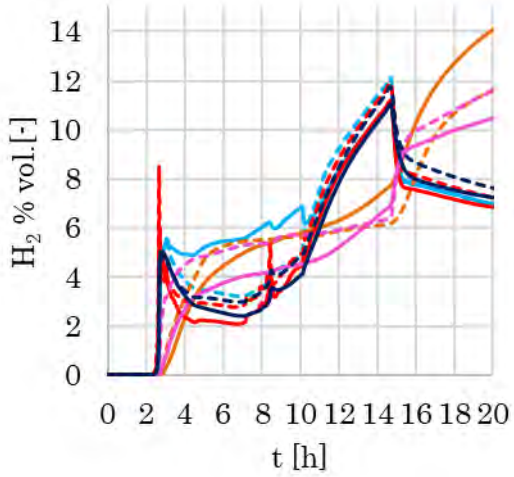
- MELCOR vs GOTHIC LP (equivalent CVs) vs GOTHIC 3D (equivalent free volume).
- Unmitigated (U) scenario (wo/ PARs).
- GOTHIC 3D ran on 4 core CPU (i7-9700@3.0 GHz) w/ $t_{step_max} = 0.04$ s
- GOTHIC CPU time: 2,13 h (LP case), ~355 hours (14,8 days) (3D case).

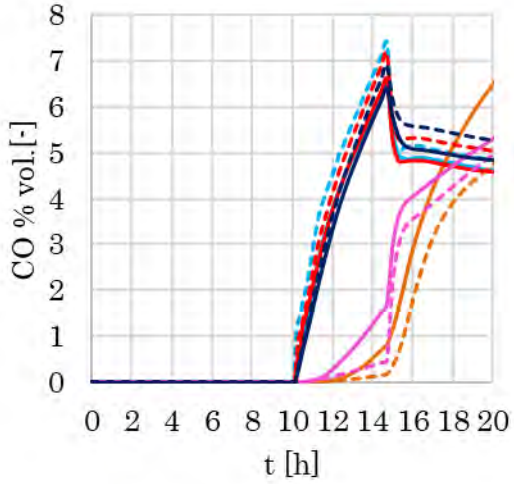


GOTHIC systematically predicts higher pressure

5. MELCOR vs GOTHIC 3D application case



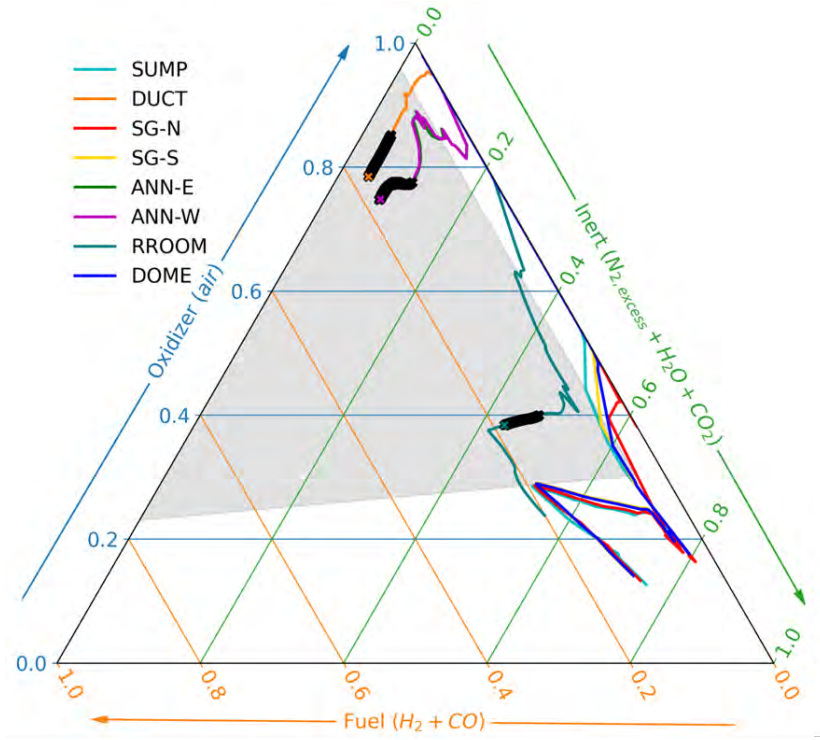




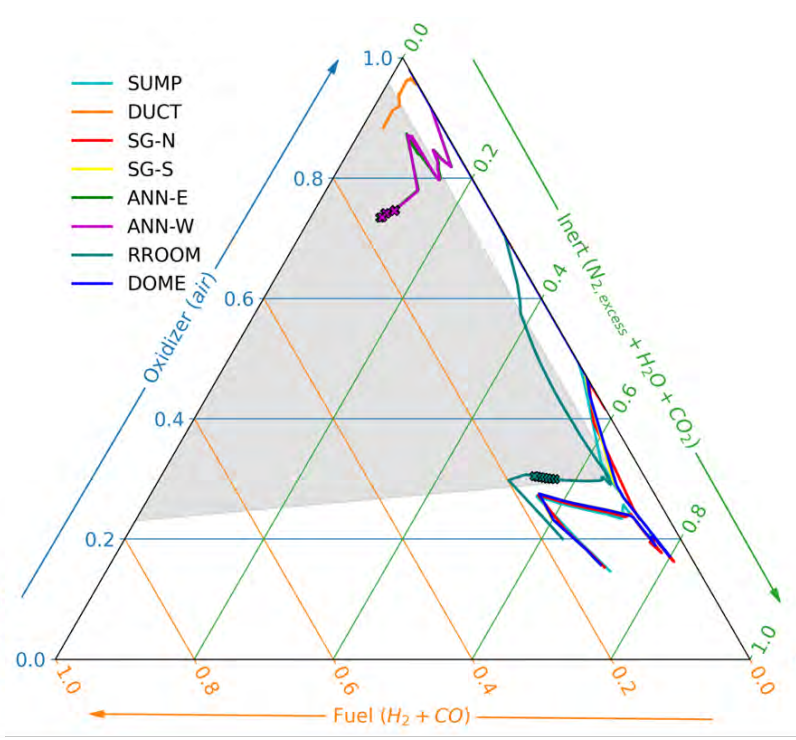
- All approaches reproduce the same global accident progression.
- Reasonable agreement in main circulation and accumulation regions.
- Main discrepancies are linked to condensation, heat transfer and mixing treatment.
- DUCT and ANN-W are the most sensitive regions; DOME: smoother agreement.

5. MELCOR vs GOTHIC LP/3D application case

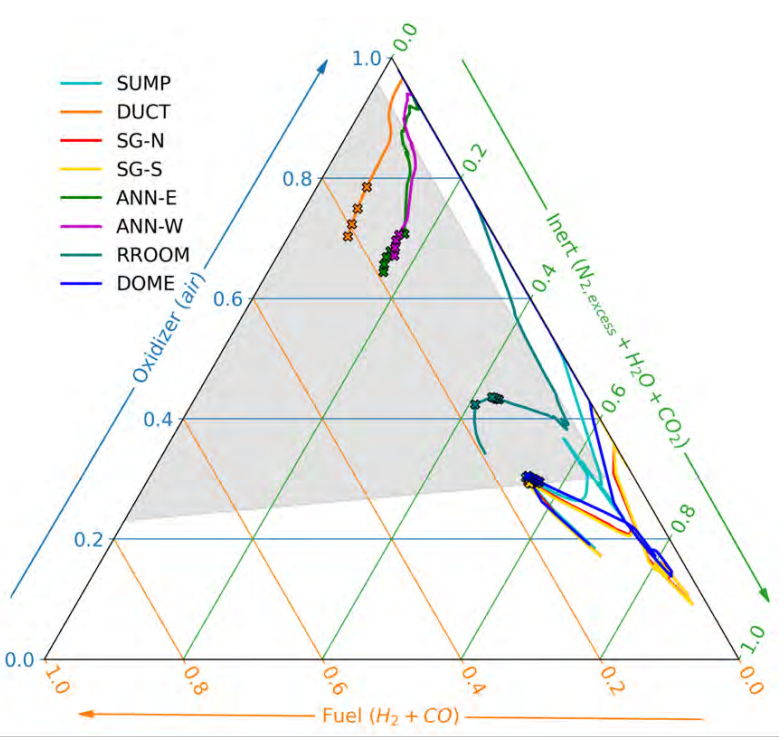
- Main objective: verify pre-ignition screening figures of merit.



MELCOR

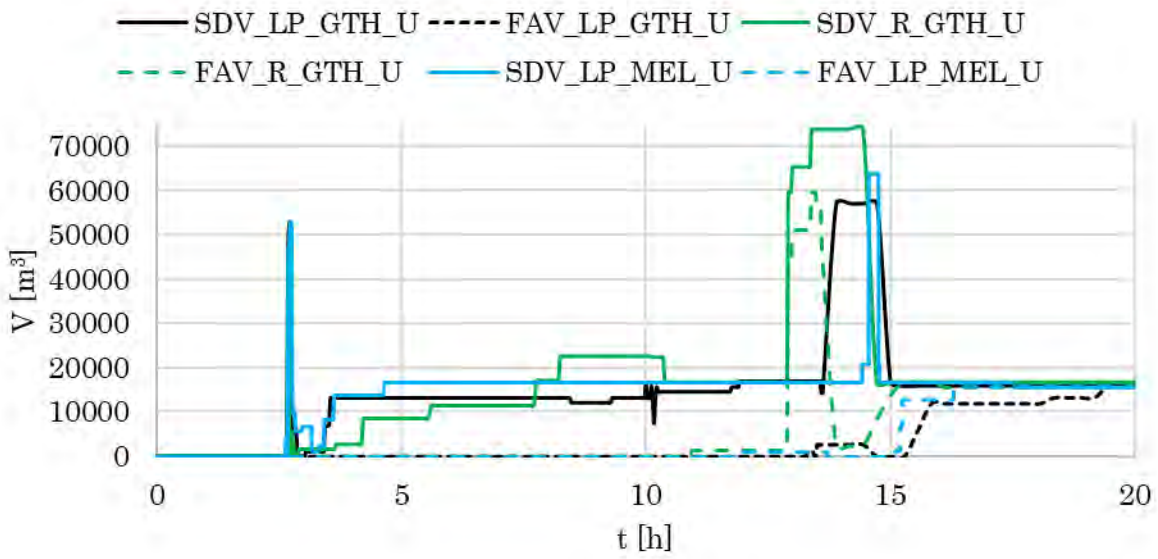


GOTHIC - LP



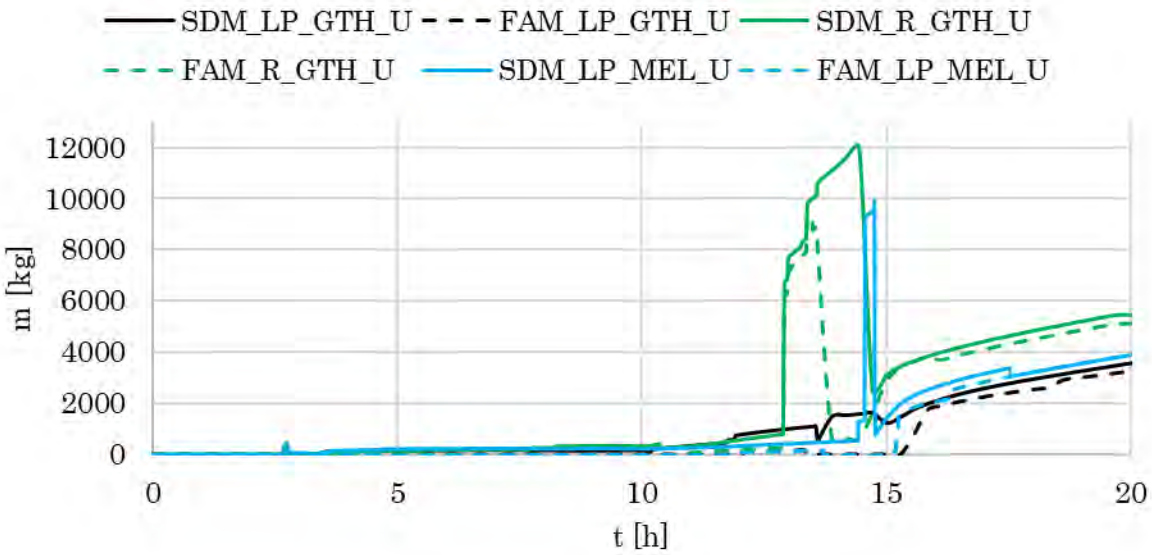
GOTHIC – 3D

5. MELCOR vs GOTHIC LP/3D application case



Time evolution of flammable-cloud and FA-prone-cloud free-gas volumes (V) and corresponding fuel masses (M) (H_2+CO), reported as global totals

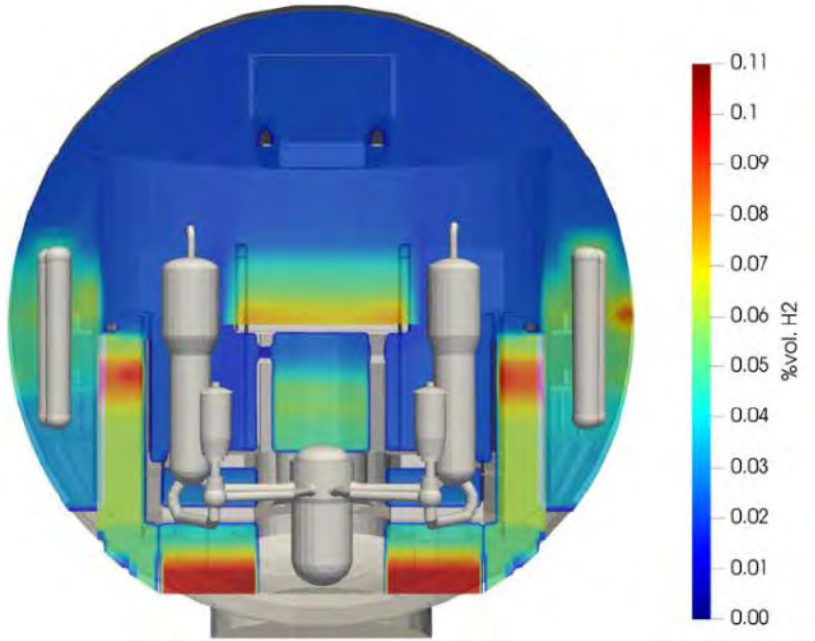
SD = slow deflagration
FA = flame acceleration
R= 3D equivalent region



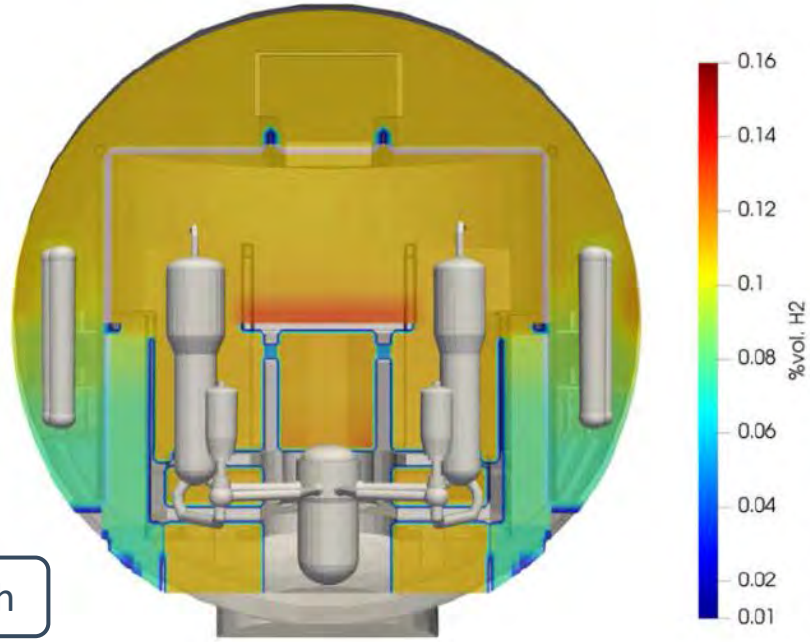
- Both codes can predict a very similar flammable atmosphere.
- Differences propagate to the total free-gas V and fuel M classified as flammable or FA-prone.

5. MELCOR vs GOTHIC 3D application case

- 3D resolved stratification footprints hidden by LP averages.
- Early phase: localized H_2 enrichment and lower-level accumulation.
- Ex-vessel phase: broader stratified structure driven by sustained releases.
- 3D highlighted transport-sensitive regions such as the DUCT.
- Added value: local accumulation and combustion-relevant pockets.



4.5 h



14.5 h

6. Conclusions and outlook

GOTHIC 3D can be extended to the ex-vessel phase in a robust and traceable way, combining an embedded LP cavity with a systematic MELCOR-to-GOTHIC boundary-condition translation.

MELCOR and GOTHIC provided a consistent global accident narrative, which supports the use of GOTHIC for cross-code benchmarking of late-phase containment response.

GOTHIC 3D resolved stratification and local accumulation footprints that remained hidden in LP approaches and were directly relevant for combustion-risk interpretation.

ABSTRACT

From the Design Basis Accident (DBA) perspective, the actuation of the containment safety systems has been focused on pressure and temperature control. However, the complex phenomenology inside the containment during severe accidents makes such systems cause unexpected effects, like heterogeneity in the temperature distribution and local flammable gas clouds. This last phenomenon is a cause for serious concern due to the potential risk of a fast hydrogen detonation occurring inside small rooms or ventilation ducts, which could lead to conditions exceeding the containment's design parameters.

This fact has motivated the present study, where the Containment Air-Cooling System (CAS) of a PWR Western-designed (PWR-W) containment has been implemented in a GOTHIC 3D model for the first time in the literature. In detail, this work, conducted within the framework of the CSN's INTERCON3D project, shows how containment safety systems (CAS and sprays) influence global and local thermal-hydraulic and flammable conditions.

The paper presents different large break Loss of Coolant Accident (LOCA) scenarios, performed with GOTHIC 8.3(QA), which consider the temporary interruption of the safety injection to the reactor cooling system. This simulation involves the generation of a relevant amount of hydrogen that challenges the conventional performance of safety and mitigation systems. Simulations show how safety systems promote the cooling of the containment atmosphere, resulting in a fast depressurisation. Nevertheless, the condensation of the steam makes the installation of PARs crucial to address flammable gases in the evaluated scenarios.

CONTAINMENT ANALYSIS, GOTHIC, HYDROGEN, SPRAY, FAN COOLERS

1. INTRODUCTION

The containment building is a crucial component for the accident management of PWR reactors, playing the role of the last barrier against a potential radiological release. In addition, this enclosure serves as protection for the reactor against external threats and provides biological protection while operating [1]. During its design and commissioning phases, the containment is tested to comply with the highest safety standards. Those include withstanding postulated internal/external Design Basis Accidents (DBA) and, last designs, Beyond DBA (BDBA); such as Severe Accidents (SA) [2]. To be able to manage these scenarios, the containment includes safety and mitigation systems, which minimise the consequences of accidents to avoid exceeding its design limits. Safety systems of conventional PWRs, such as the spray system, the air-cooling system or ice condensers, have the safety function of depressurising and cooling down the containment after an accident [1]. On the other hand, mitigation systems in conventional PWRs, such as Passive Autocatalytic Recombiners (PARs) and Filtering Containment Venting System (FCVS), were mainly considered after the Fukushima Daiichi accident [3]. These systems are useful for the late phases of BDBA accidents, controlling the concentration of flammable gases and the containment pressure, as well as minimising the source term released in case of venting.

The presence of safety and mitigation systems in the PWR Western-designed (PWR-W) containment should be enough to ensure containment integrity. Nevertheless, the use of these systems may involve drawbacks during the accident progression. One example is the increase in the hydrogen volume fraction due to the sprays' actuation, pointed out by Dimmelmeier et al. in [4] and Paranjape et al in [5]. There are several references in the literature focused on the performance of the containment spray system. However, there are fewer authors who study the impact of safety-related ventilation systems in the presence of flammable gases. The safety function of this system matches the spray function; thus, its operation may also be subject to similar drawbacks. Studies which include this kind of system, such as those carried out by Kapulla et al. in [6] and Soloviev et al. in [7], do not address their performance in a 3D full-containment scale, including flammable gases. These reasons led to the creation of the INTERCON3D project, a national project financed by the Spanish regulator (CSN) to analyse the interaction between safety and mitigation systems of a PWR-W dry containment building under severe accident conditions. In addition, another objective of this project is to identify alternative strategies in system operation which involve a lower risk of flammability.

In line with the objectives of the INTERCON3D project, this paper examines the use of safety and mitigation systems during a BDBA in a PWR-W dry containment, using a 3D computational model with GOTHIC 8.3(QA) [8]. In sections 2-4, the base model and the functioning of the systems are described. Then, section 5 introduces the description of the accident and initial conditions for the simulation. Finally, section 6 addresses the impact of considering safety/mitigation systems on variables related to the conventional safety analysis, such as pressure and temperature, and the risk associated with flammable gases.

2. THE PWR-W DRY CONTAINMENT MODEL

The UPM PWR-W dry containment model has been built with the general-purpose thermal-hydraulic GOTHIC code, which allows for studying the local conditions inside a containment due to its 3D capabilities [8]. This model has been developed and modified throughout the last ten years by the UPM research group [9]. The last version, which is the base for this study, was created following the "Preventive methodology", a specific model-building process for GOTHIC which reduces computational errors and simulation bottlenecks [10]. This model uses a single volume of 40x40x67 m, with a mesh of 1.0 x 1.0 x 1.5 m and 68800 cells.

2.1. CONTAINMENT AIR-COOLING SYSTEM (CAS) IMPLEMENTATION

As was previously mentioned, the Containment air-cooling system (CAS) is a safety system designed to deal with postulated accidental scenarios. Nevertheless, this system has multiple purposes, working during both normal operation and emergency modes. During normal operation, its goal is to keep the inner atmosphere of the containment in adequate environmental conditions for components, equipment and maintenance activities. On the other hand, during emergencies, this system works together with the spray system, depressurising and evacuating the heat load introduced by mass and energy releases into the containment [1]. To address this hybrid purpose, the CAS is composed of different sub-systems, which are:

- **The main Cooling units**. These units are responsible for removing the main heat load of the containment. These are designed with multiple cooling coils and a high-capacity fan to cool down and drive gases to the lower zones of the containment through integrated vertical shafts. Based on current operating plant values, the volumetric output of these units has been estimated at ~45 m^3/s for normal operation and ~20 m^3/s for emergency scenarios. The subsystem has four units, separated into two redundant trains of 100% capacity. These units are interconnected and connected with the containment by means of an extensive duct network. The duct network ensures that cold gases reach most of the lower zones. In an emergency involving Reactor Cooling System (RCS) release, the operation of these units changes, turning on the units on reserve, reducing the velocity of heat-capacity fans and opening a connection between units and the containment dome. This alignment promotes the cooling of gases in the upper zones by the generation of new convection loops. This sub-system is the only one required in most of the emergency scenarios; the following sub-systems are only required in specific accident situations, out of normal operation.

- **The Control Rod Driven Mechanism (CRDM) cooling units.** The CRDM is an energised component that is operated to insert/remove the control rods from the reactor core. According to operating plant values, cooling units must address a heat load of ~600 kW during normal operation to ensure the proper functioning of the CRDM. For this purpose, the present PWR-W design incorporates two redundant, high-capacity fans that evacuate gases surrounding the CRDM. Based on current NPPs, these units deliver ~20 m^3/s. Finally, the main cooling units cool down these gases.

- **The Cavity cooling units**. The cavity is one of the most isolated zones of the containment; thus, its cooling requirements during normal operation are not fulfilled by the main cooling units. In the PWR-W design, the cavity contains relevant elements that require cooling, such as the vessel the nuclear instrumentation. This subsystem introduces two additional Fan-Coolers (FCs) to address the cavity heat load. For similar systems in current NPPs, their output is ~12 m^3/s and ~110 kW.

- **The Filtering units**. These units have the single purpose of removing particles and dust from the containment atmosphere during normal operation, ensuring air quality standards. However, they help with the aerosol retention purpose of the spray system in accidents using a combination of filters and fans. In addition, the unit's fans, which provide ~7 m^3/s (based on operating NPPs) of filtered gas, may be useful due to the mixing effect on the containment atmosphere.

All these subsystems were implemented in the generic PWR-W 3D model in GOTHIC to study the impact of their operation in complex accidental sequences such as severe accidents that may involve the presence of flammable gases. Available data allowed us to create a generic configuration for cooling units and the ducts above the operational floor (see Figure 1). The position of the ducts throughout the containment is not trivial; however, the analysis of the conditions inside them may be relevant for safety analyses. For this reason, the main cooling units and the duct network were geometrically integrated into the 3D model using the Preventive methodology (See Figure 1). The rest of the devices and ducts were implemented with GOTHIC built-in components, such as coolers, fans and junctions.

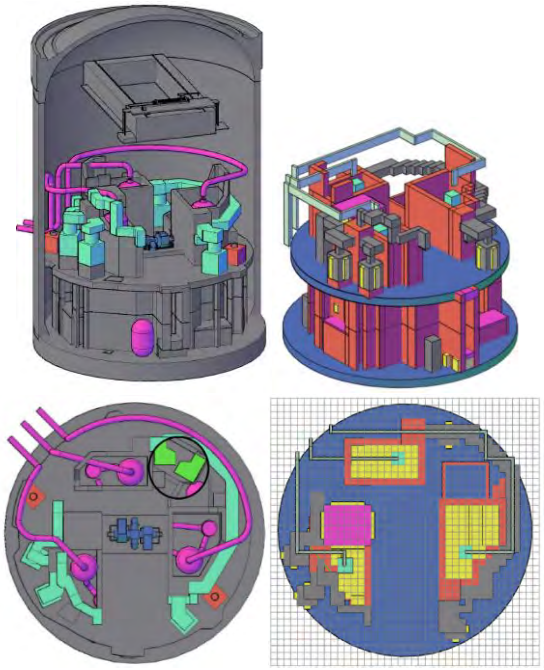

Figure 1:CAS implementation in the detailed 3D CAD model and its geometrical simplification using the preventive methodology.[1]

In detail, the main cooling units and ducts were simplified, adapting their geometry to GOTHIC's Cartesian mesh. In particular, Figure 2 shows how these elements are modified to match the mesh. This process ensures the hydraulic independence of cells that represent the system's inner volume. The mesh was selected previously to the CAS implementation; thus, the design tries to match as much as possible the original duct size, preserving the area throughout the entire duct.

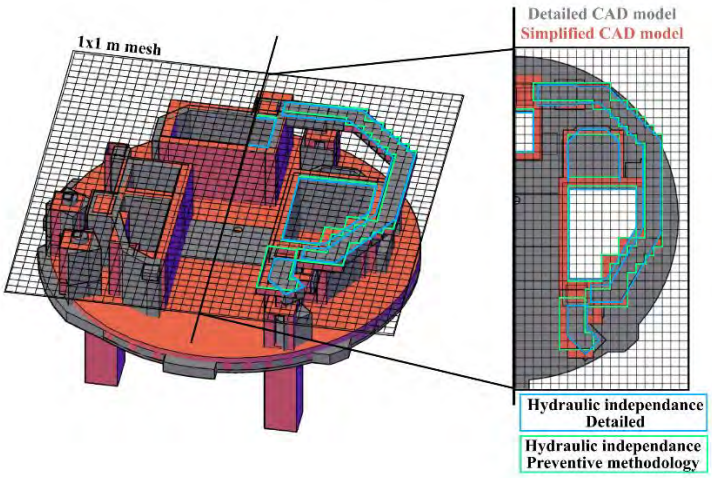

Figure 2: Geometrical simplification of the Main cooling units and ducts.

[1] CAS elements located at the detailed CAD model: Main cooling units (TURQUOISE), cavity cooling units (GREEN), CRDM cooling units (BLUE) and filtering units (RED)

Apart from geometry, the CAS model uses GOTHIC built-in components for Fans and cooling coils. In particular, the FCs cooling coils were introduced as "Coolers". These built-in components are the simplest way of representing a specified heat sink, such as condensers or heat exchangers. These elements do not need much data, because they remove/add a specific amount of heat from the cell where they are placed, promoting the condensation of steam in the cell if its temperature decreases below the saturation temperature. Regarding the performance of these coolers, a heat removal model is included for "coolers" of the main cooling units. This heat removal model uses reference data reserved for the UPM group within the INTERCON3D project. The model calculates the total heat removal by one main cooling unit depending on the temperature of the gases in the cell and the temperature of the water inside the cooling coil tubes. Despite the reference data considering the temperature inside the tubes at ~45 ºC, this model is adapted to match other temperatures. Finally, the reference data include a limitation on the removed heat load from ~135 ºC. This limitation has not been included in this work for: (i) being non-conservative from the hydrogen risk evaluation perspective; and (ii) because of the lack of information on the physical mechanism behind this limitation, probably coming from a conservative threshold for containment cooling.

2.2. OTHER SAFETY/MITIGATION-RELATED CONTAINMENT SYSTEMS

In the present analysis, two additional PWR-W safety-related and mitigation-related components have been considered: the spray system and the Passive Autocatalytic Recombiners (PARs). Their importance for the early stages of an accident and their impact on the late phases, especially in the presence of combustible gases, make them crucial to perform a comprehensive analysis of the CAS. The FCVS is considered out of scope because the accident postulated for the present analysis does not cause the activation set-point of this system to be achieved. Nevertheless, this system may involve drawbacks in a heterogeneous atmosphere in the presence of flammable gases.

- **Spray system**

The spray system is the most used containment safety system on PWR reactors. This system uses several nozzles to inject small cold drops into the containment, which condense steam, mix and cool down the containment atmosphere. This phenomenology causes a fast decrease in pressure and temperature in the case of an accident involving an RCS release. However, the increase of elements, like droplets, which promote steam condensation, may result in issues related to the containment inertisation against combustion reactions. This system actuates during an emergency, after the containment high-pressure signal is generated (P > 250 kPa). This system may operate in two different regimes: injection from external sources and recirculation from the containment sump. The spray system implemented in the PWR-W dry containment 3D model includes two redundant trains of 100 nozzles, each injecting 1 l/s of droplets at ~25 ºC (injection) or ~80 ºC (recirculation). These nozzles are radially distributed in three rings at different elevations to cover 90 % of the containment free volume [1]. Regarding their modelling in GOTHIC, Sprays are created by the built-in component "Spray nozzles", which turn the spray mass through a junction into drops of a specific size.

- **Passive Autocatalytic Recombiners (PARs)**

The PARs are mitigation components included in a large fleet of PWR-W containment, especially after the Fukushima-Daiichi accident. These devices are completely passive, and their operational basis is to promote the removal of flammable gases, such as hydrogen, from the containment by their recombination with oxygen on catalytic surfaces. The design of a PAR configuration must be adapted to the space and capacity requirements of the NPPs [11]. In particular, the present PWR-W 3D model incorporates 40 Framatome-type PARs, distributed throughout the containment following the lessons learnt from the AMHYCO project [12]. Regarding their modelling in GOTHIC, PARs are created by the built-in component "H2 recombiners", which enables the recombination of the hydrogen mass through a junction with a provided efficiency. This efficiency is externally calculated and provided for each time step with a script that includes an engineering correlation provided by Framatome for the AMHYCO project.

2.3. INITIAL CONDITIONS AND OPERATIONAL SPECIFICATIONS

The case selected to analyse the impact of the implementation of the safety/mitigation systems has been a 10.000 s large break LOCA in the cold leg. However, it includes a delay of the Low-Pressure Safety Injection (LPSI) actuation until ~15 min of the simulation. This event, which does not involve core damage, causes a strong oxidation of fuel Zr cladding and the generation of hydrogen (~334 kg) when the core turns partially uncovered and not properly cooled. The recovery of the safety injection causes a quench effect, promoting the fast generation of hydrogen and steam at high temperatures. This input, generated from previous simulations using the PWR-W 3-loop RCS model running in MELCOR, allows us to study the performance of the CAS in the presence of flammable gases. This model was created in the UPM research group in the 80's and updated later by the same group [13]. The communication between MELCOR and GOTHIC is not made by direct coupling; the key variables to simulate the rupture, such as mass, pressure or temperature of streams through the rupture, are introduced as boundary conditions.

On the other hand, initial conditions were generated by a previous steady-state case, which ensures quasi-stationary conditions considering the normal operation of the CAS components. This steady state was validated by the Spanish regulatory body (CSN) within the INTERCON3D project.

3. SAFETY ANALYSIS RESULTS

The present analysis is focused on the impact of the safety/mitigation systems interaction with the containment atmosphere in a post-accidental scenario. In particular, the implementation of the CAS and its operation. For this reason, it is convenient to address how this system impacts the evolution of the transient, independently and in conjunction with other systems or devices, such as the Sprays and PARs. In addition, this section aims to show the differences promoted by two possible operational behaviours of the CAS, the one described in the system's manual and the success criterion required for the containment cooling system during an emergency. Taking this into account, the next cases are proposed:

1. **"W/o SYSTEMS"**. The base case of the comparison. This case considers all safety and mitigation systems not available during the simulation.
2. **"CAS" case**. This case considers only the actuation of the CAS, which follows the description of the system. The system's description considers 3/4 main cooling units before the break takes place and 4/4 main cooling units operating at low load after. In addition, cooling units incorporate discharging gates that open a direct connection between units and the containment dome at high temperature. Regarding other changes, the second filtering unit starts operating, the CRDM is de-energised, and the Cavity cooling starts working on close loop to isolate the zone.
3. **"Sprays +CAS (Syst. description)" case**. This case considers the actuation of Sprays and the CAS, following the description of systems. The CAS actuates as described above, while the Sprays system works by injecting spherical drops (0.1 cm) through 1/2 trains of nozzles located at the top of the containment.
4. **"Sprays +CAS (Succ. criterion)" case**. This case considers the actuation of Sprays and the CAS. However, for this case, a common "success criterion" has been considered. The "success criterion", a concept which sets the minimum sufficient condition on systems or components to progress towards a safety shutdown after a postulated accident. In this specific case, the correct operation of 1/2 redundant trains of both systems (100 nozzles and 2/4 main cooling units).
5. **"Sprays +CAS (Syst. Description) +PARs" case.** This case introduces PARs as the main mitigation action against the flammability potential of hydrogen. This configuration matches case 3, which is the most conservative case in terms of flammability risk, with the greatest number of condensing mechanisms working simultaneously. This case will be considered only for the flammability risk analysis due to the low impact of PARs on pressure and temperature.

First, it is important to describe the containment thermal hydraulics before and after the LOCA-type event. As shown in Figure 3, during normal operation, the main cooling units take gases which surround them and drive them into the ducts and vertical shafts. This operation creates large convection loops in the lower zones of the containment, cooling down the main components and equipment. In Figure 3, it is visible how the configuration of units generates a flow pattern throughout the ducts. This flow pattern helps to understand which units contribute more to cool down all containment zones. This is especially relevant for the selection of the units in operation for case 4. Five seconds after the break, the flow patterns change radically (see Figure 3). The fast release of gases from the RCS produces a chaotic atmosphere inside the containment. However, hot gases tend to flow towards the upper parts of the containment, changing the cooling needs. For that reason, the main cooling units change their operation, driving the cooled gases into the containment dome. This mode generates large convection loops in this zone, which enhance condensation. Nevertheless, after the break, the flow through the ducts and vertical shafts decreases, with the flow reversing in some zones (see Figure 3).

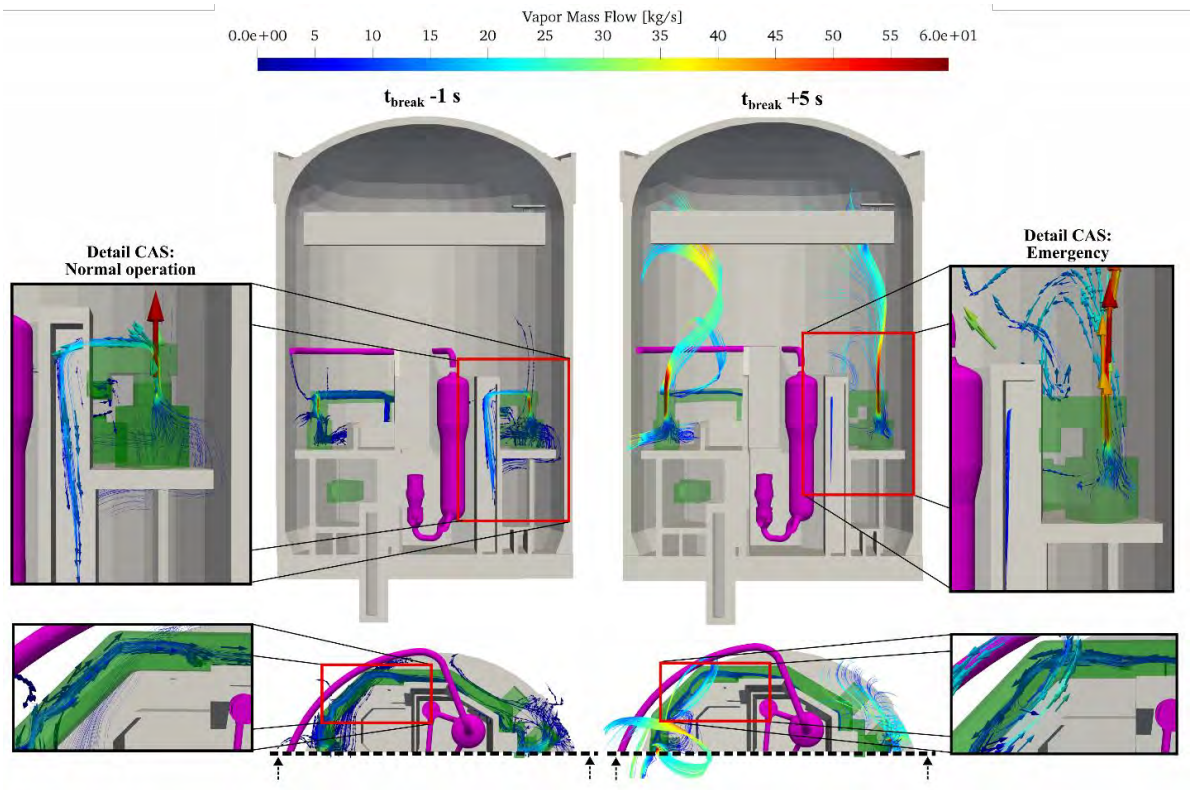

Figure 3: Gas stream paths from the main cooling units for different operational modes.[2]

In Figure 4, the evolution in global pressure and temperature is shown; these variables are the result of an average by volume, considering values cell by cell. Focusing on pressure, systems have a low impact on the first pressure peak because systems need time to absorb the load released in the first seconds of the LOCA. Then, the introduction of safety systems led to a significant depressurisation of the containment minutes after the break. The depressurisation is caused by the increase of elements which promote steam condensation, such as drops and coolers, which condense the steam introduced by the break. Cases involving

[2] CAS components and ducts coloured in green.

safety systems have a similar pressure evolution. The case with the highest depressurisation involves both sprays and the CAS at full capacity, as expected. On the other hand, cases without sprays or systems working to comply with the success criteria show similar results. These results are reasonable, considering the redundant design of both systems.

Regarding temperature, apart from the significant difference between the cases with and without safety systems, some relevant deviations exist between the rest of the cases. In Figure 4, around 1000 s after the break, the highest temperature peak takes place, caused by the recovery of the safety injection, which promotes the release of steam and hydrogen from the core at high temperatures. These gases ascend quickly from the affected cold leg to the containment dome. The cases that include sprays can buffer the impact of the release of those gases because of the influence of the system on the entire containment dome and Steam Generator (SG) compartments. On the other hand, the CAS has a more localised influence; thus, these units need more time to produce an equivalent cooling effect than the spray system. The configuration of the main cooling units after the break causes hot gases to have to reach the containment dome and take part in the convection loops to be cooled down by these devices. The differences in the cooling process provoke an avoidable temperature peak in the case without sprays. After the peak, the evolution of temperature becomes similar to the pressure evolution for cases with safety systems.

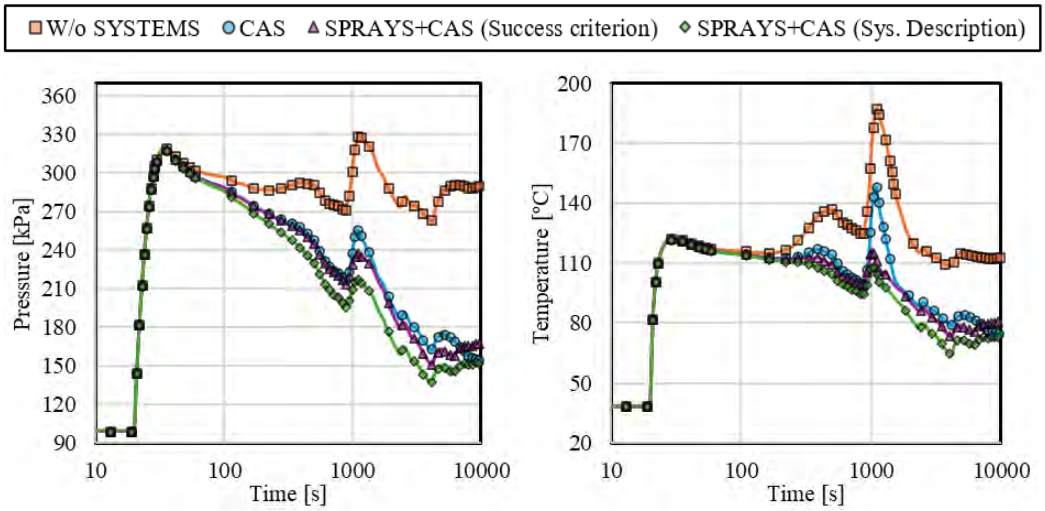

Figure 4: Evolution in global pressure and temperature of analysed cases.

As mentioned before, hydrogen is introduced to the containment when the core is not properly cooled, a situation provoked by a delay in the LPSI actuation. That hydrogen may accumulate in specific locations depending on the containment geometry and flow patterns. Local concentrations of hydrogen may pose a risk to the integrity of the containment. Nevertheless, hydrogen flammability risk is governed by certain chemical, geometrical and thermal conditions. This risk may be quantified by the calculation of flammability limits; these are the lowest (LFL) and highest (UFL) hydrogen concentrations which may combust at a specific temperature. In addition, the amounts of O_2 and steam affect these flammability limits. The Shapiro-Mofette diagram [14] is commonly used, due to its simplicity, to evaluate the risk of hydrogen deflagration or detonation. However, this diagram just represents the flammability limits at specific thermal conditions, being sensitive to temperature variations. For this reason, Martin-Valdepeñas et al. in [15] propose the linearization of those limits, whose expressions depend on molar fractions of gases (x_{H_2}, x_{H_2O}, x_{O_2}) and temperature (T). These expressions are included below (1) – (3). In addition, the fourth expression considers that O_2 must achieve a specific molar fraction to permit the combustion reaction to take place [16].

$$x_{H_2}^{LFL} \geq 0.037 + 0.011x_{H_2O} - 4.16 \times 10^{-5}(T - 373) \quad (1)$$

$$x_{H_2}^{UFL} \leq 0.772 + 1.087x_{H_2O} - 2.71 \times 10^{-4}(T - 373) \quad (2)$$

$$x_{H_2O} \leq 0.63 + 3 \times 10^{-4}(T - 373) \quad (3)$$

$$x_{O_2} \geq 0.05 \quad (4)$$

These equations can be used to identify flammable gases in each cell of the 3D model. This enables us to locate flammable clouds and study their propagation throughout the containment free volume by summing the volume of the cells in a flammable state. This calculation is performed using the UPM post-processing tool, ProTON [17]. As an example of applications, Figure 5, created by this tool, shows how the safety systems impact the flammable cloud volume.

As was mentioned before, the safety systems involve the introduction of new elements which promote steam condensation, contributing to the depressurisation of the containment following a LOCA accident. However, the steam condensation also increases the hydrogen volume fraction. This is clearly noticeable in Figure 5, where, in contrast to the "W/o SYSTEMS" case, the flammable volume occupies the entire containment before 3000 s of the simulation. Among cases that consider safety systems, the one with sprays the CAS at full capacity represents the worst-case scenario. Nevertheless, in the other cases, the simulation predicts how flammable clouds take more time to spread throughout the entire containment's free volume. This window could be crucial to actuate on the system's operation, based on flammable gas or steam pressure measures, to avoid the complete propagation of clouds.

Finally, the case including PARs is shown as well in Figure 5. The introduction of these devices is crucial due to their impact on the control of flammable gases. In this case, the safety systems can operate with a lower risk of local deflagration of flammable clouds. Nevertheless, as shown in Figure 5, even the case with PARs has a time window where 10% of the containment volume is flammable. This is why, even considering mitigation measures, it is important to locate those clouds to take specific actions against their formation, expansion and combustion.

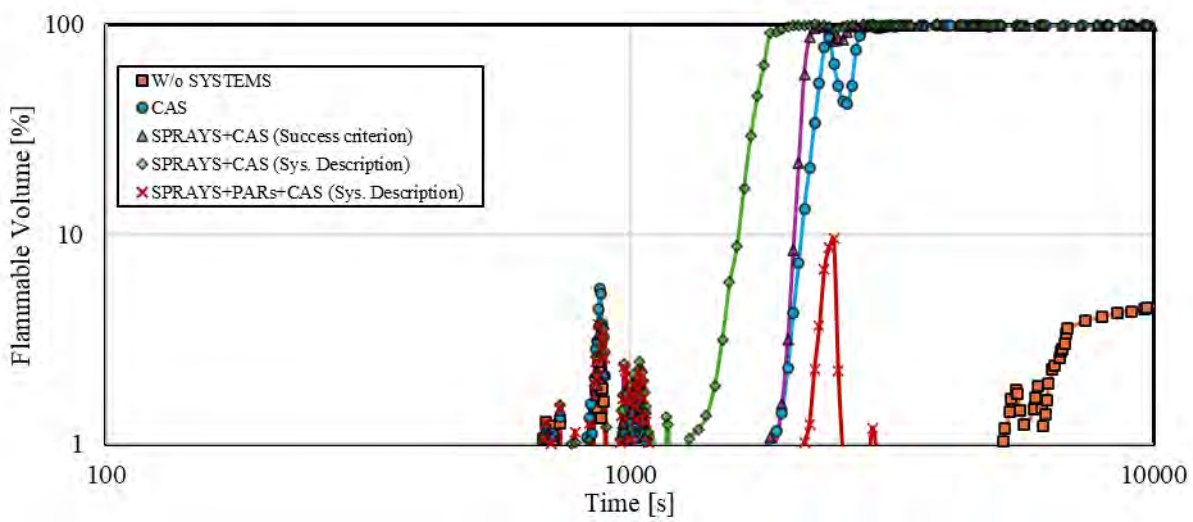

Figure 5: Evolution in containment volume in flammable conditions of analysed cases.

Regarding the location, Figure 6, created using ProTON and visualisation Software Paraview, shows the formation of flammable clouds (in RED) and how safety/mitigation systems impact it. For space limitations, only the most restrictive case is displayed, the "Sprays +CAS (Syst. description)" case. As shown in Figure 6, during the progression of the accident, flammable clouds start appearing. At the beginning, the effect of hydrogen and the sprays govern the formation of clouds. Nevertheless, the main cooling units start to accumulate flammable gases, which are driven to the dome. The effect of both systems, together with the rest of the elements which promote steam condensation, causes the entire containment to achieve flammable conditions. If the PARs were added, they would help to address this severe scenario. However, this would not imply a zero-risk situation, because the FCs continue condensing gases and promoting the presence of flammable clouds. In view of these results, even in the presence of PARs, the conventional operation of safety systems may result in a safety issue for scenarios involving flammable gases.

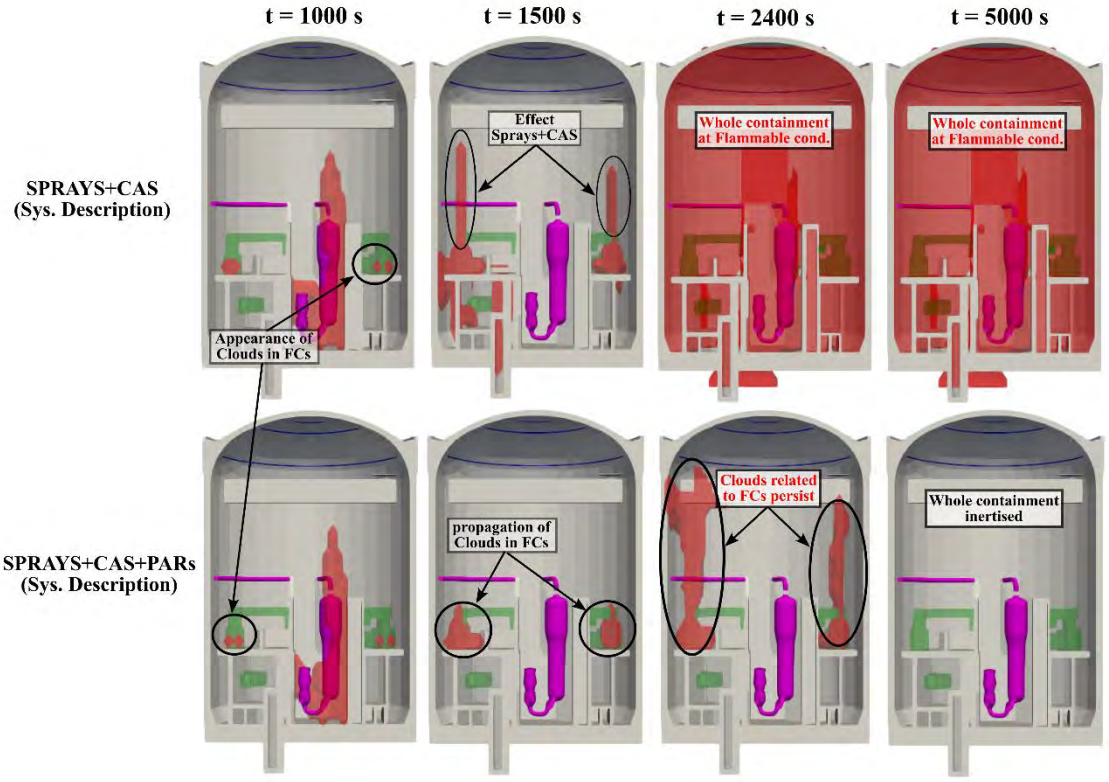

Figure 6: Evolution of flammable clouds inside the containment considering safety/mitigation systems.

4. CONCLUSIONS

The implementation of the main components and ducts of the CAS into a PWR-W 3D model in GOTHIC, using the preventive methodology, has allowed us to locally study the advantages and drawbacks of their operation in scenarios involving flammable gases.

The simulation of an LOCA-type scenario shows the effectiveness of the conventional use of safety systems for managing DBAs, providing a fast depressurisation and temperature decrease. Nevertheless, the continuous use of these systems during the accident and their cooling effect may result in a significant safety issue in the presence of hydrogen.

As the present study shows, PARs are crucial to address sequences involving safety systems, due to their capabilities to effectively remove the hydrogen clouds inside the containment in a few hours for the cases shown. However, their operation, which strongly depends on recombination capacity and location, may not mitigate some flammable clouds, which may persist for a longer time in isolated zones or components, such as FCs and ducts. For this reason, an operation strategy of systems based on the monitoring of containment atmospheric conditions would be a step forward towards safety in conventional PWR NPPs. The new strategies could be based on a method for detecting flammable gases or on a method for maintaining steam pressure above inerting conditions inside the CAS. The choice of method should depend on the utility company and the resources available.

ABSTRACT

In the exhaust ventilation path of the vacuum vessel pressure suppression system in the ITER fusion reactor, the possibly present hydrogen shall be removed by a hydrogen mitigation system utilizing catalytic recombination. For this application, the Framatome passive autocatalytic recombiner (PAR) technology, as used in fission plants, was adapted.

On one side, Framatome has an in-house developed and fully nuclear qualified catalytic material, reducing overall physical uncertainties and supply chain issues. On the other side, the anticipated application of the catalytic recombiner in ITER significantly deviates from the application of PARs in nuclear fission plants, causing new phenomena to dominate the catalyst behavior.

For the application in ITER, a corrugated catalyst carrier was selected and experimentally charactered at lab-scale. Based on the obtained experimental data, an engineering correlation was constructed, allowing a numerical representation of this component in integral simulations. The validation of the correlation on full-scale tests is pending.

KEYWORDS
Hydrogen, Tritium, Passive Autocatalytic Recombiner, PAR, Wet recombiner, WRC

1. INTRODUCTION

In the ITER fusion reactor, certain accident sequences may release hydrogen, especially due a water ingression into the vacuum vessel. There, a redox reaction between water and the hot metallic vacuum vessel walls or present metallic dust may reduce water to hydrogen. To prevent an overpressure damage to the vacuum vessel, the vacuum vessel atmosphere is discharged into a pressure suppression system. To minimize a hydrogen combustion risk within the pressure suppression system, it is ventilated by a heating, ventilation, and air conditioning system (HVAC). At the exhaust of the ventilation system, the hydrogen shall be recombined, and the subsequent steam condensed for the following reasons:

- Safety function: Exclude any gas combustibility in the subsequent HVAC system
- Safety function: Minimize the release of radioactive material (tritium) from the plant
- Operational Function: Recover tritium in the condensate to be reused as fusion fuel

To counteract an accumulation of hydrogen within the containment of a nuclear fission plant during a severe accident with core damage, passive autocatalytic recombiners (PAR) were invented [1], developed, and qualified to nuclear standards [2] [3] by Framatome (as successor of Siemens Kraftwerk Union / AREVA). Due to the highly reliable performance in tests, the proven resistance against poisoning [4] and due to the extensive qualification [5] and test program [6], the availability of Framatome PAR during a nuclear incident or accident is broadly accepted by regulatory institutions.

For PARs in fission plants, the catalytic material is carried by numerous thin stainless-steel plates [5]. The coated steel plates are arranged vertically in a drawer at the bottom end of a larger metal housing, see Figure 1(left). These housings are then installed in the containment of a fission nuclear plant. In case of the presence of hydrogen, the natural convection through these housings draws the gases into the catalytic region. To not impede the natural convection flow, the packing of the catalyst plates is rather loose, resulting in a larger system size, which, however, is not an issue as large space in a nuclear fission plant containment does not impose restrictive size constraints.

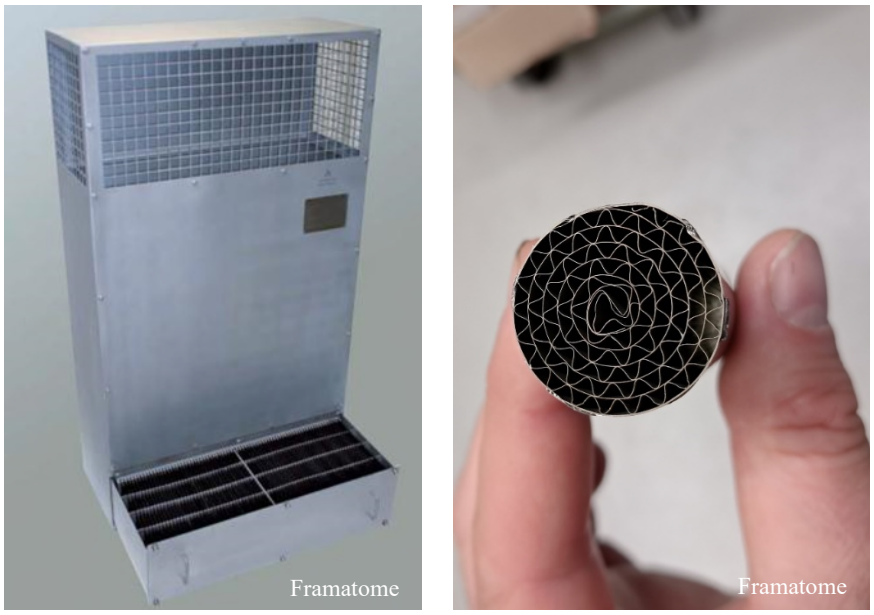

Figure 1. Comparison of plate-type PAR (left) and corrugated WRC (right)

For the application in the fusion plant ITER, Framatome proposed to use the same well-developed, characterized, and validated catalytically active material as used on the plate-type PAR. However, the recombiner shall be installed within a closed HVAC system, which enforces a defined volume gas flow. Therefore, instead of plates, a corrugated cylindrical stainless-steel structure is chosen as carrier structure, see Figure 1(right). This carrier geometry increases the active surface area per volume, shrinking the component size to facilitate the installation in a closed cylindrical pipe or vessel. An unavoidable disadvantage of this design is that it doesn't allow for a visual inspection of the catalytic surface anymore, which was possible in plate-type PARs.

In the following text, the different catalyst applications and designs are labelled as "plate-type PAR" in fission plants and "corrugated wet recombiner (WRC)" in fusion plants respectively.

Plate-type PARs in a nuclear fission reactor containment must operate under a wide range of atmospheric conditions. In contrast, the corrugated WRC in ITER will operate under much more defined conditions. However, these conditions can significantly deviate from the accidental conditions in a fission plant:

- Low concentrations of hydrogen ≤ 8% in normal air
  (i.e. oxygen is always in excess, no transition to oxygen starvation)

- Low inflowing gas temperatures 30°C – 60°C
  (defined by the temperature of the scrubbing liquid in the pressure suppression system and an electric heating register prior WRC entry)
- Humidity of up to 100%
  (due to the scrubbing in the suppression tanks)
- Operation at sub-atmospheric pressures
  (0.75 to 1 bar-abs instead of 1 to 6 bar-abs for plate-type PAR – not expected to make significant impact, see Reference [8])
- Externally defined flow velocity 0.5 m/s to 1.2 m/s
  (forced flow conditions instead of the natural convection through a plate-type PAR, albeit the flow velocities do not differ much)
- Absence of strong catalyst poisons like carbon monoxide
  (also other materials possibly acting as catalyst poisoning must be considered)

To characterize the performance of the corrugated WRC, lab-scale experiments were performed, see Chapter 2. Based on that characterization, a numerical representation of the corrugated WRC was developed (compare Chapter 3) to credit the component in numerical system simulations.

Note that all statements within this work are only valid for the catalytic material of the nuclear vendor Framatome. No claims about catalytic recombination at other materials are made. Experimental evaluation of different catalysts, e.g., in Phebus, showed that catalytic materials of different origin are not interchangeable, neither in performance nor in reliability.

2. LAB-SCALE EXPERIMENTS

The lab scale experiments to characterize the corrugated WRC were performed at the VB265 facility, see Figure 2, located at the Framatome Technical Center Karlstein. The Framatome Technical Center is accredited according to DIN EN ISO/IEC 17020 & 17025.

Figure 2. Photo of the VB265 facility at the Framatome Technical Center Karlstein

In the VB265 vessel facility, a stack of four corrugated WRC cartridges was exposed to specified environmental conditions, and a defined gas volume flow forced through the WRC stack. A test matrix was developed, to exposes the WRC to conditions enveloping the conditions expected in the pressure

suppression system of the ITER, to test for poisoning, ageing, and delayed light-off of the catalyst. A typical test result can be seen in Figure 3.

After a calibration phase, environmental air is forced through the WRC cartridge stack. At t=0s, the atmosphere from the VB265 vessel, having a high humidity and a predefined hydrogen content, gets discharged through the WRC. The catalyst reacts to the incoming hydrogen-containing gas. However, due to its low reactivity at low temperatures, and the cooling effect of the forced flow gas, the catalyst shows a certain startup delay. This will be elaborated in more detail later.

After light-off of the catalyst, the hydrogen concentration in the exhaust drops down to the measurement limit hydrogen (~0.02 vol%). Interestingly, already the first WRC cartridge fully consumes all incoming hydrogen, Thus, in steady-state operation, the first cartridge becomes the hottest. The temperatures of the subsequent WRC cartridges are given by the heating via the hot exhaust gases and the radial heat losses out of the WRC mounting pipe. Note that this is a different behavior of the corrugated WRC in comparison to the plate-type PAR.

In the Framatome plate-type PAR design for fission plants, the limiting factor is the gas transport from the reactor containment onto the catalytic surface [7]. Gas is transported into the PAR housing by a convective gas flow, created by the draught within the PAR housing. Additionally, within the PAR housing, the oxygen and hydrogen molecules must diffuse out of the gas phase onto the catalytic plates. Overall, for hydrogen gas concentrations >1 vol%, this leads to a gas flow velocity of typically 1 m/s through the PAR and a recombination efficiency of ~50% (i.e. half of the hydrogen entering the PAR housing leaves the PAR housing unrecombined). This is consistently observed e.g. in the THAI experiments [9]. The spacing of the catalytic plates in the PAR housing, see Figure 1(left), are a trade-off to keep the hydraulic distances large, not impeding the convective gas flow, and keeping the required gas diffusion length as short as possible.

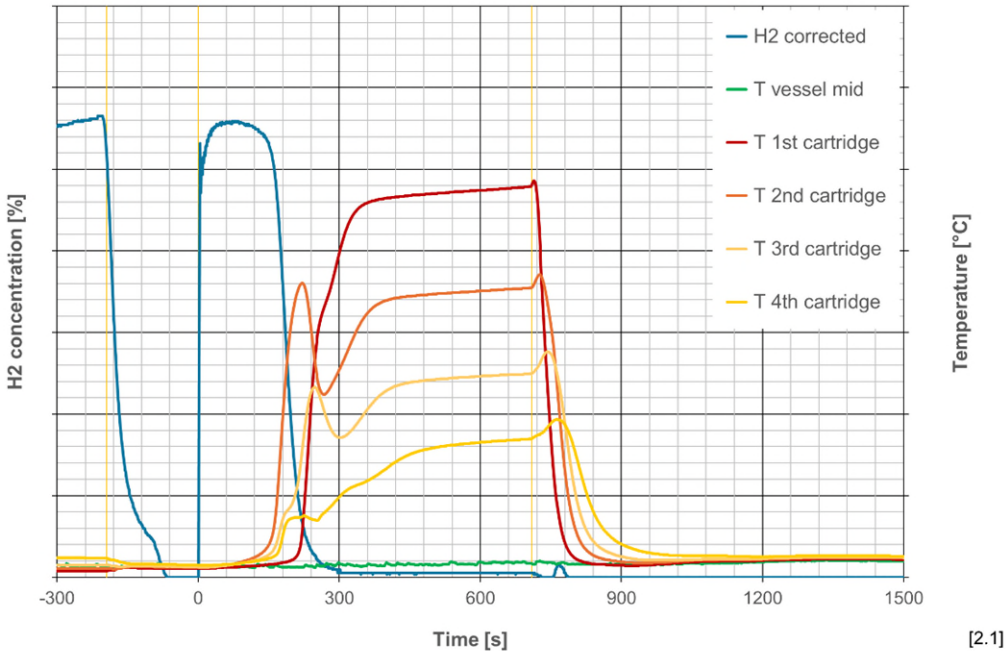

Figure 3. Hydrogen concentration and cartridge temperatures (Experiment 2.1)

In the corrugated WRC, the gas is transported into the cartridges by a forced flow. There is no need to keep the hydraulic distances large. This corrugated carrier design offers a larger catalytic surface/volume ratio, improving the molecular transport onto the surface linearly, but it also reduces the required gas diffusing length, generating an exponential leverage. Thus, after WRC startup, already a single corrugated WRC

cartridge consumes practically all incoming hydrogen. This was later confirmed by using only a single cartridge instead of a stack of four.

3. COMPUTATIONAL MODEL OF THE CORRUGATED WRC

For the deduction of an engineering correlation, the experimental raw data, especially the hydrogen measurement was adapted to correct for measurement artefacts and finite detector responsiveness. Based on the refined data, the following engineering correlation is constructed, relating the hydrogen concentration x_{ex} (in vol%) in the exhaust of the corrugated WRC, to the inlet hydrogen concentration x_{in} as

$$x_{\mathrm{ex}} = x_{\mathrm{in}} \cdot \left(1 - c_{\mathrm{start}} \cdot c_{\mathrm{delay}} \cdot c_{\mathrm{stop}}\right). \quad (1)$$

The unitless factor c_{start} describes the ability of the WRC catalyst to light-off (see Chapter 3.1), the factor c_{delay} describes the WRC startup delay (see Chapter 3.2), and the factor c_{stop} describing the shutdown of the WRC at low hydrogen concentrations (see Chapter 3.3). These factors are binary, i.e. have a numerical value of either zero or one. Mathematically, c_{delay} fully envelopes c_{start}, so that latter factor could be omitted. However, the separate consideration of these factors makes the deduction of this engineering correlation in the following subchapters more transparent.

The fact that the engineering correlation complies with all evaluated experiments, irrespective of their boundary conditions, can be seen as a nuclear-grade Verification and Validation in accordance to IAEA standards [10] [11]. An additional validation step at full system scale remains to be done.

3.1. WRC Startup Criterion

That the WRC can switch from its off-state into its autocatalytic on-state, the catalyst must be able to heat up. The catalyst temperature is given by the competition of chemical energy release due to the hydrogen recombination and heat losses, mostly by the process gas itself, forced with a defined flow rate though the WRC. If the inlet gas is sufficiently cold or the hydrogen concentration in the gas sufficiently low, the cooling capacity of the forced gas flow can overcome the heat generation on the catalytic surface. Thus, the WRC is unable to startup.

To deduce a criterion when the WRC can startup, the parameter space of inlet gas temperature T_{in} and inlet gas hydrogen concentration x_{in} is shown in Figure 4. The green markers represent experiments where the WRC started up, completely consuming all incoming hydrogen. The yellow markers indicate experiments where the WRC operated instable, but still consumed >50% of the incoming hydrogen. The red markers indicate experiments where the WRC did not consume a significant amount of hydrogen. The markers without boarder indicate experiments with a flow velocity of 1 m/s, and the markers with black boarder indicate experiments with 0.5 m/s flow velocity.

As the temperature reached within the WRC should depend linearly on the initial gas temperature and on the hydrogen concentration, a straight line (red-dashed line in Figure 4) should split the parameter space into an active and an inactive zone. Further, the equivalence of 1 vol% hydrogen to 80 K heat-up should define the inclination of the line separating the parameter. Thus, only the lateral positioning of the line is fitted to the available data. Based on the available data in Figure 4, the WRC startup criterion c_{start} is proposed as

$$c_{\mathrm{start}} = \begin{cases} 1 \text{ if } T_{\mathrm{in}} > \left(\boldsymbol{T}_{\mathrm{Start}} - \dfrac{80\ \mathrm{K}}{1\ \mathrm{vol\%}} \cdot x_{\mathrm{in}}\right) \\ 1 \text{ if start criterion was reached before}' \\ 0 \text{ otherwise} \end{cases} \quad (2)$$

with $\boldsymbol{T}_{Start}$ as only free fit parameter.

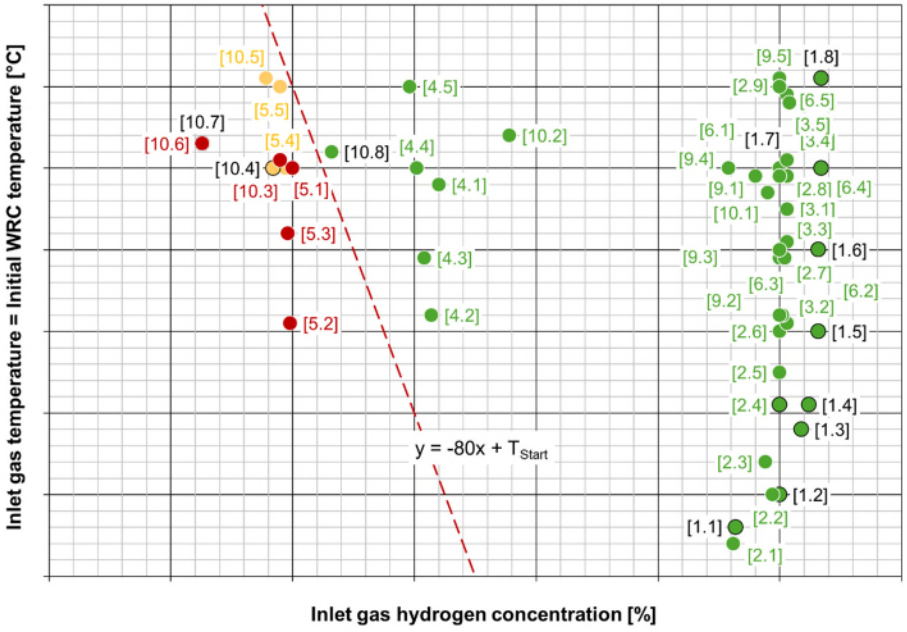

Figure 4. Parameter space for WRC startup

3.2. WRC Startup Delay & Hydrogen

In the lab-scale experiments, when the cartridge inlet valve is opened, hydrogen rushes through the WRC cartridges. Usually, in the initial time after valve opening, hydrogen is recorded in the exhaust gas stream. The WRC first must heat up to be able to consume all the inflowing hydrogen. Thus, even though the boundary conditions would allow for a WRC startup, a WRC may exhibit a certain startup delay during which hydrogen breaks through.

This startup delay is related to the low heating power of the catalyst in its autocatalytic off-state, the heat capacity of the WRC carrier material and mounting pipe, the radial heat loss of the carrier mounting pipe, as well as possible humidity and other contaminants attached to the catalytic surface. Based on the experiences with plate-type PARs, it is expected that especially the experimentally unknown surface contaminations of the catalyst lead to significant uncertainty regarding the startup delay.

In the THAI experiments it can be observed that a plate-type PAR only exhibits a noticeable startup delay if the PAR was not active before in the respective experimental day. This is interpreted that when the PAR was active before, it burned away the surface contaminations. In Reference [7], an energy criterion is proposed for the PAR startup delay.

For the lab-scale experiments, the WRC cartridges were pre-aged for each experimental series. Thus, the 1st test point of each testing day may be more representative for the WRC startup delay than the subsequent experiments. The following observations were made during the experimental campaign:

- The startup delay increases for lower inlet gas temperatures
- There is an inlet gas temperature $\mathbf{T}_D$, where any WRC startup delay vanishes.
- The startup delay increases for lower inlet gas hydrogen concentrations

- For some test series, the pre-ageing of the cartridges has a noticeable impact. However, the inlet gas temperature seems to have a stronger impact than the fact that the cartridges were pre-aged.
- Series 1 shows a constant startup delay of ~70 s for high inlet gas temperatures. This is an artefact of the experimental procedure, which was changed in the subsequent experimental series.
- The data show a significant spreading also for situations where the boundary conditions are equivalent.
- For high hydrogen concentrations (Series 7 and Series 8), practically no hydrogen breakthrough is seen. With sufficient hydrogen available, the WRC starts up faster than the responsiveness of the hydrogen measurement equipment.

For constructing a numerical description of the WRC startup delay, the following assumptions were made.

- The catalyst temperature is the relevant criterion for start of the hydrogen consumption.
- The startup delay should diverge in case the WRC cannot operate at all.
- The WRC startup delay shall decrease with increasing distance in parameter space from the startup criterion.
- The WRC startup delay should depend on the actual temperature of the catalyst (determining the surface chemical reaction speed), and not on the inlet gas temperature. If the inlet gas is warmer than the catalyst, the catalyst will rapidly approach the gas temperature due to surface heat transfer. However, if the catalyst temperature is already elevated, then it will likely require a shorter period to switch into the autocatalytic on-state.

From these considerations, the following phenomenological equation for the WRC startup delay $\Delta t_{\mathrm{delay}}$ (in s) is deduced

$$\Delta t_{\mathrm{delay}} = 500\mathrm{s} \cdot \frac{\boldsymbol{T}_{\mathrm{D}} - \max\left(T_{\mathrm{WRC,initial}}, T_{\mathrm{in}}\right)}{\left(T_{\mathrm{in}} + \frac{80\ \mathrm{K}}{1\ \mathrm{vol\%}} \cdot \mathrm{x}_{\mathrm{in}} - \boldsymbol{T}_{\mathrm{Start}}\right)}, \tag{3}$$

with the initial catalyst temperature $T_{\mathrm{WRC,initial}}$ (in °C) when the hydrogen inflow starts (in the experiments equal to T_{in}). The denominator represents the startup criterion in Equation (2), and the numerator represents the temperature the catalyst needs to heat up until no delay is observed anymore. The temperatures $\boldsymbol{T}_{\mathrm{Start}}$ (see Chapter 3.1), $\boldsymbol{T}_{\mathrm{D}}$ (see discussion above), as well as the leading factor of "500 s" are fit parameters.

In Figure 5 the experimentally observed startup delay is plotted versus the delay predicted in Equation (3) as blue marker. To allow for a logarithmic plot, the experiments with no measurable startup delay are indicated as having 5 s startup delay. The red line represents the x=y condition.

For all data points below the red line, Equation (3) conservatively predicts a longer startup delay. For the markers above the red line, Equation (3) underestimates the startup delay. Note that due to experimental limitations, the Series 1 data points (white-filled marker) show a systematic too long measured startup delay. Thus, these data points shall not be considered when judging the accuracy of the correlation. Based on the available data, it can be stated that the startup delay predicted in Equation (3) is either rather accurate or conservatively enveloping the experimentally observed delays. With the knowledge of the WRC startup delay duration, the criterion for the WRC start delay becomes

$$c_{\mathrm{delay}} = \begin{cases} 1 \text{ if } \mathrm{t} > \Delta t_{\mathrm{delay}} \\ 0 \text{ otherwise} \end{cases}, \tag{4}$$

whereby t is the time since start of a hydrogen exposure of the WRC. Note that Equation (4) is deduced for constant hydrogen concentration. For a generalization to variable hydrogen concentrations in the inflow gas

stream, the mathematical approach of a cumulative damage function as e.g. used to describe creep failure can be used.

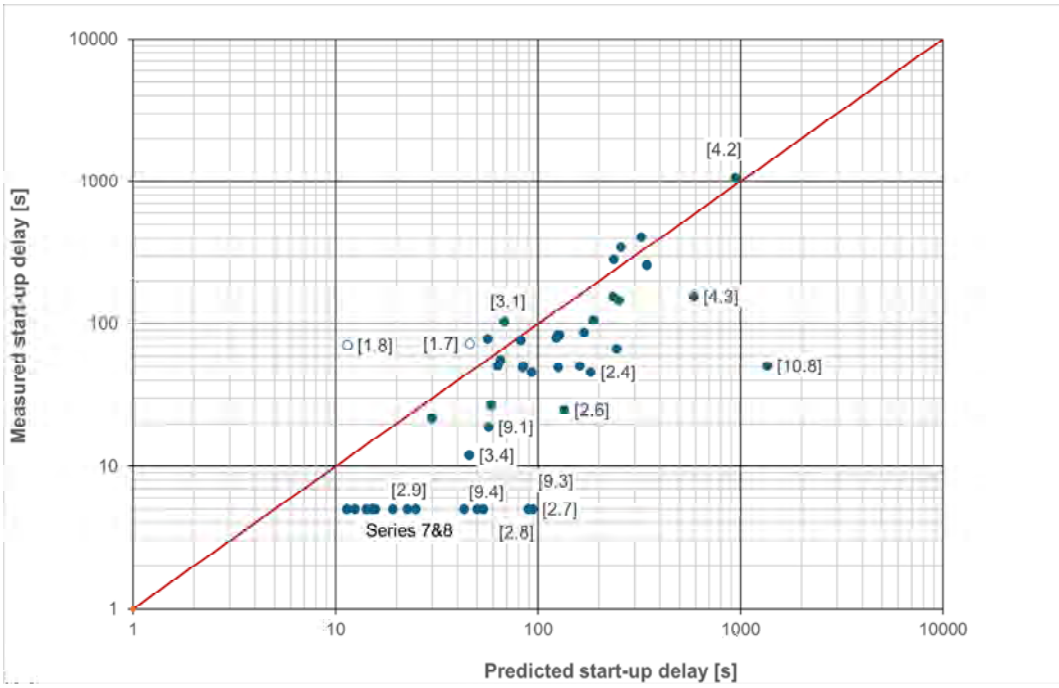

Figure 5. WRC startup delay – comparison observation and prediction

3.3. WRC Shut-down at low Gas Concentrations / Catalyst Temperatures

From the THAI experiments it is known that in case a plate-type PAR is in its autocatalytic on-state, it is hard to bring the PAR in its off-state again as long as even traces of combustible gases are present. As example, in the experiment HR-13, the catalytic foil temperature remained well above ambient temperature even down to ~0.1 vol% hydrogen. The operating characteristics of a plate-type PAR exhibits a certain hysteresis - it remains longer in operation even in circumstances where it would not start up.

To examine the shut-down behavior of a corrugated WRC, the hydrogen concentration was continuously reduced in the inlet gas at the end of Experiment [9.5]. The WRC operated stable down to a hydrogen concentration of ~ 0.4 vol% at an inflowing gas temperature of ~54°C. Thereafter, hydrogen started to leak through the WRC. And at an even lower hydrogen concentration, the WRC started to be come inactive altogether.

For the engineering correlation of the corrugated WRC, it is conservatively assumed that the WRC stops working entirely when the experiment shows a start of incomplete hydrogen recombination. With the equivalence of 80 K temperature increase per vol% hydrogen consumed, the shut-down criterion c_{stop} is deduced in analogy to the start-up criterion as

$$c_{\mathrm{stop}} = \begin{cases} 0 \text{ if } T_{\mathrm{in}} < \left(\mathbf{T}_{\mathrm{Stop}} - \dfrac{80\ \mathrm{K}}{1\ \mathrm{vol\%}} \cdot x_{\mathrm{in}}\right), \\ 1 \text{ otherwise} \end{cases} \tag{5}$$

with the fit parameter $\mathbf{T}_{\mathrm{Stop}}$. As seen at the plate-type PAR, the corrugated WRC exhibit a certain hysteretic operating behavior as $\mathbf{T}_{\mathrm{Stop}} < \mathbf{T}_{\mathrm{Start}}$, i.e. when started, then the WRC consumes hydrogen also in a

parameter space where it would not be able to start. Note that Equation (5), is based on one experiment only. Thus, a limited validity of this criterion must be considered.

3.4. Absence of WRC Poisoning

Catalytic reactions can be sensitive to poisoning, which could endanger the hydrogen-mitigating function of WRC or PARs. In Reference [7], it was shown that Framatome PAR are highly resistant against especially carbon monoxide, the strongest catalytic poison expected to be present during a severe accident in a fission plant [12]. In a fusion plant, other materials and possible reactor poisons could be present. Therefore, the WRC performance was tested under the influence of

- noble gases (He, Ar, Ne),
- tungsten dust (e.g. ablated from the vacuum vessel walls),
- SF_6 as Sulphur-containing compound, and
- hydrazine from water conditioning.

The lab-scale test results show no noticeable impact of these contaminant materials on the WRC operation, within the overall experimental uncertainties. Based on this result, the engineering correlation for the corrugated WRC does not consider poisoning by these materials.

4. CONCLUSIONS

For the ITER fusion plant, the ventilation exhaust of the vacuum vessel pressure suppression system shall be equipped with an autocatalytic wet recombiner (WRC) to convert possible present hydrogen into steam. For this application, a newly designed corrugated carrier structure was coated with the proven and nuclear qualified Framatome catalytic material which is used on the passive autocatalytic recombiner (PAR) for fission plants. The choice for this design is based on the extensive operating experience of Framatome PARs, and the existing nuclear-qualified supply chain.

A lab-scale experimental campaign was conducted to explore the operating characteristics of the WRC, its compliance with bounding environmental conditions in a fusion plant, and its resistance against contaminants possibly present in a fusion plant. Overall, the WRC operated better than initially expected and showed no noticeable impact (within the experimental accuracy) to the tested contaminants.

Based on the experimental results, a phenomenological correlation for the WRC was developed. This correlation describes the impact of temperature and hydrogen concentration of the inflowing gas on the WRC operation, and defines criteria for WRC startup, startup delay, and shutdown.

The fact that the engineering correlation complies with all evaluated experiments, irrespective of their boundary conditions, can be seen as a nuclear-grade Verification and Validation in accordance to IAEA standards [10] [11]. A validation at a full-sized system remains to be done.

Note that all statements within this report are to be considered valid only for catalyst material and catalyst carrier design from the nuclear supplier Framatome. No statements concerning reliability or performance can be made for designs of other nuclear vendors.

Issue

Fusion reactor with magnetic plasma confinement

- Large components not designed against internal pressure
- In case of water coolant LOCA → discharge into pressure suppression system
- Water reaction with vacuum vessel wall / Tungsten dust may generate hydrogen

ITER pressure suppression system design

- Scrubber tanks to condense steam
- Air space of tanks is actively ventilated to dilute hydrogen

→ HVAC exhaust contains possibly hydrogen and tritium

Passive autocatalytic hydrogen recombiner in HVAC exhaust path, with subsequent chiller and condensate recovery

- Safety function: Exclude any gas combustibility in the subsequent HVAC system
- Safety function: Minimize the release of radioactive material (tritium) from the plant
- Operational function: Recover tritium from the condensate to be reused as fusion fuel

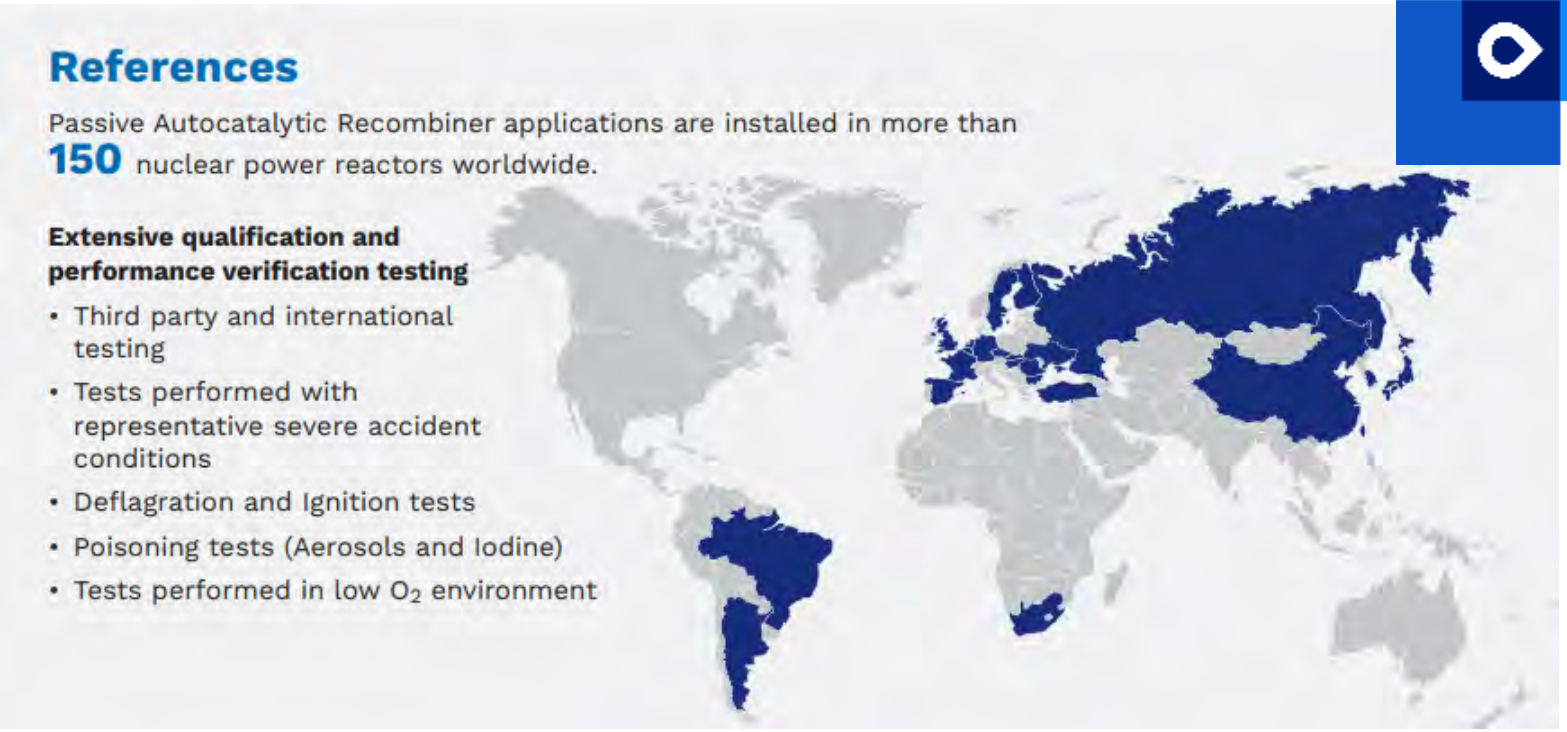
Available Solution



https://www.framatome.com/solutions-portfolio/app/uploads/2025/10/a0642-p-ge-g-en-202405-par.pdf

Framatome PAR Technology

- Nuclear qualified catalytic material - accepted worldwide by nuclear regulators
- Long-term operating experience
- Long history of internal and independent tests (startup, efficiency, ageing, poisoning, ignition)
- Established supply chain

2026 © Framatome – All rights reserved / C1 - Framatome Restricted / Framatome's know-how / Export Control EU EC: DE–N US EC: N

Adaption of Framatome PAR Technology

Changed carrier form-factor – from plates to corrugated geometry

- Forced flow allows for smaller hydraulic diameter
- Size constraint in HVAC system
- No surface inspection possible

Catalyst operating regimes in ITER

- Low concentrations of hydrogen ≤ 8% in normal air
  (flushing of tank air space, no transition to oxygen starvation)
- Humidity of up to 100%
  (due to the scrubbing in the suppression tanks)
- Low gas temperatures 30°C – 60°C
  (cold scrubbing liquid, possible pre-heating)
- Operation at sub-atmospheric pressures
  (0.75 to 1 bar-abs instead of 1 to 6 bar-abs in NPP)
- Externally defined HVAC flow velocity 0.5 m/s to 1.2 m/s
  (forced flow conditions instead of the natural convection)
- Absence of strong catalyst poisons like carbon monoxide
  (other materials possibly acting as catalyst poisoning)

Small-Scale Test Facility

Testing at Framatome Technical Center Karlstein

- Accredited according to DIN EN ISO/IEC 17020 & 17025.
- Stack of four 5 cm diameter scaled catalyst carrier cartridges
- Fixed boundary conditions (H2 concentration, flow velocity, temperature, humidity)

2026 © Framatome – All rights reser

Small-Scale Test Campaign

Typical Test

- Flushed with humid cold air
- At t=0, co-mixing of hydrogen
- After catalyst light-off
  - H2 drops to zero in exhaust
  - Cartridges heat up
- Shut-down of H2, and flushing

Complete consumption of H2

- In NPP-PARs ~ 50%
- Corrugated carrier → smaller diffusion length

Cartridge Temperature

- Not always the first cartridge starts first
- After stabilization, first cartridge is hottest
- Temperature gradient over cartridges
  → First cartridge consumes all H2
  → High lateral heat loss in experiment

Summary

- **Framatome PAR technology was adapted to needs in ITER pressure suppression system**
- **Main changes**
  - Change of carrier form plates to corrugated structure
  - Forced flow boundary condition
  - Colder gas
- **Smal-Scale test campaign was executed to numerically characterize the component**
- **No poisoning with fusion-related materials observed**
- **Fusion pressure suppression systems very similar to filtered containment venting system [1]**
  - Industrial base available
  - Nuclear qualified components

ABSTRACT

The long-term leaching of the corium formed during a severe nuclear accident will partly depend on the integrity of the corium matrix. One of the major matrix constituents of the corium is UO_2 which in general has relatively low solubility. However, when oxidized to U(VI), the material is more readily dissolved. This will facilitate the release of radiotoxic fission products and heavier actinides. Ionizing radiation emitted from the corium induces water radiolysis and thereby creates oxidizing conditions. The aqueous radiolysis product primarily driving oxidative dissolution of UO_2 is H_2O_2.

The rate of matrix dissolution is also influenced by corium composition as well as by solutes present in the water. A major corium constituent is Zr from the fuel cladding. In this work we have explored the reactivity of a mixture of UO_2 and ZrO_2 towards H_2O_2. The results show that the dissolution of U(VI) from UO_2 decreases with increasing amount of ZrO_2. This is attributed to competing reactions between H_2O_2 and UO_2 on one hand and between H_2O_2 and ZrO_2 on the other hand.

Water in contact with corium may contain borate/boric acid. For this reason, we also explored the impact of boric acid/borate on the H_2O_2-induced oxidative dissolution of UO_2. The results show that borate/boric acid reduces the reactivity of UO_2.

The mechanistic reasons behind these observations will be discussed.

1. INTRODUCTION

The global energy demand is increasing constantly and considering the limitations in the fossil fuel reserves and the environmental impact of burning fossil fuels, the need to move towards alternative and more clean energy sources like nuclear power, is strong. Nuclear power offers advantages, like low greenhouse gas emissions and stable long-term energy production among others.

However, there are also significant challenges such as handling of the extremely long-lived radioactive waste and the risk of severe accidents including loss of coolant accidents (LOCA). Although extremely rare, loss of coolant accidents can result in partial or complete melting of the nuclear reactor core and subsequent release of radionuclides into the environment.

A loss of coolant accident occurs when there is a total loss or significant reduction of coolant in the reactor coolant system. This loss may occur for different reasons. Even after reactor shutdown, radioactive decay continues to generate heat, thereby increasing the temperature in the core [1]. If this excess of heat is not removed effectively, it can lead to partial or total core meltdown [1].

If the core melts, the resulting high density and high temperature mass can break the reactor vessel and reach the concrete cavity underneath. The interaction between the concrete and the corium will cause ablation [1].

The composition of the molten core, or corium, can vary depending on different factors such as the reactor and cladding materials and the type of reactor, the progression of the accident and the phyisico-chemical transformations that occur during the accident. Hence, corium is not a well-defined material. For light water reactors (LWR), the main constituents are UO_2 from the fuel and Zr/ZrO_2 from the fuel cladding [1]

Boric acid is used in specific nuclear reactors, like pressurized water reactors (PWR) to control the reactivity of the core. Since boric acid absorbs neutrons, it regulates the fission reaction and thereby the power output [2]. Boron compounds (sodium borate) can also be used as corrosion inhibitors in the secondary circuit of PWRs [3]. In addition, boron plays a key-role in critical emergency situations. In boiling water reactors (BWRs), boron is injected to immediately shut down the reactor [3].

In the case of a severe nuclear accident, the initial phase is normally characterized by the release of volatile radionuclides into the atmosphere and subsequently, the long-term release of radionuclides coming from corium in contact with water [4]. The water in contact with corium can come from different sources, such as groundwater, seawater, or the reactor's cooling systems. The rate of radionuclide release will depend on the composition of both the corium and the contacting water [5] [4]. Most of the radionuclides are incorporated in the UO_2 matrix of the fuel and this applies also in corium. In general, UO_2 has low solubility in water. However, oxidation of UO_2 produces significantly more soluble U(VI) and may therefore drive radionuclide release. After a severe accident, oxidants could be present as a result of intrusion of atmospheric oxygen or simply due to radiolysis of water induced by the inherent radioactivity of corium. Radiolysis of water produces oxidizing species ($HO\bullet$, H_2O_2, and $HO_2\bullet$) and reducing species (e_{aq}^-, $H\bullet$, and H_2) [6].

In research focusing on dissolution of UO_2-based spent nuclear fuel under deep repository conditions it has been shown that H_2O_2 is the primary oxidant. It is therefore reasonable to assume that H_2O_2 plays a major role in the dissolution of corium as well [7] [6]. H_2O_2 reacts with UO_2 through dissociative adsorption producing surface-associated hydroxyl radicals. These reactive species can oxidize UO_2 directly or react with additional H_2O_2 to form $HO_2\bullet$, ultimately producing H_2O_2 and O_2. This sequence of reactions leads to the catalytic decomposition of H_2O_2, like processes observed on other oxide surfaces [7] [8]

In this work we have explored the mechanism and kinetics of H_2O_2-induced dissolution of UO_2 in systems containing ZrO_2 and boric acid/borate

2. EXPERIMENTAL

All aqueous solutions were prepared using ultrapure water obtained from a Millipore Milli-Q system. The UO_2 powder used in the experiments was supplied by Westinghouse AB (specific surface area to be specified). Hydrogen peroxide (30 wt%, Merck KGaA, Lot K52822909 040) was diluted from the stock solution to obtain a working concentration of 0.2 mM. ZrO_2 powder was obtained from Aldrich Chemistry (CAS 1314-23-4; particle size 5 μm; 99% purity, trace-metal basis).

Sodium bicarbonate ($NaHCO_3$; Merck KGaA, Lot K31463629 304; ACS reagent grade) was used to prepare the bicarbonate buffer. Ammonium acetate (CAS 631-61-8, ≥99%), potassium iodide (CAS 7681-11-0, Merck KGaA), and ammonium phosphomolybdate ($(NH_4)_3PMo_2O_7$, ≥99.0%, CAS 12054-85-2) were used as reagents in the analytical measurements.

All experiments were conducted under the same experimental conditions. A known mass of UO_2 powder (40 mg) using an analytical balance (Mettler Toledo AT261; capacity 0–200 g; readability 0.1 mg and 0.01 mg) was accurately weighed and introduced into a 50 mL sealed vial under a nitrogen atmosphere to prevent unwanted oxidation.

Prior to initiating the reaction, the UO_2 powder was washed with a 10 mM sodium bicarbonate solution to remove any pre-oxidized surface layers. Immediately before starting the experiment, the washing solution was discarded and replaced with 15 mL of a 10 mM sodium bicarbonate solution containing borate/boric acid at the desired concentration (0, 20, 80, 120, 160, or 300 mM). In the experiments with ZrO_2, borate/boric acid was not present. The amounts of ZrO_2 powder used in the experiments were 1.0,

1.2, 1.8, and 2.4 g. The ZrO_2 powder was added to the vial after the washing of the UO_2 powder had been completed and before the reaction solution was added. It should be noted that the ZrO_2 and UO_2 powders were used as separate powders and were physically mixed in the vial; no mixed $(Zr,U)O_2$ solid solution was prepared or used in these experiments.

Subsequently, 15 mL of a 0.4 mM H_2O_2 solution—prepared in 10 mM sodium bicarbonate and containing the same borate/boric acid concentration as the reaction medium—was added to the powder suspension to initiate the reaction (total volume 30 ml). All experiments were conducted under continuous nitrogen purging, with continuous stirring at 950 rpm using a magnetic stirrer and temperature control maintained at 25 °C using a thermostated water bath.

Liquid samples were withdrawn at predetermined time intervals for analysis. 1 mL aliquots were withdrawn using a 5 mL medical syringe fitted with a needle. The samples were immediately filtered through 0.22 μm cellulose acetate syringe filters. Aliquots of 100–200 μL of the filtered solution were subsequently used for quantitative analysis of uranyl and hydrogen peroxide.

Hydrogen peroxide concentrations were determined using the Ghormley triiodide method [9], [10]. In this method, iodide ions (I^-) react with H_2O_2 to form triiodide (I_3^-) in the presence of potassium iodide and a catalyst mixture consisting of ammonium phosphomolybdate, acetic acid, and sodium acetate. The absorbance of I_3^- was measured at 360 nm using a Thermo Fisher Scientific, Model 4001/4 UV-vis spectrophotometer. Each measurement was performed by mixing 0.100 mL of filtered sample, 0.100 mL of catalyst solution, 0.100 mL of KI solution and dissolved with water until 2ml [9], [10].

U(V) is known to undergo disproportionation in solution, yielding U(IV) and U(VI). In addition, no interactions between U(V) and HCO_3^-/CO_3^{2-} species, nor direct dissolution of U(V), have previously been reported. Therefore, only U(VI)-Arsenazo complexes were considered in the measurements [11] [12], [13].

Uranyl concentrations were measured using the Arsenazo III spectrophotometric method [14] , [15]. The analysis was performed by adding 1 $mol \cdot L^{-1}$ HCl and 0.16% (w/v) Arsenazo III reagent to the filtered samples. The measurement solution consisted of 0.40 mL Arsenazo III reagent, 0.60 mL HCl, 0.200 mL of filtered sample, and Milli-Q water added to a final volume of 1.6 mL. The resulting colour intensity, measured at 653 nm, is directly proportional to the uranium concentration. Uranyl concentrations were quantified using a calibration curve constructed from standards of known uranyl concentration [14], [15].

3. RESULTS AND DISCUSSION

3.1 Impact of ZrO_2

The concentrations of uranyl and hydrogen peroxide were monitored as a function of reaction time for pure UO_2 powder suspensions and for mixed UO_2/ZrO_2 powder suspensions. At the bicarbonate concentrations used in these experiment (10 mM), U(VI) is rapidly and quantitatively dissolved due to the formation of soluble carbonate complexes. In figure 1, the uranyl and hydrogen peroxide concentrations are given as function of time for the UO_2/ZrO_2 powder suspension containing 1.2 g ZrO_2.

.

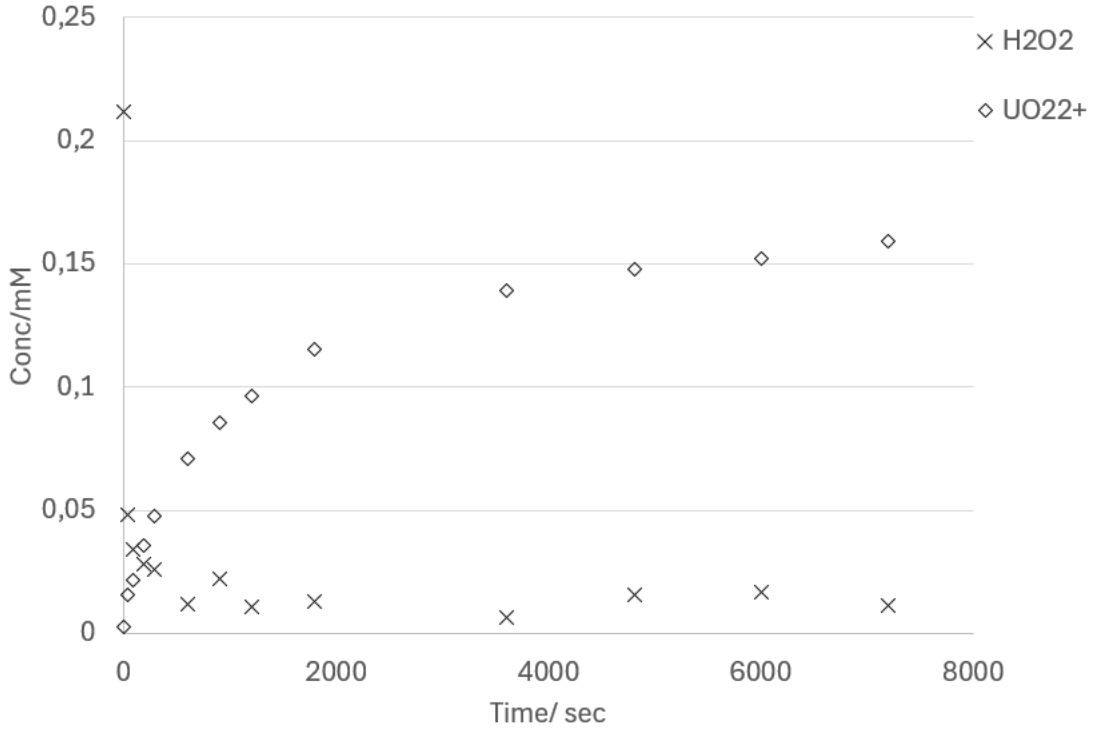

Figure 1: Concentrations of Uranyl dissolution (square) and hydrogen peroxide consumption concentrations (cross) as a function of time for powder suspensions 40 mg of UO_2 and powder suspensions 1.2 grams zirconium dioxide in presence of 10 mM HCO_3^- and 0.2mM H_2O_2.

In a real scenario involving corium–water interactions, radiolysis initially generates H_2O_2, causing its concentration to increase from zero over time. Eventually, the system reaches a steady-state where the rate of H_2O_2 production equals the rate of its consumption through chemical reactions of which one is the reaction with the corium surface.

As can be seen, in the experiments where hydrogen peroxide was added initially, the hydrogen peroxide concentration decreases very rapidly while the release of uranyl is significantly slower. In a system containing only UO_2, two competing reactions involving hydrogen peroxide can occur on the UO_2 surface. The surface-bound hydroxyl radicals formed upon adsorption of H_2O_2 can either oxidize UO_2 resulting in dissolution or react with H_2O_2 resulting in catalytic decomposition of H_2O_2. The latter reaction is favoured by higher H_2O_2-concentration. At 0.2 mM H_2O_2, catalytic decomposition on UO_2 powder is negligible [7], [8]. The mechanism is summarized below:

$$H_2O_2 + 2\ UO_2 \rightarrow 2\ HO\bullet —UO_2 \quad (1)$$

$$H_2O_2 + HO\bullet —UO_2 \rightarrow HO_2\bullet + H_2O + UO_2 \quad (2)$$

$$HO_2\bullet + HO_2\bullet \rightarrow H_2O_2 + O_2 \quad (3)$$

$$HO\bullet —UO_2 \rightarrow OH^- + UO_2^+ \quad (4)$$

ZrO_2 is also known to react with H_2O_2 [16] In this case, the only possible reaction is catalytic decomposition of H_2O_2 (corresponding to reaction 1-3), since Zr cannot be oxidized beyond Zr (IV). The expected effect of mixing UO_2 and ZrO_2 is therefore decreased dissolution of uranyl since part of the H_2O_2 will be consumed by ZrO_2. In

figure 1 we can see that the concentration of dissolved uranyl is lower than the initial H_2O_2 -concentration. This is, at least qualitatively, what would be expected from competition kinetics.

In figure 2, the normalized hydrogen peroxide concentration is plotted as a function of reaction time for a pure UO_2 powder suspension and for UO_2/ZrO_2 powder mixtures containing 1.0, 1.8 and 2.4 g ZrO_2, respectively. All suspensions contain 40mg of UO_2.

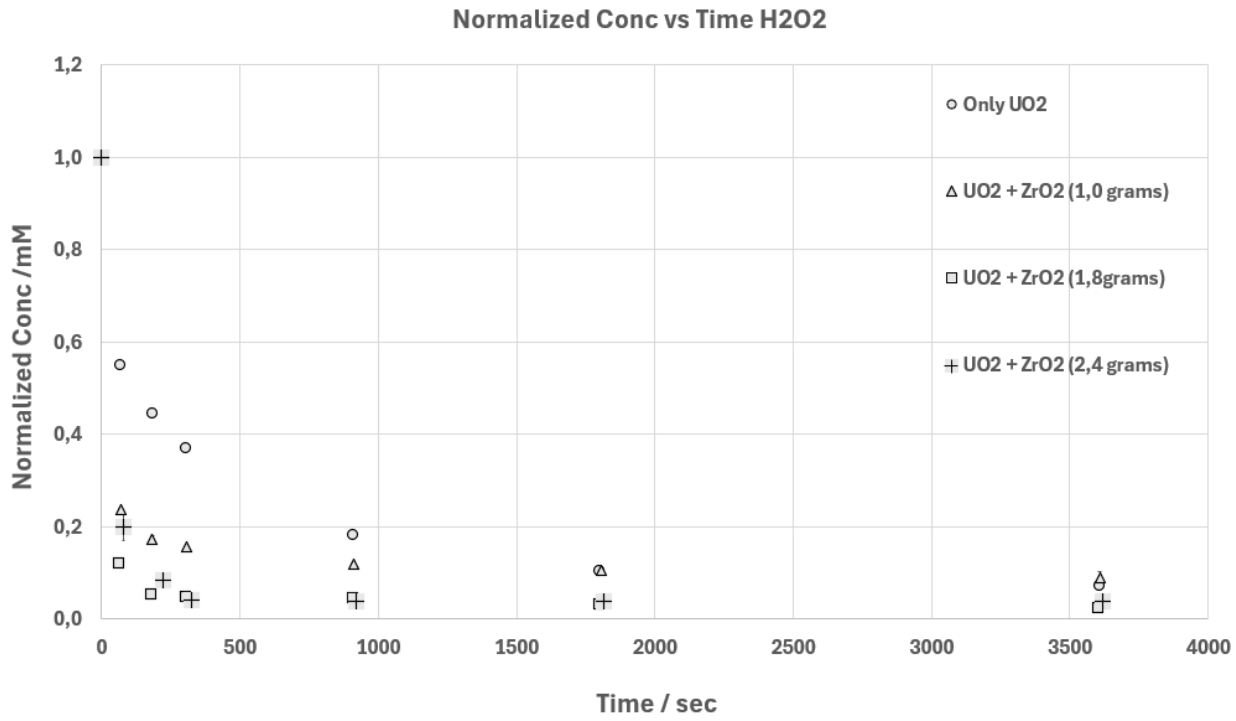

Figure 2: Normalized hydrogen peroxide consumption concentrations as a function of time for systems with powder suspensions of 40 mg UO_2 and with different quantities of zirconium dioxide powder suspensions 1,0grams, 1,8grams and 2,4grams and without, in presence of 10 mM HCO_3^- and 0.2mM H_2O_2.

The graph clearly shows that the rate of H_2O_2-consumption increases in the presence of ZrO_2 powder. Again, this is what would be expected from competition kinetics. Judging from the plot, the rate of H_2O_2 consumption increases with the amount of ZrO_2 although this trend cannot be quantified based on the present data.

The competition between UO_2 oxidation and catalytic decomposition of H_2O_2 in these systems can be quantified using the so-called dissolution yield[17] The dissolution yield is the ratio between the amount of dissolved uranyl and the amount of consumed H_2O_2. In a system with only oxidation the dissolution yield is 100 %. The final dissolution yields for the systems under study here are presented in Table 1.

Table 1: Percentage of dissolution yield of Uranyl in the different systems with different concentrations of ZrO_2.

System	% Dissolution yield
UO_2	95.9
UO_2 + ZrO_2 (1,0gram)	80.2
UO_2 + ZrO_2 (1,8gram)	68.1
UO_2 + ZrO_2 (2.4gram)	47.6

As expected, the dissolution yield decreases with increasing amount of ZrO_2. In a recent study, Kumagai et al., studied H_2O_2-induced oxidation of UO_2 in UO_2/ZrO_2 powder mixtures produced from crushed

pellets that were originally produced from mixtures of UO_2 and ZrO_2 oxide powders pressed and sintered at 2023 ± 10 K for 6 h under an Ar atmosphere [18]. These mixtures are solid solutions. At a UO_2/ZrO_2 powder mass ratio of 1:25 (corresponding to 1 g of ZrO_2 in our system), very little uranyl dissolution was observed, and the dissolution yield was close to 0 %. In the present study, the dissolution yield under the same conditions is around 80 %. A dissolution yield of 80 % for a powder mixture is well in line with what can be expected from competition kinetics. The reduced dissolution yield at higher ZrO_2/UO_2-ratios is also in line with competition kinetics. The discrepancy between the results presented here and the results presented by Kumagai et al., [18], can most probably be attributed to the fact that a solid solution of UO_2/ZrO_2 powder displays a different reactivity towards H_2O_2 as compared to the UO_2/ZrO_2 powder mixture. Previous studies of the reactivity of solid solutions of UO_2 and other oxides have shown that the solid solutions are much less redox active than pure UO_2 [19], [20]. As shown above, catalytic decomposition of H_2O_2 on oxide surfaces produces O_2, which is also capable of oxidizing UO_2. However, the powders suspensions studied in this work are continuously purged with N_2, which will rapidly remove the O_2 from the system. Hence, the reduced dissolution yields at increasing ZrO_2/UO_2-ratios.

3.2 Impact of Borate/Boric acid

Boric acid/borate has long been assumed not to interfere significantly with aqueous radiolysis products. However, recent studies have shown that boric acid/borate displays reactivity towards hydroxyl radicals [21]. It is also known that boric acid/borate forms complexes with hydrogen peroxide [22] and this may also influence oxidative dissolution of corium as well as spent nuclear fuel. In figure 3 the normalized H_2O_2 concentration is plotted as a function of reaction time for UO_2 suspensions containing different concentrations of borate/boric acid.

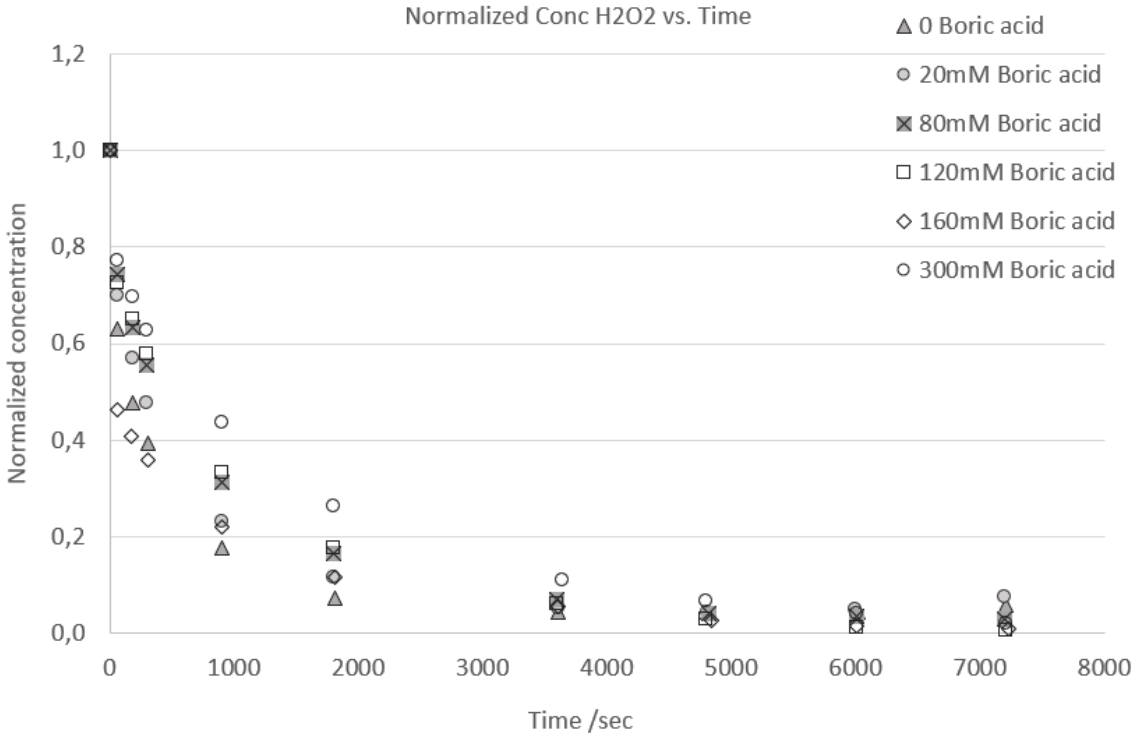

Figure 3: Normalized hydrogen peroxide consumption concentrations as a function of time for systems with powder suspensions of 40 mg UO_2 in presence of 0.2mM H_2O_2, 10 mM HCO_3^- and different concentrations of boric acid in each system (no boric acid, 20mM, 80mM, 120mM, 160mM, 300mM).

The difference in the rate of H_2O_2-consumption between the different borate/boric acid concentrations is very small and no trend can be established with statistical significance. However, it is quite clear that

the H_2O_2-consumption is fastest in the absence of boric acid/borate and slowest at the highest concentration of boric acid/borate. The uranyl concentration was also monitored in these experiments, and the resulting final dissolution yields are plotted as a function of boric acid/borate concentration in figure 4.

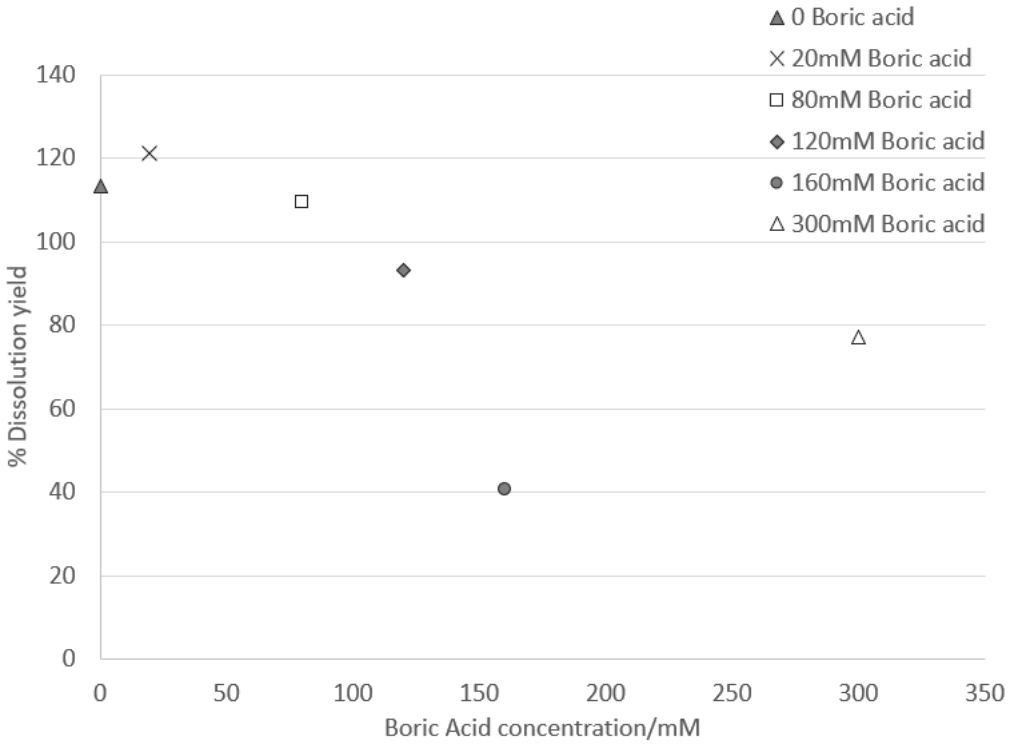

Figure 4: Percentage of Uranyl dissolution yield as a function of boric acid concentrations for systems with powder suspensions of 40 mg UO_2 in presence of 0.2mM H_2O_2, 10 mM HCO_3^- and different concentrations of boric acid in each system (no boric acid, 20mM, 80mM, 120mM, 160mM, 300mM).

Interestingly, the dissolution yield decreases with increasing boric acid/borate concentration with the notable exception of the highest concentration for which the dissolution yield is increasing compared to the second highest concentration. These experiments have been repeated several times, and the observed trend is reproducible. In other systems (other oxides) it has been observed that boric acid/borate decreases the reactivity of H_2O_2. As mentioned above, it is also known that boric acid/borate and hydrogen peroxide can form complexes [21] [22].These complexes are likely less reactive than free hydrogen peroxide as has been observed for other peroxide complexes [21] [22].

4. CONCLUSIONS

The results obtained in this study show that the presence of ZrO_2 and the presence of boric acid/borate, have significant impact on the oxidative dissolution of uranium dioxide. In both cases, the dissolution yield (i.e., the amount of dissolved uranium divided by the amount of consumed hydrogen peroxide) decreases compared to the reference system containing only UO_2 and no boric acid/borate. This implies that the presence of ZrO_2 in corium and the presence of boric acid/borate in water in contact with corium will reduce rate of radiation-induced leaching of radionuclides in case of a severe accident.

The influence of boric acid/borate could possibly be attributed to the formation of complexes with H_2O_2.

- Results
- Conclusions

Background:

Post-accident scenarios:

After debris cooling, Corium can come in contact with water, which enables dissolution of the matrix and therefore, release of radionuclides.

The radionuclide release depends on:

1. Availability, radionuclides present on the surface will be dissolved first upon contact with water.
2. Rate of corium dissolution. Radionuclides in the corium matrix will be released as the corium matrix is dissolved.

Questions: How does corium matrix dissolution depend on corium composition and water composition?

Chernobyl's Elephant's Foot, HowStuffWorks.

What can we learn from spend nuclear fuel dissolution?

- Spend nuclear fuel is mainly UO_2.
- UO_2 has low solubility in water.
- In the presence of oxidants UO_2 can be oxidized to U(VI) which is much more soluble.
- The radiation emitted from the fuel induces radiolysis of water.

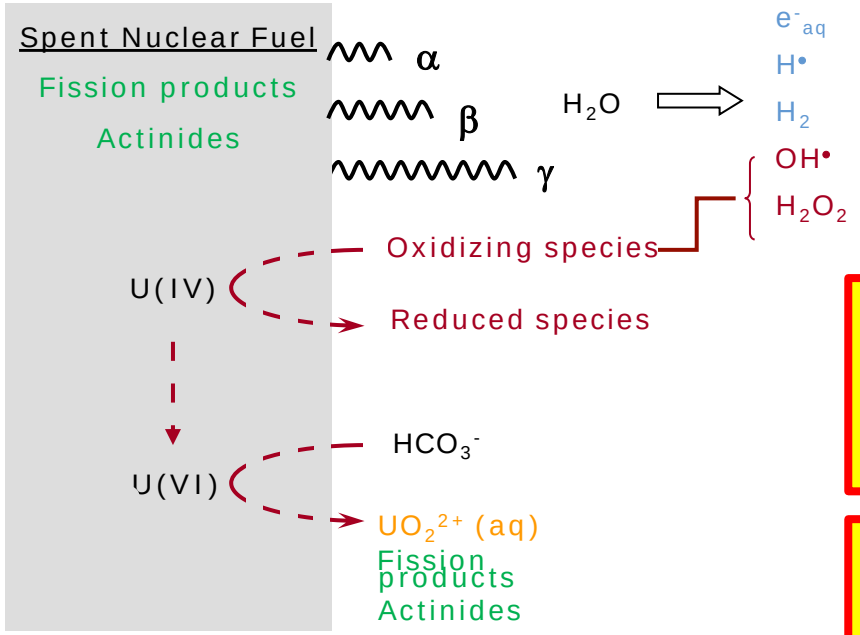
Le Caër, Sophie Water 2011, 3, 235-253

The carbonate radical ion, is produced as a secondary product of the radiolysis of water, by the reaction of carbonate or bicarbonate ions with hydroxyl radicals.

*(The Journal of Physical Chemistry **1970** 74 (10), 2206-2210)*

The radiation from the fuel drives the oxidative dissolution, and the same will happen with Corium.

The mechanism of radiation induced dissolution of spent nuclear fuel (simplified)



Oxidative radiolysis products of relevance:

H_2O_2, O_2, $HO_2^{\bullet}/O_2^{\bullet-}$, $CO_3^{\bullet-}$, $HO^{\bullet}$, $HOCl^{\bullet-}$

In a system where reactive species are produced at a constant rate, steady-state will eventually be approached (production balanced by consumption)

The maximum rate of fuel matrix oxidation is then given by the rate of production of radiolytic oxidants

How to calculate the rate of radiation-induced dissolution

- The **maximum rate** of oxidative dissolution is given by the rate of production of **radiolytic oxidants**

(Journal of Nuclear Materials2008, 374, 286–289, Journal of Nuclear Materials, 2012, 420, 409–423)

- The rate of production of **radiolytic oxidants** depends on the **dose rate** (and the radiation chemical yields)

(Journal of Nuclear Materials, 2008, 372, 32–35)

- The **dose rate** depends on the **specific activity** of the fuel.

- The **specific activity** of the fuel depends on the burn-up, fuel irradiation history and time after removal from the reactor.

- The specific activity and dose rate profiles can be accurately modelled using existing codes.
(Nuclear Engineering and Technology, 2025, 57, 103814)

Reactivity of H_2O_2 towards UO_2

H_2O_2 is the radiolytic oxidant of highest impact:

- It is more stable than other radiolytic oxidants which allows H2O2 formed further away from the surface to diffuse to the surface making more H2O2 available to the surface.

(*Journal of Nuclear Materials 355 (2006) 38–46*)

Therefore, **hydrogen peroxide** is expected to be the main oxidant for both spent nuclear fuel and corium, while molecular **oxygen** from air may also contribute to the oxidation of corium.

H_2O_2 reacts with UO_2 :

1. **By catalytic decomposition** producing O2 and H2O → $H_2O_2 \rightarrow 2\ H_2O + ½\ O2$
2. **Oxidative dissolution,** oxidizing U(IV) to U(VI). → $H_2O_2 + UO_2 \rightarrow 2OH^- + UO_2^{2+}$

Journal of Nuclear Materials, 410(1-3), 89–93. (2011)

Dissolution yield

- **Dissolution yield**, defined as the ratio between dissolved uranyl with consumed hydrogen peroxide.

  ↑ Dissolution yield → **H_2O_2** reacts by Oxidative dissolution.

(Journal of Nuclear Materials 410 (2011) 89–93)

- Oxides from fission products present in the **UO_2 modify the surface redox chemistry of UO_2.**

  ↓ **Dissolution yield will be reduced**

- **The reactivity of UO_2 towards H_2O_2** depends how the surface has been exposed previously to oxidizing or reducing conditions. Exposures of H_2O_2 changes the **UO_2** surface chemically, over time the surface becomes partially oxidized **As a consequence:**

  ↑ H_2O_2 decomposes catalytically

  ↓ Smaller fraction contributes to uranium oxidation and release ↓ Dissolution yield

(Dalton Trans., 2020, 49, 1241)

Reaction mechanism between oxides and H_2O_2.

1. For metal oxides where metal is in the highets oxidation state **H_2O_2** reacts **by catalytic decomposition** (producing O2 and H_2O).
2. $H_2O_2 \rightarrow 2\ H_2O + ½\ O2$

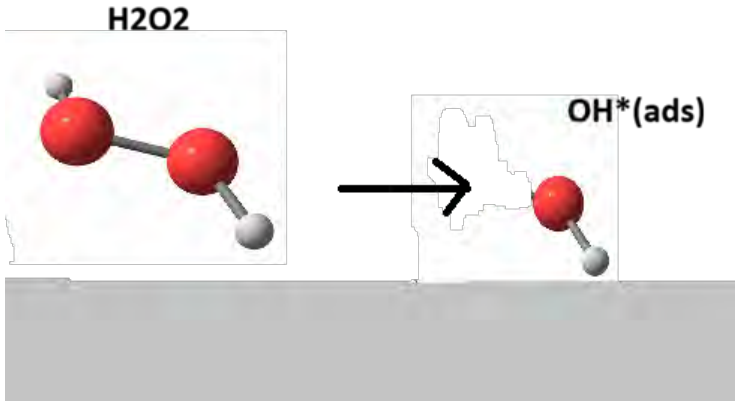
The mechanism:

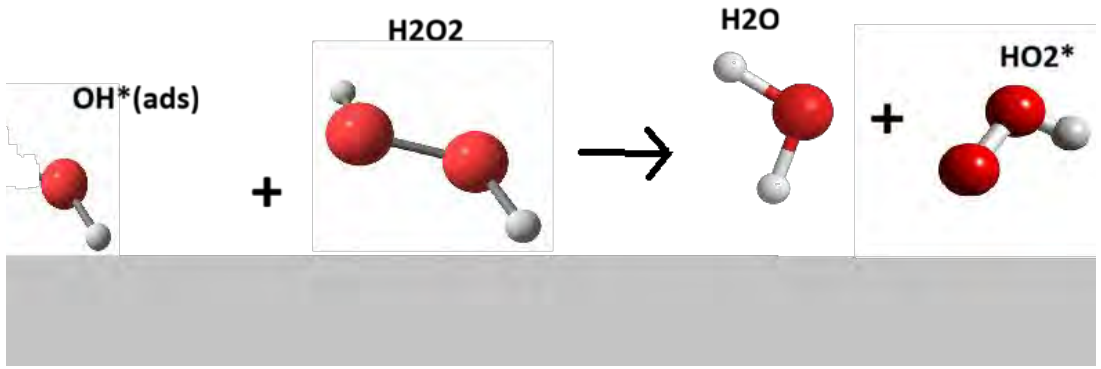
$$H_2O_2 \rightarrow 2OH^{\cdot}(ads)$$

$$OH^{\cdot}(ads) + H_2O_2 \rightarrow H_2O + OH^{\cdot}{}_2$$

$$2OH^{\cdot}{}_2 \rightarrow H_2O_2 + O_2$$

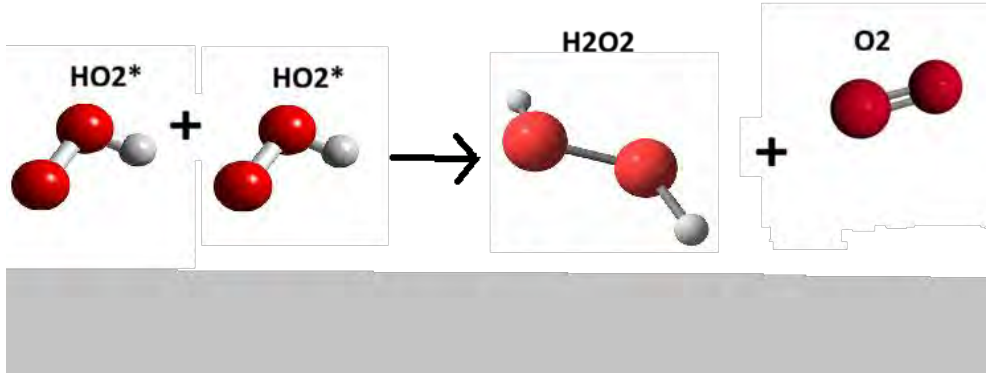
(A. Hiroki, J.A. LaVerne. J. Phys. Chem. B, 109, 3364 (2005))





These radicals are largely **surface-bound**:

- They react very close to where they are formed,



Previous observations

- This is the behaviour of UO_2 with H_2O_2 in the presence of bicarbonate.
- Bicarbonate is present in most types of waters, and it is good complexant of U(VI).

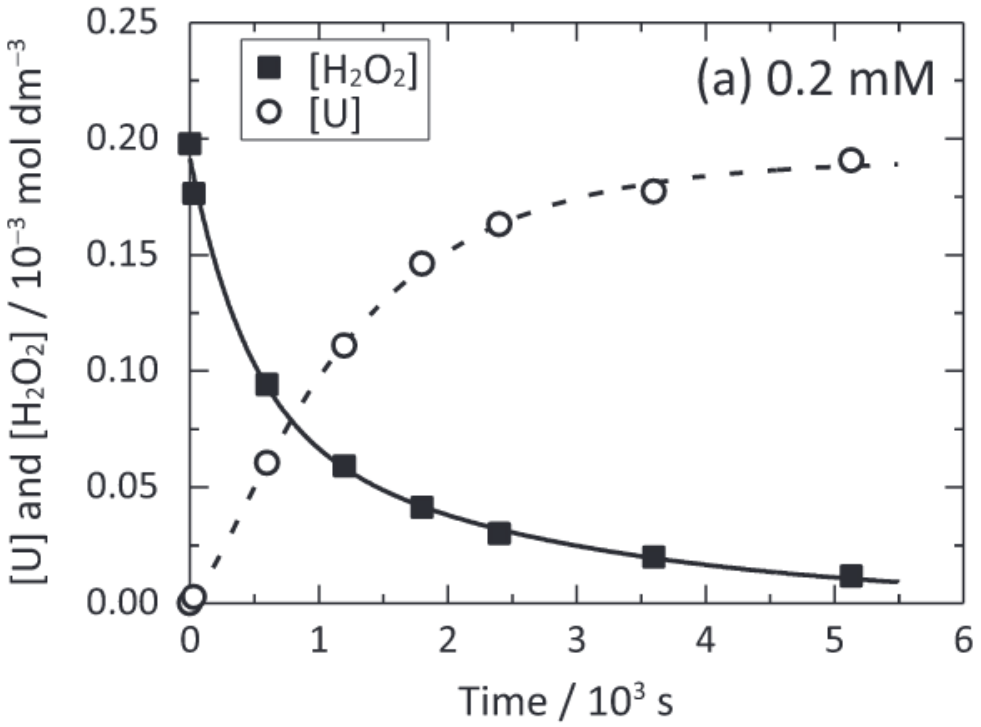


Fig 4: Journal of Coordination Chemistry. (2018), 71:11-13, 1799-1807.

Objective and methodology overview

Objective:
To explore the kinetics and mechanism for H_2O_2 induce dissolution of corium models

Experimental setup:

- **Corium analogue:**
  -UO_2, ZrO_2
- **Aqueous phase conditions:**
  -Boric acid, HCO_3^-/CO_3^{2-}

*Boric acid is used in **PWR** dissolved in the water system as **a neutron moderator**, and in **BWR,** as an **emergency stop**.*

Analysis of the solutions

- Monitoring H_2O_2 and U(VI) concentrations with time using **UV-vis spectrophotometer**.

- H_2O_2 was measured using the **Ghormley triiodide** method, at 360nm wavelength.

- Concentrations of H_2O_2 are measured indirectly

$$2I^- + H_2O_2 \rightarrow I_2 + 2OH^-$$

$$I_2 + I^- \rightarrow I_3^-$$

- Hydrogen peroxide can oxidize potassium iodide (KI) with catalytic $(NH_4)_6Mo_7O_{24}$ to produce triiodide, which absorbs light at 352 nm.

(Journal of the American Chemical Society, 1956, 78 (13), 2934-2939, and Journal of physical chemistry. 1952, 56, 587-594.)

Analysis of the solutions

- UO_2^{2+} was measured using **Arsenazo-III** method, at 653nm wavelength.
- Reagent Arsenazo III form coloured complexes with metal ions, like Uranium.
- Materials containing these elements can be analysed directly in the solutions formed after dissolving the sample.

(Talanta 1961, 8, 673–685. and Analytical chemistry (Washington), 1984,.56 (12) .2269-2271)

Previous investigations

- Previous investigations (Kumagai, 2017) showed high stability of UO_2/ZrO_2 compared to UO_2 against H_2O_2.
- This experiment was done from sintered pellets of UO_2 and ZrO_2 and crashed.
- There is a decrease in dissolution yield of Uranyl when there is ZrO_2
- Rate constant consumption of H_2O_2 increases with the amount of ZrO_2.
- The trend can be attributed to competing consumption of H_2O_2 on ZrO_2 and UO_2, respectively.

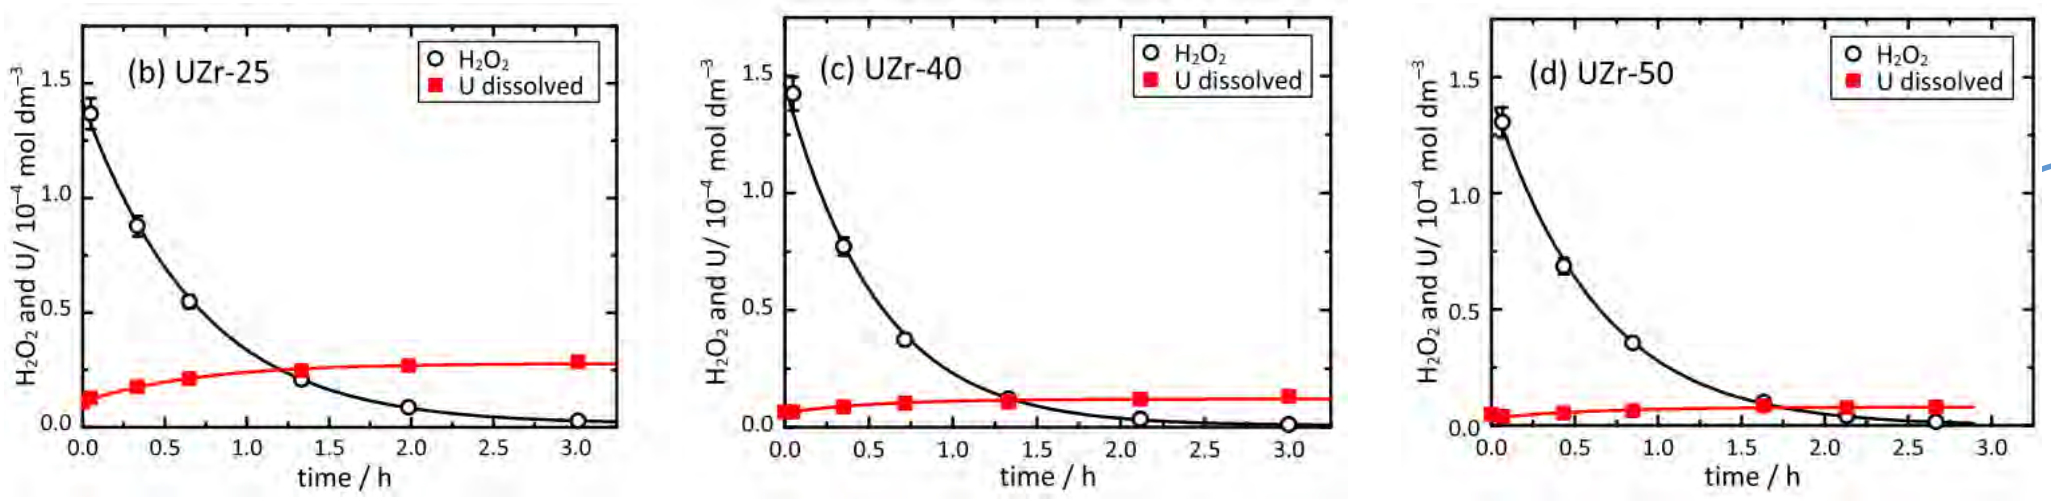

Fig 5, 6, 7: Journal of Nuclear Materials 497 (2017): 54–59..

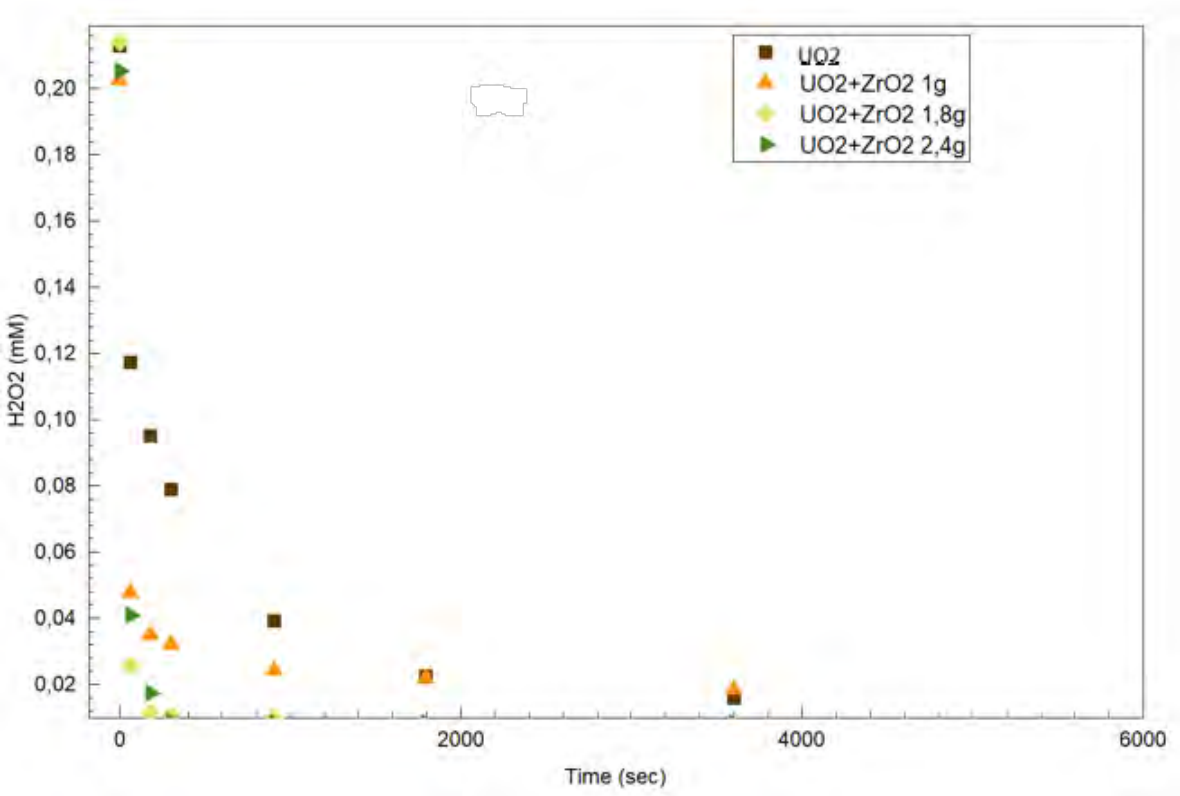
Expected results in the UO_2/ZrO_2 experiments

1. O_2 form from the catalytic decomposition, is continuously removed from the system by N_2 purging.

2. In our experiments at current **ZrO_2/UO_2 ratios compared with systems with only UO_2** we expect:
   1. **Faster consumption** of **H_2O_2** becasue it is reacting with ZrO_2 and UO_2.
   2. **Less oxidation** of UO_2 (since O_2 is removed from the system).

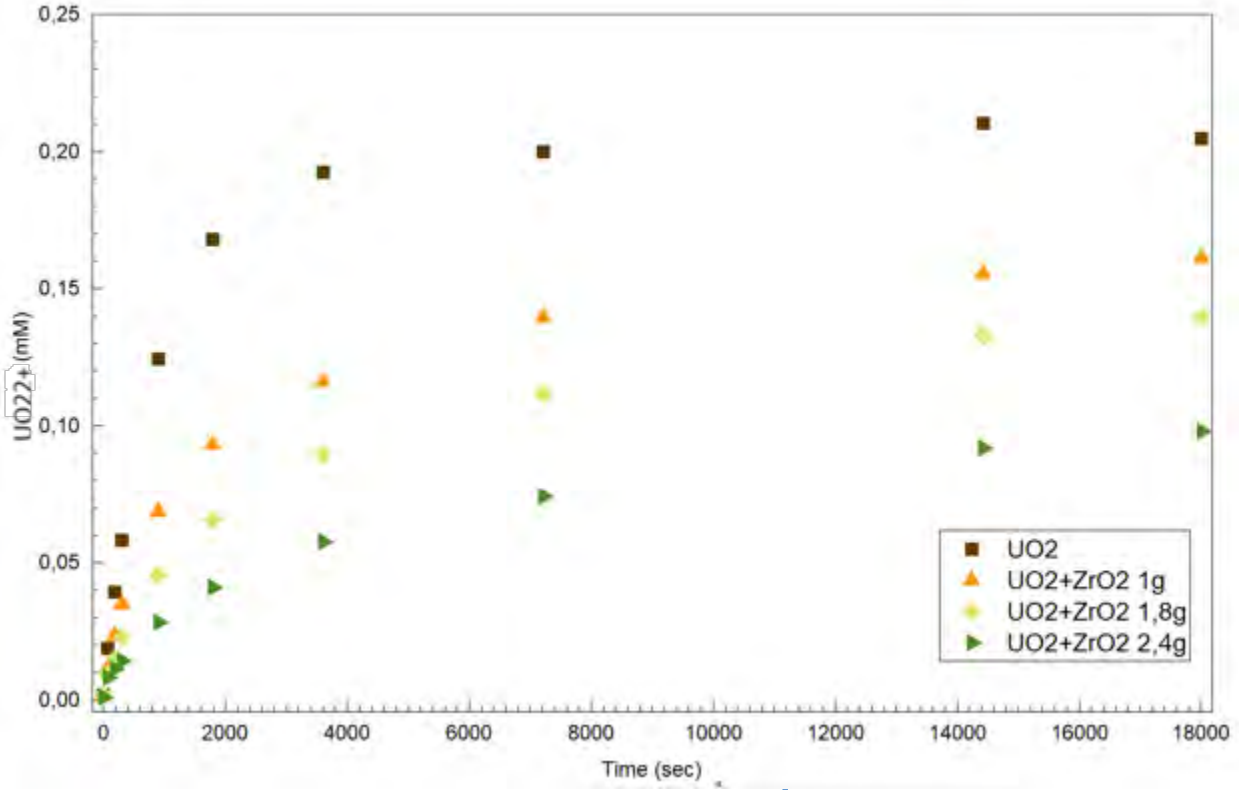
H_2O_2 consumption and UO_2^{2+} dissolution in UO_2/ZrO_2 systems purged with N2

Consumption of hydrogen peroxide:



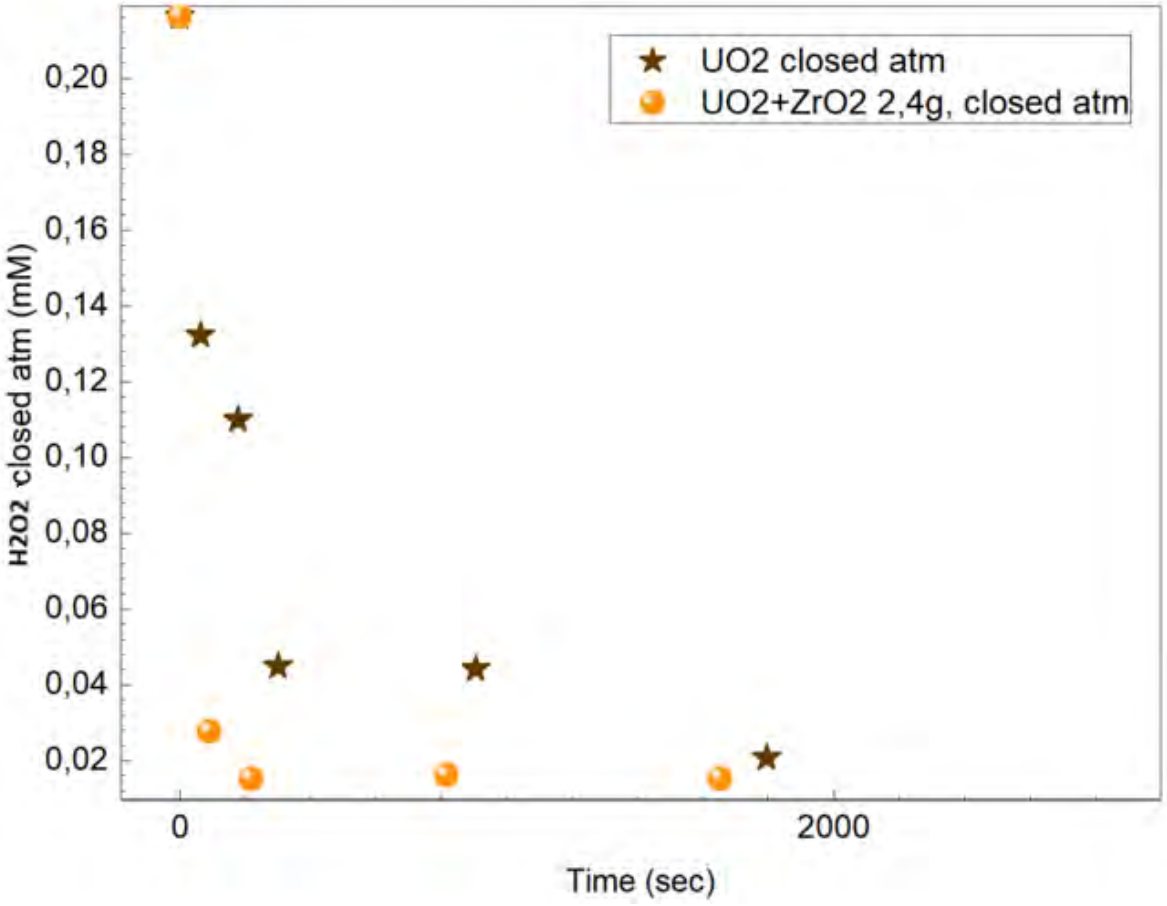
Dissolution of Uranyl:

UO2-ZrO2 (mass ratio 96)
UO2-ZrO2 (97.8)
UO2-ZrO2 (98.3)



H_2O_2 consumption and UO_2^{2+} dissolution in UO2/ZrO2 systems in sealed reaction vessels

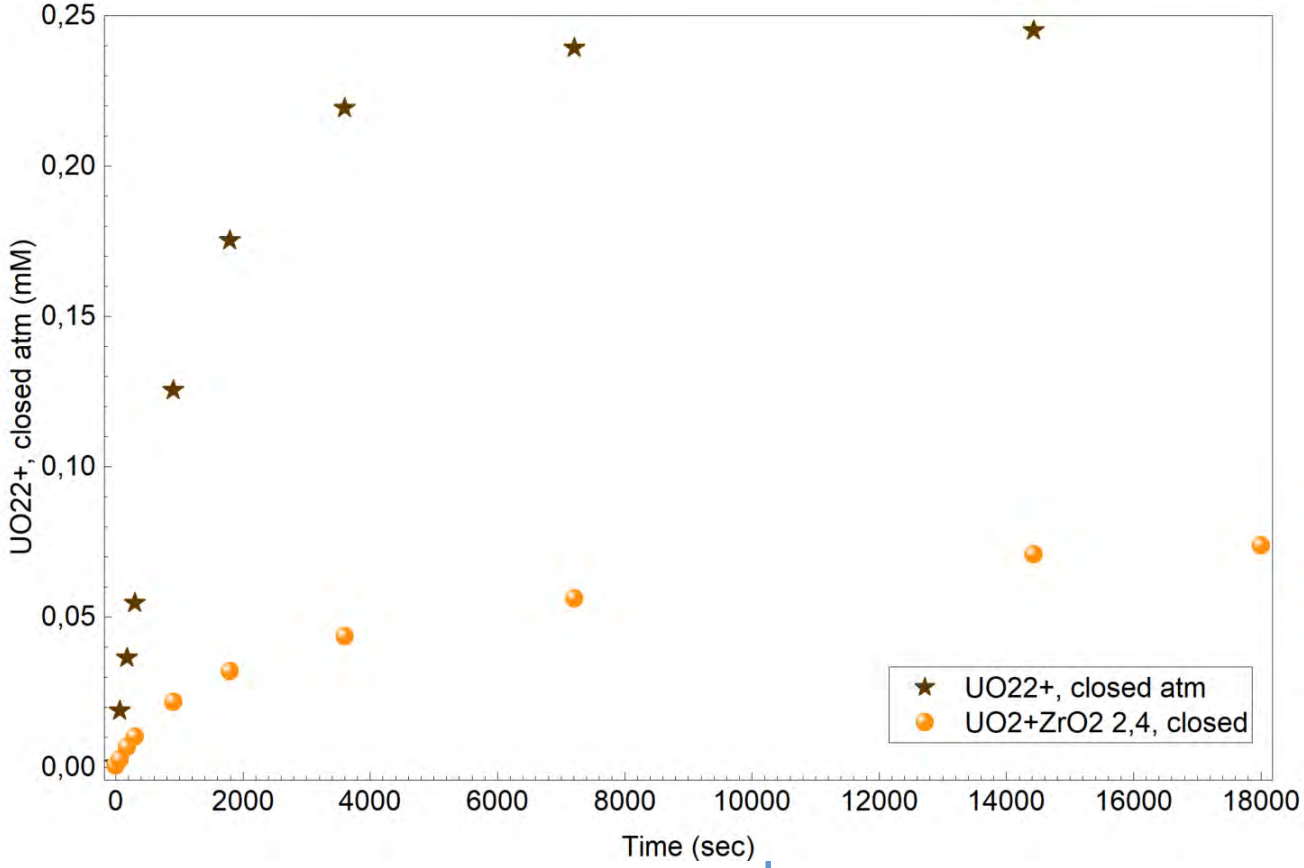
Consumption of hydrogen peroxide:



Dissolution of Uranyl:

UO2

UO2-ZrO2 (mass ratio 98.3



Conclusions

- Presence of ZrO_2 has an impact in the dissolution yield of Uranyl.
- In the closed systems, we observe that the results are the same, what it means that the molecular oxygen does not contribute to the oxidation of UO_2.

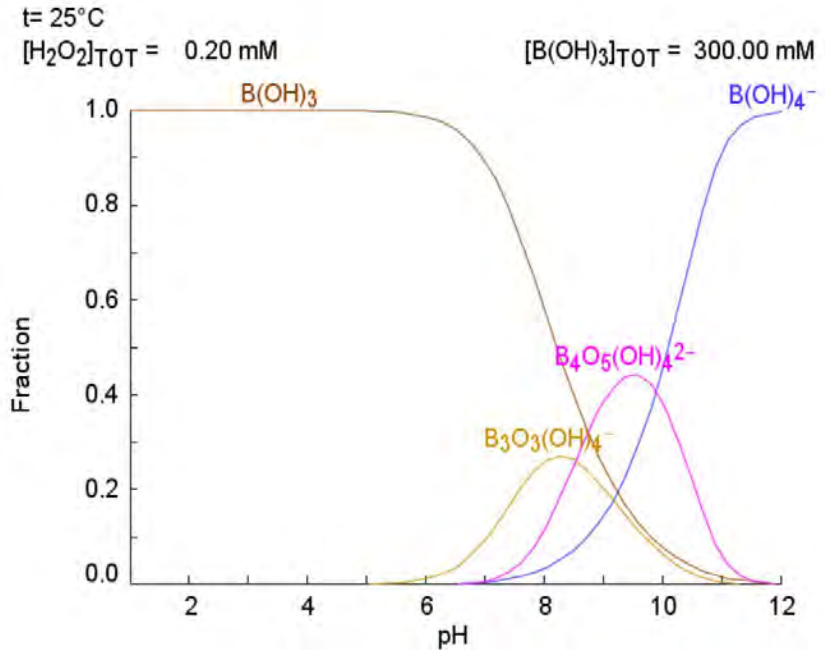
Experiments with Boric Acid and expected Impact

- Boric acid is used in some nuclear reactors, for this reason we performed experiments with Boric acid/borate.
- Same experiments were performed with presence of Boric acid/borate with the pH at 9.4. At this pH, the system will expect to have:
  - ✓ The counter-base borate ($B(OH)_4^-$)
  - ✓ And two polyanion species diborate and tetraborate
- We know they can act as a **competitive scavenger of •OH radicals**.

J.Phys.Chem.A2024,128,7593−7600

- Boric acid/borate can be absorbed in oxide surfaces and change the reactivity.

(Under review in ACS Omega)



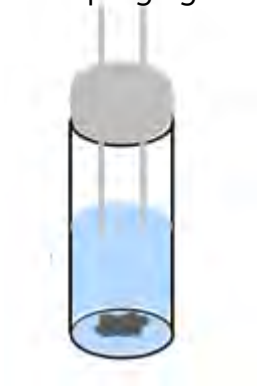
Reaction between UO_2 and H_2O_2 in the presence of bicarbonate and boric acid

Experiments were performed in the same conditions.

We changed the aqueous phase, adding different concentrations of boric acid: 20mM, 80mM, 120mM, 160mM and 300mM.

1) Washing:

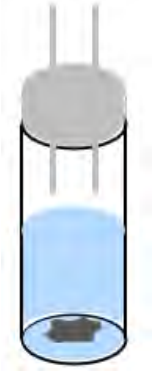
N2 purging



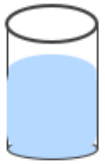
10mM Sodium bicarbonate Solution
40mg UO_2 powder.

2) Leaching:

N2 purging



H_2O_2 0,2mM.



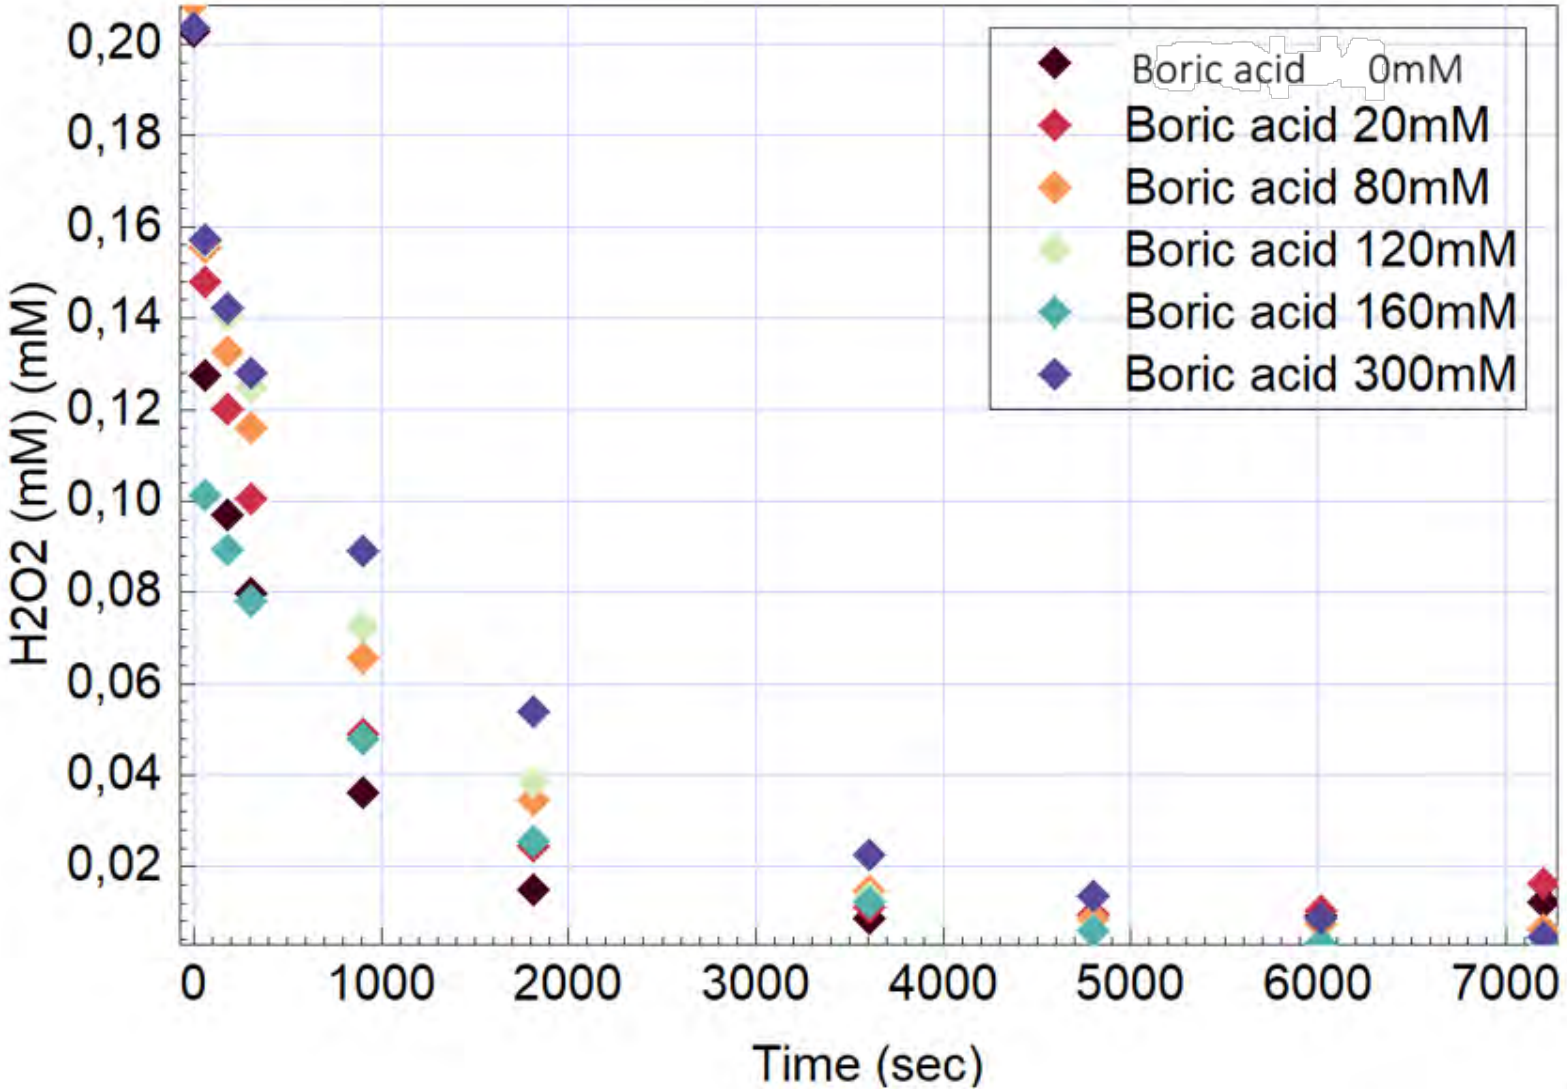
N2 purging and stirring constantly

Aliquots at specific times

0,22µm Cellulose Acetate Syringe filter

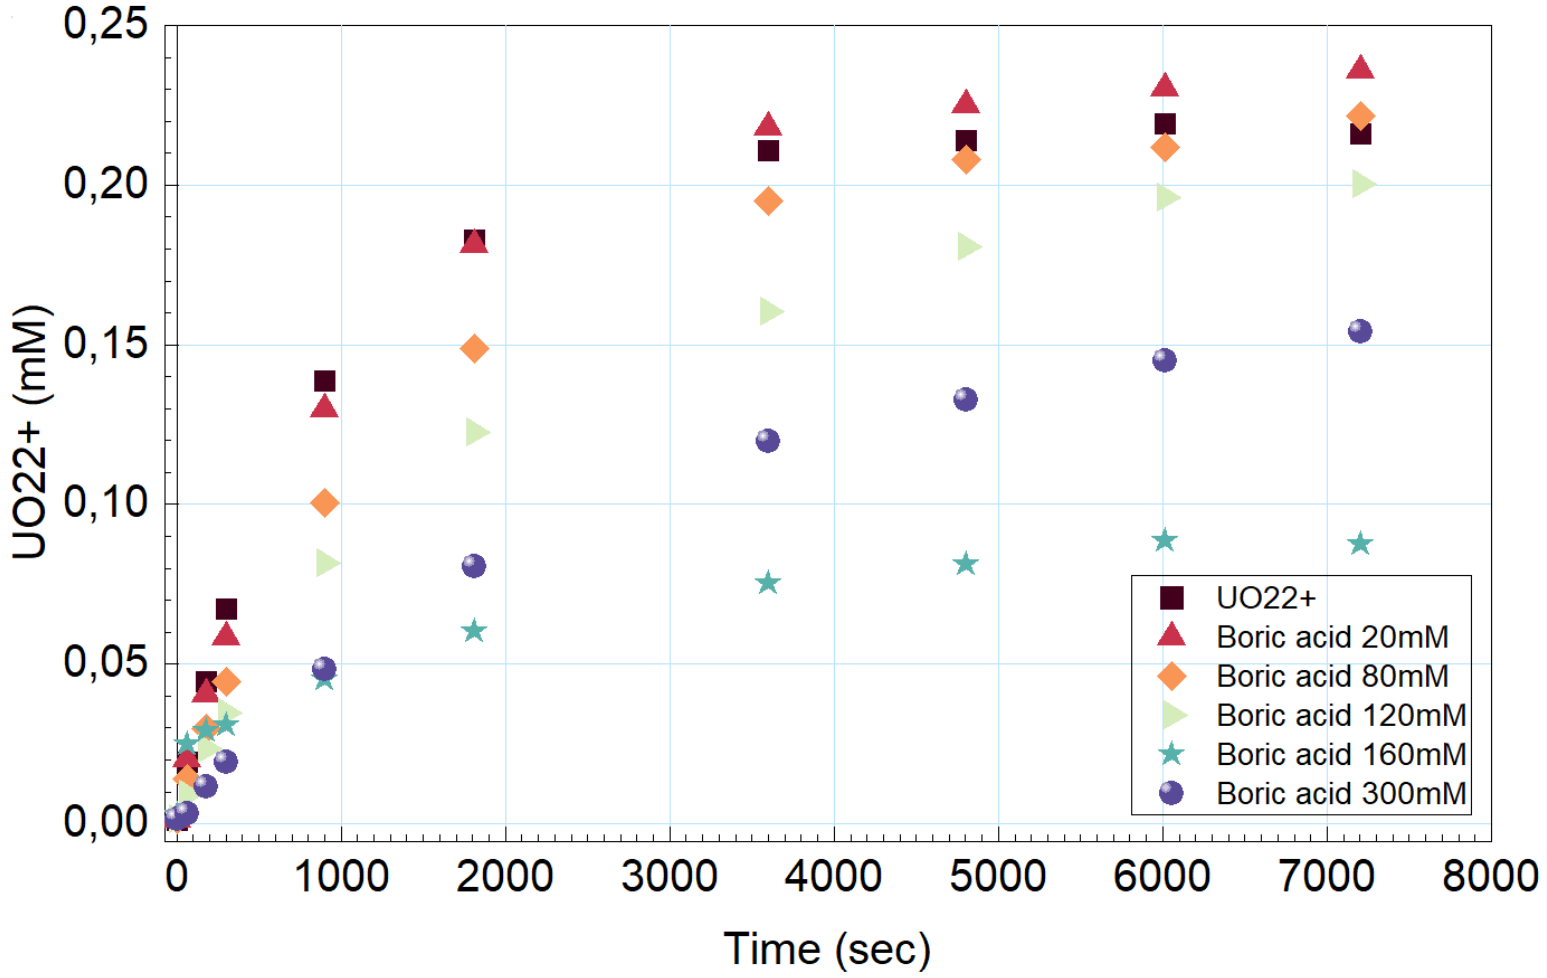
Results of experiments of UO_2 against H_2O_2 with boric acid

Consumption of Hydrogen peroxide:

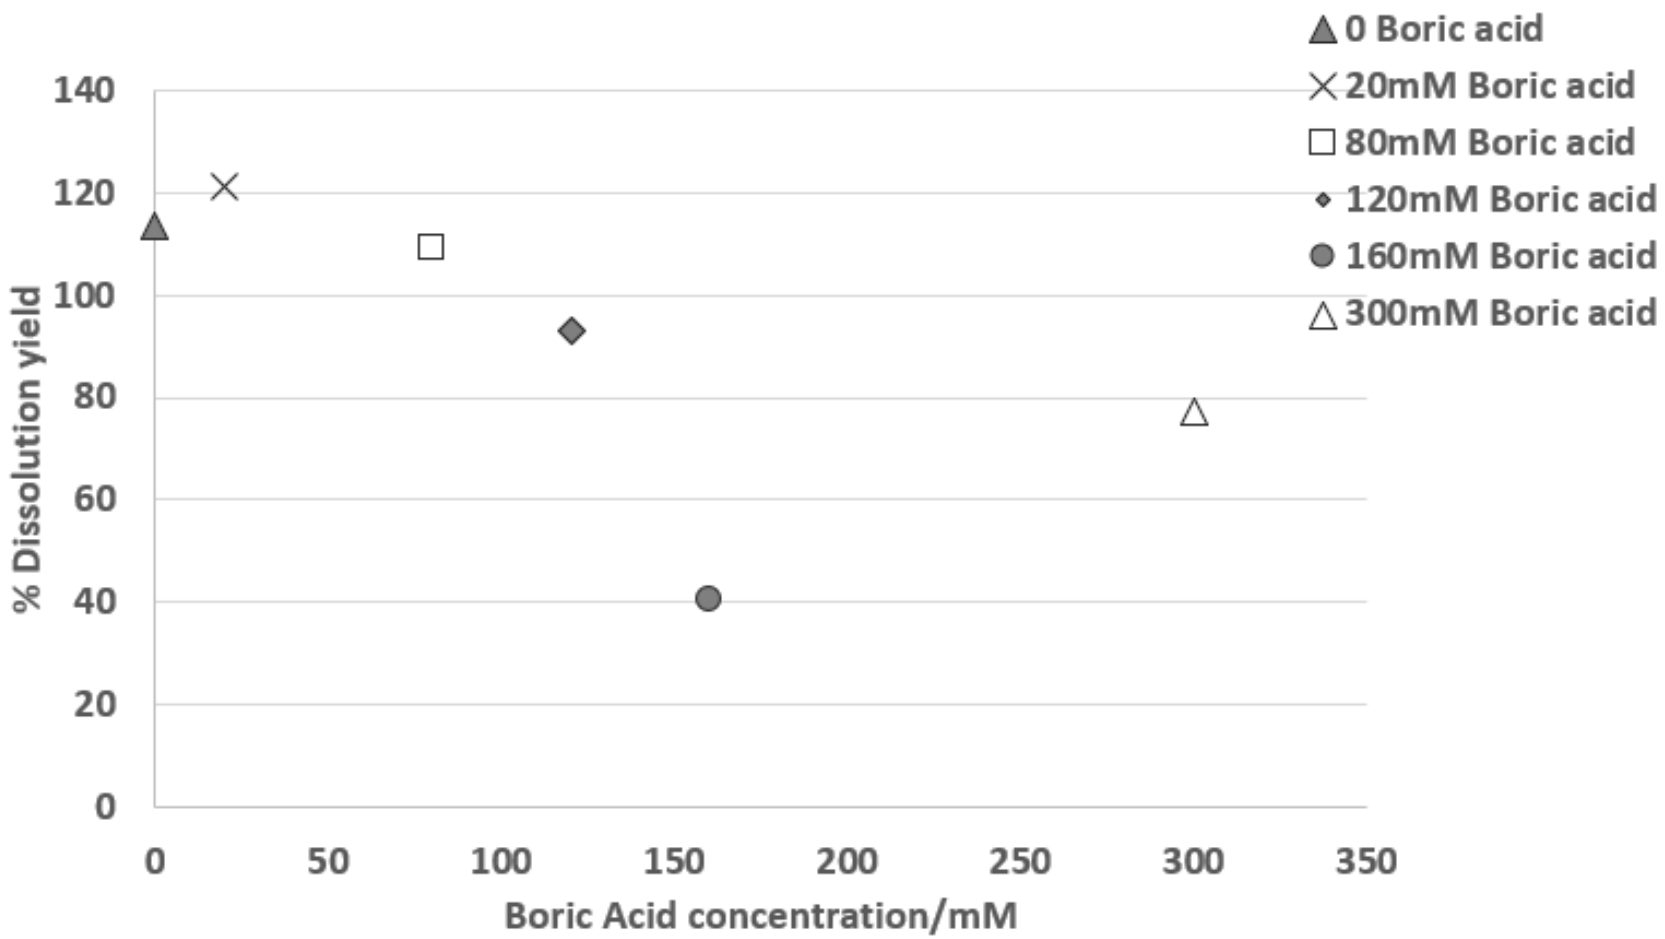


Results of experiments of UO_2 against H_2O_2 with boric acid

Dissolution of Uranyl with time:



Dissolution yield of Uranyl in boric acid



Conclusions

- We can have absorption of boric acid in the surface, blocking the surface.
- Peroxoborates have different reactivity than free Hydrogen peroxide.

ABSTRACT

Electrostatic precipitation (ESP) is widely recognized as an efficient method for removing aerosol particles and is frequently employed in industrial applications. In this study, a laboratory-scale tubular ESP was designed and operated in dry and wet configurations to investigate the migration and capture of caesium iodide (CsI) aerosols relevant to nuclear accident scenarios. ESP performance was assessed through measurements of overall particle removal efficiency while key operational parameters were systematically varied. Factors investigated included discharge-electrode geometry, inlet particle concentration, and interactions between suspended particles and water droplets in the wet configuration. Three electrode geometries (fishbone, sawtooth, and wire) were compared. Among these, the electrodes with protrusion (i.e., fishbone and sawtooth) achieved the best collection efficiencies in both dry and wet configurations for particles larger than 0.1 μm. The higher efficiency of the wet ESP was due to aggregation of the particles with water droplets, which improved removal relative to the dry mode. These efficiencies were maintained over a voltage range of 10–18 kV and temperatures from ambient up to 300 °C. These results highlight the importance of electrical, geometric, and physicochemical parameters in determining ESP effectiveness. The findings provide practical guidance for optimizing ESP design and operation for the mitigation of iodine-containing and other radioactive aerosols, with implications for both nuclear safety systems and broader industrial applications where fine-particle control is essential.

Electrostatic precipitators, electrode geometry, CsI, aerosol, severe accidents

1. INTRODUCTION

The effective removal of radioactive aerosols plays a crucial role in mitigating radiological risks during nuclear power plant accidents. Following the failure of containment barriers, volatile fission products such as caesium and iodine readily form aerosols that can be transported throughout the containment and potentially released into the environment [1]. These particles dominate airborne release and are particularly difficult to remove using traditional methods such as filtration, natural deposition, or containment sprays due to their relatively small size, which is typically below a micron [2], [3]. The difficulty with iodine is further associated with its frequent phase change from gaseous to solid and vice versa during the accident. As a result, the development of advanced technologies that can efficiently capture such aerosols under accident-relevant conditions remains a crucial objective for enhancing nuclear safety.

Electrostatic precipitation (ESP) represents one of the most promising active techniques for fine particle removal. The principle of ESP operation is based on imparting an electric charge to suspended particles and collecting them on surfaces maintained at an opposite potential [4]. Owing to their high efficiency, scalability, and long operational history, ESPs have been widely adopted in industrial applications such as

power generation, metallurgy, and waste incineration for controlling particulate emissions [5], [6], [7]. Their application to nuclear systems, however, has only recently gained interest as a possible method for reducing the airborne source term during severe accidents and filtered containment venting [3], [8], [9]. Experimental and modeling studies have indicated that properly designed ESPs can achieve over 90–99% removal efficiency for caesium iodide (CsI) and similar aerosols, even under high-temperature, steam-rich, or radiation-intense environments [8], [9], [10].

Despite these advantages, the practical application of ESPs to nuclear containment systems still faces several challenges. The efficiency of collection depends strongly on particle charge distribution, gas composition, and electric field strength, all of which vary under accident conditions. In addition, most previous investigations have focused on industrial dust or soot aerosols, with limited studies addressing fission product analogs such as caesium iodide [10], [11], [12]. The influence of electrode geometry, applied voltage, and temperature on ESP performance for fission product aerosols remains insufficiently understood. Similarly, the comparative performance between dry and wet ESP configurations has not been systematically evaluated under identical test conditions. Wet ESPs, which utilize water films or droplets to wash collection surfaces continuously, can mitigate re-entrainment and fouling [13]; however, their interaction with particle charging and collection processes requires detailed examination [10], [11], [14].

To address these research gaps, the present study investigates the removal of CsI aerosols using both dry and wet tubular electrostatic precipitators developed at the laboratory scale. Three discharge electrode types, wire, sawtooth, and fishbone, were tested across three voltages (10, 15, and 18 kV). The performance was assessed based on corona discharge characteristics, aerosol migration behavior, and total collection efficiency. The results provide insights into the effect of electrode geometry, electric field intensity, and their interactions on ESP operation under nuclear-relevant conditions. The findings from this study will contribute to the ongoing efforts to enhance source term mitigation systems by integrating ESP technology into containment and venting architectures. Understanding how particle charge, collection area, droplet, and water flow interaction influences removal efficiency can guide the design of more robust and efficient filtration systems for severe accident management. Moreover, the results may be applied to broader applications of ESP beyond the traditional nuclear industry and into small modular reactors, along with the high-temperature and droplet-laden environments.

2. EXPERIMENTAL IMPLEMENTATION

2.1. Electrostatic Precipitator Configuration

The study was conducted to evaluate the collection performance of laboratory-scale ESPs for CsI aerosols under controlled flow, temperature, and voltage conditions. Both dry and wet ESP configurations were examined to compare their performance in removing aerosols representative of fission product particles.

Two ESP systems, dry and wet, were designed with identical tubular geometries to enable direct comparison of their operating characteristics. Each ESP consisted of a galvanized steel cylindrical collection tube with an internal diameter of 100 mm and a length of 1000 mm. The discharge electrode was positioned axially at the center of the tube, supported by a plastic insulator. The discharge electrode was interchangeable to allow testing of three different geometries: a wire electrode with a straight metal wire of 1 mm diameter, a sawtooth electrode with a stainless-steel stripe featuring evenly spaced triangular protrusions, and a fishbone electrode with a central spine and lateral, pointed branches.

For the wet ESP, a continuous thin film of water was maintained along the collection surface using a top-mounted nozzle system. The liquid flow rate was regulated at 1.5 l/min to ensure uniform coverage without droplet entrainment.

2.2. Electrical and Flow Conditions

All tests were conducted under direct current (DC) corona discharge using a high-voltage power supply (Genvolt 72030 series, 0–20 kV, 1.5 mA). Three applied voltages, 10, 15, and 18 kV, were selected to evaluate the impact of electric field intensity on charging and collection performance. The volumetric air flow rate was maintained at 15 l/min, corresponding to an average residence time of approximately 31 seconds inside the ESP.

Three temperature levels were selected to simulate varying thermal conditions (room temperature (25 °C), 100 °C, and 300 °C) post-severe accident for the generated aerosols. Desired temperatures were achieved by passing the aerosols through a tube furnace, which was monitored with K-type thermocouples. The aerosols were then cooled in a separate chamber before entering the ESP. This chamber, before the ESP, was further utilized as a mixing chamber for aerosols during experiments with water droplets.

For the wet ESP with water droplets (referred hereafter as droplet-assisted ESP), the influence of droplet interaction with particles was examined by introducing a controlled spray of fine mist of water droplets generated via an ultrasonic atomizer. The average droplet diameter was approximately 5 μm. The interactions between droplets and CsI particles were analyzed through their aggregation and charge-neutralization behavior, which were observed indirectly as changes in the measured particle size spectra downstream.

2.3. Aerosol Generation and Characterization

High-purity CsI powder (99.9%, Sigma-Aldrich) was dissolved in Milli-Q water to prepare a 0.5% CsI solution. CsI aerosol was generated with an RBI Pyrosol and was carried with a controlled carrier nitrogen stream. Aerosol mass and number concentrations were continuously measured upstream and downstream of the ESP using an Electrical Low-Pressure Impactor (ELPI, Dekati). The instrument provided real-time data on particle size distribution and concentration over the 0.01–10 μm range.

The results are presented as a comparison between the inlet and outlet of the ESP from ELPI measurements, according to Eq.1, and defined as the filtration efficiency (η) of the ESP, based on the measured particle number.

$$\eta = \left(1 - \frac{Aerosol_{out}}{Aerosol_{in}}\right) \times 100 \quad (1)$$

3. RESULTS AND DISCUSSION

The measurements showed clear differences in the removal of CsI aerosol with different discharge electrode geometries, the applied voltages, and the ESP operating modes. Table 1 summarizes the removal efficiency of CsI aerosol (based on particle number concentration) under all tested configurations. The initial aerosol size distribution ranged primarily between 0.1 and 5 μm, with a geometric mean diameter of approximately 0.8 μm under baseline conditions. The wet ESP with the fishbone discharge electrode produced the highest mean particle number removal efficiency (≈ 99.6%) and the lowest variability (standard deviation ≈ 0.06%). The wire electrode, especially under dry and droplet-assisted modes, showed the largest variability and the lowest average efficiency among all configurations.

Table I. Summary of CsI aerosol experiments. The table reports ESP filtration efficiency for three ESP modes; each operated with three electrodes and at three different voltages. Geometric mean diameter (GMD) and geometric standard deviation (GSD) are derived from ELPI particle number

size distributions. Efficiency was calculated from upstream and downstream particle number concentrations.

ESP mode	Electrode type	Voltage (kV)	Mean particle number filtration efficiency (%)	GMD (nm)	GSD	Number of tests (n)
Dry	Wire	10	77.72	725.3	3.02	3
	Wire	15	92.92	390.1	2.81	3
	Wire	18	95.20	30.62	1.71	3
	Sawtooth	10	98.18	33.27	1.78	3
	Sawtooth	15	93.37	36.51	1.80	3
	Sawtooth	18	89.60	33.88	1.78	3
	Fishbone	10	95.74	29.19	1.75	3
	Fishbone	15	91.01	30.90	1.76	3
	Fishbone	18	95.70	31.54	1.75	3
Droplet-assisted	Wire	10	64.08	366.9	2.79	3
	Wire	15	90.54	242.5	2.68	3
	Wire	18	97.37	25.11	1.72	3
	Sawtooth	10	97.11	28.49	1.72	3

	Fishbone	10	99.53	25.52	1.65	3
	Fishbone	15	99.64	26.22	1.63	3
	Fishbone	18	99.58	25.12	1.66	3

3.1. Performance of dry ESPs

Under dry conditions, removal efficiency strongly depended on electrode shape and applied voltage (Figure 1). The fishbone electrode provided stable, high removal across all voltages tested, with the smallest standard deviation among the dry ESPs, see Table 1. Downstream size distributions (Figure 2b) show nearly complete removal of particles below 1μm for all applied voltages, suggesting efficient charging and uniform migration of the particles to the collection surface. This indicates a uniform electric field distribution and stable corona conditions along the fishbone electrode, which enhance particle charging and transport across the cross-section. It also agrees with observations from surface-enhanced corona electrodes described by Bendilmi et al. (2022).

The sawtooth electrode showed an interesting variable voltage dependence. At 10 kV, the removal efficiency exceeded that at 18 kV (98.2%) (Figure 1). This suggests that local field enhancement at the sawtooth tips can compensate for lower overall voltage, maintaining sufficient ion production and charging for migration. This result highlights that electrode geometry can counterbalance lower voltage under certain conditions [16].

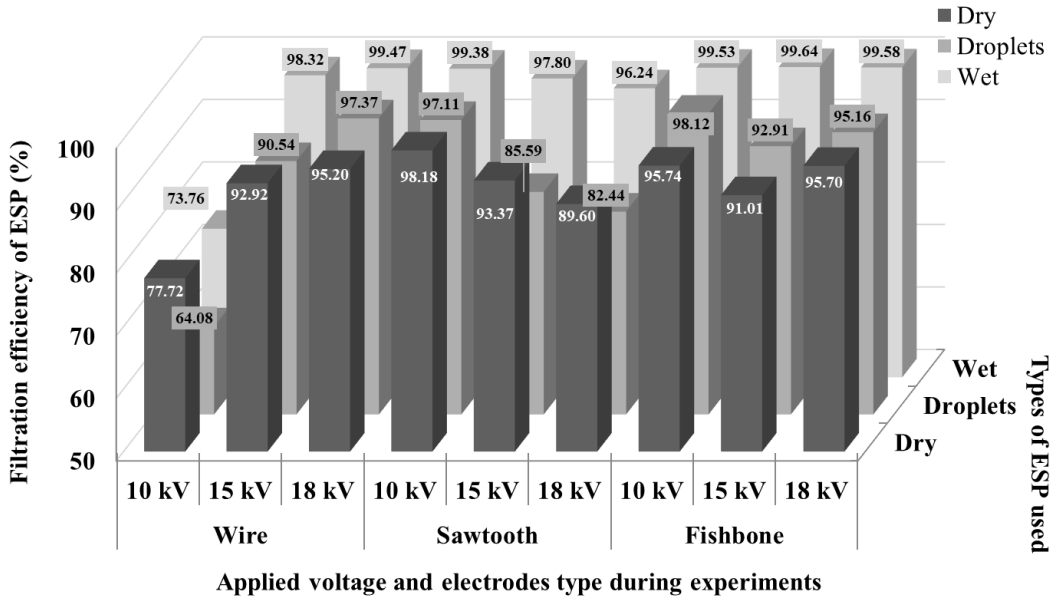

Figure 1. Filtration efficiency of the ESP as a function of applied voltage and electrode geometry. Results are shown for wire, sawtooth, and fishbone electrodes at 10, 15, and 18 kV under dry, droplet-assisted, and wet operating conditions.

In contrast, the wire electrode exhibited the poorest performance under dry conditions. At 15 kV, efficiency dropped to roughly 71.8%. The ELPI spectra (Figure 2b) show that a measurable fraction of mid-size particles remained downstream. This indicates that a simple wire-type electrode lacks sufficient ion dispersion or field uniformity for effective charging and migration, particularly under corona conditions that may be unstable or spatially non-uniform. Under dry ESP, a uniform field or proper geometry is critical to reach high and consistent removal [17], [18]. These results confirm that dry ESP performance can be limited by non-uniform corona discharge and poor ion distribution. Such limitations are well documented in particulate control literature, especially for fine or resistive aerosols.

3.2. Performance of the droplet-assisted ESP

Introducing droplets changed the aerosol removal dynamics (Figures 1). The fishbone electrode maintained high efficiency (> 92.9%) across all voltages in droplet-assisted mode. The outlet ELPI spectra (Figure 2d) show almost complete removal of particles above ~300 nm diameters. This indicates that droplet presence did not prevent charging and migration; instead, the system maintained very good collection efficiency, which was further aided by droplet–particle interactions or aggregation.

Once again, for the sawtooth electrode, the highest performance was recorded at the lowest experimental voltage of 10 kV (≈ 97.1%). The strong electric field at the sawtooth tips and the sharp edges around it may

have offset droplet-induced charge losses, maintaining sufficient ion concentration for charging [19]. By contrast, the wire electrode under droplet conditions exhibited poor performance at 10 kV, with removal dropping to ~64.1%. The outlet spectra show residual particles in the 200–500 nm range, suggesting that droplets may have neutralized some particle charge or scavenged ions before charging could occur, thereby reducing net charge on CsI aerosol. This phenomenon likely impaired the migration effectiveness of particles toward the collection surface.

These observations reveal that droplet injection into the ESP does not guarantee improved performance. The benefit depends strongly on electrode geometry and applied field. Wire electrodes under low voltage appear particularly vulnerable to droplet-induced charge losses. The results align with prior studies on wet ESPs, indicating that droplet–particle interactions and ion scavenging can influence collection efficiency depending on geometry and operating conditions [19], [20], [21], [22].

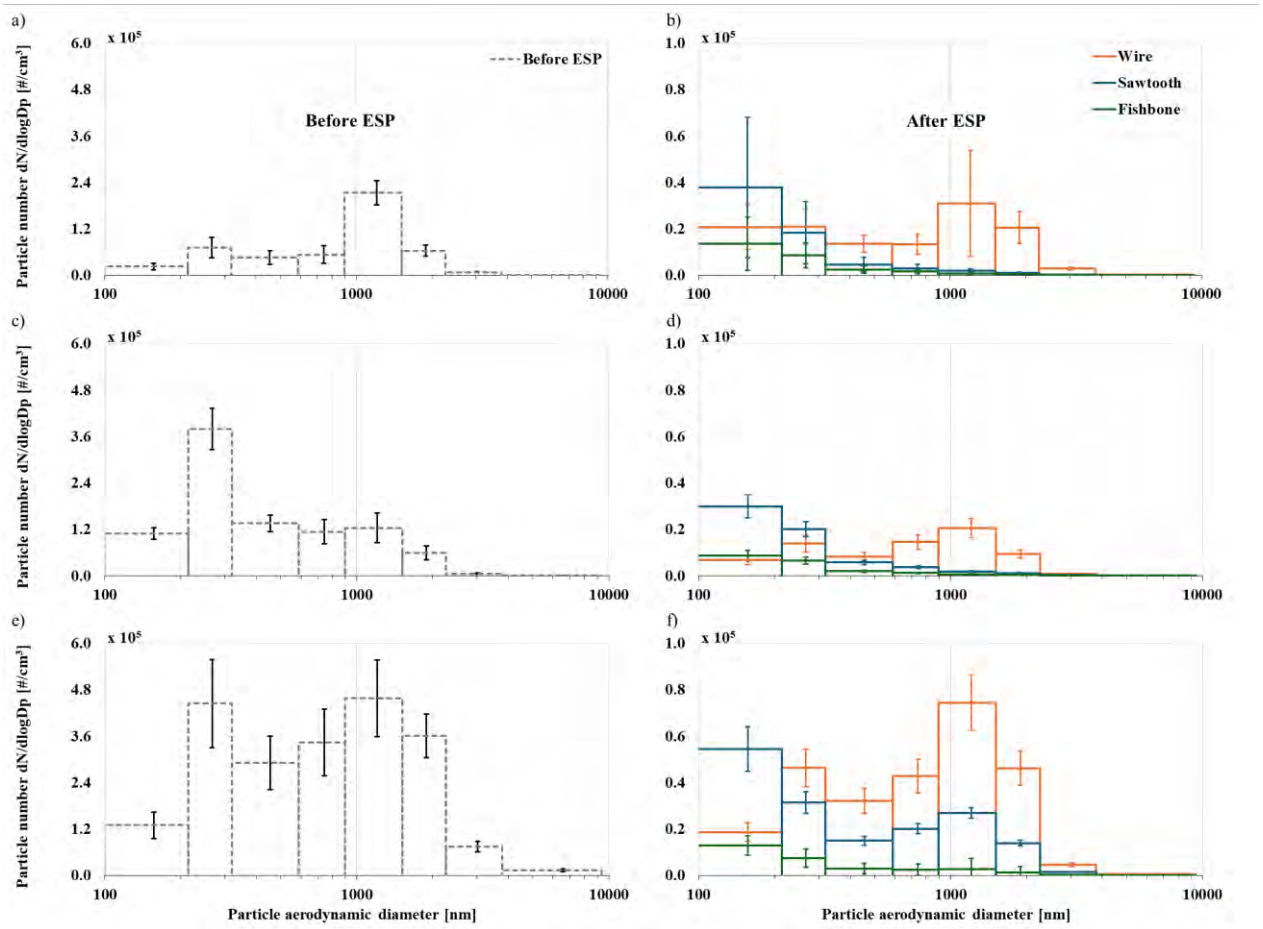

Figure 2. Average particle size distributions measured by the ELPI upstream (left) and downstream (right) of the ESP. Data are averaged over applied voltages (10 - 18 kV) and all temperatures. Panels a and b show the dry ESP. Panels c and d show the droplet-assisted ESP. Panels e and f show the wet ESP. Downstream results (After ESP) compare wire, sawtooth, and fishbone electrodes. Error bars indicate standard deviation.

3.3. Performance of wet ESP

The wet mode produced the most consistent and highest removal efficiencies for CsI aerosol (Figure 1). The wet ESP operation enhanced performance across all geometries, but the degree of improvement strongly depended on geometry and applied field, as shown in the previous studies [11], [23]. The combination of fishbone geometry and wet film proved most effective and stable across all applied voltages. The downstream ELPI spectra (Figure 2f) and the reduction efficiency (Figure 1) show the removal of particles across the full measured size range. The fishbone electrode in wet mode reached nearly 100% removal at all tested voltages (≈ 99.6%). This is due to the combination of a continuous conductive water film and a uniform field geometry, which stabilizes a corona discharge, enhances charge transfer, and suppresses particle re-entrainment or back-corona [11]. The sawtooth electrode in wet mode also performed well, with efficiencies above 96.2% for all voltages. The water film likely helped distribute charge uniformly from the sawtooth tips and improved particle adhesion to the wet surface. The results support conclusions from recent studies that wet ESPs outperform dry ESPs in removing fine or resistive particles and mitigate common issues such as dust cake build-up or re-entrainment [13], [19].

The wire electrode in wet mode was affected by the applied voltage, unlike with other geometries, especially at 10 kV, when efficiency dropped to ~73.8%. The ELPI spectra show residual mid-size particles under these conditions. However, at 15 and 18 kV, the wire-wet ESP reached high efficiency (≥98.3%). These results indicate that the water film alone cannot fully compensate for weak or non-uniform fields in simple wire geometries; sufficient applied voltage remains necessary to ensure efficient charging and migration [24].

3.4. Implication of Particle Size, Voltage, and ESP Design

Size-resolved efficiency data (Figure 2) show that particle aerodynamic diameter influences removal significantly. In dry and droplet-assisted modes with wire electrodes, submicron particles, particularly those around and below ~300 nm, were less efficiently removed. These results align with the known behavior of ESPs' charging behavior, reducing migration velocity, and collection probability [25], [26], [27]. In contrast, wet mode using fishbone or sawtooth electrodes achieved near-complete removal across the entire measured size range (100 nm and above). Similar results have been reported by [9], [11], [23]. This is achieved by combining charging with conductive film deposition, which enhances charge transfer efficiency, reduces re-entrainment, and mitigates back-corona [11], [13].

The dataset shows a clear effect of applied voltage on removal efficiency. Across all conditions (both dry and wet ESPs and all electrode types), the overall efficiency increased from ≈ 86.4% at 10 kV to ≈ 98.6% at 18 kV. The increase reflects stronger ion generation, higher electric field strength, and therefore increased migration velocity of charged particles. In size-resolved data, efficiencies for the removal of particles above a few hundred nanometers improved notably with higher voltage under all tested electrode geometries. However, voltage did not always dominate. In all experiments with sawtooth geometry, the low voltage (10 kV) outperformed the higher voltage. For the fishbone electrode, filtration efficiencies changed with the change in voltage, but the variation was small and depending on the ESP type, the lower voltage could already achieve the maximum efficiency (Figure 1). This indicates that electrode geometry can compensate for lower applied voltage by creating locally enhanced fields, especially in tip-type electrodes [12], [19]. These observations underscore the interplay between applied field, electrode design, and particle dynamics.

Based on the present data, the optimal configuration for a laboratory-scale ESP treating CsI aerosol combines a fishbone discharge electrode, a wet collection surface, and a moderate voltage (≥ 10 kV). This configuration produces high removal efficiency (> 99.5%) with low variability across tested conditions. The results suggest that such an ESP would perform robustly under a wide range of operational conditions, including variations in particle size distribution, aerosol load, and possibly environmental parameters (e.g.,

humidity). These findings support the potential application of wet ESPs for the removal of radioactive aerosol analogs (such as CsI) in nuclear safety systems. The high efficiency, stability, and robustness suggest that wet ESP could be integrated into source-term mitigation or filtered venting architectures, provided that operational conditions (voltage, water supply, corrosion resistance) are properly managed.

4. CONCLUSIONS

The experiments demonstrate that CsI aerosol removal depends strongly on electrode geometry, operating mode, and applied voltage. The wet ESP equipped with a fishbone electrode delivered the highest and most stable performance. Mean removal efficiency remained close to 99 % across all voltages, and the variability across repeated tests stayed low. The sawtooth electrode also performed well in wet mode and maintained high efficiency even at reduced voltage. The wire electrode showed the highest sensitivity to voltage and operating mode. It required a higher voltage to reach efficiencies comparable to the two structured electrodes.

With three different ESP types, where the individual ESP was tested with three different types of electrodes and operated at three different voltages, the wet ESP demonstrated improved performance for all electrode types. Dry operation showed that the charging environment is dependent on the electrode geometry, while droplet-assisted operation altered the charging behavior. The water film in the wet system stabilized the corona, reduced local discharge fluctuations, and enhanced particle adhesion. The fishbone and sawtooth electrodes showed the highest removal across the full-size range. The wire electrode benefited when operated at a higher voltage. The size-resolved data confirm that wet operation controls both submicron and micron-size CsI particles. These findings demonstrate that a wet ESP equipped with a fishbone electrode and operating at voltages above 15 kV yields the most robust configuration for CsI aerosol control. This setup produces high efficiency, low variability, and minimal sensitivity to operating conditions. These characteristics make it suitable for applications that require reliable mitigation of radioactive aerosols.

Future work should quantify the long-term stability of wet ESP operation and examine how film thickness, water conductivity, and flow rate influence particle removal. Additional studies should investigate how mixed aerosols containing CsI and other fission products respond to wet and droplet-assisted charging. Experiments under transient voltage conditions and fluctuating inlet concentrations would support the evaluation of ESP robustness during accident scenarios. Computational modelling of particle charging and migration in structured electrodes would help optimize electrode design for next-generation mitigation systems.

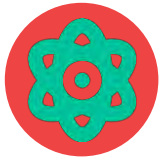
Severe Accidents | CsI Aerosols | Electrostatic Precipitation | FCVS

Motivation: Severe Nuclear Accidents & Radioactive Releases



Fission Product Release

Degraded fuel releases Cs and I into containment — as gases and aerosols. Both can be discharged to the environment through containment venting.

Current FCVS Limitations

Filtered Containment Venting Systems (FCVS) are effective for large particles but struggle with submicron iodine oxide aerosols in the most-penetrating size range.

Enhancement Needed

Post-Fukushima reinforcement of FCVS required. Fine-particle control remains a critical gap. ESP offers a promising complementary technology due to:

- High efficiency for fine and ultrafine particles.
- Low pressure drop, crucial for venting systems.
- Can operate at high temperatures and in humid/corrosive environments.
- A promising complementary technology to enhance FCVS.

Why CsI? Iodine & Cesium Chemistry in Containment

Iodine Speciation

- CsI (particulate) — non-volatile, dissolves in water
- Gaseous I_2 — from radiolytic oxidation of dissolved I^-
- Organic iodine (CH_3I) — surface & organic reactions
- Iodine oxides — radiolysis → submicron aerosols
- Continuous interconversion creates dynamic aerosol population

Radiological Impact

Iodine (I)

Short-term health impact — thyroid uptake. Requires rapid intervention.

Cesium (Cs)

Long-term environmental contamination. Persists for decades in soil.

Submicron aerosols

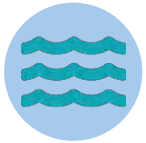
Most hazardous — evade conventional filters, deep lung penetration.

CsI (focus)

Major particulate form. Stable, non-volatile, water-soluble — ideal ESP target.

Research Objectives

This study systematically investigates how ESP design parameters govern CsI aerosol removal efficiency under accident-relevant conditions.



Operating Mode

- Dry
- Droplet-assisted (~5 µm diameter water mist)
- Wet ESP operation for re-entrainment prevention and back-corona suppression

Electrode Geometry

- Fishbone (multiple sharp points)
- Sawtooth (strip with trapezoidal protrusions)
- Wire (1 mm diameter) discharge electrodes for corona uniformity and particle charging efficacy

Applied Voltage

- 10 kV
- 15 kV
- 18 kV DC on corona stability, space charge, and size-resolved collection efficiency

Temperature Effects

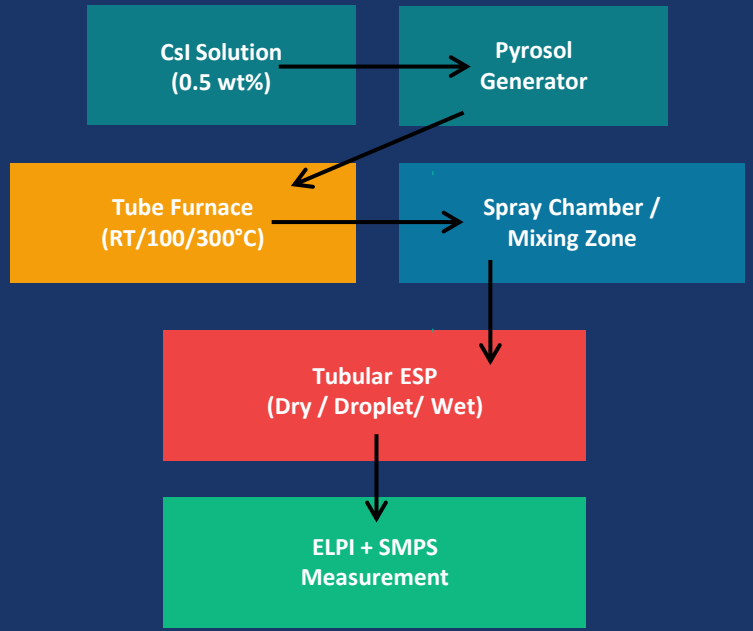
- Room temperature
- 100 °C
- 300°C to cover accident-relevant thermal evolution in containment

Experimental Setup & Aerosol Generation

Tubular ESP Specifications

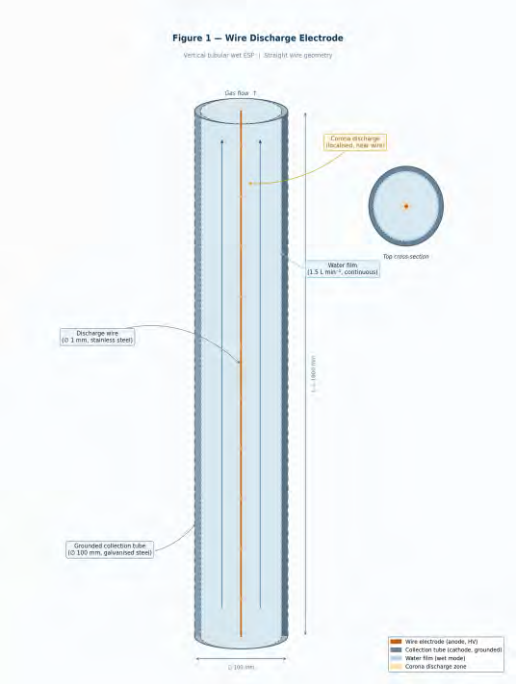
Collection tube:	Galvanized steel, Ø 100 mm, L = 1000 mm
Flow rate:	15 lpm (residence time ~31 s)
Voltage supply:	10, 15, 18 kV DC (Genvolt 72030)
Temperature:	Room temp / 100°C / 300°C
Water film (wet):	1.5 lpm – continuous wall flushing
Aerosol:	CsI 0.5 wt% solution (Pyrosol 7901)
Carrier gas:	Nitrogen
Measurements:	ELPI + SMPS (0.01–10 µm)

Flow Path

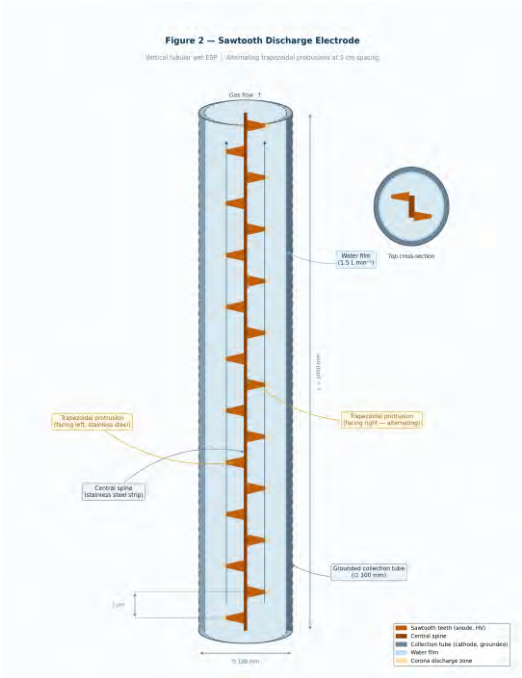


Discharge Electrode Geometries

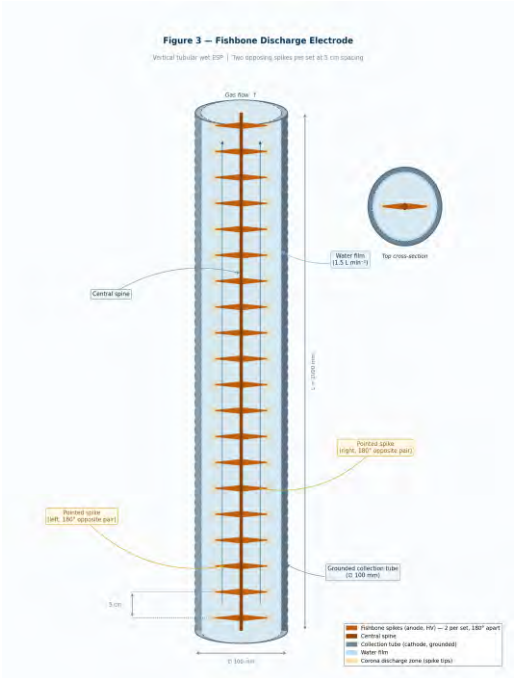
Wire Electrode



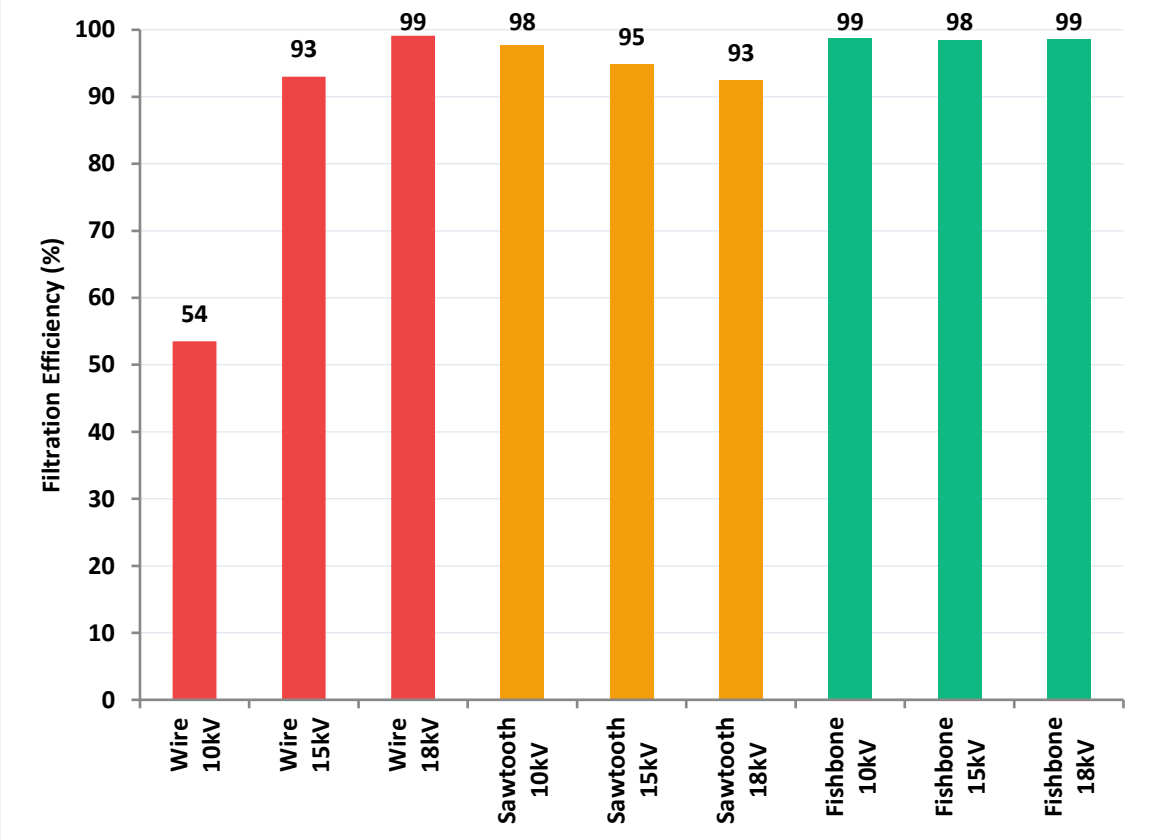
Sawtooth Electrode



Fishbone Electrode



Result 1: Electrode Geometry Dominates Performance



Wet Mode — Filtration Efficiency (%) by Electrode & Voltage

Performance Hierarchy:

Fishbone

Consistently >97%
All voltages robust

Sawtooth

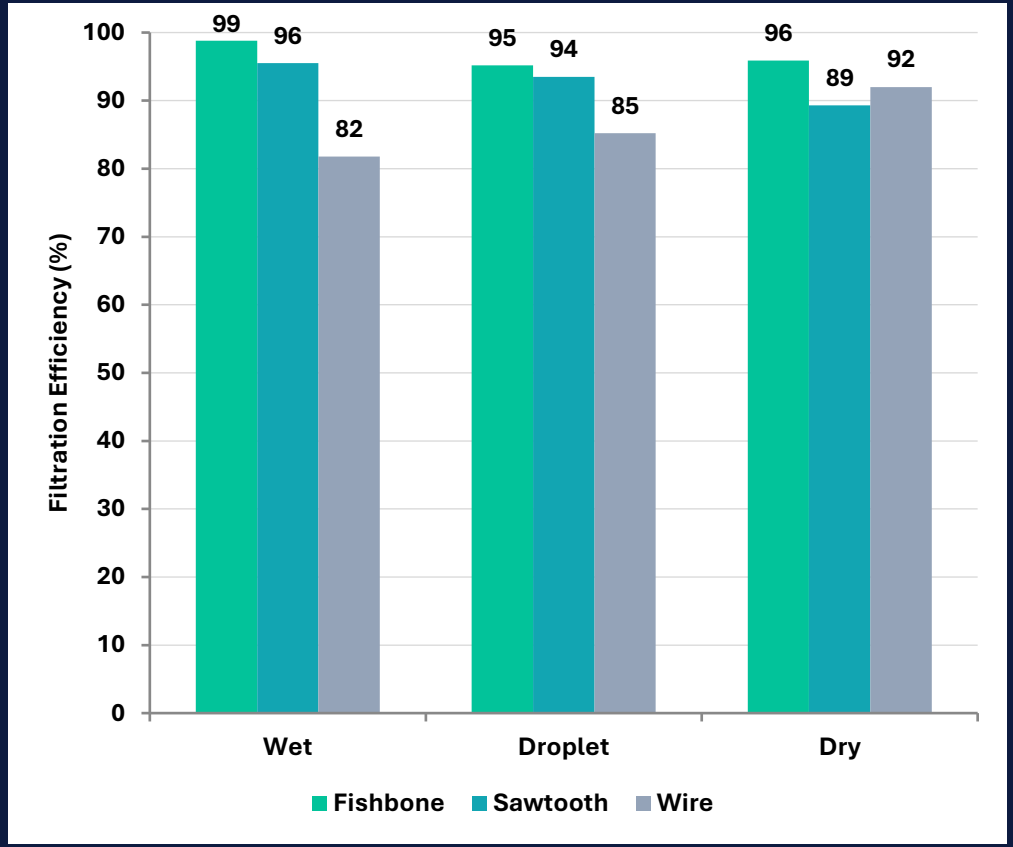
88–99.7%
Voltage-dependent

Wire

44–99%
Highly variable

Fishbone > Sawtooth >> Wire
Consistent across all modes & temperatures

Result 2: Wet Operation — Why It Outperforms Dry & Droplet-Assisted



Mean Filtration Efficiency (%) by Operating Mode & Electrode (all voltages & temperatures)

Why Wet Mode Wins:

- Prevents back-corona — conductive water film maintains consistent collection surface
- Eliminates re-entrainment — collected particles continuously washed away
- Stabilizes corona discharge — suppresses space charge buildup on plates
- Critical for CsI — water solubility ensures permanent capture and retention

Water film quality is as critical as corona strength!

Result 3: Voltage & Temperature as Conditional Drivers

Voltage Effects

Fishbone (wet):

Plateaus >99% across 10–18 kV. Optimal charging achieved even at 10 kV — low voltage sufficient with structured electrode.

Wire electrode:

Acutely voltage-dependent. Efficiency jumps from 10→15 kV but may decline at 18 kV (corona saturation / space charge opposition).

Key insight:

Higher voltage is NOT always better. Space charge buildup at 18 kV can hinder particle migration, especially for wire electrodes.

Temperature Effects

300°C enhances structured electrodes:

Reduced gas density → longer electron mean free path → stable corona, higher ion mobility → better diffusion charging.

Wire electrode at high T:

May worsen performance. Thermal effects disrupt already marginal corona stability; ionic agitation increases turbulent mixing.

Practical implication:

Temperature benefit is conditional — only realized when a stable, uniform corona exists. Electrode design determines the thermal response.

Top-Performing Configurations (>99% Efficiency)

ESP Mode	Electrode	Voltage (kV)	Temperature	Efficiency (%)	GMD Out (nm)
Wet	Fishbone	10	300°C	**99.90 ★**	24.2
Wet	Fishbone	15	300°C	**99.28**	26.5
Wet	Fishbone	18	Room temp	**99.29**	26.0
Wet	Sawtooth	15	300°C	**99.66**	24.1
Wet	Sawtooth	10	300°C	**99.78**	30.6

★ Best configuration: Wet + Fishbone + 10 kV + 300°C → 99.90% efficiency, outlet GMD = 24 nm

Result 4: Size-Selective Collection & Outlet Size Distributions

Inlet aerosol GMD: 400–800 nm (accumulation mode) → Best-case outlet GMD: 20–40 nm (nucleation/Aitken mode)

Charging Physics

> 300 nm

Field charging dominates — charge ∝ dp^2. Strong electrophoretic force → efficient collection.

< 100 nm

Diffusion charging — low charge levels, low migration velocity, drag dominates → nanoparticle escape.

100–300 nm

Transition zone — efficiency minimum. Most challenging size range for any ESP.

Practical Implications

- GMD shift from ~600 nm to 20–30 nm means mass concentration is reduced far more than number concentration alone suggests
- Wire electrode in dry mode: outlet GMD can exceed inlet GMD — re-entrainment of agglomerates or selective small-particle removal
- Even with near-100% number efficiency, some nanoparticle penetration remains — multi-stage filtration may be required for maximum DF
- Fission product aerosols span 0.1–10 µm; ESP alone may not capture all freshly nucleated particles without condensational pretreatment

Result 5: Particle Charge Analysis — Mechanistic Evidence

Measuring charge on penetrating particles reveals WHETHER failure is charging or migration — a key diagnostic beyond efficiency alone.

High Charge on Penetrators

(Fishbone — Wet)

Penetrating nanoparticles carry measurable positive charge — charging was successful. Escape is due to boundary layer slippage or micro-scale re-entrainment, **NOT** charging failure. Performance limited by hydrodynamics.

Intermediate Charge

(Sawtooth — Droplet/Dry)

Mixed charging efficacy. Some particles escape uncharged, others with partial charge. Suggests non-uniform field zones between sawtooth protrusions. Design is functional but not optimal.

Near-Zero Charge

(Wire — Dry/Droplet)

Primary failure mode is **INCOMPLETE CHARGING**. Particles pass through the corona zone acquiring insufficient charge to respond to the electric field. Ion density too low in dead zones. Geometry is the root cause.

Temperature effect on charge: Fishbone shows increasing charge at 300°C (improved corona); Wire may show decreasing charge (corona disruption)

Mechanistic Summary: How Electrode Design Controls Performance

	Corona Discharge	Particle Charging	Space Charge	Migration & Collection
Fishbone	Dense, uniform multi-point ion cloud	Uniform across entire duct cross-section	Distributed → lower local density	Strong, uniform → near 100%
Wire	Narrow, localized sheath	Only particles near wire zone	Concentrated → opposing field	Weak, localized → dead zones

Key principle: Electrode design must prioritize a WIDE, STABLE ionization zone over peak field intensity at the discharge tip.

Optimal Configuration: Synergistic Parameter Combination

Fishbone Electrode

Dense, uniform multi-point corona ensures every particle is exposed to charging field regardless of trajectory

Wet Operation

Conductive water film prevents back-corona and re-entrainment; permanent particle capture via dissolution

WET ESP
Fishbone
10 kV
300°C
→ 99.90%

10–15 kV Moderate Voltage

Sufficient ion production without space charge suppression; reduced energy use and insulation stress

300°C Temperature

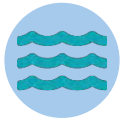
Reduced gas density stabilizes corona; enhanced ion mobility boosts diffusion charging of submicron particles

This optimal combination is not parameter maximization — it is SYNERGISTIC BALANCE of complementary mechanisms.

Design Implications for FCVS in Severe Accident Management

1. Use Structured Electrodes

Fishbone or multi-point designs are essential for nuclear safety applications. Wire electrodes are unsuitable where high reliability is required — their dead zones are unacceptable in safety-critical filtration.



2. Prioritize Wet Operation

Water film quality is a primary performance parameter. Back-corona suppression and re-entrainment elimination are decisive, especially for sticky or reactive CsI and iodine oxide aerosols.

3. Operate at Moderate Voltage (10–15 kV)

Higher voltage does not guarantee higher efficiency. 10 kV with fishbone achieves near-100%; maximizing voltage increases energy use and failure risk without benefit.

4. Consider Multi-Stage Filtration

Even the best ESP allows some nanoparticle penetration (<50 nm). Multi-stage or complementary mechanisms (condensation growth, pool scrubbing + ESP) are recommended for maximum decontamination factor.

5. Charge Diagnostics for Validation

Measure electrical charge on penetrating particles — not just efficiency. This identifies whether failure is in charging or migration and enables targeted design improvements.

Comparison with Prior Dry ESP Studies & Broader Applicability

vs. Prior Dry ESP Study (Basnet et al. 2025)

	Dry	Wet
Configuration	Dry ESP — no water	Wet ESP — water film
Re-entrainment	Significant risk	Eliminated
Back-corona	Occurs at high load	Suppressed
Best efficiency	Moderate (design-dependent)	99.90% (fishbone, 10kV)
Key limitation	Resistive particle layer	Water supply management

Broader Applicability

Small Modular Reactors (SMR)

Compact tubular ESP geometry is ideal for space-constrained SMR containment venting designs

High-Temperature Environments

300°C performance demonstrated — applicable to industrial hot-gas filtration beyond nuclear sector

Iodine Oxide Filtration

Mechanism-based design provides pathway for targeting hard-to-capture iodine oxide aerosols in future FCVS

Industrial Fine-Particle Control

Fishbone electrode and wet mode principles transfer directly to power plant stack emission control

Conclusions

1

Electrode geometry is the decisive hardware parameter

Fishbone > Sawtooth >> Wire across virtually all conditions. Multi-point designs providing wide, stable ionization zones outperform localized discharge.

2

Wet operation provides superior and stable performance

Back-corona suppression, re-entrainment elimination, and stable corona discharge make wet mode the preferred configuration for nuclear safety applications.

3

Voltage optimization beats voltage maximization

10–15 kV with fishbone achieves near-100% efficiency. Pushing to 18 kV risks space charge suppression with no additional gain — especially for wire electrodes.

4

Charge diagnostics identify the root cause of failure

High charge on penetrators → hydrodynamic limit. Near-zero charge → charging failure. This diagnostic framework enables targeted design improvements.

5

Clear design roadmap for FCVS integration

Wet ESP + structured electrode at 10–15 kV delivers the decontamination factors needed for severe accident source term mitigation with minimal power consumption.

SAFER 2028

Overview of Fission Product Behavior Modeling in the SIRIUS Code

Jaehyun Ham*, Kwang-Soon Ha
Korea Atomic Energy Research Institute (KAERI)

jhham@kaeri.re.kr, tomo@kaeri.re.kr

ABSTRACT

SIRIUS has been developed at KAERI since 2015 as a C++ language-based code for analyzing fission product (FP) behavior under severe accident conditions. It models FP release from molten corium, gas-to-aerosol conversion, and transport in steam–gas mixtures, including deposition on structures or water surfaces.
Instead of solving thermal-hydraulic equations, SIRIUS receives input from lumped-parameter thermal-hydraulics analysis codes. It can be coupled in real time via MS-MPI or run stand-alone using text input, enabling analyses of systems such as Pressurized Water Reactors (PWRs) and Molten Salt Reactors (MSRs). Initial FP inventories and decay heat are provided by core analysis codes such as ORIGEN.
For PWRs, SIRIUS calculates gap release axially connected fuel rods, Arrhenius-based release from the core, and release from structural components such as shrouds. Chemical combinations (e.g., CsI, Cs_2MoO_4) are modeled with user-defined combination ratios. For MSRs, FP gas release follows evaporation–condensation. FPs moving into cooler regions may form aerosols based on saturation vapor pressure, while hygroscopic Cs compounds absorb water vapor depending on humidity. Aerosols are subject to spray removal and several deposition mechanisms, with resuspension from pools modeled by evaporation–condensation.
Mass conservation of gaseous and aerosol FPs can be solved using implicit or explicit schemes, with removal processes represented by λ-coefficients. The time step can be optimized for large-scale analyses such as uncertainty analysis and AI-based surrogate model development. Recently, SIRIUS has been validated against various separate-effect tests (AHMED, etc.) and integral experiments (PHEBUS, etc.) to support the licensing of PWR-based i-SMRs. In addition, comparative studies against the MAAP code have been conducted for large-scale containment cases. Future work includes a multi-component sectional method and coupling with chemical codes such as GEMS to incorporate Gibbs free energy minimization based saturation pressure models.

KEYWORDS
SIRIUS Code, Severe Accident, Fission Product Behavior Analysis, Lumped Parameter Approach

1. Introduction

CINEMA code, which has recently been utilized in the licensing of integral Small Modular Reactor (i-SMR), is an integral code developed in Korea since 2011 for Pressurized Water Reactor (PWR) applications, based on a lumped-parameter approach. Figure 1 shows CINEMA code structure. CSPACE and SACAP codes each analyze in-vessel and ex-vessel phenomena based on separate thermal-hydraulic analyses. These two codes interlink their thermal-hydraulic data at each time step through MASTER, which collects and shares the data to facilitate integrated analysis [1]. Within this framework, SIRIUS performs fission product

* Footnote, if necessary, in Times New Roman font and font size 10

(FP) behavior analysis based on mass conservation equations using external thermal-hydraulic analysis results. The scope of SIRIUS covers the release, transport, and removal behavior of FPs within reactor pressure vessel (RPV), reactor coolant system (RCS), and containment.

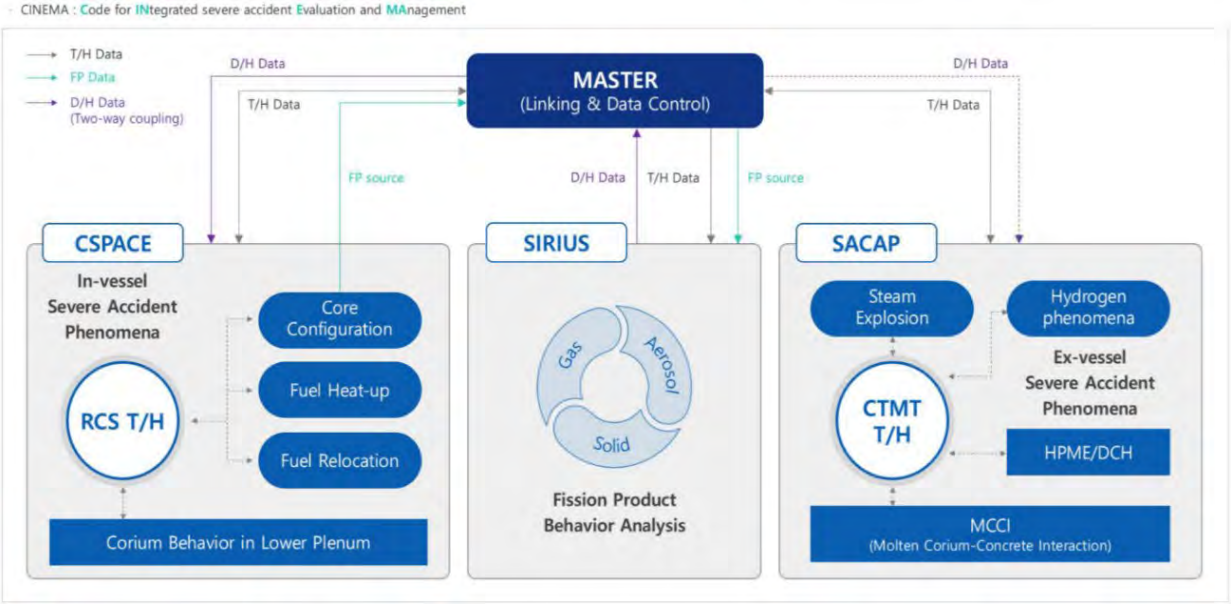

Figure 1. CINEMA code structure

Specifically, it models FP release mechanisms such as gap release from fuel rods and release due to fuel melting, as well as inter-node transport of released FPs. The code simulates condensation, evaporation, impaction, gravitational settling, diffusion, thermophoresis, and removal processes due to containment spray systems. In addition, SIRIUS tracks and calculates the FP decay heat associated with the release, transport, and wall deposition.

As the necessity for FP behavior analysis has expanded to advanced reactors such as Molten Salt Reactor (MSR), SIRIUS has been enhanced to evaluate FP release through the evaporation and condensation of compounds within liquid fuel. This improved framework utilizes a saturation vapor pressure database to simulate release mechanisms at the salt-gas interface, accounting for the unique absence of traditional fuel cladding.

This paper is organized as follows. Chapters 2 and 3 establish the core framework and physical models of SIRIUS for FP behavior in Pressurized Water Reactors (PWRs). Chapter 4 presents technical extensions and modifications for advanced reactor applications.

2. Modeling of Fission Product Behavior for PWR

Figure 2 illustrates the calculation flow of SIRIUS. It is initialized using node and link information provided by user input or coupled thermal–hydraulic modules (CSPACE and/or SACAP), and the initial inventories of FPs are evaluated. FPs are treated in three phases at each node: solid (retained), gaseous, and aerosol. Based on fuel rod temperature, solid-phase FPs are released as gaseous species and transported between nodes. Aerosol FPs are likewise transported with the carrier gas flow, while undergoing removal processes. Phase transitions between gaseous and aerosol states are determined by local node temperatures, and the final inventories of each phase are calculated at every time step. Released gaseous and aerosol FPs are assumed to instantaneously reach thermal equilibrium with the local fluid, and therefore energy equations are not solved. For efficient computation, SIRIUS time step can be set larger than the time steps of the thermal–hydraulic modules. The user can determine whether the decay heat of FPs is considered as a heat source in the thermal–hydraulic modules through the two-way coupling option.

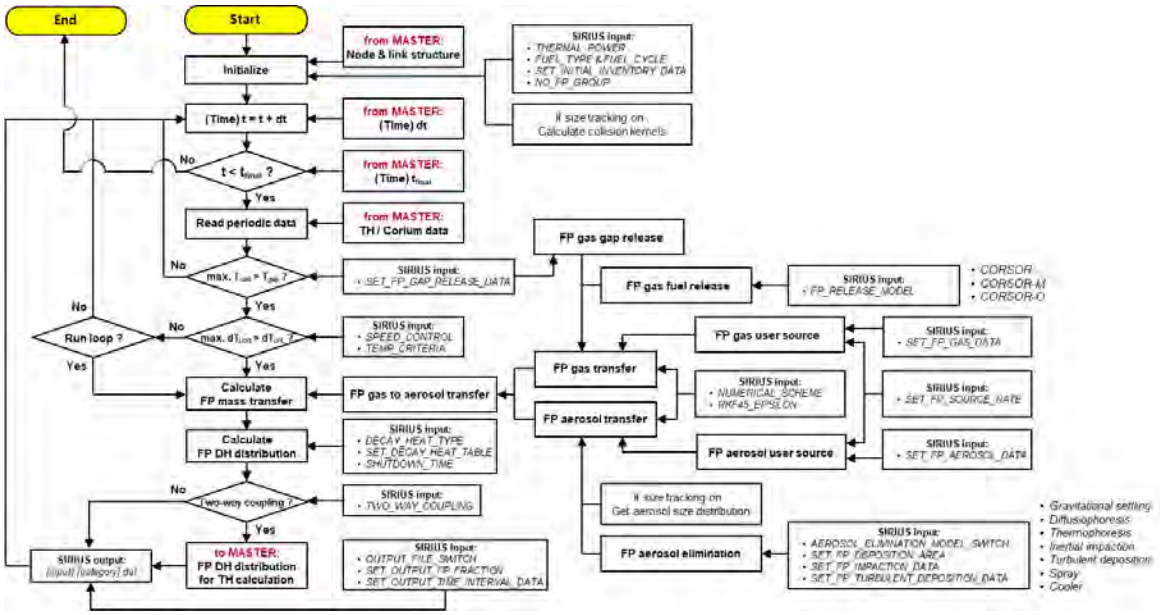

Figure 2. SIRIUS calculation flowchart

2.1. Initial Inventory and Transport of Solid-Phase Fission Products

For best-estimate calculations, SIRIUS provides optional generalized initial inventories of major FP nuclides for representative nuclear power plants, expressed as mass per thermal power (g/MW_{th}) as a function of core burnup. In addition to the built-in options, users may directly specify nuclide-specific initial inventories based on fuel cycle characteristics by utilizing core calculation results obtained from codes such as ORIGEN or OpenMC.

Using user-provided information on reactor thermal power and burnup, SIRIUS evaluates the total initial inventories of individual FP nuclides present in the entire core. The total mass of solid-phase (retained) FP is then distributed to each core node according to the fraction of UO_2 mass contained in that node. The UO_2 initial mass assigned to each node is provided by the thermal–hydraulic module.

Solid-phase (retained) FP elements contained within the fuel and structures in the core region are released as gas as the temperature increases. In addition, when the temperature rise compromises the structural integrity of the fuel or structures, relocation toward lower nodes occurs. In this process, the solid-phase FP initially contained in the fuel and structures is transported downward along with phenomena such as candling and slumping.

SIRIUS receives inter-node transfer rates from the CSPACE and directly calculates the time-dependent change in FP mass from the initial mass of each core node. The transfer rate between core nodes is defined as the mass of fuel or structure relocated from the sending node divided by the total fuel or structure mass in that node. The reason for transferring the rates rather than directly coupling the time-dependent node masses is that, when temperature distributions vary among nodes, the FP mass can change independently of the fuel mass. Therefore, accurate calculation of solid-phase FP release requires that inter-node transport be calculated precisely first.

To simulate transport between non-directly connected nodes, such as the relocation of fuel to the lower hemisphere due to core support plate failure, in the same manner as the CSPACE, SIRIUS applies a vertical-node-specific model: when the fuel mass in an upper core node falls below 2% of its initial value (in CSPACE, transfer is terminated when the fuel mass falls below 1% of the initial value to avoid numerical issues, effectively setting the node's fuel mass to zero), the remaining mass is transferred entirely to the lower node.

$$m_{s,i}^{n}(t+\Delta t) = \sum_{k=1}^{N} m_{s,i}^{n}(t)\frac{\Delta m_{cspace}^{k-n}(t+\Delta t)}{m_{cspace}^{k}(t)} \quad (1)$$

Equation (1) describes the update of the mass of solid-phase FP *i* in node *n* at time $t+\Delta t$, denoted $m_{s,i}^{n}(t+\Delta t)$. The mass is updated based on its value at the previous time step, $m_{s,i}^{n}(t)$, scaled by the fraction of the carrier mass (fuel and structural materials) transferred from each node *k* to node *n*, given by $\frac{\Delta m_{cspace}^{k-n}(t+\Delta t)}{m_{cspace}^{k}(t)}$.

2.2. Release Modeling of Gaseous Fission Products

In SIRIUS, when the temperatures of the fuel rods and other structures rise, various FPs contained in the fuel rods are released in gaseous form as illustrated in Figure 3. Gas release is categorized into two types: gap release and meltdown release. The activated core is divided into *m x n* grid in the axial and radial directions, and the temperature and mass of the cladding and fuel in each node are calculated. Gap release is calculated for each node with a UO_2 mass greater than zero at the initial condition when the cladding temperature exceeds the gap release setpoint temperature (the default value assumed in SIRIUS is 1173 K).

Since the fuel and cladding are a single structure in the axial direction, gap release actually occurs for each individual structure (i.e., the gaps are connected along the axial direction). To simulate this more realistic behavior, users can manually specify the axial connections between core nodes, allowing gap release to occur simultaneously across axially connected nodes. In other words, for core nodes connected in the axial direction, gap release can be simulated to occur simultaneously regardless of the cladding temperature.

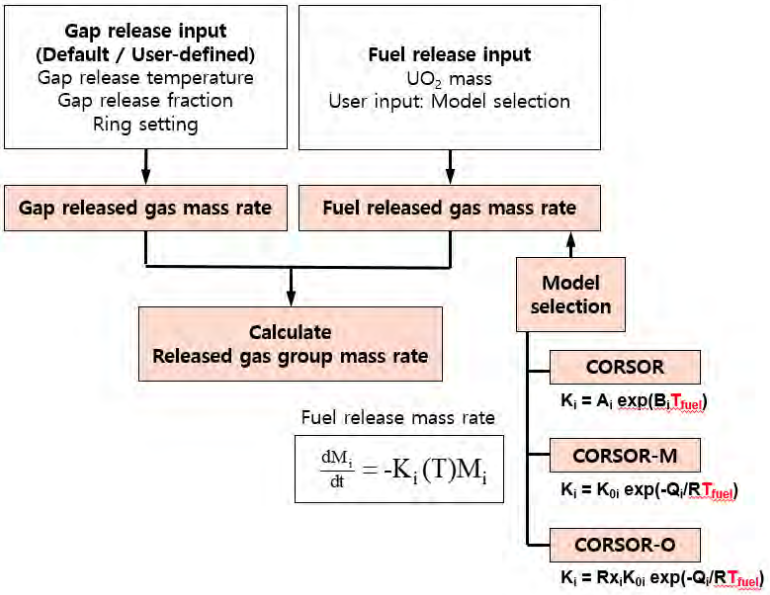

Figure 3. Calculation procedure for gaseous fission product release in SIRIUS

Gaseous release from fuel and structural materials can be simulated using three models in SIRIUS: CORSOR, CORSOR-M, and CORSOR-O. In CSPACE, energy exchange between core nodes and surrounding structures, such as the shroud, upper head, and core support plate, is calculated. These structures are discretized into *m x n* grid for temperature evaluation, and, similar to nuclear fuel, they can undergo melting, relocation. Based on this information, SIRIUS evaluates temperature-dependent gas generation not only from structures within the core nodes, such as cladding and spacer grids, but also from ex-core structures including the core support plate and upper head. These structures are assumed to be composed of

stainless steel, and the releasable species considered are iron (Fe), chromium (Cr), nickel (Ni), and copper (Cu). These species are known to be released more slowly at high temperatures compared to other FPs. However, because their initial masses are significantly larger than those of typical volatile FPs, their release can substantially increase the aerosol concentration in the atmosphere when gas generation is taken into account.

2.3. Fission Product Groups and Inter-Group Combination Model

SIRIUS allows the analysis of major volatile FPs by grouping them based on the NUREG-1465 report [3] and has recently been improved to enable grouping based on the SAND2011-0128 report [4] as well. FP grouping based on the SAND2011-0128 report, as shown in Table I, classifies 41 FPs into 15 groups. The bolded nuclides are used as the representative molecular weights for each group.

Table II. Fission product group based on the SAND2011-0128 report [4]

No.	Group name	Components	Molar weight (g/mole)
1	Noble gases	**Xe**, Kr	131.3
2	Alkali metals	**CsOH**, RbOH	149.913
3	Cesium iodide	**CsI**	259.8054
4	Cesium molybdate	**Cs_2MoO_4**	425.75
5	Halogens	**I_2**, Br_2	253.8008
6	More volatile main group	**Cd**, Sb, As	112.4
7	Less volatile main group	**Sn**, Ag, In	118.69
8	Alkaline earths	**BaO**, SrO	153.34
9	Chalcogens	**Te**, Se	127.6
10	Early transition elements	**Mo**, Nb, Tc	95.94
11	Platinoids	**Ru**, Rh, Pd	101.07
12	Trivalents	**La**, Y, Pr, Nd, Pm, Sm, Eu, Gd, Am, Cm	138.91
13	Uranium	**UO_2**	270.03
14	Tetravalent	**Ce**, Zr, Np, Pu	140.12
15	Structural materials	**Fe**, Cr, Ni, Mn	55.845

When using the group classification based on the SAND2011-0128 report, the combination ratio for Group 3 (CsI) and Group 4 (Cs_2MoO_4) in Table II can be specified. The combination ratio set by the user represents the maximum fraction achievable under “possible conditions.” The combination ratio is a real value between 0 and 1. For example, if the “I→CsI” value is 1, all released iodine can combine with the released cesium to form CsI under possible conditions. Here, “possible conditions” refer to situations in which the mass of released cesium is greater than the mass of released iodine. If the released cesium mass is less than that of iodine, the effective combination ratio becomes less than 1. Combination between nuclide groups is first calculated during the release from the fuel, and then recalculated after the transport and deposition of gaseous and aerosol species to each node (i.e., after solving the mass conservation equations). This approach is used to ensure that the combination between species with significantly different release rates, such as Cs and Mo, can approach the user-defined combination ratio, as illustrated in Figure 4. The reactivity of the combination is assumed to be higher for CsI than for Cs_2MoO_4, allowing sequential combination to be modeled. That is, iodine first combines with cesium according to the specified combination ratio, and any remaining cesium then combines with molybdenum according to its defined combination ratio.

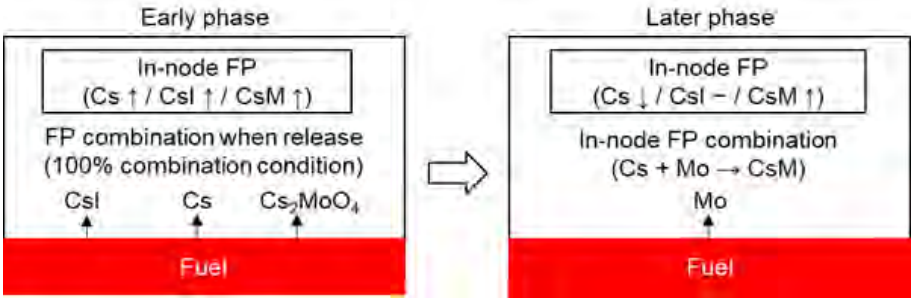

Figure 4. Inter-group combination modeling in SIRIUS

2.4. Transformation, Condensation, and Evaporation of Gaseous and Aerosol Fission Products

FP groups can exist in both gaseous and aerosol phases. The masses of the gaseous and aerosol phases are calculated based on the temperature-dependent vapor pressure. If the pressure of the gaseous FP group exceeds the vapor pressure, the excess gaseous FP is assumed to condense into aerosols. In other words, for each node, the number of moles that can exist in the gas phase is limited by the saturation vapor pressure, and any moles exceeding this limit are converted to aerosols.

For a node n with temperature T^n and volume V^n, let the number of moles of group i gaseous FP be $n_{v,i}^n$. The mass of group i aerosol FP formed, $\Delta m_{a,i}^n$, can then be expressed as Equation (2). In Equation (2), M_i represents the molecular weight of the group i FP, and the saturation mole number of the group i, $n_{v,sat,i}^n$, can be calculated using the saturation vapor pressure $P_{i,sat}^n$ as shown in Equation (3).

$$\Delta m_{a,i}^n = \left(n_{v,i}^n - n_{v,sat,i}^n\right) M_i \tag{2}$$

$$n_{v,sat,i}^n = \frac{P_{i,sat}^n V^n}{R\,T^n} \tag{3}$$

The saturation vapor pressure of group i FP in Equation (3) can be calculated using the equation form shown in Equation (4), with coefficients A, B, and C for each group taken from references [5, 6]. The coefficients for the structural material group are assumed to be the same as those for the Mo group, following the methodology of references [5, 6].

$$log_{10}\left[P_{i,sat}(mmHg)\right] = -\frac{A_i}{T} + B_i + C_i\, log_{10}(T) \tag{4}$$

If group i aerosol FP exists in a given node and the vapor pressure of group i gaseous FP is below the saturation vapor pressure, the aerosol is assumed to evaporate into the gas phase. In other words, whenever aerosol FP is present, the gaseous FP is always maintained at its saturation vapor pressure. Inert gases always exist in the gaseous phase, so no conversion between gas and aerosol is calculated.

SIRIUS includes a model to calculate evaporation and condensation based on the saturation vapor pressure, as shown in Equation (5), in order to simulate the interactions between gas and liquid phases that can occur in actual conditions. Equation (5) calculates the amount of evaporation for each type of fission product in the liquid based on the saturation vapor pressure and the concentration difference in air. In a closed system, as fission products evaporate from the liquid, the saturation vapor pressure decreases and the concentration in the air increases, gradually reducing the evaporation rate while increasing condensation, until an equilibrium between the two phases is reached.

$$\frac{dm_i}{dt} = \mathrm{A}k_i(C_i^a - C_i^s) \tag{5}$$

m_i represents the condensed mass of group i, C_i^a is the airborne concentration of group i, C_i^s is the saturated concentration of group i, A is the surface area, and k_i is the mass transfer coefficient for group i.

Gaseous fission products can undergo evaporation and condensation reactions with liquids, as illustrated in Figure 5, and can also be converted into aerosols.

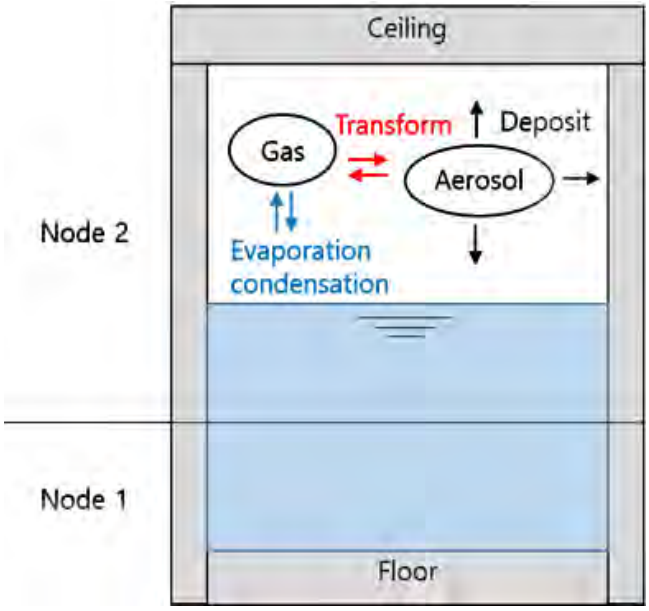

Figure 5. Modeling of aerosol deposition on liquid surfaces and gas phase evaporation/condensation in SIRIUS

2.5. Modeling of Aerosol Fission Products

The aerosol deposition and removal model simulate the reduction of aerosol mass as aerosols are transported within the RCS and containment due to various physical phenomena. Six mechanisms of aerosol deposition and removal are considered in SIRIUS.

1. Sedimentation or Gravitational Settling: Aerosols collide and agglomerate, increasing in size and mass, and settle to the RCS floor under the influence of gravity.
2. Inertial Impaction: Aerosols carried by the vapor–non-condensable gas mixture flow collide with surfaces, such as bends in RCS piping, and attach to the walls.
3. Thermophoresis: Aerosols move toward cooler surfaces due to temperature gradients in the vapor–non-condensable gas mixture and deposit on these surfaces.
4. Diffusiophoresis: As vapor condenses on cold surfaces, non-uniform aerosol distributions are created. Aerosols migrate radially due to concentration gradients and attach to walls upon collision.
5. Turbulent Deposition: In high-velocity pipe flows, aerosols deviate from the streamlines and deposit on the pipe walls or other surfaces.
6. Spray: Aerosols are removed from the air and deposited onto floors or walls by water droplets sprayed from containment spray systems.

To simulate such aerosol removal phenomena, a total removal rate, λ_t, was introduced as shown in Equation (6), which is a correlation developed based on experimental results.

$$\lambda_t = \lambda_{sed} + \lambda_{imp} + \lambda_{diff} + \lambda_{th} + \lambda_{turb} + \lambda_{spray} \quad (6)$$

The total removal rate (λ_t) has units of "1/s" and is multiplied by the aerosol mass on the right-hand side of the mass conservation equation to simulate the rate of aerosol mass reduction. When both inertial

impaction and gravitational settling are considered simultaneously, the deposition removal rates for each mechanism are corrected according to reference [7], as expressed in Equations (7) and (8).

$$\lambda_{sed} = \lambda_{sed} * e^{-\frac{1}{3}\left(\frac{\lambda_{imp}}{\lambda_{sed}}\right)^2} \quad (7)$$

$$\lambda_{imp} = \lambda_{imp} * e^{-\frac{1}{3}\left(\frac{\lambda_{sed}}{\lambda_{imp}}\right)^2} \quad (8)$$

SIRIUS tracks the amount of aerosol deposited on surfaces using six different models. Figure 6 illustrates the definition of aerosol deposition surfaces. In SIRIUS, each node is treated as having a cylindrical shape, with the upward-facing surface defined as the floor, the vertically oriented surfaces as walls, and the downward-facing surface as the ceiling. Considering the porosity of the node, gaseous and aerosol FPs are assumed to be uniformly distributed within the gas volume, and deposition is assumed to occur only within this gas volume (shown as the green area in Figure 6).

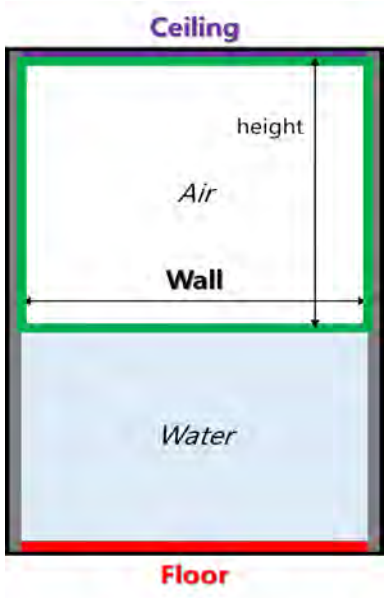

Figure 6. Definition of aerosol deposition surfaces in SIRIUS

When nodes are connected vertically, for example as shown in Figure 5, if *Node 1* is completely filled with liquid (void fraction = 0) and *Node 2* contains liquid only partially (0 < void fraction < 1, liquid height ≥ 1 cm), the amount of aerosol deposition is calculated based on the liquid surface area. The liquid surface area is assumed to be equal to the node's floor area, so the floor area value is used regardless of whether liquid is present. Thus, the regions available for aerosol deposition include the floor, walls, ceiling, and the liquid surface on the floor, for a total of four regions. Aerosols deposited on the liquid surface are resuspended into the gas phase if the liquid completely evaporates (i.e., void fraction = 1), allowing the resuspension of aerosols previously dissolved in the liquid to be calculated.

When a liquid layer exists on wall or ceiling surfaces, deposited aerosols can be transported downward along with the liquid. A fraction of the aerosol mass deposited on walls and ceilings, as defined by user input, is reclassified as floor-deposited aerosol mass due to mechanisms such as diffusiophoresis and thermophoresis. For example, if this fraction is set to 1, the aerosol mass on walls and ceilings is calculated as zero, and the corresponding mass is added entirely to the floor deposition.

SIRIUS utilizes wall temperatures by linking to the temperatures of heat structures connected to each node in the thermal-hydraulic modules. A thermal–hydraulic node may be connected to multiple heat structures, but in actual physical phenomena, aerosol deposition predominantly occurs on the coldest

surfaces, such as heat exchangers, regardless of their area. Therefore, by default, the lowest surface temperature among all heat structures connected to a single node is used in the calculations. If needed, the highest surface temperature can also be used, which can be specified through user input.

The growth of hygroscopic aerosols is not calculated incrementally over time steps in SIRIUS; instead, it is assumed that particles immediately reach the maximum diameter allowed under the prevailing thermal–hydraulic conditions. The saturation vapor pressure used for relative humidity calculations is based on the water temperature if liquid is present, or on the vapor temperature if no liquid exists. A node is considered to contain water if the liquid height is 1 cm or greater. The particle diameter ratio reflecting hygroscopic growth is calculated using an equation based on Mason formula. The density and surface tension of water are assumed to remain constant. When the particle diameter ratio is much greater than 1, the properties of water dominate, making this assumption reasonable. The base diameter of aerosols is set to 1 μm. By default, CsOH, CsI, and Cs_2MoO_4 are treated as hygroscopic aerosols, and their solubility is calculated by linear interpolation based on the gas temperature. When the gas temperature exceeds 600 K, the solubility begins to decrease, and it becomes zero at temperatures of 647 K or higher.

2.6. Numerical Methods

Gaseous FPs are assumed to be generated and released from the fuel and to move together with the carrier gas. Aerosol FPs are assumed to form from the gaseous FPs and, like the gaseous phase, move together with the carrier gas. Therefore, only mass conservation is considered, and separate momentum conservation equations are not solved. Figure 7 illustrates the concept of FP transport between nodes as considered in SIRIUS.

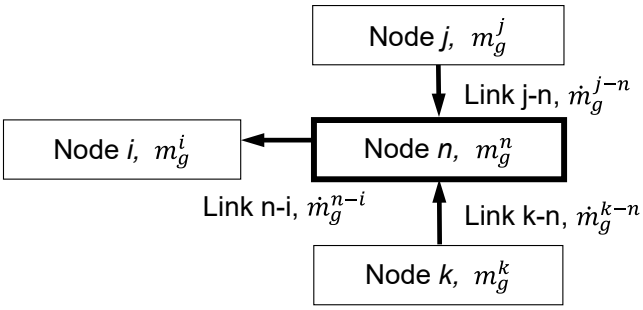

Figure 7. Fission product transport calculation in SIRIUS

The transport of gaseous and aerosol FPs can be expressed using the mass conservation equations shown in Equations (9) and (10). SIRIUS allows the use of either explicit or implicit methods to numerically solve the FP transport equations in the RCS and containment.

$$\frac{dm_{v,i}^n}{dt} = \dot{m}_{v,i,in}^n - \dot{m}_{v,i,out}^n + \dot{G}_{v,i}^n \tag{9}$$

$$\frac{dm_{a,i}^n}{dt} = \dot{m}_{a,i,in}^n - \dot{m}_{a,i,out}^n - \lambda_{t,i}^n m_{a,i}^n + \dot{G}_{a,i}^n \tag{10}$$

$m_{v,i}^n$ represents the mass of gaseous group *i* FP in node n. $\dot{m}_{v,i,in}^n$ is the mass flow rate of gaseous group *i* FP entering node *n*. $\dot{m}_{v,i,out}^n$ is the mass flow rate of gaseous group *i* FP leaving node *n*. $\dot{G}_{v,i}^n$ represents the mass generation rate of gaseous group *i* FP in node *n*. $m_{a,i}^n$ is the mass of aerosol group *i* FP in node *n*. $\dot{m}_{a,i,in}^n$ represents the mass flow rate of aerosol group *i* FP entering node *n*. $\dot{m}_{a,i,out}^n$ is the mass flow rate of aerosol group *i* FP leaving node *n*. $\dot{G}_{a,i}^n$ represents the mass generation rate of aerosol group *i* FP in node *n*. Finally, $\lambda_{t,i}^n$ is the total removal rate of aerosol group *i* FP in node *n*.

By default, SIRIUS performs calculations using the same time step as the coupled thermal–hydraulic modules. However, since SIRIUS simulates FP generation based on core fuel temperatures and transport between thermal–hydraulic nodes according to gas flow rates, the results do not change significantly if there are no substantial variations in thermal–hydraulic conditions. This characteristic allows the user to set SIRIUS time step larger than that of the thermal–hydraulic module to increase computational speed.

However, this approach does not utilize the thermal–hydraulic module data at every time step, which may lead to distorted results. That is, important changes in thermal–hydraulic conditions, such as variations in gas flow rates between thermal–hydraulic nodes, may not be reflected in the FP behavior calculations. To prevent such issues when setting SIRIUS time step, the thermal–hydraulic data at all time steps are compared with the values used at the previous SIRIUS calculation. If the change in any variable exceeds a predefined threshold, SIRIUS is forced to perform a calculation at that time step. The threshold for forced calculation can be set individually for the following four variables.

- Core fuel temperature
- Gas temperature in the thermal–hydraulic node
- Pressure in the thermal–hydraulic node
- Gas flow rate between thermal–hydraulic nodes

If the rate of change exceeds the threshold due to gradual variations, it does not pose a problem; however, if it results from numerical noise or a sudden fluctuation, the integration may produce distorted results. To prevent this, when the rate of change of a key thermal–hydraulic variable exceeds the threshold (i.e., at a time step satisfying the forced calculation condition), the previous time step is first recalculated using the same time step as CINEMA code, and then the current time step is computed consecutively, eliminating the possibility of result distortion.

When the time step of SIRIUS is not the same as that of the CSPACE, differences in the core fuel mass may occur. Therefore, the calculation of gaseous FP release from the core fuel uses CINEMA code time step. The gaseous FPs released from the core continue to accumulate in the core nodes during the periods when SIRIUS is not performing calculations, and are then transported and converted to aerosols at the next calculation time step.

The purpose of SIRIUS time step model is to optimize the computational speed of CINEMA code while maintaining “calculation accuracy.” Here, “calculation accuracy” refers to the difference between the results obtained using SIRIUS time step and those obtained when CINEMA code is run without SIRIUS time step model, i.e., using the original CINEMA code time step. As shown in Figure 8, using SIRIUS time step model can significantly reduce the calculation frequency while maintaining “calculation accuracy”. This capability may also be useful for large-scale SIRIUS calculations related to uncertainty analysis and AI-based surrogate model training.

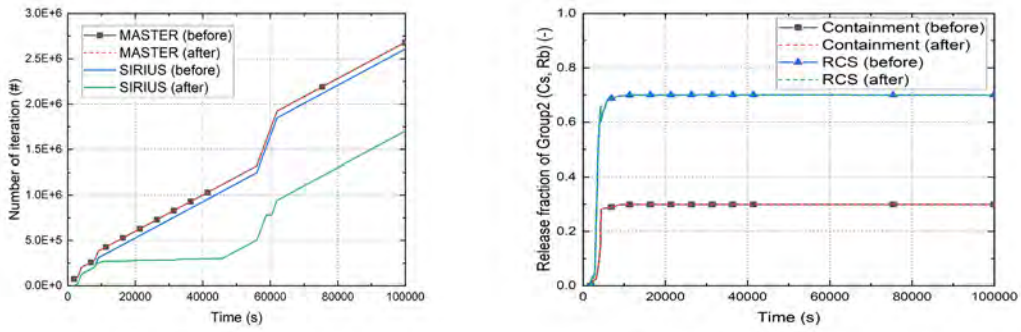

Figure 8. Effect of increasing time step on SIRIUS calculation frequency and comparison of key results using CINEMA time step and SIRIUS time step

3. Extensions for Advanced Reactor Applications

Unlike pressurized water reactors, MSRs do not have fuel cladding; therefore, under normal operating conditions, FPs exist while circulating together with the liquid fuel salt. As a result, FPs can chemically react and combine with the molten salt during normal operation, and condensation and evaporation can be calculated based on the concentration differences between the liquid fuel interface and the surrounding atmosphere. Information on releasable compounds can be obtained through calculations of inter-nuclide molecular binding based on Gibbs free energy, and thermochemical analysis codes such as FactSage and GEMS can be used for these calculations. Based on the approaches presented in references [8] and [9], a FP release calculation model for accident conditions in an MSR was developed. The time-dependent evaporation amount of compound *i* in the molten salt can be calculated as shown in Equation (5).

The molten salt can consist of multiple compounds, and Equation (5) represents the formulation used to calculate the evaporation or condensation rate from the molten salt based on the difference between the saturated mole fraction of compound *i* in the molten salt and the mole fraction of compound *i* in the atmosphere. Equation (11) is used to calculate the saturated mole fraction from the saturation vapor pressure based on the ideal gas law.

$$C_i^S = \frac{P_i^S(T) M_i}{RT} \tag{11}$$

The time-dependent values of the Lennard–Jones parameters can be obtained through thermodynamic behavior analyses and should be provided as input for fission product release calculations. After release, fission product behaviors such as phase change, transport, and deposition are evaluated using the same models as those described above for the PWR-oriented SIRIUS code.

4. Conclusions

This study introduced the C++ based SIRIUS code, a computational tool for analyzing the release, transport, and removal of FPs under severe accident conditions in RPV, RCS, and containment, using results from an external lumped-parameter thermal–hydraulic analysis. For PWR applications, the modeling framework includes node-wise initialization of solid-, gaseous-, and aerosol-phase FP inventories; temperature-dependent solid-to-gas release from fuel and structural materials; inter-node redistribution associated with fuel and structural material behavior; volatile FP grouping with user-defined inter-group chemical combination; gas–aerosol phase transformation governed by saturation vapor pressure; and multiple aerosol deposition mechanisms represented by λ-type removal coefficients. Numerical solution schemes based on mass conservation equations for gaseous and aerosol phases were presented, together with a dedicated time-step control approach that enables efficient coupling with CINEMA code while maintaining consistency with the underlying thermal–hydraulic behavior. In addition, an extended SIRIUS modeling approach for MSRs was described, incorporating evaporation–condensation at the salt–gas interface, evaluation of releasable chemical compounds through thermochemical analysis, and application of the same phase-change, transport, and deposition models as those used for pressurized water reactor analyses to simulate FP behavior.

Future work will first focus on introducing a multicomponent sectional aerosol model into SIRIUS code to enable more detailed analysis of particle size distribution and compositional changes during transport and deposition processes in the reactor coolant system and the containment. In addition, the coupling with external thermochemical equilibrium codes such as GEMS will be extended to establish a database of saturation vapor pressures and chemical species distributions based on Gibbs free energy minimization, and to develop a computational framework that consistently incorporates these data into evaporation–condensation and chemical combination models under both pressurized water reactor and MSR conditions.

CONTENTS

01 Introduction

02 SIRIUS modeling

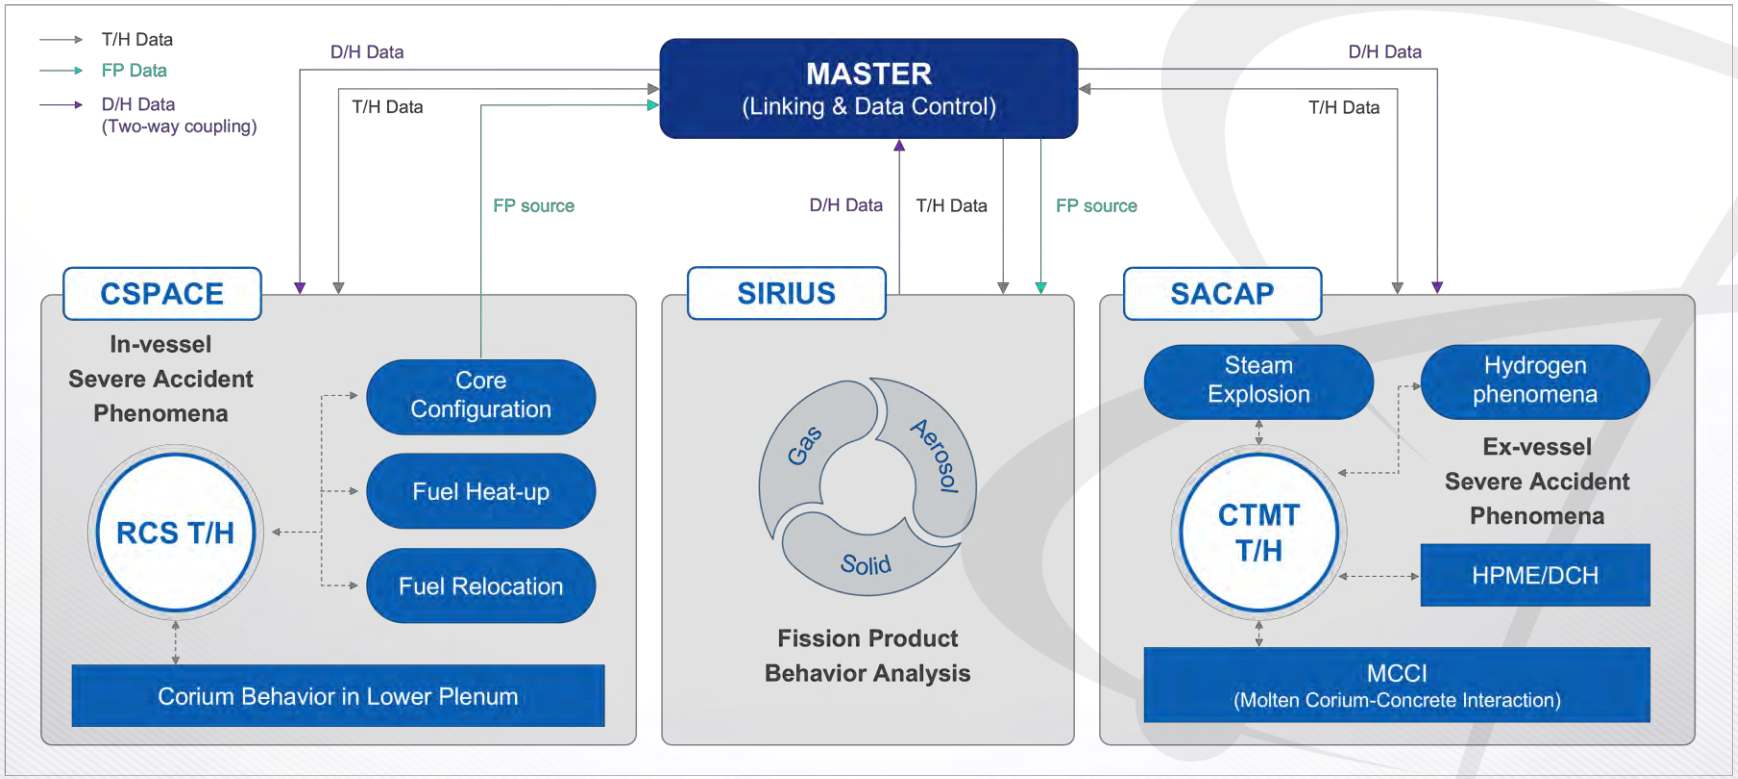
03 Application examples

04 Conclusion

❖ SIRIUS within CINEMA framework

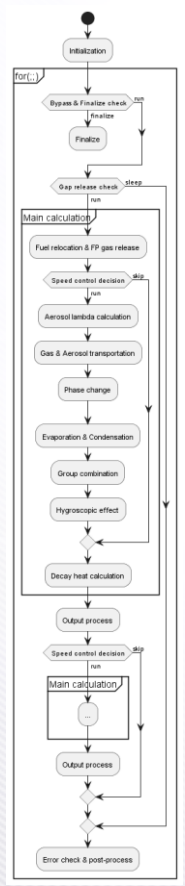
- CINEMA is a lumped-parameter integral code for PWR SA analysis, recently utilized in Korean i-SMR licensing.
- CSPACE, SACAP, and SIRIUS are C++ based modules, coupled via MASTER using MS-MPI.
- SIRIUS analyzes FP behavior using T/H data, with optional decay heat feedback to coupled modules.

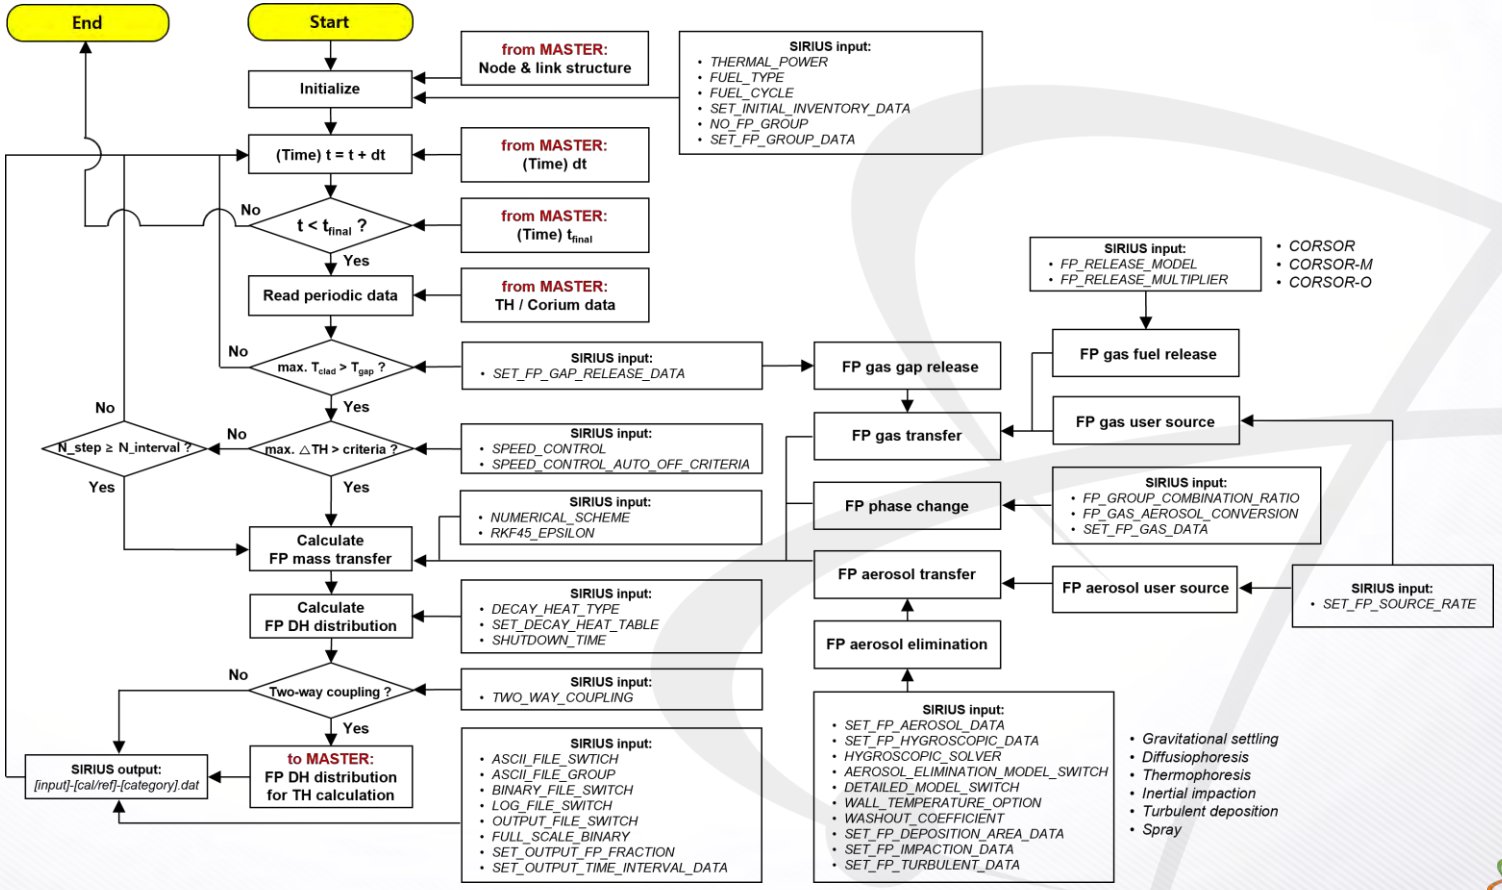
· CINEMA : Code for INtegrated severe accident Evaluation and MAnagement



❖ Calculation flow

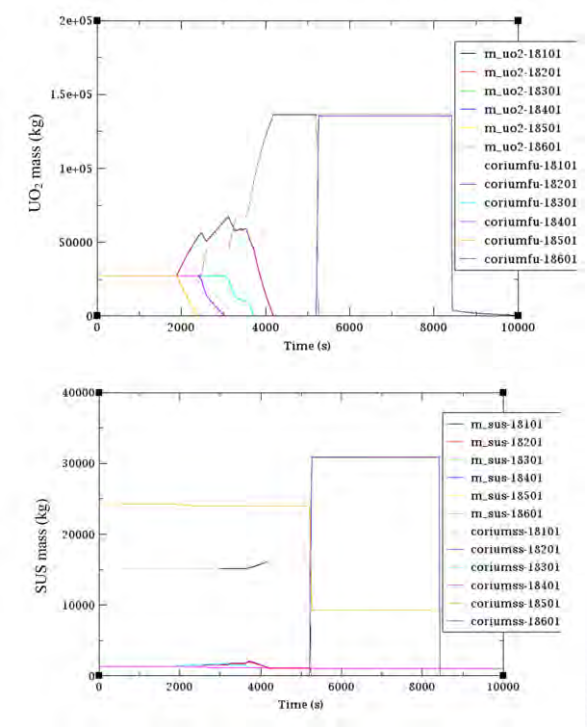
- SIRIUS activation (when $T_{clad} > T_{gap}$) → Time step control → Solid FP relocation & Gas release → Aerosol removal rate (λ) → Transport (mass conservation) → FP phase/state update → Decay heat & T/H feedback

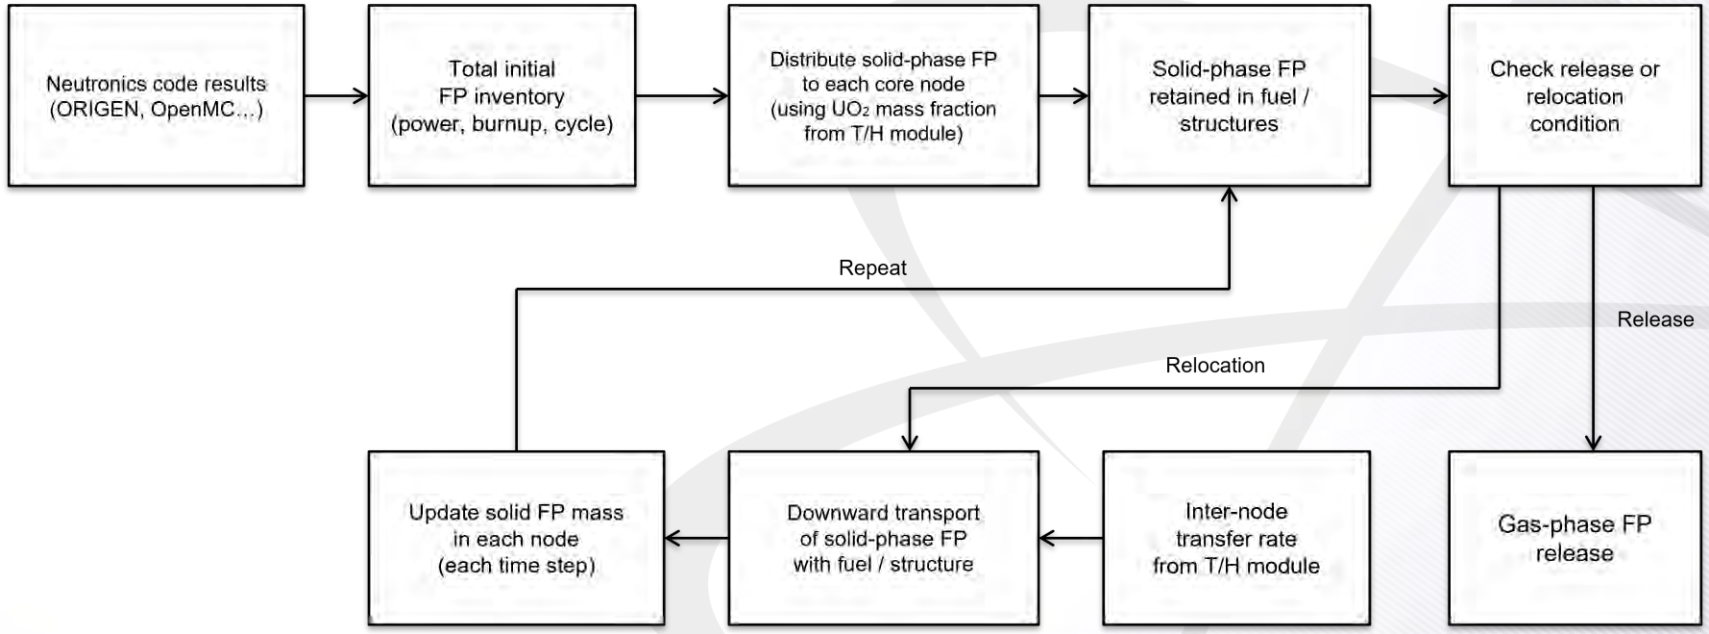




❖ Initial inventory & Transport of solid FP

- Initial FP inventories are evaluated from reactor power, burnup, and fuel-cycle data.
- Solid FP are distributed to core nodes according to the local UO_2 mass.
- CSPACE transfer rates are used to track retained FP relocation during core degradation.

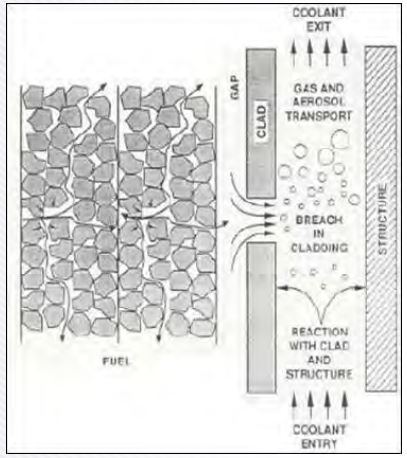


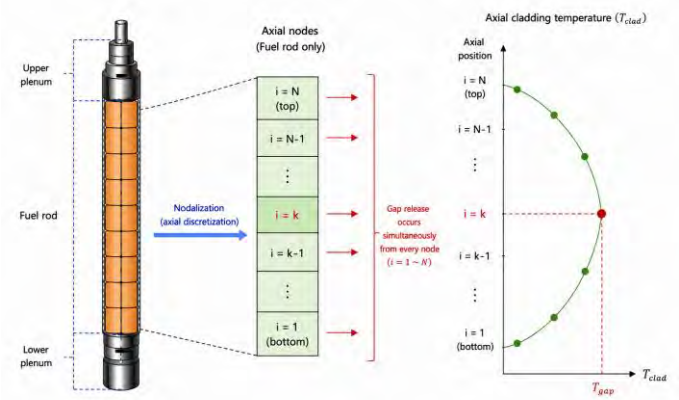


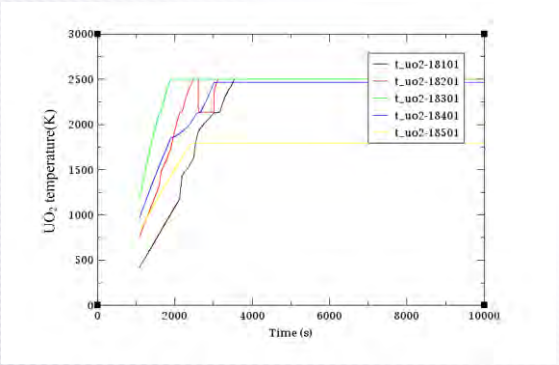
$$m_{s,i}^{n}(t+\Delta t) = \sum_{k=1}^{N} m_{s,i}^{n}(t)\frac{\Delta m_{cspace}^{k-n}(t+\Delta t)}{m_{cspace}^{k}(t)}$$

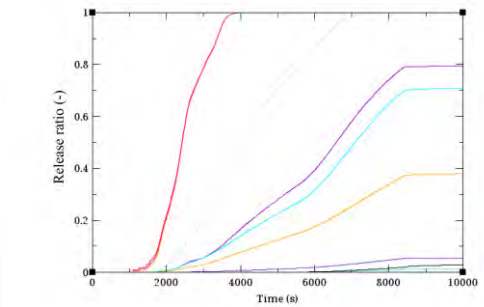
❖ FP gas release

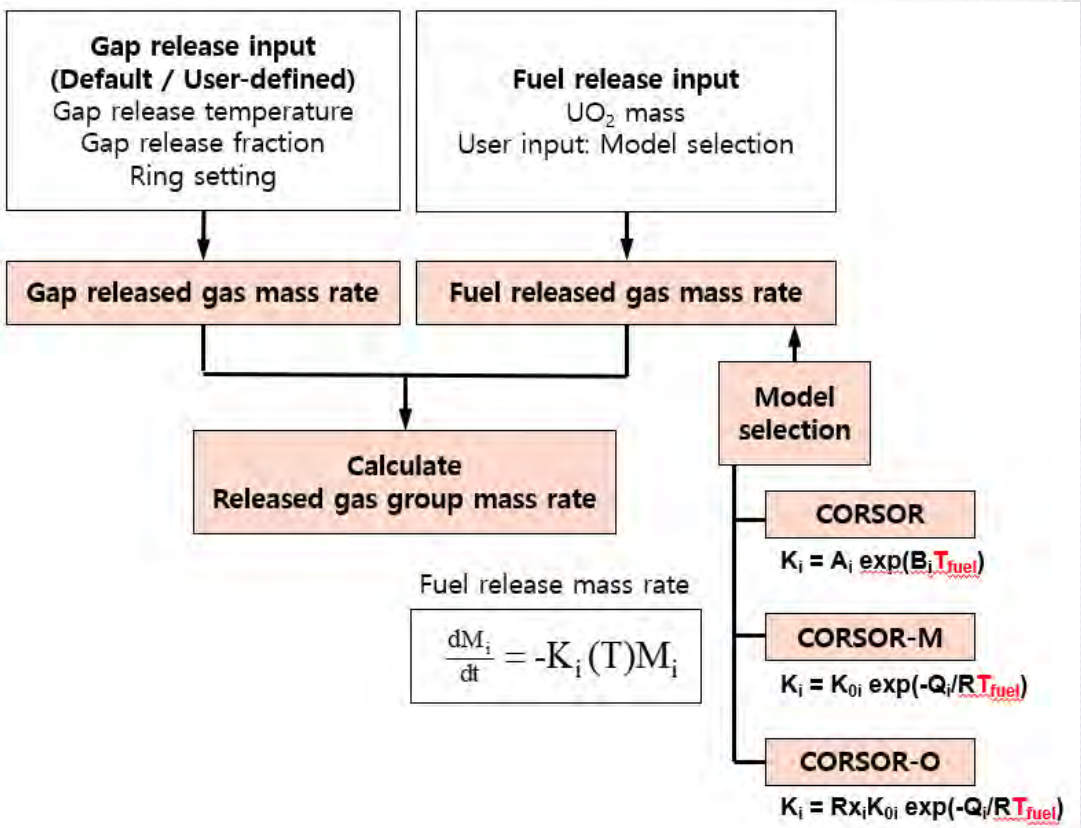
- Gap release is calculated per node; axially connected nodes release simultaneously via ‘ring’ setting.
- Gas generation from ex-core structures (Shroud,CSP, …) is also evaluated based on temperature.





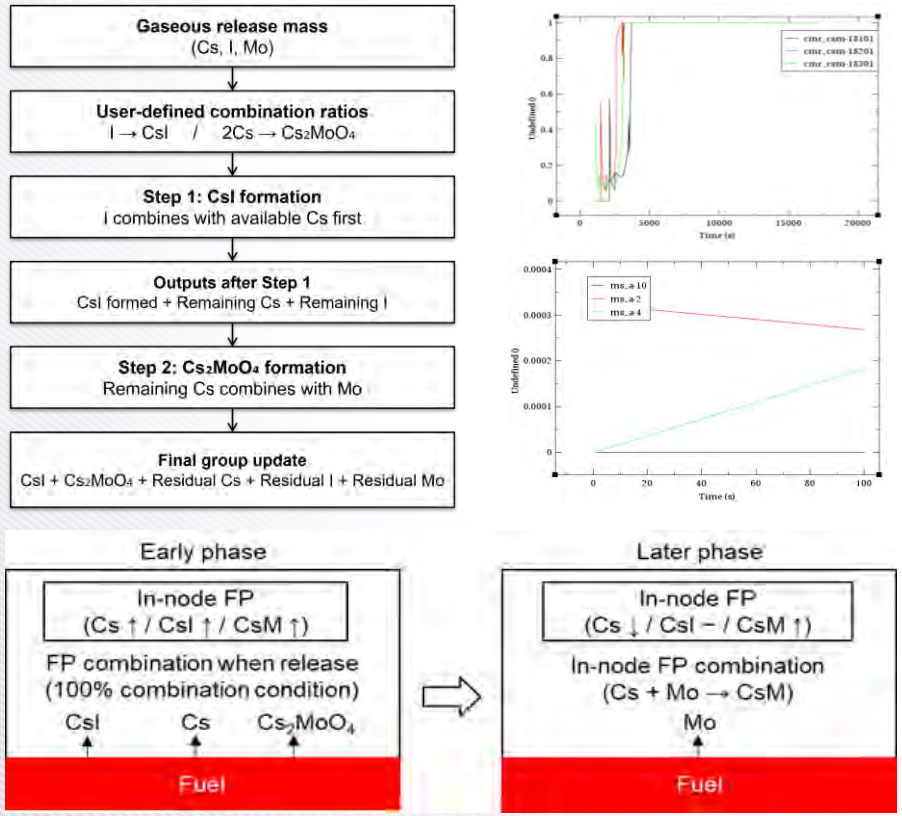






❖ FP grouping & Inter-group combination

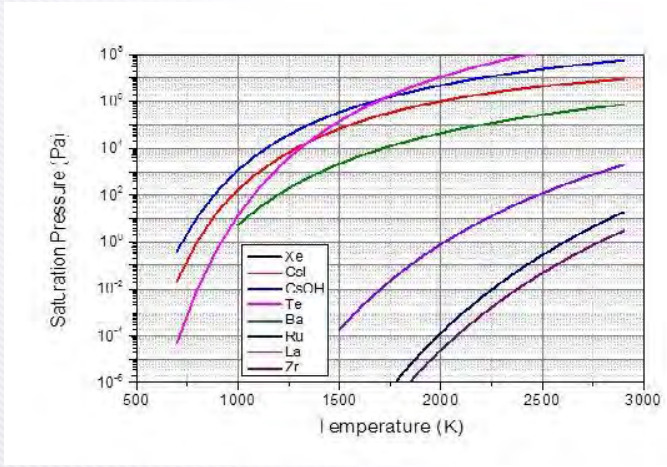
- FPs are grouped into 8 groups (NUREG-1465) or 15 groups (SAND2011-0128) based on chemical properties.
- User-defined combination ratios for CsI and Cs_2MoO_4 represent the maximum fraction achievable.
- Combination is first calculated at release from fuel, then recalculated after transport and deposition at each node.

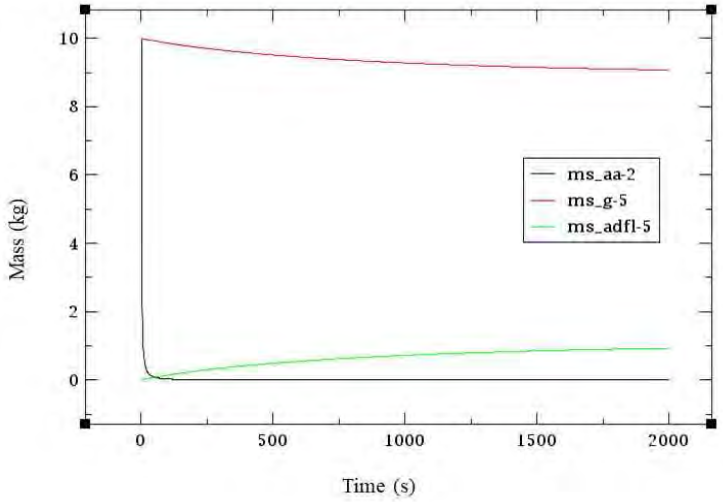


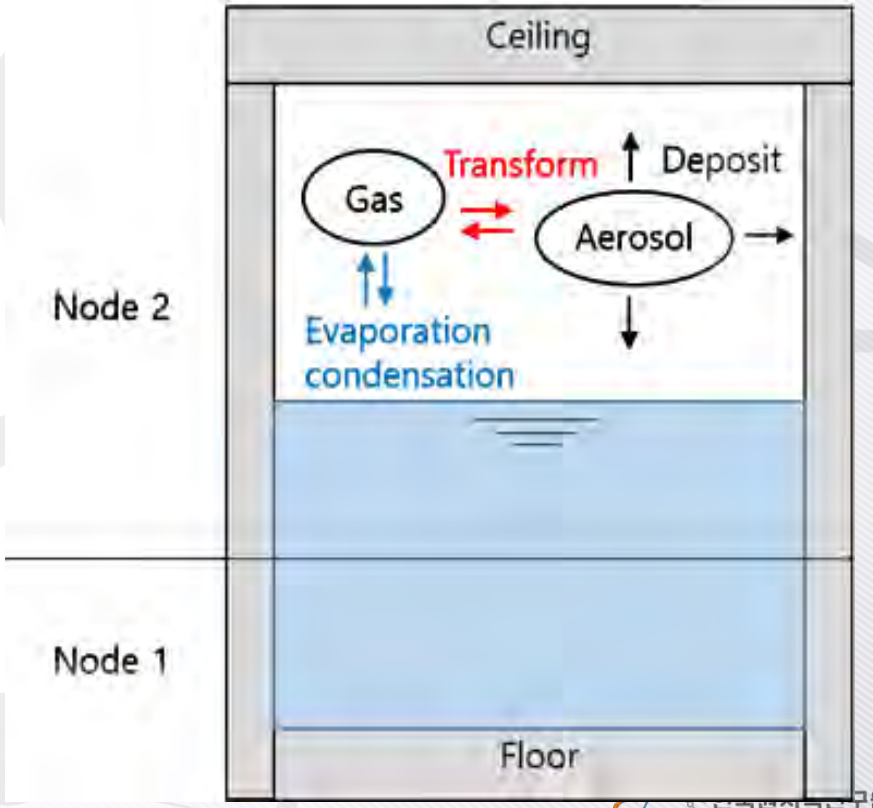
No.	Group name	Components
1	Noble gases	**Xe**, Kr
2	Alkali metals	**CsOH**, RbOH
3	Cesium iodide	**CsI**
4	Cesium molybdate	**Cs_2MoO_4**
5	Halogens	**I_2**, Br_2
6	More volatile main group	**Cd**, Sb, As
7	Less volatile main group	**Sn**, Ag, In
8	Alkaline earths	**BaO**, SrO
9	Chalcogens	**Te**, Se
10	Early transition elements	**Mo**, Nb, Tc
11	Platinoids	**Ru**, Rh, Pd
12	Trivalents	**La**, Y, Pr, Nd, Pm, Sm, Eu, Gd, Am, Cm
13	Uranium	**UO_2**
14	Tetravalent	**Ce**, Zr, Np, Pu
15	Structural materials	**Fe**, Cr, Ni, Mn

❖ Transformation & Evaporation/Condensation

- Gaseous FP converts to aerosol when its partial pressure exceeds sat. vapor pressure at local node temperature.
- Evaporation/condensation between gas and liquid phase calculated based on concentration difference.
- Gas–liquid interfacial transport is represented by a lumped mass-transfer coefficient.







$$\Delta m_{a,i}^{n} = \left(n_{v,i}^{n} - n_{v,sat,i}^{n}\right) M_i$$

$$n_{v,sat,i}^{n} = \frac{P_{i,sat}^{n}\, V^{n}}{R\, T^{n}}$$

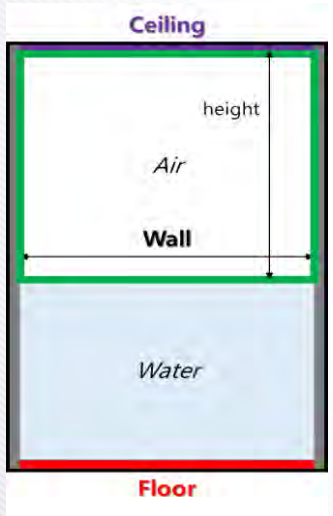
$$log_{10}\left[P_{i,sat}(mmHg)\right] = -\frac{A_i}{T} + B_i + C_i\, log_{10}(T)$$

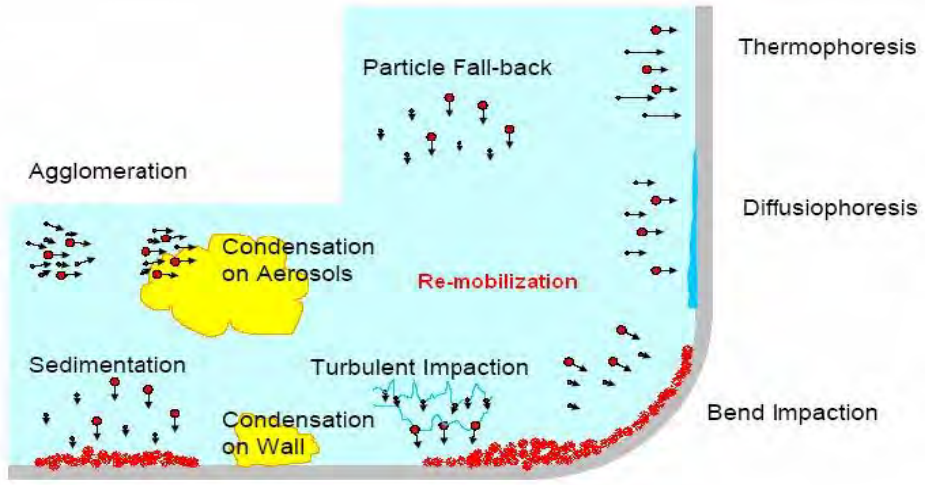
$$\frac{dm_i}{dt} = \mathrm{A} k_i (C_i^{a} - C_i^{s})$$

$$C_i^{s} = \frac{P_i^{s}(T) M_i}{RT}$$

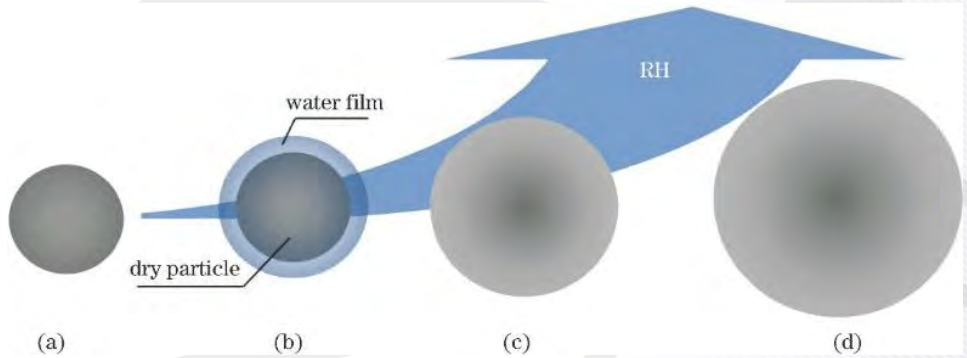
❖ Aerosol deposition, removal & Hygroscopic growth

- The total removal rate, λ_t [1/s], is multiplied to the airborne aerosol mass in the conservation equation.
- Deposited aerosols on liquid can be resuspended by evaporation or when the liquid completely evaporates.
- Hygroscopic growth is not time-resolved; aerosols are simply assumed to be in equilibrium for each time step.





$$\lambda_t = \lambda_{sed} + \lambda_{imp} + \lambda_{diff} + \lambda_{th} + \lambda_{turb} + \lambda_{spray}$$

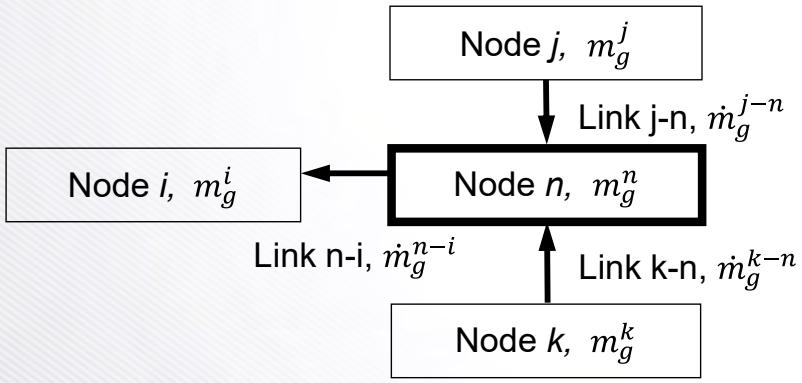


$$M_{aw} = (V_{wet}\,\rho_W)(r^3 - 1)$$

$$M_{aw} \leq \emptyset^n * S * M_a \;\; (S = \textit{hygroscopic solubility})$$

❖ Numerical methods

- Gas and aerosol FP transport is calculated using node-wise mass conservation equations.
  - ➢ Implicit or Explicit (RKF45) schemes can be selected.
- SIRIUS time step can be increased to reduce calculation frequency.
  - ➢ Forced calculations are triggered by significant changes in key T/H variables.



$$\frac{dm_{v,i}^n}{dt} = \dot{m}_{v,i,in}^n - \dot{m}_{v,i,out}^n + \dot{G}_{v,i}^n$$

$$\frac{dm_{a,i}^n}{dt} = \dot{m}_{a,i,in}^n - \dot{m}_{a,i,out}^n - \lambda_{t,i}^n m_{a,i}^n + \dot{G}_{a,i}^n$$

1. Core fuel temperature
2. T/H node gas temperature
3. T/H node pressure
4. Gas flow rate between T/H nodes

ABSTRACT

This paper presents simulations of two VERCORS annealing tests (VC5 and HT2), performed on fuels irradiated to average burnups of 38 and 48 GWd/t_U, respectively, and conducted under oxidizing conditions, using the MARGARET–Active FP model coupled with the OpenCalphad thermochemical solver and the TAF-ID database. Initially developed to simulate the production, decay, and transport of over 70 fission products during standard PWR irradiation, MARGARET Active FP provides key microstructural parameters—such as bubble distribution, high burnup structure, and fuel swelling—to describe irradiated fuel. In this work, a new model has been introduced to describe the intragranular transport of bubbles under annealing conditions, representative of scenarios without a thermal gradient, as in VERCORS tests. MARGARET is coupled with a thermochemical module within the ALCYONE fuel performance code to provide a more mechanistic description of non-inert fission product behavior during severe accidents, taking into account their chemical state prior to transient conditions. Model predictions are compared with experimental data, focusing on the release of fission products. The results demonstrate that the coupled mechanistic–thermochemical approach provides a consistent and detailed description of fission-product release under annealing conditions.

1. INTRODUCTION

Different tests at various scales, including both integral and separate-effect tests (such as the VERCORS program [1–4]), are reported in the literature and have provided fundamental insights into the behavior of Fission Products (FPs) during severe accident. It has been highlighted that temperature, oxygen potential, fuel burnup, and cladding–pellet interactions play a crucial role in this context.
These experimental programs enabled the classification of FPs into four main categories: volatile, semi-volatile, low-volatile, and non-volatile. Volatile FPs—such as Xe, Kr, I, Cs, Te, Sb, Cd, Rb, and Ag—are almost completely released by the end of the tests, and their final release is largely insensitive to external conditions (e.g., thermochemical environment), whether oxidizing or reducing [1–4].
Semi-volatile FPs, including Mo, Ba, Rh, Tc, and Pd, exhibit release fractions ranging from 50% to 100%, with both the extent and kinetics of release being strongly influenced by the surrounding atmosphere and by interactions with the cladding [1–4].
Low-volatile FPs—such as Ru, Ce, Sr, Y, Eu, and Nb—generally exhibit release fractions below 10% of their initial inventory, although variations may occur depending on atmospheric conditions or fuel sample

characteristics. Finally, non-volatile species, including most actinides as well as U and Zr, remain essentially unreleased (i.e., final release below 1%) regardless of experimental conditions [1–4].
In the context of FP-release modelling, several computational codes have been developed, depending on the load sequence considered and on the external factors that may influence the release [5–7]. For the simulation of severe accident scenarios in particular, the level of model complexity varies according to the scale and scope of the analysis. Integrated system codes typically rely on simplified models to represent FP behavior [8,9]. At smaller scales—down to the fuel-grain scale—and when focusing on specific aspects of severe accident phenomena, models originally developed for normal operation and incidental conditions have been extended to address severe accident sequences. In this framework, the inclusion of detailed thermochemical calculations is essential to accurately represent FP chemical speciation and its impact on release kinetics [6,10].
Germain et al. enhanced the PLEIADES/ALCYONE fuel performance code by incorporating a gas diffusion model coupled with thermodynamic equilibrium calculations to evaluate the release of non-inert FPs. Their approach considers only the stable elements, not their isotopes, and employs a simplified model for fission gas transport [10].
The main limitation of mechanistic modeling using the typical fission gas model [5] for the considered scenario (annealing sequence) lies in the description of intra-granular FP transport to the grain surface. Experimental results for inert FPs, where thermochemistry has no significant effect, show that nearly complete Xe release is achieved. However, intra-granular fission gas release during annealing tests cannot be accurately predicted without accounting for bubble migration. Indeed, in the absence of irradiation, the equilibrium between gas trapping and re-solution is strongly shifted toward trapping, as the dynamic resolution caused by fission spikes is no longer present. Gas trapped in apparently immobile bubbles would not escape, which contradicts experimental observations.
By analyzing high-temperature release of volatile fission products, Germain et al., showed that assuming gaseous species to be transported to the grain boundary with the same kinetics as xenon yields accurate predictions, suggesting that these species and xenon migrate via the same moving bubbles [10].
Verma et al. showed that neither bubble motion driven by vacancy gradients, nor Brownian motion, nor a combination of the two, is sufficient to account for the large fission gas release observed during post-irradiation annealing [11]. In a subsequent study, Noirot et al. proposed a mechanism involving the coupled transport of bubbles pinned to edge dislocations and the climb of these dislocations. They demonstrated that this mechanism can lead to significant intra-granular fission gas release and provides a consistent explanation for the migration of intragranular bubbles toward the grain boundary [12].
In this paper, we advance FP-release modelling within the PLEIADES/ALCYONE fuel performance code by employing a mechanistic transport model capable of computing the release of radioactive fission products and explicitly incorporating thermochemistry. Specifically, we use the MARGARET Active FP model coupled with the OpenCalphad thermochemical solver and the TAF-ID database [13]. The dislocation-climb mechanism proposed by Noirot et al. has been implemented in MARGARET to address transport limitations under annealing conditions (i.e., in the absence of thermal gradients). Two post-irradiation severe-accident annealing scenarios—VERCORS 5 (VC5), with a fuel average burnup of 38 GWd/t_U and VERCORS HT2 (HT2), with fuel average burnup of 48 GWd/t_U—have been simulated [1]. After a brief presentation of the modelling framework—comprising the ALCYONE fuel performance code, the MARGARET Active FP module, and the thermochemical model—the simulations of the two tests are presented. A comparison between measured and calculated releases of volatile, semi-volatile, low-volatile, and non-volatile FPs is performed to assess the predictive capabilities of the model.

2. ALCYONE Fuel Performance Code

ALCYONE is a fuel performance code co-developed by CEA, EDF, and FRAMATOME within the PLEIADES computational platform [14]. It provides multi-dimensional (1.5D, 2D, 3D) modelling capabilities for fuel rods under normal operation, incidental conditions and, severe accidents. In the present

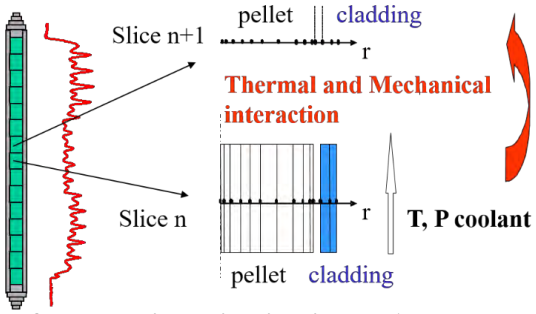

Figure 1. Typical fuel rod discretization in the 1.5D scheme of ALCYONE.

work, only the 1.5D calculation scheme is employed. As shown in Figure 1, the fuel rod is discretized axially into slices and radially into concentric annular rings.

In normal operation conditions, ALCYONE simulation relies on three main solvers: (i) a thermo-mechanical solver that computes temperature and stress fields in the fuel and cladding, (ii) a neutronic solver that evaluates local power deposition and FP inventories, (iii) a mechanistic fission-gas solver predicting FGR and fuel swelling due to Xe and Kr.

The thermo-mechanical module is based on the CAST3M finite-element code and solves the heat balance and mechanical equilibrium equations, accounting for potential fuel–clad contact; iterations are performed until convergence in temperature, stress, fuel–clad gap, and swelling. More details can be found in reference [15]. The neutronic solver, PRODHEL, tracks 199 FP isotopes and 23 actinide isotopes, modelling their production, depletion, and decay using the JEFF-3.1.1 library [16]. The mechanistic fission-gas module, MARGARET, provides a detailed description of Xe and Kr behavior in each radial ring, including dissolution in grains, bubble and pore evolution, grain-boundary accumulation, release to the rod free volume, and HBS formation [5].

The advanced version of the ALCYONE fuel performance code is developed and used in this work to evaluate FP release under severe-accident conditions. Specifically, a dedicated sub-model of MARGARET, referred to as MARGARET–Active FP, is employed to simulate the transport of radioactive fission products. This module is coupled with a thermochemical solver—OpenCalphad solver using the TAF-ID database—which determines through equilibrium calculations the composition of compounds formed through reactions among FPs, actinides, and oxygen within the fuel [13].

As shown in Figure 2, multiple interactions occur during the simulation. In this work, it is important to note that the input parameters for the thermochemical calculations rely on information provided both by MARGARET–Active FP (FP composition, pressure, and temperature) and by PRODHEL (actinide inventories). Details on the coupling strategy are presented in the following sections.

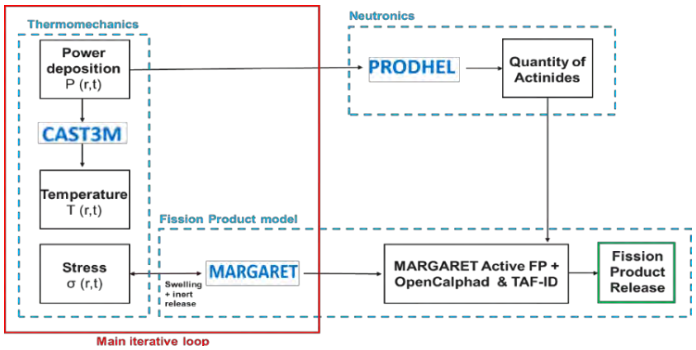

Figure 2. Schematics of the interactions in the updated version of ALCYONE between the thermomechanical, neutronic, fission-gas, and thermochemical solvers. (r, t) denote the radial position of a ring and the time within the simulated irradiation sequence.

3. MARGARET

MARGARET is a mechanistic fission-gas model that describes Xe and Kr migration at the grain scale under normal, transient, and incidental conditions. It operates as a point model, providing—for each radial position—the released gas fraction, the swelling induced by fission gases, and the formation of the high-burnup structure (HBS).
Figure 3 illustrates the main intra-granular and inter-granular phenomena described by MARGARET. The HBS description is not shown, as it is not the focus of this work; the analyzed cases do not reach sufficiently high burnup for this phenomenon to be relevant. On the left, intra-granular processes include gas production, atomic diffusion, bubble nucleation and growth, trapping and re-solution due to fission spike interaction, and bubble or pore motion toward the grain boundary.
Gas escaping the grain becomes the source term for inter-granular behavior. On the right, inter-granular processes involve gas accumulation at the grain boundary, the formation and growth of inter-granular bubbles, swelling, and eventual bubble coalescence that creates interconnected pathways enabling fission-gas release by percolation, as well as direct release when parts of the grain surface are directly exposed to the fuel rod free volume. Details on MARGARET model can be found in [5].

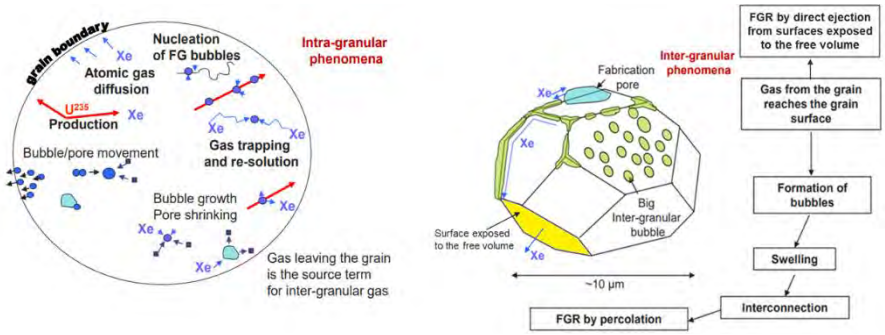

Figure 3. Intra- and inter- granular phenomena described by MARGARET. Scheme reproduced with the permission from Noirot et al., J. Nuclear Science and Technology, 2006.

As stated in Section 1, the original MARGARET model is not able to reproduce the massive intra-granular gas release under annealing conditions, because—without irradiation—insoluble gas remains trapped in intra-granular bubbles, dynamic re-solution is absent, and random bubble motion is not sufficient (absence of thermal gradient). To address this limitation, the dislocation-climb mechanism proposed by Noirot et al. [12] has been implemented in MARGARET.
Figure 4 (left) shows an over-pressurized intragranular bubble pinned at the core of an edge dislocation, which provides the driving force for dislocation motion. The schematic on the right of the Figure 4 illustrates

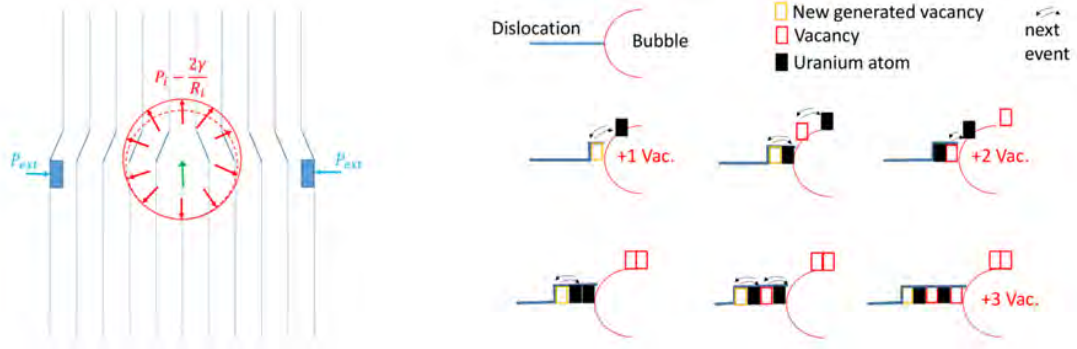

Figure 4. (left) Overpressurised intra-granular bubbles pinned at the core of an edge dislocation. (Right) Vacancy generation, diffusion along the dislocation core, and trapping by the bubble. Scheme reproduced with the permission from Noirot et al., J. Nuclear Materials, 2023.

the coupled bubble–dislocation mechanism: the high internal pressure of the pinned bubble generates vacancies along the dislocation, which diffuse toward the bubble, while uranium atoms accumulate along the dislocation line. This enables dislocation climb, leading to bubble growth, pressure relaxation, and ultimately bubble motion, leading to intra-granular gas transport. Further details on the model are provided in the cited references [12].

To model the dislocation-climb mechanism, new state variables and bubble populations have been introduced in MARGARET. In particular, a dislocation density ρ_d^{climb} associated with climb (edge dislocation) and a population of bubbles pinned on climbing dislocations (referred to as *bprec*) are defined. These bubbles are characterized by their concentration C_{bprec}, xenon content $C_{Xebprec}$, and volume V_{bprec}. Their evolution is governed by several coupled processes: gas exchange between the dissolved phase and *bprec*, swelling of pinned bubbles, pinning of free intra-granular bubbles onto dislocations, bubble coalescence, and the release *bprec* when they reach the grain boundaries. The velocity of climbing dislocations v_d, which controls the transport of gas toward the grain boundary, as well as the associated swelling, depends on the characteristics of *bprec* and is expressed by the relations reported below:

$$v_d = \frac{12D^*}{kT} \frac{P_{bprec} - {2\gamma}/{R_{bprec}} - P_{hydr}}{\frac{C_{bprec}}{\rho_d^{climb}} \left(\frac{\rho_d^{climb}}{C_{bprec}} - 2R_{bprec} \right)^3} \times \Omega^{4/3} \qquad \frac{dV_{bprec}}{dt}\Big|_{climb} = v_d \times w \times \rho_d^{climb}$$

where D^* is the coefficient of vacancy creation and diffusion on the dislocation, P_{bprec} and R_{bprec} are respectively the internal pressure and radius of *bprec* bubbles, P_{hydr} is the hydrostatic pressure, T is the temperature, k is the Boltzmann constant, Ω is the volume of the UO_2 pattern, and w is the width of the dislocation core. The dislocation density ρ_d^{climb} is estimated using the correlation proposed by Nogita et al. [17], under the assumption that the density of dislocations capable of climb is of the same order of magnitude as the experimentally measurable total dislocation density. At present, experimental techniques do not allow this specific dislocation population to be identified and quantified separately. The input parameters of the model— D^*, described by an Arrhenius-type expression with a pre-exponential factor and an activation energy—were fitted using three isothermal annealing experiments reported in the PhD thesis of Valin [18]. In these experiments, UO_2 fuel pellets from a PWR, irradiated for one cycle to a burnup of 14.2 GWd/t_U, were used. Three pellet were annealed for 3 h at temperatures of 1600, 1500, and 1400 °C, respectively, while krypton release was continuously monitored using a gamma spectrometry [18]. The results of the fitting procedure are shown in Figure 5, yielding an activation energy of 4 eV and a pre-exponential factor of 2×10^{-7} m^2s^{-1}.

It is important to emphasize that this represents a first implementation of the model within MARGARET, and its parameters require deeper investigation.

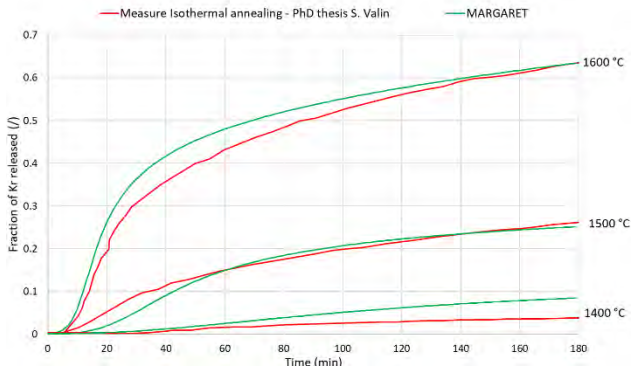

Figure 5. Comparison between measured and calculated krypton release fractions during isothermal annealing experiments at 1400, 1500, and 1600 °C. Experimental data from the PhD thesis of S. Valin are shown in red, while MARGARET simulations are shown in green.

4. MARGARET Active FP

MARGARET–Active FP is a dedicated sub-model within MARGARET to account for chemically reactive and radioactive fission products. Initially, MARGARET Active FP was developed to investigate potential contamination of the primary circuit by radioactive fission products, during base irradiation. It handles 75 isotopes, ranging from short-lived to long-lived isotopes. The transport of each isotope follows the same procedural framework as the original MARGARET model and is governed by equations derived analogously, accounting also for production by fission as well as by radioactive decay and neutron capture of precursor nuclides [13].
MARGARET Active FP does not provide feedback to the MARGARET model, under the assumption that radioactive fission products are present in quantities sufficiently small compared to stable gases that their influence on microstructural evolution is negligible. Consequently, all microstructural parameters—such as the evolution of bubble populations—are taken directly from MARGARET. The model enables the specification of isotope-dependent intrinsic diffusion coefficients and re-solution frequencies (via fission spikes), typically using inert gases from MARGARET as reference values [13].
MARGARET–Active FP includes the capability to account for the impact of thermochemistry on the transport of fission products, which is crucial during high-temperature sequences as it strongly affects release behavior, as demonstrated by severe-accident experiments and corresponding modelling [10]. A coupling strategy between MARGARET-Active FP and a thermochemical module, composed of the OpenCalphad solver and the TAF-ID database, was proposed, successfully tested, and applied in previous work to simulate fission-product release during incidental sequences, such as power-ramp experiments [13]. This coupling was subsequently implemented in ALCYONE.

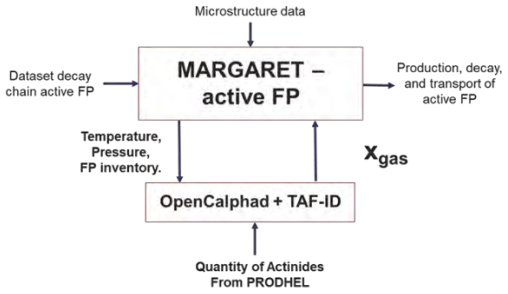

Figure 6. Coupling scheme between MARGARET Active FP and the thermochemical model.

The coupling scheme is shown in Figure 6. The thermochemical behavior is incorporated through the variable x_{gas}, calculated by the thermochemical module, which represents the fraction of each fission product present in the gas phase: $x_{gas} = mol_{FP}\ in\ gas\ phase / mol_{FP}\ in\ all\ phases$.
This fraction is used in the mechanisms that govern release from grain boundaries, namely percolation through intergranular cavities and direct ejection when portions of the grain surface are exposed to the free volume. A key assumption of the model is that only the gaseous fraction of fission products is releasable, while condensed phases remain confined within the fuel [13].

5. Fuel Thermochemistry

The thermochemical module is used to compute x_{gas} using as input the temperature and pressure from MARGARET–Active FP and the actinide inventories provided by PRODHEL. The chemical system considered in the calculation includes the elements: He, Kr, Xe, U, O, Pu, Ba, Sr, Zr, Cs, Rb, I, Br, Te, Se, Mo, Ru, Rh, Tc, Pd, Ce, Pr, La, Y, Gd, Eu, Sm, and Nd. Details on the assumptions adopted for the thermochemical system are provided in reference [13].
Fuel thermochemistry modelling in this work relies on the OpenCalphad Gibbs energy minimizer [19,20], which computes the equilibrium state of the multicomponent nuclear-fuel system and determines phase

compositions (gas, solid solution, liquid) and the stoichiometric compounds formed through chemical interactions between actinides, fission products, and oxygen. In this work, the thermodynamic descriptions are taken from the OECD Thermodynamics of Advanced Fuels – International Database (TAF-ID) [21], developed to support calculations under both normal and accidental conditions. TAF-ID includes an extensive set of fission products, structural materials, and absorbers, enabling detailed modelling of irradiated-fuel thermochemistry and chemical interactions with surrounding materials. The version used here (v20) contains thermodynamic assessments for 257 binary systems, 145 ternary systems, and 3 quaternary systems.

6. Modeling of the VERCORS 5 & HT2 tests

This section describes the two simulated tests, VC5 and HT2. The experiments consist of thermal annealing of fuel-rod segments in a furnace. Both tests were performed on three-pellet samples extracted from two different fuel rods, previously irradiated to an average burnup of 38 GWd/t_U for VC5 and 48 GWd/t_U for HT2 [1].

The experimental sequences were similar, as illustrated in Figure 7. An initial temperature plateau was applied at approximately 350–400 °C under a helium flow. The temperature was then increased to 1300 °C for VC5 and 1500 °C for HT2 under an oxidizing atmosphere (steam) and maintained for 60–75 minutes, depending on the test, in order to fully oxidize the cladding. After this oxidizing plateau, one temperature ramp was applied in the VC5 test, whereas several ramps with intermediate plateaus were performed in the HT2 test. In both experiments, the carrier gas consisted of steam (H_2O) with a small fraction of hydrogen (H_2) to ensure oxidizing conditions within the furnace [1].

Before simulating the two tests, preliminary calculations were carried out with ALCYONE to reproduce the base irradiation, the cooling and storage period, and the pre-test re-irradiation. This step was required to rebuild the fission-product inventory, including short-, medium-, and long-lived isotopes.

In the simulations of the two experimental sequences, the fuel rod was represented using a single axial slice, while the fuel pellet was discretized radially using 41 nodes, with increased refinement near the pellet periphery. Also in the simulation, the impact of the carrier-gas composition on fission-product behaviour is explicitly taken into account in the thermochemical calculations.

Regarding the experimental measurements, all isotopes, FG excepted, discussed in the following were measured by gamma spectrometry sighting on the fuel samples located inside the fournace. Inert fission gases (Xe, Kr) were monitored on-line by gamma spectrometry using a dedicated gas capacity. For the HT2 test, gamma spectrometry on the fuel was not performed until the end of the experiment due to specimen movement within the furnace chamber; nevertheless, sufficient data were collected to allow a comprehensive analysis of volatile (Xe, Kr, Cs, I) and semi-volatile (Mo, Ba, Ru) fission-product release. Further details on the experimental setup are provided in references [1,2].

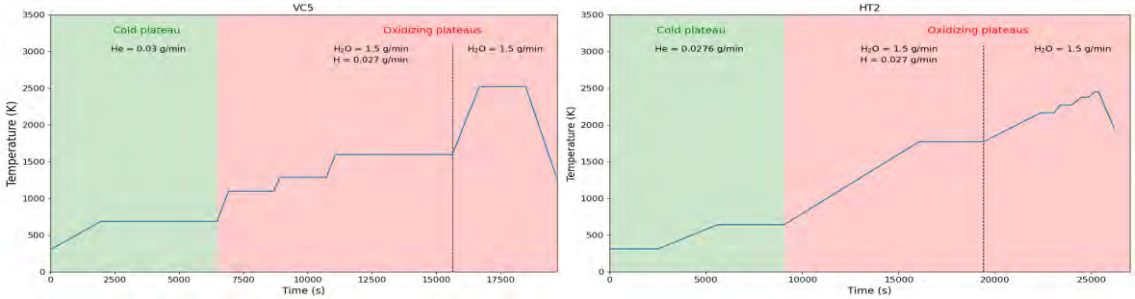

Figure 7. Temperature evolution during the VC5 (left) and HT2 (right) annealing tests.

The analysis starts with the release of fission gases and volatile fission products. For the VC5 test, the fission gas analysed is ^{133}Xe, whereas for the HT2 test the fission gas considered is ^{85}Kr. Concerning volatile fission products, the elements examined in both tests are ^{137}Cs and ^{131}I.

In the VC5 case, both fission gases and volatile fission products reach final release fractions between 90% and 100%, as shown in Figure 8. Experimental data show a difference in release kinetics between these two groups. Release starts for both during the plateau at 1570 K; however, volatile fission products are released more rapidly than fission gases. The release kinetics of volatile species exhibit larger experimental uncertainties at this temperature and at lower temperatures, as indicated by increased data scatter. In addition, since fission-gas measurements are performed in a downstream gas-capacity system rather than directly on the fuel, the thermo-hydraulic behaviour of the experimental setup may influence the observed release kinetics.

Simulations provide a good representation of the final release fractions for both fission gases and volatile fission products during VC5 (Figure 8, left). For ^{133}Xe, the model predicts only limited release during the 1570 K plateau, due to the negligible presence of this short-lived isotope at the grain boundaries. The main release occurs between 1600 and 1800 K, with a release rate higher than that observed experimentally. In this temperature range, intra-granular release is driven by the dislocation-climb transport mechanism implemented in the model. The release kinetics are strongly dependent on the assumed dislocation density, which is estimated using the correlation proposed by Nogita et al. as a function of burnup. However, in both experiments a low-temperature re-irradiation phase was applied prior to annealing, potentially leading to the formation of additional defects. This introduces increased uncertainty in the effective dislocation density and, consequently, in the predicted release kinetics. This uncertainty also propagates to the release of other fission products, as the same transport parameters as those used for inert gases are applied, with differences arising only from their thermochemical behaviour.

For volatile fission products (Figure 8, right), the model predicts their complete final release, consistent with the high chemical volatility predicted by the thermochemical calculations. In particular, a fraction of ^{137}Cs is released during the 1570 K plateau, reflecting its longer half-life and presence at the grain boundaries. In contrast, ^{131}I follows a release pattern similar to that of ^{133}Xe, owing to its short half-life.

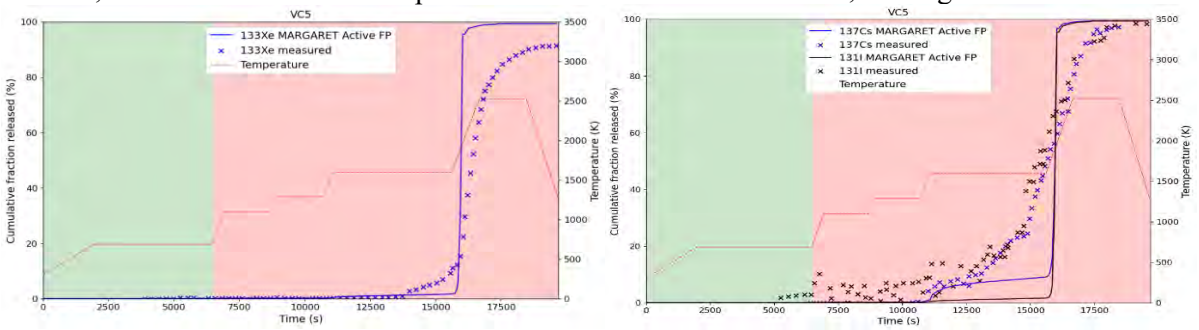

Figure 8. Measured and calculated cumulative release of ^{133}Xe (left), ^{137}Cs and ^{131}I (right) during the Vercors 5 test.

The analysis is extended to the HT2 test. Experimentally, complete release is observed for both FP categories, as illustrated in Figure 9. As in the VC5 case, similar differences are observed between fission gases and volatile species. Release starts at temperatures around 1500 K, and at lower temperatures volatile fission products exhibit higher release rates than fission gases, a trend that generally persists throughout the test. Simulations also predict complete release for ^{85}Kr, ^{137}Cs, and ^{131}I. In this case, the model provides a better representation of the release rate of ^{85}Kr compared to ^{133}Xe in the VC5 test. For volatile fission products, the trends are consistent with those observed in the VC5 test, with differences at lower temperatures arising from the short half-life of iodine, which limits its presence at the grain boundaries. Thermochemical calculations indicate that, also in this case, iodine and cesium are entirely present in the gas phase when released.

The analysis is now extended to semi-volatile and low-volatile fission products. For the VC5 test, the isotopes considered are ^{99}Mo, ^{140}Ba, and ^{103}Ru. For the HT2 test, the analysis is limited to ^{99}Mo, as the data collected for ^{140}Ba, and ^{103}Ru were not sufficiently significant for the analysis due to specimen movement

within the furnace chamber. The experimental results and the corresponding calculations are shown in Figure 10.

For molybdenum, both tests exhibit trends similar to those observed for volatile fission products. This behaviour is attributed to the oxidizing environment, which enhances the volatility of Mo and leads to comparable release kinetics. For the VC5 test, the model predicts a nearly complete final release, in agreement with the experimental data. In this case, the release kinetics resemble those observed for volatile short-lived species: no significant release is predicted during the 1570 K plateau, and most of the release occurs during the final temperature transient leading to the last plateau. At that stage, molybdenum is predicted to be entirely present in the gas phase.

For the HT2 test, the model tends to underestimate the final release, predicting 82% compared to the complete release observed experimentally. This discrepancy arises because, according to the thermochemical calculations, part of the molybdenum inventory remains trapped in the liquid phase. Nevertheless, the model provides a good representation of the release kinetics, closely reproducing the experimental trends.

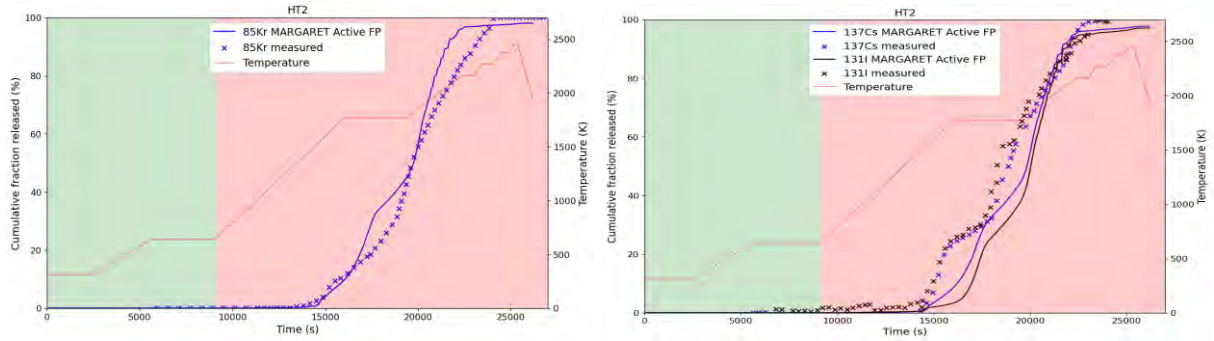

Figure 9. Measured and calculated cumulative release of ^{85}Kr (left), ^{137}Cs and ^{131}I (right) during the HT2 test.

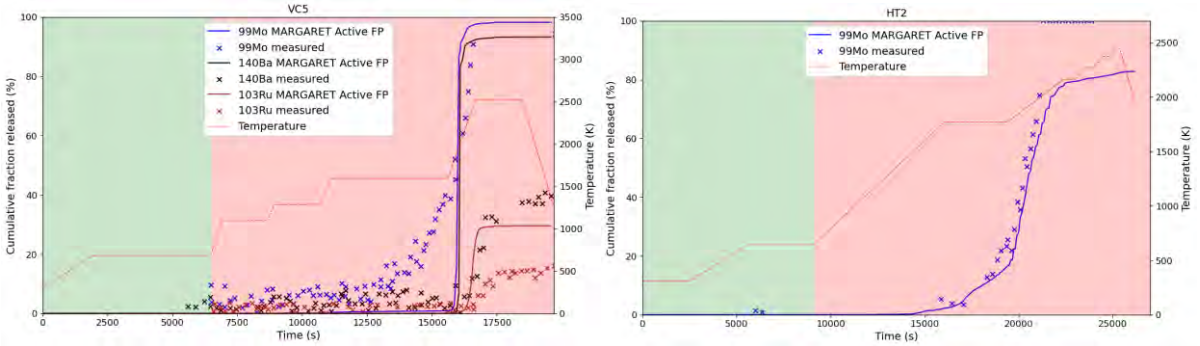

Figure 10. Measured and calculated cumulative release of semi-volatile and low-volatile fission products during the VC5 test (^{99}Mo, ^{140}Ba, and ^{103}Ru) (left), and of the semi-volatile fission product ^{99}Mo during the HT2 test (right).

Considering the experimental release of ^{140}Ba in VC5 case, the final release fraction is approximately 40%, with the release occurring at higher temperatures and later in the test compared to molybdenum. This is attributed to the thermochemical behaviour of barium. Post-annealing analyses of the specimens, including gamma tomography, show that barium reacts with the cladding—which is oxidized at the time of Ba release—and remains trapped as a result [3].

In the simulation, barium exhibits a release behaviour similar to that of molybdenum, with a predicted final release close to 90%, resulting in a significant overestimation compared to the experimental data. Indeed, according to the thermochemical calculation results, barium is fully present in the gas phase during the final temperature plateau, whereas during the preceding temperature transient it is distributed between the gas

and liquid phases (see Figure 11, left). This discrepancy arises because the interaction between barium and the cladding is not considered in the current modelling framework. As a consequence, when only fuel-side processes are taken into account, Ba release is overestimated. Moreover, on-line gamma spectrometry does not allow potential interactions of fission products with the cladding to be distinguished, and therefore does not permit isolation of the release originating solely from the fuel. As a result, a dedicated modelling approach that explicitly includes fission-product interactions with the cladding is required to achieve a more realistic representation of barium release.

In the case of ^{103}Ru (low-volatile) in the VC5 test, the experimental data indicate a final release of about 18%, with a release rate lower than that observed for Ba or Mo. Model calculations also overestimate the final release in this case, predicting a value approximately twice the experimental one. This discrepancy originates from the thermochemical calculations. Analysis of the phase distribution of Ru predicted by the model shows that it is mainly found into an hexagonal close-packed (HCP) metallic phase, with small fractions in the gas phase and in a face center cubic (FCC) metallic phase (see Figure 11, right). The tendency of Ru to form metallic phases suggests that additional metallic phases potentially formed through interactions between fission products and the cladding may react with ruthenium, thereby affecting its release.

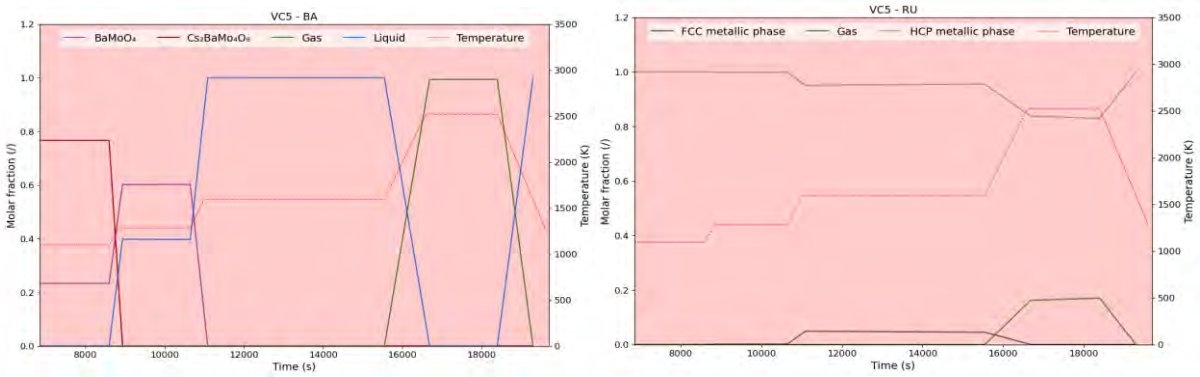

Figure 11. Distribution of Ba (left) and Ru (right) among all phases and stoichiometric solid compounds during the VC5 test.

For non-volatile fission products, such as ^{95}Zr, no release is observed experimentally. This result is consistent for both the VC5 and HT2 tests and is fully reproduced by the model calculations, which also predict no release for these species.

To further investigate the discrepancies observed between experimental results and model predictions, particularly for Ba and Ru fission products, an additional post-processing analysis was performed to assess potential chemical interactions between the cladding and fission products. Specifically, a thermochemical equilibrium calculation was carried out between the cladding material and the fission products released from the fuel, using the temperature and pressure conditions of the VC5 test.

The calculation was performed considering the entire cladding. In this case, the cladding was assumed to be fully oxidized (ZrO_2), consistent with the highly oxidizing environment of the test. The calculation includes the total inventory of fission products released from the fuel, as well as a fraction of uranium. The latter accounts for fuel–cladding interaction under oxidizing conditions. Indeed, Veshchunov et al. investigated this interaction and reported the formation of a ceramic $(U,Zr)O_x$ phase. Their results indicate that between 3% and 6% of the total fuel can interact with ZrO_2 [22]; in the present calculation, the upper bound of 6% was conservatively assumed.

It is important to emphasize that this represents a first-order approach, in which it is assumed that the entire released fission-product inventory can potentially interact with the cladding. In addition, spatial effects and kinetic limitations of these interactions are not considered.

The results of this post-processing calculation indicate that only Ba and Ru are retained by the cladding, while all other fission products remain in the gas phase; consequently, no chemical interaction with the cladding is predicted for these FP other than Ba and Ru.

As shown in Figure 12, the released quantities of ^{140}Ba and ^{103}Ru are drastically reduced, bringing the predicted final release into much closer agreement with the experimental data. In addition, the release kinetics are also improved in this case, highlighting the importance of explicitly accounting for interactions with the cladding. These results further emphasize the level of detail provided by the thermochemical modelling and by the database employed. The calculations show that barium preferentially reacts with and is retained by zirconium oxide, but also forms a hexagonal close-packed (HCP) metallic phase with zirconium. This metallic phase, in turn, traps part of the ruthenium inventory, thereby limiting its release.

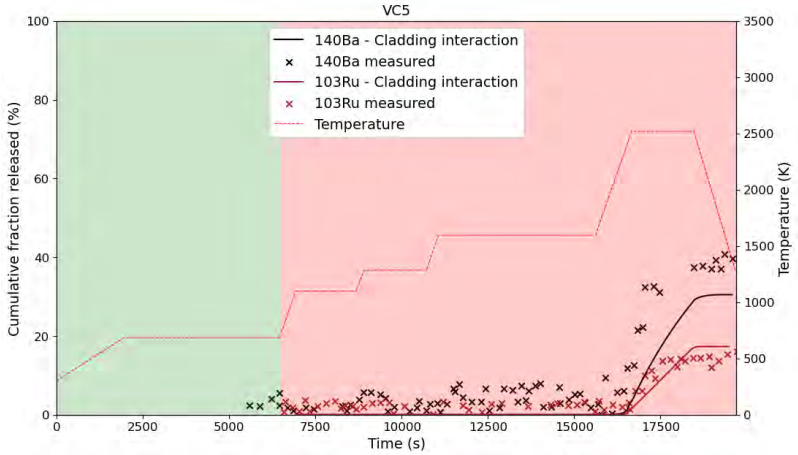

Figure 12. Measured and calculated cumulative release of semi-volatile and low-volatile fission products during the VC5 test (^{140}Ba, and ^{103}Ru), after accounting for thermochemical equilibrium with the cladding.

7. Conclusions

In this paper, simulations of two accidental scenario sequences were performed using an advanced modelling approach that couples a mechanistic fission-gas transport model with a thermochemical model within the ALCYONE fuel performance code.

The mechanistic fission-product model MARGARET was extended through the implementation of a transport approach based on a dislocation-climb mechanism. This development overcomes a key limitation of the original model in annealing scenarios, where—in the absence of irradiation and thermal gradients—gas would otherwise remain trapped within intra-granular bubbles. The dislocation density was estimated using the correlation proposed by Nogita et al. [17], while the vacancy creation and diffusion coefficients were fitted using three isothermal annealing experiments reported in the PhD thesis of Valin [18].

The coupling between the MARGARET–Active FP transport model and the thermochemical module was also introduced, enabling the explicit treatment of chemical interaction on fission-product transport and release, which is particularly important for high-temperature accidental conditions.

The analysed cases correspond to two annealing experiments, VC5 and HT2, performed on fuels irradiated to burnups of 38 GWd/tU and 48 GWd/tU, respectively. Although the two tests involve slightly different temperature ramp sequences, they are conducted under similar chemical environments. Model predictions were compared with experimental gamma-spectrometry measurements.

For fission gases and volatile fission products, the model reproduces well the final release fractions in both tests, with an improved representation of release kinetics for the HT2 case. In both scenarios, the predicted release is directly driven by the dislocation-climb transport mechanism, yielding encouraging results in terms of released quantities. Nevertheless, uncertainties remain, mainly related to the assumed dislocation density. In particular, the low-temperature re-irradiation applied prior to annealing may promote additional defect formation, while the parameter fitting was performed using fuel samples irradiated for a single cycle and characterized by significantly lower burnup than that of the VC5 and HT2 tests. Both aspects may affect the predicted release kinetics and warrant further investigation.

From a thermochemical perspective, volatile fission products behave as expected, exhibiting high volatility and release patterns similar to those of fission gases. For semi-volatile and low-volatile fission products, the model predicts high volatility in both tests. For molybdenum, good agreement with experimental final release is obtained in the VC5 test, whereas release is underestimated in HT2, partly due to the presence of Mo in the liquid phase during the temperature transient. Under these conditions, additional Mo release via aerosol formation transported by the carrier gas may occur, a mechanism not currently included in the modelling framework.
For Ba and Ru, the model initially overestimates their release. However, post-processing calculations accounting for cladding–fission product interactions demonstrate that these interactions effectively limit their release, bringing model predictions into agreement with experimental observations, particularly for Ba retention in the cladding. This highlights the fundamental role of the cladding, which cannot be neglected in this type of analysis.
Finally, non-volatile fission products behave as expected, with no release observed experimentally or predicted by the model for species such as Zr.
Overall, this work demonstrates the high level of detail achieved by the modelling approach, from both mechanistic and thermochemical perspectives. The influence of key model parameters has been clearly identified and will be the focus of future, more detailed investigations.

1. Introduction

Fission Products Behavior in Oxide Fuel during Severe Accident

Focus:

- Modeling the **source term** during a **severe accident** in a PWR is essential for developing effective mitigation strategies.
- Experimental programs like **VERCORS**, **VERDON** (CEA) :
  - **Classification of Fission Products (FP) behavior**

VOLATILE

Fission gases, iodine, caesium, antimony, tellurium, cadmium, rubidium, silver

SEMI-VOLATILE

Molybdenum, rhodium, barium, palladium, technetium

LOW-VOLATILE

Ruthenium, cerium, strontium, yttrium, europium, niobium, lanthanum

NON-VOLATILE

Zirconium, neodymium, praseodymium

Fission Products Behavior in Oxide Fuel during Severe Accident

Focus:

- Modeling the **source term** during a **severe accident** in a PWR is essential for developing effective mitigation strategies.

- Experimental programs like **VERCORS**, **VERDON** (CEA) :

  - Classification of Fission Products (FP) behavior

  - **Main parameters** influencing release kinetics/rates:
    - **Temperature**
    - **Chemical conditions**
    - **Fuel burn-up**
    - **Interaction with structural materials**
    - **Fuel state**

Implication for Modeling:
Accurate mechanistic model for the description of FP release
+
Accurate thermochemistry for predicting the release of FP

Research Aim

The focus of this work is the coupling between a mechanistic model for the description of FP release and a model for the thermochemistry of irradiated fuel in the **fuel performance code PLEIADES/ALCYONE**:

- Fission product release: **MARGARET (stable + active FP*);**
- Thermochemistry: **OpenCalphad (Gibbs Energy Minimizer) + TAF-ID (thermodynamic database).**

This work also presents **the simulations of two annealing experiments reproducing severe accident conditions (VERCORS 5 & HT2)**, with FP release results compared to experimental data.

**active FP* refer collectively to chemically reactive and radioactive fission products.*

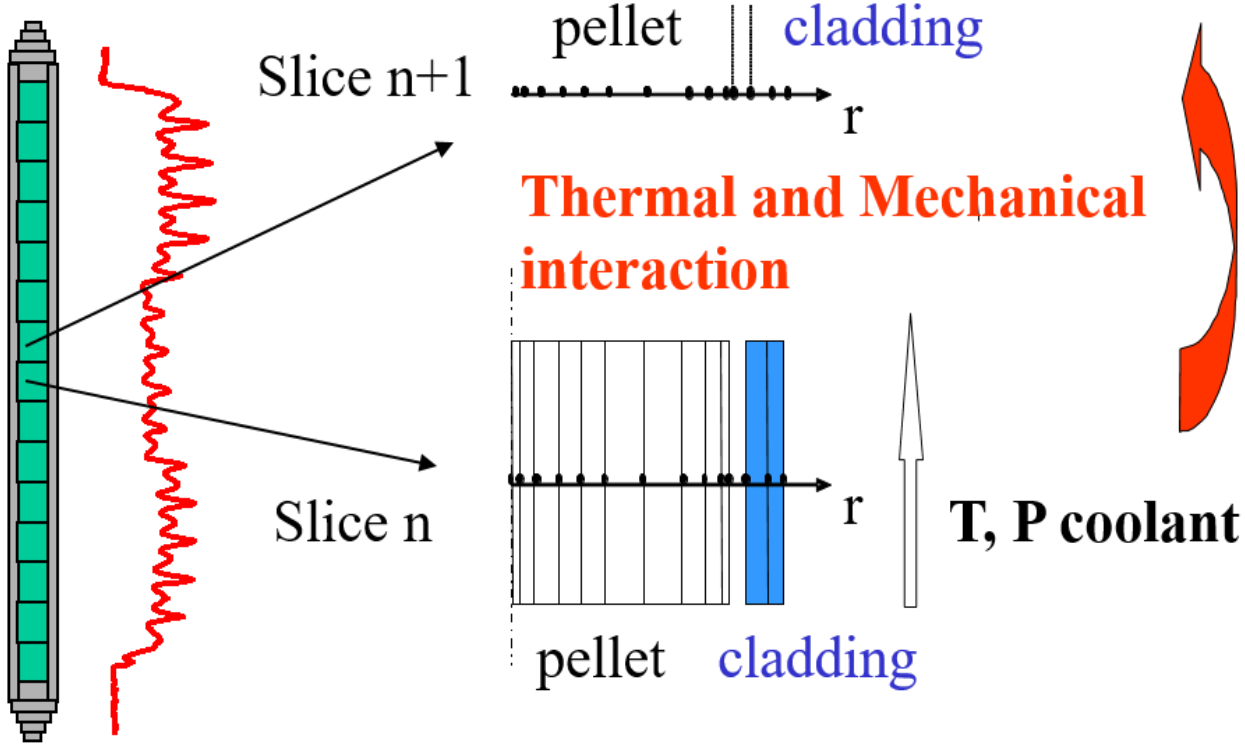
Fuel Performance Code

ALCYONE FUEL PERFORMANCE CODE (standard version)



ALCYONE 1.5D scheme is used to model the fuel rod behavior during:

- Nominal irradiation in PWR,
- Incidental condition (Power ramps)
- Accidental condition (RIA, LOCA)
- Annealing
- pool and dry interim storage.

Typical fuel rod discretization in the 1.5D scheme of ALCYONE

(C. Introini et al. , doi.org/10.1016/j.anucene.2024.110711)

ALCYONE FUEL PERFORMANCE CODE (advanced version)

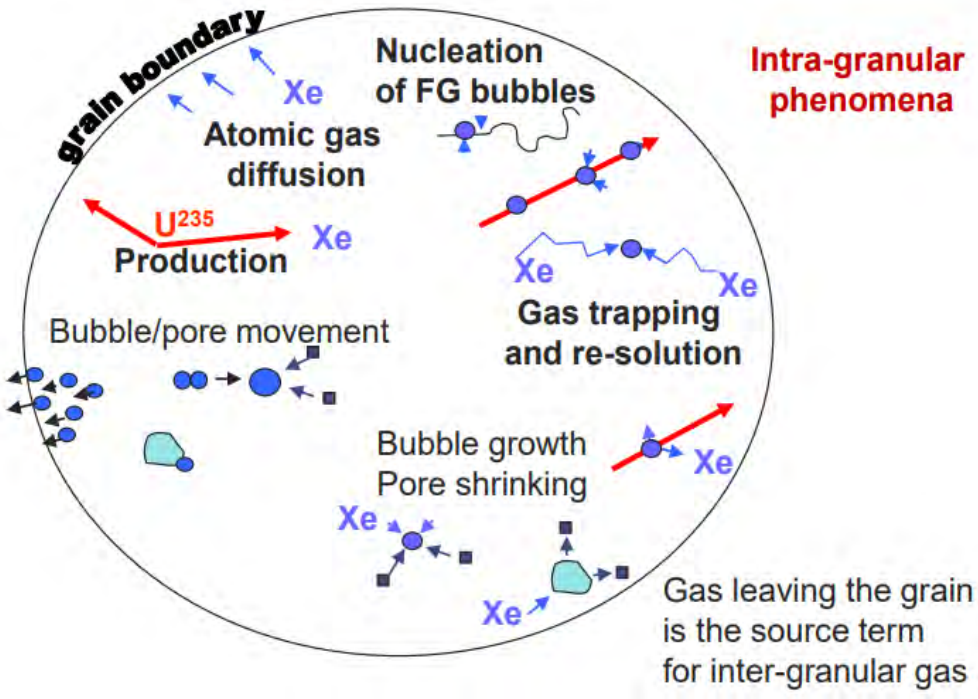
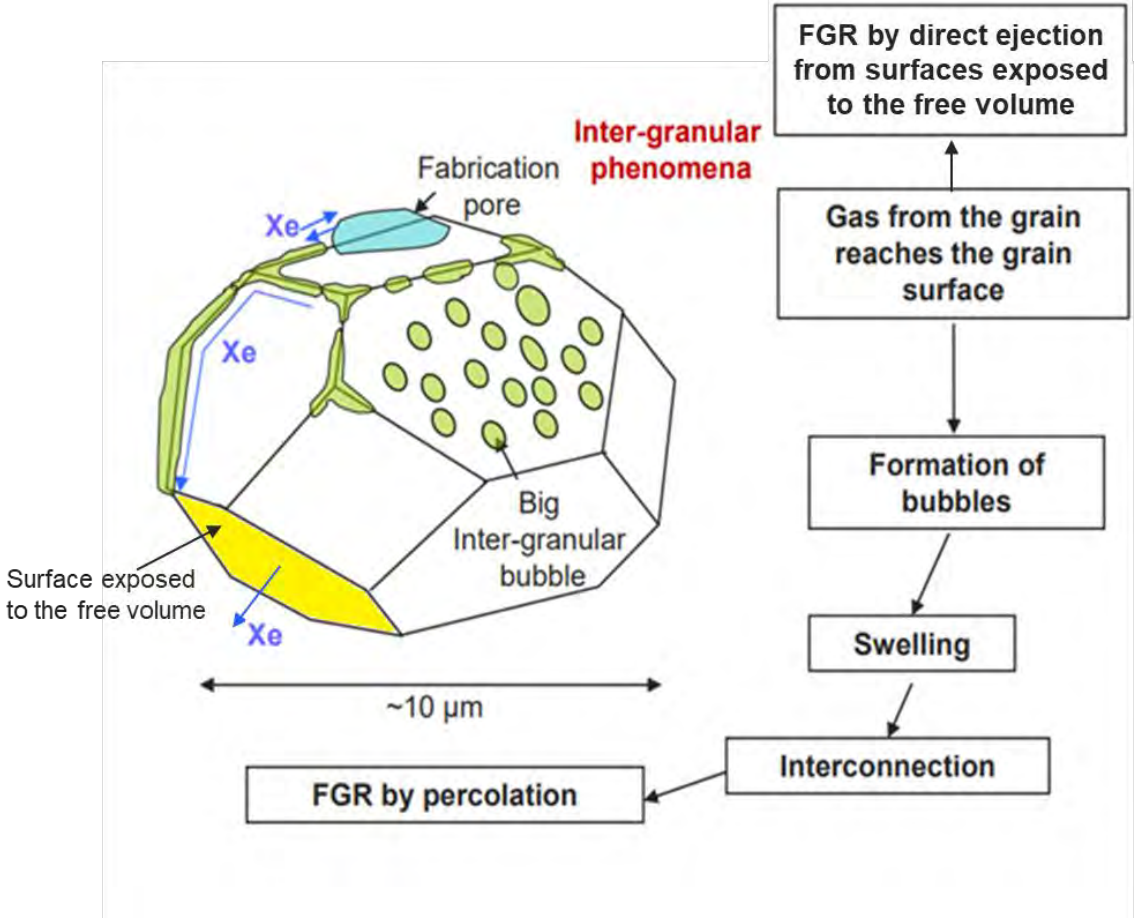
Fuel Performance Code

Margaret Stable

MARGARET Stable

MARGARET Stable is a mechanistic model to describe the behaviour of the inert and stable gases (xenon and krypton) generated by fission of uranium in the fuel at the grain scale.





(L. Noirot ,doi.org/10.1016/j.nucengdes.2011.03.044)

Fission Gas Behavior During Irradiation & Annealing

❖ **Base Irradiation and Power Ramp Irradiation:**

- Dynamic re-solution from **bubble/fission fragment interactions**
- **Part of Xenon is retained** in UO_2 matrix, able to diffuse within grains

❖ **Annealing:**

- **No fissions → no dynamic re-solution**
- **Fission gas rapidly trapped** in bubbles

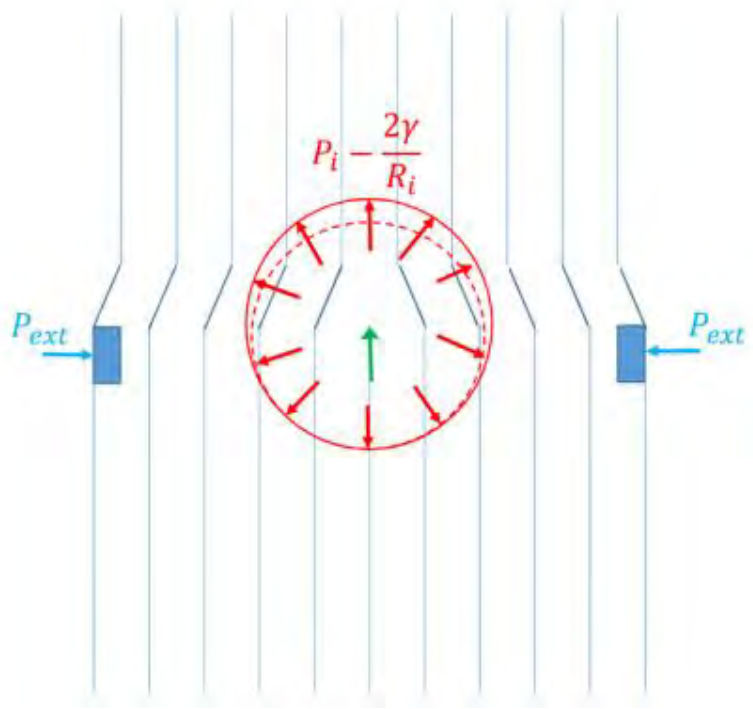
❖ **Key Issue with annealing:**

- **Intragranular → intergranular migration** depends on bubble movement
- **Random motion insufficient** to explain high release rates

Coupled bubble/dislocation mechanism in MARGARET Stable

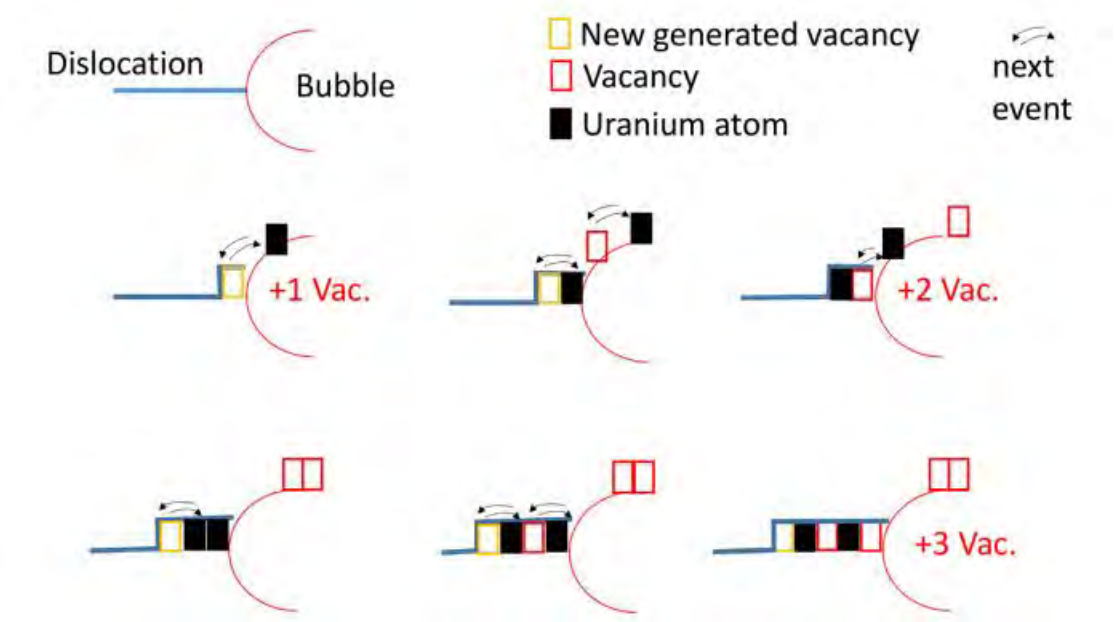
Driving Forces & Vacancy Creation:

- Work of **gas pressure inside bubbles** (driving)
- Opposed by **external pressure**
- Provides **energy for vacancy creation** along the dislocation



(L. Noirot et al. , doi.org/10.1016/j.jnucmat.2023.154311)

Coupled bubble/dislocation mechanism in MARGARET Stable



Vacancy Diffusion & Dislocation Climb

- **Vacancies diffuse** toward the bubble
- **U atoms accumulate** along the dislocation
- Leads to:
  - **Dislocation climb**
  - **Bubble growth**
  - **Relaxation of internal pressure**

(L. Noirot et al. , doi.org/10.1016/j.jnucmat.2023.154311)

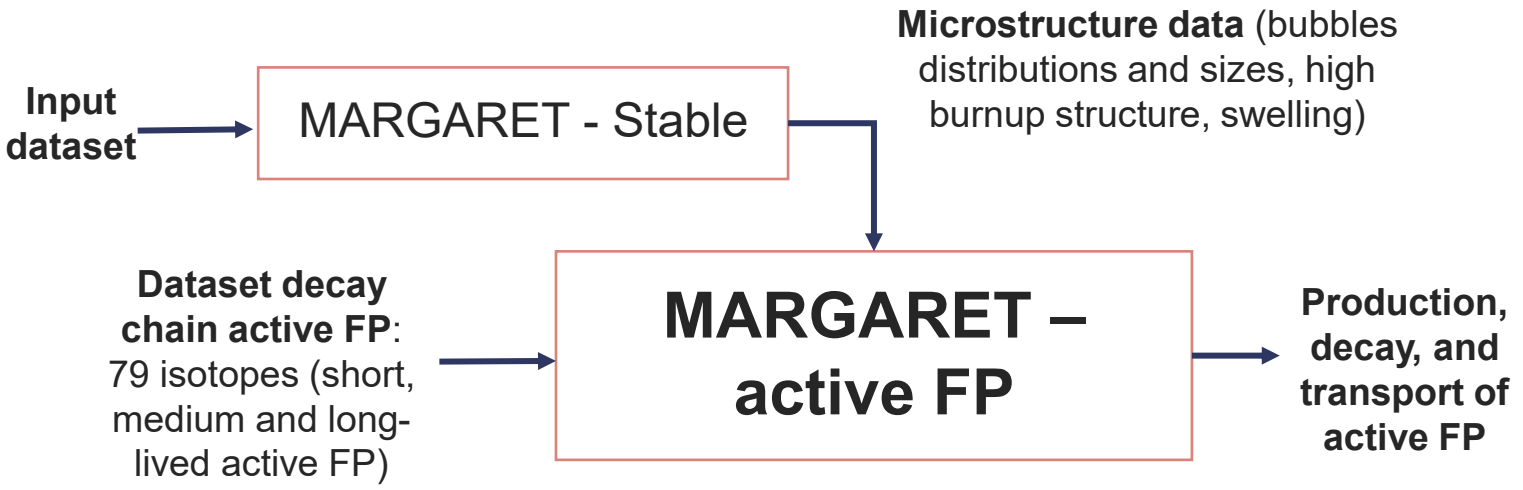
Margaret Active FP

Overview of MARGARET-active FP

Element	Atomic Number
Xe	130, 131, 132, 133, 134, 135, 136
Kr	82, 83, 84, 85, 86
Ba	134, 135, 136, 137, 138
Sr	86, 88, 89, 90
Zr	95, 96
Cs	133, 134, 135, 136, 137
Rb	85, 86, 87
I	127, 129, 130, 131, 132
Br	81, 81m
Te	125, 126, 127, 127m, 128, 129m, 130,132
Se	77, 78, 79, 80, 82
Mo	95, 96, 97, 98, 99, 100
Ru	100, 101, 102, 103, 104, 106
Rh	103, 104, 105, 106
Tc	99, 100
Pd	104, 105, 106, 107, 108,109



MARGARET-active FP Modeling Assumptions:

- **No feedback from active FP** on stable gases.
- **Isotope-Specific Parameters**: the stable (Xe) transport parameters are taken as default.

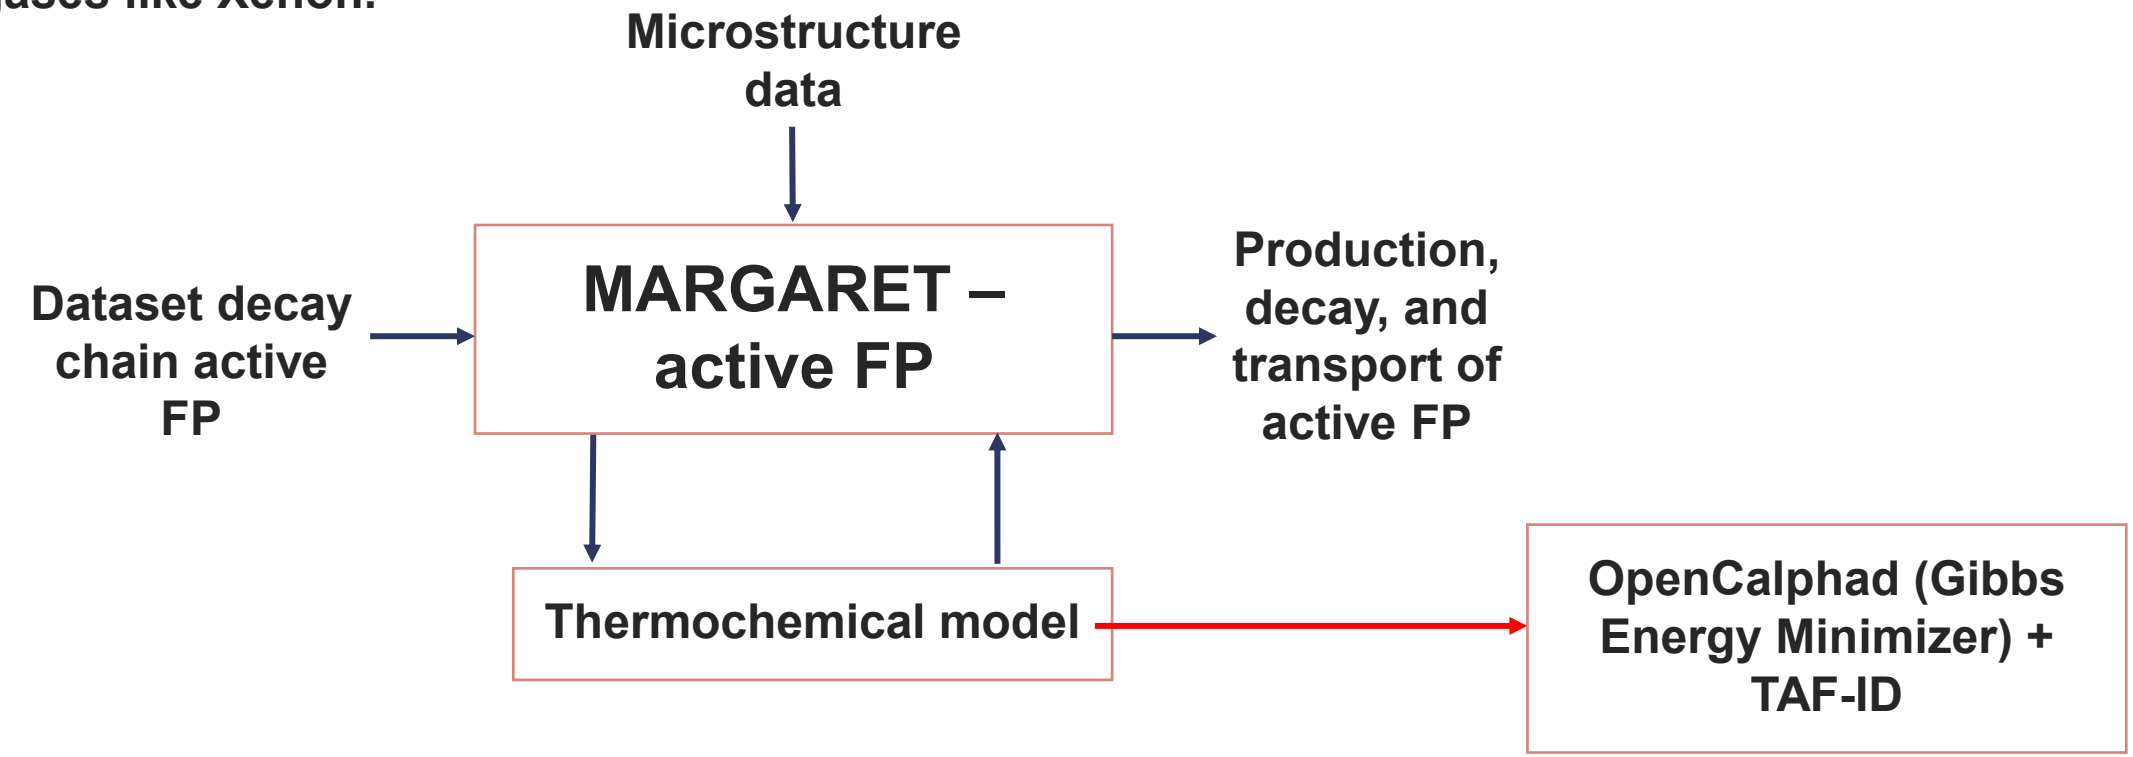
Margaret Active FP

Margaret Active FP + thermochemistry

MARGARET-active FP & Thermochemistry

During a high temperature transient, active FP behavior varies based on chemical reactivity, unlike inert gases like Xenon.

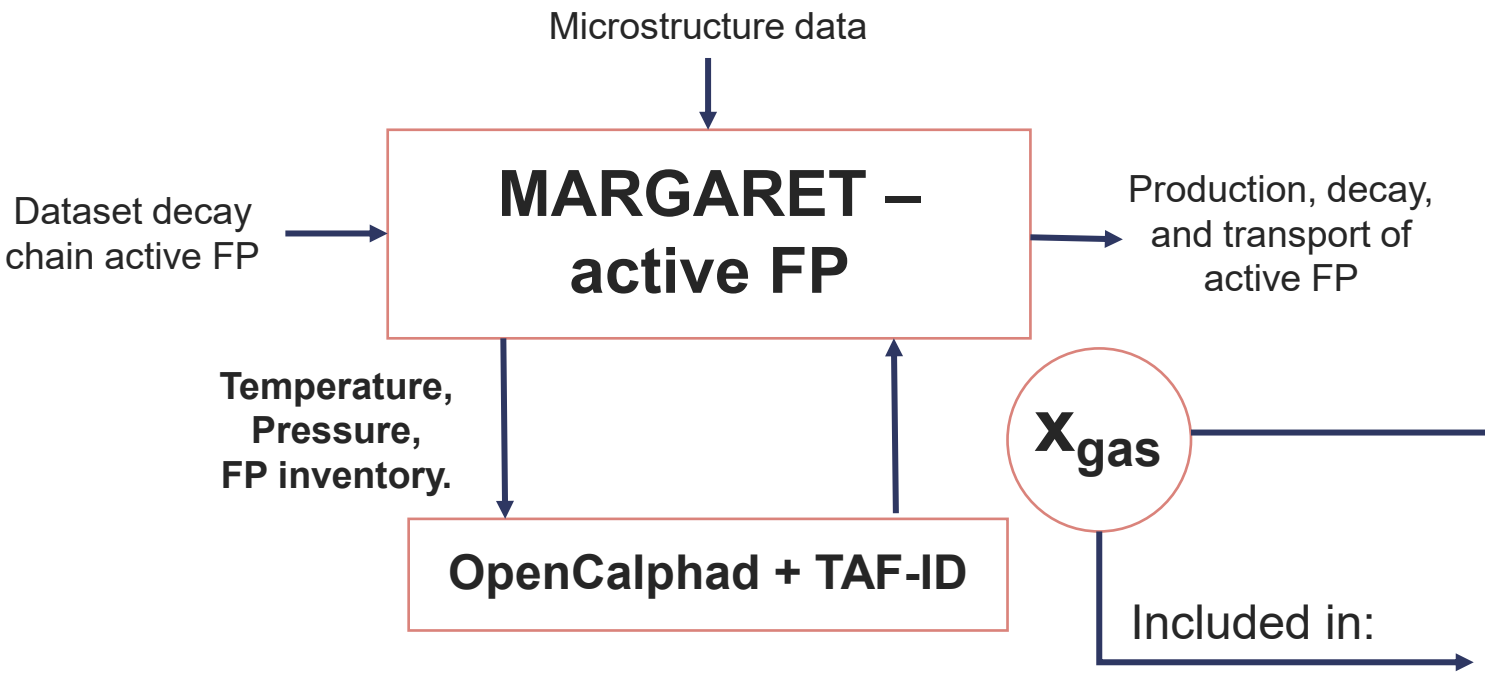


(B. Sundman et al., doi.org/10.1016/j.commatsci.2016.08.045,
C. Guéneau et al., doi.org/10.1016/j.calphad.2020.102212)

He	Kr	Xe	U	O	Ba	Sr	Zr
Cs	Rb	I	Br	Te	Se	Mo	Ru
Rh	Tc	Pd	Ce	Pr	La	Y	Gd
Eu	Sm	Nd					

Composition of the system used for the thermochemical calculations.

MARGARET-active FP & Thermochemistry



Fraction of FP in the gas phase

$$x_{gas} = \frac{mol_{FP}\ in\ the\ gas\ phase}{mol_{FP}\ in\ all\ phases}$$

Assumption:

Only the gas phase can be release; other phases remain confined.

Fission product release from grain boundaries

- **Percolation via intergranular cavities → free volume**

$$-K_{tunj}\frac{k_{perm}}{\mu T_k} f_p x_{gas}(P^2_{int(bjv)} - P^2_{ext})$$

- **Grain boundary fracture**

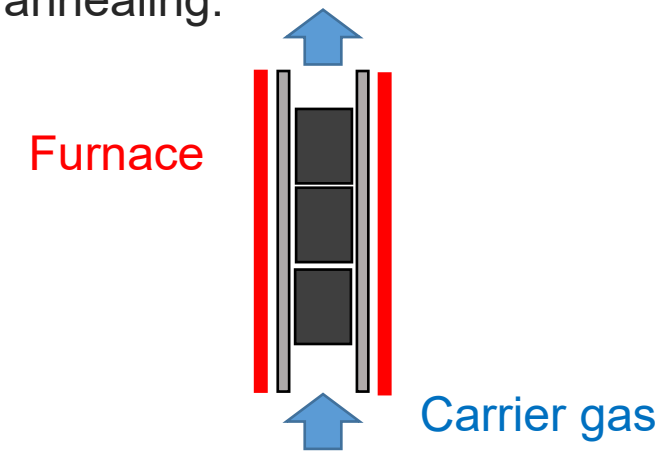
3. Annealing simulations & comparison with Experimental Data

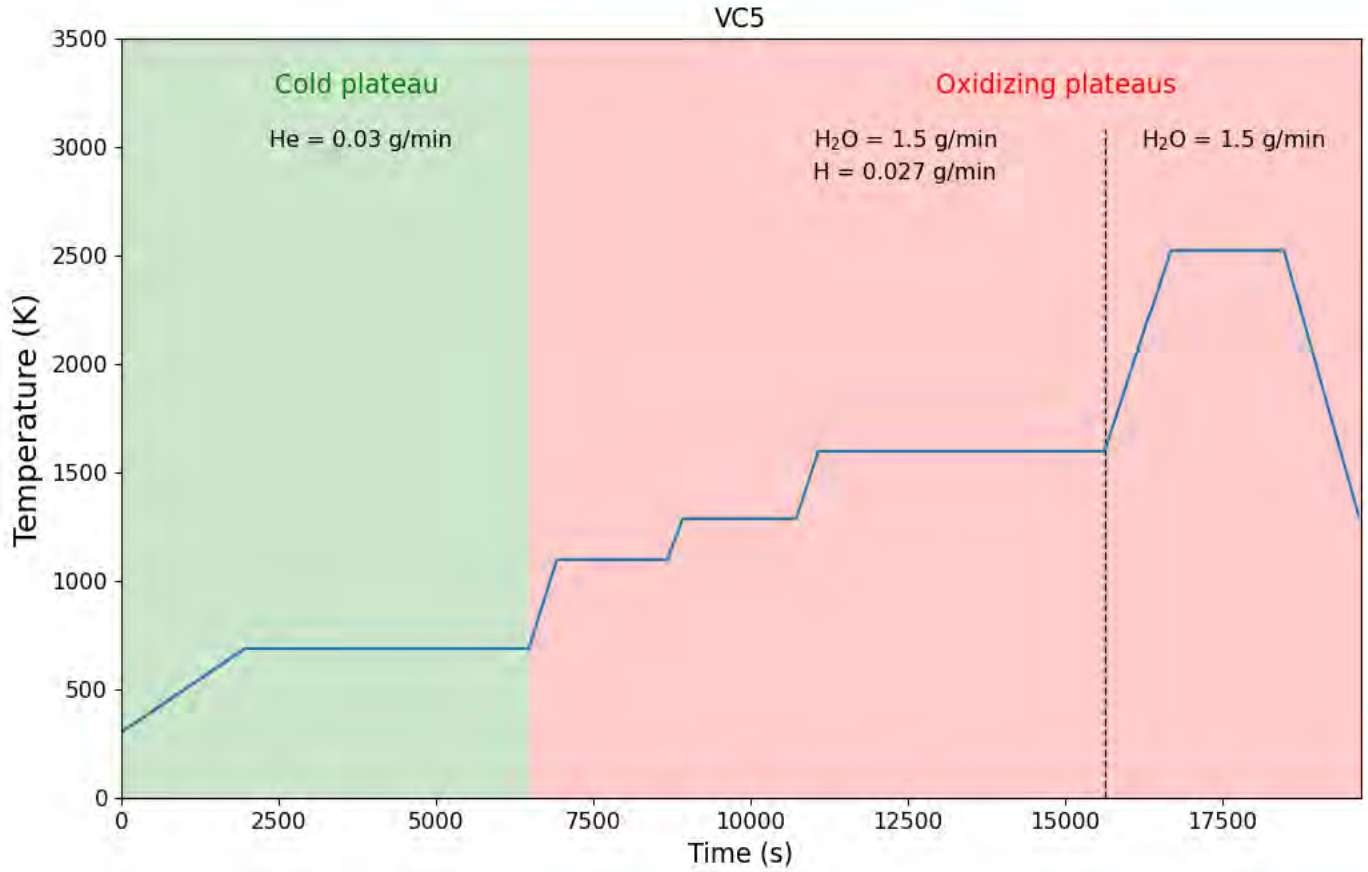
Case under analysis

VERCORS 5 (38 GWd/tU)

Main characteristics of the case:

- **Thermal annealing** of a fuel rod segment (UO_2-Zy_4) in a furnace (crucible model geometry)
- Specimen exposed to **oxidizing conditions** (carrier gas) during annealing.





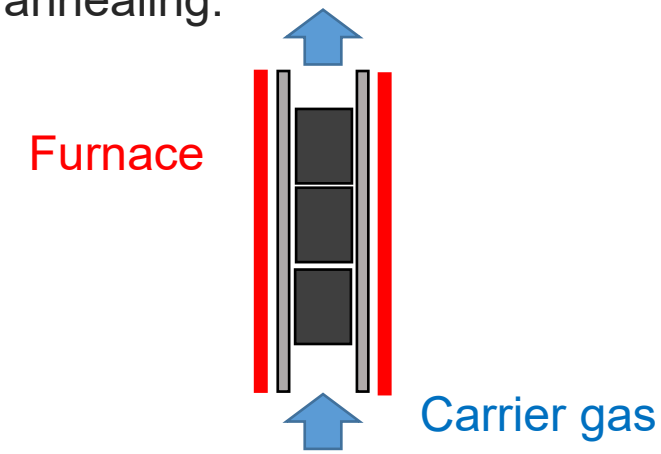
(Y. Pontillon et al. , doi.org/10.1016/j.nucengdes.2009.06.028)

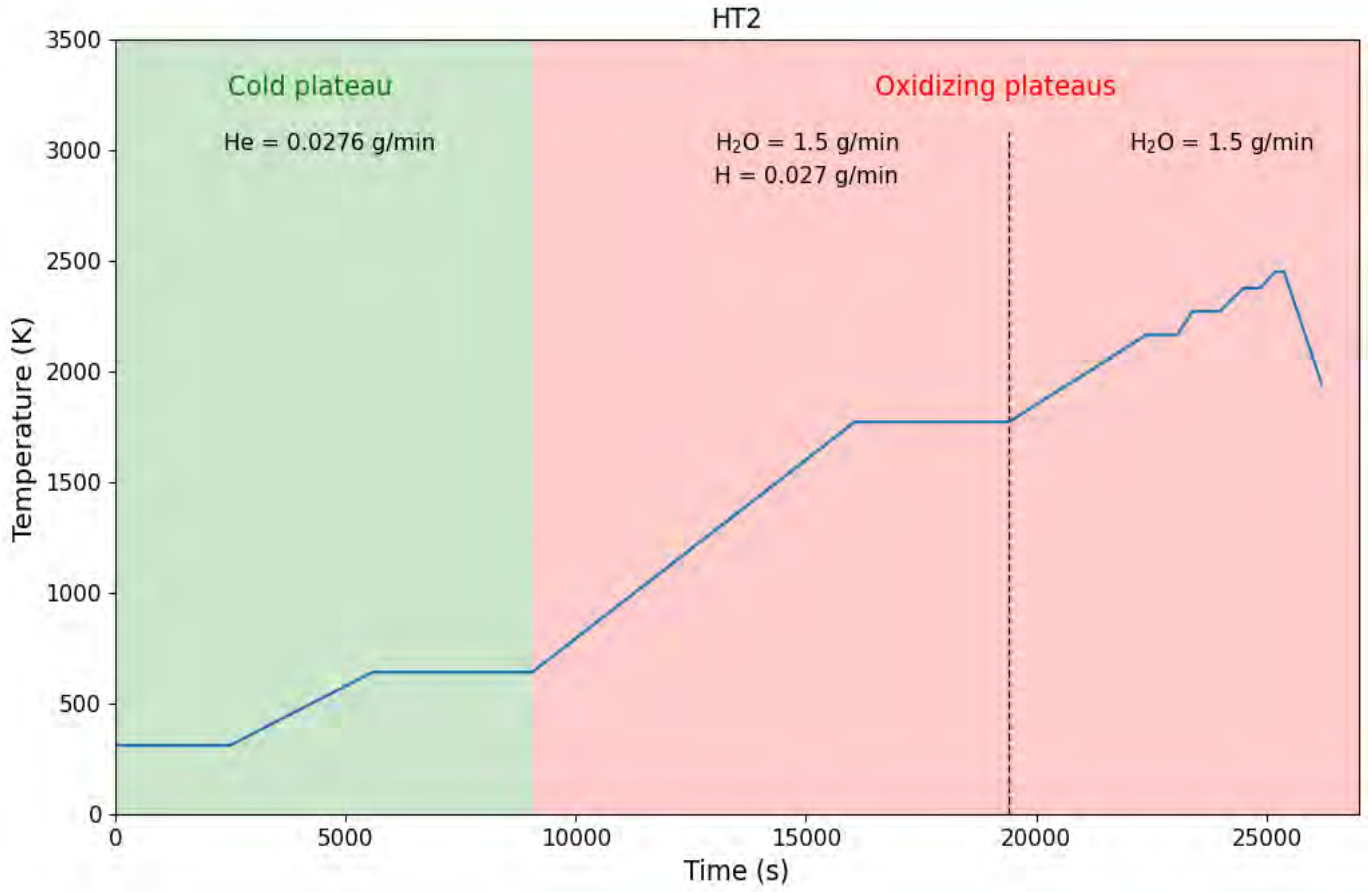
Case under analysis

VERCORS HT2 (48 GWd/tU)

Main characteristics of the case:

- **Thermal annealing** of a fuel rod segment (UO_2-Zy_4) in a furnace (crucible model geometry)
- Specimen exposed to **oxidizing conditions** (carrier gas) during annealing.





In the thermochemical calculation the impact of the carrier gas is considered.

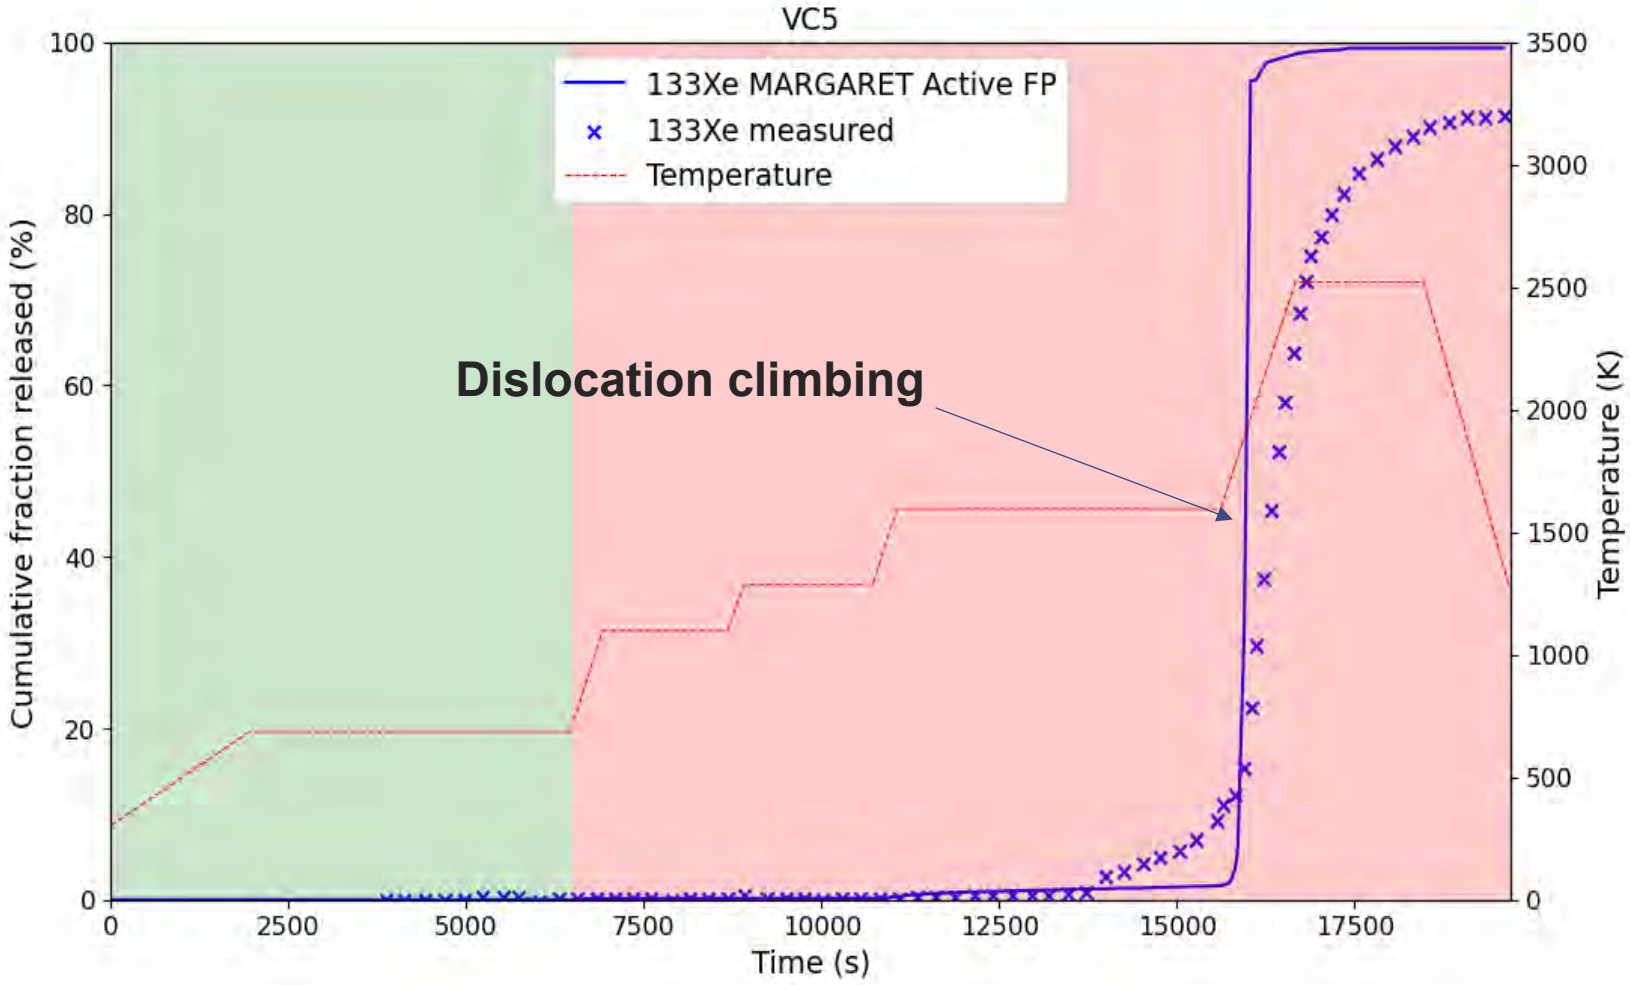
(Y. Pontillon et al. , doi.org/10.1016/j.nucengdes.2009.06.028)

Calculated FP release from the whole pellet

VERCORS 5
Inert: 133Xe

Final release well captured (~95%)

- Driven by dislocation-climb mechanism above 1600 K
- Limited release during 1570 K plateau (short half-life)

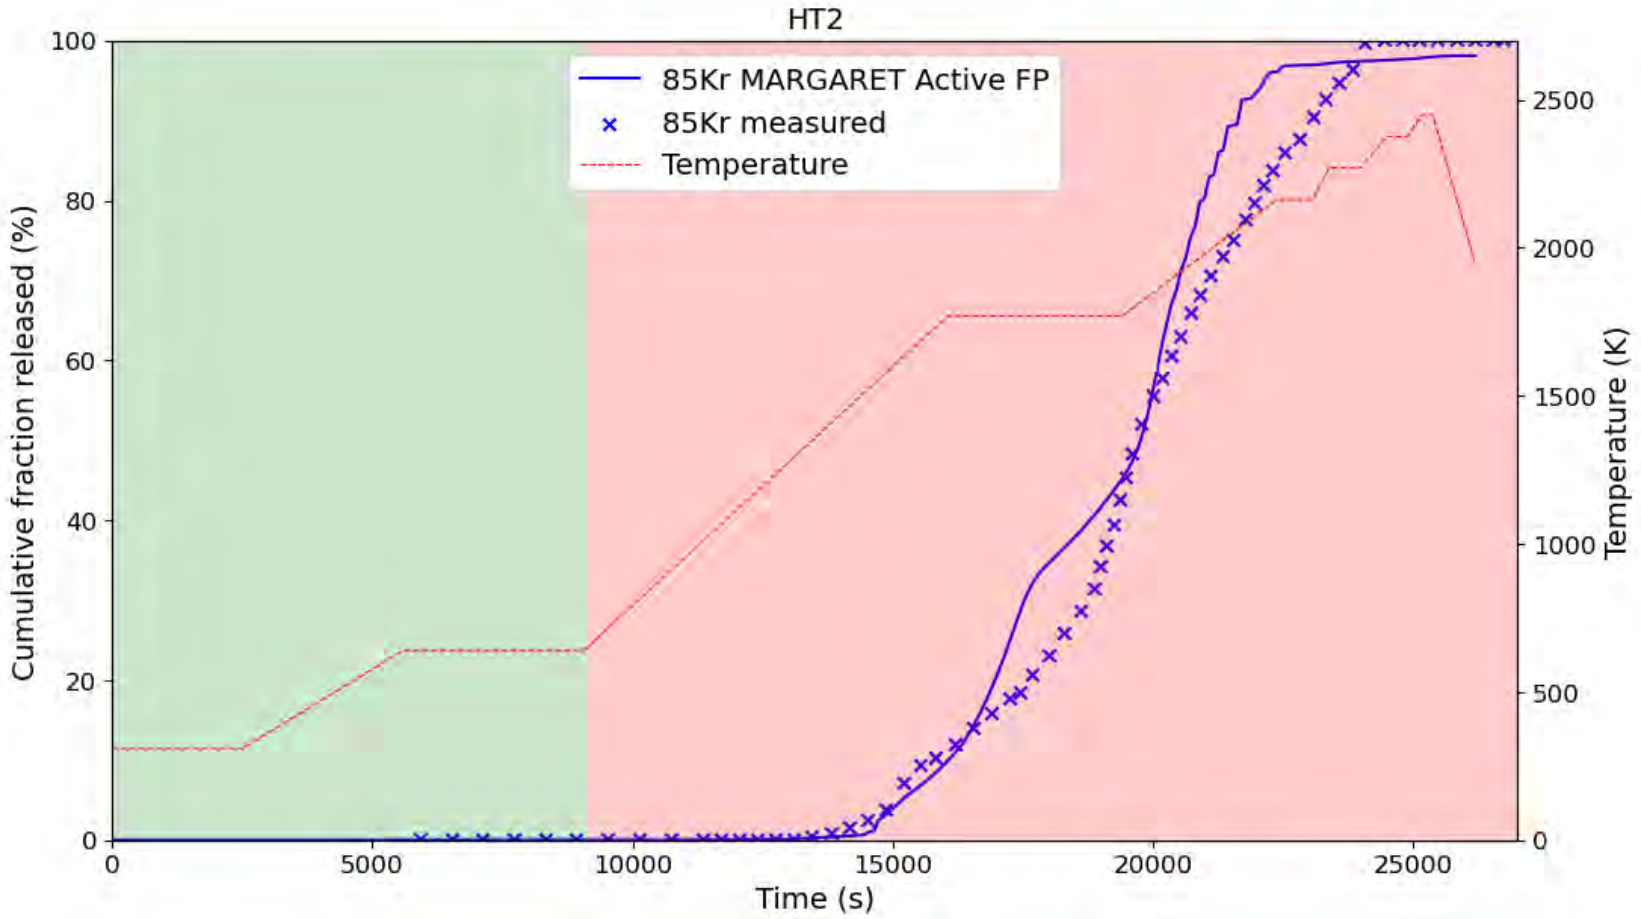


Calculated FP release from the whole pellet

VERCORS HT2
Inert: 85Kr

Kinetics better reproduced than VC5

- Long half-life → grain-boundary inventory available
- Release onset ~1500 K well captured

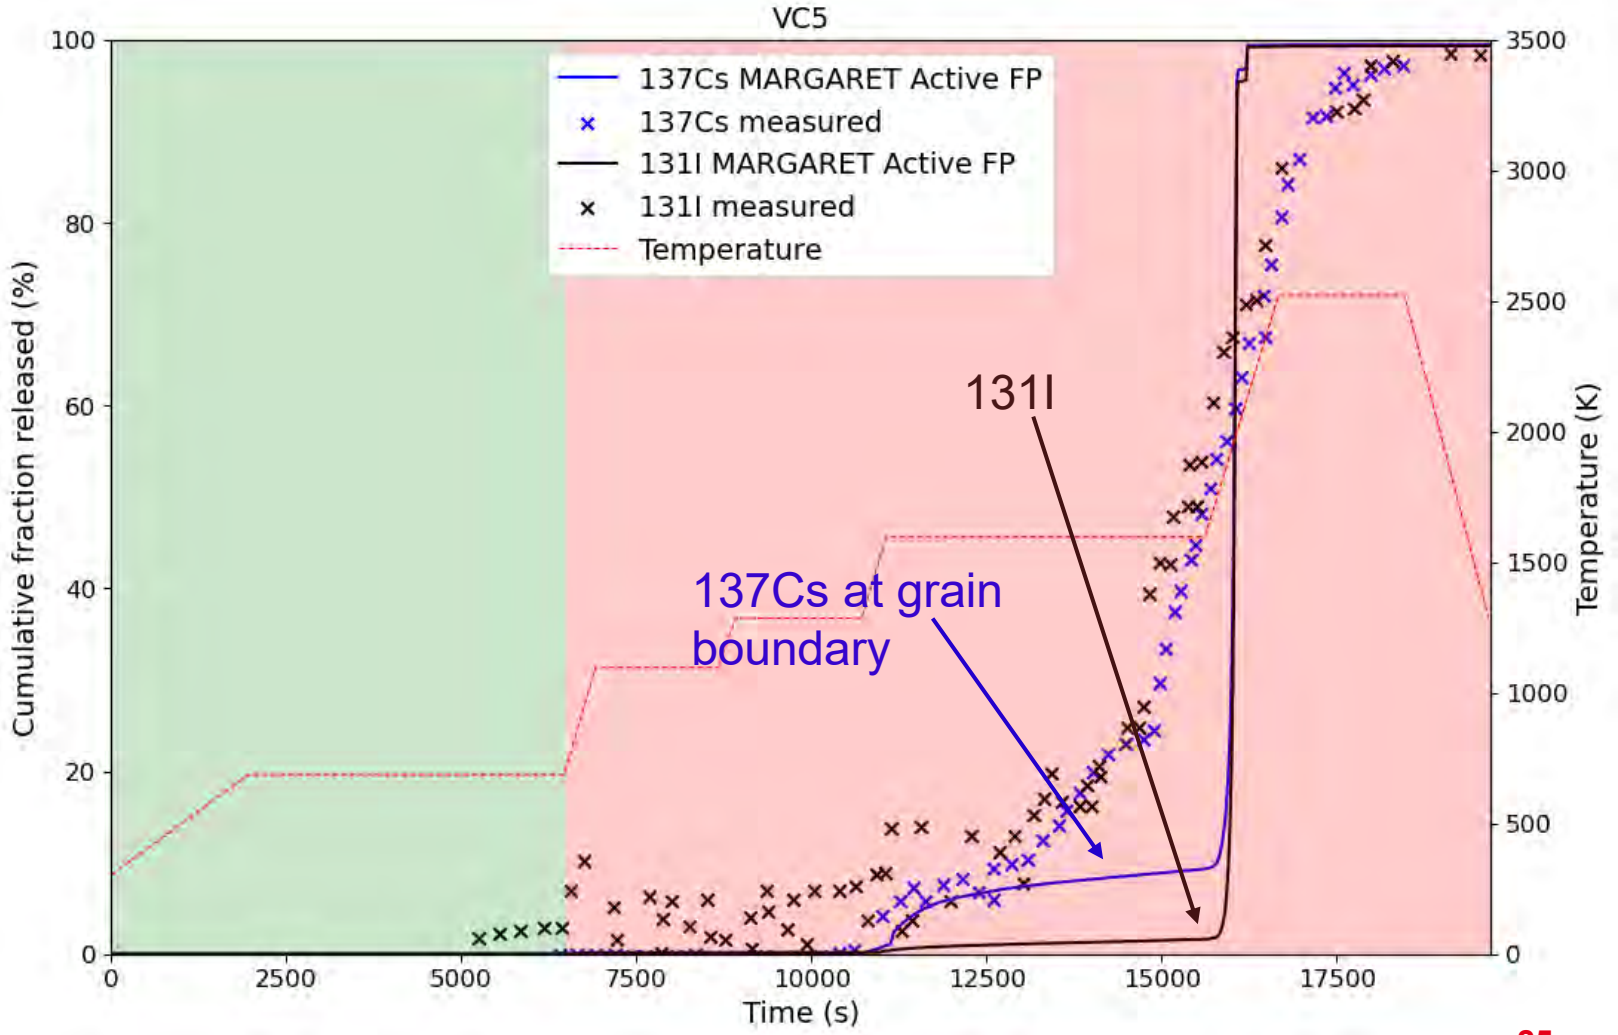


Calculated FP release from the whole pellet

VERCORS 5
Volatile: 137Cs and 131I

Complete release, consistent with experimental data

- 137Cs released already at 1570 K plateau (longer half-life)
- 131I follows 133Xe kinetics (short half-life)

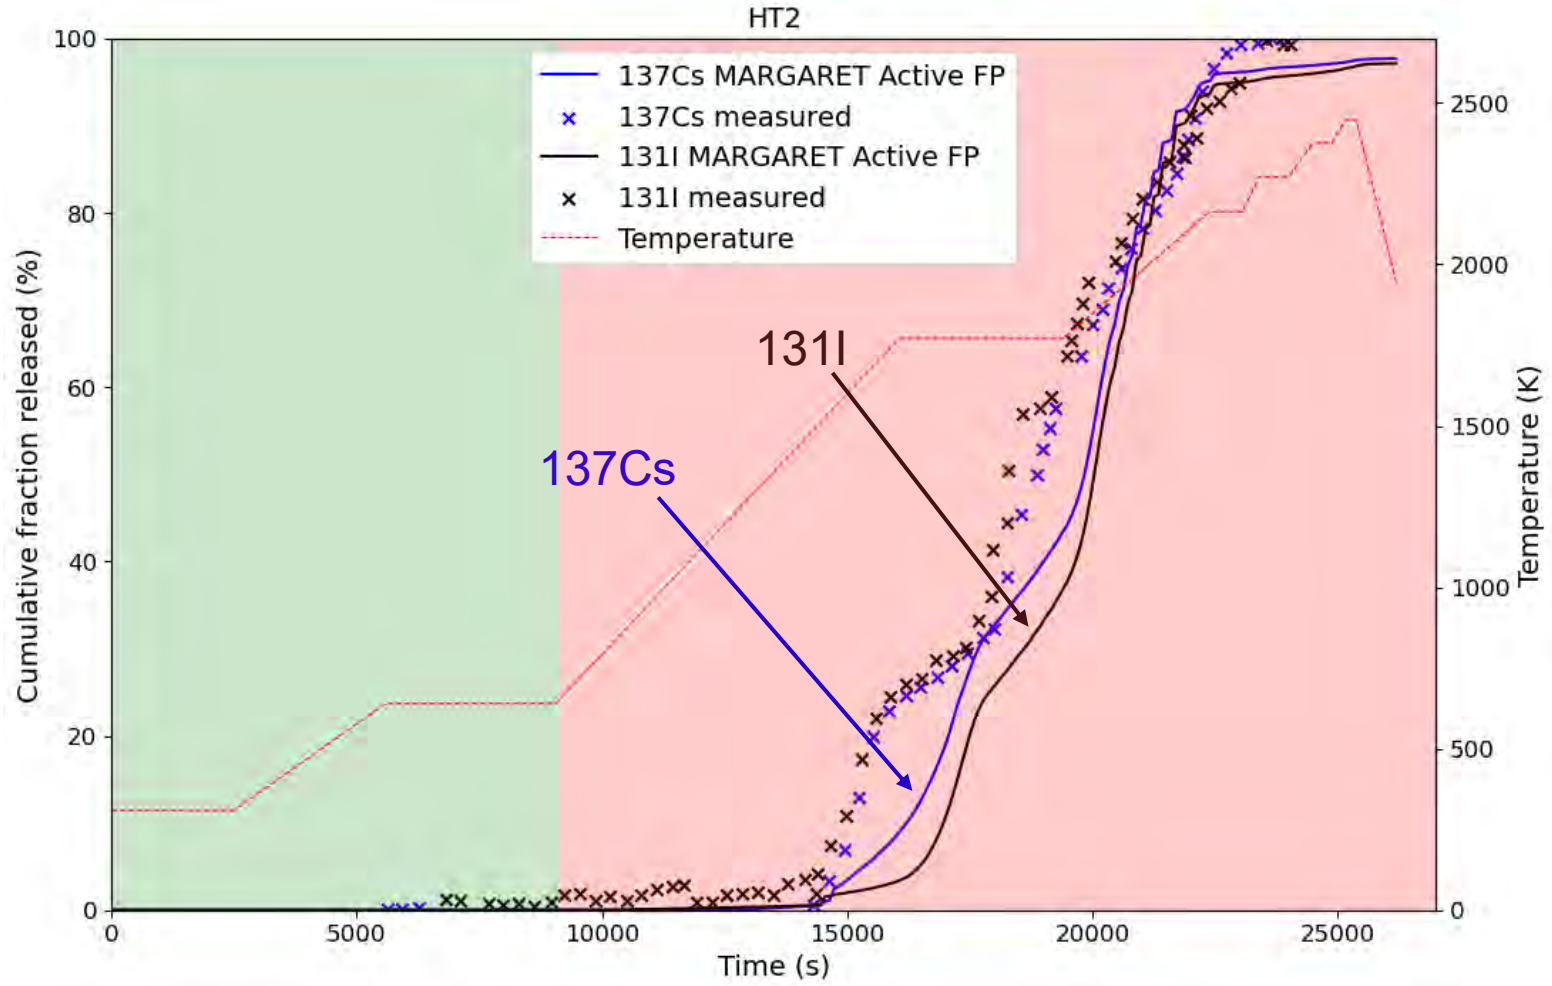


Calculated FP release from the whole pellet

VERCORS HT2
Volatile: 137Cs and 131I

Complete release reproduced

- Trends consistent with VC5



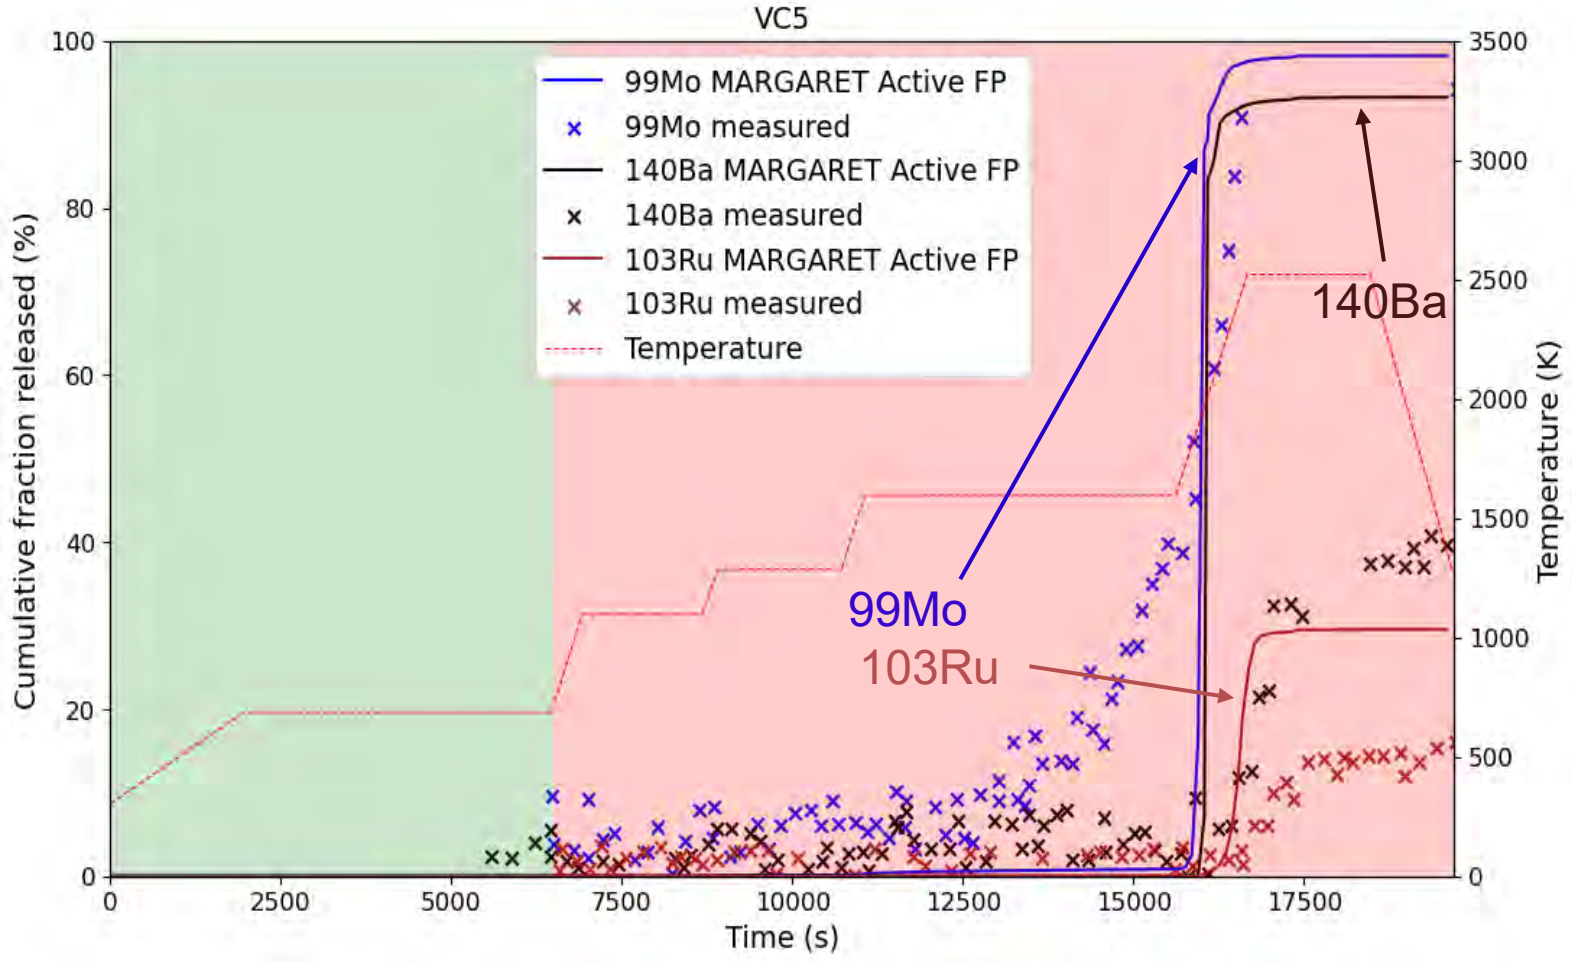
Calculated FP release from the whole pellet

VERCORS 5

Semi – volatile and low - volatile: 99Mo, 140Ba and 103Ru

Mo well captured;
Ba and Ru overestimated

- 99Mo ~100%: oxidizing atmosphere enhances volatility
- 140Ba and 103Ru: cladding interaction missing in fuel-side model



Calculated FP release from the whole pellet

VERCORS 5

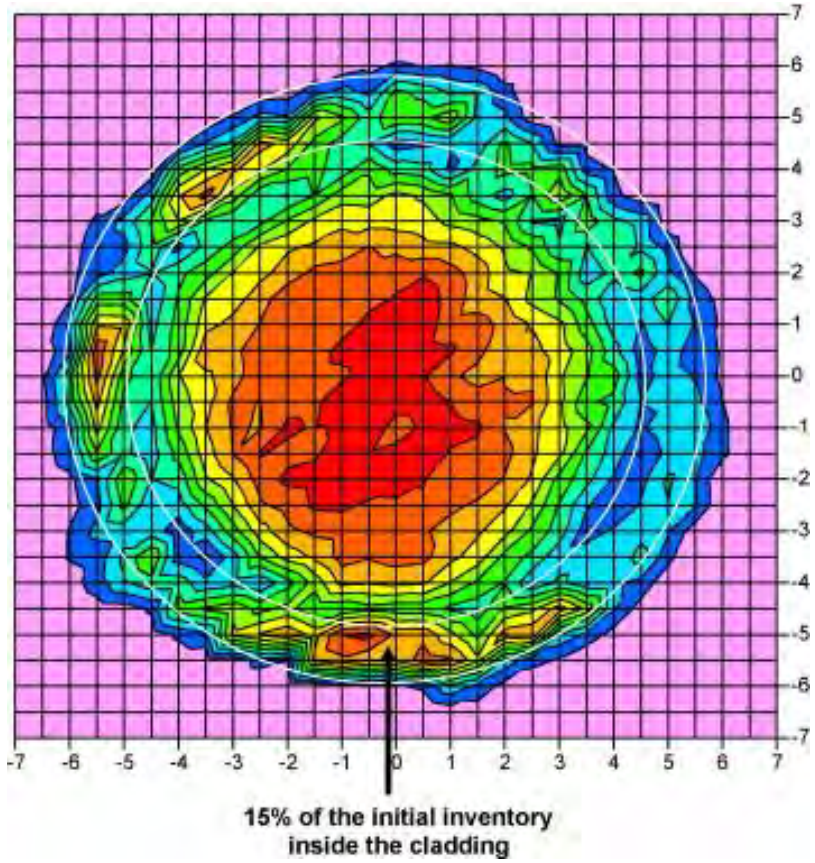
Semi – volatile and low - volatile: 99Mo, 140Ba and 103Ru

Mo well captured;
Ba and Ru overestimated

- 99Mo ~100%: oxidizing atmosphere enhances volatility
- 140Ba and 103Ru: cladding interaction missing in fuel-side model

Post-annealing analyses of the specimens, including gamma tomography, show that barium reacts with the cladding.

(Y. Pontillon et al. , doi.org/10.1016/j.nucengdes.2009.06.028)

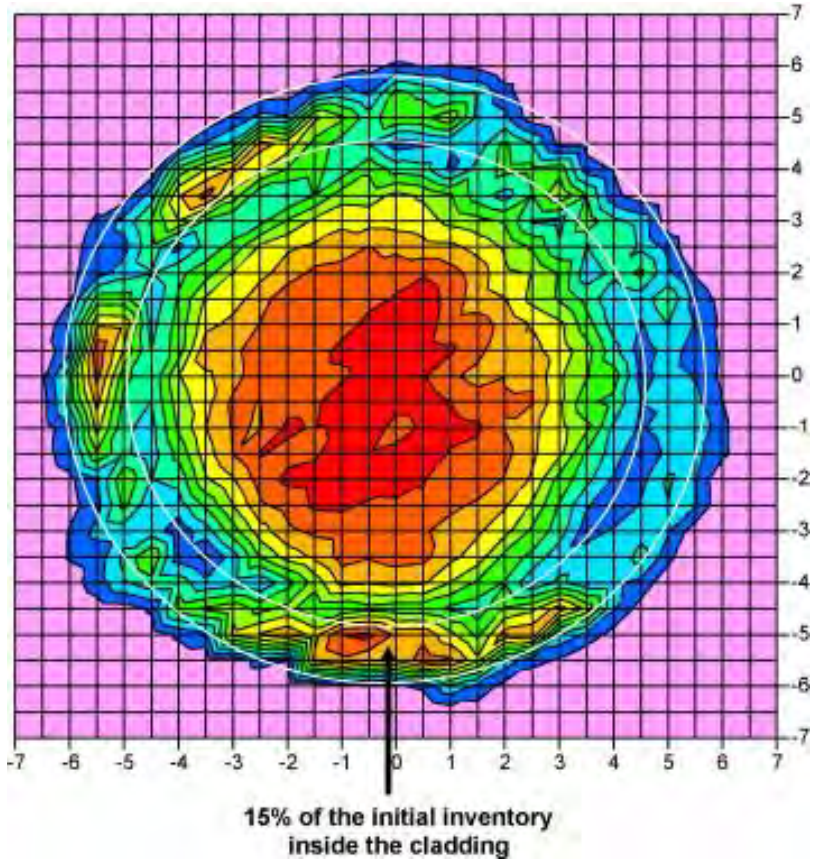


Gamma emission tomography of ^{140}Ba after VERCORS 5.

Semi-volatile and low-volatile cladding interaction

- Discrepancies observed for Ba and Ru → **thermochemical equilibrium calculation on cladding performed**
- **Cladding assumed fully oxidized (ZrO_2)**, consistent with test conditions
- Inputs: **Released fission product inventory + uranium fraction** (fuel–cladding interaction)
- Veshchunov et al. 1990**: formation of ceramic ($(U,Zr)O_x$ phase** → 3%–6% of fuel interacts with ZrO_2
- **Conservative assumption**: 6% upper bound adopted

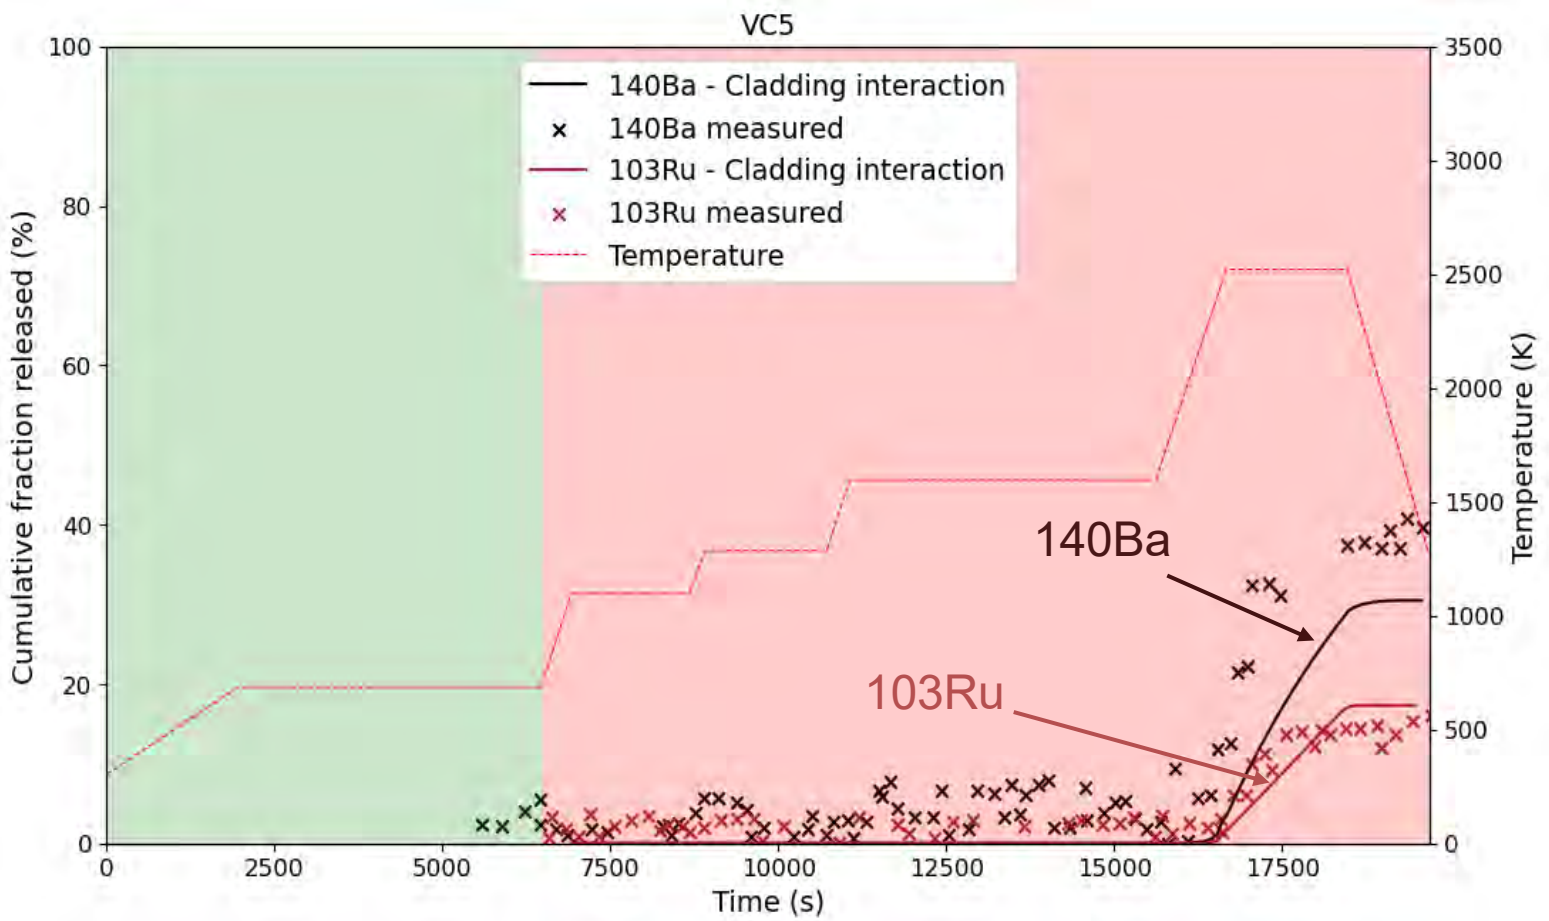
(Veshchunov et al., doi.org/10.1016/0022-3115(90)90422-J)



Gamma emission tomography of ^{140}Ba after VERCORS 5.

Semi-volatile and low-volatile cladding interaction

- **Only Ba and Ru retained by cladding**
- Released quantities of 140Ba and 103Ru **drastically reduced**
- **Release kinetics also improved**
- **Ba preferentially reacts with ZrO_2 and it forms also an HCP metallic phase with Zr**
- **This metallic phase traps part of the Ru inventory, limiting its release**

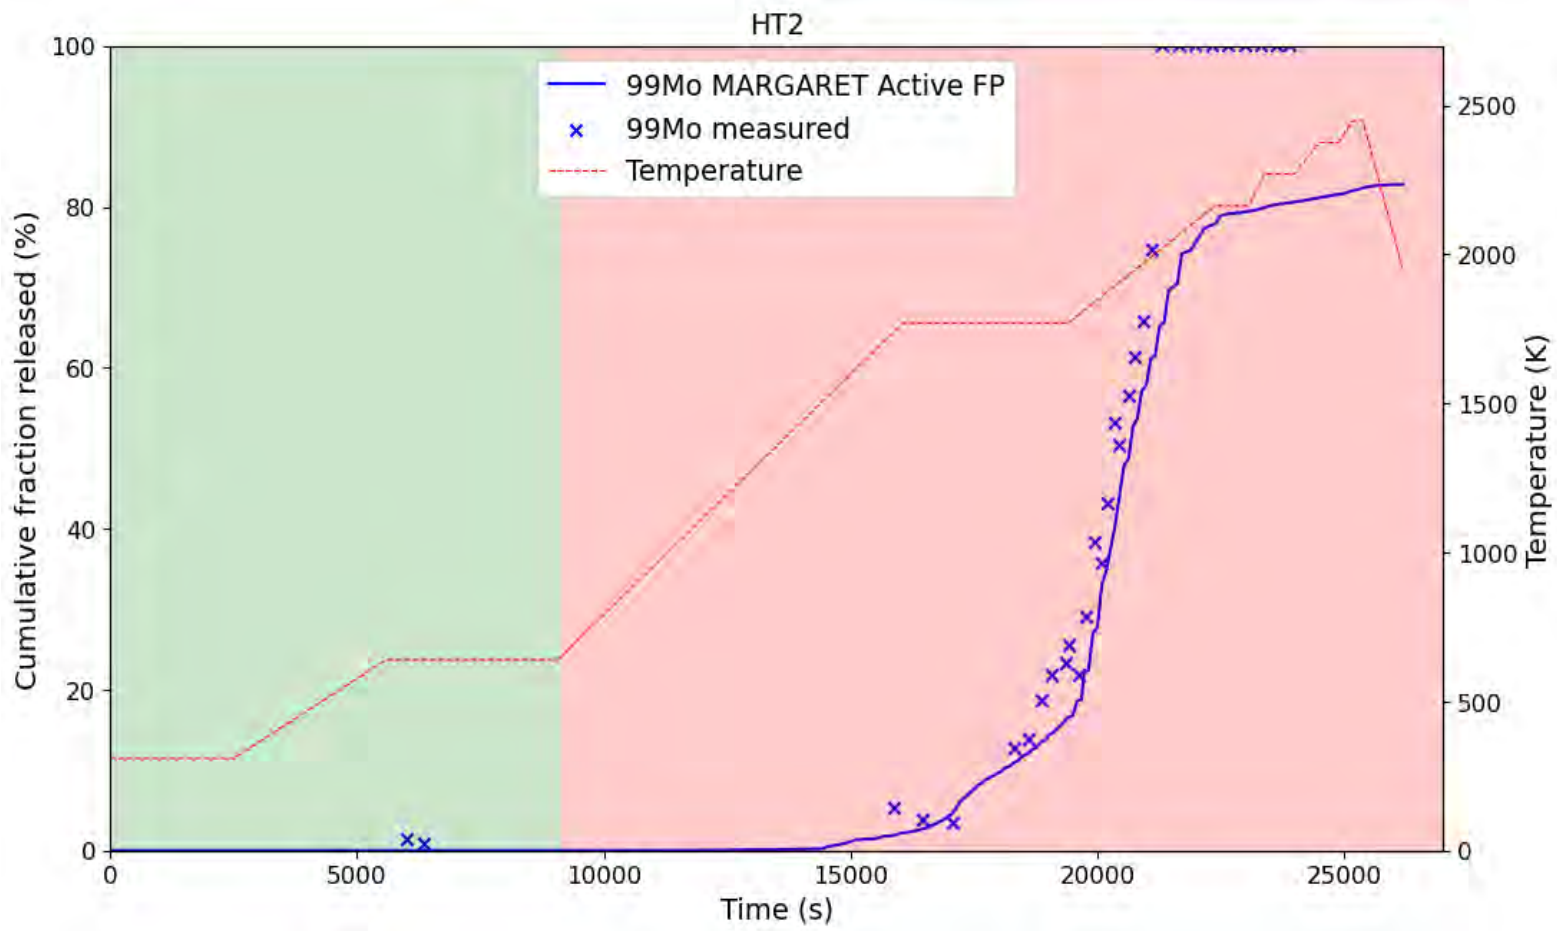


Calculated FP release from the whole pellet

VERCORS HT2
Semi – volatile: 99Mo

Kinetics well reproduced;
final release underestimated (82%)

- Part of Mo inventory predicted in liquid phase
- Possible aerosol release not modeled



4. Conclusions

Conclusions

A model is proposed to specifically address the **behavior of active fission products (active FP) during severe accident:**

- Capable of modeling a **large number of isotopes**

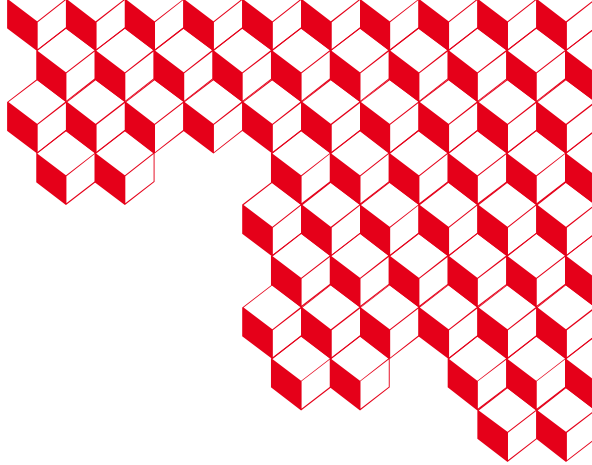
- Considers **multiple phenomena**, including:
  - Grain boundary fracturing and percolation
  - Dislocation climb and bubble migration

- **Impact of thermochemistry of FP** is included in the calculation

- **Results:**

  - good agreement for fission gases and volatile FPs

  - Thermochemistry essential for semi-volatile and low-volatile species (Mo, Ba and Ru) → sensitive to chemical environment and cladding–FP interaction



Thank you for your attention.

Coupled bubble/dislocation mechanism in MARGARET Stable

New variable introduced:

- **Dislocation Density** ρ_d^{climb} : correlation proposed by Nogita et al.
- New Bubble Populations:
  - **BPREC:** Pinned bubbles on climbing dislocations characterized by:
    - C_{bprec} : pinned bubble concentration
    - $C_{xebprec}$: Xe concentration in pinned bubble
    - V_{bprec} : volume of the pinned bubbble

Dynamics:

- **Gas exchange** between dissolved phase ↔ BPREC
- BPREC **Swelling**
- **Pinning of free bubbles** (B) on climbing dislocations
- **Coalescences**: B/BPREC and BPREC/BPREC
- **Exit of climbing dislocations and BPREC at grain boundaries**

The velocity of the climbing dislocations v_d and the associated swelling of BPREC are related to the characteristics of BPREC, through

$$v_d = \frac{12D^*}{kT} \frac{P_{bprec} - \frac{2\gamma}{R_{bprec}} - P_{hydr}}{\frac{C_{bprec}}{\rho_d^{climb}} \left(\frac{\rho_d^{climb}}{C_{bprec}} - 2R_{bprec} \right)^3} \times \Omega^{\frac{4}{3}}$$

$$\frac{dV_{bprec}}{dt}|_{climb} = v_d \times w \times \rho_d^{climb}$$

(L. Noirot et al. , doi.org/10.1016/j.jnucmat.2023.154311)

Coupled bubble/dislocation mechanism in MARGARET Stable

D^* evaluation from experimental data

$$v_d = \frac{12D^*}{kT} \frac{P_{bprec} - \frac{2\gamma}{R_{bprec}} - P_{hydr}}{\frac{C_{bprec}}{\rho_d^{climb}} \left(\frac{\rho_d^{climb}}{C_{bprec}} - 2R_{bprec} \right)^3} \times \Omega^{\frac{4}{3}}$$

Isothermal annealing

The TAF-ID database has a crucial role in the description of the active FP release.

VOLATILE

Fission gases, iodine, caesium, antimony, tellurium, cadmium, rubidium and silver

SEMI-VOLATILE

Molybdenum, rhodium, barium, palladium and technetium

LOW-VOLATILE

Ruthenium, cerium, strontium, yttrium, europium, niobium and lanthanum

NON-VOLATILE

Zirconium, neodymium and praseodymium

Thermochemical calculation and grouping elements

Concentration Data for the thermochemical equilibrium calculation:

- Volatile and semi-volatile fission product concentrations are obtained via MARGARET-active FP (green).
- Concentrations of uranium, oxygen, and low/non-volatile elements are obtained from ALCYONE's PRODHEL module (yellow).

Grouping of Elements:

- **TAF-ID Database Limitations:** Includes a limited number of fission products. Elements are grouped based on similar chemical properties and release behavior.

Thermochemical Equilibrium Calculations:

- **Representative Elements:** For each group, a representative element from the TAF-ID database is selected. The representative element's concentration is the sum of all group elements' concentrations.

Validation of MELCOR Pool Scrubbing Model on UW Bubble Transport Experiments

Water and sodium pool scrubbing · single bubble and swarm rise · benchmark to ANL SRT

Bradley Beeny · Brandon De Luna
Sandia National Laboratories

SAND2026-XXXXP

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Why pool scrubbing matters for SFR source term

- A liquid pool standing over a gas-injection source acts as a passive filter: rising bubbles carry FP aerosols and vapors, which transfer to the pool and are retained there.
- This mechanism is well established for LWRs and is the dominant source-term reduction credited in BWR suppression pools.
- For pool-type metal-fueled SFRs the geometry is similar — molten sodium sits over the core — so a comparable scrubbing role is expected, but had not been quantified.
- ANL identified sodium pool scrubbing as a **high-importance, high-uncertainty** knowledge gap for SFR source-term work.
- ANL developed the SRT code as a stand-alone scrubbing benchmark; NEUP funded the UW experiments that anchor it.
- SNL was tasked under the FY25 DOE Fast Reactor Program to use the UW data to validate MELCOR's pool-scrubbing model.

MELCOR's relevant features

- A **generalized EOS** lets the same pool model handle either LWR (water) or non-LWR (sodium) pools without code branches.
- Bubble composition is unrestricted — condensable vapor, NCG, or any mixture — so the same closures cover vapor-rich LWR conditions and dry-argon SFR injection.
- Arbitrarily many FP species can be carried in aerosol form, each with its own size distribution and density.
- The pool-scrubbing kinetics derive from **SPARC-90**, extended in MELCOR to handle bubble swarms in addition to single isolated bubbles.

PART 1

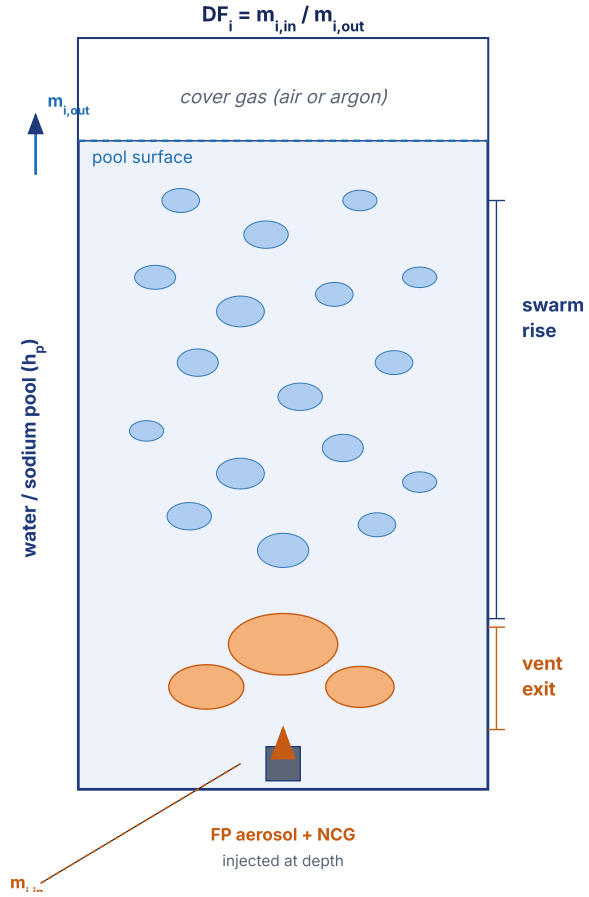
Pool Scrubbing Theory in MELCOR

Vent-exit and swarm-rise regions

- FP-aerosol-laden gas is injected at depth, and the rising flow splits into two distinct hydrodynamic regions.
- **Vent-exit region** — large globules form just above the nozzle and break up into the rising swarm; deposition here is driven by jet inertia and orifice geometry.
- **Swarm-rise region** — many oblate-spheroid bubbles coalesce and redisperse as they rise; centrifugal, Brownian, and gravitational mechanisms remove aerosol from the bubble interior.
- **DF** = (aerosol mass entering the pool) / (aerosol mass leaving the surface), reported per particle-size bin so the kernel can be probed across the diameter spectrum.

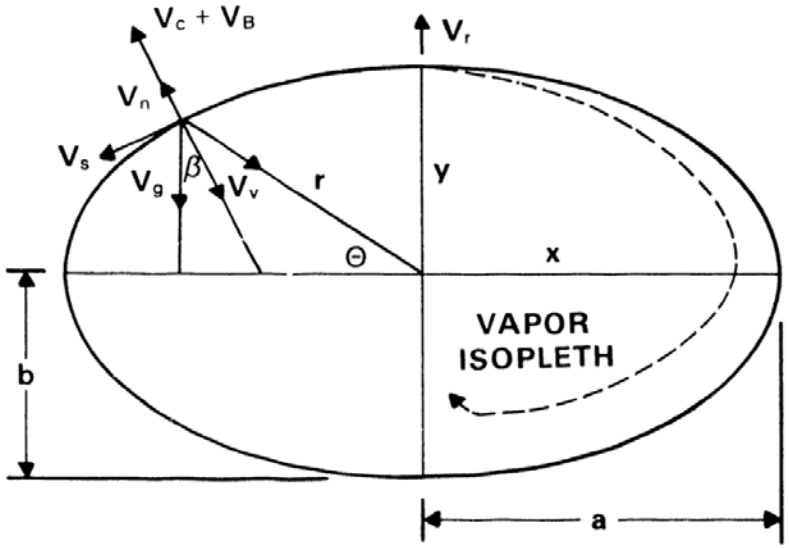
Why only swarm rise is exercised by the UW conditions

- The UW pools are deep and subcooled, with pure NCG bubbling — no boiling, no condensable vapor in the carrier gas.
- Injection velocity is low, so inertial deposition at the vent is negligible.
- The injector is a single low-velocity inverted nozzle, not a high-velocity multi-hole quencher — there is no jet-driven impaction, no shear-driven small-bubble formation, and no vent-region condensation, so the SPARC-90 vent-exit term is essentially inert.
- No Stefan flow and no FP vapor in the carrier gas — phase-change perturbations are absent by design.



Swarm scrubbing mechanisms

- **Centrifugal capture** — particles drift toward the bubble wall as the rising bubble oscillates; dominates for larger aerosol.
- **Brownian diffusion** — random thermal motion deposits sub-micron particles onto the interface.
- **Gravitational sedimentation** — settling onto the upward-facing lower surface of the oblate bubble; matters most for dense/coarse particles.
- Each mechanism contributes an aerosol flux normal to the interior interface; their sum gives the **net deposition velocity** that sets the first-order scrubbing rate inside every bubble.
- **Phase change perturbs the kernel.** When the bubble is supersaturated, the condensable vapor (water vapor over a water pool, sodium vapor over a sodium pool) condenses on the cooler interface and drives **Stefan flow inward**, sweeping particles to the wall and boosting DF; evaporation reverses the flow and degrades it. SPARC-90 absorbs this into the deposition velocity.



Swarm-rise bubble geometry and deposition-velocity components.

Bubble geometry in the swarm

EQUIVALENT DIAMETER

$$d_{vm}[cm] = 0.7 \times 10^{(-0.2265 + (0.0203 + 0.0313 \cdot x_{ncg})^{1/2})}$$

ASPECT RATIO

$$a/b = 0.84107 + 1.13466 \cdot d_{vm} - 0.3795 \cdot d_{vm}^{2}$$

- The UW injection is essentially pure NCG ($x_{ncg} \approx 1$), so the default correlation predicts $d_{vm} \approx 0.7$ cm regardless of test conditions.
- Every numerical constant in these correlations is exposed as an RN-package sensitivity coefficient, so the same equations can be re-anchored to a specific experiment without code edits.

Default vs. user geometry

- **Default** — the correlation form is retained and the RN coefficients are scaled proportionally; closest to the SPARC-90 baseline.
- **User** — the same coefficients are set directly to match a measured bubble size and aspect ratio, overriding the correlation.

The water experiments show the **default** geometry actually agrees with data better than heavy-handed user overrides — the correlation captures the swarm-averaged effective bubble better than a single measured value.

Bubble and swarm rise velocities

BUBBLE RISE VELOCITY

$$V_r[\mathrm{cm/s}] = 7.875\cdot(\sigma/\rho_l)^{1/4},\ d_{vm} \le 0.5\ \mathrm{cm}$$

$$V_r[\mathrm{cm/s}] = 1.40713\cdot d_{vm}^{\,0.49275}\cdot V_r(d_{vm}=0.5),\ \text{else}$$

SWARM RISE VELOCITY

$$V_s(y)[\mathrm{cm/s}] = [(Q_s+5.33)/0.003011]^{1/2}\cdot[1 - y\cdot 3.975\times 10^{-4}]$$

AVERAGE SWARM VELOCITY (USED BY MELCOR)

$$\bar{V}_s = \tfrac{1}{2}[V_s(0) + V_s(h_p)]$$

- **V_r** — single-bubble rise velocity, set by pool surface tension σ, liquid density ρ_l, and the equivalent diameter d_{vm}; piecewise to handle the small-bubble Stokes-like and large-bubble cap-bubble regimes.
- **$V_s(y)$** — swarm rise velocity at depth **y**, driven by the total gas volumetric flux Q_s; MELCOR averages it head-to-base to get the height-averaged swarm velocity used in the kinetics.
- Every numerical constant is exposed as an RN-package sensitivity coefficient, so the correlations can be re-anchored without code edits.
- Scrubbing along the column is then computed by spatially marching the first-order absorption equation up the rise height.

Aerosol scrubbing kinetics

SECTIONAL SCRUBBING RATE

$$dc_i/dt = -[(1/v_b)\int(A_b \cdot V_{n,i})\,dA]\,c_i$$

NET NORMAL DEPOSITION VELOCITY

$$V_{n,i} = V_{c,i} + V_{B,i} - V_{g,i}\cdot\cos(\beta) - V_v$$

- Scrubbing is treated as **first-order absorption** at the bubble surface — the depletion rate is linear in the bubble's aerosol concentration c_i.
- Any particle that reaches the interface is assumed to be captured with unit efficiency; the kernel is therefore a flux-to-surface, not a sticking, problem.

STOKES SEDIMENTATION

$$V_{g,i} = \rho_i \cdot g \cdot S_i \cdot d_i^2 \,/\, (18 \cdot \mu)$$

CENTRIFUGAL CAPTURE (SCALED FROM V_G)

$$V_{c,i} = V_{g,i} \cdot (V_s^2/r_c) \,/\, g$$

BROWNIAN (PENETRATION THEORY)

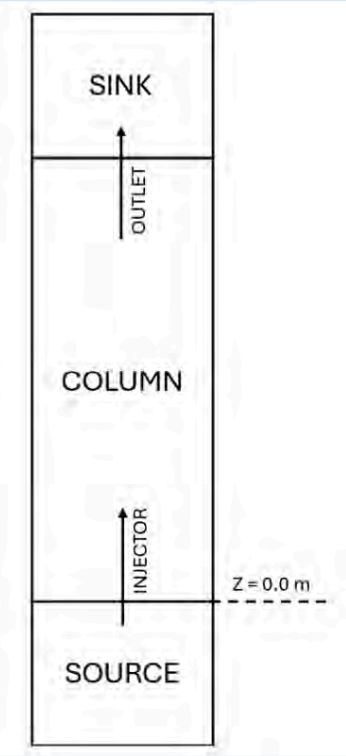
$$V_{B,i} = (D_i/\pi\cdot\tau_e)^{1/2}, \quad D_i = k_B T_{pool} S_i/(3\pi\cdot\mu\cdot d_i)$$

PART 2

MELCOR Input Deck for the UW Facility

Nodalization and RN inputs — common across all experiments

- **SOURCE** CV (1 m^3) — inlet boundary representing the aerosol generator that delivers FP-laden NCG to the nozzle.
- **COLUMN** CV — the active scrubbing volume; holds the liquid pool plus the cover-gas headspace and is where the SPARC-90 kinetics fire.
- **SINK** CV (1 m^3) — outlet boundary held at constant thermodynamic state to mimic the laboratory exhaust train.
- **INJECTOR** FL — nozzle geometry connecting SOURCE to COLUMN; one bubble per second; this is the flow path that activates pool scrubbing.
- **OUTLET** FL — passive flow path that vents COLUMN to SINK so the model can run to steady-state DF.
- Same nodalization in every run; only the pool fluid (water / sodium) and cover gas (air / argon) change.



UW pool-scrubbing MELCOR CV/FL nodalization.

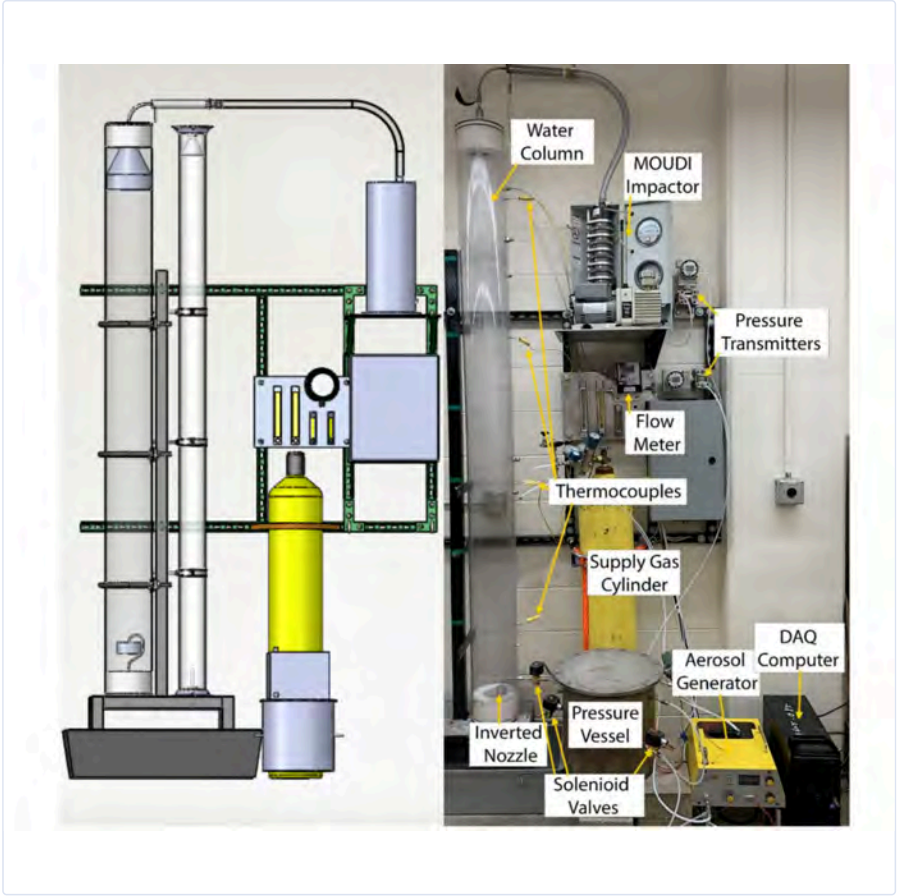
RN aerosol inputs — defaults exercised, only the size grid refined

- **20 size bins over 0.001 – 18 µm** (vs. default 10 bins over 0.1 – 50 µm) to resolve the DF U-shape across the UW measurement window.
- **Aerosol density** set per material via RN1_ASP (Al 2.7 / Ni 8.9 / W 19.3 g/cm^3); initial mass and source size-distribution set via RN1_AG / RN1_AS.
- **Single-class FP with vapor pressure forced to zero** — the species stays in aerosol form so the test exercises scrubbing kinetics, not condensation onto droplets.
- **Vent associated to COLUMN** via RN2_PLS as a single hole with area = INJECTOR; class-level sensitivity coefficients (RN1_CSC) left at defaults.

PART 3

UW Experimental Setup

UW pool-scrubbing facility — CAD model and as-built rig



UW bubble-transport facility (Becker, K. PhD dissertation, U. Wisconsin–Madison, 2022).

Two experimental classes

- **Single isolated bubble rise** — one bubble at a time, with tightly controlled size and shape, isolating the per-bubble scrubbing kernel.
- **Bubble swarm rise** — a continuous bubble swarm with a realistic size distribution, exercising the collective behavior MELCOR's swarm-rise extension is meant to capture.

Key components on the rig

- **Aerosol generator + supply-gas cylinder** — deliver the aerosol-laden NCG (air for water tests, argon for sodium) at controlled flow.
- **Inverted nozzle / pressure vessel** — carefully designed injection geometry that sets bubble size and detaches them cleanly into the pool.
- **Water (or sodium) column** — the scrubbing volume itself; depth selected per test; instrumented for thermocouples and pressure transmitters.
- **MOUDI impactor + flow meter + DAQ** — size-resolved aerosol sampling above the pool surface to compute DF(d_p).

Parametric matrix: aerosol size, material density, and gas-phase concentration; bubble equivalent diameter; pool depth; pool temperature (sodium only) — each varied while holding the rest fixed.

Test conditions — water and sodium pools

Water pool

- Pool and atmosphere held at room conditions (297 K) with an air cover gas; no thermal sweep.
- Aerosol diameter spans three decades: **0.018 – 18 µm**, straddling the DF U-shape.
- Two aerosol materials chosen for density contrast: **Al** 2.7 g/cm^3 vs. **Ni** 8.9 g/cm^3.
- Four gas-bubble sizes (1.81 / 2.19 / 2.87 / 3.27 cm) tracking the single-bubble correlation regime.
- Two carrier-gas aerosol concentrations — 13.2 (low) and 26.5 (high) g/m^3 — to probe first-order scrubbing.
- Two pool depths — 0.9 m (low) and 1.8 m (high) — doubling the rise residence time.

Sodium pool

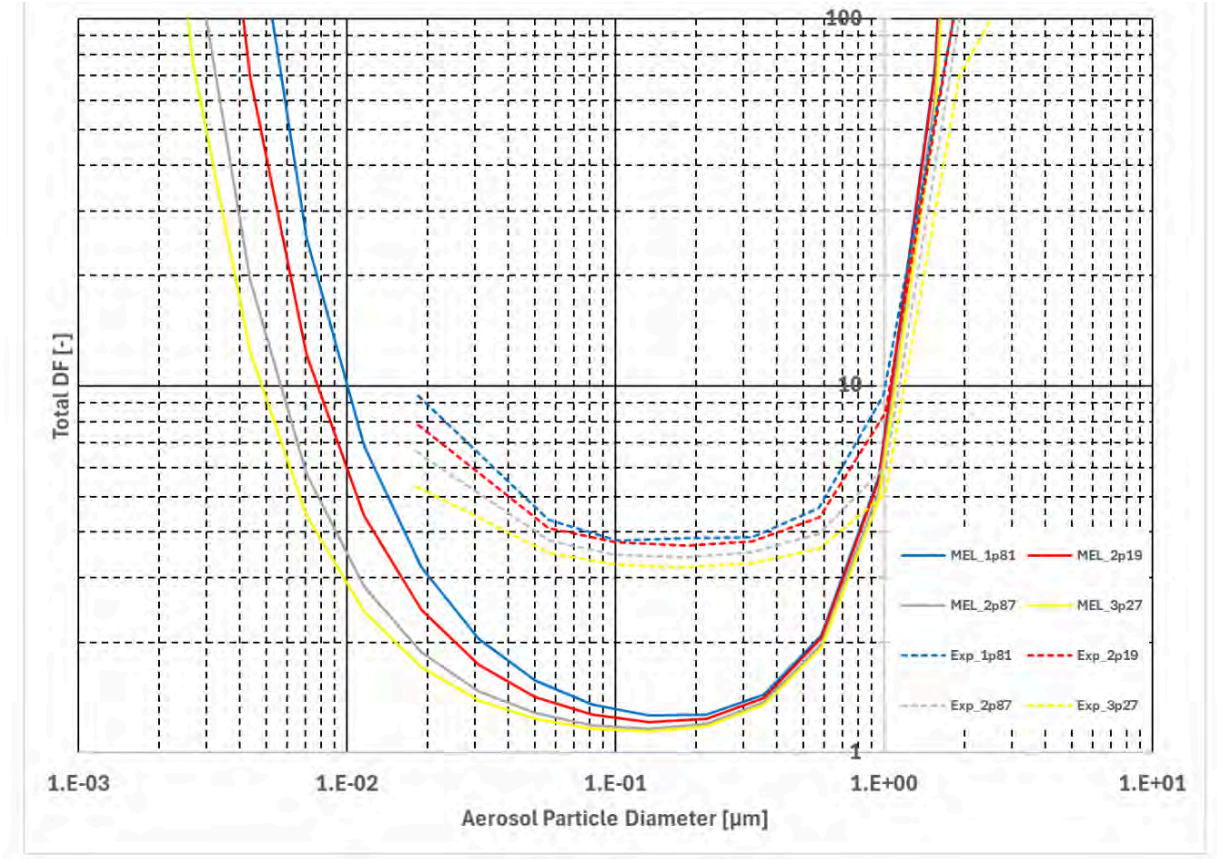
- Argon cover gas throughout; pool and atmosphere temperatures swept to probe the sodium kinetics.
- Four pool temperatures (423.15 / 473.15 / 523.15 / 573.15 K) covering the SFR primary-pool range.
- Same aerosol diameter window as the water tests: **0.018 – 18 µm**.
- Three aerosol materials for a wider density spread: **Al** 2.7 / **Ni** 8.9 / **W** 19.3 g/cm^3.
- Four bubble sizes (2.36 / 2.86 / 3.63 / 4.11 cm) — the larger sodium-pool bubbles reflect surface-tension scaling.
- Two concentrations (5.4 / 15.3 g/m^3) and two depths (0.9 / 1.8 m), so the same parametric handles are exercised as for water.

PART 4

Water Pool Validation

Water — variation across particle diameter and bubble size

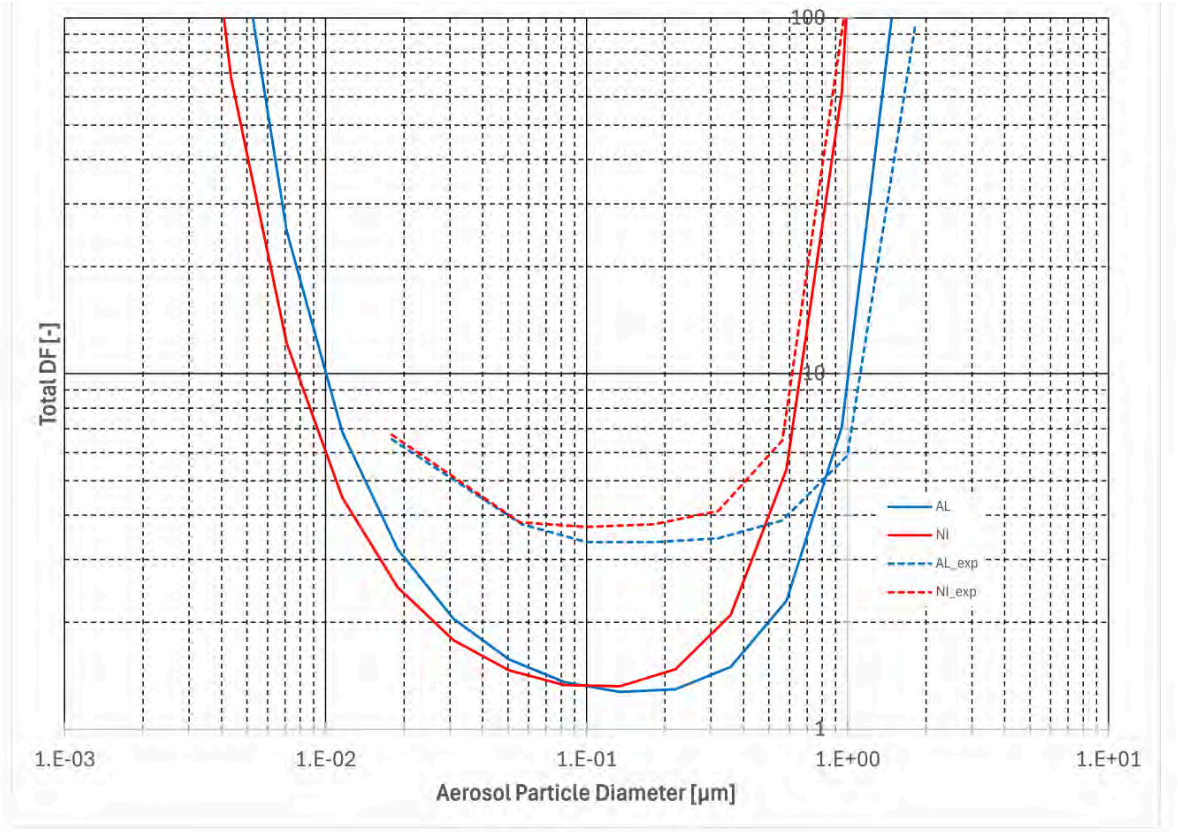
- Conditions: water single-bubble experiment #1 with Al aerosol, swept across four bubble sizes (1.81 – 3.27 cm).
- The characteristic **U-shape** of DF(d_p) — high DF at both small (diffusion-dominated) and large (inertial) ends — is reproduced at every bubble size.
- Quantitative agreement is excellent in the 1 µm neighborhood where centrifugal and Brownian kernels are both modest.
- In the 0.1 – 1 µm valley — where Brownian, gravitational, and centrifugal kernels all weaken — MELCOR **under**-predicts DF by a factor of 2 – 3.
- Below 0.1 µm the trend is still matched; the 2 – 3× under-prediction persists but does not diverge with diameter.
- MELCOR and SRT track each other tightly across every bubble size, suggesting the under-prediction is a kernel-level issue shared by both codes.



Water single-bubble #1 — MELCOR (default geometry) vs. UW data.

Water — parametric sensitivities for single-bubble rise

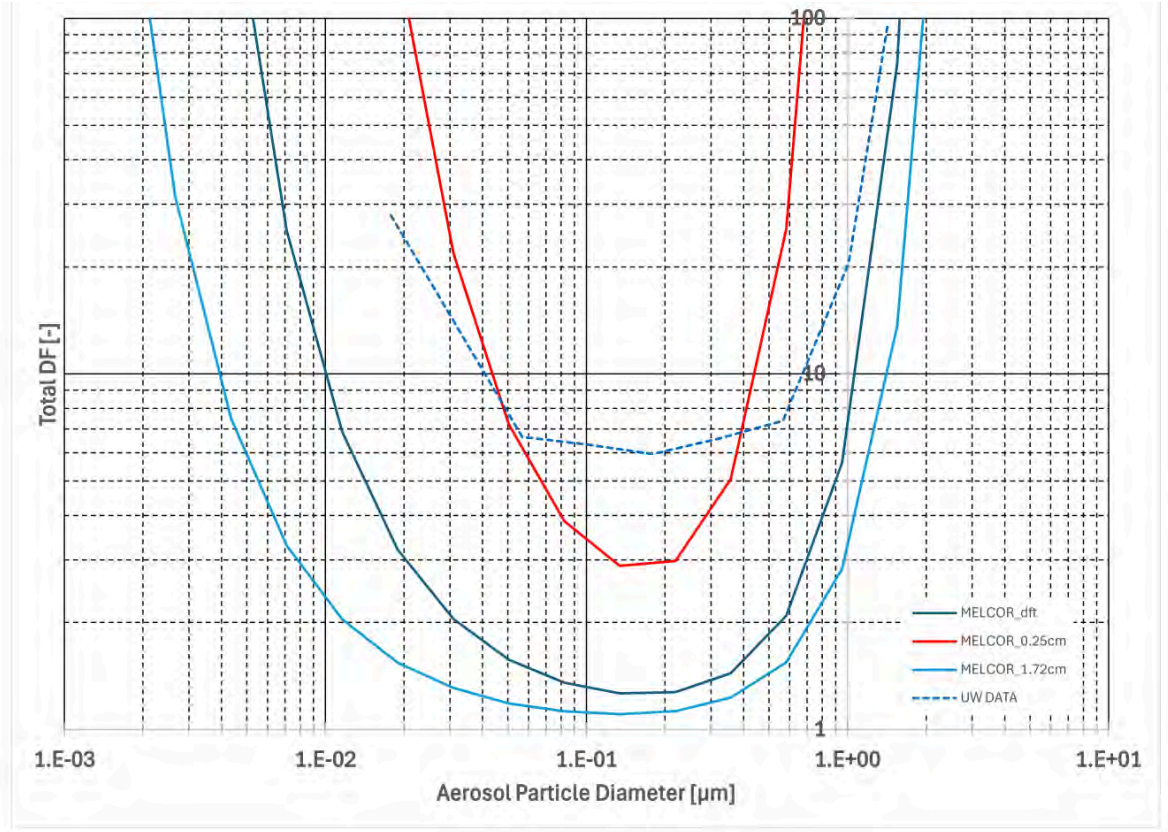
- **Material density** — heavier aerosol (Ni vs. Al) pulls the large-d_p side of the curve apart through the V_g, V_c dependence on ρ_i; MELCOR captures the separation.
- **Pool depth** — doubling the depth doubles the residence time and the data show the expected DF increase, which MELCOR matches.
- **Aerosol concentration** — high vs. low loadings collapse onto the same curve, confirming the first-order absorption regime in both data and model.
- **Default vs. user bubble geometry** — defaults consistently agree with the data better than user-specified geometry, even when the user inputs come from direct bubble measurements.



Density effect — Al vs. Ni aerosol, water single-bubble rise.

Water — bubble-swarm rise validation

- The single-bubble correlation is replaced by the swarm-rise extension: the same kernels, but with a swarm-averaged equivalent diameter d_{vm} and a height-averaged rise velocity.
- **Sensitivity to d_{vm}** — smaller swarm-averaged bubbles raise DF, just as the single-bubble correlation predicts; the trend direction is correct at every diameter tested.
- At **d_{vm} = 0.25 cm** MELCOR is within 2× of the swarm DF data across the entire 0.05 – 0.5 µm range — the same band where the single-bubble runs show their largest under-prediction.



Swarm rise — equivalent-diameter sensitivity vs. UW swarm data.

PART 5

Sodium Pool Validation

Sodium scrubbing — experiment matrix

Six experiments, dry aerosol-laden argon

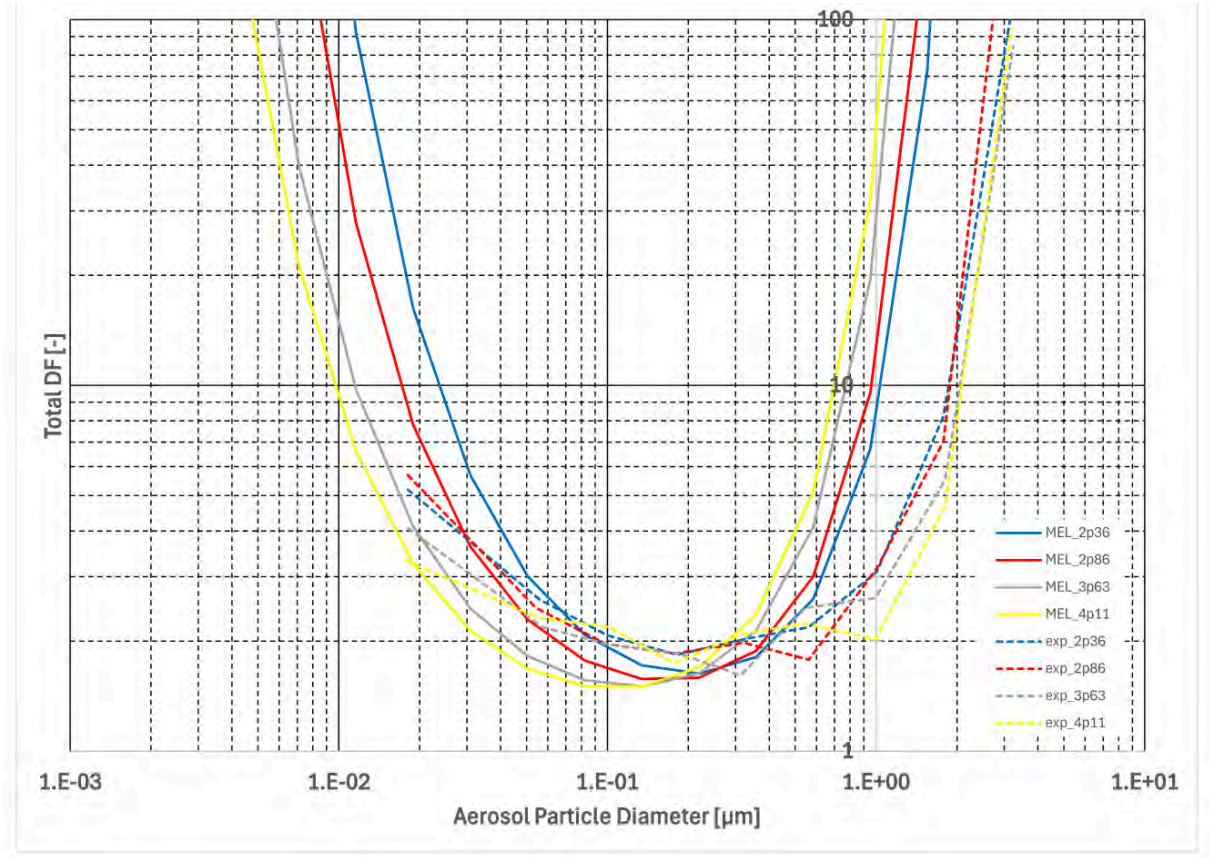
- **#1 Bubble size** — four argon bubble sizes (2.36 / 2.86 / 3.63 / 4.11 cm), all other inputs fixed; isolates the bubble-diameter dependence of the scrubbing kernel.
- **#2 Material** — Al / Ni / W to span an order of magnitude in aerosol density.
- **#3 Concentration** — high vs. low loading to verify the first-order absorption regime in sodium.
- **#4 Pool depth** — 0.9 m vs. 1.8 m, doubling residence time at fixed bubble dynamics.
- **#5 Pool temperature** — four temperatures (423 / 473 / 523 / 573 K) probing sodium-property and Stokes–Einstein effects.
- **#6 Swarm** — full bubble-swarm rise at one nominal condition for direct comparison to MELCOR's swarm extension.

Conditions held in common

- Aerosol diameter range matches the water tests: 0.018 — 18 µm, sectionalized into 20 MELCOR bins.
- Aerosol materials span density: Al 2.7 / Ni 8.9 / W 19.3 g/cm^3.
- Pool and atmosphere temperatures co-vary per run; cover gas is argon throughout to suppress sodium combustion.

Sodium Exp #1 — bubble size variation

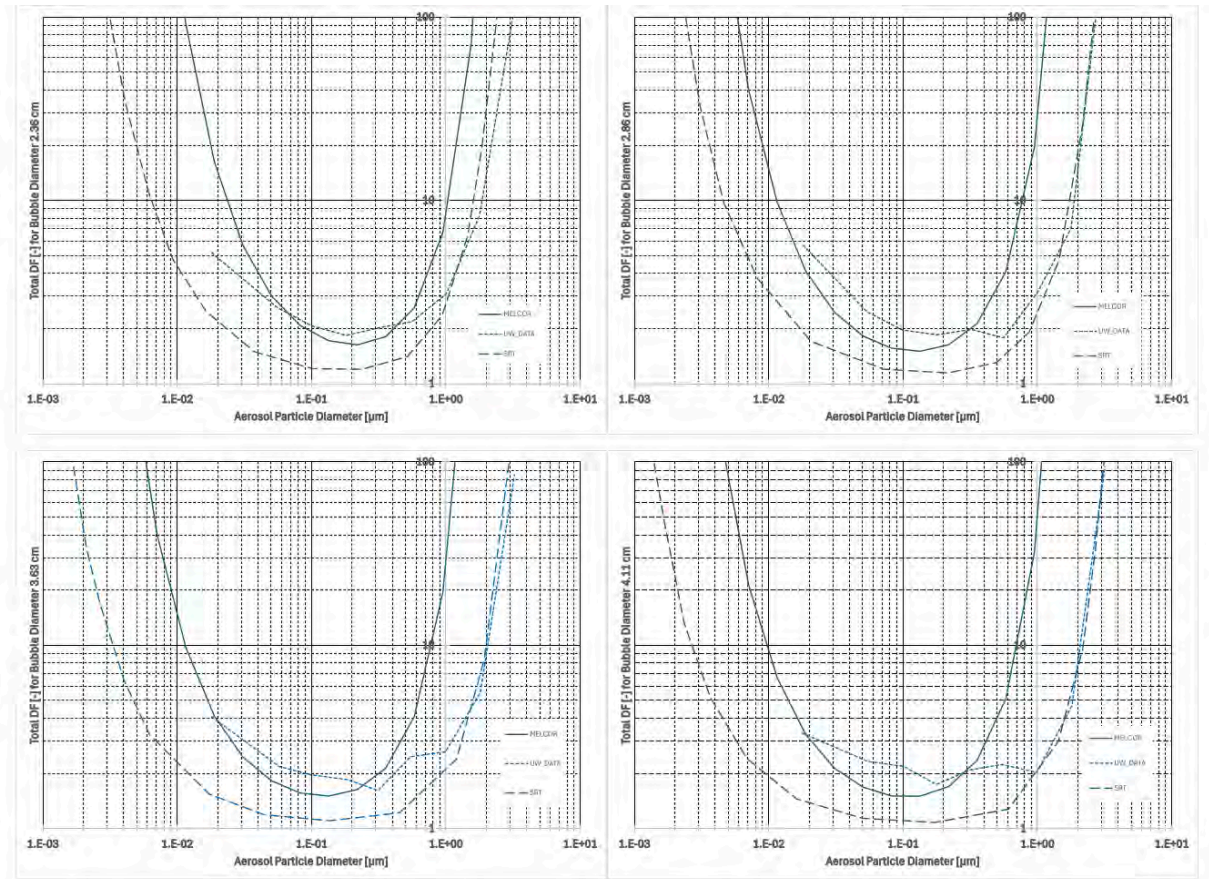
- Conditions: four argon bubble sizes; Al aerosol; high concentration; deep pool; 473.15 K. Bubble size is the only thing swept.
- Across 0.02 — 0.4 µm MELCOR predictions sit inside the data error bars for all four bubble sizes.
- The lone soft spot is the smallest (2.36 cm) bubble at the small-d_p end of the curve.
- Above ~0.4 µm MELCOR consistently **over**-predicts DF — the centrifugal kernel pulls aerosol out too aggressively in this regime, a pattern that recurs in the next experiments.



Sodium #1 — bubble size.

Sodium — MELCOR benchmark to ANL SRT

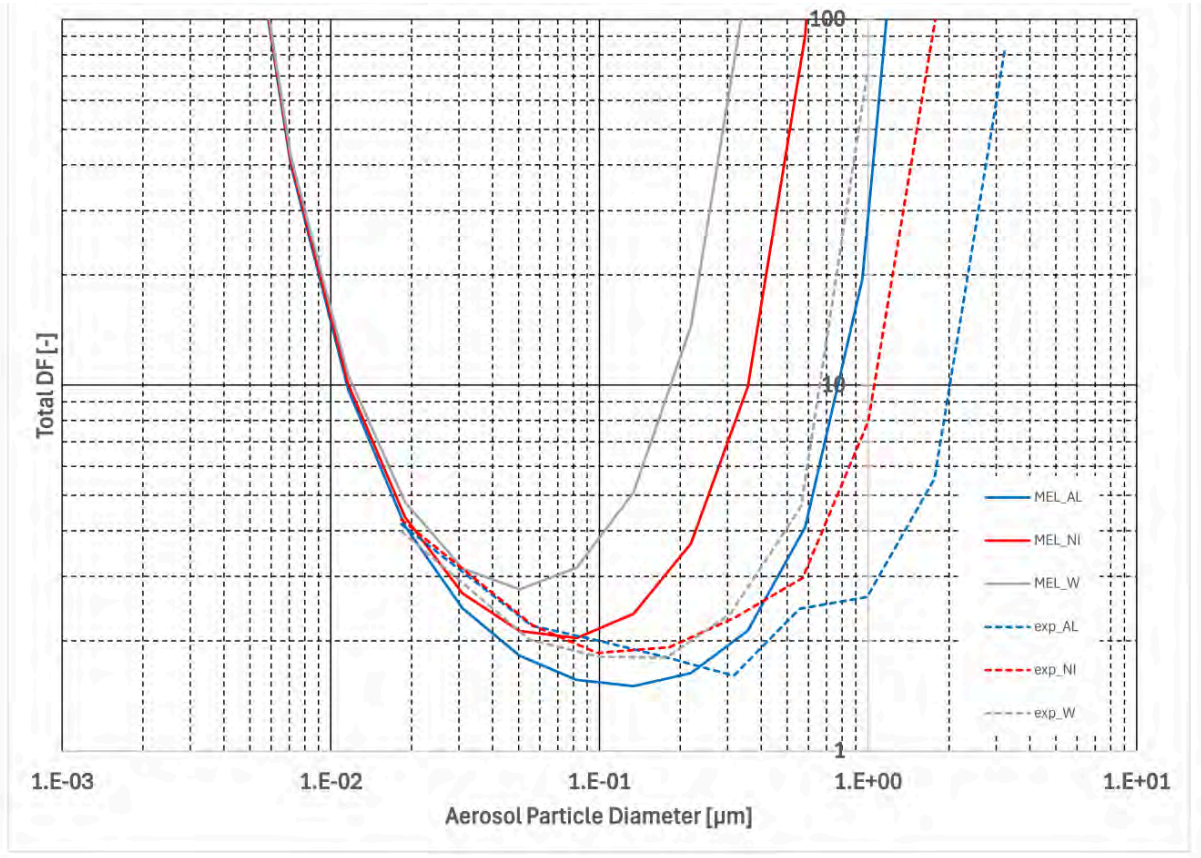
- The two codes are qualitatively in step across the entire d_p spectrum and all four bubble sizes.
- Where they diverge quantitatively it is in distinct diameter ranges, not in the overall U-shape — the disagreements are diagnosable rather than chaotic.
- At small d_p MELCOR sits closer to the data than SRT, suggesting its Brownian/diffusion kernel is the better-tuned of the two.
- At large d_p MELCOR **over**-predicts both SRT and the data — the centrifugal capture is the kernel most worth revisiting.



Sodium #1 — MELCOR vs SRT vs UW data.

Sodium Exp #2 — aerosol material / density

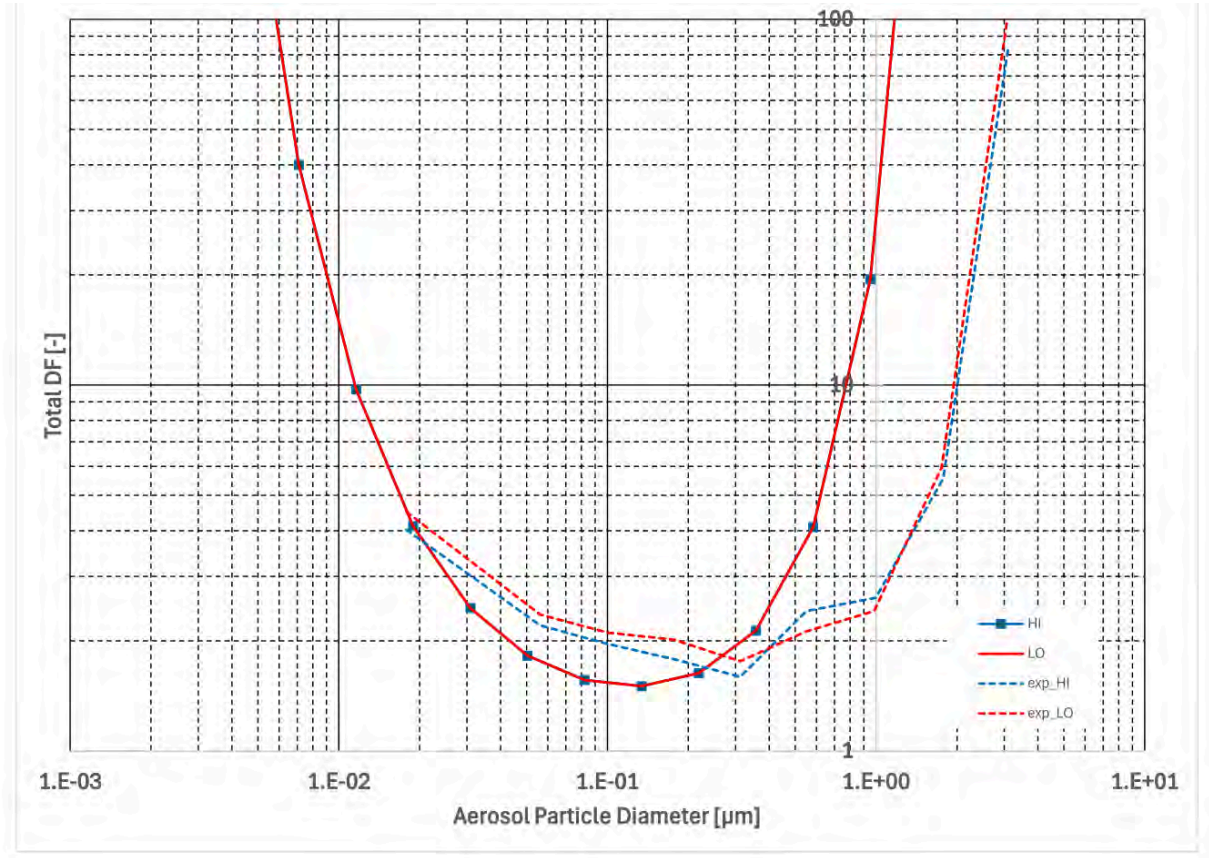
- Conditions: Al / Ni / W aerosols at fixed 3.63 cm bubbles, high concentration, 473.15 K. Aerosol density is the only sweep.
- The same large-d_p over-prediction seen in Exp #1 reappears here, confirming it is not an artifact of a single material.
- The onset of the over-prediction shifts to **smaller** d_p as material density rises from Al → Ni → W — heavier particles cross the centrifugal-dominated threshold sooner.
- This is the expected fingerprint of the V_g and V_c dependence on ρ_i, pointing the discrepancy at the inertial side of the deposition velocity rather than a material-specific error.



Sodium #2 — aerosol material.

Sodium Exp #3 — aerosol concentration in bubbles

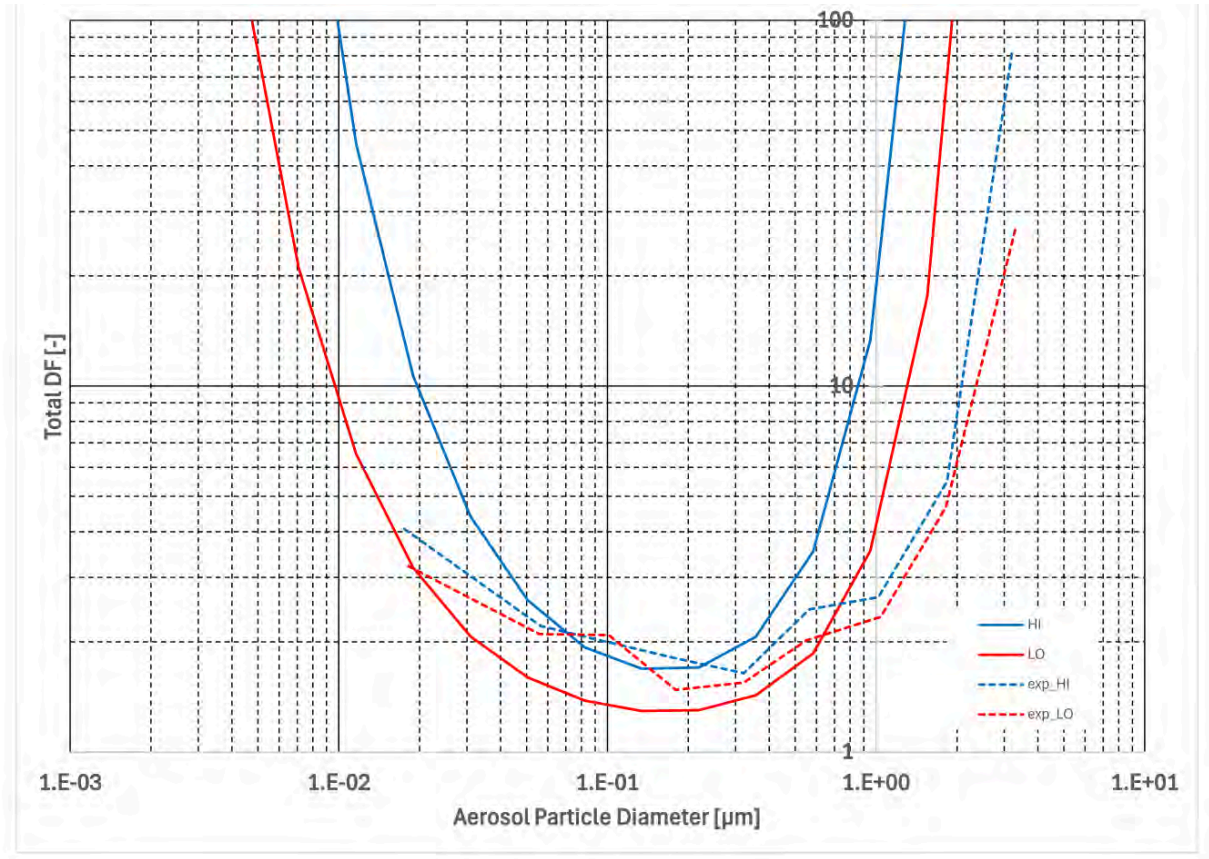
- Conditions: Al aerosol; deep pool; 473.15 K; 3.63 cm bubbles. Loading varied between low and high.
- Doubling the aerosol concentration leaves DF essentially unchanged in the measurements, just as the model predicts.
- MELCOR reproduces this insensitivity exactly — the predicted high- and low-concentration curves overlay.
- This is the cleanest direct confirmation that pool scrubbing in this regime is genuinely first-order: the depletion rate is linear in c_i, so loading cancels out of DF.



Sodium #3 — aerosol concentration.

Sodium Exp #4 — pool depth

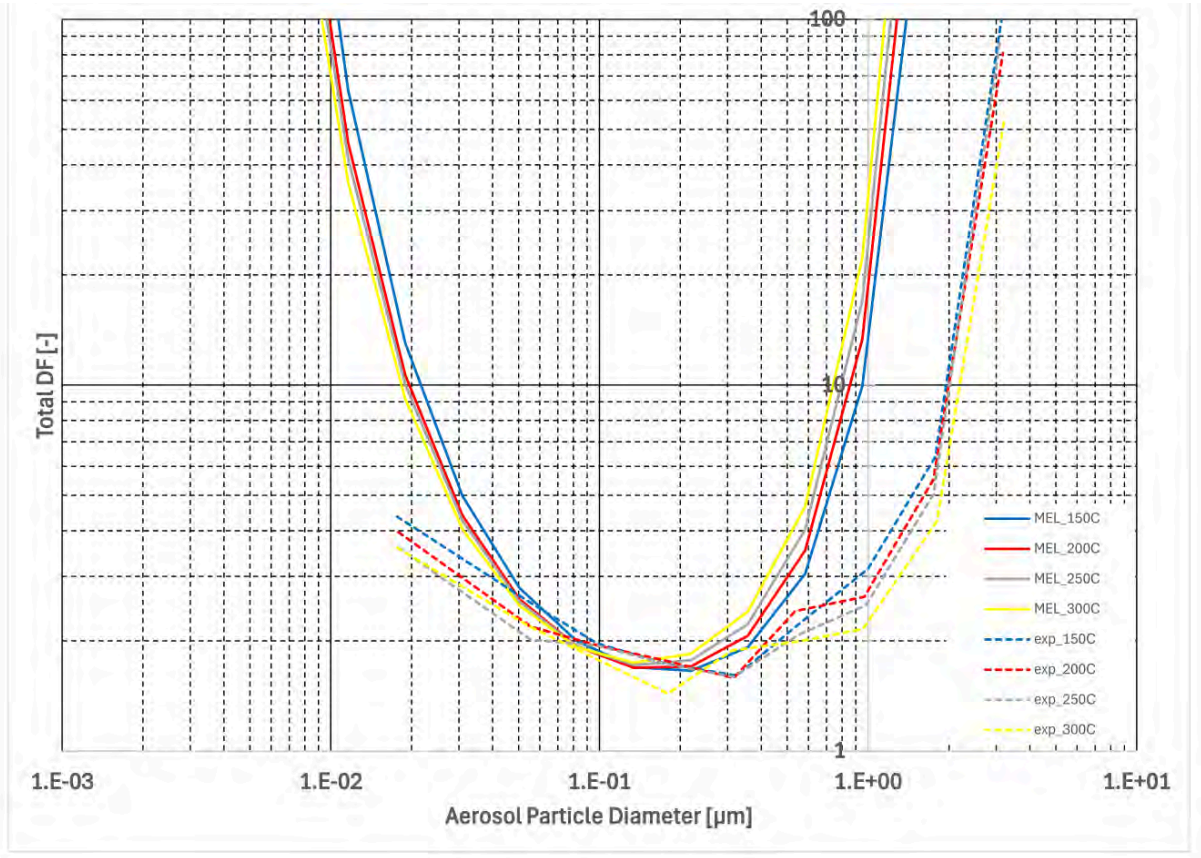
- Conditions: 0.9 m vs. 1.8 m pool depths; Al aerosol; high concentration; 473.15 K; 2.87 cm bubbles. Pool depth is the only sweep.
- MELCOR predicts increased DF in the deeper sodium pool, consistent with longer bubble residence time and a longer integration of the first-order absorption.
- The data show the same qualitative trend, so the direction of the depth effect is correct.
- At the small- and large-d_p ends, however, MELCOR appears to **over**-state how much extra DF the deeper pool buys, suggesting the column-march kernel is too aggressive in those wings.
- For intermediate d_p the depth scaling matches the measurements quantitatively, indicating the issue is band-localized, not global.



Sodium #4 — pool depth.

Sodium Exp #5 — pool temperature

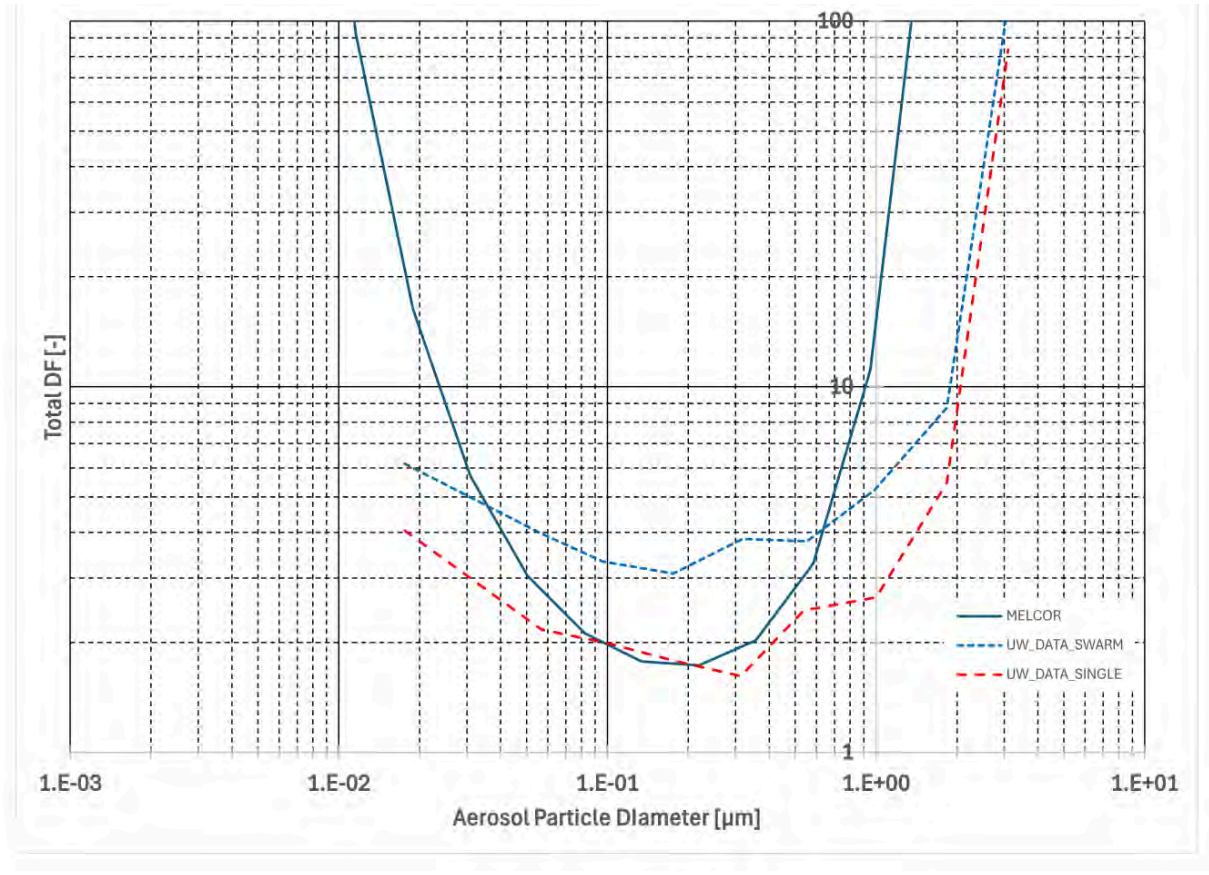
- Conditions: four pool temperatures spanning 150 — 300 °C; Al aerosol; high concentration. The full SFR primary-pool temperature range.
- Both measurements and MELCOR show a **small** temperature effect on DF — the curves shift slightly but do not change shape.
- The temperature-driven variation is well below the bubble-size variation seen in Exp #1, so geometry (not thermophysics) dominates the kernel.
- Temperature enters the kernel through the Brownian diffusivity D_i (Stokes–Einstein) and through sodium fluid properties (μ, ρ_l, σ); their net effect is muted in this regime.



Sodium #5 — pool temperature.

Sodium Exp #6 — bubble swarm

- Conditions: Al aerosol; high concentration; deep pool; 473.15 K; default swarm geometry. The first direct test of MELCOR's swarm-rise extension on sodium.
- MELCOR is qualitatively consistent with both the single-bubble and swarm data sets, so the swarm extension does not break the kernel.
- At the small- and large-d_p tails the predicted DF approaches the swarm data quantitatively.
- MELCOR **over**-predicts for d_p < 0.035 µm and > 0.6 µm — the same large-d_p centrifugal pattern as the single-bubble sodium runs, now extended to the small-d_p wing as well.
- In between, MELCOR under-predicts the swarm DF and instead tracks the single-bubble curve — the swarm coupling is too weak in this intermediate band.



Sodium #6 — bubble swarm.

Conclusions

Validation outcome

- Across both fluids and every parametric sweep, MELCOR qualitatively reproduces the UW DF(d_p) trends — no surprises and no missed regimes.
- Quantitative agreement is good over wide diameter ranges; where MELCOR misses, it misses in identifiable, kernel-localized ways.
- The MELCOR ↔ SRT benchmark closes well in both qualitative and quantitative terms, so the two independent code bases corroborate one another.
- None of this required physics development or heavy-handed user tuning — the shipped defaults did the work.

Implication for SFR source term

- MELCOR is suitable for SFR sodium pool-scrubbing best-estimate and uncertainty analysis at the level of fidelity these experiments resolve.
- The model plugs directly into integral SFR source-term workflows — from in-vessel release through cover-gas leakage to environment — without a stand-alone scrubbing code.
- That out-of-the-box defaults are this credible is encouraging for the broader non-LWR source-term effort — the modeling framework generalizes.

ABSTRACT

In the frame of Horizon-Euratom ESFR-SIMPLE project, the safety design of the European SFR is being developed further, building on previous designs developed during earlier European projects (CP-ESFR, ESFR-SMART). Of the many safety issues, special concern is given to the implementation of safety measures for an ESFR-type in-vessel core catcher. Based on the knowledge gained from the ESFR-SMART project, that the ablation of the core catcher by a melt jet originated from a core-melt accident scenario could be a very fast process under jet impingement, the current ESFR-SIMPLE project suggests local enhancement measures inside the core catcher to mitigate the localized ablation, such as pods at the impingement locations. To validate the effect of the local enhancements during a long-term ablation period after the molten material has been collected in the core catcher, which poses a threat to the core catcher integrity, three tests were performed in the LIVE-Core Catcher facility at Karlsruhe Institute of Technology. These tests provided experimental benchmark including the ablation dynamics, heat transfer inside and around the enhancements as well as the thermos-hydraulics of pre-ablated core-catcher in a molten pool with all-boundary cooling conditions. The numerical simulation is the other part of the task in the project is not the context in this study. The three experiments were successfully conducted using a eutectic binary K-Na-NO_3 salt as liquid melt under simulated internal heating condition. Salt pods were used as meltable enhancements and metal pods as non-meltable enhancements. Many beneficial impacts have been observed of such enhancement in a molten pool configuration. Many insights concerning the melting dynamics and heat transfer to the local enhancement are achieved.

Gen-IV ESFR, ESFR-SIMPLE, core catcher, LIVE-CC experiment

1. INTRODUCTION

The core catcher in the lower plenum of a SFR reactor vessel is an important safety implementation of a future European type SFR [1]. In the event of hypothetical severe accident, it must minimize the neutron positive criticality inside the core by collecting the discharged liquid core material, also named as corium. At the same time, it must protect the reactor vessel from corium jet thermal attack during the downward melt relocation and long-term exposure in the decay-heat-generating corium. In this context, the safety of the European SFR core-catcher was initially assessed the ESFR-SMART project [2, 3] [4] in which the vulnerability of the core catcher have been demonstrated in certain critical circumstances, e.g. under a high-temperature jet of metallic corium during the corium relocation period, or insufficient cooling of the upper surface during long-term exposure to corium [5]. The safety measures for the core-catcher are continually investigated in the follow-up ESFR-SIMPLE project, which

assesses protective measures against the core-catcher ablation. Local objects placed under the jet shall protect against the jet impingent and under the thermal attack of a melt pool in the long term. The long-term behavior of the core catcher was experimentally evaluated in the LIVE-CC experimental facility at KIT. In the following, the experimental set up and the test condition is described in Section 2, Section 3 depicts the dynamics of the melting or solidification and heat transfer of the local protective objects, Section 4 arises the discussion of the similarity issue and the overall effect of the objects, which is followed by Section 5 Conclusion.

2. DESCRIPTION OF EXPERIMENTAL CONDITIONS

LIVE-CC mockup is tailer-designed for ESFR-Core catcher research. Several tests regarding the general character of core catcher safety have been investigated in ESFR-SMART project. The activities in the current project are focused on local protective measures against short-term jet ablation and their long-term resilience exposed in a molten pool enclosed in the core-catcher.

2.1 The LIVE-CC Test Facility

The test vessel of LIVE-CC is located at a 3m-platform**,** see Figure 1**.** It mimics the typical tray geometry of an in-vessel ESFR core catcher: with a truncated cone-form lower part ad cylindrical upper part, as shown in Figure 2**.** The height of the truncated cone is 0.08 m**,** and the inner diameter of the upper cylinder is 1 m. The upper part corresponds to 1:6 scale of the prototype. The whole height of the test vessel inner cavity is 0.38 m.

An external cooling vessel with a cooling channel width of 6 cm embraces the test vessel. The cooling fluid liquid Na is simulated by water cooling. The cooling water inflow locates at the central bottom and the four outflows at the vessel upper flange. The flow rate is controlled to enable a temperature difference between the inlet and outlet of about 10 °C. This difference is large enough for a precisive determination of the water-side heat removal rate. The top surface cooling of the vessel is realized by a floating water-cooled lid (Figure 1). The cooling lid can be placed at all the vertical position of the cylindrical part.

Besides the test vessel, the platform includes apparatus for the melt preparation, pouring and extraction. A heating furnace melts and store the simulant melt material and serves also as discharge device of the melt to be poured into the test vessel. In addition, the heating furnace is equipped with a vacuum pump for the extraction of the residual liquid melt from the test vessel back into the heating furnace once the test is ended.

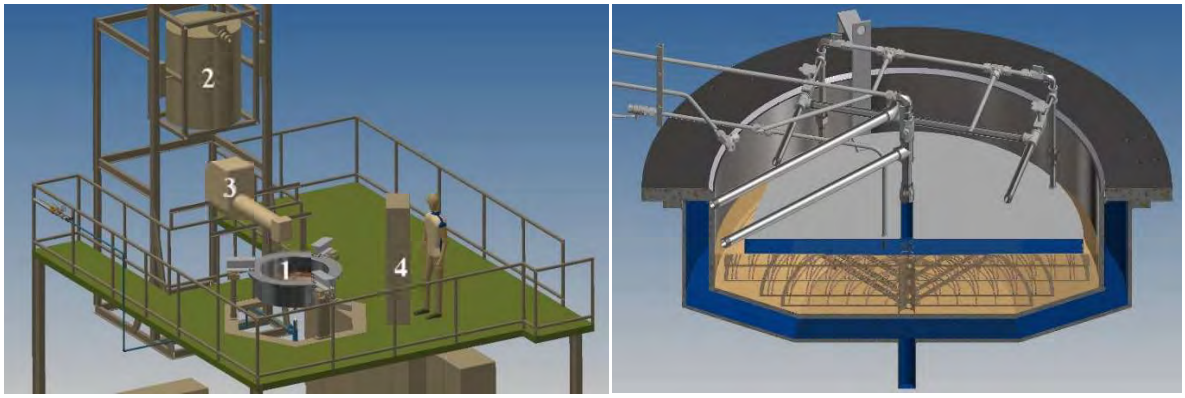

Figure 1. Left: LIVE experimental platform with LIVE-CC facility. 1- ESFR test vessel, 2 - heating furnace for melt preparation, 3 - pouring spout, 4 - instrumentation board. Right: Cooling and heating system.

Four planes of 4 mm resistance heating cable in the form of spiral winding are designed to simulate the volumetrically dissipated decay heat of the corium, which are named HE1 to HE4 from the bottom upwards, as

shown in Figure 2. Two planes are in the truncated cone (HE1 and HE2) and the other two are in the cylindrical part (HE3 and HE4). The heating cables were adapted in the current experiments to make space for the local objects.

The measurements are mainly temperatures with Type K thermocouples (TCs). This includes 44 pairs TCs on the inner and outside of test vessels, distributed at 225-45 °C axis, 49 TCs inside the vessel. Beneath the top cooling lid, the boundary temperatures were measured with three arrays of TCs. Besides, cooling water temperature and flow rates were recorded.

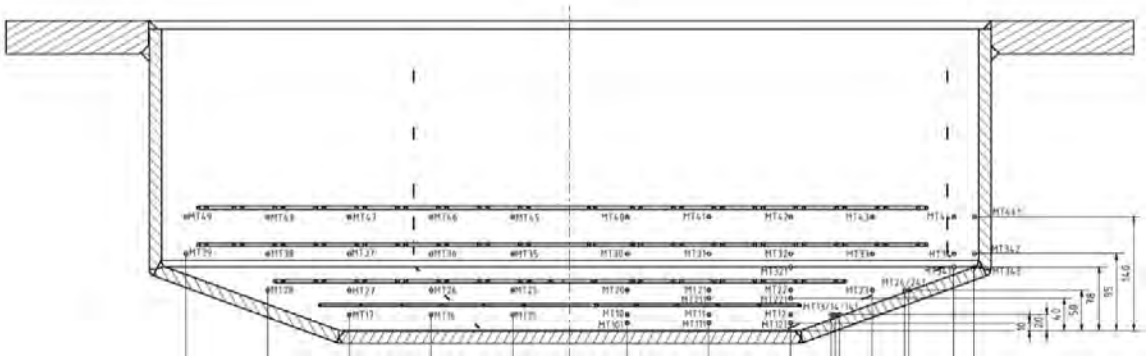

Figure 2. Instrumentation of test vessel.

2.2 The Realization of Local Protective Measures

For each of these LIVE-CC tests, local objects were implemented at two positions in the test vessel, see Figure 3. The geometry of the objects, either pods or holes is cylindrical in 80 mm diameter. The heating wires, which has a distance of 45mm between each winding, were bent at these positions to enable the space of these local objects.

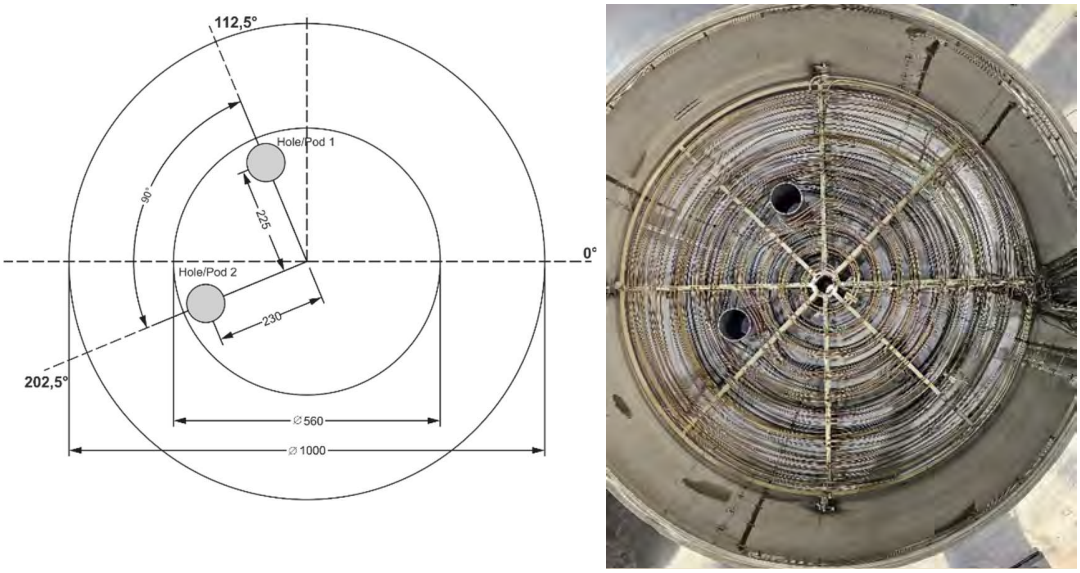

Figure 3. Position of pods in the LIVE-CC test vessel.

2.3 Test Condition

Three test series have been performed: LIVE-CCH (**C**ore-**C**atcher with **H**oles), LIVE-CCS (**C**ore-**C**atcher with **S**alt pods) and LIVE-CCM (**C**ore-**C**atcher with **M**etal pods). LIVE-CCH test investigates whether and how an ablated cavity in core-catcher bottom plate can be filled if the cooling of sodium around the core catcher is available. LIVE-CCS test assesses the ablation dynamic of meltable pods. LIVE-CCM evaluates the heat transfer around and inside pods. A eutectic mixture of $NaNO_3$ and KNO_3 with the melting point 220 °C was used as the liquid melt and as the bottom plate material in the LIVE-CCH test, as well as the solid pods in the LIVE-CCM test. The pods in LIVE-CCM were made of stainless steel und are not meltable during the experiment. For all the experiments, the test vessel was cooled externally and at the melt top surface. External cooling was already activated before the melt pour. There is a slight delay of ~ 10 minutes of top cooling after the melt pour, since this period was needed to place the cooling lid on the melt pool.

Table I. LIVE-CCH test conditions

tests	Local objects	Material of object	Geometry	Heaters in operation	Vessel initial condition
CCH	Hole in the bottom crust	Solid salt crust plate with holes	Depth of hole: 40mm Thickness of plate: 80 mm	No heating in the 80 mm bottom plate	With bottom plate
CCS	Salt pods	Solid salt	Height of pods: 80 mm	All heaters	Only with two pods
CCM	Metal pods	Stainless steel	Height of pods: 80 mm	All heaters	Only with two pods

For each test, additional 90 pieces of TCs were installed inside and near the two objects to capture the melting front or the local heat transfer features. One TC shows the solidification temperature as the solidification front passes through its position. In this way, the position and the time point of the changing contour of the hole /pod can be detected. In Figure 4, the instrumentation schema and its realization are shown for one hole in CCH test. The TCs were arranged in the middle between the two heating windings and are assigned to 0° and 180 ° for the same radius. This arrangement allows a low influence of the heating cable at the measured position.

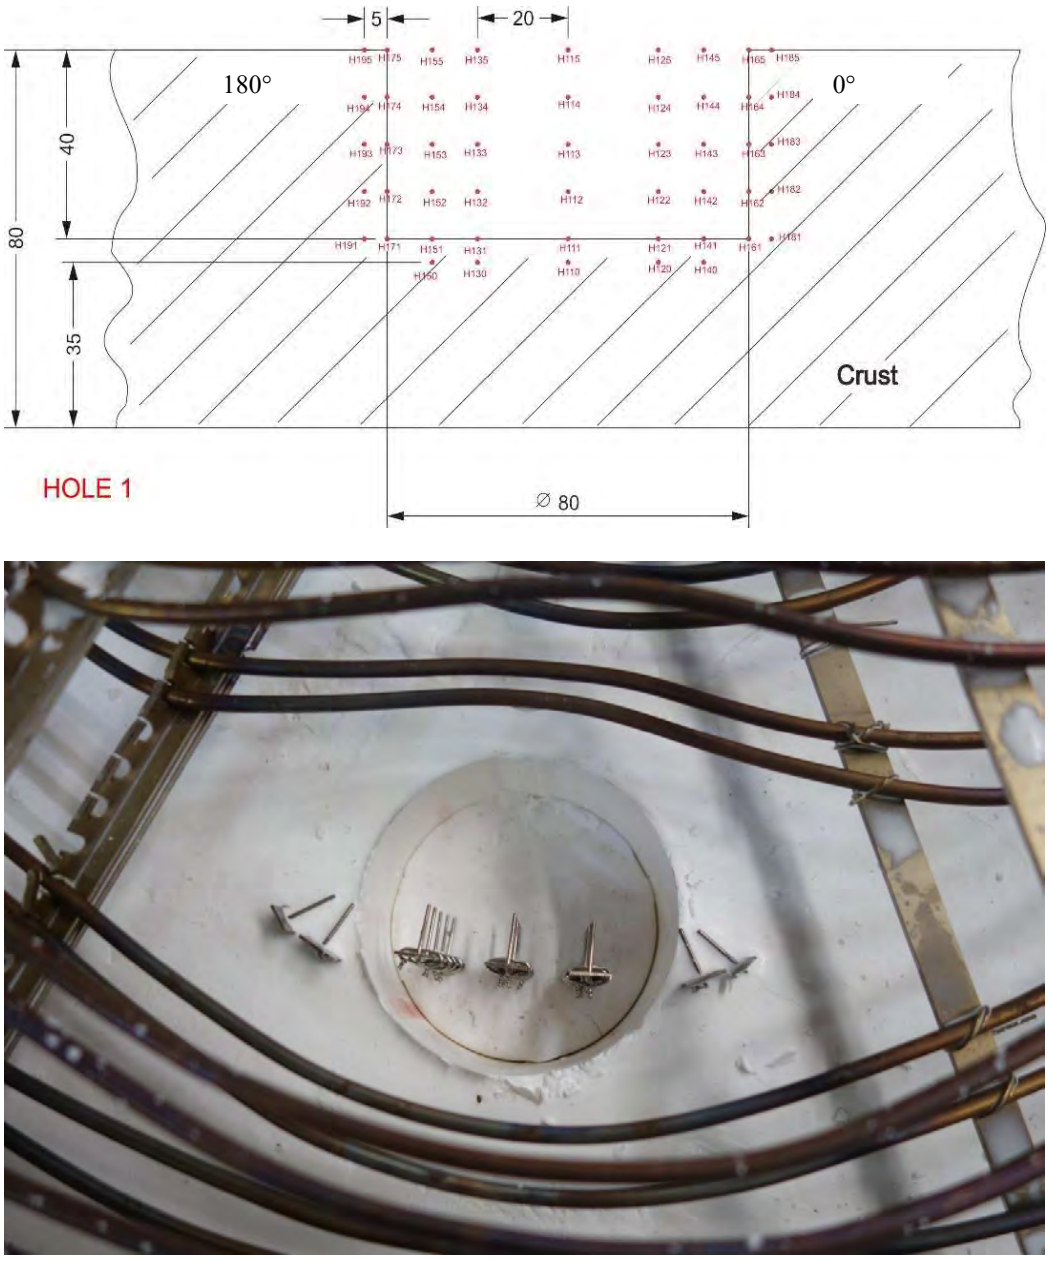

Figure 4. Positions of TCs for one hole in LIVE-CCH test. Bottom image: TCs installed inside and adjacent of the hole at the bottom plate before the melt pour.

3. EXPERIMENTAL RESULTS

3.1 LIVE-CCH Results

Inside the ablated hole at the bottom plate, solidification took place due to the external cooling around the test vessel. In Figure 5, the shrinkage process of the contour of the hole 1 is depicted. The solidification progressed upwards and inwards simultaneously, and the holes were totally filled with solidified salt at about 3000 sec. The results prove the beneficial effect of the sodium cooling in general to heal a previously ablated cavity.

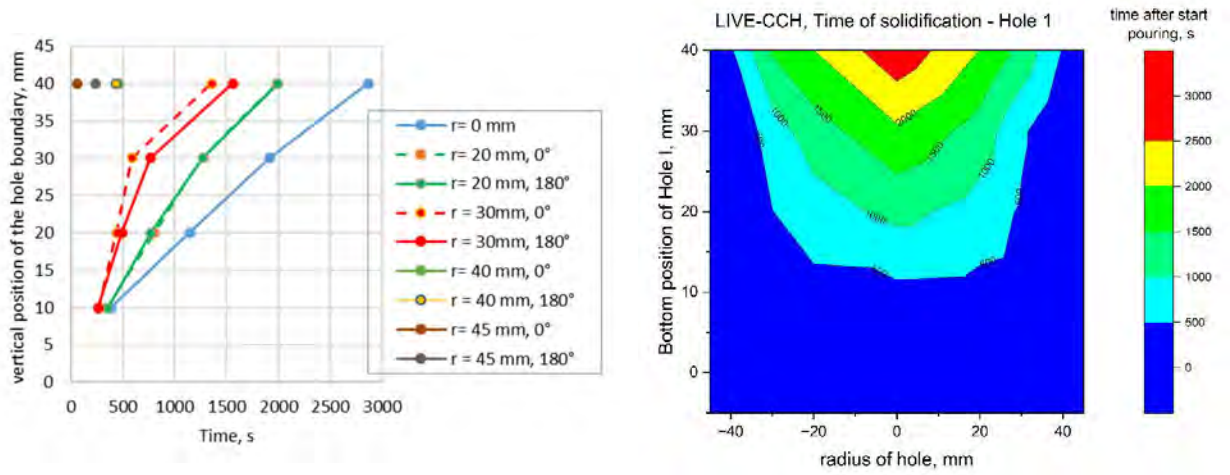

Figure 5. Left: boundary position of the hole 1 measured by TCs. Right: Illustration of the changing contour of hole 1 with time.

3.2 LIVE-CCS Results

The test started with the melt pour, marked as 0 sec. 236 kg liquid salt at 260 °C was poured into the vessel to form a 186 mm height pool. The power was provided by the upper two heaters which was totally 9.5 kW before the cooling lid was placed on the melt at the 707 sec. Thereafter the power was increased to 19 kW. The adjust of power input before and after the top cooling bears the purpose to maintain the melt temperature stable.

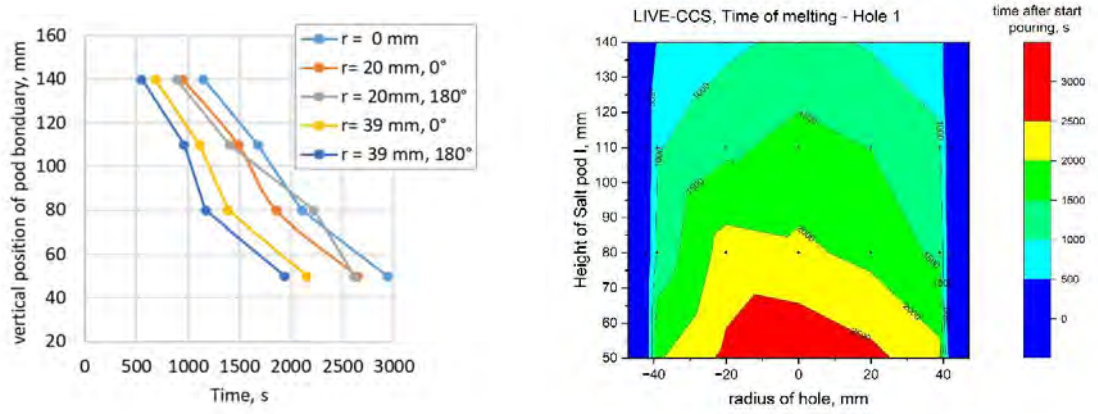

Figure 6. Progression of melting process of the Salt pod I. left: boundary position of the pod measured by TCs. Left: Illustration of the melting process of the pods I based on the measurement.

The progression of melting the two salt pods is illustrated in Figure 6. The melting progressed straight inwards and downwards which was completed at ~3000 sec. The pods molten to the level of the bottom crust. Their lower parts were merged into the newly formed bottom crust. The temperature responses inside the Pod 1 during the initial transient period are shown in Figure **7**.

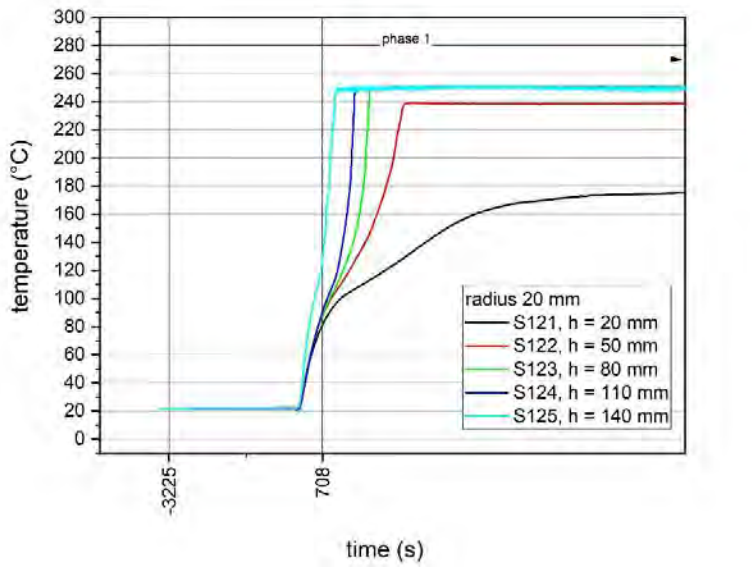

Figure 7. Temperature inside the Pod 1 after the melt pour (0 sec). The TC positions are 20 mm radially to the central axis. The time point at 708 marked the start of top cooling.

3.3 LIVE-CCM Results

An array of TCs was installed at a cross section inside the pods and adjacent to the pods. In the left image of Figure 8, the positions of the local TCs are shown. 234 kg of liquid salt with initially 310 °C was poured into the test vessel containing the two previously installed metal pods. All the four heaters were switched on and provided totally 33,5 kW during the time from melt pour till the cooling lid was placed on the melt surface at 917s. As soon as the top cooling was activated, the melt temperature dropped due to the very strong cooling by the top lid. The temperature decline was stopped at 1240 s because the total heat input was increased from 33,5 kW to 67 kW.

The responses of the local TCs during the initial period after melt pour are shown in the right image of Figure 8. It is noted that a delay of the temperature inside the pods to the bulk temperature, e.g. by comparing M155 (in the pod) to M195 /MT40 (out of the pod). It indicates the existence of a temperature boundary layer around the pods. The fact that the upper part of the metal pod was colder than its surrounding melt was not only induced by a heat transfer delay radially from the surface to the core of the pod, but also the result of an effective top-down heat removal inside the pod due to the high thermal conductivity of the metallic pod. This temperature discrepancy, which was the driving force of the local heat transfer, was declined with time. Its thermal inertia can also be observed between 917 s and 1240 s in decreasing temperature. During this time that the cooling down of the bulk melt took place, the metallic pod remains slightly hotter than its surrounding melt.

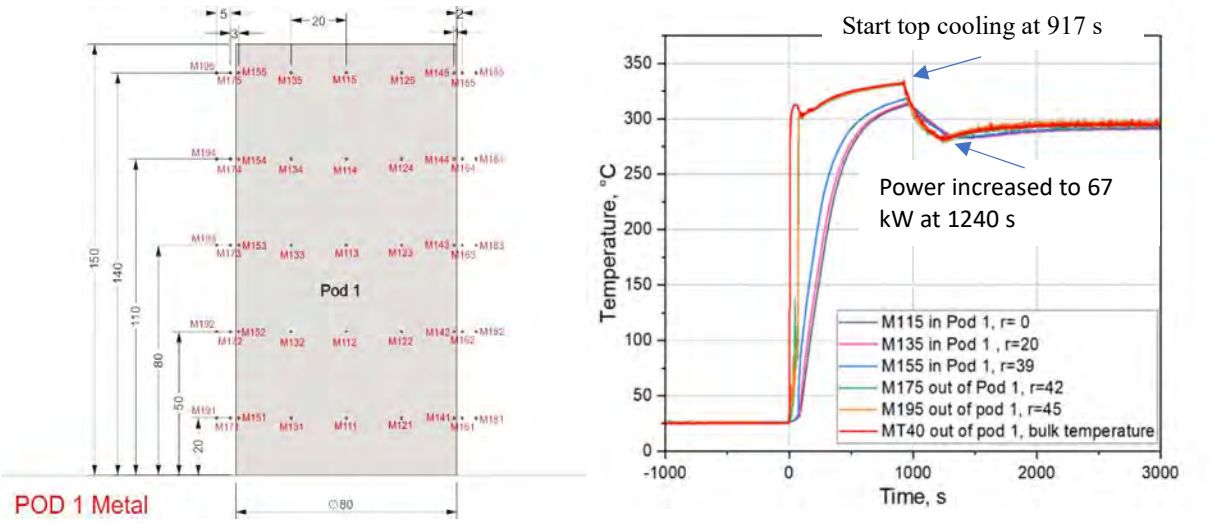

Figure 8. Left: TC positions inside and near the metallic metal pod 1. Right: Response of temperature after the melt pour.

3.4 Overall Heat Transfer

The heat balance of the molten pool is firstly to examine the credibility of the measurement and to secondly to allocate the heat transfer rate upwards and sidewards. The heat balance shown in the Figure 9 proves the balance between the power input on one side and the heat removal rate from the external cooling and from the top cooling on the other side.

The overall heat transfer from the liquid pool through the vessel wall to the external coolant are characterized with isotherm boundary defined by the solid solidification temperature. Similar results are obtained as the LIVE- test in the LIVE-SMART project with following heat transfer features with a heating density of 454 kW/m³ corresponding a heating power of 37 kW LIVE-CCM test:

- Bulk temperature: 300 °C, boundary temperature 220 °C
- Ra upwards: $5 \cdot 10^{8,}$ Ra sidewards: $11 \cdot 10^{9}$
- HF_{up} = 33 kW, HF_{side} = 18 kW, HF_{bottom} = 2 kW
- $Q_{up} / Q_{sidewards}$ = 2

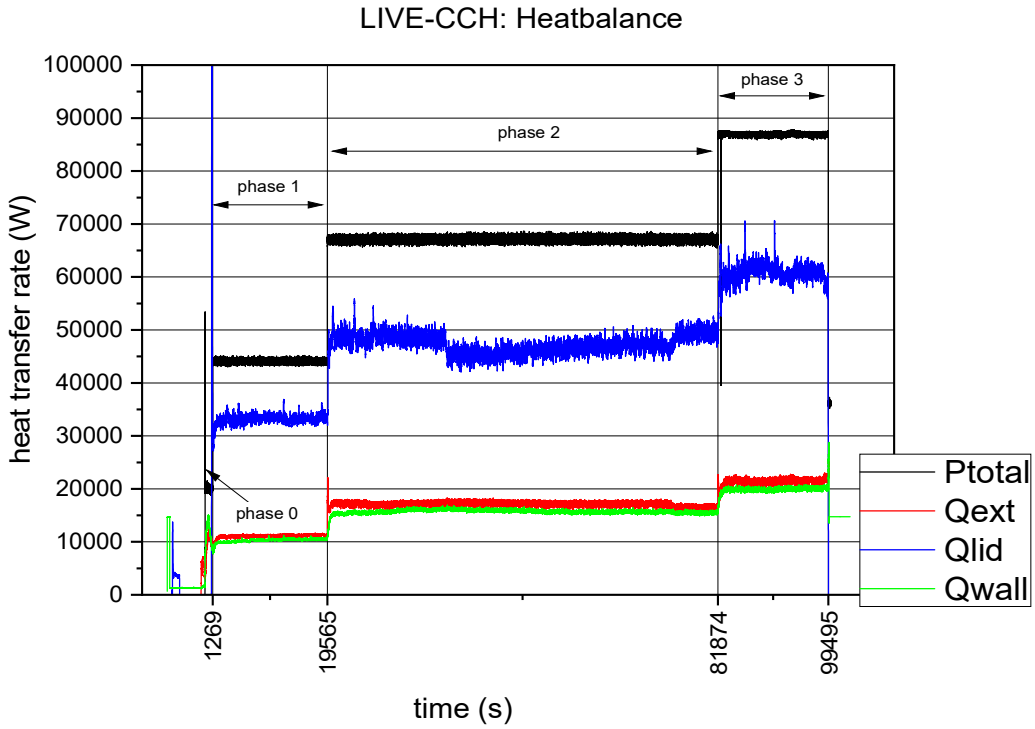

Figure 9. Heat rate of power input (P_{total}), removed heat via top cooling lid (Q_{lid}), and the heat through the sidewall (Q_{wall}), the heat removed by external cooling water ($_{Qext}$).

4. DISCUSSION

4.1 Treatment of experimental data and similarity issues

The data acquisition frequency was one measurement pre second. The TCs used for temperature measurement were calibrated to minimize their own measurement uncertainties prior to installation. By evaluation of parameters based on the temperature difference from two TCs, the offset-difference of the TCs at same temperature were balanced to zero during the post-test data analysis. The average data during a steady state were 120-second mean values at the end of this steady state with a standard error of 1%. The reliability of the whole measurement is further confirmed by the heat balance shown in Figure 9 for example. The time-dependent values, such as the contour of a hole or a pod during the solidification or ablation process is based on the TC measurements which act as detectors of the boundary in way that they react very sensibly and mark the change point in the temperature course as soon as they are involved in the solidification or melting process.

As the case of any experiment employs many simulate conditions to investigate prototypical scenario, the similarity of the experiment results to the prototypical ones shall be discussed. Concerning this test series, three similarity issues are focused on: cavity geometry, heating method and the simulant material.

- Cavity geometry: The most important parameter in the geometry in the sense of heat transfer is the characteristic length, which influence the scale of natural heat convection. In this study the height of the pool is the characteristic length, given that the vessel wall boundary does not limit the turbulent flow. In all the three test series, the strong top cooling owns the character of Rayleigh-Bernard convection [6]. Since the up and down swirl cells repeatedly appears in the whole region, the vessel wall boundary doesn´t constitute the restriction of the convection. The pool height in LIVE CC test vessel is 185 mm, which

constituted the same scale of the characteristic length of a prototypical pool, which has the internal Ra-$9{\cdot}10^{11}$ at a maximal power of 67 kW.

- Influence of the heating wire in the whole pool and near the local objects. Due to the strong turbulent flow inside the melt pool, the heating wire doesn´t constitute overall disturbance in the bulk melt pool region. However, the lower heater constraint the lower bottom crust thickness, since the crust cannot grow beyond the lowest heating plane. The influence of this aspect is comparable low since the downward heat rate was very low, only driven by thermal conduction. The heat wires near the local pods or holes could build temperature hot spot. However, the instrumentation scheme was arranged in the middle between the wings, where there was almost not influenced by the heating wires.

- Similarity of simulant material: The crust formed at the vessel wall build isothermal boundary condition at all boundaries, which is a very important feature in prototypical case. LIVE-CC tests do consider and enable this feature.

4.2 The General Effects of Local Objects on the Overall Heat Transfer

The local objects as protective measure against the ablation of the melt jet coming from the core regio exert beneficial influences in long term in the point of view of thermal inertia and material addition. The own thermal initial of the initially cold objects acts as heat sink inside the hot melt. The addition of no-decay heat-spending objects in the melt, either meltable or not, enlarges the volume and the mass of the whole pool without increasing the total decay dissipation, leading correspondingly to lower heat density, larger heat transfer area at the boundary.

5. CONCLUSION

Three test series have been performed to validate local protective measures in a long-term inside a melt pool in an ESFR-core catcher. The results brought the insights of the solidification process of an ablated cavity in the core catcher, the melting process of the pods and the heat transfer through the pods during the initial period of the formation of melt pool. LIVE-CCH test verifies that the ablated cavity can be restrengthen by the solidification of the melt inside the hole. The local objects positioned under the corium transfer tube can not only prevent direct thermal attack of the jet the core catcher, but also act as heat sink und sacrificing material in the pool to retard and to mitigate the overall thermal attack at the core catcher in the long term.

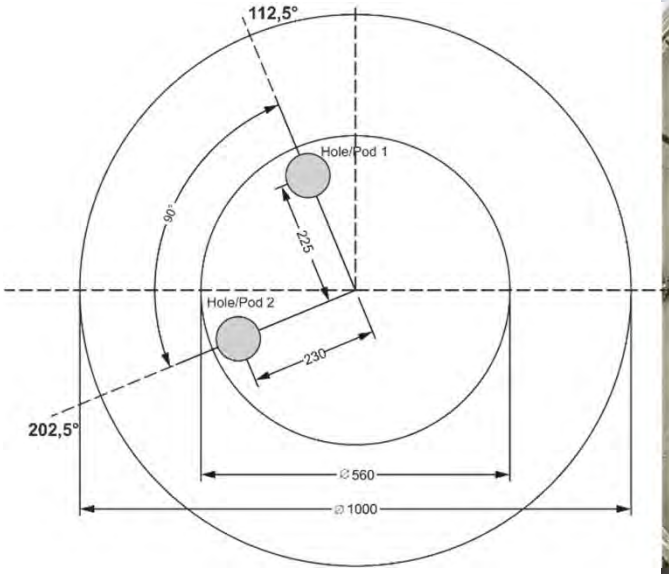
Three test series in the LIVE-CC facility

Three tests on long-term ablation of Core-Catcher:

- **LIVE-CCH**: **H**ole test
- **LIVE-CCS**: **S**alt pod test
- **LIVE-CCM**: **M**etal pod test



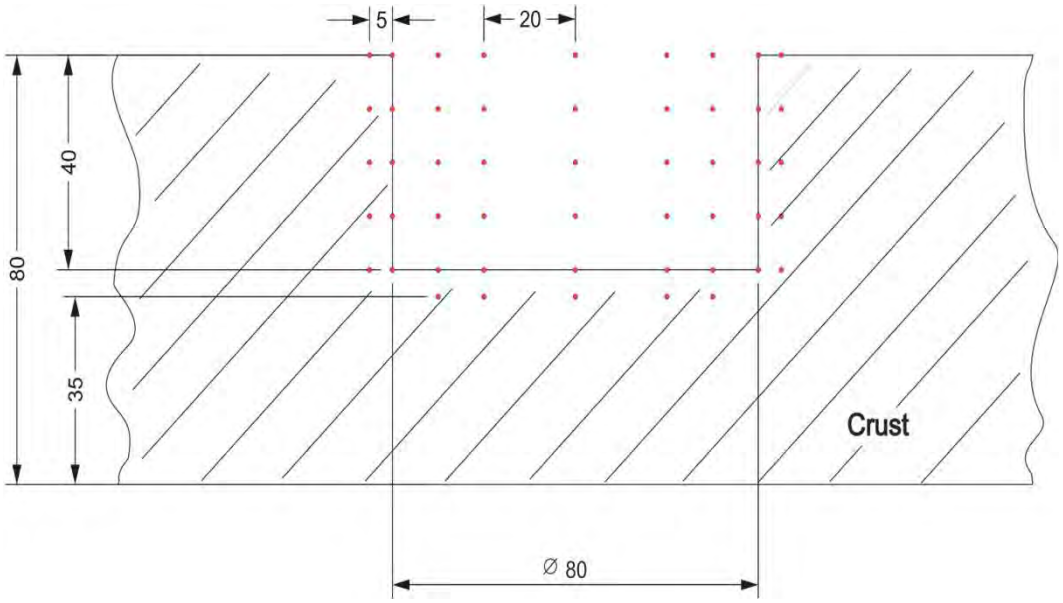
- Two local objects in each test
- Located in the enlarged spaces between heating wires

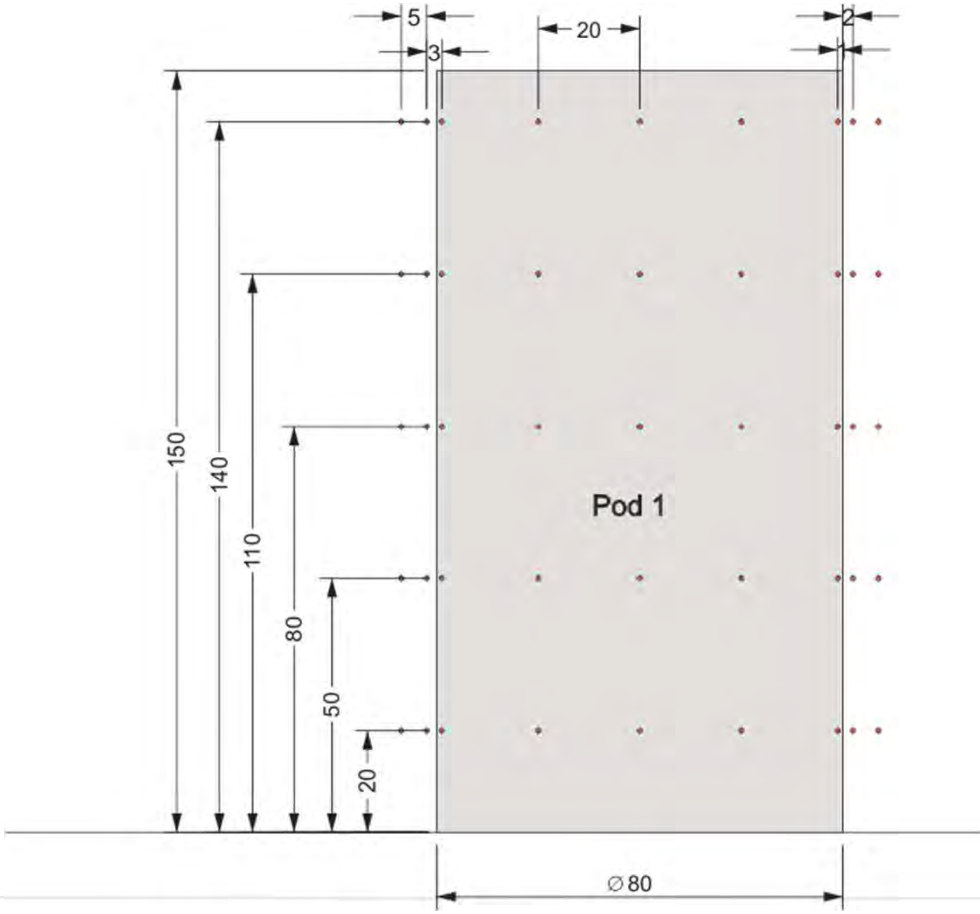
Test conditions

Tests	Local objects	Material of object	Geometry	Heaters in operation	Power level and chronology, kW	Vessel initial condition
CCH	Hole in the bottom crust	Solid salt crust plate with holes	Depth of hole: 40mm Thickness of plate: 80 mm	No heating in the 80 mm bottom plate	44, 67 , 90	With bottom plate
CCS	Salt pods	Solid salt	Height of pods: 150 mm	All heaters	19	Only with two pods
CCM	Metal pods	Stainless steel	Height of pods: 150 mm	All heaters	67, 35, 50, 20	Only with two pods

Geometry of local objects

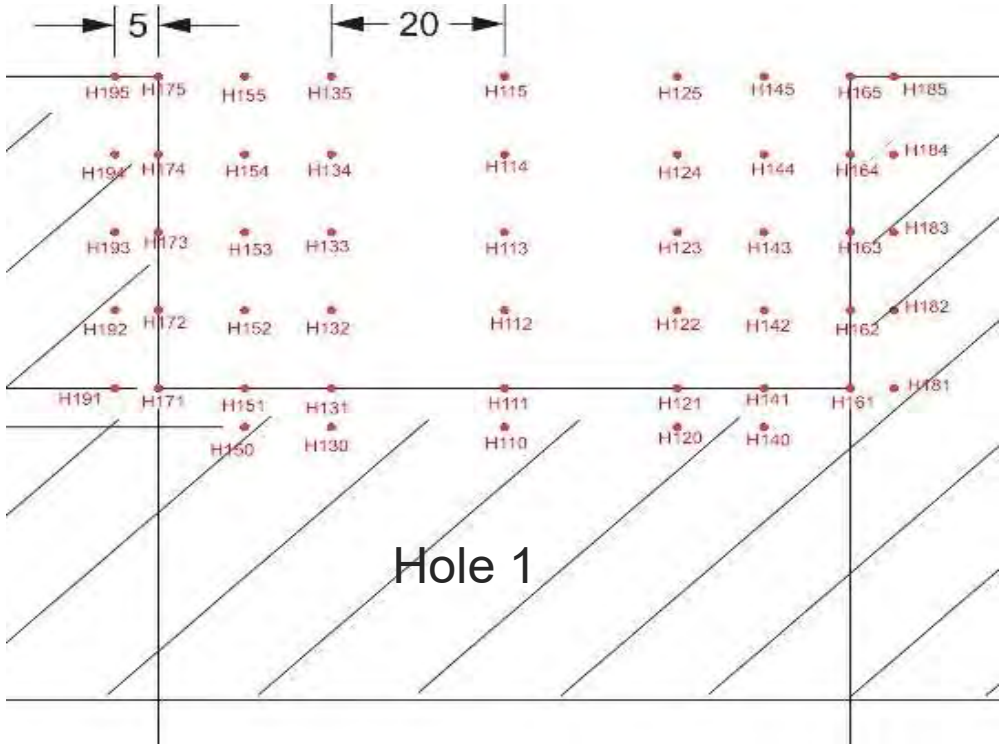
Hole geometries: Diameter: 80 mm, depth: 40 mm.
Pod geometries: Diameter: 80mm, height: 150 mm.

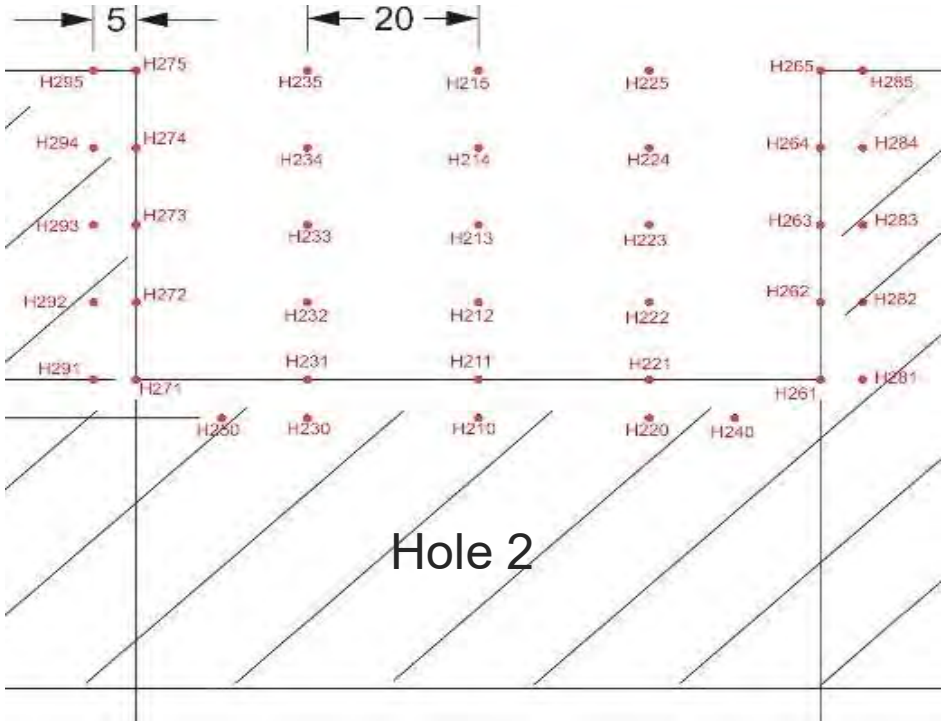




Additional TC Instrumentation

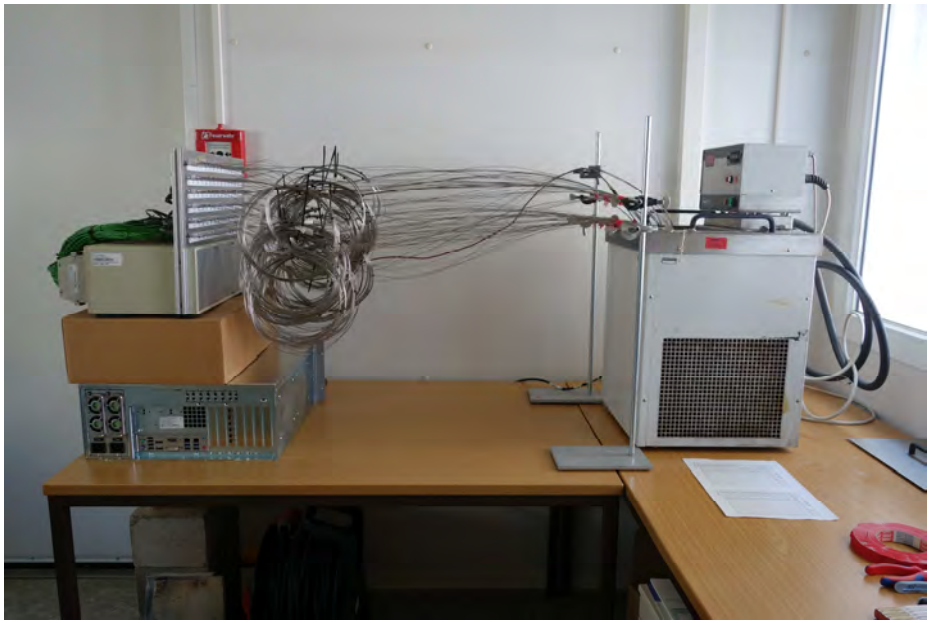
Totally 90 additional thermocouples for one test





Preperation and Installation of thermocouples

- Calibration of thermocouples before the installation
- Installation of new thermocouples inside the vessel
- General calibration of heaters



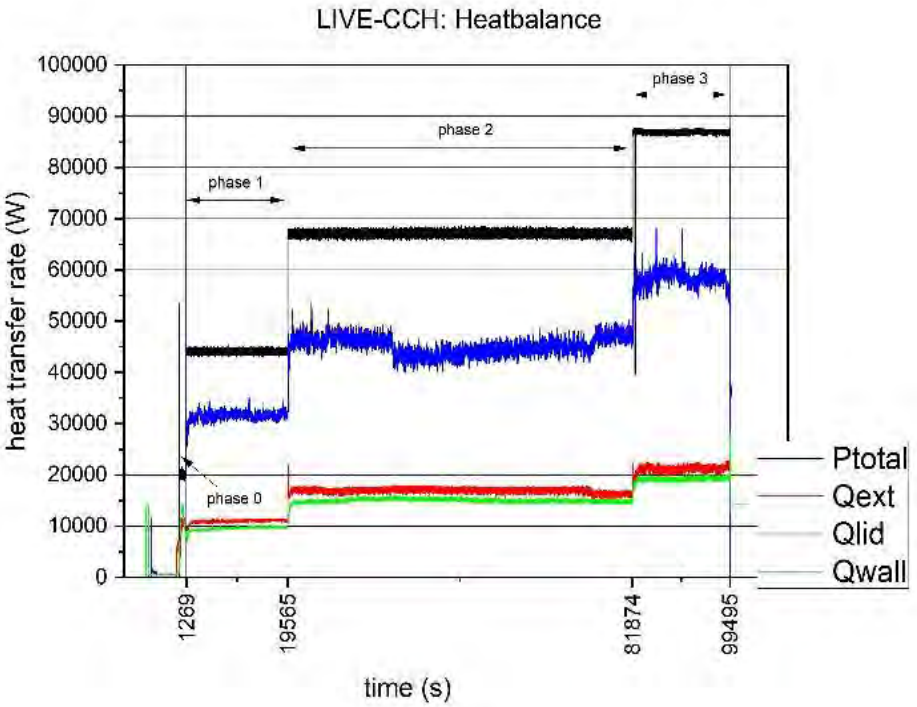
Generation of the two holes in the crust in 3 steps

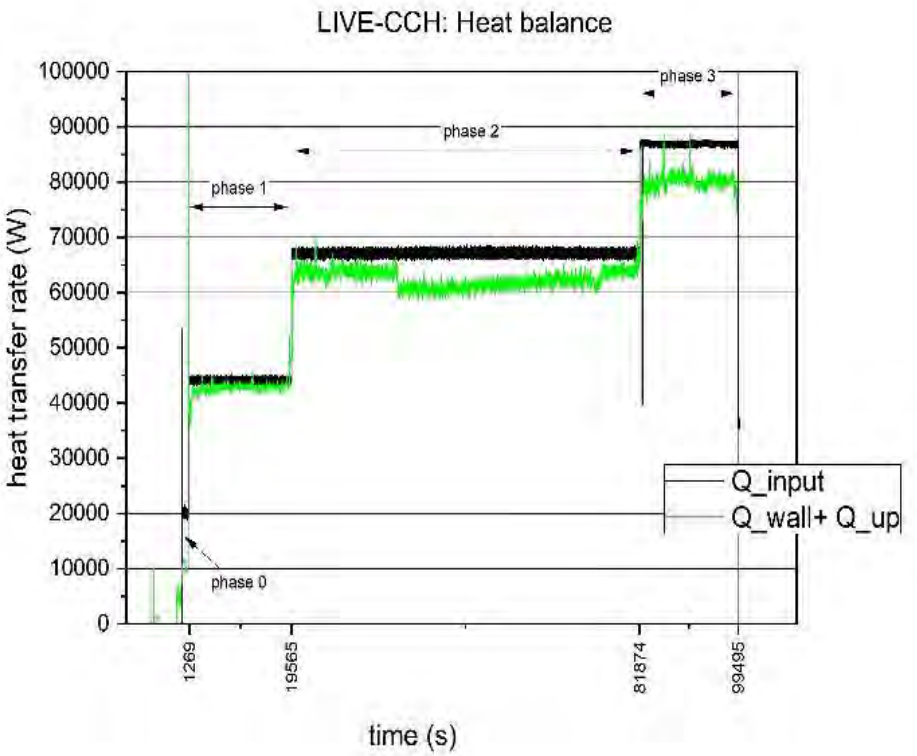
- Step 1: Place holder for two holes

- Step 2: 80 mm crust with two holes

- Step 3: fill in the hole bottom till 40 mm

Heat balance in LIVE-CCH test





Heat balance in LIVE-CCM test

	20kW	35kW	50kW	67kW
%Q_w/Q_in	34.1%	32.6%	32.1%	32.9%
%Qlid/Qin	64.0%	63.8%	66.9%	66.3%
%Q_wall+Q_lid	98.1%	96.4%	99.0%	99.2%

Performance of LIVE-CCH test

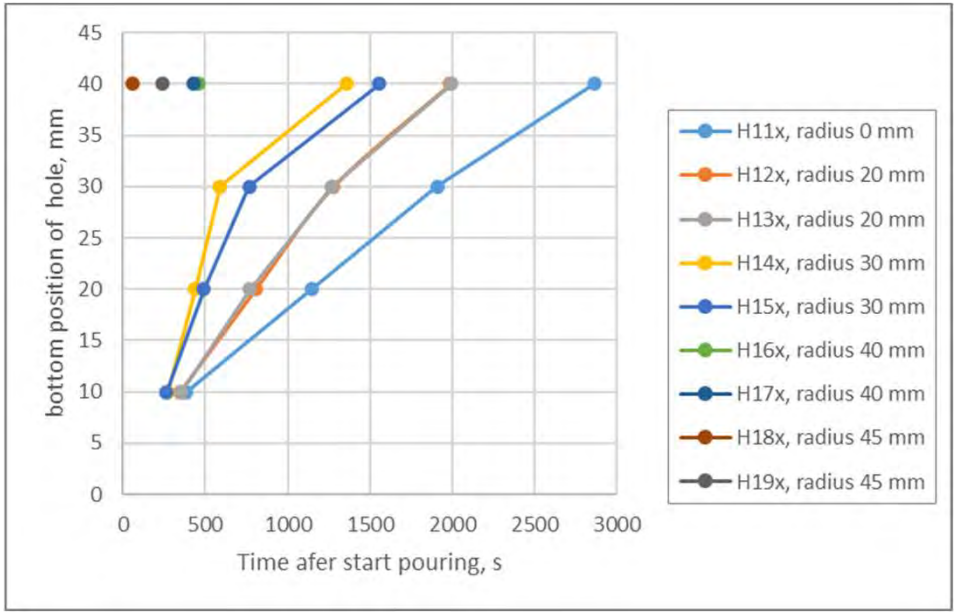
Temperature curves in Hole 1

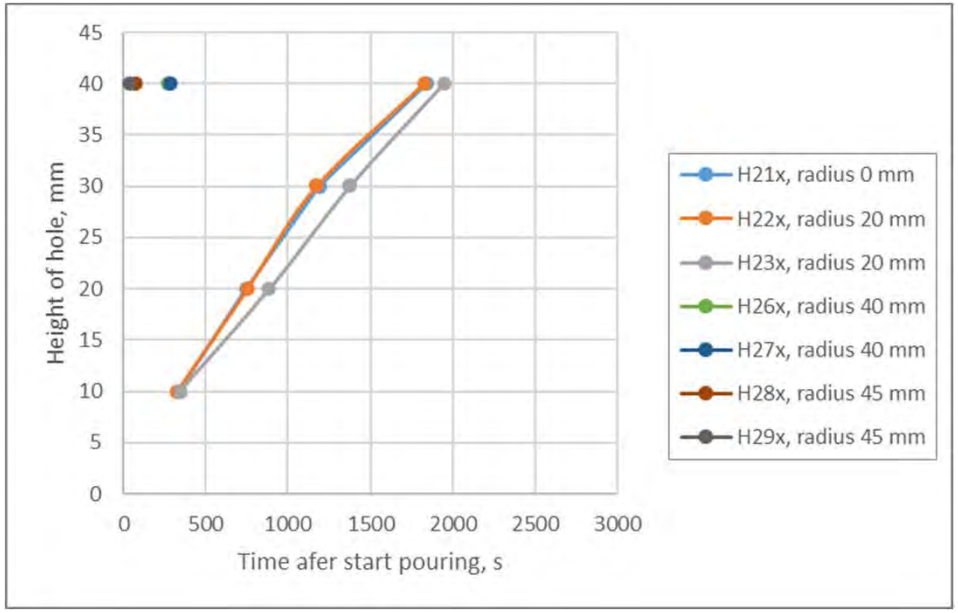
- Indication of time of solidification (at 220 °C)

LIVE-CCH: Solidification dynamics in ablated holes



Hole 1

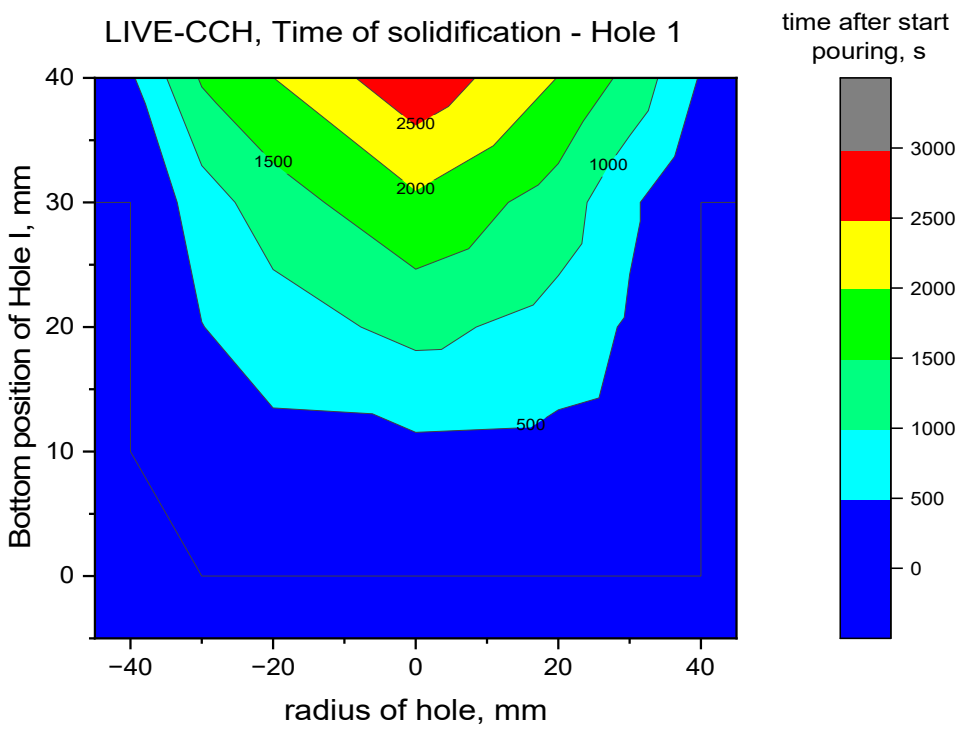
- Simultaneous solidification inwards and upwards
- Completion in 2800 sec



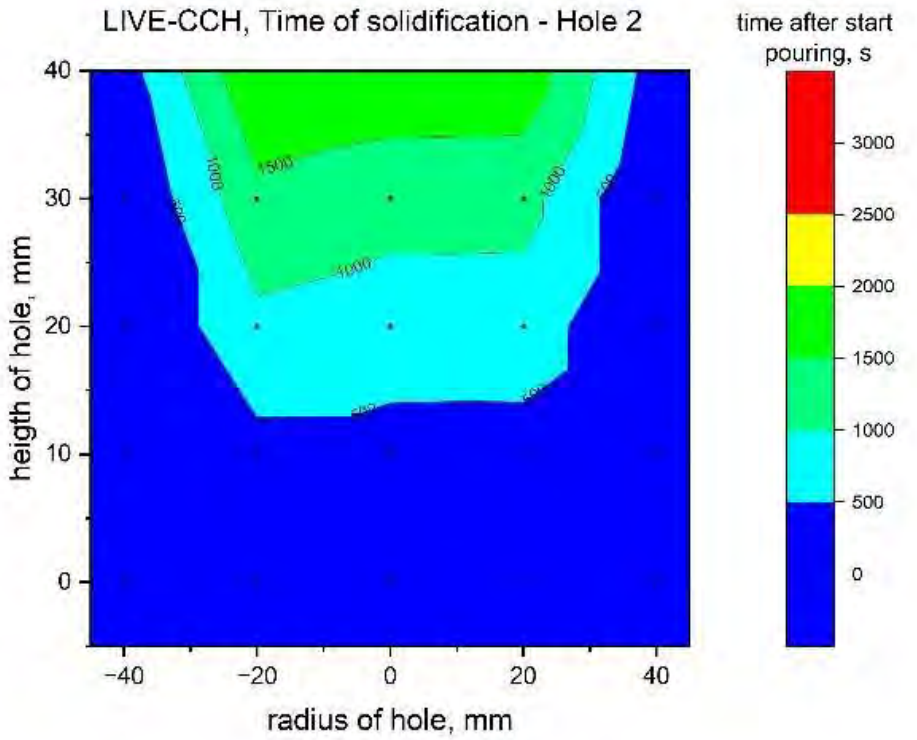
Hole 2

- Upwards ablation for all radial positions
- Almost constant ablation rate
- Completion in 2000 sec.

LIVE-CCH: Progression of the contours of holes

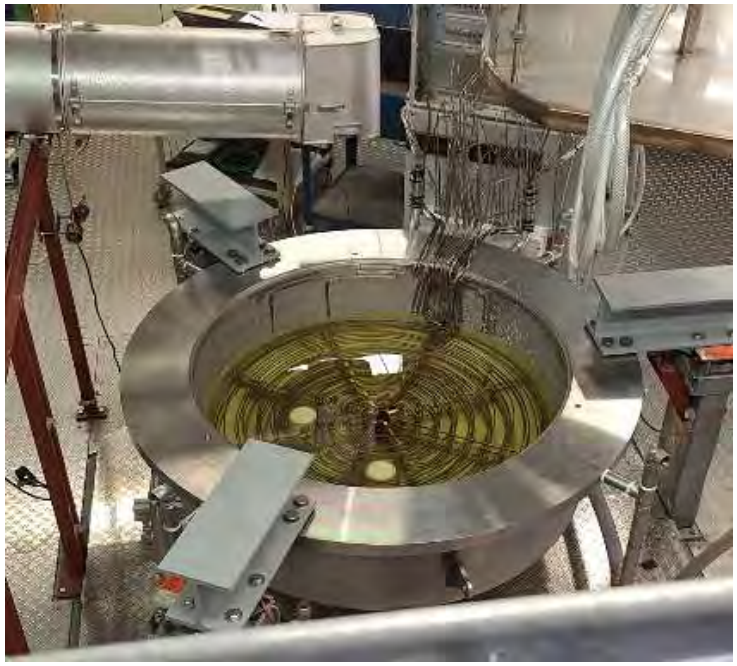


Hole 1



Hole 2

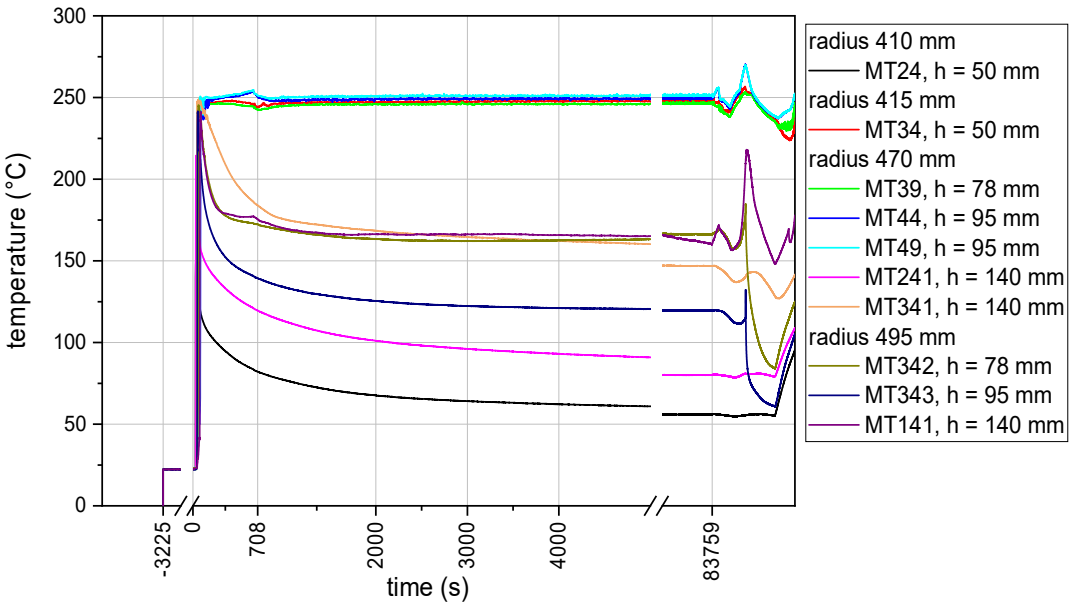
LIVE-CCS: Ablation of meltable pods in a melt pool



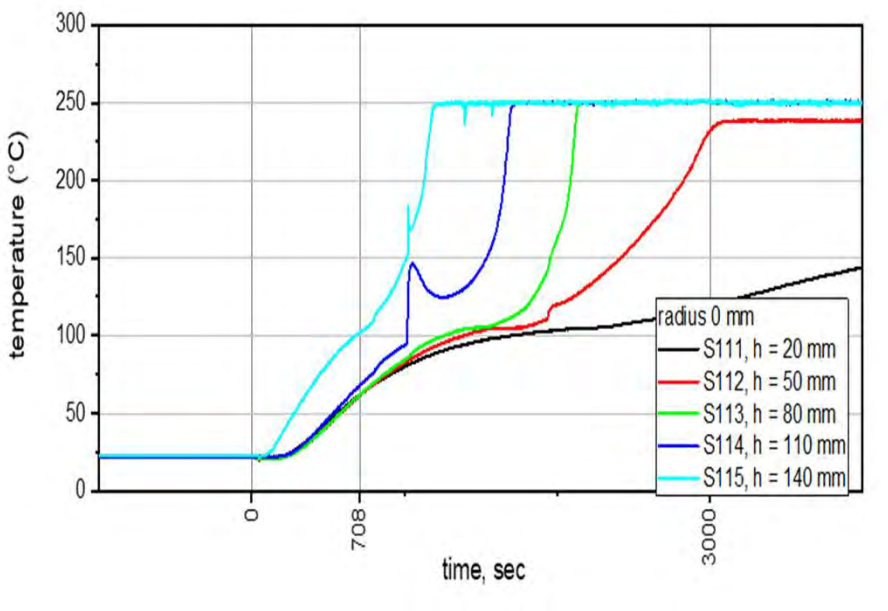
Phase	Time [s]	Top cooling	External cooling	Heating power
0	0 - 707	no	yes	9.5 kW
1	708 - 83759	yes	yes	19 kW

LIVE-CCS: Melting of local objects

Synchronic melting of pods and pool temperature stratification

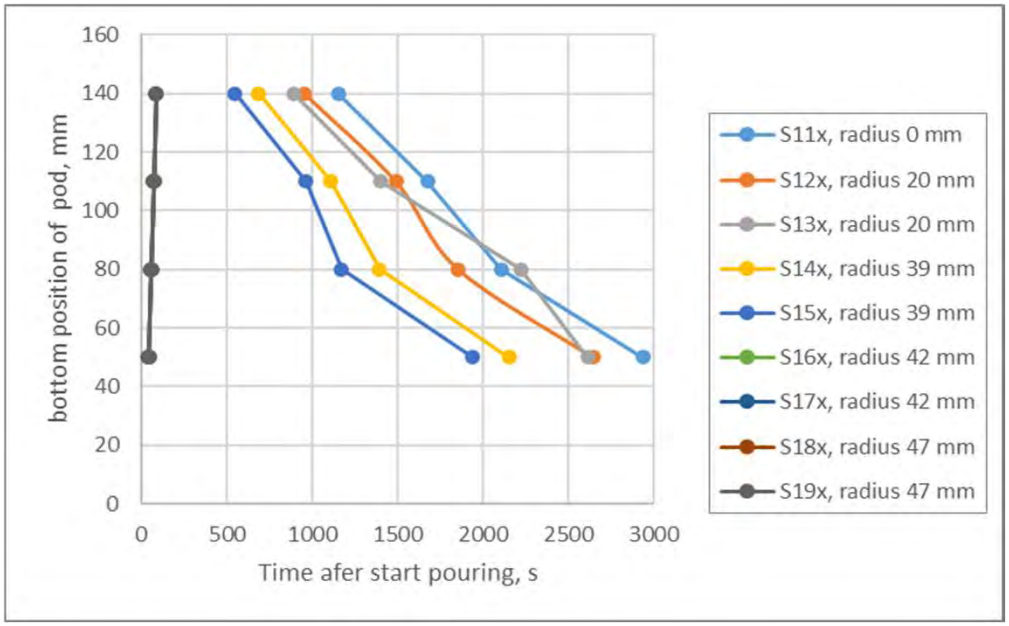


Melt pool under temperature stratification

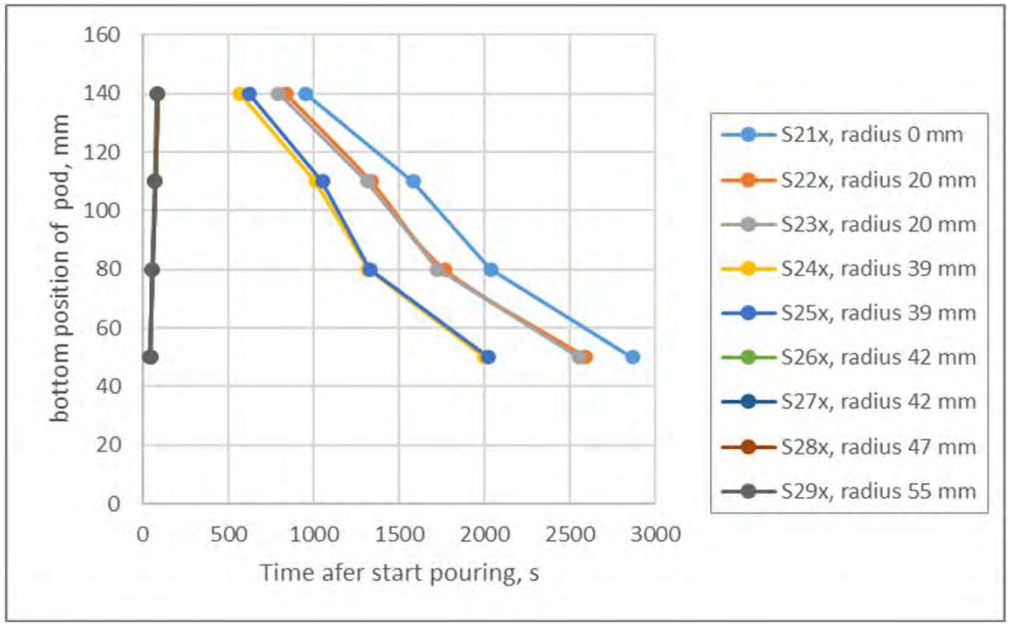


Ablation of melt pod, at the vertical axis.

LIVE-CCS: Ablation dynamics of meltable pods



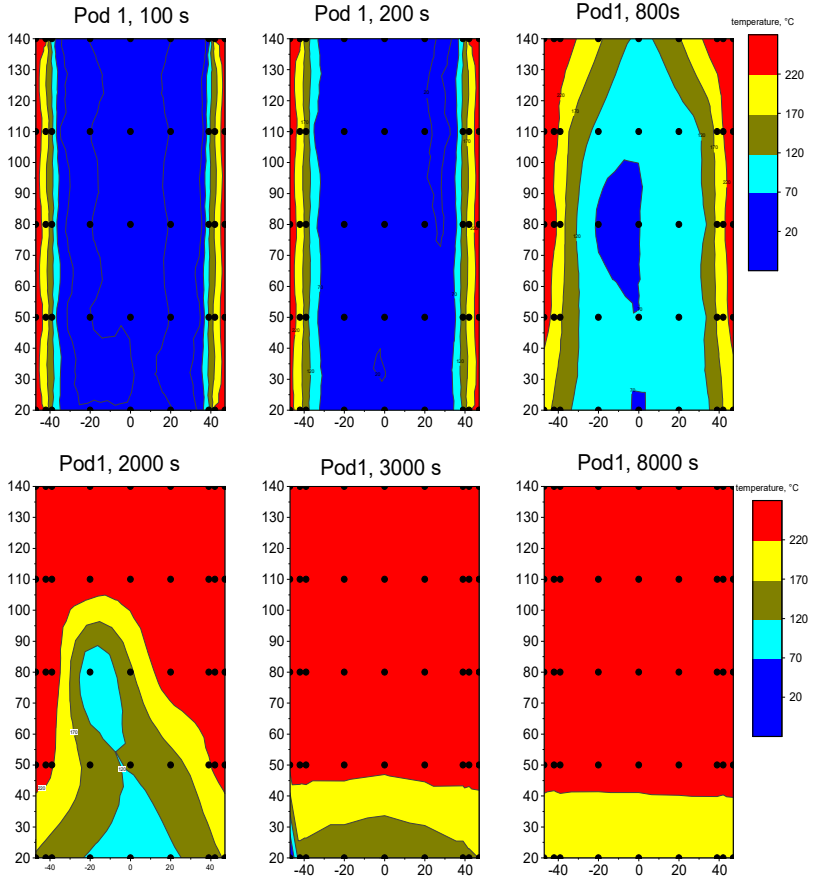
Pod 1



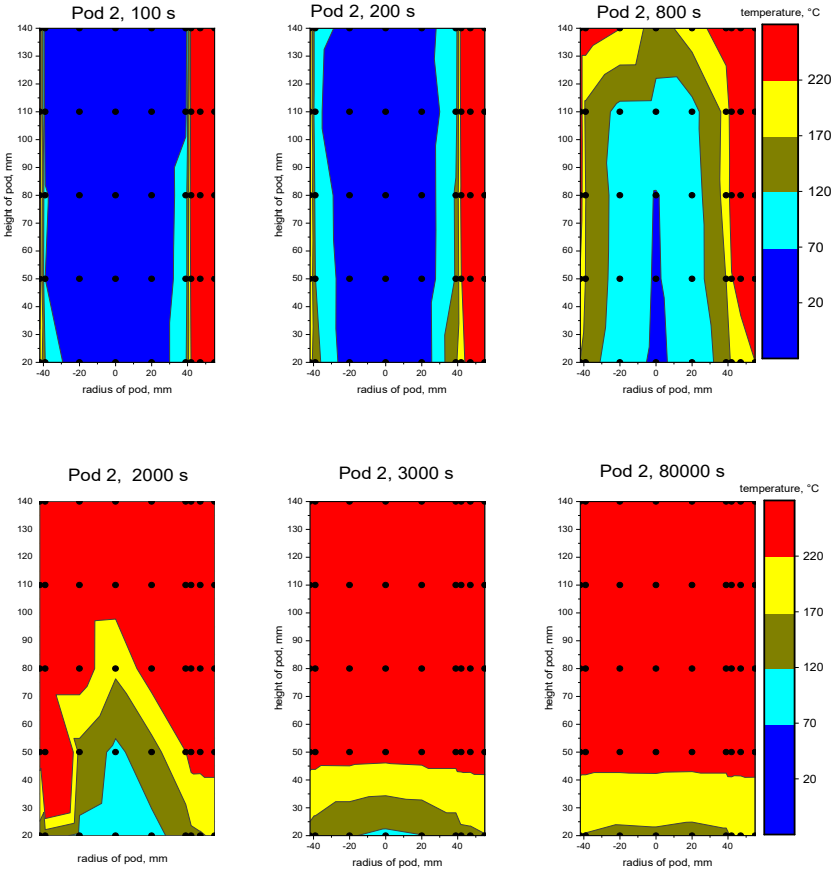
Pod 2

- Simultaneous inwards and downwards ablation of both pods.
- The total ablation period were about 3000 sec.

LIVE-CCS: Ablation dynamics

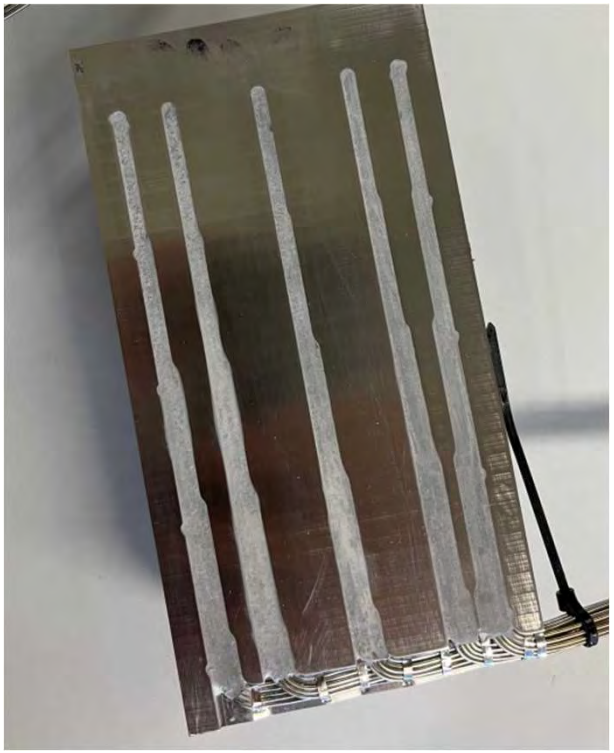


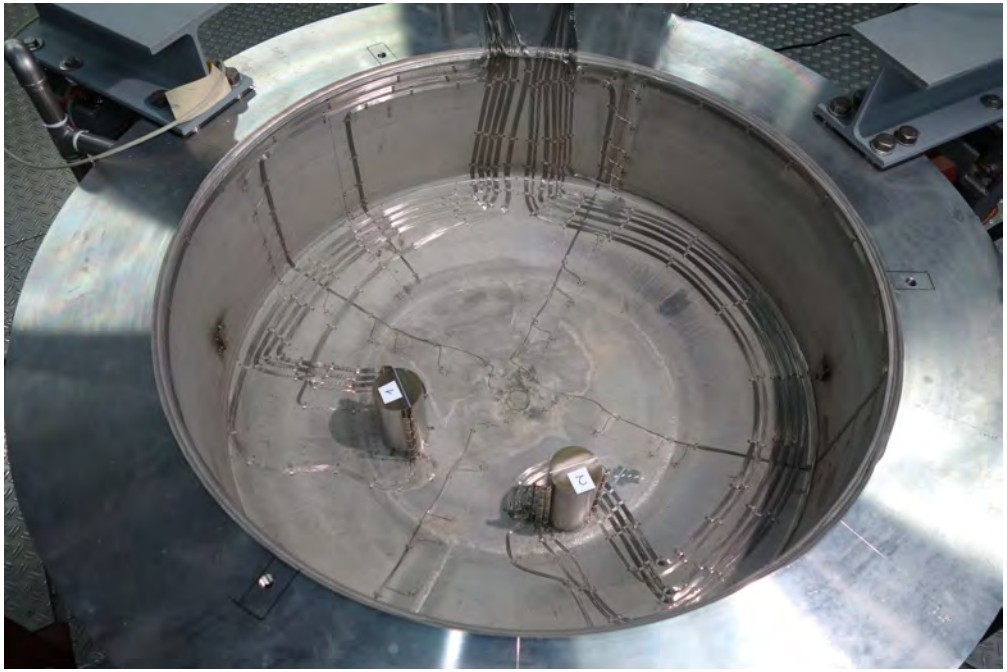
Pod 1



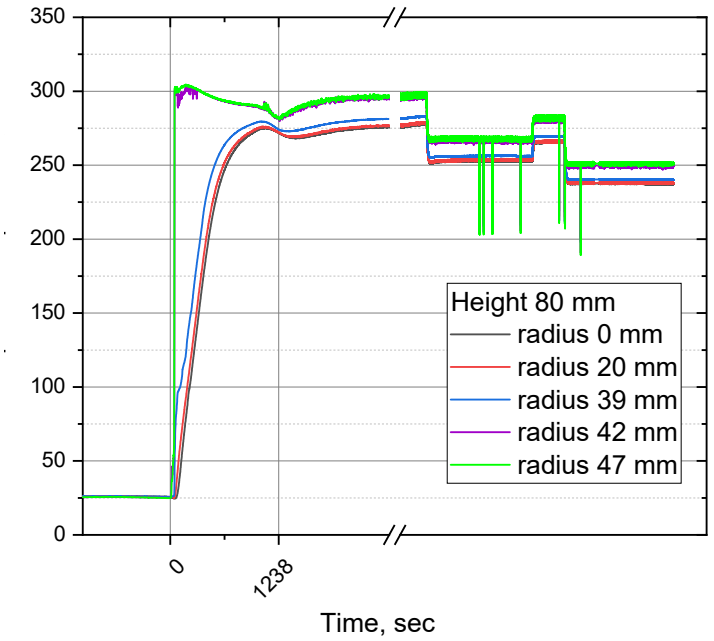
Pod 2

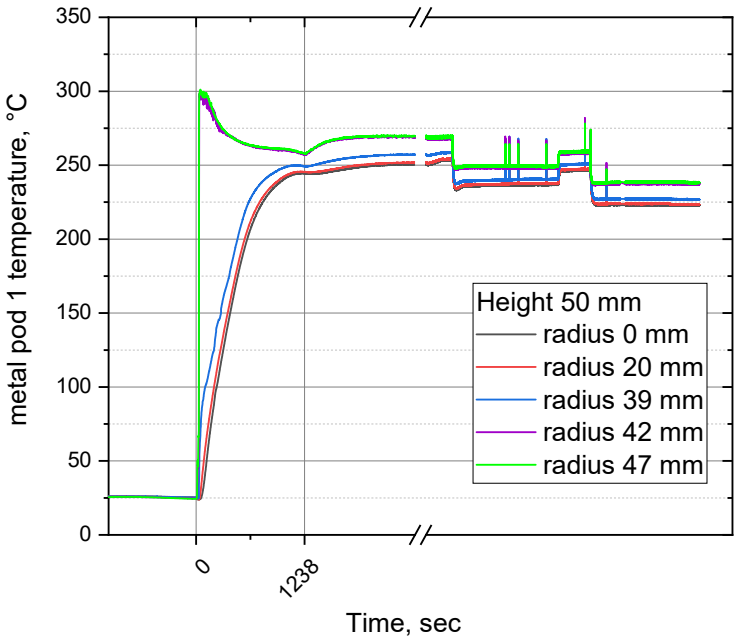
LIVE-CCM test: Instrumentation of metal pods





LIVE-CCM: Temperature inside and around metallic pods





- Pods are high thermal conductive;
- Almost no temperature difference inside the pods;
- Temperature difference between pod and the surrounding salt existed over the entire period, demonstrating a good heat sink effect of the pods.

Conclusions

General heat transfer characteristics

Overall heat transfer	Upward heat transfer of a cooling surface amounts of ~ 66% of total heat inside the molten pool

Long-term behaviour of local objects

Ablated holes	▪ The holes can be completely filled by solidified melt despite of the overlaid hot liquid melt ▪ The experiment has demonstrated the effectiveness of the thermal conductive cooling from the bottom plate
Ablation of additive objects	▪ Synchronic process of pod melting and melt pool stratification; ▪ Bottom part of pods was integrated in the bottom crust
Heat transfer of the local objects	▪ Heat sink effect of metallic objects observed ▪ Acting as an extension of the cold bottom plate inside the pool

This work is funded by the EU ESFR-SIMPLE project and the German government.

ABSTRACT

Fuel Coolant Interaction (FCI), during a Severe Accident in a Sodium-cooled Fast neutron Reactor, strongly depends on the film boiling regime around liquid corium droplets at ~3000 °C under quenching in liquid sodium between ~400 °C (reactor nominal temperature) and ~880 °C (sodium saturation temperature). The intrinsic complexity of film boiling at very high temperature makes experiments with simulant fluids irrelevant to derive predictive models. Yet, most of current knowledge concerning film boiling regimes in sodium relies on the only experimental study involving sodium, performed by M. Farahat in the 1970's, which basically consisted in quenching a high temperature tantalum sphere heated by induction into a liquid sodium pool at regulated temperature close to saturation. The detailed re-analysis of Farahat results and limitations of the experimental device showed that they are not sufficient to validate our theoretical approach. The objective of the SERUA experimental program is to fill this gap of knowledge by producing more precise experimental data on film boiling regimes in liquid sodium. Before the SERUA facility construction and commissioning, a qualification program involving both experimental tests and associated numerical simulations has been conducted to validate our technological choices and ensure our control on the physical conditions concerning the inductive heating of the sphere (up to ~2300 °C), its instrumentation and the heating of the sodium close to the saturation point (at ~860 °C). The positive results of this qualification program now support commissioning of the SERUA facility, expected by the end of 2026.

SFR, FCI, Sodium, Film boiling

1 INTRODUCTION

Fuel-Coolant Interaction (FCI) is anticipated during the relocation phase of a hypothetical Core Disruptive Accident (CDA) in a Sodium-cooled Fast neutron Reactor (SFR) [1]. More precisely, it might occur when

* Corresponding author

molten core materials (commonly designated as "corium") penetrate as a more-or-less-coherent jet in the lower plenum *via* Control Rod Guide Tube (CRGT), ingression through the core diagrid, or specifically-designed corium discharge tubes (DCS-M-TT / FAIDUS concept), as represented on the Figure 1.

FCI has received considerable attention from the scientific community since the 1970's, with a large number of experiments involving interaction of sodium and oxide or metallic fuel at different scales from a few kg to ~100 kg. The most significant of which, used for the safety demonstration of previous SFRs, were:

- The CORECT II program in France [3], where subcooled sodium was poured onto a pool of 5 kg of molten UO_2, resulting in significant pressure peaks, up to 70 bar for the most energetic one.
- The FARO-TERMOS experiments at the European Joint Research Centre, in Italy [4], where up to 140 kg of molten UO_2 were released into sodium, bringing the sodium to saturation over a depth of 1 m along which a coherent jet could penetrate before fragmenting under hydrodynamic and thermal effects. Pressure peaks up to 60 bar have been observed into the sodium pool.

The physical interpretation of the above "large"-scale experiments, using computing tools such as the SCONE (Software for COrium-Na interaction Evaluation) simulation code under development at CEA, requires a better understanding of smaller-scale phenomena. In particular, heat transfers between corium droplets and boiling sodium must be more precisely characterized in the different boiling regimes, especially in film boiling and transition boiling [5,6]. This is the purpose of the SERUA facility (Sodium boiling Experimental Rig for Understanding of fuel-coolant interAction), proposed by the CEA, and inspired by the Farahat experiments [7], whereby a tantalum sphere heated by induction at high temperature is quenched in a liquid sodium pool close to saturation. This experimental program will provide crucial data for the development of SCONE, and more generally for severe accident codes in SFR like SIMMER.

2 SCIENTIFIC INTEREST OF THE SERUA PROGRAM

This section presents with more details how the study of film boiling in sodium contributes to the global efforts for FCI modelling. FCI is very complex and involves many physical phenomena which are still not fully understood at this time. Several initial configurations can be considered depending on technical details of the reactor. The scope of this paper focuses on the SFR technology so the following presentation is oriented for sodium-related experiments but most of the presented phenomena may be encountered in severe accidents in other kinds of reactors (PWR, BWR, etc.).

2.1 Fuel-Coolant Interaction

FCI starts when a large corium mass, typically a liquid jet with T~3000 °C, comes into contact with the sodium coolant with T~400-880 °C, depending on the accident history. The time sequence of FCI is basically divided into the "premixing" phase and the "expansion" phase. In the case of strongly sub-cooled sodium, the premixing phase is very short, and FCI may be better described by a succession of weak expansion phases. When the sodium is close to its saturation point (T~880 °C), however, the premixing phase itself includes the so-called "primary" and "secondary" fragmentations, and lasts as long as the fragmentation of corium and the subsequent sodium vaporization are sufficiently slow to allow the system to relax smoothly. The expansion phase corresponds to quasi-simultaneous droplet fragmentations that rapidly increase the vapor generation. This induces pressure waves in the medium, whose coalescence leads to the steam explosion. The reader interested in a more detailed description of FCI may refer, for instance, to Jiang *et al.* [8] for a recent review on the state-of-knowledge concerning FCI physical phenomena.

Film boiling may occur or not around the corium during the premixing phase, depending on the sodium sub-cooling. In the case where the sodium is close to saturation, for example because it has been locally heated up by previous corium relocations, film boiling initiates around the corium jet because of the conductive thermal transfers that provoke the vaporization of the sodium immediately after the contact. At the same

time, destabilization phenomena such as Rayleigh instabilities (due to surface tension) or Kelvin-Helmholtz instabilities (due to shear stress between the gravity-driven corium and the liquid sodium carrier phase) develop in the jet, leading to the so-called "primary fragmentation" of the jet (Figure 1). The corium droplets generated by the primary fragmentation also induce film boiling of the surrounding sodium. Then the "secondary fragmentation" occurs, resulting in various sizes of corium droplets. Mainly three physical phenomena are considered in the literature as the source of the secondary fragmentation: hydrodynamic instabilities may develop at the surface of the biggest droplets, as for the jet; some liquid sodium may be trapped within a corium droplet, vaporize and fragment the droplet; and, in case of film-boiling, the destabilization of liquid-vapor interface leads to direct contacts between the corium and the liquid sodium, inducing thermomechanical constraints within the droplet.

Film boiling is then involved at various stages of the premixing phase, and is thus of major interest to better understand FCI. In particular, film boiling around corium droplets appears as a potential "trigger" for vapor explosion.

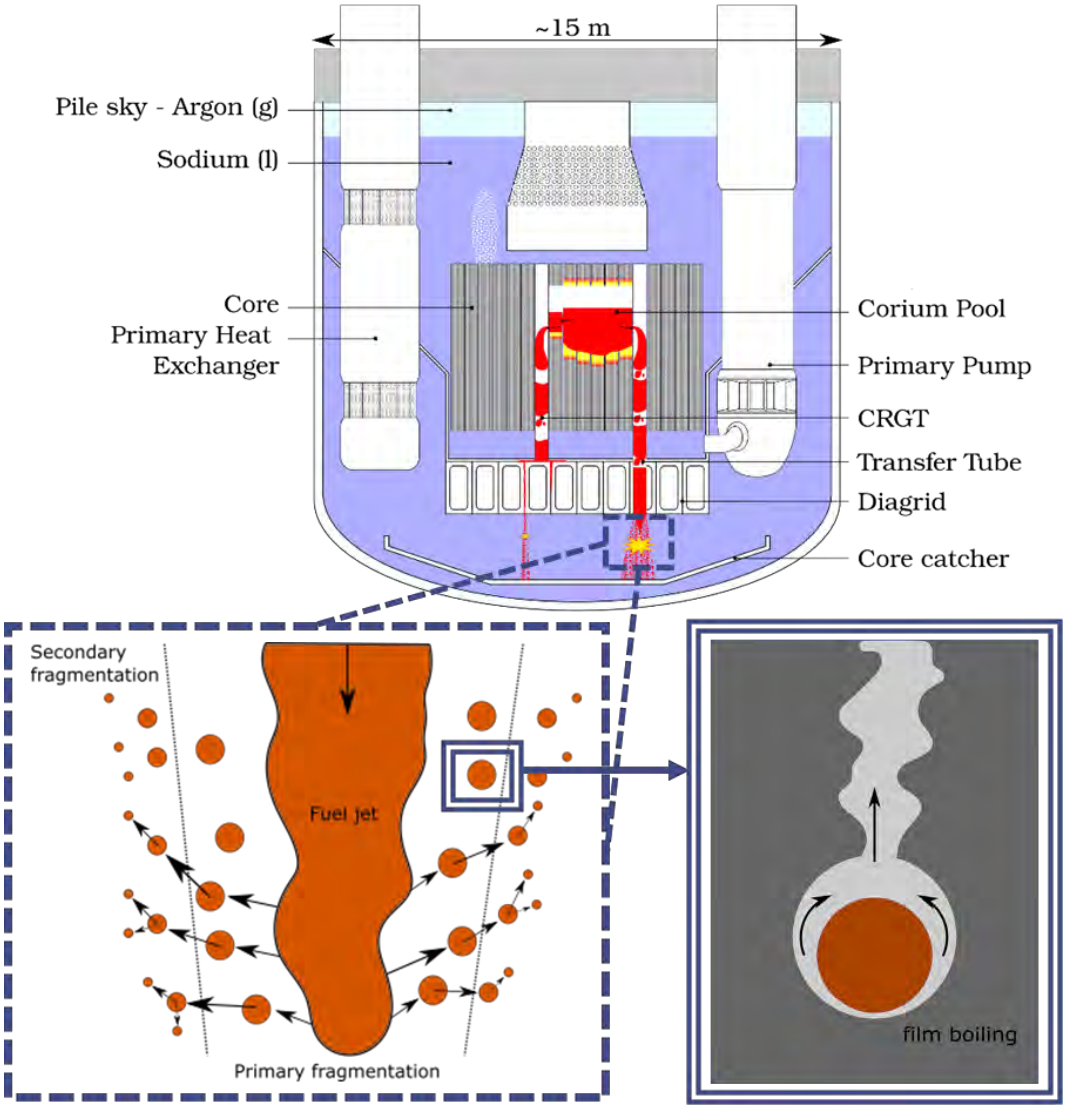

Figure 1. From corium jet to film boiling around a fragmented droplet in FCI event

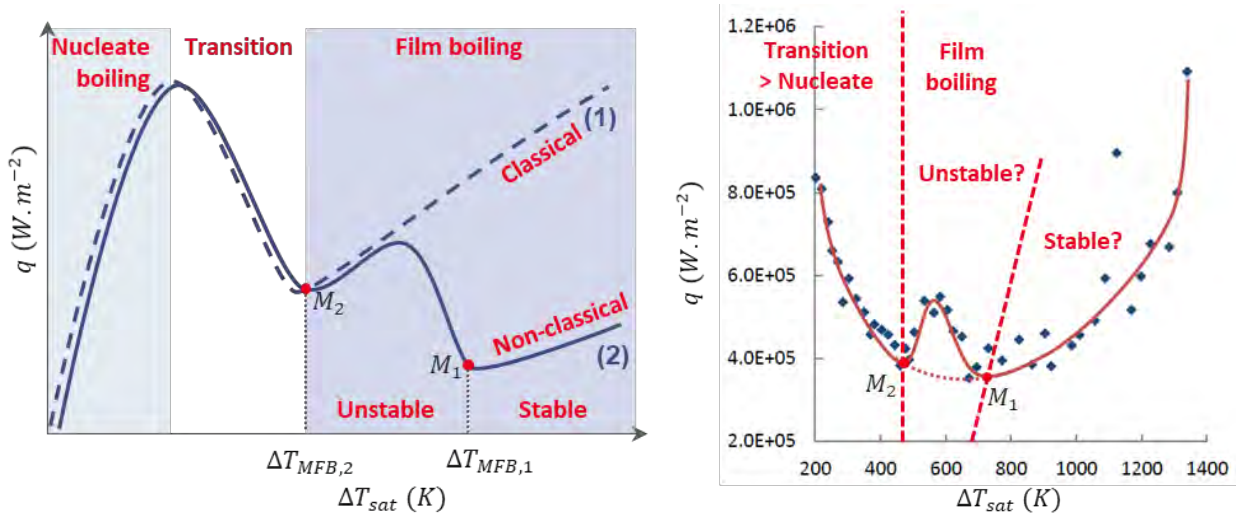
2.2 Film-boiling around spheres in sodium

The classical Nukiyama curve [9], for a quasi-static system with imposed wall temperature, exhibits 3 boiling regimes (see Figure 2a): nucleate boiling is observed for relatively low wall temperature, while film boiling regime occurs above the so-called "Temperature Minimum Film Boiling" T_{MFB}. In fast-transient systems like quenching, a 4th regime may be observed between the classical film boiling and the transition regime, where unstable vapor films still exist but regularly collapse and reform. This regime has been experimentally observed in water, for example by Honda *et al.* [10].

Experimental characterization of film boiling in sodium are very scarce in the literature: only one experimental work has been reported, carried out by M. Farahat [7] in the 1970's, where a sphere of Tantalum was heated by induction then quenched it in a pool of resting liquid sodium close to saturation. Heat transfer were monitored by a single thermocouple placed inside the sphere. Wall temperature and heat flux were determined from the measured temperature thanks to a postprocessing method based on a simplified inverse problem, in order to produce boiling curves at imposed wall temperature from the film boiling to the nucleate boiling regime. A possible unstable film boiling regime has been highlighted as shown in Figure 2b [5].



(a) **(b)**

Figure 2: (a) The Nukiyama boiling curve at imposed surface temperature; and (b) experiment in sodium by M. Farahat [7], analyzed by Le Belguet [5]

The modelling of film boiling in sodium have been studied by Le Belguet and Berthoud et al. [5,6] on the basis of a previous modeling for water by Dhir and Purohit [11] and considering experimental data of Farahat for validation. The analyzed parameters included the sphere superheat, the emissivity, the sodium temperature and the sodium velocity. The experimental parameters and the postprocessing methods proposed by Farahat induced significant uncertainties on the results. New experiments with film boiling around superheated spheres in sodium therefore appear necessary for the development of future numerical tools for FCI like SCONE. Indeed, sub-cell models are required to account for the heat exchange between a large number of particles and the sodium carrier phase:

$$\phi_{droplet \to Na} = h\left(T_{droplet} - T_{Na}\right) \quad (1)$$

The heat transfer coefficient (h) in the equation above must be provided by experimental correlations. The correlation proposed by Epstein and Hauser [12] is currently considered as the most precise one, but its reliability remains questionable in sodium. The data obtained thanks to the SERUA facility should reduce these uncertainties.

3 SERUA DESIGN AND PRINCIPLE

This section presents the principle of the SERUA facility, a typical test conduct and the instrumentation.

3.1 Experimental Layout

The SERUA facility basically includes 3 main parts (Figure 3):

- The induction furnace (Figure 3a) ensures the tantalum sphere heating. The atmosphere of the sphere is separated from the one of the inductor by a quartz tube. A glass window allows the visualization of the sphere during the heating, which allows to ensure the initial temperature of the sphere by pyrometry, and eventually to determine the emissivity of the sphere (see section 4.1);
- The thermostatic sodium pot (Figure 3b) is placed under the induction furnace and is isolated from it by a dedicated insulation valve during the heating phase. It contains the sodium pool, suspended to the cap, inside the isolation vessel filled with Argon gas and protected from the hot sodium pool by insulation blankets. The sodium pool is heated by 3 heating canes and the temperature of the sodium is measured all around the sphere thanks to an instrumented grid (see section 3.3);
- The sphere transfer device (Figure 3c) ensures the correct transfer of the heated sphere from the induction furnace to the sodium pool. It contains the support rod of the sphere, which must be long enough to cover the distance between the furnace and the sodium pool. The transfer velocity must be high enough for the sphere to reach the sodium with sufficient temperature to generate film boiling and low enough to avoid too much sodium projection when the sphere penetrates through the surface [13].

3.2 Typical test conduct

The principle SERUA test conduct is very similar to Farahat's [7]:

- The instrumented sphere in tantalum suspended to a tantalum rod mimics the corium droplet. The sphere is heated by an induction furnace up to ~2300 °C;
- At the same time, a pool of liquid sodium is heated up to the desired temperature close to saturation;
- The inductive heating is suddenly cut-off and the sphere is quenched into the sodium volume;
- The evolution of the heat flux and wall temperature of the sphere is monitored during quenching until the complete thermalization of the sphere with the sodium.

3.3 Instrumentation

The central element of the experiment is the instrumented sphere (Figure 4a). The reference results, stemming from Farahat's experiment, were obtained with a single hot junction. This will be improved in the SERUA experiment, as a so-called duplex type-C thermocouple sensor will be used, with two separated hot junctions of tungsten-rhenium wires. This duplex thermocouple is used to measure and monitor the heat fluxes and wall temperatures of the sphere, following the method described briefly in the following section.

The sodium transition boiling regime is expected to occur for $\Delta T_{\mathrm{sat}} \in [450; 650]$ °C, *i.e.* for a sphere surface temperature between ~1350 °C and ~1550 °C. The tantalum sphere will be quenched very rapidly from 2300 °C to the sodium temperature, leaving a measurement window of a few dozens of seconds to observe

the film boiling regime and a few seconds to capture the transition regime. This requires a dedicated instrumentation with a suitable response time and data acquisition frequency (around 100 Hz).

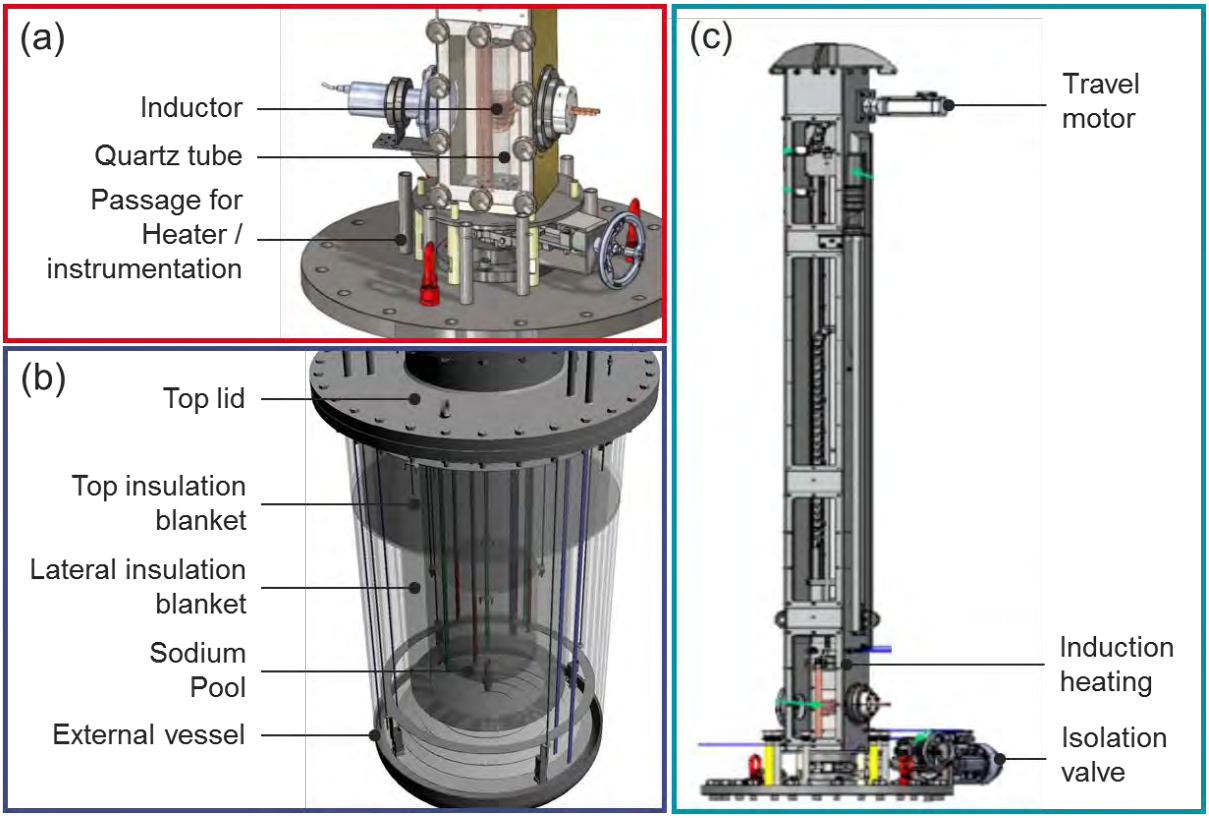


Figure 3: The SERUA experimental layout

(a) **(b)**

Figure 4: (a) Instrumentation inside the sphere; (b) Instrumented grid immersed into the sodium pool to measure the temperature field around the sphere

It is equally important to access the temperature of the liquid sodium, to determine a heat transfer coefficient in equation (1). To this end, an instrumented grid is immersed as close as possible to the vicinity of the sphere (Figure 4b), with 24 type-K thermocouples homogeneously distributed on 4 axes for thermal mapping of the sodium volume surrounding the sphere. This instrumented grid will also include piezoelectric sensors to detect the pressure waves due to the direct contacts between the liquid sodium and

the sphere in the unstable film boiling regime, as well as the generation of bubbles in the nucleate boiling regime, giving some hints at the occurrence of different boiling regimes. Before immersion, it can also help to detect a possible nucleate boiling around heating rods, for the sake of test conduct.

Besides, at such high temperatures, radiative heat transfer plays a significant role in the thermal balance of the tantalum sphere. Its contribution in the heat transfer coefficient must be assessed, through the tantalum emissivity. The latter is not well-known at high temperatures, and presents several sources of uncertainties (impurities, roughness, etc.). A set of pyrometers with different working wavelengths shall be implemented in the upper part of the facility, focusing on the tantalum sphere during the induction heating process. The pyrometers measurements will be used not only to monitor the induction heating and verify the sphere temperature, but also to estimate its emissivity, following the approach described in the section 4.1.

3.4 Determination of wall temperature and heat flux

The determination of wall temperature and heat flux in the sphere is the central element of SERUA data analysis. The used method relies on the resolution of non-linear inverse heat conduction problem at sphere scale, whose methodology is well-documented in the literature, following the reference work of Monde *et al*. [14]. This methodology relies on an analytical solution of the heat equation in the Laplace space. The wall temperature and heat transfer may then be expressed as convolution products between the measured temperatures and the inverse Laplace transform of transfer functions, estimated using the Stehfest algorithm. Input data of the method are the thermocouples measurements and their positions (1st and 2nd hot junctions in the sphere, fluid temperature in liquid sodium), and the thermal diffusivity of the sphere. The results may then be used to determine the time evolution of the heat transfer coefficient h (including both convective and radiative effects) between the sphere and the surrounding sodium.

The quantification of the performance of the method in terms of applicability and uncertainty is still under investigation.

4 QUALIFICATION OF SERUA CONCEPT

The main elements for the SERUA qualification program are shown in Figure 5, and can be distinguished between the upper and lower part of the experiment: the sphere design and characterization during the induction heating process has been qualified on the VITI facility, and the control of the high-temperature sodium pool, qualified during the ESCOBAR test series. The experience acquired after the VITI qualification program has been used to adapt a new induction device, PELE, to the SERUA requirements.

4.1 Sphere design and characterization: VITI qualification program

A key aspect of the characterization of boiling heat transfer at the surface of the tantalum sphere concerns the precision to which the wall temperature, heat flux and heat transfer coefficient can be determined from measurements and understanding of the thermal behavior of the sphere, including the contribution of radiative heat transfer through emissivity. Another important issue regarding the preparation of the SERUA experiments is the prediction of the cooling rate of the sphere between the end of the heating phase and its entry into the liquid sodium, so that the conditions of transition boiling regime characterization are ensured. To address both issues, dedicated experiments have been conducted in the VITI facility, coupled to magneto-thermal simulations.

The VITI facility consists of an induction furnace, contained inside a water-cooled confinement vessel, whose configuration inspired the design of the SERUA furnace. The temperature distribution across the surface of the tantalum sphere was investigated through multi-wavelength pyrometry and infrared thermal imaging during heat treatment representative from the SERUA experiments.

Classical pyrometry without emissivity correction gives access to blackbody surface temperature distribution, assuming that emissivity is constant and equal to unity. However, Allen *et al.* [15] determined emissivity values of 0.288-0.324 for polished tantalum surfaces in the 2300-3300 K range, increasing with temperature. More precise characterization of the emissivity of the spheres under investigation is therefore required to determine the real temperature, because their level of impurities, roughness, and other surface features can significantly differ from the one used in reference [15]. Preliminary calculations have shown that 20 % uncertainty in the emissivity values may lead to more than 100 °C error in surface temperature estimation. This is why a specific methodology is under development to get a better estimation of the tantalum sphere emissivity and to improve the predictability of the calculations. This methodology is summarized in the Figure 6 and may be divided into two main steps: i) experimental data treatment to determine the accurate surface temperature; and ii) adjustment of the total emissivity in a numerical model based on COMSOL Multiphysics© to match the previous surface temperature.

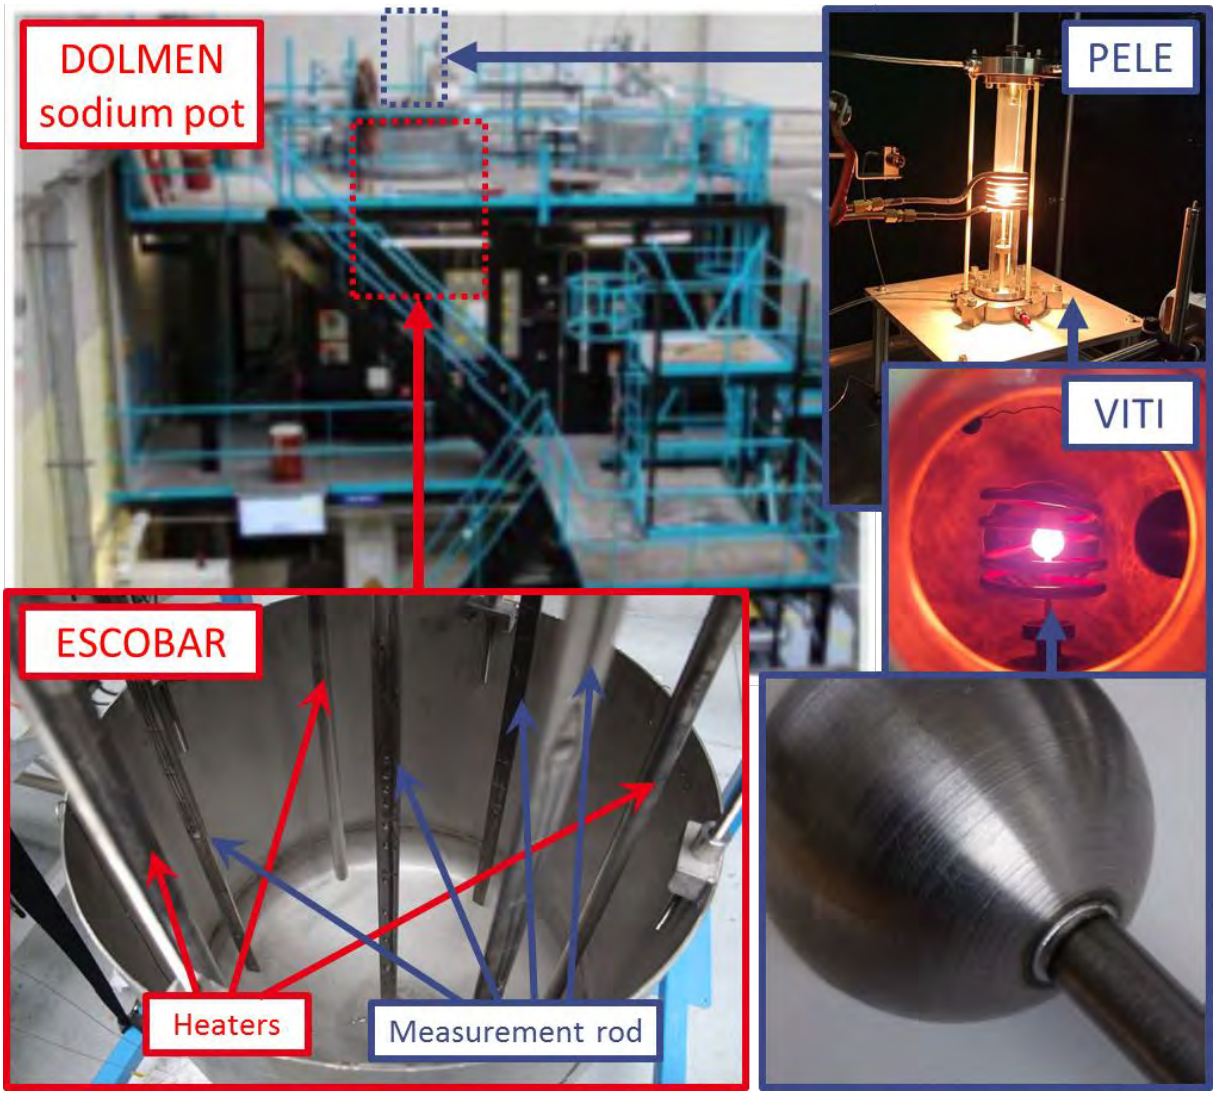

Figure 5: Main elements for the qualification of the SERUA concept. (Top left) the DOLMEN loop who will host the SERUA experiment; (Top right) the PELE induction furnace to qualify the sphere heating process; (Bottom left) the sodium pot used in ESCOBAR experiments to qualify the sodium heating process; (Bottom right) the Tantalum sphere welded on its support tube.

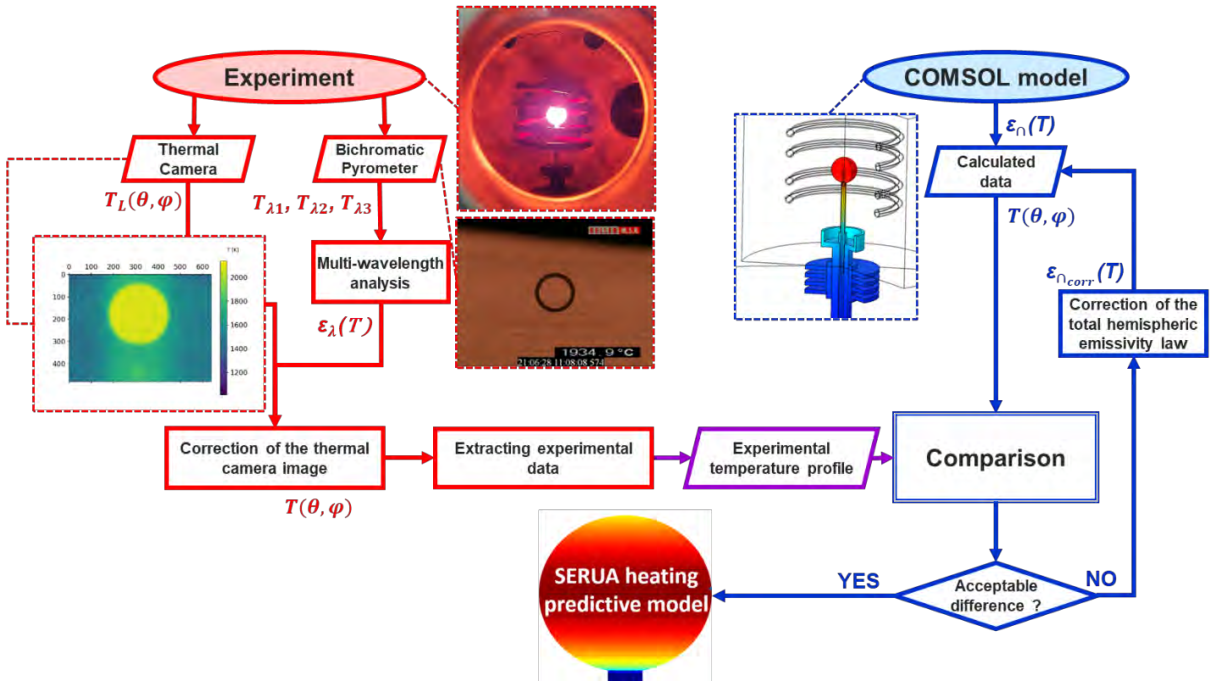

Figure 6: Coupled experimental and numerical approach for the estimation of emissivity and temperature fields at tantalum sphere scale for SERUA experiments.

4.2 Sodium pool control: ESCOBAR qualification program

The production and characterization of a stable liquid sodium pool at ~860 °C is another key aspect for the feasibility of the SERUA program. The ESCOBAR experimental program has been conducted in the future host facility for SERUA to demonstrate the validity and robustness of the selected technology for the heating of the sodium pool, as well as for the characterization of the sodium temperature field in representative conditions of the SERUA experiments. In parallel, numerical simulations are carried out with OpenFoam in order to get a deeper insight of the sodium pool configuration, notably to characterize the velocity field (Figure 7).

The Figure 8 shows the temperature measurements inside the sodium pool during the maximal power plateau of the ESCOBAR experiments. The capability of the selected sodium heating technology to maintain a stable temperature of 860 °C during ~30 min has been demonstrated, which is the objective for the first SERUA experiments.

Taking advantage of the many temperature measurements inside the sodium pool, the OpenFoam numerical model has been used to extend our knowledge of the state of the sodium pool to the velocity field, which will be an important parameter for the SERUA experiments. The model performs 3D simulations of the natural convection with turbulence modelling (k-ε and k-ω have been tested) on 1/6th of the test section. Simple boundary conditions are used (Figure 7, left): symmetry on the sodium edges, to reflect the symmetry of the problem, no-slip condition on the lateral wall and the heater, heat convection on the lateral wall with a user-adjusted heat transfer coefficient, imposed heat flux in the heating part of the heater. Finally, a slipping-wall condition with heat convection, including another user-adjusted heat transfer coefficient, is imposed at the top, and is considered as a satisfactory approximation of the sodium pool free-surface conditions. By adjusting the external heat exchange coefficients, the model is able to match the measured temperature profiles with a satisfactory agreement (Figure 9).

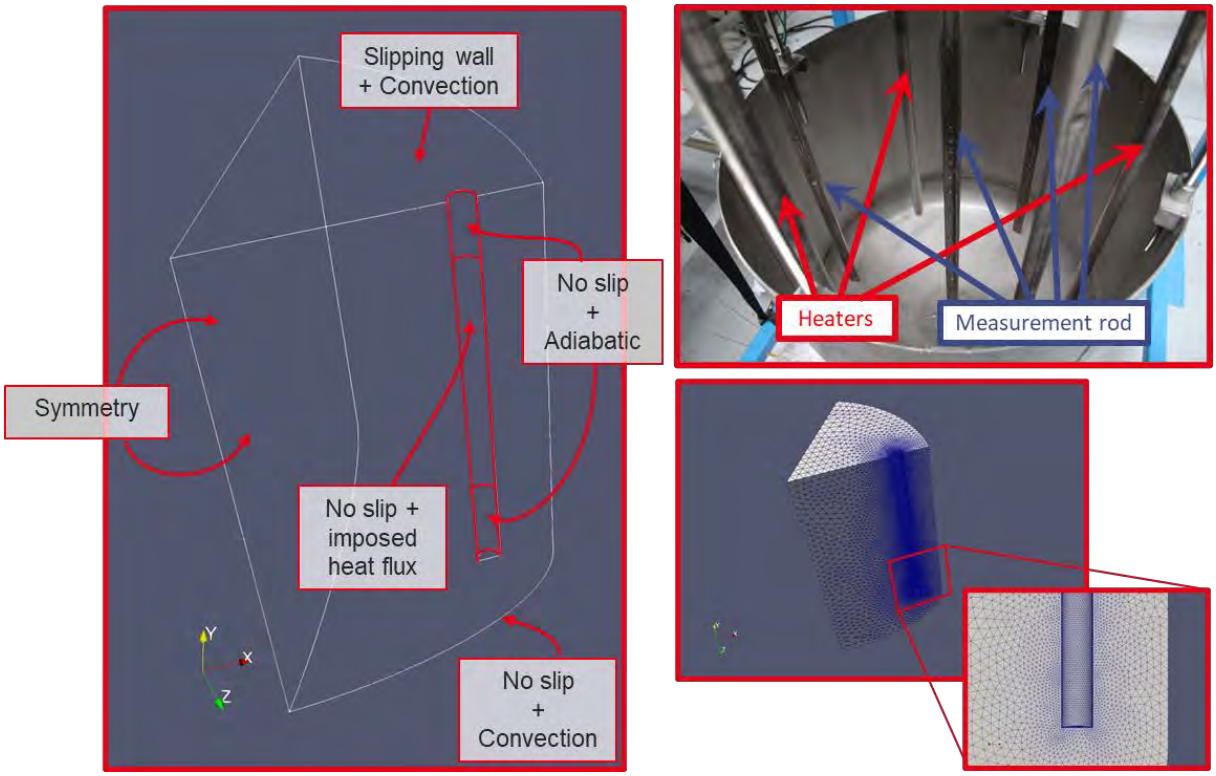

Figure 7: (Top right) Experimental pot for ESCOBAR experiments and (Left and Bottom right) corresponding OpenFoam modelling

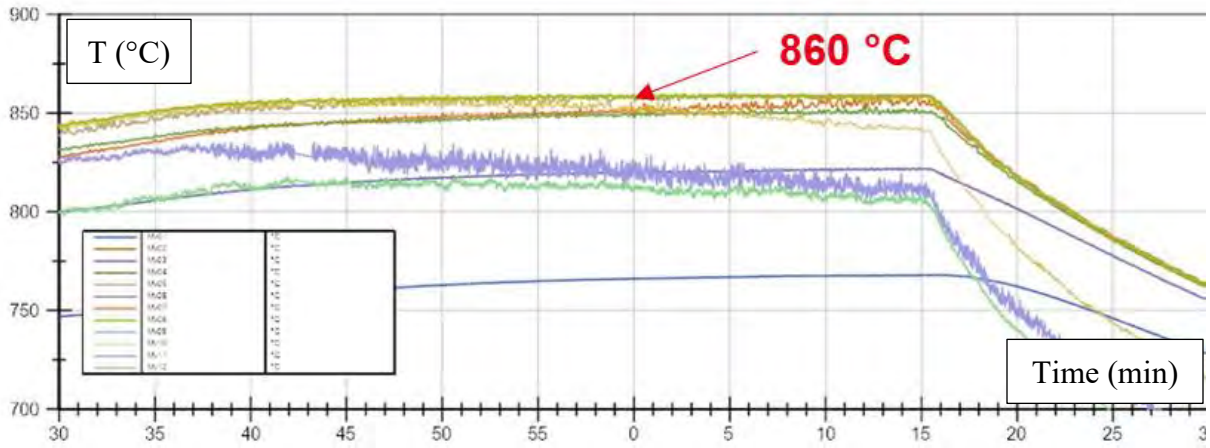

Figure 8: Sodium temperature measurements at the end of ESCOBAR experiments

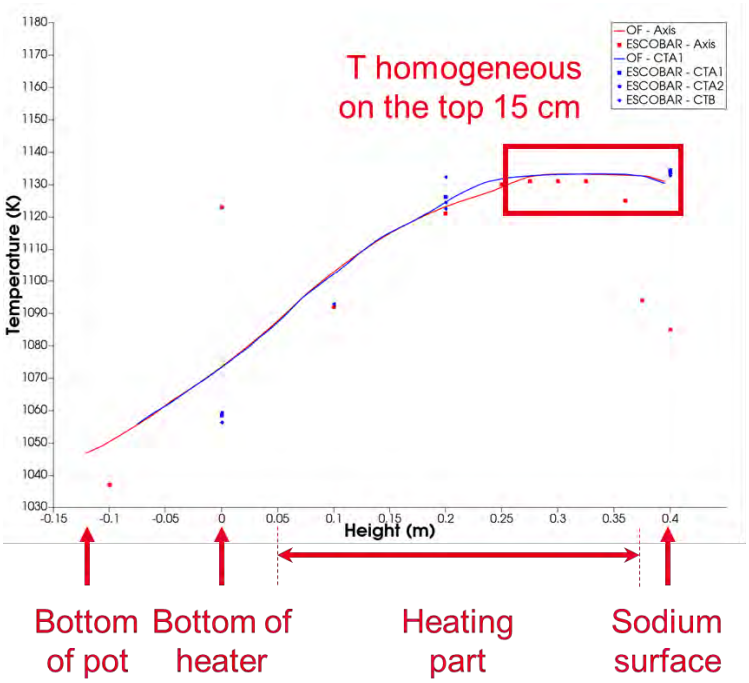

Figure 9: Comparison of simulation results with ESCOBAR experimental data on the central axis

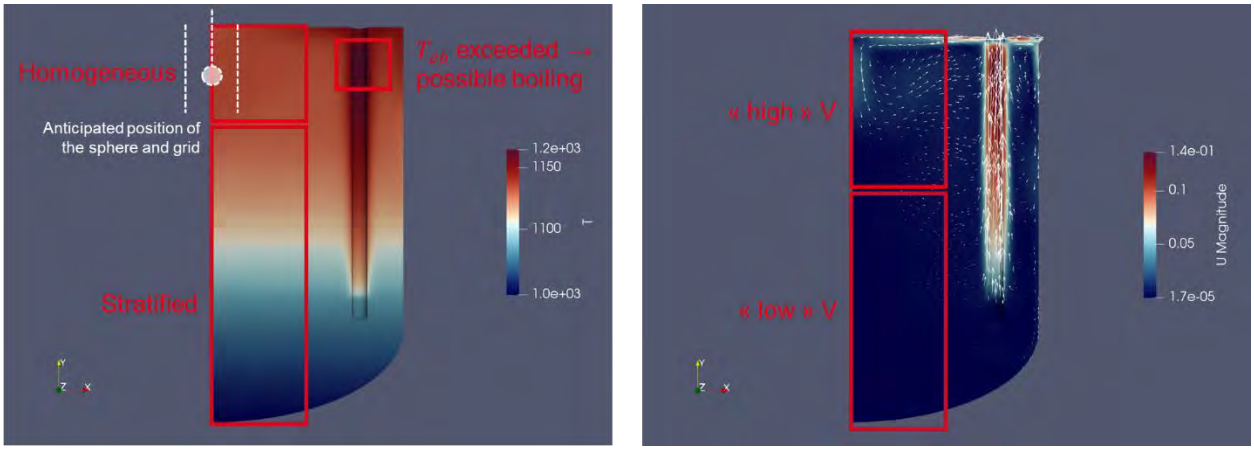
The temperature (Figure 10a) and velocity (Figure 10b) fields in the adjusted model reveal that before the arrival of the heated sphere in the SERUA experiments, the sodium temperature should be almost homogeneous in a ~Ø15 x 15 cm cylinder near the top center of the pool, which is where the sphere and instrumented grid will be placed (white dashed lines on the figure). Furthermore, a moderate velocity of ~3 cm/s is calculated in this homogeneous temperature zone. Considering the adopted boundary conditions for the simulations (symmetry planes at the lateral boundaries), this value constitutes a maximum rather than a real estimate of the sodium velocity in the future SERUA experiments, but it remains an interesting order of magnitude for their interpretation.



(a) **(b)**

Figure 10: (a) Temperature and (b) velocity fields calculated in the sodium at the end of ESCOBAR experiments

4.3 Further qualification and commissioning activities

The SERUA experimental device is currently under construction at the CEA Cadarache center. After completion of its assembly, a qualification test program in air is planned, which will consist in validating the operability and safety of the facility in the various configurable configurations such as (the list is not exhaustive): the argon inerting of the induction furnace; the heating of the sphere; the high-velocity transfer of the sphere in argon; the slow-velocity movement at the moment of the immersion of the sphere in the sodium; the holding time in the sodium bath. The commissioning of the facility is planned at the end of 2026.

5 CONCLUSIONS

The objective of the SERUA experiments is the characterization of film boiling regimes in liquid sodium close to saturation, which is a key-aspect for the modelling of Fuel-Coolant Interaction (FCI) during a severe accident in a Sodium-cooled Fast neutron Reactor. More particularly, it should provide validated heat transfer correlations for the heat transfer coefficient between corium droplets and sodium, and transition temperatures for the boiling regime, to be implemented into FCI simulation codes like SCONE as a sub-mesh model.

The experimental device is inspired by experiments conducted by Farahat in 1972, which remain the only experiments of this kind performed with sodium, and is intended to improve those results in terms of precision and reliability. The principle of the experiment consists in i) heating a tantalum sphere up to ~2300 °C with induction; ii) stabilize the temperature of a sodium pool close to the saturation point of the sodium; iii) quench the heated sphere into the sodium.

The facility is currently under construction at the CEA Cadarache center. A dedicated qualification program has been conducted in order to demonstrate that the desired experimental conditions are achievable with accurate precision and stability. The induction heating of the sphere at 2300 °C is feasible, and it will be measured in two points in the sphere using a duplex thermocouple during the quenching. The sodium temperature can be regulated at 860 °C during ~30 min with sufficient stability and homogeneity and it will be monitored during the quench by a specific instrumented grid immersed into the sodium. The sphere characteristics (initial temperature, emissivity) can be characterized by use of a dedicated pyrometry instrumentation. This will allow to measure the wall temperature, heat flux and heat exchange coefficients in all boiling regimes.

After completion of the experimental device assembly, the end of the qualification program and commissioning is anticipated by the end of 2026.

ACKNOWLEDGEMENTS

The authors express their warmest acknowledgements to Dr. Magali ZABIEGO, Dr. Alix LE BELGUET and Dr. Georges BERTHOUD who originally proposed the SERUA experiment and demonstrated its scientific interest.

Induction heating qualification test of the SERUA sphere

12th Conference on Severe Accident Research, ERMSAR 2026, Madrid, Spain, 18-22 may, 2026

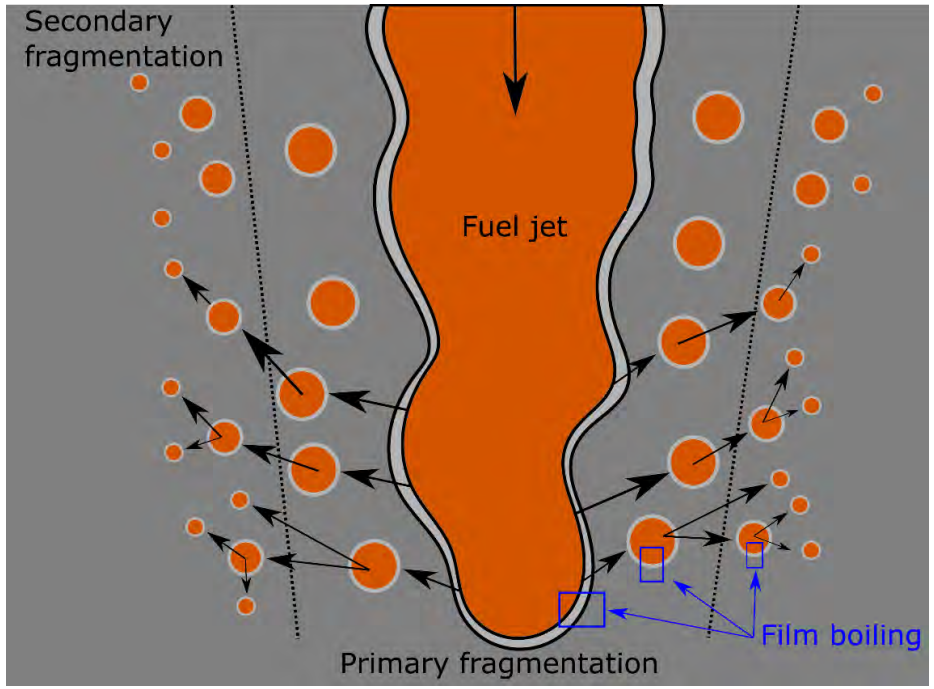
Why studying film boiling in liquid sodium?

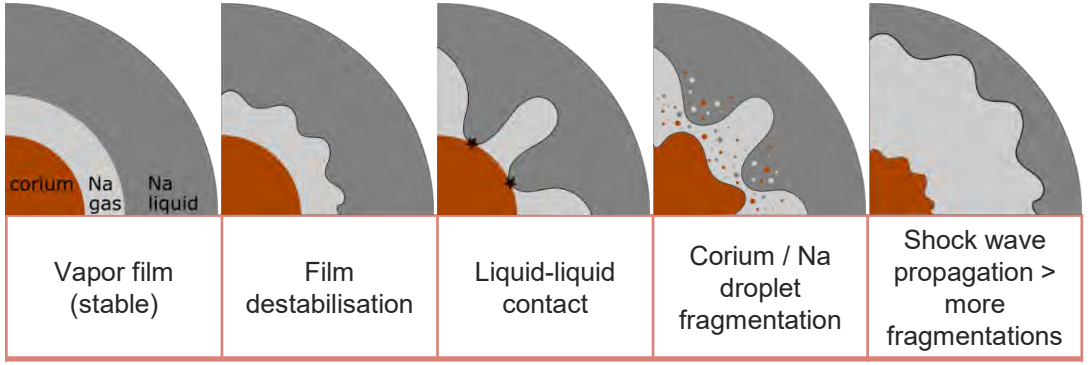
Modelling of **Fuel-Coolant Interaction** in Severe Accident Situation in a **Sodium** Fast-neutron Reactor

- Contact between high T corium (~3000 K) and “low” T liquid coolant (~1000 K) > **Na film boiling around corium**
- Risk: **“steam” explosion**, resulting from:
  - High **Na vaporisation** rate, due to
  - An increasing **heat exchange surface**, due to
  - The **fragmentation** of the corium:
    - Primary fragmentation > hydrodynamic constraint
    - Secondary fragmentation
      - Mechanical > Na droplet entrainment into corium
      - Thermal > Liquid-liquid contact > shock wave / **vapor film destabilisation**
- Vapor film destabilisation > **“trigger” for steam explosion**
  - Necessary to predict the occurrence and energy of the steam explosion
  - Need to rely on validated correlation(s) for film boiling heat transfer (vapor production) and boiling regime transitions

Objective: Calibration of FCI numerical simulation software like **SCONE**

(Software for COrium Na interaction Evaluation)





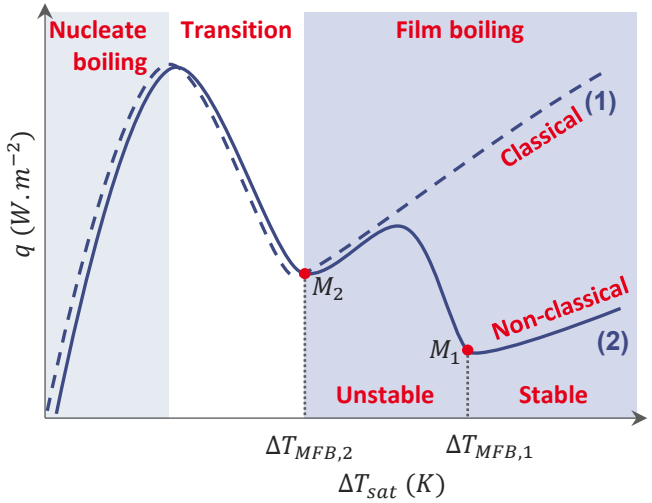
Current state of knowledge on film boiling in liquid sodium

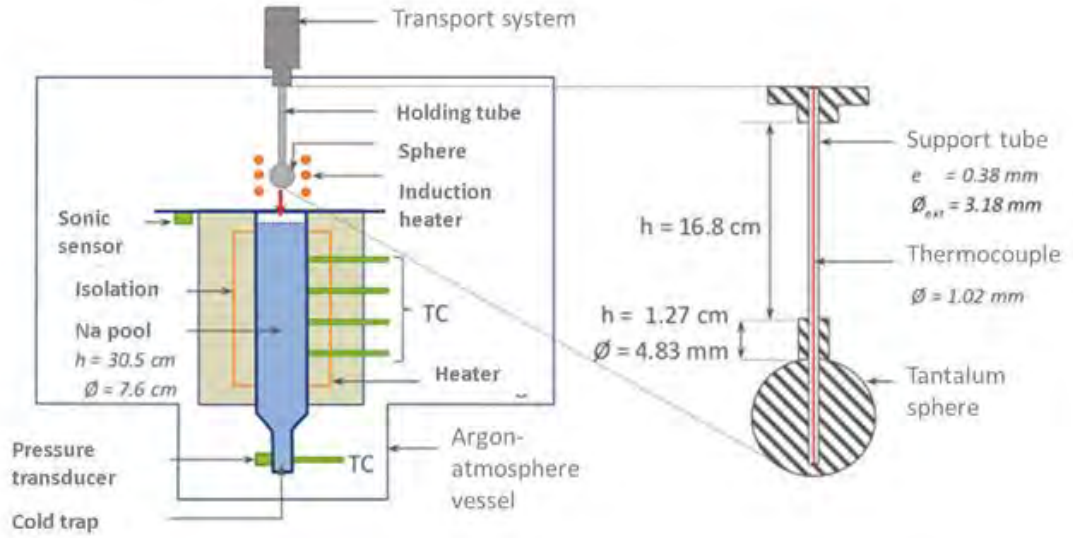
Theory: Nukiyama curve around a sphere with imposed wall temperature

- Non-classical form (2): 2 film boiling sub-regimes:
  - Stable: high contact T (above M1), low flux
  - Unstable: lower contact T (between M1 – M2), liquid Na/sphere contacts, higher flux

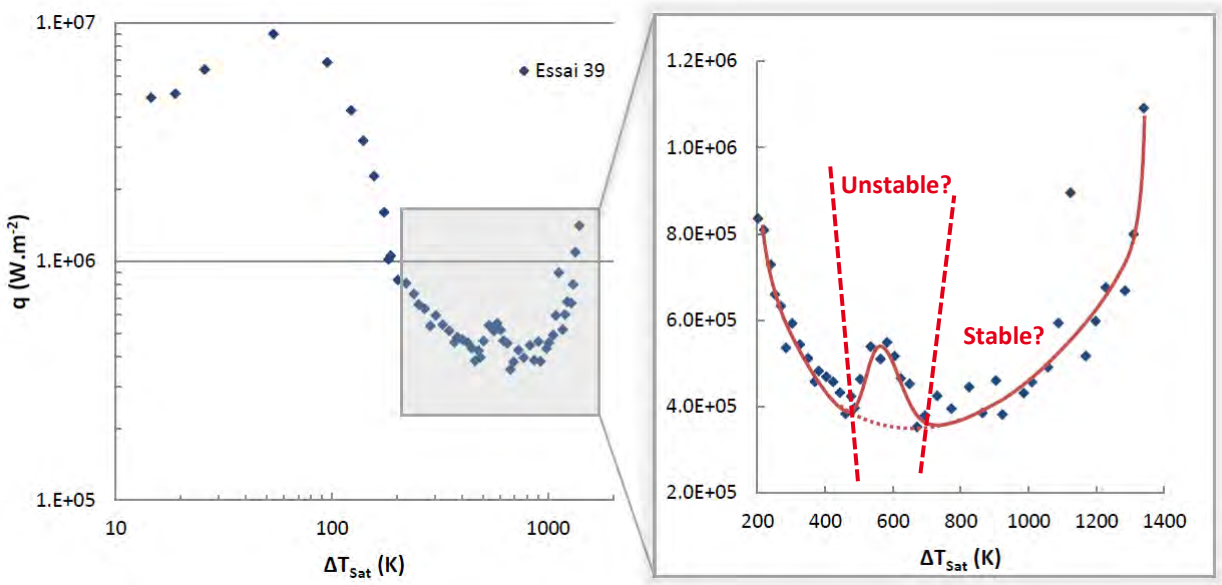
Experimental observations:

- Complex physical phenomena > experiments with simulant fluid irrelevant for quantitative predictions
- **Only one experimental program in sodium: Farahat, 1972** > Confirmation of general phenomenology but uncertainties are too important for the needs of the simulation tools





Farahat (1972) experimental setup



Shape of the heat flux density at the wall with respect to the wall overheat (Le Belguet, 2013)

SERUA experimental program at CEA

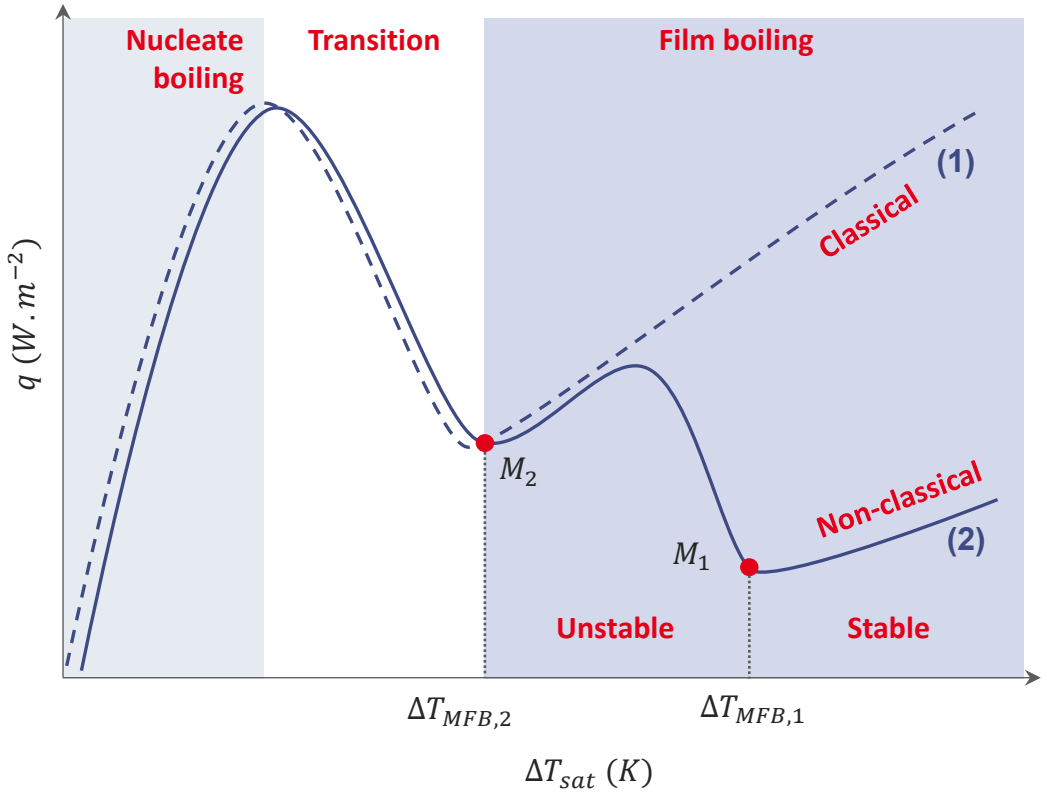
Sodium boiling Experimental Rig for Understanding of fuel-coolant interAction

Objective: fill the knowledge gaps left after Farahat experiments:

- Describe the Na boiling curve
  - Measure the heat exchanges in the different boiling regimes
  - Characterize the transitions between boiling regimes

- Experimental parameters
  - Sphere initial temperature ~2000 – 2500 °C
  - Na temperature ~800 – 870 °C
  - Sphere diameter ~12 – 25 mm

- Measurements: 2-points TC sensors to measure:
  - Transient heat flux in all the boiling regimes (Stable film, unstable film, transition, nucleate)
  - Wall temperature evolution

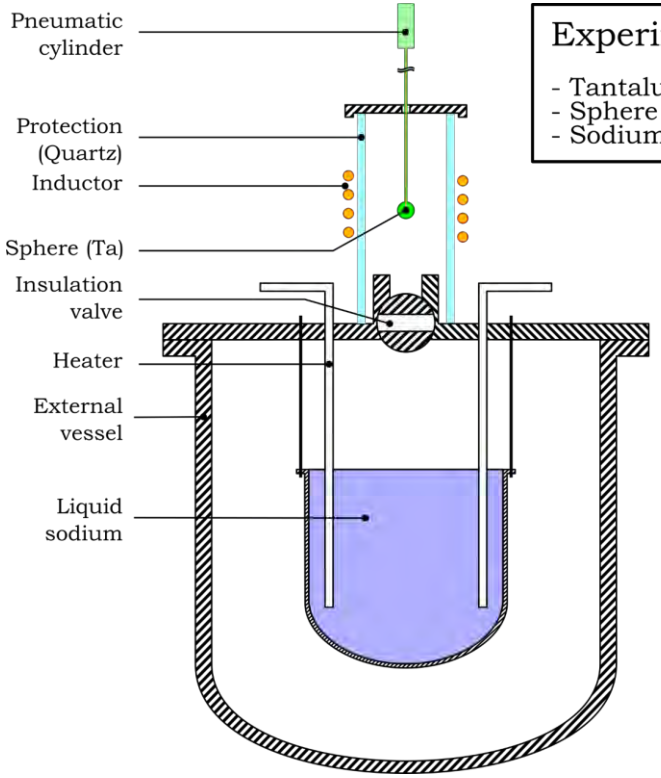


Conceptual design of SERUA experiments

1 – Inductive heating of the Tantalum sphere ~2500 °C

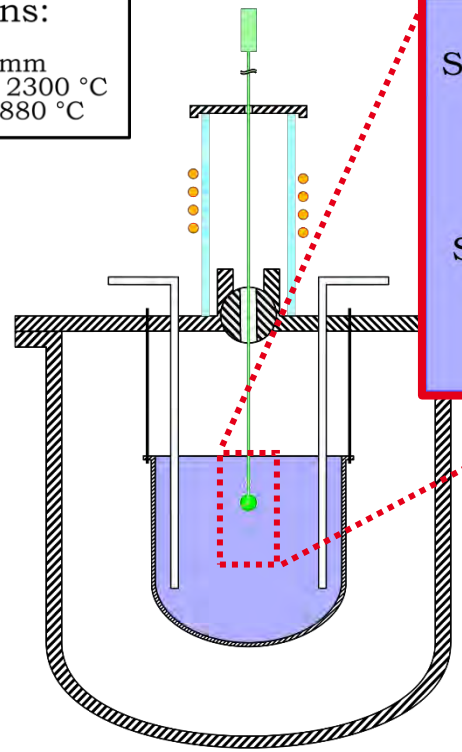
2 – Sphere quenching in sodium (~870 °C)

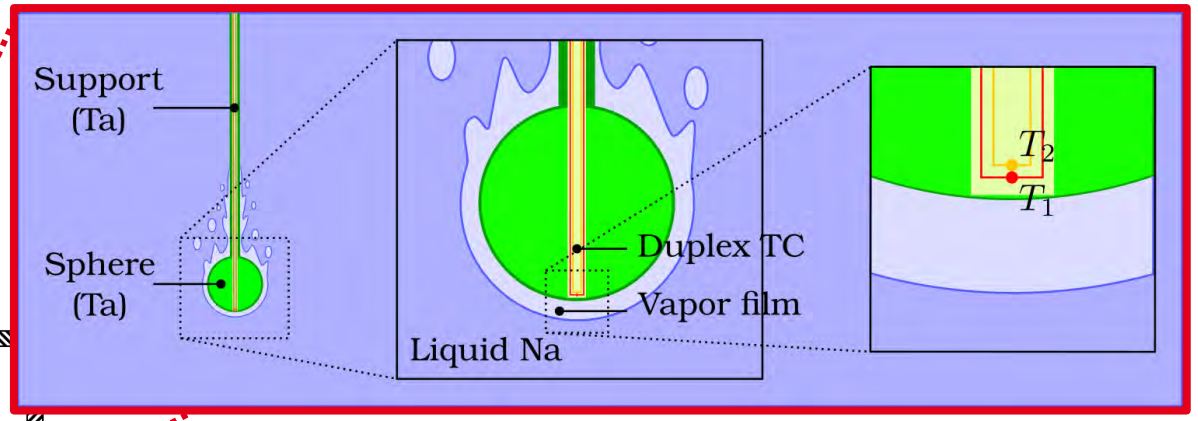
3 – Study of film boiling around the sphere



Experimental conditions:

- Tantalum sphere size: 25.4 mm
- Sphere temperature: 1500 - 2300 °C
- Sodium temperature: 400 - 880 °C





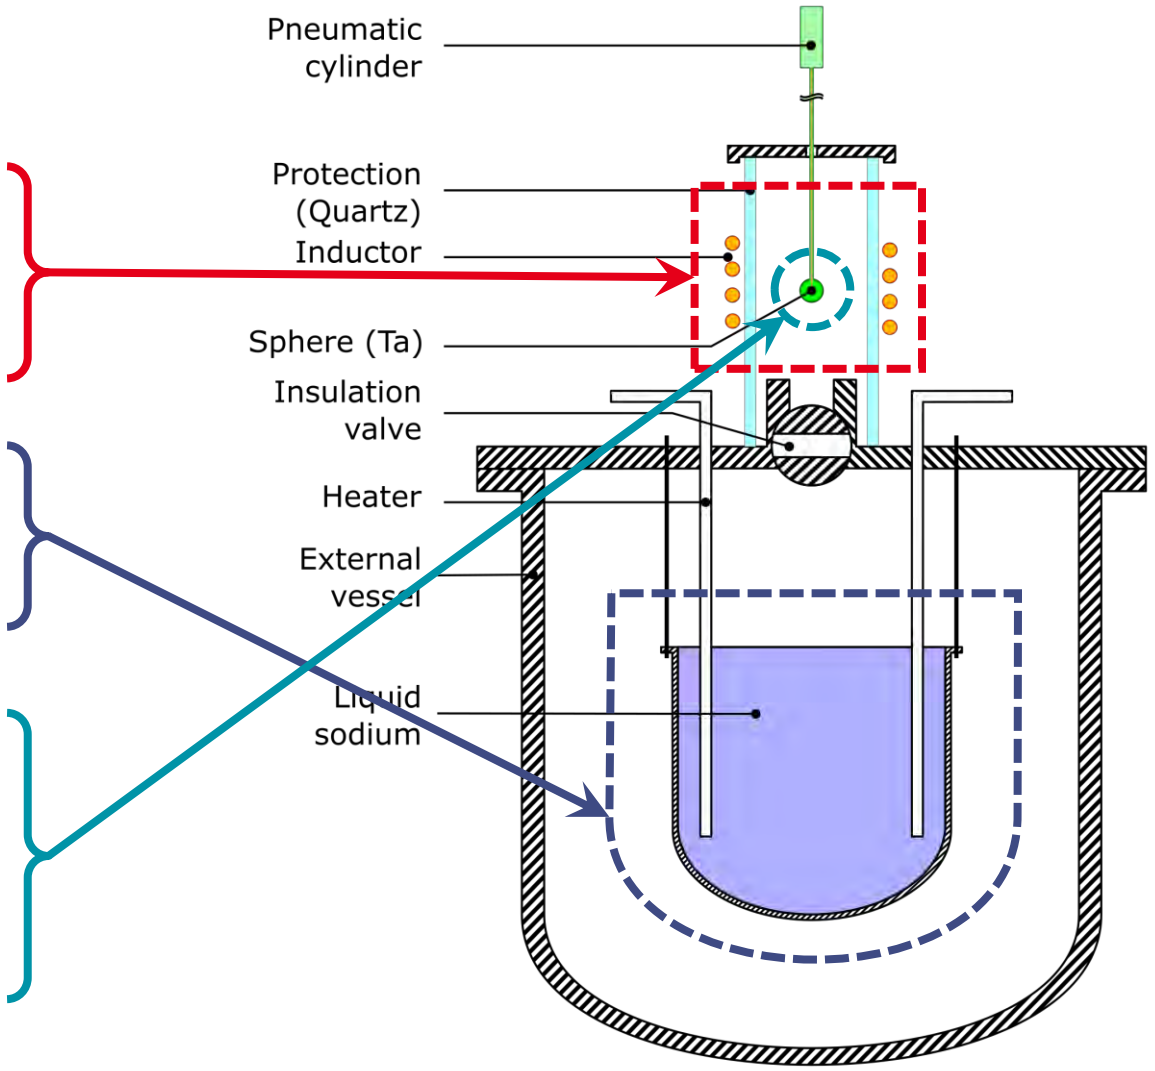
Study of boiling regimes at imposed temperature ($\varphi - \Delta T$):

- Film boiling (beyond Leidenfrost point)
- Transition (below Leidenfrost point)
- Nucleate boiling (end of experiment)

From the conceptual design to actual experiments

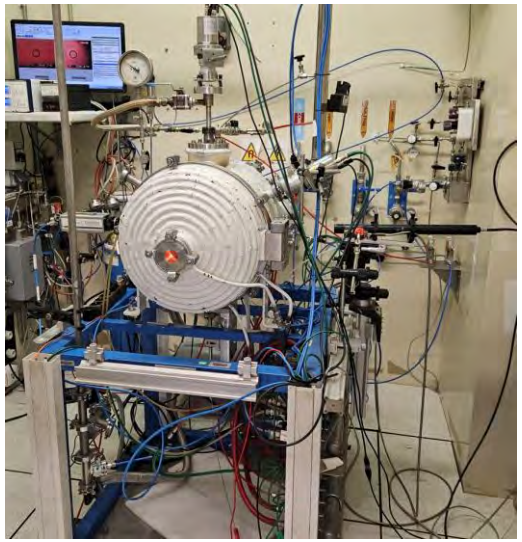
3 technological challenges:

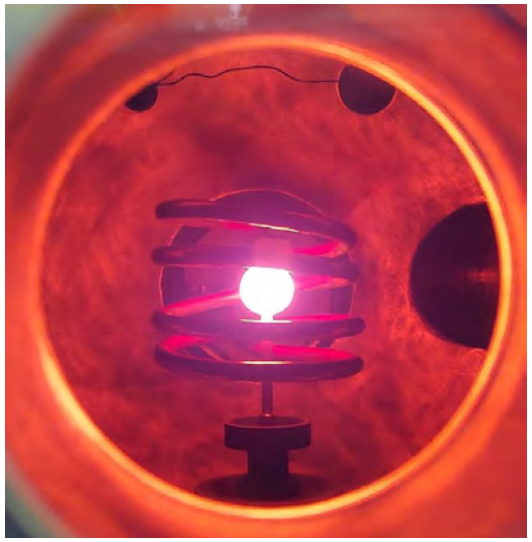
- **Sphere heating system** (~2500 °C)
  - Induction generator
  - Insulation from environment
- **Na pool control**
  - Heating (~870 °C)
  - T / v characterization
- **Sphere design and characterization**
  - Initial surface temperature measurement and emissivity
  - Surface temperature and heat flux during quench



Sphere heating system: Induction generator

VITI





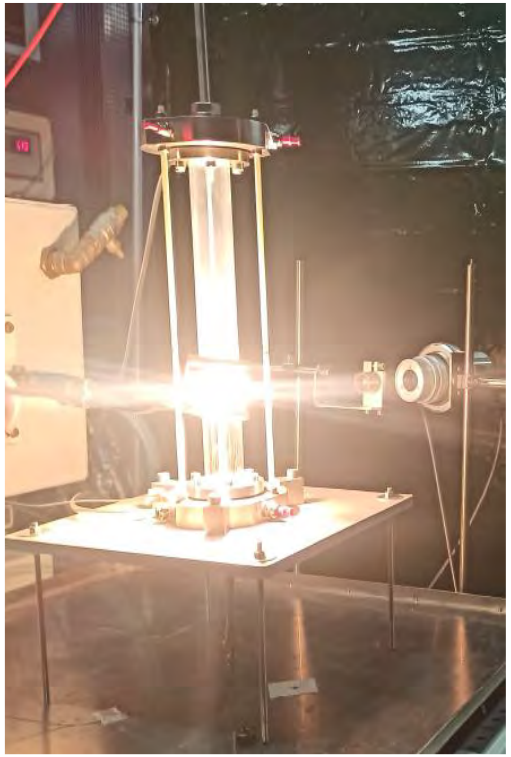
Technological qualification

- Inductive heating up to 2300 °C → OK

Sphere characterization and instrumentation

- Emissivity of the sphere
- Pyrometry and thermal camera

PELE

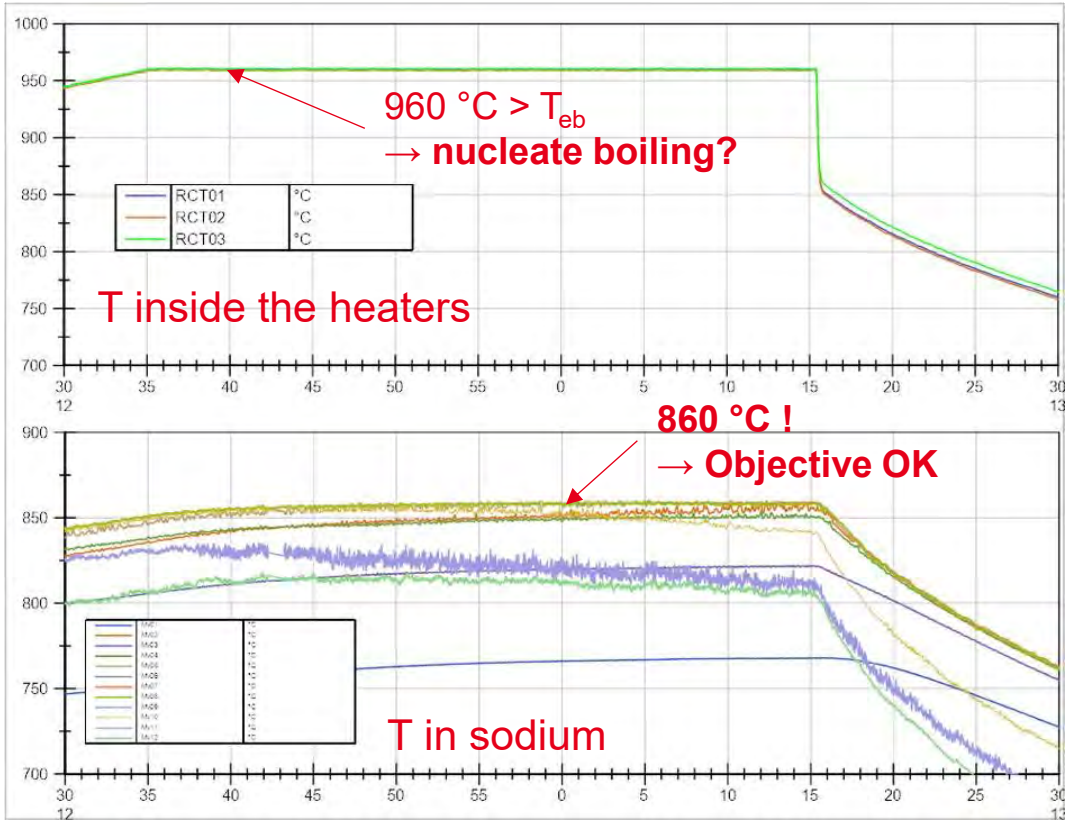


Transposition to the sodium platform

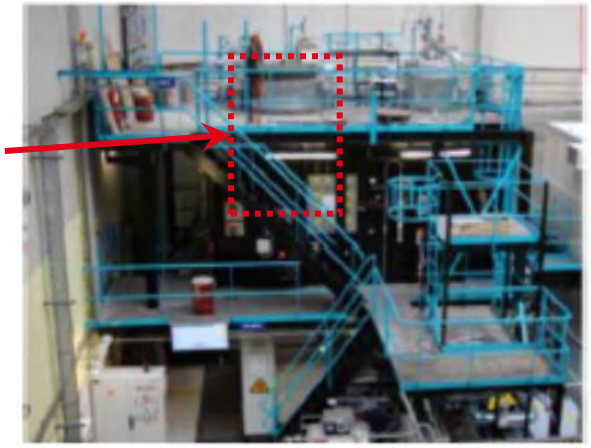
- Adapted induction generator
- Quartz tube for isolation
- Laser welding of the sphere and its support

Na pool control: ESCOBAR experiments

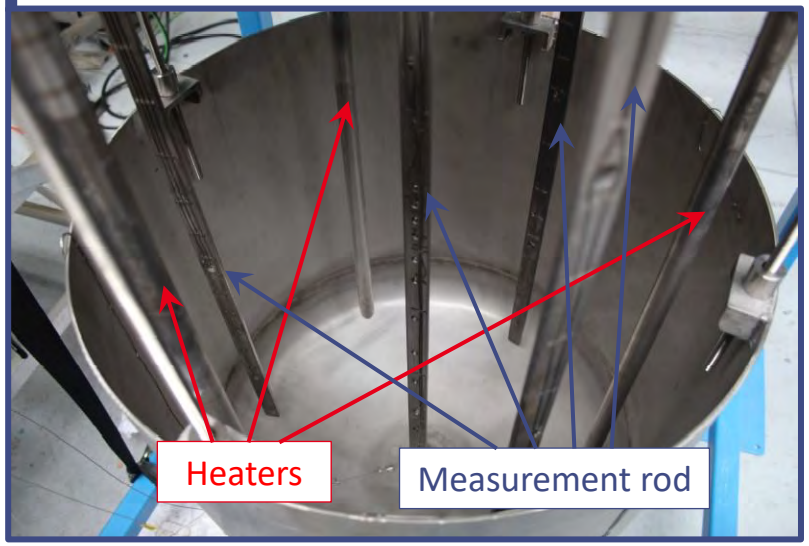
Goal : achieve stable liquid sodium heating at ~860 °C



DOLMEN sodium pot



Experimental pot and instrumentation (before insertion inside the vessel and filling with sodium)

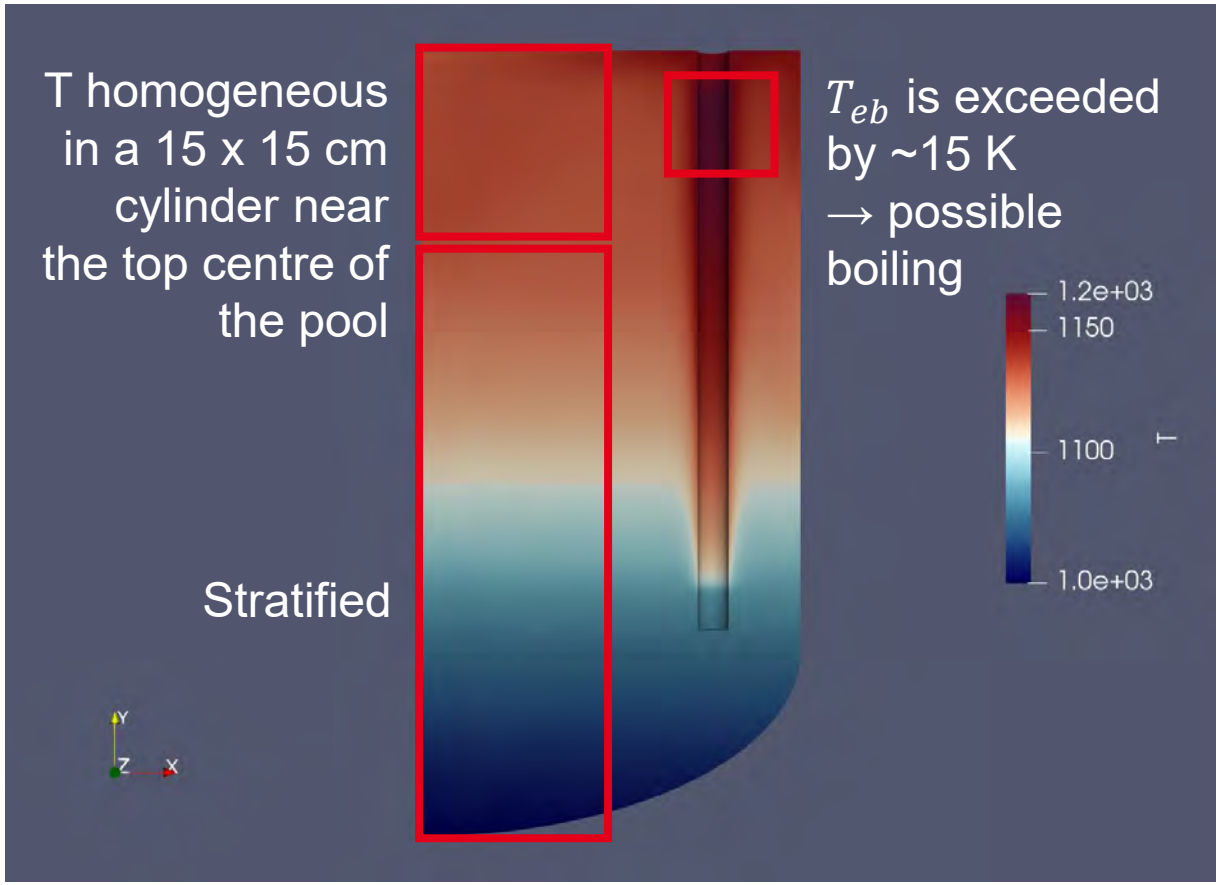


Fully assembled experimental pot during its transfer towards the DOLMEN facility

Na pool control: CFD study (OpenFoam)

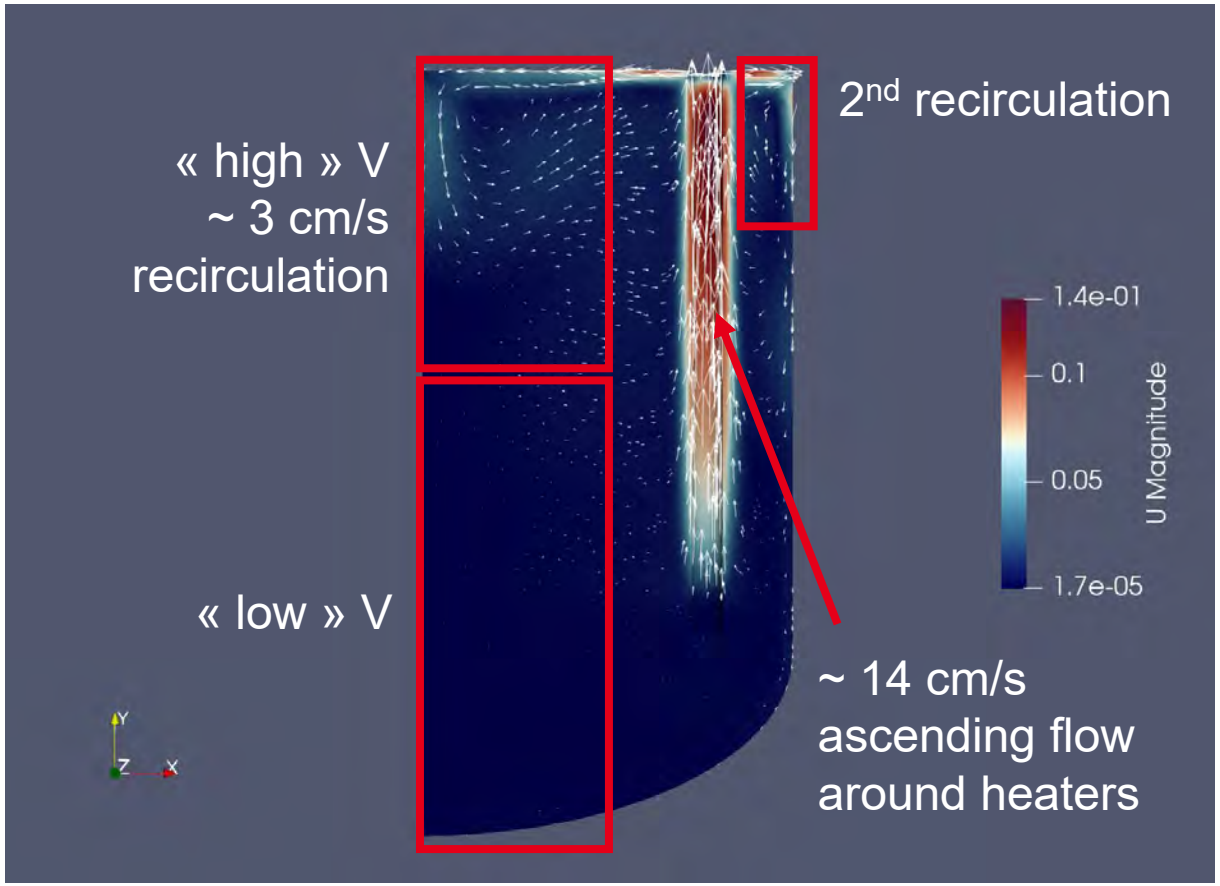
3D calculation

- 1/3 test section
- Satisfactory agreement with experiment

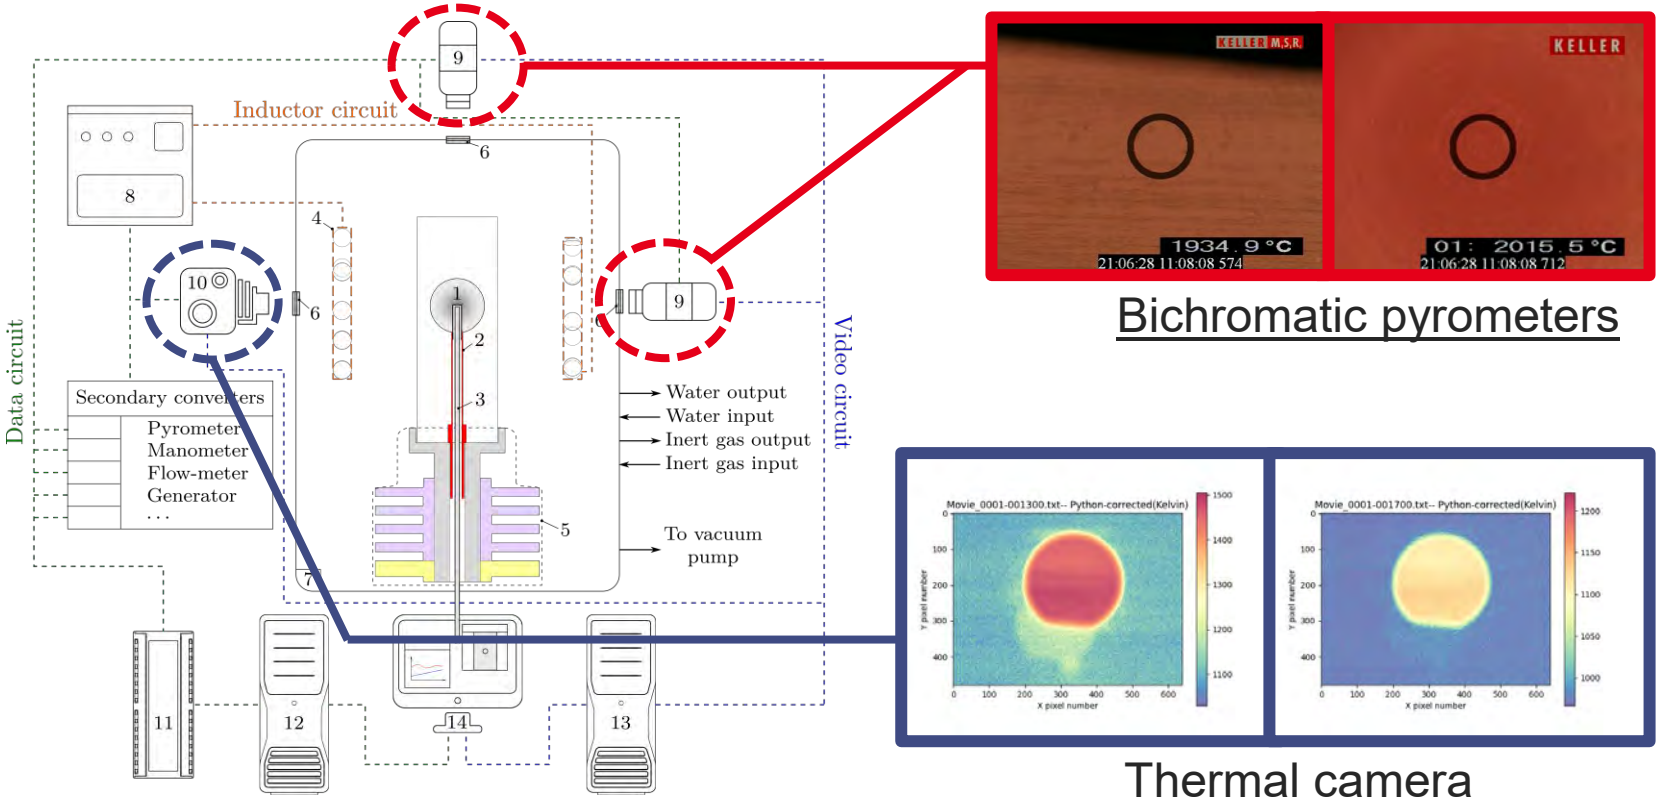


Open Foam model

- buoyantBoussinesqSimpleFoam solver (steady-state)
- Natural convection with turbulence model



Sphere design and caracterisation: Initial surface temperature measurement and emissivity



Bichromatic pyrometers

Thermal camera

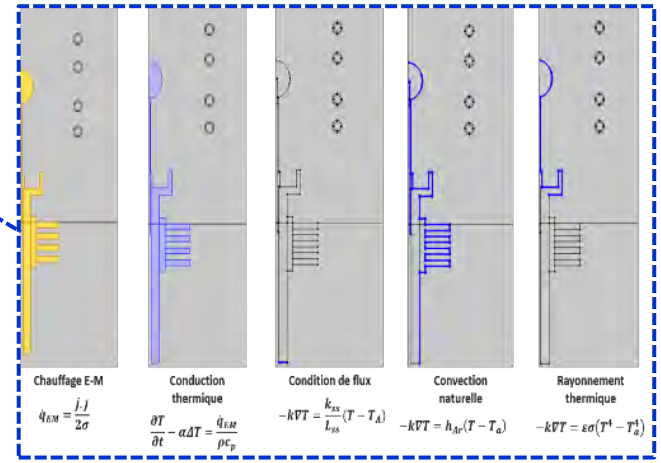
Instrumentation used in VITI qualification tests

To be used in SERUA

The sphere emissivity is required:

- Pyrometers and thermal camera provide black-body temperatures → The sphere **spectral emissivity is needed** to correct black-body temperatures
- The sphere **total emissivity is needed** to interpret the SERUA experiments

Sphere design and caracterisation: Initial surface temperature measurement and emissivity



Experiment

Bichromatic Pyrometer → $T_{\lambda 1}, T_{\lambda 2}, T_c$

Emissivity leading to $T_{\lambda_1}^{cor} = T_{\lambda_2}^{cor} = T_c^{cor}$ → $\varepsilon_\lambda(T), T$

Experimental temperature at $\theta = 90°$

COMSOL model

(initial guess) $\varepsilon_\cap(T)$

$T(\theta)$ ← Solve T field

Calculated temperature at $\theta = 90°$

Comparison

Acceptable difference ?

YES → SERUA heating predictive model

NO → Correction of the total hemispheric emissivity law → $\varepsilon_\cap^{cor}(T)$

Sphere design and caracterisation: T measurement

Required output data

- Wall temperature T_W
- Wall heat flux density φ_W

Measurements → **Duplex TC**

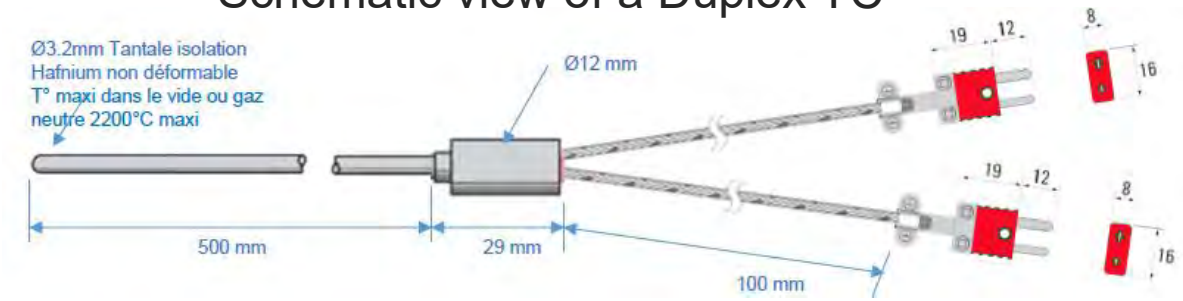
- Temperature T_1 at $r = r_1$
- Temperature T_2 at $r = r_2$

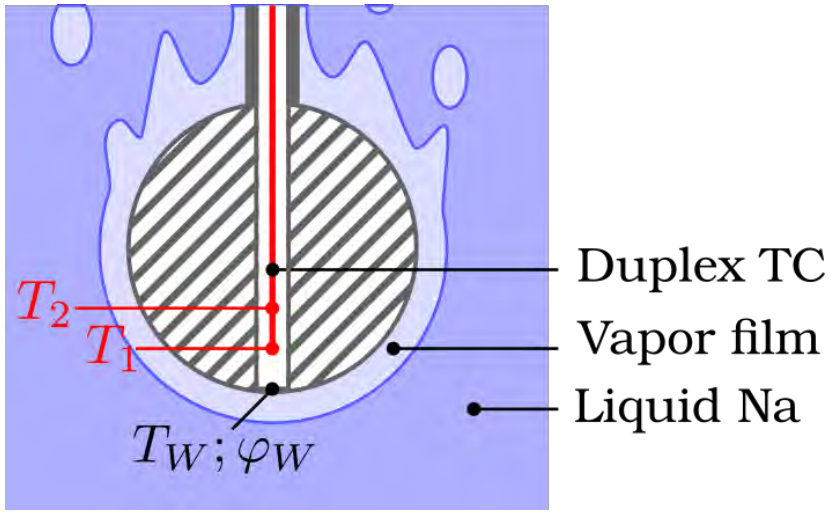
→ Resolution of an **inverse problem**

Methodology (work in progress)

- Resolution of Fourier Equation in the Laplace space using temperature measurements T_1 and T_2
- Laplace inversion → T_W and φ_W

Schematic view of a Duplex TC





Conclusions

Objectives of the SERUA experiments:

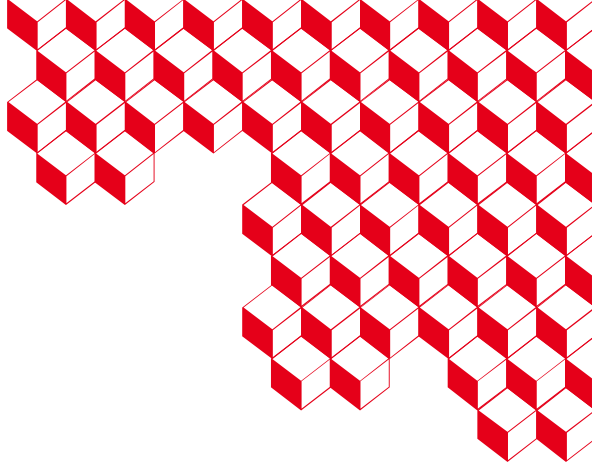
- Characterisation of film boiling regimes in liquid sodium close to saturation
- Get a more precise insight compared to the reference experiments by Farahat in 1972
- Necessary input for Fuel-Coolant Interaction simulation codes (SCONE)

Perspectives

- Completion of the instrumentation of the sphere
- Device assembly and commissioning by the end of 2026
- First test in 2027

Technical issues and current status

- Sphere heating system (~2300 °C) → OK
- Na pool heating (~870 °C) and control
  - Stable heating at 860 °C → OK
  - Temperature homogeneity and velocity field investigated by CFD simulation
- Sphere design and characterization
  - Determination of the initial temperature by pyrometry → OK
  - Methodology for emissivity characterisation
  - Measurement interpretation for the determination of wall temperature and heat flux → On-progress



Thank you!

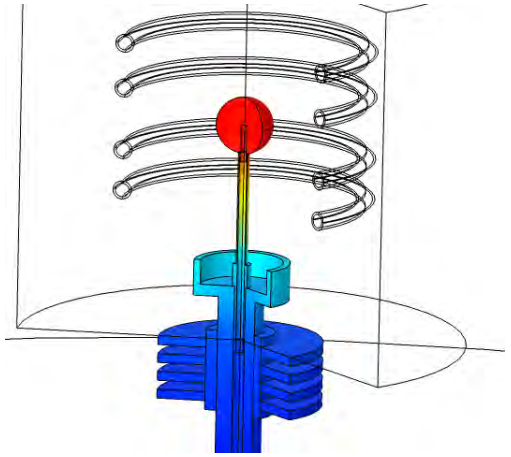
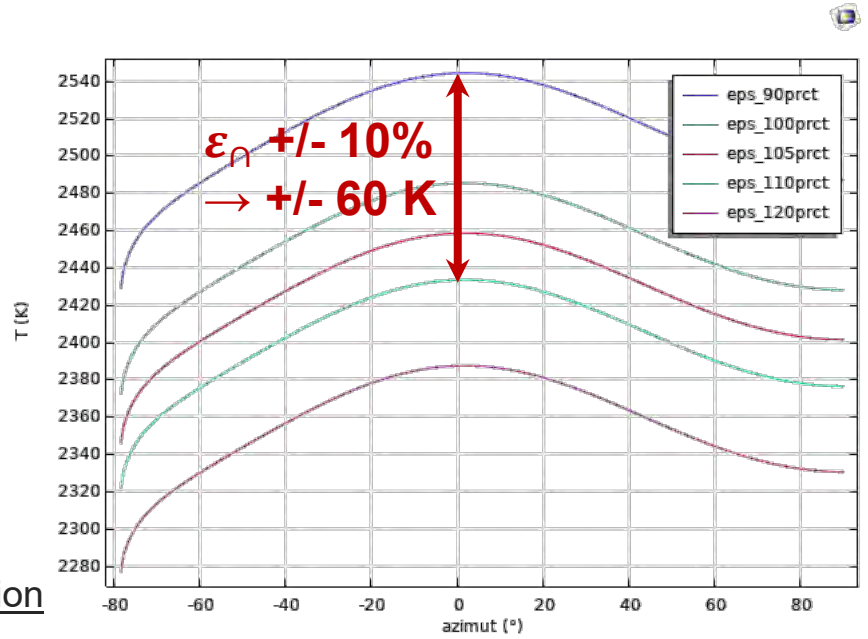
Appendix

Sphere design and caracterisation: Emissivity

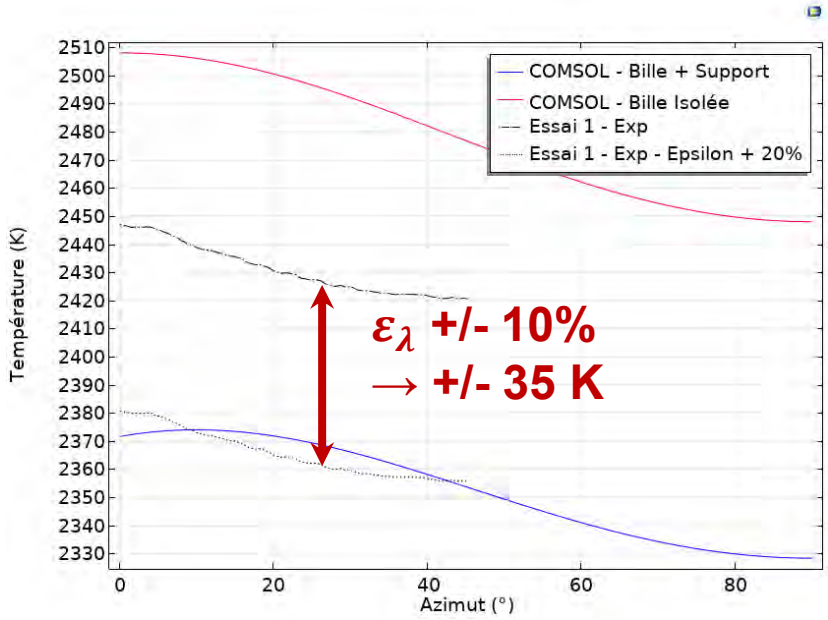


COMSOL model for the VITI configuration

- Tantalum sphere – central hole
- Tantalum tube
- Graphite support



Sensitivity of the surface temperature to emissivity

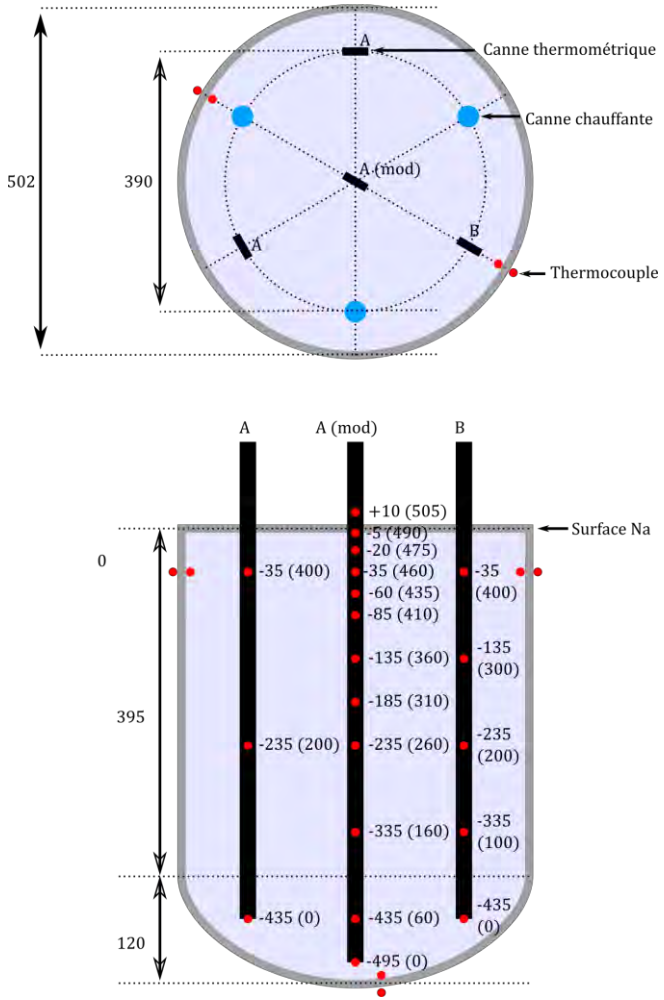


Sensitivity of the corrected black-body temperature to emissivity

On the importance of the spectral emissivity ε for pyrometry measurement interpretation

- **Significant sensitivity on ε** of both calculated and measured temperatures regarding the desired precision for SERUA
- **Significant uncertainty** on this parameter: at least 30%
- *In situ* characterisation is necessary → A **specific methodology** has been developed

Instrumentation and physical conditions



Heating:

- 3 heaters (4,9 kW each) regularly located in the pool

Instrumentation (thermocouples)

- 4 measurement rods (measure the temperature profile along the rod)
- Thermocouples on the experiment pot (internal / external)

Na physical properties	
ρ	744 kg.m^{-3}
β	3,40×10^{-4} K^{-1}
k	49,4 W.m^{-1}.K^{-1}
c_p	1280 J.kg^{-1}.K^{-1}
α	5,19×10^{-5} m^2.s^{-1}
μ	1,59×10^{-4} Pa.s
ν	2,14×10^{-7} m^2.s^{-1}

Turbulent natural convection in the liquid pool.

Turbulence around the heaters is characterized by the Grashof number:

$$Gr = \frac{g\beta\Delta T L^3}{\nu^2} = 5 \times 10^{10} > 10^9 \Rightarrow \text{Turbulent}$$

Prandtl number for sodium

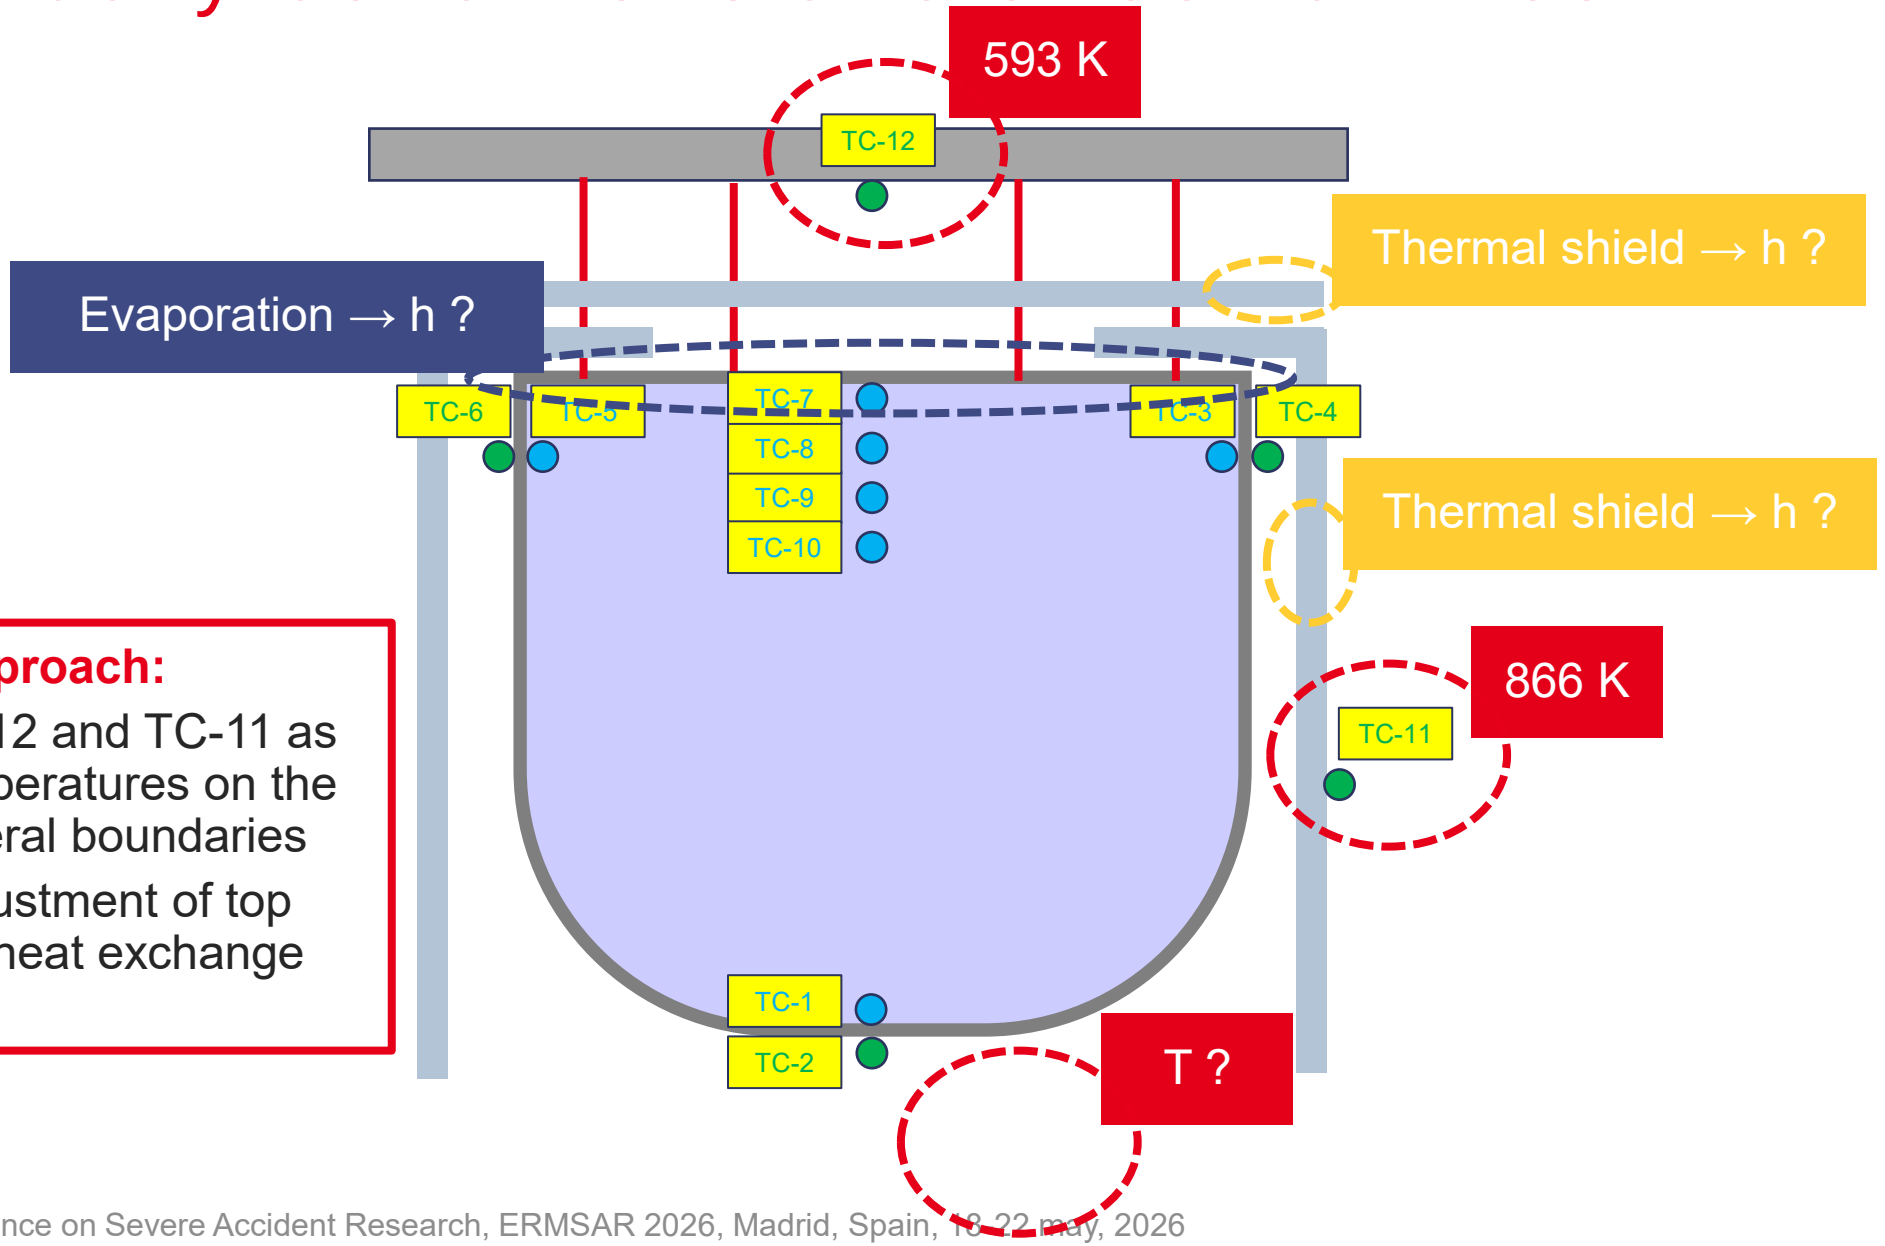
$$Pr = \frac{\nu}{\alpha} = 4 \times 10^{-3} \ll 1$$

$$\Rightarrow \text{heat diffusion} \gg \text{momentum diffusion}$$

- **Need to check that the used turbulence model is adapted to low Pr numbers**

Physical conditions	
g	9,81 m.s^{-2}
β	3,40×10^{-4} K^{-1}
ΔT	~20 K
L	0,325 m

Boundary conditions and uncertainties



Modelling approach:

- Use of TC-12 and TC-11 as “room” temperatures on the top and lateral boundaries
- Manual adjustment of top and lateral heat exchange coefficients

Validation of turbulence models

Experiment by Betts et and Bokhari

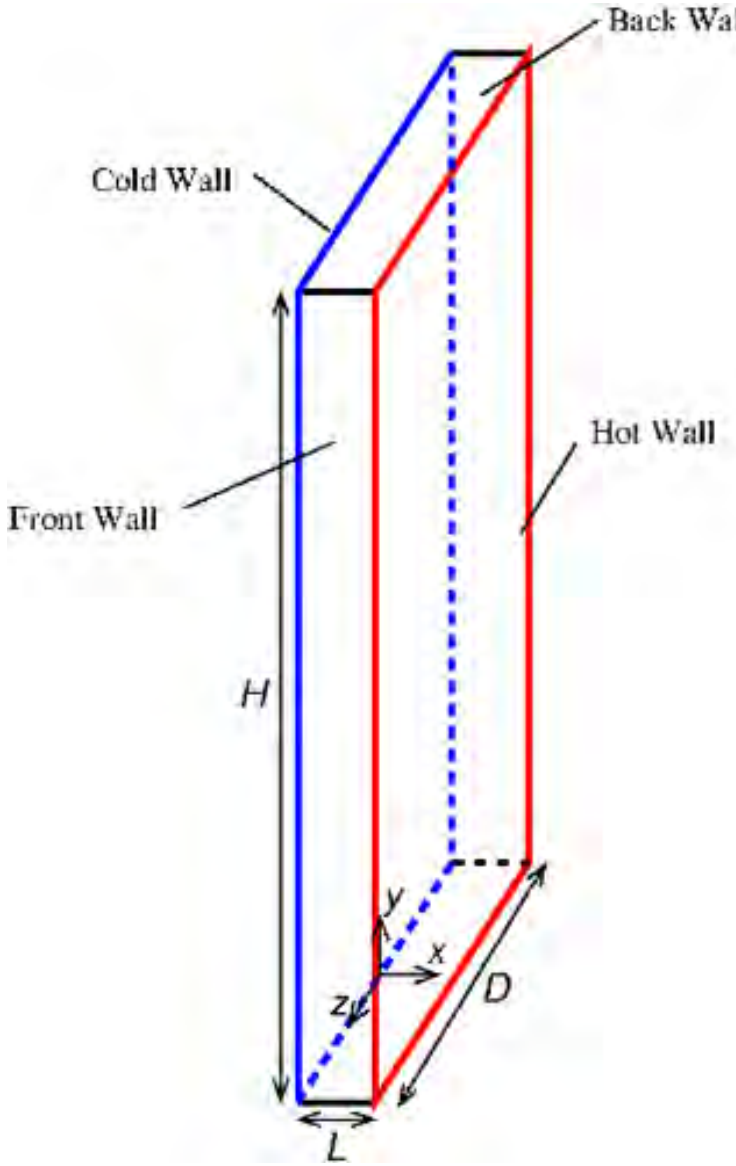
- Imposed temperatures at both walls
- $Gr = 8.5 \times 10^5$
- $Pr = 0.704$

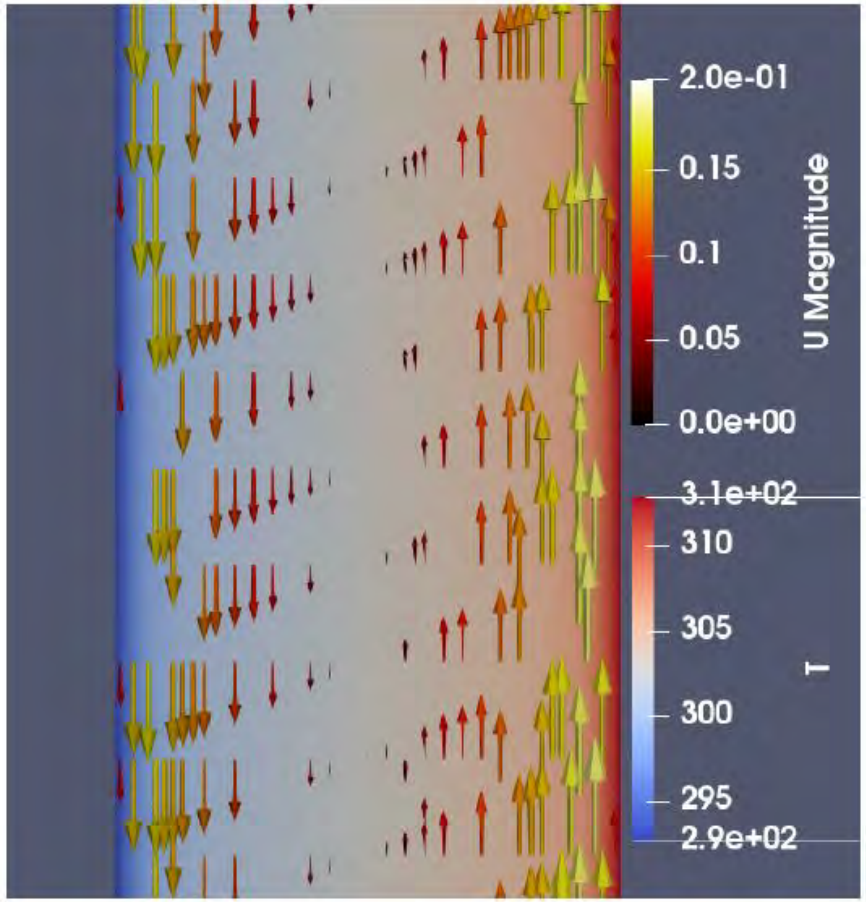
Geometry of the benchmark case:

- L = 76 mm
- H = 2.18 m
- D = 260 mm

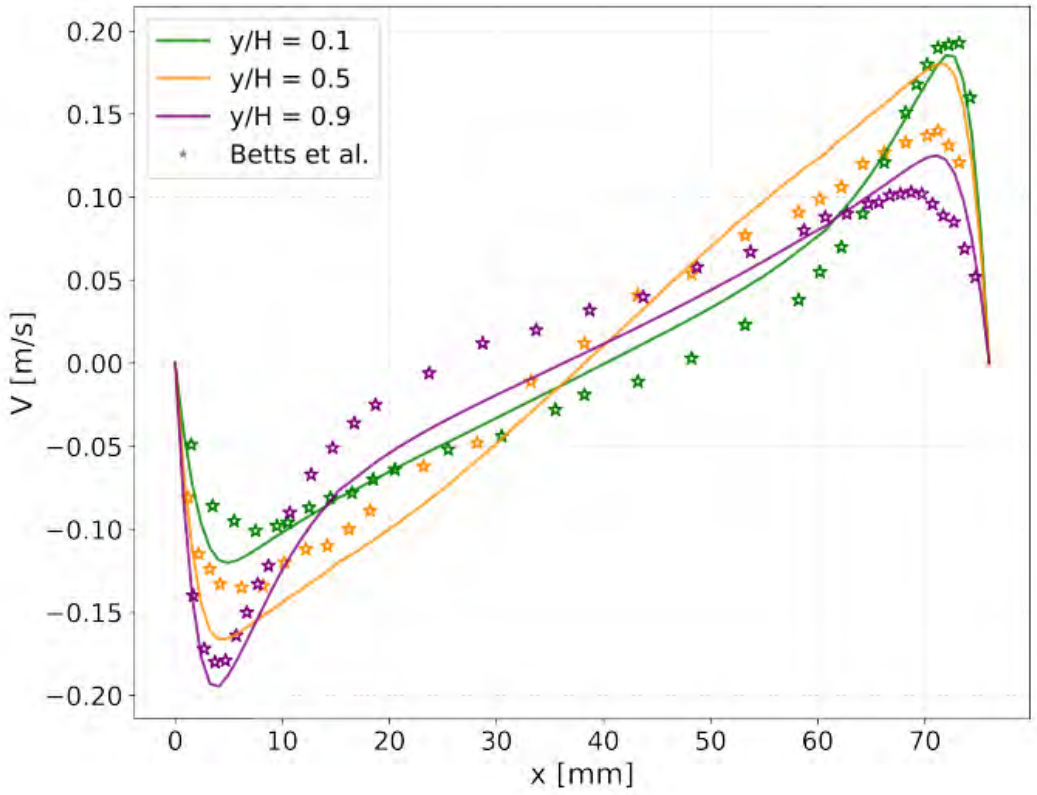
Available data:

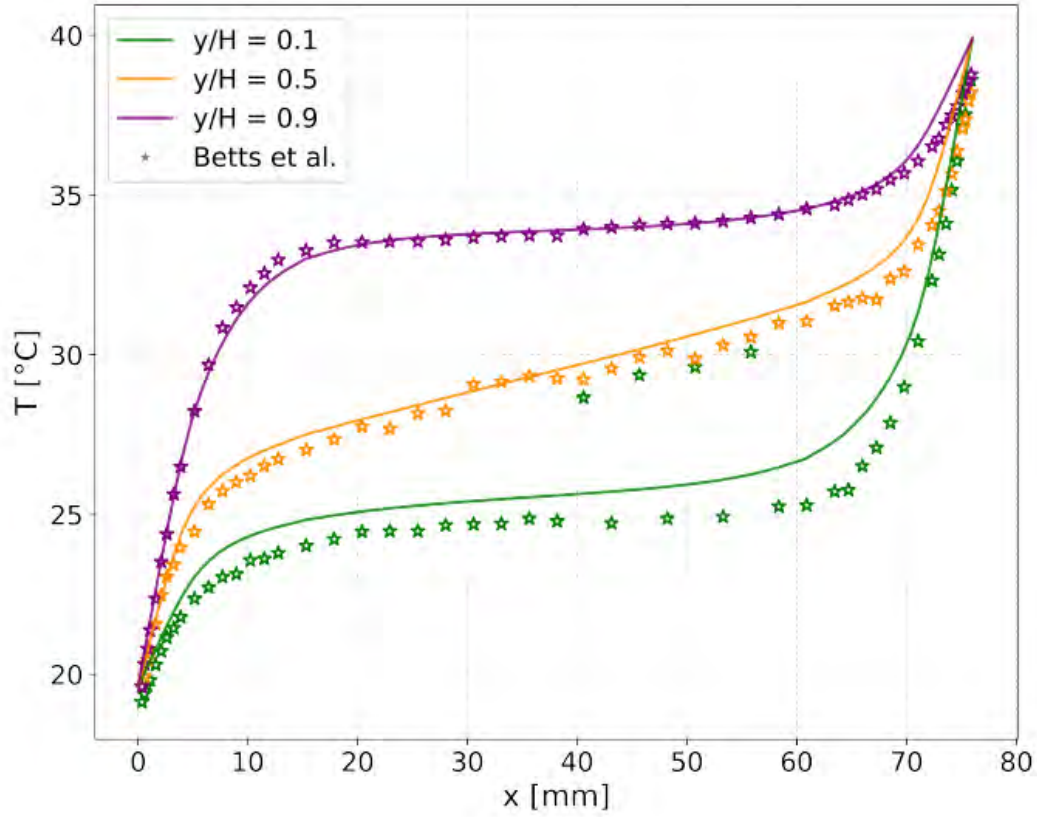
- Mean Temperature profiles
- Mean Vertical Velocity profiles





Validation of turbulence models

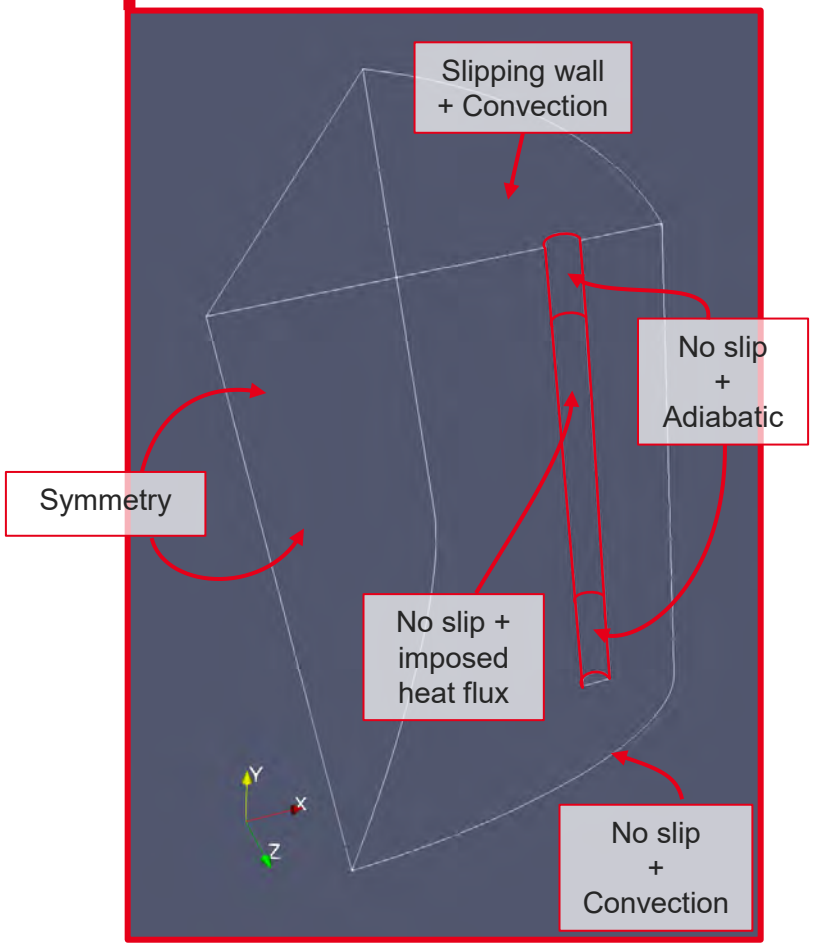




Good agreement between simulation and experimental data

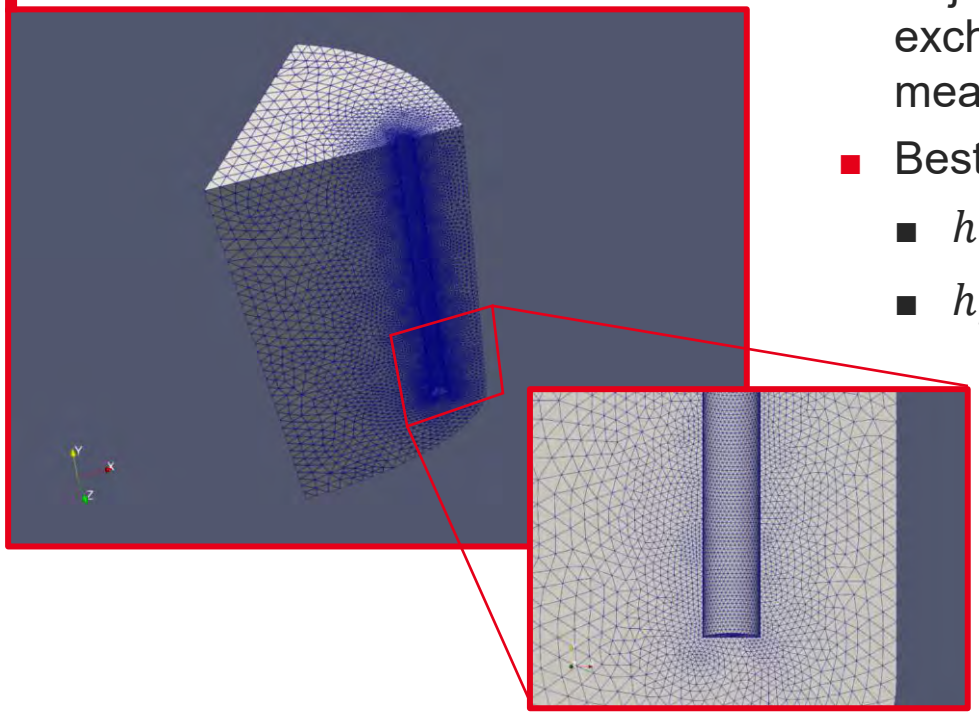
Modelling approach

1/3 test section



Open Foam model

- buoyantBoussinesqSimpleFoam solver
- Natural convection
- Steady-state
- Turbulence



Method:

- Validation of turbulence models on similar experiments
- Modelling of the test section with adapted boundary conditions
- Adjustment of external heat exchange coefficients to match the measured temperature profiles
- Best-match values:
  - $h_{top} = 60\ W.m^{-2}.K^{-1}$
  - $h_{bottom} = 30\ W.m^{-2}.K^{-1}$

Results: Temperature profiles along the measurement rods (axis + outer region)

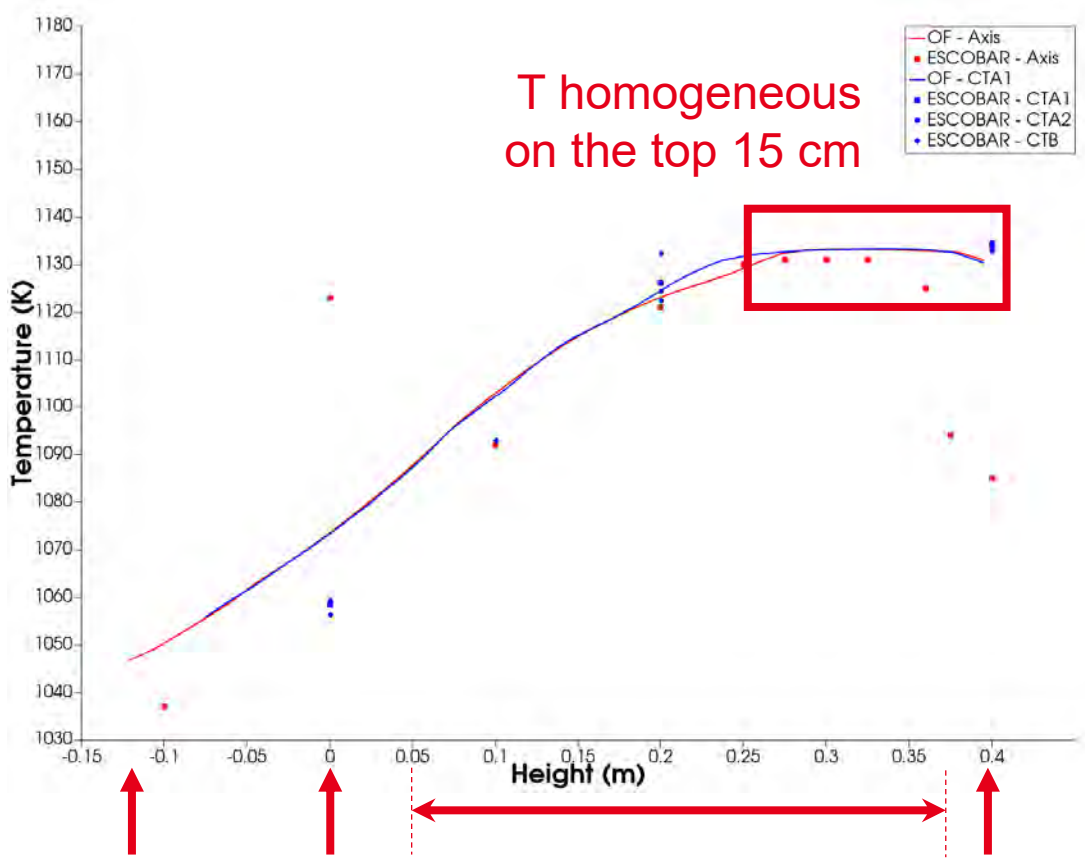
Results obtained for:

- $k - \omega$ turbulence model
- $h_{top} = 60\ W.m^{-2}.K^{-1}$
- $h_{bottom} = 30\ W.m^{-2}.K^{-1}$

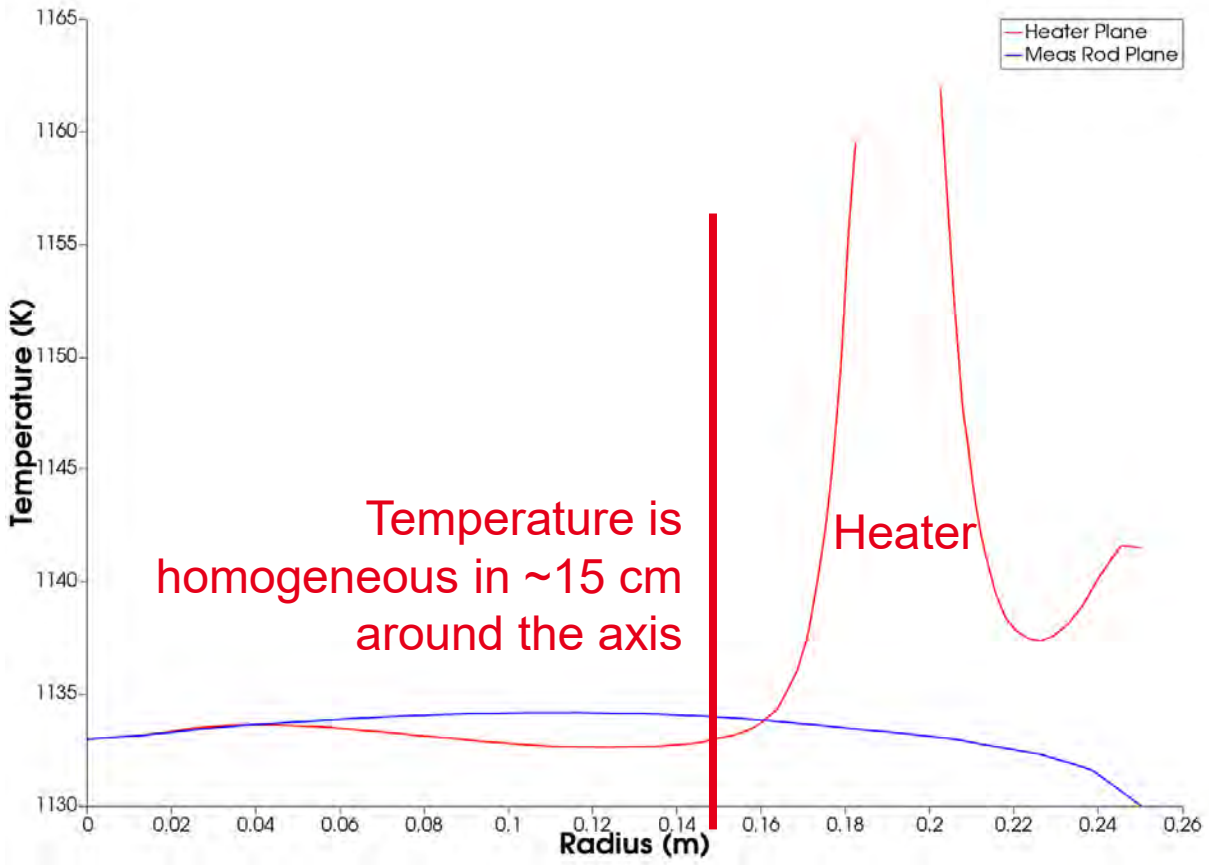
Satisfactory agreeement between simulation and experiments

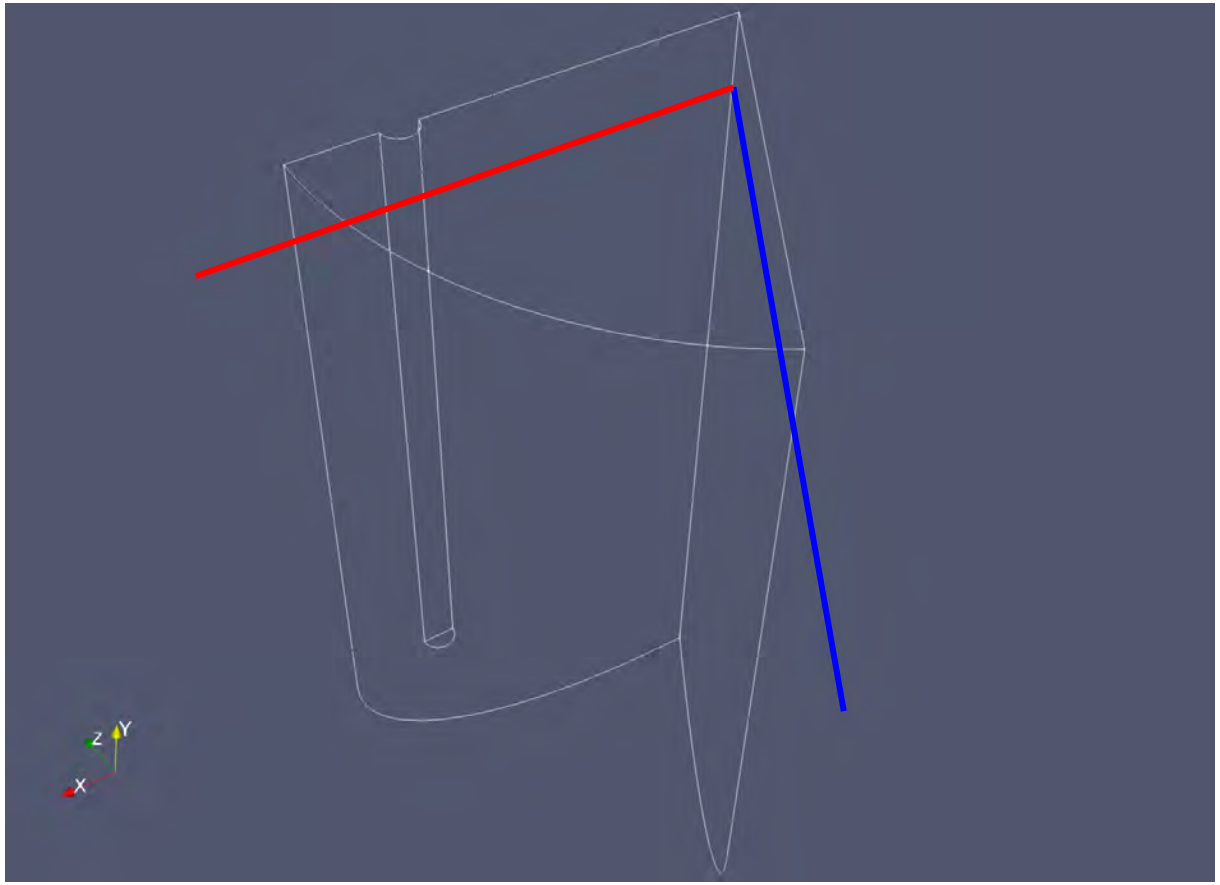
Observations:

- Heat exchange at the surface is not correctly reproduced → not surprising since the physics is not integrally reproduced (evaporation)
- Temperature underestimated by 10-15 K in the stratified zone → probably due to uncertainties in the boundary conditions

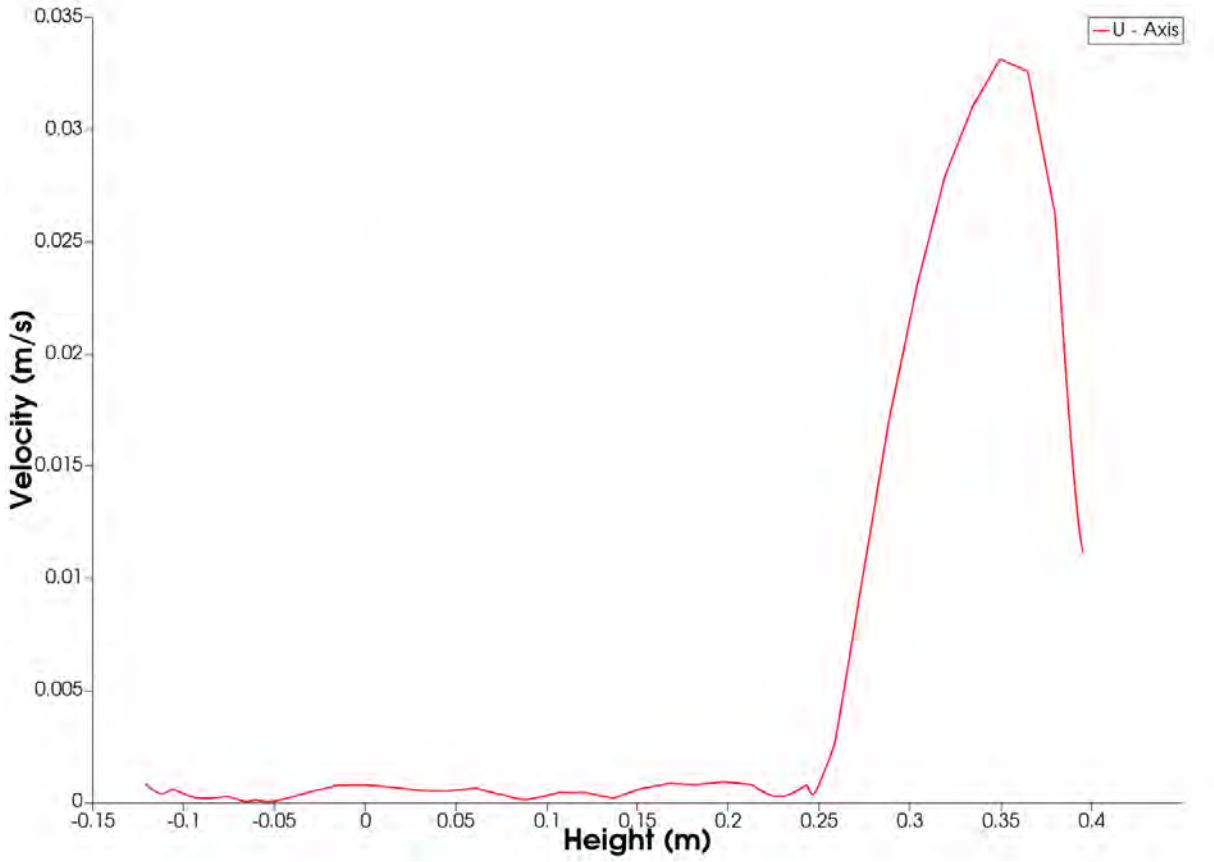


Results: Temperature radial profiles in the homogeneous region (top ~15 cm)





Results: Velocity profile along the axis



Significant velocity in the top ~15 cm under the sodium surface

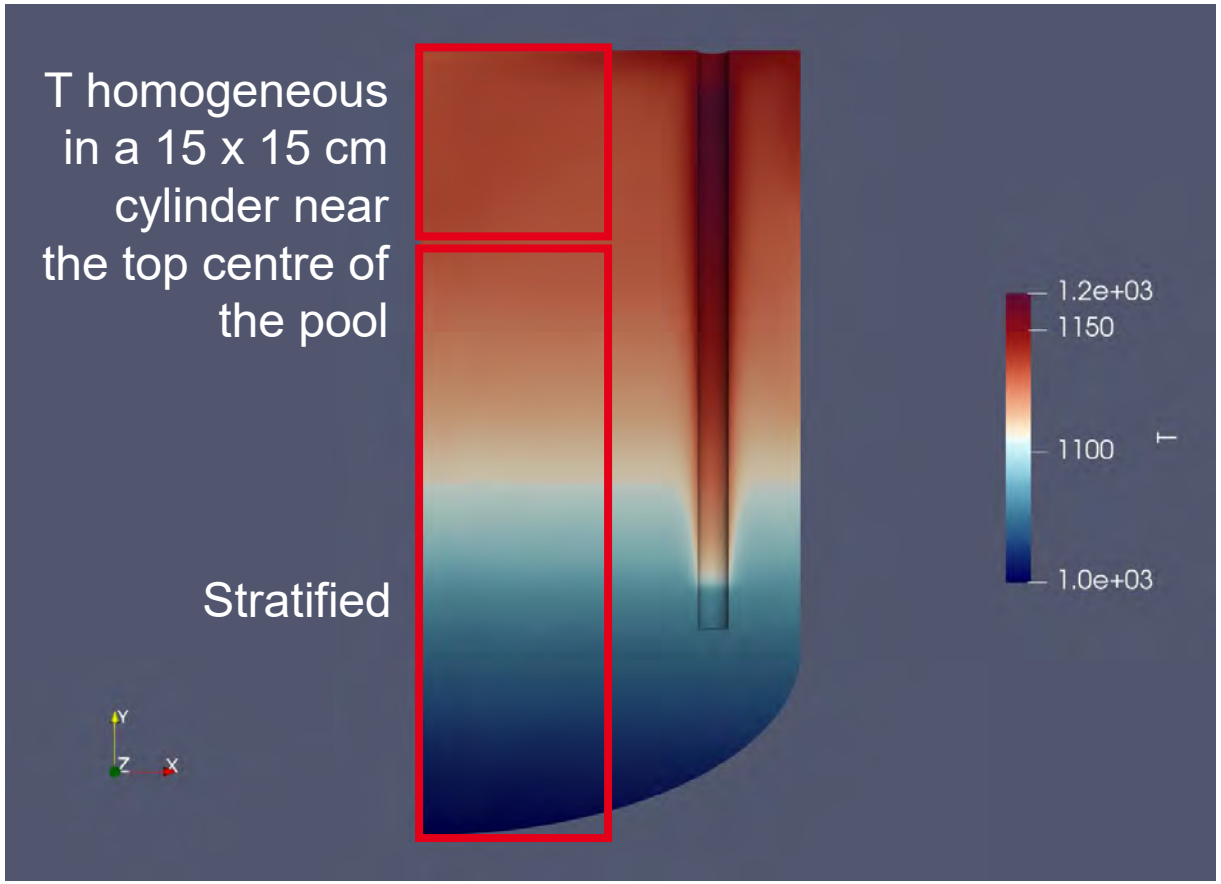
Maximum velocity in this zone: ~3 cm/s

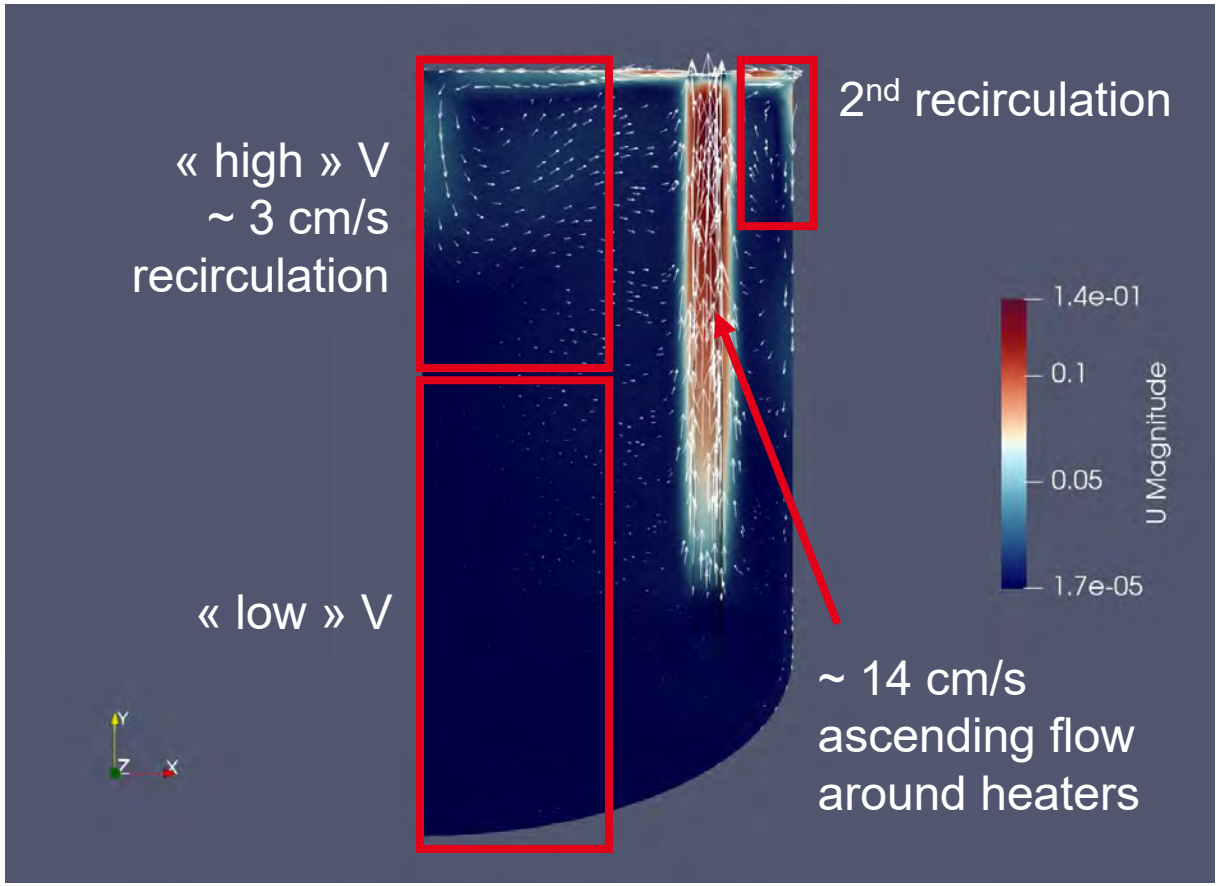
This order of magnitude represents a maximum estimate of the real velocity:

- Velocity is forced to be vertical by the symmetry boundary conditions
- In reality, the downards recirculation at the centre of the pool should move around the axis so the velocity on the axis should be more homogeneous around the axis (lower on the axis and higher near the axis)

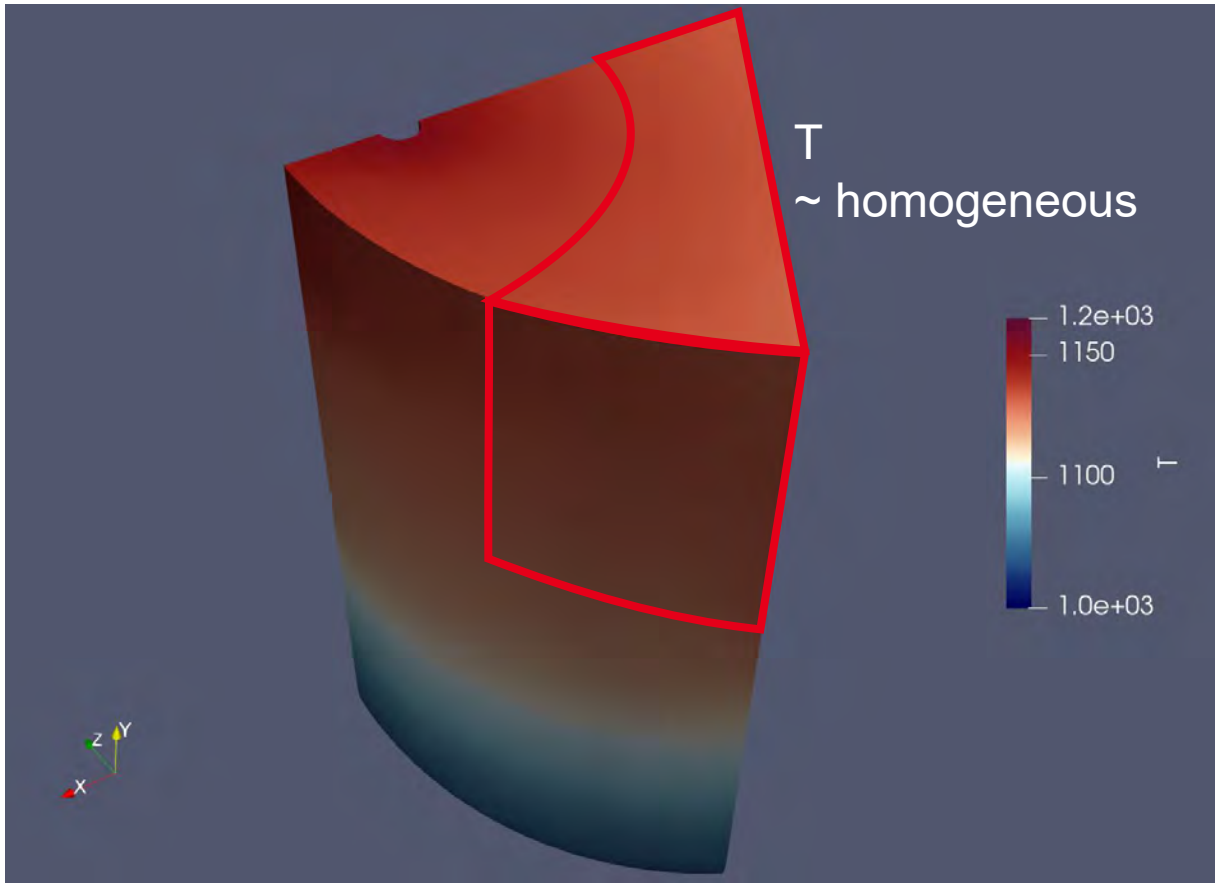
It is pointless to try characterizing the effect of the flow velocity below ~50 cm/s with SERUA

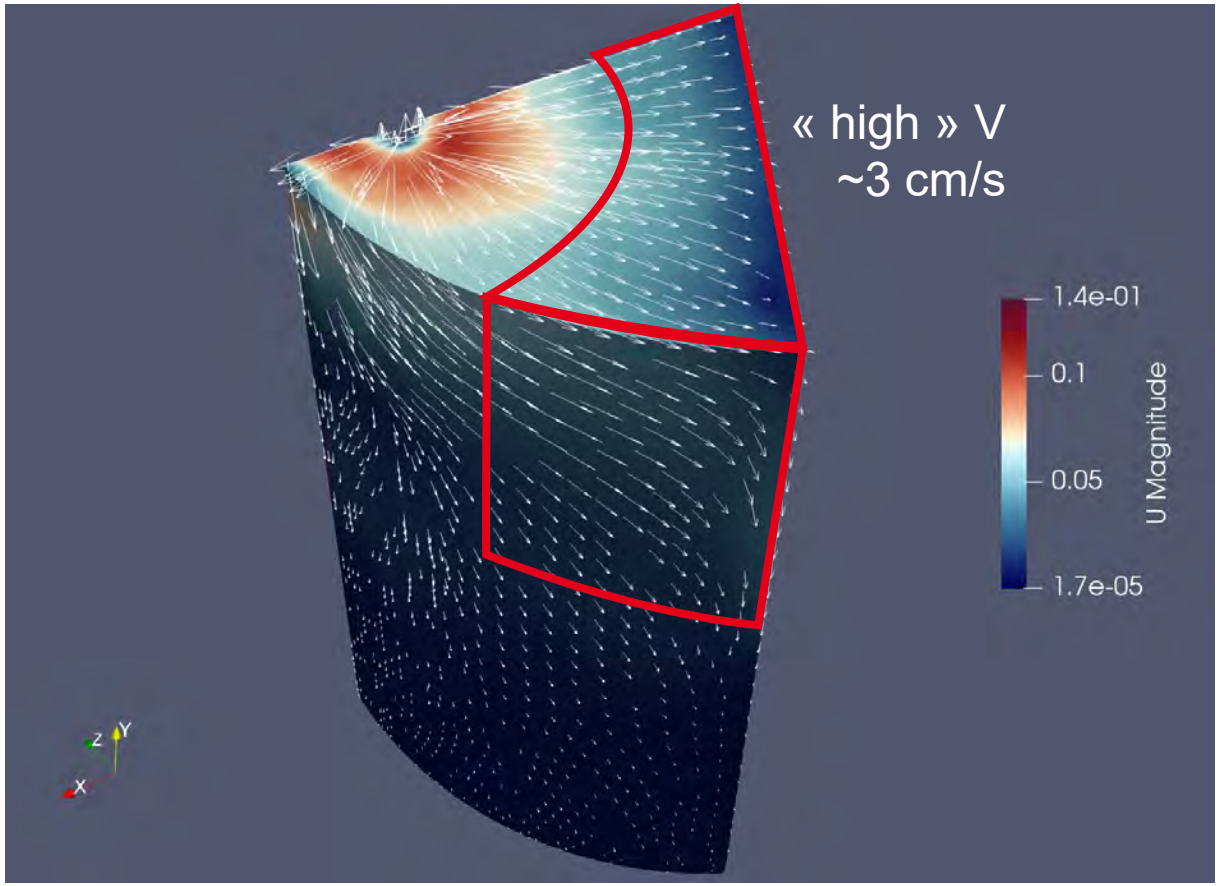
Results: Temperature and velocity fields in the axis-heaters plane



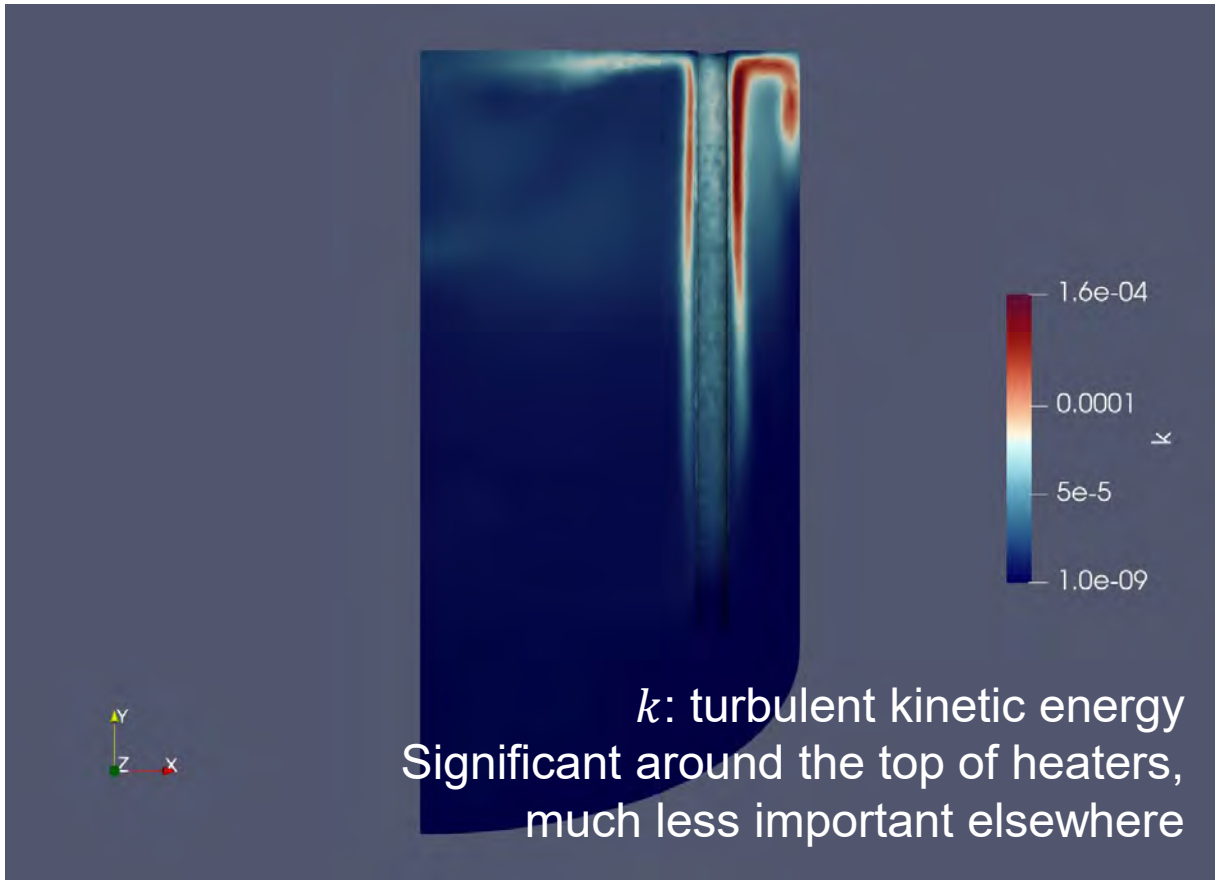


Results: Temperature and velocity fields at the top and lateral walls

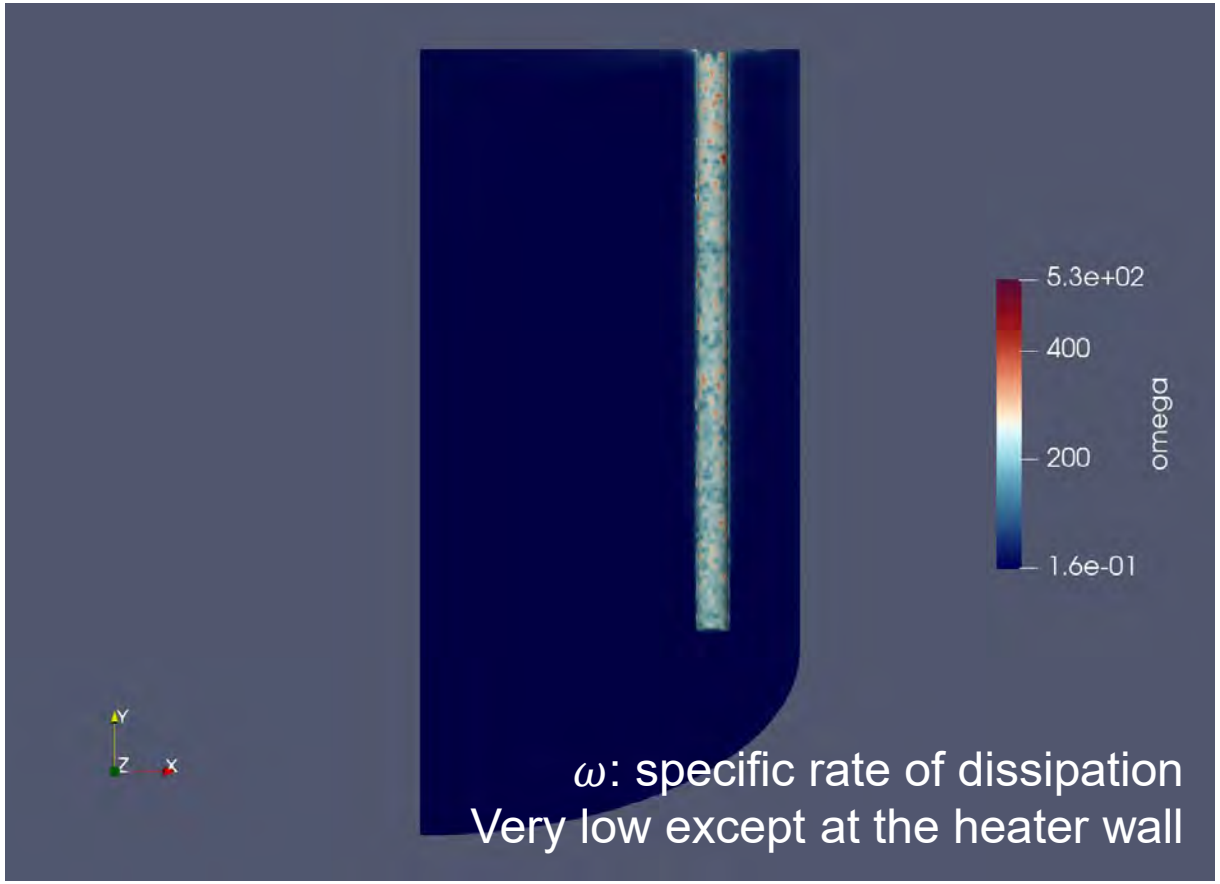




Results: Turbulence intensity in the axis-heaters plane

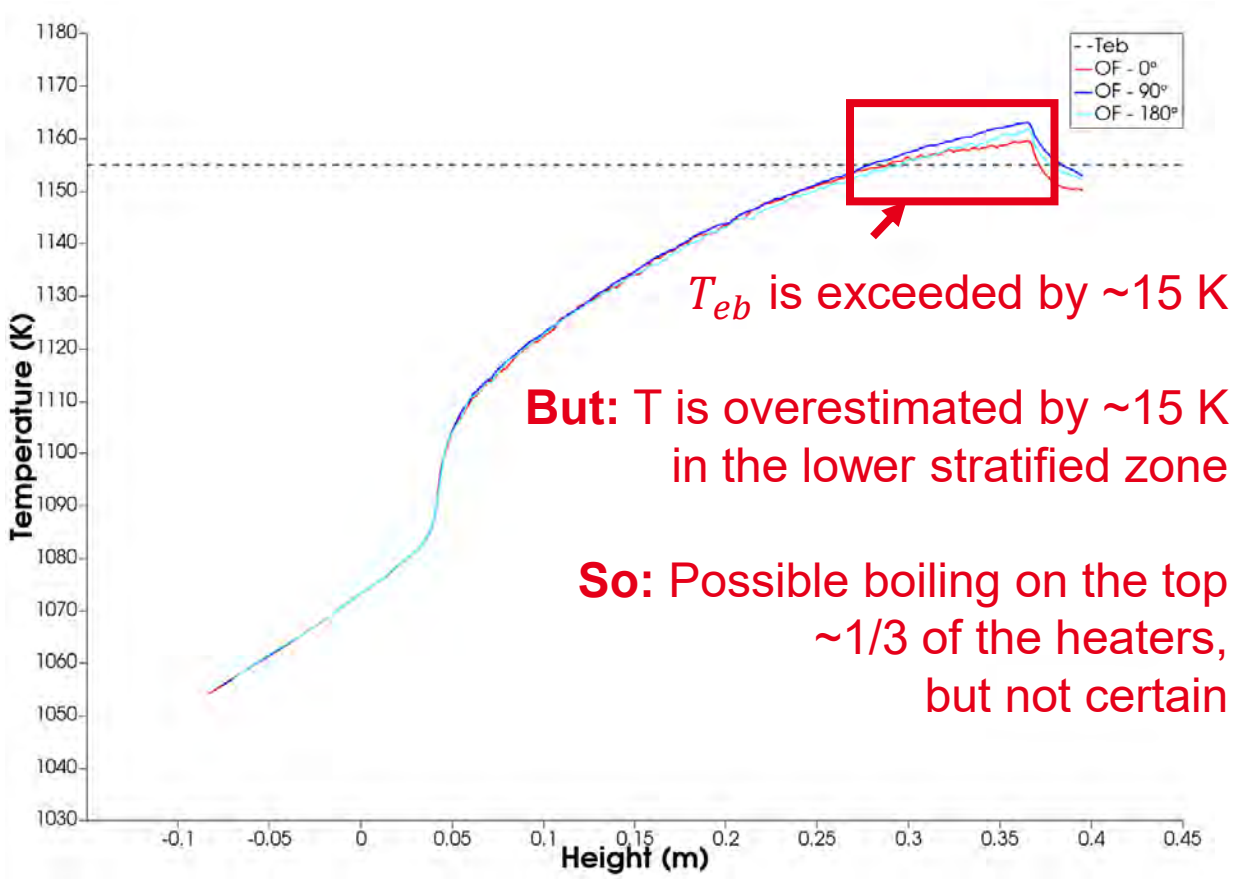


k: turbulent kinetic energy
Significant around the top of heaters, much less important elsewhere



ω: specific rate of dissipation
Very low except at the heater wall

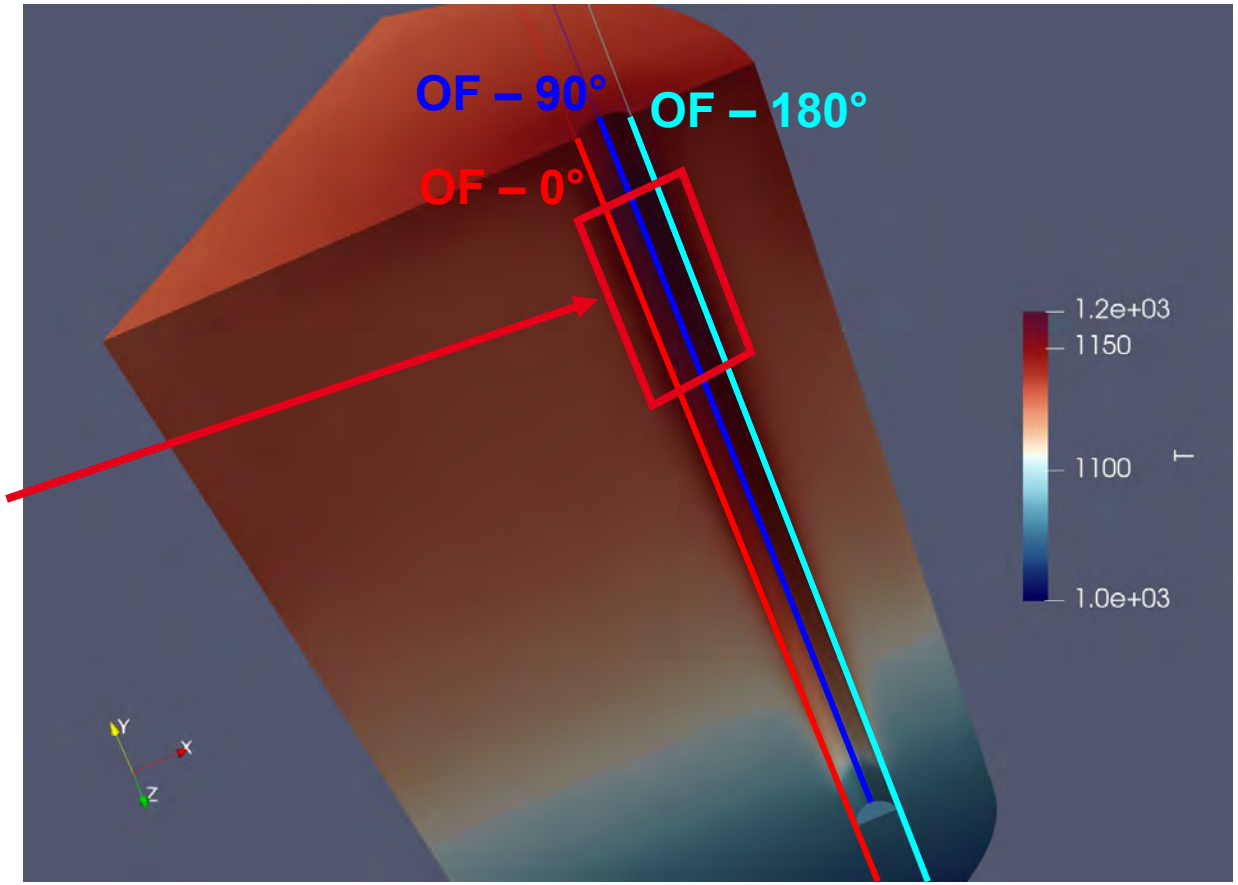
Results: Wall temperature along the heaters



T_{eb} is exceeded by ~15 K

But: T is overestimated by ~15 K in the lower stratified zone

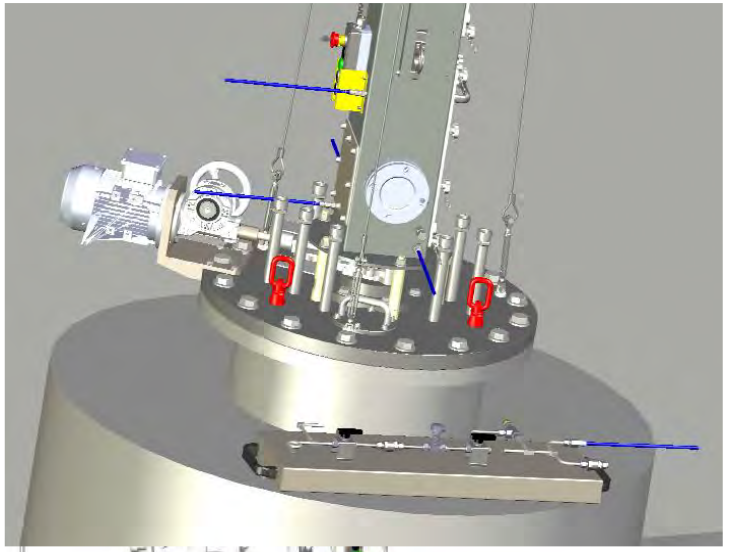
So: Possible boiling on the top ~1/3 of the heaters, but not certain

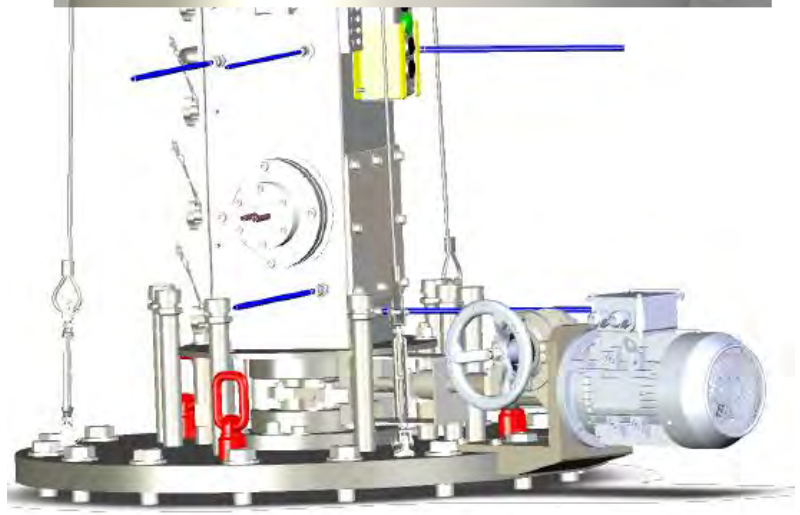


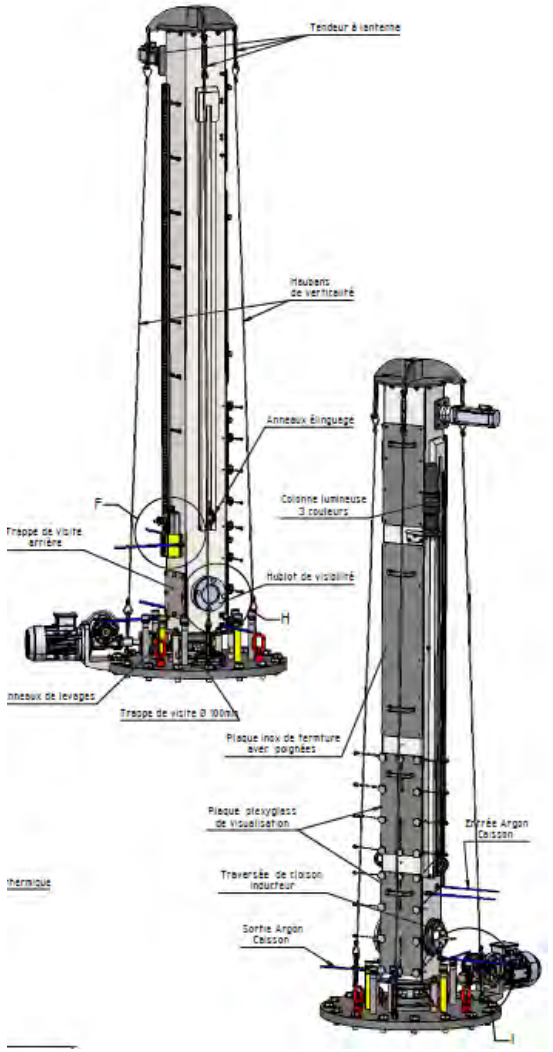
Experimental device assembly

Integration of all elements on DOLMEN:

- Induction furnace
  - Included into a protection vessel
  - Heating / sodium part separation valve
- Sphere suspension and transfer system
  - Velocity adaptation during transfer
    - Fast transfer from the furnace to the gas cover above the sodium pool
    - Slow velocity during the immersion of the sphere into the sodium
  - Adjustable immersion time







Benchmarking of Advanced GPU-Accelerated Discrete Element Method and Elastoplastic Constitutive Granular Flow Models for Large-Scale Debris Bed Formation in Severe Accidents of Sodium Fast Reactors

ABSTRACT

Ensuring the safety integrity of the core catcher system during a hypothetical core disruptive accident (CDA) in a sodium fast reactor (SFR) is essential, particularly with respect to debris bed formation. Because the expected debris size is less than 1.0 mm—owing to the rapid quenching of corium caused by the high thermal conductivity and high melting temperature of sodium—the number of particles accumulating on the core catcher is extremely large. This makes direct numerical simulation of debris bed formation computationally very demanding.

To address this challenge, we developed and compared two advanced simulation approaches for SFR applications: a GPU-accelerated fully explicit discrete element method coupled with moving particle hydrodynamics (DEM–MPH), and elastoplastic constitutive model based granular flow simulation method (MPH-Granular). The DEM–MPH method is a fully meshless approach in which the debris phase is modeled using a spring–dashpot interaction, while the fluid phase is solved by MPH with a weakly compressible formulation. In contrast, elastoplastic constitutive granular flow model solves the bulk behavior of the granular materials without solving individual discrete particle to avoid computing massive particle numbers.

Validation was carried out against debris bed formation experiments performed in China. Both methods successfully reproduced sedimentation and dispersion trends depending on particle size. DEM–MPH offered more robust predictions of solid behavior; however, its application to full 3D simulations was constrained by the high computational cost. Conversely, MPH-based granular flow model efficiently handled larger-scale problems owing to its continuum formulation, although it exhibited reduced accuracy in describing the compression of sedimented particles. Overall, DEM–MPH provides higher fidelity at smaller scales, while MPH-Granular would ensure scalability, highlighting a complementary relationship between the two approaches.

1. INTRODUCTION

Lessons learned from the Fukushima Daiichi Nuclear Power Plant (1F NPP) accident highlighted the critical importance of retaining corium—consisting of molten fuel and in-core structural materials—inside the reactor vessel. Preventing its relocation beyond the vessel and maintaining it in a controllable state is essential to substantially reduce the risk associated with the loss of core inventory. For Generation IV reactors, particularly sodium-cooled fast reactors (SFRs), core catcher systems are therefore being considered to efficiently cool the relocated core debris and mitigate the risk of re-criticality. During a postulated core disruptive accident, corium may be released into the surrounding sodium. Owing to the high boiling point and high thermal conductivity of sodium, the contact interface between corium and sodium can remain a liquid–liquid interface without the formation of a stable vapor film, which has a much lower heat transfer coefficient of the film boiling. As a result of the rapid quenching, fragmentation of the corium is expected due to the generation of the mechanical energy, and the characteristic debris particle size is estimated to be on the order of 0.1–1.0 mm [1]. these fragmented debris would pile up over the core-catcher. In order to ensure the integrity of the core-catcher system, understanding the debris bed formation over the core-catcher system is crucial. Although many experiments have been performed by the various organizations to clarify the effect of the particle size [2,3], particle characteristics, and the dimension, the numerical simulation is one of the promising approaches to deepen our knowledge as the simulation offers the insight that we cannot measure or visualize.

For the debris bed formation analysis, the most well-known approach is the discrete element method (DEM) in which Newton's second law is applied and each collision and damping are modeled with the spring-dashpot model together with the friction slider [4]. As the DEM approach is quite straightforward and can reproduce the complicated granular flow behavior, DEM can be also applied to the nuclear engineering [5]. However, the DEM has several difficulties to apply to the practical nuclear scale analysis. First, DEM typically resolves particles at or near their actual size, so modeling very small particles across meter-scale domains becomes computationally prohibitive. Second, neighbor searching—essential for contact detection—scales as $O(N^2)$ in its basic form, making large-scale simulations costly. Third, strong polydispersity in particle size and shape introduces additional difficulties. Size variation complicates neighbor-search algorithms which is initially designed for uniform radii, while non-spherical particles require orientation-dependent contact detection and specialized force models to correctly simulate its impulse.

In order to address these issues, we propose two numerical simulation methods. The first is a discrete element method (DEM) coupled with Moving Particle Hydrodynamics (MPH) [6], which is a fully explicit algorithm parallelized on graphics processing units (GPUs) to handle an enormous number of particles that would be almost impossible to treat with conventional Central Processing Units (CPUs)-based simulations. The second is a bulk granular-flow simulation method incorporating an elastic–perfectly plastic Drucker–Prager constitutive law (namely MPH-Granular) [7], which reduces the computational burden by avoiding the need to resolve individual particle–particle collisions. Moreover, this method does not need to consider the heterogeneity of the debris shape and the size distribution. In this paper, we present benchmark simulations to demonstrate and validate these two approaches.

2. Mathematical Formulation of all approaches [6,7]

In this sentence, the mathematical formulation of DEM, MPH, and MPH-Granular flow simulation and their discretization are presented.

2.1. Discrete Element Method (DEM)

The governing equation of DEM is Newton's second law which consists of translation motion equation

$$m\frac{\mathrm{D}\mathbf{u}}{\mathrm{Dt}} = \overrightarrow{\mathrm{F_g}} + \overrightarrow{\mathrm{F_{nc}}} + \overrightarrow{\mathrm{F_{tc}}}, \tag{1}$$

and the rotational motion equation

$$\frac{\mathrm{D}\boldsymbol{\omega}}{\mathrm{D}t} = \mathrm{I}^{-1}\mathrm{T}, \tag{2}$$

respectively. Here, m, $\mathbf{u}$, I, T, $\overrightarrow{F_g}$, $\overrightarrow{F_{nc}}$, $\overrightarrow{F_{dc}}$, and $\boldsymbol{\omega}$ denote the mass of particle, velocity vector, inertial tensor, torque, gravitational force, normal direction force, tangential direction force, and angular velocity vector, respectively. For the contacting force, spring-dashpot model is applied. Fig.1 illustrates the schematic of the spring-dashpot model. The normal direction force is calculated as

$$\overrightarrow{\mathrm{F_{nc}}} = -K_{n,ij}X_n\boldsymbol{n_{ij}} - \eta_{n,ij}\mathbf{u}_{\boldsymbol{n,ij}}, \tag{3}$$

where K, X, $\boldsymbol{n}$, $\boldsymbol{u}$, and η render the spring constant, displacement, unit vector, relative velocity vector, and damping constant, respectively. Subscript n, i and j represent the normal direction, particle i and particle j. For the translational motion force, we need to take the frictional effect into consideration. If the tangential force is greater than the maximum friction coefficient, the following formula is given as:

$$\overrightarrow{F_{tc}} = \begin{cases} -K_{t,ij}\mathrm{X}_t - \eta_{t,ij}\mathbf{u}_{\boldsymbol{t,ij}} & \left(\overrightarrow{F_{tc}} \le \mu\left|\overrightarrow{F_{nc}}\right|\right) \\ \varphi\left|\overrightarrow{F_{nc}}\right|\dfrac{\mathbf{u}_{\boldsymbol{t,ij}}}{\left|\mathbf{u}_{\boldsymbol{t,ij}}\right|} & \left(\overrightarrow{F_{tc}} > \mu\left|\overrightarrow{F_{nc}}\right|\right) \end{cases}, \tag{4}$$

where φ is the viscous friction coefficient. The subscript t denotes the tangential direction. The spring constant and viscous damping constant for each direction are calculated with Herltz theorem and Mindlin contact theorem [8,9].

The spring constant and the damping constant for the normal direction are calculated as

$$K_{ij}^n = \frac{4}{3}\frac{E_iE_j}{\left(1-\nu_i^2\right)E_j + (1-\nu^2)E_i}\sqrt{\frac{R_iR_j}{R_i+R_j}\sqrt{\delta}}, \tag{5}$$

and

$$\eta_{ij}^n = -\frac{2\ln e}{\sqrt{\pi^2 + (\ln e)^2}}\sqrt{\frac{m_im_j}{m_i+m_j}K_{ij}^n}, \tag{6}$$

where E, ν, e, and δ are Young modulus, Poisson ratio, attenuation coefficient, and effective overlap distance. Similarly, the spring constant and the damping constant for the tangential direction are computed as

$$K_{ij}^t = \frac{8E_iE_j}{(1+\nu_i)(2-\nu_i)E_j + \left(1+\nu_j\right)\left(2-\nu_j\right)E_i}\sqrt{\frac{R_iR_j}{R_i+R_j}\sqrt{\delta}}, \tag{7}$$

$$\eta_{ij}^t = -\frac{2\ln e}{\sqrt{\pi^2 + (\ln e)^2}}\sqrt{\frac{m_im_j}{\mathrm{m}_i+m_j}K_{ij}^t}. \tag{8}$$

2.2. Moving Particle Hydrodynamics for weakly compressible flow and elastic–perfectly plastic Drucker–Prager constitutive law

2.2.1. Particle Interaction models for the discretization

In the present study, the governing equations are discretized using particle interaction models—namely, the gradient, divergence, and Laplacian operators—evaluated with a particle-based weight (kernel) function. The particle interaction models are given as follows:

$$\nabla\phi = \sum_{i\neq j}\left(\phi_j - \phi_i\right)\mathbf{e}_{ij}w'_{ij}\,, \tag{9}$$

$$\nabla\cdot\mathbf{A} = \sum_{i\neq j}\left(\mathbf{A}_j + \mathbf{A}_i\right)\cdot\mathbf{e}_{ij}w'_{ij}\,, \tag{10}$$

$$\nabla^2\phi = 2\sum_{i\neq j}\frac{\left(\phi_j - \phi_i\right)}{\left|r_{ij}\right|}w'_{ij}\,, \tag{11}$$

where the terms ϕ, $\boldsymbol{A}$, and $\mathbf{e}_{ij}$ are an arbitrary scalar parameter, an arbitrary vector and the unit vector from particle *i* to *j*, which is defined as

$$\mathbf{e}_{ij} = \frac{r_{ij}}{\left|r_{ij}\right|}, \tag{12}$$

where $\boldsymbol{r}_{ij}$ is the relative velocity between particle *i* and *j*.

The term w'_{ij} represents the derivative of the normalized weight function w_{ij}, which are defined as:

$$w_{ij} = w\left(\left|r_{ij}\right|\right), \tag{13}$$

$$w(r) = \begin{cases}\dfrac{1}{S_f}\dfrac{1}{r_e^{dim}}\left(1-\dfrac{r}{r_e}\right)^2 & (r\le r_e)\\ 0 & (r > r_e)\end{cases}, \tag{14}$$

$$S_f = \frac{1}{l^{dim}}\int_{r<r_e}\frac{1}{r_e^{dim}}\left(1-\frac{r}{r_e}\right)^2 dv\,, \tag{15}$$

and

$$w'_{ij} = -\frac{\partial w(r)}{\partial r}, \tag{16}$$

where w, r_e, and *l* denote that the weight function, the effective radius of the particle *i*, and the particle diameter, respectively

2.2.2 Weakly compressible flow model and its discretization

The governing equation of the weakly compressible fluid is consisting of momentum equation

$$\rho_0\frac{\mathrm{D}\mathbf{u}}{\mathrm{Dt}} = -\nabla\mathrm{P} + \mu\nabla^2\mathbf{u} + \rho_0\mathbf{g}, \tag{17}$$

and pressure equation for incompressible control

$$\mathrm{P} = -\lambda\nabla\cdot\mathbf{u} + \kappa\frac{\Delta\rho}{\rho_0}, \tag{18}$$

where ρ_0, $\mathbf{u}$, P , μ, $\mathbf{g}$, λ, and κ, correspond to the density, pressure, dynamic viscosity, gravity acceleratio n, bulk viscosity, and bulk modulus, respectively. The governing equations (Eqs. (18)-(20)) are discretized with the particle interaction models (Eqs.(21) and (23)) as

$$\rho_0\frac{\mathrm{D}\mathbf{u}}{\mathrm{Dt}} = -\sum_j\left(\mathrm{P}_j + \mathrm{P}_i\right)\frac{\boldsymbol{r}_{ij}}{\left|\boldsymbol{r}_{ij}\right|}w'_{ij} + 2\mu\sum_j\left(\mathbf{u}_j - \mathbf{u}_i\right)\frac{w'_{ij}}{\left|\boldsymbol{r}_{ij}\right|} + \rho_0\mathbf{g}, \tag{19}$$

$$\mathrm{P} = -\lambda\sum_j\left(\mathbf{u}_j - \mathbf{u}_i\right)\cdot\frac{\boldsymbol{r}_{ij}}{\left|\boldsymbol{r}_{ij}\right|}w'_{ij} + \kappa(n_i - n_0). \tag{20}$$

Finally, the position of the fluid is updated as

$$\mathbf{x}^{(k+1)} = \mathbf{x}^k + \mathbf{u}^{(k+1)}Dt. \tag{21}$$

2.2.3 MPH-Granular: Hyper elastoplastic constitutive law for the granular material

The governing equation of the hyper elastoplastic constitutive law is mass conservation

$$\frac{D\rho}{Dt} + \rho\nabla\cdot\mathbf{u} = 0, \tag{22}$$

and momentum conservation

$$\frac{D\mathbf{u}}{D\mathrm{t}} = \frac{1}{\rho}\nabla\cdot\boldsymbol{\sigma} + \mathbf{g}. \tag{23}$$

Here $\boldsymbol{\sigma}$ is the stress tensor. In order to handle the large deformation of the granular flow, time derivative of $\boldsymbol{\sigma}$ with the Jaumann stress tensor can be expressed as:

$$\dot{\boldsymbol{\sigma}} = \dot{\boldsymbol{\omega}}\boldsymbol{\sigma} - \boldsymbol{\sigma}\dot{\boldsymbol{\omega}} + \lambda_e tr(\dot{\boldsymbol{\varepsilon}}_e)\boldsymbol{I} + 2\mu_e\dot{\boldsymbol{\varepsilon}}_e, \tag{24}$$

$$\dot{\boldsymbol{\varepsilon}}_e = \dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}_p, \tag{25}$$

$$\dot{\boldsymbol{\varepsilon}} = \frac{1}{2}(\nabla\mathbf{u} + (\nabla\mathbf{u})^T), \tag{26}$$

$$\dot{\boldsymbol{\omega}} = \frac{1}{2}(\nabla\mathbf{u} - (\nabla\mathbf{u})^T), \tag{27}$$

Lames constants λ_e and μ_e are defined as

$$\lambda_e = \frac{E\nu}{(1+\nu)(1-2\nu)}, \tag{28}$$

$$\mu_e = \frac{E}{2(1+\nu)}, \tag{29}$$

where E and ν stand for the Young's modulus and Poisson's ratio, respectively. The plastic strain rate is estimated from the following plastic flow rule:

$$\dot{\boldsymbol{\varepsilon}}_p = \dot{\lambda}\frac{\partial \mathrm{g}_p}{\partial\boldsymbol{\sigma}}, \tag{30}$$

where g_p is the plastic potential function. $\dot{\lambda}$ is the rate of change of the plastic multiplier, which are defined as

$$\mathrm{g}_p = \sqrt{3J_2} - \alpha_\psi p, \tag{31}$$

$$\dot{\lambda} = \frac{\lambda_e tr(\dot{\boldsymbol{\varepsilon}})tr\left(\frac{\partial f_p}{\partial\boldsymbol{\sigma}}\right) + 2\mu_e\frac{\partial f_p}{\partial\boldsymbol{\sigma}}:\dot{\boldsymbol{\varepsilon}}}{\lambda_e tr\left(\frac{\partial f_p}{\partial\boldsymbol{\sigma}}\right)tr\left(\frac{\partial \mathrm{g}_p}{\partial\boldsymbol{\sigma}}\right)2\mu_e\frac{\partial f_p}{\partial\boldsymbol{\sigma}}:\frac{\partial \mathrm{g}_p}{\partial\boldsymbol{\sigma}}}. \tag{32}$$

Here we install the yield function f_p which is a pressure-dependent Drucker-Prager function. If $f_p < 0$, the elastic deformation occurs whereas the plastic deformation occurs if $f_p \geq 0$. f_p can be described as

$$f_p = \sqrt{3J_2} + \frac{\alpha_\phi}{dim}tr(\boldsymbol{\sigma}) - \kappa, \tag{33}$$

where J_2 is the second invariant of the deviatoric stress tensor. In this yield function, constitutive parameters α_ϕ and κ should be determined with the physics based parameters. Following equations relevant to the material dependent internal friction angle and cohesion are introduced.

$$\alpha_\phi = \frac{3\,tan\phi}{\sqrt{9+12tan^2\phi}}, \tag{34}$$

$$\kappa = \frac{3c}{\sqrt{9+12tan^2\phi}}. \tag{35}$$

where ϕ and c are internal friction angle and the cohesion of the granular material. Generally, the c=0 under the dry condition.

More detailed information is available in our published papers and on my GitHub repository [6,7,13].

2.2.4 Solid-Liquid Interaction models

The solid–liquid interaction model is essential for reproducing jet fragmentation. To simulate the interaction force between the fluid and particles, we introduce a drag-force model. The drag force arises from the relative motion between the particle and the surrounding fluid and is given by

$$F_d = \frac{1}{2} C_d \rho_0 A |V_s| V_s, \tag{36}$$

where C_D, A_p, and $\mathbf{V}_s$ denote the particle drag coefficient, the projected area of a particle, and the relative velocity between the solid and fluid phases, respectively. We employ the Wen–Yu and Ergun correlations [10,11] to evaluate the drag force acting on spherical solid particles. Although these correlations were originally developed for gas–solid flows, their applicability to liquid–solid systems has also been confirmed [12].

$$C_d = \frac{4}{3}(150\frac{1-\alpha}{\alpha Re} + 1.75), \qquad (\alpha < 0.8) \tag{37}$$

otherwise

$$C_d = \frac{24(1 + 0.15Re^{0.687})}{\alpha Re}\alpha^{-2.65}, \qquad (Re \le 1000) \tag{38}$$

$$C_d = 0.44, \qquad (Re > 1000) \tag{39}$$

where α is volume fraction in the local area and Re is Reynolds number given by

$$Re = \frac{\alpha \rho_0 |V_s| l}{\mu}. \tag{40}$$

3. Validation of the granular simulation model

The validation of the granular simulation models is presented in this section. Figure 1 shows the experimental setup used for validation. The experiments were conducted in an acrylic tank, in which stainless-steel (SS) balls with a diameter of 5.0×10^{-4} m were initially packed in a narrow compartment with a width of 2.0 cm. The initial bed height H and the opening size O were selected as the primary control parameters. The x-coordinate of the advancing granular front along the substrate was extracted via image processing, and the runout distance was evaluated by aggregating the front position over all video frames.

In addition, the angle of repose—defined as the slope angle at the advancing front—was quantified during post-processing. In the numerical simulations, the free surface was identified as the region with low particle number density. The coordinates of the free-surface particles were exported to ImageJ, and the angle of repose was determined by applying a linear fit to the extracted free-surface profile. The initial conditions, boundary conditions, and material properties employed in the experiments and simulations are summarized in Table I (DEM) and Table II (MPH-Granular).

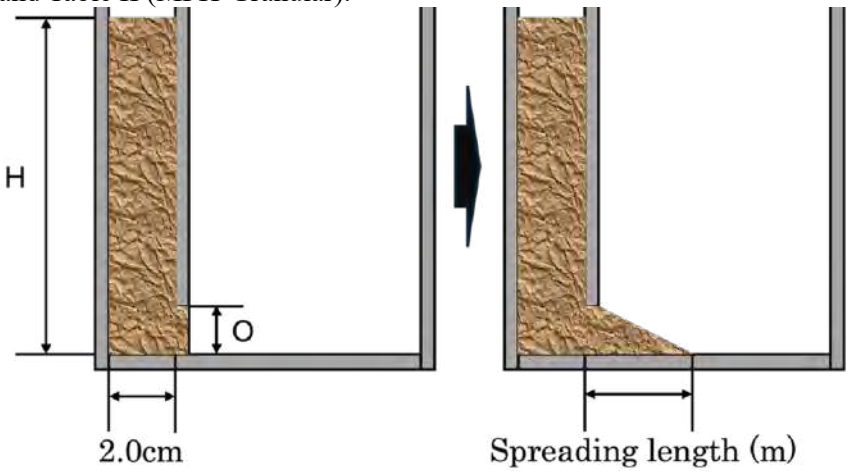

Figure 1 benchmark target experiments: granular dam breaking experiment with 0.5mm spherical SS balls

Table I. DEM calculation parameters

Parameters	SS	Wall
Density (kg m^{-3})	7900	4000
Young's Modulus (GPa)	20	10
Poisson's Ratio (-)	0.3	0.3
Viscous Friction Constant (-)	0.18	0.1
Time Step (s)	1.0×10^{-6}	

Table II. MPH-Granular calculation parameters

	Case 1	Case 2	Case 3
Height H (cm)	5.0	10	15
Outlet O (cm)	1.0	1.0	3.0
Particle size l (m)	5.0×10^{-4}	5.0×10^{-4}	5.0×10^{-4}
Effective radius r_e(m)	$2.5\times l$	$2.5\times l$	$2.5\times l$
Young's modulus (Pa)	3.0×10^{5}	3.0×10^{5}	3.0×10^{5}
Poisson's ratio (-)	0.3	0.3	0.3

Dilatancy Angle (°)	0.2	0.2	0.2
Cohesion (Pa)	0.0	0.0	0.0

Figure 3 illustrates the final resting configuration of the granular mass after motion ceases. The color scale indicates the magnitude of the vertical stress within the deposit. Overall, the stopping position of the granular front is primarily controlled by the outlet width O and is largely insensitive to the initial filling height H. Accordingly, the runout distances in cases 1 and 2 differ only slightly. Moreover, the steep angle of repose observed in the experiments is successfully reproduced under all test conditions.

The MPH-Granular simulations exhibit a similar trend. For case 1, the experimental runout length is 0.052 m, whereas the simulation predicts 0.049 m. For case 2, the experiment yields 0.051 m and the simulation gives 0.052 m. The characteristic sharp slope at the leading edge of the deposit is also captured. For case 3, the experiment shows a distinct sharp front, whereas the MPH-Granular simulation produces a slightly smoother front. This discrepancy is likely attributable to particles near the outlet being pushed forward by subsequent discharge through the larger opening, which tends to round the front edge.

A notable advantage of the proposed MPH-Granular is that it enables direct evaluation of internal stress fields. The simulations indicate elevated stresses near the corner regions in all cases. In cases 2 and 3, pronounced stress concentrations are also observed along the vertical wall adjacent to the outlet. These results suggest that spreading is arrested when particles near the wall experience high shear stresses, become effectively immobilized, and thereby impede further motion of the granular mass.

Figure 4 summarizes the runout lengths obtained from the experiments, the DEM reference calculations, and the MPH-Granular simulations. Overall, smaller particles tend to spread farther, irrespective of the configuration. In case 1 (Figure 4(a)), the coarse-particle simulation departs noticeably from the experimental data, whereas the fine-particle simulation reproduces the experimental trend well. A comparable behavior is found in case 3 (Figure 4(c)), for which the smallest particle size of 1.0×10^{-4} m provides the best agreement with the experiment. By contrast, in case 2 (Figure 4(b)), simulations with relatively coarse particle sizes (5.0×10^{-4} m and 3.0×10^{-4} m) still yield reasonable agreement with the measurements.

Finally, it should be emphasized that Young's modulus and Poisson's ratio are treated as effective (calibrat ed) parameters in the present formulation, similar to how spring stiffness and friction coefficients are tune d in DEM. Consequently, minor deviations from the experimental measurements are inevitable.

4. Validation on debris bed formation under water

Validation results of the DEM–MPH and MPH-Granular methods, benchmarked against experimental measurements reported by the SYSU group, are presented in this section. The results demonstrate that particle size plays a critical role in debris-bed characterization because it alters the flow regime and, consequently, the deposition behavior [3].

Figure 4 shows the computational geometry, which was designed to replicate the experimental facility described in Cheng et al.[3]. In the simulations, particles are discharged from an outlet nozzle with an inner diameter of 3.0 cm. According to the experimental observations, the falling height has a negligible influence on debris-bed formation because the particle terminal velocity is primarily governed by the water level (Cheng et al., 2017a; Cheng et al., 2017b). Therefore, the falling height is fixed at 120 cm throughout this study.

Table III summarizes the physical properties used in the DEM–MPH simulations, whereas Table IV lists those adopted in the MPH-Granular simulations. Unless otherwise noted, the particle diameter is set to 5.0 mm in the present validation cases.

Figure 5 presents snapshots of the debris-bed formation process. The top row shows the DEM–MPH results, and the bottom row shows the MPH-Granular results. At $t = 5.0\,\mathrm{s}$, no clear difference is observed between the two approaches. At $t = 12.0\,\mathrm{s}$, however, noticeable discrepancies emerge: in the DEM–MPH simulation, the debris does not spread toward the side walls, whereas the MPH-granular simulation shows apparent lateral spreading. This behavior is attributed to the fact that granular–wall friction is not explicitly modeled in the current MPH-Granular formulation, which leads to less resistance to lateral motion and therefore larger spreading compared with DEM–MPH. After $t = 12.0\,\mathrm{s}$, both simulations exhibit substantial piling-up and the formation of a steep deposit profile. Differences are also observed in the velocity field of the surrounding water. In the DEM–MPH simulation, forced convection in the pool is not pronounced, while in the MPH-Granular simulation a clear circulation pattern is already visible at $t = 5.0\,\mathrm{s}$. In the MPH-Granular model, a representative particle diameter is introduced to evaluate buoyancy and drag forces. As a result, the interphase momentum exchange acting on the MPH-Granular "particles" may differ from that acting on the discrete DEM particles, potentially leading to an overestimation of drag and/or buoyancy and, consequently, a stronger induced flow.

Figure 6 compares the debris-bed height obtained in the simulations with the experimental measurements: panel (a) shows the DEM–MPH results and panel (b) shows the MPH-granular results. The DEM–MPH prediction at $t = 73\,\mathrm{s}$ agrees well with the experimentally observed sedimentation height. In contrast, the MPH-Granular simulation exhibits a notable discrepancy in the final bed height. One reason for the improved agreement of DEM–MPH is that its input parameters (e.g., particle density, diameter, and contact model parameters) can be set close to the physical properties of the materials used in the experiments; consequently, the experimental trend is reproduced without dedicated parameter calibration. By comparison, the MPH-Granular approach relies on a continuum constitutive description, and its effective material parameters—such as Young's modulus and internal friction coefficients—must be calibrated to represent the bulk response of the granular assembly. Therefore, a more systematic and sensitive calibration with respect to these parameters is required to reduce the discrepancy in the sedimentation height.

Overall, DEM–MPH is well suited for high-resolution, small-scale analyses and for producing reference data. For realistic core-catcher–scale simulations, however, the MPH-Granular solver is more practical because it can represent the bulk debris behavior efficiently without explicitly resolving an enormous number of individual particles or accounting for particle-size and shape heterogeneity in detail.

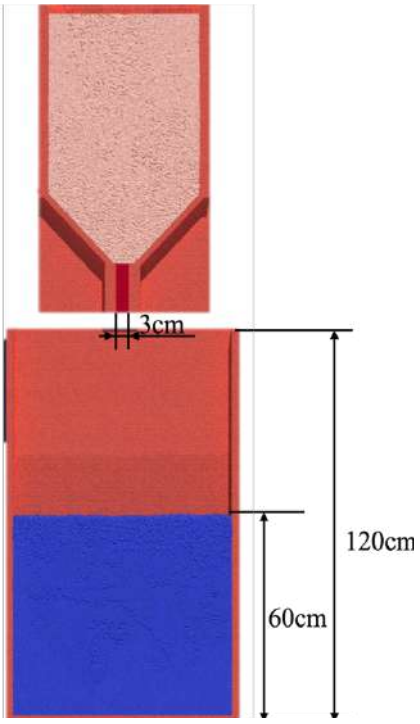

Figure 4 debris bed simulation geometry [6]

Table III. DEM-MPH calculation parameters

Parameters	Debris	Water
Density (kg m^{-3})	2300	1000
Young's Modulus (GPa)	10	
Poisson's Ratio (-)	0.37	
Viscous Friction Constant (-)	0.1

5. CONCLUSIONS

Ensuring the safety integrity of the core catcher system during a hypothetical core disruptive accident (CDA) in a sodium-cooled fast reactor (SFR) requires reliable prediction of debris-bed formation. Because the expected debris size is typically below 1.0 mm due to rapid quenching in liquid sodium, an enormous number of fragments can accumulate on the core catcher, making direct high-fidelity simulation computationally impractical. To address this challenge, this study developed and evaluated two complementary numerical approaches for SFR applications: a GPU-accelerated, fully explicit discrete element method coupled with moving particle hydrodynamics (DEM–MPH), and an MPH-Granular flow model incorporating an elastoplastic constitutive law.

Validation was conducted against debris-bed formation experiments performed by the SYSU group and at the University of Tokyo. Both approaches successfully reproduced the key macroscopic trends of sedimentation and dispersion, including the pronounced dependence of debris-bed characteristics on particle size. DEM–MPH provided a more detailed representation of solid-phase dynamics through explicit spring–dashpot interactions, resulting in higher fidelity in capturing local kinematics and deposit morphology. However, its applicability to full three-dimensional, reactor-relevant scales is limited by the high computational cost associated with resolving a vast number of discrete particles.
In contrast, the MPH-Granular model enables efficient large-scale simulations without explicitly tracking individual fragments, offering practical scalability for reactor-scale assessments. Although it captures the overall spreading and settling behavior, it underestimates the compression and packing of the sedimented debris, indicating that improved constitutive descriptions and/or more systematic calibration strategies are needed for dense deposition regimes.

Overall, the results show that DEM–MPH is well suited for high-resolution, small-scale analyses and for generating reference data, whereas the MPH-Granular provides a promising path toward scalable evaluations of debris-bed formation on core-catcher geometries. The two approaches are therefore complementary, motivating a multi-fidelity strategy for future SFR safety assessments: using DEM–MPH to support calibration and uncertainty quantification, and employing the continuum formulation for practical three-dimensional, plant-scale simulations.

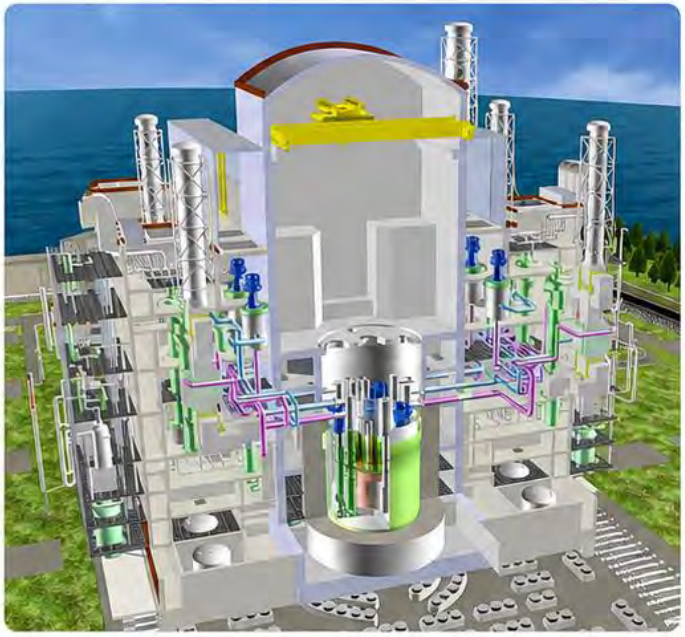
Motivation (1)

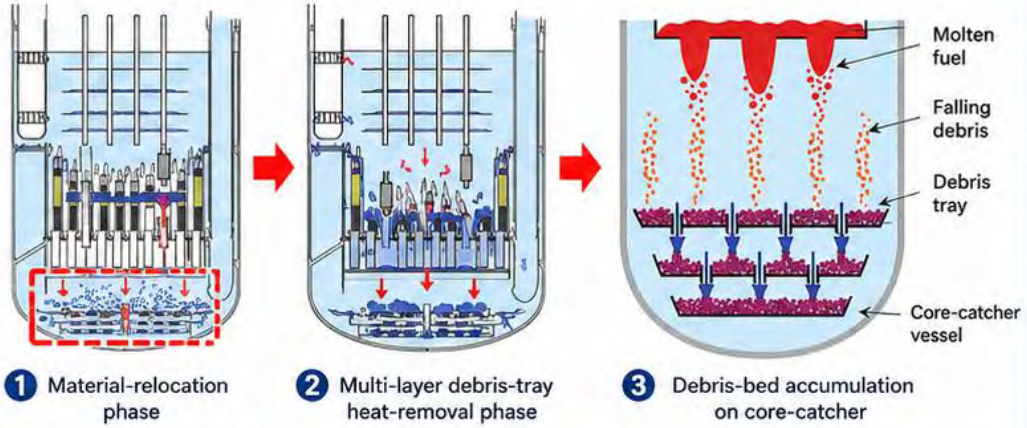
Sodium Fast Reactor (SFR) R&D in Japan

- Medium-size tank-type SFR is the candidate for the demonstration reactor
- Both Monju and Joyo are loop type (high earthquake resistance)
- Fundamental R&D for Japan's advanced SFR beyond Monju should be completed by FY2028



Conceptual image of demonstration SFR in Japan [1]

Major Concern: Core Disruptive Accident (CDA) [2]



- Fragmented debris piles up on the core-catcher
- Integrity of the core-catcher is of significant importance

[1] https://www.mhi.com/jp/group/mfbr/company/technology/project
[2] Suzuki, T et al., 2014. A scenario of core disruptive accident for Japan sodium-cooled fast reactor to achieve in-vessel retention. J. Nucl. Sci. Technol. 51, 493–513.

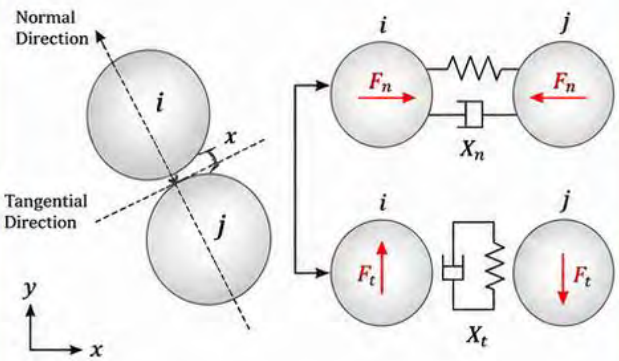
Motivation (2)

Numerical Simulation of the Debris Bed Formation

- **DEM** based simulation is the most popular in solving the debris phase
- CFD either **Eulerian** or **Lagrangian** is employed for fluid phase

Target phenomena

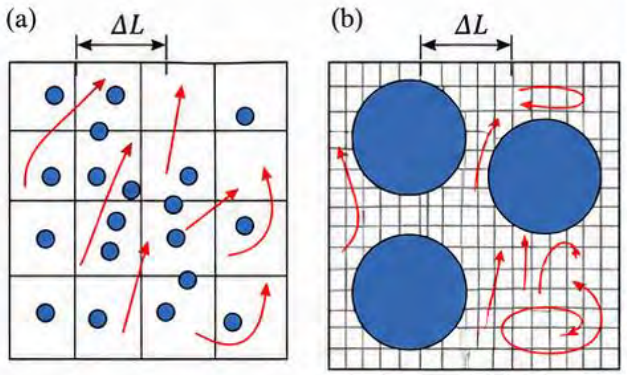
Solid-Solid Collision



$$m\frac{\mathrm{D}\mathbf{u}}{\mathrm{D}t} = \overrightarrow{F_{\mathrm{g}}} + \overrightarrow{F_{\mathrm{nc}}} + \overrightarrow{F_{\mathrm{tc}}} + \overrightarrow{F_{\mathrm{b}}}$$

$$\frac{\mathrm{D}\omega}{\mathrm{D}t} = I^{-1}\mathbf{T}$$

Solid-Fluid Coupling Scheme



$$\nabla \cdot \mathbf{u} = 0$$

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\cdot\nabla)\mathbf{u} = -\frac{1}{\rho}\nabla p + \nu\nabla^2\mathbf{u} + \mathbf{g}$$

Issues of Discrete Element Method for CDA

DEM is

- A robust approach for granular flow
- But NOT a practical approach for CDA

1. Computational cost

The DEM resolution must be comparable to the actual resolution of the target phenomenon, which makes it unsuitable for very large-scale systems such as NPPs (potentially involving nearly a billion particles). Moreover, the DEM time step, Δt, is generally extremely small.

2. Polydispersity

DEM is primarily designed for monodisperse or simplified particle systems, whereas debris generated during CDA is highly polydisperse.

3. Shape inhomogeneity

Standard DEM contact models are mainly based on spherical particles and are not orientation dependent. Therefore, when particle shapes differ significantly, the applicability of DEM becomes limited.

Research Objective

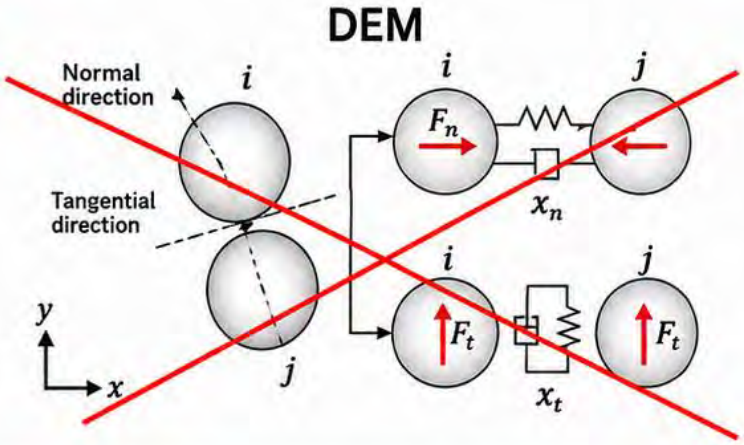
Previous method

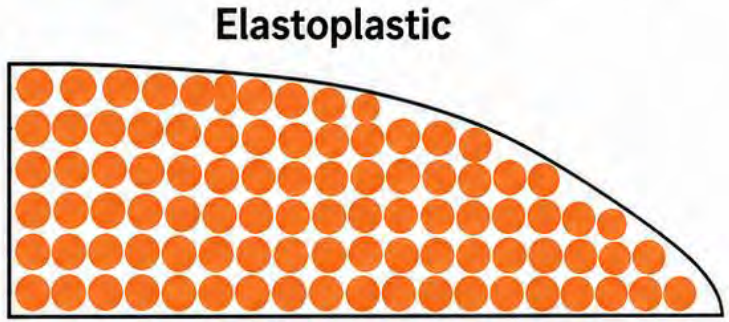
- ~~DEM: Discrete model~~
- CFD: Continuum model

Present method

- MK-SPH: Continuum model
- CFD: Continuum model

✓ Good for large scale
✓ No need to consider the monodisperse
✓ Easily handle shape inhomogeneity





Research Objective

For assessing debris-bed formation on the core catcher, a fully continuum-based solid–liquid two-phase simulation method was developed and compared with a DEM–CFD approach.

Multi-Kernel Moving Particle Hydrodynamics For Solid-Liquid Two Phase Flow

Governing Equations and Explicit Time Integration

1. Governing equation

$$\rho \frac{D\mathbf{u}}{Dt} = \mathbf{F}^{internal} + \mathbf{F}^{external}$$

$$\mathbf{F}^{internal} = \nabla \cdot \boldsymbol{\sigma}$$

$$\mathbf{F}^{external} = \rho \mathbf{g}$$

2. Quantities needed for stress update

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}^k + \frac{\partial \sigma}{\partial t} \Delta t$$

$$\frac{\partial \sigma}{\partial t} = \dot{\boldsymbol{\omega}}\, \boldsymbol{\sigma}^k - \boldsymbol{\sigma}^k\, \dot{\boldsymbol{\omega}} + \lambda_e\, tr(\dot{\boldsymbol{\varepsilon}}) I + 2\mu_e \dot{\boldsymbol{\varepsilon}}$$

$$\dot{\boldsymbol{\varepsilon}} = \frac{1}{2}\left(\nabla \mathbf{u} + (\nabla \mathbf{u})^T\right)$$

$$\dot{\boldsymbol{\omega}} = \frac{1}{2}\left(\nabla \mathbf{u} - (\nabla \mathbf{u})^T\right)$$

$$\lambda_e = \frac{E\nu}{(1+\nu)(1-2\nu)}$$

$$\mu_e = \frac{E}{2(1+\nu)}$$

3. Time update by Forward Euler

$$\mathbf{u}^{(k+1)} = \mathbf{u}^k + \frac{\mathbf{F}^{internal} + \mathbf{F}^{external}}{m} \Delta t$$

$$\boldsymbol{x}^{(k+1)} = \boldsymbol{x}^k + \mathbf{u}^{(k+1)} \Delta t$$

$\nabla \mathbf{u}$ ➡ $\dot{\boldsymbol{\varepsilon}}, \dot{\boldsymbol{\omega}}$ ➡ $\frac{\partial \sigma}{\partial t}$ ➡ $\boldsymbol{\sigma}$ ➡ $\mathbf{F}^{internal}$ ➡ $\mathbf{u}^{(k+1)}$ ➡ $\boldsymbol{x}^{(k+1)}$

✓ Update the stress from the strain rate and spin, compute the internal force from the stress, and then update velocity and position using the Forward Euler method.

○**Ryo Yokoyama et al.,** , A particle-based method for fine granular flow and degradation analysis with an elastic–perfectly plastic Drucker–Prager law, Powder Technology, 469, (2026), 121927

Elastoplastic Stress Update by Return Mapping

Assume the total strain is elastic at first, and apply plastic correction only when yielding occurs.

1. Elastic trial stress

$$\boldsymbol{\sigma}^{trial} = \boldsymbol{\sigma}^{k} + \frac{\partial \boldsymbol{\sigma}}{\partial t}\Delta t$$

2. Yield check

$$f^{trial} = q^{trial} - \alpha_\phi p^{trial} - \kappa$$

$$q = \sqrt{3J_2}$$

$$p = \frac{1}{3}tr(\boldsymbol{\sigma})$$

$$J_2 = \frac{1}{2}\boldsymbol{s} : \boldsymbol{s}$$

$$\boldsymbol{s} = \boldsymbol{\sigma} - p\boldsymbol{I}$$

3. Plastic multiplier

$$K = \lambda_e + \frac{2}{3}\mu_e$$

$$\Delta\gamma = \frac{f^{trial}}{3\mu + K\alpha_\phi\alpha_\psi}$$

4. Stress correction

$$q^{(k+1)} = q^{trial} - 3\mu\Delta\gamma$$

$$p^{(k+1)} = p^{trial} - K\alpha_\psi\Delta\gamma$$

5. Stress reconstruction

$$\boldsymbol{\sigma}^{(k+1)} = \boldsymbol{s}^{(k+1)} + p^{(k+1)}\boldsymbol{I}$$

If no yielding occurs:

$$\boldsymbol{\sigma}^{(k+1)} = \boldsymbol{\sigma}^{trial}$$

Elastic predictor → **Yield check** → **Compute $\Delta\gamma$** → **Stress projection** → **Stress update**

In return mapping, the elastic trial stress is computed first. Only when the yield condition is satisfied is the stress returned to the Drucker–Prager yield surface. This allows the stress to be updated without directly computing the plastic strain.

Fluid Formulation from Lagrangian-Rayleigh Dissipation

1. Lagrangian with Rayleigh dissipation

$$\frac{d}{dt}\left(\frac{\partial \mathcal{L}}{\partial \mathbf{u}_i}\right) - \left(\frac{\partial \mathcal{L}}{\partial x_i}\right) + \left(\frac{\partial \mathcal{D}}{\partial \mathbf{u}_i}\right) = 0$$

$$\mathcal{L} = \mathcal{T} - \mathcal{V}$$

$\mathcal{L}$: Lagrangian
$\mathcal{D}$: Dissipation energy
$\mathcal{T}$: Kinetic energy
$\mathcal{V}$: Potential energy

2. MPH assumptions

$$\mathcal{L} = \sum_i \left(\frac{1}{2}\rho^f \left|\mathbf{u}_i^f\right|^2 + \rho^f \mathbf{g}\cdot\mathbf{x}_i^f\right) V$$

$$\mathcal{D} = \sum_{j'} \left(\frac{\lambda^f}{2}(G_{ij})^2 + \nu^f \sum_{j'} \left(\mathbf{u}_j^f - \mathbf{u}_i^f\right)^2 \frac{w'_{ij}}{|r_{ij}|}\right) V$$

$$G_i = \sum_{j'} \left(\left(\mathbf{u}_j^f\right)^k - \left(\mathbf{u}_i^f\right)^k\right) \cdot \mathbf{e}_{ij}\, w'_{ij}$$

3. Discrete terms

$$\frac{d}{dt}\left(\frac{\partial \mathcal{L}}{\partial \mathbf{u}_i}\right) = \rho^f \frac{D\mathbf{u}_i^f}{Dt} V \qquad \frac{\partial \mathcal{L}}{\partial x_i} = \rho^f \mathbf{g}\, V$$

$$\frac{\partial D_1}{\partial \mathbf{u}_i} = \sum_j (p_j + p_i)\, \mathbf{e}_{ij}\, w'_{ij}\, V$$

$$\frac{\partial D_2}{\partial \mathbf{u}_i} = -2\mu^f \sum_j \left(\mathbf{u}_j^f - \mathbf{u}_i^f\right) \frac{w'_{ij}}{|r_{ij}|} V$$

$$p_i = -\lambda^f G_i + \kappa^f (n_i - n_0)$$

4. Resulting fluid momentum equation & explicit update

$$\frac{D\mathbf{u}_i^f}{Dt} = -\frac{1}{\rho_0^f}\sum_j (p_j + p_i)\, \mathbf{e}_{ij}\, w'_{ij} + 2\nu^f \sum_j \left(\mathbf{u}_j^f - \mathbf{u}_i^f\right) \frac{w'_{ij}}{|r_{ij}|} + \mathbf{g}$$

Explicit time integration (fluid solver only)

$$p_i^k = -\lambda^f \sum_j \left(\left(\mathbf{u}_j^f\right)^k - \left(\mathbf{u}_i^f\right)^k\right) \cdot \mathbf{e}_{ij}\, w'_{ij} + \kappa^f (n_i - n_0)$$

$$\left(\mathbf{u}_i^f\right)^{k+1} = \left(\mathbf{u}_i^f\right)^k + \left[-\frac{1}{\rho_0^f}\sum_j (p_j^k + p_i^k)\mathbf{e}_{ij}\, w'_{ij} + 2\nu^f \sum_j \left(\left(\mathbf{u}_j^f\right)^k - \left(\mathbf{u}_i^f\right)^k\right) \frac{w'_{ij}}{|r_{ij}|} + \mathbf{g} + \frac{1}{\rho_0^f}\mathbf{F}_{ext}\right] \Delta t$$

$$\left(\mathbf{x}_i^f\right)^{k+1} = \left(\mathbf{x}_i^f\right)^k + \left(\mathbf{u}_i^f\right)^{k+1} \Delta t$$

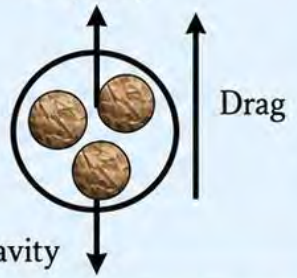
The Lagrangian–Rayleigh formulation yields a mathematically and physically consistent discretized fluid momentum equation, and the explicit fluid scheme remains stable without artificial force.

Fluid-Granular 2 Way Coupling

1. DEM-CFD: Granular size = DEM size, thus modeling is straightforward
2. Present method: Granular size ≠ particle size, thus a control-volume-based scaling is introduced

1 DEM-based simulation

DEM size = Debris size



2 MK-MPH based simulation

MK-SPH size ≠ Debris size

1 DEM-CFD formulation

$$F_{Buoyancy} = \rho_f V_d g$$

$$F_{Drag} = \frac{1}{2} C_d \rho_s A_d |V_d| V_d$$

Drag coefficient C_d

$$C_d = \frac{4}{3}\left(150\frac{1-\varepsilon_f}{\varepsilon_f Re} + 1.75\right), \quad (\varepsilon_f < 0.8)$$

$$C_d = \frac{24(1+0.15Re^{0.687})}{\varepsilon_f Re}\varepsilon_f^{-2.65}, \quad (Re \le 1000)$$

$$C_d = 0.44, \quad (Re > 1000)$$

2 MK-MPH based formulation (control-volume scaling)

$$V_{control} = \Delta x^3$$

$$V_d = \frac{\pi {d_d}^3}{6}$$

$$\alpha_s = \frac{N_d V_d}{V_{control}}$$

$$\varepsilon_f = 1 - \alpha_s$$

$$F_{Buoyancy} = \rho_f \alpha_s V_{control} g$$

$$F_{Drag} = \beta V_{control}(\mathbf{u}_f - \mathbf{u}_d)$$

$$\beta = \frac{3}{4} C_d \rho_f \alpha_s \frac{|\mathbf{u}_f - \mathbf{u}_d|}{d_d}$$

- α_s: solid volume fraction of actual debris in one control volume
- ε_f: fluid volume fraction / porosity
- β: interphase momentum exchange coefficient

Thus, buoyancy and drag are scaled by the **actual debris fraction** and **actual debris size**, not by the numerical particle size.

Calculation Results

Dam Break Simulation

Granular Flow Dam Break:

1. Angle of Repose
2. Spreading Length depends on outlet

Conclusion

<Objective> Establish a novel MK-SPH/MPH-based solid–liquid flow simulation framework to enable practical and accurate analysis of debris bed formation in SFRs.

- To overcome the practical limitations of DEM, including high computational cost and complex polydisperse/inhomogeneous behavior, a fully continuum fluid–granular model based on the elastoplastic Drucker–Prager framework is developed.
- The return-mapping stress update enables fast and stable computation through an implicit update of the plastic strain.
- Scaled solid–liquid coupling models are employed to account for the difference between the computational particle size and the actual debris size.
- Benchmarking against in-house GPU DEM shows accurate granular-flow reproduction with reduced computational cost.
- The MK-SPH/MPH method successfully reproduces large-scale debris-bed formation experiments, regardless of particle size.
- High computational speed and scalability enable real-scale debris-bed formation simulations in SFRs.

ABSTRACT

The Accident Source Term Evaluation Code (ASTEC) developed by ASNR is dedicated to simulating Severe Accidents (SA) in nuclear facilities. It has been continuously improved since its first developments in 1996, following the two objectives of being at the state of the art of scientific knowledge and increasing the scope of code application with consideration of new reactor designs. In the last decade, significant work was done worldwide to propose new materials for the reactor core, with the objective of improving efficiency and safety. Those Advanced Technology Fuels (ATF) are numerous and cover both fuel and claddings materials. Among them, the Cr-coated Zr-based claddings have attracted a lot of interest and are considered today as a mature concept for application in light water nuclear reactors. Dedicated models for Cr-coated claddings have thus been recently developed in ASTEC code based on available knowledge from R&D. They will be part of V3.2 ASTEC version.
Based on experimental data published in literature, it is shown that the protective effect of the Cr-coating against oxidation at low temperature is well reproduced by ASTEC code. It is also the case for the Cr diffusion into Zr substrate leading to possible loss of protective effect even below the Cr-Zr eutectic temperature. Lack of experimental data at high temperatures (above 1300°C) prevents further model development and validation. The simplified model proposed for the oxidation runaway at the Zr-Cr eutectic temperature may underestimate this effect, particularly for the high heating rates expected. With regard to the simulation of the cladding failure and material relocation phenomena, in the absence of quantitative data, no modifications taking into account the impact of the Cr coating have been implemented in the code at this stage. Applications at reactor scale were performed and allow quantification of impact of Cr-coated claddings for two different Station Black Out (SBO) SA scenarios in a typical Pressurized Water Reactor (PWR) of 900MWe. Results showed that the Cr-coated claddings have a noticeable impact on the behaviour of the core heating and the H_2 production. However, this effect is dependent on the SA scenario considered. No generic conclusions on the H_2 mass and production rate can be drawn due to combination of several effects. In particular, the main impacts of the residual power and of the possible water injections in the vessel are illustrated.
In the future, modelling improvements should continue for the behaviour at higher temperatures and up to the mechanical failure or melting of Cr-coated claddings.

KEYWORDS
ASTEC code, Cr-coated Zr-based cladding, modelling, severe accident

1. INTRODUCTION

The Accident Source Term Evaluation Code (ASTEC) developed by ASNR is dedicated to simulating severe accidents in nuclear facilities [1]. This mechanistic computer code models the ongoing accident sequence from initiating events to release of the source term outside the containment, covering core degradation,

fission product chemistry and transport up to environment and containment behaviour. ASTEC has been continuously improved since its first developments in 1996, following the two objectives of being at the state of the art of scientific knowledge and increasing the scope of code application with consideration of new reactor designs [2][3][4]. In addition, code versatility and flexibility allow performing exploratory evaluations. Such evaluations were done in particular to estimate impact of new fuel material properties [5][6]. Indeed, in the last decade, significant work was done worldwide to propose new materials for the reactor core, with the objective of improving efficiency and safety. Those Advanced Technology Fuels (ATF) are numerous and cover both fuel and claddings materials. Among them, the Cr-coated Zr-based claddings have attracted a lot of interest and are considered today as a mature concept for application in light water nuclear reactors. In this context, ASNR decided to implement dedicated models in ASTEC code to properly deal with such cladding material. Even if these new materials cannot significantly affect the evolution of a severe accident and core degradation kinetics in a scenario without effective cooling system, it is necessary to adapt the modelling in the SA codes to be able to predict their behaviour at least with the same level of uncertainties as for existing fuels.

Most of the experimental and modelling works performed up to now have been done for Design Basis Accident (DBA). The phenomenology of Cr-coatings under steam oxidizing atmosphere until Zr-Cr eutectic temperature has been well characterized and understood. However, for higher temperatures, the experimental data remain limited. Recently, the first bundle test in SA conditions was performed in the scope of the OECD QUENCH-ATF project [7]. In the late phase of the SA, the impact of the Cr-coating is expected to be negligible due to the limited mass of Cr added. Nevertheless, existing models in SA codes already consider the presence of Cr in the corium pool due to its incorporation after the melting of steel structures in the reactor.

In this paper, models implemented in ASTEC V3.2 code for the simulation of Cr-coated Zr-based claddings in early phase of SA are presented and validated based on available experimental results published in literature. The transition phase around the Zr-Cr eutectic temperature after which oxidation acceleration is observed is also modelled with a simplified approach and results are compared with experimental data. Further needs for better understanding of the phenomena involved and model improvements are identified. Finally, applications at reactor scale in a generic PWR900 reactor for two SBO scenarios with different levels of residual power in the core when degradation occurs, are presented. These evaluations highlight the impact of Cr-coated claddings on the core degradation as predictable based on existing knowledge.

2. ASTEC MODELLING

The Cr-coating is simulated in ASTEC code with a dedicated layer modelled at the surface of the cladding component. The concept of 'LAYER' in ASTEC code has been used for many years, in particular to model the Zr oxidation and associated formation of α-Zr and ZrO_2 layers at the surface of the claddings. Each 'LAYER' has its own composition and material properties but the different 'LAYER' which belong to the same cladding component have the same temperature. The main phenomena associated with this Cr-coating during the early phase of a SA have been modelled in ASTEC code and are listed below:

- Cr oxidation to form Cr_2O_3 layer at the external surface of the cladding
- Cr diffusion into β-Zr substrate
- Progressive loss of Cr protection below Cr-Zr eutectic temperature
- Cr-Zr eutectic leading to loss of Cr layer integrity
- Once burst opening is reached, the internal surface of the cladding, made of Zr is oxidized in parallel with the oxidation of the Cr-coated external surface

The modelling developed in ASTEC for the first four points are described in the paragraphs below. The last point uses ASTEC capacities already developed in the past. Associated description of these phenomena (burst opening, oxidation of claddings internal surface and Zr oxidation models) is available in the code documentation [8][9]. It should be noted that, at this stage, the Cr volatilization is neglected. Indeed, it was shown experimentally [10] that the volatilization rate remains limited for temperatures under which the Cr layer remains protective (i.e. typically below the one of the Cr-Zr eutectic temperature). In accordance, both

experimental results analyses proposed by Brachet et al. 2020 [11] and modelling work of Wu et al. 2023 [12] show negligible impact of the consideration of the Cr_2O_3 volatilization in the evolution of the Cr consumption kinetics up to 1300°C.

2.1. Cr oxidation

Cr oxidation reaction is modelled as a parabolic law for oxygen mass gain, as classically used for metals oxidation when the kinetics are driven by diffusion process through the oxide layer. By default in ASTEC code, the kinetics proposed is derived from experimental data of Brachet [11] and associated correlation for Cr_2O_3 thickness evolution, as illustrated Figure 1. Compared with other available experimental data, this kinetics is valid for dense Cr layer providing an efficient protection regarding oxygen diffusion and thus Zr-substrate oxidation. As described by Kashkarov [13], higher oxidation kinetics have been measured especially for columnar Cr-coating. This effect was also studied in [11], with experimental study of the effect of annealing on the coating layer microstructure and consequently on oxidation kinetics. Thanks to user parameters which allow modification of the Cr oxidation law in ASTEC code, different kinds of coating can be simulated. The kinetic of Cr oxidation modelled in ASTEC code is calculated with following mass evolution equation:

$$\frac{m_O(t+dt)}{S} = \left(\left(\frac{m_O(t)}{S}\right)^2 + A\, e^{-\frac{B}{RT}} dt\right)^{0.5} \quad (1)$$

With m_o the Oxygen mass (kg), S the surface (m²), R=8.314 J/mole.K, T the temperature (K), t the time (s) and dt the time step (s). Default value derived from Brachet's data [11] for constants A and B are respectively A=16.75 kg²/m⁴/s and B=238.7 kJ/mole.

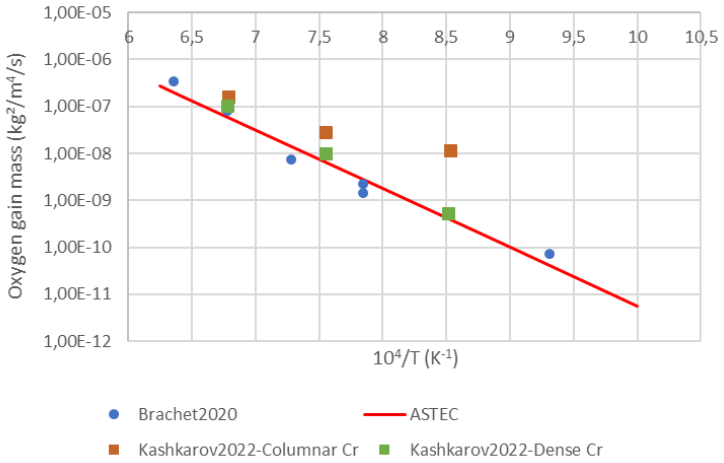

Figure 1. Oxidation law for Cr-coated claddings in ASTEC code and comparison with experimental data [11][13][1].

2.2. Cr diffusion and loss of Cr protectiveness

Cr diffusion into β-Zr has been observed experimentally and reported in many studies, for examples Brachet [11], Yang [15], Kim [16] and Li [17]. At the Cr/Zr interface, a $ZrCr_2$-intermetallic layer is formed, consistently with the Zr-Cr phase diagram [18], even at low temperatures. During high temperature

[1] Note that correlations are usually derived based on experimental measurements of Cr_2O_3 thickness. In ASTEC code, oxidation law is based on Oxygen mass gain and conversion has been done for all experimental data presented in Figure 1 based on the same reference for the Cr_2O_3 density law depending on temperature [14].

oxidation, Cr-Zr inter-diffusion takes place and may, after a certain time, lead to loss of the Cr layer integrity. This transition from protective to non-protective Cr-coating was phenomenologically described by Brachet in 2020 [11] and further by Wu [12] for example. It involves several complex physical phenomena induced by Cr oxidation at the external surface, diffusion through $ZrCr_2$ layer into the β-Zr phase, formation of porosities and deformation at the interfaces of the Cr layer and intergranular diffusion of Zr through the residual metallic Cr layer with finally formation of a zirconia intergranular network leading to loss of Cr protectiveness. Models have been developed to simulate the Cr diffusion into the β-Zr phase as well as the $ZrCr_2$ thickness evolution [12][16][19]. However, due to the complexity of the phenomena involved, there is no model available to simulate the porosities and intergranular network formations. In the scope of Design Basis Accident (DBA) studies, Brachet proposed a macroscopic criterion able to represent the fragilization of the Cr-coating called Equivalent Chromium Reacted (ECrR) in reference to the Equivalent Cladding reacted (ECR) parameter used for Loss Of Coolant Accident (LOCA) [20]. This parameter takes into account the Cr-coating "consumption kinetics" under high temperature oxidizing environment and the influence of the initial Cr-coating thickness. It corresponds to the fraction of the Cr-coating that has been consumed either due to the oxidation or to the diffusion. Experimental tests reveal that post quenching Ductile-to-Brittle Transition (DBT) is reached for a ECrR of nearly 70%. This fragilization of the cladding can be related to the loss of Cr layer integrity. This approach is used in ASTEC code to model the loss of Cr protectiveness below the Zr-Cr eutectic temperature.

In this model, the thickness of the $ZrCr_2$ layer is neglected and a parabolic law is used for the reduction of the Cr layer thickness due to Cr diffusion into β-Zr based on the kinetics given by Brachet [20]. It should be noted that implicitly the $ZrCr_2$ phase formation is considered in this modelling since its presence limits the diffusion of Cr in β-Zr and impacts the kinetic. The default values implemented in the ASTEC model for the Cr diffusion kinetics based on Brachet's work and recalled below are applicable to dense Cr coating. As shown by Yang [15] and Kashkarov [13], different types of Cr coating may lead to faster Cr diffusion and Cr oxidation kinetics. For such coating, it is possible for the ASTEC user to adapt, similarly to the oxidation kinetic, the diffusion kinetics in order to represent coating specificities.

$$\Delta Cr_{Cr\ diffusion\ into\ \beta-Zr}(t+dt) = \left(\left(\Delta Cr_{Cr\ diffusion\ into\ \beta-Zr}(t)\right)^2 + \left(ADIF\ e^{-\frac{BDIF}{RT}}\right)^2 dt\right)^{0.5} \quad (2)$$

With $\Delta \mathrm{Cr}_{Cr\ diffusion\ into\ \beta-Zr}$ the thickness of Cr layer consumed due to Cr diffusion into β-Zr. Default value from Brachet's work [20] for constants ADIF and BDIF are respectively ADIF=8610 μm/$s^{0.5}$ and BDIFF=142.7 kJ/mole.

The progressive loss of the coating protectiveness is evaluated based on the evolution of the ECrR parameter (XREA parameter in ASTEC code) considering the following law for the surface fraction of Zr in contact with Oxygen:

$$Xzr = (1 - XPRO_MIN).\left(\frac{XREA - XREA_MIN}{XREA_MAX - XREA_MIN}\right)^2 \quad (3)$$

With XPRO_MIN, XREA_MIN and XREA_MAX three parameters of the model which are by default chosen to represent the loss of Cr protectiveness for dense Cr layer respectively to 0.3, 0.6 and 0.9. The determination of these values will be presented and discussed in § 3.1.2 dedicated to validation works.

When XREA variable (fraction of initial Cr thickness which has reacted due to oxidation or diffusion) is below XREA_MIN, the Cr layer is fully protective. Then, the oxidation of the Zr begins progressively until XREA reaches the value of XREA_MAX at which the surface of Zr available for oxidation is considered equal to (1-XPRO_MIN) i.e. 70% of the available surface for XPRO_MIN default value of 0.3. Indeed, it is assumed that not all the Zr surface is available for oxidation even after disappearance of the Cr layer due to the presence of the chromia layer. This parameter can be changed by the user for sensitivity study.

It is worth noting that the loss of protection remains limited after reaching the XREA_MIN threshold and becomes significant when the XREA variable approaches the XREA_MAX parameter, due to the parabolic function used in equation (3). This modelling is used to represent in a simplified way the physical transition

from intergranular diffusion of Zr through the residual metallic Cr layer to formation of a zirconia intergranular network observed experimentally [11]. For less dense coating, the criteria used for loss of coating integrity may be adapted by the users. Indeed, the coating deposition method significantly affects the coating properties involved in the loss of integrity due to differences in microstructures of the layer.

2.3. Zr-Cr eutectic

Formation of Zr-Cr eutectic in the cladding is not simulated in ASTEC code for now. Its effect on the evolution of the cladding oxidation being predominant with strong increase of H_2 production once Cr protection is lost at this temperature, it is modelled by the melting of the Cr layer leading to expose of the Zr surface to steam. Eutectic temperature is specified in the input deck thanks to the modification of the Cr solidus and liquidus temperatures (respectively to 1332°C and 1333°C). Once molten, the Cr layer below the oxidized Cr layer is no longer protective and Zr oxidation begins in the code. The liquid Cr layer is however maintained at the periphery of the cladding until mechanical failure (user defined failure criteria for claddings) or melting of the Cr_2O_3 external layer.

3. VALIDATION BASED ON AVAILABLE EXPERIMENTAL RESULTS

3.1. Isothermal tests

3.1.1. Inert atmosphere

Isothermal tests performed in inert atmosphere are designed to study the Cr-Zr interaction. They allow validation of the Cr diffusion model implemented in ASTEC code. Since the kinetics used in ASTEC has been proposed by Brachet based on CEA and Framatome experimental results, it is proposed to validate ASTEC based on independent data obtained by Kim [16] and Yang [17]. In Figure 2, the evolution of the residual Cr thickness with time, at different temperatures ranging from 1000°C to 1300°C, evaluated by ASTEC code is compared with experimental data. These validations show satisfactory results and thus confirm validity of the simplifying assumptions considered in the model as neglecting the $ZrCr_2$ thickness. In particular, it should be noted that more complex models, as presented in [16], show comparable deviation with experimental results.

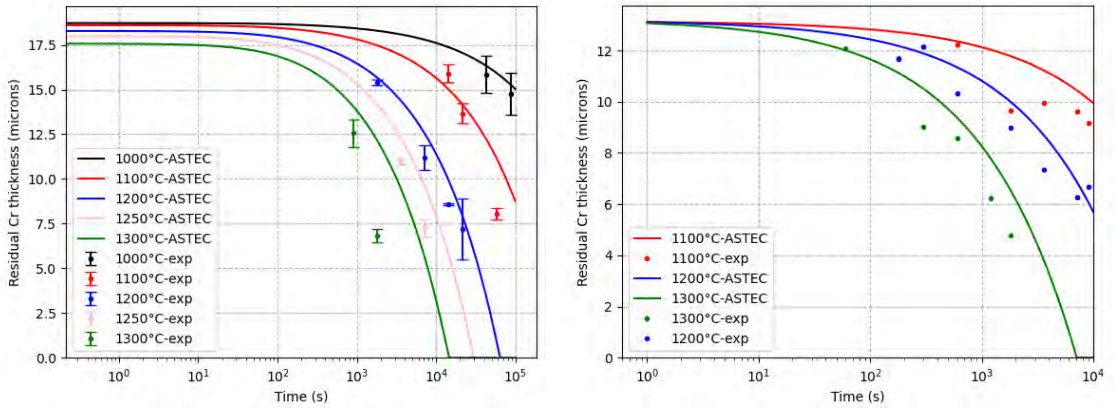

Figure 2. Validation of Cr diffusion model in ASTEC code against experimental results of Kim et al. [16] (left) and Yang et al. [17] (right).

3.1.2. Oxidizing atmosphere

Experimental results obtained in oxidizing atmosphere are used to validate first the kinetics of Cr oxidation (equation (1)) and then the progressive loss of Cr protectiveness (equation (3)).

Figure 3 shows ASTEC results for isothermal oxidation of a 15µm protective Cr coating and comparison with non-coated case and experimental results at 1100°C and 1200°C. Bischoff and Brachet data are obtained for cylindrical geometry and a 10-15µm Cr coating on M5 substrate. A good agreement with experimental data is obtained and the strong reduction of oxidation due to the Cr coating is well captured.

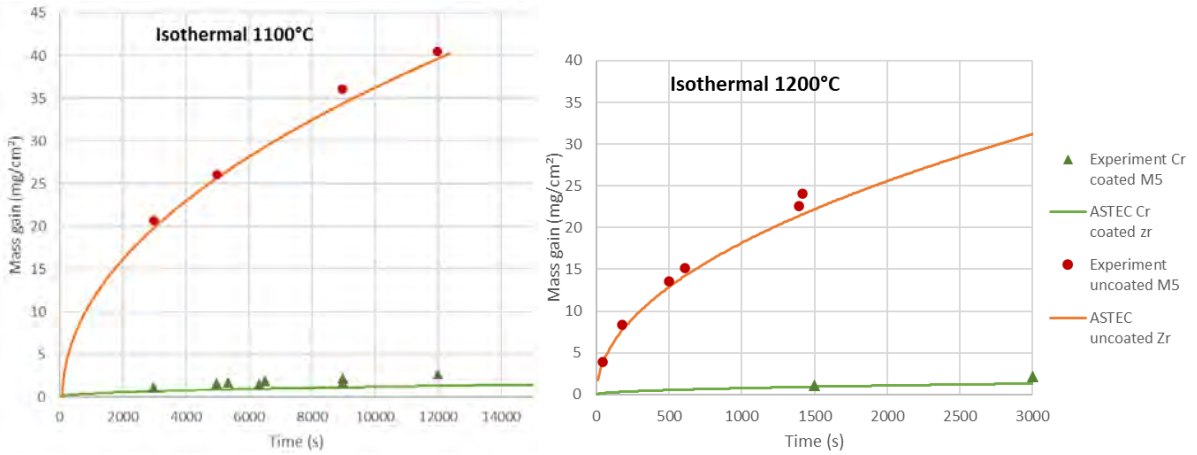

Figure 3. Comparison of ASTEC code oxidation results at 1100°C (left) and 1200°C (right) against experimental data from Bischoff [21] and Brachet [22] when Cr layer is protective.

Then, oxidation law for protective Cr coating and its transition to unprotective coating below Cr-Zr eutectic temperature as implemented in ASTEC code are compared to the same experimental data available also for longer durations. As illustrated in Figure 4, ASTEC code well predicts experimental results. The loss of Cr layer integrity and subsequent start of Zr oxidation is clearly visible with changes in the oxidation rates. As expected, the transition occurs earlier for higher temperatures. The experimental results obtained at 1200°C have been used to select the default parameters of the transition model as illustrated in Figure 5.

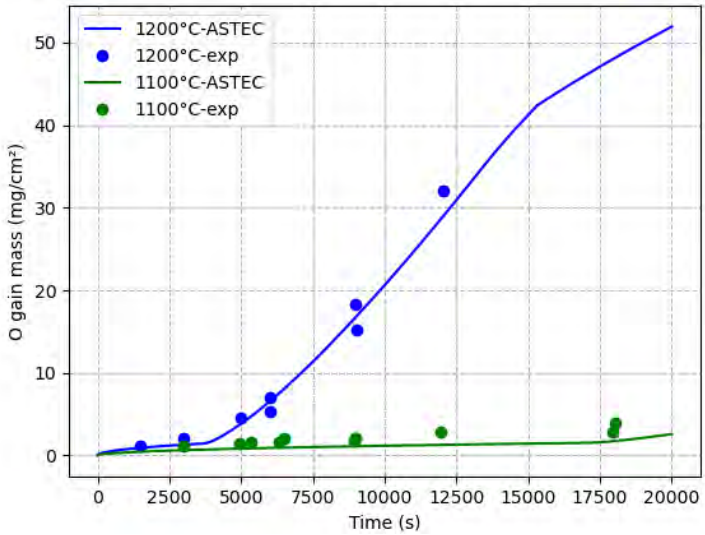

Figure 4. Comparison of ASTEC code oxidation results at 1100°C and 1200°C against experimental data from Bischoff [21] and Brachet [22] up to loss of protective Cr layer.

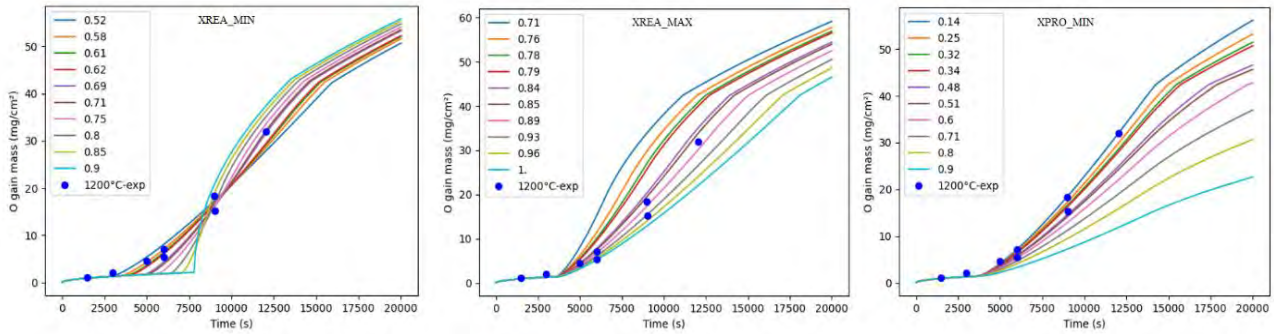

Figure 5. Influence of ASTEC code modelling parameters for the simulation of the transition phase.

3.2. Transient tests up to temperature above the Zr-Cr eutectic

In this part, it is proposed to check ASTEC predictions at higher temperatures above Zr-Cr eutectic temperature, even if simplified modelling is considered in the code for now. For this purpose, experimental results published by Kim et al. [23] are used. In these tests, Zircaloy 4 plates coated with 17µm Cr layer are oxidized and heated up to 1380°C with different heating rates. Results of ASTEC simulations presented in the left side of Figure 6 show that acceleration of oxidation reaction above eutectic temperature, compared to uncoated claddings is well reproduced by the code. A reduction of the maximum mass gain rate for the case of 2K/min heating rate, is visible and can be explained by the loss of the protectiveness of the Cr layer before reaching the Zr-Cr eutectic temperature. This reduction for low heat rate is also obtained experimentally (see Figure 6, right). For the other cases, a maximum mass gain rate of about 70mg/min is evaluated by ASTEC. In the experiment, this maximum value reaches 100mg/min for the highest heating rate of 50K/min but is about 35mg/min for 30K/min. A rapid decrease of the mass gain rate is observed in the ASTEC simulation after the runaways which is not observed experimentally, at least in this small range above eutectic temperature (only 50 K). This analysis shows that, as expected, the simplified approach proposed currently in ASTEC code is not sufficient to reproduce the physical phenomena occurring in the Cr-coated claddings when Zr-Cr eutectic temperature is reached. However, it is also interesting to see that for high heating rate (typically 50K/min) the proposed modelling is not conservative, despite the instantaneous switch to the Zr oxidation model considered. This can be interpreted as an indication of the primary role of the liquid eutectic phase in this runaway of the oxidation kinetics which requires further studies before drawing any conclusion.

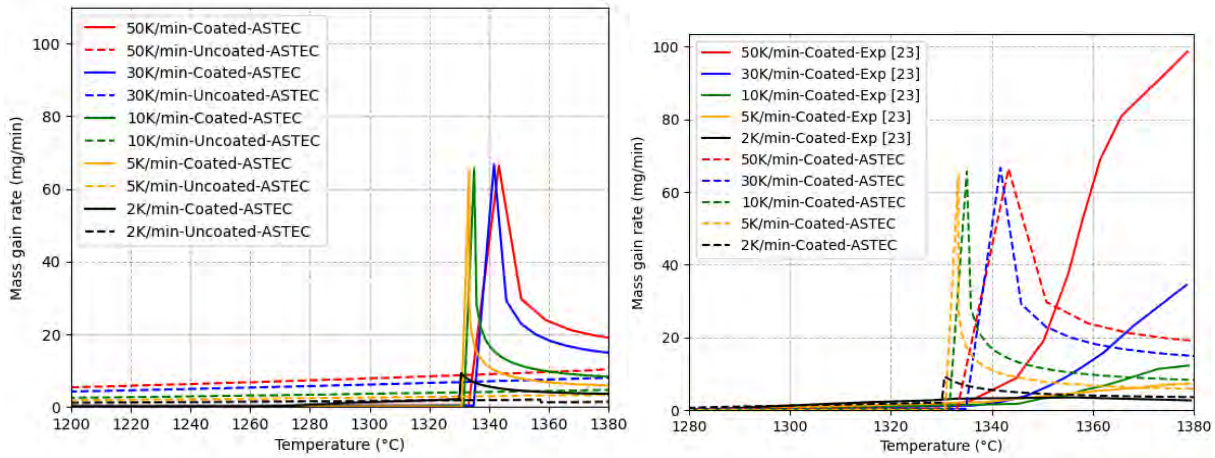

Figure 6. ASTEC code results for transient heating tests with coated and uncoated claddings (left) and comparison for coated claddings with Kim experimental data [23] (right).

Further experiments, in particular in cylindrical geometry, are thus necessary to better understand the main physical processes occurring and to propose adapted models for severe accident codes. Indeed, the plane geometry may have an impact on the kinetics of the loss of Cr layer protectiveness compared to cylindrical geometry.

4. REACTOR APPLICATIONS

Knowing the validation status of the models developed in ASTEC code for Cr-coated claddings, it is proposed in this part to present exploratory calculations at reactor scale to evaluate potential impact of these new claddings. Since too few experimental data (one QUENCH test [7]) are available at temperatures corresponding to the mechanical failure and melting of the Cr-coated claddings, the integrity criteria used for uncoated claddings are used also for the Cr-coated claddings, in these exploratory simulations of SA at reactor scale. This means that it is assumed that the Zr-Cr eutectic has no impact on the cladding mechanical strength. The failure is achieved considering the two following steps:

- Cracking of the oxide layer allows relocation of molten materials (including Cr) when temperature and zirconia thickness criteria are met (melting temperature of Zr if no zirconia layer and linear function up to 2500K for 500µm of ZrO_2).
- Collapse of the claddings and solid debris formation between 2550K and 2600K depending on the zirconia thickness.

It should be kept in mind that for Cr-coated claddings, it would be necessary to justify the validity of these criteria. In particular, it can be expected that loss of cladding integrity will be reached at lower temperature due to Zr interaction with Cr but no quantitative data is available at this time.

A Station Black Out (SBO) scenario is selected. The main events occurring in this scenario for the reference ASTEC simulation (i.e. with uncoated claddings) are summarized below:

- Start of core dewatering ~2h20 after the reactor scram
- Degradation begins at high pressure
- Break opening in the hot leg at about 3h, leading to vessel depressurization
- Start of accumulators discharge, leading to reflood partially the core
- 3h45 restart of core degradation

In order to study the impact of the residual power, a second scenario has also been considered based on the first one but considering the availability of safety injection systems during 24h after the start of the accident. In this case, the water inventory in the vessel is maintained thanks to the high-pressure injection system, as long as it is operational. Then, the main events occurring are similar to the first SBO scenario: The core dewatering occurs 28h after the reactor scram and the second core degradation after accumulators discharge (due to breach opening in the primary circuit and depressurization) at about 30h. For simulations with Cr-coated cladding, a coating of 10µm is considered for all fuel claddings. Control rods guide tubes and instrumentation guide tubes in Zr are also coated but not the grids. The creep law used to evaluate the ballooning and the burst opening of the claddings is considered not modified by the coating. In any case, differences can be considered as negligeable for SA progression. Once burst opening is achieved, internal oxidation of the cladding starts but is limited at the corresponding elevation. Associated impact at reactor scale remains thus limited.

Comparison of hydrogen production with or without Cr coating and for the two SBO scenarios is presented in Figure 7. After the start of the H_2 production, a plateau is visible in the curves associated with the accumulators discharge as discussed above. Then, degradation restarts and further H_2 is produced until reactor vessel failure and corium transfer to the reactor pit. In the first scenario, a delay in the H_2 production is visible of about 15min. The total hydrogen produced is reduced by about 100kg in the simulation with the Cr-coated claddings. The origin of the H_2 masses is also described in the Figure 7. It is worth noting that here, H_2 production from corium includes molten or resolidified materials either in form of corium films or corium pool. It allows identifying that this reduction is mainly due to the reduced oxidation of the claddings surface before melting of material and relocation outside of the claddings. Oxidation of corium is not

impacted by the Cr-coating in this scenario with current modelling assumptions of claddings failures. In the second scenario, with core dewatering delayed of about 24h, a strong reduction of the H_2 production before accumulator's discharge is visible (Figure 7, right). The Cr-coated claddings prevent significant core heating before accumulators discharge. Then, the total H_2 masses produced during core degradation are comparable. This is explained by a larger oxidation of the corium in case of Cr-coated claddings compensating partly for the reduction of the cladding oxidation (reducing the Zr oxidation of the claddings leads to the formation of a corium with a lower degree of oxidation, which will then potentially be more oxidized). At the end the total mass of H_2 produced is lower for Cr-coated claddings mainly due to the reduced production during the first degradation phase. Thanks to the accumulators discharge, the massive hydrogen production (100kg) is delayed by about 2h. However, considering the time when the cumulated H_2 mass reaches 200kg, this delay is reduced to 30min. These results highlight the combined effect of the water injection and the residual power on the capacity of Cr-coated claddings to delay accident progression.

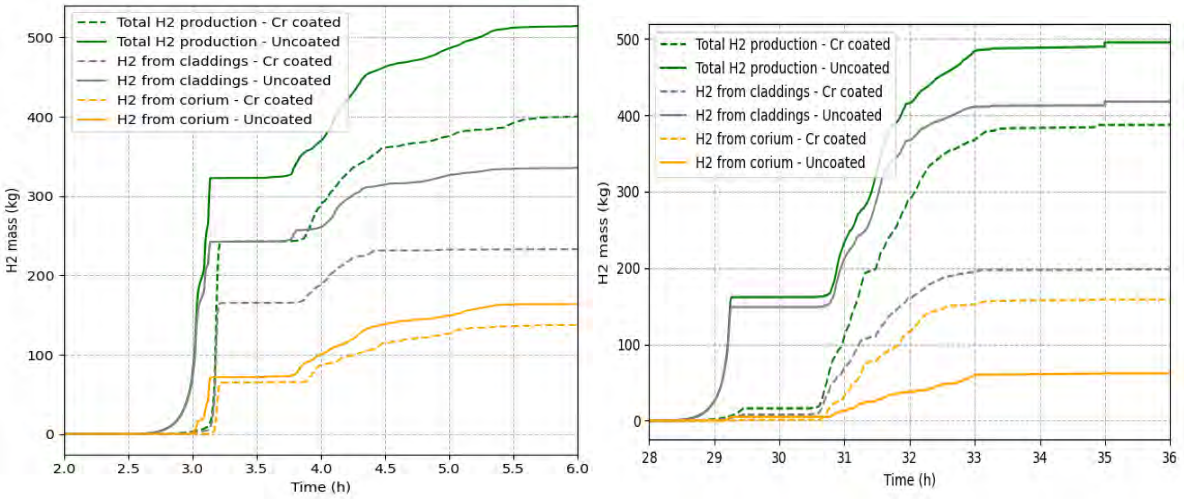

Figure 7. H_2 production during core degradation: impact of Cr-coating on claddings and corium oxidation for SBO scenario with loss of all safety system (left) and SBO scenario with loss of high- and low-pressure injection systems 24h after the reactor shutdown (right).

Comparison of temperature evolutions in case of uncoated and Cr-coated claddings is presented on the left of Figure 8 for the SBO reference scenario. It exhibits the start of exothermic Zr oxidation reaction in the case of uncoated claddings with a progressive increase of the slope of the curves until about 1800K, where oxidation runaway is predicted by Zr oxidation law. On the contrary, the temperatures evolution for Cr-coated claddings remains mainly affected only by the residual power until reaching the Zr-Cr-eutectic temperature at 1600K. At this point, Zr oxidation begins with strong impact and stiff temperature escalation. Due to this sudden loss of Cr protection, the maximum instantaneous heating rates calculated in the case of Cr-coated claddings are even higher than those observed for uncoated claddings at oxidation runaway (cf. right side of Figure 8). This behaviour is also observed at reactor scale for the total H_2 mass produced, as illustrated on the left of Figure 9: the kinetics of cumulated H_2 production rate is higher for Cr-coated claddings compared to uncoated.

On the contrary, in the SBO scenario with 24h delay, the first degradation phase is stronger for uncoated materials leading to higher H_2 production rates. Then, during the second degradation phase, the Cr-coated simulation does not exhibit high H_2 production rate at reactor scale. This may be explained by two factors associated with the reduced residual power in this scenario (15MW at start of core dewatering versus 30MW for the reference scenario) leading to a lower heating rate of the core before oxidation runs away. Firstly, due to a more progressive heating of the core (in the case of the reference SBO scenario, a large part of the core heats up at the same time), the Zr-Cr eutectic temperature is reached only locally and, as a consequence, the local increase of H_2 production rate is not visible at reactor scale. Secondly, in this scenario, part of the

claddings loses the Cr protectiveness before reaching the Zr-Cr eutectic temperature. As observed in § 3.2 for the validation based on Kim experiments, this phenomenon prevents the strong oxidation above Zr-Cr eutectic temperature due to the preliminary formation of protective ZrO_2 layer.

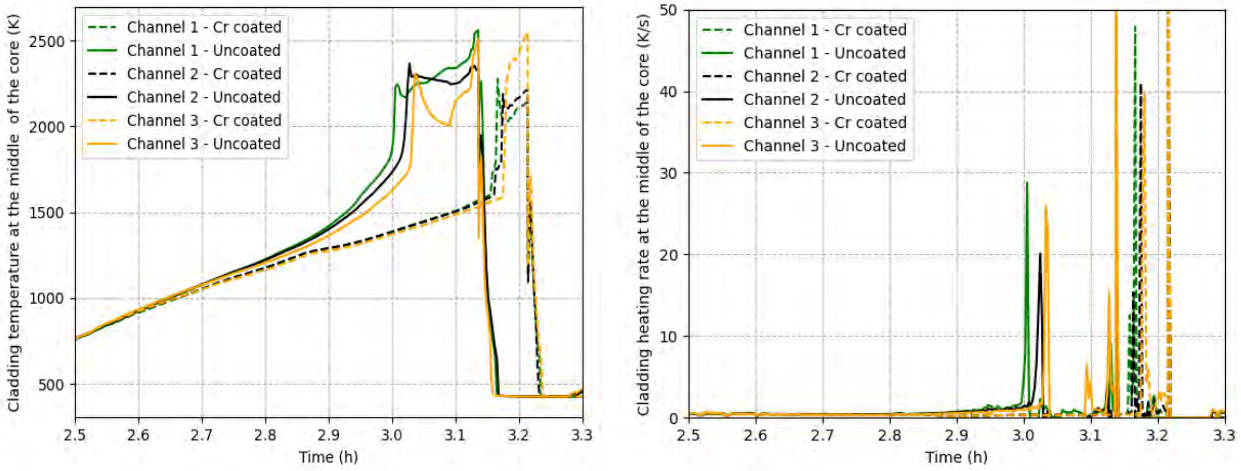

Figure 8. Evolution of claddings temperatures (left) and heating rates (right) at the middle of the core (axially and for the 3 channels in the center of the core[2])

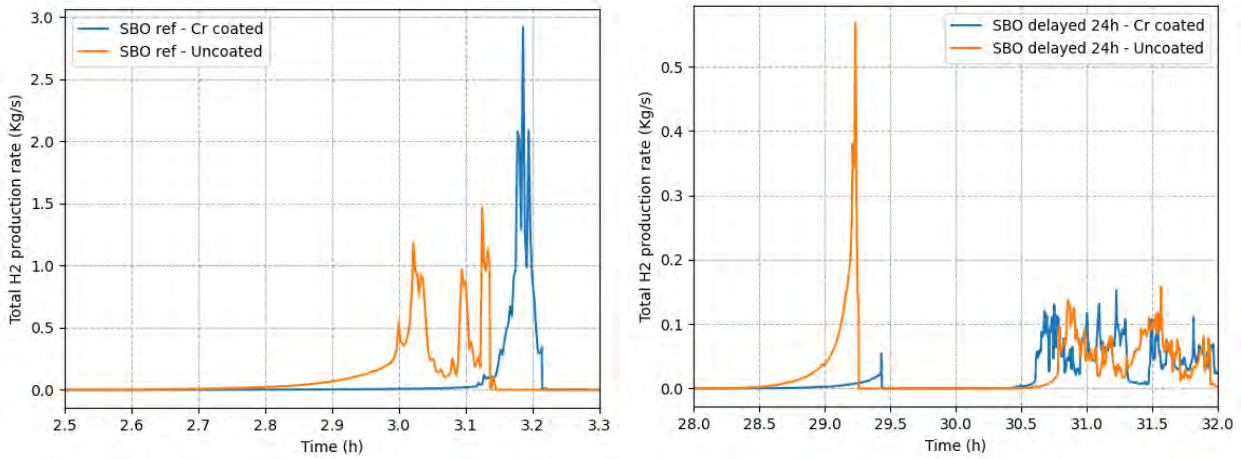

Figure 9. Evolution of H_2 production rate for uncoated and Cr-coated claddings during core degradation for the two SBO scenarios studied

The evolution of the maximum value of Cr reaction rate (XREA parameter) in all the claddings in the core during the degradation is presented for both SBO scenarios on the left side of Figure 10. It is shown that in the case of the reference SBO scenario, the Cr coating integrity is not lost before reaching the eutectic temperature of Zr-Cr. A maximum value of 0.57 is obtained which is close to the minimum value of 0.6 considered in the model (XREA_MIN parameter, cf. § 2.2). For the SBO scenario with the delay of 24h, as mentioned above, the lower residual power in the core leads to slower heating rate of the claddings and the maximum cladding's reaction rate in the core reaches 0.7. Locally loss of Cr protection has thus been reached below Zr-Cr eutectic temperature in this scenario.

[2]A total of 5 channels is used for the radial discretization of the core. The temperatures evolutions in the two channels at the periphery of the core are not presented because they are influenced by the relocation of molten material from the central part of the core which prevents identification of claddings oxidation at high temperature.

In the right side of Figure 10, a detailed study of the loss of cladding integrity at one selected location in the reactor among places, where it is observed, is proposed. The evolution of the Cr cladding reaction rate is presented in relation with the cladding temperature, the fraction of Zr surface available for oxidation and the associated H_2 production. At 30h, the accumulators' discharge is finished, and the cladding temperature is rising again. During the first degradation phase before reflooding, the Zr-Cr eutectic temperature has not been reached at this location, but the Cr reaction rate has already reached the threshold value of 60%. However, it has been for a short time, and the associated hydrogen production is negligible. When the temperature is above 1100K, the impact of Zr oxidation begins to be visible in both temperature evolution and H_2 production. The Cr reaction rate and the surface fraction of Zr available for oxidation increases in accordance with the temperature increase until Zr-Cr eutectic temperature is reached and melting of Cr layer. It is observed that even a limited fraction of Zr surface (about 3%) has a measurable impact on both temperature and H_2 evolutions at a given location in the reactor core. On the opposite of isothermal tests, high Cr reaction rate cannot be reached because small loss of Cr protectiveness induces temperature increase and the time interval before reaching Zr-Cr eutectic temperature is thus reduced.

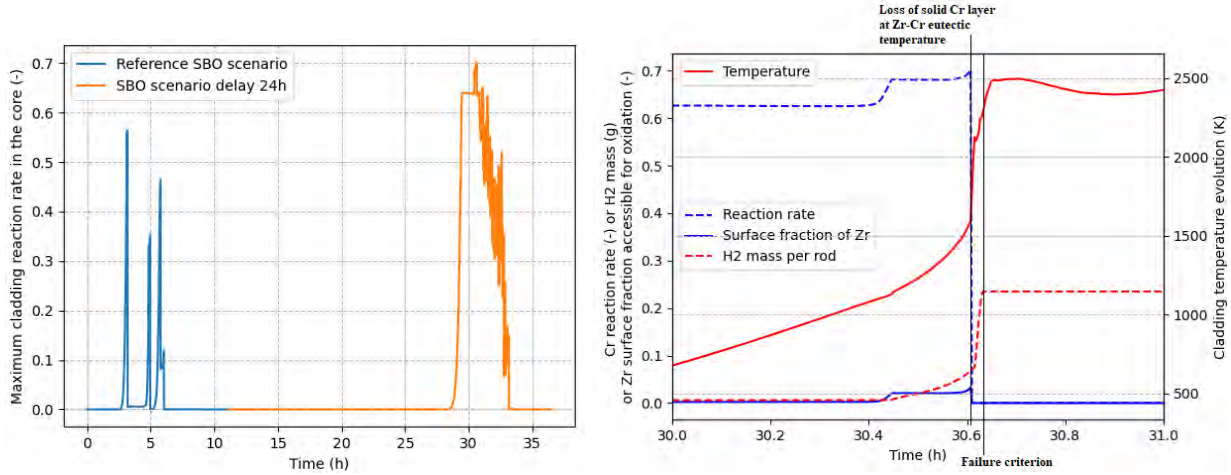

Figure 10 – Evolution of maximum Cr reaction rate in all the claddings during core degradation for the two SBO scenarios studied (left) and evolution of main parameters during loss of Cr protectiveness before Zr-Cr eutectic (analysis at the top of the core in channel 2 during SBO scenario with 24h delay) (right).

5. CONCLUSIONS

In this paper, ASTEC models developed to simulate Cr-coated Zr based claddings during SA have been presented. Based on available experimental data, these models mainly focus on early phase of the core degradation and low temperatures (typically below 1600K). The validation works performed illustrate the good capacities of ASTEC code to capture the protective effect of the Cr coating against oxidation and the Cr diffusion in the Zr substrate. Based on the ECrR approach developed by Brachet [20], a simplified model suitable for SA codes has been proposed and implemented in ASTEC code for the prediction of the loss of the Cr protectiveness at temperature below the Zr-Cr eutectic. Kinetics of oxidation, Cr diffusion and Cr layer progressive loss of integrity have been considered for dense Cr coating. However, the possibility is given to the user to adapt those kinetics in order to simulate different coating microstructures such as columnar Cr-coating.

Simplified modelling for the transition at the Zr-Cr eutectic temperature has also been proposed but its validation remains partial due to lack of experimental data. It was shown that, depending on the heating rate, the proposed approach may be conservative or not. There is thus a clear need to further study the behaviour of Cr-coated claddings when reaching Zr-Cr eutectic temperature and above. In addition, the study of the possible impact of the Cr coating on the loss of cladding integrity at high temperatures remains to be done. For such issue, both separate effect tests and bundle tests are necessary.

Exploratory simulations at reactor scale have been performed with these new models to assess the potential impact of Cr-coated claddings for two SBO scenarios. In the SBO reference scenario with loss of all safety injection systems at the beginning of the accident, the core degradation occurs in 3h. The presence of Cr-coated claddings delays the H_2 production of about 15min. The total hydrogen mass at the vessel failure is reduced by 20% (400kg compared to 500kg) due to less H_2 produced by the Cr-coated claddings. For the SBO scenario with a 24h delay before failure of safety injection systems, the core degradation occurs 28h after the reactor scram. The residual power is divided by two compared to the first scenario and this has a significant effect on the Cr-coated claddings behaviour, even if the total H_2 mass reduction due to Cr-coated claddings is comparable. In the transient core dewatering before accumulators discharge, due to the reduced residual power (15MW), Cr-coated claddings prevent significant H_2 production and core heating. Consequently, the production of 100kg of H_2 is delayed by about 2h but this delay is reduced to 30min when considering the times at which 200kg of H_2 have been produced. A compensating effect is also identified with a higher corium oxidation due to the reduced Zr oxidation in the rod geometry.
The loss of Cr protectiveness below the Cr-Zr temperature due to Cr consumption by diffusion and oxidation reactions is observed in the SBO scenario with delayed loss of high- and low-pressure safety injection systems. It is shown that when Cr reaction rate reached criterion for start of progressive Zr surface oxidation, even limited access of Oxygen to the Zr substrate has a significant impact on both H_2 production and temperature increase. Due to the exothermic reaction of the Zr oxidation, the Zr-Cr eutectic temperature is then reached rapidly and before significant increase of the Zr surface fraction accessible to Oxygen below the Cr layer.
Finally, in the fast kinetics scenario, it is observed that the maximum H_2 production rate is higher for Cr-coated claddings due to the fact that Zr oxidation occurs at higher temperature after Zr-Cr eutectic without protective oxide layer. On the contrary, for the SBO scenario with 24h delay, this effect is not visible at reactor scale. Only local increase of H_2 production is observed when Zr-Cr eutectic temperature is reached. In addition, the beginning of Zr oxidation before Zr-Cr eutectic temperature at some locations in the core also contributes to the reduction of this bifurcating effect.
In conclusion, based on these first integral calculations, interesting specificities of Cr-coated claddings and respective influences of the different assumptions considered for the modelling have been highlighted. In general, it can be said that the Cr-coated claddings have a noticeable impact on the behaviour of the core heating and the H_2 production. However, this effect is dependent on the SA scenario considered. No generic conclusions on the H_2 mass and production rate can be drawn due to combination of several effects. In particular, the main impacts of the residual power and of the possible water injections in the vessel were illustrated. Dedicated models for such coating in SA codes appear then as necessary before performing any safety studies. Modelling improvements should continue for the behaviour at higher temperatures and up to the mechanical failure or melting of Cr-coated claddings.

Cr-COATED CLADDINGS MODELLING IN THE SEVERE ACCIDENT CODE ASTEC

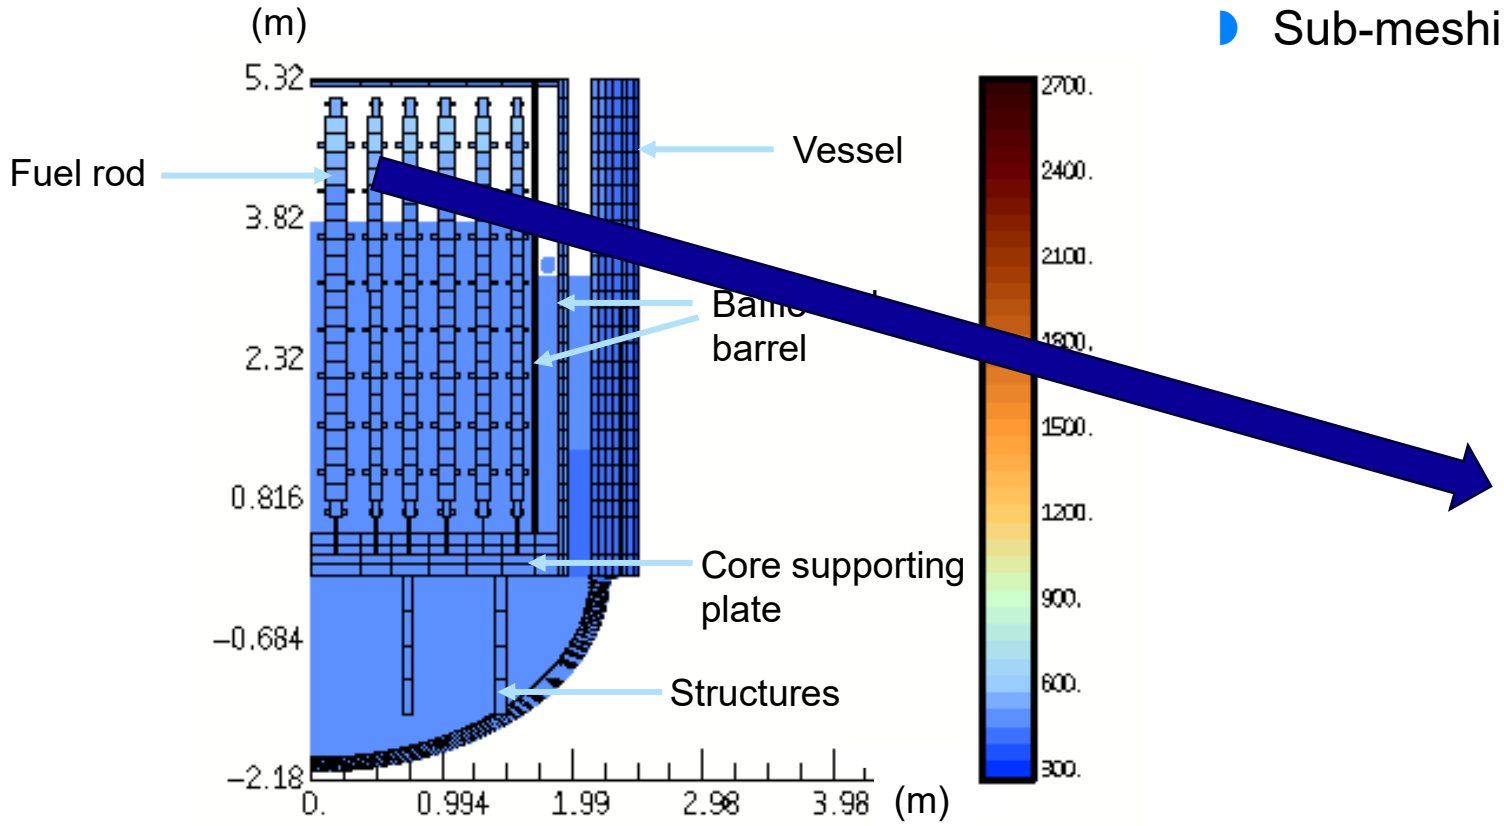
L. CARÉNINI

ERMSAR Conference, Madrid (Spain)

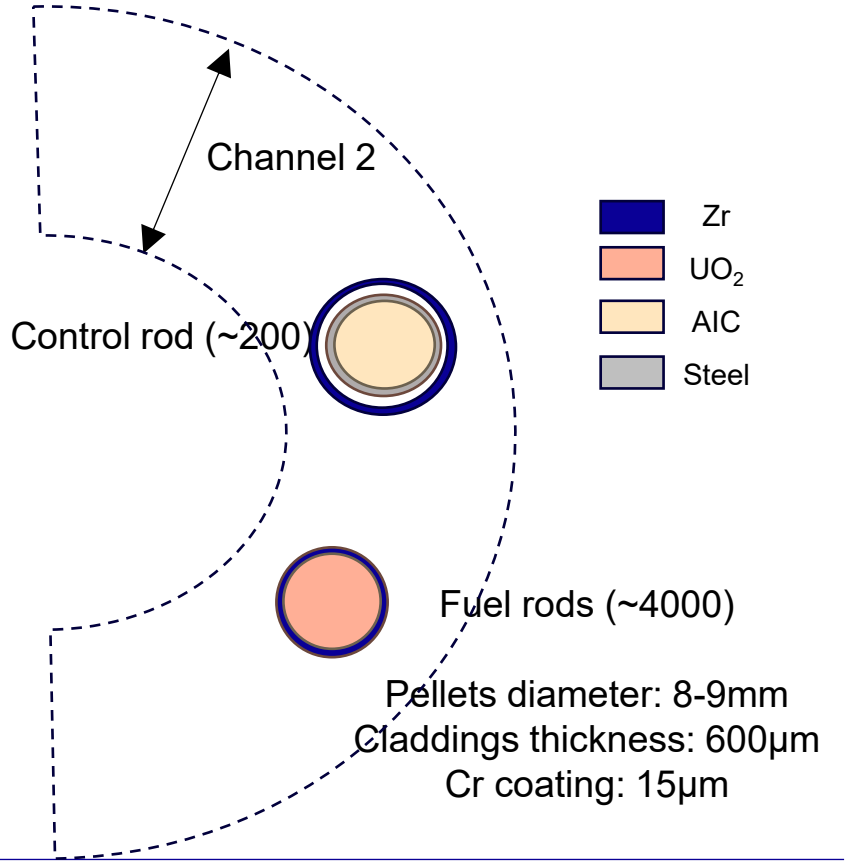
MODELLING OF THE REACTOR CORE IN ASTEC CODE

ASTEC
ACCIDENT SOURCE TERM EVALUATION CODE

- 2D axisymmetric
- Radial (~25cm) and axial (~15cm) meshing
- Sub-meshing of the structures



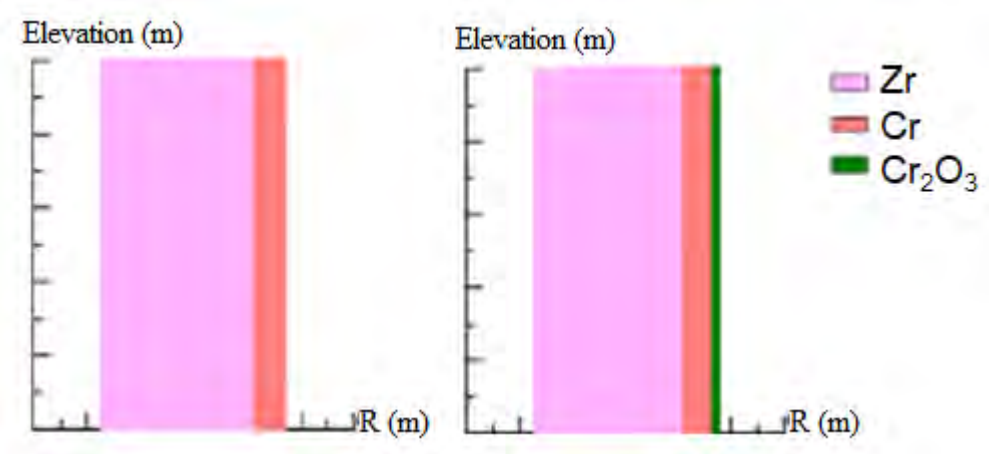
Temperature field (K)



Pellets diameter: 8-9mm
Claddings thickness: 600µm
Cr coating: 15µm

Cr COATED Zr CLADDING MODELLING IN ASTEC V3.2

- Main phenomena observed experimentally and modelled in ASTEC code:
  - Cr oxidation by steam to form Cr_2O_3 layer at the external surface of the cladding
  - Cr diffusion into β-Zr substrate
  - Once burst opening is reached, the internal surface of the cladding, made of Zr is oxidized
  - Cr-Zr eutectic (1332°C) leading to loss of Cr layer integrity
  - Progressive loss of Cr protection below Cr-Zr eutectic temperature

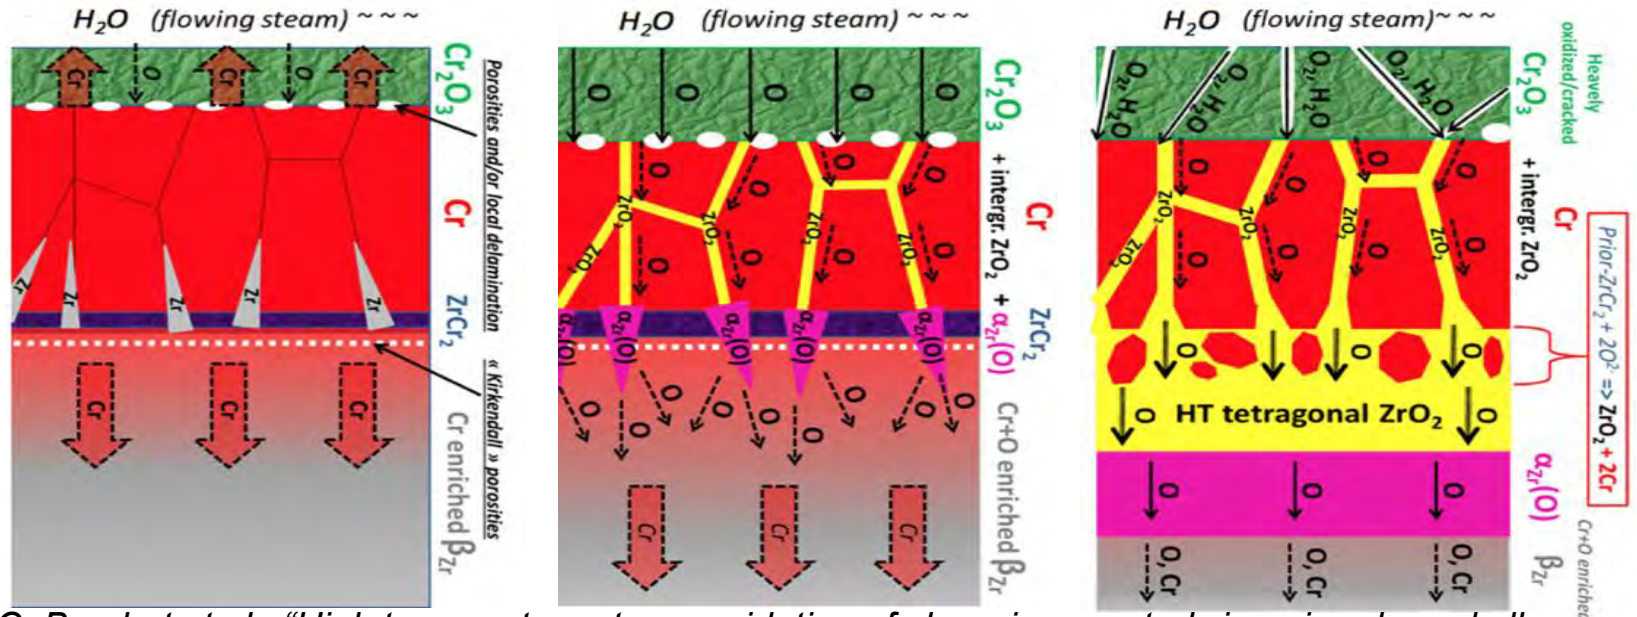


PROGRESSIVE LOSS OF Cr PROTECTION BELOW Cr-Zr EUTECTIC TEMPERATURE

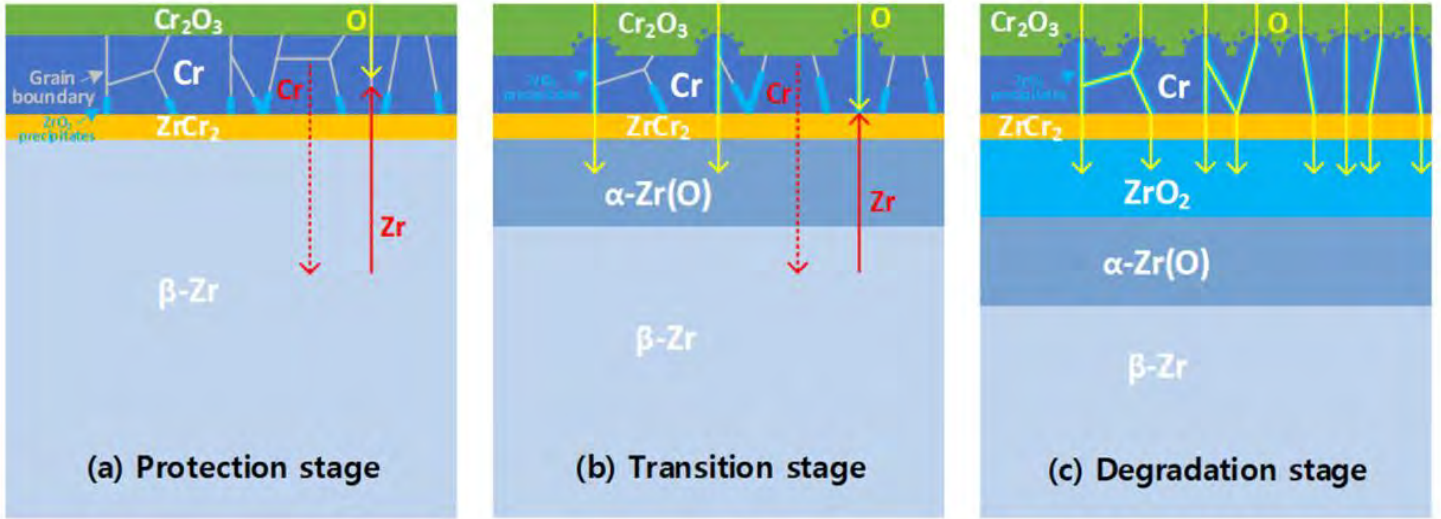
- Several phenomena identified:
  - Oxidation of Cr at the external surface
  - Diffusion of Cr in the Zr substrate
  - Formation of porosities and deformation at interfaces
  - Intergranular diffusion of Zr in the remaining Cr layer
  - Formation of Zirconia channels at the grain boundaries

→ Complex phenomena but well studied experimentally

- Summary of the proposed oxidation and degradation mechanisms for Cr-coated Zr alloy in steam atmosphere (below Zr-Cr eutectic temperature)



J.C. Brachet et al., "High temperature steam oxidation of chromium-coated zirconium-based alloys: kinetics and process", Corros. Sci. 167 (2020)



S. Wu et al., "Model development for oxidation and degradation behavior of accident tolerant Cr coating on Zr alloy cladding under high temperature steam atmosphere", J. Nucl. Mater. 589 (2024)

PROGRESSIVE LOSS OF Cr PROTECTION BELOW Cr-Zr EUTECTIC TEMPERATURE

- Work from J.C. Brachet (2025) dedicated to the DBA: *J.C. Brachet et al., J. Nucl. Nat. 606 (2025)*
  - Definition of a new criterion ECrR (Equivalent Chromium Reacted) for the identification of the mechanical failure of the cladding

$$\text{ECrR} = \frac{\text{Thickness of consummed Cr due to diffusion and oxidation}}{\text{Initial Cr thickness}}$$

  - Threshold identified experimentally at 70% for mechanical properties
  - Interpretation: **loss of mechanical resistance due the creation of the channels in the Cr layer leading to Zr oxidation**

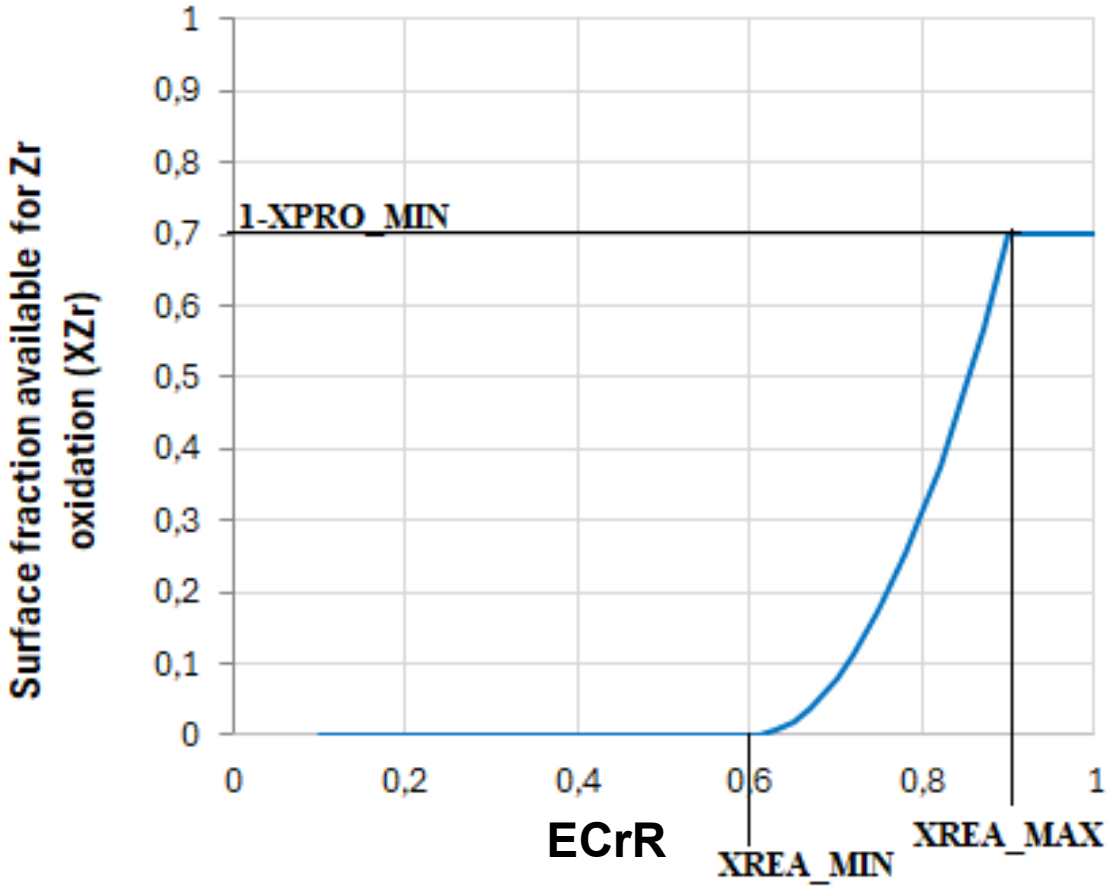
PROGRESSIVE LOSS OF Cr PROTECTION BELOW Cr-Zr EUTECTIC TEMPERATURE

- Steps followed:
  - Diffusion of Cr in the Zr substrate → validation in inert atmosphere
  - Oxidation of Cr at the external surface → validation based on the kinetics of H_2 production when Cr remains protective
  - Transition between protective to non protective after a certain threshold of ECrR → choice of model parameters based on experimental results

TRANSITION LAW BASED ON ECrR

- The law proposed is dedicated to the surface fraction of Zr in contact with oxygen
- A parabolic function is used: transition from intergranular diffusion of Zr through the metallic Cr layer to formation of a zirconia intergranular network observed experimentally
- A maximum fraction of the Zr surface is available for oxidation below Zr-Cr eutectic.

$$Xzr = (1 - XPRO_MIN).\left(\frac{ECrR - XREA_MIN}{XREA_MAX - XREA_MIN}\right)^2$$



PROGRESSIVE LOSS OF Cr PROTECTION BELOW Cr-Zr EUTECTIC TEMPERATURE

Brachet 2017

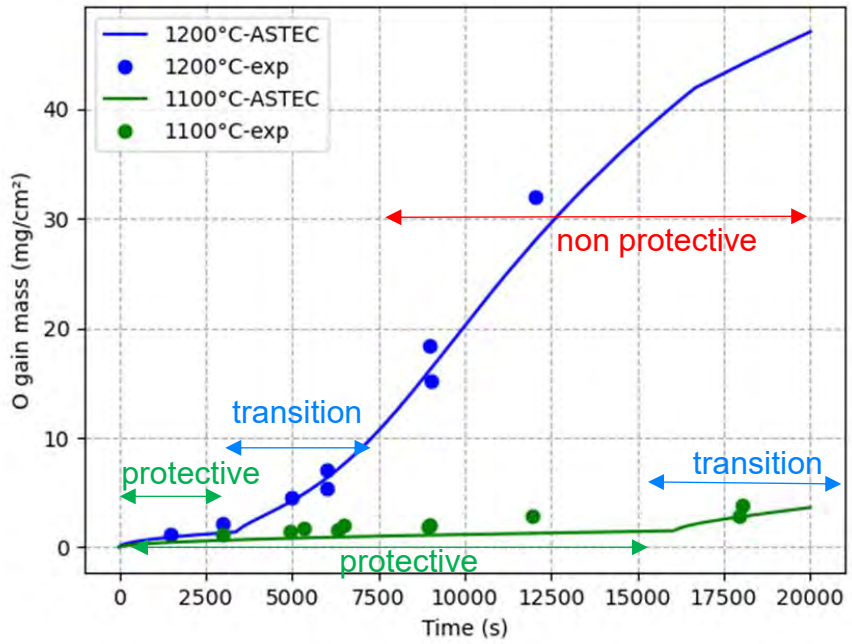
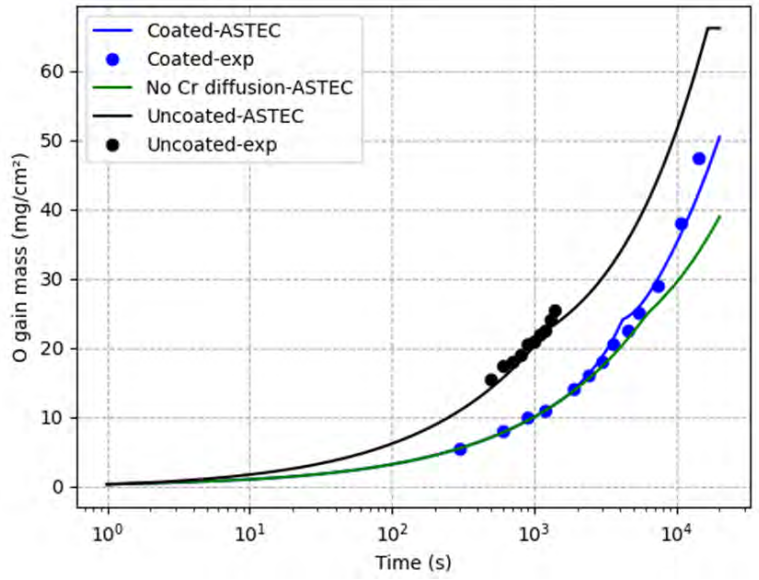
PROGRESSIVE LOSS OF Cr PROTECTION BELOW Cr-Zr EUTECTIC TEMPERATURE

- Satisfying results obtained on published experimental data

→ Validity of the approach proposed



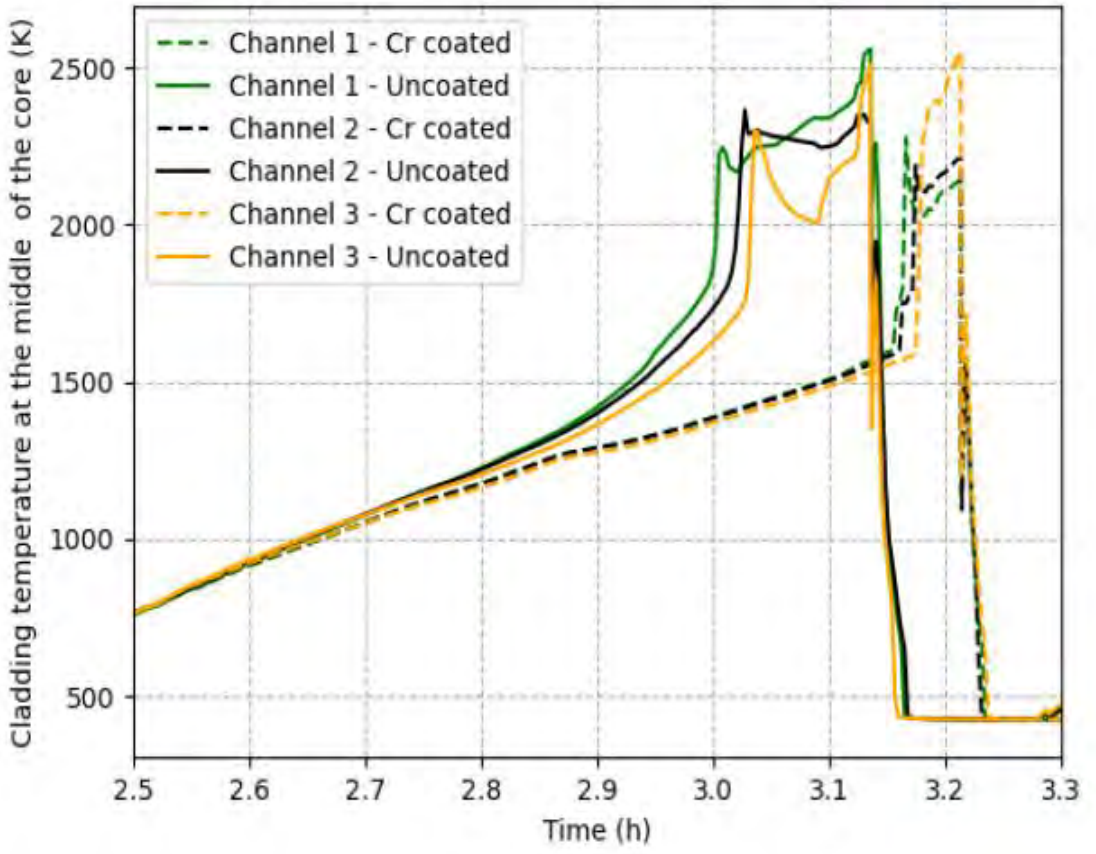
Brachet 2017, Bischoff 2018



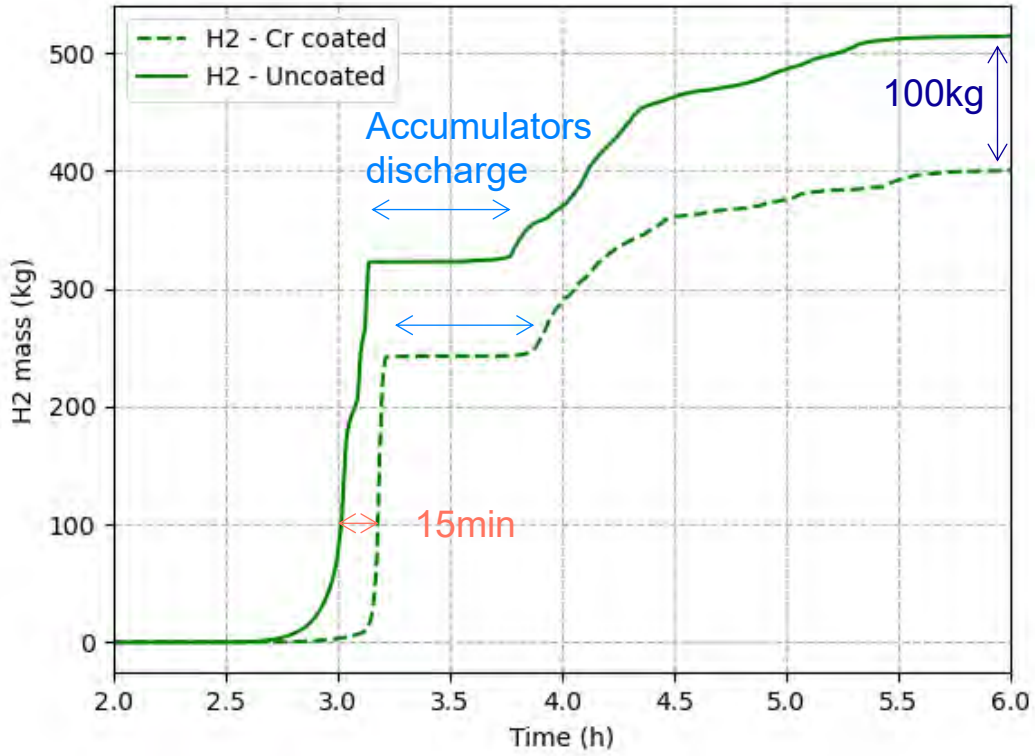
Wang 2022, Isotherm 1200°C, External coating and double-sided oxidation

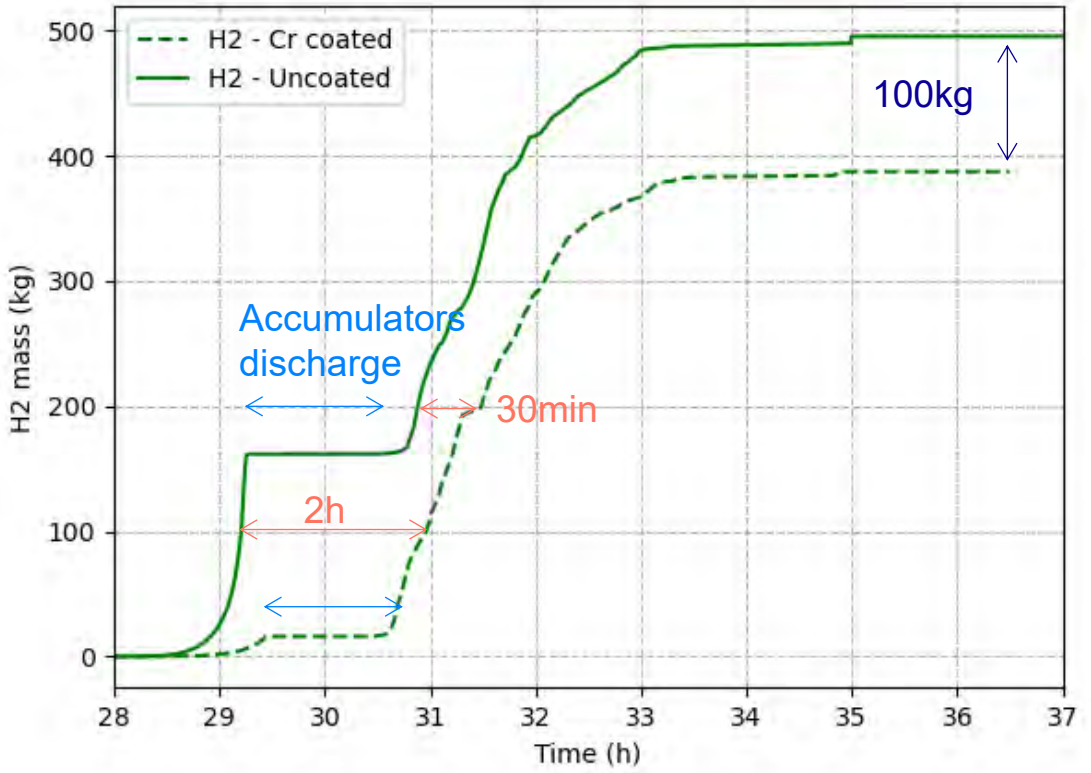
PRELIMINARY REACTOR APPLICATIONS

- Generic PWR900 reactor and SBO scenario
- Failure criteria of uncoated claddings are kept
- Cr layer impacts the cladding temperature evolution
- After Zr-Cr eutectic, strong temperature escalation



PRELIMINARY REACTOR APPLICATIONS

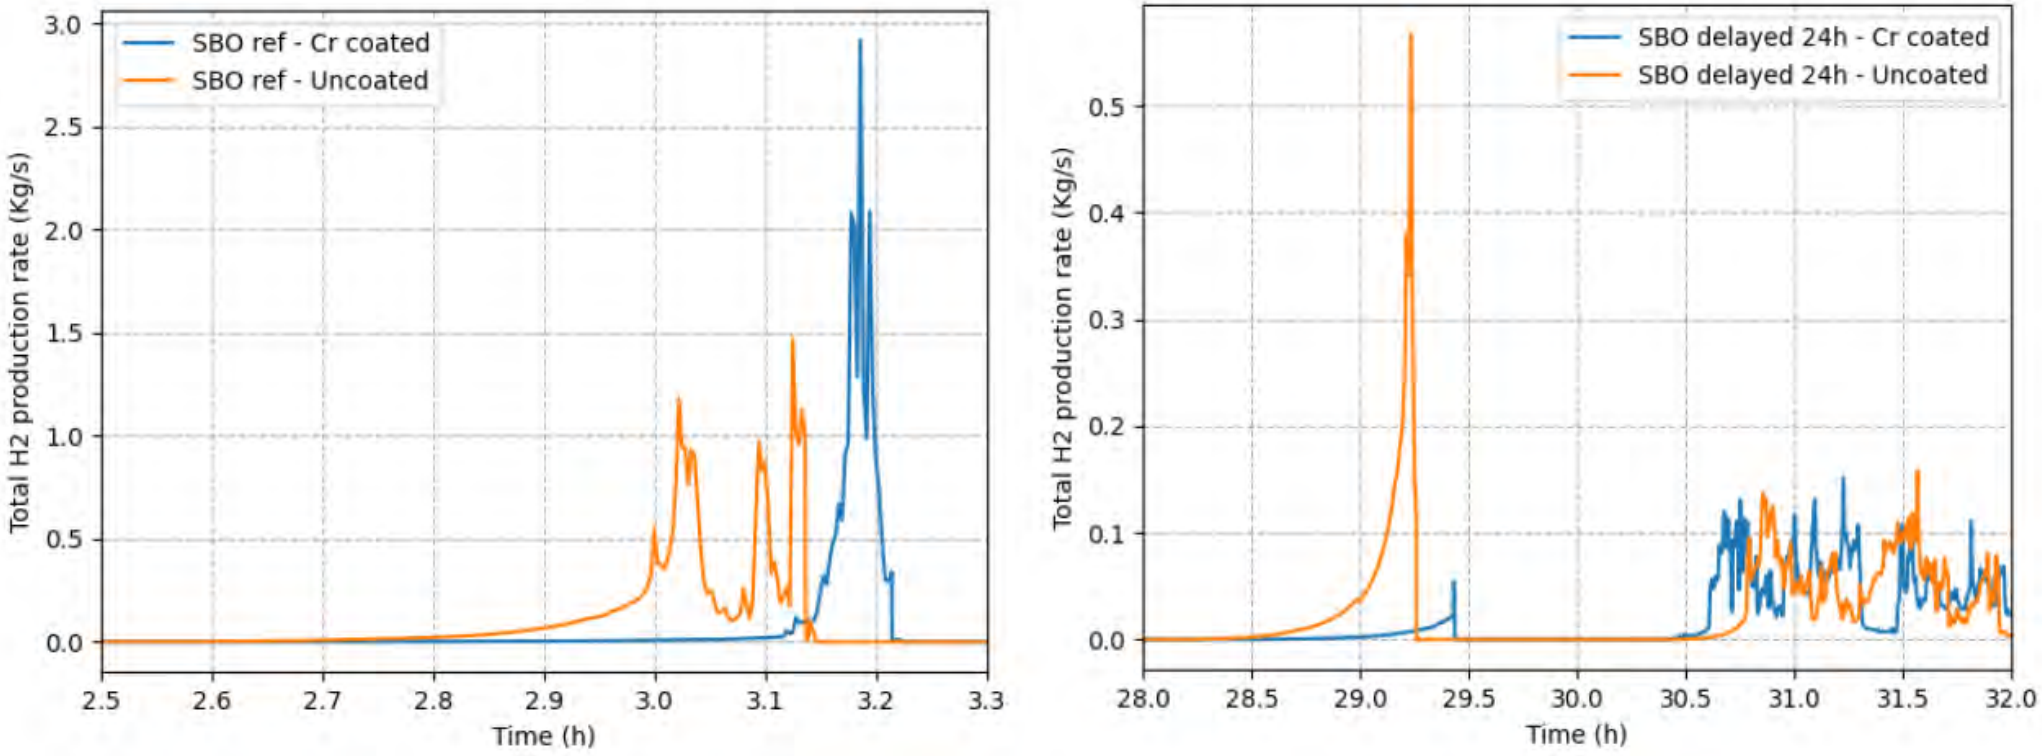




- Impact of residual power in the core when degradation occurs

→ Start of core dewatering ~2h20 or 28h after the reactor scram

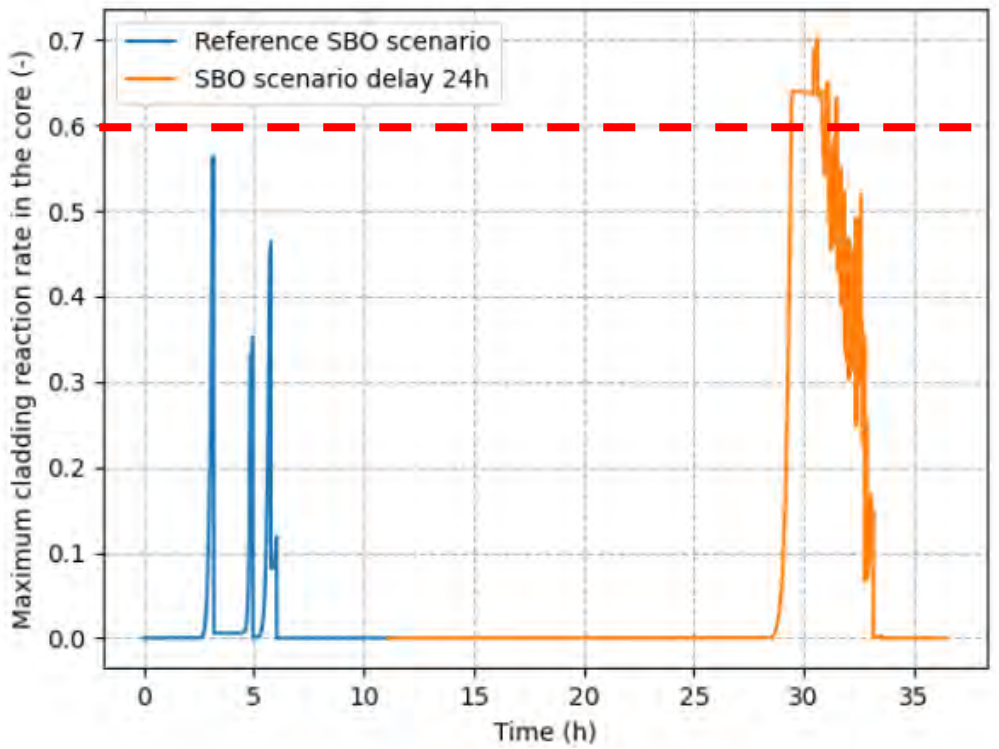
PRELIMINARY REACTOR APPLICATIONS

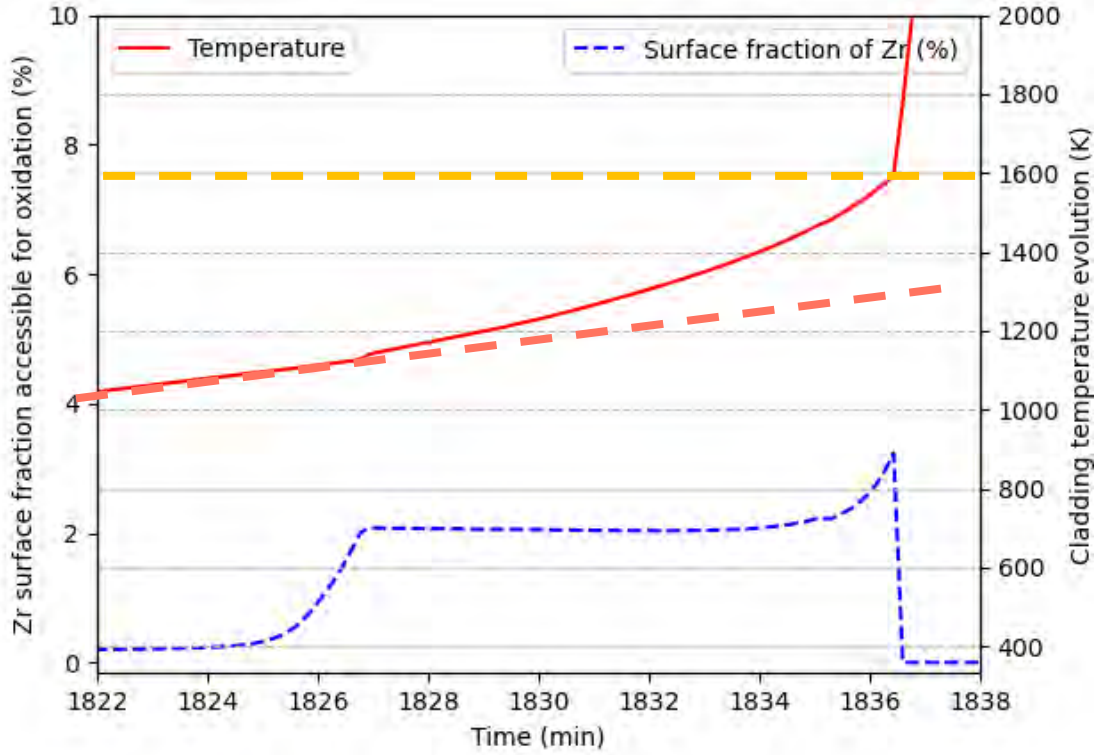


- Possible higher H_2 rate production for Cr coated claddings due to strong oxidation when Cr protection is lost.
- Impact of core heat up kinetics (temperature gradients in the core): H2 rate increase may remain local

PRELIMINARY REACTOR APPLICATIONS

- Loss of Cr protection before Zr-Cr eutectic





- Impact of exothermic reactor of Zr oxidation on the heating rate → the Zr fraction oxidized before Zr-Cr eutectic temperature is limited

CONCLUSION AND PERSPECTIVES

- Models for Cr-coated claddings have been implemented in ASTEC code based on available experimental data
- In particular, a **new model for loss of Cr protectiveness against oxidation** adapted for SA codes has been proposed based on the work of J. C. Brachet (ECrR concept)
- **Need for more experimental data (single rod and bundle tests) for modelling at Zr-Cr eutectic temperature and above** (oxidation runaway and failure criteria) → OECD projects QUENCH-ATF Phase I and II
- Impact at reactor scale (based on simplified assumptions for high temperature behaviour):
  - **Limited but noticeable impact on the kinetics of core heating and H_2 production** → need to be modelled in SA codes
  - Dependent on the SA scenario considered (combination of mainly the residual power and of the possible water injections in the vessel) the **impact of Cr-coated cladding on the degradation evolution or H_2 production will be different**

ABSTRACT

Nuclear-grade FeCrAl alloys, a type of Advanced-Technology Fuels (ATFs), show outstanding resistance to oxidation at high temperatures, and represent a promising alternative to Zircaloy (Zry-4) cladding, which could enhance the safety of Nuclear Power Plants (NPPs). Understanding and modelling their oxidation behavior is therefore essential to reliably assess their performance under normal and off-normal conditions. The Karlsruhe Institute of Technology (KIT) actively contributes by providing reference data through the experimental test at the KIT QUENCH facility and by extending the range of application of integral codes to such innovative materials. This paper presents an analytical model to describe the oxidation behavior of FeCrAl alloys under a steam environment. The model was developed through a joint KIT/ASNR effort to improve the ATF-related modelling capabilities of the Accident Source Term Evaluation Code (ASTEC, developed by ASNR), using the Separate-Effect Tests (SETs) performed by KIT as the experimental basis. The oxidation model consists of implementing a parabolic rate law to predict the oxygen mass gain due to Al oxidation at low temperatures. Then, at higher temperatures (above ~1600K), the Fe and Cr oxidation model already available in ASTEC is used. The model has been integrated into the ASTEC code, and validation was performed against the QUENCH-19 bundle test conducted at KIT, which provides integral data on FeCrAl behavior under Beyond Design Basis Accident (BDBA) conditions. The simulation results with their experimental comparison demonstrate that the model is capable of estimating key parameters, including oxygen mass gain, oxide layer thickness, and hydrogen (H_2) production.

ATFs, FeCrAl, ASTEC, BDBA, Steam Oxidation

1. INTRODUCTION

Following major nuclear SA such as Three Mile Island accident, Chernobyl disaster, and Fukushima Daiichi nuclear disaster, substantial efforts have been undertaken worldwide to enhance NPPs safety. In this framework, ATFs classified as near- or long-term concepts depending on technological maturity, have attracted significant attention due to their potential to improve fuel and cladding performance and mitigate SA consequences [1]. Among the proposed cladding candidates, nuclear-grade FeCrAl alloys are considered strong alternatives to conventional Zry-4 claddings, owing to their high mechanical strength, resistance to hydride formation under H_2 exposure, and superior oxidation resistance in high-temperature steam environments [2].
The application of FeCrAl alloys as cladding materials in nuclear reactors has the potential to significantly reduce H_2 generation and to extend the time to cladding failure during SA scenarios. These characteristics

are particularly relevant for Beyond Design Basis Accidents (BDBAs), whose progression and consequences are typically assessed using integral severe accident codes [3]. Despite the growing experimental database on ATFs, most integral codes currently lack validated models capable of accurately describing the behavior of FeCrAl claddings. This limitation hinders the consistent assessment of ATF concepts within SA analyses and highlights the need for dedicated modelling approaches that capture the underlying physicochemical phenomena [4].

In response to this need, the Karlsruhe Institute of Technology (KIT), in collaboration with the French Authority for Nuclear Safety and Radiation Protection (ASNR), has extended the capabilities of the Accident Source Term Evaluation Code (ASTEC), developed by ASNR [5], [10], through the development and validation of a new model for FeCrAl alloys. The model development is based on Single Effect Tests (SETs), while its validation relies on the QUENCH19 bundle test, both conducted at KIT. This paper presents the modelling methodology and discusses the corresponding simulation results in comparison with experimental data.

2. FeCrAl ALLOYS

Iron–chromium–aluminum (FeCrAl) alloys are structural materials widely used in high-temperature applications requiring enhanced oxidation resistance. Due to their favorable performance, they have attracted increasing interest for NPP applications and are considered promising from a safety perspective because of their potential to significantly reduce H_2 generation during high-temperature oxidation.

Nuclear-grade FeCrAl alloys are primarily composed of iron (Fe), chromium (Cr), and aluminum (Al), with typical weight fractions of approximately 80%, 13%, and 6%, respectively. In addition to these major constituents, minor alloying elements such as carbon (C), yttrium (Y), and silicon (Si) are included in small amounts to tailor the material properties [6]. Depending on their specific composition, a wide range of FeCrAl alloys exists, among which B136Y3 and C26M2 are representative examples studied in reference experiments [7]. Alloys from the C series are further characterized by the presence of molybdenum (Mo) and niobium (Nb) as additional alloying elements [8]. Both alloys were developed by Oak Ridge National Laboratory and supplied to the KIT for experimental investigations at the large-scale QUENCH facility; in this study, B136Y3 is used as the reference alloy.

The presence of Al promotes the formation of a stable and protective alumina (Al_2O_3) oxide layer, which is responsible for the high oxidation resistance of FeCrAl alloys at elevated temperatures. Cr contributes to corrosion resistance and phase stability, while minor additions of yttrium and silicon enhance the adherence and integrity of the oxide scale, limiting spallation and reducing oxygen diffusion through the oxide layer. These beneficial effects, however, may be accompanied by a moderate reduction in thermal conductivity and, at very high temperatures, by the potential breakdown of the protective alumina layer followed by rapid iron oxidation, which must be considered in reactor design and BDBA safety analyses [9]. Overall, the combination of high-temperature mechanical strength, oxidation resistance, and corrosion resistance makes FeCrAl alloys suitable candidates for demanding NPP applications.

2.1. Steam Environment Oxidation Kinetics

After extensive experimental analyses aimed at characterizing the B136Y3 and C26M2 alloys were performed at KIT QUENCH facility, the oxidation behavior of nuclear-grade FeCrAl alloys in steam environments was identified as being governed by distinct kinetic regimes, depending on the nature of the oxide scale formed on the material surface. Based on results obtained from isothermal SETs, the oxidation kinetics of the B136Y3 alloy can be classified according to temperature as follows.
At lower temperatures, the oxidation process is controlled by θ-alumina–dominated kinetics, associated with the formation of a metastable oxide layer. With increasing temperature, a transition to stable, protective α-

alumina–controlled kinetics is observed, providing enhanced oxidation resistance. At higher temperatures, this protective behavior deteriorates, and iron oxide–dominated kinetics become prevalent, leading to the loss of oxide scale integrity, material deformation, and rapid degradation characteristic of catastrophic oxidation [7]. Based on the description above, the oxidation kinetic regimes are distributed as a function of temperature as follows:

- **873 K < T < 1173 K:** θ-alumina–controlled oxidation
- **1173 K ≤ T ≤ 1273 K:** constant oxidation rate regime
- **1273 K < T < 1600 K:** α-alumina–controlled oxidation
- **T ≥ 1600 K:** iron oxide–dominated oxidation

This classification enables the identification of the kinetic coefficients associated with each oxidation regime, which are presented and discussed in the following section.

3. ASTEC CODE IMPLEMENTATION

ASTEC is an integral severe accident code developed by ASNR [5], [10] to simulate the complete progression of an accident sequence, from its initiation to the release of radioactive source terms into the environment. Prior to the present work, ASTEC was capable of modelling conventional cladding materials such as Zircaloy-4. To extend its capabilities to ATFs concepts, KIT, developed and implemented in collaboration with ASNR a dedicated oxidation model for FeCrAl alloy claddings.

The implementation of the new model was carried out following a three-stage methodology. The first stage consisted of the definition of the oxidation model based on experimental observations. Results from SETs indicated that FeCrAl alloys predominantly form aluminum-based oxides at lower temperatures, while iron-based oxides become dominant at higher temperatures. This experimental evidence enabled the development of an oxidation model in which the FeCrAl alloy behavior is represented through the contribution of two material systems—aluminum and stainless steel—and their corresponding oxides. While ASTEC already includes a validated model to simulate stainless steel oxidation in steam environments, no equivalent model was available for Al when considered as a cladding material.

The second stage involved formulating and developing the aluminum oxidation model, in accordance with the underlying physical phenomena. The approach is based on a two-layer oxidation model, in which oxidation initiates upon contact with steam at temperatures above 800 K and leads to the formation of a protective Al oxide layer within the temperature range corresponding to stable alumina-controlled kinetics.

The final stage comprised two main steps. First, the model performance was assessed against the QUENCH SETs by calculating and comparing experimental measurements of key model parameters, including oxygen mass gain, oxide layer thickness, and cumulative H_2 production, which characterize the oxidation behavior of FeCrAl alloys in steam environments. Second, the model validation against the QUENCH-19 bundle test by comparing cladding temperatures at different axial elevations and the total cumulative H_2 production, thereby providing a comprehensive assessment of the model under severe accident conditions.

4. MODEL DEVELOPMENT AND VALIDATION

Isothermal and transient single-effect tests (SETs) were performed at KIT on two different FeCrAl alloys, namely B136Y3 and C26M2. The temperature dependence of the parabolic oxidation rate constants for both alloys provided the basis for the development of the oxidation model. Selected results from the isothermal experiments conducted on the B136Y3 alloy were used as reference data for assess the model.

The isothermal tests consisted of exposing small cylindrical FeCrAl specimens to a steam environment for a duration of 20 hours. The experiments were conducted over two distinct temperature ranges, depending on the experimental facility employed. The low-temperature tests covered the range from 873 K to 1373 K,

while the high-temperature tests were performed between 1573 K and 1773 K [7]. Prior to steam exposure, the samples were preheated under an argon atmosphere to reach the target temperature. Experimental parameters such as specimen diameter and length, preheating time, argon flow rate, and steam flow rate differed between the low- and high-temperature tests. The geometric characteristics of the specimens and the main experimental conditions are summarized in Table 1.

Table I. Experiment Description: geometric characteristics and conditions of the experiment.

Parameter / Temperature	Length [mm]	Outer Diameter [mm]	Preheating time [min]	Argon flow rate [l/h]	Steam rate [g/h]
Low	10	9.6	10	20	2
High	20	9.6	30	20	20

The experimental test enabled the measurement of oxygen mass gain and the determination of oxidation parabolic rate constants at each investigated temperature. In addition, the oxide layer thickness was measured, and for the high-temperature tests, cumulative hydrogen production was also quantified.

Based on the oxidation behavior observed during the isothermal tests, the parabolic rate constant k_p was categorized into three distinct temperature ranges corresponding to the oxidation kinetic regimes identified for the B136Y3 alloy. These regimes were determined from post-test X-ray diffraction (XRD) analyses and are associated with θ-alumina–controlled kinetics, α-alumina–controlled kinetics, and iron oxide–dominated kinetics [7]. From the resulting k_p values, the oxidation kinetic coefficients were derived assuming a parabolic oxidation law with Arrhenius-type temperature dependence for each identified oxidation regime. The corresponding kinetic parameters were obtained through linear regression according to the following equation [11]:

$$k_p = Ae^{\left(\frac{-E_a}{RT}\right)} \quad \ldots(1)$$

Where, **A** represents the pre-exponential and $\mathbf{E_a}$ the activation energy. The coefficients were calculated and integrated into ASTEC as part of the oxidation model for Aluminum, and are shown in Table II. For T ≥ 1648 K, where iron-controlled kinetics becomes dominant, the coefficients of the SSTEEL model available in ASTEC were retained without modification.

Table II. Experiment Description: Oxidation kinetic coefficients as a function of temperature range

Temperature [K] / Coefficient	873<T<1173	1173 ≤ T ≤1273	1273<T<1600	T ≥ 1600
A $\left[\frac{kg^2}{m^4 s}\right]$	$5.376\text{x}10^{-03}$	$4.692\text{x}10^{-12}$	5.018	$2.399\text{x}10^{+08}$
$\mathbf{E_a}$ $\left[\frac{kJ}{mol}\right]$	184.730	0.000	287.748	352.514

4.1. ASTEC Performance Assessment against QUENCH SETs

The ASTEC representations of the SETs performed at KIT were assessed using the previously described dedicated ASTEC model developed for FeCrAl alloys. In this representation, the geometry consists of a cylindrical specimen surrounded by a steam flow. The outer surface of the cylinder is modeled as a composite material, accounting for the FeCrAl alloy composition through two distinct constituents: aluminum (6%) and an iron–chromium–based material (94%), corresponding to the typical composition of the B136Y3 alloy. According to this configuration, the outermost surface is assumed to be enriched in Al, and the initial oxidation process upon exposure to steam is governed by the formation of an Al oxide layer. As the temperature increases and reaches 1648 K, the oxidation of the iron–chromium–based material is activated in the model, leading to the formation of iron oxides and reflecting the transition toward non-protective oxidation regimes.

The implementation of the SET configuration in ASTEC allows the calculation of the same parameters measured during the experiments and provides a direct means to assess the performance of the newly developed Al oxide model. This comparison enables the evaluation of the code capability to reproduce the experimental results and, consequently, to represent the underlying physical oxidation phenomena.

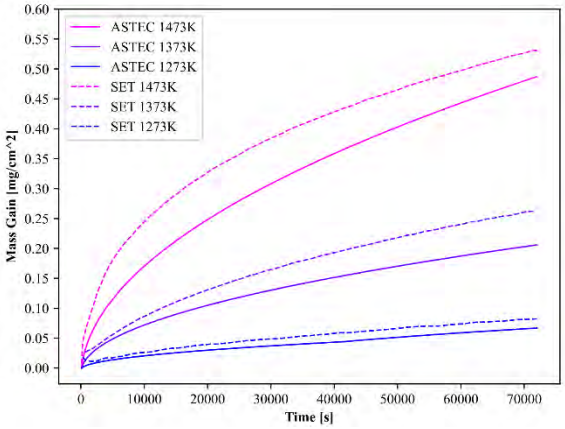

Figure 2. Weight gains comparison SETs vs. ASTEC code

Figure 2 presents a comparison between calculated and experimental oxygen mass gain at three different temperatures—1273, 1373, and 1473 K—within the temperature range where α-alumina–controlled oxidation is dominant. The continuous lines represent the results calculated using the ASTEC code, while the dotted lines correspond to the experimental data. The maximum relative error observed in this dataset does not exceed 25% and occurs at 1473 K at 20,000 s, which corresponds to the largest deviation between the experimental measurements and the simulation results.

Table III. Model Development: Comparison of oxide layer thickness SETs vs. ASTEC

Temperature [K]	Thickness SETs (µm)	ASTEC (µm)
1373	~1.500	1.110
1473	~3.000	2.616
1573	~6.500	5.538

On the other hand, Table III reports the calculated and measured oxide layer thicknesses at selected temperatures. For this parameter, the maximum relative error is observed at 1273 K and amounts to 26%.

Overall, the results show reasonable agreement between simulations and experimental data, supporting the validity of the implemented oxidation model.

4.2. Bundle Test QUENCH-19 Description

The KIT QUENCH facility is an integral experimental installation that provides a scaled representation of a reactor fuel assembly with a reduced number of fuel rods, designed to reproduce the dominant thermal–hydraulic and chemical conditions in a nuclear reactor core. It is widely used for testing material and the validation of SA models implemented in integral codes. The QUENCH-19 bundle test represents the first integral BDBA experiment conducted with FeCrAl alloy cladding [12]. The experiment was performed at KIT on 29th August 2018 using the B136Y3 FeCrAl alloy as cladding material, with the objective of assessing its behavior under SA conditions and comparing it with that of conventional ZIRLO cladding tubes [12].

The configuration consisted of a Pressurized Water Reactor (PWR)–type fuel bundle comprising 24 rods, with tungsten heater rods located at the center to simulate the electrical power input. The cladding material was B136Y3 FeCrAl alloy, and the heaters were surrounded by annular ZrO_2 pellets to represent the fuel. The bundle also included seven corner rods and five grid spacers; the shroud and shroud insulation were made of Kanthal and ZrO_2 fiber, respectively, while the cooling jacket was composed of Inconel. The experiment lasted 10,281 s and was conducted in four main phases: first, the bundle was heated to approximately 873 K, corresponding to the onset of FeCrAl oxidation; subsequently, the electrical power was increased to 11.5 kW to establish pre-oxidation conditions; in the third phase, the power was further raised to 18.12 kW, leading to a maximum temperature of about 1730 K; finally, following the quenching phase, the power was reduced to 4.1 kW.

The experiment was instrumented with thermocouples installed at different axial elevations to monitor the temperature evolution along the bundle, while hydrogen production was measured using a quadrupole mass spectrometer (GAM300). These measurements provide key experimental data for validating the FeCrAl oxidation model implemented in ASTEC. The results indicate that the cumulative hydrogen generation during the QUENCH-19 test was significantly lower for FeCrAl cladding (9.2 g H_2) than for ZIRLO (47.6 g H_2) [12], the latter having been previously investigated in the QUENCH-15 bundle experiment as a reference for conventional cladding materials. This marked reduction in hydrogen release confirms the superior oxidation resistance of FeCrAl alloys under severe accident conditions.

4.3. Bundle Test QUENCH-19 Implementation

The ASTEC model of the QUENCH-19 test was assessed through a nodalized representation of the experimental configuration. The total number of fuel rods was distributed among three separate thermal–hydraulic channels, comprising four, twelve, and eight rods, respectively, as illustrated in Figure 3.

This radial discretization allows for an efficient representation of the bundle while preserving the main thermal and oxidation phenomena observed experimentally. The rod cladding was modeled using the B136Y3 FeCrAl alloy for the fuel rods, corner rods, shroud, and four of the five grid spacers. The remaining grid spacer and the cooling jacket were represented using the SSTEEL material. Although SSTEEL corresponds to a Fe–Cr–Ni alloy with compositional differences compared to Inconel, it was employed as a surrogate material consistent with the experimental configuration.

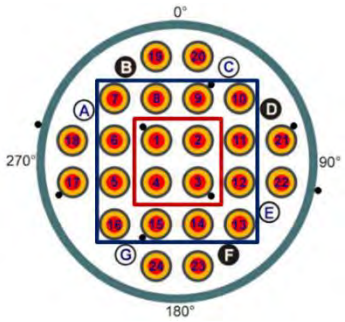

Figure 3. Channel distribution for implementation (adapted from Stuckert et al., 2017).

Several key events observed during the QUENCH-19 experiment were reproduced in the simulation. These include the continuous increase in hydrogen release starting at approximately 6570 s, followed by a sharp rise at around 8260 s, the attainment of a maximum temperature of about 1773 K at 9110 s, and the onset of probable massive cladding failures at approximately 9119 s, shortly after the quenching phase. The experiment was instrumented to monitor relevant physical parameters, including cladding temperature at different elevations and cumulative hydrogen production, which were also calculated by the ASTEC simulation for model validation purposes.

Figure 4 presents a comparison between calculated and measured cladding temperatures at two axial elevations, 850 mm and 950 mm, where post-test examinations identified the largest number of damaged claddings. The continuous lines represent the temperatures obtained from ASTEC simulations, while the dotted lines correspond to experimental measurements acquired using thermocouples. The plots include at least one experimental reference value for each channel and, in some cases, two values corresponding to different fuel rods located at different positions within the bundle.

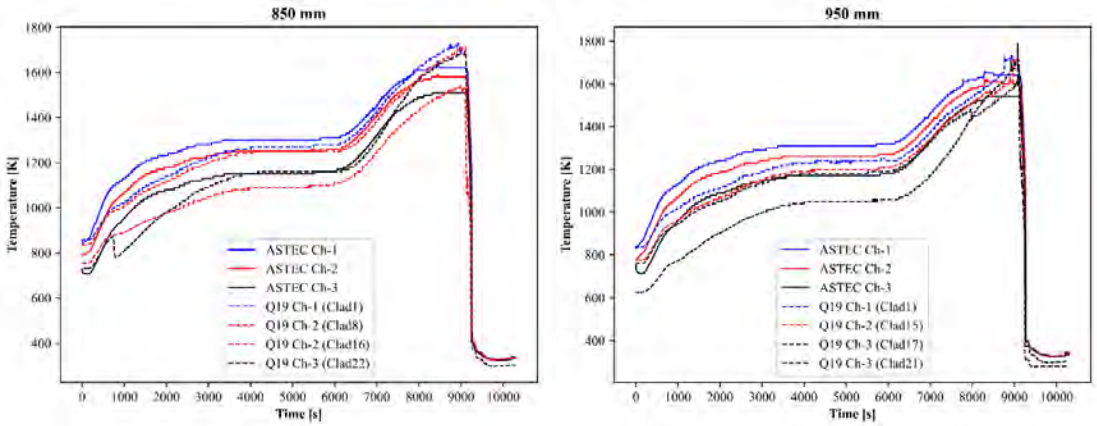

Figure 4. Axial cladding temperature profiles at 850 mm and 950 mm: Simulation–Experiment comparison

The maximum temperature difference between experimental measurements and ASTEC predictions does not exceed 50 K in most cases, which is considered an acceptable criterion for model validation from a thermal–hydraulic perspective. In the cases where this criterion is not met, the discrepancy can be attributed to the specific position of the fuel rod within the bundle, likely closer to the periphery of the channel. This positioning results in lower measured temperatures and, consequently, larger deviations when compared with the simulated values.

Figure 5 shows the evolution of cumulative hydrogen production as a function of time. Compared with the experimental data, the ASTEC simulation underestimates hydrogen generation up to approximately 7800 s and slightly overestimates the total hydrogen release thereafter, resulting in a final cumulative hydrogen production that is about 6.6% higher than the experimental value. The above-mentioned underestimation of hydrogen generation is attributed to the non-consideration of thermocouples' oxidation in the model [12]. Overall, ASTEC provides a reasonable estimate of the total hydrogen production, reaffirming the applicability of the implemented model [12].

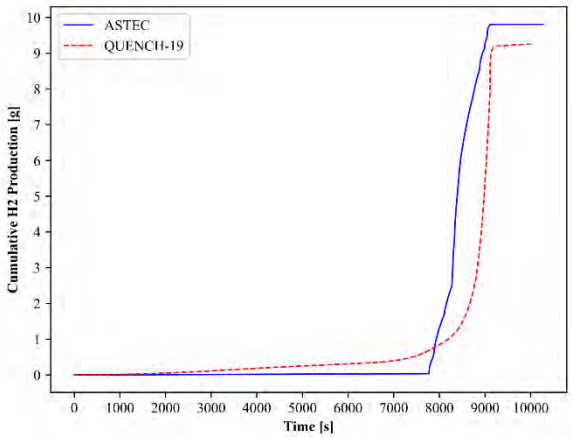

Figure 5. Total hydrogen release ASTEC vs. Bundle Test Q19

5. LIMITATIONS AND OUTLOOK

The next step will involve evaluating the functionality of the Al oxidation model, recently integrated into the ASTEC code, by simulating a hypothetical BDBA scenario in an SMR. This analysis will serve as a case study to evaluate ASTEC's capability to simulate the progression of an SA involving FeCrAl cladding oxidation and to predict the associated physical and chemical phenomena.

The simulation of this scenario will pose significant challenges, mainly due to current limitations in the code regarding the modelling of specific phenomena once core degradation initiates, which involves the interaction between FeCrAl alloys and other materials present in the reactor core. Several modelling criteria will require adjustment to ensure a consistent and physically meaningful simulation. Therefore, the simulation should be considered a preliminary investigation of the capabilities of the FeCrAl oxidation model when applied to plant-level analyses.

Models describing UO_2 and ZrO_2 dissolution by liquid Zircaloy, as well as cladding dissolution by Inconel, liquid Ag–In–Cd alloy, and solid stainless steel, should not be activated in either simulation (FeCrAl and Zircaloy). This approach will be adopted to ensure methodological consistency, as equivalent dissolution models are not yet available for FeCrAl claddings, as well as for FeCrAl oxidation in debris or magma components, thereby limiting the analysis to the stage of core degradation.

Furthermore, the material integrity criteria and the conditions governing the decanting phenomenon must be adapted for FeCrAl alloys. The first criterion involves the change in material state and the activation of the steel oxidation process, which are defined by the component temperature and the oxide layer thickness, and represent the loss of integrity of the Al_2O_3 layer above a specific temperature. The second criterion refers to the liquid fraction of the material, from which material decantation may occur.

We expect that applying this to the plant will allow us to analyze the material's behavior up to the loss of cladding geometry, through the core state, assess the impact of FeCrAl alloys as cladding materials, and their potential for mitigating the progression of SA in comparison with traditional cladding.

In this context, the sequence of events during the severe accident scenario will play an important role, as will the generation of hydrogen at the end of the simulation.

6. CONCLUSIONS

The single-effect tests performed at KIT provided a robust foundation for the development of a model capable of reproducing the physical phenomena governing the oxidation behavior of FeCrAl alloys. This foundation enabled significant improvements to the ASTEC code, which is now capable of modelling the behavior of FeCrAl alloys as a cladding material in steam environments up to the loss of the cladding geometry. To achieve this, the implementation of dedicated modelling extensions was successfully validated by accurately reproducing the SET and the QUENCH-19 (bundle test) experimental results.

The appropriate configuration for predicting the behavior of FeCrAl alloys within the ASTEC framework requires the representation of two distinct oxidation mechanisms and, consequently, the implementation of two complementary models. The first one, Al oxidation model, addresses aluminum oxidation at temperatures up to 1600 K and was recently integrated into the code. In this regime, the formation of a stable Al_2O_3 layer provides a protective effect against further oxidation. The second model, FEOX, is applied at higher temperatures and accounts for the oxidation behavior of an iron–chromium mixture, including the formation of the corresponding oxide layers.

Future work includes the application of the model to the plant level in order to make a preliminary assessment of the analysis of a postulated BDBA scenario in an SMR with FeCrAl claddings. The goal of that proposed activity is to evaluate the potential benefits of FeCrAl to mitigate hydrogen generation and extend the coping time. Nevertheless, further modelling efforts will be required to properly quantify material behavior after cladding rupture, and fully capture the phenomenology under BDBA conditions.

- FeCrAl 0.01 kg → 35 kg

Conclusion

- Modelling extensions have been implemented in ASTEC for FeCrAl alloys also based on the QUENCH Experiments results
  - Validation of the ASTEC FeCrAl modeling has been performed
  - ALOX model for temperatures T<1500K
    - The Al_2O_3 layer leads to a strong, stable protective role
  - SSTEEL model at very high T
    - Real Fe oxidation is included in the modelling, with corresponding oxide layers
- QUENCH SETs:
  - Modeling strategy for FeCrAl alloys (multilayer material) reproduce reasonable the experimental data with respect to Weight gain and Thickness oxide layer.
- QUENCH-19
  - ASTEC was used to performed the QUENCH-19 bundle test simulations.
    - The code is able to reproduces with good agreement the experimental temperatures and H_2 production, considering two different oxidation processes.
- SMR Application
  - Preliminary assessment of the analysis of a postulated BDBA scenario with FeCrAl cladding was performed
    - Some results must be interpreted qualitatively due to the previously mentioned limitations of the FeCrAl oxidation model once core degradation initiates.
    - Further modelling efforts are required to validate the assumptions adopted for the FeCrAl failure criteria and properly quantify material behavior after cladding rupture.

THE INTEGRAL AIR INGRESS CODEX-ATF-AIT EXPERIMENT

Róbert Farkas, Nóra Vér, Berta Bürger, Zoltán Hózer
HUN-REN Centre for Energy Research (HUN-REN EK)
29-33 Konkoly-Thege Miklós rd., 1121, Budapest, Hungary
robert.farkas@ek.hun-ren.hu

ABSTRACT

The experimental scenario was designed to investigate key phenomena of chromium coated zirconium cladding behavior during air ingress accident conditions, including cladding burst, oxidation, nitriding, and eutectic formation. During the preparatory phase, the facility was heated to 600 °C under a steam-argon atmosphere. In the subsequent pre-oxidation phase, the rod heating power was increased stepwise, leading to pressurization and cladding burst between 750–800 °C in most rods. The burst openings allowed coolant ingress, initiating chemical reactions on both sides of the cladding.
In the air ingress phase, the temperature rise was significantly slower and smoother compared to the reference experiment CODEX-AIT-3 [1] conducted with traditional Zr materials, demonstrating the protective effect of the Cr coating. The duration of the air ingress phase was extended to 1.5 hours (compared to 1 hour in the reference test), with a maximum cladding temperature of 1545 °C (compared to 1600 °C). The temperature profile shifted during this phase, with the peak moving from the upper bundle section to lower elevations due to intense chemical interactions in the less oxidized regions.
Gas analysis confirmed steam and oxygen starvation conditions during air ingress. The partial consumption of nitrogen indicated nitride formation. A total of 1.4 g of hydrogen was generated during the pre-oxidation phase, followed by 3.3 g during the air ingress phase. A controlled cool-down in argon flow was performed to avoid further reactions.

KEYWORDS
Bundle test, ATF cladding, air ingress, Cr-Zr eutectic reaction, burst

1. INTRODUCTION

The main objective of the CODEX-ATF-AIT test was to determine whether accident-tolerant fuel (ATF) cladding with a chromium (Cr) coating would provide protection in the event of severe accidents at nuclear power plants (NPPs) involving air ingress. An integral bundle test involving electrically heated chromium-coated fuel rod simulators was conducted at the CODEX facility [2] at the HUN-REN Centre for Energy Research. The proposed scenario involved a reactor accident in which corium melted through the bottom head of the pressure vessel, resulting in an air and steam mixture penetrating from the reactor cavity into the reactor vessel. The experiment focused on several phenomena of fuel behaviour during accidents, such as bursting, oxidation, nitriding and eutectic formation. Slow cooling was selected to provide information on the bundle's state before quenching.

2. THE TEST FACILITY

A Hexagonal bundle was built in VVER geometry using VVER type Cr coated spacer grids. In the bundle Cr coated optZIRLO^{TM} cladding tubes were used. The height of test section was 1000 mm, but the active part with the rods was only 890 mm, so the upper part of the shroud was used for thermocouples, without fuel rods. The fuel rods were filled with zirconia pellets. The rods were pressurised by krypton. Electrical

heating with two tungsten heaters in each rod was used. External heating was also applied to the test section. The bottom of the test section was connected to the steam generator unit. The condenser cooled down the hot steam+gas flowing out from the top of the test section. The bundle was covered by Cr coated Zr shroud. The shroud had no perforations and it was surrounded by several thermal insulation layers, electrical heaters and a steel tube (Fig. 1). SiO_2+Al_2O_3+ZrO_2 fibre was used between the Zr shroud and the steel tube.

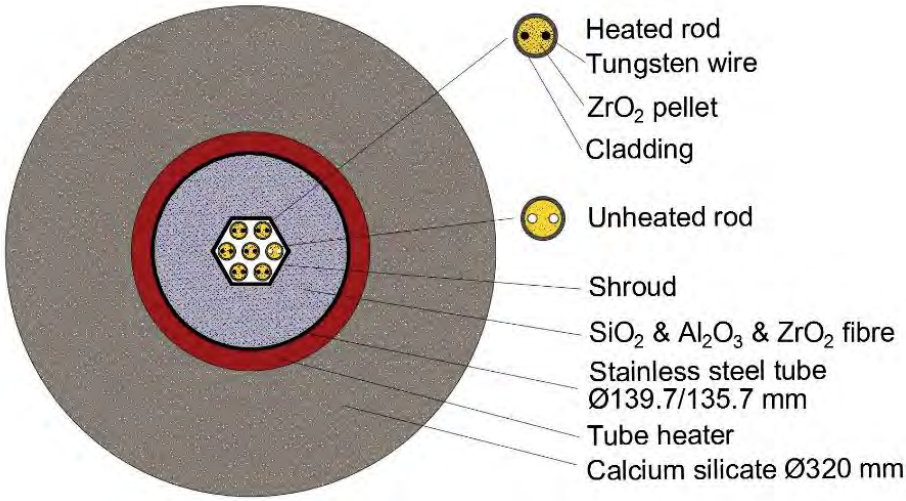

Figure 1. Horizontal cross section of the test section with thermal insulations

Steel vessel (diameter 139.7/135.7 mm) with external electrical heating housed the test section with fibre insulation. External heaters were applied on the surface of the stainless steel tube. Calcium silicate covered the steel tube as external layer of thermal insulation with external diameter of 320 mm.

The instrumentation included a large number of thermocouples in and around the heated bundle and a mass spectrometer for analysing the composition of the outlet gas.

3. SELECTED SCENARIO

The scenario consisted of the following phases (Fig. 2):

- Preparation phase: technological heat-up of the facility, initiation of steam supply, moderate power and target temperature of 500 °C.
- Pre-oxidation phase: further heat-up with increased power, pressurisation of fuel rods to reach burst, target temperature of 1100 °C.
  In case of Cr coated zirconium materials, no significant oxidation of cladding external surface is expected during the pre-oxidation phase. However, if the Cr coated zirconium cladding tubes suffer significant ballooning, the Cr-layer may become cracked and the oxidation of zirconium could start locally through the cracks of the Cr-layer. On the other hand, oxidation of inner (non-coated) cladding surface and secondary hydriding may take place after cladding burst and penetration of steam into the fuel rods.
- Intermediate cool-down phase: slow cooling down the bundle to 900 °C at reduced power.
- Steam-air phase: steam and oxygen-starvation condition, heat-up with moderated power, target temperature of 1400 °C.
- In the steam-air phase, a steam- and oxygen-starvation condition was aimed at, in order to investigate the effect of nitriding. Because one of the main failure mechanisms of Cr coated zirconium claddings is the Cr-Zr eutectic formation, it was intended to reach about 1400 °C in this

phase in order to observe the oxidation behaviour of ATF cladding in air above the Cr-Zr eutectic formation temperature.

- Slow cool-down: slow cool-down was selected to provide information on the state of the bundle before quench.

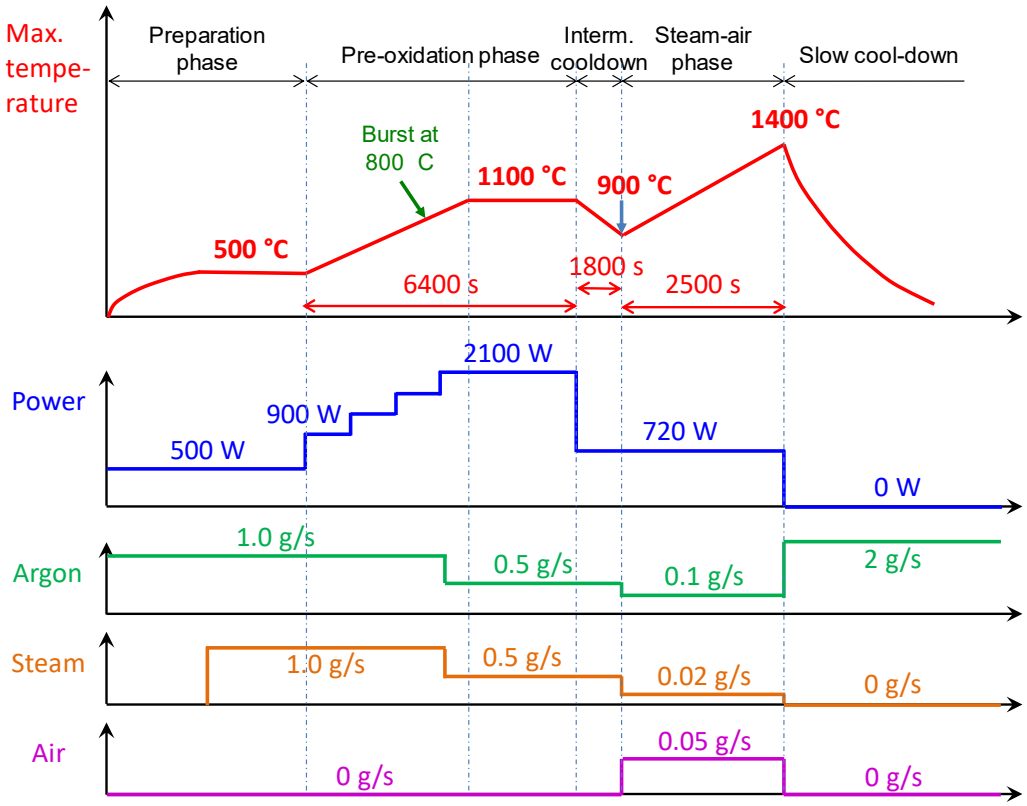

Figure 2. Main parameters of proposed CODEX-ATF-AIT scenario

4. THE CODEX-ATF-AIT EXPERIMENT

I. Preparation phase

The preparation phase started with switching on the external heaters with 750 W power (Fig. 3). The argon and steam flows through the bundle were set to 1.0 g/s. The water cooling system was put into operation, the bundle power was set to 500 W and later were varied up to 1000 W. The fuel rod internal pressure was set individually for each rod between 20-30 bars after 5112 s.

II. Pre-oxidation phase

The pre-oxidation phase was initiated after 6883 s. From this phase the same power history was applied than in the CODEX-AIT-3 experiment, but with reduced power (90% of the CODEX-AIT-3, Fig. 3). The reduction in performance compared to the reference experiment was due to the fact that the rods were 10% shorter. The bundle power was increased in a stepwise manner up to 1728 W, the flow rate of both steam and argon was 1.0 g/s. The power increase resulted in significant heat-up of the bundle. The argon and the steam flow rate was reduced from 1.0 g/s to 0.5 g/s after 10181 s in order to reach higher temperature increment for the bundle. The maximum temperature at 750 mm elevation was 1170 °C and it was reached at 12344 s (Fig.4). In order to avoid too high degree of oxidation in this phase, the high temperature plateau was maintained for 15 min by

manipulating the bundle power. The maximum electric power of the bundle was 2129 W. At the end of the pre-oxidation phase the rod maximum temperature was 1084 °C, while the shroud heated up to 1013 °C and the stainless steel tube temperature was above 725 °C.

The cladding bursts took place in the pre-oxidation phase, mainly between 8850-9250 s (Fig. 5). Rod No. 5. failed at 37.0 bar (≈760 °C at 750 mm), rod No. 4. at 36.4 bar (≈770 °C at 750 mm), rod No. 1. at 29.7 bar (≈780 °C at 750 mm) and rod No. 2. at 35.3 bar (≈810 °C at 750 mm). The delay between the measured pressure drops inside the rods and the Kr signals at the mass spectrometer was about 10 s. Because of leakage, rod No. 6. was not pressurized and rod No. 3. and rod No. 7. were pressurized but did not burst.

The total hydrogen release measured in the pre-oxidation phase was around 1.4 g.

III. Intermediate cool-down

The bundle power was reduced in three steps after 13195 s (Fig. 3). The maximum rod temperature decreased to 728 °C (Fig. 4).

IV. Steam-air phase

The steam-air phase started after 15082 s. The steam generator was switched off. The argon flow rate was reduced from 0.5 g/s to 0.1 g/s and the air flow was initiated with 0.05 g/s flow rate. The operation of small HPLC pump was started resulting in 0.02 g/s water injection to the bottom of the bundle. The bundle power was increased to 720 W (Fig. 3). The maximum cladding temperature was ≈1030 °C and it was measured at 750 mm elevation (Fig. 4).

Unlike in the CODEX-AIT-3 experiment, no temperature escalation occurred during the steam-air phase with the Cr coated cladding and shroud material. In order to observe the air oxidation behaviour of ATF cladding above the Cr-Zr eutectic formation temperature, the test was continued with a slight power increase to 1000 W (Fig. 3). The maximum temperatures were initially recorded at the top of the bundle (≈1350 °C at 650-750 mm). However, over time, the hottest section of the bundle moved gradually downwards and in succession levels of 500, 400, 200 and 150 mm reached the highest (≈1500 °C) temperature (Fig. 4). A possible explanation could be that eutectic melt formation occurred, and the melted zirconium reacted strongly with the limited steam and air available in the coolant. The maximum measured cladding temperature was 1544 °C and it was recorded at 400 mm elevation. The maximum shroud temperature was 1480 °C and it was measured at 750 mm elevation.

In the extended air ingress phase oxygen was completely consumed from the gas stream though the bundle at about 18700 s (Fig. 6). Shortly afterwards, from about 19000 s considerable nitrogen consumption started, which indicates an overall oxygen and steam starvation. This coincides with the temperature escalation of the middle-lower part of the bundle (at 500-150 mm). Parallel with oxygen, steam was also consumed from the beginning of the air-ingress phase. Interestingly, not complete steam consumption was experienced in the outlet gas. Despite the detected steam consumption from the start of the air-ingress phase, hydrogen produced by the zirconium (chromium) – steam reaction became detectable in the outlet gas only after the complete consumption of oxygen. As long as oxygen was available, the produced hydrogen could recombine with oxygen and produce water.

From about 19200 s the quantity of nitrogen started to increase in the outlet gas due to the re-oxidation of the formed nitrides. The total hydrogen release measured in the extended air-ingress phase was about 3.3 g, while the total uptakes of oxygen and nitrogen also calculated only for the extended air-ingress phase were about 17 and 9 g, respectively.

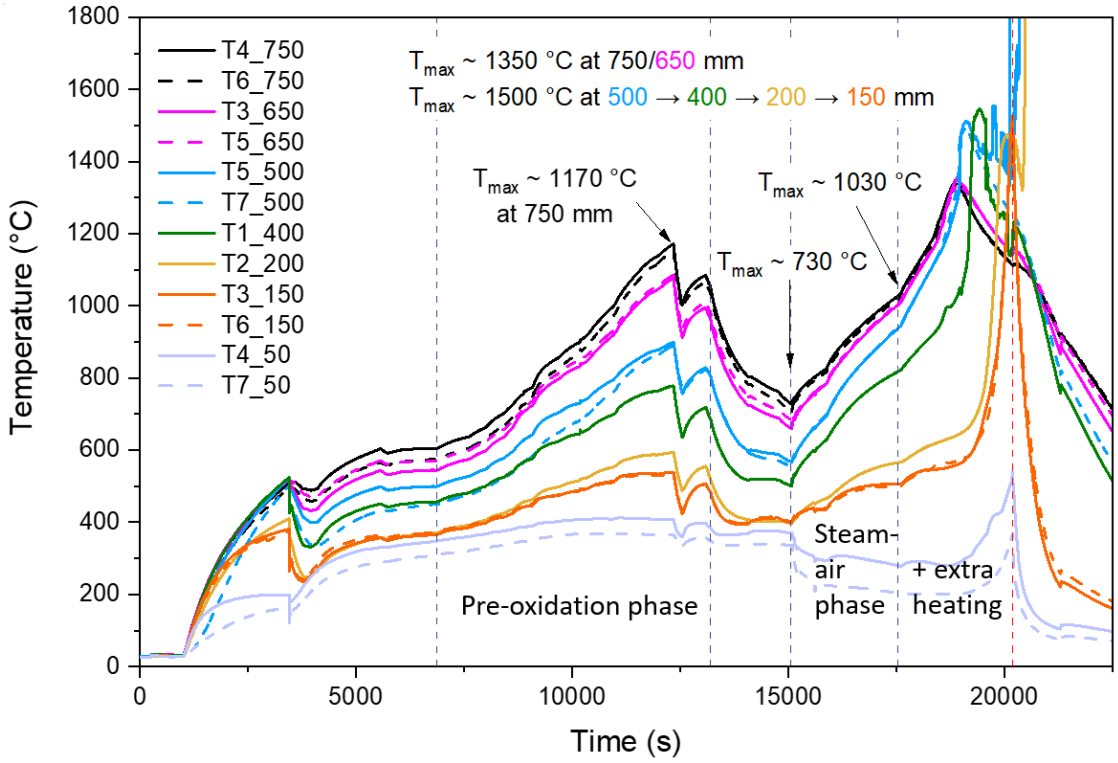

Figure 4. Cladding temperatures in the CODEX-ATF-AIT test

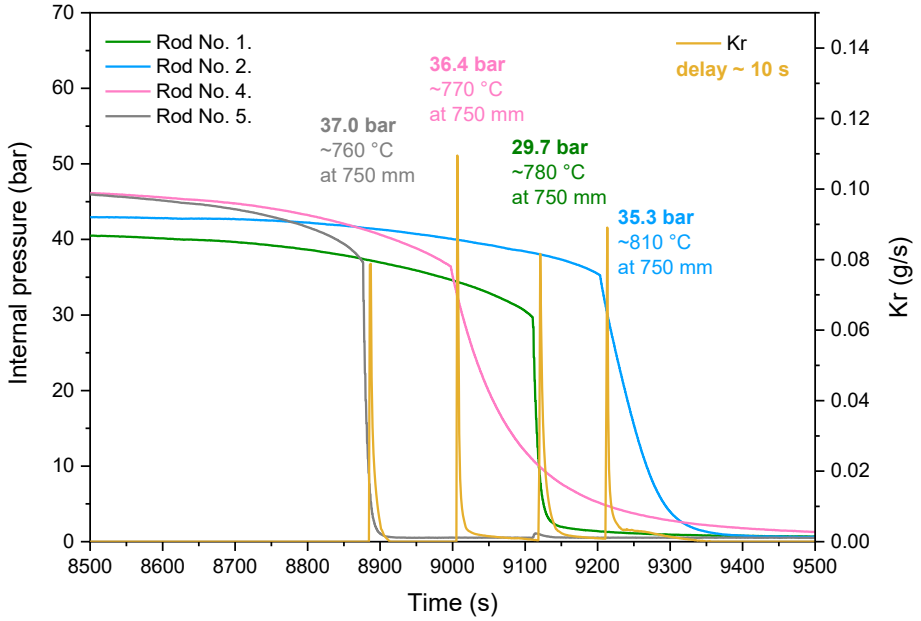

Figure 5. Comparison of measured fuel rod pressure drops and Kr signals at MS in the CODEX-ATF-AIT test

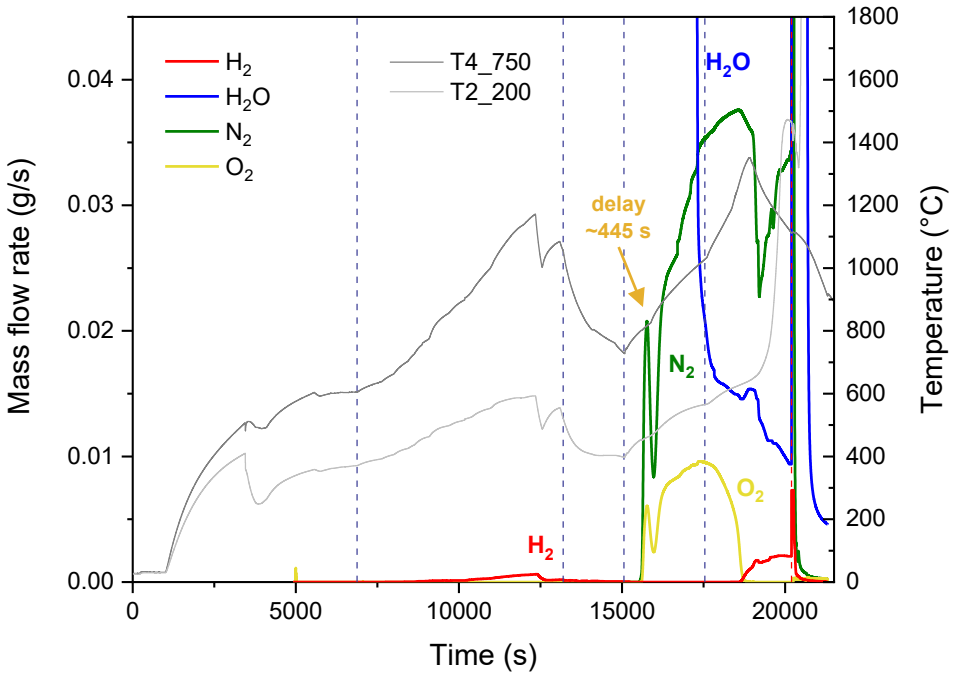

Figure 6. Outlet gas flow rates in the CODEX-ATF-AIT test

V. Slow cool-down

The slow cool-down was initiated at 20212 s with switching off the bundle and the external heater power (Fig. 3). The steam and air flow rates were set to zero, while the argon flow rate was increased to 2.0 g/s. It took two and a half hours to cool down the facility and after that the argon flow rate was set to zero.

5. SUMMARY

The CODEX-ATF-AIT test was successfully performed on 29 October 2024 at the HUN-REN Centre for Energy Research (EK) in Budapest. The test section included a seven-rod bundle that was electrically heated and composed of zirconium (Zr) cladding tubes coated with chromium (Cr) and provided by the Czech Technical University in Prague (CTU).
During the preparatory phase, the facility was heated to 600 °C using a steam-argon flow, with heat supplied by both external and fuel rod heaters. The pre-oxidation phase continued with the same flow rates and stepwise increased heating power on the rods. During the heating phase, the rods were pressurised, resulting in a cladding burst between 750 and 800 °C on most of the rods. This allowed the coolant to enter the rods and initiate chemical reactions on both sides of the cladding. During the intermediate cooling phase, the temperatures were reduced below 750 °C. During the steam-air phase, the temperature increased more smoothly than in the reference experiment, CODEX-AIT-3. The slower temperature increase was due to the protective effect of the Cr coating. The air ingress phase in the reference experiment lasted 1 hour, with a maximum cladding temperature of 1600 °C, whereas in the CODEX-ATF-AIT it lasted 1.5 hours, with a maximum cladding temperature of 1545 °C. Similar to the reference experiment, the temperature profile changed significantly during the air ingress phase: the maximum temperature (≈1500 °C) moved from the upper section of the bundle to lower elevations due to intense chemical interactions in the less oxidised and/or melted lower part. The maximum shroud temperature was around 1470 °C at elevations of 300, 500, and 700 mm.

Analysis of the outlet gas composition showed that steam and oxygen starvation conditions were established during the air ingress phase. The partial consumption of nitrogen also indicated the formation of nitrides. A total of 1.4 g of hydrogen was produced during the pre-oxidation phase, compared to 3.3 g during the air ingress phase. The bundle was slowly cooled in an argon flow to avoid interactions that might occur during water quenching.

ACKNOWLEDGMENTS

The CODEX-ATF-AIT experiment was conducted with the support of EURATOM OFFERR project and the Paks Nuclear Power Plant.

ABSTRACT

During severe accidents of a light water reactor, the relocation of the molten core to the lower head of the reactor pressure vessel (RPV) may exert challenging thermal loads to the RPV wall due to extreme high temperatures, potentially leading to creep failure or melt-through of the lower head. Consequently, modeling the creep behavior of the RPV wall plays an important role in severe accident analysis. A key limitation of widely used creep models in reactor safety analysis is their inability to simulate the tertiary stage, which is crucial for material failure prediction. The present study is motivated to calibrate a continuum damage mechanics (CDM) creep model (Liu-Murakami model) for reactor pressure vessel (RPV) steel SA533B1. The calibration is performed using experimental data across a wide temperature range from 900 to 1623 K, ensuring wide thermo-mechanical applicability of the model. Furthermore, to facilitate scenarios involving significant temperature variations, temperature-dependent relationships for the model constants are established to reduce the interpolation errors. Comparative evaluation demonstrates that the Liu-Murakami model offers superior predictive performance over the full temperature range. These findings provide a more reliable creep model for thermo-mechanical analysis of RPV deformation during severe accidents.

1. INTRODUCTION

Creep refers to the time-dependent, permanent deformation of a solid structural material when subjected to sustained mechanical stress, and it becomes particularly pronounced at elevated temperatures [1, 2]. High-temperature conditions may be encountered during severe accidents of light water reactors, where molten core (corium) relocates to the lower head of the reactor pressure vessel (RPV) and consequently heats up the vessel wall [3,4]. Under the thermal and mechanical loads, the RPV lower head undergoes considerable creep deformation, and fails ultimately [5-7]. Consequently, creep analysis is essential for predicting severe accident progression, where the fidelity and accuracy of creep models for RPV steels play an important role, especially under the very high temperatures occurring in severe accidents.

Mant creep models have been developed and applied in thermo-mechanical analysis (i.e. finite element analysis – FEA). The most widely used creep model is the power law model, commonly referred to as the Norton model [8]. Through mathematical transformations, the Norton model has yielded several variants, including the time hardening model [9]. Another example is the MPC omega model proposed by Prager [10]. While these models are effective in describing the primary and/or secondary creep stages, they generally lack predictive capability for the tertiary stage of the creep curve. In response, researchers have tried to explore alternative formulations which can be divided into two principal approaches. One is the theta-projection model introduced by Evans et al. [11]. Another principal approach is based on continuum damage mechanics (CDM), such as the Kachanov-Rabotnov (K-R) model [12]. To address notable limitations in the K-R model, such as convergence difficulties and mesh dependency, Liu & Murakami proposed an enhanced CDM creep damage model [13].

The present study is conducted to advance the Liu & Murakami (L-M) creep model by using the

available experimental data for the creep behavior of RPV steel SA533B1 specimens. The datasets are from the series of creep tests [5,6] performed by Idaho National Engineering Laboratory (INEL) for SA533B1 material temperature range of 900~1373 K, and the tests carried out by Japan Atomic Energy Agency (JAEA) for temperature ranging from 1250 K to 1623 K which is near the melting point of S533B1 [14,15]. The chemical composition of SA533B1 steel is detailed in Table **I**. The test matrix of both INEL and JAEA creep tests are shown in Table **II**.

Table I**. Chemical composition of SA533B1 steel (wt.%) [5]**

	C	Si	Mn	P	S	Ni	Cr	Mo	V	Cu

		26.30	26.50			17.0	4.99	2.61	2.37

The structure of this paper is organized as follows: Section 2 introduces the L-M creep model [13] and its modification based on the INEL and JAEA creep tests [5-6, 14-15]; Section 3 illustrates the predictive capabilities of the new model, in terms of agreement with experimental creep curves and key parameters (e.g., minimum creep strain rate), as well as the interpolation accuracy; Finally, Section 4 presents the conclusions.

2. CREEP MODEL

The Liu & Murakami creep model is a creep damage model based on continuum damage mechanics [13]. Its multiaxial form of creep damage and creep strain equation is as follows:

$$\dot{\varepsilon}_c = \frac{3}{2} C \sigma_{eq}^{n} \frac{S_{ij}}{\sigma_{eq}} \exp\left(\frac{2(n+1)}{\pi\sqrt{1+3/n}}\left(\frac{\sigma_1}{\sigma_{eq}}\right) \cdot \omega^{3/2}\right) \tag{1}$$

where C and n are material constants. $\dot{\varepsilon}_c$ is the creep strain rate, σ_{eq} is the equivalent stress, $\sigma_1$is the maximum principal stress, ω is the damage factor, S_{ij} is deviatoric stress.

If we neglect the multiaxial influence in the present study, the multiaxial Liu-Murakami (L-M) creep model can be simplified to a uniaxial form:

$$\dot{\varepsilon}_c = C \sigma_{eq}^{n} \, exp\left(\frac{2(n+1)}{\pi\sqrt{1+3/n}} \cdot \omega^{3/2}\right) \tag{2}$$

$$\dot{\omega} = D \frac{(1-e^{-q})}{q} \sigma_{eq}^{p} e^{q\omega} \tag{3}$$

where p and q are model constants. All parameters (constants: C, n, D and p) except q (q=1.5) are obtained from regression analyses of the experimental data. The regression analyses yield:

$$C(T) = \begin{cases} \exp\left(-0.0372T + 12.449\right) & T \leq 1050 \text{ K} \\ \exp\left(0.0263T - 54.1\right) & T > 1050 \text{ K} \end{cases} \tag{4}$$

$$n(T) = \begin{cases} 0.0216T - 18.312 & T \leq 1050 \text{ K} \\ -0.0046T + 9.2 & T > 1050 \text{ K} \end{cases} \tag{5}$$

$$D(T) = \begin{cases} \exp(-0.0299T + 6.862) & T \leq 1050\ \text{K} \\ \exp(0.00235T - 49) & T > 1050\ \text{K} \end{cases} \quad (6)$$

$$p(T) = \begin{cases} 0.0173T - 14 & T \leq 1050\ \text{K} \\ -0.0045T + 8.64 & T > 1050\ \text{K} \end{cases} \quad (7)$$

Table **III** shows the values of the constants in the modified L-M creep model for the temperature points employed in the INEL and JAEA tests. Figures 1(a) through 1(d) illustrate the variation of the modified L-M model constant with temperature.

3. RRSULTS AND DISCUSSION

3.1 Simulation of INEL Tensile Tests

Finite element analyses (FEA) of the INEL creep tensile tests were conducted to assess the predictive capability of the modified L-M creep model. The schematic diagram and axisymmetric FE model of the test specimen are shown in Figure 2. Specimen dimensions follow the ASTM standards. In the simulation, stress was applied uniformly to the cross-section of the reduced section to maintain a steady stress state throughout the analysis.

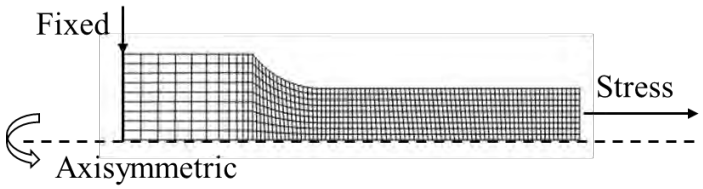

Figure 2. Schematic of Axis-symmetric FE model for creep test simulation.

The remaining material properties of SA533B1 steel, including Young's modulus, density, thermal conductivity, thermal expansion coefficient, heat capacity, were taken from previous studies [5].

All numerical simulations were performed using the Ansys code. The modified L-M creep model was implemented via User Programmable Features (UPF) of Ansys. Two other well-known creep models, Norton creep model [16] and Modified Time Hardening (MTH) creep model [17] were also employed to compare their predictive capability with the modified L-M creep model.

Figures 3 through 7 present comparisons between the INEL experimental data and simulation results of different creep models. As shown in Figure 3, when temperature is 900 K and stress is 69.7 MPa, the modified L-M model exhibits excellent agreement with the experimental data across the entire creep curve. In contrast, both the MTH and Norton models tend to overestimate creep strain during the primary and secondary stages. As these two models primarily describe secondary creep behavior, they fail to accurately capture the accelerated creep deformation characteristic of the tertiary stage, resulting in underpredictions of creep strain near failure.

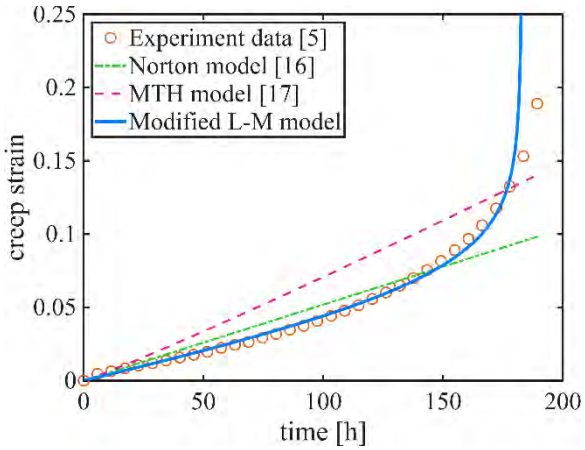

Figure 3. Comparison of the experimental creep strain with the simulation results: T= 900 K, Stress=69.7 MPa

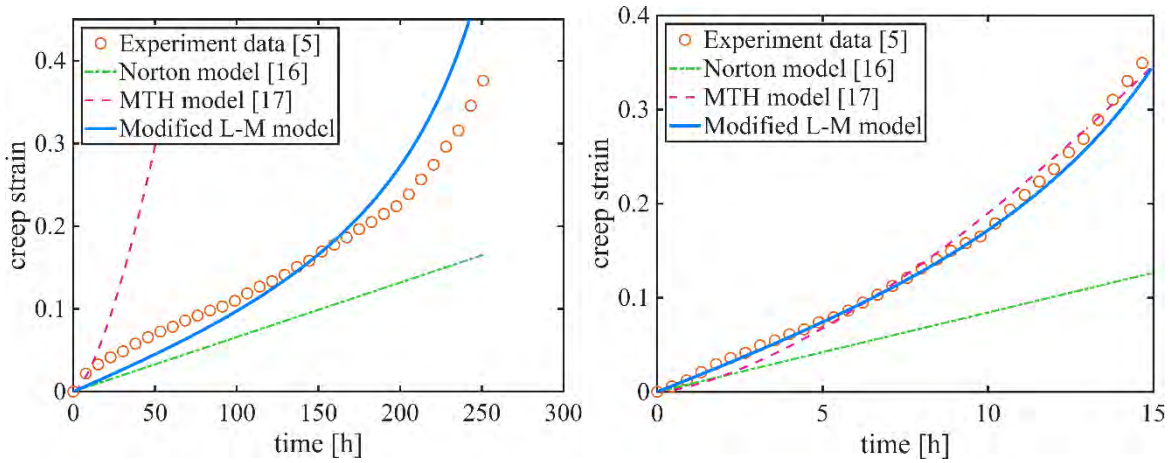
Figure 4(a) and 4(b) present a comparison between the model predictions and experimental data at a temperature of 1150 K under the stress levels of 12.5 MPa and 26.5 MPa, respectively. In Figure 4(a),

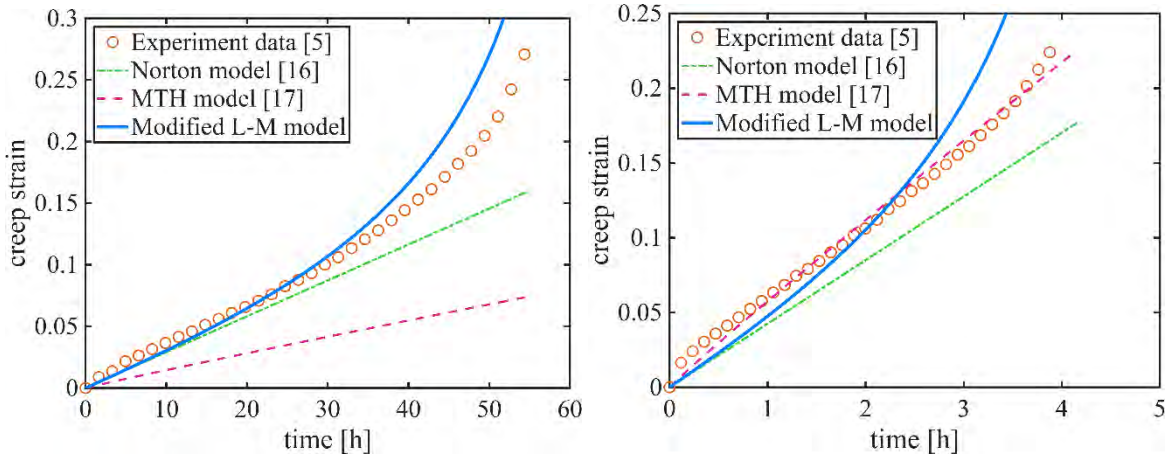
the modified L-M model shows superior agreement with the experiment data compared to other models. The Norton model consistently underestimates creep strain throughout the test duration, whereas the MTH model significantly overestimates it. In Figure 4(b), both the modified L-M and MTH models demonstrate good agreement with the experimental data, while the Norton model prediction remains lower than observed.



(a) Stress=13.9 MPa (b) Stress=26.3 MPa

Figure 4. Comparison of the experimental creep strain with the simulation results: T= 1050 K.

Figure 5(a) and 5(b) compare the model predictions with experimental data at 1150 K under stress level of 12.5 MPa and 26.5 MPa. As shown in Figure 5(a), the modified L-M model successfully captures non-linear behavior during the tertiary stage, while the Norton and MTH model exhibit linear trends. The Norton model prediction matches the experimental data during the initial half stage; however, the difference increases significantly as creep progresses into the tertiary stage. While the modified L-M model slightly underestimates creep strain, its overall performance surpasses the other models in critical phase. In Figure 5(b), the modified L-M model overpredicts creep strain during the tertiary stage, whereas the MTH model demonstrates improved agreement with experimental results. The Norton model continues to slightly underestimate creep strain.



(a) Stress=12.5 MPa (b) Stress=26.5 MPa

Figure 5. Comparison of the experimental creep strain with the simulation results: T= 1150 K

Figure 6 presents a comparison between the predicted creep behavior from various models and the experimental data at 1250 K and stress of 8 MPa. Both the L- M and MTH models demonstrate good agreement with the experimental results. However, the modified L-M model exhibits a superior ability

to capture the nonlinear deformation trend throughout the entire creep stage. This improved performance is further pronounced in **Figure 7**.

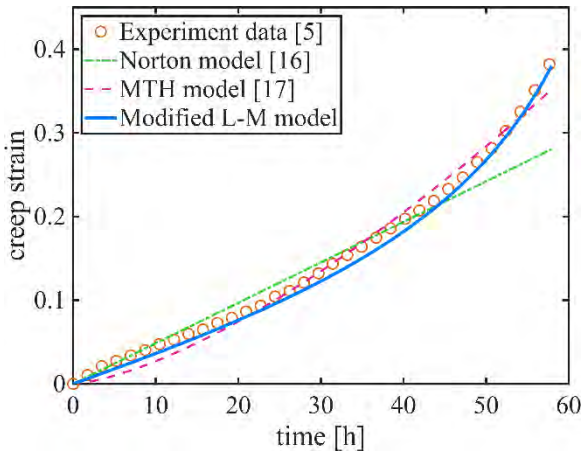


Figure 6. T=1250 K, stress=8 MPa.

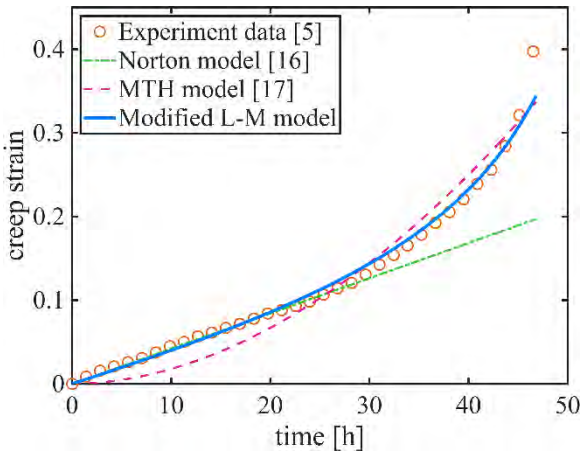

Figure 7. T=1373 K, stress=3.5 MPa.

In summary, the comparison clearly demonstrates that the modified L-M model offers substantially improved prediction accuracy over both the Norton and MTH models in capturing the full-range creep deformation behavior of SA533B1 steel under diverse conditions.

3.2. Simulation of JAEA Tensile Tests

Complete creep strain versus time curves were not provided in the relevant JAEA tensile test literature. However, key creep parameters, specifically the minimum creep strain rate and rupture time, have been reported and are summarized in Table IV [14,15].

Table IV. Experimental conditions and results of JAEA creep test for SA533B1.

Temp (K)	Stress (MPa)	Time to failure (h)	Minimum creep strain rate (/h)
1250	12.60	18.40	0.022
	17.00	6.91	0.056
1473	4.50	10.40	0.018
	4.99	8.52	0.02
1573	2.27	17.70	0.01
	2.61	11.30	0.027
1623	2.07	5.80	0.055
	2.37	3.40	0.10

A Kachanov-Rabotnov (K-R) model has been recommended in the JAEA literature for describing the creep behavior of SA533B1 steel at very high temperature (1250 K-1623 K). To evaluate the predictive accuracy of various models, a comparative analysis was conducted among experimental data from INEL and JAEA, and simulation results obtained using the Norton model, the K-R model, and the modified L-M model.

Figure 8 illustrates the predictive capability of different models for the minimum creep strain rate at elevated temperatures. The height of each bar represents the absolute value of the minimum creep strain rate, with the corresponding error between experimental and simulated values indicated above each bar. As shown in Figure 8 (a), at 1250 K and 8 MPa, the modified L-M model exhibits superior accuracy compared to the K-R model and Norton model. When the stress increases to 12.6 MPa, the K-R model achieves the lowest error of 0.5%, while the error in the modified L-M model rises to 16%. However,

at 17 MPa, the modified L-M model's performance matches that of the K-R model. At a higher temperature of 1473 K, as shown in Figure 8(b), both the K-R and Norton models overpredict the minimum creep strain rate, whereas the modified L-M model maintains good agreement, underestimating the experimental value by 13.3% at 4.5 MPa and matching it closely at 4.99 MPa. Figure 8 (c) and 8(d) further demonstrate that the Norton model significantly overestimates minimum creep strain rates at very high temperatures, while the modified L-M model remains consistent with experimental data at relatively higher stress levels. Overall, both the modified L-M and K-R models demonstrate strong capability in predicting minimum creep strain rates under high-temperature conditions, though their relative effectiveness depends on the specific stress level.

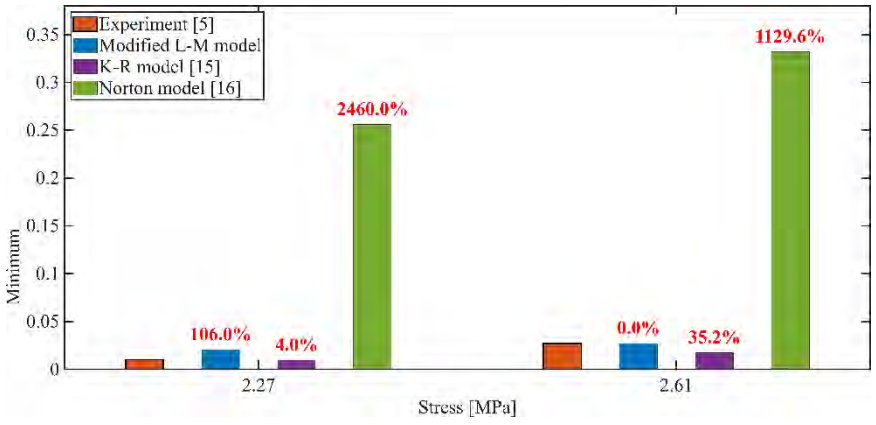
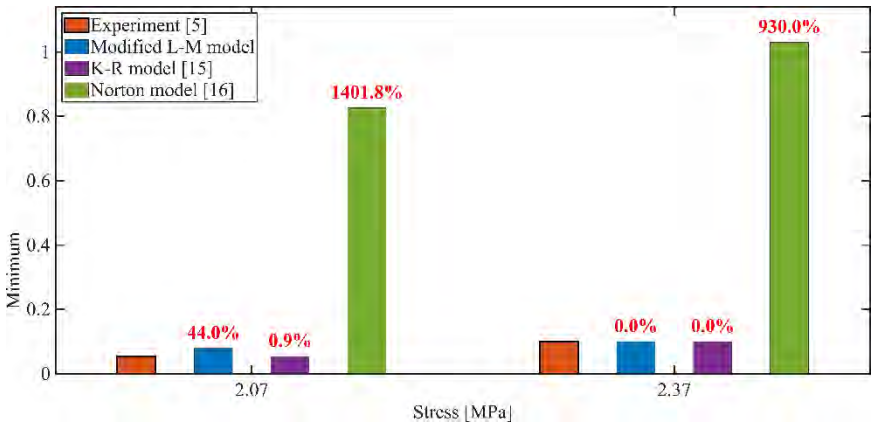
(b) T=1473 K



(c) T=1573 K

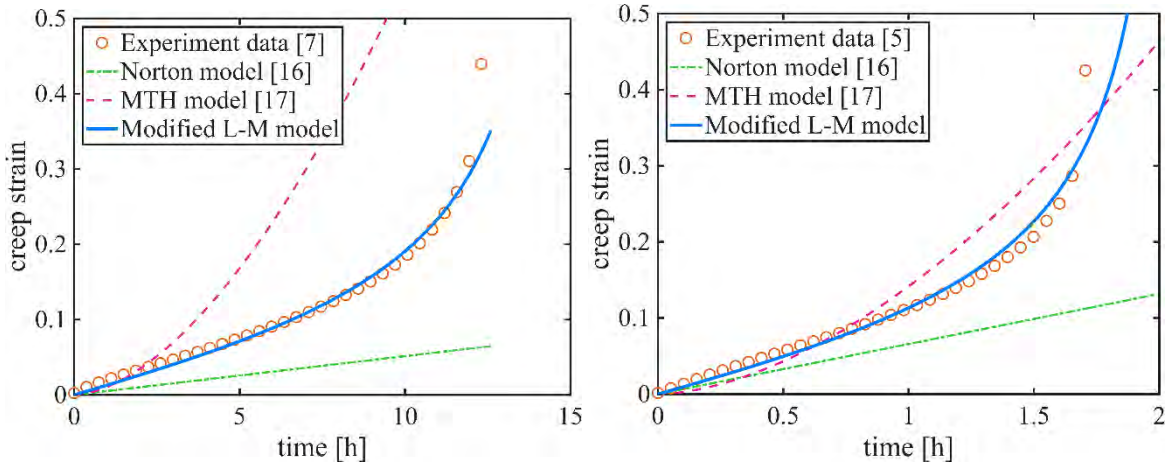


(d) T=1623 K

Figure 8. Comparison of the experimental minimum creep strain rate with simulation results.

3.3 The Interpolation of Creep Model

The OECD lower head failure (OLHF) program conducted creep tests at 1000 K on SA533B1 steel supplied by INEL [7]. Figure 9 compares the simulation results with the corresponding experimental creep curves. Regardless of whether the applied stress is 40.2 MPa or 73.6 MPa, the modified L-M model shows good agreement with the experimental data. This demonstrates that at intermediate temperatures, using regression equations to derive model constants does not introduce significant interpolation errors.



(a) Stress=40.2 MPa (b) Stress=73.6 MPa

Figure 9 Comparison of the experimental creep strain with the simulation results: T= 1000 K.

4. CONCLUSIONS

Creep deformation is a critical factor in lower head failure research during severe accidents. A reliable creep model is essential for accurate thermo-mechanical simulation of deformation and failure behavior. In this research, a continuous-parameter Liu-Murakami creep model for reactor pressure vessel steel SA533B1 is proposed based on the analysis of creep tensile tests conducted by INEL and JAEA. This model effectively describes the tertiary creep stage by incorporating a damage factor and establishes functional relationships between material constants and temperature. The main findings and contributions of this work are summarized as follows:

(1) Compared to existing creep models for SA533B1, such as Norton and MTH models, the modified L-M model successfully captures the tertiary creep behavior and accurately predicts key parameters including the minimum creep strain rate. Simulation results closely align with experimental creep strain curves.

(2) The new model significantly extends the applicable temperature range from 900 K, where creep behavior becomes clearly observable, up to 1623 K, near the melting point of the steel.

(3) By expressing the material constants of the modified L-M model as continuous functions of temperature, interpolation errors during simulations involving temperature changes are greatly reduced, thereby improving stability and accuracy.

PART ONE

Introduction

Background & Research Motivation

1.1 Background

Background

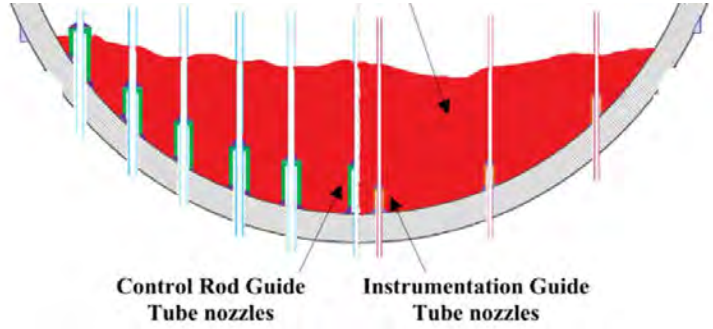
- **Severe Accidents:** Molten core relocation poses extreme thermal-mechanical loads on RPV lower head;
- **Failure Prediction:** Finite Element Analysis (FEA) is a critical tool to predict '**when, where, and why**' RPV fails for accident management.
- **Crucial Mechanism: creep** is one of the primary mechanism leading to lower head failure.
- **The Key:** Accurate **creep models** are essential for reliable FEA predictions.

Challenges:

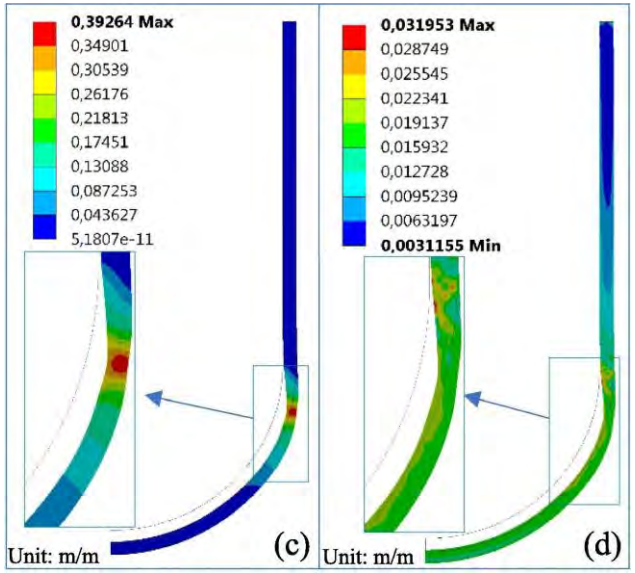
- **Existing creep models (SA533B1) are limited in:**
  - Applicable temperature ranges.
  - Tertiary stage prediction: the critical stage for failure.
  - Interpolation errors in transient thermal analysis.

Objectives:

- **Calibrate a creep model for SA533B1 covering:**
  - Wide temperature scopes.
  - Tertiary stage prediction.
  - Less interpolation errors in transient thermal analysis.



RPV lower head with penetrations & molten pool



Field of creep strain and plastic strain closed to failure [1]

1.2 Model Development and Evaluation Process

Problem Definition → Input & Selection → Model Calibration → Comparative Evaluation

Core limitations:

- Restricted thermal range;
- Failure to simulate the tertiary creep stage;
- Interpolation errors in transient thermo-mechanical analysis.

Experimental Data (900 – 1623 K):

- INEL lower head failure program (900-1373 K);
- JAEA high-temperature data (1250-1623 K).

Model selection:

- Liu-Murakami (L-M) creep model

Key enhancement:

- Establishing temperature-dependent relationships for model constants;

Evaluation:

- Comparison against traditional models across the full temperature range;

02

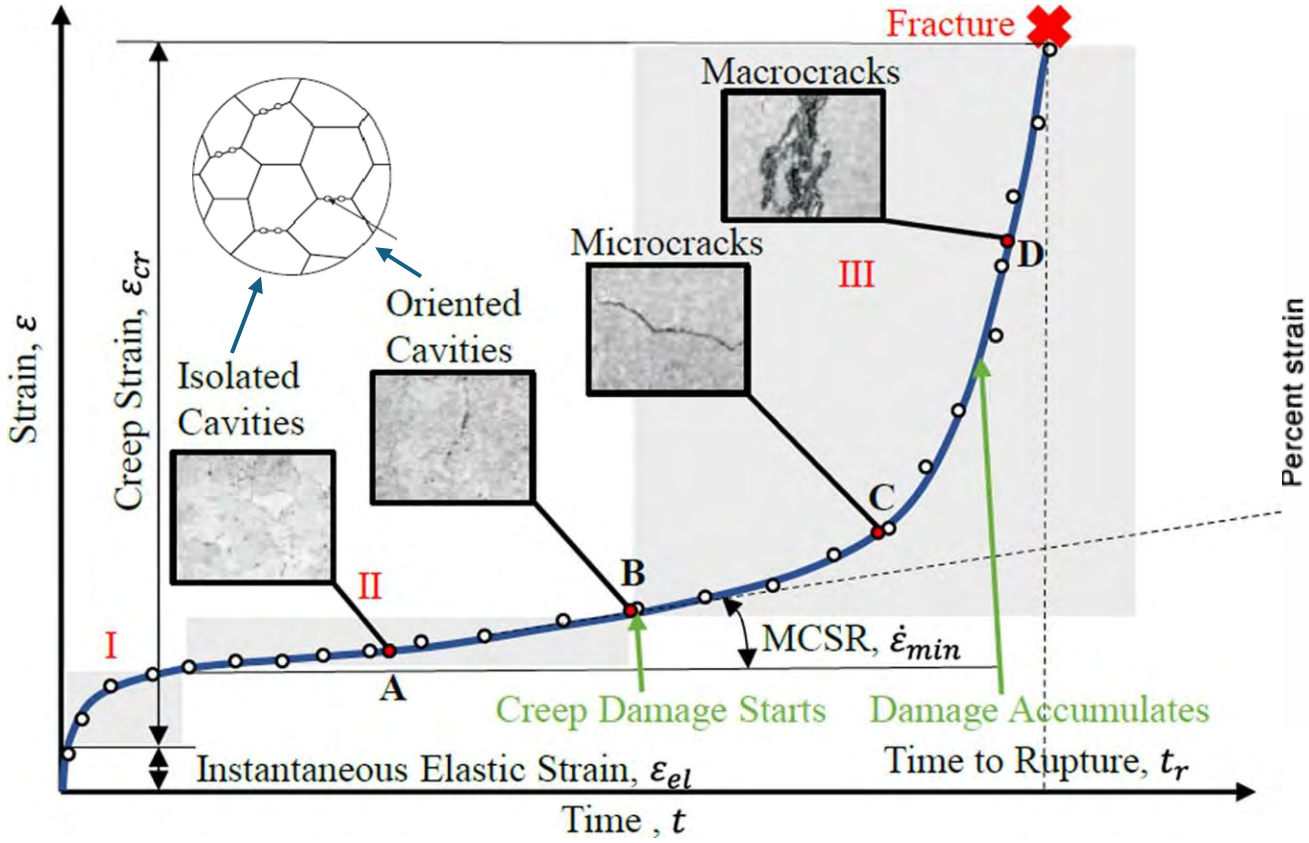
PART TWO

Methodology

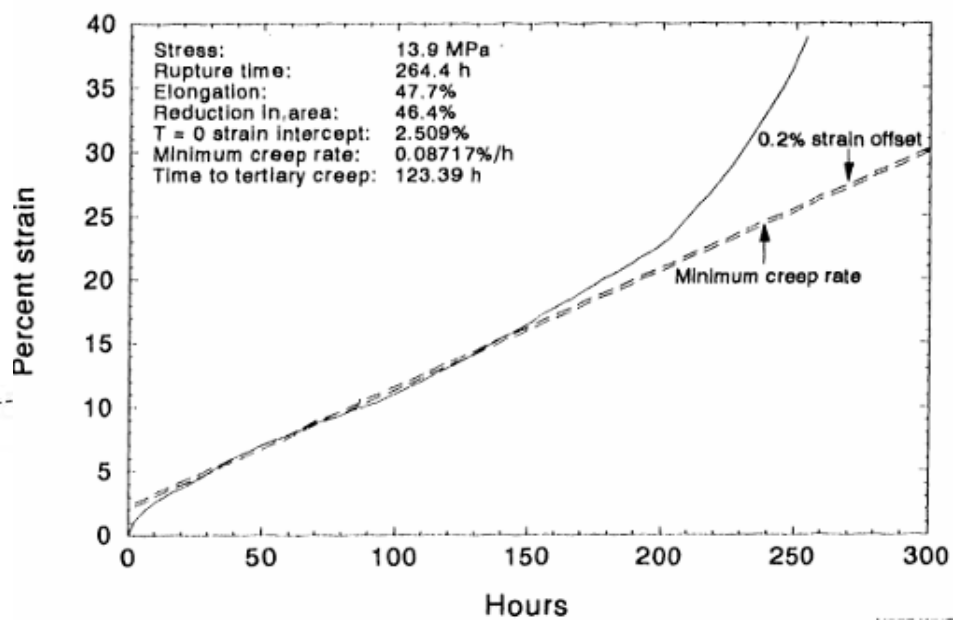
CDM Modeling & Parameter Calibration

2.1 Introduction of Creep

Creep refers to the **time-dependent, permanent deformation** of a solid material when subjected to **sustained mechanical stress**, especially at **high temperature**. Typical creep curves can be characterized by three stages: primary, secondary, and tertiary stage.



Formation of cavities and cracks at different stages of creep deformation [2]



Experimental creep strain with time[3].

2.2 Creep Models

Liu-Murakami (L-M) creep model[4]:

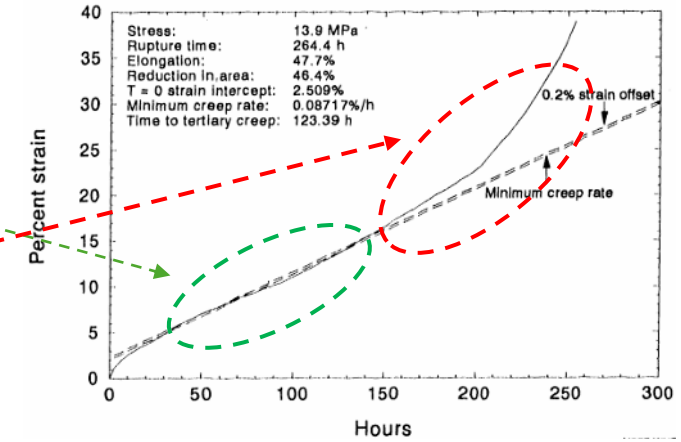
$$\dot{\varepsilon}_c = C\sigma_{eq}^n \cdot exp\left(\frac{2(n+1)}{\pi\sqrt{1+3/n}} \cdot \omega^{3/2}\right) \quad (1)$$

$$\dot{\omega} = D\frac{(1-e^{-q})}{q}\sigma_{eq}^p e^{q\omega} \quad (2)$$

Where $\dot{\boldsymbol{\varepsilon}}$ is the steady state creep rate; $\boldsymbol{C, n, D, p, q}$ are the model constants, $\boldsymbol{\sigma_{eq}}$ is the equivalent stress, and $\boldsymbol{\omega}$ is the damage factor.

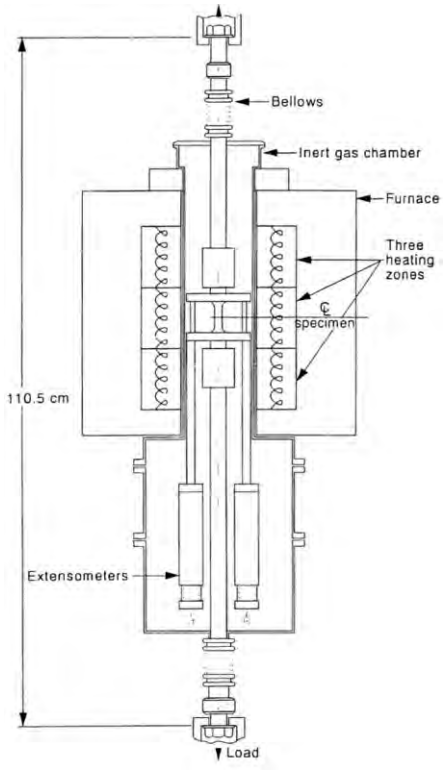
The L-M model can be divided into two parts: $\dot{\varepsilon}_c = C\sigma_{eq}^n$ & $exp\left(\frac{2(n+1)}{\pi\sqrt{1+3/n}} \cdot \omega^{3/2}\right)$

The first part is the Norton's power law (Norton model) [5], which is the most widely used creep model. It describes the **secondary creep stage** by building the relationship between the minimum creep strain rate and equivalent stress at a given temperature. The second part is the damage term for describing the **tertiary creep stage**.

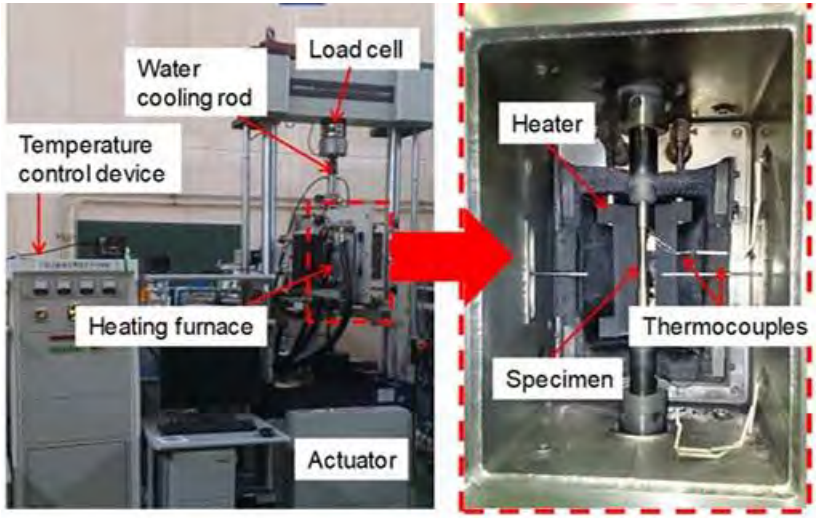


2.3 Experiments

The creep tests for SA533B1 steel conducted by the Idaho National Engineering Laboratory (INEL) [3] and the Japan Atomic Energy Agency (JAEA) [6]. The INEL experiment covered a temperature range from 900 K to 1373 K. The JAEA experiment covered a temperature range from 1250 K to 1623 K.



Schematic of the INEL creep test setup [3]

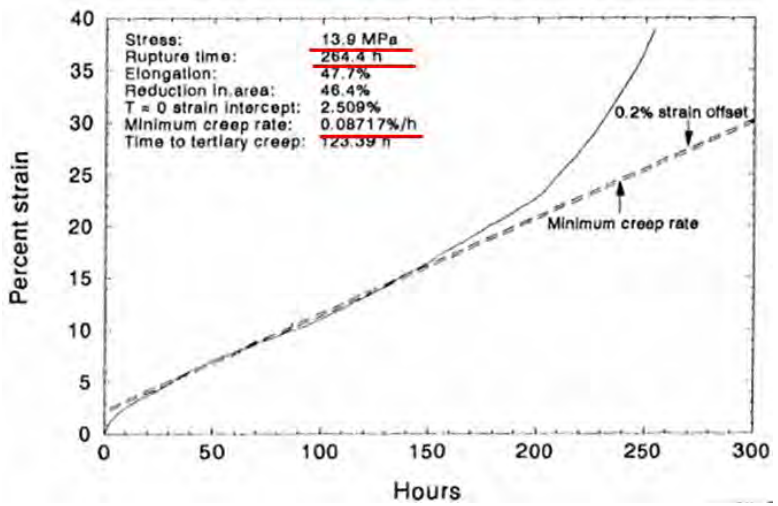


Schematic of the JAEA creep test setup [6]

Adopted Creep Test Matrix from INEL and JAEA

	INEL					JAEA			
Temp (K)	900	1050	1150	1250	1373	1250	1473	1573	1623
Stress (MPa)	69.70	13.90	12.50	8.00	3.50	12.60	4.50	2.27	2.07
		26.30	26.50			17.00	4.99	2.61	2.37

2.4 Parameter Calibration



Primary experimental inputs for parameter fitting:

- **Equivalent stress (σ_{eq})**
- **Minimum creep strain rate ($\dot{\varepsilon}_c$)**
- **Rupture time (t_r)**

Step A: Creep strain rate calibration

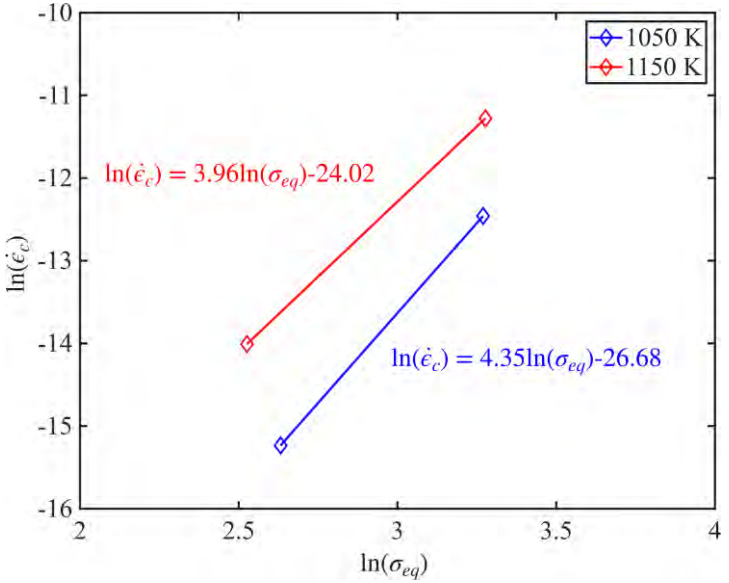
$$\dot{\varepsilon}_c = C\sigma_{eq}^{n}\, exp\left(\frac{2(n+1)}{\pi\sqrt{1+3/n}}\cdot\omega^{3/2}\right)$$

$$\boldsymbol{ln(\dot{\varepsilon}_c) = nln(\sigma_{eq}) + ln(C)}$$

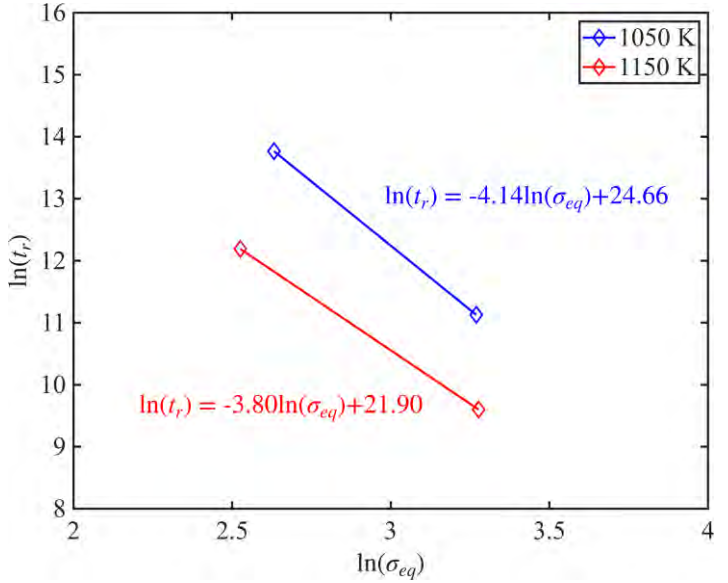
Step B: Damage/Failure time calibration

$$\dot{\omega} = D\frac{(1-e^{-q})}{q}\sigma_{eq}^{p}e^{q\omega}$$

$$\boldsymbol{ln(t_r) = -pln(\sigma_{eq}) - ln(D)}$$



Fitting of $ln(\dot{\varepsilon}_c)$ to $ln(\sigma_{eq})$ for material constants C and n



Fitting of $ln(t_r)$ to $ln(\sigma_{eq})$ for material constants D and p

2.5 Model Constants

Functional relationships between model constants and temperature are obtained to reduce the interpolation errors during temperature-change conditions.

Temp (K)	C	n	D	p	q
900	7.12×10^{-10}	1.19	1.87×10^{-9}	1.64	1.31
1050	2.58×10^{-12}	4.35	1.96×10^{-11}	4.14	2.57
1150	3.68×10^{-11}	3.96	3.08×10^{-10}	3.80	1.89
1250	5.29×10^{-10}	3.65	3.40×10^{-9}	3.39	1.2
1373	2.44×10^{-8}	3.03	1.47×10^{-7}	2.95	0.3
1473	1.20×10^{-7}	2.38	6.03×10^{-7}	2.48	0.3
1573	1.16×10^{-6}	1.94	3.57×10^{-6}	2.01	0.3
1623	6.27×10^{-6}	1.72	1.76×10^{-5}	1.78	0.3

$$C(T) = \begin{cases} \exp(-0.037T + 12.45) & T \le 1050\ K \\ \exp(0.026T - 53.70) & T > 1050\ K \end{cases}$$

$$n(T) = \begin{cases} 0.022T - 18.7 & T \le 1050\ K \\ -0.0046T + 9.2 & T > 1050\ K \end{cases}$$

$$D(T) = \begin{cases} \exp(-0.030T + 6.86) & T \le 1050\ K \\ \exp(0.0023T - 48.25) & T > 1050\ K \end{cases}$$

$$p(T) = \begin{cases} 0.017T - 13.70 & T \le 1050\ K \\ -0.0042T + 8.64 & T > 1050\ K \end{cases}$$

Phase transformation from ferrite to austenite alters the creep mechanism at 1000~1050 K [9].

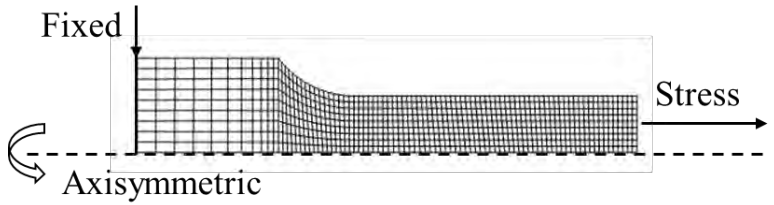
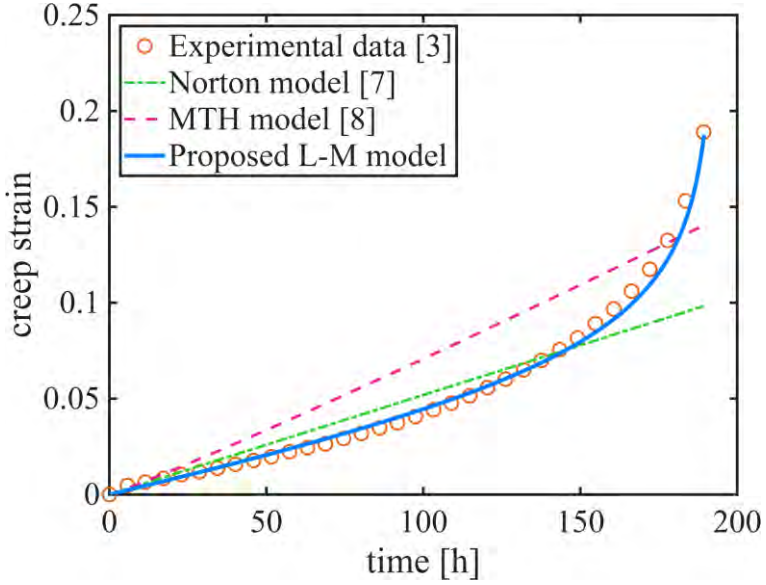
3.2 Simulation vs. INEL Tensile Test Results (900 - 1373 K):

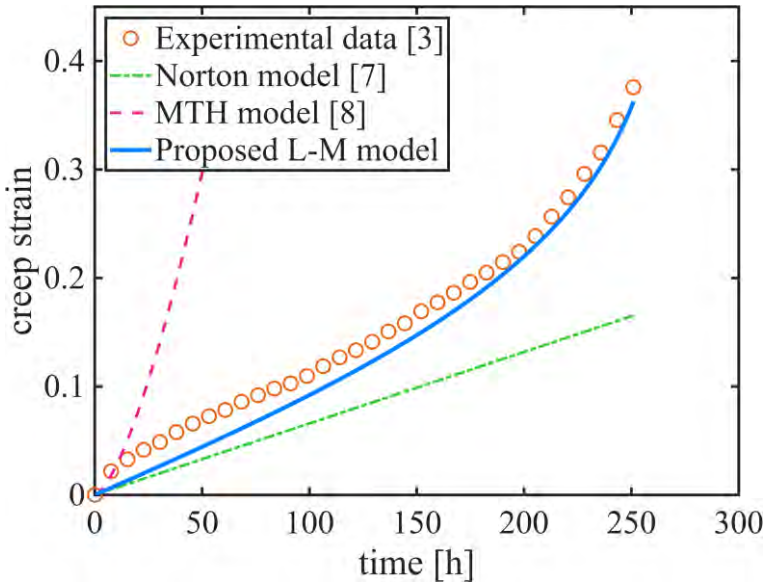
Finite element analysis (FEA) of creep tensile test was conducted in ANSYS to assess the predictive capability of the L-M creep model.



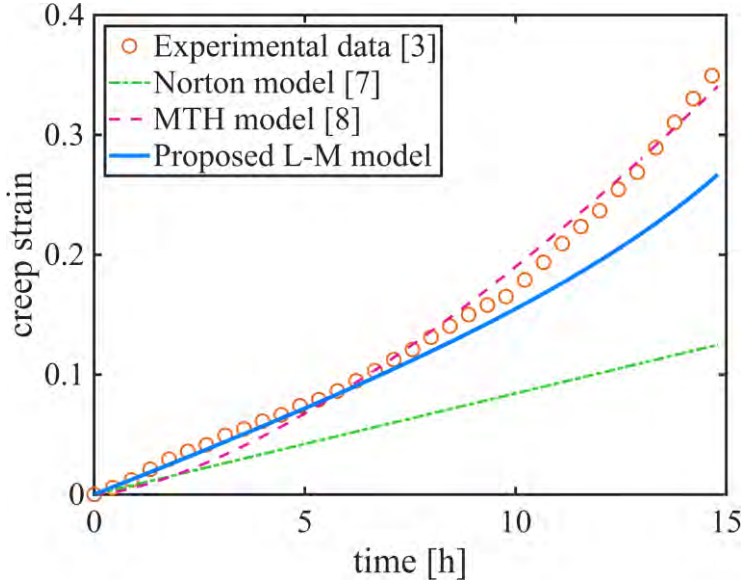
Schematic of Axis-symmetric FE model for simulation



T= 900 K, Stress=69.7 MPa

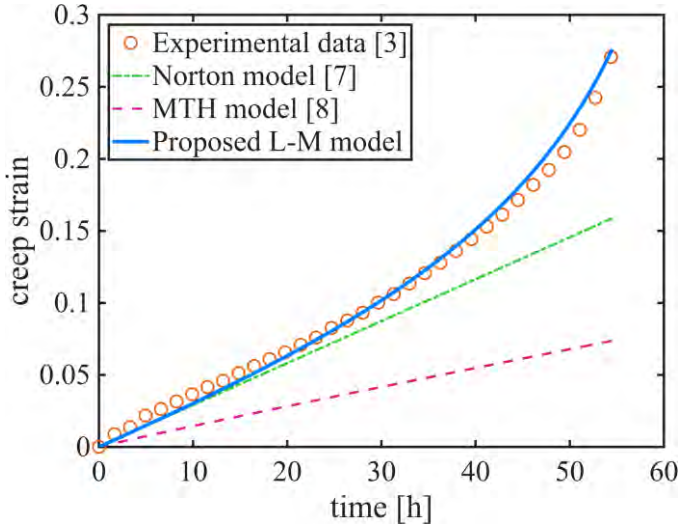


T= 1050 K, Stress=13.9 MPa

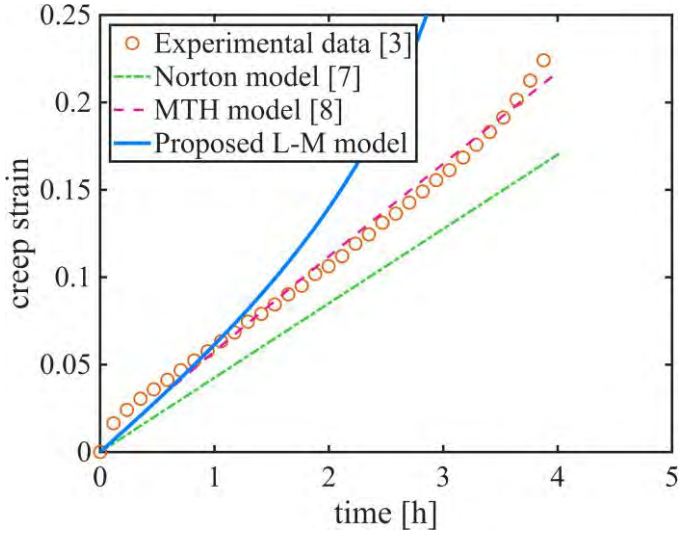


T= 1050 K, Stress=26.3 MPa

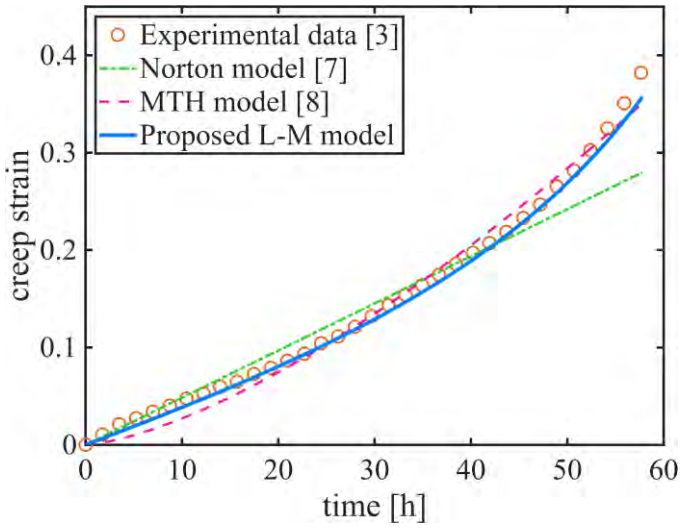
3.2 Simulation vs. INEL Tensile Test Results (900 - 1373 K):



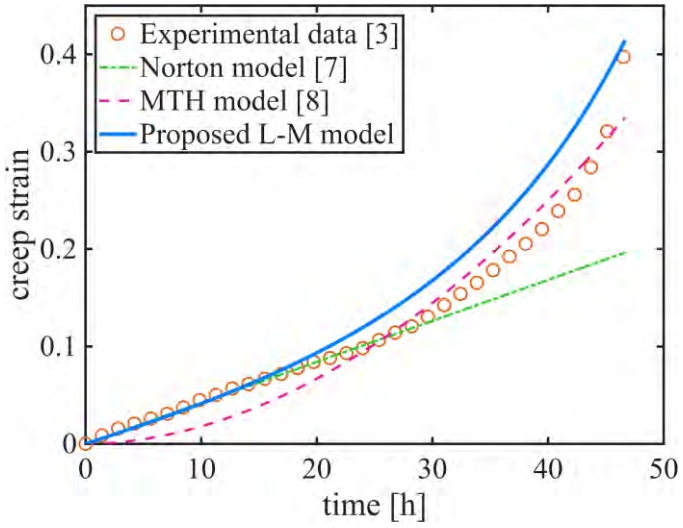
T= 1150 K, Stress=12.5 MPa



T= 1150 K, Stress=26.5 MPa



T= 1250 K, Stress=8 MPa



T= 1373 K, Stress=3.5 MPa

The L-M model demonstrates **higher accuracy** and better performance in **capturing the overall trend** of creep behavior throughout the entire stage.

3.3 Simulation vs. JAEA Tensile Test Results (1250 - 1623 K):

	LM model (Proposed)	K-R model
Scatter factor (strain rate)	1.19	1.13
Scatter factor (failure time)	1.13	1.07
Temp. range	900-1623 K	1250-1623 K
Temp. consistency	Superior	Bad

While maintaining high accuracy (comparable to K-R model), the proposed LM model offers **superior temperature consistency** and a significantly **broader thermal application range** (900–1623 K).

3.4 Model Generalizability and Interpolation Capability

Simulation vs. OECD Tensile Test Results (1000 & 1250 K):

The OECD lower head failure (OLHF) program [9] conducted creep tests at 1000 K & 1250 K on SA533B1 steel supplied by INEL. The interpolation accuracy and generalizability of **L-M model** are validated with this experiment.

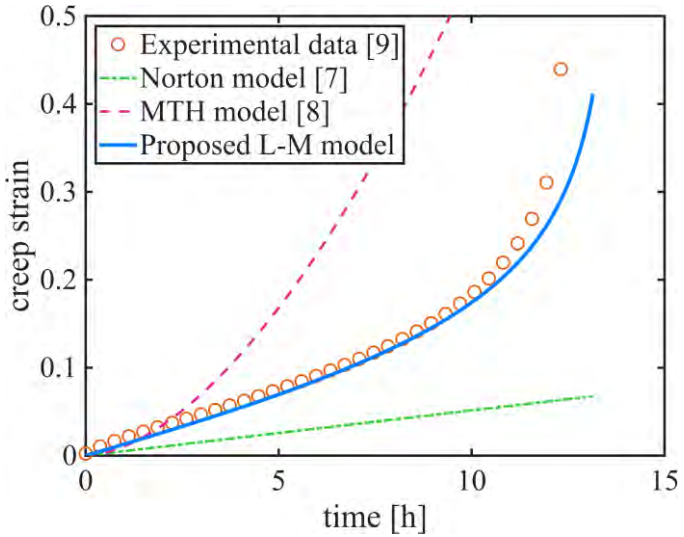
$$C(T) = \begin{cases} exp(-0.037T + 12.45) & T \le 1050\ K \\ exp(0.026T - 53.70) & T > 1050\ K \end{cases}$$

$$n(T) = \begin{cases} 0.022T - 18.7 & T \le 1050\ K \\ -0.0046T + 9.2 & T > 1050\ K \end{cases}$$

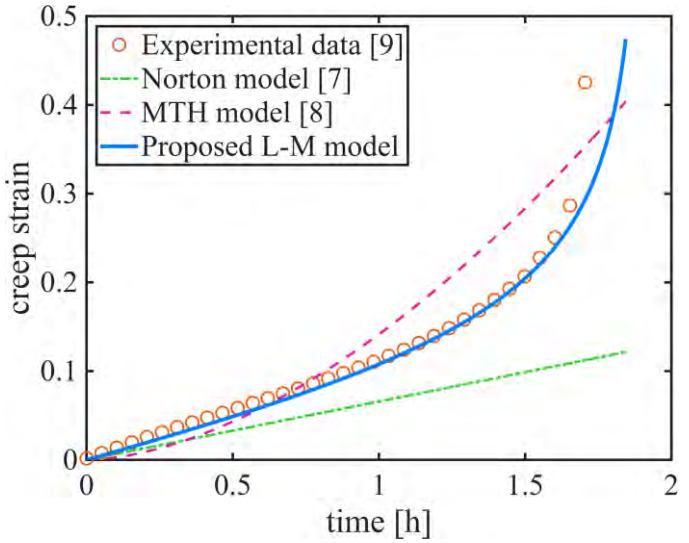
$$D(T) = \begin{cases} exp(-0.030T + 6.86) & T \le 1050\ K \\ exp(0.0023T - 48.25) & T > 1050\ K \end{cases}$$

$$p(T) = \begin{cases} 0.017T - 13.70 & T \le 1050\ K \\ -0.0042T + 8.64 & T > 1050\ K \end{cases}$$

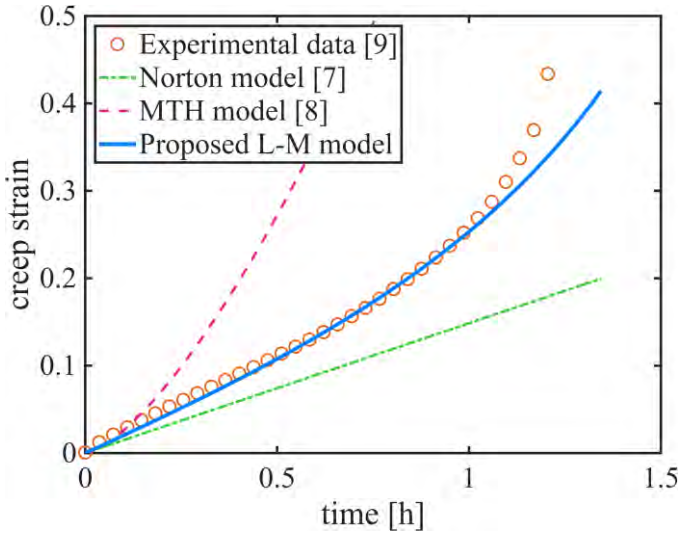
The model constants are calculated by fitted equations!



T= 1000 K, Stress=40.2 MPa



T= 1000 K, Stress=73.6 MPa



T= 1250 K, Stress=23.8 MPa

04 PART FOUR

Conclusion & Outlook

4 Conclusion

Conclusion:

Our research calibrated and validated the Liu-Murakami creep model for SA533B1, the results show that:

- The proposed model successfully captures the critical tertiary creep stage, demonstrating superior accuracy over traditional models.
- The newly developed model successfully extends the applicable temperature range continuously from 900 K to 1623 K.
- The model exhibits exceptional generalizability when applied to independent test data, alongside interpolation capability.

Outlook:

- High-quality experimental data at near-melting regimes (above 1623 K) is highly desirable.
- A multiaxial L-M creep model are needed to better replicate the multi-dimensional stress state of an actual RPV lower head.

ABSTRACT

This study introduces the development of a Corium–Coolant Interaction module within the SAFARI (Safety Analysis Code for Severe Accident Risk Identification) code, which is currently under development in Korea as an analysis tool to support regulating evaluation for Nuclear Power Plants. The module is of particular importance because it represents the initial phase of ex-vessel accidents following reactor pressure vessel failure, and it directly governs the boundary conditions for subsequent phenomena such as molten core–concrete interaction (MCCI) and steam explosions, both of which critically affect containment integrity.

The module has been designed with the primary objective of evaluating the redistribution and coolability of ex-vessel corium during the accident progression with designed Severe Accident Management (SAM). The module has been developed as a C++-based lumped-parameter code, incorporating mechanistic models for melt jet breakup, particle size distribution, and particle/corium lump heat transfer and sedimentation dynamics, as well as a debris-bed/corium formation model. In addition, the module is coupled with the containment thermal-hydraulic model, SAVANAH to account for system-level interactions.

Validation has been carried out against representative experimental programs, such as DAVINCI test [1], DEFOR experiment [2]. The module reproduced key experimental trends across these benchmarks, including jet breakup length, particle size distribution, and debris-bed morphology.

Overall, the module is under active development to establish a comprehensive and predictive framework for mechanistic analysis of Corium–Coolant Interaction during severe accidents. In this work, we present our development status of the module.

1. INTRODUCTION

1.1. Background and Motivation

In the current regulatory environment, severe accident analysis has become a core element of nuclear power plant safety evaluation, with increasing emphasis on quantitative assessment of accident progression beyond reactor vessel failure. In particular, corium relocation into the containment and subsequent ex-vessel phenomena, such as corium–coolant interaction and molten core–concrete interaction, play a critical role in determining containment thermal-hydraulic conditions and associated safety margins under beyond-design-basis scenarios.

Integrated severe accident analysis codes, including MELCOR, MAAP, and ASTEC, have been widely applied for safety and regulatory evaluations. However, these tools are developed and maintained by foreign organizations, and their modeling assumptions and update pathways are not always fully transparent or readily adaptable to domestic regulatory requirements and reactor-specific features.

To address the need for an independent and mechanistic analysis capability for ex-vessel severe accident phenomena, the SAFARI (Safety Analysis code for Severe Accident Risk Identification) program has been initiated in Korea. SAFARI is conceived as a modular integration framework for ex-vessel severe accident analysis, emphasizing physical consistency, traceable model development, and regulatory-oriented application.

1.2. Scope of the Present Work

The SAFARI framework integrates dedicated mechanistic modules for key ex-vessel severe accident phenomena with a simplified containment thermal-hydraulic model, enabling consistent evaluation of corium behavior and containment response following reactor vessel failure. Within this framework, the HIPPO module addresses early-phase ex-vessel corium–coolant interaction.

The present study describes the development and validation of HIPPO, which models melt jet breakup, particle generation and sedimentation, debris bed formation, and thermal interaction with continuous melt. The module provides time-dependent heat and mass source terms to the containment model through a structured coupling strategy. Validation against representative experiments is performed to demonstrate the applicability of HIPPO as a mechanistic, regulatory-oriented tool for evaluating ex-vessel corium redistribution and coolability within the SAFARI framework.

2. OVERVIEW OF THE HIPPO COMPUTATIONAL FRAMEWORK

HIPPO is a mechanistic, lumped-parameter framework developed to represent corium–coolant interaction during the early ex-vessel phase of severe accidents, with emphasis on computational efficiency and consistent coupling with containment thermal-hydraulic behavior.

2.1. Modeling Philosophy and Assumptions

HIPPO is designed to predict ex-vessel corium redistribution and coolability following reactor pressure vessel failure and to provide consistent thermal and mass boundary conditions for debris bed cooling, melt lump evolution, and containment response.

Fragmented corium produced by melt jet breakup is modeled using a particle-based approach based on empirical correlations. Particles are characterized by statistical size distributions and treated as discrete elements during sedimentation to evaluate transport and heat transfer to the coolant.

Sedimented particles either form a debris bed or merge into a continuous melt lump according to temperature-based criteria. Both are represented as lumped control volumes conserving mass and energy, with debris bed geometry governed by slope-angle-controlled redistribution. Thermodynamic equilibrium is assumed between vapor and saturated liquid phases, while subcooled liquid is treated separately. HIPPO is sequentially coupled with a simplified containment thermal-hydraulic model through exchange of boundary conditions and buffered heat and mass source terms to ensure conservation and numerical stability.

2.2. Modular Structure and Coupling Strategy

The framework consists of a corium–coolant interaction block, which evaluates melt fragmentation, particle transport, debris bed formation, and melt lump evolution, and a containment block that determines global thermodynamic conditions using lumped control volumes.

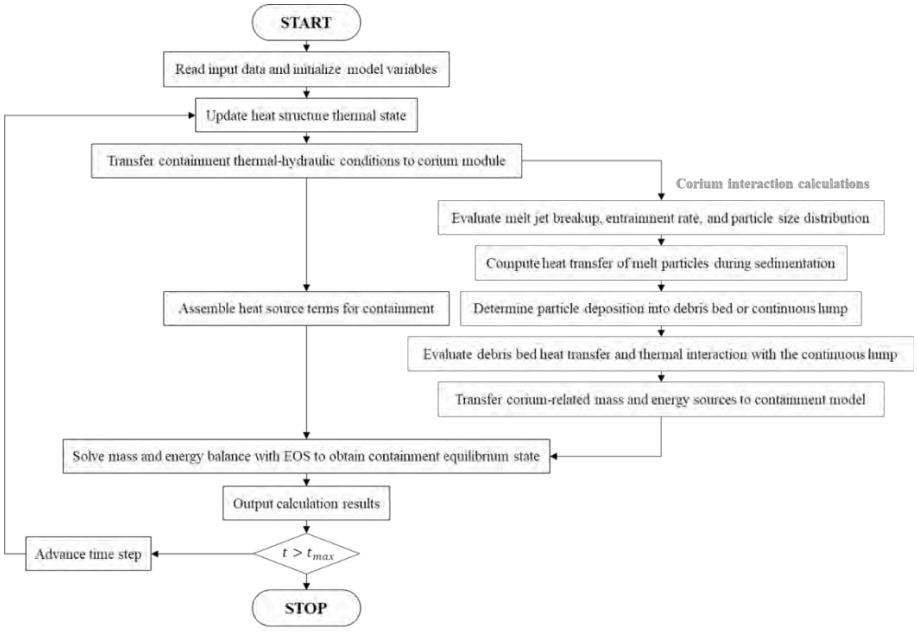

Figure 1. Overall computational flow of the HIPPO Corium–Coolant Interaction module coupled with the simplified containment thermal-hydraulic model(HOTCB)

Coupling between the two blocks is implemented sequentially through exchange of boundary conditions and time-dependent heat and mass source terms. At each global time step, coolant conditions provided by the containment model are supplied to the corium block, which computes local corium phenomena and returns the resulting source terms.

3. CORIUM-COOLANT INTERACTION MODELING (HIPPO MODULE)

This section describes the HIPPO module for mechanistic modeling of melt jet breakup, particle generation and sedimentation, debris bed formation, and thermal interaction with a continuous melt lump during ex-vessel corium–coolant interaction.

3.1. Melt Jet Breakup and Particle Generation

Melt jet breakup defines the initial mass, size, and velocity distributions of dispersed corium particles and thus establishes the primary conditions for downstream transport, deposition, and coolability evaluation.

3.1.1. Jet breakup correlations and entrainment modeling

Melt jet breakup is treated as the primary mechanism governing the redistribution of corium mass between a coherent jet and dispersed particulate phases. To represent the effective extent of jet fragmentation under different hydrodynamic and thermodynamic conditions, selectable empirical correlations are adopted.

The Taylor-type [3] and Saito-type [4] correlations are expressed as

$$\frac{L_{br}}{D_{jet}}\left(\frac{\rho_m}{\rho_l}\right)^{-0.5} = 10\mathrm{C_{br}} \tag{1}$$

$$\frac{L_{br}}{D_{jet}}\left(\frac{\rho_m}{\rho_l}\right)^{-0.5} = 2.1\mathrm{C_{br}}\left(\frac{V_j^2}{gD_{jet}}\right)^{0.5} \tag{2}$$

To explicitly account for the influence of vapor generation and condensation on jet fragmentation behavior, the Jung-type [5] correlation is employed:

$$\frac{L_{br}}{D_{jet}}\left(\frac{\rho_m}{\rho_l}\right)^{-0.5} = 3.3C_{br}\mathrm{Fr}^{0.5\left[1-\frac{1}{2154Q+1}\right]} \tag{3}$$

This formulation introduces thermodynamic coupling between jet breakup behavior and coolant subcooling conditions through the vapor generation intensity parameter.

3.1.2. Particle size distribution formulation

The size distribution of generated particles is represented using a Rosin–Rammler formulation to provide a statistically consistent description of fragmented melt:

$$F = 1 - exp\left[-\left(\frac{D_p}{D_e}\right)^n\right] \tag{4}$$

where F is the cumulative mass fraction of particles with diameter smaller than D_p, D_e is the characteristic distribution diameter, and n is the distribution constant, taken as $n = 1.5$.

The characteristic diameter D_e is related to the mass median diameter (MMD) through

$$D_e = \frac{MMD}{(log2)^{(1/n)}} \tag{5}$$

The mass median diameter is evaluated using an empirical correlation expressed in terms of the Bond number based on the particle diameter,

$$\mathrm{Bo}_p = \frac{g\rho_m D_{MM}^2}{\sigma_m} \tag{6}$$

which is related to coolant subcooling and density ratio by

$$Bo_p^{1/2} = C_{dmm} F_{sb} \left(\frac{\rho_v}{\rho_l}\right)^{1/3} \left(\frac{\rho_l}{\rho_m}\right)^{2/3} \tag{7}$$

with

$$F_{sb} = 25\{2.2 - \exp(-13N_{sb})\}, \qquad N_{sb} = \frac{c_{pl}\Delta T_{sub}}{\Delta h_{fg}} \tag{8}$$

For particles deposited into the debris bed, a truncated Rosin–Rammler distribution [6] is applied to exclude unrealistically small particles while preserving the statistical characteristics of the original distribution:

$$F = \begin{cases} 0, & D_P < D_{min} \\ 1 - exp\left[-\left(\frac{D_p}{D_e}\right)^n + -\left(\frac{D_{min}}{D_e}\right)^n\right], & D_p \geq D_{min} \end{cases} \tag{9}$$

Particle diameters are sampled under an ergodicity assumption and grouped into representative particle elements with identical thermomechanical properties. Initial particle velocities are derived from the jet velocity with stochastic perturbations to represent turbulence-induced dispersion.

3.2. Particle Sedimentation and Heat Transfer

Heat transfer from sedimenting melt particles to the surrounding coolant is evaluated by coupling implicit particle energy conservation with regime-dependent surface heat flux correlations. This formulation ensures stable evaluation of particle cooling across boiling regimes while avoiding numerical stiffness associated with explicit heat transfer treatment.

The internal energy change of a representative particle over a time step is expressed as

$$\Delta Q = -m_p c_{pm}(T_{av}^n - T_{av}^{n-1}) \tag{10}$$

The corresponding heat transferred to the coolant during the same time step is given by

$$\Delta Q = \Delta t\, A_p h_{eff}(T_{av}^n - T_l) \tag{11}$$

Combining the two relations yields the coupled implicit energy balance

$$-m_p c_{pm}(T_{av}^n - T_{av}^{n-1}) = \Delta t\, A_p h_{eff}(T_{av}^n - T_l) \tag{12}$$

The effective heat transfer coefficient is defined in terms of the regime-dependent surface heat flux as

$$h_{eff} = C_{htc} \left|\frac{q''}{T_{av} - T_l}\right| \tag{13}$$

To account for internal temperature gradients within particles, a simplified thermal boundary layer model is adopted. The evolution of the thermal boundary layer thickness is evaluated from

$$\delta\left(1-\frac{3\delta}{4R}+\frac{1}{5}\left(\frac{\delta}{R}\right)^2\right)\frac{d\delta}{dt}=3k \tag{14}$$

with the initial value approximated by

$$\delta_0=\sqrt{6k\Delta t} \tag{15}$$

The surface temperature is related to the average particle temperature through

$$T_{av}-T_{sf}=\frac{q^{''}\delta}{2\lambda} \tag{16}$$

For a computational node containing identical particles, the total heat released to the coolant is evaluated as

$$\Delta Q_{node}=N_{node}\Delta Q \tag{17}$$

After heat transfer is evaluated, the particle internal energy is updated including decay heat generation:

$$e_{int}^{n}=e_{int}^{n-1}-\frac{\Delta Q}{m_p}+q_{decay}\Delta t \tag{18}$$

Through this formulation, particle cooling during sedimentation is evaluated by consistently coupling implicit energy conservation, regime-dependent surface heat transfer, and internal temperature correction. The resulting heat release histories are subsequently supplied as source terms to debris bed formation and containment thermal-hydraulic coupling calculations.

3.3. Debris Bed and Melt Lump Evolution

This section describes the formation and thermal evolution of the debris bed and its interaction with the underlying continuous melt lump. The modeling objective is to provide a conservative and physically consistent evaluation of long-term corium coolability while preserving mass and energy during phase transition between particulate debris and coherent melt.

The debris bed and continuous melt lump are treated as coupled but distinct control volumes. This separation enables explicit representation of porous-bed cooling limitations governed by two-phase flow interactions, as well as enhanced vapor generation driven by heat input from the continuous melt.

3.3.1. Deposition criteria and debris bed formation

Sedimented particles are deposited into debris bed nodes or merged into a continuous melt lump according to temperature-based criteria:

$$\begin{aligned} &T_{av}>T_{mel}+0.5f_{tcr}\left(T_{liq}-T_{sol}\right), \qquad or\\ &T_{sf}>T_{sol}+f_{tcr}\left(T_{liq}-T_{sol}\right) \end{aligned} \tag{19}$$

This criterion is applied consistently to newly deposited particles and to debris bed particles reheated by decay heat, allowing reversible transition between particulate and coherent melt phases while preserving energy conservation.

The macroscopic geometry of the debris bed is governed by vapor-induced lateral particle transport. Under strong vapor generation, lateral dispersion becomes significant, resulting in a conical debris bed characterized by a side slope angle. Based on an energy flux interaction model, the slope angle is evaluated as

$$\tan(\theta_s) = 4.127\left(\frac{\rho_g h_{lg}}{(\rho_l-\rho_g)^2}\right)\left(\frac{\dot{m}^2}{q_d''' H_s^2}\right)\left(\frac{u_p^4}{\alpha u_b D_{pc}^4}\right) \tag{20}$$

A critical slope angle is imposed to represent the limiting repose angle of wet granular materials. When the calculated slope exceeds this limit, lateral redistribution of upper debris bed nodes is applied to maintain geometric stability.

3.3.2. Debris bed heat transfer and thermal interaction with continuous melt lump

Heat removal from the debris bed is governed by two competing mechanisms: (i) local particle-scale heat transfer evaluated from microscopic heat transfer correlations, and (ii) global limitation imposed by counter-current flow limitation due to vapor generation within the porous debris bed.

For each debris bed node, local heat transfer is evaluated using the same particle heat transfer models applied during sedimentation, with attenuation to account for particle crowding effects. Assuming a fully developed internal thermal boundary layer, the relation between average and surface temperatures is expressed as

$$T_{av} - T_{sf} = \frac{q''R}{5\lambda} \tag{21}$$

In parallel, the maximum allowable heat removal rate is constrained by the dryout heat flux, which originates from counter-current flow limitation between upward vapor flow and downward liquid penetration. The actual debris bed heat removal rate is determined as

$$Q_{dbr} = \min(Q_{htr}, Q_{lim}) \tag{22}$$

where the limitation term is defined as

$$Q_{lim} = F_{dhf} Q_{dhf} - Q_{btm} \tag{23}$$

The influence of the continuous melt lump beneath the debris bed is explicitly accounted for through the heat input term

$$Q_{btm} = \min\left(A_b F_{htmp} \lambda_m \frac{T_{lmp} - T_{sat}}{H_{lmp}/2}, F_{qbdhf} F_{dhf} Q_{dhf}\right) \tag{24}$$

The debris bed energy balance per unit mass is expressed as

$$(-\dot{q} + \dot{q}_{dc})\Delta t = e(T_{av}^{(n)}) - e(T_{av}) \tag{25}$$

which can be rewritten in terms of temperature difference as

$$\dot{q} = R_{eff}(T_{av}^{(n)} - T_{sat}) \tag{26}$$

When the debris bed temperature reaches the melting criterion, partial re-melting is allowed. The re-melted mass is evaluated from

$$m[(-\dot{q} + \dot{q}_{dc})\Delta t - e(T_{cr}) + e(T_{av})] = m_{rm}\left[e(T_{liq}) - e(T_{cr})\right] \tag{27}$$

Through this coupled formulation, debris bed heat transfer is constrained by both microscopic particle-scale heat transfer and macroscopic counter-current flow limitation. Interaction with the underlying continuous melt lump further reduces the effective cooling capacity, providing a physically consistent and conservative evaluation of debris bed coolability during ex-vessel corium–coolant interaction.

4. SIMPLIFIED CONTAINMENT THERMAL-HYDRAULIC MODEL

This section briefly describes the simplified containment thermal-hydraulic model used to couple with the HIPPO corium–coolant interaction module. The model provides the thermodynamic boundary conditions for HIPPO and receives time-dependent heat and mass source terms generated by corium cooling processes.

The containment is represented using a lumped control-volume formulation under vapor–liquid thermodynamic equilibrium. Corium components, including melt particles, debris beds, and continuous melt lumps, are treated as internal heat and mass sources. Mass and energy balance equations are solved using an implicit equilibrium scheme to ensure numerical stability under strong thermal coupling.

4.1. Containment Modeling Approach

The containment atmosphere is modeled as a well-mixed control volume composed of vapor, liquid, and non-condensable gas components. Vapor and saturated liquid are assumed to be in thermodynamic equilibrium, while subcooled liquid is treated separately. Heat structures are represented as lumped heat-capacity bodies exchanging energy with the fluid.

This simplified formulation provides a computationally efficient and physically consistent basis for coupling with the HIPPO module without resolving detailed spatial thermal-hydraulic fields.

4.2. Governing mass and energy balance equations

The containment control volume conserves total mass and internal energy while accounting for inflow/outflow, phase change, and volumetric heat sources. The governing equations are expressed as

$$\frac{dM_k}{dt} = \sum(\dot{m}_{k,in}) - \sum(\dot{m}_{k,out}) + \dot{m}_{k,ph} \tag{28}$$

$$\frac{dE}{dt} = \sum(\dot{m}_{in}h_{in}) - \sum(\dot{m}_{out}h_{out}) + Q_{src} - P\frac{dV}{dt} \tag{29}$$

where Q_{src} includes decay heat and thermal energy transferred from corium components evaluated by HIPPO. The total pressure is evaluated as the sum of vapor and non-condensable gas partial pressures.

4.3. Coupling with the HIPPO Module

The containment model is sequentially coupled with HIPPO through the exchange of boundary conditions and source terms at each global time step. The containment model provides the thermodynamic state of the coolant to HIPPO, while HIPPO returns the heat and mass sources generated by melt particles, debris beds, and the continuous melt lump.

From the containment model to HIPPO, the transferred state variables are defined as

$$\mathbf{X}_{cav} = \{p_{tot}, T_l, T_s, \rho_l, c_{p,l}, \beta_l, h_l, V_l, \dot{m}_{dil}, e_l, e_v, p_v, \rho_v, m_v\} \tag{30}$$

The total heat source transferred from HIPPO is expressed as

$$\dot{Q}_{cor}(t) = \dot{Q}_{par}(t) + \dot{Q}_{dbr}(t) + \dot{Q}_{lmp}(t) \tag{31}$$

To account for residence-time effects associated with particle tracking and sedimentation, HIPPO employs a time-dependent heat buffer. The buffered heat source is supplied to the containment model as an external volumetric heat source. Mass exchange due to evaporation and condensation induced by corium cooling is also transferred as a source term.

The coupled HIPPO–containment system is advanced in time using an explicit sequential procedure combined with an implicit equilibrium solver in the containment model, ensuring numerical stability and global mass and energy conservation.

5. VERIFICATION AND VALIDATION OVERVIEW

To evaluate the predictive capability of the HIPPO module for corium–coolant interaction phenomena, validation was performed against representative melt jet breakup and debris bed formation experiments. The validation focuses on key integral quantities governing ex-vessel accident progression, including jet breakup length, particle size distribution, and debris bed geometry.

Two experimental programs were selected: the DAVINCI experiment, providing quantitative data on debris bed formation under flooded conditions, and the DEFOR experiment, offering detailed measurements of melt jet breakup and fragmentation behavior in a water pool. Validation is conducted by comparing numerical predictions with experimental results, emphasizing dominant trends and integral characteristics rather than local small-scale fluctuations.

5.1. Validation against DAVINCI Experiment

The DAVINCI experiment was used to validate the debris bed formation model implemented in HIPPO. The experiment provides axisymmetric debris bed profiles formed by particle sedimentation in a quiescent water pool, allowing direct comparison of deposited layer geometry.

Figure 2 compares the experimentally measured debris bed profiles with the corresponding numerical predictions. Both results show similar overall growth behavior, with a maximum height near the center and a gradual decrease toward the outer radius, indicating that HIPPO reproduces the conical debris bed geometry and its temporal evolution.

The numerical results exhibit a slightly wider radial spread at later times, leading to a modest overprediction of the bed radius. This difference is attributed to particle representation, as cylindrical particles were used in the experiment whereas spherical particles with a representative mean diameter are assumed in HIPPO. Despite this discrepancy, the validation demonstrates that HIPPO captures the principal features of debris bed formation under quiescent pool conditions.

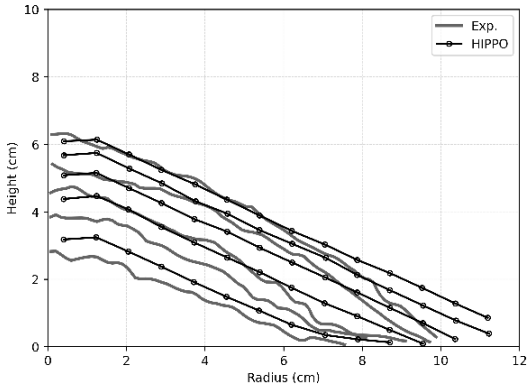

Figure 2. Time evolution of debris bed height profiles: DAVINCI experiment vs. HIPPO predictions.

5.2. Validation against DEFOR Experiment

The HIPPO module was further validated against the DEFOR experiment, which provides detailed measurements of melt jet breakup behavior and resulting particle characteristics in a water pool. The validation addresses three key aspects: jet breakup length, particle size distribution, and debris bed formation.

5.2.1. Jet breakup length

Figure 3 compares the experimentally measured melt jet breakup length with the numerical prediction obtained by the HIPPO module. In the DEFOR experiment, the breakup length is evaluated from the axial variation of the melt jet front-edge velocity, showing a distinct transition from coherent jet behavior in air to rapid fragmentation after entering the water pool.

In the numerical analysis, the breakup length is extracted from the time evolution of the under-water melt jet length predicted by HIPPO. A representative breakup length is defined from the quasi-steady phase prior to the onset of rapid jet collapse. The predicted breakup length of 0.36951m shows close agreement with the experimental value of 0.37104 m, with a relative difference of approximately 0.4%.

The numerical results reproduce the experimentally observed breakup behavior, including the abrupt loss of jet coherence upon water entry. The close agreement in the breakup length indicates that the implemented jet breakup correlations and entrainment modeling in HIPPO provide a physically consistent representation of melt jet fragmentation under DEFOR experimental conditions.

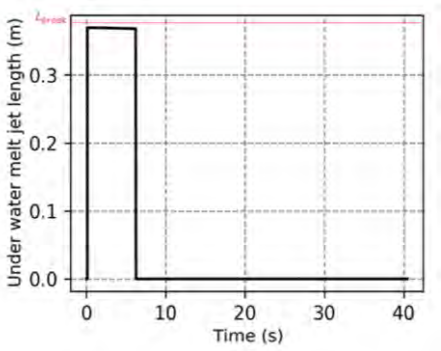

Figure 3. Time evolution of under-water melt jet length and the resulting breakup length in the DEFOR M-12 case (HIPPO prediction).

5.2.2. Particle size distribution

The particle size distribution obtained from the DEFOR experiment was compared with numerical predictions. The numerical model reproduces the overall shape of the particle size distribution, including the dominant particle size range and the monotonic increase of cumulative mass fraction with particle diameter.

Both experimental and numerical results indicate that most of the fragmented mass is concentrated in the millimeter-scale particle range. The agreement in cumulative mass fraction demonstrates that the implemented breakup and particle generation models provide a realistic representation of fragmentation behavior. Discrepancies observed in the distribution tails, particularly for the smallest particle classes, are attributed to experimental resolution limits and the use of representative particle sizes in the numerical model.

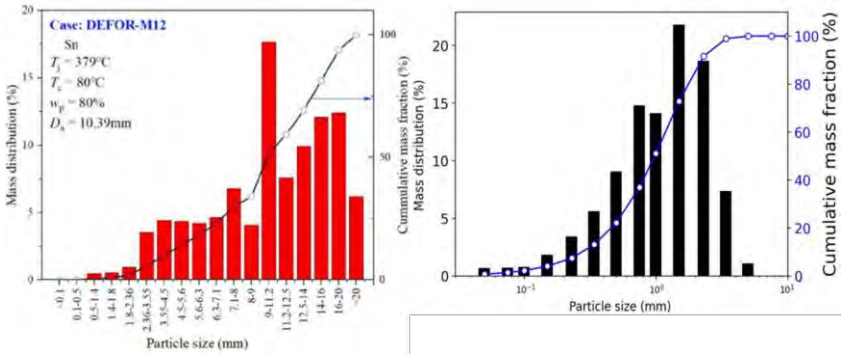

Figure 4. Comparison of particle size distributions between the DEFOR M-12 experiment and HIPPO prediction.

5.2.3. Debris bed formation

The final debris bed configuration in the DEFOR experiment was examined qualitatively. Figure 5 compares the experimentally observed debris bed with the numerical prediction. The experimental debris bed exhibits a mound-shaped structure with a maximum height near the jet impingement region and a gradual decrease toward the outer radius.

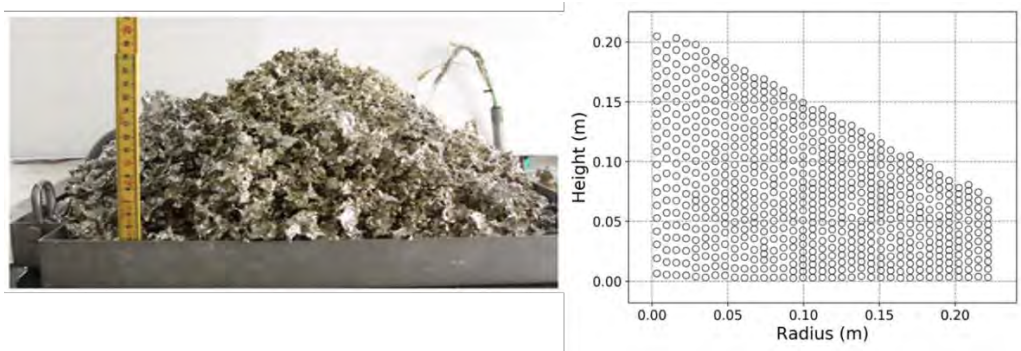

Figure 5. Comparison of debris bed configuration in the DEFOR M-12 experiment and HIPPO prediction

The numerical result reproduces the overall debris bed morphology, including the inclined surface and radial spreading of deposited particles. Although local irregularities observed in the experiment are not

fully resolved due to model discretization, the predicted debris bed geometry is consistent with the global experimental pattern.

6. CONCLUSIONS

This paper presented the development of the HIPPO corium–coolant interaction module coupled with a simplified containment thermal-hydraulic model. The HIPPO framework provides a mechanistic representation of melt jet breakup, particle generation and sedimentation, debris bed formation, and thermal interaction with a continuous melt lump within a unified computational structure.

The coupling strategy employs a sequential exchange of boundary conditions and time-dependent heat and mass source terms, enabling consistent integration of local corium cooling processes with global containment thermal-hydraulic behavior. A time-dependent heat buffering scheme was adopted to ensure numerical stability and conservation of mass and energy.

Validation was conducted against the DAVINCI and DEFOR experiments, focusing on debris bed formation, jet breakup length, and particle size distribution. The results showed that the HIPPO module reproduces the dominant experimental trends and integral characteristics of melt fragmentation and deposition under flooded conditions.

Overall, the developed HIPPO framework offers a physically consistent and computationally efficient tool for analyzing early ex-vessel corium–coolant interaction and its coupling with containment thermal-hydraulic response. Further work will extend the validation database and improve model fidelity for broader severe accident applications.

Development of the SAFARI Code for Comprehensive Severe Accident Analysis

Korea's Regulatory-Oriented Ex-vessel Severe Accident Analysis Framework
SAFARI and the HIPPO CCI Module

Minchan Kwon, Eung Soo Kim, Hyun Sun Park*

Seoul National University

PRESENTATION OUTLINE

Roadmap for a 20-minute talk

1. Why SAFARI?
Domestic, traceable severe accident analysis capability for regulatory-oriented evaluation

2. SAFARI Modules
HIPPO within a broader module ecosystem: MAMBA, SCORPION, containment T-H

3. HIPPO Framework
Jet breakup → particles → debris bed/lump → containment source terms

4. Brief V&V Status
Only a compact status snapshot; detailed model-by-model V&V is not the focus today

5. Publication Roadmap
Correlation-level V&V will be expanded as a continuing conference and journal series

6. SAFARI Coupling
Detailed MAMBA–HIPPO and HIPPO–SCORPION pathways, with future SAVANNAH linkage

AUDIENCE-DRIVEN FRAMING

What is strengthened in this presentation

Overview first

Position HIPPO as the CCI/FCI entry module inside SAFARI, rather than as a standalone validation talk.

V&V scoped

Use DAVINCI, DEFOR, and FARO L33 only as compact status anchors in this overview presentation.

Series plan

Keep detailed V&V for each modeling correlation as a continuing conference and journal publication track.

Ecosystem answer

Answer the expected question: how HIPPO connects to SCORPION, MAMBA, and SAVANNAH within SAFARI.

Response strategy

Use HIPPO to explain SAFARI's modular severe-accident ecosystem, while reserving detailed V&V for follow-up papers.

Ex-vessel severe accident progression

Core melt
Relocation to lower plenum

→

RPV failure
Melt discharge into cavity

→

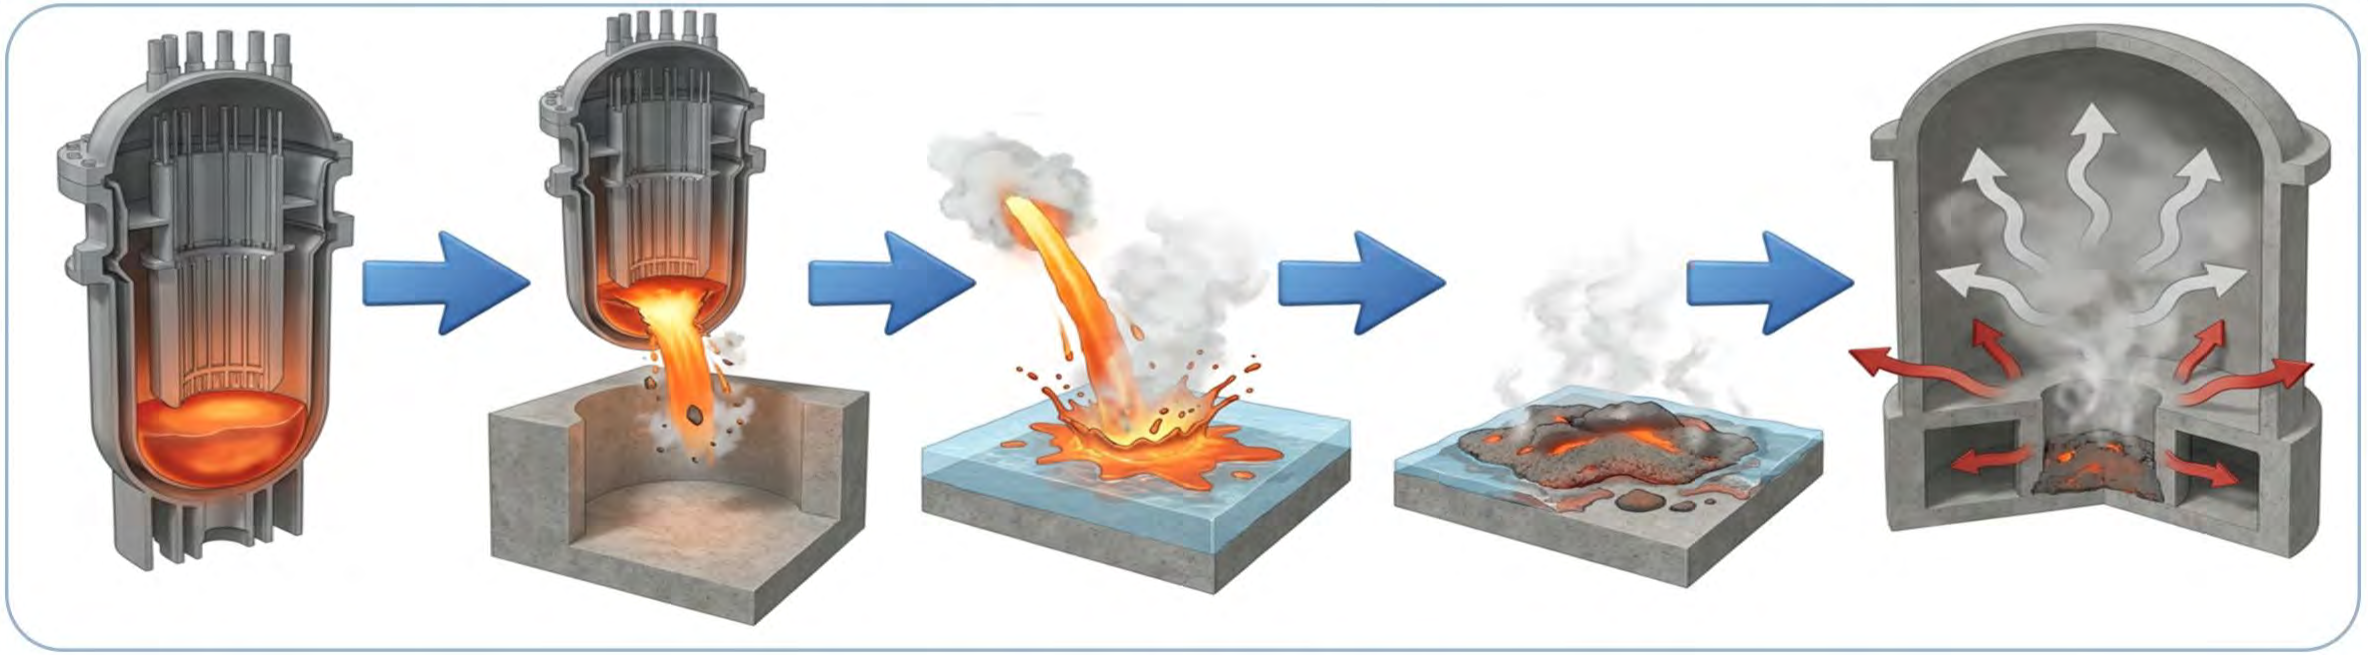
Ex-vessel CCI
Jet breakup and fragmentation

→

Debris / lump
Deposition, cooling, remelting

→

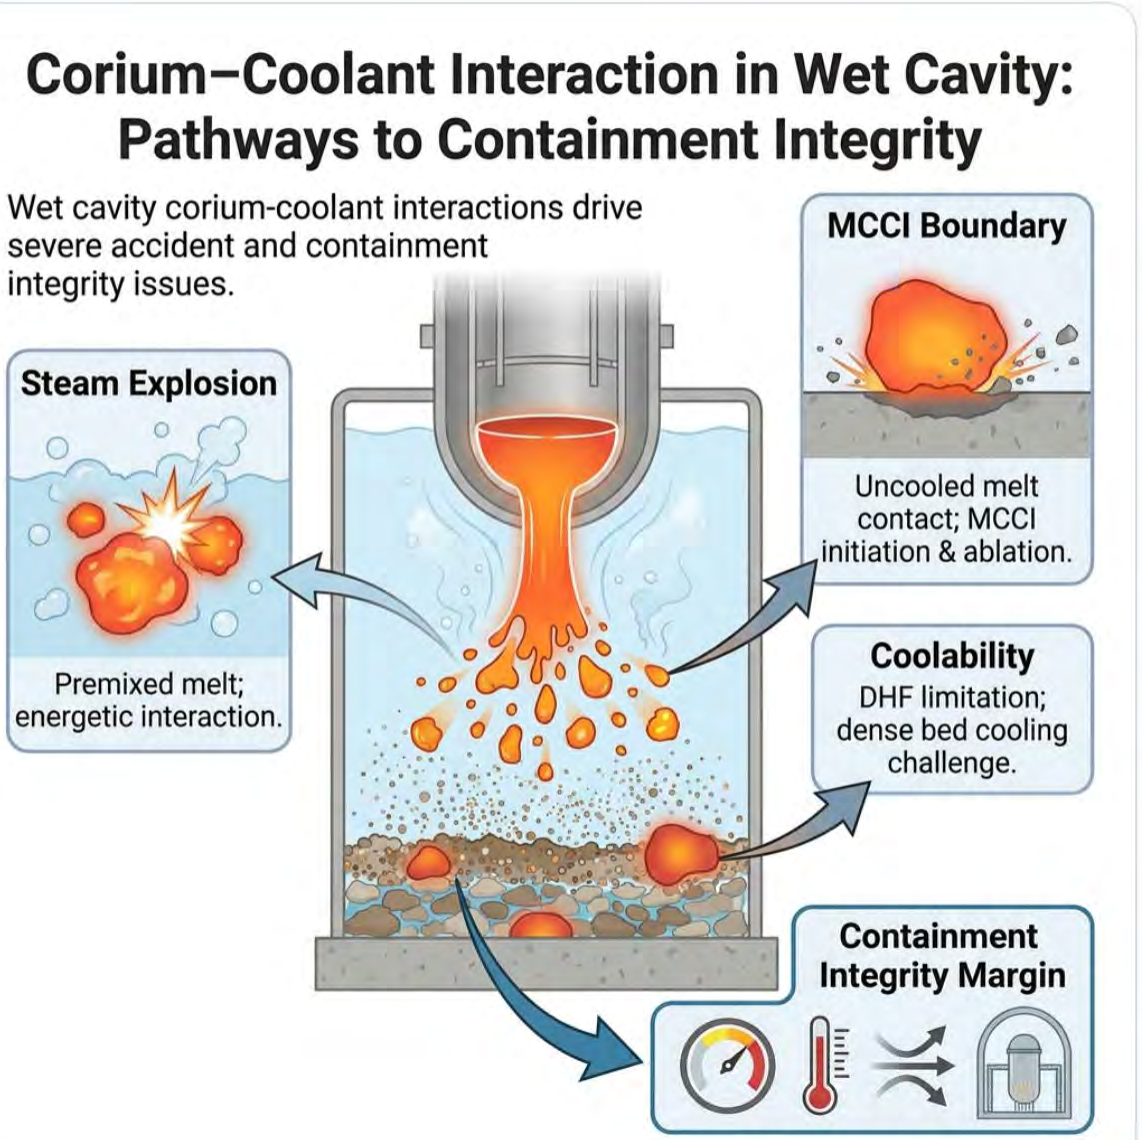
Containment response
Heat and mass source terms



Analysis focus
Early ex-vessel phase immediately after reactor pressure vessel failure

Modeling need
Traceable domestic severe accident analysis for regulatory-oriented evaluation

Why corium–coolant interaction matters



CCI
Melt jet breakup
particle generation
debris/lump formation

↓

Steam explosion
Premixed melt mass and energetic interaction potential

MCCI boundary
Amount and morphology of corium reaching concrete

Coolability
Debris bed DHF limitation and residual melt lump

↓

Containment integrity margin

Pressure, temperature, heat/mass source terms, and long-term cooling state

Reliable CCI analysis is required to quantify ex-vessel accident progression and preserve containment integrity margin.

Objective: introduce SAFARI through the HIPPO module

Introduce SAFARI
Korea's regulatory-oriented framework for integrated ex-vessel severe accident analysis

Demonstrate HIPPO
Representative CCI module producing corium redistribution and heat/mass source terms

Show integration path
Coupled analysis with MAMBA and SCORPION for downstream severe-accident phenomena

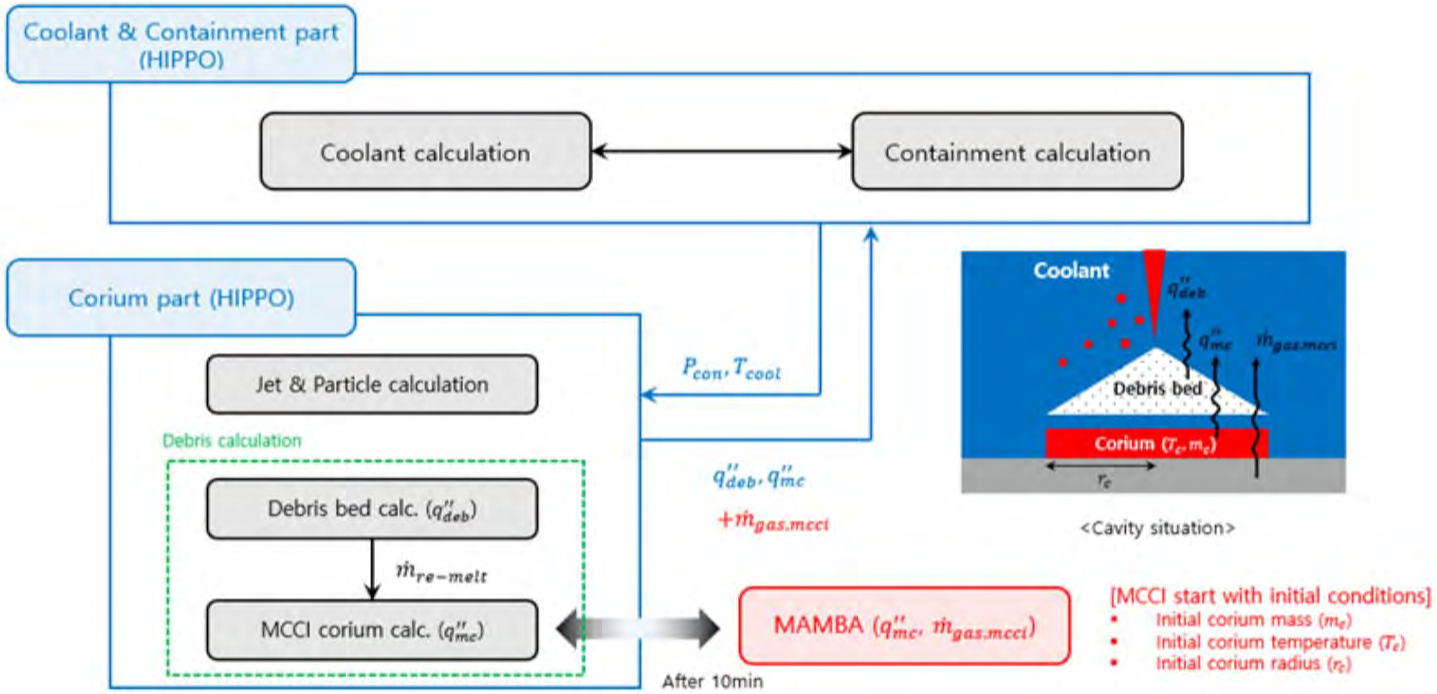
Not only
A detailed model-by-model explanation of HIPPO

→

Main message
HIPPO is the entry point for presenting SAFARI's integrated ex-vessel analysis capability.

HIPPO is presented not as an isolated code, but as a gateway module for SAFARI's integrated ex-vessel severe accident analysis capability.

SAFARI: beyond a single CCI module



SAFARI should be introduced as a Korean integrated ex-vessel severe accident framework — not as a single HIPPO presentation.

Integration message

HIPPO provides the early ex-vessel CCI state that can feed downstream phenomenon modules in SAFARI.

CCI / FCI

HIPPO

Jet breakup, particles, debris bed, melt lump, and containment source terms

MCCI

MAMBA

Melt–concrete interaction and concrete ablation after corium relocation

STEAM EXPLOSION

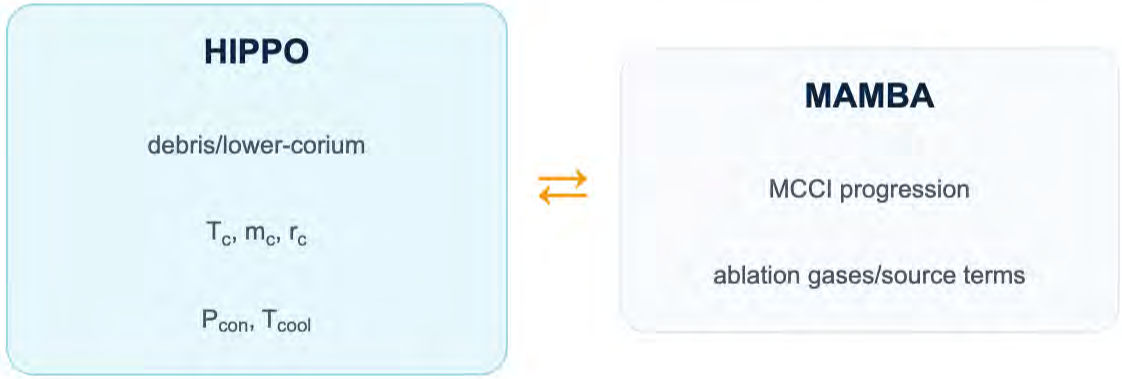
SCORPION

Steam-explosion evaluation using premixing-related information

Coupled analysis pathways enabled by HIPPO

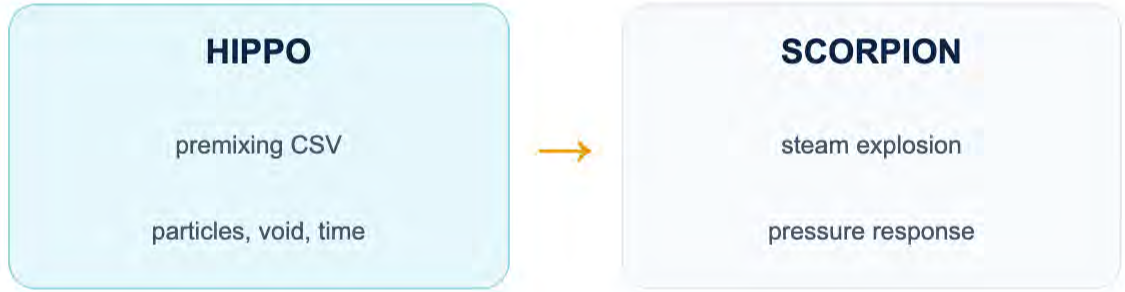
MAMBA–HIPPO two-way pathway

HIPPO supplies the FCI-informed cavity state, while MAMBA returns MCCI source terms through containment/coolant coupling.



HIPPO–SCORPION pathway

HIPPO premixing time series is transferred through a standardized CSV interface to steam-explosion analysis.



Strategic role of HIPPO

HIPPO couples early ex-vessel CCI with MCCI in two directions, and transfers premixing state to SCORPION for steam-explosion load.

Development lineage: COOLAP-II to HIPPO

COOLAP-II heritage

Simplified melt jet breakup, particle tracking, debris bed/lump cooling, DHF limitation, and HOTCB coupling.

melt jet | particles | DHF | HOTCB

HIPPO present module

SAFARI-oriented CCI module extended with additional breakup, particle distribution, and bed morphology models.

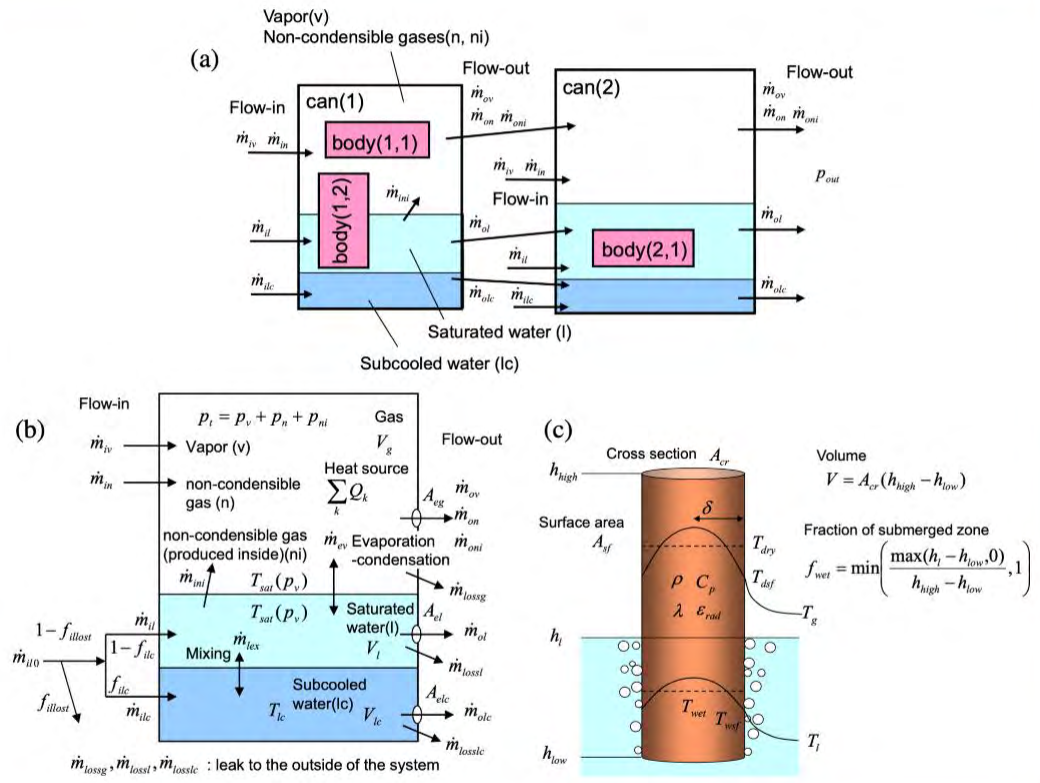
Jung-type breakup | Truncated R-R PSD | Conical bed

Inherited
Jet profile, sedimentation, heat transfer

Extended
Jung breakup, truncated PSD, conical bed

Separated
Heritage review ≠ HIPPO validation

Containment coupling: HOTCB now, SAVANNAH next



Current simplified coupling

HIPPO contains a simplified containment/coolant part based on HOTCB to exchange boundary conditions and heat/mass sources.

Can model

Water / steam / non-condensable gas equilibrium

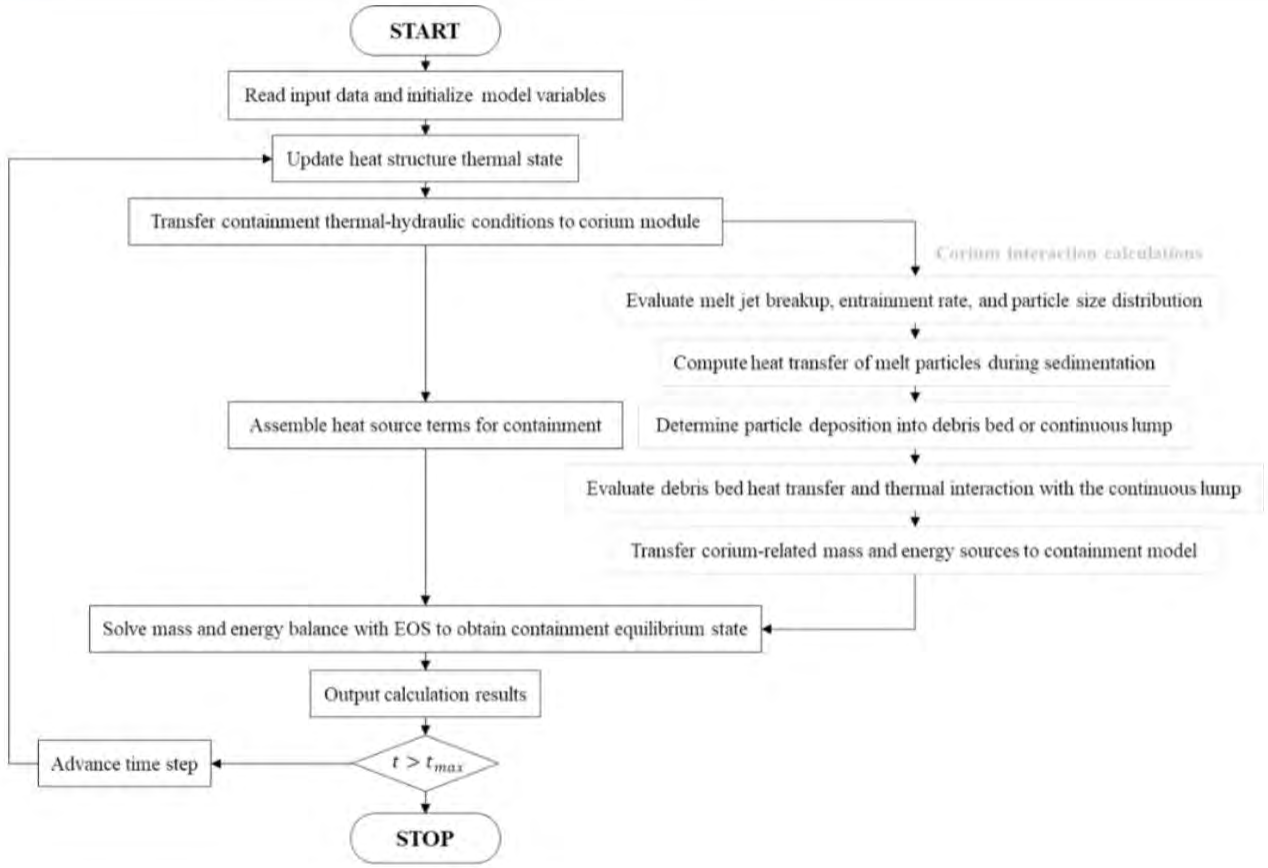
Body model

Solid heat-capacity structures

Future SAFARI integration

SAVANNAH is expected to replace or extend HOTCB for more detailed containment thermal-hydraulic response.

Overall HIPPO computational flow



1. Containment state

Coolant pressure, temperature, liquid/vapor properties

2. Corium module

Jet breakup, particles, debris bed, melt lump

3. Mass and energy feedback

Mass and energy returned to the containment model

Closure map for reproducibility

Model element	Closure / correlation used	Constants or criteria to state	Status / V&V use
Jet breakup	Taylor, Saito, and Jung-type breakup models with vapor-generation intensity term	C_{br}; Fr; ρ_m/ρ_l; q''_{gen}/q''_{cond}	Brief DEFOR status anchor; detailed breakup V&V reserved for follow-up paper
Particle PSD	Rosin-Rammler distribution; MMD from Bond-number basis; truncated R-R for deposited debris	n = 1.5; D_{MM}; D_{min}; truncation/stretching rule	PSD publication thread: $D_{10}/D_{50}/D_{90}$ and fit-error metrics
Particle heat flux	Forced convection, nucleate boiling, transition boiling, film boiling, CHF, MFB, radiation	Regime transition temperatures; q" map; implicit particle energy balance	Model-basis transparency; detailed heat-transfer validation deferred
Debris bed	Particle-scale heat transfer with crowding attenuation; 1D top-flooding DHF / CCFL limit	$C_{htc,bed} \approx 0.1$; $F_{dhf} = 1.0$ default; Q_{dhf}	Brief DAVINCI morphology anchor; detailed profile metrics in later V&V work
Bed-lump interaction	Bottom heat input from continuous melt lump reduces allowable debris-bed heat removal	$Q_{lim} = F_{dhf}Q_{dhf} - Q_{btm}$; $F_{qbdhf} = 0.5$ default	Coolability publication thread: DHF margin, remelting, and heat removal
Containment coupling	HOTCB-style can/body mass-energy balance with source-term heat buffer	Sequential coupling; vapor-saturated liquid equilibrium; source conservation check	Source-term accounting check and future SAVANNAH/M1 coupling path

Core equations inherited from COOLAP-II

Taylor type breakup

$L_{br}/D'_j = C_{br} \cdot 10 \cdot (\rho_m/\rho_l)^{1/2}$

Saito type breakup

$L_{br}/D'_j = C_{br} \cdot 2.1 \cdot (\rho_m/\rho_l)^{1/2} \cdot (V'^2_j/gD'_j)^{1/2}$

Jet entrainment source

$m''_e = \rho_m D'_j V'_j/(2L_{br})$, then $m'_e(\zeta)$ is distributed along the shrinking jet profile.

Rosin-Rammler PSD

$F(D_p) = 1 - \exp[-\ln 2(D_p/D_{MM})^n]$, with $n = 1.5$

MMD correlation basis

$Bo_p^{1/2} = C_{dmm}F_{sb}(\rho_v/\rho_l)^{1/3}(\rho_l/\rho_m)^{2/3}$

Particle heat balance

$-Q_{ex} = -m_p c_{pm}(T_{av}^{n+1}-T_{av}^{n}) = \Delta t A_p h_{eff}(T_{av}^{n+1}-T_l)$

HIPPO extensions: equations to state explicitly

Jung-type breakup extension

$L_{br}/D'_j = f(Fr, \rho_m/\rho_l, Q)$, where $Q = q''_{gen}/q''_{cond}$.

Truncated Rosin-Rammler PSD

$F_{tr}(D) = [F(D)-F(D_{min})]/[1-F(D_{min})]$ for $D \geq D_{min}$

Surface-temperature correction in bed

$T_{av}-T_{sf} = q''R/(5\lambda_m)$, or $T_{sf} = (T_{av} + CT_{sat})/(1+C)$

Conical debris-bed morphology

$R_{75\%} = 0.414\Phi^{1/3}$, $\Phi = [(\rho_l-\rho_g)^2(q'''_d H_s^2 \tau)(u_b D_{pc}^4)]/[\rho_p \rho_g h_{lg} \dot{m}(1-\varepsilon)u_p^4]$

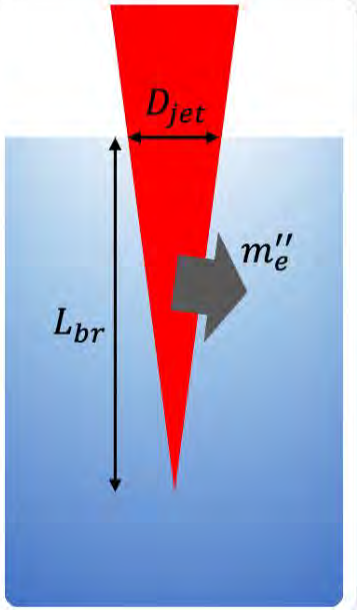
DHF-limited bed cooling

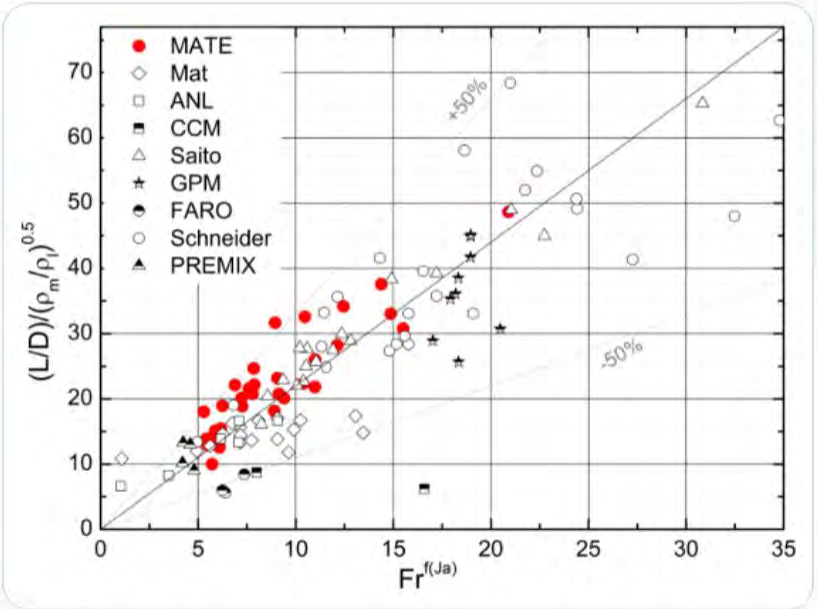
$Q_{lim} = F_{dhf}Q_{dhf} - Q_{btm}$, and $Q_{dbr} = \min(Q_{htr}, Q_{lim})$

Deposit / remelt threshold

$T_{sf} > T_{sol} + f_{tcr}(T_{liq}-T_{sol})$, with $f_{tcr} = 0$ as the documented default.

Melt jet breakup and particle generation





<Mass Flux on the jet surface>

$$m_e'' = \frac{\rho_m D_{jet} V_{jet}}{2\sqrt{L_{br}^2 + \frac{1}{4}D_{jet}^2}}$$

Breakup length determines

coherent jet fraction | particle source location | debris/lump split

Selectable correlations

Taylor-type and Saito-type correlations are inherited basis; Jung-type correlation adds thermodynamic coupling through vapor generation and subcooling effects.

<Jet Breakup Length Correlation>

- Taylor type

$$\frac{L_{br}}{D_{jet}}\left(\frac{\rho_m}{\rho_l}\right)^{-0.5} = 10C_{br}$$

- Saito type

$$\frac{L_{br}}{D_{jet}}\left(\frac{\rho_m}{\rho_l}\right)^{-0.5} = 2.1C_{br}Fr$$

- Vapor generation intensity parameter

$$Q = \frac{Heat\ flux\ for\ vapor\ generation}{Heat\ flux\ for\ vapor\ condensation} = \frac{Ja_v}{Ja_l}$$

$$Ja_l = \frac{\rho_l c_p (T_w - T_{sat})}{\rho_v h_{fg}} \qquad Ja_v = \frac{c_p (T_l - T_{sat})}{h_{fg}}$$

$$\frac{L_{br}}{D_{jet}}\left(\frac{\rho_m}{\rho_l}\right)^{-0.5} = 3.3C_{br}Fr^{0.5\left[1-\frac{1}{2154Q+1}\right]}$$

Particle size distribution model

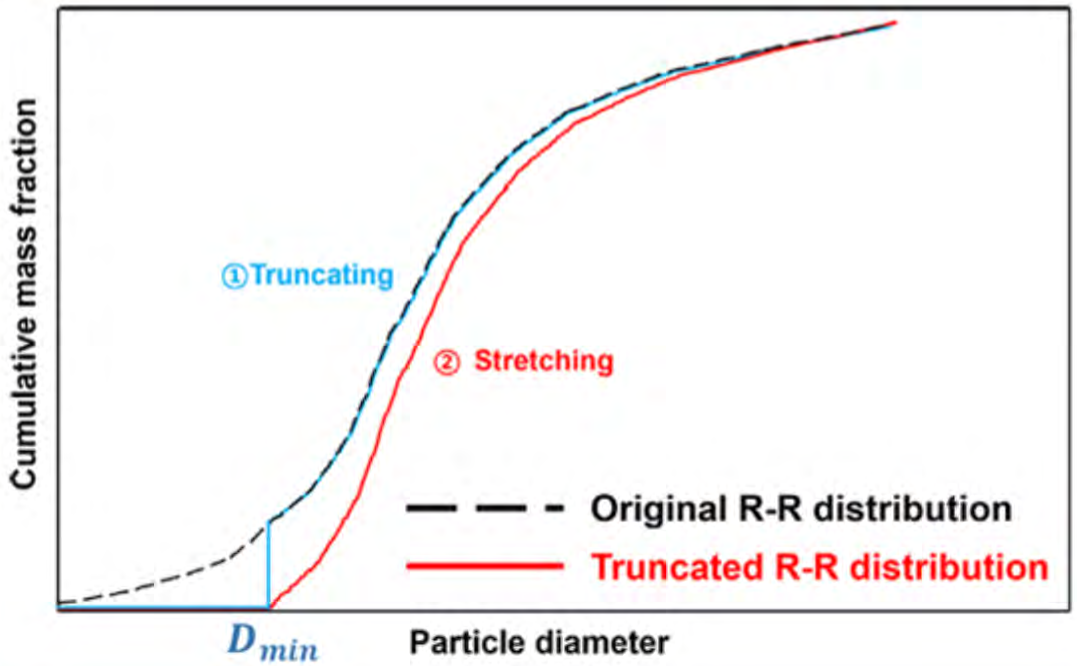
Rosin–Rammler distribution

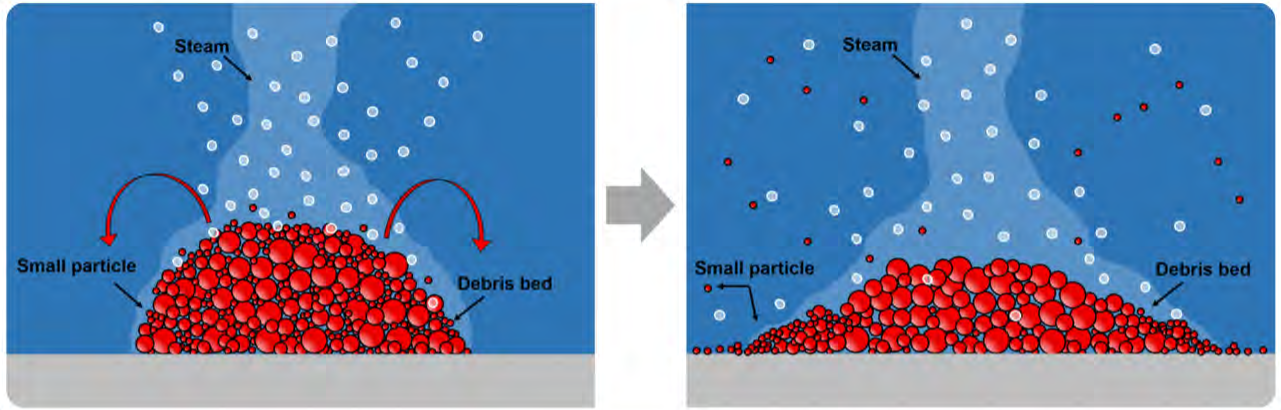
Represents cumulative mass fraction of fragmented melt particles.

↓ lower cutoff

Truncated distribution

Excludes unrealistically small deposited particles while preserving statistical characteristics of the original distribution.





<Original Distribution>

$$F = 1 - \exp\left[-\left(\frac{D_p}{D_e}\right)^n\right]$$

<Truncated Distribution>

$$F = \begin{cases} 0, & D_P < D_{min} \\ 1 - \exp\left[-\left(\frac{D_p}{D_e}\right)^n + -\left(\frac{D_{min}}{D_e}\right)^n\right], & D_p \geq D_{min} \end{cases}$$

$$d = F^{-1}(U) = D_e[-\ln(1-U)]^{\frac{1}{n}} = D_{mm}\left(-\frac{\ln(1-U)}{\ln 2}\right)^{\frac{1}{n}}$$

$$Bo_p \equiv \frac{g\rho_m D_{mm}^2}{\sigma_m}$$

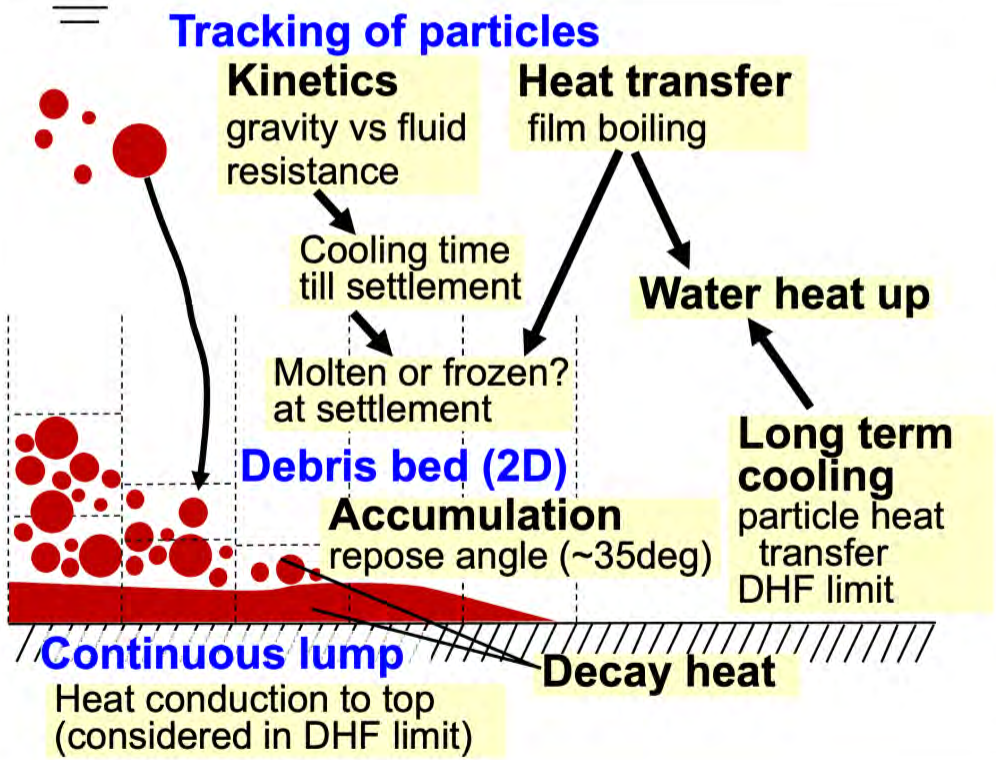
$$Bo_p^{1/2} = C_{dmm} F_{sb} \left(\frac{\rho_v}{\rho_l}\right)^{\frac{1}{3}} \left(\frac{\rho_l}{\rho_m}\right)^{\frac{2}{3}}$$

$$F_{sb} = 25[2.2 - \exp(-13N_{sb})]$$

$$N_{sb} = \frac{c_l \Delta T_{sub}}{\Delta h_{fg}}$$

$$D_{min} = \frac{q''^2 + \sqrt{q''^4 + 8ab\rho_g(\rho_p - \rho_l)gh_{latent}^3\mu_g q''}}{2b\rho_g(\rho_p - \rho_l)gh_{latent}^2}, \quad a = 33.7, b = 0.0408$$

Particle sedimentation and heat transfer



- Internal energy loss

$$\Delta Q = -m_p c_{pm}(T_{av}^n - T_{av}^{n-1})$$

- Heat transfer to coolant during a time step

$$\Delta Q = \Delta t A_p h_{eff}(T_{sf} - T_l) \approx \Delta t A_p h_{eff}(T_{av}^n - T_l)$$

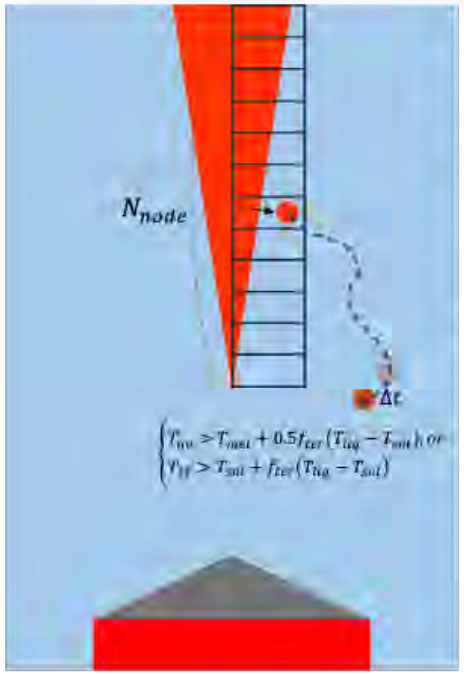
$$\Delta Q = -m_p c_{pm}(T_{av}^n - T_{av}^{n-1}) = \Delta t A_p h_{eff}(T_{av}^n - T_l)$$

During sedimentation

drag-controlled motion | boiling-regime heat flux | implicit energy balance

Surface temperature correction

A thermal boundary layer model accounts for lower particle surface temperature caused by low oxide thermal conductivity.



1. Calculate heat transfer from a particle

$$\Delta Q = m_p c_{pm}\Delta T\left(1 - \frac{m_p c_{pm}\Delta T}{\Delta t A_p C_{htc}|q''| + m_p c_{pm}\Delta T}\right) = \frac{x_1}{1+x_2}(T_{av}^{n-1} - T_l)$$

2. Update e_{int}

$$e = e - \frac{\Delta Q}{m_p} + q_{decay}\Delta t$$

3. Update T_m from e_{int}
4. Update particle properties

5. Update T_{sf} considered δ

$$\delta_0 = \sqrt{6\kappa\Delta t} \longrightarrow \delta\left\{1 - 0.75\frac{\delta}{R} + 0.2\left(\frac{\delta}{R}\right)^2\right\}d\delta = 3\kappa dt$$

$$\delta = \delta + d\delta$$

$$T_{sf} = T_{av} - \frac{q''\delta}{2\lambda}\left\{1 - \frac{\delta}{R}\left\{1 - 0.5\frac{\delta}{R} + 0.1\left(\frac{\delta}{R}\right)^2\right\}\right\}$$

Particle heat-flux regime map

Regime / quantity	Correlation used in COOLAP-II/HIPPO heritage	How it enters HIPPO
Forced convection	Sphere convection Nusselt correlation	Fallback or pre-boiling convective heat transfer around sedimenting particles
Nucleate boiling	Kutateladze correlation	Boiling heat flux below CHF
Critical heat flux	Zuber CHF	Upper point for boiling curve and transition to film/transition boiling
Film boiling	Liu-Theofanous film-boiling model plus radiation correction	Dominant high-temperature particle cooling mode
Minimum film boiling	Kondo et al. MFB temperature	Lower point for film-boiling stability
Transition boiling	Linear interpolation between CHF and MFB points	Provides continuous heat-flux evaluation across regime transition
Surface-temperature correction	Thermal boundary-layer model	κ is thermal diffusivity [m^2/s]; λ is thermal conductivity [W/m-K]
Numerical treatment	Implicit particle energy balance	q'' is evaluated through the regime-dependent boiling curve

Deposition pathway: debris bed or continuous melt lump

Arriving particle state

Average temperature and surface temperature are evaluated after sedimentation cooling.

Temperature-based decision

If the particle remains sufficiently molten, it merges into the continuous melt lump; otherwise, it is deposited into the debris bed.

↓

Solidified / cooled

Deposited into 2D debris bed nodes

Molten / reheated

Merged into continuous melt lump
or re-melted from debris bed

Threshold parameter

f_{tcr} shifts the merge/remelt threshold within the solidus-liquidus interval. COOLAP-II documents $f_{tcr} = 0$ as the default, with surface-temperature and average-temperature criteria treated as sensitivity options.

Debris bed formation and conical shape model

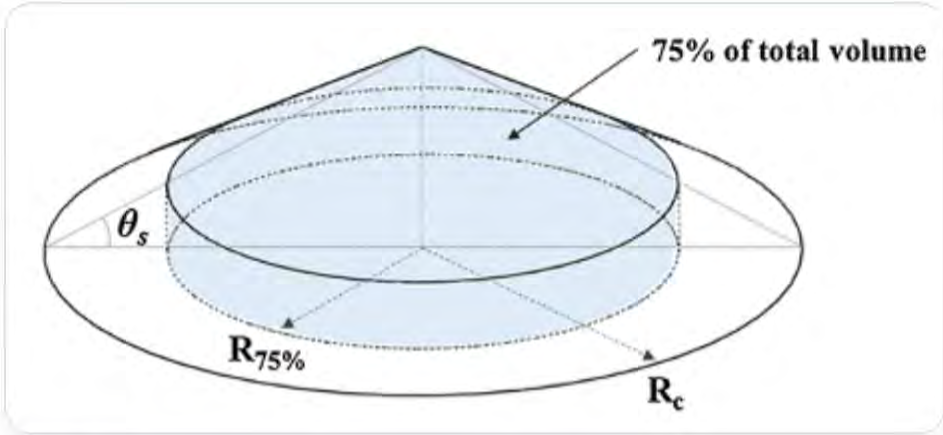
Vapor-induced lateral transport

Upward vapor flow promotes radial spreading of sedimented particles.

↓

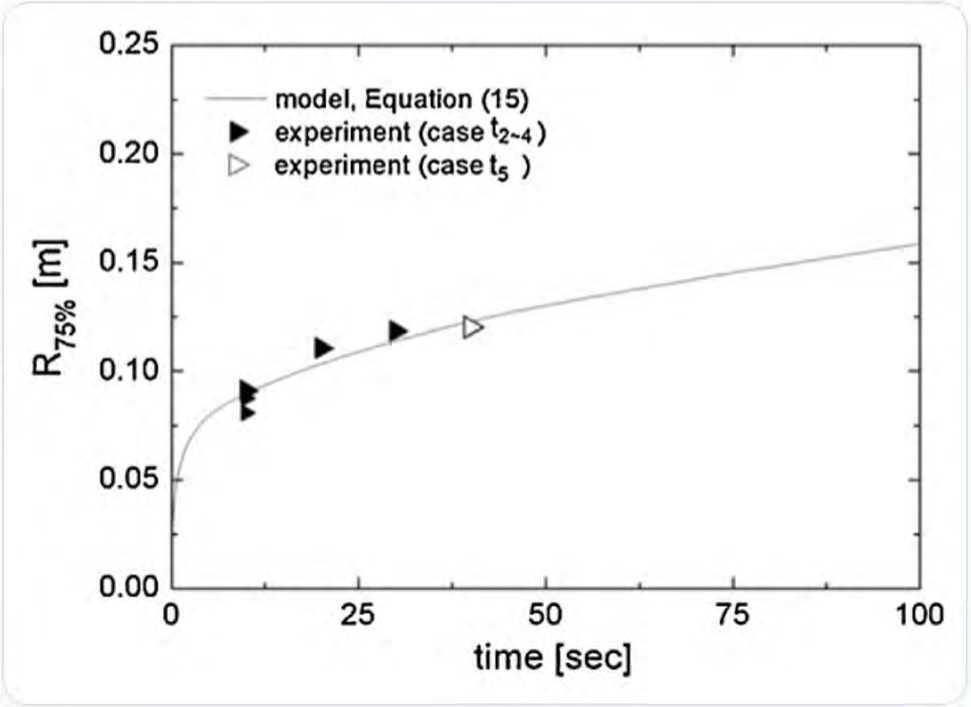
Slope-angle control

If the calculated slope exceeds a critical value, upper debris nodes are laterally redistributed.



$$R_{75\%} = 0.414\left[\left(\frac{(\rho_l-\rho_g)^2}{\rho_p\rho_g\Delta h_{lg}}\left(\frac{q_d'''H_s^2\tau}{\dot{m}}\right)\left(\frac{\alpha u_b D_{pc}^4}{(1-\varepsilon)u_p^4}\right)\right)\right]^{\frac{1}{3}}$$

$$\theta_s = \operatorname{atan}\left(4.127\left(\frac{\rho_g\Delta h_{lg}}{(\rho_l-\rho_g)^2}\right)\left(\frac{\dot{m}^2}{q_d'''H_s^2}\right)\left(\frac{u_p^4}{\alpha u_b D_{pc}^4}\right)\right)$$



Debris bed and melt lump cooling

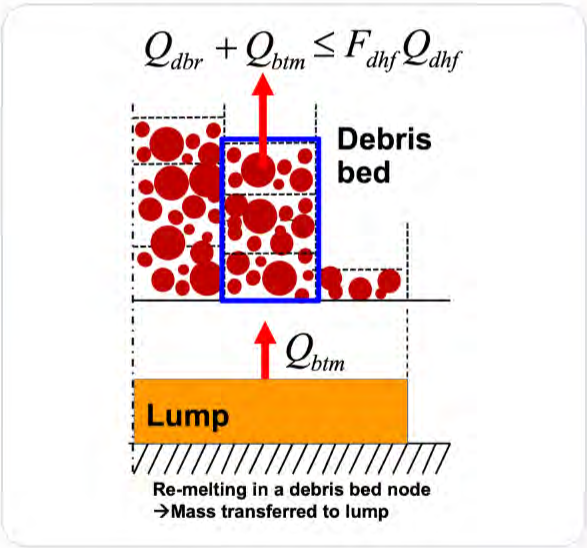
Top-flooded debris bed
Particle-scale heat transfer

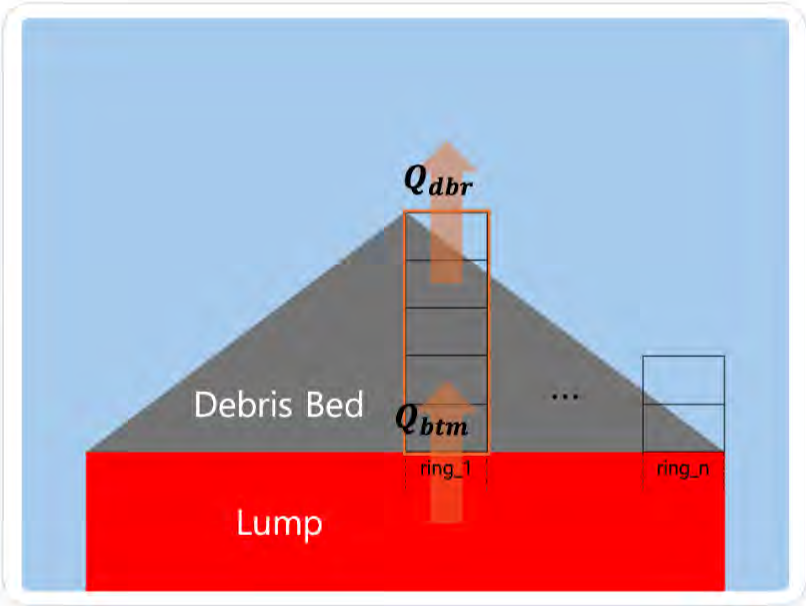
limited by

DHF / CCFL limit
Vapor outflow vs liquid ingression

reduced by

Bottom heat input
Continuous melt lump beneath the bed





- Q_{dbr} in the ring

$$Q_{htr} = \sum_{Node_{vertical}} q'' A_p \qquad q'' = q''_{boil} + q''_{cond} + \frac{7}{8} q''_{rad}$$

$$Q_{lim} = F_{dhf} Q_{dhf} - Q_{btm} \qquad Q_{btm} = \min\left(A_b F_{htlmp} \lambda_m \frac{T_{lmp} - T_{sat}}{H_{lmp}/2}, F_{qbdhf} F_{dhf} Q_{dhf} \right)$$

  - $\therefore Q_{dbr} = \min(Q_{htr}, Q_{lim})$

- Update T_{av} of D.B by Energy Balance Equation

$$(-\dot{q} + \dot{q_{dec}})\Delta t = e(T_{av}^n) - e(T_{av}^{n-1}) \approx \frac{de}{dT}(T_{av}^n - T_{av}^{n-1})$$

$$\rightarrow T_{av}^n = \frac{(R_{eff} T_{sat} + \dot{q}_{dc})\Delta t + \frac{de}{dT} T_{av}^{n-1}}{\frac{de}{dT} + R_{eff}\Delta t} \qquad R_{eff} = \frac{q''_{dbr}}{T_{av}^{n-1} - T_{sat}}$$

- Update T_{sf} of D.B by δ

$$T_{av} - T_{sf} = \frac{q'' R}{5\lambda} = \frac{h_{eff}(T_{sf} - T_{sat})R}{5\lambda}$$

$$\rightarrow T_{sf}^n = \frac{T_{av}^n + C T_{sat}}{1 + C}, \qquad C = \frac{h_{eff} R}{5\lambda}$$

Debris-bed cooling closures made explicit

Closure item	Model treatment	Equation / setting	Default or note
Crowding attenuation	Debris-node heat transfer reuses the particle heat-transfer model with a crowding multiplier	$C_{htc,bed} \cdot q''_{particle}$	$C_{htc,bed} \approx 0.1$
DHF model	One-dimensional top-flooding dryout heat flux with Lipinski-type CCFL framework	Q_{dhf} from porous-media option	Rahman / Reed / Lee options
Actual heat removal	Node/ring heat removal is limited by local heat transfer or dryout capacity	$Q_{dbr} = \min(Q_{htr}, Q_{lim})$	Prevents overcooling above DHF
DHF limit	Bottom heat input reduces the allowable top-flooded debris-bed cooling capacity	$Q_{lim} = F_{dhf}Q_{dhf} - Q_{btm}$	$F_{dhf} = 1.0$ default
Bottom heat cap	Heat input from the continuous melt lump is bounded relative to DHF	$F_{qbdhf}F_{dhf}Q_{dhf}$	$F_{qbdhf} = 0.5$ default
Porosity	Debris-bed hydraulic resistance and DHF calculation use a porosity input	ε in porous-bed correlations	Reference cases commonly use 0.5

Coupled containment accounting check

Accounting item	Balance or tracked state	Expected behavior	Use in this talk
Mass accounting	HOTCB can track vapor, saturated water, subcooled water, and non-condensable gas masses	Mass changes follow inflow/outflow, evaporation, and condensation	Shows how CCI-generated vapor enters the containment-side balance
Energy accounting	Particle, debris-bed, and lump source terms enter the containment energy balance	Σ heat removed from corium matches supplied containment heat source over the same window	Connects local CCI cooling to containment pressure/temperature response
Buffer accounting	Particle heat-release histories are accumulated in time bins	Residence-time effects are preserved instead of collapsed into one instant	Explains why particle sedimentation heat release is time-dependent
Corium inventory	Jet, particles, debris bed, and lump are treated as redistribution reservoirs	Total corium mass is conserved across deposition and remelting	Supports the later MAMBA-HIPPO and HIPPO-SCORPION coupling discussion

V&V scope for this overview talk

Purpose today
Introduce the overall SAFARI code direction and HIPPO's role as the CCI/FCI entry module.

V&V today
Show only compact status anchors: DAVINCI/DEFOR for HIPPO and FARO L33 for the HIPPO–SCORPION chain.

V&V later
Publish detailed model-by-model validation as a continuing conference and journal paper series.

How to present it	What is included in this talk	What is intentionally deferred
V&V depth	Representative evidence and current status	Full uncertainty bands, complete test matrices, and case-by-case sensitivity studies
Validation claim	Dominant trends and integral quantities are reproduced for selected anchors	Regulatory-grade correlation validation for every model closure
Presentation focus	Why HIPPO matters inside SAFARI and how the modules exchange information	Detailed derivation and justification of every empirical correlation

Model-by-model V&V publication roadmap

Publication thread	Modeling target	Validation anchor	Primary metrics
Jet breakup	Breakup length and jet penetration	DEFOR / FARO-type tests	Breakup length, penetration time, sensitivity to inlet velocity
Fragmentation / PSD	Particle-size distribution and sampling model	DEFOR, TROI/KROTOS follow-up	D_{10}, D_{50}, D_{90}, fit error, dominant particle range
Debris morphology	Conical bed formation and spreading	DAVINCI and debris-bed experiments	Top height, $R_{75\%}$, $H/R_{75\%}$, bed volume uncertainty
Coolability	DHF limitation, debris/lump cooling, remelting	Dedicated cooling benchmarks	Heat removal, dryout margin, remelting mass flux
FCI–SE chain	HIPPO–SCORPION premixing-to-load interface	FARO L33, later KROTOS/TROI	Peak pressure, impulse, trigger-time sensitivity, C_{fr} range
FCI–MCCI chain	MAMBA–HIPPO pre-flooded cavity analysis	PWR-scale cavity scenarios	Corium geometry, ablation depth, gas generation, containment source terms

MAMBA–HIPPO: FCI-informed MCCI analysis

Why the coupling matters

- Pre-flooded cavity cases require FCI-informed MCCI initial conditions.
- HIPPO estimates debris-bed and lower-corium geometry after jet breakup and sedimentation.
- MAMBA can start from cavity-dependent corium distribution, not a uniform floor-spreading assumption.

Current staged workflow

- External in-vessel discharge input defines the melt release into the cavity.
- HIPPO runs the early FCI period until debris-bed stabilization, assumed about 10 min in the report example.
- MAMBA then performs long-term MCCI calculation, e.g., 72 h scale.

Information path	Transferred information	Physical meaning
HIPPO → MAMBA	Debris/lower-corium shape, corium temperature T_c, mass m_c, radius r_c	Initial MCCI state after FCI, including non-uniform cavity loading
HIPPO containment → MAMBA	Containment pressure P_{con} and cavity coolant temperature T_{cool}	Boundary conditions controlling heat transfer and cooling
MAMBA → HIPPO containment	Concrete-ablation gases and source terms, including H_2O, CO_2, H_2, CO	Noncondensable/steam source terms affecting containment pressure

HIPPO–SCORPION: premixing to explosion load

Coupling interface

HIPPO

premixing time series

particles, void, coolant state

CSV

SCORPION

steam explosion

pressure / impulse

A standardized CSV interface preserves the premixing time axis and reduces manual input conversion.

Direct HIPPO variables

Fuel/coolant temperature, pool depth, upper slug area, jet diameter, fuel/coolant mass, slug mass, interacting fuel mass, average mixing diameter, void fraction, and mixing time.

FARO L33 is used as a coupled-analysis anchor because both premixing and explosion response are measured at large scale.

Validation anchor

HIPPO premixing output is used directly as SCORPION input for FARO L33 coupled analysis.

Key sensitivity

Fragmentation constant C_{fr} controls fine fragmentation, steam generation, peak pressure, and timing.

Numerical robustness

SCORPION_BETA 2.0 uses a ResNet-supported property path near the critical region for stable pressure response.

4. V&V SCOPE AND SAFARI COUPLING

Why the SAFARI ecosystem is different

Conventional integrated-code expectation

- One code package gives a broad accident sequence solution.
- Phenomenon-specific assumptions may be hidden inside a large integrated workflow.
- Changing one phenomenon model can be difficult to validate independently.

SAFARI module ecosystem

- HIPPO, MAMBA, SCORPION, and SAVANNAH retain phenomenon-focused physics roles.
- Interfaces preserve physically meaningful variables and time histories.
- Each module and each coupling path can be validated and published transparently.

Role clarity

HIPPO handles early CCI/FCI; MAMBA handles long-term MCCI; SCORPION handles steam-explosion load.

Traceable coupling

Data exchanged through explicit variables such as debris geometry, P_{con}, T_{cool}, void fraction, and premixing mass.

Regulatory path

Focused V&V papers can build evidence module by module before full SAFARI integration.

Answer to the expected audience question

HIPPO is the early ex-vessel state generator that lets SAFARI connect CCI to MCCI, steam explosion, and containment thermal hydraulics in a traceable modular ecosystem.

Conclusions and future work

Message / work item	Content	Purpose for the presentation
SAFARI introduced	Korean regulatory-oriented framework for integrated ex-vessel severe accident analysis	Positions the talk beyond a single HIPPO module result
HIPPO positioned	CCI/FCI entry module producing debris/lump state, premixing state, and heat/mass source terms	Answers what HIPPO does inside SAFARI
V&V scoped	Representative anchors are shown briefly; detailed correlation-level V&V is deferred to a paper series	Keeps this talk aligned with the code-overview objective
MAMBA link explained	HIPPO-derived debris/lower-corium geometry and T_c, m_c, r_c initialize FCI-informed MCCI	Shows why pre-flooded cavity analysis needs the HIPPO–MAMBA path
SCORPION link explained	HIPPO premixing time series is passed by CSV to steam-explosion load calculation	Shows how SAFARI connects premixing to pressure/impulse evaluation
Next integration	Strengthen MAMBA–HIPPO, HIPPO–SCORPION, and SAVANNAH/M1 containment T-H coupling	Builds the modular evidence base for full SAFARI applications

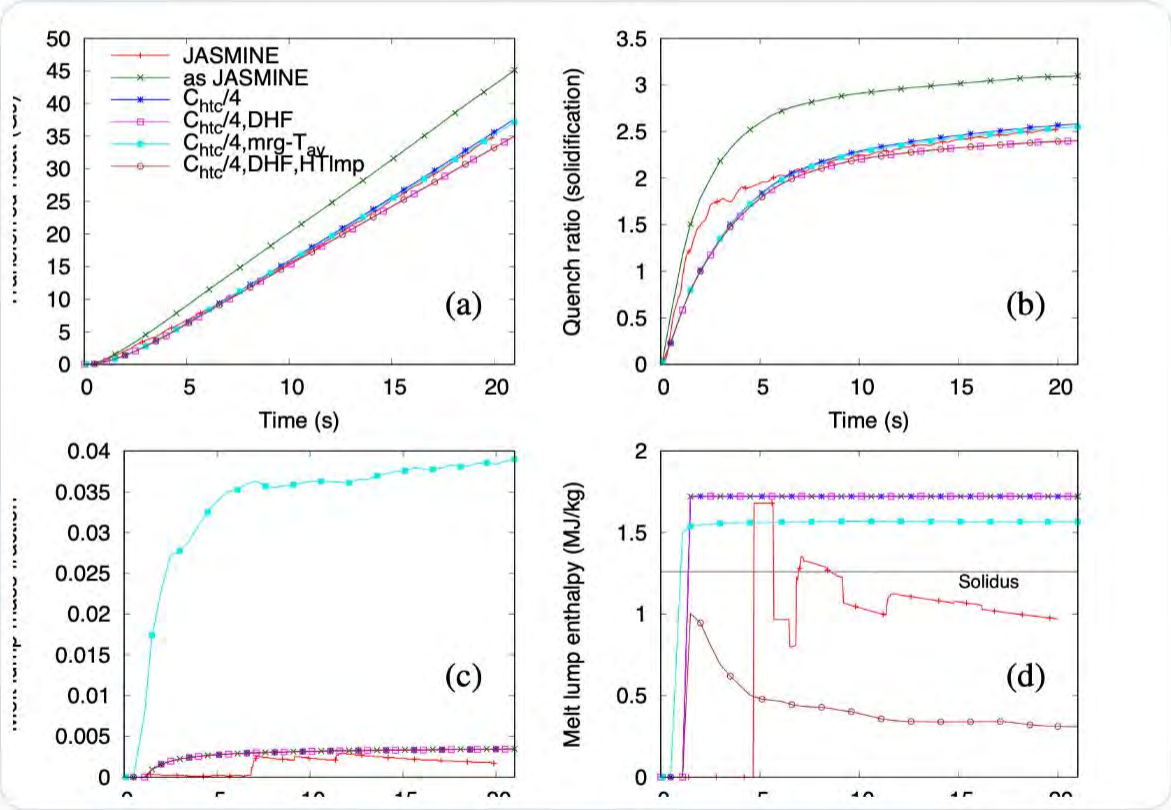
Q&A

Thank you for your attention.

Questions and comments are welcome.

BACKUP

COOLAP-II model basis and review history



Purpose of COOLAP-II

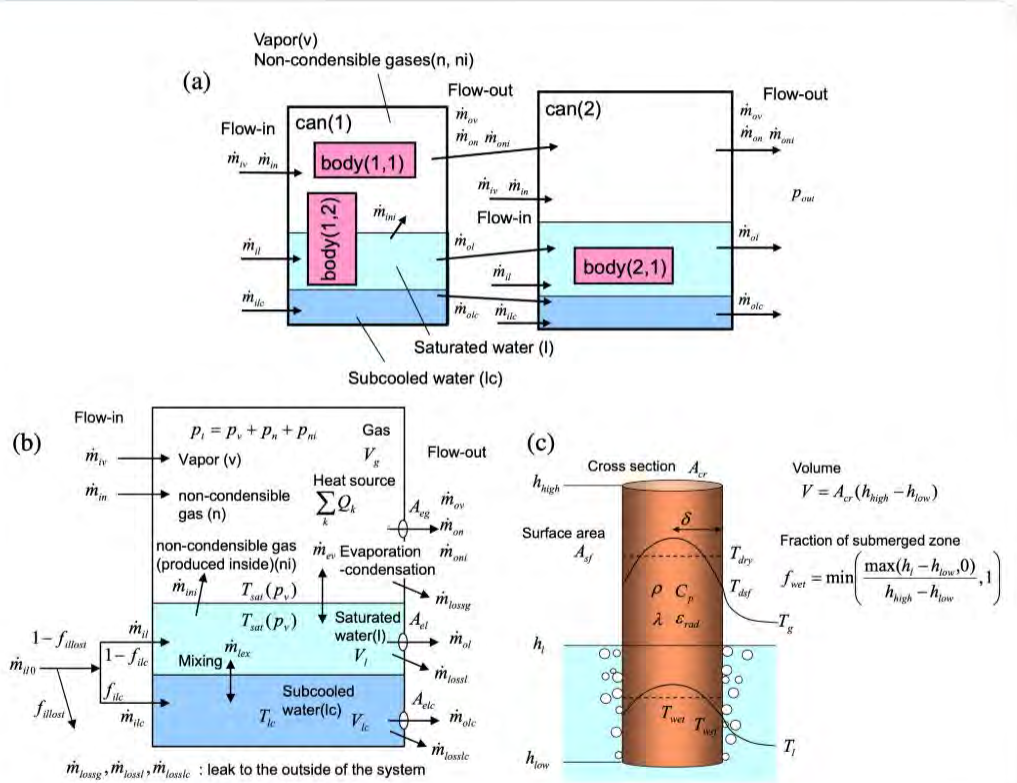
Simplified assessment of ex-vessel melt jet breakup, sedimentation, heat transfer, debris bed formation, and cooling.

How to use in this talk

Heritage review only. COOLAP-II/JASMINE/FARO comparisons should not be presented as HIPPO validation results.

BACKUP

HOTCB reference and assumptions



HOTCB

Hot Cans and Bodies: a JAEA code for simplified mass and energy balance of water/steam/non-condensable gas systems.

Key assumptions

- Lumped control-volume representation
- Vapor–liquid thermal equilibrium for saturated phases
- Heat-capacity bodies coupled to fluid regions

BACKUP

Selected model correlations and parameters

Model component	Representative treatment	Constants / settings to state in Q&A
Jet breakup length	Taylor / Saito / Jung-type correlations	C_{br} default 1.0 in COOLAP-II; Jung term uses vapor-generation intensity from heat-flux ratio
Particle size distribution	Rosin-Rammler; truncated distribution for debris bed particles	n = 1.5; MMD from Bond-number/subcooling correlation; minimum diameter from fluidization concept
Particle heat transfer	Convection, Kutateladze nucleate boiling, Zuber CHF, Liu-Theofanous film boiling, Kondo MFB, transition interpolation, radiation	C_{htc} is a model multiplier; COOLAP-II sensitivity used particle C_{htc} = 0.5 after comparison with JASMINE
Debris bed cooling	Local particle heat transfer limited by DHF / CCFL	$C_{htc,bed} \approx 0.1$ for crowding; porosity commonly 0.5 in reference cases; F_{dhf} default 1.0
Melt lump interaction	Bottom heat input to debris bed reduces Q_{lim}	$Q_{lim} = F_{dhf}Q_{dhf} - Q_{btm}$; F_{qbdhf} default 0.5
Deposit / remelt criterion	Surface-temperature or average-temperature threshold	f_{tcr} shifts threshold; default 0; criterion should be treated as sensitivity parameter

κ	Thermal diffusivity [m^2/s]	Used for transient thermal boundary-layer growth in particle surface-temperature correction
λ	Thermal conductivity [W/m-K]	Used in average-to-surface temperature drop; λ_m for melt/lump conduction
q''	Surface heat flux [W/m^2]	Selected from regime-dependent boiling curve and radiation correction
q'''_d	Volumetric decay heat rate [W/m^3]	Input/accident-condition parameter in DAVINCI conical-bed model
ρ_g, ρ_l, ρ_p	Vapor, liquid, particle densities [kg/m^3]	Fluid properties from containment/coolant state; particle density from material input
h_{lg}	Latent heat of vaporization [J/kg]	Water/steam property used in vapor-generation and energy-flux terms
θ_s, $R_{75\%}$	Side slope angle [deg], radius containing 75% of bed volume [m]	DAVINCI morphology metrics for conical bed spreading
f_{tcr}	Threshold modifier [-]	User/sensitivity parameter; COOLAP-II default 0

BACKUP

Current limitations and uncertainty considerations

Current limitations

- Limited validation database and mostly M-12 HIPPO comparison for DEFOR
- Lumped/discretized treatment of local morphology and non-axisymmetric cavities
- Ergodic particle sampling and representative debris-node diameter
- Vapor/saturated-liquid equilibrium in simplified containment model

Breakdown conditions to state

- Highly transient venting or pressure relief with strong spatial gradients
- Strong non-condensable stratification affecting condensation and breakup enhancement
- Subcooling/condensation regimes outside Jung-type correlation database
- Long-term remelting where bed permeability and morphology evolve beyond current closure

EVALUATION OF CONCRETE ABLATION BY A HOT HEAT-GENERATING SOLID

Villarreal Larrauri A*, Tourniaire B

ABSTRACT

Accurate evaluation of concrete ablation during a Molten Corium-Concrete Interaction (MCCI) is a key element of Severe Accident (SA) management in scenarios in which vessel failure cannot be avoided. In cases for which water can be injected on top of the corium, it is considered that corium can be stabilized due to the formation of a debris bed by corium ejection, a fractured crust by water ingression, and a dense crust. Nevertheless, in that configuration, once the corium is completely solidified, a part of the decay heat can still be transferred to the concrete by heat conduction through the crust in contact with the concrete. If that part of the decay heat cannot be evacuated by conduction in the concrete, then MCCI goes on until heat transfer by conduction in the concrete balances the decay heat transferred to the concrete. Thus, the evaluation of the final concrete erosion by MCCI should take into account the ablation that could result from the interaction between a solidified corium with decay heat and concrete.
To enable evaluation of post corium-solidification concrete ablation following an MCCI, a one-dimensional transient heat conduction model has been developed. Validation against experimental results using a heated metallic solid ingot in contact with concrete demonstrates that the model can successfully reproduce the kinetics of concrete ablation driven by a hot, internally heat-generating solid. The purpose of this paper is to present the model that has been developed to calculate the interaction between a solidified corium and concrete and the validation that has been performed.

KEYWORDS
Molten Corium-Concrete Interaction, heat conduction, concrete ablation

1. INTRODUCTION

Accurate evaluation of concrete ablation during a Molten Corium-Concrete Interaction (MCCI) is a key element of Severe Accident (SA) management in scenario in which vessel failure cannot be avoided [1]. In cases for which water can be injected on top of the corium, it is considered that corium may be stabilized due to the formation of a debris bed by corium ejection, a fractured crust by water ingression in contact with water, and a dense crust in contact with concrete [2].
The stabilization of corium during a severe accident depends on the kinetics of the MCCI. The progression of MCCI, in turn, is conditioned by the thermophysical properties of the corium, the accidental scenario, the chemical composition of the concrete basemat, amongst others. The phenomena governing the phases of MCCI (dry and flooded) are highly non-linear and can lead to a vastly large array of stabilization conditions. If the concrete releases a large percentage of decomposition gases, melt-ejection will be predominant leading to a stabilized corium in the form of, mainly, a large debris bed. Conversely, in case of concrete with a low

* Corresponding author

gas content, corium stabilization is controlled by crust formation and fracturing, i.e. water-ingression. In some cases, the analysis of the final configuration show that heat flux towards the concrete and the erosion rate remains non-zero [1]. Since the concrete has a relatively low thermal conductivity and this heat flux is not negligible in some conditions (i.e., it cannot be entirely transferred by conduction within the concrete), a one-dimensional model enabling the calculation of the erosion of the concrete basemat by a solidified heat-generating corium is here established.

2. POST-SOLIDIFICATION ONE-DIMENSIONAL HEAT-CONDUCION MODEL FOR CORIUM-INDUCED CONCRETE ABLATION

The model presented in this paper was proposed by Rhodes and Quintiere [3] to calculate the mass loss rate of a solid during combustion. As explained in [4], the mass loss rate measured in the experiments in [3] can be related to the erosion velocity of a solid. For this reason, the model proposed in [3] has been adapted to calculate long-term phase of molten-core concrete interaction when transient conduction heat transfer could lead to concrete ablation despite complete solidification of corium in [4]. This model has recently been modified to improve its behavior during the transition between the solid heating phase (i.e. without ablation) and the ablation phase. A similar model is also presented as an option in CORQUENCH [5] to calculate ablation during MCCI .

2.2. Transient Conduction Heat Transfer Modeling in Concrete for the Simulation of Long-Term Phase of Molten Core-Concrete Interaction

2.1.1. Governing Equations and Boundary Conditions

Fig. 1 here below shows the post corium-solidification configuration which serves as boundary conditions for the model presented hereafter. Inside the concrete basemat, the one-dimensional transient heat conduction equation can be written as:

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial z^2} \tag{1}$$

with the following boundary conditions:

$$\begin{aligned} \mathrm{T}(z) = \begin{cases} T_{fus}, & z = z_{cr} = e_{sup} + e_{inf} \\ T_0 \ , & z = z_{cr} + \delta \end{cases} \\ \frac{\partial T}{\partial z} = 0, \qquad z = z_{cr} + \delta \\ \frac{dz}{dt} = v_{ablation} = \frac{m''}{\rho_{con}} \\ m'' \, \Delta \mathrm{H} = \mathrm{q}_{\mathrm{net}} + \lambda_{con} \frac{\partial T}{\partial z}, \quad z = z_{cr} \end{aligned} \tag{2}$$

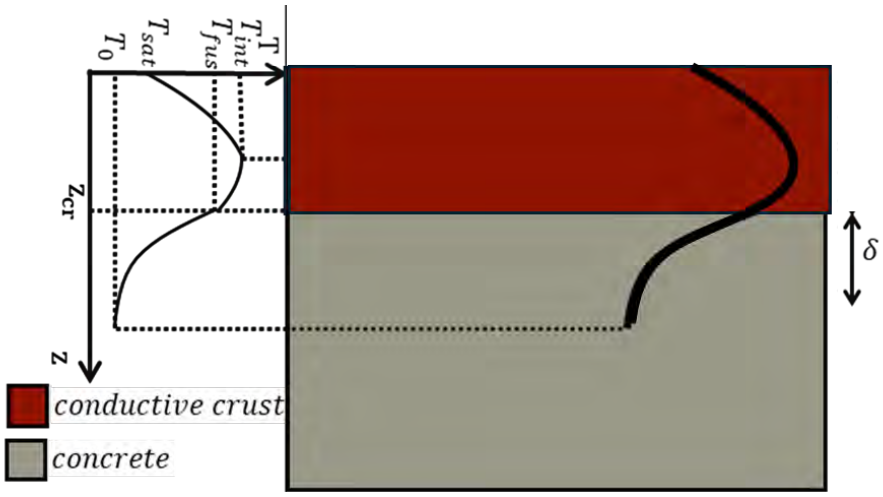

Figure 1. Final corium configuration upon its solidification following MCCI.

Contrary to the quadratic temperature profile assumed in [2] inside the concrete, the present approach employs a fourth-order polynomial representation of the temperature field inside the concrete which can be written as:

$$\frac{T-T_0}{T_{fus}-T_0} = \left(1-\frac{z-z_{cr}}{\delta}\right)^4 \tag{3}$$

From (3):

$$\left.\frac{\partial T}{\partial z}\right|_{z=z_{cr}} = -\frac{4}{\delta}\left(T_{fus}-T_0\right) \tag{4}$$

hence (2) becomes

$$m'' \, \Delta H = q_{net} - \frac{4\lambda_{con}}{\delta}\left(T_{fus}-T_0\right) \tag{5}$$

with q_{net} the heat flux between the corium and the concrete. Eq. (5) expresses the evolution of the surface mass flow rate of concrete degradation induced by the heat flux emanating from the solidified corium at the interface limited by heat conduction through the concrete.

The partial derivative of the temperature of the moving boundary with respect to time $\frac{\partial T}{\partial t}$ can be expressed as:

$$\frac{\partial T}{\partial t} = \frac{\partial T}{\partial z_{cr}} \cdot \frac{dz_{cr}}{d_t} + \frac{\partial T}{\partial \delta} \cdot \frac{d\delta}{d_t} \tag{6}$$

hence (1) becomes:

$$\frac{\partial T}{\partial z_{cr}} \cdot \frac{dz_{cr}}{d_t} + \frac{\partial T}{\partial \delta} \cdot \frac{d\delta}{d_t} = \alpha \frac{\partial^2 T}{\partial z^2} \tag{7}$$

To solve the system of equations, the thermal boundary layer needs to be evaluated. This can be done by solving for $\frac{d\delta}{d_t}$. To achieve this eq. (7) can be integrated between z_{cr} and $z_{cr}+\delta$, as:

$$\underbrace{\int_{z_{cr}}^{z_{cr}+\delta}\left(\frac{\partial T}{\partial z_{cr}}\cdot\frac{dz_{cr}}{d_t}\right)d_z}_{A}+\underbrace{\int_{z_{cr}}^{z_{cr}+\delta}\left(\frac{\partial T}{\partial \delta}\cdot\frac{d\delta}{d_t}\right)d_z}_{B}=\underbrace{\int_{z_{cr}}^{z_{cr}+\delta}\left(\alpha\frac{\partial^2 T}{\partial z^2}\right)d_z}_{C} \tag{7a}$$

where it can be found that terms A, B, and C are:

$$A\rightarrow\int_{z_{cr}}^{z_{cr}+\delta}\left(\frac{\partial T}{\partial z_{cr}}\cdot\frac{dz_{cr}}{d_t}\right)d_z=v_{ablation}(T_{fus}-T_0) \tag{8}$$

$$B\rightarrow\int_{z_{cr}}^{z_{cr}+\delta}\left(\frac{\partial T}{\partial \delta}\cdot\frac{d\delta}{d_t}\right)d_z=\frac{d\delta}{dt}\left[\frac{1}{5}\left(T_{fus}-T_0\right)\right] \tag{9}$$

$$C\rightarrow\int_{z_{cr}}^{z_{cr}+\delta}\left(\alpha\frac{\partial^2 T}{\partial z^2}\right)d_z=\frac{4\alpha}{\delta}\left(T_{fus}-T_0\right) \tag{10}$$

Substituting (8), (9), and (10) into (7a) gives:

$$\frac{d\delta}{d_t}=\frac{20\alpha}{\delta}-\frac{5m''}{\rho} \tag{11}$$

The temperature difference that drives the heat conduction from the corium's crust to the concrete $\left(T_p(t)-T_{fus}\right)$ can be calculated by solving the heat transfer equation, with internal heat generation, within the crust:

$$\rho_{cr}c_{p_{cr}}\frac{\partial T}{\partial t}=\lambda_{cr}\frac{\partial^2 T}{\partial z^2}+q_v \tag{12}$$

Eq. (5) depends not only on the thermal boundary layers' thickness, but also on the heat flux transferred to the concrete by the corium's crust. This last can be calculated as:

$$q_{net}(t)=\frac{\lambda_{cr}}{\Delta z^2}\cdot\left(T_p(t)-T_{fus}\right) \tag{13}$$

To calculate $T_p(t)$ in eq. (13), eq. (12) can be discretized (as shown in Fig. 2) and solved explicitly as follows:

$$T_i^{n+1}=T_i^n+\frac{\lambda_{cr}\,\Delta t}{\rho_{cr}c_{p_{cr}}\Delta z^2}\left(T_{i+1}^n-2T_i^n+T_{i-1}^n\right)+\frac{q_v\,\Delta t}{\rho_{cr}c_{p_{cr}}} \tag{14a}$$

$$T_1^{n+1}=T_i^n+\frac{\lambda_{cr}\,\Delta t}{\rho_{cr}c_{p_{cr}}\Delta z^2}\left(T_2^n-3T_i^n+2T_{sat}\right)+\frac{q_v\,\Delta t}{\rho_{cr}c_{p_{cr}}} \tag{14b}$$

$$T_p^{n+1}=T_p^n+\frac{\lambda_{cr}\,\Delta t}{\rho_{cr}c_{p_{cr}}\Delta z^2}\left(2T_{fus}-3T_p^n+T_{p-1}\right)+\frac{q_v\,\Delta t}{\rho_{cr}c_{p_{cr}}} \tag{14c}$$

where eq. (14b) and eq. (14c) are slightly adapted to take into account that the boundary condition temperatures (T_{sat} in the case of the first mesh following the fractured crust, and T_{fus} in the case of the mesh just next to the corium-concrete interface) are located at a distance $\frac{\Delta z}{2}$ from the center of the mesh. Eq. (14a) then gives the temperature at the center of all other meshes. This scheme is nevertheless limited by the choice of time step Δt which must satisfy the following condition for numerical stability:

$$\lambda_{cr}\cdot\Delta t<\frac{1}{2}\rho_{cr}c_{p_{cr}}\Delta z^2 \tag{15}$$

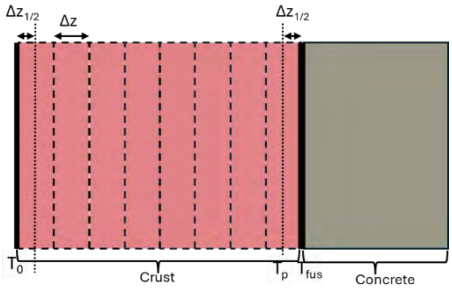

Figure 2. Spatial discretization of the corium's crust.

2.2. Validation with Hot Solid Block - Concrete Interaction Experiment

In the context of the Hot Solid program [6] two tests were performed to assess, amongst others, the concrete ablation induced by a hot heat-generating solid block. In this work, only HSS-1 will be analyzed. The experimental set-up, show in Fig. 3, included thermocouples in the concrete block, as well as X-ray imaging to follow the concrete erosion rates, and a coil to inductively heat the solid block. The experimental measurement uncertainties are not discussed in the paper (except the thermocouple location uncertainty of 2 mm in both directions). The tests occurred in two phases: a pre-heating phase that aimed to heat the solid block up to a target temperature that allows concrete ablation but does not result in solid block melting, followed by a heating phase that aimed to keep the solid block at the target temperature and continue the concrete ablation. The test parameters are summarized in Table I.

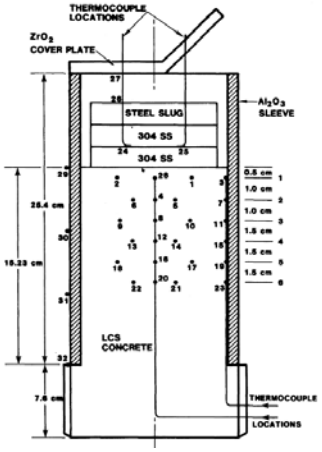

Figure 3. HSS-1 geometry, from [6].

Table I. HSS-1 input parameters, from [6].

Test	Block's composition	Dimensions [cm]	Block's Mass [kg]	Initial Temperature [K]	Avg. Power [kW] (q_{in})	Avg. Losses [W/cm²]	Concrete type
HSS-1	Stainless Steel 304	14 x 8	9	491	3.2	4.9	Limestone Common Sand (LCS)

As can be seen in Table I, the thermal power loss is given as an average without explicitly stating how it was evaluated. In this work, the heat losses will be considered to occur only through the surfaces not in contact with the concrete. Furthermore, as can be seen in Fig. 4, the inductive heating does not appear to affect the temperature of the steel block before the 25-minute mark. Here the power losses are calculated only during the heating period, where they increase linearly interval between the 25th minute and the ablation start (~85th minute), and then kept constant until the end of the heating period, around the 300th minute (see Fig. 5).

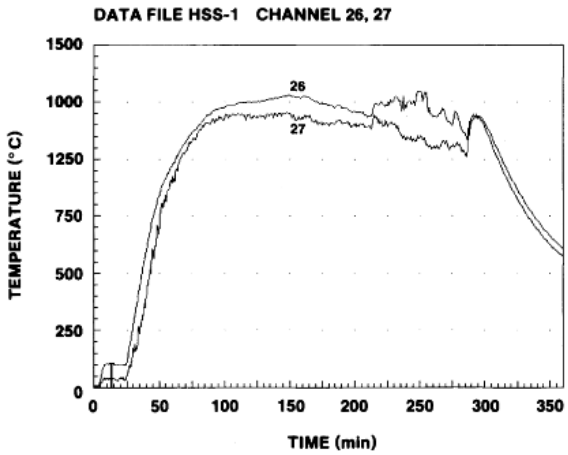

Figure 4. Steel's surface temperature (channel 26), from [6].

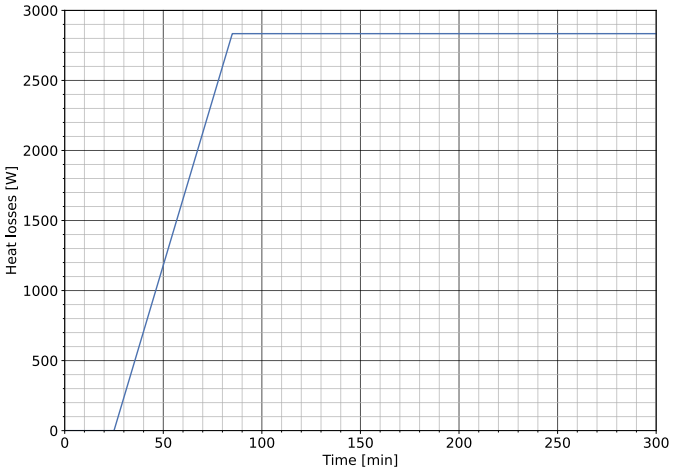

Figure 5. Estimated heat losses, where the total heat loss by cm² approximates the one reported Table I.

To properly evaluate the thickness of the thermal boundary layer when the ablation starts, the experimental preheating phase is simulated using a similar discretization scheme as the one presented above (see Fig. 2) where the corium crust represents the steel ingot (initialized at a temperature of 491K at 25 minutes) and the concrete is also discretized (with an initial temperature of 283 K). Eq. (14) would stay the same, but eq. (13) becomes for the solid block and the concrete domain respectively:

$$\rho_{cr} c_{p_{cr}} \frac{\partial T}{\partial t} = \lambda_{cr} \frac{\partial^2 T}{\partial z^2} + q_v - q_{th} \quad (16a)$$

$$\rho_{con} c_{p_{con}} \frac{\partial T}{\partial t} = \lambda_{con} \frac{\partial^2 T}{\partial z^2} \quad (16b)$$

where q_{th} is the estimated heat loss presented in Fig. 5. The results of the heat conduction calculations for the pre-heating phase are here shown in Fig. 6 where the concrete temperature at different depths is shown as a function of time and is compared to the experimental measures. Furthermore, the temperature of the whole domain (solid steel ingot and concrete) is shown in Fig. 7 at the moment when the temperature at the steel-concrete interface is estimated to reach the concrete ablation temperature. Finally, the steel ingot surface temperature is plotted in Fig. 8 as a function of time for the pre-heating phase.

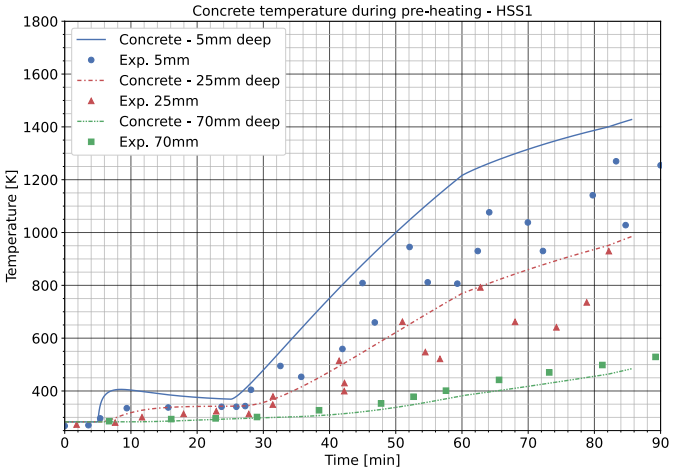

Figure 6. Concrete temperature for different depths as a function of time during the pre-heat phase.

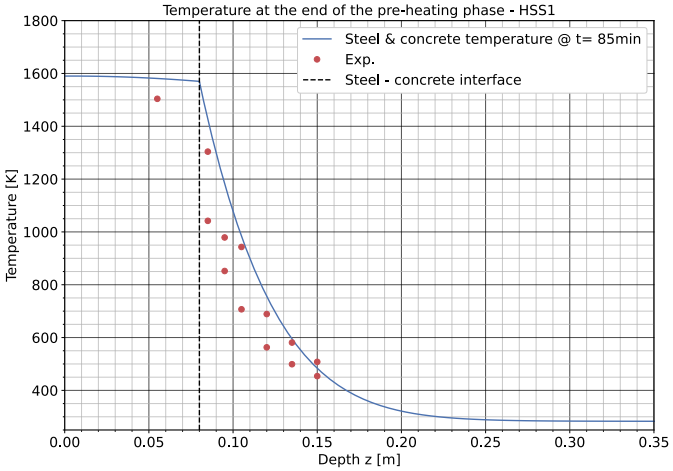

Figure 7. Temperature profile at the end of the pre-heating phase as a function of depth at ~85 min.

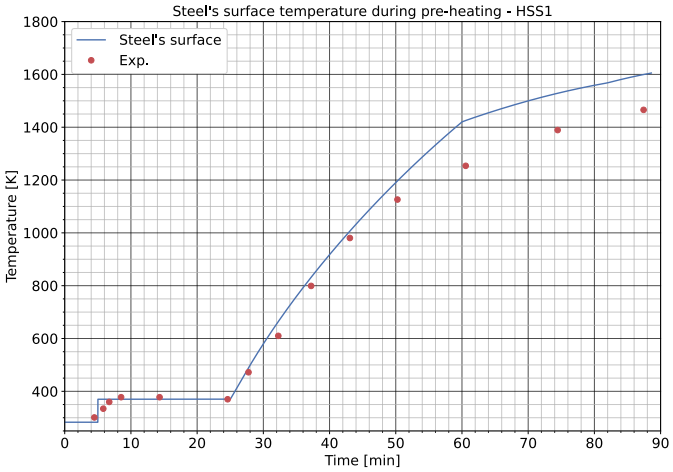

Figure 8. Steel ingots' temperature as a function of time during the pre-heat phase.

The temperature differences shown in Fig. 6 can be attributed to the limitations of the 1D modeling approach, to the simplified treatment of heat losses, the absence of consideration of possible thermal contact resistance, and uncertainties of sensor positioning. Nevertheless, the figure shows an overall good agreement with the experimental measurements. Improving the pre-heating phase agreement can be expected if volumetric heat loss is imposed individually to each cell depending on its temperature or if the discretization scheme is improved, but this is out of the scope of this work.

The initial conditions for the ablation phase are shown in Fig. 7 where good accordance is shown with respect to the temperatures of the domain. As expected, the steel ingot temperature is rather homogeneous ($z < 0.08$ m) given the good thermal conductivity of the material. In order to calculate the erosion using eq. (12) to eq. (14), the initial thermal boundary layer thickness, δ, is determined by finding the value for which the temperature profile given by eq. (3) matches the right-hand portion of the computed temperature as shown in Fig. 9. The value here retained is $\delta = 18$ cm since it is in better agreement with the results of the one-dimensional discretization. Indeed, a small variation of this parameter shows a limited impact on the final temperature profile, which serves as an indication of the pertinence of using a degree-4 polynomial to describe the temperature of the corium crust.

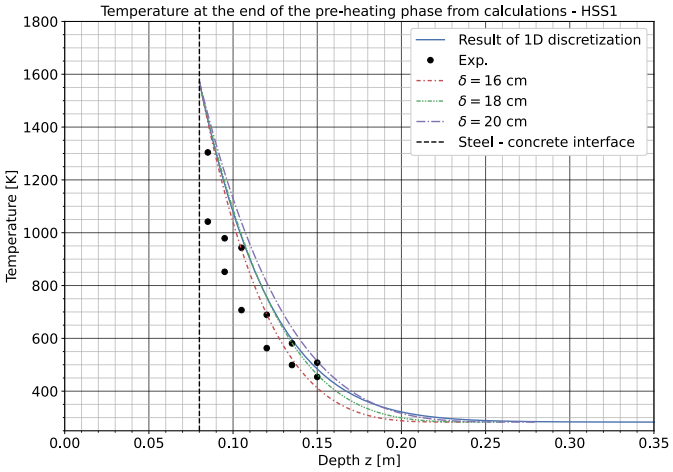

Figure 9 Temperature profile at the end of the pre-heating phase (~85 min) calculated by spatial discretization and solving eq. (3) with different values of δ.

Fig. 10 shows the evolution of the concrete ablation during the ablation phase (t>~85 min) obtained from the experimental results, and the results obtained by solving eq. (12) to eq. (14) with different values of q_v in order to evaluate the effect of the heat losses. As can be seen, even though the results of the experiment can be reproduced by introducing $q_v = 0.42 \cdot q_{in}$ into the model, the results are quite sensitive to the power. Indeed, some small changes to this factor can either double or halve the ablation depth. This can be explained by comparing the total estimated heat losses (~2.8 kW, see Fig. 5) to the power input (~3.2 kW). During the ablation phase, the heat losses are quite elevated and are close to the average power input, hence the power introduced to the steel ingot is somewhat difficult to properly estimate.

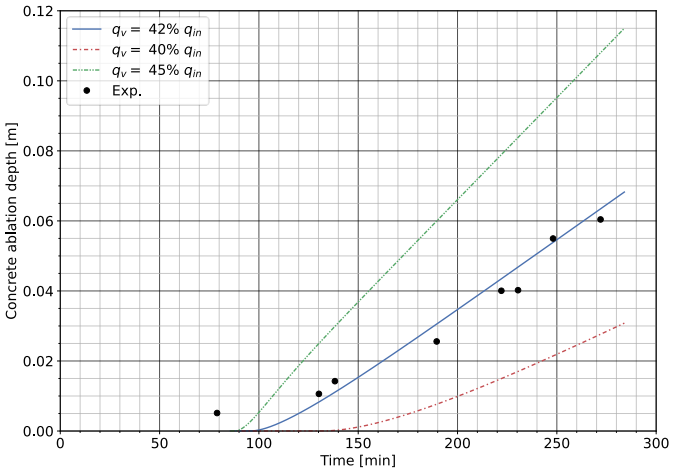

Figure 10 Concrete ablation calculated by solving eq. (12) – eq. (14) with different values of q_v.to analyze the effects of heat losses

Finally, having calculated both the concrete ablation depth and the thickness of the thermal layer using the values that fit the experimental result the most ($q_v = 0.42 \cdot q_{in}$) it is possible to confirm the validity of this assumption by calculating the temperature profile during the ablation phase at different concrete depths. The concrete temperatures during the pre-heating phase are the same as the ones shown in Fig. 6, whilst those of the ablation phase are calculated using eq. (3)[1]. The slight discontinuities of the curves between the pre-heating phase and the ablation phase are due to the limitations of the discretization scheme used to calculate the former. These results show a notable rise in the concrete temperature before the arrival of the ablation front. In other words, this indicates that the ablation speed is not fast enough to impede the propagation of a conduction-limited temperature front within the concrete. The curves show a general agreement with the tendencies of the experimental results, without matching exactly the time at which a certain concrete depth reaches the ablation temperature. Nevertheless, in view of the uncertainties induced by the heat losses, the agreement is rather acceptable.

[1] For these evaluations both z and δ are set to the results of the ablation calculations using $q_v = 0.42 q_{in}$ at each depth

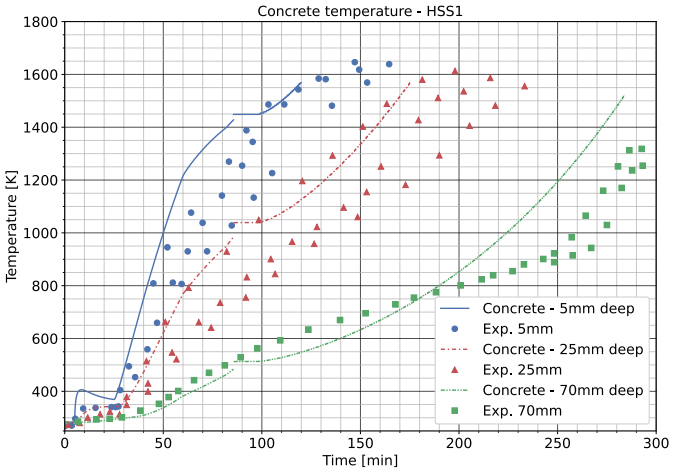

Figure 11 Concrete temperature for different depths as a function of time during both the pre-heat phase and the ablation phase

3. CONCLUSIONS

The objective of this work was to validate the model developed to evaluate whether specific configurations of post-solidification corium–concrete heat flux may still induce concrete ablation. This work was based on a comparison between the results of the model and the results of the HSS experiment, which aimed to study the interaction between a solid block heated volumetrically and concrete. From this work the following can be concluded:

- The HSS-1 main results are successfully reproduced, namely the concrete ablation rates and the temperature profiles as a function of concrete depth, within the limits of the simple model here developed. The results serve also to validates a key assumption of the model, which consists in considering that the evolution of temperature in the concrete can be described by a fourth-degree polynomial.
- The calculations are very sensitive to the assumptions made regarding the thermal losses. The analysis carried out in this work makes it possible to explain this behavior by the fact that, in these experiments, most of the injected power is dissipated through thermal losses.

The model developed can be thus used to evaluate the impact of the conduction-induced concrete ablation post corium solidification for reactor-scale MCCI calculations. Indeed, the surfaces of the final corium-concrete interfaces in reactor calculations are rather large, meaning that the applicability of the hypothesis of a one-dimensional configuration, such as the one described in the model, is sufficiently validated here.

NOMENCLATURE

$T_i[K]$	Temperature of the layer "i" where i = int for interface temperature between the upper and lower conductive corium crusts, fus for concrete fusion temperature, sat for saturation temperature of water, and 0 for initial concrete temperature respectively.
$\alpha\left[\frac{m^2}{s}\right]$	Thermal diffusivity calculated as $\frac{\lambda}{\rho \cdot c_p}$.
$t[s]$	Time.
$z\,[m]$	Position within the corium crust.

$e_i\ [m]$	Thickness of the layer "i" where i = "ME" for debris bed from Melt Ejection, "WI" for Water Ingression induced fractured corium crust, "sup" for upper conductive corium crust, and "inf" for total lower conductive corium crust.
$\delta\ [m]$	Thermal boundary layer.
$m''\left[\frac{kg}{m^2 s}\right]$	Concrete mass flux at ablation front.
$\Delta H\left[\frac{J}{kg}\right]$	Concrete ablation enthalpy (latent heat + sensible heat).
$\rho_i\left[\frac{kg}{m^3}\right]$	Density of the layer "i" where i = con for the concrete, and i = cr for the corium's crust.
$\lambda_i\left[\frac{W}{m \cdot k}\right]$	Thermal conductivity of the layer "i" where i = con for the concrete, and i = cr for the corium's crust.
$c_{p_i}\left[\frac{J}{\mathrm{kg\ K}}\right]$	Heat capacity of the layer "i" where i = con for the concrete, and i = cr for the corium's crust.
$q_{net}\left[\frac{kW}{m^2}\right]$	Heat flux from the corium to the concrete.
$q_v\left[\frac{MW}{m^3}\right]$	Volumetric decay heat.
$q_{in}\left[\frac{kW}{m^3}\right]$	Average induction power.

4. Conclusion

1.

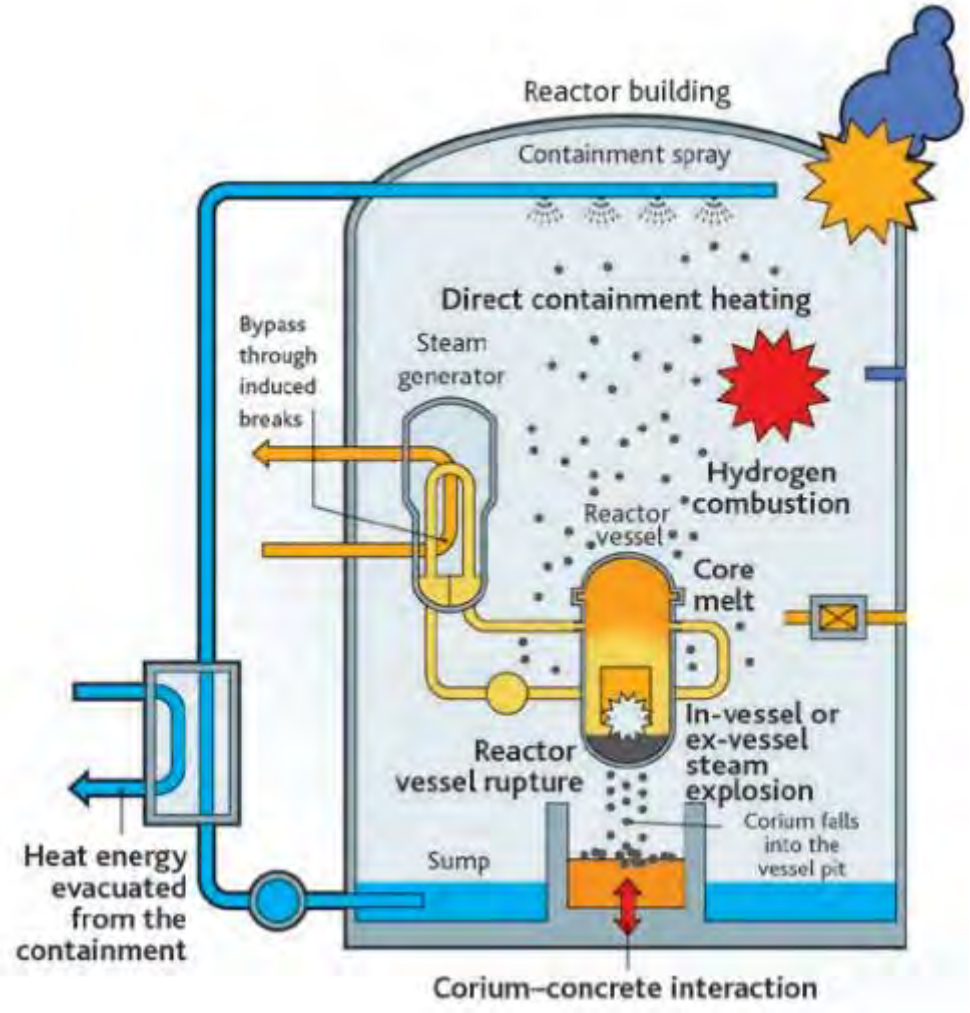
Introduction

Long-term MCCI configuration

Introduction

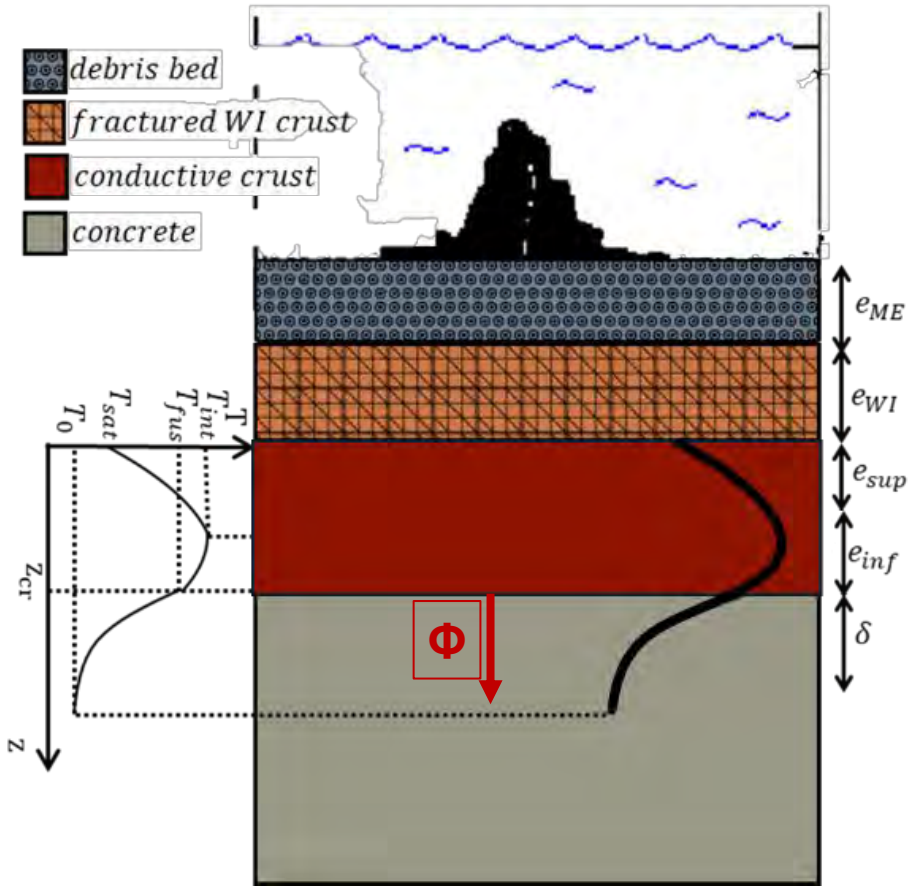
Frame of the study = severe accident with vessel failure

- Corium spread over the basemat of the reactor cavity.
- The residual power released by low-volatily fission products keeps the corium at a high temperature → concrete ablation by the corium
- Basemat melt-through should be avoided to limit fission product release outside the containment.
- Concrete ablation during molten core concrete interaction must be evaluated accurately to assess the risk of basemate melt-through.
- In case MCCI can be stopped before basemat melt-through, complex configuration with solidified corium in contact with concrete can be obtained.



Introduction

Corium post-solidification configuration



- Corium stabilization after long term MCCI is conditioned by the thermophysical properties of the corium, the accidental scenario, the chemical composition of the concrete basemat...
- Phenomena governing the phases of MCCI (dry and flooded) are highly non-linear and can lead to a vastly large array of stabilization conditions.
- In some cases, the analysis of the final configuration (i.e. once the corium is solidified) show that heat flux towards the concrete and the erosion rate remains non-zero.

Can the concrete accommodate the heat flux (Φ) coming from the corium crust? If not, how can post-solidification ablation be evaluated?

A model dealing with concrete ablation by a hot heat generating solid has been studied, modified and validated.

1D Transient Conduction Heat Transfer Modeling in Concrete

1D Transient Conduction Heat Transfer Modeling in Concrete

Main assumptions of the model

- Ablation of a solid by heating (q_{net}) with heat conduction in the solid.
- Quadratic temperature profile in the concrete due to heat conduction.
- Thickness of the thermal gradient (δ).
- End of ablation when m”=0 i.e. when the heat flux transferred to the solid is equal to the heat flux that can be transferred by conduction inside the concrete.

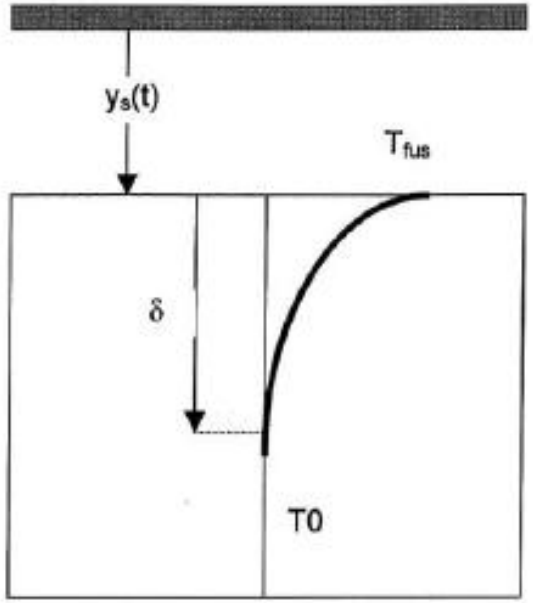

Fig. 1. Modeling of the temperature profile.

$$\frac{T - T_0}{T_{fus} - T_0} = \left(1 - \frac{y - y_s}{\delta}\right)^2$$

$$\frac{d\delta}{dt} = \frac{6 \cdot \alpha}{\delta} - \frac{3 \cdot m''}{\rho} \qquad m'' \cdot \Delta H = q_{net} - \frac{2 \cdot \lambda}{\delta}(T_{fus} - T_0)$$

[1]

1D Transient Conduction Heat Transfer Modeling in Concrete

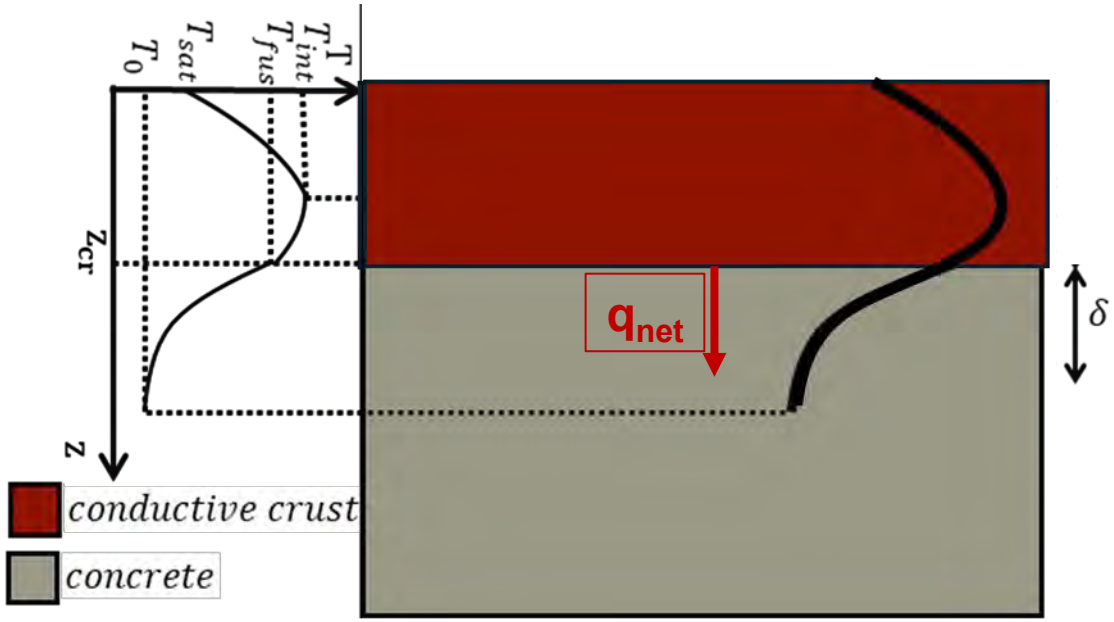
- Model adapted to MCCI to address concrete ablation by a solid corium (crust) generating heat.
- Evolution of the model → the degree of the polynomial has been increased (2 → 4) to improve the accuracy of the model (a new equation for δ has been derived).

concrete

$$\frac{T - T_0}{T_{fus} - T_0} = \left(1 - \frac{z - z_{cr}}{\delta}\right)^4$$

$$\frac{d\delta}{d_t} = \frac{20\alpha}{\delta} - \frac{5m''}{\rho}$$

$$m'' \, \Delta H = q_{net} - \frac{4\lambda_{con}}{\delta}\left(T_{fus} - T_0\right)$$



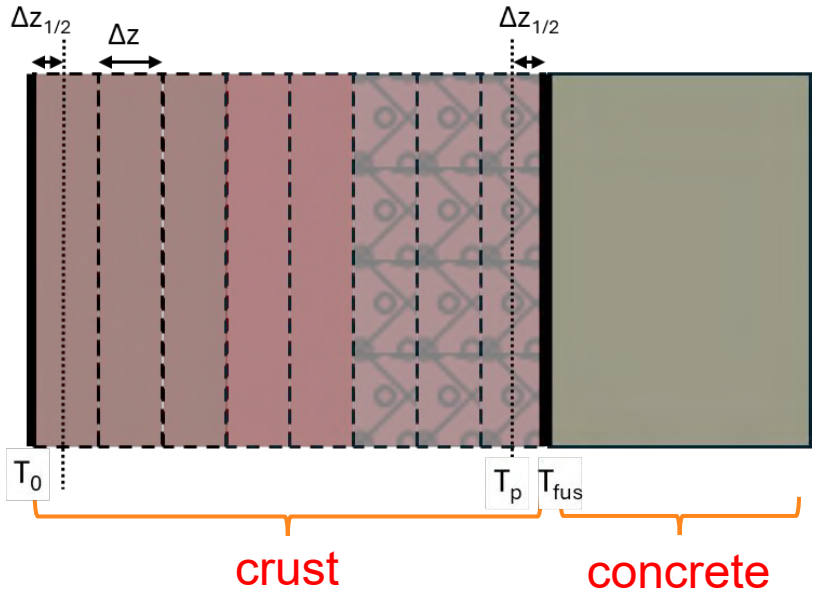
crust

$$\rho_{cr} c_{p_{cr}} \frac{\partial T}{\partial t} = \lambda_{cr} \frac{\partial^2 T}{\partial z^2} + q_v$$ + Temperature profile in the crust to calculate q_{net}

1D Transient Conduction Heat Transfer Modeling in Concrete

- The temperature profile in the crust with residual power is calculated to estimate the heat flux between the crust and the concrete.
- A classical spatial discretization is used + explicit approach for the transient term

Spatial discretization of the corium's crust



Discretization

$$\rho_{cr} c_{p_{cr}} \frac{\partial T}{\partial t} = \lambda_{cr} \frac{\partial^2 T}{\partial z^2} + q_v$$

$$T_i^{n+1} = T_i^n + \frac{\lambda_{cr}\,\Delta t}{\rho_{cr} c_{p_{cr}} \Delta z^2}\left(T_{i+1}^n - 2T_i^n + T_{i-1}^n\right) + \frac{q_v\,\Delta t}{\rho_{cr} c_{p_{cr}}}$$

$$T_1^{n+1} = T_i^n + \frac{\lambda_{cr}\,\Delta t}{\rho_{cr} c_{p_{cr}} \Delta z^2}\left(T_2^n - 3T_i^n + 2T_0\right) + \frac{q_v\,\Delta t}{\rho_{cr} c_{p_{cr}}}$$

$$T_p^{n+1} = T_p^n + \frac{\lambda_{cr}\,\Delta t}{\rho_{cr} c_{p_{cr}} \Delta z^2}\left(2T_{fus} - 3T_p^n + T_{p-1}\right) + \frac{q_v\,\Delta t}{\rho_{cr} c_{p_{cr}}}$$

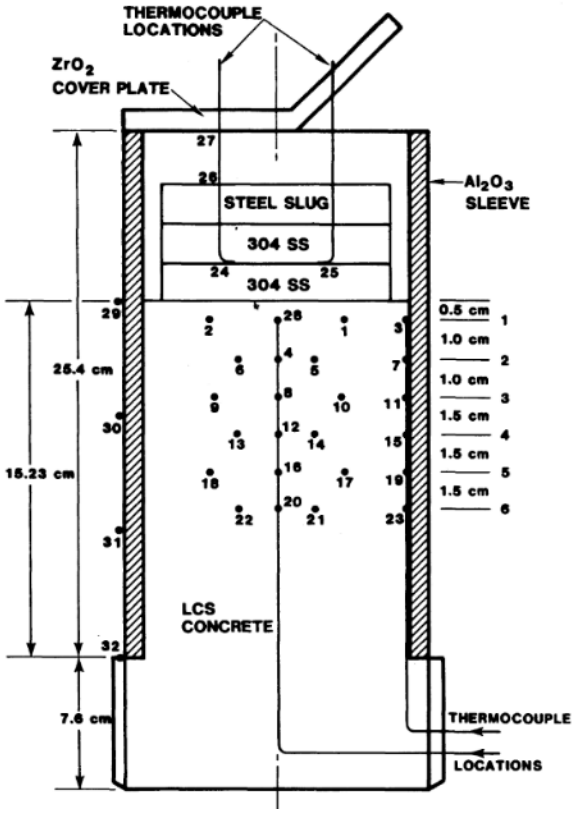
Validation with Hot Solid Block - Concrete Interaction Experiment (HSS tests)

Validation with Hot Solid Block - Concrete Interaction Experiment

DESIGN & TECHNOLOGY BRANCH

HSS-1

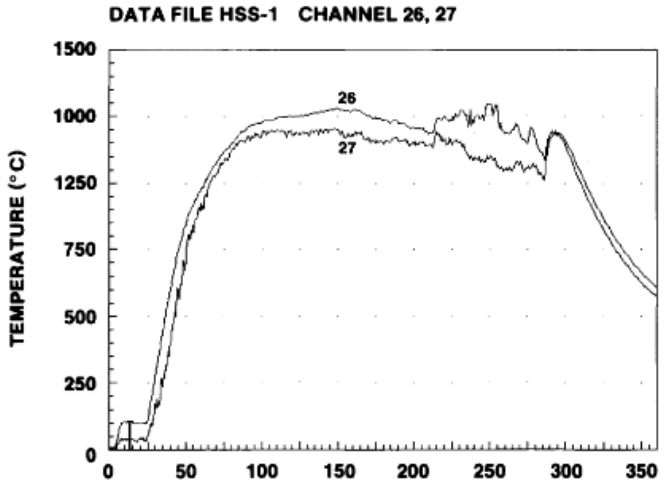


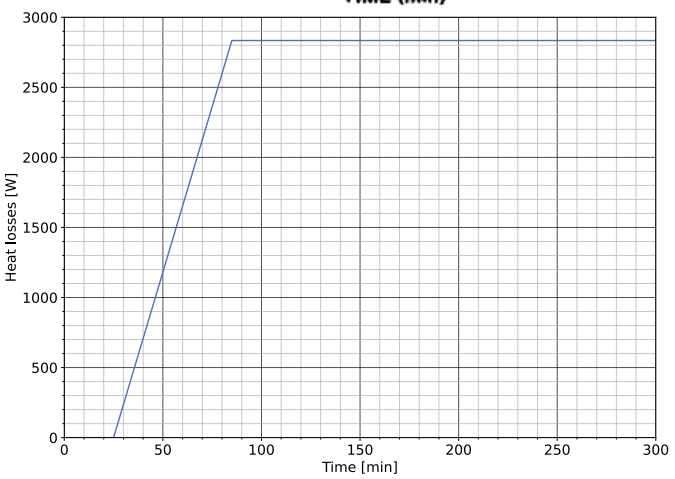
[2]

Tests	HSS-1
Block's composition	Stainless Steel 304
Dimensions [cm]	14 x 8
Block's Mass [kg]	9
Initial Temperature [K]	491
Avg. Power [kW] (q_{in})	3.2
Avg. Losses [W/cm²]	4.9
Concrete type	Limestone Common Sand (LCS)

Pre-heating phase

- Inductive heating used to pre-heat the steel slug to reach 1400°C.
- The pre-heating phase ends around 80 minutes once the temperature of the steel ingot is high enough to start concrete ablation. Power is then slightly reduced to maintain ablation without melting the steel ingot.
- Power losses from the induction coils are considered minor before the 25th minute and are calculated linearly between the 25th and 85th minute and then continues until the 300th minute (end of the heating period) so that the integral matches the reported data (4.9 W/cm²).





Validation with Hot Solid Block - Concrete Interaction Experiment

Pre-heating phase

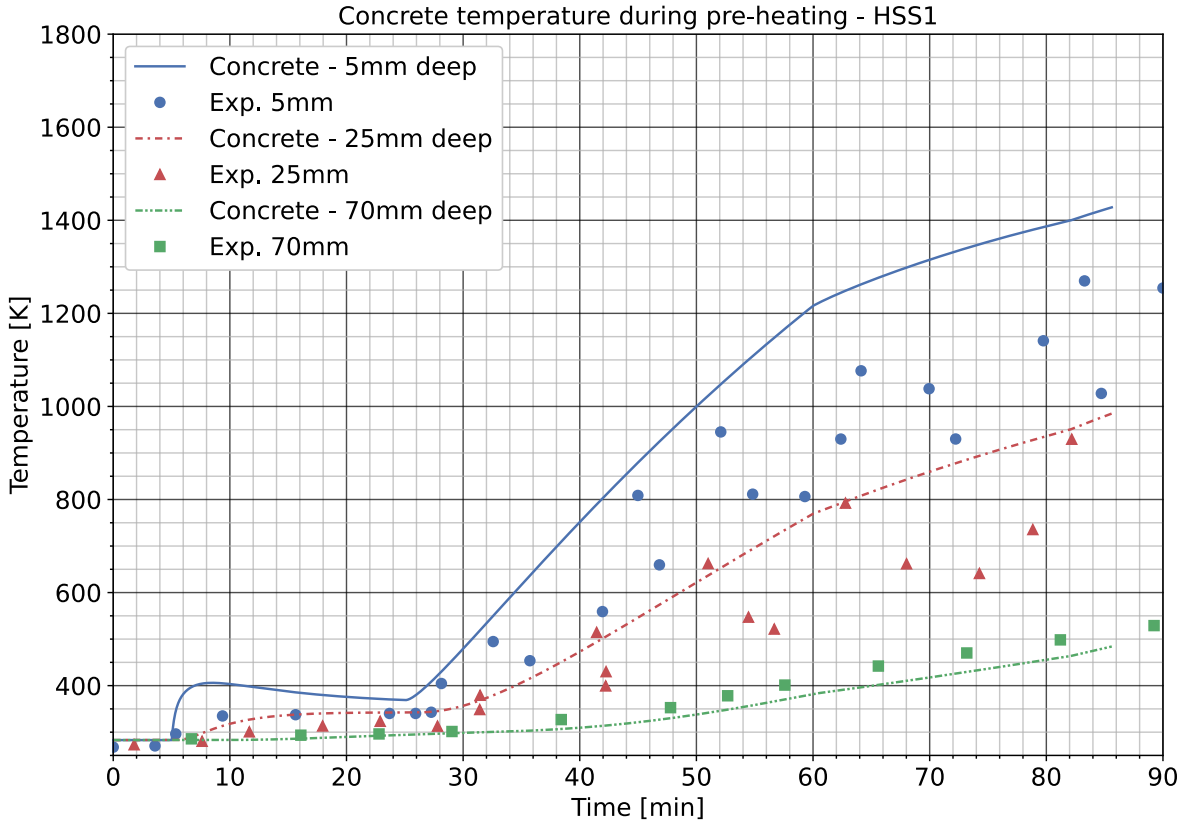
- To initialize the ablation phase, the pre-heating phase must be modeled to obtain the initial conditions and an initial thermal boundary layer thickness in the concrete.

- Similar discretization scheme is used to model the crust and the concrete layer:

$$\rho_{cr} c_{p_{cr}} \frac{\partial T}{\partial t} = \lambda_{cr} \frac{\partial^2 T}{\partial z^2} + q_v - q_{th}$$

$$\rho_{con} c_{p_{con}} \frac{\partial T}{\partial t} = \lambda_{con} \frac{\partial^2 T}{\partial z^2}$$

- Results of the heat conduction calculations for the pre-heating phase match with sufficient degree of satisfaction the experimental results. Overestimation of the temperature close to the steel surface can be attributed to limitations of 1D modeling.



Validation with Hot Solid Block - Concrete Interaction Experiment

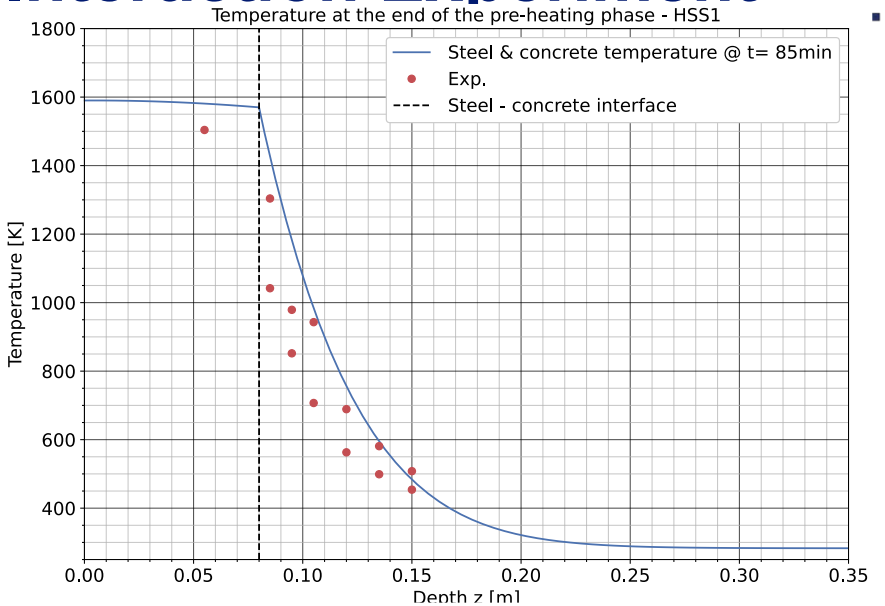
Pre-heating phase

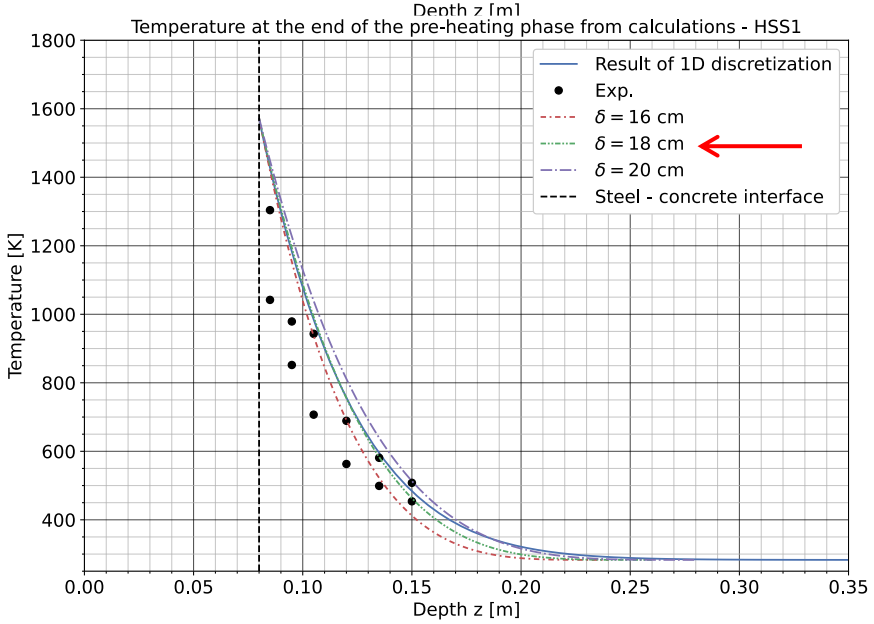
- Pre-heating phase heat conduction calculations show good agreement with concrete temperature measurements at the time when the temperature at the steel-concrete interface is estimated to reach the concrete ablation temperature (~85 min).

- To model the ablation phase, the initial thermal boundary layer's thickness is determined by identifying the value for which the temperature best matches the results of pre-heating calculations:

  δ= 18 cm

- A small variation of this parameter shows a limited impact on the final temperature profile : degree-4 polynomial is a good fit to describe the temperature of the corium crust.





Validation with Hot Solid Block - Concrete Interaction Experiment

DESIGN & TECHNOLOGY BRANCH

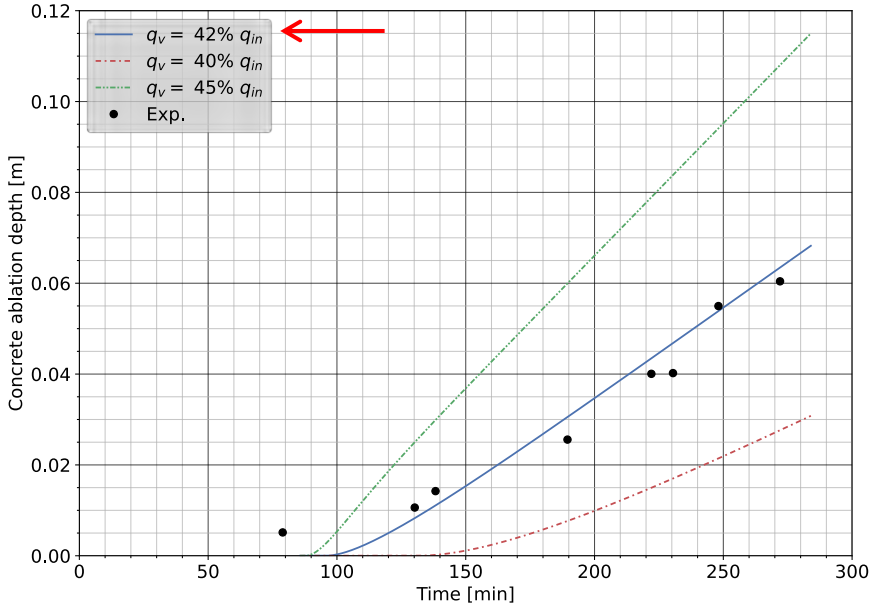
Concrete ablation during heating phase

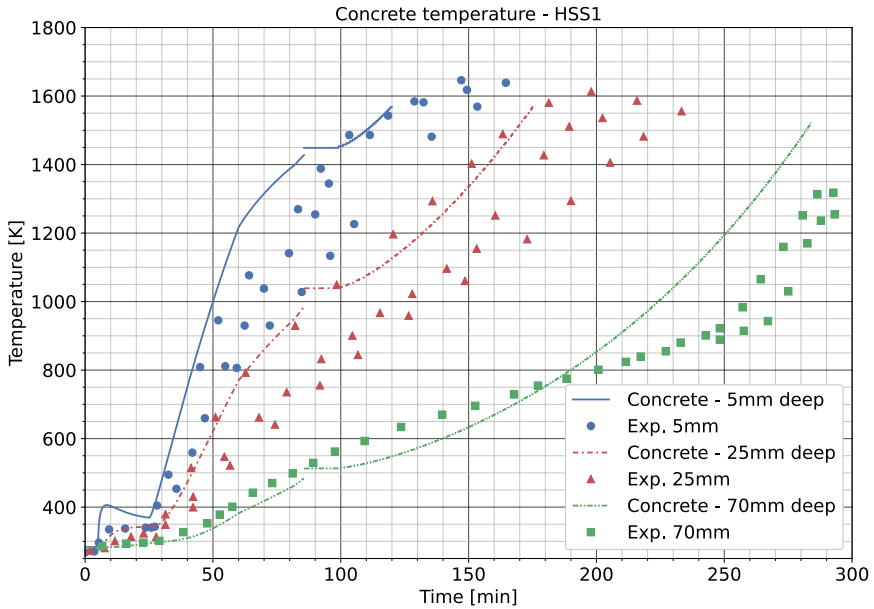
- Power losses during the ablation phase (~2.8 kW) are comparable to the power input (~3.2 kW) → sensitivity study shows a significant impact of the power input with respect to the concrete ablation compared to the experimental measurements. A value of $\mathbf{q_v = 42\%\ q_{in}}$ is retained.

- The validity of the retained power introduced to the steel ingot is verified by calculating the temperature profile during the ablation phase at different concrete depths.

- The concrete temperatures during the ablation phase reproduce properly the tendencies measured during the experiments (the discontinuities of the curves between the pre-heating phase and the ablation phase are due to the limitations of the discretization scheme used to calculate the former).

- These results show a notable rise in the concrete temperature before the arrival of the ablation front, i.e. the ablation speed is not fast enough to impede the propagation of a conduction-limited temperature front within the concrete.





4.

Conclusion

Conclusion

- A 1D model was developed to evaluate whether specific configurations of post-solidification corium–concrete heat flux may still induce concrete ablation

- The HSS-1 main results are successfully reproduced, namely the concrete ablation rates and the temperature profiles as a function of concrete depth, within the limits of the simple model here developed.

The model developed can be thus used to evaluate the impact of the conduction-induced concrete ablation post corium solidification for reactor-scale MCCI calculations (the surfaces of the final corium-concrete interfaces in reactor calculations are rather large, hence the applicability of a one-dimensional configuration is sufficiently validated).

Thank you

ABSTRACT

Having an anti-oxidation property is one of the pivotal roles of the silicon carbide (SiC) fuel matrix for safety during air ingress accident which is the worst scenario among Beyond Design Basis Accidents (BDBAs) in Generation-IV reactors such as high-temperature gas-cooled reactors (HTGRs). At high temperature oxidation, SiC has two different modes: passive or active oxidation mode. Passivated SiC contributes to nuclear fuel safety, preventing unpreferable chemical reaction between the fuel matrix and oxidation gas, reducing risks of fuel damage and radioactive release from the embedded TRISO fuel particles. Depending on oxygen partial pressures, however, active mode may be dominant that causes a huge degradation of mass while accelerating volatile SiO and CO gases release from the surface. Given the importance of oxidation resistance in the fuel matrix, investigating oxidation behavior, phase changes, morphology characterization, and microstructure observation at high temperatures are valuable for predicting the fuel behavior during the accidents and evaluating the reactor safety. We report that passive mode is dominant up to 1400 ℃ in air, which is the accidental scenario; at the same temperature with 1 ppm oxygen/argon mixed gases, however, active mode occurs. The result indicates that with very few amounts of oxygen existing in the highly purified helium coolant may cause corrosion of the fuel matrix at higher temperatures as burn-up progresses. The study suggests the corrosion during normal service operation has potential concerns rather than high-temperature oxidation during the accidents. This knowledge is valuable for determining the operational range of the reactor cores and improving the system design as feedback for future demonstration of innovative nuclear reactors.

1. INTRODUCTION

Having an anti-corrosion property is one of the pivotal roles of the nuclear fuel matrices for safety during normal operation service and even accidental phenomena; preventing unpreferable chemical reaction between the fuel matrix and primary coolant ensures material integrity, reducing risks of fuel damage and radioactive release. Given the importance of anti-corrosion property in the fuel matrix, investigating potential interaction between the fuel matrix and coolant, phase changes, morphology characterization and microstructure observation at high temperatures offer insightful knowledges that would allow us to predict the fuel behavior in the core and estimate the lifetime of fuel assembly for the following maintenance or replacement.

In the case of sleeveless fuel design of high-temperature gas-cooled reactors (HTGRs) [1], each fuel compact directly contacts with helium coolant gas at high temperatures, thus heat transfer from the fuel

compact to helium gas would be significantly improved which results in higher power density operation compared with the current fuel assembly with graphite sleeve in entire axial direction. This innovative fuel design benefits economic and reactor safety such as simplified fuel structure and higher power outputs with lower fuel temperatures. Many attractive features, however, the solid-gas interaction between the fuel compact and helium gas may pose a potential concern of the fuel matrix degradation in the worst scenario [2]. SiC fuel matrix exhibits an excellent oxidation resistance to air ingress accident at high temperatures [3]; on the contrary very few amounts of oxygen existing in the highly purified helium coolant may cause corrosion with a huge degradation of mass (active oxidation) [4]. Which means that the active oxidation mode may jeopardize the fuel matrix in a long term during the normal operation period, reducing lifetime of the fuel assembly. This corrosion may be a crucial issue for the fuel safety, which requires any prevention technology or limitations on the reactor operational conditions.

In an effort to mitigate or partially control the corrosion, this work investigates the oxidation behavior of well-passivated SiC substrate in an active oxidation condition at 1400 C with 1 ppm argon/oxygen mixed gas flow. We assume that silica oxide layer may inhibit the following corrosion in the active condition. The measurement aims to evaluate how the pre-passivation works on the passive/active transition that suggests a boundary of limit for nuclear engineering use. The present study, however, reports that this very simple surface modification of SiC cannot fully prevent the active oxidation mode. Through morphology observation and characterization of the test specimens, we find intricate silica microstructures and nanowires products near the active oxidation spot. In this paper, we report their characterization and propose a dynamic model that offers potential mechanisms how these silica structures are formed. Also, we discuss the application of this technology for the nuclear fuel matrix.

The outline of this paper is provided as follows; in the Experimental details section, the experimental procedures, materials and methods are shown; Results and discussion section briefly summarize all the findings and discuss the model with measured data; finally, the conclusive remarks are presented.

2. EXPERIMENTAL DETAILS

The SiC oxidation tests were conducted within a vertically oriented alumina tube furnace (Thermogravimetry Differential Thermal Analysis (TG-DTA), Bruker, model TG-DTA2020SA). The substrates employed for pre-passivation consisted of SiC spheres with an approximate diameter of 4 mm (Sato Tekko Co. Ltd.). Prior to oxidation, the substrates underwent ultrasonic cleaning in acetone for 10 minutes, followed by air drying, and were subsequently arranged in alumina dishes inside the tube furnace. The mass variation during the oxidation process was continuously monitored at a sampling interval of 1.0 second with a precision of 0.1 μg, utilizing an electronic balance integrated into the furnace.

The SiC substrates were subjected to high-temperature oxidation to ensure effective passivation. The substrates were gradually heated to 1000 ℃ at a controlled rate of 20 ℃/min and maintained at this temperature for either 1 or 2 hours in static air. This process induced passive oxidation, resulting in the formation of a silica layer on the substrate surface. The duration of oxidation determined the oxide layer thickness, reaching approximately 0.8 μm after 1 hour and 1.5 μm after 2 hours. Following confirmation of complete oxide coverage, the substrates were reintroduced into the tube furnace.

Subsequently, the furnace chamber was evacuated to a pressure below 1.0 Pa over a duration of 1 hour using a mechanical rotary pump. To minimize residual oxygen levels, ultra-high-purity argon gas (purity: 99.9995%) was introduced at a controlled flow rate of 50 mL/min. The furnace was then heated to 1400 ℃ at a ramp rate of 20 ℃/min under continuous argon flow. Upon reaching 1400 ℃, the argon supply was discontinued, and a gas mixture comprising 1 ppm oxygen in argon (JAPAN FINE PRODUCTS) was introduced at the same flow rate for 30 minutes. Based on our previous research, exposure to 1400 ℃ in a 1 ppm oxygen environment induces active oxidation and SiO gas evaporation [2], which provides the targeted corrosion environment. Finally, the furnace was gradually cooled to ambient temperature while maintaining an argon atmosphere.

Following the oxidation tests, the morphology and microstructure observation of the SiC substrates were examined using a field emission scanning electron microscope (FE-SEM; S-4800, Hitachi High-Tech Corporation, Japan) and transmission electron microscopy (TEM; FE-TEM, JEM-2010F, JEOL, Japan). The TEM system was further equipped with an energy-dispersive spectrometer (EDS, Genesis APEX2, EDAX, USA) for compositional analysis.

3. RESULTS AND DISCUSSION

3.1. Localized active oxidation after one-hour passivation: silica nanowires formation

SiC substrates exposed to 1 ppm O_2/argon at 1400 ℃ developed distinct circular patterns. A scanning electron microscopy (SEM) image (Figure 1(a)) of the SiC top surface verifies the formation of these patterns. Zone 1 (Figure 1(b)) corresponds to exposed SiC, where the SiO_2 layer formed during passivation is nearly absent. In contrast, Zone 2 (Figure 1(c)) exhibits a substantial presence of elongated fiber-like structures (nanowires). The occurrence of exposed SiC in Zone 1 indicates active oxidation, which resulted in the degradation of the oxide film and subsequent corrosion of the SiC. This oxidation process follows Eq. 1, leading to the generation of SiO gas. Further confirmation of active oxidation and material degradation was obtained through thermogravimetric analysis.

$$\mathrm{SiC} + \mathrm{O_2} \rightarrow \mathrm{SiO\,(g)} + \mathrm{CO\,(g)} \qquad (Eq.1)$$

Localized eruptions resulting from interfacial reactions between the SiO_2 film and the underlying SiC substrate [5] can significantly enhance SiO gas production (Equation 2). As the oxygen partial pressure declines, a critical threshold is reached at which SiO and CO gases readily form at the interface, governing the transition from passive to active oxidation [6]. This transition is characterized by the degradation of the protective SiO_2 layer, leading to the formation of pits at the boundary between exposed SiC and the remaining oxide film [7]. These localized corrosion sites play a crucial role in supplying SiO gas for nanowire synthesis.

$$\mathrm{SiC} + \mathrm{2SiO_2} \rightarrow \mathrm{3SiO\,(g)} + \mathrm{CO\,(g)} \qquad (Eq.2)$$

Under specific conditions, the volatile SiO gas can migrate to other regions, particularly those with slightly lower temperatures or higher oxygen partial pressures. We propose that SiO gas released from the corrosion sites diffuses outward to Zones 2, facilitating nanowire growth.

A substantial quantity of nanowires was observed on the substrate within Zone 2. SEM images of the synthesized nanowires are presented in Figure 1 (d), illustrating a uniform diameter distribution. The nanowires exhibit a relatively straight morphology, with an average diameter of 63±18 nm and lengths

extending to tens of micrometers, featuring exceptionally clean surfaces. Most of the nanowires appear extremely long and randomly oriented. The nanowires exhibit uniform diameters and smooth surfaces, with a distinct nanoparticle encapsulated within a shell at the nanowire tip. The pronounced contrast difference between the shell and the nanoparticle suggests a variation in elemental composition. The nanoparticle is generally spherical and enclosed by a relatively thick amorphous layer, resulting in a total diameter of 130–170 nm. The relationship between the nanowire diameter and the nanoparticle diameter aligns well with an empirical equation describing silicon nanowires synthesized via SiO evaporation combined with the vapor-liquid-solid (VLS) mechanism [8].

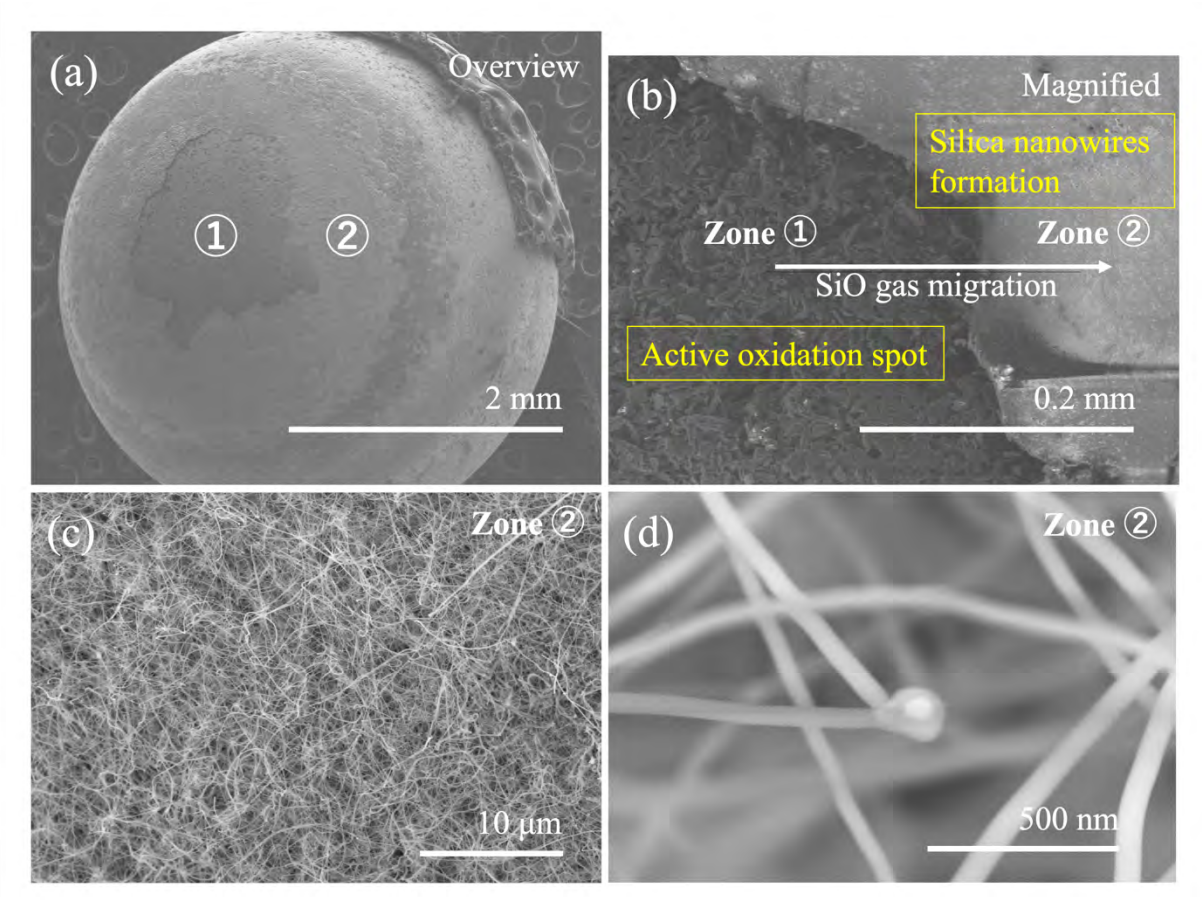

Figure 1. FE-SEM images of SiC substrate (pre-passivated for 1 hour) after oxidation at 1400 ℃ for 30 min. (a) Low-magnification top-view image showing three distinct zones. (b) Boundary between the exposed SiC area without a SiO_2 film (Zone 1) and the silica nanowires area (Zone 2). (c) Typical nanowires synthesized in Zone 2. (d) Nanowires view in higher magnification.

A typical nanowire morphology, including its associated nanoparticle, is further illustrated in the TEM image (Figure 2(a) and (b)), with corresponding EDS spectra provided onset. The EDS analysis reveals that the nanowire consists exclusively of Si and O, while the nanoparticle comprises Si, Mo, Rh, W, and Pt, with Mo and Si being the predominant elements. The detected Cu signal originates from the TEM sample mesh, while the presence of Rh, W, and Pt is attributed to evaporation from the heater inside the furnace. Notably, Mo is detected exclusively within the nanoparticles and is absent in the nanowires.

The presence of nanoparticles at the tips of the nanowires strongly suggests that the silica nanowires formed via a vapor-liquid-solid (VLS) growth mechanism [9]. This process involves the formation of a liquid

catalyst, the nucleation and growth of eutectic alloy droplets containing nanowire components, and subsequent nanowire growth driven by supersaturation within the liquid droplets. Given that the synthesis temperature in this study is significantly lower than the melting point of Mo (2900 K), the formation of a liquid catalyst containing Mo requires further explanation. Based on the EDS results, the small amount of Si detected in the nanoparticle likely plays a key role in lowering the melting point of Mo [10], thereby facilitating the formation of a liquid catalyst. Additionally, nanoparticles generally exhibit lower melting points compared to their bulk counterparts [11], further supporting the possibility of liquid-phase catalyst formation under the given experimental conditions.

In this study the Si-Mo alloy is likely the primary catalyst, given that $MoSi_2$ is commonly used as a sintering additive for bulk SiC fabrication [12]. To the best of our knowledge, based on an extensive literature review, Mo has not been previously reported as a catalyst for nanowire growth. The findings of this study demonstrate that Si-Mo alloy nanoparticles can serve as a viable catalyst for nanowire growth via the VLS mechanism.

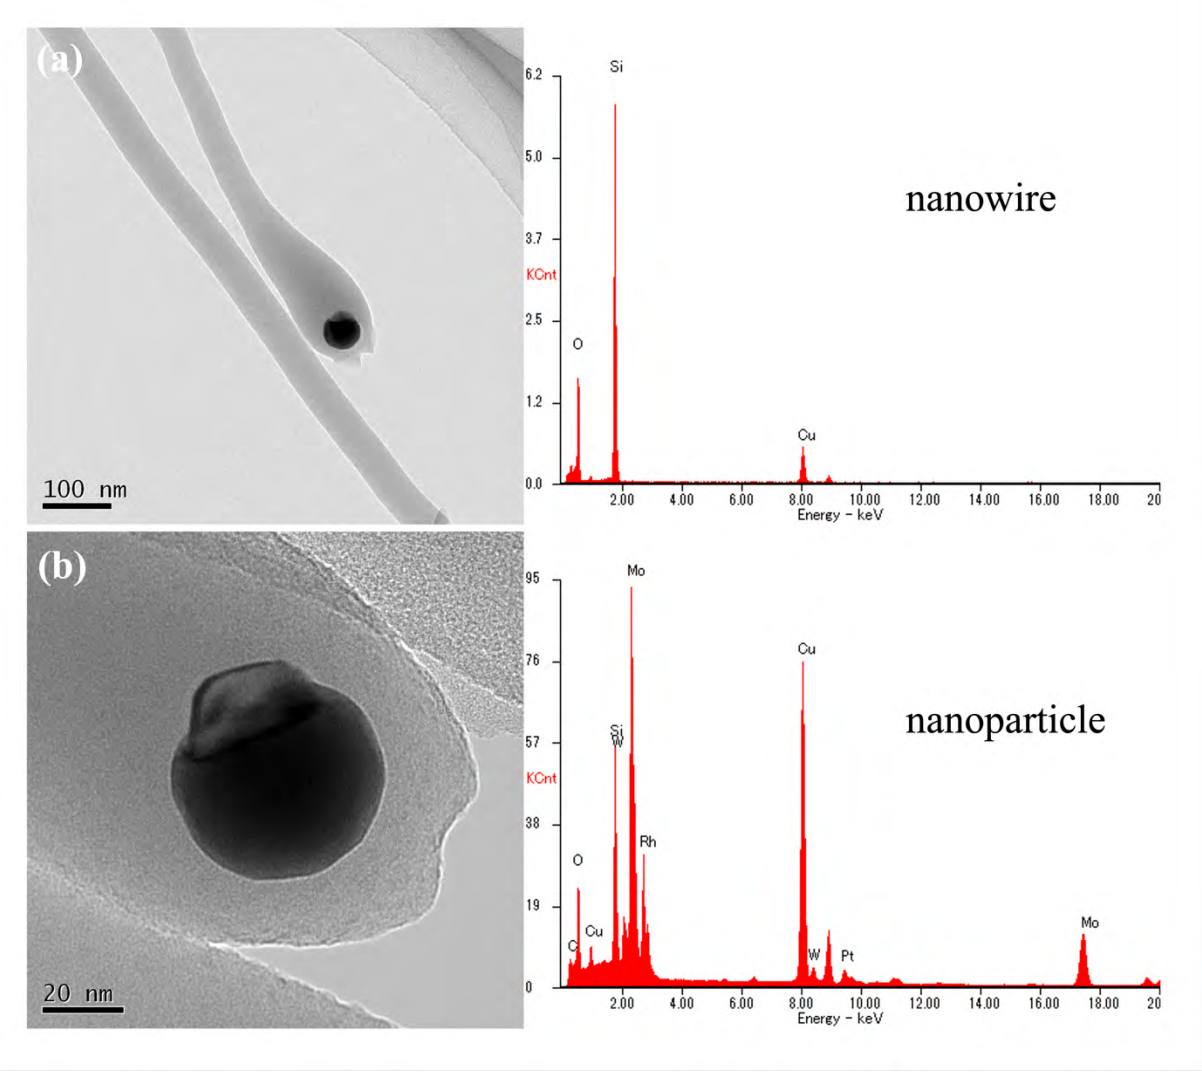

Figure 2. (a) (b) TEM image of a typical nanowire with a nanoparticle encapsulated (dark region) at the nanowire with EDS spectra of the nanowire and nanoparticle (inset), indicating that the nanowire is

composed of Si and O (the Cu signal comes from the TEM grids). The Si-rich stoichiometry also implies the presence of Si in the nanoparticle.

The presence of the SiO_2 film is a critical factor in significantly enhancing nucleation and promoting the development of one-dimensional nanostructures. The nucleation of nanoparticles is governed by the decomposition of oxide vapor species at specific temperatures. Concurrently, the system reaches equilibrium through the reaction described in Equation 3, further supporting the growth of nanowires.

$$2SiO \rightarrow Si + SiO_2 \qquad (Eq.3)$$

This decomposition process led to the precipitation of silicon nanoparticles, which serve as the nuclei for Si-Mo alloy nanoparticles, encapsulated by a silicon oxide shell, as observed. The influence of the oxide boat on nanowire synthesis has been previously confirmed [13]. Initially, dense SiO vapor condenses near the Si-Mo nuclei, forming deposits. Subsequently, these nuclei clusters act as reservoirs, effectively absorbing additional SiO vapor. As more SiO vapor is absorbed, nanowires grow preferentially along a specific orientation, facilitating rapid elongation.
Finally, the formation of an outer SiO_2 layer may result from the oxidation of residual SiO vapor and/or the introduction of 1 ppm O_2/argon gas. The supersaturation of Si and O induces phase separation [14] between Si and SiO_2, a process driven by the cooling effect of the gas flow within the furnace.

3.2. Localized active oxidation after two-hour passivation: silica whiskers formation

To highlight the critical role of oxide control during pre-passivation, a detailed microstructural characterization of a sample subjected to a 2-hour passivation process is presented as a reference. At the top region (Zone 1, Figure 3 (a)) of the spherical sample, a similar circular pattern on the test sample's surface after 2 hours of passivation, followed by exposure to an active oxidation environment of 1 ppm O_2/argon at 1400 °C. That corresponds to the region where active oxidation of SiC occurs, leading to the release of SiO gas.

Zone 1 serves as the primary source of SiO gas, which is subsequently transported to Zone 2, where more intricate silica structures develop. In Zone 2, a substantial accumulation of silica microstructures is observed, including worm-like (Figure 3 (b)), needle-like (Figure 3 (c) and (d)), and flower-like whiskers (Figure 3 (e)) as shown with SEM-EDS images onset. These whiskers exhibit diameters ranging from 1.0 to 1.4 μm and lengths extending up to 10 μm. The anisotropic growth of these structures is likely attributed to variations in surface energy along different crystallographic planes of SiO_2. The needle-like whiskers in Zone 2 possess a high aspect ratio, characterized by relatively small diameters and elongated lengths.

Although the synthesis mechanisms for silica micro- and nanostructures share similarities, both being driven by the chemical pump effect of SiC vapor supply during the active oxidation of pre-passivated SiC, the final products exhibit notable differences.

The worm-like structures, on the other hand, appear more irregular in shape but share similar growth mechanisms with the needle-like whiskers. The flower-like structures likely represent agglomerations of whiskers that have grown from a single nucleation point and spread out radially.

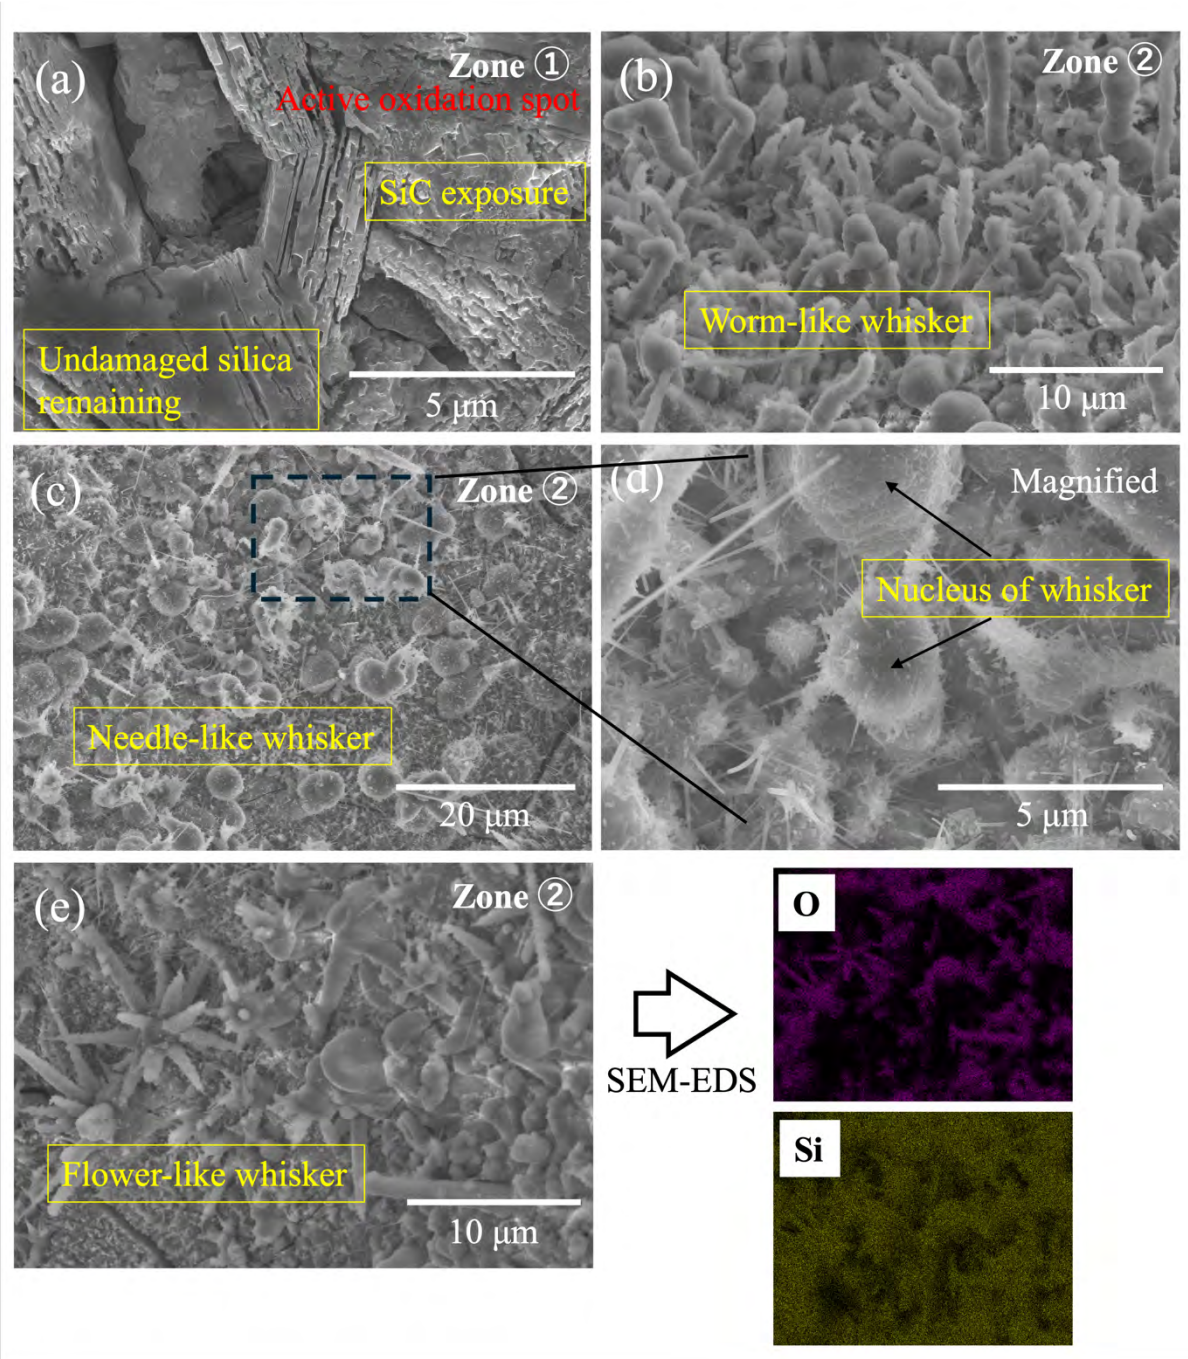

Figure 3. FE-SEM images of SiC sample (pre-passivated for 2 hours) after oxidation at 1400 °C. (a) Active oxidation spot in Zone 1. (b) Worm-like silica whisker in Zone 2. (c) Needle-like silica whisker in Zone 2 with magnified (d). (e) Flower-like silica whisker in Zone 2 with SEM-EDS results (inset).

The growth of silica whiskers and other structures observed in these zones can be explained by the vapor-liquid-solid (VLS) mechanism or, more specifically in this case, the vapor-solid (VS) mechanism, since no liquid phase is involved in the oxidation of SiC. The VS mechanism involves the following steps: SiO gas produced in Zone 1 migrates to Zone 2, where it encounters a slightly different environment, such as higher local oxygen concentrations or lower temperatures. This creates the conditions necessary for SiO_2 to nucleate on the surface of the SiC substrate (Nucleation). Once nucleation occurs, the whiskers grow via

anisotropic deposition of SiO_2. The growth is primarily governed by the diffusion of SiO gas to the growth front. The needle-like shape of the whiskers suggests that the diffusion process is anisotropic, with growth favoring one crystallographic direction more than others (Growth). In some areas, multiple whiskers nucleate close to each other and grow in different directions. These agglomerations can result in flower-like structures, as observed in Zone 2 (Coalescence).

The formation of these silica whiskers has significant implications for high-temperature applications, such as nuclear reactors, where SiC is used as a structural material or as a fuel cladding material. The oxidation behavior of SiC in environments containing small amounts of oxygen, such as in accident scenarios in gas-cooled reactors, is a critical concern for material integrity and safety. The formation of silica whiskers could contribute to the formation of a protective SiO_2 layer that prevents further oxidation of the SiC substrate. The whiskers could act as a diffusion barrier, slowing the transport of oxygen to the underlying SiC and reducing the rate of oxidation. The growth of whiskers, especially in the form of needle-like structures, however, could lead to a reduction in mechanical integrity, particularly if the whiskers act as stress concentrators or if they grow in such a way that they weaken the material. Further studies would be needed to assess the mechanical properties of SiC after whisker formation.

As previously discussed, excessive pre-passivation hinders the formation of silica nanowires, favoring the development of more complex whisker-like microstructures instead. We propose that, in the case of the 2-hour pre-passivation, the resultant oxide layer became too thick to effectively support the vapor-liquid-solid (VLS) mechanism essential for nanowire synthesis.

In summary, the growth mechanism of silica nanowires is proposed to be governed by several phenomena and enhanced by three key factors (active oxidation, VLS growth and passivated oxide), all influenced by the chemical pump effect. First, a SiOx cluster is anchored on the SiC substrate through active oxidation, consistent with the nucleation dynamics observed on metal silicides. The transport of SiO gas from the active oxidation region to the outer circular patterns can be described by the chemical pump effect, where localized SiO gas production creates a concentration gradient that drives its migration to other regions. This gas-phase transport of SiO is essential for the formation of complex nanostructures. Additionally, the catalytic activity of SiOx clusters likely aids in the oxide-assisted growth of silica nanowires. For the formation of these silica micro-nano structures, however, oxide thickness plays most important role. Depending on the pre-passivation thickness, either silica nanowires or whiskers are formed. As seen from Figure 4, at the initial stage of the reaction, severe mass loss occurs (active mode); then total mass gain reaction follows, resulting in SiO gas transportation to silica production areas. Apparently, the mass change is positive during their synthesis but both local active mode and passive mode occur simultaneously. Although the present pre-passivation treatment cannot completely prevent active mode, these silica microstructures synthesis largely contribute to enhance passive mode.

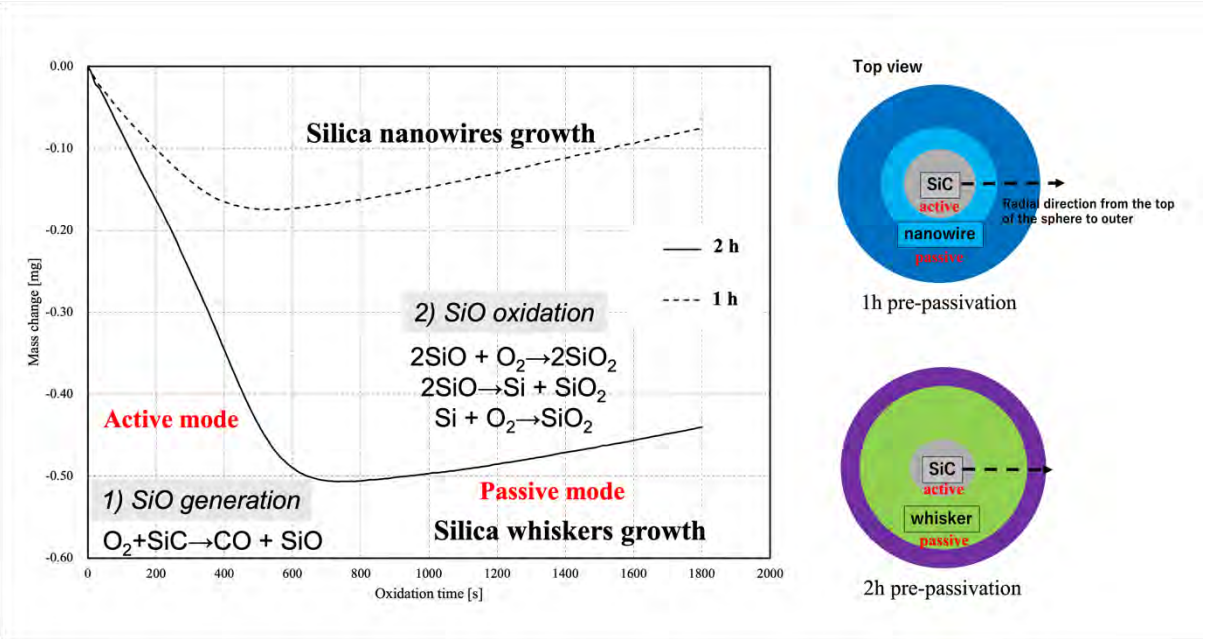

Figure 4. Measurement of mass changes of the samples (1-hour/2-hour pre-passivation) during the silica nanowire/whisker synthesis with simplified illustration of each sample.

As highlighted in this study, the pre-passivation time significantly impacts microstructure development. An optimal oxide thickness promotes nanowire growth, while excessive oxide thickness hinders the participation of nanoparticles within the SiC in the VLS mechanism, thereby impeding nanowire formation (Figure 5). Nanowire growth can also proceed in strongly oxidative conditions, contributing to silica nanowire synthesis. Concurrently, the oxidation of the nanowire walls (from SiOx to SiO_2) serves to passivate their surfaces [15]. At steady-state, equilibrium is reached between further SiOx deposition and its oxidation, resulting in a constant nanowire diameter, as observed in both SEM and TEM images. The uniformity of the nanowires indicates a stable growth environment, with minimal fluctuations in local gas concentrations or temperature gradients.

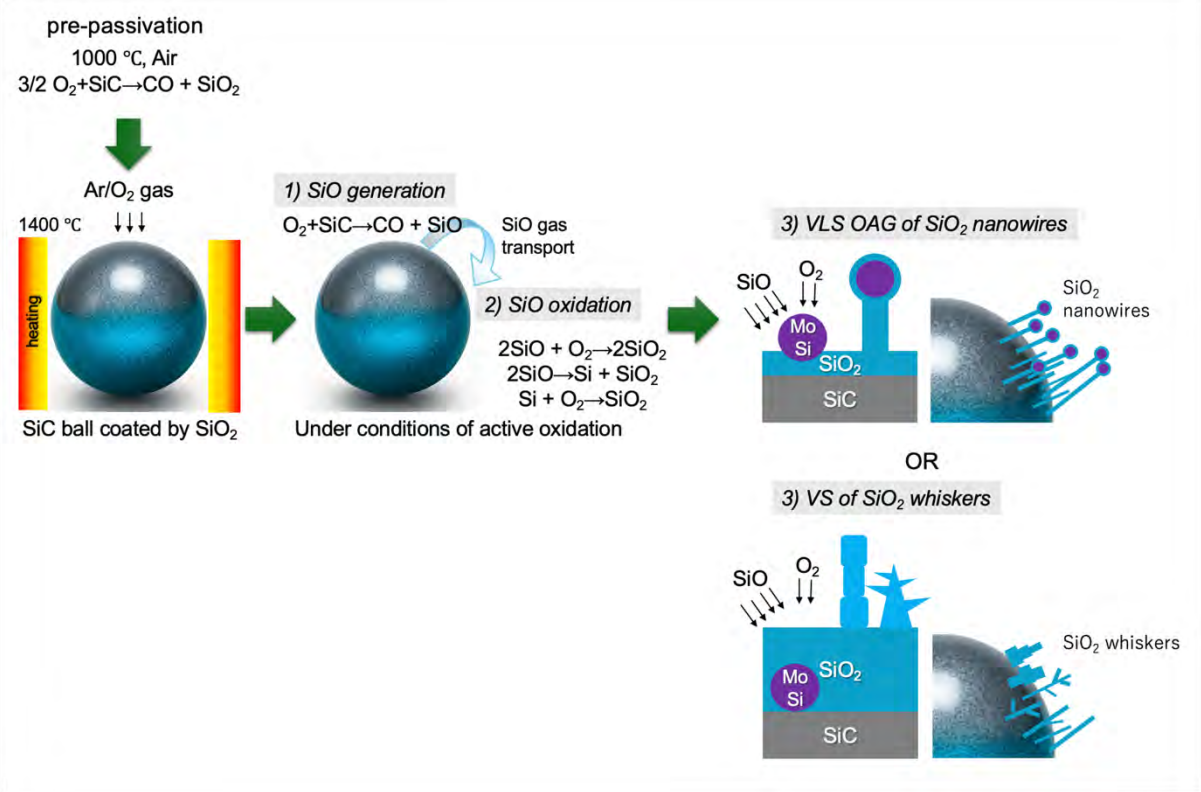

Figure 5. The proposed mechanisms on silica nanowires/whiskers growth associated with OAG.

3. CONCLUSIONS

To minimize the risk of nuclear fuel damage and prevent unacceptable corrosion during use, we investigate the effects of pre-passivation on the active oxidation of SiC at high temperatures in an extremely low-oxygen gas flow. While active oxidation still occurs locally, pre-passivation significantly mitigates long-term mass degradation. This treatment has a proven effect on active oxidation and simultaneously induces the formation of various intricate silica microstructures on SiC due to the chemical pump effect. During this process, the thickness of the passivated oxide layer plays a crucial role in determining the synthesis, growth, and morphology of silica nanowires or whiskers. In particular, the growth of nanowires is initiated by metal nanoparticles such as Mo, making the selection of sintering additives in SiC manufacturing a critical consideration. We propose synthesis mechanisms for these silica microstructures, which provide a useful model for evaluating nuclear fuel behavior.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Why molten-salt source-term physics is different

Molten salt reactors change the source-term picture in five qualitative ways. Each motivates an element of the framework presented in this deck.

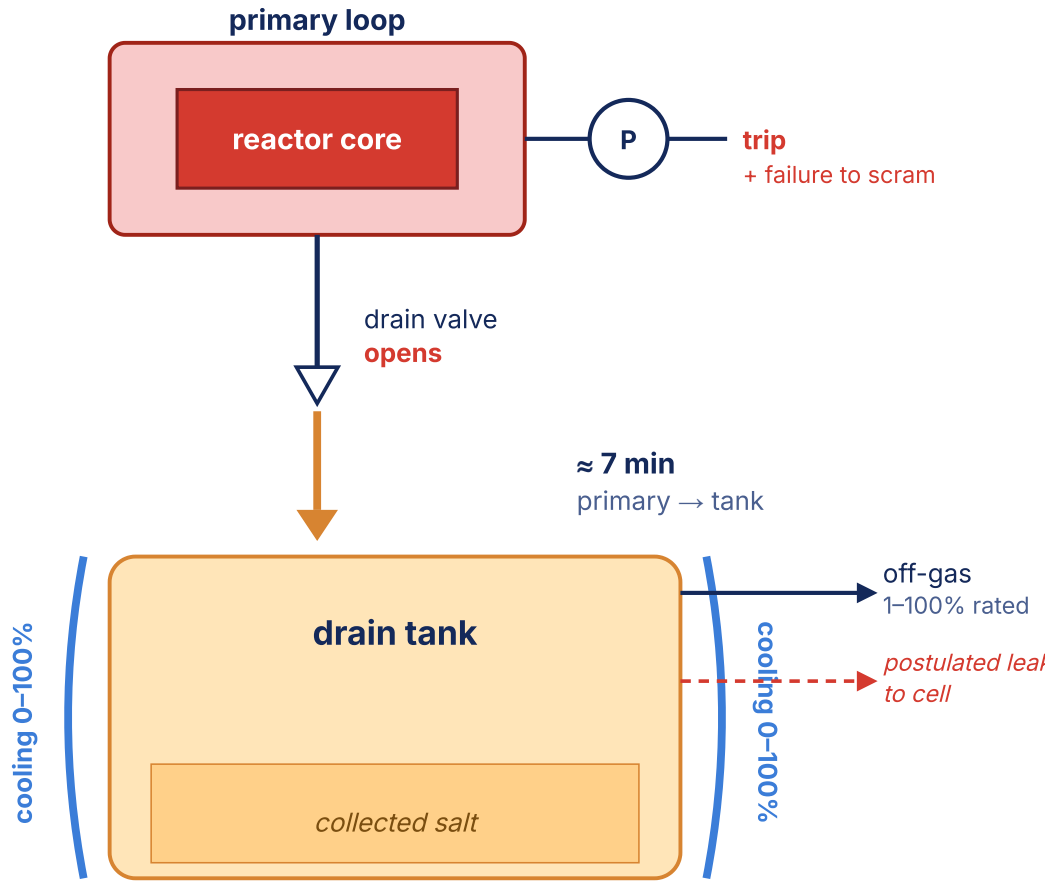
- **Fuel is the coolant.** Soluble FPs (Cs, I, Sr) stay in the salt; noble metals (Mo, Ru, Pd) precipitate; noble gases (Xe, Kr) sparge out continuously.
- **The carrier salt is itself multi-component.** BeF_2 is more volatile than LiF; the liquid composition drifts; partial pressures must be computed per constituent. In MSBR fuel salt at 1000 °C, $P_{sat,BeF_2} \approx 1100$ Pa while $P_{sat,UF_4} \approx 39$ Pa.
- **Particulate nucleation happens in the liquid.** Classical aerosol PBE only carries vapor-phase particulates — here we need a sectional PBE in both phases.
- **Freezing is normal operation.** Freeze plugs and drain-tank crusts trap dissolved FPs; melt-back releases them.
- **Tritium dominates the dose path?** It is generated in the salt, transports through structures by diffusion + trapping, and needs Soret thermophoresis in the liquid.

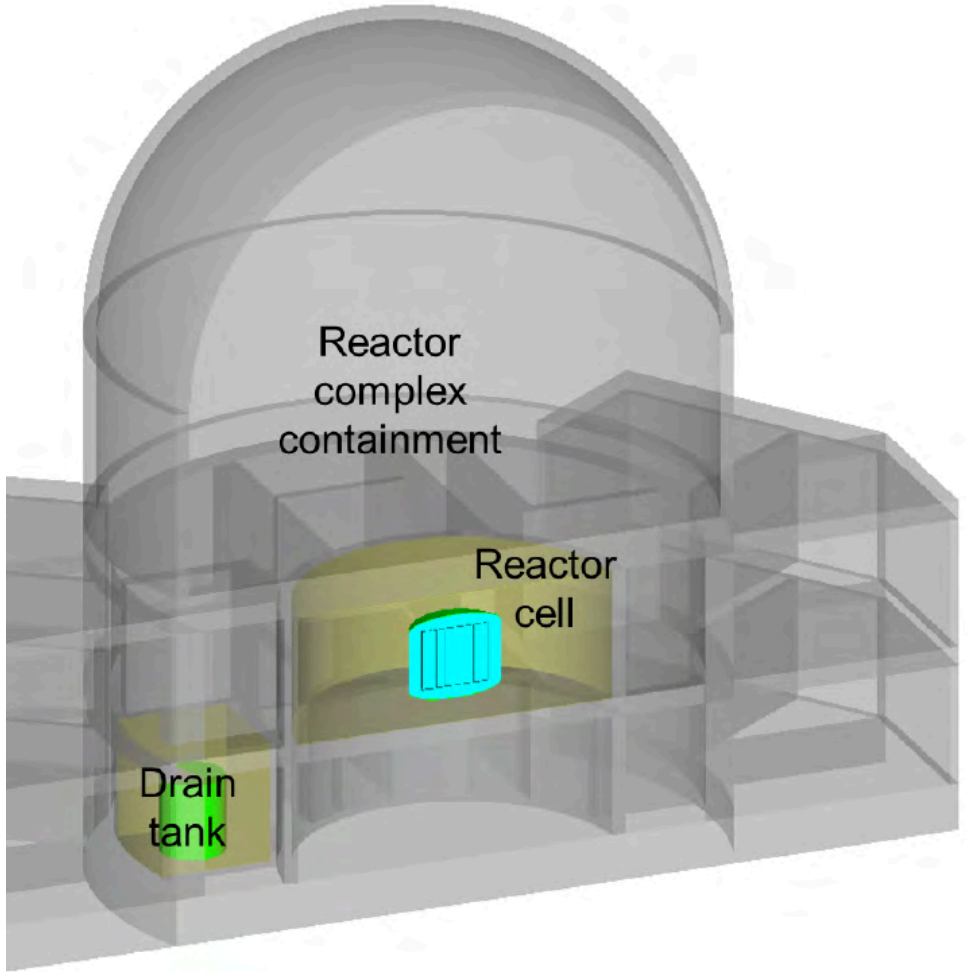
PART 1 — CURRENT CAPABILITY

MELCOR for the MSBR fuel cycle

Scenario — emergency drain to a cooled drain tank

Pump trip with failure to insert shutdown rods initiates an emergency salt drain from the primary loop to the drain tank, completing in approximately 7 minutes.





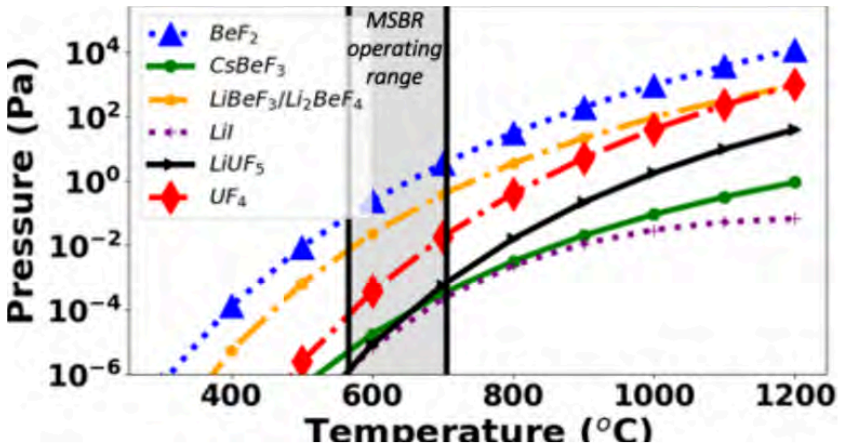
Reactor complex containment, reactor cell, drain tank. After Robertson et al. ORNL-4541 (1971); model build per Duchnowski et al., SAND2024-07835PE.

Species partial pressures decide release

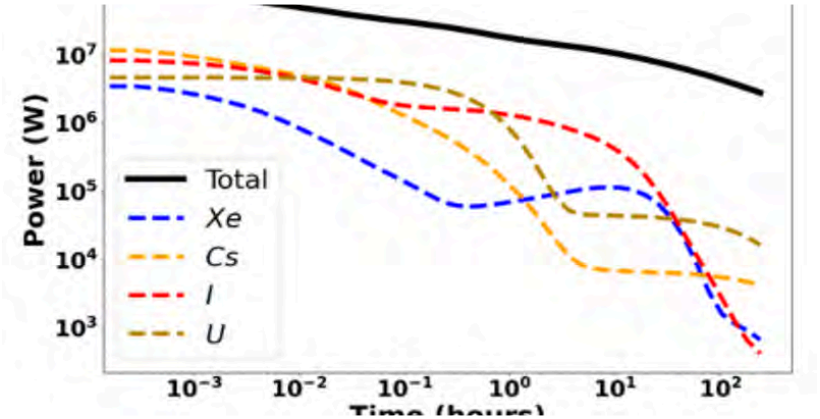
The vapor-pressure curve determines the volatility hierarchy at the salt-cover-gas interface. Decay heat by class sets the thermal driver for that hierarchy as the transient evolves.

- **BeF_2** — volatile carrier; P_{sat} ≈ 1100 Pa at 1000 °C; dominates airborne mass once released.
- **UF_4** — fuel; P_{sat} ≈ 39 Pa at 1000 °C; non-negligible at drain-tank temperatures.
- **$CsBeF_3$, LiI** — dominant Cs and I compounds; sub-pascal in the MSBR operating window. Direct vaporization is not the release pathway for these species.

> BeF_2 and UF_4 are assigned dedicated radionuclide classes. Aggregation into generic carrier or fuel classes would obscure the per-constituent partial pressure that governs release.



P_{sat}(T) for the species classes tracked; MSBR operating range shaded.

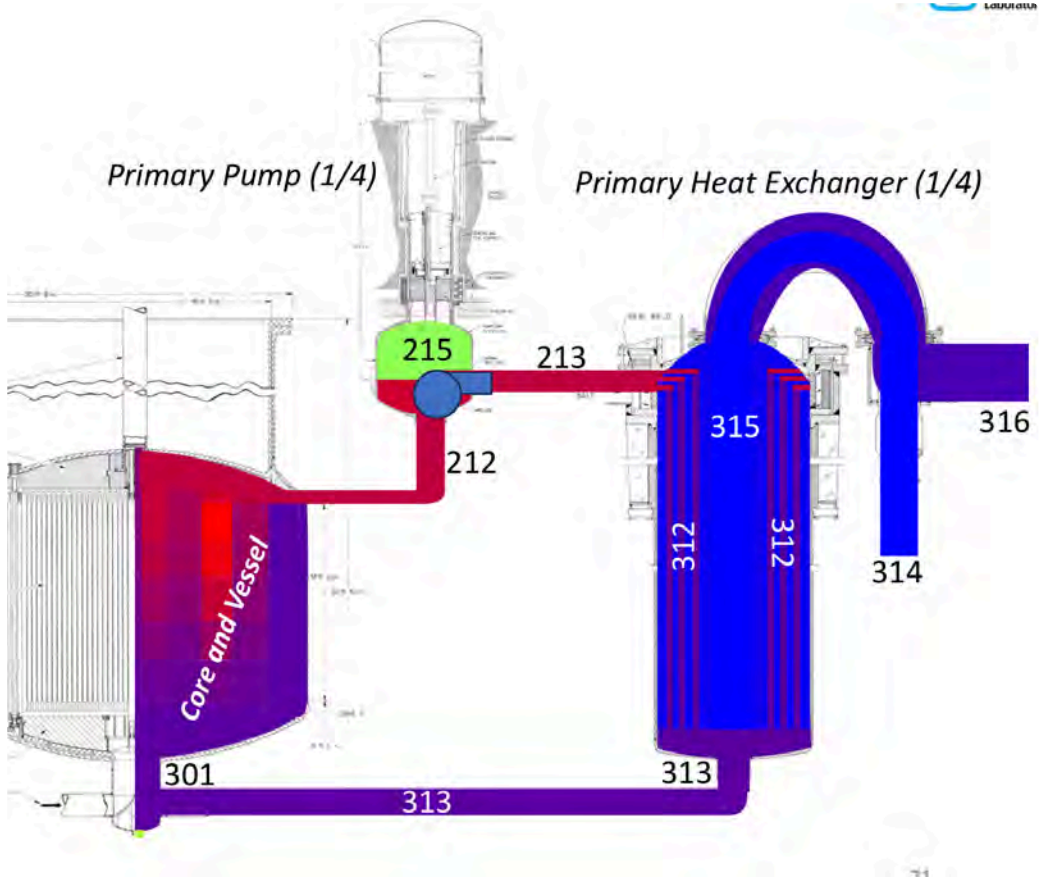


Decay heat by class (Xe, Cs, I, U) and total — Xe dominates early; Cs takes over after ~hours.

MELCOR nodalization — primary loop

- Four identical loops — one shown. CV-212, CV-213, CV-312, CV-313 are a single loop; all loops recombine at CV-301.
- Each hot leg carries a pump with a pump bowl — the bowls are the off-gas source.
- Primary heat exchangers are shell-and-tube; the secondary side is a **boundary condition**, not a coupled secondary CV network.
- Core (left) is the same node grid that receives the SCALE-averaged power map — seven axial levels, eight radial channels per level, plus inlet/upper plenum.

> Boundary-condition coupling on the secondary side isolates the primary-side response; secondary-loop thermal hydraulics are not resolved in this scenario.



Core/vessel → pump bowl (215) → hot leg (213) → PHX (312) → return (313) → CV-301. After Duchnowski et al., SAND2024-07835PE.

Drain tank and off-gas system

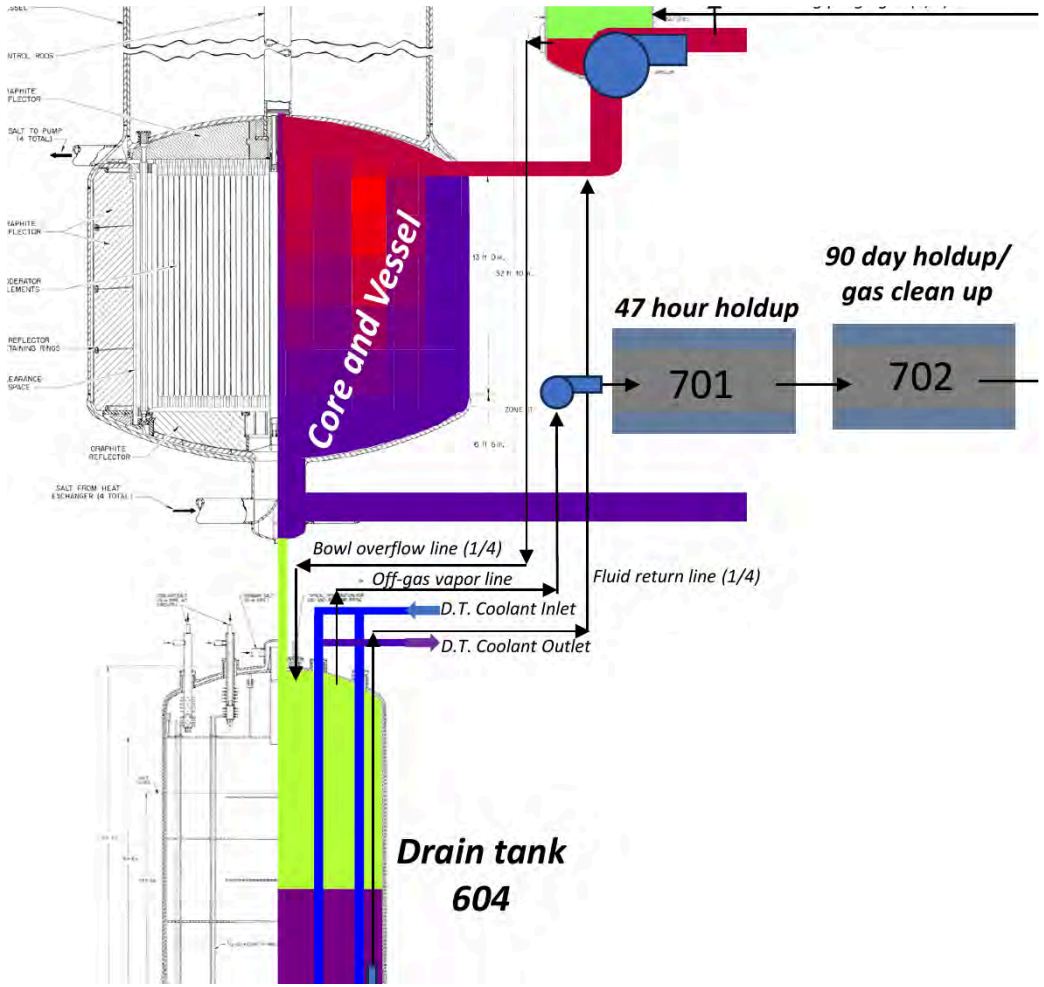
Off-gas loop

- **47-hour holdup tank** — sized for Xe decay.
- **90-day holdup / gas clean-up** — long-lived isotopes.

Drain tank (CV-604)

- 2-hour holdup of off-gases from the pump bowls.
- Filled from pump-bowl overflow, returned to the primary loop — closed circuit by design.
- Active cooling system handles decay heat from the drained salt.

The drain tank must dissipate approximately 30 MW of residual decay heat over an extended period while limiting carrier vaporization to the off-gas path.

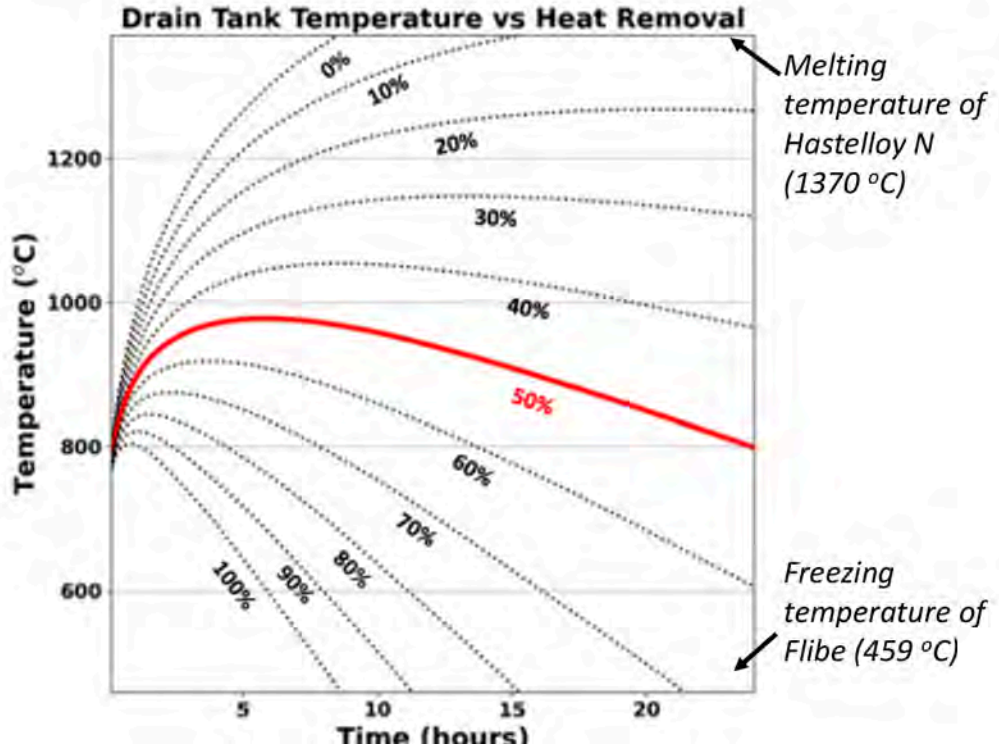


Pump bowl → off-gas vapor line → drain tank (604) → 47-h holdup (701) → 90-d clean-up (702).

Drain-tank thermal response — cooling-effectiveness sweep

- Active cooling capacity is swept from 0% (passive only) to 100% (18 MW nominal).
- At the 50% baseline, peak liquid temperature is below 1000 °C, well under the Hastelloy N solidus (1370 °C).
- At 0% active cooling, passive radiation and conduction from the tank walls bound the temperature response.
- The FLiBe freezing temperature (459 °C) bounds the 100% case from below; over-cooling can produce wall solidification.

> The sweep operates entirely within the FLiBe freezing temperature and the Hastelloy N solidus. The two-population solidification closures apply throughout.

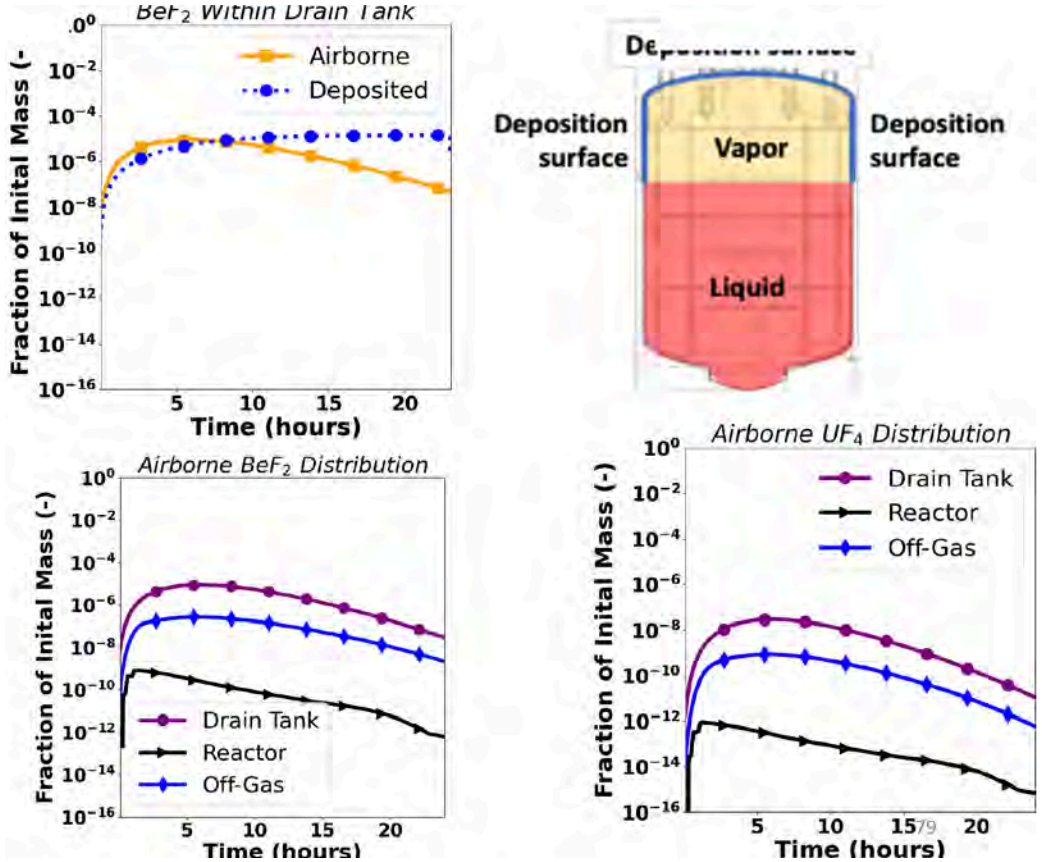


Drain-tank temperature family for active-cooling capacity 0–100%; 50% baseline highlighted (red). Hastelloy N melting and FLiBe freezing bracket the window.

Carrier release — airborne BeF_2 and UF_4

- BeF_2 and UF_4 are continuously released from the drained inventory at rates determined by their partial pressure at the instantaneous liquid temperature.
- Airborne species condense onto the pool surface and deposit on the cooled drain-tank walls via the standard evaporation/deposition closures.
- The majority of airborne inventory remains within the drain tank; off-gas inventory is approximately an order of magnitude lower.

Under baseline cooling, airborne BeF_2 peaks at approximately 10^{-4} of initial inventory; airborne UF_4 peaks at approximately 10^{-7}. The three-decade separation reflects the ratio of partial pressures.



BeF_2 within the drain tank — airborne vs deposited (top-left); deposition surfaces on the drain-tank dome and walls (top-right); airborne BeF_2 and UF_4 distribution by region (bottom).

ORIGEN coupling on vs off — release pathways change

The same drain transient is run with and without ORIGEN-driven transmutation between radionuclide classes.

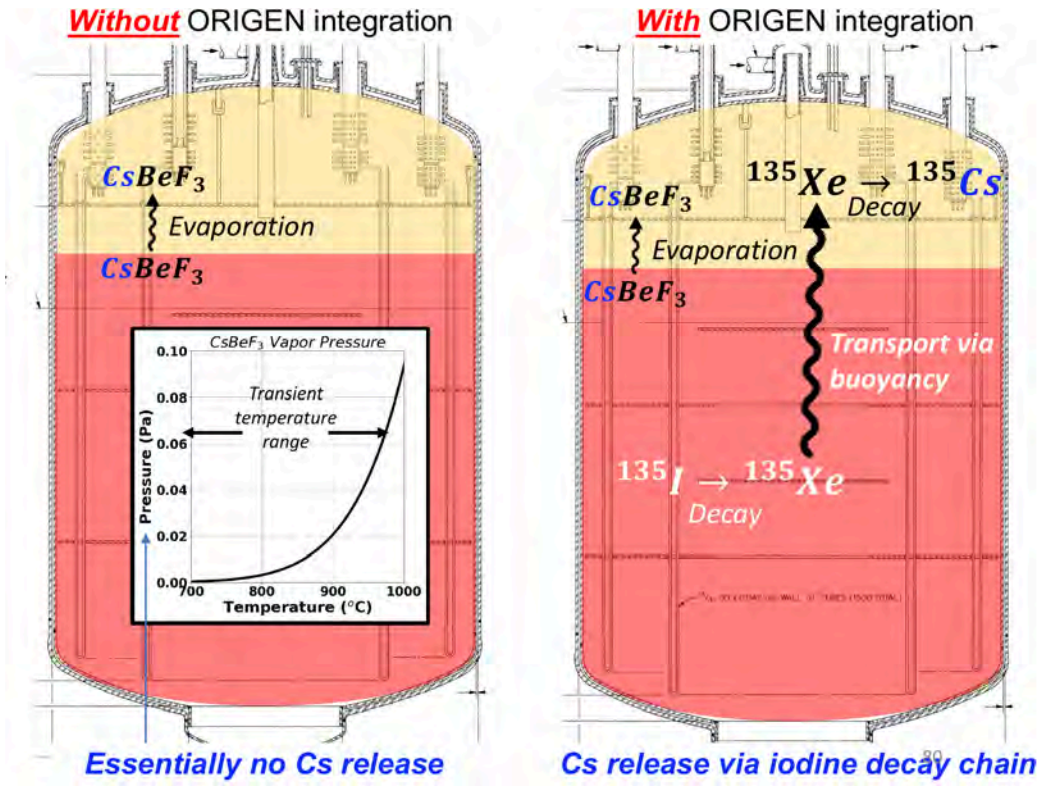
Without ORIGEN coupling

- Elements grouped into classes (solubility, isolating non-soluble corrosion products).
- MELCOR transports the classes — advection and evaporation only.
- $CsBeF_3$ partial pressure is sub-pascal → **essentially no Cs release**.

With ORIGEN coupling

- Transmutation transfers mass between classes during the transient.
- $^{135}I \rightarrow {}^{135}Xe \rightarrow {}^{135}Cs$ — the iodine decay chain produces Cs in regions that initially contained no Cs.
- Cs reaches the off-gas via the Xe transport route, not via salt vaporization.

The closures are identical in both runs. The Cs source-term result derives from inter-class transmutation operating on a registered channel, not from MSR-specific source-term logic.



Left: $CsBeF_3$ evaporation only — essentially no Cs release. Right: I → Xe → Cs decay chain produces Cs that the Xe-class transport then carries.

PART 2 — NEW CAPABILITIES

Capabilities we are adding for MSR (and other) systems

CAPABILITY 1

Particulates in Liquid and Vapor Phases

Sectional PBE on two carrier phases

The sectional PBE state is (bin × species × carrier × volume). The same closure registry serves the liquid-borne distribution and the vapor-borne distribution.

SECTIONAL BALANCE PER (BIN **K**, SPECIES **S**, CARRIER **C**)

$$\partial n_{k,s,c}/\partial t = J^{nuc}_{k,s,c} + G^{cond}_{k,s,c} + A^{agg}_{k,s,c} - B^{brk}_{k,s,c} - D^{dep}_{k,s,c} + T^{L\leftrightarrow V}_{k,s}$$

- **Carrier-aware closures.** In molten salt, electrostatic double-layer stabilization collapses (Debye length is atomic-scale) so liquid-phase agglomeration is governed by Brownian collision plus interfacial-energy-driven attraction; vapor-phase agglomeration uses Brownian plus turbulent shear. Same closure interface; different kernels selected per carrier.
- **Phase transfer $T^{L\leftrightarrow V}$** is what couples the two distributions when the salt vaporizes or condenses.

Terms in the sectional balance

- $n_{k,s,c}$ — number density of particles in size bin **k**, species **s**, carrier **c**.
- J^{nuc} — nucleation source: new particles formed from supersaturated dissolved solute (liquid) or vapor (gas).
- G^{cond} — condensational growth: monomers / dissolved species deposit onto existing particles, moving mass across bins.
- A^{agg} — agglomeration source: particles collide and merge into bin **k** (Brownian + interfacial-energy attraction in salt; Brownian + turbulent shear in vapor).
- B^{brk} — breakup sink: fragmentation of larger particles by shear or thermal stress.
- D^{dep} — deposition sink: particle loss to wetted surfaces, gravitational settling, or pump-bowl trapping.
- $T^{L\leftrightarrow V}$ — inter-phase transfer: particles cross between the liquid-borne and vapor-borne distributions as the salt vaporizes or condenses.

In MSR the gas plenum, the cover-gas system, and the salt itself all carry particulate FPs. One PBE engine populates all three with different carrier closures plugged in.

Nucleation — in salt and on solid seeds

Classical Nucleation Theory provides homogeneous rates driven by supersaturation. For vapor-phase nucleation (CsI, CsOH, NaI condensing from the cover gas) $S = p / p_{sat}(T)$ where p is the species partial pressure. For liquid-phase nucleation in molten salt (noble metals, oxide impurities) $S = c / c_{sat}(T)$ where c is the dissolved concentration and $c_{sat}(T)$ is the salt-phase solubility limit at temperature T. The CNT functional form is unchanged; only the driving force is redefined per carrier.

HOMOGENEOUS CNT

$$J^{hom} = K(T) \cdot \exp[\, -16\pi\sigma^3 v_m^2 / (3\, k_B^3 T^3 (\ln S)^2) \,]$$

HETEROGENEOUS ON SOLID PARTICLES

$$J^{het} = J^{hom} \cdot (1 + \gamma \cdot \alpha_{sp})$$

When the bulk salt produces solid seeds (precipitating noble metals, crust fragments), J^{het} dominates and the PBE picks up the enhancement automatically.

Material data ship with the model

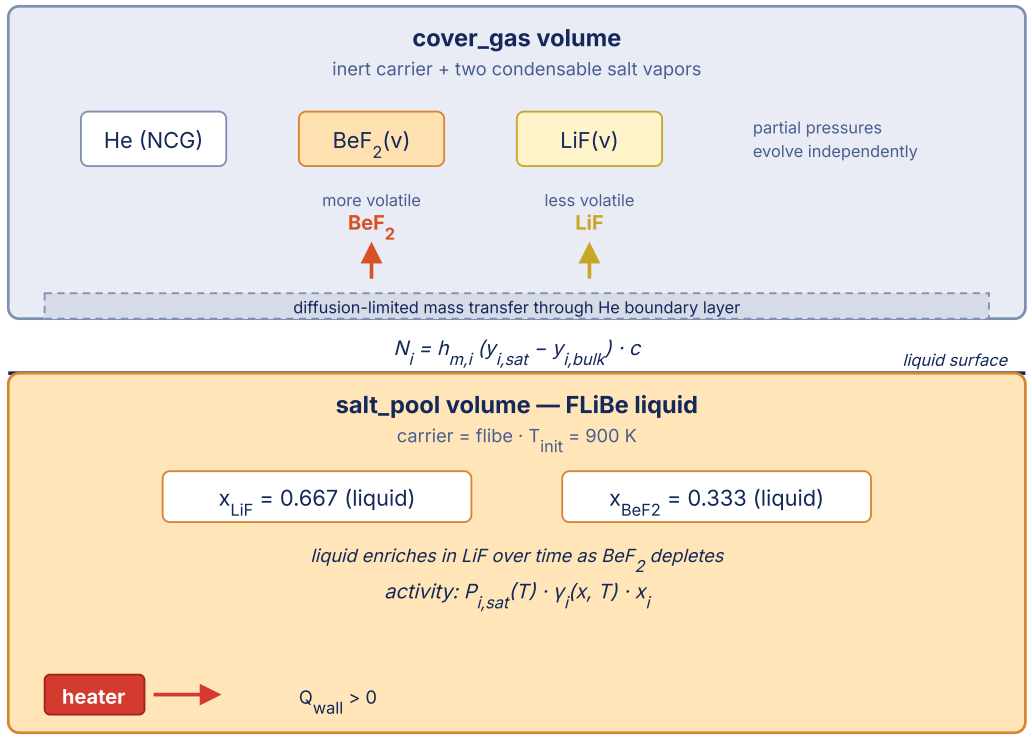
- CsI: ρ=4510 kg/m^3, σ=0.07 N/m, $P_{sat}(T)$ from JANAF
- CsOH: ρ=3680 kg/m^3, σ=0.10 N/m
- NaI: ρ=3670 kg/m^3, σ=0.09 N/m

Liquid-phase precipitation of noble metals (Mo, Ru, Pd) applies the same homogeneous and heterogeneous CNT closures with molten salt as the carrier phase. The closure form is unchanged; the supersaturation S is defined relative to the salt-phase solubility limit.

CAPABILITY 2

Differential Vaporization

Two-component vaporization from a FLiBe pool



A hot FLiBe pool sits below a cover-gas plenum. FLiBe is two components — LiF and BeF_2 — with different saturation pressures. The cover gas receives both as separate vapor species.

Why a single-species condensable model is insufficient

- The condensable phase is a mixture — one saturation curve does not define it.
- BeF_2 vaporizes faster than LiF; pool composition drifts as the transient evolves.
- Cover-gas partial pressures of LiF and BeF_2 evolve independently.
- Source-term predictions depend on **which** salt enters the gas phase, not on the total vapor mass.

Link to the MSBR drain-tank scenario. After the emergency drain, hot salt sits in the cooled drain tank for hours. BeF_2 — a beryllium-bearing chemical hazard — vaporizes preferentially and is the dominant carrier of airborne mass into the cover gas (Part 1 result: peak airborne $BeF_2 \approx 10^{-4}$ of initial inventory). LiF vaporizes more slowly but carries activation and tritium inventory on a longer timescale. A postulated leak from the drain tank into the surrounding cell transports both vapor species; the chemical-hazard and radiological source terms scale with the composition that vaporizes, not with the total vapor

Concrete example — hazardous BeF_2 release from a heated FLiBe pool

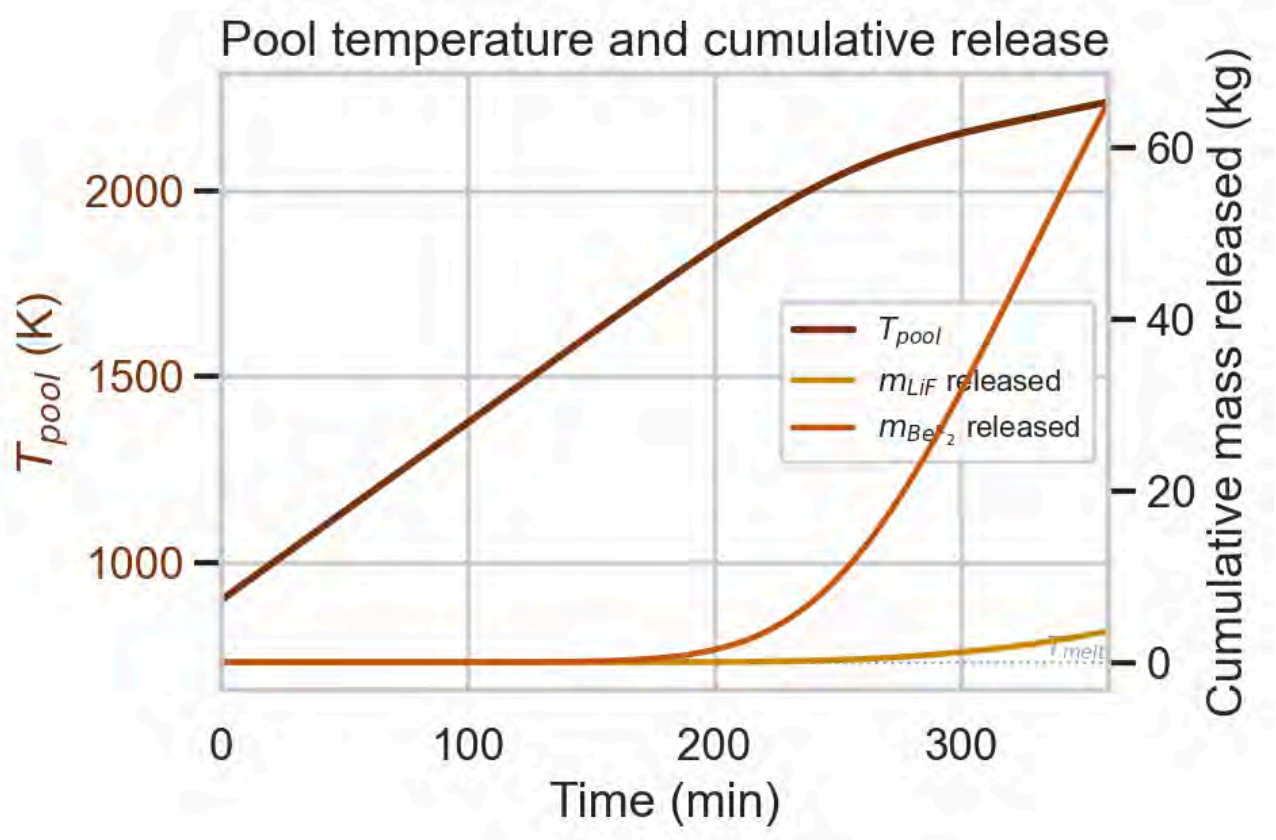
Be is the most toxicologically significant constituent in MSR fuel salt; occupational exposure limits are in the µg/m^3 range. The multi-component vaporization closure produces a quantitative release rate.

MASS-TRANSFER-LIMITED RELEASE FROM THE SALT SURFACE

$$F_{BeF_2} = A_{surf} \cdot k_m \cdot (P_{sat,BeF_2}(T) \cdot M / RT),$$

$$k_m = Sh\, D_{vap}/L$$

- Drain tank: ~30 m^2 free surface; Sh ~ 10^2 on natural convection; $D_{vap} \sim 10^{-5}$ m^2/s.
- $P_{sat,BeF_2}(T)$: 1100 Pa at 1000 °C, approximately 10 Pa at 700 °C — two decades over a 300 K range.



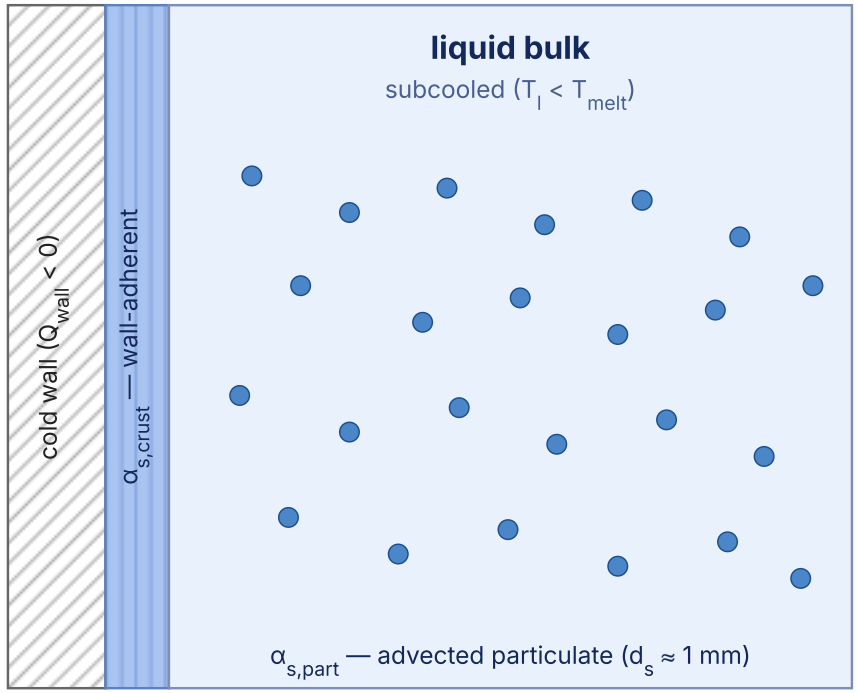
Closure output — pool temperature (left axis) and cumulative LiF and BeF_2 release (right axis) for a generic FLiBe pool heated from ~700 K through ~2200 K. BeF_2 release dominates and rises sharply above ~1700 K. At 1000 °C the corresponding release rate is of order 1 g·s^{-1}; at 700 °C it is approximately two decades lower.

CAPABILITY 3

Freezing and the Frozen Carrier

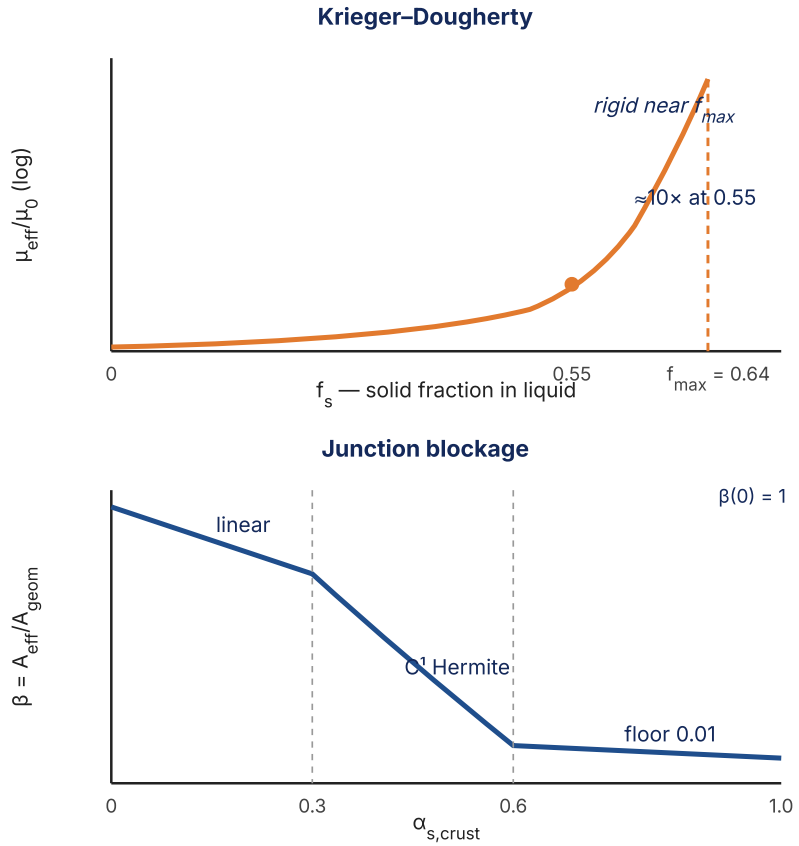
Solidification model — what it tracks

Volume cross-section at the cold wall



TWO SOLID POPULATIONS — WALL CRUST AND ADVECTED PARTICULATE

Mushy viscosity & junction blockage



TWO NONLINEARITIES THE SOLVER HAS TO SEE TOGETHER

C^1 continuity across regime transitions. Every activation, the K–D viscosity curve, and the Hermite blending region have continuous values **and** continuous slopes. Newton sees one smooth residual and does not stall at regime transitions. $A_{eff} = A_{geom} \cdot \beta$; $D_{h,eff} = D_h \cdot \sqrt{\beta}$; donor-cell advection of β keeps crust transport consistent with the flow.

Freeze trapping — species into the frozen carrier

When the salt freezes, dissolved fission products partition into the advancing front in proportion to their liquid mass fraction. The species ledger is closed across liquid, frozen, and decayed inventories.

PER SPECIES IN THE LIQUID

$$d\mathbf{m}_{diss}/d\mathbf{t} \mathrel{-}= \Gamma_{freeze} \cdot \mathbf{Y}_{species}$$

PER SPECIES IN THE FROZEN LAYER

$$d\mathbf{m}_{frozen}/d\mathbf{t} \mathrel{+}= \Gamma_{freeze} \cdot \mathbf{Y}_{species} - \Gamma_{melt} \cdot \mathbf{Y}_{frozen}$$

Frozen species continue to decay; the radioactive chain solver runs on the frozen inventory. Frozen species do not advect, so convective transport sees only the liquid inventory.

Three coupled processes during freezing

- **Solute trapping.** Dissolved Cs, I, Sr, and soluble fluorides are captured at the freezing front (above).
- **PBE crust deposition.** `pbe_solidification_coupling`: existing PBE particulates deposit onto the growing crust face at an efficiency η_{dep}.
- **Heterogeneous nucleation seed.** The newly-formed solid particles α_{sp} seed further homogeneous-supersaturated species via J^{het}.

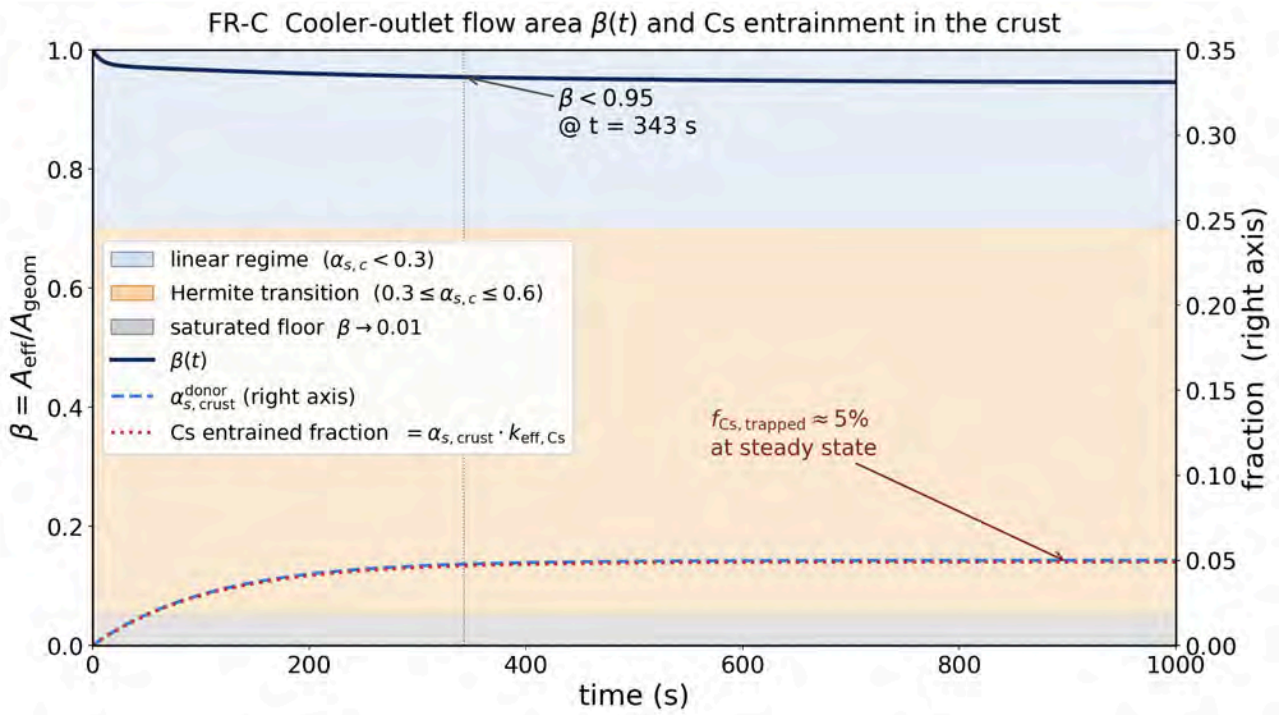
Melt-back resuspension is the symmetric inverse: $R_{resusp} \propto \Gamma_{melt}$. A freeze plug that thaws releases its trapped inventory with a decay-shifted isotopic composition.

Concrete example — freeze trapping of dissolved FPs in a drain-tank crust

During an emergency drain, salt at the cooled tank wall freezes inward at $v_f \approx 1$ mm/min. Dissolved Cs, I, and soluble fluorides are entrained by the advancing front. The closure quantifies the resulting trap inventory.

The initial closure assumes a species partition coefficient of approximately unity for the tracked FPs in their FLiBe carrier. Each parcel of salt that freezes into the crust carries its dissolved FP inventory with it, so the trapped FP fraction matches the frozen-mass fraction. More accurate species-specific partition coefficients can be substituted as phase-equilibrium data become available without changing the closure interface.

- **Cs example.** Trapped Cs fraction equals $\alpha_{s,crust}(t)$; at the cooler outlet this reaches ≈ 5% of the local dissolved inventory by 1000 s of solidification.
- The freeze-trapping ledger is run per species. Radioactive decay continues on the trapped inventory while convective transport treats it as removed from the liquid.



Closure output — flow-area ratio β(t) at a cooled outlet (left axis) with the donor-cell solid fraction and the Cs-entrained fraction $f_{Cs,trapped} = \alpha_{s,crust} \cdot k_{eff,Cs}$ on the right axis. For CsF in FLiBe, $k_{eff,Cs} \approx 1$, so the trapped Cs fraction matches the crust fraction and reaches ≈ 5% by 1000 s.

CAPABILITY 4

Interfaces and Tritium Through Structures

Mass transfer across interfaces — Sherwood correlations

The species flux across a fluid-fluid or fluid-solid interface uses the heat-mass transfer analogy. A catalog of Sh(Re, Sc) and Sh(Gr, Sc) correlations is available for the relevant flow regimes.

INTERFACE FLUX

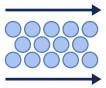
$$J_i = k_m \cdot (C_{i,bulk} - C_{i,interface}) \,, \quad k_m = Sh\, D_i / L$$

Flat plate laminar: $Sh = 0.664\, Re^{1/2}\, Sc^{1/3}$

Flat plate turbulent: $Sh = 0.037\, Re^{0.8}\, Sc^{1/3}$

Tube turbulent (Dittus–Boelter): $Sh = 0.023\, Re^{0.8}\, Sc^{0.4}$

Natural convection (vertical): $Sh = 0.59\, (Gr\, Sc)^{1/4}$



Packed bed (Wakao–Funazkri): $Sh = 2 + 1.1\, Re^{0.6}\, Sc^{1/3}$

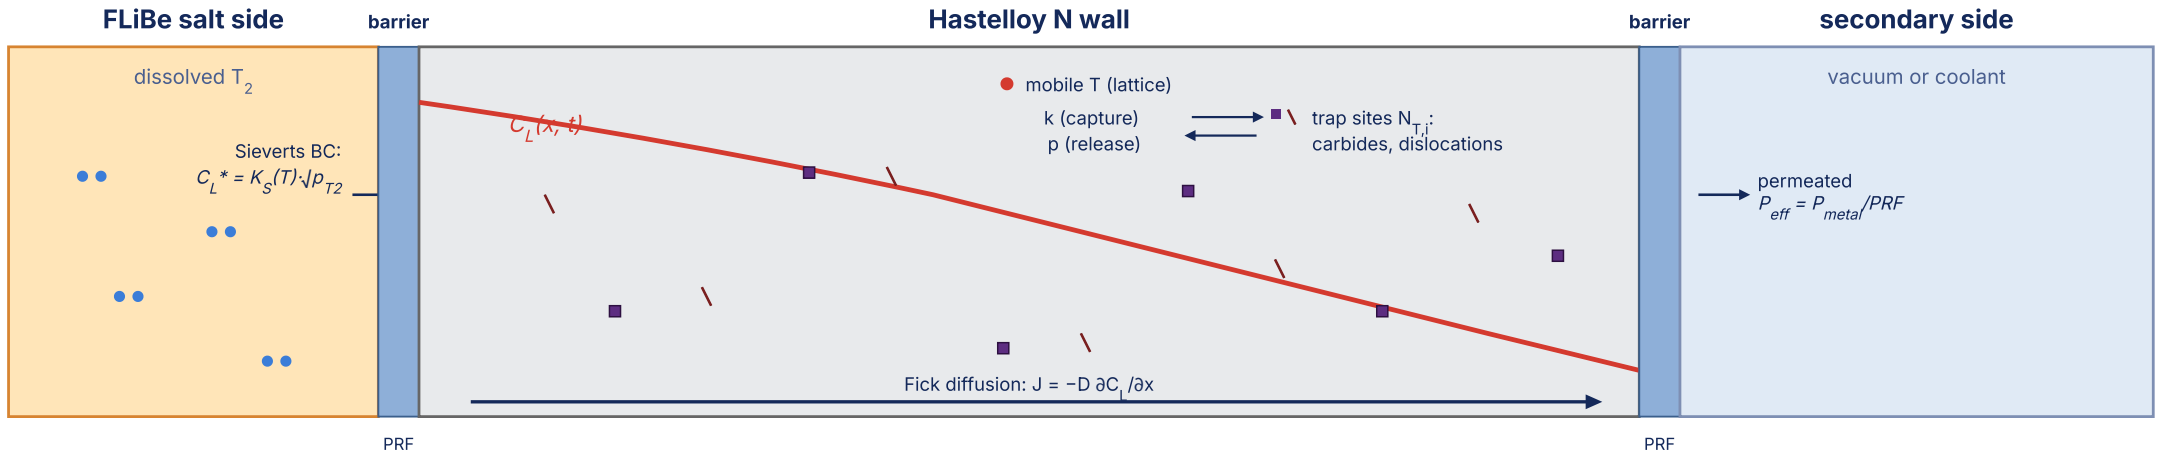
Where each one shows up in MSR

- **Liquid ↔ cover gas free surface** — natural convection on the vapor side, sets the volatile-species partition rate
- **Liquid ↔ pipe wall** — Dittus–Boelter for both sensible heat and species deposition
- **Liquid ↔ crust face** — flat plate laminar; couples to `pbe_solidification_coupling`
- **Off-gas ↔ charcoal bed** — Wakao–Funazkri
- **Cell-to-cell transport through a leak path** — natural convection on both sides; the same closure describes airborne BeF_2 transport from a leaking drain tank into the drain-tank cell and on to the reactor cell.

Equilibrium at the interface is set by Raoult / Henry / partition coefficient; the Sherwood closure controls how fast the bulk approaches that equilibrium.

Tritium in structures — trap kinetics and barrier coatings

Inside metal walls, mobile tritium C_L and trapped tritium $C_{T,i}$ at each trap class i evolve together. The structure closure provides both an equilibrium and a kinetic trapping model with optional permeation-barrier coatings on either face.



ORIANI LOCAL EQUILIBRIUM

$$K_i = \exp(E_{b,i} / RT)\,,\quad C_{T,i} = N_{T,i} \cdot K_i\,\theta_L / (1 + K_i\,\theta_L)$$

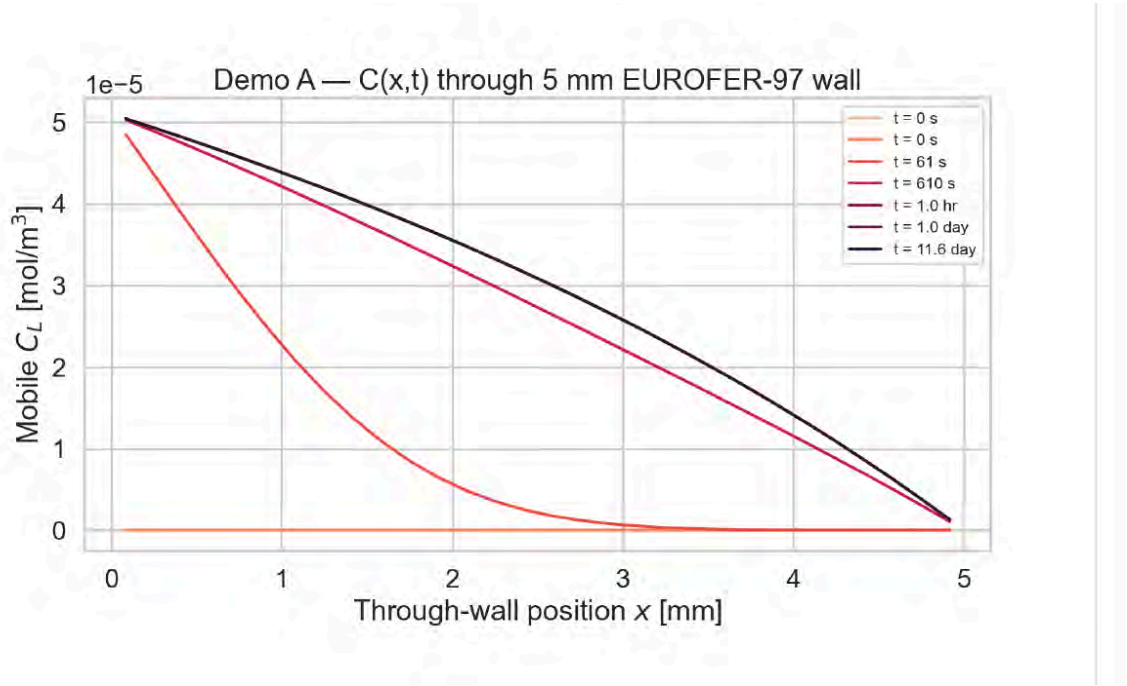
MCNABB–FOSTER KINETIC

$$dC_{T,i}/dt = k \cdot C_L \cdot (N_{T,i} - C_{T,i}) - p \cdot C_{T,i}$$

Permeation barrier coatings

- Barrier specification: **PRF** (permeation reduction factor) and coating type
- Built-in entries: Al_2O_3, Er_2O_3, Cr_2O_3
- Applied at the structure boundary; effective permeability becomes $P_{eff} = P_{metal}/PRF$

Demonstration — tritium permeation through a 5 mm wall



$C_L(x, t)$ at t = 0 s, 61 s, 610 s, 1 hr, 1 day, 11.6 day. Classic permeation-front shape; trapping retards breakthrough toward the He-side.

The structure-transport closure is exercised on a 5 mm wall with a Sieverts boundary condition on the upstream face and a vacuum sink on the downstream face. Fick diffusion is coupled to McNabb–Foster trapping on dislocations and carbides.

What the demo verifies

- The front shape evolves from a sharp profile near the upstream face through a transient permeation regime to the linear steady state.
- Trapping retards breakthrough — the t = 1 hr and t = 1 day curves remain well below the steady profile near the He-side.
- Three-ledger mass balance: |source − storage − permeated| / total < 3×10^{-5} over the 12-day transient.

Demo uses EUROFER-97 properties from the fusion-blanket literature. The same closure operates on Hastelloy N with FLiBe-relevant $K_S(T)$, $D(T)$, and trap-density inputs; permeation barriers are layered as $P_{eff} = P_{metal}/PRF$.

Recap

Particulate transport

- Sectional PBE in liquid **and** vapor carriers
- Multi-species, multi-component particles
- CNT homogeneous + heterogeneous nucleation
- Brownian collision with interfacial-energy attraction (no DLVO stabilization in molten salt); deposition coupling

Salt thermodynamics

- Multi-component liquid provider with per-constituent $P_{sat}(T)$
- FLiBe and FLiNaK constituents (LiF, BeF_2, NaF, KF)
- Incongruent vaporization producing a quantitative BeF_2 release from a heated pool
- Two-population solidification with freeze trapping of dissolved FPs

Interface and structure transport

- Sherwood catalog (laminar, turbulent, natural convection, packed bed)
- Oriani equilibrium and McNabb–Foster kinetic trap models in metals
- Permeation barriers via PRF (Al_2O_3, Er_2O_3, Cr_2O_3)

Each capability is a registered closure against a named channel. The PBE engine that tracks LWR aerosols runs unchanged in molten salt; the freeze closures developed for sodium pool solidification handle FLiBe crusts; the trap-kinetic closures developed for fusion blanket structures apply to MSR tritium permeation.

ABSTRACT

This paper addresses the description of the computational verification process for the design of the core catcher of the ALLEGRO demonstration reactor. The aim is to present the methodology and results of the analysis that ensure the safety and effectiveness of the core catcher during long-term cooling of the corium melt. For the calculations, various simulation tools were used, specifically the CORQUENCH, Thermo-Calc codes, and the CFD code Ansys Fluent. By combining these codes and methodologies, a comprehensive analysis of the long-term cooling of the core melt in the core catcher was developed, providing important insights for the verification of the safety characteristics of the ALLEGRO reactor.

KEYWORDS
Core Catcher, Ex-Vessel Retention, Severe Accident, Numerical Simulations, ALLEGRO

1. INTRODUCTION

The objective of this study is to employ the CFD code Ansys Fluent [1] to simulate the cooling of reactor core melt within a core catcher, with heat being transferred through the individual structural layers of the core catcher to cooling water circulating by natural convection beneath the structure.

Preparatory analyses were performed using the CORQUENCH code [2], as well as Thermo-Calc with the NUCLEA database [3], to obtain the necessary material properties of the reactor core melt. Using these codes we were able to ascertain necessary corium properties for subsequent CFD simulation of long-term cooling of the corium using Ansys Fluent 2025R1.

The CFD simulation represents a bounding scenario corresponding to an unfavorable progression of the late phase of an ex-vessel severe accident and the subsequent long-term cooling of the resulting corium. In this scenario, the sacrificial material is assumed to underperform and to be fully consumed without reducing the corium temperature to the required solidus level.

2. ALLEGRO CORE CATCHER

ALLEGRO is a gas-cooled fast reactor (GFR) demonstrator unit currently under development by the V4G4 CoE (Visegrad 4 for Generation IV Centre of Excellence) [4]. The primary objective of the ALLEGRO demonstrator is to provide an experimental platform that supports the research and development activities required for the future deployment and operation of commercial nuclear reactors based on GFR technology.

Among the systems specifically designed for ALLEGRO is the core catcher. This dedicated safety system is intended for the stabilization and localization of corium in the event of a severe accident involving reactor core melt. Its principal function is to retain and cool the corium, thereby preventing melt-through of the containment concrete basemat and reducing the risk of significant radionuclide release. The device is conceived as a dry, spreading, ex-vessel core catcher incorporating extensive use of sacrificial materials.

Presented work is of a late ex-vessel phase of severe accident in the ALLEGRO reactor and is a part of a broader scope of core catcher design and follows directly after long term simulation of corium ablation of sacrificial materials atop with focus of long-term cooling capabilities of the core catcher. Following figures 1 and 2. describe the core catcher system and individual layers of the core catcher floor.

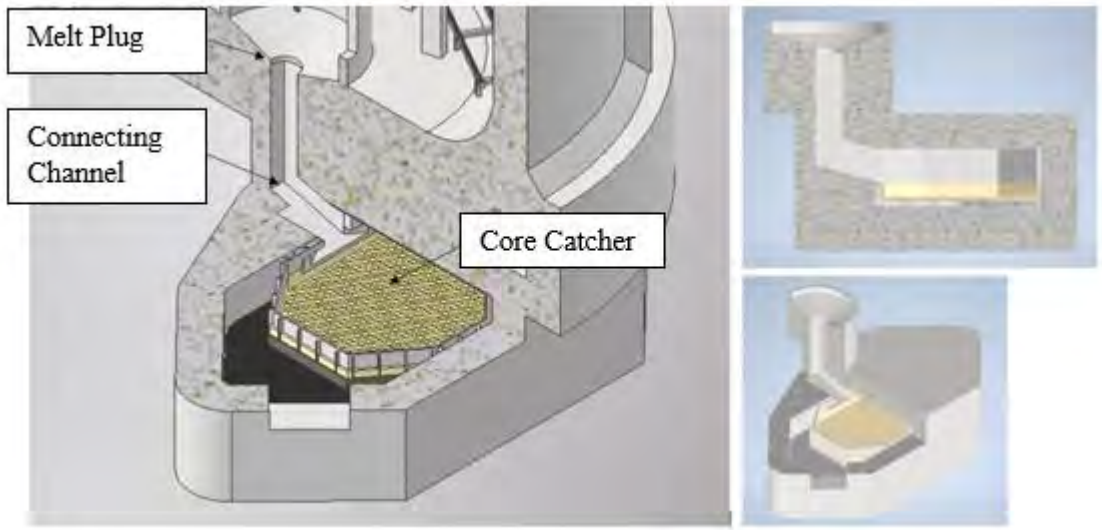

Figure 1. ALLEGRO Core Catcher

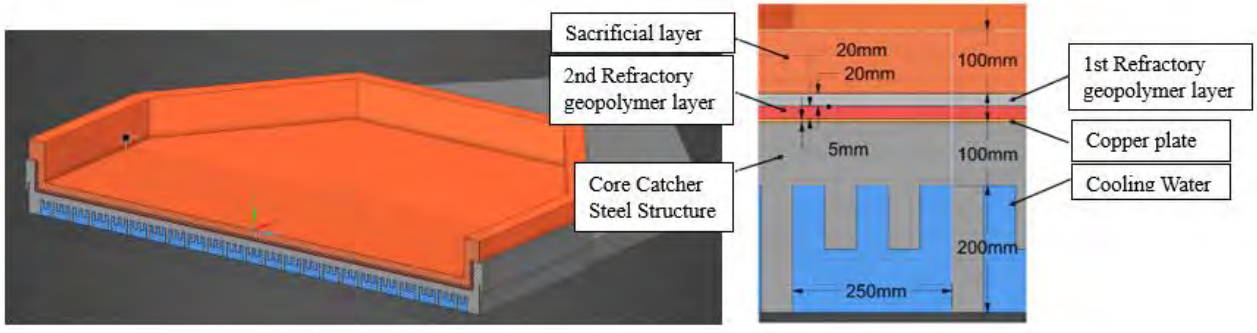

Figure 2. Core Catcher cross-section with layer descriptions

2.1 Core Catcher Cooling System

The cooling system outside the core catcher itself is designed on natural circulation principle and is connected to the same cooling loop as the DHR system [5]. It makes use of a significant height difference between the heated section (the core catcher) and the heat exchanger (see Fig, 3), which is realized by a tubular heat exchanger submerged in a water pool at the top of the containment guard vessel.

During normal reactor operation, residual decay heat from the containment is removed by the cooling system in an amount that is 20 times lower than the maximum design capacity of the cooling system. During a hypothetical severe accident, heat losses from the primary circuit decrease to approximately 5% of nominal, which should theoretically be sufficient to keep the core catcher cooling loop in a standby state, while at the same time there is no risk of its damage.

If corium melts through the bottom of the reactor vessel and is released into the core catcher space, there is no longer any significant heat source inside the primary reactor circuit. Consequently, the core catcher cooling system is then loaded only by the heat produced by the decay heat of the corium, for which it has been designed.

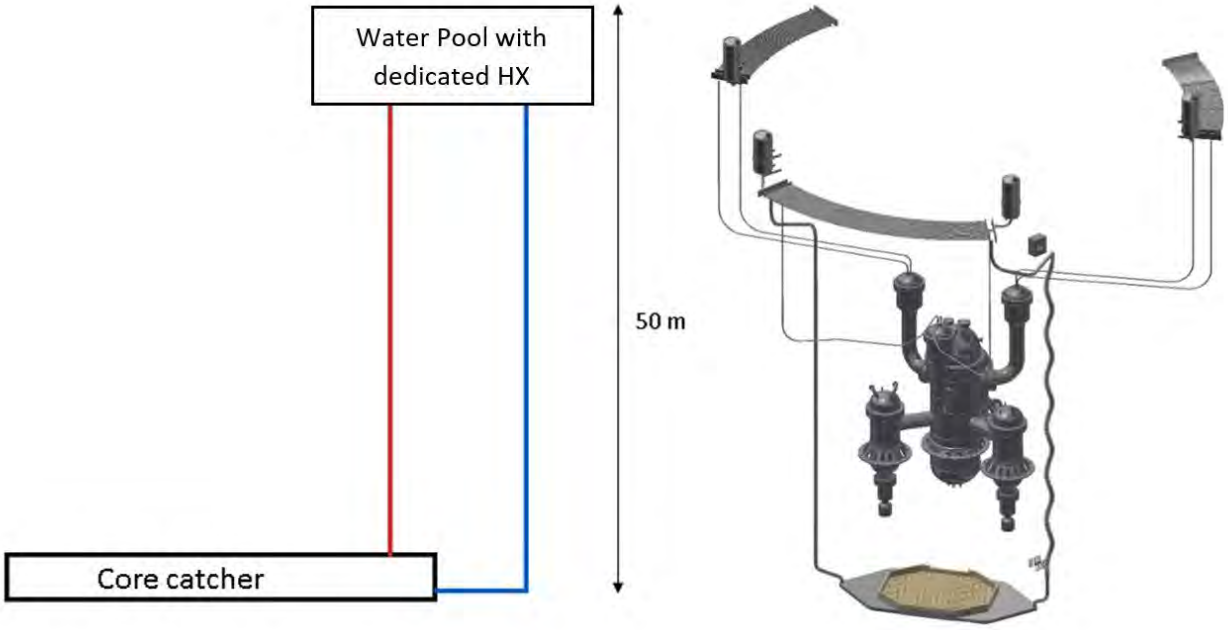

Figure 3. Core Catcher Cooling System

3. SUMMARY OF PREPARATORY ANALYSES USING THERMO-CALC (NUCLEA) AND CORQUENCH 4.1

NUCLEA is a database used to obtain corium properties based on the composition and initial conditions specified in the Thermo-Calc program. This database can be applied to both the IVR and EVR phases of a severe accident. Using this database, it is possible to calculate thermochemical equilibrium states of individual compounds (O–U–Zr–Ag–In–B–C–Fe–Cr–Ni–Ba–La–Sr–Ru–Al–Ca–Mg–Si + Ar–H) during a severe accident.

The input conditions for the equilibrium model calculation were the initial corium temperature, the pressure of the defined system, the system size (mass), and the elemental composition of the considered system.

The initial conditions of this model assumed a temperature of 1900 K and atmospheric pressure of 0.1 MPa. The total mass was taken as the corium mass after melt plug failure, 10,653.08 kg, and the mass of ablated sacrificial materials (geopolymers with high Fe_2O_3 content [6,7]), 14,109.73 kg. The total mass of the considered system was therefore 24,762.81 kg.

It was further necessary to decompose the entire system—i.e., the corium and the ablated materials—into elements using the atomic ratios of the individual materials. The corium + ablated materials system was decomposed into the following elemental composition (Table 1.):

Table I. Initial boundary Corium composition

Element	Molar concentration of element [-]
Oxygen	0.5212
Hydrogen	0.0578
Silicon	0.08
Calcium	0.03
Magnesium	0.01
Aluminium	0.0425
Iron	0.2445
Uranium	0.014

The calculation of corium material properties was performed as a function of temperature in the range from 1500 to 1930 K with a step of 10 K. This temperature interval was selected based on analyses in the CORQUENCH code, which indicate that at about 1500 K the corium begins to cool progressively, and significant crust formation occurs at the corium boundaries.

The result of this analysis is the temperature-dependent material composition of the corium (see Fig.4). The composition plot shows the gradual cooling of LIQUID and LIQUID#2, which represent the metallic phase and the oxidic phase of the corium:

- Metallic corium phase: represented by LIQUID, which at approximately 1800 K cools into the BCC_A2_2 phase and at approximately 1660 K transitions into the solid FCC_A1_1 phase.
- Oxidic corium phase: denoted as LIQUID#2, which begins to cool at about 1810 K into the FCC_C1 phase. At around 1550 K, the solid SPINEL phase forms from the oxidic corium.

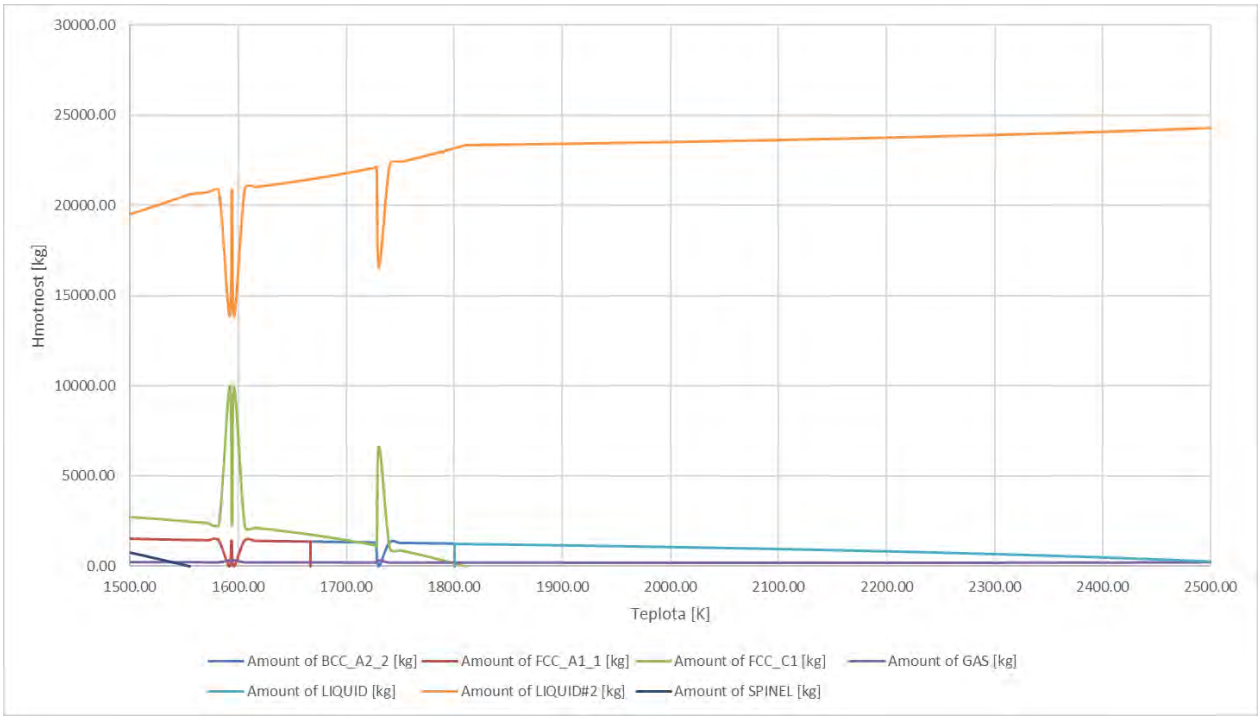

Figure 4. Thermo-Calc results of various corium compositions

From the perspective of using these properties, we are mainly interested in the situation at 1700 K, which was selected as the initial temperature for the CFD simulation of long-term cooling of the reactor core melt. Using NUCLEA, we can determine how thick the layers of stratified corium will be, which then allows us to prepare the geometry and the CFD model.

According to source [8], steel at very high temperatures has a density of about 7000 kg/m³. At 1700 K, the mass of this steel is 1330 kg. Converting using the density, the phase volume, and the core-catcher area—assuming a uniform distribution of the metallic corium layer—yields a metallic corium layer height of approximately 3.5 mm.

Using the same approach, and the calculated density of oxidic corium 3741.7 kg/m³ (from the CORQUENCH code analysis), we obtain a resulting oxidic corium layer height of approximately 115 mm.

Unfortunately, in used version of the program (Thermo-Calc 2024 A), it is not possible to obtain the thermophysical properties of corium from NUCLEA database. It was therefore necessary to use the CORQUENCH code, where additional analyses of the material properties of the oxidic corium layer were performed for the use in final CFD calculations.

The CORQUENCH code was used to obtain the thermophysical properties of the oxidic phase of corium, since this was not possible using only Thermo-Calc with the NUCLEA database. A parametric study of thermophysical properties as a function of temperature was carried out in CORQUENCH. The resulting properties of the oxidic phase are presented in the Table 3.:

Table II. Initial boundary Corium composition for CORQUENCH simulation

Core Catcher layer material	Solidus Temperature [K]	Liquidus Temperature [K]	Ablation Temperature [K]	Initial layer Temperature[K]	Layer Height [mm]
Sacrificial layer – Geopolymer with higher Fe_2O_3 cont.	1120	1750	1370	323.15	100
Refractory layer- Geopolymer with higher Al_2O_3 cont.	1120	2250	1400	323.15	20

2000	3.94	3741.7	1030.4	0.20625	0.52	0.83

4. CFD SIMULATION OF LONG-TERM COOLING OF CORIUM

The primary requirement for verifying the functionality of the core-catcher cooling system is the reduction of the corium temperature to 1450 K (1176.85 °C), which - according to CORQUENCH results - corresponds to the solidus temperature and thus to the condition where the corium is fully solidified. In addition, it is required that the maximum temperature of the cooling water does not exceed its saturation temperature. At the design pressure of 2 MPa in the core catcher, the corresponding boiling temperature is 485.55 K (212.4 °C).

With respect to the initial conditions of the simulation, a scenario representing an unfavourable progression of the late phase of a severe accident was selected. In this case, the sacrificial material may fail to perform as intended and could become completely consumed without cooling the corium to the required solidus temperature. Accordingly, the initial corium temperature was set to 1700 K, and the

corium composition was defined assuming complete ablation of the 100 mm sacrificial material layer on the floor of the core catcher.

As noted above, the considered scenario corresponds to the state after complete ablation of all sacrificial materials with which the core catcher was equipped. In this late phase of a severe accident, the corium is assumed to be stratified into two layers: an oxidic layer and a metallic layer.

This represents a computationally demanding problem, both in terms of mesh size and the necessary modelling simplifications. It was necessary to adjust the composition and thicknesses of the individual layers of the core catcher to generate a computational mesh suitable for performing the simulation.

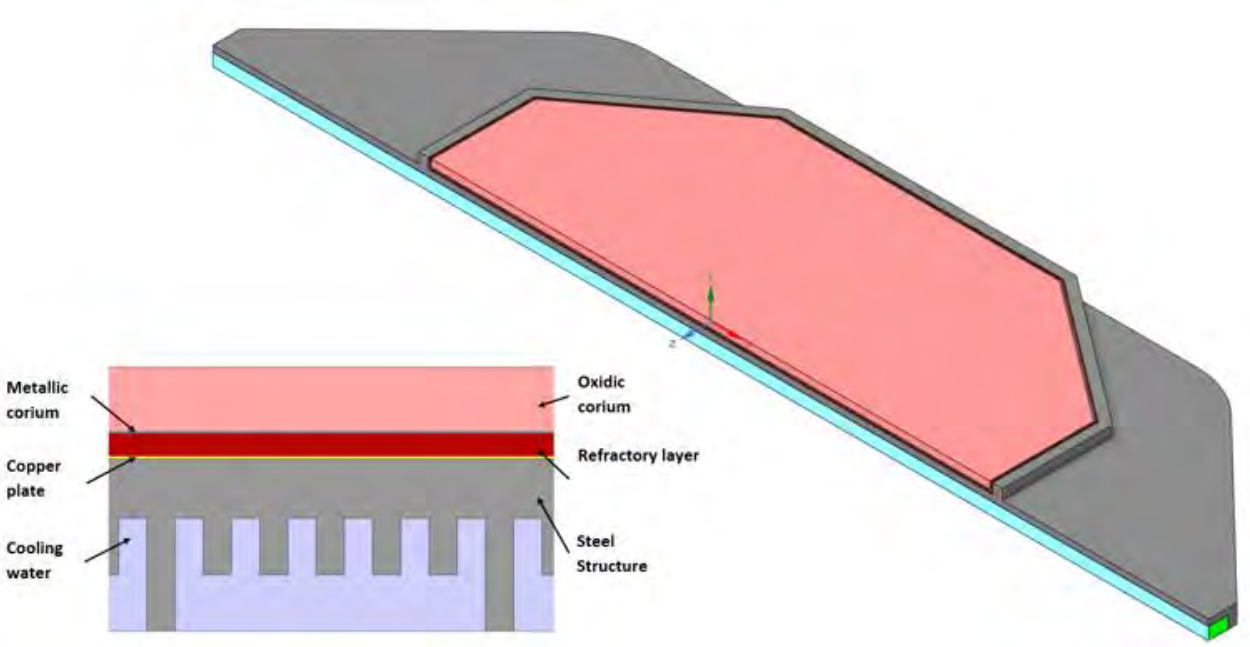

Figure 5. ½ Symmetry of CFD calculation domain

4.1 Used Simplifications

From the computational standpoint, several simplifications were introduced that significantly affect the calculation time and simulation convergence. A minor geometric modification of the so-called core-catcher rim was implemented by shortening it to a height equal to the maximum melt level. This reduced the computational domain by excluding a region that is not relevant for the melt cooling analysis and can instead be represented by an appropriate boundary condition.

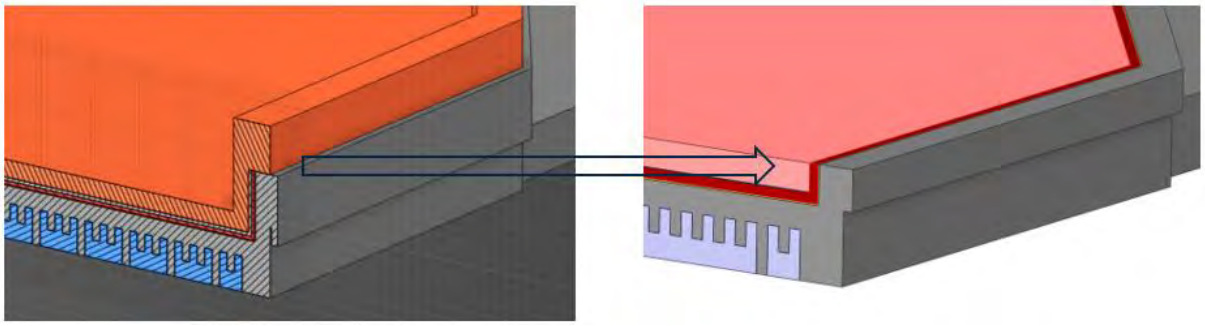

Figure 6. Core Catcher rim simplification

Furthermore, it was necessary to implement one major modification in the layer arrangement of the core catcher. This simplification was adopted due to the inability to generate a sufficiently high-quality computational mesh for the original layer configuration of the core catcher, as shown in Figure 7. The primary cause was the extremely small thickness of the metallic corium layer (3.5 mm) and the similarly thin copper layer (5 mm).

These dimensions, being significantly smaller than the other characteristic dimensions of the core catcher, resulted in extreme disparities in adjacent cell sizes and consequently very unfavourable aspect ratio values. Several test calculations were performed; however, the mesh quality issues repeatedly led to divergence of the numerical solution.

Therefore, a simplification of the core catcher layer arrangement was introduced as follows:

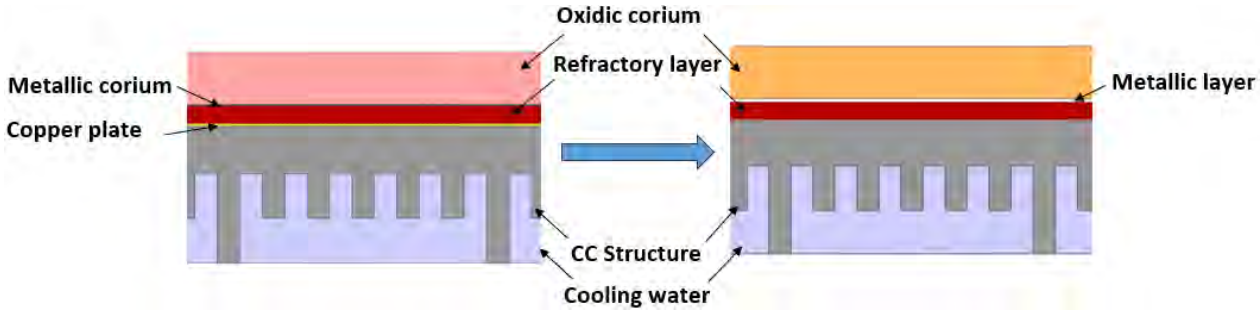

Figure 7. Core Catcher layer rearrangement simplification

Since the metallic corium layer is already considered solid at the initial simulation temperature of 1700 K, only heat conduction to the cooling water takes place within this layer. Moreover, because the material is metallic, it can be reasonably assumed to exhibit conductive behaviour like that of the copper plate. Therefore, to obtain a convergent solution and improve mesh quality, an approximation was introduced in which the two metallic layers were merged into a single equivalent layer with properties averaged according to the original thicknesses of the individual layers.

4.2 CFD Computational Mesh

The computational mesh was generated using polyhedral cells. Initially, tetrahedral cells of the specified sizes were created throughout the entire volume, after which they were converted into polyhedral cells.
In total, 38,442,704 volume cells were generated. The minimum orthogonal quality reached 0.15, and the maximum aspect ratio was 92.65. The relatively high aspect ratio is a consequence of the very fine mesh in the boundary layer combined with the effort to maintain the largest possible cell size in the bulk fluid region.

Given the large fluid volume and the presence of multiple regions requiring local refinement, the mesh was constructed to ensure at least 15 computational cells across the fluid regions (reactor core melt and cooling water) between adjacent solid surfaces. In the solid regions, where only heat conduction occurs (metals, refractory layer, and steel structure), a minimum of 4 cells across the wall thickness was prescribed.

The minimum cell size was set to 4 mm and the maximum to 40 mm. In the metallic layer region, a BOI (Body of Influence) function was applied to locally refine the mesh to a maximum cell size of 2 mm. Near the core catcher walls (in the fluid regions—the reactor core melt and the cooling water), a uniform boundary layer mesh was generated with a first cell height of 0.75 mm, 5 boundary-layer layers, and a growth rate of 1.2.

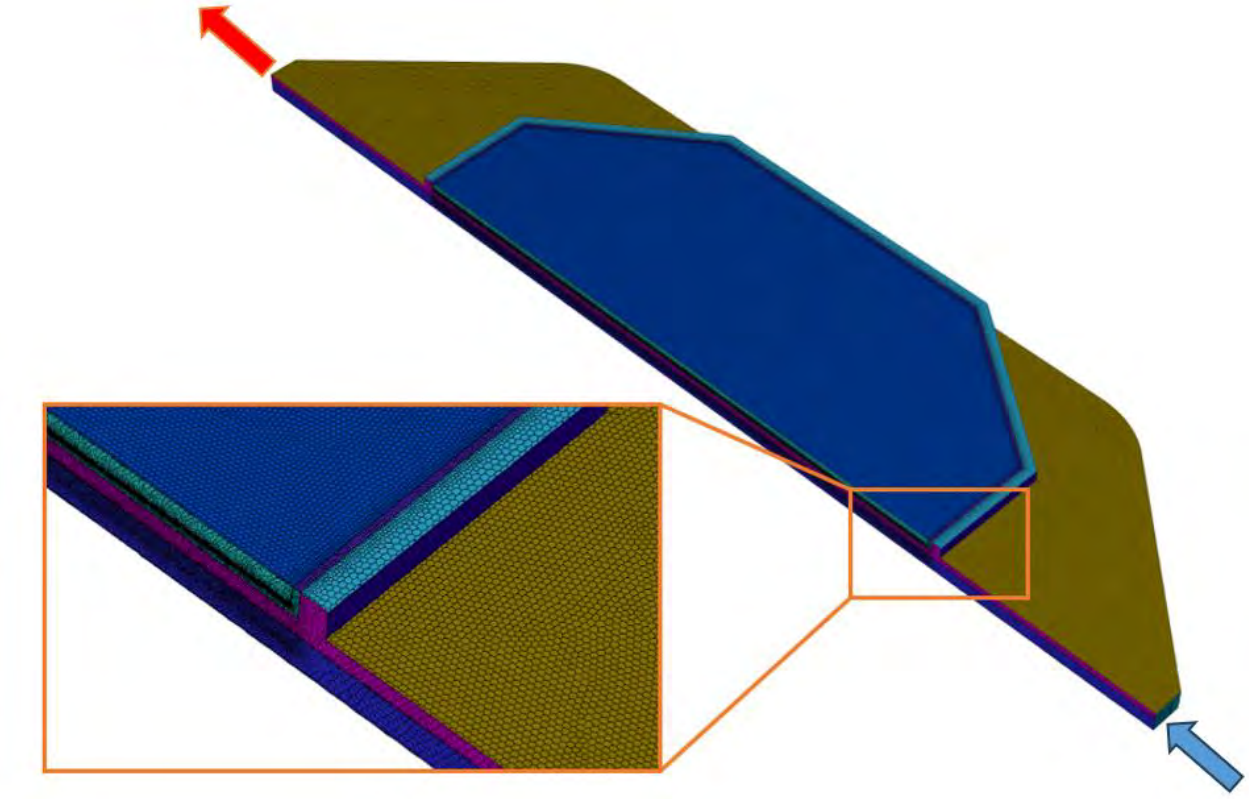

Figure 8. Computational CFD Mesh with designated water inlet (blue) and outlet (red)

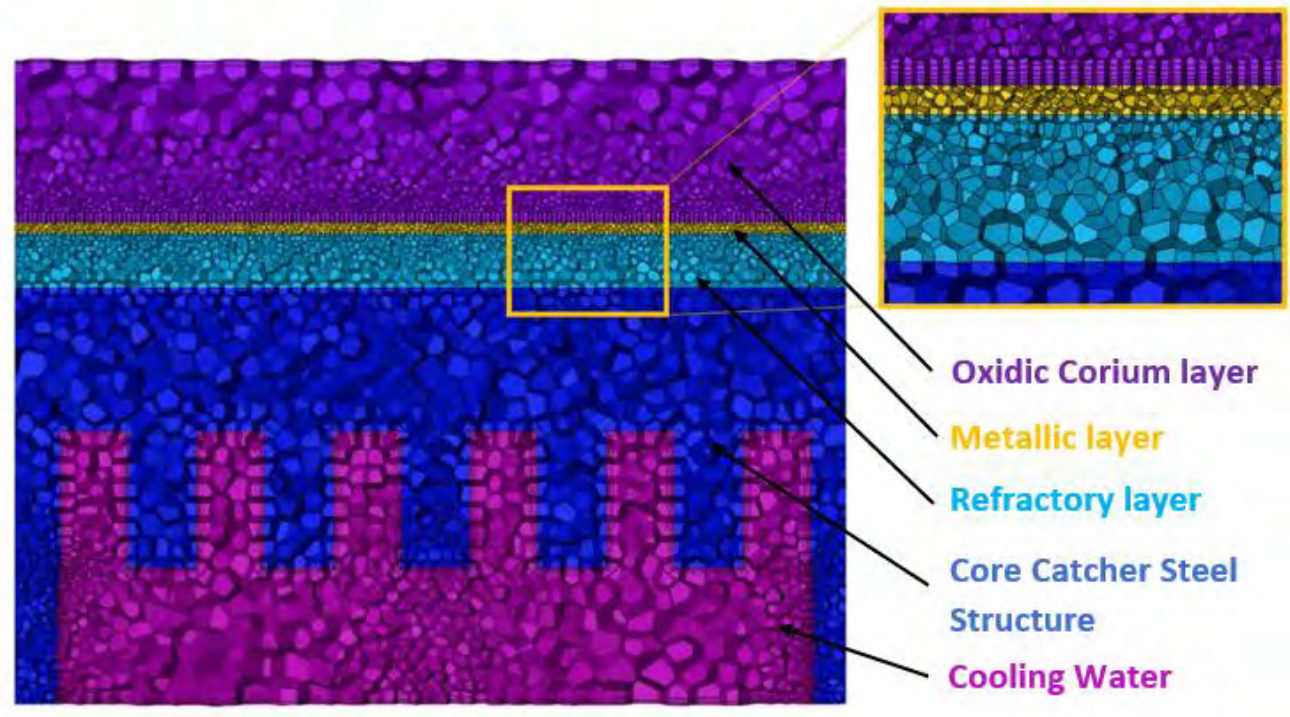

Figure 9. Cross-Section of CFD Mesh

4.3 CFD Simulation Setup and Boundary Conditions

A bounding scenario representing an unfavourable late phase of a severe accident was considered, in which the sacrificial material is fully ablated without cooling the corium below the solidus. The initial corium temperature was set to 1700 K, assuming complete depletion of the 100 mm sacrificial layer.

The key acceptance criterion is cooling the corium to 1450 K (1176.85 °C), corresponding to the solidus temperature from CORQUENCH results. Additionally, the cooling-water temperature must remain below the saturation temperature of 485.55 K (212.4 °C) at 2 MPa. Corium decay heat is removed through the core-catcher walls to the water below and from the top by radiation and natural convection (modelled via boundary conditions).

A cooling-water mass flow rate of 17.531 kg/s was prescribed at the inlet. Convergence was monitored via equation residuals and by tracking velocity and pressure to exclude nonphysical behaviour. The simulation was terminated once the flow field stabilized and the average corium temperature fell below 1450 K.

Crust formation during cooling was modelled by imposing step changes in corium thermal conductivity and viscosity at 1450 K, effectively suppressing corium motion and representing solidification. The coolant flow behaviour had been pre-validated in earlier optimization studies, which supported the stable coupling of two-fluid flow with conductive heat transfer in the present model.

5. CFD CALCULATION RESULTS

The results are primarily presented through graphical outputs of the core catcher temperature field and temperatures of both fluid regions (corium and cooling water) in the CFD simulation. The simulation time step was initially set to 0.001 s and was gradually increased up to 0.1 s, while maintaining convergence within 20 inner iterations at each time step. The maximum water pressure drop stabilized and oscillated around 1511 Pa ± 2 Pa. The maximum cooling-water velocity reached 1.76 m/s, and the average cooling-water velocity in the computational domain was 0.045 m/s.

The following figures show the resulting temperature field after the average temperature of the reactor core melt dropped below the solidus temperature (1450 K). This value is taken as the criterion for successful completion of the calculation. The plots (Figures 11 and 12) present the evolution of the maximum and average corium temperatures, as well as the maximum cooling-water temperature.

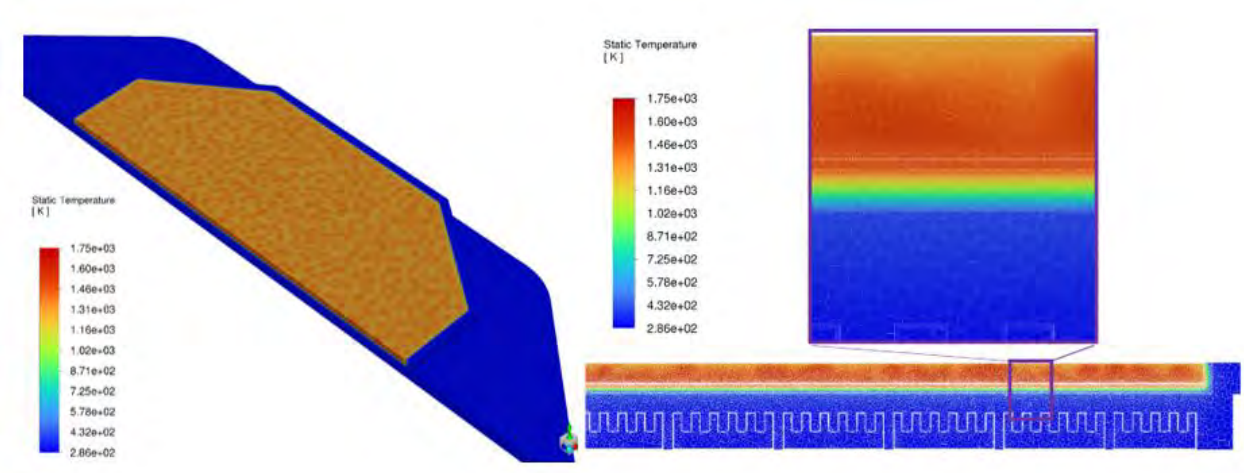

Figure 10. ½ Symmetry and Cross-Section of Temperature Field within the Core Catcher

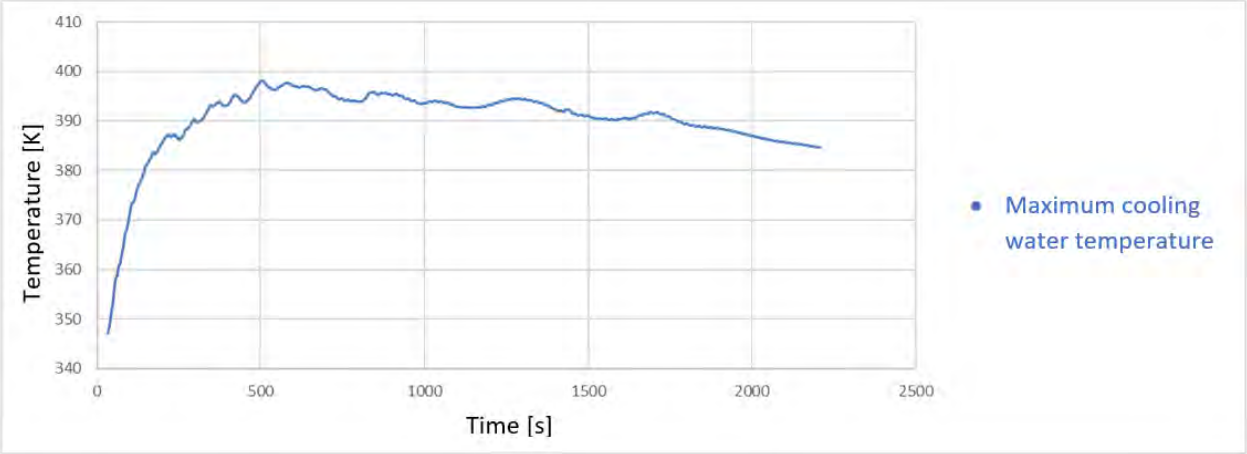

Figure 11. Graph of Maximum Water Temperature in the CFD Simulation

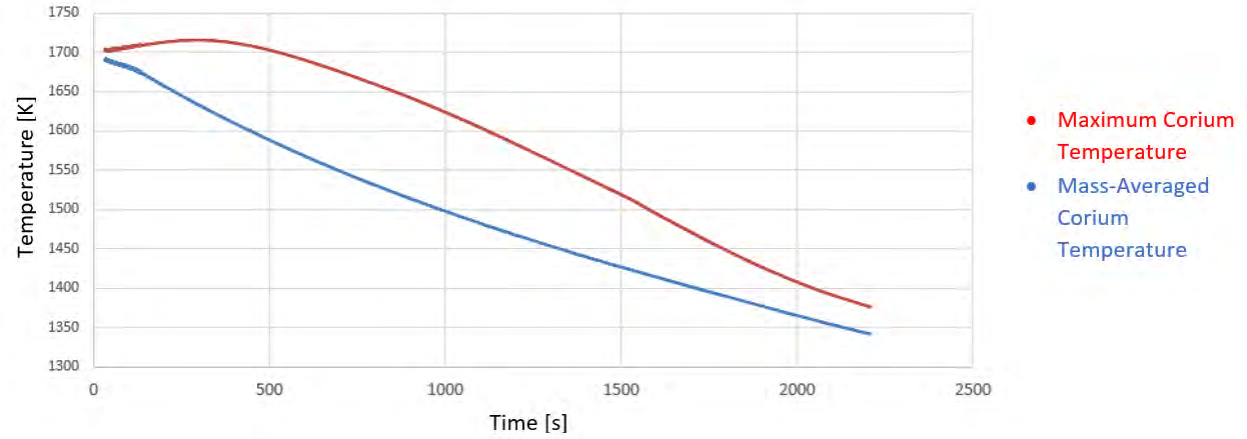

Figure 12. Graph of Maximum and Mass-Averaged Oxidic Corium Temperature

The maximum water temperature of 398.4 K did not exceed the boiling threshold of 485.55 K at any time during the simulation. The margin to the onset of boiling in the transient case was approximately 90 K, and after reaching its peak the water temperature gradually decreased. It can therefore be concluded that no boiling of the cooling water occurs anywhere within the computational domain.

The temperature of the steel structures does not exceed 480 K, which is safely below the melting temperature. The transient simulation was continued to temperatures even lower than 1450 K, and it was further confirmed that all monitored temperatures continued to exhibit a decreasing trend.

6. CONCLUSIONS

This CFD model represents the culmination of the preceding analyses and describes a scenario in which the sacrificial materials have been fully ablated while the corium has not yet cooled below the solidus temperature. The simulation considers a stratified corium pool consisting of metallic and oxidic phases, with a defined residual decay heat source in the oxidic layer, cooled by water flowing via natural circulation beneath the core catcher. The objective was to verify effective corium cooling and to confirm that boiling of the cooling water does not occur. The simulation was considered successfully completed when the average corium temperature decreased below the solidus temperature of 1450 K.

The results indicate progressive cooling of the melt down to the solidus temperature, with the temperature trend suggesting continued decrease beyond this point. The maximum cooling-water temperature reached 398.4 K in the transient simulation, well below the saturation temperature of 485.55 K at 2 MPa.

Based on the performed analysis, it can be concluded that the functionality of the conceptual design of the core melt localization and stabilization system—the core catcher—has been successfully verified through detailed CFD simulations using Ansys Fluent.

Introduction

CFD simulation of corium cooling in a conceptual core catcher using Ansys Fluent

Heat transfer through core catcher layers to naturally circulating cooling water

Corium properties obtained using:

- CORQUENCH
- Thermo-Calc + NUCLEA database

Long-term cooling analyzed in Ansys Fluent 2025 R1

Bounding severe accident scenario considered:

- Late-phase ex-vessel accident
- Sacrificial material fully consumed (poor performance leading to consumption of entire layer)
- Corium remains above solidus temperature

ALLEGRO Core Catcher Design

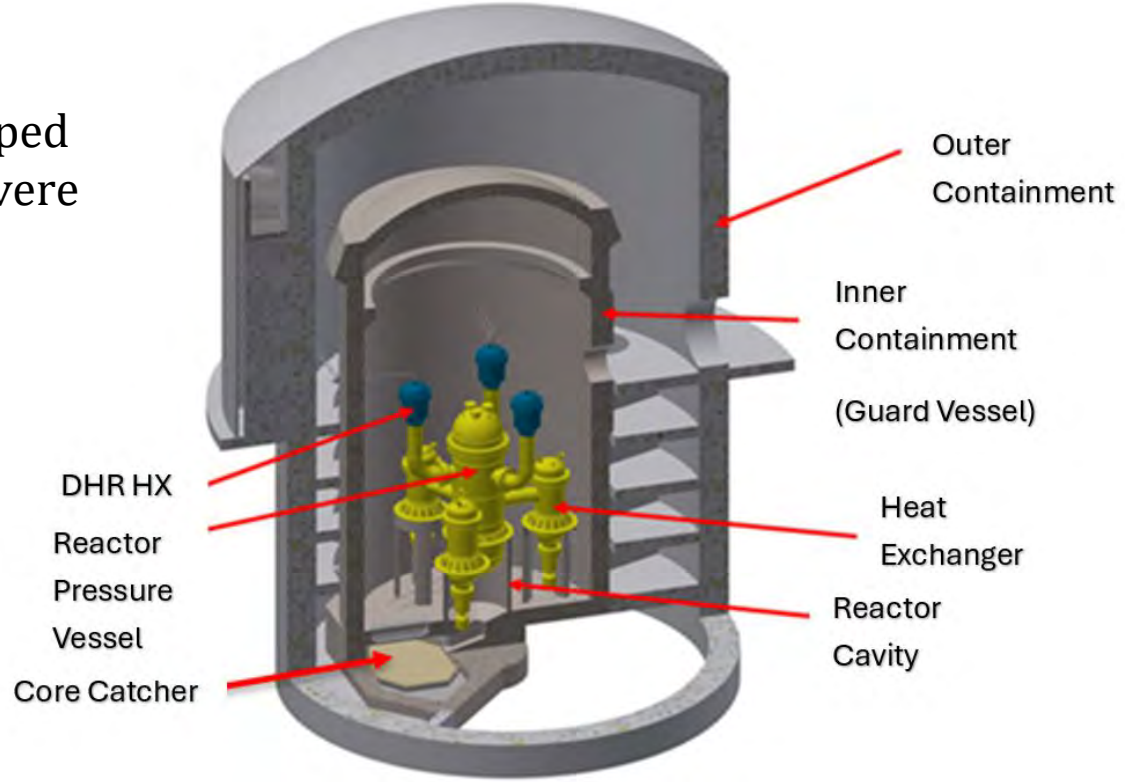
ALLEGRO is a gas-cooled fast reactor (GFR) demonstrator developed by V4G4 CoE and includes a dedicated core catcher system for severe accidents

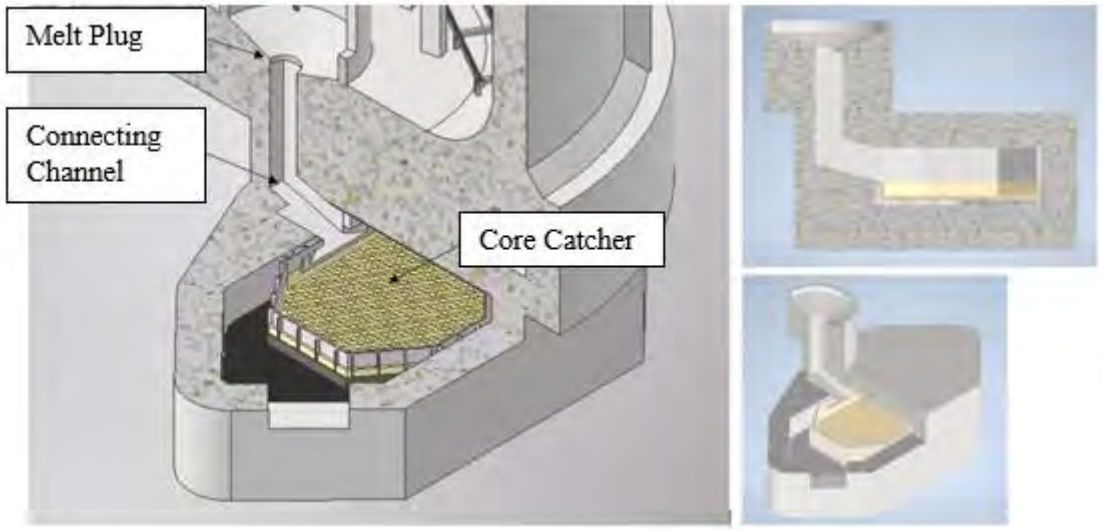
Core catcher functions:

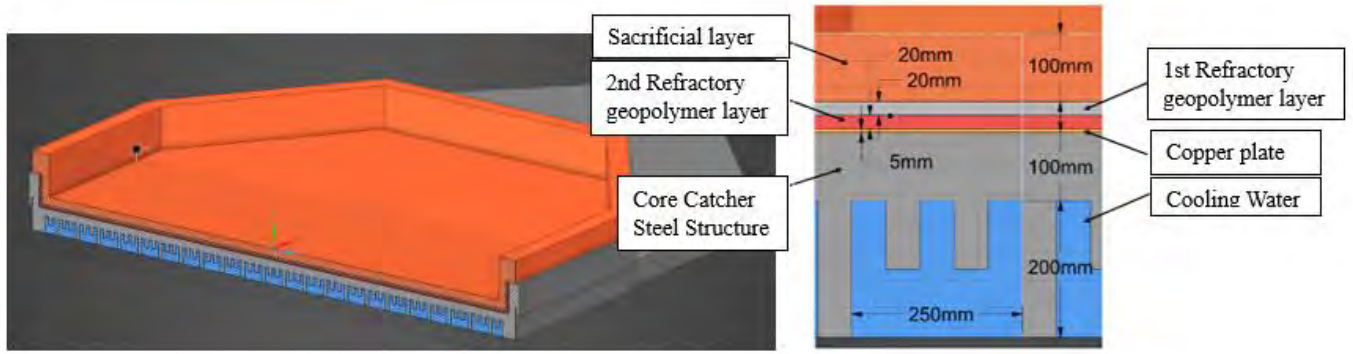
- Stabilize and retain corium
- Provide long-term cooling
- Prevent containment basemat melt-through
- Reduce radionuclide release risk

Design concept:

- Dry, spreading, ex-vessel core catcher
- Extensive use of sacrificial materials







ALLEGRO Core Catcher Cooling System

Core catcher cooling system operates via natural circulation

Connected to the same loop as the Decay Heat Removal system

Design principle:

- Relies on height difference between core catcher (heat source) and heat exchanger
- Heat exchanger is a tubular design submerged in a water pool at the top of the containment guard vessel

Normal operation:

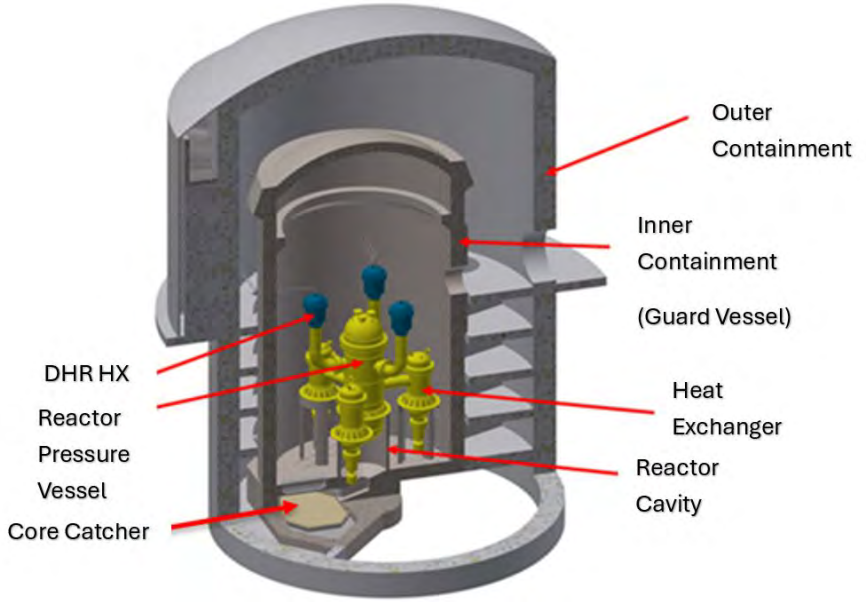
- Removes residual decay heat
- Operates at ~20× lower load than maximum capacity

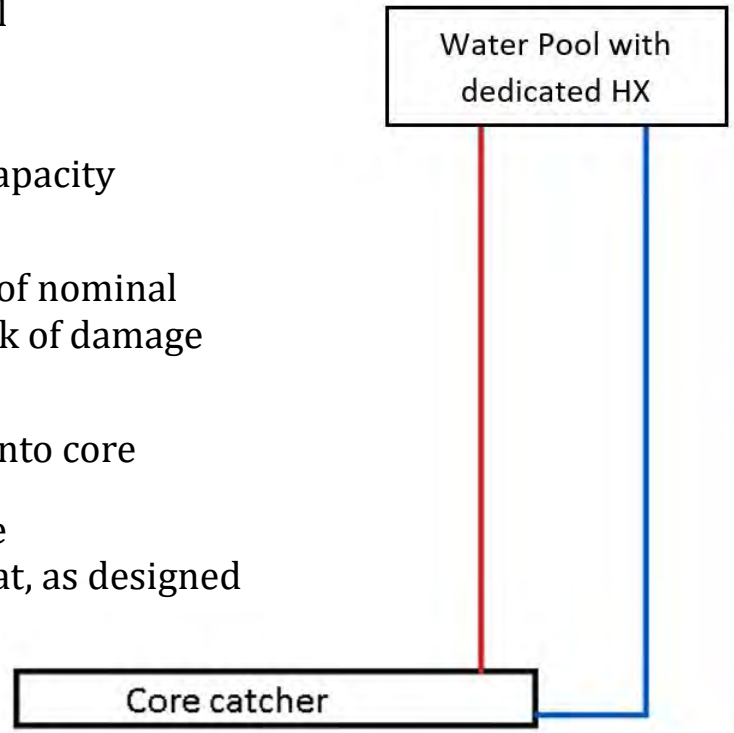
Severe accident conditions:

- Heat losses from primary circuit drop to ~5% of nominal
- Cooling system remains in standby without risk of damage

Core melt scenario:

- Reactor vessel failure leads to corium release into core catcher
- Primary circuit heat source becomes negligible
- Cooling system removes only corium decay heat, as designed





ALLEGRO Core Catcher Design Process

- MCCI of reactor pit and Melt plug
- Corium properties

MELCOR 2.2

CORQUENCH 4.1 + Thermo-Calc NUCLEA

- Additional Corium properties

Summary of Preparatory Analyses – Thermocalc + NUCLEA

NUCLEA used to determine corium properties via Thermo-Calc

Application:

- Supports both IVR (in-vessel retention) and EVR (ex-vessel retention) severe accident phases
- Calculates thermochemical equilibrium of multi-component systems
- Modeled chemical system includes:
  - O–U–Zr–Ag–In–B–C–Fe–Cr–Ni–Ba–La–Sr–Ru–Al–Ca–Mg–Si + Ar–H

Input parameters for equilibrium calculation:

- Initial temperature: 1900 K
- Pressure: 0.1 MPa (atmospheric)
- Total system mass: 24,762 kg
  - Corium: 10,653 kg
  - Ablated sacrificial materials: 14,109 kg

Element	Molar concentration of element [-]
Oxygen	0.5212
Hydrogen	0.0578
Silicon	0.08
Calcium	0.03
Magnesium	0.01
Aluminium	0.0425
Iron	0.2445
Uranium	0.014

Summary of Preparatory Analyses – Thermocalc + NUCLEA - Results

Late Ex-Vessel scenario after all sacrificial materials were consumed

Corium properties calculated in the 1500–1930 K range (10 K steps)

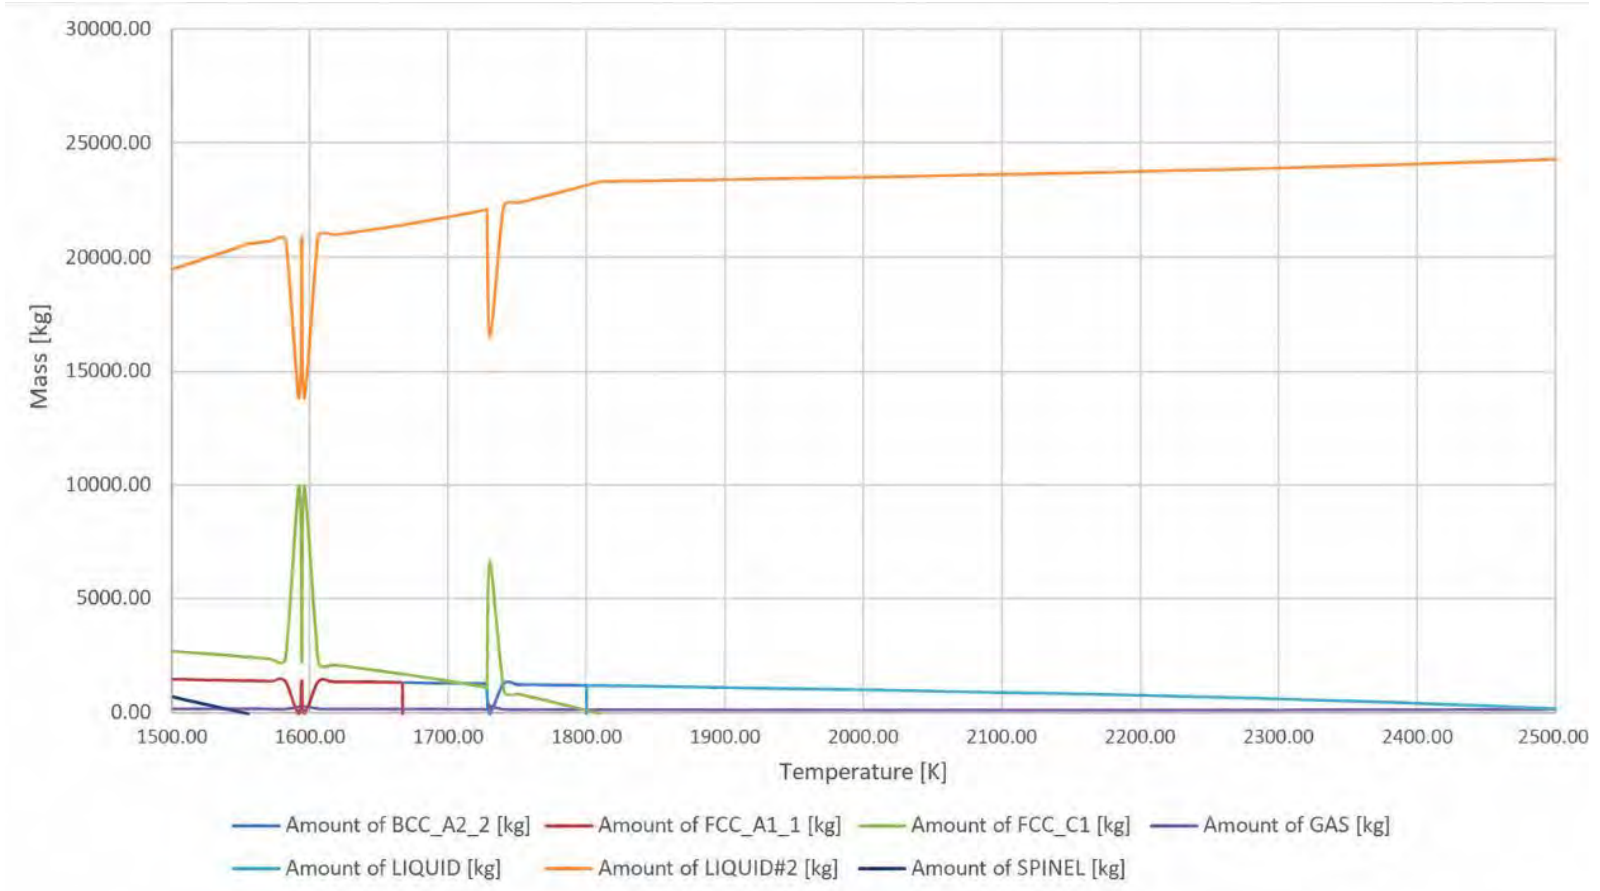
Temperature-dependent corium composition obtained using Thermo-Calc + NUCLEA database

Metallic phase behavior (LIQUID):

- Transitions to BCC_A2_2 at ~1800 K
- Solidifies into FCC_A1_1 at ~1660 K

Oxidic phase behavior (LIQUID#2):

- Begins cooling into FCC_C1 at ~1810 K
- Forms solid SPINEL phase at ~1550 K



Summary of Preparatory Analyses – CORQUENCH

Thermo-Calc 2024A + NUCLEA database could not provide corium thermophysical properties directly for use in CFD calculations

Additional analyses performed using CORQUENCH Which was used to determine thermophysical properties of the oxidic corium phase

Core Catcher layer material	Solidus Temperature [K]	Liquidus Temperature [K]	Ablation Temperature [K]	Initial layer Temperature[K]	Layer Height [mm]
Sacrificial layer – Geopolymer with higher Fe_2O_3 cont.	1120	1750	1370	323.15	100
Refractory layer- Geopolymer with higher Al_2O_3 cont.	1120	2250	1400	323.15	20
Refractory layer – Geopolymer with higher MgO cont.	1120	2250	1470	323.15	20

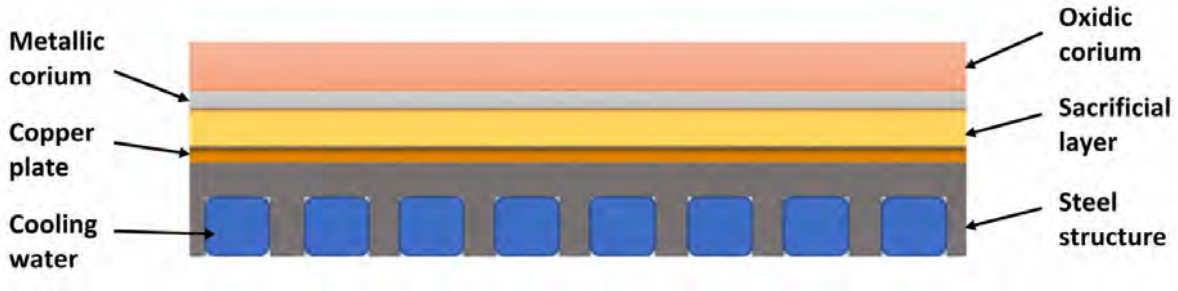
2000	3.94	3741.7	1030.4	0.20625	0.52	0.83

We were able to obtain temperature-dependent oxidic corium properties for final CFD simulations



CFD Simulation of Long-Term Cooling of Corium

Core Catcher functionality criterion:

- Corium cooled below solidus temperature of 1450 K
- Cooling water temperature must remain below saturation temperature of 485.55 K at 2 MPa

Bounding severe accident scenario assumed:

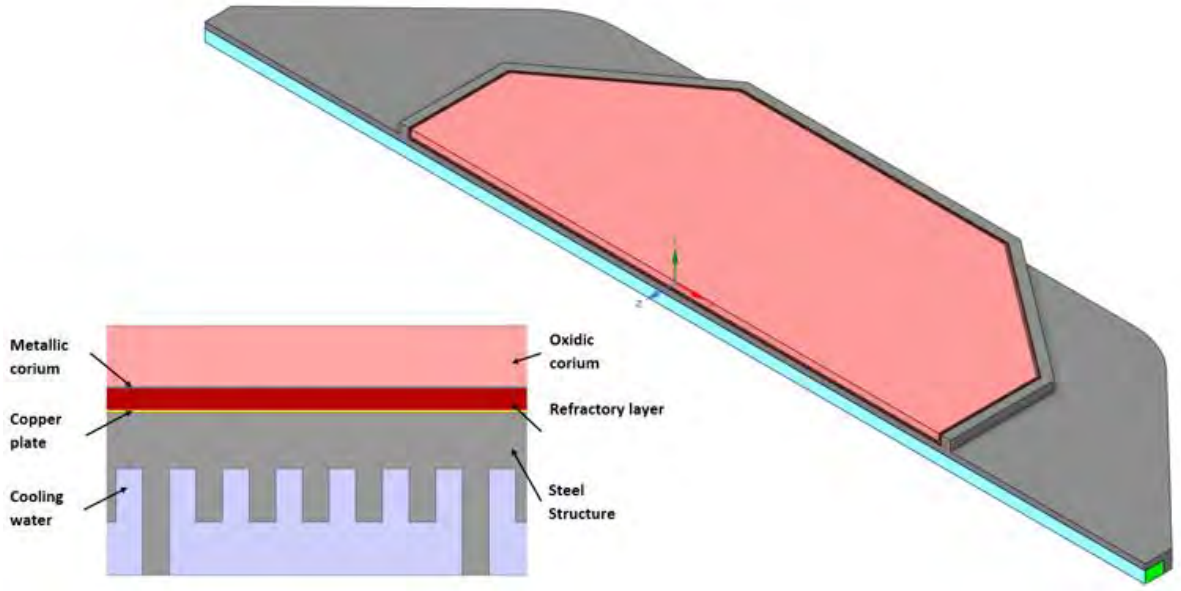
- Full ablation of 100 mm sacrificial layer

Initial simulation conditions:

- Corium initial temperature of 1700 K
- Corium composition includes fully ablated sacrificial material

Late accident phase modeled with two stratified corium layers:

- Oxidic layer
- Metallic layer



CFD Simulation of Long-Term Cooling of Corium – Used Simplifications

Several computational simplifications introduced to improve convergence and reduce calculation time

Geometric simplification:

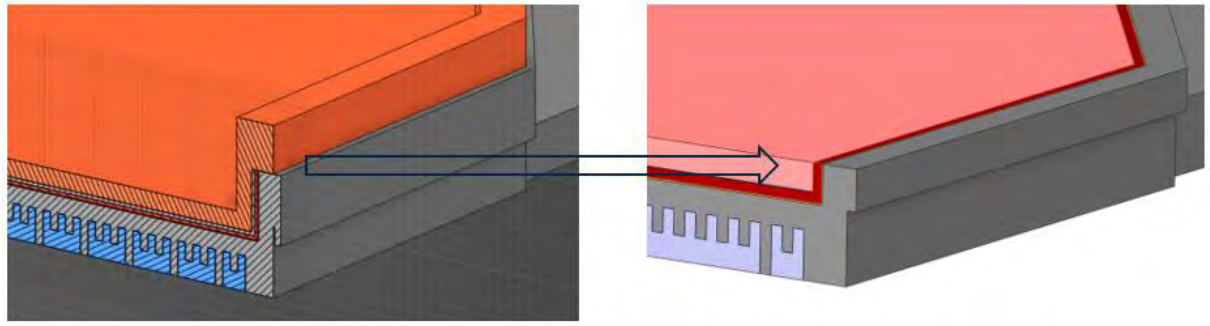
- Core-catcher rim shortened to maximum melt level
  - Reduced computational domain using boundary conditions
- Simplification in core catcher layer arrangement required for mesh generation
  - Original thin layers caused poor mesh quality:
    - Metallic corium layer: 3.5 mm
    - Copper layer: 5 mm
  - Resulting mesh issues:
    - Large disparities in cell sizes
    - High aspect ratio cells
    - Repeated divergence in test simulations
  - Metallic layers merged into one layer with mass-averaged properties
- ½ Symmetry

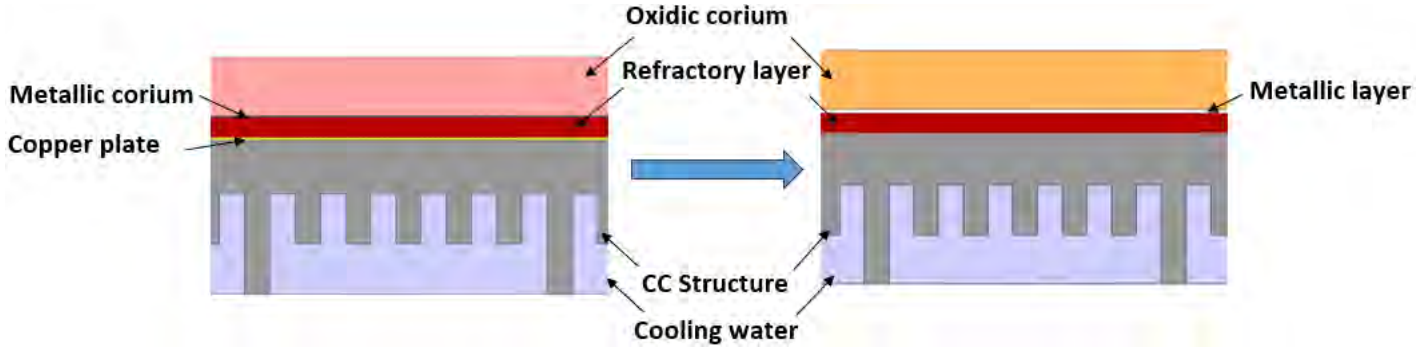
Metallic corium layer assumed solid at initial temperature of 1700 K

Heat transfer in metallic layers dominated by conduction

Final approximation:

- Metallic corium and copper layers merged into one equivalent layer
- Effective properties averaged according to original layer thicknesses





CFD Simulation of Long-Term Cooling of Corium – CFD Mesh

Mesh size and quality:

- 38,442,704 total volume cells
- Minimum orthogonal quality: 0.15
- Maximum aspect ratio: 92.65 (due to boundary layer refinement + large bulk cells)

Mesh Resolution strategy:

- ≥15 cells across fluid regions (corium + cooling water)
- ≥4 cells across solid thicknesses (conduction-dominated regions)

Mesh sizing:

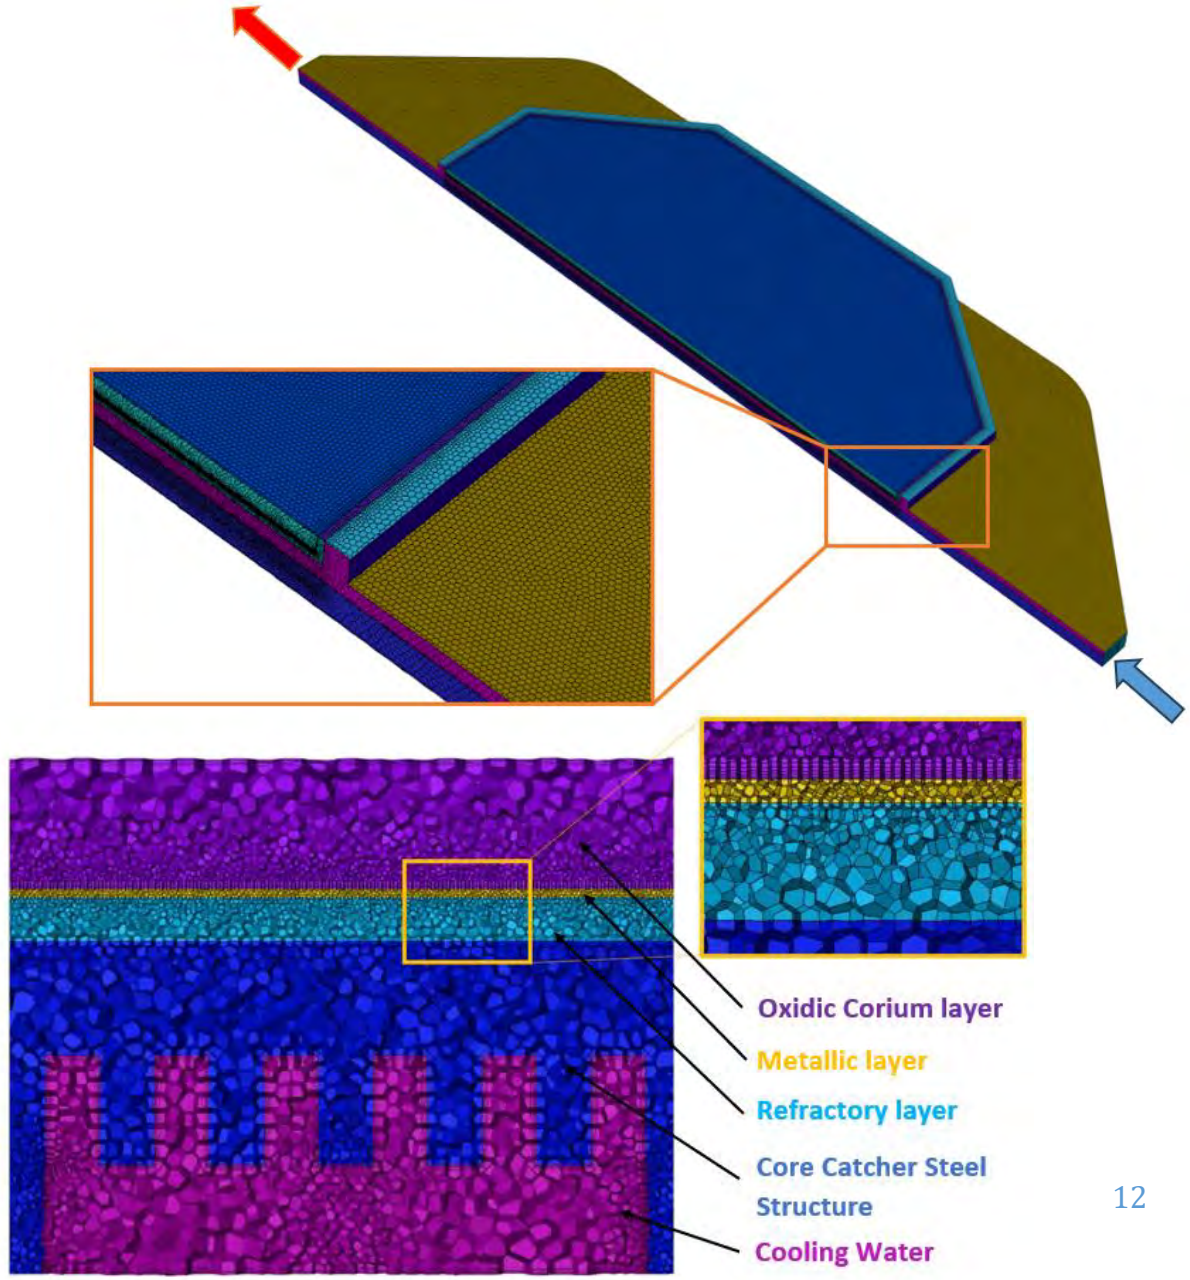
- Minimum cell size: 4 mm
- Maximum cell size: 40 mm

Local refinement:

- BOI (Body of Influence) applied in metallic layer region
- Local max cell size reduced to 2 mm

Boundary layer mesh (fluid–wall regions):

- First layer height: 0.75 mm
- 5 layers total
- Growth rate: 1.2



CFD Simulation of Long-Term Cooling of Corium – Boundary Conditions

Bounding severe accident scenario:

- Late-phase ex-vessel accident
- Full ablation of 100 mm sacrificial material
- Initial corium temperature: 1700 K
- Radiation and natural convection from top surface (boundary conditions – Atmosphere = 1048 K, Emissivity = 0.83)
- Cooling-water inlet mass flow rate: 17.531 kg/s

Numerical setup:

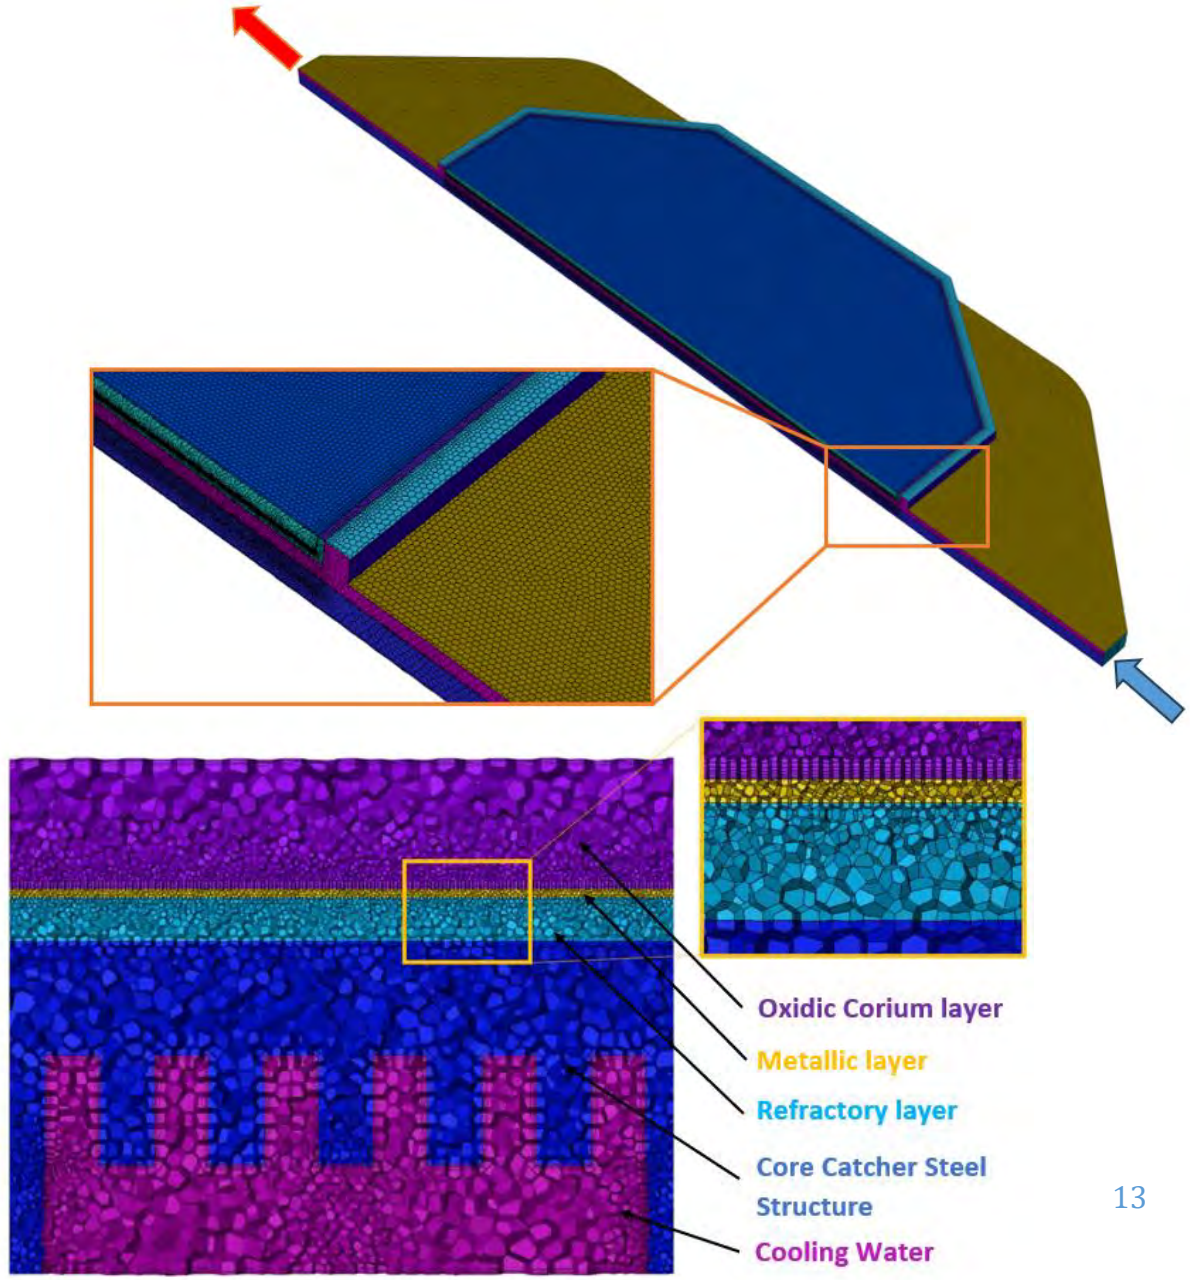
- Convergence monitored via residuals, velocity, and pressure fields
- Simulation stopped after flow stabilization and corium temperature < 1450 K

Solidification modelling:

- Crust formation enforced via step change in thermal conductivity and viscosity at 1450 K
- Corium motion effectively suppressed after solidification

Acceptance criteria:

- Corium cooled to 1450 K (solidus, from CORQUENCH results)
- Cooling water temperature < 485.55 K at 2 MPa (saturation limit)



CFD Simulation of Long-Term Cooling of Corium – Results

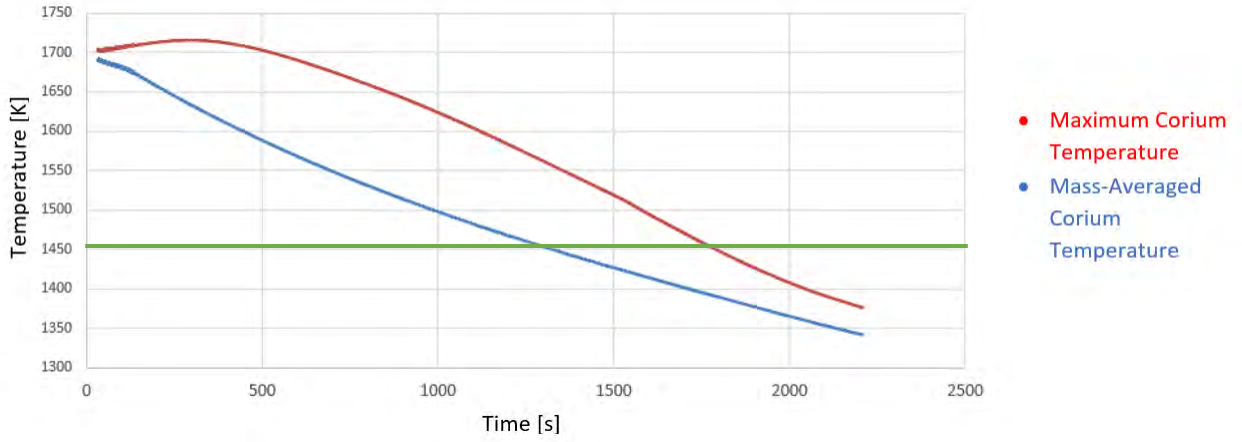
Numerical setup:
- Time step: 0.001 s → gradually increased to 0.1 s
- 20 inner iterations per time step

Water Flow stability:
- Pressure drop stabilized at 1511 Pa ± 2 Pa
- Max cooling-water velocity: 1.76 m/s
- Average cooling-water velocity: 0.045 m/s

Core Catcher Thermal performance:
- Corium cooled below solidus criterion (1450 K) → **simulation success condition achieved**
- Max cooling-water temperature: 398.4 K
- Boiling threshold: 485.55 K (2 MPa) → **not exceeded**
- **Safety margin to boiling: ~90 K**

Structural integrity:
- Steel structures remain below 480 K (safe vs melting limit)

Overall outcome:
- No boiling occurs in the domain
- All temperatures show continuous decreasing trend beyond 1450 K
- Stable and successful long-term cooling of corium demonstrated



Conclusions & Outlooks

CFD model represents final integration of preceding analyses for core catcher performance assessment

The objective was to verify effective corium cooling and to confirm that boiling of the cooling water does not occur

The simulation was considered successfully completed when the average corium temperature decreased below the solidus temperature of 1450 K

- The results indicate progressive cooling of the melt down to the solidus temperature, with the temperature trend suggesting continued to decrease beyond this point

Further work to be performed includes:

- CC Room ceiling heat effects
- More initial scenarios (with more realistic oxidic/metallic corium distribution)
- Reduce number of simplifications

Thank you for your attention!

The work carried out on the ALLEGRO core catcher was done under the auspices of the 101164616 — TREASURE — HORIZON-EURATOM-2023-NRT-01.
