- What we are changing for Task 6.3 BE work: Will generally be various refinements.
- Old, classic methodology seems usable also for SMRs (cf. the conclusions of the IAEA SMR Regulators' Forum Pilot Project report on EPZ).

- With very small source term, and consequently emphasis of very near range, the usual dispersion & doses methodology might not be sufficient, perhaps requiring microscale modeling.
- Co-location has many cases: co-location of several modules / units, reactor(s) in a populated city, or reactor(s) in industrial area (like oil refinery, hydrogen production, fertilizers, steel, etc).
- Recommended to develop methods to account for the near-field effects in atmospheric dispersion.
- Recommended to develop more high-fidelity short range / built environment modelling.
- See next slide: Some ideas for built area dispersion and doses modelling.

Built area modelling: descriptive parameters

Generic vs. generalized EPZ methodology

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

Generic methodology: not plant-specific (accident evolution, radiological release, site-specific meteorological data, etc.)

- Source term evaluation
- EPZ distance evaluation
  - Criteria driven by protective actions: Action-specific thresholds, e.g. Germany 10 km evac. & 100 km ITB
  - Criteria driven by reference doses: Single generic threshold, e.g. US: 0.05 Sv whole body, 0.25 Sv thyroid

Generalized methodology: design/plant-specific; safety analysis, accident selection, ST evaluation, criteria for EPZ distance

- Source term evaluation
  - Deterministic approach: set of representative, bounding severe accidents
  - Probabilistic approach: plant-specific PRA level 2 >> spectrum of scenarios (release category & frequency)
- EPZ distance evaluation
  - Based on bounding scenarios (WP6): e.g. Belgian dispersion model, parameters for standard scenarios
  - Based on frequency limitation
  - Based on risk (reduced to level of tolerable risk)
  - Risk-informed approach

Frequent comment from IAEA colleagues: EP&R / EPZ is not a design issue, but by definition, beyond what was considered

Off-site dispersion & dose assessment, EPZ

ABSTRACT

To enhance the safety of nuclear power plants, advanced reactor designs such as Small Modular Reactors (SMRs) adopt Passive Safety Systems (PSSs). These systems aim to improve the inherent safety of the plant while reducing system complexity and overall plant costs. However, since PSS operation relies on relatively low driving forces, such as natural circulation and gravity injection, their reliability must be assessed under all conditions that may occur during accident scenarios to ensure proper functioning.
In this work, a reliability analysis of an Emergency Heat Removal System (EHRS), representative of a PSS that passively removes residual core heat via natural circulation, was conducted using the REPAS methodology. This probabilistic–deterministic framework enables the assessment of PSS reliability, supporting the characterization of performance and the identification of conditions that guarantee correct operability. The methodology was applied considering a generic integral-PWR SMR design in which a small break-LOCA was simulated. The MELCOR code has been used, and a set of runs was performed, each corresponding to a different realization of uncertain parameters sampled through a Monte Carlo procedure. The uncertainty space covered thermal-hydraulic conditions that can affect the PSS operation, with particular emphasis on non-condensable gas (NCG) inventory, valves opening ratio, loss coefficients and tube roughness of the EHRS in-pool heat exchanger and liquid level in pools. This study investigates the scenarios leading to SA conditions, assessing the impact of NCG accumulation on EHRS performance, and identifying the boundary conditions associated with passive system functional failure. In this view, the SA scenarios are collectively characterized to highlight the behavior and conditions driving the transition from Design Basis Accidents (DBAs) to Design Extension Conditions (DECs). This first sensitivity analysis shows that NCG inventories as small as about 0.6% of the total EHRS volume are sufficient to drive the analyzed system into SA conditions within the simulated transient, confirming NCG accumulation as a critical factor for passive systems relying on natural circulation.

Passive Safety Systems; EHRS; Severe Accident; SMR; Non-Condensable Gas.

1. INTRODUCTION

Nuclear reactors safety is a fundamental aspect of nuclear technology development, particularly in the case of Small Modular Reactors (SMRs). Among them, integral Pressurized Water Reactors (iPWRs) are considered for near-term deployment. These designs build upon established reactor technology while incorporating evolutionary modifications to enhance inherent safety, including the integration of Passive Safety Systems (PSSs) that operate without reliance on external power or active components. One key PSS in these designs is the Emergency Heat Removal System (EHRS), which provides residual decay heat removal from the core during accident conditions.

Unlike mechanical failures, which involve physical damage or malfunction of components, functional failures occur when a PSS is unable to perform its intended safety function despite all components operating correctly. In fact, PSS performance relies on natural driving forces, such as natural circulation and gravity, which are sensitive to initial and boundary conditions. As a result, even small deviations in system parameters or operational conditions can significantly affect the ability of a PSS to fulfill its safety function [1].

To investigate these effects, this work leverages results from a previous application of the Reliability Evaluation of Passive Systems (REPAS) methodology [2] [3], a probabilistic–deterministic framework designed to assess PSS performance and identify conditions that may lead to functional failures. In the prior REPAS study [4], a set of uncertainty parameters was selected to represent key influences on the EHRS, including Valve Opening Ratio (VOR), heat exchanger tube roughness, Non-Condensable Gas (NCG) content, and pool water inventory. These parameters are used in the present work to systematically analyze the behavior of the EHRS under off-nominal conditions, revealing the operational limits and vulnerabilities that may lead to functional failures.

The present paper focuses on a detailed analysis of scenarios in which off-nominal EHRS operation leads the reactor into Severe Accident (SA) conditions, identifying the factors and mechanisms that drive the system toward functional failure. Following this analysis, a sensitivity study is conducted to investigate the influence of the NCG content on EHRS performance, highlighting its role as a critical factor in system response. Deterministic calculations of the reactor response under these conditions are carried out using the MELCOR code [5] [6], a fully integrated SA simulation tool capable of modelling thermal-hydraulic behavior, as well as degradation phenomena affecting the reactor pressure vessel during a SA.

2. REFERENCE REACTOR AND TRANSIENT

2.1. Reactor Design

The reference reactor considered in this study is a generic iPWR with an electrical power of approximately 300 [MWe], representative of a SMR concept [7] [8]. The selected configuration corresponds to the so-called *Design 2* (**Figure 1**), developed within the Horizon Euratom SASPAM-SA project [7] [8] [9] [10], and is adopted here as a reference layout for the assessment of accident mitigation strategies based on PSSs. The plant layout features a dry containment (composed by Drywell, DW and Reactor Cavity, RC) and an integral Reactor Pressure Vessel (RPV), which houses the reactor core together with the main primary system components. These include compact Steam Generators (SGs), the control rod drive mechanisms, the primary coolant pumps, and the pressurizer, which is integrated into the upper head of the vessel. The integral configuration reduces primary loop complexity and enhances system compactness.

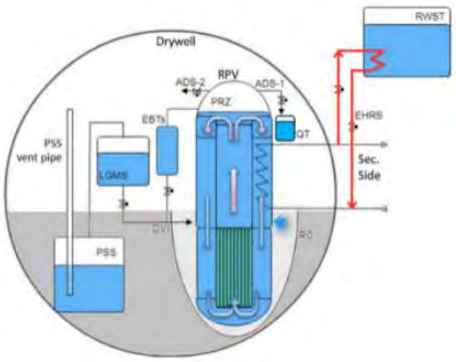

Figure 1. Generic iPWR design considered with the EHRS circuit highlighted in red.

The safety strategy adopted by the design relies extensively on passive safety systems. The systems considered include the Emergency Heat Removal System (EHRS), the Automatic Depressurization System (ADS), the Emergency Borated Tank (EBT), the Pressure Suppression System (with the acronym PSS in **Figure 1** and **Figure 4**), and the Long-term Gravity Make-up System (LGMS), as well as the possibility of reactor cavity flooding for SA mitigation. During normal operation, the reactor operates under forced circulation, while passive systems are activated to manage and mitigate accidental transients.
This reference design provides the basis for the development of the MELCOR input model described in Section 3, which is used to simulate the plant response under SA conditions.

2.2. Reference Transient

The reference scenario considered in this work is a Design Basis Accident (DBA) and specifically the reference transient is a small break-LOCA [11], identified as one of the most challenging scenarios for the considered iPWR design. The postulated initiating event is a double-ended guillotine break of one of the two Direct Vessel Injection (DVI) lines, i.e., the safety injection lines that deliver emergency coolant directly into the reactor vessel, with the availability of all passive safety systems, including the EHRS which removes residual decay heat via natural circulation to the RWST pool.
Long-term core cooling is ensured by the combined action of the EHRS, steam condensation in the DW, and the water inventory accumulated in the RC. For the analyzed conditions, the core remains covered throughout the transient (see the core level trend in **Figure 2**), with no onset of core degradation or hydrogen production, confirming the effectiveness of the passive mitigation strategy for the selected reference scenario. This is confirmed by **Figure 3**, which shows the power balance over the transient. The figure highlights the decay power generated in the core, the power transferred from the core to the primary coolant, from the primary system to the secondary system, and finally from the secondary system to the EHRS, showing that the generated power is fully removed throughout the transient.
By the end of the simulated 50000 s, the reference case has reached nearly stationary conditions on the main figures of merit (core level, decay-heat removal balance), so that the effectiveness of the passive mitigation strategy can be regarded as firmly established for this scenario. The 50000 s time window was adopted throughout the present study as a compromise, in view of the computational cost of the detailed nodalization, most notably the explicit modeling of the two EHRS trains as separate hydraulic loops (Section 3).

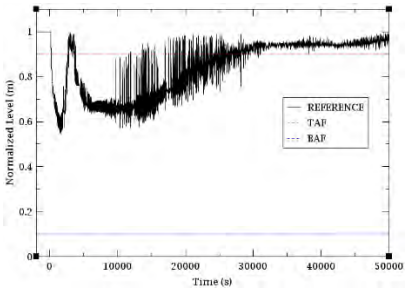

Figure 2. Normalized core coolant level of the core.

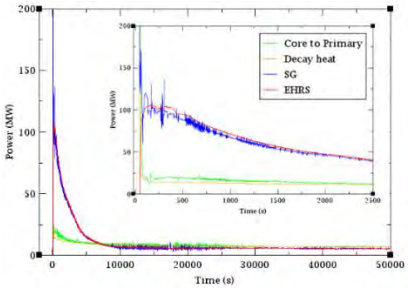

Figure 3. Power balance of the system during the transient.

3. MELCOR CODE AND NODALIZATION

The calculations in this work are performed using the integral SA code MELCOR, developed by Sandia National Laboratories for the U.S. Nuclear Regulatory Commission. MELCOR simulates the behaviour of light water reactors under steady-state and transient conditions, with a focus on SA sequences. It models thermal–hydraulic phenomena, core degradation, reactor pressure vessel and containment response, and estimates the radioactive source term.

In the present work, MELCOR version 2023 is used, and the input deck was developed using SNAP [12], which facilitates model construction and post-processing. A detailed description of the code and its models can be found in [5] [6].

The nodalization, developed by ENEA within the SASPAM-SA project for a generic iPWR design, is based on a generic design derived from IRIS [13] and balances computational efficiency and accuracy in representing thermal–hydraulic and core degradation phenomena. It has been developed exclusively using publicly available information, without reliance on proprietary data, by scaling experimental data from the SPES-3 facility [14] and through engineering evaluations based on open literature sources.

The Reactor Pressure Vessel and primary system are subdivided into hydraulic regions (reactor core, Lower/Upper Plenum, core bypass, riser, downcomer, pressurizer, SG primary side and bypass), modelled through control volumes and flow paths, while heat transfer is handled via associated heat structures. Pressure losses and thermal contributions from internal components are included.

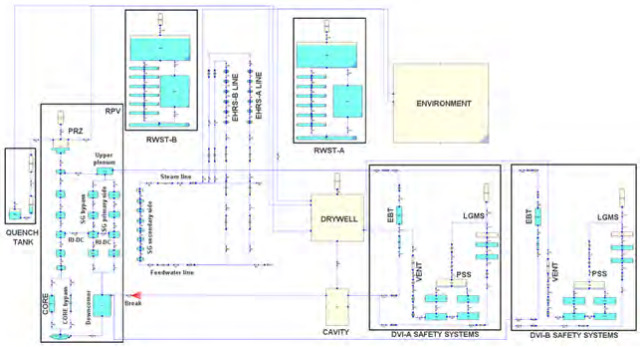

Figure 4. MECLOR CVH nodalization [4].

Passive safety system lines (EBT, Pressure Suppression System, PSS vent, LGMS) are represented independently. The EHRS is simplified to two equivalent heat exchanger lines thermally coupled to Refuelling Water Storage Tanks (RWSTs). SGs are represented as a single equivalent unit with multiple control volumes on primary and secondary sides. The reactor core is modelled as a single hydraulic control volume coupled to the COR package, which adopts multi-level axial and radial discretization. The containment uses separate control volumes for the reactor cavity and drywell; the reactor cavity couples

with the CAV package, while the drywell is thermally coupled to the environment. The postulated break connects the downcomer and containment via relevant safety system lines.
A schematic view of the MELCOR CVH nodalization for the considered iPWR design is shown in **Figure 4**. The model consists of 130 control volumes, 145 flow paths, and 139 heat structures [4].

4. REPAS APPLICATION & MAIN RESULTS

The REPAS methodology estimates the probability of failure of a passive system to perform its mission by accounting for uncertainties in physical and geometric parameters that may compromise the expected thermal-hydraulic phenomena. The general objective of the methodology is to analytically characterize the performance of a passive system, verify its proper functioning, and enable comparisons with active systems or alternative passive concepts.
The roadmap of the methodology can be summarized as follows: system characterization and definition of the Target Mission (TM); identification of the uncertain parameters and their probability distributions; development of the input deck and execution of the reference calculation; definition of the Failure Criteria (FCs); execution of a simulation campaign with a sample size sufficient to achieve a statistically meaningful characterization of system performance; and reliability estimation through comparison of the outcomes with the FCs.
In the present application, the system under investigation is the EHRS of the iPWR Design 2 (**Figure 1**), whose TM is the transfer of decay heat from the core to an external pool under accident conditions. Based on engineering judgement, the uncertain parameters considered most relevant for our application were the loss coefficient (k), surface roughness of the EHRS-HXs tubes, VOR, NCG fraction, and pool initial water level. Each parameter was assigned a variability range and a probability distribution.
After the execution of the reference transient, the results of the calculation were then used to define the FCs for the EHRS, one for each FOM: cladding temperature > 600 K after system activation, collapsed coolant level in the core < 1/2 of the active core height, and EHRS removed power < 70 MW.
A set of N simulations was then performed, each characterized by different values of the uncertain parameters sampled through a Monte Carlo technique. The minimum sample size N required to ensure the selected statistical confidence and probability levels was determined through Wilks' formula [15] for the one-sided tolerance interval, resulting in a minimum required sample size of N=124 simulations. The adopted statistical target consists of a confidence level of 0.95 and a probability content of 0.95, considering three figures of merit.
For the present REPAS application, 150 MELCOR runs were executed; however, 24 runs were excluded due to numerical failures. **Figure 5** shows the time-dependent profiles of the maximum cladding temperature (first FOM), in which seven simulations exceeded the defined FC. The simple rank correlation diagram reported in **Figure 6** highlights the relative influence of uncertain parameters on the maximum cladding temperature.

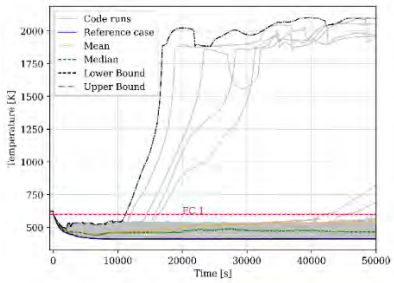

Figure 5. Max cladding temperature for the REPAS calculations.

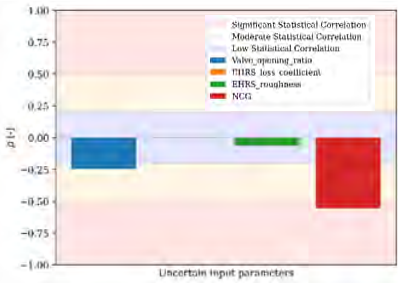

Figure 6. Simple rank correlation coefficient for the maximum cladding temperature.

These results indicate that the NCG fraction[1] and VOR are the most influential parameters affecting system reliability.
Finally, the REPAS methodology concludes by comparing the simulation outcomes with the defined FCs, allowing the reliability of the EHRS to be quantified in terms of selected FOMs, i.e., as the probability of system failure associated with the occurrence of the sampled scenarios.

5. ANALYSIS OF SEVERE ACCIDENT CASES

After the application of the REPAS methodology, more than one hundred simulations were analyzed, from which five cases were identified as evolving into SA conditions. The progression of these cases is illustrated in **Figure 7**, showing the temporal evolution of the Maximum Cladding Temperature, and in **Figure 8**, reporting the normalized core collapsed coolant level.

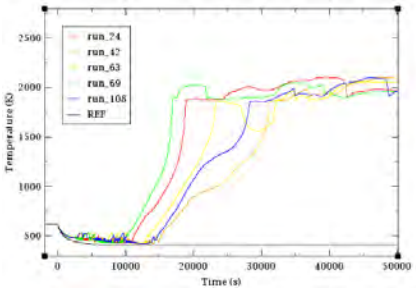

Figure 7. Max cladding temperature for the five SA cases and for the reference.

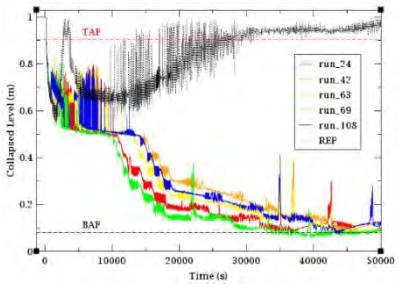

Figure 8. Normalized core coolant level for the five SA cases and for the reference.

Figure 7 shows the increase in cladding temperature for all five cases, followed by stabilization in the range of 1800–2000 K, indicating cladding failure and exceeding the safety criteria defined in [16], according to which the cladding temperature during a LOCA should not exceed 1400 K. **Figure 8** shows the evolution of the collapsed liquid level in the core, indicating that, in all five cases, the curves remain consistently below the Top of Active Fuel (TAF), leaving the active core region almost entirely uncovered.
Following the application of the REPAS methodology, the uncertainty parameters having the greatest influence on the three FOMs, namely the maximum cladding temperature, the minimum core level, and the maximum power removed by the EHRS, were identified by means of the Simple Rank Correlation Coefficient, calculated using Spearman's rank correlation [17]. The most influential parameters were found to be the EHRS circuit VOR, and the amount of NCG present in the EHRS-HXs.
For completeness, **Table 1** reports the percentage deviations from the reference values of all uncertainty parameters considered in the analysis for the five SA cases. The table includes the two parameters identified as the most influential by the Spearman correlation analysis, as well as the three less influential ones, namely the initial liquid level in the RWST pool, the pressure loss coefficient and the surface roughness of the EHRS-HXs piping.
The positive and negative values in **Table 1** are to be understood as percentage increases and decreases, respectively, with respect to the nominal value of each parameter considered, , except for NCG, whose value

[1] Additional clarification is required regarding the sampling approach adopted for the NCG fraction. Due to the method used to provide input data into the code, it is not straightforward to directly sample the NCG amount. Since the initial quantity of NCG inside the EHRS tubes affect the initial water inventory, the initial water level in the EHRS was used as a surrogate sampling variable. Consequently, a high liquid level in EHRS heat exchangers (EHRS-HXs) corresponds to a low NCG fraction, whereas a low liquid level indicates a higher NCG presence. As a result, correlations involving NCG in the Spearman diagrams must be interpreted inversely.

represents the nitrogen volume fraction within the sampled control volume (one out of the six composing the EHRS-HX of each EHRS train; each of 0.07 m³).

Table 1. Percentage deviation of uncertainty parameters from their nominal values.

Run id	$\Delta k_{\%}$	$\Delta RWST\ lev_{\%}$	$\Delta NCG_{\%}$	$\Delta VOR_{\%}$	$\Delta roughness_{\%}$
24	+53.22	-52.29	+64.59	-45.65	-1.16
42	+13.86	-24.3	+96.43	-0.19	-2.47
63	+10.33	-34.08	+80.06	-90.28	-2.42
69	+66.13	-59.61	+41.38	-51.95	+1.6
108	+34.6	-28.93	+85.86	-72.19	-1.82

From the uncertainty parameter deviations reported in **Table 1**, it is possible to understand why runs 69 and 24 represent the most severe cases (in terms of the three FOMs considered in this work) from a safety perspective, whereas runs 108 and, in particular, 42 are the least severe.

Table 1 shows that runs 69 and 24 exhibit medium-to-high deviations across almost all uncertainty parameters considered with surface roughness representing the only limited variation. By contrast, the other cases are characterized by large deviations for selected parameters but do not show the same simultaneous occurrence of multiple unfavorable conditions. Among them, run 69 is particularly challenging, as **Figure *7*** and **Figure *8*** indicate that it is the SA case in which the cladding temperature sharply increases, and the core water level significantly drops earliest in time. Runs 42 and 108, on the other hand, exhibit a delayed onset of both phenomena.

To illustrate the magnitude of these differences, cladding temperature begins at approximately 9000 s for run 69 versus 14000 s for run 42, and the second rapid decrease of the core water level (following the initial break-induced drop) occurs shortly after 10000 s for run 69 versus around 14500 s for run 42.

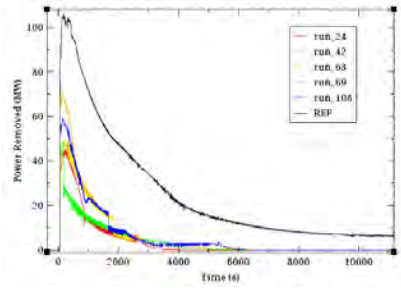

Figure 9. Max EHRS power removed for the five SA cases and for the reference.

Figure 9 shows the time evolution of the maximum power removed by the EHRS system. The graph indicates that all initial peaks of maximum power removal in the SA cases are lower than that observed in the reference calculation, where the PSS operates correctly, and the maximum power removed reaches 106.5 MW. Once again, the most penalizing cases are runs 24 and 69, which exhibit a maximum power removed around 48 MW. In particular, run 69 shows the fastest decline in the power curve, confirming it as the most severe case among those analyzed.

Before concluding this paragraph, some consideration is warranted for run 42. Based on the data reported in **Table 1** for this run, the critical events, namely the sharp increase in cladding temperature and the significant reduction of the core liquid level, occur later than in the other runs, particularly compared to the most severe cases, 69 and 24. The same data also reveal the significant contribution of NCG to the passive system failure. Aside from minor deviations in the pressure loss coefficient and surface roughness, the EHRS valve is nearly fully open (VOR = 99.81%), the RWST pool liquid level is moderately reduced (less than a quarter below its nominal value), and the NCG volume fraction is 96.43% of the sampled control volume. Thus, even though four out of the five uncertainty parameters do not deviate drastically from their

reference values, the elevated presence of NCG alone leads the transient to reach SA. This observation justifies the sensitivity study on NCG in the EHRS-HXs presented in the following section.

6. SENSITIVITY STUDY

Based on the conclusions drawn in the previous section, the present analysis focuses on a more detailed investigation of the effects of NCG on the performance of the EHRS passive safety system. The significant role played by NCG in driving the system toward SA conditions is consistent with the well-established degradation of condensation heat transfer in the presence of NCG [18], which impairs vapor transport to the condensing surface and reduces heat exchanger effectiveness, a particularly critical effect for systems relying on natural circulation as the sole driving force. For this reason, a dedicated sensitivity study is carried out by varying the NCG inventory in the EHRS-HXs across a progressively wider range of configurations. During the REPAS application, the sampling of the NCG inventory was restricted to one control volume per EHRS train out of the six composing the pool-immersed EHRS-HX. To better assess the impact of this modeling assumption, a preliminary sensitivity analysis was performed by varying the NCG volume fraction within these two control volumes (one per EHRS train) considered in the REPAS sampling. Specifically, five cases were defined with increasing NCG fractions, namely 85% (NCG_1), 90% (NCG_2), 95% (NCG_3), 98% (NCG_4), and 100%, corresponding to a fully gas-filled control volume (NCG_5). **Figure 10** and **Figure 11** show the time evolution of the maximum cladding temperature and the power removed by the EHRS, respectively, for the five NCG_cases and for the reference calculation.

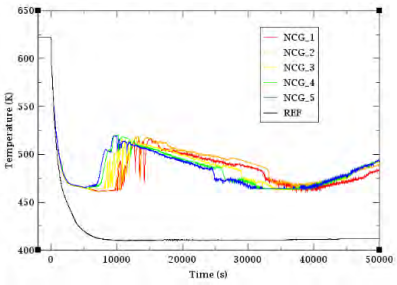

Figure 10. Max cladding temperature for the five NCG_cases and for the reference.

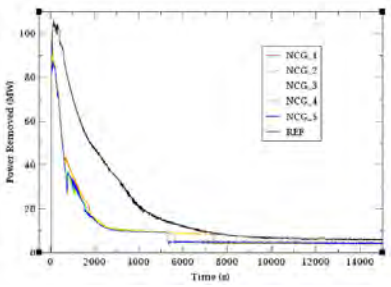

Figure 11. Max EHRS power removed for the five NCG_cases and for the reference.

From **Figure 10** and **Figure 11** it emerges that, despite the NCG volume fraction in the sampled control volume, none of the simulated scenarios reach SA conditions within the simulated time window, although a monotonic increase of the cladding temperature is observed in all cases after about 38000 s. In particular, **Figure 10** shows that the maximum cladding temperature remains below 520 K in all cases after the post-SCRAM temperature drop, indicating that the fuel cladding integrity is preserved over the simulated interval; however, the non-stationary trend suggests that a long-term evolution toward SA conditions cannot be excluded on the basis of the present calculations alone.

Nevertheless, increasing the NCG fraction progressively degrades EHRS performance, as reflected in the trends of removed power shown in **Figure 11**. The final power drop occurs at progressively later times, with the minimum power removed reached first in NCG_5 (5345 s from the start of the transient), followed by NCG_4 (5635 s), NCG_3 (6205 s), NCG_2 (7205 s), and NCG_1 (7385 s), respectively. This corresponds to a total delay of approximately 34 minutes between the earliest and latest cases, highlighting the impact of increasing NCG content on the timing of EHRS performance degradation. It is worth underlining that in these sensitivity cases the minimum removed power is around 4.5 MW, while in the reference case is around 5.5 MW. In particular, the continued rise of the cladding temperature observed around 38000 s indicates that these cases have not yet reached a stationary condition at 50000 s; extended simulations are therefore required to conclusively assess whether this first set of configurations ultimately avoids SA conditions.

With regard to the core collapsed coolant level, the water level decreases following the small-break LOCA and, due to the partial effectiveness of the EHRS, does not fully recover to nominal values. Nevertheless, for all five NCG_cases considered in this initial sensitivity study, the level remains below the TAF but consistently above the Bottom of Active Fuel (BAF).
Since none of the NCG configurations in the first set proved excessively penalizing for the system under investigation, the analysis was extended with an additional set of five simulations. Five new cases, labeled NCG_6 through NCG_10, were defined by progressively adding one more EHRS-HX control volume fully occupied by NCG per EHRS train. Specifically, case NCG_6 includes, in addition to the fully gas-filled volume considered in NCG_5, a second heat exchanger volume filled with NCG. This procedure was continued up to NCG_10, in which all heat exchanger volumes (i.e., the entire EHRS-HXs) are fully filled with NCG. **Figure 12** and **Figure 13** show the time evolution of the maximum cladding temperature and the core collapsed coolant level, respectively, for these additional five NCG sensitivity cases.

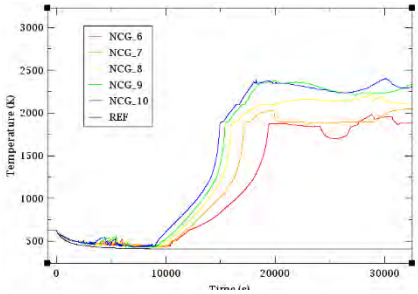

Figure 12. Max cladding temperature for the additional five NCG_cases and for the reference.

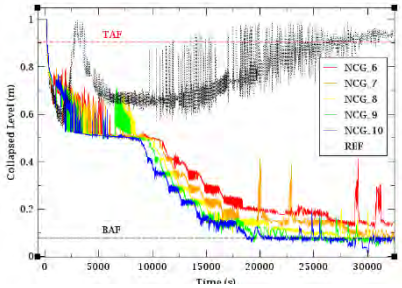

Figure 13. Normalized core coolant level for the additional five NCG_cases and for the reference.

The cladding temperature trends reported in **Figure 12** indicate that all five cases evolve into SA conditions. A combined inspection of **Figure 12** and **Figure 13** shows that the onset of cladding temperature escalation occurs concurrently with a rapid reduction of the core coolant level. This behavior is observed at progressively earlier times as the NCG inventory increases, from approximately 10300 s for NCG_6 to 9000 s for NCG_10. Beyond 30000 s, the core water level in all five cases stabilizes around the BAF. Finally, **Figure 14** and **Figure 15** show the EHRS removed power and circuit mass flow rate for these cases and for the reference.

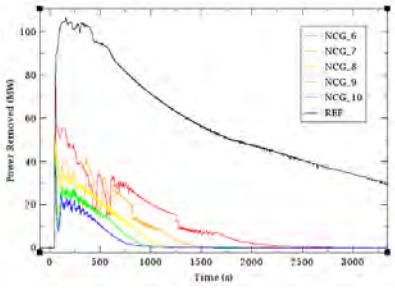

Figure 14. Max EHRS power removed for the additional five NCG_cases and for the reference.

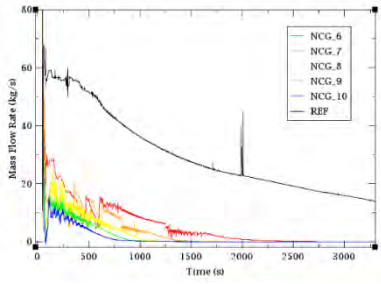

Figure 15. EHRS Mass flow rate for the additional five NCG_cases and for the reference.

A comparison between the EHRS removed power and the circulating mass flow rate shows that the temporal trends of these two quantities are qualitatively very similar within each analyzed case. This behavior is consistently observed across all scenarios from NCG_6 to NCG_10, confirming that the EHRS heat removal capability is directly governed by the natural circulation established in the loop: as the circulating mass flow rate drops, the power removed from the core drops accordingly. For all cases in the second set (NCG_6 through NCG_10), both the EHRS removed power and the circulating mass flow rate decrease rapidly to near-zero values, though at different instants. Moving from the least penalizing scenario (NCG_6) to the

most unfavorable one (NCG_10), the time at which these minima are reached occurs progressively earlier, indicating an earlier loss of EHRS effectiveness with increasing NCG inventory.
A direct comparison between cases NCG_5 and NCG_6 further highlights the impact of NCG accumulation on EHRS performance. In case NCG_5, where only one of the six heat exchanger control volumes is fully filled with NCG, the system does not evolve into SA conditions. Although the circulating mass flow rate undergoes a faster and more pronounced reduction compared to the reference case, it stabilizes shortly after 5000 s at an approximately constant value of about 2 kg/s. Conversely, in case NCG_6, where two heat exchanger control volumes are completely filled with NCG, the system evolves into SA conditions, and the circulating mass flow rate drops below 1 kg/s before 2000 s. In the present configuration, a single heat exchanger control volume corresponds to approximately 0.214% of the total EHRS volume; accordingly, the transition from NCG_5 to NCG_6 results in an NCG volume fraction of 0.86%, sufficient to drive the system into SA conditions.
To obtain a first estimate of the NCG volume fraction leading to a DBA-to-DEC transition, an additional sensitivity cycle is performed to investigate the system behavior for NCG fractions between those of NCG_5 and NCG_6. Five additional cases are therefore defined, labeled NCG_5-2, NCG_5-4, NCG_5-6, NCG_5-8, and NCG_5-9. Starting from the NCG_5 configuration, in which the first of the six heat exchanger control volumes per EHRS train is fully occupied by nitrogen, the second control volume is progressively filled with NCG at increasing fractions of 20%, 40%, 60%, 80%, and 90%, respectively, thus bridging the gap between NCG_5 and NCG_6.
Figure 16 and **Figure 17** show the time evolution of the maximum cladding temperature and the power removed by the EHRS, respectively, for these last five NCG sensitivity cases.

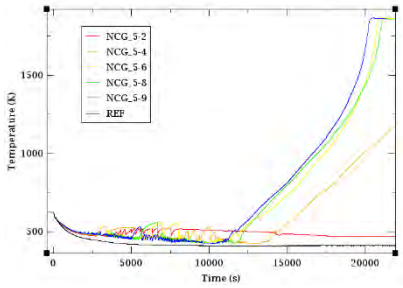

Figure 16. Max cladding temperature for the last five NCG cases and for the reference.

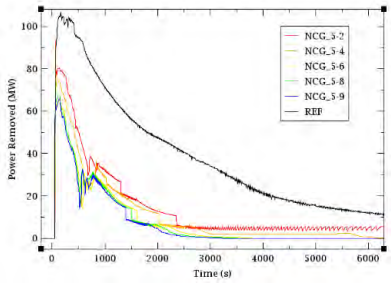

Figure 17. Max EHRS power removed for the last five NCG cases and for the reference.

Figure 16 and **Figure 17** show that, among the five additional sensitivity cases, only NCG_5-2 does not reach SA conditions within the simulated time window. As clearly visible in **Figure 16**, cases NCG_5-4 through NCG_5-9 all exhibit a sharp escalation of the maximum cladding temperature, confirming the onset of core degradation. This behavior is corroborated by **Figure 17**, which shows that only NCG_5-2 maintains a non-negligible removed power, sufficient to ensure adequate heat removal from the core and to prevent the transition to SA over the analyzed time span. In all other cases, the removed power progressively drops to zero, with the collapse occurring earlier as the NCG fraction in the second heat exchanger control volume increases.
The present sensitivity study provides an indication of the volume fraction of NCG that may drive the system into SA conditions within the simulated time window. The least penalizing case evolving into SA is NCG_5-4: a nitrogen volume fraction of approximately 0.6%[2] of the total EHRS system volume is therefore sufficient to lead the system to SA within 50000 s. It should be emphasized that this figure represents a sufficient, rather than strictly minimum, NCG inventory

[2] This value is computed as the ratio between the total NCG volume present in both EHRS trains in case NCG_5-4 and the total EHRS volume.

for SA onset, since the lower-NCG_cases (NCG_1–NCG_5 and NCG_5-2) display non-stationary trends at 50000 s whose long-term outcome cannot be conclusively assessed from the present calculations.
This result, combined with the findings of the previous sensitivity sets, provides a first characterization of the EHRS response to increasing NCG content within the 50000 s simulation window, progressively narrowing the NCG inventory range within which SA onset is observed, from the initial case-to-case resolution of the first two sets down to the finer resolution achieved in the present one.

7. CONCLUSIONS

This work presents a detailed analysis of severe accident scenarios emerging from a prior application of the REPAS methodology to the EHRS of a generic iPWR SMR design, with focus on the role of NCG accumulation in driving functional failures of the passive safety system. Beyond the methodological application itself, the study shows how the combined REPAS–MELCOR approach can be exploited to investigate how specific governing parameters drive the transition from DBA to DEC conditions through the progressive loss of passive system functionality.
Among the cases identified in the REPAS campaign, five evolved into SA conditions. Their analysis revealed that the Valve Opening Ratio (VOR) and the Non-Condensable Gas (NCG) fraction within the EHRS-HXs are the most influential parameters, with their simultaneous unfavorable combination as the primary driver toward core degradation. A dedicated sensitivity study, based on deterministic MELCOR simulations with progressively increasing NCG inventory, showed that small amounts of NCG can impair natural circulation in the EHRS and degrade its heat removal capability, consistent with the degradation of condensation heat transfer reported in the open literature. Rather than aiming at the quantitative identification of a precise NCG threshold for SA onset, which would require a more extensive analysis, this study demonstrates that small quantities of NCG on the tube side can affect the passive system mission. Extending the simulated transients well beyond the 50000 s considered here is essential to properly quantify the long-term impact of NCG on the EHRS performance in the present model and represents the natural continuation of this work.

PERFORMANCE ASSESSMENT OF PASSIVE SAFETY SYSTEMS AND IDENTIFICATION OF CONDITIONS LEADING TO DESIGN EXTENSION SCENARIOS

The 12th Conference on SEVERE ACCIDENTS RESEARCH – ERMSAR 2026, 18 – 22 May 2026, Madrid, Spain

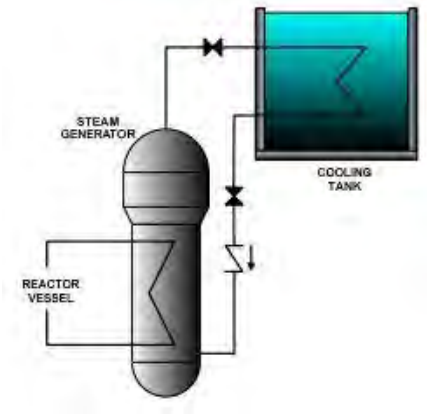
Erik Cilia[1], Fulvio Mascari[2]

[1]University of Bologna, Italy
[2]ENEA, Bologna, Italy

Purpose of the study

In this work, a reliability analysis of a **Decay Heat Removal System (DHRS)** was performeed strarting from a previous **REPAS** application and exending it with a sensitivity analysis.

- **DHRS** is a fundamental system to **remove the decay power** from the core;
- It works in **Natural Circulation (NC);**
- There are valves that connect system to the reactor vessel ➔ **need the activation**;
- **His failure can lead to Design Extension Condition**.

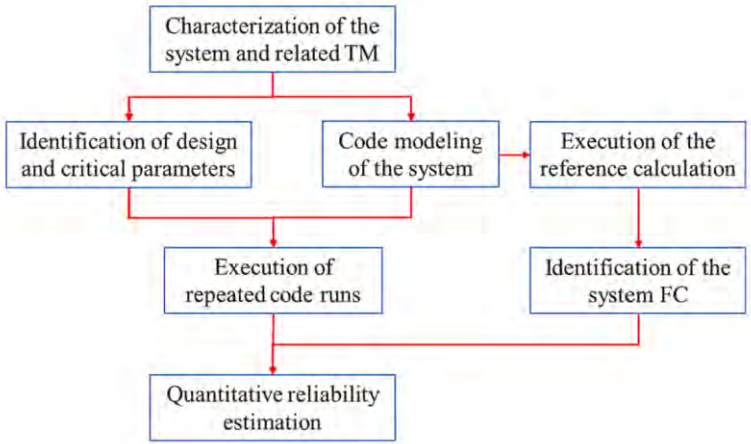


The present activity has been conducted in the framework of the Horizon Euratom **SASPAM-SA project**. The project is coordinated by ENEA and 23 organization from 14 countries are involved.

Funded by the European Union

REPAS methodology

REPAS methodology was developed for the evaluation of the reliability of passive systems.



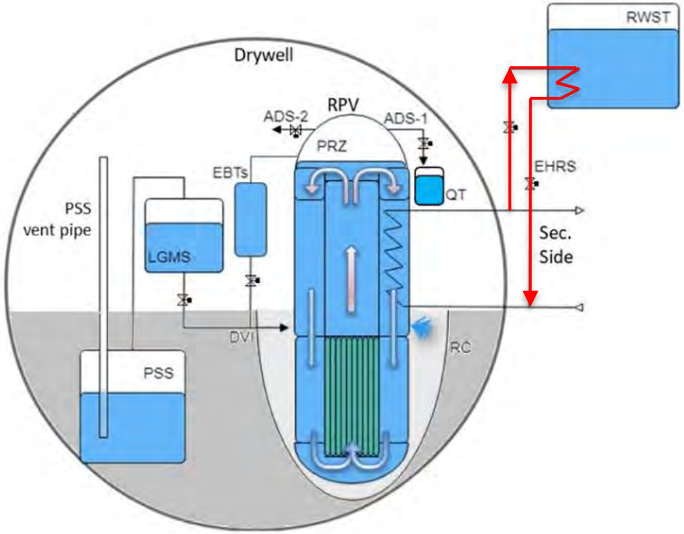
Main steps of the method:

- Characterization of the design of the system, its operating conditions and **Target Mission (TM),**
- Identification of design and critical parameters, with their reference values, ranges of variability and probability distributions,
- Code modeling of the system and execution of the reference calculation.
- Identification of the system **Failure Criteria (FC),**
- Execution of repeated code runs,
- Quantitative reliability estimation.

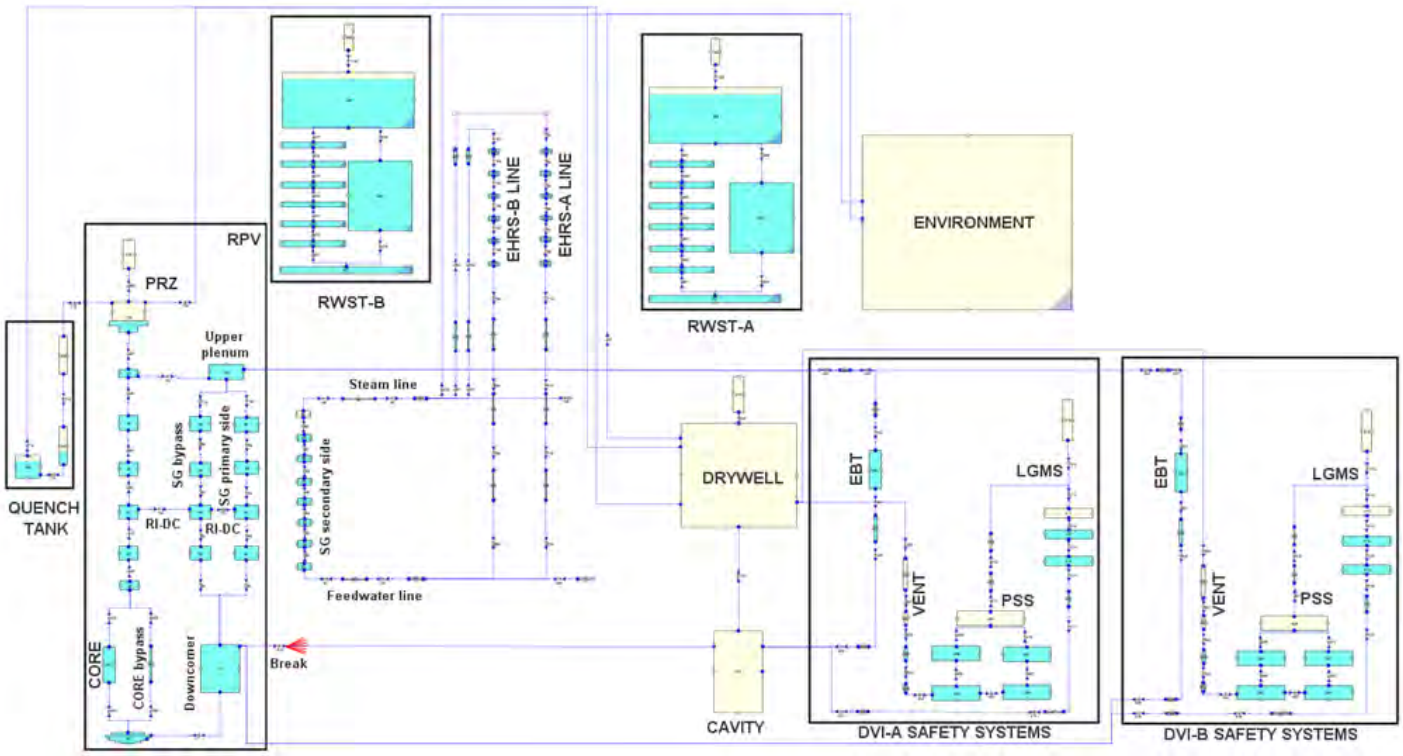
Generic iPWR Design

The **iPWR** here considered is characterized by the use of several passive systems, by a dry containment and a power of about 300 MWe:

- The reactor operates in **forced circulation during normal operation** and employs a passive mitigation strategy in accidental transients;
- It consists of an **integral RPV**, which contains the core, a compact SGs, the Control Rod Drive Mechanism (CRDM), the primary pumps and the pressurizer included in the upper head;
- The hot water at the core outlet flows **upward in a circular riser** up to the primary pumps suction. The flow path continues through the annular region of the DC, outside the core, to the LP and then back to the core.

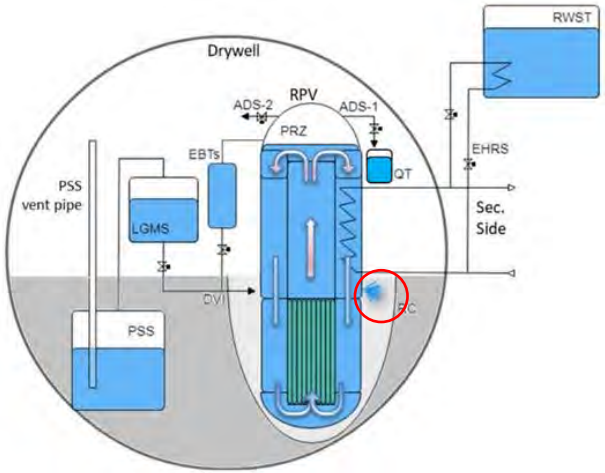


MELCOR nodalization



Reference Transient

DBA scenario: Guillotine break of one Direct Vessel Injection (DVI) line, considering the availability of all safety systems.



BREAK OF DVI LINE

High Containment Pressure signal
- SCRAM
- Secondary system isolation
- EHRS actuation

Low PRZ level signal
- RCP coastdown
- RI-DC valves opening

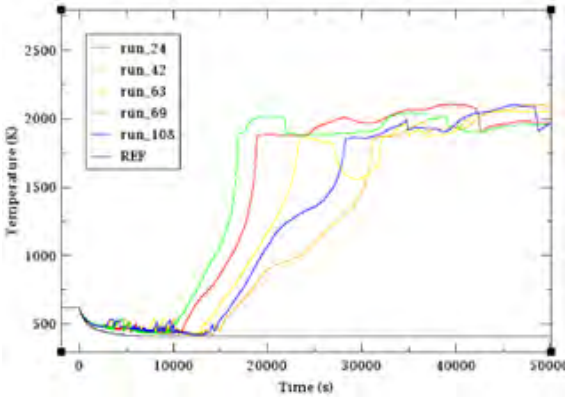
Low PRZ pressure signal
- EBTs actuation
- ADS stage-1 actuation

Low DP RPV-Containment signal
- LGMSs actuation

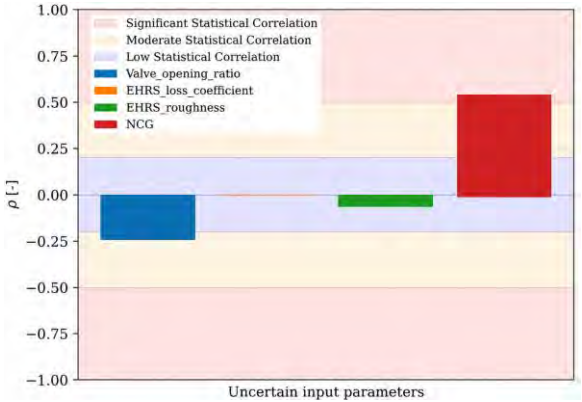
Low LGMS mass signal
- ADS stage-2 actuation

REPAS application

Among the **150 MELCOR simulations** performed, **5 resulted** into a **Severe Accident.**



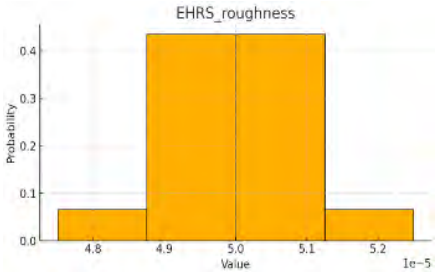
Max Cladding temperature



Simple rank correlation coefficient

Uncertain parameters

Parameter	Nominal value	PDF
Loss coefficient (k)	0.6	Stepwise
Surface roughness	5 E-05 m	Normal
Valve Opening Ratio (VOR)	1	Stepwise
Non-Condensable Gas (NCG) fraction	0	Stepwise
RWST initial level	2 m	Stepwise

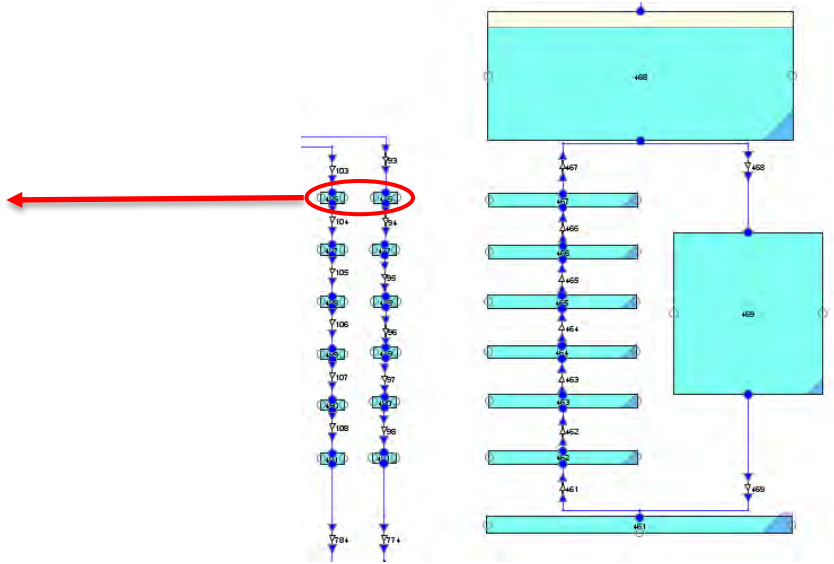


Sensitivity Analysis

Three separate sensitivity analysis campaigns were carried out, each comprising five different calculations, with the aim of identifying the threshold level of NCG that leads to SA.

1° Sensitivity calculations set:

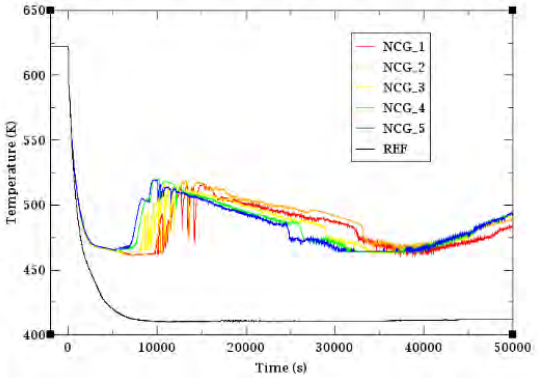
- **NCG_1**: 85% vol. of N_2 for the considered control volume (for each line)
- **NCG_2**: 90% vol. of N_2 for the considered control volume (for each line)
- **NCG_3**: 95% vol. of N_2 for the considered control volume (for each line)
- **NCG_4**: 98% vol. of N_2 for the considered control volume (for each line)
- **NCG_5**: 100% vol. of N_2 for the considered control volume (for both line)



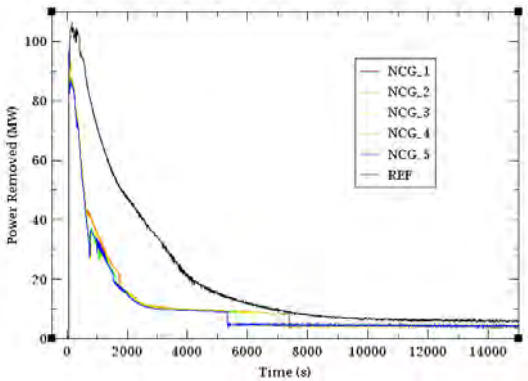
Sensitivity Analysis

Three separate sensitivity analysis campaigns were conducted, each consisting of five different calculations.

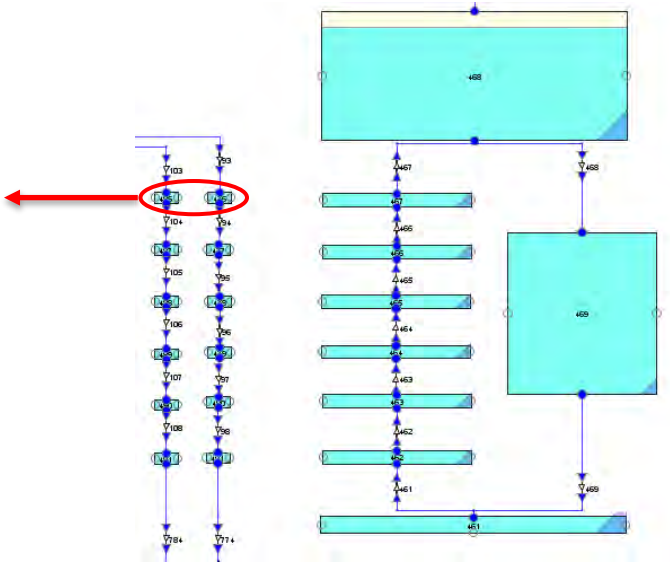
1° Sensitivity calculations set:



Max Cladding temperature



EHRS power removed

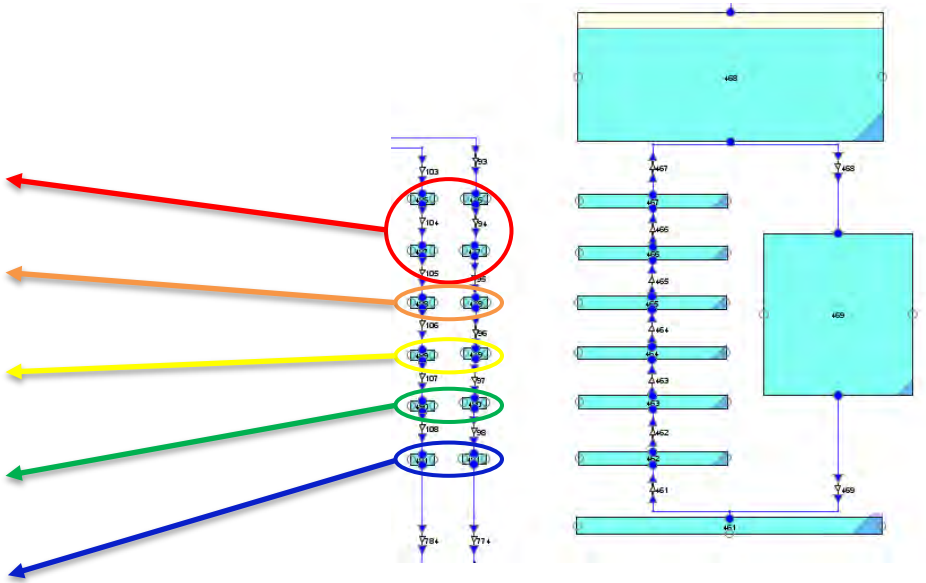


Sensitivity Analysis

Three separate sensitivity analysis campaigns were carried out, each comprising five different calculations, with the aim of identifying the threshold level of NCG that leads to SA.

2° Sensitivity calculations set:

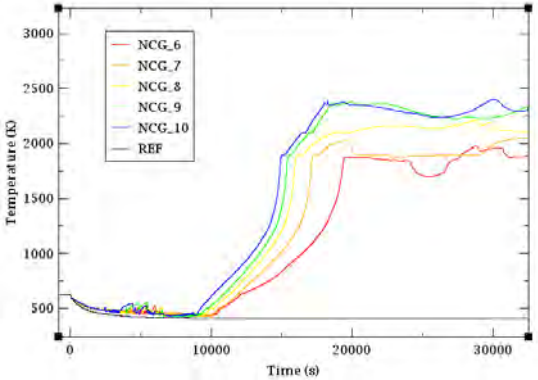
- **NCG_6**: Two control volumes full of N_2 (for each line)
- **NCG_7**:Three control volumes full of N_2 (for each line)
- **NCG_8**: Four control volumes full of N_2 (for each line)
- **NCG_9**: Five control volumes full of N_2 (for each line)
- **NCG_10**: Six control volumes full of N_2 (for each line)



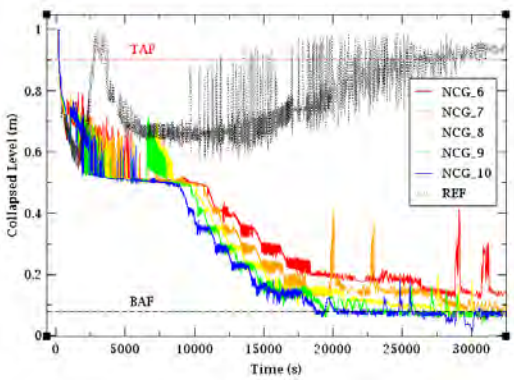
Sensitivity Analysis

Three separate sensitivity analysis campaigns were carried out, each comprising five different calculations, with the aim of identifying the threshold level of NCG that leads to SA.

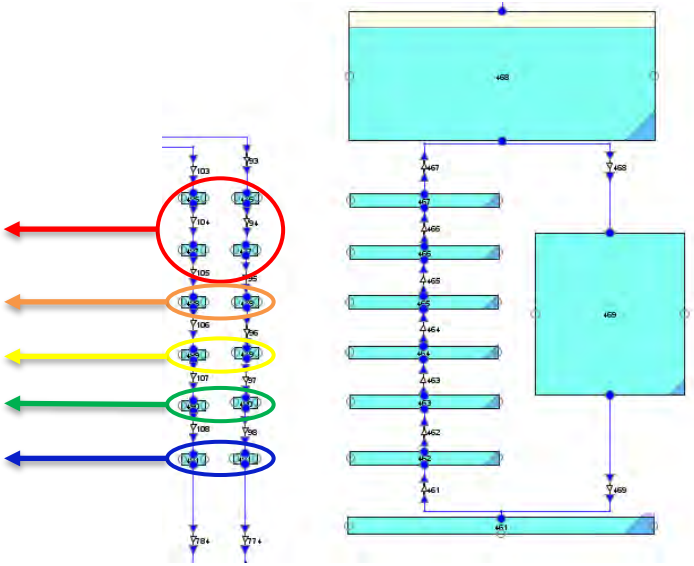
2° Sensitivity calculations set:



Max Cladding temperature



Collapsed core coolant level

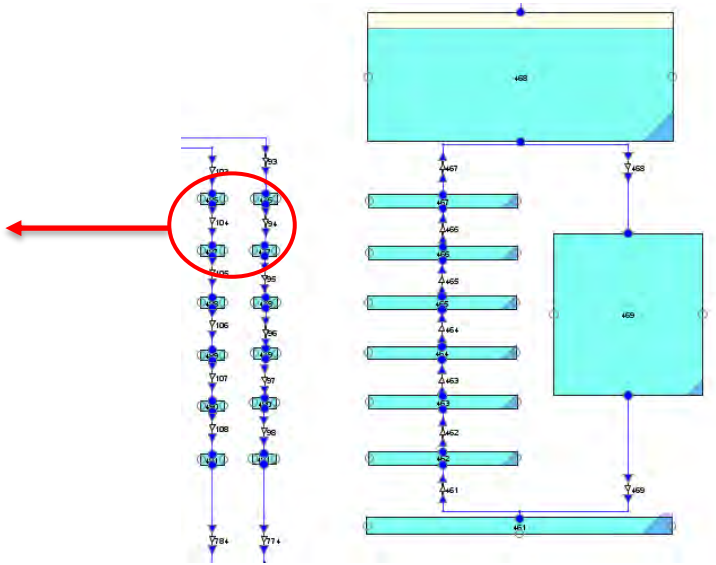


Sensitivity Analysis

Three separate sensitivity analysis campaigns were carried out, each comprising five different calculations, with the aim of identifying the threshold level of NCG that leads to SA.

3° Sensitivity calculations set: Starting with the first control volume filled with N_2, we proceed by adding increasing amounts to the second volume only.

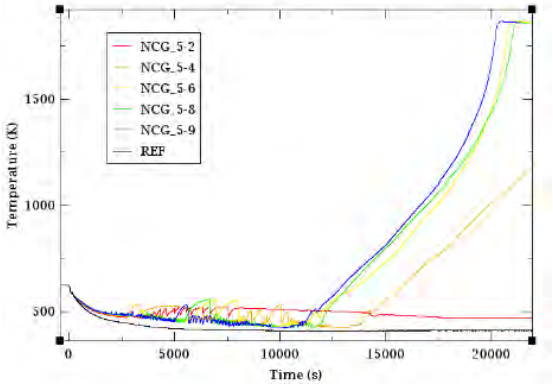
- **NCG_5-2**: 20% vol. of N_2 for the 2° control volume considered(for each line)
- **NCG_5-4**: 40% vol. of N_2 for the 2° control volume considered (for each line)
- **NCG_5-6**: 60% vol. of N_2 for the 2° control volume considered (for each line)
- **NCG_5-8**: 80% vol. of N_2 for the 2° control volume considered (for each line)
- **NCG_5-9**: 90% vol. of N_2 for the 2° control volume considered (for both line)



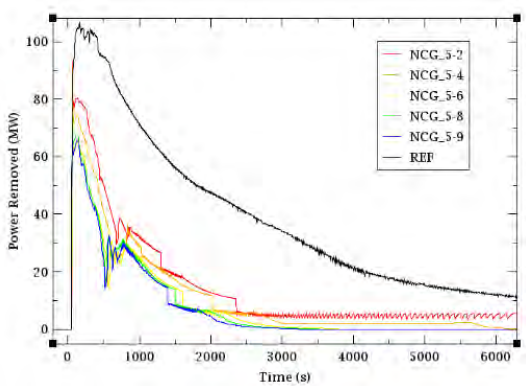
Sensitivity Analysis

Three separate sensitivity analysis campaigns were carried out, each comprising five different calculations, with the aim of identifying the threshold level of NCG that leads to SA.

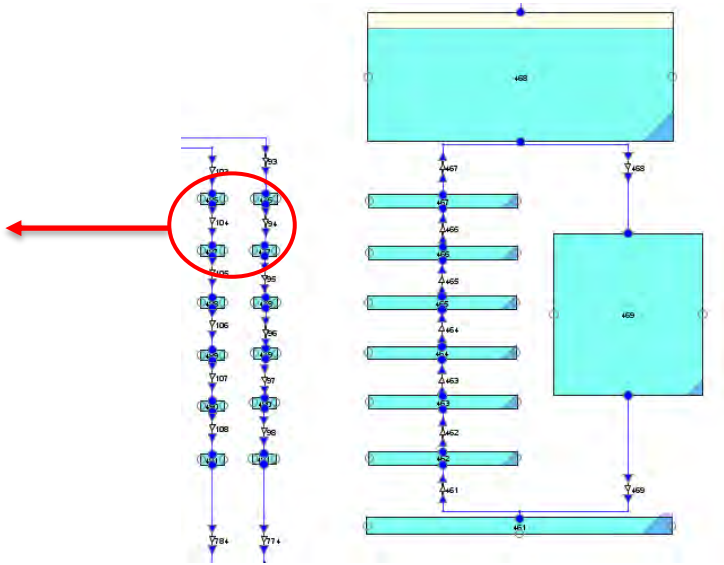
3° Sensitivity calculations set: Starting with the first control volume filled with N_2, we proceed by adding increasing amounts to the second volume only.



Max Cladding temperature



Power removed



Conclusions

- The **REPAS** methodology, applied together with **MELCOR**, was used in a **generic iPWR** SMR under **SB-LOCA** conditions to investigate **EHRS** behavior and characterize the **transition from DBA to DEC** and SA scenarios.
- Five scenarios evolved into SA conditions. **The most influential parameters** were the Valve Opening Ratio (**VOR**) and the accumulation of **NCGs** inside the EHRS-HXs, which strongly degraded natural circulation and condensation heat transfer.
- The sensitivity study showed that **increasing NCG content progressively reduced EHRS heat removal capability**, leading to earlier coolant level decrease and core degradation. In the present model, an **NCG fraction of about 0.6%** of the total EHRS volume was **sufficient to trigger SA conditions within 50000 s**.
- Extending the simulated transients well beyond the 50000 s considered here is essential to properly quantify the long-term impact of NCG on the EHRS performance in the present model.

ABSTRACT

The Emergency Core Cooling System in an Integral Pressurized Water Reactor promises enhanced safety of the reactor during transients and accidents. In particular, during Loss of Coolant Accidents, this system enables long-term cooling of the reactor, by way of opening of the 3 Reactor Ventilation Valves at the top of the Reactor Pressure Vessel and 2 Reactor Recirculation Valves above the core thereby establishing a natural circulation loop. The ECCS actuation signal is typically triggered when the Module Protection System at high containment water level and low differential pressure between RPV and containment vessel. In this study, operation of these valves with delayed manual actuation and opening is simulated using MELCOR for 72h. Time delays for opening of RVVs and RRVs were uniformly sampled in a period up to 27,000s after the initiating event that includes Loss of Coolant Accident and Steam Generator Tube Rupture. The focus of this paper is the core degradation progression and the thermal-hydraulic properties in the containment vessel. The core cooling process is sensitive to the full availability of ECCS, and it can be fully achieved if RRVs are open within about 15,000s irrespective of timing of RVVs opening. Debris properties and hydrogen generation due to oxidation are also characterized, and timing of melt relocation is found to be sensitive to timing of ECCS activation. These findings are important for in-vessel debris coolability, risk-performance and risk-informed assessment of passive safety features in Small Modular Reactors, and aid in better understanding of code capabilities and uncertainties involved in severe accident analysis.

1. INTRODUCTION

Small Modular Reactors (SMRs) have a large growing interest in the international community to cater to growing energy demands by large data centers and industries, and to replace energy sources with large carbon footprint increasingly due to their ability in meeting flexible power needs [1]. SMRs enjoy better safety features, including inherent, passive, integral safety features, than conventional reactors, drawing to its appeal [2]. SMRs also promise simplification and standardization making it economically feasible. An innovative safety component of the passively safe SMRs is the Emergency Core Cooling System (ECCS). The ECCS in these SMRs propose 2 sets of redundant valves comprising of 3 independent Reactor Ventilation Valves (RVVs) at the top of the Reactor Pressure Vessel (RPV) that discharges into the Containment Vessel (CNT) and 2 independent Reactor Recirculation Valves (RRVs) just above the core [36] that lets water in to the RPV thereby establishing a natural circulation loop. Unlike conventional Pressurized Water Reactors (PWRs), where ECCS comprises of several safety injection tanks and pumps that inject borated water in case of Anticipated Operational Occurrences (AOOs) and postulated accidents like Loss-of-Coolant Accidents (LOCAs), ECCS in Integral PWRs (iPWRs) are much smaller and simpler in operation [4]. iPWRs, such as the NuScale reactor, in order to simplify and adhere to regulations on system reliability [3], have developed novel engineered systems such as Inadvertent Actuation Block (IAB) feature

to the main ECCS valves [37]. Achieving low Core Damage Frequency (CDF $<10^{-9}$/year) and Large Release Frequency (LRF $< 10^{-10}$/year) [5][38], demands exceptional reliability and innovative systems to ensure effective accident mitigation even in the absence of offsite power.

Single Failure Criteria (SFC) is an important issue that has received attention in the case of functioning of the ECCS valves. ECCS is "considered to be designed against an assumed single failure if a single failure of any active or passive component does not result in the loss of the capability of the system to perform its safety functions" according to Appendix A to 10 CFR Part 50 [39], and during the audit by the US NRC the design itself was revised [39]. This issue was also reviewed in innovative-SMR design [40] as it aims to satisfy stringent safety criteria for Standard Design Approval. [6] also examined single failure accident conditions initiated by partial failures of the ECCS stuck closed. [7] performed safety assessment assuming ideal operating conditions with no safety degradation due to component level failures in i-SMRs, which then was recently followed by another assessment assuming partial valve failures [8]. This also highlighted multi-valve failure being a driver for accelerated core heat-up and hydrogen generation.

Degraded ECCS function in traditional PWRs due to blockages and clogging have been a part of reactor safety assessments [9][10][11][12]. Such blockages were identified as a relevant issue after the Barsebäck-2 accident in 1992 [13], with accumulation of fibrous material potentially hampering core cooling. It is a possibility that, even if SFC is resolved in iPWRs, there may be other such instances, even if conditions are extrapolated from traditional PWRs, that may jeopardize the ability of the ECCS valves to operate as intended, effectively leading to uncovery and subsequent damage of the core.

In response to growing international interest and technical knowledge gaps, the EURATOM SASPAM-SA project – the framework for this research – was launched in 2022 to tackle these issues and support European licensing requirements for severe accident (SA) analysis and emergency planning zone (EPZ) evaluation [14]. The distinct designs of iPWRs present challenges for system codes and analytical tools in simulating complex reactor phenomena during off-normal events, a difficulty explored in multiple studies [20][21][22][23]. Key focus areas include hydrogen explosions [15], forced and natural circulation passive safety [16][17], in-vessel cooling and debris retention [18], containment phenomena and behaviour [19]. Severe accident codes like MELCOR and ASTEC, typically employed to model accidents and validated against experimental data, were originally developed for large reactors. Applying these integral codes to novel phenomena in SMRs – where extensive experimental data are scarce – can introduce uncertainties rooted in modeling assumptions or design decisions. This underscores the need for thorough understanding of code strengths and limitations, which drives ongoing investigation.

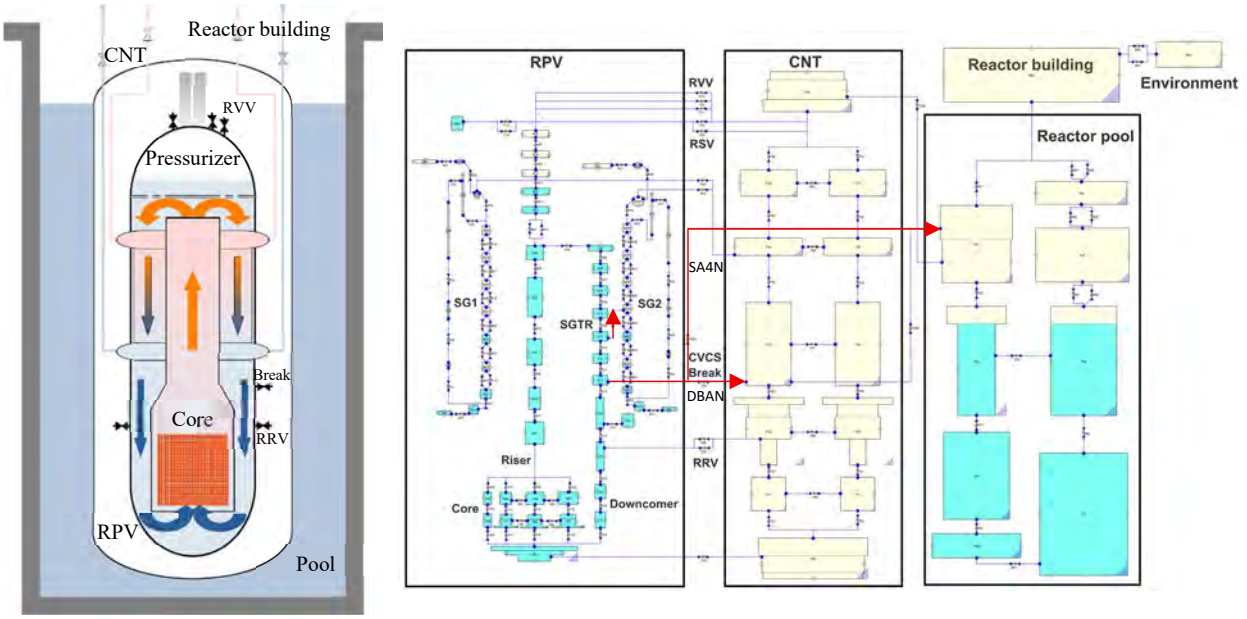
Recent analyses of generic iPWR designs have simulated design basis accidents (DBAs) and certain design extension conditions [14][24][25]. Studies have shown MELCOR's ability to perform stable and accurate simulations of iPWRs during LOCAs [26][27][28]. The complete core degradation phenomena and conservative source term behaviour in iPWR during several severe accident scenarios were analyzed in complementary studies [29][30]. In the present study, the consequences of delayed activation of ECCS on thermal-hydraulic and core degradation during SAs in a generic iPWR is studied using MELCOR code.

2. iPWR MODEL DESCRIPTION

Here the generic iPWR design in consideration is of the submerged containment type, where the integral reactor vessel is housed inside a larger containment which is submerged inside a pool of water, shown in Figure 1(a). Specifications for the development of the model are gathered from open literature and do not represent any specific reactor design. The study therefore provide a largely qualitative set of results. The MELCOR v2.2.r2023.0 model used here has undergone several modifications from the original input deck developed by [24][25]. The iPWR is a 160MWth, naturally cooled integral reactor with 2 helical tube steam generators (HTSG). The RPV is contained inside a CNT to maintain core cooling in case of potential loss

of reactor vessel integrity. The primary system operating pressure is 8.3MPa and CNT is almost at vacuum. The core has 37 17x17 fuel assemblies, about half the height of typical PWR assemblies located at the bottom of the RPV. Above the core, a cylindrical riser tube terminates in the pressurizer (PRZ). The downcomer, an annular region surrounding the riser, houses the two HTSGs in the upper part and the core in the lower part. The HTSG consists of a set of tube bundles with separate feedwater inlet and steam outlet lines. The MELCOR model of the iPWR, shown in Figure 1(b), comprises of control volumes (CVs) representing parts of RPV, SGs, CNT, RP, reactor building and the environment, and flowpaths (FLs) representing connections between CVs. Details of packages used to develop inputs in MELCOR can be found in the guides [26][27]. As done in many other studies, the MELCOR model lacks the Decay Heat Removal System (DHRS), for conservativeness and mainly as the scenarios modelled are of LOCA-type SA where DHRS may be insignificant [31].

The T/H behaviour is dependent on the assumptions and choices made in nodalization of these CVs and properties of FLs. In case of accidents the steam generators (SGs) are isolated and ECCS is activated which establishes coolant circulation between the reactor coolant system (RCS) and the containment side transferring decay heat to the reactor pool (RP) acting as the ultimate heat sink (UHS).



(a) Generic design. (b) MELCOR nodalization.

Figure 1. Schematic of the generic iPWR design (based on [24]).

The CNT is defined by 12 CVs, separately for the cold and hot side to support natural convection, to reduce instabilities in simulations, while RP has 8 CVs. The SG is a bundle of once through HTSG, whose secondary side has 2 sets with 7 CVs each. The heat transfer inside is modelled using HelicalSG HS in MELCOR. HSs also exist for the CNT designed to support natural convection in the pool. FLs exist between CVs in the core, riser, downcomer, SGs and CNT. A leakage FL is added to the top of CNT with the top of RP, and the flow rate is controlled by a tabular depending on pressure differences. The core is modelled in the COR package, as 4 rings radially and 10 levels axially. Active core is in the central 3 rings and levels 6-9, the lower plate in level 4 and lower plenum in levels 1-3. 2 reactor safety valves (RSV) are included to protect RPV from over-pressure. Decay heat tables based on ANS73 standard are implemented. The radionuclide transport is handled by the RN package, where hygroscopic and chemisorption models are activated. Revised CORSOR-Booth high burnup model is used for fission product (FP) release.

2.1. Emergency Core Cooling System

The ECCS valves comprise the main valve, IAB valve, and two solenoid (trip and reset) valves. The reset valve links fluid from the Chemical and Volume Control System (CVCS) to pressurize the interior of the ECCS valve. It opens only when fluid is supplied, remains closed during normal operation in a fail-closed state. Conversely, the trip valve serves to depressurize the ECCS valve by connecting it to the CNT during accident conditions; it is normally closed but assumes a fail-open state [36].

The main valve opens in response to the pressure differential between the main chamber and the CNT. During normal operation, pressure inside the ECCS compresses a spring, which holds the main valve closed. The IAB valve, normally open, permits pressure equalization between the main chamber and the ECCS valve. It is actuated by the pressure difference between the RPV and the ECCS valve. When this differential exceeds ~9 MPa, RPV pressure compresses the IAB valve's spring, thereby isolating the pressure connection between the main chamber and the ECCS valve [36].

ECCS activation is controlled by the Module Protection System (MPS). There are a few conditions to be met for the actuation of the ECCS, however not all are applicable in the generic model. The only conditions defined for ECCS actuation are the following,

1. High CNT level – >5.8m.
2. Low PRZ-CNT pressure difference – <6.2MPa.

When both conditions are met, both RVVs and RRVs are set to open after an opening delay of 15s. Additionally, the ECCS can be manually operated in the control room.

2.2. Accident Scenario Definitions

The SA initiating events considered here is based on the preliminary results obtained from conservative reference scenarios run in [29][30]. In particular it was observed that, within 72h of the initiating event, LOCA type scenario in the Chemical Volume and Control System (CVCS) discharge line outside the CNT (SA reference ID SA4/SA4N) and SG Tube Rupture (SGTR) accident (SA reference ID SA6N) leads to failure of the RPV lowerhead. Similar LOCA scenario inside the CNT, with a CNT bypass line so that mass transfer from the CNT to the reactor building (RB) can occur (SA reference ID SA5N), leads to RPV dryout with imminent lowerhead failure, just after 72h. In all the cases it was assumed that ECCS is unavailable. It should be noted that for SA6N and SA5N ECCS was assumed to be unavailable. In cases where it is available, RPV failure could be possible long after 72h and not before. However in the case of SA4 despite ECCS being available the scenario leads to rapid RPV failure. The DBA scenario considered was the CVCS LOCA inside the CNT with all ECCS valves functional. A case with non-functional ECCS (SA reference ID DBAN) showed that RPV can be devoid of water, however core remains in partially damaged state for a long period of time without undergoing further degradation.

Considering these facts, in this paper DBAN, SA4N and SA6N are simulated (reference cases defined in Table I) – which represent different types of SA scenarios with ECCS failure at the beginning of the accident – whereby, after a brief delay, ECCS function is recovered manually by the operators. Readers are directed to [30] for more details of the reference cases of these scenarios. Here the scenarios with delayed ECCS recovery is identified as DBAN-ECCS, SA4N-ECCS and SA6N-ECCS. Such risk-informed analyses have been performed in probabilistic safety assessment (PSA) of large reactors, such as the Nordic Boiling Water Reactors (BWRs), where operators can manually activate pumps, valves, etc. to recover safety systems and study the impact of timing on essential core degradation characteristics [32][33][34]. A typical block diagram for the event description is provided in Figure 2. Note that RVV is assumed to be recovered before RRV. ECCS failure can be pinned to mechanical or electrical factors. Although their likelihood to fail is small, the consequences if they do can be extreme, and lessons from Fukushima accident is a reminder to anticipate the worst case scenario that can result in core damage [35].

Table I. Accident scenarios considered for analysis.

Scenario ID	Initiator	ECCS availability		Comments
		RVV	RRV	
DBAN	CVCS discharge LOCA	No	No	1.6” LOCA in CVCS discharge to CNT
SA4N	CVCS discharge LOCA	No	No	1.6” LOCA in CVCS to RP (outside CNT)
SA6N	SG tube rupture (SGTR)	No	No	No steam line isolation, feedwater line isolated

The scenario begins with an initiating event (LOCA or SGTR), followed by reactor scram and isolation of CNT and SG (in the case of LOCA). DHRS is unavailable, ECCS valves fail to function initially and steam can escape through the RSV cycling when RSVs are activated if necessary to prevent overpressure. Either just before or after uncovery and onset of core damage, RVVs are recovered by the operators with a delay (t_{RVV}) followed by recovery of RRVs (t_{RRV}). Time delays for both RVVs and RRVs are uniformly sampled in [0, 27000]s for all scenarios and all MELCOR simulations are run for 72h from initiating event using a MATLAB setup that restarts crashed simulations with automatic time-step refinement.

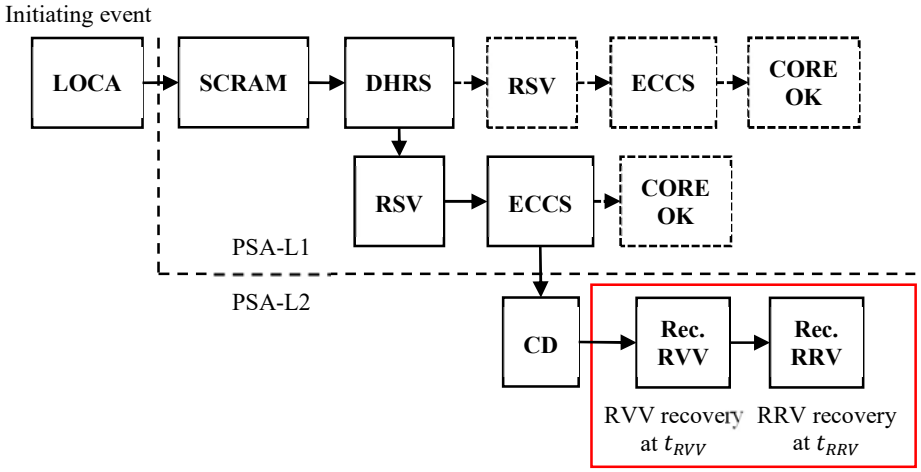


Figure 2. Block diagram for potential core damage in absence of ECCS and recovery of RVV and RRV function. CD: core damage.

From the perspective of FP releases to the environment: DBAN-ECCS considers only the leakage path from the CNT to the RP – essentially CNT is isolated even if core damage occurs, and small releases can be expected which represents RC1; SA4N-ECCS considers large releases directly to the RP and the environment as CNT is bypassed which represents RC2; and SA6N-ECCS again represents RC2 which considers a combination of core damage and CNT bypass scenario, where it is conservatively assumed that any FP collected beyond SG control volumes (turbine CVs) are part of the environmental source term. Typically, a scenario defined by loss of support systems account for a large fraction of CDF and LRF.

3. RESULTS

Here, results of MELCOR simulations are presented with T/H considerations, core behaviour and timing of events. All accident scenarios were run using MELCOR v2.2.r2023 for 72h.

3.1. Results of the Reference Cases – DBAN, SA4N and SA6N

Table II shows the timing of reactor trip signal, ECCS signal, core uncovery and core damage process for the reference cases. As seen, in the case of SA4/SA4N and SA6/SA6N, as the CNT is bypassed, the high

CNT level condition is not met, and a modification is made especially for SA4 and SA6, where the ECCS is activated even when just the pressure difference condition is satisfied. In these 2 cases, it is observed that the core damage is minimized for a long time. In the case of SA4, the lowerhead (LH) indeed fails much later than when ECCS does not activate. In the scenario with SGTR and functioning ECCS, the core remains covered for the duration of 72h. And in the case with failure of ECCS, a failure of the LH is observed at ~24h. While in SA4N there is a period of ~6h between failure of the core plate and failure of LH, there is only ~1.5h between the two events in SA6N. The time of recovery of ECCS [0, 27000]s extends across the core degradation progression for DBAN and SA4N, and only until core uncovery for SA6N. Another observation is that events (except for the failure of RPV) in SA4N occur later than in SA4 where ECCS functions as expected, indicating that activating ECCS may sometimes accelerate core degradation as the core uncovery is quicker in those conditions.

Table II. Timing of events during the reference accident scenarios [30].

Scenario ID	SCRAM	High CNT level	ECCS signal	Core uncovery	Gap release	PD formation	Relocation to LH	Core plate failure	LH failure
DBA	19	520	520	-	-	-	-	-	-
DBAN	19	520	-	4950	12782	13728	-	-	-
SA4	44	-	815	848	3300	4178	10426	12057	232843
SA4N	44	-	-	1814	7412	8565	13071	13071	33682
SA6	30	-	1380	-	-	-	-	-	-
SA6N	30	-	-	27350	40220	42934	72145	79230	84320

SCRAM - safety control rod axe man/reactor trip; PD - particulate debris; LH - RPV lower head.

3.2. Delayed ECCS Recovery in DBAN Scenario

The 28 cases resulting from the sampling of the time of delays are shown for reference in Figure 3(a). The collapsed liquid level and the pressure in the RPV are presented in Figure 3(b) and (c). As seen, initially 3 different trajectories evolve as a result of availability of the RVV, numbers marked on the figure, and subsequent delays result in continuation of the trajectories and bifurcations occur only later upon activation of the RRVs. Correspondingly the pressure evolves according to different sets of trajectories, initially linked to depressurization with the loss of coolant inventory in the RPV and subsequent boiling and evaporation related pressurization. For the first few cases, the ECCS activates before the core is uncovered and hence SA is averted, however in the succeeding cases, core is either partially or fully exposed before the RRV is activated, whereby the coolant that is lost to the CNT is circulated back to the RPV (seen as vertical jumps in the liquid level). As a result, those cases where the RVV opens at time t = 0s (001, 002, 004, 007, 011, 016, 022), are saved from any form of core damage, even if the core is partially uncovered. Cases 012, 013 and 014, corresponding to RRV activating at t = 18000s, see very minor damage (<0.3%) following uncovery, oxidation and failure of the cladding in the central topmost ring of the fuel assemblies. Here, the core is not fully uncovered. Any further delay in opening of the RRV result in low core damage (11-17%) with small fraction of the debris being relocated to the LP, as the core is fully uncovered for at least an hour before activation of RRV.

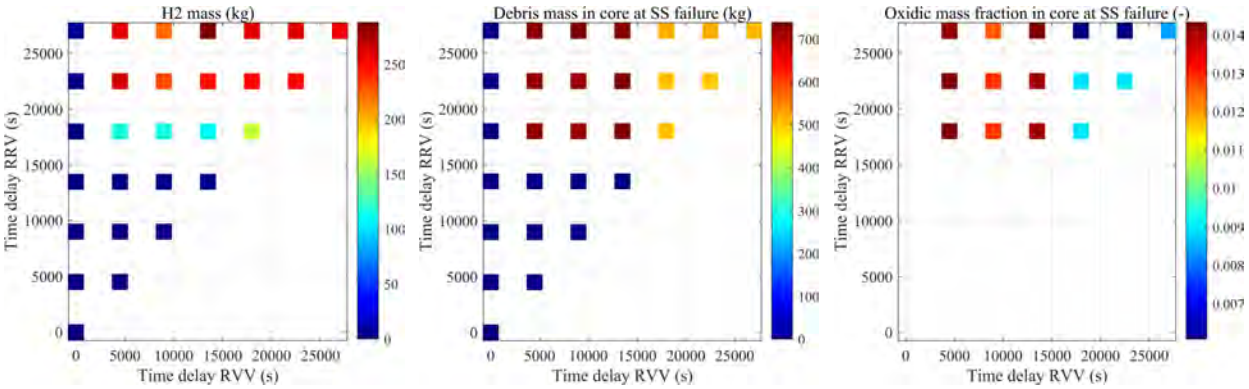
(c) Pressure in the RPV.

Figure 3. Evolution of T/H properties during DBAN-ECCS scenario. Colors represent the case corresponding to a particular set of RVV and RRV delays.

Hydrogen mass generated as a result of oxidation of the structures and cladding is presented in Figure 4(a). Most of the hydrogen mass is generated in cases from late activation of RVVs (>4500s) and RRVs (>18000s), thereby slower loss of coolant inventory and for longer period of time, similar to progression in TMI wet-core scenario. Figure 4(b) and (c) show the debris (combined particulate (PD) and conglomerate debris (DC)) properties in the core region at the time of failure of the core support structures (SS). Cases where damage occurs with early opening of RVVs (<18000s), at the time of SS failure, have slightly larger fraction of debris above the support plate than cases where RVVs open at a later time (>18000s). This is because the SS fails at a slightly later time compared to cases with late RVV activation, which likely enhances natural circulation and thus produces better core cooling. The oxidic mass fraction also corroborates this fact, given that cases with early opening of RVVs have a higher oxidic fraction as the core stays at uncovered state longer until SS failure. Upon SS failure, some mass of debris relocates to the LP, where the remaining water quenches any falling molten material. This causes the pressure to rise, seen as secondary peaks in the RPV, see Figure 3(c). Because all the coolant inventory stays within the CNT, though this debris relocates to the LP, it is cooled by surrounding water in the RPV and the CNT, arresting further degradation. The debris mass that has relocated to the LP at the end of simulation, shown in Figure 5(a), indicates that late opening of RVVs results in larger relocation (>3400kg) subsequent to the failure of support plate compared to early opening.



(a) Hydrogen generation in the core.

(b) Total debris in core region at SS failure.

(c) Oxidic mass fraction in the core region at SS failure.

Figure 4. Core properties during DBAN-ECCS scenario. SS: support structures.

Figure 5(b) presents the final oxidic mass fraction in the core region, showing that late opening of RRVs (>25000s) combined with early opening of RVVs (<18000s), provide the core a combination of long period of uncovery and sufficient amount of steam circulation to enhance oxidation of the cladding and the structures, and corresponding hydrogen generation (see Figure 4(a)). Figure 5(c) shows the total convective heat transfer from the core as a function of time of activation of RVVs and RRVs. The COR package uses Lipinski dryout correlation to compute the limiting heat transfer rate from the porous particulate debris bed and in case any of the axial levels give more heat transfer rates than the limit, no convection is calculated for debris or structures below this level. This is also the case when debris undergoes quenching at this limiting rate, no convection from other components to the water pool is considered [26][27]. Early ECCS activation results in large decay heat removal by convection to the CVH package, however when the RRVs are activated late (>18000s) a reduction in convective heat transfer is observed. The least heat removal coincides with the scenario that leads to some of the highest hydrogen generation (Case 025). Once the RRVs are activated, all the debris above the core support plate is quenched by reflooding.

(b) Grouping based on timing of events. Event that occurs first is placed first in the group ID.

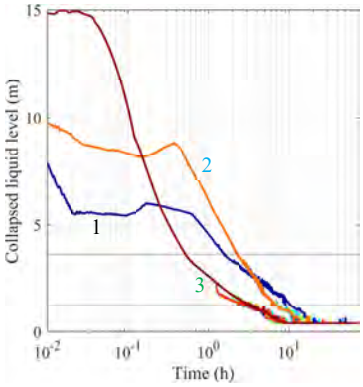
Figure 6. Timing of major events during DBAN-ECCS scenario. 1 RVV: time of activation of RVV, 2 RRV: time of activation of RRV, 3 H2: time of commencement of H2 generation, 4 FUNC: time of full core uncovery, 5 GAP: time of onset of gap release, 6 SSF: time of failure of SS, 7 LHF: time of failure of LH.

Figure 6(a) shows the timing of major events (activation of RVVs and RRVs, commencement of oxidation, full core uncovery, gap release, failure of SS and failure of the LH) for all the considered scenarios. Figure 6(b) shows the grouping of the cases based on the order of the above events. This is a concise way of expressing clusters of cases that behave similarly during the accident. Whenever RVVs are activated early,

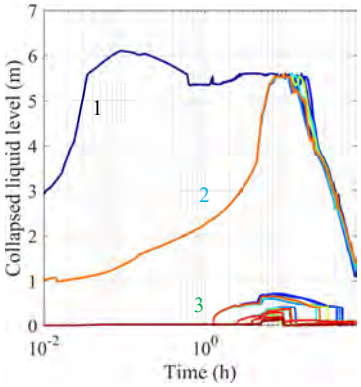
a SA is prevented from occurring: groups **1345672**, **1467352**, 3456**712** (here the first 5 events i.e. 3rd, 4th, 5th, 6th 7th events do not occur at all, they have t = 0s) and 467**1352** (here the first 3 events i.e. 4th, 6th, 7th events do not occur, they have t = 0s) avoid any core damage. Group 467**3512** has delayed activation of RVV and RRV, and despite uncovery of core, oxidation of cladding once ECCS is activated at 13500s, it ceases core damage and is the latest time for the operator to activate ECCS to maintain an intact core in this type of accident scenario.

3.3. Delayed ECCS Recovery in SA4N Scenario

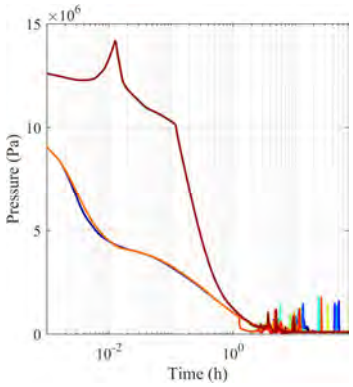
The collapsed liquid levels in the RPV and the CNT for the 28 delayed scenarios of SA4N-ECCS are presented in Figure 7(a) and (b). Similar to the DBAN-ECCS scenario, 3 sets of evolution of parameters are observed corresponding to different rates of loss of coolant from the RPV (break is outside the CNT). Unlike the DBAN-ECCS scenarios, for some cases (set 3) RVVs and RRVs are activated at such late times that, the water that is eventually collected/condensed in the CNT will never circulate back into the RPV as the liquid level never reaches the height of RRV valves (5.6m). Consequently, no natural circulation is established and there is no heat transfer from the core debris in the lower parts of the RPV to the UHS, leading to core damage due to inadequate core inventory. Core degradation further proceeds with LH attack by the molten melt in the and its failure with ejection of debris to the CNT. The pressure evolution is shown in Figure 7(c).



(a) Collapsed liquid level in the RPV. Dashed lines represent active core region.



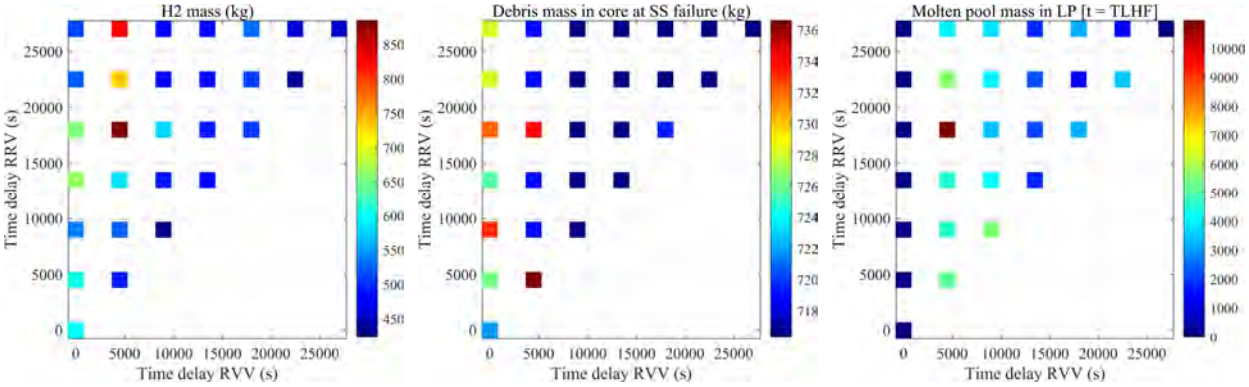
(b) Collapsed liquid level in the CNT. RRV is at 5.6m.



(c) Pressure in the RPV.

Figure 7. Evolution of T/H properties during SA4N-ECCS scenario. Colors represent the case corresponding to a particular set of RVV and RRV delays, as in Figure 3(a).

Figure 8(a) shows the total hydrogen generated as a function of RVV and RRV activation times. In this type of scenario where the RPV is losing coolant directly to outside the CNT, late opening of RVV valves have no drastic effect on oxidation in the core. Largest hydrogen mass is generated when the RVVs open at 4500s, and increases with increasing delay of RRV opening times. In this scenario, opening of RRV only serves to circulate steam from the CNT to the RPV, thereby increasing oxidation of the core materials, eventually expelling steam to the RB via the break. Early activating of RVVs (>4500s) also leads to the formation of larger amounts of debris in the core just before SS failure, as seen in Figure 8(b). This is likely due to loss of coolant to the CNT which does not enhance core cooling, but only exacerbates core degradation. Consequently, by the time SS fails and the debris relocation has taken place, due to lack of RPV LH cooling by surrounding water in the CNT, solid debris that is quenched in the water present in the LP evaporates all the water, increasing its temperature, and undergoes melting to form a pool in the LH. The total mass of this debris pool just before failure of the RPV LH is shown in Figure 8(c). Late ECCS activation (>13500s), results in slightly smaller amount of melt in the LP, compared to cases with early RVV activation (<9000s).



(a) Hydrogen generation in the core.

(b) Total debris in core region at SS failure.

(c) Molten mass in the LP at RPV failure.

Figure 8. Core properties during SA4N-ECCS scenario. SS: support structures.

SA4N being one of the few scenarios leading to RPV failure, can expect roughly 10-22ton of debris mass being ejected from the RPV, as shown in Figure 9. MELCOR by default assumes both solid and molten debris is ejected to the cavity. Based on the size of the breach and porosity of the debris in the LH, if any, there is likely a mixture of the two being ejected, and this would necessitate further sensitivity study using codes and experimental verification. Except for the cases with RVVs activating at t = 0s, all cases observe RPV failure. It is likely that if the simulations extended a few hours beyond 72h, these cases would also lead to failure once the coolant in the CNT would evaporate, see Figure 7(b). As with delayed RVVs activation affecting the molten debris in the LP, similar effect can be made out for mass of debris ejected to the CNT. Based on the timing of events, in Figure 10(a), it is seen that late ECCS activation, leads to early LHF (~10h), and subsequently time of LHF for cases with early ECCS activation can extend from 24-50h. Another observation regarding the timing of onset of oxidation and gap release of FPs is that these events occur roughly in 3 groups as predicted by MELCOR. Earliest hydrogen generation (at ~2h) can be expected from cases with late (>13500s) ECCS activation. Onset of hydrogen generation at ~6h is expected from RVVs activation at t = 0s and delayed RRVs activation (>22500s), while earliest ECCS activation (RVVs at t = 0s and RRVs < 22500s) result in the late oxidation. Consequently, based on the order of timing of these events, cases can be grouped as shown in Figure 10(c). From the perspective of arresting SA progression in SA4N like accident, operators may either recover RVVs instantly, irrespective of availability of RRVs, or delay the activation of ECCS to let the coolant evaporate by itself than accelerate it.

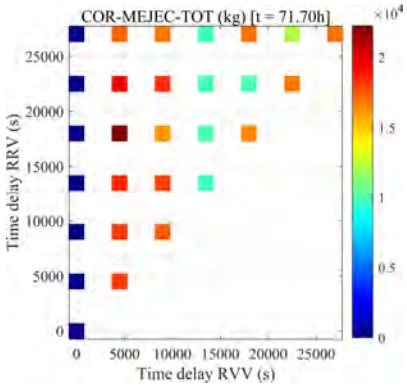


Figure 9. Total debris mass ejected upon RPV failure.

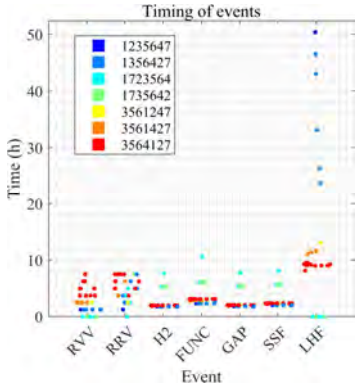
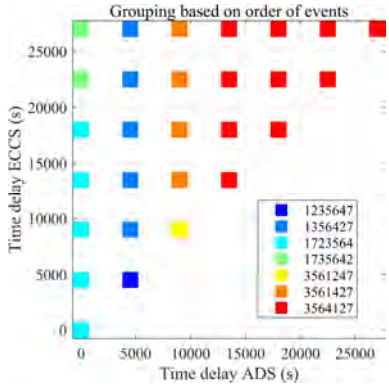


(b) Timing of events in 1-7.

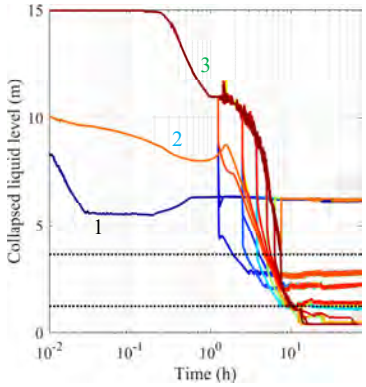


(c) Grouping based on timing of events. Event that occurs first is placed first in the group ID.

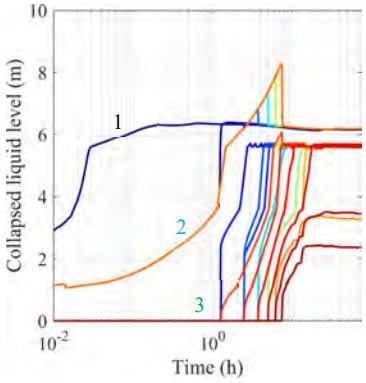
Figure 10. Timing of major events during SA4N-ECCS scenario.

3.4. Delayed ECCS Recovery in SA6N Scenario

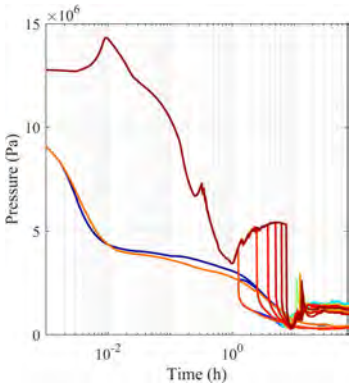
The time evolution of the liquid levels in the RPV and the CNT are provided in Figure 11(a) and (b). Similar to the previous scenarios, three different trajectories are observed for the collapsed liquid levels, however unlike the previous accidents (SA4N particularly), cases in set 3 lead to the core being partially flooded with water once the RRVs are open. Water inside the RPV evaporates into the CNT where it condenses, up to the level of the RRVs. Because the flow out through the small SGTR is governed by the pressure difference across the primary and secondary sides, once the RVVs are open, the primary side instantly depressurizes, seen as vertical drops in the pressure evolution in Figure 11(c), leading to loss in flow rate through the tube rupture. In essence, small quantities of water may trickle down the RRVs, get instantly vapourized in the core, flow out through the open RVVs and circulate back. This keeps the core partially wet for extended periods. For cases with late ECCS opening (>13500s, Cases 010, 014, 015, 019, 020, 021, 025, 026, 027, 028), water from the CNT may not be able to circulate back in through the RRVs to even partially cover the core and thus complete core may be uncovered. For cases with extreme delays (> 22500, Cases 021, 027, 028), water in the CNT is too low to replenish the core.



(a) Collapsed liquid level in the RPV. Dashed lines represent active core region.



(b) Collapsed liquid level in the CNT. RRV is at 5.6m.

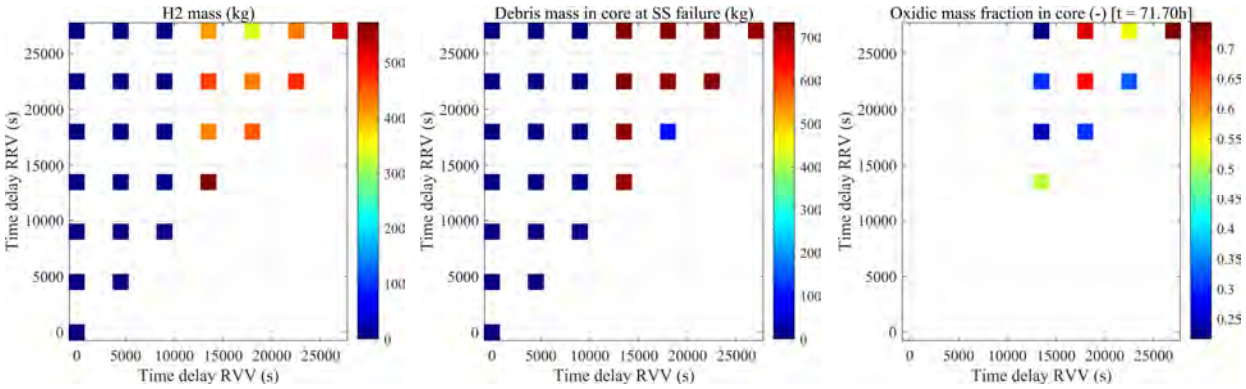


(c) Pressure in the RPV.

Figure 11. Evolution of T/H properties during SA6N-ECCS scenario. Colors represent the case corresponding to a particular set of RVV and RRV delays, as in Figure 3(a).

As a result of inadequate core cooling, cases with late ECCS opening (>13500s) see oxidation of the core producing about ~350-580kg of hydrogen, as shown in Figure 12(a). Unlike, the late RRV activation cases in DBAN-ECCS that produce hydrogen in the core, only those cases with late RRV and RVV activation undergoes oxidation. As shown in Figure 12(b), roughly 700kg of debris can be seen in the core region at the time of SS failure, corresponding to the same case of activation of ECCS. When the debris relocates to the LP, shown in Figure 13, further accident progression is arrested by the water pool in the LP. Case 010, results in largest hydrogen generated as well as some of the highest mass of debris relocated, mainly due to the fact that, early RRV activation combined with inability of water circulation and complete core uncovery for extended period oxidizing, melting and relocation of the debris. Consequently, this case has the least oxidic mass remaining in the core at end of the simulation, as shown in Figure 12(c).

Unlike, SA4N-ECCS cases, there is no complete loss of coolant from the CNT. Therefore, the operation of ECCS within this period [0, 27000]s, successfully manages in-vessel retention of the debris and prevents ex-vessel accident progression, which was the case in SA6N [30]. The maximum fraction of damaged core is around 70% (for the extremely delayed Case 028). While operator intervention was considered early in the accident progression (before core uncovery, see SA6N in Table II), it may be necessary to also investigate actions in the later phase of the accident, where severity of core damage state may worsen the situation. In tandem, it is also worthy to investigate the effect of size of SGTR on the accident progression.



(a) Hydrogen generation in the core. (b) Total debris in core region at SS failure. (c) Oxidic mass fraction in the core region at 72h.

Figure 12. Core properties during SA6N-ECCS scenario. SS: support structures.

Finally, the timing of major events and grouping according to the order of these events are presented in Figure 14(a) and (b). Onset of gap release and oxidation, in the case of DBAN-ECCS was restricted to ~3.4-3.8h and in the case of SA4N-ECCS restricted to 3 different time periods: ~2h, ~5h and ~8h. While in the case of SA6N-ECCS, these two events occur between 6-8h after the start of the accident, and the least ordered groups of events occur (4 v/s 8 and 7 in the former 2 scenarios). Phenomenologically, the grid based uniform sampling method may give a quick way of exploring the input space. As was noted earlier, expanding the operator intervention space to include late accident phase, may vastly increase the number of calculations. This will necessitate use of other methods, such as genetic algorithms, to reduce the user effect in identifying scenarios that can lead to SA and non-trivial scenarios. One such scenario can be identified (as red in color) in Figure 14(b). For instance, Case 015, does not experience failure of the SS while nearby cases all have SS failure in 6.2-8.2h. This may likely be a one off outlier or a result of time-step refinement when the code restarts after a crash and possibly missing cliff-edge effects in SS failure models.

Figure 14. Timing of major events during SA6N-ECCS scenario.

4. CONCLUSIONS

In this study, mitigation of SA progression in a generic iPWR by considering delayed recovery of ECCS was presented. The effect delayed activation of RVVs and RRVs have on debris properties, oxidation, integrity of the RPV and in-vessel melt retention strategy of submerged SMRs have been assessed using MELCOR code. Three different accident scenarios were assessed for the effect of the delayed ECCS

function. Different operation domains were identified that leads to specific set of events that may leads to severe core damage and relocation.

It was observed that in the case of DBAN-ECCS, late RRV activation can result in large debris formation and hydrogen generation, irrespective of time of activation of RVVs. However as the coolant inventory remains within the CNT, RPV failure is not observed for any time of delay. In the case of SA4N-ECCS, all cases where RVVs are not activated along with LOCA, lead to RPV failure and debris in ex-vessel state. This is also the scenario where largest oxidation of the cladding and structures takes place. Early activation of RVVs may postpone RPV failure at a cost of large amounts of hydrogen being generated. In the case of SA6N-ECCS, all delayed RVV activation scenarios lead to core damage, without RPV failure.

The reliability analysis of ECCS with operator actions have shown, in most cases, dominating sequences for core damage are inability of RRVs to open early, or inability of water inventory in the CNT to establish natural circulation through the RRVs. It has already been shown in [30] that size of break effect the speed of accident progression, it has to be investigated how the accident proceeds with capacity of ECCS severely reduced along with operator delays. This assessment, along with the sensitivity analysis, will be performed in a separate future study.

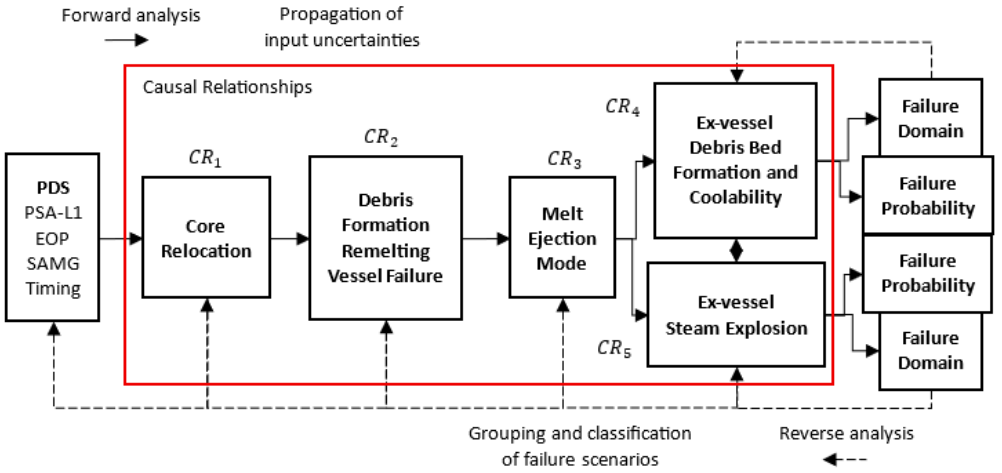
Stockholm, Sweden

Background: Risk Oriented Accident Analysis Methodology+

- ROAAM+ framework is being developed at KTH for risk assessment in Nordic BWR, It addresses uncertainties in:
  - Scenarios – aleatory.
  - Phenomena – epistemic.
- ROAAM+ is a risk analysis framework which is comprised of:
  - Detailed full models (FMs) – for key information about physics.
  - Coupled Fast-running surrogate models (SMs) – for sensitivity, uncertainty and failure domain analysis.
- ROAAM+ connect SA scenario with in-vessel, ex-vessel accident progression and ultimately release to environment.
- Latest analysis highlighted importance of ex-vessel phenomena:
  - Debris bed coolability – needs deep pool of water in cavity.
  - Steam explosion risks – necessitates reinforcement of hatch doors in the cavity.
- Need to further develop and demonstrate failure domain identification methodology.



Current ROAAM+ framework for Nordic BWR. The top layer of the framework is shown, that decomposes the various phenomenon into multistage causal relationships (CRs) propagating uncertainties from the initial plant damage state (PDS) to the ex-vessel phenomenon, represented by SMs within an envelope of bounding assessment. EOP: emergency operating procedure, SAMG: SAM guidelines.

Work Packages: KTH Contributions

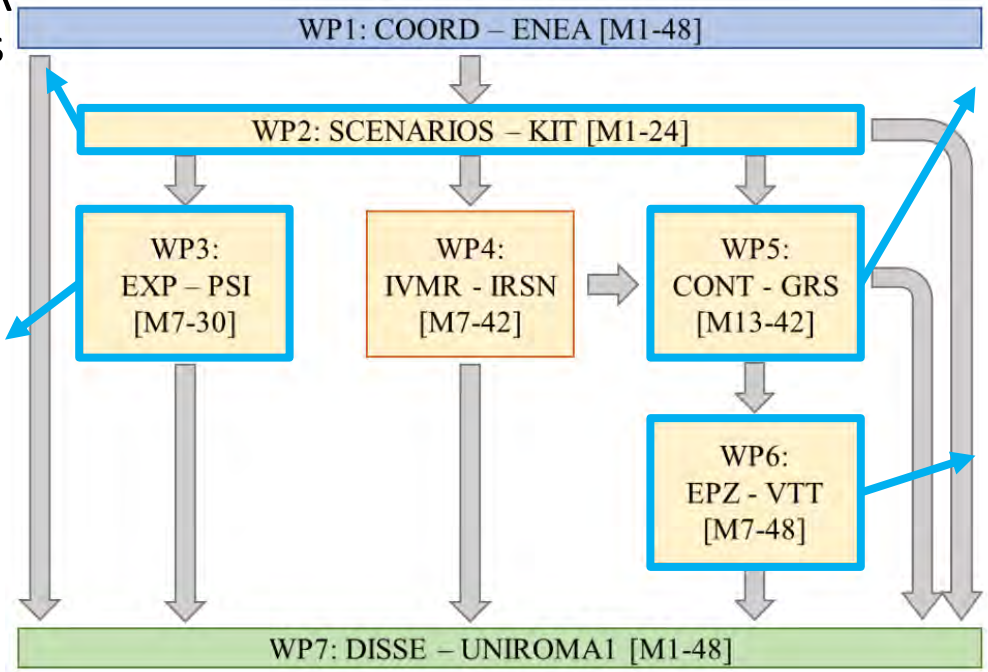
G. Acharya, et al., (2026)

Develop and assess generic but representative iPWR SA code input-decks and to identify plausible SA scenarios.

2.1

Review the existing experimental database, to assess its applicability to iPWR, to propose methods to apply existing data to iPWR, and to identify new experimental needs.

3.1, 3.2



Assess the codes to simulate the main containment behaviour (TH, FP and aerosol) and characterize the efficiency of passive measures for accident mitigation.

5.1, 5.2

Provide EPZ size and extension for selected SA scenarios coupling the results of ST codes to radiological consequences tools.

6.2, 6.3, 6.4

G. Acharya, et al., (2025)

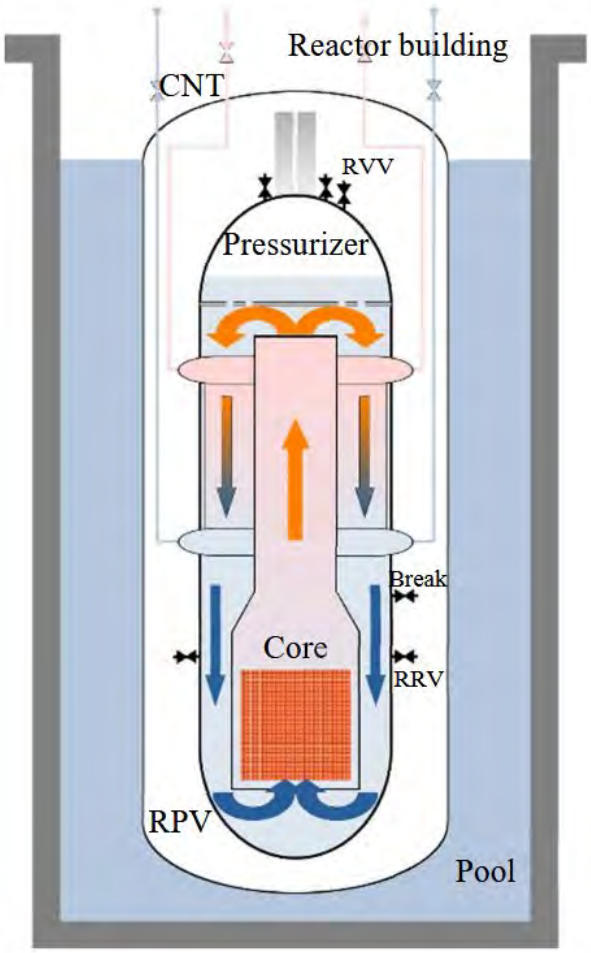
Motivation and Goals

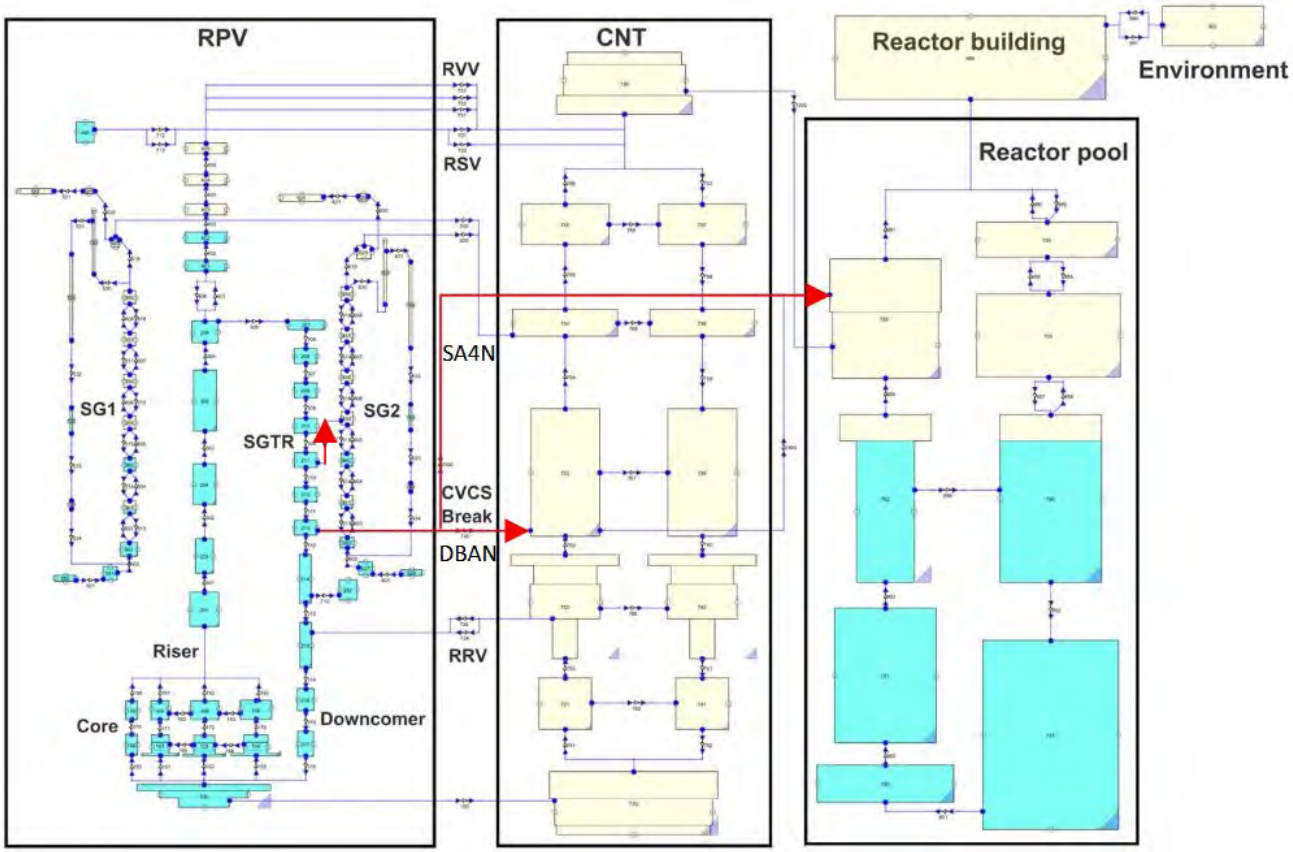
- Reduction of user effect in the selection of scenarios that can lead to severe accidents.
- Genetic algorithm based scenario space/failure domain identification is under development.
  - Efficient surrogate modelling approaches can replace expensive SA code (MELCOR) full model simulations.
  - Need for a training database.
- Ultimate goals:
  - Define a set of events (failure/recovery of the systems etc.) and ranges of possible timing for those events.
  - Sample in the space of the possible scenarios (each scenario is created by different combinations and timing of the events).
  - For each scenario (automatically generated using genetic algorithm) run FM code to find out if such scenario will lead to
    - core damage and
    - release of fission products.

Current Study Objectives

- Investigation of degraded ECCS function and partial recovery of RVVs and RRVs in a generic iPWR.
  - Analysis of events and timing of those events during representative accident scenarios.
  - Creation of a training database for development of SMs.

SASPAM-SA Generic iPWR Design 1





M. Malicki, et al., (2024)

Design 1: ECCS Description

- ECCS activation is controlled by the Module Protection System (MPS). There are a few conditions to be met for the actuation of the ECCS, however not all are applicable in the generic model.
- The only conditions defined for ECCS actuation are the following,
  - High CNT level – >5.8m.
  - Low PRZ-CNT pressure difference – <6.2MPa.
- When both conditions are met, both RVVs and RRVs are set to open after an opening delay of 15s.
- Additionally, the ECCS can be manually operated in the control room > manual operator delay + 15s.

Design 1: Accident Scenarios Description

- 3 accident scenario families considered

Scenario ID	Initiator	ECCS availability		Comments
		RVV	RRV	
DBAN	CVCS discharge LOCA	No	No	1.6" LOCA in CVCS discharge to CNT
SA4N	CVCS discharge LOCA	No	No	1.6" LOCA in CVCS to RP (outside CNT)
SA6N	SG tube rupture (SGTR)	No	No	No steam line isolation, feedwater line isolated

  - Identified here as DBAN-ECCS, SA4N-ECCS and SA6N-ECCS.

Time delays for recovery of ECCS are selected with a uniform grid sampling strategy in the range [0, 27000s] subjected to $t_{RRV} > t_{RVV}$.
28 cases per accident scenario are sampled.

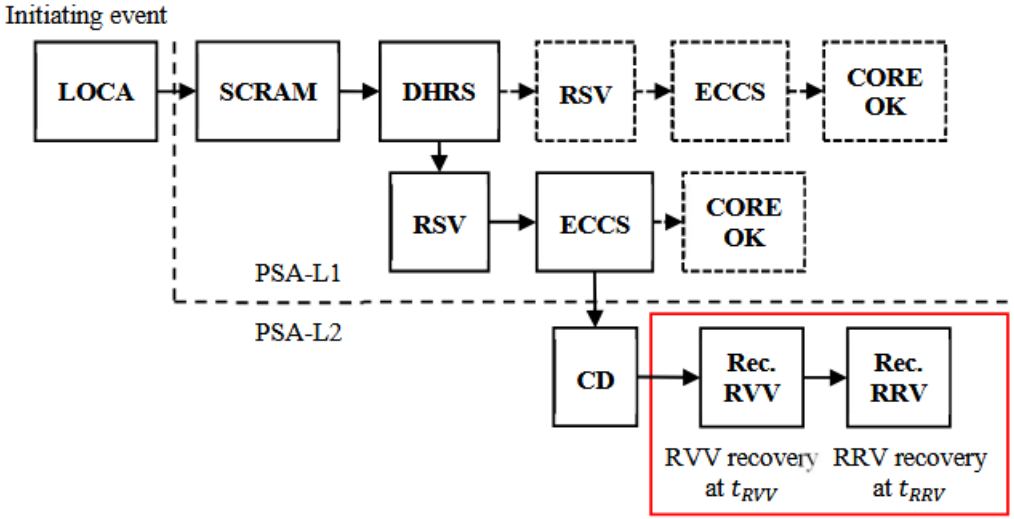


Figure 2. Block diagram for potential core damage in absence of ECCS and recovery of RVV and RRV function. CD: core damage.

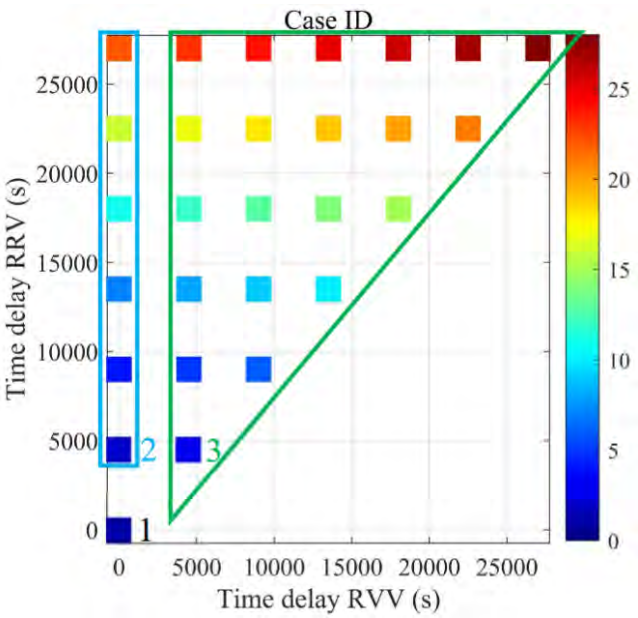
Results: Reference Scenarios

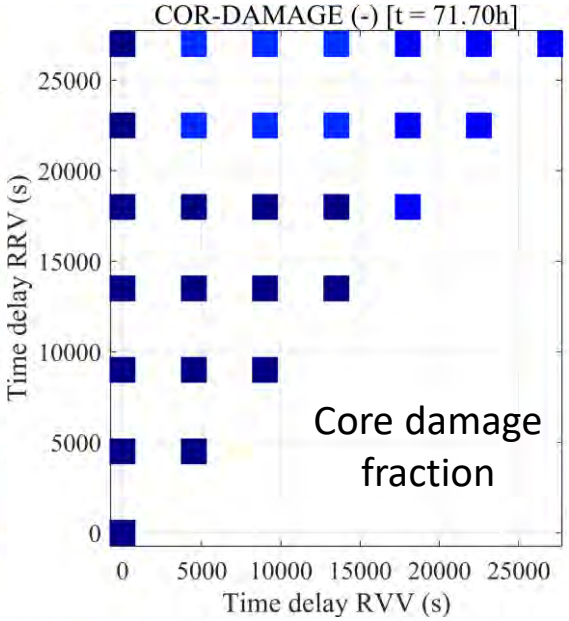
Scenario ID	SCRAM	High CNT level	ECCS signal	Core uncovery	Gap release	PD formation	Relocation to LH	Core plate failure	LH failure
DBA	19	520	520	-	-	-	-	-	-
DBAN	19	520	-	4950	12782	13728	-	-	-
SA4	44	-	815	848	3300	4178	10426	12057	232843
SA4N	44	-	-	1814	7412	8565	13071	13071	33682
SA6	30	-	1380	-	-	-	-	-	-
SA6N	30	-	-	27350	40220	42934	72145	79230	84320

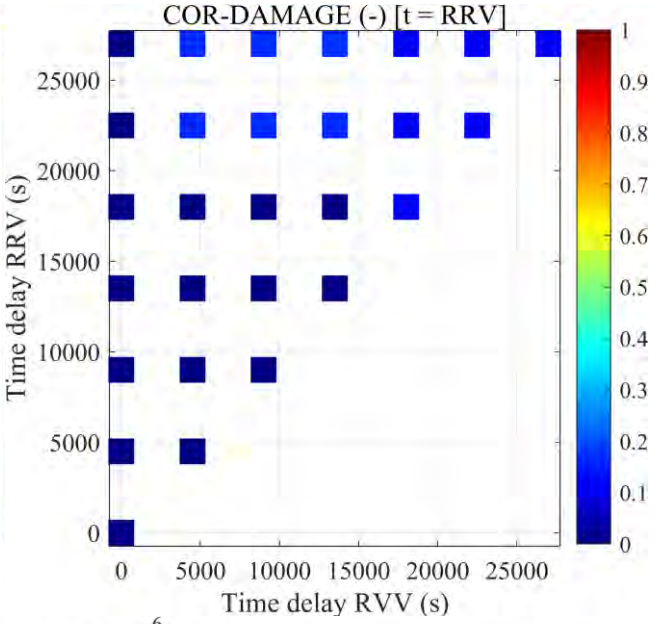
SCRAM - safety control rod axe man/reactor trip; PD - particulate debris; LH - RPV lower head.

- CNT bypass scenarios (SA4[N]/SA6[N]) leads to no activation of ECCS – control logic is altered.
- DBAN – no debris relocation, no LH failure
- SA4/SA4N – early relocation to LP, no ECCS leads to quicker LH failure than with ECCS.
  - SA4N events occur later than in SA4 – activating ECCS may faster core degradation.
- SA6N – Core uncovery is slower, however time from relocation to LP to LH failure is very short.

Results: DBAN-ECCS



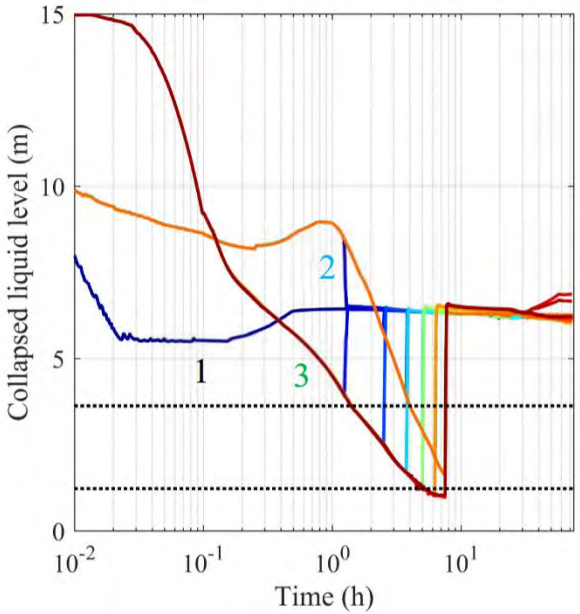


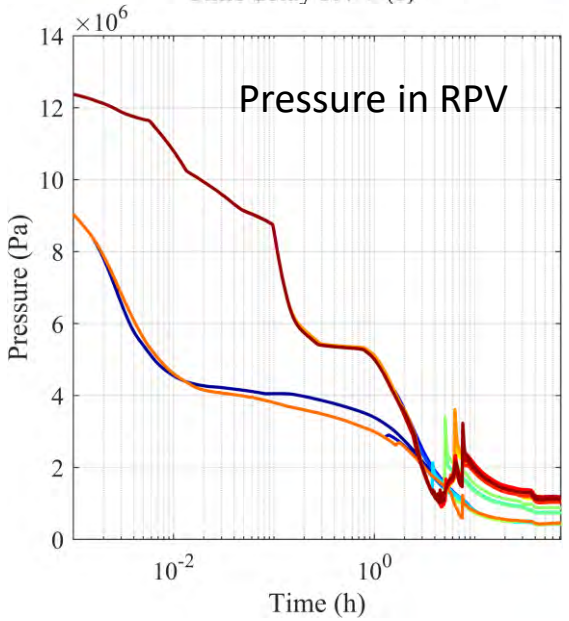


Core damage fraction

Coloured representation of case IDs.

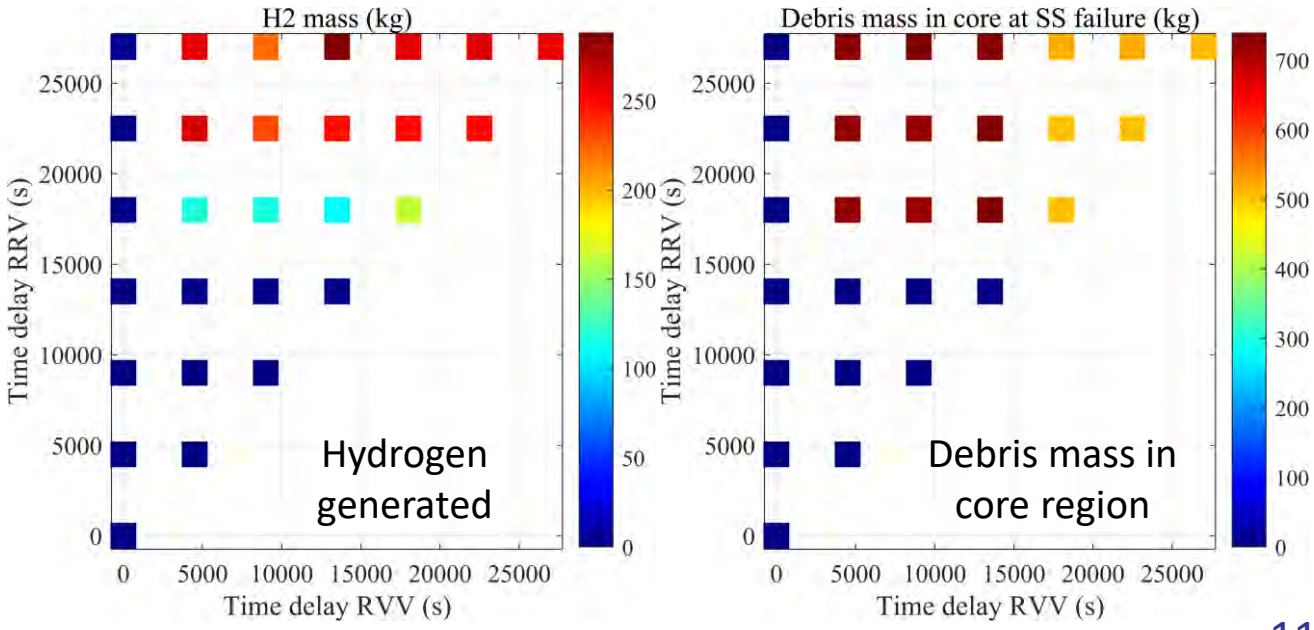
Collapsed liquid level





Results: DBAN-ECCS

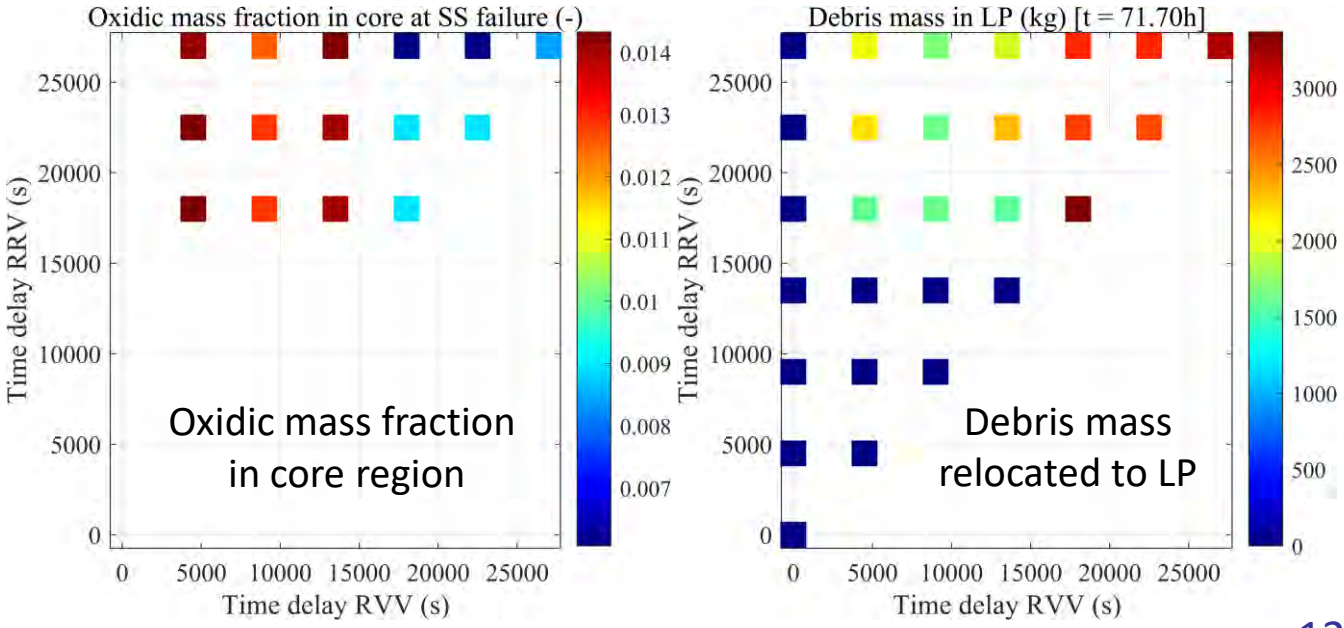
- For the first few cases, the ECCS activates before the core is uncovered and hence SA is averted.
- However, in the succeeding cases, core is either partially or fully exposed before the RRV is activated.
- Most hydrogen generated in cases with t_{RVV}>4500s and t_{RRV}>18000s.



Results: DBAN-ECCS

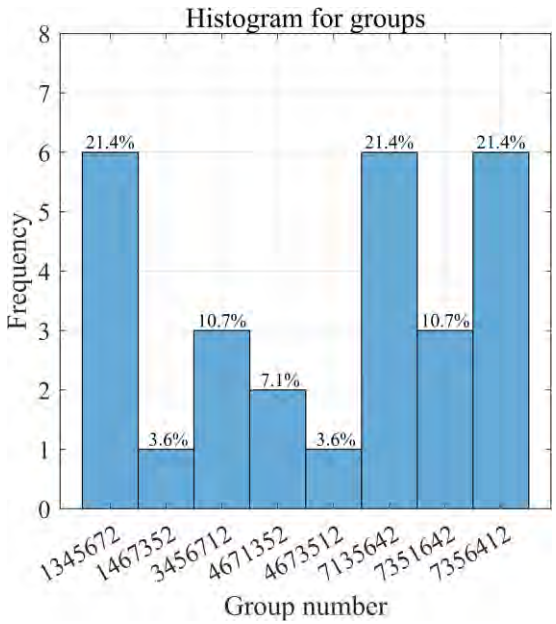
- Cases where damage occurs with early opening of RVVs (<18000s), at the time of SS failure, have slightly larger fraction of debris above the support plate than cases where RVVs open at a later time (>18000s).
  - SS fails at a later time compared to cases with late RVV activation > larger accumulation of debris.

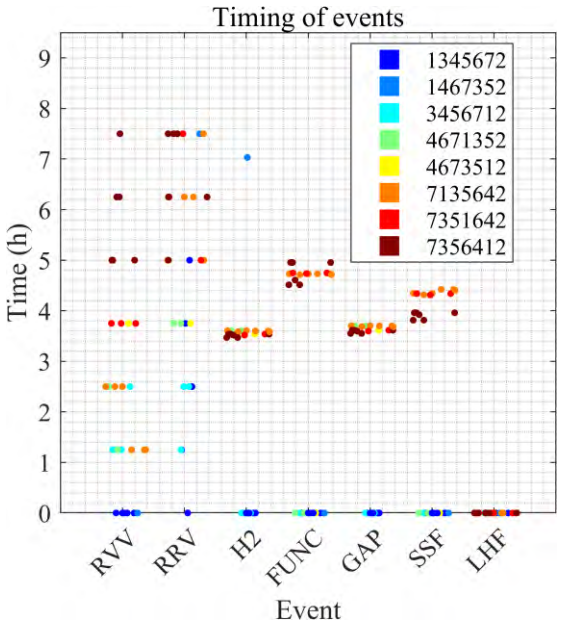
- Cases with early opening of RVVs have a higher oxidic fraction as the core stays at uncovered state longer until SS failure.
- Late opening of RVVs results in larger relocation (>3400kg) subsequent to the failure of support plate compared to early opening.

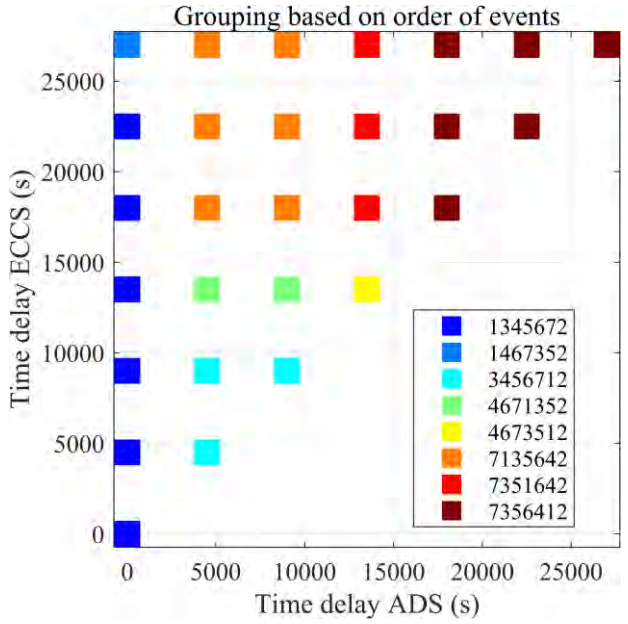


Results: DBAN-ECCS

- Grouping according to order of events: expresses clusters of cases that behave similarly during the accident.
- Whenever RVVs are activated early, a SA is prevented from occurring.
- 13500s is the latest time for the operator to activate ECCS to maintain an intact core in this type of accident scenario.

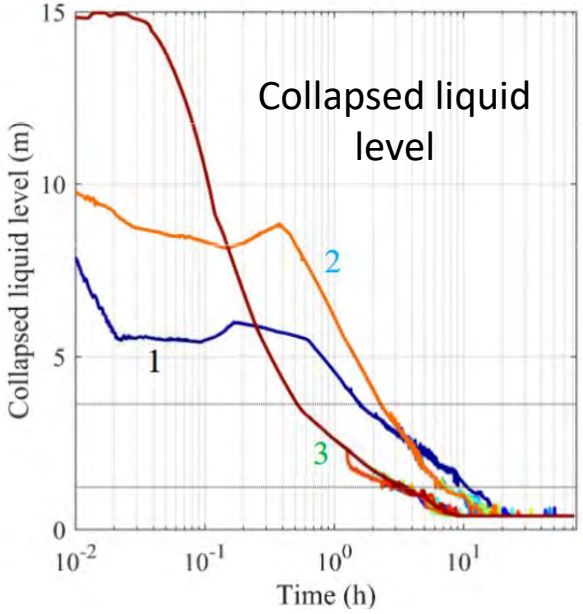


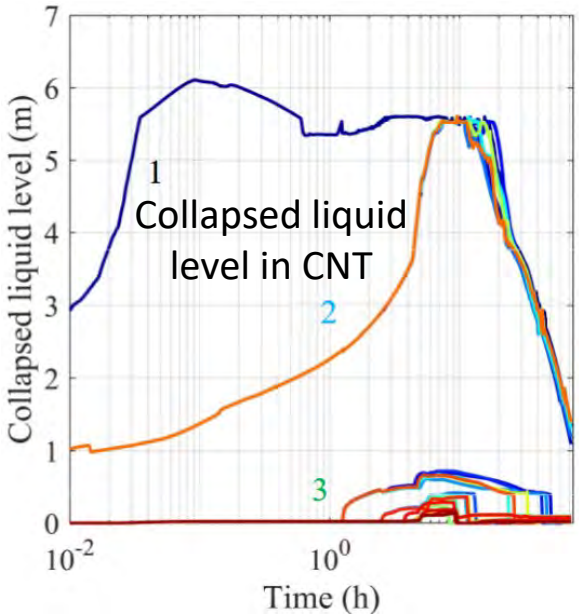


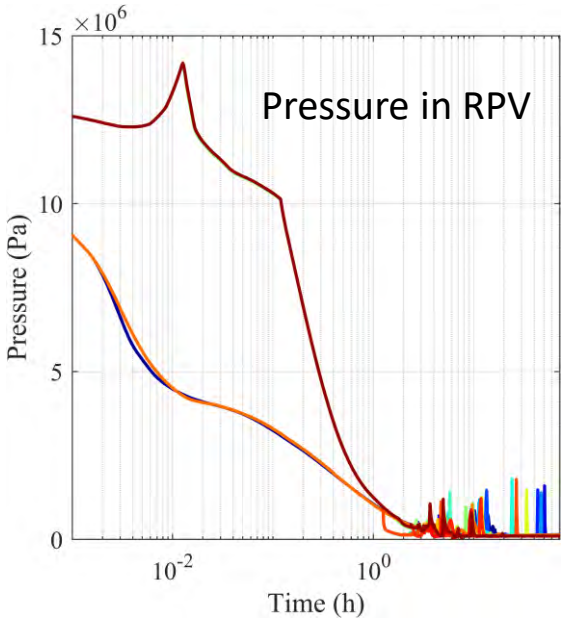


Results: SA4N-ECCS

- Similar to the DBAN-ECCS scenario, 3 sets of evolution of parameters are observed corresponding to different rates of loss of coolant from the RPV.
- Unlike the DBAN-ECCS scenarios, for some cases (set 3) RVVs and RRVs are activated at such late times that, the water that is eventually collected/condensed in the CNT will never circulate back into the RPV.
- Core degradation further proceeds with LH attack by the molten melt in the and its failure with ejection of debris to the CNT.

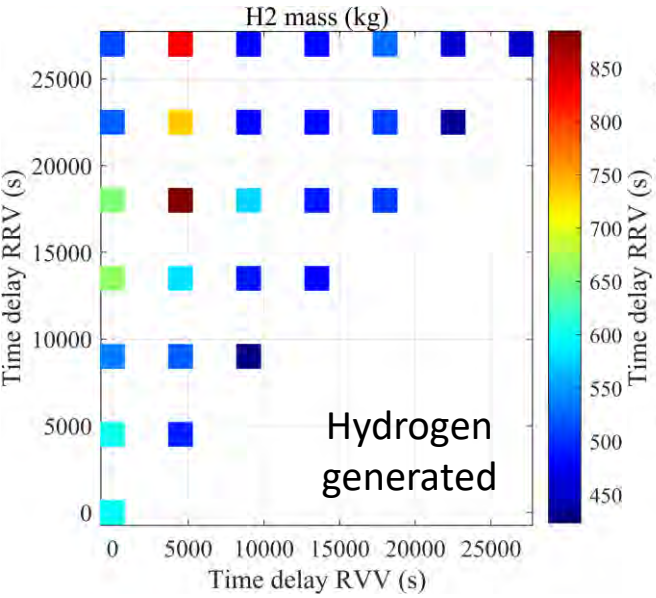


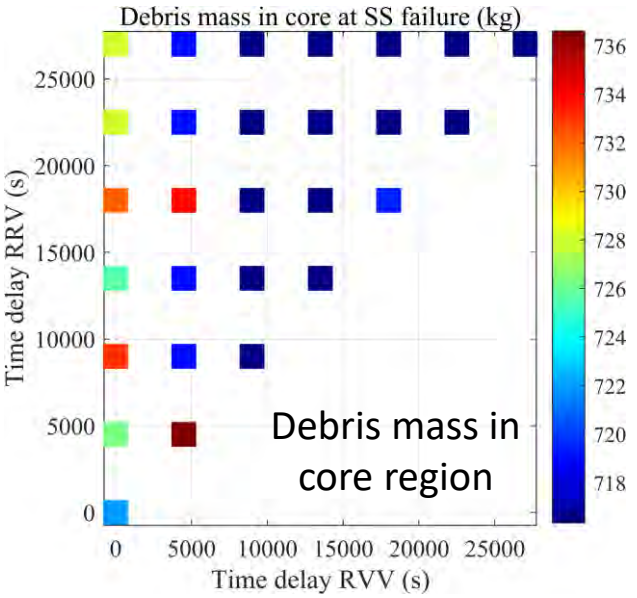


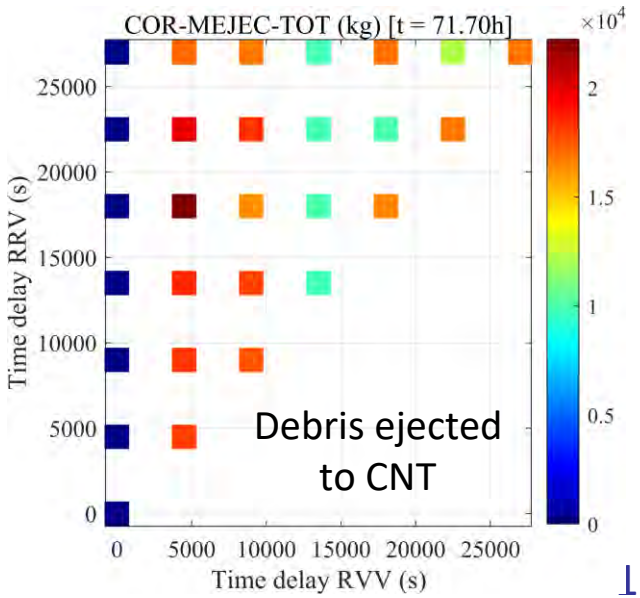


Results: SA4N-ECCS

- Late opening of RVV valves have no drastic effect on oxidation in the core.
- Largest hydrogen mass is generated when the RVVs open at 4500s.
- Essentially, opening of RRV only serves to circulate steam from the CNT to the RPV.
- Early activating of RVVs (>4500s) also leads to the formation of larger amounts of debris in the core just before SS failure.
- SA4N being one of the few scenarios leading to RPV failure, can expect roughly 10-22ton of debris mass being ejected from the RPV.

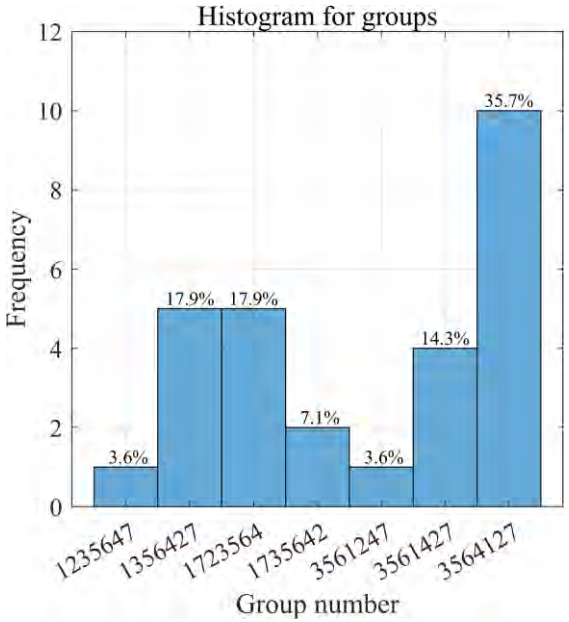


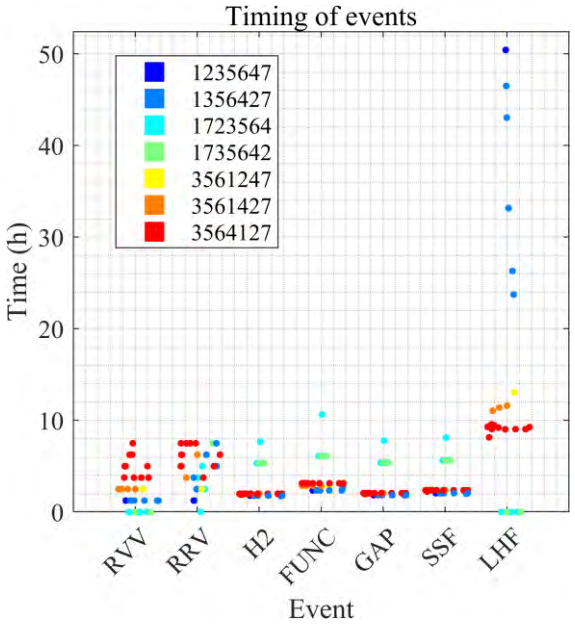


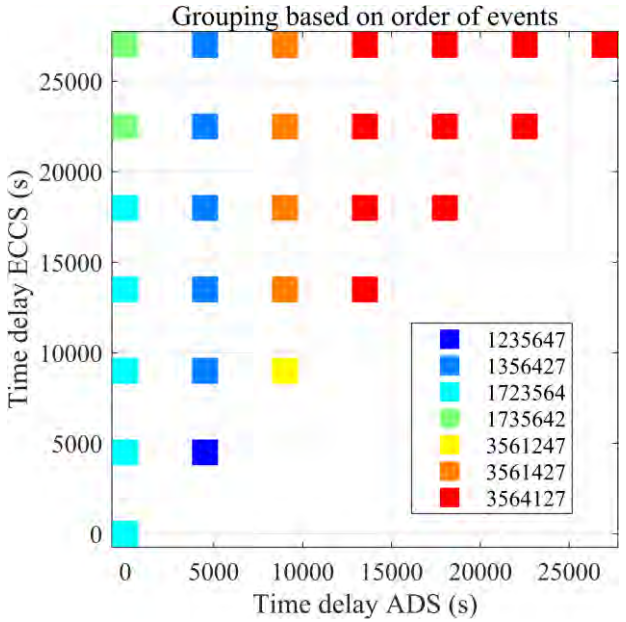


Results: SA4N-ECCS

- Grouping according to order of events: late ECCS activation, leads to early LHF (~10h), and subsequently time of LHF for cases with early ECCS activation can extend from 24-50h.
- From the perspective of arresting SA progression in SA4N like accident, operators may either recover RVVs instantly, irrespective of availability of RRVs, or delay the activation of ECCS to let the coolant evaporate by itself than accelerate it, i.e. keep the core covered for as long as possible > needs further cases and analysis of results.

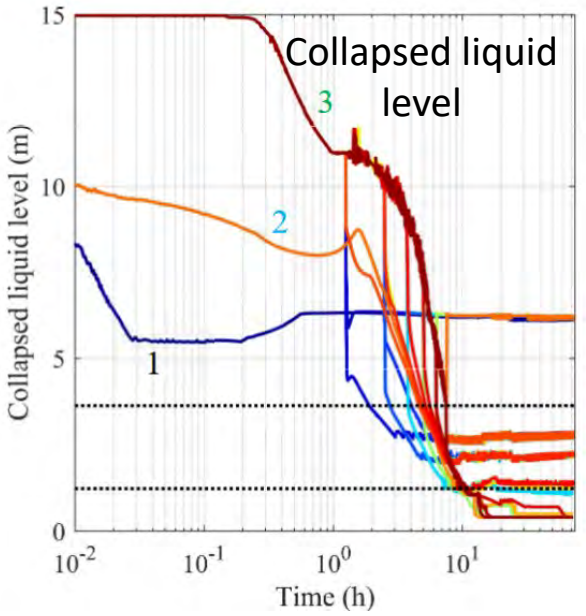


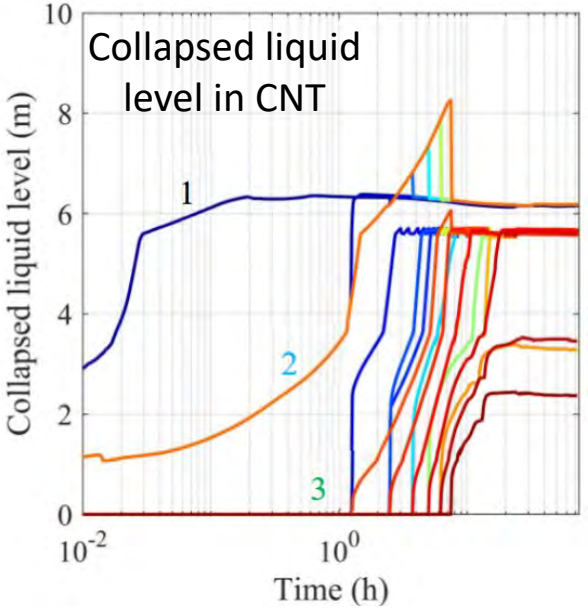


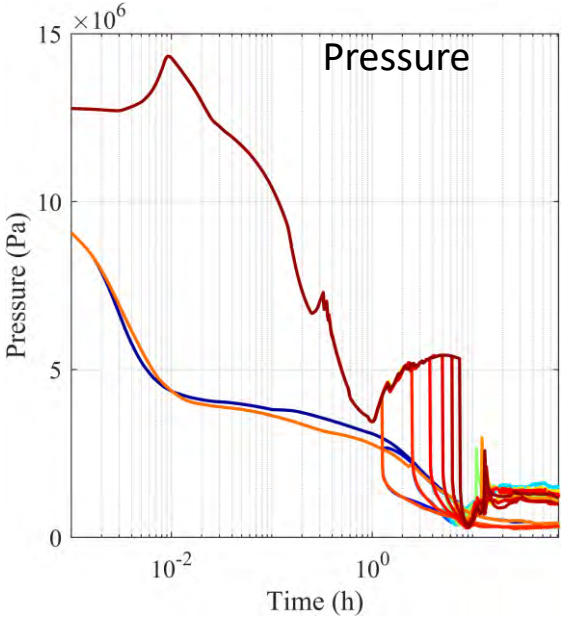


Results: SA6N-ECCS

- Similar to the previous scenarios, 3 different trajectories are observed for the collapsed liquid levels.
- However, unlike the previous accidents (SA4N particularly), cases in set 3 lead to the core being partially flooded with water once the RRVs are open.
- For cases with late ECCS opening (>13500s, Cases 010, 014, 015, 019, 020, 021, 025, 026, 027, 028), water from the CNT may not be able to circulate back in through the RRVs to even partially cover the core and thus complete core may be uncovered.
- For cases with extreme delays (> 22500, Cases 021, 027, 028), water in the CNT is too low to replenish the core.

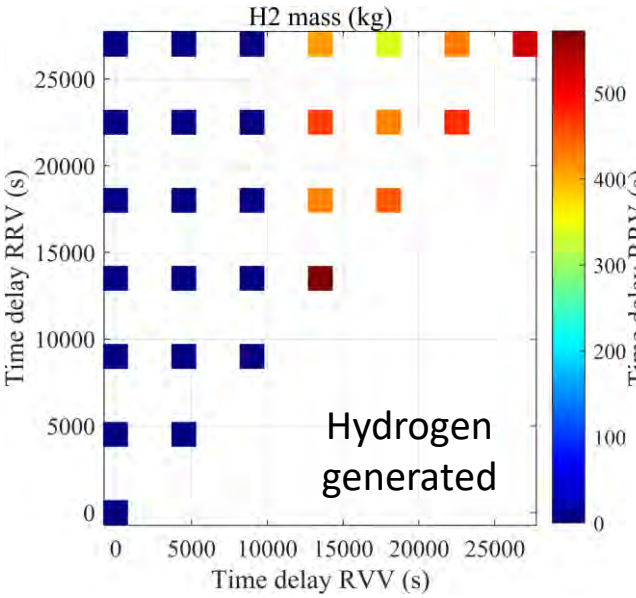


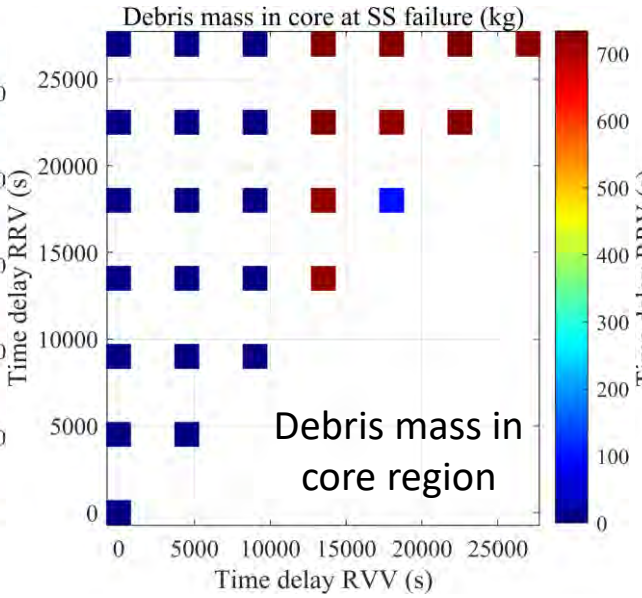


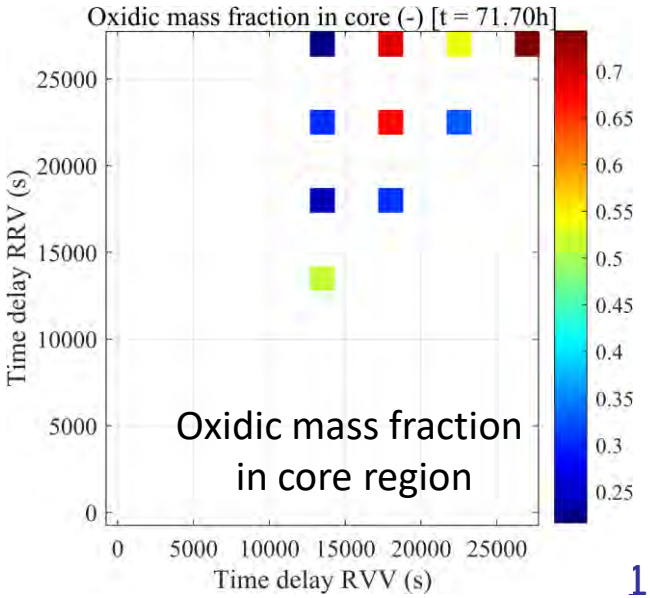


Results: SA6N-ECCS

- As a result of inadequate core cooling, cases with late ECCS opening (>13500s) see oxidation of the core producing about ~350-580kg of hydrogen.
- Only those cases with late RRV and RVV activation (>13500s) undergoes oxidation.
- Unlike, SA4N-ECCS cases, there is no complete loss of coolant from the CNT.
- Therefore, the operation of ECCS within this period [0, 27000]s, successfully manages in-vessel retention of the debris and prevents ex-vessel accident progression, which was the case in SA6N.
  - it may be necessary to also investigate recovery actions in the later phase of the accident (>27000s), where severity of core damage state may worsen the situation.

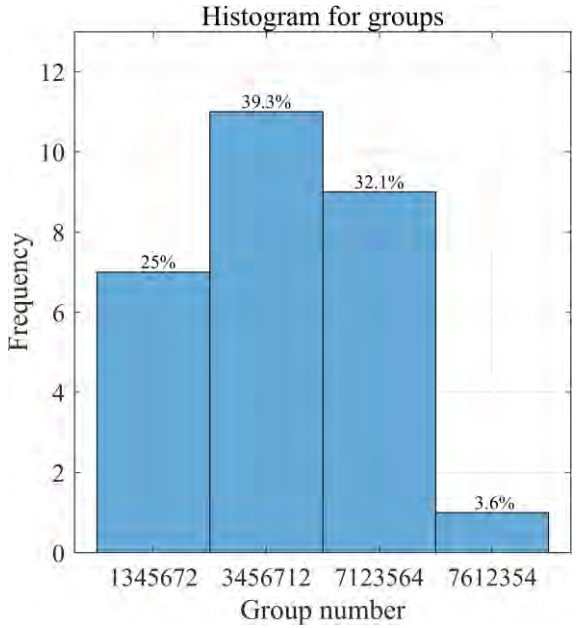


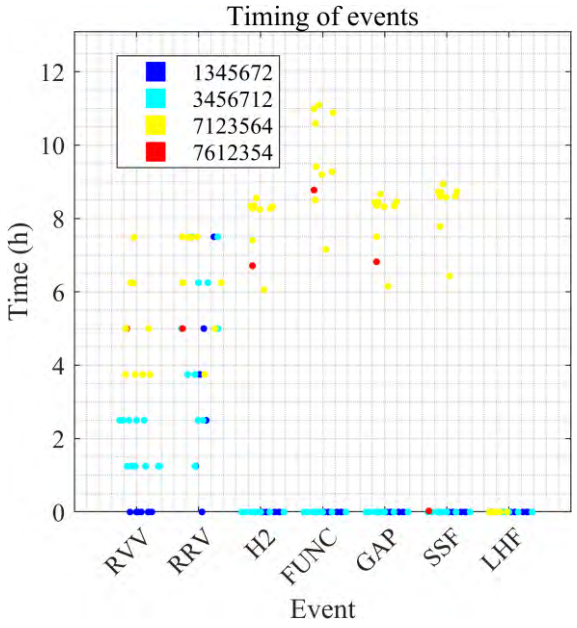


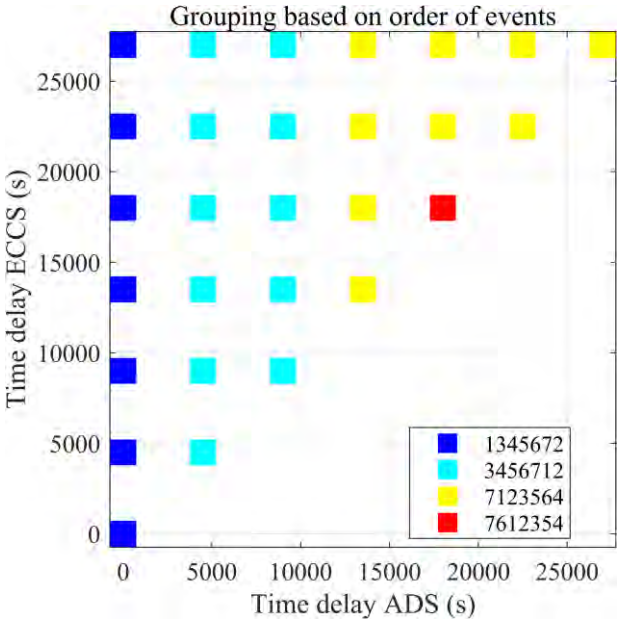


Results: SA6N-ECCS

- Grouping according to order of events: least ordered groups of events occur (4 v/s 8 and 7 in the former 2 scenarios).
- Case 015, does not experience failure of the SS while nearby cases all have SS failure in 6.2-8.2h.
  - This may likely be a one-off outlier or a result of time-step refinement when the code restarts after a crash and possibly missing cliff-edge effects in SS failure models, and may warrant further analysis to resolve potential uncertainties.







Summary and Outlook

- Mitigation of SA progression in a generic iPWR by considering delayed recovery of ECCS was presented.
- Three different accident scenarios were assessed for the effect of the delayed ECCS function.
- Different operation domains were identified that leads to specific set of events that may leads to severe core damage and relocation.
- In the case of DBAN-ECCS, late RRV activation can result in large debris formation and hydrogen generation, irrespective of time of activation of RVVs. However, as the coolant inventory remains within the CNT, RPV failure is not observed for any time of delay.
- In the case of SA4N-ECCS, all cases where RVVs are not activated along with LOCA, lead to RPV failure and debris in ex-vessel state.
- In the case of SA6N-ECCS, all delayed RVV activation scenarios lead to core damage, without RPV failure.
- The reliability analysis of ECCS with operator actions have shown, in most cases, dominating sequences for core damage are inability of RRVs to open early, or inability of water inventory in the CNT to establish natural circulation through the RRVs.
- Data valuable for the development of GA based search algorithm for SA domain identification and training of surrogate models.

ABSTRACT

Within Work Package 4 of the SASPAM-SA project, funded under the Horizon-EURATOM programme, some established severe accident codes are assessed as to their capability of modelling In-Vessel Corium Melt Retention in two candidate Small Modular Reactor designs. Project participants were asked to set up a Best-Estimate-Plus-Uncertainty analysis by simulating accident transients in a stand-alone Lower Plenum model, with a set of agreed initial and boundary conditions.
This paper reports results of analyses that have been carried out around the task set in SASPAM-SA, with the Severe Accident code ASTEC V3.1.2 and its Uncertainty-Analysis front end SUNSET, for the integrated PWR design #1 of SASPAM; an external reactor vessel cooling loop driven by natural convection is part of the model to explore the functioning of the "ERVC pipe" feature of ASTEC. Five Uncertainty and Sensitivity Analyses of 500 simulations each have been carried out, three for an initial set of 15 uniformly distributed uncertain model variables and two where this set of uncertain input parameters has been varied to target the investigation. Their results have been evaluated regarding their impact on the residual thickness of the partly ablated Reactor Pressure Vessel wall, on the forming of a heavy-metal layer at the bottom of the Corium pool, and on other target model outputs. The global sensitivity of these target values has been analysed by correlation-based (Pearson coefficients) and by variance-based (Sobol' indices) methods.
The results discussed indicate that the code produces plausible results for the melt retention scenario. It is shown that natural convection in the ASTEC model of the external reactor vessel cooling loop is established and that all residual heat is removed through the vessel wall and to the ultimate heat sink. ASTEC simulations provide plausible results for the interaction of the different uncertain-parameter assumptions and vessel ablation. The initial mass of UO_2, by determining the amount of residual heat, and the heat resistance of the cooling path are examples of this. The paper underlines that the method of simulating the lower plenum during In-Vessel Melt Retention is credible. It must be stressed that the assumptions in the stand-alone model are conservative and that the degree of ablation computed cannot be taken at face value. For that goal, a comprehensive model will be applied in future work

IVMR, ASTEC, SASPAM-SA, sensitivity analysis

1. INTRODUCTION

In the context of developing and licensing the Small Modular Reactors that are expected to cover some of the energy needs of the future, it is important to insist on high nuclear safety standards including the resilience against severe accidents. The research carried out and tools developed for SA analyses in past decades have naturally been focused on large reactor concepts. Current research in the field is addressed to the question of whether existing SA codes cover with sufficient accuracy the phenomena that could take place in, and are thus applicable to, SMR. This is particularly important for an integrated PWR design that is a strong evolution of large reactor designs, with potential changes to the importance of physical phenomena; and example mentioned often is a higher reliance on condensation when passing residual heat to the ultimate heat sink. One of the situations of interest is the attack on the RPV after the hypothetical case of a reactor core melting and dropping into the Lower Plenum.
In terms of evaluating the results of SA simulations, Uncertainty Analysis has been increasingly made use of starting almost a decade ago, see e.g. [1] and [2] that are in the field of IVMR; the MUSA project [3] that was dedicated to broadly investigating UaSA application in SA simulation and Source Term evaluation; and [4] that added a detailed UaSA to extend the original SOARCA study on accident consequences. The approach to generating simulation data from the SA model requires the random perturbation of selected parameters, with the difference that sensitivity analysis does not demand the knowledge of realistic uncertainties of those parameters. In the SA context, running detailed simulations represents a large effort: one simulation in ASTEC can take more than 24 hours, multiplied by 100 simulations carried out by most contributors in MUSA. Also, code “failures” (typically reaching the minimum time step) for some UP combinations were experienced and complicate the analyses further. The sensitivity analyses carried out in MUSA used correlation techniques to attribute the sensitivity of target outputs.
This paper reports on the analyses carried out for the SMR design #1 considered as one of two designs in the Horizon-Europe project SASPAM-SA [5]. In the Work Package 4 of this project, the contributing partners agreed to run stand-alone Lower Plenum models addressed at analysing In-Vessel Melt Retention, using a range of SA codes used by different research groups. Boundary conditions for simulating a reference case and for setting up an Uncertainty and Sensitivity Analysis were agreed. This application follows the scheme broadly explored in [6].
For the work reported, analyses have been carried out with the severe accident code ASTEC V3. In addition to the SASPAM-agreed analysis, some changes related to the uncertain parameters were made and additional UaSA were run to broaden the interpretation of the results. Also, the submodel in the ASTEC code that is crucial for computing the Corium layer configuration in the Lower Plenum was given a closer look by establishing the effect of uncertainties in its key parameters. The post-processing and interpretation of results added to the commonly used Pearson correlation coefficients a recent algorithm that calculates first-order variances and covariances: so-called Sobol’ indices [7].
In the first section of the paper, the analysis approach is set out in terms of the input deck and in explaining the cases considered and evaluation methods applied. The results are then reported first for a best estimate reference simulation, and in further sections for the different sensitivity analyses. The paper closes with Conclusions and Acknowledgements.

2. ANALYSIS DESCRIPTION

2.1. Model Input Deck

The model used is based on an input deck for the stand-alone Lower Plenum of a PWR1000 reactor that is included in the ASTEC V3.1.2 software distribution. This has been adapted to fit the Design #1 considered in SASPAM-SA in that

- the overall size of the Lower Plenum was adapted to Design #1;
- the shape of the LP was changed to semi-ellipsoidal (from semi-spherical as coded in the original input deck);
- masses of materials in the Corium pool were revised.

For the Corium pool, a phase separation model based on interface equilibrium for oxide and metal layers was chosen.
The input deck was extended by adding an ERVC loop, including a containment volume and heat flux connections between the loop and a surrounding pool that serves as ultimate heat sink.
Main initial conditions of this model are constant temperatures in each of the entities RPV steel, oxide layer, top metal layer, and ERVC loop.
The simulation starts from a LP filled with two layers: one with UO_2, Zr, ZrO_2 (according to the chosen level of Zr oxidation), at a temperature of 2700 K, and a top layer of steel at 1700 K. This means that the make-up of the metallic and oxide layers of the pool is an initial condition and is changing towards an equilibrium found by that model. Residual heat generation is defined by the specific heat of U, either in its oxidic or its metallic form. The migration of species means that according to the evolution of the equilibrium residual heat is produced in both oxide and metal layers.

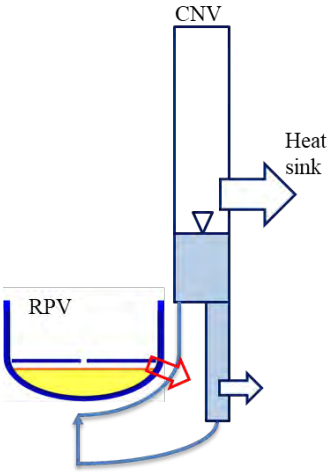

Figure 1. Lower Plenum with External Reactor Vessel Cooling loop.

The boundary conditions of the model are:

1. The only connection between the LP and the ERVC loop is the heat transfer through the LP wall. The connection between RPV and CNV that would be created by an opening pressure relief valve at the top of the RPV is neglected. However, it is assumed that, at this stage of the accident, the containment is filled with water to a certain level.
2. The heat removal to the ultimate heat sink (a pool in which the containment vessel is situated) is defined by heat exchange surface, a heat transfer coefficient and the temperature of the heat sink.
3. For the containment atmosphere, it is assumed that hydrogen as a non-condensable gas is present, at 10 bar initial pressure. Hydrogen explosion is no objective of the analysis and is not modelled.
4. The metallic top layer experiences radiative heat losses, but rather than setting a boundary condition, these losses are calculated by ASTEC's RADCAV model that calculates the radiation between the metal surface and the structures present: these are the core support plate and the RPV walls above the Corium pool.

2.2. Reference Case and Sensitivity Analysis

Table I displays the data agreed in SASPAM-SA WP4.2 for key input parameters in the reference case and in the subsequent UaSA; it is appended by 4 parameters that are mostly related to the ERVC loop. All UP in the UaSA were assumed to be uniformly distributed between the minimum and maximum values provided in the table.
The UaSA was run with the help of the SUNSET tool that is part of the ASTEC software distribution. The SUNSET tool managed the generation of random uniform input parameter distributions for 500 simulations in each of the analyses below. The random generator was initialized with a different 5- or 6-

digit integer number, and the statistical independence of the input demonstrated by the insignificant values of the input correlation matrix.
For the post-processing of the data in Microsoft® Excel®, Python routines were developed to convert the SUNSET output. The statistical evaluation of the data was carried out by two different methods: (i) by computing Pearson correlation coefficients using functions provided by Excel®. It was assumed that the largest part of the accordance of outputs and random inputs is linear; (ii) by a global sensitivity analysis by variance decomposition as offered by the software tool SIML@B [8]. The software implements a recent algorithm [9] to compute Sobol' indices [7] and identify the input uncertainties whose variances contribute most to the variance of the MRVT. For this paper it is important to know that S_i are normalized variance contributions of individual UP, while ST_i are total contributions that also include covariances between different UP.

Five different UaSA are discussed in the following:

1. The original UaSA as agreed in SASPAM-SA WP4
2. Acknowledging that treating initial masses of UO2, Zr and steel as statistically independent does not reflect the physical reality of a molten core, and thus moving to initial conditions where the bulk of Zr and steel is a function of the (random) amount of UO2 and only a part of 10 – 20% of Zr and steel is modelled as an statistically independent variation.
3. The UaSA submitted within WP4.2 of SASPAM-SA that deviated from 2. by the amount of steel in the simulation.
4. Realising that ASTECs submodel for the corium pool is key to whether a HM layer forms in addition to the light metal and the oxide layer, an UaSA with 4 parameters of the SEPALOWE taken as UP in a separate analysis
5. Synthesizing the previous analyses, an UaSA where the UP found significant in 1. and 4., are kept while all others are taken at their constant reference value.

Table I. Reference data and uncertainty ranges for uncertain parameters

Parameter	Name	Reference	Minimum	Maximum
Geometry of LP				
Thickness of vessel (cm)	thives0	0.12	0.10	0.14
Degradation				
Mass of UO2 in LP (t)	mmm0	9.	4.5	9.
Mass of Zr in LP (t) (U/Zr ratio is constant)	mmzr0	2.5	0.9	2.5
Zr fraction oxidized in LP	rzrox0	0.5	0.3	0.8
Mass of Steel (t) in LP	mmu0	4.0	1.5	4.5
Power per unit mass of UO2 (W/kg)	powe_i0	190	178	200
Containment				
Pressure (bar)	pCNV0	12	11	13
Material properties				
Oxide conductivity (W/K/m)	condox0	2.0	1.0	3.0
Molten steel conductivity (W/K/m)	condst0	20	20	40
Vessel conductivity (W/K/m)	condves0	30	25	35
Metal emissivity (-)	emissliq	0.5	0.2	0.8
ERVC loop and core support plate				
Temperature UHS [K]	tpool	323.15	303.15	343.15
HTC to UHS [W/m2/K]	htcpool	1000	1000	2000
ERVC thickness factor	etf	1.0	0.8	1.2
Initial temp. of core support plate [K]	Tplt	873	560	1100

3. REFERENCE CASE RESULTS

Figure 2 illustrates the temperature distribution in the Lower Plenum, and the ablation of the RPV wall, at the end of the simulation at 20,000 s. Ablation of the wall has taken place, and the residual thickness is down to 5.85 cm from the initial 12 cm.
Figure 2(bottom) adds the information of how the mass of 3 material layers in the lower plenum is evolving; it confirms that the initial configuration of 2 layers evolves into 3 layers at the slump of the top metal layer to the bottom of the LP, at about 1,650 s, and that that bottom HM layer is disappearing over time. The melting of the core support plate and thus the addition of 1,500 kg of steel to the pool takes place between 2500 and 3500 s into the transient.
Other steady-state results of the reference case are:

- Heat generation and removal in the system are balanced.
- The passive ERVC loop is functioning. After a transient phase, and starting from a small initial value, the flow is 36.5 kg/s.
- The composition of the light metal layer is mostly steel at about 4,200 kg, but also about 1,400 kg of U and a bit less than 500 kg of Zr.

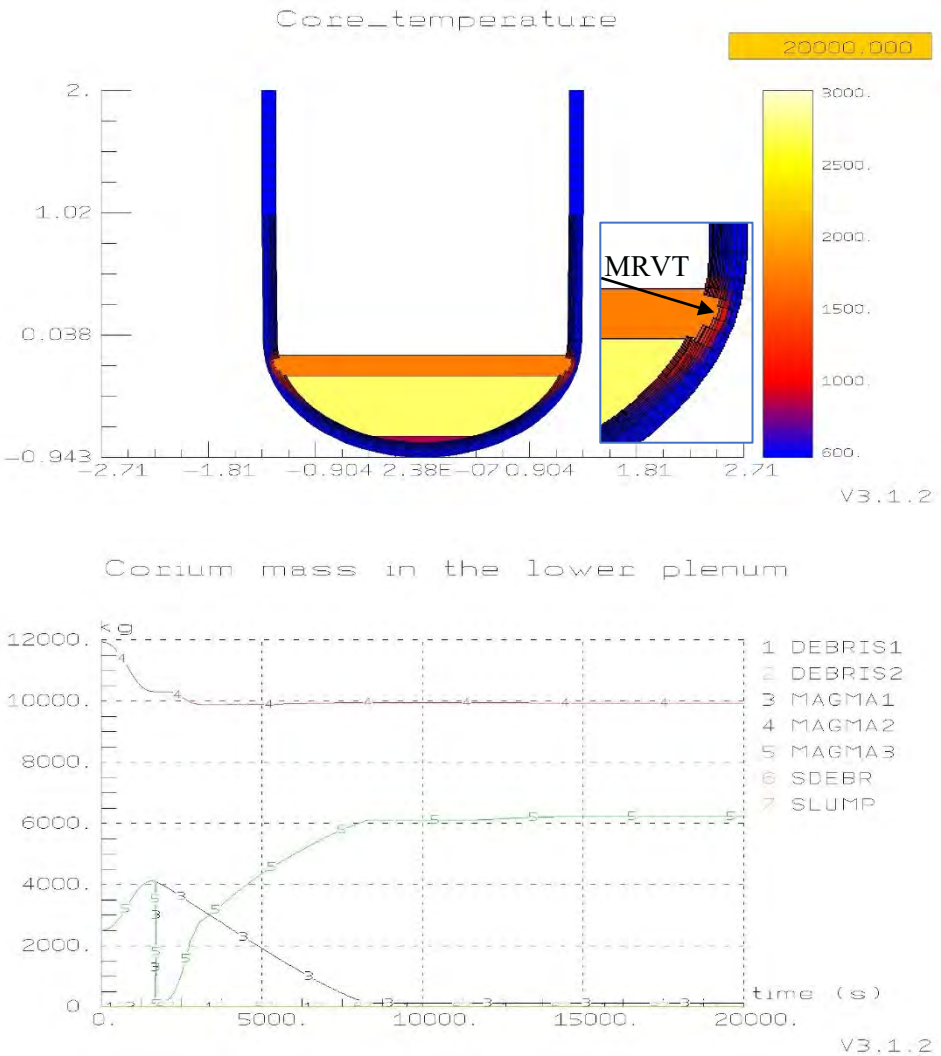

Figure 2. Reference case. Temperature field in RPV and Corium pool at steady state (top); evolution of the mass of the different layers of the Corium pool (bottom).

4. UNCERTAINTY AND SENSITIVITY ANALYSIS RESULTS

4.1. SASPAM-agreed Case (random-generator initializer: 52447)

In this case, uncertain parameters were selected according to Table I. The evolution of residual wall thickness for the first 100 simulations is displayed in Figure 3 alongside the reference case. Under the assumptions made, considerable wall ablation is to be expected; after some ablation, the heat resistance of the remaining wall thickness is small enough to pass heat without the inside of the RPV wall exceeding melting temperature. In all 500 simulations, the residual thickness stays above 2.8 cm.

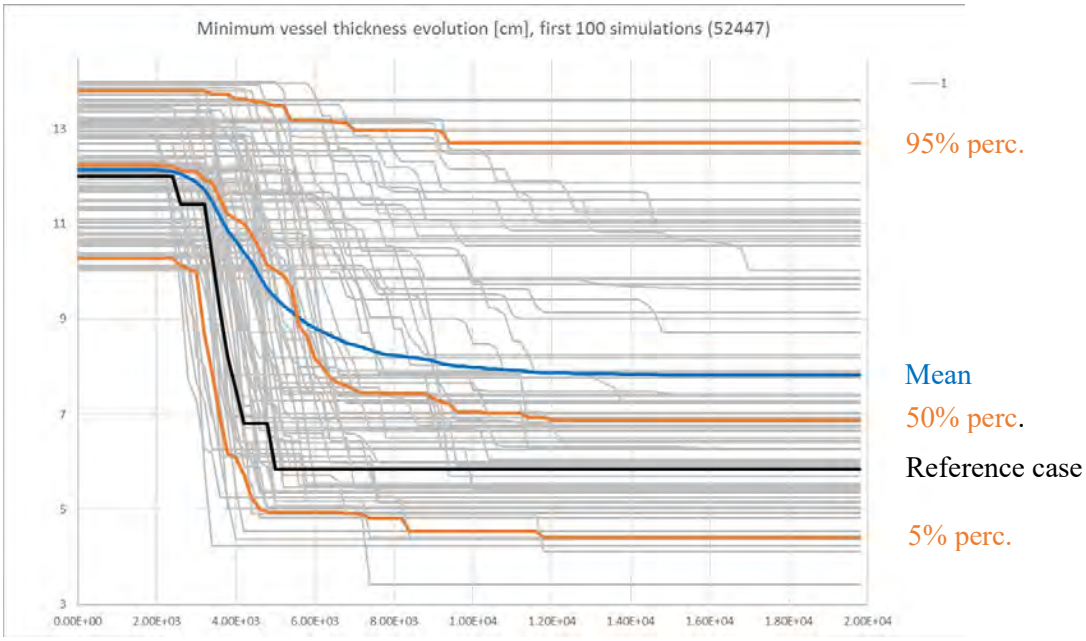

Figure 3. Horsehair diagram of minimum residual vessel thickness

Table II shows statistics of key simulation outputs at 20,000 s that is taken as steady state. The main message is that the uniformly distributed uncertain parameters are providing significant perturbation to the IVMR model output. In 262 out of the 500 simulations a HM layer exists at the end of the transient. Pearson coefficients computed for a broad set of outputs are displayed in Table III; at 500 samples, CC larger than 0.088 are significant (p-value < 0.05). They suggest that initial material masses and Zr oxidation degree significantly influence the physics in the lower Plenum: heights *HMAG* and densities *RHO* of Corium layers; the occurrence of a HM third layer in addition to oxide layer and top metal layer; power lost from the layers through the wall, *Pex*, and through radiation, *Prad3*; the crust thickness of the oxide layer *crstox*; and, ultimately, the residual thickness $s_{v,rem}$ of the RPV at the location with the largest ablation. This ablation is also correlated to the vessel conductivity and top-layer emissivity.

Table II. Means and ranges of outputs at steady state in the SASPAM-SA WP4.2 case

Output	5% perc.	mean	95% perc.
MRVT [cm]	4.689	8.033	12.811
HF top metal to inside RPV [kW/m^2]	373.944	943.215	1436.939
HF oxide to inside RPV [kW/m^2]	34.402	60.973	98.521
Relative difference with CHF	40.2%	68.6%	93.4%
Thickness of top metal layer [m]	0.000	0.112	0.172
Thickness of oxide layer [m]	0.257	0.396	0.511
Oxide crust thickness RPV wall [cm]	2.429	6.931	10.129
Top crust thickness [cm]	0.000	0.077	0.333
Power lost by radiative HF	9.7%	20.2%	36.3%

Oxide/Metal density ratio	0.906	0.988	1.045

While not shown here, it is no surprise that the temperatures along the vessel wall – highest in the elements that are close to the interface of oxide and top metal layer – are strongly correlated with the ultimate heat sink temperature *tpool*.

Table IV. Global Sensitivity Analysis by Sobol' indices for the minimum residual vessel thickness

Variances			Covariances		
S_2	mmm0	0.44 ± 0.03	$S_{3,4,5}$	mmzr0, rzrox0, mmu0	0.02
S_5	mmu0	0.11 ± 0.02	$S_{3,5}$	mmzr0, mmu0	0.03
S_{11}	emissliq	0.08 ± 0.02	$S_{4,5}$	rzrox0, mmu0	0.01
S_{10}	condves0	0.06 ± 0.02			
S_1	thives0	0.03 ± 0.01	Relative Training Error		0.16098
S_3	mmzr0	0.01 ± 0.01	Sample Variance of vessthimin		7.135

Table IV shows how the variance of the MRVT can be attributed to the UP. The order of significance is identical to the Pearson CC, with the benefit that the values are easier to interpret – 44% of the output variance are explained by *mmm0*. Capturing second-order effects, the covariances are less important in this application. However, in case of *mmzr0* the overall impact dominated by the covariances. The table shows that the "training error" is relatively large at about 16%: the variances calculated explain only 84% of the output variance.

4.2. SASPAM-agreed Case with Modification (337249)

The UaSA simulations were set up with the reference, minimum and maximum values defined in Table I. However, for the initial masses of UO_2, Zr and steel, equations were introduced to limit their statistical independence:

$$m_{Zr} = \frac{2.5}{9} m_{UO2} - \Delta m_{Zr} \quad (1)$$

$$m_{steel} = \frac{4.5}{9} m_{UO2} - \Delta m_{steel} - m_{CSP} \quad (2)$$

where the uncertain parameters m_{UO2} [4.5 t, 9 t], Δm_{Zr} [0 t, 0.35 t] and Δm_{steel} [0 t, 0.7 t] are all uniformly distributed in the intervals given, and m_{CSP} = 1.5 t is the mass of the core support plate. The justification for this limitation is the fact that a molten core will always consist of a mix of UO2, Zr and steel that resembles the intact core. Random deviations from this mix can be assumed, but an independence where

e.g. a maximum amount of UO_2 meets the minimum amount of Zr and steel seems far-fetched. The adhoc equations lead to ranges m_{Zr} and m_{steel} that agree with minima/maxima in the original case in Table I.

Key results computed in the modified approach are displayed in Table V. Most notably, the 5% and 95% percentile values are less extreme than in the original case; particularly for the HF in the top metal layer. Furthermore, the mean value of HF in the top metal layer is significantly different. Most other mean values are similar, as is the number of cases where a HM layer is formed: 256 out of 500. Comparing Pearson coefficients with those of the SASPAM-agreed case shows the same patterns, but weaker.

Table V. Key results' ranges for the modified case, again at 20,000 s.

Output	5% perc.	mean	95% perc.
MRVT [cm]	4.978	7.624	11.112
HF top metal to inside RPV [kW/m^2]	508.007	679.529	921.409
HF oxide to inside RPV [kW/m^2]	35.399	63.786	100.645
Relative difference with CHF	48.5%	71.0%	93.6%
Thickness of top metal layer [m]	0.079	0.125	0.168
Thickness of oxide layer [m]	0.284	0.412	0.536
Oxide crust thickness/ RPV wall [cm]	2.747	6.754	9.869
Top crust thickness [cm]	0.000	0.055	0.307
Power lost by radiative HF	9.9%	18.6%	28.9%
Oxide/Metal relative density	0.942	0.995	1.036
Containment pressure [bar]	6.92	7.60	8.43

4.3. SASPAM-agreed Case with Modification and High Steel Content (94271)

These results shown above differ from the JRC results submitted in WP4.2 of SASPAM-SA, where the modifications (1), (2) were made but where, in addition, the "steel mass in the LP" of Table I was taken as the initial steel mass; this meant that, together with the melted core support plate, the amount of steel was 1.5 t larger. Here, it is briefly touched to understand the impact on the results.

Table VI. Key results' ranges for the modified case with large steel content, at 20,000 s.

Output	5% perc.	mean	95% perc.
MRVT [cm]	7.160	9.927	12.526
HF top metal to inside RPV [kW/m^2]	402.891	497.055	611.673
HF oxide to inside RPV [kW/m^2]	37.393	65.227	101.651
Relative difference with CHF	65.2%	77.0%	88.4%
Thickness of top metal layer [m]	0.133	0.180	0.223
Thickness of oxide layer [m]	0.354	0.442	0.532
Oxide crust thickness/ RPV wall [cm]	2.729	6.624	9.759
Top crust thickness [cm]	0.000	0.108	0.388
Power fraction lost by radiative HF	12.1%	17.3%	23.2%
Oxide/Metal relative density	0.982	1.022	1.078
Containment pressure [bar]	6.95	7.62	8.50

The strong correlation of a 3rd layer and the initial steel mass mmu0, -0.58 as shown in Table III, indicates that this would have a big impact. And indeed, in the submitted results, a 3rd layer was only formed in 7 of 500 simulations.

Table VI displays key results of this UaSA; the most notable differences with Table V are indeed linked to the much higher amount of steel present: the top metal layer is thicker, and as a consequence heat flux and vessel ablation are smaller.

4.4. A closer look into the Corium-pool model (111111)

The lower plenum model of the severe accident code is undoubtedly at the centre of predicting the attack of the Corium pool at the RPV. In particular, the heat distribution and the effect of a light top metal layer focussing heat on a small part of the RPV wall determine whether vessel ablation will lead to RPV failure. Of the Corium phase separation and stratification models offered by ASTEC, the interface equilibrium model [10, 11] as the most recent and developed, has been used.

Table VII. Choice of uncertain parameters and their intervals in the SEPALOWE model.

Parameter	Name	Default	Minimum	Maximum
SEPALOWE model				
Threshold for beginning of stratification inversion [%]	tresh	5.0	4.0	6.0
Heat exchange oxide/moving metal [%]	frac	100	80	100
Species diffusion coefficent	diff	1.E-8	8.E-9	12.E-9
Height ratio of interaction zones	coef	0.1	0.08	0.12

Parameters in the model that can be selected by the user, and that were taken as uncertain parameters, are:

- the threshold of density difference (in percent) before a heavier upper layer slumps through a lower layer, initialising a stratification inversion
- a parameter determining the heat exchange between a moving (rising or slumping) metal species and the oxide layer, ranging between 0 and 100% - the latter meaning instantaneous thermal equilibrium
- the species diffusion coefficient
- the height ratio of the top to bottom interaction zones between layers that are characteristic for the interface equilibrium model

The ranges of the uniform distributions assumed are shown in Table VII. The UaSA is similar to previous analyses, with the same key outputs. The input uncertainties lead to output variations (not displayed here) that are small in terms of the physical problem. As in the analyses shown earlier, the overall result is a bifurcation where 74% (369/500) of simulations end up with 3 layers (i.e. including a HM layer at the LP bottom), and 26% (131/500) with 2 layers (just light metal and oxide layer).
The GSA is applied to get information on how the model parameters influence the results:

- the Sobol' indices in Table VIII tell that the appearance of a third layer is exclusively linked to parameter *tresh* that defines at which density difference between two layers slumping occurs.
- When just looking at results of the 3-layer branch of the bifurcation, the MRVT is mainly sensitive to parameter *frac* that determines the heat exchange of the slumping/rising metal fraction with the surrounding oxide layer; see Table VIII (right).
- The parameters *diff* and *coef* are insignificant in these analyses.

Table VIII. Individual S_i and total Sobol' indices ST_i provided by SIMLAB [4, 5]. Sensitivity of the occurrence of a heavy metal layer (left); sensitivity of residual wall thickness in the 369 cases where a HM layer is formed (right)

Name	S_i	$\pm\Delta S_i$	ST_i	$\pm\Delta ST_i$
tresh	0.85	± 0.02	0.85	± 0.02
frac	0.00	± 0.00	0.00	± 0.00
diff	0.00	± 0.00	0.00	± 0.00
coef	0.00	± 0.00	0.00	± 0.00

Name	S_i	$\pm\Delta S_i$	ST_i	$\pm\Delta ST_i$
treshval	0.07	± 0.02	0.12	± 0.03
fracval	0.67	± 0.04	0.70	± 0.04
diffval	0.00	± 0.00	0.01	± 0.01
coefval	0.01	± 0.01	0.01	± 0.01

4.5. Combination of significant UP from SASPAM and SEPALOWE analyses (123457)

To conclude, it seems interesting to combine the previous analyses to get an importance ranking among UP linked to initial conditions and those linked to the lower plenum model. UP selected for are: *mmm0*, *mmzr0*, *rzrox0*, *mmu0*, *condves0* and *emissliq* from Table I and *tresh*, *frac* from Table VII.
The key output values turn out to be close to those of the original SASPAM-SA WP4.2 analysis in Table II. The sensitivity of the MRVT as the target value of the analysis as expressed by Sobol' indices and Pearson correlation coefficients is displayed in Table IX. 41% of the variance in $s_{v,rem}$ is due to *mmm0*, followed by 22% due to *mmu0*. The correlation coefficients support the top of the ranking, without telling which one of *mmu0*, *condves0* and *emissliq* is second-ranked. However, the CC tell that larger *mmm0* reduces MRVT while larger *mmu0*, *condves0* and *emissliq* lead to larger MRVT.

Table IX. Sensitivity of residual wall thickness to the UP. Sobol' indices of the GSA (left); Pearson correlation coefficients (right).

Number	Name	Si	±ΔSi	STi	±ΔSTi
1	mmm0	0.41	± 0.04	0.41	± 0.04
2	mmzr0	0.01	± 0.01	0.07	± 0.02
3	rzrox0	0	± 0.00	0.07	± 0.02
4	mmu0	0.14	± 0.03	0.22	± 0.04
5	condVES0	0.07	± 0.02	0.07	± 0.02
6	emissliq	0.08	± 0.02	0.08	± 0.02
7	treshval	0	± 0.00	0	± 0.00
8	fracval	0	± 0.00	0	± 0.00

	vessthimin
mmm0	-0.607
mmzr0	0.080
rzrox0	-0.019
mmu0	0.285
condVES0	0.278
emissliq	0.291
treshval	0.003
fracval	0.015

As in the previous UaSA, the overall result shows a bifurcation; 49% (243/500) of simulations end up with 3 layers and 51% (257/500) with 2 layers. To go into further detail of this behaviour and its link to wall ablation, the results have been separated and the two branches looked at separately.
The comparison of results for the 2 branches reveals some interesting points:

- Most importantly, the mean of $s_{v,rem}$ is smaller in cases with a HM layer and the minimum remaining wall thickness of that branch is 3.31 cm, as compared to 4.9 cm for the 2-layer branch.
- In the branch with HM layer, there are cases with disappearing top metal layer. A closer look at the data confirms that, in this problem set-up, 14 simulations do not feature a top metal layer at tend = 20,000 s. Also, huge heat fluxes in the top metal layer (4.55 MW/m2 as 95% percentile, and even 10.6 MW/m2 in the most extreme case of simulations with HM layer) are computed. This is the sign of singular, unphysical cases that occur when the (random) UO_2 and Zr masses are large and coincide with a small initial steel mass.
- The fact that there is a steel fraction in the HM layer is indicated by a top metal layer mean height of 8.6 cm with HM layer, when it is 13.9 cm without.

Table X shows how MRVT is correlated to the uncertain parameters. Next to the known importance of the UO_2 mass for both branches, the marked difference is the positive effect of the steel mass mmu0 in the 2-layer branch, while no correlation is shown in the branch with HM layer. Apparently, the consumption of steel in the HM layer annihilates the influence.
It is seen as a sign of robustness that the parameters of the Corium layer separation model that had a visible effect in the previous UaSA are insignificant when compared to the effect of initial conditions.

5. CONCLUSIONS

Based on the UaSA within SASPAM-SA WP4 for a stand-alone model, this paper has explored several variations of the uncertain parameter base to highlight sensitivities of key model outputs and in particular the MRVT at steady-state, when ablation has stopped. In addition to the thermal-hydraulic modelling of the cooling loop, the modelling of the stratification evolution of the Corium pool in the Lower Plenum has been the focus. For the evaluation of statistical dependencies in the simulation data, a variance-decomposition technique was applied in addition to Pearson correlation coefficients.

The list of conclusions is multi-faceted. Starting with the input deck, the pipe element offered by ASTEC for a simple implementation of ERVC worked well for modelling the natural convection mechanism. The model was robust and results delivered were found plausible.

The analyses of vessel ablation suggest that it is most sensitive to the mass of UO_2; this is of little surprise, as this mass is the dominating factor in defining the amount of residual heat in the system. The MRVT also shows sensitivity to the mass of steel in the Lower Plenum, to the emissivity of the top metal layer and to vessel wall conductivity, as pointed out in the paper.

The comparison of the effect of uncorrelated vs. correlated, and physically more realistic, initial masses demonstrates that the former leads to more simulations with extreme, unrealistic, results. 5% and 95% percentile show the difference, while the mean of key outputs is not diverging very much. Also important, the MRVT in any of the simulations is found to be 2.8 cm, as compared to 3.3 cm when the more realistic material ratios are used.

The formation of a HM layer in ASTEC has been the subject of several sensitivity analyses. It has been demonstrated that within the Corium pool model, the formation depends entirely on the density difference threshold that defines the onset of metal slump or rise through the oxide layer. When looking at the broader SASPAM-SA analyses, Pearson correlation coefficients and the number of simulations ending up with a HM layer suggest that high steel content reduces the likelihood of a HM layer.

It has been shown that the presence of a HM layer tends to increase the heat flux in the top metal layer, simply by incorporating part of the steel in the system in the HM layer.

In the final UaSA, the combination of initial-condition UP with Corium pool model UP showed that the results are sensitive to the former – in particular again mass of steel -, not the latter. This is regarded as a positive sign that there are no over-sensitivities in the Corium pool model that show up in simulations using that submodel.

The evaluation of UaSA results with two different methods demonstrated that correlation coefficients and Sobol' indices identify the same most significant sensitivities. It highlighted that Sobol' indices, by attributing variance to the different uncertain parameters, are easier to interpret and are providing a more detailed picture of direct and, by covariances, joint influences on the target quantities. The initial Zr mass is an example of such joint influence, see Table IV. Correlation coefficients have the useful property of indicating positive/negative direction of an influence, which is useful information for scrutinizing results.

This stand-alone model is limited in addressing some effects that are likely to influence heat removal, the most important being the simplification of not modelling the RPV to containment connection that exists through the pressurizer release valves. Ablation results are also strongly dependent on the assumption of initial material masses in the Corium pool – in the existing complex large ASTEC model

of design #1 those masses would be the result of the modelled core melting process and could be very different. However, that analysis is very challenging due to the computational effort and the smaller robustness than the stand-alone model and has been set aside until now.

NOMENCLATURE

CC	Correlation Coefficient

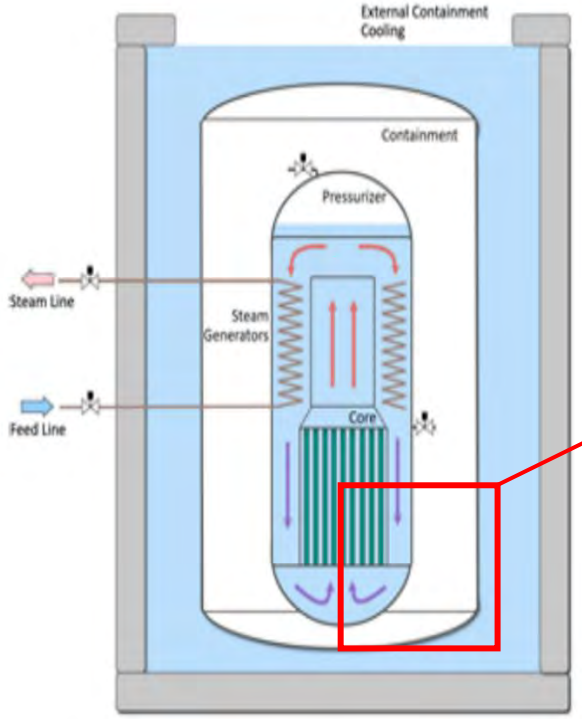
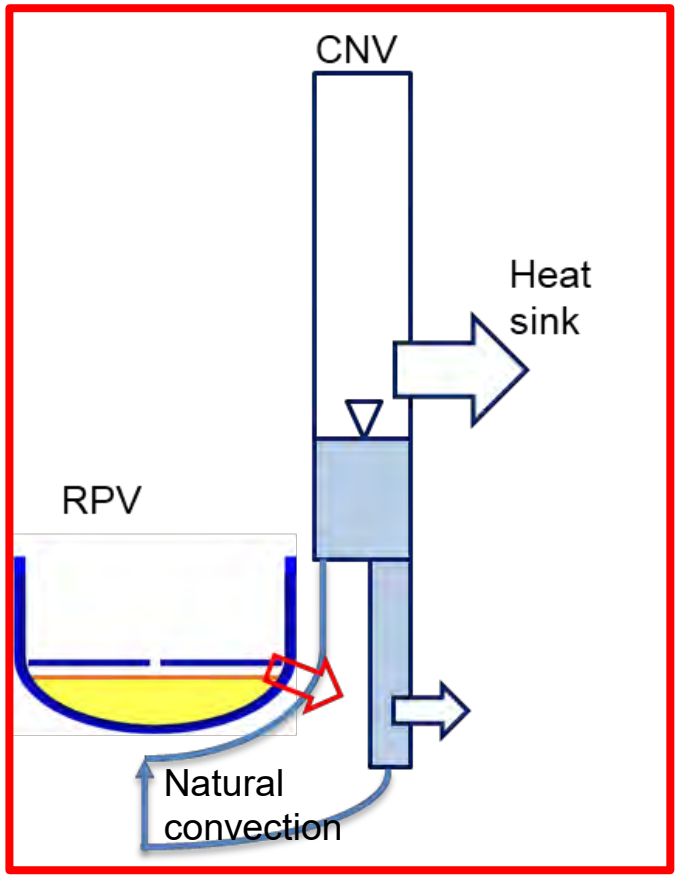
The stand-alone model



Integrated Pressurized Water Reactor design #1

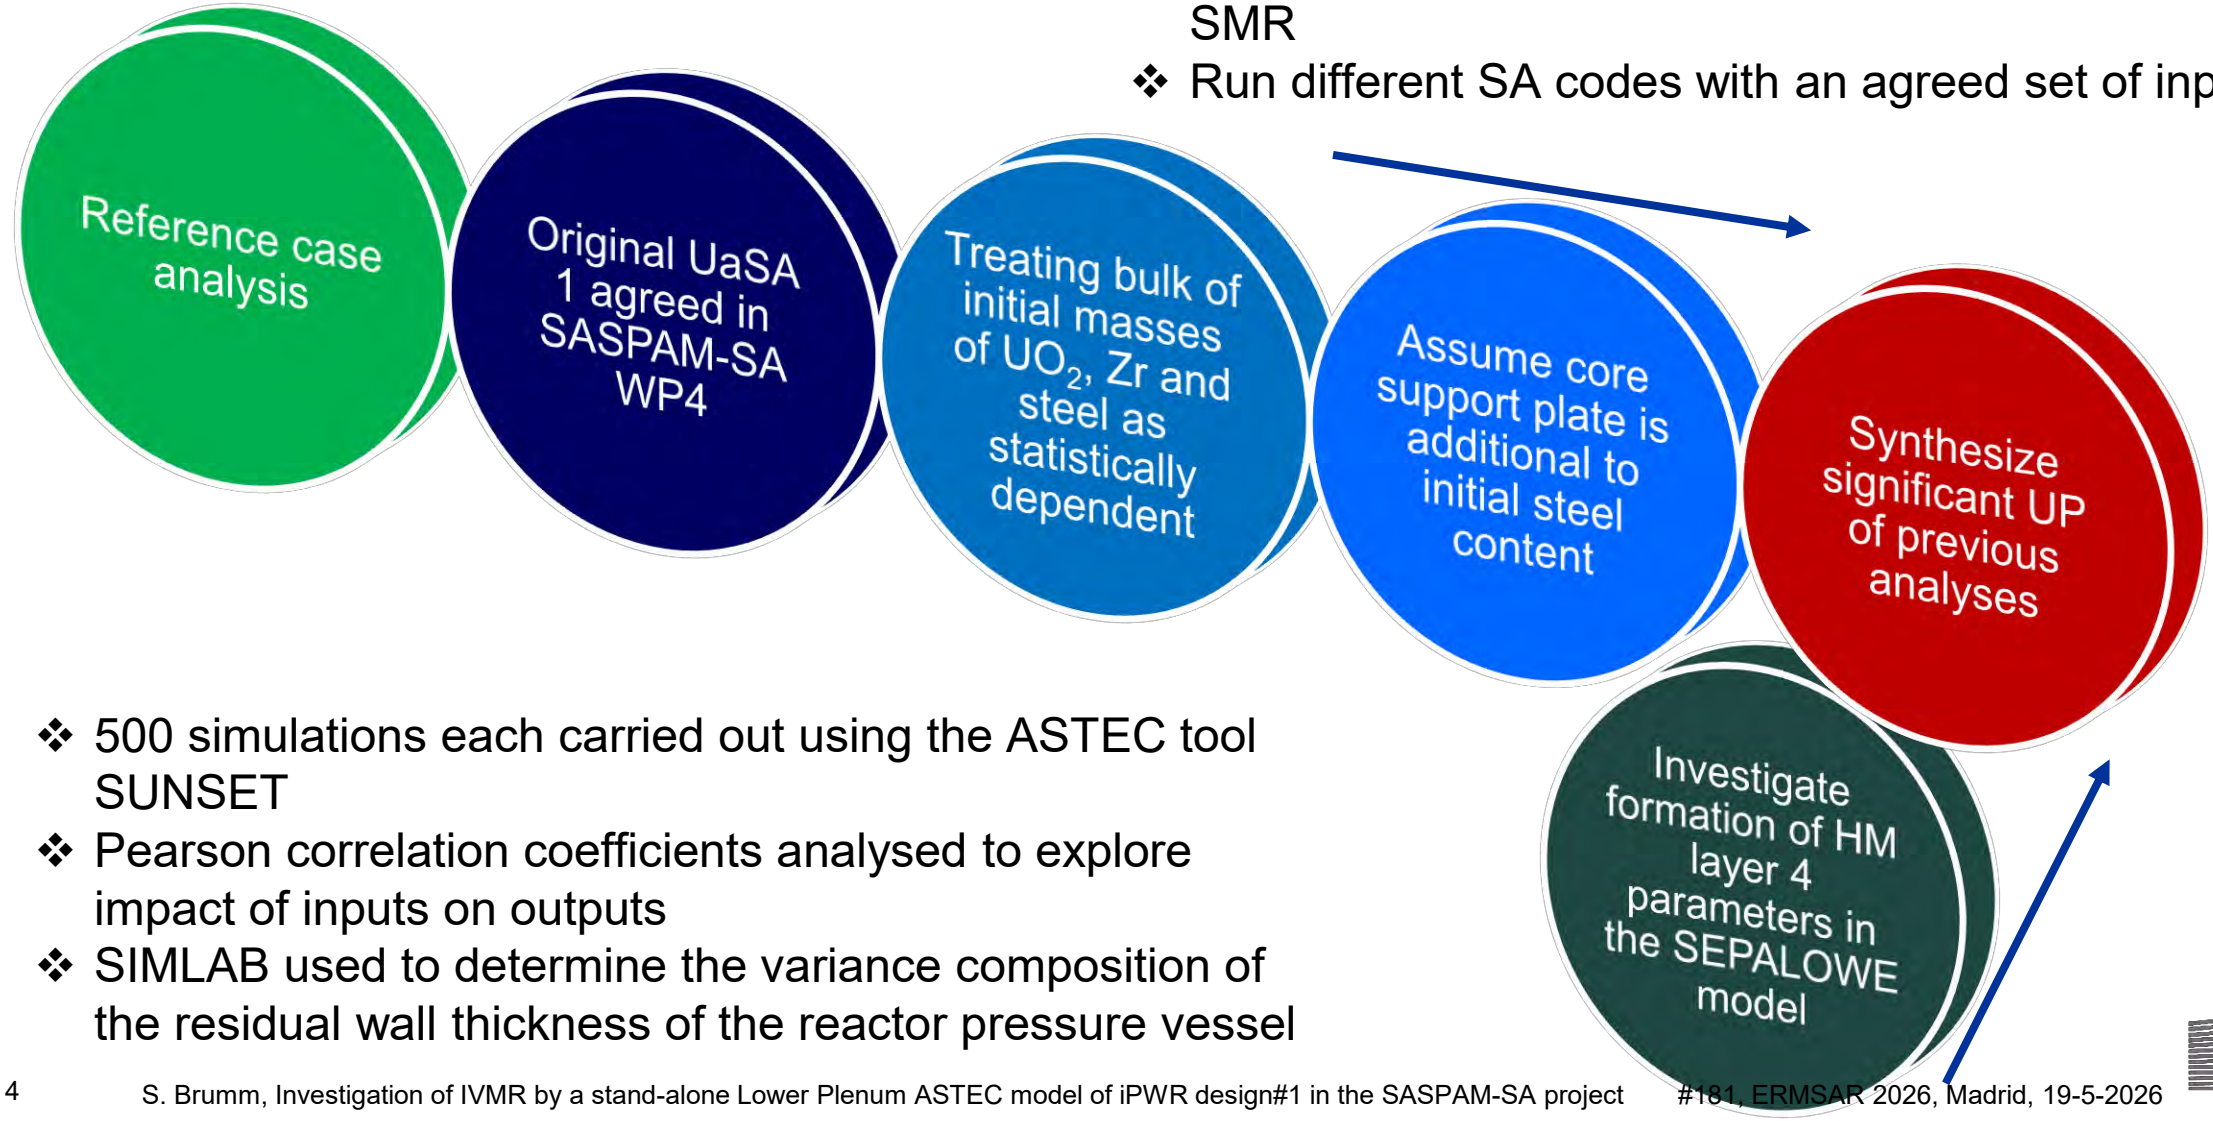


Severe Accident. Model of molten core in the Lower Plenum (yellow) and natural convection cooling

- ASTEC V3.1.2
- Initial conditions: material masses in the two-layered molten pool; residual power; thermal hydraulics
- Residual heat melts the wall of the reactor pressure vessel
- Investigate how sensitive the key output is to uncertain input parameters
- Key output: residual vessel thickness

Six analyses

- SASPAM-SA's objective to demonstrate capability and/or shortcomings of SA codes when applied to SMR
- Run different SA codes with an agreed set of inputs



- 500 simulations each carried out using the ASTEC tool SUNSET
- Pearson correlation coefficients analysed to explore impact of inputs on outputs
- SIMLAB used to determine the variance composition of the residual wall thickness of the reactor pressure vessel

Conclusions

- Reference case: the model meets expectations
- Scenario-specific:
  - Initial mass of UO_2, and thus residual heat, is the largest impact on vessel ablation
  - Initial mass of steel affects strongly the probability of a heavy metal layer (neg. correlation) and, indirectly, vessel ablation (pos. correlation)
  - Compared to initial conditions, the overall sensitivity of HM layer to SEPALOWE model parameters is not significant
- Evaluation:
  - Variance attribution (Sobol' indices) provides a detailed picture of how uncertain inputs impact the uncertainty of the target variable
  - Covariances add to the picture
  - Correlation coefficients support the plausibility check by predicting negative/positive correlation
- General:
  - ASTEC is capable of simulating IVMR in SMR
  - Validation of models more important for SMR than for large reactors needs to be explored

Outlook

- The stand-alone model relies on assumptions (i.c., b.c.) and simplifications; results will be more credible from a more complete model
- The large ASTEC iPWR #1 model by Tractebel, used in SASPAM-SA WP2, has been run as a best estimate case, with significant deviation from the stand-alone model
  - For comparison: t_0 = 0 s; t_{slump} = 24,000 s; t_{end} = 44,000 s
  - 10 - 15% of the core is not slumping into the LP
  - With volatile FP and non-slump accounted, the residual heat in the Corium pool is 73% of total
  - The core support plate is not melting after the Corium slump
  - The Corium pool consists of an oxide layer and a heavy metal layer
- While this comparison will be further explored, the first indication is that the stand-alone model initial conditions are very conservative

ABSTRACT

Monitoring nuclear containment atmosphere in severe accidents is essential for accident management. However, most nuclear plants do not have hydrogen measurement capabilities because the methods for hydrogen detection are limited and have constraints due to power requirements. Any hydrogen measurement technology adopted for use in the containment must meet certain sensing, certification/regulatory, environmental, and power requirements. Passive autocatalytic recombiners (PARs) have been installed in many reactor containments where they mitigate hydrogen explosion risks by utilizing catalysts to facilitate the recombination reaction between hydrogen and oxygen (from air). PARs are not only optimally located in the containment area, where hydrogen may be present during an accident, but are also qualified as a safety system in containments. In addition, PARs can simplify the approach to hydrogen sensing in containment, since they do not need gas sampling lines and have the potential to not require containment boundary penetrations or power. When the PAR is activated, there is a quantitative relationship between the catalyst temperature and the hydrogen concentration in the environment. To determine the local hydrogen concentration, the PAR catalyst temperature can be measured and transmitted wirelessly outside of the containment building. This study outlines the use of PARs as a reliable approach to hydrogen concentration measurements in post-accident containments. The details of the proof-of-concept experiments used for this study are presented. Its applicability and operating range are also discussed.

PAR, hydrogen, recombiner, sensor, catalyst

1. INTRODUCTION

The accumulation of hydrogen (H_2) within the reactor containment building at nuclear power plants (NPPs) during a severe accident has long been a concern for the nuclear industry given the potential for the formation of combustible H_2-air mixtures that can lead to explosions. Such explosions can cause severe damage to critical equipment and the reactor containment building itself, resulting in the potential for release of fission products into the environment. It is, therefore, important for NPPs to be able to measure and monitor H_2 concentration within the reactor containment building during accidents [1]. A suitable H_2 measurement technique can provide real time data on H_2 concentrations and its distribution giving operators important insight that not only enhances the safe operation of NPPs, but also their ability to make critical accident management decisions should a severe accident scenario unfold.

In Canada, the H_2 concentration in the reactor containment building is only measured at Point Lepreau Nuclear Generating Station (PNGS), where gas is drawn from a single sample location to a remote analyzing cabinet outside the containment boundary [2]. Outside of Canada, similar methods to PNGS are employed

for H_2 detection, as well as other technologies including catalytic bead-type sensors and electrochemical sensors. The shortcomings of these measurement approaches are their limited numbers in reactor containment buildings potentially giving a false representation of the H_2 distribution, and their power requirements, which will be lost if a station blackout scenario occurs [2].

Numerous H_2 sensing/measurement technologies have been deployed in non-nuclear applications; however, it is unknown whether they can be successfully deployed in a reactor containment building to accurately measure H_2 concentrations. To effectively function in the post-accident atmosphere, these H_2 measuring technologies must be able to operate under high temperature (i.e., >100 °C) and high humidity, be resistant to radiation and have low drift [1]. In addition, the need to power the sensor will add additional requirements to ensure the operation during all situations, including station blackout.

Passive autocatalytic recombiners (PARs) are already present in many reactor containment buildings where they serve to mitigate H_2 explosion risk should an accident unfold. PARs are not only strategically located where H_2 may be present but also qualified for operation in NPPs. Numerous PARs (i.e., 15 to 30) are installed in CANDU reactor containment buildings. So, if utilized as a network of H_2 sensors, they can provide a reasonable estimate of the H_2 distribution, compared to, for example, a single measurement location currently employed in some NPPs. PARs are radiation resistant/tolerant and utilize noble metals to catalyse the exothermic reaction between H_2 and air (oxygen, O_2). It is the exothermic nature of the recombination reaction between H_2 and O_2 that results in an increase in catalyst temperature that can be correlated with H_2 concentration. This relationship has formed the basis of the concept of the present work to use the PAR as a H_2 sensing/measuring device in NPPs.

There are, however, two main challenges that must be addressed before the PAR can be used as a H_2 measurement device in reactor containment buildings. The first is to develop a sufficiently accurate and reliable correlation between PAR catalyst temperature and H_2 concentration. The second is to establish a reliable method of transmitting the acquired catalyst temperature signal out of the reactor containment building. This difficulty arises from the limitations of using powered technologies in reactor containment buildings and the challenge of transmitting a signal through the ~1 m thick concrete reactor containment building boundary. Once outside of the boundary, it is assumed that conventional means to transmit the signal can be used.

This paper will introduce the conventional methods used for H_2 measurement and discuss their limitations, and present experimental results from proof of concept and concept development testing to demonstrate the potential for the application of the PAR as a H_2 sensor.

2. BACKGROUND

2.1. Hydrogen measurement in containment

An assessment of commercially available H_2 sensor technologies was performed to investigate their suitability for deployment in reactor containment buildings of NPPs. Such H_2 measurement devices/technologies must meet sensing, certification/regulatory, environmental, and power requirements. Additional considerations may include operational lifetime, reliability, reproducibility, and any unique/specific requirements as may be necessary for a particular utility or reactor containment building within which they will be deployed.

Thermal conductivity, electrochemical, resistance-based (e.g., catalytic bead sensors), optical and work function-based sensing technologies were reviewed for use in nuclear containment buildings. Key factors considered in the assessment of H_2 sensors for any given scenario (nuclear or non-nuclear) have been classified into two broad categories, namely, deployment matrices and operational matrices [4]. Deployment matrices are typically one-time considerations that include capital costs, control wiring, electronic interface, cost of installation, commercial maturity, placement, physical size and power requirements. Operational

metrics pertain to on-going and recurring requirements that include calibration requirements, consumables, device to device repeatability, maintenance effects, mechanical stability, minimum analyte volume, operation lifetime, orientation effect and warm-up/start-up time [4].

Notwithstanding the abovementioned general requirements, an attempt to develop specific requirements for H_2 concentration measurement in CANDU containment buildings was made by assembling the range of conditions that the H_2 sensor may be exposed to during a severe accident. These conditions have been identified and grouped into the following specific requirements:

I. Sensing Requirements

It is imperative that the H_2 sensing device is able to have a range of measurement with reasonable accuracy that includes the lower flammability limit (LFL) of H_2-in-air (4 vol.%). The desired range of measurement for H_2 extends to the limit that the PAR could induce a H_2 ignition. Thus, the maximum H_2 concentration is 7 vol.% (in dry conditions) with an accuracy to within ± 0.5 vol.% [1][5].

II. Certification/Regulatory Requirements

The H_2 sensing device must meet the requirements stipulated in relevant codes and standards (e.g., CSA N290.3 [6] and N290.6 [7]) related to control systems, safety systems, instrumentation and requirements for monitoring and display of plant status in the event of a severe accident.

III. Environmental Requirements

H_2 sensors should be robust enough to withstand chemical interference, presence of poisons and radiation that may be present in the containment building environment. For radiation tolerance, the sensor must withstand the presence of gamma, beta and neutron radiation. For chemical interference, the sensor must retain functionality in the presence of steam (100% relative humidity/RH), H_2, helium, O_2 (to very low levels) and fission products. The sensor must be able to be operational at ambient temperatures up to 200 °C and at high temperatures up to 500 °C for very short periods of time (e.g., potentially from H_2 combustion). The presence of carbon monoxide is not considered as its release in severe accident scenarios for CANDU reactors is precluded by in-vessel retention.

IV. Power Requirements

The power requirements should be low enough to be supplied by technologies such as power harvesting in the containment or by batteries that can last from installation to the next routine shut down (during which time the battery can then be replaced).

V. Others

Operational lifetime, reliability, reproducibility and any other specific requirement imposed by the reactor containment that will be hosting the H_2 sensor must be considered.

A summary of the desirable range of values for some of the key parameters is presented in Table I. It is worth mentioning that although the commercially available H_2 sensors/detectors find applications in a wide range of industries and circumstances where high accuracy is required, the review of their methods of operation and limitations indicate that most of them would not be suitable for deployment in the reactor containment building of a NPP without compromising requirements or significant modifications that may end up impacting their functionality when all the factors for suitability are considered. Most commonly, the power requirements for the H_2 sensing technologies limit their use in scenarios where a station is without power. Furthermore, other common issues found with deploying commercial H_2 sensors to nuclear containment buildings include sensitivity toward high humidity and radiation environments.

Table I. Summary of sensor parameters and range of requirements.

Parameter/ Variable	Range	Comments	Ref.
Ambient Temp.	15 – 300 °C	Should not lose functionality from prolonged exposure at max. temp.	[2]
Transient Temp.	Up to 500 °C	Should not lose functionality from brief exposure to max. temp.	[2]
H_2 Conc.	Up to 10 vol.%	Must measure up to 10 vol.% (in dry conditions) with an error of ±0.5 vol.% (to avoid detonation range)	[1]
O_2 Conc.	0 - 20 vol.%	If sensor requires O_2 to function, it must also function at low O_2 vol.% (i.e., < 1 vol.%)	[1]
Steam	Up to 100 vol.%	In the presence of inert gas and diminishing O_2	[1]
Pressure	Up to 400 kPa(g)	Must retain functionality up to design pressure of containment	[2]
Radiation (total integrated dose)	20 Mrad	Presence of beta/gamma/neutron radiation - 1000 krad/h for 200 h	[8]
Energy	Capable of operating for extended periods	Battery or energy harvesting	[1]
Lifetime	>2 years	Based on the outage frequency	
Accuracy	± 0.5%	Must retain high accuracy within measurement range	[1]
Response time	≤ 2 s	Lag between temp. detection transmission and receiving must be small	[1]

2.2. PAR as a hydrogen sensor: adoptability and technical feasibility

PARs facilitate the catalytic oxidation of H_2 to water. The catalysts, as well as the appropriate design of PARs, have been extensively investigated with numerous publications available in open literature. While it is not the aim of this paper to focus on the intended function of PARs, it is important to point out the key attributes that have made this technology a key presence in the containment structures of NPPs worldwide.

The general attributes of PARs that are fundamental to their use as a H_2 sensor include their optimal locations in the containment building for contact with H_2 in the event of an accident, their radiation resistance/tolerance, their qualification as a safety system in NPPs, and their operation without a power supply. Notwithstanding these attributes, PARs still require O_2 to function and contaminants like volatile organic compounds (VOCs) can impair its function if present in the containment. These VOCs may evolve into the containment atmosphere from insulation materials, paints or other organic materials (greases, solvents, oils, lubricants, etc.) that may be used during maintenance operations in NPPs.

The principle of the application of the PAR as a H_2 sensor is based on the relationship between catalyst temperature and H_2 concentration. It is well understood that the exothermic recombination reaction between H_2 and O_2 yield a measurable increase in catalyst temperature. In fact, for many experiments performed on PARs, based upon the H_2 concentration, the catalyst temperature is a predictable value that has been an indicator of whether the catalyst condition is acceptable, or the experiment is performed correctly. It is known that the PAR catalyst temperature increases with an increase in the H_2 concentration and PAR self-starts at low H_2 concentration (i.e., <2 vol.% H_2 in air) [5]. However, very little (if any) research has been conducted on using the PAR catalyst as a method to monitor H_2 concentration within containment and no publications in open literature have been found.

In addition, resistance-based H_2 sensors known as catalytic bead sensors use catalyst technology and the temperature rise of the catalyst to derive a H_2 concentration. Therefore, the catalyst temperature-H_2 concentration relationship is considered as a reliable method for H_2 concentration determination once the catalyst temperature is measured with some precision and accuracy. Furthermore, Liang et. al. [2] identified that PARs were instrumented with thermocouples to "inform on a tendency of H_2 production and H_2 concentrations inside the containment" in France and Japan. The fact that PARs are already installed in reactor containments and the numerous shortcomings of existing H_2 sensing technologies makes the use of PARs as a H_2 sensing technique an option worth investigating.

2.3. Methods for signal transmission

Two schemes to transmit the catalyst temperature signal out of the containment building were investigated. The first method is to run thermocouple wire directly from the PAR to and through the containment boundary. The advantage to this approach is that a thermocouple signal (over a relatively short distance) does not require power, as it is generated by the temperature difference typically between two metals. The biggest drawback is the need to be run wiring throughout containment and through the containment boundary. The second approach is to connect a thermocouple to a wireless transmitter in a location near the PAR, then receive the catalyst temperature signal outside the containment boundary with a wireless receiver unit. The main advantage to this scheme is the minimal use of wires, which eliminates any concerns regarding passing wires throughout the containment building and boundary. The major drawback is that this type of technology has not been widely qualified for use in NPPs. There is also the challenge of supplying adequate power to the wireless device.

3. PROOF OF CONCEPT/PRELIMINARY TESTING

3.1. PAR catalyst temperature versus hydrogen concentration

The surface temperature of the AECL PAR catalyst plate has consistently been monitored in a large portion of tests on the full-size PAR in the large-scale vented combustion test facility (LSVCTF) at CNL's Whiteshell Laboratories (WL). A description of the LSVCTF can be found elsewhere [5]. The catalyst plate located in the centre of the PAR has always been instrumented with three Type-K thermocouples, since it typically experiences the highest temperatures, with measurements taken at the horizontal centre of the plate in the top, middle and bottom sections. The method includes strapping the thermocouple to the plate by tack welding ribbons of stainless-steel shim stock to the catalyst plate. Prior to tack welding, the catalyst is sand blasted from the plate to allow a reliable thermal contact between the shim stock and the plate. Fig. 1 shows a photo of a PAR catalyst plate with the three thermocouples attached.

The H_2 concentration sampling and analysis approaches have not changed significantly over the duration of the full-scale PAR testing. The locations where the gas samples were taken have been consistent. H_2 concentration measurements are sequentially taken from four or five different locations within the LSVCTF combustion chamber. The standard gas sampling locations are at the inlet and outlet of the PAR, and at the top and middle locations in the room. For the current evaluation, only the PAR inlet sample location was investigated, since it has the strongest relationship to the PAR catalyst temperatures due to its proximity to the catalyst plates. The PAR inlet sample line was located in the centre of the PAR inlet, approximately 20 cm below the inlet of the PAR.

Figure 1. Photograph of a PAR catalyst plate instrumented with thermocouples at the top, middle and bottom locations when tested at the LSVCTF.

Forty-six (46) experiments were selected for the evaluation, after meeting a small set of criteria to ensure that the PAR geometry, catalyst material, facility instrumentation and experimental conditions were consistent. The experimental data were processed and plotted, and a second order/quadratic polynomial curve fit was applied to provide an equation that could be used to relate the three catalyst plate temperature locations with the PAR inlet H_2 concentration. A measured PAR catalyst plate temperature can therefore be correlated with the corresponding PAR inlet H_2 concentration by using the developed polynomial equation.

An analysis of the accuracy of the three catalyst plate temperatures was also performed to select the best location on the catalyst plate (top, middle or bottom) to use as a H_2 sensor. An error of 5% and 10% was applied to the full-scale H_2 concentration value. The full-scale value of 6.5 vol.% H_2 was used, since above this concentration the likelihood of the PAR inducing a H_2 ignition increases significantly. The error associated to each equation was 0.33 vol.% and 0.65 vol.% for 5% and 10% error, respectively. The figures for bottom, middle and top catalyst plate temperature measurement locations with the polynomial fit and errors are given in Fig. 2. Residual analysis of the curve fitting indicate that curves fit the data well (data not shown here).

Based on the information shown in Fig. 2., the temperature measurement location that has the least amount of error is at the top of the catalyst plate. Some of the data for the temperature measured at the top of the catalyst plate falls outside of the 10% error lines; however compared with the fit of the bottom and middle catalyst plate temperature measurements, the top has the least amount of data outside of the 10% error lines. Therefore, the catalyst temperature measurement at the top of the catalyst plate was selected as the measurement location moving forward.

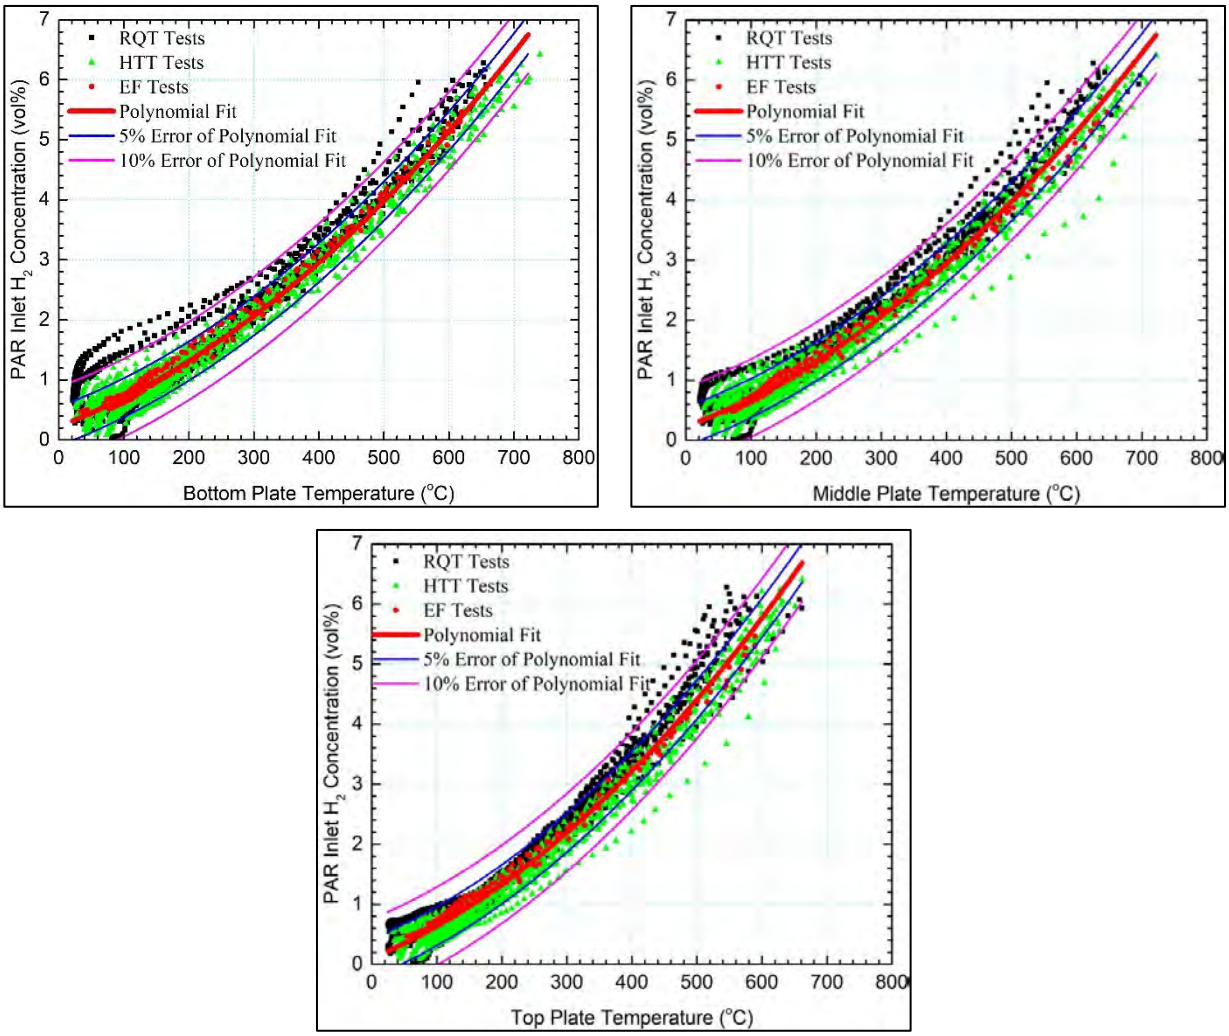

Figure 2. Data of inlet H_2 concentration vs. bottom (top left), middle (top right) and top (bottom left) catalyst plate temperatures with 2nd order polynomial fit and 5% and 10% error applied to the polynomial.

3.2. Wireless signal transmission

Wireless sensor networks are feasible options for monitoring various equipment or environment conditions in NPPs. They have the main advantages of low cost and high flexibility when compared to wired networks. Wireless sensor nodes are mostly powered by chemical batteries with fixed energy densities and replacing depleted batteries frequently is a shortcoming for its (wireless) adoption. Usually, a wireless sensor network consumes a lot of power to function while in continuous active mode, which shortens the battery and sensor lives significantly. To decrease the power consumption, wireless sensor networks can be programmed so that they can *wake-up* periodically for the transmissions and stay in *sleeping* mode between transmissions. Moreover, a low power consumption of a wireless sensor node also enables the use of conventional batteries with minimum power management for long-term operation.

An industrial wireless high temperature sensor network tool was purchased and used to validate the use of a wireless sensor network to monitor the PAR catalyst plate temperatures reliably in the reactor containment building. This wireless sensor network was selected because of its unique features, including long

communication range and ability to sense high temperatures (i.e., use of Type K thermocouples). The system consists of a transmitter, receiver and Labview-based software to adjust the sensor parameters and record the temperature data. The transmitter and receiver form a wireless sensor network for remote temperature sensing governed by a low power operation DigiMesh protocol. Each module has a Radio Frequency (RF) device and an adapter board enclosed in a polycarbonate box with an external RF antenna of 2.1 dBi (dBi is the amount of focus applied by an antenna with respect to an Isotropic Radiator). With polycarbonate enclosures, both modules have an operating temperature range of -20 to +85 °C.

The wireless transmitter is powered by four AA batteries and has a Type K thermocouple connector next to the RF antenna. The transmitter can provide measurements for temperatures up to 980 °C with an accuracy of ±1.1 °C. The RF device within the transmitter has a power efficient sleeping mode and can deliver up to 500,000 transmissions from four AA batteries. The user can also configure its sleeping mode by changing the transmission frequency which can increase the battery life for up to 10 years. The receiver module is a wireless-to-USB modem that connects to the computer through USB for data processing and its RF device can be powered using an external power supply (5 V to 32 VDC). With on-board RF antennas, the RF devices in the modules have a 3.2 km of line-of-sight communication range that can be increased up to 45 km using high gain antennas.

3.2.1. Power consumption

An important factor in using wireless sensing networks in reactor containment buildings is the power requirements for such networks and how such power is to be provided. To verify the power consumption of the wireless transmitter in all its possible states, it was necessary to perform a real time power consumption study on the wireless transmitter when it performs remote temperature sensing at given program settings. The information gained can also be useful to run the wireless transmitter with an optimized program to achieve the desired battery life.

The power consumption analysis with two AA batteries found that it is unable to power the wireless transmitter for the period of time (years) that is required for an NPP. Since it consumes only a few milliwatts less power in the sleep mode compared to the active mode, the analysis estimated that the transmitter would not last more than a month. Nonetheless, the power requirement (~75 mW) of the active mode is quite low given that the PAR on its own does not require power. When the power requirement for wireless transmission is compared with the power requirements of other H_2 sensing technologies [1], it is more feasible to adopt this approach as a method for measuring H_2 concentration in containment.

Further effort is required toward modifying the firmware of the RF device to set it at the lowest possible power consumption in sleep. Further analysis will be performed to determine the power consumption at the lowest power level, which is expected to decrease the power consumption from milliwatts to microwatts when the wireless transmitter is in sleep mode. An evaluation will also be performed to determine the lifetime of the battery at the lowest power setting at a range of transmission frequencies. An alternative option to this is to use more batteries to provide more power to the transmitter.

3.2.2. Wireless transmission

The Hydrogen Safety Test Facility (HSTF) at Chalk River Laboratories (CRL), described in Ref. [9], was used to determine if a thermocouple signal could be wirelessly transmitted through a significant boundary (e.g., vessel and concrete wall). The HSTF spherical test vessel has a carbon steel wall thickness of 12.7 mm (0.5 inches), and the walls to the laboratory are approximately 1 m thick concrete, which are considered to be representative of the inner liner and walls of the containment building.

The wireless transmitter was attached to the inside wall of the HSTF. The receiver module of the wireless sensor network was coupled to a laptop equipped with the LabVIEW software and placed outside the lab

concentre wall, approximately 5 m away from the sealed HSTF vessel. The experiment was performed at dry conditions (no steam was used to alter the relative humidity). Three catalysts coupons of 4 cm by 6 cm were installed in a scaled PAR housing. Two thermocouples (Type K) were attached to the middle catalyst coupon, one feeding the data acquisition system and the other feeding the wireless transmitter.

Fig. 3 shows the results from the experiment, demonstrating that both catalyst temperature measurements are in excellent agreement. Fig. 3 also shows an excellent match between the hydrogen concentration and catalyst temperature. The test demonstrated that it is possible to transmit catalyst plate temperature through a 12.7 mm thick carbon steel and approximately 1 m thick concrete boundary wirelessly to a receiver.

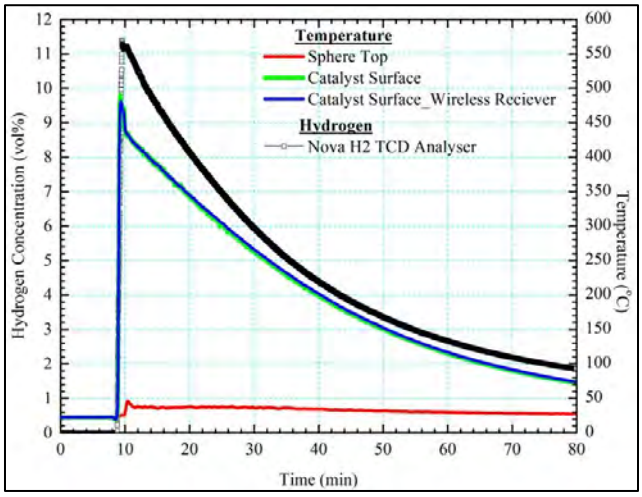

Figure 3. Temperature (wireless and wired data acquisition) and H_2 concentration profile for PAR experiment through metal and concrete boundary.

4. ADVANCED TESTING

After experimentally establishing the potential use of PAR as a H_2 sensor, the next step was to ensure that such use of PARs (and relevant accessories like transmitters and suitable power sources) can meet the requirements for deployment into CANDU containment. A series of tests were performed to experimentally validate the use of PARs together with a transmitting device for H_2 sensing in containment, such that it retains functionality under same qualification requirements already met by the AECL PAR. A summary of the results from the tests are provided in Table II and discussed in the Sections 4.1 to 4.6.

Table II. Summary of results comparing PAR as a H_2 sensor versus qualification requirements.

Requirements		Test Results	
Parameter/ Variable	**Range**	**(Pass / Fail, or successfully tested range)**	**Comments**
Ambient Temp.	15 – 150 °C	Partial Pass	Tests covered up to 100 °C. Modifications needed to transmitter housing and further testing to 150 °C for extended periods
Transient Temp.	Up to 500 °C	Pass	
H_2 Conc.	0.6 - 10 vol.%	Partial Pass	PARs will measure H_2 up to ~7 - 8 vol.% when they will ignite H_2 and limit H_2 concentration in containment building to less than ~8 vol.%
O_2 Conc.	0.6 - 20 vol.%	Fail	The min. O_2 concentration identified is 0.6 vol% but is dependent on the H_2 concentration.
Steam	Up to 100 vol.%	Partial Pass	Accuracy is not affected by steam concentration. Environmental tests on the transmitter covered up to 55 vol.%. Further testing needed to cover up to 100 vol.% for extended periods
Pressure	Up to 250 kPag	Partial Pass	Transmitter passed transient pressure tests. Further tests needed to qualify transmitter under static pressure conditions
Radiation (total integrated dose)	20 Mrad	Fail	Modifications needed to transmitter housing to protect internal electronics from radiation or modify electronics to better handle radiation.
Energy	Capable of operating for extended periods	Not Tested	Modifications to firmware and analysis needed to ensure the transmitter can operate long term without replacing batteries or additional batteries
Lifetime	≥ 2 years	Not Tested	
Accuracy	± 0.5%	Not Tested	
Response time	≤ 2 s	Fail	The PAR as a H_2 sensor response time was found to range from 1 - 2 min

4.1. High ambient temperature

The wireless temperature transmitter was assessed for high temperature (100 °C) for extended periods of time (days). This parameter is to ensure that the transmitter can survive the containment building post-accident ambient temperature.

Originally, a value of 150 °C was planned for the exposures to cover the envelope of containment building temperatures in accident scenarios; however, standard lithium batteries (such as, Energizer Ultimate Lithium Batteries) have a maximum temperature rating of 60 °C. Thus, alternative batteries with an extended temperature range (Tadiran TLH-5903 Lithium Batteries) were used in the wireless temperature transmitter that have a maximum temperature rating of 125 °C. Due to these limitations, the wireless transmitter was exposed to 100 °C, so that the maximum temperature of the battery was not exceeded. It should be noted that the high temperature batteries were hard wired to the wireless temperature transmitter because of the design of the high temperature batteries.

Exposures were performed by installing the transmitter in an oven and operating the oven for about 8 h per day. The exposure was performed this way to observe the wireless transmitter and prevent any fires or damage to the oven. The wireless transmitter was exposed to 100 °C in the oven for 11 days and a total of 65.5 hours. The transmitter remained functional throughout the exposure period with no physical or functional degradation found.

A method to expose the wireless transmitter to higher ambient temperatures (e.g., 150 °C), but not expose the battery to such temperatures, could be to insulate the transmitter housing. However, the heat generated by the electronics would also need to be considered before insulating the housing to prevent heating the transmitter from the inside. In general, the PAR as a H_2 sensor has come close to meeting the ambient temperature parameter identified in Table III without making significant modifications to the transmitter housing.

4.2. Transient temperature and pressure

The wireless temperature transmitter was installed inside the HSTF during H_2 combustion tests. In the experiment the transmitter was exposed to a brief pressure transient with an overpressure greater than 100 kPa. High frequency temperature measurements were not made; however, it is expected that the temperature transient from the H_2 combustion was well above 300 °C. Once the H_2 combustion was initiated, the temperature and pressure would instantaneously rise in the vessel, and decay over approximately one minute

These experiments provided a simulated H_2 combustion exposure to the wireless transmitter, and no damage or noticeable effects were found on the transmitter housing or electronics enclosed in the temperature transmitter. These results satisfy the requirements identified of the transient temperature parameter in Table II.

4.3. Steam exposure

4.3.1 Sensor Accuracy

The correlation developed between H_2 concentration and catalyst temperature included experimental data with initial RH ranging from 5 – 100% at 20 – 25 °C. In addition, data from more than 20 experiments conducted at steam concentrations ranging from 0.6 vol% to 44.7 vol% were reviewed to investigate if the steam concentration impacted the catalyst temperature measurement. It was found that the steam concentration does not impact the PAR catalyst temperature. Therefore, the accuracy of the H_2 concentration measurement by the PAR as a H_2 sensor is not affected by steam concentration.

4.3.2 Environmental

To investigate the effect of a high steam concentration on the wireless temperature transmitter, tests were performed to expose the wireless temperature transmitter to high temperature and high humidity. With the recombiner installed in the HSTF, H_2 was injected into the vessel with the expectation for the recombination reaction to increase the temperature and humidity inside the vessel. In these tests, H_2 was injected during two periods to allow the H_2 concentration to be consumed and the steam concentration and temperature in the vessel to increase. After the second H_2 injection, the humidity was above 70% for the entire 80 minutes and the ambient temperature increased from approximately 50 °C to approximately 85 °C near the end of the test. The RH decreased as a result of the ambient temperature increase. The steam concentration at the beginning of the test (e.g., 100% RH and 50 °C) was calculated to be approximately 12 vol.% and toward the end of the test (e.g., 70% RH and 85 °C) was approximately 55 vol.%. The wireless temperature

transmitter was exposed to the maximum steam concentration for approximately 30 – 40 minutes in each test.

In both tests the transmitter stopped functioning about midway through the test. Upon inspection after testing, it was found that the unit had failed due to a faulty battery connection in the transmitter. As a result, the transmitter did not have sufficient power to continue to operate. This issue occurred in both high steam concentration tests and is attributed to the higher temperature causing the battery connectors to loosen and cause a weak connection to the battery. This issue can be resolved by adding additional support or hard wiring the battery to the transmitter, as was done in the ambient temperature tests. In general, the wireless temperature transmitter could operate in the high humidity environment as the exposure to the steam was not found to damage the transmitter; however, the duration of the exposure to high humidity environment over the two tests was only about one hour. A longer-term exposure would provide further confidence in the capability of the system to operate in such environments.

The results of these experiments provide confidence and a step towards meeting the requirements identified in Table II; however, the wireless temperature transmitter does not fully satisfy the requirements identified in Table II regarding the steam parameter. More tests to expose the transmitter to higher steam concentrations and for longer durations are required to meet the identified requirement.

4.4. Radiation dose

The wireless temperature transmitter was exposed to gamma radiation in one of CNL's Nordion Gammacells with a cobalt-60 source providing a dose rate of 0.0291 Mrad/h. Three separate attempts were made where a wireless temperature transmitter was placed inside of the Gammacell and was briefly exposed to gamma radiation. In all three cases, upon checking the wireless temperature transmitter signal with the receiver, it was found that the transmitter was not responding. After the transmitter was removed from the Gammacell, an inspection on the wireless transmitter and batteries was performed. In all three cases it was found that the batteries remained functional, while the temperature transmitter had failed. It was assumed that the electrical components (semiconductor) had failed due to exposure to radiation from the Gammacell [10].

The three exposure time periods were 20.0, 287.3 and 24.2 hours. Therefore, a minimum exposure dose of 0.58 Mrad was received by the wireless temperature transmitters and resulted in a failure of the transmitter. This result indicated that the wireless transmitter has a very low tolerance for radiation exposure compared with the required dose of 37 Mrad identified in Table II.

A method to potentially prevent the internal electronics' exposure to radiation is to replace the transmitter housing with a housing made from a material that has radiation shielding properties, such as lead. The wireless signal could still be accessed through the antenna, which is threaded into the transmitter housing.

4.5. Oxygen concentration

Many tests were performed with the PAR under low O_2 conditions [11]. The limits of PAR operation were identified in these tests, where if the O_2 concentration is less than H_2 concentration, the PAR recombination rate becomes reduced. The reduction in recombination rate will impact the catalyst temperature, which in turn will impact the correlated H_2 concentration if the PAR was used as a H_2 sensor. Therefore, the minimum O_2 concentration for the PAR as a H_2 sensor is related to the H_2 concentration. The minimum H_2 concentration is about 0.6 vol%. Therefore, the minimum O_2 concentration is 0.6 vol%, but may be a greater value depending on the H_2 concentration.

The O_2 concentration parameter in Table I suggests that the sensor must operate at O_2 concentrations down to 0 vol.%. Thus, the PAR as a H_2 sensor does not meet this requirement. On the other hand, self-start was

found to be minimally affected by low O_2 concentration [11]. Thus, it can be assumed that the response time of the PAR as a H_2 sensor is not affected by low O_2 concentration.

4.6. Response time

Response time of the PAR is defined here as the time for the PAR to respond to the local H_2 concentration after it has self-started. This definition does not include the PAR self-start. This is an important distinction, as the self-start parameter is dependent on the degradation level of the catalyst, post-accident containment temperature and the local H_2 concentration. However, if it is assumed that the initial post-accident temperature or hydrogen concentration are high, or the catalyst degradation level is low, the PAR is expected to self-start with minimal delay as the hydrogen is released.

To assess the response time, tests performed at room conditions were reviewed to determine the response time of the PAR, which will provide insight into the PAR as a H_2 sensor. An example of the delay time for the PAR to start functioning and attain the temperature that would align with the catalyst plate temperature and the local H_2 concentration is provided in Fig. 4 for a test performed in the HSTF. H_2 is injected into the facility multiple times to determine the minimum H_2 concentration required for the PAR to self-start. After the fourth injection, at about 1.2 vol.% H_2, the PAR self-starts, and the response time of the PAR can be assessed. The final H_2 injection is complete, and the mixing fan is turned off at 46 minutes. The PAR catalyst temperature immediately begins to increase when the fans are turned off and reaches a 10 °C increase in about 1.5 minutes. The 10 °C increase signifies a notable rise in the hydrogen concentration and is considered a 'response' from the PAR. Data from large-scale tests in the LSVCTF was also reviewed and a similar range of data was found. Thus, for new or regenerated catalyst plates, a response time for the PAR as a H_2 sensor can be considered to range from 1 - 2 minutes, which is well above the required response time of less than 2 seconds identified in Table II.

To determine the response time of the PAR as a H_2 sensor more accurately, a series of tests could be performed where the wireless temperature transmitter and point-type H_2 sensors are installed in the HSTF. H_2 injections would then be performed to pre-selected H_2 concentrations. The test would then compare the response time of the PAR as a H_2 sensor against the point-type sensors.

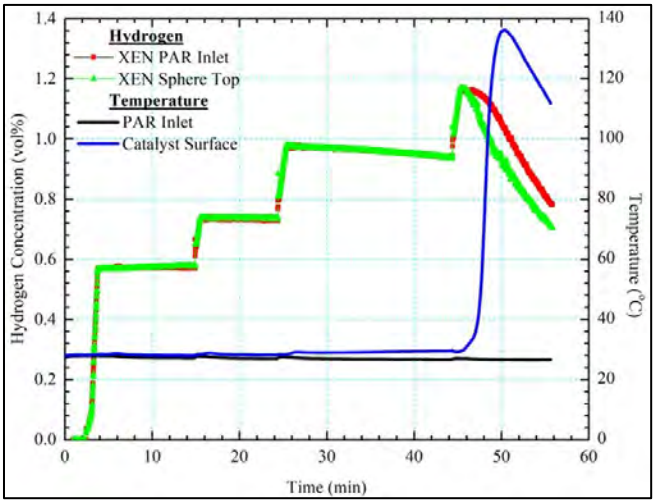

Figure 4. Self-start test demonstrating response time of PAR as a H_2 sensor.

5. SUMMARY

Many different approaches to measure H_2 in air are commercially available or in development for utilization for non-nuclear applications. As part of the review, it was determined that due to power requirements for commercially available H_2 sensors (i.e., > 1 Watt), and the power limitations in the reactor containment building (i.e., < 100 mW), the PAR that has been installed in NPPs for H_2 mitigation during an accident, has a very valuable complementary applicability as a H_2 sensor.

An empirical equation had been developed, relating the PAR catalyst plate temperature to the local H_2 concentration. This relationship can be utilized to estimate the local H_2 concentration in the reactor containment building during an accident requiring transmission of the temperature signal outside of the reactor containment building either by a hardwired approach using cables or wirelessly using a suitable wireless network. It has been demonstrated that a wireless signal can be transmitted and received across a boundary representative of the reactor containment building wall. It was also found that using thermocouple specifications and appropriate attachment methods the response time and stability of the temperature measurement can be improved.

To continue to develop the PAR as a H_2 sensor concept, more testing and qualification is required. Investigations into the static pressure, humidity, but mainly radiation resistance of the wireless temperature transmitter, would provide significant confidence in the ability of the transmitter to withstand nuclear reactor containment building post-accident conditions.

PARs for Hydrogen Measurement in Nuclear Containments in Severe Accidents

Lee Gardner (lee.gardner@cnl.ca) and Blessing Ibeh

European Review Meeting in Severe Accident Research
2026 May 18-22

Canadian Nuclear Laboratories | Laboratoires Nucléaires Canadiens

Background - Hydrogen Measurements for Nuclear Containment

- Current Status
  - Common approach: sampling systems connected to gas analysis equipment
  - Alternatives: in-situ sensors (catalytic bead, electrochemical, thermal conductivity)
- Type of Sensors Reviewed
  - Thermal conductivity, electrochemical, resistance-based (e.g., catalytic bead sensors), optical and work function-based sensing technologies
- Limitations
  - Power
  - Cross-sensitive or require oxygen
  - Signal transmission
  - Limited number in containment
  - Qualification

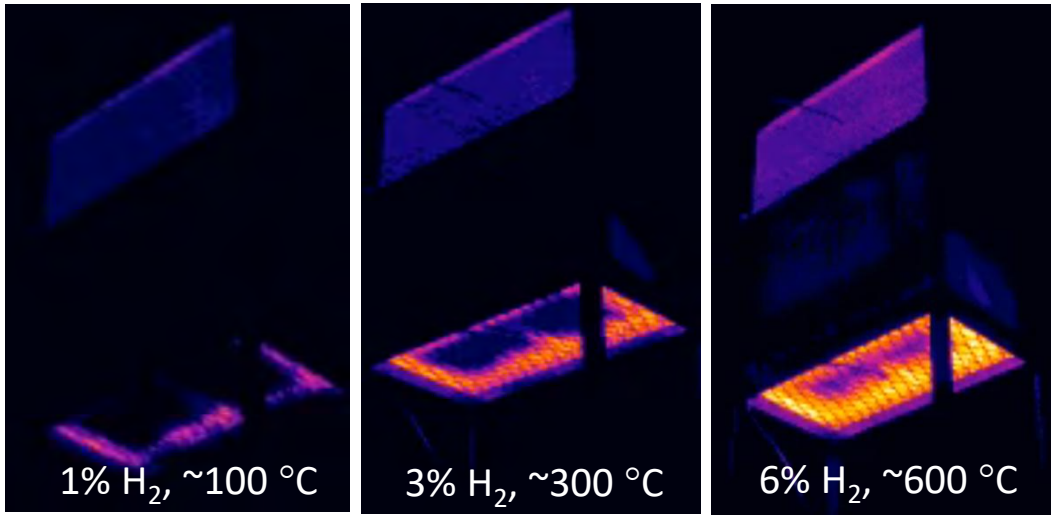
Background – Sensor Requirements in Accidents (CANDU)

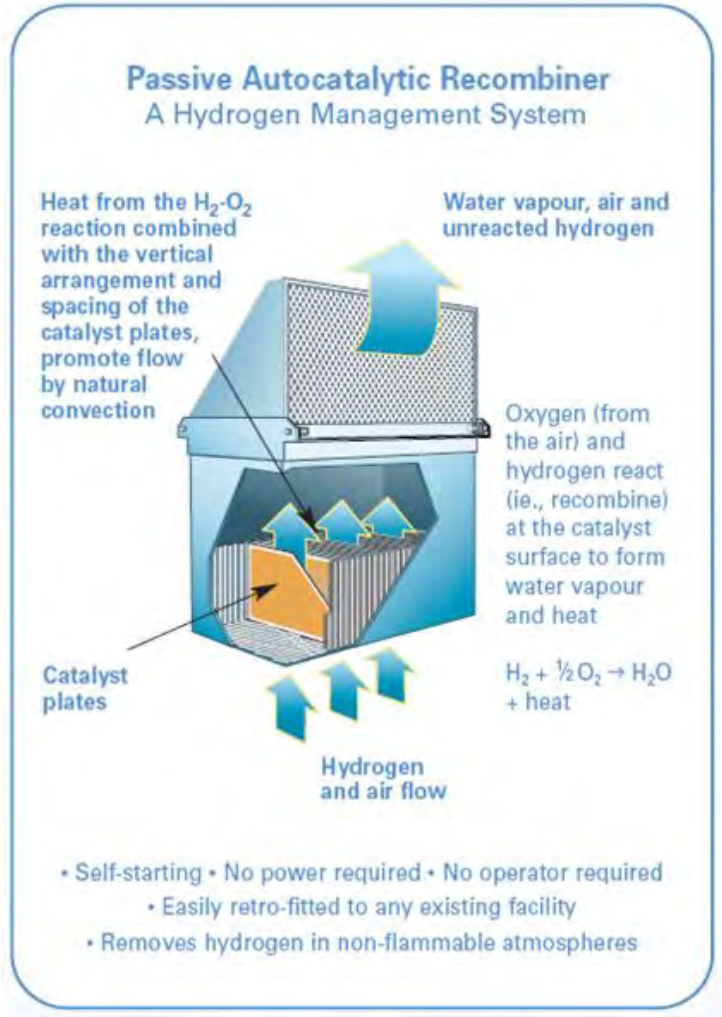
Parameter/ Variable	Range	Comments
Ambient Temperature	15 – 300 °C	
Transient Temperature	Up to 500 °C	
H_2 Concentration	Up to 10 vol.%	With error of ±0.5 vol.% (to avoid detonation range)
O_2 Concentration	0 - 20 vol.%	If sensor requires O_2, must function at low O_2 (i.e., < 1 vol.%)
Steam	Up to 100 vol.%	In the presence of inert gas and diminishing O_2
Pressure	Up to 400 kPa(g)	Retain functionality up to design pressure of containment
Radiation (total integrated dose)	20 Mrad	Beta/gamma/neutron - 1000 krad/h for 200 h
Energy	Can operate for extended periods	Source from battery or energy harvesting
Lifetime	>2 years	Based on the outage frequency
Accuracy	± 0.5%	
Response time	≤ 2 s	

PAR as a Hydrogen Sensor - Concept

- Heat generated from exothermic recombination reaction
- Catalyst instrumented with thermocouples, provide temperature measurements
- Measured catalyst temperature can be correlated with H_2 concentration

IR Image of Operating PAR





PAR as Hydrogen Sensor - Feasibility

Adoptability

- PAR already installed in containment
- Very little or no power needed for signal transmission
- PAR qualified for nuclear containment & SAs
  - PAR operation in SAs studied extensively

Signal Transmission

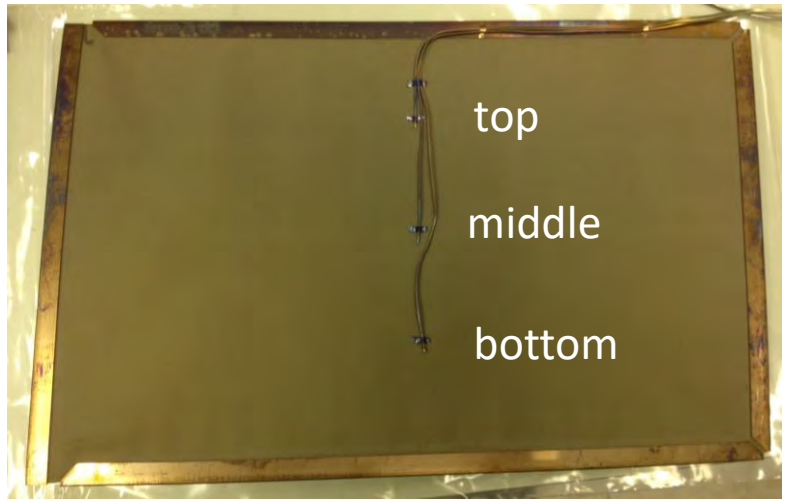
- Wired (thermocouple wire)
  - \+ No power needed
  - \- Penetration through containment boundary

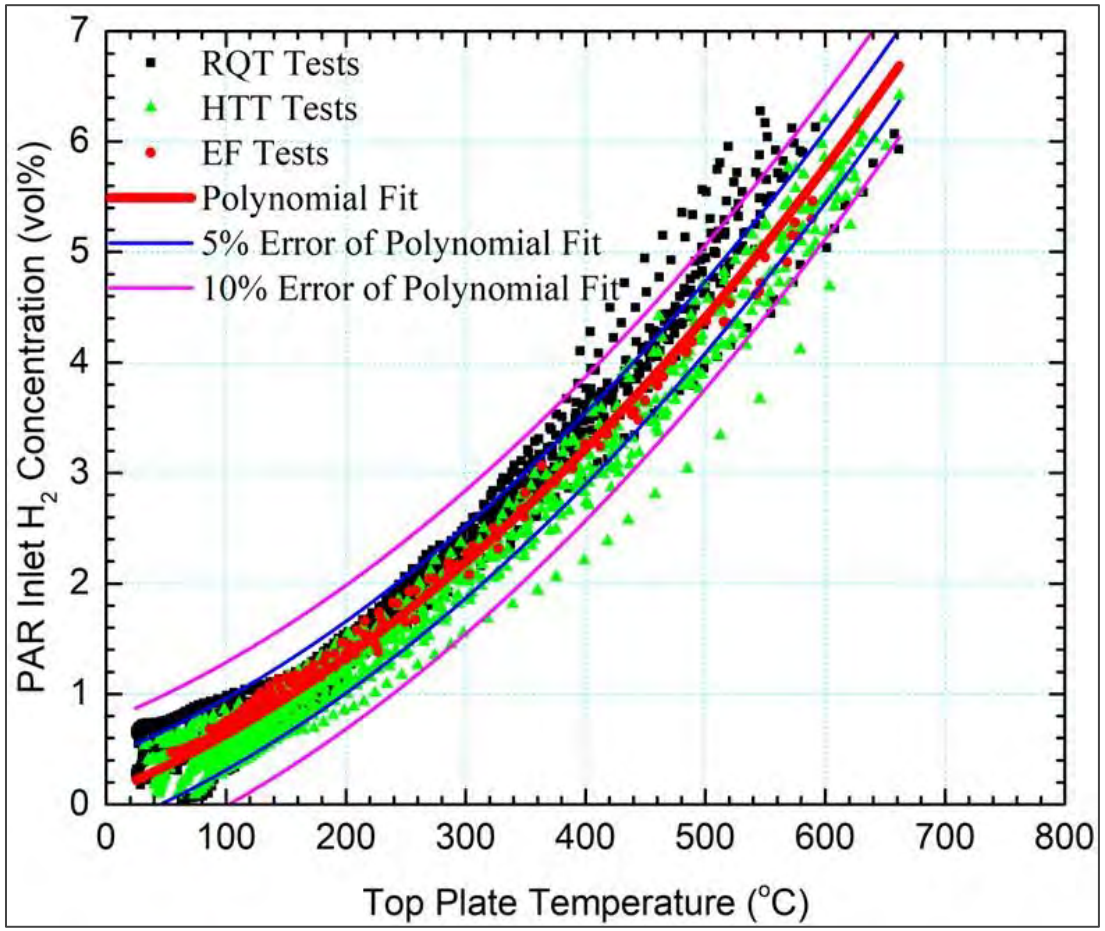
- Wireless (transmitter/receiver)
  - \+ No penetration through containment boundary needed
  - \- Wireless transmitter for nuclear containment are under development
  - \- Power required for transmitters

Proof of Concept/Preliminary Testing

- Catalyst temperatures measured at 3 locations (top, middle, bottom in horizontal centre)
- Data used from 46 large-scale experiments
- Best fit was found in the top catalyst plate location

Catalyst Plate



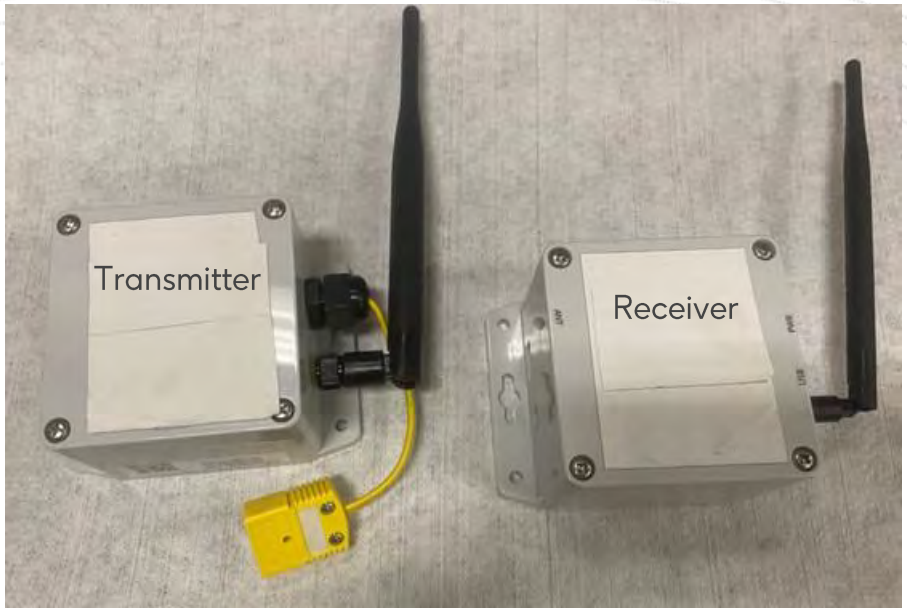


Proof of Concept/Preliminary Testing

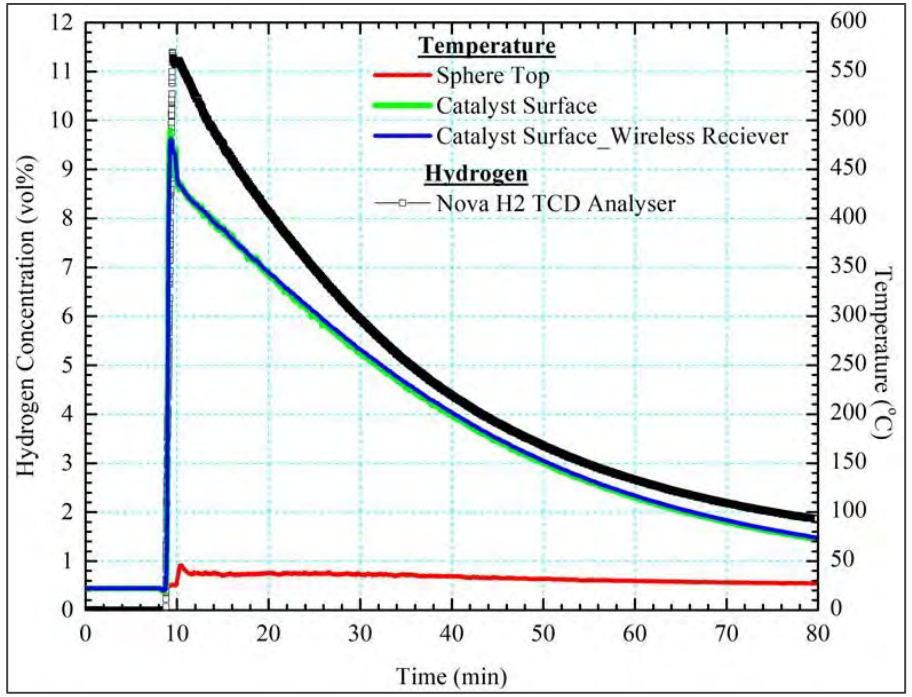
Wireless Transmission

- Power Consumption Analysis
  - 2 AA batteries were insufficient to power transmitter
  - Firmware can be modified to set transmitter to sleep between transmissions

- Wireless Transmission Boundary Tested
  - 12.7 mm thick carbon steel
  - 1 m thick concrete



Commercial Wireless Thermocouple Transmitter/Receiver



Advanced Testing

Requirements		Test Results	
Parameter/ Variable	**Range**	**(Pass / Fail, or successfully tested range)**	**Comments**
Ambient Temp.	15 – 150 °C	Partial Pass	Tests up to 100 °C. Modifications needed to transmitter housing & further testing to 150 °C for extended periods
Transient Temp.	Up to 500 °C	Pass	
H_2 Conc.	≤ 10 vol.%	Partial Pass	PARs measure H_2 up to ~7 - 8 vol.% when they can ignite H_2
O_2 Conc.	0 - 20 vol.%	Fail	The min. O_2 conc. identified is 7 vol.%
Steam	Up to 100 vol.%	Partial Pass	Tests covered up to 55 vol.%. Further testing needed to cover up to 100 vol.% for extended periods
Pressure	Up to 250 kPag	Partial Pass	Transmitter passed transient pressure tests. Further tests needed to qualify transmitter under static pressure conditions
Radiation (total integrated dose)	20 Mrad	Fail	Modifications needed to transmitter to protect electronics from radiation or modify electronics
Energy	Capable of operating for extended periods	Not Tested	Modifications to firmware & analysis needed to ensure the transmitter can operate long term without replacing or additional batteries
Lifetime	≥ 2 years	Not Tested	
Accuracy	± 0.5%	Not Tested	
Response time	≤ 2 s	Fail	The PAR as H_2 sensor response time range from 1 - 2 min

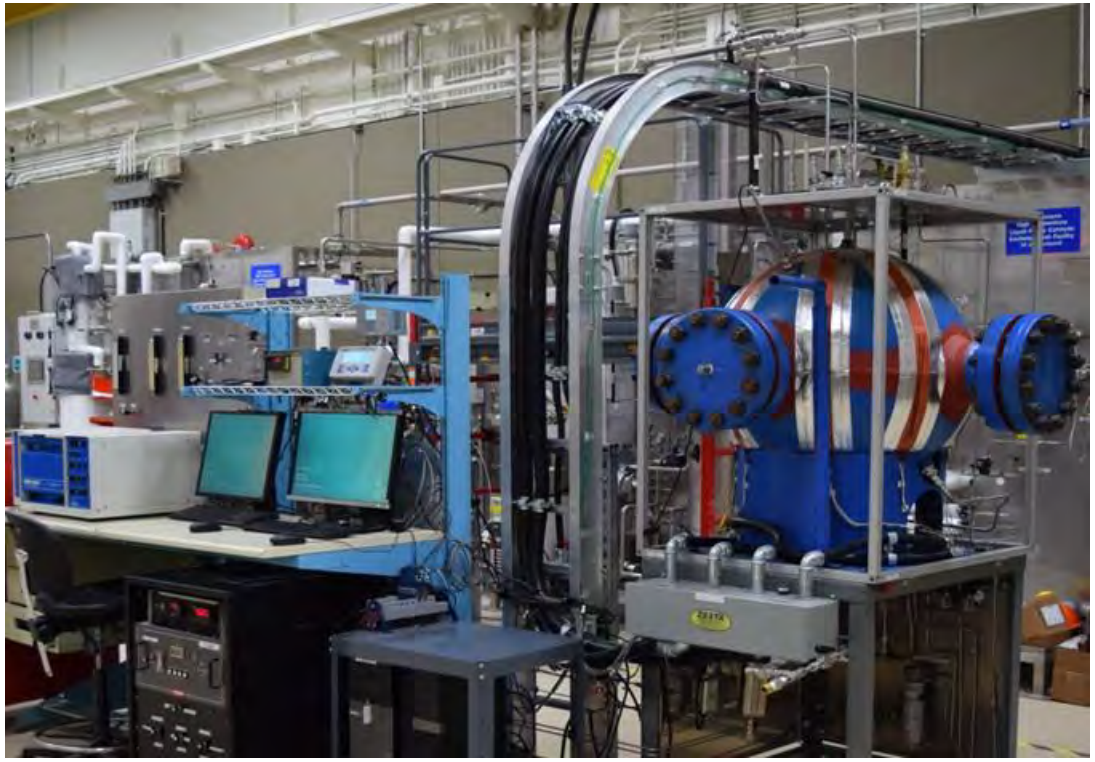
Advanced Testing

High Ambient Temperature

- Wireless transmitter installed in ventilated oven
- Exposed to 100 °C for 65.5 h
- No physical or functional degradation found

Transient Temperature & Pressure

- Wireless transmitter connected to thermocouples attached to recombiner catalyst in HSTF
- H_2 combustion test performed in HSTF
- Overpressure >100 kPa
- Max. temperature > 300 °C
- No physical damage or noticeable effects to transmitter

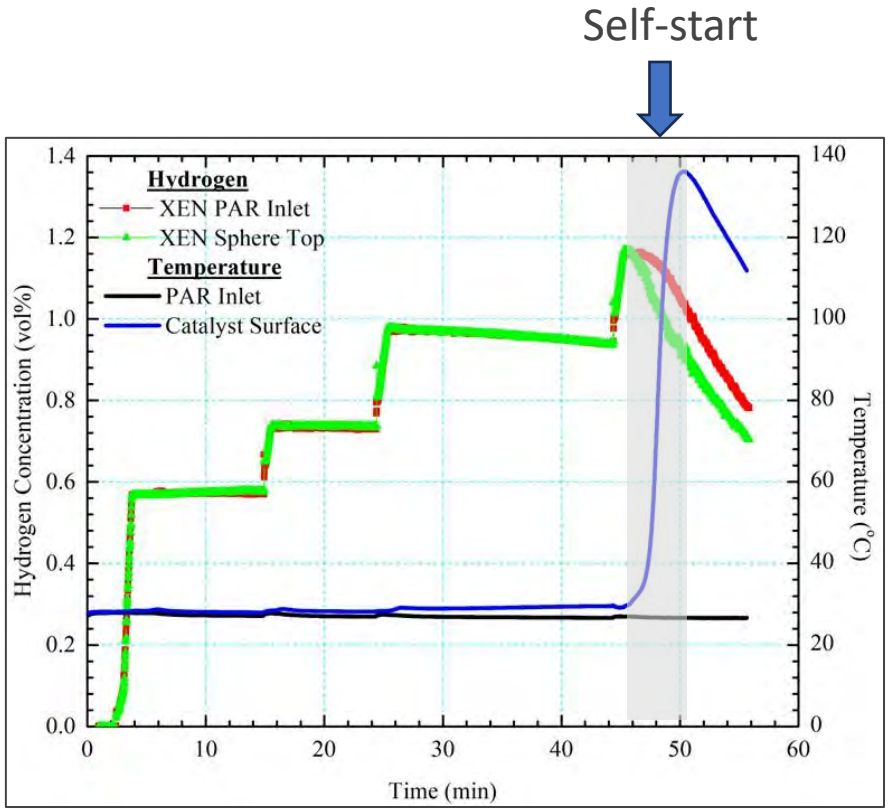


Hydrogen Safety Test Facility (HSTF)

Advanced Testing

Steam Exposure

- Wireless transmitter connected to thermocouples attached to recombiner catalyst in the HSTF
- Multiple tests performed in HSTF. Each with multiple H_2 injections to increase steam concentration
- Wireless transmitter exposed to 55 vol% steam
- High temperature caused issues with battery connections
  - Modifications made to battery housing



Response Time

- Time for PAR to respond to local H_2 conc. after start-up
- Does not include PAR start-up time
  - many factors impact start up (containment conditions, etc.)
- 10 °C catalyst temperature rise in 1.5 min (in example)
- Data from large-scale tests reviewed: response time is 1 – 2 min

Advanced Testing

Radiation Dose

- Wireless transmitter exposed to gamma radiation
- Three exposure attempts made. All found that transmitter had failed due to semiconductor failure.
- Exposure periods were 20.0, 287.3 and 24.2 h
- Minimum dose = 0.58 Mrad

CNL's Gamma cell Facility

Oxygen Concentration

- Historical work[1] reviewed to assess minimum O_2 concentration
- PAR requires O_2 to operate
- PAR operates with as low as 0.1 vol% O_2
  - Temperature correlation needs to adapt for O_2 limiting conditions

[1] L. Gardner, B. Ibeh, J. Murphy, M. Thomas, S. Cotosman, "PAR performance under oxygen-limited conditions," *The 19th International Topical Meeting on Nuclear Reactor Thermal Hydraulics (NURETH-19)*, Brussels, Belgium, March 6-11, 2022.

Summary & Future Work

- PAR as a H_2 sensor has potential for H_2 detection and measurement in containment for SAs
- Potential for low cost and simplified adoption
- Further work is needed on wireless transmission in containment
  - Prevent radiation from failing semiconductors
  - Improve power consumption
- Further work on correlation behaviour in oxygen limiting conditions and extend steam and pressure exposure limits
- Demonstration/evaluation in NPP containment?

FISSION PRODUCT BEHAVIOR AND SOURCE TERM IMPACTS IN EX-VESSEL PHASE USING THAI TEST DATA: THE OECD/NEA THEMIS PROJECT

ABSTRACT

Gaseous iodine released into the containment during hypothetical severe accidents in light water reactors could be oxidized by air radiolysis products, forming gaseous iodine oxides (IO_x). Such aerosols are considered source-term relevant because these very fine particles can remain airborne long-term or can be easily resuspended from structures. The OECD/NEA THEMIS project aimed to investigate phenomena where the knowledge base for safety assessment has not been sufficiently developed and to provide data for code-model validation of lumped parameter and computational fluid dynamics codes for reactor applications. The test Iod-36 aimed to quantify the adsorption and agglomeration of IO_x onto nuclear background aerosols. Silver was used as the mid and long-term phase accident aerosol. The test Iod-37 focused on the thermal stability of gas-borne IO_x and the potential conversion of IO_x to I_2 under accident typical temperatures, ranging from 80 °C up to 140 °C. Both tests were executed in the technical-scale THAI$^+$ test facility with an initial temperature of 80 °C and a relative humidity of 50 %. Ozone was used to promote the formation of IO_x inside the vessel and the molecular iodine was injected once the preconditioning phase was completed. Several instruments were installed to monitor iodine gas concentration, ozone concentration, iodine surface depletion and thermohydraulic parameters such as pressure, humidity and temperature. The agglomeration of IO_x with background reactive silver aerosols (Iod-36) led to the removal of iodine from the vessel atmosphere correlated with the settling process of the larger silver particles. The results of Iod-37 showed that for an increasing temperature, the formation of gaseous iodine could be observed.

KEYWORDS
THAI, severe accident, fission products, source term, iodine oxides

1. INTRODUCTION

Gaseous molecular iodine (I_2) released into the containment during hypothetical severe accidents in light water reactors (LWRs) could be oxidized by air radiolysis products, forming gaseous iodine oxides (IO_x) [1]. IO_x can form aerosols which can behave differently from I_2. The conversion from gaseous I_2 into IO_x by air radiolysis products was measured in lab-scale investigations, e.g. [1], [2], [3], [4] and in technical scale tests using the THAI$^+$ test facility, e.g. Iod-13 and Iod-14, [5], [6]. IO_x aerosols are considered source-term relevant because these fine particles can remain airborne long-term or can easily be resuspended from

structures [7]. Furthermore, IO_x compounds can thermally decompose at high gas temperatures. Additionally, factors such as humidity and temperature have been the focus of recent investigations to study the formation and stability of different IO_x compounds and aerosol species [8], [9] [10].

The OECD/NEA THEMIS project aimed to investigate phenomena where the knowledge base for safety assessment has not been sufficiently developed and to provide data for code-model validation of Lumped Parameter (LP) and Computational Fluid Dynamics (CFD) codes for reactor applications. The investigations focused on processes and phenomena occurring in the late phase of severe accidents. Specifically, source-term-related issues such as the depletion or further chemical reactions of IO_x particles with nuclear background aerosols (test Iod-36) and the thermal stability of IO_x at high temperatures (test Iod-37) were investigated [11].

Test Iod-36 aimed to investigate the adsorption and agglomeration of IO_x onto nuclear background aerosols, which are considered to be chemically reactive with respect to iodine. Some candidates for aerosols that are known to be representative for the mid and long-term phase of an accident were Ag, CsI and CsOH, from which silver (Ag) was chosen for this test due to the potential advantages for the measurement system and quality of the experimental data in the $THAI^+$ test facility. The investigation included the adsorption of IO_x particles onto the Ag aerosol and their impact on depletion mechanisms, such as aerosol deposition onto horizontal and vertical vessel surfaces. The thermo-hydraulic conditions were set to be representative of prototypical accident conditions in terms of gas atmosphere (air-steam mixture) and aerosol characteristics (size distribution and mass concentration) [7]. Test Iod-37 focused on the thermal stability of gas-borne IO_x and the potential conversion of IO_x to I_2 under accident-typical gas temperatures, ranging from 80 °C up to 140 °C [12].

Both tests were performed at approximately 50 % relative humidity, which is high enough to ensure representativeness of severe accident conditions and low enough prevent possible deliquescence of IO_x in the investigated temperature range of test Iod-37 [13]. The thermal stability of the formed IO_x was investigated by measuring IO_x as aerosol and inorganic iodine as gaseous species.

2. FACILITY DESCRIPTION

The technical-scale $THAI^+$ test facility consists of the THAI test vessel (TTV) and the Parallel Attachable Drum (PAD) as shown in Figure 1. The PAD vessel is connected to the TTV through a lower and upper pipe that can be removed for different configurations. For the execution of the tests Iod-36 and Iod-37, the TTV was used in a standalone configuration. For this purpose, the TTV was closed and the inner cylinder was removed. The dimensions of the TTV are 3.15 m in diameter and 9.3 m in height, leading to an inner volume of 60 m^3. The TTV is made of stainless steel and it is completely covered by 120 mm mineral wool for thermal insulation. The cylindrical part of the TTV is double walled with a 16.5 mm gap that is filled with thermal oil for wall heating and/or cooling. The remaining vessel wall sections can be electrically heated to achieve the desired temperature. The maximum admissible overpressure of the TTV is 14 bar at a corresponding temperature of 180 °C.

The facility is equipped with the necessary supply systems for steam, compressed air, nitrogen, oxygen, light gas (helium), combustible gases (hydrogen and carbon monoxide), aerosols and gaseous iodine. An advanced instrumentation and data acquisition system is installed to monitor the relevant physical quantities with high spatial and temporal resolution.

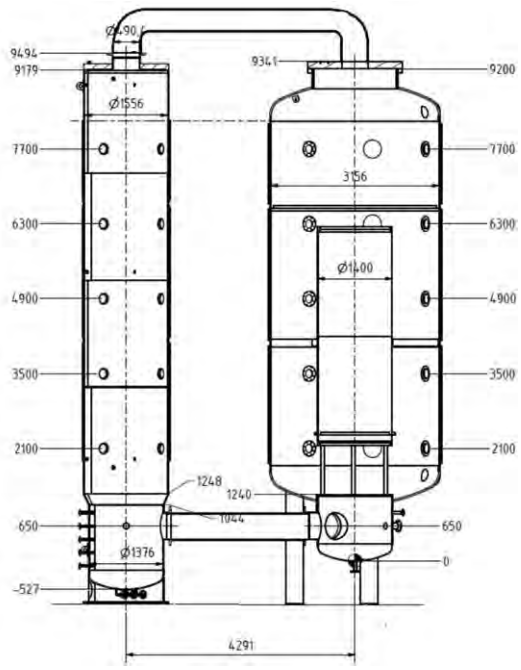

Figure 1: THAI$^+$ configuration and dimensions (mm) of the THAI$^+$ test facility.

1. EXPERIMENTAL METHODOLOGY

The experimental configuration of the TTV, i.e. injection locations and sensor positions, was similar for both tests Iod-36 and Iod-37. However, the main difference between both tests was the absence of the fluidized bed Ag aerosol injection in test Iod-37 (see Figure 2). The specified initial conditions of both tests are given in Table 1.

Table 1: Specified initial tests conditions

Test ID	Initial conditions	Iodine and Ozone injection	Ag-Aerosol concentration
Iod-36	1.5 bar, ~ 80 °C superheated, r.H. 50 %, 0.24 bar steam partial pressure	< 1 g I_2 O_3/I_2 molar ratio: 20… 30	> 1 g/m^3
Iod-37	1.5 bar, ~ 80 °C superheated, r.H. 50%, 0.24 bar steam partial pressure	< 1 g I_2 O_3/I_2 molar ratio: 20… 30	None

1.1. IO_x behavior and the interaction with nuclear background aerosol (Iod-36)

The test procedure for the test Iod-36 consisted of a preconditioning phase followed by the main test phases as listed below:

- Preconditioning phase to establish initial conditions within the TTV, including heating of the vessel and steam injection to generate a relative humidity of approx. 50 %
- Ozone injection to establish a dedicated ozone concentration in the vessel
- I_2 gas injection following the THAI standard procedure

- IO_x formation and measurement
- Background Ag aerosol injection and measurement of IO_x-Ag-aerosol coagulation and depletion

The heating of the vessel was controlled by the oil flow in the vessel mantles and the electrical heating circuits. The ozone was generated by an ozoniser OT-020 from Lenntech with a nominal flow rate between 8 to 10 g/h. I_2 was injected using pre-heated nitrogen as carrier gas at an elevation of H = 8.4 m. The injected gaseous molecular iodine was radiolabeled with I-123. Ag aerosol particles were injected through a 9 mm inner diameter pipe near the centerline at an elevation of H = 1.9 m (only test Iod-36). Steam was injected with an upwards directed injection tube at an elevation of H = 1.13 m at the vessel centerline, provided by an electrical 108 kW steam generator. Air was injected in horizontal direction towards the vessel center at an elevation of H = 3.5 m and it was provided by the THAI$^+$ test facility compressed air supply system (dehumidified and free of oil).

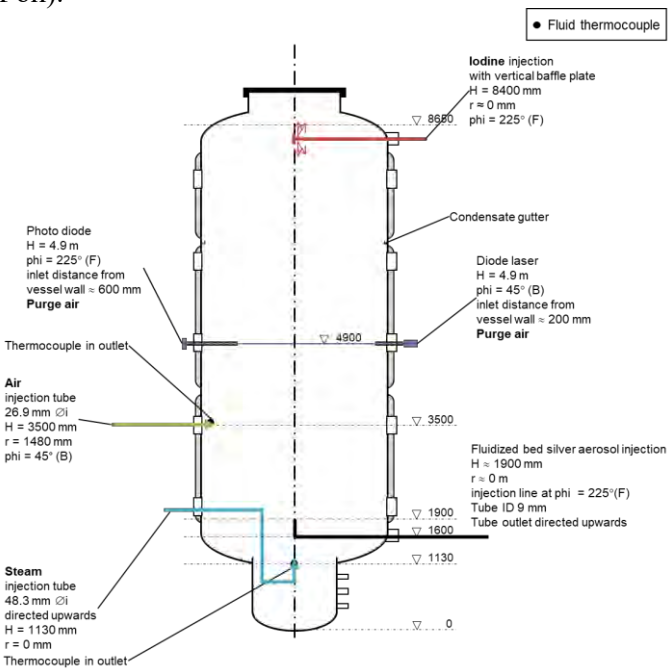

Figure 2: Test configuration – Iodine, Ag aerosol, air and steam injection; laser absorption system (test Iod-36).

The sampling and measurement system consisted of the following equipment:

- 6 gas scrubbers were used to measure iodine concentrations in the gas phase (see positions in Figure 3). The absorber liquid of the gas scrubbers was an aqueous solution of 0.1 mol/L sodium hydroxide and 0.5 wt% sodium thiosulfate (pH = 13). Sampling times were between 2 and 5 minutes at flow rates of 1 l/min inside the vessel, driven by the pressure difference between vessel and environment.
- 2 external gas scrubbers were used to measure the ozone concentration with a phosphate buffered KI solution as solvent.
- 2 Maypack filtering stations were used to measure iodine concentrations in the gas phase.
- 2 Bulk filters were used to measure aerosol mass concentration. Each filter was equipped with 47 mm borosilicate glass microfibers and one cascade impactor station to separate 10 particle size classes.

- 1 laser light extinction measurement (photo diode) was used to provide a continuous, in-line and non-intrusive measurement of the aerosol concentration.
- Aerosol measurements were conducted using a scanning mobility particle sizer (SMPS) from GRIMM Aerosol Technik (model SMPS+C 5416 with L-DMA) which is comprised of a differential mobility analyzer (DMA) and a condensation particle counter (CPC).
- An additional ozone and iodine measurement was performed by wide spectral light absorption spectroscopy (LASI-SPEC).
- 2 lead-shielded NaI scintillation detectors were used to monitor the I-123 radiation inside the vessel.
- Several thermal hydraulic instruments to record humidity, pressure, fluid and surface temperature.

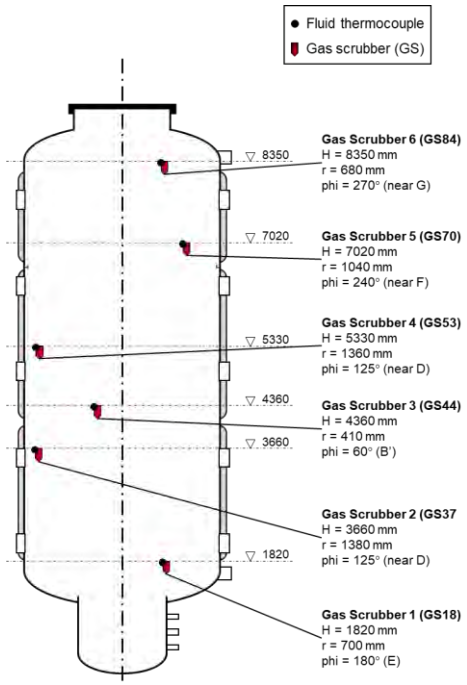

Figure 3: Test configuration – Positions of the gas scrubbers (tests Iod-36 and Iod-37).

1.2. IO_x stability under high temperature (Iod-37)

The test configuration and instrumentation used in test Iod-37 were the same as in test Iod-36, except for test Iod-37 not having an Ag injection phase. However, the positions of the injections shown in Figure 2 and the positions of the gas scrubbers in Figure 3 remained the same.

The test procedure for the test Iod-37 was conducted as follows:

- Preconditioning phase to establish initial conditions within the TTV, including heating of the vessel and steam injection to generate a relative humidity of approx. 50 %
- Ozone injection to establish a dedicated ozone concentration in the vessel
- Short I_2 gas injection following the THAI standard procedure
- IO_x formation and measurement
- Long term heating of the facility at full power up to 140 °C and steam injection to maintain 50 % r.H., 1.8 bar steam partial pressure

2. RESULTS AND DISCUSSION

2.1. IO_x behavior and the interaction with nuclear background aerosol (Iod-36)

The average gas temperature in the TTV was approx. 80 °C before the first steam injection. The relative humidity measured was about 50 % on average, showing sufficient homogeneity within the plenum of the vessel. The injection of ozone did not significantly change the vessel pressure and temperature due to the low amount. The injection of I_2 together with the nitrogen carrier gas slightly increased the pressure. However, it did not influence the gas temperature which stayed constant at around 80 °C. The Ag aerosol injection slightly increased the pressure due to the air carrier gas. After this step, the pressure remained quasi constant and it only changed slowly due to the gas sampling measurements (i.e. CNC, sampling filter, impactor, Maypack and gas scrubber measurement) and by the dry purging air used to prevent particle deposition at the optical extinction probe.

The gas phase iodine concentration measured with the gas scrubbers is shown in Figure 4. Following the injection of I_2, the first gas scrubber measurements show comparatively low but increasing iodine concentrations. This phenomenon has also been observed in previous tests including iodine and ozone like Iod-14 or Iod-37. One possible explanation for this phenomenon is insufficient retention of the formed iodine oxides by the absorber solution ($Na_2S_2O_2$/NaOH). It is most likely that the oxidation process of iodine, the formation of water-soluble species, such as HIO_3, I_2O_4, I_2O_5 or I_4O_9 and their coagulation, had not yet been completed shortly after the I_2 injection. It is also possible that non-dissolvable intermediate IO_x species, such as IO or IO_2, had formed. Following the start of the Ag injection, the total iodine concentration measured with the gas scrubbers shows a steady, nearly exponential decrease. This effect was more pronounced at lower measurement positions, as the aerosol particles settled under the influence of gravity. However, a comparative analysis of earlier tests (e.g. test Iod-26 from the OECD/NEA THAI-2 project) showed that Ag aerosols are highly effective at removing iodine oxides and gaseous iodine, which is most likely caused by agglomeration and sedimentation [14]. The test confirmed that reactive background aerosols can play a significant role in reducing airborne iodine in accident scenarios.

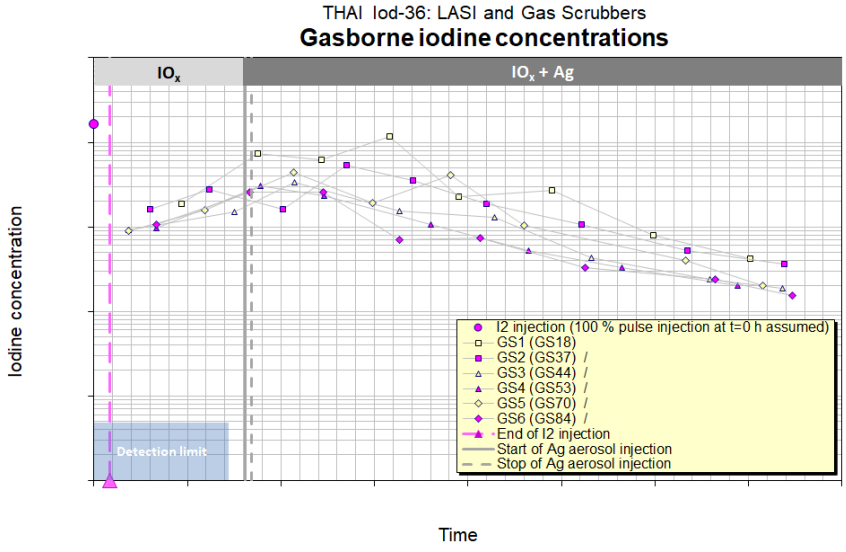

Figure 4: Iod-36: Gasborne iodine concentrations from gas scrubbers.

The surface loading of iodine on the steel coupon was obtained from the conversion of the corrected count rate measured by the online detector OS21D (see Figure 5). The measured raw value was corrected by the contribution of iodine in the gas phase between the glass and the steel coupon, based on total iodine measured by the Maypacks. The measurement curve in Figure 5 shows that some iodine was deposited on the vertical steel coupon in the first phase of the test, a process that was then enhanced by the injection of the Ag aerosol.

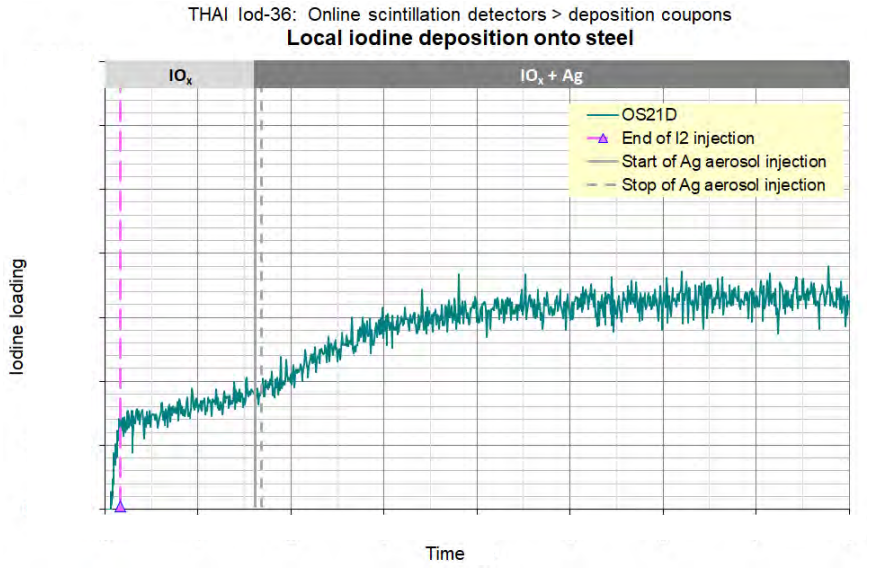

Figure 5: Iod-36: Local iodine loadings on steel deposition coupon (linear scale).

2.2. IO_x stability under high temperature (Iod-37)

The test Iod-37 examined the thermal stability of IO_x formed by the reaction of I_2 and ozone in a humid atmosphere. The average gas temperature in the TTV was about 80 °C prior to the first steam injection. The pressure increased after the first steam injection. The relative humidity was mostly about 50%, indicating that the plenum region was sufficiently well mixed. The injection of ozone did not have an significant impact on the vessel pressure or temperature, but the injection of iodine, the following steam injection and the gas heating increased the pressure. Approximately 1 hour after the start of the I_2 injection, the vessel heated up at an almost linear rate until reaching a gas temperature of up to 140 °C. As the vessel gas temperature increased, the particle number concentration decreased, most likely due to agglomeration. At the end of the test, the vessel pressure decreased due to gas temperature reduction and gas sampling procedures.

The gasborne iodine concentrations measured using the gas scrubbers are shown in Figure 6. Similarly to former iodine/ozone tests as well as the measurement results in test Iod-36, the iodine concentrations initially increased slowly, most likely attributed to the limited scrubbing efficiency caused by the small particle size of the newly formed IO_x. Over time, the IO_x particles agglomerated and the scrubbing efficiency improved, resulting in a more effective retention. The ozone concentrations, which were monitored using both LASI and external gas scrubbers, decreased at a nearly linear rate with the iodine injection, proving that the molecular I_2 was oxidized. Approximately 1 to 1.5 hours after the I_2 injection, the concentrations stabilized at a comparatively low level which persisted throughout the temperature increase from 80 °C to 140 °C.

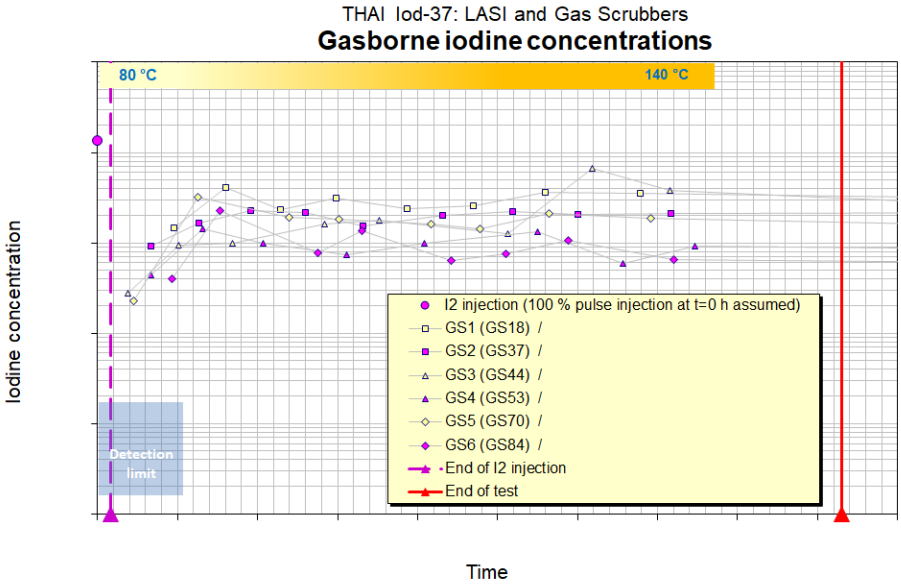

Figure 6: Iod-37: Gas-borne iodine concentrations from gas scrubbers.

Maypack filter measurements indicated that most of the iodine was present in the form of an aerosol, which is consistent with the measurement results for rapid formation of IO_x. Aerosol concentrations declined only slightly during the first 1 to 1.5 hours. As the temperature increased, the concentration of inorganic gaseous iodine began to rise, most probably due to the thermal decomposition of IO_x (see Figure 7). This decomposition process seemed to dominate the competing I_2/steel surface reactions, confirming that elevated temperatures promote the conversion of aerosol-bound IO_x into gaseous iodine species under the tested conditions. These findings emphasize the thermal instability of IO_x and its potential remobilization at high temperatures, which is an important consideration for source term assessments in late-phase severe accidents.

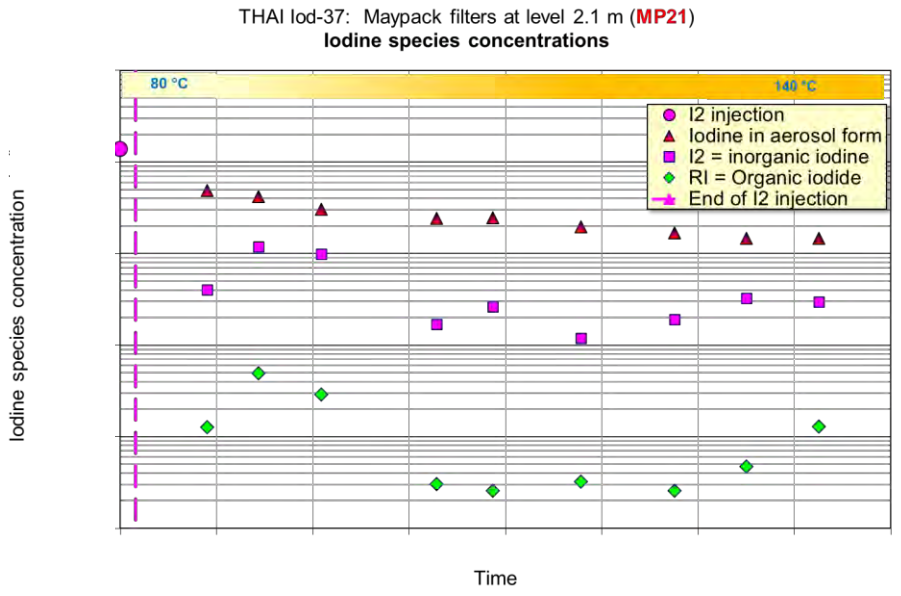

Figure 7: Iod-37: Iodine species concentrations from Maypack filters.

3. SUMMARY AND CONCLUSIONS

This paper reports the results of the THAI test Iod-36 and test Iod-37 performed in the frame of the OECD/NEA THEMIS project by Becker Technologies and with the support of Framatome on the iodine specific measurements. On one hand, the objective of test Iod-36 was to study the formation of IO_x particles and their interaction and adsorption onto containment typical nuclear background aerosols, considered to be chemically reactive with iodine. Therefore, Ag was chosen as representative background aerosol. On the other hand, the objective of test Iod-37 was to study the formation and long-term thermal stability of IO_x particles at elevated gas temperatures ranging from 80 to 140°C.

The initial conditions and preconditioning phases of both tests were set to be similar. The initial gas temperature and relative humidity established in test Iod-36 and test Iod-37, prior to the ozone and I_2 injection phases, were approximately 80 °C and 50 %. In both tests, the IO_x particle formation was initiated by a short injection of gaseous I_2 into an ozone containing atmosphere. After these test phases, test transients and the corresponding results of the tests differ from each other. In the case of test Iod-36, Ag was injected into the vessel at a constant temperature, while in test Iod-37 the vessel was heated up to a maximum temperature of up to 140°C without Ag being present. In test Iod-36, the formation and particle agglomeration of IO_x was measured before the injection of Ag aerosol, whereas in test Iod-37, the formation and particle agglomeration of IO_x was measured before the heating phase.

Gas scrubbers and Maypack filters were the main instrumentations to monitor the gasborne iodine concentration, while scintillation detectors were used to measure the iodine deposition at the steel coupons. Several thermohydraulic sensors were used to monitor the pressure, temperature and humidity. The ozone over I_2 ratio in both tests was set to be larger than 10. Measurements of total atmospheric iodine concentrations and iodine loadings on stainless steel were provided for both tests.

In test Iod-36, the gas scrubbers showed that the iodine concentration decreased steadily and nearly exponentially until the end of the test with the addition of Ag aerosols in the vessel atmosphere. This trend was also observed in prior tests performed at the THAI$^+$ test facility, which demonstrates that the removal rate of IO_x from the containment atmosphere is governed by the settling of the Ag aerosol particles. The activity measurements indicated that the activity went from IO_x particles to the depleted particles with the Ag injection. This confirms that reactive background aerosols can play a critical role in reducing airborne iodine in severe accident scenarios. This does not necessarily mean that IO_x aerosols have chemically reacted with Ag aerosol, because the settling mechanism might be accompanied by a coagulative or adsorptive mechanism. The Ag aerosol concentration was monitored by laser extinction and at the end of the test more than 90 % of the initial airborne Ag was depleted.

In test Iod-37, upon injection, iodine rapidly formed IO_x particles, with particle concentrations increasing sharply before gradually declining, primarily due to agglomeration. Measurements of atmospheric iodine species, total atmospheric iodine concentrations and iodine loadings on stainless steel consistently indicate that iodine was quickly converted into stable, aerosol-bound IO_x particles shortly after injection. The total concentration of airborne iodine persisted in the atmosphere over extended periods, maintaining a relatively constant level even during heating. However, the analysis of the Maypack filter measurements showed that fraction of iodine aerosol decreased slowly, while the fraction of inorganic iodine species increased at elevated temperatures. This shift is attributed mainly to the thermal decomposition of IO_x, which becomes more significant than competing surface reactions that remove gaseous iodine.

ABSTRACT

The installation of passive autocatalytic recombiners (PARs) for hydrogen risk mitigation inside the containment is a world-wide standard for light-water reactors. Numerical PAR models enable the simulation of PAR operation under severe accident conditions. In combination with containment simulation codes, they are a valuable tool for demonstrating the efficient reduction of combustible gas accumulations and for evaluating mitigation strategies.
A comprehensive experimental program conducted within the OECD/NEA projects THAI and THEMIS provided extensive test data on PAR performance that model developers use to demonstrate the performance of their codes. However, due to the transient character of these tests, analyses have often been limited to selected tests, while a comprehensive review of the entire validation results has been difficult to achieve.
As part of the European AMHYCO project, a database of quasi-steady state measurement points was derived from these transient experiments. This new database enables the performance of PAR models to be validated for the boundary conditions of the entire test program. Furthermore, a critical analysis of measured and derived data was performed, enabling an assessment of uncertainties.
The new database was used to assess the validity of numerical PAR models used in AMHYCO analyses. First, the mechanistic code REKO-DIREKT was validated. Then, the performance of an engineering correlation for Framatome PARs under late-phase conditions was evaluated, before model improvements were implemented and confirmed.

KEYWORDS
Hydrogen mitigation, Passive autocatalytic recombiners (PAR), model validation, validation database

1. INTRODUCTION

In the context of protecting nuclear power plants from the consequences of accident-related massive hydrogen and carbon monoxide releases, the European AMHYCO project (2020-2025) focused particularly on the late phase of severe accidents in light water reactors (LWR). Here, the molten corium-concrete interaction (MCCI) can be a source of significant amounts of gaseous products, of which carbon monoxide

* Corresponding author

is of particular interest, being another combustible gas like hydrogen [1]. Consequently, the project addressed open issues related to the understanding of the impact of carbon monoxide on both hydrogen combustion phenomena and hydrogen mitigation by PARs under the conditions of the late accident phase.

The installation of 40-60 passive autocatalytic recombiners (PARs) inside the containment has become a key element in the hydrogen mitigation strategy of most western LWRs. Consequently, in AMHYCO specific attention was focused on understanding the performance of PARs under the challenging conditions of ex-vessel conditions. These conditions include specifically oxygen-lean conditions and involve the presence of carbon monoxide. For these conditions, only sparse knowledge was publicly available. Hence, the overall target was to advance the predictive capabilities of numerical PAR models, which were used in scenario analyses, to obtain a realistic picture of the PAR behaviour.

The further advancement of numerical PAR models was supported by an experimental program performed in the REKO facilities at Forschungszentrum Jülich [2]. Besides this AMHYCO-internal experimental campaign, the project made also use of data from the international OECD/NEA THAI projects. For this purpose, a specific database was extracted from selected THAI experiments that provided an additional validation step for the advanced PAR models towards the ultimate goal of the modelling activities in AMHYCO.

2. DATABASE GENERATION

The following section outlines the requirements for test data for PAR modelling (see also Figure 1, right) and describes the composition of the AMHYCO THAI database. The PAR models used within the project were the Framatome engineering correlation [3], the mechanistic models REKO-DIREKT (Forschungszentrum Jülich, Germany) [4] and PARUPM (Universidad Politécnica de Madrid, Spain) [5], and the CFD model SPARK developed by IRSN, France [6] (Figure 1, left).

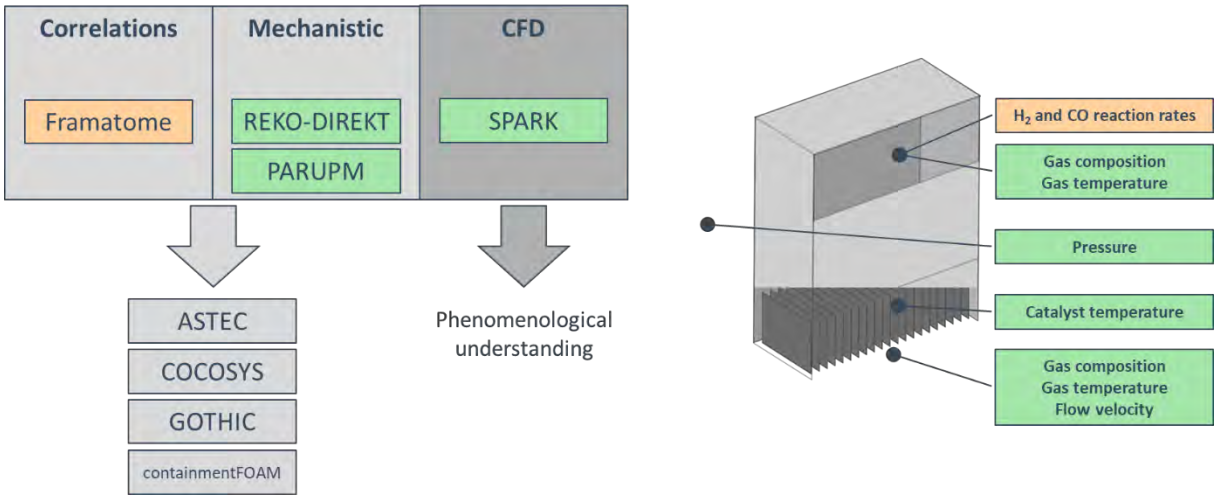

Figure 1. PAR models used in AMHYCO (left), data required for PAR model validation (right).

2.1. Requirements for a PAR Database

The minimum goal of the most fundamental PAR models is to predict the recombination rate of hydrogen based on the conditions of the atmosphere in the vicinity of the respective PAR. These conditions are typically

- pressure,
- gas temperature,
- and the composition of the gas mixture.

In severe accident scenario simulations, this information is available regardless of whether lumped parameter or CFD tools are used. Engineering correlations have become most widely established, e.g. for PARs by Framatome, CNL, or NIS [3]. These are relatively easy to implement due to their mathematical simplicity and require only minimal computing time. More complex PAR models provide further information beyond the recombination rate, such as

- catalyst temperature,
- outlet gas temperature,
- outlet gas composition,
- and the gas flow velocity,

at the price of increasing complexity and computational cost.

Within the scope of the AMHYCO project, another important step in model development was the consideration of the conversion of carbon monoxide to carbon dioxide inside PARs, which occurs specifically in the late accident phase. The corresponding conversion rates are also required for model validation. However, since the test data from the corresponding OECD/NEA projects for carbon monoxide are not yet publicly available, they cannot be presented here.

2.2. The AMHYCO THAI Database

The THAI facility operated by Becker Technologies in Eschborn/Germany is the centrepiece of several ambitious experimental programs conducted under the auspices of the OECD/NEA [7]. The experiments address various accident phenomena inside LWR containments and cover a wide range of thermophysical boundary conditions. Of specific interest for the AMHYCO project were experiments on the operational behaviour of Framatome PARs. A total of around 50 experiments were conducted with this PAR type. Framatome PARs thus represent the devices with the largest available independent database worldwide.

The PAR experiments were performed with a single PAR inside the THAI vessel with a volume of approx. 60 m^3. The experiments are of transient nature, which means that the boundary conditions of PAR operation are continuously changing. When hydrogen is fed into the vessel and the PAR starts operation, there is a continuous change of the hydrogen concentration – increasing during the injection phase, decreasing during the depletion phase. Additionally, due to the energy release, gas temperature inside the vessel atmosphere increases continuously. In the past, the validation of PAR models against these transient data has always been performed using single selected experiments. By this approach, the general view at strengths and weaknesses of models was lost.

In AMHYCO, the generation of a database of quasi-steady state measurement points derived from the transient THAI experiments aimed at providing a validation database, which allows to gain an overview of the PAR model performance for the entire experimental program rather than only comparing single transient experiments with model calculations. The database is suited for testing both, correlation model and detailed PAR models.

Figure 2 shows the progression of the hydrogen concentration at the PAR inlet over time of a typical THAI HR test sequence (here: HR-3). After reaching the initial atmosphere conditions (pressure, temperature, humidity, a prototypical test involves the following steps:

- hydrogen injection until reaching approx. 6 vol.% (1st injection phase)
- stop of injection and subsequent depletion of hydrogen by the PAR (1st depletion phase)
- hydrogen injection until ignition occurs (2nd injection phase)
- stop of injection and subsequent depletion of hydrogen by the PAR (2nd depletion phase)

Instead of evaluating the entire time evolution of the experiment, only some quasi-steady state measurement points were identified as indicated by the coloured circles in Figure 2. The measurement values were averaged for 60 s around these selected measurement points.

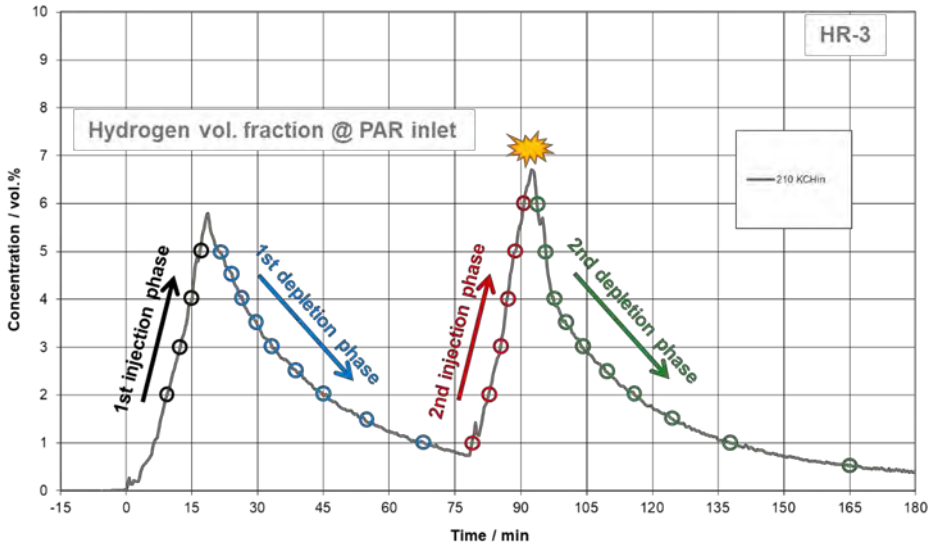

Figure 2. Progression of the hydrogen concentration in a typical PAR test sequence.

Figure 3 and Figure 4 show the obtained averaged flow velocity through the PAR and the hydrogen outlet concentration over the inlet hydrogen concentration for all four experimental phases. During both injection phases (black and red circles) as well as during the first measurement points of the first depletion phase (blue circles for concentrations above 3 vol.%) the PAR performance is not yet well developed. It takes until the second depletion phase until the PAR is in quasi-steady state operation. Based on this observation, the database considers only data from the second depletion phase (green circles).

The following data values were taken from the second depletion phases to serve as PAR model input conditions, see Figure 1 (right):

- Total pressure in bar
- Gas temperature in °C at the PAR inlet

  As the temperature measurement at the PAR inlet is significantly influenced by the heat radiation from the hot catalyst sheets [8], the value from a different thermocouple has been selected (HR-1 - HR-28: 067 BTF21H12; HR-51ff: 118 BTF13B07). These thermocouples are mounted at a similar elevation inside the THAI vessel as the PAR, but being located on the opposite side of the inner cylinder they are well shielded against heat radiation.

- Gas composition (hydrogen, oxygen, steam, later carbon monoxide and carbon dioxide) in vol.% at the PAR inlet

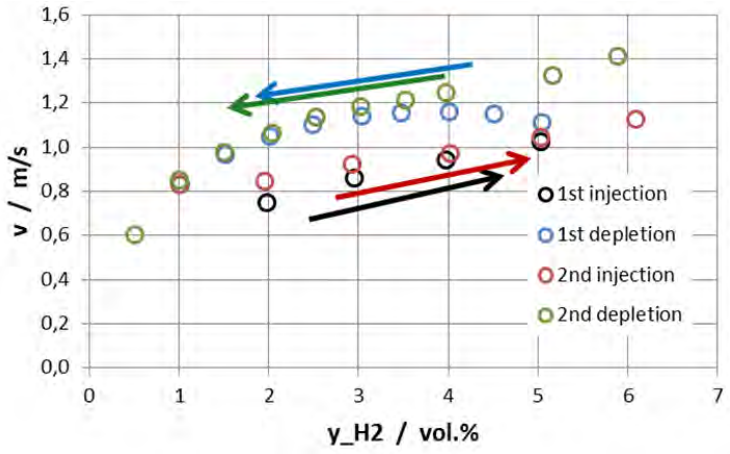

Figure 3. Experimental phases and selected measurement points for the flow velocity.

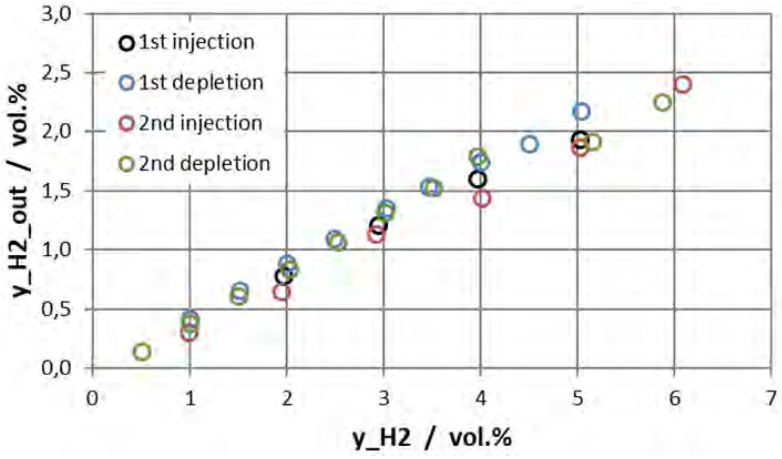

Figure 4. Experimental phases and selected measurement points for the outlet hydrogen concentration.

The following data values were derived to be used for the PAR models to validate the calculation results (PAR model output), see Figure 1 (right):

- Gas temperature in °C at the PAR outlet

  The outlet temperature is measured at three different positions in THAI. As PAR models don't consider the temperature distribution in the PAR outlet cross section, the average value has been calculated.
- Gas composition (hydrogen, oxygen, steam, in later tests carbon monoxide and carbon dioxide) in vol.% at the PAR outlet

  Like for the gas temperature, the outlet gas concentrations are measured at three different positions in THAI. Again, PAR models require averaged values for the PAR outlet. Due to the

unclear measurement signal of one of the three measurement positions (in [8] it is suggested, that buoyant backflow occurs at the measurement gas probe at the lower edge of the PAR outlet), the user selects between an average of either the two remaining sensor values or all three values. The discrepancy between both options provides a measure for the measurement uncertainty.

- Flow velocity in m/s
- Recombination rates (for hydrogen, later also for carbon monoxide) in g/s

  Two different equations are used to calculate the recombination rates. The official equation proposed in the THAI project is based on a hydrogen mass balance of the catalyst section and uses the measurement values of the hydrogen concentration at the PAR inlet and outlet ($y_{H2,in}$ and $y_{H2,out}$), pressure (p), flow velocity (v) and gas temperature at the PAR inlet (T_{in}) with the PAR inlet cross section (A_{in}), and the specific ideal gas constant for hydrogen (RH2):

  $$\dot{r}_{H2} = \left(y_{H2,in} - y_{H2,out}\right) \cdot (p \cdot v \cdot A_{in})/(R_{H2} \cdot T_{in}) \quad (1)$$

  This equation omits the reduction of the outlet molar flow. Hence, an alternative value for the recombination rate was added to the database, which is calculated according to a molar balance of the catalyst section:

  $$\dot{r}_{H2} = \left(y_{H2,in} - y_{H2,out}\right)/\left(1 - 0.5 \cdot y_{H2,out}\right) \cdot (p \cdot v \cdot A_{in})/(R_{H2} \cdot T_{in}) \quad (2)$$

  Furthermore, Equation 2 uses the cross section of the instrumentation inlet channel instead of the PAR inlet cross section. Due to the uncertainties with regard to inlet temperature and outlet gas composition (see above), each of both equations is calculated with different values: (i) official inlet temperature and average outlet concentrations of three values; (ii) alternate inlet temperature and average outlet concentrations of three values; (iii) alternate inlet temperature and average outlet concentrations of two values. The six different values for the recombination rate are used to obtain uncertainty bars for the recombination rates (see example in Figure 5).
- Catalyst temperatures in °C at three vertical positions of the catalyst sheet
  (low = 1 cm, mid = 7 cm, up = 13 cm)

  For measurements values from different catalyst sheets at identical positions, average values are provided. Similar as for the recombination rates, the measurement discrepancies are used to obtain uncertainty bars for the catalyst temperature values.

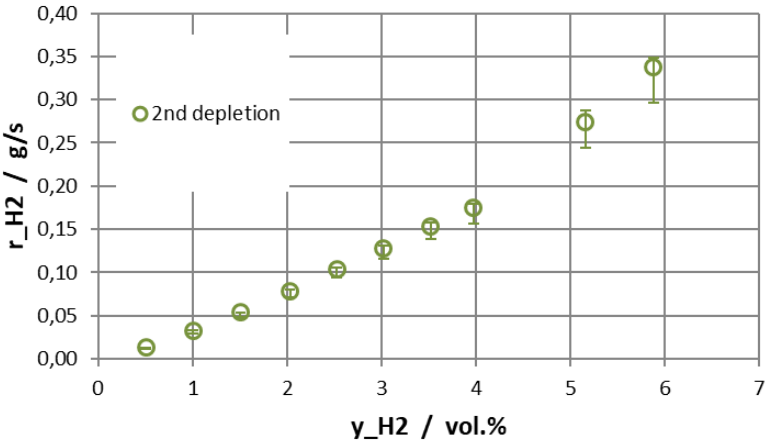

Figure 5. Example for recombination rates with uncertainty bars.

Table I gives an overview of selected tests from the THAI HR program for Framatome PARs that were selected to be included in the AMHYCO database due to their suitability to obtain quasi-steady state data.

The tests that were omitted had different objectives, some of which involved significant transients. The selected tests cover a comprehensive range of boundary conditions, with pressure between 1 bar and 3 bar, gas temperature between 25 °C and 117 °C, and up to 60 vol.% steam, and both oxygen-rich and oxygen-lean gas mixtures. Overall, the database consists of 132 quasi-steady state measurements.

Table I. HR tests selected for the AMHYCO database

Test number	Pressure	Temperature	Humidity
HR-1, HR-2	1.0 bar	25 °C	Dry
HR-13		86 °C	60 vol.% steam
HR-3, HR-28, HR-51	1.5 bar	25 °C	Dry
HR-7		74 °C	25 vol.% steam
HR-9		90 °C	47 vol.% steam
HR-11		97 °C	60 vol.% steam
HR-5	3.0 bar	25 °C	Dry
HR-12, HR-52, HR-53		117 °C	60 vol.% steam

3. MODEL VALIDATION

In the framework of the AMHYCO project, a total of four PAR models have been advanced according to the databases developed in the experimental program. The new AMHYCO THAI database was specifically used to further advance the Framatome engineering correlation and to validate the REKO-DIREKT code.

3.1. Advancement of the Engineering Correlation for Framatome PARs

Based on progress made within the AMHYCO project and its predecessor, the SAMHYCO-NET project [9], the engineering correlation for Framatome PARs was further developed. A detailed description of the new so-called AMHYCO correlation is given in reference [10]. One focus of the advancement was on the refinement of the recombination rate predictions for oxygen-lean conditions. The new THAI database proved to be a very useful basis for identifying model deficiencies as well as demonstrating the progress made.

Figure 6 (top) shows a plot of the hydrogen recombination rates obtained with the existing engineering correlation against the recombination rates obtained from the THAI database. The experiments performed under oxygen-rich conditions are marked with open symbols, while experiments performed under oxygen-lean conditions are represented by filled symbols. While the original correlation performs well under oxygen-rich conditions, a significant uncertainty (over- as well as underprediction) is visible for oxygen-lean conditions. This was a relevant point for the AMHYCO project as oxygen-lean conditions are expected to be present during almost the entire ex-vessel phase of the accident scenarios to be analysed.

The observed uncertainty was significantly reduced by the new AMHYCO correlation. The comparison of recombination rates with the AMHYCO THAI database (Figure 6, bottom) demonstrates the successful improvement of the correlation as well as the suitability of the new database to support targeted model advancement.

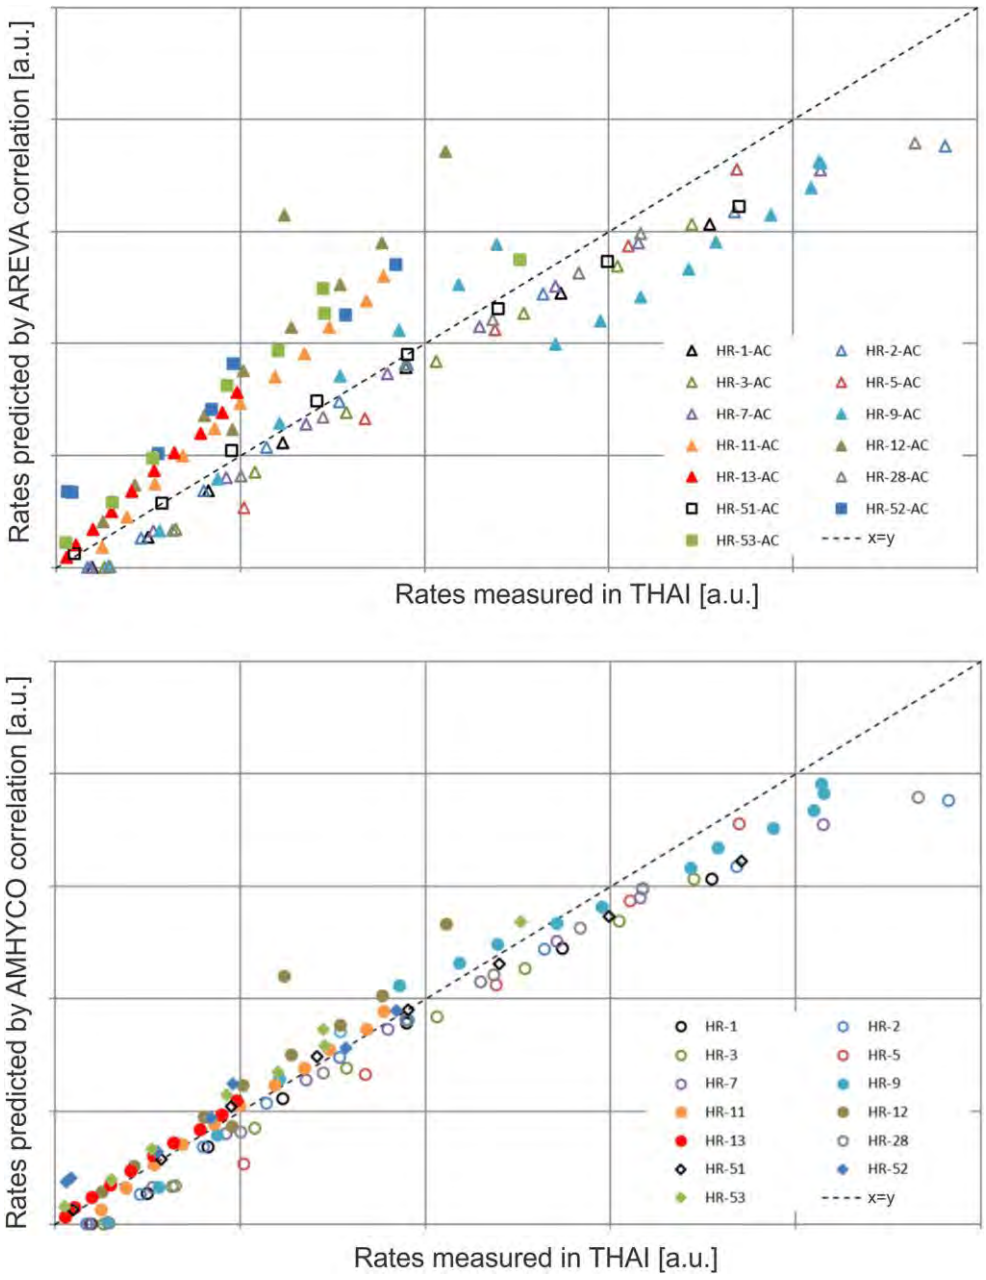

Figure 6. Comparison of calculated recombination rates with the AMHYCO THAI database (top: original correlation, bottom: new AMHYCO correlation) [10]

The rates for carbon monoxide recombination (not included here) show a comparable trend. The corresponding validation data, which involve new experiment from the OECD/NEA THEMIS project, cannot be shown in the present paper due to contractual reasons.

3.2. Validation of REKO-DIREKT

REKO-DIREKT is a mechanistic PAR model that provides several additional information on PAR performance data, such as the catalyst temperature distribution and an internal model to calculate the chimney flow velocity. It can be used for arbitrary PAR geometries. Having been developed with in-house single-effect experiments, the AMHYCO THAI database was used to validate the model.

Figure 7 shows the comparison of calculated hydrogen outlet concentrations with the values from the THAI database. The database allows for quantification of the agreement by calculating statistical deviations. In this example, the results confirm the overall good prediction of the hydrogen outlet concentration for the entire pressure range. Similarly, it is confirmed that the oxygen conditions (rich or lean) have no influence on the quality of the results.

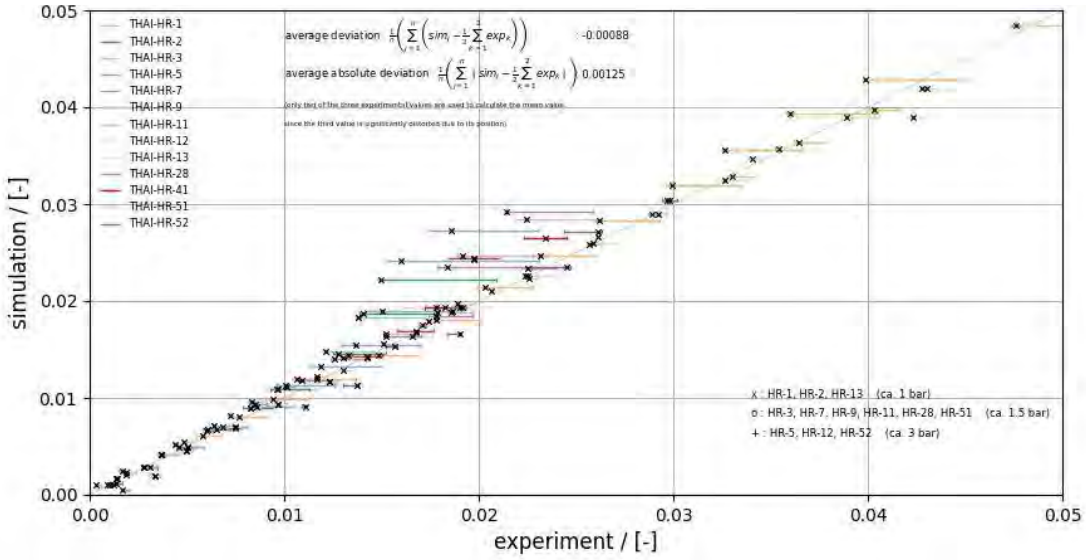

Figure 7. Calculated outlet hydrogen concentration (REKO-DIREKT) compared with values from the AMHYCO THAI database.

A specific feature of REKO-DIREKT is the calculation of the temperature profile along the catalyst sheets. A comparison of calculated and measured values is shown in Figure 8. Again, the quality of the results is independent from the pressure. Overall, the agreement is good, although the calculated temperature values are systematically too high.

As these examples show, the AMHYCO database supports consistent model improvements for PAR models. Model adjustments that lead to an improvement in the code can be immediately tested and evaluated in the way demonstrated.

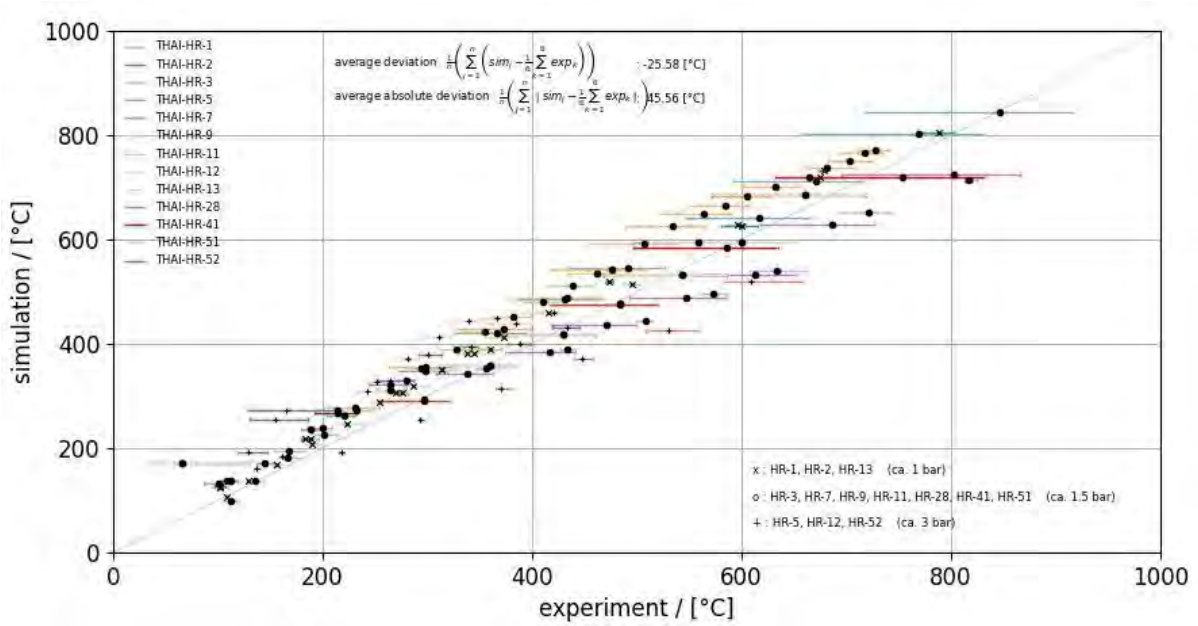

Figure 8. Calculated catalyst temperatures (REKO-DIREKT) compared with data from the AMHYCO THAI database.

4. CONCLUSIONS

PAR models are a valuable tool to assess the efficiency of the hydrogen mitigation strategy for severe accidents in LWRs. Part of the work within the AMHYCO project has specifically focused on advancing and validating PAR models with regard to the boundary conditions of the late phase of a severe accident. Careful validation of the advanced PAR models is mandatory for reliable scenario simulations.

In AMHYCO, a database was developed that consists of quasi-steady state measurement data from the transient PAR experiments performed in the framework of the OECD/NEA THAI projects. The database allows to simultaneously compare PAR model calculations with the entire range of boundary conditions studied in the experiments. Optional evaluation paths for some variables, e.g. the recombination rate or the outlet concentration, allow to assess uncertainties beyond the measurement accuracies based on the respective measurement devices.

The new AMHYCO THAI database represents a significant improvement compared to the consecutive validation of PAR models against single experiments. By this, model deficiencies can be more conveniently and more precisely identified, and the accuracy of the PAR model can be quantitatively assessed. Both aspects have been successfully demonstrated with the engineering correlation for Framatome PARs and the mechanistic PAR code REKO-DIREKT for generic PARs.

The AMHYCO project has also been studying the effect of carbon monoxide-induced catalyst poisoning and the corresponding relevant boundary conditions and gas mixtures. The future development of the database aims to include these aspects as well as introducing new experiments performed as the OECD/NEA THEMIS project continues.

OUTLINE

Development of a Database for PAR Model Validation based on THAI Experiments and its Application in the Framework of the AMHYCO Project

- Background
- Needs for PAR Model Development
- Database Generation
- Adding Uncertainties
- Model Validation
  - Framatome Engineering Correlation
  - REKO-DIREKT
- Conclusions

BACKGROUND: PARS

Passive Auto-Catalytic Recombiners (PARs)

- PARs are qualified safety systems for conditions of nuclear power plant accidents for flameless conversion of hydrogen.
- Due to the exothermal reaction, a buoyancy-driven flow is induced through the chimney on top of the catalyst section.
- Being an entirely passive safety measure, PARs will operate even in case of SBO and without operator's interaction.

Framatome (France)

AECL/CNL (Canada)

NIS (Germany)

RET (Russia)

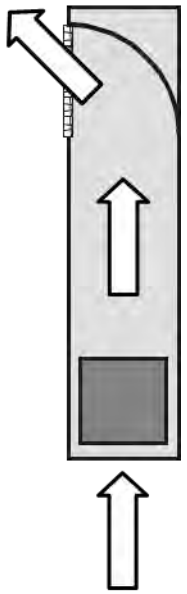
Ceracomb (Korea)

OUTLET
Air, produced vapor and residual hydrogen leaving the PAR box

CHIMNEY
Amplification of the buoyancy effect due to exothermal reaction

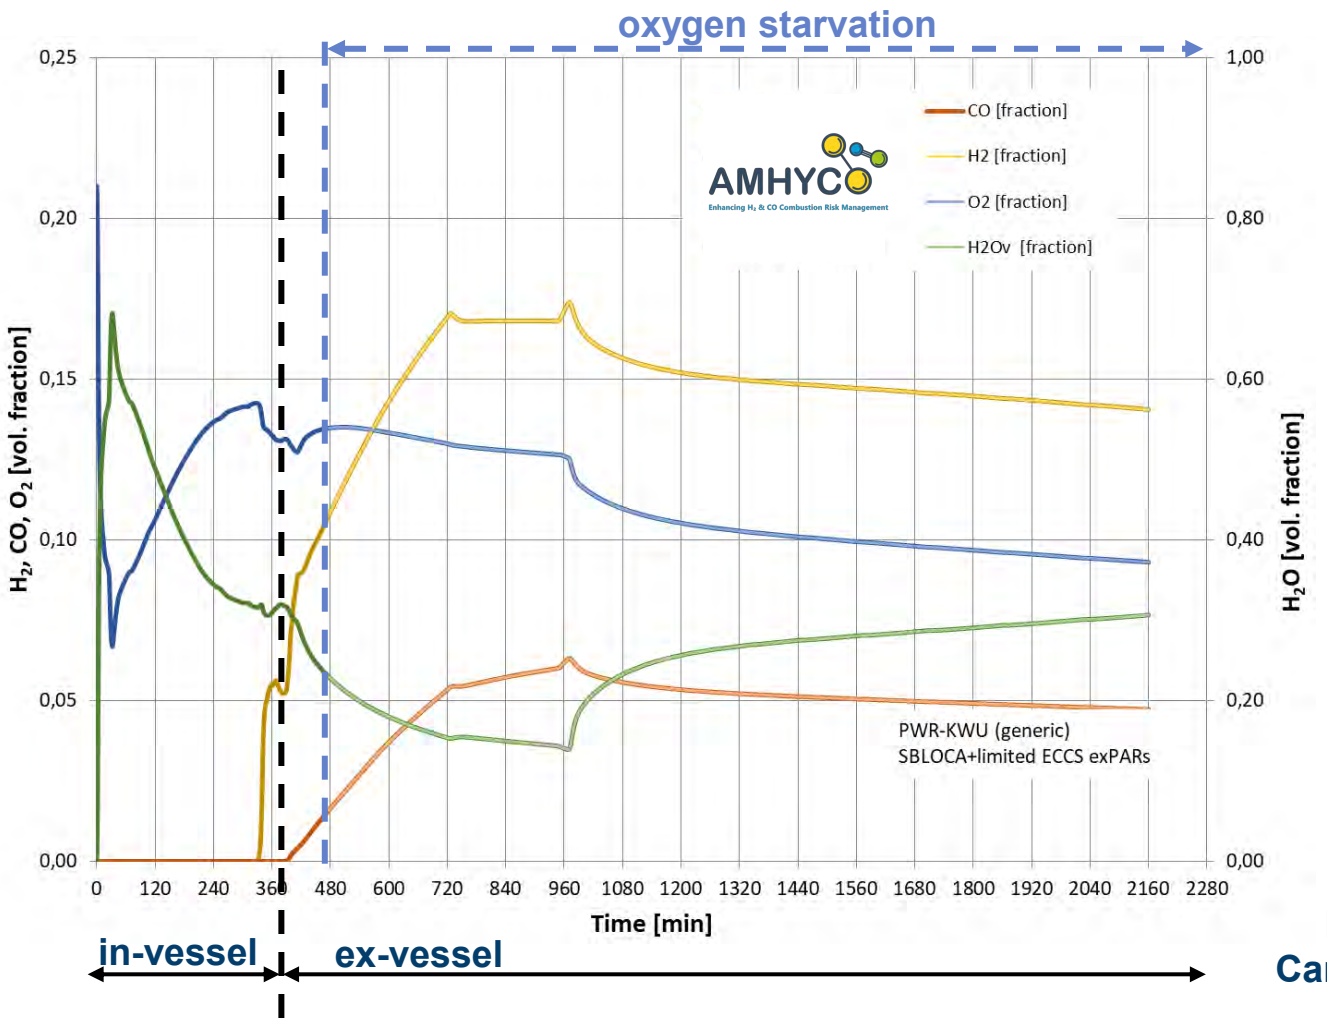
CATALYST SECTION
$H_2 + ½\ O_2 \Rightarrow H_2O$ + heat
$CO + ½O_2 \rightarrow CO_2$ + heat

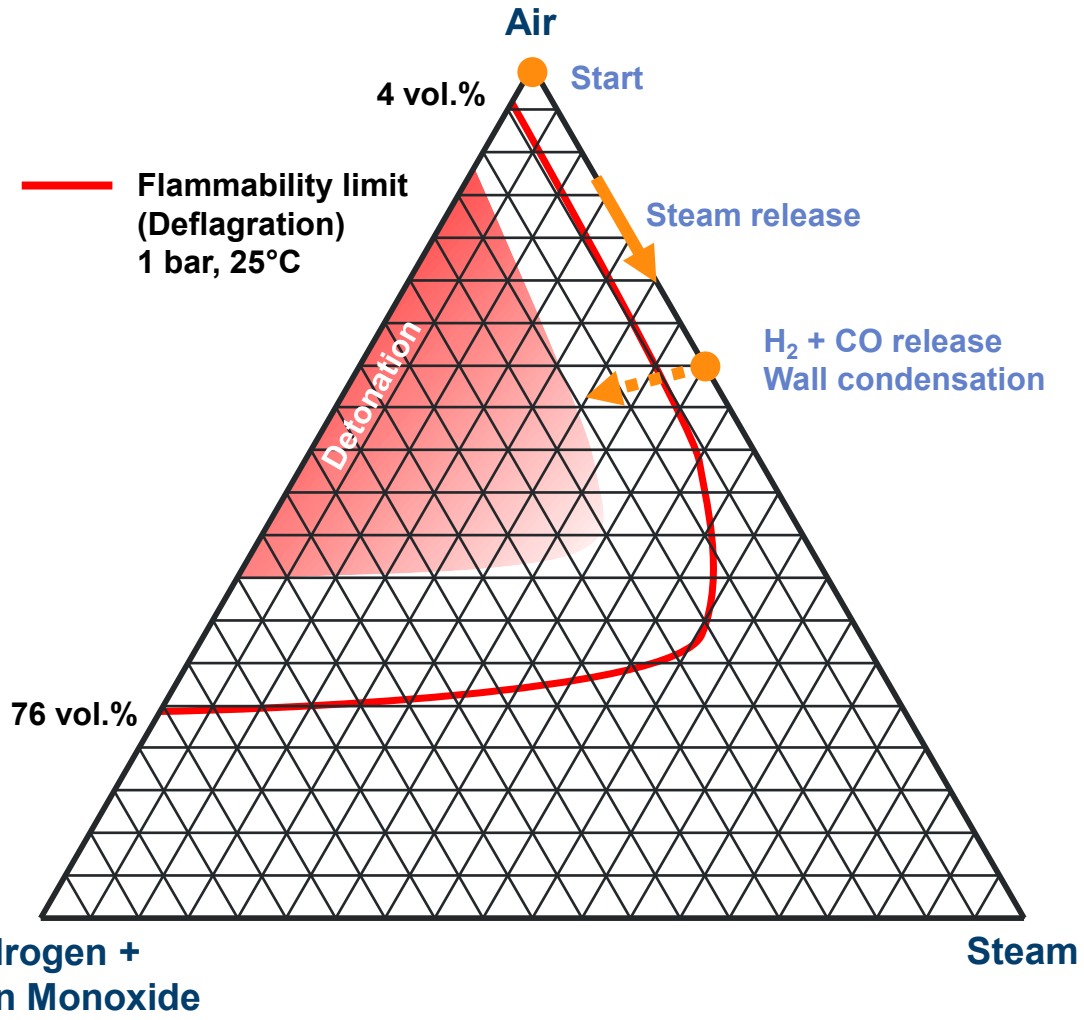
INLET
Hydrogen and air entering the PAR box



BACKGROUND: SEVERE ACCIDENT – LATE PHASE

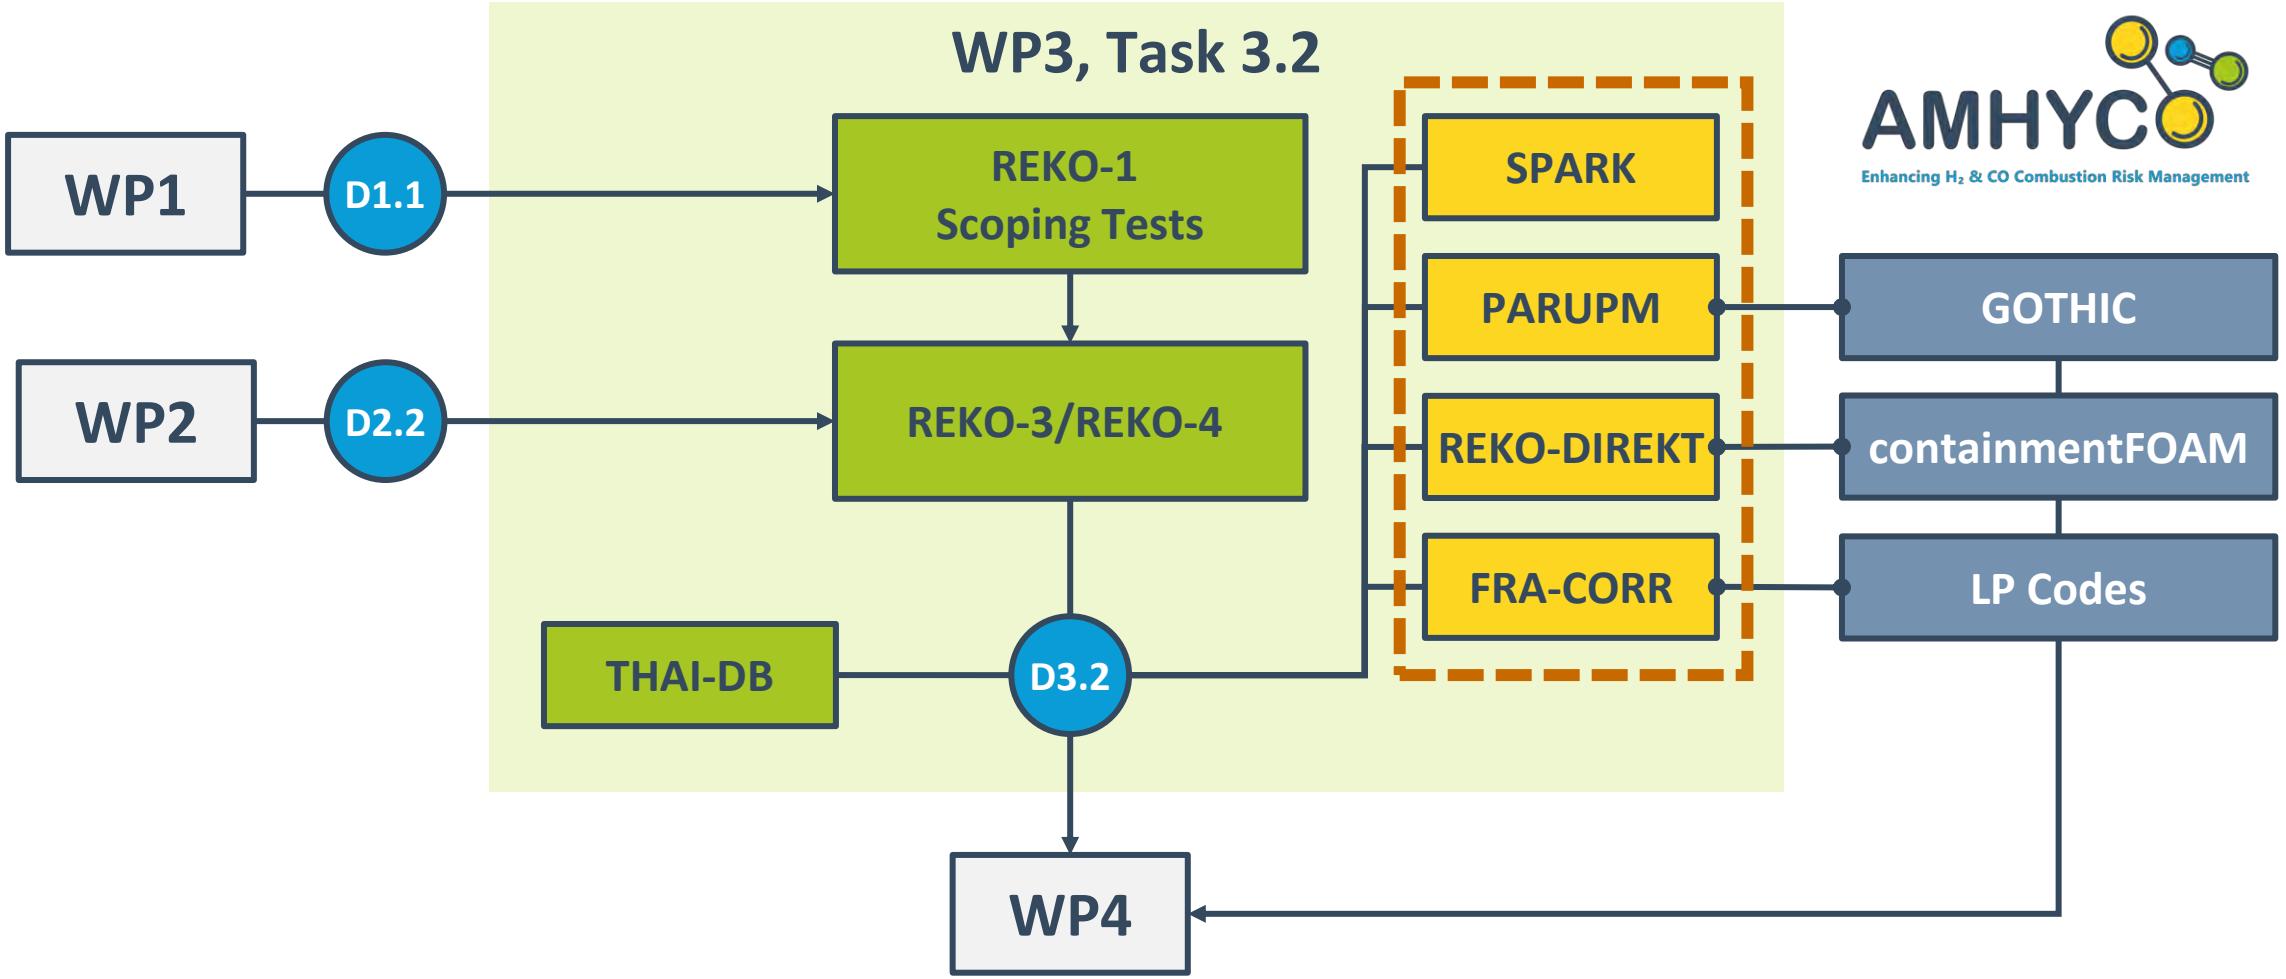
Mitigation of the Combustion Risk under Challenging Conditions





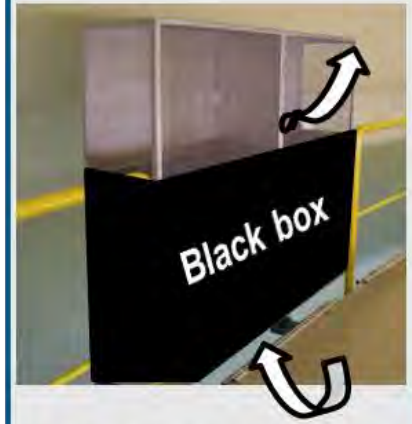
BACKGROUND: AMHYCO – WP3

Objective: Realistic PAR Behavior in Accident Simulations



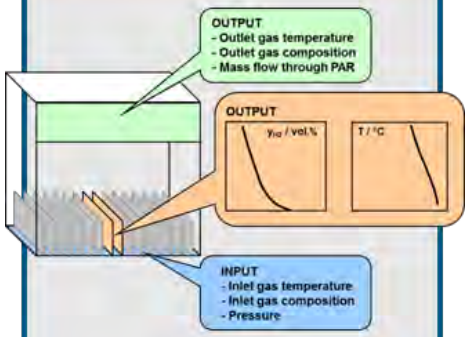
BACKGROUND: PAR CODES

Model Strategies



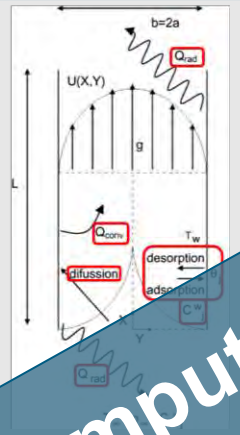
Rate Correlations (Manufacturers)

- Integral recombination rate



REKO-DIREKT (JÜLICH)

+ addition of
- Local recombination rate
- Local catalyst temperature
- Chimney flow



ARUPM (UPM)

+ addition of
- Surface reaction

ANSYS-CFX (JÜLICH)

CONCLUSIONS

Development of a Database for PAR Model Validation based on THAI Experiments and its Application in the Framework of the AMHYCO Project

- In AMHYCO, a database was developed that consists of quasi-steady state measurement data from the transient PAR experiments performed in the framework of the OECD/NEA THAI projects.
- The database allows to simultaneously compare PAR model calculations with the entire range of boundary conditions studied in the experiments.
- Optional evaluation paths for some variables, e.g. the recombination rate or the outlet concentration, allow to assess uncertainties beyond the measurement accuracies based on the respective measurement devices.
- Database application has been demonstrated with the engineering correlation for Framatome PARs and the mechanistic PAR code REKO-DIREKT for generic PARs.

Introduction

Introduction

Background and Motivation

- Gaseous iodine released into the containment during hypothetical severe accidents in LWR could be oxidized by air radiolysis products
  - Iodine oxides (IO_x) can be formed
  - Aerosols are considered source-term relevant
    - ➢ long-term airborne
    - ➢ can be resuspended from structures

Objective

- Gain experimental data for LP and CDF code validation
- Improve knowledge base for safety assessment

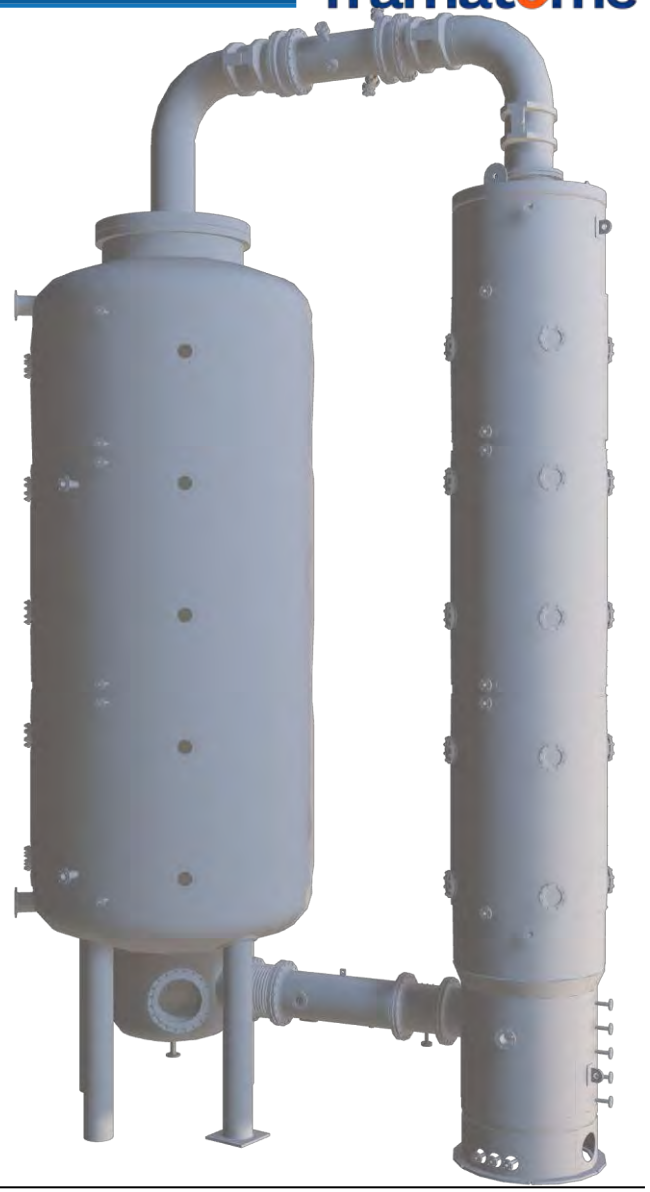
Aim

- Iod-36 aimed to quantify the adsorption and agglomeration of IO_x onto nuclear background aerosols
  - Silver was used as the mid and long-term phase accident aerosol
- Iod-37 focused on the thermal stability of gas-borne IO_x and the potential conversion of IO_x to I_2
  - accident-typical gas temperatures ranging from 80 up to 140 °C

Experimental setup

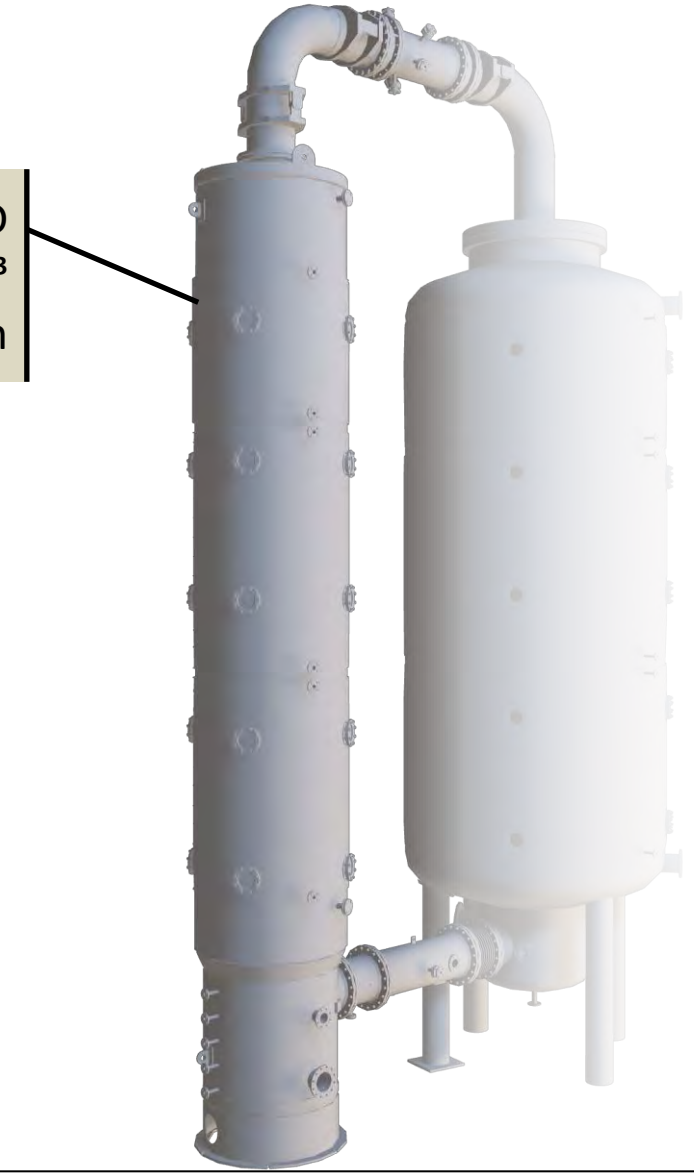
Experimental setup

- THAI$^+$: Thermal-hydraulics, Hydrogen, Aerosols, Iodine, + Multi-compartment
- 2 vessel configuration
  - 14 bar at 180 °C max
  - 10 bar at 250 °C max
- System can be heated or cooled independently via three thermal oil mantles (accuracy +/- 1 °C)
- Access trough flanges for (optical) measurement systems
- Approved for H_2, CO and radiolabeled I_2 in combination with deflagrations



Experimental setup

- THAI$^+$: Thermal-hydraulics, Hydrogen, Aerosols, Iodine, + Multi-compartment
- 2 vessel configuration
  - 14 bar at 180 °C max
  - 10 bar at 250 °C max
- System can be heated or cooled independently via three thermal oil mantles (accuracy +/- 1 °C)
- Access trough flanges for (optical) measurement systems
- Approved for H_2, CO and radiolabeled I_2 in combination with deflagrations



Experimental setup

- THAI$^+$: Thermal-hydraulics, Hydrogen, Aerosols, Iodine, + Multi-compartment
- 2 vessel configuration
  - 14 bar at 180 °C max
  - 10 bar at 250 °C max
- System can be heated or cooled independently via three thermal oil mantles (accuracy +/- 1 °C)
- Access trough flanges for (optical) measurement systems
- Approved for H_2, CO and radiolabeled I_2 in combination with deflagrations

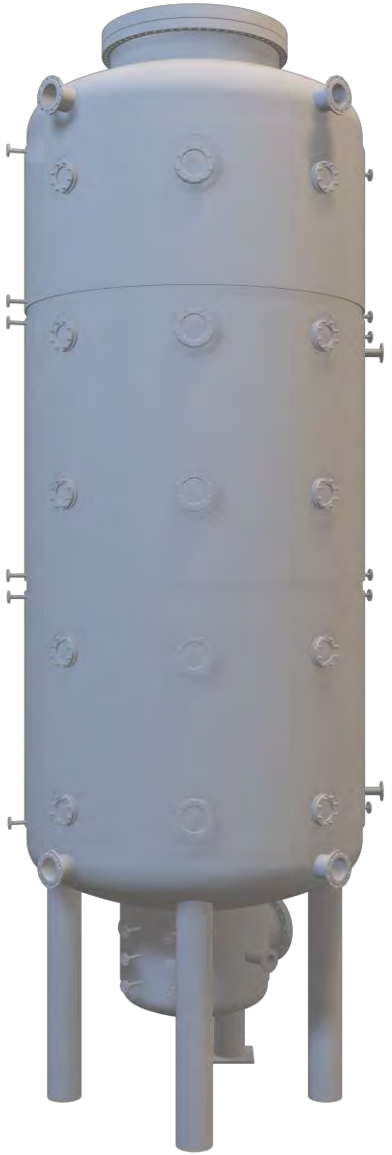
Experimental setup

Aerosol and iodine

- 6x internal and 2x external gas scrubbers
- 2x Maypacks
- scanning mobility particle sizer
- 2x bulk filters and impactors
- LASI-SPEC & laser extinction
- 2x lead-shielded NaI scintillation detectors pointing at coupons

Thermal hydraulics

- Temperature (fluid and surface)
- Pressure
- Humidity
- Gas concentration measurement system



Test procedure

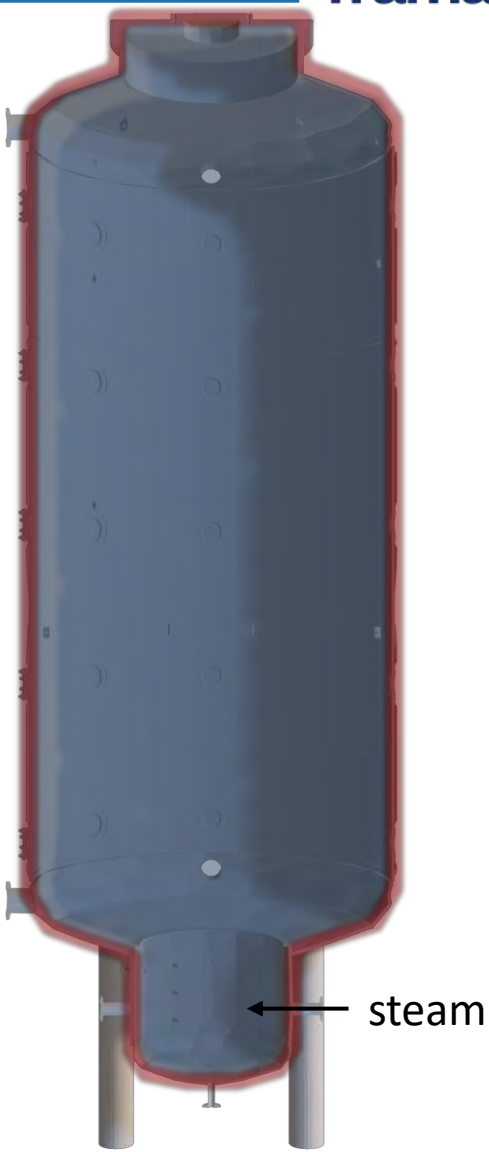
Test procedure

- Preconditioning phase 1
  - Temperature: 80 °C
  - 50 vol.-% of superheated steam
  - Pressure: 1.5 bar

- Preconditioning phase 2
  - Injection of ozone
  - Injection of gaseous I_2
    - ➢ IO_x formation and measurement

- Main phase **Iod-36**
  - Injection of Ag aerosol

- Main phase **Iod-37**
  - Long-term heating up to 140 °C



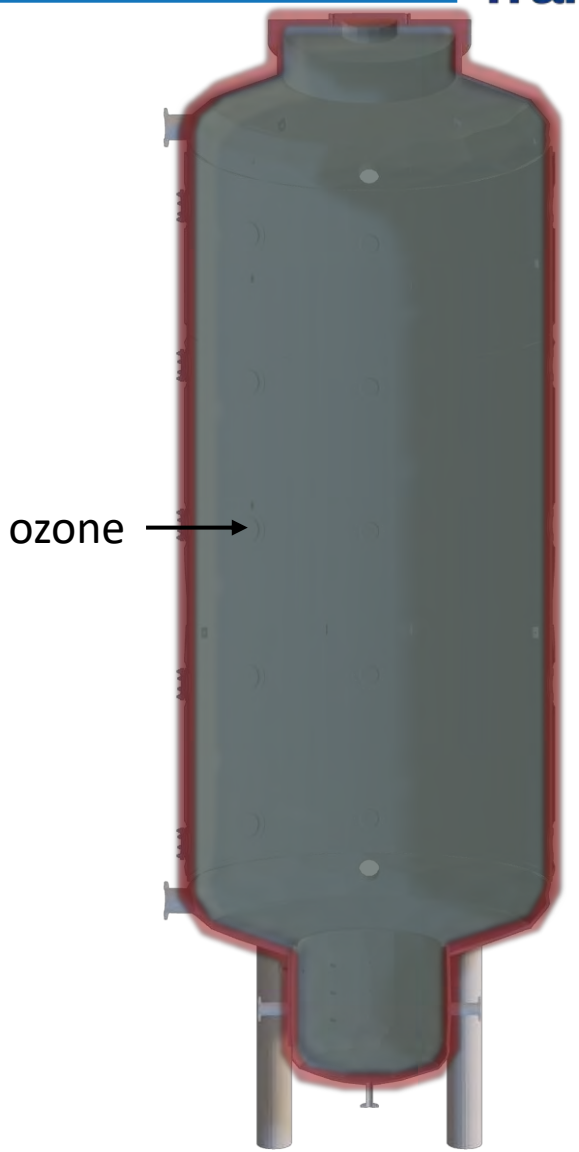
Test procedure

- Preconditioning phase 1
  - Temperature: 80 °C
  - 50 vol.-% of superheated steam
  - Pressure: 1.5 bar

- Preconditioning phase 2
  - Injection of ozone
  - Injection of gaseous I_2
    - ➢ IO_x formation and measurement

- Main phase **Iod-36**
  - Injection of Ag aerosol

- Main phase **Iod-37**
  - Long-term heating up to 140 °C



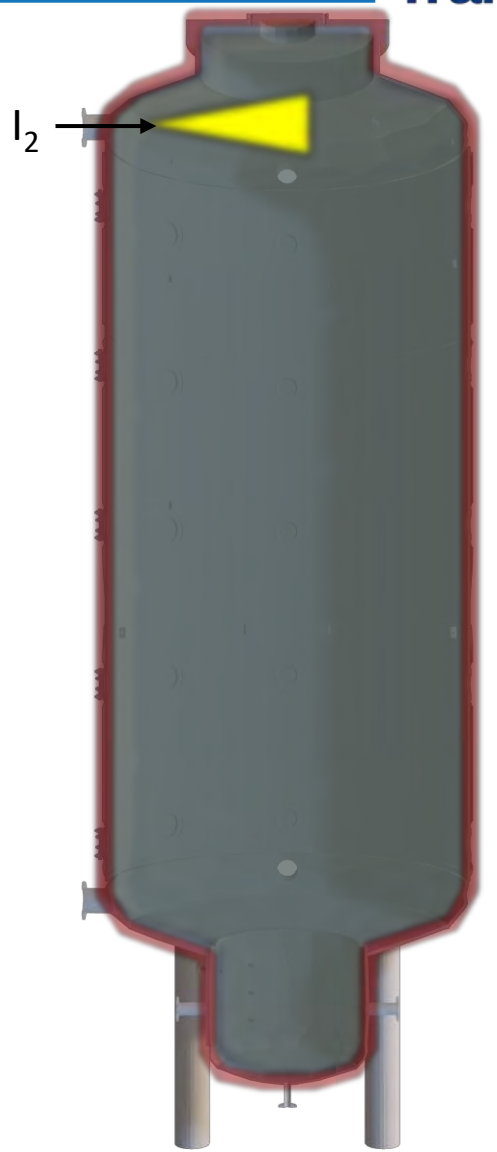
Test procedure

- Preconditioning phase 1
  - Temperature: 80 °C
  - 50 vol.-% of superheated steam
  - Pressure: 1.5 bar

- Preconditioning phase 2
  - Injection of ozone
  - Injection of gaseous I_2
    - ➢ IO_x formation and measurement

- Main phase **Iod-36**
  - Injection of Ag aerosol

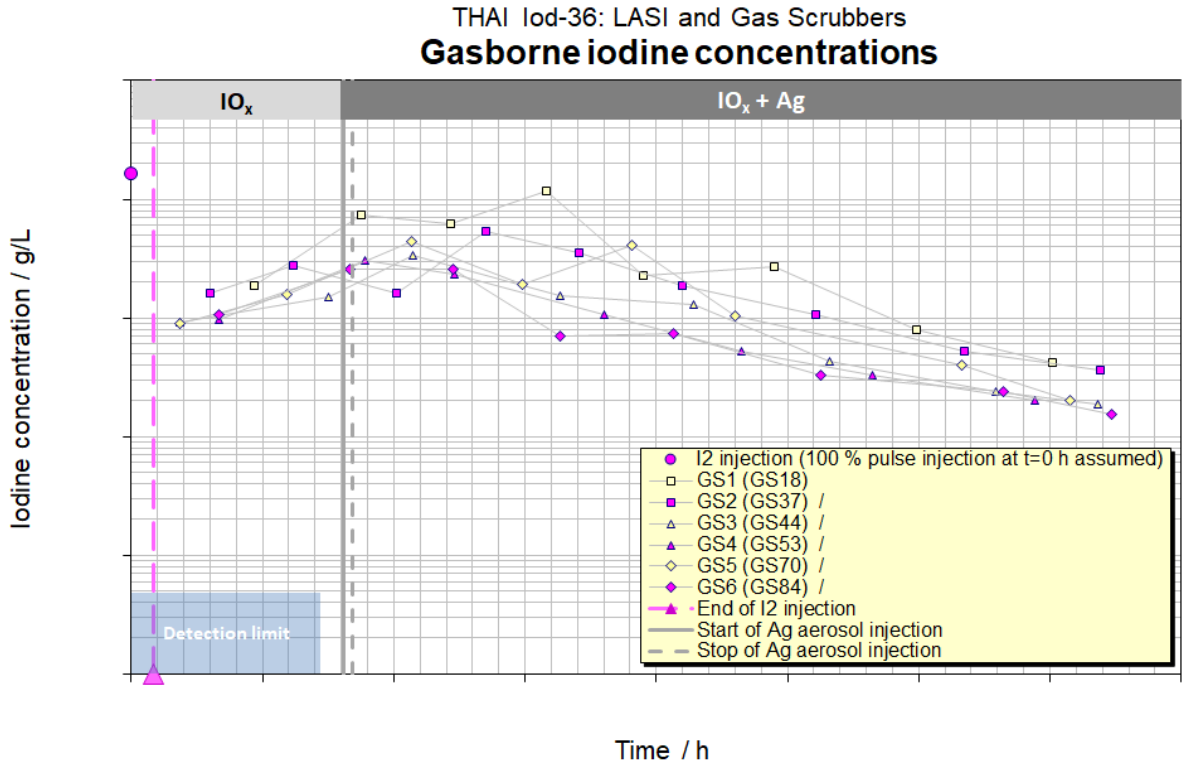
- Main phase **Iod-37**
  - Long-term heating up to 140 °C



Results Iod-36

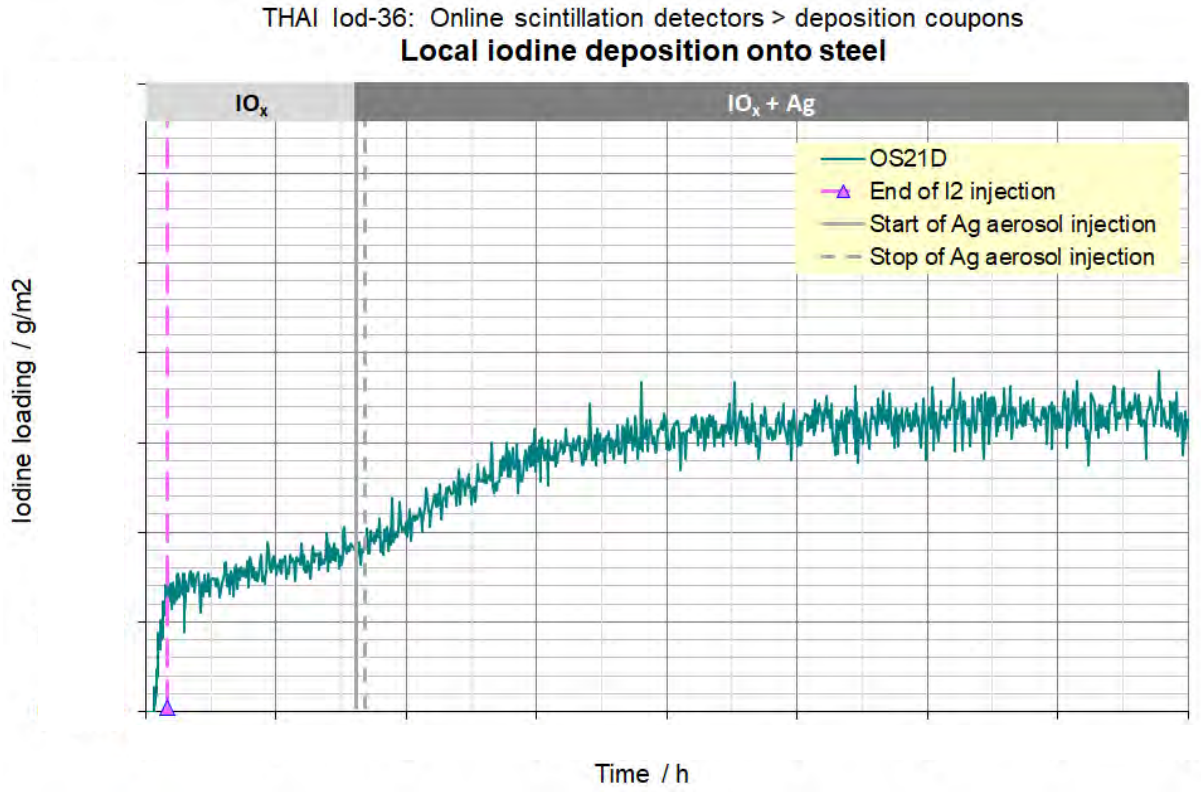
Results Iod-36

- Initial gas scrubber measurements showed low but increasing iodine concentrations
- Possible reasons
  - Incomplete oxidation
  - Coagulation of iodine species after I_2 injection
  - Formation of intermediate non-soluble IO_x species (e.g. IO, IO_2)
- After Ag aerosol injection, iodine concentration decreased steadily and nearly exponentially
- Stronger reduction observed at lower measurement positions due to particle settling
- Main removal mechanisms
  - Agglomeration
  - Sedimentation
- Conclusion
  - Reactive background aerosols can significantly reduce airborne iodine during accident scenarios



Results Iod-36

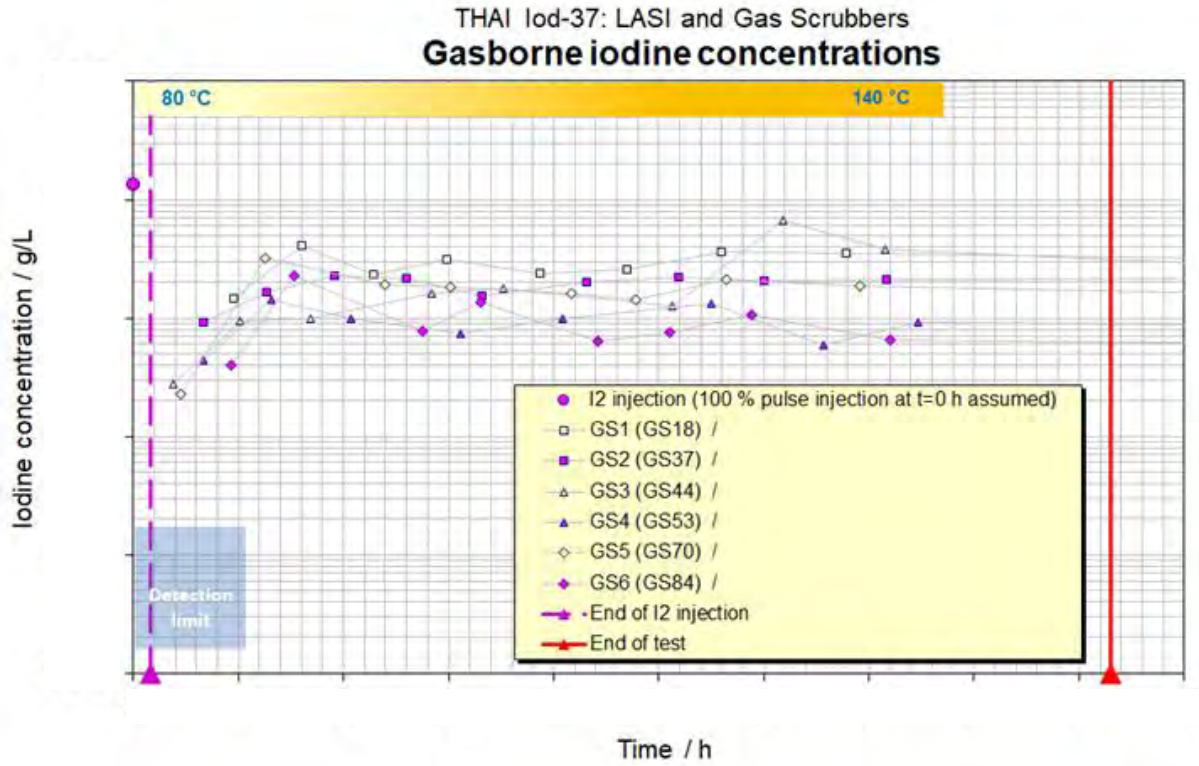
- Surface iodine loading determined from corrected count rate measured by online detector OS21D
- Raw detector signal corrected for
  - Contribution of gaseous iodine between glass and steel coupon
  - Total iodine concentration measured by Maypack systems
- Measurement results showed
  - Initial iodine deposition on the vertical steel coupon during early test phase
  - Deposition process significantly enhanced after Ag aerosol injection
- Results indicate that Ag aerosols promote iodine removal from the gas phase and increase surface deposition



Results Iod-37

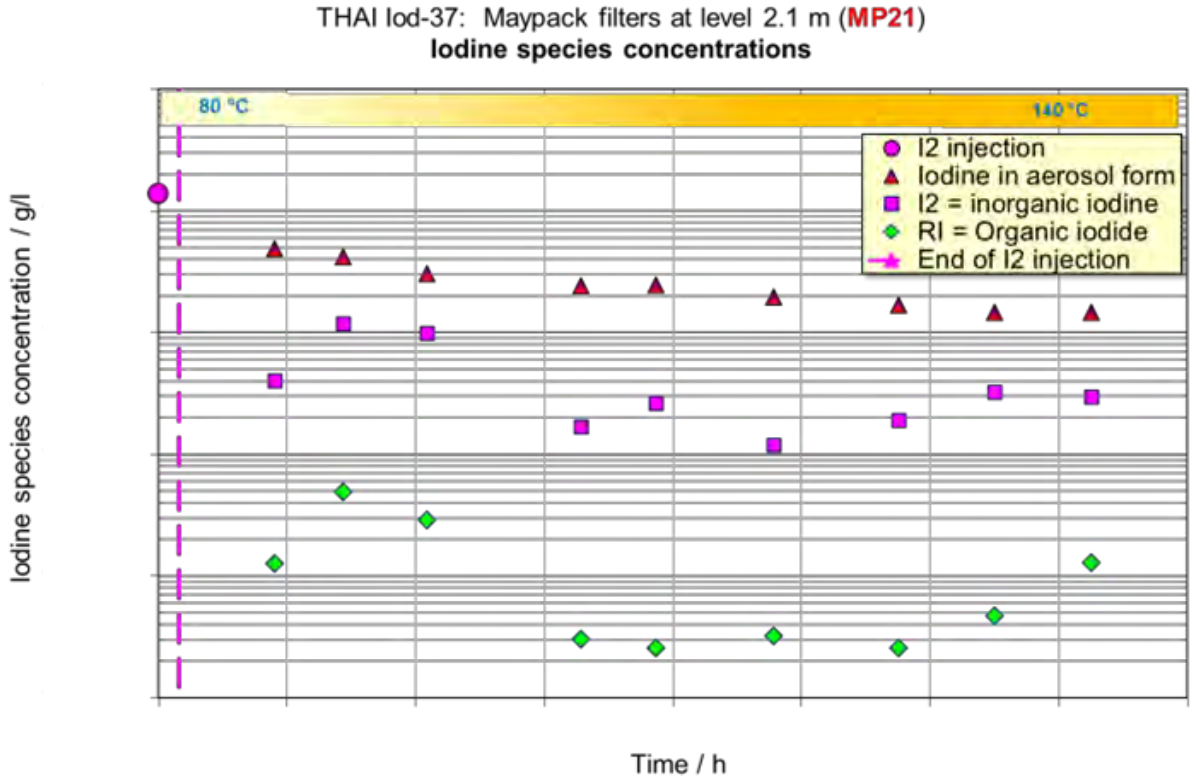
Results Iod-37

- Ozone concentration decreased nearly linearly during iodine injection
  - Succesfull oxidation of molecular I_2
- Gas scrubber measurements showed initially slow increase in airborne iodine concentration
- Likely explanation
  - Newly formed IOx particles were initially very small
  - Reduced scrubbing efficiency at early stages
- Over time
  - IO_x particles agglomerated
  - Scrubber retention efficiency improved
- About 1 - 1.5 hours after I_2 injection
  - Iodine concentrations stabilized at a low level
  - Low concentration persisted during heating from 80 °C to 140 °C



Results

- Maypack measurements showed that most iodine was present as aerosol-bound IO_x
- Confirms rapid formation of iodine oxide particles after I_2/ozone reaction
- Aerosol concentration decreased only slightly during the first 1 - 1.5 hours
- With increasing temperature
  - Concentration of inorganic gaseous iodine increased
  - Most likely caused by thermal decomposition of IO_x
- Decomposition process dominated over competing I_2/steel surface reactions
- Key conclusion
  - Aerosol-bound IO_x exhibits significant thermal instability
  - High temperatures can increase airborne iodine release (remobilization)
- Important implication for
  - Source term assessment
  - Late-phase severe accident analysis



Summary and conclusions

Summary and conclusions

- Formation and behavior of iodine oxide particles (IO_x) under severe accident conditions was investigated
- Test Iod-36 (with Ag aerosol)
  - Ag aerosols strongly reduced airborne iodine concentration
  - Removal mainly caused by
    - Aerosol settling
    - Agglomeration and/or adsorption effects
  - More than 90 % of airborne Ag aerosol was depleted by the end of the test
  - Reactive background aerosols can significantly mitigate airborne iodine in containment atmospheres
- Test Iod-37 (thermal stability study)
  - IO_x initially formed stable aerosol-bound iodine species
  - Particle concentrations decreased over time mainly due to agglomeration
  - Elevated temperatures (80 - 140 °C) promoted thermal decomposition of IO_x
  - Increasing fraction of inorganic gaseous iodine observed at high temperatures
- Findings are highly relevant for severe accident source term assessments and containment safety analyses

ABSTRACT

We are developing a flammability risk monitoring system for real-time tracking of the flammability of combustible gases that threaten the integrity of containment buildings during severe accidents. Previous sampling methods for measuring hydrogen concentration during accidents have functional limitations, such as time delays associated with gas transport. In this study, we are designing a modular sampling system to overcome these limitations and developing a non-sampling concentration assessment method that utilizes the catalyst temperature response of passive autocatalytic recombiners (PARs) installed within the containment building. Performance evaluations of the sampling-based measurement system have demonstrated an accuracy of less than 0.1 vol.% within a hydrogen concentration range of 0.1 to 9.0 vol.%, while maintaining stable control of gas sensor operating temperature and pressure, even under simulated accident conditions. Experiments on the hydrogen recombination behavior of PARs are currently being conducted in an 80 m³ severe accident simulation facility, and a correlation equation for non-sampling hydrogen concentration assessment is under development. The data processing algorithm converts dry hydrogen concentrations, obtained via the sampling method, into actual wet concentrations under accident conditions. When combined with hydrogen concentrations obtained by the PAR-operation-based non-sampling method and compared with flammability limits, this can provide real-time combustion hazard information during an accident. This flammability risk monitoring system is expected to enhance the effectiveness of combustible gas control strategies during severe accidents.

KEYWORDS
Severe accident, Hydrogen, Flammability, Monitoring system

1. INTRODUCTION

In a severe accident, hydrogen and carbon monoxide are generated during core degradation and molten core-concrete interaction (MCCI). These gases, if released into the upper containment building and mixed with atmospheric oxygen, can form an explosive mixture. Hydrogen, in particular, possesses a low ignition energy and a wide flammability range. The dynamic and thermal loads produced during its combustion pose a significant threat to the structural integrity of the containment building. Consequently, accurately assessing the combustion risk of these flammable gases in real-time is a crucial countermeasure for enhancing nuclear power plant safety within accident mitigation strategies.

Currently, most operational nuclear power plants utilize sampling-based instrumentation to measure hydrogen concentration by drawing atmospheric air from within the containment building to an external measurement unit. [1] While this sampling method offers the advantage of protecting concentration sensors from high-temperature steam and radioactive aerosols inside the containment, it introduces uncertainties

due to inherent delays. Specifically, there is a suction time delay caused by the length of the sampling pipeline and the flow rate, as well as a response time delay attributable to the free volume of the pre-processing equipment. Consequently, these delays prevent the instrumentation from providing an immediate, real-time reflection of the conditions within the containment building. Furthermore, safety concerns have been raised regarding the sampling pipeline itself, as it could potentially serve as a bypass leakage path for radioactive materials.

To address these limitations, we are developing a monitoring system that integrates two distinct approaches, as illustrated in Figure 1. Firstly, a sampling system has been designed and is currently undergoing performance evaluation. This design incorporates functional modularization to minimize suction time delay and utilizes a pool scrubbing method to reduce steam condensation trap and filter housing volume. Secondly, the research aims to leverage the dozens of passive autocatalytic recombiners (PARs) already installed within the containment building as a non-sampling tool for hydrogen concentration assessment. The thermal reaction occurring on the catalyst surface during PAR operation exhibits a strong correlation with the ambient hydrogen concentration. This correlation enables the real-time acquisition of hydrogen concentration data from various locations within the containment, even in the absence of sampling lines.

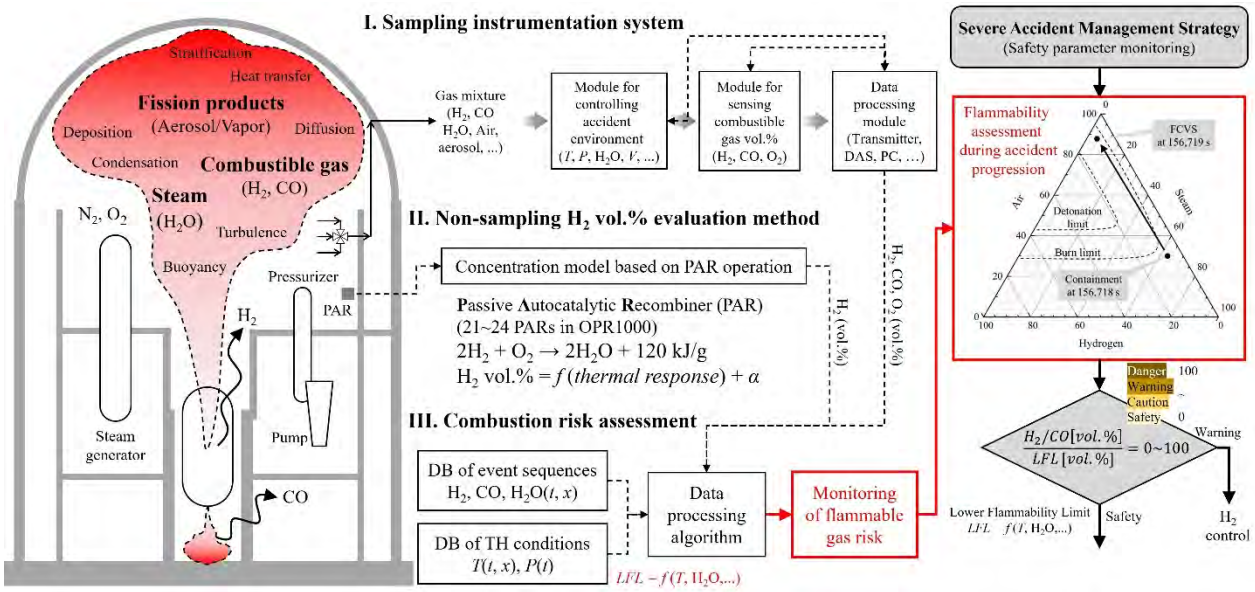

Figure 1. Conceptual Diagram for the Development of a Flammable Gas Risk Monitoring System.

This paper presents the results of performance validation for an advanced sampling module and outlines the current development status of a PAR-based non-sampling concentration assessment method, which is being implemented in a large-scale experimental facility simulating severe accident environments. Furthermore, a data processing algorithm is under development to convert dry hydrogen concentrations obtained from the sampling module into actual wet concentrations relevant to accident conditions. This algorithm will also facilitate real-time monitoring of flammable gas hazards by comparing the calculated hydrogen concentrations, derived from the PAR-based non-sampling method, with the flammability limits. This integrated technology is expected to provide critical data for determining optimal mitigation strategies within severe accident management guidelines.

2. MODULAR SAMPLING INSTRUMENTATION SYSTEM

To ensure reliability in severe accident environments, the sampling-based measurement system employs a modular design comprising an environmental control module and a flammable gas concentration sensing

module. As depicted in Figure 2, the environmental control module draws a gas mixture from the experimental vessel (or containment building), subjects it to a pre-treatment process, and then discharges it back into the vessel (or containment building). During this process, a portion of the gas is directed to the concentration sensing module via pressure control [2]. Notably, to mitigate the inherent time delay, a functional limitation of conventional sampling systems, the design incorporates a mechanism to optimize the suction flow rate by controlling the rotational speed of the circulation pump.

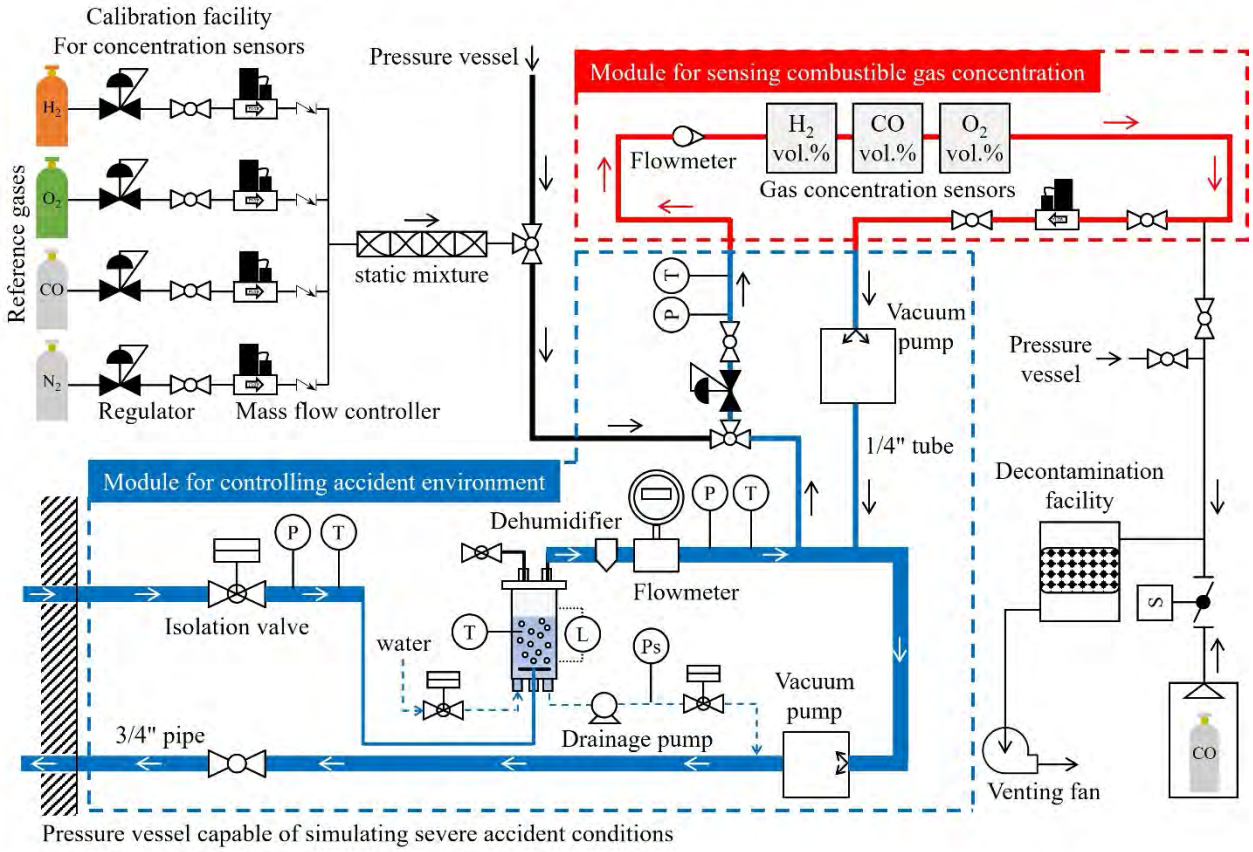

Figure 2. Conceptual Diagram of the Modular Instrumentation System and Performance Evaluation Test Facility.

The pool scrubbing technology employed in the environmental control module serves to protect sensor integrity by condensing superheated steam and removing aerosolized fission products. Concurrently, it minimizes hydrogen concentration dilution and reaction time delays attributed to the volume of the condensation trap and aerosol filter housing. To enhance aerosol removal efficiency, the nozzle within the pool was designed as a sparger, featuring 48 uniformly distributed 1.5 mm diameter holes.

The concentration sensing module incorporates three types of sensors, arranged in series, for monitoring hydrogen, carbon monoxide, and oxygen concentrations. A thermal conductivity sensor was selected to measure hydrogen concentration over a range of 0 to 100 vol.%. For carbon monoxide and oxygen concentrations, an optical sensor and a paramagnetic sensor were chosen, respectively. To ensure precise sensor measurements, the sampling flow rate is maintained at a constant 1 l/min using a mass flow controller.

The environmental control module and the concentration sensing module were designed, as shown in Figure 3, and subsequently fabricated into cabinet-type enclosures for individual performance evaluation.

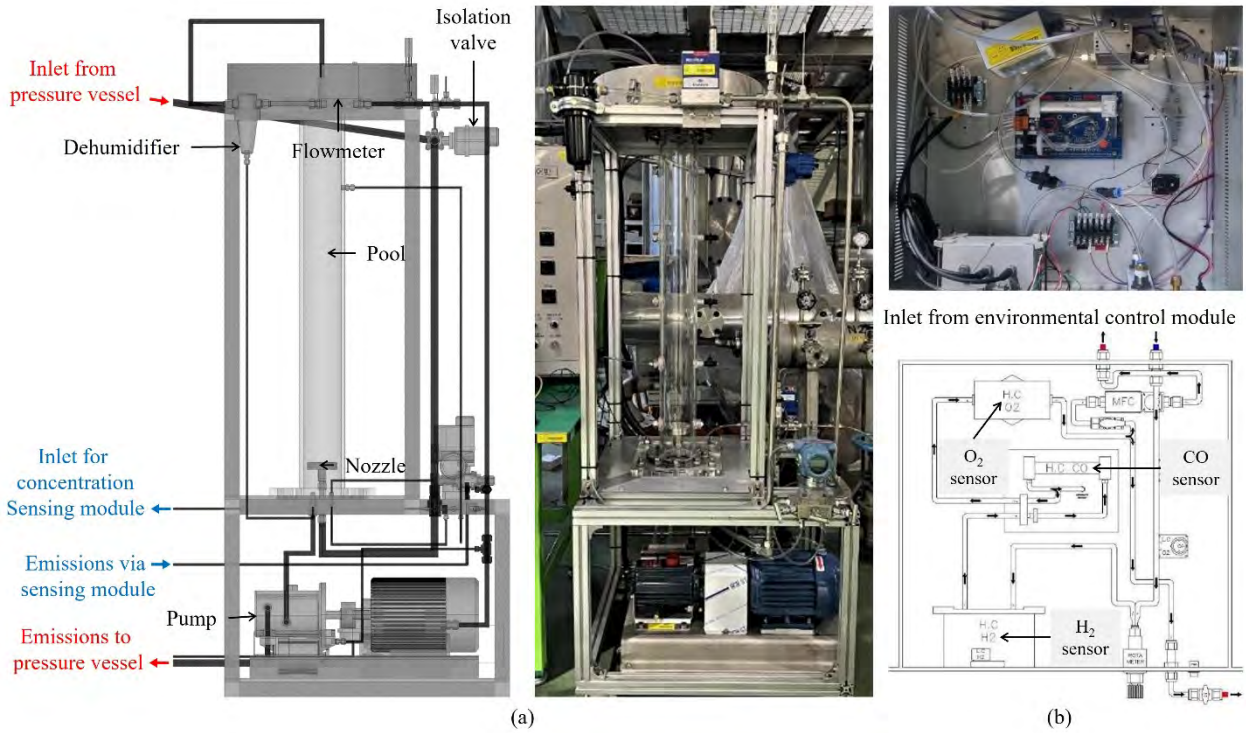

Figure 3. Design and Fabrication of the Modular Measurement System: (a) Environmental Control Module Drawing (Left) and Assembled Unit (Right), (b) Concentration Sensing Module Drawing (Bottom) and Assembled Unit (Top).

3. NON-SAMPLING EVALUATION METHOD BASED ON PAR OPERATION

To address the risks of leakage in sampling lines and the limitations of measurement locations, a non-sampling concentration assessment method is being developed, which utilizes the operational characteristics of passive autocatalytic recombiners (PARs) installed within containment buildings. The PAR unit was designed as a catalytic body coated with platinum (Pt) at a concentration of 60 g/ft³, integrated into a lattice structure, and housed within a chimney intended to generate buoyancy-driven flow [3]. The catalytic body has dimensions of 93.5 mm in width, 190 mm in length, and 25 mm in height. Its lattice structure features a cell density of 36 cpsi (cells per square inch), with a wall thickness of 0.7 mm between cells. Each individual cell measures 3.5 x 3.5 mm^2, resulting in a total of 990 cells. The exothermic reaction that occurs when hydrogen and oxygen recombine on the catalyst surface is closely correlated with the surrounding hydrogen concentration. This allows for the inverse calculation of hydrogen concentration around a PAR by measuring the temperature rise with thermocouples affixed to the catalyst surface.

Figure 4 illustrates the experimental setup within the SPARC (Spray-Aerosol-Recombiner-Combustion) facility, operated by the Korea Atomic Energy Research Institute (KAERI). A Passive Autocatalytic Recombiner (PAR) was installed inside a cylindrical SPARC vessel measuring 3.4 m in diameter, 9.5 m in height, and with a volume of 80 m³. Hydrogen recombination experiments using the PAR were subsequently conducted under simulated severe accident conditions, involving controlled hydrogen injection. [3] Initial thermohydraulic conditions for hydrogen injection were determined based on severe accident scenario calculations of a small-break loss-of-coolant accident (SBLOCA) in a Korean Standard Nuclear Power Plant (OPR1000) using the MELCOR code. For the hydrogen recombination experiments, conditions within a pressure range of 1.32 to 1.93 bar and steam-saturated temperatures from 60.4 to 88.3 °C were selected. [4] Following the transient region characterized by a rapid increase in catalyst temperature, the correlation between the catalyst surface temperature and the hydrogen concentration around the PAR was observed.

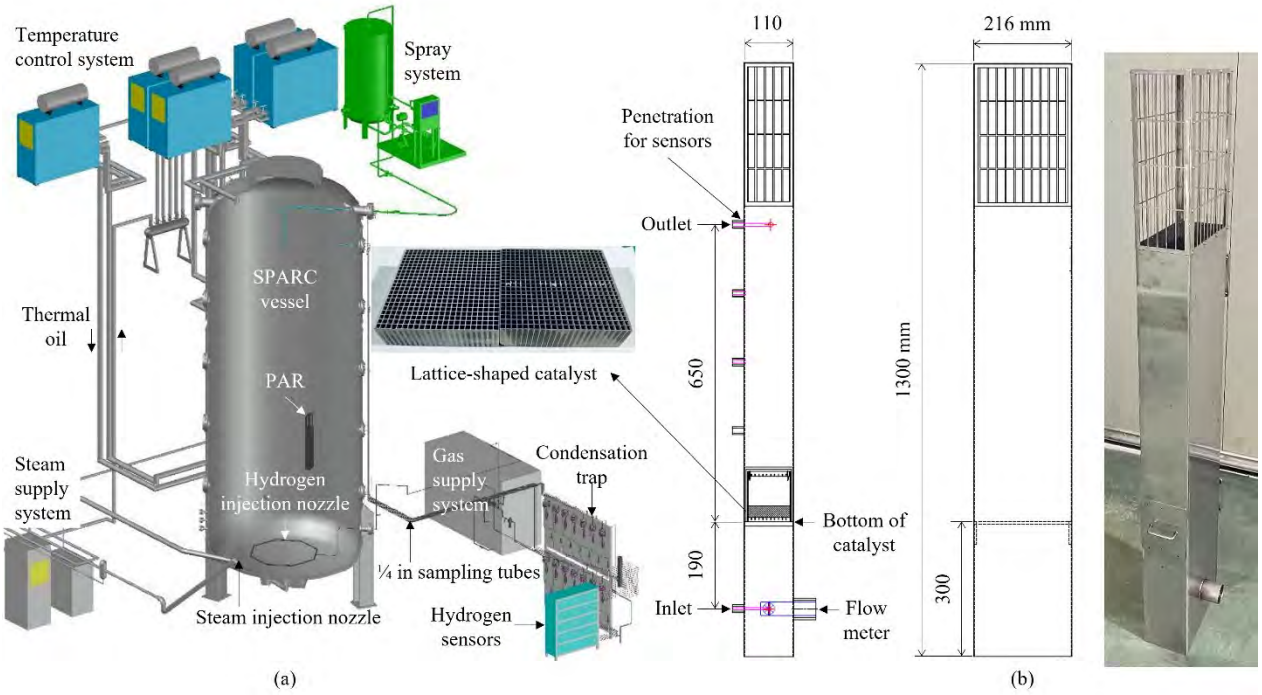

Figure 4. (a) PAR Installed within the SPARC Vessel; (b) Fabrication Diagram and Photograph of the PAR.

4. INTEGRATED DATA PROCESSING ALGORITHM

The raw data acquired from the sampling system represents a dry hydrogen concentration, with steam removed during the preprocessing stage. Consequently, it is essential to convert this to a wet concentration, reflecting the actual conditions within the containment building. This conversion to a wet concentration is performed using Equation 1, which calculates the steam concentration based on relative humidity and saturated vapor pressure, subsequently incorporating this into the dry hydrogen concentration. [3]

$$(C_h)_w = \left(1 - \frac{C_s}{100}\right)(C_h)_d \quad (1)$$

We developed Python 3.11-based code that automates time-delay compensation and wet hydrogen concentration conversion processes. The wet hydrogen concentration, measured through a sampling method, and the hydrogen concentration calculated using a non-sampling method based on PAR operation, are both utilized in a flammability assessment algorithm to diagnose combustion risk. By comparing the experimentally derived correlation for the flammability limits of hydrogen-steam-air mixtures [5] with the hydrogen concentrations obtained using both sampling and non-sampling methods, a hazardous percentage for the current atmospheric conditions can be determined.

5. RESULTS

5.1. Accuracy and Interference Characteristics of Sensing Modules

Figure 5 illustrates the performance evaluation of the concentration sensing module utilizing a standard gas. The thermal conductivity-based hydrogen sensor demonstrated an accuracy with less than 0.1 vol.% error

within the range of 0.1 to 9.0 vol.%. [2] Notably, in concentrations exceeding 2.0 vol.%, the residual standard deviation remained stable at approximately 0.1.

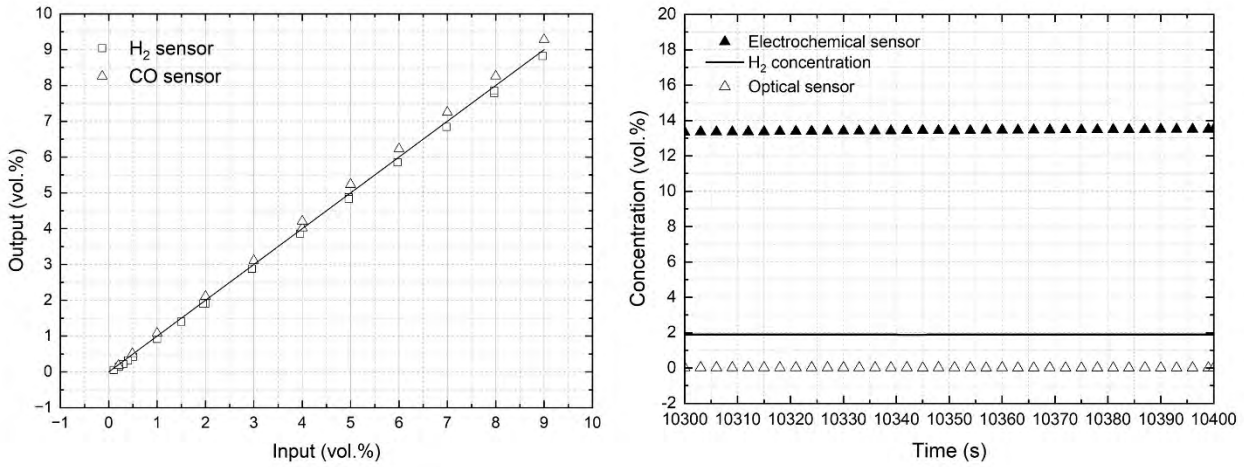

Figure 5. Hydrogen/Carbon Monoxide Sensor Accuracy (Left) and the Effect of Gas Interference on the Carbon Monoxide Sensor (Right).

In an evaluation of gaseous interference effects on carbon monoxide concentration sensors based on their measurement principles, injecting 2 vol.% hydrogen gas into the sensing module caused electrochemical carbon monoxide sensors to exhibit a false concentration reading of approximately 13.44 vol.%. In contrast, the optical carbon monoxide sensor employed in this system maintained an error of less than 0.02 vol.%, irrespective of hydrogen concentration. This demonstrates the suitability of optical sensors for late severe accident environments where both hydrogen and carbon monoxide are produced simultaneously.

5.2. Stability of Environmental Control under Transient Conditions

The performance of the environmental control module was validated under rapid pressure rise conditions of 0.9 kPa/s, which are more severe than those stipulated for major accident scenarios. Despite a sharp increase in experimental vessel pressure from 1.07 bar to 2.0 bar, the inlet pressure of the sensing module was consistently maintained at 1.09 bar by the pressure regulator. Furthermore, even when the inlet temperature to the water bath rose to 42.1 °C, owing to the intake of the 60 °C atmosphere from within the experimental vessel, the gas exiting the water bath was cooled to 23.7 °C. This successfully met the operational temperature requirement for the sensor, which is below 25 °C.

5.3. Time Delay and Response Time Analysis

By simplifying only the pool scrubber section of the environmental control module in the sampling system and evaluating the time delay as show in Figure 6, it was observed that the physical intake delay time (td)—defined as the period from the initiation of hydrogen injection until the sensor outputs the hydrogen concentration—remained constant at approximately 26 to 27 seconds (Figure 7). However, the response time (tr), which is the duration required for the hydrogen sensor's output to increase proportionally to the injected hydrogen concentration after the initial output, varied from 13 seconds (for a free volume ratio of 0.41) to 32 seconds (for a free volume ratio of 1.0, representing a water tank filled with air). This response time was found to be directly proportional to the free volume ratio of the water tank, which serves as a pre-treatment facility. In a comparative experiment, a bypass pipeline with an equivalent volume to the water bath was employed. This configuration resulted in a slight increase in the suction delay time to 35 seconds due to the extended pipeline length, while the reaction time was significantly reduced to 5 seconds. This observation suggests that gas drawn into the water bath tank follows a specific path through the free volume

of the bath and that optimizing the design of the water bath tank and the water level is a critical parameter for the real-time monitoring performance of sampling-based measurement systems.

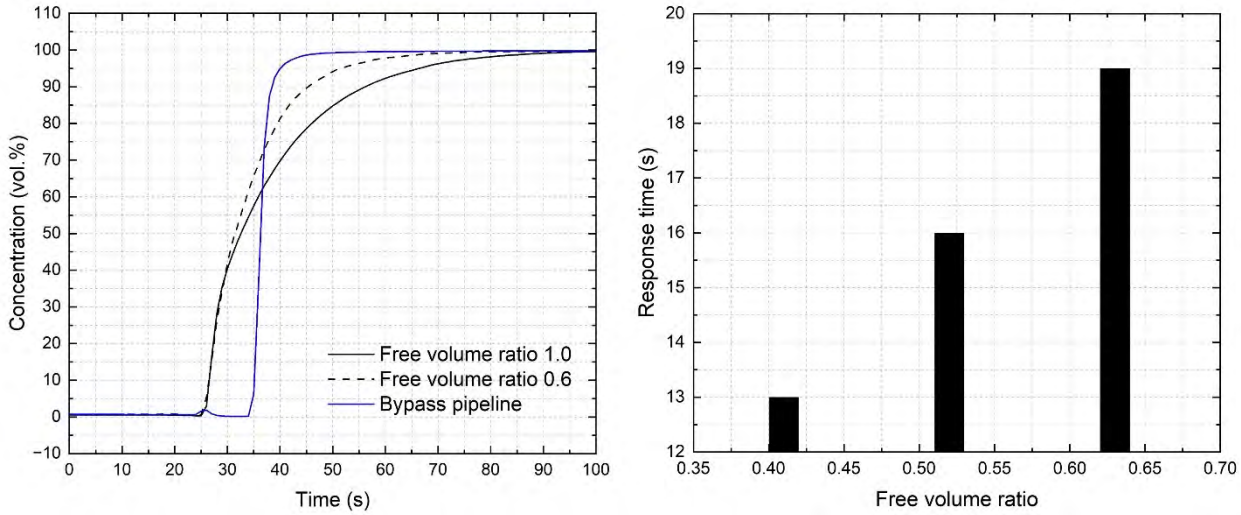

Figure 7. Intake delay and Response Time as Functions of Free Volume Ratio in a Water Tank.

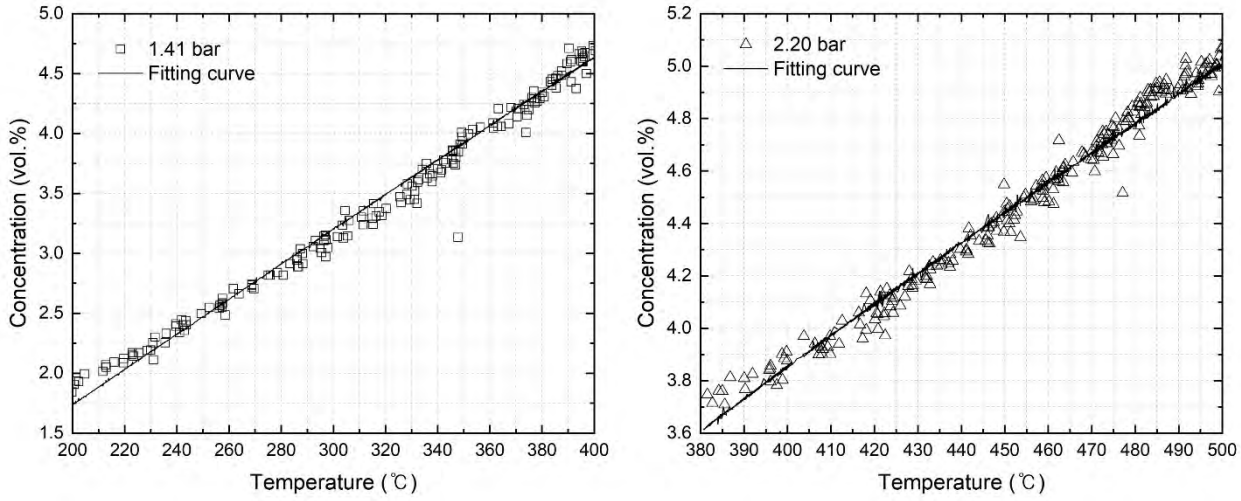

Figure 8. Correlation Between Hydrogen Concentration around the PAR and Catalyst Temperature: 1.41 bar (Left) and 2.20 bar (Right).

5.4. Validation of PAR-based Hydrogen Estimation

Experiments on hydrogen recombination conducted at the SPARC facility validated the effectiveness of the PAR-based hydrogen concentration assessment method across an average pressure range of 1.41 to 2.2 bar and an average ambient temperature range of 64.4 to 94.6 °C. A linear correlation was observed between the catalyst surface temperature and the hydrogen concentration around the PAR, as depicted in Figure 8.

6. CONCLUSIONS

We are currently developing a flammability risk monitoring system specifically designed for severe accidents, comprising three key components: advanced sampling instrumentation, PAR-based non-sampling hydrogen concentration assessment, and a data processing algorithm. This paper presents a preliminary evaluation of the performance and validity of certain individual system components.

Firstly, the environmental control module consistently maintained the operational temperature and pressure of its sensors, even within accident conditions. The implementation of pool scrubbing can effectively mitigate the time delay issues previously caused by concentration dilution within conventional condensation traps and filter housings. Both hydrogen and carbon monoxide sensors demonstrated high accuracy.

Second, experiments on hydrogen recombination conducted within a severe accident simulation environment revealed a linear correlation between the thermal response of the PAR catalyst surface and the hydrogen concentration around the PAR. This finding suggests that PARs could potentially serve as a type of non-sampling sensor to augment concentration data at various locations within a containment building.

Third, the data processing algorithm can compensate for time delays during the sampling process and convert dry hydrogen concentrations to wet concentrations by accounting for the steam removed during sampling. By comparing the hydrogen concentrations obtained from both the sampling-based measurement system and the PAR-operation-based non-sampling method with the flammability limit in real time, a quantitative risk index can be generated.

These findings will contribute to the real-time provision of combustible gas hazard levels in severe accidents, enabling the preemption of potential adverse effects that could arise during spray operations.

ABSTRACT

The decommissioning of the Fukushima Daiichi Nuclear Power Plant presents an exceptional challenge in long-term safety management, specifically regarding the stabilisation and treatment of the "Liquid Source Term". In frame of the EU project SCORATES, investigations focus is on improving understanding of the post-operation liquid source term, with the aim of enhancing strategies to mitigate and monitor the release of radionuclides into the environment. Leaching phenomena from different scientific fields are analysed with regard to their suitability for the modelling of severe accident scenarios and especially the long-term liquid source term. Different approaches from the literature are presented and discussed as well as past investigations in the frame of the decontamination intentions of the damaged TMI-2 nuclear power plant.

Leaching mechanisms are being investigated in order to develop a model that takes into account the relevant phenomena and enables predictions to be made about the mass of released radionuclides into the aqueous phase depending on specific boundary conditions. Given that no established leaching models yet exist, the basic concept here is to develop a framework for the future model by incorporating several validated sub-models from different disciplines, each representing a specific sub-phenomenon. Temperatures, composition and surface area of corium, the liquid, its pH value and redox potential are included in the model development as relevant influencing factors.

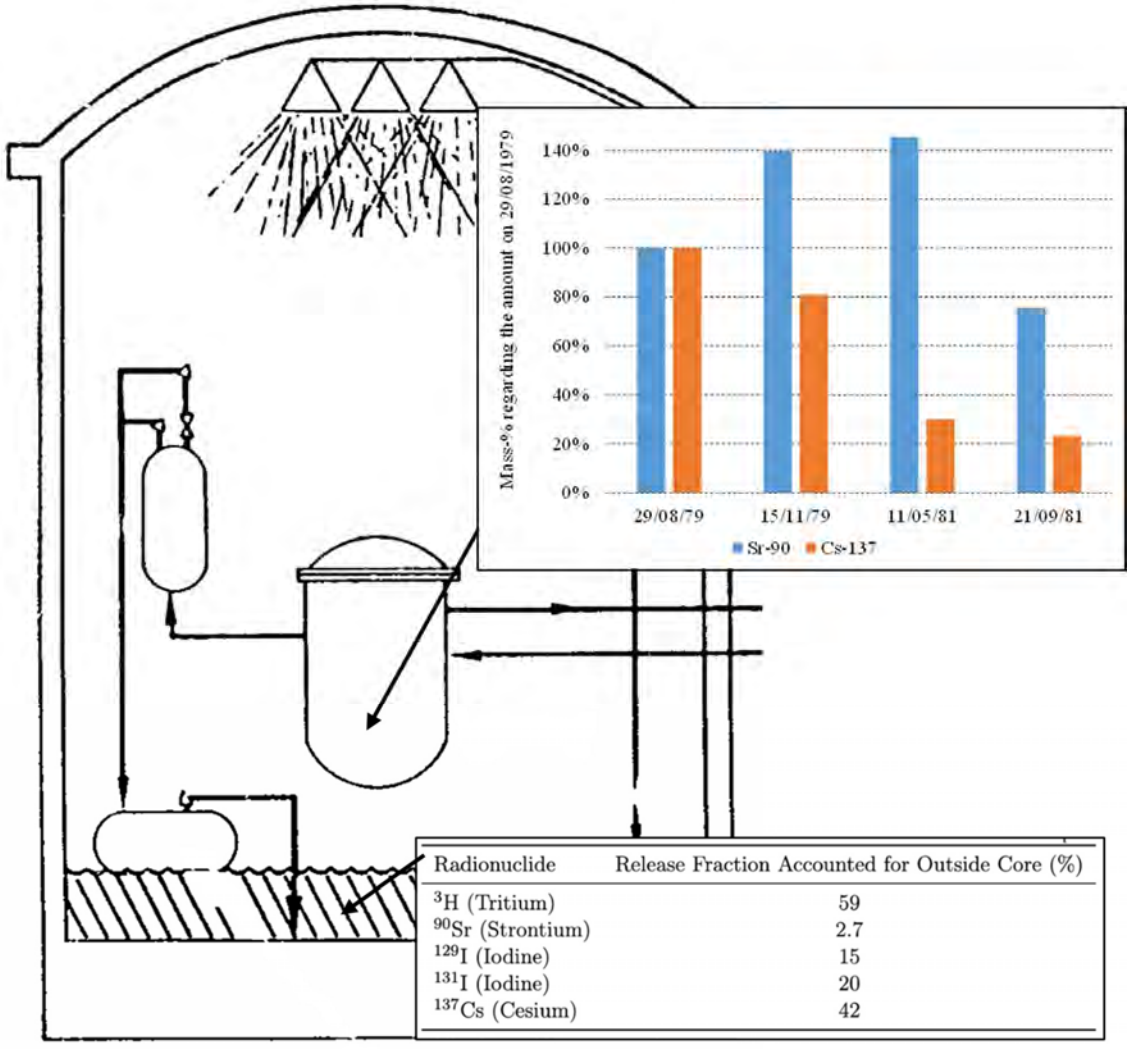
1. INTRODUCTION

Ensuring safe long-term cooling after a meltdown event is a major technical challenge. A current key issue regarding the post-operation at Fukushima Daiichi nuclear power plant is the potential and actual leaching rates of radionuclides from the solidified materials of the degraded nuclear reactor into the surrounding liquid. In the frame of the decommissioning activities, a huge amount of contaminated water needs to be treated. As the damaged reactors were cooled by injection of water, these amounts of water were exposed to contamination. As part of the EC Euratom SOCRATES project, comprising a consortium of 18 institutions from nine countries, the knowledge and modelling of long-term leaching of radionuclides from molten core material is being enhanced.

Data from the accident at Three Mile Island's Unit 2 (TMI-2) nuclear power plant demonstrate the scale of this challenge, with large amounts of the core inventory found outside the reactor core. In the frame of the decontamination efforts at the damaged TMI-2 reactor, investigations have been conducted regarding the

distribution of fission products within and outside the reactor cooling system. Analyses of TMI-2 samples confirmed that the majority of released radionuclides, except for ^{90}Sr and ^{144}Ce, were found dispersed in the basement water and sediment. Specifically, measurements showed that 59 % of the ^{3}H, 2.7 % of the ^{90}Sr, 15 % of the ^{129}I, 20 % of the ^{131}I and 42 % of the ^{137}Cs that were initially present in the core could be found outside the core in the reactor building after the accident. [1, 2]

Further, it was investigated how long contaminated components would need to remain in the water in order to be decontaminated. Although it became apparent that the decontamination periods were impractical, it was also found that there was a continuous increase in ^{90}Sr in the cooling circuit, which was attributed to leaching within the RPV. Figure 1 shows the normalised in-vessel measurement values for ^{90}Sr compared ^{137}Cs, as well as the radioactive isotopes detected outside the primary circuit. Following the accident, the reinjection of water and subsequent exchange within the primary system was expected to decrease the concentration of radioactive isotopes, as observed with ^{137}Cs. However, an increase in the concentration of ^{90}Sr was measured during the first 18 months after the accident, before it eventually dropped as well. [1]



Radionuclide	Release Fraction Accounted for Outside Core (%)
^{3}H (Tritium)	59
^{90}Sr (Strontium)	2.7
^{129}I (Iodine)	15
^{131}I (Iodine)	20
^{137}Cs (Cesium)	42

Figure 1. TMI-2 Reactor building source term measurements, based on [1]

Leaching can essentially be described as a function of the kinetic and thermodynamic interactions occurring at the debris-water interface over decades. In severe accident scenarios, the heterogeneity of corium – comprising fuel isotopes, cladding, structural metals and concrete ablation products – presents a challenge to standardized prediction methods. Decommissioning strategies must account for these complex material identities to design effective water treatment. Furthermore, the evolution of the debris physical state – from highly porous to dense solidified ingots – serves as the primary boundary condition for kinetic modelling. [3–6]

In this paper a brief material characterisation to account for specific material properties is given (chapter 2), which is necessary for a fundamental description of the mechanisms related to leaching (chapter 3). Chapter 4 introduces a conceptual framework for the relevant sub-phenomena, which will support the development of leaching models in later stages of the SOCRATES project. The paper includes a brief discussion of uncertainties (chapter 5) and concludes with a summary of the analysis (chapter 6).

2. PHYSICAL AND CHEMICAL CHARACTERIZATION OF CORIUM DEBRIS

The material structure of corium and debris resulting from a reactor core meltdown, particularly in the context of the Fukushima Daiichi accident, is characterized by extreme heterogeneity and a complex two-phase architecture at both the macroscopic and molecular levels. At the macroscopic level, the materials can be considered as corium, i.e. the material that forms during the melting of the fuel elements in the reactor core, and as debris, i.e. the resolidified product resulting from the interaction of molten corium with structural materials or concrete. Debris can be categorised as either in-vessel, interacting with reactor internals (like in TMI-2), or ex-vessel, resulting from the molten core-concrete interaction (MCCI) when the melt reaches the concrete basement. Macroscopic fragments range from dense, stony blocks to highly porous, friable materials. Unlike the glass-like debris found at Chernobyl, which showed a high degree of homogeneity, Fukushima's ex-vessel debris is a complex MCCI product with distinct phase partitioning. In this work, investigations focus on debris resulting from MCCI with silicate concrete, which is typically used in western pressurised water reactors, cf. [7, 8]. [3, 9]

In general, MCCI debris can be considered as a two-phase system consisting of a silicate-rich glassy matrix and various crystalline inclusions. The amorphous phase of the debris is represented by a multioxide silicate with a complex chemical structure that inherits its composition from the ablated concrete (primarily SiO_2, Al_2O_3, and CaO). This matrix is characterized by a network of Si-O-Si bridging bonds and Si-O-M bonds (where M is Al, Ca, or Fe). This phase is significantly more soluble than the crystalline fuel inclusions. During interaction with water, it undergoes incongruent dissolution, where divalent (Ca^{2+}) and trivalent (Al^{3+}) ions are released faster than the tetravalent silicon network, potentially leading to the formation of a silicon-enriched hydrated surface layer [3, 9]

Embedded within the relatively soluble glassy matrix are chemically more stable crystalline structures, where $(U, Zr)O_2$ solid solutions are the predominant crystalline phases consisting of an isomorphic mixture of uranium and zirconium oxides. Previous studies investigated MCCI-representative samples. In [5] a heterogeneous sample was prepared in which the fragments were mainly composed of U (between 64 and 86 wt%), Zr (between 0.5 and 7.5 wt%) and a more homogeneous sample in which the main elements were U (approximately 52 wt%) and Zr (approximately 16.5 wt%). In [9] five debris compositions were produced, each with a different ratio of core to cement components, shown in Figure 2. Investigations show that the $(U, Zr)O_2$ phase in the samples tend to adopt a fluorite structure and can occur as cubic phase dendrites or tetragonal crystallites. Structural materials from the reactor (stainless steel and Inconel) contribute to the formation of metallic and oxide phases. These appear as spinels, specifically $Fe(Fe, Cr, Ni)_2O_4$, which are isomorphic mixtures containing iron, nickel, and chromium [3, 5, 9]

The leaching behaviour of corium is intrinsically linked to the microscopic heterogeneity existing between its amorphous glassy phases and crystalline inclusions. The phase boundaries between the silicate-rich glassy phases and crystalline phases of $(U, Zr)O_2$ solid solutions and Fe-Cr-Ni spinels govern the macroscopic release of radionuclides since the glassy silicate phase often dissolves at rates that are orders of magnitude higher than those of the chemically stable fuel-bearing inclusions. In synthesized Fukushima-type debris, heavy metal silicates are rarely detected, suggesting that uranium and zirconium oxides do not participate significantly in the silicate network. This lack of interaction leaves radionuclides trapped within a relatively soluble silicate glass, while the bulk of the uranium remains in a poorly soluble crystalline state. Consequently, the macroscopic leaching rate represents an average of these individual phase contributions. [2, 3, 5, 9]

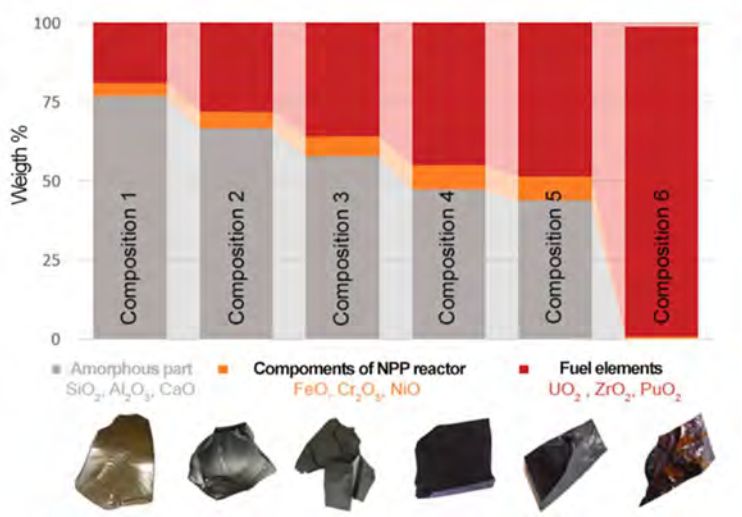


Figure 2. Compositions of synthesized ex-vessel debris samples [9]

3. LEACHING PHENOMENA

Leaching of corium and debris can be described as a multi-stage process governed by various physical and chemical mechanisms. This process is typically divided into several distinct phases, ranging from immediate mobilization to long-term structural evolution. The classification into several characteristic phases here is based on findings from studies with different research focuses on the ageing processes of corium and debris in aqueous environments including studies on vitrified waste. The classification applies to leaching from MCCI debris. The limits of the validity of the conclusions must be critically examined in further studies.

a. Initial Phase: Rapid Release and Surface Wash-off

The first stage of interaction between the debris and water is characterized by the rapid mobilisation of radionuclides located on the external surface or within accessible pores and cracks. Depending on the context this phase is referred to as surface wash-off or the release of the "Instant Release Fraction" (in context of spent fuel) and involves the near-instantaneous dissolution of soluble fission product deposits, such as cesium and iodine compounds. While critical for experimental validation, this fraction is expected to be more limited in corium than in spent fuel due to the high temperatures reached during the melting process, which may have already volatilized a large proportion of these inventories. [1, 10, 11]

b. Early Matrix Alteration: Interdiffusion and Hydrolysis

Once the surface-accessible inventory is depleted, the leaching process enters a stage where the solid matrix begins to degrade. Water molecules penetrate the matrix, while mobile modifier ions (such as Calcium in MCCI debris) exchange with hydronium ions (H_3O^+) from the solution. Simultaneously, the chemical bonds

of the silicate network (in MCCI debris) undergo hydrolysis. Investigations on Fukushima-type debris show, that the dissolution may be incongruent, as discussed in chapter 2. [3, 12]

c. Transition Phase: The Rate Drop

As the leaching progresses, experimental studies on nuclear waste suggest a significant decrease in release rates, possibly by several orders of magnitude. There are two primary scientific perspectives on possible reasons for this rate drop [3, 13]:

1. Chemical Affinity: This approach suggests that the rate decreases as the concentration of silicon in the solution approaches a saturation limit (thermodynamic control) [12].
2. Diffusion Barrier: This view argues that the hydrated surface layer reorganizes into a dense, passivating Interfacial Diffusion Barrier (IDB) that physically inhibits further transport of water and ions [3].

As an integrated approach consideration should be given to couple these mechanisms, suggesting that affinity controls silicon distribution while the IDB governs the diffusive resistance for mobile elements like Cs.

d. Long-Term Phase: Residual Rate and Surface Etching

The system eventually reaches a quasi-steady state known as the residual rate. For MCCI debris, this phase is described as a surface etching process. As the relatively soluble glassy silicate matrix erodes, the surface becomes enriched with a "dusty layer" of low-soluble crystalline oxides, such as $(U, Zr)O_2$ and spinels. This enrichment is critical for long-term assessments, as it governs the properties of the debris surface over decades of underwater storage. [3, 9]

e. Potential Late Phase: Resumption of Alteration

Investigations on vitrified waste show that under specific environmental conditions, a sudden acceleration of leaching can occur long after the rate drop. This phenomenon, referred to as “Resumption of Alteration”, is systematically linked to the precipitation of secondary phases, particularly zeolites (e.g., scolecite). These phases consume silicon and aluminium from the solution and the IDB, effectively stripping the protective properties of the alteration layer and allowing the matrix to dissolve rapidly once more. [12, 13]

4. SUB-MODEL FRAMEWORK

Prediction of the liquid source term requires a fundamental understanding of all relevant sub-phenomena related to any kind of radionuclide release into the aqueous phase. While leaching comprises the time-dependent physical-chemical pathways of solid-state degradation, such as interdiffusion and matrix hydrolysis, the liquid source term is considered as the integrated outcome of all mobilisation processes under specific boundary conditions. This framework develops a multidisciplinary concept breaking down the liquid source term modelling into five primary sub-phenomena, each influenced by the thermochemical boundary conditions. The approaches describing the sub-phenomena are focused on leaching-related mechanisms, whilst also considering rapid mobilization of labile inventories during early-stage, the initial "wash-off". [5]

4.1. Initial Surface Wash-off and Labile Inventory

The initial contact between fuel debris and the aqueous environment is dominated by the “surface wash-off”, which comprises radionuclides located on accessible surfaces and within open pores [11]. TMI-2 measurements provided the first large-scale empirical data on the initial wash-off of radionuclides, documenting that volatile fission products were primarily dispersed in the building’s basement water and sediment [1]. This surface wash-off is critical for model validation and experimental data interpretation, as it accounts for the concentration spikes observed in the early stages of experimental leaching tests [10]. Diagnostic diagrams, which plot normalized release rates against time, typically reveal initial spikes that are

several orders of magnitude higher than steady-state dissolution [14]. These spikes represent the dissolution of fine particulates and the removal of loosely bound ions, such as ^{137}Cs, from the debris surface [3]. Quantifying this labile inventory is essential for immediate safety assessments during debris retrieval and handling. Data from TMI-2 suggests that these surface-accessible radionuclides constitute the main part of the initial liquid source term [1]. While these rapid effects are transient, they establish the chemical baseline for long-term matrix degradation [14]. Furthermore, sea salt interactions can enhance this initial release by altering the ionic strength and ion-exchange kinetics at the debris surface [15]

4.2 Diffusion and Geometrical Kinetics

The transport of dissolved radionuclides within corium is driven by diffusion, necessitating a shift towards mechanistic kinetic modelling. The molecular diffusion coefficient D_i cannot directly be applied here, as it is only valid for diffusion in free solution, not within a porous solid. Different phenomena limit the effective transport [16]. These include interdiffusion of water molecules into the silicate matrix, ion exchange between radionuclides and protons from the cooling water, and the hydrolysis of the Si-O-Si bonds in the silicate network. The "combined resistances" method addresses the simultaneous diffusion of water into the matrix and the outward migration of dissolved species [17]. In the non-stationary and three-dimensional case, Fick's second law applies [3]:

$$\frac{\partial C_i}{\partial t} = D_{i,\text{eff}}\,\nabla^2 C_i, with \quad D_{i,\text{eff}} = \frac{D_i}{R_i}, \tag{1}$$

where C_i is the concentration of the diffusing radionuclide i in the pore fluid and $D_{i,\text{eff}}$ the effective diffusion coefficient which is derived by the molar diffusion coefficient in the solution D_i and the retention factor R_i. The retention factor is an effective parameter that summarises various physico-chemical processes that decelerate transport and includes morphological factors describing the micro-structure of the debris. [3]

In this approach, the geometry of the corium is considered in a simplified form. For spherical geometry, the analytical solution for the differential equation describing the diffusion-controlled release from an object with an initial uniform concentration C_0 and boundary condition $C = 0$ at the surface (infinite reservoir, negligible reverse dissolution) is given (see [16]):

$$M_{diff,i}(t) = m_{0,i}^{\text{diff}} \cdot \frac{S_A}{V} \cdot \sqrt{\frac{D_{eff,i}\,t}{\pi}} \tag{2}$$

Here, the factors involved are the mass of radionuclide i remaining in the body after the instant release $m_{0,i}^{\text{diff}}$, the surface area S_A and the volume of the corium object V. The equation applies to small time scales and demonstrates the characteristic √-behaviour of the diffusion-controlled phase. The surface-to-volume ratio is a key parameter for real corium, but one that is difficult to determine in cases of non-uniform porosity. For long time scales, when the concentration in the solid has decreased significantly, the release approaches an exponential decay behaviour. The short-time approximation (√-regime) is considered valid for time scales ranging from days to years in a first approach.

4.3. Matrix Dissolution

Once the diffusive depletion of the readily accessible inventory is well advanced, the rate of matrix dissolution controls further radionuclide release. Long-term radionuclide release is thus governed by the dissolution of the silicate matrix or crystalline phases of $(U, Zr)O_2$ solid solutions [17]. The Normalized Mass Loss $N_{L,i}$ represents the mass of the total solid matrix that must theoretically be dissolved in order to

reach the measured concentration of a radionuclide C_i in the solution (assuming congruent dissolution) and can therefore be considered a measure of matrix stability [3]:

$$N_{L,i} = \frac{C_i V}{f_i S_A}. \quad (3)$$

By incorporating the surface-to-volume ratio and – with the mass fraction f_i in the solid matrix – the specific inventory, $N_{L,i}$ allows the comparison of the stability of different materials and the mobility of different radionuclides, independent of the specific sample geometry.

For the $(U,Zr)O_2$ matrix, the driving force is oxidative dissolution by radiolysis products, in particular H_2O_2. The dissolution-controlled phase is characterised by linear time dependence. For the $(U,Zr)O_2$ matrix, the dissolution-controlles release under oxidising conditions can be described (for $C \ll C_{sat}$) with the rate of matrix dissolution R_{Matrix} (see [12]). To determine the release rate of a radionuclide i, the dissolution rate normalised to the reactive surface area is multiplied by the given surface area S_A and corrected by the concentration ratio of the radionuclide relative to uranium in the matrix $\frac{c_i}{c_U}$:

$$M_{diss,i}(t) = \frac{c_i}{c_U} \cdot R_{Matrix} \cdot S_A \cdot t. \quad (4)$$

Regarding MCCI debris, perspectively, the breaking of Si-O-Si bonds and the subsequent formation of internal silanol groups should be examined. Surface Complexation Models (SCM) and Surface Precipitation Models (SPM) allow for the mathematical description of interfacial reactions [17]. The kinetic rates derived from these models provide the maximum release potential before thermodynamic attenuation occurs [see 3, 14].

4.4. Thermodynamic Affinity and Interfacial Diffusion Barriers (IDB)

The “rate drop” phenomenon, where leaching rates decrease significantly over time, is governed by chemical saturation and the formation of Interfacial Diffusion Barriers (IDB) [12]. As the concentration of dissolved Si and Al in the leachate approaches equilibrium, the thermodynamic affinity for further dissolution diminishes. Secondary mineral layers, such as gel layers or protective re-condensed silica, act as transport barriers that isolate the bulk material from the solution. While the bulk dissolution rate slows, local chemical environments can still drive the migration of specific high-mobility elements. The IDB model is essential for predicting the stabilization of debris under static storage conditions. The interaction between thermodynamic saturation and protective layer growth determines the transition from kinetic to residual leaching regimes. [3, 9, 12, 13]

4.5. Redox Dynamics and Radiolysis Effects

The radiation field within the debris affects chemical stability through radiolysis of water [18]. Alpha-radiolysis generates reactive oxidants like H_2O_2 which enhance the oxidative dissolution of the $(U,Zr)O_2$ matrix [14]. This process is effectively countered by “chemical buffering” from structural materials like metallic iron [19]. Metallic iron serves as a reducing agent, consuming radiolytic oxidants and maintaining a low redox potential (Eh), which reduces the mobility of redox-sensitive actinides [18]. Diagnostic diagrams illustrate that the presence of Fe can lower the fractional release rates of uranium by several orders of magnitude [14]. Models that ignore these dynamics likely overestimate the long-term leaching of fuel isotopes in high-activity environments [19].

4.6. Influence of Environmental Variables: Sea Salt and pH

Fukushima's environmental context, characterized by seawater exposure, requires specific sub-modelling of salt-debris interactions. Seawater alters radionuclide solubility by providing complexing agents and increasing the ionic strength of the leachate. Furthermore, the pH of the system, which ranges from acidic to highly alkaline depending on concrete interaction, strongly influences dissolution rates. Experiments show that Si and Al release rates are minimized at neutral pH but increase significantly under acidic and basic conditions. These pH-dependent dissolution profiles directly control the exposure of fuel-bearing phases to the aqueous environment. Including these variables in the predictive model enables site-specific effects to be considered. [3–5, 15]

5. DISCUSSION OF UNCERTAINTIES

Uncertainties in leaching prediction involve the risk of leaching "resumption" caused by secondary phase precipitation, such as zeolites. Zeolite formation consumes dissolved silica, lowering the saturation level and driving further matrix degradation. The altering processes influencing the leaching behaviour is schematically shown in Figure 3. Additionally, mechanical degradation, including cracking and exfoliation, can increase the effective surface area (S_A) beyond geometric estimates. Such structural failures potentially lead to release rates significantly higher than those predicted by initial models. Validation is achieved by comparing model predictions with suitable experimental data or the observed chemical composition of the Fukushima reactor cooling water. Long-term irradiation effects on the $(U,Zr)O_2$ solid solution also remain a subject of active study. [3, 5, 9, 13]

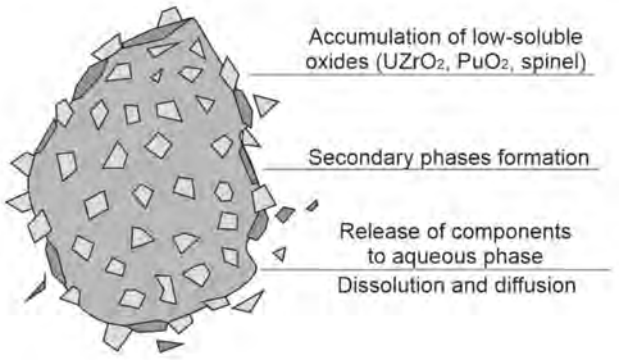

Figure 3. Altering processes influencing the leaching behaviour [9]

6. CONCLUSION

This paper addresses the technical challenge of predicting the liquid source term after core melt accidents such as those at Fukushima Daiichi or TMI-2. The overall objective is to improve the mitigation and monitoring of the release of radionuclides into the cooling water during decommissioning. The pronounced material heterogeneity of the corium, consisting of fuel, claddings, structural metals and concrete ablation products, prevents the application of standardised prediction methods. Corium debris, especially from the melt-concrete interaction, is considered as a complex two-phase system consisting of an amorphous, glass-like silicate matrix (based on concrete components) and embedded chemically more stable crystalline phases, such as the $(U,Zr)O_2$ matrix or Fe-Cr-Ni spinels. The glass phase shows a higher solubility than the crystalline components and is subject to incongruent dissolution. The leaching process is described in terms of five mechanistic phases. These take into account the rapid mobilisation of the labile inventory, early matrix dissolution up to long-term effects.

The methodology proposed for the prediction of long-term radionuclide leaching from Fukushima corium debris is based on a multidisciplinary approach that integrates physical, chemical, and mathematical sub-models. The model framework is intended to bridge the gap between laboratory-scale data and long-term/multi-scale projections. By incorporating matrix dissolution, redox dynamics, and environmental variables, the framework aims to become a reliable tool for decommissioning safety assessments. The integration of the sub-models should consider the complex material structure.

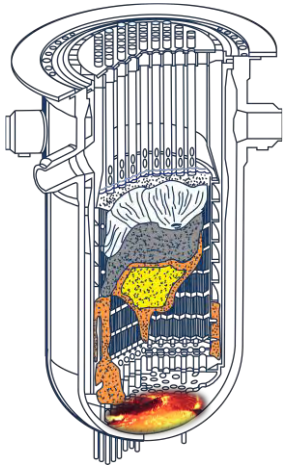
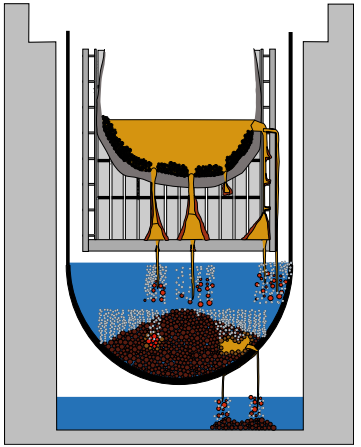
Source Term Analysis

- Possible fission products (FP) release during and after a severe accident
- Early Accident Phase
  - Release of volatile FP (e.g. Kr, Xe, I)
- Late Accident Phase
  - Relocation of core material, formation of debris beds
  - Possible RPV failure
  - Release of semi and low volatile FP (e.g. Mo, Ba, Sr)
- Long-Term
  - Fukushima Daiichi: 15 years of water cooling
  - Continuous flow of contaminated water requiring complex treatment
  - Release of radionuclides from debris through leaching (e.g. Cs, Sr, actinides)





PSS Plant Simulation and Safety

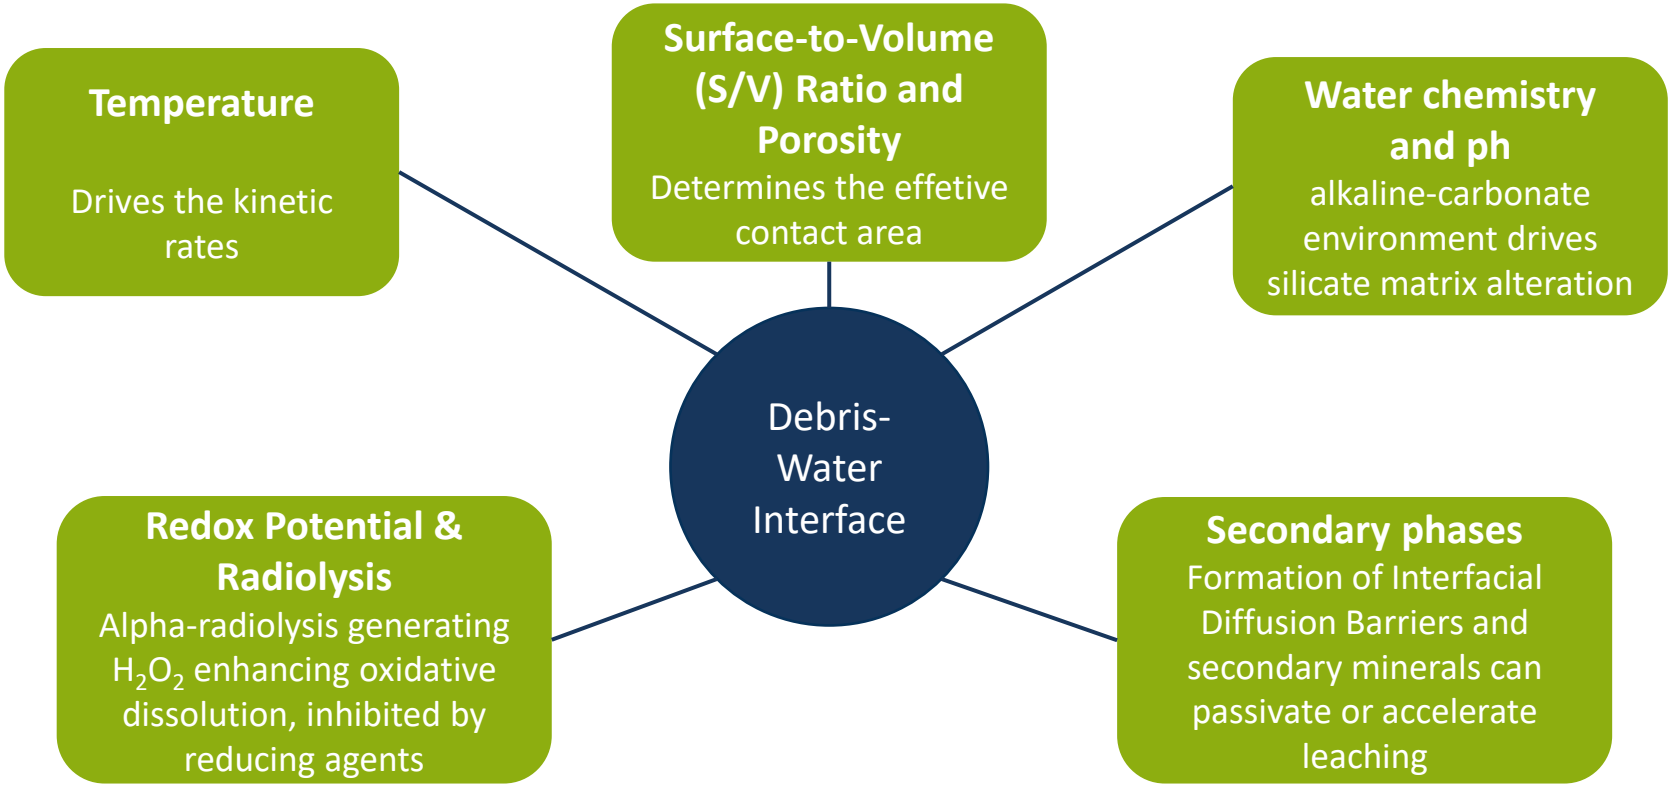
Leaching: Governing Parameters and Boundary Conditions



PSS Plant Simulation and Safety
Prof. Dr.-Ing. Marco K. Koch
RUHR UNIVERSITÄT BOCHUM
RUB

Model Framework: Basic Ideas

Instant Release (Surface Wash-off)	Diffusion-Controlled Release	Dissolution-Controlled Release
• Rapid mobilisation of species on surfaces	• Slow migration of species along grain boundaries and pore networks • Kinetics: Follow a characteristic $\sqrt{t}$ dependence	• Oxidative dissolution of debris matrix • Kinetics: Linear dependence over time

$$M_{total,i}(t) = M_{IR,i} + M_{diff,i}(t) + M_{diss,i}(t)$$

- Each term representing a different release mechanisms
- Parameters should be derived from independant thermodynamic and strucural variables

PSS Plant Simulation and Safety
Prof. Dr.-Ing. Marco K. Koch
RUHR UNIVERSITÄT BOCHUM
RUB

Model Framework: Mathematic Approaches

Instant Release

Variable: $f_{IR,i}$
Instant Release Fraction

- Determined by intertial history, volatility of species and accessible porosity

$$M_{IR,i} = f_{IR,i} \cdot m_{0,i}$$

Diffusion

Variable: $D_{\mathrm{eff},i}$
Effective Diffusion Coefficient

- Governed by internal tortuosity, pore networks and temperature
- Scales with S/V ratio

$$M_{diff,i}(t) = m_{0,i}^{\mathrm{diff}} \cdot \frac{S}{V} \cdot \sqrt{\frac{D_{\mathrm{eff},i} \cdot t}{\pi}}$$

Dissolution

Variable: R_{Matrix}
Fractional Matrix Dissol. Rate

- Governed by redox potential and H_2O_2 concentration
- Opposing mechanisms: oxidative dissolution and chemical buffering by structural metals

$$M_{diss,i}(t) = \frac{c_i}{c_U} \cdot R_{Matrix} \cdot S \cdot t$$

Model Framework: Parameter and Uncertainties

Parameter	Reference value	Range	Source
$f_{IR,Cs}$	20 - 35 %	5 - 50 %	Kirishima et al. 2015
$f_{IR,U}$	0,05 - 0,1 %	< 0,5 %	Kirishima et al. 2022
D_{eff}	10^{-9} m²/s	10^{-9} - 10^{-11} m²/s	Riba et al. 2020
R_{Matrix}	10^{-6}-10^{-7} /d	10^{-5} - 10^{-8} /d	Nakayoshi et al. 2020
S/V	material-specific	Factor of 100	Benson et al. 2001

- Overall uncertainty: roughly 3 orders of magnitude
- Challenges for the acquisition of reliable material data

PSS Plant Simulation and Safety
Prof. Dr.-Ing. Marco K. Koch
RUHR UNIVERSITÄT BOCHUM
RUB

Model Framework:
Limitations and systematic uncertainties

- Temperature range: 20 – 100 °C
- Homogenity assumption
  - Model approach assumes debris to be chemically and structurally homogeneous to allow for LP code integration, neglecting the micro-heterogeneity of the phases
- Missing spatial resolution
  - Averaging out local saturation effects
- Simplified chemistry
  - Neglection of secondary phases (e.g. zeolites)
  - pH changes treated via static adjustments rather than dynamic equilibrium
- Handling the uncertainty band of parameters

PSS Plant Simulation and Safety
Prof. Dr.-Ing. Marco K. Koch
RUHR UNIVERSITÄT BOCHUM
RUB

CONCLUSION

- Review of leaching mechanisms and debris properties
  - Element-specific release paths
  - Heterogeneity of debris as a major challenge
- Development of a conceptional framework for modeling of leaching rates of radionuclides
  - Three physically transparent terms
  - Parameters derivable from literature
  - Possibility of extension the model to include boundary conditions not yet considered/investigated
- Validation needs
  - Long-term experiments (>1 year)
  - Investigation on the temperature dependence of $(U,Zr)O_2$ dissolution rate
  - D_{eff}: Measurement with known porosity/tortuosity

ABSTRACT

With the growing interest in advanced design fuels and particularly Cr/Al-doped fuel, Cr-containing cladding and the consideration of Fe-Cr-Al claddings on the longer-term, ASNR and the Source Term (ST) community partners have decided to launch an international OECD research initiative, called FORESEEN (2026-2029), to investigate the effects of chromium and aluminium on the behaviour of fission products under severe accident conditions and their potential impacts on ST.

A comprehensive set of research though OECD international and EU-programs investigated the source term and fission products behaviour of "historic" Light Water Reactor. Nevertheless, recent reviews on the State of the Art on Light Water Reactor Accident-Tolerant Fuels (NEA 7317, NUREG/CR-7283 and NEA 7576 reports) pointed out the lack of knowledge about behaviour of advanced fuels during severe accident. The objective of the FORESEEN project is to assess whether the presence of Cr and Al might affect the behaviour of FPs during their transportation in the RCV as well as on their behaviour in sump and containment, thereby impacting the source term. The impact of chromium itself has to be assessed considering vaporisation of activated ^{51}Cr or formation of the highly toxic Cr-VI oxidation state. The FORESEEN project is organized in two axis: i/ FP transportation in the RCV. Tests will be carried out at ASNR's CHIP facility to study Cr and Al interaction with the main volatile FPs and its impact on deposition and transport ii/ FP chemistry in the containment. Experiments at the ASNR's EPICUR facility, under irradiation, will focus on Cr and Al influence on FP behaviour in the containment/sump, including liquid phase and aerosol chemistry.

Beyond improving the understanding of the underlying phenomenology, the main objective is to extend the validation database and, if needed, update the SA simulation tools to cover these new fuels.

KEYWORDS

Advanced Fuel, Chromium, Aluminium, severe accident, source term

1. INTRODUCTION

Among the various designs of advanced fuel, chromium-doped fuel has received particular attention from manufacturers. Its increased grain size is expected to mitigate pellet-clad interaction and reduce Fission Gas Release (FGR) during reactor operation [1], and potentially under LOCA conditions [2]. Similarly, chromium-coated and Fe-Cr-Al claddings are being considered to enhance fuel protection during accidents. However, international assessments have identified significant knowledge gaps regarding the behavior and release of chromium and aluminum under severe accident (SA) conditions [3],[4].

Releases of chromium and aluminum from doped fuel or from Cr- and Al-containing claddings are expected under SA scenarios involving extended core degradation. The potential release of these elements and their interactions with other fission products during transport through the reactor coolant system (RCS) represent key concerns [5]. The chromium and aluminum content in such a core can be substantial; for example, chromium may reach several hundred kilograms in the case of Cr-doped fuel and Cr-coated claddings, Aluminium is present in smaller quantities than chromium, typically up to a few tens of kilograms, though the amount can be higher if Fe-Cr-Al claddings are used. These amounts are higher than the quantities of fission products present in spent fuel, such as caesium (~150–200 kg), molybdenum (~200 kg) and iodine (~10–20 kg) [6]. Significant chromium /aluminium release could have multiple consequences, including chemical or radiological toxicity following the release of activation product such as ^{51}**Cr** ($t_{1/2}$ = 27 days). Cr and Al high reactivity may also alter the physico-chemical behavior of other volatile fission products (Cs, Mo, I), potentially modifying the source term released into the containment and, possibly, the environment.

Over the past decades, extensive experimental and modelling research has significantly advanced our understanding of fission product behavior. This knowledge has been incorporated into simulation tools such as ASTEC, MELCOR, and AC², enabling the estimation of releases during the short- and medium-term phases of an accident scenario. Such ST evaluations support effective accident management plan and the application of countermeasures to protect populations. The central challenge is to determine how the presence of chromium and aluminum may affect the transport of radioactive fission products into the containment and in which extent they will modify long term behavior in the containment building.

In this view, ASNR has submitted the international OECD project **FORESEEN (2026-2029)** to investigate the effects of chromium and aluminium on fission product behaviour under severe accident conditions. The findings will inform the development of severe accident simulation tools, to accurately model these new fuel and cladding types. To investigate this range of phenomena, the **FORESEEN** project is structured around two complementary axes.

- **Axis 1** focuses on fission product transport within the reactor coolant system (RCS). Experiments will be conducted at ASNR's **ACCRAS** and **CHIP** facilities, aiming to evaluate the interactions of chromium and aluminium with fission products and their influence on deposition and transport behaviour.
- **Axis 2** addresses fission product chemistry within the containment building. Tests performed at the **EPICUR** facility, under irradiation, will examine the effects of chromium and aluminium on the liquid source term considering precipitation, vaporization, or solubilization of fission products in the sump—as well as on aerosols within the containment.

The objectives, work plan, as well as the current state of the art and identified knowledge gaps, are described in further detail below.

2. FP TRANSPORTATION IN THE RCV IN PRESENCE OF CHROMIUM AND ALUMINIUM

2.1. Chromium and aluminium volatilization and reactivity in RCS conditions during a SA

The release of Cr species from the degraded core according to SA scenarios can be significant in the temperature range (1400-2000°C) where the volatilization of the main FPs (Cs, I Mo) is observed [3]. Cr_2O_3 volatilisation under reducing conditions is mentioned in the literature ([7] to [14]) whereas in oxidizing conditions (under air or air/water vapour), the formation of volatile Cr- species (as Cr(VI) as oxide or oxo-hydroxide) is well known ([7] to [13],[15]). Simulation at thermodynamic equilibrium (NUCLEA Tool box

calculations, Figure 1.1) indicates indeed that in pure steam conditions Cr vaporization becomes significant from 1450°C on (1% of Cr vaporized), at 1550°C it amounts up to 8% and is completed just above 1700°C. $Cr^{(IV)}O_2$ dominates in the vapour phase, but $Cr^{(VI)}O_3$ and $Cr(VI)O_2(OH)$ species can be formed too. In Steam/air mix, vaporization starts at 1200°C, is completed close to 1600°C and $Cr(VI)O_3$ is the main vaporized species. In the solid phase (below 1500-1600°C) Cr_2O_3 remains the most stable species.

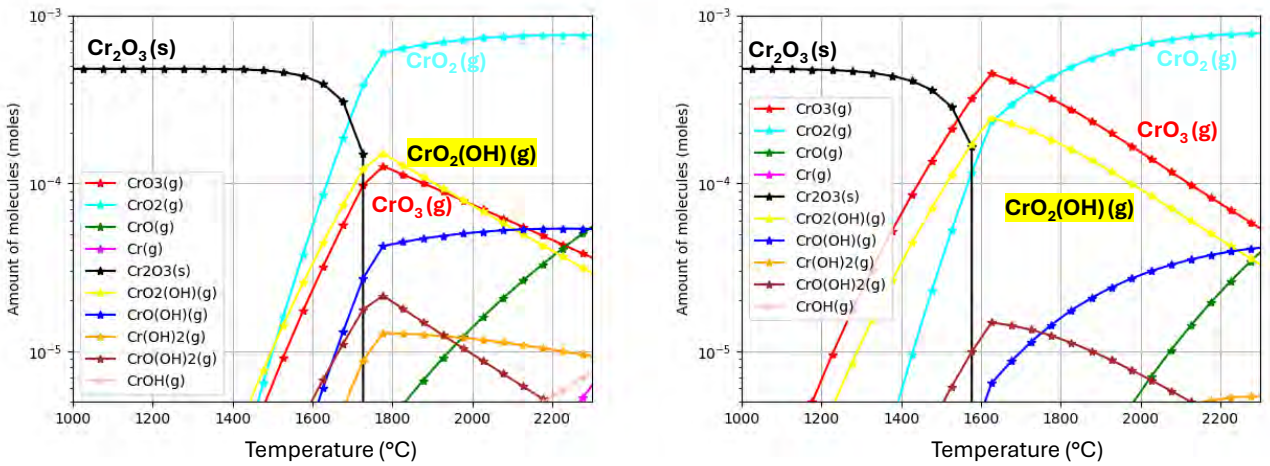

Figure 1: Predicted chromium species at thermodynamic equilibrium as a function of temperature (1000–2200 °C) in steam (left panel) and steam/air atmosphere (right panel).
*Simulations were performed using the **NUCLEA Toolbox** with dataset **DB SGSUB_23-1** under the following initial conditions: Cr = 50 mg, P = 1 bar. For the steam-only case (left panel), the molar ratio $n_{steam}/n_{Cr} \approx 1.7$, with argon added to maintain the same non-condensable gas volume as in the steam/air case. For the steam/air case (right panel), the atmosphere consists of 80% steam / 20% air, with $n_{steam}/n_{Cr} \approx 1.7\times10^4$ and $n_{O2}/n_{Cr} \approx 800$.*

Depending on the atmospheric and temperature conditions, substantial amounts of vaporized chromium species can be transported in the reactor coolant system (RCS) alongside the main volatile fission products (I, Cs, Mo, Te) and control rod materials (SIC, B_4C), with which they may react. Chromium's reactivity with iodine is not considered as a major mechanism. In contrast, chromium is known to react with caesium to form caesium chromates ($Cr_xCs_yO_z$) under oxidative atmospheres [16], though the formation of Cs–Cr species cannot be excluded in experiments simulating TMI-2 [17] and the Fukushima-Daiichi accident conditions [18]. Chromium can also react with molybdenum to produce chromium molybdates such as $CrMoO_4$ or $Cr_2O_3\cdot3(MoO_3)$, the latter potentially forming even in steam environments [19]. The formation of other metallic chromates involving silver, cadmium, or indium is likewise possible [20],[21].

This high chemical reactivity can significantly alter the nature of species released into the containment vessel. The effect is particularly important because chromium can indirectly influence iodine behavior:

- Chromium may act as a sink for Cs, Cd, or Ag, reducing the scavenging effect of these elements on iodine and thereby promoting gaseous iodine transport through the RCS.
- Chromium can also act as a molybdenum scavenger, preventing the formation of other metallic molybdates (e.g., Cs, Ag, Cd…), which may promote the formation of metallic iodides.

In high-temperature steam environments (>1000 °C), Fe-Cr-Al exhibits superior performance compared to a Cr_2O_3 protective layer due to the formation of a stable, corundum-type α-Al_2O_3 oxide layer. This layer

generally forms a uniform, columnar-grained protective coating across the surface [22], even though Cr_2O_3 tends to evaporate above 1000 °C [23].

For alumina, in steam-rich atmospheres, it was observed that solid alumina can react to form the volatile $Al(OH)_3$ species at elevated temperatures [24]. According to experimental measurements presented by Opila et al.[24], partial pressures of $Al(OH)_3$ in the 1600-1800°C range (0.1 to 1 Pa) are of the same order of magnitude as those of the volatile fission products released in the RCS in severe accident conditions (lower bound). Therefore, reactivity of volatile aluminum compounds with other volatile species (FPs or control rod material) cannot be ruled out.

The Al-Cs system is not reactive [25]. On the contrary, the formation of aluminium molybdates ($Al_2(MoO_4)_3$) by solid reaction between $Al(OH)_3$ and molybdenum oxide above 973K is reported by Matsumoto et al [26]. Knowing that Mo chemistry governs the overall behavior of Cs-chemistry and thus of I- chemistry [27], [28], the possible influence of Al should be investigated. In addition, reactivity between aluminium oxide and borates species cannot be excluded in conditions prevailing in the RCS in SA, as expected from the Al_2O_3-B_2O_3 binary diagram [29]. Finally, direct reaction of iodine with aluminium metal can be expected [30] resulting in the formation of AlI_3 compounds (strong exothermic reaction), even in the presence of a protective layer of Al_2O_3.

2.2. Experimental work proposal

The proposed work aims at two primary objectives: (i) to generate the knowledge necessary for developing chemical models that account for chromium reactivity under RCS conditions, and (ii) to validate these models to ensure confidence in their application to reactor scenarios. To achieve these objectives, the experimental strategy combines **analytical-scale experiments**—partly conducted within an ongoing PhD project—with **semi-integral tests** to be carried out in the CHIP facility.

Under the high-temperature conditions prevailing in the reactor coolant system (RCS), thermal reactions dominate over radiolytic processes; therefore, experiments will be conducted using natural simulants for both fission products and chromium.

2.2.1 Analytical tests

These tests will be conducted in the **ACCRAS** device (Figure 5), designed as a high temperature open flow reactor. Since surface conditions can influence chemical reactivity, the main line (alumina tube) will be modified (i) to minimize unwanted high-temperature reactions—achieved by lining the high-temperature zone (1500–1100 °C) with yttria-stabilized zirconia (Zr-Y8), which is unreactive with chromium oxide vapors, unlike alumina; and (ii) to reproduce surface conditions at lower temperatures (900–150 °C) representative of the RCS during a severe accident, using pre-oxidized stainless steel or Inconel surfaces.

Chemical system with increasing complexity, involving up to three elements of interest, will be investigated. First, volatilization/ transport behaviour of chromium or aluminium alone in specific atmosphere (reducing or oxidising) will be considered. Mix with precursors representative of the main volatile fission products (Cs, Mo, …) will be then studied. All species will be vaporized from crucibles placed directly in the line. Vaporization temperature and atmospheric composition will be adjusted to achieve different Cr or Al/FP ratios (either in excess or default), thereby covering all relevant scenarios. The same thermal gradient will be applied across all tests to ensure consistent conditions.

Concerning aluminium reactivity, the effect of boron is of particular interest, as boron aluminates may form under these conditions. On the contrary, air is not included in the test atmosphere, as it promotes the formation of alumina—a highly refractory and relatively unreactive compound.

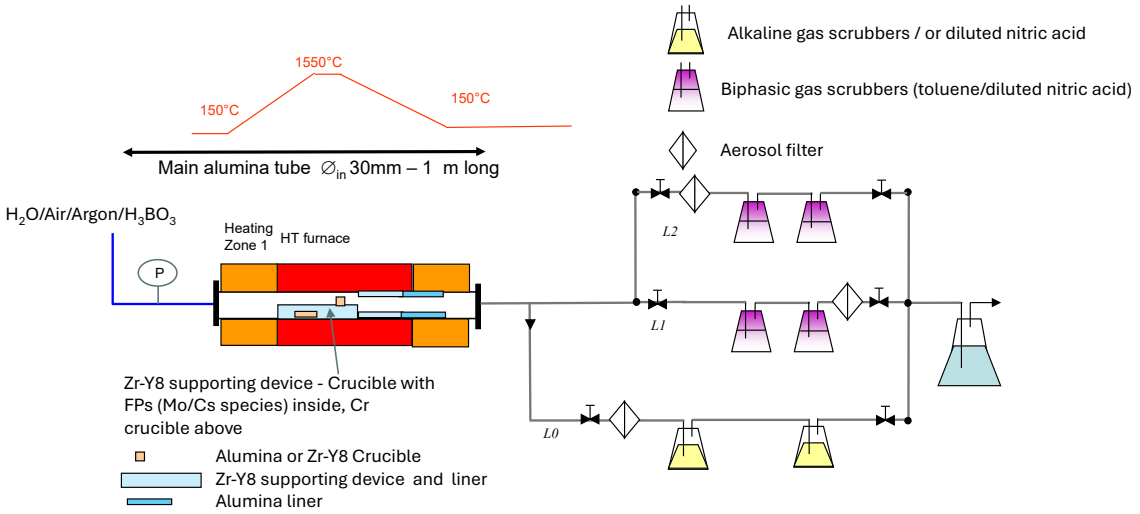

Figure 5: the ACCRAS test device.

The data obtained will include the elemental distribution along the line (deposition and transport) and, as far as possible, the chemical nature of the deposited and transported species (surface characterisation techniques such SEM -EDX, XRD ...). Deposition profiles along the thermal gradient will be determined using collecting plates—Zr-Y8 or alumina plates in the high-temperature zone, and stainless steel or Inconel at lower temperatures. These experiments will subsequently be simulated using the SOPHAEROS module of the ASTEC code.

The key advantage of these analytical-scale tests is their ability to provide accurate and comprehensive data for a simplified chemical system involving up two or three elements if CsI is included as a precursor of caesium. However, they do not address coupled effects, such as the competitive influence of chromium on caesium or molybdenum reactivity and the resulting indirect consequences for iodine transport.

2.2.2 Semi-integral tests: CHIP facility

The CHIP facility consists of a high-temperature furnace, a thermal gradient tube (TGT), and associated instrumentation (Figure 6). Semi-integral tests involve the simultaneous injection of various fission products (FPs) and/or control rod materials, such as silver or boron, into the CHIP line along with chromium. Chromium and aluminium species will be vaporized directly in the high-temperature zone. The possibility of external injection—using an aerosol generator and transport through a separate line to the high-temperature zone—will also be explored.

Four tests are planned. Two of these will investigate the influence of chromium and/or aluminium on the transport of key FPs (I, Cs, Mo) alone in steam atmosphere. Element ratios will be selected to be as representative as possible of severe accident scenarios, with Cr or Al/FP ratios defined based on prior results from analytical tests. Results will be compared with the MoCsI reference test [27]. The third test will

consider the addition of control rod elements (Ag, Cd) and compared to the **CHIP+ test** [28]. The last test will be defined according to results obtained during the project from analytical and semi-integral tests.

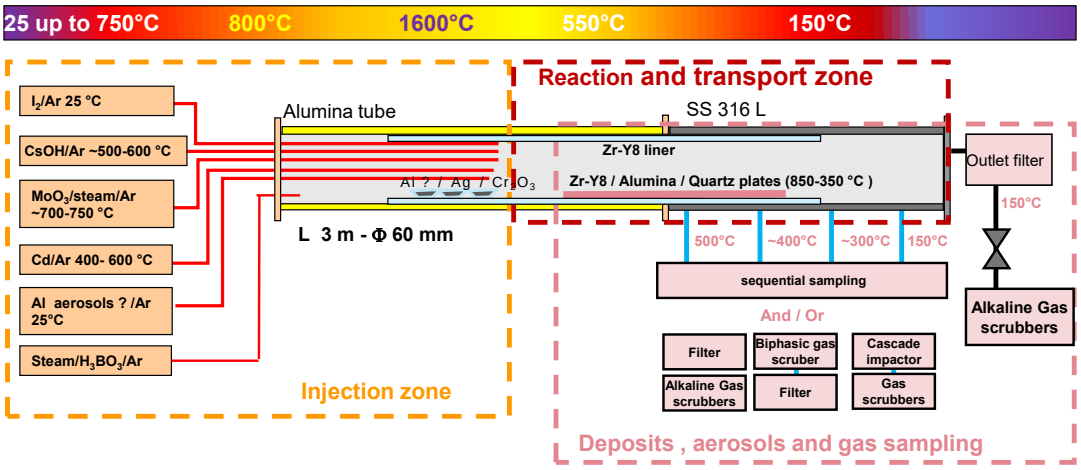

Figure 6: Scheme of the CHIP line - configuration for FP transport studies.

The measured data will include the amount of each element deposited along the TGT, the fraction of gas and aerosol transported at low temperatures, the chemical speciation of iodine (gaseous molecular iodine, other gaseous iodine species, and iodine aerosols), and the aerosol size distribution. Special attention will be given to molybdenum and iodine chemistry with deposited species analyzed using XRD or Raman spectroscopy to identify potential aluminium molybdate, aluminium borates or aluminium iodides compounds, such as and to assess any effects on caesium chemical speciation.

3. FP BEHAVIOUR IN THE CONTAINMENT IN PRESENCE OF CHROMIUM AND ALUMINIUM

The objective is to investigate key phenomena occurring in the containment that may influence accident consequences and management strategies. These include the formation of precipitates, the partitioning between soluble and insoluble species, the chemistry of chromium and aluminium under irradiation, and the agglomeration of metallic particles.

For defining the initial chemical composition for these studies, information on chromium and aluminium releases—both in terms of quantities, chemical forms, and speciation—into the containment will be supported by simulations, in complement to the experimental results obtained in Axis 1. This includes other possible sources – such as containment structural material leaching.

3.1 Chromium and aluminium reactivity in the containment conditions during a SA

To complement the state of the art developed for Axis 1, which focus on gaseous and condensed phases, this section presents key information on the chemistry of chromium and aluminium in aqueous solution, as a preliminary step to studying its impact on containment sump chemistry.

Chromium can exist in several oxidation states, most commonly +2, +3, and +6. The +3 state (Cr(III)) is the most stable, while the +4 and +5 states are relatively rare. Cr(VI) compounds are strong oxidizing agents, whereas Cr(II) acts as a reducing agent. Generally, Cr(III) oxides are poorly soluble, while Cr(VI) species are highly soluble and chemically toxic [31]. Pourbaix diagrams representing the dominant chromium

species in aqueous solution, as a function of pH and redox potential were established at 25°C[32] [33] and 100°C [32]. These diagrams highlight the predominance of insoluble chromium oxide (Cr_2O_3) under most conditions. However, under oxidizing conditions, chromium species in the +VI oxidation state can form [34] and become dominant across the full pH range. Such conditions can be assumed as H_2O_2 generated by radiolysis is known to be a strong oxidant. The oxidation–reduction potential of chromium ($E°(Cr^{3+}/Cr_2O_7^{2-})$ = 1.33 V/ENSH) is comparable to that of ruthenium ($E°(RuO_2/RuO_4)$ = 1.39 V/ENSH), underscoring its strong oxidizing potential. The relative fractions of Cr(III) and Cr(VI) depend on pH, dose rate (which influences the redox potential), and temperature. As for aluminium, only one oxidation state is stable in aqueous media (III).as soluble Al^{3+} ions in acidic media or AlO_2^- in strong alkaline media. In the pH 4-8 range, the dominant species is the poorly soluble Al_2O_3 oxide.

Only limited data are currently available on the chemistry of fission products with chromium and aluminium in aqueous phase. Regarding caesium chemistry, reference [35] indicates the possible formation of highly soluble caesium chromate (Cs_2CrO_4) and less soluble caesium dichromate ($Cs_2Cr_2O_7$). A preliminary review of geochemical databases integrated in tools such as PHREEQC—including NEA, Thermoddem, Thermochimie, and LLNL databases ([36] to [39]), —reveals the presence of precipitated species such as strontium chromate ($SrCrO_4$), chromium triiodide (CrI_3), and strontium iodide (SrI_2), and caesium alumino-silicates but no thermodynamic data for caesium chromate species.

These considerations raise several key questions regarding the influence of chromium and aluminium on fission product chemistry in the containment and, consequently, on the source term:

- What is the chemical speciation of chromium in the containment atmosphere and liquid phases in the short and medium term?
- What is the impact of chromium (particularly Cr(VI)) and aluminium on caesium chemical speciation in solution? Could caesium chromates form? and would this alter the soluble/insoluble fraction of caesium in the liquid phase?
- How might chromium and aluminium affect strontium chemistry? Given that strontium is generally soluble, could the elements influence its soluble/insoluble partitioning in the liquid phase?
- Finally, could chromium impact iodine chemistry in the liquid phase and thereby affect the volatilization of gaseous iodine in the containment atmosphere?

The objectives of Axis 2 is therefore to investigate the behaviour of chromium and aluminium in the liquid phase at around 100°C and under controlled radiation conditions, through experiments using boric acid and sodium hydroxide solutions together with main soluble FPs (Cs, Mo, I, Sr). Soluble and insoluble fractions of Cs and Sr will be investigated, and the potential impact of chromium on iodine volatility assessed.

3.2 Experimental works (EPICUR facilities and laboratory-scale tests)

To address these questions, seven experimental tests are proposed on the EPICUR facility (Figure 8), complemented by laboratory-scale tests involving various analytical techniques (XRD, ICP-MS, SEM-EDX, etc.).

The EPICUR facility is initially devoted to study iodine reactivity under radiolysis and allow the use of labelled iodine (^{131}I) to monitor iodine releases by on-line γ-spectrometry achieving thus very low detection

limits. It is composed of i/ a panoramic irradiator that delivers an average gamma dose rate of several kGy.h^{-1}, ii/ an irradiation stainless steel vessel (4.8 liters) adapted for both liquid or solid samples, itself connected to iii/ a specific iodine filtering device (May pack system). This May pack system contains different species-selective filters for the retention of iodine aerosols, molecular iodine or organic iodides. The volatile species produced in the irradiation vessel are transferred to this May-pack device with an adapted gas flow. On-line gamma measurements are provided by 4 NaI (Tl) counters placed above each stage of filters of the May-pack device. The irradiation vessel is equipped with a pH probe that is directly in contact with the fluid. Preparation and post-test operations of labelled samples are performed in a dedicated radiochemistry laboratory, adjacent to the EPICUR facility.

Several long duration (2-3 days) tests will be conducted in a boric acid–sodium hydroxide solution at pH 7 Firstly, the reactivity of chromium alone will be investigated, to quantify the formation of hexavalent chromium (Cr(VI)) under irradiation, starting from chromium oxide powder. The following tests will consider chromium influence on caesium and iodine chemistry by performing tests in presence of caesium hydroxide and caesium iodide while maintaining the other conditions unchanged. The objective is to determine the soluble fraction of caesium (formation of insoluble caesium chromate species?) and the volatile fraction of iodine formed. Then after, the role of additional presence of strontium under similar conditions will be considered. A second series of tests will investigate the impact of aluminium on molybdenum solubility. Outputs of Axis 1 work will help to define the most relevant precursors to consider. Same conditions (buffer, duration, temperature) as for the previous tests will be applied. The fraction of soluble /insoluble species will be evaluated.

The last test series will investigate the stability under irradiation of multi-component aerosols in the Cr–Cs–I system in the gas phase. Previous results from the STEM2 programme have shown that the decomposition of multi-component aerosols can significantly influence the concentration of gaseous iodine, making this analysis particularly relevant.

In parallel, laboratory-scale tests will be conducted at ~100°C without irradiation. In these tests, the behaviour of chromium/aluminium will be examined in the presence of hydrogen peroxide to simulate radiolysis products, with the objective of obtaining complementary data on the influence of temperature, pH, and redox potential on their chemistry.

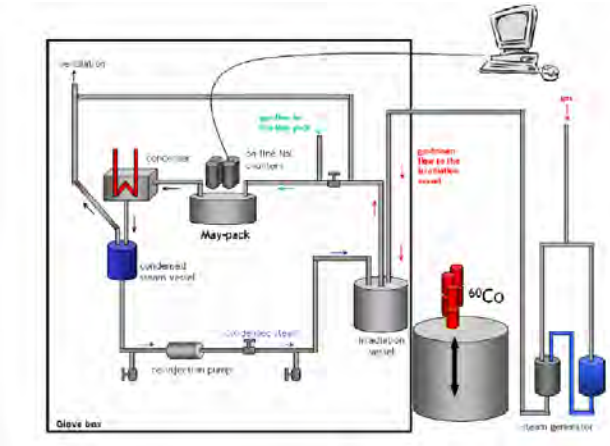

Figure 8: Schematic view of the ASNR - EPICUR facility.

4. CONCLUSIONS

After the Fukushima Daichii Accident, growing interest was put in advanced fuel concepts which involve Cr/Al-doped fuel, Cr-containing cladding and on the longer term, Fe-Cr-Al claddings. Chromium-doped fuel is expected to mitigate pellet-clad interaction and reduce Fission Gas Release (FGR) during reactor operation, and potentially under LOCA conditions. Similarly, chromium-coated and Fe-Cr-Al claddings are being considered to enhance fuel protection during accidents.

Nevertheless, recent reviews on the State of the Art on Light Water Reactor Accident-Tolerant Fuels (NEA 7317, NUREC/CR-7283 and NEA 7576 reports) pointed out the lack of knowledge about the behaviour of these new fuel concept during severe accident. To address this issue, ASNR and several partners have launched an international OECD research initiative, called FORESEEN (2026-2029), to investigate the effects of chromium and aluminium on the behaviour of fission products under severe accident conditions. The FORESEEN project aims to assess whether the presence of Cr and Al may affect the behaviour of FPs during their transportation through the RCV (axis 1) and on their behaviour in the sump and containment (axis 2). The programme has two primary objectives: (i) to generate the knowledge necessary for developing chemical models that account for chromium reactivity under RCS conditions, and (ii) to validate these models to ensure confidence in their application to reactor scenarios. To achieve these objectives, the experimental strategy combines analytical-scale experiments with semi-integral tests.

Analysis of experimental results and their interpretation will be conducted within the Analytical Working Group (AWG). Its primary objective is to propose adaptations to existing source term models to account for the effects of chromium and aluminium on fission product behaviour. Benchmarks and sensitivity analyses will be proposed and conducted.

The outcomes of the OECD FORESEEN program will support partners in enhancing/consolidating their models/safety view and reducing uncertainties on source term assessments for the new fuel/cladding concepts.

ACKNOWLEDGMENTS

ASNR's acknowledges the OECD and EPRI, INL, VTT, KINS, KENTECH university, NRA, SSM, GRS partners for their support and fruitful discussion to elaborate the OECD FORESEEN project.

Fission Products behavior under severe accident with new fuel concepts : THE OECD/NEA FORESEEN PROJECT

Grégoire A.C., Alvarez C., Denis J., Cantrel L.

EMRSAR 2026 – MADRID, MAY 18-22

FORESEEN OECD PROJECT

FissiOn pRoducts bEhavior under SeverE accidEnt with New fuel concepts

OECD/NEA JOINT PROJECT CONCERNING S/T RELATIVE TO ATF FUEL IN SA CONDITIONS

OPERATED BY ASNR

WITH THE FOLLOWING PARTNERS AT THAT TIME: EPRI, NRA, VTT, KINS, KENTECH, SSM

STARTED APRIL 2026 – DURATION 4 YEARS

"It is far better to foresee even without certainty than not to foresee at all."
Henri Poincaré 1854-1912

SA BEHAVIOR OF ATF FUEL

PROPOSAL BUILT FROM CONCLUSIONS OF SOAR & PIRT

- State-of-the-Art on Light Water Reactor Accident-Tolerant Fuels, NEA 7317 (2018)
- Phenomena Identification Ranking Tables for Accident Tolerant Fuel Designs Applicable to Severe Accident Conditions, NUREG/CR-7283 (2021)
- WGFS TOP-ATF which included Source Term issue

These reports pointed out the lack of knowledge about behavior of ATF in severe accident conditions.

The FORESEEN should deepen the:

➔ impact of chromium and aluminium on fission product release (Cr-doped fuel and Cr-coated Zr& Fe-Cr-Al claddings)

➔ role of these elements on transport and containment chemistry

And thus, extent the validation database of the SA simulation tools to these new designs of fuel for ST assessment

THE MAIN EXPECTED PHENOMENA ARE :

- Formation of chromium or aluminum based species modifying the Cs & Mo chemistry and indirectly the iodine one
- Chemistry/transport through the RCS and in the containment

CHROMIUM AND ALUMINIUM IN ATF FUEL

LARGE AMOUNTS :

Chromium: several hundred of kilograms in the case of Cr-doped fuel and Cr-coated claddings

Aluminium in smaller quantities : up to a few tens of kilograms, though the amount can be higher if Fe-Cr-Al claddings are used

In comparison the quantities of fission products present in spent fuel amounts up to :

Caesium ~150–200 kg,

Molybdenum ~200 kg

Iodine ~15–20 kg

Cr AND Al: DIRECT AND INDIRECT EFFECT ON THE SOURCE TERM

- Cr dopant could have antagonist effects on fission product release from degraded fuel (increase the fission product path for release & increase their diffusion coefficient)
- Cr and Al volatility (cladding) can be significant above 1400 °C
- Literature or past post-accident analysis (TMI, Chornobyl, Fukushima-Daichii) show possible interaction between Cr or Al and several FP like Mo and Cs ➔ indirect impact on the gaseous iodine formation with antagonist effects
- Under neutron irradiation, ^{50}Cr (13% of natural Cr) form ^{51}Cr which is a γ-emitter with a half-life of 27,7 d and high mass activity (3,4 10^{15} bq/g) – impact of the volatilized Cr on ST
- Cr exists with several oxidation states (principally Cr-III and Cr-VI) with different impact on solubility : Cr-III under oxide form is rather insoluble whereas Cr-VI is soluble.
- Cr-VI is highly toxic and may be formed by oxidative radiolysis of Cr-III

FORESEEN PROJECT OBJECTIVES

GAIN KNOWLEDGE AND EXTENT CAPABILITY OF EXISTING SIMULATION TOOLS TO COVER THESE NEW FUELS AND ASSESS ST FOR EACH PHASE OF THE SEVERE ACCIDENT

FPs release from irradiated fuel samples : Cr or Al impact on kinetics, species and quantities of FP releases ? ➔ to be addressed in a second phase

AXIS 1 focuses on the chemistry/transport of fission products within the reactor coolant system (RCS) Experiments will be conducted on dedicated facilities hosted at ASNR, aiming to evaluate the interactions of chromium and aluminium with fission products and their influence on deposition and transport behaviour.

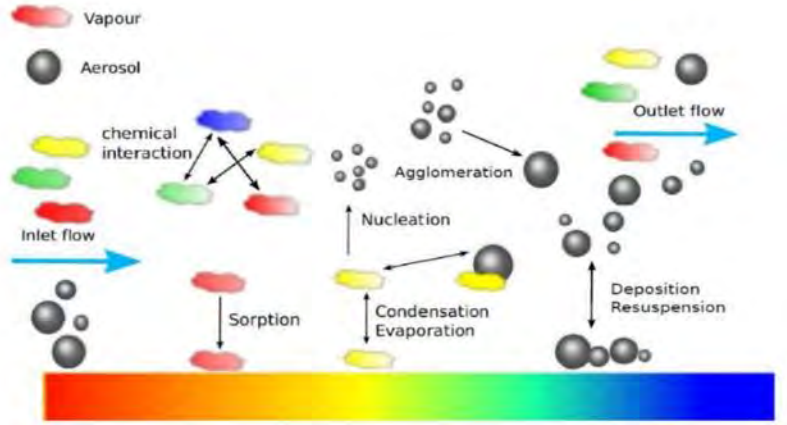
AXIS 2 addresses the chemistry of fission products within the containment building

Tests performed at the EPICUR facility will examine the effects of chromium and aluminium on the liquid source term considering precipitation, vaporization, or solubilization of fission products in the sump—as well as on aerosols within the containment.

AXIS -1 – FP transportation in the rcs in presence of chromium and aluminium

Chemical reactivity and transport in the RCS:

- ☞ **Amounts of FPs deposited inside the RCS**
- ☞ **Chemical speciation of FPs reaching the containment (Gazeous /Aerosol form)**
- ☞ **Intensively studied over the past decades with a focus on iodine chemistry**
- ☞ **Role of Mo: governs the overall behaviour of Cs-chemistry and thus of I- chemistry**



RCS transport : main phenomena to be taken into account

Source : https://research-assessment.asnr.fr/sites/en/files/2024-02/TransportEtChimieDesPF_ASTEC2.jpg.pngportEtChimieDesPF_ASTEC2.jpg.png (834×506)

AXIS 1 – SCIENTIFIC ISSUES

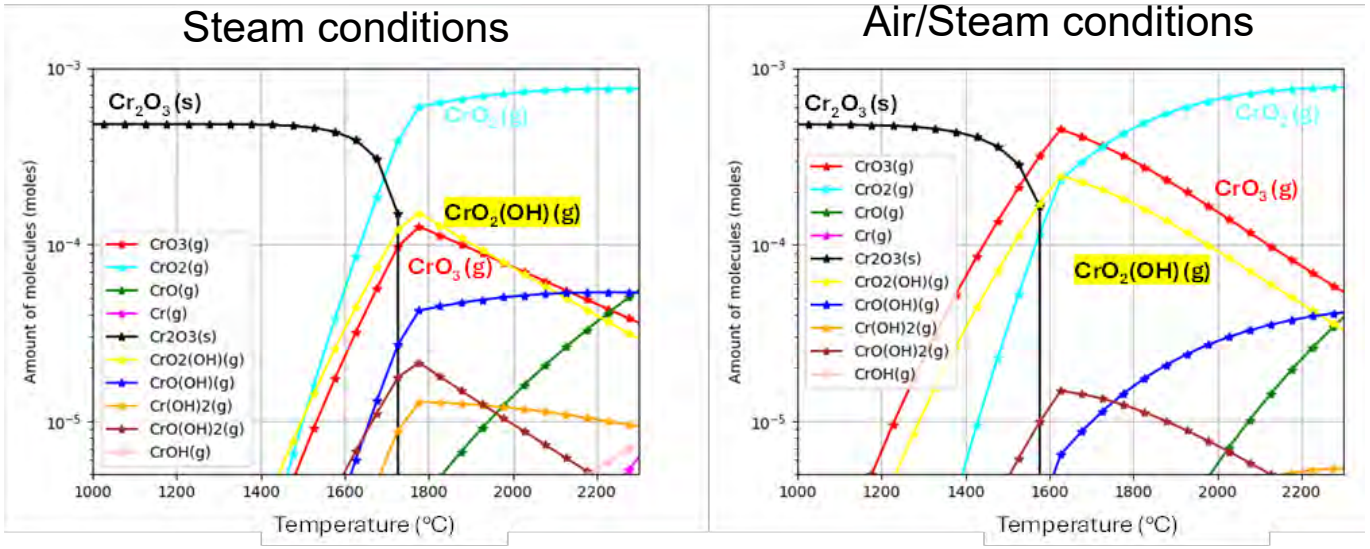
What should be the role of Cr and Al in the RCS chemistry and in which extent it may affect the transport of the FPs (Cs, Mo) and control rod material (Cd, Ag) ?

What would be the consequences for the release of gaseous iodine species at the break

↗ (if Cr act as a Cs, Cd or Ag sink) or ↘ (if Cr or Al acts mainly as Mo sink) ?

Cr Volatility

- **Steam : Vaporization > 1450°C, completed above 1700°C, mainly as Cr(IV)**
- **Air/Steam : Vaporization > 1200°C, completed above 1600°C, mainly as Cr(VI)**



*Simulations were performed using the **NUCLEA Toolbox** with dataset **DB SGSUB_23-1** under the following initial conditions: Cr = 50 mg, P = 1 bar. For the steam-only case (left panel), the molar ratio $n_{steam}/n_{Cr} \approx 1.7$, with argon added to maintain the same non-condensable gas volume as in the steam/air case. For the steam/air case (right panel), the atmosphere consists of 80% steam / 20% air, with $n_{steam}/n_{Cr} \approx 1.7\times10^{4}$ and $n_{O2}/n_{Cr} \approx 800$.*

Al Volatility

- **In high-temperature steam environments (>1000 °C), Fe-Cr-Al exhibits a protective layer due to the formation of a stable, corundum-type α-Al_2O_3 oxide layer**
- **In steam-rich atmospheres, solid alumina can react to form the volatile $Al(OH)_3$ species**

CHROMIUM AND ALUMINUM REACTIVITY IN RCS CONDITIONS

- **Cr-Cs-O and Al-Cs-O systems: Various $Cr_xCs_yO_z$ forms cited in lit.** [2]/some available in thermo DB (as SGPS: **$Cr_2^{(VI)}Cs_2O_7$)**/ not predicted in steam conditions by Facstage calculations / Cs-Cr species formation not excluded in experiments reproducing TMI2[3] and FD [4] SA conditions **. No Al-Cs species referenced ➔ Cr can act as a Cs sink**

- **Cr-MoO_3 system: $Cr_2O_3.3(MoO_3)$ or $CrMoO_4$** cited in literature [1] but not present in thermodynamic data base (SGPS), **$Cr_2O_3.3(MoO_3)$** can be expected in steam conditions (Cr^{III}) **➔ Cr can act as a Mo sink**

- Chromite/Chromate species cited in the literature : **$CdCr_2O_4$, $Ag_2Cr_2O_4$** [5;6]

- **Al-MoO_3:** system expected to be highly reactive – formation of $Al_2(MoO_4)_3$ from $Al(OH)_3$ and MoO_3 precursor occurs above 973K [7] – MoO_3 used a MCC for Al metal surface protection [8]

- **Al_2O_3 –B_2O_3 system:** aluminoborates can form at high temperature entering in competition with cesium borate formation [8]

Oxidative conditions promotes the formation of stable alumina

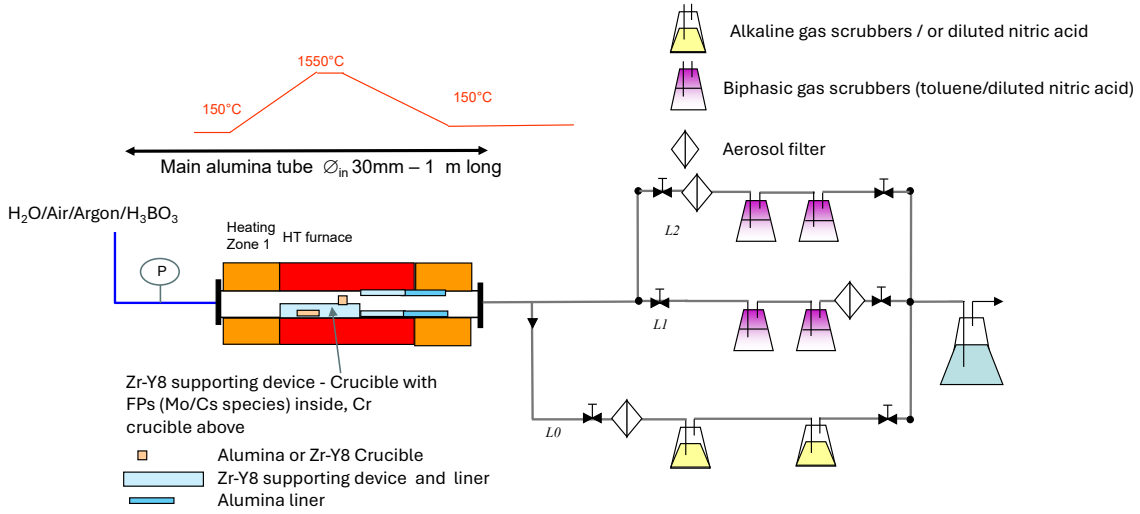
Axis 1: two complementary experimental approaches

Analytical tests

- ☞ Devoted to study Cr or Al transport at high temperature in a simple configuration
- ☞ Influence of carrier gas composition: steam and/or steam/air and/or steam/boric acid/air
- ☞ Interaction with main volatile FPs (Mo or Cs) : investigation of the conditions enhancing reactivity / identification of deposited/transported species
- ☞ Comparison with simulation at thermodynamic equilibrium – identification of needed data



ACCRAS line configuration allows to vaporizes only **two different precursors** in the main line

Carrier gaz (involving up to O_2, H_2O, Boric acid, N_2, Ar) is injected at the main flange inlet

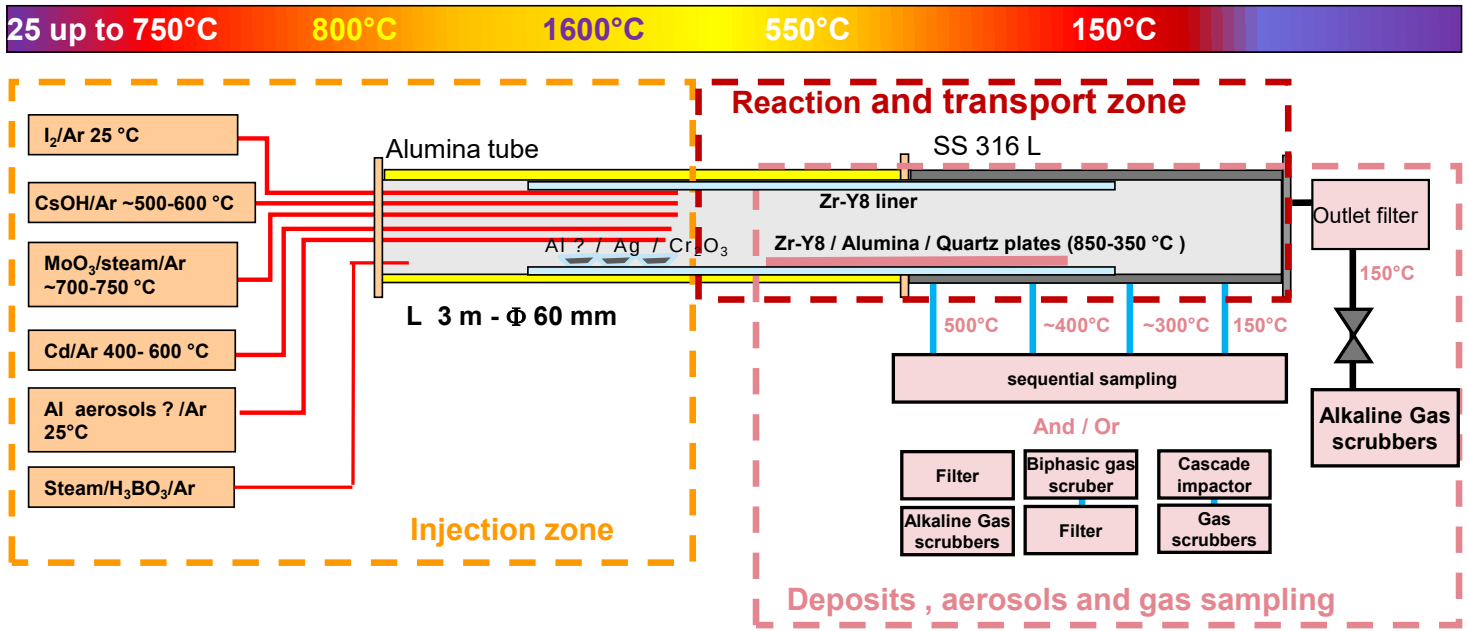
Axis 1: two complementary experimental approaches

Semi integral tests (CHIP experimental set up)

☞ Tests for studying coupled effects on the most representative chemical composition featuring the main volatile FPs and control rod material

☞ Assess influence of Cr/Al on FP transport in more realistic conditions (element ratio, atmosphere conditions)

☞ First tests with Cr of Al + Mo-Cs-I chemical system, then tests with additional injection of CR elements (Ag, Cd, B)



AXIS -2 – FP behaviour in the containment

Introduction

- **Containment chemistry involves gaseous / solid / aqueous phases in steam/ hydrothermal conditions (short term) and radiolytic environment**
  ➔ numerous interdependent phenomena

- **Chromium/Aluminium may affect fission product chemistry in the containment**
  - **Modification of sump chemistry with potential impact on gaseous source term (iodine)**
  - **Insoluble form may be deposited on surfaces leading to higher dose impact on structures (pumps, sump filters …)**

- **Long-Term Severe Accident Management issues:**
  - **Ensure permanent safety and environmental protection against the mid-term consequences involving liquid source terms**
  - **Fission product speciation resulting of chemical process is essential for the development of appropriate accident mitigation devices and measures**
  - **Cooling functions (water recirculation) to be maintained at long term**

- **FORESEEN project complements SOCRATES project (2024), integrating the impact of chromium and aluminium (ATF fuel)**

Axis 2 – scientific issues

Scientific issues:

- **Chemical speciation of Cr and Al inside the containment at short/middle term in gas and liquid phases**
- **Direct impact of cesium chemistry (aerosol composition – cesium solubility)**
- **Direct impact of strontium chemistry (liquid phase - strontium chromate, strontium solubility)**
- **Indirect impact on iodine chemistry to be assessed (volatility)**

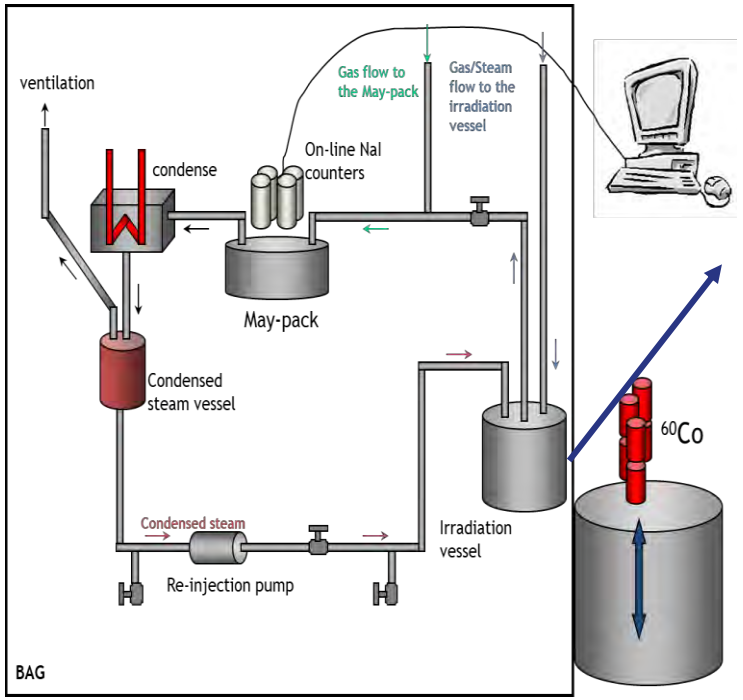
Data of Cr and Al releases (amounts, chemical forms and speciation) inside the containment will be provided from simulations in complements of experimental data of Axis 1 (Cr doped fuel + cladding and/or iron-chromium-aluminum (FeCrAl) alloys)

Technical proposal to study Cr and Al behaviour in CV conditions

Investigate the behaviour of Cr and Al in the aqueous phase at 100°C under controlled irradiation conditions together with main soluble FPs (Cs, Mo, I, Sr). Study of Cs and Sr solubility and the potential impact on iodine volatility .

TESTs in EPICUR irradiator facility

- Long duration (2-3 days) tests in a boric acid–sodium hydroxide solution at pH 7
- Reactivity of chromium (Cr_2O_3) : quantify the formation of hexavalent chromium (Cr(VI)) under irradiation
- Chromium influence on caesium and iodine chemistry : tests in presence of caesium hydroxide and caesium iodide while maintaining the other conditions unchanged . Investigate soluble fraction of Cs and iodine volatility
- The same with addition of strontium ($Sr(OH)_2$)
- Impact of aluminium on molybdenum solubility
- Stability under irradiation of multi-component aerosols in the Cr–Cs–I system in the gas phase



Complementary tests outside EPICUR (High pressure / high temperature reactor)

- Same conditions
- Hydrogen peroxide to simulate irradiation effect

CONCLUSION / PERSPECTIVES

The FORESEEN project aims to assess if Cr and Al may affect the behaviour of FPs during their transportation through the RCV (axis 1) and on their behaviour in the sump and containment (axis 2) – with to primary objectives :

(i) to generate knowledge necessary for developing chemical models that account for chromium reactivity under RCS conditions,

(ii) to validate these models to ensure confidence in their application to reactor scenarios. To achieve these objectives, the experimental strategy combines analytical-scale experiments with semi-integral tests.

Analysis and interpretation of experimental results will be conducted within the **Analytical Working Group (AWG)** with the objective

(i) to propose adaptations to existing source term models to account for the effects of chromium and aluminium on fission product behaviour with a focus on Cr transport / deposit in the RCS in presence of the other main FPs

(ii) To benchmark different simulations tools

ABSTRACT

Filtered Containment Venting Systems (FCVS) allow controlled depressurization and filtration of the containment atmosphere during severe accidents, reducing overpressure and radiological releases. Following the Fukushima-Daiichi accident and the associated challenges with controlled venting, efforts were intensified to improve iodine retention - particularly for organic iodine species. In response, Framatome developed and qualified a dedicated adsorbent section designed to enhance gaseous iodine retention in its existing FCVS applications.

The development and qualification efforts comprised laboratory-scale pre-qualification and subsequent performance verification in the technical-scale JAVA-PLUS facility. The qualification program demonstrates that iodine retention in FCVS adsorbent stages depends on both chemical kinetics and thermo-hydraulic system behavior. Laboratory tests establish intrinsic adsorption performance and material robustness, but do not account for hydrodynamic non-idealities present at full scale. Large-scale testing shows that retention efficiency is strongly influenced by flow distribution, temperature homogeneity, and gas-solid contact, leading to non-linear scaling effects. Adsorption efficiency emerges as a system property, shaped by the interaction of material characteristics and reactor geometry. The observed differences due to scale effects were further analysed using CFD simulations, which confirmed that flow distribution and residence time in the actual design are at least as favourable as in the JAVA-PLUS facility, supporting the transferability of test results.

This paper presents the main outcomes of these efforts, discusses key parameters influencing iodine retention under various operating conditions, highlights key factors for qualification programmes and summarizes practical experiences and lessons learned from retrofit projects considering both dry- and wet-filtration systems installed in NPPs.

KEYWORDS
FCVS, Iodine retention, Adsorbent, Scaling, Reactor application, Experiments, CFD

1. INTRODUCTION

Filtered Containment Venting Systems (FCVS) are implemented in many nuclear power plants as a final severe accident management measure to preserve containment integrity. During severe accident scenarios, decay heat, hydrogen generation, and steam production may lead to a progressive increase in containment pressure. FCVS enable controlled depressurization of the containment atmosphere while filtering

radioactive materials, thereby reducing the risk of containment failure and limiting radiological releases to the environment.

Several FCVS concepts are deployed worldwide, including dry sand-bed filters, metallic dry filters, wet scrubbers, and hybrid filters (e.g. metal-sand-bed) [1]. Wet FCVS rely on scrubbing processes in alkaline solutions to remove aerosols and water-soluble gaseous species. For aerosols, the current FCVS designs have reached a high degree of maturity, and extensive experimental qualification programmes have demonstrated decontamination factors (DFs) – generally defined as ratio of the total mass of a contaminant entering a filtered containment venting system to the mass exiting it - typically exceeding 10^3, including scenarios with high steam fractions and transient severe accident conditions [1]. In contrast to aerosols, gaseous iodine remains a key challenge for FCVS. Iodine is radiologically important due to its volatility and high biological uptake. Under severe accident conditions, iodine can be present in different chemical forms, including aerosol-bound iodides, molecular iodine (I_2), hydrogen iodide (HI), and organic iodides. While wet scrubbing is effective for molecular iodine and hydrogen iodide, organic iodine, most commonly represented by methyl iodide (CH_3I) is only weakly soluble and largely unaffected by conventional scrubbing or standard dry filtration stages. Furthermore, the retention or release of gaseous radionuclides (mainly iodine) from water pools is governed by physical and chemical processes that differ significantly from those affecting aerosol retention in water pools (“pool scrubbing”) [2]. This is because the release of gaseous radionuclides from the pool surface can be largely independent of the mass flow of gaseous radionuclides injected into the pool water, due to other processes occurring in the pool, such as hydrolysis, interactions with surfaces, and the effects of impurities.

Post-Fukushima research has highlighted the potential importance of organic iodine in the residual iodine source term during containment venting. International and European programmes, such as EC-PASSAM project [2], identified organic iodine formation and retention as major contributors to source-term uncertainty. As a consequence, expectations for FCVS performance increasingly include not only high aerosol DFs but also demonstrable retention of gaseous iodine, particularly organic iodine.

To meet the increased expectations for gaseous iodine mitigation, recent FCVS designs and retrofit concepts - already implemented in several nuclear power plants worldwide (such as the Gösgen NPP in Switzerland) - include dedicated adsorbent stages downstream of the primary aerosol retention components. This requires the selection of materials and system configurations compatible with severe accident conditions, including high temperature, high steam content, and fully passive operation. Silver-based zeolites are commonly used for this purpose due to their chemical affinity for organic iodine and their stability in steam-rich environments. The present paper focuses primarily on the performance of wet FCVS systems, particularly configurations incorporating an upstream wet scrubber. However, it also highlights findings and design considerations that could be relevant for application in dry filter technologies - especially regarding the design of an upstream adsorbent stage for gaseous iodine retention.

This paper outlines the testing approach used to select and qualify an additional adsorbent material specifically to enhance gaseous iodine retention in the FCVS system. The new adsorbent stage is designed to be installed downstream of the existing wet (venturi scrubber) and dry (metal fiber filter) filtration stages in a standard FCVS. It is designed to be easily retrofitted into already operating FCVS installations, offering fully passive and reliable operation without the need for active controls or external power. The testing methodology integrates laboratory-scale pre-screening of adsorbent materials, performance verification in the technical-scale JAVA PLUS facility, and supporting computational fluid dynamics (CFD) analyses to assess the suitability of candidate materials for reactor-scale application, with a primary focus on gaseous iodine capture. Particular emphasis is placed on understanding scale effects, identifying key parameters governing iodine retention, and demonstrating the relevance of technical scale experiments under representative boundary conditions to ensure an optimal FCVS iodine retention performance at reactor scale under typical severe accident conditions.

2. DEVELOPMENT AND QUALIFICATION PHASE - REQUIREMENTS

The development and qualification of the adsorbent filter section followed a structured two-phase experimental program designed to meet the requirements of FCVS operation at NPPs following a severe accident. In the first phase, small-scale laboratory tests were conducted to screen candidate adsorbent materials and evaluate the selected material under a range of accident-relevant conditions, including high temperatures, steam-saturated atmospheres, and other relevant conditions such as the effect of containment impurities. Particular emphasis was placed on ensuring that the adsorbent provided sufficient retention for organic iodine with a target decontamination factor (DF) > 50, or retention efficiency > 98%. The adsorbent material also needed to ensure maintaining the requested high retention for molecular iodine (DF > 1000). Additionally, the selected materials were evaluated for chemical and mechanical stability under aging and thermal cycling, and for consistent performance without degradation due to exposure to chemically active gases. To ensure reproducibility and reliability of the test results, the DFs were independently verified by independent experts (TÜV) by employing their own test facilities.

In the second phase, the selected adsorbent's performance was validated in a large-scale test facility replicating the geometric and thermal characteristics of a real FCVS system. This allowed for assessment of the adsorbent's behavior under representative flow rates, pressure conditions, and environmental stresses, to confirm its suitability for field application. The qualification campaign ensured that the adsorbent met all operational and safety requirements, including long-term stability and consistent performance under both normal and accident conditions.

As part of qualification testing, the design requirements for the additional adsorbent stage considered both initial and final containment pressures (up to 8 bar) to preserve containment integrity during venting, including operation in steam-saturated atmospheres at the end of venting at relatively lower pressure (down to 1.5 bar), ensuring robust system performance over complete venting cycle. The adsorbent stage was originally qualified for retrofitting to the Framatome wet FCVS. Later on, conditions relevant to dry filters were also tested. Therefore, the adsorbent material needed to be verified to be chemically and mechanically stable under radiation exposure, high steam content, and in the presence of potential inhibitor gases (e.g. HNO_3, NO_x, HCl) without significant degradation of retention capability. Further, decay heat from gaseous iodine and aerosols must be quantified for FCVS qualification; including this heat load in adsorbent design ensures thermal stability and retention efficiency. Long-term stability under passive stand-by conditions and compatibility with FCVS operational lifetimes (≥20 years) were set as additional requirements.

3. EXPERIMENTAL RESULTS

3.1. Laboratory scale tests

The laboratory-scale qualification program was conducted to (i) pre-select suitable adsorbent materials, (ii) quantify retention efficiencies for CH_3I and I_2 under representative thermal hydraulic conditions as expected during a severe accident (SA), and (iii) verify material robustness against typical severe accident stressors, including elevated temperatures, high humidity, and radiological loads.

Several zeolite variants were evaluated as candidate adsorbent materials. The zeolite variants had different pore structures and sizes, depending on the specific type of zeolite used. One of the parameters varied in the candidate material was the molar SiO_2/Al_2O_3 ratio, in addition to the amount and form of silver. The laboratory scale tests were conducted independently by a third party (TÜV) using their own test facility.

The schematic diagram of the adsorbent test section used for testing at Framatome is shown in Fig. 1. Parametric investigations were performed in testing apparatus consisting of fixed-bed columns typically comprising adsorption columns with bed volumes of approximately 5–20 mL and bed heights of a few

centimetres. Tests were conducted under controlled steam–gas mixtures (0–100 % steam), temperatures of approximately 80–160 °C, and at ambient pressure. Organic iodine was introduced as CH_3I, generally at concentrations on the order of 10^{-8} mol L^{-1}, and for duration of about 1h.

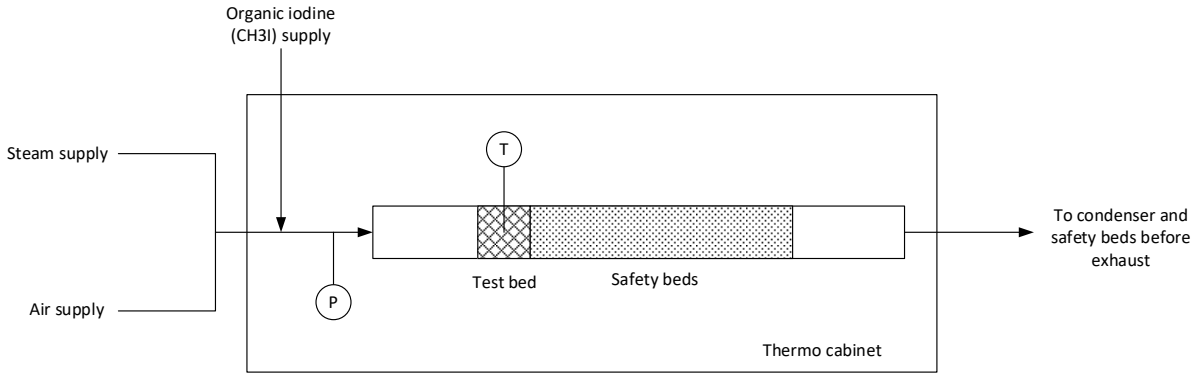

Figure 1: Exemplary schema of the laboratory scale test facility

As part of the material screening phase, 26 adsorbent materials were tested under standardized conditions representative of normal FCVS venting, using a steam-air mixture, fixed flow rate, and a superheating margin of approximately 13 K. Under these reference conditions, a widespread organic iodine retention performance was observed, with measured decontamination factors for CH_3I differing by more than one order of magnitude between the lowest- and highest-performing materials. Based on these results, four adsorbents were selected for further comparative evaluation under varying operating conditions, including both FCVS equilibrium states with high superheating and end-of-venting scenarios characterized by low superheating (Fig. 2, top).

The results confirmed residence time and superheating as the dominant parameters for CH_3I retention. Increasing residence time from approximately 0.1s to 1.0s resulted in a systematic increase in decontamination factor, while a reduction of superheating from ~13 K to below 5 K led to a pronounced decrease in retention efficiency for all candidates. Temperature variations within the investigated range of 120 - 160 °C had a secondary influence compared with residence time and superheating. The four selected materials were compared on the basis of performance index (k) defined as:

$$K - Value = \frac{\log D\,F}{t}$$

where,
k = Performance index [s^{-1})
DF = Decontamination factor [-]
t = Residence time [s]

Out of the two best performing candidates, the final selection was based on the specific structural details demonstrating higher hydrothermal stability with higher resistance against condensing conditions and high humidity. Extended parametric and sensitivity testing of the selected adsorbent showed no significant loss of organic iodine retention during long-term operation up to 120 h, after exposure to 10 vol% hydrogen, or after radiation doses up to 5000 kGy. Thermal stability tests up to 300 °C confirmed preservation of mechanical integrity and adsorption functionality.

The finally selected adsorbent material (Sorbent 3) was then subject to detailed DF investigations. Under investigated conditions, organic iodine DF were typically in the range of 10^2 to 10^3, depending predominantly on superheating and residence time. Molecular iodine retention exceeded CH_3I retention under identical boundary conditions (Fig. 2, bottom). Importantly, even at low superheating (≤ 2 K),

adsorption performance degraded gradually rather than abruptly, and no cliff-edge behavior was detected across the investigated parameter space.

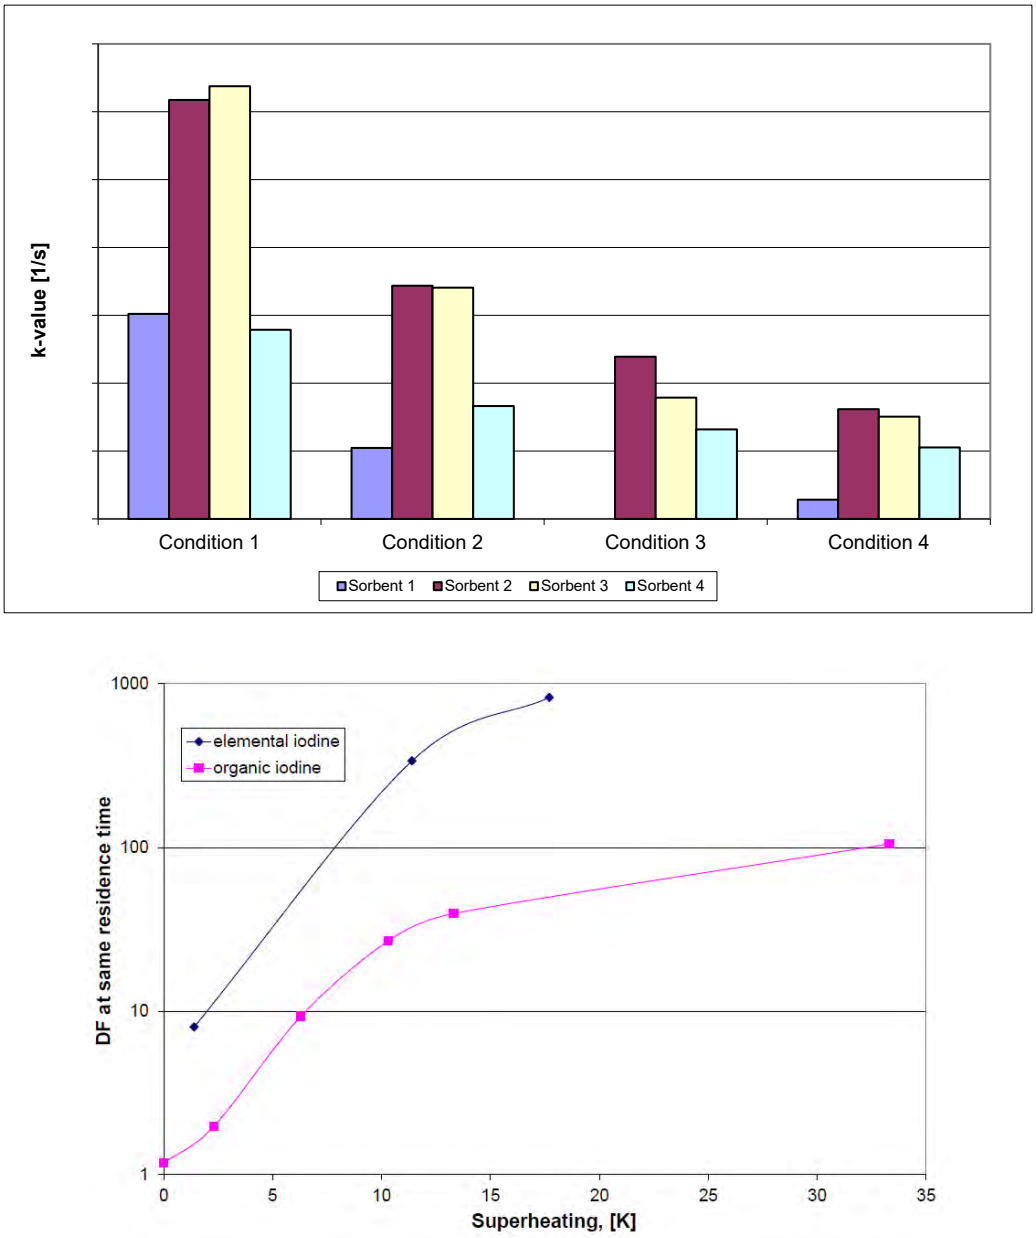

Figure 2: K-value comparison for 4 candidate materials (top); gaseous iodine retention (bottom)

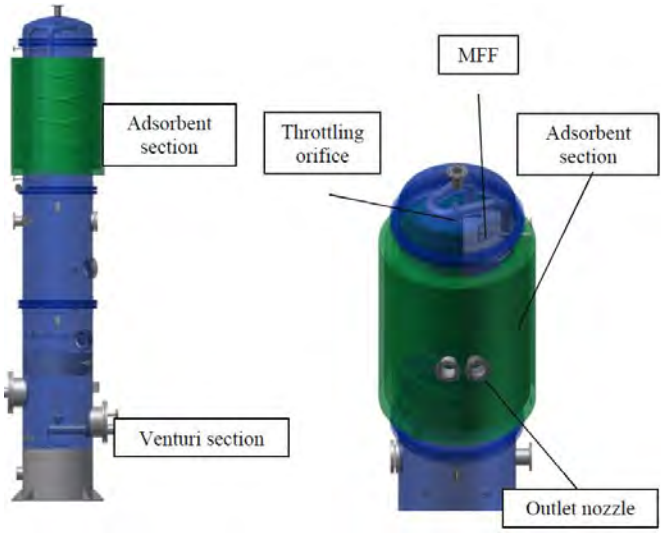
3.2. Technical scale tests at JAVA-PLUS facility

The JAVA test facility, which represents the Framatome FCVS system, was extended to JAVA-PLUS by adding a third retention stage, the adsorbent section, see Fig. 3a. The adsorbent section in JAVA PLUS has a height of approximately 2 m, a diameter of about 1.2 m (Fig. 3a & 3c). The selected dimension and mass of the absorbent allowed investigation of scale-dependent thermal-hydraulic effects, which were not possible at the laboratory scale tests discussed in section 3.1. The required superheating in the adsorbent section can be generated by isenthalpic throttling at the throttling orifice (Fig. 3a). The facility allows transient operation, including start-up phases, pressure decay during venting, and operation near the

saturation, where condensation may occur. The operating characteristics of the JAVA PLUS test facility are shown in Table 1.



(a)JAVA PLUS test facility with the adsorbent section

(b) Lower section of the JAVA PLUS facility

(c) Adsorbent section (picture)

Figure 3: JAVA PLUS test facility

Table 1: Operating characteristics of the JAVA PLUS test facility

PARAMETER	VALUE
Pressure Before Venturi Scrubber Inlet	1 – 10 bara
Temperature	Up to 200 °C
Gas Composition	Steam / air mixtures in the range: 0 % - 100 % steam
Liquid Phase Composition	Demineralized water, sodium thiosulfate, sodium hydroxide
Scaling Factor Compared to Typical FCVS installed in a NPP	Height: 1/1 Volume: 1/3 Mass flow: 1/3
Mass Flow	Up to 2 kg/s (steam and air mixture) - steam 1.5 kg/s - air 0.5 kg/s
Volume of Test Facility	8 m^3
Height of Adsorbent Section	2 m
Diameter of Adsorbent Section	1.2 m

The test matrix covered:

- Pressure: from approximately 5 bar (a) at vent opening down to 1.5 bar(a) at end of venting
- Temperature: up to 160 °C at the adsorbent inlet
- Thermodynamic state of the gas-mixture: adjustable by water injection at JAVA facility inlet: near-saturation conditions at the metal-fibre filter inlet, and slightly superheated conditions at inlet to the adsorbent section.
- Residence time: mean values in the order of 0.3–1.5 s, depending on flow regime
- Superheating: from >10 K down to <5 K above the dew point
- Transient operation: vent opening, transient start-up and depressurization phases

Large-scale tests revealed that decontamination factors (DF) for CH_3I were systematically lower than laboratory values, typically reduced by a factor of 10 to 100 for comparable superheating and residence times. Nevertheless, the target DF > 50 was confirmed under worst-case conditions, with values exceeding 100 under medium and high-pressure conditions. The primary reason for the observed differences in DFs is expected to be due to the nearly ideal hydrodynamic conditions in laboratory experiments - such as uniform velocity profiles, minimal radial temperature gradients, short bed heights, and high surface-to-volume ratios- which allow adsorption to be governed mainly by reaction kinetics and effective gas-solid contact, resulting in high apparent DFs. In contrast, large-scale systems inherently exhibit geometric and hydrodynamic non-idealities that are suppressed in laboratory setups, leading to lower observed decontamination factors in industrial applications.

Similar to the laboratory scale tests, superheating and residence time emerged as the primary parameters controlling CH_3I retention. Empirical correlations from JAVA PLUS tests confirmed a linear relationship between normalized k-value and superheating, with deviations observed below 5 K (Fig. 4), mainly due to condensation risks near the dew point.

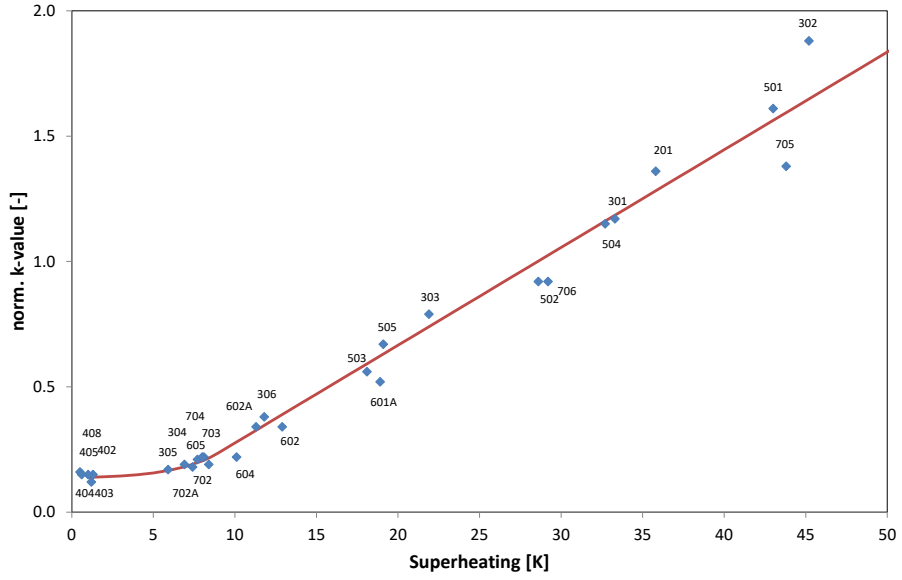


Figure 4: Dependency of normalized k-value on superheating of JAVA PLUS results

Secondary influences included temperature, gas composition, flow distribution, and wall heat losses. Temperature variations affected retention indirectly by altering saturation conditions. Gas composition influenced absolute temperature, but superheating remained nearly unchanged for similar pressures. Flow distribution and wall heat losses, negligible at laboratory scale, had a measurable impact on adsorbent utilization at technical scale.

Based on JAVA PLUS testing, superheating and residence time are confirmed as the principal parameters governing CH_3I retention, forming the basis for reactor-scale design and performance evaluation of the adsorbent section. The vent gas volume flow rate is dictated by operational variables (mass flow rate, composition, pressure, density), while adsorbent volume is fixed by section geometry. Normalized residence time, calculated proportional to actual residence time, is used to account for these factors. Attaining a target DF, therefore requires a minimum residence time in the adsorbent section. Fig.5 shows a viewgraph correlating normalized residence time and superheating, with a design curve for DF = 50. This systematic approach enables precise evaluation and optimization of adsorbent performance under varying reactor-scale operational conditions.

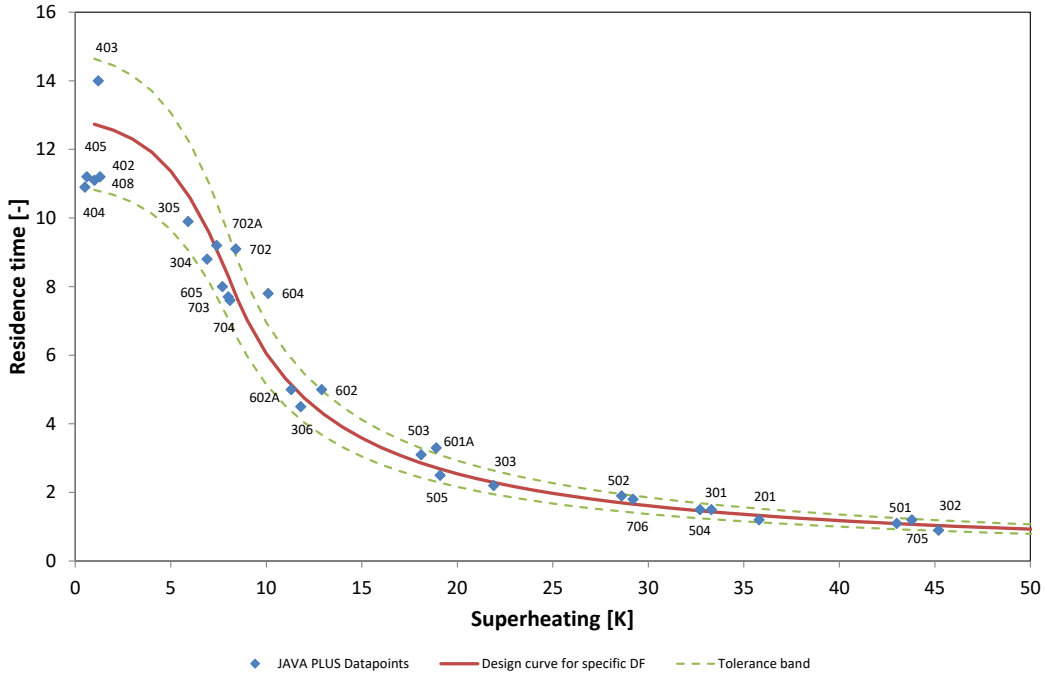

Figure 5: Normalized residence time depending on superheating for design DF valve of 50

4. SCALING EFFECTS AND EXTRAPOLATION OF RESULTS TO REACTOR SCALE

Comparing laboratory and technical-scale JAVA PLUS tests shows that CH_3I retention in FCVS adsorbent stages depends on both chemical reactions, system flow and temperature conditions. Laboratory tests measure basic adsorption and chemical stability, but do not include flow and temperature variations found at larger scale. In technical-scale systems, retention efficiency is mainly affected by flow distribution, temperature uniformity, and gas -solid contact.

The abovementioned factors cause non-linear scaling effects that cannot be described by mean residence time alone. Technical-scale systems have wider residence-time distributions, so some parts of the flow have less contact with the adsorbent, reducing overall retention. Comparison of the superheating versus residence time in Fig. 6 show that large-scale tests need longer residence times to reach the same retention efficiency as small-scale tests. This is due to uneven flow and temperature profiles. Optimization at the JAVA PLUS facility improved flow and temperature uniformity, which increased retention efficiency (see Fig. 6).

However, it is not possible to fully reproduce small-scale conditions in large-scale systems. In real applications, uneven flow is typical. This means that scaling challenges are not limited to residence time. It is important to consider realistic boundary conditions, flow variations, and the resulting thermal-hydraulic inhomogeneities when designing and evaluating large-scale systems.

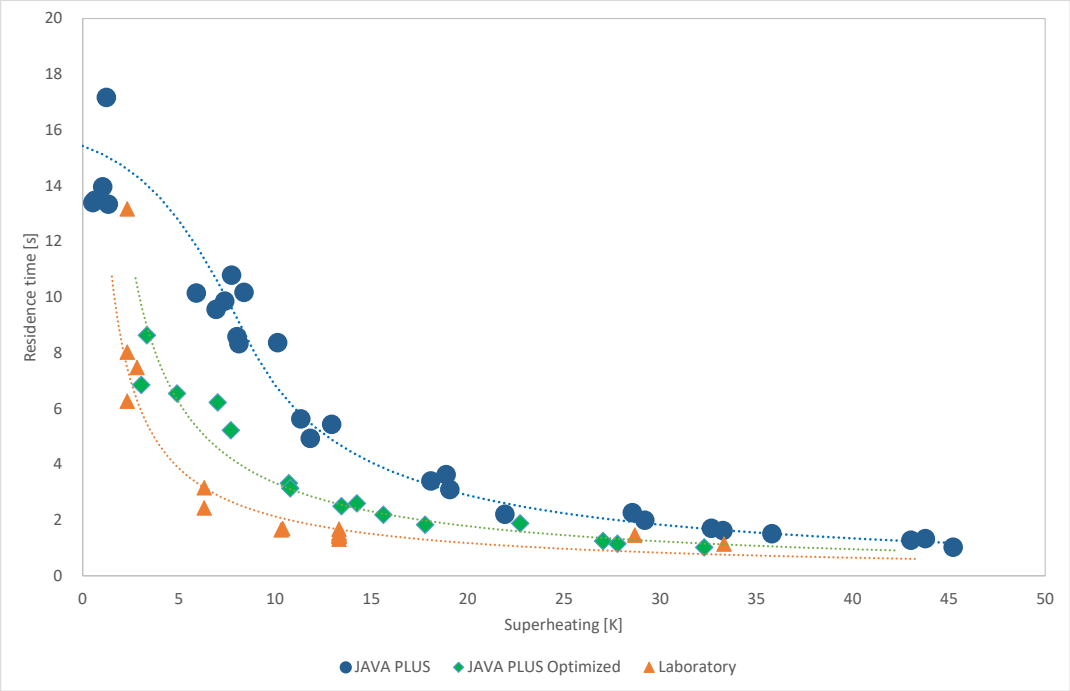

Figure 6: Comparison of results from small-scale and JAVA PLUS with and without optimized flow conditions

CFD analysis, utilizing CFD code ANSYS FLUENT version 14.5, was conducted to bridge the findings from technical-scale tests at the JAVA PLUS facility with the design of reactor-scale adsorbent stages. The simulations utilized Gambit version 2.4.6 as the preprocessor to generate a hybrid mesh with approximately 19.2 million cells. The k-ω SST turbulence model and a second-order discretization scheme were employed to improve solution accuracy.

The CFD analysis simulations showed that flow inside the JAVA PLUS adsorbent section is not uniform. Inlet and outlet geometry, along with internal structures, lead to preferential flow paths especially near the vessel walls (see Fig. 7 top), which revealed clear temperature inhomogeneity at the inlet and throughout the adsorbent bed. Velocity profiles from the CFD simulations highlighted low-velocity regions. The design of the inlet and outlet was identified as the main cause of flow maldistribution. Based on these findings, the adsorbent section design was optimized, such as by adapting an optical traveling length along the wall relative to the bed depth. Additionally, specific measures – such as adding baffle plates - were implemented and tested in the JAVA PLUS (see Fig. 6 in previous section) facility. These actions resulted in improved flow uniformity and iodine retention during the testing campaign.

Another important outcome from the CFD evaluation is that mean residence time alone does not capture the real behavior at larger scale. Instead, the shape and width of the residence-time distribution (RTD) are crucial. A broader RTD means that some portions of the gas pass through the adsorbent with much shorter contact times, mainly due to velocity gradients caused by the inlet design and geometric constraints. These short contact times are responsible for lower CH_3I retention and explain why technical-scale decontamination factors are lower than those measured in laboratory setups, even when nominal conditions are similar.

Figure 7 (bottom) presents the inflow conditions of the adsorbent section in the JAVA PLUS test facility and in a separate adsorbent vessel (representative of the solution for retrofit solutions for different venting systems). The influence of different parameters was evaluated and analyzed. As relevant value for comparison the standard deviation of residence time within sorbent bed was found. As the two most relevant influencing factors the depth of sorbent bed and therewith the pressure loss of the sorbent bed as well as in- and outflow were identified. As result of the analysis, it was validated that the distribution of residence time in the applied or real design is better or equal to the JAVA PLUS sorbent section to allow transfer of the test results.

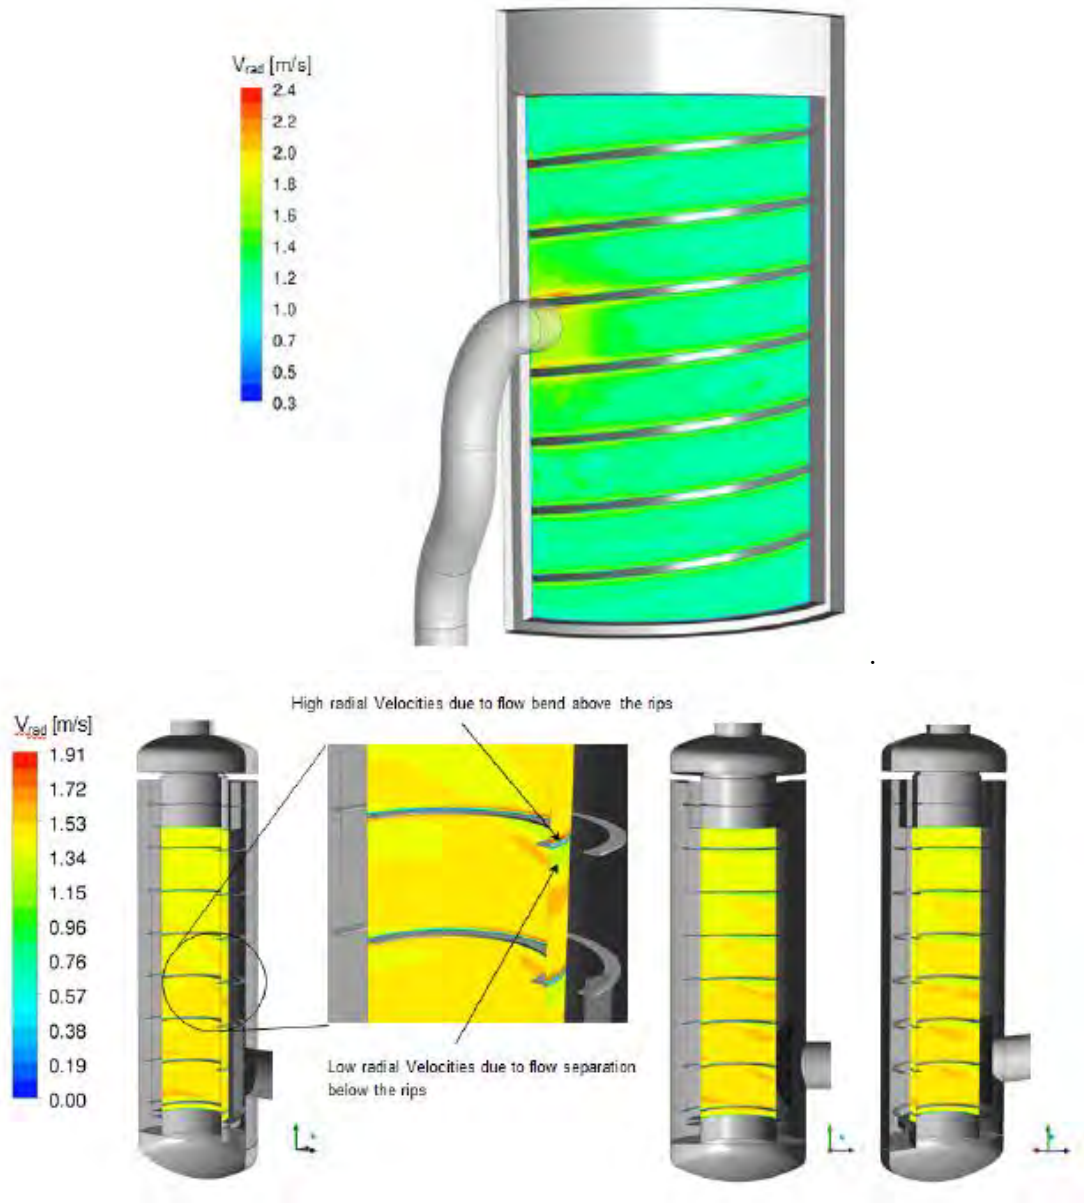

Figure 7: Inflow conditions of the adsorbent section of the JAVA PLUS test facility (top), real-scale retrofitting vessel (bottom)

Finally, transient CFD simulations were used to analyse vent opening and pressure decay phases, during which rapid changes in flow rate and pressure can temporarily reduce local superheating or modify flow

distribution. These analyses quantified the duration and spatial extent of limiting conditions and demonstrated that such transients remain bounded within the qualification envelope established by the technical-scale testing programme.

The safety implication from scaling effects arises when laboratory data are used for adsorbent design, leading to underestimated bed thickness or mass. Under severe accident venting conditions - high steam, variable flow, transient superheating—this can cause earlier iodine breakthrough and reduced DF. Gaseous iodine, especially CH_3I, dominates the volatile fraction not retained by filters, so its release depends on realistic, large-scale retention performance. A tenfold drop in DF as observed between laboratory scale and JAVA PLUS tests, implies a tenfold increase in released organic iodine activity, directly impacting off-site dose projections and Emergency Planning Zone (EPZ) sizing. Adsorbent sizing must therefore use full-scale k-values from representative conditions, with conservative residence time and avoidance of condensation-sensitive designs, as scaling directly determines adsorbent mass, bed geometry, and iodine source term for emergency planning.

5. STANDARD FCVS SYSTEM WITH RETROFIT POTENTIAL OF ADSORBENT SECTION

The Framatome FCVS concept (Fig. 8 & Table 2) is based on a modular system architecture designed to ensure effective retention of aerosols and gaseous iodine species, including both elemental and organic iodine, under severe accident conditions. Primary filtration stages provide high and stable aerosol retention, while downstream iodine retention stages are integrated to meet defined acceptance criteria without adversely affecting the hydraulic performance or passive operation of the venting system over the relevant range of pressure, temperature, and steam conditions.

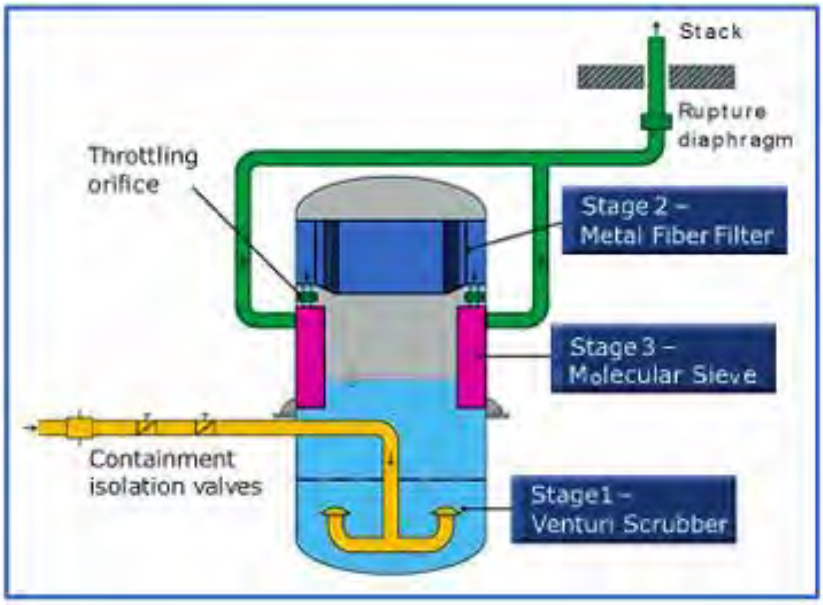

Figure 8: Schematic of Framatome FCVS system

Table 2: Main design features of Framatome FCVS

Main stages	Function	Operating characteristics	Retained species
Stage 1 – Venturi scrubber	Primary filtration	• Operation at near-containment pressure • Gas acceleration in venturi nozzles • Injection into scrubbing liquid • Passive heat transfer to liquid	• Aerosols • Elemental iodine
Stage 2 – Metal fiber filter	Secondary filtration	• Removal of fine and re-suspended aerosols • Droplet and condensate separation • Low pressure drop design	• Fine aerosols • Liquid droplets
Stage 3 – Silver-doped molecular sieve	Gaseous iodine filtration (optional)	• Silver-doped zeolite bed • Chemisorption forming AgI • Modular integration / retrofit	• Gaseous iodine • Organic iodine

The current paper presents performance results for an FCVS configuration incorporating an upstream wet scrubber. In such a configuration, the scrubber provides efficient aerosol removal, significant quenching of the gas stream, and partial retention of soluble iodine species, thereby substantially reducing aerosol loading, gas temperature, and chemical aggressiveness at the inlet of the downstream dry adsorbent stage. As a consequence, parameters such as particulate fouling, excessive pressure drop due to dust accumulation, and direct exposure to peak thermal-hydraulic conditions do not represent dominant design drivers for the adsorbent section. In particular, aerosol-induced clogging, untreated acid gas spikes, and uncontrolled condensation effects are mitigated upstream, limiting their impact on residence time requirements, hydrothermal stability margins, and long-term adsorbent performance.

However, the testing campaign also included performance testing with only upstream dry filter section without wet filtration stage. In such situation, the adsorbent stage will probably be directly exposed to acid gases without prior quenching and decontamination. In any case, aerosols will not reach the adsorbent section because there is always an aerosol filter positioned before it. This filter may take the form of filter mesh, cartridges, or a sand bed. Furthermore, the amount of iodine within the specified ranges does not actually have any impact. The system design is based on kinetic considerations. This means that even if no iodine is retained in the preceding section, the required quantity of adsorbent does not increase, as there is always sufficient buffer available. Nevertheless, the design requirements for the dry filtration stage become more stringent in terms of aerosol pre-separation (higher DF for particulates), thermal conditioning to ensure sufficient superheating and avoid condensation within the bed and increased chemical resistance against HCl/HNO_3. Moreover, structural and hydraulic design must consider higher pressure drop and fouling risks, as well as enhanced decay heat management within the adsorbent bed.

The operational experience with the Framatome FCVS installed in NPPs has been accumulated through routine periodic inspections. Samples have been collected and analyzed at intervals of 1 to 5 years, resulting in a consistent operational record spanning more than a decade. Throughout this period, no decrease in iodine retention has been observed, demonstrating stable and reliable adsorbent performance under the tested conditions.

Conclusions

This paper summarizes the main outcomes of testing done towards developing a dedicated gaseous iodine retention stage for FCVS systems installed worldwide. While conventional filtration systems achieve high aerosol decontamination factors, their efficiency for volatile iodine species, particularly organic iodide remains limited, necessitating complementary retention mechanisms.

Framatome's systematic development approach combined laboratory-scale qualification—demonstrating intrinsic DF for organic iodine (CH_3I) well above 50 under broad range of typical severe accident conditions. For this purpose, industrial-scale verification under representative thermo-hydraulic conditions were carried out. Large-scale testing confirmed the robustness of the selected silver-impregnated zeolite and highlighted the critical importance of full-scale validation to capture hydrodynamic scaling effects.

Overall, the study underlines that for dimensioning of FCVS adsorbent stages, conservative DF values must therefore be based on large-scale verification results. Laboratory data remain indispensable for material selection, parametric understanding, and development of design correlations, but cannot serve as sole performance validation.

CFD analyses provided valuable insights into flow distribution, temperature homogeneity, and residence time behavior, supporting optimized reactor-scale implementation. The modular adsorbent concept enables flexible integration and backfitting across diverse FCVS configurations within the existing nuclear power plant fleet.

Importantly, adding an adsorbent stage for gaseous iodine retention is a technically feasible backfit for existing nuclear power plants, regardless of the original FCVS design. Whether the current system uses a dry aerosol filter or a wet scrubber, a dry adsorbent module can be integrated as a modular add-on without major changes to the primary venting approach.

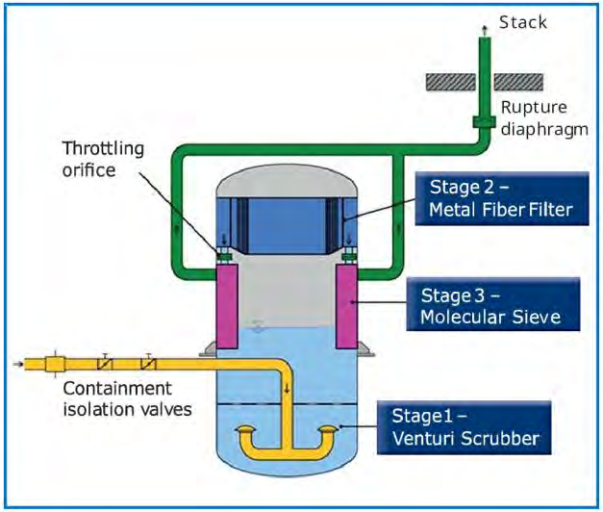
Background: FCVS in severe accident management

- Filtered Containment Venting Systems (FCVS) are implemented as a final severe accident management measure to preserve containment integrity.
- During severe accidents, decay heat, hydrogen generation and steam production may progressively increase containment pressure.
- FCVS enable controlled depressurization while filtering radioactive materials, such as:
  - Aerosols
  - Iodine



Framatome FCVS PLUS with - Venturi scrubber, metal fiber filter and iodine filtration stage

C1 - Framatome Restricted - . / Framatome know-how / Export Control - AL : N ECCN : N

Background: Gaseous iodine retention

- During Venting iodine is released by 3 transport mechanism from the containment:
  - **Aerosol-bound iodides** — Efficient aerosol filtration in mature filter design
  - **I_2 / HI** — Efficient retention by wet scrubbing and sorbent filter
  - **Organic iodides (e.g. CH3I)** — Largely unaffected by conventional scrubbing and aerosol filters

- Research projects, like EC-PASSAM, identified organic iodine formation and retention as major contributors to source-term uncertainty.
- Post-Fukushima research:
  Organic iodine is highlighted as an important iodine source term during venting.
- Safety authorities increasingly request FCVSs with qualified organic iodine retention

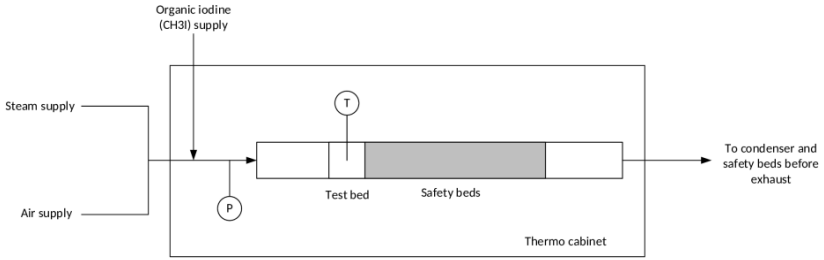
 © Framatome - All rights reserved

Framatomes FCVS PLUS qualification program:

- **Objective**:
  Develop and qualify a additional filter section to enhance gaseous iodine retention in existing FCVS applications→ ***Organic Iodine DF > 50***
- **Scope**
  - **Laboratory tests**: screen candidate adsorbent materials and evaluate the selected material under a range of accident-relevant conditions
  - **Large-scale** (JAVA-PLUS) tests: verification of the selected adsorbent materials in a large-scale test facility replicating the geometric and thermal-hydraulic characteristics of a real FCVS system
  - **CFD analysis** to support in experimental set-up design and assessment towards extrapolation of test results to reactor scale venting systems.

Screening	Lab qualification	JAVA-PLUS	CFD
26 adsorbent variants	**CH_3I / I_2 DFs**	**Technical-scale validation**	**Test-design calculations, reactor-scale extrapolation**

Laboratory scale tests



An exemplary sketch of laboratory scale set-up

Performance comparison

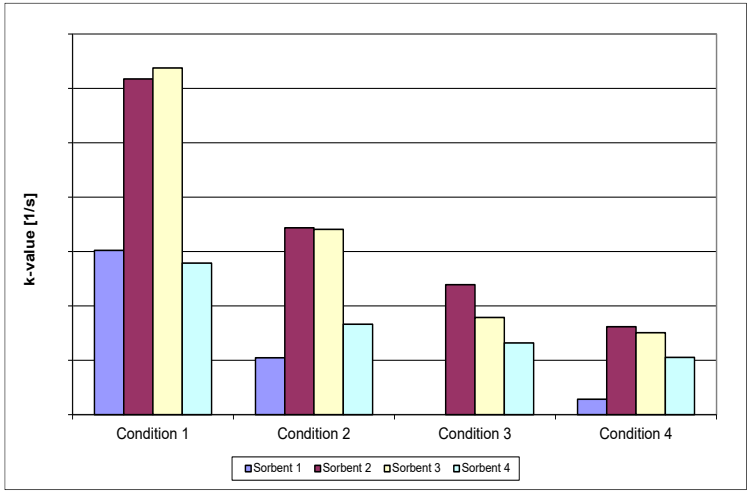
$$k = \frac{ln(DF)}{t}$$

Where:
k = performance index [1/s]
DF = decontamination factor [-]
t = residence time [s]

Typical laboratory parameters

- Fixed-bed columns with sorbent beds
  - Diameter: ~2.5 cm
  - Bed height: ~2.5 cm
- Parametric testing
  - 0 - 100% steam/air
  - 60 - 120 °C (condensing & superheated)
  - Flow velocity
  - …
- Organic iodine is continuously injected at stable conditions for about 1h (tracered test)
- Tests conducted independently by TÜV to verify decontamination factors
  - Values verified by in-house laboratory testing

Laboratory scale tests – Results



$k = \ln(DF)/t$

Figure 2 (top): K-value comparison for four candidate materials

- 26 adsorbent materials were screened under standardized conditions
  - Silver zeolite are best adapted
- CH_3I DFs differed by more than one order of magnitude between the lowest- and highest-performing materials.
- 4 adsorbents were selected for further comparison under FCVS start-of-cycle and end-of-venting conditions.

→ **Residence time and superheating are the dominant parameters for CH_3I retention.**

Final selection was based on performance and higher hydrothermal stability

Technical scale tests – JAVA-PLUS

- **Test facility parameters**
  - Total height: 8 m
  - Height sorbent section: 2 m
  - Diameter: 1.2 m
  - Mass flow Scale: ~ 1:3
- **Operating conditions for tests**
  - Gas flow rate: up to 1.5 kg/s
  - Gas phase composition: steam-air mixture
  - Inlet pressure: 1.5 – 8 bar abs
  - Pressure in the adsorbent stage: up to 2 bar abs
  - Temperature: 50 – 180°C
  - Transient
    - Venting cycle (depressurization of containment)
    - Start-up transient

Safety implication of scaling effects

→ Using laboratory data alone can underestimate needed adsorbent bed volume

- Under severe accident venting - high steam, variable flow and transient superheating - undersized beds may cause reduced DF.
- A tenfold drop in DF implies a tenfold increase in released organic iodine activity
- Released volatile iodine directly affects off-site dose projections and Emergency Planning Zone sizing.
- Adsorbent sizing should use full-scale k-values from representative conditions with conservative residence time.

FCVS dimensioning principle

Laboratory scale test data is indispensable for material selection and parametric understanding.

Laboratory data is not sufficient as sole performance validation for upscaling (factor << 10)

Scaling directly determines adsorbent mass, bed geometry and iodine source term

 © Framatome - All rights reserved

Conclusions

- A dedicated adsorbent stage is necessary to complement FCVS filtration for volatile iodine, particularly organic iodide.
- Technical-scale JAVA-PLUS tests confirmed robustness and exposed hydrodynamic scaling effects that reduce observed DFs relative to laboratory tests by factor 10 - 100
- Conservative FCVS adsorbent design should be based on large-scale verification.
- The modular adsorbent concept is a technically feasible backfit for existing NPPs with wet or dry FCVS configurations.

Main outcome
Iodine retention in FCVS adsorbent stages is a system property shaped by material behavior, thermal-hydraulics and reactor geometry

Large scale tests data are a key for reactor application

ABSTRACT

Rapid and accurate prediction of the atmospheric radionuclide dispersion is critical for emergency response following a severe accident in Nuclear Power Plant (NPP). Java based Real-time Online DecisiOn Support System (JRODOS) code was developed at the Karlsruhe Institute of Technology (KIT) to analyze radiological consequences of the radionuclides dispersions. In order to complete a single simulation in JRODOS, weather condition data was on selected time frame processed by the code and selected atmospheric dispersion model applied to calculate the movement and deposition of the radionuclide material over a selected region. Based on the source term and duration of the release, one simulation can take minutes and this computational cost makes multi-year extensive risk assessments costly in terms of calculation power and time. In order to overcome this problem an Artificial Neural Network (ANN) was trained on a dataset of simulations generated by JRODOS for a reference arbitrary plant location at KIT Campus North, assuming a constant release source term. The network learns the complex, non-linear relationship between meteorological input parameters and the resulting radiological dose rate maps. This surrogate model accurately reproduces the dispersion consequences and reduces the analysis time from minutes to seconds. Additionally, the model can provide more information about dispersion span by considering a larger timeframe dataset and weather conditions around the plant. This acceleration allows for the consideration of multiple calendar years which strengthens emergency preparedness by enabling faster evaluation of potential outcomes under a wide range of weather conditions. Further results will be shown and discussed in the paper.

KEYWORDS
Severe Accident, JRODOS, Machine Learning, Neural Network, Radionuclide Dispersion

1. Introduction

In the event of radiological dispersion caused by the nuclear emergencies such as severe accidents, priority of the authorities is to accurately predicts the trajectory of the release and put the emergency plans into action. For this purpose, regulatory bodies rely on advance decision support systems. The European Java based Real-time Online DecisiOn Support System (JRODOS) [1], developed by the Karlsruhe Institute of Technology (KIT), stands as European standard tool for regulators and it is currently operational in many countries. JRODOS integrates meteorological forecasts by including source term and complex atmospheric dispersion models to calculate radiological dispersion over a selected domain in any place over the globe and draw conclusions for protective measures such as sheltering, evacuation, iodine tablet distribution.

JRODOS relies on the Gaussian puff models and Lagrangian particle models to resolve and simulate radioactive plume dispersion and how the cloud interacts with topography and wind fields. Even though simulation results bring accurate calculation, these physical calculations can be computationally expensive. Especially considering statistical analysis which involves thousands of individual analyses on selected domain is highly time consuming. In a previous work [2] it was showed that in order to create a dispersion map to better understand possible consequences around the selected plant by including large span of weather

conditions, significant amount of time is required and yet the results were still not mature enough to draw a generic conclusion on the selected region.

In order to create a connection between computational speed and physical accuracy, advancements on machine learning applications offers promising alternative of data-driven Artificial Neural Network (ANN) models. The network can learn complex behavior between weather parameters by training an ANN with precalculated numerous of simulation. Despite the dispersion models in the JRODOS or in any other dispersion code, trained ANN does not solve physical equations, but it performs matrix multiplications to predict the phenomena and this brings significant speed boost to the simulations.

Previous work on ANN applications focused on spatial dose rate interpolation and integration of the virtual reality in order to reduce exposure of doses inside facilities [3]. Expanding from facility level to environmental releases, estimation of the effective doses in case of Loss of Coolant Accidents also predicted by using multi-layer perceptron models and dose predictions showed acceptable up to certain level [4]. After that, radiological releases on NPP level were further investigated by taking advantage from GPU based accelerations on multi-layer perceptron to reduce training time [5]. More recently, focus has been given to the capturing the temporal dynamics of radioactive plumes and tracking extreme points on the grid and exploration whole body doses [6]. Furthermore, integration of machine learning with established code like HotSpot has enabled to investigate different severe accident scenarios and to predict effective doses to make comparison between different transients [7].

In this study, an ANN model has been developed and trained with pre-defined datasets of JRODOS simulations. After construction of the ANN model, validation of the prediction has been performed with test cases and the capability of the model has been proven. The selected base case in JRODOS and the methodology of the ANN structure and training procedure is given Section 2. After that comparison between ANN model and JRODOS simulations are presented for the evaluate model prediction capability and conclusion and next steps are described afterwards.

2. Methodology of Artificial Neural Network Model Construction

The initial step in constructing an ANN is the establishment of a database to train the model. A set of 1000 JRODOS simulation have been completed to create a database around the selected NPP location. A fictitious power plant location in the KIT Campus North has been selected and grid has been established within a 100 km radius. Simulations were for a time period of 24 hours with 30-minute time steps by using RIMPUFF dispersion model. The starting time of the dispersions in each simulation randomly selected within the calendar year 2021. Early countermeasures and prevention actions have not been considered for the simulations and the stack height of the release point has been selected as 150 meters. Weather data for the simulations has been provided by the American NOMAD servers which are hosted by the U.S. National Oceanic and Atmospheric Administration. Source term has been selected by the one of the pre-defined constant releases in the bank of the JRODOS library. Details about the released isotopes are given in the Table I. All isotopes are defined to be released within a single time interval (30 minutes) in the simulations.

Table I. Total released activity to the atmosphere within 30 minutes time interval.

Isotope	Activity (Bq)	Isotope	Activity (Bq)
Cs-134	1.1E+15	Kr-87	9.0E+15
Cs-136	4.7E+14	Kr-88	1.8E+17
Cs-137	6.5E+14	Sr-90	4.7E+13
I-131	9.5E+15	Sr-91	6.4E+14
I-132	1.3E+16	Te-131m	1.1E+15

Kr-85	2.4E+16	Xe-135	2.1E+18
Kr-85m	1.5E+17		

Numerical weather prediction files, known as GRIB files, from the American NOMAD servers provide global weather data with a resolution of 0.5 degrees in latitude and longitude grid [8]. Files contains complex and non-standardized structures of data as well as vertical layers of atmosphere over the whole globe. In order to create a basic model to test the methodology, the number of parameters selected has been kept as low as possible. In this way, the ANN model parameter size and training effort has been kept as minimum. The parameters that have been selected for investigation are as follows: the U-Component and V-Component of the wind at the level of the stack height; the temperature of the atmosphere at the stack height level and surface pressure level. These parameters have been selected from each of 1000 simulations that have been performed to create a simulation database. Since the single grid point is not enough to capture the parameter behavior, selection of parameters were extracted over the KIT Campus Nord spatial domain. GRIB files have resolution of 0.5 degrees, which corresponds to the around 50 km size of meshes. A 5x5 grid (two neighbors in every direction) has been used to extract the parameters every grid point, and feature matrix has been constructed for each time step. The general layout of the matrix is given in Equation 1. Each row in the matrix corresponds to a single time line over the 25 grid points for four selected parameters.

The total effective gamma dose rate results of the performed simulations have been utilized to establish the result matrix, which is given in Equation 2. JRODOS can provide wide range of dispersion analysis results which can be used in the machine learning algorithms. However, for the purpose of the simplicity, only a global parameter of the total effective gamma dose rate has been selected. Each simulation has been subdivided into 48 snapshot points of the time step, and each 30-minute time step points have been considered as an independent sample. In this way, total number of the result with their corresponding time stamp increased to 48.000 for 1000 simulation. After that, 90% of the simulations and the corresponding weather parameters have been separated to create a training set and remaining 10% of the data has been used as a test set in order to evaluate the prediction capability of the model after trained on the training set.

Following the construction of the matrices, the multilayer perceptron regression model is established. The input layer consists of 100 nodes, the function of which is to store selected weather parameters in the feature matrix. Afterwards, three hidden layers follows with 512, 1024 and 2048 nodes and the final output layer consist of 8056 nodes. These nodes at the output layer corresponds each mesh point in the described grid over the KIT Campus North domain. Each operation in the hidden layers applies rectified linear unit (ReLU) activation function to the parameters to catch up the non-linear behavior of the database.

The training operation of the model starts with feeding input matrix from the rows of the feature matrix. In order to ensure that gradient updates of the selected parameters are maintained at a comparable level, it is also necessary to normalize the input parameters. Since the pressure values are in the range of six-digit

numbers and temperature levels are in one or two digits at most, their contribution to the results with equal gradients will not be the same and consequently, the model can have unrealistic biases for certain parameters. After operation with their assigned weights and activation function, all parameters pass through to the final output layer to construct the total effective gamma dose rates in each mesh point on the grid. Subsequently, a comparison is made between the ANN prediction and the results of the JRODOS simulation, which are stored in the result matrix. The loss of the model prediction is then determined. Following backward pass operation applies optimization algorithm to update the weights of the approximately 19 million parameters in the network. This process is repeated iteratively in an attempt to minimize the loss function. General layout of the network structure is given in Figure 1.

$$X = \begin{matrix} u_{t_0}^{0} \dots u_{t_0}^{24} \\ \vdots \\ u_{t_43199}^{0} \dots u_{t_43199}^{24} \end{matrix} \quad \begin{matrix} v_{t_0}^{0} \dots v_{t_0}^{24} \\ \vdots \\ v_{t_43199}^{0} \dots v_{t_43199}^{24} \end{matrix} \quad \begin{matrix} T_{t_0}^{0} \dots T_{t_0}^{24} \\ \vdots \\ T_{t_43199}^{0} \dots T_{t_43199}^{24} \end{matrix} \quad \begin{matrix} P_{t_0}^{0} \dots P_{t_0}^{24} \\ \vdots \\ P_{t_43199}^{0} \dots P_{t_43199}^{24} \end{matrix} \tag{1}$$

$$y = \begin{matrix} dose_{t_0}^{mesh_0} & \dots & dose_{t_0}^{mesh_8055} \\ \vdots & \vdots & \vdots \\ dose_{t_43199}^{mesh_0} & \dots & dose_{t_43199}^{mesh_8055} \end{matrix} \tag{2}$$

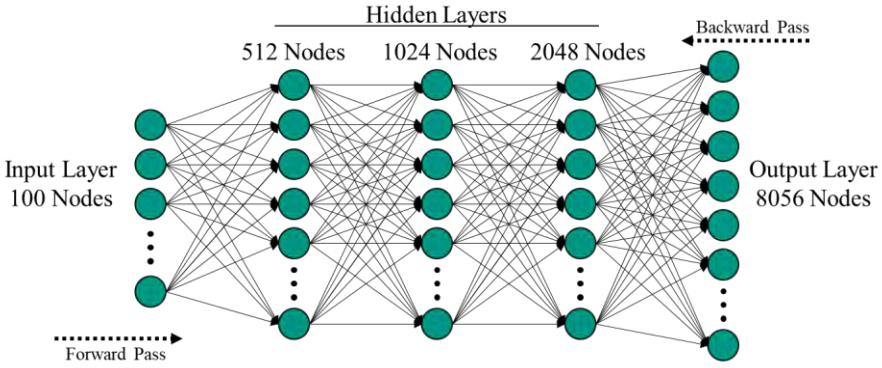

Figure 1. Structural layout of the Neural Network for the JRODOS surrogate model.

Furthermore, a validation strategy has been implemented to the ANN structure to check the model estimations in every training loop to evaluate the model performance. The standard application of the ANN structure involves the utilization of the training dataset, with the training loss being calculated using known historical data. However, trained model may calculate a low level of training loss and it may estimate unrealistic results for the test dataset. One potential explanation for this phenomenon could be an excessive number of iterations over the training set, leading to overfitting of the known data. In order to overcome this problem, at the end of every one full pass-through of the training set, the averaged mean squared error of the entire test set has been saved as validation loss and it was tracked over the ongoing loops. This result gives the evolution of the model to predict the test cases and gives the performance of the ability to predict new dataset that the model has never seen before. Early stopping functionality, which tracks the validation loss, automatically terminates the training loops when model began the overfit.

3. Results

The initial strategy of the training resulted in a model that predicts safe averages over the entire grid but fails to captures extreme points. Due to fact that the radiological dispersion plume only gets peak points on very limited number of mesh points over the domain, the rest of the points on the grid receives a zero or a very small dose value. For this reason, initial guess of zeros or very small numbers for the entire grid provides reasonable level of loss value in general and the model does not search for any improvement in order to catch peak points.

In order to overcome this issue during training a logarithmic transformation was applied to the target output matrice (y) in order to teach gradients and shape of the dose map over the grid effectively without being overwhelmed between magnitude differences between peak points and the overall average. Specifically, a log(1+x) function was utilized to handle zero-value total effective gamma dose rates, preventing undefined negative infinity errors. Furthermore, a dynamic penalty weighting factor has been calculated based on the magnitude of the actual target value and this weight has been multiplied by mean square error for loss calculation in the training loops. Consequently, the model has been punished heavily for underestimating high magnitude dose rate peaks and this approach forces the ANN not to pass extreme peak points.

The training of the model has been established by using CPU and GPU units separately. The training has been completed within a timeframe of approximately 20 hours, utilizing an 12th generation Intel i9-12900 CPU. It took around 15 minutes with a NVIDIA GeForce GTX 1050 Ti GPU. The total effective gamma dose rate prediction of the ANN model has been achieved in approximately 0.08 seconds. This is very fast compared to the JRODOS simulations during the production of training cases where each simulation required around 2 minutes and 15 seconds.

Regarding the temporal mechanics of the model, the current ANN model is designed as a direct, instantaneous mapping function rather than a time-series forecasting model. The ANN predicts the spatial dose rate map at any specific time step t utilizing the meteorological conditions and source term parameters available at that exact time t. It does not utilize a sliding time window or a historical memory of meteorological conditions. Because the network architecture is a standard Feedforward Neural Network (Multi-Layer Perceptron), it treats each temporal slice independently. Consequently, the predicted dose distribution at time t is calculated strictly as a localized function of the atmospheric and release state at that moment.

In order to evaluate the ANN dynamic performance over a continuous release scenario, a full 24-hour simulation sequence was selected from the database for direct comparison, given in Figure 2. The X-axis of the plotted figures corresponds to the meshing points of the JRODOS grid at the selected KIT Campus North NPP location, while the Y-axis corresponds to the total effective gamma dose rate. The results demonstrate a good agreement between the JRODOS simulations and the ANN predictions in terms of level of dose rate. ANN successfully captures the overall magnitude of the dose rates as well as the complex spatial distribution over the computational grid. The point-by-point mesh comparisons indicate that the neural network accurately reproduces the transport and dispersion patterns as they evolve over the 24-hour period.

In order to represent the performance of the model in general, the predictions of the ANN model and the JRODOS results of a randomly selected cases from the test sets are presented in Figure 3. The model predicts elevated dose values where the JRODOS simulations registers a plume and dose reading. This indicates that the model has internalized the complex and non-linear behavior of the dispersion dynamic. The model successfully produces the plume's footprint however, the level of dose rates is often overestimated. Since the weighting factor are applied where the dose peaks are read for the losses, an over estimation can be seen at the peak points between 0-1000 mesh points for case #1338 and #336 in the Figure 3. Last case #1952 shows the highest dose reading levels among the randomly selected cases. The number of readings in that

case over the grid is not crowded as other cases and this shows that plume did not travel too far but stays around the NPP. Consequently, very high dose rates compare to other cases have been recorded for the case #1952. Since this kind of release cases are rare among the training set, the ANN model could not catch this scenario and overlooked the penalty loss on this case as long as the overall average is getting better in total.

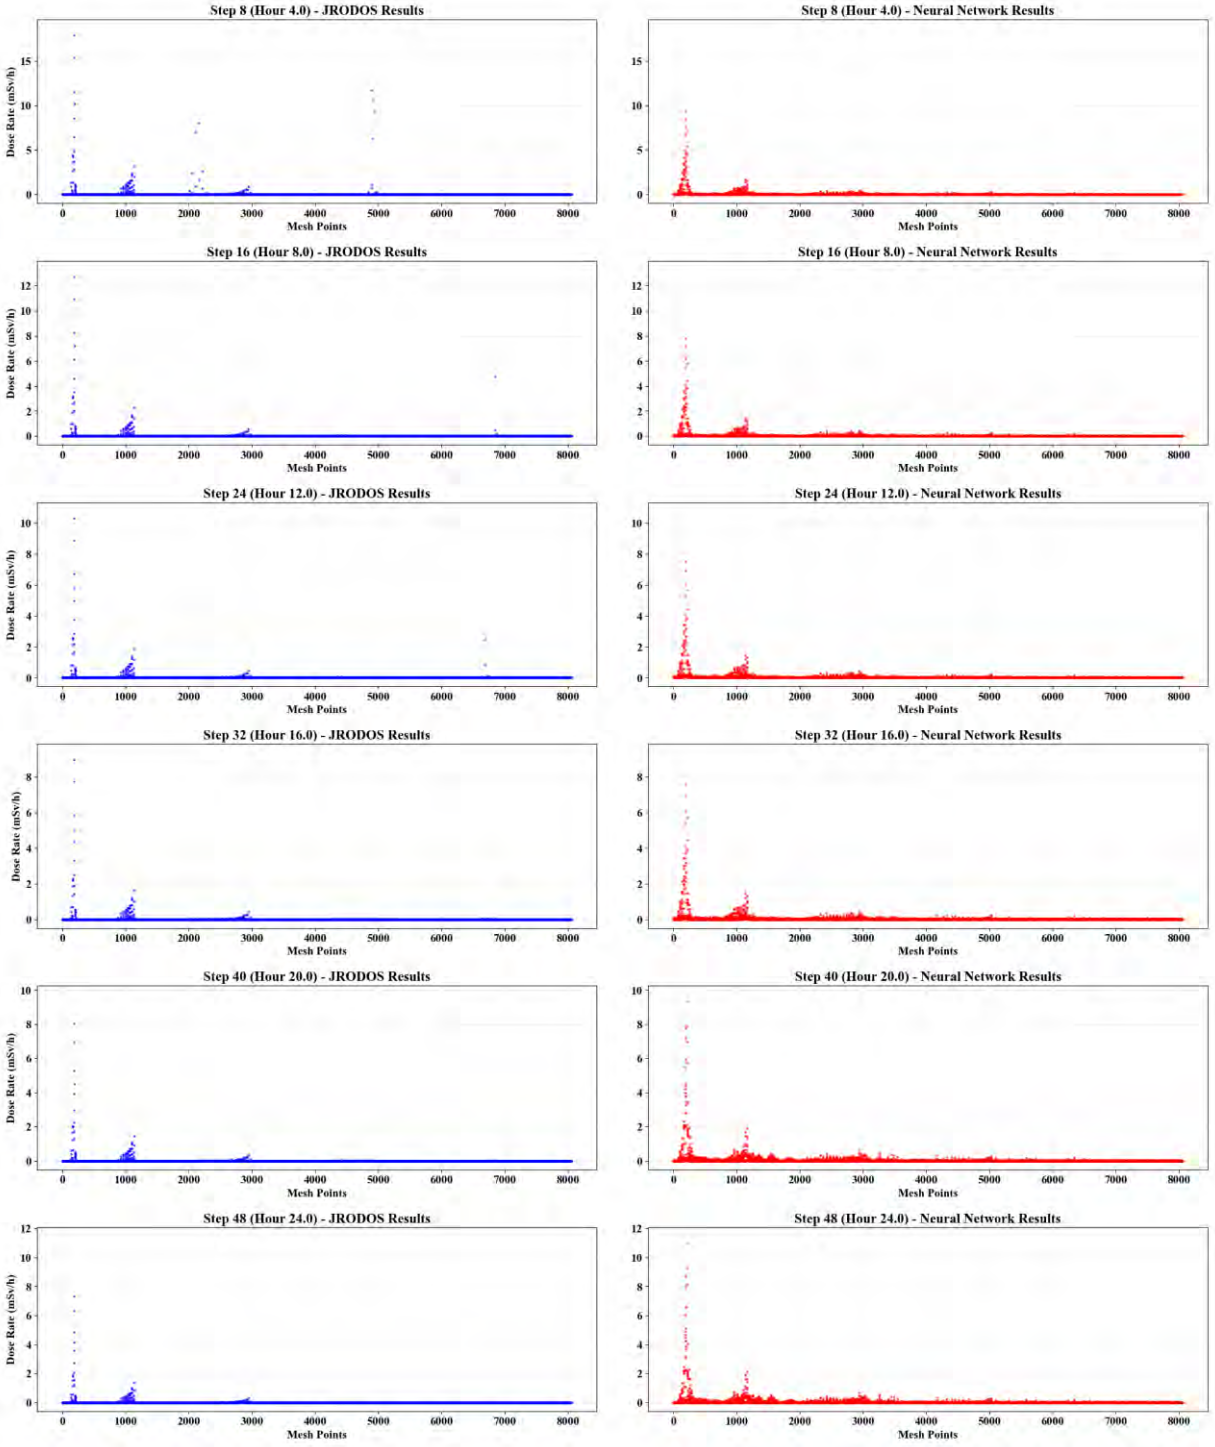

Figure 2. Comparison of selected 24h simulation steps between JRODOS and Neural Network predictions.

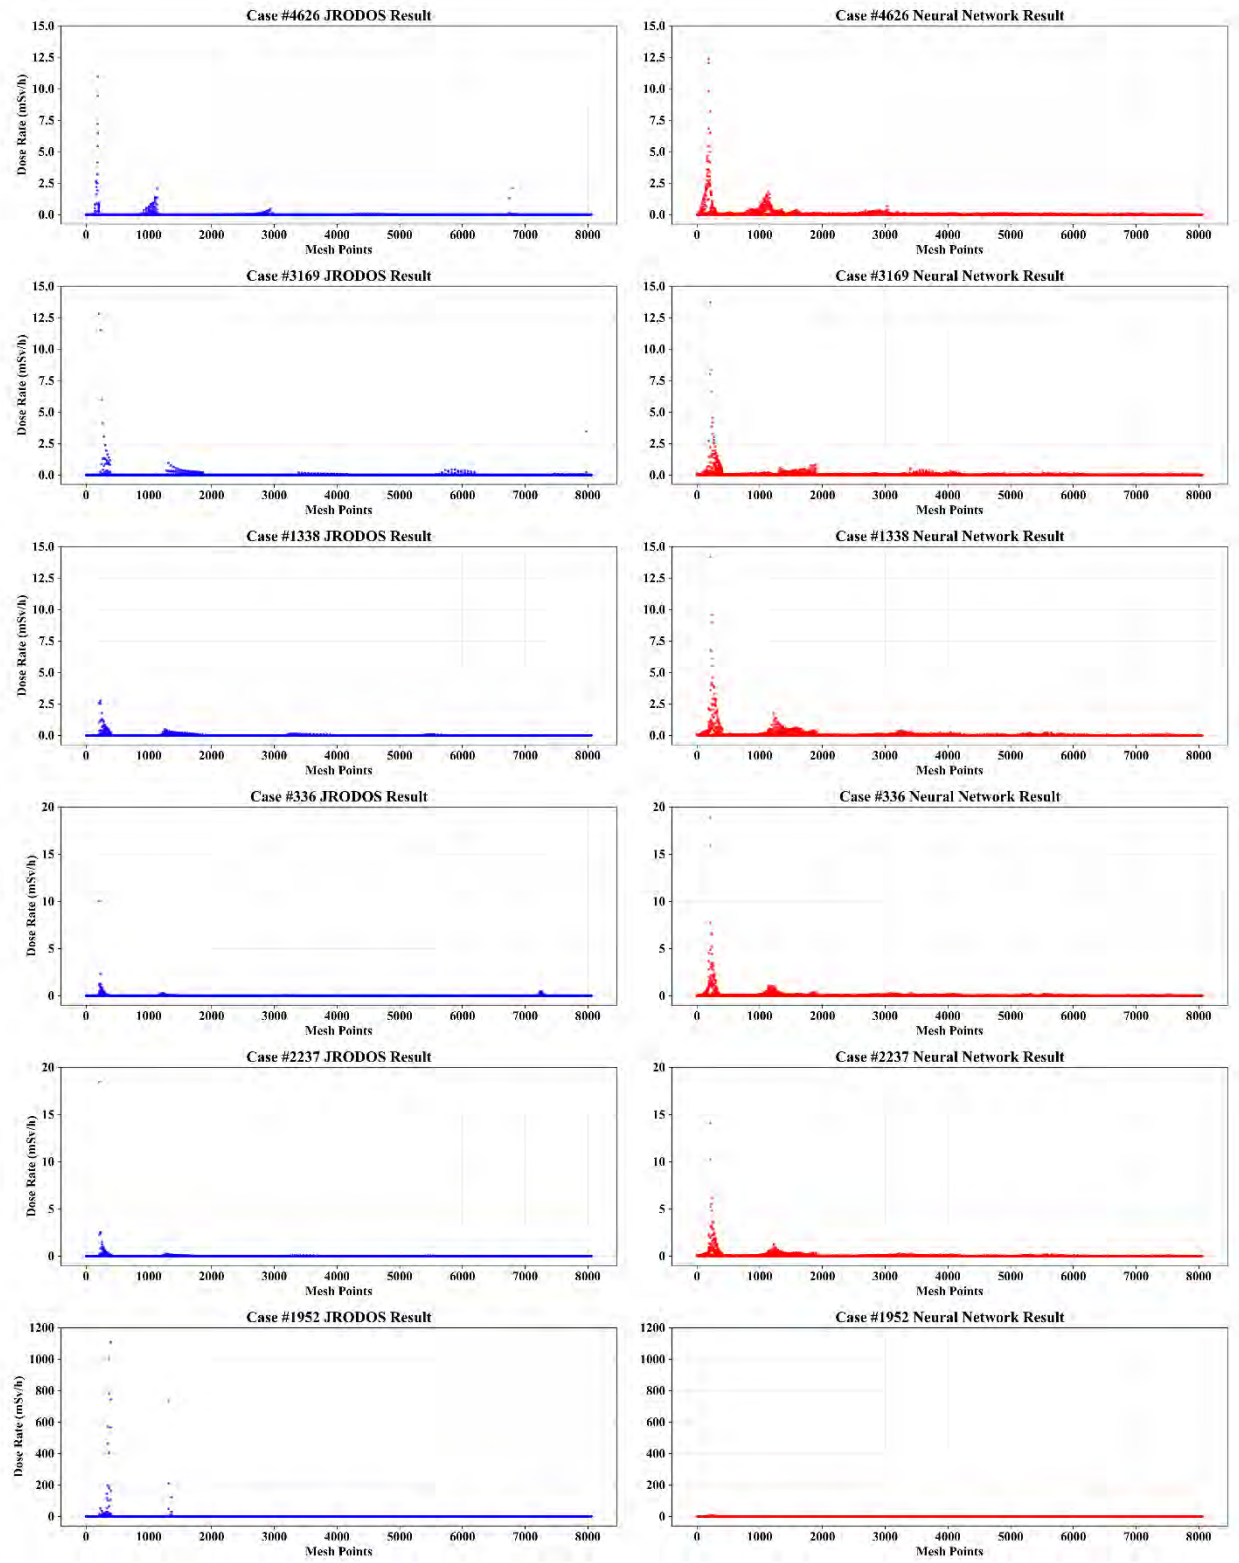

Figure 3. Comparison between JRODOS simulation results and Neural Network predictions for random selected time instants of the evaluation cases.

The application of the ANN model demonstrated that it provides significant speed up for dispersion calculations. This achievement is not only important to rapidly evaluate possible consequences over the considered regions, but it also provides ability to create massive number of calculations to enlarge the result databank in order to take into account larger span of weather conditions. Since the beginning of the 20th century human activities plays an important role in the dynamics of the atmosphere, meteorological conditions are rapidly changing and new conditions need to be taken into account to incorporate current and possible future conditions of the atmosphere. In order to show rate of changes in the atmosphere; weather parameters extracted from European Climate Data Store Copernicus [9] and average of the temperature for month of February in Figure 3 is pictured over the KIT Campus Nord region enclosed by latitude 48°-50° North and longitude 7°-10° East coordinates for each calendar year from 1940 to 2025. It can be seen that average temperature is getting higher and hottest recordings on average in February are being observed. This might end up result of dispersion which has never been unpredicted before considering recorded conditions in history. All those rates of changes will continue to contribute to the variation of extreme weather conditions in the future. Dispersion analyses based on the previous recorded conditions on the considered region will not be enough to correctly determine consequences. For this reason, including large variety of conditions and extrapolation will be necessary by taking into account expected future conditions to create more comprehensive emergency plans. Consequently, the computational speed advantage of ANN models will be an important asset for expanding risk databases and conducting forward-looking emergency planning.

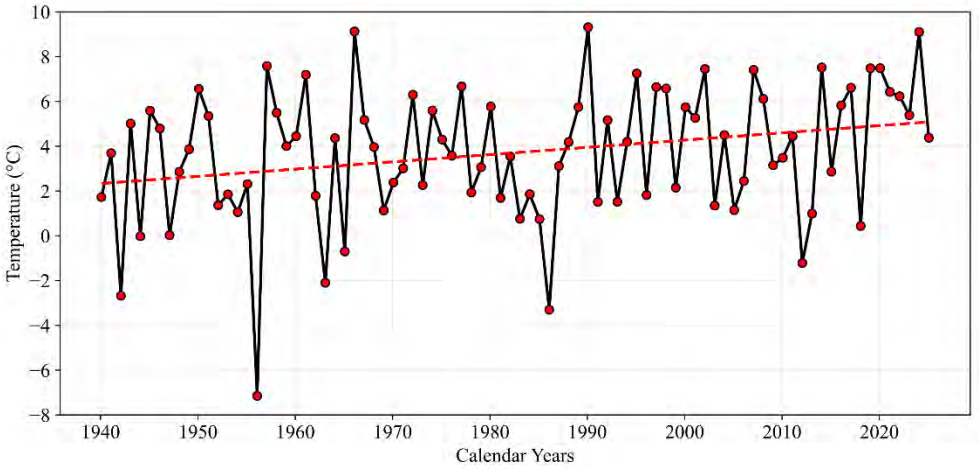

Figure 3. Monthly average of temperatures for February in the KIT Campus North.

4. Conclusion

A calculation methodology based on the use of ANN has been developed to speed up the radionuclide dispersion analysis. The ANN model has been trained with built training database and validated against the JRODOS using by the test samples. Since the radioactive isotope dispersion into the atmosphere is the last step to evaluate public and environmental safety during severe accident progression, estimation of the transfer of the particles provides roadmap to better preparation of emergency planning and mitigation strategies. The ANN application accelerates simulation process significantly and, in this way, large number of weather conditions can be utilized to picture possible consequences on the selected region. It is clear that the conditions in the atmosphere rapidly changing and this method can be used to predict future conditions and produce a dispersion analysis and outcome map.

Future improvement on the ANN model will focus on source term release data, which are derived from severe accident codes, in order to refine the result space for nuclear applications. This enhancement is particularly important for Small Modular Reactors which are intended to be deployed diverse industrial and public locations. Environmental Impact Assessments and Emergency Planning and Response strategies can be enhanced significantly by utilizing ANN models to accelerate the evaluation of radiological dispersion analyses.

It can be stated that, prediction capability of ANN models is as good as the data quality used for the training. Consequently, the current model generally overlooks the rare and extreme dispersion scenarios over the region. Expanding both training database and considered weather parameters and iteration of the model with enlarged database, the prediction accuracy of ANN will be better equipped to recognize and accurately predict these rare cases.

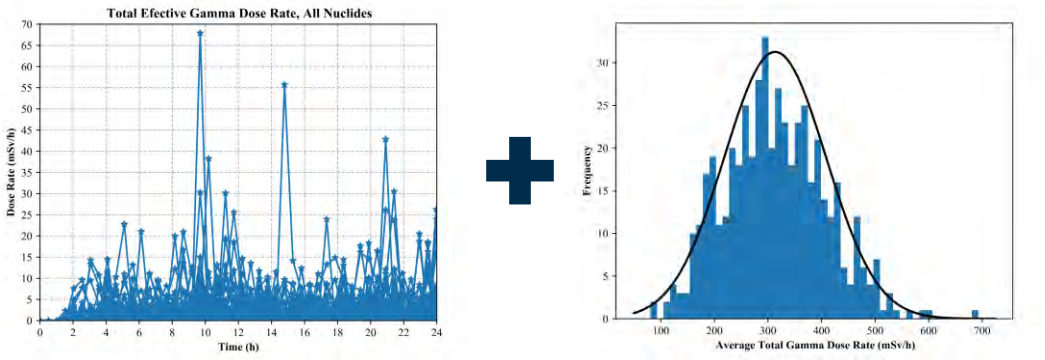
Content

1. Motivation
2. Tool: JRODOS
3. Artificial Neural Network (ANN) Surrogate Approach
4. Database & Setup
5. ANN Architecture and Training
6. Results
7. Importance of ANN Application
8. Conclusion

Motivation

- In the event of a severe accident, emergency response authorities require fast and accurate predictions of radionuclides.
  - Emergency Management Guidelines
  - Identification of Emergency Planning Zones
- Comprehensive risk assessments covering multiple calendar years and thousands of weather scenarios are computationally prohibitive.

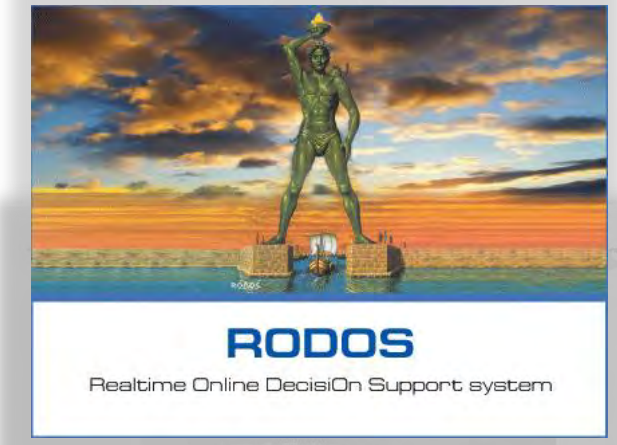


JRODOS Simulation of large batches requires
years of CPU time

60,000 simulation + Central Limit Theorem
25 days CPU time

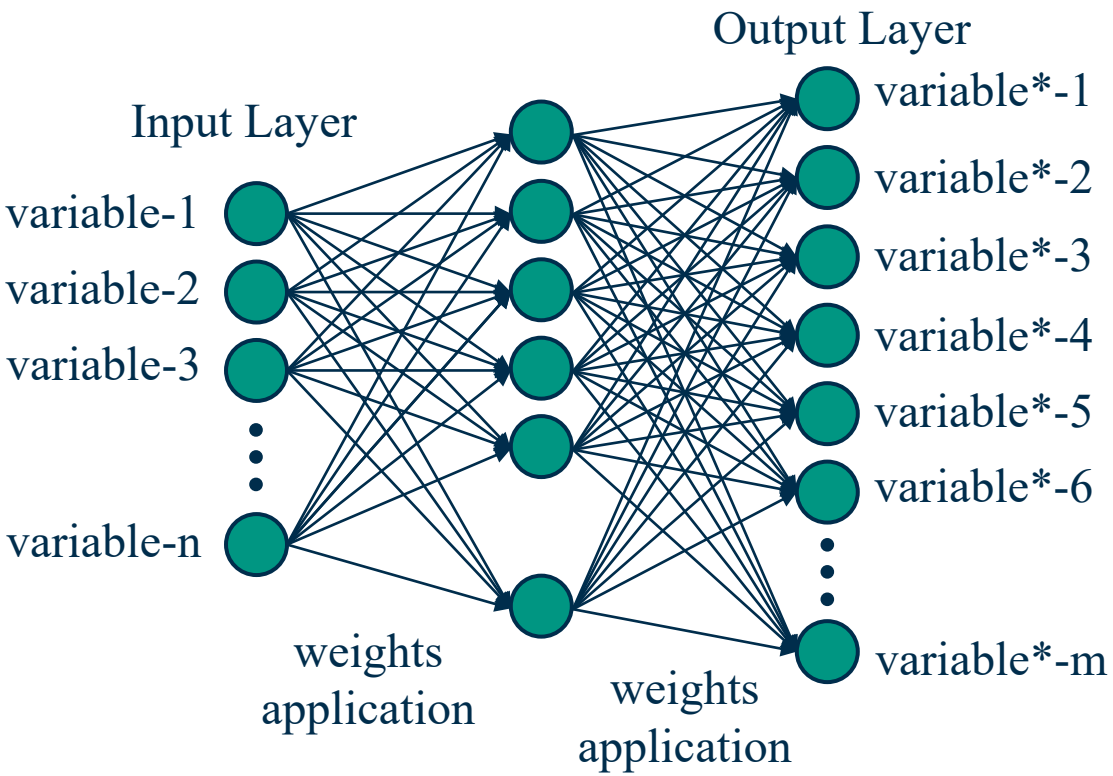
- A surrogate model is needed that can reproduce the Code (JRODOS) quality dispersion maps in a fraction of the time.

What is JRODOS?

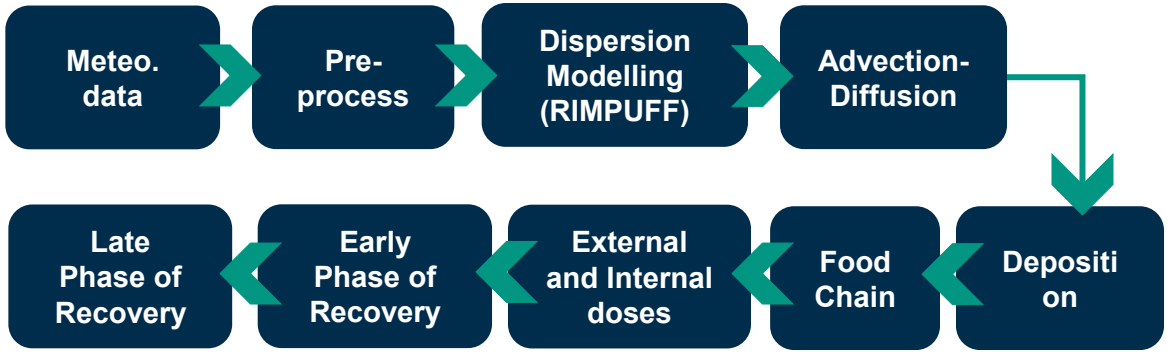


- JRODOS (Java-based Real-time Online Decision Support) System is the European standard tool for radiological emergency management, currently operational in regulatory bodies across many countries.
- The system integrates meteorological forecast data with user-defined source terms and advanced atmospheric dispersion models to calculate radionuclide transport and deposition over any region on the globe.
- Simulation outputs guide protective actions such as population sheltering, evacuation zone definition, and iodine tablet distribution.
- JRODOS relies on physically rigorous Gaussian puff and Lagrangian particle models, which accurately capture plume behavior and topographic interactions but at significant computational cost.

Artificial Neural Network (ANN) Surrogate Approach



- JRODOS or any other dispersion tool deals with differential equations, wrappers and libraries.



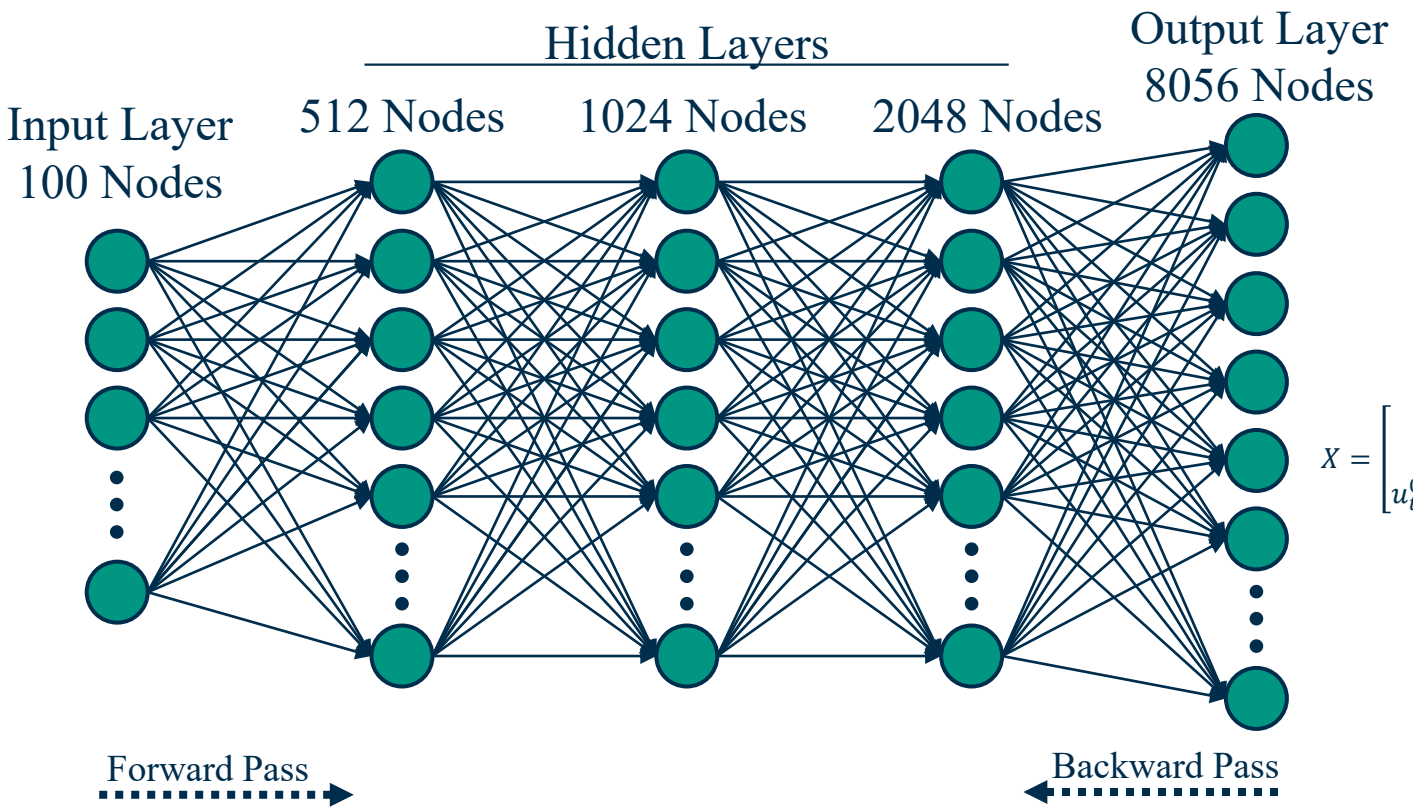
- An Artificial Neural Network (ANN) can be trained on a large database of pre-computed JRODOS simulations.
  - No equations are solved at runtime, only a series of fast matrix multiplications
- This acceleration makes it feasible to evaluate dispersion consequences across thousands of weather scenarios and multiple calendar years

Database and Setup

Isotope	Activity (Bq)	Isotope	Activity (Bq)
Cs-134	1.1E+15	**Kr-87**	9.0E+15
Cs-136	4.7E+14	**Kr-88**	1.8E+17
Cs-137	6.5E+14	**Sr-90**	4.7E+13
I-131	9.5E+15	**Sr-91**	6.4E+14
I-132	1.3E+16	**Te-131m**	1.1E+15
I-133	1.5E+16	**Te-132**	1.3E+16
I-135	7.0E+15	**Xe133**	4.6E+18
Kr-85	2.4E+16	**Xe-135**	2.1E+18
Kr-85m	1.5E+17		

- 1,000 JRODOS simulations was generated using a fictitious NPP location at KIT Campus North.
  - 100 km radius
  - 30 minutes time-steps over 24 hours simulation windows
- Radionuclides discharged into the atmosphere within a single 30-minute interval from a stack height of 150 meters.
- Weather data from U.S. NOAA NOMADS servers in GRIB format at 0.5-degree spatial resolution.
  - Random sampling of analysis starting time in year 2021
- 4 atmospheric parameters were extracted over a 5×5 grid centered on the plant.
  - U, V component of wind
  - Temperature
  - Surface pressure
- The dataset was divided into **90% for training** and **10% for testing.**

ANN Architecture and Training 1/2

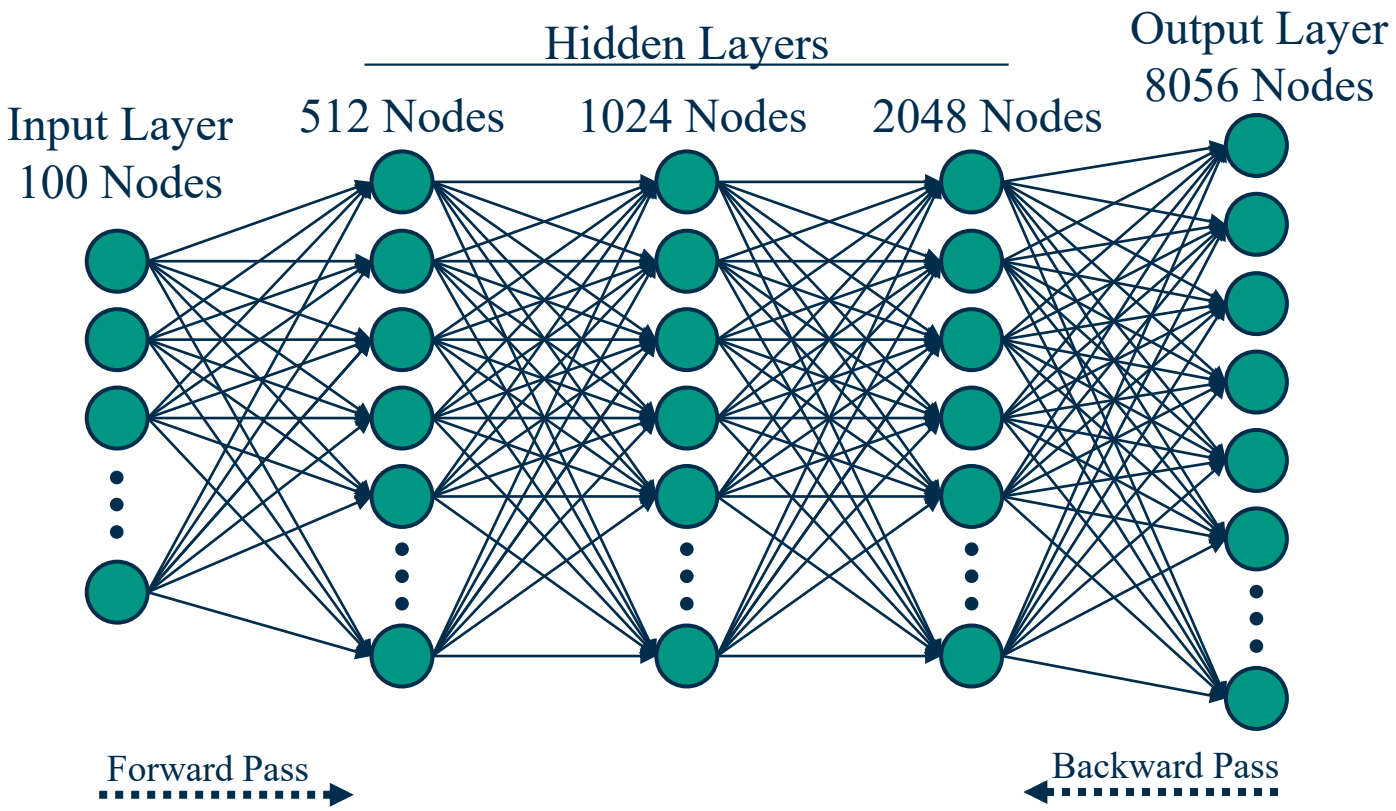


- Multilayer Perceptron (MLP) regressor with around 19 millions trainable parameters.
  - 100 nodes for meteorological input.
  - 8,056 output nodes for dose rate values corresponding to every mesh.

$$X = \begin{bmatrix} u^{0}_{t_0} \dots u^{24}_{t_0} & v^{0}_{t_0} \dots v^{24}_{t_0} & T^{0}_{t_0} \dots T^{24}_{t_0} & P^{0}_{t_0} \dots P^{24}_{t_0} \\ \vdots & \vdots & \vdots & \vdots \\ u^{0}_{t_47999} \dots u^{24}_{t_47999} & v^{0}_{t_47999} \dots v^{24}_{t_47999} & T^{0}_{t_47999} \dots T^{24}_{t_47999} & P^{0}_{t_47999} \dots P^{24}_{t_47999} \end{bmatrix}$$

$$y = \begin{bmatrix} dose^{mesh_0}_{t_0} & \dots & dose^{mesh_8055}_{t_0} \\ \vdots & \vdots & \vdots \\ dose^{mesh_0}_{t_47999} & \dots & dose^{mesh_8055}_{t_47999} \end{bmatrix}$$

ANN Architecture and Training 2/2

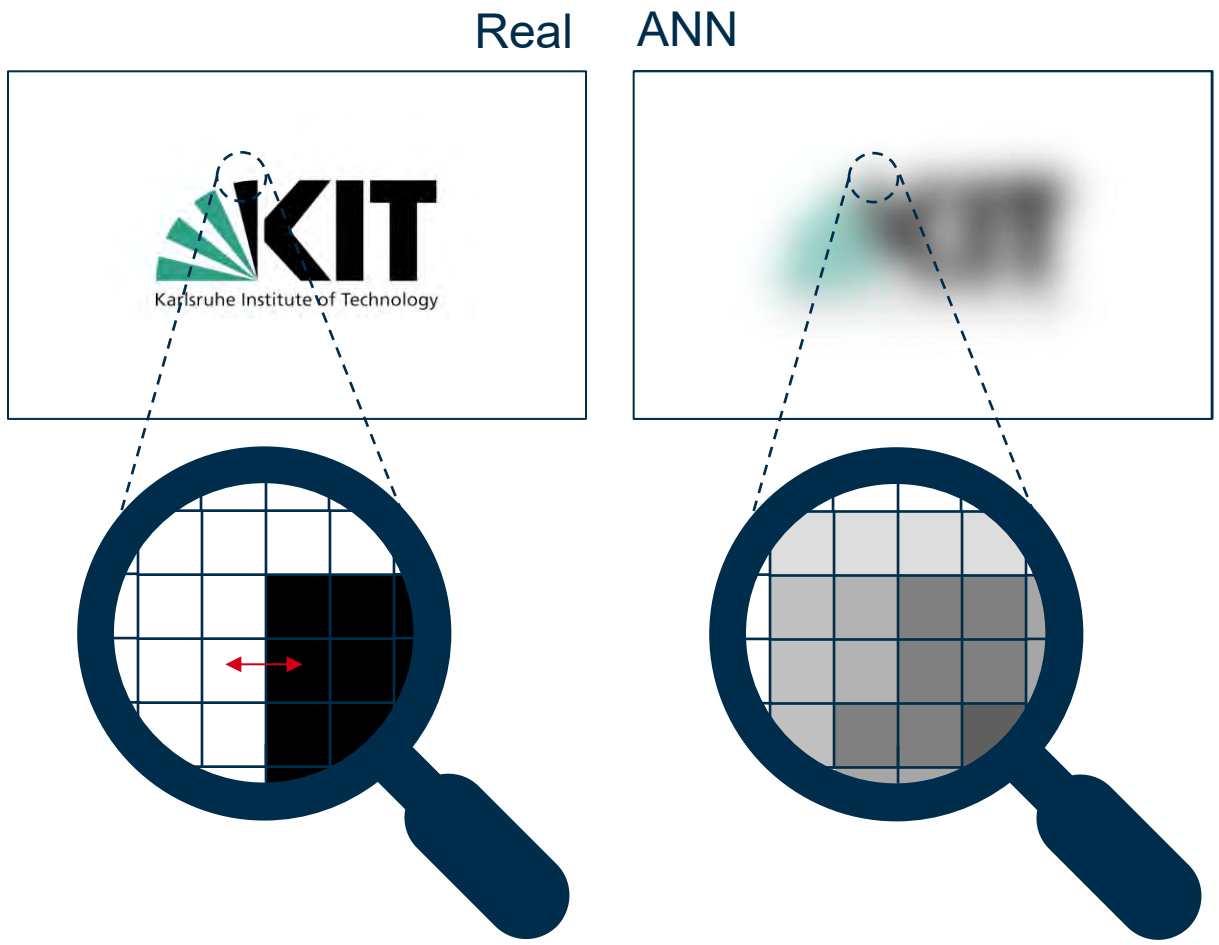


- ReLU activation functions are applied throughout the hidden layers to capture the non-linear behavior of the dispersion physics.
- Input parameters are normalized to prevent large-magnitude values like surface pressure from dominating gradient updates.
- Overfitting prevention: early stopping based on validation loss.

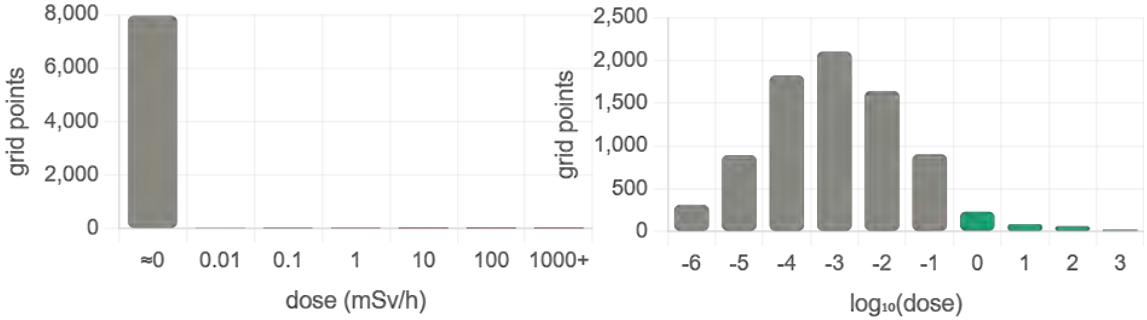
intel ~20 hours

NVIDIA ~15 minutes

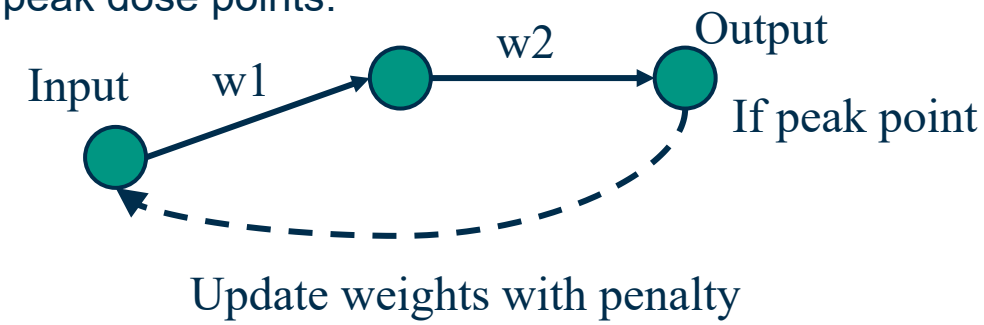
Training Challenges and Solutions



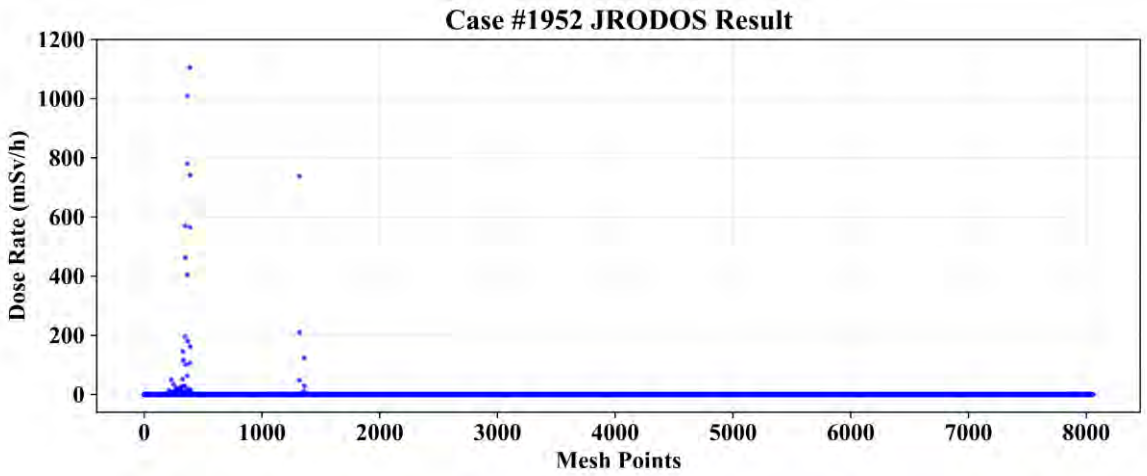
- Radioactive dispersion affects only a small fraction of the grid at any time.
  - Most grid points have near-zero dose → model learns to predict zeros.
- **Logarithmic scaling:** compressing the dynamic range and allowing the network to learn the shape.

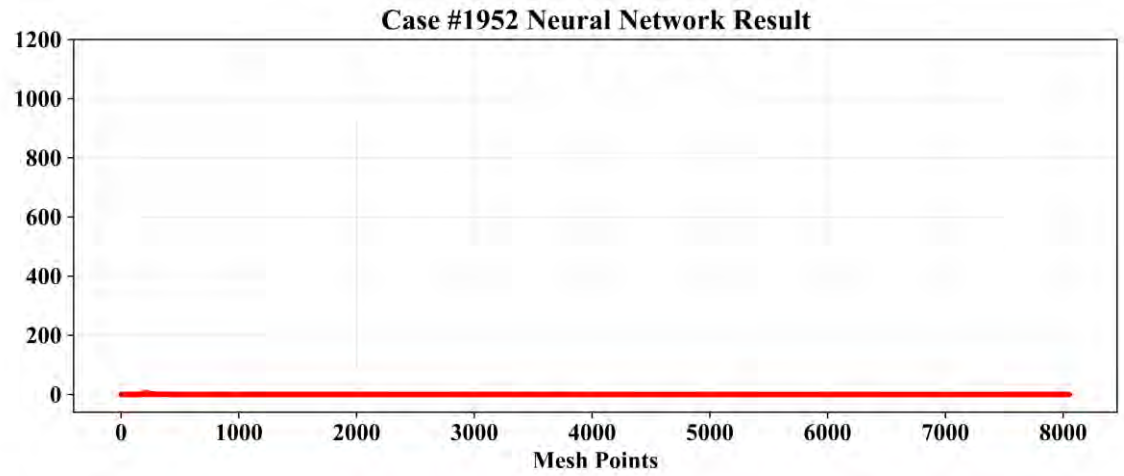


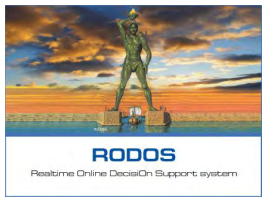
- **Penalty weighting:** penalty for underestimation of peak dose points.



Results: JRODOS vs ANN Prediction







~135 seconds

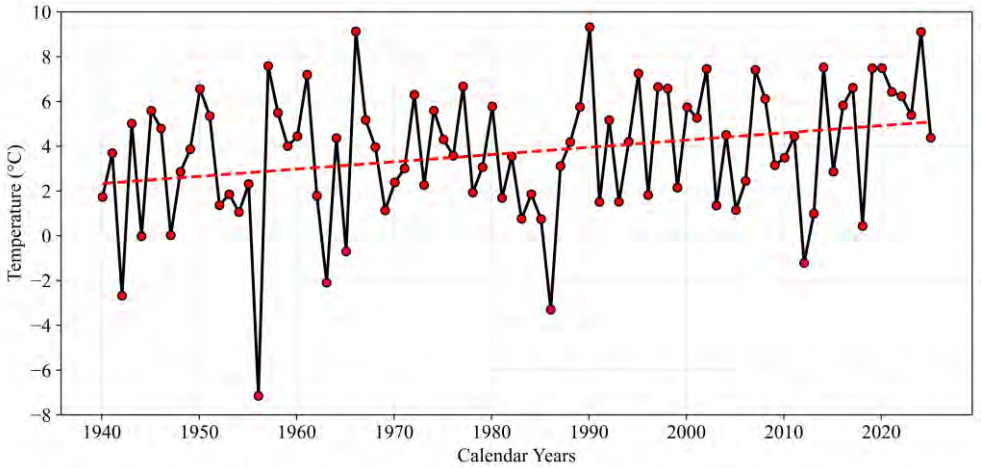
ANN **~0.08 seconds**

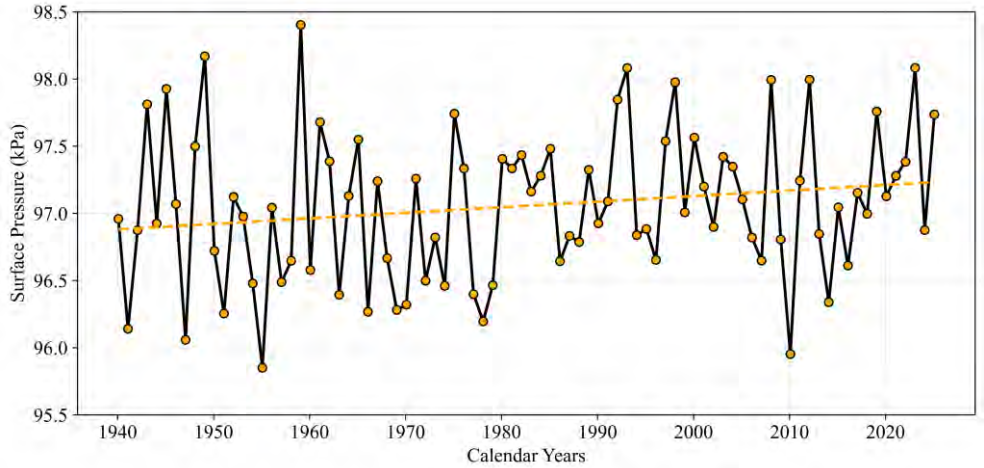
- The ANN model successfully identifies the spatial location and general footprint of the radioactive plume across the majority of test cases.
- For most test cases, dose rate predictions show good agreement with JRODOS results, with some tendency to overestimate peak values which is consequence of the penalty weighting.
- Model currently fails to capture cases where the plume remains close to the release point and does not travel far result in very high localized dose readings.

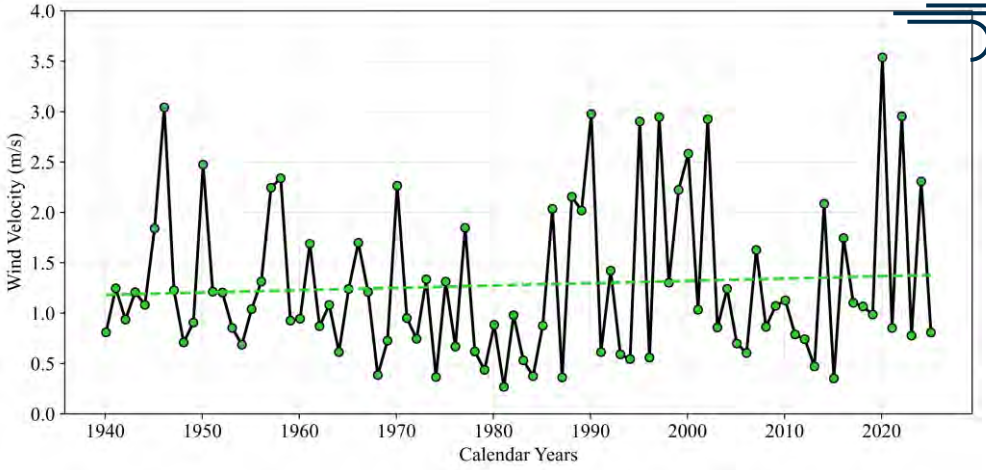
Why is it important? Climate Change

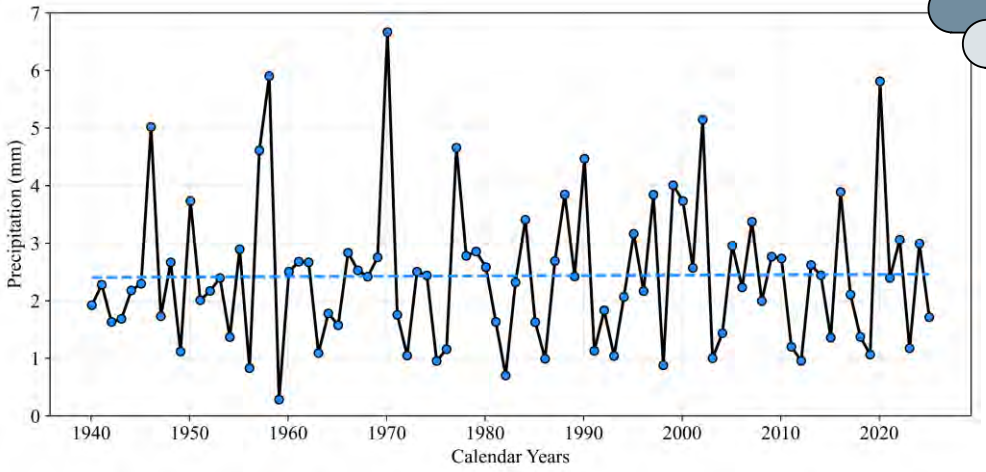
PROGRAMME OF THE EUROPEAN UNION

opernicus
Europe's eyes on Earth









Conclusion

- A deep learning surrogate model was successfully developed and validated against JRODOS, reducing dispersion prediction time from over 2 minutes to less than 0.1 seconds.
- The ANN accurately captures plume location and footprint across a wide range of meteorological conditions, demonstrating the viability of data-driven surrogate models as a complement to physics-based dispersion codes.
- The speed advantage opens the door to comprehensive multi-year, multi-scenario statistical assessments that significantly strengthen nuclear emergency preparedness and planning.
- The model will be extended for variable source terms derived from severe accident simulation codes. Scenario-specific dose predictions for different accident progressions is going to be considered.
- Investigation of application to Small Modular Reactor (SMR) siting studies, Environmental Impact Assessments, and Emergency Planning Zone definition is in agenda.
- The model accuracy will be improved iteratively for high-consequence, low-probability dispersion events through targeted data augmentation and advanced loss function design.

CSN CONSEJO DE SEGURIDAD NUCLEAR

Regulatory Interest in SA R&D

- Severe Accident R&D (SAR&D) is essential worldwide for **evidence-based nuclear regulation**, **continuous safety improvement**, and **increased knowledge of severe accident.**
- SAR&D enhances the capability of regulators ensuring that NPPs are designed, operated, and maintained with **robust defense-in-depth measures against low-probability-high-consequence events**, as well.
- Regulatory Decision-Making processes rely on (well validated, V&V) **Dynamic Simulation Computational Tools** (and the associated plant models), **Risk Assessment** (Level 2&3 PSA in the case of SA) **methods**, and **Uncertainty Quantification (UQ) methods** (hopefully!).
- **Experimental and analytical research** remain essential to reduce uncertainties and improve severe accident management strategies.
- Licensing frameworks for advanced reactor designs (NEI 18-04, 10CFR53, …) will increasingly depend on **validated models**, **PSA methodologies**, and **uncertainty-informed decision-making**

Improvement of Tools and Methods

Dynamic Simulation Computational Tools and V&V

- Regulators rely on validated severe accident integral codes for independent safety assessments.
- Validated computational tools improve confidence in predictions and safety evaluations.
- Feedback from experiments to simulation codes is essential to continuously improve model accuracy and predictive capabilities.
- Experimental R&D programs provide essential data for Verification and Validation (V&V) activities.

Risk Assessment (Level 2 & 3 PSA)

- PSA methodologies help regulators prioritize safety improvements according to risk significance.
- Containment event trees and release categories support evaluation of plant risk profiles.
- Subsidiary analytical tools of L2PSA methods need to be well validated against experimental results.
- SAR&D provides models and input data for Level 2 Probabilistic Safety Assessments (PSA).
- SAR&D results enhance the understanding and delineation of dominant accident sequences and overall plant risk.

Uncertainty Quantification (UQ)

- Experimental and analytical research remain essential to reduce uncertainties.
- SAR&D provides data/knowledge to characterize uncertainties in the phenomena/parameters.
- Development of Systematic UQ Methodologies, including comprehensive PIRT studies, (i.e., a potential "Severe Accident Uncertainty Handbook") would significantly enhance safety assessments.
- Inverse UQ (IUQ) methods would improve the characterization of uncertain inputs to UQ (parameters/phenomena).
- *Advanced reactor licensing frameworks (NEI 18-04, 10CFR53, ...) will increasingly depend on "Validated Models, PSA Methodologies, and Uncertainty-informed" decision-making.*

CSN CONSEJO DE SEGURIDAD NUCLEAR

Summary of Expectations

- **Experimental Programs** to provide essential data for V&V and improvements of SA simulation tools.
  - Need for international collaboration in supporting experimental facilities, data bases, expertise, ….
- **Development and Deployment of Systematic UQ Methodologies for SA**, including comprehensive PIRT studies to enhance SA safety assessments and RIDM.
  - **Inverse UQ (IUQ) methods** to improve the characterization of uncertain inputs to UQ (parameters/phenomena).
- **Extensive use of AI and ML techniques** in any of the pillars.
- Eventual **applicability of IDPSA methods to SA analysis** (e.g., advanced reactor designs)
  - To address the mutual interactions between disturbances (e.g., failures of the equipment, human actions, stochastic physical phenomena) and the corresponding transients (i.e., deterministic response).
  - To compute consistently the tight coupling of the Scenarios, their Consequences (deterministic), and their Frequency (probabilistic) (i.e., all the three ingredients of Risk).
  - All the three ingredients intrinsically uncertain: IDPSA a consistent and integrated treatment of the different sources of uncertainties.

CSN CONSEJO DE SEGURIDAD NUCLEAR

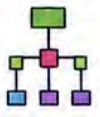
Regulatory Use of SAR&D

Regulatory Use of SAR&D (1/3)

Development of Regulatory Frameworks

- SAR&D supports development of regulations for BDBAs, DECs, containment performance, and severe accident management.
- Advanced reactor licensing frameworks (NEI 18-04, 10CFR53, ...) will increasingly depend on validated models, PSA methodologies, and uncertainty-informed decision-making.



Risk-Informed Decision Making

- Provides PSA input for risk-informed and performance-based regulation using metrics such as LERF.
- Advanced reactor licensing frameworks (NEI 18-04, 10CFR53, ...) will increasingly depend on validated models, PSA methodologies, and uncertainty-informed decision-making.

Licensing and Safety Review

- Support verification of vendor analyses and evaluation of SA mitigation systems and associated SA guidelines using SA codes and Risk methods.

Validation of Safety Analysis Codes

- Experimental SAR&D data support the improvement of simulation tools (ASTEC, MELCOR, MAAP, ...), and the subsidiary analytical tools on L2 PSA methods.
- Experimental investigations improve understanding of degraded core behavior.
- SAR&D analyzes in-vessel and ex-vessel core melt progression phenomena, evaluate melt retention strategies, core catcher requirements and debris coolability.

Regulatory Use of SAR&D (2/3)

Accident Management and SAMGs Review

- Contributed to the development and validation of Severe Accident Management Guidelines (SAMGs).
- Help to evaluate whether operators can effectively mitigate core damage progression.
- Help to analyze containment protection strategies and accident mitigation actions, e.g., supporting the assessment of combustible gases control, depressurization, and containment protection strategies
- Research also investigates possible negative effects of mitigation actions.
- Understanding uncertainties helps avoid unrealistic overly conservative approaches.

Containment Performance and Combustion Risk Mitigation

- Experimental programs support combustible gases (hydrogen, and CO) generation, transport and combustion.
- Helps to defines requirements for PARs, igniters, and venting systems under SA conditions and supports their safety evaluations
- Experimental SAR&D data support the improvement of simulation tools (ASTEC, MELCOR, MAAP, ….), and the subsidiary analytical tools on L2 PSA methods

Source Term Evaluation and Emergency Planning

- Experimental and analytical programs improve source term realism for emergency planning and offsite consequence assessment.
- Simulation tools support the definition of emergency planning zones and protective actions, and help to evaluate evacuation timing, sheltering, and iodine distribution strategies.
- Results strengthen public communication and emergency response coordination.
- Research also investigates possible negative effects of mitigation actions.
- Understanding uncertainties helps avoid unrealistic overly conservative approaches.

Regulatory Use of SAR&D (3/3)

Post-Accident Monitoring and Instrumentation

- Help to define survivable instrumentation requirements for SA management decision-making.
- Help in the characterization and guarantee of proper functioning of the instrumentation under SA challenging levels

Post-Fukushima Enhancements and SFP Safety

- Post-Fukushima SAR&D strengthened the deployment and optimization of:
  - ❑ SBO mitigation (and other DEC-A),
  - ❑ mobile equipment (FLEX),
  - ❑ associated guidelines (EDMGs and FSGs) deployment,
  - ❑ filtered containment vents,
  - ❑ beyond-design-basis preparedness, ...
- Spent Fuel Pool (SFP) studies improved cooling and makeup water strategies.

International Collaboration and Harmonization

- EU, OECD/NEA and IAEA cooperation improves consistency and sharing of SAR&D knowledge.
- Accomplish international compromises in supporting experimental facilities, data bases, expertise, ...
- Help to fulfill commitments aimed at maintaining national expert groups in SA.

Inspection, Oversight, and Enforcement

- Help to focus oversight on systems critical for SA mitigation and BDBA readiness.

Notes to the Severe Accident Research Community Based on the Experience of the Fukushima Dai-ichi Accident

NDF **Toyoshi FUKETA** UTokyo

Nuclear Damage Compensation and Decommissioning Facilitation Corporation

May 19, 2026

Plenary Session 2 'EXPECTATIONS FROM SA R&D'

TEPCO Fukushima Dai-ichi Accident

Pre-accident

- ✓ Overconfidence: Safety myth
- ✓ Belief among industries, regulators, and academia in “sufficient knowledge of NPP risks”

Reality revealed

- ✓ Critical gaps in knowledge and risk awareness
- ✓ Inability to take effective actions

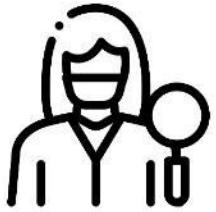
Post-accident global consensus

- ✓ Recognition of the need for enhanced safety measures
- ✓ Commitment to additional actions for strengthening NPP resilience

Peace-time preparedness

- ✓ Once an accident occurs, numerous self-proclaimed experts emerge, and their misleading views can compromise critical decision-making.
- ✓ Prior to the accident, there was a tendency in our society to discourage SA studies for fear of inciting public unease over nuclear energy.
- ✓ Establishing public recognition of credible information sources before a crisis is essential.
- ✓ An authoritative entity is essential to filter out dubious technical claims with a firm stance.

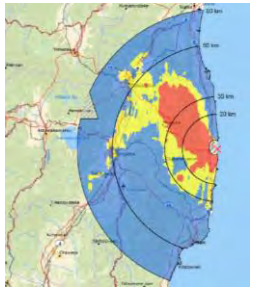
Analyzing accident scenarios takes the highest priority



- ✓ While understanding individual phenomena is important, prioritizing accident progression and scenarios is critical.
- ✓ Once an accident occurs, public attention shifts to what happens next, and authorities are immediately required to estimate the worst-case scenario.
- ✓ Many people now seem to be trying to believe that SAs can be practically eliminated by design. However, new accident scenarios should be considered for new designs.
- ✓ Research into detecting the onset and progression of phenomena is also essential.

Magnitude of consequence

- ✓ The greatest damage of the F-1 accident is the long-term relocation due to environmental contamination.
- ✓ Accident consequences cannot be assessed solely by radiation exposure.
- ✓ Is LRF, Large Release Frequency, an adequate indicator for large-scale releases?
  There may be ethically unacceptable consequences that must not be exceeded, regardless of probability.



- ✓ The long-term post-accident response largely determines the magnitude of damage.

Recommendation, e.g.,

- ✓ Establish the technical basis for the practical elimination of major radioactive release in advanced reactors and define its requirements.
- ✓ Evaluate severe accident measures for existing plants, incorporating Fukushima insights and long-term operation plans.
- ✓ Identify containment-threatening scenarios in advanced systems, considering diverse safety designs and concepts.
- ✓ Develop advanced instrumentations for SA monitoring and management.
- ✓ Organize a framework with the widest possible community to lead collaborative experimental projects around structured collaborative experimental research platforms.

Innovation requires strong and independent regulatory body

Under-regulation

- ✓ Cause fundamental threat to market stability
- ✓ Increase “Weakest link” risk

  Devastate the entire industry due to a failure by a single poor competitor

Strong and independent regulator

- ✓ Provide objective evaluation of diverse technologies
- ✓ Ensure a level playing field to foster healthy competition
- ✓ Enable the best concepts and companies to prevail

ABSTRACT

The safety assessment of Small Modular Reactors (SMRs) requires rigorous analysis of severe accident scenarios, particularly high-pressure transients, which pose greater challenges in compact designs compared to conventional PWRs with large containments. This study evaluates a high-pressure severe accident in a PWR-type SMR using the MAAP5 code, focusing on a total loss of feedwater (TLOFW) event. Results show that despite core uncovery and entry into a severe accident phase, the reactor maintains long-term coolability through inherent passive mechanisms. Natural circulation within the reactor vessel and passive heat removal via the external vessel wall prevent significant core damage. The passive containment cooling system effectively transfers heat to the emergency cooling tank, maintaining containment integrity. Hydrogen generation is minimal, and the high steam environment precludes combustion risk. The analysis demonstrates that the SMR's passive safety systems effectively mitigate high-pressure accident progression, ensuring stable cooling and enhanced safety without operator intervention.

KEYWORDS
SMR, high-pressure, passive safety, severe accident

1. INTRODUCTION

Small Modular Reactors (SMRs) possess inherent safety characteristics that fundamentally reduce the likelihood of severe accidents, owing to their lower thermal power, integral design, and reliance on passive safety systems, compared to large-scale nuclear power plants. These features enable long-term decay heat removal without external power or operator intervention, thereby enhancing resilience under multiple failure accident scenarios, including high-pressure severe accidents.

A variety of SMR designs have been proposed worldwide. According to the OECD/NEA SMR Dashboard [1], designs incorporating passive cooling systems are receiving significant attention. In particular, designs such as NuScale [2] and i-SMR [3], which employ passive heat removal systems that circulate internal atmosphere and condensed water between the Reactor Vessel (RV) and the Containment Vessel (CV), offer favorable characteristics for long-term cooling. However, due to the relatively small free volume of SMRs compared to large Pressurized Water Reactors (PWRs), high-pressure conditions are more likely to persist during the progression of a severe accident. This increases the significance of high-risk accident sequences such as High-Pressure Melt Ejection (HPME) and Direct Containment Heating (DCH).

In this study, a high-pressure severe accident scenario is analyzed using the Modular Accident Analysis Program (MAAP5.06) [4] for an SMR design incorporating passive safety systems. The primary system responses, pressure evolution, fuel damage timing, and performance of passive safety equipment are

evaluated. The objective is to quantitatively assess the SMR's response characteristics under high-pressure severe accident conditions and to derive design insights for enhancing safety.

2. DESIGN CHARACTERISITCS OF SMALL MODULAR REACTOR

The SMR analyzed in this study features an integral design, with the reactor core, pressurizer, steam generator, and reactor coolant pumps housed within a single RV. The RV is enclosed by a steel CV, which provides structural and radiological protection. At the upper part of the CV, heat exchangers for the Passive Containment Cooling System (PCCS) are installed and connected to an external water source in the Emergency Cooling Tank (ECT). The PCCS removes heat from the CV's internal atmosphere. Condensate formed on the heat exchanger surface falls by gravity into the annular gap between the RV outer wall and the CV inner wall, forming a condensate pool. This pool provides long-term passive cooling of the RV outer surface. A pressurizer located at the top of the RV is equipped with two Pressurizer Safety and Relief Valves (PSRVs) and an Emergency Depressurization Valve (EDV), which function to mitigate Reactor Coolant System (RCS) overpressure during transient or accident conditions. Additionally, an Emergency Recirculation Valve (ERV) is installed on the lower side of the RV. This valve allows the condensate pool water to be naturally recirculated back into the core region, supporting accident mitigation through passive cooling.

3. SELECTED SEQUENCE

Among various initiating events that could lead to a high-pressure severe accident, a Total Loss of Feedwater (TLOFW) is selected for analysis due to its rapid accident progression and high decay heat load. The scenario assumes a simultaneous loss of both main and passive auxiliary feedwater systems, followed by failure of automatic opening of the EDV and ERV - representing a conservative and challenging condition. Under this scenario, RCS overpressure control relies solely on the cycling operation of the two PSRVs, while the CV is cooled passively by the PCCS. The total simulation period extends for 7 days (168 hours) from the initiation of the transient.

4. CALCULATION RESULTS AND ANALYSIS

Immediately after the TLOFW event, the reactor coolant pumps (RCPs) trip and a reactor scram are assumed, leading to a rapid rise in RCS temperature and pressure. Approximately 400 seconds after the initiating event, the PSRVs open for the first time, discharging coolant and steam into the CV. The valves close again at 488 seconds, and subsequently cycle based on pressure setpoints. As shown in Figure 1, the RCS pressure is maintained within a range of 14.0 to 17.2 MPa due to the PSRV cycling. By 10.6 hours (38,304 seconds), the RCS pressure no longer reaches the PSRV opening setpoint, and discharge ceases. The total cumulative mass released through the PSRVs is approximately 141 tons, with a peak mass flow rate of up to 31 kg/s during initial discharge.

As the RCS inventory decreases, the water level in the RV gradually drops. The top of the core becomes uncovered at 13,761 seconds (~3.8 hours), and the water level stabilizes, leaving approximately 75% of the core height exposed (Figure 2). Although the severe accident entry conditions are initiated at 30,597 seconds (~8.5 hours), the maximum fuel temperature does not exceed 1,125 K and gradually decreases over time. This indicates that significant core melt or structural failure does not occur. A strong natural circulation flow is established between the uncovered core and the upper plenum, with a peak natural circulation flow rate of 10 kg/s.

The PCCS functions as designed, forming a condensate pool of approximately 8.2 m depth at the bottom of the CV, which effectively cools the RV outer wall (Figure 2). The outer tube wall temperature of the PCCS heat exchanger remains 80 to 100 K lower than the bulk CV atmosphere temperature, enabling continuous

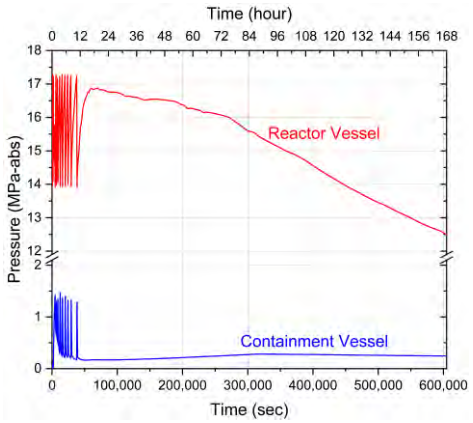

Figure 1. RCS and CV pressure transients during the 7-day accident sequence.

condensation. The condensation rate peaks at 50 kg/s initially and stabilizes at around 29 kg/s during long-term operation (Figure 3). The ECT water temperature increases gradually and reaches saturation at approximately 86 hours (3,096 minutes), after which evaporation begins (Figure 3). However, sufficient water inventory remains at the end of the 7-day period, ensuring that the CV is protected from overpressure threats (Figure 1). This confirms that the PCCS heat removal capacity is sufficient to manage decay heat over the long term.

The total hydrogen generated over the 7-day period is approximately 24 kg, which corresponds to about 12% of the theoretical maximum from complete cladding oxidation. The hydrogen is uniformly distributed within the CV. Given the extremely high steam concentration (over 95%) and low oxygen and hydrogen concentrations, the risk of hydrogen combustion is deemed negligible.

5. SUMMARY

This study evaluates the response of a passive-safety-based Small Modular Reactor (SMR) under high-pressure severe accident conditions. A conservative scenario involving total loss of feedwater and failure of emergency depressurization and recirculation systems was analyzed using the MAAP5.06 code over a 7-day period.

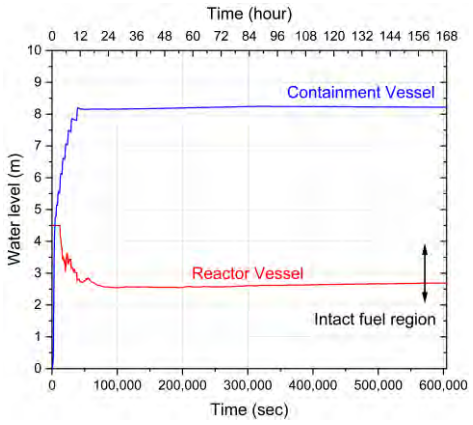

Figure 2. Core water level and condensate pool formation in the CV.

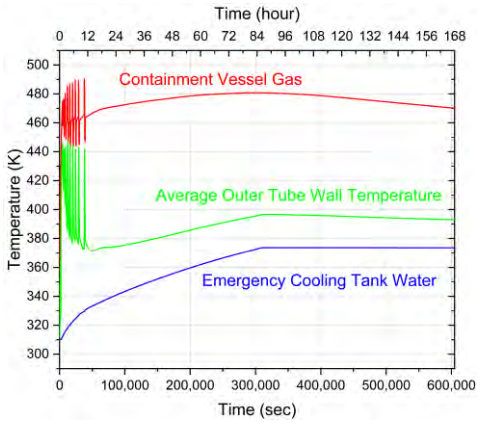

Figure 3. CV atmosphere temperature, PCCS heat exchanger outer wall temperature, and ECT water temperature.

The results show that RCS pressure is effectively controlled through the cycling operation of the PSRVs. The PCCS functions as intended, forming and maintaining a condensate pool that provides sustained passive cooling of the RV outer wall. This, combined with natural circulation within the core region, effectively suppresses fuel temperature rise. Although the core becomes largely uncovered (~75%), no significant core melt or structural failure is observed, and the maximum fuel temperature remains below 1,125 K.
Hydrogen generation is limited to 24 kg (~12% of full oxidation), and the high steam concentration and low oxygen environment within the CV eliminate the risk of hydrogen combustion.

These findings demonstrate that, even under severe and conservative assumptions, the inherent safety features and passive cooling systems of the SMR effectively mitigate accident progression. In particular, the prevention of RV rupture under high pressure and the sustained long-term heat removal capability confirms that SMRs can provide a high level of safety during severe accident scenarios.

This study provides valuable insights for the development of high-pressure severe accident management strategies and the design validation of passive safety systems in SMR applications.

MAAP5 ANALYSIS OF HIGH-PRESSURE SEVERE ACCIDENTS IN A SMALL MODULAR REACTOR

Byung Jo KIM, Yong Ju CHO, and Dong Min PARK
KEPCO Engineering and Construction Co., KOREA

1. Background and Motivation

In the event of a severe accident in a Small Modular Reactor (SMR), there exists a potential threat of radioactive material release to the environment. Compared to conventional large-scale pressurized water reactors (PWRs), the free volume of the Containment Vessel (CV) in an SMR is approximately one-tenth to one-twentieth that of a conventional large PWR, which may increase the risk of containment overpressurization during high-pressure severe accidents.

Key Concern: The substantially smaller CV free volume in SMRs means that high-pressure severe accidents may pose a greater risk of containment over-pressurization and potential failure compared to large conventional PWRs.

This study evaluates the progression and consequences of a high-pressure severe accident in a PWR-type SMR using the MAAP5, with particular focus on the effectiveness of passive safety features.

2. Methodology and Assumptions

The severe accident progression in an SMR under high-pressure conditions was simulated using the MAAP5 (Modular Accident Analysis Program, Version 5) code.

MAAP5 Code | PWR-type SMR | Passive Safety | Containment Vessel Integrity

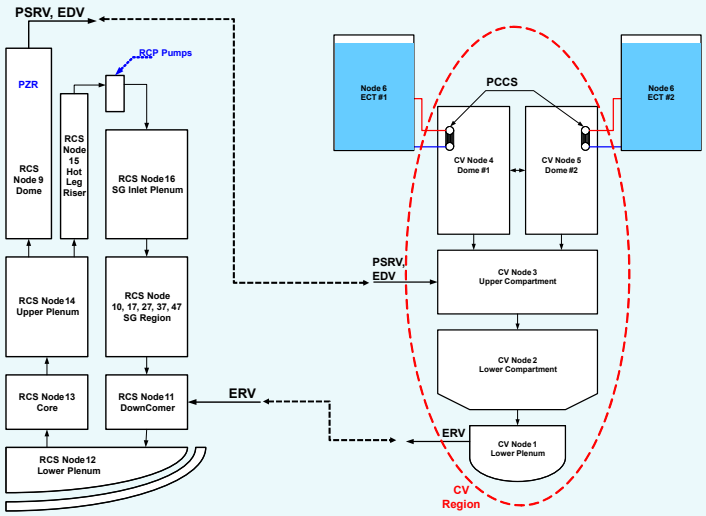
Key Assumptions:

- High-pressure transient initiated with loss of main feed water system.
- Only the Passive Containment Cooling System (PCCS) is assumed to remain available.
- All other passive safety systems (e.g., Passive Auxiliary Feedwater System, Passive Emergency Core Cooling System) are assumed to fail.
- No operator action is credited throughout the transient.

Initiating Event (Loss of Main Feed water) → Passive Systems Fail (except PCCS) → High-Pressure Transient → Core Damage → PCSS Mitigation

3. MAAP5 Nodalization Schematic

Reactor Vessel (RV) | **Containment Vessel (CV)**



4. Accident Progression

Phase 1 – High Pressure Blowdown & Core Damage:

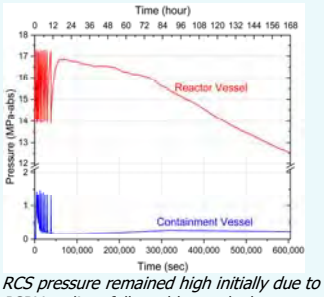
- Following the initiating event, RCS pressure remained at an elevated level within the automatic open/close pressure band of PSRV (Pressurizer Safety Relief Valve).
- RCS inventory was discharged through the PSRV cycling, leading to the core uncovery and onset of severe accident conditions.

Phase 2 – PCCS Mitigation & Accident Termination:

- PCCS forms a condensate pool on the external surface of the RV.
- Combined with natural circulation inside the RV and passive heat sink, large-scale core melting and relocation to the lower head were prevented.

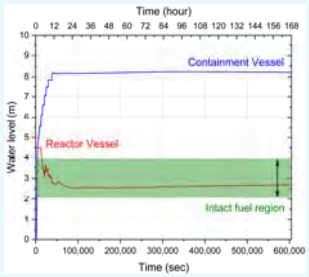
5. Analysis Results

Primary System Pressure Transient:



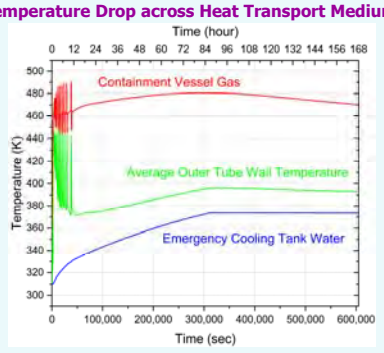
RCS pressure remained high initially due to PSRV cycling, followed by gradual depressurization as passive cooling progressed.

Core Water Level and Condensed Pool Level:



Although core level decreased initially, condensate accumulation on the RV exterior contributed to long-term heat removal.

Temperature Drop across Heat Transport Medium:



The maintained temperature gradient indicates continued passive heat transfer from the RV to the containment-side cooling path.

6. Conclusions

Summary of Findings

- A high-pressure severe accident was initiated by loss of main feed water with only PCCS available.
- MAAP5 was used to analyze a accident in SMR.
- PCCS-induced external RV cooling and natural circulation mitigated accident progression.
- Passive heat removal mechanisms provided sustained long-term cooling.
- No high-pressure failure of the RV or CV was predicted under assumed conditions.

★ The results indicate strong passive accident mitigation capability without credited operator action.

Development and Evaluation of an Ablation-Resistant Basemat Concrete for Severe Accident Mitigation in LWRs

Type of abstract: Poster
Subject area: Ex-vessel corium interactions and coolability
Keywords: ablation-resistant concrete; basemat concrete; COLOR facility; MCCI; severe accident

During a severe accident in a light water reactor, molten corium may enter the reactor cavity and erode the basemat concrete through molten core–concrete interaction (MCCI), potentially threatening containment integrity through basemat penetration and overpressure. Previous studies have shown that the concrete type and its material properties are critical factors affecting both the ablation rate and gas generation. This work presents a systematic method for screening ablation-resistant concrete, developed from practical engineering requirements and a corium–concrete erosion model. Based on CALPHAD thermodynamic calculations, an optimal composition enriched in MgO and Al_2O_3 was identified. Mechanical tests and thermodynamic analyses confirm that the designed concrete meets nuclear-grade structural strength standards while exhibiting a high melting point and large melting enthalpy. One-dimensional MCCI experiments conducted in the COLOR facility, using ZrO_2–Zr–Fe as a corium simulant, show that its ablation rate is significantly lower than that of conventional siliceous concrete, demonstrating strong potential for application in severe accident mitigation.

Development of an Ablation-Resistant Basemat Concrete for Severe Accident Mitigation in LWRs

Erhui Chen, Li Zhang, Nan Li, Jie Pei, Wei Li, Yidan Yuan*

Introduction

During severe accidents of LWRs, molten corium may enter the reactor cavity and erode the basemat concrete through molten core–concrete interaction (MCCI), potentially threatening containment integrity through basemat penetration and over-pressure. Concrete type and properties are known to critically influence MCCI outcomes. Therefore, modifying the concrete mix design to reduce the ablation rate and limit non-condensable gas production represents an effective strategy for MCCI mitigation.

Research Objectives

- **Screening:** develop a systematic screening criteria for ablation-resistant concrete
- **Selection:** perform thermodynamic calculations to identify high-performance candidate formulations
- **Simulation:** evaluate the selected concrete via MAAP5
- **Validation:** via experimental MCCI test (In Progress)

Screening Methodology

During the MCCI phase, the novel concrete is designed to:

- Reduce the ablation rate
- Suppress non-condensable gases (H_2,CO,CO_2)
- Lower the melt pool temperature
- Promote homogenization or layer inversion (metal layer below oxide layer) through oxidation

Additional requirements: C40 strength grade and adequate workability for construction.

Based on a one-dimensional ablation model for concrete (Fig.1), the concrete ablation rate is given by:

$$v_{abl} = \begin{cases} \dfrac{h\left(T_F - T_{F,m}\right) + q_v x_{cr} - k_{cn}\dfrac{T_{dc} - T_0}{\delta}}{\rho_{cn}\Delta H_{cn}}, & \text{with crust} \\ \dfrac{h\left(T_F - T_{dc}\right) - k_{cn}\dfrac{T_{dc} - T_0}{\delta}}{\rho_{cn}\Delta H_{cn}}, & \text{without crust} \end{cases}$$

T_F : corium temperatur $T_{F,m}$: liquidus temperature of corium

T_{dc} : melt temperature of concrete T_0 : initial temperature of concrete

ΔH_{cn}: melt enthalpy of concrete (from T_0 to T_{dc})

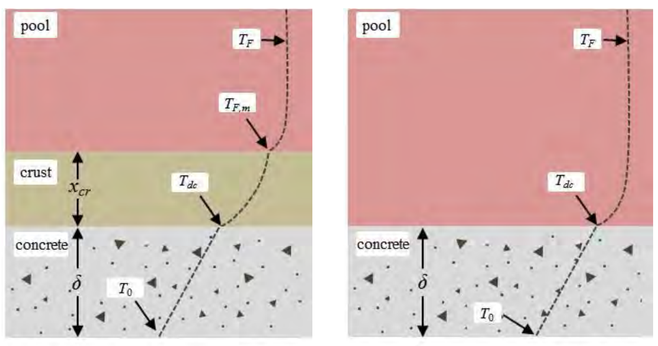

Fig.1 1D concrete ablation model (left: with crust, right: without crust)

According to the above equation, the concrete ablation rate decreases with:

- Higher melt temperature of concrete
- Higher melt enthalpy of concrete
- Higher density of concrete
- Higher thermal conductivity of concrete
- Lower convection heat transfer coefficient
- Lower melt pool temperature
- Higher liquidus temperature of corium-concrete mixture

Screening Assumptions and Tools:

- Thermodynamic equilibrium between molten corium and concrete with representative decay heat
- No transient, no kinetics, no external cooling (adiabatic system)

The properties and thermal equilibrium of various candidate concrete formulations are evaluated using Thermo-Calc software and NUCLEA database.

Ablation-Resistant Basemat Concrete

The composition of concrete is dominated by various oxides. To identify an optimal formulation, binary and ternary combinations were prepared from a set six common oxides (Fe_2O_3, Al_2O_3, CaO, SiO_2, MgO, SrO). Based on the screening criteria, the novel formulation characterized by a **MgO-Al_2O_3 rich system (M3)** was identified. This composition was compared against an ordinary siliceous concrete (**P1**, listed in Table 1).

Table 1 concrete	P1 compositions
MgO	1.04
Al_2O_3	12.39
Fe_2O_3	2.09
SiO_2	63.07
CaO	8.56
SrO	0.06
K_2O	3.69
Na_2O	2.66
MnO_2	0.06
TiO_2	0.29
Cr_2O_3	0.03
CO_2	0.5
H_2O	5.16

Key Property Enhancements (M3 vs. P1, see Table 2)

Compare to P1, the novel M3 concrete offers:

- Increased compressive strength
- Higher liquidus/solidus/melt temperature
- Higher melt enthalpy and specific heat.
- Greater heat conductivity and density.

Table 2 properties comparison between P1 and M3

Property	P1	M3	units
Slump	160	140	mm
Compressive strength (28d)	68.6	92.1	MPa
Splitting tensile strength (28d)	5.6	5.7	MPa
Specific heat	0.97	1.1	kJ/(kg▪K)
Thermal conductivity	2.38	5.56	W/(m▪K)
Density	2580	2950	kg/m^3
Porosity	7.2%	12.9%	--
Liquidus T *	1620.5	2940.4	K
Solidus T *	1411	1577.7	K
T_{dc} *	1562.2	2846.2	K
ΔH_{cn} *	2.0×10^6	5.1×10^6	J/kg

* : calculated from Thermo-Calc with NUCLEA database

MAAP5 Simulation Parameters

- **Accident scenario:** double-ended cold leg LOCA (1000MWe Zion-like PWR) with dry cavity
- **PRV failure:** at 5686s after accident initiation
- **Corium state**: detailed in Table 3, with a residual decay heat of 43.5MW.

MCCI Mitigation Results

- **Ablation resistance:** M3 demonstrates a dramatic reduction in erosion rate compared to P1 **(2.22cm/h vs. 9.82cm/h)**.
- **Gas generation:** limited gas production due to the absence of carbonate aggregates in both P1 and

Table 3 corium composition at lower plenum when RPV fails

Power	Maximum 500 kW
Frequency range	100~150 kHZ
Atmosphere	Vacuum / Ar

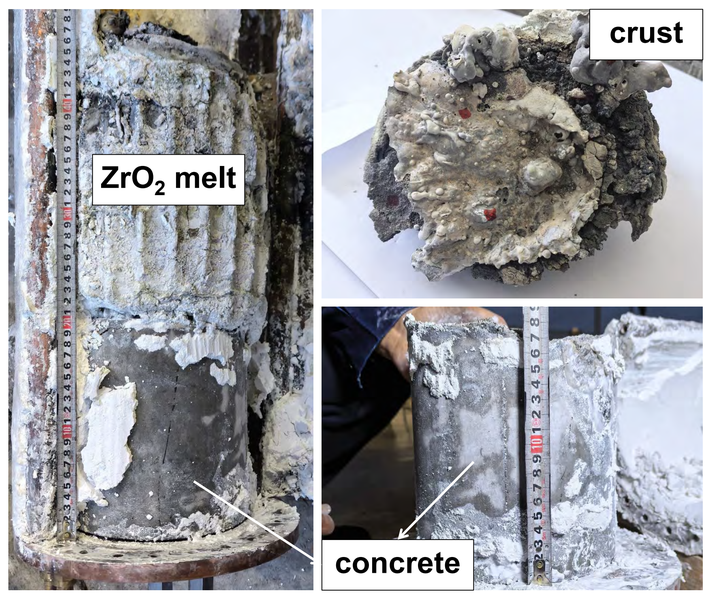

Fig.4 pre-test result

Conclusions

- Established a systematic screening method for ablation-resistant concrete.
- Identified a high-performance MgO-Al_2O_3 rich system through thermodynamic calculations.
- Confirmed that the designed concrete meets nuclear-grade structural strength standards while exhibiting a higher melting point and larger melting enthalpy.
- MAAP5 simulations demonstrate that the designed concrete significantly reduces the ablation rate during MCCI.
- Validation one-dimensional MCCI experiments are currently underway.

ABSTRACT

Aerosol behavior by water spray were experimentally investigated to examine the fission product removal in containment by spray system. The test facility is composed of a vessel, a spray system with different nozzles, and two multi-stage impactors to measure the aerosol concentration by size. The test vessel was initially filled with air with 0.7 μm SiO_2 aerosol particles until the particle density saturated, and then the inlet and the outlet of the vessel were closed. The aerosol concentration decreases slowly by time by different mechanisms, mainly by the gravitational settling. Meanwhile, the aerosols agglomerates and therefore the number of larger particles increases. After keeping the vessel isolated for a moment, water sprayed from the nozzle at the vessel top. The spray droplets wash out the aerosol, resulting in an abrupt drop of aerosol concentration in the vessel. The spray nozzle was designed such that the droplet size and the mass flow rate per covering area are the same as that in the operating nuclear power plant, OPR1000. In addition to the reference nozzle, nozzles having different characteristics in terms of droplet diameter and the mass flow rate per area were also tested. 5 different tests including no-spray case were conducted with the facility. The aerosol removal becomes faster as the mass flow rate increases, however, the removal rate seemed not influenced by the droplet size. The model for the spray decontamination in containment was formulated, and the calculation results were compared with the tests.

KEYWORDS
Containment spray, Aerosol, Fission product, Droplet, Decontamination

1. INTRODUCTION

Containment spray system is an engineering safety feature of nuclear power plants, to decrease the temperature and pressure also to remove fission products during accidents. Also, the spray also removes airborne fission products. The airborne fission products released by an accident are either deposited on structures or wall surfaces by different deposition mechanisms, such as gravitational settling, thermophoresis, and diffusion. In addition to those mechanisms, the spray water droplets absorb aerosols in their falling trajectory, removing the aerosols effectively.

In the mechanism of aerosol removal by spray, the droplet size determines the falling speed, and the mass flow rate of the spray is related to the population of droplets. Both of them affects the aerosol removal efficiency. At the same time, the aerosol removal rate differs by the particle size.

In this article, the aerosol behavior in containment were examined experimentally by using a vessel and a spray system. The aerosol concentration in the vessel were measured by particle size along time, with different spray nozzles. The experimental results were then compared with the model calculation considering the mechanisms of aerosol removal by droplets.

2. AEROSOL-SPRAY EXPERIMENT

2.1. Experimental Facility

Figure 1 shows the schematic of ART (Aerosol Retention Test with spray) facility for spray-aerosol experiments. The test vessel is designed to simulate a reactor containment, with an inner diameter of 1580 mm and a height of 2080 mm. The volume of the vessel is about 3.5 m^3. The aerosol concentration was measured by using ELPI (electrical low-pressure impactor, DEKATI) at two different positions, top and bottom in the vessel. The sampling nozzles are vertically aligned, and the distance between the nozzles is 700mm. A containment spray-simulating nozzle is installed at the top of the vessel.

In the beginning of the test, the carrier gas (air) with aerosols is injected into the vessel until the aerosol concentration in the vessel is saturated, and then the inlet and the outlet of the vessel were closed. The vessel was kept isolated for a while to observe the change of the aerosol concentration without spray, and then the spray is activated at the top of the vessel. Then, the water spray washes out aerosols and the aerosol concentration in the vessel decrease rapidly. Throughout the tests, the aerosol concentration by size were monitored and recorded with the ELPI.

Table 1 shows the specification of the aerosol nozzles installed in existing OPR1000 nuclear power plant and the nozzle used in the experiment, which is designed such that the flow rate per area and the droplet diameter are the same as those of OPR1000 [1]. The nozzle in the table is a reference nozzle which simulate the actual plant condition, and there are other nozzles which are different in droplet size and flow rate.

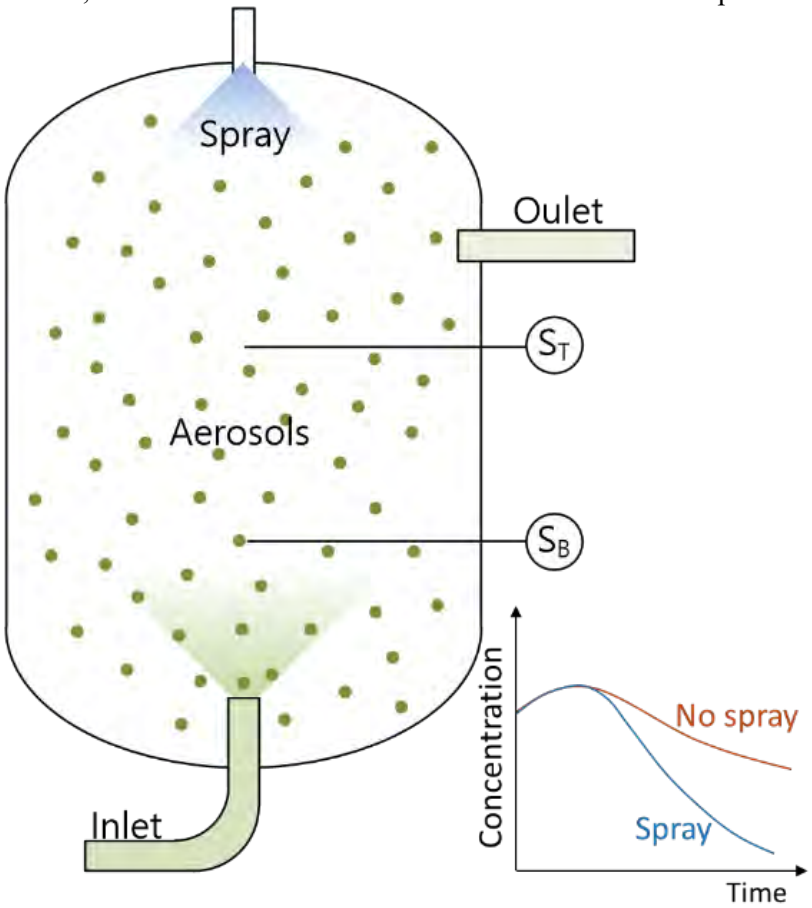

Figure 1. Schematic of ART experimental facility

Table I. Spray variables for ART reference nozzle

Variable	OPR1000	ART(Ref.)
$D_{droplet}$ (μm)	295	300
Flow rate (slpm)	57.6	17.2
Area per nozzle (m^2)	6.58	1.96
Flow rate per area (slpm/m^2)	8.8	8.8

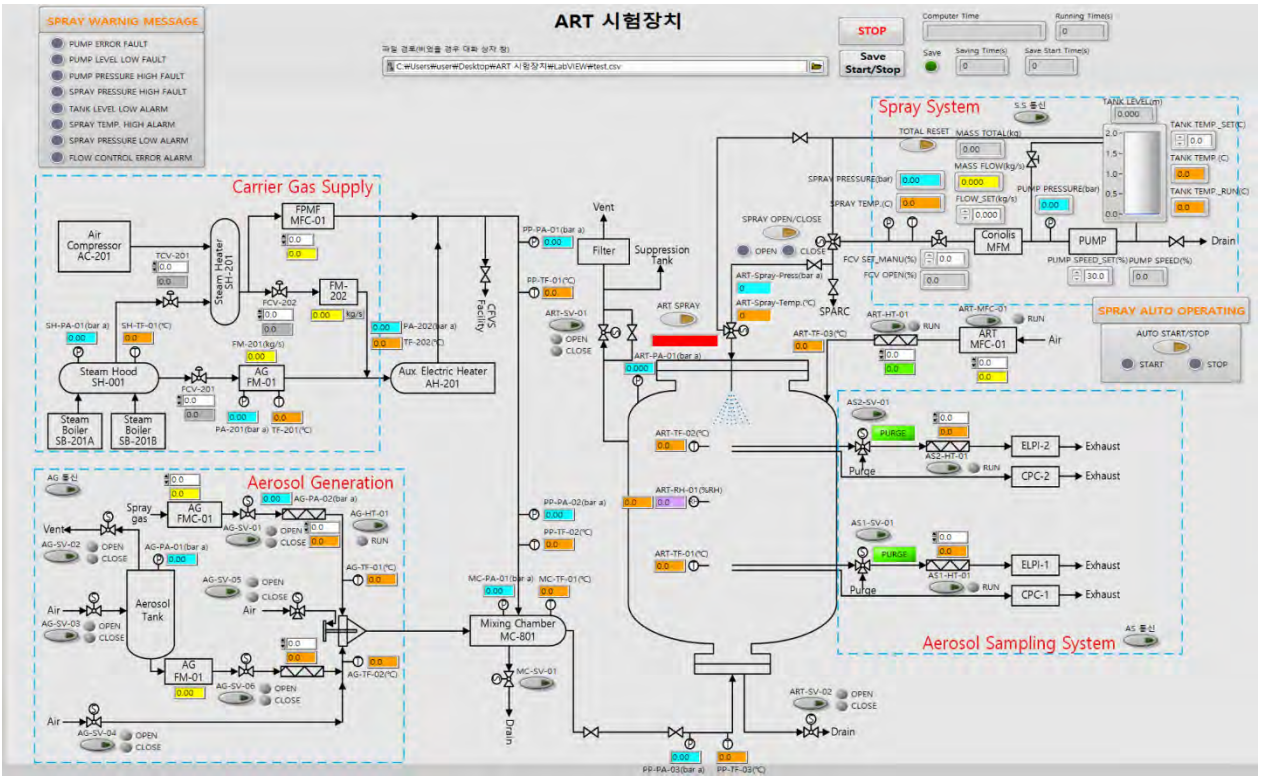

Figure 2. Control panel of ART experimental facility

Figure 2 shows the control panel of ART facility. The facility is composed of a carrier gas supply system, an aerosol generation system, a test vessel, two aerosol sampling systems, and a spray system. The carrier gas supply system provides air or steam at a temperature of the experimental condition. The aerosols are airborne by ejecting aerosol-dispersed ethanol together with heated air in the mixing chamber of the aerosol supply system. The temperature of the mixing chamber was set to be higher than the boiling temperature of ethanol, and the temperatures of pipes and the vessel were set to be the experimental condition. The spray system supplies water at the designated temperature and flow rate to the spray nozzle. The two sampling nozzles were connected from the vessel to the ELPI, via the diluter unit to decrease the aerosol concentration down to the allowed range of the ELPI.

2.2. Experimental Conditions

Table 2 shows the test matrix which shows the characteristics of the spray nozzles for each test cases. The variables of the test are droplet size and flow rate of the spray, which are affecting the aerosol removal characteristics. The first case, NSA, was performed to examine the aerosol behavior in the vessel without spray. Depending on the spray nozzle, the droplet diameter is 200 μm, 300 μm, or 500 μm, and the flow rate is 5.0 slpm or 17.2 slpm.

Table 3 shows the thermal-hydraulic conditions of experiments. The carrier gas in the experiments is air to eliminate the effect of condensation of steam. The aerosol particles are SiO_2 with diameter of 0.7 μm from a previous review about the aerosol particle characteristics during a severe accident, which was AMMD of 1-2 μm [2]. The gas temperature was kept identical at the inlet, vessel, and outlet. The temperature of the spray water was also the same as the gas temperature, to remove the effect of thermophoresis during the experiment.

Table 2 Test matrix of ART experiments

No.	Test Name	Spray	Droplet size (μm)	Flow rate (slpm)

3. RESULTS

2.1. Aerosol Behavior without Spray

Figure 3 shows the mass concentrations of the aerosol at the top and at the bottom of the vessel. All the test cases except non-spray case (NSA) were presented, to show the overall aerosol behavior during the experiments. NSA test case is not presented here, because the aerosol behaviors before the spray represent the non-spray case. The aerosol concentration increases during the injection period, and then decreases slowly after the vessel is isolated by closing the inlet and the outlet.

When the spray is activated, the aerosol concentration decreased abruptly because the particles were washed out by the spray droplets. In the figure, the total mass concentration is higher at the top then that at the bottom. The higher aerosol concentration at the top is observed in all test cases, because the aerosol containing gas were injected from the bottom of the vessel, pushing the aerosols toward the top of the vessel.

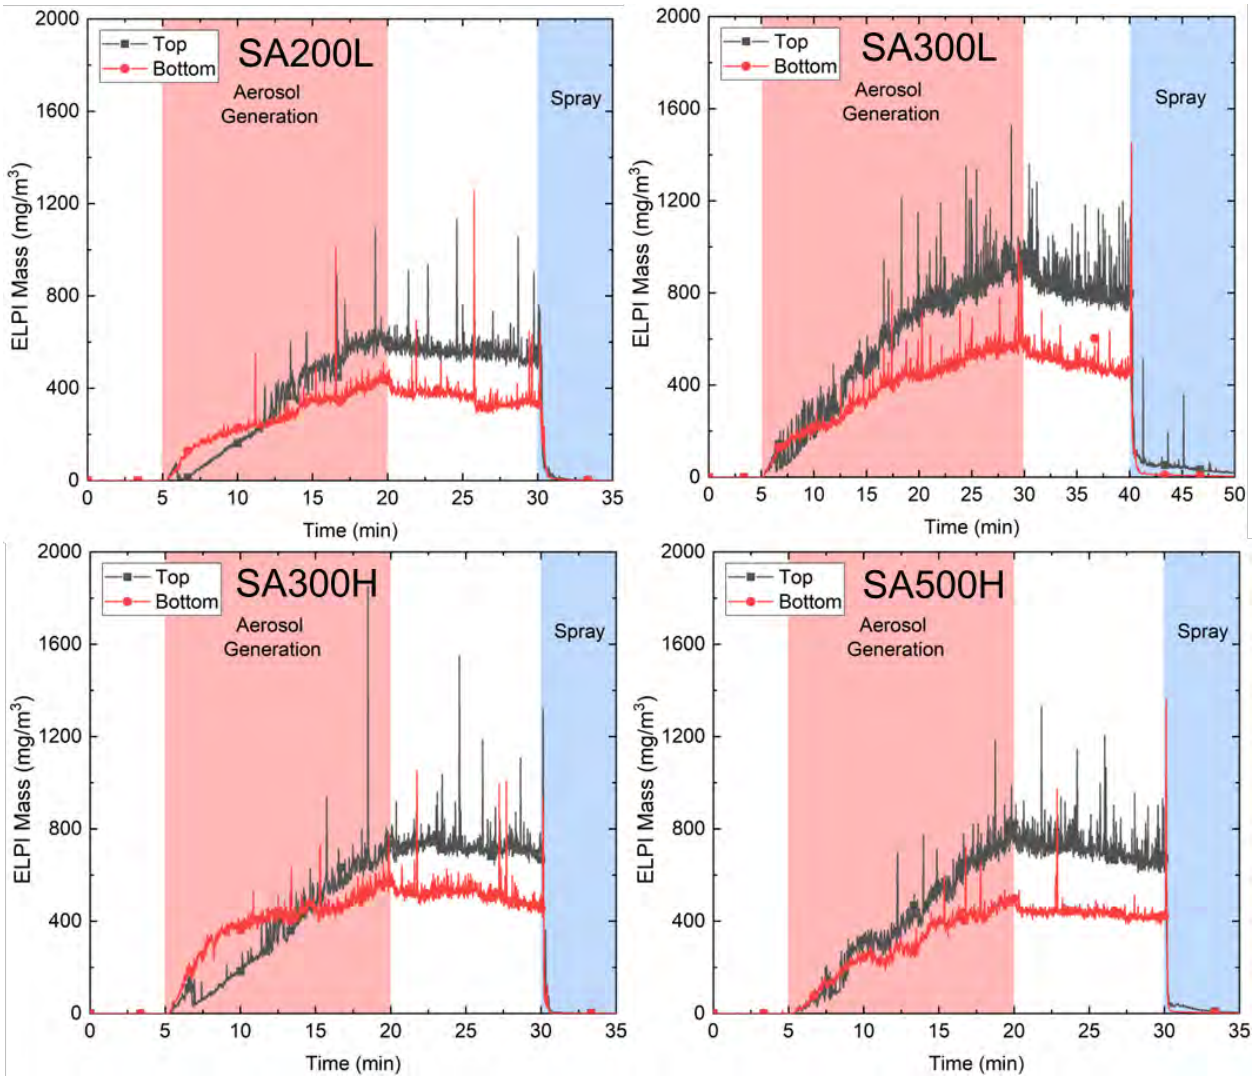

Figure 3. Overall mass concentrations of tests

Figure 4 shows the mass concentration and the number density of the aerosol at the top and at the bottom of the vessel for SA300H test. The overall aerosol behaviors before the spray are almost similar in the other tests because the test conditions are identical in every test except the spray variables. The aerosol behaviors after the spray are not visible well in the figures due to the abrupt decreases of the concentration, therefore they will be analyzed in the next chapter.

ELPI measured the aerosol concentration by 14 different size bin. Among them, the dominant size bins in terms of the mass and the number concentration, 0.75 μm, 1.2 μm, 2 μm, and 3 μm, are presented here. Note that the aerosols injected into the vessel were monodispersed SiO_2 particles with diameter of 0.7 μm. Therefore, the larger particles in the figures are considered as the result of particle agglomeration. One of the evidence of the agglomeration is that the concentration of 3 μm particles at the vessel top increases slowly after the vessel isolation, which means that the injected aerosols agglomerate and become larger. As the results of the agglomeration, the 2 μm particles had the highest mass concentration, whereas the 0.75 μm particles had the highest number density.

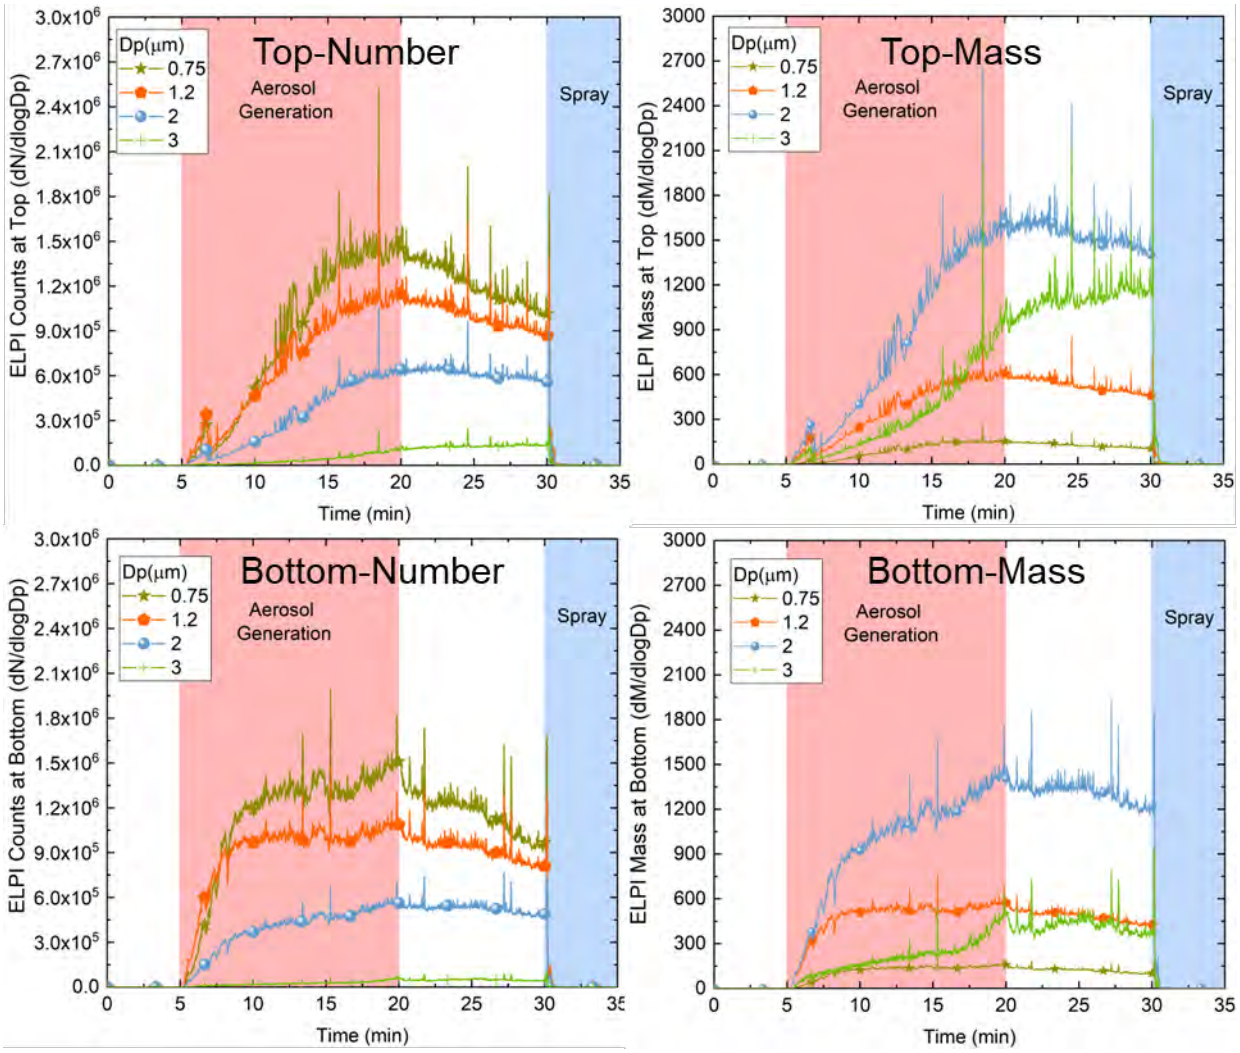

Figure 4. Mass and number concentration by aerosol size in SA300H test

Without a spray, two important aerosol deposition mechanisms are a gravitational settling and a diffusion [3]. The deposition velocity by gravitational settling is

$$v_{grav} = \frac{d_p^2 \rho_p g C_m}{18\mu} \quad (1)$$

where d_p is particle diameter, ρ_p is particle density and μ is dynamic viscosity of air. And the deposition velocity by diffusion is

$$v_{diff} = \frac{kTC_m}{3\pi\mu d_p \delta} \quad (2)$$

where k is Boltzmann constant, T is temperature, and δ is diffusion boundary layer thickness assumed to be 10 μm. The Cunningham slip correction is given by

$$C_m = 1 + \frac{2\lambda}{d_p}\left[1.257 + 0.4\exp\left(-\frac{1.1 d_p}{2\lambda}\right)\right] \quad (3)$$

where λ is the mean free path which can be calculated by

$$\lambda = \frac{\mu}{\rho_g}\sqrt{\frac{\pi M}{2RT}} \quad (4)$$

where M is molecular weight and R is gas constant. The thermophoresis is not important in this experiment due to the isothermal condition in the vessel.

Table 4 shows the deposition velocities of aerosol particles by gravitational settling and those by diffusion. For the particle size from 0.75 to 3 μm, deposition velocity of gravitational settling is more than 10 times larger than that of diffusion. Therefore, the aerosol behavior is dominated by the gravitational settling. Even for the largest 3 μm particle, the deposition velocity, which means the falling velocity of aerosol is only 0.68 mm/s, therefore the aerosol concentration decreases very slowly. This explains the slow decrease of aerosol concentration in the experiment before the spray activation.

Table 4 Deposition velocity of aerosol particle

		Particle size (μm)			
		0.75	1.2	2	3
Deposition velocity (m/s)	Grav. settling	5.0E-5	1.2E-4	3.1E-4	6.8E-4
	Diffusion	4.1E-6	2.4E-6	1.3E-6	8.7E-7
Time to travel 1 m by gravitational settling (hr)		5.5	2.3	0.9	0.4

2.1. Aerosol Behavior without Spray

Figure 5 shows the aerosol concentration decrease by the spray activation. In all cases, the aerosol concentration decreases abruptly upon the spray activation, however, the rate of decrease varies among cases. In general, the cases with smaller spray flow rate shows slower decrease of aerosol concentration. However, the droplet size seems not very Relative for the aerosol removal. Larger droplets wash out more aerosol particle on its falling trajectory, however, the number of spray droplets decreases as the droplet volume increases for the same flow rate of the spray, which compensate each other. It is note that, the decreasing rate seems not depend on the aerosol particle size.

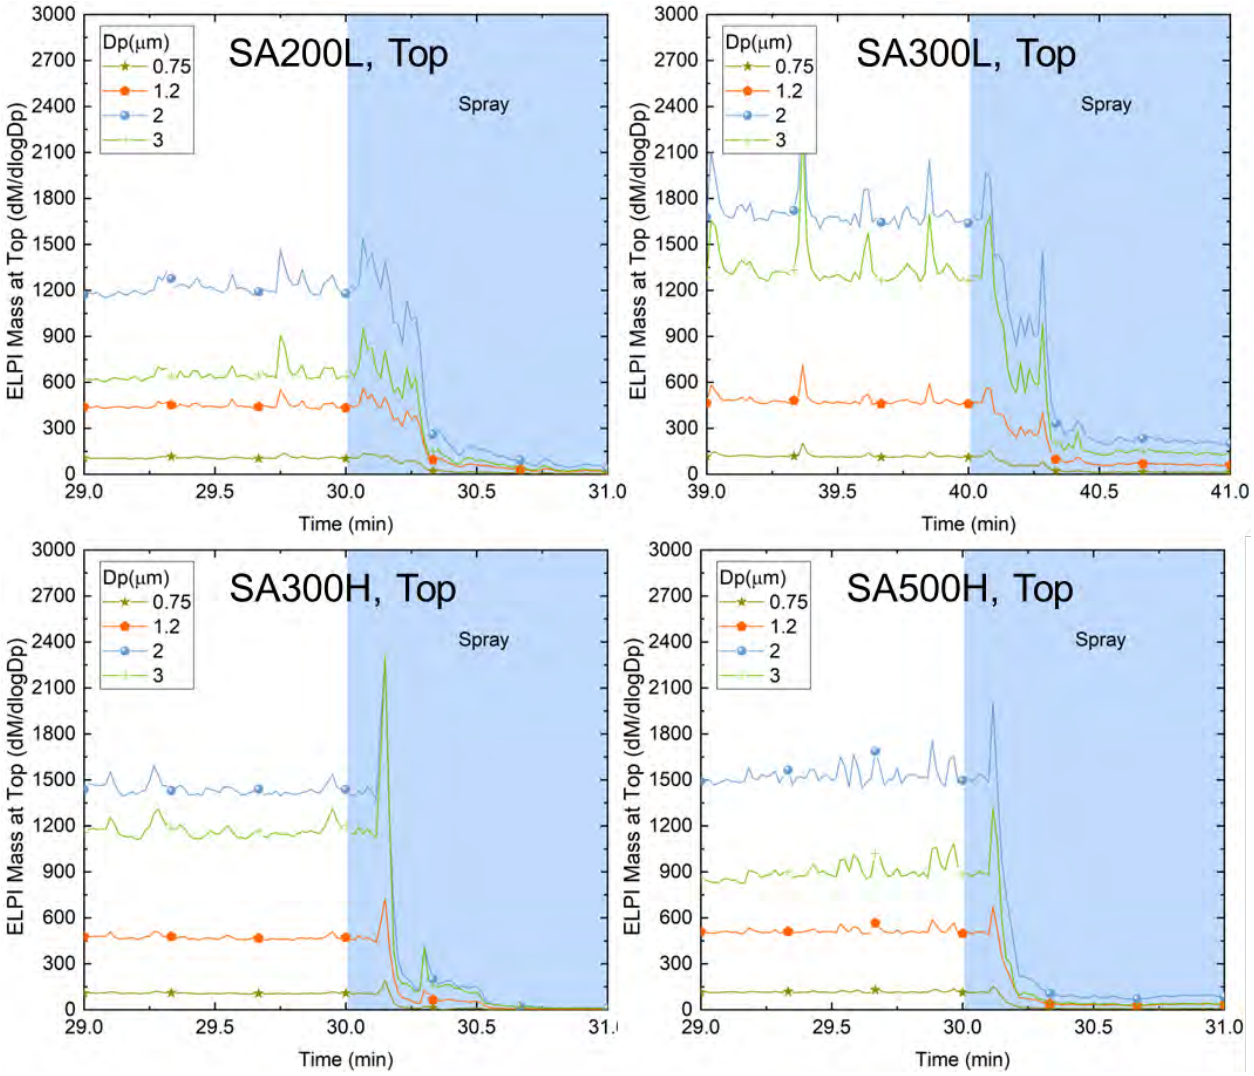

Figure 5. Mass and number concentration by aerosol size in SA300H test

The aerosol removal by spray can be formulated as a first-order rate equation [4]

$$\frac{dM_k}{dt} = -\lambda_{k,i} M_k \tag{5}$$

Where M_k is the particle mass of size k and $\lambda_{k,i}$ is the removal rate constant of the particle size k by the droplet size i. The removal rate constant is

$$\lambda_{k,i} = \frac{3F_i h E_{i,j}}{4Vr_i} \tag{6}$$

Where F_i is the volumetric flow rate for droplet size i, $E_{i,j}$ is the collection efficiency for droplet size k, h is the fall height of the droplet, V is the control volume, and r_i is the droplet radius.

The dominant mechanism of aerosol removal by spray droplets depends on the droplet size. When the droplet size is larger than 10 μm, inertial impaction and interception are dominant mechanisms of aerosol removal, and the other mechanisms such as diffusiophoresis or diffusion are negligible.

The collection efficiencies of interception depend on the flow regime around the droplet,

$$\varepsilon_{in,vis} = (1+l)^2\left[1 - \frac{3}{2(1+l)} + \frac{1}{2(1+l)^3}\right] \quad \text{(for viscous flow)} \tag{7}$$

$$\varepsilon_{in,pot} = (1+l)^2 - (1+l) \quad \text{(for potential flow)} \tag{8}$$

The collection efficiencies of impaction also depend on the flow regime, and that for potential flow is

$$\varepsilon_{im,pot} = \left[\frac{Stk}{Stk+0.5}\right]^2 \quad \text{for Stk}\geq 0.2 \tag{9}$$

and $\varepsilon_{im,pot}$ is 0 for Stk≤0.0834, and is linearly interpolated for 0.0834<Stk<0.2. The collection efficiency of impaction for viscous flow is

$$\varepsilon_{im,vis} = \left[1 + \frac{0.75 log_e(2Stk)}{Stk-1.214}\right]^{-2} \quad \text{for Stk}>1.214 \tag{10}$$

and is zero otherwise. Stk is the Stokes number,

$$Stk = \frac{2r_p^2 \rho_p (v_d - v_p)}{9\mu r_d} \tag{11}$$

where v_d and v_p are the terminal velocities of the droplet and particle, respectively, and μ is the gas viscosity. When the flow is between potential and viscous regime, the collection efficiency can be interpolated by

$$\varepsilon_x = \frac{\varepsilon_{x,vis} + \varepsilon_{x,pot}(\frac{Re}{60})}{1+(\frac{Re}{60})} \tag{12}$$

where Re is the droplet Reynolds number.

A terminal velocity of a droplet is important parameter to estimate the collection efficiency. The terminal velocity of a sphere can be calculated theoretically, however, the terminal velocity of droplet is not simply calculated by that because of the flow inside the droplet. Instead, the terminal velocity of a droplet can be

estimated by empirical equations or experimental results. The terminal velocities of droplets with diameter of 200 μm, 300 μm, and 500 μm are approximately 0.8 m/s, 1.2 m/s and 2.0 m/s, respectively [5].

Figure 6 shows the comparison between the calculation and the experiment for the tests at the vessel top. The calculation shows that the concentration of small particles decreases slower than that of large particles, whereas the experiment shows that decreasing rates of the aerosol concentration seem identical for every sizes. In addition, the decreasing rate of aerosol concentration in the experiments are even faster than that of largest particle in the calculation. That is, there are removal mechanisms of aerosol particles other than the impaction and the interception of droplet. However, a thermophoresis is not plausible for the experiment because the vessel wall and gas temperature are the same. The diffusion or diffusiophoresis are also not probable due to the large droplet size.

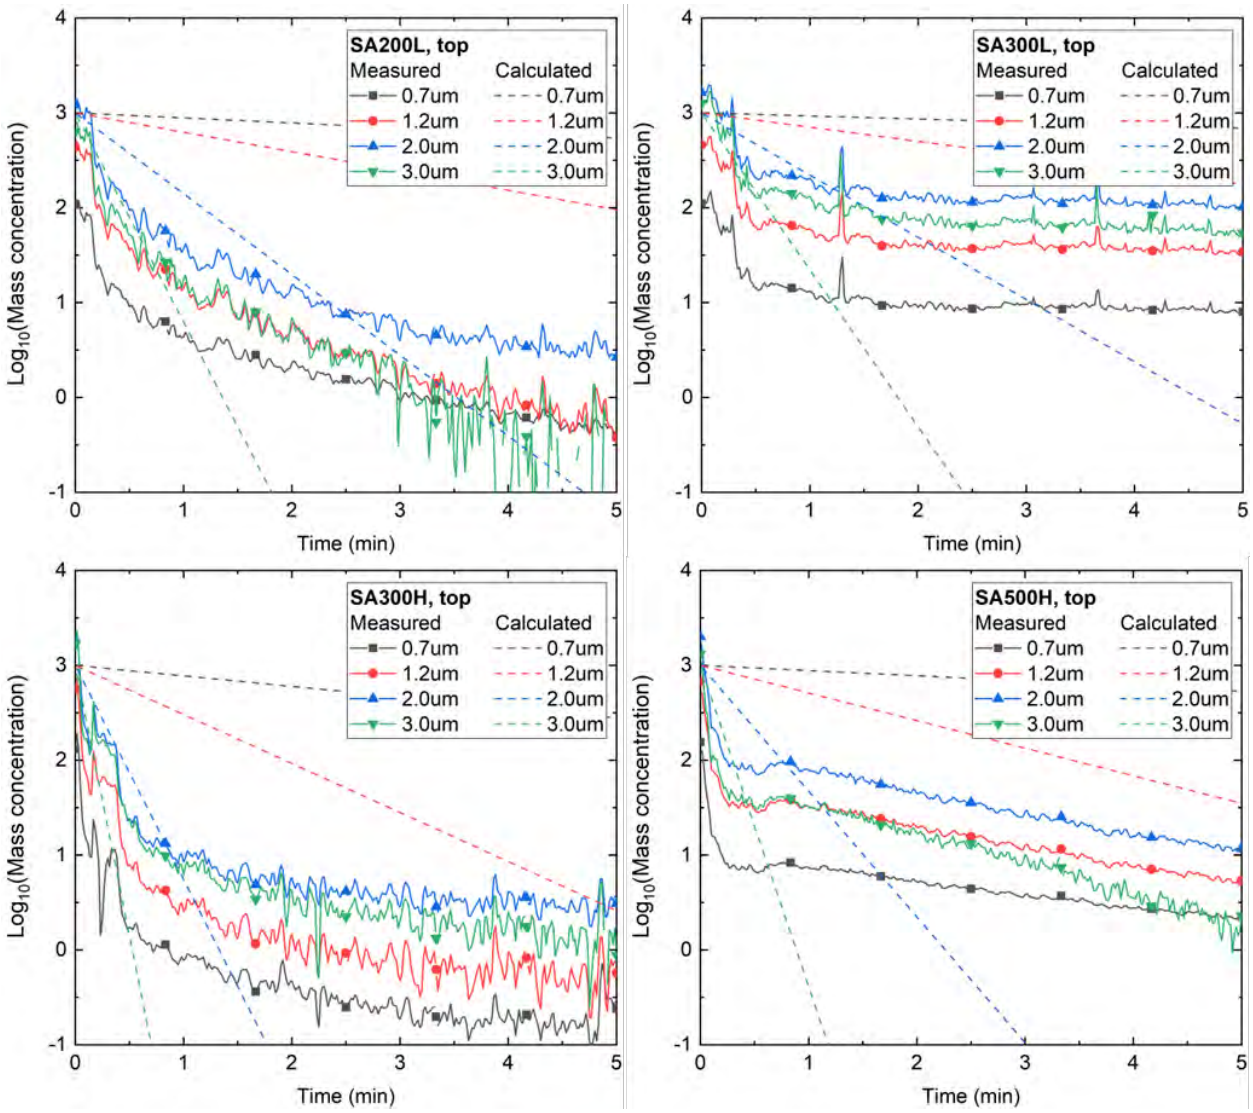

Figure 6. Calculation and measurement of aerosol removal by spray

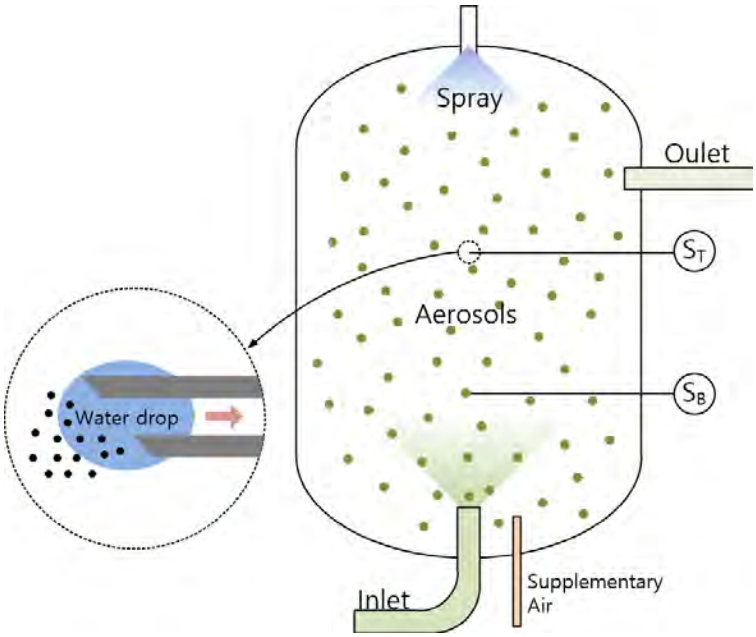

Figure 7. Water trap at sampling nozzle inlet

Figure 7 shows the one possible reason why the aerosol concentrations showed the same decreasing rate regardless of the particle size. By the spray, the inlets of the sampling nozzles are wet, which forms water traps. All aerosol particles drawn through the sampling port subsequently pass through the water trap. Then, the aerosols are removed mostly by the water trap before they reach the ELPI.

One solution to prevent the aerosol removal by water trap at the sampling nozzle inlet is to alternate between sampling and spraying. Water is sprayed for a few to several seconds and then the spray is stopped, and then the aerosol sampling started for a few tens of seconds. Currently, the alternating between sampling and spraying is under examination. After that, the experiments will be conducted again with the method.

4. CONCLUSIONS

Aerosol removal behavior by water spray were tested for different spray conditions with ART experimental facility. The test vessel was filled with the SiO_2 aerosol particles with diameter of 0.7 μm, and then the vessel is isolated for a while by closing the inlet and outlet. The aerosol concentration decreases slowly mainly by gravitational settling, and then decreases abruptly when the spray is activated. Meanwhile, the aerosols were agglomerates and therefore the particles of 2 μm showed the highest mass concentration, although the 0.75 μm particles showed the highest number density. The deposition velocity by gravitational settling were calculated to be less than 1 mm/s even for the largest particles, therefore the concentration decreases very slowly without spray.

The aerosol removal by spray, on the other hand, was calculated for the dominant removal mechanisms, impaction and interception. The removal rates were calculated for the experimental condition, for the different particle sizes. The calculation showed that the concentration of small particles decreases slower than that of large particles. However, the experiments showed almost identical removal rates of particles regardless the size, which do not correspond the calculation. The possible explanation of the phenomena is the formation of water trap at the inlet of the sampling nozzle. To avoid the aerosol capture by the water trap, the method of alternating the spray and the sampling is currently under examination, and the tests will be performed again with the method.

ABSTRACT

During the severe accident in nuclear power plants (NPPs), lots of radioactive materials are released into the containment building. To prevent the containment overpressure failure and reduce release of radioactive materials into the environment, the filtered containment venting system (FCVS) installed outside the containment building was developed. In Korea, to more enhance the safety of NPPs, a passive radioactive material filtration system is being developed. This another system installed in the containment building aims to minimize release of radioactive materials into the environment by capturing radioactive materials in both airborne and gaseous phases within the containment. It consists of two main components, which are the passive fluid induction component and the fission product filtration component. To evaluate and verify the performance of this system, the development of a reasonable and reliable test methodology is essential. This paper introduces several test methods using simulants conducted by KAERI and the supporting evidence.

KEYWORDS
Filtration, Radioactive material, Aerosol, Iodine, Organic iodide

1. INTRODUCTION

Severe accidents at NPPs lead to the release of significant amounts of radioactive materials inside the containment building. A passive radioactive material filtration system, designed for installation in the containment building to capture the radioactive materials in both airborne and gaseous phases, is currently under development in Korea [1]. It is in the shape of a rectangular duct, which consists of a hydrogen catalyst, an aerosol filter, and an iodine adsorbent [2]. The exothermic reaction caused by hydrogen recombination in the catalyst induces natural convection from the bottom to the top of the duct.

KAERI is developing the test methodology to conduct verification tests on the system's radioactive materials reduction performance using simulants (SiO_2, I_2, CH_3I). This paper reviews relevant literature on capturing methods to measure the simulant concentrations, and proposes the performance verification test methods.

2. SIMULANT MEASURING METHODS

2.1. Silicon Dioxide (SiO_2)

Spherical monodisperse non-disintegrating SiO_2 particles are representative simulant of nuclear aerosols [3]. A common method for measuring the mass concentration of particulate matter in a gas is to collect the particles from the sampled gas using a filter and measure the change in the filter weight. Considering the high-temperature steam environment within the containment building during a severe accident, the sampling strategy of EPA Method 5, which prevents condensation utilizing a heated sampling train, provides a relevant framework for developing a suitable measurement procedure. Regarding the filter weight measurement, variations in humidity and temperature can affect the gravimetric measurement of the particulate matter by altering the mass of the filters [4]. Thus, the filters should be conditioned identically before both the pre- and post-sampling weighing.

2.2. Iodine (I_2)

There are two methods for capturing I_2 in the sampling gas: liquid trapping method, solid adsorption method. In the former, a specific aqueous solution, such as ascorbic acid or sodium hydroxide (NaOH) solution, is used to collect and convert iodine into iodide ion (I^-) and iodate ion (IO_3^-) [5]. Regarding the latter, although there are many studies on development of adsorbents for I_2, especially silver-exchanged zeolite showed complete retention of I_2 up to 900 ℃ regardless of the oxidizing or reducing condition in the presence of hydrogen [6]. The I_2 captured by silver-exchanged zeolite has the form of silver iodide (AgI) and silver iodate ($AgIO_3$); the latter decomposes to form AgI at temperatures exceeding 190 ℃ [7]. Although AgI is highly stable and insoluble, appropriate pretreatment before analysis, for example the elution reaction using aqueous sodium sulfide (Na_2S), results in dissolution of I^- into the solution [8]. Therefore, I_2 concentration can be measured using ion selective electrode (ISE), ion chromatograph (IC) or inductively coupled plasma-mass spectrometry (ICP-MS).

2.3. Methyl Iodide (CH_3I)

There are two methods for capturing CH_3I in the sampling gas: liquid trapping method, solid adsorption method. In the former, a specific nonpolar solvent, such as toluene, is used to dissolve CH_3I. Due to the high volatility of CH_3I, several precautions are required for handling: low-temperature capture is more effective, and upon completion of capture, the samples must be sealed and analyzed as quickly as possible, and airtightness should be maintained using headspace vials and gas-tight syringes during sample extraction for analysis [9]. CH_3I concentration can be measured gas chromatography-flame ionization detector (GC-FID) or gas chromatography-mass spectrometry (GC-MS). Regarding the latter, silver-exchanged zeolite captures CH_3I through the decomposition reaction, resulting in the formation of AgI and subsequent organic byproducts such as methanol, dimethyl ether, alkanes, and alkenes [7]. The AgI analysis method noted above can be used to determine the CH_3I concentration. Meanwhile, activated carbon is the only adsorbent media for normal atmosphere cleanup systems mentioned in NRC Regulatory Guide (RG) 1.140, which specifies that its CH_3I removal performance must be tested according to ASTM D3803 and pass the specified criteria. For example, triethylenediamine (TEDA)-impregnated AC showed 98.4% adsorption efficiency for CH_3I under the conditions of 70 ℃ temperature, 90 % relative humidity (RH), and 15 ppm CH_3I concentration [10]. Because TEDA-impregnated AC captures CH_3I through physical adsorption and chemical reaction, a chemical extraction method is necessary as thermal desorption cannot fully desorb the captured CH_3I for measuring the concentration [11].

3. PERFORMANCE VERIFICATION TEST METHODS

KAERI plans to conduct performance verification tests for the passive radioactive material filtration system in two ways: in-line test, in-vessel test. The former is to install the system in a pipeline with carrier gas flows containing a simulant, and then measure the simulant concentrations at the system's inlet and outlet. The

latter is to install the system inside a pressure vessel with an internal volume of 80 m^3, and then measure the concentrations at several points inside the vessel.

3.1. In-line Test Method

The in-line test method is used to obtain the decontamination factor (DF) and pressure drop of the filtration system for each simulant. The carrier gas consists of air and steam, and contains at a time a single species of simulant. However, this method is not suitable for verifying the radioactive material reduction performance as a passive system. Due to the absence of hydrogen in the carrier gas, the flow inducement part does not operate. Criteria for sampling location selection and sampling system design could be referenced from ANSI/HPS N 13.1, and CFD analysis would be performed concurrently.

3.2. In-vessel Test Method

The in-vessel test method is used to verify the radioactive material reduction performance as a passive system in a defined space. Air, steam, hydrogen, and simulants can be injected into the vessel. A key challenge in this method is how to estimate the mean simulant concentration within the vessel from a limited number of sampling locations. The interior of the vessel would be virtually partitioned into several regions. The simulant concentration measured from the sampling point in each region could be assumed to be representative of the mean concentration of that region.

The mean concentration of a simulant in the vessel ($\overline{C_{tot}}$) is :

$$\overline{C_{tot}} = \sum C_i V_i \,/\, \sum V_i \tag{1}$$

where C_i is the simulant concentration in the i-th region, and V_i is the volume in the i-th region.

CFD analysis could be employed to validate this estimation method of the mean concentration in the vessel.

ANSI/AHAM AC-1, which is the standard for measuring performance of portable household air cleaners, provides a relevant framework for verifying the performance of the filtration system. This standard defines the method for measuring the CADR (Clean Air Delivery Rate) value, a key performance indicator of air cleaners. KAERI plans to evaluate the performance of the filtration system using the CADR value.

The mean concentration of a simulant in the vessel over time is :

$$\overline{C_{tot}}(t) = C_0 e^{-kt} \tag{2}$$

where C_0 is the initial concentration of a simulant in the vessel, and k is the decay rate constant.

Sampling should be initiated and terminated simultaneously across all sampling points. Due to the difficulty in real-time measurement of the simulant concentration, sampling is carried out at fixed time intervals and subsequently analyzed offline. The concentration trends over the test period would be then estimated from these results.

The method for calculating CADR is :

$$CADR = V\left(k_{on} - k_{off}\right) \tag{3}$$

where V is volume of the test chamber, k_{on} is the decay rate when the filtration system is operating, and k_{off} is the decay rate when the filtration system is not operating.

4. CONCLUSIONS

KAERI is developing the test methodology for the performance evaluation and verification of a passive radioactive material filtration system, currently under development in Korea, using simulants (SiO_2, I_2, CH_3I). Various literatures for measuring simulant concentrations were reviewed: a filter-based gravimetric method for SiO_2, and both liquid trapping and solid adsorption methods for I_2 and CH_3I. For verifying the performance for the filtration system, two methods are proposed. The in-line test is conducted by installing the system in a pipeline with carrier gas flows containing a simulant and measuring the simulant concentrations at the inlet and outlet to obtain the DF and pressure drop of the filtration system for each simulant. The in-vessel test is conducted by installing the system inside a pressure vessel with an internal volume of 80 m^3 and measuring the simulant concentrations at several points to calculate the mean concentration in the vessel over time and determine the CADR value, providing a quantitative performance indicator for the filtration system.

1. Introduction

- **During the severe accident in nuclear power plants (NPPs),**
  lots of radioactive materials are released into a containment building. To prevent the containment overpressure failure and reduce release of radioactive materials into the environment, it has been developed that the filtered containment venting system (FCVS) which is installed outside the containment building. jet pool scrubbing.
- **To capture the airborne radioactive materials,**
  A passive radioactive material filtration system, designed for installation in the containment building, is currently under development in Korea.
- **To evaluate and verify the performance of this system,**
  KAERI is developing the test methodology to conduct verification tests on the system's radioactive materials reduction performance using simulants (SiO_2, I_2, CH_3I). This poster reviews relevant literature on capturing methods to measure the simulant concentrations, and proposes the performance verification test methods.
- **Keywords :** Filtration, Radioactive material, Aerosol, Iodine, Organic iodide

2. Passive Radioactive Material Filtration System

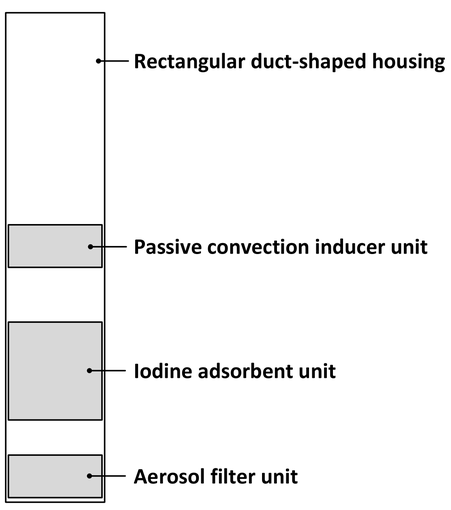

Fig. 1. Schematic diagram of passive radioactive material filtration system

- The system features a rectangular duct shape, consisting of a passive convection inducer unit, an aerosol filter unit, and an iodine adsorbent unit.
- The passive convection inducer unit consists of a hydrogen catalyst, where the exothermic reaction driven by hydrogen recombination induces natural convection from the bottom to the top of the duct.
- The aerosol filter unit utilizes a metal fiber filter to capture particulate radioactive materials.
- The iodine adsorbent unit employs silver-exchanged zeolite to capture gaseous iodine and organic iodide.
- To evaluate and verify the system's performance in reducing radioactive materials using simulants (SiO_2, I_2, CH_3I), it is essential to measure their concentrations.
- Considering the extreme environment within the containment building during a severe accident and the use of stimulant mixtures, the simulants were captured in stages over specific intervals for post-test concentration measurements.

3. Simulant Concentration Measuring Methods

Silicon Dioxide (SiO_2)

- Spherical monodisperse non-disintegrating SiO_2 particles are representative simulant of nuclear aerosols.
- A common method for measuring the mass concentration of particulate matter in a gas is to collect the particles from the sampled gas using a filter and measure the change in the filter weight.
- Given the high-temperature steam conditions in the containment building, the sampling strategy of EPA Method 5, which determines particulate matter emissions from stationary sources using a heated sampling train to prevent condensation, provides a relevant framework for developing a suitable measurement procedure.
- Regarding the filter weight measurement, variations in humidity and temperature can affect the gravimetric measurement of the particulate matter by altering the mass of the filters. Thus, the filters should be conditioned identically before both the pre- and post-sampling weighing.

Iodine (I_2)

- There are two methods for capturing I_2 in the sampling gas: liquid trapping method, solid adsorption method. In the former, a specific aqueous solution, such as ascorbic acid or sodium hydroxide (NaOH) solution, is used to collect and convert iodine into iodide ion (I^-) and iodate ion (IO_3^-).
- In the latter, although there are many studies on development of adsorbents for I_2, especially silver-exchanged zeolite showed complete retention of I_2 up to 900 ℃ regardless of the oxidizing or reducing condition in the presence of hydrogen.
- The I_2 captured by silver-exchanged zeolite has the form of silver iodide (AgI) and silver iodate ($AgIO_3$); the latter decomposes to form AgI at temperatures exceeding 190 ℃.
- Although AgI is highly stable and insoluble, appropriate pretreatment before analysis, for example the elution reaction using aqueous sodium sulfide (Na_2S), results in dissolution of I^- into the solution.
- Therefore, I_2 concentration can be measured using ion selective electrode (ISE), ion chromatograph (IC) or inductively coupled plasma-mass spectrometry (ICP-MS).

Methyl Iodide (CH_3I)

- There are two methods for capturing CH_3I in the sampling gas: liquid trapping method, solid adsorption method. In the former, a specific nonpolar solvent, such as toluene, is used to dissolve CH_3I.
- Due to the high volatility of CH_3I, several precautions are required for handling: low-temperature capture is more effective, and upon completion of capture, the samples must be sealed and analyzed as quickly as possible, and airtightness should be maintained using headspace vials and gas-tight syringes during sample extraction for analysis.
- CH_3I concentration can be measured gas chromatography-flame ionization detector (GC-FID) or gas chromatography-mass spectrometry (GC-MS).
- In the solid adsorption method, silver-exchanged zeolite captures the iodine species from CH_3I via a decomposition reaction to form stable AgI, thereby allowing the CH_3I concentration to be determined through the aforementioned AgI analysis method.
- Meanwhile, activated carbon (AC) is the only adsorbent media for normal atmosphere cleanup systems mentioned in NRC Regulatory Guide (RG) 1.140, which specifies that its CH_3I removal performance must be tested according to ASTM D3803 and pass the specified criteria.
- For example, triethylenediamine (TEDA)-impregnated AC showed 98.4% adsorption efficiency for CH_3I under the conditions of 70 ℃ temperature, 90 % relative humidity (RH), and 15 ppm CH_3I concentration.
- Because TEDA-impregnated AC captures CH_3I through physical adsorption and chemical reaction, a chemical extraction method is necessary as thermal desorption cannot fully desorb the captured CH_3I for measuring the concentration.

4. Performance Verification Test Methods

In-line Test Method

- The in-line test method is used to obtain the decontamination factor (DF) and pressure drop of the filtration system for each simulant.
- The carrier gas consists of air and steam, and contains at a time a single species of simulant. However, this method is not suitable for verifying the radioactive material reduction performance as a passive system. Due to the absence of hydrogen in the carrier gas, the flow inducement part does not operate.
- Criteria for sampling location selection and sampling system design could be referenced from ANSI/HPS N 13.1, and CFD analysis would be performed concurrently.

In-vessel Test Method

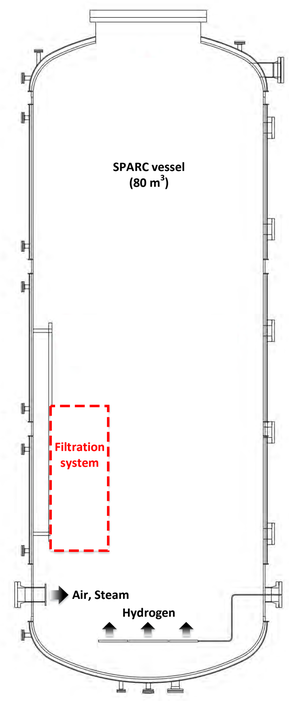

Fig. 2. Schematic diagram of in-vessel test method

- The in-vessel test method is used to verify the radioactive material reduction performance as a passive system in a defined space, such as 80 m^3 SPARC vessel at KAERI. Air, steam, hydrogen, and simulants can be injected into the vessel.
- To estimate the mean simulant concentration within the vessel from a limited number of sampling locations, the interior would be partitioned into several virtual regions. The simulant concentration measured at a specific sampling point within each region would then be taken as a representative value for its respective region.
- The mean concentration of a simulant in the vessel ($\overline{C_{tot}}$) is :

$$\overline{C_{tot}} = \sum C_i V_i \,/\, \sum V_i$$

where C_i is the simulant concentration in the i-th region, and V_i is the volume in the i-th region.

- CFD analysis could be employed to validate this estimation method of the mean concentration in the vessel.
- ANSI/AHAM AC-1, which is the standard for measuring performance of portable household air cleaners, provides a relevant framework for verifying the performance of the filtration system. This standard defines the method for measuring the CADR (Clean Air Delivery Rate) value, a key performance indicator of air cleaners.
- KAERI plans to evaluate the performance of the filtration system using the CADR value.

- The mean concentration of a simulant in the vessel over time is :

$$\overline{C_{tot}}(t) = C_0 e^{-kt}$$

where C_0 is the initial concentration of a simulant in the vessel, and k is the decay rate constant.

- Sampling should be initiated and terminated simultaneously across all sampling points. Due to the difficulty in real-time measurement of the simulant concentration, sampling is carried out at fixed time intervals and subsequently analyzed offline.
- The concentration trends over the test period would be then estimated from these results.
- The method for calculating CADR is :

$$CADR = V\left(k_{on} - k_{off}\right)$$

where V is volume of the test chamber, k_{on} is the decay rate when the filtration system is operating, and k_{off} is the decay rate when the filtration system is not operating.

5. Conclusions

- KAERI is developing the test methodology for the performance evaluation and verification of a passive radioactive material filtration system, currently under development in Korea, using simulants (SiO_2, I_2, CH_3I).
- Various literatures for measuring simulant concentrations were reviewed: a filter-based gravimetric method for SiO_2, and both liquid trapping and solid adsorption methods for I_2 and CH_3I.
- For verifying the performance for the filtration system, two methods are proposed. The in-line test is conducted by installing the system in a pipeline with carrier gas flows containing a simulant and measuring the simulant concentrations at the inlet and outlet to obtain the decontamination factor (DF) and pressure drop of the filtration system for each simulant.
- The in-vessel test is conducted by installing the system inside a pressure vessel with an internal volume of 80 m^3 and measuring the simulant concentrations at several points to calculate the mean concentration in the vessel over time and determine the CADR value, providing a quantitative performance indicator for the filtration system.

ABSTRACT

Present study is to report the preliminary result about molten salt evaporation. Simulant salt (NaCl-KCl, 5:5) of which temperature is from 600 to 800 C is evaporated under atmospheric pressure. As salt gas undergoes rapid condensation, and turns into an aerosol form. Present study evaluated the evaporated mass flux, particle shape and chemical composition using SEM/EDS. The evaporation characteristics can be utilized as boundary conditions for future experiments evaluating airborne/wall-deposited aerosol behavior using a tank.

KEYWORDS
Molten Salt Reactor (MSR), Aerosol, Condensation, Evaporation, Deposition

1. INTRODUCTION

When molten salt is heated above its melting point, significant amounts of salt vapor are generated due to evaporation. If the molten salt contains fission products, the molten salt vapor and aerosols can serve as major carriers for the transport of fission products. Therefore, a test apparatus was constructed to develop a methodology for evaluating the evaporation and aerosol behavior of molten salts using surrogate salts, with the aim of extending this methodology to assess the radiation source release due to aerosol formation in salt spill accident of a Molten Salt Reactor (MSR) system.

To design test apparatus for evaluating salt aerosols, a prior research analysis on molten salt evaporation, wall deposition, and aerosol behavior was conducted as follows. The vapor pressure of molten salts is relatively low, so experimental studies related to molten salt evaporation have largely been conducted under vacuum conditions. For NaCl-KCl, a melting point around 650°C, it has been reported that a weight loss of approximately 30% occurs after 1 hour of evaporation under vacuum at 770°C [**1**]. The behavior of molten salt evaporation under atmospheric pressure is significantly suppressed due to the low vapor pressure of molten salts, and it is known that evaporation of single NaCl gradually begins at temperatures above 1095K [**2**]. Therefore, it is evident that a molten salt heating system capable of maintaining high temperatures for extended periods is required to evaluate the vapor generation and aerosol behavior due to molten salt evaporation. Implementing vacuum conditions is considered an ideal scenario that does not closely resemble the atmospheric conditions inside the containment vessel of an actual MSR. For aerosol behavior evaluation, test designs based on atmospheric pressure conditions are required. However, the evaporation rate under atmospheric pressure is expected to be significantly lower than under vacuum, potentially requiring extended test durations (over 1 hour). There are no predictive correlations for the evaporation rate of molten salts according to prior research, and this test aims to determine the evaporation rate by measuring the mass loss due to evaporation at different temperatures relative to the initial molten salt mass.

Preceding research on the wall deposition due to the condensation of molten salt vapor is quite limited. When molten salt vapor condenses on surfaces, irregular nucleation leading to crystalline wall deposits is observed, which differs from the aggregation forms of mono-dispersed particles. Additionally, it has been

experimentally reported that the condensation mechanisms from vapor to liquid or vapor to solid depend on the molten salt temperature and the ambient air temperature [**3**]. This prior research is an individual-effect study involving the insertion of a condensation tube into a relatively small (O.D. 20 mm) test apparatus, and it does not include evaluations of the airborne aerosol and deposition behaviors on wall surfaces in a large volume similar to an MSR containment vessel.

Major research on the characterization of molten salt aerosols primarily focuses on developing non-contact aerosol measurement techniques for the application of MSR systems. The most significant advantage of non-contact aerosol measurement techniques is their ability to provide real-time aerosol characterization and elemental analysis even under high radiation and harsh reactor environments. (1) The U.S. Argonne National Laboratory (ANL) conducted evaluations of aerosol behavior by evaporating CsI salt (melting point 632°C) using an optical light scattering aerosol spectrometer [**4,5**]. This non-contact aerosol characterization methodology involves irradiating aerosol particles with a light source and evaluating their scattering properties, enabling the assessment of aerosol diameter (0.1-10 microns) and number concentration. CsI salt was used due to its higher vapor pressure compared to chlorides, resulting in a relatively higher evaporation rate. The aerosol transport gas was argon. The key results indicated that aerosols with diameters below 1 micron were predominantly measured, and the volume-average particle concentration was approximately 65,000 P/cm³, equating to a mass-average particle concentration of 1.2 mg/cm³ considering the CsI density of 4.5 g/cm³, which is a significantly high value. (2) The U.S. Oak Ridge National Laboratory (ORNL) used Laser-induced breakdown spectroscopy (LIBS) to evaluate aerosol characteristics generated from NaNO3-KNO3 molten salt [**6,7**]. LIBS enables aerosol concentration measurement based on the scattering properties of aerosol particles when irradiated with a laser, providing the advantage of real-time elemental composition assessment of aerosols while aerosol diameter distribution cannot be measured. Based on this, evaluations of this methodology were conducted using inert gases (Xe, Kr) and aerosols (Cs), and various individual-effect tests are being reported for direct application to MSR systems. Summarizing the preceding research, the evaluation of molten salt aerosol characteristics primarily employs non-contact optical methodologies, clearly revealing their pros and cons. A notable disadvantage is that the detection limit and uncertainty are significantly high under conditions of low aerosol formation, and uncertainties arising from non-contact methods (focus, calibration, and difficulty in absolute quantification) exist. Therefore, test under present study intends to apply a contact aerosol measurement methodology using an Electrical Low Pressure Impactor (ELPI). ELPI is advantageous for quantifying aerosol diameter distribution and number concentration, and has the benefit of elemental and chemical analysis through sample recovery.

Based on the analysis of existing researches, the aerosol characterization methodology was established, and the test apparatus was designed and constructed, which is divided into two types: (I) Evaporation rate measurement and (II) Aerosol behavior characterization. Present study introduces the design progress of test apparatus as well as preliminary result of salt evaporation.

2. MATERIAL AND METHOD

Experimental investigations about salt evaporation and aerosol dynamics are conducted through two independent tests: (1) measurement of evaporation rates at steady-state molten salt temperatures, and (2) characterization of airborne/wall-deposited aerosols at steady-state molten salt temperatures. First, the evaporation rate measurement test involves evaluating the change in molten salt mass due to evaporation over a set period, without a simulated containment vessel tank atop the furnace. Metal crucible containing molten salt includea a gas transfer line (diameter 1/4", length approximately 3.5m) between the furnace and the crucible to preheat the carrier gas (nitrogen), ensuring that the temperature of the molten salt, gas line, and carrier gas remains consistent throughout the experiment. This prevents local cooling of the molten salt and its gas due to the gas convection or heat loss. The evaporation mass is measured using a filtering device installed at the exit port of the crucible cover. The crucible, with an inner diameter of 78mm and height of

190mm, is a cylindrical design and is welded rather than bolted to prevent molten salt vapor leakage during the test. The filtering device consists of a condenser, a filter (WHATMAN GF/F, glass fiber, 500°C, 0.7 um), and a scrubber. The main role of the condenser is to condense the molten salt vapor into aerosols. The filter captures aerosol particles, and the scrubber collects any residual aerosols not captured by the filter through liquid sparging.

For the evaluation of airborne/wall-deposited aerosols, a tank installed atop the furnace simulates the containment vessel of an MSR, allowing for the condensation and aerosol formation of molten salt vapor due to volume expansion. The tank has a diameter and height of 0.6m and is cylindrical. Airborne aerosol concentration (#N) and size distribution within the tank can be evaluated using an ELPI. The aerosol deposition mass on the tank bottom surface due to gravitational settling or on the side walls due to thermophoresis can also be assessed.

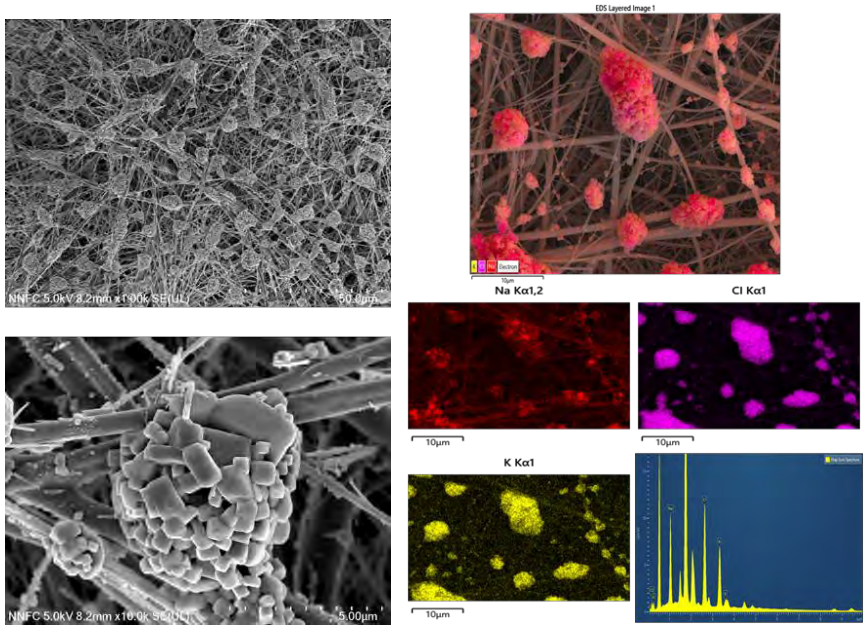

Figure 1. SEM/EDS images about salt aerosol particles captured in the filter (NaCl-KCl 5:5, 600C)

3. RESULTS AND DISCUSSION

The molten salt evaporation rate measurement is performed sequentially at four different temperature cases (800°C, 700°C, 650°C, and 600°C). Initially, the furnace power is gradually increased to form a molten salt pool inside the crucible. Once the temperature of the molten salt sample exceeds the melting point and begins to form a molten salt pool, a carrier gas (nitrogen) is injected into the pool at a constant flow rate to create a uniformly heated molten salt. The furnace power is then adjusted to control the molten salt temperature. When the molten salt reaches the target temperature, a pressure test (1.5 bar) is conducted first to determine the leak rate, which can introduce errors in the evaporation rate measurement. After confirming the leak rate through the pressure test, the evaporation rate is measured under steady-state temperature conditions at 800°C, with measurement conditions set at a duration of 1800 seconds or a maximum crucible pressure of 1.5 bar. Once the 800°C experiment is completed, the furnace power is adjusted to change the molten salt temperature (700°C, 650°C, 600°C), and the measurements are repeated.

As temperature increases, the amount of molten salt vapor generated by evaporation also increases, leading to a corresponding increase in evaporation mass. The evaporation mass per unit area is approximately 15 mg/m2-s at 800°C, indicating that a significant amount of salt vaporizes and can form aerosols despite the

relatively low vapor pressure of the molten salt. The collected evaporation mass was measured through a three-stage process involving a condenser, filter, and scrubber, with most of the molten salt aerosol being captured by the filter. Interestingly, although the amount is relatively small compared to above the melting point, some evaporation mass was still collected below the melting point. Even though solidified salt has a lower diffusion coefficient compared to its molten state, under the test conditions, which are significantly higher than room temperature, salt vaporization can occur, enabling aerosol formation. This finding is consistent with previous studies. Analysis of the collected molten salt aerosol particles revealed that they formed crystalline structures with sizes on the order of 1 micron, significantly smaller than the original salt particles during the initial filling. SEM analysis of the molten salt aerosol particles within the filter showed that they consisted of agglomerations of hundreds of nanoparticles, indicating substantial agglomeration. As temperature increased, the evaporation mass of the molten salt increased, indicating a corresponding increase in aerosol generation. With higher temperatures, the molten salt aerosol particles formed porous layers by agglomerating. EDS analysis confirmed that the primary components of the collected aerosol particles matched the major constituents of the surrogate salt used in the test. However, the initial molar ratio of the binary salt was different from the molar ratio of the captured aerosol, which can be attributed to the relatively higher evaporation flux of KCl compared to NaCl [**1**]. Through this preliminary test, the evaporation behavior of molten salt near the melting point was quantitatively evaluated, providing boundary conditions for future experiments (airborne aerosol characterization) with the tank.

4. CONCLUSIONS

Present study into the evaporation and aerosol behavior of molten salts provides a comprehensive understanding of their dynamics under various temperature conditions. The experiments, conducted at 800°C, 700°C, 650°C, and 600°C, demonstrated a notable increase in evaporation mass with rising temperatures, reflecting the increasing vaporization of molten salts. Even below the melting point, a measurable amount of evaporation occurred, suggesting that vaporization is possible despite the relatively low vapor pressure of molten salts. Analysis of collected molten salt aerosol particles revealed crystalline structures with sizes on the order of 1 micron, and primary components of the collected aerosol particles matched the constituents of the surrogate salt used in the tests.

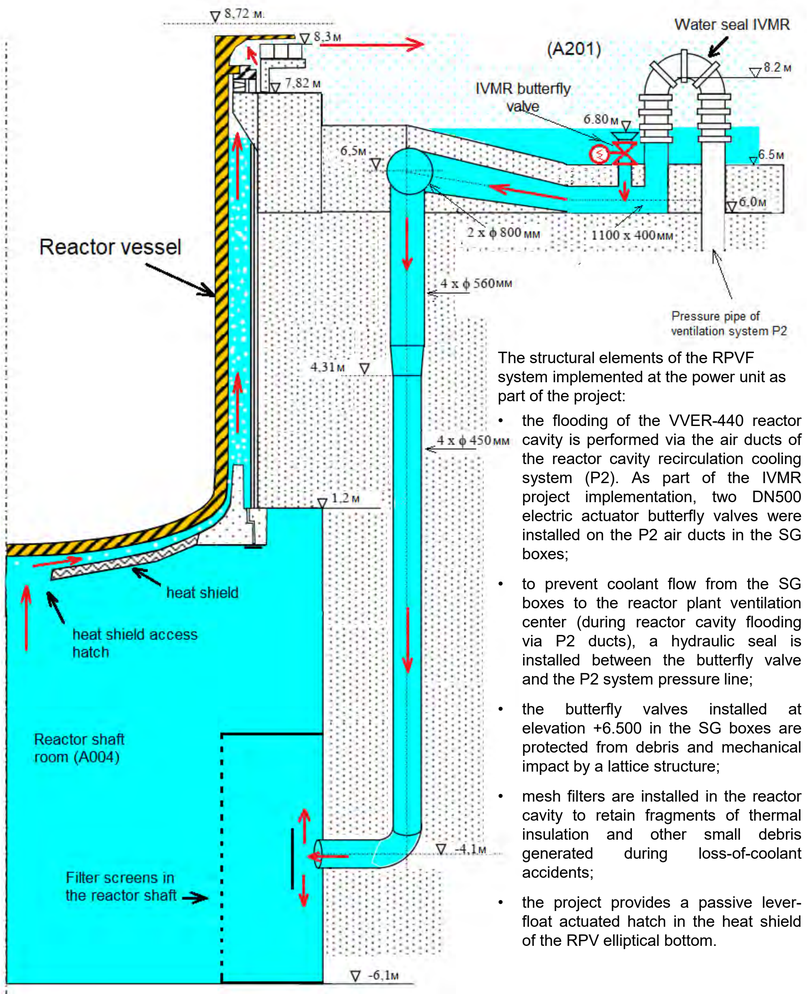
ENERGY SAFETY GROUP

Introduction

To minimize the consequences of Severe Accident (SA) with core damage, the In-Vessel Melt Retention (IVMR) system has been implemented at Rivne NPP Units 1 and 2 with VVER-440/V-213 (RNPP-1,2) in Ukraine. This system is designed to retain the melt in the Reactor Pressure Vessel (RPV) and prevent the SA from progressing to the ex-vessel stage by creating a closed natural circulation loop for external RPV cooling. For this purpose, water is supplied to the reactor cavity and the reactor vessel is submerged in water up to the support embeds, while the steam generated during cooling returns to the Steam Generator (SG) box and condenses.

The implementation of the IVMR system for RNPP-1,2 was carried out by Energy Safety Group LLC (ES Group), together with VÚEZ, a.s.



The structural elements of the RPVF system implemented at the power unit as part of the project:

- the flooding of the VVER-440 reactor cavity is performed via the air ducts of the reactor cavity recirculation cooling system (P2). As part of the IVMR project implementation, two DN500 electric actuator butterfly valves were installed on the P2 air ducts in the SG boxes;
- to prevent coolant flow from the SG boxes to the reactor plant ventilation center (during reactor cavity flooding via P2 ducts), a hydraulic seal is installed between the butterfly valve and the P2 system pressure line;
- the butterfly valves installed at elevation +6.500 in the SG boxes are protected from debris and mechanical impact by a lattice structure;
- mesh filters are installed in the reactor cavity to retain fragments of thermal insulation and other small debris generated during loss-of-coolant accidents;
- the project provides a passive lever-float actuated hatch in the heat shield of the RPV elliptical bottom.

The results of the analytical justification showed that in the event of an accident with a total power unit blackout and a sealed primary circuit, the conditions for starting the IVMR system occurred. The IVMR system is put into operation upon reaching a core outlet temperature of 450 °C, which is a condition for transitioning to the Severe Accident Management Guidelines (SAMG).

In the event of further SA development, to reduce the load on the reactor vessel in case of a sealed primary circuit, it is necessary to simultaneously perform primary circuit depressurization to preserve the integrity of the reactor vessel. Therefore, upon reaching the conditions for transitioning to the SAMGs, the relevant SAMG procedures provide for actions aimed at reducing the primary circuit pressure to values less than 6 kgf/cm². For this, the staff must ensure power supply and manually open the Pressurizer Safety Valves (PRZ SVs), the valves on the PRZ SV bypass line, and the valves of the Emergency Gas Removal System (EGRS valves).

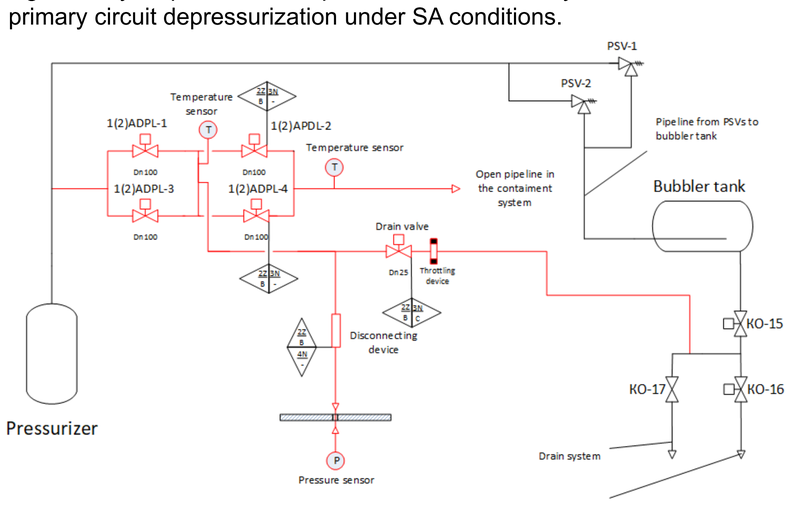
In the event of an accident with a total power unit blackout and a sealed primary circuit, the conditions for starting the IVMR system and performing primary circuit depressurization occur after ≈(11÷12.5) hours. Without the use of external power sources, by this time the accumulator batteries will be discharged, which will not allow depressurization of the primary circuit using the existing design-basis means. Moreover, the PRZ SVs, the valves on the PRZ SV bypass line, and the EGRS valves are not qualified for SA conditions; therefore, the question of their effective use remains open even if power supply becomes available.

Consequently, ES Group, together with VÚEZ, a.s., has developed a solution to enhance the safety of the unit by introducing the Additional Primary Depressurized Line (APDL), in compliance with the SAMG-2 requirement for primary circuit depressurization.

The APDL valve does not require electrical power to remain open, unlike PRZ SVs, and will open once the conditions for primary depressurization are met, subsequently remaining in the open position.

The main purpose of implementing the APDL is the ability to perform primary circuit depressurization, to preserve the integrity of the reactor vessel and ensure reliable operation of the IVMR system during a SA with core damage, in the event when the existing primary circuit depressurization means (PRZ SVs and EGRS) become unavailable.

The object of modification is the primary circuit pressure compensation system at RNPP-1,2. The modification involves implementation of the APDL by installing new equipment (not included in the original design) at RNPP-1,2. The implementation of the APDL does not duplicate the design-basis systems (PRZ SVs and EGRS). The introduction of the APDL significantly expands the capabilities and reliability of staff actions for primary circuit depressurization under SA conditions.



Technological diagram of the APDL for RNPP-1,2

APDL Concept

The APDL for RNPP-1,2 provides the following functions:

- primary circuit depressurization in the course of a SA, when existing primary circuit pressure reduction means (PRZ SVs, the valves on the PRZ SV bypass line, and EGRS valves) will be unavailable;
- preservation of reactor vessel integrity due to the reliable functioning of the IVMR system;
- reliable maintenance of primary circuit pressure at a low level (less than 6 kgf/cm²) on a long-term basis without additional staff actions;
- enhances the overall safety of the unit by utilizing equipment qualified for SA conditions, that allows for performing actions in accordance with SAMG-2 for primary circuit depressurization.

Short description of APDL

The main APDL pipeline (DN100) is a cut-in on the pipeline connecting the pressurizer and the PRZ SVs. The main APDL pipeline is divided into two identical lines to ensure the reliability of APDL operation.

On each of the lines, there are two consecutively connected main APDL valves – 1(2)APDL-1÷4 (DN100), which are in the closed position under normal operating conditions. The sequential arrangement of the two valves 1(2)APDL-1÷4 ensures reliable isolation of the high-pressure side.

The medium is discharged into the premises of the bubbler tank and pressurizer A527/1(2) through the open part of the pipeline. The medium discharge pipeline to the containment premises gradually increases in diameter from DN100 to DN125, and then to DN150. This is done to reduce the dynamic impact of the steam-gas jet discharged by the APDL.

A drain pipeline is also included for collecting and diverting operational leakages caused by the design-basis tightness limits of the main APDL valve. The drain pipeline is connected to the leak detection system of the primary circuit and has connection with the drain system. On the drain pipeline, a normally closed drain valve and a throttling device are installed to reduce the parameters of the leakages received from the main APDL valves to the operating parameters of the organized leakage system of the primary circuit.

The APDL incorporates measuring instruments that ensure monitoring of equipment parameters at a level sufficient for the APDL's functionality.

The APDL is equipped with the Process Control System (PCS), which is designed to control the APDL valves based on operator commands from the main control room (MCR)/emergency control room (ECR), display the valve status, and measure the temperature and pressure.

When the IVMR system is operating, the primary circuit depressurization must be continuous. Thus, the primary circuit depressurization through the PRZ SVs will require constant power supply to the pulse valve solenoids to hold the PRZ SVs in the open position.

The APDL valve does not require electrical power to remain open. The APDL valve opens once the conditions for primary circuit depressurization are met and subsequently remains in the open position.

The APDL valve can be controlled only from the MCR and ECR. This ensures direct operator control of the APDL valve, without the need for additional actions.

The main APDL valves are qualified for SA conditions.

APDL refers to a protective safety system, classification designation of the APDL as a whole – 23 and seismic category I .

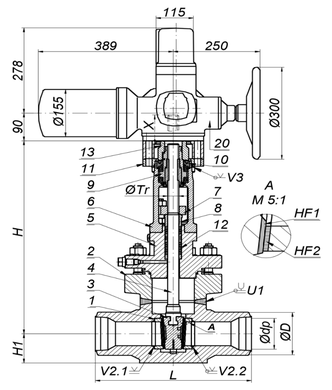
Based on placement conditions, the APDL components are classified as items located at the NPP in the containment.

Parameters of the APDL environmental

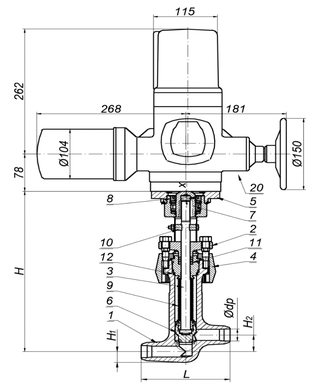
№	Parameter Name	Value
1	Pressure, kgf/cm²	2,5
2	Temperature, ºC	127
3	Medium	steam-water mixture
4	Humidity, %	100
5	Chemical composition	primary circuit coolant
6	Dose rate, R/h	4,85×10⁴

Operating medium parameters of the APDL

№	Parameter Name		Value
1	Pressure, kgf/cm² (abs.)	NOC	up to 140
		SA	up to 140
2	Temperature, ºC	NOC	up to 335
		SA	up to 450 (inclusive)
3	Hydrostatic test pressure, kgf/cm²	up to 165	
4	Medium	steam, water, steam-water mixture, nitrogen	
5	pH	from 4,2 to 10,3	
6	Boric acid concentration, g/dm³	from 0 to 20	
7	Hydrogen concentration, mg/dm³	from 2,2 to 4,5	
8	Chloride ion concentration, mg/dm³	up to 0,005	
9	Total activity, Ci/L	up to 10^{-1}	
10	Corrosion product concentration, mg/dm³	up to 1	
11	Ammonia concentration, mg/dm³	more than 3,0	



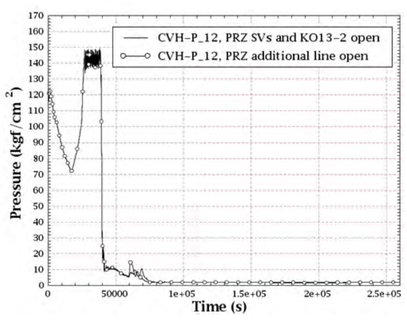
Main valve – a wedge gate valve with an integrated electric actuator



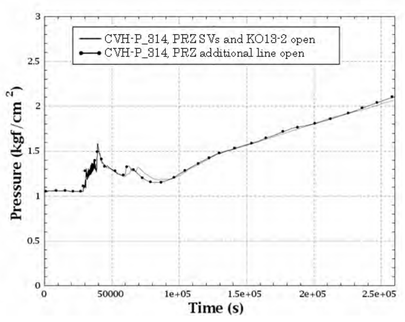
Drain valve – a bellows-sealed valve with an integrated electric actuator

The APDL has a flow capacity of 64 kg/s, corresponding to the combined flow rate of two PRZ SVs (the flow through one PRZ SV is 32 kg/s). This capacity is sufficient to reliably reduce and maintain the primary circuit pressure at a low level.

For all SA scenarios considered, the pressure in the containment remains below the design limit of 2.5 kgf/cm² (abs). Due to the presence of passive autocatalytic recombiners in the containment, conditions leading to hydrogen detonation do not develop during the APDL operation.



Primary circuit pressure (comparison of the APDL and PRZSVs)



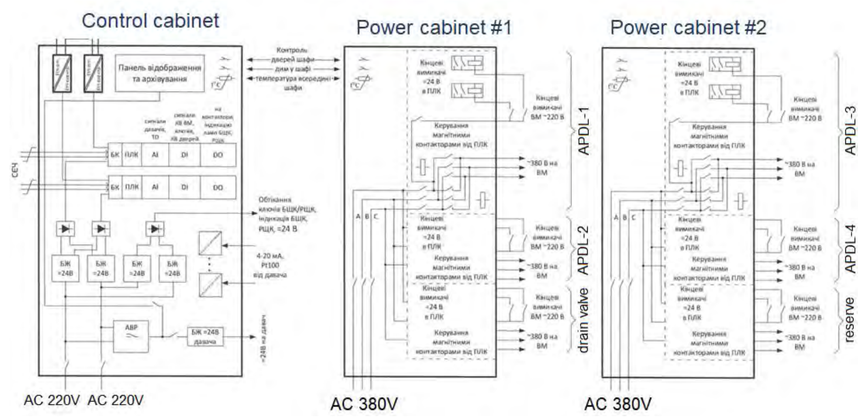
Pressure in containment (comparison of the APDL and PRZSVs)

APDL Process Control System (PCS)

A PCS was developed for the APDL, which implements the control of the APDL valves according to the commands of the MCR/ECR operator, visualization of the valve status, and measurement of temperature and pressure.

The PCS performs the following functions:

- formation of APDL valve control commands considering the position of the valve control keys, the position of the limit switches and the closing torque clutch;
- reception of signals from temperature and pressure sensors;
- exchange of digital communication channels with the "Black Box" / IOS and the signal of the unified time system;
- continuous automatic archiving, signaling, display and registration of technological and electrical parameters during the operation of the APDL equipment;
- automatic diagnostics, archiving, signaling and display of data on the technical condition of the APDL equipment;
- notification of malfunctions;
- notification of unauthorized access attempts;
- protection against unauthorized access;
- prevention of personnel errors;
- performs diagnostics and self-monitoring.



Structural diagram of the APDL PCS

APDL operation

During normal operation and Design Extension Conditions (Category A), the APDL remains in standby mode in a "ready for operation" state. The main APDL valves and the drain APDL valve are operable and in the closed position.

The APDL must be put into operation in accordance with the SAMG-2 requirement for primary circuit depressurization and should start no later than the start-up of the IVMR system.

For successful depressurization of the primary circuit, it is sufficient to open at least two consecutive main APDL valves (1(2)APDL-1÷4) in a combination that enables discharge of the medium from the primary circuit. That is, these can be combinations using one of the parallel lines or opening the corresponding valves in cross-combinations.

General Conclusions

- The implementation of the APDL significantly expands the capabilities and reliability of staff actions specifically under SA conditions.
- The APDL equipment is designed for operation throughout the progression of a SA, and the implementation scheme ensures a high level of reliability, ensuring continued APDL functionality even in the presence of single failures.
- The system allows performance of actions in accordance with SAMG-2 for primary circuit depressurization using equipment qualified for the corresponding operating conditions.
- It ensures the reliable operation of the IVMR system.

The drain pipeline is connected to the leak detection system of the primary circuit and has connection with the drain system. On the drain pipeline, a normally closed drain valve and a throttling device are installed to reduce the parameters of the leakages received from the main APDL valves to the operating parameters of the organized leakage system of the primary circuit.

The APDL incorporates measuring instruments that ensure monitoring of equipment parameters at a level sufficient for the APDL's functionality. The APDL is equipped with the Process Control System (PCS), which is designed to control the APDL valves based on operator commands from the main control room (MCR)/emergency control room (ECR), display the valve status, and measure the temperature and pressure.

When the IVMR system is operating, the primary circuit depressurization must be continuous. Thus, the primary circuit depressurization through the PRZ SVs will require constant power supply to the pulse valve solenoids to hold the PRZ SVs in the open position. The APDL valve does not require electrical power to remain open. The APDL valve opens once the conditions for primary circuit depressurization are met and subsequently remains in the open position.

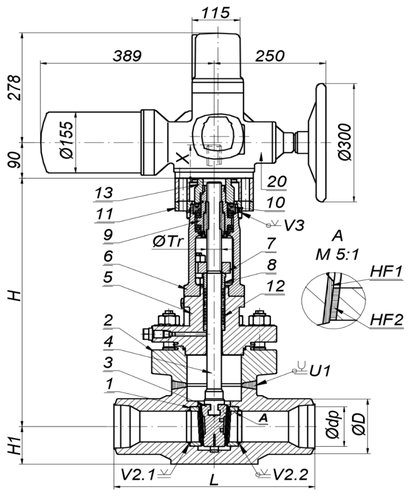
The APDL valve can be controlled only from the MCR and ECR. This ensures direct operator control of the APDL valve, without the need for additional actions. The main APDL valves are qualified for SA conditions. APDL refers to a protective safety system, classification designation of the APDL as a whole – 23 and seismic category I . Based on placement conditions, the APDL components are classified as items located at the NPP in the containment.

Parameters of the APDL environmental

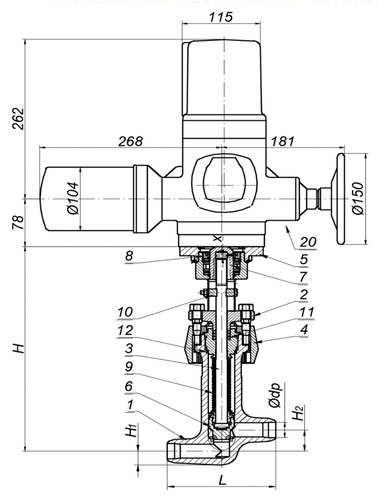
№	Parameter Name	Value
1	Pressure, kgf/cm²	2,5
2	Temperature, ºC	127
3	Medium	steam-water mixture
4	Humidity, %	100
5	Chemical composition	primary circuit coolant
6	Dose rate, R/h	$4{,}85\times10^4$

Operating medium parameters of the APDL

№	Parameter Name		Value
1	Pressure, kgf/cm² (abs.)	NOC	up to 140
		SA	up to 140
2	Temperature, ºC	NOC	up to 335
		SA	up to 450
3	Hydrostatic test pressure, kgf/cm²		up to 165
4	Medium		steam, water, steam-water mixture, nitrogen
5	pH		from 4,2 to 10,3
6	Boric acid concentration, g/dm³		from 0 to 20
7	Hydrogen concentration, mg/dm³		from 2,2 to 4,5
8	Chloride ion concentration, mg/dm³		up to 0,005
9	Total activity, Ci/L		up to 10^{-1}
10	Corrosion product concentration, mg/dm³		up to 1
11	Ammonia concentration, mg/dm³		more than 3,0



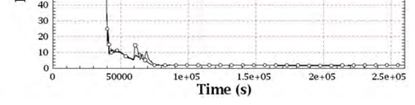
Main valve – a wedge gate valve with an integrated electric actuator



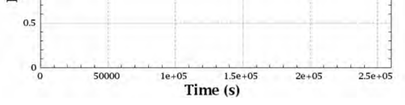
Drain valve – a bellows-sealed valve with an integrated electric actuator

The APDL has a flow capacity of 64 kg/s, corresponding to the combined flow rate of two PRZ SVs (the flow through one PRZ SV is 32 kg/s). This capacity is sufficient to reliably reduce and maintain the primary circuit pressure at a low level.

For all SA scenarios considered, the pressure in the containment remains below the design limit of 2.5 kgf/cm² (abs). Due to the presence of passive autocatalytic recombiners in the containment, conditions leading to hydrogen detonation do not develop during the APDL operation.



Primary circuit pressure (comparison of the APDL and PRZSVs)



Pressure in containment (comparison of the APDL and PRZSVs)

APDL Process Control System (PCS)

A PCS was developed for the APDL, which implements the control of the APDL valves according to the commands of the MCR/ECR operator, visualization of the valve status, and measurement of temperature and pressure.

The PCS performs the following functions:

- formation of APDL valve control commands considering the position of the valve control keys, the position of the limit switches and the closing torque clutch;
- reception of signals from temperature and pressure sensors;
- exchange of digital communication channels with the "Black Box" / IOS and the signal of the unified time system;
- continuous automatic archiving, signaling, display and registration of technological and electrical parameters during the operation of the APDL equipment;
- automatic diagnostics, archiving, signaling and display of data on the technical condition of the APDL equipment;
- notification of malfunctions;
- notification of unauthorized access attempts;
- protection against unauthorized access;
- prevention of personnel errors;
- performs diagnostics and self-monitoring.

APDL operation

During normal operation and Design Extension Conditions (Category A), the APDL remains in standby mode in a "ready for operation" state. The main APDL valves and the drain APDL valve are operable and in the closed position.

The APDL must be put into operation in accordance with the SAMG-2 requirement for primary circuit depressurization and should start no later than the start-up of the IVMR system.

For successful depressurization of the primary circuit, it is sufficient to open at least two consecutive main APDL valves (1(2)APDL-1÷4) in a combination that enables discharge of the medium from the primary circuit. That is, these can be combinations using one of the parallel lines or opening the corresponding valves in cross-combinations.

General Conclusions

- The implementation of the APDL significantly expands the capabilities and reliability of staff actions specifically under SA conditions.
- The APDL equipment is designed for operation throughout the progression of a SA, and the implementation scheme ensures a high level of reliability, ensuring continued APDL functionality even in the presence of single failures.
- The system allows performance of actions in accordance with SAMG-2 for primary circuit depressurization using equipment qualified for the corresponding operating conditions.
- It ensures the reliable operation of the IVMR system.

SOCRATES EU project on liquid source term during a severe nuclear accident – WP 3: Boundary evolution conditions in the bulk liquid phase

ABSTRACT

During normal operations in a Nuclear Power Plant, strict control of water chemistry is essential to prevent corrosion and preserve the integrity of components. In case of a severe accident, contaminated water present in containment sump or in spent fuel pools can harm system operations (by oxidation, corrosion or clogging processes) and compromise post-accident cooling capacities. Within the SOCRATES Horizon Euratom project, the objective of work package 3 is to investigate, through laboratory-scale tests, the intricacies of liquid chemistry in such complex situation. The focus is made on understanding how common materials in nuclear facilities interact with fission products when immersed in liquids.
Experiment test matrix will be based on a meticulous inventory of debris that could potentially be present in water during accidents. These encompass concrete or metallic particles, fragments of glass fibre insulation, paint chips arising from erosion or corrosion processes. Dissolution of such debris releases elements like silicon, calcium, metallic cations into aqueous media. Boundary conditions of the liquid present after a severe accident occurring in NPP (chemical buffer, pH, temperature) as well as inventories of key radionuclides will be defined based on the outputs of SOCRATES work package 2.
Laboratory-scale tests will be performed to characterize pool chemistry evolution in terms of pH, redox potential, soluble compounds, precipitates/colloids formation. Chemical and physical behaviours of debris and sludges, together with stable isotopes representative of highly soluble fission products (cesium and strontium) will be investigated. Particular attention will be given to how thermal and radiolytic stresses influence debris dissolution/degradation and next interactions with Cs and Sr. Furthermore, experiments will actively assess the kinetics of evolution in liquid properties by monitoring precipitate formation and size evolution.
These experiments will provide critical insights into the long-term fate of cesium and strontium in liquid phase following severe nuclear accidents.

KEYWORDS
SOCRATES, severe accident, liquid source term, caesium, strontium

1. INTRODUCTION

In the aftermath of Fukushima Daiichi NPP accident, open questions were raised related to long-term management of SA. Depending on SA scenario, huge volumes of water released from the RCS and from the emergency core cooling systems are collected in the lower parts of the reactor containment building. If these volumes exceed the capacity of the sump and recirculating pumps, flooding of the CV basement occurs, inducing contamination in areas that are difficult to access. Such large inventories were observed in the case of TMI-2 accident, when CV basement was flooded by ~2500 m^3 of contaminated water [1]. Contaminated water (debris, soluble/insoluble radionuclides) can harm system operations (by oxidation, corrosion, clogging processes) resulting in possible leakage leading to ground water contamination and having consequences on degraded fuel coolability and post-accident management.
In this view, needs have been identified for exploring comprehensively the chemistry and behavior of the liquid source term that arises from aerosols (including the most soluble radionuclides as Cs and Sr) and debris sedimentation in the water, from material leached from the containment walls and from interaction with immersed surfaces.
Within the SOCRATES program, the objective of WP3 is to investigate by laboratory scale tests, the intricacies of liquid chemistry in such complex situations and delving deep into how common materials in nuclear facilities react with fission products when immersed in liquids.

2. TEST BOUNDARY CONDITIONS

The term boundary conditions encompass all the parameters used to characterize the liquid phases found in the lower part of the containment vessel (sump in PWR or lower drywell/wetwell for BWR) or spent fuel pools, in the short and long term in SA conditions. It includes

- physical parameters as temperature and pressure evolution of the atmosphere in contact with the liquid phase.
- identification of the various chemical buffers (e.g., boric acid/soda, trisodium phosphate) to regulate pH; a comprehensive inventory of debris that could potentially be present in water during accident: concrete or metallic particles, fragments of glass fiber insulation, paint chips arising from erosion or corrosion processes. Debris dissolution introduces elements like silicon, calcium, and metallic cations.
- chemical parameters such as pH and redox potential, which results of the liquid phase composition evolution (taking account of chemical buffer, water radiolysis, material leaching, radionuclides release from degraded core, water supply).

Based on past accident data [1-3], on literature review on debris leaching in LOCA situation [4-5] and on literature review on cesium and strontium behaviour in accidental conditions [5] and their reactivity [6-8], the most likely conditions that can prevail in the liquid phase at mid/long term after a severe accident are summarized below.

Sump water temperature evolves rapidly in the hours following the accident initiation [1-3]. At short term (few hours after accident sequence), sump liquid temperatures up to 140°C can be still expected if the containment vessel remains pressurized (up to 5 bars). At long term, the temperature of the water collected in the lower parts of the containment vessel depends on the final state of the reactor (e.g. in-vessel corium or ex-vessels corium) and the possibility to operate closed recirculating cooling loops or not. A reasonable estimate of the temperature of water collected in the sump lies in the 40-80°C range.

Sump/basement water pH in the short term depends on the buffering agent used (soda, boric acid, sodium tetraborate, trisodium phosphate…) and the injection scenarios [3]. In order to stabilize halogen species (iodine) in the liquid phase, the objective is to maintain high pH conditions in the sump phase despite the release of highly soluble acidic species in the containment atmosphere following air radiolysis (nitric acid) and thermal/radiolysis degradation of cable insulation (hydrochloric acid). At short term, some scenarios predict acidic conditions (6.5-7.0), but final pH in the 7.8-8.7 range are expected in most scenarios with sodium tetraborates dissolution whatever the contribution of the acidic species generated in the containment

atmosphere. At long term, sump pH evolution will be linked to post accident operations, with the objective of maintaining slightly alkaline conditions (pH in between 8.5 and 9).

To the best of our knowledge, there is no publication related to long term impact of water radiolysis on sump water composition in SA conditions. Water radiolysis is expected to produce ROS (reactive oxygenated species) among them H_2O_2 is identified as the most stable in the long term (for timescales ranging from minutes to days). Expected H_2O_2 concentrations range from 10^{-8} up to 10^{-4} mol/l [9]. Generation of nitric acid following the radiolysis of nitrogen dissolved in water in equilibrium with air leads to a slow acidification of the liquid phase [10-11]. As oxidative species, ROS and HNO_3 are expected to play a role on sump chemistry in the long-term.

Dissolution behaviour and reactivity (e.g. secondary phase formation) of debris was investigated in LOCA situation [4-5] for different sump conditions. Final average cation concentration lies in between several dozen up to several hundred ppm for Si, Ca, Al but remains limited for Zn, Fe. In boric acid/soda buffer solution (pH 8.5), the formation of secondary phase featuring silica and calcium borates (colemanite) and zinc silicates (willemite) or zinc oxides was evidenced in analytical tests [5]. Enhanced precipitation processes are observed in the lower temperature range (40-60°C). In presence of borates ions, formation of borates species may compete with the formation silicate or carbonate phases.

Cesium is one of the main fission products in spent fuel. Its mass can amount up to 150-400 kg depending on the total initial fuel mass and fuel burn up [3]. Cesium is volatile and its fractional release during a severe accident can exceed 80% of its initial core inventory [3]. Main Cs released/transported forms up to the containment vessel are CsOH, CsI which are quite soluble in aqueous acidic or alkaline media. Aqueous phase contamination occurs following aerosol sedimentation/entrainment and containment vessel wall washing following the activation of emergency core cooling systems. Long-lasting low continuous contamination can also occur, following leaching of the degraded core, resulting in very high Cs contamination levels with concentration up to several dozen of ppm. Very low fractions of Cs are found in the basement sludges or deposited on the concrete immersed walls for both TMI-2 [1] and Chornobyl accidents (in between 0.2% and 4% of total Cs inventory found in the basements). Although representing a small fraction of cesium released from degraded core, the mass deposited or absorbed on surfaces poses a challenge for decontamination operations, inducing high dose rates preventing any human intervention. In the hydrothermal conditions prevailing in the sump liquid phase, several Cs- containing secondary phases can be hypothesized: pollucite [6], cesium aluminophosphate, Cs borates crystal [7].

Fission product Sr mass in a core amounts up to 50-130 kg depending on the total initial fuel mass and fuel burn up [3]. Strontium is considered as non-volatile with releases during a severe accident of less than 1% of its initial core inventory [3], these releases occur when high temperature are reached in the degraded core – mainly during the second oxidation phase. SrO is the main released/ transported form, but other species are not excluded. Important Sr deposition is expected to occur on the RCS walls; As a consequence of its low volatility, early Sr incomes in the liquid phase are low compared to that of Cs: only 0.7% of initial Sr core inventory were found in the liquid phase after TMI-2 accident [1] and 3.3% for the FD accident (Unit 2 - sampling of end of March 2011 [2]). Over time, a continuous strontium supply in the liquid phase is expected resulting from RCS surfaces washing and core leaching. Sr is mainly found in the bulk liquid, expected as hydrated Sr^{2+} cation. A higher Sr fraction than for Cs is found in the solid phase (sludges). Indeed, the formation of low soluble strontium carbonates (strontianite), strontium silicates and strontium borates upon mild heating in alkaline media is reported by [8].

3. CONCLUSION / PERSPECTIVE

Laboratory-scale tests will be performed at VTT and ASNR to characterize pool chemistry evolution in terms of pH, redox potential, soluble compounds, precipitates/colloids formation. Chemical and physical behaviour of debris and sludges together with stable isotopes of caesium and strontium will be investigated. Of particular interest is understanding how thermal/radiolytic stresses influences debris

dissolution/degradation and next interactions with Cs and Sr. Furthermore, experiments will actively assess the kinetics of liquid properties evolution by monitoring precipitate formation and size evolution.

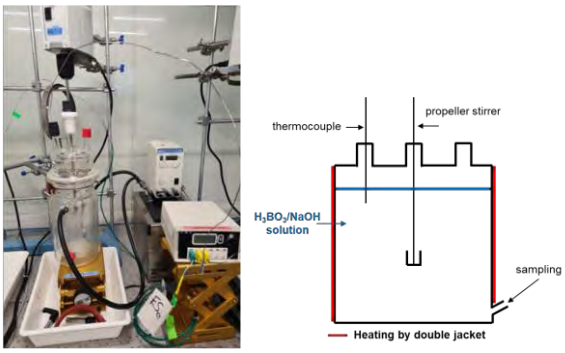

Figure 1 : typical batch device for study of sump reactivity.

To produce reliable data set on sump chemistry evolution, experimental work will consider chemical system with increasing complexity: analytical test devoted to better understand element reactivity will be firstly conducted, phenomenological tests will be performed in a second phase. Experiments' boundary conditions will be based on the parameters. Long-duration tests (from several hours up to several weeks) will be performed in batch conditions.

A. Context – Objectives

In case of a severe accident, huge volume of water released from the RCS and from the emergency core cooling systems are collected in the reactor containment building – flooding of the CV basement (TMI-2 and FD accidents)

- Such contaminated water (Debris, RN) can harm system operations (by oxidation, corrosion, clogging etc.) resulting in possible leakage leading to ground water contamination and having consequences on degraded fuel coolability.
- **Presence of specific (soluble/insoluble) impurities may affect radiolytic and corrosion reactions as well as precipitation processes and fission products chemistry** (e.g. chlorine affecting iodine chemistry) and play a role on the kinetics of these processes.

Needs for exploring comprehensively the chemistry and behaviour of the liquid source term that arises from aerosols (incl. soluble RNs such as Cs and Sr), debris sedimentation in the water, material leached from the containment walls and from interaction with immersed surfaces

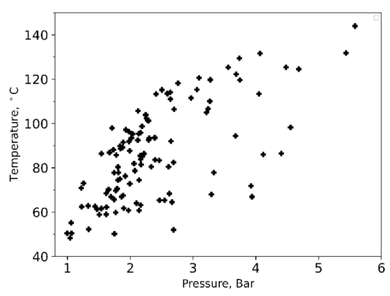
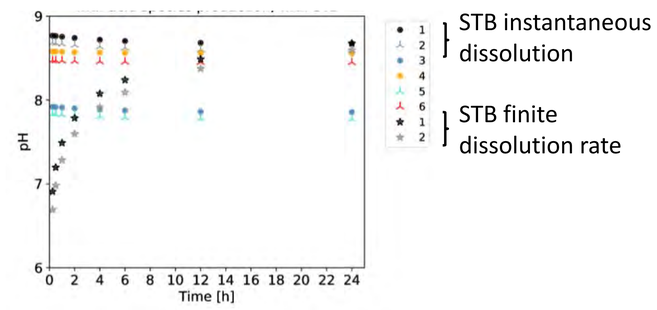
B. Bulk Liquid phase boundary conditions

Thermal – Hydraulics



Sump temperature and CV pressure – ASTEC simulations of SA scenarii on a 1300 MWe PWR (Nowack et al., 2025).

Sump composition and pH

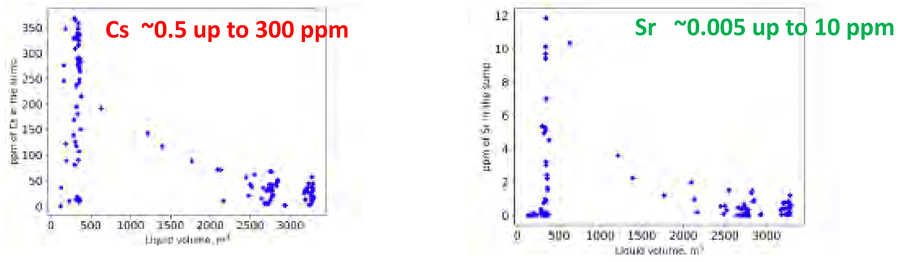


Sump pH evolution ASTEC simulations of a SA on a 1300 MWe PWR scenarii (1-6) involving water from RCS and supply tanks . Scenario 1-2 : Sodium Tetra Borate baskets

Temperature	100-130°C for studies reproducing early post-accident phase (1-2 days) 40-80 °C for studies focused on long term evolution phase (weeks up to months)
pH	pH ~ 4 - 5 for early post-accident phase (several hours after accident) pH > 7 for long term phases, experiments up to pH 9 can be considered
Main water Radiolysis product	H_2O_2 estimated level 10^{-6} up to 10^{-4} mol/L
Buffering media	NaOH/Boric acid/STB [Na] 2000-5000 ppm, [B] 2000-5000 ppm
Cl	10 to 15000 ppm (high bound value = sea water as coolant/ lower bond value = HCl production from atmosphere radiolysis of cable insulation)
Mg	6-1000 ppm (high bound value linked to use of sea water as coolant)
K	20-300 ppm
Sulfates	<2000 ppm
Carbonates	Equilibrium with air atmosphere
Nitrates	Air/Water radiolysis product

Review of material immersed / leached in the sump containment

Debris leaching	Large concentration ranges / local inhomogeneities
Ca (concrete)	10-100 ppm
Si (concrete, insulation)	30-450 ppm
Al (dry glue)	5 ppm (400 ppm if metallic surfaces)
Zn (galvanized steel)	5-50 ppm
Fe (galvanized steel)	1-10 ppm



Cs, Sr concentrations (ppm) in the sump as a function of liquid final volume at the end of ASTEC simulations of SA scenarii on a 1300 MWe PWR (Nowack et al., 2025).

C. Experiment strategy (Grégoire et al., 2025)

Characterize pool chemistry evolution in terms of pH, redox potential, precipitates and colloids formation

Several subtask to investigate pool chemistry step by step

- **Evaluate long term corrosion of immersed debris (insulation, paints) and surfaces (metallic and concrete) ; Si, Ca, Zn, Fe source term role of buffer, pH , temperature and radiolysis**
- **Bulk solution reactivity of elements from debris : simple chemical system up to complex mix involving Ca, Cs, Zn, Fe in pure water or tap water or NaOH/boric acid/ STB – role of temperature, pH, Boron species and radiolysis**
- **Bulk solution reactivity with Cs and Sr**
- **Investigation of Cs and Sr adsorption on immersed debris surface (bare/painted concrete surfaces)**
- **Phenomenological tests involving Cs and/or Sr : long-term trials are planned. Two tests (allowing up to 3 x 5 days irradiation duration) scheduled in ASNR-EPICUR facility in 2027**

ABSTRACT

After the Fukushima accident, various safety systems have been developed to enhance the safety of nuclear power plants. To further strengthen safety, a passive radioactive material filtration system is being developed for operation inside the containment building to minimize environmental impacts during severe accidents. The system consists of a passive gas entrainment system and a fission product mitigation system. To enhance its effectiveness, the performance and characteristics of each subsystem must be systematically evaluated and optimized. For this purpose, KAERI is preparing aerosol, elemental iodine, and organic iodine tests. Among these efforts, this paper specifically introduces the elemental iodine experiment, including the experimental facility and preliminary results.
An elemental iodine test setup was established to evaluate the removal efficiency of an iodine adsorption filter. Preliminary experiments were conducted to investigate the effects of parameters such as pressure and velocity on the first-stage adsorption filter. The results provided insights into performance trends and limitations of the first design. Based on these findings, improvements to the filter design are currently in progress. This paper presents the overall filtration system, the elemental iodine experimental facility, and key findings from the preliminary tests.

KEYWORDS
Severe accident, Filtration, Radioactive material, Iodine

1. INTRODUCTION

After the Fukushima accident, lots of safety systems have been developed, and the safety of domestic nuclear power plants (NPPs) has also improved. To further improve the safety of NPPs, it is necessary to develop a radioactive material filtration system which operates in containment to minimize damage caused by release of radioactive material to the environment during the severe accident.
The goal of this project is the development of a passive radioactive material filtration system which can be applied to the operating NPPs[1]. It consists of two main components, the passive fluid induction system and a fission product filtration system. To evaluate the performance of the radioactive filtration system in the containment using the severe accident analysis code, it is necessary to develop the fission product removal efficiency model. Also, to optimize the system, we need to understand the characteristics of each component.
KAERI is preparing for the aerosol, elemental and organic iodine tests to understand the characteristics of each component. This paper introduces the elemental iodine test set up for obtaining the elemental iodine removal efficiency and characteristics of adsorbents.

2. EXPERIMENT FACILITY FOR IODINE TEST

Figure 1 presents a schematic diagram of experimental facility used for iodine mitigation performance evaluation. The facility consists of three main subsystems: 1. Performance test section, 2. Thermal-hydraulic system (gas supply, cooling, storage, and discharge), 3. Fission product simulation and measurement system The gas supply system is designed to simulate thermal-hydraulic conditions relevant to severe accidents. In a mixing chamber, the supplied gas is mixed with simulated fission products (iodine) before entering the performance test section. After passing through the performance test section, the exhaust gas is cooled, treated to remove aerosols and iodine, and finally discharged to the atmosphere.

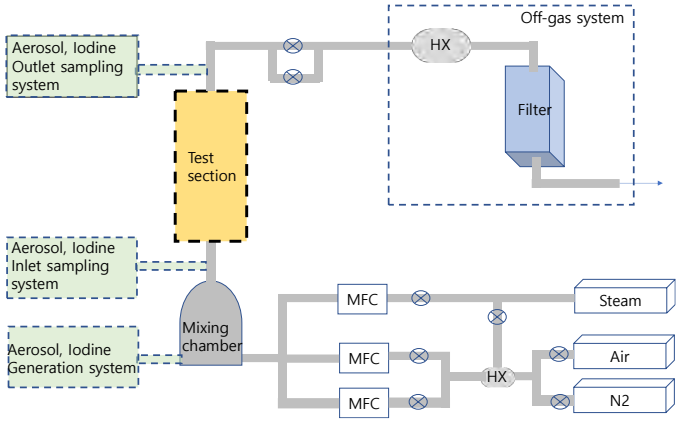

Figure 1. Schematic of experimental setup

2.1. Thermal-Hydraulic System

The gas supply system provides air as the primary test fluid using a steam boiler and an air compressor (Table 2). A receiver tank is installed downstream of the supply system to reduce flow pulsations and ensure stable gas delivery. Gas flow rate and pressure are controlled using flow meters and control valves.
The experiments were conducted at pressures ranging from 1.5 to 5 bar, with face velocities of approximately 0.2 to 1.0 m/s for a filter size of 305 × 305 mm. To accommodate a wide range of flow rates, the injection line was branched, as shown in Fig. 1. Additionally, the outlet line was divided into two branches to facilitate pressure control under low-flow conditions.
Although most iodine is removed in the performance test section, residual contaminants may remain in the exhaust gas. Therefore, the exhaust passes through a water-filled scrubber system, followed by HEPA and charcoal filters, before being released to the atmosphere.

2.2. Performance Test Section

The performance test section includes the iodine mitigation system to be evaluated. To minimize scaling effects, the iodine adsorption filter installed in the test section has the same dimensions and installation configuration as the actual filter used in the mitigation system. To evaluate the performance limits of the filter, differential pressure across the filter was also measured.

2.3. Iodine Generation and Measurement System

The iodine generation system is shown in the left part of Fig.2, and the iodine sampling system is shown in the right part.
To simulate iodine released during severe accidents, an iodine injection system was developed. Solid iodine crystals (up to 50 g) were heated to generate gaseous elemental iodine, which was then transported into the main test system using nitrogen or air as a carrier gas[2].

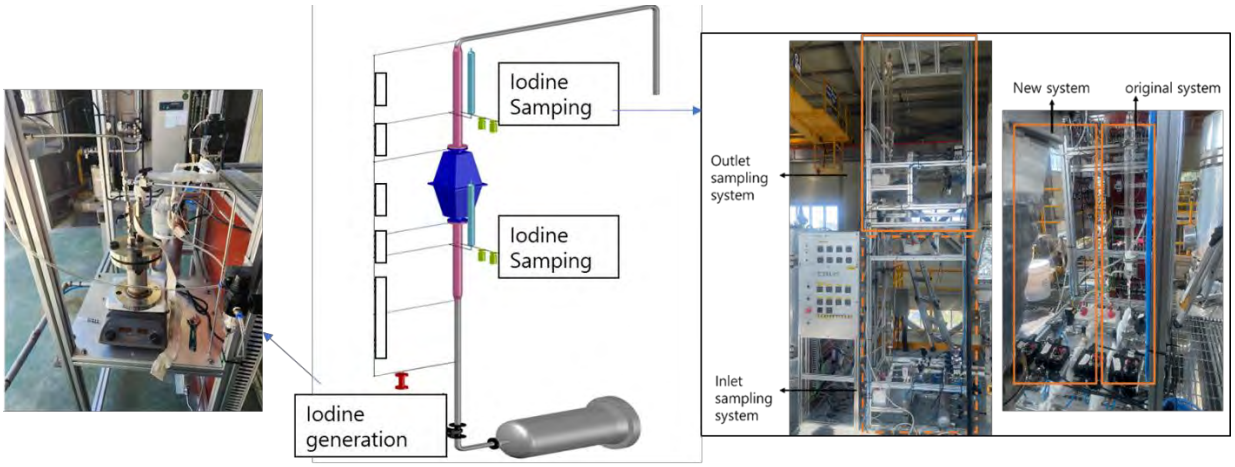

Figure 2. Iodine Generation and Measurement System

Iodine concentrations at the inlet and outlet of the test section were measured. The sampling flow rates and pressure were controlled using needle valves. To prevent steam condensation and reduce iodine losses on cold surfaces, the sampling lines were maintained at elevated temperatures.
Elemental iodine was collected using liquid gas scrubber columns equipped with coolant jackets. The coolant jackets prevented evaporation of the scrubber solution during the sampling. After the primary scrubber, an additional scrubber was installed to confirm complete iodine collection [3].
The collected samples were analyzed using iodide ion-selective electrodes (ISE). Ascorbic acid was added to the scrubber solution to reduce molecular iodine (I_2) to iodide ions (I^-). Although the ISE system can provide near real-time trends of iodine concentration, its sensitivity to temperature variations limits its accuracy. Therefore, precise measurements were obtained through post-test calibration under controlled temperature conditions.

3. PRELIMINARY TEST RESULTS AND DISCUSSION

3.1. System Performance Verification

Several preliminary experiments were conducted to characterize system behavior and support detailed test planning. The test conditions are summarized in Table 1. Inlet pressures upstream of the iodine injection nozzle ranged from 1.5 to 5 bar(g), and gas velocities were between 0.5 and 0.8 m/s. During the experiments, gas temperature, wall temperature, absolute pressure, gauge pressure, differential pressure, and sampling flow rates were measured along the test section.
The preliminary tests confirmed that pressure, temperature, and steam and air velocity were well controlled. In addition, stable operation of the iodine generation and sampling systems was verified.

3.2. Discussion

The relationships between decontamination factor (DF), pressure, gas velocity, and test gas composition were analyzed. The DF is defined as the ratio of the iodine concentration at the inlet and outlet.
Air-only conditions: Increasing pressure from 1.5 to 3 bar had little effect on DF, whereas increasing pressure to 5 bar resulted in approximately a 50% reduction in DF. This trend is attributed to the increased mass flow rate, which reduces the residence time required for iodine-adsorbent interaction.
Air–steam mixture: When both air and steam were used, DF decreased significantly as pressure increased from 1.5 to 3 bar, while further pressure increase to 5 bar had a minor effect.

Effect of steam fraction: At 1.5 and 5 bar, steam had little influence on DF. However, at 3 bar, DF decreased noticeably with steam addition. Comparison of air-only, air/steam = 5:5 wt%, and air/steam = 3:7 wt% conditions at 3 bar showed a clear trend of decreasing DF with increasing steam content.
The observed phenomena at 3 bar suggest complex interactions among pressure, steam content, and adsorption kinetics. Additional experimental and theoretical investigations are required, which are planned for future studies.

Table I. Preliminary Test Results

Test No.	Test Results						
	Pressure	Air flow rate (kg/s)	Steam flow rate (kg/s)	Inlet concentration (ppm)	Outlet concentration (ppm)	DF	Pressure difference (Pa)
1	1.5	0.062	0.000	18.45	0.77	**24.11**	217.50
2	1.5	0.015	0.033	22.65	0.88	**25.83**	370.1
3	3	0.025	0.061	9.04	1.30	**6.97**	917
4	3	0.043	0.094	5.72	0.70	**8.23**	1080.11

4. CONCLUSIONS

An experimental facility was developed to evaluate the iodine removal performance of an adsorbent-based mitigation system under simulated severe accident conditions. Thermal-hydraulic tests confirmed stable control of pressure, temperature, gas velocity, and iodine generation and sampling systems.
Preliminary results indicate that pressure and steam content significantly affect iodine removal performance, particularly at intermediate pressure conditions. Future experiments will focus on a wider range of operating conditions to develop a predictive model for iodine removal efficiency.

Introduction

1. Introduction

- After the Fukushima accident, lots of safety systems have been developed, and the safety of domestic nuclear power plants(NPPs) has also improved. To further improve the safety of NPPs, it is necessary to development of radioactive material filtration system which operates in containment to minimize damage caused by release of radioactive material to the environment during the severe accident.
- The goal of this project is the development of a passive radioactive material filtration system which can be applied the operating nuclear power plants. Before developing the passive radioactive material filtration system development, it is needed to confirm the effect of fission product removal efficiency when applying the radioactive material filtration system inside containment.
- KAERI is preparing for the aerosol, elemental and organic iodine tests to understand the characteristics of each component. This paper introduces the elemental iodine test set up for obtaining the elemental iodine removal efficiency and characteristics of adsorbents.

Experimental setup

2. Thermal-Hydraulic System

Experimental setup

- Figure 1 presents a schematic diagram of experimental facility used for iodine mitigation performance evaluation. The facility consists of three main subsystems:
  - 1. Performance test section,
  - 2. Thermal-hydraulic system
  - 3. Fission product simulation and measurement system

Thermal-Hydraulic System

- The gas supply system provides air as the primary test fluid using a steam boiler and an air compressor. Gas flow rate and pressure are controlled using flow meters and control valves.
- The experiments were conducted at pressures ranging from 1.5 to 5 bar, with face velocities of approximately 0.2 to 1.0 m/s for a filter size of 305 × 305 mm.
- The exhaust passes through a water-filled scrubber system, followed by HEPA and charcoal filters, before being released to the atmosphere.

Fig. 1 Schematic diagram of test set up

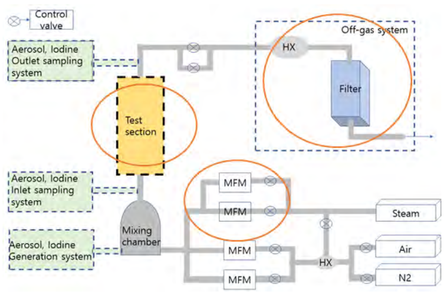

Table. 1 Capacity of test facility

Parameter	Value
Maximum operating pressure	10 bar a
System temperature	25 ~ 200 °C
Steam generator capacity	5000 kg/hr
Nitrogen generator capacity	1800 kg/hr
Air supply capacity	1800 kg/hr
핵분열 생성물 관련 성능	
Aeorosol Concnetration (SiO2)	$\mu g/m^3$~10 g/m^3
Elemental iodine(I_2) concentration	max. ~1000 ppm
Organic iodine(CH_3I) concentration	Max. ~1000 ppm

3. Performance Test Section

Performance Test Section

- The performance test section includes the iodine mitigation system to be evaluated.
- To minimize scaling effects, the iodine adsorption filter installed in the test section has the same dimensions and installation configuration as the actual filter used in the mitigation system.
- To evaluate the performance limits of the filter, differential pressure across the filter was also measured.

Iodine Generation and Measurement System

- Solid iodine crystals (up to 50 g) were heated to generate gaseous elemental iodine, which was then transported into the main test system using nitrogen or air as a carrier gas
- Iodine concentrations at the inlet and outlet of the test section were measured.
- The sampling flow rates and pressure were controlled using needle valves.
- Elemental iodine was collected using liquid gas scrubber columns equipped with coolant jackets. The coolant jackets prevented evaporation of the scrubber solution during the sampling.
- The collected samples were analyzed using iodide ion-selective electrodes (ISE).

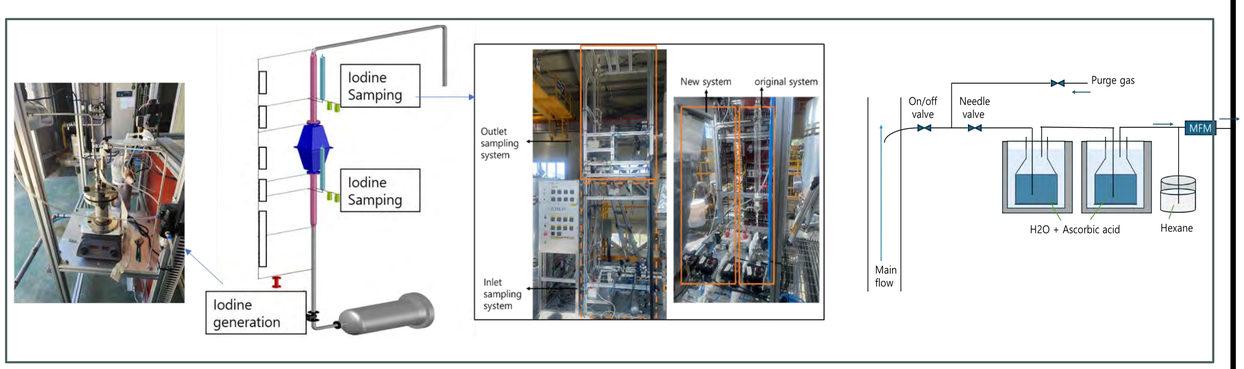

Fig. 2 Elemental iodine generation and sampling system

Preliminary test results

4. System Performance Verification

- The test conditions are summarized in Table 3. Inlet pressures upstream of the iodine injection nozzle ranged from 1.5 to 5 bar(g), and gas velocities were between 0.5 and 0.8 m/s. During the experiments, gas temperature, wall temperature, absolute pressure, gauge pressure, differential pressure, and sampling flow rates were measured along the test section.
- The preliminary tests confirmed that pressure, temperature, and steam and air velocity were well controlled. In addition, stable operation of the iodine generation and sampling systems was verified.

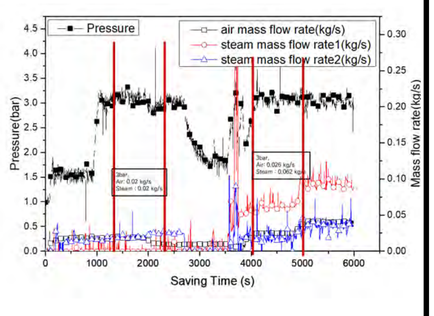
Fig. 3 Experimental results at 3 bar



5. Discussion & Conclusions

- The relationships between decontamination factor (DF), pressure, gas velocity, and test gas composition were analyzed. The DF is defined as the ratio of the iodine concentration at the inlet and outlet.
- Air-only conditions: Increasing pressure from 1.5 to 3 bar had little effect on DF, whereas increasing pressure to 5 bar resulted in approximately a 50% reduction in DF. This trend is attributed to the increased mass flow rate, which reduces the residence time required for iodine-adsorbent interaction.
- Air–steam mixture: When both air and steam were used, DF decreased significantly as pressure increased from 1.5 to 3 bar, while further pressure increase to 5 bar had a minor effect.
- Effect of steam fraction: At 1.5 and 5 bar, steam had little influence on DF. However, DF decreased with steam addition at 3 bar. Comparison of air-only, it showed a clear trend of decreasing DF with increasing steam content.
- The observed phenomena at 3 bar suggest complex interactions among pressure, steam content, and adsorption kinetics. Additional experimental and theoretical investigations are required, which are planned for future studies.

ABSTRACT
Lessons learned from the Fukushima Daiichi Accident (1F), where molten corium spread across the ex-vessel floor, underscore the importance of understanding corium spreading behavior for both accident reconstruction and the design of core-catcher systems. Recent experiments, notably the VULCANO VE-U9 test at CEA Cadarache, have shown that substrate conditions significantly affect corium spreadability. These studies also revealed that crust breaching can occur during spreading, adding complexity to melt–substrate interactions. However, the underlying mechanism of crust breaching remains insufficiently explored. In this work, the VULCANO VE-U9 experiment is re-examined using a novel particle-based approach coupled with a crust breaching model based on the Drucker–Prager yield criterion. A pressure-substitution implicit solver was developed to efficiently handle the highly viscous corium flow. When the yield function exceeded zero, the model reduced viscosity to represent crust fracture and subsequent flow. Simulations reproduced the grinding-like motion of viscous corium and successfully captured crust breaching at the advancing front due to compressive stress surpassing the yield strength. The proposed model reproduces fundamental breaching phenomena without artificial adjustments. To improve agreement with experimental observations, sensitivity analyses of key parameters—such as internal friction angle and cohesion constant—are recommended, as these govern the yield stress magnitude.

1. INTRODUCTION
High-temperature, highly viscous corium spreading is one of the crucial ex-vessel phenomena during a hypothetical nuclear severe accident, as it can determine the initial condition of the debris and the subsequent accident progression, such as molten core–concrete interaction (MCCI) [1,2]. Recently, the VULCANO VE-U9 experimental program observed prototypic corium spreading over sacrificial concrete and ablation-resistant ceramic substrates to investigate the role of MCCI in spreading dynamics [3]. A grinding-type motion of the corium can be seen over the ablation-resistant ceramic substrates, whereas a sliding motion of the corium is observed over the sacrificial concrete substrates. The low-viscosity lubricating boundary layer generated locally by MCCI enhances the spreadability of the corium. Furthermore, in the ablation-resistant ceramics experiment, crust breaching at the advancing front of the corium is observed, causing re-spreading of the corium encapsulated inside the crust. To gain deeper insight into the VULCANO VE-U9 experiments, a Lagrangian Moving Particle Hydrodynamics (MPH) model, which is one of the mesh-free particle methods, is developed and applied to simulate the experiments [4,5]. In this model, appropriate slip and no-slip boundary conditions are implemented to mimic the substrate-dependent spreading morphologies. However, the present methods cannot simulate crust-breaching behavior. Although a

previous study proposed a crust-breaching model based on the von Mises stress, this approach has uncertainties because the yield stress is manually prescribed and the von Mises equivalent stress is a scalar invariant that does not retain the directionality of the stress state or the difference between tensile and compressive failure modes [6]. In the context of the compression-dominated crust breaching that is observed in the experiment, a more suitable and physically consistent crust breaching model is indispensable.
In this study, we re-examine the VULCANO VE-U9 corium spreading experiment on ablation-resistant ceramics by introducing a crust-breaching model. In the previous MPH method, a pressure–viscosity simultaneous implicit solver was employed, in which the unknown pressure and velocity fields are solved implicitly and simultaneously. In contrast, the present study adopts a pressure-substitution implicit solver, in which only the unknown velocity field is solved implicitly while the pressure is substituted, leading to a lower computational burden than the original algorithm.

2. Numerical model

2.1 Control Equations

The governing equations consist of the momentum equation

$$\rho_0 \frac{\mathrm{D}\mathbf{u}}{\mathrm{D}t} = -\nabla \mathrm{P} + \mu \nabla^2 \mathbf{u} + \rho_0 \mathbf{g}, \tag{1}$$

Pressure equation for the incompressible control

$$\mathrm{P} = -\lambda \nabla \cdot \mathbf{u} + \kappa \frac{\Delta \rho}{\rho_0}, \tag{2}$$

And the energy conservation equation

$$\frac{\mathrm{DH}}{\mathrm{D}t} = k \nabla^2 T + \dot{Q}, \tag{3}$$

where ρ_0, $\mathbf{u}$, P, μ, $\mathbf{g}$, λ, κ, H, k, T, and $\dot{Q}$ correspond to the density, pressure, dynamic viscosity, gravity ac celeration, bulk viscosity, bulk modulus, enthalpy per unit volume, thermal conductivity, temperature, and volumetric heat source term, respectively. When Eq.(2) is substituted into Eq.(1), the following equation, whose unknown value is only $\mathbf{u}$, can be obtained.

$$\rho_0 \frac{\mathrm{D}\mathbf{u}}{\mathrm{D}t} = \lambda \nabla (\nabla \cdot \mathbf{u}) - \kappa \nabla \left(\frac{\Delta \rho}{\rho_0} \right) + \mu \nabla^2 \mathbf{u} + \rho_0 \mathbf{g}, \tag{4}$$

If we discretize Eq.(4) with the MPH method framework, the following linear matrix equation can be obta ined.

$$\rho_0 \frac{\mathbf{u}^{k+1}}{\Delta t} = -2\mu(dim+2) \sum_j \left(\frac{\mathbf{u}_j^{k+1} - \mathbf{u}_i^{k+1}}{|\boldsymbol{r}_{ij}|} \cdot \mathbf{e}_{ij} \right) \mathbf{e}_{ij} w'_{ij} -$$

$$\sum_j \left(\lambda \sum_l \left(\mathbf{u}_l^{k+1} - \mathbf{u}_i^{k+1} \right) \cdot \mathbf{e}_{li} w'_{li} + \lambda \sum_l \left(\mathbf{u}_l^{k+1} - \mathbf{u}_i^{k+1} \right) \cdot \mathbf{e}_{il} w'_{il} \right) \mathbf{e}_{ij} w'_{ij}$$

$$= \rho_0 \frac{\mathbf{u}^k}{\Delta t} - \kappa \sum_j \left((n_j - n_0) + (n_i - n_0) \right) \mathbf{e}_{ij} w'_{ij} + \rho_0 \mathbf{g}, \tag{5}$$

In which unknown velocity $\mathbf{u}^{k+1}$ is solved by CG (Conjugated Gradient) solver.

2.1 Crust Breaching model

The present crust-breaching model assumes that the structural collapse occurs when the local stress exceeds the yield strength defined by the Drucker–Prager yield criterion. Once a particle is identified as a breached crust element, its rheological behavior is switched from solid-like to elasto-viscous fluid, in which the flowability is governed by the local shear rate. Firstly, the local stress of the crust is assumed as

$$\boldsymbol{\sigma} = 2\mu \boldsymbol{\varepsilon} - \mathrm{P}\mathbf{I}, \tag{6}$$

where $\boldsymbol{\sigma}$, $\boldsymbol{\varepsilon}$, and $\mathbf{I}$ are Cauchy stress tensor, strain rate tensor, and identity tensor, respectively. From the Cauchy stress tensor, the second invariant of stress J_2 can be calculated as

$$J_2 = \sqrt{\frac{1}{2}(\boldsymbol{\sigma} + \mathrm{P}\mathbf{I}) : (\boldsymbol{\sigma} + \mathrm{P}\mathbf{I})}. \quad (7)$$

As the yield stress, the following Drucker–Prager yield criterion is employed:

$$f_p = \sqrt{3J_2} - (\alpha_\phi \mathrm{P} + \kappa), \quad (8)$$

where

$$\alpha_\phi = \frac{3\,tan\phi}{\sqrt{9 + 12tan^2\phi}}$$
$$\kappa = \frac{3c}{\sqrt{9 + 12tan^2\phi}}. \quad (9)$$

Here ϕ and c are the internal friction angle and the cohesion. In the present simulation, the yield criteria are set following conditions as it likely occurs compression conditions.

$$Breached\ Crust = \begin{cases} f > 0 \\ and \\ tr(\boldsymbol{\varepsilon}) < 0 \end{cases}, \quad (10)$$

Once the crust breaching occurs, the following simple elastoviscous model is applied to the breached particle.

$$\mu_{eff} = \frac{\alpha_\phi \mathrm{P} + \kappa}{2\dot{\boldsymbol{\gamma}}}, \quad (11)$$

where $\dot{\gamma}$ is shear rate which is calculated as

$$\dot{\boldsymbol{\gamma}} = \sqrt{2\boldsymbol{\varepsilon} : \boldsymbol{\varepsilon}}. \quad (12)$$

3. 2D VULCANO VE-U9 simulation

The present study simulated a two-dimensional configuration of the VULCANO VE-U9 experiment. Simulations were performed both with and without activation of the crust-breaching model for comparison. The simulation results are summarized in Figure 1, where the color label represents the solid fraction. Up to 8.0 s, the spreading behavior of the corium is similar in both cases, while crust breaching is observed at 12.0 s. The disruption occurs only at the advancing front position due to the compressive stress present there. After 12.0 s, the corium encapsulated within the crust re-spreads from the breaching point. Subsequently, the spreading gradually ceases due to a combination of reduced inertial force and cooling from radiative heat transfer at the free surface. The spreading length at the advancing front is also summarized in Figure 1. Pink and green markers indicate the simulation results, while the blue line represents the experimental data. In the experiment, re-spreading occurred around 17.0 s, whereas it occurred at 12.0 s in the simulation. Since the current crust breaching model includes sensitivity parameters such as the internal friction angle and cohesion constant, which determine the yield criteria, it is necessary to perform sensitivity analyses with respect to these parameters to better match the experimental results. In the experiment, a 16% extension in spreading distance was observed, compared to 12% in the simulation. The results indicated that the present method can simulate the crust breaching behavior without any artificial approximation while the sensitivity analyses are essential to mimic the timing of the crust breaching behavior.

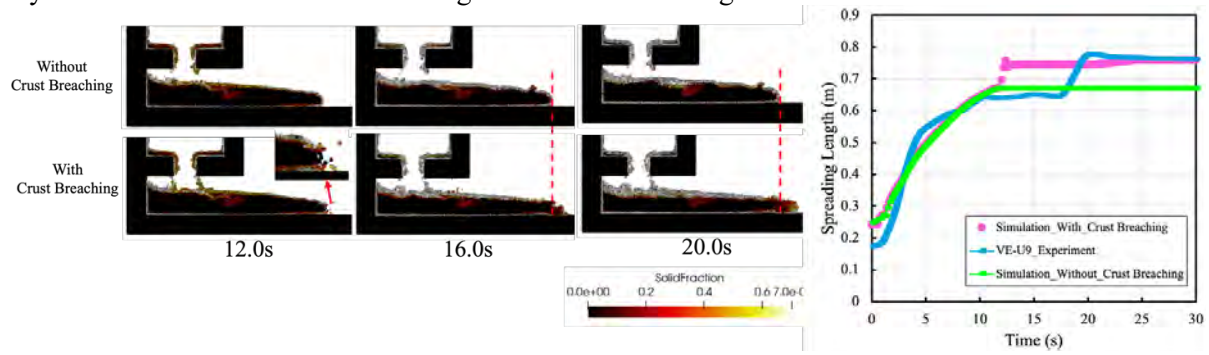

Figure 1 (left) snapshots of the spreading behavior with/without crust breaching model (right) spreading length at the advancing front position

4. CONCLUSIONS

This study presents corium spreading simulations that incorporate a crust breaching model together with a pressure-substitution implicit calculation method to re-examine the VULCANO VE-U9 experiment, where crust breaching behavior was observed on a ceramic substrate. The crust breaching model is based on the Drucker–Prager yield criterion, which defines crust failure when the local stress exceeds the yield threshold under compressive conditions. Once breaching occurs, the affected particles are treated as an elasto-viscous fluid whose viscosity depends on the local shear rate, enabling realistic representation of post-fracture flow. Two-dimensional simulations of the VULCANO VE-U9 configuration were conducted. The proposed approach successfully reproduced crust breaching at the advancing front and the characteristic stop-and-go spreading behavior frequently observed in experiments. Unlike previous studies, this model captures the fundamental physics of crust breaching without relying on artificial adjustments or empirical tuning. A quantitative comparison of spreading length revealed that the simulation achieved a 12% extension, slightly underestimating the experimental observation of approximately 16%. These discrepancies highlight the need for sensitivity analyses of key parameters—such as internal friction angle and cohesion constant—which govern the yield stress and thus influence the timing of crust failure.
Overall, the present method demonstrates strong potential for simulating physics-based crust breaching phenomena during corium spreading, providing a more robust framework for accident analysis and core-catcher design.

Type of abstract: Poster
Subject area: Source term issues
Keywords: Liquid source term, corium, leaching, experiments, radionuclides

The HORIZON-EURATOM SOCRATES project addresses critical gaps in our understanding of the liquid source term during severe nuclear accidents. In addition, it offers innovative solutions to mitigate and better assess the release of radionuclides into the environment. This topic has gained significant interest after the Fukushima Daichi nuclear power plant accident as a result of the large volumes of contaminated water to be treated, and the behaviour of radionuclides in the water. The aim of SOCRATES is to directly contribute to the mid-to-long-term accident management of nuclear power plants, enhancing safety, environmental protection, and safe waste management.

The main objective of the Work Package 4 is to investigate the source and formation of liquid phase contamination. The first tasks are to identify boundary conditions and key parameters for the leaching of radionuclides from the fuel, and to define test matrix for the experimental research. For this, literature survey has been carried out and documented. In the next phase, leaching experiments with different materials will be carried out by following a process of step-by-step progress from “simple experiments” to “more complex experiments”. The materials used in the experimental work are: i) inactive ceramic material models with representative fission product species, ii) simulated fuel pellets, and iii) prototypic, uranium-containing corium debris and TMI-2 corium.

The results of the literature survey will be presented with the aim of summarizing existing data on debris leaching and any other relevant leaching data, as well as depicting the test conditions to be used in the leaching tests. The planned leaching tests will also be briefly described.

WP4: Leaching experiments

The objective of the WP4 is to experimentally investigate the source and formation of liquid phase contamination:

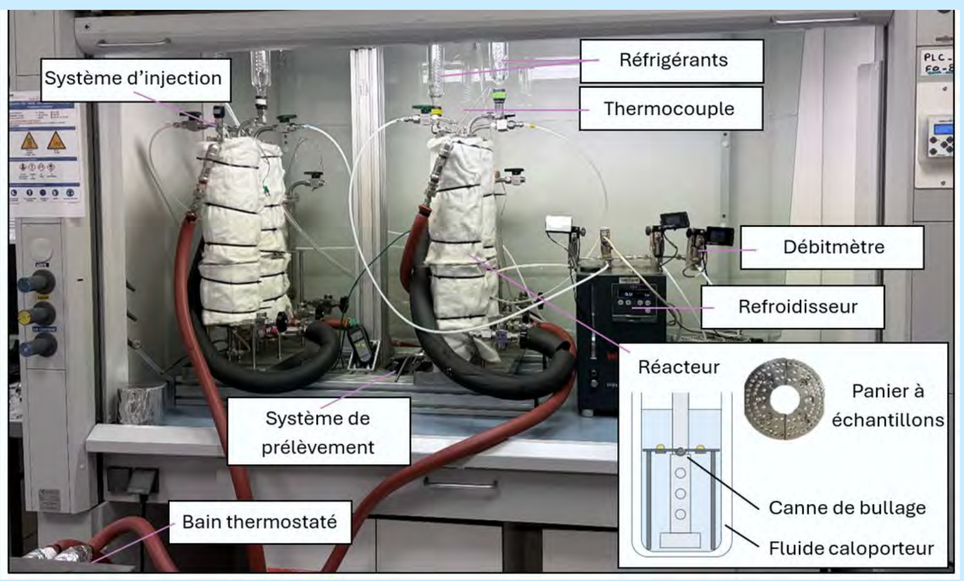
- to identify boundary conditions and key parameters for the leaching of radionuclides from the fuel
- to define test matrix for the experimental research by carrying out a literature search and summary
- to conduct leaching experiments with different materials:
  - inactive ceramic material models with fission product species
  - simulated fuel pellets
  - prototypic, uranium-containing corium debris
  - TMI-2 corium.

LEACHING TESTS

Experimental data for leaching of radionuclides in water include leaching tests of simulant materials for both in-vessel and ex-vessel corium as well as leaching tests with corium collected from the TMI-2 and Chornobyl plants. The results for in-vessel corium show that the atmosphere under which the simulant debris is synthesized has a decisive effect on the leaching behaviour of actinides, oxidizing conditions during synthesis resulting in increased leaching. Similarly, leaching in seawater increases dissolution rate as compared to distilled or pure water. Volatile fission products, e.g., Cs, have a much higher leachability than actinides.

TMI-2 corium samples collected from two different locations, i.e., molten core and lower crust, showed no major differences between the samples or water composition. Comparison of leaching behaviour of TMI-2 corium with that of spent nuclear fuel revealed that the U dissolution rate from both TMI samples was two orders of magnitude higher than dissolution from spent fuel in deionized water. Dissolution of Cs did not vary much between different samples.

An example of the experimental facilities: cyclone at ASNR



DATA FROM PAST ACCIDENTS

According to the available data, large fractions of Cs and I were found in contaminated water in TMI-2 (up to 50% of initial inventory) and Fukushima Daiichi (20-70% of initial inventory for units 2 and 3), whereas significantly smaller fractions of 137Cs and 90Sr were analysed in the water in Chronobyl plant (3-10% of initial inventory). In the long term, the main contributors to the water activity were different isotopes of Cs and Sr as well as tritium, the other radionuclides being less important to the activity in water.

The Issue of Radioactive Water Accumulation During Severe Accident Management

The problem of accumulation and management of significant volumes of radioactive water during severe accidents (SA) is associated with the need for continuous cooling of nuclear fuel in the reactor core, regardless of the extent of fuel damage. The volumes of accumulated radioactive water depend on the design features of the power units, the selected SA management strategy, and the characteristics of the nuclear power plant (NPP) site.

Conceptually, two approaches can be identified for managing large volumes of radioactive water generated during SA:

- storage outside the containment in dedicated tanks;
- long-term retention of radioactive water within the containment, followed by its gradual purification.

Disadvantages of Storing Radioactive Water in Tanks Outside the Containment

At the destroyed Fukushima Daiichi NPP more than 1.34 million tons of radioactive water have accumulated as a result of the operation of open-loop cooling systems. Further storage of radioactive water in additional tanks at the Fukushima Daiichi NPP site has revealed the disadvantages of this method, including limitations on tank capacity, risks of leakage, and radioactive contamination of the environment.

In general, the concept of storing radioactive water in tanks outside the containment is suboptimal for the following reasons:

- the need to establish dedicated areas with a large number of tanks for radioactive water storage;
- the need for an extensive system of technological connections;
- risks of leakage and radioactive contamination of the environment;
- risks of personnel radiation exposure when storing water outside the containment;
- potentially significant financial costs, taking into account all stages of work (procurement, testing, long-term storage, and maintenance).

Radioactive water storage tanks at the Fukushima Daiichi NPP

Closed-Loop Cooling Using Design-Basis Systems

The type of coolant circulation in the reactor core cooling circuit has a significant impact on the volume of radioactive water accumulated during SA: open (as implemented at the Fukushima Daiichi NPP) and closed.

A closed circulation loop using design-basis Emergency Core Cooling Systems (ECCS) at VVER-1000 power units can reduce the amount of radioactive water through repeated circulation of the coolant within the containment. However, at the ex-vessel stage of SA, the use of the design-basis ECCS will lead to the leaching of highly radioactive fuel-containing materials from the corium and their subsequent accumulation in ECCS equipment.

The design-basis ECCS of VVER-1000 reactors are not qualified for SA conditions. Therefore, use of the ECCS in SA will involve certain risks and disadvantages:

- contamination of the cooling circuit with radioactive particles of corium due to direct contact of the coolant (water) with corium;
- clogging of filters in ECCS pump suction lines, damage to ECCS pump seals by mechanical particles;
- heating and potential additional degradation of ECCS equipment due to residual heat release from corium particles;
- inability to maintain ECCS equipment due to high radiation levels.

This may result in a failure of the ECCS pumps and the occurrence of radioactive water leaks in non-leak-tight areas of the reactor compartment.

Closed-Loop Water Exchange and Purification

To extend the operating time of the ECCS equipment during SA, water exchange and purification of the closed cooling loop can be applied. However, this mode also has certain limitations:

- coolant purification via water circulation will result in the accumulation of additional radioactive water of approximately 240–720 m³/day;
- design-basis water purification systems are not designed to treat highly radioactive water containing corium particles, resulting in loss of their operability and inability to perform maintenance;
- formation of highly radioactive waste containing corium particles.

According to the results of calculations based on coolant water circulation, all potentially available tank capacity will be completely filled within 9-34 days (for various NPPs with VVER-1000 power units, based on water exchange calculations for only one affected power unit). At the same time the volume of tanks in the reactor building of a single (affected) power unit is about 1900 m³. The total volume of tanks in the NPP's special buildings and affected power unit is about 7400-10600 m³.

Increasing capacity for receiving, processing, and disposing of radioactive water beyond design limits does not solve the problem of long-term heat removal from the corium. A more optimal approach is to develop and implement measures that prevent large amounts of radioactive water from leaving the containment.

Concept of the Long-Term Containment Cooling System for VVER-1000

An alternative closed-loop option is proposed for implementation – the use of a steam-gas mixture in the cooling circuit, which is formed within the containment in the corium flooding area. Advantages:

- higher heat removal efficiency due to boiling;
- no leakage of liquid radioactive coolant containing corium particles outside the containment and the possibility of system maintenance;
- long-term retention of radioactive water within the containment without further increase in water volumes.

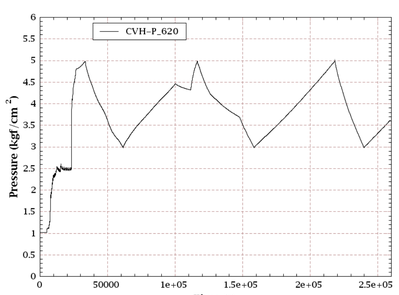
It should be noted that following the accident at the Fukushima Daiichi NPP, a significant number of safety improvement measures have been implemented at all NPPs in Ukraine. These measures are aimed at increasing the resilience of NPPs to external hazards and extended design-basis conditions. However, at least the following interrelated issues remain unresolved, which affect the ability to manage SA:

- proper handling of large volumes of radioactive water generated during SA, when applying a strategy of accident management involving water injection into the containment and its subsequent discharge outside;
- ensuring long-term (72 hours after the start of the accident) heat removal and pressure relief from the containment at the ex-vessel stage of the accident, and preventing exceedance of containment temperature and pressure limits and potential containment failure;
- cooling of the corium in the ex-vessel stage during SA, since there are currently no clear research conclusions regarding the feasibility of retaining the melt within the reactor vessel for VVER-1000 power units.

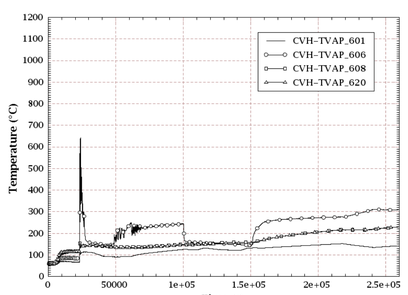
At VVER-1000 power units the Containment Filtered Venting System (CFVS) has already been implemented. The CFVS prevents containment failure under accident conditions by automatically opening when the containment pressure reaches 5.0 kgf/cm² (abs) (design limit), followed by operator control. However, operation of the CFVS does not ensure long-term heat removal from the containment (beyond 72 hours), and the containment temperature reaches the accident condition limit of 250 °C.

Containment Medium Parameter Limits for VVER-1000

Containment limit parameters	Design basis accident «LB-LOCA»	SA	FCVS operation during SA
Temperature, °C	150	250	Increasing
Pressure (abs.), kgf/cm²	5,0	5,0	5,0



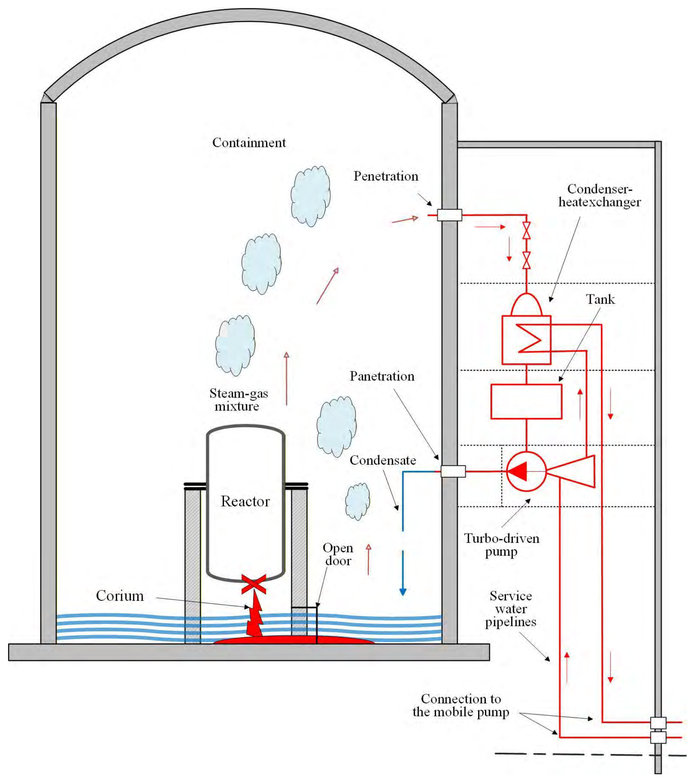
Containment Pressure during CFVS Operation



Containment Temperature during CFVS Operation

However, the introduction of the Long-Term Containment Cooling System (LTCCS) will resolve the above-mentioned safety issues.

Currently, ES Group and Westinghouse are jointly implementing the LTCCS at Rivne NPP Units 1,2 with VVER-440 reactors, and a separate LTCCS concept is being developed for NPP with VVER-1000 (LTCCS-1000).



General Diagram of the LTCCS-1000

The main function of the LTCCS-1000 power units is to maintain the containment integrity by:

- reducing the adverse effects of corium on the containment base slab;
- preventing exceedance of permissible pressure and temperature limits in the containment through heat removal from the corium.

The LTCCS-1000 operational concept Includes:

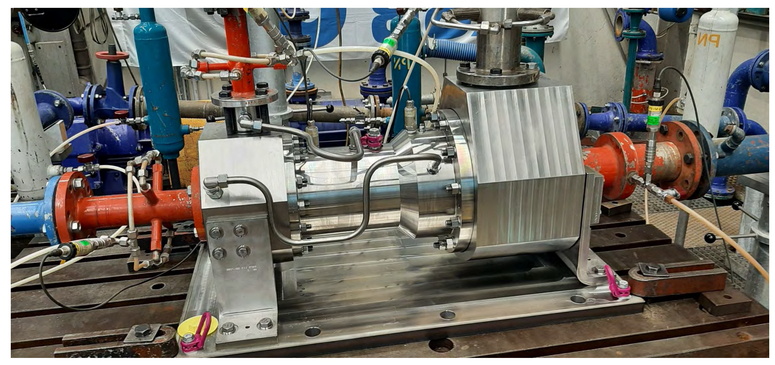
- the heat source in the containment during the ex-vessel phase of SA is corium located in the reactor cavity;
- the primary purpose of the LTCCS is to remove heat from the corium and to reduce pressure and temperature in the containment;
- prevention of an increase in the volume of radioactive water by the LTCCS through closed-loop circulation and removal of the steam-gas mixture from the containment;
- independence from other systems during accident management;
- capability to function alongside the FCVS;
- activation of the LTCCS during the ex-vessel phase of SA.

Design and Operation of the LTCCS-1000

The LTCCS-1000 power units consists of two loops.

The first loop operates using a pump unit driven by a hydraulic turbine. The turbine-driven pump and heat exchanger are located outside the containment in the reactor building.

The LTCCS-1000 is designed to use a turbine-driven pump similar to that implemented in the LTCCS at Rivne NPP Units 1,2 with VVER-440 reactors.



Turbine-driven pump by KSB SE & Co. KGaA

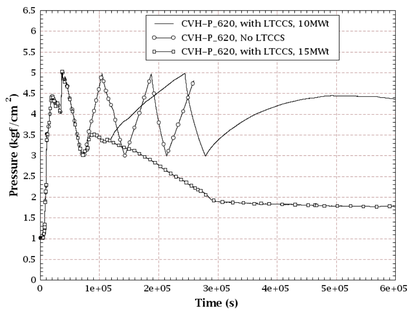
During the ex-vessel phase of SA, the water covering the corium heats up and evaporates inside the containment. Due to the excess pressure in the containment, the steam is directed through the first loop of the LTCCS to the heat exchanger for condensation and cooling. The condensate is collected in an intermediate tank and then, using the turbine-driven pump, returned to the containment. This configuration provides a closed circulation loop for the steam-water coolant and prevents mechanical impurities containing highly radioactive corium fragments and debris from entering the LTCCS equipment. Full water coverage of the corium, achieved by creating a "pool" on the containment base slab, ensures uniform cooling over the entire corium spreading area compared to sprinkler-based cooling.

The second loop of the LTCCS is a "clean" technical water circuit that does not come into direct contact with radioactive fission products. Separate mobile pump units are planned to supply water to the second loop. Initially, the technical water is used as the working fluid to drive the turbine of the turbine-driven pump. The technical water is then supplied to the LTCCS heat exchanger to cool the steam coming from the containment. The pressure in the second loop is maintained higher than in the first loop. This prevents the potential leakage of radioactive water through the LTCCS equipment, its entry into the reactor building, and subsequently into the environment. The removed heat is dissipated into an open water reservoir near the power unit.

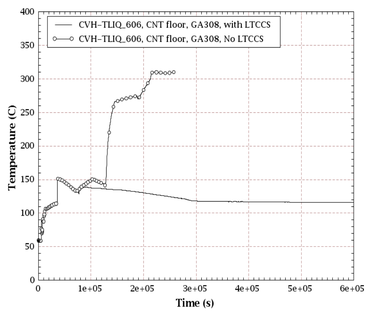
Preliminary Calculation Results

Preliminary calculations were performed for the VVER-1000/V-320 design model.

- The LTCCS reduces and stabilizes containment pressure and temperature below design limits during an accident.
- The number of CFVS cycles is reduced after the LTCCS is activated.



Containment Pressure for the "Total Station Blackout" Scenario



Containment Temperature for the "Total Station Blackout" Scenario

- Stopping further forced pressure relief from the containment via the CFVS significantly slows down the decrease of the water level in the retention pool due to evaporation.
- After 3–5 days, the LTCCS capacity can match the residual heat generation, depending on the selected equipment.
- By reducing containment pressure during the LTCCS operation, the release of radioactivity into the environment is decreased.
- The LTCCS capacity can be regulated by adjusting the blowdown opening after the condenser (blowdown into the scrubber).
- Before the LTCCS operation, additional water must be supplied to the containment to raise the level above the corium layer.
- The LTCCS operation in the late phases of SA does not affect hydrogen safety. Most of the hydrogen in the containment has already been recombined by passive autocatalytic recombiners (PARs), and the LTCCS does not condense steam within the containment atmosphere.

Conclusions (Advantages of the LTCCS-1000)

- Long-term cooling and prevention of containment failure.
- Removal of only the steam-gas mixture from the containment, with no significant carryover or accumulation of highly radioactive corium particles in the LTCCS equipment.
- Prevention of an increase in radioactive water volume by LTCCS closed-loop circulation, retaining existing radioactive water inside the containment.
- No need for additional storage tanks for radioactive water.
- Capability for long-term management of radioactive water at later stages of accident mitigation.
- Independence of the LTCCS from other plant systems.
- Possibility of using standardized design solutions on serial power units with VVER-1000/V-320 reactors.
- The LTCCS-1000 concept can be applied similarly to power units of VVER-1000/V-302,V-338 designs (South Ukraine NPP).

The Issue of Radioactive Water Accumulation During Severe Accident Management

Accumulation and management of significant volumes of radioactive water during severe accidents (SA) is associated with continuous cooling of nuclear fuel/debris. Accumulated radioactive water volume depends on the design features and SA management (SAM) strategy for nuclear power plant (NPP).

Disadvantages of Storing Radioactive Water in Tanks Outside the Containment

At Fukushima Daiichi NPP (Fukushima-1) more than 1.34 million tons of radioactive water have accumulated after operation of open-loop cooling systems. The concept of radioactive water storage in tanks outside the containment has features:

- special areas with many tanks;
- extensive system of technological connections;
- risks of leakage and contamination of the environment;
- risks of personnel radiation exposure;
- potentially significant financial long-term costs.

Radioactive water storage tanks at the Fukushima-1

Closed-Loop Cooling Using Design-Basis Systems

Closed loop cooling with Emergency Core Cooling Systems (ECCS) at VVER-1000 power units can reduce the amount of radioactive water. However, ECCS operation has some features:

- needs considerable electric energy supply;
- cooling circuit contamination by corium particles;
- possible clogging of ECCS filters, pump seals damage;
- ECCS equipment failure due to decay heat in circle;
- inability to perform maintenance actions for ECCS equipment;
- risk of leaks outside containment in case of ECCS failures.

Closed-Loop Water Exchange and Purification Limitations

Water exchange and purification of the closed ECCS cooling loop can be applied, but with following limitations:

- additional radioactive water accumulation by 240–720 m³/day;
- tank capacities will be exhausted within 9-34 days;
- water purification systems are not designed to treat highly radioactive water containing corium particles;
- highly radioactive waste formation with corium particles.

Unresolved SAM Issues for VVER-1000 (Ex-vessel Phase)

Safety improvements have been implemented at Ukrainian NPPs following Fukushima accident. Some issues remained unresolved:

- handling of large radioactive water volumes after SAM strategies application;
- ensuring long-term (beyond 72 hours) containment heat removal and pressure control at SA ex-vessel phase;
- large mass of post-accident hydrogen in containment;
- corium/debris cooling during SA ex-vessel phase.

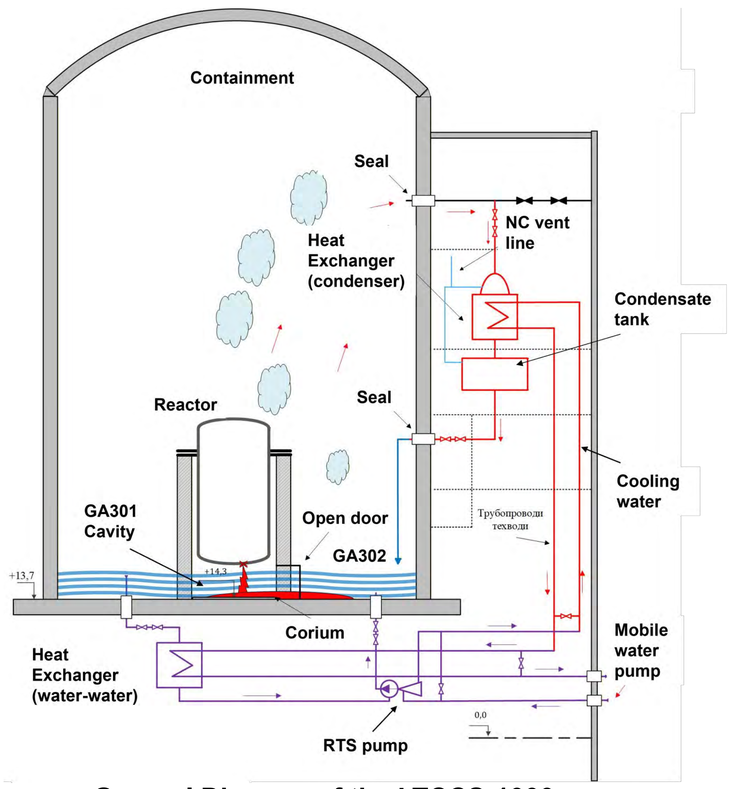
All VVER-1000 units are equipped with Containment Filtered Venting System (CFVS) with scrubber or dry filter with passive opening at pressure 5.0 kgf/cm² (abs) (design limit), followed by operator control. However, CFVS operation does not ensure long-term containment heat removal (beyond 72 hours).

Concept of the Long-Term Containment Cooling System (LTCCS) for VVER-1000 (Ex-vessel Phase)

An alternative closed-loop system is proposed for implementation. Main subsystem is steam-gas mixture condensing circuit (containment atmosphere cooling), and auxiliary is a containment water cooling circuit (containment pool cooling). Advantages are:

- high heat removal efficiency due to boiling over core debris (steam circuit);
- corium stabilization outside the reactor pressure vessel (RPV)
- containment pressure decrease to nearly atmospheric values;
- containment water temperature decrease less than 100 ºC (water circuit);
- functional independence from DBA equipment;
- long-term radioactive water retention within the containment;
- system components maintenance availability;

Implementation of LTCCS resolves the above-mentioned safety issues. Currently, ES Group and WEC are jointly implementing the LTCCS at Rivne NPP Units 1,2 with VVER-440 reactors, and a separate LTCCS concept is being developed for NPP with VVER-1000 (LTCCS-1000).



General Diagram of the LTCCS-1000

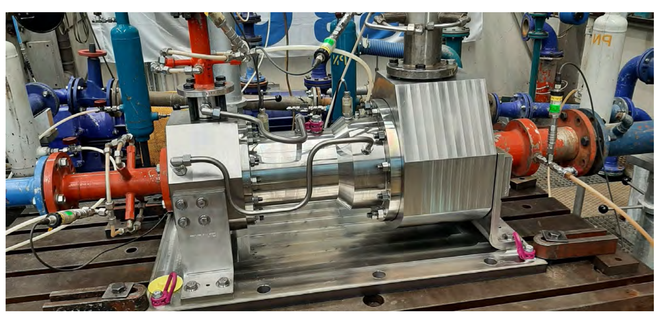
LTCCS-1000 concept accounts for :

- removal of non-condensable (NC) gases (to support condensation) including hydrogen;
- integration with the CFVS;
- dry reactor cavity prior RPV failure (prevent steam explosions);
- heat removal both from the corium and the spent fuel pool (SFP);
- long-term containment floor water cooling;
- reducing the adverse effects of corium on the base slab.

Design and Operation of the LTCCS-1000

The LTCCS-1000 consists of two containment circuits (steam and water) and cooling water loop. The water circuit operates using a pump unit driven by a hydraulic turbine. The condenser, turbine-driven (RTS) pump and heat exchanger are located outside the containment in the reactor building.

The turbine-driven pump for LTCCS-1000 is similar to the implemented one for LTCCS at Rivne NPP with VVER-440 reactors.



Turbine-driven pump

LTCCS Operation for VVER-1000 (Ex-vessel Phase)

Functioning of “contaminated” containment circuits:

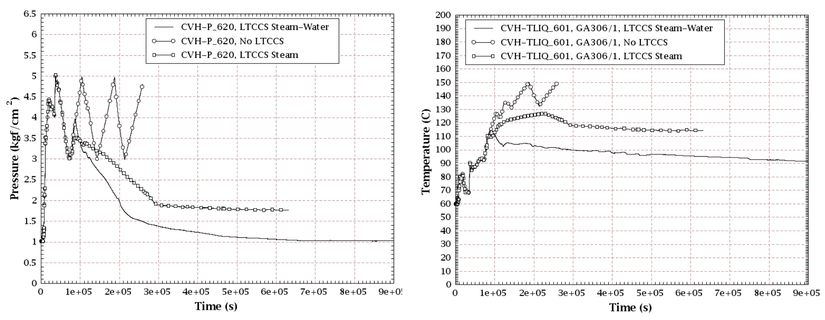
- corium spreading on the containment floor;
- corium is flooded with cooling water (some water added);
- boiling over core debris produces steam and increases containment pressure;
- steam condenses in condenser (steam circuit);
- NCs are vented after condenser through CFVS;
- condensate is drained/pumped back to containment;
- containment water is cooled via heat exchanger by turbine-driven pump (water circuit);

Functioning of “clean” circuit (external cooling circuit/circuits):

- mobile water source unit;
- first supplies water to condenser cooling;
- secondly supplies water to heat exchanger and RTS pump;
- hot water discharges to environment;
- cooling circuit can be split in two separate ones.

Example analysis for unit blackout with SAM actions:

- LTCCS total capacity matches decay heat after 3–5 days;
- radioactivity release is decreased;
- LTCCS condensation capacity initially is controlled by NC venting after condenser (to CFVS scrubber);
- LTCCS operation fully resolves late containment hydrogen problem.



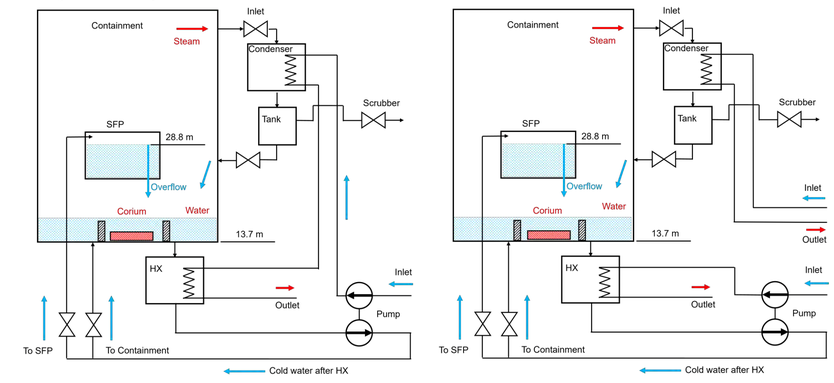
a) **b)**

Containment pressure (a) and containment water temperature (b) for cases with LTCCS water-steam circuits operation, without LTCCS and with LTCCS steam circuit only operation

LTCCS Specific Design

LTCCS specific design is under development by considering:

- external cooling circuits amount (see fig. below);
- coolable corium spreading issues;
- condenser aerosol load;
- number of turbine-driven pumps and water heat exchangers;
- SFP cooling line;
- long-term water balance in containment;
- system specifications and initiation criteria.



a) **b)**

Some LTCCS concept design schemes with common external cooling circuit (a) and two separate external circuits (b)

Conclusions for LTCCS-1000

- long-term cooling and prevention of containment failure;
- radioactive water storage inside containment;
- late post-accident hydrogen problem resolved;
- SFP cooling resolved;
- open-ready containment conditions after LTCCS operation;
- no need for additional storage tanks for radioactive water;
- independence of LTCCS from other plant systems.

ENERGY SAFETY GROUP

Introduction

To minimize the consequences of a severe accident (SA) with core damage, the In-Vessel Melt Retention (IVMR) system has been implemented at power units 1 and 2 of the Rivne Nuclear Power Plant (RNPP) with VVER-440/V-213 reactors. This system is designed to retain the melt within the reactor pressure vessel (RPV) and prevent progression of a SA to the ex-vessel phase by creating a closed natural circulation loop for external RPV cooling.

During operation of the IVMR system at RNPP power units 1&2, the pressure and temperature limits in the containment are not exceeded for 72 hours. However, the containment pressure and temperature continue to rise steadily due to the lack of heat removal from the containment. This inevitably results in further violation of containment design limits after 72 hours.

To prevent containment parameters from exceeding their design limits, the Long-Term Containment Cooling System (LTCCS) is used to ensure adequate heat removal from the containment.

The primary objective of the LTCCS is to maintain the containment integrity and ensure the reliable and efficient operation of the IVMR system.

ES Group and Westinghouse jointly developed and delivered this innovative system to improve the safety of the Ukrainian VVER-440 units during severe accidents and the long-term post-accident period.

The LTCCS is a supplementary system designed to enhance the safety of RNPP power units 1&2 under accident conditions. During normal operation, the LTCCS is in standby mode.

Requirements

The LTCCS belongs to safety systems, classified as a whole as Safety Class 2L (confinement-related system) and Seismic Category I.

Design functions of the LTCCS:

- maintain containment temperature and pressure over a long period of time (up to 6 months), ensuring that these parameters remain below their maximum design limits of 127 °C and 2.5 kgf/cm² (abs);
- provide removal of the decay heat (capacity not less than 4 MW) from the containment over a long period of time;
- maintain containment integrity and minimize the release of radioactive products outside the containment by reducing the parameters in the accident localization area (ALA);
- ensure the reliable and efficient operation of the IVMR system.

Design requirements to the LTCCS:

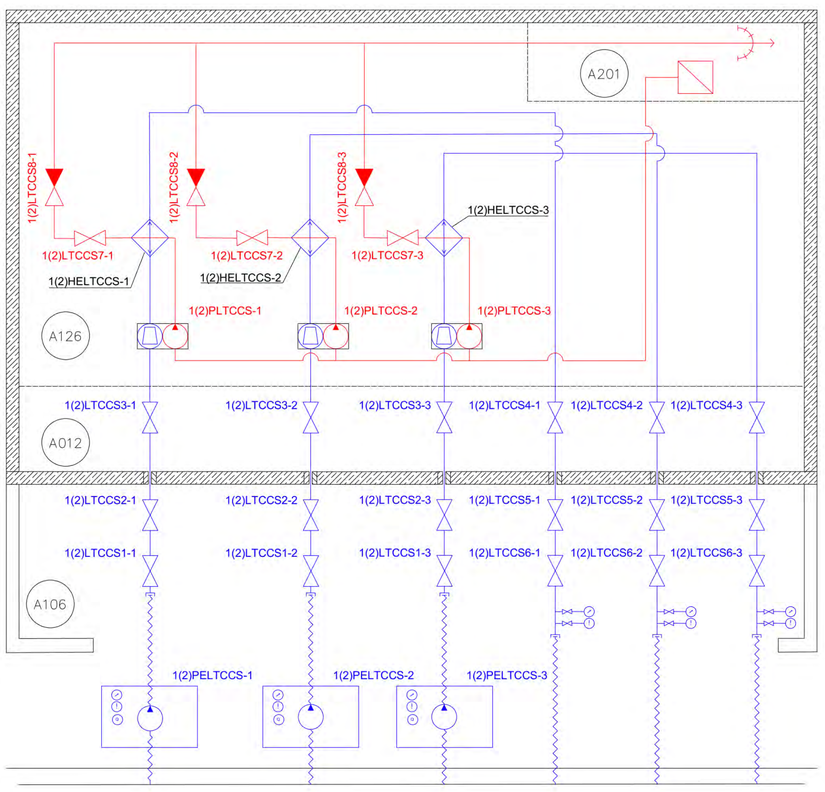
- operation of the LTCCS for 6 months (short-term stops are allowed, but they should not affect the design functions);
- operating pressure of the LTCCS secondary circuit must be higher than the operating pressure in both the primary circuit and the containment to prevent the leakage of radioactive products outside the ALA.

Layout

The LTCCS consists of two loops/circuits:

- primary circuit – contaminated. The primary circuit components are in the containment rooms. The working medium of the primary circuit is a radioactive coolant (boron solution) accumulated in containment rooms during accidents;
- secondary circuit – “clean” (non-contaminated). The secondary circuit components are in the containment rooms, reactor building and industrial site of the RNPP. The working medium (water) is not contaminated.

The LTCCS consists of three channels that have the same number of components. Common to all three channels are the Additional Spray Circuit and the water intake point in the containment.



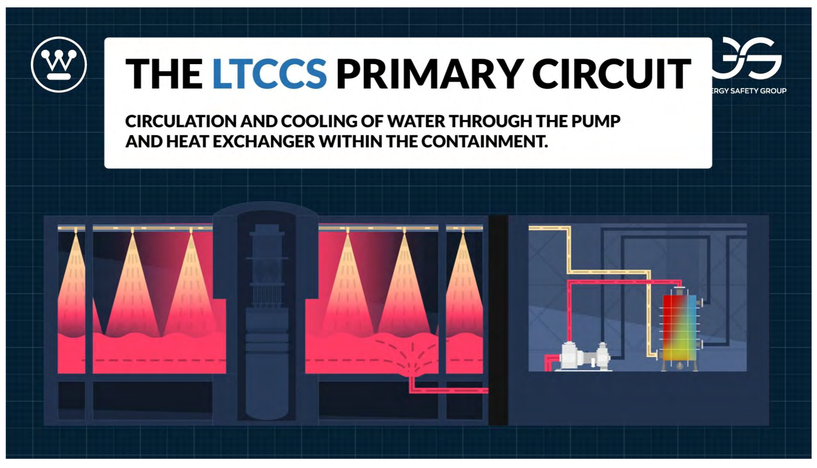
Process Flow Diagram of the LTCCS for Units No. 1,2 of RNPP

Short description of the LTCCS

The primary circuit coolant is pumped from the containment by a dynamic pump unit with a hydraulic drive turbine - Reactor-Turbine-Sump-Pump (RTS pump), cooled down in heat exchangers and then sprayed through the nozzles of the Additional Spray Circuit to reduce both pressure and temperature inside the containment.

The primary circuit of the LTCCS comprises the pump part of the RTS pumps 1(2)PLTCCS-1(2,3), heat exchangers 1(2)HELTCCS-1(2,3) (coolant side), shut-off valves 1(2)LTCCS7-1(2,3) and check valves 1(2)LTCCS8-1(2,3).

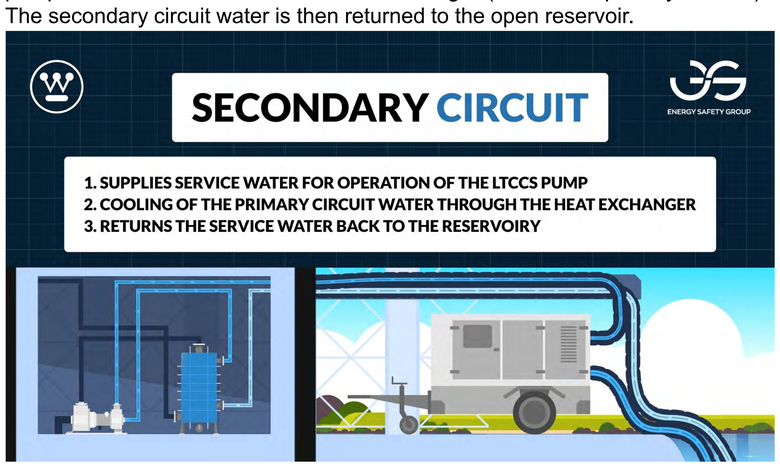
The primary circuit with contaminated water is located only in the containment. The active element of the primary circuit is the RTS pump. The RTS pump is actuated by the water flow supplied to the turbine



Primary circuit of the LTCCS

The secondary circuit of the LTCCS comprises the intermediate pump units 1(2)PELTCCS-1(2,3), flexible hoses, hermetic penetrations, localizing valves 1(2)LTCCS1,2,3,4,5,6-1(2,3), turbine part of the RTS pumps 1(2)PLTCCS-1(2,3), heat exchangers 1(2)HELTCCS-1(2,3) (cooling water side).

The secondary circuit is designed to ensure the proper functioning of the primary circuit. Service water is drawn from an open reservoir located near the power unit by an external pump station, supplied to the turbine of the RTS pump and further directed to the heat exchanger (to cool the primary coolant). The secondary circuit water is then returned to the open reservoir.

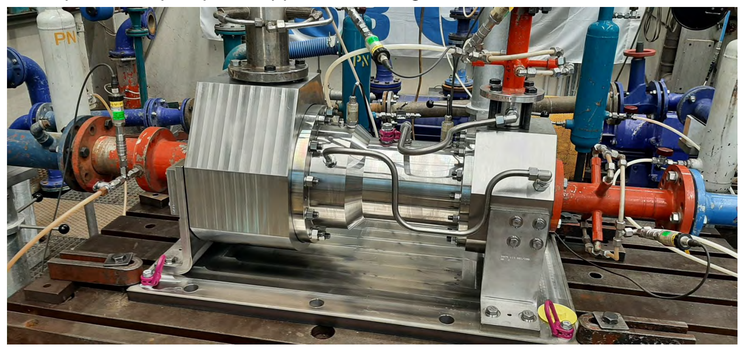


Secondary circuit of the LTCCS

The RTS pump, manufactured by KSB SE & Co. KGaA, is the heart of the LTCCS, which circulates radioactive coolant inside the containment.

The RTS pump consists of a pump and turbine parts, with the turbine and pump impellers connected by a common shaft. Water flow rotates the turbine, which drives the pump part.

The pump section is part of the LTCCS primary circuit, while the turbine section is part of the secondary circuit. A mechanical seal separates the turbine and pump parts of the RTS pump to prevent contaminated water from entering the turbine part if the pump is stopped or running.



RTS Pump

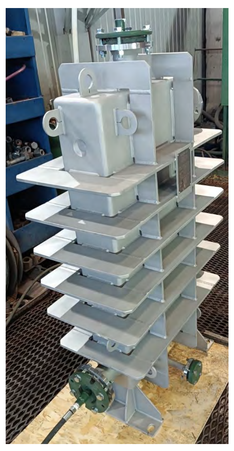
External pump units (mobile pump stations) located outside the power unit near an open reservoir are used to supply water to the secondary circuit of the LTCCS. Water is supplied to and returned from the system through flexible hoses.

The external pump units can be taken out of service on a train-by-train basis for scheduled maintenance and refueling while the LTCCS is in operation, thereby ensuring continuous operation of the system. It is sufficient to operate two out of three LTCCS channels to maintain containment parameters within acceptable limits after 3 days.

Cooling of the LTCCS primary circuit is performed using a plate heat exchanger with a welded housing.

The advantages of this solution are relatively small dimensions of the equipment with a sufficient heat exchange surface. This allows new equipment to be installed in the limited space available inside the containment and transported to the installation site.

A heat capacity of 2.2 MW per train has been selected to maintain an operational efficiency margin of the heat exchanger in the event of internal surface contamination over a period of 6 months.



Environmental conditions in containment

№	Parameter Name	Value
1	Pressure, kgf/cm²	2,5
2	Temperature, ºC	127
3	Medium	steam-water mixture

Working medium

№	Parameter Name	Value
	Primary circuit	
1	Medium	boric acid solution 16-20 g/l
2	Temperature, ºC	up to 127
	Secondary circuit	
3	Medium	service water
4	Temperature, ºC	5÷45

Main technical parameters of components

№	Parameter Name	Value
	RTS pump (3 units included in LTCCS)	
1	Pump part (primary circuit)	
1.1	Drive type	hydraulic (from turbine part)
1.2	Nominal head, m	20
1.3	Nominal flow rate, m³/h	67
2	Turbine part (secondary circuit)	
2.1	Nominal head, m	68
2.2	Nominal flow rate, m³/h	57
	Heat exchangers (3 units included in LTCCS)	
1	Heat capacity, MW	2,2
2	Coolant temperature (primary circuit), °C	127
3	Cooling water temperature (secondary circuit), °C	45
	Intermediate pump units (3 units included in LTCCS)	
1	Nominal head, m	140
2	Nominal flow rate, m³/h	57
	Nozzles (8 pieces included in LTCCS)	
1	Spray angle, °	120
2	Total flow rate through the nozzle group, m³/h	201
3	Maximum flow rate through the nozzle, l/min	630

Analytical justifications of the LTCCS

The analytical justification of the thermal-hydraulic behavior of the LTCCS, reactor, and containment was performed using the MELCOR and RELAP calculation codes.

Acceptance criteria for the LTCCS operation applied in the justification analysis:

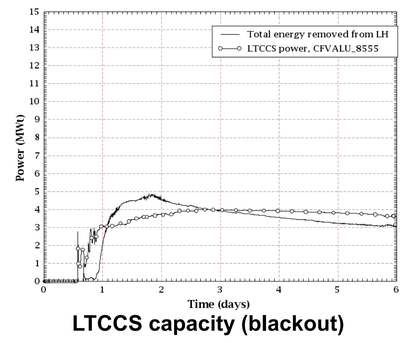
- Containment pressure during accident progression is less than the design limit of 2.5 kgf/cm² (abs.);
- Minimum water level in the SG boxes is at least 6.85 m;
- Ratio of gas mixture components in the containment on the Shapiro-Moffett diagram does not enter the detonation region;
- In case of a spontaneous hydrogen combustion, containment pressure is less than 2.5 kgf/cm² (abs.);
- Containment pressure is reduced to less than 1.1 kgf/cm² (abs.) and is maintained consistently below this value (strong criterion);
- Containment pressure is steadily decreasing (weak criterion);
- Containment water temperature in the SG boxes (corridors to the IVMR suction) is reduced below 90ºC and maintained consistently below this value (strong criterion);
- Containment water temperature in the SG boxes (corridors to the IVMR suction) is steadily decreasing (weak criterion).

Results of the Analytical justification

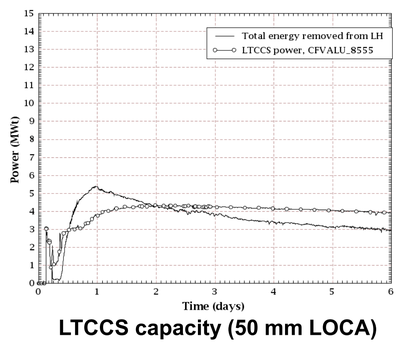
The LTCCS (3 channels) heat removal capacity for a maximum cooling water temperature of 45°C and a nominal flow rate of 67 m3/h matches the decay heat in 3-6 days at containment water temperatures in the range of 95 °C÷110 °C.

Cooling water with 25 °C temperature after 3 days can equalize the LTCCS capacity to the decay heat at a containment water temperature of 95 °C, and for 6 days at the temperature of 80 °C. Stable operation of three LTCCS channels reduces the pressure in the containment to atmospheric level.

With two LTCCS channels in operation, the containment parameters may begin to decrease after 6-8 days. Lower cooling water temperatures would help this happen earlier. In this case the containment pressure increases maximally to 1.4÷1.5 kgf/cm² that is less than the design limit. Therefore, operation of the LTCCS with two channels is also successful but needs a longer stabilization time.



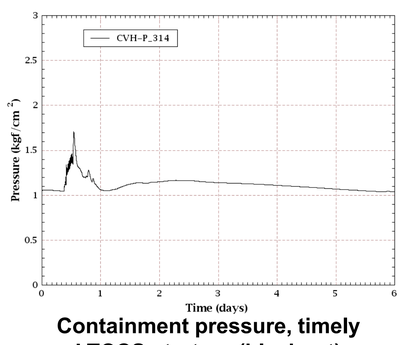
LTCCS capacity (blackout)



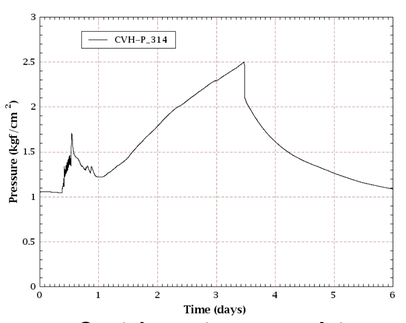
LTCCS capacity (50 mm LOCA)

In all calculated accident sequences with a timely start-up of the IVMR system and simultaneous operation of the LTCCS, the criterion of a maximum containment pressure less than 2.5 kgf/cm² (abs) is met. After the IVMR and LTCCS systems start, the containment pressure decreases and later temporarily rises to 1.2÷1.4 kgf/cm² (abs) before the final decrease.

A late LTCCS start-up with high containment pressure is followed by a more rapid decrease in containment parameters and a successful reduction of pressure to less than 1.1 kgf/cm² (abs).

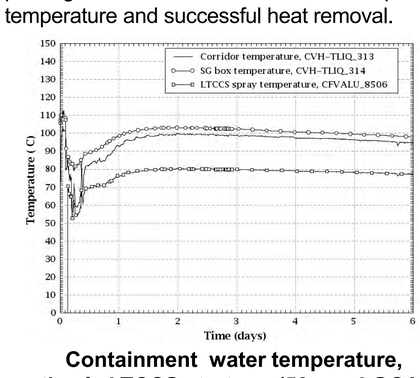


Containment pressure, timely LTCCS start-up (blackout)

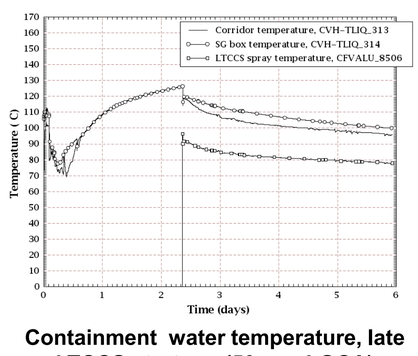


Containment pressure, late LTCCS start-up (blackout)

The containment water temperature follows the containment pressure behavior. After the IVMR and LTCCS timely start-up and the initial temperature decrease, it rises temporarily to 96÷101 °C. Water temperatures are slightly higher for the primary circuit breaks of any size. Afterwards, the water temperature decreases continuously that might be significantly prolonged in time. A late LTCCS start-up is followed by a more rapid decrease in water temperature and successful heat removal.



Containment water temperature, timely LTCCS start-up, (50 mm LOCA)



Containment water temperature, late LTCCS start-up, (50 mm LOCA)

Hydrogen safety

Operation of the LTCCS causes condensation of water vapor inside the containment and a corresponding increase in the fraction of non-condensable gases (including hydrogen). To ensure hydrogen safety during the LTCCS operation, an optimal reconfiguration of the existing passive autocatalytic recombiners (PAR) was determined through iterative calculations. A modified layout of installed PARs was proposed, and installation locations for four additional PAR modules of NIS-PAR-44KKH type, supplied as part of the LTCCS delivery set, were specified.

As a result, conditions for hydrogen detonation during the LTCCS operation are avoided inside the containment. The long-term hydrogen safety is improved in the spray tower. Localized hydrogen combustion associated with vapor condensation is temporarily and may occur only in areas where PARs installation is impossible. The containment pressure in case of hydrogen combustion at any time during the accident progression is estimated to be less than the design limit of 2.5 kgf/cm² (abs).

Conclusions of the LTCCS Analytical Justification

1. The LTCCS significantly expands the capabilities and reliability of stabilizing and bringing the containment and reactor to a safe state during severe accidents.

2. The three-channel LTCCS design makes it possible to reduce the containment pressure and temperature along with the IVMR system operation. The LTCCS heat removal capacity in realistic cases can be equal to residual core power in 3 days.

3. With two of the three LTCCS channels in operation, the conservative analysis indicates that the containment pressure and temperature begin to decrease after 6-8 days. Lower cooling water temperatures shift this effect to earlier times. No violation of the containment pressure limit is expected for any configuration.

4. All LTCCS acceptance criteria selected for the justification analysis are met.

5. The release of activity to the environment is reduced compared to cases without the LTCCS operation due to lower containment pressure and removal of aerosols by the LTCCS sprays.

IMPLEMENTATION AND ANALYTICAL JUSTIFICATION OF LONG-TERM CONTAINMENT COOLING SYSTEM WITH ADDITIONAL SPRAY CIRCUIT, HEAT EXCHANGERS, AND TURBINE-DRIVEN PUMPS FOR NPPS WITH VVER-440 REACTORS

Ivanov Vadym, Mazurok Oleksandr (Ph.D.), Vorobyov Yuriy, Tiurin Artem, Mykhailenko Oleksandr, Energy Safety Group (ES Group)
Kostov Emil (Ph.D.), Pérez-Salado Kamps Álvaro, Hartmann Christoph (Ph.D.), Troselius Hans, Westinghouse Electric Company (WEC)

Introduction

To minimize the consequences of a severe accident (SA) with core damage, the In-Vessel Melt Retention (IVMR) system has been implemented at power units 1&2 of the Rivne Nuclear Power Plant (RNPP) with VVER-440/V-213 reactors. This system is designed to retain the melt within the reactor pressure vessel (RPV) and prevent progression of a SA to the ex-vessel phase by creating a closed natural circulation loop for external RPV cooling.

During operation of the IVMR system at RNPP power units 1&2, the pressure and temperature limits in the containment are not exceeded for 72 hours. However, the containment pressure and temperature continue to rise steadily due to the lack of heat removal from the containment. This inevitably results in further violation of containment design limits after 72 hours.

To prevent containment parameters from exceeding their design limits, the Long-Term Containment Cooling System (LTCCS) is used to ensure adequate heat removal from the containment.

The primary objective of the LTCCS is to maintain the containment integrity and ensure the reliable and efficient operation of the IVMR system. ES Group and WEC jointly developed and delivered this innovative system to improve the safety of the Ukrainian VVER-440 units during severe accidents and the long-term post-accident period.

The LTCCS is a supplementary system designed to enhance the safety of RNPP power units 1&2 under accident conditions. During normal operation, the LTCCS is in standby mode.

Requirements

Design functions of the LTCCS:

- maintain containment temperature and pressure over a long period of time (up to 6 months), ensuring that these parameters remain below their maximum design limits of 127 ºC and 2.5 kgf/cm² (abs);
- provide removal of the decay heat (capacity not less than 4 MW) from the containment over a long period of time;
- maintain containment integrity and minimize the release of radioactive products outside the containment by reducing the parameters in the accident localization area (ALA);
- ensure the reliable and efficient operation of the IVMR system.

Design requirements to the LTCCS:

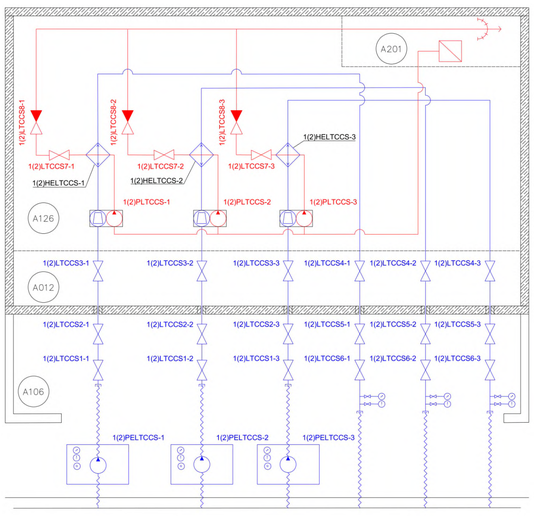
- operation of the LTCCS for 6 months (short-term stops are allowed, but they should not affect the design functions);
- operating pressure of the LTCCS secondary circuit must be higher than the operating pressure in both the primary circuit and the containment to prevent the leakage of radioactive products outside the ALA.

Layout

The LTCCS consists of two loops/circuits:

- primary circuit – contaminated. The primary circuit components are in the containment rooms. The working medium of the primary circuit is a radioactive coolant (boron solution) accumulated in containment rooms during accidents;
- secondary circuit – “clean” (non-contaminated). The secondary circuit components are in the containment rooms, reactor building and industrial site of the RNPP. The working medium (water) is not contaminated.

The LTCCS consists of three channels that have the same number of components. Common to all three channels are the Additional Spray Circuit and the water intake point in the containment.



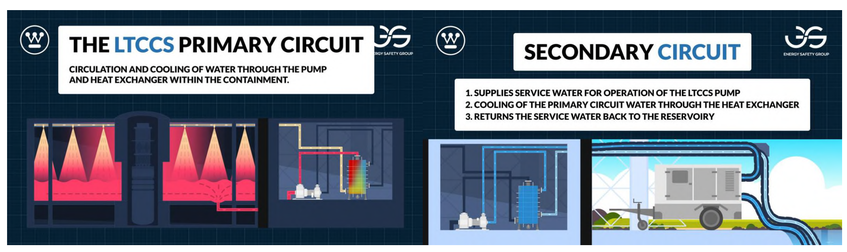
Process Flow Diagram of the LTCCS for RNPP-1,2

Short description of the LTCCS

The primary circuit coolant is pumped from the containment by a dynamic pump unit with a hydraulic drive turbine - Reactor-Turbine-Sump-Pump (RTS pump), cooled down in heat exchangers and then sprayed through the nozzles of the Additional Spray Circuit to reduce both pressure and temperature inside the containment.

The primary circuit of the LTCCS comprises the pump part of the RTS pumps, heat exchangers (coolant side), shut-off and check valves.

The primary circuit with contaminated water is located only in the containment. The active element of the primary circuit is the RTS pumps. The RTS pump is actuated by the water flow supplied to the turbine.

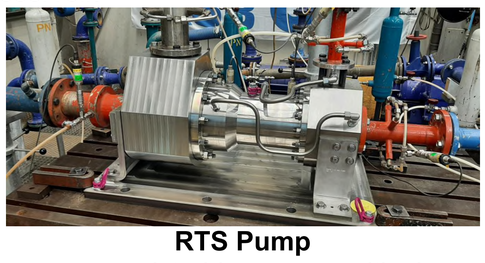


Primary circuit of the LTCCS **Secondary circuit of the LTCCS**

The secondary circuit of the LTCCS comprises the intermediate pump units, flexible hoses, hermetic penetrations, localizing valves, turbine part of the RTS pumps, heat exchangers (cooling water side).

The secondary circuit is designed to ensure the proper functioning of the primary circuit. Service water is drawn from an open reservoir located near the power unit by an external pump station, supplied to the turbine of the RTS pump and further directed to the heat exchanger (to cool the primary coolant). The secondary circuit water is then returned to the open reservoir.

The RTS pump, manufactured by KSB SE & Co. KGaA, is the heart of the LTCCS, which circulates radioactive coolant inside the containment.



RTS Pump

The RTS pump consists of a pump and turbine parts, with the turbine and pump impellers connected by a common shaft. Water flow rotates the turbine, which drives the pump part.

The pump section is part of the LTCCS primary circuit, while the turbine section is part of the secondary circuit. A mechanical seal separates the turbine and pump parts of the RTS pump to prevent contaminated water from entering the turbine part if the pump is stopped or running.

Environmental conditions in containment

№	Parameter Name	Value
1	Pressure, kgf/cm²	2,5
2	Temperature, ºC	127
3	Medium	steam-water mixture

Working medium

№	Parameter Name	Value
	Primary circuit	
1	Medium	boric acid solution 16-20 g/l
2	Temperature, ºC	up to 127
	Secondary circuit	
3	Medium	service water
4	Temperature, ºC	5÷45

Main technical parameters of components

№	Parameter Name	Value
	RTS pump (3 units included in LTCCS)	
1	Pump part (primary circuit)	
1.1	Drive type	hydraulic (from turbine part)
1.2	Nominal head, m	20
1.3	Nominal flow rate, m³/h	67
2	Turbine part (secondary circuit)	
2.1	Nominal head, m	68
2.2	Nominal flow rate, m³/h	57
	Heat exchangers (3 units included in LTCCS)	
1	Heat capacity, MW	2,2
2	Coolant temperature (primary circuit), °C	127
3	Cooling water temperature (secondary circuit), °C	45
	Intermediate pump units (3 units included in LTCCS)	
1	Nominal head, m	140
2	Nominal flow rate, m³/h	57
	Nozzles (8 pieces included in LTCCS)	
1	Spray angle, °	120
2	Total flow rate through the nozzle group, m³/h	201
3	Maximum flow rate through the nozzle, l/min	630

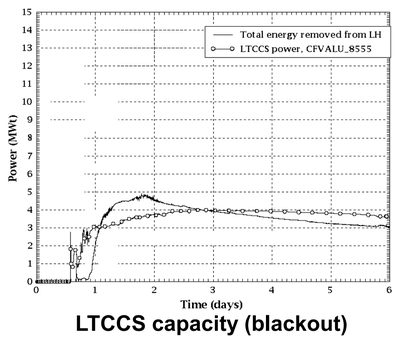
Results of the Analytical justification of the LTCCS

The analytical justification of the thermal-hydraulic behavior of the LTCCS, reactor, and containment was performed using the MELCOR and RELAP calculation codes.

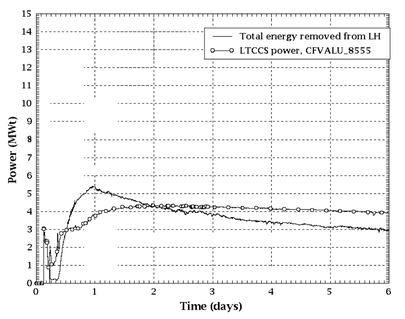
The LTCCS (3 channels) heat removal capacity for a maximum cooling water temperature of 45 ºC and a nominal flow rate of 67 m³/h matches the decay heat in 3-6 days at containment water temperatures in the range of 95 ÷ 110 ºC.

Stable operation of three LTCCS channels reduces the pressure in the containment to atmospheric level.

Cooling water with 25 ºC temperature after 3 days can equalize the LTCCS capacity to the decay heat at a containment water temperature of 95 ºC, and for 6 days at the temperature of 80 ºC. With two LTCCS channels in operation, the containment parameters may begin to decrease after 6-8 days. Lower cooling water temperatures would help this happen earlier. In this case the containment pressure increases maximally to 1.4÷1.5 kgf/cm² that is less than the design limit. Therefore, operation of the LTCCS with two channels is also successful but needs a longer stabilization time.



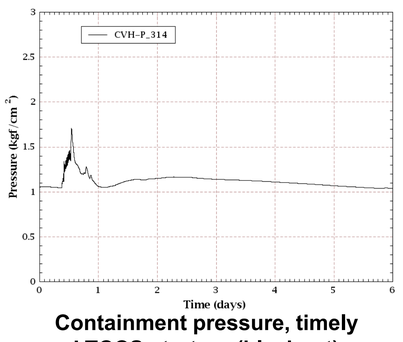
LTCCS capacity (blackout)



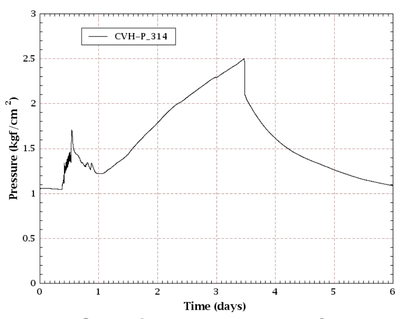
LTCCS capacity (50 mm LOCA)

In all calculated accident sequences with a timely start-up of the IVMR system and simultaneous operation of the LTCCS, the criterion of a maximum containment pressure less than 2.5 kgf/cm² (abs) is met. After the IVMR and LTCCS systems start, the containment pressure decreases and later temporarily rises to 1.2÷1.4 kgf/cm² (abs) before the final decrease.

A late LTCCS start-up with high containment pressure is followed by a more rapid decrease in containment parameters and a successful reduction of pressure to less than 1.1 kgf/cm² (abs).

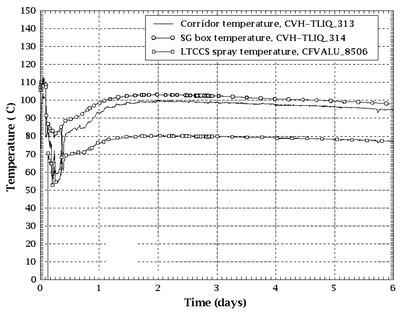


Containment pressure, timely LTCCS start-up (blackout)

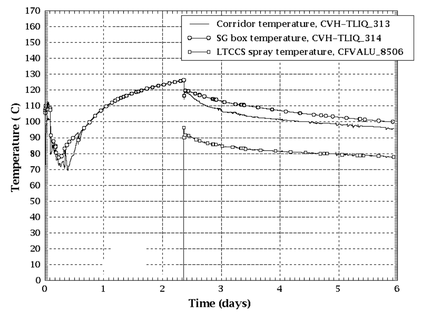


Containment pressure, late LTCCS start-up (blackout)

The containment water temperature follows the containment pressure behavior. After the IVMR and LTCCS timely start-up and the initial temperature decrease, it rises temporarily to 96÷101 ºC. Water temperatures are slightly higher for the primary circuit breaks of any size. Afterwards, the water temperature decreases continuously that might be significantly prolonged in time. A late LTCCS start-up is followed by a more rapid decrease in water temperature and successful heat removal.



Containment water temperature, timely LTCCS start-up (50 mm LOCA)



Containment water temperature, late LTCCS start-up, (50 mm LOCA)

Conditions for hydrogen detonation during the LTCCS operation are avoided inside the containment. The long-term hydrogen safety is improved in the spray tower. Localized hydrogen combustion associated with vapor condensation is temporarily and may occur only in areas where PARs installation is impossible. The containment pressure in case of hydrogen combustion at any time during the accident progression is estimated to be less than the design limit of 2.5 kgf/cm² (abs).

Conclusions of the LTCCS Analytical Justification

1. The LTCCS significantly expands the capabilities and reliability of stabilizing and bringing the containment and reactor to a safe state during severe accidents.
2. The three-channel LTCCS design makes it possible to reduce the containment pressure and temperature along with the IVMR system operation.
3. With two of the three LTCCS channels in operation, the conservative analysis indicates that the containment pressure and temperature begin to decrease after 6-8 days. No violation of the containment pressure limit is expected for any configuration.
4. All LTCCS acceptance criteria selected for the justification analysis are met.
5. The release of activity to the environment is reduced compared to cases without the LTCCS operation due to lower containment pressure and removal of aerosols by the LTCCS sprays.

Motivation

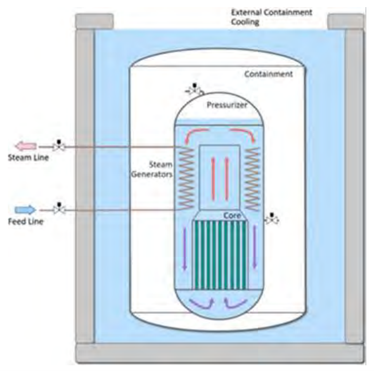
- 'Safety Analysis of SMR with PAssive Mitigation strategies - Severe Accidents' (SASPAM-SA) project (2022-2026), coordinated by ENEA (F. Mascari) - 23 partners from 13 European countries
  - assessing the applicability of knowledge gained from large Light Water Reactors (LWRs) to iPWRs, supporting licensing and siting activities and contributing to a European, independent perspective on iPWR safety for DiD levels 4 and 5

WP2 (SCENARIO): Objectives

- **Evaluating the capabilities of state-of-art European and non-European integral SA codes and Computational Fluid Dynamics (CFD) tools to simulate the key phenomena occurring in generic iPWR designs**
- Methodology:
  - iPWR Design-1 and Design-2 database (generic designs, decay heat) based on open-literature
  - Assessment of generic, but representative, SA and CFD codes' datasets
  - Postulating Design Basis Accident (DBA) and SA sequences
  - Analysis the postulated DBA and SA scenarios
  - No PSA assessments employed in postulating the scenarios (generic designs)
  - Codes' datasets shared among the partners upon request

The generic iPWR Design-1 and Design-2

iPWR Design-1 (P~60 MWe)
Submerged containment



iPWR Design-2 (P~300 MWe)
Dry containment, several passive systems

Three-Dimensional Numerical Prediction of Natural Convection in Corium Pools Using Advanced RANS Turbulence Models

Alsalman Shahad (1), Alasif Abdullah (2), Siddiqui Osman, Shams Afaque

(1) King Fahad University of Petroleum and Minerals (KFUPM), (2) King Fahd University of Petroleum & Minerals (KFUPM)

Type of abstract: Poster
Subject area: In-vessel corium and debris coolability
Keywords: Severe accidents, corium pool, CFD, turbulence modeling, RANS

In the event of a severe nuclear accident, the reactor core is subjected to extreme thermal conditions leading to melting of the structural elements. This molten material is called corium and its accumulation at the lower plenum of the reactor pressure vessel (RPV) is often referred to as the corium pool. This corium pool continues to generate energy due to radioactive material, while the heat is rejected through the walls of the lower plenum and resulting in a strong natural convection regime at a very high Rayleigh number (Ra). In-vessel melt retention is one of the key accident management strategies, and a thorough understanding of this high Ra number natural convection within the corium pool is essential for studying the integrity of the RPV.

However, a proper understanding of such a high Ra flow regime in the corium pool is extremely challenging for an off-the-shelf Reynolds Averaged Navier Stokes (RANS) based Computational Fluid Dynamics (CFD) approach. Therefore, a thorough investigation of these RANS based modelling approaches must be performed to assess their prediction capabilities. In this study, a wide range of RANS turbulence models are tested and validated against an available reference database. Two commonly used commercial software are selected to perform this validation study, i.e. Simcenter STAR-CCM+ and Ansys Fluent. The study has shown that off-the-shelf RANS models are not capable of accurately predicting the strong buoyancy forces that appear at very high Ra flows. Hence, a much more sophisticated modeling of turbulent heat flux is needed which should take into account the complex flow behaviour exhibited in the corium pool. In a nutshell, the validation efforts performed in this research work establish a foundation to study and investigate severe accident scenarios and support the development of reliable strategies for in-vessel melt retention and nuclear safety in general.

Recalescence Behavior of Molten Refractory Oxides during Fast Cooling by Aerodynamic Levitation

Gong Yaopeng (1)

Type of abstract: Poster
Subject area: Other applications (fusion reactors, interim SNF storage, Accident Tolerant Fuels (ATFs), etc
Keywords: recalescence behavior□refractory oxides□aerodynamic levitation□fast cooling□melting point

During the rapid cooling process of molten crystals, when the temperature drops to a deeply undercooled state, the material's temperature quickly rises back to near the melting point in a short time due to the release of latent heat during the solidification process, accompanied by a luminescence phenomenon. This is a possible method for measuring the melting point of refractory materials. Based on the containerless installation ALSEE(Aerodynamic Levitation-laSer heating installation for mElt propErties), recalescence behavior of Al2O3, ZrO2 and Y2O3 were described in the study and a discussion on different recalescence temperatures under various gas environments was conducted. Besides, phase transformation analysis of the cooling process was performed through thermo-dynamic calculation, so as to compare with the approximate melting point obtained from the experiment. This work lays the foundation for the performance verification of refractory materials used in nuclear power industry

Recalescence behavior of molten refractory oxides during fast cooling by aerodynamic levitation

Yaopeng GONG, Li ZHANG, Zhiqiang DONG, Yidan YUAN*
Email: gongyp@cnpe.cc, yidanyuan2010@aliyun.com
CNNC Key Laboratory for Severe Accident Research in Nuclear Power Safety, China Nuclear Power Engineering Co., Ltd., Beijing, China

Introduction

During the rapid cooling of a high-temperature liquid drop, the temperature of the drop falls into an undercooling region. Thereafter, the temperature increases rapidly back to the melting temperature due to the nucleation and release of heat of fusion. This phenomenon is referred to as recalescence. Density [1] and isobaric heat capacity [2] can be measured during the process of cooling, while melting temperature and heat of fusion [3] can be measured according to the recalescence behavior. This study presents the melting temperature and heat of fusion measurements of molten refractory oxides using aerodynamic levitation, a non-contact technique for property measurements. This method can be applied to the measurements of corium components, thereby enriching the experimental thermodynamic data of corium and facilitating the accurate prediction of corium behavior under severe accident scenarios [4].

Experimental Setup

The experimental setup, called ALSEE (Aerodynamic Levitation-laSEr hEating installation for melt properties), is developed at China Nuclear Power Engineering Co., Ltd. for the precise thermophysical and thermodynamic property measurements of corium (see Figure 1). Aerodynamic levitation was achieved by a conical converging-diverging nozzle, enabling the levitation of a spherical sample in the diameter range of 2 to 3 mm. Argon gas was chosen as the levitating gas due to its inert nature. Sample heating was performed using two CO_2 laser devices. Temperature of the sample was measured by a 2-color pyrometer with the uncertainty of 0.5%. Sample behavior was observed using a high-speed camera.

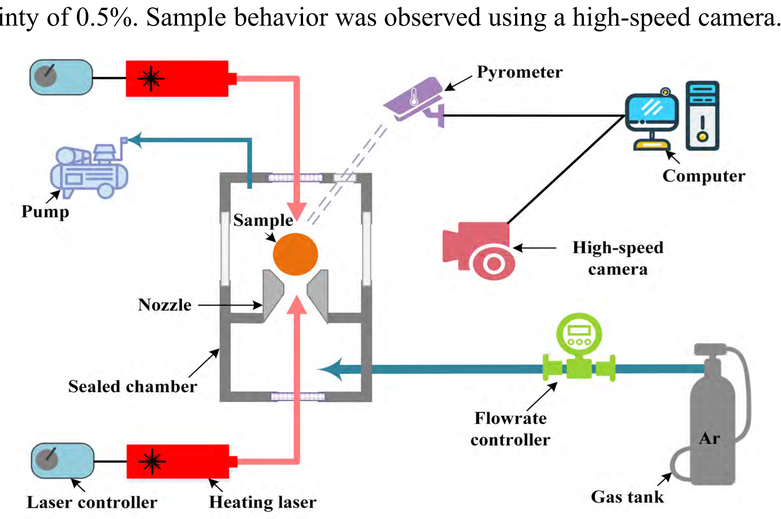

Figure 1. Schematic view of ALSEE facility

Melting Temperature Measurement

The temperature during rapid cooling is shown in Figure 2. A 2-color pyrometer operates by evaluating the ratio of the spectral radiant brightness of the target object at two selected wavelengths which is independent of the object emissivity. An increase in image brightness corresponds to a rapid rise in sample temperature during nucleation. The recalescence temperature is considered to be the melting temperature. As shown in Figure 2, the measured melting temperature of 2323.95K for Al_2O_3 is in good agreement with the reference value of 2327K [5], with the error of 3.05K less than the measurement uncertainty(0.5%). Therefore, it is convincing to measure melting point based on the recalescence phenomenon for oxides.

Figure 3 shows the result of ZrO_2 and a Fe_2O_3-CaO mixture. The melting temperature of 2973.6K for ZrO_2 is also close to the reference value of 2988K [1]. The melting temperature of Fe_2O_3-CaO is 1633K, which is in good agreement with the thermodynamic calculation(TC) results using Thermo-Calc 2023a software with the OXDEMO database.

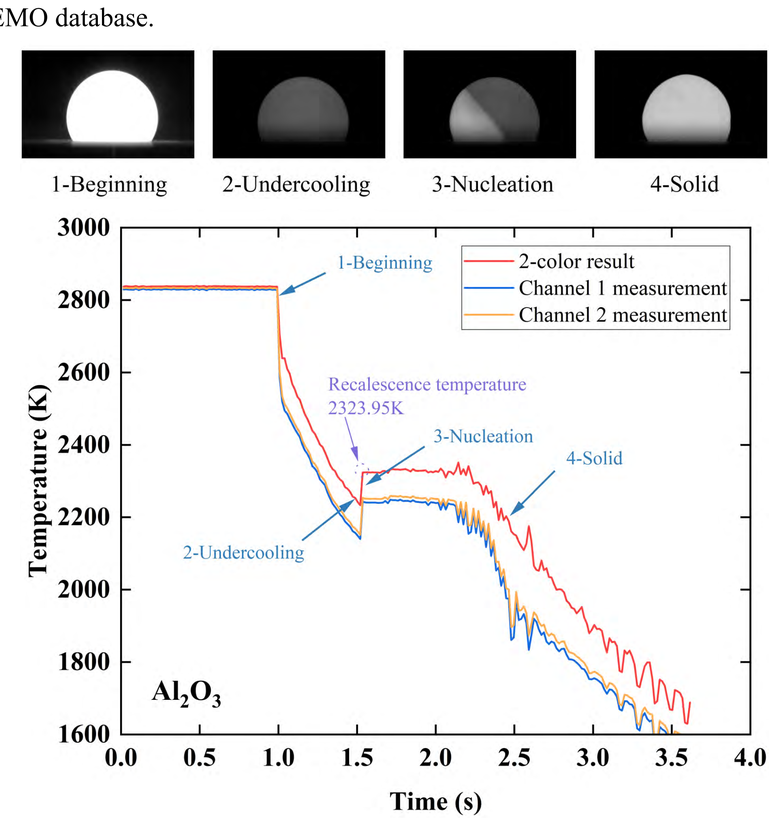

Figure 2. Recalescence behavior of Al_2O_3

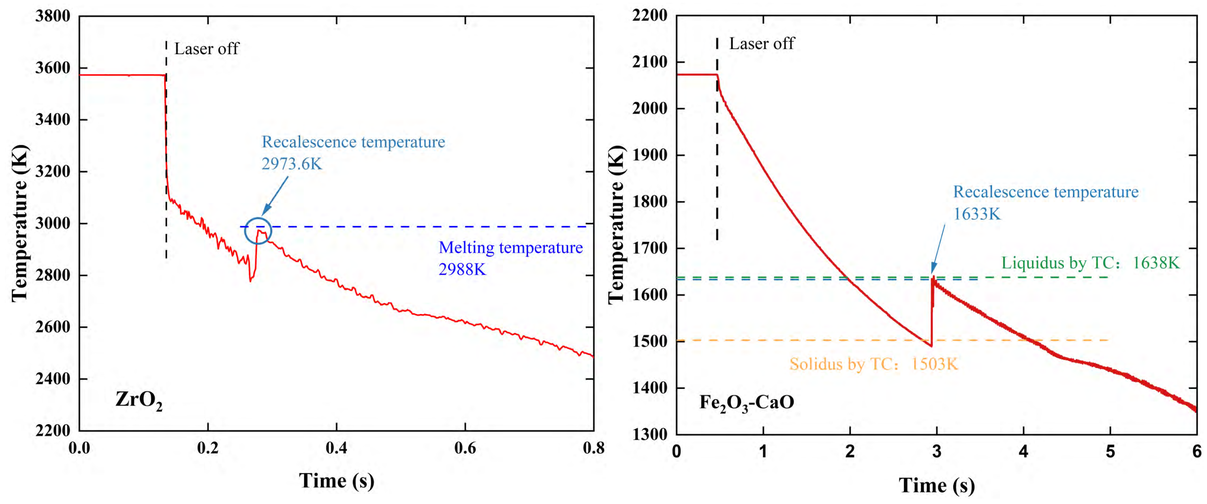

Figure 3. Recalescence behavior of ZrO_2 and Fe_2O_3-CaO

Heat of fusion Measurement

For the sample, the total heat lost during cooling in argon gas can be expressed in general as:

$$m\int C_p dT = A\int\left[\varepsilon\sigma(T^4 - T_{amb}^4) + h(T - T_g)\right]dt$$

Prior to solidification, the sample undergoes a temperature increase to T_m following nucleation. When the heat of fusion released by solidification is balanced with radiation and heat transfer, the sample temperature stays at the metling temeprature, showing a plateau in the temeprature profile, as shown in Figure 4. The heat of fusion is experssed as follows:

$$\Delta H_f = C_p\Delta T + \frac{A}{m}\int\left[\varepsilon\sigma(T^4 - T_{amb}^4) + h(T - T_g)\right]dt$$

As temperature difference during nucleation ΔT increases, plateau duration Δt decreases. When Δt decreases to zero, the hypercooling limit (the maximum of ΔT, ΔT_{hyp}) is reached. The heat of fusion is all consumed to elevate the sample temperature up to T_m. Therefore, the heat of fusion can be determined by:

$$\Delta H_f = C_p\Delta T_{hyp}$$

The measurement results for Al_2O_3 are given in Figure 4. The relationship between Δt and ΔT is obtained through linear fitting of experimental data. ΔT_{hyp} is calculated to be 672K when Δt equals to 0. Considering the isobaric capacity of 153.5 J/(mol·K) for liquid Al_2O_3 [6], the heat of fusion is calculated to be 103.0 kJ/mol, showing small deviations from the published value of 109.0 kJ/mol [6]. The measurement uncertainty is about 9.5 kJ/mol. The measurement errors may source from the limited number of experimental data points, the subjective determination of plateau time, and the impact of impurities inside samples on the recalescence behavior.

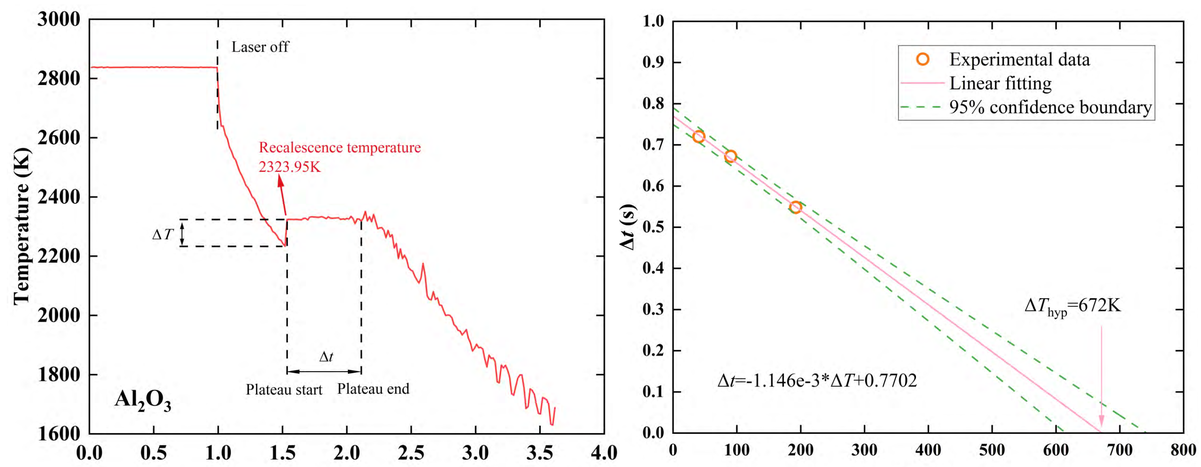

Figure 4. Heat of fusion measurement of Al_2O_3

Conclusion

This study shows the ability of ALSEE measuring melting temperature and heat of fusion by analyzing the recalescence behavior during the fast cooling. The measurement of melting temperature is convincing while the design of the experiment need to be modified to enhance reliability for heat of fusion measurement.

Subject area: In-vessel corium and debris coolability
Keywords: corium, cold crucible, material analysis. IVMR, induction heating

The 2011 accident at the Fukushima Daiichi Unit 3 boiling water reactor (BWR-4, Mark I) resulted in extensive core degradation. To replicate the accident conditions during the in-vessel phase, we conducted experiments using induction melting in a cold crucible, observing the interaction between partially oxidized corium, stainless steel, and boron carbide. Our previous work validated these experiments by comparing the produced aerosols with samples from the actual accident site. Building on this, the present study investigates material characteristics of solidified corium melt to support decommissioning efforts at the Fukushima Daiichi Unit 3 reactor. The rapid solidification following the gas-producing reaction of the corium with B4C prevented significant phase separation, resulting in a well-mixed metallic/oxidic melt. Analysis of the cross-section of the solidified ingot using scanning electron microscopy with energy-dispersive X-ray spectroscopy revealed a relatively homogeneous composition within the oxidic regions, while the metallic areas were heterogeneous. These findings offer crucial insights into the post-accident state of the core melt and can inform the development of effective decommissioning strategies.

HIGH-TEMPERATURE INTERACTIONS OF CORIUM, STEEL, AND BORON CARBIDE: EXPERIMENTAL SIMULATION OF FUKUSHIMA DAIICHI UNIT 3

Bence Mészáros (bence.meszaros@cvrez.cz), Jana Sklenka, Karin Čížková, Ayumi Itoh, Jan Hrbek, Mykhaylo Paukov, Yoshinao Kobayashi, Václav Tyrpekl

Introduction

- The Fukushima Daiichi accident highlighted the importance of understanding corium behaviour for accident management and decommissioning activities.
- Effective severe accident mitigation strategies, including in-vessel and ex-vessel melt retention, require reliable experimental data on prototypic corium materials.
- Experimental research on corium is challenging due to its complex composition, high temperatures, and multiphase behaviour.
- Induction skull melting (cold crucible) enables preparation and investigation of high-temperature prototypic corium under representative conditions.
- This work presents experimental studies of Fukushima Unit 3 prototypic corium prepared in a cold crucible, followed by elemental, phase, and microstructural characterization of the resulting ingots.

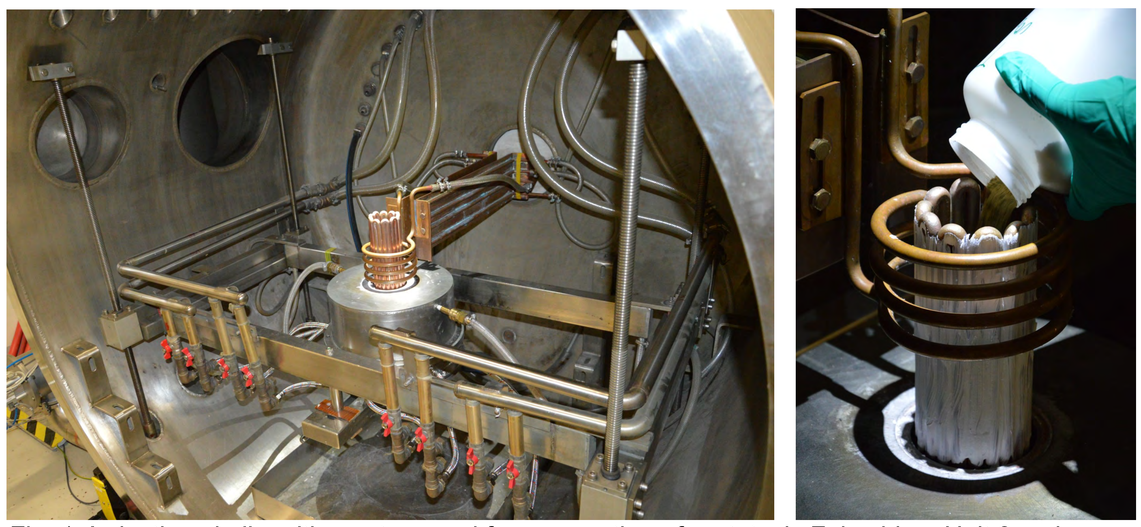

Fig. 1: Induction skull melting setup used for preparation of prototypic Fukushima Unit 3 corium.

Experimental section

- Two induction skull melting experiments (T-1 and T-2) were performed to prepare prototypic sub-oxidized Fukushima Unit 3 corium.
- Corium was prepared in a segmented water-cooled copper cold crucible under a protective argon atmosphere.
- Metallic zirconium was gradually added to the molten oxide pool to achieve sub-oxidized corium conditions representative of severe accident scenarios (C43 and C65).
- In T-1 interaction with stainless steel were conducted to simulate reactor material interactions during accident progression.
- In T-2 interaction with stainless steel and B_4C were conducted.
- Resulting ingots were sectioned and prepared for detailed characterization.
- Microstructural and elemental analyses were performed using SEM/EDS, while phase composition was determined by X-ray diffraction (XRD).

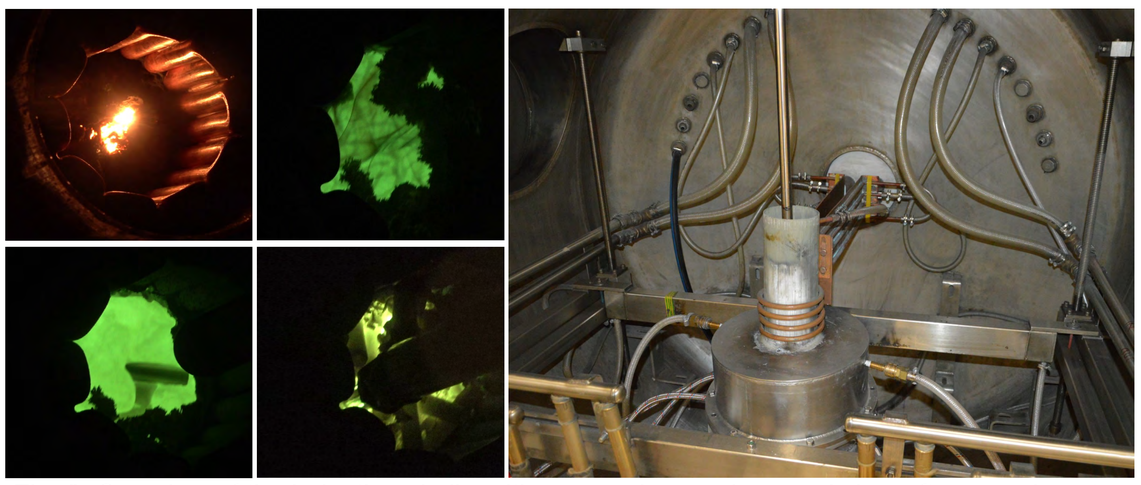

Fig. 2: Overview of the induction skull melting procedure and general view after experiment.

Table 1: Corium compositions of T-1 and T-2 experiments.

	experiment	T-1 (C43)	T-2 (C65)
	component	mass [g]	mass [g]
input components	UO_2	434.6	455.0
	ZrO_2	164.0	168.3
starting material	Zr	5.0	4.8
additives	Zr	170.7	73.9
	stainless steel	13.1	10.1
	B_4C	-	4.2

Acknowledgements

The presented work has been realized with in Institutional Support by the Ministry of Industry and Trade of the Czech Republic. The presented results were obtained using the CICRR infrastructure, which is financially supported by the Ministry of Education, Youth and Sports project LM2023041.

This work was supported by the Japan Atomic Energy Agency's Nuclear Energy S&T and Human Resource Development Project funded by Japanese government with the Grant Number of JPJA21F21461577.

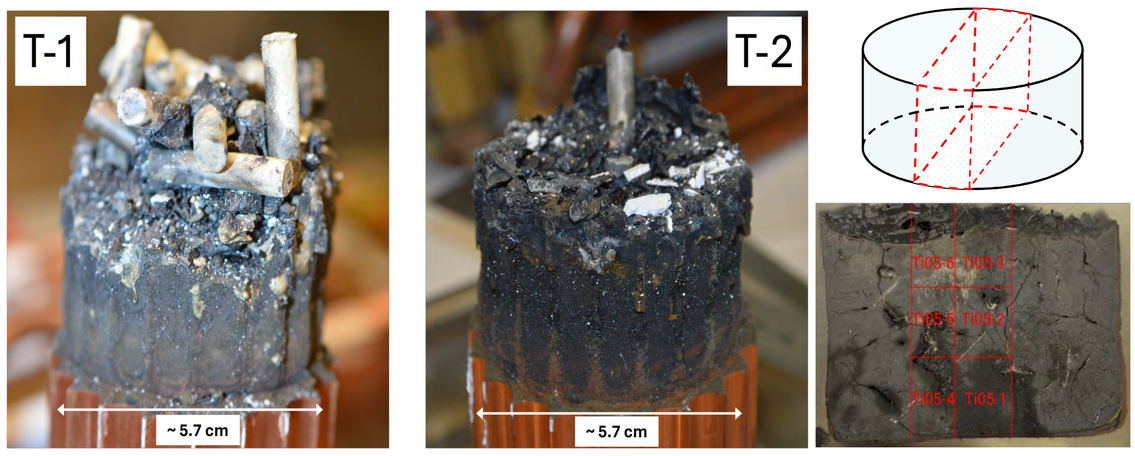

Fig. 3: Solidified corium ingots after corium–steel interaction experiments.

Results

- Prototypic sub-oxidized corium corresponding to Fukushima Unit 3 was successfully prepared using induction skull melting technology.
- Corium–steel interaction occurred at temperatures between corium solidus and liquidus temperatures.
- Stainless steel interaction remained localized in T-1.
- In T-2, metallic interaction zones extended through a much larger volume.
- Cr–Mn spinel phases formed due to oxidation of steel components.
- B_4C caused intensive gas generation and enhanced melt convection.
- Melt stirring induced by B_4C redistributed metallic phases throughout the ingot.
- Oxidation of B_4C enhanced uranium reduction within the melt.
- B_4C may accelerate severe accident progression through enhanced melt mixing and uranium reduction.
- Zr-rich U–Zr–O solid solutions similar to TMI-2 debris were identified.
- Separate ZrO_2 formation may indicate zirconium solubility limitations in suboxidized corium.

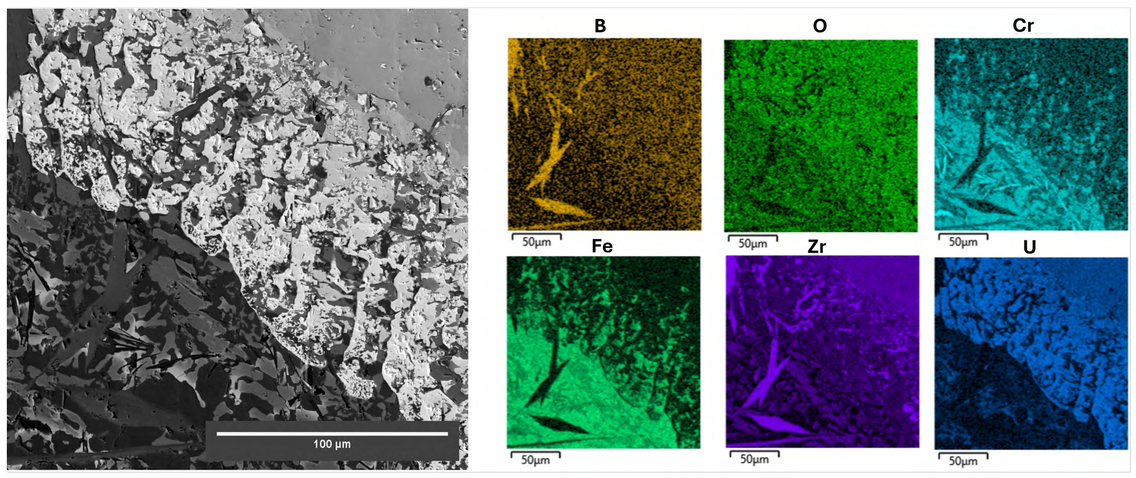

Fig. 4: Influence of B_4C on phase formation and metallic alloy evolution during corium interaction.

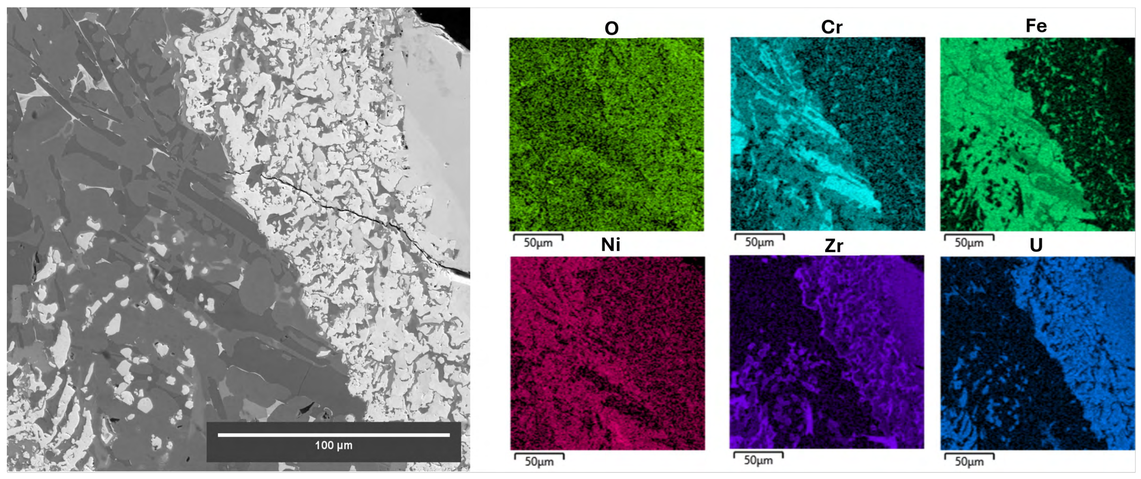

Fig. 5: SEM image and EDS elemental maps of the interaction zone between corium and stainless steel showing formation of metallic alloys and oxidic phases.

Conclusion

- Prototypic sub-oxidized corium representative of Fukushima Daiichi Nuclear Power Plant Unit 3 was successfully synthesized using induction skull melting technology under severe accident conditions.
- The experiments demonstrated that corium–stainless steel interaction occurred between corium solidus and liquidus temperatures.
- Addition of B_4C significantly modified melt behavior by enhancing gas generation, melt convection, and uranium reduction.
- Separate ZrO_2 formations were identified, indicating possible zirconium solubility limitations in suboxidized corium.
- The results provide new experimental insight into early-stage corium evolution and demonstrate the strong influence of B_4C on severe accident progression and corium–steel interaction phenomena.

ABSTRACT

Pool scrubbing is considered one of the most effective mechanisms for mitigating fission product release during severe accidents in NPP. The efficiency of this process is governed by bubble hydrodynamics, as the rising bubbles and their interaction with aerosol particles determine the overall removal performance. Consequently, accurate characterization of bubble parameters – including diameter, size distribution, rise velocity, and relaxation time – is essential for reliable prediction of the decontamination factor (DF). Despite the availability of various physical models, discrepancies between simulations and experimental data remain significant, largely due to uncertainties in bubble parameters. In recent years, machine learning has been widely applied to bubble imaging to improve parameter estimation. While most existing models perform well on trained datasets acquired under simplified laboratory conditions, their accuracy decreases under complex boundary conditions such as high void fractions, turbulence, significant overlapping, and large-scale pool facilities. In this overview, we present an extended U-Net model, that has been retrained on experimental images from the SAAB facility at Forschungszentrum Jülich. The bubbles images in this dataset are taken under more realistic and challenging boundary conditions. First preliminary results show a promising prediction on bubble binary segmentation, highlighting its potential to enhance bubble characterization in complex multiphase flow experiments.

1. INTRODUCTION

The simulation of aerosol removal phenomena and the reliable prediction of DFs in pool scrubbing processes have gained increasing interest in recent years. Over the past decades, many experimental projects, including THAI, POSEIDON and SAAB [1-4], have focused on understanding the physical behavior of pool scrubbing better. However, several issues remain unsolved. DFs assessed from different facilities under similar experimental conditions often differ by several orders of magnitude, making meaningful comparison difficult and challenging the validation of simulation results. Besides, most pool scrubbing models (SPARC-B/98 within COCOSYS or MELCOR) rely on simplified input parameters. These simplifications cause discrepancies between experimental observations and numerical predictions [5, 6]. To improve simulation results, it is therefore essential to employ reliable, clean, and CFD-grade input bubble information as much as possible.

In recent years, machine learning has seen extensive exploration and rapid development in science applications, offering a promising bridge between experimental and numerical studies. In particular, deep learning has proven effective for bubble identification and segmentation [7-9] and is regarded as a potential approach for obtaining reliable bubble physical parameters to enhance simulation accuracy. Haas et al. [8]

have proposed a faster, region-based convolutional neural network detector (RCNN) to locate bubbles by identifying anchor points with the corresponding bubble bounding boxes, together with a shape-regression CNN assuming elliptical bubble geometries. Kim et al. [10] presented a slightly modified Mask R- for automatic bubble detection, demonstrating high accuracy at low gas volume fractions; however, its robustness under diverse experimental conditions remains limited. Cui et al. [11] achieved bubble detection and segmentation at gas contents up to 20% using the Mask R-CNN model and applied spherical reconstruction for submillimeter-scale bubbles. Hessenkemper et al. [9] evaluated three different CNN-based methods − Double U-Net, StarDist, and Mask R-CNN − for identifying and segmenting overlapping bubbles using synthetic images and tested two methods (ellipse fitting and radial distance correction) to recover hidden parts of overlapped bubbles.

The literature review reveals several open challenges that remain to be addressed:

- Accuracy remains insufficient at high gas content, especially for heavily overlapping bubbles.
- Current bubble-detection models are not universally applicable and are often sensitive to change in experimental conditions and configurations.
- Existing models are primarily trained by the datasets derived from small-scale facilities and lack data from large-scale experiments.
- Bubble reconstruction typically relies on ellipse fitting, which is not well suited for irregular bubbles.

In this extended abstract, we present the preliminary results for a binary segmentation task using the U-Net model with a ResNet-32 backbone. Images acquired from the large-scale SAAB Facility [4,12] (Figure 1, l eft) provided by the ongoing NAMPS project (German national project conducted by IATF-KIT, grant no. 1501652) are used for training and validation. Our work aims to address aforementioned challenges through more robust deep CNN techniques.

1. U-NET ARCHITECTURE

The U-Net architecture has been widely proven as an effective solution for image segmentation tasks. Inspired by the model developed by our colleagues at HZDR, we employ a PyTorch-based U-Net with a ResNet-34 backbone to perform bubble-image segmentation in our work.

For bubble hydrodynamic experiments, the camera and illumination system are positioned opposite each other, as shown in Figure 1 (middle). Images are recorded under various hydrodynamic conditions with different gas-injection velocities. The resulting recordings capture swarms of bubbles, often overlapping and associated with relatively high gas void fractions. Figure 1 (right) presents an example of a captured image. It is noted that bubble image shows inhomogeneous illumination distribution, which is a limitation of the SAAB facility itself. The center of the image is overexposed, while the surrounding areas appear darker. Considering significant bubble overlaps makes bubbles identification and segmentation to be challenged.

The task is firstly considered as a binary segmentation problem in which the background is labeled as 0 and the objects (bubbles) as 1. The encoder adopts a pretrained ResNet-34 consisting of six stages for hierarchical feature extraction. The initial learning rate is set to 2×10^{-4} and the weight decay to 1×10^{-4}. The decoder follows the standard U-Net structure with skip connections linking encoder and decoder layers. During training, the loss function is defined as a weighted combination of the Dice loss and the Focal loss, with weights of 0.7 and 0.3, respectively. The Focal loss parameters α and γ are set to 0.25 and 2, consistent with recommended values in literature. The complete loss function is given in Eq. (1):

$$\min L = 0.7\left(1 - \frac{2\sum(py)+\varepsilon}{\sum p+\sum y+\varepsilon}\right) + 0.3\left(-\alpha(1-p)^{\gamma} y \log p - (1-\alpha)p^{\gamma}(1-y)\log(1-p)\right) \quad (1)$$

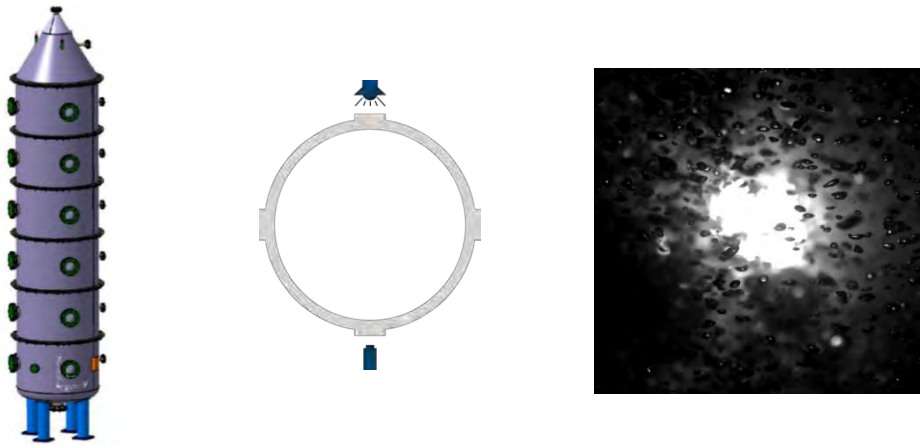

Figure 1. Overview of the SAAB facility vessel (left), orientation of the high-speed camera and illumination system (middle), and representative example of a captured bubble image (right).

2. PRELIMINARY RESULTS AND FIRST CONCLUSIONS

In our binary segmentation study, we increased the input cropped image size from 256×256 to 512×512 and explored a range of training configurations. The experimental parameters included the use of data augmentation, different batch sizes (8, 16, 32), various segmentation architectures (U-Net, U-Net++, FPN, SegFormer, PAN), different pre-trained backbones (ResNet-34, EfficientNet-B7, mit-b2), multiple weighted loss-function combinations, and different dropout rates, with the goal of achieving the best F1 and IoU scores. Our best preliminary results were obtained using a U-Net with a mit-b2 backbone, an input image size of 512×512, data augmentation enabled, a dropout rate of 0.2, a batch size of 16, and a Dice–Focal loss weighting of 0.7 to 0.3. The best F1 score achieved was 0.8229 at a threshold of 0.4747. The corresponding IoU at this optimal threshold was 0.70, indicating that the resulting model is reasonably effective and suitable for further investigation.

Figure 3 shows the training and validation loss, as well as the IoU curves, over the training epochs. It is noted that during the decreasing of training loss, the validation loss also decreases and eventually stabilizes, indicating no clear signs of overfitting. However, the IoU scores still have potential for improvement. Figure 2 illustrates the differences between the predicted masks and the ground truth. It can be observed that some errors come from missed bubbles (false negatives), while others result from incorrectly predicted bubbles (false positives) highlighting the necessity to further improve the manual mask annotations, which is expected to increase both the training IoU and the overall model accuracy. Nevertheless, the preliminary prediction results for the 1024×1024 bubble images are a promising first attempt. The next step will be to extend the current binary segmentation approach to a bubble-classification segmentation capable of identifying overlapping bubble situations.

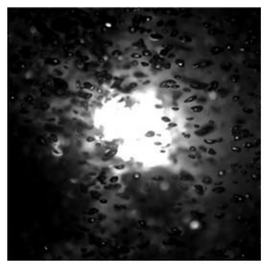
DETECTION AND SEGMENTATION OF OVERLAPPING BUBBLES IN POOL SCRUBBING EXPERIMENTS AT THE SAAB FACILITY

Yihui Wu, Michael Klauck, Forschungszentrum Jülich GmbH, Germany

Introduction & Motivation

Challenges: The simulation of aerosol removal phenomena and the reliable prediction of DFs in pool scrubbing processes have gained increasing interest in recent years. DFs assessed from different facilities under similar experimental conditions often differ by several orders of magnitude, making meaningful comparison difficult and challenging the validation of simulation results. Most pool scrubbing models (SPARC-B/98 within COCOSYS or MELCOR) rely on simplified input parameters, which cause discrepancies between experimental observations and numerical predictions. [1, 2]

Approach: Deep learning has proven effective for bubble identification and segmentation and is regarded as a potential approach for obtaining reliable bubble physical parameters to enhance simulation accuracy [3, 4]. In the CNN-OBA project, we apply a well-established U-Net architecture with various pre-trained encoders for binary segmentation. The bubbles image data were obtained from the large-scale SAAB Facility within the NAMPS project. This approach aims to provide more robust bubble physical parameters, ultimately enhancing the predictive capability of pool scrubbing simulations.



Hydrodynamic Experiments

Modular SAAB facility: [5]

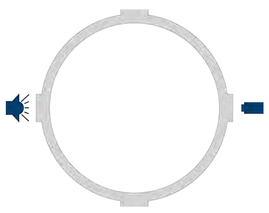
- **flexibility:** various gas injection geometries (upward, downward, and sideways)
- **scalability:** pool height 0.5-5.5 m; heating options up to boiling conditions
- **setup:** camera and illumination system in a counter-position

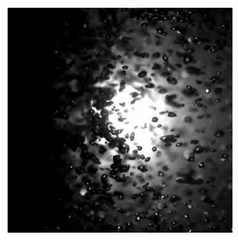
Experimental conditions:

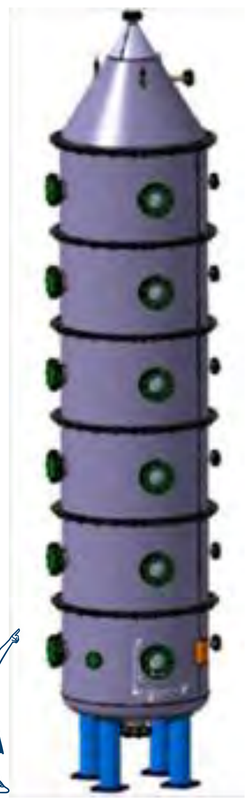
- various **hydrodynamic conditions** with different gas-injection velocities
- focusing on the **swarms of bubbles**

Key technical challenges:

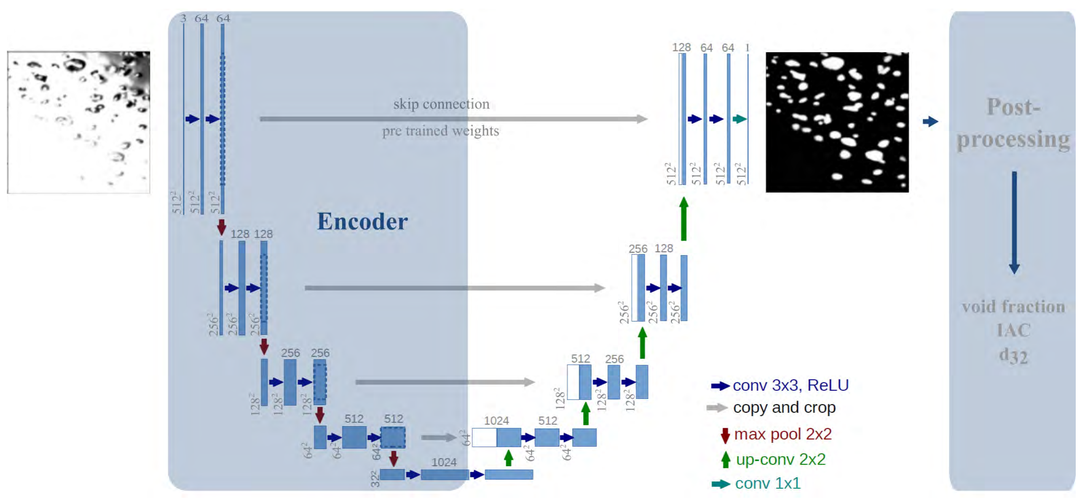
- **overlapping bubbles**: relatively high gas void fractions up to 30%
- **illumination limitation:** inhomogeneous distribution (center overexposure dark periphery)
- **segmentation difficulty:** challenging to conventional image processing and existed models







Machine Learning (U-Net Architecture[6])



Task: Binary segmentation (0: Background, 1: Bubbles) with manually labeled annotation (CVAT)

Pre-processing: Resize / crop from 1024 x 1024 images

Augmentation: flipping, rotation, contrast, noises (only for training sets)

Encoder Backbone options: ResNet34, Mit-b2 (SegFormer), EfficientNet-b7

- initialized with ImageNet-pretrained weights to accelerate convergence

Loss function: $\mathcal{L}_{loss} = 0.7\mathcal{L}_{Dice} + 0.3\mathcal{L}_{focal}(\alpha = 0.25, \gamma = 2)$ with **Adam optimizer**

Hyperparameters: Learning Rate: 0.0002| Weight decay: 0.0001| Dropout: 0.2 | Batch size: 16

Results

Ablation: Larger training patches improve performance

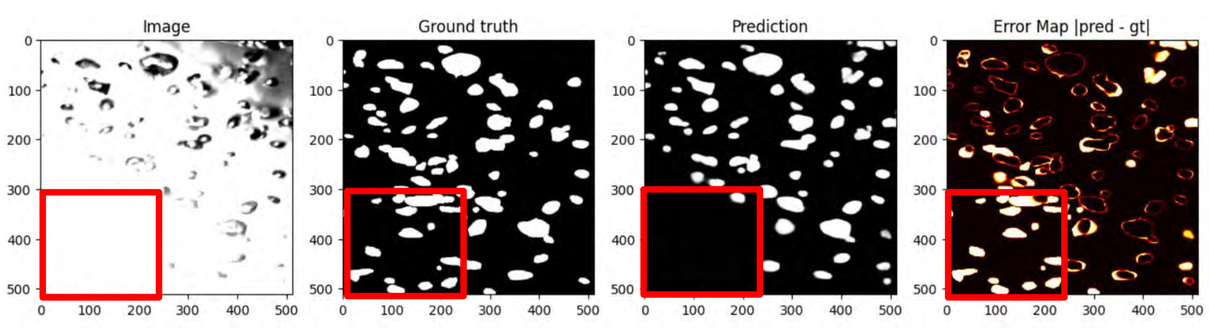
Encoders:

- SegFormer encoder achieves the best results (modern Transformer backbone)
- pure U-Net also achieves relatively high performance

Metrics: Dice and IoU indicate robust learning of bubble boundaries

Error source: Performance mainly limited by low-quality manual annotations

Encoder Backbone	Input sizes	Dice	IoU
UNet	512×512	0.8101	0.6809
ResNet-34	512×512	0.8048	0.6735
SegFormer mit-b2_L	512×512	**0.8229**	**0.6978**
EfficientNet-b7	512×512	0.7989	0.6651
SegFormer mit-b2_S	128×128	0.8062	0.6808



Outlook

High Fidelity Ground Truth:

- implementing semi-automated labeling tools and human cross verification
- reducing the labeling image size from 1024×1024 resolution to 128×128

Synthetic Inputs: 3D-bubble modeling to provide bubble physical information ground truth, enabling rigorous validation of segmentation model post-processing

Beyond Binary: Instance-Level Segmentation

- focusing on decoupling overlapping bubbles and acquiring bubbles size distribution information at highly void fraction (swarm flow)

Physics-coupled Post-Processing:

- **bubble parameters**: Sauter mean diameter (d_{32}), local void fraction (α), , Interfacial Area Concentration (IAC)
- **SPARC-98 integration**: providing physical and statistical based bubble information for pool scrubbing simulation

Experimental Study of Molten Corium–Serpentinite Concrete Interaction Using Cold Crucible Induction Melting

Nikolaiev Borys (1)

(1) CVŘ

Type of abstract: Poster
Subject area: Ex-vessel corium interactions and coolability
Keywords: Cold crucible induction melting Molten corium-concrete interaction

Molten corium concrete interaction (MCCI) is a key phenomenon during the ex-vessel phase of severe accidents of nuclear power plants. Research in this topic is essential for improving safety protocols and aiding decommissioning efforts for nuclear power plants. Study of the interaction between corium and serpentinite concrete has historically been neglected compared to other concrete types. This study thus focused on investigating the interaction between prototypic oxidic corium and serpentinite concrete using induction melting in a cold crucible. Off-gas composition was studied and post-test material analyses using X-Ray diffraction (XRD) and scanning electron microscopy (SEM) were performed. The gained knowledge will serve to increase safety during severe accidents.

EFFECT OF PT COATING METHODS ON HYDROGEN RECOMBINATION ACTIVATION FOR PASSIVE AUTOCATALYTIC RECOMBINERS

ABSTRACT

The mitigation of hydrogen in nuclear containment buildings during a severe accident relies heavily on passive autocatalytic recombiners (PARs). Inside a PAR, hydrogen and oxygen react on platinum-based catalysts that are coated on a plate or mesh structure. Effective operation of PARs requires the initiation of recombination at hydrogen concentrations as low as 1 vol.%, a concentration significantly below the lower flammability limit of hydrogen in air (4 vol.%). Achieving this low-concentration activation hinges on the development of practical techniques for coating the expensive platinum catalysts onto the metallic or ceramic substrates. In this study, the recombination performance and activation conditions of three catalyst types were experimentally investigated in a laboratory-scale PAR device. Two of the catalysts were flat stainless-steel plates coated with platinum via sputtering and electroplating, respectively. The third, serving as a reference, was a commercial honeycomb-type catalyst (KE-7580, Heesung Catalysts Corp.) in which the catalyst material is wash-coated onto a cordierite mesh. To evaluate the activation characteristics, the flat-plate catalysts were preheated to surface temperatures of up to 250°C, and their activity was evaluated by observing the surface temperature increase and maintenance due to the exothermic reaction upon the supply of hydrogen–air mixtures with hydrogen concentrations ranging from 4 to 6 vol.%. In contrast, the honeycomb catalyst was tested under ambient conditions, and its performance was assessed by measuring the catalyst surface temperature and the hydrogen concentrations at the inlet and outlet to calculate the catalytic removal rate. This study aims to experimentally determine the operational activation limits of these catalysts, thereby contributing to the enhancement of catalyst plate performance for PARs.

Passive autocatalytic recombiner, Hydrogen recombination, Catalyst reaction, Catalyst coating methods

1. INTRODUCTION

Hydrogen mitigation within nuclear power plant containment buildings is an important aspect of safety management for preventing the risk of gas explosions that may occur during severe accidents. The initiation

of PAR operation generally occurs at low hydrogen concentrations below the flammability limit, and this early activation characteristic is important for suppressing hydrogen accumulation during the early phase of an accident. Therefore, the catalytic activation characteristics under low hydrogen concentration conditions are an important factor in evaluating PAR performance. The activation behavior of PAR catalysts depends not only on the chemical composition of the catalyst but also on the surface structure [1]. Previous studies have focused on optimizing reaction efficiency within porous supports with large specific surface areas, whereas studies directly addressing activation limits in densely formed catalytic layers remain relatively limited [2,3]. In this study, the activation characteristics of a commercial honeycomb catalyst and plate-type catalysts coated with platinum via sputtering and electroplating were experimentally compared. The catalytic activation was examined as functions of the preheating temperature of plate-type catalysts and hydrogen concentration, and the effects of surface structural differences on reaction activation under low hydrogen concentration conditions were elucidated through comparisons of catalyst surface structures and platinum distributions using SEM–EDX analysis.

2. EXPERIMENTS AND RESULTS

Three types of catalysts were used to compare activation characteristics depending on the coating method. The commercial honeycomb catalyst KE-7580 consisted of a cordierite support with a cell density of approximately 46 CPSI and was coated with Pt on the surface. The sputtered catalyst was fabricated by depositing a 30 μm-thick Ti layer on a stainless steel plate to prevent oxidation and subsequently depositing Pt to a thickness of 100 μm. The electroplated catalyst was fabricated by electroplating Pt onto a Ti plate to a thickness of 0.5 μm. The plate-type catalysts had an area of 100×100 mm^2 and a thickness of 1.5 mm. Catalyst activation tests were conducted in a lab-scale PAR test facility as shown in Figure 1. The hydrogen–air mixture flow rate and concentration were controlled using mass flow controllers (MFC), and the mixture was uniformly mixed using a static mixer before entering the bottom of the test facility. The plate-type catalysts were preheated to a surface temperature of 250~300°C using a hot air blower to determine the activation limit and the gas mixture was then introduced. Thermocouples were attached at the center of the plate surface and at positions 25 mm above and below the center and catalyst activation was identified from surface temperature changes induced by the exothermal reaction. The honeycomb catalyst was tested at ambient temperature without separate preheating. Thermocouples were attached to the upper and lower surfaces of the honeycomb channels to measure temperature changes during the reaction and the hydrogen concentration was measured 100 mm downstream of the catalyst. The hydrogen removal rate and recombination performance were analyzed by comparing the concentration differences between the inlet and outlet for different hydrogen concentrations and flow rates.

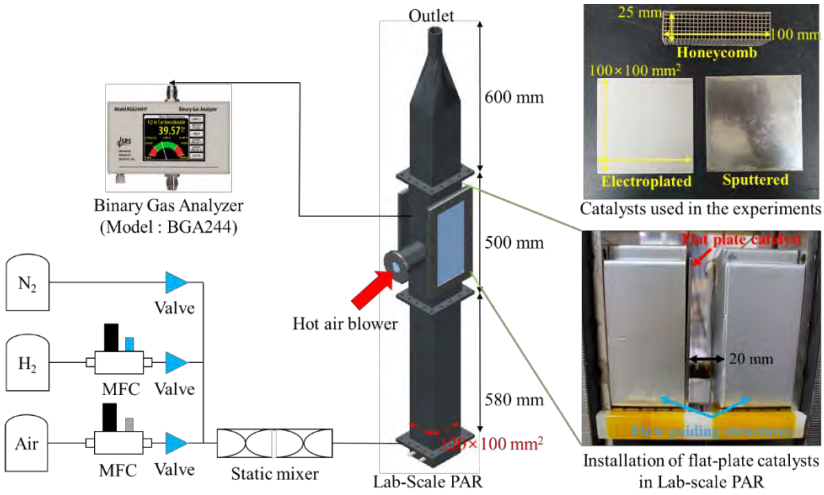

Figure 1. Schematic of a lab-scale PAR experiment.

Figure 2 shows the surface temperatures of the plate-type catalysts as functions of the preheating temperature and hydrogen concentration. The sputtered catalyst maintained a surface temperature above approximately 180℃ at the lower region due to the exothermic reaction after the surface was preheated to 250℃ and 6 vol.% hydrogen was subsequently introduced as shown in Figure 2(a). However, at the same hydrogen concentration the surface temperature continuously decreased and the reaction was not activated even after the gas mixture was introduced when the preheating temperature was increased to 300℃. In contrast, when the plate-type catalyst was preheated to 300℃ and the gas mixture was subsequently introduced at the same hydrogen concentration, the surface temperature fell below 100℃ and the reaction was not activated. Therefore, the sputtered catalyst may exhibit transient reactions but does not achieve stable activation. The electroplated catalyst showed catalytic reactions only at a hydrogen concentration of 6 vol.% after preheating to 300℃, and the surface temperature was maintained at approximately 250℃ as shown in Figure 2(b). Therefore, lower hydrogen concentrations are considered to require higher activation energy for the initiation of the reaction. The honeycomb catalyst was activated upon hydrogen injection at ambient temperature without a separate preheating process and the outlet hydrogen concentration decreased even at a low inlet hydrogen concentration of 1 vol.% as shown in Figure 3(a). Figure 3(b) and (c) show the surface temperature and hydrogen removal rate for different flow conditions. As the hydrogen concentration increased, the catalyst surface temperature rose due to exothermic reactions, while the hydrogen removal rate decreased because the amount of hydrogen supplied per unit time increased and the removable fraction became relatively smaller. In contrast, an increase in flow rate reduced the surface temperature by shortening the residence time and limiting the effective reaction on the catalyst surface while the hydrogen removal rate increased due to enhanced mass transfer. In contrast, an increase in flow rate reduced the surface temperature by shortening the residence time and limiting the effective reaction on the catalyst surface, while the hydrogen removal rate was analyzed to increase as mass transfer was enhanced and reactants were more effectively supplied to the catalyst surface.

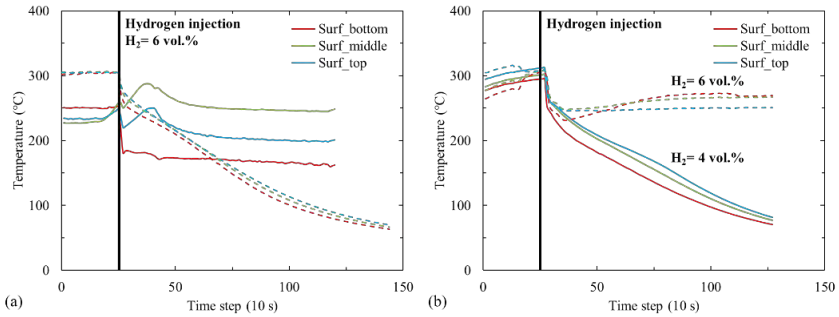

Figure 2. Surface temperature results of plate type catalysts under hydrogen and air mixture injection after preheating (a) sputtered plate preheated to 250, 300℃ with 6 vol% hydrogen injection, (b) electroplated plate preheated to 300℃ with 4, 6 vol% hydrogen injection.

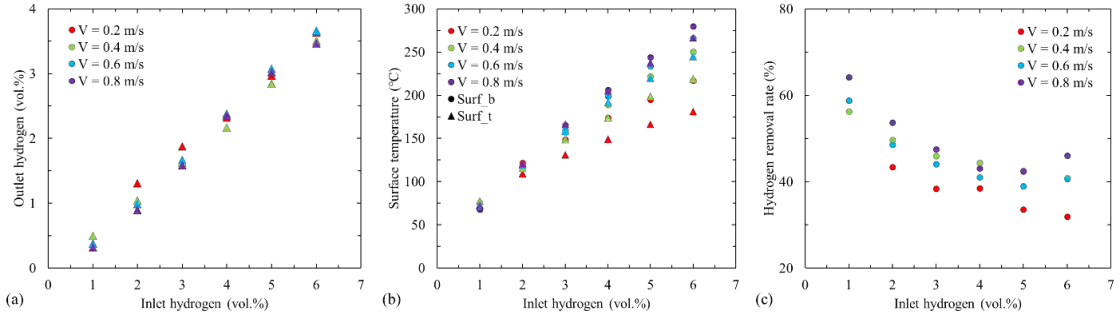

Figure 3. Experimental results of honeycomb catalyst according to inlet velocity and hydrogen concentration (a) outlet hydrogen concentration (b) surface temperature (c) hydrogen removal rate.

Figure 4 shows the Pt distribution on the catalyst surfaces from SEM–EDX analysis displayed in red. The honeycomb catalyst exhibits a porous surface structure with Pt present on the surface, providing diffusion pathways for gas penetration into the catalyst and a large effective reaction area. The sputtered catalyst shows a dense Pt distribution in the form of a thin film, and the electroplated catalyst exhibits locally aggregated Pt particles. As a result, the limited gas diffusion pathways and effective reaction areas of the plate-type catalysts limit the occurrence of catalytic reactions.

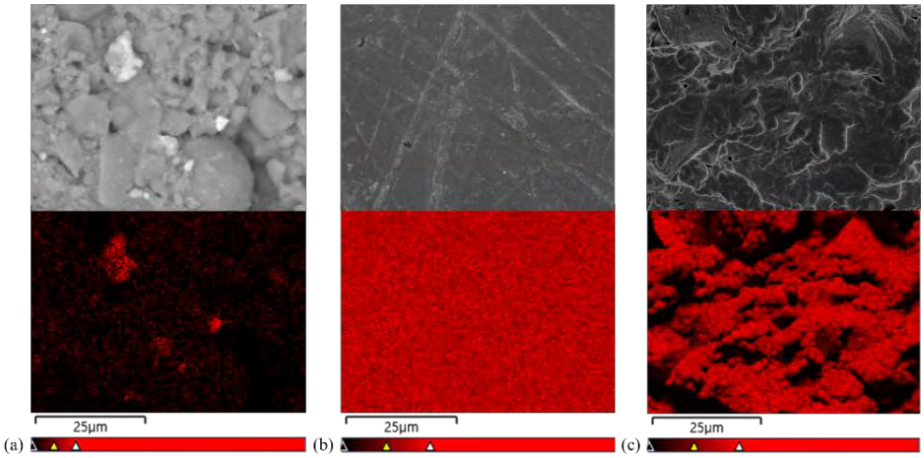

Figure 4. SEM-EDX analysis results of catalyst surfaces according to coating methods (a) honeycomb catalyst (b) sputtered catalyst (c) electroplated catalyst.

3. CONCLUSIONS

In this study, the activation characteristics of PAR catalysts were compared according to Pt coating methods. The honeycomb catalyst initiated catalytic reactions at ambient temperature and low hydrogen concentration conditions, whereas the sputtered and electroplated plate-type catalysts exhibited limited activation despite high-temperature preheating. SEM–EDX analysis showed that the honeycomb catalyst featured a porous structure with well-distributed Pt, providing sufficient gas diffusion pathways and a large reaction area, whereas the sputtered and electroplated catalysts exhibited dense surface structures with localized Pt distribution, resulting in structural limitations unfavorable for activation. These findings suggest that the initiation behavior of PAR catalysts under low hydrogen concentration conditions is more strongly influenced by surface structure and diffusion characteristics than by the Pt coating method itself.

EFFECT OF PT COATING METHODS ON HYDROGEN RECOMBINATION ACTIVATION FOR PASSIVE AUTOCATALYTIC RECOMBINERS

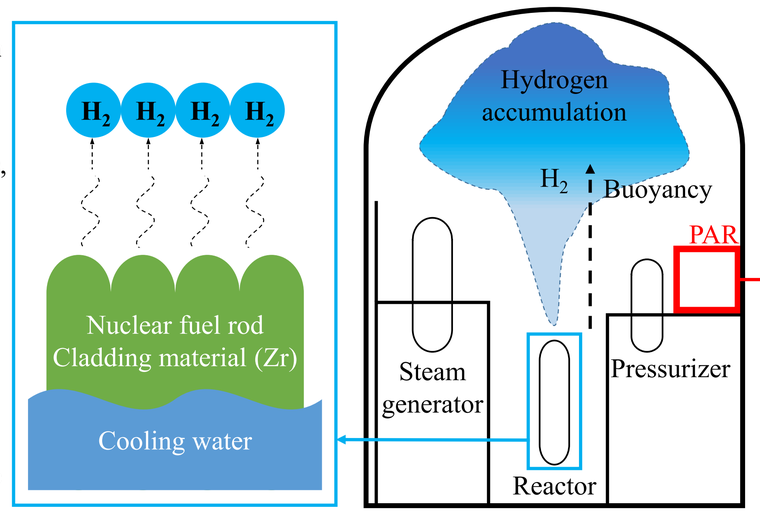
Dae-Hyun Kim[1], Youngsu Na[2], Dong-Wook Oh[1]
[1] Chosun University, Korea. [2] Korea Atomic Energy Research Institute, Korea.

1. INTRODUCTION

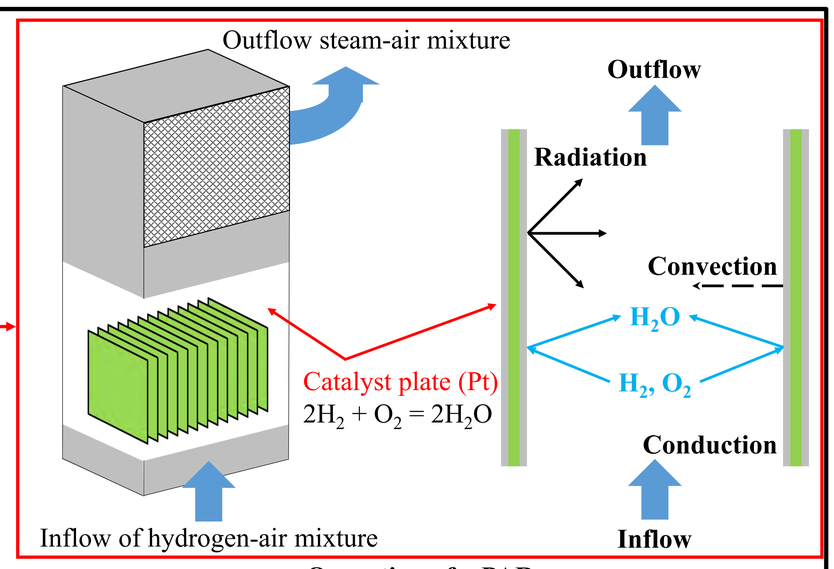
● **Passive autocatalytic recombiner (PAR)**

- In the event of a severe accident at a nuclear power plant, a large amount of **hydrogen is produced** by a reaction of high-temperature water vapor and zircaloy, which is a shell material for nuclear fuel rods.
- Hydrogen can be ignited with very little energy at low concentrations (below 4% vol.), so if hydrogen accumulates in the upper region of the containment due to buoyancy, there is a risk of explosion.
- **PAR**s prevent hydrogen explosions in nuclear power plants by reducing the hydrogen concentration within the combustible limit range through the passive catalytic recombination of hydrogen and oxygen.

▸ To compare **hydrogen recombination activation** characteristics depending on **Pt coating methods** and catalyst surface structures, and to **interpret the relationship between surface characteristics and reaction activation** under ambient-temperature and low-concentration hydrogen conditions.



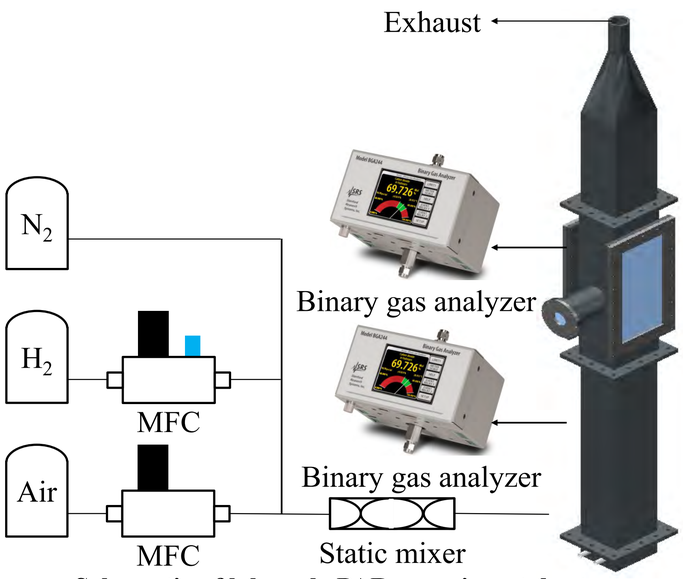
Hydrogen production process



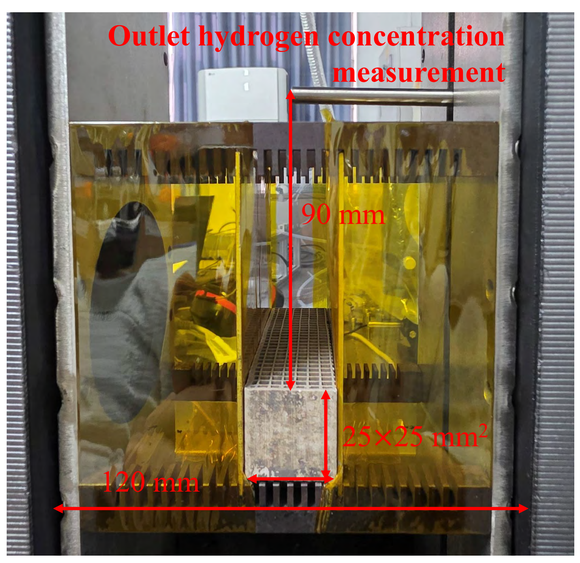
Operation of a PAR

2. EXPERIMENTAL METHOD

● **Lab-scale PAR catalytic activation experiment**



Schematic of lab-scale PAR experimental setup



Installation of Lattice type catalyst

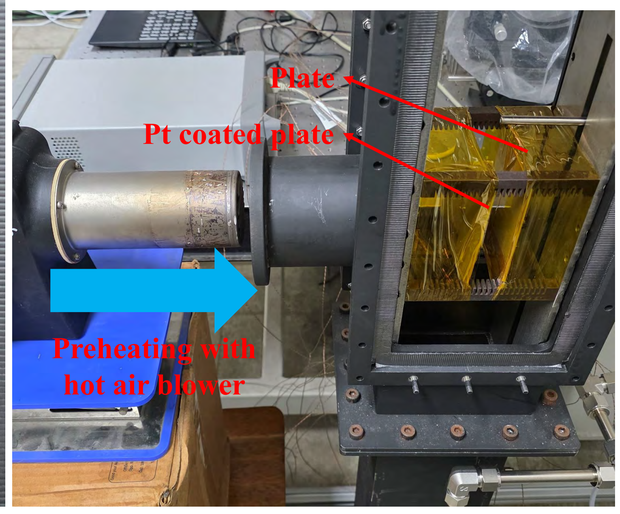


Plate catalyst preheating

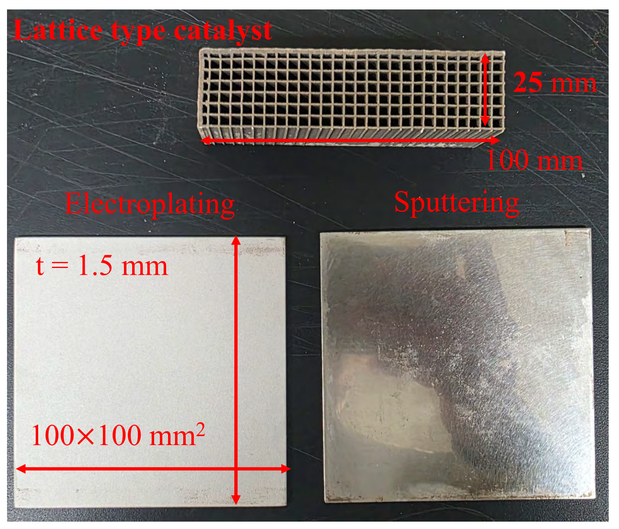


Test catalysts for reaction activation

► **Experimental Method**

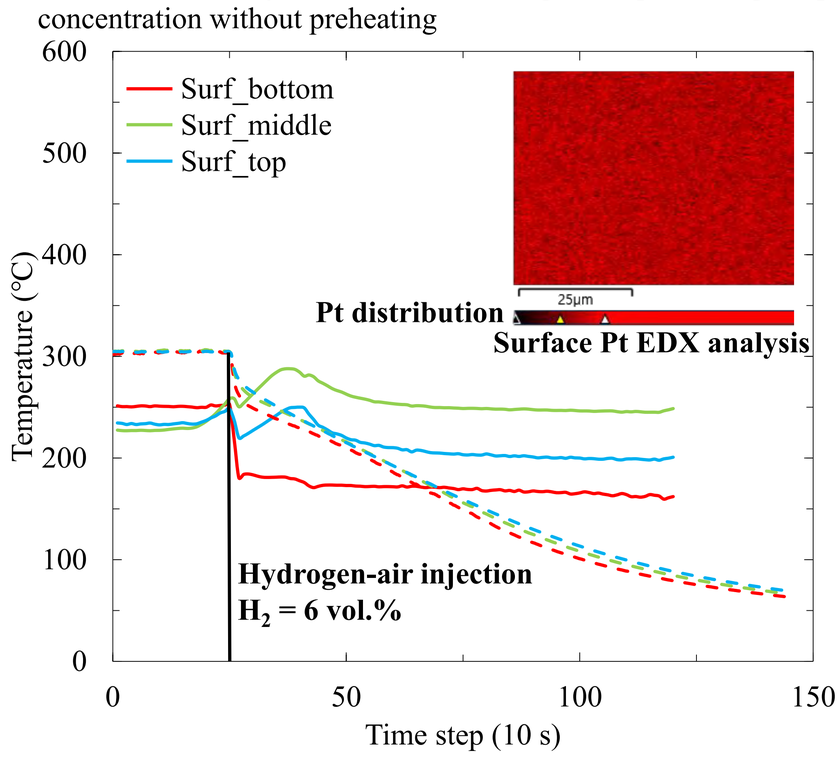
- Hydrogen-air mixtures were supplied at hydrogen concentrations of **1~6 vol.%** and inlet velocities of **0.2~0.8 m/s** using MFCs.
- For the **lattice -type catalyst**, the hydrogen removal rate was evaluated by measuring the hydrogen concentrations at the catalyst inlet and outlet.
- For the plate type catalyst, the plates were preheated to **250~300°C** using a hot-air blower, followed by the injection of the hydrogen-air mixture.
- **Catalyst activation** was evaluated by measuring the increase in **plate surface temperature** caused by the **exothermal reaction between hydrogen and oxygen**.

► **Catalyst Specifications**

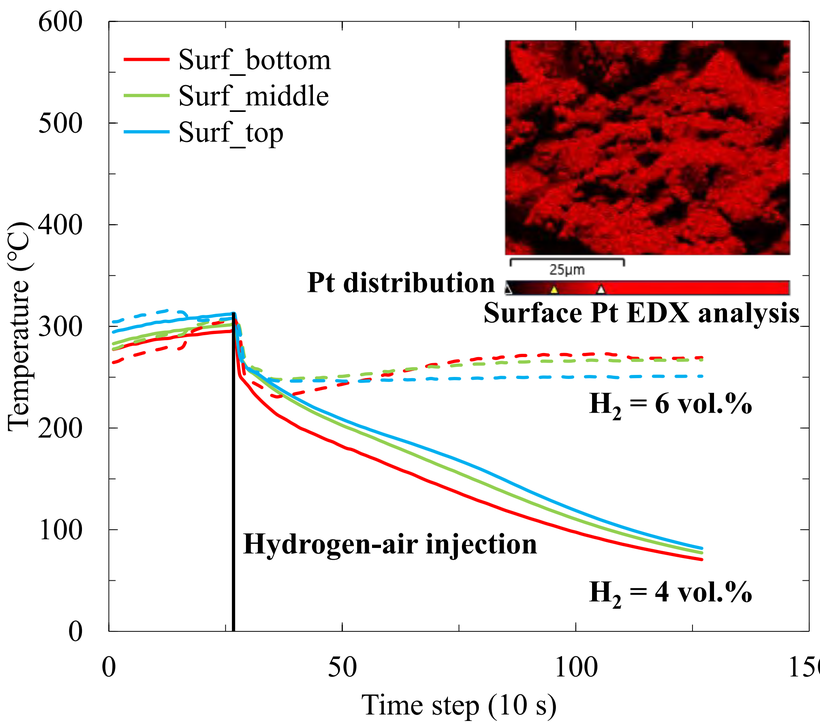
- Lattice Type Catalyst
  : KE-7580 from Heesung Catalysts Corp.
  : Hydraulic diameter of one cell: 3.04 mm, wall thickness: 0.7 mm
- Electroplated Catalyst : Pt electroplated on a titanium plate with a thickness of 0.5 μm
- Sputtered Catalyst : Ti and Pt deposited on an AISI 304 (EN 1.4301) plate with thicknesses of 20 nm and 100 nm, respectively.

3. RESULTS AND CONCLUSIONS

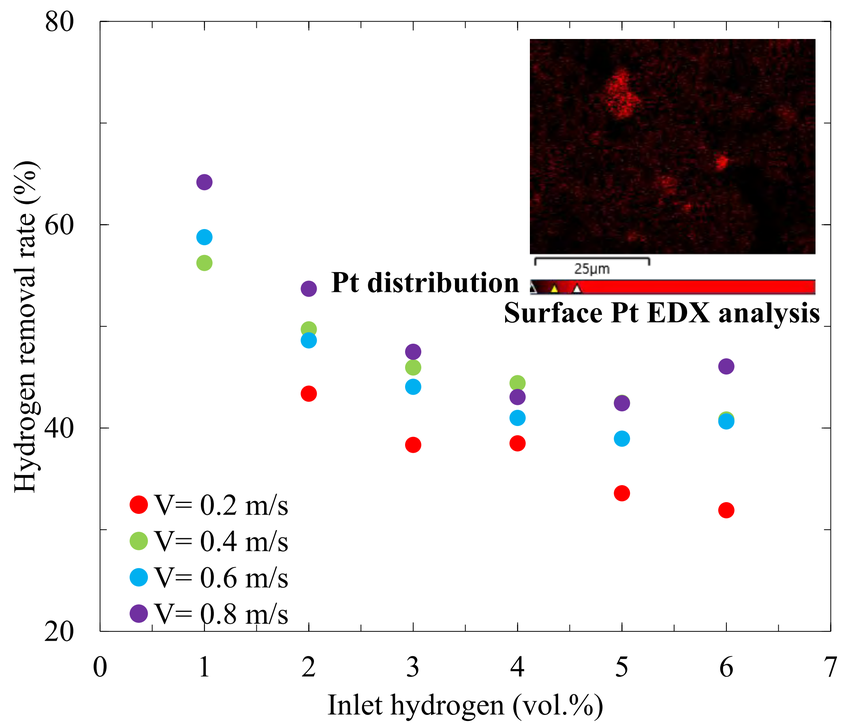
● Evaluation of catalyst activation according to the preheating temperature of plate type catalysts and the hydrogen removal rate of the lattice type catalyst according to inlet velocity and hydrogen concentration without preheating



Surface temperature at the center of the plate when the hydrogen concentration is 6 vol.% after preheating the sputtering plate to 250, 300°C



Surface temperature at the center of the plate when the hydrogen concentration is 4, 6 vol.% after preheating the electroplated plate to over 300°C



Hydrogen removal rate according to inlet velocitye and hydrogen concentration without preheating of honeycomb catalyst

- The **sputtered and electroplated Pt-coated plate** type catalysts were **not activated** under ambient-temperature and low-concentration hydrogen conditions, but **catalytic activation occurred and the surface temperature increased** when the catalysts were **preheated to 250~300°C** and supplied with hydrogen-air mixtures containing **6 vol.% hydrogen**
- The **lattice type catalyst** had Pt particles distributed on its porous surface, and **catalytic reaction activation occurred under ambient-temperature and low-concentration hydrogen conditions**, with the **hydrogen removal rate decreasing as the hydrogen concentration increased or the inlet velocity decreased**
- The **sputtered** catalyst plate had a **Pt thin-film structure** with few pores, and the **electroplated** catalyst plate had an **aggregated Pt structure**, resulting in a **limited active Pt surface area compared with the lattice type catalyst**
- Therefore, **porous gas diffusion pathways** and **a large active Pt surface area** are considered important for **activating Pt-catalyzed reactions** under ambient-temperature and low-concentration hydrogen conditions

Study of prototypical corium at solid state containing fission products: crystallographic and microstructural analysis, impact on weathering and leaching mechanisms

Type of abstract: Poster
Subject area: Ex-vessel corium interactions and coolability
Keywords: - prototypical corium - corium crystallographic structure - microstructure - fission products

In a water-cooled nuclear reactor, a loss of cooling systems can lead to core meltdown. This magma, formed at very high temperatures (T>2000K), is called corium and can pierce the reactor vessel to interact with the containment. Molten Core-Concrete Interaction (MCCI) occurred in three reactors at Fukushima-Daiichi in 2011 and in Chernobyl in 1986.

Tackling safety issues is crucial for nuclear energy. In this context, analysing the microstructure of coriums provides a better understanding of the environment in which this kind of specific material is formed to implement accident prevention and mitigation strategies. The dismantling of the Fukushima-Daiichi site raises scientific issues related to corium solid state knowledge. First, dismantling the damaged core is a long-term task, allowing time for the material to interact with environment through leaching process. Studying the final microstructural state of the corium provides informations on the material's ability to keep some non-volatile fission products. Secondly, the need to develop safe decommissioning strategies requires a prior knowledge of the main characteristics of the material.

For studying the mechanisms of formation and alteration of corium formed through MCCI, prototypical coriums are synthesised on the PLINIUS platform (CEA Cadarache). The synthesis used to simulate corium obtained by MCCI involves, beside oxygen, around twenty elements, the main ones being aluminium, silicon, calcium, chromium, iron, zirconium and uranium, and the minor ones being non-volatile fission products surrogates. The synthesis consists in melting at high temperature a mix of oxide powders. The crucible is then cut into slices to be analysed by energy-dispersive x-ray spectroscopy, electron backscatter diffraction and high-resolution x-ray diffraction. A quantitative analyse was performed on the x-ray diffraction diagrams with the Rietveld method implemented on the MAUD software.

These analyses show a complex material with $U_xZr_{1-x}O_2$ solid solutions, $Fe_{1-x}Cr_{2+x}O_4$ solid solutions and silicate phases.

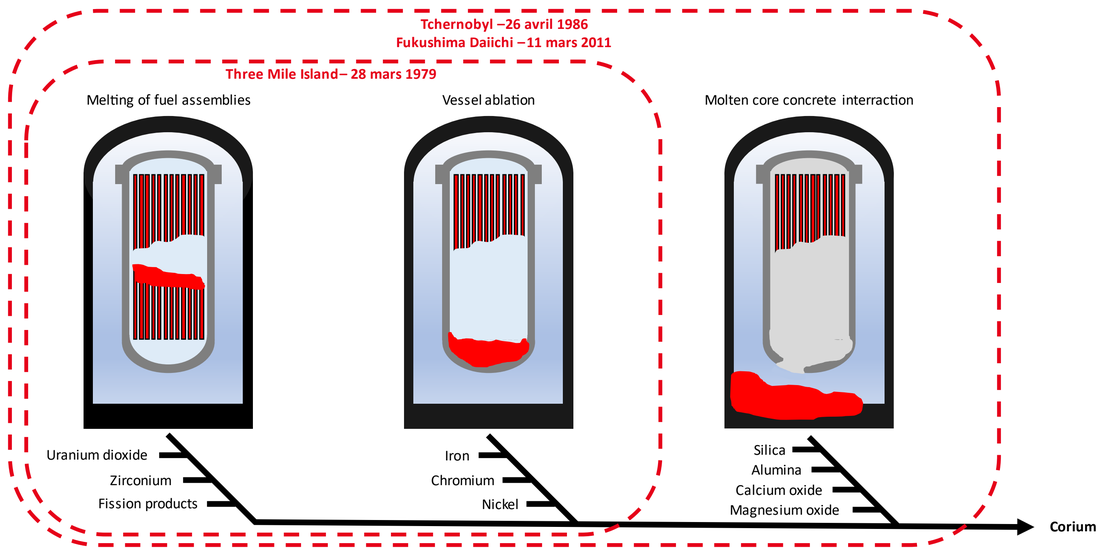
Context

- Corium is a liquid magma formed at hight temperature by the melting of a nuclear reactor core [1].
- Corium's composition depend on the reactor conception (type of fuel, type of concrete…) and the accident scenario (temperature, pressure, atmosphere…) [2] [3].



Schematic corium enrichment through nuclear incident

Theoretical composition of the prototypical corium

- The prototypical corium is made by melting at hight temperature a mix of powders representing the elements involved in the accident and their quantity

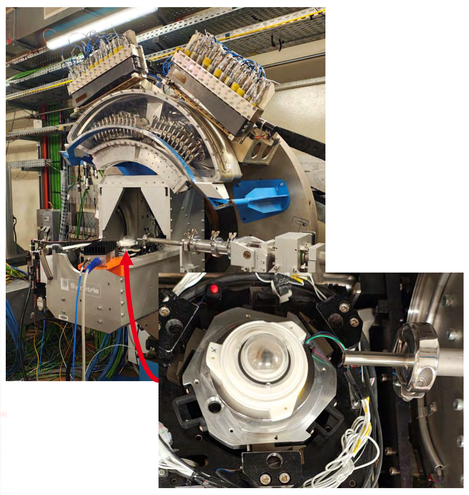
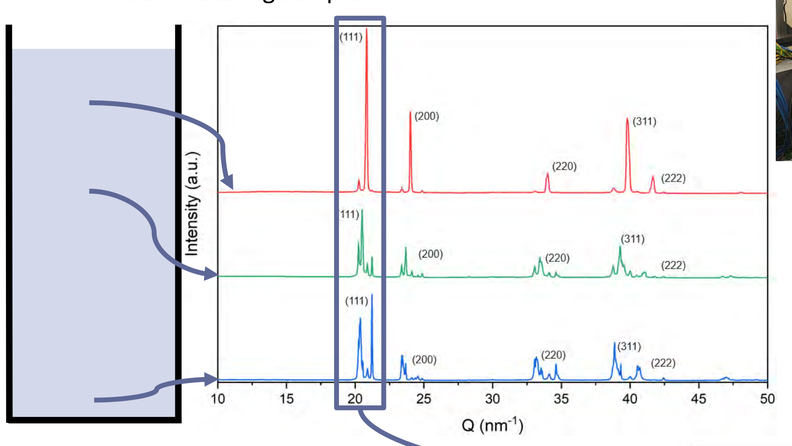
Solid solution : the $U_{1-x}Zr_xO_{2\pm y}$ case

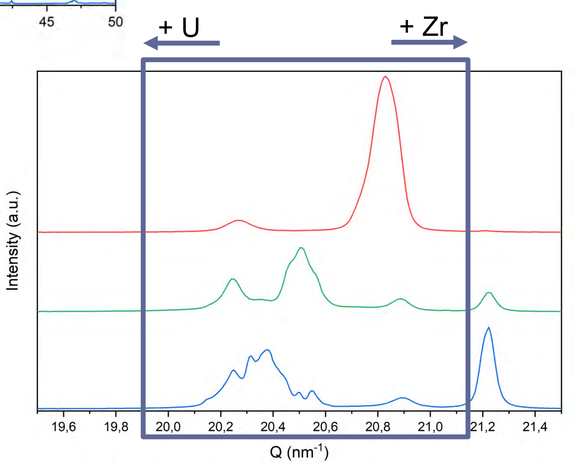
- X-ray diffraction measurements are carried out at the CX2 station on the MARS beamline at the SOLEIL synchrotron, using:
  - an incident beam energy of 17 keV;
  - an incident beam size of 0.45 mm × 1 mm;
  - a flat and rotating sample.



CX2 measurement station on MARS beamline, SOLEIL synchrotron [6]



X-ray diffractograms of samples taken from three different heights within the synthesis crucible



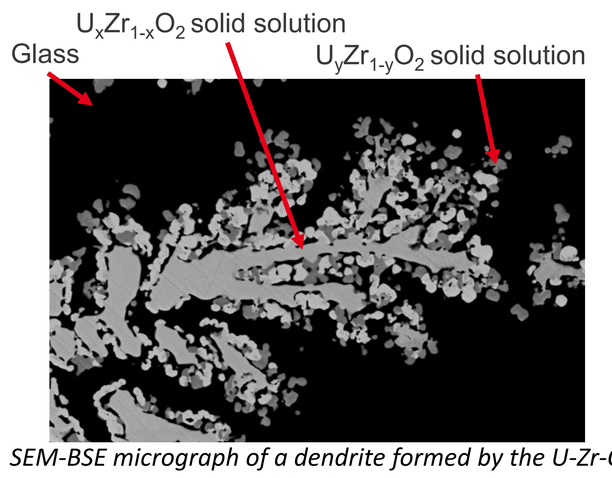
X-ray diffractograms of samples taken from three different heights within the synthesis crucible (plane family with Miller index (111) of the $U_xZr_{1-x}O_2$ solid solution)

- The elemental composition of the U-Zr-O solid solution varies with the height within the crucible used for the synthesis.
- **Assumption 1:** the O/M ratio is 2.00.
- The lattice parameter can be related to the zirconium content for the solid solution $U_xZr_{1-x}O_2$ by Végard's law [5]:

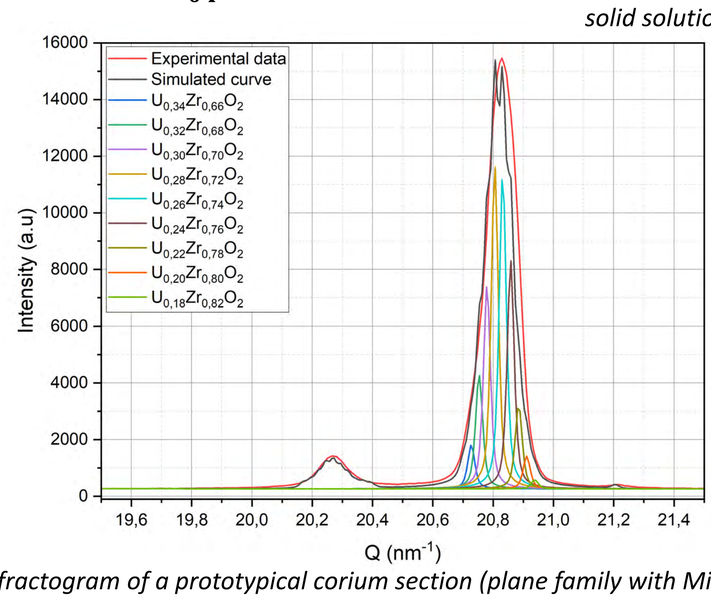
$$\mathbf{a = 5,468 - 0,3296\ x}$$

- **Assumption 2:** the crystals are micrometre-sized (verified by electron diffraction).
- Rietveld method: quantification of phases by refining a theoretical diffraction pattern (MAUD software) [6].
  - Using synchrotron radiation to achieve sufficient angular resolution
- Houska's method [2]: discretisation of the broadened peaks into a series of N elementary peaks, the parameters of which are obtained from a LaB6 standard. This method allows the continuous variation in the compositions of the solid solution $U_xZr_{1-x}O_2$ to be simulated

$$\mathbf{N = \frac{full\ width\ of\ U_xZr_{1-x}O_2\ peak}{mid-height\ width\ of\ LaB_6\ peak}}$$



SEM-BSE micrograph of a prototypical corium solid solution



X-ray diffractogram of a prototypical corium section (plane family with Miller index (111) of the $U_xZr_{1-x}O_2$ solid solution) and distribution of 9 elemental compositions

Conclusion and outlook

- A combined analysis using SEM-EDS, EBSD and high-resolution X-ray diffraction allows to identify the microstructures of corium
- The addition of other methods, such as X-ray fluorescence spectroscopy (micro-XRF) and X-ray microdiffraction, should enable the localisation of fission products within the material
  - MARS beamline , NANOSCOPIUM beamline, (SOLEIL synchrotron facility)
- The collected data will be used to link the microstructure of the corium, the location of the fission product and the leaching behaviour.

ABSTRACT

In a postulated severe accident (SA) in a nuclear power plant, one of the applied SA management strategies is core melt retention in ex-vessel core catcher (CC). For VVER-1000 and VVER-1200 reactors, this strategy is implemented by installing a crucible-type CC beneath the reactor vessel to accommodate the relocated corium. Sacrificial materials (SM), consisting of sacrificial steel and oxidic components, are incorporated into the CC to regulate the melt composition and thermophysical properties in a manner that promotes melt coolability and retention within the CC, suppresses fission product release, reduces hydrogen generation, and prevents corium re-criticality. One of the functional requirements for the SM is to lower the oxidic melt density below that of the metallic melt, thereby promoting the inversion of the oxidic and metallic layers and the formation of a molten corium pool with an oxidic top layer. The focusing effect of top metal layer is prevented in this configuration, and the risk of steam explosion or energetic interaction during top flooding of the molten pool is reduced compared to the state before layer inversion. In this study, a computational thermodynamic approach based on the NUCLEA-20 database is employed to investigate the influence of the reacted SM fractions on the compositions of oxidic and metallic layers in the stratified corium pool within the CC. The densities of the immiscible oxidic and metallic melts are evaluated to estimate conditions of layer inversion. Furthermore, the variations in phase composition underlying the layer inversion phenomenon are analysed from a thermodynamic perspective.

KEYWORDS
Severe accident, Ex-vessel melt retention, Sacrificial material, Thermodynamics

1. INTRODUCTION

The VVER-1000 design employs a crucible-type CC installed beneath the RPV to implement the EVR strategy. The CC is partially filled with sacrificial material (SM), which interacts with the relocated corium, promoting its cooling and stabilization [1,2]. Specifically, SM is employed to promote the inversion between the oxidic and metallic layers in the molten corium. This layer inversion is critical for the successful implementation of the EVR strategy, as it eliminates the focusing effect that locally increases heat flux to the cooling water at the surface of the molten metallic layer, mitigating steam explosions and reducing hydrogen generation during corium top flooding [3]. The present study employs a computational thermodynamics approach to investigate how varying fractions of reacted SM influences melt properties and molten pool behavior during ex-vessel melt stabilization, with particular emphasis on the possible inversion between the two immiscible oxidic and metallic layers.

2. METHODOLOGY

Thermodynamic modeling to obtain phase composition at equilibrium state is performed using the NUCLEA-20 thermodynamic database, which is specially developed for thermodynamic assessment of corium compositions in LWR SAs [4], in combination with the Thermo-Calc software [5], which employs Gibbs energy minimization. The calculation procedure and the computational tools employed in this study are illustrated in Fig. 1. To estimate the phase density, the model for ideal mixture of molar volumes was adopted [6].

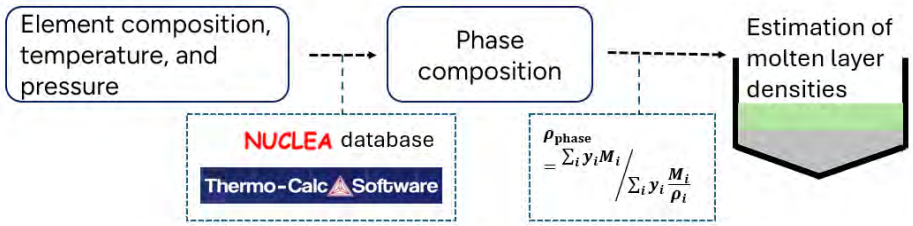

Figure 1. Calculation process and computational tools.

3. CASE STUDY

The input data for thermodynamic analysis consisting of masses and compositions of SM and relocated corium for specific VVER-1000 SA scenario was taken from Khabensky et al. [7]. Initial system for thermodynamic modeling includes 90 tons of SM and 117 tons of relocated corium (first and second release of corium from reference scenario [7]) with detailed composition presented in Table I.

Table I. Masses of SM and relocated corium components used in thermodynamic modeling

Material	Mass (t)	Composition
SM	27.6	Fe_2O_3
	11.6	Al_2O_3
	0.8	SiO_2
	50	Steel (71 wt.% Fe, 19 wt.% Cr, 10 wt.% Ni)
Relocated corium	33.5	UO_2
	4.5	ZrO_2
	9.5	Zr
	69.5	Steel (71 wt.% Fe, 19 wt.% Cr, 10 wt.% Ni)

To apply the thermal equilibrium condition, the temperature used for thermodynamic modelling of the molten pool in the core catcher was assumed to be the liquidus temperature of the corium, with a fraction of SM reacting with the corium and dissolving into both the oxidic and metallic melts, despite the significant temperature difference between metallic and oxidic liquids in reference data [7].

4. MODELLING RESULTS

The thermodynamic modeling results show that the immiscible oxidic and metallic liquid phases coexist in the corium prior to interaction with the SM, as illustrated in Fig. 2. The predicted presence of these two immiscible liquid phases is in good agreement with the modeling results reported by Khabensky et al. [7].

The density variation of the two distinct liquid phases with increasing SM participation is illustrated in Fig. 3. Under the SA scenario and assuming the system temperature equals to the liquidus temperature, when 36 wt.% of SM has reacted with the relocated corium, the metallic melt density becomes lower than that of the oxidic melt. With a further increase in the reacted SM fraction, a layer inversion is therefore expected.

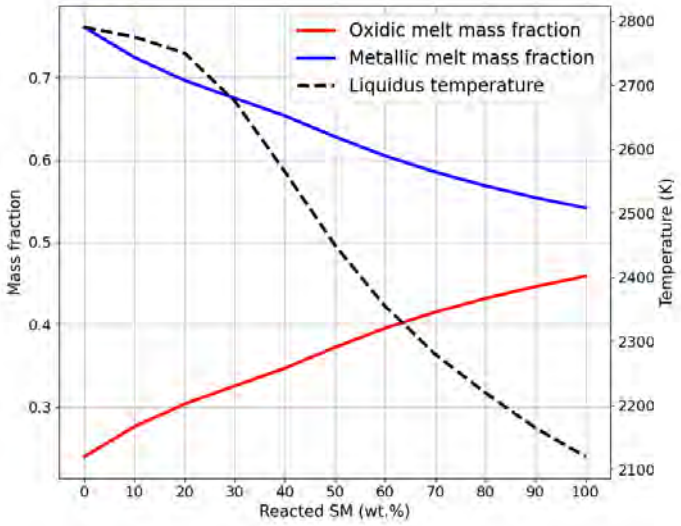

Figure 2. Mass fraction evolution of the two immiscible liquid phases and the system liquidus temperature with increasing fraction of reacted SM.

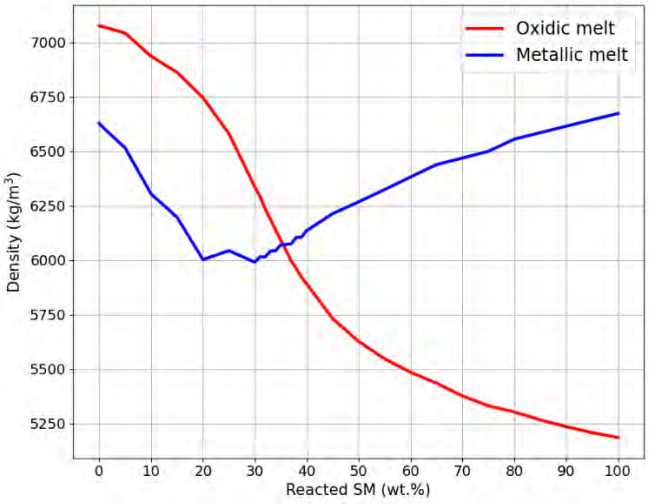

Figure 3. Density evolution of two immiscible liquid phases with increasing fraction of reacted SM.

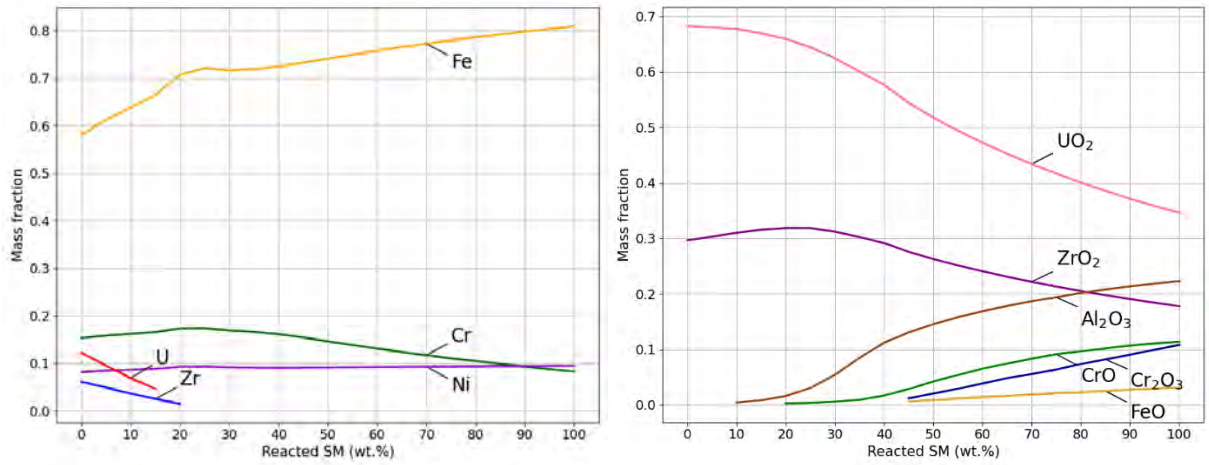
As shown in Fig. 4(a), when approximately 20 wt.% of the SM has reacted, U and Zr become fully oxidized and no longer remain in the metallic melt, leading to a decrease in the metallic melt density. With further SM participation, the composition changes in the metallic melt occur mainly between Fe and Cr, whose densities are very similar. Therefore, the subsequent increase in density should be attributed to SM interaction with and dissolution in the metallic and oxidic melts, system oxidation, repartition of elements, and decrease in liquidus temperature of the system. As shown in Fig. 4(b), the mass fractions of the lighter oxides in oxidic melt, primarily Al_2O_3, increase, while those of the heavier oxides, primarily UO_2, decrease correspondingly.



(a) (b)

Figure 4. Composition evolution of two immiscible liquid phases with increasing fraction of reacted SM: (a) Metallic liquid phase; (b) Oxidic liquid phase.

5. CONCLUSIONS

The main conclusions are as follows:

- With increasing SM fraction reacted and dissolved in the corium system, the liquidus temperature continuously decreases from 2790 K for the initial corium to almost 2100 K (Fig. 2).
- Inversion of originally top metallic and bottom oxidic layers happens after reaction and dissolution of approximately 36 wt.% of SM (Fig. 3).
- Due to the effective dissolution of low-density oxides, primarily Al_2O_3, in corium oxidic melt, its density continuously and effectively reduces from approximately 7100 to 5200 kg/m^3.
- Decrease of metal melt density before 20 wt.% of reacted SM can be explained by uranium oxidation and repartitioning into oxidic melt. Visible increase of metal melt density after 30 wt.% obviously follows its liquidus temperature decrease.

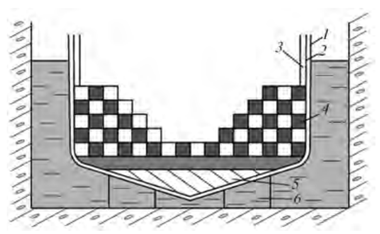
INTRODUCTION

The VVER-1000 design employs a crucible-type core catcher (CC) installed beneath the RPV to implement the ex-vessel retention (EVR) strategy for severe accident (SA) management. The CC is partially filled with sacrificial material (SM), which interacts with the relocated corium, promoting its cooling and stabilization [1,2].



1. shell, 2. bin,
3. thermal protection shield,
4. SM, 5. concrete, 6.support.

Fig.1. The scheme of CC for VVER-1000 reactor [8].

Specifically, SM is employed to promote the **inversion between the immiscible oxidic and metallic layers in the molten corium.**

This layer inversion is critical for the successful implementation of the EVR strategy as it [3]:
- o eliminate the focusing effect that locally increases heat flux at the surface of the molten metallic layer,
- o mitigate steam explosions and reduce hydrogen generation during corium top water flooding.

The present study employs a computational thermodynamics approach to investigate how varying fractions of reacted SM influence melt properties and molten pool behavior during ex-vessel melt stabilization, with particular emphasis on the melt densities and the layer inversion.

METHODOLOGY

Thermodynamic modeling to obtain phase composition at equilibrium state is performed.

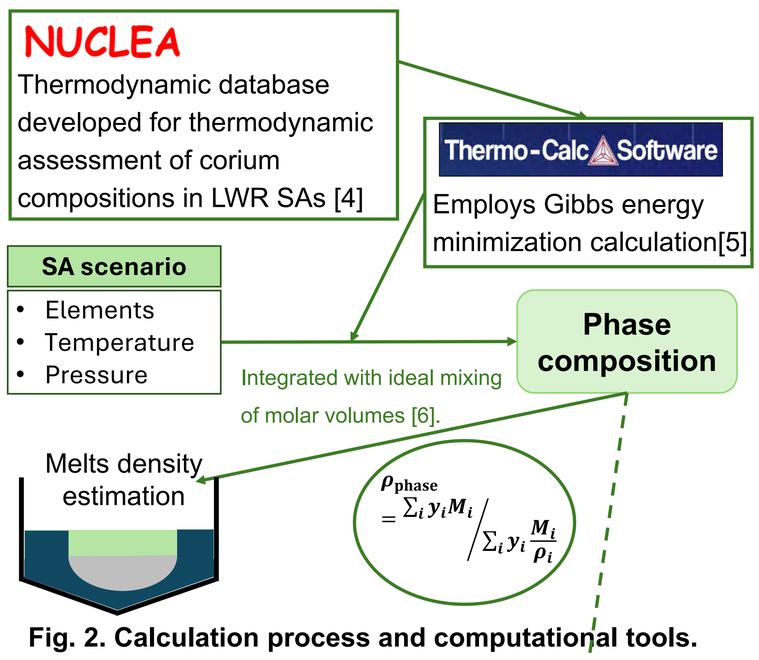


Fig. 2. Calculation process and computational tools.

By integrating additional physical properties into corium systems under diverse SA scenarios, this methodology has the potential to investigate a wide range of phenomena.

CASE STUDY

Table I. The initial system composition

	Mass	Composition
Sacrificial material	27.6 t	Fe_2O_3
	11.6 t	Al_2O_3
	0.8 t	SiO_2
	50 t	Carbon steel (Fe: 99.5 wt.%, C: 0.2 wt.%, Si: 0.3 wt.%)
Relocated corium	Oxidic melt: 28.1 t	UO_2: 68.3 wt.%, ZrO_2: 29.6 wt.%, Zr: 0.8 wt.%, U: 0.9 wt.%, Cr: 0.4 wt.%.
	Metallic melt: 88.9 t	Fe: 57.3 wt.%, Cr: 15.1 wt.%, U: 12 wt.%, Ni: 8.1 wt.%, Zr: 6.0 wt.%, ZrO_2: 1.5 wt.%.

The input data for thermodynamic analysis reflecting masses and compositions of SM and relocated corium for specific VVER-1000 SA scenario are taken from Khabensky et al. [7].

To apply the thermal equilibrium condition, the temperature used for thermodynamic modelling of the molten pool in the core catcher was assumed to be the liquidus temperature of the corium composition containing a fraction of reacted SM and dissolved in the melt.

MODELLING RESULTS

The predicted presence of these **two immiscible liquid phases** is in good agreement with the modeling results reported by Khabensky et al. [7].

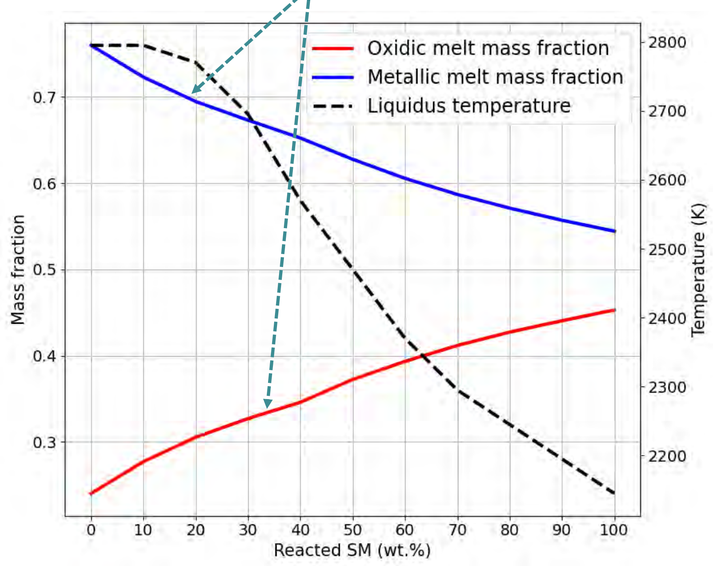

Fig. 3. Mass fractions of oxidic/metallic melts and system liquidus temperature vs. reacted SM fraction.

In the range of **30 wt.% to 40 wt.% of SM has reacted** with the relocated corium, the oxidic melt density becomes lower than that of the metallic melt.

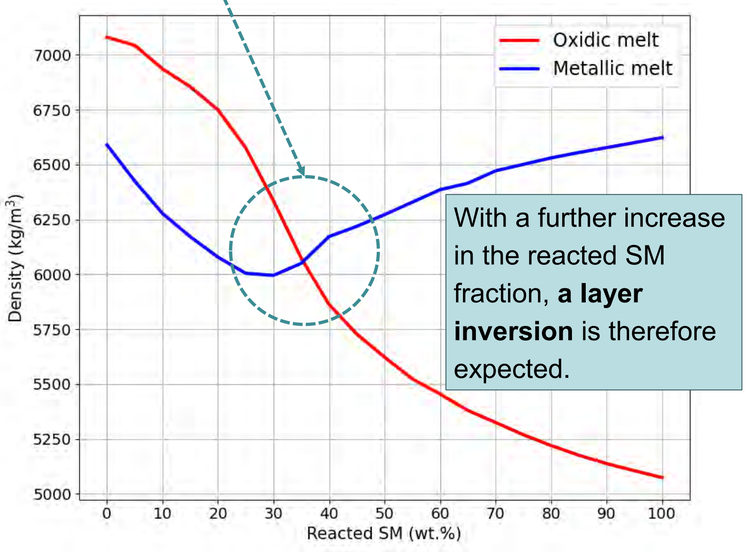

Fig. 4. Density evolution of oxidic/metallic melts vs. reacted SM fraction.

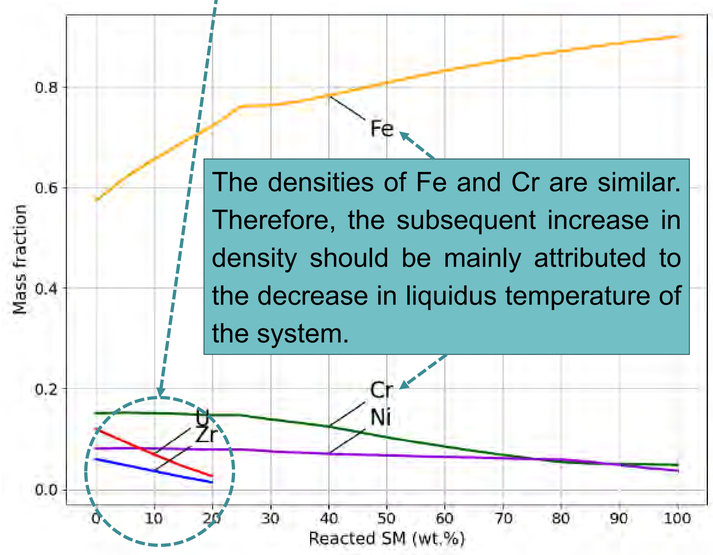
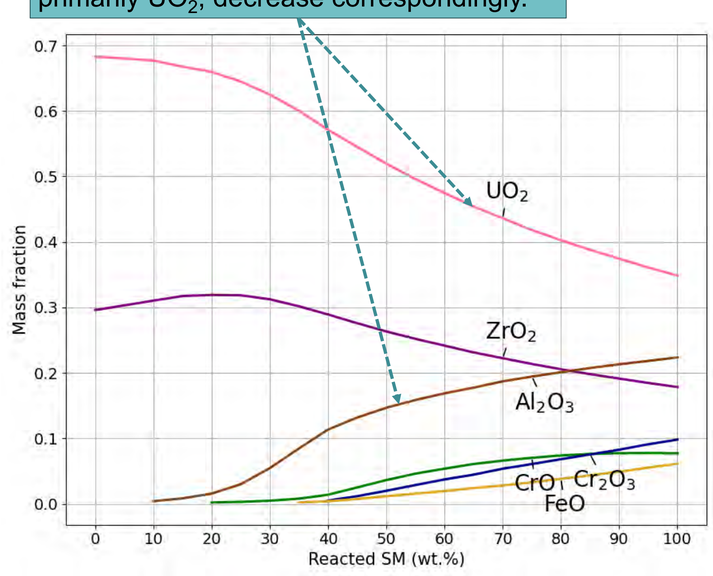
The mechanism of density variation is analyzed from the perspective of phase composition, as depicted in Fig. 5.

When approximately 20 wt.% of the SM has reacted, **U and Zr become fully oxidized** and no longer remain in the metallic melt, leading to a decrease in the metallic melt density.



(a)

The mass fractions of the low-density oxides in oxidic melt, **primarily Al_2O_3, increase**, while those of the denser oxides, primarily UO_2, decrease correspondingly.



(b)

Fig. 5. Compositions of metallic (a) and oxidic melts (b) at different fractions of reacted SM.

CONCLUSIONS

The main conclusions are as follows:

- o With increasing SM fraction reacted and dissolved in the corium system, the liquidus temperature continuously and considerably decreases from 2795 K for the initial corium to almost 2145 K (Fig. 2).
- o Inversion of originally top metallic and bottom oxidic layers happens after reaction and dissolution of approximately 35 wt.% of SM (Fig. 3).
- o Due to the effective dissolution of low-density oxides, primarily Al_2O_3, in corium oxidic melt, its density continuously and effectively reduces from approximately 7100 to 5100 kg/m^3 (Fig. 3).
- o Decrease of metallic melt density before 20 wt.% of reacted SM can be explained by uranium oxidation and repartitioning into oxidic melt. Visible increase of metallic melt density after 30 wt.% obviously follows its liquidus temperature decrease (Fig. 4).

Evaluation of accident tolerant fuel using MELCOR2.2 on representative accident sequences in typical Japanese PWR

Sekine Masashi (1), Kaneko Junichi, Kikuchi Wataru, Kojo Retsu

(1) NRA

Type of abstract: Poster
Subject area: Other applications (fusion reactors, interim SNF storage, Accident Tolerant Fuels (ATFs), etc
Keywords: ATF, Severe accident, PWR, MELCOR2.2

Accident Tolerant Fuel (ATF) has been proposed as a safety enhancement for existing nuclear reactors. ATF is expected to mitigate metal-water reactions, reduce hydrogen generation during accidents, and extend the time available for accident management before core degradation occurs. However, its influence on the progression of severe accidents has not been sufficiently investigated.

This study evaluates the effects of different cladding materials, including Zircaloy, Cr-coated Zircaloy, FeCrAl, and SiC, on cladding temperature, hydrogen generation, and the timing of lower reactor vessel head failure during representative accident sequences such as Station Blackout and Loss of Coolant Accident in a typical Japanese Pressurized Water Reactor, using MELCOR 2.2. The analysis shows that when cladding temperature remains below 1200°C, which is the criterion for a design basis accident, both cladding temperature and hydrogen generation follow the oxidation reaction rate equation. As temperature increases and the accident progresses, however, hydrogen generation from ATF cladding can become comparable to or even exceed that from Zircaloy cladding, depending on the ATF type and accident sequence. These results suggest that during severe accident progression, hydrogen generation is influenced by factors such as accident sequence and cladding melting point than oxidation kinetics alone. The study showed that differences in cladding materials affect the timing of molten core release following reactor vessel failure.

Evaluation of Accident Tolerant Fuel using MELCOR2.2 on Representative Accident Sequences in Typical Japanese PWR

NRA, **Masashi SEKINE**, Junichi KANEKO, Wataru KIKUCHI, Retsu KOJO

1. Background & Objective

Background

- Accident Tolerant Fuel (ATF) has been proposed as a safety enhancement for existing nuclear reactors. ATF is expected to mitigate metal-water reactions, reduce hydrogen generation during accidents, and extend the time available for accident management before core degradation occurs.
- However, its influence on the progression of severe accidents has not been sufficiently investigated.

Objective

- ✓ This study investigates the impact of ATF cladding materials on cladding temperature, hydrogen generation, and reactor vessel lower head failure timing in Japanese PWR accident sequences using MELCOR 2.2.

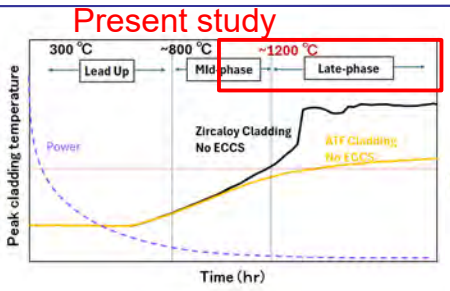

Fig. 1 Overview of cladding temperature progression under coolant-limited conditions in an LWR core.

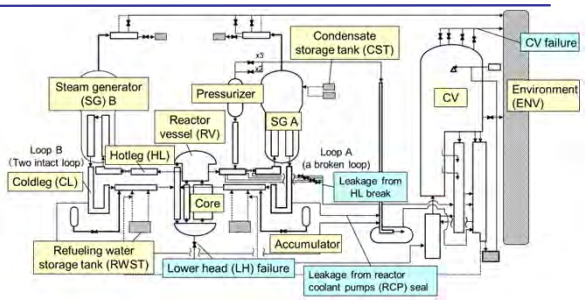

Fig. 2 MELCOR evaluation model of a typical three-loop PWR.

2. Modeling of ATF using MELCOR

	Zircaloy	Cr-coating [1, 2]	FeCrAl-ORNL [2, 3]	FeCrAl-MIT [2, 4]	SiC [5, 6]
Oxidation kinetics	MELCOR Default Model (Urbanic-Heidrick). Above 1,873 K, the oxidation model transitions to the high-temperature regime.	<1,600 K: Cr oxidation only; >1,600 K:, Zr oxidation only.	The oxidation model is based on the ORNL-developed B136Y model. Two models are considered to assess the impact of the transition temperature for iron-dominated oxidation: 1,648 K (MIT model) and 1,703 K (ORNL model).		Although both oxidation and oxide decomposition reactions can occur simultaneously for SiC, only the oxidation reaction is considered.
Melting temperature (K)	2,098 (Zr) 2,990 (Oxides)		1,773 (FeCrAl) 1,901 (Oxides)		1,804 (SiC) 2,900 (Oxides)
Failure temperature (K)	2,500		1,804	2,800	2,000

LOCA	Zircaloy	Cr-coating	FeCrAl-ORNL	FeCrAl-MIT	SiC
PCT [K]	2,497	2,499	1,804	1,901	2,900
Lower head failure timing [hr]	2.5	2.5	2.6	2.6	3.0
H² mass [kg]	343	301	347	400	450

4. Conclusion

- Analyses using MELCOR 2.2, reflecting differences in cladding materials, resulted in differences in PCT, hydrogen generation, and reactor lower head failure timing.
- These differences are mainly attributed to variations in the specified oxidation kinetics models, melting temperature, and failure temperature.
- Although cladding oxidation increases the melting temperature, severe oxidation can cause cladding failure and relocation below the melting point.
- In DBA (mid-phase) conditions, hydrogen generation from ATF is lower than that from conventional fuel. In contrast, it increases with accident progression in SA (late-phase) conditions.

QUENCH-19: Bundle Experiment on ATF FeCrAl Claddings under Severe Accident Conditions

Bachurina Diana (1), Schaefer Daniel Auri (1), Große Mirco (1), Steinbrück Martin (1), Stuckert Juri (1)

(1) Karlsruhe Institute of Technology

Type of abstract: Poster
Subject area: Other applications (fusion reactors, interim SNF storage, Accident Tolerant Fuels (ATFs), etc
Keywords: QUENCH; ATF; FeCrAl cladding

The QUENCH-19 experiment was the worldwide first bundle test to simulate severe accident conditions with accident-tolerant fuel (ATF) cladding materials. The test featured 24 FeCrAl cladding tubes developed and provided by Oak Ridge National Laboratory, along with FeCrAl Kanthal spacer grids, corner rods, and a shroud. The objective was to compare the behavior of FeCrAl cladding with conventional ZIRLO, previously tested in the QUENCH-15 experiment. The experiment was executed in four distinct stages: pre-oxidation (~6000s), transient heating (~1130s), extended constant-power heating (~1970s at 18.32kW), and termination by water flooding at a rate of 48g/s at peak cladding temperatures of ~1800K. During the test, a thin, 2–3µm protective aluminum oxide layer formed on the cladding at the highest temperature region. However, this layer was destroyed in some places, especially on the inner bundle rods, leading to complete cladding oxidation. Cladding failure occurred due to several mechanisms, including circumferential cracking from internal stresses induced by thermal expansion, eutectic interaction with thermocouples, the formation of molten FeO, and the relocation of FeCrAl melt into the gap between the ZrO_2 pellets and the cladding. Despite a longer high-power exposure (~2000s), the FeCrAl bundle produced significantly less hydrogen than the ZIRLO bundle (9.2g vs. 47.6g, respectively). The main source was the loss of the protective aluminum oxide layer and the melting of the claddings of the inner rods. The maximum hydrogen release rate reached during reflood was 280mg/s, which was considerably lower than the 1830mg/s measured in QUENCH-15. The results highlight both the advantages and challenges of FeCrAl alloys as ATF cladding materials. The key advantages are reduced hydrogen production and extended coping time, while the main challenges are their susceptibility to melt-induced degradation and oxide scale breakdown at high temperatures.

QUENCH-19: Bundle Experiment On ATF FeCrAl Claddings Under Severe Accident Conditions

Diana Bachurina, **Daniel Auri Schaefer**, Mirco Große, Martin Steinbrück, Juri Stuckert

Introduction

After Fukushima accident, focus shifted to Accident Tolerant Fuel (ATF) research.
Current goal: evaluate new materials behavior.

QUENCH-19 experiment: first bundle test with FeCrAl claddings **[1-2]**.
Serves as a benchmark to improve accident simulation codes (IAEA-ATF-TS project).

Experimental setup

Bundle Composition:

- 24 Cladding Tubes: B136Y ($Fe_{bal}Cr_{13}Al_{6.2}Y_{0.03}C_{0.01}$).
- Spacer Grids: 4 Kanthal AF.
- Corner Rods & Shroud: 7 Kanthal APM and Shroud.

Test Procedure (4 Stages):

- Stages 1 & 2: Pre-oxidation (~6000 s) and transient heating (~1130 s). Reference: Electrical power supply identical to test QUENCH-15 (ZIRLO).
- Stage 3: Constant power of 18.32 kW for ≈1970 s until expected local melting.
- Termination: Quenching at 1728 K (peak cladding temperature) via water flooding at 48 g/s.

Simulation Benchmark:

- **Collaboration**: Study involving 7 organizations.
- **Scope**: Simulation of temperature history (17 assembly elevations) and total H_2 release.

Results

The QUENCH-19 experiment resulted in a lower amount of hydrogen release (totally **9.2 g** with **1.2 g** during quench), even with longer time (**≈1970 s**) at highest temperature, compared to the **47.6 g** totally (**7 g** during quench) of the reference test (QUENCH-15).

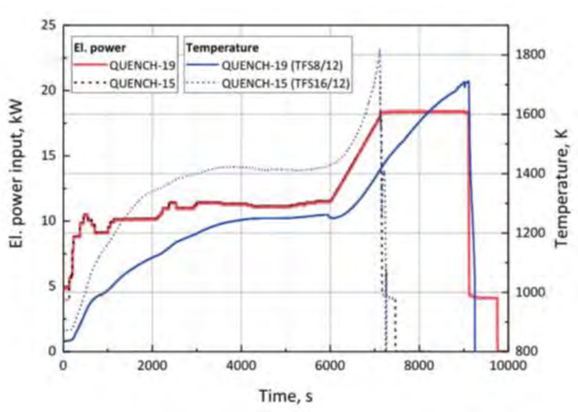

Fig. 1. Electric power input and bundle temperature in the hot zone for QUENCH-19 (FeCrAl) and reference test QUENCH-15.

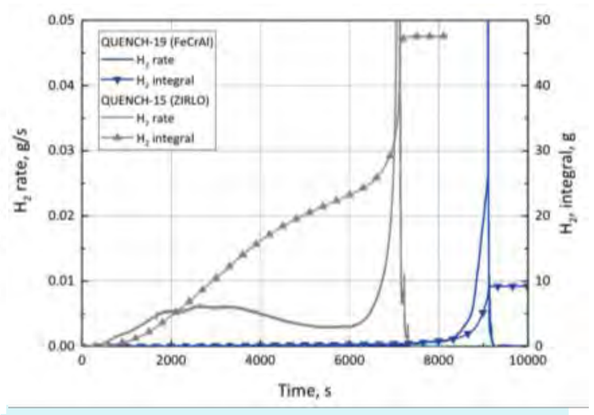

Fig. 2. Hydrogen release (total and rate) during the QUENCH-19 (FeCrAl) and reference test QUENCH-15.

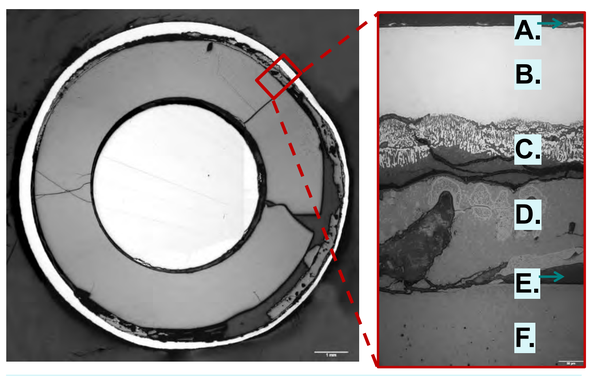
Protective Layer: Generation of a thin Al_2O_3 layer (**2-3 µm**) on the outer cladding surface.

Local Failure: Destruction of the protective Al_2O_3 layer in inner rods, leading to complete cladding oxidation.

Melt Formation: Melting of FeO oxide at T>1650 K with subsequent relocation into the pellet-cladding gap and penetration between pellet grains, resulting in pellet destruction.



A. 2-3 µm Al_2O_3 layer;
B. residual metal cladding;
C. two layers of oxidized inner surface of cladding;
D. FeO melt with (FeCrAl)Ox precipitates;
E. FeO melt;
F. porous part of the pellet.

Fig. 3. rod 1 at 750 mm: melt interaction with cladding, depicting the residual cladding, the melt relocation.

Cladding Rupture: Observed failure of the cladding tubes following the quenching process.

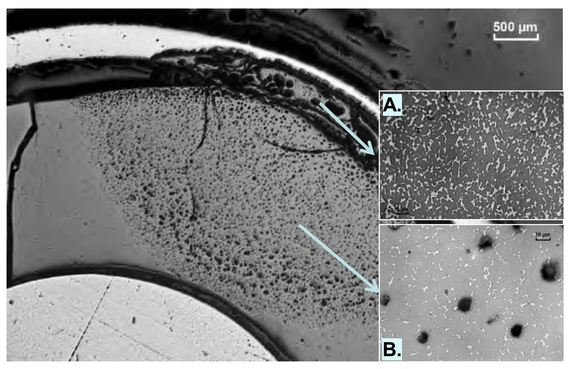


Fig. 4. rod 4 at 850 mm: interaction of melt with pellet and cladding thinning. **A.** oxidized FeCrAl precipitates (dark) in frozen FeO melt (light); and **B.** FeO melt (light) penetrated between the grains of ZrO_2 pellet.

Root Cause:

Higher thermal expansion coefficients compared to traditional Zr-based alloys.

Fig. 5. bundle side view: axial rupture of many claddings during quenching due to high thermal expansion coefficient.

Simulation Benchmark

➢ ***Temperature distributions***:

- Axial temperature: Most codes accurately predicted the position of maximum temperature at the 950 mm elevation.
- At 950 mm bundle elevation: Generally overestimated by all codes throughout the experiment.
  - **Internal Rods**: Results were considered satisfactory.
  - **Shroud**: Values were significantly overestimated.

➢ ***Hydrogen (H_2) Release*:**

- **Methodology**: All codes applied oxidation kinetic correlations from existing literature [**3 - 4**].
- Three codes achieved very good predictions for total H_2 mass, driven by accurate bundle temperature calculations.

Prediction Deviations

- **Overprediction of H_2** : Resulted from increased calculated temperatures.
- **Underprediction of H_2**: Resulted from individual modifications to the oxidation correlation for iron.

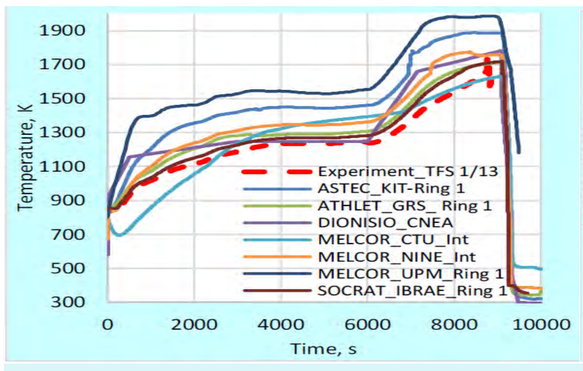

Fig. 6. Simulation for temperature progress for internal rods of the QUENCH-19 bundle. All codes overestimated the temperatures for the internal rods, but with satisfactory results.

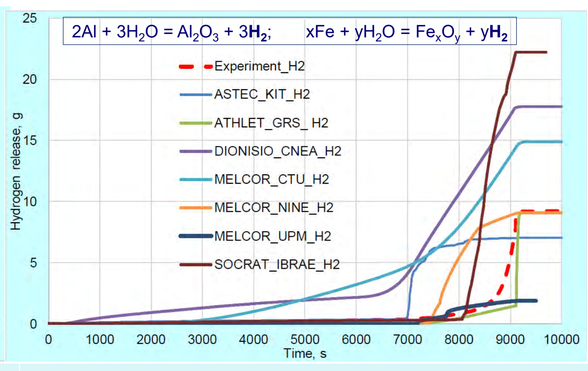

Fig. 7. Simulation results for hydrogen release during the QUENCH-19 bundle test. Good agreement with the experimental data for three codes.

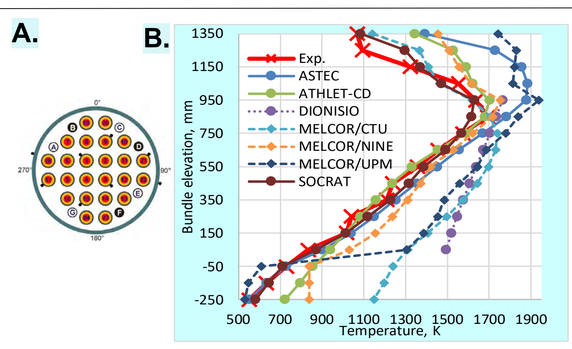

Fig. 8. A. Thermocouple disposition at bundle elevation 950 mm. B. Simulation for axial temperature distribution of the QUENCH-19 bundle for the measured values at a time 300 s before reflood.

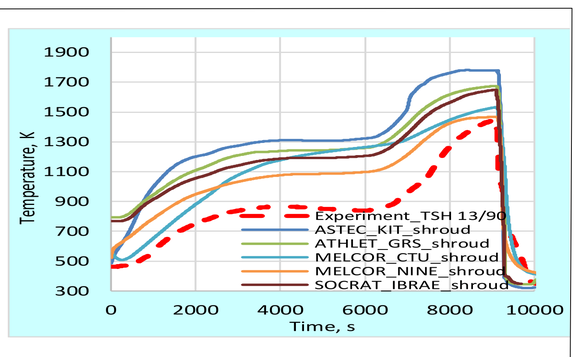

Fig. 9. Simulation for temperature progress for internal rods of the QUENCH-19 bundle. All codes significantly overestimated the temperatures for the shroud.

Conclusions

- ➢ Reduced hydrogen release for QUENCH-19 (9.2 g compared to 47.6 g in QUENCH-15).
- ➢ "Qualitative" Coping time: ≈ 2000 s for the FeCrAl claddings
- ➢ Oxidation of iron → lower melting temperature than the traditional Zry alloys.
- ➢ Higher thermal expansions coefficient of the FeCrAl alloy → failures of the cladding tubes during the quenching stage.
- ➢ Benchmark for simulating the bundle experiment: solid basis for adapting the simulation codes to new ATF materials.
- ➢ Good agreement with measured temperatures and hydrogen release achieved for some codes.

Experimental investigation of top-flooding of corium in the MERELAVA facility

Sébastien Renaudière de Vaux (1), Viviane Bouyer (1), Christophe Journeau (1), Arthur Denoix (1)

(1) CEA, IRESNE, DTN, SMTA, LEAG, Cadarache, F-13108 Saint-Paul-Lez-Durance, France

Type of abstract: Poster
Subject area: Ex-vessel corium interactions and coolability
Keywords: Ex-vessel coolability, corium concrete interaction, water ingression, experimental facility

In a severe nuclear accident scenario, the reactor core melts and mixes with other materials, forming a substance called corium. This molten mass can breach the reactor vessel, spill out below it, and interact with the concrete structure (Corium-concrete interaction). Stopping the spread of corium in this situation is critical, and this configuration is known as ex-vessel retention. A key strategy for ex-vessel corium cooling involves top-flooding, whereby a solidified crust forms atop the corium and subsequently fractures. This process enables water to penetrate the crust's pores, enhancing heat extraction through boiling and latent heat mechanisms. This phenomenon is known as water ingression. Studied for over two decades, this mechanism remains a critical focus of nuclear safety research, as it is not fully understood to this day.

To further investigate water ingression, the MERELAVA facility was designed and built at CEA Cadarache. One of MERELAVA's key advantages is its ability to include a concrete layer beneath the corium, which allows to explore how water ingression behaves when corium interacts with concrete. Additionally, following the in-situ thermite reaction to generate up to 80 kg of corium, some trials employed an electromagnetic inductor to simulate decay heat, providing deeper insights into cooling dynamics under realistic conditions, in order to highlight steady-state coolability.

The unique features of the MERELAVA facility enable to investigate the water ingression mechanism in depth. The facility's instrumentation and capabilities provide a foundation for future experiments.

EXPERIMENTAL INVESTIGATION OF TOP-FLOODING OF CORIUM IN THE MERELAVA FACILITY

Sébastien RENAUDIÈRE DE VAUX, Viviane BOUYER, Christophe JOURNEAU, Arthur DENOIX

Energy Division – Severe accident experimental laboratory – Cadarache Center

Funding partners: anr© INVESTIR L'AVENIR EDF framatome

I - THE MERELAVA FACILITY: STUDY OF WATER INGRESSION

Top flooding of corium with water is a key strategy for severe accident mitigation, in the ex-vessel phase. The extracted heat flux is higher than the classical view of the conductive heat flux, thanks to the **water ingression phenomenon**.

Understanding how this phenomenon impacts the **sacrificial concrete ablation rate** is crucial for nuclear power plant safety. In the **CEA center of Cadarache**, the **MERELAVA facility** (Fig. 1) was built to study in depth the mechanisms at play, and the effect of the melt composition.

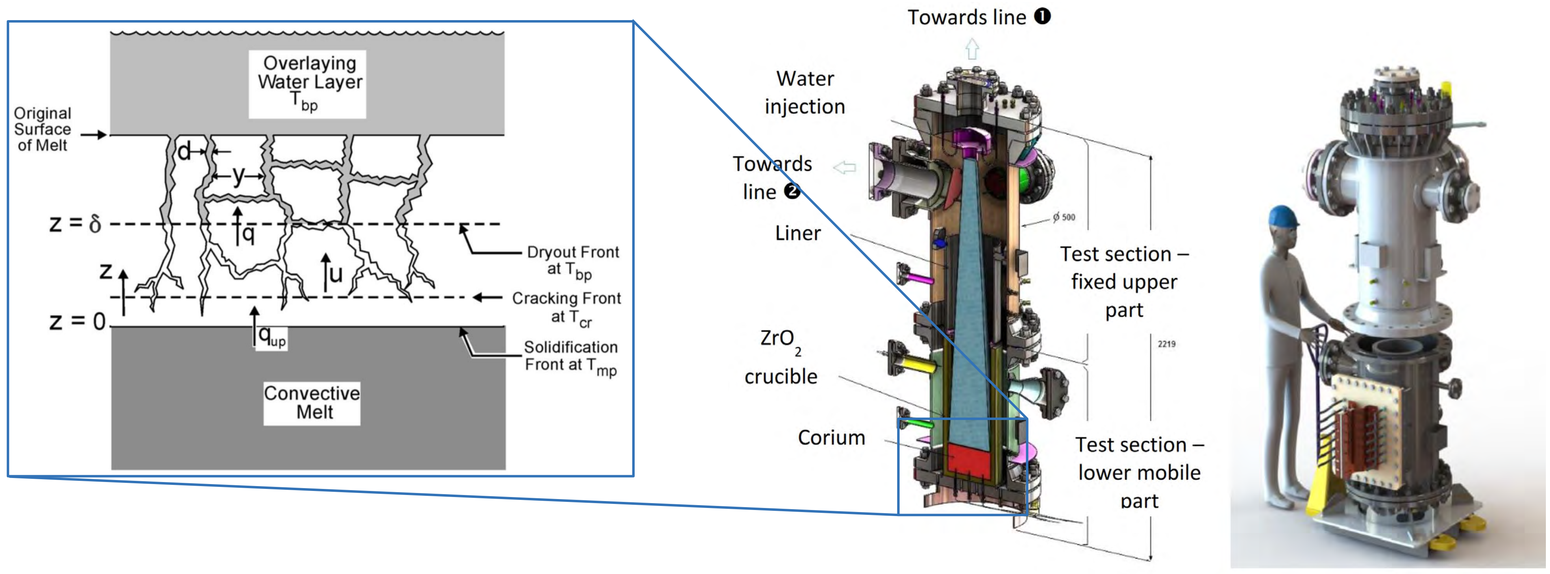

Fig 1. Water ingression mechanism [1] and sketch of the MERELAVA test-section [2] with and without induction heating.

II - TEST CONDITIONS AND SETUP

Possibility to use induction heating to mimic decay heat
→ tests ME-U4 and ME-U5;
→ concrete ablation.

The main parameters of the five tests presented are summarized in this Table.

	ME-U1	ME-U2	ME-U3	ME-U4	ME-U5
Initial melt composition (mass %)	UO_2/ZrO_2/Concrete/Cr: 64/26/4/6 (sand/lime)	UO_2/ZrO_2/Concrete/Steel: 54,4/23,3/8/14,3 Siliceous	UO_2/ZrO_2/Concrete/Steel: 49,9/21,4/13,6/15,1 Siliceous	UO_2/ZrO_2/Concrete/Steel: 54,4/23,3/8/14,3 Same as ME-U2, Siliceous	UO_2/ZrO_2/Zr/Steel/FP simulants: 37/25/25/9/3
Liquidus temperature	1797°C	2329°C	2202°C	2329°C	2353°C
Induction heating and concrete ablation	✗ No induction	✗ No induction	✗ No induction	✓ Induction heating during the whole trial / several cm of concrete ablation	✓ Induction heating only during the initial instants→ only ~ 1 – 2 cm ablation
Volume of water injected	91L in 13 injections of ~7L each/ average flowrate 8.4L/min	~74L in 9 injections of ~8.2 L each/ average flowrate 8L/min	~72.8L in 9 injections of ~8.5±0,9L each / average flowrate 8.8L/min	~74L in 9 injections of ~8.2L each average flowrate 8.8L/min	~74L in 9 injections of ~8.2L average flowrate 8.8L/min (same as ME-U4)

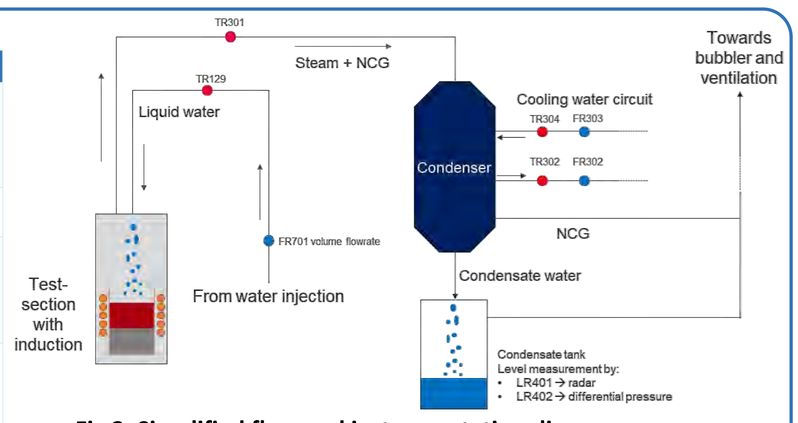

Fig 2. Simplified flow and instrumentation diagram.

III - FOCUS ON THE FIRST TEST WITH INDUCTION HEATING: ME-U4

A - WATER INJECTION SEQUENCE AND VOLUME HEATING

Electromagnetic power is started at the end of the thermitic reaction [3], and is gradually increased until coupling with the melt is ensured. After, power is reduced and varied manually during the test.

Water is injected by successive sequences of ~8 to ~9 liters, for safety reasons.

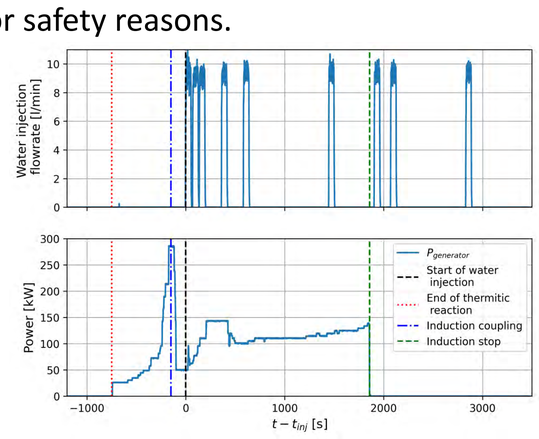

Fig 2. Water injection sequence and power injected during the trial.

B - HEAT FLUX ESTIMATES IN ME-U4

Two methods are used to measure the condensate flowrate:

1. Direct measurement of water level in the condensate tank (CT) by radar sensor (LR401): strongly perturbed by surface waves;
2. Measurement of differential pressure between the top and bottom of the tank (LR402). Assuming that the water is at rest, the flowrate is:

$$\dot{m}_{cond} = \frac{\pi R_{tank}^2}{g} \times \frac{d\Delta P_{LR402}}{dt} = \rho \pi R_{tank}^2 \times \frac{dz_{tank}}{dt}.$$

Both methods show similar tendencies, but due to the high noise level on the radar sensor, the differential pressure is selected for further analysis.

Then, two methods can be used to estimate the heat flux density in this configuration:

1. Injection temperature is close to saturation:

$$q'' \approx \dot{m}_{cond} h_{lv} / S_{pool}$$

with $\dot{m}_{cond}$ the condensate flowrate (LR402) in the condensate tank (CT) and h_{lv} the latent heat of vaporization.

2. Direct measurement from the heat exchanger (HX) as:

$$q'' = \dot{m}_{HX} c_p \Delta T_{HX} / S_{pool}$$

with $\dot{m}_{HX}$ and ΔT_{HX} the mass flowrate and temperature difference on the secondary side of the HX.

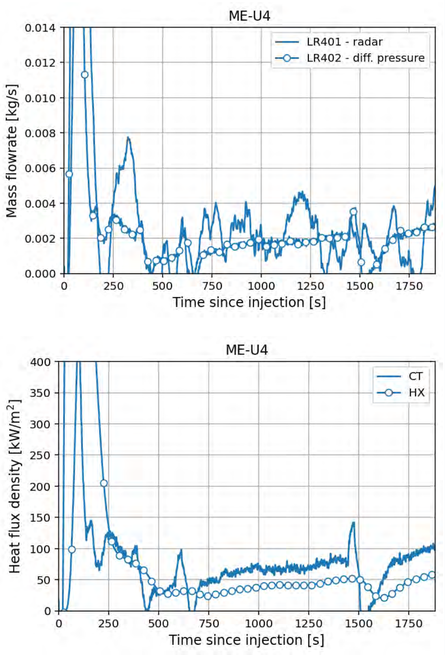

Fig 3. Steam (condensate) mass flowrates and heat flux density estimates.

C - MATERIAL REPARTITION IN ME-U4

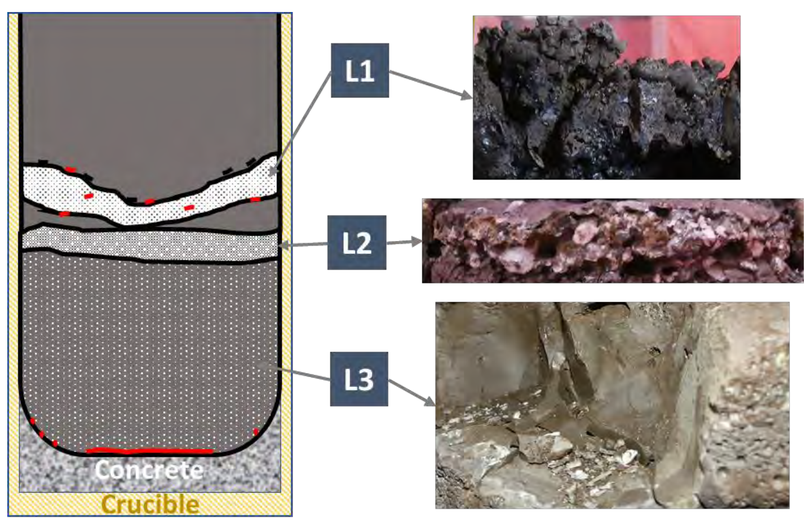

Fig 4. Material repartition in the ME-U4 test after cooling.

Main observations:

- Layered configuration in ME-U4
- Fractured layer (L1) on top of the block
- Concrete agregates in the upper part of the melt (L2)
- Compact corium layer (L3)

III - CONCLUSIONS

- **ME-U4 is the first test** carried out in the MERELAVA facility **with induction heating and concrete ablation.**
- Two methods for **heat flux estimates** are used and show consistent results.
- Results are **consistent with previous findings** of experimental programs. Analysis of melt after cooling reveals a **layered configuration** in the ME-U4 test.
- Future work will focus on data interpretation and in the experimental setup improvement.

ABSTRACT

Wetwell or pressure suppression pool in Boiling Water Reactors plays a vital role in severe accident mitigation by acting as a heat sink for escaping steam from the reactor primary system, a source of water for the emergency core cooling system, containment spray system and flooding of the cavity for debris cooling and retaining fission products released to the containment. During a station blackout accident (SBO) large amount of steam is discharged into the wetwell upon activation of the Automatic Depressurization System spargers. MELCOR is used in this study to simulate SBO in a Nordic BWR to characterize the conditions of steam and gases entering the pool, and retention of the fission products in the pool. The thermal hydraulic behaviour of the pool is also analyzed. The effects of MELCOR modelling parameters on the mass of fission products, mainly cesium and iodine mass fractions, in the pool are determined by sensitivity analysis performed in combination with DAKOTA. Correlation measures and Morris global sensitivity metrics for the modelling parameters are determined. It is observed that, unlike as in LOCAs, the mode of melt ejection from the vessel is not one of the major sources of uncertainty in SBOs. It is seen that aerosol agglomeration, CORSOR-Booth diffusion, and vapour diffusivity models are the most significant to the uncertainty in mass of fission products retained in the pool.

KEYWORDS
MELCOR, Nordic BWR, wetwell, fission product behaviour, severe accidents, DAKOTA

1. INTRODUCTION

Pressure suppression pool (PSP), or the wetwell (WW), is a defining safety feature of Boiling Water Reactor (BWR) containments. During loss of coolant accident (LOCA), steam is directed via blowdown (BD) pipes into the submerged pool where it condenses. This process simultaneously scrubs the fission products (FPs) – both aerosols particles and vapours – from the gas stream as bubbles rise through the water, thereby performing a critical function of radioactive source term reduction. As a consequence, during possible ex-vessel phase of the accident, the pool may boil by the decay heat of the ejected debris leading to remobilization of FPs. Post Fukushima Daiichi accident of 2011, research has intensified focus on this scrubbing phenomenon under extended severe accident sequences like station blackout (SBO), where pool dynamics are paramount [1]. A significant finding across studies is the large uncertainty in accident progression analysis, often due to incomplete knowledge of system states and complex, coupled phenomena. Reducing these uncertainties, especially regarding FP retention and source term release, is essential for reliable risk assessment and is fundamentally tied to the thermal-hydraulic behaviour of the WW [2][3][4][5].

The containment's pressure response depends on the WW's suppression function. Impairments such as thermal stratification can degrade condensation efficiency, potentially leading to sharp pressure spikes as witnessed at Fukushima [1]. The WW's performance is governed by competing processes: stratification

induced by steam injection into subcooled water, and mixing driven by pool convection or operator actions like spray initiation. These conditions create a dynamic environment that can either enhance scrubbing or lead to the re-release of deposited FPs [18]. Analytical tools for FP scrubbing include dedicated pool scrubbing codes like SPARC-90 [6], SUPRA [8] and BUSCA [7], which are implemented and validated within integrated severe accident codes such as MELCOR [9] and ASTEC [10]. Experimental programs like EPRI/BCL [11], POSEIDON [12], LACE-España [13], and the more recent OECD/NEA IPRESCA project [14] provide data on decontamination factors and hydrodynamics under prototypic pool conditions.

In the context of Nordic BWR, uncertainties relating to source term in Nordic BWRs are being assessed at KTH under the Risk Oriented Accident Assessment Methodology+ (ROAAM+) with the aim of improving current methodology for addressing safety issues [19][20][21][22][23][24][25]. The thermal-hydraulic performance of the WW during severe accidents is being studied in [15][16][17][18]. The present work extends the MELCOR analysis performed earlier in [24][25][32], to the uncertainties in the Nordic BWR WW response to SBO, and its effect on FP retention within the WW.

2. APPROACH AND METHODOLOGY

2.1. Nordic BWR Model Description

In continuation with the previous work performed to analyze LOCA, the input deck developed for the Oskarshamn Unit 3 with MELCOR v1.8.5 and subsequently upgraded to v2.2.18019 and maintained at KTH, was used in this study. Briefly, the reactor of study – as shown in Figure 1 is described here and for complete details can be found in the literature [23][25][26]. The model comprises of reactor pressure vessel (RPV) and the containment (CNT) represented by 27 control volumes (CVs), connected with 45 flow paths (FLs) and 73 heat structures (HSs). The vessel is represented by 6 rings and 19 axial levels, with the first 10 axial levels representing the lower plenum (LP); the 11th level represents the core support plate; 12th and 19th represent the core inlet and outlet regions; and levels 13-18 represent the active core region. The core is represented by 5 radial rings and the 6th ring represents the downcomer region.

2.2. SBO Accident Description

For the Nordic BWR Level 2 PSA, of the 6 main release categories, RC4 containment bypass scenarios – transients like SBO or LOCA – majorly contribute to unacceptable release frequency and large early release frequency. Since the Fukushima accident, SBO has been a focus of many studies with modern computational tools. Here, the reactor experiences a simultaneous loss of the offsite power (LOOP) and diesel backup generators, which leads to complete loss of safety systems – high pressure and low pressure injection and spray systems – eventually causing core damage. The only systems available in the RPV for the removal of decay heat are the safety relief valves (SRVs) that are installed on the main steam lines, shown in the figure above as System 314 (FL314), to protect against over-pressure and operate as automatic depressurization system (ADS) that allow for coolant injection to the RPV (here unavailable). The other system available as a heat sink is the WW.

Once the turbine valves close and is isolated with no steam dump, the system 314 valves controls the pressure at 7MPa, maximum 7.05MPs. From the 4 main steam lines 64 blowdown pipes end in the WW pool which comprise the spargers discharging steam. Initially this performs a safety relief function. Upon sensing low downcomer level (L6 - 1m below top of active fuel (TAF)), ADS is initiated with all valves fully open. This action, while reducing primary pressure, also causes rapid loss of coolant and core uncovery. The steam from the blowdown heats the drywell, gradually increasing the pressure of the CNT. Uncovery of the core oxidizes the cladding, overheats the fuel elements and leads to their failure. Hydrogen released as a result also discharges along with steam into the WW space. FP aerosols and vapours released as cladding fails are forced in through the steam lines into the WW, where they are largely scrubbed at the vent exit. The debris so formed slumps to the core support plate, which fails leading to debris pool formation in the lowerhead (LH). With quenching of the slumped debris, water from the lower plenum (LP) now as superheated steam exits the RPV into the WW thereby rapidly increasing containment pressure. Though the peak pressure observed during this instance does not exceed the filtered containment venting (FCVS) limit (5.5bar), it is high at 2bar. The LH walls and control rod/instrumentation penetrations then fail under thermal stress or over-temperature, thereby ejecting debris and molten material to the cavity.

Timing of the above events as calculated by MELCOR for a reference case of SBO are presented in Table I. As a severe accident management (SAM) strategy cavity flooding is employed in Nordic BWRs for debris cooling during the ex-vessel phase. On detecting low downcomer level (L4 - 0.5m above TAF) water from the WW floods the lower drywell (LDW) cavity with a 600s delay, in preparation to arrest further progression of the debris. Upon ejection from the RPV the debris quenches and forms a cooled bed with negligible attack on the concrete floor, if any. In its absence, an uncoolable debris bed causes basemat failure by molten core concrete interaction (MCCI) or failure of the cable penetrations in the floor. However with this strategy there is a larger risk of energetic fuel coolant interaction (FCI), like a steam explosion (SE), that can compromise the containment integrity. An assumption is made for this RC4 accident that upon RPV failure, coincidentally the containment fails due to ex-vessel phenomenon, with a pathway for FPs opening to the environment. This is modelled as a $2m^2$ flowpath from the upper drywell (UDW). This effectively voids activating FCVS as the CNT is instantly depressurized.

Table I. Key events and timing during SBO.

Key event	Time [h]
L4 level	0.2
Uncovery of core	0.23
L6 level	0.31
Gap release	0.56
Particulate debris formation	0.62
Relocation to lowerhead	2.01
Core plate failure	2.01
RPV failure	2.73
LDW boiling	2.73
WW boiling	20

Mode of debris ejection to the cavity (parameter IDEJ in MELCOR, 0 (default) for both solid + molten, and 1 for molten) is a significant factor affecting uncertainties in FP release and behaviour during the ex-vessel

phase of the accident [25]. In the default case, when both solid and molten debris are ejected, all the mass and associated decay heat transfers to the cavity almost in short span (large release) or in small quantities (dripping mode), leaving no significant quantities of debris to remelt and eject later on. Whereas in IDEJ1, Hence, 2 splinter scenarios SBO-IDEJ0 and SBO-IDEJ1 are considered for study here.

2.3. Uncertainty Analysis using DAKOTA

MELCOR models are sensitive to input parameters, some more significant than others. Relying on a single calculation is therefore unreasonable, and quantification of sensitivities and uncertainties is necessary in safety evaluation. Firstly, based on literature, significant phenomena and 50 underlying uncertain parameters were listed. Then, an initial screening for sensitivity was performed if the selected figures-of-merit (FOMs) were greater or lesser than 50% of the reference case values. Subsequently, a calculation matrix with the 18 screened parameters was developed using DAKOTA [30] to perform Morris global sensitivity analysis [28] for each (IDEJ0 and IDEJ1) accident scenario and identify the most significant parameters to the respective FOMs. Here, with 5 level input space and trajectory of length 20, 380 samples were generated per splinter. Following Morris sensitivity analysis, uncertainty quantification is performed with 160 code runs for each of the splinter scenario with cases generated using Latin Hypercube Sampling (LHS) method. This sample number can yield good results with 95% confidence for one sided bound [29]. A MATLAB simulation platform couples DAKOTA and MELCOR input/output files to generate input, run simulations, and post-process the results. It automatically handles cases that crash by restarting them with time-step refinement. It should however be noted that time step itself is a parameter of significance, as accident progression varies for different time-step description [21].

For the application in this study cesium mass fraction and iodine mass fraction are selected as FOMs. More details of the methodology can be found in [23][24]. A total of 50 parameters were selected and 18 of them were screened for SBO. The list of uncertain parameters and their ranges considered is presented in APPENDIX A. For SBO, aerosol agglomeration shape factor (GAMMA), critical breach temperature in oxide shells (SC11312), activation energy in the CORSOR-Booth model (SC710641) and multiplication constant in the inertial impaction DF correlation for large Stokes number (SC71555) were found to be most significant for cesium and iodine (mainly as CsI) release in the source term [23][24]. The effect of these parameters, that are significant to source term, in modelling pool behaviour and retention is addressed.

3. MELCOR PHENOMENA MODELLING

MELCOR is a fully integrated, engineering computer code that comprises of several modules or packages that calculates equations concerning different phenomena occurring in a typical accident, core degradation, thermal-hydraulics, radionuclide (RN) release, transport and behaviour, structures oxidation, corium concrete interactions, to name a few. While MELCOR tries to mimic the complex nature of severe accidents, it is in some aspects limited by the nature of the code itself and the underlying assumptions. Specific to FP retention in the WW are the phenomena of instantaneous steam condensation upon exit from the sparger vents of the ADS valves, overestimation of water mass for decontamination, insufficient consideration of inertial impaction, and overestimation of the bubble breakup with submergence [27]. As the WW here is assumed to be a single CV, all the thermal-hydraulic properties are lumped together with no higher spatial resolution, in particular for thermal stratification and associated behaviour. Below, a brief description of choices made for important MELCOR RN release and transport models is provided [32].

3.1. Fission Product Release from the Core and Transport

The present study employs the revised CORSOR-Booth model (ICRLSE = -5 parameter in MELCOR) to simulate fission product release from high-burnup fuel. This formulation accounts for mass transport limitations by utilizing the Booth diffusion model alongside empirical correlations for cesium release, with

release fractions of other radionuclide classes scaled relative to the cesium release rates. The model was updated to reflect findings from the Phebus FPT1 experiments, that revealed cesium release speciation deviated from earlier assumptions. Specifically, the release was reformulated to consider cesium transport not only as cesium hydroxide (CsOH) but also as cesium molybdate (Cs_2MoO_4). Accordingly, radionuclides are grouped into 17 classes, with cesium represented in three distinct classes: CsOH (Class 2), CsI (Class 16), and Cs_2MoO_4 (Class 17). All vapour-phase iodine (Class 4) is assumed to combine with cesium to form CsI – a simplification, as the present MELCOR model does not treat detailed iodine pool chemistry. Initial FP inventory in the core is shown in Table II. Volatile fission products may be released at moderate temperatures, even prior to significant core degradation. Once released from the fuel, fission products may exist as vapours or aerosols depending on their class-specific vapour pressure and local temperature. Condensed particles are transported by bulk fluid flow as aerosols. These particles are also subject to Brownian diffusion and gravitational settling. Aerosols are tracked across discrete size sections with varying chemical compositions. Their distributions evolve due to five primary processes: (i) condensation and evaporation of water and fission products, (ii) particle agglomeration, (iii) deposition onto surfaces, (iv) advection between control volumes, and (v) engineered removal via filters, sprays, and pool scrubbing. While deposited aerosols can typically be resuspended and revapourized, resuspension was deactivated in this study, though all deposition models remained active.

Table II. Initial inventory of the first 12 RN classes in the core [kg].

XE	CS	BA	I_2	TE	RU	MO	CE	LA	UO_2 [ton]	CD	AG
505.4	292.5	226.2	22.8	44.5	334.6	382.2	647.3	622.4	12.6	1.5	9.4

3.2. Pool Scrubbing

Steam, gases and aerosols exiting a submerged vent into a pool are modelled to form large unstable globules that breakup into smaller bubble swarm that saturates with local conditions, rises upwards at a constant velocity and eventually break at the surface. Gases, such as hydrogen (non-condensable gases (NCGs)) instantly form thermal equilibrium with the pool. Absence of NCGs lead to condensation of a fraction of vapour (steam) in the bubbles that increases pool mass while remaining is transferred to the atmosphere. These processes ultimately remove FP aerosols and vapours from the injection material into the pool. This is quantified using the decontamination factor (DF), defined as the ratio of the mass of a radioactive material entering the pool to its mass leaving the pool.

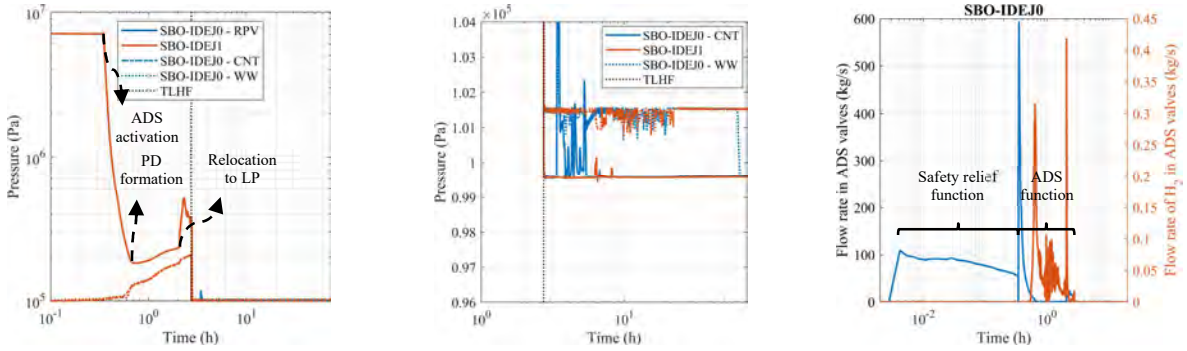
The DF is calculated as the product of contributions from three successive regions: (i) Injection zone – at the vent exit, removal occurs due to: (a) Stefan flow from steam condensation, (b) inertial impaction and interception, especially for high-velocity jet regimes, and (c) centrifugal, diffusional, and gravitational deposition, particularly for multi-hole vents; (ii) Bubble swarm rise zone – during ascent, hydrodynamic interactions cause bubbles to coalesce and redisperse. Aerosol removal within each bubble continues via centrifugal, diffusional, and gravitational deposition. Particle size may also change due to steam absorption or evaporation, while vapours are removed primarily by diffusion; (iii) Pool surface zone – when bubbles break at the surface, droplet entrainment may carry fission products upward, with some droplets settling back by gravity. The efficiency of scrubbing depends on several factors, including vent submergence, pool subcooling, inlet velocity, particle size, and gas composition (steam and NCG content) [27]. In this study, all applicable scrubbing models are activated for the vent of interest, the ADS valves and BD exit, and not elsewhere (e.g., overflow pipe exit) to maximize decontamination.

4. RESULTS AND DISCUSSION

Results of MELCOR simulations for the reference SBO cases, sensitivity and uncertainty analysis are provided here. Of the few code crashes observed (<10%), all were successfully completed after a restart.

4.1. Wetwell Thermal-hydraulics

The wetwell behaviour in the reference MELCOR SBO case is provided here, for both IDEJ0 and IDEJ1 scenarios. All calculations have been run for 72h. The pressure in the RPV and the WW is shown in Figure 2(a) and (b). Following activation of the ADS at 0.34h, primary pressure rapidly reduces until active core is almost uncovered and cladding starts to melt. By then, most of the coolant inventory has transferred to WW. Subsequently, during the core degradation phase the pressure in the RPV increases gradually, as well as the pressure in the WW. Once debris slumps to the LP and is quenched, a small pressure spike is observed in the RPV. Following failure of the LH (LHF), the RPV is almost at the environment pressure (due to CNT failure at RPV). The flow rate of steam and hydrogen through the ADS valves is shown in Figure 2(c). The steam flux corresponding to the 2 functions of the ADS is shown in Figure 3(c).



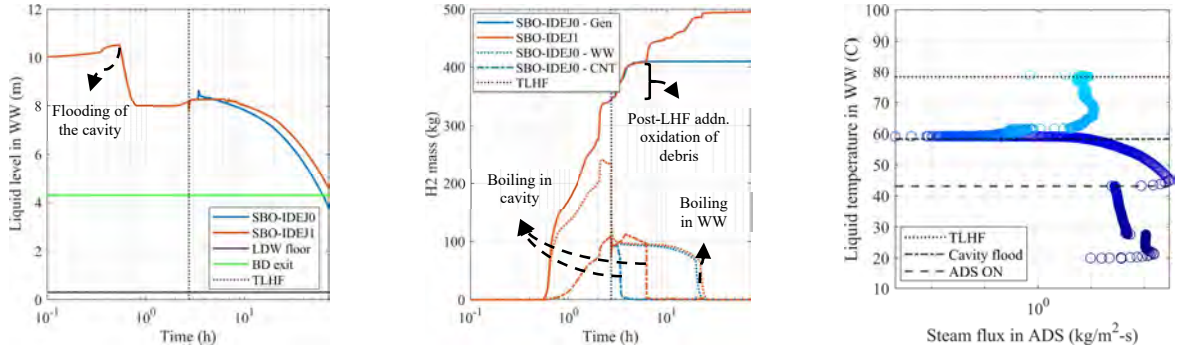
(a) Pressure in the RPV, CNT and WW.

(b) Pressure in CNT and WW (enlarged).

(c) Flow rate (of steam and H_2) in the ADS valves (FL314).

Figure 2. Time evolution of parameters in the reactor.

During the safety relief function to control the RPV pressure at ~7MPa, steam flux through the ADS valves is about 25-45kg/m^2-s. This roughly corresponds to condensation oscillation regime [31], where steam inflow rate is smaller than steam condensation rate, at relatively low pool bulk temperature. During ADS function, where steam flux reaches a maximum of 300kg/m^2-s, it forms a jet – the jetting regime – that holds its shape for some time as the steam condenses and other vapours and FPs are scrubbed. Following this, the steam flux gradually reduces as it bubbles through the valves, corresponding to slightly higher pool temperatures. During the peak pressure induced by quenching, a flux of about 10kg/m^2-s is observed. Hydrogen generated as a result of oxidation of the core is shown in Figure 3(b).



(a) Collapsed liquid level in the WW.

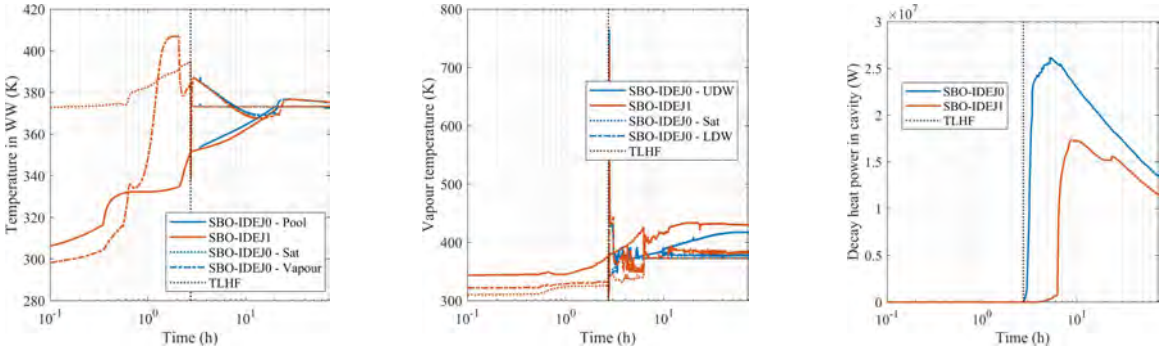
(b) Hydrogen generation and accumulation.

(c) Steam flux of the ADS against pool temperature.

Figure 3. Time evolution of parameters in the reactor.

Along with steam, a major fraction of H_2 is transferred to WW with almost 230kg at the time of LHF accumulated in the WW. A smaller fraction of H_2 generated, about 100kg at LHF, is transferred also the CNT through the vacuum breakers, which are activated when the WW has a greater pressure than the CNT.

Roughly 130kg of H_2 from the WW flows to the CNT and eventually to the environment when the RPV and the CNT fails at 2.73h. Subsequently when the cavity starts to boil producing large amounts of steam in the CNT, all H_2 from the CNT is expelled. Similarly, when the WW starts to boil, roughly at 20-25h depending on the scenario, all H_2 from the WW is also displaced. The liquid level in the WW is shown in Figure 3(a). As the WW is the source for the cavity flooding SAM strategy, at 0.54h liquid level falls by 2m, and once the RPV fails and boils away the water in the cavity, WW continuously replenishes it. Thereby, gradually the WW pool temperature, see Figure 4(a), increases while the liquid level reduces until it starts to boil.



(a) Temperature in the WW. (b) Temperature in the CNT. (c) Decay power in the cavity.

Figure 4. Time evolution of parameters in the reactor.

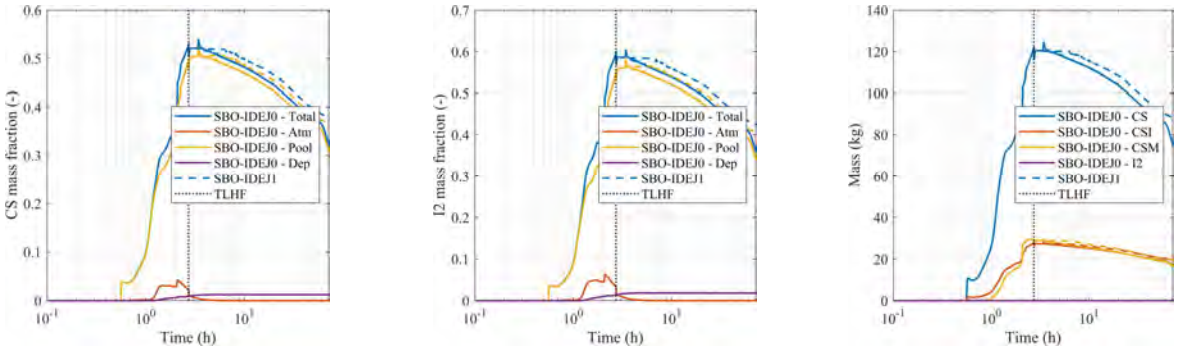
By the end of 72h, WW liquid level has fallen to less than 4m, about 0.2m below exit of the BD pipes in the case of IDEJ0 and about 0.2m above exit of BD pipes in the case of IDEJ1. Differences between the two scenarios arise due to magnitude of decay power that is ejected to the cavity, shown in Figure 4(c). In the case of IDEJ1, large mass of molten debris is ejected at 6.5h instead of ~3h in case of IDEJ0. The final magnitude of debris ejected is slightly lesser in IDEJ1 than IDEJ0 as well. In IDEJ1, the remaining solid debris in the RPV, combined with molten debris being cooled in the cavity water, leads to higher vapour temperature (430K v/s 415K) in the UDW, shown in Figure 4(b). Post-LHF the damaged core in the RPV also leads to generation of ~95kg more H_2 in IDEJ1 than in IDEJ0, especially once cavity pool boils generating steam that flows in to the RPV through the breach in the LH.

4.2. Fission Product Behaviour

As mentioned earlier, FOMs considered in this study include cesium (CsOH, CsI and Cs_2MoO_4) and iodine (I_2 and CsI). The relative masses of these species in the WW during SBO-IDEJ0 and IDEJ1 and the absolute masses are shown in Figure 5(a), (b) and (c). Unlike in the case of LOCA where the maximum mass fraction of CS and I2 is about 0.23 and 0.25 [32], here during SBO the maximum mass fractions are more than twice, about 0.5 and 0.6 respectively. One can observe from Figure 5(a) and (b) that majority of CS and I2 in the WW is retained in the pool phase (>90%).

From the onset of gap release from the fuel matrix up to ~1.1h, FPs in the atmosphere phase of the WW control volume are negligible. Once the steam injected comprises large amounts of NCGs and is at temperatures greater than the saturation temperature, FP retention in the pool appears to reduce and RN mass in the atmosphere phase can be observed. Around 0.02 and 0.03 atmosphere mass fractions, and 0.01 and 0.02 deposited mass fractions of CS and I2 respectively are accumulated in the WW at time of LHF. During the ex-vessel phase the retained CS and I2 masses in the WW gradually reduce as a consequence of, (i) the WW inventory refilling the cavity and (ii) the WW pool boiling itself that re-entrains soluble FPs (particularly CsI) and vapours, seen as gradual reduction of CsI and CsM post LHF in Figure 5(c). The SPARC-90 model, and its implementation in MELCOR, generally assumes high retention when the pool is subcooled. When boiling occurs, the assumptions that lead to high retention (like efficient aerosol deposition in bubbles) are severely challenged, reducing the overall fission product scrubbing efficiency [33][9]. In the

case of IDEJ0, where the water in the WW is lost to the environment faster than in IDEJ1, by ~60h the liquid level falls below BD exit. Until then, the only meaningful pathway for the FPs to the CNT was through the pool along the valve connecting WW to cavity. However, after uncovery of the BD exit, all airborne aerosols and vapours have a direct course to the UDW, which is seen a rapid fall in CS and I2 fractions retained in the WW after ~60h. Looking closer at Figure 2(b), the pressure in the WW finally equalizes with the CNT at ~60h for this reason.



(a) Cesium mass fraction. (b) Iodine mass fraction. (c) Absolute mass of species.

Figure 5. Time evolution of FPs in the WW.

The decontamination factors at the ADS valves and the mass median diameters (MMD) of the airborne aerosols in the UDW, RPV and WW for the two accident scenarios are shown in Figure 6. Here, the MMD for RPV is from the steamdome that is at the top of RPV, just before steam lines, and is assumed to be the inlet CV for the ADS flowpath. From the time of PD formation the MMD in the RPV increases to ~5μm roughly corresponding water level in the RPV falling to LP.

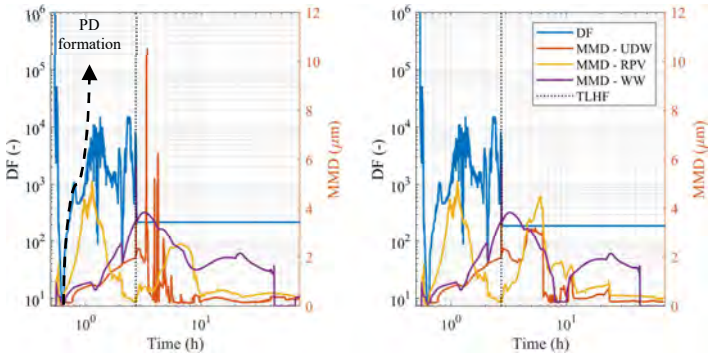


Figure 6. DF and size of particles during IDEJ0 (left) and IDEJ0 (right).

While dependence of DF on particle size cannot be strictly determined based on experimental results, analytical linear dependence can be determined [34]. Subsequently, as the pressure in the RPV starts to increase at ~1.1h when large degradation occurs and small sized aerosols are released from the core (also see [25] for more information on core degradation process during SBO-IDEJ0 and IDEJ1), the MMD reduces. When the size of aerosols entering the ADS valves (from the RPV steamdome) reduces, the amount of small sized aerosols (1μm) retained by scrubbing processes in the WW pool seems to also reduce, leading to these particles rising with the bubbles and entering the atmosphere phase of the WW – seen as the accumulation of CS and I2 in Figure 5(a) and (b) at ~1.1h. This and the effect of large presence of NCGs in the inlet reduces steam condensation and therefore pool scrubbing. The decontamination factor in the ADS valves is also observed to correspondingly rise to the order of 10^4 at ~1.1h and then reduce to ~10^3 by 2h, when core support plate fails, leading to quenching of hot debris and possible energetic remobilization of smaller aerosols. This is seen as a drop in MMD and coincidentally in the DF and the atmosphere mass fraction of FPs in Figure 5(c). Following LHF and energetic ejection of all debris, the MMD in the UDW is

below 1µm until end of the simulation. In the case of IDEJ1, it is observed that until that large mass ejection at ~6h, the MMD in the RPV rises once again to >4µm and this time, because there is an established pathway directly from RPV to the CNT along the breach, the MMD in the UDW also follows suit, increasing to ~3.5µm. While it is expected that the thermal-hydraulic behaviour of the WW should affect the FP scrubbing and behaviour, it is observed that at ~40h MMD sees an unexplained drop (and recovers at ~60h in the case of IDEJ0 likely due to transfer of some aerosols from the UDW to the WW via now uncovered BD pipes) without no other observable changes in other parameters in the WW. This may be due to complete flushing of all the airborne particles from the WW once the pool starts to boil off at ~20h. Further analysis is needed to properly ascertain the reason for this behaviour.

4.3. Initial Screening of Uncertain Parameters

About 73 different cases per splinter (IDEJ0 and IDEJ1) were run – from the initial 50 uncertain parameters for some parameters both upper and lower limit cases were included. Cases that resulted in more than 50% variation in the FOMs (cesium and iodine releases) from the reference case were selected for further sensitivity and uncertainty analysis. Unlike in the case of LOCA [] where bifurcations were observed in the thermal-hydraulic parameters of the plant due to FCVS being activated or not, here during SBO accident, FCVS driven grouping of accident progression are not observed. However in the case of SBO-IDEJ1, post LHF and massive ejection of molten debris to the cavity, leftover solid debris in the RPV leads to superheating the vapour in the atmosphere. The evolution of important plant parameters during SBO-IDEJ1 are presented in Figure 7 and Figure 8. As can be seen, those cases which result in larger debris to remain (and consequently smaller mass being ejected to the cavity) the decay heat in the core remaining after the RPV failure is larger. Because vapour can flow in through the breach it gets heated to a higher degree, almost 50°C more. This does not reflect in fission product retention in the WW.

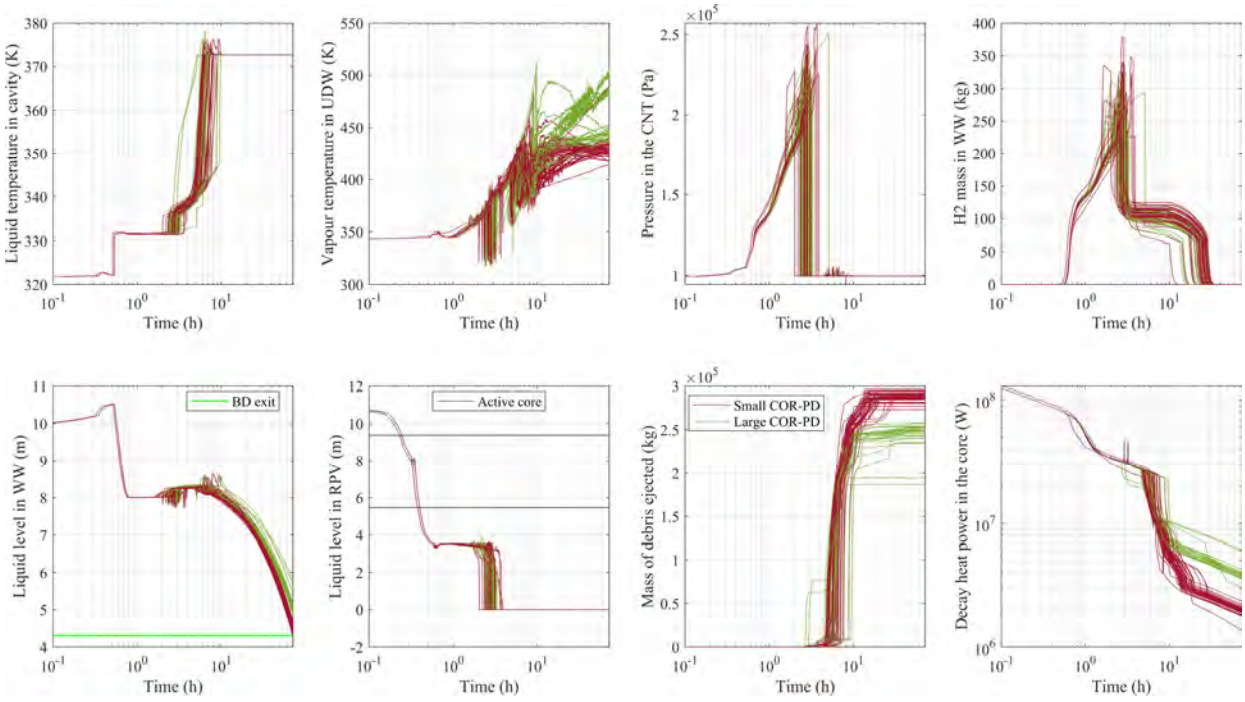

Figure 7. Time evolution of T/H parameters during SBO-IDEJ1.

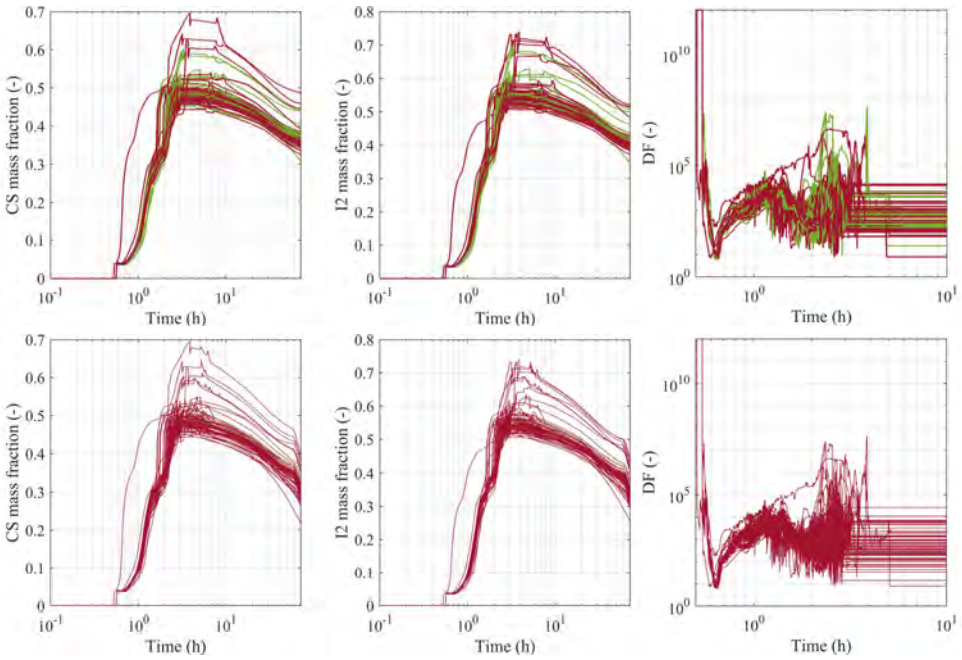

Figure 8. Time evolution of FPs during SBO-IDEJ1 (1st row) and SBO-IDEJ0 (2nd row).

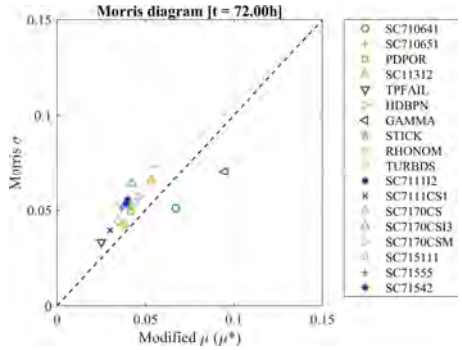
Similar trends are observed for DF in the two scenarios, as most of the scrubbing occurs before LHF and the effect of mode of debris ejection is seen after LHF. Largely similar trends are observed in cesium and iodine mass fractions, except in the case of IDEJ0 where WW pool boils off below BD exit beyond ~60h when loss of FPs is increased.

4.4. Sensitivity and Uncertainty Analysis

For the 18 screened parameters Morris global sensitivity study was performed using samples generated using DAKOTA. The Morris index μ^* gives the significance of a parameter while Morris index σ gives the potential interaction with other parameters and non-linear input behaviour of the parameter. The Morris diagrams for CS and I2 mass fractions in the WW during SBO-IDEJ0 and IDEJ1 are presented in Figure 9 and Figure 10 respectively. The traditional correlation (Pearson and Spearman coefficients) plots for the same FOMs are presented in Figure 11 and Figure 12. The aerosol agglomeration shape factor (GAMMA) is the most significant factor in the amount of CS and I2 retained in the WW. This factor also has the largest linear correlation coefficients, indicating that increasing irregularity in aerosols increases the retention of FPs in the WW, mainly by gravitational settling and deposition. This is true in the case of both cesium and iodine irrespective of mode of debris ejection.

(a)



(b)

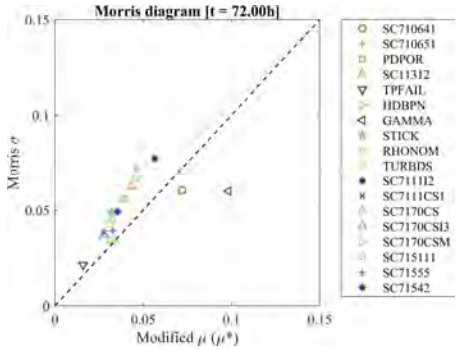


Figure 9. Morris diagrams for CS mass fraction in (a) SBO-IDEJ0 and (b) SBO-IDEJ1.

(a) (b)

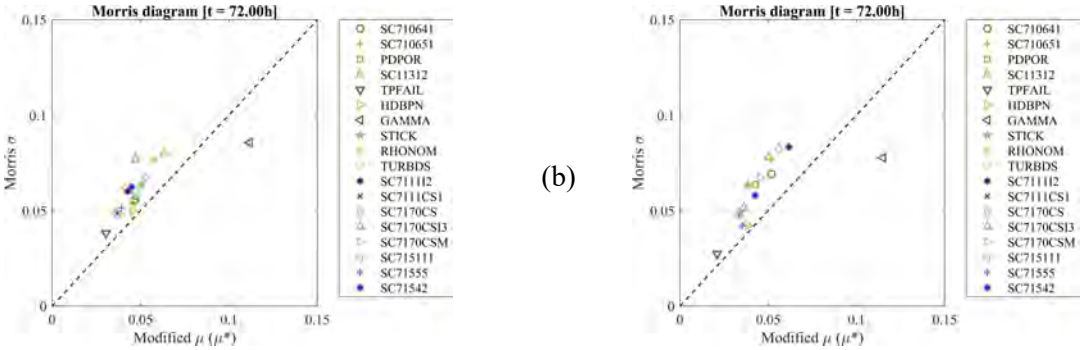

Figure 10. Morris diagrams for I2 mass fraction in (a) SBO-IDEJ0 and (b) SBO-IDEJ1.

(a) (b)

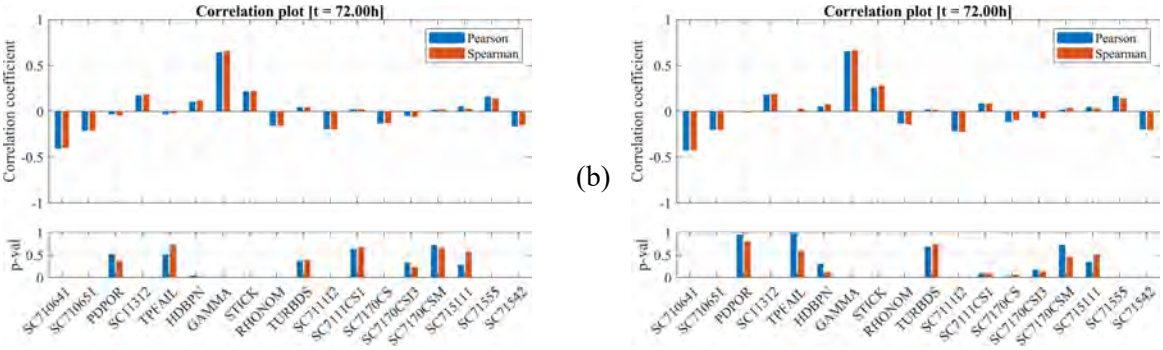

Figure 11. Correlation coefficients for CS mass fraction in (a) SBO-IDEJ0 and (b) SBO-IDEJ1.

(a) (b)

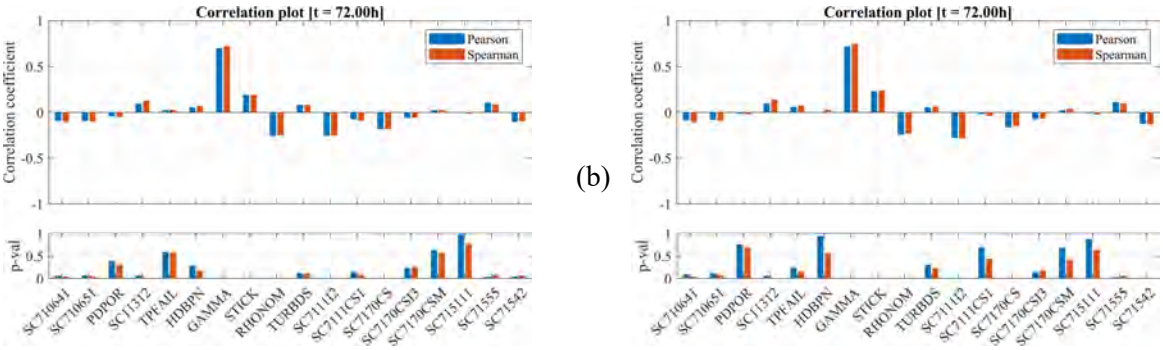

Figure 12. Correlation coefficients for I2 mass fraction in (a) SBO-IDEJ0 and (b) SBO-IDEJ1.

Next to GAMMA, the Activation energy in CORSOR-Booth release model (SC710641) is the most significant and negatively correlated to CS mass fraction. This is especially when one considers the most significant phenomenon that affects WW FP is the release of FPs from the fuel right after ADS is activated, so that any FP transfer to WW is affected by the release model. This is not however significant to I2, indicating most of the impact is towards species not containing CsI aerosols. SC11312 and SC7111I2, the critical temperature when molten material is released from oxide shells and vapour diffusivity constant for iodine RN class respectively, are significant parameters for iodine mass in WW during SBO-IDE0 and SBO-IDEJ1. SC1112 also affects debris relocation in the core which can be assumed to impact whether or not debris remains after LHF. These parameters are important due to their interaction and non-linear behaviour after the debris has been ejected to the cavity, and until just few hours after LHF it is only SC710641 which is the most significant parameter, indicating any future model development for analysis of WW FP retention should focus on advancing study of FP release models in the fuel.

(a) (b)

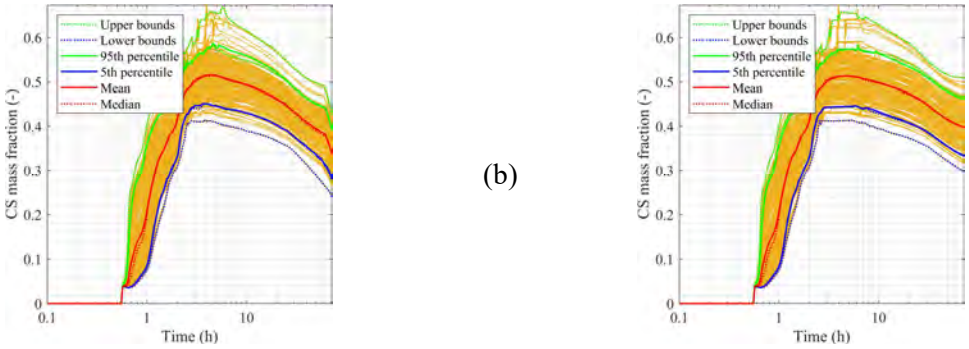

Figure 13. Uncertainty distributions in CS mass fraction in (a) SBO-IDEJ0 and (b) SBO-IDEJ1.

(a) (b)

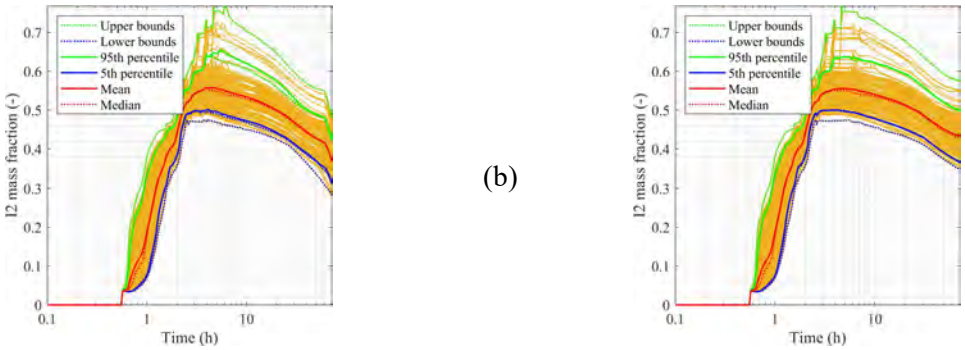

Figure 14. Uncertainty distributions in I2 mass fraction in (a) SBO-IDEJ0 and (b) SBO-IDEJ1.

Following the sensitivity analysis, the same 18 screened parameters were used to generate 160 samples with LHS in DAKOTA. The distributions of the FOMs in the WW are presented in Figure 13 and Figure 14. It is seen that 95th percentile of CS mass fraction in the IDEJ0 scenario lies around 0.39 and in the case of IDEJ1 around 0.46. From the peak mean retention of 0.5 at around LHF, due to evaporation and revapourization of aerosols, CS fraction reduces by 30% in IDEJ0 and 20% in IDEJ1. For the I2 mass fraction in the WW, the 95th percentile in IDEJ0 is around 0.47 and in IDEJ1 around 0.5. Consequently from the peak I2 retention of 0.55 at LHF, IDEJ0 sees around 32% and IDEJ1 around 15% by the end of 72h.

5. CONCLUSIONS

This paper analyzed the behaviour of the WW during an unmitigated SBO accident in Nordic BWR using MELCOR. Initially a reference accident case was analyzed to understand the thermal-hydraulics and fission product transport from the time of release in the RPV to the end of simulation at 72h for 2 splinter modes of debris ejection. It has to be kept in mind that all the analysis performed was with a single CV representing the WW without any axial distributions or natural circulation in the pool. As expected, it was observed that WW accumulates majority of the FPs such as cesium and iodine fractions in its pool phase. Presence of NCGs along with steam in the inlet of the ADS is seen to reduce scrubbing of the aerosols that are then transferred to the gas space. Differences in FPs retained based on mode of debris ejection was not as predominant as in LOCA, mainly because all the FPs released from the fuel have accumulated in the WW than elsewhere in the reactor (such as in CNT), where the mode of debris ejected can play a role. Based on the sensitivity analysis performed with 18 screened uncertain parameters, it was observed that SC710641 of the CORSOR-Booth release model and GAMMA of the aerosol dynamics model are the most significant parameters in the mass accumulated in the WW respectively before and after massive debris ejection to the cavity. From the magnitude of FPs in the WW itself, there appears to be no large impact of mode of debris ejection (IDEJ) during SBO on mass of FP retention in the WW. While effect of particle size, pool bulk temperature and NCGs on the DF was observed, effect of other variables such as nodalization and submergence of ADS valves needs to be assessed in the future.

APPENDIX A

No	Parameter	Description	Range	Units
1	SC710641	Activation energy in Booth release model	241000 - 381400	J/kg-mole
2	SC710651	Equivalent sphere radius of fuel grain in Booth release model	0.000006 - 0.00001	m
3	PDPOR	Porosity of particulate debris	0.3 - 0.5	
4	SC11312	Critical breach temperature at which molten materials are released from an oxide shell or local blockage (crust)	2100 - 2500	K
5	TPFAIL	Failure temperature of the penetrations or the LH	1273 - 1600	K
6	HDBPN	Heat transfer coefficient between particulate debris and LH penetration	100 - 1000	W/m^2-K
7	GAMMA	Aerosol agglomeration shape factor	1 - 3	
8	STICK	Particle sticking coefficient	0.5 - 1	
9	RHONOM	Nominal aerosol density in gravitational deposition	1000 - 4900	kg/m^3
10	TURBDS	Turbulence energy dissipation rate	0.00075 - 0.00125	m^2/s^3
11	SC7111I2	Vapour diffusivity constant (characteristic energy of interaction between the molecules divided by the Boltzmann constant) for the FP vapours in the bulk gas (class 4)	467.5 - 632.5	K
12	SC7111CS1	Vapour diffusivity constant (characteristic diameter of the molecule) for the fission product vapours in the bulk gas (class 2)	3.0745 - 401595	A
13	SC7170CS	Saturation solubility at low and high temperature reference for Cs	3.3575 - 4.5425	kg/kg H_2O
14	SC7170CSI3	Saturation solubility at low temperature reference for CsI	0.374 - 0.506	kg/kg H_2O
15	SC7170CSM	Saturation solubility at low and high temperature reference for CsM	0.5695 - 0.7705	kg/kg H_2O
16	SC715111	Weber number multiplier used in the equation for the initial diameter of the gas globule for a sparger-type vent	2.9325 - 3.9675	
17	SC71555	Multiplication constant in the DF factor correlations for large Stokes number	0.9681 - 1.3098	
18	SC71542	Constant in the swarm velocity correlation	0.0025593 - 0.0034626	$I-s/cm^2$

1. INTRODUCTION

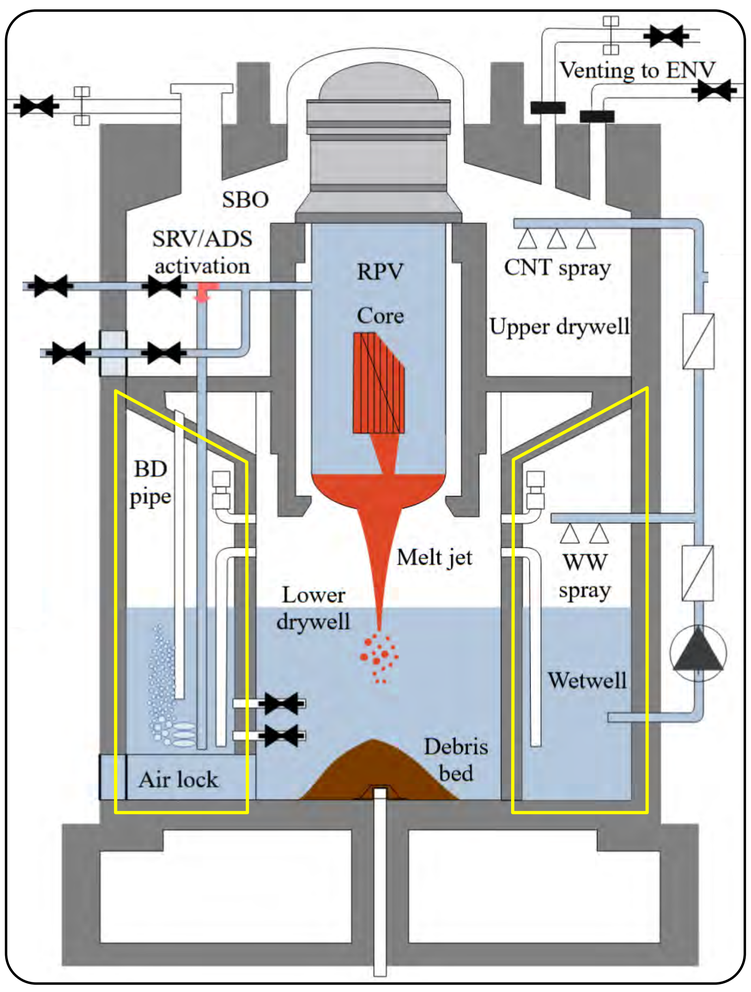
Pressure suppression pool (PSP), or the wetwell (WW), is a defining safety feature of Boiling Water Reactor(BWR) containments. During loss of coolant accident (LOCA), steam is directed via blowdown (BD) pipes into the submerged pool where it condenses. This process simultaneously scrubs the fission products (FPs) – both aerosols and vapours – from the gas stream as bubbles rise through the water, performing a critical function of radioactive source term reduction.

Post Fukushima Daiichi accident of 2011, research has intensified focus on this scrubbing phenomenon under extended severe accident sequences like station blackout (SBO), where pool dynamics are paramount. A significant finding across studies is the large uncertainty in accident progression analysis, often due to incomplete knowledge of system states and complex, coupled phenomena. Reducing these uncertainties, especially regarding FP retention and source term release, is essential for risk assessment.

In the context of Nordic BWR, uncertainties relating to source term in Nordic BWRs are being assessed at KTH under Risk Oriented Accident Assessment Methodology+ (ROAAM+) with the aim of improving current methodology for addressing safety issues. The present work extends the MELCOR analysis performed earlier to the uncertainties in the WW response to SBO, and its effect on FP retention.

2. METHODOLOGY

A reference unmitigated SBO scenario was initially run with MELCOR v2.2.18019 to set the baseline calculation. (i) Based on literature, significant phenomena and 50 underlying uncertain parameters were listed. (ii) An initial screening for sensitivity was performed for the selected figures-of-merit (FOMs) (> 50% variation from the reference). (iii) A calculation matrix with the 18 screened parameters was developed using DAKOTA to perform Morris OAT global sensitivity analysis and identify the most significant parameters. For Morris analysis, 5 level input space and trajectory of length 20, 380 samples were generated. (iv) Uncertainty quantification was performed with 160 code runs (2nd order Wilks' 95/95 estimates) with cases generated using LHS. Cesium and Iodine mass fractions in WW were considered for the FOMs.



Screened uncertain input parameters.

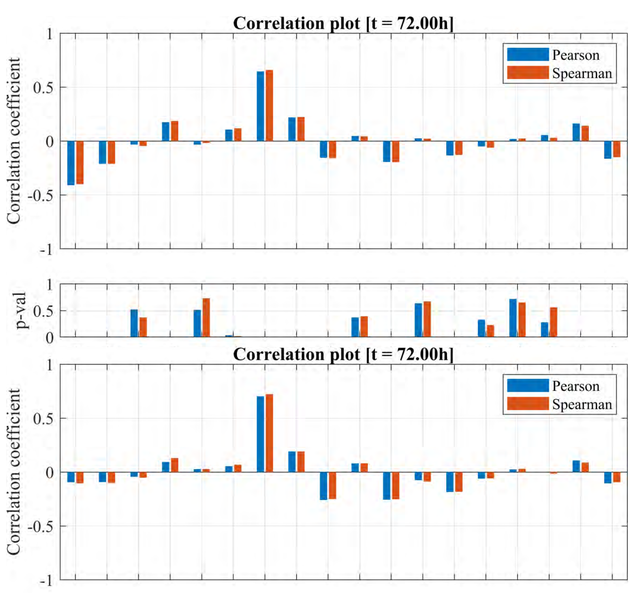
No	Parameter	Description
1	SC710641	Activation energy in Booth release model
2	SC710651	Equivalent sphere radius of fuel grain
3	PDPOR	Porosity of particulate debris
4	SC11312	Critical breach temperature for release from an oxide shell or local blockage (crust)
5	TPFAIL	Failure temperature of the penetrations
6	HDBPN	Heat transfer coefficient between particulate debris and LH penetration
7	GAMMA	Aerosol agglomeration shape factor
8	STICK	Particle sticking coefficient
9	RHONOM	Nominal aerosol density
10	TURBDS	Turbulence energy dissipation rate
11	SC7111I2	Vapour diffusivity constant (characteristic energy of interaction by Boltzmann constant)
12	SC7111CS1	Vapour diffusivity constant (characteristic diameter of the molecule)
13	SC7170CS	Saturation solubility for Cs
14	SC7170CSI3	Saturation solubility for CsI
15	SC7170CSM	Saturation solubility for CsM
16	SC715111	Weber number multiplier in the initial diameter of the gas globule for a sparger-type vent
17	SC71555	Multiplication constant in the DF factor correlations for large Stokes number
18	SC71542	Constant in the swarm velocity correlation

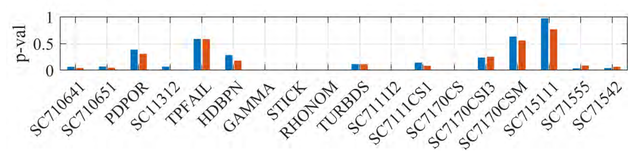
3. RESULTS

Cesium fraction includes,
RN Class 2 – CsOH.
RN Class 16 – CsI.
RN Class 17 – CsM.
Iodine fraction includes,
RN Class 4 – I2.
RN Class 16 – CsI.

Key events and timing during SBO.

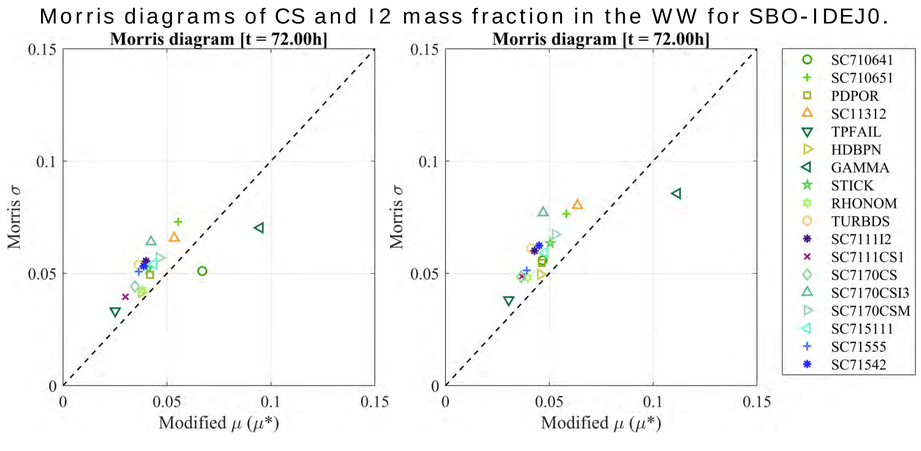
Key event	Time [h]
L4 level	0.2
Uncovery of core	0.23
L6 level	0.31
Gap release	0.56
Particulate debris formation	0.62
Relocation to lowerhead	2.01
Core plate failure	2.01
RPV failure	2.73
LDW boiling	2.73
WW boiling	20



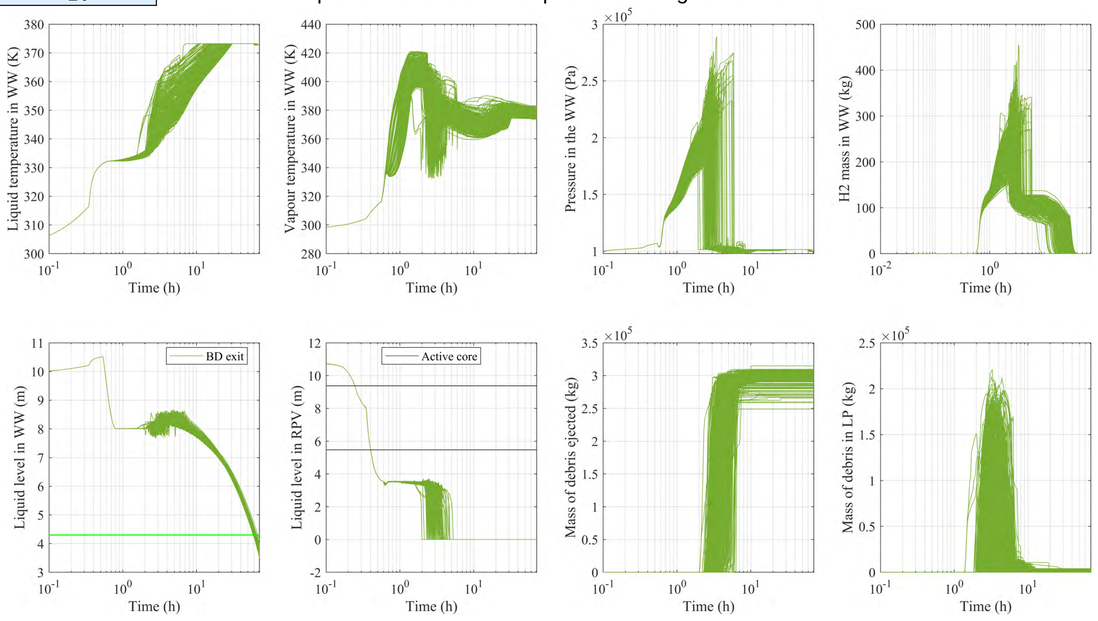


Correlation coefficients of CS and I2 mass fraction in the WW for SBO-IDEJ0.

Morris diagrams of CS and I2 mass fraction in the WW for SBO-IDEJ0.

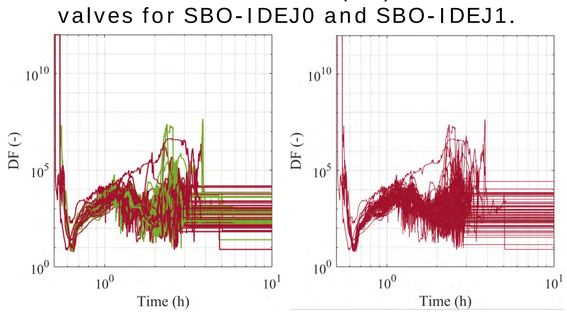


T/H parameters of the plant during SBO-IDEJ0.



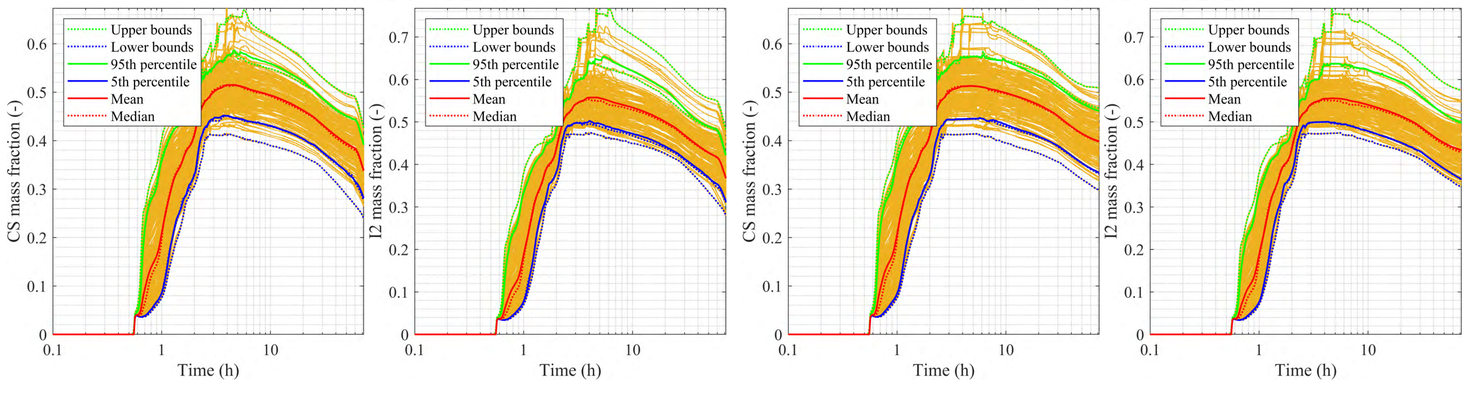
All deposition models and hygroscopic model turned ON, while resuspension model was turned OFF. Scrubbing was active only at the exit of BD pipes and ADS valves. 2 splinter scenarios – MELCOR parameter IDEJ0 and IDEJ1 – with and w/o solid debris ejection mode were tested. A MATLAB driver handles simulation crashes and restarts with automatic time-step refinement. All cases run for 72h.

Decontamination factor (DF) in the ADS valves for SBO-IDEJ0 and SBO-IDEJ1.



Uncertainty distributions of CS and I2 mass fraction in the WW for SBO-IDEJ0.

Uncertainty distributions of CS and I2 mass fraction in the WW for SBO-IDEJ1.



4. CONCLUSIONS

(i) WW accumulates majority of the FPs such as cesium and iodine fractions in its pool phase.
(ii) Effect of mode of debris ejection (IDEJ) was not as predominant as in LOCA, mainly because all the FPs released from the fuel have accumulated in the WW than elsewhere in the reactor (such as in CNT), where the mode of debris ejected can play a role.
(iii) SC710641 of the CORSOR-Booth release model and GAMMA of the aerosol dynamics model are the most important parameters in the mass accumulated in the WW.
(iv) While effect of particle size, pool bulk temperature and non-condensable gases on the DF was observed, effect of WW nodalization and submergence of ADS valves needs to be assessed in the future. It would also be interesting to study the effect of pool thermal stratification on the FP retention capabilities and its behaviour.

ACKNOWLEDGMENTS

This work is supported by the Nordic Nuclear Safety Research (NKS), under the NKS-R STATUS activity (Contract: AFT/NKS-R(21)133/5) and by the SSM ROAAM+ project at the Royal Institute of Technology (KTH), Stockholm, Sweden.

WW: wetwell, SRV: safety relief valve, ADS: automatic depressurization system, RPV: reactor pressure vessel, CNT: containment, BD: blowdown, DF: decontamination factor.

Assessing the Capabilities of MELCOR V2.2 against the QUENCH-19 Bundle Test with FeCrAl Cladding

Type of abstract: Poster
Subject area: Other applications (fusion reactors, interim SNF storage, Accident Tolerant Fuels (ATFs), etc
Keywords: QUENCH-19 FeCrAl alloy Hydrogen Generation MELCOR

Advanced Technology Fuel (ATF) concepts have been under development for over a decade, with a significant acceleration in recent years. The aim of these advanced materials is to enhance the safety margins of nuclear reactors in the event of a severe accident (SA) by limiting the hydrogen generation and preserving cladding integrity at high temperatures. Among the proposed ATF candidates, FeCrAl alloys have emerged as a promising option due to their excellent high-temperature oxidation resistance and their ability to reduce hydrogen release compared to conventional Zr-based claddings.

To evaluate the capability of integral SA codes to model innovative materials, this study compares the simulation performance of MELCOR V2.2 against the QUENCH-19 bundle test, which was conducted at the QUENCH large scale facility of the Karlsruhe Institute of Technology (KIT) in 2018. This experiment examined the thermal response, oxidation behaviour and hydrogen release of FeCrAl cladding rods in a bundle configuration under conditions representative of a severe accident. A MELCOR input model was developed to reproduce the experimental configuration and the results were compared with the measured temperatures and hydrogen generation data. Despite some deviations, the comparison shows a satisfactory agreement with the experimental data, highlighting the capability of MELCOR V2.2 to simulate SA scenarios involving ATF claddings such as FeCrAl.

ASSESSING THE CAPABILITIES OF MELCOR V2.2 AGAINST THE QUENCH-19 BUNDLE TEST WITH FECRAL CLADDING

F. Rosi[1,2], M. E. Cazado[1], M. Angelucci[2], S. Paci[2], F. Gabrielli[1], V. H. Sánchez-Espinoza[1]

[1]Institute for Neutron Physics and Reactor Technology, Karlsruhe Institute of Technology (KIT), Germany
[2]Department of Civil and Industrial Engineering, University of Pisa (UNIPI), Italy.

1. Introduction & Motivation

- ATF concepts aim to improve reactor safety margins by **reducing hydrogen generation and extending coping** time under off-normal and accident conditions.
- FeCrAl alloys are particularly promising due to their **superior oxidation resistance** in high-temperature steam environments, compared to conventional Zr-based claddings.
- To evaluate the capability of **MELCOR V2.2** to model innovative cladding materials, this study compares simulation results against the **QUENCH-19 bundle test**, conducted at KIT's QUENCH large-scale facility in 2018, focusing on thermal response and hydrogen generation under representative severe accident conditions.

2. FeCrAl Cladding Concept

- Nuclear-grade FeCrAl typically contains ~10-13 wt% Cr and ~5-6 wt% Al. Mo/Y additives enhance oxidation and mechanical performance
- A protective Al_2O_3 layer provides strong oxidation resistance below ~1300 °C, above ~1400 °C Fe-oxide kinetics become dominant.
- **Main advantages**: reduced steam reaction kinetics and lower hydrogen generation.
- **Main challenges**: higher neutron absorption than Zircaloy, tritium permeability, and UO_2-FeO eutectic interactions at ~ 1335 °C.

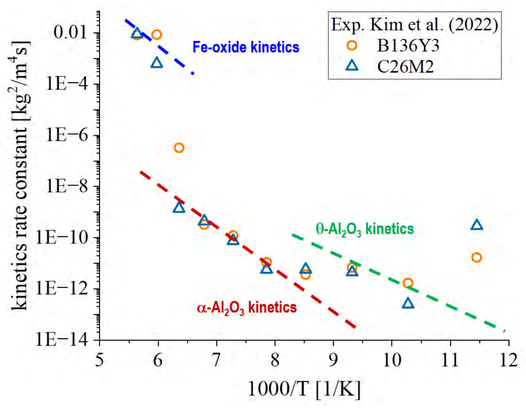

Fig. 1 - Parabolic rate constants of B136Y3 and C26M2 alloys with the parabolic constants of Fe-oxide, α-alumina and θ-alumina [1].

3. QUENCH-19 Bundle Test Modelling with MELCOR

QUENCH-19: first integral ATF bundle test worldwide, performed at KIT in 2018 with FeCrAl (B136Y3) rods.

It assessed the thermal response, oxidation behaviour, and hydrogen release of FeCrAl cladding under severe accident conditions.

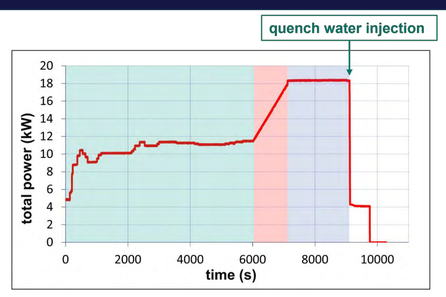

Fig. 2 – QUENCH-19 Electric power [2]

Key experimental findings

✓ No early temperature runaway relative to ZIRLO reference exp (QUENCH-15).
✓ Max. temperature ~200 K lower in the pre-oxidation phase.
✓ Strong H_2 reduction: 9.2 g vs 47.6 g (QUENCH-15).

MELCOR Modelling

CVH Nodalization

- **Test section** divided in **9 Control Volumes** (CVs).
- Additional CVs included for lower plenum, off-gas collector, argon insulation and auxiliary regions.

COR Radial Nodalization

- Test section divided in **three radial rings**.
- Ring 1 and 2 represent the heated region: 12 rods each.
- Ring 3 contains 7 corner rods (unheated) and shroud.

Core Components

- **B136Y3** material defined as the oxidizable user material. Properties obtained from literature and KIT data [3, 4] Claddings, corner rods, shroud, and spacer grids are represented with this user-defined material.
- **B136Y3OX oxide** material represented using MELCOR default properties.
- **W**, **Mo**, and **Cu** (heater/electrode) properties defined through the MP package.
- **ZrO_2 pellets** modelled via UO_2 as a placeholder material with ZrO_2 properties.

FeCrAl Oxidation Model

- Oxidation implemented via a user-defined **GOX model**.
- Ox. kinetics adapted from KIT separate-effect tests (SETs).
- Transition from α-Al_2O_3 to Fe-oxide kinetics at 1400 °C.

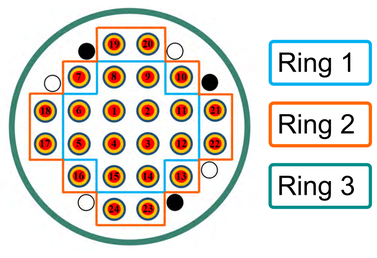

Fig. 3 – Radial Nodalization

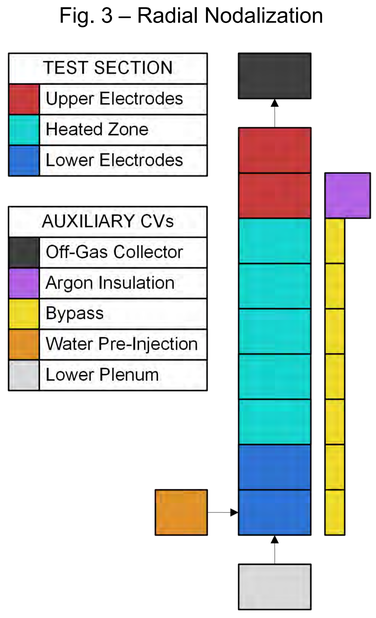

Fig. 4 – CVH Nodalization

4. Simulation Results

A. Cladding Temperature Evolution

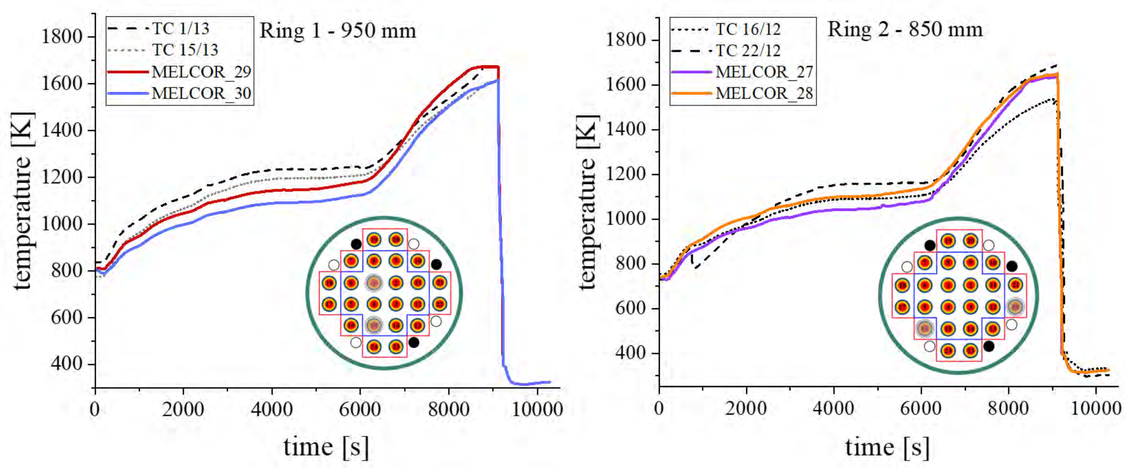

Fig. 5 – Cladding temperature comparison between the experimental data [2] and simulated results at 950 mm elevation in Ring 1 (left) and at 850 mm in Ring 2 (right). The dotted and dashed curves correspond to the experimental thermocouple data: the associated rod positions are highlighted in grey in the test cross-sections.

B. Hydrogen Generation

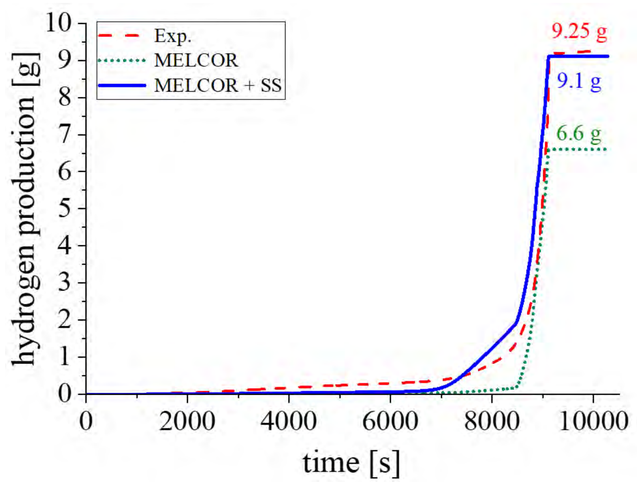

Fig. 6 – Cumulative hydrogen production comparison between the experimental data [2] and MELCOR results. The dotted line shows the MELCOR simulation that considers only the H_2 generated by the FeCrAl material. In contrast, the solid blue line includes the contribution of the oxidation of the stainless steel thermocouple sheaths.

- It is estimated that ~2 g of the experimental H_2 production originates from the **oxidation of stainless-steel thermocouple sheaths**, accounting for ~ 22% of the total measured H_2.
- As these components are not modelled explicitly in MELCOR, their contribution was estimated separately using simulated temperatures and the area of the exposed sheaths.

5. Conclusions

- A MELCOR input deck for QUENCH-19 was developed based on KIT report specifications and FeCrAl oxidation data obtained from KIT SETs.
- Despite some deviations, mainly attributed to core nodalization constraints, **MELCOR shows good agreement with QUENCH-19 data** for temperature evolution and cumulative hydrogen generation.
- **FeCrAl** cladding **significantly mitigates hydrogen generation below ~1400 °C** compared with equivalent tests using Zr-based alloys.
- Oxidation of stainless-steel thermocouple sheaths can provide a relevant additional hydrogen source in ATF experiments and should be considered in the interpretation of the results.

Type of abstract: Poster
Keywords: Preparedness, Radiological impact, Risk communication, AMRs, Urban siting

The PIANOFORTE CATAPULT project, coordinated by KIT (Germany) and launched in 2025, aims to build comprehensive guidance for Environmental Impact Assessment (EIA) and Emergency Preparedness and Response (EP&R) applied to small (water-cooled) and advanced modular reactors (gas- and lead-cooled), with strong integration of technical and social aspects.

The current knowledge supporting EIA and EP&R, regulatory approaches, and risk communication is mainly based on large water-cooled reactors. Nevertheless, SMRs and AMRs pose several challenges regarding i) limited state-of-art modelling for EIA and EP&R for near field, ii) the need to address the Euratom Basic Safety Standards for modular reactors' deployment, and iii) public concerns about new nuclear technologies, for which communication and community engagement must rely on trust and transparency.

Since EIA is not independent of public concerns and broader risks (and vice versa), a comprehensive approach to address these challenges is studied in CATAPULT. To this end, a highly interdisciplinary consortium (ASNR, COFAC - Lusófona University, KIT, Merience, NRG Pallas, RATEN, SCK CEN, STUK) has been established, combining a broad range of disciplines in radiation protection.

The project is structured around three scientific pillars: 1) Environmental and dose modelling, developing framework of computational methodologies for dose impact and environmental transport analyses tailored to EIA and EP&R for modular reactors; 2) Science-based regulatory compliance, providing recommendations to authorities, operators, and licensees to ensure scientifically credible demonstrations of radiation protection for the public, workers, and environment; and 3) Community Engagement & Risk communication, establishing a community-driven participatory framework by engaging general public, stakeholders, and communities to increase trust, transparency and co-decisions, while delivering evidence-based guidelines and materials for communicating EIA results and informing the public about modular reactor development and implementation.

This work presents CATAPULT's objectives, the strategy adopted to achieve them, and preliminary results.

The PIANOFORTE CATAPULT Project: Comprehensive Assessment and Preparedness for Emerging Nuclear Technologies

F. Gabrielli, M. E. Cazado

Karlsruhe Institute of Technology (KIT), Germany

Motivation

- The current knowledge supporting Environmental Impact Assessment (EIA) and Emergency Preparedness and Response (EP&R), regulatory approaches, and risk communication is mainly based on large water-cooled reactors
- SMRs and AMRs pose several challenges regarding
  - **limited state-of-art modelling for EIA and EP&R for near field**
  - need to address the **Euratom Basic Safety Standards** for deployment
  - the public concerns about new nuclear technologies, for which **communication and community engagement must rely on trust and transparency**
- **EIA not independent from the public concerns and wider risks at stake and vice versa**
- Further isolated research in the modelling, compliance, and communication areas will not deliver on practical solutions to the existing challenges

The CATAPULT Project

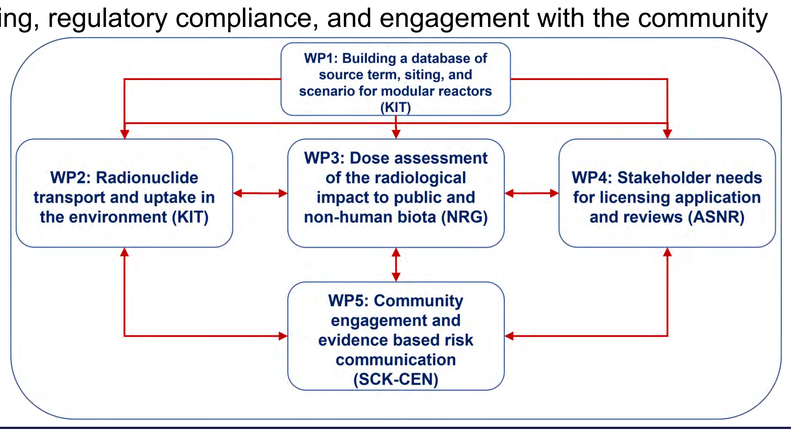
- **CATAPULT aims at building a comprehensive guidance for EIA and EP&R applied to Small (water-cooled) and Advanced Modular Reactors (Gas- and Lead-cooled) with tight cross-links between technical and social aspects**
- Highly interdisciplinary team (research centers, TSO, universities)
- PIANOFORTE Call 2, Topic 2, duration: 3 years (01.02.2025-31.01.2028)

Pillars, Scope, and Main Goals

- **Environmental and dose modelling**
  - **Improving/adapting the dose** impact and the environmental **transport models**
  - Delivering an **analysis framework tailored to the needs of modular reactors and their typical site locations** to guide end-users in EIA and EP&R modelling
- **Science-based regulatory compliance**
  - **Delivering a comprehensive set of recommendations to authorities, operators, and licensees** to ensure the scientific credibility of the demonstration of radiation protection of the public, including workers from nearby industries, and the environment
- **Community Engagement & Risk communication**
  - **Community-driven participatory framework**, to engage general public, relevant stakeholders, and communities to increase trust, transparency and co-decisions, towards a more holistic EIA
  - **Providing evidence-based, co-designed communication tools that clearly present EIA results and inform the public about modular reactors**

Work Plan and Methodology

- Cross-fertilization of research disciplines tailored to develop a fit-for purpose framework on EIA modelling, regulatory compliance, and engagement with the community



WP1 – Building a database of source term, siting, and scenario for modular reactors (KIT, RATEN, STUK)

- **Source terms database (nominal and accident conditions, atmospheric and effluent)**
  - Water-cooled SMR (submerged containment, 60 Mwe)
  - Lead-cooled ALFRED-like (125 MWe)
  - Gas-cooled HTR-like (200 MWth)
- **Extensive database of the siting (websites, maps, tables)**
  - **Industrial site** next to heavy/chemical industry (Stein, Limburg, Netherlands)
  - **Urbanized site** - close to urban and industrial zones (Arnhem, Gelderland, Netherlands)
  - **Natura2000 site** - Petten (Netherlands)
  - **Urbanized site for district heating** (Helsinki, Finland)

WP2 – Radionuclide transport and uptake in the environment (KIT, ASNR, NRG, SCK-CEN, STUK)

- **Adaptation and enhancement of state-of-the-art atmospheric and aquatic radionuclide transport and dispersion** as well as food chain models
- Improving the atmospheric transport and dispersion models for small-scale and urban conditions (LASAIR + JRODOS, FLEXPART + AROME)
- Aquatic transport and dispersion models (3D hydrological/compartment, high-resolution 2D-3D hydrological modelling of radionuclide pollutants, freshwater and low-flow rivers)
- Food chain models (e.g., JRODOS, SYMBIOSE, D-DAT)

WP3 – Dose assessment of the radiological impact to public and non-human biota (NRG, ASNR, SCK CEN, STUK)

- **Review and analysis of present models and selection of exposure conditions** for members of the public including workers from nearby industries and for non-human biota **based on stakeholder needs**
  - Dose calculations and a sensitivity analysis on the variations in exposure conditions to establish variations in dose for the (critical) reference person and wildlife
  - Identify deficiencies providing input for a work plan on future development
- **Prioritisation of features** that are important in the assessment (interaction with WP4)

WP4 – Stakeholder needs for licensing application and reviews (ASNR, NRG, RATEN, STUK)

- **Development of regulatory guidance** based on
  - **case studies** (WP1, WP2, WP3)
  - **round-tables with experts** from authorities and TSO involved in the reviewing of applications from prospective licensees
  - **feedback from a wider audience**, including developers of modular reactors, their subcontractors and representatives of public engagement and risk communication (WP5)

WP5 – Community engagement and evidence based risk communication (SCK CEN, COFAC-UL, MERIENCE)

- **Develop a two-stage Community-Driven approach** to enhance public perception and address public mistrust, mitigating “not in my backyard” (NIMBY) responses
- **Develop citizen-centred and evidence-based risk communication strategy and materials** related to EIA by providing transparent, accurate and comprehensible information from the other WPs (**Design Thinking Approach**)
- The **Delphi method** will be used to provide implementation guidance for effective and evidence-based risk communication by leveraging a panel of communication experts

Summary

- CATAPULT is tailored at the **specific needs of modular reactors** in assessing their radiological risks to the environment during routine and accidental operation
- CATAPULT uses **cutting-edge modelling**, **novel communication science**, and **broad stakeholder co-design** to deliver transparent, evidence-based EIAs
- With a **multi-disciplinary team**, CATAPULT aims at delivering **essential guidance** to authorities, TSOs, operators, and licensees, advancing a standardized, **fit-for-purpose EIA and EP&R approach**

3D Estimation Diagrams of Units 1–3 at the Fukushima Daiichi Nuclear Power Station Updated in 2025

Yamashita Takuya (1), Shimomura Kenta Shimomura, Nagai Eiichi, Yasumatsu Tomohiro, Nakashima Satoru, Ogino Shoya, Mizokami Shinya

(1) JAEA

Type of abstract: Poster
Subject area: Other applications (fusion reactors, interim SNF storage, Accident Tolerant Fuels (ATFs), etc
Keywords: Fukushima Daiichi Nuclear Power Station, 3D estimation diagrams

Internal investigations at the Fukushima Daiichi Nuclear Power Station (1F) have gradually clarified the plant conditions. Trial debris retrieval has provided additional insights, but individual datasets alone are insufficient to fully understand accident progression and overall plant status. Previously, two-dimensional estimation diagrams were developed to support visualization and comprehension of reactor conditions; however, these diagrams were limited in conveying spatial relationships and detailed information.

To enhance visualization and support decommissioning activities, three-dimensional estimation diagrams (3D estimation diagrams) have been developed by constructing a 3D model of the entire plant based on internal investigation results, design information, and estimates from analyses and simulated test results. The 3D diagrams enable interactive visualization from any viewpoint, allowing users to examine complex structures, assess debris locations, and interpret accident progression more intuitively.

By integrating data from multiple sources and presenting them in a spatially coherent 3D format, these diagrams facilitate better understanding of plant conditions, support planning of decommissioning operations, and improve communication among engineers and stakeholders.

The updated 3D estimation diagrams for Units 1–3, developed through 2025, are described, highlighting their role in enhancing comprehension of accident progression and contributing to more effective and efficient decommissioning strategies.

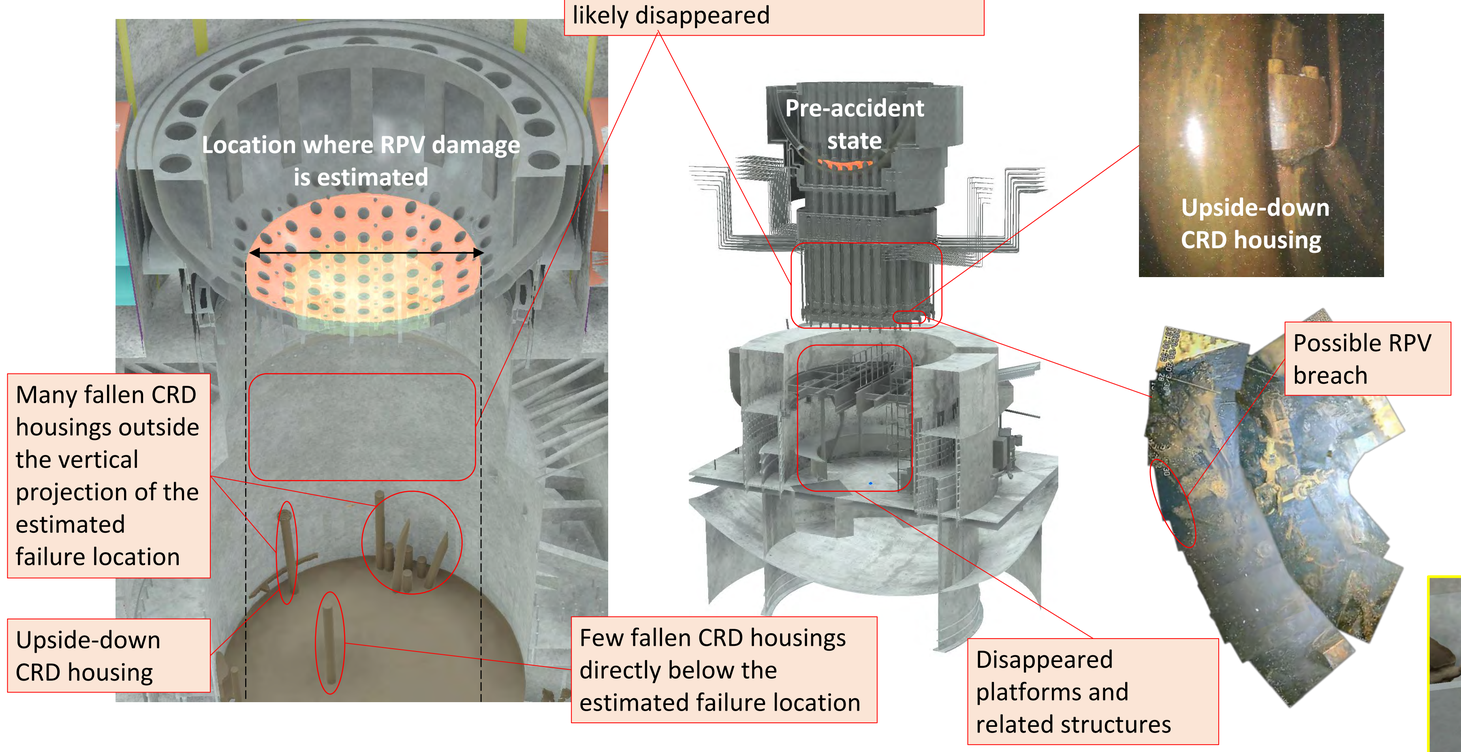
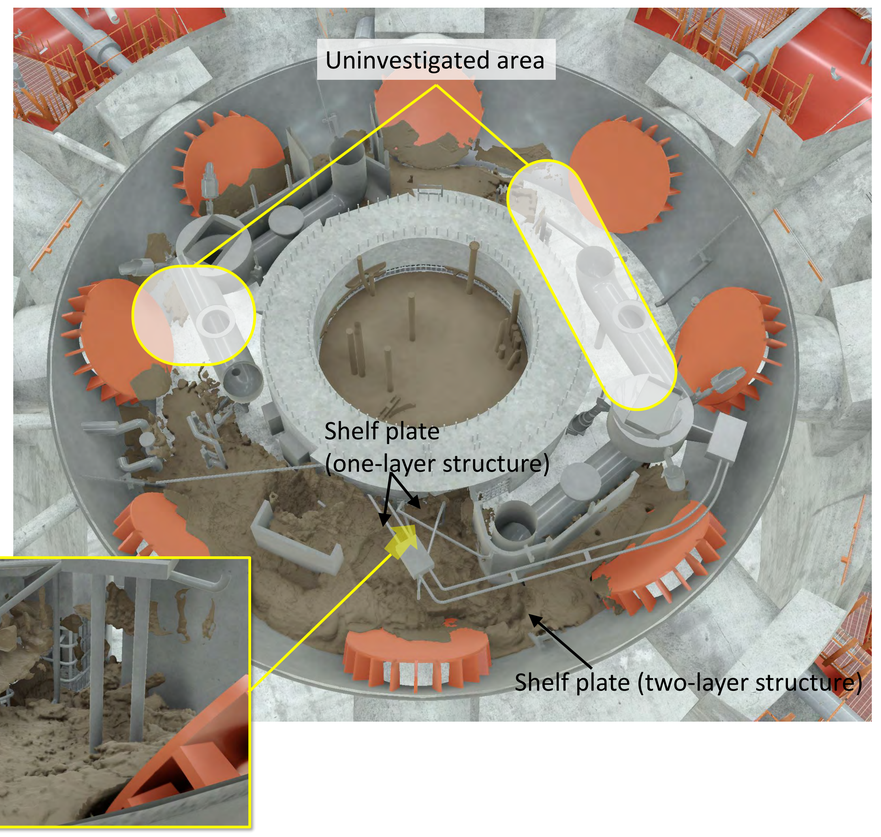
Abstract

Internal investigations at the Fukushima Daiichi Nuclear Power Station (1F) have gradually clarified the plant conditions. Trial debris retrieval has provided additional insights, but individual datasets alone are insufficient to fully understand accident progression and overall plant status. Previously, two-dimensional estimation diagrams were developed to support visualization and comprehension of reactor conditions; however, these diagrams were limited in conveying spatial relationships and detailed information. To enhance visualization and support decommissioning activities, three-dimensional estimation diagrams (3D estimation diagrams) have been developed by constructing a 3D model of the entire plant based on internal investigation results, design information, and estimates from analyses and simulated test results. The 3D diagrams enable interactive visualization from any viewpoint, allowing users to examine complex structures, assess debris locations, and interpret accident progression more intuitively.

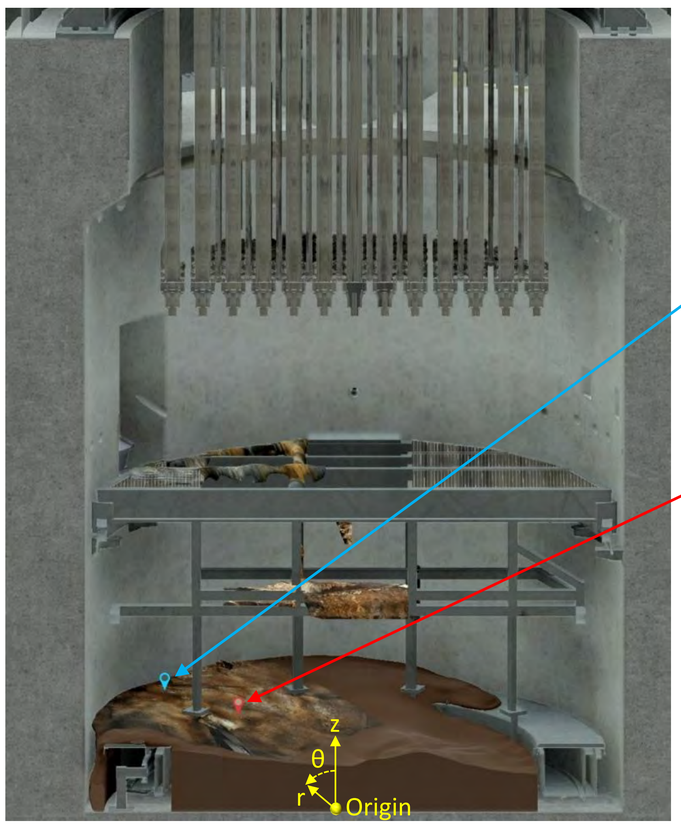
By integrating data from multiple sources and presenting them in a spatially coherent 3D format, these diagrams facilitate better understanding of plant conditions, support planning of decommissioning operations, and improve communication among engineers and stakeholders. The updated 3D estimation diagrams for Units 1–3, developed through 2025, are described, highlighting their role in enhancing comprehension of accident progression and contributing to more effective and efficient decommissioning strategies.

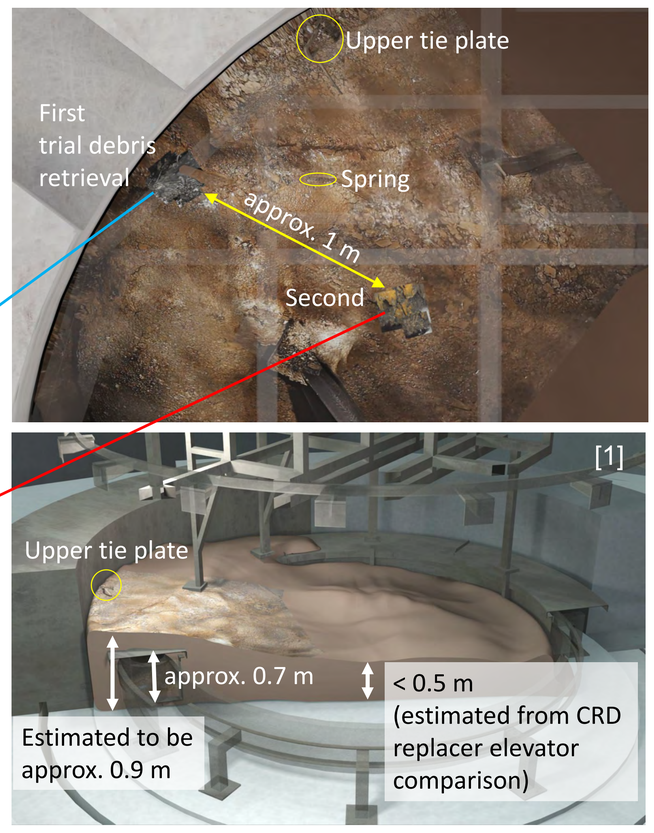
Unit 1





Unit 2





Estimated sampling locations

	Radial distance (r)	Angle from north (θ)	Height from floor (z)
First trial debris retrieval	approx. 2.4 m	approx. 54°	approx. 0.9 m
Second trial debris retrieval	approx. 1.4 m	approx. 42°	approx. 0.8 m

- Shown in a cylindrical coordinate system with origin at the pedestal floor center.
- Fuel debris height is estimated from platform leg coverage and is not directly measured; thus, it is a reference value.

Unit 3

In March 2026, the RPV lower head above this location was internally investigated using a micro-drone [2]. This will be reflected in the 3D estimation diagram in the near future.

SOCRATES Horizon Euratom project on liquid source term

Kärkelä Teemu, Herranz Luis Enrique, Gregoire Anne Cécile, Lind Terttaliisa, Foreman Mark, Souvi Sidi, Komlev Andrei

Type of abstract: Poster
Subject area: Source term issues
Keywords: severe accident, source term, liquid phase chemistry, leaching, innovative

The SOCRATES Horizon Euratom project is joining 17 European and international organizations to advance nuclear safety. SOCRATES is dedicated to tackling the risks associated with the release of radioactive materials in liquid form during severe accident in nuclear power plant. At first, the project conducts an in-depth review of current knowledge on liquid source term, also focusing on how existing severe accident analysis codes can predict the chemical forms of radionuclides in liquid phase. This ensures that new findings are built on a well-established scientific baseline.

Experimental part of the SOCRATES project includes real/simulant corium leaching studies by combining water with representative severe accident chemistry conditions to better assess release kinetics of key radionuclides. Long term behaviour of water chemistry involving debris from concrete, paint and structural materials will be scrutinized with particular attention on cesium and strontium fate. SOCRATES will establish a robust experimental database allowing to refine computer models that predict radionuclides releases and reactivity in aqueous media. SOCRATES develops advanced computer models to simulate a range of liquid release scenarios, some of which might be integrated into European SA analysis codes, like ASTEC and AC^2.

From the innovative point of view, and recognizing the urgent need for effective clean-up, the project is also identifying and evaluating innovative absorbent materials (e.g. zeolites, clays, MOFs, and silicas). These new materials are being synthesized and tested for their potential to capture and remove radionuclides from water. To further support the timely actions and effectiveness of accident management responses, SOCRATES is developing an innovative miniaturized radiochemical laboratory to enable rapid on-site measurement of critical radionuclides like cesium and strontium in liquid phase.

SOCRATES will engage young researchers and students via visits to SOCRATES partner organizations and hands-on tasks in experiments, modelling and education.

ASSESSMENT OF LIQUID SOURCE TERM FOR ACCIDENTAL POST MANAGEMENT PHASE (EURATOM SOCRATES)

Teemu Kärkelä (VTT), Luis Herranz (CIEMAT), Anne Cécile Grégoire (ASNR), Terttaliisa Lind (PSI), Mark Foreman (CHALMERS), Sidi Souvi (ASNR), Andrei Komlev (KTH)

Objectives

- The EURATOM SOCRATES project addresses critical gaps in our understanding of the liquid source term during severe nuclear accidents and offers innovative solutions to mitigate and monitor the release of radionuclides into the environment.
- The project contributes to the mid-to-long-term management of nuclear power plants after a severe accident by enhancing safety, environmental protection, safe waste management and public well-being.

Key numbers

- Project duration from October 2024 to September 2028 with a total budget of €5.5 million.
- Involvement of 16 partners in the initiative.

Expected Impact

- **Comprehensive State-of-the-Art Report.** SOCRATES will review the current understanding of the liquid source term in SA, with emphasis on evaluating the capabilities of existing accident analysis codes.
- **Experimental database**. SOCRATES is building a database on water chemistry during nuclear accidents. Experiments will place major emphasis in investigating: specific fission products behavior in water; fuel debris leaching, including tests with real corium samples.
- **New computer code models**. SOCRATES will develop computer code models capable of predicting and managing the potential release of radioactive materials in liquid form during severe nuclear power plant accidents.
- **Innovative Absorbent Materials**. Promising absorbents for mitigating the release of radioactive materials in liquid form are being identified, and performance to demonstrated, including their own synthesis in SOCRATES.
- **Innovative Miniature Size Radiochemical Laboratory**. A novel miniature size radiochemical laboratory is being developed in SOCRATES to allow the early measurement of radionuclides of interest.

ABSTRACT

The paper presents selected outcomes of an uncertainty quantification (UQ) study for a Generation-III pressurized water reactor (PWR, 4500 MWth) subjected to an unmitigated large-break loss-of-coolant (LB-LOCA) leading to core melt. Two approaches were compared: (i) a Wilks'-theorem-based method using small samples to estimate a 95/95 tolerance interval, and (ii) Monte Carlo with a large sample to estimate the percentile intervals via the empirical cumulative distribution function (eCDF). Severe-accident behavior was modeled with MELCOR 2.2 within the EU Horizon 2020 NARSIS project. The figure of merit was total hydrogen generation during the in-vessel phase. Additionally, the impact of the sampling strategy on Monte Carlo results was compared for Simple Random Sampling (SRS) and Latin Hypercube Sampling (LHS). The results confirm that the Wilks approach yields conservative tolerance interval estimates, as expected. For Monte Carlo, differences between SRS and LHS were minimal, but some were observed.

Uncertainty quantification; PWR; MELCOR; large-break LOCA; hydrogen

1. INTRODUCTION

Uncertainty quantification (UQ) for severe accidents has become a popular topic not only for academia but also for industry and regulators. In the past, quantifying uncertainty in severe accidents was quite challenging, as it often required advanced tools and a large number of calculations, which were limited by resource constraints. Nowadays, it has become easier, and this is one of the reasons for the development we observe in the field. Severe accidents are characterized by complex phenomena with multi-physics and multi-scale features, with the propagation of uncertainties and interdependencies. At some point, it becomes clear that uncertainties must be studied for proper safety assessment. Within the field of traditional design-basis analysis, UQ is well established, at least for some applications. [1]. Nevertheless, in severe accident-related fields, it remains a novel topic.

It is worth mentioning that IAEA SSG-2 recommends uncertainty assessment for severe accidents [2]. An important example from the author's perspective is that the Polish regulatory framework requires uncertainty assessment in severe accident analysis within Deterministic Safety Analysis [3]. It is not specified how to perform it. Still, one possible approach is to apply modern methods with statistical assessment of uncertainty, such as the GRS method with the Wilks approach. It is a demanding but provides more informed answers than simple parametric sensitivity studies.

Some research projects were conducted, some are ongoing, or planned – e.g., the recognized H2020 EU-MUSA (2019-2023), which focused entirely on the quantification of severe accident uncertainty. [4], [5], [6]. Another example is the H2020 NARSIS project (2017-2022), where one of the small tasks within the safety analysis work package was to explore S&UA for severe accidents (see [7], [8], [9]). This paper aims to share selected outcomes of the NARSIS with the community.

This paper presents an exercise comparing the popular Wilks/GRS approach. [10], with a limited number of samples (N=93), and Monte Carlo-type calculations with a larger sample (N=400). The motivation was to test these two approaches with a practical case and eventually observe the kinds of differences in results that are possible. Especially to observe if Wilks provides a conservative estimate of the tolerance interval. Additionally, results obtained with Monte Carlo Simple Random Sampling (SRS) and Latin Hypercube Sampling (LHS) are compared. The motivation is that many references use LHS (e.g., SOARCA report [11]), and the author used it in [7]. However, discussions can be found that claim this is not an appropriate approach. [12]. It is argued that Wilks' method requires an entirely random sample and that LHS is not recommended for tolerance limit estimation. The authors wanted to investigate possible effects in a practical case. These exercises were prepared within the NARSIS project, activities are ongoing to extend this work and this paper is part of it. A detailed report related to this work is in the NARSIS WP4 Deliverable 4.5 [8].

2. METHODS

2.1. Plant model and studied scenario

In the NARSIS project, a definition for a generic Gen-III 1600 MWe PWR plant was developed [13]. The computational model was prepared for the MELCOR2.2.18 computer code [14], [15]. This model was studied in [7] and also used in this work. It has a typical core model with a simplified RPV TH model (see Figure 1 (Right)) and a relatively simple RCS model (see Figure 1(Left)). It has simple single-node containment, which was added to reduce computational effort. Despite being simple, it is considered enough for a low-pressure large LOCA-type scenario and in-vessel phenomena. The scenario considered in this paper is LB-LOCA with a double-ended break of the hot leg (HL). The break is located on the loop with the pressurizer, with all active safety injections unavailable.

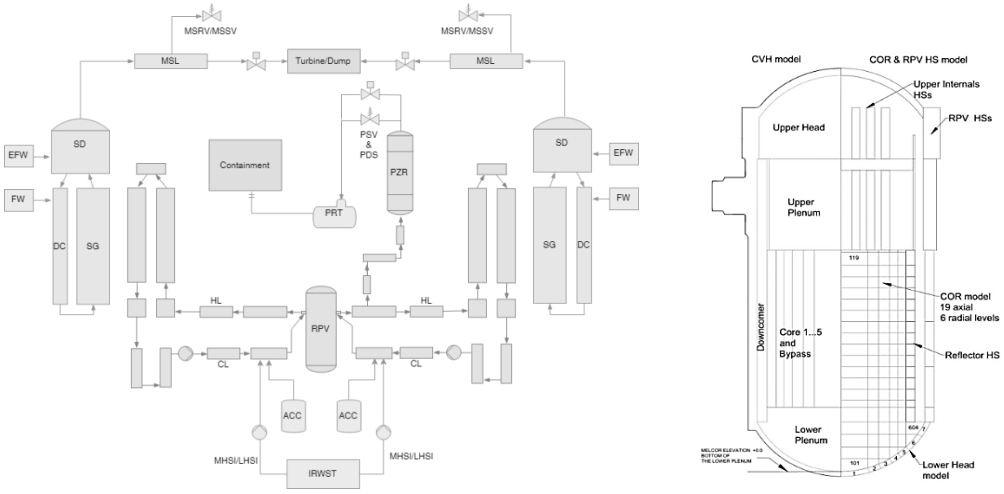

Figure 1. Left – RCS model. Right – RPV model. Based on [8] and [7].

2.2. Uncertainty methods

The in-house open-source tool dedicated to S&UA, the MelSUA, was applied [9]. The code version used to produce the results in this work is available on GitLab [16]. The tool was developed for the NARSIS project and was also applied in the report [8] and paper [7].
In this paper, results based on best estimate distributions are presented. Table I shows the MELCOR uncertainty parameters and their distribution data. Discussion and motivation behind using each parameter are available in [7]. The study is limited to the impact of different MELCOR-specific modelling parameters.

Table I. Uncertainty parameters and distributions selected for the study.

2.3. Studied cases and sampling

The first case compares the Monte Carlo calculation with N=400 samples and the Wilks with N=93 samples, necessary to achieve a two-sided non-parametric 95/95 tolerance interval. For Monte Carlo, it is assumed that samples are enough to find a reasonable empirical Cumulative Distribution Function (eCDF) for FoM and estimate percentiles. However, 400 samples still can be considered a relatively low value, but much larger than the typical Wilks sample. Both cases were sampled using the Simple Random Sampling (SRS). In the second case, a Monte Carlo calculation via SRS is compared with a similar calculation using LHS sampling.

3. RESULTS AND DISCUSSION

3.1. Monte Carlo vs Wilks

In this section, results for the Wilks and Monte Carlo-based methods are compared. The hydrogen mass as a function of time for the Wilks dataset is presented in Figure 2 (Left), and the Monte Carlo in Figure 2 (Right). The black line presents the calculation with Best Estimate parameters. Fully completed MELCOR runs are presented as grey lines (Success), and partially successful cases are presented by red lines (Partial). Partially successful cases that converged after the time limit – the 2500s, which is the expected time when most hydrogen will be generated in most cases – have a small impact on the final FoM value, even when calculations fail. The mean value evolution is shown as a dark blue line, and is based on the interpolation

and extrapolation for both fully and partially successful cases. A box chart is presented, with the central bar representing the median value for the final FoM, the lower and upper quartiles shown as boxes, the minimum and maximum values that are not outliers (black whiskers), and outliers shown as blue circles. Table II presents numerical values for the final FoM.

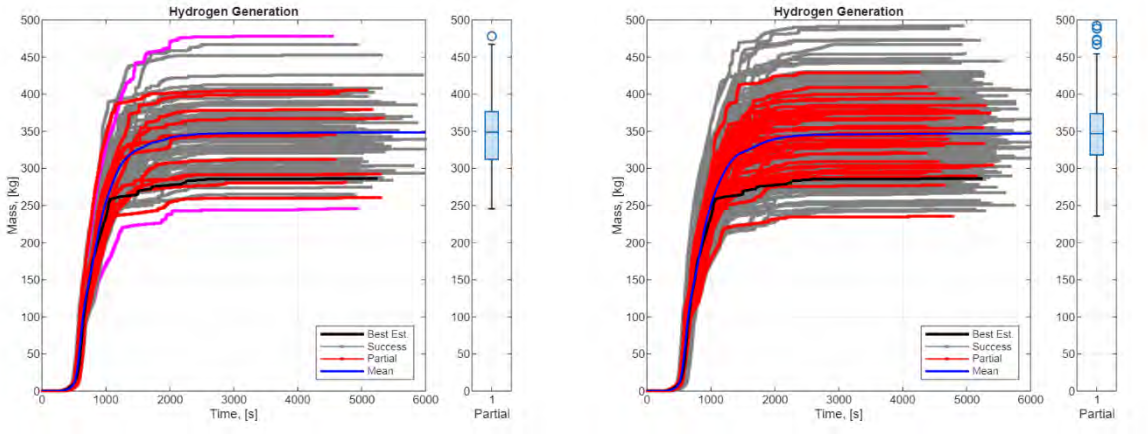

Figure 2. H2 mass vs time. Left – Wilks N=93 (min/max magenta). Right – Monte Carlo with SRS N=400.

It can be observed (see Figure 2 and Table II) that there are some differences between Wilks and MC. First of all, in MC, there are more upper outliers (Figure 2); the maximum/minimum values are larger/smaller than in Wilks (Table II). A larger sample has a solution covering a larger output space. For Wilks, the mean and median are slightly higher than for MC, and the central two quartiles interval (25 and 75) and percentile intervals (2.5, 5, 95, 97.5) have a larger spread (Table II). It is worth noting that the best estimate of FoM is substantially below the Median or Mean for both cases.

Table II. Selected metrics for final FoM (H2 [kg]) for Wilks and Monte Carlo (BE case excluded).

Final time FoM	Wilks 93	Monte Carlo SRS 400
Mean	348.3	346.6
Median	349.1	346.9
Standard Deviation	46.1	43.6
Quartile 25	312.8	317.6
Quartile 75	377.0	373.6
5/95 percentile	275.4 / 412.5	279.6 / 421.8
2.5/97.5 percentile	262.0 / 455.4	266.8 / 436.4
Min	**245.6**	235.8
Max	**478.3**	492.0
Best Estimate	286.6	286.6

Figure 3 (Left) presents Monte Carlo-based central intervals covering 50% (dark blue), 90% (medium blue), and 95% (light blue) of the sample, and compared with the Wilks minimum and maximum curves (magenta), indicating a 95/95 tolerance interval. The blue curve is the median from the Monte Carlo simulation. Data for MC presented in Figure 3 (Left) were processed, interpolated, and extrapolated to yield both successful and partially successful results. Figure 3 (Right) presents a comparison of the final time-step FoM empirical CDFs for Wilks and MC. Bounding curves for Wilks results representing 95/95 two-sided tolerance intervals can be compared with the 2.5-97.5 central interval represented by corresponding percentiles for MC. Where MC is single sample estimates of the percentiles, and Wilks provides a tolerance interval with

given confidence (95%) and coverage (95%). Importantly, Wilks' method does not estimate percentiles in the usual sense, and it does not guarantee that the resulting tolerance interval is central. Remembering about differences, we can, for comparison, estimate margins for FoM. For top/bottom bounds, Wilks predicted 478.3 kg and 245.6 kg, and for MC, 97.5% and 2.5% percentiles are 436.4 kg and 266.8 kg (see Table II). It gives margins equal to 41.9 kg and 21.2 kg, respectively.

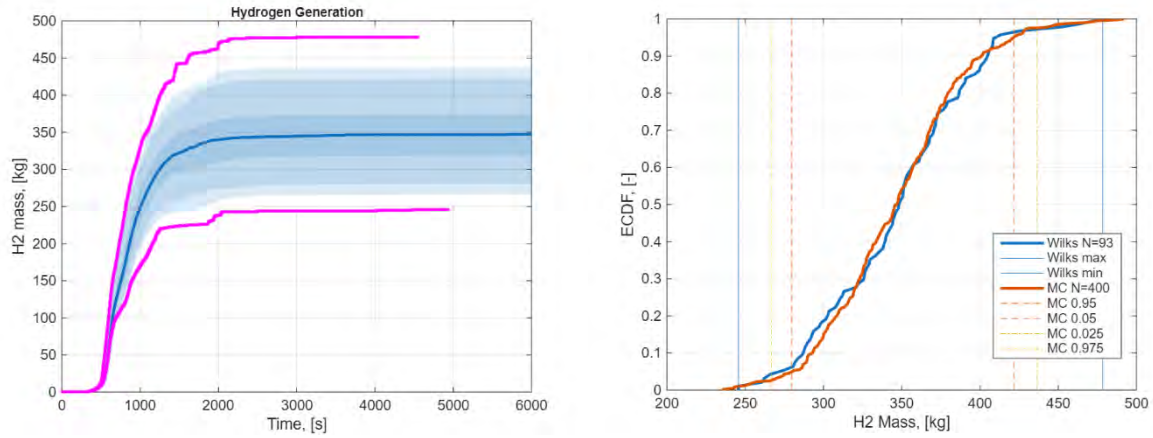

Figure 3. Left – Hydrogen mass (FoM) vs time with 50%, 90% and 95% central intervals for Monte Carlo and Wilks two-sided 95/95 tolerance intervals (magenta). Right – empirical CDFs for final FoM for Wilks and Monte Carlo with 2.5/97.5 and 5/95 percentiles (vertical lines).

From Figure 3, we observe that both the top and bottom limits are larger/lower than both 90% and 95% percentile regions for the Monte Carlo. It is the case for the whole transient. It was expected that the two-sided Wilks approach should conservatively bound the 2.5% and 97.5% percentile curves. Hence, it works as expected for this exercise. Empirical CDFs are slightly different for both Monte Carlo and Wilks (see Figure 3 (Right)). The MC curve is much smoother, which is due to the larger sample.

3.2. SRS vs LHS for Monte Carlo

Results for Monte Carlo with LHS are presented in Figure 4. The comparison of SRS and LHS is shown in Figure 5 and Table III. Hydrogen mass as a function of time in Figure 5 (Left) with SRS (blue) and LHS (red), where the plot covers the median curve, and central intervals with 50% (dark), 90% (medium shade), and 95% (light blue/red). Figure 5 (Right) presents the eCDFs for the final hydrogen mass. Numerical data for the final time FoM are presented in Table III.

Studying Figure 5, it can be observed that there is a small difference between the SRS and LHS results. There is a minimal downward shift of the 95% region for LHS – the top and bottom tails are shifted, and the distribution is shifted. It is also visible when studying percentiles in Table III. In the central 50% region, there is a minor effect. There is a substantial difference in the minimum value and a small difference in the maximum values (Table III). There are more outliers for LHS (see Figure 4 and Figure 2), as indicated by the max/min values (Table III). It is possible, as LHS should cover the input space more evenly, and it can produce more extreme outputs, but it can also be a random effect. LHS eCDF is smoother, a result of the even distribution of input parameters in the input phase space.

Table III. Selected final FoM (H2 [kg]) for Monte Carlo with SRS and LHS (BE case excluded).

Final time FoM	Monte Carlo LHS 400	Monte Carlo SRS 400
Mean	347.6	346.6
Median	346.1	346.9
Standard Deviation	42.8	43.6
Quartile 25	318.8	317.6
Quartile 75	373.8	373.6
5/95 percentile	277.4 / 419.5	279.6 / 421.8
2.5/97.5 percentile	263.9 / 429.5	266.8 / 436.4
Min	220.3	235.8
Max	495.5	492.0
Best Estimate	286.6	286.6

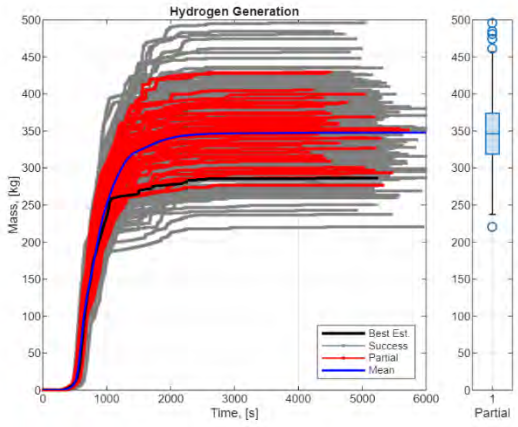

Figure 4. H2 mass vs time for MC with LHS.

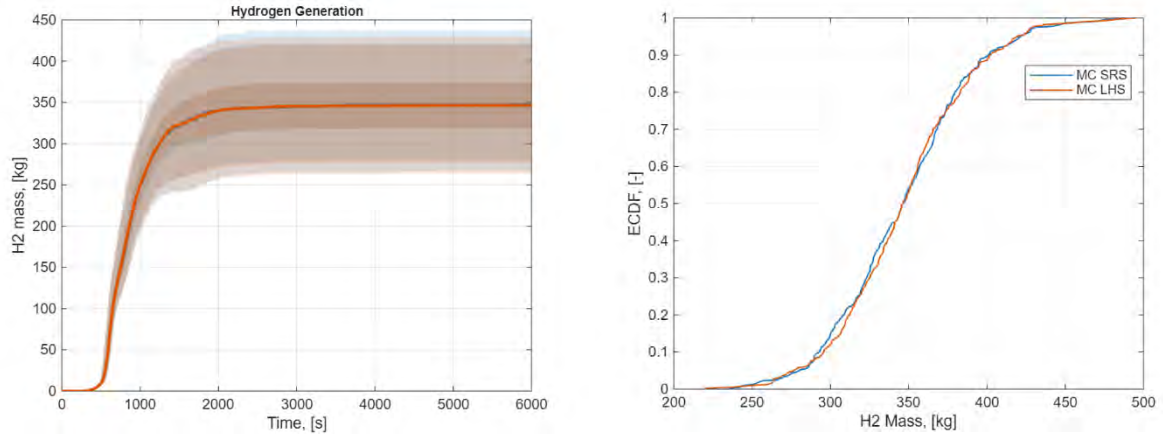

Figure 5. Left – Hydrogen mass (FoM) vs time with 50%, 90%, 95% central intervals for MC LHS (red) and SRS (blue). Right – empirical CDFs for final FoM for LHS (red) and SRS (blue).

3.3. Run statistics

A list of computed cases and statistics of success, partial success, and failed cases is presented in Table IV. Failed cases and partially failed cases introduce bias into the statistics of the obtained results. It is still a common issue in severe accident S&UA. The best approach would be to correct all failed cases, but it is a

challenging task when a dozen failures occur. In the case of Wilks, the results of the initial two instances failed before the partial success limit. Still, they were corrected successfully, and, as a result, all instances converged above the partial success limit of 2500 seconds. The authors were not able to correct failed cases in the Monte Carlo datasets.

Table IV. List of calculated cases/datasets and statistics. Additional case (+1) is the BE run.

Name	Sampling Method	No. of runs	Success/ Partial Success/Failed	Success / Partial Success Percentage
MC SRS	SRS (N=400)	400+1	353/397/3	88.2%/99.3%
MC LHS	LHS (N=400)	400+1	350/395/5	87.5%/98.5%
Wilks 93	SRS Wilks (N=93)	93+1	82/93/0	88.2%/100%

4. CONCLUSIONS

In the comparison between Wilks (N=93) and Monte Carlo (N=400), the practical test case illustrates that the Wilks yields a two-sided 95/95 nonparametric tolerance interval. In this particular case, the Wilks min–max envelopes the MC central 95% interval (2.5^{th}–97.5^{th} percentiles). In principle, it is not guaranteed, since Wilks provides a tolerance interval (coverage/confidence) rather than a central percentile interval. The observed differences in the figure of merit (FoM) between the MC bands and the Wilks bounds were relatively large, which is consistent with the conservative character of the Wilks approach. The final hydrogen mass (FoM) prediction margin, for top and bottom bounding values, was 41 kg and 21 kg, respectively between Wilks and MC percentiles (2.5^{th} –97.5^{th}).

Comparing Monte Carlo LHS and SRS, we did not observe a substantial difference in the overall results or in the cumulative distribution function of the final FoM. The main difference was the outliers for LHS. These are likely due to LHS's greater ability to reach the parameter space, leading to outliers. However, it is inconclusive because it could also be a random effect rather than a sampling method. Still, the difference due to outliers can be considered as not very significant, at least considering the studied FoM.

What is also essential is that some failed cases were observed, which is why the reader should have a proper margin of confidence. In the next step, it is possible to produce a larger sample (e.g., 900), use a set of independent samples (e.g., 3x300), or other approaches, to increase confidence in Monte Carlo outcomes. Other approach is to test various Wilks samples and study the impact of repeatability.

COMPARISON OF MONTE CARLO AND WILKS' METHODS FOR UNCERTAINTY QUANTIFICATION OF A SEVERE ACCIDENT IN A PWR

Piotr Darnowski, Institute of Heat Engineering, Warsaw University of Technology, Nowowiejska 21/25, 00-665, Warsaw, Poland, piotr.darnowski@pw.edu.pl, **Paper 158**

Abstract The paper presents selected outcomes of an uncertainty quantification (UQ) study for a Generation-III pressurized water reactor (PWR, 4500 MWth) subjected to an unmitigated large-break loss-of-coolant (LB-LOCA) leading to core melt. Two approaches were compared: (i) a Wilks'-theorem-based method using small samples to estimate a 95/95 tolerance interval, and (ii) Monte Carlo (MC) with a large sample to estimate the percentile intervals via the empirical cumulative distribution function (eCDF). Severe-accident behavior was modeled with MELCOR 2.2 within the EU Horizon 2020 NARSIS project. The figure of merit was total hydrogen generation during the in-vessel phase. Additionally, the impact of the sampling strategy on Monte Carlo results was compared for Simple Random Sampling (SRS) and Latin Hypercube Sampling (LHS). The results confirm that the Wilks approach yields conservative tolerance interval estimates, as expected. For Monte Carlo, differences between SRS and LHS were minimal, but some were observed.

Motivation The exercise compares Wilks/GRS approach [10], with a limited number of samples (N=93), and MC calculations with a larger sample (N=400). The motivation was to test these two approaches with a practical case and eventually observe the kinds of differences in results that are possible. Especially to observe if Wilks provides a conservative estimate of the tolerance interval. Additionally, results obtained with MC SRS and LHS are compared. The motivation is that many references use LHS (e.g. [11]), and the author used it in [7]. However, discussions can be found that it is not an appropriate approach [12]. The authors wanted to investigate possible effects in a practical case. A detailed report related to this work is in the NARSIS D4.5 [8].

Plant model and studied scenario In the NARSIS, a definition for a generic Gen-III 1600 MWe PWR plant was developed [13]. The model was prepared for the MELCOR2.2.18 computer code [14], [15]. The scenario considered is LB-LOCA with a double-ended break of the hot leg (HL). The break is located on the loop with the pressurizer, with all active safety injections unavailable.

Uncertainty methods The in-house open-source tool dedicated to S&UA, the MelSUA, was applied [9]. The code is available on GitLab [16]. The tool was developed for the NARSIS project and was also applied in the report [8] and paper [7]. In this paper, results based on best estimate distributions are presented. Table I shows the uncertainty parameters.

Studied cases and sampling The first case compares the MC with N=400 samples and the Wilks with N=93 samples, necessary to achieve a two-sided non-parametric 95/95 tolerance interval. For MC, it is assumed that samples are enough to find a reasonable empirical Cumulative Distribution Function (eCDF) for FoM and estimate percentiles. However, N=400 still can be considered a relatively low value, but much larger than the typical Wilks sample. Both cases were sampled using the SRS. In the second case, a MC calculation was performed using LHS sampling with N=400.

Table I. Uncertainty parameters and distributions selected for the study.

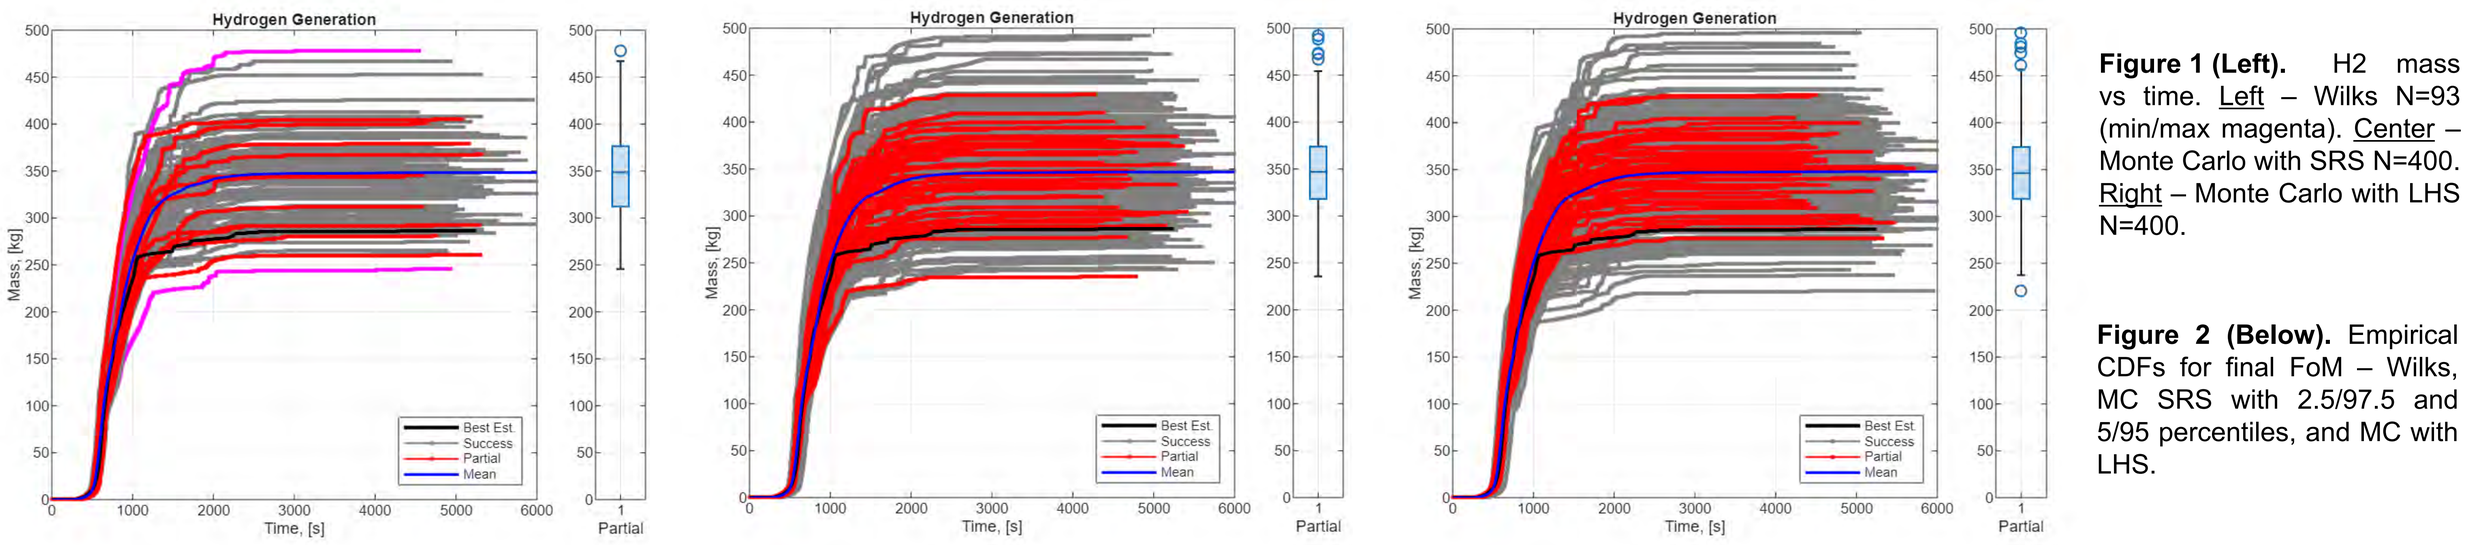

Figure 1 (Left). H2 mass vs time. Left – Wilks N=93 (min/max magenta). Center – Monte Carlo with SRS N=400. Right – Monte Carlo with LHS N=400.

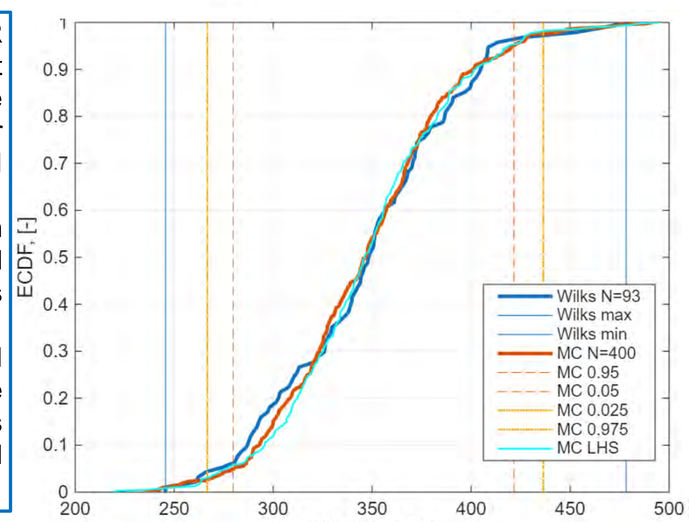

Figure 2 (Below). Empirical CDFs for final FoM – Wilks, MC SRS with 2.5/97.5 and 5/95 percentiles, and MC with LHS.

Results Monte Carlo vs Wilks The Wilks and MC SRS are compared in Figure 1. The black line presents the BE result. Fully completed MELCOR runs are presented as grey lines (Success), and partially successful cases are presented by red lines (Partial). Partially successful cases that converged after the time limit – the 2500s, which is the expected time when most hydrogen will be generated in most cases. The mean value evolution is shown as a dark blue line. A box chart, with the central bar is representing the median value for the final FoM, the lower and upper quartiles shown as boxes, the minimum and maximum values that are not outliers (black whiskers), and outliers shown as blue circles. Table II presents numerical values for the final FoM.

There are some differences between Wilks and MC. In MC, there are more upper outliers (Figure 1); the max/min values are larger/smaller than in Wilks (Table II). A larger sample has a solution covering a larger output space. For Wilks, the mean and median are slightly higher than for MC, and the central two quartiles interval (25 and 75) and percentile intervals (2.5, 5, 95, 97.5) have a larger spread (Table II). The best estimate FoM is substantially below the Median or Mean for both cases.

Figure 2 presents the eCDFs. Min/max curves for Wilks representing 95/95 two-sided tolerance intervals can be compared with the 2.5-97.5 central interval represented by corresponding percentiles for MC. Where MC is single sample estimates of the percentiles, and Wilks provides a tolerance interval with given confidence (95%) and coverage (95%). Importantly, Wilks' method does not estimate percentiles in the usual sense, and it does not guarantee that the resulting tolerance interval is central. We can estimate margins for FoM. For top/bottom bounds, Wilks predicted 478.3 kg and 245.6 kg, and for MC, 97.5% and 2.5% percentiles are 436.4 kg and 266.8 kg (Table II).

Results SRS vs LHS Results for MC with LHS are presented in Figure 1 (Right) and eCDFs in Figure 2. Data for the final time FoM are presented in Table II. It can be observed that there is a small difference between the SRS and LHS results. There is a minimal downward shift of the 95% region for LHS – the top and bottom tails are shifted, and the distribution is shifted. It is also visible when studying percentiles in Table II. In the central 50% region, there is a minor effect. There is a substantial difference in the minimum value and a small difference in the maximum values (Table II). There are more outliers for LHS (see Figure 1), as indicated by the max/min values (Table II). It is possible, as LHS should cover the input space more evenly, and it can produce more extreme outputs, but it can also be a random effect. LHS eCDF is smoother, a result of the even distribution of input parameters in the input phase space.

Conclusions In the comparison between Wilks and MC, the practical test case illustrates that the Wilks yields a two-sided 95/95 nonparametric tolerance interval. In this particular case, the Wilks min–max envelopes the MC central 95% interval (2.5th–97.5th percentiles). In principle, it is not guaranteed, since Wilks provides a tolerance interval rather than a central percentile interval. The observed differences in the FoM between the MC bands and the Wilks bounds were relatively large, which is consistent with the conservative character of the Wilks approach.

Comparing Monte Carlo LHS and SRS, we did not observe a substantial difference in the overall results or in the cumulative distribution function of the final FoM. The main difference was the outliers for LHS. These are likely due to LHS's greater ability to reach the parameter space, leading to outliers. However, it is inconclusive because it could also be a random effect rather than a sampling method. Still, the difference due to outliers can be considered as not very significant, at least considering the FoM.

What is also essential is that some failed cases were observed, which is why the reader should have a proper margin of confidence.

Table II. Selected metrics for (H2 [kg]) for Wilks and MC with SRS and LHS).

Final time FoM	Wilks N=93	Monte Carlo SRS N=400	Monte Carlo LHS N=400
Mean	348.3	346.6	347.6
Median	349.1	346.9	346.1
Standard Deviation	46.1	43.6	42.8
Quartile 25	312.8	317.6	318.8
Quartile 75	377.0	373.6	373.8
5/95 percentile	275.4 / 412.5	279.6 / 421.8	277.4 / 419.5
2.5/97.5 percentile	262.0 / 455.4	266.8 / 436.4	263.9 / 429.5
Min	245.6	235.8	220.3
Max	478.3	492.0	495.5
Best Estimate	286.6	286.6	286.6

ABSTRACT

This paper describes the development and assessment of the SAVANNAH (Severe Accident Vessel-exterior Analysis of Non-equilibrium Nodal thermAl Hydraulics) module, a component of the SAFARI code designed for integrated severe accident analysis in nuclear reactors. The SAVANNAH module evaluates containment thermal-hydraulic behavior by modeling compartments as 'CELL' nodes and inter-compartment flows as 'FLOP' paths. The module utilizes discretized conservation equations for mass, energy, and momentum, which are solved via an iterative numerical scheme to account for the strong coupling between thermodynamic states and fluid velocities. Various constitutive models, including wall heat transfer and friction, are implemented to capture complex physical phenomena. The module was verified using conceptual problems—such as adiabatic hydrogen expansion and 1-D flow with minor losses —and validated against the HDR V44 large-scale containment experiment. Assessment results indicate that SAVANNAH accurately predicts analytical solutions and demonstrates good agreement with experimental data, particularly in long-term containment pressure and temperature trends.

SAFARI, SAVANNAH, Containment, Thermal-hydraulics

1. INTRODUCTION

The accurate prediction of containment thermal-hydraulic responses during a severe accident is fundamental to ensuring reactor safety and evaluating the efficacy of mitigation strategies. In South Korea, severe accident management and regulatory compliance have predominantly relied on international computational tools such as MELCOR [1], developed under the support of the U.S. Nuclear Regulatory Commission (NRC). However, recent restrictions on source code access imposed by the NRC have created significant hurdles for domestic researchers and regulators in adapting these codes to address South Korea's specific safety requirements and unique regulatory needs. Consequently, there is a pressing and urgent need to develop an independent, domestic analysis code tailored to Korea's severe accident management landscape.

To address this need, the SAFARI code is being developed as an integrated platform for comprehensive severe accident analysis, with the SAVANNAH (Severe Accident Vessel-exterior Analysis of Non-equilibrium Nodal thermAl Hydraulics) module specifically dedicated to simulating ex-vessel containment behavior. As the final barrier against radioactive release, the containment's integrity depends

* Footnote, if necessary, in Times New Roman font and font size 10

on complex interactions between coolant, non-condensable gases, and corium-related thermal loads. The SAVANNAH module employs a lumped-parameter approach, modeling the containment environment using distinct regions: a water pool and an atmospheric phase. Its numerical framework is strategically designed to align with proven methodologies used in MELCOR to ensure reliability while providing the necessary flexibility for local adaptation and source-level modifications.

This paper introduces the theoretical framework of the SAVANNAH module, including its governing equations, constitutive models, and numerical solution schemes. Furthermore, the module's performance is evaluated through verification against conceptual benchmarks and validation using the HDR V44 large-scale containment experiment.

2. CONCEPT OF SAVANNAH MODULE

The SAVANNAH (Severe Accident Vessel-exterior Analysis of Non-equilibrium Nodal thermAl Hydraulics) module within the SAFARI code is responsible for analyzing the thermal-hydraulic behavior inside the containment. This module models each compartment within the containment as a single numerical node, while the fluid flow between compartments is simulated as flow paths. In the SAVANNAH module, these nodes are called 'CELL,' and the flow paths are called 'FLOP.' Each CELL consists of a pool and an atmosphere, which can have different thermodynamic states. The pool is composed solely of water in liquid and vapor phases, without considering dissolved non-condensable gases. The atmosphere consists of water vapor and non-condensable gases.

During severe accidents, SAVANNAH tracks the mass of molten core (CORIUM) and radioactive substances released into the containment. While phenomena like FCI and MCCI are handled by specific SAFARI submodules, SAVANNAH integrates their effects by accounting for decay heat and the generation of non-condensable gases like hydrogen and carbon dioxide.

3. MODELS OF SAVANNAH MODULE

3.1. Discretized Governing Equations

3.1.1. Discretized mass conversion equation

Equation (1) represents the discretized mass conservation equations for each material within compartment i. Here, i denotes the compartment index, m the material index (1 for pool water, 2 for water vapor in the atmosphere, and 3 and above for non-condensable gases), Φ the phase (pool or atmosphere), and j the flow path index. The superscript d indicates the upstream (donor) compartment value, n the current time step, and o the previous time step. The variable $M_{i,m}$ denotes the mass of material m in compartment i, $\delta M_{i,m}$ represents the external mass source, and σ_{ij} describes the connectivity between compartment i and flow path j. The value of σ_{ij} is –1 if compartment i is connected as the 'from' node of flow path j, 1 if connected as the 'to' node, and 0 if no connection exists. The primary unknowns in this discretized mass conservation equation are the mass of each material ($M_{i,m}^{n}$) and the velocity of each phase within the flow path ($v_{j,\phi}^{n}$).

$$M_{i,m}^{n} - M_{i,m}^{n} = \sum_j \sigma_{ij} \alpha_{j,\phi}^{n} \rho_{j,m}^{d} v_{j,\phi}^{n} A_j \Delta t + \delta M_{i,m} \quad (1)$$

3.1.2. Discretized energy conversion equation

Equation (2) expresses the discretized energy conservation equations for each phase within compartment i. Here, $E_{i,\phi}$ represents the total internal energy of phase Φ in compartment i, and $\delta E_{i,\phi}$ denotes the external energy source. The primary unknowns in this discretized energy conservation equation are the internal energy of each phase ($E^n_{i,\phi}$), and the velocity of each phase in the flow path ($v^n_{j,\phi}$).

$$E^n_{i,\phi} - E^n_{i,\phi} = \sum_j \sigma_{ij}\alpha^n_{j,\phi}(\rho^d_{j,m}h^d_{j,m})v^n_{j,\phi}A_j\Delta t + \delta E_{i,\phi} \quad (2)$$

3.1.3. Discretized momentum conservation equation

Equation (3) describes the discretized momentum conservation equation for each phase in flow path j, where the momentum is influenced by the pressures of adjacent compartments i and k ($P_i^{\tilde{n}}$, $P_k^{\tilde{n}}$). In this equation, ΔP_{pp} represents the pressure change due to the pump, f is the friction coefficient, and K is the minor loss coefficient.

The momentum change in the flow path is governed by the pressure (including local head) of adjacent compartments, while the pressure and water level in each compartment are affected by the velocity along the flow path. Therefore, the momentum of the flow path is closely coupled with the mass and energy of the compartments, requiring iterative calculations. Variables with superscript d vary due to convection terms; for example, $P_i^{\tilde{n}}$ represents the pressure updated by considering pressure changes due to mass and energy transfer through the flow path based on the previous pressure value.

$$v^n_{j,\phi} = v^o_{j,\phi} + \frac{\Delta t}{\rho_{j,\phi}L_j}\left[P_i^{\tilde{n}} + \Delta P_{pp} - P_k^{\tilde{n}} + (\rho g \Delta z)^{\tilde{n}}_{j,\phi} - \left(f\frac{L_j}{D} + \sum K\right)\frac{\rho_{j,\phi}}{2}\left(|v^{n-1}_{j,\phi} + v^{n-2}_{j,\phi}|v^n_{j,\phi} - |v^{n-2}_{j,\phi}|v^{n-1}_{j,\phi}\right)\right] \quad (3)$$

3.2. Heat Structure Model

The heat structure model analyzes heat transfer inside and between compartments due to solids such as concrete or steel plates within the containment. The SAVANNAH heat structure model simulates heat conduction in solids using the one-dimensional heat conduction equation as shown in Equation (4).

$$\frac{\partial}{\partial t}\left(\rho C_p T\right) = \nabla \cdot (k\nabla T) + \dot{q} \quad (4)$$

Here, ρ, C_p, k, T, and $\dot{q}$ represent density, specific heat at constant pressure, thermal conductivity, temperature, and volumetric heat source, respectively.

3.3. Constitutive Equations

The constitutive equations in SAVANNAH include wall heat transfer models, wall friction models, and interfacial heat and mass transfer models between the pool and atmosphere. Representative constitutive equations implemented in SAVANNAH are summarized in Table I.

Wall heat transfer models include convection, condensation, and boiling, while radiation heat transfer is not yet implemented. Walls exchange heat with either the pool or the atmosphere within a CELL. The heat transfer area with each phase is determined by the wall geometry and the submersion ratio.

The wall friction model is divided into three regions based on Reynolds number (Re): laminar, turbulent, and transitional, with criteria as follows:

- Laminar: Re < 2200

- Turbulent: Re > 3000
- Transitional: 2200 ≤ Re ≤ 3000

When water and gas flow simultaneously through a flow path, horizontal stratified flow is assumed, and wall friction for two-phase flow is considered by adding interfacial friction to wall friction for each phase.

The interfacial heat and mass transfer model addresses heat and mass transfer across the pool-atmosphere interface within compartments, implemented based on heat and mass transfer analogy.

Table I. Constitutive equations of the SAVANNAH module

Type		Models	References
Natural Convection	**Larminar**	$Nu = 0.59Ra^{1/4}$	[2]
	Turbulent	$Nu = 0.13Ra^{1/3}$	[2]

Condensation		HMTA, $\Gamma'' = \frac{M_s Sh D_{sg} \bar{c}}{D_h} ln\left(\frac{P_{tot} - P_{s,i}}{P_{tot} - P_{s,b}}\right)$	[4]
Boiling		$q'' = F \cdot h_{cv}(T_w - T_p) + S \cdot h_{npb}(T_w - T_{sat})$	[5]
Wall Friction (Darcy)	**Larminar**	$f_\phi = \frac{64}{Re}$	[6]
	Turbulent	$\frac{1}{\sqrt{f_\phi}} = -2\log_{10}\left[\frac{1}{3.7}\frac{\varepsilon}{d} + \frac{2.51}{Re}\left\{1.14 - 2\log_{10}\left(\frac{\varepsilon}{d} + \frac{21.5}{Re^{0.9}}\right)\right\}\right]$	[6]
	Transient	$f_\phi = \left(3.75 - \frac{8250}{Re}\right)\left(f_{\phi,Re=3000} - f_{\phi,Re=2200}\right) + f_{\phi,Re=2200}$	[6]
Interfacial Friction		$f_i = 900\left[\alpha\sqrt{\rho_g} + (1-\alpha)\sqrt{\rho_l}\right]$	[1]
Interfacial Heat & Mass Transfer		HMTA, $\Gamma'' = \frac{M_s Sh D_{sg} \bar{c}}{D_h} ln\left(\frac{P_{tot} - P_{s,i}}{P_{tot} - P_{s,b}}\right)$	[4]

4. NUMERICAL SOLUTION SCHEME

4.1. Iterative Scheme

Equations (1)–(3) represent the discretized mass conservation, energy conservation, and momentum conservation equations, respectively. To solve the mass and energy conservation equations, the convective terms in the flow paths must be determined. These convective terms are calculated through the momentum conservation equation. However, since the convective terms depend on the pressures of adjacent compartments, mass and energy information must be known beforehand. Because mass, energy, and momentum are closely interrelated, iterative calculations are required.

Figure 1 shows the flowchart for solving the governing equations in the SAVANNAH module. The 'Update Pressure Equation' step converts the pressures of adjacent compartments into velocity-related expressions, reformulating Equation (3) as a function of velocity. This allows the configuration and solution of a matrix for velocity calculation, yielding velocities of each phase within the flow paths. After velocity calculation, the mass and energy conservation equations are solved to determine the mass and energy of all compartments. Subsequently, the thermodynamic states of the pool and atmosphere consistent with the compartment mass and energy are found. The iteration continues until the difference

between the compartment pressure and the pressure from the previous iteration falls below a specified tolerance. Primary and secondary unknowns of this numerical method are summarized in Table II.

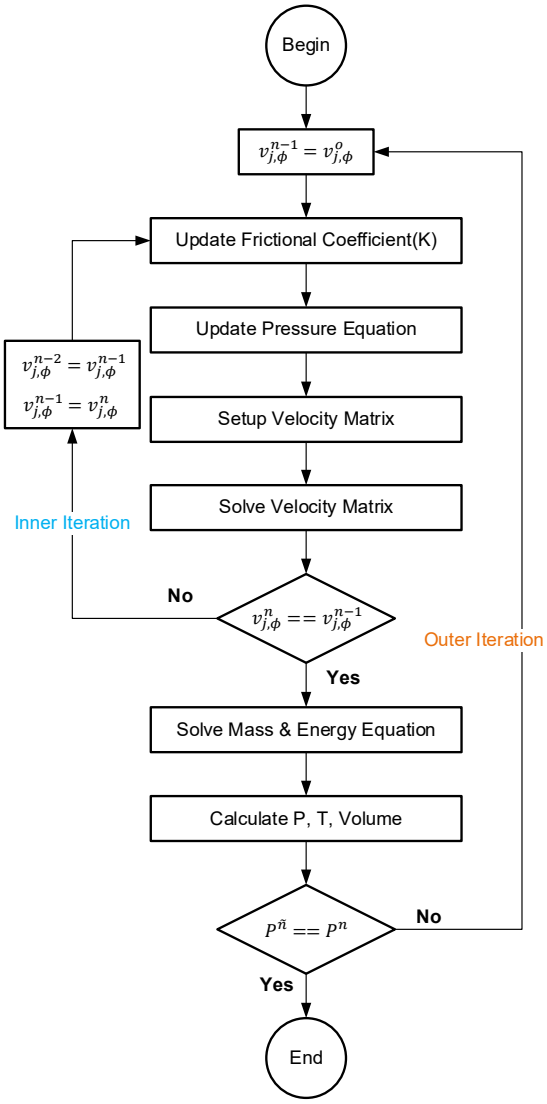

Figure 1. Flowchart for solving the governing equations

Table II. Unknown variables of the SAVANNAH module

Type	Variables	Unit
Primary Unknown	Material Mass	kg
	Phase Internal Energy	J
	Phase Velocity	m/s
Secondary Unknown	Pressure	Pa
	Phase Temperature	K
	Phase Volume	m^3

4.2. Equation of State (EOS)

Water properties are calculated based on IFC67 [7], while properties of non-condensable gases are computed according to McBride [8, 9].

Figure 2 illustrates the flowchart for determining the thermodynamic states of the pool and atmosphere consistent with the compartment mass and energy. Subscripts p and a denote the pool and atmosphere, respectively. As described previously, the compartment mass and energy are obtained by solving the mass and energy conservation equations. Since the volumes of each phase are initially unknown, the thermodynamic state of the pool is estimated using its specific internal energy and an assumed pressure. Next, the pool volume is calculated by multiplying the pool mass by its specific volume. Using the total compartment volume minus the pool volume, the atmosphere volume is determined. With the atmosphere volume known, the densities of its constituent gases can be calculated. Then, the thermodynamic state of the atmosphere is found based on its internal energy and constituent densities. Finally, the pressure difference between the assumed pressure and the calculated atmospheric pressure is evaluated. This entire process is repeated iteratively until the pressure difference falls below a predefined tolerance, confirming consistent thermodynamic states for both phases.

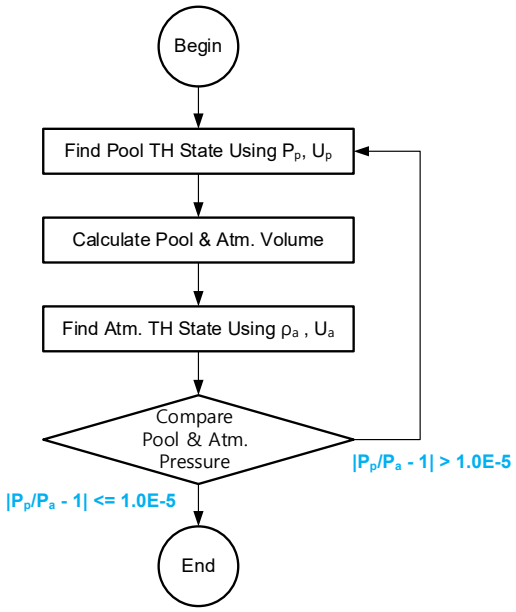

Figure 2. Flowchart for finding thermal-hydraulic states

5. ASSESSMENT

The assessment of the SAVANNAH module utilizes a V&V matrix consistent with those used for the V&V of the MELCOR and CAP codes. This assessment is categorized into conceptual problem assessments and experimental assessments. The conceptual problems consist of simplified scenarios with analytical solutions, serving as a verification phase to ensure that the fundamental functions and physical models of the code are correctly implemented. The experimental assessments represent the validation phase, where the module's performance is evaluated by simulating a containment test and comparing the results with experimental data. This paper presents a selected set of these assessment results.

5.1. Conceptual Problem Assessment

5.1.1. Adiabatic expansion of hydrogen

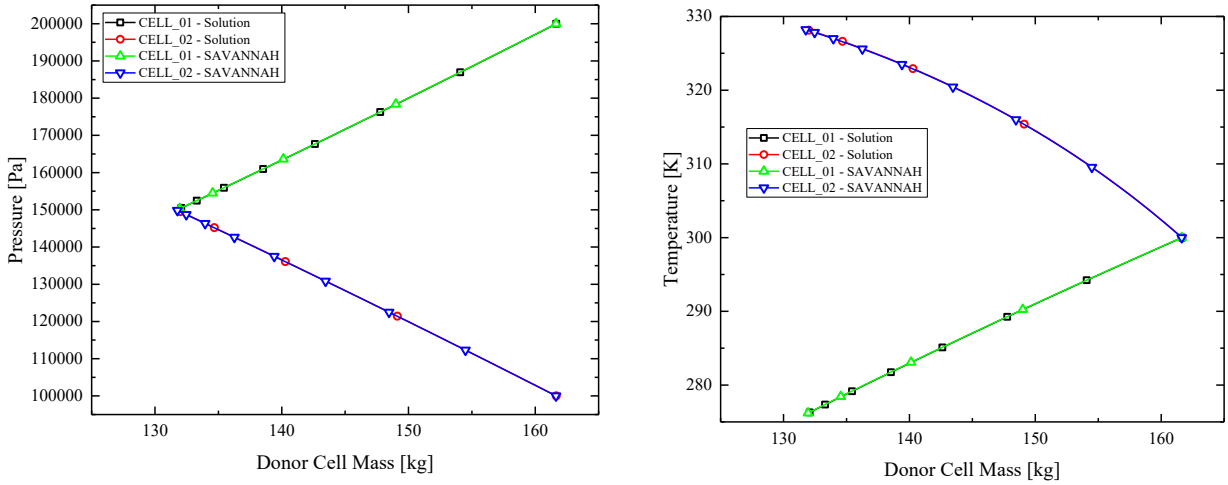
This conceptual problem evaluates pressure and temperature changes driven by the adiabatic expansion of hydrogen, a scenario previously utilized for MELCOR verification. The nodalization for this problem

consists of two control volumes (CELLs) and one flow path (FLOP). The test conditions for the control volumes and flow path are summarized in Table III.

Figure 3 illustrates a comparison between the analytical solution and the SAVANNAH calculation results for the pressure and temperature in Case 1. In these figures, the x-axis represents the mass of the donor cell (Cell #1), and the y-axis indicates the pressure or temperature. The results demonstrate that SAVANNAH accurately predicts the pressure and temperature behavior during hydrogen expansion. While not detailed in this paper, SAVANNAH also exhibited highly consistent results with the solutions in the remaining test cases.

Table III. Test condition for adiabatic expansion of hydrogen

Case	Cell #1			Cell #2			Flop	
	Volume [m^3]	P [bar]	T [K]	Volume [m^3]	P [bar]	T [K]	Area [m^2]	Minor loss [-]
1	1000	2.0	300	1000	1.0	300	0.05	2
2	1000	5.0	300	1000	1.0	300	0.05	2
3	100	2.0	300	1000	1.0	300	0.05	2
4	10000	2.0	300	1000	1.0	300	0.05	2
5	1000	2.0	300	1000	1.0	300	50.0	2
6	1000	2.0	300	1000	1.0	300	0.05	0.1



(a) Pressure (b) Temperature

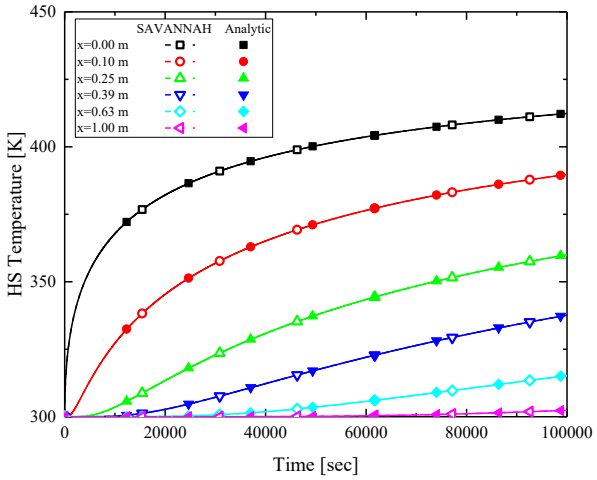
Figure 3. Adiabatic expansion of hydrogen assessment results – Case 1

5.1.2. Semi-Infinite Solid Heat Structure

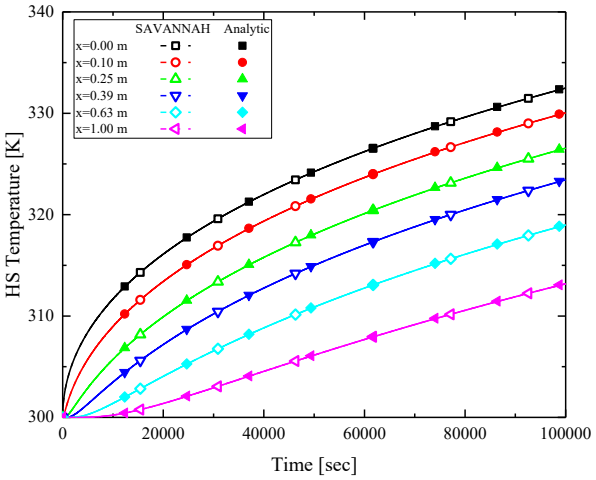
This problem is designed to verify whether the Heat Structure package accurately calculates the internal temperature distribution of a solid, a test case also adopted in MELCOR verification. The structure has a thickness of 10.0 m and a heat transfer coefficient of 10.0 W/m²-K between the wall and fluid. Other test conditions are provided in Table IV. Figure 4 compares the time-series temperature distribution within the structure between the analytical solution and the SAVANNAH calculation. The results confirm that the Heat Structure package in SAVANNAH appropriately predicts the temperature profile within the solid.

Table IV. Test condition for Semi-Infinite Solid Heat Structure

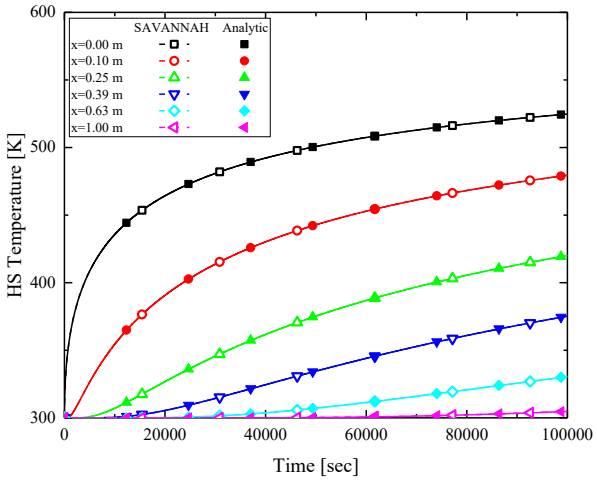
Case	Initial Temp. [K]	Bulk Temp. [K]	Material	Density [kg/m^3]	Heat Capacity [J/kg-K]	Conductivity [W/m-K]
1	300.0	450.0	Concrete	2300.0	650.0	1.6
2	300.0	450.0	Steel	7850.0	500.0	47.0
3	300.0	600.0	Concrete	2300.0	650.0	1.6



(a) Case #1



(b) Case #2



(c) Case #3

Figure 4. Semi-Infinite solid heat structure assessment results

5.1.3. 1-D flow with minor loss

Figure 5 defines this conceptual problem, which involves two sufficiently large control volumes connected by a single flow path. The flow path incorporates various components that induce minor losses and includes an elevation change. The flow path is characterized by a length of 160 m, a diameter of 0.2 m, and a surface roughness of 0.046 mm, with a total elevation change of 20 m. The total minor loss coefficient is 12.2, accounting for a sharp entrance (0.5), an open globe valve (6.9), a 12-inch bend (0.15), a regular 90° elbow (0.95), a half-closed gate valve (2.7), and a sharp exit (1.0). Figure 6 shows that the SAVANNAH calculation results are in good agreement with the analytical solution, demonstrating the module's capability to accurately simulate flow behavior in paths with significant minor losses.

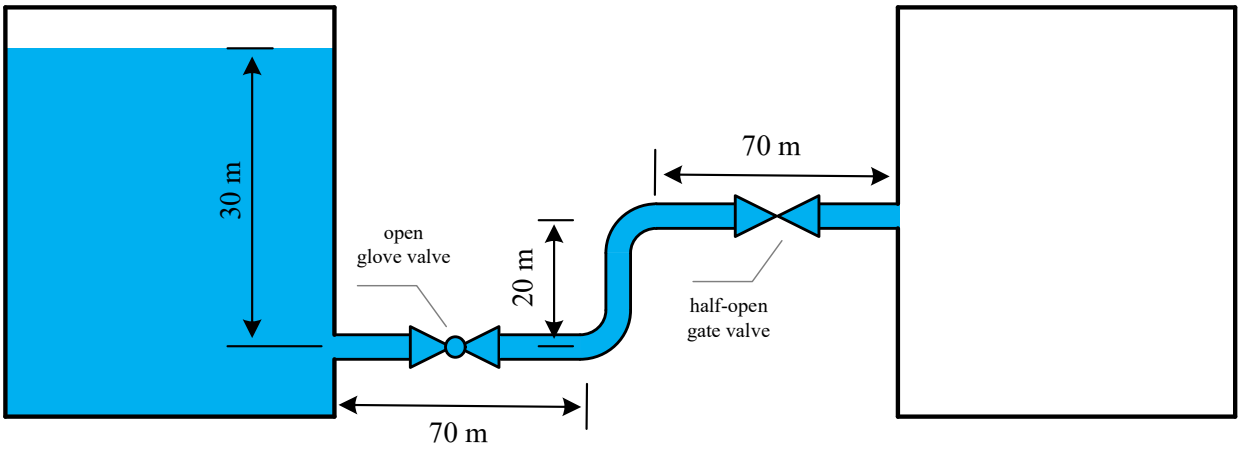


Figure 5. Conceptual problem: 1-D flow with minor loss

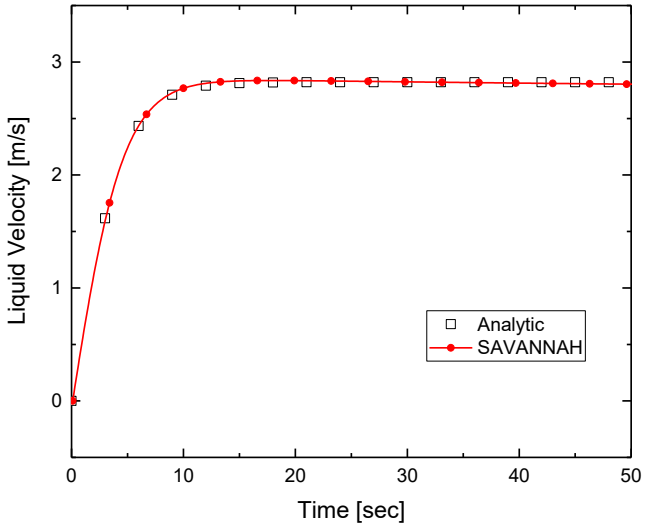

Figure 6. 1-D flow with minor loss assessment results

5.2. Experiment Assessment

5.2.1. HDR V44

Heissdampfreaktor (HDR) is a German superheated steam reactor, which was decommissioned. Through the experiments conducted in this facility, documents that describe the thermohydraulic behavior within a full-scale containment during a blowdown of water or steam/water in the reactor vessel of the containment [10, 11].

Main equipments of the experimental facility is a pressure vessel and a containment building. The indoor pressure vessel has a diameter of 3 m and a height of 11 m. Before a blowdown experiment, most structures inside the pressure vessel are removed to maximize the blowdown flow rate, and the free volume of the vessel is equal to 75 m3. The diameter, height, and total free volume of the containment are 20 m, 60 m, and 11,300 m3, respectively.

The blowdown experiments conducted in the HDR are sorted into several groups depending on their characteristics. Test V44 has a break in the compartment 1603, and the initial pressure of the compartment is 100 kPa. Moreover, the initial temperature of the compartment is generally about 25 ℃, and there is a minor stratification from the bottom to the top of the containment. The initial temperature is about 60 ℃ in a circular crack around the pressure vessel. Initial pressure and temperature of the pressure vessel are 11.1 MPa and 318 ℃, respectively. Finally, the water level of the pressure vessel is approximately 9.2 m.

The input information related to the Test V44 is written based on the reference [11]. Figure 7 illustrates the nodalization, which consists of five lumped volumes connected by junctions. Among the 41 thermal conductors modeled, three structures consist of steel-lined concrete. One side of each conductor is coupled to the lumped volumes, while the other side is assumed to be insulated.

Figure 8 compares the experimental data with the SAVANNAH calculation results for the states in the upper rooms. While SAVANNAH slightly overestimates both pressure and temperature in the early stages of the blowdown, the long-term results (after approximately 200 seconds) show a high degree of similarity to the experimental measurements.

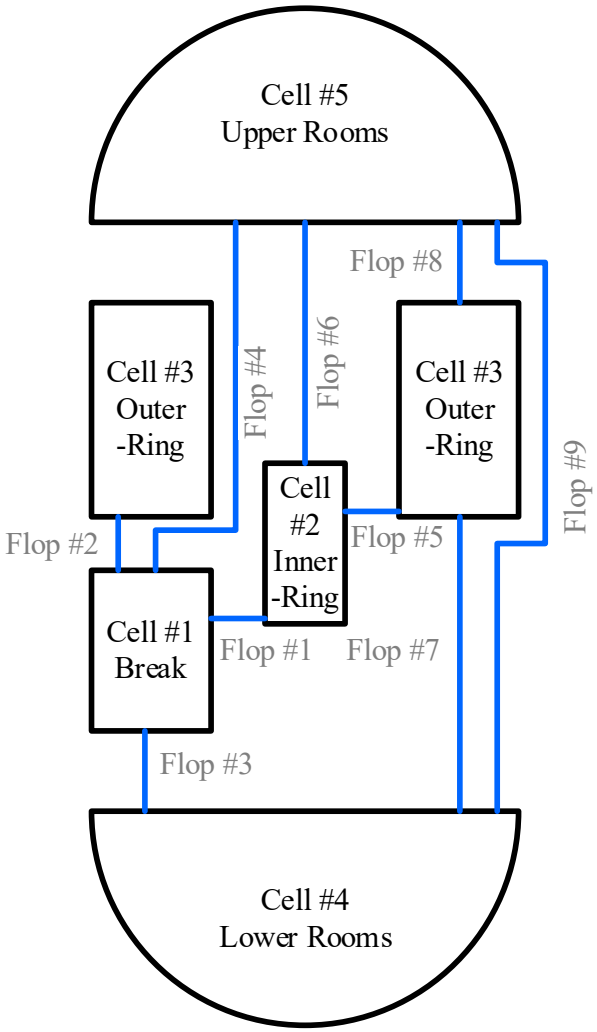

Figure 7. SAVANNAH nodalization: HDR Test V44

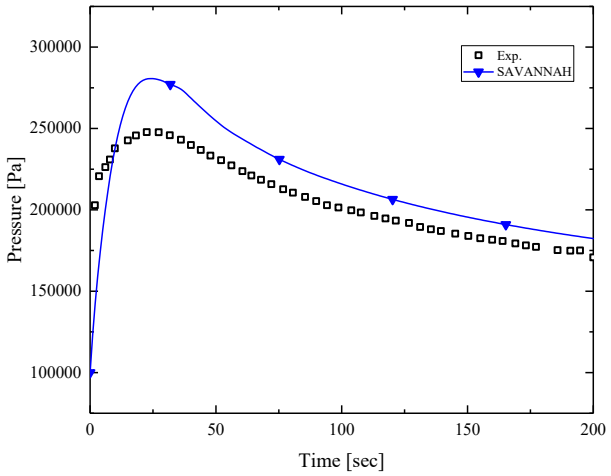
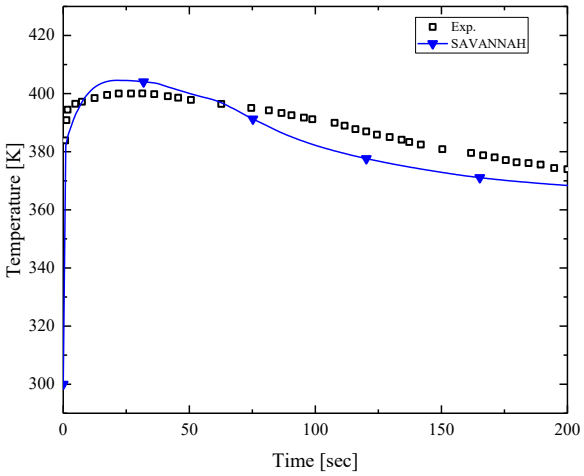
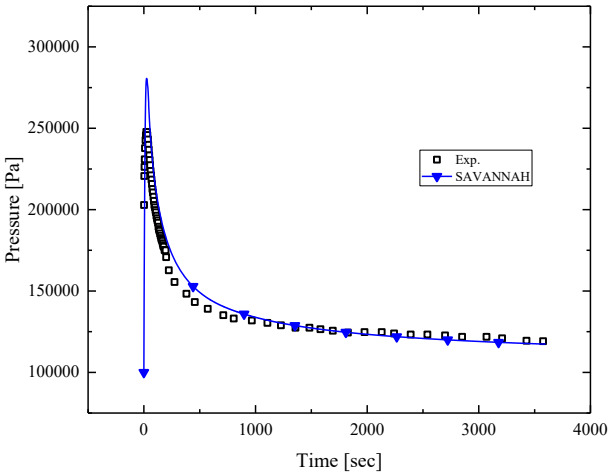


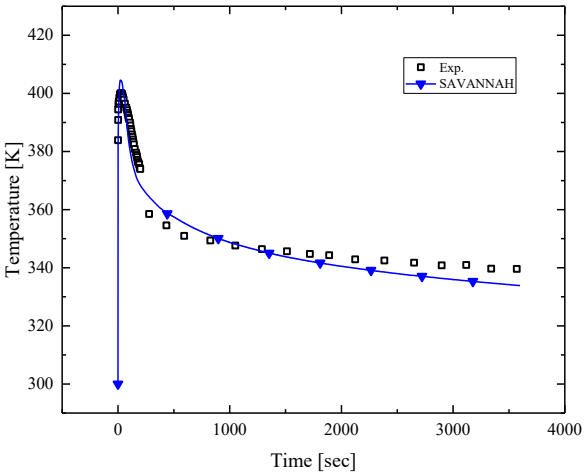
(a) Short-term results: Pressure



(b) Short-term results: Temperature



(c) Long-term results: Pressure



(d) Long-term results: Temperature

Figure 8. Assessment results of HDR V44

6. CONCLUSIONS

The SAVANNAH module has been developed to simulate containment thermal-hydraulic behavior during severe accidents within the SAFARI code framework. By employing a nodal approach and an iterative numerical scheme, the module effectively couples mass, energy, and momentum conservation equations. Verification against conceptual problems confirmed the correct implementation of fundamental physical models, while validation using the HDR V44 experiment demonstrated the module's capability to predict large-scale containment transients. Although slight overestimation occurred in the early blowdown phase of the HDR experiment, long-term trends showed high consistency with experimental data.

Type of abstract: Poster
Subject area: Other applications (fusion reactors, interim SNF storage, Accident Tolerant Fuels (ATFs), etc
Keywords: Severe Accident, FeCrAl alloy, BWR, Hydrogen Generation, ASTEC

FeCrAl alloys have gained significant attention as Advanced Technology Fuel (ATF) materials due to their superior high-temperature oxidation resistance compared to the conventional Zr-based alloys, and they are expected to mitigate hydrogen generation during Severe Accident (SA) transients. Furthermore, also motivated by the lessons learned from the Fukushima Daiichi accident, efforts have been undertaken at ASNR to extend the range of application of the ASTEC code to the analysis of SA scenarios in Boiling Water Reactors (BWRs). In particular, models of BWR-specific components have been developed and implemented in ASTEC.

The present work evaluates the performance of the ASTEC code by analyzing a short-term Station Black Out (SBO) sequence in a generic BWR4 Mark I reactor. The analysis, which did not account for the implementation of any emergency core cooling system, follows the relatively fast transient. Impact of adopting FeCrAl as ATF cladding material is assessed by using an oxidation correlation derived from separate effect test measurements conducted using the QUENCH facility at the Karlsruhe Institute of Technology (KIT) and thermophysical properties obtained from open literature sources, complemented by expert assessment at KIT.

The results demonstrate that the application of ATF cladding material led to a delay in the degradation of the fuel cladding and kept cladding material's integrity over an extended period of time due to a slower heat up in the core. Additionally, the ASTEC simulations indicated a decrease in the overall production of hydrogen gas. These findings contribute to the ongoing evaluation of ATF concepts within integral systems codes by establishing the advantages of such advanced materials and identifying the challenges in modelling their behavior across different accident phases.

IMPACT OF FeCrAl CLADDING MATERIAL ON THE PROGRESSION OF A SEVERE ACCIDENT IN A GENERIC BWR4 MARK-1 NPP: ANALYSIS OF A SBO SCENARIO WITH THE ASTEC CODE

Onur Murat[1], Eddy Gazzola[1,2], Mauricio Exequiel Cazado[1], Michela Angelucci[2], Sandro Paci[2], Fabrizio Gabrielli[1], Victor Hugo Sánchez-Espinoza[1]

[2]University of Pisa (UNIPI), Department of Civil and Industrial Engineering, Italy

1. MOTIVATION

- A **Station Blackout** (SBO) event can lead to severe accident if electrical power is not restored within the coping time.
- Conventional **Zr-based alloys** cladding has limitations under severe accident (SA) conditions, specifically rapid oxidation and massive hydrogen release.
- This study uses the ASTEC code to assess the potential of **Advanced Technology Fuels** (ATF) concepts. Particularly, **FeCrAl** cladding, to mitigate or limit the accident progression.

2. ASTEC MODEL AND ATF IMPLEMENTATION

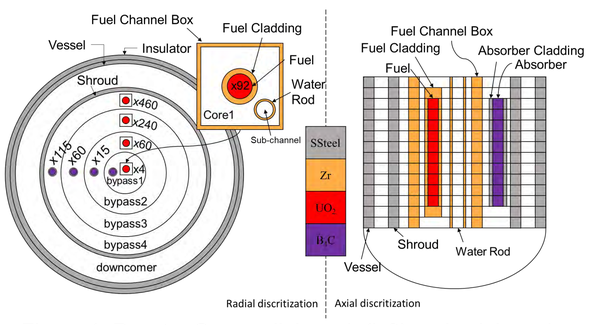

Figure 1. Reactor Core radial mesh (left) and axial mesh (right) loaded with GE14 10x10 fuel assembly [1]

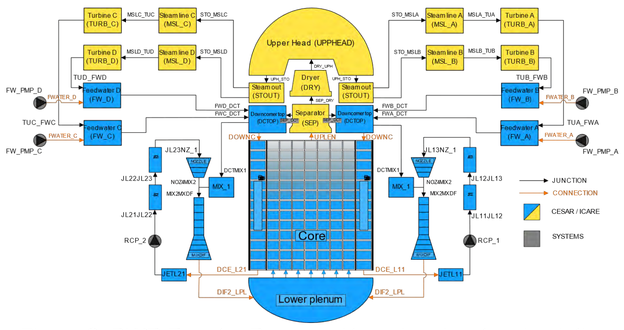

Figure 2. BWR Reactor Pressure Vessel and water circulation system [1]

- The reactor concept analyzed is [1] is a generic BWR-4 Mark-I with loaded 764 GE10x10 fuel assemblies.
- The active core discritized radially into 5 rings and axially 10 uniform meshes.

FeCrAl Implementation

- FeCrAl thermal properties were assess and defined for both solid and liquid phases.
- These properties are critical for accurately calculating the core's heat capacity and thermal response during the SBO transient.
- The oxidation model follows a Parabolic Rate Law where the oxygen mass gain:

$$\frac{dm_{O_2}^2}{dt} = K_P$$

$$K_P = A_{Gain} \cdot \left(e^{-\frac{B_{Gain}}{R \cdot T}}\right) \left[\frac{Kg^2}{m^4\, s}\right]$$

Temperature [K]	A_{Gain} $\left[\frac{Kg^2}{m^4\, s}\right]$	B_{Gain} $\left[\frac{J}{mol}\right]$	Comments
873 ≤ **T** < 1173	$5.376 \cdot 10^{-3}$	$1.847 \cdot 10^{5}$	θ-alumina
1173 ≤ **T** < 1273	$4.692 \cdot 10^{-12}$	0.0	-
1273 ≤ **T** <1648	5.018	$2.877 \cdot 10^{5}$	α-alumina
T ≥ 1648	$2.4 \cdot 10^{8}$	$3.527 \cdot 10^{5}$	Fe-oxide

- Strong oxidation rate occur at 1648 K from α-Al2O3 to Fe-oxide formation.

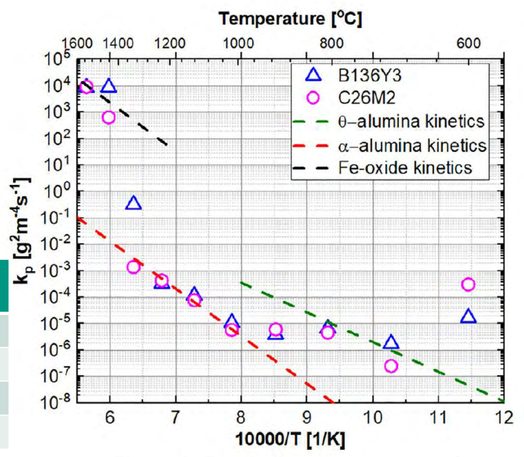

Figure 3. Parabolic rate constants of B136Y3 and C26M2 as a function of the temperature with the parabolic constants of Fe-oxide, θ-alumina and α-alumina [2]

3. BEST ESTIMATE CASE RESULTS

- Simulations indicate that substituting Zircaloy with FeCrAl significantly delays cladding failure and temperature escalation.
- FeCrAl cladding demonstrates a strong reduction in oxidation rates, leading to a significant decrease in total hydrogen production, in particular before the cladding failure.
- After extensive cladding failure and core degradation, the late-phase models still rely on Zr-based assumptions; therefore, late in-vessel results should be interpreted with caution.

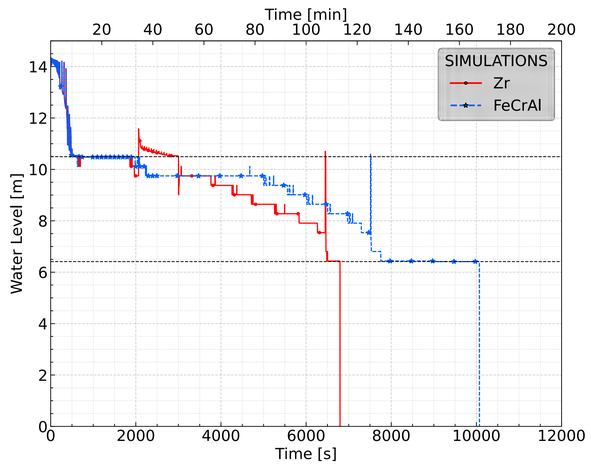

Figure 4. Water level in the vessel during accident progression

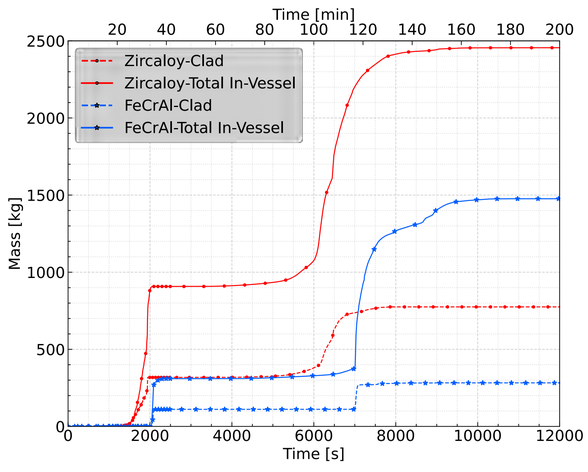

Figure 5. Hydrogen production resulted by the oxidation reaction

4. UNCERTAINTY AND SENSITIVITY ANALYSIS

- An Uncertainty and Sensitivity Analysis (U&SA) was conducted using the KIT in-house **KATUSA** tool [3]. Flow chart of the tool for uncertainty analysis is given below:

Sampling → Simulations → Identify failed simulations → Collect data from non-failed simulations → Adjust time grid and interpolate data → U&SA

- The analysis quantified the impact of uncertain inputs on Figures of Merit, specifically the cumulative hydrogen mass and total activity in containment.
- Two primary parameters were evaluated: an absolute temperature shift (T_{usa} between -50 and +50) and a kinetic multiplier (A_{usa} between 0.85 and 1.15).

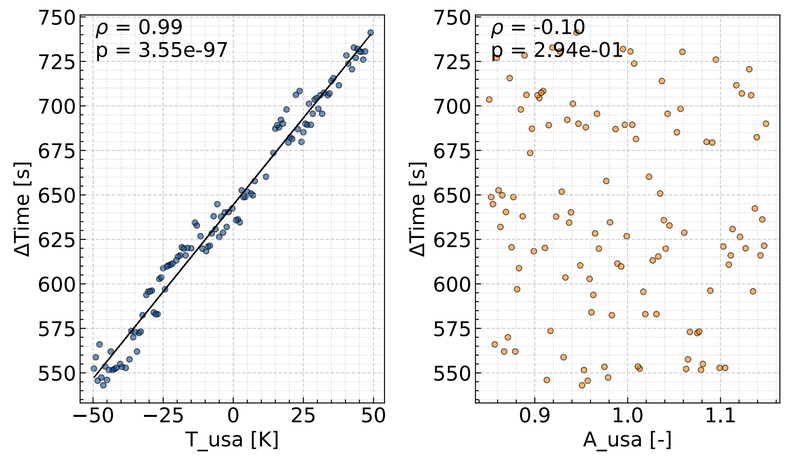

Figure 6. Spearman correlation analysis for hydrogen production delay

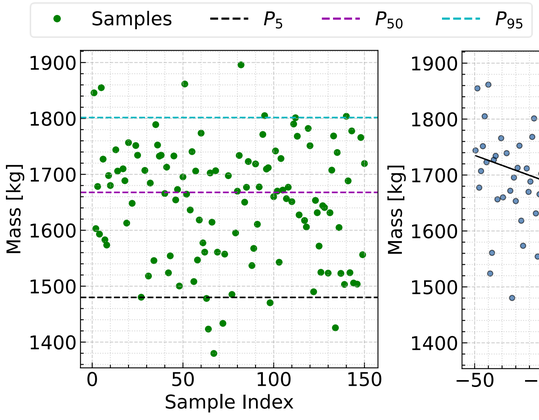

Figure 7. Uncertainty distribution and sensitivity of total RPV hydrogen generation to transition temperature T_{usa}

The very high Spearman correlation coefficient (ρ = 0.99) and negligible p-value (3.55e-97) indicate an almost perfect linear relationship between the temperature shift and the timing of hydrogen production.

Time delay is directly proportional to how long the protective α-alumina layer remains stable.

Even with uncertainties, the maximum hydrogen produced in the vessel (~1900 kg) is still significantly lower than the Zircaloy baseline (~2460 kg), confirming benefit of the FeCrAl material in terms of reactor safety.

The spearman coefficient indicate a moderate negative relationship between switching temperature and produces total hydrogen mass.

Increasing the transition temperature keeps the material in the α-alumina regime (slow oxidation) for a longer duration. Consequently, the core spends less time in the Fe-oxide regime (rapid oxidation) before the simulation ends or the geometry fails, leading to less hydrogen production.

5. CONCLUSION

- In an unmitigated SBO scenario, a generic BWR-4 Mark-I experiences rapid core degradation when utilizing standard Zircaloy cladding.
- The implementation of **FeCrAl ATF concepts successfully delays** the accident progression and massively decreases hydrogen generation.
- While oxidation kinetics strongly drive the accident progression, dedicated model for FeCrAl are still required to assess late-phase phenomena.

Type of abstract: Poster
Subject area: Containment behavior incl. H2 explosion risk
Keywords: GOTHIC, THERMAL HYDRAULICS, SPRAY SYSTEM

During a severe accident in a Pressurized Water Reactor, a significant amount of hydrogen could be generated and released into the containment building. Hydrogen, when combined with steam and air has the potential to create a local gas mixture that could be flammable or even detonable. In this context, the activation of the containment building spray system may hinder hydrogen risk, as gas mixing is enhanced. However, condensation driven by the spray system could lead to a reduction of steam, potentially promoting the formation of a local combustible mixture. Therefore, the study of the spray system performance is essential for evaluating hydrogen combustion risk in the containment building.

The simulation of the spray system efficiency can significantly depend on the size distribution of the injected droplets. It can be treated by two different approaches: using a single characteristic droplet size (monodispersed) or considering a polydisperse distribution of droplet diameters classified into sections by size. The definition of different droplet size sections is essential to precisely capture their respective effects. However, due to the demanding computational requirements, the three-dimensional analyses often combine simpler approaches, using coarse meshes and monodisperse droplet populations.

In the framework of the GO-MERES 2 project, a collaborative agreement between the CSN and the Spanish Regulatory Council (CSN), the GOTHIC 8.3(QA) code is used to carry out an analysis of the spray actuation system using a polydisperse distribution in a 3D model. This has been accomplished through the simulation of H2P5 experimental series carried out at the PANDA facility in the OCDE/NEA HYMERES 2 project. The study presents a direct comparison between monodisperse and polydisperse distributions, analyzing the main thermal-hydraulic variables of interest.

INTRODUCTION

INFLUENCE OF CONTAINMENT SPRAYS – During Severe Accident (SA)

The main purpose of containment sprays is to decrease the containment pressure by causing steam condensation on spray droplets

The mechanisms of condensation and entrainment have the opposite consequences on hydrogen combustion

The atmosphere mixing due to the entrainment by falling droplets causes **a more uniform hydrogen concentration in the containment**

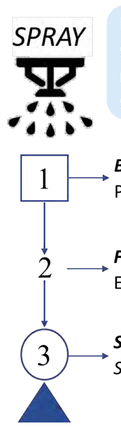
Steam condensation on droplets causes **a decrease of steam concentration** in the atmosphere and a corresponding **increase of hydrogen concentration**

DROPLET SIZE affects both the condensation rate and droplet velocity, which in turn influences entrainment

- The **H2P5 series** expanded the PANDA sprays test database by comparing a spray ring to a single nozzle configuration, proposing a scenario more representative of conditions expected in a nuclear power plant. Both configurations were tested under a stratified atmosphere formed by steam, air and helium
- This experiment was previously analyzed with the GOTHIC code using a monodisperse droplet size distribution (using the average drop diameter) and the simulations calculated a faster depressurization. One of the authors' main recommendations was considering the implementation of a polydisperse droplet size distribution as it has never been done before with the GOTHIC code

GOTHIC treats droplets as a distinct phase, separated from the continous liquid and vapor phases.

This enables defining various droplet sizes via the drop-field menu, allowing the model to simulate and independently track droplets of different sizes.



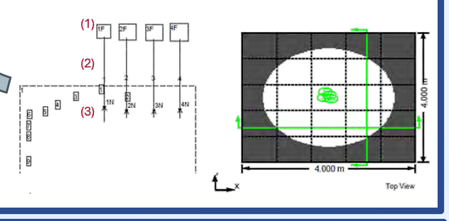
In GOTHIC, defining a spray nozzle as a source of mass, energy, and momentum requires three separate steps.

Boundary condition (BC)
Pressure, temperature, Flow rate

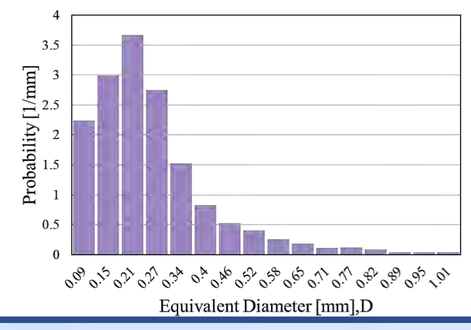
Flow Path (FP)
Elevation, hydraulic diameter, area

Spray component (SC)
SMD, GSD, cone angle

When multiple droplet sizes are injected, each size requires its own BC, FP, and SC. To ensure they all represent a single physical nozzle, all FP must be located in the same computational cell.



For this analysis only the **one nozzle configuration** was simulated



The 16 droplet sizes obtained from the spray probability density function were combined into four groups for computational efficiency.

	SMD (cm)
GROUP 1	0.018

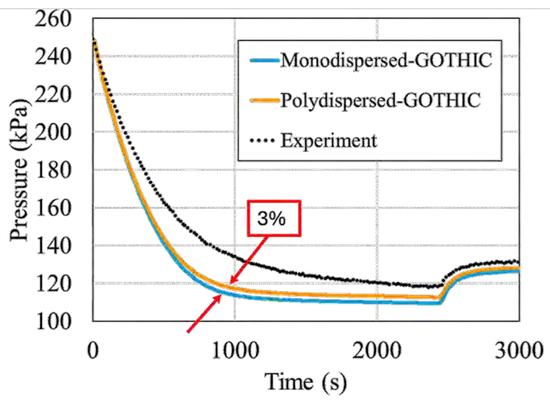
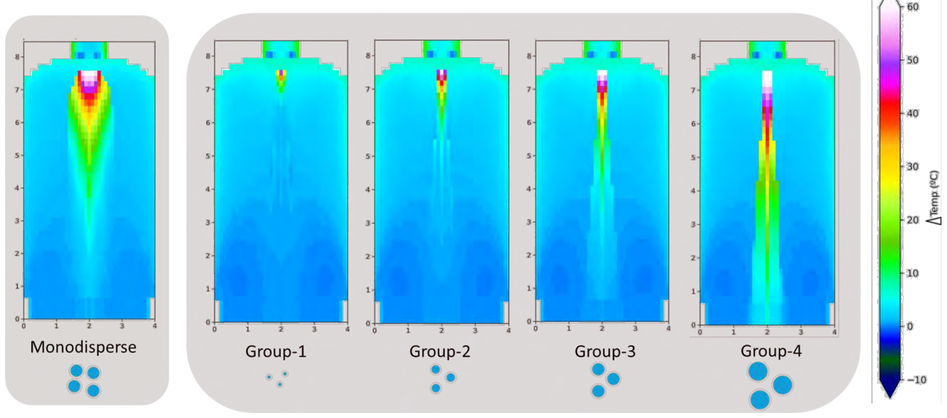
RESULTS

PRESSURE



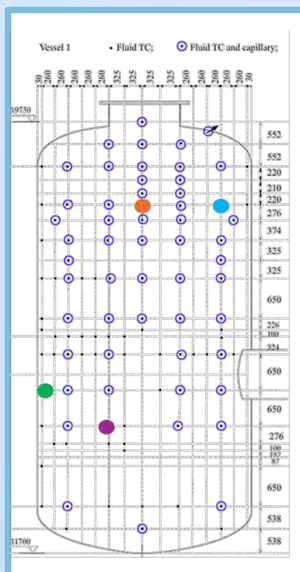
MONODISPERSE POLYDISPERSE

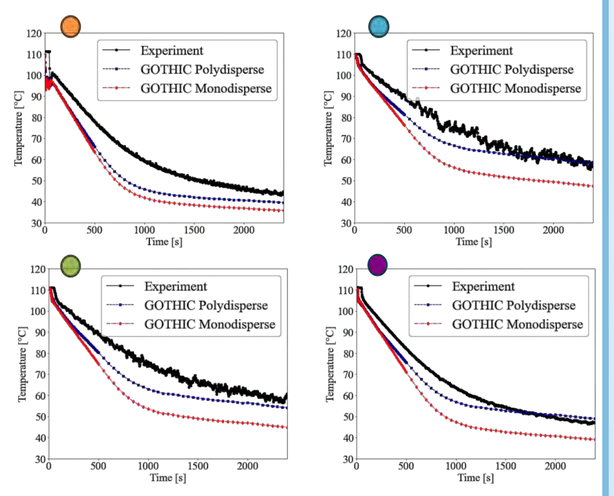


2D MAP illustrating the droplet–air thermal equilibrium at 250 s.

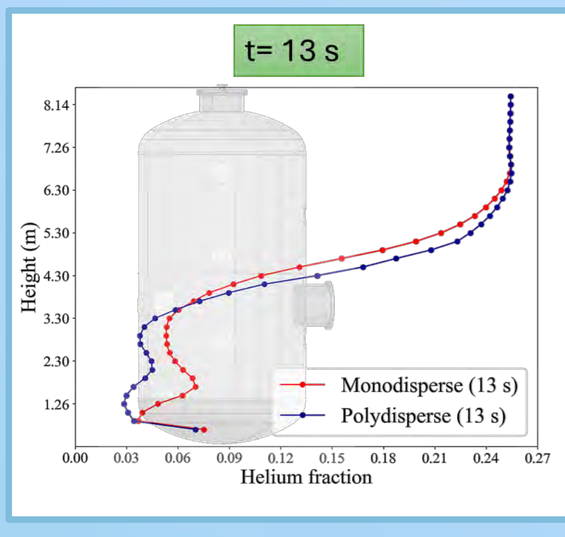
- In the monodisperse configuration, all droplets reach thermal equilibrium before arriving at the bottom (artificially maximizing the amount of energy they are able to extract.)
- Within the polydisperse spray, small droplets equilibrate rapidly owing to their higher surface-to-volume ratio, whereas larger droplets require significantly more time to heat up. As a result, the larger droplets reach the bottom of the vessel without attaining thermal equilibrium, thereby extracting less energy than their theoretical potential.

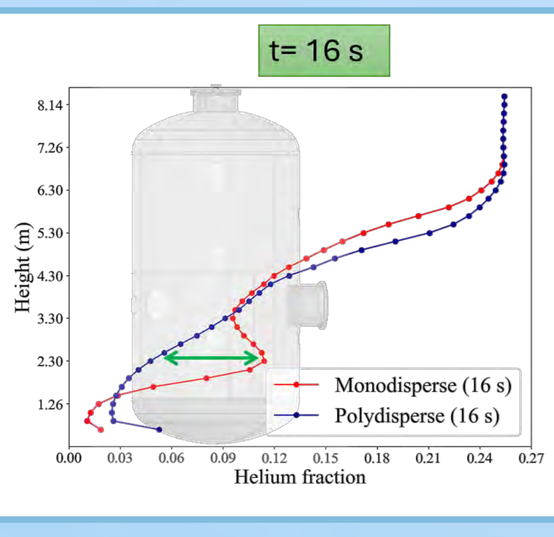
GAS TEMPERATURE





Improvement in the cooling trend when using the polydisperse model, which is now able to replicate the experimental values toward the end of the spray phase. This improvement is particularly evident near the walls and in the lower regions of the vessel.



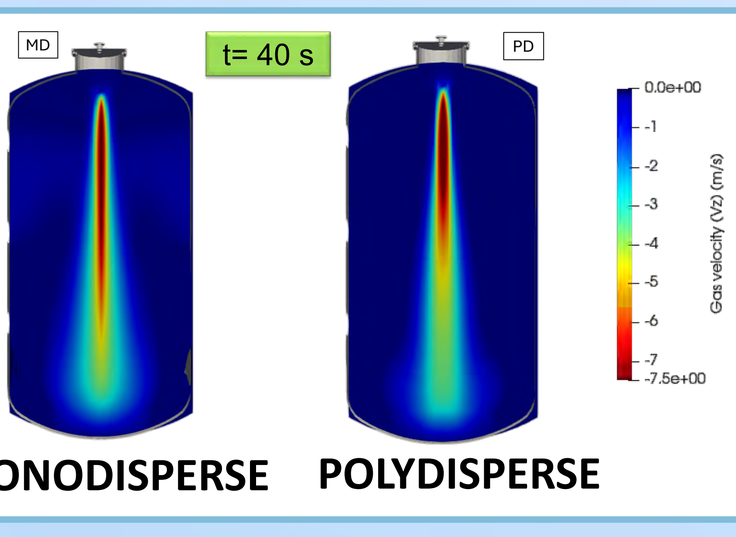


HELIUM FRACTION

HELIUM FRACTION 6% HIGHER IN THE MONODISPERSE CASE

This behavior can be driven by the gas-phase velocity field induced by droplet momentum transfer.

GAS VELOCITY



MONODISPERSE **POLYDISPERSE**

CONCLUSIONS

- While both approaches show similar overall trends, important local differences were identified in terms of heat and mass transfer, especially regarding vapor cooling and mixing patterns.
- The polydisperse model provided a more realistic representation of droplet behavior, revealing complex interactions between droplet size, temperature, and residence time. These findings suggest that droplet size distribution plays a significant role in the thermal-hydraulic response of spray systems and it's impact should be investigated at plant scale

ABSTRACT

Novel nuclear reactors (NNRs) challenge generic source-term assumptions used in emergency planning. This work presents the GIROSCOPE framework, coupling mechanistic source-term modelling with consequence assessment to support risk-informed Emergency Preparedness and Response (EP&R). Reactor-specific releases are derived for representative high-temperature gas-cooled reactors (HTGRs), light-water small modular reactors (SLWRs), and compact molten salt reactors (CMSRs) under beyond-design-basis conditions. Results indicate that HTGR air ingress scenarios yield release fractions orders of magnitude lower than those assumed for large light-water reactors, while SLWR releases are highly sensitive to passive safety systems and natural retention mechanisms. No single accident sequence is universally bounding, motivating representative accident spectra for proportionate Emergency Planning Zone (EPZ) definition. GIROSCOPE provides a technical basis for tailoring EP&R to NNR risk profiles.

KEYWORDS

Mechanistic source term; Advanced reactors; Severe accidents; EP&R; EPZ

1. INTRODUCTION

NNRs, including small modular reactors and Generation IV concepts, differ fundamentally from conventional large light-water reactors in fuel forms, coolant systems, containment configurations, and passive safety features, challenging established approaches to radiological source-term estimation based on generic conservative assumptions. Their potential deployment in diverse environments further increases the importance of proportionate and technology-specific EP&R.

A central question for regulators and emergency planners is how severe accident source terms and off-site consequences for NNRs compare with those of conventional reactors, and how these differences should be reflected in EPZ definition. To address this need, the GIROSCOPE project develops an integrated framework for the mechanistic characterisation of radionuclide releases and their propagation to consequence assessment. This paper presents the GIROSCOPE methodology and its application to

representative advanced reactor concepts, focusing on severe-accident source terms and implications for EP&R.

2. GIROSCOPE FRAMEWORK AND METHODOLOGY

GIROSCOPE applies a Mechanistic Source Term (MST) approach, replacing generic conservative source terms with reactor-specific, physically based assessments of fission product generation, transport, retention, and release (Figure 1). Initial radionuclide inventories are derived from neutronic and depletion calculations and propagated through coupled fuel performance and integrated severe accident analyses to simulate accident progression and release pathways. Key phenomena include fuel degradation, aerosol formation and deposition, pool scrubbing, and containment retention. For compact light-water SLWR designs, natural retention mechanisms such as gravitational settling and diffusiophoresis are particularly influential due to high surface-area-to-volume ratios.

Time-dependent source terms from system-level severe accident modelling are propagated to consequence assessment tools and/or model chains to estimate dose, dispersion, and longer-term contamination relevant for emergency planning [1]. For emerging reactor technologies, probabilistic safety assessment data are often limited; representative accident scenarios are therefore defined using available design information and phenomenological understanding, supplemented where necessary by conservative assumptions [2,3]. Rather than relying on a single bounding sequence, GIROSCOPE adopts a spectrum-based approach, analysing multiple credible severe accident scenarios to support proportionate EPZ development.

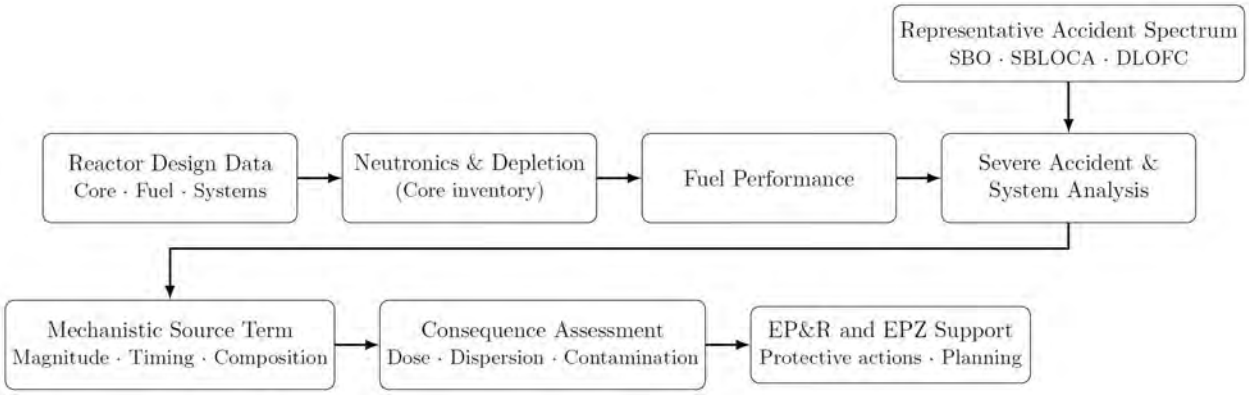

Figure 1. GIROSCOPE workflow coupling mechanistic source-term modelling with consequence assessment to support EP&R and spectrum-based EPZ definition.

3. REPRESENTATIVE CASE STUDIES AND ACCIDENT SCENARIOS

The GIROSCOPE framework was applied to representative HTGR, SLWR, iPWR, and CMSR concepts (Table I), including pebble-bed (Canada) and prismatic (Poland) HTGRs and BWR-type (Canada), PWR-type (Sweden) SLWRs, and a fluoride-salt CMSR (Denmark), enabling assessment of how core configuration, fuel form, containment layout, and passive safety features influence radionuclide release behaviour.

For HTGRs, depressurised loss-of-forced-cooling (DLOFC), or severe air ingress, was analysed to evaluate natural circulation onset, graphite oxidation, fuel temperature evolution, and radionuclide transport [4]. Both configurations employ TRISO fuel [5], providing micro-containment of fission products. Predicted release fractions for pebble-bed HTGRs were orders of magnitude lower than those typically reported for light-water reactors, even under severe air ingress. These source terms were incorporated into consequence studies that demonstrated reduced early-phase doses and indicated potential longer-term contaminated areas exceeding protective action guidelines (Figure 2) [6].

Figure 2 presents Total Effective Dose Equivalent (TEDE), consistent with the legacy framework implemented in NRC tools such as RASCAL. European emergency reference levels are defined in terms of effective dose within the ICRP 103 system adopted in the IAEA Basic Safety Standards [7,8]. Although numerical differences between TEDE and effective dose are expected to be small, the underlying conceptual distinction should be acknowledged.

SLWR analyses focused on station blackout (SBO) and small-break loss-of-coolant accidents (SBLOCA) [9]. Accident progression is governed by passive decay heat removal and containment thermal-hydraulics. In BWR designs, isolation-condenser operation may create containment bypass pathways, while pool scrubbing dominates caesium retention. PWR-type SLWRs similarly show strong sensitivity to passive coolant flow and containment retention.

For iPWRs, SBO scenarios with varying decay heat removal impairment were analysed alongside additional failures to develop source-term spectra for EPZ studies [3]. No single accident sequence is universally bounding, motivating the use of representative accident spectra. CMSR analyses are ongoing, focusing on radionuclide inventories and release behaviour in liquid-fuel systems.

Table I. Representative reactor concepts considered in GIROSCOPE

Reactor concept	Core config.	Coolant	Fuel	Power (MWth)	Key passive / retention feature	Representative severe accident
HTGR – Pola	Prismatic	Helium	TRISO	~30	TRISO fuel, graphite core, RCCS	DLOFC (air ingress)
HTGR – Canada	Pebble-bed	Helium	TRISO	~200	TRISO fuel, graphite core, RCCS	DLOFC (air ingress)
SLWR – Canada	BWR lattice	Light water	UO_2	~870	Pool scrubbing, passive containment cooling	SBO, SBLOCA
SLWR – Sweden	PWR lattice	Light water	UO_2	~1358	Passive coolant flow, containment retention	SBO, SBLOCA
iPWR – Canada	PWR lattice	Light water	UO_2	~160	Passive decay heat removal	SBO
CMSR	Liquid-fuel MSR	Molten salt	Liquid fuel	~30	Low-pressure system, online retention	Under definition

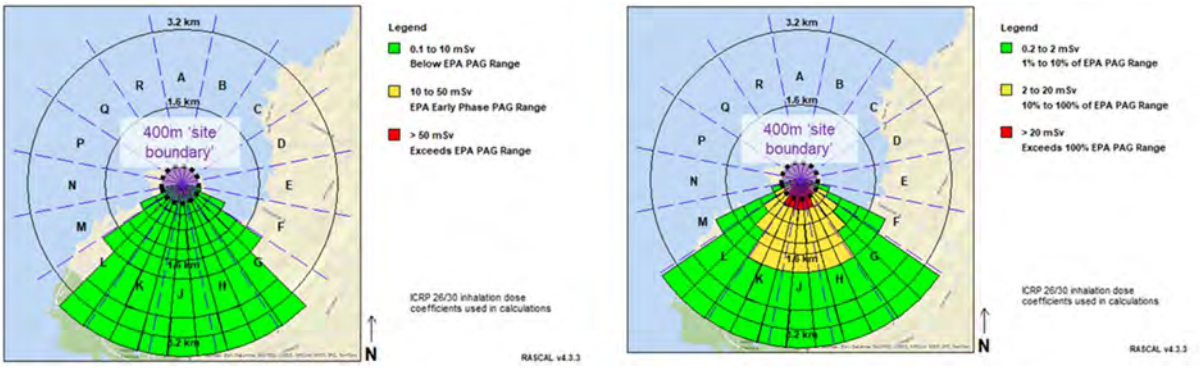

Figure 2. Representative TEDE predictions for an HTGR DLOFC accident (early phase left, one year right), adapted from Lebel et al. [6]. TEDE follows the ICRP 26 framework; comparison with European effective dose criteria is indicative.

4. IMPLICATIONS FOR EP&R AND CONCLUSIONS

The case studies demonstrate that radionuclide release characteristics for novel reactors strongly depend on reactor concept, containment configuration, and accident progression. HTGR analyses indicate substantially lower early-phase doses than conventional reactors, although longer-term contamination may still require protective actions [6]. For SLWRs, releases are highly sensitive to passive safety performance and natural retention mechanisms, including pool scrubbing and aerosol deposition.

Across all concepts, no single accident sequence is universally bounding, supporting representative accident spectra for proportionate, technology-specific EPZs. Overall, GIROSCOPE demonstrates the value of mechanistic source term methodologies for evidence-based EP&R, providing a technical basis for risk-informed emergency planning and regulatory safety cases for advanced nuclear reactor technologies.

Severe Accident Source Terms for Novel Nuclear Reactors

The GIROSCOPE Methodological Framework for EP&R

A. Wawrzynczak[1], V. Hansen[2], E. Bergbäck Knudsen[2], L. Lebel[3], G. Patterson[3], M. Skrzypek[1], P. Kopka[1], M. Isaksson[2]

contact e-mail: anna.wawrzynczak-szaban@ncbj.gov.pl

Motivation and GIROSCOPE Methodological Framework

- Generic LWR source term assumptions are not directly transferable to novel nuclear reactors (NNRs).
- Severe accident releases may be strongly reactor and scenario specific.
- EP&R and EPZ arrangements should be based on traceable, technology specific source terms.
- GIROSCOPE WP2 develops a structured methodology for severe accident source term assessment.
- The source term describes release magnitude, isotopic composition, physical and chemical form, timing, duration, height, and dominant retention or bypass pathways.
- The resulting source terms provide inputs for consequence assessment and EP&R studies in WP3/WP4.

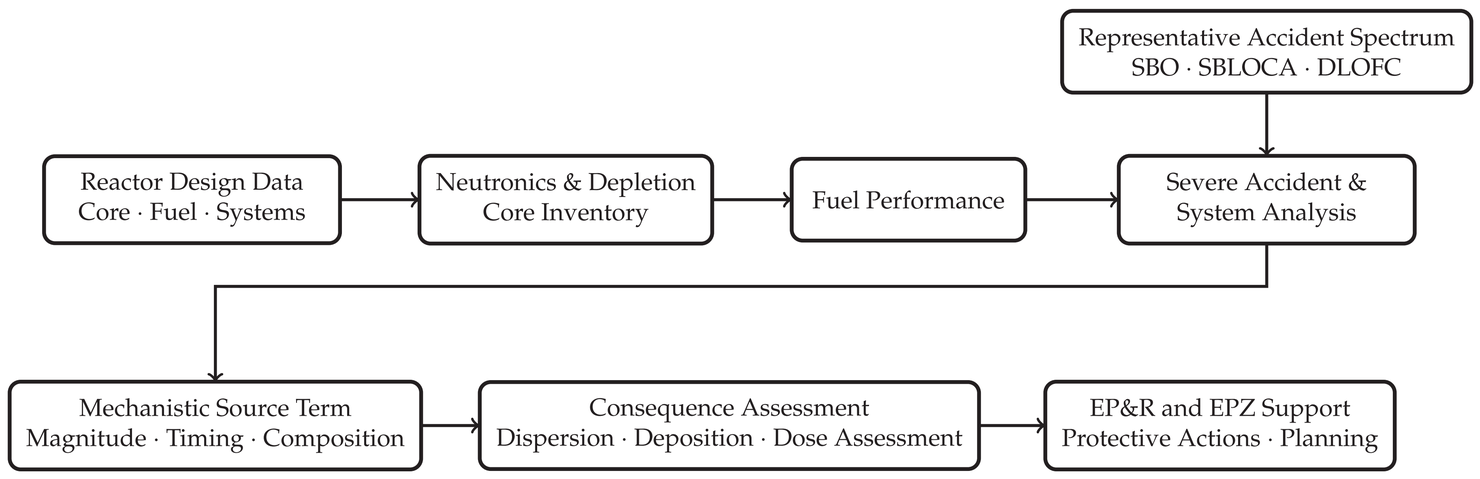

Fig. 1. GIROSCOPE workflow linking reactor design data, core inventory, accident progression, mechanistic source-term assessment, consequence assessment, and EP&R/EPZ support.

Key Findings from Case Studies

- **HTGR-POLA:** Severe accident source term estimated by using MELCOR/SERPENT inputs, STACY release calculations, and plant-level attenuation factors.
- **HTGRs:** TRISO fuel and graphite structures provide strong retention; DLOFC/air ingress cases indicate reduced early release potential.
- **SLWRs/iPWRs:** Releases are sensitive to passive safety performance, pool scrubbing, aerosol deposition, bypass pathways, and accident progression.
- **CMSR:** Source term assessment requires treatment of liquid-fuel inventory, salt chemistry, off-gas, tritium, and radionuclide partitioning.

Conclusions

- GIROSCOPE develops a structured and traceable methodology for severe accident source-term assessment in selected NNR concepts.
- Source terms for NNRs require technology-specific treatment of inventories, fuel forms, barriers, retention mechanisms, release pathways, timing, duration, height, and chemical/physical form.
- HTGR, SLWR, iPWR, and CMSR case studies show that release behaviour is strongly dependent on reactor concept, passive safety performance, containment or confinement design, and accident progression.
- Representative accident spectra provide a stronger technical basis for EP&R and EPZ studies than reliance on a single bounding sequence.
- Mechanistic Source Term methods provide traceable inputs for consequence assessment and support proportionate, risk-informed emergency planning.

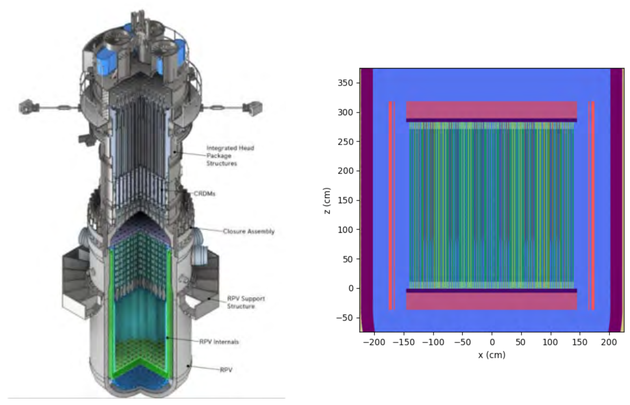

Fig. 2b. Rolls-Royce SLWR core model [Rolls Royce SRM Public Document Repository, 2025 https://gda.rolls-royce-smr.com/documents],and Xz cut through the neutronics model

Consequence Assessment and EPZ Implications

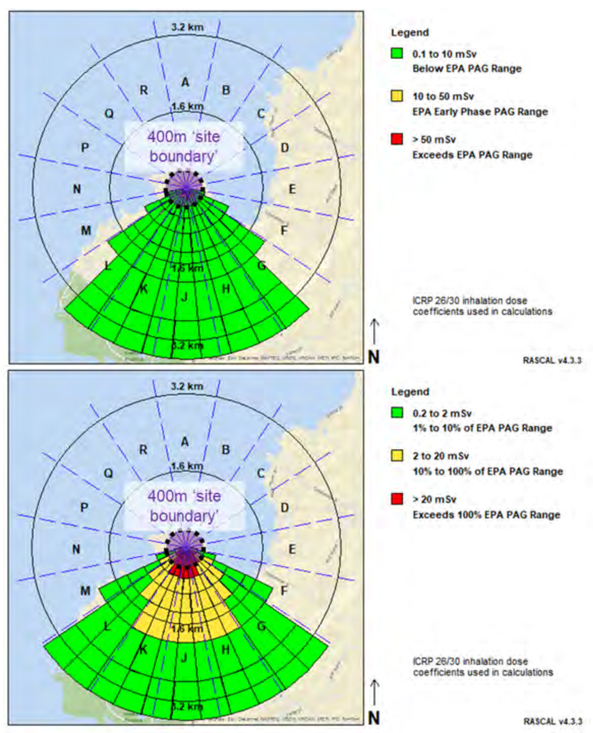

Fig. 3. Representative Total Effective Dose Equivalent predictions for an HTGR DLOFC accident: early phase, top; one-year impact, bottom. [Adapted from Lebel et al. 2026,DOI:10.1016/j.anucene.2025.111808].

- Reactor-specific, time-dependent source terms are propagated to consequence assessment tools.
- Outputs support assessment of dose, plume dispersion, deposition, and long-term contamination.
- Example HTGR calculations indicate limited early-phase doses for selected DLOFC cases, while longer-term contamination may still require protective actions.
- EPZ sizing should be supported by representative accident spectra rather than a single bounding sequence.

3D SIMULATION OF DEBRIS BED QUENCHING WITH TOP-FLOODING FOR FLOAT EXPEIMENTS

ABSTRACT

In hypothetical severe nuclear accidents, the coolability of a debris bed formed after core meltdown is essential. Insufficient cooling can compromise containment integrity. Failure to ensure effective cooling can lead to further structural damage and the release of radioactive materials, posing a risk to the environment. To analyse this process, experiments were conducted at the FLOAT test facility of IKE, University of Stuttgart, Germany, focusing on the investigation of debris bed quenching under top-flooding conditions. The experimental configuration consisted of a cylindrical test section filled with approximately 44 kg of stainless-steel spheres, having a porosity of about 0.4, which was used as a physical model of a debris bed. Experiments were conducted at various initial temperatures, with and without counter-current gas injection, to reproduce the non-condensable gases released during molten corium–concrete interaction (MCCI).
Numerical simulations were performed using the MC3D computer code. The code was applied in 3D geometry to replicate the FLOAT experiments. With a sufficiently refined computational grid and by considering heterogeneous temperature and porosity distributions, the simulations captured three-dimensional effects observed experimentally, such as asymmetric front propagation and front instabilities. This work demonstrates the occurrence of 3D phenomena in the quenching process. It also estimates the code's ability to reproduce these effects and provides a direct comparison between simulated and measured data.

KEYWORDS
Nuclear safety, severe accidents, reflooding of debris bed.

1. INTRODUCTION

In a nuclear reactor, insufficient cooling can lead to fuel overheating, melting, and its relocation to the bottom of the reactor pressure vessel, where interaction with water forms porous debris [1]. The decay heat must still be removed to prevent remelting and further structural degradation. If the corium melts through the reactor pressure vessel, it can form debris in the reactor cavity, where interactions with water and concrete produce gases that may obstruct cooling [2].
To better understand debris-bed quenching phenomena, several experiments have investigated reflooding behaviour under different conditions. The FLOAT facility is designed to study debris-bed quenching under a range of initial conditions. The setup consisted of a cylindrical test section filled with stainless-steel spheres modelling the debris bed, with a layer of ceramic spheres placed underneath for support. Tests were performed at different initial temperatures and with or without bottom gas injection to mimic non-condensable gas release during MCCI (Molten-Core-Concrete-Interaction) [3].
The experimental results show that top-flooding quenching proceeds in two distinct stages. Initially, water infiltrates the bed along the wall due to lower porosity and reduced temperature. Once the lowest part of the debris bed is quenched, a water pool forms at the bottom, fed by the preferential water channels formed during the first cooling phase. The continued inflow raises the water level within the test section [4]. Once the front reaches the bottom and a stable water pool forms beneath the bed, overall cooling accelerates. The rising pool uniformly quenches the remaining hot spheres. Gas injection was found to hinder downward water penetration and increase the total quench time [4].
In this work, we develop a three-dimensional numerical model of debris-bed quenching using the MC3D code and compare the results with the FLOAT experimental data, with a focus on three-dimensional effects observed under varying initial configurations.

2. COMPUTATIONAL MODEL

To reproduce the experimental conditions, several grid configurations and initial setups were used. The main simulation domain consisted of three regions: a supporting layer composed of ceramic spheres, a debris-bed region formed by stainless-steel spheres with an average porosity of 0.4, and an upper zone in which the water pool above the debris bed could develop. The inflow of water was modelled at the top of the computational domain. Heterogeneities in debris bed temperature and reduced porosity near the wall were considered. To account for MCCI-driven gas release in some cases, upward gas injection was introduced at the bottom of the supporting structure.
The computational grid was cylindrical, with 91 cells in the axial direction and 12 cells in the radial direction. Two circumferential configurations were examined: one with six angular zones (6,480 total cells) and another with twelve angular zones (12,960 total cells). For comparison, a two-dimensional case with a 12 × 91 mesh was also evaluated.

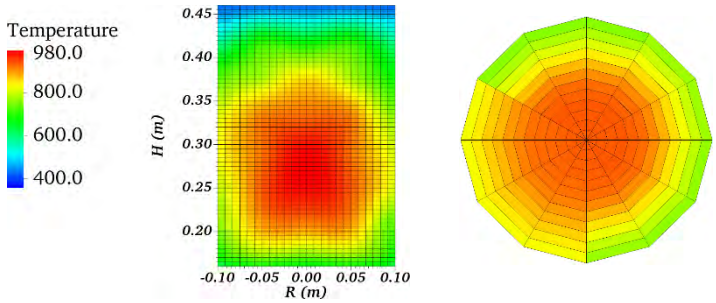

Figure 1: Simulated temperature profile of debris bed at cross-section 0°-180° (left) and temperature profile at height = 0.33 m (right).

The initial conditions were based on experiment F.33, which featured a maximum debris-bed temperature of 700 °C and its total mass of 44.1 kg. Using the thermocouple measurements, the temperature distribution across the entire debris bed was extrapolated.

3. SIMULATION RESULTS

The circumferential mesh resolution was evaluated by gradually increasing the number of partitions. With fewer than ten divisions, no significant asymmetries were observed, and the results remained consistent with the reference 2D simulation. Using twelve angular divisions, however, showed asymmetries that are qualitatively similar to those observed experimentally. It should be noted that the limited number of thermocouples in the experiment prevents a precise description of three-dimensional effects.
Figure 1 shows the comparison between the 2D simulation, the 3D case with six angular divisions, and the 3D case with twelve angular divisions.

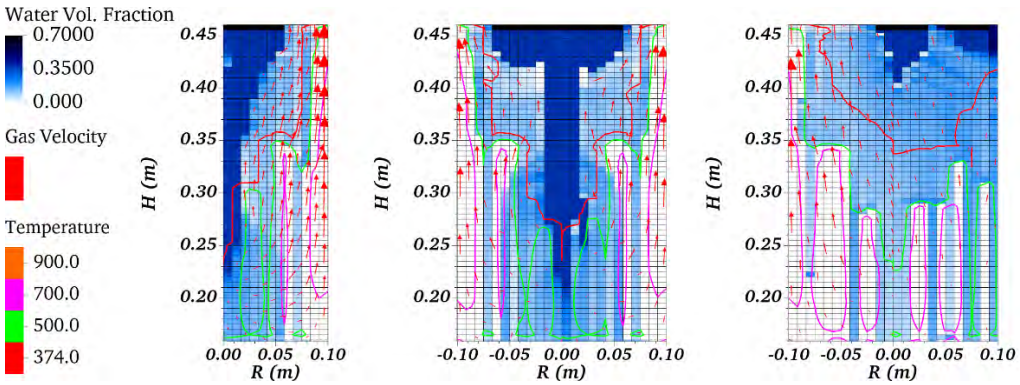

Figure 1: Comparison between the 2D simulation, the 3D case with six angular divisions, and the 3D case with twelve angular divisions at time = 120s

Quenching times, defined as the moment when a thermocouple reaches the water saturation temperature of 100 °C, were compared between the experiment and the simulation. In the experiment, the thermocouples located near the bed centre quenched first, along with some sensors at radial positions R = 50 mm and R = 90 mm. During the second phase, the remaining thermocouples indicate a more uniform quenching front propagation [5].
The simulations showed the onset of quenching approximately 30s later than observed experimentally, which seems to be the consequence of the finite thermal capacity of the stainless-steel particles modelled in the simulation, in comparison to the more immediate temperature drop registered by thermocouples in the experiment. All thermocouples located near the bed centre quenched during the first phase. Most sensors at a radius of 90 mm quenched uniformly during the second phase as the water pool advanced upward, with the exception of locations where downward-spreading flow channels caused earlier quenching. In this phase, a localized hot pocket formed at a radius of 50 mm in certain angular sections, causing the delay of thermocouples quenching. As shown in **Error! Reference source not found.**, the simulated thermocouples at 50 mm radius quenched later than those at 90 mm at the same height.
In the simulation with twelve circumferential divisions, the quench front initially formed near the bed centre, where preferential channels also began to develop at mid-radius. After approximately 40s, the main flow shifted locally toward the wall in certain angular sectors, while in other regions it remained centred but less intense and more dispersed. The second phase started once the water pool formed at the bottom of the supporting structure reached the lowest region of the debris bed. The water pool then rose to the top, completing the quench.

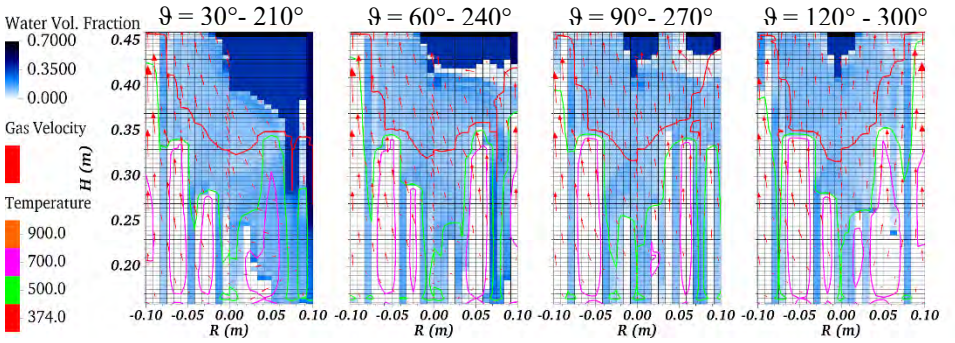

Figure 2: Results of simulation showing different angular partition at time 130s

To examine ex-vessel debris–concrete interaction (MCCI), additional experiments were performed with gas injection from the bottom. In this simulation, data from experiment F.32 are considered, which used initial conditions similar to those of F.33 but included bottom gas injection. The simulations with additional gas injection exhibited longer quenching times, while the quenching process remained generally unchanged.

4. CONCLUSIONS

The advantage of using a three-dimensional mesh with fine enough circumferential refinement is the ability to capture more detailed quenching processes and cooling asymmetries within the debris bed. The results demonstrate three-dimensional effects consistent with the experimental observations. At the onset of quenching, flow instabilities and water fingers develop, leading to partial cooling of the debris. When temperature and porosity heterogeneities are included, water flow in the near-wall region becomes apparent, further indicating that a 3D modelling represents the progression of quenching more accurately than a 2D model. During the first phase, water fingers and near-wall flow quench approximately 60% of the debris. Strong steam generation in regions not reached by the downward flow, together with the faster upward water penetration along the higher porosity region near the wall, restricts cooling in the mid-radius zone and leads to the formation of hot pockets. Such hot pockets pose a risk of local remelting of debris bed during the severe accident and complicate the overall quenching process. Consistent with experimental findings, additional non-condensable gases increase the quenching time. Overall, the simulations confirm that debris-bed quenching under top-flooding conditions is a complex process and that three-dimensional effects must be considered.

3D SIMULATION OF DEBRIS BED QUENCHING WITH TOP-FLOODING FOR FLOAT EXPERIMENTS

Anej Kukovič[1], Janez Kokalj[1], Mitja Uršič[1], Joerg Starflinger[2], Renaud Meignen[3]

Motivation

In hypothetical severe accidents, failure to ensure effective debris bed cooling can lead to further structural damage and the release of radioactive materials.

To analyse this process, simulation analysis of the experiments at the FLOAT test facility of IKE, University of Stuttgart, Germany, was performed. A 3D geometry was used to investigate more detailed local phenomena.

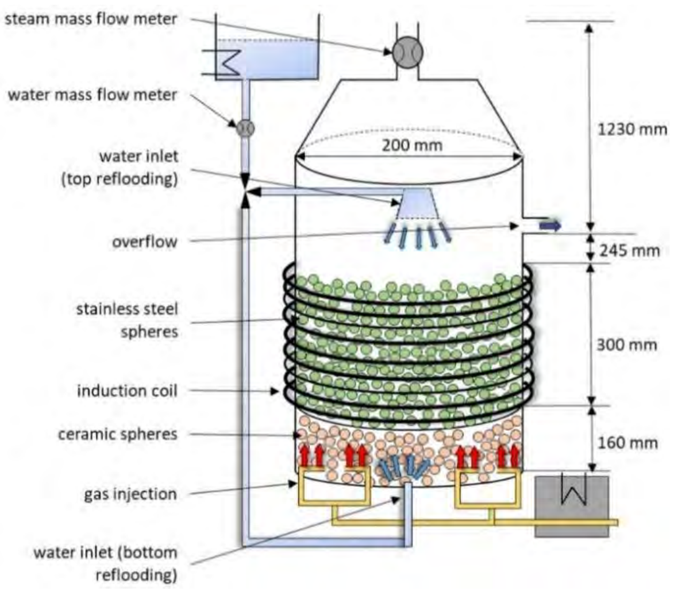

Figure 1: Design of FLOAT facility (IKE, University of Stuttgart, Germany).

Simulation Approach

Fuel-coolant interaction code MC3D (IRSN, France) was used. Main simulation characteristics:

- The main simulation domain regions are support zone with ceramic spheres, debris bed zone formed by stainless-steel spheres, and top zone filled with air.
- The temperature across the debris bed was extrapolated using the thermocouple measurements.

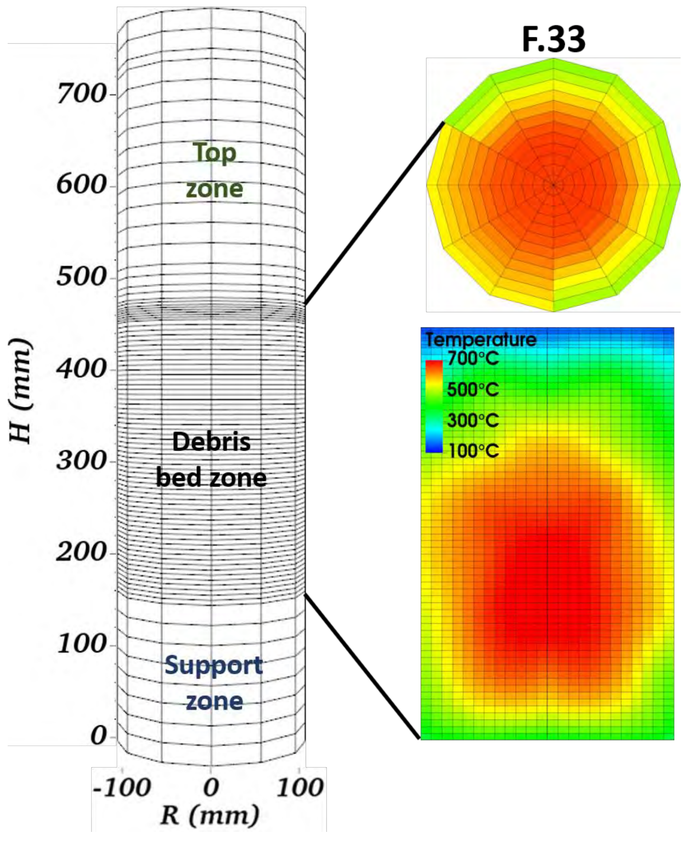

Figure 2: Simulation setup. Cylindrical computational grid with 91 cells in the axial direction, 12 in the radial direction, and 12 angular zones (12,960 total cells).

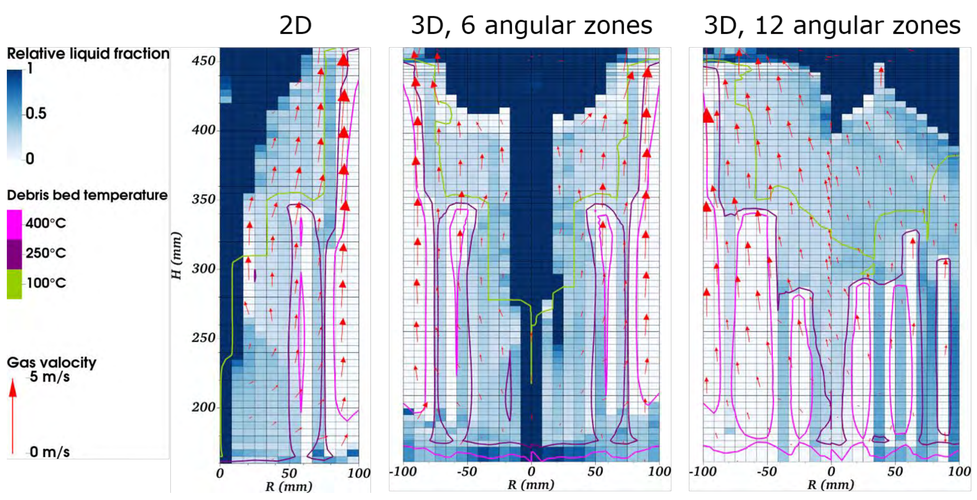
Simulation Results and Interpretation



Simulation based on case F.33 with T_{AVG} = 524°C, without counter-current gas injection.

Figure 3: Comparison of 2D and 3D simulations with 6 and 12 angular divisions, at t = 130s.

Fine angular refinement allows us to observe 3D effect.

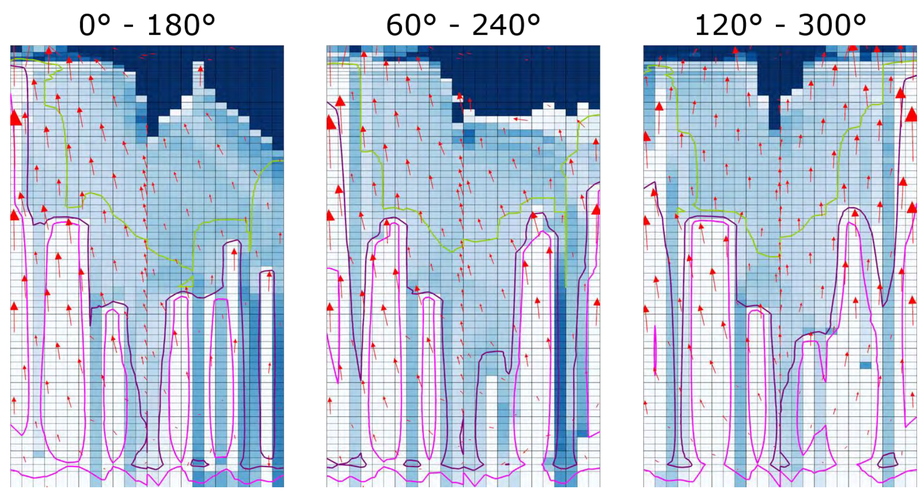


Figure 4: Results of 3D simulation with 12 angular divisions at angles 0° - 180° (left), 60° - 240° (middle), 120° - 300° (right), at t = 130 s.

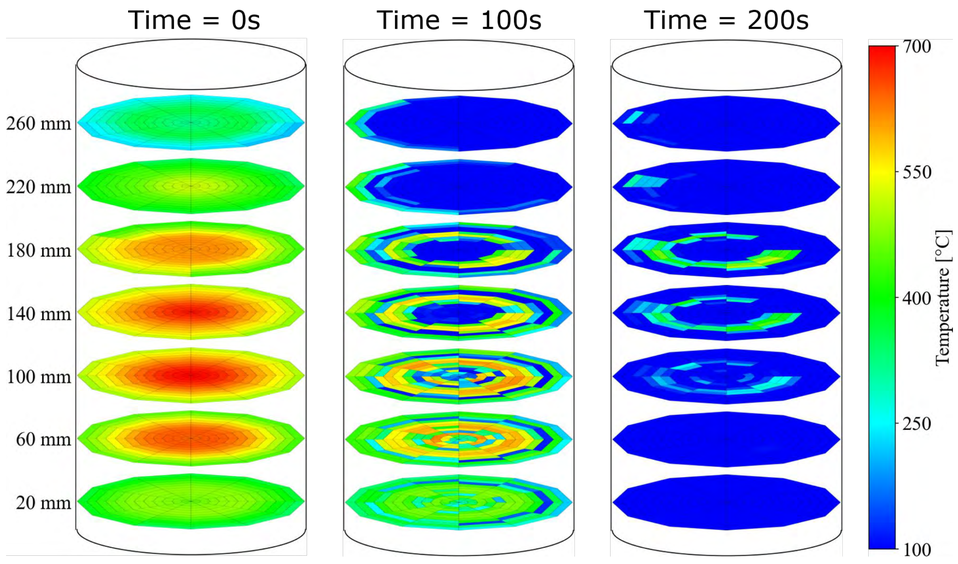

The quenching pattern shows preferential water penetration in the centre and partial penetration along the edge.

Figure 5: Cross-sectional views of the debris-bed temperature during quenching.

Delay in the beginning can be related to the heat capacity of stainless-steel spheres.

Quenching velocity is comparable to the experiment.

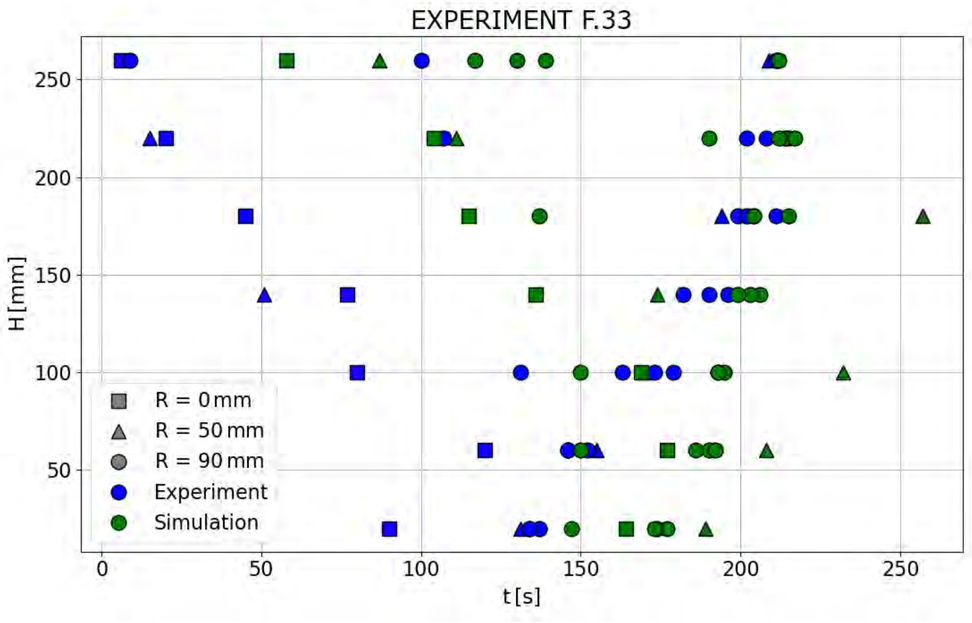

Figure 6: Comparison of debris bed quenching in simulation and experiment.

Discussion and Conclusions

- The advantage of using a three-dimensional mesh with fine enough circumferential refinement is the ability to capture more detailed quenching processes and cooling asymmetries within the debris bed.
- At the onset of quenching, flow instabilities and water fingers develop, leading to partial cooling of the debris. During the first phase, water fingers and near-wall flow quench approximately 60% of the debris.
- Strong steam generation in regions not reached by the downward flow, together with the faster upward water penetration along the higher porosity region near the wall, restricts cooling in the mid-radius zone and leads to the formation of hot pockets.

MELCOR Severe Accident Analysis in LDR-lite: a District Heating Reactor

Marcello Principato (1)

(1) Sapienza University of Rome

Type of abstract: Poster
Subject area: Severe accidents in innovative reactor concepts such as Gen IV and Small Modular Reactors (SMRs)
Keywords: SANE, MELCOR, Design Extended Condition, Mitigation strategies.

In the recent years a district heating reactor has been developed at the VTT Research Centre of Finland. In this context, the Horizon Euratom Project SANE aims to explore the adapted reactor's design, as well as other non-electric nuclear applications. This work regards MELCOR simulations in the LDR-lite reactor, a small 50 MWth PWR. The MELCOR input deck is comprehensive of the overall design, from the primary system to the containment vessel, cavity pool and reactor hall, where other three operational units are located, simulated as heat losses to their corresponding pools. The results show the progression of the overall accidental sequence, from the initiating event to meltdown, and propose a preliminary evaluation of mitigation strategies related to LDR-lite.

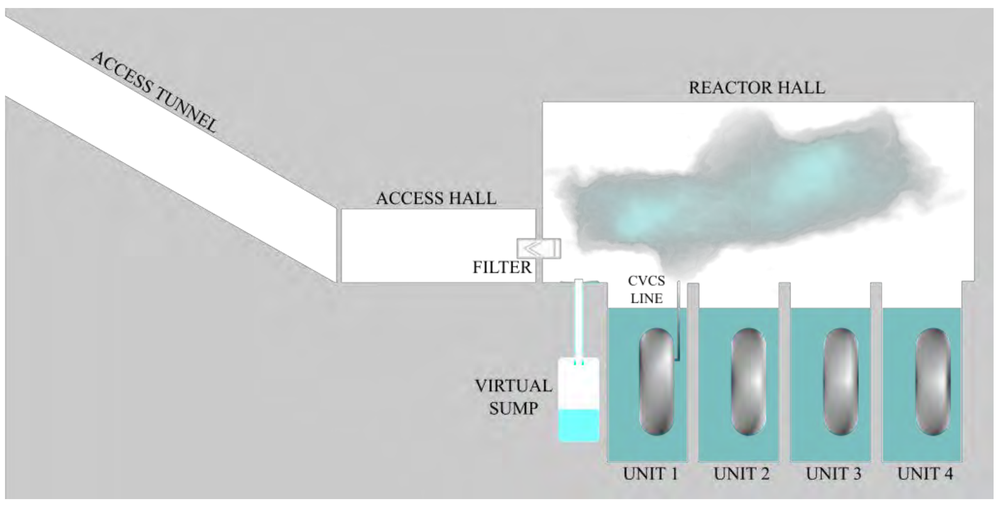
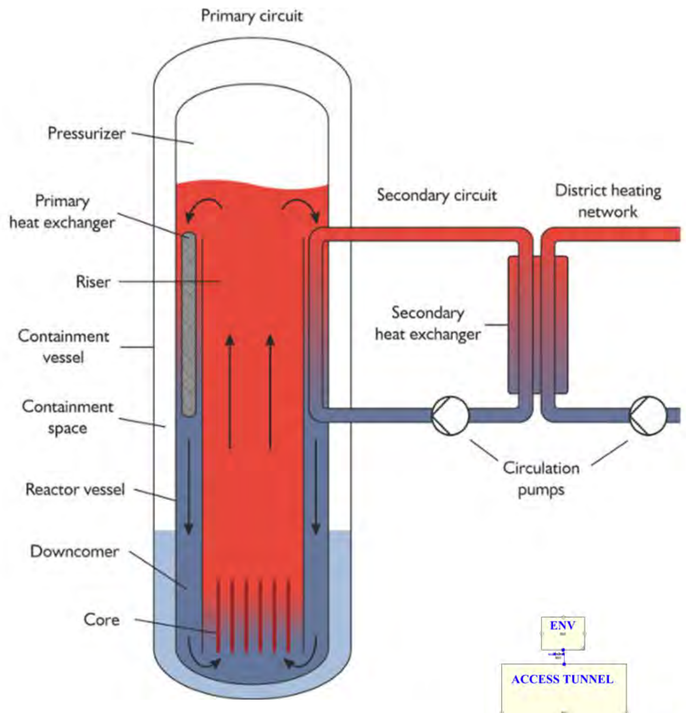
Explore the non-electric uses of nuclear power, such as district heating , hydrogen production and desalination

Task 2.3: Severe accident analyses on LDR-lite



SA Scenario

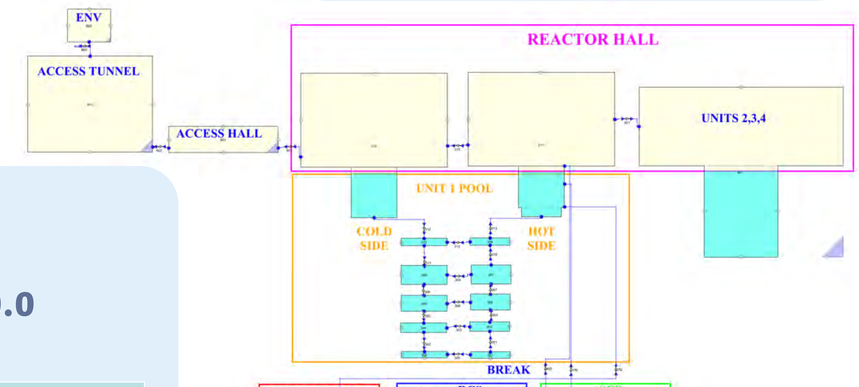
Initiating event: CVCS line rupture + SBO
Simulation time: 21 days (~500 h)
Computational time: 5-10 days



LDR-lite

Benchmark version of LDR-50 : district heating reactor by Steady Energy

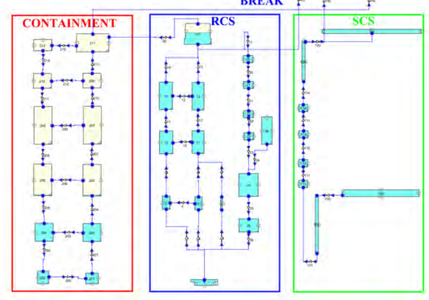
Key features: normal operation primary circulation, N_2 bubble pressurizer, boron-free operation, passive heat removal, short reactor core



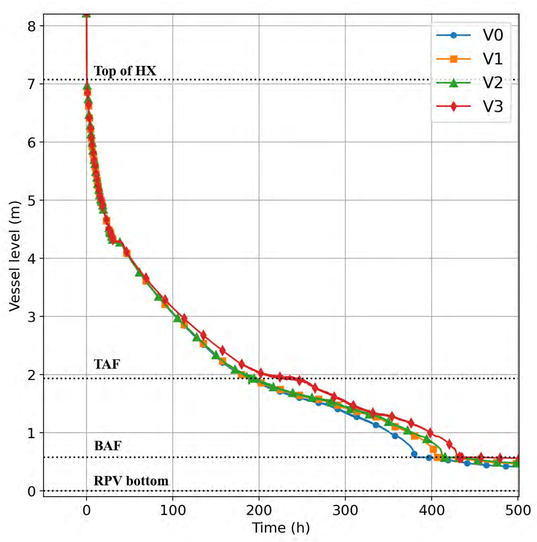
MELCOR

Code version: v2025.0.0
4 input versions:

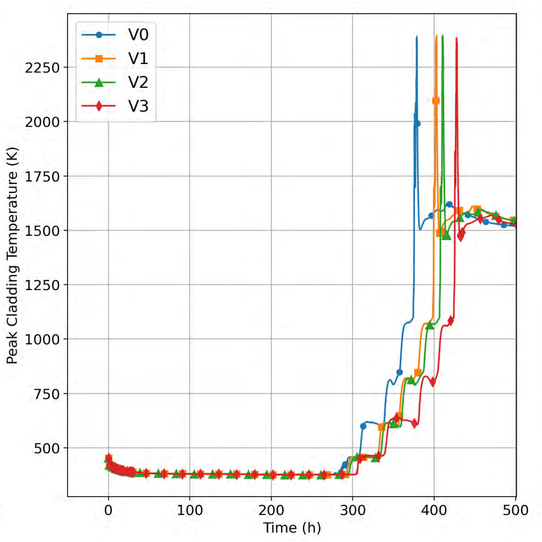
NAME	Reactor Hall CVH	Reactor Hall HSs thickness	U1 pool HSs thickness
V0	3	1 m	None
V1	3	5 m	1 m
V2	3	5m	5 m floor 1 m wall
V3	31	5m	5 m floor 1 m wall



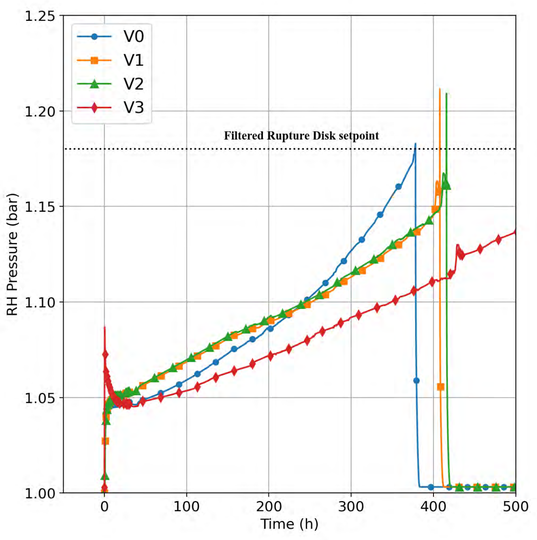
Vessel Water Level (m)



Peak Cladding Temperature (K)



RH pressure (bar)



Results

Sequence:

- Primary water is discharged in the RH at 15 m (1m above the water pool).
- The RPV water level decreases slowly, and in turn the RH pressure increases.
- Minor Core damage is registered, resulting in a gap release.
- Core cooling is ensured by steam recirculation once the water level is below the core support plate (Decay heat is low).
- RH is equipped with a rupture disk that is opened at 0.18 bar_{gauge}. Releases dynamics will be investigated with an uncertainty and sensitivity analysis (the deposition time between the gap release and the rupture disk opening is a key parameter).

Conclusions

RH thermal inertia delays significantly the accident's sequence, granting substantial grace time.

No Unit 1 pool thermal stratification observed (high recirculation).

Core damage is limited to the upper portion of cladding (gap release).

Releases are very limited due to the filter's presence. Aerosol – borne classes are also mitigated by deposition on RH structures.

Future development

A sensitivity and uncertainty analysis will be carried out to explore the output realm in terms of RN releases and Core damage.

H_2 risk will be investigated with a high-fidelity code (containmentFOAM), to capture hydrogen dynamics in the Reactor Hall.

Noble gases behavior at the instant of release will also be investigated with containmentFOAM (low pressure difference, fast equalization)

ABSTRACT

Analysis on the IVMR(In-Vessel Melt Retention) through ERVC (External Reactor Vessel Cooling) for the i-SMR (innovative Small Modular Reactor) using CINEMA computer code has been performed. Best estimate calculations from the initiating event of the SBLOCA of 2-inch equivalent diameter at inside containment has been performed to evaluate the maintenance possibility of the reactor vessel integrity by the ERVC for 96 hours. In this sequence, one EDV (Emergency Depressurization Valve) and one ERV (Emergency Recirculation Valve) were opened by low pressurizer level signal, which resulted in the ERVC condition. A steady state calculation was performed in order to verify the input nodalization of CINEMA for the i-SMR. The steady state results for a selected set of parameters were in very good agreement with the operating conditions of the i-SMR. At the end of calculation, the masses of oxide corium and metallic corium are 24.9 ton and 24.8 ton, respectively. The reactor vessel did not fail by the ERVC in spite of some melting of the reactor vessel. The reactor vessel was melted to 60 % of the initial thickness of 0.182m. Maximum heat flux from the outer reactor vessel wall to the water inside containment is approximately 0.4 MW/m^2.

KEYWORDS
Small Modular Reactor, IVMR, ERVC, CINEMA Computer Code, SBLOCA

1. INTRODUCTION

As an integrated severe accident computer code development in Korea, CINEMA (Code for INtegrated severe accidEnt Management Analysis) has been developed for a stand-alone severe accident analysis [1]. The basic goal of this code development is to design a severe accident analysis code package by exploiting the existing domestic DBA (Design Basis Analysis) code system for the severe accident analysis. The CINEMA computer code is composed of CSPACE [2], SACAP (Severe Accident Containment Analysis Package) [3], and SIRIUS (SImulation of Radioactive nuclide Interaction Under Severe accident) [4], which are capable of core melt progression with thermal hydraulic analysis of the RCS (Reactor Coolant System), severe accident analysis of the containment, and fission product analysis, respectively. The CSPACE is the result of merging the COMPASS (COre Meltdown Progression Accident Simulation Software) and SPACE (Safety and Performance Analysis CodE for nuclear power plants) models [5], which is designed to calculate the severe accident situations of an overall RCS thermal-hydraulic response in SPACE modules and a core damage progression in COMPASS modules.
The i-SMR (innovative Small Modular Reactor) has been developing in Korea. The design and safety concepts were explained in reference [6]. This small reactor adopted the IVMR (In-Vessel Melt Retention) through ERVC (External Reactor Vessel Cooling) as a severe accident mitigation measure to prevent reactor vessel failure. This study is focused on a preliminary analysis on IVR-ERVC for the i-SMR using CINEMA

computer code. Best estimate calculations from the initiating events of the SBLOCA (Small Break LOCA) of 2-inch equivalent diameter at outside containment in the i-SMR has been performed to evaluate the maintenance possibility of the reactor vessel integrity by ERVC

2. CSPACE INPUT MODEL

The input model for the CINEMA calculation of the i-SMR was a combination of the SPACE and COMPASS input models. Heat structures for the fuel rods and the lower part of the reactor vessel in the SPACE input model were replaced by the COMPASS input models. In the SPACE model, the reactor core was simulated as five channels to evaluate the thermal-hydraulic behavior in detail, and each channel was composed of five axial volumes. In the COMPASS input model of this analysis, the component numbers for the fuel and control rods were five and five, respectively. The total masses of fuel and cladding are 21.4 ton and 6.4 ton, respectively. As shown in Fig.1, one SPACE volume is modelled for ERVC analysis. The lower reactor vessel is divided into 5 radial and 10 axial nodes. Lower vessel thickness is 0.182m. A steady state calculation was performed in order to verify the input nodalization of CINEMA for the i-SMR. The steady state results for a selected set of parameters were in very good agreement with the operating conditions of the i-SMR. The steady state conditions obtained from the simulation were used as initial conditions for the transient calculation.

3. RESULTS AND DISCUSSION

A best estimate calculation from the initiating event of the SBLOCA at outside containment was performed using the CINEMA computer code for 96 hours(4 days, 345,600 sec). In this sequence, one EDV (Emergency Depressurization Valve) and one ERV (Emergency Recirculation Valve) were opened by low pressurizer level signal, which resulted in the ERVC condition. Table I shows CINEMA results on the major events. When the cladding surface temperature reached 1,700 K, oxidation of the zircaloy was accelerated as the steam was supplied from the bottom of the reactor vessel. The bottom of the core dried out at 26,600 sec. At about 2,100K of the cladding surface temperature, the zircaloy inside the oxide shell began to liquefy and the outer portion of the fuel pellets was dissolved. The relatively thin ZrO_2 shell ruptured at about 2,390 K because the shell strength decreased with the temperature increase at 32,900 sec . The debris formed at the bottom of the fuel rods, where the liquefied mixture had resolidified. The melting temperature of the zirconium dioxide is 2,390 K, and that of the uranium dioxide is 2,400 K in these calculations. The melted core material had relocated to the lower plenum of the reactor vessel at 128,000 sec. In this calculation, the reactor vessel did not fail by ERVC. The total hydrogen generation mass was estimated as 233.2 kg.

Table I. CINEMA results on the major events.

Major Events	SBLOCA (sec)
Transient Initiated	0
Core Dryout	26,600
Fuel Melting and Relocation	32,970
Corium Relocation into Lower Head	128,000
Reactor Vessel Failure	No Failure
Total Hydrogen Generation Mass	233.2 kg

Fig. 1 shows CINEMA results on corium mass and height lower plenum. At the end of calculation, the masses of oxide corium and metallic corium are 24.9 ton and 24.8 ton, respectively. The mass of oxide

corium is equivalent to the metallic corium, which is different from the general PWR (Pressurized Water Reactor). Mass of metallic corium is higher than that of general PWR, because of higher initial mass. At the initial stage, all height was water. After the corium in the core initially relocates to the lower plenum at 128,000 sec, corium heights of oxide and metallic and debris increases, but the water height rapidly decreases. The two-phase mixture level is not zero, because of the condensed water injection through the ERV from the PCCS (Passive Containment Cooling System).

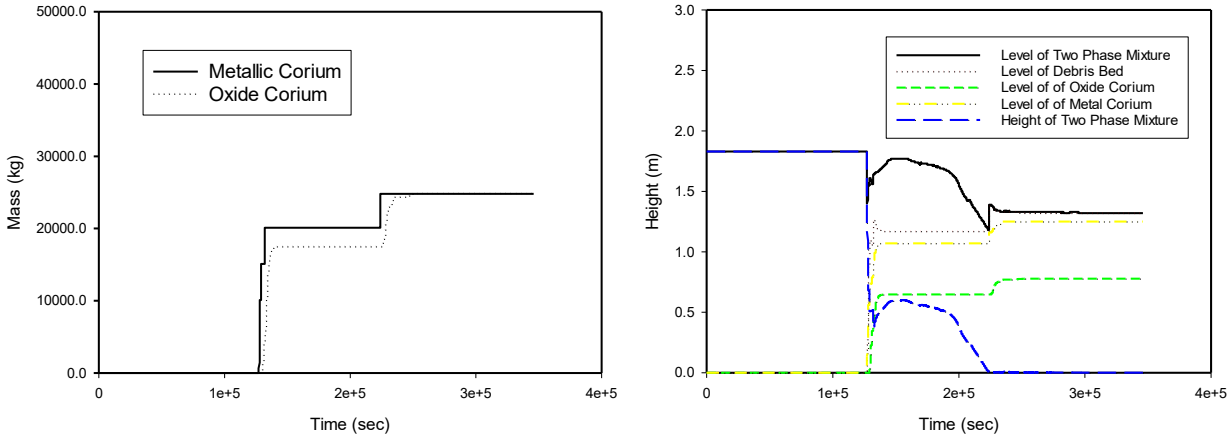

Figure 1. CSPACE Results on Corium Mass and Height in Lower Plenum.

Fig. 2 shows CINEMA results on heat flux from the outer vessel wall to water inside containment and reactor vessel thickness. Maximum heat flux is approximately 0.4 MW/m^2., which was based on El-Genk and Z. Guo correlation [7]. The initial reactor vessel thickness is 0.182 m. The reactor vessel did not fail by ERVC. However, the reactor vessel was melted to 60 % of the initial thickness. Fig. 3 shows CINEMA results on reactor vessel temperature. Node 1 and Node 10 are inside and outside reactor vessel, respectively. Maximum temperatures of Nodes 1 to 6 are melting temperature, which means the melting of reactor vessel inside.

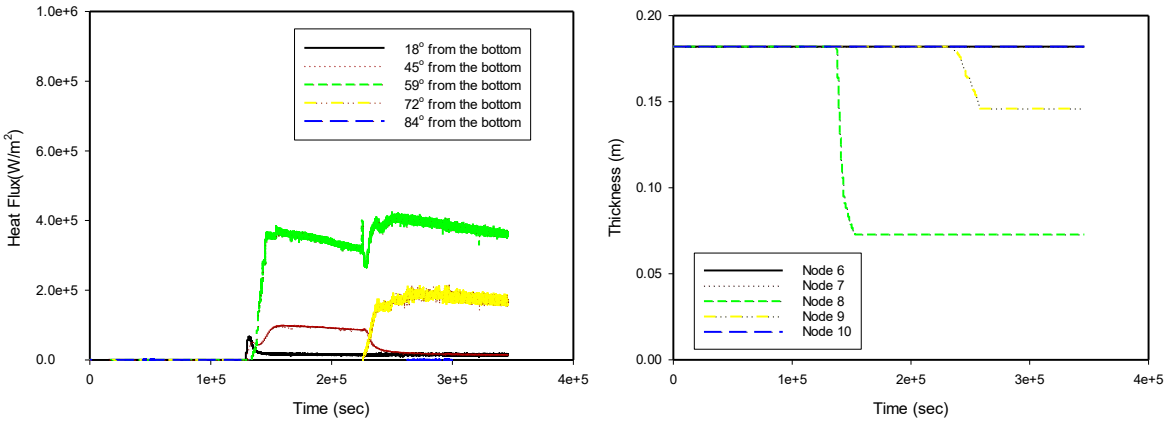

Figure 2 CINEMA Results on Heat Flux from the Vessel Wall to Water and Vessel Thickness.

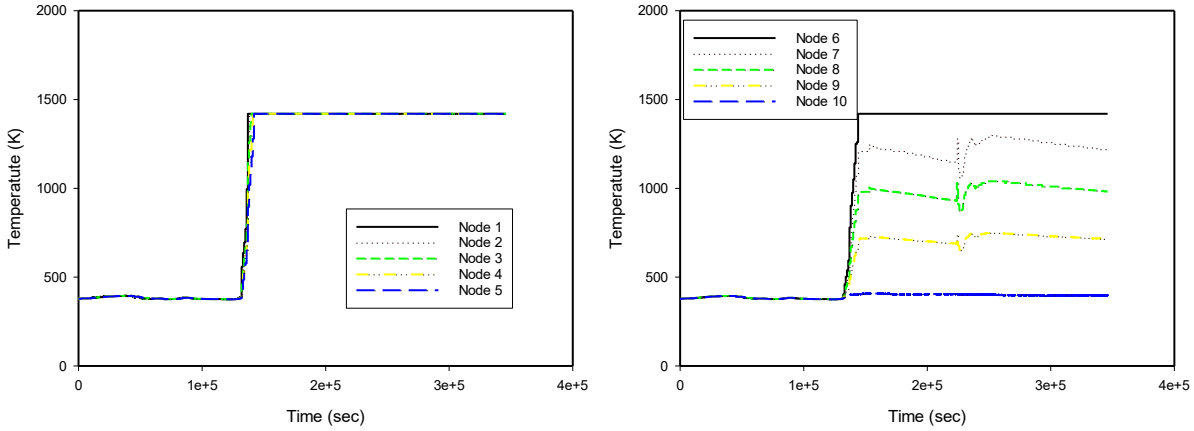

Figure 3. CINEMA Results on Reactor Vessel Temperature.

4. CONCLUSIONS

An analysis on the IVMR through the ERVC for the i-SMR using the CINEMA computer code. Best estimate calculations from the initiating event of the SBLOCA of 2-inch equivalent diameter at outside containment has been performed to evaluate the maintenance possibility of the reactor vessel integrity by the ERVC. The reactor vessel did not fail by the ERVC in spite of some melting of the reactor vessel. The reactor vessel was melted to 60 % of the initial thickness of 0.182m. Maximum heat flux from the outer reactor vessel wall to the water inside containment is approximately 0.4 MW/m^2. More detailed analysis of the ERVC for the i-SMR is necessary to evaluate the IVMR through the ERVC.

ABSTRACT

As a part of small reactor developments for the GEN-IV (Generation IV) reactors, a MSR (Molten Salt Reactor) is selected for reactor technology and safety aspects worldwide. The spreading and heat transfer behavior of radionuclide-bearing molten salt directly and indirectly affect the distribution of radionuclides during and after a salt spill accident. For this reason, the spreading and cooling process of the spill molten salt is very important for MSR safety. Analysis on spreading distance for the spill molten salt of KCl-NaCl-UCl_3 or KCl-UCl_3 in MSR has been performed using the ANSYS-Fluent computer code. The spreading distance of spill molten salt of KCl-NaCl-UCl_3 estimates as approximately 12.9 cm for 20 sec in condition with the mass flow rate of the spill molten salt of 0.1 kg/s for 20 sec and initial salt temperature of 923 K. The spreading distance of spill molten salt is 17.7 cm at 120 sec. The spreading distance of KCl-NaCl-UCl_3 is longer that of KCl-UCl_3, because the solidification temperature of KCl-UCl_3 is higher than that of KCl-NaCl-UCl_3. The spreading distance of 0.1 kg/s for 120 sec is longer that of 0.1 kg/s for 20 sec, because the spill molten salt is larger. An increase in the spill mass flow rate leads to increase in spreading distance, but it is not in proportion.

molten salt reactor, spill out accident, spreading distance, CFD, ANSYS-Fluent

1. INTRODUCTION

As a part of small reactor developments for the GEN-IV (Generation IV) reactors, a MSR (Molten Salt Reactor) is selected for reactor technology and safety aspects worldwide. In the MSRs, the molten liquid salt is the fuel and the cooling liquid at the same time. The first MSR was developed in the USA from 1,960 till 1,970 years, which was thermal-neutron-spectrum graphite moderated concepts [1]. Since 2005, European R&D (Research and Development) interest has focused on fast neutron MSR (MSFR) as a long-term alternative to solid-fueled fast neutrons reactors [2]. The general characteristics of MSR is molten fluorides or chloride salt as fuel fluid and low-pressure, high boiling-point coolant. In a safety of the MSR, the most important thing is a loss of the molten fuel salt with the coolant in the primary system. The spreading and heat transfer behavior of radionuclide-bearing molten salt directly and indirectly affect the distribution of radionuclides during and after a salt spill accident. For this reason, the spreading and cooling process of the spill molten salt is very important for MSR safety. Fig. 1 shows spreading and cooling concept of the spill molten salt in an environment condition.
Test and analysis on the spreading and cooling of the spill molten salt was performed in the SNL (Sandia National Laboratory) recently [3, 4]. Tests were conducted using a chloride salt composition representative of fast spectrum MSRs (eutectic NaCl-UCl_3) to highlight individual processes expected to affect the fate of

spill molten fuel salt and the radionuclides within during a salt spill accident. Spreading and cooling of the spill molten salt were analyzed using the MELTSPREAD computer code [5] for a scenario of molten FLiNaK spilling onto a flat stainless-steel substrate.

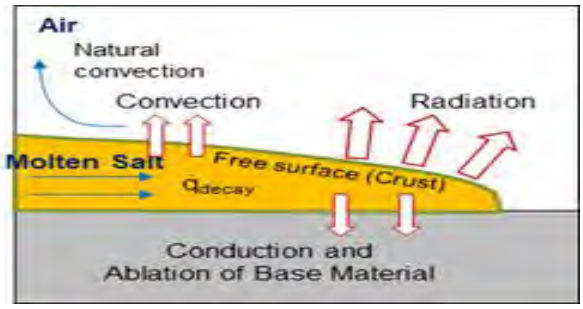

Figure 1 Spreading and Cooling Concept of the Spill Molten Salt.

Analysis on spreading and cooling in PWR was widely studied for severe accident mitigation. The developed methodology for corium spreading may be used for spreading of the molten salt for the MSR. Analysis on spreading distance of the spill molten salt as salt composition of KCl-NaCl-UCl_3 for marine MSR or KCl-UCl_3 for very small MSR has been performed using the ANSYS-Fluent computer code of CFD (Computational Fluid Dynamics) tool.

2. INPUT FOR ANSYS-FLUENT ANALYSIS

Input model for ANSYS-Fluent analysis on spreading and cooling of the spill molten salt was developed. Fig. 1 shows ANSYS-Fluent input model and mesh for spreading analysis of the spill molten salt.

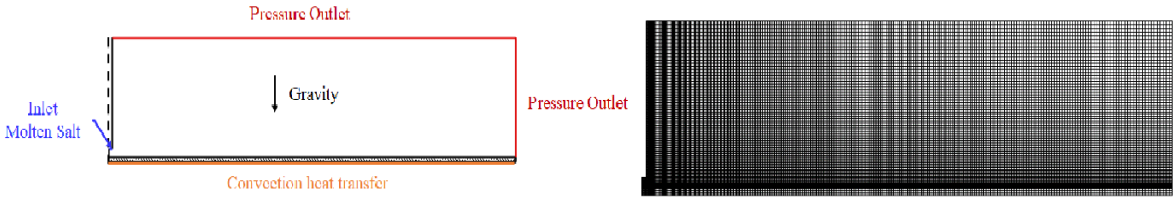

Figure 2 ANSYS-Fluent input model and mesh for spreading analysis of the spill molten salt.

In this study, the following conditions are used.

- Spill molten salt: KCl-NaCl-UCl_3(20.3-42.9-36.8 mol%) or KCl-UCl_3(47-53 mol%)
- Mass flow rate of spill molten salt: 0.1 kg/s to 20 kg/s for 20 sec, 0.1 kg/s for 120 sec
- Initial salt temperature: 923 K
- Solidification temperature: 743 K of KCl-NaCl-UCl_3 or 809 K of KCl-UCl_3
- Temperature of flat floor, atmosphere, and surrounding structures: 630 K
- Geometry: length 60 cm, height 15 cm, Bottom plate thickness: 6.35 mm
- Number of mesh: 32,000, Time step: 0.01 sec, Calculation time: 120 sec
- Analysis method: two-dimensional Axisymmetric
- Bottom condition: hear transfer coefficient input of 10 $W/m^2.K$

Table I shows material properties of spill molten salt of KCl-NaCl-UCl_3 and KCl-UCl_3 in ANSYS-Fluent analysis. In general, solidification temperatures and latent heat of fusion are very effective on the spreading distance of the spill molten salt. The Solidification temperature of KCl-NaCl-UCl_3 is higher than that of KCl-UCl_3, but the latent heat of fusion of KCl-NaCl-UCl_3 is less that of KCl-UCl_3.

Table I. Material properties of spill molten salt in ANSYS-Fluent analysis.

	KCl-NaCl-UCl_3	KCl-UCl_3
Composition (%)	20.3-42.9-36.8	47-53
Solidification Temperature (K)	743	809
Density (kg/m^3)	3,282	3,654
Specific Heat (J/kg.K)	570	475
Thermal Conductivity (W/m.K)	0.38	0.283
Dynamic Viscosity (m^2/s)	7.23 x 10^{-7}	7.86 x 10^{-7}
Latent Heat of Fusion (J/kg)	144,657	68,000

3. RESULTS AND DISCUSSION

Fig. 3 shows ANSYS-Fluent results on spreading distance of the spill molten salt (0.1 kg/s for 20 sec, 0.1 kg/s for 120 sec) with time increases as salt composition of KCl-UCl_3 or KCl-NaCl-UCl_3 in MSR. The spreading distance of spill molten salt of KCl-NaCl-UCl_3 estimates as approximately 15.0 cm for 20 sec in condition with the mass flow rate of the spill molten salt of 0.1 kg/s for 20 sec and initial salt temperature of 923 K. After this time, the spreading distance increases gradually to 120 sec, because the spill out of the molten salt was stopped at 20 sec. Finally, the spreading distance of spill molten salt is 17.7 cm at 120 sec. The spreading distance of KCl-NaCl-UCl_3 is longer that of KCl-UCl_3, because the solidification temperature of KCl-UCl_3 is higher than that of KCl-NaCl-UCl_3. The superheat of spill molten salt is effective on the spreading distance. The spreading distance of 0.1 kg/s for 120 sec is longer that of 0.1 kg/s for 20 sec, because the spill molten salt is larger. Fig. 4 shows ANSYS-Fluent results on spreading distance of the spill molten salt with time and spill mass flow rate as salt composition of KCl-NaCl-UCl_3. The spreading distance of the spill molten salt rapidly increases for initial 20 sec. After this time, the spreading distance increases gradually to 120 sec, because the spill out of the molten salt was stopped at 20 sec. An increase in the spill mass flow rate leads to increase in spreading distance, but it is not in proportion.

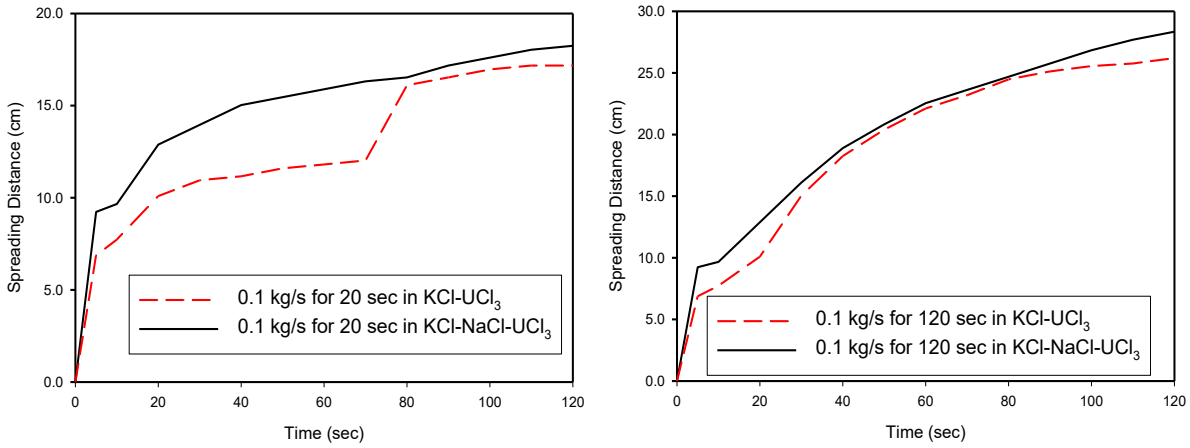

Figure 3 ANSYS-Fluent results on spreading distance

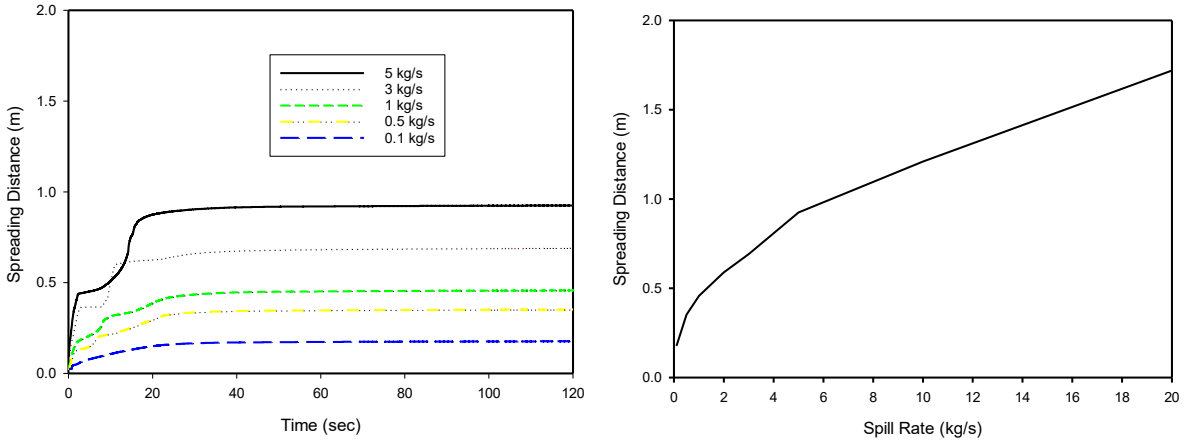

Figure 4 ANSYS-Fluent results on spreading distance

4. CONCLUSIONS

An analysis on spreading distance of the spill molten salt of KCl-NaCl-UCl_3 or KCl-UCl_3 in MSR has been performed using the ANSYS-Fluent computer code of CFD tool. The spreading distance of spill molten salt of KCl-NaCl-UCl_3 estimates as approximately 12.9 cm for 20 sec in condition with the mass flow rate of the spill molten salt of 0.1 kg/s for 20 sec and initial salt temperature of 923 K. After this time, the spreading distance increases gradually to 120 sec, because the spill out of the molten salt was stopped at 20 s. Finally, the spreading distance of spill molten salt is 17.7 cm at 120 sec. The spreading distance of KCl-NaCl-UCl_3 is longer that of KCl-UCl_3, because the solidification temperature of KCl-UCl_3 is higher than that of KCl-NaCl-UCl_3. The spreading distance of 0.1 kg/s for 120 sec is longer that of 0.1 kg/s for 20 sec, because the spill molten salt is larger. An increase in the spill mass flow rate leads to increase in spreading distance, but it is not in proportion. More calculations for the spill molten salt are necessary to estimate effect of the main parameters, such as material properties, released time and spreading channel width.

ANALYSIS OF SPREADING DISTANCE IN SPILL OUT ACCIDENT OF MOLTEN SALT REACTOR

Rae-Joon Park, Sang Mo An, Jun-young Kang, Jun Ho Bae, Sungll Kim (Korea Atomic Energy Research Institute)

KAERI Korea Atomic Energy Research Institute

1. Introduction

In a severe safety of the MSR, the most important thing is a loss of the molten fuel salt with the coolant in the primary system. The spreading and heat transfer behavior of radionuclide-bearing molten salt directly and indirectly affect the distribution of radionuclides during and after a salt spill accident. For this reason, the spreading and cooling process of the spill molten fuel salt is very important for MSR safety. Fig. 1 shows spreading and cooling concept of the spill molten salt in an environment condition.

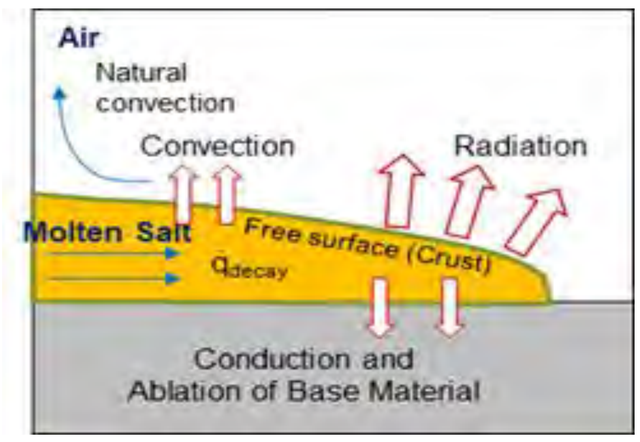

Fig. 1. Spreading and cooling concept of the spill molten salt.

Analysis on spreading and cooling in PWR was widely studied for severe accident mitigation. The developed methodology for corium spreading may be used for spreading of the molten salt for the MSR. Analysis on spreading distance of the spill molten salt as salt composition of KCl-NaCl-UCl_3 for marine MSR or KCl-UCl_3 for very small MSR has been performed using the ANSYS-Fluent computer code of CFD.

2. Input Model

In this study, the following conditions are used.

- Spill molten salt: KCl-NaCl-UCl_3(20.3-42.9-36.8 mol%) or KCl-UCl_3(47-53 mol%)
- Mass flow rate of spill molten salt: 0.1 kg/s or 0.5 kg/s for 20 sec or 120 sec
- Initial salt temperature: 923 K
- Solidification temperature: 743 K of KCl-NaCl-UCl_3 or 809 K of KCl-UCl_3
- Temperature of flat floor, atmosphere, and surrounding structures: 630 K
- Geometry: length 100 cm, height 15 cm
- Bottom plate thickness: 6.35 mm, Number of mesh: 32,000
- Time step: 0.0002 sec. Calculation time: 120 sec
- Analysis method: two-dimensional
- Bottom condition: hear transfer coefficient input of 10 W/m^2.K

The following models are used.

- Multiphase model: VOF (Volume Of Fluid)
- Viscous Model: K-epsilon, Realizable
- Mushy Zone Parameter on Solidification & Melting Model: 1e+5

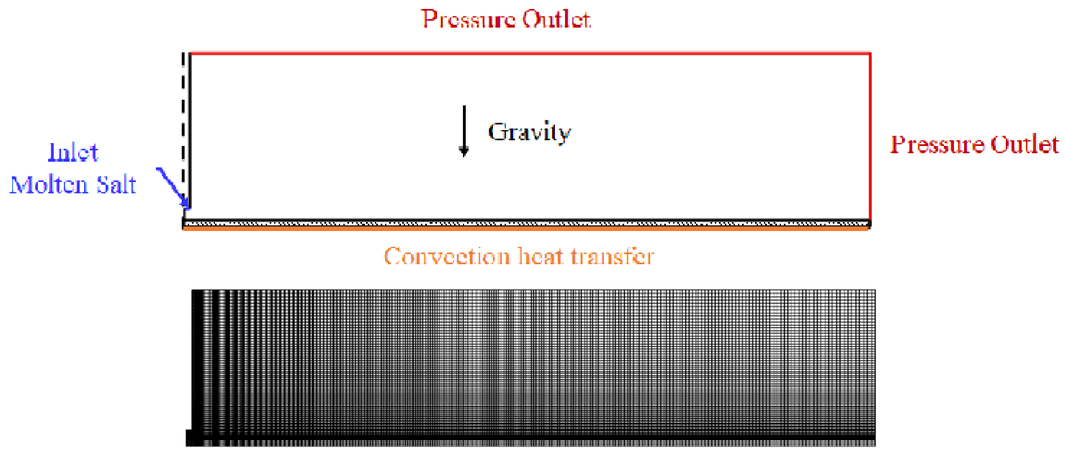

Fig. 2. Fluent input model and mesh generation.

4. Summary

The spreading distance of spill molten salt of KCl-NaCl-UCl_3 estimates as approximately 12.9 cm for 20 sec in condition with the mass flow rate of the spill molten salt of 0.1 kg/s for 20 sec and initial salt temperature of 923 K. After this time, the spreading distance increases gradually to 120 sec, because the spill out of the molten salt was stopped at 20 s. Finally, the spreading distance of spill molten salt is 17.7 cm at 120 sec. The spreading distance of KCl-NaCl-UCl_3 is longer that of KCl-UCl_3, because the solidification temperature of KCl-UCl_3 is higher than that of KCl-NaCl-UCl_3. The spreading distance of 0.1 kg/s for 120 sec is longer that of 0.1 kg/s for 20 sec, because the spill molten salt is larger.

DEVELOPMENT OF A FISSION PRODUCT MITIGATION SYSTEM FOR SEVERE ACCDIENT CONDITIONS IN SMALL MODULAR REACTORS

ABSTRACT

Small Modular Reactors (SMRs) and advanced reactors feature enhanced inherent and passive safety, resulting in very low probabilities of severe accidents. Nevertheless, additional engineered measures can further reduce potential radioactive releases under beyond design basis conditions. This paper presents the development of a compact fission product mitigation system for SMR applications, designed to remove airborne radioactive aerosols within the reactor protection building using a multi-stage, metal-fiber-based filtration concept. The current system focuses on aerosol mitigation, while allowing optional integration of iodine removal filters if required. Experimental evaluations confirm stable and high aerosol removal performance under representative severe-accident conditions, demonstrating the applicability of the proposed system as a building-integrated mitigation option for next-generation reactors.

KEYWORDS
Severe Accident, fission product, mitigation system, small modular reactors

1. INTRODUCTION

Small Modular Reactors (SMRs) and advanced nuclear reactor designs have gained significant attention as low-carbon energy sources capable of supporting global decarbonization goals. Compared with conventional large-scale nuclear power plants, SMRs feature lower core power, simplified system layouts, and extensive use of passive safety systems, which significantly reduce both the frequency and consequences of severe accidents. As a result, many SMR designs target core damage frequencies and large release frequencies several orders of magnitude lower than those of existing reactors. For example, the Korean innovative Small Modular Reactor(i-SMR), currently under development in Korea, is designed to

achieve an extremely low Core Damage Frequency (CDF) and Large Release Frequency (LRF) of 1×10^{-9} and 1×10^{-10} per reactor year, respectively [1].
Despite these favorable safety characteristics, the potential deployment of SMRs in proximity to population centers motivates the consideration of additional engineered measures to further limit radioactive material release under extremely unlikely severe accident scenarios. In particular, mitigation of airborne fission products within the reactor protection building can provide an effective means of reducing off-site radiological consequences and supporting emergency planning zone.
This paper introduces a compact fission product mitigation system currently under development for SMR and advanced reactor applications. The proposed system is designed to operate within the reactor protection building and focuses on the removal of airborne radioactive materials generated during severe accidents. Unlike conventional filtered containment venting systems used in large reactors, the proposed system operates in a closed-loop, recirculating mode to continuously reduce aerosol concentration within the building. It is further designed to achieve a reduction in airborne aerosol concentration by at least one order of magnitude during severe accident progression, depending on building design and system capacity. The system is compact, modular, and intended to be integrated into the building layout, making it compatible with the spatial and economic constraints of SMRs.

2. DESIGN CONCEPT OF THE FISSION PRODUCT MITIGATION SYSTEM

2.1. System overview

A collaborative effort between KAERI, FNC, and CENTURY is underway to develop a Radioactive Material Reduction System (RMRS) designed to reduce airborne radioactive material concentrations within the reactor protection building during severe accidents. The RMRS adopts a fan-driven forced ventilation approach to actively withdraw contaminated gas from the reactor protection building and deliver it to the filtration unit.
Once processed through the filtration unit, the decontaminated gas is returned to the building volume. This recirculating configuration minimizes direct environmental releases while progressively reducing in-building radioactive source terms. The modular design allows multiple RMRS units to be deployed depending on building volume and specific plant requirements. The concept is applicable to SMRs as well as other advanced reactor types.
Unlike passive safety systems, this approach enables stable and controllable flow rates independent of natural convection or pressure-driven leakage, which can be highly uncertain under transient severe accident conditions. It should be emphasized that the RMRS is not intended to replace inherent or passive safety features of SMR designs, but rather to serve as a complementary mitigation measure under beyond design basis accident scenarios when active system operation is available.
The current concept assumes powered operation of the system. While a detailed strategy for ensuring power availability under severe accident conditions is part of the overall accident management framework, it is beyond the scope of this study and may vary depending on plant specific accident management strategies. In practical applications, plant specific provisions, such as battery backed systems or dedicated emergency power supplies, may be incorporated to enhance system operability during station blackout (SBO) scenarios. Even in SBO scenarios, delayed or intermittent operation of the RMRS can still provide meaningful source term reduction, since aerosol concentrations typically evolve over extended time scales during severe accident progression.

2.2. Multi-Stage Filtration Configuration

The mitigation system employs a hierarchical, multi-stage filtration configuration optimized for severe accident environments:

1. Demister stage: Removes moisture droplets and large particles entrained in the gas stream.

2. Pre-filter stage: Captures micron-scale aerosol particles and reduces the loading on the downstream main filter.
3. Main filter stage: Utilizes a metal-fiber filter element designed to remove aerosol particles with high efficiency under elevated temperature and humidity conditions.

Metal-fiber filter materials fabricated from stainless steel or high-temperature alloys are adopted to ensure thermal resistance, mechanical robustness, and chemical stability under severe accident conditions [2,3]. Compared with conventional glass fiber HEPA filters, metal fiber filters provide superior durability and are less susceptible to thermal degradation, fire, and mechanical failure.

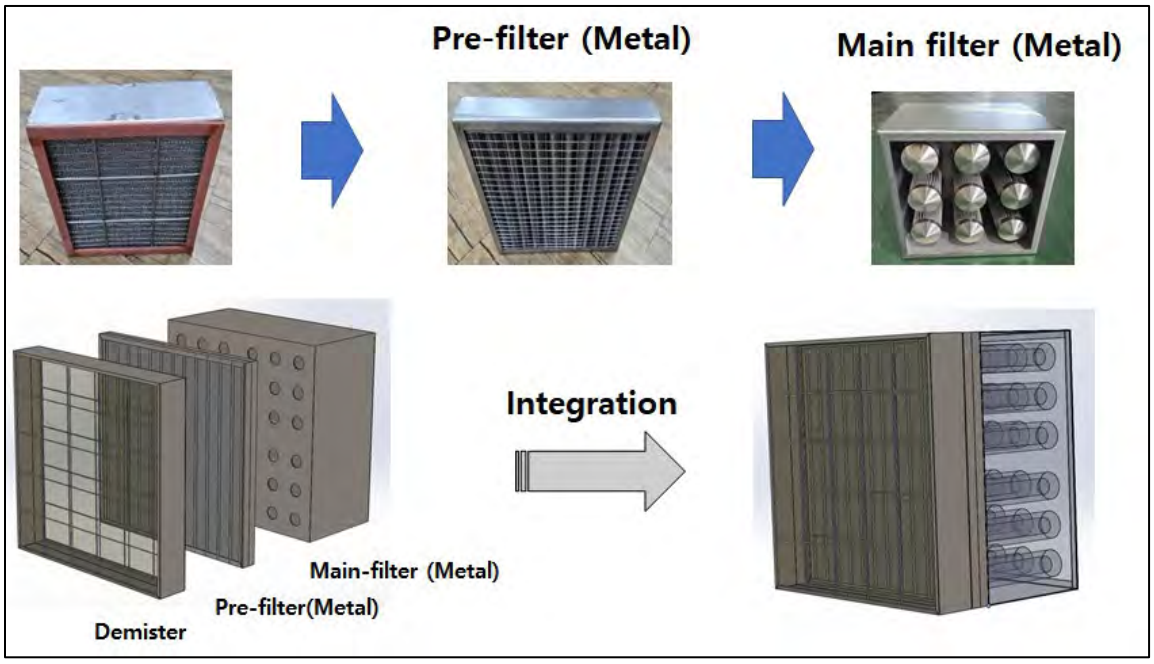

Figure 1. Conceptual images of multiple filtration system in RMRS [2]

3. OPERATING PRINCIPLE AND FUNCTIONAL SCOPE

3.1. Aerosol-Focused Mitigation Strategy

The current development phase of the mitigation system focuses on the removal of aerosolized fission products, which are known to contribute significantly to radiological source terms during severe accidents. Aerosol particles can be efficiently captured through filtration mechanisms such as interception, inertial impaction, diffusion, and thermophoresis, particularly when high-temperature-resistant filter media are employed.

To evaluate filtration performance under representative conditions, in the experiment reported in Ref. [4], solid spherical aerosol particles with a physical diameter of 0.3 μm were used as test particles. The particles were dispersed in ethanol and injected into the test section using a two-fluid nozzle. Experimental evaluations show that the metal-fiber filter achieves the targeted decontamination factor (DF) for aerosol removal of 100 under representative face velocities (0.047 ~0.06 m/s) and temperature conditions (30~90 ℃) relevant to reactor protection building environments during accident scenarios.

At the system level, the RMRS is designed with a target space decontamination capacity corresponding to a nominal flow rate 8 m3/min, which has been successfully achieved in the current system configuration.

3.2. Optional Iodine Removal Capability

While the baseline system configuration is optimized for aerosol removal, the overall design allows for the optional integration of iodine-specific removal components when required by plant safety objectives or regulatory requirements. Such components may include iodine adsorption filters based on silver-impregnated materials or other advanced sorbents. The target DF for iodine removal is approximately 50.
This flexible design approach allows the mitigation system to be adapted to various reactor designs and source term characteristics while maintaining the compactness and operational simplicity of the baseline configuration.

4. DEVELOPMENT STATUS AND APPLICABILITY TO ADVANCED REACTORS

A prototype-scale mitigation system has been developed and subjected to experimental performance testing using representative aerosol conditions. The tests demonstrate stable filtration performance across a range of temperatures and flow conditions, confirming the suitability of metal-fiber filters for severe accident environments.
The system is currently being developed for application in Korean i-SMR concepts; however, its design philosophy and operating principles are directly applicable to a wide range of advanced reactors, including integral pressurized water reactors and other compact reactor concepts. By providing an additional layer of in-building source-term reduction, the mitigation system can complement inherent and passive safety features and contribute to enhanced defense-in-depth.

5. CONCLUSIONS

This paper presented the concept and development status of a compact fission product mitigation system intended for severe accident conditions in Small Modular Reactors and advanced nuclear reactors. The system employs a multi-stage, metal-fiber-based filtration configuration to remove airborne radioactive aerosols within the reactor protection building.
The current design prioritizes aerosol fission product mitigation while allowing optional integration of iodine removal filters if required. Experimental evaluations confirm high filtration efficiency and robust performance under representative thermal–hydraulic conditions. The proposed system offers a practical and scalable option for enhancing source-term mitigation and strengthening safety margins in next-generation nuclear reactor designs.

ABSTRACT

This paper presents uncertainty quantification and sensitivity analysis of severe accident progression for the Rolls-Royce Small Modular Reactor (SMR) using the MAAP code. The study focuses on phenomenological uncertainty and its impact on reactor pressure vessel and containment integrity during a loss of secondary heat sink fault. Key Figures of Merit (FoMs) analysed are peak containment pressure, primary circuit depressurisation timing, total hydrogen generation, time of first core relocation, and peak nodal heat transfer at the lower head.

A global probabilistic approach was applied, varying a wide range of phenomenological input parameters based on best-estimate probability distributions. Analysis using 2000 Latin Hypercube-sampled cases showed the base case is representative of the broader population, with narrow confidence intervals indicating robust sampling.

Correlation coefficients and linear regression identified correlated input parameters for each FoM. Most FoMs were found to be correlated to only a small subset of parameters, particularly those related to heat removal, core oxidation, and melt behaviour highlighting where improved input characterisation could reduce uncertainty.

A separate analysis with very small input variation was performed to attempt to isolate numerical uncertainty. Some FoMs showed highly condensed ranges, confirming that their uncertainty is largely driven by input variation and is reducible. Others retained significant spread, indicating numerical instability within the MAAP model contributes to residual uncertainty.

Overall, the results show that phenomenological uncertainty in MAAP severe accident modelling is dominated by a limited number of physical processes and model parameters. This analysis supports targeted model improvements, and enhances confidence in current MAAP-based severe accident analyses.

Uncertainty Quantification, MAAP, sensitivity analysis, SMR

1. INTRODUCTION

Severe accident analysis includes representation of many physical processes that are not fully understood and are represented in MAAP using empirical parameters whose values are not precisely known. These include parameters affecting heat transfer, oxidation behaviour, melt progression, natural circulation, etc. This complexity makes uncertainty quantification essential for demonstrating robustness of safety conclusions and for prioritising model and data improvements.

Public – Not Listed – Not Subject to Export Controls

To understand the impact of input parameter uncertainty on results and to identify input parameters which have a large impact on output uncertainty, global probabilistic uncertainty and sensitivity analysis has been performed.

In this paper a global, probabilistic Uncertainty Quantification (UQ) and Sensitivity Analysis (SA) framework is applied to the Rolls-Royce SMR MAAP model to assess key safety-relevant metrics for Reactor Pressure Vessel (RPV) and containment integrity in a Loss of Secondary Heat Sink (LoSHS) sequence.

2. METHODOLOGY

2.1. Overview

Five Figures of Merit (FoMs) relating to RPV and containment vessel integrity were analysed: (1) peak containment pressure, (2) time to primary circuit depressurisation, (3) total hydrogen generated in the core, (4) time of first core relocation, and (5) peak nodal heat transfer to the lower head. This paper pays particular attention to the results of peak nodal heat transfer to the lower head and total hydrogen generated in the core. Peak nodal heat transfer to the lower head is a key parameter linked to RPV integrity and total hydrogen generated in the core is linked to the potential for hydrogen deflagration and containment integrity.

RPV and containment vessel integrity are key to severe accident management, and it is important to understand whether the results from deterministic analyses are subject to high uncertainty and whether there is a risk of cliff edge effects. This analysis explores how uncertain modelling assumptions and inputs influence key output metrics and should identify areas where small changes in input parameters may lead to abrupt changes in system behaviour.

Once the FoMs were defined, an appropriate fault sequence was selected to effectively challenge and assess these metrics. The selected scenario is a LoSHS, this event initiates with a complete break of the main feedline to one steam generator, this is followed by failure of automatic depressurisation systems, mitigated by operator depressurisation of the primary circuit after the core exit temperature reaches a key threshold. Severe accident mitigative safety measures are assumed to function as intended. This sequence was selected as it is sufficient to test all of the chosen figures of merit while being similar in fault evolution to a number of other severe accident scenarios so that results from this work have wide applicability.

Latin Hypercube Sampling (LHS) was used to generate input samples, it is a type of stratified sampling. The range of each variable is divided into equally probable intervals, and an equal number of samples are taken from each interval for each variable.

Using LHS rather than simple random sampling gives improved coverage over the more probable areas of parameter space and lower coverage over the highly unlikely areas of parameter space. This improves sampling efficiency and therefore a reduced number of simulations is required to give adequate coverage.

For the baseline analysis 2000 cases were analysed, this was judged to be an appropriate balance between computational effort and the increased certainty gained from larger sample sizes.

2.1. Parameter Selection and Characterisation

Public – Not Listed – Not Subject to Export Controls

In this analysis, only continuous input parameters have been varied. Discrete parameters, such as binary switches, introduce abrupt changes in model behaviour that are not easily captured by the statistical methods chosen and would require a much larger set of analysis cases.

The set of input parameters included in the analysis was derived from the following sources:

- Variables highlighted in the Rolls-Royce SMR Severe Accident Test & Assessment Matrix.
- Variables used in prior targeted Rolls-Royce SMR sensitivity studies.
- Expert judgement on high-uncertainty phenomena for the chosen FoMs.
- Best practise from published UQ&SA MAAP studies for large PWRs [1] and [2].

Ranges and probability distributions for each input parameter prioritised physical plausibility, previous EPRI work [2] and MAAP parameter-file guidance. Probability distributions were uniform where knowledge was sparse, triangular or histogram bin captured skewness where evidence supported it, log-uniform was used where orders of magnitude were important.

2.2. Campaigns

This paper covers three coordinated UQ&SA campaigns:

- Baseline campaign: 2000 cases, sampling all 162 continuous phenomenological parameters, looking at uncertainty quantification and correlation coefficients.
- High-correlation campaign: 500 cases varying only the 20 parameters which showed the strongest correlations to any FoM based on correlation coefficients in the baseline campaign. This was used to perform a linear regression only.
- Small-range campaign: 500 cases with all parameters varied based on a uniform distribution, contracted to 1/100th of the original ranges. This was used to attempt to isolate residual numerical/model noise from input-driven variability. If a FoM's distribution remained wide under near-fixed inputs, this was interpreted as numerical sensitivity.

All calculations used MAAPv5.06 with the Rolls-Royce SMR MAAP model.

2.3. Error Catching

Identifying any cases which fail in any way which means the results are not reliable and deciding whether to exclude their results from the statistical analyses was done in two ways: looking at calculation failure times for those cases which terminated before the mission time and looking at mass and energy errors in the primary circuit and containment.

Rules have been developed which are specific for each FoM ensuring peaks or event times were achieved without unreasonable error values in order to use the result. Analysis case outputs judged to be unsuitable have been excluded from all statistical analysis and plots for that FoM.

Of the 2000 MAAP cases which were run in the baseline campaign, 26 of them failed less than 40 hours into the transient, a failure rate of 1.3%, and up to a maximum of 82 cases were excluded in total from one FoM, a maximum exclusion rate of 4.1%.

2.4. Uncertainty and Sensitivity analysis methods

Uncertainty quantification methods used included:

Public – Not Listed – Not Subject to Export Controls

- Calculation of the mean, standard deviation, coefficients of variation.
- 95% percentile tolerance intervals on data spread.
- 95% confidence intervals on the mean and standard deviations derived via the central limit theorem.

Sensitivity analysis methods used included:

- Partial Spearman rank correlations. Correlation coefficients are used to assess the strength and direction of association between each input variable and each output variable. The Spearman correlation assesses monotonic relationships in ordinal or non-normally distributed data and is robust to outliers. The partial spearman correlation evaluated the relationship between two variables while controlling for the influence of other variables.
- Stepwise linear regressions are used to develop best-fit models for each output metric based on the input parameters. By systematically relating variations in input parameters to changes in output FoMs, regression provides a quantitative means to identify which inputs are most influential and to what extent the model's behaviour can be predicted from its inputs

3. RESULTS

3.1. Baseline and high correlation campaign

The 2000 case baseline campaign shows narrow confidence intervals on the means and standard deviations for all FoMs, indicating that sufficient samples have been analysed to give statistically reliable characterisation of each FoM's distribution, with sampling error small relative to the observed variability. Additionally, the deterministic results obtained using best-estimate values for all input variables lie close to the mean and median across the FoMs. This indicates that the deterministic outputs are representative and not outliers and reflect high-probability behaviour for this scenario.

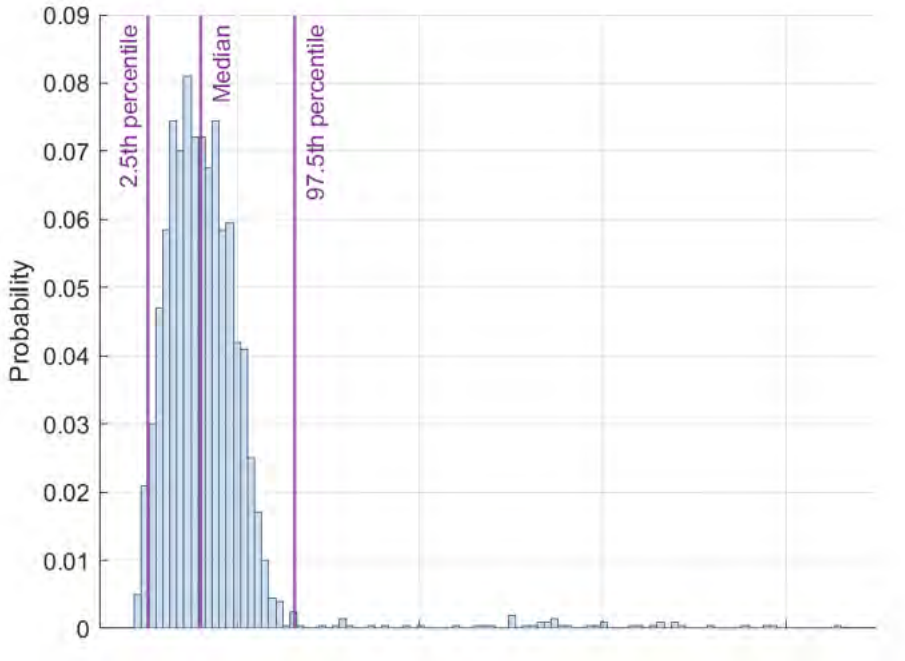

Figure 1 - Probability histogram for Peak Nodal heat transfer at the lower head

The coefficient of variation of a dataset is the ratio of the standard deviation to the mean, it gives a dimensionless way to compare the magnitude of variation between different FoMs. Peak nodal heat transfer at the lower head has a coefficient of variation of 0.41, meaning that the standard deviation is 41%

Public – Not Listed – Not Subject to Export Controls

of the mean, this indicates a high degree of variation. Figure 1 shows a probability histogram for the results from peak nodal heat transfer at the lower head, this shows a highly skewed distribution with a pronounced tail toward higher heat transfer.

This FoM is critical for assessing in vessel retention viability. The presence of high heat transfer outliers indicates that while most cases remain within acceptable bounds, the current assumptions on input parameter uncertainty suggest a small risk of very high heat transfer at the lower head. However it should be noted that Monte Carlo sampling will produce some input datasets which are highly improbable, and therefore the existence of a case that results in an increased risk of lower head failure would not indicate that this is a realistic outcome.

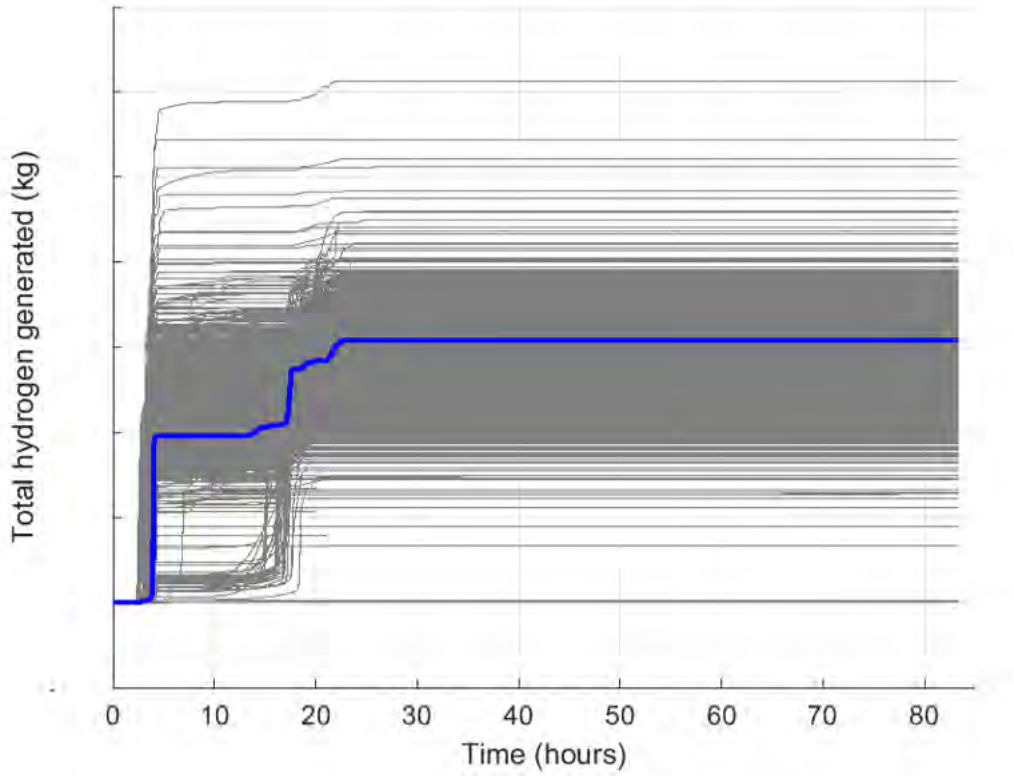

Figure 2 - Dispersion plot of cumulative total hydrogen generated in the core, MAAP variable MH2GEN1

Figure 2 shows the dispersion plot of total hydrogen generated in the core for all cases run, the base case deterministic analysis result is shown in blue. This shows a wide range of total amount of hydrogen produced with the timing of hydrogen production and the shape of the profile being similar in most cases. The deterministic case is shown to be around the middle of the results, in the area of high probability.

Figure 3 shows the probability histogram for total hydrogen production in the core. The population results appear to be close to a normal distribution and therefore the 95% tolerance intervals marked on the histogram, from the 2.5th percentile to the 97.5th percentile are very close to the tolerance interval calculated using the empirical rule.

Public – Not Listed – Not Subject to Export Controls

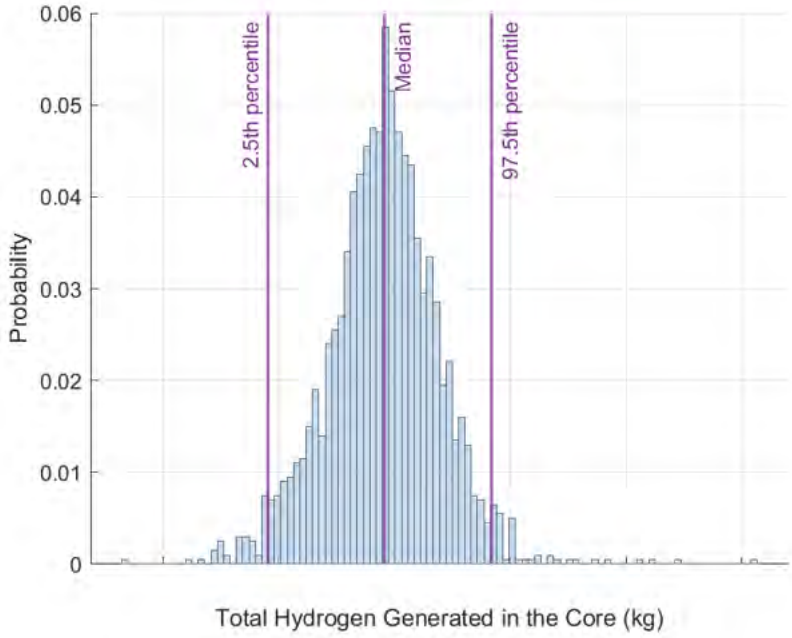

Figure 3 - Probability histogram for total hydrogen generated in the core

Figure 4 and 5 show the results of calculating the partial spearman correlation coefficient, with bars for the top 5 highest correlated parameters.

All high correlation coefficient input parameters have understandable physical reasons why they may be correlated with the FoM of interest. The amount of hydrogen generated in the core is linked to core temperature and how quickly the core melts, and the five highest correlated parameters are all related to this. The top three are VFCRCO, which is the porosity of a collapsed core region, FGBYPA which diverts gas flows in the core to the bypass channel when an entire axial row in the core is completely blocked and FVISC which is the multiplier for material viscosity used in the candling calculation. The highest correlation coefficient for total hydrogen generated in the core is only 0.3 which is a weak correlation.

A stepwise linear regression performed on the high correlation parameters campaign for total hydrogen generated in the core had an R-squared value of 0.46, indicating that 46% of the variability in the data could be explained by the regression. Four of the top five parameters with the highest correlation coefficients were also found to be significant in the regression, supporting the finding of a strong link between variation in these input parameters and variation in predictions of total hydrogen generated in the core.

In addition to those parameters defined above, EPSCUT and EPSCU2 which are related to the cutoff porosity which determine when the MAAP model moves between different fuel melt phases were also in the top 5 highest correlation coefficients and were found to be significant in the regression, and TCLMAX, the temperature that will lead to rupture if the cladding is at this temperature for 36 seconds was found to be significant in the regression.

Public – Not Listed – Not Subject to Export Controls

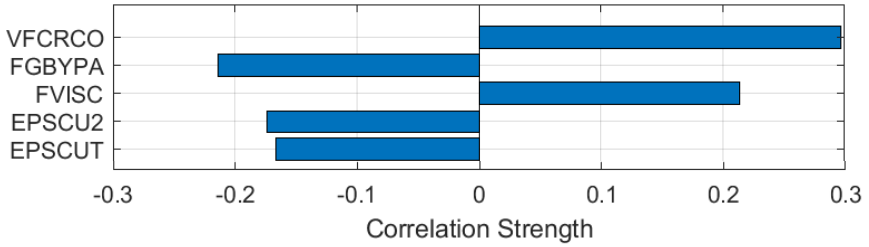

Figure 4 - Partial Spearman Correlation Coefficients, between mass of hydrogen generated in the core and the top 20 input variables

Peak heat transfer on the lower head shows much stronger correlation coefficients in comparison with total hydrogen generated in the core, up to a maximum of 0.67. All three parameters are related to heat transfer in the corium pool in the lower head. EMETALAYER is the emissivity of the light metal layer, FHDNA is the multiplier to the heat transfer coefficient to the lower crust in the corium molten pool and FHUPA is the multiplier to the heat transfer coefficient to the upper crust in the corium molten pool.

When a linear stepwise regression was attempted on the peak heat transfer on the lower head the regression was found to have a low explanatory power with an r-squared value of 0.24. This is likely to be because the long tail towards higher heat transfer suggests nonlinear behaviour.

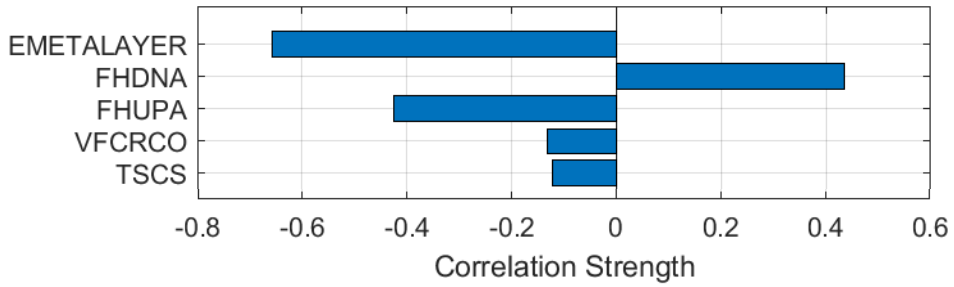

Figure 5 - Partial Spearman Correlation Coefficients, between peak nodal heat transfer at the lower head and the top 20 input variables

3.2. Small input range campaign

Table 1 compares coefficients of variation from the baseline and small input range campaign and describes the visible change in the probability histograms for each FoM.

FoM	Baseline coefficient of variation	Small-Range coefficient of variation	Qualitative Change
Peak Containment Pressure	0.07	0.02	Strong contraction; very narrow 95% tolerance interval range but small tail remains
Timing of RCS Depressurisation	0.04	0.02	Strong contraction, very narrow distribution remains
Peak heat transfer at lower head	0.41	0.17	More than 50% reduction; right tail significantly reduced but still present

Public – Not Listed – Not Subject to Export Controls

Total Hydrogen Generated in the Core	0.17	0.10	Partial reduction; residual spread significant
Time of first core relocation	0.27	0.05	Strong contraction; long tail to early relocation times significantly reduced

Peak heat transfer at the lower head shows a strong contraction in total distribution and a significant reduction in the length and density of the high heat transfer tail. This suggests that the majority of variation in this FoM is driven by input variation uncertainty, however the coefficient of variation is still the highest amount from the FoMs studied. Most other FoMs also show a strong contraction in distribution and a limited amount of remaining variation. This indicates that the majority of uncertainty in these FoMs can be explained by input variation.

On the other hand, for hydrogen generated in the core the coefficient of variation reduces by only around 41% and a broad distribution remains. This indicates that a large amount of uncertainty in hydrogen generated in the core cannot be removed by better understanding of input parameters and may be due to numerical instability.

4. CONCLUSIONS

Overall this analysis shows that out of the 162 MAAP input parameters whose impact on output uncertainty has been assessed, only a small number show any trends with the output FoMs for the accident scenario of interest. This suggests that for a LoSHS case, improvements to uncertainty levels on RPV and containment vessel integrity may be achieved by improving understanding of input uncertainty on a small number of input parameters.

However, the severe accident predictions have also been shown to have a large amount of noise and numerical uncertainty. Analysis of uncertainty with very small input ranges indicated that even if all input parameters are extremely well understood there will still be uncertainty in the output, potentially due to numerical uncertainty in the code.

This work has supported a number of Rolls-Royce SMR severe accident analysis team workstreams including:

- Updates to the Test Assessment Matrix (TAM), to highlight which variables had been found to be influential on phenomena of interest and which had not been found to be influential for this fault sequence.
- Quantifying uncertainty in predictions of FoMs in comparison to margin to safety acceptance criteria. For example showing that the margin to safety acceptance criteria is unlikely to be challenged by phenomenology uncertainty in the results of deterministic analysis.
- Identifying conservative assumptions for methodologies to ensure appropriate assessments when considering relative uncertainty.
- Sensitivity analysis results are used to prioritise areas of the MAAP model and parameters for improvement, by highlighting where input parameter improvement can have the greatest impact. However the small-range study demonstrates that for hydrogen generated in the core, variance in results are unlikely to be significantly reduced by input data improvements alone and bounding conservative assumptions are used.

Together these activities strengthen and help to substantiate a robust analysis method. This analysis method, in turn, provides evidence which supports key safety case claims and contributes to the probabilistic safety assessment.

PROJECT AIMS

Rolls-Royce SMR Severe Accident team's first look at overall MAAP model sensitivity and uncertainty.

The Plan

- Develop sensitivity analysis and uncertainty quantification analysis route.
- First use of route to test uncertainty in reactor pressure vessel and containment vessel integrity predictions.
- Investigate phenomenological and modelling uncertainty only.

Expected Outcomes

- Quantify level of uncertainty in chosen Figures of Merit (FoMs).
- Investigate how much of observed uncertainty may be attributable to irreducible numerical uncertainty in the model rather than reducible phenomenological uncertainty
- Identify input parameters whose uncertainty has a large impact on output uncertainty in the FoMs.

Public – Not Listed – Not Subject to Export Controls

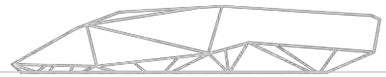
METHODOLOGY - OVERVIEW

1. Select Figures of Merit (FoM)
2. Select accident scenario which will test the selected FoMs
3. Identify input parameters which may influence FoMs
4. Input parameter characterisation
5. Input parameter sampling
6. MAAP calculations
7. Process outputs and identify and remove failed runs
8. Uncertainty analysis
9. Sensitivity analysis

Public – Not Listed – Not Subject to Export Controls

METHODOLOGY – INITIAL DECISIONS

1. Select Figures of Merit (FoM)
   - Peak containment pressure (bara)
   - Timing of Reactor Coolant System (RCS) depressurisation (minutes)
   - Total hydrogen generated in the core (kg)
   - Time of first core relocation (minutes)
   - Peak heat transfer at the lower head (W)
2. Select accident scenario
   - Loss of Secondary Heat Sink (LoSHS) with no high pressure (HP) or low pressure (LP) blowdown via the Automatic Depressurisation System (ADS) and delayed blowdown via the Severe Accident Depressurisation Valve (SADV).
3. Identify input parameters
   - Continuous parameters only in this analysis
   - 162 identified from TAM, EPRI work, literature review and par file review
4. Input parameter characterisation
   - Triangular, uniform, normal or using histogram bins
5. Input parameter sampling
   - Latin Hypercube Sampling



Public – Not Listed – Not Subject to Export Controls

METHODOLOGY – ANALYSIS METHODS

Sensitivity Analysis

- Correlation coefficients
  - Pearson and Spearman, rank and partial
- Linear stepwise regressions
- Pair plots used to visually display and identify relationships

Uncertainty Quantification

- Mean, range, standard deviation, coefficient of variation, 95% tolerance intervals on each output FoM
- 95% confidence intervals on the mean and standard deviation
- Histograms and overlay time series plots used to visually display spread of each FoM

Public – Not Listed – Not Subject to Export Controls

ANALYSIS – 3 SETS COMPLETED

1. Main analysis - *for overall uncertainty quantification*
   - 2000 LHS cases varying all 162 input parameters with best estimate probability distributions.

2. High correlation analysis - *for noise reduction and linear regression analysis*
   - 500 cases, varying only the 20 parameters with the highest correlations from the main analysis with best estimate probability distributions.

3. Very small input variations – *to isolate numerical uncertainty*
   - Attempts to remove any uncertainty driven by real changes in phenomena and isolate numerical uncertainty
   - 500 cases, varying all 162 input parameters with very small uniform distributions
   - Output FoM ranges compared with main analysis

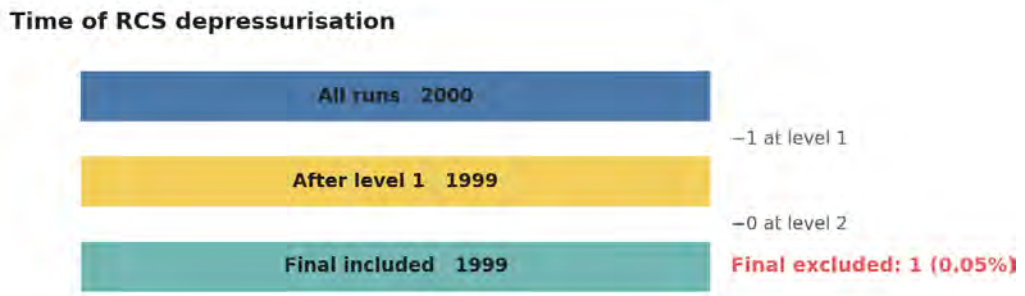
Public – Not Listed – Not Subject to Export Controls

ANALYSIS – ERROR CATCHING

Two-stage error screening, FoM dependent:

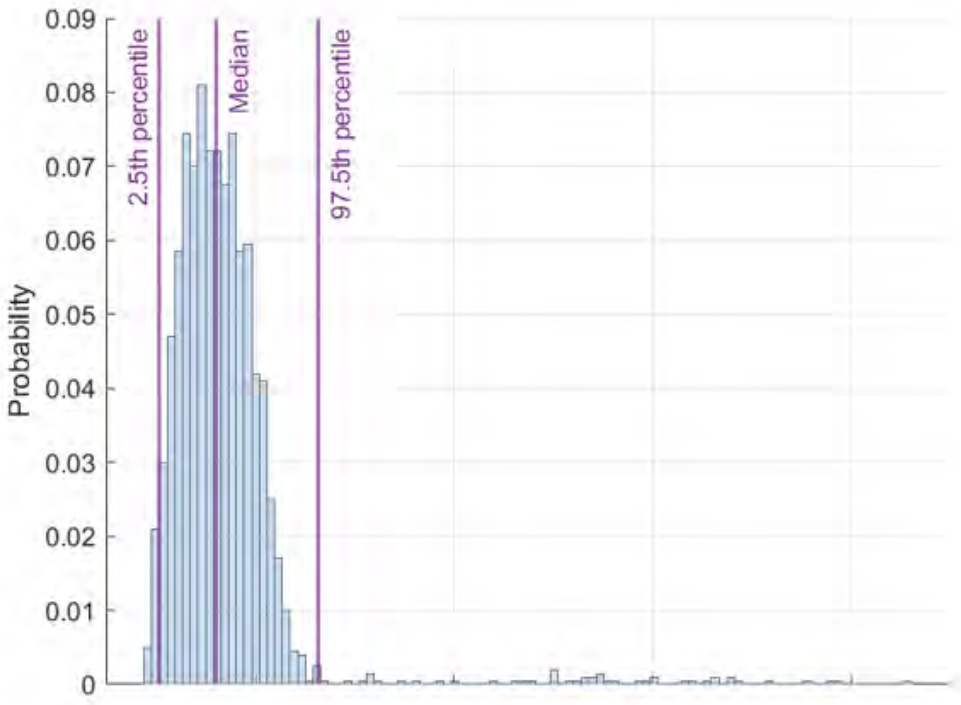
1. Runtime-based screening. This excludes up to 1.3% of cases which fail before 40 hours.
2. Mass and energy balance screening, high mass errors in primary circuit allowable when primary circuit is almost empty.

Stage two is subjective, thresholds set for error inclusion limits and primary circuit emptiness criteria do change results, especially for outliers showing high heat transfer on the lower head.



Public – Not Listed – Not Subject to Export Controls

RESULTS UNCERTAINTY QUANTIFICATION
PEAK HEAT TRANSFER AT THE LOWER HEAD (W)

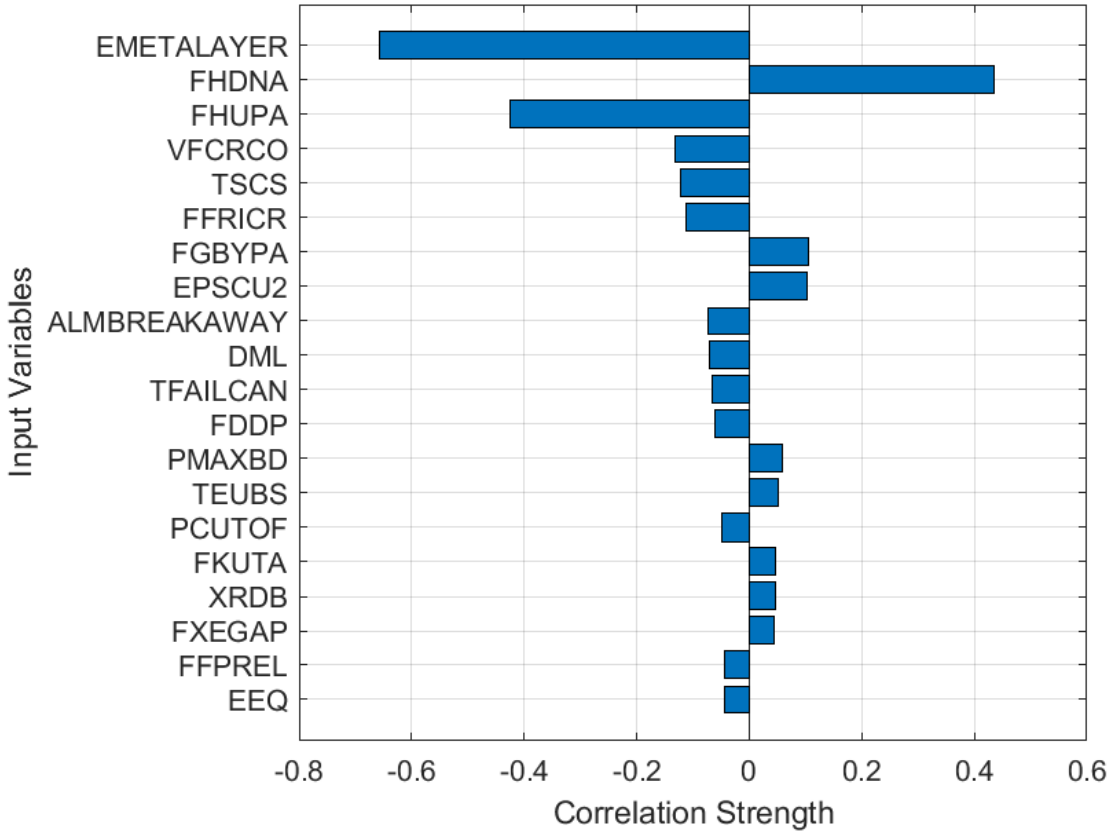


- 95% confidence intervals on the mean and standard deviation are small indicating a sufficient number of cases have been analysed.
- Lower-head heat transfer shows the largest relative uncertainty of all five FoMs. Coefficient of variation of 0.41.
- High heat transfer outliers drive this uncertainty.
- Right-skewed distribution with long upper tail
- Base case is near mean and median

Public – Not Listed – Not Subject to Export Controls

RESULTS SENSITIVITY ANALYSIS

PEAK HEAT TRANSFER AT THE LOWER HEAD (W)

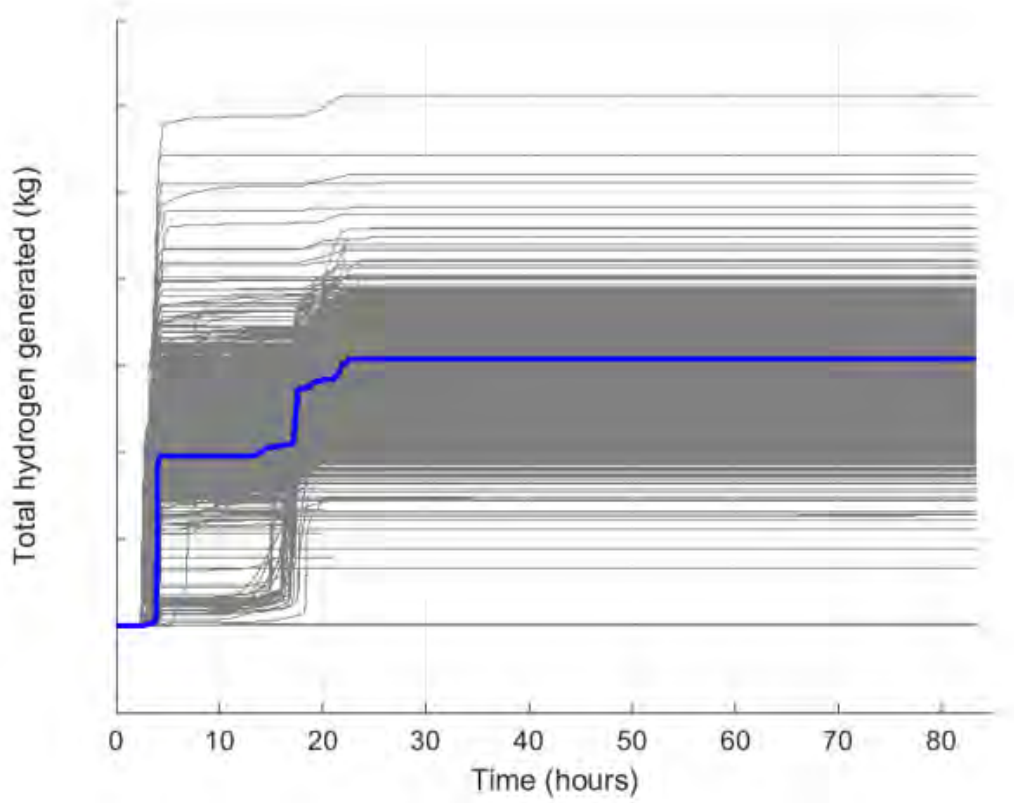


Uncertainty in lower head heat transfer uncertainty is driven by parameters which affect heat transfer within the molten corium

- EMETALAYER - the emissivity of the metal layer
- FHDNA - multiplier to the heat transfer coefficient to the lower crust in the corium molten pool
- FHUPA - multiplier to the heat transfer coefficient to the upper crust in the corium molten pool

Public – Not Listed – Not Subject to Export Controls

RESULTS UNCERTAINTY QUANTIFICATION
TOTAL HYDROGEN GENERATED IN THE CORE (KG)

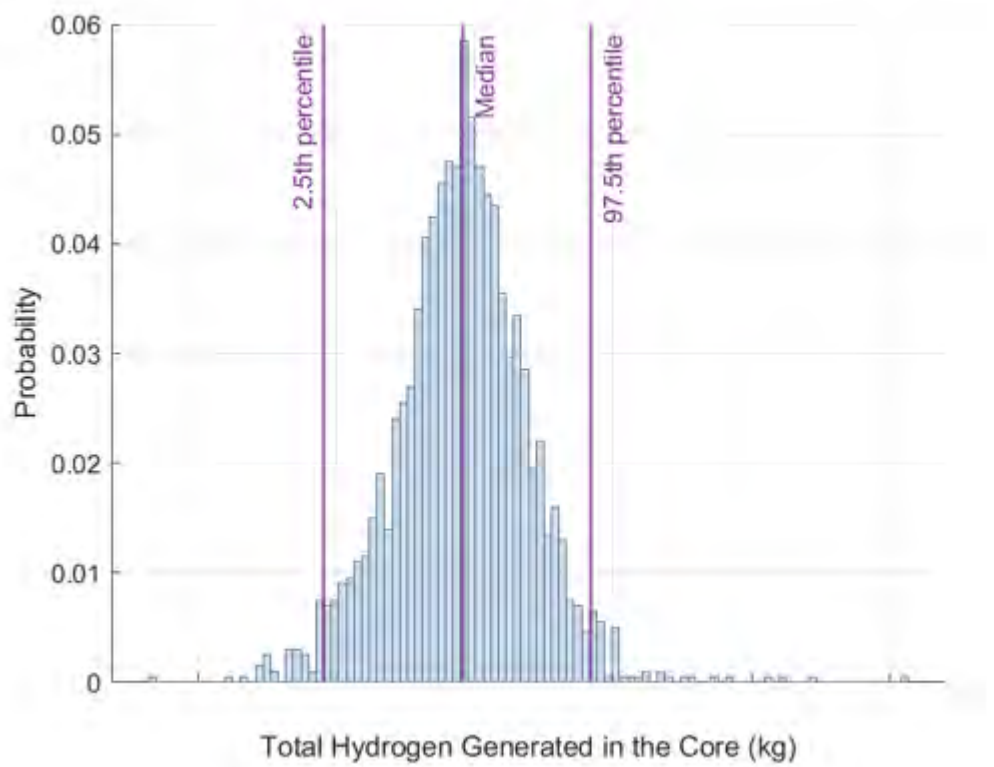


- Large absolute variation in total mass of hydrogen generated
- Significant proportion of the cases generate all their hydrogen very rapidly all at once, unlike the base case.
- Absolute base case result close to mean and median values

Public – Not Listed – Not Subject to Export Controls

RESULTS UNCERTAINTY QUANTIFICATION
TOTAL HYDROGEN GENERATED IN THE CORE (KG)

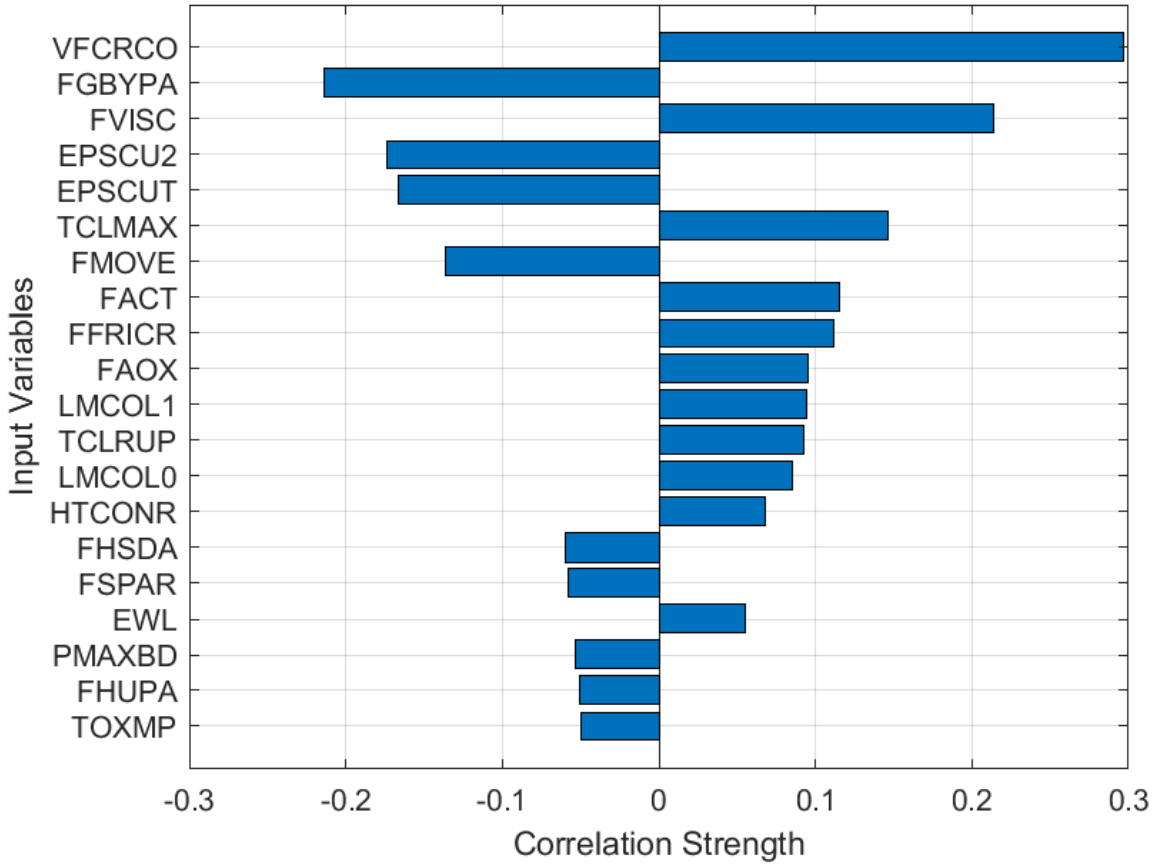
- 95% confidence intervals on the mean and standard deviation are small indicating a sufficient number of cases have been analysed.
- Distribution of results is close to a normal distribution.
- Coefficient of variation is 0.17, lower than for heat transfer at the lower head but still significant.



Public – Not Listed – Not Subject to Export Controls

RESULTS SENSITIVITY ANALYSIS

TOTAL HYDROGEN GENERATED IN THE CORE (KG)



Uncertainty in hydrogen generation from the core is dominated by variables affecting core melt.

- VFCRCO – the porosity of a collapsed core region
- FGBYPA - diverts gas flows in the core to the bypass channel when an entire axial row in the core is completely blocked
- FVISC - multiplier for material viscosity used in the candling calculations

Public – Not Listed – Not Subject to Export Controls

RESULTS – SMALL INPUT VARIATION ANALYSIS
PEAK HEAT TRANSFER AT THE LOWER HEAD (W)

	Main Analysis	Small input variation analysis
Coefficient of variation	0.41	0.17

RESULTS – SMALL INPUT VARIATION ANALYSIS
TOTAL HYDROGEN GENERATED IN THE CORE (KG)

	Main Analysis	Small input variation analysis
Coefficient of variation	0.17	0.1

Public – Not Listed – Not Subject to Export Controls

RESULTS SUMMARY

- Peak lower-head heat transfer showed the largest relative uncertainty, with a right-skewed distribution and a small number of high-flux outliers driving the upper tail.
- Uncertainty in peak lower head heat transfer appeared to be driven mainly by corium heat transfer related parameters. Its uncertainty reduced substantially when the input ranges were narrowed. However, a residual upper tail remained, indicating that some uncertainty is still linked to numerical uncertainty in MAAP.
- Total hydrogen generation showed a broad, nearly normal distribution.
- Even with very small input ranges, hydrogen uncertainty remained significant: the 95% tolerance interval reduced by 43%, showing that a substantial part of the remaining uncertainty is not reducible through better parameter characterisation alone.

Public – Not Listed – Not Subject to Export Controls

USES

- Uses of the work to date:
  - Informed update to the Rolls-Royce SMR MAAP TAM
  - Part of justification that uncertainty is not greater than margin for IVR
  - Used to support hydrogen methodology development by showing irreducible modelling uncertainty in predicting hydrogen generation
  - Supports PSA level 2 development
- Potential future uses
  - Targeted uncertainty reduction by better understanding the most important input parameters

Public – Not Listed – Not Subject to Export Controls

POTENTIAL FUTURE WORK

1. **Investigation of outliers which show high heat flux at the lower head.**
2. **Inclusion of discrete parameters in the methodology, use of nested continuous parameter sampling within each sampled discrete parameter scenario.**
3. **Repeat the same methodology for a different fault sequence with same FoMs.**
4. **Improving parameter characterisation for the input parameters found to be most influential.**
5. Look at different figures of merit, potentially radiological consequences.
6. Additional more complex sensitivity analysis such as Sobol indices and physically based or machine learning regressions.

ABSTRACT

In view of the ongoing licensing process of Small Modular Reactors (SMRs) in Europe, increasing attention is devoted to assessing the capability of Severe Accident (SA) codes, such as MELCOR and ASTEC, to simulate SMR-specific phenomena under postulated transients. Among SMR concepts, integral Pressurized Water Reactors (iPWRs) represent a promising solution since they are based on the well proven technology and operational experience of large Light Water Reactors (LWRs). Within this framework, the present work, carried out in the context of the Horizon Euratom project "Safety Analysis of SMR with Passive Mitigation strategies – Severe Accident" (SASPAM-SA) coordinated by ENEA (Italy), investigates the application of the integral SA code MELCOR to the simulation of a SA scenario in a generic iPWR design. The analyzed sequence consists of a Loss of Coolant Accident (LOCA) initiated by the double-ended guillotine break of a Direct Vessel Injection (DVI) line, combined with the postulated failure of all passive safety systems. The present analysis focuses on the assessment of the main thermal-hydraulic and core degradation phenomena, with particular focus on production of hydrogen by oxidation of Zircaloy in the core. A Best Estimate Plus Uncertainty (BEPU) approach has been adopted to quantify the impact of uncertainties associated with key input parameters governing Zircaloy oxidation kinetics and core material behaviour. The results show a total hydrogen production from Zircaloy oxidation of about 400 kg, with an uncertainty band of 160 kg and a coefficient of variation of about 10%. The statistical analysis highlights the dominant role of oxidation kinetics parameters and eutectic temperature of the ZrO_2/UO_2 mixture in driving hydrogen generation. Finally, the study demonstrates the feasibility of applying BEPU methodologies to SA analysis in iPWR designs and provides preliminary insights into the uncertainty affecting hydrogen production predictions, supporting ongoing efforts in SMR safety assessment and licensing.

KEYWORDS
SASPAM-SA, SMR, MELCOR, BEPU

1. INTRODUCTION

In view of the ongoing licensing process for Small Modular Reactors (SMRs) in Europe, increasing attention is devoted to assessing the capability of computational integral Severe Accident (SA) codes to simulate SMR-specific phenomena under postulated accident scenarios. Codes such as MELCOR [1] [2] and ASTEC [3], originally developed for large Light Water Reactors (LWRs), are currently being applied to simulate advanced reactor concepts, including integral Pressurized Water Reactors (iPWRs). They are based on the well-established technology and operational experience of LWRs and are characterized by the integration of the main components of the Reactor Cooling System (RCS) within the Reactor Pressure Vessel (RPV) as well as the extensive use of passive safety systems. In view of their licensing process, state-of-the-art SA codes should be capable of simulating their advanced features and related phenomenology[1].
Within this framework, the Horizon Euratom SASPAM-SA project [4] [5], coordinated by ENEA (Italy), aims at assessing the capability of internationally recognized European and Non-European computational tools (largely used in Europe)[2] to simulate SA scenarios in iPWRs and to evaluate the associated radiological consequences. Previous activities have mainly focused on thermal-hydraulic analyses under Design Basis Accident (DBA) conditions, including uncertainty quantification using Best Estimate Plus Uncertainty (BEPU) methodologies, providing insights into key system responses during mitigated transients [6]. In line with the previous work, the aim of this paper is to apply the uncertainty methodology in the SA domain in a generic iPWR design and to give preliminary insights into the uncertainty of the code on the total production of hydrogen, representing a key Figure Of Merit (FOM) for nuclear safety. The analyzed sequence is a Loss of Coolant Accident (LOCA) with the postulated failure of all passive systems. Uncertain input parameters related to the main processes leading to hydrogen production during an SA sequence in LWR described in [7] [8] have been selected.

[1] Advanced designs, as iPWRs, are in general characterized by common features with the current operating large-LWR and by other specific features typical of their evolutionary designs, providing safety advantages that reinforce the first three levels of the Defence in Depth (DiD) principle. However, even if a plant is designed with advanced inherent features (through the reinforcement of the DiD levels 1, 2 and 3) allowing a reduction of the Core Damage Frequency (CDF), independent features for preventing and mitigating a severe accident sequence have to be included in its design (DiD level 4) together with the offsite emergency response (DiD level 5). Therefore, some scenarios that could lead to SAs need to be postulated and deterministically studied. Therefore, it is necessary to assess the capability of internationally recognized SA code to describe the behaviour of the most promising iPWR designs during SA scenarios and to predict the resulting radiological impact on-site and off-site.

[2] In order to maximize the knowledge transferability and impacts of the project two generic design-concepts, characterized by different design innovations in comparison with larger operating reactors, have been selected for the analyses: a) iPWR characterized by a submerged containment and electric power of about 60 MWe, called Design-1; b) iPWR characterized by the use of several passive systems, a dry containment and an electric power of about 300 MWe, called Design-2. These two generic reactor concepts include the main iPWR design features, considered in the most promising designs ready to go on the European market, allowing to assess in a wider way the capability of codes (SA and CFD) to simulate the SA phenomena typical of iPWR. It is not the project's objective to assess the generic reactor designs selected but, based on the project findings, to allow a more general statement on the code's applicability to currently favored designs under postulated SA condition. No Probabilistic Safety Assessment (PSA) considerations will be done in the project due to the generic nature of the reactor concept considered, then the scenarios identified will be characterized in terms of severity but not in terms of probability.

2. DESCRIPTION OF THE GENERIC IPWR DESIGN

The reference reactor considered in this work is a generic iPWR with a nominal power of 1000 MWth and an electrical output of 300 MWe [9] [10]. The design adopts an integral configuration in which all the main components of the Reactor Cooling System (RCS), including the core, Pressurizer (PRZ), Steam Generators (SGs) and Reactor Coolant Pumps (RCPs), are located inside the Reactor Pressure Vessel (RPV), as presented in Figure 1. The primary coolant flows upward through the core and riser region, then is directed radially into the upper annular plenum and circulated through compact helical-coil SGs by means of RCPs. After heat exchange in the SGs, the coolant flows downward through the downcomer and returns to the Lower Plenum (LP), closing the primary loop. As presented in Figure 2, the RPV is enclosed within a dry containment divided into two main regions: the Drywell (DW) and the Reactor Cavity (RC). This configuration plays a key role during potential accident conditions since the RPV-Containment coupling governs pressure evolution and heat transfer.

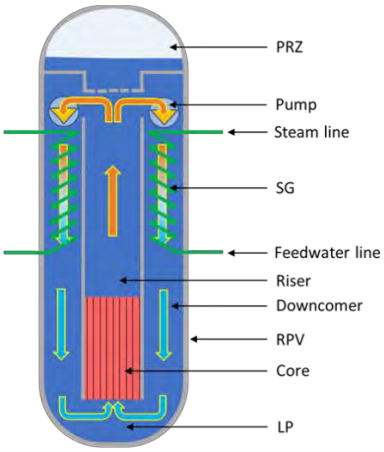

Figure 1. View of the RPV.

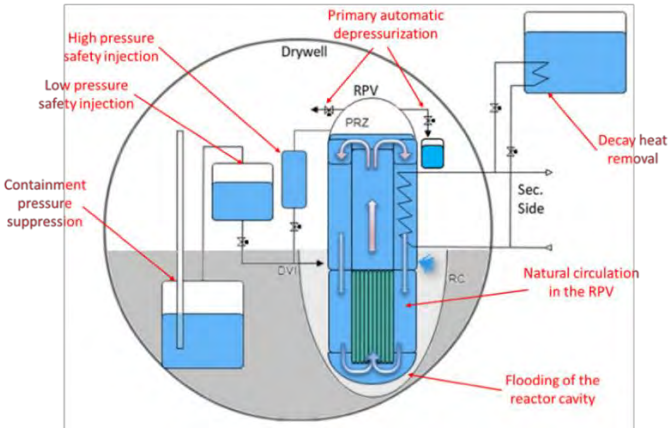

Figure 2. Layout of the RPV, containment and passive safety systems configuration.

The safety strategy of the iPWR fully relies on the use of passive safety systems, designed to enable natural circulation within the RPV via Riser-Downcomer (RI-DC) valves, passive decay heat removal (Emergency Heat Removal System, EHRS), primary automatic depressurization (Automatic Depressurization System, ADS), passive high-pressure safety injection (Emergency Boration Tanks, EBTs), passive low-pressure safety injection (Long-term Gravity Make-up System, LGMS), passive containment pressure suppression (Pressure Suppression System, PSS), passive flooding of the RC. Except for the heat sink of the decay heat removal system, these systems are largely located within the containment.

3. DESCRIPTION OF THE IPWR MELCOR NODALIZATION

The present SA analysis has been performed using the fully integrated SA code MELCOR [1] [2], able to simulate the thermal-hydraulic phenomena in steady-state and transient conditions and the main SA phenomena characterizing the RPV, the RC, the containment, and the confinement buildings typical of LWRs. More specifically, the MELCOR code v2023 has been used for the calculation reported in the present manuscript. A MELCOR nodalization of the generic iPWR design [11], based on a generic International Reactor Innovative and Secure (IRIS) [12] design, has been developed within the SASPAM-SA project based on publicly available data, scaling the available data of the SPES-3 experimental facility [13] [14] as well as by engineering evaluation from public general data available. The model, shown in Figure 3 in the SNAP view [15], combines a trade-off between the computational time and a detailed prediction capability of the transient thermal-hydraulic and core degradation phenomenology.

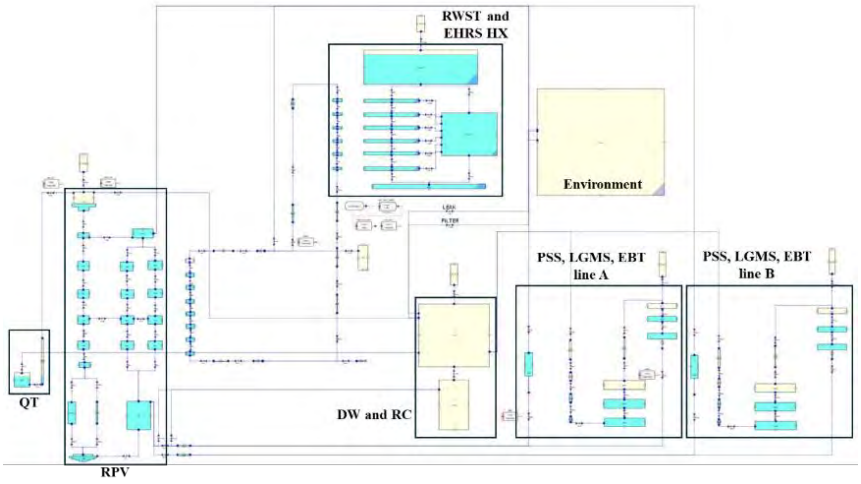

Figure 3. SNAP view of the MELCOR nodalization.

The RPV is modelled using multiple Control Volumes (CVs) representing the LP, core region, riser, Upper Plenum (UP), SGs, and downcomer. Furthermore, the core is modelled by the dedicated COR package to simulate the main core degradation phenomena. To simplify the model, the eight SGs have been modelled as an equivalent one, with four CVs on the primary side and eight CVs on the secondary side. The containment is modelled by two main CVs corresponding to the DW and the RC. The DW is thermally coupled with the environment through heat structures, while the RC is coupled with the MELCOR cavity model to simulate corium relocation and cavity flooding. The film tracking model has been implemented in the DW Heat Structures (HSs) to track the water film draining from the HS surfaces. No other models are considered. In order to prevent the DW rupture reaching the project pressure of 23 bar [10], leakage to the environment and fission vapors and aerosol filters have been considered. The filters and the leakage have been modelled as two flow path junctions, allowing communication between the DW and the environment (modelled as a single CV). In particular, the junction simulating the filter has been coupled with the aerosol and fission product filter models, and it operates when the DW pressure is between 8 and 16 bar. The leakage has been modeled considering 0.1% containment gas volume leaked per day at design pressure. Passive safety systems are present in the design with two parallel Direct Vessel Injection (DVI) lines. In this model, these lines have been modelled separately, including the EBT, the PSS, the PSS-vent and the LGMS. The EHRS has been modelled with a set of CVs hydraulically connected to the secondary side of the SGs. The loop is connected thermally with the Refueling Water Storage Tank (RWST), which represents the ultimate heat sink connected to the environment. In this regard, the equivalent EHRS Heat Exchanger has been modelled with six CVs thermally coupled with six CVs of the RWST. In total, nine CVs have been considered to model the RWST. The double-ended guillotine break of one DVI line is simulated by dynamically modifying the junction connections between the injection line and the primary system. At the Start Of the Transient (SOT) the junction connecting the injection systems to the RPV is closed, while junctions towards the control volume simulating the RC are opened, allowing the discharge of coolant into the containment. This modelling approach allows the representation of mass and energy release into the containment following the break, preserving the asymmetric behavior between the intact and broken passive safety system trains.

4. ANALYSIS OF THE REFERENCE CASE

The reference scenario is a LOCA initiated by the double-ended guillotine break of one of the two DVI lines [13] [16] [17] [18]. The DVI lines connect the two passive systems trains to the RPV, at an elevation located below the SGs outlet in the primary side. Considering the design layout, the selected LOCA is the worst accidental scenario since it occurs at the lowest possible elevation on the RPV. In this work, the postulated

failure of all the passive safety systems as well as the failure of ADS Stage-1 and ADS Stage-2 have been considered. Therefore, the transient can be divided into the following Phenomenological Windows (PhWs):

I. **Thermal-Hydraulic phase – PhW 1**: it evolves from the SOT to the core heat-up, identified when the cladding temperature reaches 1473 K. It includes the reactor SCRAM, the pumps coast-down, the Top Of Active Fuel (TAF) uncover, the Primary Coolant System (PCS) depressurization and containment pressurization.
II. **Early phase – PhW 2**: it starts with the fuel heat-up and ends with the start of loss of geometry of the core and its relocation into the LP (slumping). It is characterized by the Bottom of Active Fuel (BAF) uncover, onset of Zircaloy oxidation reactions, the runaway of Zircaloy oxidation reactions, the massive in-vessel hydrogen production.
III. **Late phase – PhW 3**: it starts when the corium is entirely relocated into the LP and includes the rest of the transient.

Following the break, the transient is driven by the blowdown of the RPV. Due to the loss of coolant from the PCS, the DW pressure increases and, at about 18 seconds after the SOT, the high containment pressure set-point triggers the S-signal, causing the transition from fission power to decay heat. After the S-signal, the Secondary Coolant System (SCS) pressure increases. The code predicts a pressure peak of about 120 bar. Figure 4 shows the PCS, SCS and containment pressure evolution. Due to the blowdown, the inventory of primary coolant decreases as well as the collapsed coolant level in the core region. As shown in Figure 5, the code predicts the uncover of the TAF at about 618 seconds after the SOT.

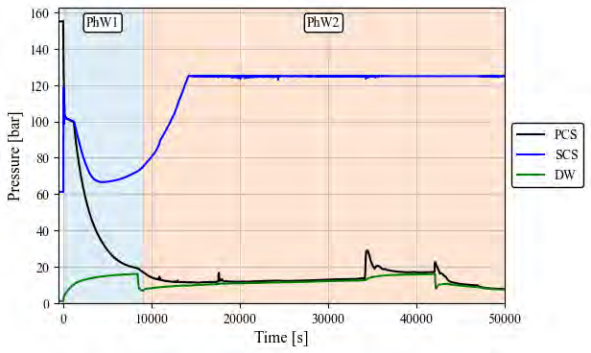

Figure 4. PCS, SCS and containment pressure.

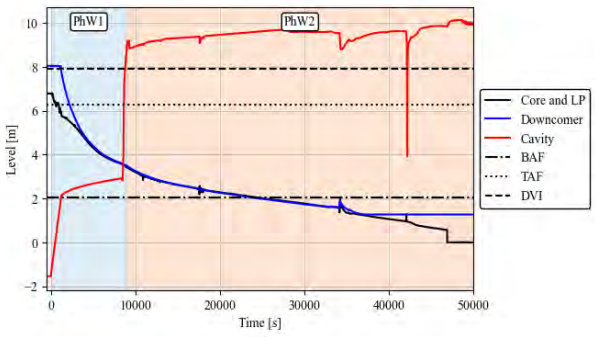

Figure 5. Core, downcomer and cavity collapsed coolant level.

During PhW 1, the PCS pressure follows the SCS pressure at about 100 bar. At about 3000 seconds after the SOT, the collapsed coolant level in the downcomer reaches the DVI elevation. The steam inside the RPV is vented into the containment, and the PCS pressure drops rapidly, followed by the decrease of the SCS pressure. At about 7300 seconds after the SOT, the DW pressure reaches the leak opening set-point. This causes a rapid depressurization of the containment to the atmospheric pressure, shown in Figure 4. Due to the fast depressurization of the DW, the code predicts the rapid rise of water level inside the PSSs through the PSS vent pipes and the injection into the DW. This causes a rapid increase in the collapsed coolant level in the RC, as observed in Figure 5. Although the collapsed level of coolant in the cavity reaches a level higher than the DVI level, no coolant is injected into the RPV because the primary pressure at this stage is still higher than the pressure prevailing in the DW. At this stage of the transient, the core is uncovered, and the collapsed level continues to decrease. The SCS pressure starts to increase again because heat removal through the SGs is no longer sufficient to balance the energy transferred from the PCS. The pressure rise is

eventually limited by the onset of SGs safety-valve cycling, as shown in Figure 4. The core uncover causes the fuel heat-up and the increase of the cladding temperature as shown in Figure 6.

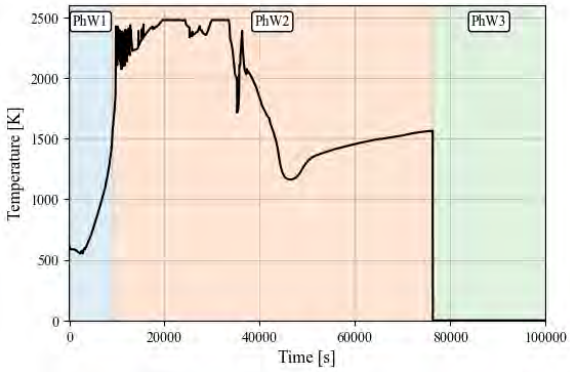

Figure 6. Maximum cladding temperature.

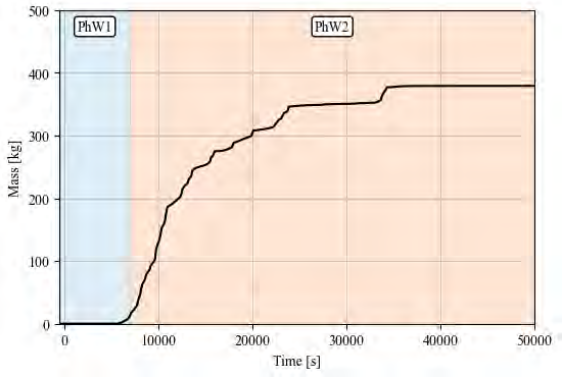

Figure 7. Cumulative hydrogen production.

During PhW 2, at about 8980 seconds after the SOT, the cladding temperature reaches the onset value for the Zircaloy oxidation reaction and the beginning of hydrogen generation. The cumulative hydrogen production predicted by the code is presented in Figure 7. At about 23000 seconds after the SOT, the collapsed level in the RPV reaches the BAF, leaving the core uncovered. Then, the core degradation mechanisms continue, and the corium relocation begins at about 35000 seconds, as highlighted in Figure 4 by the primary pressure peaks. In Table 1 the main events characterizing the SA sequence are reported.

Table 1. Main events of the SA reference case.

Event	Time [s]
Break	0
High Containment pressure signal (SCRAM, isolation SGs)	18
Low PRZ water level signal (Pumps coast-down and RI-DC valves opening)	70
Low PRZ pressure signal	92
TAF uncovered	618
Containment leak opening	7300
Start of H2 generation	8980
Start of the core relocation	35000
End of core relocation	76320

5. HYPOTHESES OF THE UNCERTAINTY ANALYSIS

The following uncertainty analysis has been conducted adopting the BEPU approach, in particular the probabilistic method to propagate input uncertainty [19]. The present uncertainty methodology has been used in several works in the thermal-hydraulics field [20] [21] [22] [23] and in the SA domain [24] [25] [26] [27] [28] [29]. It is generally based on statistical approaches to propagate input uncertainty, characterized by uncertain input parameters, to output uncertainty, expressed as the uncertainty in selected FOMs. Each uncertain input parameter is identified by a Probability Density Function (PDF), usually selected based on previous analyses, available experimental data, and engineering judgment [30]. Furthermore, a statistical correlation analysis involving FOMs and the uncertain input parameters is generally carried out. According to past activities developed in the framework of uncertainty quantification in Deterministic Safety Analysis [20] [22] [26], the simple and simple rank correlation coefficient are computed [31] [32]. For the present analysis, the simple rank correlation coefficient has been considered, and it has been calculated by using the

Spearman's correlation. It is representative of the degree of monotonous correlation between an uncertain input parameter and the FOM. As indicated in [32], the statistical correlation is significant if the coefficient is greater than 0.5 (or less than -0.5) or moderate if it is between 0.2 and 0.5 (or -0.2 and -0.5). Then, if the coefficient is between 0 and 0.2 (or between 0 and -0.2) the correlation is low. The Uncertainty Tool (UT) used in this uncertainty application has been developed by ENEA in collaboration with University of Palermo in the framework of the H2020 MUSA project, coordinated by CIEMAT (Spain) [26] [33] [34], and finalized in the framework of the International Atomic Energy Agency (IAEA) Coordinated Research Program (CRP) [27] [35] [36]. The goal of this uncertainty analysis is to apply the following uncertainty methodology to a postulated SA sequence in an advanced reactor design, such as the iPWR design. Furthermore, a key point is to investigate and characterize the uncertainties of the code about the production of hydrogen from Zircaloy oxidation. Thus, the FOM considered for the present uncertainty application is the total cumulative hydrogen production by Zircaloy oxidation the in core.
Seven of the main uncertain input parameters influencing the production of hydrogen in LWRs have been considered [7] [8]:

- **Zircaloy oxidation reaction kinetics - k_i**: kinetics parameters related to Zircaloy oxidation reaction. These coefficients are used to calculate the rate constant for Zircaloy oxidation following parabolic kinetics [1]. The rate constant R, expressed in $kg^2/m^4 \cdot s^{-1}$ as a function of temperature T(K) is calculated for Zircaloy by the following relations:

$$R(T) = \begin{cases} k_1 e^{-\frac{k_2}{T}}, & T \leq 1853\ K \\ k_3 e^{-\frac{k_4}{T}}, & T \geq 1873\ K \end{cases} \quad (1)$$

  The code uses an interpolated value in the temperature range between 1853 K and 1873 K. In the MELCOR oxidation model, these parameters can be edited as sensitivity coefficients.
- **Zircaloy Melt Breakout Temperature – Zr_Melt**: the oxidation of the fuel cladding forms a shell of ZrO_2 which can contain molten clad materials until the thickness of ZrO_2 or the temperature limit is crossed. For this reason, the molten mass candles and relocates. This parameter influences flow obstructions, steam interaction with zirconium and, consequently, hydrogen generation. In the MELCOR oxidation model, the breakout temperature for the cladding component is editable as a sensitivity coefficient.
- **Debris Porosity**: the porosity of core debris has an impact on oxidation processes because it influences heat transfer and surface area.
- **Eutectic temperature of ZrO_2/UO_2 mixture**: the melting point of the binary eutectic mixture of ZrO2 and UO_2 can affect the dynamics of blockage by candling materials and, consequently, oxidation processes. In MELCOR, this parameter has been modified by adjusting the value of the melting temperature of ZrO_2 and UO_2 and by varying the core component failure parameter.

Table 2 shows the uncertain input parameter with their distribution type and range of variation. Following Wilks' formula [37] [38] for the one-sided tolerance interval, at 95% probability content and 95% confidence level, a total of 59 runs are needed.

6. RESULTS

The uncertainty band of the FOM has been estimated as well as the mean, median and standard deviation. The statistical parameters of the FOM are reported in Table 3. The estimated uncertainty band is about 162.87 kg and the mean and median values are 401.44 and 414.45 kg respectively. Figure 8 shows the estimated PDF compared with the reference case, mean, median and upper and lower bounds. The simple rank correlation coefficients are shown in Figure 9. The statistical coefficients highlight a significant negative statistical correlation with the k_2 oxidation parameter and a significant positive statistical

correlation with the eutectic temperature of ZrO_2/UO_2 mixture. This behavior reflects the strong dependence of hydrogen production on oxidation kinetics and core degradation progression: higher oxidation rates enhance early hydrogen generation, while higher eutectic temperatures delay material relocation, prolonging high-temperature oxidation conditions. The uncertainty band of the hydrogen cumulative production from Zircaloy oxidation in the core during the entire SA sequence has been analyzed and presented in Figure 10. The uncertainty band increases after the Zircaloy oxidation runaway, reaching a value of about 160 kg at the slumping, consistently with the final uncertainty band. This trend indicates that most of the uncertainty is accumulated during the high-temperature oxidation phase preceding core relocation.

Table 2 Uncertain input parameters [7]**.**

By calculating the simple rank correlation coefficient, it is possible to investigate along the entire sequence how the uncertain input parameters affect the production of hydrogen from Zircaloy oxidation in core from a statistical correlation point of view. In Figure 11 the time trend of the correlation coefficient has been represented. Before the slumping of the molten core into the LP (35000 s after the SOT), cumulative hydrogen production presents a significant negative correlation with the parameter k_2, confirming the dominant role of oxidation kinetics during the early phase. Then, during the late phase of the transient, the EUT_T and k_2 parameters present a significant positive and negative statistical correlation with the hydrogen cumulative production from Zircaloy oxidation, respectively. This indicates a transition from kinetics-controlled to relocation-influenced behavior in hydrogen generation.

7. CONCLUSIONS

This work presents the application of the MELCOR code to the analysis of a SA scenario in a generic iPWR using the BEPU approach to quantify uncertainties affecting SA progression. The analysed scenario consists of a LOCA initiated by the double-ended guillotine break of one DVI line combined with the failure of all passive systems, leading to an early core uncover and core degradation conditions, promoting Zircaloy oxidation and significant hydrogen generation during the early phase of the transient. The reference calculation predicts a total hydrogen production from Zircaloy oxidation in the core of about 400 kg. The uncertainty analysis shows an uncertainty band of approximately 160 kg, with a coefficient of variation of 10%. The statistical correlation analysis highlights the dominant role of the Zircaloy oxidation kinetics parameters and the eutectic temperature of the ZrO_2/UO_2 mixture. In particular, the k2 parameter exhibits a significant negative correlation with hydrogen production, while the eutectic temperature shows a positive significant correlation, reflecting their influence on oxidation rates and core degradation mechanisms.

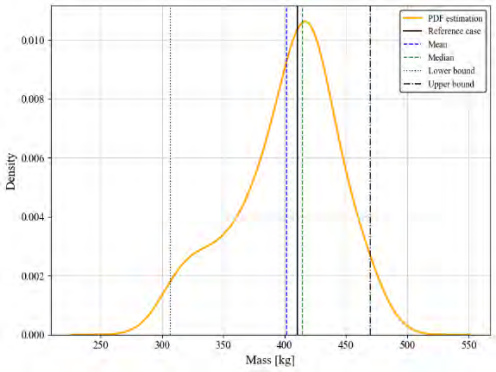

Figure 8 Estimation of the PDF of the FOM.

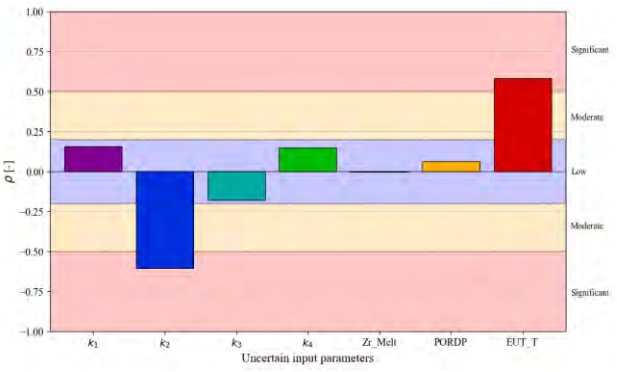

Figure 9 Simple rank correlation coefficients.

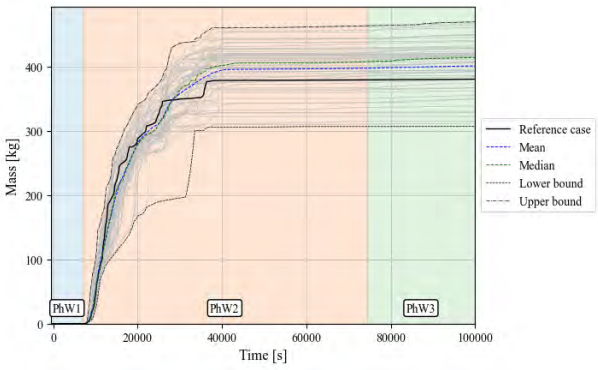

Figure 10 Hydrogen cumulative mass uncertainty band.

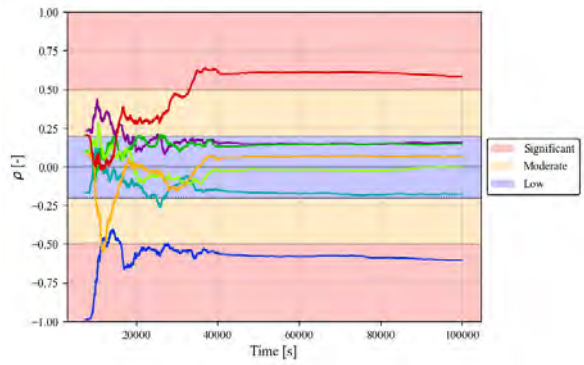

Figure 11 Simple rank correlation coefficient calculated along the transient.

The time-dependent analysis of correlation coefficients indicates that the afore mentioned parameters affect the early phase of the transient, before core relocation into the LP, while their influence tends to be stable during the late phase of the transient. Finally, the results demonstrate the feasibility of applying BEPU methodology to SA analysis in iPWR designs and provide preliminary insights into the uncertainty analysis associated with hydrogen production assessment. These findings contribute to ongoing efforts aimed at supporting the safety assessment and licensing of SMRs. Future work will extend the uncertainty analysis to additional FOMs, including fission products release and containment behavior, and to a set of different SA scenarios with different postulated failure of passive safety systems.

INTRODUCTION

- In view of the ongoing licensing process for **Small Modular Reactors** (SMRs) in Europe, increasing attention is devoted to assessing the capability of computational integral **Severe Accident** (SA) codes to simulate SMR-specific phenomena under postulated accident scenarios.
- Within this framework, the Horizon Euratom **SASPAM-SA** project, coordinated by ENEA (Italy), aims at assessing the capability of internationally recognized **European and Non-European computational tools** (largely used in Europe) to simulate SA scenarios in integral PWRs (iPWRs) and to evaluate the associated radiological consequences.
- The aim of this activity is to apply the **probabilistic method to propagate input uncertainty** in the SA domain in a generic iPWR design and to give preliminary insights into the uncertainty of the code on the **hydrogen production** from zircalloy oxidation, representing a key Figure Of Merit (FOM) for nuclear safety.

DESCRIPTION OF THE GENERIC IPWR DESIGN AND MELCOR NODALIZATION

- The reference reactor considered in this work is a **generic iPWR** with a nominal power of 1000 MW_{th}.
- The design adopt an **integral configuration** in which all the main components of the Reactor Cooling System (RCS) are located inside the Reactor Pressure Vessel (RPV), enclosed within a dry containment.
- The safety strategy of the iPWR fully relies on the **use of passive safety systems** such as Riser-Downcomer valves (RI-DC), Emergency Heat Removal System (EHRS), Emergency Boration Tanks (EBTs), Long-term Gravity Make-up System (LGMS) and Passive Suppression System (PSS).

ANALYSIS OF THE REFERENCE CASE

- The reference scenario is a **Loss Of Coolant Accident** (LOCA) initiated by the double-ended guillotine break of one of the two DVI lines.
- The **failure of all passive safety systems** has been postulated.
- The transient can be divided into **three Phenomenological Windows** (PhWs).

N.	PhW	Phenomena involved
1	*Thermal-hydraulic phase*	SCRAM, pumps coast-down, TAF uncover, Primary Coolant System depressurization, containment pressurization.
2	*Early phase*	BAF uncover, onset of Zircalloy oxidation reactions, runaway of Zircalloy oxidation reactions, massive in-vessel hydrogen production.
3	*Late phase*	Relocation of corium into the Lower Plenum (LP) and Lower Head (LH) heating.

HYPOTHESES OF THE UNCERTAINTY ANALYSIS

- The **BEPU approach** has been used, adopting the probabilistic method to propagate input uncertainty.
- Key point is to investigate and characterize the **uncertainties** of the code about the **production of hydrogen from Zircaloy oxidation**. Thus, the FOM considered for the present uncertainty application is the **total cumulative hydrogen production by Zircaloy oxidation** the in core.
- Seven of the main uncertain input parameters influencing the production of hydrogen in LWRs have been considered.

ABSTRACT

Energy Software S.L. (ENSO) has undertaken an innovative project to address the inherent uncertainties present in severe-accident analysis codes used in nuclear safety assessments. Building on the outcomes of two major international initiatives—IAEA CRP I31033 and the HORIZON-2020 MUSA project—ENSO has established a solid foundation for identifying and quantifying the main sources of uncertainty in severe-accident simulations. These initiatives also revealed key limitations, such as excessive computational time, frequent simulation failures, and truncation effects.

The proposed approach follows a stepwise structure, applying the Wilks methodology in two consecutive phases:

- In-vessel phase, focused on accident progression up to reactor pressure vessel failure, and
- Ex-vessel phase, analyzing the subsequent phenomena occurring within the containment.

This stepwise strategy enables the identification and quantification of uncertainty sources at different stages of the accident, providing essential insights for emergency decision making and supporting the design of future research in the field.

To validate the methodology, ENSO has developed an evaluation model of a Generation II four loop Westinghouse PWR reactor subjected to a low-pressure station blackout (SBO) scenario. The RELAP/SCDAPSIM code has been used for the in-vessel phase, while MELCOR has been employed for the ex-vessel containment analysis. An uncertainty analysis has been performed, and early results indicate both the robustness of the proposed methodology and its benefits in terms of computational efficiency and improved calculation stability.

However, several challenges have emerged during the long-term Molten Core Concrete Interaction (MCCI) phase, highlighting the need for further development and refinement.

1. INTRODUCTION

Following the Fukushima nuclear accident in 2011, nuclear regulatory authorities intensified efforts to study emergency procedures associated with Beyond Design Basis Accident (BDBA) scenarios [1][2]. As noted by the IAEA [3], analyzing BDBAs helps enhance the safety of Nuclear Power Plants (NPPs) by considering additional failures beyond those in Design Basis Accidents (DBAs). In Europe, comprehensive “stress tests” were conducted to evaluate reactor performance under Fukushima-like Severe Accident (SA) conditions, leading to safety improvements and reinforcing the need for deterministic analyses in BDBA studies.

A key challenge in deterministic methodologies lies in the uncertainties associated with physical models, correlations, and nodalization—such as initial/boundary conditions, discretization, and user effect. Over the last two decades, OECD/NEA initiatives have advanced Uncertainty Analysis (UA) using Best Estimate

* Footnote, if necessary, in Times New Roman font and font size 10

codes (BEPU), focusing on thermal-hydraulic, neutronic, and thermomechanical tools (UAM [4][5], EGUAM [6], WPRS [7]) and, especially, thermal-hydraulic codes (BEMUSE [8], PREMIUM [9], SAPIUM [10], ATRIUM [11]). BEPU methodologies based on Wilks/Wald formulations are now widely accepted. In Spain, CSN-funded projects have significantly expanded the related bibliography [12-29].

For BDBA scenarios involving core damage, Severe Accident (SA) codes such as MELCOR, MAAP, ASTEC, and RELAP/SCDAPSIM are required. However, only limited UA applications exist for these tools. In 2010, the USNRC performed a MELCOR-based UA within the SOARCA project [30] for Station Blackout (SBO) scenarios at Peach Bottom [31] and Sequoyah [32]. Additional UAs with ASTEC [33] and MAAP [34] in 2013 assessed uncertainties in source term and hydrogen generation, respectively.

More recently, two major projects have extended UA methodologies to SA conditions: the IAEA CRP I31033 [35][36] and the HORIZON-2020 MUSA project [37-42]. The IAEA initiative, involving CIEMAT and ENSO, examined the use of UAs across multiple reactor designs. MUSA, coordinated by CIEMAT with ENSO participation, identified key uncertainty sources in SA codes and tested multiple UA approaches for both reactors [38] and spent fuel pools [44]. MUSA also established comprehensive input-parameter lists with associated uncertainty ranges and PDFs for MELCOR, MAAP, ASTEC, and RELAP/SCDAPSIM, as well as detailed figures of merit (FOMs) for different scenarios.

Analyses of integral plant and containment models revealed that:

- Full-containment simulations are computationally demanding.
- Applying wide uncertainty ranges often caused simulation failures, hindering Wilks-based evaluations.
- SA scenarios require simultaneous estimation of multiple FOMs, necessitating the Wald methodology and more code runs.
- Bifurcations and cliff-edge effects were frequent, especially in the in-vessel phase, strongly influenced by fuel damage and molten-material accumulation, which affect vessel-failure timing and release magnitudes.

To address these challenges, ENSO is developing the Stepwise Uncertainty Analysis Methodology (SUAM) for source-term calculations in SA scenarios. Section 2 of this work describes the methodology, while Section 3 applies SUAM to a PWR SBO sequence. The final section summarizes the main insights and outcomes.

2. STEPWISE UNCERTAINTY ANALYSIS METHODOLOGY (SUAM)

The Stepwise Uncertainty Analysis Methodology (SUAM) provides a structured framework to independently and sequentially quantify uncertainties associated with the in-vessel and ex-vessel phases of a Severe Accident (SA). In this approach, tolerance limits obtained from the in-vessel analysis (up to reactor pressure vessel failure) are transferred as boundary conditions (BCs) to the ex-vessel containment calculations (see Figure 1). Each phase is modeled using its own dedicated nodalization, and, when appropriate, different computational codes may be employed to further isolate uncertainty sources and improve numerical robustness.

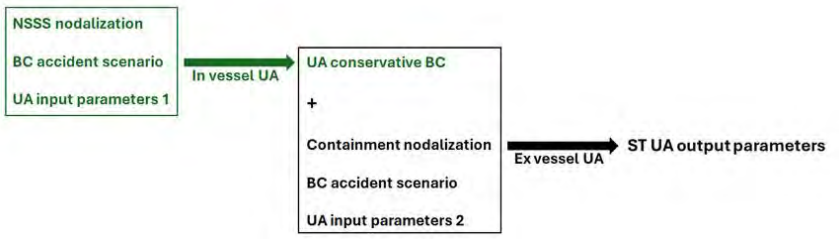

Figure 1: Stepwise Uncertainty Analysis Methodology for source term estimation

The methodology relies on two fundamental premises:

1. independent nodalization for the containment and the nuclear steam supply system (NSSS), and
2. ex-vessel boundary conditions derived directly from the in-vessel tolerance limits.

These principles were adopted to address limitations identified during ENSO's participation in the IAEA CRP I31033 [36] and HORIZON-2020 MUSA [37-42] projects. In those studies, large output variability in the in-vessel phase (driven by cliff-edge behavior and bifurcation phenomena) led to an unrealistic propagation of uncertainty into the source-term predictions. Additionally, uncertainty analyses requiring large sample sizes resulted in frequent simulation failures and prohibitive computational times. Segregating the NSSS and containment models improves numerical stability and significantly reduces the computational burden of large-scale UA campaigns.

SUAM follows the GRS uncertainty-evaluation framework [12], implementing the Wald's tolerance-limit formulation [33][34][45]. This approach determines the minimum sample size required to derive statistically consistent tolerance limits for multiple figures of merit (FOMs) simultaneously—an essential requirement for SA analysis, where numerous interdependent outputs must be treated collectively. A one-sided 95/95 statistical criterion is applied, selecting the most limiting value of the tolerance bound. This choice minimizes the required number of simulations—higher-order Wald formulations would increase the sample size—and reduces the sensitivity of the ex-vessel uncertainty quantification to cliff-edge or bifurcation effects occurring in the in-vessel phase.

3. APPLICATION OF SUAM TO A LONG-TERM SBO IN A PWR

The selected scenario is the long-term Station Black Out (SBO) in a Gen-II PWR. The reactor is a generic 4-loop Westinghouse design with a thermal power of 3400 MW and 17X17 fuel assemblies.

The specific requirements of the SUAM methodology for the simulation of the selected scenario are:

1. SA code for simulating the NSSS for the in-vessel phase: RELAP/SCDAPSIM.
2. SA code capable of simulating the containment during ex-vessel phase: MELCOR.
3. Independent nodalization for the NSSS and the containment.
4. In-vessel phase FOMs for obtaining the coupling BCs:
   a. Hydrogen released from the core into the containment.
   b. Noble gases (NG) released into the containment through Pressurizer (PZR) Power
   c. Operated Relief Valve (PORV) (He, Xe, Kr)
   d. Fission product (FP) released into the containment through PZR PORV (CsI, CsOH, Te, Sn, Cd)
   e. Debris released into the containment (Ag, Zr, UO2, ZrO2)
   f. Debris decay power.
   g. Time of Creep rupture.
   h. Coolant mass and energy released to containment.
5. Ex-vessel phase FOMs:
   a. Max. containment pressure.
   b. Max. containment Temperature.
   c. FP concentration and distribution into the containment.

d. FP leaked to environment

3.1. NSSS Evaluation Model

The NPP nodalization is derived from the RELAP/SCDAPSIM MOD3.4 (RS3.4) model developed by ENSO within the framework of its contribution to the MUSA WP5 project [38].

The in-vessel uncertainty analysis was carried out using the upgraded uncertainty analysis module (IUA2) implemented in RELAP/SCDAPSIM MOD3.4 [46]. The main features of this module include an automated procedure for performing Wilks/Wald-based uncertainty analyses, encompassing the determination of the required sample size, random sampling of input parameters from probability density functions (PDFs), and access to built-in code correlations for the perturbation of selected coefficients.

As indicated in Section 2, the uncertainty analysis was conducted using the multivariate formulation of the Wilks' equation developed by Wald. The Wald approach was selected because the output of the in-vessel analysis requires the statistical coverage of the tolerance limits for each figure of merit (FOM) to be ensured simultaneously. In the present study, five groups of independent FOMs were considered, as listed below:

- Maximum mass of H2 at the time of creep rupture.
- Maximum mass of NG released to the containment through PZR at the time of creep rupture (He, Xe, Kr)
- Maximum mass of FP released to the containment through PZR at the time of creep rupture (CsI, CsOH, Te, Sn, Cd)
- Maximum mass of Debris (UO2, ZrO2, Zr, Ag), maximum debris decay power and minimum time for the time creep rupture.
- Maximum inventory of water leaked into the containment and maximum enthalpy of water at the time of creep rupture

According to Wald's equation, the minimum number of runs required to estimate the 95/95 (or 5/95) tolerance limits for five output variables is 181 (see Table 1.1 in [47]).

In addition to the determination of the tolerance limits, the output data were used to assess potential correlations between input and output variables by calculating the Pearson, Spearman, and Kendall correlation coefficients. The selection of these coefficients allows for the identification of linear and monotonic relationships. The statistical significance of each coefficient was evaluated under the null hypothesis by computing the corresponding p-value, which represents the probability of observing a correlation by chance, and comparing it with the conventional threshold value of 0.05.

Table 1 presents the selected input parameters, which are associated with heat transfer, critical heat flux, interphase heat transfer, material properties, cladding behavior, radiation, core power, safety systems, and natural circulation. The table also specifies the corresponding probability density functions (PDFs) and the affected components.

Table 1: List of uncertain parameters for the in-vessel BEPU analysis

#	Phenomenon	Parameter [1]		PDF[2]	Components	Ref [3]
1	Heat transfer across solid surfaces	Film boiling HTC to liquid	HT-1	U [0.74; 1.29]	RELAP heat structures (heat transfer to the secondary) and SCDAP components (core)	[44]
2		Film boiling HTC to vapor	HT-2	U [0.49; 3.43]		[44]
3		Nucleate boiling HTC - subcooled	HT-3	T [0.76; 0.86; 1.19; 1.43]		[45]

3.2. Containment Evaluation Model

For the ex-vessel phase, the MELCOR code was employed. The verification of the coupling between RELAP/SCDAPSIM and MELCOR was performed using the results obtained from the in-vessel calculations carried out with the RELAP/SCDAPSIM code within the framework of the MUSA project [37]. In the subsequent phases of the present project, the results of the in-vessel uncertainty analysis presented in Section 3.1 will be used to perform both the base case simulation and the ex-vessel uncertainty analysis.

The containment nodalization is based on the information provided in [48]. It consists of 16 control volumes (CVs), which are used to represent the main compartments, including the steam generator cages, reactor

cavity, containment dome, lower compartments, among others. One of these control volumes is used to represent the boundary conditions of the environment.

The hydraulic connections between the containment compartments are modeled using 29 flow paths (FLs), while the containment heat sinks are represented by 39 heat structures (HSs). The COR and DCH packages are disabled, as the present analysis is a stand-alone containment calculation. However, the RN and CAV packages are kept active in order to capture fission product transport and corium–concrete interaction phenomena.

The mass and energy sources released into the containment are introduced through boundary conditions. The coolant mass and energy discharged into the containment through the pressurizer (PZR) power-operated relief valves (PORVs), together with the hydrogen generated by zirconium oxidation, are directly introduced into control volume CV 206 (lower compartments) using the "external source" option in MELCOR. The debris mass ejected from the reactor vessel is introduced into the reactor cavity (CV 101) by means of the Fuel Dispersal Interaction Package, which allows data to be extracted from an external data file, processed, and subsequently introduced into the CAV package. In a similar manner, fission product masses are introduced into the "Lower Compartments" control volume (CV 206) using the Radionuclide Package option "aerosol and vapor source," since it is assumed that all fission products are released through the PZR.

The uncertainty analysis was conducted using the two-sided Wilks' formulation of tolerance intervals rather than the Wald approach, since all figures of merit associated with the ex-vessel phase were considered to be independent of one another. Under this assumption, the required number of calculation cases was determined to be 93.

The input variables considered uncertain are listed in Table 2, together with the type of probability density function and their main parameters.

Table 2: List of uncertain parameters for the ex-vessel BEPU analysis

№	Parameter	Type	PDF	PDF parameters

28	INP_H2O_Pow	Factor	Normal	μ:1.0 σ:0.0408 [0.92, 1.08]

The pre-processing stage is performed using the uncertainty analysis tool integrated into the SNAP software, which is based on DAKOTA. The recommendations provided in NUREG/IA-0532 have been followed. This process significantly simplifies the inclusion and generation of the set of calculation cases required to obtain an adequate sample for the estimation of uncertainty in the figures of merit.

Regarding post-processing, a dedicated Python-based tool has been developed to read each of the output files generated by MELCOR for the full set of calculation cases. These outputs are processed to determine the uncertainty ranges and correlation coefficients for each figure of merit. Subsequently, all the information is exported to an automatically generated Excel file, which also includes the necessary plots to enable a comprehensive analysis by the analyst.

3.3. Accident sequence, results and discussion

3.3.1. In-Vessel phase

The accident sequence begins with reactor shutdown and isolation of the secondary system. As a result, the pressure in the secondary system increases above 7 MPa, leading to the automatic actuation of the steam generator (SG) relief valves. During this initial stage of the transient, decay heat is efficiently removed through heat transfer from the primary to the secondary system. Approximately 2 hours later, since the Auxiliary Feedwater System is not available, the SGs are depleted and the pressure in the primary system begins to rise, inducing liquid expansion in the pressurizer (PZR). About 10 minutes later, the setpoint of the PZR power-operated relief valve (PORV) is reached (16.2 MPa), initiating PZR relief action and resulting in a reduction of the primary system liquid inventory. Subsequently, approximately 2.5 hours after the onset of the transient, the first core uncover occurs, and an operator action (full opening of the PZR PORV) is performed when the core exit thermocouple (CET) temperature reaches approximately 623 K. This action causes a rapid depressurization of the primary system, which triggers accumulator (ACC) injection and core cooling. Figure 2 shows the water discharged through the PZR PORV during the different phases described above.

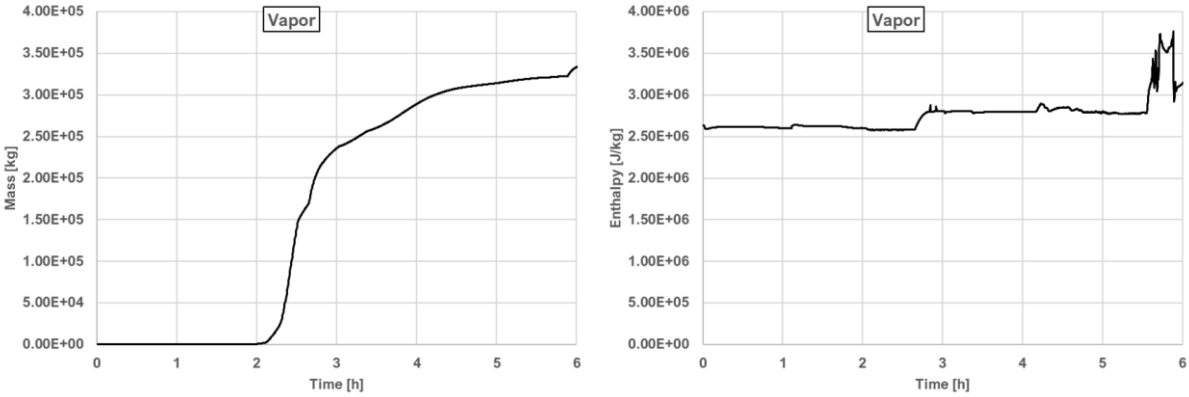

Figure 2: Mass and energy of the coolant released into the containment

Cladding oxidation begins at 1200 K, leading to an increase in heat generation within the fuel elements. As a consequence, core surface temperatures rise to approximately 2400 K, causing cladding expansion (ballooning), fuel rod rupture, and the release of volatile and soluble fission products, as well as hydrogen generated by the H_2O–Zr interaction. A fraction of these fission products, together with the generated hydrogen, are subsequently released into the containment through the pressurizer PORV, as shown in Figure 3.

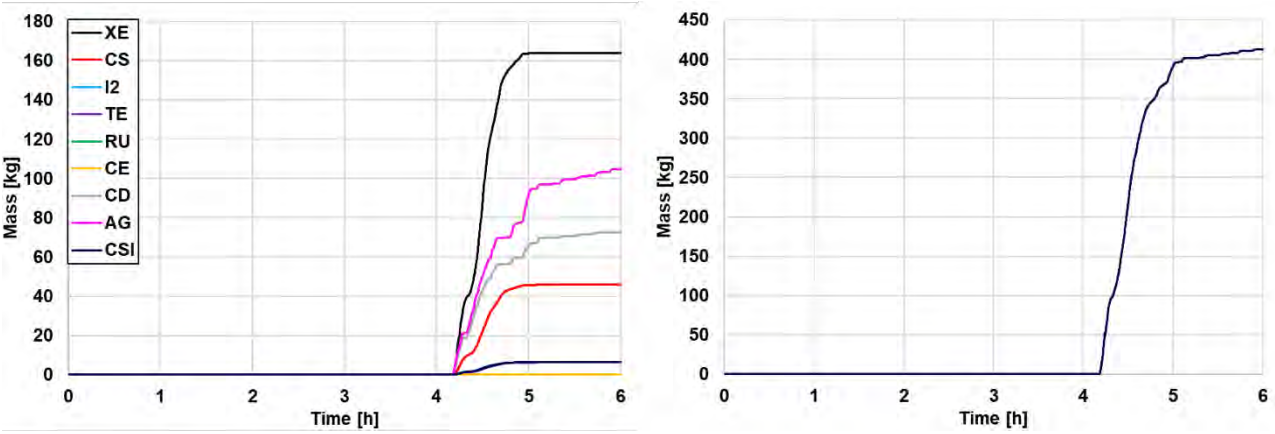

Figure 3: Mass of fission products (left) and hydrogen (right) released into the containment through the PZR.

Approximately 4.2 hours after the beginning of the transient, when the core surface temperature reaches 2873 K, oxide (U–Zr–O) formation and the development of a molten material pool occur. The molten material accumulates in the lower part of the core at around 5.65 hours, when core collapse takes place. Subsequently, structural materials accumulate in the lower plenum, leading to an increase in the reactor pressure vessel (RPV) wall temperature until creep rupture occurs (6.2 hours after the onset of the transient), resulting in the release of corium into the cavity (see Figure 4). At this point, the calculation is terminated.

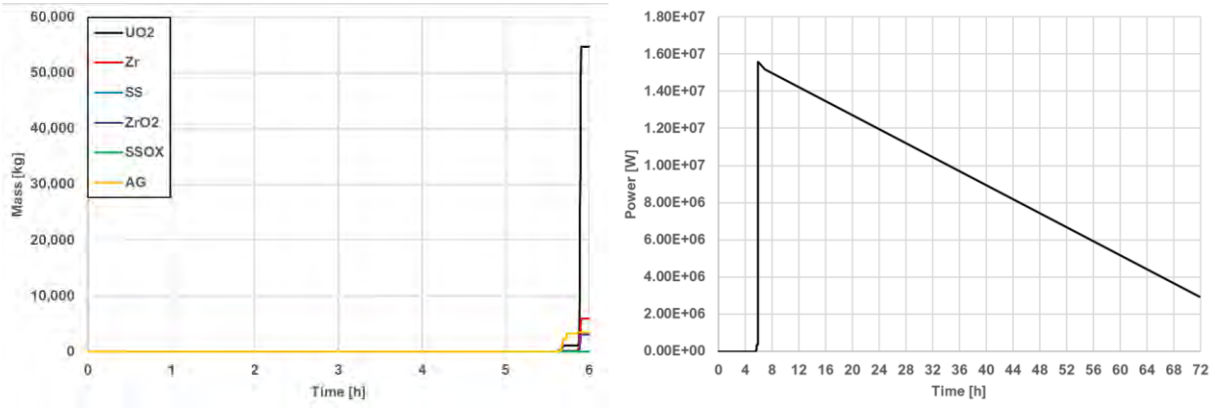

Figure 4: Mass of materials ejected through the RPV (left) and corresponding energy (right).

The results of the uncertainty analysis (UA) are presented in Table 3.

Table III. Tolerance limits for in-vessel FOMs

TAG	Units	Type	Base case	Tolerance limit 181
tPCT	hours	MIN	3.1	**2.7**
tFRUP	seconds	MIN	35.4	**20.8**
tDEB	minutes	MIN	33.2	**19.8**
tSLUMP	hours	MIN	1.7	**0.8**
tCREEP	**hours**	**MIN**	**2.2**	**1.3**
cumH2	**kg**	**MAX**	**262.1**	**420.9**
cumFPNC	kg	MAX	163.9	**225.0**
cumXe	**kg**	**MAX**	**147.3**	**202.2**

cumKr	**kg**	**MAX**	**16.6**	**22.8**
cumHe	**kg**	**MAX**	**4.7**	**6.2**
cumFPS	kg	MAX	111.1	**153.1**
contAg	**kg**	**MAX**	**107.4**	**945.5**
contCd	**kg**	**MAX**	**72.8**	**524.3**
contCsI	**kg**	**MAX**	**6.4**	**13.7**
contCsOH	**kg**	**MAX**	**45.9**	**102.0**
contSn	**kg**	**MAX**	**1.8**	**47.2**
contTe	**kg**	**MAX**	**6.2**	**15.4**
debAg	**tons**	**MAX**	**3.4**	**3.4**

The results show large deviations in the aerosols released from the control rods (contAg, contCd, and contSn in Table 3), with the base case value lying far from the tolerance limits.

3.3.2. Ex-Vessel phase

During the first 2 hours of the transient, pressure and temperature in the containment remain constant, as no releases occur either from the core or from the Reactor Coolant System (RCS). Shortly thereafter, pressurizer (PZR) relief operation begins and, when the pressurizer PORV fully opens, a rapid discharge of the RCS inventory results in a sharp increase in containment pressure (see Figure 5). The pressure evolution is practically uniform throughout all compartments, exceeding the pressure beyond which containment failure due to overpressure is assumed in most of the cases, leading to the release of inventory to the environment. Containment failure due to overpressure occurs over a wide time range, from approximately 19 to 65 hours, with a clear bifurcation in the scenario, as some cases do not exhibit overpressure failure. The dotted line represents the containment failure time in the base case calculation. A thorough analysis is required to determine which parameter needs to be truncated to avoid this bifurcation, as otherwise it would invalidate the determination of uncertainty ranges for this figure of merit.

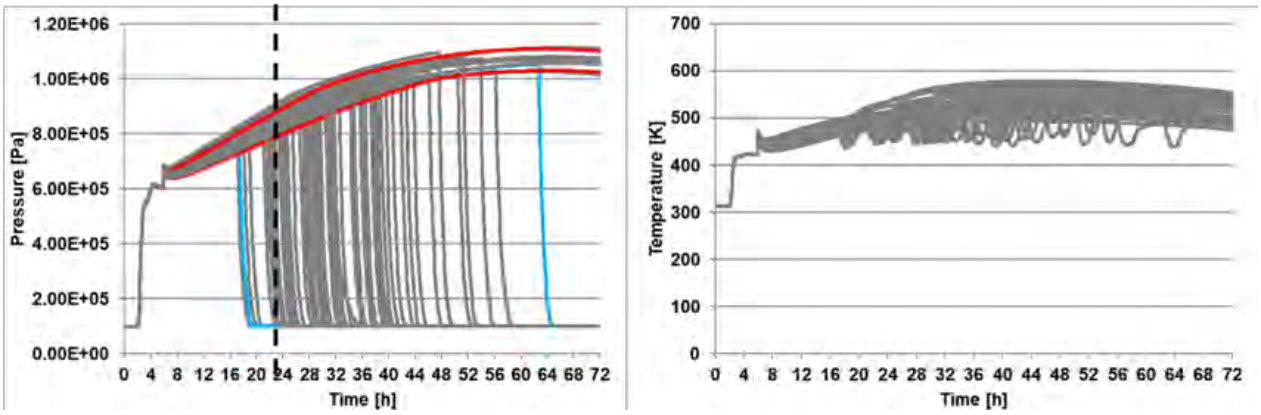

Figure 5: Containment dome pressure and temperature

Temperature also increases; however, unlike pressure, its evolution is heterogeneous. The highest temperature peak is reached in the reactor cavity when corium is ejected from the core. In the remainder of the containment, temperatures in some compartments slightly exceed 420 K approx. until containment failure occurs, at which point a slight cooling takes place due to the release of inventory to the environment. Subsequently, temperatures increase significantly, reaching up to 1070 K in the reactor cavity and between 620 - 820 K in the other compartments. This behavior is driven, among other phenomena, by forced convection induced by the chimney effect within the containment, which enhances heat removal from the corium in the cavity.

With regard to radionuclide (RN) release, Figure 6 shows the release of radionuclides to the environment. On the one hand, the release of nearly the entire vapor inventory can be observed, represented in this case by halogens (I_2 class). A clear bifurcation of the scenario is evident, showing that in cases where containment failure does not occur, the release of I_2 is limited and is solely due to containment leakage. Conversely, in cases where containment fails due to overpressure, the variability in the magnitude of the released mass is minimal, as nearly the entire inventory is released. Dispersion is observed only in the timing of the release, which is influenced by the containment rupture threshold.

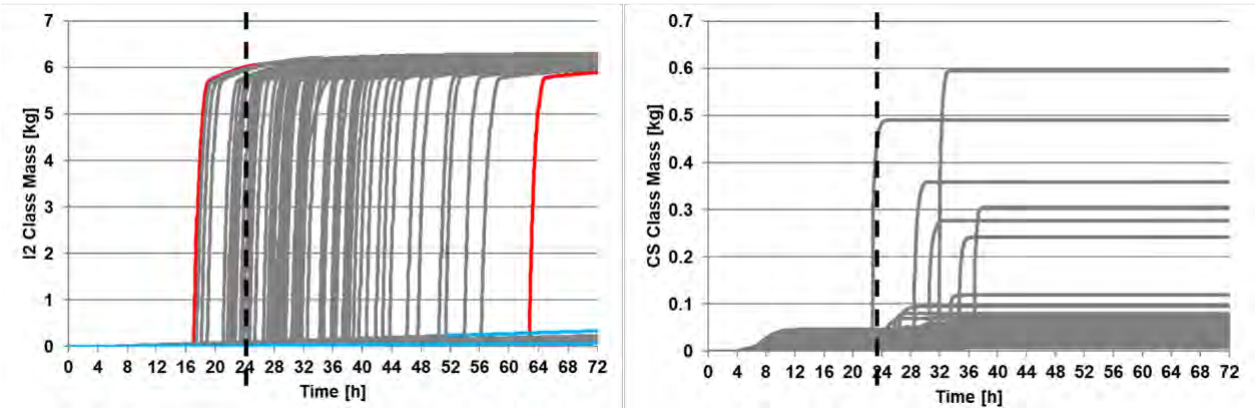

Figure 6: Halogens (left) and alkali metals (right) masses released to environment.

4. CONCLUSIONS

This work presents a first uncertainty analysis (UA) framework for severe accident (SA) calculations, addressing separately both the in-vessel and ex-vessel phases while explicitly accounting for key practical limitations typically encountered when applying integral SA codes within UA studies.

For the in-vessel phase analysis, a total of 208 simulations were performed, with 0 failed cases. The overall computation time was approximately 32 hours on an Intel i7-8700 (12 cores) platform, indicating that the in-vessel UA can be executed with robust numerical performance under the adopted setup.

For the ex-vessel phase analysis, a base case was first computed to verify the adequacy of the coupling between the NSSS and containment calculations. The coupling was found to operate correctly and produced reasonable results. The computational cost of the base case (corresponding to 72 hours of simulation time) was approximately 13.68 minutes on an Intel i7-12700H. A preliminary UQ was then carried out with 93 cases, requiring approximately 6.2 hours using 8 cores on the same platform. No failed cases were observed for $t < 24$ h, whereas 23 run cases (24%) failed for $t > 48$ h, which points to the relevance of the long-term MCCI phase and supports the need for further investigation on modeling the long-term MCCI scenarios with MELCOR.

Overall, the results confirm the feasibility of the proposed staged UA strategy and highlight long-term ex-vessel phenomena, particularly MCCI, as a key driver for late failures and a priority topic for continued methodological refinement.

5. ACKNOWLEDGEMENTS

The authors want to acknowledge the Spanish Nuclear Council for its support to this project under the framework of the CSN program of R&D.

Introduction

Recent international initiatives related to Uncertainty Analysis:

- TH ➔ BEMUSE, PREMIUM, SAPIUM, ATRIUM
- SA ➔ MUSA, IAEA-CRP I31033

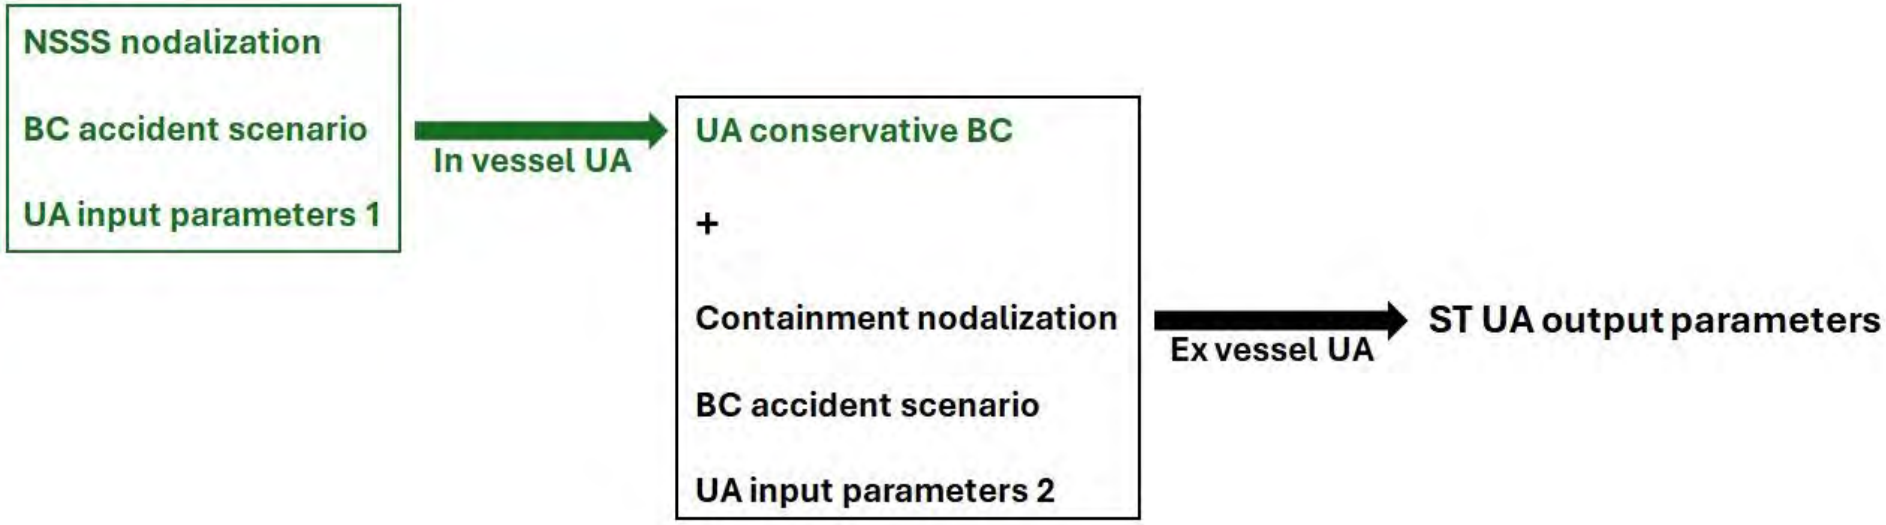
Observations made when using integral SA models:

- Computationally intensive
- Many input param. variations ➔ calculation instabilities
- Scenario bifurcations and/or cliff-edge effects

Objective:

- Develop a method to deal with (or avoid) the above-mentioned points

Stepwise Uncertainty Analysis Method (SUAM)



- **In-** and **Ex-**vessel phases computed separately
- Lesser input param. variations ➔ calculations more stable
- Increased control over the identification bifurcations and/or cliff-edge effects

In-vessel Phase Analysis

- NPP design: **Generic 4-Loop PWR**
- Code: **RELAP/SCADPSIM mod3.4**
- Scenario: **SBO with no mitigation**
- Systems available: **ACCs & RPV PORVs**
- Duration: **until RPV creep rupture**
- Number of simulations: **208** ➔ 6º order Wald (one-sided)

In-vessel Phase Analysis

Main Remarks

Observations made when using integral SA models in UA:

- Computationally intensive
- Many input param. variations ➔ calculation instabilities
- Scenario bifurcations and/or cliff-edge effects

Objective: Develop a method to deal with (or avoid) the above-mentioned points

- **In-** and **Ex-**vessel phases computed separately
- Lesser input param. variations ➔ calculations more stable
- Increased control over the identification bifurcations and/or cliff-edge effects
- Selection of an adequate containment code ➔ e.g. Hydrogen distribution

Main Remarks

In-Vessel Phase Analysis:

- Number of simulations: **208**
- Failed cases: **0**
- Computation time: **~ 32 hours (i7-8700 12 cores)**

Main Remarks

Ex-Vessel Phase Analysis:

- Base case to test the adequacy of coupling NSSS and cont. calculations.
- Reasonable results
- Base Case comp. time (72 hours simulation): **~ 13.68 min (i7-12700H)**
- Preliminary UQ (93 cases): **~ 6.2 hours (i7-12700H 12-cores)**
- Failed cases (< 48 h): **0**
- Failed cases (> 48 h): **6 (6.5%) ➔ Long-term MCCI phase**

Future Works

- Refine the ex-vessel phase evaluation model
  - Check CAV Package configuration ➔ Long-term MCCI calculation
  - Include the containment filtered venting system
- Complete the UQ using the input parameters derived from MUSA project.
- Employ an adequate code for H_2 distribution ➔ e.g. GOTHIC

ABSTRACT

Within the framework of the Euratom project SASPAM-SA Work package 4, a 0D model for In Vessel Melt Retention has been developed by the University of Rome Nuclear Engineering Research Group (NERG) in collaboration with ASNR. The python tool called W-STORM already identified specificities in integral Pressurized Water Reactors (iPWR) with respect to Light Water reactors (LWR), highlighting needed adaptations in the integral Severe Accident (SA) codes models. A validation with respect to MASCA experimental results has been carried out to further strengthen W-STORM prediction of the thermochemical equilibrium established in the two pool scenario considered. Furthermore, a sensitivity and uncertainty analysis has been performed for the two different generic iPWR designs studied in SASPAM-SA project. The uncertainties associated with material properties, corium characteristics in the lower plenum and top boundary condition were selected from the literature and from SASPAM-SA WP2 activities dedicated to integral SA simulations in these designs. To perform the numerous calculations needed for the analysis, the python module Monaco has been used, which focuses on forward uncertainty propagation with basic Monte Carlo sampling. This analysis allows to cover a large scope of configurations for the study of In Vessel Retention. It also further quantifies the need for modelling improvements. The consideration of steady state configurations only is not sufficient when stratification inversion occurs and associated probability of forming a heavy metal layer is evaluated to be greater than 50% in both reactor designs. In addition, steady state configurations with light metal layer leading to significantly higher heat fluxes and vessel ablation, compared to the reference case were identified (average heat flux multiplied by a factor 2.7-2.8). Analysis performed showed that such configurations are due to the use of a simplified model for the radiative heat transfer at the top of the corium associated with high uncertainties. This highlights the benefits of improving radiation heat transfer models at the top of the pool, particularly for iPWR applications, where residual power losses due to radiation heat transfer play a major role, which is not the case for high-power PWRs.

1 INTRODUCTION

In recent years, an increasing interest in studying Small Modular Reactors (SMR) has sparked throughout the nuclear community. Indeed, their deployment would tackle important aspects such as decarbonization, resilient electricity systems, and post-Fukushima regulatory expectations on accident prevention and mitigation [1]. In this framework, the paper is addressed towards integral Pressurized Water Reactors (iPWR), the type of SMRs which are the most easily deployable due to the know-how inherited from reactors of previous generations. In this context, a Horizon Euratom funded project, named SASPAM- SA, aims to investigate the applicability and transferability of the large operating experience associated with Light Water Reactors (LWR) to the near-term deployment of iPWRs, in view of Severe Accident (SA) and Emergency Planning Zone and European licensing needs. More information about the project can be found in [2].

Regarding iPWR, many of the numerous available reactor designs employ In Vessel Melt Retention (IVMR) as their mitigation strategy in case of SA [3][4][5][6]. This is a further common design feature that iPWRs share with some LWRs, such as the AP1000 [7] and HPR1000 [8]. The IVMR strategy aim is to retain corium in the Reactor Pressure Vessel (RPV), thanks to external vessel cooling. In most papers in literature, corium stratification is supposed to be a two-layered structure, with molten oxidic materials at the bottom, and molten metallic materials on top of it. This approach is indeed possible, but a three-layered configuration (light metal on top, oxidic pool in the middle, heavy metal at the bottom), also has been deemed possible by experimental data [9][10]. This configuration is characterized by transient behavior [11], and its imposed heat flux to the vessel might be even higher [10][12]. To preliminarily characterize IVMR in iPWRs, in the framework of SASPAM-SA, a Water cooled Small modular reacTors 0D in-vessel melt Retention Model (W-STORM) has been developed at the University of Rome, in collaboration with ASNR. The model's main purpose was to identify specificities in IVMR modelling in these reactors, to furnish partners with a tool that could give the magnitude of expected results and to be used as a teaching tool. W-STORM does not employ new heat transfer models with respect to other 0D models in the literature, but implements a thermochemical module, which was a valuable addition in terms of representativeness. Also, the model has been developed to be adaptable to many iPWR designs, with a flexible structure that can adapt to different iPWRs and their specific features (i.e. low volume of fuel and low volume of molten steel with respect to the lower plenum). In previous analyses [13], the model highlighted key features of iPWRs in IVMR, and suggested model improvements or implementation in current Severe Accident (SA) codes. Indeed, the code highlights that a larger quota of power from the oxide is transferred to the metal pool, due to the low aspect ratio of the former. Also, a thick oxide crust is registered (often neglected in LWRs, since its thickness is of some millimeters), and the occurrence of very thin metal layers is shown, leading to high radiation losses, whose models need to be refined in SA codes due to their impact. Also, it has been preliminarily evaluated that the occurrence of a metallic phase heavier than the oxide leading to stratification inversion would appear in iPWRs (mainly due to a small value of mass of steel with respect to the fuel mass). It could be even possible to have mixed pools, a situation for which there is no heat transfer model in literature. Some of the model issues mentioned above are being addressed in SASPAM-SA.

In this paper, a W-STORM validation for the thermochemical model is performed, together with a sensitivity and uncertainty analysis, with the Python tool Monaco [14]. Parameters' distributions and uncertainties come from literature, from SASPAM-SA data, or from engineering judgement. The main aim of this work is to further strengthen the conclusions from [13], supporting them with a broader set of input data. The paper starts with a brief description of W-STORM and its validation against MASCA experiments and a code benchmark on material properties. Then the sensitivity and uncertainty analysis framework is described, starting with a brief description of the Python package Monaco. A complete description of the

input distributions used in the calculations is provided, and the results, for three calculations applied to the two SASPAM-SA iPWR generic designs, are outlined.

2 W-STORM DESCRIPTION

In case of SA, core degradation can lead to relocation of RPV internals in the Lower Plenum (LP). Such events, in the absence of water reflooding, should lead to complete melting of the relocated material [15]. Since no deterministic models for Corium progress in the LP are yet available, in the early 2000s [16] the problem was addressed with conservative plausible scenarios. The developed Python tool represents indeed a steady state configuration of corium in the LP. A simple schematic of the configuration is displayed in Figure 1. Molten core materials (i.e. ZrO_2, UO_2, Stainless Steel (SS), Zr, U) are repartitioned in two pools, one made of oxides, and one made of metals. Fission products are neglected in this model, and decay heat is estimated based on the repartition of uranium content in the two pools. W-STORM employs three main models in its architecture: thermochemical, geometrical and heat transfer. For the first one, the model from [17] has been employed, whose results are discussed in the next section. The geometrical model is described in [13], and consists in the geometrical evaluation of molten pools' heights and surfaces, starting from the molten masses of their constituents. Regarding heat transfer, W-STORM's model is derived starting from the indications in [16], but employs spherical coordinates for the conduction problem and includes additional features, as widely discussed in [13].

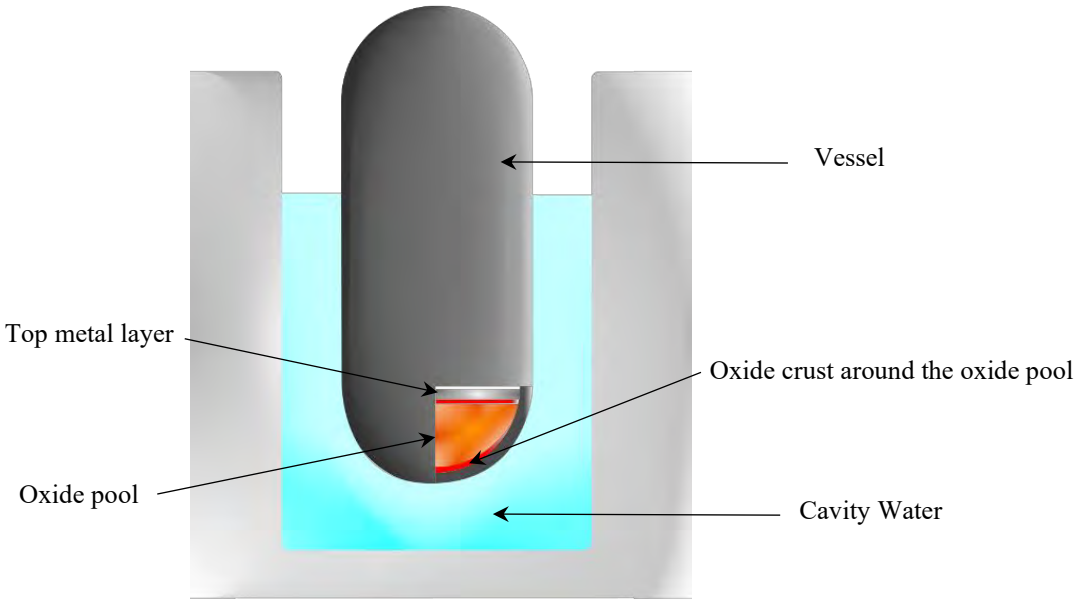

Figure 1: IVMR light metal configuration

W-STORM's computational sequence is briefly recalled, but a more detailed description can be found in [13]. The code's workflow starts with inputting the molten masses of Zr, UO_2 and SS, the Zr Degree of oxidation (C_{ox}), the decay power, LP geometrical characteristics, radiative heat transfer parameters, cavity atmosphere pressure and liquid level. Firstly, the thermochemical equilibrium is computed, defining the molar fraction of each element per phase. Both pools' thermophysical properties are then evaluated, following indications from [16]. If the metal phase obtained is able to stay on the top of the oxide pool (density threshold, cf. part 3), the model moves on to compute the system's geometrical characteristics. Once the geometries are defined, the heat transfer problem can be solved, starting with the oxidic pool's bulk temperature. Its evaluation is followed by the determination of heat fluxes in the downwards and upwards directions, with appropriate experimental correlations for the Nusselt numbers. The thermal field inside the vessel, the downwards crust thickness and the Critical Heat Flux are then evaluated at each polar

mesh. Lastly the heat transfer problem in the metal layer is solved, estimating the inner temperature of the vessel at Liquid Metal (LM) height. The heat transfer problem is then repeated until the generated power in the crusts converges. As an outer loop, the code checks if the vessel's inner temperature is higher than its melting point. If it is, the vessel's thickness is reduced and the corresponding mass is added to the SS mass, repeating the described cycle.

3 THERMOCHEMICAL MODEL COMPARISON WITH MASCA EXPERIMENTS

The oxide and liquid metal pools relative position strongly affects the IVMR heat transfer problem. Indeed, the occurring corium stratification in the LP drives what will be the heat load on the vessel. If the only configuration that can be treated by W-STORM heat transfer module is the two-phase pool with the oxidic pool on the bottom and the metallic one on top, thanks to the thermochemical model, W-STORM can predict also the configurations where the metal phase is heavier than the oxide (but not the associated thermal load on the vessel). The Iso-Density curves (lines representing where the oxide density is equal to the LM density) in the C_{ox} vs SS to UO_2 mass ratio are presented in Figure 2. A similar evaluation was conducted in [13], but in this instance the iso-density curves are compared against MASCA experimental results [18]. This kind of analysis is generic in nature, since the two generic SASPAM-SA designs are considered, as well as a generic PWR described in the IVMR EU funded project, named High Power Reactor (HPR) in this paper [19]. When a configuration lies above these curves, the code predicts a light metal stratification (i.e. LM on top, oxide at the bottom). On the other hand, if it is below the curves, the heavy metal layer configuration is predicted. In W-STORM, a 5% threshold is considered before the density inversion occurs (i.e. the metal layer is considered to be a "heavy metal" only when its density is 5% larger than the oxidic one). Indeed, a minimum mass density difference is necessary for triggering Rayleigh-Taylor instabilities leading to stratification inversion. In addition, intermediate configurations with close densities between oxide and metal phases and thus no clear stratification (as observed experimentally in the case of the MASCA MA-2 test) are also possible. As a consequence, the corium stratification evaluated by the code is determined in Figure 2 for each reactor considering the dashed line with the corresponding color. The MASCA experimental values are displayed as dots: the red experiments (MA-1, MA-3, MA-4, MA-5, MA-5b) indicate that the resulting experimental configuration is a heavy metal one, the green experiment (MA-6) refers to a light metal configuration, while the orange experiment (MA-2) exhibits no clear stratification.

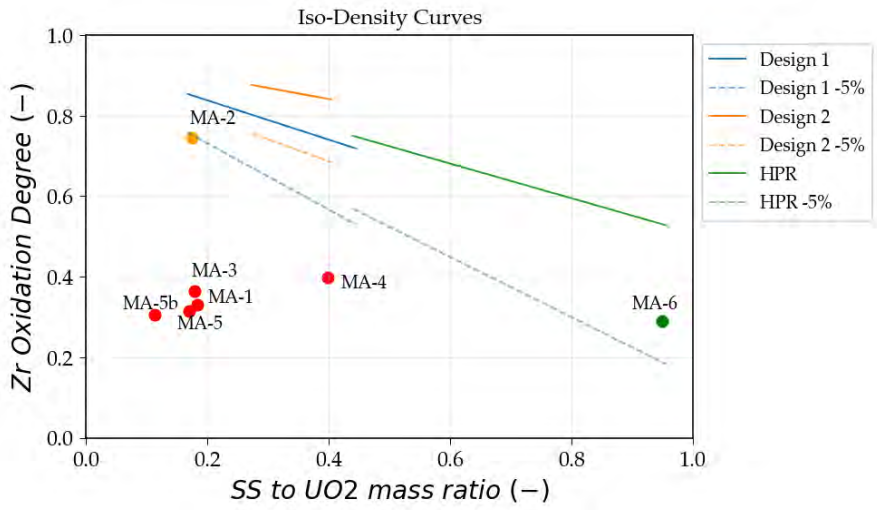

Figure 2: Iso-density curves for SASPAM-SA Design 1, Design 2, HPR and MASCA experimental results

For the 7 MA tests considered, W-STORM can predict experimental stratification configurations when the densities of the two phases is not too close as in MA-2 and MA- 4 tests, as synthetized in Table 1 and Table 2. It is important to highlight that this result depends on both thermochemical model and on the correlations used for the calculation of the densities of the phases.

Table 1: W-STORM comparison of predicted corium stratification with respect to MASCA experimental results

	Experimental Result	W-STORM (densities difference $\frac{oxide-metal}{oxide}$ in %)
MA-1	Heavy metal	Heavy metal (-6.7%)
MA-2	No clear stratification	Light metal (6.7%)
MA-3	Heavy metal	Heavy metal (-9.1%)
MA-4	Heavy metal	Light metal but less than 5% density difference (1.6%)
MA-5	Heavy metal	Heavy metal (-14.0%)
MA-5b	Heavy metal	Heavy metal (-18.7%)
MA-6	Light metal	Light metal (7.9%)

Table 2: W-STORM comparison of predicted mass fractions with respect to MASCA experimental values - oxide mass fraction w_{oxy} (i.e. mass of oxidic layer divided by the total mass), uranium mass fraction in the LM layer $w_{u,met}$ (i.e. mass of uranium in the LM pool divided by the total mass of the LM pool) and Zr mass fraction in the metal $w_{Zr,met}$

	Experimental Data			W-STORM			% Error		
	w_{oxy}	$w_{u,met}$	$w_{Zr,met}$	w_{oxy}	$w_{u,met}$	$w_{Zr,met}$	w_{oxy}	$w_{u,met}$	$w_{Zr,met}$
MA-1	0.781	0.425	0.103	0.718	0.440	0.116	8.08%	-3.42%	-12.8%
MA-2	0.878	0.201	0.055	0.832	0.242	0.073	5.19%	-20.5%	-31.9%
MA-3	0.726	0.43	0.173	0.725	0.432	0.145	0.17%	-0.53%	16.00%
MA-4	0.639	0.322	0.158	0.619	0.301	0.099	3.20%	6.47%	37.6%
MA-5	0.754	0.374	0.256	0.707	0.449	0.193	6.19%	-19.9%	24.5%
MA-5b	0.799	0.428	0.274	0.750	0.499	0.212	6.08%	-16.5%	22.5%
MA-6	0.565	0.215	0.142	0.428	0.204	0.069	24.2%	5.13%	51.7%

Results of W-STORM were also further compared to the results of other thermochemical models and codes based on the results of the benchmark published in [20]. Details of the results are presented in Appendix A. W-STORM agrees with the results from the other codes and as expected, is closer to the ones obtained with other codes based on the same Nandan Fichot thermochemical model [17]. The absence of consideration of limited Stainless Steel solubility in the oxidic phase, compared to the other codes, is also identified and proved to be limited.

This analysis highlights the appropriateness of W-STORM thermochemical model, that can predict the stratification configurations highlighted in MASCA (at least when densities of the two phases are not too close) and estimate the phases density similarly to other integral codes, while weakly underestimating the oxide layer density. This should slightly affect the occurrence of heavy metal cases in the analyses shown in the next sections.

4 SENSITIVITY AND UNCERTAINTY ANALYSIS

4.1 Monaco Python package and Input distributions

The python package Monaco [14] has been used to perform the sensitivity and uncertainty analysis. In general, Monaco requires the user to build three functions: preprocess(), run() and postprocess(). The preprocess function allows the user to define the simulation's input variables and their distributions, which will be sampled. The run function is essentially the user's model, in this case W-STORM, which returns the output variables. The postprocess method lets the user define the output variables, which are stored in the simulation's object. Once the three methods are defined, the user must initiate the simulation's object, in which the number of cases, sampling method, seed and the three pre-defined functions are passed. The simulation is then run, and the results can be collected. Monaco offers different postprocessing functions to plot the results, but custom ones were developed for W-STORM to depict the results more accurately.
The Monaco implemented sampling methods have been tested, and the Latin Hypercube method was selected. In [14], it is stated that the number of cases to run to get representativeness of the input hyperspace should be $n \geq 2^k$, where k is the number of inputs, and n the number of cases to run. Since the inputs are numerous (up to 34 for the cases with all uncertain parameters), this criterion would be infeasible in terms of CPU time. However, based on the Wilks formula [21] a relatively small number (around 100) are sufficient to get the statistical shape of the results and identify the most influential parameters[1]. Since W-STORM simulations are fast, a larger number of 2000 cases have been considered as a reasonable choice.
Three studies will be discussed in this paper. The first one is based on the SASPAM-SA Design 1 configuration and uncertainties associated with material properties are considered. Uncertain coefficients have been added in the material properties laws, following the approach developed by Rempe et al. [22] . The input distributions and the thermophysical properties considered are synthetized in Appendix B. Then, in the following studies, the main uncertain parameters identified for the corium characteristics in the LP and its top boundary condition have been considered in addition to the ones associated with the material properties. The input distributions considered for these additional uncertainty parameters are based on the results of integral SA simulations done in the scope of the SASPAM-SA project for different scenarios and for the two iPWR designs studied (Design 1 and Design 2). They are reported in Table 3. It should be noted that uncertainty associated with the modelling parameter used for the density inversion threshold is also considered.

Table 3: Main Input parameters distributions data

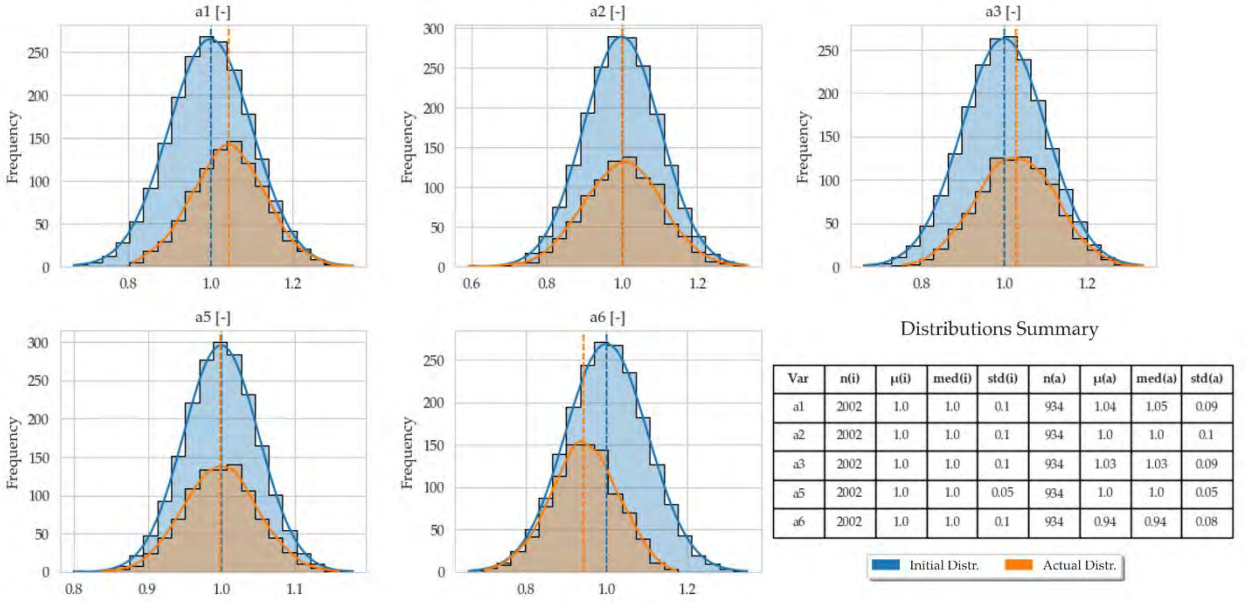
Symbol	Description	Unit	Distr. type	Min (Uniform)		Max (Uniform)	
				Design 1	Design 2	Design 1	Design 2
C	Oxide htc correlation index	-	Integer uniform	0	0	5	5
mFe	Mass of Stainless Steel	kg	Uniform	1500	15000	4500	22000
mUO_2	Mass of fuel	kg	Uniform	6000	40000	9000	55000
C_{ox}	Zr degree of oxidation	-	Uniform	0.3	0.3	0.7	0.7
ε	Metal Layer emissivity	-	Uniform	0.2	0.2	0.4	0.4

[1] $\gamma = 1 - \beta^N$, with N the number of calculations, γ the percentage of the results distribution covered, and β the confidence level. 99% of the results are thus covered with a confidence of 99% with around 500 simulations.

Ts	Average structures' temperature	K	Uniform	500	500	1500	1500
thresh	Inversion threshold	-	Uniform	0.0	0.0	0.1	0.1
P_m	Specific residual power	W/kg	Uniform	178	75	200	120

4.2 Results: Variation of material properties on Design 1

As a first analysis, only the parameters associated with the material properties have been used as input for W-STORM. Constant values were used for parameters in Table 3. They were chosen equal to the ones already adopted in [13]. For sake of brevity, only the parameters influencing materials density are reported in Figure 3. Two kinds of distributions per parameter are presented: the initial distribution (in blue) and the actual distribution (in orange). Indeed, some configurations cannot be evaluated by W-STORM. As already discussed, it is the case of configurations where LM is more than 5% denser than oxidic layer (Heavy Metal category). In addition, the code cannot deal with configuration with no ablation on the lower head and possible LM partial or complete solidification (low Focusing Effect, FE, category). On the other hand, an ablated thickness higher than 90% of the nominal thickness is also out of the scope of the code due to a possible mechanical failure (High FE category). Finally, numerical issues may also happen, but their general occurrence in these analyses is negligible. For this study the distribution of the "failed" calculations is given in Table 4. It is worth noting that, considering only uncertainties associated with material properties, about 50% of the calculations lead to the formation of a heavy metal layer. The results in Figure 3 identify the influence of the densities of UO_2 (a_1), ZrO_2 (a_3) and SS (a_6) on stratification inversion. Indeed, their actual distribution average value is shifted to values avoiding heavy metal occurrence with respect to initial input distributions. In the next section this occurrence is compared to the complete uncertainty calculations.

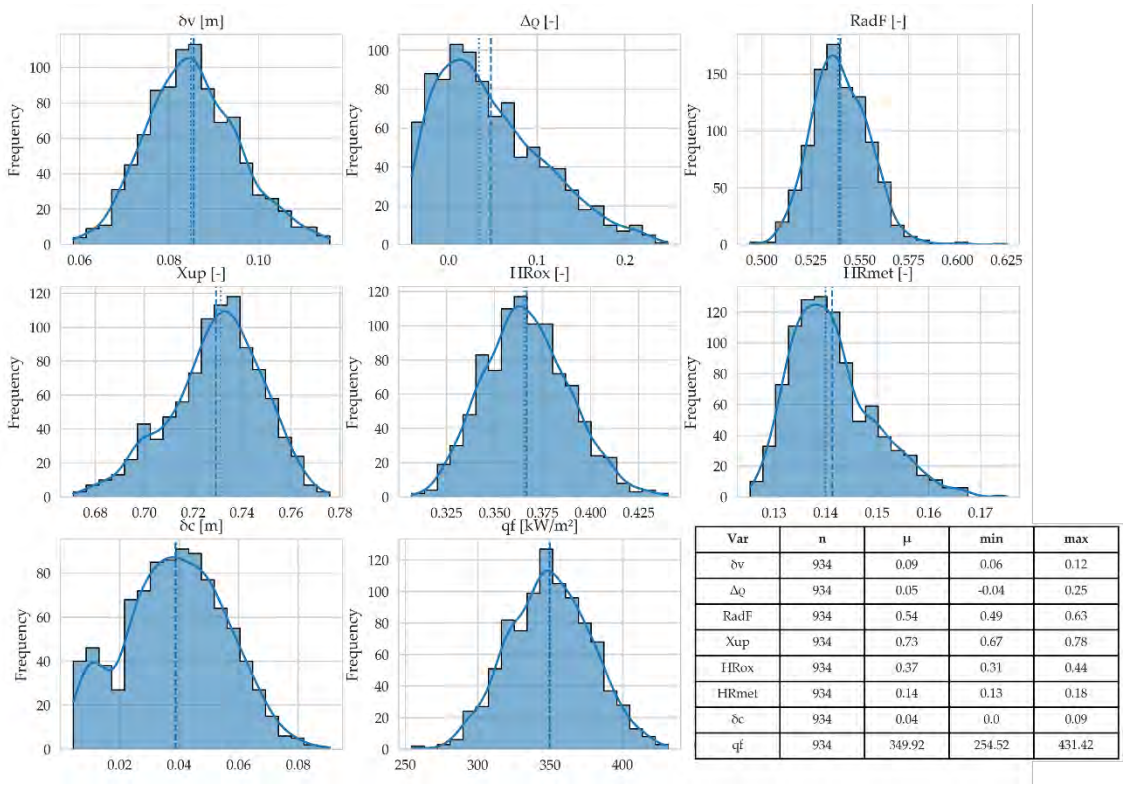


Var	n(i)	μ(i)	med(i)	std(i)	n(a)	μ(a)	med(a)	std(a)
a1	2002	1.0	1.0	0.1	934	1.04	1.05	0.09
a2	2002	1.0	1.0	0.1	934	1.0	1.0	0.1
a3	2002	1.0	1.0	0.1	934	1.03	1.03	0.09
a5	2002	1.0	1.0	0.05	934	1.0	1.0	0.05
a6	2002	1.0	1.0	0.1	934	0.94	0.94	0.08

Figure 3: Initial and Actual distribution of materials density multipliers[2] and distribution data (i subscript for initial, a for actual): n represents the number of cases, μ the mean value, med the median value and std the standard deviation

[2] The a_4 parameter is a dummy one and is not included in the graph.

In Figure 4, the distributions of main interesting output parameters are presented: the vessel residual thickness δ_v, the density difference between oxide and metal phases divided by the oxide density $\Delta\rho$, the power fraction dissipated by radiative heat flux in the metal layer RadF, the power fraction transmitted to the metal layer by the oxide Xup, the aspect ratio of the oxide HRox, the aspect ratio of the metal HRmet, the average downwards crust thickness δc and the FE heat flux (in front of the top metal layer) qf.



Var	n	μ	min	max
δv	934	0.09	0.06	0.12
ΔQ	934	0.05	-0.04	0.25
RadF	934	0.54	0.49	0.63
Xup	934	0.73	0.67	0.78
HRox	934	0.37	0.31	0.44
HRmet	934	0.14	0.13	0.18
δc	934	0.04	0.0	0.09
qf	934	349.92	254.52	431.42

Figure 4: Properties only calculation output distributions.

These results further consolidate the specificities of iPWR IVMR configurations compared to HPR identified in [13]: thick bottom oxide crust (a 4 cm mean value, one order of magnitude higher with respect to HPR), relatively high fraction of radiative power, lower aspect ratios in both oxide and metal, which respectively produce a high fraction of power transferred from the oxide to the LM, and a limited FE. The variation of the maximum heat flux around its average value remains limited when considering uncertainties associated with material properties (below +/-30% considering the minimum and maximum values). In accordance, comparable behaviour is obtained for the minimum vessel thickness.

4.3 Results: Complete input space variation on Design 1 and Design 2

In this last analysis, both the inputs from Table 3 and Appendix B are being sampled and fed to W-STORM. As in the previous section, the initial input distributions are modified into the ones corresponding to successful calculations (results are available in Appendix C). In these complete calculations, the success rate is quite low (12.9% in Design 1, 5.3% in Design 2), due to high occurrences of Heavy Metal and Low FE cases (cf. Table 4). However, the success cases correspond respectively to 257 and 105 calculations which allow performing a statistical analysis of these results.

Table 4: Occurrence frequency of W-STORM outcomes

Case	Success	Heavy Metal	High FE	Low FE	No Convergence
Design 1 Properties only	46.7%	50.2%	0.0%	1.6%	1.5%
Design 1 Complete	12.9%	55.7%	0.0%	30.4%	1.1%
Design 2 Complete	5.3%	64.7%	0.0%	29.8%	0.4%

As already hinted in Figure 2 and [13], for the analyzed iPWRs, there is a very high occurrence of stratification inversion cases. This result highlights the need for heat transfer models and experimental data in the case of stratification inversion, as their occurrence in iPWRs in IVMR conditions is rather high. Also, non-negligible occurrence of the low FE cases is registered, which are not a safety concern for the lower head, since their imposed heat flux on the vessel would be lower compared to other situations. Nevertheless, this highlights the impact of radiative heat transfer, which as depicted in Figure 5 and Figure 6, is of major importance in this heat transfer problem. In fact, the predicted average radiative fractions from the LM for both designs are higher with respect to HPR (20-30%) [19], and can go up to 80% (49% average for Design 1, 56% for Design 2). Since the radiative fractions are high, particular attention must be given to the radiative heat transfer modelling. In W-STORM case, the predicted fractions of radiated power might be the result of oversimplified modelling and the frequency of occurrencies of Low FE in Table 4 carry that uncertainty. In severe accident codes, it would be preferable to have more complex models that consider view factors and emissivity of the different surfaces.

The output distributions of main interesting parameters are reported in Figure 5 and Figure 6 respectively for Design 1 and Design 2. Regarding the average values obtained, an expected picture is depicted, as already stated in the previous section: high average downwards crust thickness, low oxide and LM aspect ratios, high radiative fractions, high fractions of power from the oxide to the LM and limited focusing effect, with respect to HPR. However, looking at extreme values, a maximum heat flux close to 1MW/m² is reached for Design 1 and 680kW/m² for Design 2. This is a significant increase compared to the average value of respectively 362kW/m² and 255kW/m² (multiplying factor of about 2.8 and 2.7). For such situations, the analysis shows that it corresponds to high mass of UO_2, low mass of steel, high residual power and low radiative heat transfer (high temperature for surrounding structures and low emissivity)[3]. This result is straightforward considering the focusing effect phenomenology (residual power concentration in front of the metal layer), but it allows quantifying the combined impact of these parameters. It is worth noting that in this analysis, considering a simplified modelling of radiative heat transfer at the top of the corium pool with significant uncertainties has a significant impact and it would be beneficial for further studies to improve this modelling as previously discussed for the occurrence of configurations with low heat flux.

It is worth noting that for such studies, the standard correlation coefficients like Pearson (based on assumption of a linear trend) or Spearman (based on ranking) are not informative. Indeed, the values obtained are either too low for allowing a robust analysis (typically below 0.3) or the relationships are obvious (for example, the value considered for the steel mass directly impacts the aspect ratio of the LM). Regarding the maximum heat flux output, the variables with the highest (in absolute terms) Spearman coefficients are around 0.3 and correspond to the mass of steel, the mass of fuel and the emissivity of the metal layer.

[3] For Design1, maximum heat flux is evaluated for mFe=1788kg, mUO2=8765kg, Pm=195W/kg, ε=0.25, Ts=1480K
For Design2, maximum heat flux is evaluated for mFe=15672kg, mUO2=53436kg, Pm=110W/kg, ε=0.25, Ts=1480K

5 CONCLUSIONS

The present paper describes the sensitivity and uncertainty analysis on W-STORM, a simple python IVMR 0D model developed in the framework of the SASPAM-SA project. W-STORM thermochemistry model was furtherly validated with respect to MASCA experiment, and its predicted properties were also compared to a code benchmark. W-STORM can predict MASCA experimental stratification configurations when the two phases' densities are sufficiently distanced. Furthermore, its prediction of corium composition as well as phases' density are included in the benchmark predicted ranges presented in [20]. The SAPSAM-SA two generic reactor concepts were analyzed in an IVMR state, and three main calculations were shown: a complete calculation varying all the presented input data (Reactor parameters + physical properties) for both designs, and a calculation with just varying physical properties. The reactor parameters input data were gathered in the SASPAM-SA project, while the physical properties data were extrapolated from literature. The Monaco python package was exploited to carry out sampling and running. The main data coming from the analysis of output variables depicts an expected picture: iPWRs are characterized by thick oxide crusts, low aspect ratios of LM and oxide, high radiative heat transfer, high power transferred from the oxide to the LM and limited FE. All parameters exhibit average values comparable to W-STORM previous work. The distribution limits associated with the maximum heat flux were identified and are inferred mainly from the radiative heat transfer model parameters.
Results further stress that in iPWRs there could be a high occurrence of Heavy Metal cases, due to a low steel to fuel mass ratio. Heat transfer models and experimental data are needed for this kind of configuration. It could even be possible that in some cases, the metallic and oxidic phases exhibit comparable densities, which would favor mixing instead of stratification. Also, the frequency of occurrence of partial/ complete solidification cases of the LM (low FE), with no ablation on the lower head was evaluated. However, the confidence in the low FE frequency is limited, since the radiative heat transfer model in W-STORM is rather simple. Indeed, more accurate radiative heat transfer models should be implemented in severe accident codes, since radiative heat transfer can play a major role in the system's dynamics.

APPENDIX A: W-STORM stratification model evaluation with respect to Benchmark [20]

The predicted density difference (calculated as LM density minus the oxide density) with respect to different codes as done in [20] were investigated. The results are collected in Table 5, and they highlight that the range of variability between codes is large, and W-STORM is close or inside the predicted ranges of other codes.

Table 5: Benchmark [20] and W-STORM comparison of the density difference between phases (metal – oxide) in kg/m³

	NRC KI - TSAR	IRSN - ASTEC	INRNE-BAS - ASTEC	IBRAE - HEFEST_URAN	CEA - PROCOR - S&F, M1	CEA - PROCOR - S&F, M2	W-STORM

MA-6	-454.4	-271.1	-296.8	-809.3	-207.4	-334.4	-582.8

Furthermore, the density of each phase was tested against the results from other codes, by varying the considered mass of steel. The results are displayed from Figure 7 to Figure 14. The first noticeable difference is in the W-STORM oxide phase density variability with respect to the other codes (Figure 8 and Figure 12). These densities are indeed independent from the mass of steel, since one of the assumptions of [17] is the non-solubility of Stainless Steel in the oxidic phase. On the other hand, in Figure 7 and Figure 11 it is noticeable that the other codes implement this solubility. W-STORM indeed cannot predict the oxide density decrease and slightly underestimates the oxide density. For the LM layer, W-STORM agrees with the results from the other codes, finding itself between the curves values in Figure 9 and Figure 13.

W-STORM Sensitivity and Uncertainty analysis for In Vessel Retention in integral Pressurized Water Reactors

ERMSAR 2026

- **M. Principato** (Sapienza, now PSI), C. Ciurluini (Sapienza), F. Giannetti (Sapienza) , L. Carénini (ASNR), F. Fichot (ASNR)

- Madrid, 19th May 2026

W-STORM *(Water cooled Small modular reacTors 0D in-vessel melt Retention Model)*

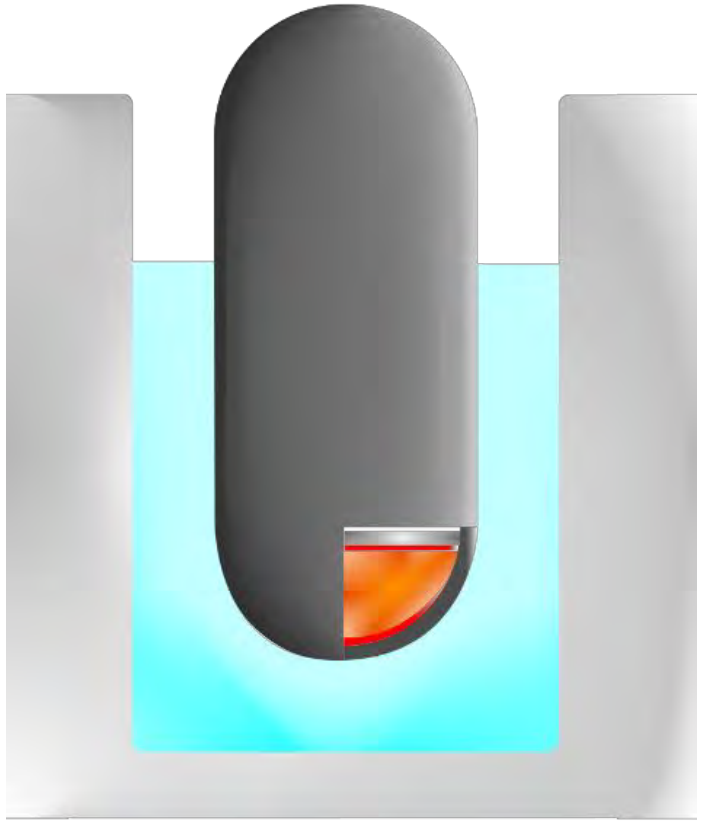
Simple Python code developed in EU project SASPAM-SA

Model Aim:

- Fast running tool to provide SASPAM partners a magnitude of expected results
- Identify specificities of iPWRs in IVMR modelling

Key features:

- Written in Python, object based
- Adaptable to any iPWR



Workflow

Input data (Masses, Geometry, Cavity, Oxidation, Iter)

Thermochemical model ***(Nandan et al.)***

Composition and properties

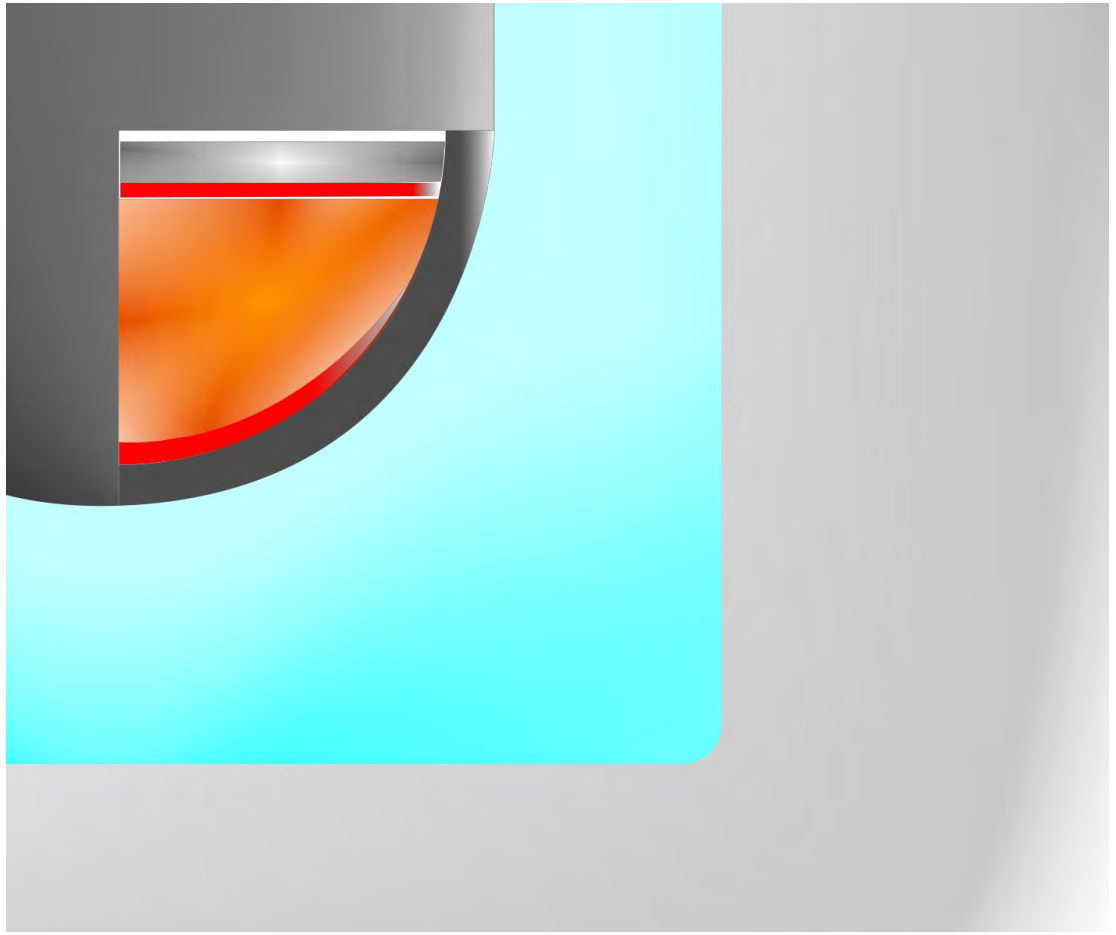
Geometrical model

Heights and surfaces

Heat transfer model

Refine Vessel thickness

Results



MASCA experiments comparison

- Since an uncertainty and sensitivity analysis is to be performed, the **Thermochemical model** (Nandan Fichot) was beforehand compared to Masca experiments
- **5%** threshold for inversion (Rayleigh-Taylor instabilities)
- Experimental stratification reproduced when the densities aren't too close

	Experimental Result	W-STORM (densities difference $\frac{\text{oxide}-\text{metal}}{\text{oxide}}$ in %)
MA-1	Heavy metal	Heavy metal (-6.7%)
MA-2	No clear stratification	Light metal (6.7%)
MA-3	Heavy metal	Heavy metal (-9.1%)
MA-4	Heavy metal	Light metal but less than 5% density difference (1.6%)
MA-5	Heavy metal	Heavy metal (-14.0%)
MA-5b	Heavy metal	Heavy metal (-18.7%)
MA-6	Light metal	Light metal (7.9%)

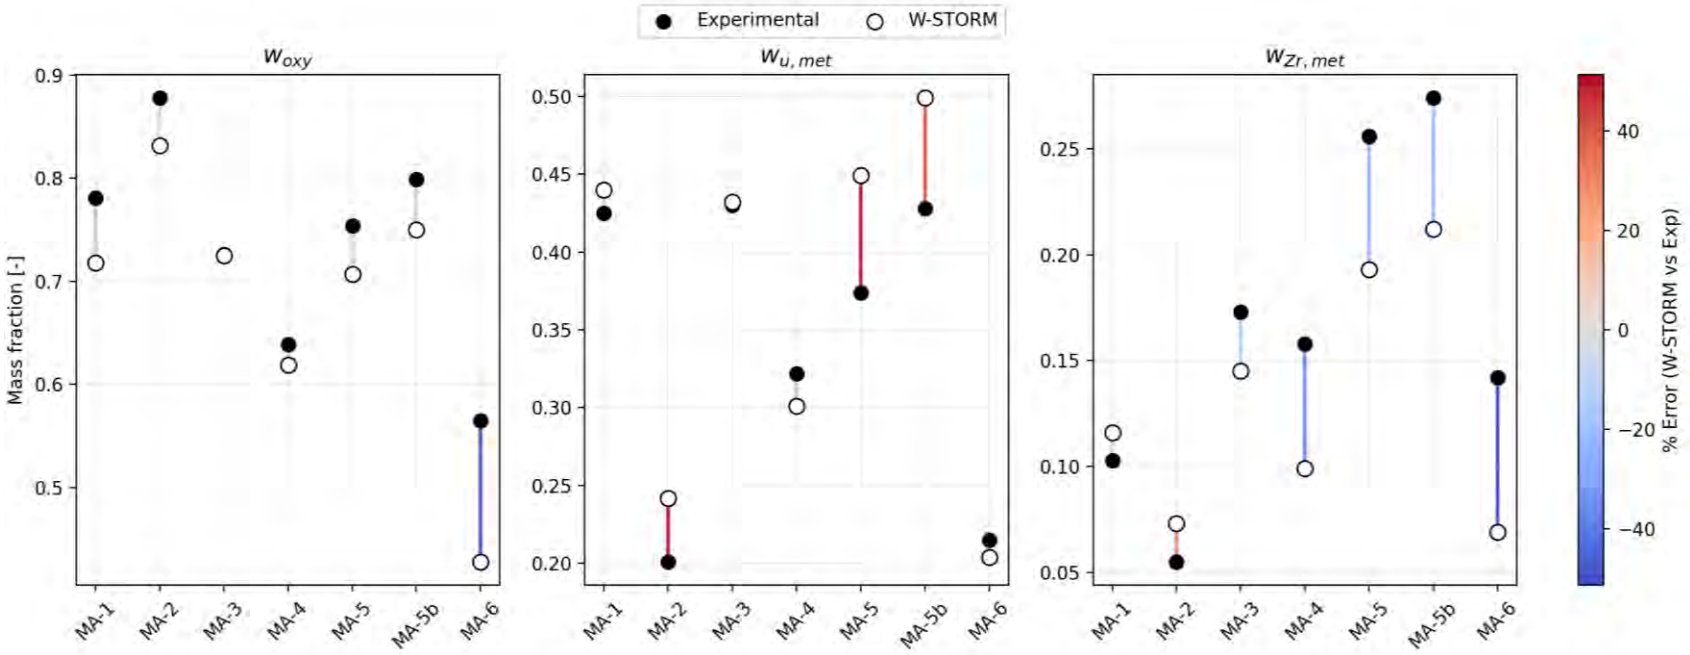
MASCA experiments comparison

Parameters:

- Mass fraction of oxide w_{oxy}
- Mass fraction of U in metal $w_{U,met}$
- Mass fraction of Zr in metal $w_{Zr,met}$

➢ MA-1, MA-2 and MA-3 are better reproduced overall, wrt to 4,5,5b and 6.

➢ Results for these parameters were also compared to a code Benchmark **(Le Tellier et al. 2025)**, and they are consistent with other codes using the same TC model (Nandan Fichot)



Benchmark comparison

Parameter:

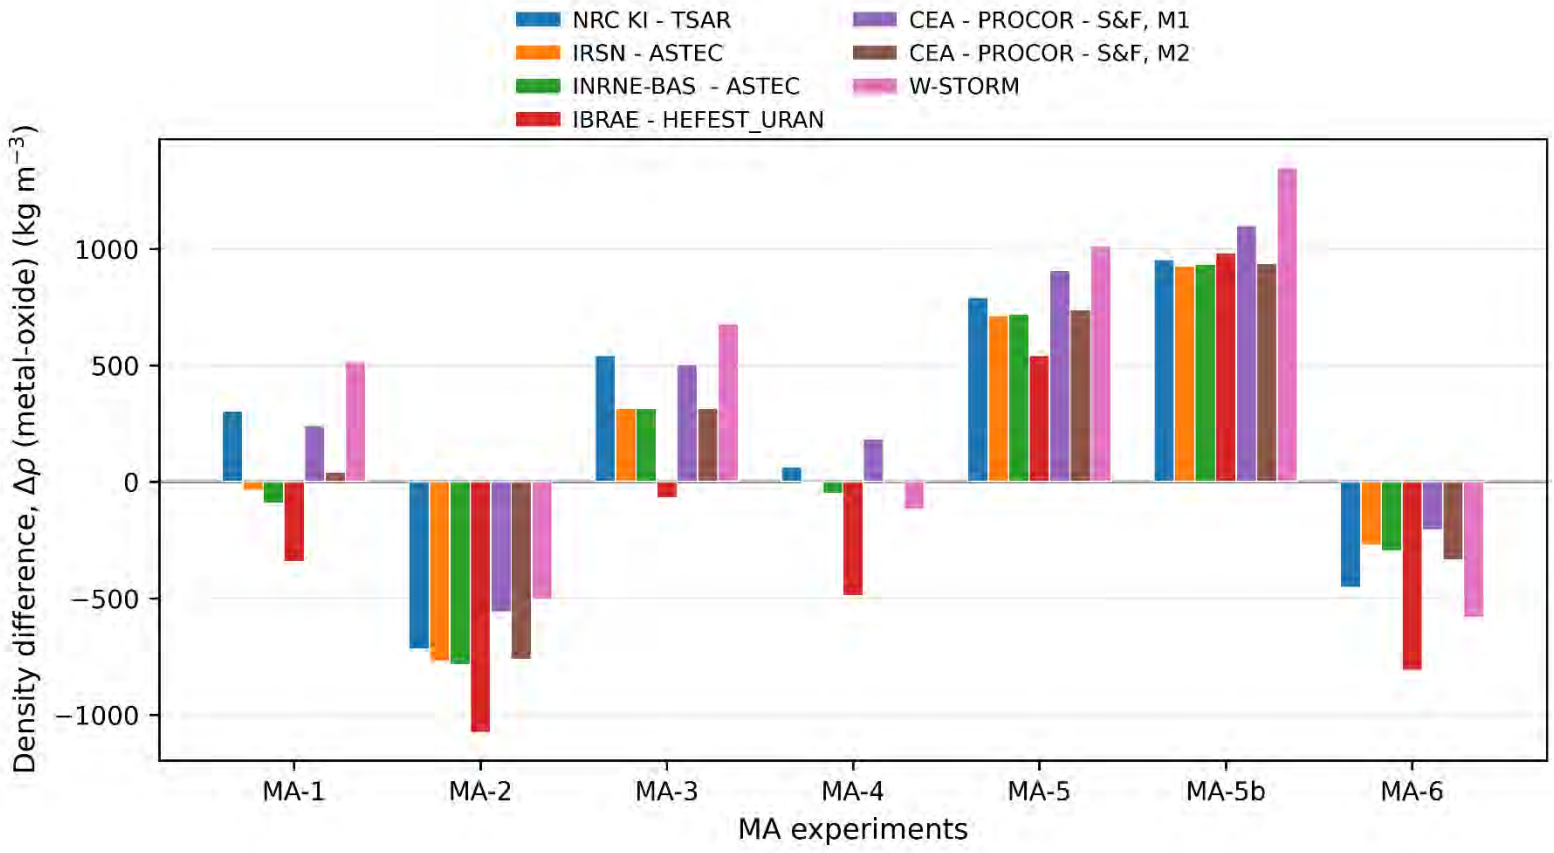
- **Metal – Oxide density difference**

Results:

- Large range of variability between codes, W-STORM is close or inside the predicted range from other codes.

- Results depend on chosen correlations for materials density (which were not highlighted in the benchmark paper), and on the predicted mass fractions (TC model)

- Variability of phase density with mass of steel was also investigated. W-STORM underestimates oxide density slightly but well represents metal density.



Sensitivity and Uncertainty analysis

➢ **Monaco Python package used to perform the analyses**

Simulations:

- Design 1 Variating only properties
- Design 1 Complete
- Design 2 Complete

- Number of cases per sim: ~2000

Parameters:

- **26 total parameters** for thermophysical properties (Density, Thermal conductivity, heat capacity, viscosity for each material)
- **7 reactor specific parameters**

- **Data from Literature and from SASPAM-SA**

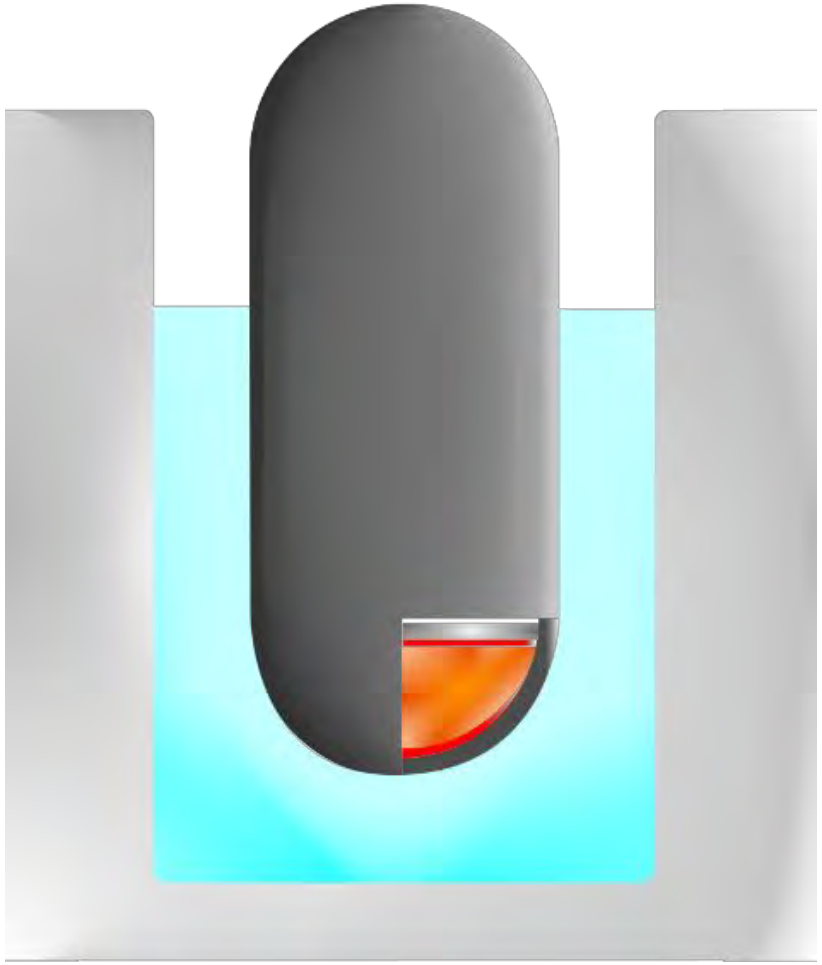
Cases handling

W-STORM cannot evaluate any IVMR configuration, only the "Classical" one. W-STORM output can be of many different types:

- Classic output (partial ablation): W-STORM success, outputting the overall results (heat fluxes, temperatures etc.)
- If there is no ablation (LM solidification): low FE
- If there is vessel failure (ablated thickness>90% nominal thickness): high FE
- If the metal layer is 5% heavier than the oxide: Heavy metal
- Numerical issues (rare)

Except for the Classic output, no results are printed for other cases, since they are out of the physical realm of the code



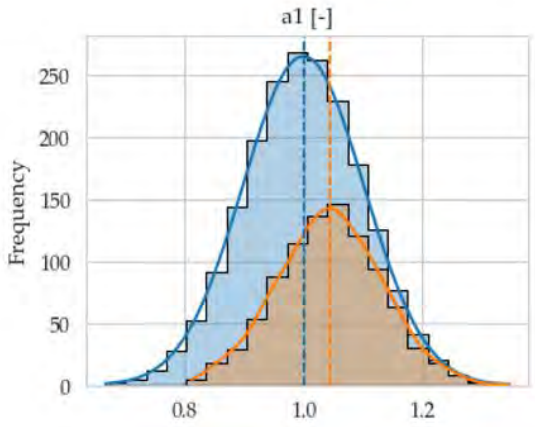
Design 1 properties only

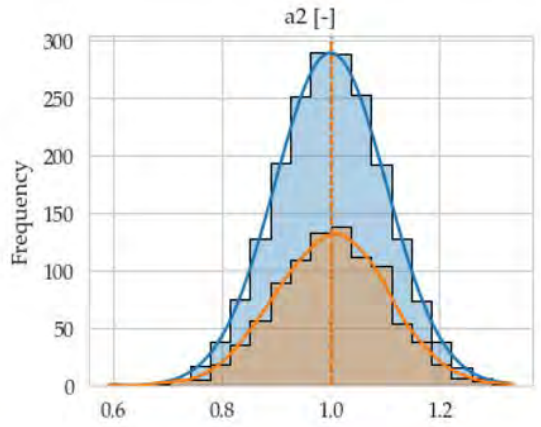
- a1: UO_2 density multiplier
- a2: Factor for metallic U density
- a3: ZrO_2 density multiplier
- a5: Zr density multiplier
- a6: SS density multiplier

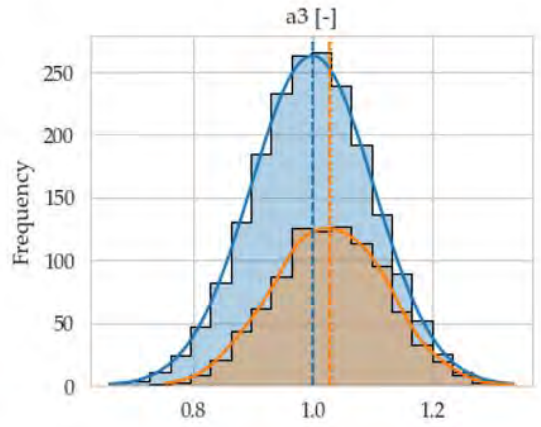
Initial distribution: given distribution by the user
Actual distribution: distribution filtered by W-STORM

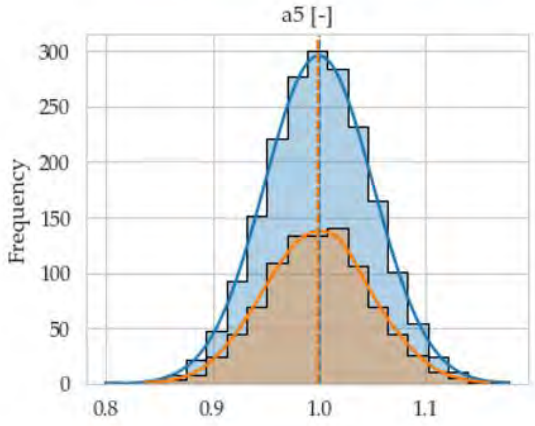
~50% of cases lead to the formation of a heavy metal!

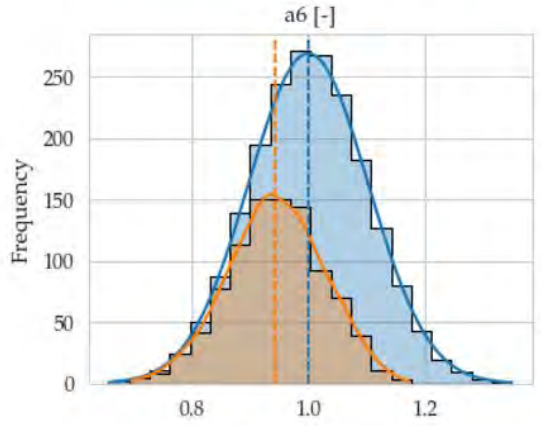
Actual distributions are shifted towards values that avoid heavy metal occurrence (i.e. , the low values for UO_2 density get filtered)











Distributions Summary

Var	n(i)	μ(i)	med(i)	std(i)	n(a)	μ(a)	med(a)	std(a)

Regarding average values, an expected picture is depicted just like the only properties calculation

Conclusions

- A W-STORM uncertainty and sensitivity analysis was carried out on SASPAM-SA designs through Monaco
- Reactor parameters and physical properties distribution were extrapolated from literature and from SASPAM-SA
- Spearman and Pearson coefficients for successful calculations are not informative (obvious relationships)
- Output parameters show an **expected picture** in IVMR in iPWR: thick dn crust, high radiative fraction, low aspect ratios, high power from oxide to metal, and limited focusing effect.
- Results further stress that in iPWRs there could be a high occurrence of Heavy Metal cases, due to a low steel to fuel mass ratio, **experimental data and heat transfer models are needed for this kind of configuration.**
- Frequency of occurrence of partial/ complete solidification cases (low FE) is significant. The confidence in this frequency is **limited**, due to the simple nature of the radiative heat transfer model in W-STORM. More **accurate radiative heat transfer models** should be implemented in SA codes, since radiative heat transfer can play a major role in the system's dynamics

ABSTRACT

The effectiveness of In-vessel Retention (IVR) strategy is critically governed by the ability of the external cooling to envelop the heat flux distribution imposed on the reactor pressure vessel (RPV) inner wall by the melt pool (i.e., the core melt relocated to the lower head of the RPV). The stratification behavior of the melt pool—particularly the separation of the light metallic layer from the oxide layer—significantly influences the heat flux profile along the RPV inner wall. Owing to its high thermal conductivity and small thickness, the upper light metallic layer may lead to a pronounced “hot-spot” (known as the “focusing effect”), which represents a critical factor threatening the integrity of the RPV.

To investigate the heat transfer mechanisms in stratified melt pools, this study employed the SAMPO test facility, which utilizes a 2D slice structure scaled 1:4 to the prototype RPV lower head as the test section. Chloride salts and Mg–Al alloy were used as simulants for the oxide and metallic layers, respectively. To reproduce the core melt relocation process in the RPV lower head, block-shaped Mg–Al alloy were first distributed inside the test section, after which prepared high-temperature molten chloride salt (600℃) was poured in. Then, the Mg–Al alloy was melted by the salt and naturally stratified with it, successfully forming a two-layer melt pool with a new stratification pattern.

1. INTRODUCTION

Nuclear power is widely recognized as an important clean energy source for humanity. Despite its distinctive characteristics and advantages as a clean energy, the massive public impact and huge socio-economic losses caused by severe accidents exert a profound influence on the global development of the nuclear industry. Historically, the Three Mile Island accident, the Chernobyl accident and the Fukushima nuclear accident [1] all triggered upheavals in the industry. To eliminate the risk of large-scale radioactive release, the third-generation nuclear power technology has developed In-Vessel Retention (IVR) and Ex-Vessel Retention (EVR) technologies respectively to respond to severe accidents. Among them, the IVR technology has been

* Footnote, if necessary, in Times New Roman font and font size 10

applied in both AP1000 and HPR1000, while the EVR technology has been adopted in EPR. This paper focuses on the heat transfer behavior of the in-vessel molten pool, a key phenomenon in the IVR technology.

Following a severe accident, the decay heat of core materials cannot be effectively dissipated, leading to core degradation. The resulting molten material migrates downward into the lower head of the reactor pressure vessel (RPV), forming a debris bed and potentially evolving into a molten pool. In the IVR scheme, to ensure the integrity of the RPV and mitigate the risk of large-scale radioactive release, the design incorporates External Reactor Vessel Cooling (ERVC)—whereby cooling water is supplied to the ex-vessel of the RPV lower head—to achieve effective cooling of the lower head. A critical challenge in this scheme is ensuring that the difference between the heat flux imposed on the inner wall of the lower head by the internal molten material and the cooling capacity of the external cooling water meets engineering threshold requirements. This ensures the lower head does not suffer melt-through or creep failure due to the decay heat of the internal molten corium.

In the early days, research on molten pool issues focused primarily on homogeneous molten pools, including experimental studies such as BALI, ACOPO and COPO, which yielded comprehensive findings on heat transfer in homogeneous molten pools [2-5].

However, with advances in materials science and the observation of metal phase separation during the MASCA project [6], the structural morphology of molten pools has evolved from homogeneous to double-layer or multi-layer configurations. Among these, the double-layer molten pool, featuring a light metal layer atop an oxide layer, has exerted a significant impact on existing IVR safety analyses. Due to its high thermal conductivity, the top metal layer induces a pronounced thermal focusing effect when it reaches a certain thickness, thereby challenging the feasibility of the IVR scheme.

International research on stratified molten pools has primarily centered on experimental facilities such as SIMECO and LIVE2D [7-8], yielding partial research data. Notably, the LIVE facility successfully achieved naturally stratified double-layer molten pools and verified the influence of the interphase shell on the thermal focusing effect. Nevertheless, molten pool experiments (including LIVE) are constrained by the temperature limits of simulant materials, preventing the simulation of heat transfer issues associated with low Prandtl (Pr) number metal layers. Consequently, uncertainties persist regarding the thermal focusing effect of metal layers in IVR applications.

To address molten pool problems involving low Pr number metal simulants, KTH Royal Institute of Technology in Sweden has developed chloride salt and low Pr alloy materials as simulants [9]. It plans to conduct experiments on heat transfer in stratified molten pools with a molten alloy top layer in the subsequent SIMECO-II experiment, aiming to supplement experimental data on heat transfer in low Pr number stratified molten pools.

To further advance experimental research on stratified molten pools, China Nuclear Power Engineering C O., Ltd. has constructed the SAMPO experimental facility [10], capable of conducting high-temperature (6 00°C) stratified molten pool experiments using chloride salt and magnesium-aluminum alloy as simulants. The first set of experiments focusing on stratified molten pools with ultra-thin metal layers has been compl eted.

2. Experimental Setup

2.1. SAMPO System

The SAMPO experimental facility adopts a two-dimensional 180° sliced configuration, with its geometric dimensions scaled at a 1:4 ratio relative to the lower head of China's HPR1000 reactor. The inner diameter

of the SAMPO test section is 1100 mm, and the slice thickness is 120 mm. The curved sidewall is made of stainless steel with a thickness of 30 mm, and a cooling water channel is designed outside the curved section to provide a constant-temperature cooling condition. The upper surface of the molten pool is a free liquid surface, and cooling water is contained in the top cover of the test section to ensure a constant temperature of the top structure. The front side adopts a double-layer glass structure: the inner layer is quartz, and the outer layer is high-temperature-resistant glass. The perimeter of the double-layer structure is equipped with a thermal insulation and sealing structure, which can effectively reduce heat loss through thermal convection. Through the visual surface, the molten pool morphology can be directly observed during the experiment.

The decay heat of the molten pool is simulated by heating with uniformly distributed heating rods. The molten material for the SAMPO experiment is prepared using the same smelting system, with the inner liner replaced according to the simulant materials at different temperatures. After the experiment, the simulant materials are recycled separately through recovery pipelines for reuse in subsequent experiments. The SAMPO system layout is shown in the Figure 1.

The molten salt furnace features an inner vessel constructed from commercially pure nickel. This material selection effectively mitigates the corrosive effects of chloride salts, ensuring structural integrity for up to 72 hours at 600 °C without severe corrosion failure. Consequently, this approach minimizes contamination of the molten salt by structural materials, thereby preserving its chemical purity.

Furthermore, in the SAMPO experimental system, an inert atmosphere is provided by argon gas from the protective gas system. Prior to the experiment, the protective gas system purges and maintains an inert atmosphere in all equipment of the experimental system. Before the injection of molten materials, the protective gas system is used to pressurize and control the system pressure, thereby facilitating the smooth injection of molten materials.

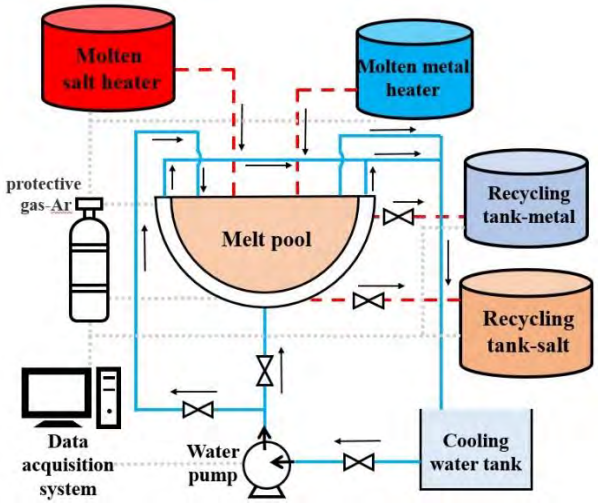

Figure 1. SAMPO System Scheme.

2.2. Simulant Materials

In the experiment, a ternary chloride mixed salt is used to simulate the lower oxide molten material, and a magnesium-aluminum alloy is used to simulate the upper metal molten material. The selected simulant materials meet the requirements for natural stratification in terms of density. Under experimental conditions, the density difference causes the magnesium-aluminum alloy to float above the molten salt layer, thereby achieving a double-layer molten pool structure similar to that of a prototype molten pool. Additionally, the Prandtl (Pr) number of the magnesium-aluminum alloy is close to that of the prototype metal layer material, enabling more accurate simulation of the molten pool heat transfer conditions. In this study, the purity of all

chloride salts employed exceeded 99%, while the magnesium-aluminum alloys were utilized in ingot form with impurity fractions below 1 wt%.

2.3. Instrumentation

The main measured data in this experiment are temperature signals, which are categorized by measurement area as follows: temperature inside the oxide layer molten pool, temperature inside the metal layer molten pool, inner wall temperature for heat flux measurement, outer wall temperature for heat flux measurement, and cooling water temperature. The scheme of the test section is presented in Figure 2.

- Thermocouples in the oxide layer molten pool: Arranged in layers at heights of 88 mm, 176 mm, 264 mm, and 352 mm respectively.
- Thermocouples in the metal layer molten pool: Start at a height of 440 mm, with a total of four layers spaced 44 mm apart.
- Thermocouple pairs for sidewall heat flux measurement: Divided into two regions, with the bottom of the test section as the 0° angle. One pair of thermocouples is installed every 5° from 0° to 65°, and another pair is installed every 2.33° above 65°. The thermocouples are perpendicular to the front surface of the curved section, and the measurement position is at the exact center of the curved section. The spacing between adjacent thermocouple pairs is 26 mm.
- The morphology of the crust layer is captured by a 4K high-definition camera. Flow meters are installed in each branch of the cooling channel of the test section to obtain actual cooling water flow rate data.

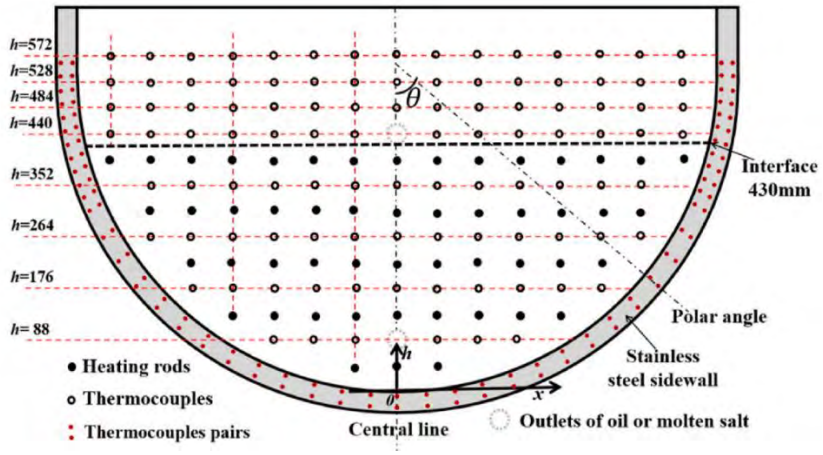

Figure 2. Distribution of TCs and Heating rods in SAMPO test section.

2.4. Experiment Matrix

To simulate the initial process of reactor core degradation and account for the threat of ultra-thin metal layers to IVR, fragmented oxide simulants and ingot-shaped metal simulants are pre-installed in the test section prior to the experiment. During the experimental preparation phase, molten chloride salt is prepared at 700℃ using a smelting furnace. After completing all preparation work, the molten chloride salt is injected into the test section via the injection system, and the heating power is gradually increased. Once the predetermined experimental operating conditions are reached, the cooling power and heating power are maintained to stabilize the system, thereby obtaining steady-state experimental data.

In this experiment, the theoretical injection level of the chloride salt reaches 430 mm, corresponding to a height angle of 77.4° for the curved section. The pre-installed magnesium-aluminum alloy in the test section melts to form a metal layer with a theoretical thickness of 40 mm. After injection, the molten salt is naturally melted by heat and forms a stratified structure. The decay heat power in this experiment is controlled at 10.8

kW. Basic experimental data of the high-temperature stratified molten pool are obtained through the establishment of a steady state. The experimental matrix is shown in Table 1.

Table I. Test Matrix

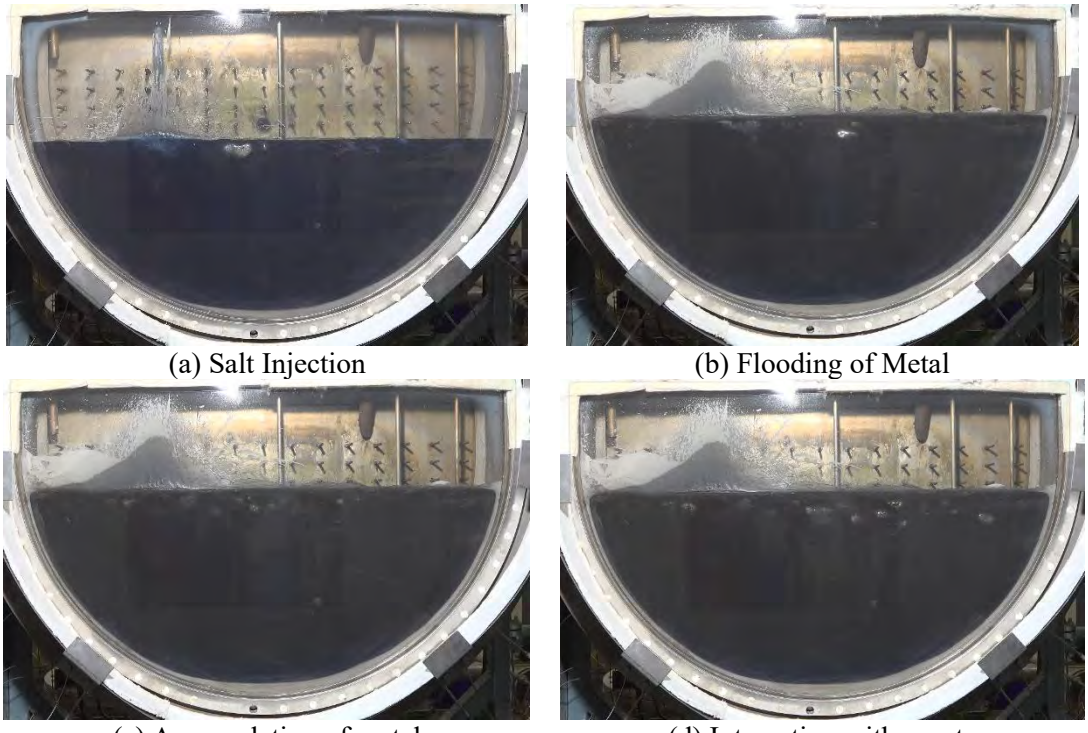
Oxide layer simulant	Height (mm)	Metallic layer simulant	Thickness (mm)	Heating Power (kW)
CsCl-KCl-LiCl	430	Mg-Al	40	10.8

3. Result

3.1. Stratification Process

After the injection of chloride salt, the gradual suspension and melting of magnesium-aluminum alloy ingots can be observed through the quartz glass. Due to their immiscible nature, obvious upward flow of molten metal droplets and aggregation at the top can be seen. However, a complete two-phase stratified state was not observed during the experiment: the formed metal layer only partially contacted the front glass surface, while most of it was encapsulated by the molten chloride salt. The entire process is shown in Figure 3.

Since aluminum in the magnesium-aluminum alloy reacts with quartz at high temperatures, the visualization process could only be maintained briefly during the high-temperature experiment. After the initial injection, as the reaction proceeded, the surface of the quartz observation window was gradually covered by reaction products. Only the gradual growth of the crust layer and the changes in crust thickness with variations in power could be observed.



(a) Salt Injection (b) Flooding of Metal

(c) Accumulation of metal (d) Interaction with quartz

Figure 3. Injection process

3.2. Temperature distribution

The temperature distribution along the centerline is shown in Figure 4. Based on the calculated volume of the molten material, the theoretical position of the phase interface should be at 430 mm, with a metal layer thickness of approximately 40 mm. Temperature signals of the metal layer near the phase interface can be obtained through the thermocouples arranged in the molten pool. The temperature signal at the centerline (0 mm horizontal position) is provided by the inner thermocouple of the 0° angle heat flux thermocouple pair. It can be observed that the temperature along the molten pool centerline increases with height, reaches the maximum below the phase interface, and the corresponding maximum centerline temperature is 518℃. Additionally, the temperature in the molten pool becomes basically uniform when the height exceeds 200 mm.

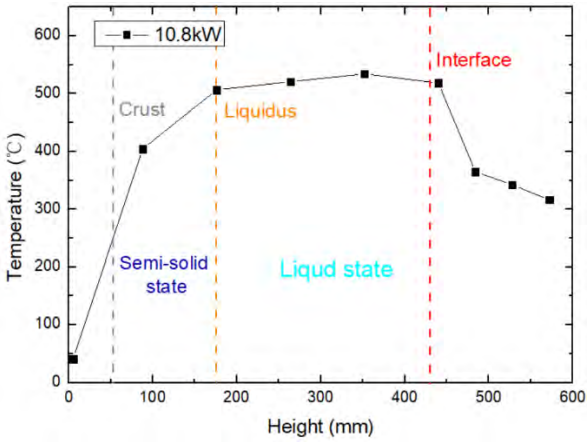


Figure 4. Centerline Temperature

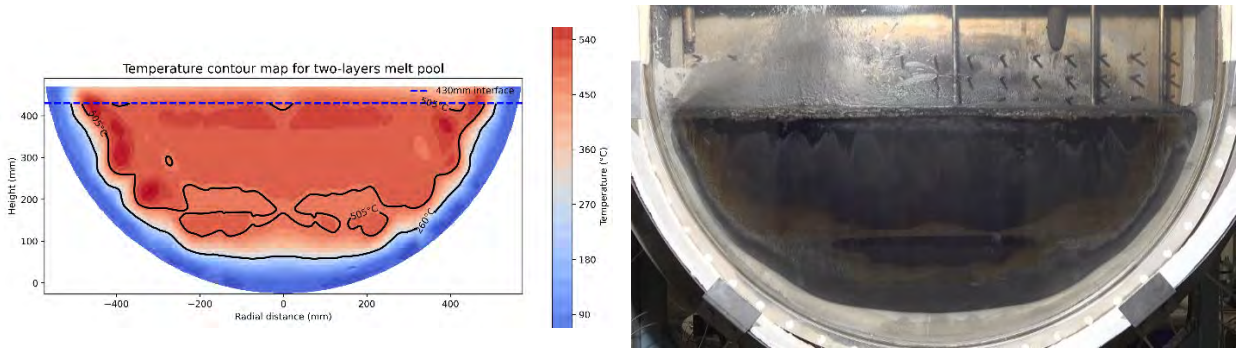
For the steady-state results, a molten pool temperature contour map was generated using the thermocouples arranged inside the molten pool, and the result is shown in Figure 5. As can be seen from the contour map, the approximate distribution structure of the crust layer is presented, where the blue dashed line marks the theoretical phase interface. Nevertheless, it can be observed that above the phase interface, the temperatures on both sides of the metal layer are relatively low, showing a temperature distribution similar to that of the shell layer. A distinct local hot spot appears near the left shell layer inside the molten pool. The visualization results show that the overall morphology of the molten pool crust layer is highly consistent with the trend of the contour map. The molten pool is completely enclosed by the shell, and no obvious metal phase interface is observed. The solidus and liquidus temperatures were superimposed on the temperature contour plots to visualize the temperature distribution within the molten pool under steady-state conditions.



(a) Temperature Contour Map (b) Visualize results

Figure 5. Result of Temperature Contour Map

Figure 5 presents the theoretical solidus and liquidus temperatures of the chloride salt analogue, denoted by the 260 °C and 505 °C isotherms, respectively. By measuring the radial distance between these isotherms

and the arc-shaped boundary of the molten pool, the corresponding crust thickness was determined. These results were subsequently compared with the steady-state crust morphology obtained via HD camera visualization, as illustrated in Figure 6.

The comparison reveals distinct trends across different circumferential angles. In the range of 0° to 45°, the crust thickness derived from HD visualization is greater than that obtained from the thermal contour analysis. Conversely, above 45°, the crust thickness calculated from the temperature field is larger. This discrepancy is attributed to the interpolation methodology applied to generate the temperature contours.

Specifically, the temperature field reconstruction utilized thermocouple readings from the sidewall heat flux sensors and internal probes as input data. Due to the non-uniform spatial distribution of measurement points—with local refinement near the wall at approximately ±65° while maintaining a constant density in the bulk melt—the cubic spline interpolation yielded a non-uniform nodal support domain. In regions with excessive near-wall point density, the interpolation function tends to pull isothermal surfaces toward the dense nodes, artificially smoothing the actual radial temperature gradient. This results in a slightly overestimated solidified crust thickness in these areas. Conversely, in the bottom region (0° ± 50°), where the mesh is relatively sparse and curvature is high, the interpolation locally amplifies the radial gradient, leading to a slight underestimation of the crust thickness. Nevertheless, the overall trend of crust distribution at the bottom remains consistent with the visual observations.

Finally, it was observed that the cooling water temperature exhibited minor sinusoidal fluctuations (amplitude: ±1 °C, period: ~5 min) during the entire steady-state process. However, no corresponding fluctuations in crust morphology were detected experimentally, likely due to the limited resolution of the optical imaging system.

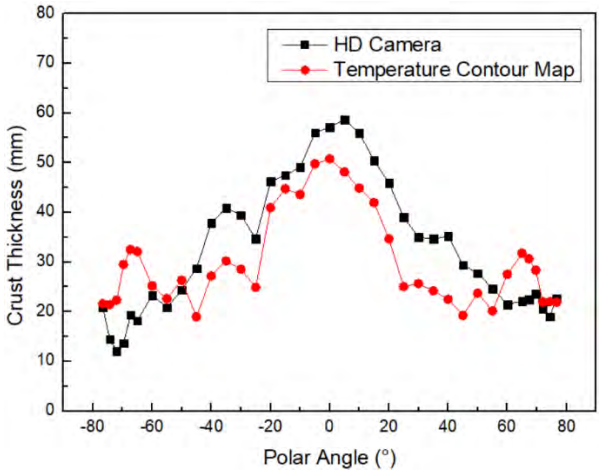


Figure 6. Crust thickness comparation between HD Camera and TC Map

3.3. Heat Flux distribution

The local heat flux was calculated using the temperature difference measured by the thermocouple pairs arranged on the sidewall and Fourier's Law of Heat Conduction:

$$q_w(\theta) = \lambda_{ss} \cdot \frac{T_{in}(\theta) - T_{out}(\theta)}{\mathrm{d}} \quad (1)$$

where $T_{in}(\theta)$ and $T_{out}(\theta)$ are the temperatures measured by the inner and outer thermocouples of the sidewall heat flux thermocouple pairs, respectively; d is the spacing between the two thermocouples, which is designed as 26 mm in this test facility; λ_{ss} is the thermal conductivity determined by the structural material. Since the test facility is made of stainless steel, the heat flux at the corresponding angle can be directly calculated using the above formula.

The distribution of heat flux on the left and right sides under the experimental operating condition is shown in the Figure 7. It can be found from the figure that the high-temperature region observed in the experimental contour map basically corresponds to the heat flux distribution. In this experiment, the theoretical phase interface position at 430 mm corresponds to a central angle of approximately 77°, a heat flux peak is observed in the heat flux distribution diagram around 70°. The theoretical maximum submergence height of the metal layer corresponds to a central angle of 81°; after the heat flux peak, a sharp decrease in heat flux is observed. However, no thermal focusing effect was observed during the entire experiment.

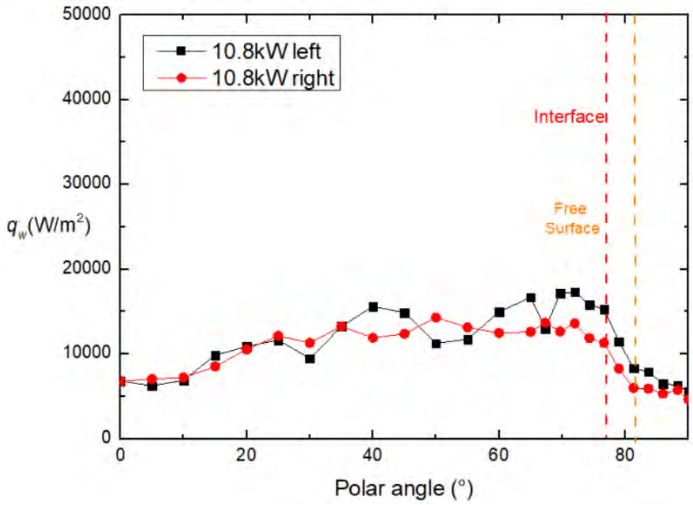

Figure 7. Heat Flux Distribution

Based on the heat flux distribution, the inner wall temperature $T_i(\theta)$ at corresponding angles can be calculated using Equation (2). Subsequently, the local solidified crust thickness and the average crust thickness are determined via Equations (3) and (4), respectively.

$$T_i(\theta) = T_{in}(\theta) + \frac{q_w(\theta) \cdot d}{\lambda_{ss}} \tag{2}$$

$$\delta_{calc}(\theta) = \lambda_{crust} \cdot \frac{T_{solid} - T_i(\theta)}{q_w(\theta)} \tag{3}$$

$$\overline{\delta_{calc}} = \frac{\sum \delta_{calc}(\theta) \cdot A(\theta)}{A_{tot}} \tag{4}$$

In Equation (2), d denotes the distance from the inner thermocouple of the pair to the inner wall surface. In Equation (3), T_{solid} represents the solidus temperature; for the data analysis in this study, the theoretical value of 260 °C was adopted. Here, $\delta_{calc}(\theta)$ corresponds to the solidified shell thickness at a given central angle. In Equation (4), $A(\theta)$ is the heat transfer area corresponding to the specific central angle, while A_{tot} refers to the total heat transfer area. A comparison of the normalized crust thickness is presented in Figure 7.

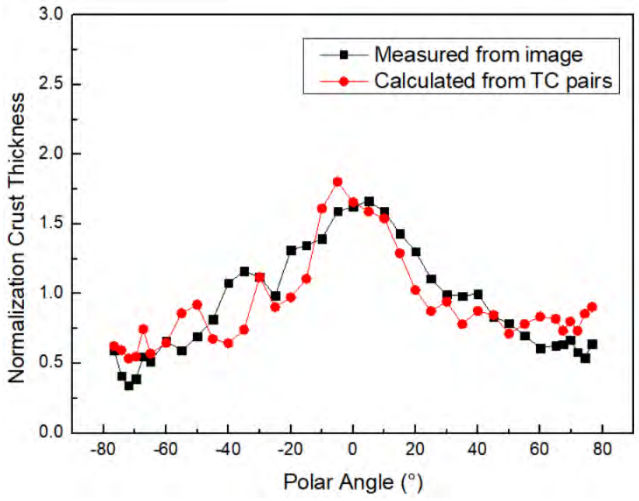

Figure 7. Comparison of normalized crust thickness between TC pairs calculation and HD visualization.

As shown in the figure, the crust thickness derived from the heat flux density exhibits a high degree of consistency with the image analysis results regarding the overall distribution trend. However, local deviations occur in the range of 40° to 60°. This anomaly is attributed to the configuration of the immersion heaters within the molten pool. The presence of the heater rods at these specific angles distorts the local heat flux measurements.

3.4. Cold-State Results

After the experiment, the system was naturally cooled while maintaining a constant-temperature boundary, and the internal state of the molten pool was observed. Upon opening the test section, the overall state of the molten pool is shown in Figure 8. A distinct gap is visible in the middle of the molten pool, which is consistent with the circumferential cooling process—since the central region cools last, a porous or vacuum structure is formed. This structure indicates that the solidification of the salt layer proceeds gradually inward from the curved section and the contact area with the top metal layer, thereby generating a local gap structure in the middle. In addition, as shown in the top view of the front side of the metal layer (Figure 9.), white chloride salt is present between the back plate and the metal layer. Combined with the observations from the front view, it is inferred that an ultra-thin contact may have formed between the metal layer and the back plate in practice.

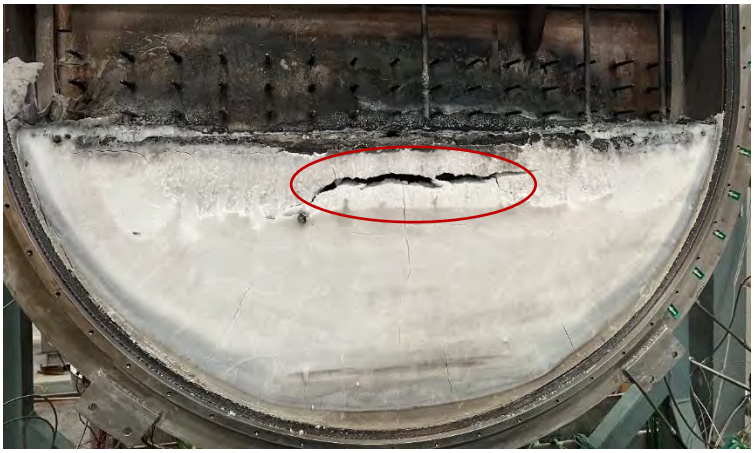

Figure 8. Solidified Molten Pool.

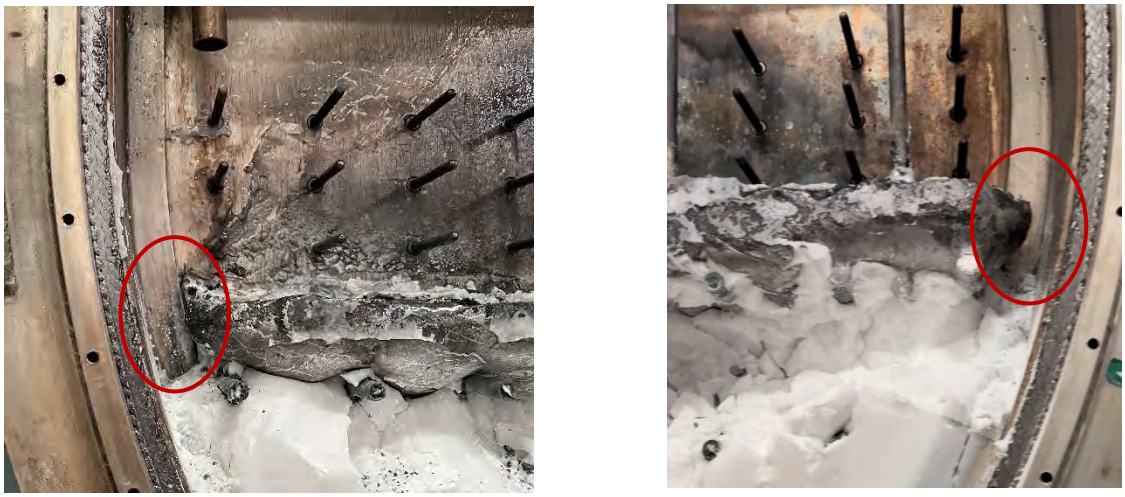
Figure 9. Solidified Molten Pool (Top View).

Further disassembly results are shown in Figure 10. After removing the salt layers on both sides, it was found that the metal layer was not in direct contact with the cooling sidewall. The bottom morphology of the metal layer is generally wavy, and the overall structure is thicker in the middle and thinner at both ends. This formed molten pool structure directly explains why no thermal focusing effect was observed in the sidewall heat flux results. Moreover, during the experiment, the volume of the metal layer caused direct displacement, leading to partial contact between the bottom of the metal layer and the heating rods. Consequently, in the temperature measurement data from the centerline thermocouples, the temperature inside the metal layer is close to the maximum temperature of the oxide layer. No temperature gradient resulting from a regular phase interface transition, such as those observed in water-oil or nitrate-heat transfer oil [10] operating conditions, was observed.



(a) Left Side (b) Right Side

Figure 10. Salt removed for Left side and right side.

4. CONCLUSIONS

The SAMPO experimental system is designed for conducting high-temperature molten pool experiments at 700℃. In this study, a naturally stratified molten pool experiment with a top metal layer having a Prandtl (Pr) number close to that of the prototype was successfully achieved. The experiment simulated the ultra-thin metal layer operating condition, and analyses were performed on the molten pool temperature

distribution, heat flux distribution, and cold-state structural morphology under high-temperature conditions. Based on the experiment, the key conclusions are summarized as follows:

- In the ultra-thin metal layer experiment, the temperature distribution along the centerline is consistent with the results of classical molten pool experiments. The centerline temperature in the molten pool first rises sharply with increasing height and then tends to stabilize. The temperature at the center and top of the molten pool is the highest and remains basically uniform.

- Affected by the morphology of the liquid metal, the top metal layer did not come into direct contact with the cooling sidewall during the actual experiment; instead, it formed an encapsulated morphology. This resulted in an overall sidewall heat flux trend similar to that of a homogeneous molten pool: the heat flux peak appears near a central angle of 70°, and the maximum submergence height angle of the molten material is approximately 82°, which is consistent with the heat flux distribution in homogeneous molten pools.

- The crust distribution trend derived from the heat flux density profile aligns closely with that obtained via visual observation. However, deviations arise primarily due to compositional changes in the chloride salt. The inherent corrosivity of high-temperature chlorides leads to metallic ion dissolution during both crucible preparation and experimental operation. Furthermore, impurities are introduced through chemical reactions between the magnesium-aluminum alloy and the quartz substrate. Since the current crust thickness calculations are predicated on the thermophysical properties of theoretically pure chloride salts, these alterations in composition inevitably result in discrepancies when comparing simulated results with visual data.

- This newly observed metal layer morphology differs from the commonly recognized stratified molten pool structure. Its formation may be attributed to the metal being pre-placed in the test section rather than injected from the top. However, due to the complexity of the actual conditions inside the reactor lower head, similar phenomena are likely to occur during core degradation. This phenomenon introduces new uncertainties: if chloride salt consistently forms an encapsulating layer on the sidewall as the metal layer thickness increases, the heat transfer characteristics of the molten pool under such conditions will be similar to those of a homogeneous molten pool, posing no threat to the existing IVR technology. Nevertheless, based on the currently observed metal layer structure, another possibility cannot be ignored: as the metal layer thickness increases, contact with the cooling sidewall may occur at a certain thickness. If this process is extremely slow, it may lead to prolonged excessively high local heat flux, thereby endangering the safety of IVR.

Therefore, as the first experiment in the series of high-temperature molten pool experiments, this study has gained valuable experimental experience. Meanwhile, the metal layer morphology observed in this experiment requires further comparison through subsequent experiments to verify and confirm the authenticity of such a morphology.

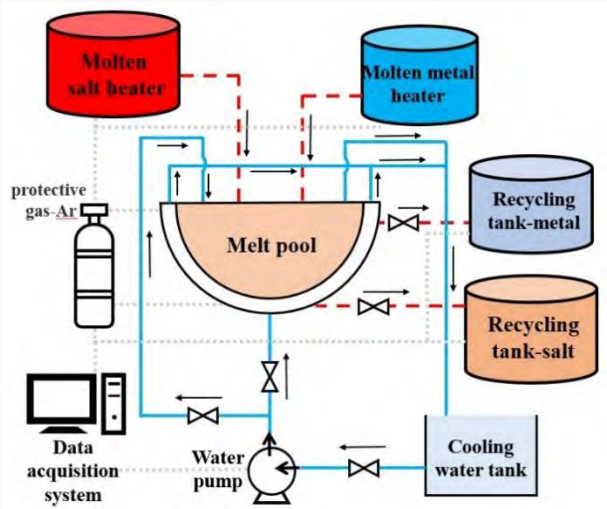
Experimental Setup

II. Experimental Setup

SAMPO | Simulant | Instrumentation | Test condition

SAMPO System Introduction



- Melt Pool Test Vessel
  - 1:4 Scale 180° 2D Slice facility
  - 120 mm Thickness
  - 30 mm thick vessel wall in ss
  - Decay heat power: up to 35 kW
- Ar-Gas protective system
- Corium preparation and recycle system
- Cooling System

II. Experimental Setup

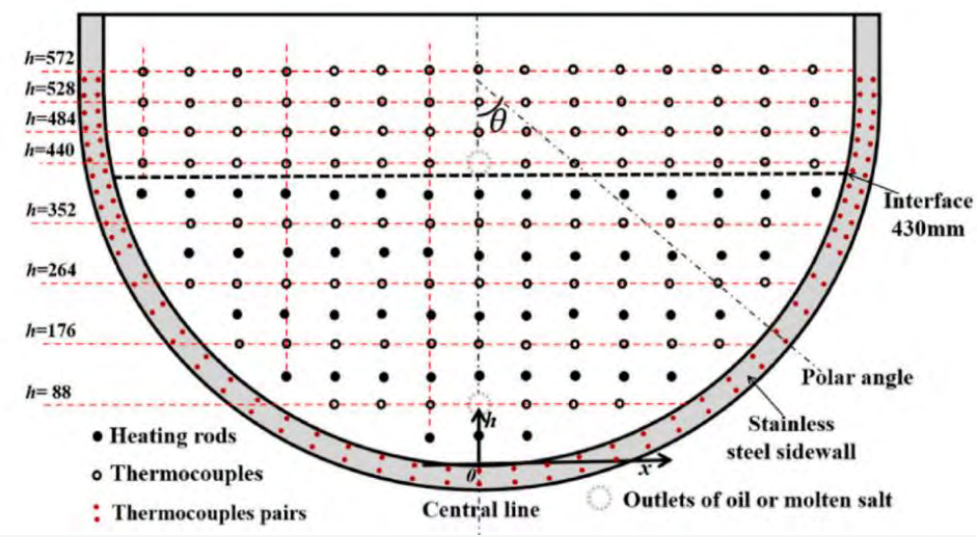
Simulant

- Oxide simulant: CsCl-KCl-LiCl (Purity ≥ 99%)
  - Stable at 600℃
  - Larger density
- Metallic simulant： Mg-Al (Ingot)
  - Melting point at 437℃
  - Low Pr (~0.01)
  - Low density

II. Experimental Setup

SAMPO | Simulant | Instrumentation | Test condition

Instrumentation



- Molten pool TC
  - Oxide layer：88 mm. 176 mm. 264 mm. 352 mm
  - Metallic layer： 440 mm, spaced at 44 mm, 4 layers in total
- Side wall TC pairs: Distance between: 26 mm
  - 0~65° ： Every 5°
  - 65~90° ： Every 2.33°
- 4K High-Definition Camera

II. Experimental Setup

SAMPO | Simulant | Instrumentation | Test condition

Test condition

- Simulate the initial process of reactor core degradation and account for the threat of ultra-thin metal layers
- Oxide layer height (theoretically): 430 mm
- Metallic layer height (theoretically): 40 mm

Oxide Simulant	Height(mm)	Metallic simulant	Height(mm)	Power(kW)
CsCl-KCl-LiCl	430	Mg-Al	40	10.8

Stratification process | Temperature Distribution | Heat Flux Distribution | Cold-State Results

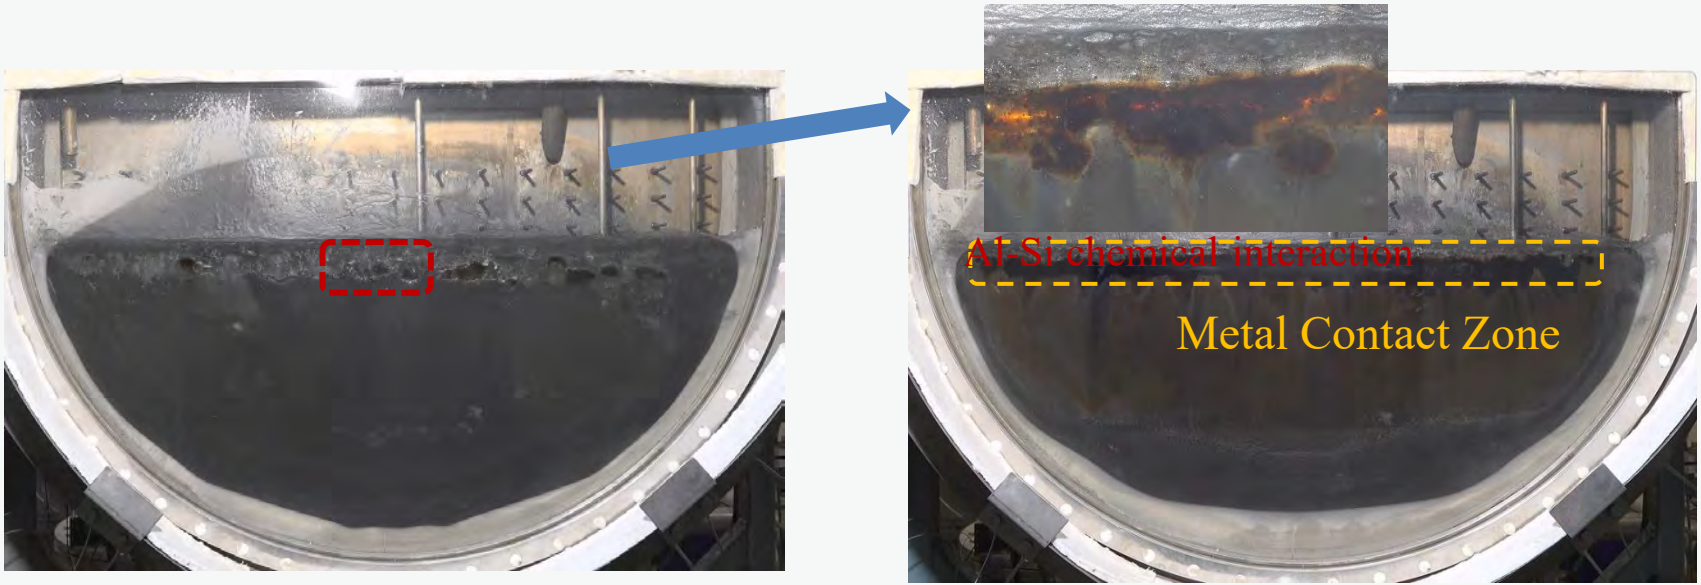
Molten metal aggregation

- Molten metal accumulates at the top of the melt pool.
- No obvious stratification was observed.
- As the reaction between quartz glass and metal progresses, observation of the metal layer morphology becomes increasingly difficult.
- The morphology of the crust layer can still be observed.

III. Results

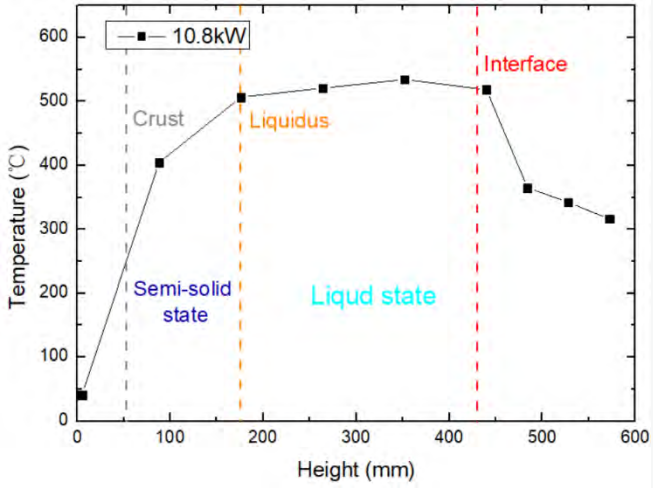
Stratification process | Temperature Distribution | Heat Flux Distribution | Cold-State Results



Reaction between metal and quartz glass

III. Results

Stratification process | Temperature Distribution | Heat Flux Distribution | Cold-State Results

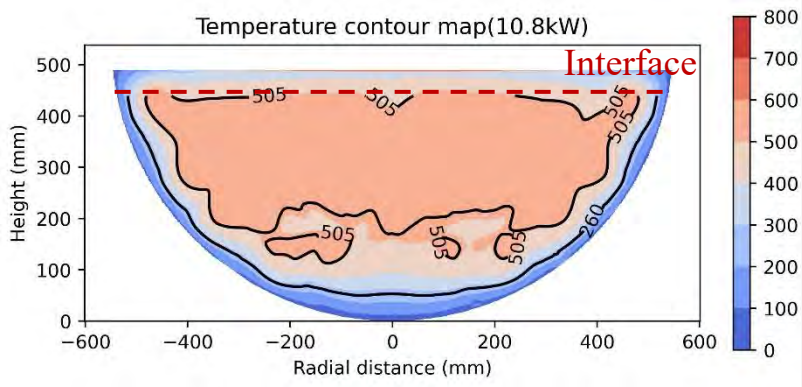


Temperature distribution along the centerline

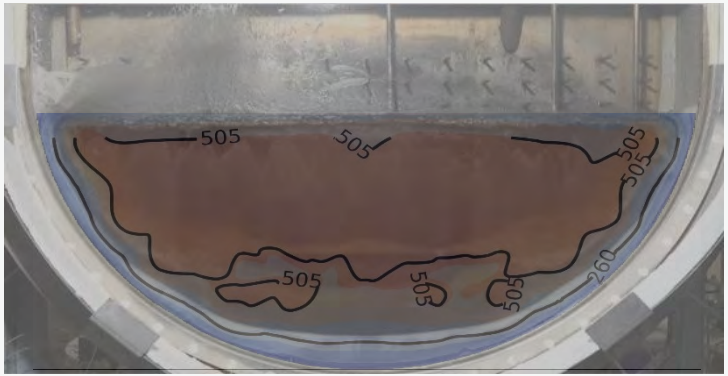
- At the 0 mm position, the centerline temperature is provided by the thermocouple pair measuring heat flux at 0° , on the inner side of the corresponding thermocouple.
- The centerline temperature increases with the height of the melt pool.
- The maximum temperature below the phase interface is 518 ℃
- Above 200 mm, the melt pool temperature is essentially uniform.

III. Results

Stratification process | Temperature Distribution | Heat Flux Distribution | Cold-State Results



Temperature Contour Map

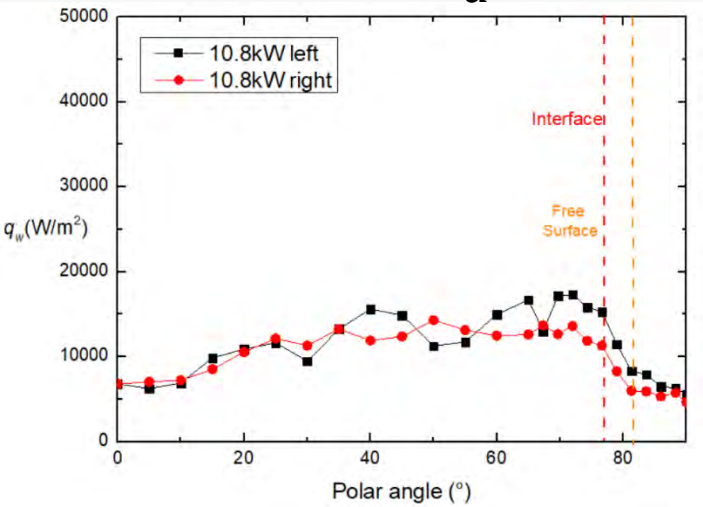


Visualize results for steady state

- On both sides of the metal layer above the interface, temperatures are lower, exhibiting temperature distribution characteristics similar to those of a shell layer.
- Localized hot spots appear clearly within the melt pool relates to the heater.
- The visualization results agree well with the contour plots, no distinct interface is observed.

III. Results

$$q_w(\theta) = \lambda \cdot \frac{T_{in}(\theta) - T_{out}(\theta)}{\mathrm{d}}$$

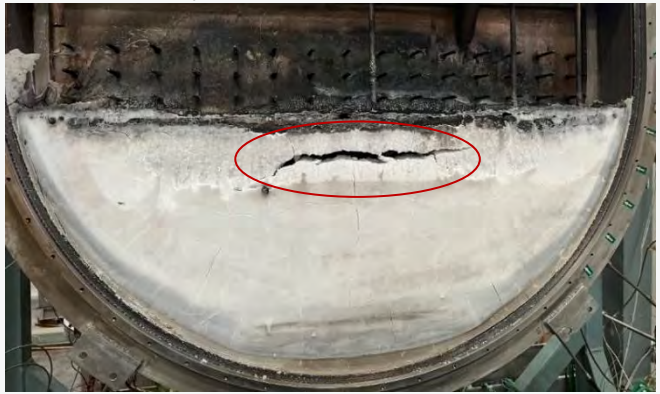


Side wall heat flux distribution

- The high-temperature regions in the experimental contour plot generally correspond to the heat flux distribution.
- At 430 mm, the theoretical phase interface is located at a center angle of 77°, while the heat flux peaks near 70°.
- The theoretical maximum liquid level is at 81°, and the heat flux drops sharply around this angle.
- No focusing effect was observed during the experiment.

III. Results

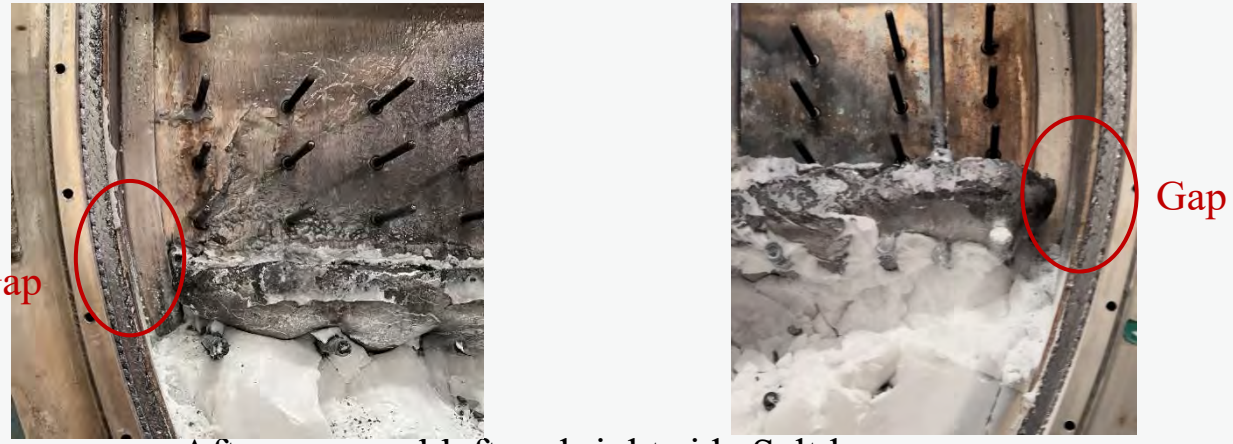
- Visible gaps appear in the solidified pool, which is consistent with the circumferential cooling process. Since the central region cools last, a porous or void structure is formed.
- White chloride salts are presented between the backplate and the metal layer; in the actual experiment, a relatively thin contact formed between the metal layer and the backplate.



Solidified Pool (Removed the quartz front)

III. Results

- The metal layer is not in contact with either side.
- Metal layer bottom shows a wavy profile: thick in the middle, thin at the ends. This melt pool structure explains why no thermal focusing effect is observed in sidewall heat flux.
- No Temperature gradient from regular phase interface transition is observed.



After removed left and right side Salt layer

04

Conclusion

IV. Conclusion

- In this thin metal layer experiments, the centerline temperature distribution agrees well with classical molten pool results. The centerline temperature initially rises sharply with height, then levels off. Temperatures at the pool center and top remain highest and essentially uniform.

- Due to the morphology of the molten metal, the top metal layer does not directly contact the cooled sidewall in the actual experiment, instead forming an encapsulated configuration. Consequently, the overall trend of sidewall heat flux resembles that of a homogeneous molten pool: the heat flux peaks near a center angle of 70°, and the maximum submergence angle of the molten material is approximately 81°, which is consistent with the heat flux distribution in a homogeneous molten pool.

IV. Conclusion

Newly observed metal morphology deviates from classic stratified pool, possibly due to pre-placed vs. injected metal. Yet, given lower head complexities, similar behavior is plausible during meltdown, introducing new uncertainties:

- If chloride salt maintains sidewall encapsulation with increasing metal thickness, pool heat transfer mimics homogeneous case, posing no risk to current IVR.
- With increasing metal layer thickness, sidewall contact may occur. If too slow, prolonged high local heat flux could compromise IVR safety.

ABSTRACT

In recent years, small and modular reactors (SMRs) have gained increasing attention in the nuclear energy sector. The SASPAM-SA project addresses, among other topics, severe accident strategies such as in-vessel melt retention (IVMR) in SMRs. Within this project, the IVMR strategy for a specific SMR design has been investigated by the Lithuanian Energy Institute (LEI) in cooperation with GRS, using the AC^2 system code (GRS, version 2023.4). This paper presents the main results of these analyses. The investigated reactor design is an integrated PWR with a classical type of spherical containment. The containment has a concrete floor and a cavity for reactor pressure vessel (RPV), which can be flooded in case of IVMR.
Using the stand-alone lower plenum module of AC^2, simulations were performed to assess the thermal response of the RPV under severe accident conditions. A comprehensive uncertainty and sensitivity analysis was performed, focusing on the uncertain parameters defining configuration and properties of molten materials (fuel mass, power density, etc.). The results show that even under conservative assumptions, the IVMR strategy is effective: the maximum outer heat flux (~259 kW/m²) remains well below critical heat flux thresholds, and the minimum residual vessel wall thickness exceeds 15 cm in all cases. The observation of focusing effect was limited, as the heat flux from the oxidic layer exceeded heat flux from the metallic layer. The analysis confirms that IVMR strategy is expected to be successful for investigated design, provided the cavity remains flooded. The findings support the applicability of AC^2 for IVMR evaluation in SMRs and highlight the importance of model assumptions and parameter uncertainties in safety margin assessments.

1. INTRODUCTION

Small Modular Reactors (SMRs) are increasingly regarded as a promising for deploying future nuclear reactor technologies. Their design focuses on achieving higher levels of safety and improving economic

performance, largely by reducing upfront investment costs and shortening construction time as a mass production.

In the range of SMRs, integral Pressurized Water Reactors (iPWRs) are considered as promising, since they are based on the previous generation Light Water Reactor (LWR) technology, but at the same time, introducing several advancements. Their inherent features are lower power output, an integrated design of Reactor Pressure Vessel (RPV) and safety ensured mainly by passive safety systems.

Even though SMR is a smaller reactor, it is nonetheless a nuclear installation, and safety is top priority. It must be demonstrated via safety analyses that the plant can operate safely. These analyses include design basis accidents (DBA), as well as design extension conditions (DEC). When it comes to severe accident (SA) management with significant core damage (DEC-B), the majority of currently developed SMR designs [1] rely on In Vessel Melt Retention (IVMR) as a severe accident management strategy (SAMS), to mitigate the consequences of SA.

In-vessel melt retention (IVMR) has been extensively investigated for High-Power Reactors (HPRs). Several modern reactor concepts, such as the AP1000 [2] and HPR1000 [3] incorporate this approach in their designs. The same strategy shows strong potential for integral pressurized water reactors (iPWRs) as well, and dedicated studies are being conducted within the Horizon Europe–Euratom project SASPAM-SA (Safety Analysis of SMR with Passive Mitigation Strategies – Severe Accident) [4], led by ENEA - a scientific research organization in Italy.

One of the key objectives of the SASPAM-SA project is to establish credible severe accident scenarios for iPWRs, assess how well existing experimental data apply to these reactor types, and identify the knowledge gaps that will require new experimental investigations. The project considers two generic iPWR designs for its analyses, named Design 1 and Design 2. Both SASPAM-SA designs share similar layouts within the RPV and SA mitigation, based on IVMR strategy.

This paper presents the work performed by the Lithuanian Energy Institute (LEI) in cooperation with GRS for Design 2 (**Figure 1**), which features several passive systems, a dry containment, and an electric power output of around 300 MWe. The analysis was performed using the AC² system code (GRS, version 2023.4), focusing on stand-alone lower plenum calculations with comprehensive uncertainty and sensitivity analysis. The uncertainty and sensitivity analysis was performed using the SUSA 4.2 software (GRS).

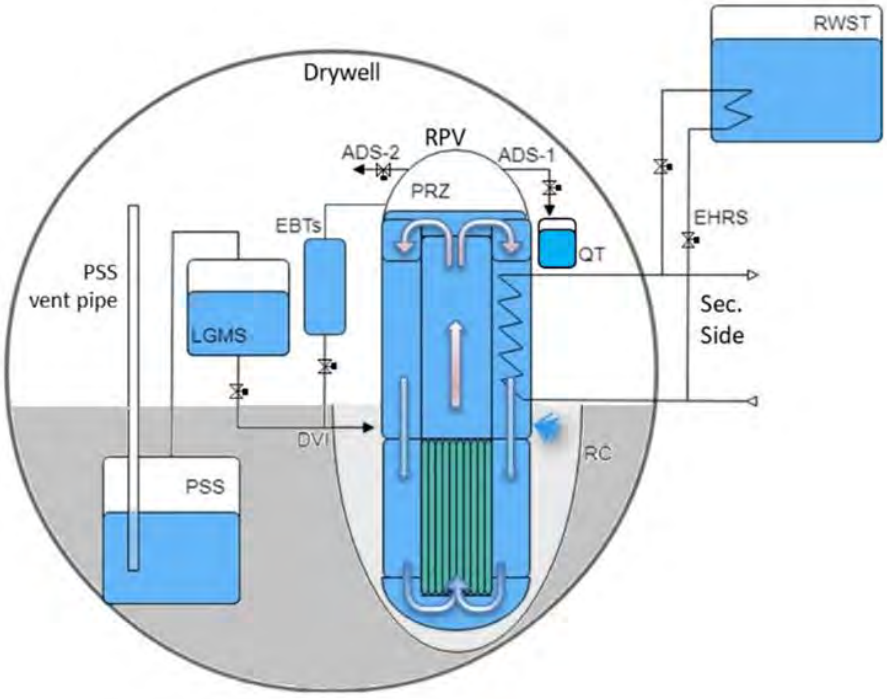

Figure 1. Design 2 layout.

2. AC² CODE AND MODELING APPROACH

2.1. AC² Code System

The code system AC² is the collection of GRS system codes ATHLET, ATHLET-CD and COCOSYS for the simulation of normal operation, transients, accidents up to severe accidents with radioactive release at the site boundary. ATHLET (Analyse der THermohydraulik von LEcks und Transienten) simulates the thermohydraulic behaviour in the reactor. ATHLET-CD (Core Degradation) extends these thermohydraulic modules with models for severe accident phenomena. The most important modules of ATHLET-CD include ECORE for core heat-up and degradation, FIPREM for fission product release, SAFT for transport and deposition, and AIDA/LHEAD for lower plenum processes and ex-vessel cooling.

2.2. AIDA Module for Lower Plenum Analysis

The AIDA module of ATHLET-CD is intended for simulation of late accident phenomena in the lower plenum. The module is an integral part of ATHLET-CD, and it also provides possibility of stand-alone simulation. It is equipped with a two-layer corium model (metal layer over the oxide layer), as illustrated in **Figure 2**. AIDA solves a 0-dimensional heat balance equation for each of the two layers and the interlayer crust. The crust formation between the wall and the oxide layer and between the oxide and metal layer is calculated with a 2-dimensional scheme.

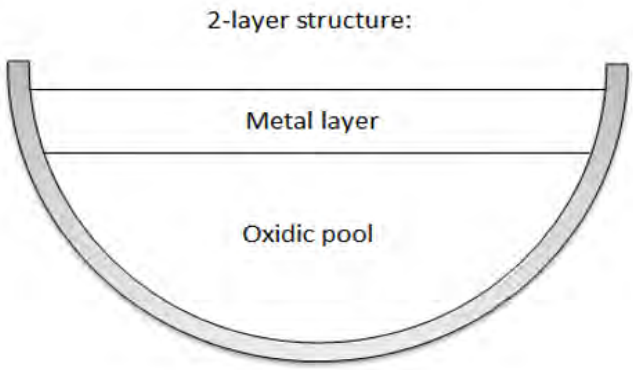

Figure 2. Two-layer corium configuration in AIDA module - metal layer above oxidic pool.

The current version of AIDA is able to simulate hemispherical, elliptical, trunked elliptical and trunked hemi-spherical lower plenum shapes together with the lower cylindrical part of the RPV. The wall ablation as well as the crust along the ablated wall are modelled.

2.3. Modelling Configuration for Design 2

For the Design 2 analysis, a stand-alone AIDA model was developed with detailed nodalization of the lower head geometry. The lower head nodalization (**Figure 3**) consists of 50 axial nodes for the hemispherical section and 27 axial nodes in the cylindrical part, with 20 radial rings providing sufficient spatial resolution for accurate heat transfer calculations.

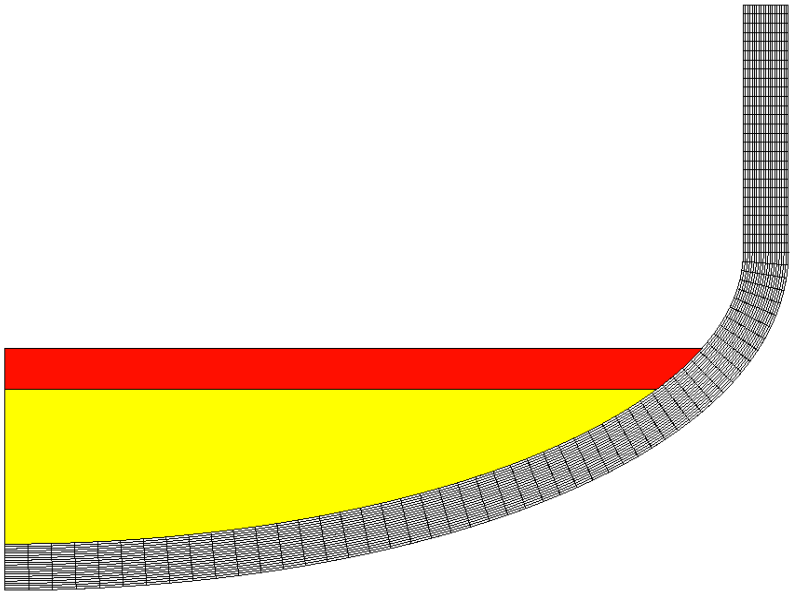

Figure 3. Lower head nodalization in AIDA showing 50 axial nodes in hemisphere and 27 nodes in cylindrical part with 20 radial rings.

A two-layer configuration is considered with the metal layer on top of the oxidic layer. Since AC² does not take into account thermochemistry, the configuration is the same during the entire simulation. For heat transfer from oxidic melt to upper crust, the Kelkar correlation was used. For heat transfer from oxidic melt to lower crust, the Asfia-Dhir correlation was used (**Figure 4**). These correlations were selected basing on AC^2 manual, where the code developers suggest using Kelkar(4)/Asfia-Dhir(7) or Bonnet-Seiler(6)/ Bonnet-Seiler(8) for upward/sideward heat transfer in real reactor simulations. However, Bonnet-Seiler correlations have a specified validity range of $10^{13}<Ra<10^{17}$, and since in current scenarios Ra is expected to be in ~10^{10} range, the Kelkar/Asfia Dhir correlations were selected. In all calculations it was assumed that 10% of the decay heat is present in the metallic layer, and 90% in the oxidic layer.
Since radiation from the metallic layer is modelled, the internal RPV structures are assumed to be at a constant 1100 K temperature as a boundary condition.

Nr.	Correlation for upward heat transfer (NCOUP)		Validity range
1	Kulacki-Emara (experimental)	$Nu = 0.34\ Ra^{0.226}$	
2	Mayinger (experimental)	$Nu = 0.345\ Ra^{0.233}$	
3	Mayinger (numerical sim.)	$Nu = 0.4\ Ra^{0.2}$	
4	Kelkar (numerical sim.)	$Nu = 0.18\ Ra^{0.237}$	
5	Reineke (numerical sim.)	$Nu = 0.49\ Ra^{0.18}\left(\frac{h}{R}\right)^{0.29}$	
6	Bonnet-Seiler (Exp. COPO-BALI)	$Nu = 0.381\ Ra^{0.234}$	$10^{13} < Ra < 10^{17}$
	Correlation for sideward heat transfer (NCODN)		
1	Mayinger (numerical sim.)	$Nu = 0.55\ Ra^{0.2}$	7 $10^{6} < Ra < 5$ 10^{14}
2	Kelkar (numerical sim.)	$Nu = 0.1\ Ra^{0.25}$	$Ra < 10^{16}$
3	Mini-ACOPO (experimental)	$Nu = 0.2\ Ra^{0.3}$	$10^{12} < Ra < 7$ 10^{14}
4	Jahn-Reineke (experimental)	$Nu = 0.54\ Ra^{0.18}\left(\frac{h}{R}\right)^{0.26}$	4 $10^{12} < Ra < 1.8\ 10^{13}$
5	Reineke (numerical sim.)	$Nu = 0.49\ Ra^{0.18}\left(\frac{h}{R}\right)^{0.29}$	
6	Reineke (numerical sim.)	$Nu = 0.64\ Ra^{0.18}\left(\frac{h}{R}\right)^{0.29}$	
7	Asfia-Dhir (experimental)	$Nu = 0.54\ Ra^{0.2}\left(\frac{h}{R}\right)^{0.25}$	
8	Bonnet-Seiler (Exp. COPO-BALI)	$Nu = 0.131\ Ra^{0.25}\left(\frac{h}{R}\right)^{0.19}$	$10^{13} < Ra < 10^{17}$

Figure 4. Available and selected correlations for heat transfer in the oxidic layer in AC² code (Kelkar for upward and Asfia-Dhir for sideward heat transfer).

The RPV surroundings (ex-vessel) temperature was set to 373 K, and heat transfer coefficient from external RPV surface to the surroundings was set to 10,000 W/m²K. The cavity is considered as always full of water, representing continuous external cooling conditions. These boundary conditions represent a bounding assumption for forced convective external cooling with the reactor cavity permanently flooded, consistent with IVMR success criteria. In this paper the focus is on in-vessel corium behavior and the resulting heat fluxes. For the actual IVMR evaluation and safety demonstration, the external reactor vessel cooling topic should be investigated separately.

3. INPUT DATA AND UNCERTAIN PARAMETERS

The input data for the Design 2 stand-alone calculations were consolidated from integral calculations results within the SASPAM-SA project. The reference design has a thermal power of 1000 MWth with a total UO_2 mass of 58 tonnes and Zr mass of 19.5 tonnes. The lower plenum internal radius is of 3.1 m for the lower head with a semi-elliptical shape and a height of 1.2 m. The vessel wall thickness is 19 cm in the reference case.

For the uncertainty analysis, ten key parameters were identified as having significant influence on IVMR performance. These parameters were varied within specified ranges. The parameters were selected based on integral simulations of SA scenarios, performed within SASPAM-SA project in a separate work package. These analyses showed the variation of material masses, proportions slumped in the lower head and other parameters, depending on the scenario, code used and applied assumptions. A uniform distribution was

assumed for all uncertain parameters in uncertainty analysis, and full dependence was considered between UO_2 mass and Zr mass. A total of 100 cases were generated to provide good coverage of the parameter space while maintaining computational efficiency. Each case was run to steady-state conditions to evaluate the corium thermal-hydraulic behavior and structural response of the vessel. The uncertain parameters and their ranges are presented in **Table I**.
The reference case was assumed to be the "expected worst case" scenario, where the entire fuel inventory slumps into the lower head with the highest power density. However, the uncertainty analysis should provide insights into whether there are some combinations, where, e.g., metal layer thickness or other parameters lead to even higher heat fluxes, despite fuel mass of power density are not at maximum.

Table I. Uncertain parameters reference values and uncertainty ranges

ID	Parameter	Reference	Minimum	Maximum
	Geometry of LP			
Par. 1	**Thickness of vessel (cm)**	**0.19**	**0.17**	**0.21**

4. RESULTS AND DISCUSSION

4.1. Reference Case Results

The reference case calculation demonstrates successful IVMR with a stable two-layer configuration. **Figure 5** shows the final steady state temperature distribution and corium layer configuration. The oxide layer settles at the bottom of the lower plenum (HPOOL=0.79 m) with the metallic layer on top (HML=0.17 m). The average temperature in the metallic layer is 1524 K, while the oxide pool reaches 3729 K. A solid crust forms at the interfaces between the molten pool and the vessel wall. The 1524 K temperature of the metallic layer is rather low, which indicates that there is a fraction of solidified light metal, since liquidus temperature of the metallic layer is set to 1600 K. Unfortunately, there is no possibility to present the metallic layer crust thickness or solidified mass, because AC^2 version 2023.1, which was used for these calculations, does not provide such quantities. Newest AC^2 version 2025.0 was updated accordingly and is now able to output these quantities.

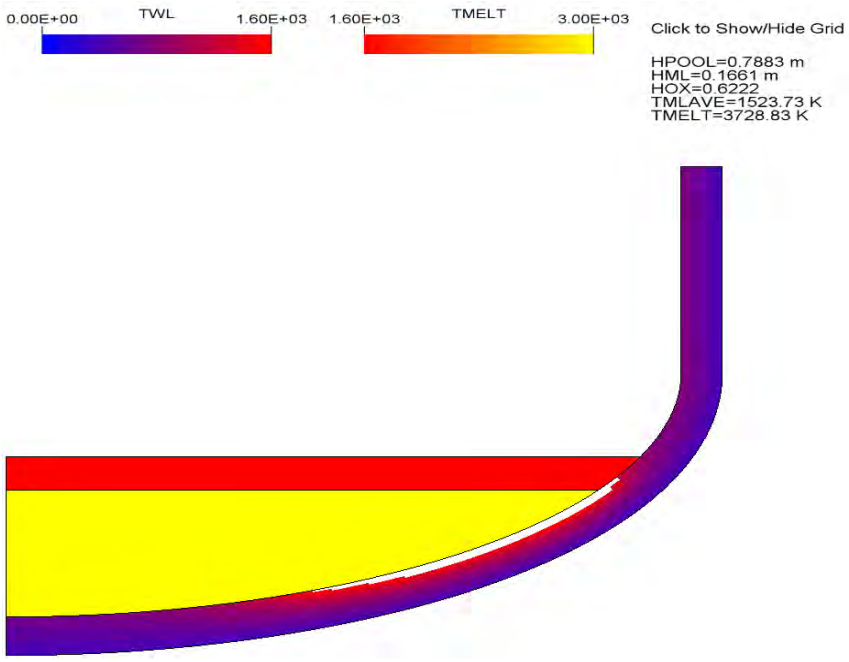

Figure 5. Final steady state of reference case showing wall temperature (TWL) and melt temperature (TMELT) distributions with layer heights.

4.2. Uncertainty Analysis Results

The uncertainty analysis performed by running 100 cases shows that IVMR is expected to be successful within the parameters range. The maximum outer heat flux is estimated from approximately 104 kW/m² to 259 kW/m² considering all cases (**Figure 6**). The minimum residual vessel wall thickness shows variation from approximately 15 cm to 21 cm (**Figure 7**). Notably, even in the worst case, the residual thickness exceeds 15 cm, well above the minimum structural requirement, which is usually assumed around 3 cm [6]. The main results of reference case and the extremes are presented in Table II.

Table II. Main results

Results	Reference	Minimum	Maximum
Min. residual vessel thickness (cm)	15.2	15.2	20.9
Max. local outer HF (kW/m²) at steady-state	259.1	104.8	259.1
Focusing factor	0.85	0.84	0.98
Thickness of top metal layer (m)	0.166	0.123	0.199
Thickness of oxide layer (m)	0.622	0.414	0.666
Lower crust thickness max. (cm)	4.7	4.7	6.7
Top crust thickness (cm)	2.9	2.8	5.6
Power lost by radiative HF / Total power	0.22	0.13	0.26

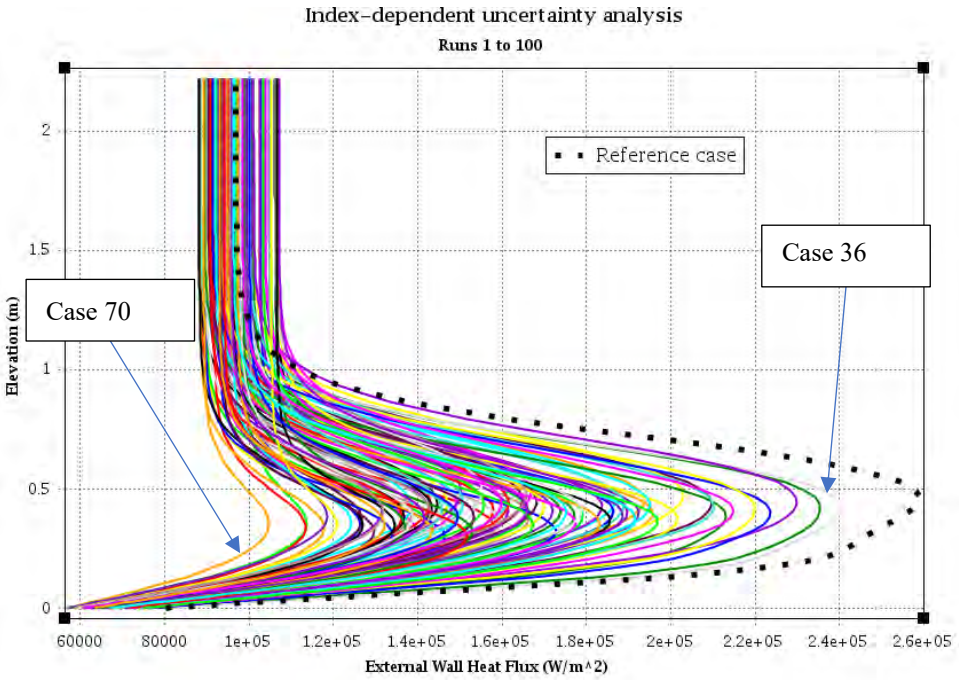

Figure 6. Uncertainty Analysis – axial Heat Flux profile (W/m²K) for all 100 cases.

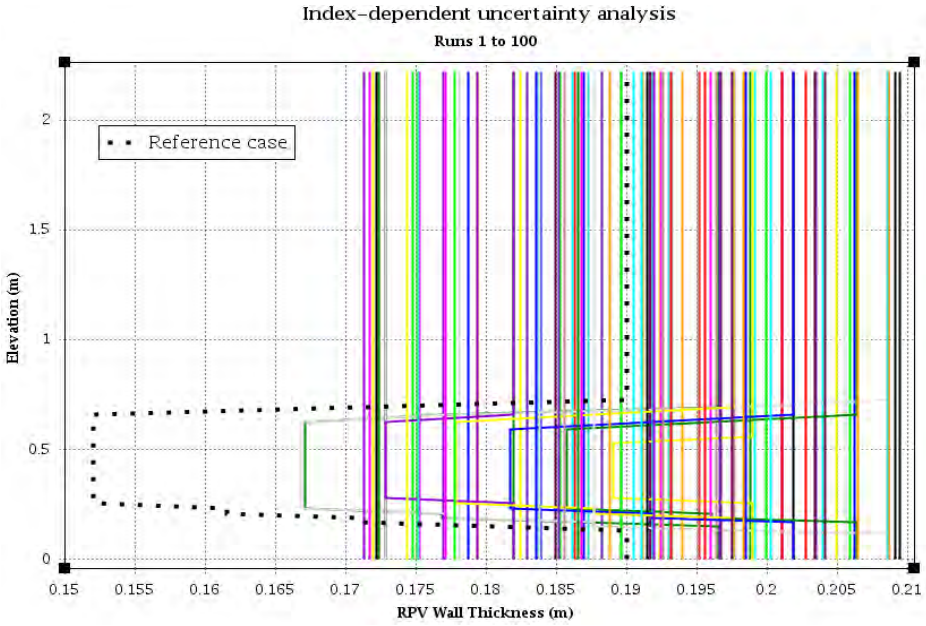

Figure 7. Axial wall thickness profiles for all 100 cases showing variation from 0.15 to 0.21 m. Reference case shown as dashed line.

The focusing factor (ratio of maximum outer heat flux in the top metal layer to maximum outer heat flux in the oxide layer) ranges from 0.84 to 0.98 across all cases. All values are less than 1.0, indicating that the oxide layer heat flux exceeds the metallic layer heat flux in all cases. This demonstrates that the focusing effect is not observed in Design 2, which is beneficial for IVMR success. However, the power split between layers is highly dependent on correlations used, so this is potentially a subject of code and user effect.

4.3. Comparison With CHF and Safety Margins

A critical aspect of IVMR evaluation is comparison of the calculated heat flux with the critical heat flux (CHF) threshold. For the external cooling configuration of Design 2, CHF findings by different experimental programs, (e.g. ULPU [5]), suggest values in the range of 1.0-1.5 MW/m² for the lower head region depending on wall inclination angle. Design 2 features a semi-elliptical lower head; the maximum heat flux of 259 kW/m² occurs at approximately 30-60° inclination from vertical, where available CHF data suggest local values in the range cited. The comparison is indicative of the safety margin; a geometry-specific CHF correlation would be required for design qualification.
The maximum heat flux calculated across all 100 uncertainty cases is approximately 259 kW/m². This represents only 17-26% of the CHF threshold, providing a safety margin of 74-83%. Even considering uncertainties in the CHF correlations themselves, the margin remains substantial.
No predicted melt-through is observed. The minimum residual wall thickness of 15 cm in the worst case significantly exceeds the typical minimum structural reference of approximately 3 cm [6], indicating that gross vessel perforation is not expected. Note that AC² does not model detailed mechanical response of the vessel; the residual wall thickness criterion is used as a surrogate indicator for melt-through prevention, not a full thermo-mechanical integrity assessment.

4.4. Sensitivity Analysis Results

The sensitivity analysis using Spearman's rank correlation coefficient identifies the most influential parameters affecting IVMR performance. **Figure 8** shows the sensitivity results for maximum heat flux, revealing that power per unit mass of UO_2 (Par. 6, gray) has the strongest positive correlation. Corium inventory parameters (UO_2 and Zr mass, Par. 2 and Par. 3, full dependence) also show significant influence, and are even more pronounced in the highest heat flux area, while thermal conductivities have moderate effects. The effect of Par. 6 having most influence at the bottom of the LP is the fact that other parameters are of the lowest impact, so this results in relatively larger impact. Moreover, if we look at **Figure 6**, we can see that the min and max difference in lowest part is significantly less than in upper LH regions in contact with corium.

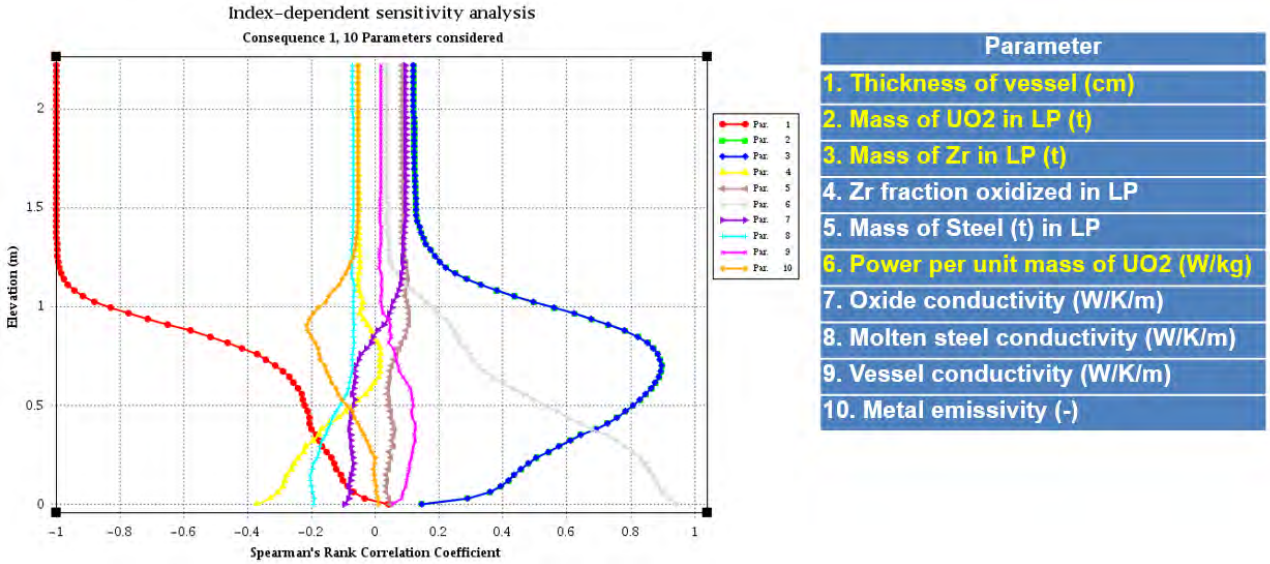

Figure 8. Sensitivity Analysis – parameters influence on axial Heat Flux profile.

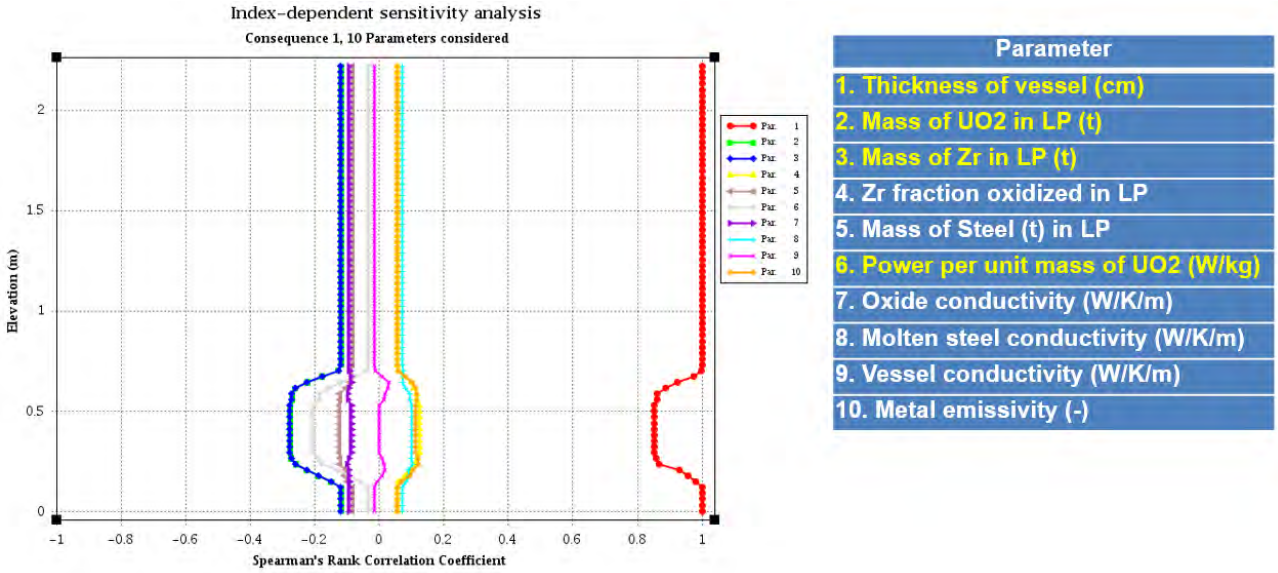

Figure 9. Sensitivity Analysis – parameters influence on axial Wall Thickness profile.

For minimum residual vessel wall thickness (**Figure 9**), the initial vessel wall thickness shows strong positive correlation - thicker initial wall provides more margin against ablation. Power parameters show negative correlation as higher power leads to more ablation and reduced residual thickness. Material thermal properties affect the thermal gradient through the vessel wall and ablation rate.

5. CONCLUSIONS

The AC² code system, particularly the AIDA module, demonstrates good applicability for IVMR analysis in SMR configurations. The stand-alone lower plenum calculations provide efficient evaluation of corium thermal-hydraulic behavior and structural response. However, several important limitations apply: (1) the 0-dimensional modelling approach and the neglect of thermochemical interactions may not capture all aspects of circulation, mixing, and layer composition evolution; (2) the stand-alone approach does not capture transient melt relocation timing or evolving decay heat distributions; (3)layer stratification is fixed throughout the simulation; and (4) model-form uncertainties from correlation selection are not included in the uncertainty quantification.. All these simplifications may lead to miss some specific cases, where transient processes causes higher heat fluxes and result in greater RPV wall ablation.
The uncertainty and sensitivity analysis highlights the importance of accurate characterization of decay heat and corium inventory. Material thermal properties show moderate influence, reflecting uncertainty in corium composition at prototypic conditions. The limited focusing effect observed is favorable and can be attributed to the relatively large lower plenum geometry, thin metallic layer, effective radiative heat transfer, and substantial oxide layer heat generation.
Compared to large reactor IVMR analyses, Design 2 benefits from lower absolute power, favorable surface-to-volume ratio, lower power density, and thicker vessel walls relative to thermal loads. These inherent advantages suggest that IVMR is more readily achievable in SMR designs, though proper external cooling system design remains essential.

After performing a comprehensive analysis of in-vessel melt retention for a generic SMR Design 2 using the AC² system code, the main conclusions are:

1. The IVMR strategy is effective for the investigated SMR design. The maximum outer heat flux (~259 kW/m²) remains well below critical heat flux thresholds (1.0-1.5 MW/m²).

2. The minimum residual vessel wall thickness exceeds 15 cm in all 100 uncertainty cases, demonstrating no predicted melt-through. Note that a full thermo-mechanical integrity assessment (creep rupture, plastic instability) is outside the scope of the AC² model and is recommended for future work.
3. The focusing effect is not observed. The heat flux from the oxidic layer equals or exceeds the metallic layer heat flux in all 100 investigated cases.
4. Sensitivity analysis identifies decay power, per unit mass (Par. 6) and corium inventory (UO_2 and Zr mass, Par. 2 and 3) as the primary parameters governing maximum heat flux. Initial vessel wall thickness (Par. 1) is the most important parameter for residual wall thickness, since with no ablation, initial wall thickness becomes the residual wall thickness. Material thermal conductivities show moderate to negligible sensitivity in the studied parameter ranges
5. The AC² code system demonstrates good applicability for IVMR evaluation in SMR configurations with efficient stand-alone analysis capabilities.
6. The findings support the viability of IVMR as a severe accident mitigation strategy for SMRs, provided the reactor cavity remains flooded.

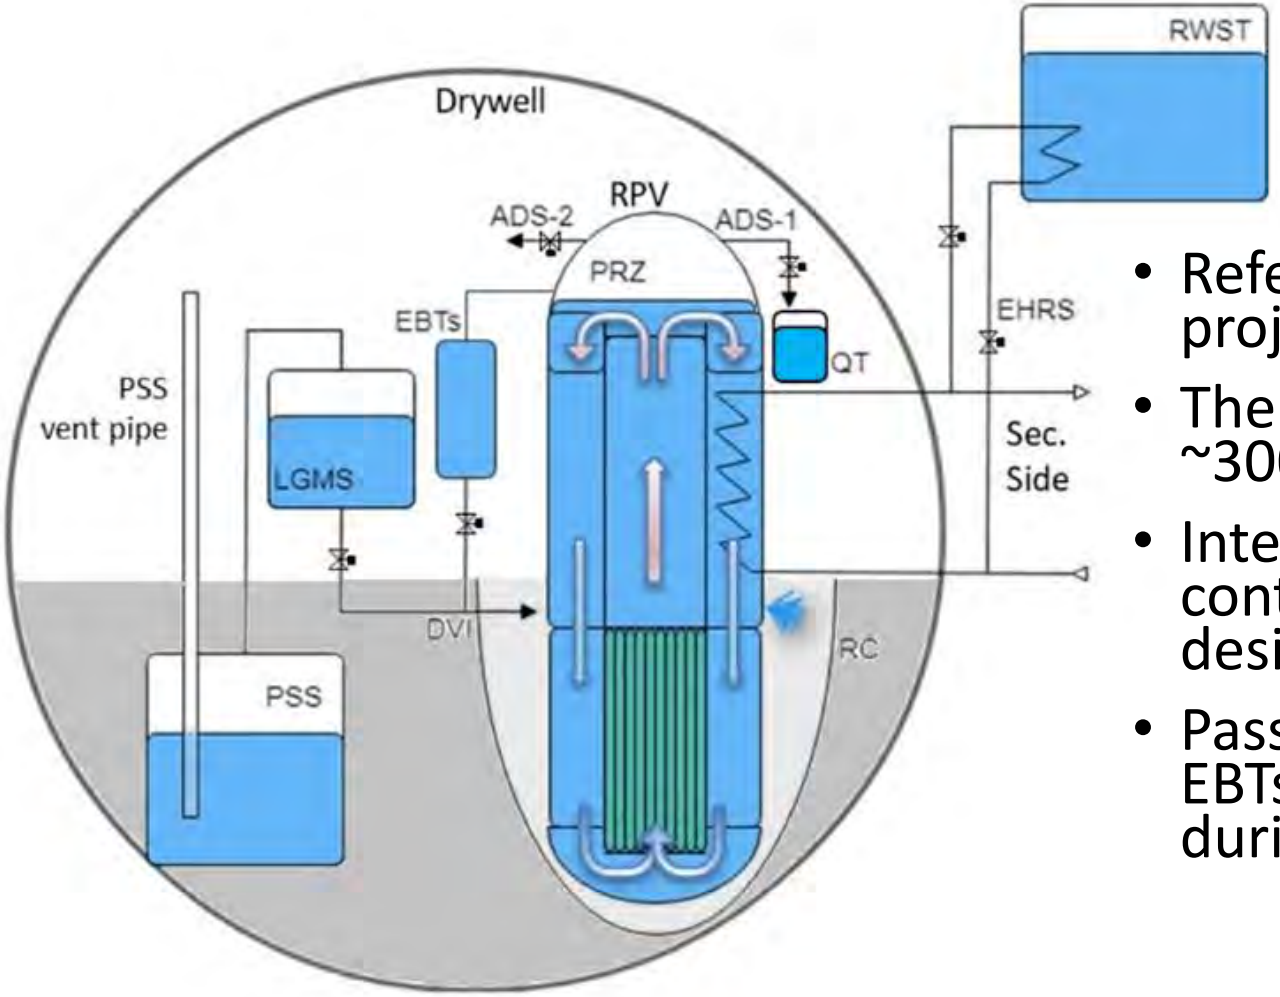
Content

- Introduction and frame of SASPAM-SA project
- Design
- Model and code specifics
- Analysis and Results
- Conclusions

SASPAM-SA overview

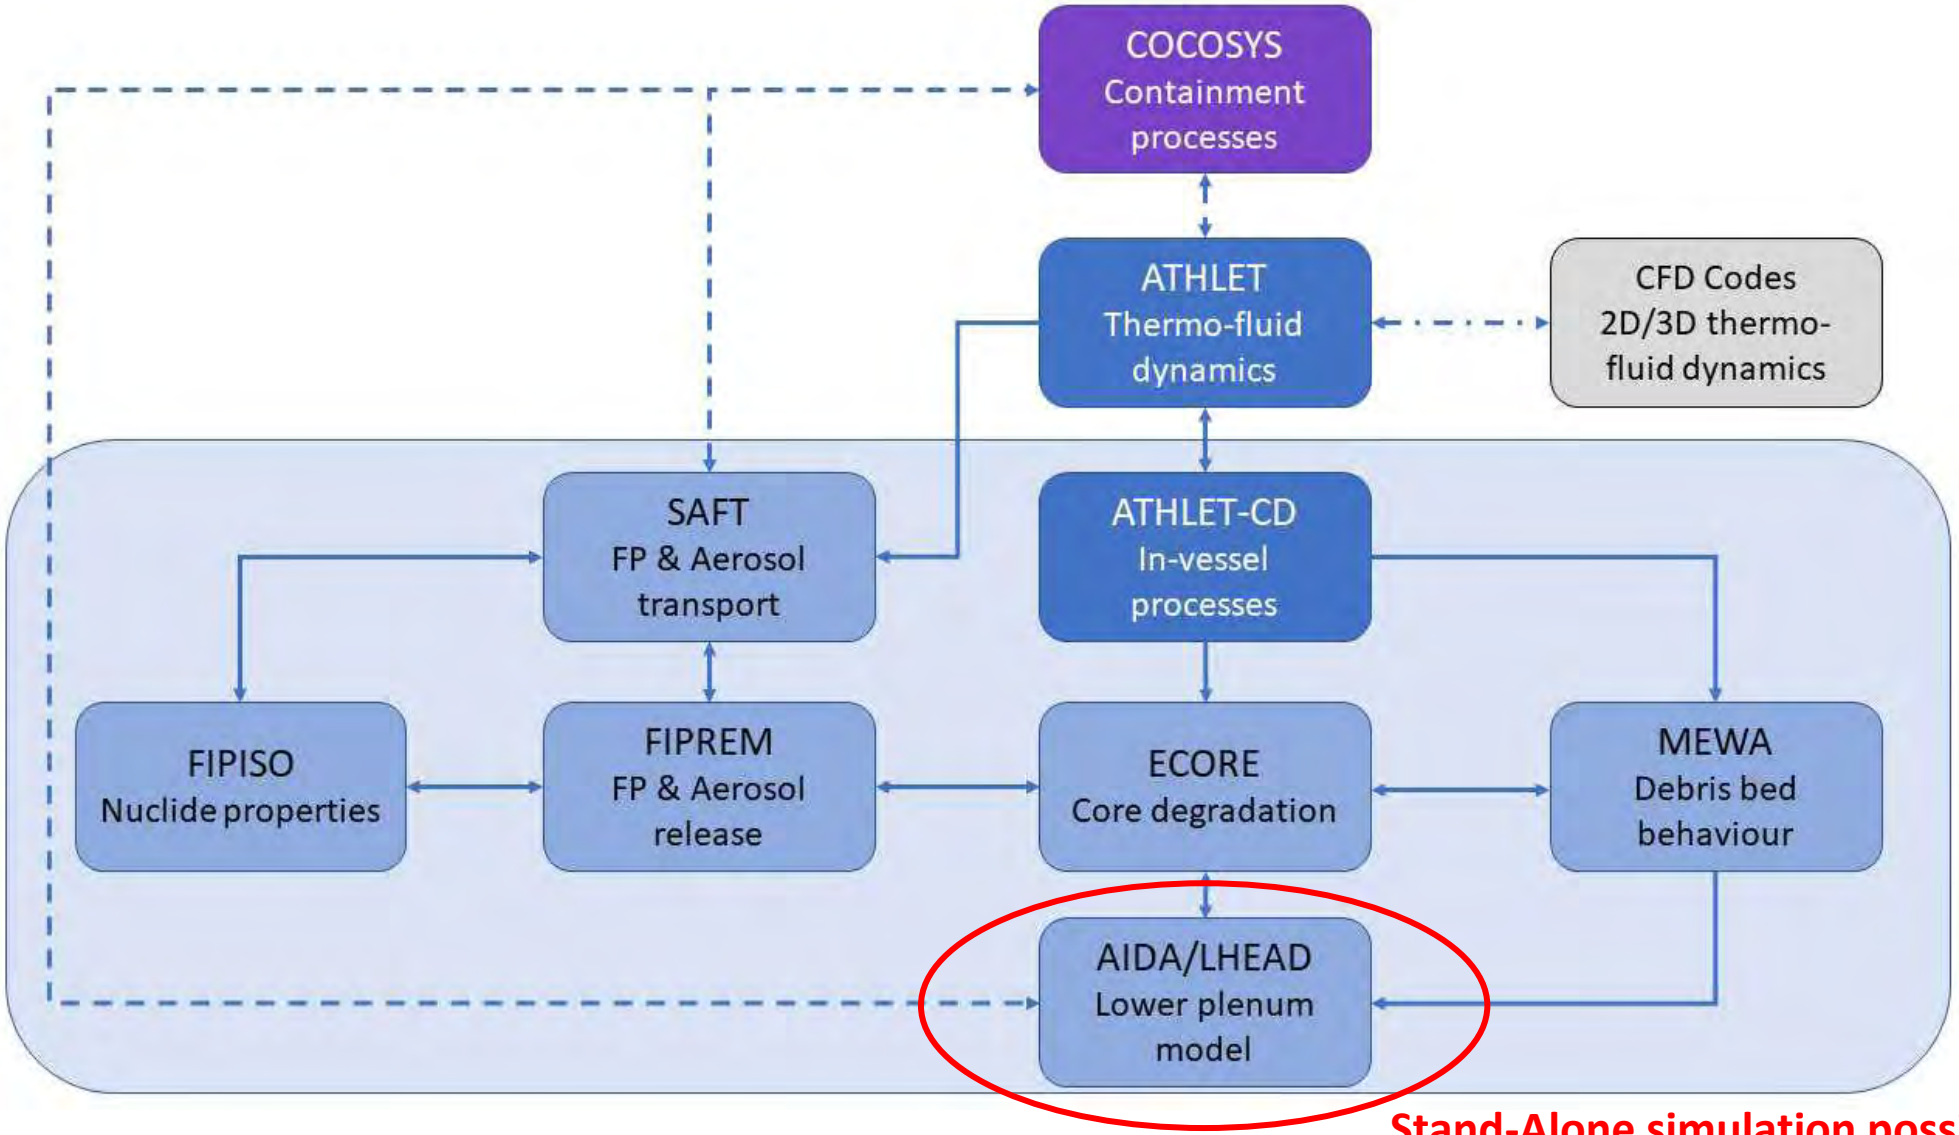
- Funded by the European Union – Horizon Europe–Euratom programme, led by ENEA (Italy)
- Aim – investigate the applicability and transfer of the operating large-LWR reactor knowledge and know-how to the near-term deployment of integral PWR (iPWR), in the view of Severe Accident (SA) and Emergency Planning Zone (EPZ) European licensing analyses needs.
- Progress – Two generic iPWR designs (Design 1 and Design 2) analysed by project partners, extended with Design 3 (BWR type) during the project
- LEI + GRS cooperation in Design 2 integral model development, modelling scenarios, including IVMR stand-alone calculations using AC^2 code and Uncertainty and Sensitivity analysis using SUSA code. As a part of benchmark exercise in SASPAM-SA project WP4 (led by ASNR).

“Design-2”



- Referenced as “Design 2” in SASPAM-SA project and related publications
- Thermal power: 1000 MWth; Electric output: ~300 MWe
- Integral PWR with classical spherical containment; concrete floor with RPV cavity designed for flooding in IVMR scenarios
- Passive safety systems (ADS, EHRS, LGMS, PSS, EBTs) ensure cooling without operator action during severe accident

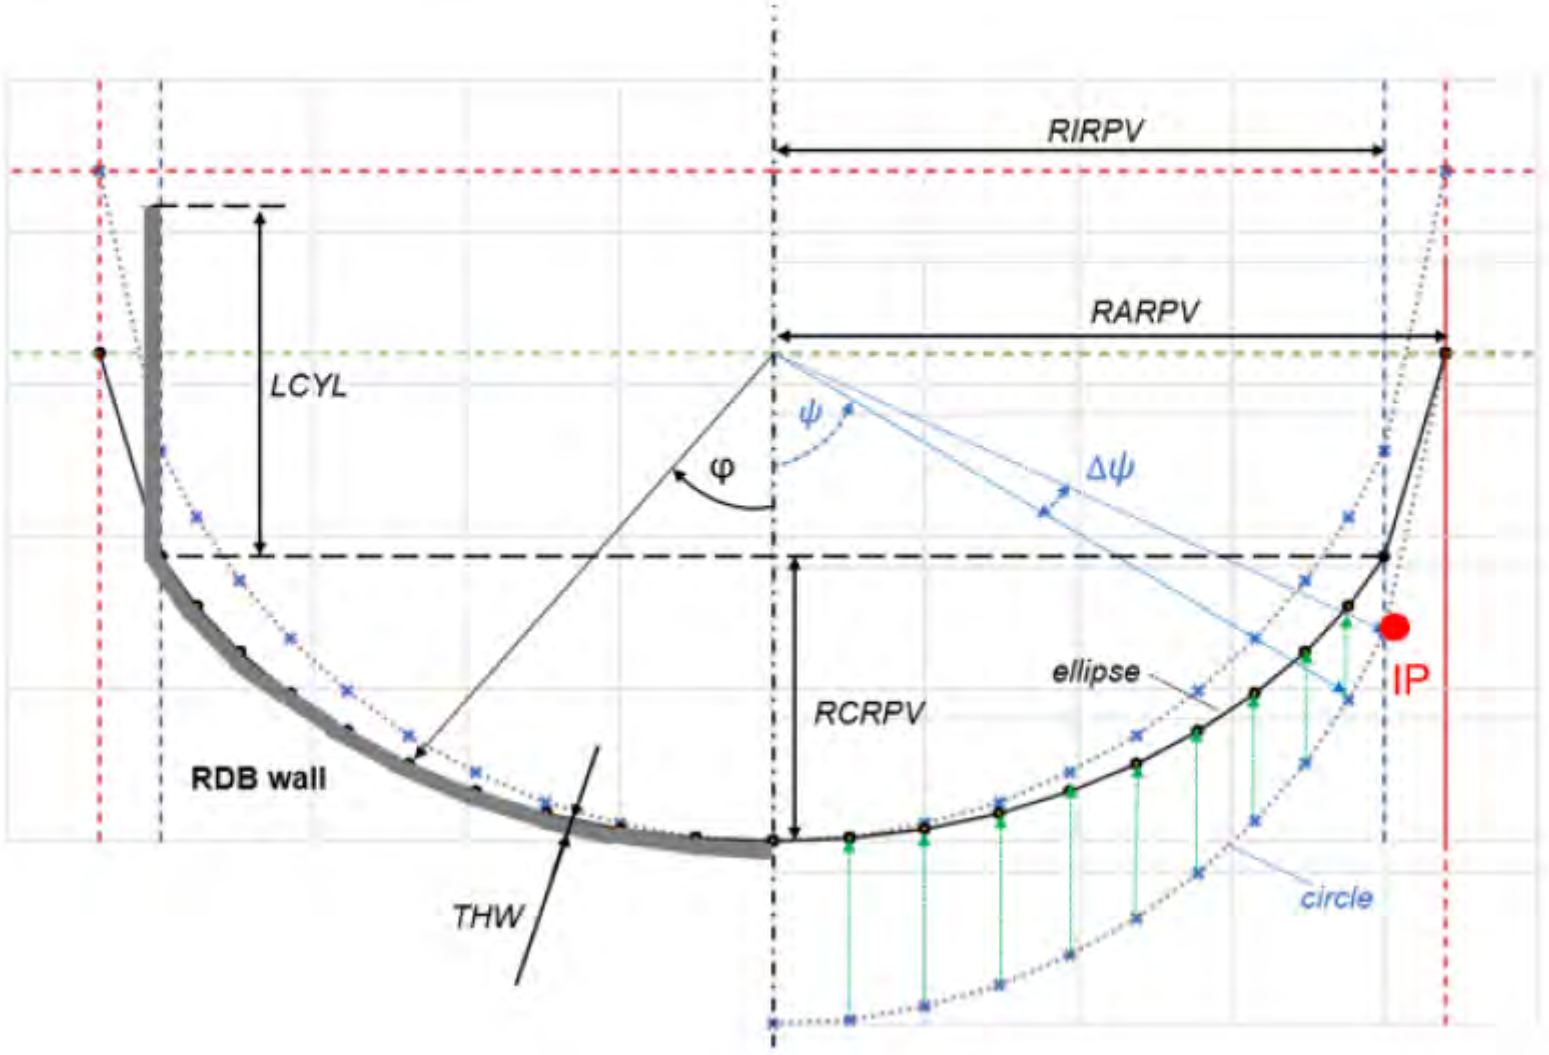
AC² code overview



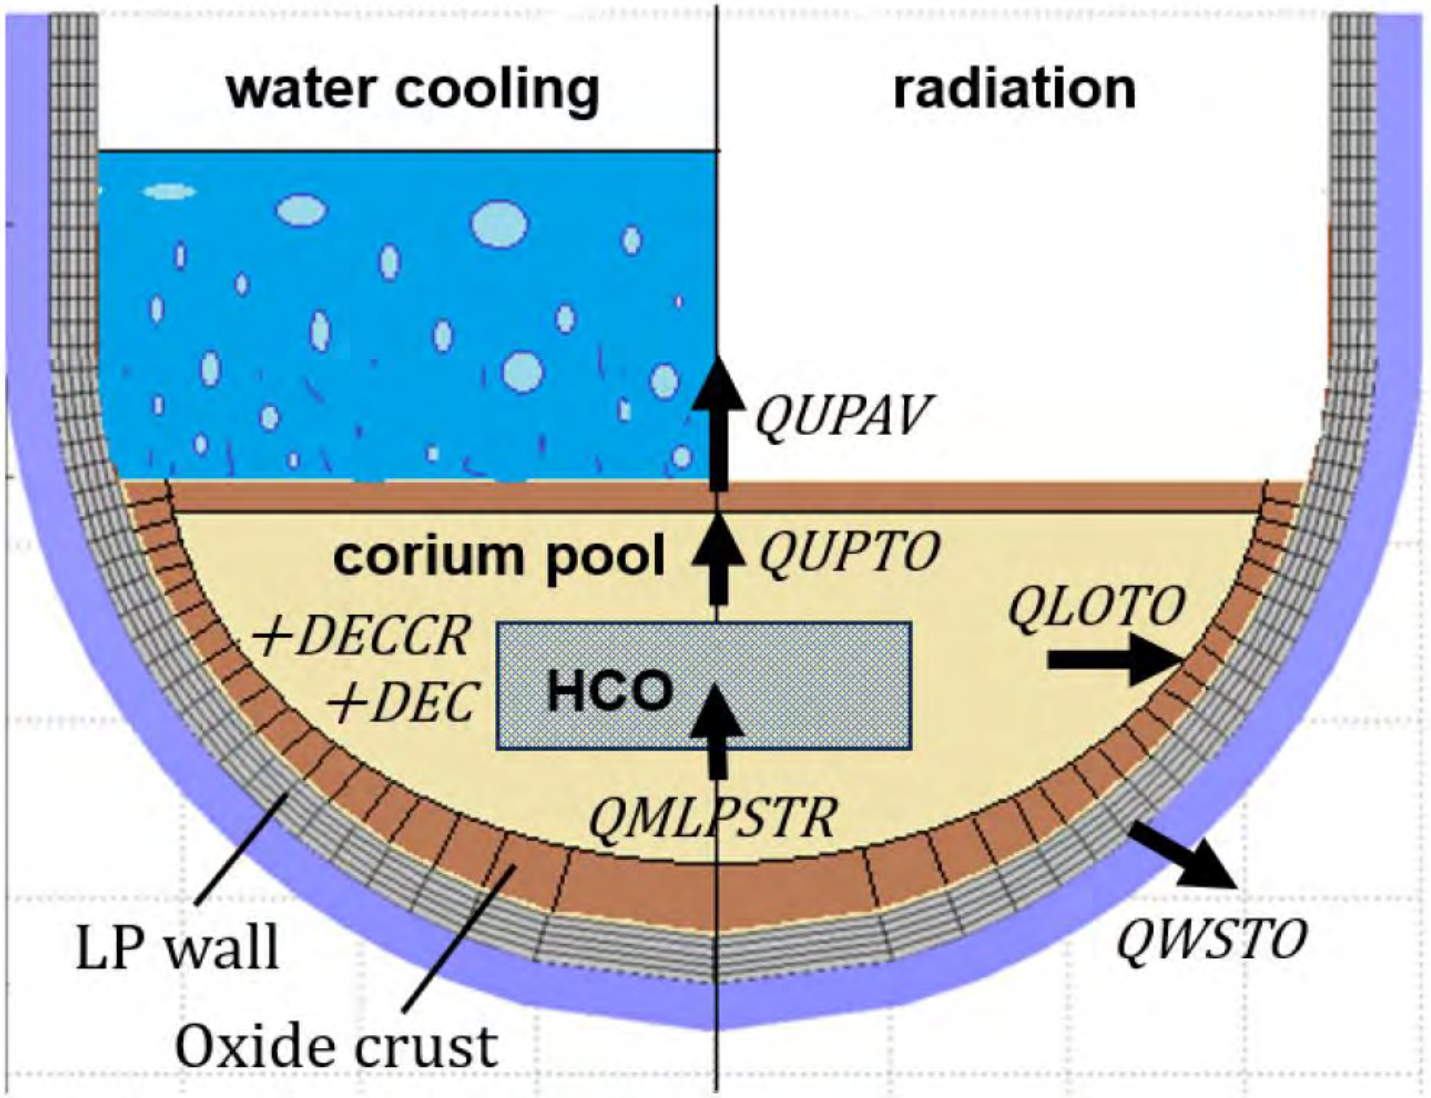
Stand-Alone simulation possible

LP simulation module AIDA in AC²

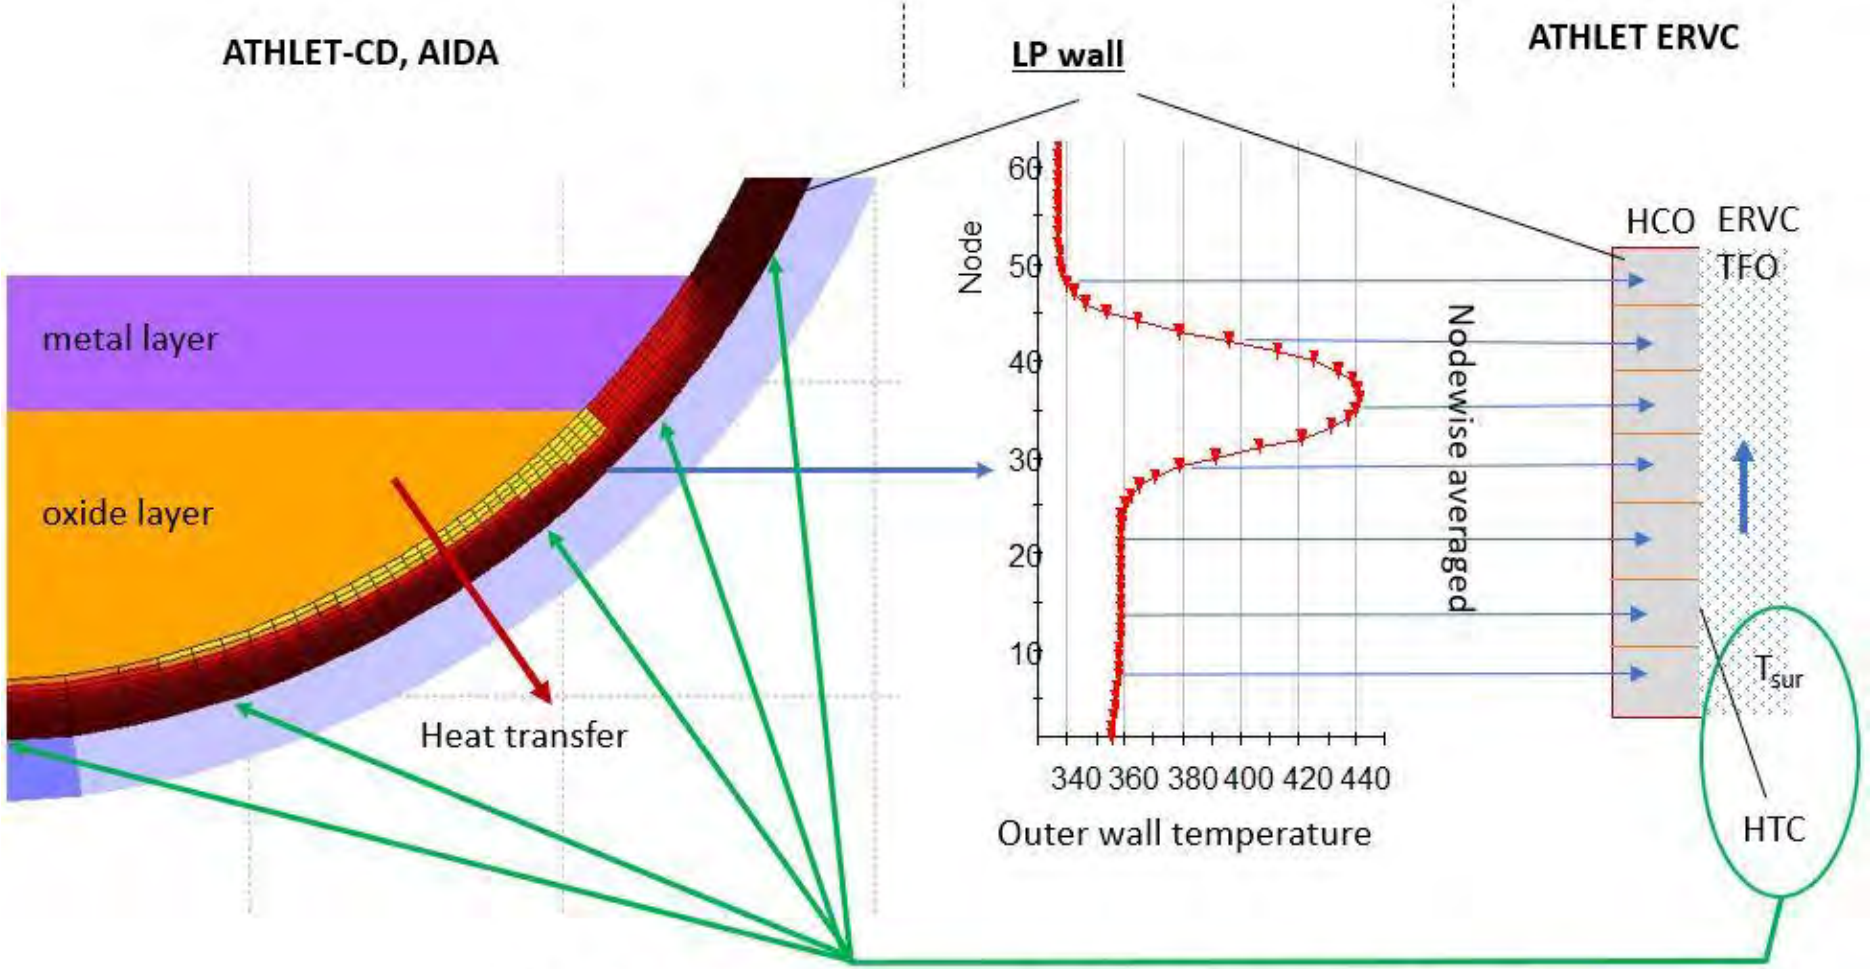
- *Trunked-elliptical*: RARPV > RIRPV and RARPV > RCRPV



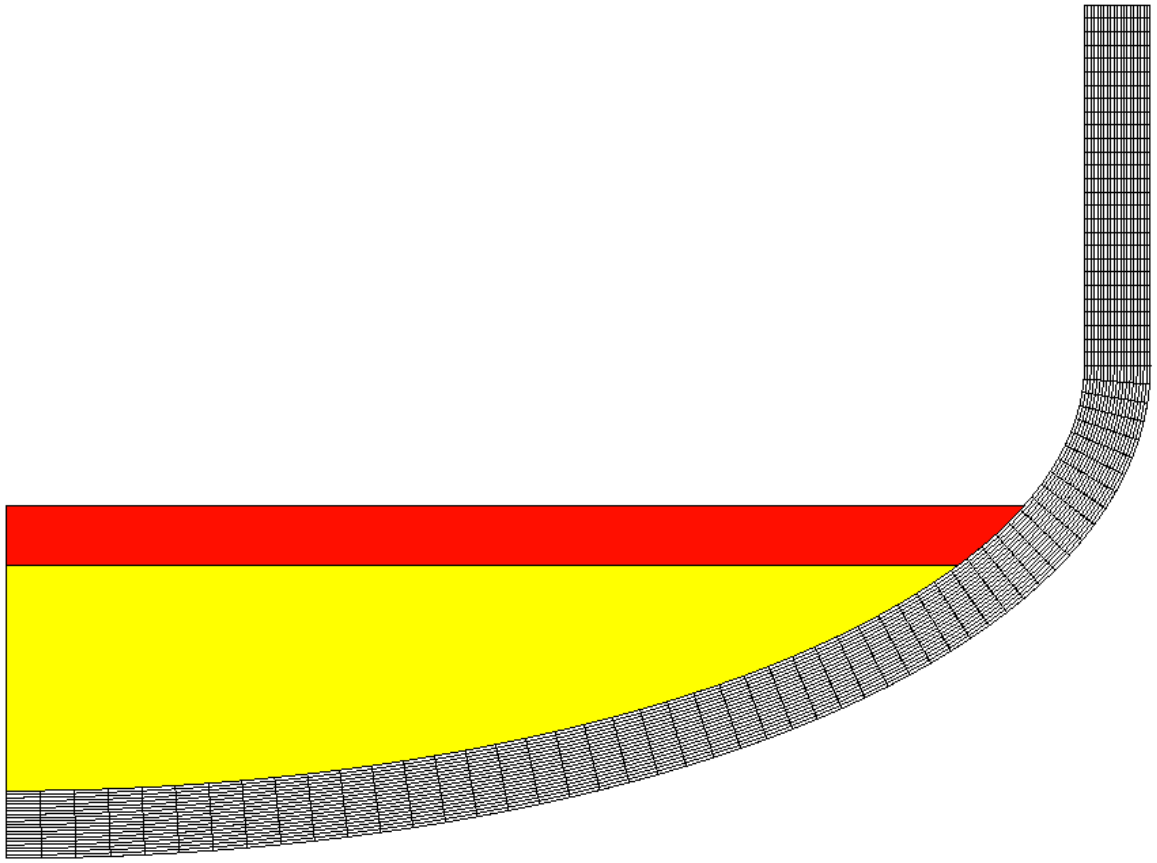
LP simulation module AIDA in AC²



LP simulation module AIDA in AC²



LP model in AIDA



- Lower plenum wall nodalization in AIDA showing 50 axial nodes in hemisphere and 27 nodes in cylindrical part with 20 radial rings.
- Oxidic and metal layer are modelled in 0D

Investigated uncertain parameters, reference case and ranges

ID	Parameter	Reference	Minimum	Maximum
	Geometry of LP			
Par. 1	Thickness of vessel (cm)	0.19	0.17	0.21
	Degradation			
Par. 2	Mass of UO_2 in LP (t)	58.	25.	58.
Par. 3	Mass of Zr in LP (t)	19.5	8.5	19.5
Par. 4	Zr fraction oxidized in LP	0.5	0.3	0.7
Par. 5	Mass of Steel (t) in LP	15.	15.	22.
Par. 6	Power per unit mass of UO_2 (W/kg)	120.	75.	120.
	Material properties			
Par. 7	Oxide conductivity (W/K/m)	2	1	3
Par. 8	Molten steel conductivity (W/K/m)	20	20	40

Par. 10	Metal emissivity (-)	0.5	0.2	0.8

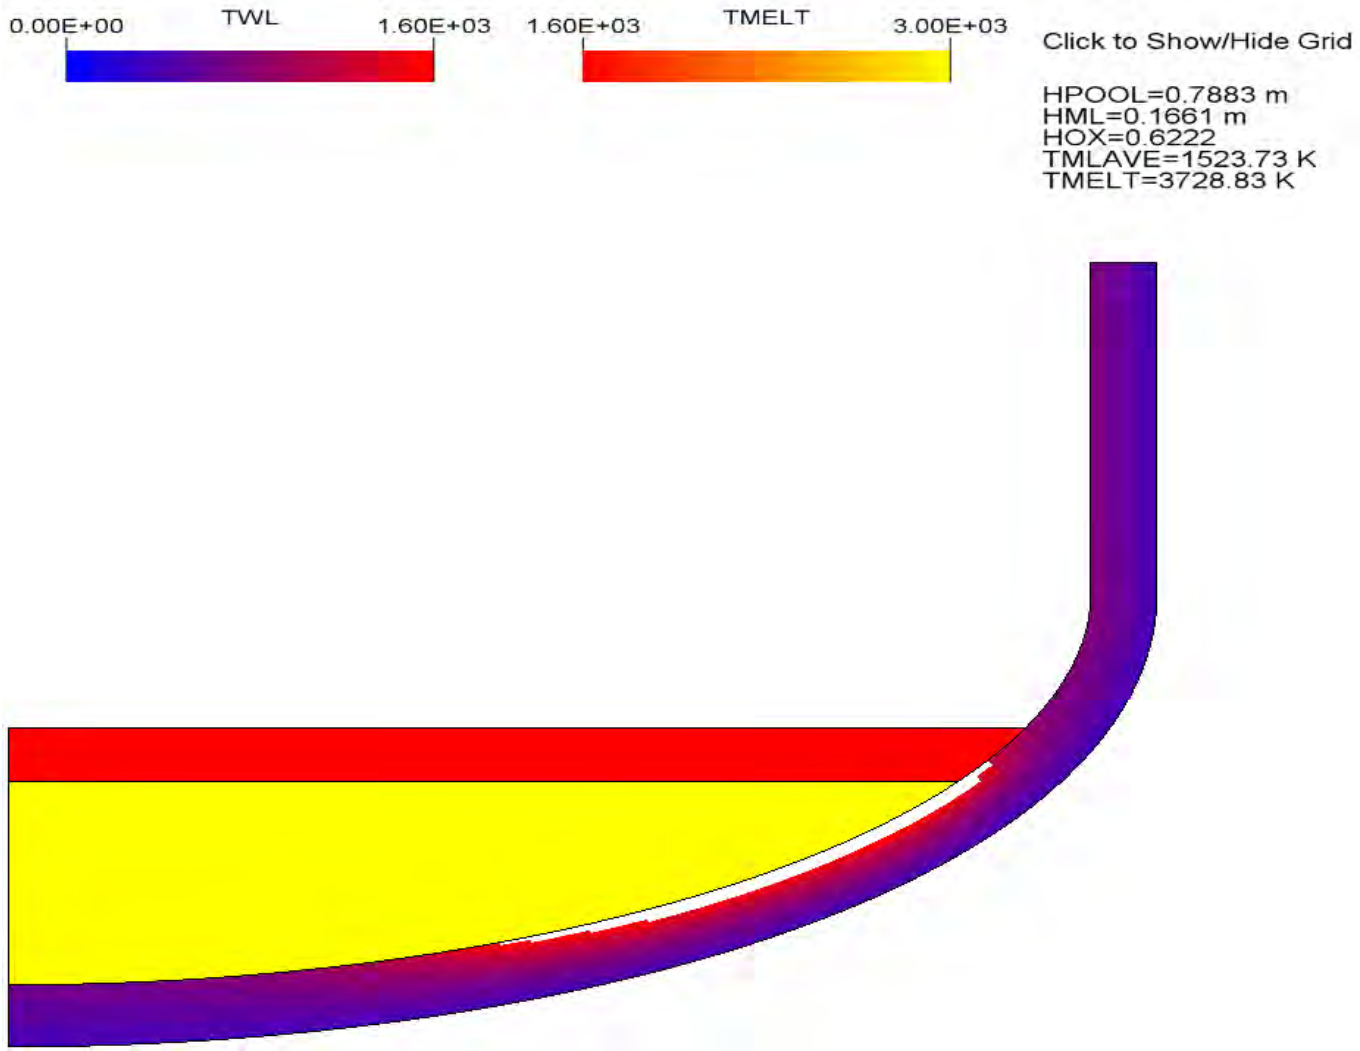
Input Data – Sources and Uncertainty Method

- **Data source:** Input data consolidated from integral SA scenario calculations within SASPAM-SA (separate work package), as a part of SASPAM-SA stand-alone benchmark type exercise. Scenarios showed variation in material masses, proportions slumped into the LP, and other parameters depending on scenario, code, and assumptions.
- **Uncertainty method:** SUSA software (GRS); Simple Random Sampling; 100 samples generated to give good parameter-space coverage while maintaining computational efficiency.
- **Distributions:** Uniform distribution assumed for all 10 parameters; full dependence applied between related parameters – UO_2 mass and Zr mass.
- **Run strategy:** Each of the 100 cases run to steady-state to evaluate thermal-hydraulic behaviour and structural integrity of the RPV lower head under the sampled parameter combinations.
- **Fixed assumptions:** Two-layer configuration constant throughout (no thermochemistry); 10% decay heat in metallic layer, 90% in oxidic layer; cavity always flooded (continuous external cooling).

Results

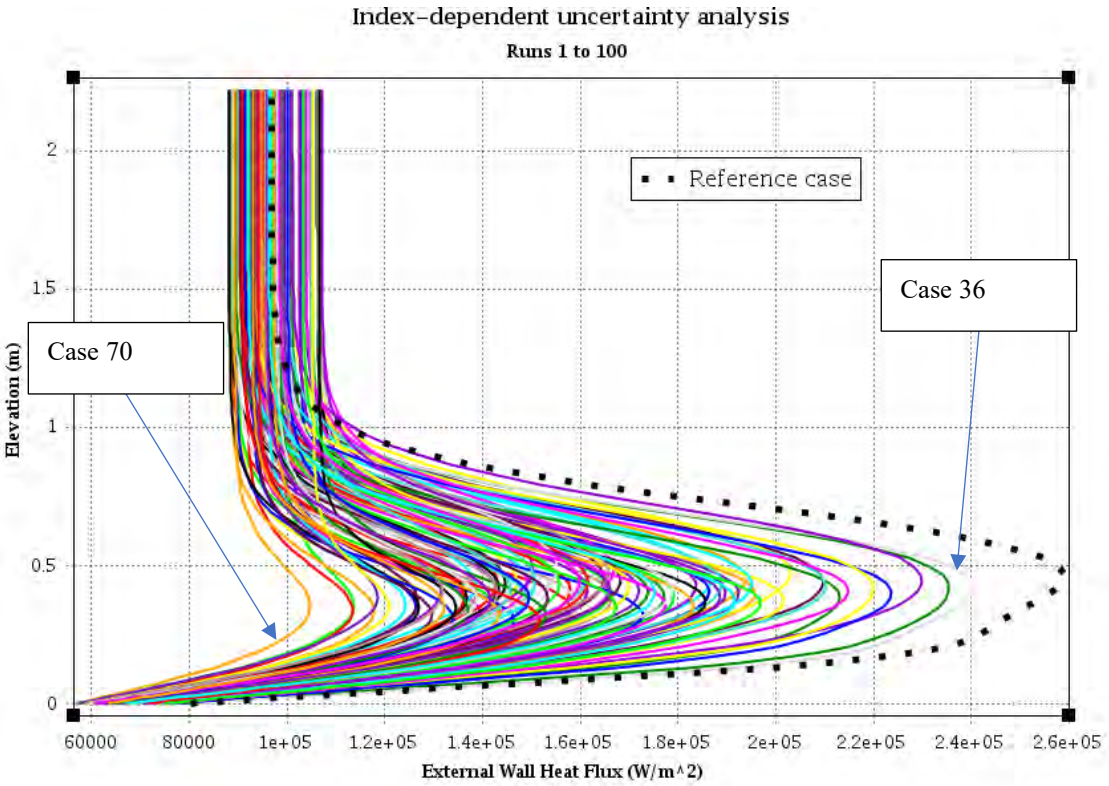
Results	Reference	Minimum	Maximum
Min. residual vessel thickness (cm)	15.2	15.2	20.9
Max. local outer HF (kW/m^2) at steady-state	259.1	104.8	259.1
Focusing factor	0.85	0.84	0.98
Thickness of top metal layer (m)	0.166	0.123	0.199
Thickness of oxide layer (m)	0.622	0.414	0.666
Lower crust thickness max. (cm)	4.7	4.7	6.7
Top crust thickness (cm)	2.9	2.8	5.6

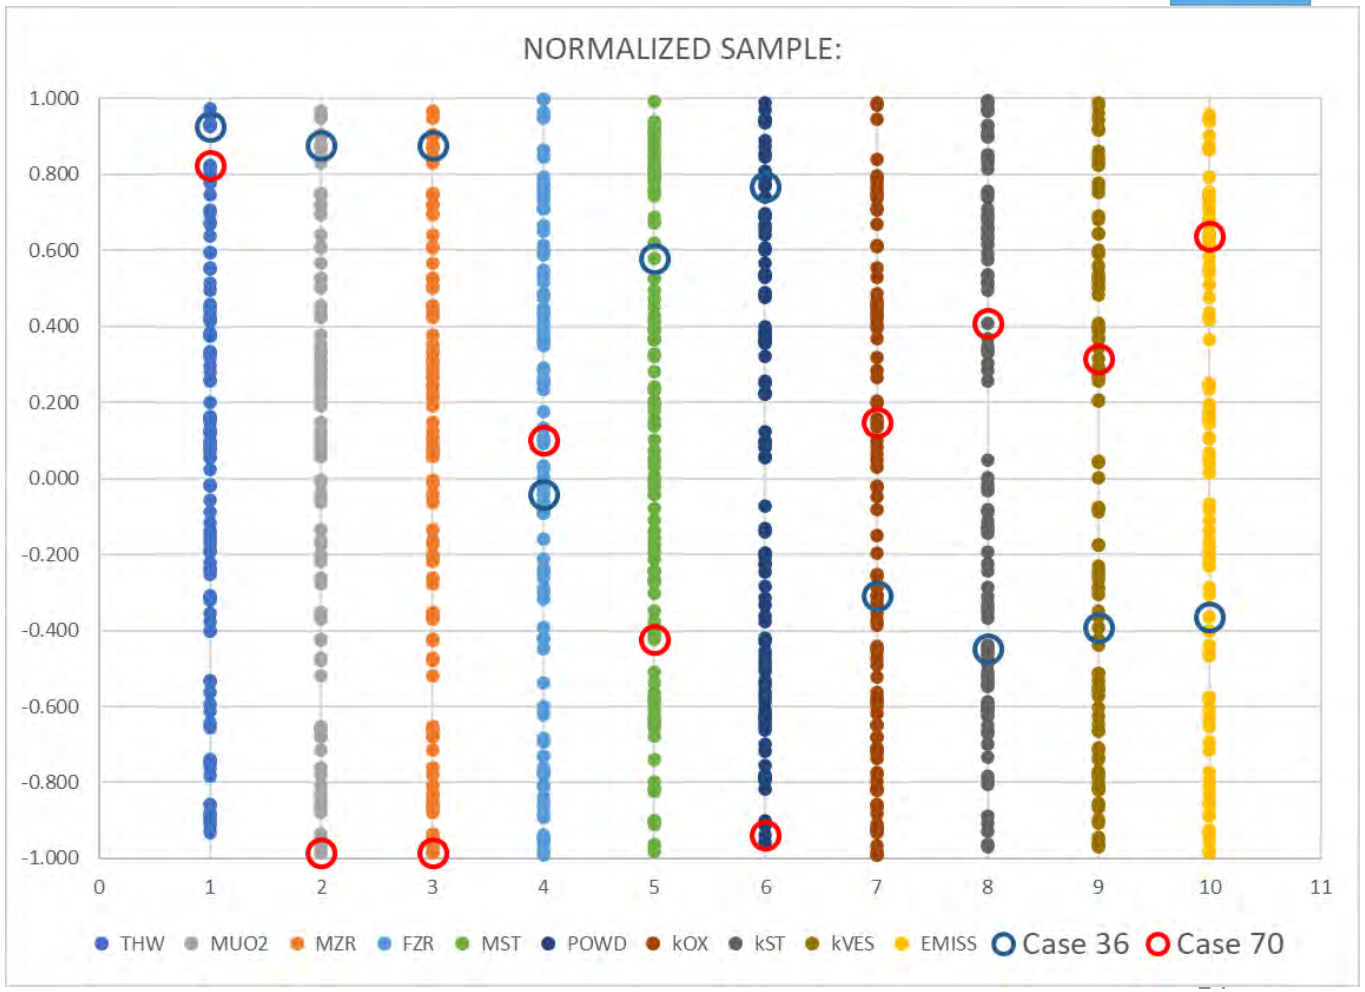
Results



- Final steady state of reference case showing wall temperature (TWL) and melt temperature (TMELT) distributions with layer heights.

Uncertainty Analysis - Wall Heat Flux



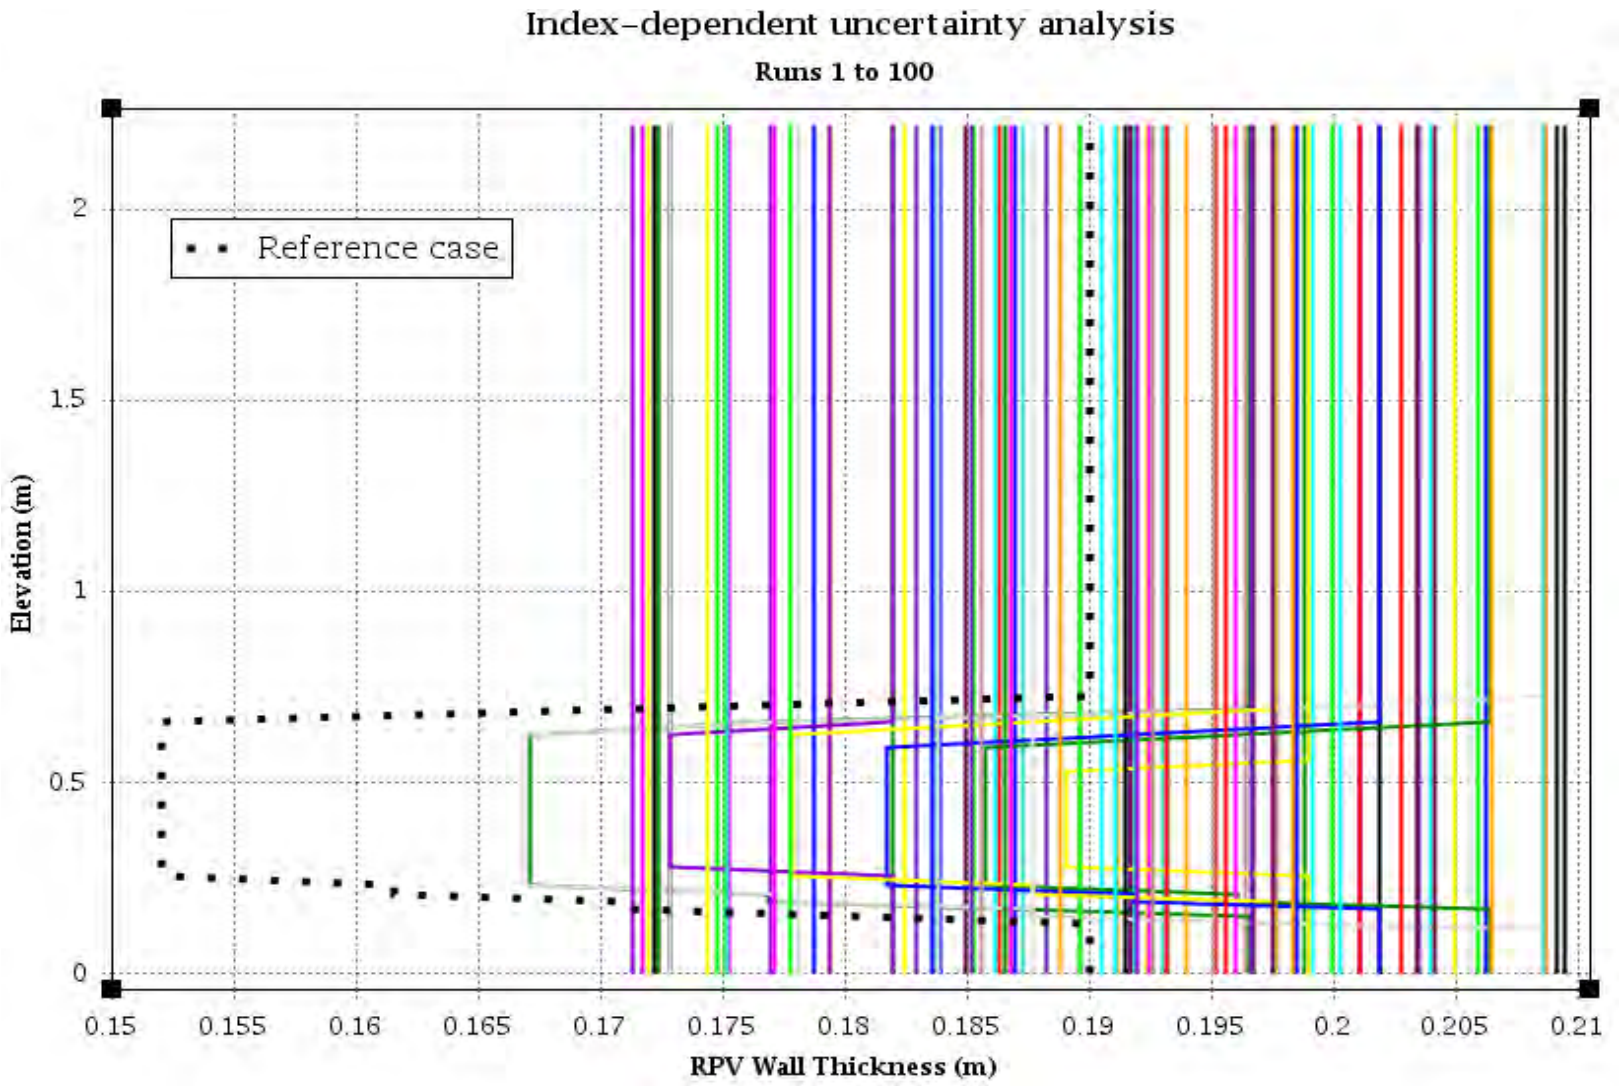


- Range 104 – 259 kW/m^2
- Reference case -> MAX heat flux

Safety Margins – Comparison with Critical Heat Flux

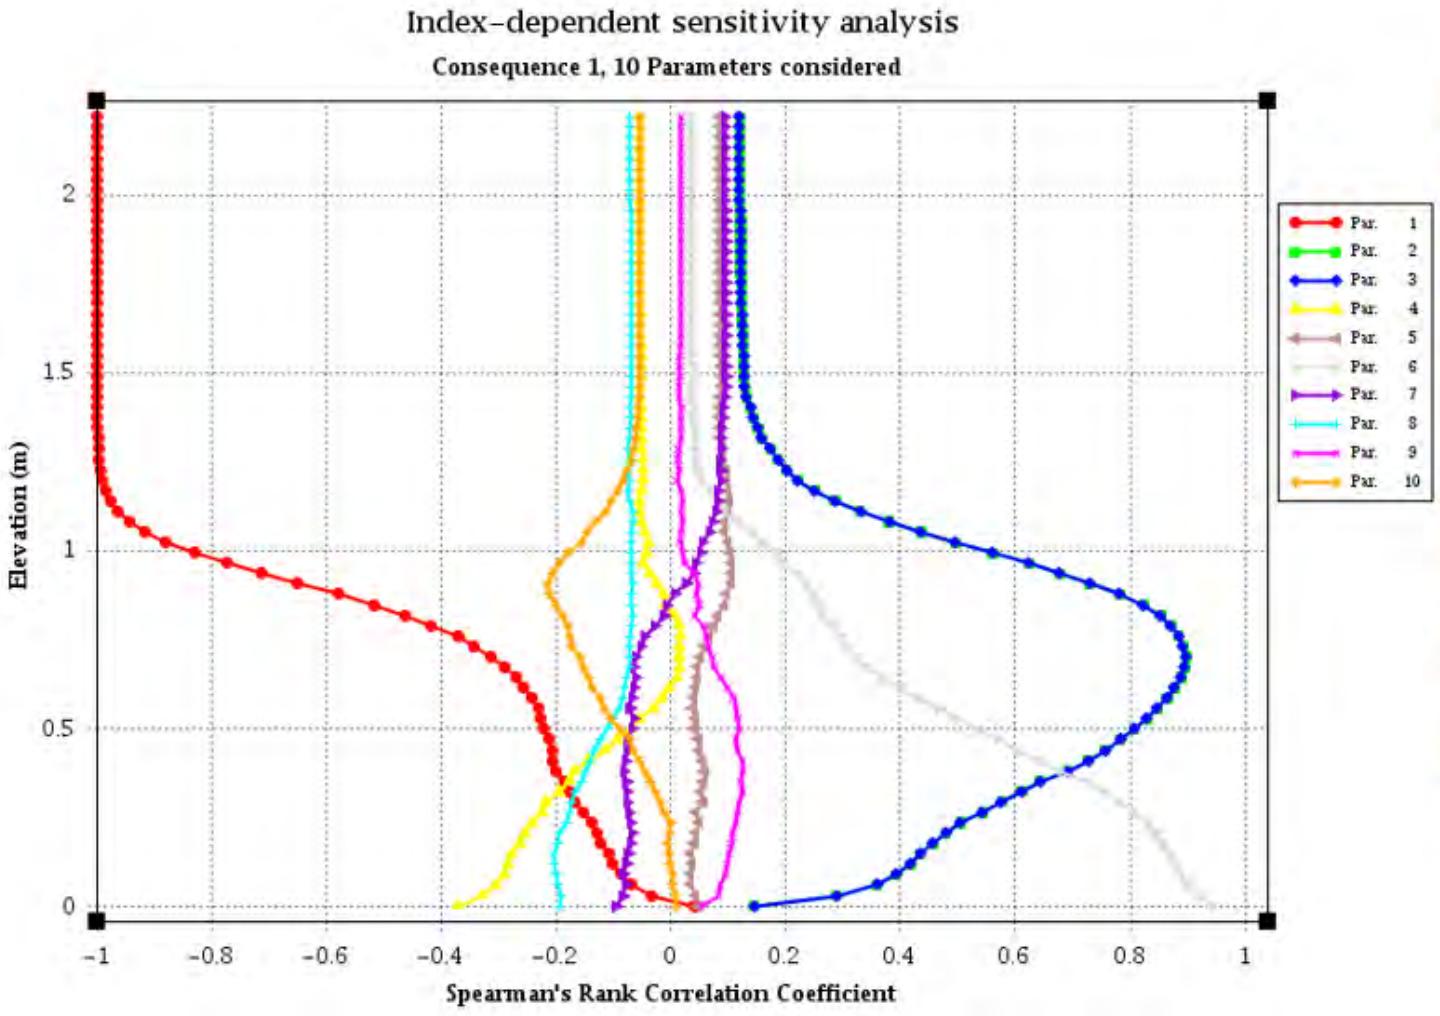
- **Maximum calculated heat flux:** ~259 kW/m² (Reference case, max of all cases) at the outer RPV wall in the upper debris region (~0.5–0.7 m elevation)
- **Critical Heat Flux (CHF):** Experimental programmes (e.g. ULPU-2000) suggest CHF in the range 1.0–1.5 MW/m² for the external cooling
- **Safety margin:** 259 kW/m² represents only a fraction of the CHF range, giving a large safety margin.
- **Focusing effect across all 100 cases:** Focusing factor (HF_metal / HF_oxide) ranges from 0.84 to 0.98. All values < 1.0, confirming that oxide layer HF exceeds metallic layer HF in every case – focusing effect NOT observed
- **Note on focusing:** Power split between layers depends on correlations and code assumptions – this is a subject of ongoing code and user-effect studies; AC² does not model thermochemistry, so the two-layer configuration is fixed

RPV Wall Ablation



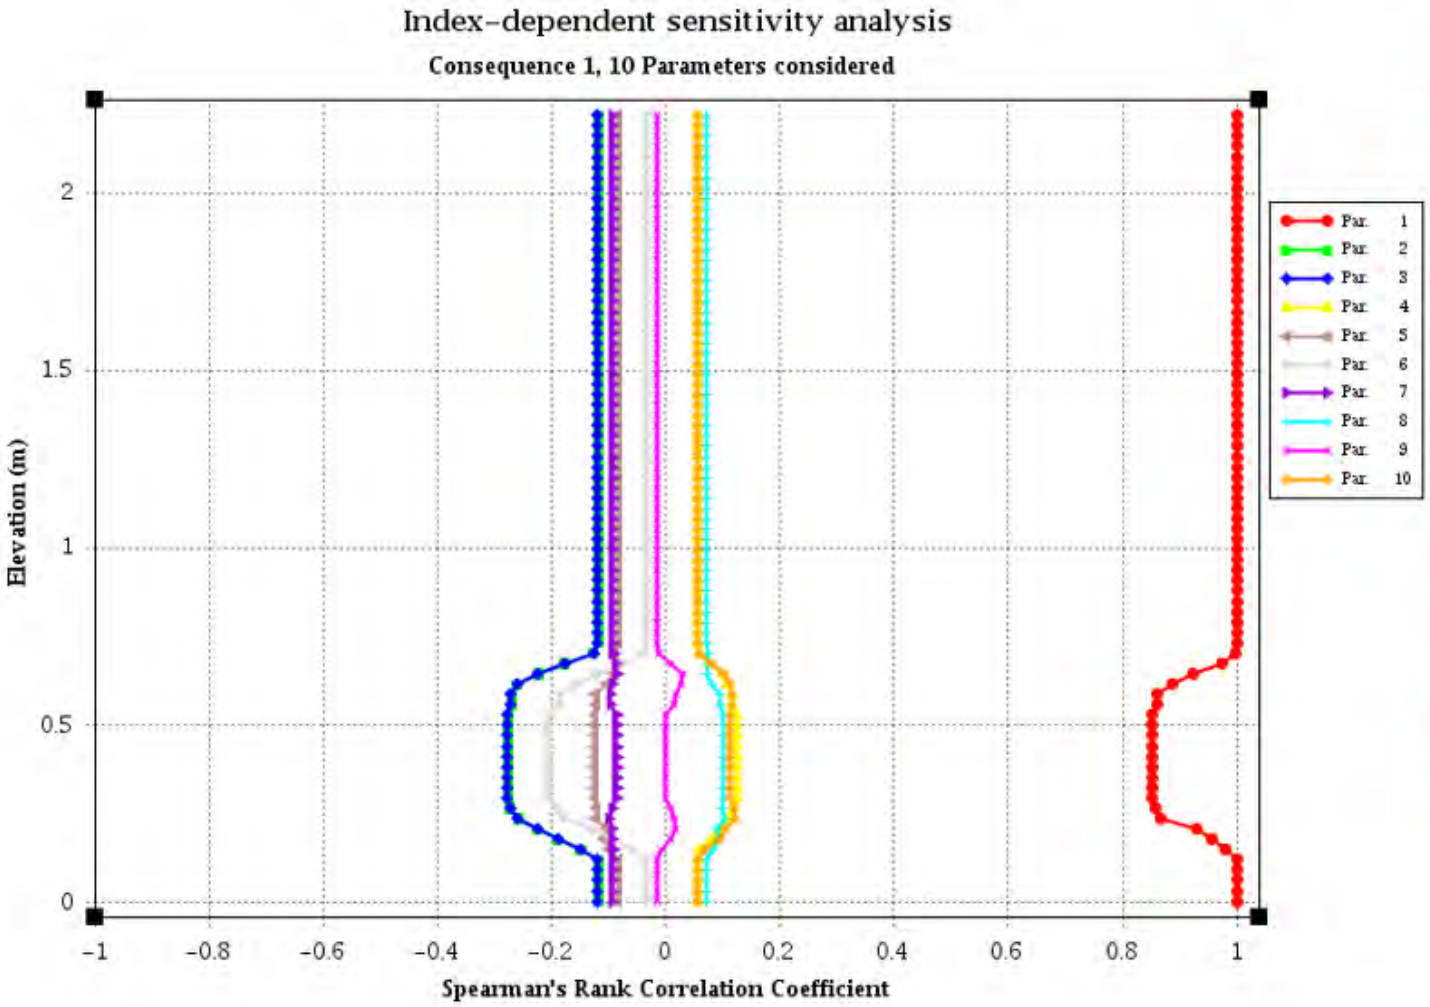
- RPV wall thickness as a function of elevation
- Wall ablation observed only in a few cases
- Reference case -> MAX heat flux, MAX ablation

Sensitivity analysis results



Parameter
1. Thickness of vessel (cm)
2. Mass of UO2 in LP (t)
3. Mass of Zr in LP (t)
4. Zr fraction oxidized in LP
5. Mass of Steel (t) in LP
6. Power per unit mass of UO2 (W/kg)
7. Oxide conductivity (W/K/m)
8. Molten steel conductivity (W/K/m)
9. Vessel conductivity (W/K/m)
10. Metal emissivity (-)

Sensitivity Analysis - Residual Wall Thickness



Parameter
1. Thickness of vessel (cm)
2. Mass of UO2 in LP (t)
3. Mass of Zr in LP (t)
4. Zr fraction oxidized in LP
5. Mass of Steel (t) in LP
6. Power per unit mass of UO2 (W/kg)
7. Oxide conductivity (W/K/m)
8. Molten steel conductivity (W/K/m)
9. Vessel conductivity (W/K/m)
10. Metal emissivity (-)

Conclusions

- The IVMR strategy is effective for the investigated SMR design. The maximum outer heat flux (~259 kW/m²) remains well below critical heat flux thresholds (1.0-1.5 MW/m²), providing a safety margin of 74-83%
- The minimum residual vessel wall thickness exceeds 15 cm in all 100 uncertainty cases + reference case, demonstrating robust structural integrity
- The focusing effect is limited. The heat flux from the oxidic layer equals or exceeds the metallic layer heat flux
- Sensitivity analysis identifies decay power, corium inventory, and thermal conductivity as key parameters. Careful characterization is needed for design-specific analyses
- The AC² code system demonstrates good applicability for IVMR evaluation in SMR configurations with efficient stand-alone analysis capabilities
- The findings support the viability of IVMR as a severe accident mitigation strategy for SMRs, provided the reactor cavity remains flooded

ABSTRACT

The flooded cavity has many advantages in terms of corium coolability and prevention of basemat melt-through and therefore has been adopted as a severe accident management strategy (SAMS) in several reactor designs such as Nordic boiling water reactors. However, the risk of steam explosion in the wet cavity should be addressed. In addition, the molten fuel-coolant interactions (FCI) in the cavity water pool may create conditions for recriticality when the resulting debris particles are either dispersed in neutron moderating water or settled on the water pool bottom. Few studies have been conducted on recriticality of infinite debris beds, but little work is attributed to finite debris beds and the dispersal phase. Given the infinite multiplication factors greater than one from the previous studies, the present study proposes an approach to estimate the reactivity loss due to neutron leakage in a finite debris-water system and obtain the geometrical conditions for ex-vessel recriticality in both dispersal and settled phases of debris particles. The geometrical parameters include the melt jet breakup length and the lateral debris dispersal distance of the dispersed particles, as well as the height, the base diameter and the angle of repose of the debris bed.

KEYWORDS
Severe accident, ex-vessel corium, recriticality, flooded cavity, melt fragmentation

1. INTRODUCTION

The Nordic boiling water reactor (BWR) severe accident management (SAM) strategy of flooding the cavity below the reactor pressure vessel (RPV) with water has advantages in cooling of ex-vessel corium and possible prevention of basemat melt-through. However, the SAM strategy has the disadvantage of increasing steam explosion risk. Moreover, it may also create recriticality conditions for the quenched debris particles either dispersed in the neutron moderating water or settled on the cavity pool bottom (i.e. forming a debris bed).

The present knowledge of in-vessel severe accident phenomena suggests that the molten corium may be axially separated into two layers of melt in the RPV lower head: a metallic layer atop an oxidic layer, and ejected sequentially in time. The oxidic melt primarily consists of uranium-oxide fuel and the low-neutron-absorbing zirconium-oxide while the metallic melt contains primarily zircalloy and stainless steel, including melted control rods. Highly neutron-absorbing boron from melted control rods in the corium could reduce the risk of recriticality, and even the key elements of stainless steel (iron, nickel and chromium) have a relatively high absorption cross-section compared to zirconium. If the boron is retained in the metallic melt, the strong neutron-absorber will be absent when the oxidic melt is ejected into the flooded cavity, possibly creating recriticality conditions. A recriticality may deteriorate the debris coolability and ultimately threaten the containment integrity if it does occur and escalate.

Motivated by the interest in the risk of ex-vessel corium recriticality, few studies have been conducted on the potential of ex-vessel recriticality with the focus on the debris beds [1–3]. To our knowledge, no one has addressed the recriticality of ex-vessel corium during its dispersal phase, i.e. when debris

particles are dispersed in the water pool after melt ejection and fragmentation. Neutronics studies performed by Freiría López et al. [2–3], indicated infinite multiplication factors, k_{inf}, of debris-water systems can easily exceed 1.1 for a large range of configurations, provided that the reactor poison presence is low. Given the infinite multiplication factor is greater than unity, the shape and size of the debris-water system, which determine the reactivity loss due to neutron leakage, will dictate the conditions for recriticality. Thus, the prerequisites for recriticality can be estimated based on predetermined k_{inf} calculations and geometric data obtained from experiments or simulations such as molten corium jet breakup length, lateral debris dispersal distance, debris bed height, base diameter, and angle of repose.

In the present work, the geometrical prerequisites are calculated and applied to ex-vessel debris settling characteristics from experiments and simulations. Although the knowledge on characteristics of molten corium jet fragmentation and debris settling, temporal separation of materials during melt ejection and late in-vessel chemistry of reactor poisons is still developing, such estimates are essential in the first step toward understanding of ex-vessel recriticality risks.

2. RECRITICALITY OF DISPERSED DEPBRIS PARTICLES

The conditions for recriticality of ex-vessel corium can be semi-quantitatively approximated according to modified one-group diffusion theory which has been applied for criticality safety estimates [4] and historically in survey calculations, e.g. [5]. Because the neutron velocity is much greater than the debris particle velocity in water and because the contribution from delayed neutrons is very small in this context, we can assume steady-state conditions. Under steady-state critical conditions, the effective multiplication factor of a quasi-homogenous system, k_{eff}, equals unity according to

$$k_{\text{eff}} = 1 = k_{\text{inf}} \frac{1}{1 + M^2 B^2} \tag{1}$$

where the k_{inf} is the infinite multiplication factor required for criticality, M^2 is the migration area and B^2 is the geometrical buckling [4, 6]. The parameters k_{inf} and M^2 can be obtained from e.g. Monte Carlo simulations while B^2 is determined by the geometrical conditions of the system. B^2 is the eigenvalue of the Helmholtz equation and represents the neutron flux distribution and neutron leakage, independent of the system composition [6]. In this study we calculate B^2 for different geometries to determine what values of M^2 and k_{inf} are required for recriticality according to Eq. (1).

2.1. Recriticality of debris particles falling in water

A molten corium jet leaving the RPV lower head cannot be critical due to its limited size and lack of moderation, but moderating conditions may occur after the jet breaks up into debris particles which are subsequently quenched and dispersed in the water. The dispersed particles form a quasi-homogenous debris-water system, suspended in the water pool before it settles on the containment floor. The geometrical size of this system dictates the loss of reactivity due to neutron leakage according to Eq. (1).

If we assume radially symmetric jet fragmentation, the debris-water system can be described with cylindrical coordinates with axial height, L_{system}, and radial diameter, D_{system}, as illustrated in Fig 1. If we neglect air resistance when the melt falls from the vessel into the pool water, the system diameter can be described by

$$D_{\text{system}} = (\alpha + 1)\, D_{\text{jet}} = (\alpha + 1) \sqrt{\frac{4}{\pi} \dot{V}_{jet} \frac{1}{\sqrt{2gH}}} \tag{2}$$

if the volumetric flow rate of corium in the jet $\dot{V}_{jet}$, corium density, ρ_{corium}, fall height, H, gravitational constant, g, and the water-to-corium volume ratio of the dispersed particle system, α, are known

(cf. Fig. 1). Assuming a continuous corium jet and dispersion of debris particles, the axial height of the system equals the elevation difference between the pool depth L_{pool} and the jet breakup length, $L_{breakup}$. The jet breakup length can be estimated by the following equation based on Saito et al. [7–8]:

$$L_{system} = L_{pool} - L_{break} = L_{pool} - 2.1\sqrt{\frac{\rho_{corium}}{\rho_{water}}\,2H\,D_{jet}} \tag{3}$$

where ρ_{corium} and ρ_{water} are the densities of corium and water, respectively and D_{jet} is the melt jet diameter from Eq. (2). The value of H depends on the water pool level and the vessel failure location. As debris particles settle on the containment floor, a debris bed will grow and may reduce the axial size of the falling-particle system or change the boundary conditions. The debris bed is, however, neglected in the further discussions of section 2.1.

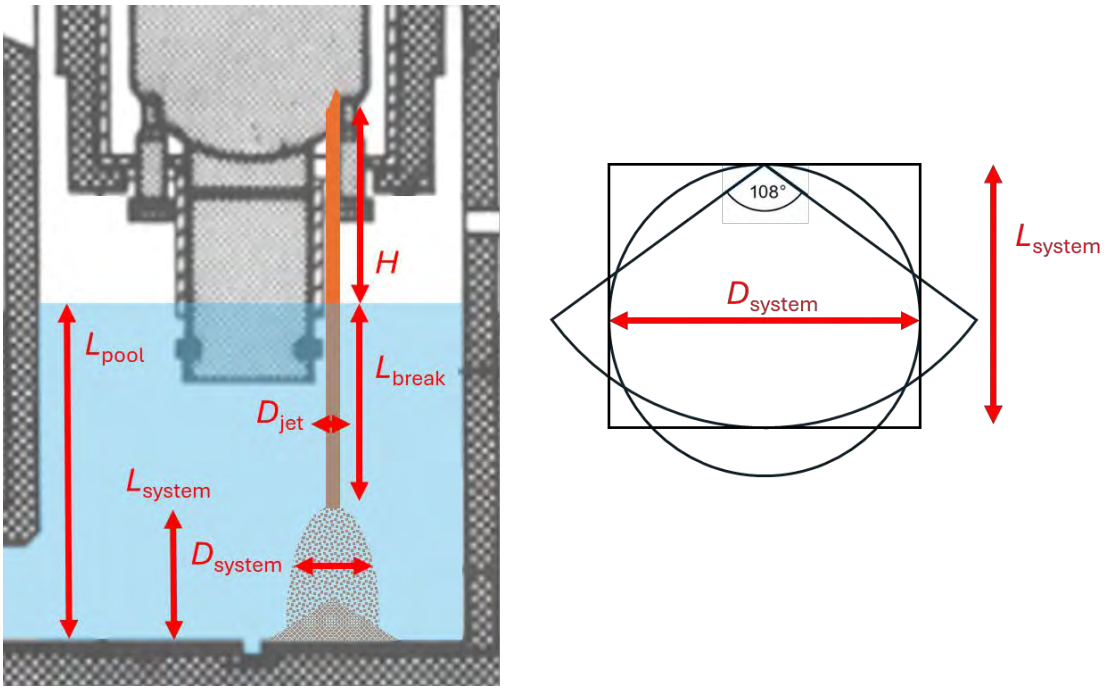

Fig. 1. Melt ejection, break-up and debris bed (left), and shapes for neutron buckling (right).

Geometrical buckling B^2 in Eq. (1) is determined by the system shape. Analytical solutions of B^2 exist for shapes that can be described in orthogonal coordinates [9]. For axially symmetrical shapes, radial diameter and axial height such as those described by Eq. (2) and Eq. (3) for a dispersed particles system can determine the buckling. For example, the following equations determine the buckling of a non-reflected system in the shape of a sphere, B^2_{sphere}, a spherical sector with aperture angle 108°, B^2_{sector}, and a cylinder, $B^2_{cylinder}$, described by

$$B^2_{sphere} = \left(\frac{3.1416}{R_{sphere}}\right)^2, \tag{4}$$

$$B^2_{sector} = \left(\frac{5.7635}{R_{sector}}\right)^2 \text{ and} \tag{5}$$

$$B^2_{cylinder} = \left(\frac{2.4048}{R_{cylinder}}\right)^2 + \left(\frac{3.1416}{L_{cylinder}}\right)^2, \tag{6}$$

respectively [4], [6], [9]. The radius and length of the dispersed particles system determine the buckling for each shape: The radius of the sphere shape R_{sphere}, is limited by half the system diameter, D_{system}, or half the system length, L_{system}. The radius of the spherical sector shape, R_{sector}, is limited by the system length, L_{system}. The radius of cylinder shape is limited by the by half the system diameter, D_{system}, and the length of the cylinder shape, $L_{cylinder}$ is limited by the system length, L_{system}.

The values of k_{inf} that are required for critical conditions, i.e. $k_{eff} = 1$, was obtained from Eq. (1) for a range of systems of debris particles dispersed in water based on corium ejected at an elevation of $H = 4.8$ m above a water pool of 8.5 m depth. The dispersion of debris particles is assumed to remain within a roughly cylindrical column, allowing the overall particle–water system to be described by Eq. (6) before the particles settle onto the containment floor. A migration area, M^2, of 50 cm^2, was chosen since the migration area for pure water and cold light water reactors is approximately 40 cm² and higher value increase leakage and decrease reactivity. Table I show the kinf required for critical conditions based on calculating B2 from Eq. (1–4), varying volumetric rates of corium ejection and water-to-corium volume ratios. Water-to-corium porosity corresponding to α are also shown for completeness (cf. [2], [3]). The cells with #### indicate large leakage with unrealistically high values of k_{inf}, i.e. greater than 2.00.

A high ejection rate produces greater system size, i.e. D_{system}. However, greater ejection rate also produces greater jet breakup-length, reducing the axial length of the system. The two counteracting effects produce a minimum required k_{inf} where the distance between the jet breakup point and the cavity floor equals the system diameter, D_{system}. If melt is slowed by structures below the vessel, the breakup length will decrease and the required k_{inf} will decrease further with ejection rates for all water-to-corium volume ratios.

Table I. Values of k_{inf} required for critical conditions with $M^2 = 50$ cm^2.

Monte Carlo calculations performed by Freiría López et al. in 2019 of water-immersed corium particles of variable size, including compositions comparable to the DEFOR and FARO experiments, suggest that k_{inf} of dispersed particles in water may be greater than unity for porosities of 0.3 to 0.9 [2–3]. Porosities greater than 0.9 were not simulated. Values of k_{inf} were found to be significantly greater than unity for porosities 0.7 to 0.8, up to 1.45 for fresh fuel [2] and up to 1.3 for uranium oxide of 12 GWd/t$_{HM}$ burnup [3]. The comparison of these results with the required k_{inf} of Table I suggests recriticality conditions in the ejection phase may be possible, depending on the melt ejection conditions, i.e. water-to-corium volume ratio, α, jet diameter, D_{jet} and volumetric flow, $\dot{V}_{jet}$.

It should be noted that additional conditions will of course influence reactivity. The assumptions made by Freiría Lopez et al. are conservative. Also, high melt temperatures will reduce reactivity slightly due to doppler broadening of ^{238}U. However, the impacts of particle temperature on k_{inf} and M^2 are expected to be small. Furthermore, the system may contain steam bubbles and steam film around debris particles which will affect the water-to-corium volume ratio in the k_{inf} calculations. The simulations in [2–3] show under-moderated conditions for porosities below 0.7–0.8, meaning the steam presence will *decrease* k_{inf} while porosities above 0.7–0.8 are over-moderated and steam will *increase* k_{inf}.

2.2. Recriticality in debris bed

When the debris particles have settled on the containment floor they will form a debris bed or pile. The geometrical prerequisites for the debris bed can be estimated analogously to the dispersal phase of debris particles. However, the shape is slightly different. As a first approximation, a spherical shape or a flat cylinder according to Eq. (4) or Eq. (6) may be appropriate. Experiments of jet fragmentation (e.g. [10]), suggest a debris bed will form a roughly conical geometry, for which no analytical solution to B^2 exist. However, B^2 estimates for arbitrary geometry can also be obtained by numerical solutions of the one-group diffusion eigenvalue equation

$$(M^2\nabla^2 + 1)\, \Phi(\bar{r}) = \frac{1}{k_{\text{eff}}}\, k_{\text{inf}}(\bar{r})\, \Phi(\bar{r}) \tag{7}$$

where $\Phi(\bar{r})$ and $k_{\text{inf}}(\bar{r})$ are the neutron flux and infinite multiplication at position given by position vector $\bar{r}$, respectively and M^2 is a position-independent migration area. By equating $k_{\text{inf}}(\bar{r})$ to unity for all positions within the desired shape and zero elsewhere, a k_{eff} value is obtained. The relationship between the k_{eff} and $k_{\text{inf}}(\bar{r}) = 1$ are related in Eq. (7) as k_{eff} and k_{inf} are related in Eq. (1). Thus, solving for B^2 in Eq. (1) with $k_{\text{inf}} = 1$ and k_{eff} obtained from Eq. (7) provides a method for obtaining an arbitrary geometric buckling estimate. Note that the buckling obtained by this method include neutrons reflected back into the system from the surrounding media whereas the analytical solutions in Eq. (4–6) does not.

Using this method, MATLAB calculations were performed in cylindrical coordinates to obtain B^2 and neutron flux distributions for three conical shapes with the angle of repose equal to 18°, 27° and 45°. Fig. 2 shows the neutron flux distribution for each case as a heat map, with brighter yellow regions indicating relatively high flux and darker blue regions indicating relatively low flux. Superimposed on the heat maps are red dots showing the conical debris geometry. As can be inferred from the flux distribution in Fig. 2, neutron flux is largely concentrated in a quasi-spherical region in the cone center, limited by cone height. From the numerical calculations, a correlation for B^2 in cm^{-2} was derived based on the angle of repose, θ and the base radius in cm, R given by

$$B^2_{\text{cone}} = 10(\tan\theta)^{-1.1}\, R^{-1.78}. \tag{8}$$

The correlation is valid to within 10% of the numerical results for θ = 18–45°, R = 60–300 cm and M^2 = 40–70 cm^2. The flux distribution in Fig. 2 and the correlation in Eq. (8) assumes complete or uniformly distributed water ingress. If void distribution inside the debris bed due to hindered water penetration or steam formation is known, the $k_{\text{inf}}(\bar{r})$ in Eq. (7) and the B^2 estimate could in principle be adjusted to account for this.

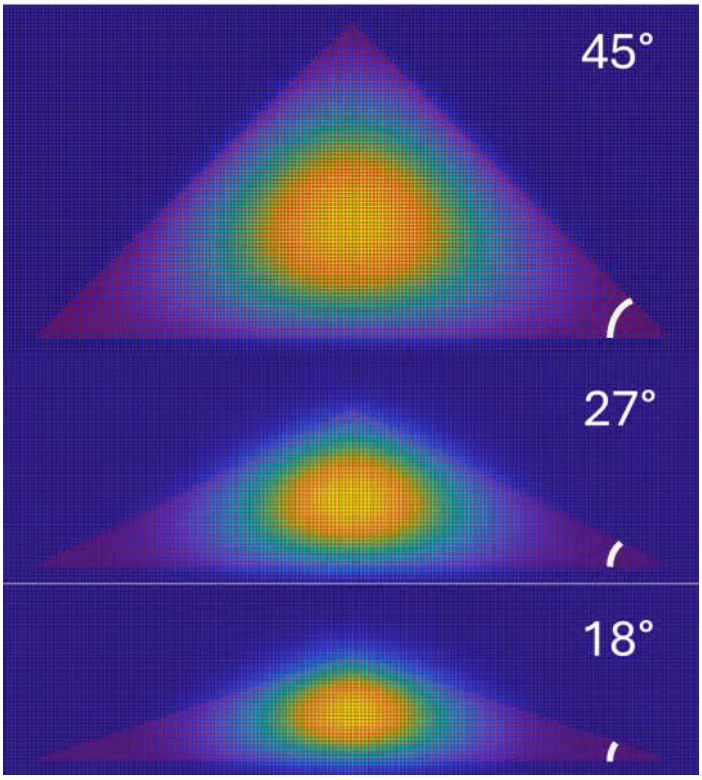

Figure 2. Neutron flux distribution and cone geometry for angles of repose of 18°, 27°, and 45°.

The migration area of the debris bed is harder to estimate than for the dispersed particles but could also be as low as 40 cm^2 or as high as 70 cm^2, roughly corresponding to a power reactor in cold and hot conditions, respectively. The correlation in Eq. (8) has been applied to plot the curves in Fig. 3, which shows the estimated bounding region of the values of k_{inf} required for critical conditions as a function of a conical debris bed radius. By comparing the region between the curves in Fig. 2 with the Monte Carlo simulations by Freiría López et al, A debris pile height exceeding 1 m would likely result in critical conditions, provided it consist of an isotropic uranium-dioxide porous bed without closed voids.

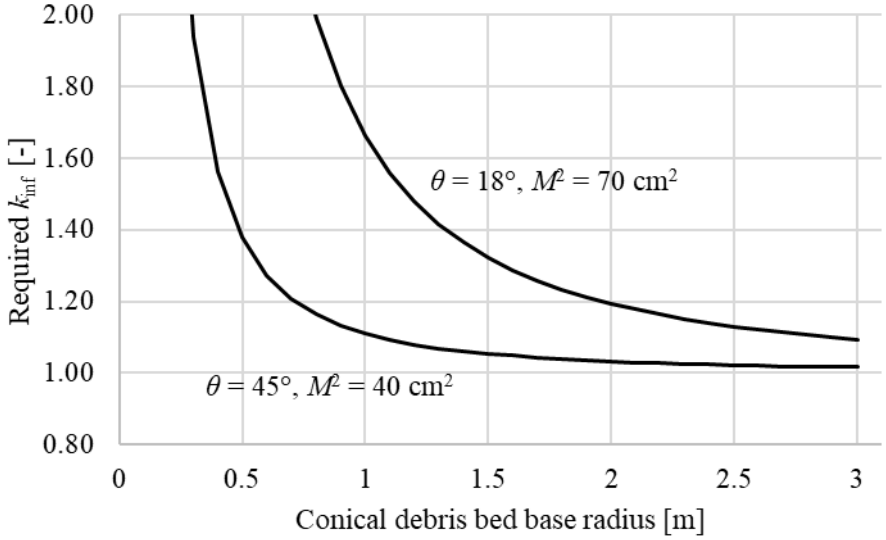

Figure 3. Required kinf for conical debris bed with angles of repose between 18° and 45°.

Consider the following illustrative example: Assume 50 tons of pure uranium oxide is ejected from a reactor vessel, forming a conical pile of porous debris with an angle of repose of 35° on a flooded containment floor. Further assume a debris bed porosity of 0.4 and a density of 8 tons/m^3 to obtain a base radius of 2.2 m and thereby a B^2 of 9.6×10^{-4} cm^{-2}. Fresh enriched uranium oxide, a particle size distribution comparable to that found in the DEFOR-A experiments and complete water ingression would yield a k_{inf} of 1.23 according to [2]. Eq. (1) and Eq. (8), together with the assumption of $M^2 = 40$ cm^2 would yield a k_{eff} of 1.18. The same example but instead assuming a porosity of 0.7 would yield a k_{eff} of 1.38. Both obtained values indicate significantly supercritical conditions.

3. CONCLUSION

The present work advances the previous studies of Freiría López et al. [2–3] on recriticality in infinite systems by also considering neutron leakage. The calculation results suggest recriticality is possible in both dispersal and settled phases of debris particles unless neutron absorbing materials (especially boron) are present. If no criticality occurs during the dispersal phase, critical conditions may occur later in a settled porous debris bed if there is sufficient water ingression and insufficient boron presence. The implication of the findings may be limited by the simple models which are incapable of coupling neutron kinetics with thermal-hydraulics in porous media, as well as incomplete knowledge of corium composition and ejection, fuel coolant interactions and resulting debris bed characteristics. Further progresses in these areas are needed to improve the understanding and assessment of ex-vessel recriticality risk. In particular, the results in this study suggest Monte Carlo simulations of k_{inf} and data of water-to-corium ratios, specifically addressing jet fragmentation and debris bed water ingress conditions, would make a significant contribution.

Geometrical Prerequisites for Ex-Vessel Recriticality in Flooded Cavity Containments

Björn Engström, Weimin Ma

Nuclear Power Safety group, Division of Nuclear Science and Engineering
Royal Institute of Technology, KTH

Introduction and Outline

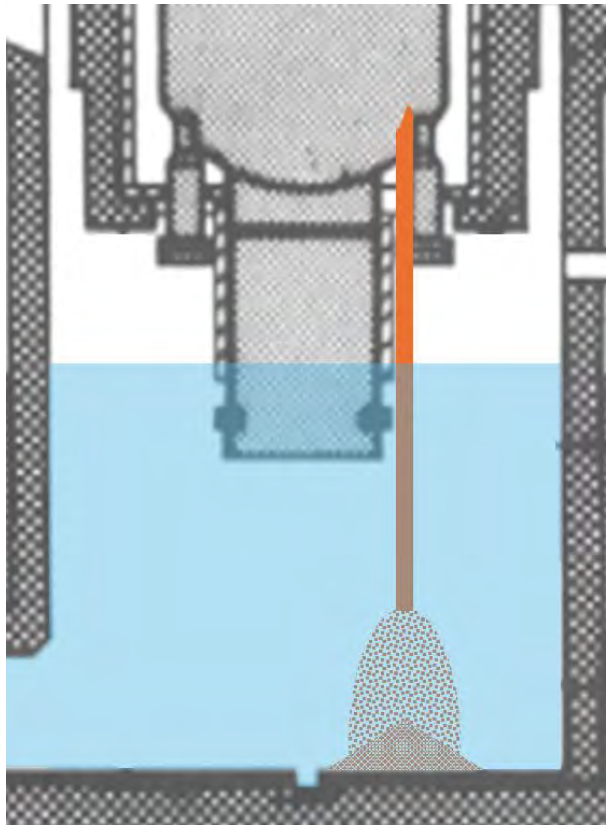
Recriticality risk during melt ejection into **deep water pool**

- Fuel may be **separated** from neutron **absorbers** before/during melt ejection
- Dispersion in water create **moderating** conditions
- Monte-Carlo simulations by Freiría López et al. (2019, 2020) suggest fuel particles in water may yield **high k-inf values**

Recriticality **important** for fuel-coolant interactions and coolability

Neutron leakage calculations can provide insights

- **Complements k-inf** simulations by Freiría López et al.
- Neutron leakage determined by **geometrical conditions**
- Appropriate considering ex-vessel phenomena uncertainties



Theory - Neutronics

Neutron leakage

- based on geometrical buckling, B^2
- Radial coordinates (r, z)

Simplified neutronics sufficient for estimates

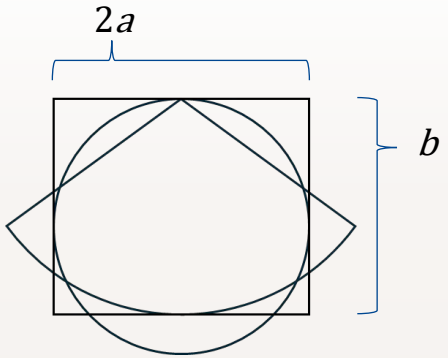
- Steady state (delayed neutron contribution negligible)
- One neutron energy group diffusion theory
- Quasi-homogenous system (uniform absorption/diffusion)
- Reasonable agreement with Monte Carlo, cf. Bowen & Busch (2023)

Some analytical solutions of B^2

$$B^2_{sphere} = \left(\frac{3.1416}{a}\right)^2$$

$$B^2_{108° sector} = \left(\frac{5.7635}{b}\right)^2$$

$$B^2_{cylinder} = \left(\frac{2.4048}{a}\right)^2 + \left(\frac{3.1416}{b}\right)^2$$

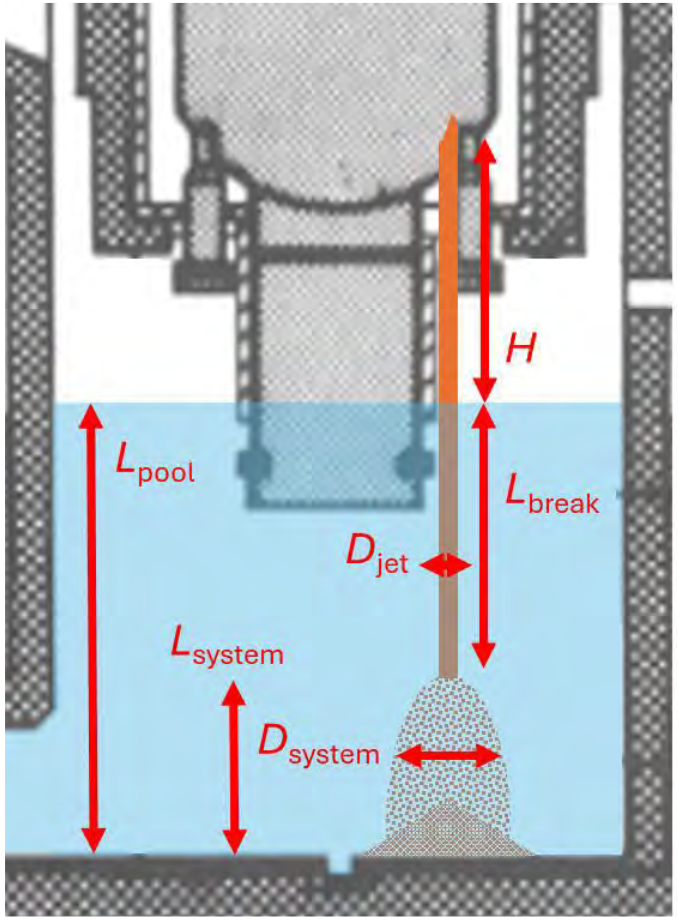


$$-\nabla \cdot D(r,z)\nabla\Psi(r,z) + \Sigma_a(r,z)\Psi(r,z) = \frac{1}{k_{\text{eff}}}\nu\Sigma_f(r,z)\Psi(r,z)$$

$$B^2M^2 + 1 = \frac{k_{\text{inf}}}{k_{\text{eff}}}$$

$\Psi(x)$	neutron flux
$D(x)$	neutron diffusion coefficient
Σ_a	condensed macroscopic absorption cross section
Σ_f	condensed macroscopic fission cross section
ν	fission neutron yield (prompt and delayed)
k_{eff}	effective multiplication factor (smallest eigenvalue)
k_{inf}	infinite multiplication factor $(\nu\Sigma_f/\Sigma_a)$
M^2	effective migration area (D/Σ_a)
B^2	Geometric buckling (helmholtz eigenvalue, $-\nabla^2\Psi/\Psi$)

Dispersed debris particles



System Length based on break-up length (Saito, 1988):

$$L_{system} = L_{pool} - 2.1\sqrt{\frac{\rho_{corium}}{\rho_{water}} 2 H D_{jet}}$$

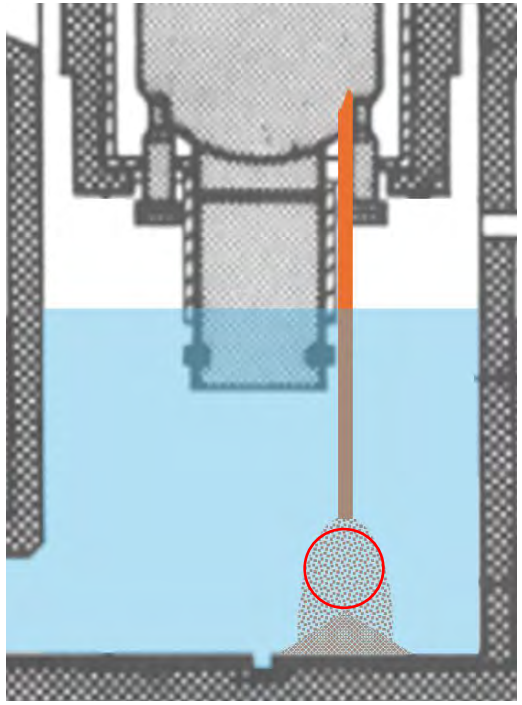
System Diameter based on free-fall and jet/water volume ratio:

$$D_{system} = (\alpha + 1) D_{jet}$$

$$D_{jet} = \sqrt{\frac{4}{\pi} \frac{\dot{m}_{corium}}{\rho_{corium}} \frac{1}{\sqrt{2gH}}}$$

H	height of vessel breach above water pool
L_{pool}	water pool depth
L_{break}	breakup length of corium jet
L_{system}	studied system height (axial length)
D_{system}	studied system diameter (radial length)
D_{jet}	corium jet diameter
ρ_{corium}	density of corium
ρ_{water}	density of water
α	water-to-corium volume ratio
$\dot{m}_{corium}$	mass flow of ejected corium from reactor vessel
g	gravitational acceleration

Dispersed debris particles cont.



k-inf required for recriticality – M^2 = 50 cm^2

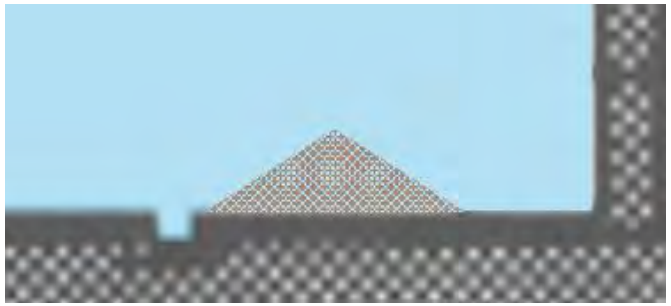
Work by Freiría López et al. suggest:

- k-inf > 1.0 for porosity 0.2-0.9 (uncertain beyond 0.9)
- k-inf 1.2-1.3 for porosity 0.7-0.8 (decreasing thereafter)

Debris bed



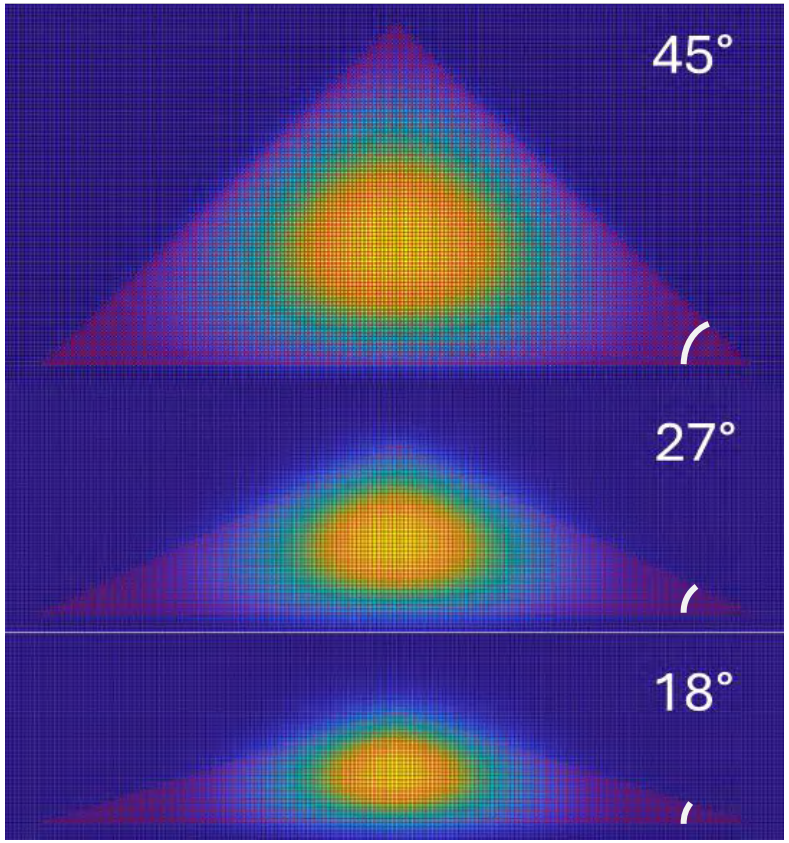
Numerical solution of cone

$$-M^2\nabla^2\Psi(r,z) + \Psi(r,z) = \frac{k_{\text{inf}}(r,z)}{k_{\text{eff}}}\Psi(r,z)$$

$$k_{\text{inf}}(r,z) = \begin{cases} 1, & r,z \in debris\ bed \\ 0, & r,z \notin debris\ bed \end{cases}$$

$$\downarrow$$

$$B^2_{cone} = \frac{1}{M^2}\left(\frac{1}{k_{\text{eff}}} - 1\right)$$



Neutron leakage predominantly determined by cone height.

Recriticality if axial size above ~1 m

- Water ingression
- Absorber presence (e.g. boron)

Correlation based on calculations

$$B^2_{cone} \approx 10\tan(\theta)^{-1.1}\,R^{-1.78}$$

accurate within 10% for:

- angle of repose, $\theta \in [18°,45°]$
- migration area, $M^2 \in [40\ cm^2, 70\ cm^2]$
- base radii, $R \in [60\ cm, 300\ cm]$.

Conclusions

- Study extends the work on k-inf by Freiría López et al. (2019, 2020) with **neutron leakage effects**.
- Results indicate **recriticality possible** for particles
  - **dispersed in a deep-water pool**
  - after **settling on the pool floor**

Additional considerations required for criticality

- sufficient **dispersion** of particles after jet break-up
- sufficient **water ingression** in debris bed
- no or weak **neutron absorbers** presence (e.g. boron)
- **steam** presence may limit moderation

- Further research required to improve **ex-vessel recriticality** analysis
  - Jet break-up and fragmentation
  - Particle dispersal, suspension & settling
  - Debris-bed composition & water ingression

Current findings are **limited** by:

- simplified modeling assumptions
- **uncertainty** in **corium ejection**, **fuel-coolant interactions** and **debris characteristics**

ABSTRACT

Severe accidents in pressurized water reactors may result in reactor pressure vessel failure, ex-vessel corium relocation, and subsequent molten core–concrete interactions (MCCI). For the VVER-1000 design, preservation of containment integrity after MCCI constitutes the ultimate barrier against fission product release. While in-vessel retention and ex-vessel cooling strategies have been extensively investigated since the Fukushima Daiichi nuclear disaster, retrofit solutions for plants under operation remain constrained by geometry and system limitations. In particular, delayed water injection may lead to prolonged dry MCCI, increasing the risk of basemat ablation and challenge containment integrity. This study proposes and evaluates a combined ex-vessel stabilization concept tailored to VVER-1000 units. The strategy integrates (i) corium spreading to a predefined area, (ii) a refractory protective layer, (iii) a geopolymer-based sacrificial layer for chemical moderation, and (iv) delayed top flooding to establish long-term cooling through water ingression and melt eruptions phenomena. Spreading behavior was assessed using MELTSPREAD in previous work, while corium–material interactions and basemat ablation were analyzed with CORQUENCH under conservative assumptions in this work. Comparative simulations between limestone common sand concrete and geopolymer sacrificial materials indicate that the geopolymer significantly reduces hydrogen generation, further lowers the fraction of unoxidized metallic species in the melt, and decreases the solidus temperature by approximately 100 K, thereby enhancing coolability. Conservative modeling suggests 0.5 m geopolymer sacrificial layer can delay basemat attack for several hours without flooding. With top flooding initiated approximately 12 hours after accident onset, total concrete ablation remains limited. The results demonstrate that the proposed layered stabilization approach can maintain thermo-mechanical containment integrity with an adequate safety margin under delayed flooding conditions.

Ex-vessel stabilization, Sacrificial materials, VVER-1000

1. INTRODUCTION

Severe accidents involving core degradation and reactor pressure vessel (RPV) failure may lead to ex-vessel corium relocation and molten core–concrete interaction (MCCI). In pressurized water reactors, including the VVER-1000 design, preservation of containment integrity represents the ultimate barrier against fission product release. After the Fukushima Daiichi nuclear disaster, intensified research focused on both in-vessel retention (IVR) and ex-vessel corium cooling (ExVC) strategies worldwide.

Corium is a complex multiphase mixture of oxidic and metallic components (UO_2–ZrO_2–Zr–Fe–steel constituents) with strong temperature-dependent viscosity and internal heat generation due to decay heat.

During spreading, its rheology evolves rapidly as solid fraction increases near the solidus temperature. In the ex-vessel phase, cooling mechanisms include top flooding, water ingression (WI), and melt eruptions (ME), which significantly enhance heat transfer compared to pure conductive cooling through a crust layer. Experimental programs such as MACE and OECD-MCCI have demonstrated that WI and ME can increase heat flux to several hundred $kW \cdot m^{-2}$ under favorable conditions [1].

However, effective cooling requires timely water delivery. In retrofit scenarios for operating plants, immediate flooding cannot always be guaranteed due to geometric and system constraints. Delayed flooding may result in prolonged dry MCCI, threatening the structural integrity of the containment basemat.

The objective of this study is to investigate measures that can ensure short-term thermal protection of the basemat before active flooding begins, and facilitate long-term stabilization once water top-cooling is established. The ultimate goal is to showcase that the thermo-mechanical integrity of the containment structure can be maintained with a sufficient margin.

Spreading is assumed successful based on prior mechanistic analyses with MELTSPREAD. The present work concentrates on post-spreading thermal protection and chemical stabilization.

2. VVER-1000 SPECIFICS RELEVANT TO THE PRESENTED STUDY

The VVER-1000 containment features a rather complex geometry between the reactor cavity and designated spreading compartments. According to feasibility analyses for VVER-1000/V320 units, corium spreading would proceed from the RPV lower plenum into the reactor cavity and subsequently through a corridor into an adjacent spreading room prepared for top flooding. [2]

Unlike some Western PWR designs, the VVER-1000 reactor cavity concrete bottom is lined with steel layers serving as thermal shielding. This configuration complicates structural modifications in the cavity region. Additionally, inspection equipment pathways and the presence of the recirculation sump at the lowest elevation introduce further constraints for implementing IVR or extensive cavity redesign.

Experimental investigations with prototypic corium compositions have shown limited penetration into these layered steel systems, with rapid crust formation at the interface. This supports the feasibility of allowing corium to spread toward a prepared ex-vessel area rather than penetrating deeply into the shaft structures.

The spreading area typically includes approximately 25 m^2 in the reactor cavity and 60 m^2 in an adjacent compartment. Successful spreading requires sufficient corium fluidity at RPV failure. MELCOR-based analyses indicate volumetric solid fractions on the order of 10–15% at vessel breach, allowing spreading under most scenarios. Sensitivity analyses highlight the influence of:

- Solid fraction–temperature relations (U–Zr–Fe–O quaternary system),
- Pour rate through the rupture opening,
- Sequence of metallic versus oxidic phase relocation.

If no mitigation is applied and corium remains dry on concrete for extended periods, MCCI may lead to substantial basemat ablation, hydrogen production, and possible containment failure due to thermos-mechanical stress.

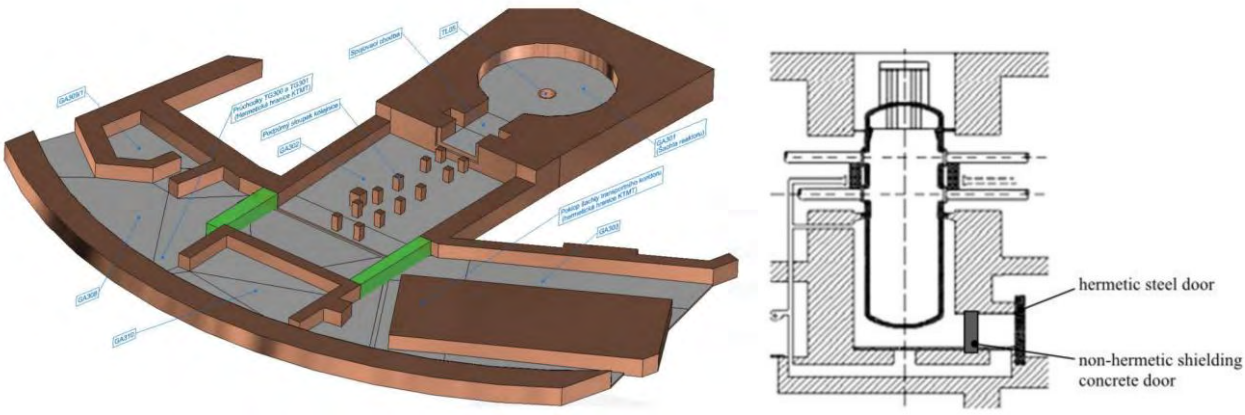

Figure 1. VVER-1000 reactor cavity and adjacent compartments. [2]

2.1. Delayed water inlet and basemat protection

Although top flooding is recognized as an effective long-term cooling strategy, its effectiveness can be significantly reduced when implemented after a substantial delay. In such cases, several adverse phenomena may occur prior to coolant injection. First, a thick and mechanically robust crust layer may form on the corium surface, impeding subsequent heat removal. Second, dense crust structures can substantially limit water ingression, thereby reducing cooling efficiency. Third, prolonged exposure to elevated temperatures may lead to progressive weakening and degradation of the underlying concrete before active cooling is initiated.

These limitations highlight the need for a passive mitigation measure capable of withstanding direct corium contact and delaying the onset of concrete damage. An effective protective system should possess a high melting temperature to ensure structural integrity under severe thermal loads, exhibit low chemical reactivity with corium to minimize detrimental interactions, and maintain mechanical stability under rapid thermal transients. Furthermore, the material should degrade in a controlled and gradual manner, avoiding abrupt or catastrophic failure that could compromise the cooling process.

3. STUDIED SOLUTION

In the light of the previous information, a combined ex-vessel corium stabilization strategy consisting of 5 steps is applied by the authors:

1. Spreading over a predefined area (assumed successful).
2. Primary thermal protection using refractory layer.
3. Chemical moderation of corium via geopolymer sacrificial layer.
4. Delayed top flooding with external water supply.
5. Enhanced cooling through WI and ME phenomena..

Short-term protection is therefore provided by refractory and insulating properties of the thermal protection layer. Long-term stabilization relies on water top flooding and reduced MCCI aggressiveness due to sacrificial material interaction.

3.1. Protective layer

A candidate protective layer material to avoid excessive basemat ablation is zirconia, used in various core catcher solutions such as EPR. Zirconia is a widely used material with melting temperatures above 2700 K. Its chemical stability against oxidic melts and corrosion resistance at high temperatures make it suitable for extreme applications such as protective layer in a core catcher. [3]

Zirconia's low thermal conductivity (2–3 $W \cdot m^{-1} \cdot K^{-1}$ at high temperature) provides significant thermal insulation, reducing heat flux to underlying concrete.

High-temperature corrosion studies [1][3] indicate that ZrO_2 exhibits limited dissolution in oxidic corium; dissolution kinetics depend on oxygen potential and interaction with metallic Zr and UO_2. Diffusion-controlled dissolution models suggest that reduction reactions are constrained by limited mass transport within the melt, particularly under stratified configurations.

Failure modes include:
- Thermochemical dissolution into oxidic corium,
- Reduction by metallic zirconium,
- Mechanical cracking due to thermal shock,
- Spallation from rapid temperature gradients.

However, ensuring complete integrity of the protective layer is not required for the studied solution. The design objective is only time delay — postponing concrete ablation for several hours until active cooling is established is deemed a success, even though the protective layer is severely damaged or completely destroyed in the process.

3.2. Sacrificial materials

Parallel research efforts have led to the development of geopolymer-based sacrificial liners intended for ex-vessel applications in severe accident scenarios. These materials are designed to replace conventional concrete in designated corium spreading areas. In contrast to ordinary siliceous or limestone concrete, geopolymers contain only minimal amounts of chemically bound water, thereby limiting steam generation during high-

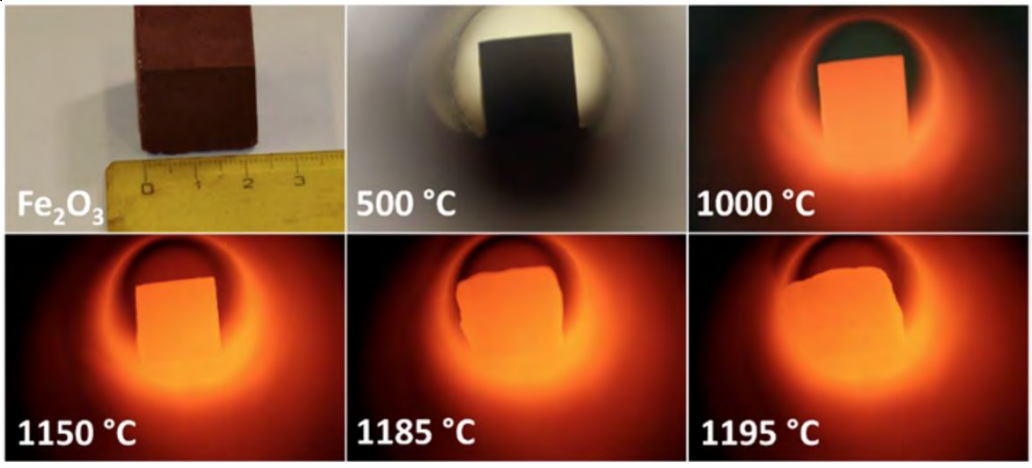

Figure 2. Geopolymer sacrificial material cube thermal resistance test.

temperature interaction. They retain their mechanical properties at temperatures up to approximately 500°C for short durations and remain stable below approximately 200°C under long-term conditions. In addition, these materials demonstrate resistance to gamma radiation, supporting their applicability in high-radiation environments.

During interaction with corium, geopolymer materials are engineered to produce significant quantities of carbon dioxide while generating only limited amounts of hydrogen. This behaviour reduces the overall production of flammable gases compared to conventional siliceous concrete. The release of gas promotes crust cracking, which may enhance heat transfer and coolability. Furthermore, chemical interactions between the geopolymer and corium can modify the oxidation state of the melt, leading to a reduction in the metallic fraction.

Comparative analyses performed using the CORQUENCH code indicate substantially lower hydrogen production and significant carbon dioxide release when geopolymer materials are used instead of conventional VVER-1000 concrete. This chemical buffering effect reduces exothermic metal oxidation reactions and mitigates the risk of containment pressurization.

The incorporation of geopolymer sacrificial layers over the zirconia protection may therefore contribute to oxidation of residual metallic zirconium, reduction of the initial corium temperature through endothermic reactions, and improved long-term coolability following flooding.

More information on the sacrificial materials chosen for this study can be found in [4] and [5].

4. ANALYSIS OF THE SACRIFICIAL MATERIAL PERFORMANCE

The studied accident scenario is a LB-LOCA, with conservative assumptions on timing of RPV failure (~4 hours). Corium spreading was analysed using the MELTSPREAD 3.0 code. More information on the scenario and the analyses of in-vessel phase and corium spreading can be found in [2].

The main aim of this study, the performance of the sacrificial material in comparison to LCS-type concrete, was studied using CORQUENCH 4.1 code. A layer of 0,5 m of sacrificial material was put on top of, with the containment basemat located underneath the protective layer. The results of interest are following:

- Chemical composition of the melt (to assess the potential of the melt to attack the protective layer)
- Amount and composition of non-condensable gases produced from the corium-sacrificial material interaction (to assess effects on containment integrity)
- Temperature of solidus and liquidus of the melt (to assess effects on corium coolability)

4.1. Modeling Considerations and CORQUENCH Conservatism

System codes such as CORQUENCH assume homogenized melt composition and do not resolve spatial distribution of species in sublayers [6]. This may lead to conservative predictions of zirconia ablation.

An illustrative example concerns CO_2 reduction to CO in contact with metallic layers. CORQUENCH predicts near-complete conversion, whereas experimental data show that approximately 90% of generated CO_2 may escape without reduction due to limited residence time. Consequently, predicted chemical aggressiveness toward refractory materials can be overstated.

To address unrealistic low-temperature ablation rates (mm·h⁻¹ below 1700 K), a cutoff bulk temperature of 2000 K was adopted in sensitivity analyses. Considering the thermal gradient across the zirconia layer, the interface temperature is significantly lower than bulk melt temperature, further supporting this assumption.

4.2. Corium properties after sacrificial material incorporation

A 500 mm-thick layer of sacrificial material was modelled in direct contact with corium immediately following completion of the spreading phase. Two candidate materials were considered: a conventional limestone common sand concrete (LCSC) and an innovative geopolymer-based formulation. The interaction between corium and the sacrificial layer was simulated using CORQUENCH. A one-dimensional (1D) modelling approach was adopted, and no top flooding with water was assumed. Each simulation was terminated once the entire sacrificial layer had been fully incorporated into the molten pool.

The calculated post-interaction melt compositions indicate that, in both cases, the overall chemical composition of the resulting melt is broadly comparable, as can be seen in Table I. However, the geopolymer scenario exhibits a lower fraction of unoxidized metallic species relative to the LCSC case. This difference is particularly relevant for zirconium-bearing phases, as the presence of unoxidized metals—especially Zr—can substantially accelerate degradation of protective layers through enhanced chemical reactivity and heat generation. The reduced content of unoxidized metals in the geopolymer case is therefore considered favourable from the standpoint of long-term melt stabilization and structural integrity.

Table I. Melt chemical composition (constituents below 1 % neglected)

	concrete	geopolymer
CONSTITUENT	**Mass fraction [-]**	**Mass fraction [-]**
UO2	0.37	0.38
ZRO2	0.17	0.16
CR2O3	0	0
NIO	0	0
B2O3	0.01	0
FE	0.03	0
CR	0	0
NI	0	0
ZR	0.01	0
U	0	0
B4C	0.01	0.02
SI	0	0
SIO2	0.03	0.09
CAO	0.16	0.06
MGO	0.02	0.04
AL2O3	0.01	0.14
FEO	0.12	0.05
FE2O3	0.03	0.03
FE3O4	0.03	0.03

Significant differences were observed in both the quantity and composition of non-condensable gases generated during corium–material interaction, see Table II. As anticipated, the geopolymer material produces relatively low amounts of hydrogen while generating predominantly carbon dioxide and limited quantities of carbon monoxide. In contrast, decomposition of the limestone concrete results in substantial hydrogen production. This distinction has important safety implications. The lower yield of flammable gases—particularly hydrogen—in the geopolymer case reduces the potential for deflagration or detonation compromising structural integrity of the containment.

Table II. Amount of NCGs produced by interaction with sacrificial material

	H_2	CO	CO_2	Total	
	mass (kg)	mass (kg)	mass(kg)	mass (kg)	amount of substance (kmol)
Concrete	1448	147	2311	3906	782
Geopolymer	202	503	7885	8590	298

With respect to thermophysical properties, the calculated solidus and liquidus temperatures of the resulting melts are similar for both materials, with one notable difference: incorporation of the geopolymer leads to a reduction in solidus temperature on the order of approximately 100 K, while the liquidus temperature remains essentially unchanged, see Table III. The lower solidus temperature implies that the melt remains fully or partially liquid over a broader temperature range during cooling. This behaviour may enhance the melt's effective cooling capability by delaying solidification and promoting improved heat transfer via convection prior to complete freezing of the melt.

Table II. Solidus and liquidus temperatures of the melt after incorporation of sacrificial materials

	Solidus T (K)	Liquidus T (K)
concrete	1508.7	2525.9
geopolymer	1403.0	2493.3

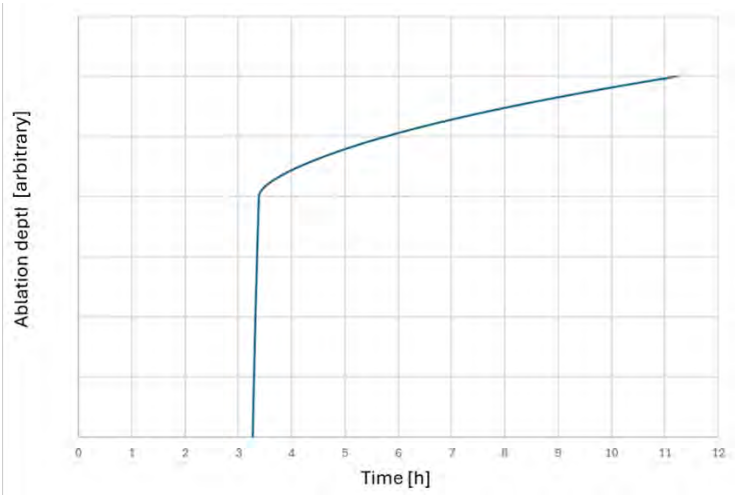

Figure 3. Rate of consumption of the sacrificial material and subsequent damage of the protective layer.

Overall, the simulations indicate that geopolymer-based sacrificial material offers several potential advantages over conventional limestone concrete, including reduced concentrations of unoxidized metals in the melt, significantly lower hydrogen production, and moderately improved thermophysical characteristics relevant to cooling performance.

4.3. Function of the protective layer

Following the incorporation of the sacrificial material, a subsequent analysis was performed using CORQUENCH to evaluate the rate of degradation of the protective layer under the assumption that no top flooding of the melt occurs. In this phase of the study, only geopolymer-based sacrificial materials were considered, as their performance was shown in the previous section to be superior to that of conventional concrete.

The primary objective of this analysis was to determine the duration for which the protective layer can maintain its integrity in the absence of top cooling by water. The results indicate that the selected refractory material can conservatively withstand thermal and chemical attack for approximately 8 hours before being fully consumed, as seen in the graph in Figure 3.

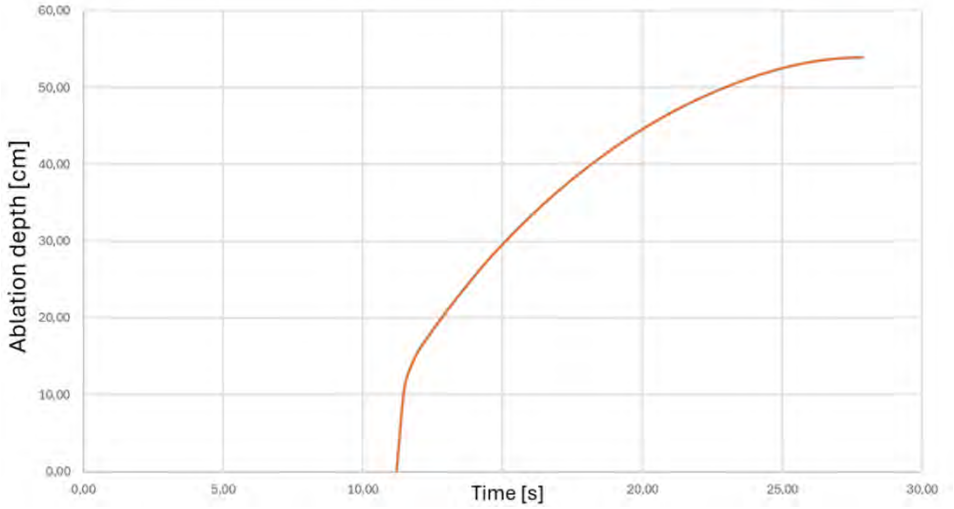

Figure 4. Rate of concrete ablation after failure of the protective layer (with top-flooded melt).

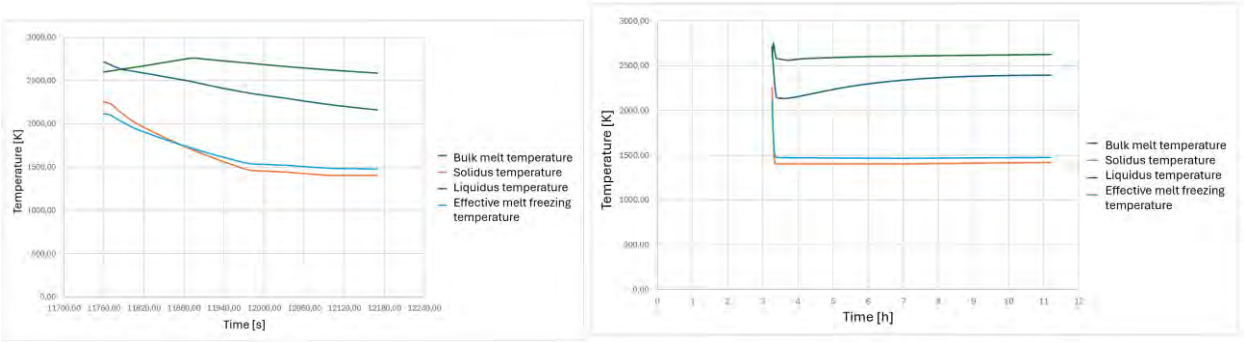

Figure 5. Temperatures in the melt during the consumption of the sacrificial material (left) and long-term during damage of the protective layer (right)

A subsequent scenario was then evaluated in which water is introduced onto the top surface of the corium after this period, corresponding to roughly 12 hours after the onset of the accident. The analysis shows that, under these conditions, the total ablation depth of the basemat concrete is limited to approximately 0.5 m, see Figure 4.

The results further demonstrate that, although the incorporation of the sacrificial material initially reduces the melt temperature due to dilution and endothermic interactions, the residual decay heat within the corium eventually offsets this cooling effect. As a result, the melt temperature begins to rise again after the initial decrease, see Figure 5.

5. CONCLUSIONS

The present study investigated a layered ex-vessel corium stabilization concept for VVER-1000 reactors under severe accident conditions with delayed water injection. The proposed approach combines refractory thermal protection, chemically engineered sacrificial materials, and subsequent top flooding to ensure both short-term basemat protection and long-term coolability.

The analyses indicate that stabilized zirconia provides effective short-term thermal insulation and chemical resistance, primarily serving as a time-delay barrier rather than a permanent containment solution. The incorporation of a geopolymer-based sacrificial layer beneath the corium significantly modifies melt chemistry compared with conventional limestone concrete. In particular, reduced hydrogen generation and lower concentrations of unoxidized metallic zirconium decrease both combustion risk and chemical aggressiveness toward protective structures. The moderate reduction in solidus temperature further supports improved cooling behaviour once flooding is established.

Conservative CORQUENCH simulations show that the combined layered system can withstand several hours of dry interaction and, with delayed top flooding, limit basemat erosion to manageable levels. Although residual decay heat eventually offsets the initial temperature reduction caused by sacrificial material incorporation, the transition to water-enhanced cooling mechanisms stabilizes the melt and prevents uncontrolled concrete attack.

Overall, the results support the technical feasibility of implementing a retrofit-oriented, layered ex-vessel stabilization system for VVER-1000 units. The concept offers a robust margin for containment integrity even in scenarios involving delayed flooding and represents a viable complementary strategy to existing severe accident management measures.

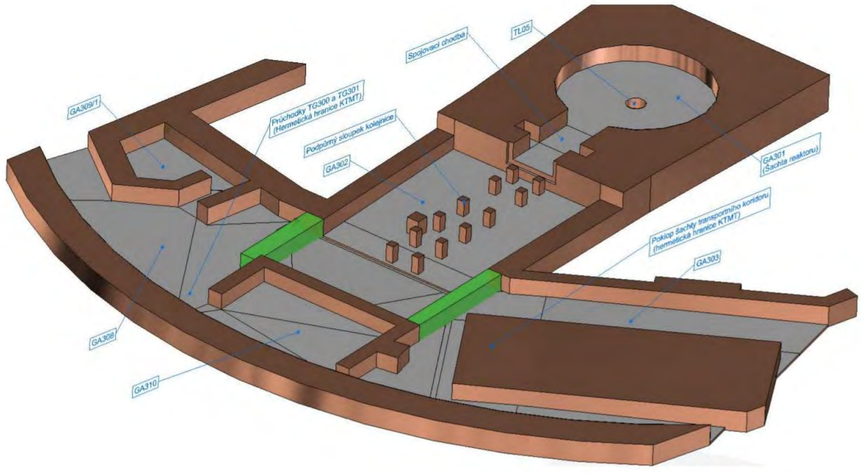
OUTLINE

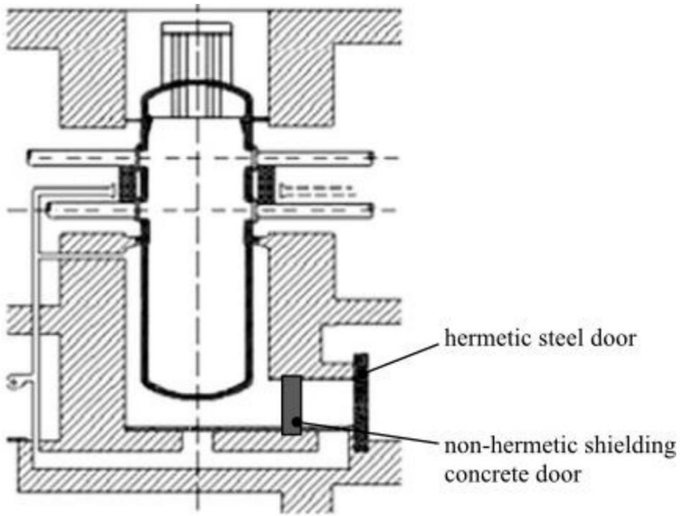
- **Background – VVER 1000 ex-vessel corium stabilization**
- **Innovative sacrificial materials based on Geopolymers**
- **Reactor case study – description**
- **Reactor case study – results**
- **Conclusions**

Background – VVER 1000 ex-vessel corium stabilization

BACKGROUND – VVER 1000 MELT STABILIZATION (1)

- **Melt stabilization in VVER-1000:**
- IVMR – theoretically possible, retrofitting would be challenging - > not yet used in any NPP
- EVMR – theoretically possible, retrofitting a little less challenging -> studied in various countries, not yet used in any NPP
  - Challenges to be solved – allowing spreading, limiting MCCI to retain basemat structural integrity, enabling timely top-flooding with water
- **In this study:**
- A possible approach to EVMR strategy in VVER-1000 using corium spreading and sacrificial materials studied
- Emphasis on the effect of sacrifical materials effects on the melt stabilization progression





M. Kotouč, et al.: "Assessment of Ex-Vessel Corium Coolability in the Containment of the VVER-1000 Reactor as a Measure of Severe Accident Mitigation," *Proceedings of the 2022 10th European Review Meeting on Severe Accident Research*, Karlsruhe, Germany, May 16-19, 2022

BACKGROUND – VVER 1000 MELT STABILIZATION (2)

- **EVMR approach used in the study based on:**
- 1) RPV breach and corium ejection into dry cavity <- Initial conditions for the study, data taken from MELCOR/ASTEC simulation
- 2) Corium spreading to adjacent compartment – Assumed in the study, not modelled in detail (extensive R&D on this subject already done)
- 3) Corium-SM interaction – Compartment floor lined with a refractory layer and a sacrificial layer
- 4) Top-flooding with water, cooling – maximum delay of start of water inlet can be derived from the results of the study

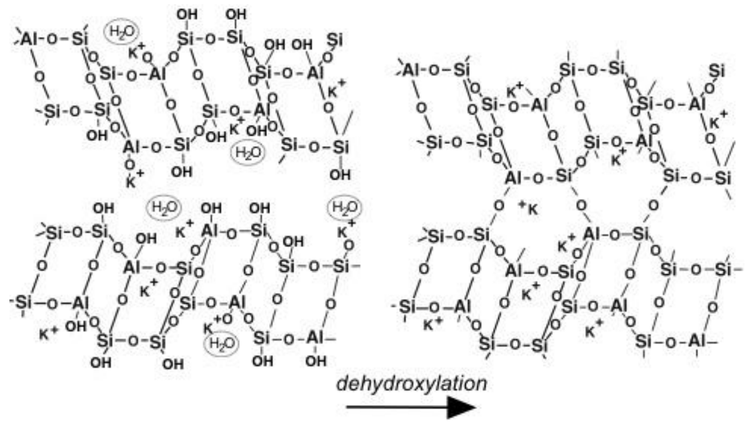
Innovative Sacrificial Materials Based on Geopolymers

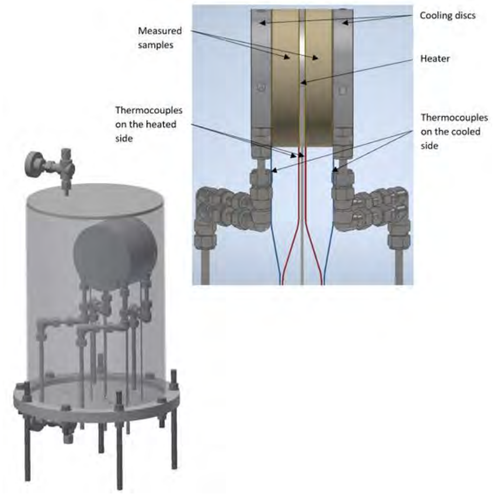
GEOPOLYMERS AS SACRIFICIAL MATERIALS (1)

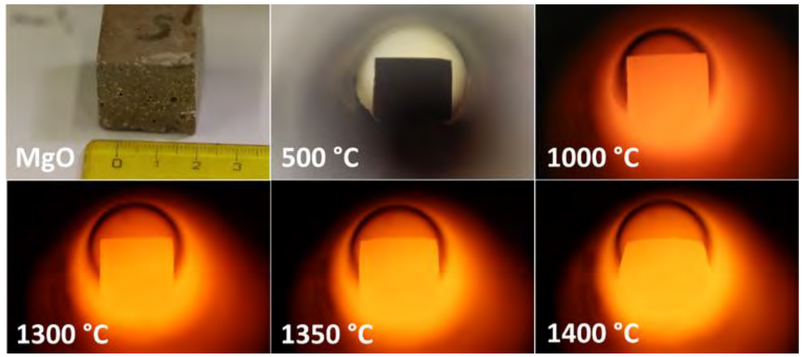
- **Geopolymers:**
- A group of inorganic polymer materials resembling concrete, based on alumino-silicates
- Coarse matrix capable of incorporating huge amounts of filler materials (up to 90 Wt.%)
- Filler materials influence properties of the geopolymer to big extent
- Modern waste immobilization candidate materials in the context of nuclear energy
- **Several key advantages compared to concrete in SA:**
- Minimum of water in the material – way below 1 Wt. % (usually around 0,1 – 0,2 %) while exhibiting similar structural properties as concrete
- The coarse geopolymer matrix can be filled with functional materials – from „simple“ oxidizers to complex compounds changing the properties of the melt



GEOPOLYMERS AS SACRIFICIAL MATERIALS (2)

- **Materials studied (experimentally and computationally) as fillers for the matrices so far:**
- $CaCO_3$ – Limestone, extensive gas production to enhance cooling via melt eruptions
- Al_2O_3 and Mg0 – refractory materials for the long-term exposure to corium
- Gd_2O_3 – neutron absorber
- Fe_2O_3 – dilution of oxide phase, functional material
- $Ca_3(PO_4)_2$ – functional material
- **All the materials very well characterized and important properties measured with excellent results:**
- Solidus and liquidus temperature (alone and in mixture with prototypical corium), thermal conductivity and specific heat capacity, thermogravimetry, mechanical strength, gamma radiation exposure, boric acid exposure
- Extensive R&D program under national and international collaborative programs





Reactor Case Study - Description

REACTOR CASE STUDY – CODES AND MODELS

- **Codes used:**
- ASTEC – in-vessel phase modelling (LB-LOCA), source of initial conditions (amount of corium, composition, properties) for the study
- (MELTSPREAD/CFD – not used in this study, but based on previous results, spreading and change in corium properties after spreading was assumed)
- CORQUENCH 4.1 – 2D modelling, 3 step approach used (separate calculations with data transfer):
    1) Sacrificial material incorporation into the corium
    2) Refractory layer attack
    3) MCCI and Top-flooding with water and cooling (top-flooding assumed at the time of protective layer failure)

- **Problem configuration:**
- Initial state: slab geometry, corium on top of 500 mm layer of sacrificial material, refractory layer underneath, basemat concrete under the refractory layer
- Materials and compositions:
    - Corium: from ASTEC calculation (see next slide)
    - Sacrificial material: limestone-geopolymer (see next slide)
    - Refractory layer: zirconia

REACTOR CASE STUDY – COMPOSITIONS

REACTOR CASE STUDY – TROUBLESHOOTING

- **Gases produced from sacrificial material decomposition:**
- Codes such as CORQUENCH do not account for reaction kinetics – as long as any reactants are present in the system, they will react completely
- CO2 produced from the SM decomposition is all instantly reduced to CO <- large source term of CO in the initial phase of corium-SM interaction
- Simple experiment performed – two layers of metallic foils (Zr and steel) on top of SM sample (thicknesses proportionally the same as in the reactor case scenario), heat-up to decomposition temperature, measurement of CO2/CO ratio
- Findings – 90 % of gas produced from the reaction is CO2, 9 % CO, 1 % other

- **Zirconia attack**
- Similar story – as long as any potentially damaging constituent is present in the problem, the zirconia layer will be attacked by it <- overestimation of attack rate (but OK, we are conservative and we do not include mechanical problems such as cracking)
- However - zirconia layer never stopped disappearing in the calculation – test case over 100h with „infinite“ layer of zirconia, rate was slower but zirconia layer was decreasing even under 1500 K
  - Based on extensive literature research – manual cutoff of further zirconia layer attack at 2000 K melt temperature.

Reactor Case Study - Results

REACTOR CASE STUDY – SM VS. CONCRETE

- **Comparison between geopolymer-based SM and LCS-type concrete sacrificial layer**

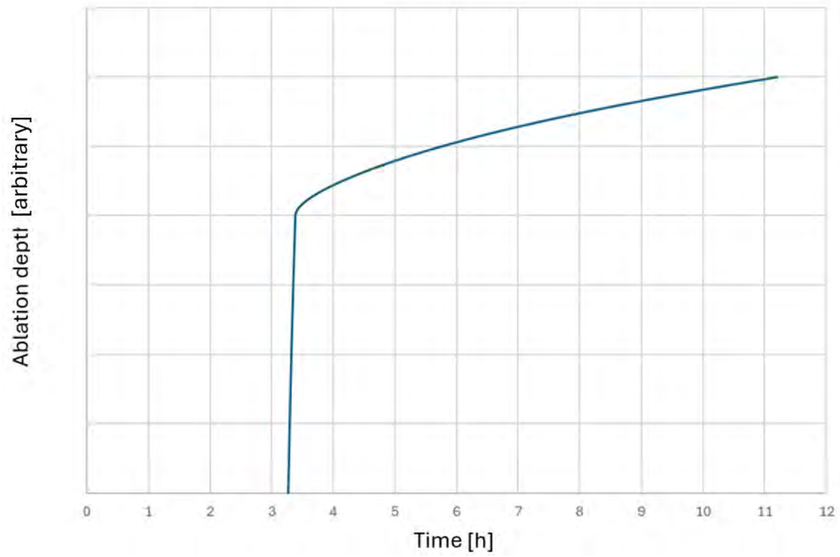
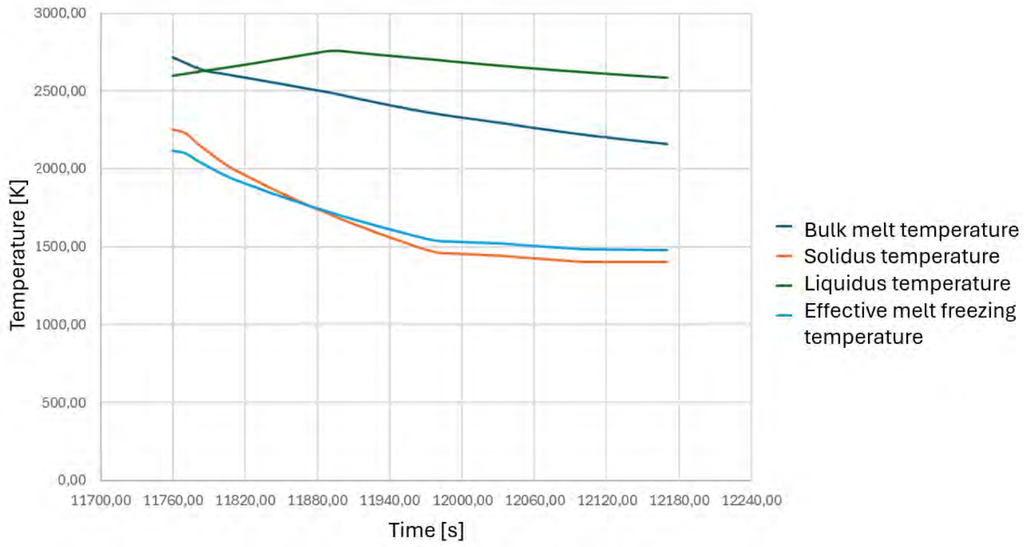
REACTOR CASE STUDY – SM PERFORMANCE

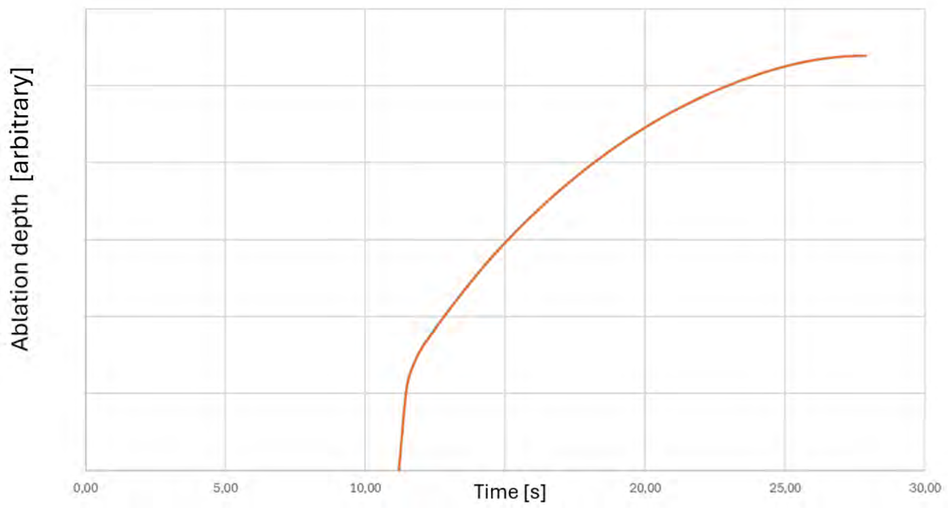
- **Results of CORQUENCH analysis:**
- SM is consumed relatively quickly (approx. 20 minutes)
- Refractory layer ablation rate stabilizes after 3 hours
- Without top-flooding, the temperatures of the system stay high-enough to consume the whole refractory layer

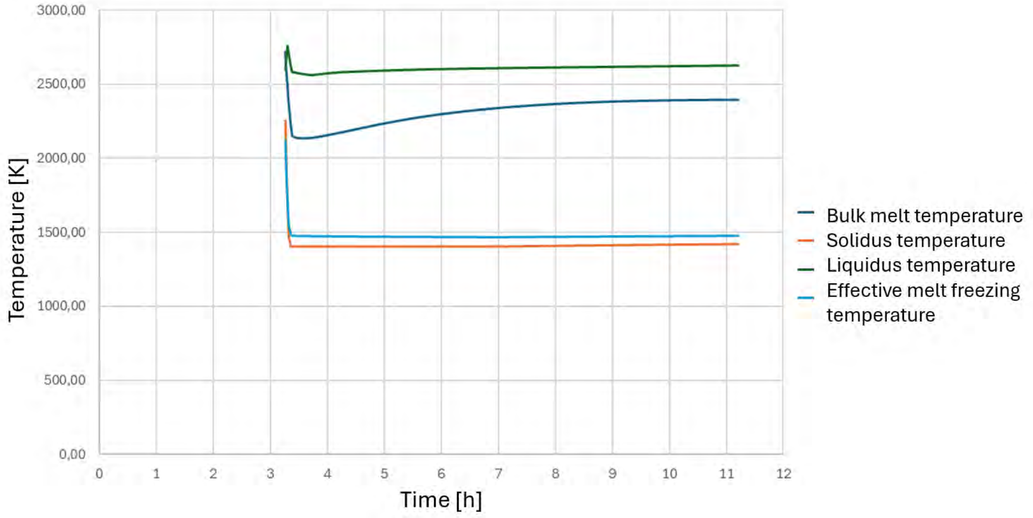




REACTOR CASE STUDY – STABILIZATION

- **Results of CORQUENCH analysis:**
- After consuming the refractory layer, a water-layer is assumed at the top of the corium
- Concrete ablation rate is steadily decreasing, reaching maximum depth at around 25 h mark
- Maximum ablation depth is relatively low, basemat retains its mechanical strength over majority of the cross-section





CONCLUSIONS

VVER-1000 ex-vessel melt stabilization

- Challenging, but possible as a retrofit
- Innovative approach in this study using the sacrificial geopolymers and refractory layer

Geopolymers

- Excellent sacrificial materials – low water content, up to 90 Wt.% of fillers to adjust corium parameters

Reactor case study

- VVER-1000 reactor, spreading assumed, focused on corium - sacrificial material interactions

Reactor case study

Promising, extensive amount of CO2 produced from geopolymer decomposition, melt temporarily stabilized (not attacking concrete) for up to 10 hours without top-flooding under the assumed conditions.

ABSTRACT

This study presents the development and validation of a Molten Core–Concrete Interaction (MCCI) analysis module within the SAFARI (Safety Analysis Code for Severe Accident Risk Identification) code, which is under development in South Korea as a regulatory-grade severe accident analysis tool. SAFARI is intended to support Severe Accident Management (SAM) strategies, and the implementation of a reliable MCCI module is a critical step in achieving this goal, as MCCI strongly influences the progression and consequences of ex-vessel severe accidents.

The MCCI module has been developed using a Python-based computational framework specifically tailored for MCCI calculations. It incorporates multi-physics models that represent the essential processes associated with corium–concrete interactions, including heat transfer, ablation, gas release, and corium pool configurations. To demonstrate its predictive capability, the module was evaluated against multiple benchmark experiments such as ACE-L2, SURC-2, CCI-2, and MOCKA 3.1. These validation cases cover a broad spectrum of conditions, including differences in corium states, concrete types, cavity geometry, and cavity boundary conditions. The results exhibited good agreement with experimental observations, capturing both thermal responses and ablation trends.

In addition, comparative studies with existing severe accident codes confirmed that the developed module provides comparable performance, reinforcing its applicability for regulatory safety evaluations. Overall, the study demonstrates that the SAFARI MCCI module offers a robust and versatile framework for analyzing ex-vessel accident progression and contributes to the broader goal of establishing an integrated severe accident analysis capability in South Korea.

KEYWORDS
MCCI, SAFARI, Severe accident, Corium, SAM

1. INTRODUCTION

When severe accident scenarios lead to core damage in a nuclear power plant, the nuclear fuel may melt and form molten fuel, commonly referred to as corium. If the accident progresses beyond reactor vessel failure, corium can be released into the reactor cavity, initiating ex-vessel severe accident phenomena that have a direct impact on containment integrity. To mitigate and terminate such accidents, various Severe Accident Management (SAM) actions are implemented, including cavity flooding and containment spray. The development and assessment of SAM strategies therefore require computational tools capable of consistently simulating a wide range of severe accident scenarios.

Integrated severe accident analysis codes have been widely used for this purpose, with representative examples including MELCOR, MAAP, ASTEC, and SAMPSON. While these codes provide comprehensive frameworks for severe accident analysis, there remains a need for analysis tools tailored to domestic reactor designs and regulatory requirements in South Korea. To address this need, the SAFARI (Safety Analysis Code For Severe Accident Risk Identification) code [1] has been under development as an integrated severe accident analysis tool for regulatory applications. SAFARI is designed to simulate accident progression from reactor vessel failure through ex-vessel phenomena, including corium coolability, molten core–concrete interaction (MCCI), and containment pressurization. The present study focuses specifically on the MCCI module within the SAFARI code.

When corium comes into contact with the concrete in the reactor cavity, MCCI occurs as a result of intense thermal and chemical interactions. Due to the high temperature of corium, typically exceeding 2000 K, substantial heat transfer to the concrete leads to concrete ablation and the formation of a molten concrete slag layer. This process progressively enlarges the cavity and generates gaseous decomposition products such as CO_2, H_2O, CO, and H_2, which can enhance convective heat transfer within the corium pool. Meanwhile, decay heat and oxidation reactions continue to supply energy to the corium, while cooling at the interfaces may result in the formation of solid crust layers. Heat removal from the corium upper surface strongly depends on cavity conditions, such as dry or flooded configurations, and significantly influences the long-term evolution of MCCI. In addition, corium stratification into oxide and metal layers may occur depending on material composition and accident conditions, further affecting heat transfer and concrete ablation behavior.

To analyze these complex phenomena, a number of MCCI analysis codes have been developed, including CORCON, COSACO, MEDICIS, CORQUENCH, and WECHSL. Among these, CORQUENCH, developed at Argonne National Laboratory, has been widely used due to its detailed treatment of key MCCI mechanisms and has served as a reference in the development of the SAFARI MCCI module. In parallel, numerous experimental programs have been conducted to investigate MCCI phenomena and provide data for code assessment. These include early metal-based experiments such as SWISS and SURC, as well as large-scale experiments using oxidic corium simulants, notably the CCI series, which provide valuable measurements of corium temperature and concrete ablation during the long-term MCCI phase.

In this study, the MCCI module of the SAFARI code is described and assessed using representative experimental data. The module has been developed to account for key factors influencing MCCI behavior, including cavity geometry, concrete type, and cavity cooling conditions. Validation calculations are performed using selected experiments, including ACE-L2, SURC-2, CCI-2 and MOCKA 3.1, which collectively cover a range of MCCI-relevant phenomena. Comparisons with experimental measurements and results from other MCCI analysis codes are presented to demonstrate the capability and performance of the SAFARI MCCI module. This paper presents an overall description of the Molten Core–Concrete Interaction (MCCI) module, referred to as MAMBA (MCCI Analysis Model with Basemat Ablation), implemented in the SAFARI code and assesses its performance using representative MCCI experimental data.

2. DESCRIPTION OF THE MAMBA MODULE

2.1. Module Overview

The MAMBA module is based on a lumped parameter method (LPM) framework and was developed with reference to the CORQUENCH code [2]. The MCCI domain is discretized into a limited number of nodes representing the corium, crust layers at the top, bottom, and side, and the underlying concrete. Governing mass and energy conservation equations are solved for each node. The module is implemented using a Python-based computational structure and evaluates a set of 10 state variables (X) that characterize the

MCCI process. These include the masses of corium and crust layers, concrete ablation depths in the axial and radial directions, crust thicknesses, and corium enthalpy

Figure 1. illustrates the calculation flow chart of the MAMBA module, in which tracking 10 state variables constitutes the core of the analysis. At the beginning of the calculation, the state variables are initialized. At each time step, the state of the corium pool is then identified as either homogeneous or stratified. Depending on the identified mode, secondary variables and surface-related quantities in each direction are evaluated. Based on these quantities, the governing equations are solved, and the resulting increments of the state variables (dX) are used to update the state variables at each time step, advancing the calculation.

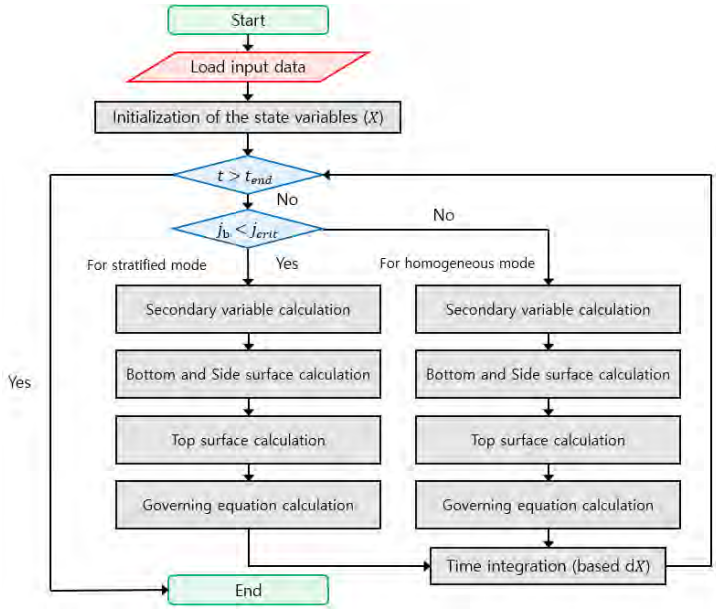

Figure 1. Calculation flow chart for the MAMBA module

2.2. Corium Configuration

The MAMBA module supports two analysis modes depending on the corium configuration: a homogeneous mode and a stratified mode. In the homogeneous mode, the corium is assumed to remain fully mixed throughout the calculation, whereas the stratified mode allows a transition from an initially homogeneous state to a layered configuration. This section describes the modeling approach adopted for the stratified configuration.

Although a stratified corium configuration with a denser oxidic layer beneath a metallic layer may exist initially, intense gas generation due to rapid concrete ablation during the early phase of MCCI promotes strong mixing, rendering the initial stratification short-lived. Accordingly, the MCCI code assumes a homogeneous corium state at the onset of the calculation and permits stratification only after gas-induced mixing subsides. The transition between the two modes is determined by the superficial gas velocity generated by bottom concrete ablation. When the gas velocity (j – Eq.1) calculated under the homogeneous assumption decreases below a critical threshold velocity (j_{crit} – Eq.2), the oxidic layer, having incorporated sufficient concrete, relocates to the upper region and the calculation proceeds in the stratified mode.

In this formulation, the stratification criterion is evaluated solely based on gas generation at the bottom concrete surface. Gas produced along the sidewalls is assumed to rise directly upward and therefore to have a negligible effect on the stratification interface. The critical gas velocity is defined using a density-based correlation derived from the BALISE experiments [3], with a constant value of C_{crit} = 0.054. In addition,

stratification is permitted only when the thickness of the metal layer exceeds 3 cm, ensuring sufficient thermal and mechanical stability of the layered configuration.

$$j = \frac{\dot{m}''_{b,gas}}{\rho_g} \tag{1}$$

$$j_{crit} = C_{crit}\frac{\rho_{met} - \rho_{ox}}{\rho_{ox}} \tag{2}$$

2.3. Governing Equations

The MAMBA module solves mass and energy conservation equations as its governing equations. Mass conservation is applied to the corium and crust nodes, while energy conservation is solved only for the corium. The concrete node does not have independent governing equations and is treated as an infinite mass reservoir that acts as a source or sink of mass and energy.

The formulation of the governing equations depends on the corium configuration. Differences in mass and energy exchange between nodes are accounted for by distinguishing between the homogeneous and stratified modes. Figure 2.3 schematically illustrates the mass and energy transfer paths among the nodes for each configuration. In the homogeneous mode, the corium interacts separately with the bottom and side concrete, whereas in the stratified mode, interactions with the side concrete are evaluated independently for the oxide and metal layers.

Accordingly, the governing equations are formulated to evaluate the time derivatives of the state variables associated with each mode. In the homogeneous mode, 5 state variable derivatives are computed, while in the stratified mode, 8 state variable derivatives are evaluated to account for the layered structure. The detailed formulations of the mass and energy conservation equations are presented in Sections 2.3.1 and 2.3.2, respectively.

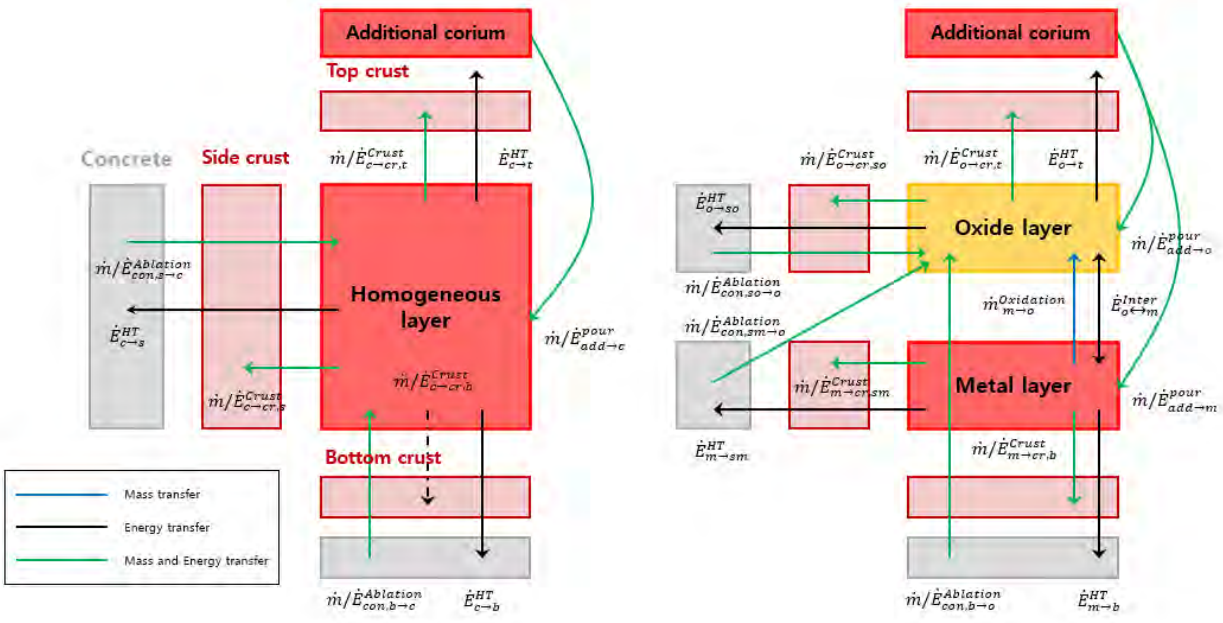

Figure 2. Calculation flow chart for the MAMBA module

2.3.1. Mass conservation equation

The mass conservation equations are formulated to evaluate the time derivatives of the corium mass in both homogeneous and stratified configurations. (Eq. 3 - 5) In the homogeneous mode, a single mass conservation equation is applied to the corium, whereas in the stratified mode, separate equations are solved for the oxide and metal layers. These equations account for the mass variations of the state variables resulting from the dominant physical processes considered in the module.

Mass changes in the crust nodes arise exclusively from crust formation at the corium boundaries. Accordingly, the mass loss associated with crust formation in the corium mass balance directly corresponds to the mass gain in the top, bottom, and side crust nodes. The crust mass evolution is evaluated based on the time derivatives of crust thickness obtained from the heat transfer model, including the effect of crust re-melting.

When stratification occurs, molten concrete generated by concrete ablation is treated as oxidic material and is added solely to the oxide layer in the mass balance. In addition, corium poured into the cavity is partitioned between the oxide and metal layers according to its composition, with oxidic components added to the oxide layer and metallic components added to the metal layer.

[Homogeneous layer]

$$\dot{m}_{c,i} = \dot{m}_{c\to c}^{Oxidation} - \dot{m}_{c\to cr,t,b,s}^{Crust} + \dot{m}_{con,b,s\to c}^{Ablation} + \dot{m}_{add\to c}^{Pour} \tag{3}$$

[Oxide layer]

$$\dot{m}_{ox,i} = \dot{m}_{met\to ox}^{Oxidation} - \dot{m}_{ox\to cr,t,so}^{Crust} + \dot{m}_{con,sm,so,b\to ox}^{Ablation} + \dot{m}_{add\to ox}^{Pour} \tag{4}$$

[Metal layer]

$$\dot{m}_{met,i} = -\dot{m}_{met\to ox}^{Oxidation} - \dot{m}_{met\to cr,b,sm}^{Crust} + \dot{m}_{add\to met}^{Pour} \tag{5}$$

2.3.2. Energy conservation equation

The energy conservation equation in the MAMBA module is solved only for the corium and is formulated to evaluate the time derivative of corium enthalpy. The enthalpy evolution is obtained by differentiating the total energy (E_c) of the corium and accounting for the dominant energy sources and sinks considered in the model. (Eq. 6)

$$\dot{E}_c = \frac{dE_c}{dt} = \dot{m}_c e + m_c \dot{e} \tag{6}$$

Depending on the corium configuration, separate energy conservation equations are applied in the homogeneous and stratified modes. (Eq. 7 - 9) The energy balance includes contributions from decay heat, heat transfer at the top, bottom, and side boundaries, and interlayer heat transfer in the stratified configuration. Decay heat is specified as a user input, while interlayer heat transfer between the oxide and

metal layers is evaluated as a function of the temperature difference between the layers using an established correlation [4].

For corium additionally poured into the cavity, the associated enthalpy is calculated based on its temperature and composition, and the distribution of this energy between the oxide and metal layers is prescribed by user input. When oxidic components are present in the incoming corium, oxidation reactions may occur due to gas generated from concrete ablation. Under the stratified configuration, oxidation is assumed to occur primarily in the upper oxide layer, with any remaining reactive species potentially continuing to react in the metal layer. Owing to the absence of a detailed physical model describing the residence time of incoming corium within the oxide layer, the partitioning of oxidation-related energy between the two layers is also treated as a user-defined parameter.

[Homogeneous layer]

$$\dot{E}_c = \dot{E}_{c\to c}^{Decay} - \dot{E}_{c\to t,b,s}^{HT} + \dot{E}_{con,b,s\to c}^{Ablation} - \dot{E}_{c\to cr,t,b,s}^{Crust} + \dot{E}_{c\to c}^{Oxidation} + \dot{E}_{add\to c}^{Pour} \quad (7)$$

[Oxide layer]

$$\dot{E}_{ox} = \dot{E}_{ox\to ox}^{Decay} - \dot{E}_{ox\to t,so}^{HT} + \dot{E}_{con,b,so,sm\to ox}^{Ablation} - \dot{E}_{ox\to cr,t,so}^{Crust} + \dot{E}_{met\to ox}^{Inter} + \dot{E}_{add\to ox}^{Pour} \quad (8)$$

[Metal layer]

$$\dot{E}_{met} = -\dot{E}_{met\to b,sm}^{HT} - \dot{E}_{met\to cr,b,sm}^{Crust} + \dot{E}_{met\to met}^{Oxidation} - \dot{E}_{ox\to met}^{Inter} + \dot{E}_{add\to met}^{Pour} \quad (9)$$

2.4. Heat Transfer Modeling

Effective cooling of the corium is one of the key factors governing the progression of MCCI phenomena. Accordingly, the MAMBA module explicitly models heat transfer in each direction relative to the corium geometry. The top heat transfer is primarily influenced by the cavity conditions, particularly the presence or absence of water, whereas heat transfer at the bottom and side surfaces is directly coupled to concrete ablation processes.

These directional heat transfer models constitute a core component of the MAMBA module, as they determine the temporal evolution of crust growth and concrete ablation. Depending on the corium configuration, the heat transfer calculations are formulated to evaluate the time derivatives of the relevant state variables associated with crust thickness and ablation depth in both homogeneous and stratified modes.

2.4.1. Top heat transfer modeling

The top heat transfer of the corium is developed to account for both dry and wet cavity conditions. The primary objective of the top heat transfer modeling is to evaluate the corium upper boundary temperature ($T_{t,I}$) and the rate of change of the top crust thickness ($\dot{\delta}_t$). Eq. 10 represents the balance equation used to determine the corium top boundary temperature, which accounts for the convective heat transfer from the corium interior and the heat transfer to the surrounding environment under dry or wet conditions.

The convective heat transfer from the corium to the top boundary is evaluated using a correlation [5] that accounts for gas generation during MCCI. For dry cavity conditions, heat removal from the top surface is

calculated based on thermal radiation, whereas for wet cavity conditions, it is evaluated using a heat transfer coefficient derived from the boiling curve of the coolant.

$$h_{r/wat}\left(T_{t,I} - T_{at/wat}\right) = h_t\left(T_c - T_{t,I}\right) \tag{10}$$

Eq.11 describes the evolution of the top crust thickness. The rate of crust growth is determined from an energy balance that considers the energy required for crust formation, heat conduction through the crust, and the convective heat transfer from the corium to the top boundary.

$$\rho_{cr}\Delta e_{cr}\dot{\delta}_t = -k_{cr}\frac{dT_{cr,t}}{dx} - h_t\left(T_c - T_{frz}\right) \tag{11}$$

2.4.2. Side and bottom heat transfer modeling

Since the side and bottom surfaces of the corium are in direct contact with the concrete, the corresponding heat transfer modeling is inherently coupled with concrete ablation. In the MAMBA module, the side and bottom heat transfer models are designed to evaluate the rate of change of concrete ablation depth ($\dot{\eta}$) as well as the evolution of crust thickness ($\dot{\delta}$). Two modeling approaches are implemented: a no-crust model and a crust-including model.

Eq. 12 represents the no-crust model used to evaluate the rate of concrete ablation. In this model, the ablation rate is determined from an energy balance between the energy required for concrete ablation and the heat transferred from the corium. The side and bottom heat transfer coefficients are evaluated by scaling the top heat transfer coefficient using a slag coefficient. [6]

$$\dot{\eta}_{b/s(so,sm)}\rho_{con}e_{dec,con} = h_{b/s(so,sm)}(T_c - T_{dc}) \tag{12}$$

Eq. 13 describes the concrete ablation rate in the crust-including model, where the energy balance accounts for the energy required for ablation, heat conduction through the crust, and heat conduction within the concrete. In addition, Eq. 14 evaluates the rate of change of crust thickness in the crust model, which is formulated in a manner analogous to the upper heat transfer modeling.

$$\rho_{con}\Delta e_{con}\dot{\eta}_{b/s(so,sm)} = -k_{cr}\frac{dT_{cr,b/s(so,sm)}}{dx} + k_{con}\frac{dT_{con}}{dx} \tag{13}$$

$$\rho_{cr}\Delta e_{cr}\dot{\delta}_{b/s(so,sm)} = -k_{cr}\frac{dT_{cr,b/s(so,sm)}}{dx} - h_{b/s(so,sm)}\left(T_c - T_{frz}\right) \tag{14}$$

3. VALIDATION AGREEMENT EXPERIMENTAL DATA

3.1. Validation Overview

To establish the reliability of the MAMBA module, several MCCI experiments were selected and used for validation. Table I. summarizes the validation experiments considered in this study. The validation was conducted using both one-dimensional (1-D) and two-dimensional (2-D) MCCI experiments. The 1-D

experiments focus exclusively on downward concrete ablation, whereas the 2-D experiments account for both downward and lateral ablation.

A total of 4 experiments were selected for validation. These experiments were chosen to represent a wide range of MCCI characteristics in terms of geometry, corium and concrete composition, and cavity conditions. By considering validation cases with diverse features, the robustness of the MAMBA module in analyzing MCCI phenomena is demonstrated.

Table I. Validation experiments for MAMBA module

	Experiment	MCCI geometry	Corium type	Concrete type	Cavity situation
1-D MCCI (Axial)	SURC-2	Cylindrical	Homogeneous	Basaltic	Dry
	ACE-L2	Rectangular	Homogeneous	Siliceous	Dry
2-D MCCI (Axial/Radial)	CCI-2	Rectangular	Homogeneous	LCS	Dry + Wet
	MOCKA 3.1	Cylindrical	Stratified	Siliceous	Dry

3.2. Validation Against 1-D MCCI Experiment

The validation of the MAMBA module against 1-D MCCI experiments was performed using the SURC-2 and ACE-L2 experiments. Figure 2 presents the validation results for the SURC-2 experiment, where the calculated corium temperature evolution and concrete ablation behavior are compared with experimental data. The results indicate that the overall experimental trends are reasonably reproduced by the MAMBA module.

In addition, to provide a reference comparison with existing severe accident analysis tools, the calculated results were compared with those obtained from MELCOR. [7] The comparison shows that the MAMBA predictions are comparable to those of MELCOR for the considered cases.

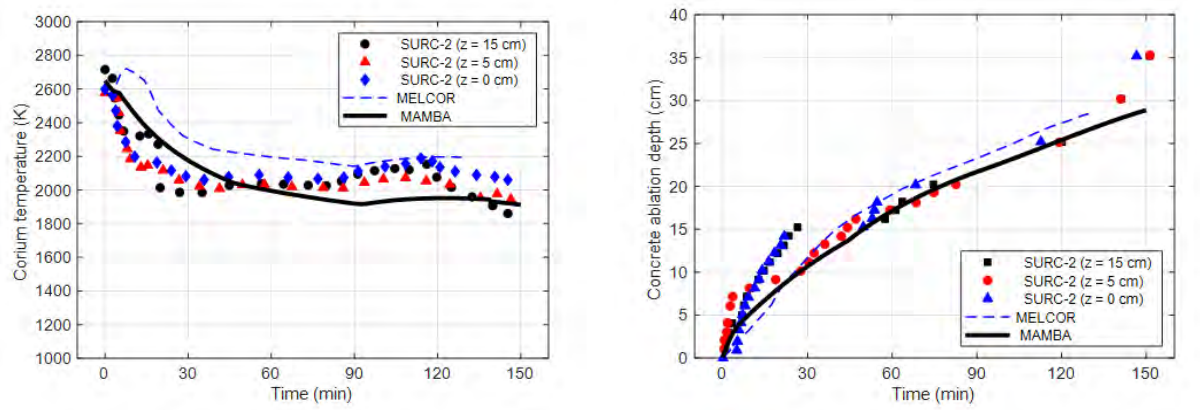

Figure 2. Validation results for SURC-2 (left: corium temperature; right: concrete ablation depth)

Figure 3 presents the validation results for the ACE-L2 experiment. The results obtained using the MAMBA module show overall agreement with the experimental data in terms of observed trends and are also comparable to those predicted by the MAAP code [8].

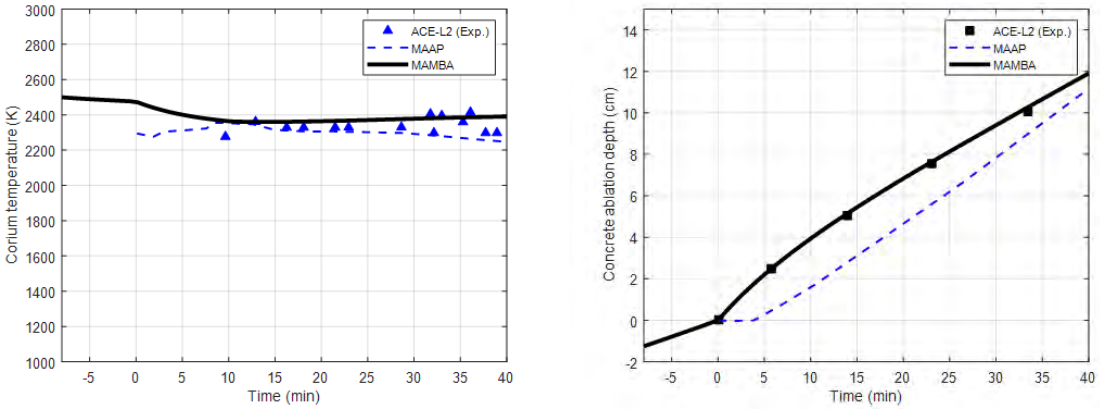

Figure 3. Validation results for ACE-L2 (left: corium temperature; right: concrete ablation depth)

3.3. Validation Against 2-D MCCI Experiment

The MAMBA module was also validated against 2-D MCCI experiments, namely the CCI-2 and MOCKA 3.1 tests. Figure 4 presents the validation results for the CCI-2 experiment. Overall, the calculated results show reasonable agreement with the experimental data in terms of observed trends and exhibit performance comparable to that of MELCOR [9].

It should be noted, however, that in the CCI-2 experiment, post-flooding is introduced after approximately 300 minutes, resulting in a transition to wet cavity conditions. While the concrete ablation behavior is reasonably reproduced under these conditions, the corium temperature tends to be underpredicted. This discrepancy is expected to be addressed through future improvements of the modeling approach.

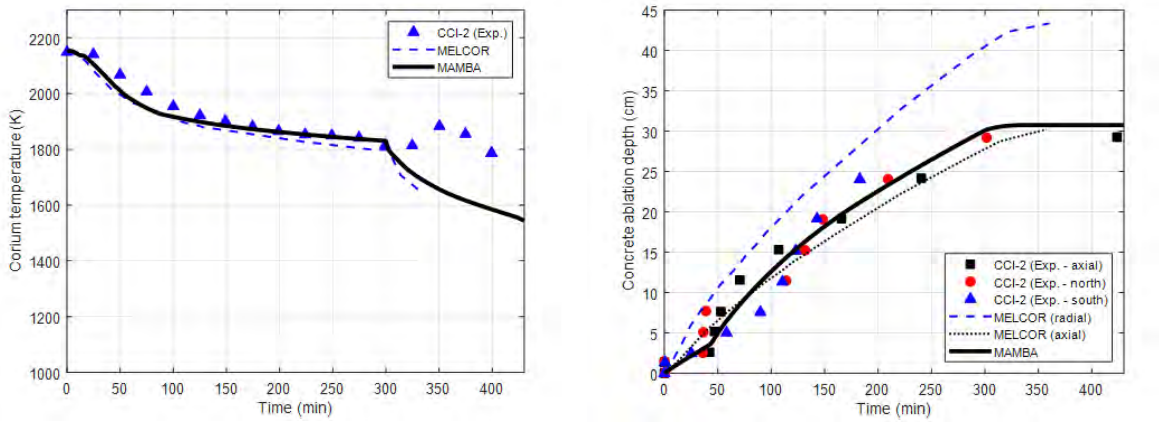

Figure 4. Validation results for CCI-2 (left: corium temperature; right: concrete ablation depth)

The MOCKA 3.1 experiment was designed to simulate MCCI conditions under corium pool stratification and was therefore selected to validate the stratified analysis mode of the MAMBA module. Figure 5 presents the validation results for the MOCKA 3.1 experiment. For this case, experimental data were available only for concrete ablation depth, and the comparison was performed accordingly.

Since validation results obtained using other MCCI codes for the MOCKA 3.1 experiment are not available, no code-to-code comparison could be performed. A key feature of the results is the transition from a homogeneous to a stratified corium configuration at approximately 3 minutes, when the stratification criterion implemented in the MAMBA module is satisfied. Following this transition, the results branch into two distinct layers, and the predicted ablation behavior for each layer shows overall agreement with the experimental measurements.

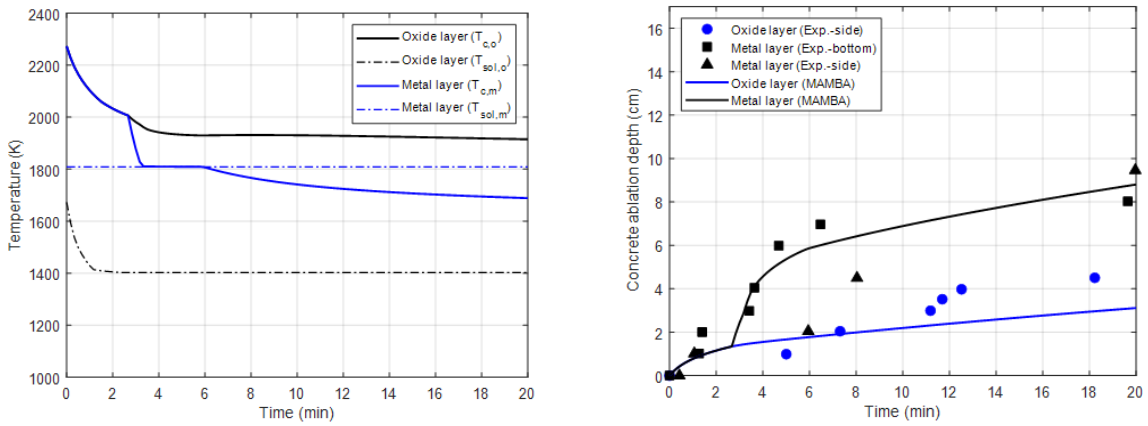

Figure 5. Validation results for MOCKA 3.1 (left: corium temperature; right: concrete ablation depth)

4. CONCLUSIONS

This paper presented the development and validation of the MCCI analysis module implemented in the SAFARI integrated severe accident analysis code. The module was developed to represent key physical processes governing corium–concrete interactions under ex-vessel accident conditions, including directional heat transfer, concrete ablation, crust formation, and corium pool configurations.

The modeling framework supports both homogeneous and stratified corium configurations and accounts for dry and wet cavity conditions through dedicated heat transfer models. The predictive capability of the module was evaluated using representative 1-D and 2-D MCCI experiments, and the results showed reasonable agreement with experimental trends across different geometries, material compositions, and boundary conditions. In addition, comparisons with existing severe accident analysis codes indicated comparable performance.

Overall, the results suggest that the developed MCCI module provides a consistent and practical analysis capability for ex-vessel severe accident scenarios within the SAFARI code and can support integrated severe accident evaluations related to SAM strategies.

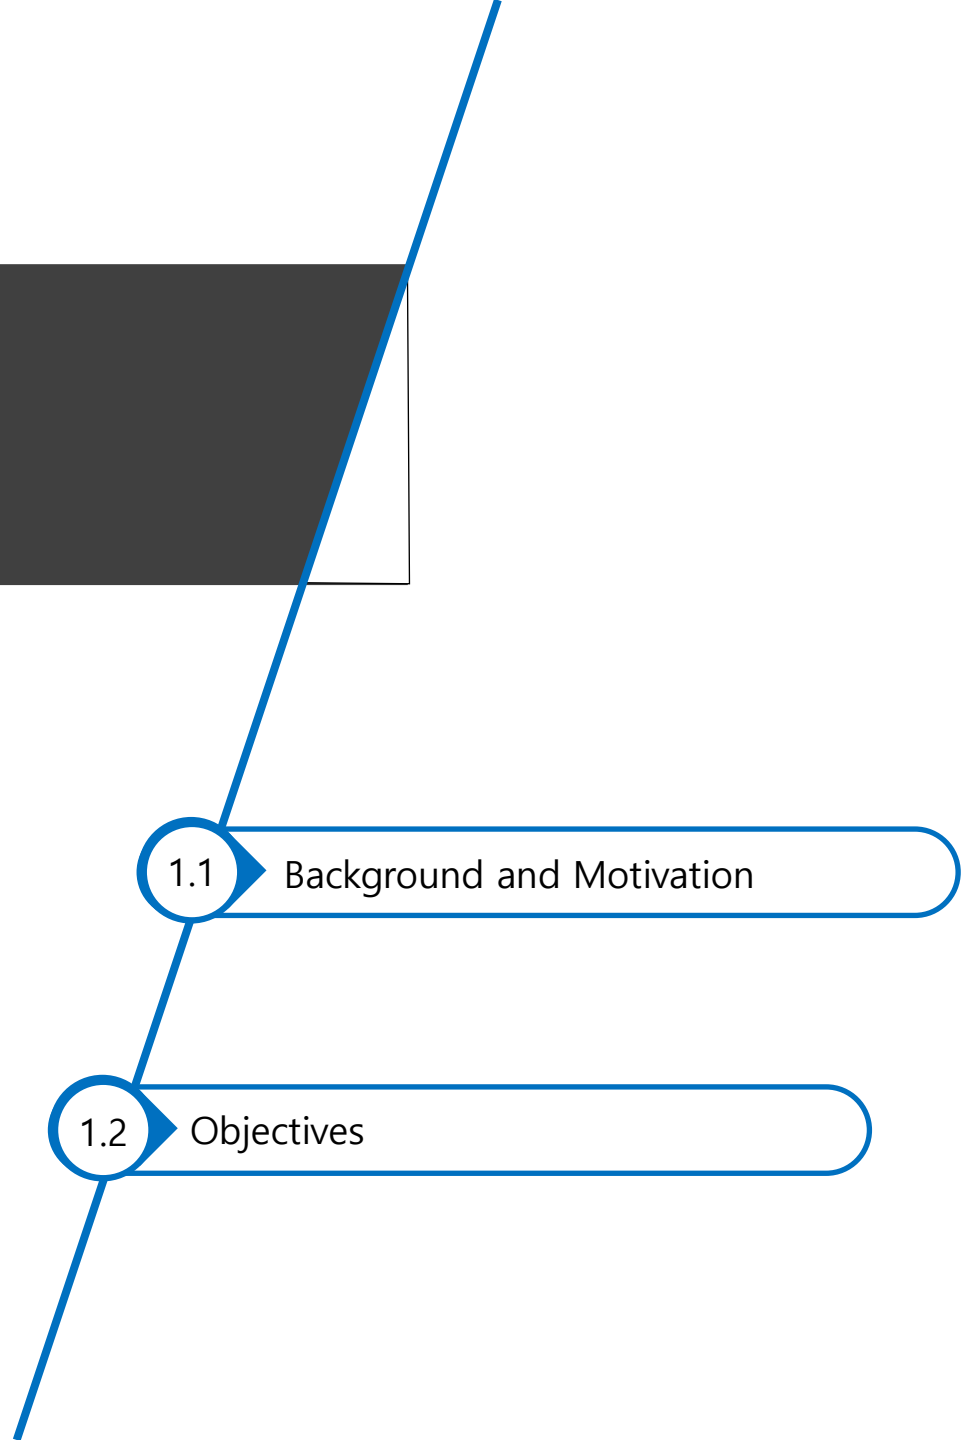
01 Introduction

02 Description of the MAMBA module

03 Validation agreement experimental data

04 Conclusions

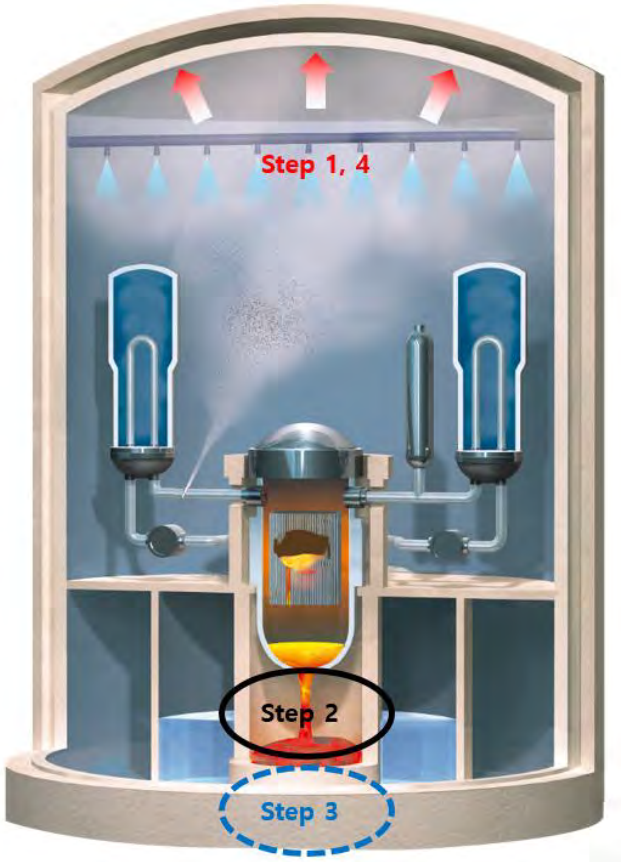
1. Introduction



Introduction

1.1 Background and Motivation

- Nuclear fuel failure ($T_{cladding} > 1204℃$) leads to a nuclear severe accident.
- There are four steps in the Ex-vessel severe accident phenomena.
- Among them, the main phenomenon covered by this presentation is the Molten Core-Concrete Interaction (MCCI).



<Sequence of ex-vessel severe accident phenomena>

Step 1: Direct Containment Heating (DCH)

Step 2: Fuel-Coolant Interaction (FCI) & Steam Explosion (SE)

Step 3: Molten Core-Concrete Interaction (MCCI)

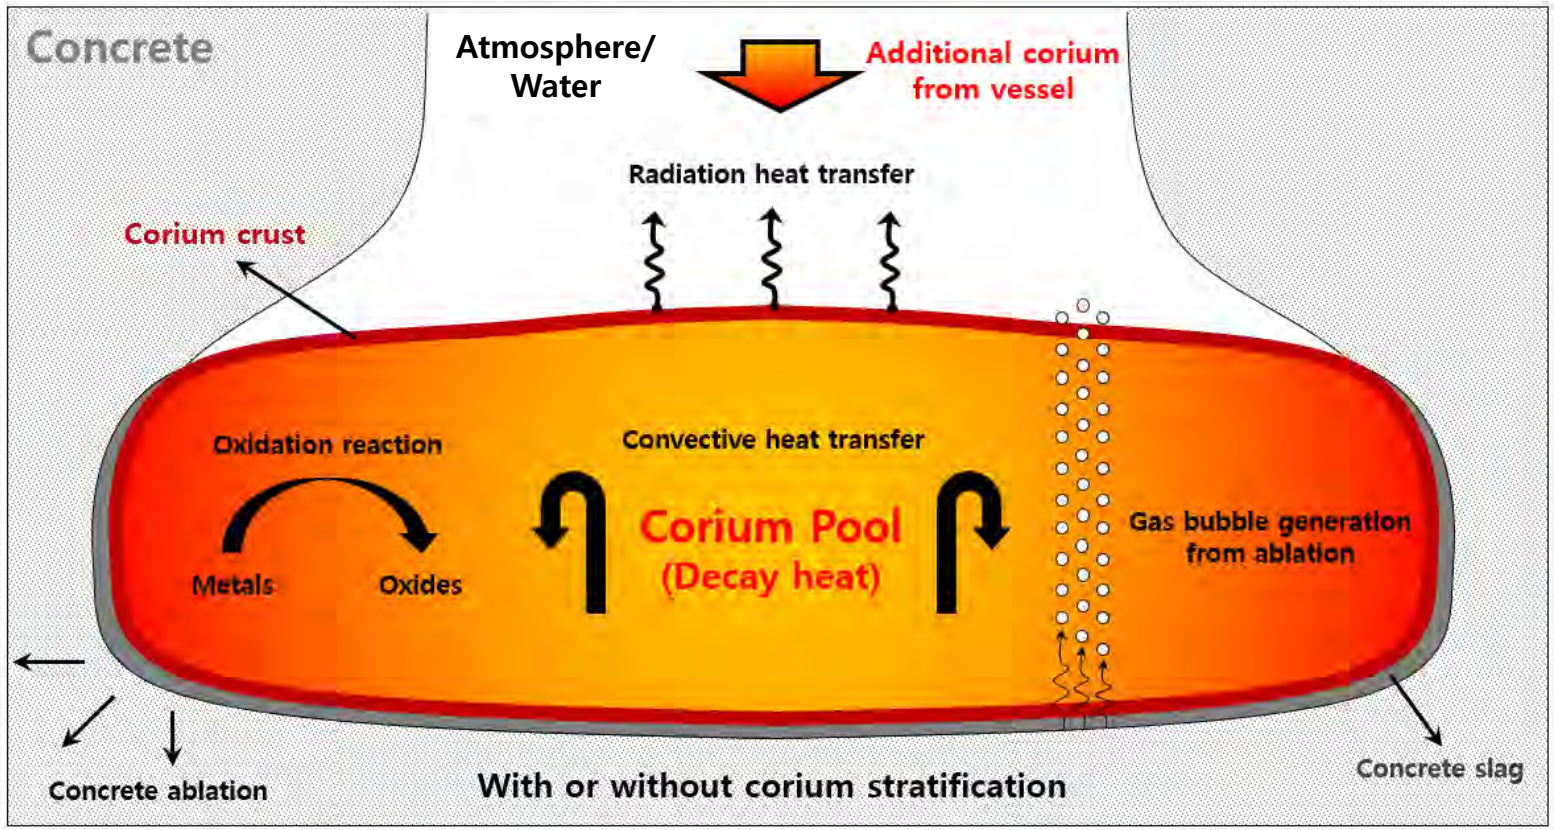
The key phenomenon in this study

Step 4: Hydrogen Explosion

Chatelard, P., Reinke, N., Arndt, S., Belon, S., Cantrel, L., Carenini, L., ... & Piar, L. (2014). ASTEC V2 severe accident integral code main features, current V2. 0 modelling status, perspectives. *Nuclear Engineering and Design*, *272*, 119-135.

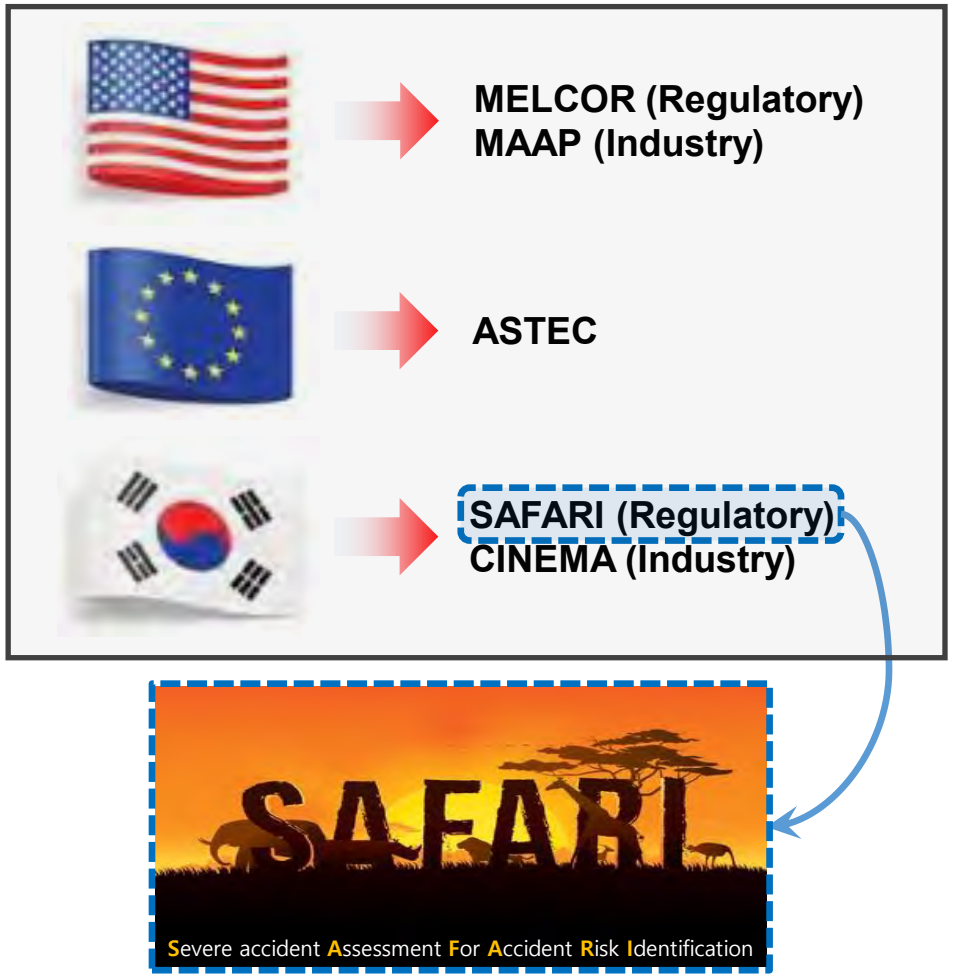
Introduction

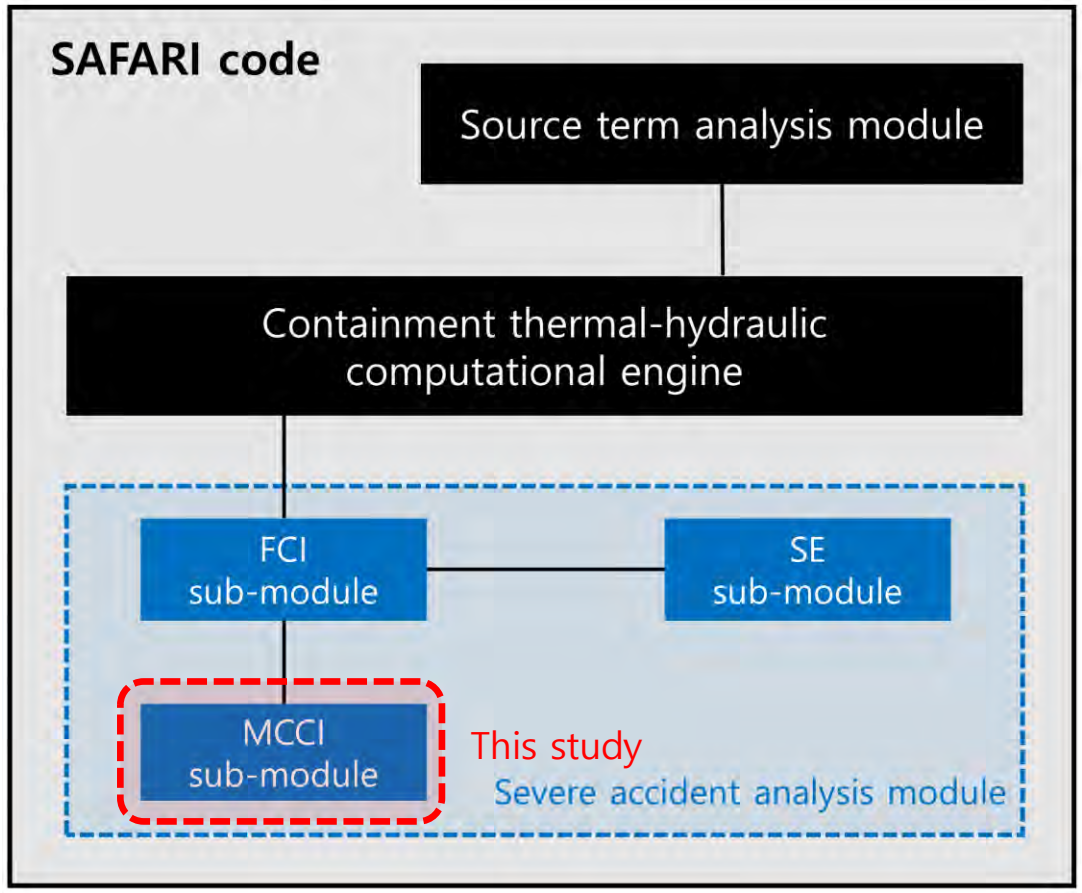
- MCCI phenomena occurs when hot corium meets cold concrete.
- In this reaction, the purpose is to maintain the integrity of the containment until the moment when non-condensable gas and decay heat no longer occur.
- Many complex physical phenomena occur simultaneously when MCCI occurs.



Introduction

- The SAFARI code is currently being developed as an integrated severe accident analysis code for domestic regulatory use in Korea, and performing a pre-flooding scenario analysis requires coupling between the MCCI and FCI codes developed within the same project.





MAMBA (MCCI Analysis Model with Basemat Ablation) module

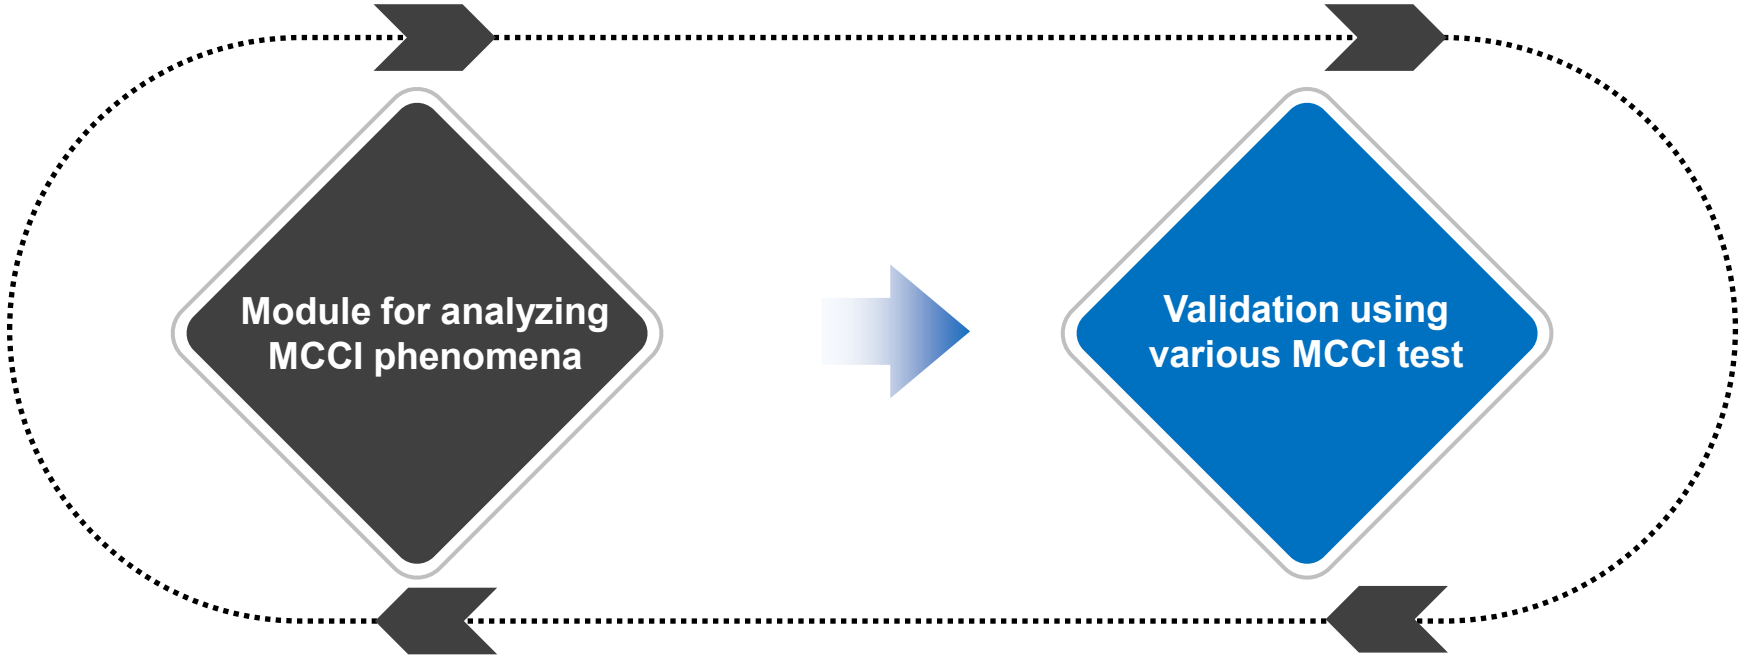
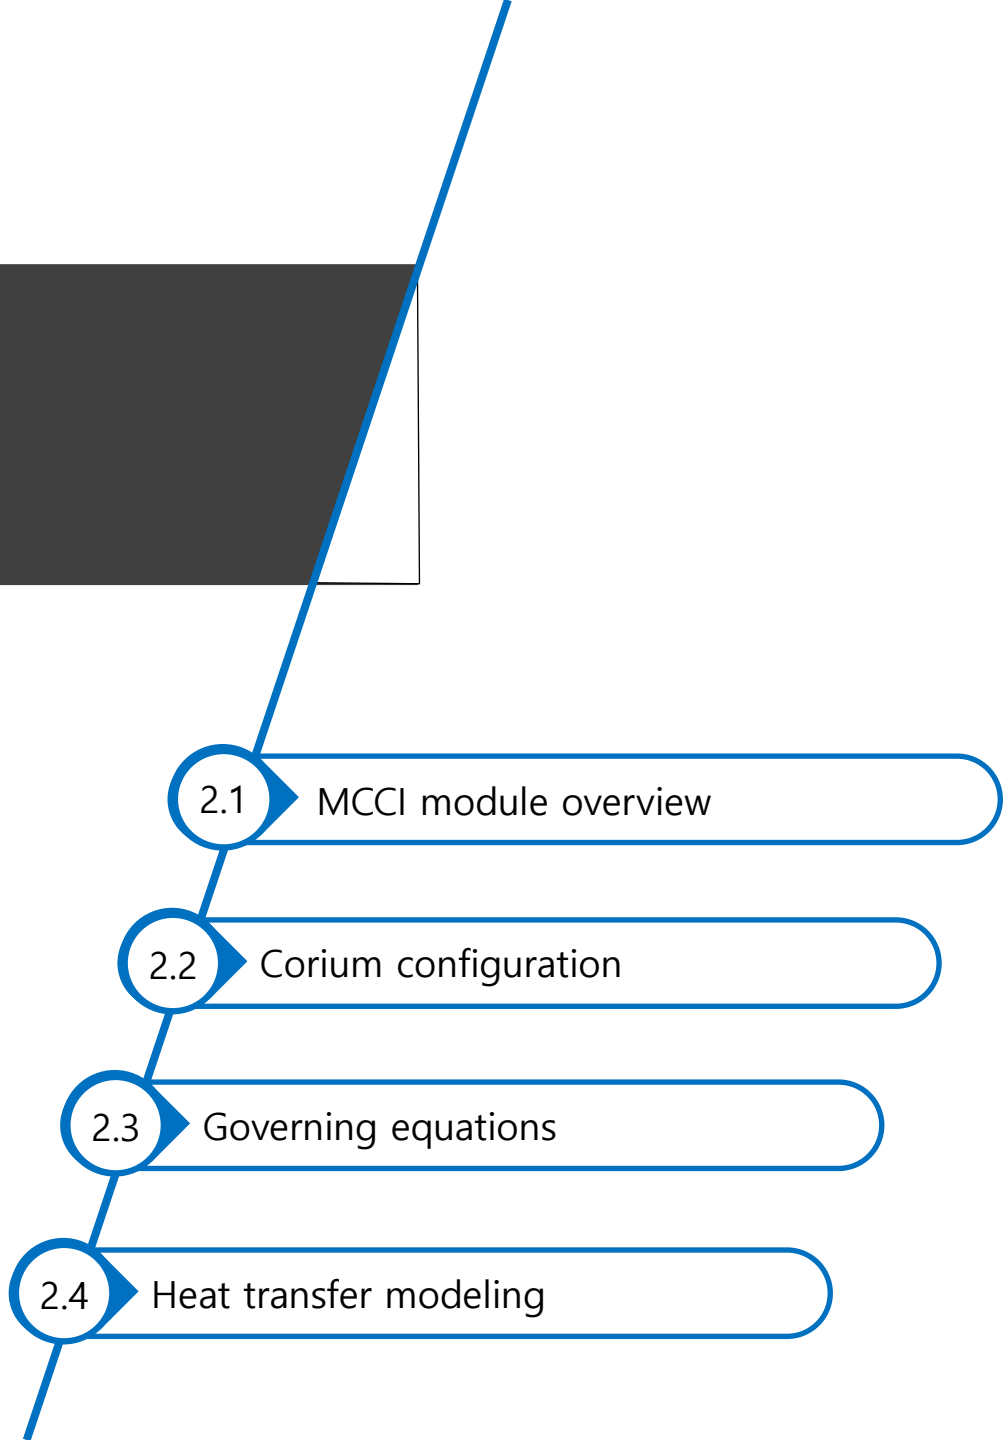
1.2 Objectives

- The objective of this study is to develop the MCCI module within the SAFARI code and to establish its reliability through validation of the developed module.

[Development of the MCCI module and Validation using MCCI experiment]



2. Description of the MAMBA module



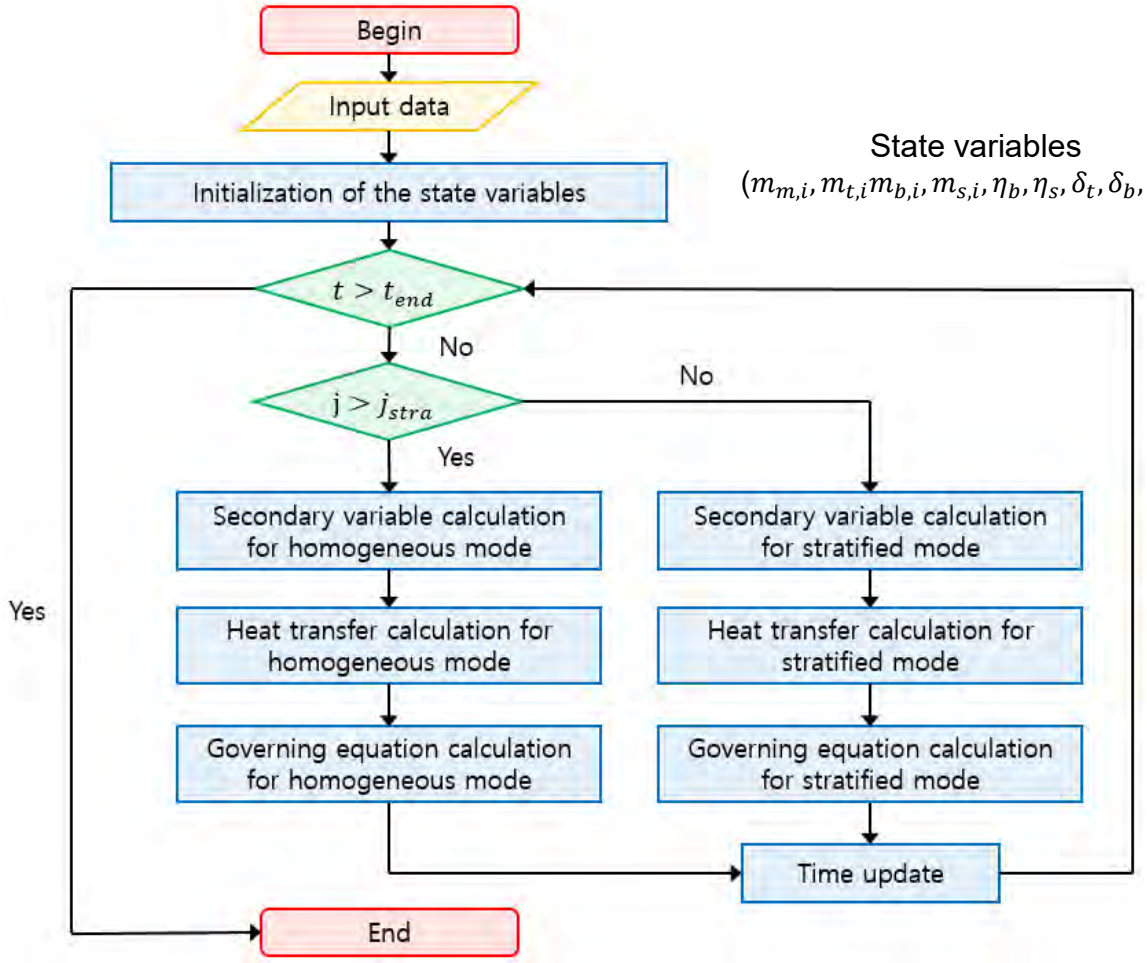
Description of the MAMBA module

2.1. MCCI module overview

Category	Details
Reference code	CORQUENCH code (ANL)
Analysis type	Lumped Parameter Method (LPM)
Language	Python
Geometry	✓ Cylindrical ✓ Rectangular
Geometry node	✓ Corium (Homogeneous and Stratified) ✓ Top crust ✓ Side crust ✓ Bottom crust ✓ Concrete
Governing equation	✓ Mass conservation equation (for each node except concrete) ✓ Energy conservation equation (for corium node)
Top heat transfer model	✓ Dry cavity model ✓ Wet cavity model
Concrete ablation model	✓ No-crust/Crust model
Material property model	✓ Corium property model ✓ Concrete property model ✓ Gas & Coolant property model

[Appendix 1]

Corium temperature **Concrete ablation depth**

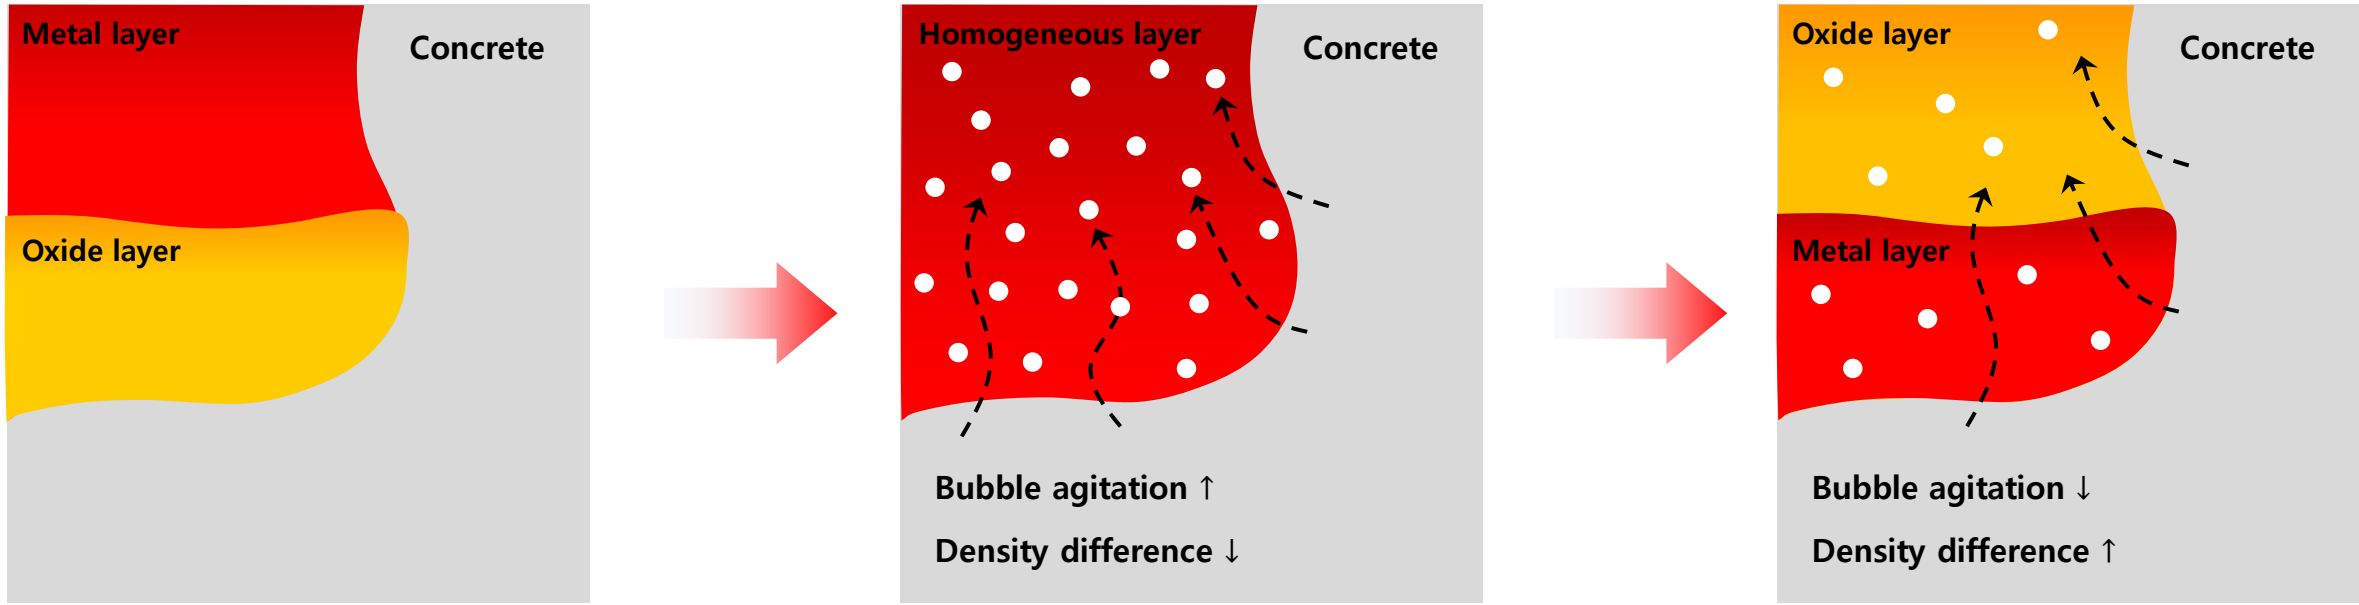


State variables
$(m_{m,i}, m_{t,i} m_{b,i}, m_{s,i}, \eta_b, \eta_s, \delta_t, \delta_b, \delta_s, e)$

<Flow chart of the MCCI code>

2.2. Corium configuration

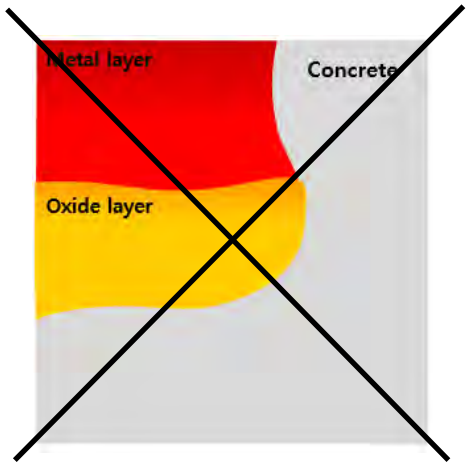
- The MCCI process can involve corium stratification.
- Stratification may progress through three stages: initial stratification, homogenization, and re-stratification.
- In late phase of MCCI, re-stratification can occur, potentially leading to different thermal and physical characteristics between layers.



<Initial stratification> <homogenization> <Re-stratification>

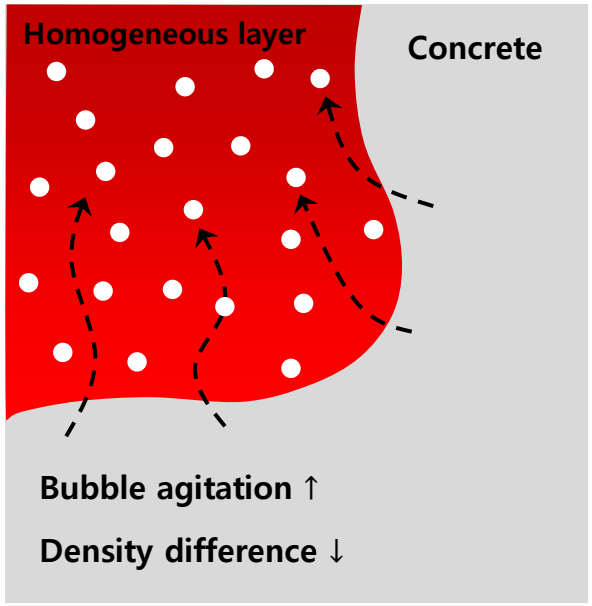
Description of the MAMBA module

- In the early phase of MCCI, strong gas generation quickly disrupts the initial stratification, leading to a homogeneous state.
- Therefore, the proposed MCCI module begins with homogeneous corium. When the gas velocity criterion is satisfied, the code transitions to the re-stratification stage and continues the calculation.



<Initial stratification – durability ↓>

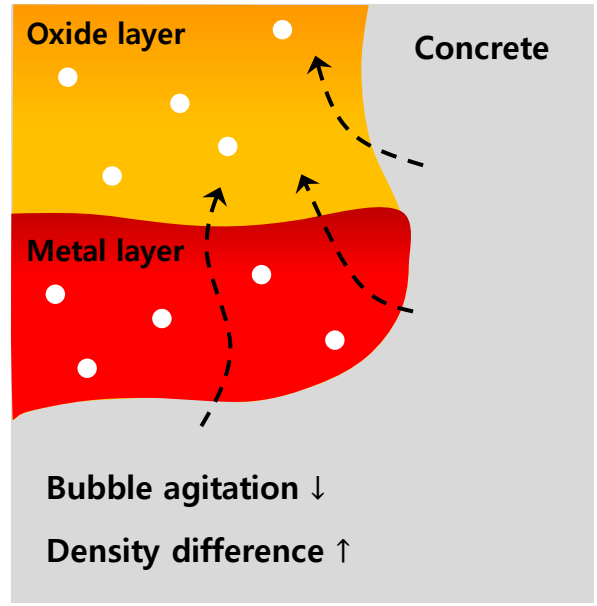
Assumption



<Homogenous mode>

Mode change

$j_b < j_{crit}$



<Stratified mode>

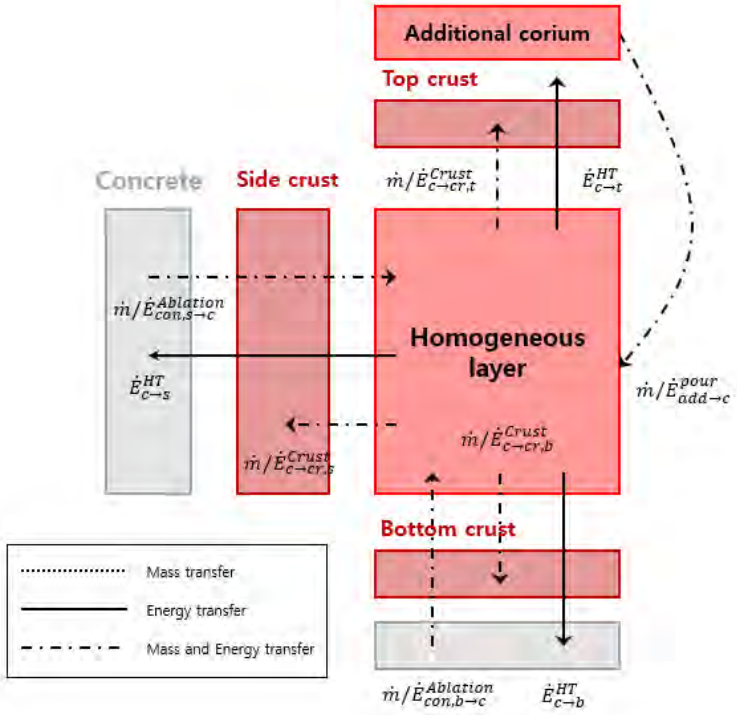
$$j_{crit} = C_{stra}\frac{\rho_m - \rho_o}{\rho_o} \qquad C_{stra} = 0.054$$ (From BALISE exp.)

[Appendix 1]

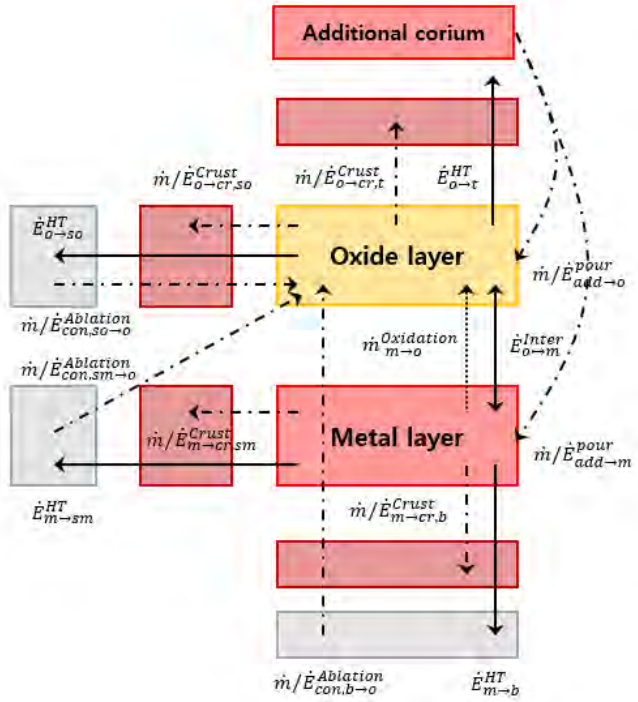
Description of the MAMBA module

2.3. Governing equations

- The governing equations consist of the mass and energy conservation equations for each mode, with each term representing various phenomena occurring in the MCCI process.



<Homogenous mode>



<Stratified mode>

[Homogeneous layer] $(+: source \ / \ -: sink)$

$$\dot{m}_{c,i} = \dot{m}^{Oxidation}_{cor\to cor} + \dot{m}^{Ablation}_{con,b,s\to cor} + \dot{m}^{Pour}_{add\to cor} - \dot{m}^{Crust}_{cor\to cr,t,b,s}$$

$$\dot{E} = \frac{dE}{dt} = \dot{m}e + m\dot{e}$$

$$\dot{E}_c = \dot{E}^{Decay}_{cor\to cor} + \dot{E}^{Ablation}_{con,b,s\to cor} + \dot{E}^{Oxidation}_{cor\to cor} + \dot{E}^{Pour}_{add\to cor} - \dot{E}^{Crust}_{cor\to cr,t,b,s} - \dot{E}^{HT}_{cor\to t,b,s}$$

[Oxide layer]

$$\dot{m}_{o,i} = \dot{m}^{Oxidation}_{m\to o} + \dot{m}^{Ablation}_{con,sm,so,b\to ox} + \dot{m}^{Pour}_{add\to o} - \dot{m}^{Crust}_{o\to cr,t,so}$$

$$\dot{E}_o = \dot{E}^{Decay}_{o\to o} + \dot{E}^{Ablation}_{con,b,so,sm\to o} + \dot{E}^{Inter}_{m\to o} + \dot{E}^{Pour}_{add\to o} - \dot{E}^{Crust}_{o\to cr,t,so} - \dot{E}^{HT}_{o\to t,so}$$

[Metal layer]

$$\dot{m}_{m,i} = \dot{m}^{Pour}_{add\to o} - \dot{m}^{Oxidation}_{m\to o} - \dot{m}^{Crust}_{m\to cr,b,sm}$$

$$\dot{E}_m = \dot{E}^{Decay}_{m\to m} + \dot{E}^{Oxidation}_{m\to m} + \dot{E}^{Inter}_{o\to m} + \dot{E}^{Pour}_{add\to m} - \dot{E}^{Crust}_{m\to cr,b,sm} - \dot{E}^{HT}_{m\to b,sm}$$

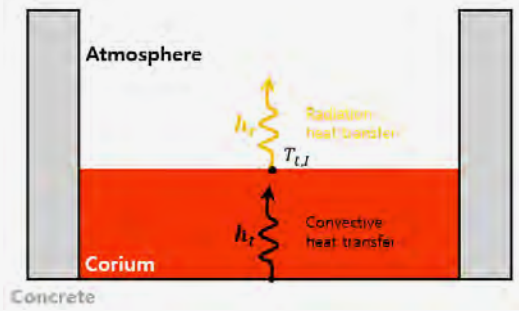
Description of the MAMBA module

2.4. Heat transfer modeling

2.4.1. Top heat transfer model

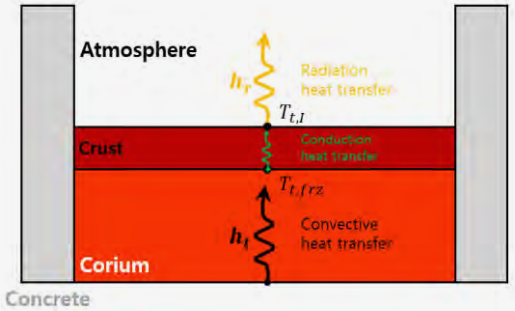
- In the proposed MCCI module, the top heat transfer model differs depending on whether the cavity is dry or wet, with the primary objective being the calculation of the top boundary temperature ($T_{t,I}$) and crust thickness derivative ($\dot{\delta}_t$).

[Dry cavity model]



<No-crust>

✓ $\mathrm{h}_r(\mathrm{T}_{t,I} - \mathrm{T}_{at}) = \mathrm{h}_t(T_c - T_{t,I})$

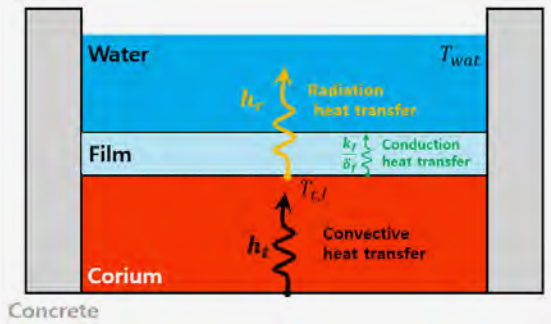


<Stable crust>

✓ $\mathrm{h}_r(\mathrm{T}_{t,I} - \mathrm{T}_{at}) = -\mathrm{k}_{t,c}\left.\frac{dT}{dx}\right|_{x=\delta_t}$

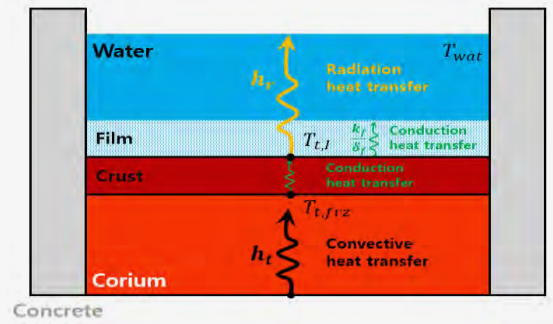
✓ $\rho_{t,c}\Delta e_{t,c}\dot{\delta}_t = -\mathrm{k}_{t,c}\left.\frac{dT}{dx}\right|_{x=0} - \mathrm{h}_t(\mathrm{T}_c - \mathrm{T}_{t,frz})$

[Wet cavity model]



<No-crust>

✓ $\mathrm{h}_{wat}(\mathrm{T}_{t,I} - \mathrm{T}_{wat}) = \mathrm{h}_t(T_c - T_{t,I})$

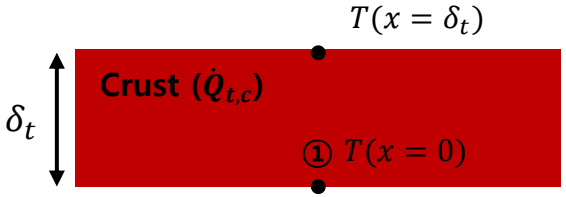


<Stable crust>

✓ $\mathrm{h}_{wat}(\mathrm{T}_{t,I} - \mathrm{T}_{wat}) = -\mathrm{k}_{t,c}\left.\frac{dT}{dx}\right|_{x=\delta_t}$

✓ $\rho_{t,c}\Delta e_{t,c}\dot{\delta}_t = -\mathrm{k}_{t,c}\left.\frac{dT}{dx}\right|_{x=0} - \mathrm{h}_t(\mathrm{T}_c - \mathrm{T}_{t,frz})$

[Temperature profile in crust]



② $\mathrm{k}_{t,c}\frac{d^2T}{dx^2} = -\dot{Q}_{t,c}$ *(Heat equation in crust)*

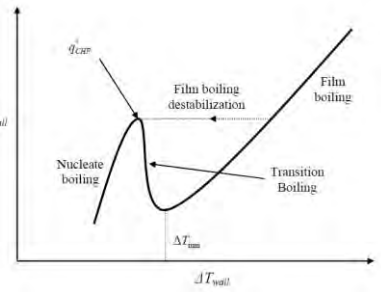
③ $-\mathrm{k}_{t,c}\left.\frac{dT}{dx}\right|_{x=\delta_t} = \mathrm{h}_r(\mathrm{T}(\mathrm{x} = \delta_t) - \mathrm{T}_{at})$

➡ *Calculation of* $T(x)$

[Heat transfer coefficient for water]

$h_{wat} = \frac{k_f}{\delta_f} + h_r \quad or \quad (from\ Boiling\ curve)$

Based Berenson's correlation

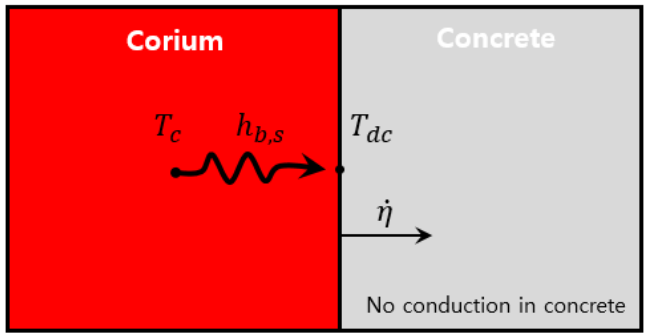


Description of the MAMBA module

2.4.2. Concrete ablation model

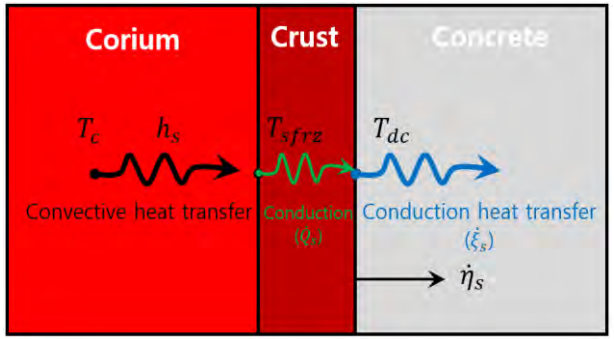
- In the proposed MCCI module, both a concrete ablation model that considers crust formation and a model that does not can be used.
- The objective of these models is to calculate the concrete ablation depth rate ($\dot{\eta}_{b,s}$) as well as the thickness rate of crust ($\dot{\delta}_{b,s}$).

[No-crust model]



$$\rho_{con} e_{con,d} \dot{\eta}_s = h_s (T_c - T_{dc})$$

[Crust model]



$$\rho_{s,c} \Delta e_{s,c} \dot{\delta}_s = -k_{t,c} \left. \frac{dT}{dx} \right|_{x=-\delta_s} - h_s (T_c - T_{s,frz})$$

$$\rho_{con} \Delta e_{con} \dot{\eta}_s - k_{con} \left. \frac{dT'}{dx} \right|_{x=\eta_s} = -k_{t,c} \left. \frac{dT}{dx} \right|_{x=0}$$

[Phase of crust model]

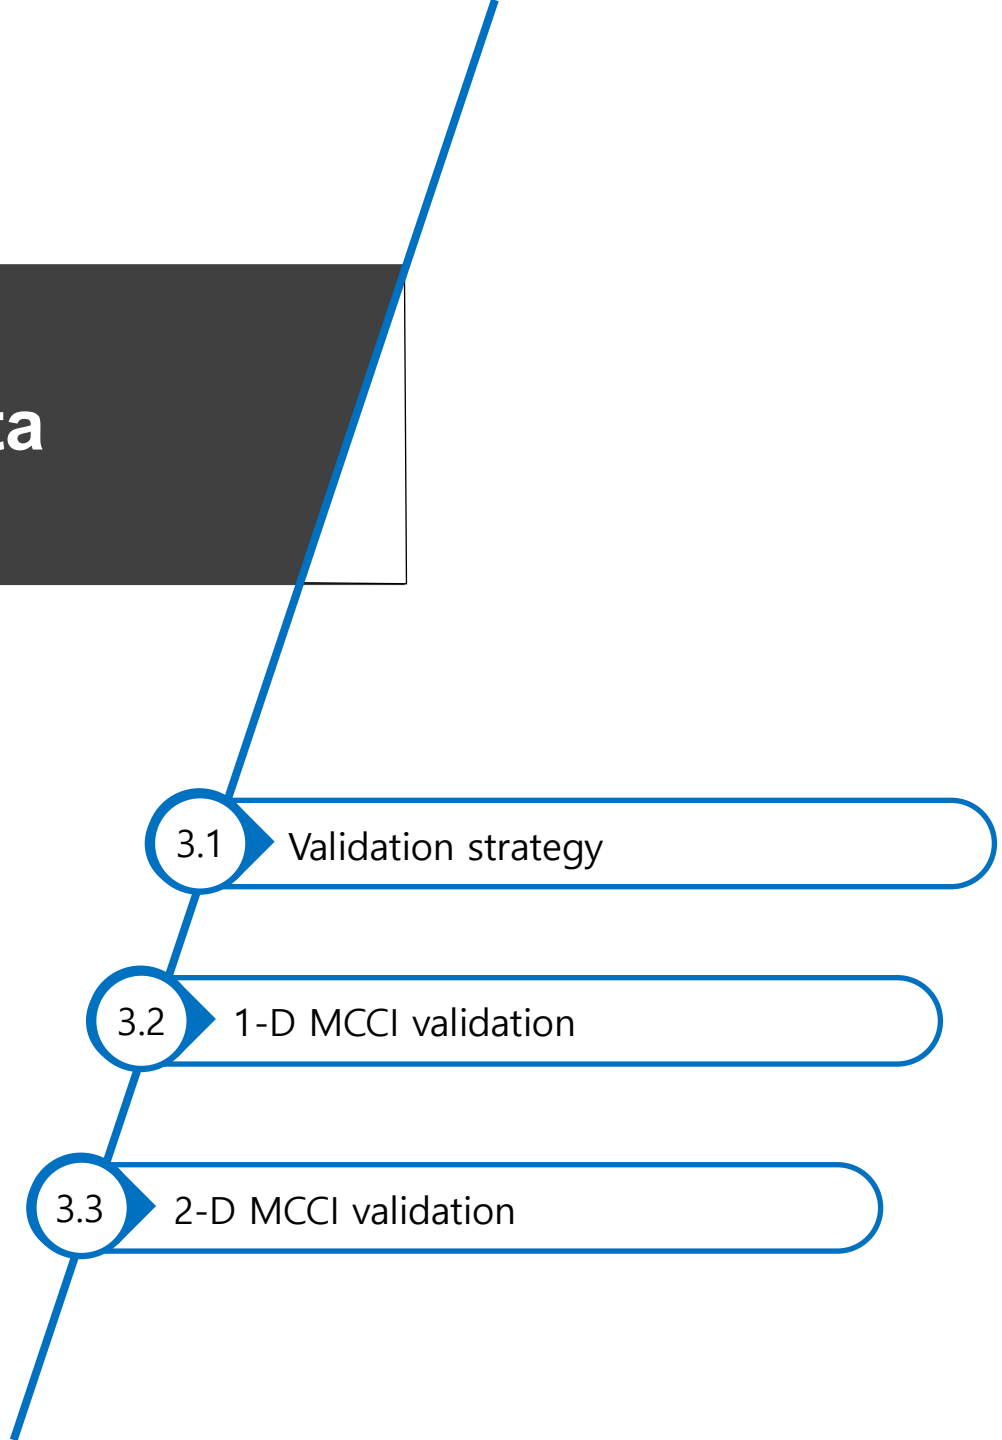
Phase 1 – Initial contact with crust growth

Phase 2 – Crust growth and re-melting with ablation

Phase 3 – No crust calculation after crust failure

[Appendix 2]

3. Validation agreement experimental data



Validation agreement experimental data

3.1. Validation strategy

- The validation of the proposed MCCI module was conducted using selected experiments that account for a wide range of corium, concrete, and coolant.

	Experiment	MCCI geometry	Corium type	Concrete type	Cavity situation
1-D MCCI (Axial)	SURC-2	Cylindrical	Homogeneous	Basaltic	Dry
	ACE-L2	Rectangular	Homogeneous (*Concrete-metal inserts)	Siliceous	Dry
2-D MCCI (Axial/Radial)	CCI-2	Rectangular	Homogeneous	LCS	Dry + Wet
	MOCKA 3.1	Cylindrical	Stratified	Siliceous	Dry

Corium temperature

Concrete ablation depth

Validation agreement experimental data

3.2. 1-D MCCI validation

- The validation of the 1-D MCCI experiment was conducted using the SURC-2 and ACE-L2 experiments.

Conditions	SURC-2	ACE-L2
Geometry	1-D cylindrical	1-D Rectangular
Initial size of cavity	0.2 m (radius)	0.5×0.5 m^2
Initial corium mass $[kg]$	200	300
Initial corium temperature $[K]$	2,720	2,500
Corium composition	UO_2/ZrO_2 based corium	
Atmosphere pressure $[MPa]$	0.1	
Decay heat [kW]	10~35	97.2
Ablation model	Crust model	No-crust model
Boundary temperature $[K]$	1600	1700
Analysis mode	Only Homogeneous mode	
Time step $[s]$	0.5	
Total time $[s]$	9,000	2,700

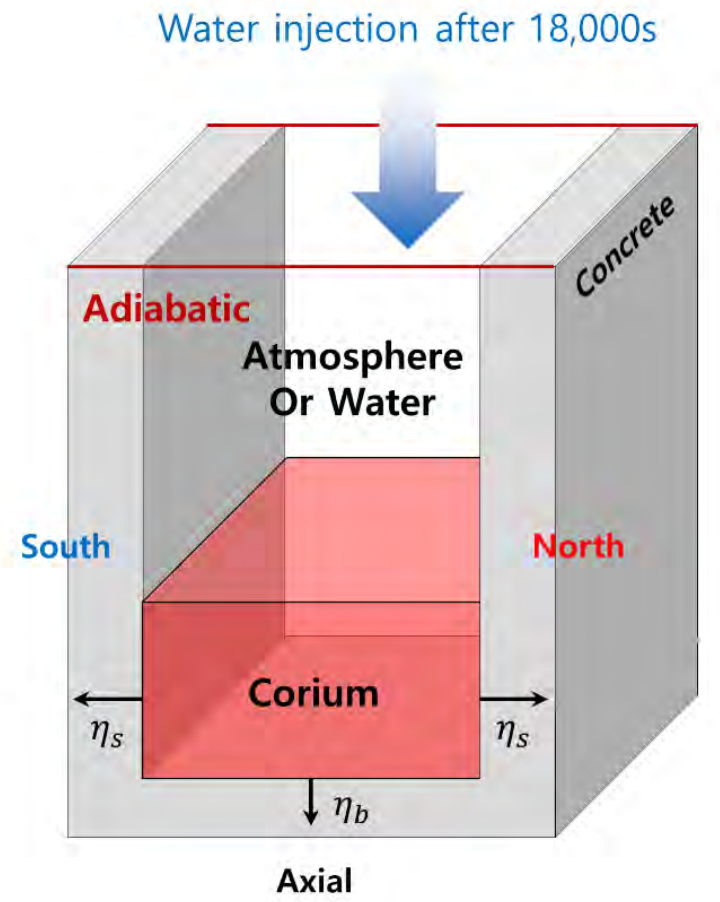
3.3. 2-D MCCI validation

- The CCI-2 experiment is widely used for MCCI validation, maintaining a dry cavity condition for the first 300 minutes, followed by a wet cavity condition through post-flooding.

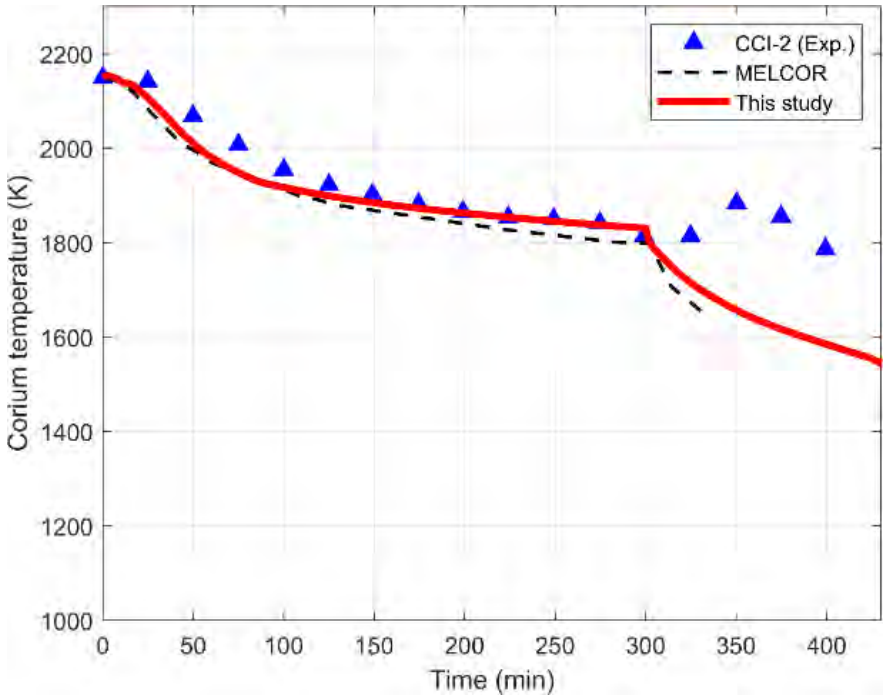
Conditions	Value
Geometry	2-D Rectangular
Initial size of cavity (L,W)	0.5×0.5 m^2
Initial corium mass $[kg]$	400
Initial corium temp. $[K]$	2,150
Corium composition	UO_2/ZrO_2 based corium
Atm. pressure $[MPa]$	0.1
Cavity condition	Dry(~18,000s) +Wet (18,000s~)
Decay heat [kW]	102
Boundary temp. $[K]$	1,350
Water temp. [K]	417
Ablation model	Crust model
Analysis mode	Only Homogeneous mode
Time step $[s]$	0.5
Total time $[s]$	27,000

[Appendix 3]

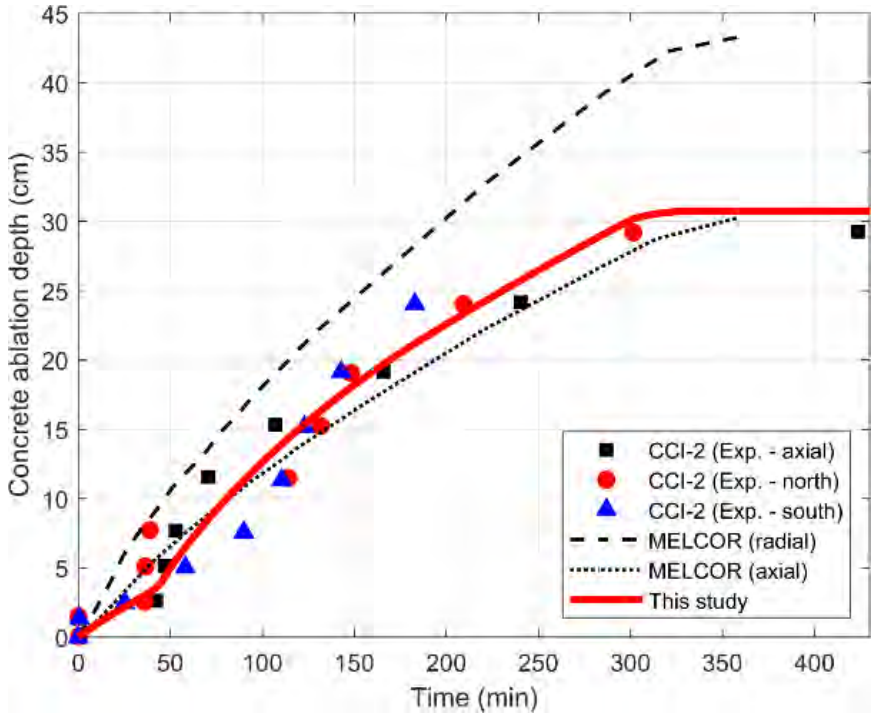


<Analysis geometry for CCI-2>

Validation agreement experimental data



<Corium temperature>



<Concrete ablation depth>

Validation agreement experimental data

- The MOCKA 3.1 experiment primarily generates corium using an alumina thermite reaction and is conducted with a light oxide layer, mainly composed of concrete constituents, and a metal layer consisting of Fe and Zr, leading to stratification.

Input data	Value
Geometry	2-D cylindrical
Initial width R $[m]$	0.125
Corium type	Alumina based
Corium mass $[kg]$	114 (initial) + 209 (additional)
Initial corium temperature $[K]$	2,273
Boundary temperature $[K]$	1,350
Cavity condition	Dry condition
Decay heat [KW]	0
Ablation modeling	No-crust model
Analysis mode	Transition to Stratified mode
Heat transfer coefficient model	Developed model
Solidus/Liquidus temp. model	$Al_2O_3 - CaO$ based model
Time step $[s]$	0.5
Total time $[s]$	1,200

Zr	64.4	0	0	0

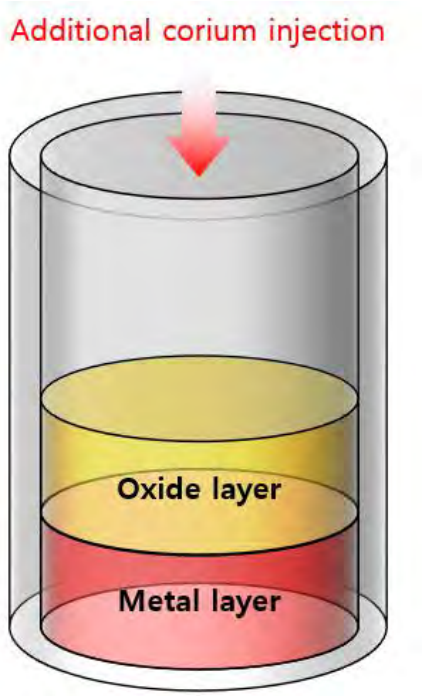
<Concrete composition for validation>

Parameter	Specification
Initial corium composition	• 68 kg (Al_2O_3 - 56 wt.%, CaO – 44 wt.%) • 42 kg (Fe) • 4 kg (Zr)
Additional corium composition (~ 21 min)	• 155 kg (Thermite) • 54 kg (Zr)
Concrete composition (main component – Siliceous type)	• 1 wt.% (CO_2) • 6.7 wt.% (H_2O) • 69.7 wt.% (SiO_2) • 13.7 wt.% (CaO)
Concrete decomposition temperature (T_{dc})	1430 K
Concrete solidus temperature ($T_{sol,con}$)	1403 K
Concrete liquidus temperature ($T_{liq,con}$)	1523 K
Initial corium temperature (T_c)	2273 K
Ambient temperature (T_{at})	850 K
Ambient pressure (P)	0.1 MPa
Simulation time (t_{end})	1,200 s (time step – 0.5 s)
Ratio of heat input from additional corium	0.75 (oxide layer) : 0.25 (metal layer)
Ratio of heat input from oxidation reactions	1 (oxide layer) : 0 (metal layer)

<Simulation conditions for MOCKA 3.1>

Appendix 4

◆ MOCKA 3.1 experiment



$Fe_2O_3 + 2Al \rightarrow 2Fe + Al_2O_3$
$(Alumina\ thermite\ reaction)$

[Initial corium composition]

	Al_2O_3	CaO	Fe	Zr	$Total$
Mass [kg]	38.1	29.9	42	4	114

[Additional corium composition – during 21min]

	Al_2O_3	Fe	Zr	$Total$
Mass [kg]	73.9	81.1	54	209

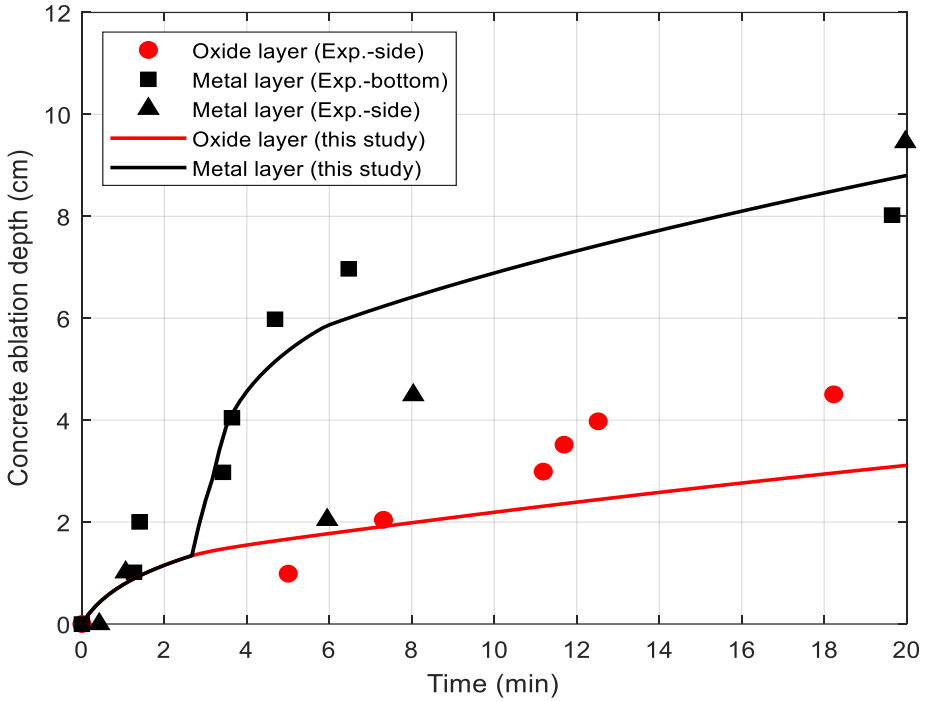
[Heat deposit in stratified layer]

	Additional corium heat	Oxidation reaction heat
Oxide layer	75%	100%
Metal layer	25%	0%

[Corium heat]
The energy possessed by the additional corium is divided between the oxide and metal layers, with 75% being applied to the oxide layer physically located above (utilizing the numerical values from the paper).

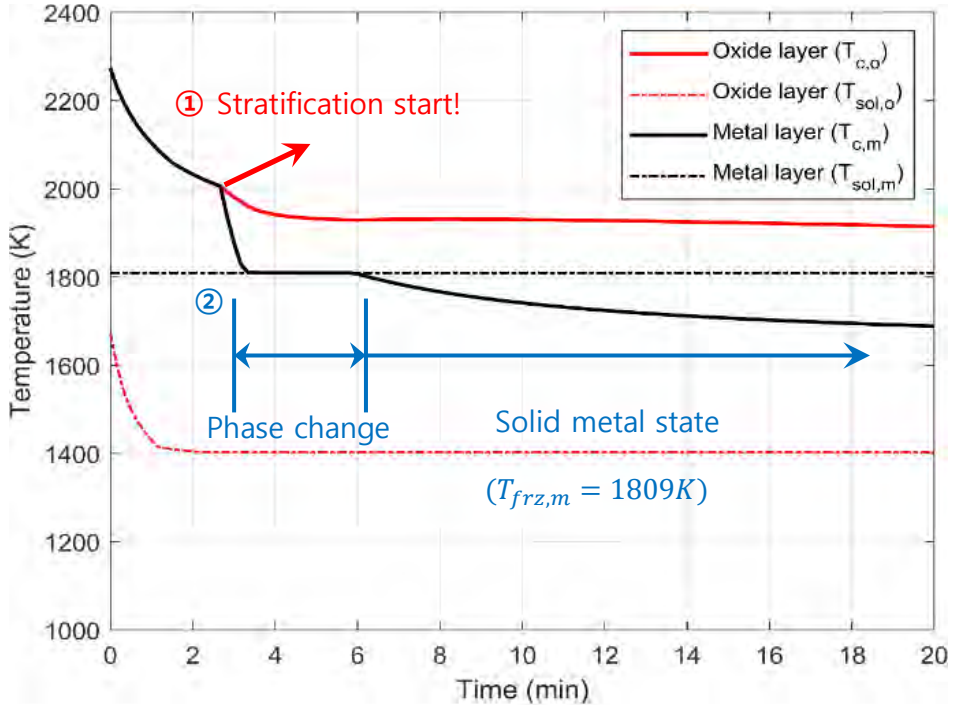
[Oxidation reaction heat]
It is assumed that the Zr contained in the additional corium undergoes oxidation as it passes through the upper oxide layer, and that all oxidation reaction heat is applied to the oxide layer (referenced from the paper).

Appendix 4



[Mention in the paper]

✓ Approximately 400 seconds after the start of the experiment, a crust forms on the metal layer.

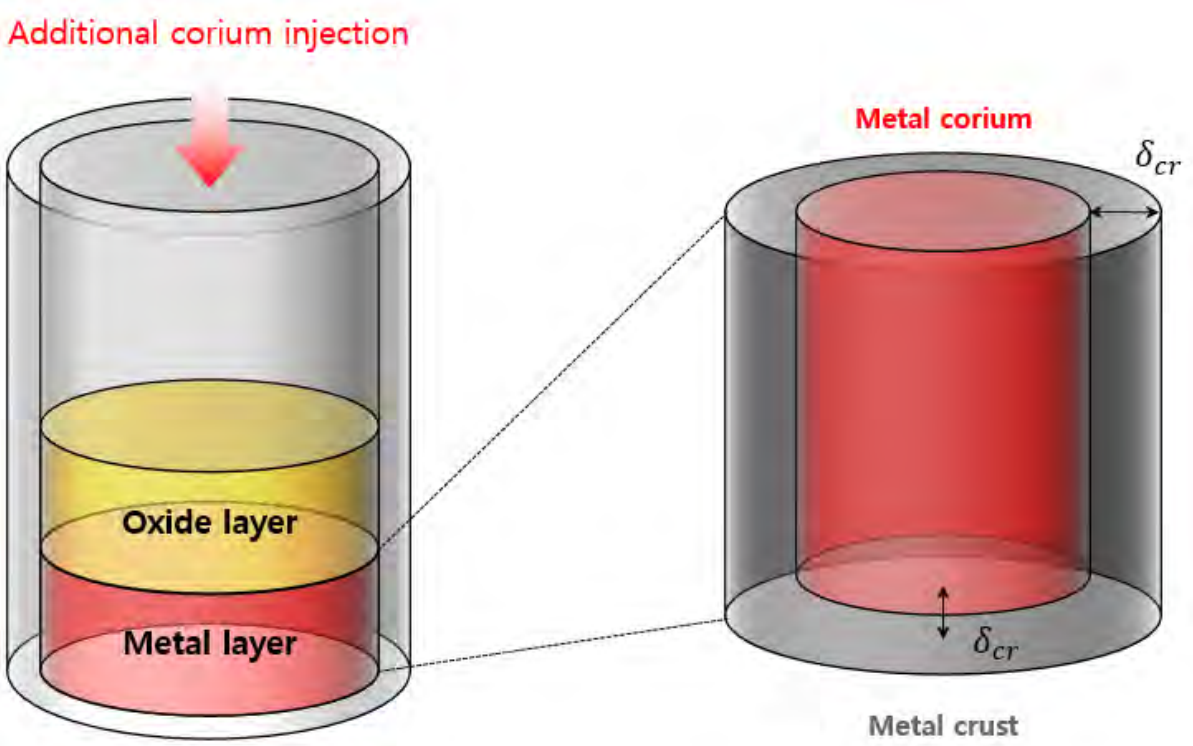


[Key aspects of the MOCKA 3.1 experiment]

✓ Transition to stratified mode

✓ Phase change of metal layer

◆ Metal layer crust modeling



$$\rho_{con} e_{con,d} \dot{\eta}_s = h_s (T_c - T_{dc})$$

[Metal solid fraction in mushy zone]

$$solf_m = \frac{T_{liq,m} - T_{c,m}}{T_{liq,m} - T_{sol,m}}$$

[Mass of metal crust]

$$m_{cr} = solf_m * m_{c,m}$$

[Total crust volume & depth]

$$V_{cr} \;\&\; \delta_{cr}$$

[Initial crust depth]

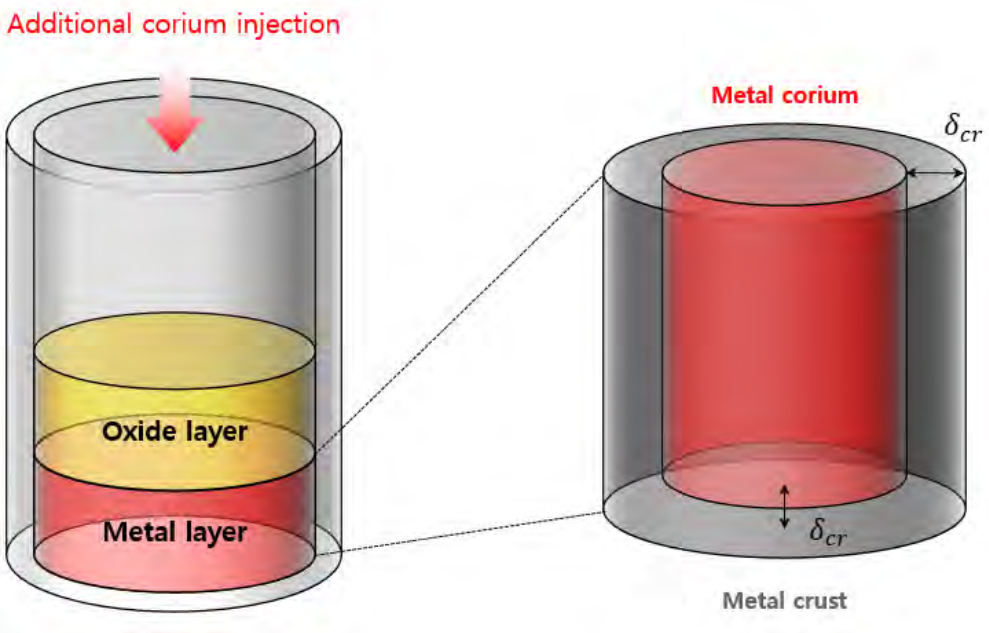
$$\dot{\delta}_{cr} \rho_s \Delta e_s = \frac{k_{cr}}{\delta_{cr}} (T_{frz} - T_{dc})$$

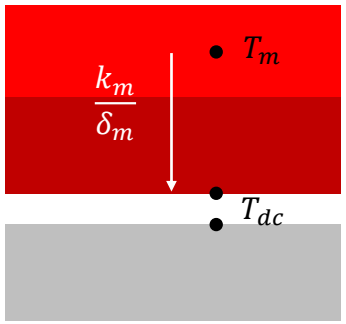
[Heat transfer coefficient - mushy]

$$h_s' = \frac{k_{cr}}{\delta_{cr}} \qquad (T_{c,m} < T_{liq,m})$$

$$h_s' = \frac{k_{cr}}{0.5 \times H_{c,m}} \qquad (T_{c,m} < T_{sol,m})$$

◆ Metal layer crust volume and thickness





[Crust volume - no bubble in crust assumption]

$$V_{cr,sol} = m_{cr}/\rho_{cr}$$

$$V_{corium} = (m_{total} - m_{cr})/(\rho_m * (1-\alpha))$$

$$V_{all} = V_{corium} + V_{cr} \Rightarrow H'_m = \frac{V_{all}}{A_b}$$

[Crust volume by geometry – boundary crust assumption]

$$V_{outer} = \pi(r_{ini} + \eta_{side})^2 H'_m$$

$$V_{inner} = \pi(r_{ini} + \eta_{side} - \delta_{cr})^2 (H'_m - \delta_{cr})$$

$$V_{cr,geo} = V_{outer} - V_{inner}$$

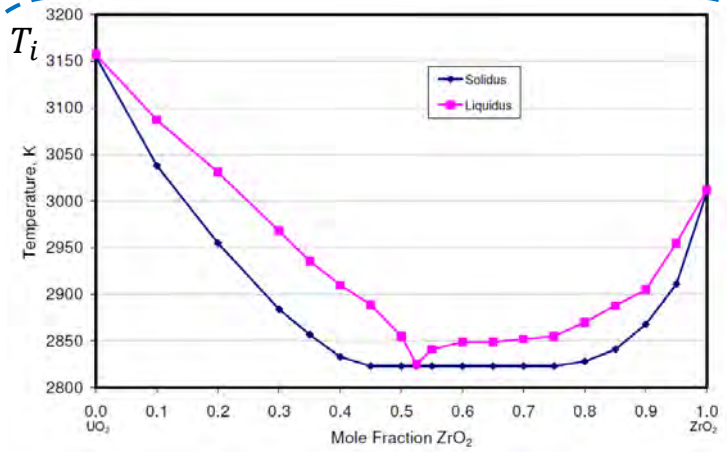
[Crust volume by solid fraction & void fraction]

$$V_{cr,sol} = V_{cr,geo}$$

$$\pi(r_{ini} + \eta_{side})^2 H'_m - \pi(r_{ini} + \eta_{side} - \delta_{cr})^2 (H'_m - \delta_{cr}) = m_{cr}/\rho_{cr}$$

◆ Solidus and Liquidus temperature model

T_i



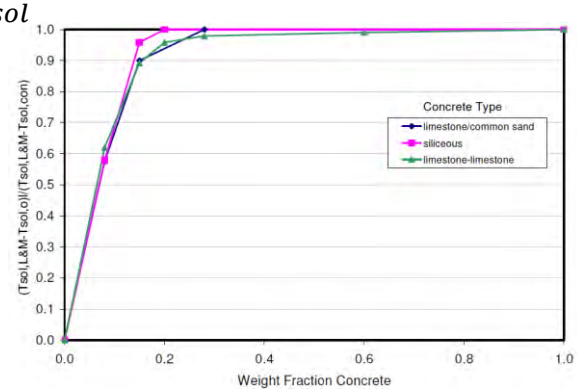
<$UO_2 - ZrO_2$ phase diagram >

Target value

$$F_{sol} = \frac{T_{sol,i} - T_{sol,o}}{T_{sol,i,} - T_{sol,con}}$$

$$F_{liq} = \frac{T_{liq,i} - T_{liq,o}}{T_{liq,i} - T_{liq,con}}$$

F_{sol}



F_{liq}

Euratom Research activities on Severe Accidents

Angelgiorgio IORIZZO
Unit C.4–Euratom Research
DG RTD Research & Innovation
European Commission

Outline

1. EC Policy Context on Nuclear Energy
2. The Euratom research and training programme
3. The Euratom Work programme 2026-2027
4. The next Euratom Research and Training Programme 2028-2032

EC Policy Context on Nuclear Energy

Speech by President von der Leyen at the Nuclear Energy Summit, Paris, 10.03.2026

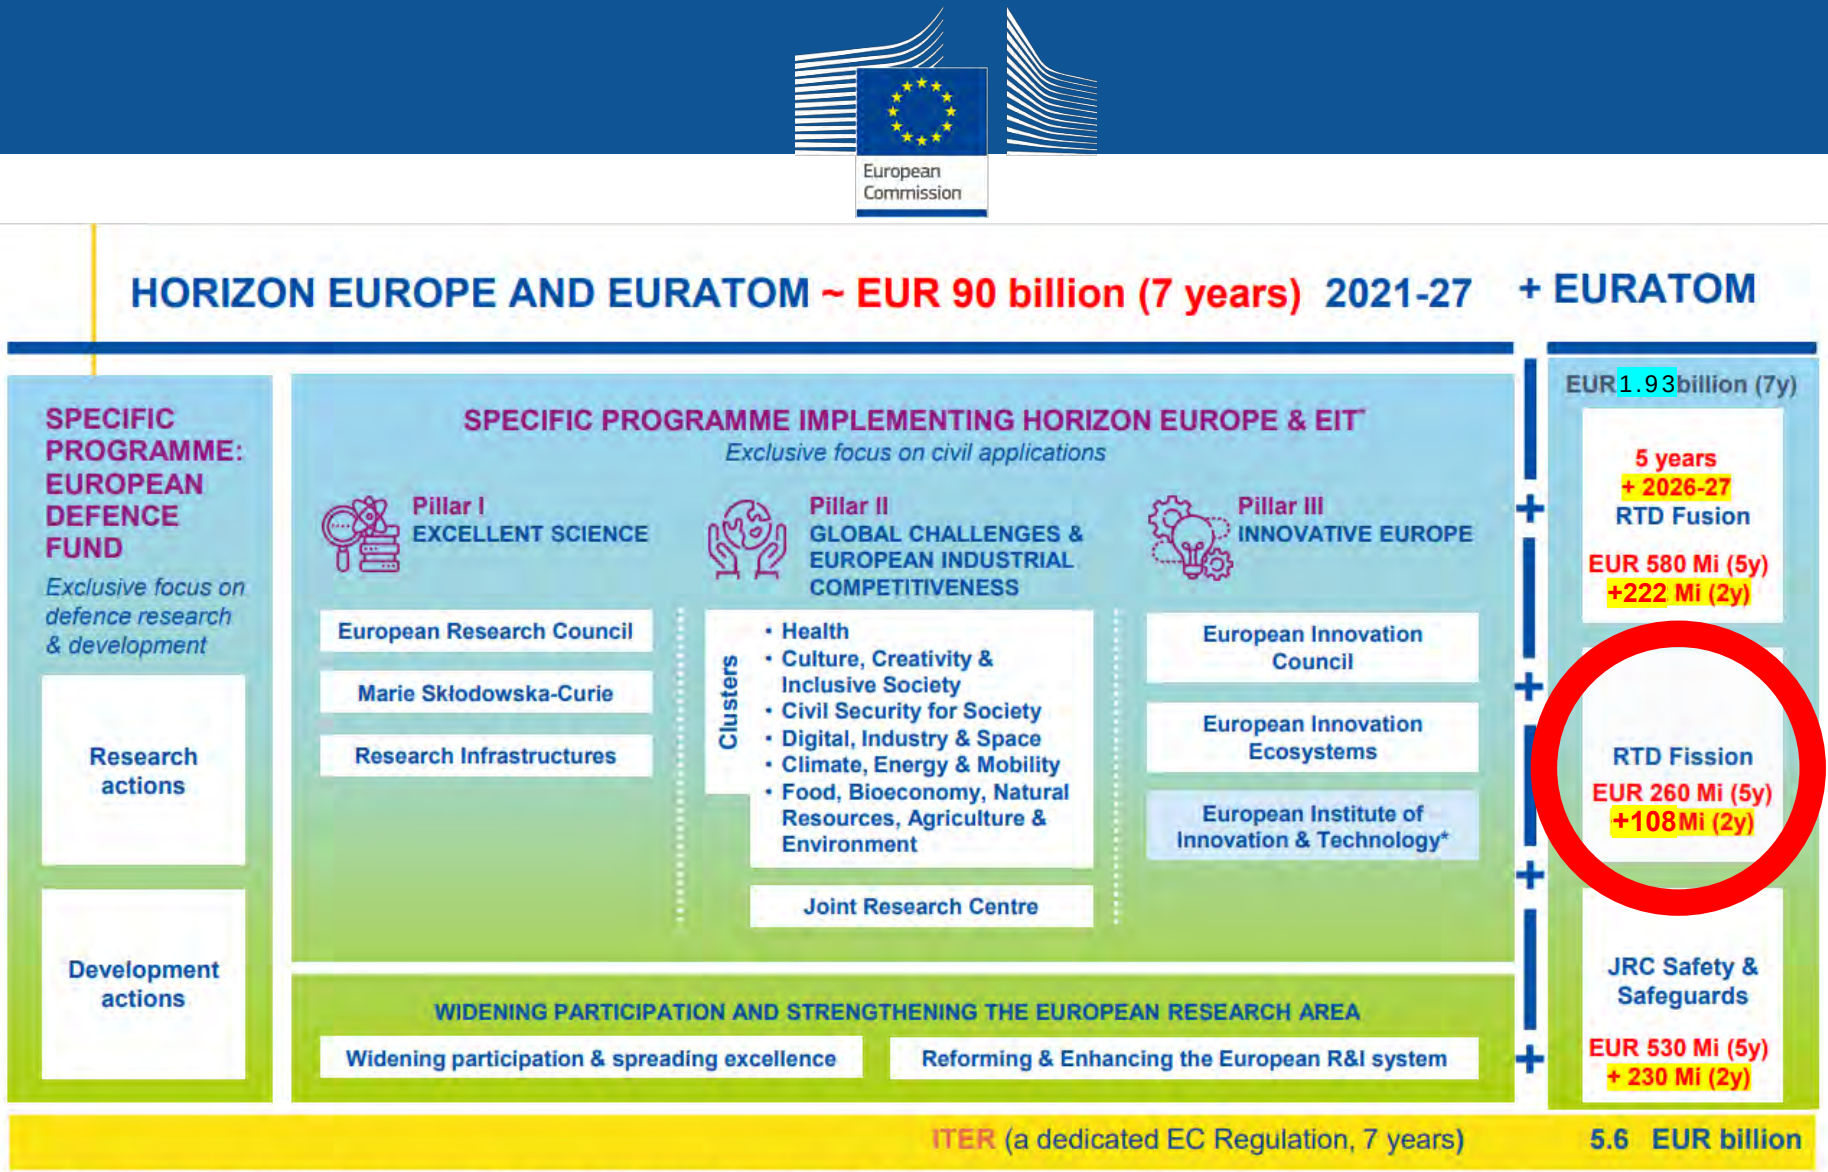
"After years of declining investment, we need more to turn the tide. [...] We want this new technology [SMRs] to be operational in Europe by the early 2030s, so that it can play a key role alongside traditional nuclear reactors, in a flexible, safe, and efficient energy system."

Commissioner Zaharieva -Startups, Research and Innovation-, on the adoption of the Euratom WP 2026-27, Brussels, 19.03.2026

"The EU wants to lead the world in innovative nuclear technologies, which will be key to securing our energy independence, competitiveness and decarbonisation."

The Euratom research and training programme

- The Euratom Research and Training Programme is a complementary funding programme to Horizon Europe which covers nuclear research and innovation.
- The programme is planned in five-year cycles, with an extension for another two years in order to align with the Multiannual Financial Framework, the EU's seven-year budget cycle.
- It funds direct actions, which are research activities undertaken by the Commission's Joint Research Centre, and indirect actions - research activities undertaken by multi-partner consortia. The indirect actions are coordinated by the Directorate-General for Research and Innovation of the European Commission.



https://research-and-innovation.ec.europa.eu/index_en and Euratom https://research-and-innovation.ec.europa.eu/funding/funding-opportunities/funding-programmes-and-open-calls/horizon-europe/euratom-research-and-training-programme_en

→ Council Regulation (Euratom) 2025/1304 of 23 June 2025 https://eur-lex.europa.eu/eli/reg/2025/1304/oj/eng

The Euratom Work programme 2026-2027

- The 2026-2027 Euratom work programme for research is extending the 2021-2025 programme. It has a budget of €330 million:
  - €222 million for indirect actions in fusion research and development
  - **€108 million for indirect actions in nuclear fission,** safety and radiation protection

Euratom Research WP 2026-27

OPERATION:

- *The EC-DG RTD representing Euratom drafts the Euratom Research and Training WP containing topics of research*
- *Potential beneficiaries apply with proposals for research Projects*
- *These research Projects are evaluated by independent Experts panels*

TIMING:

- Adoption of the WP 2026-27 on 19 of March 2026, publication on 24 March 2026
- Deadline for application by 15 September 2026
- Evaluation October- November 2026
- Results of the evaluation by January 2027
- Indicative signature of the research projects by May 2027
- Projects to start from June 2027 on.

Euratom Research WP 2026-27 adopted on 19.03.2026

Safety of operating nuclear power plants and research reactors

HORIZON-EURATOM-2026-01-01 | Calls for proposals

Opening date: **23 April 2026** | Deadline date: **15 September 2026** | Single-stage

Open For Submission

Programme: **Euratom Research and Training Programme (EURATOM)** | Type of action: **EURATOM Research and Innovation Actions**

Safety of SMRs, advanced and innovative nuclear reactors and fuels

HORIZON-EURATOM-2026-01-02 | Calls for proposals

Opening date: **23 April 2026** | Deadline date: **15 September 2026** | Single-stage

Open For Submission

Programme: **Euratom Research and Training Programme (EURATOM)** | Type of action: **EURATOM Innovation Actions**

European Partnership for research in radiation protection and detection of ionisin...

HORIZON-EURATOM-2026-01-09 | Calls for proposals

Opening date: **23 April 2026** | Deadline date: **15 September 2026** | Single-stage

Open For Submission

Programme: **Euratom Research and Training Programme (EURATOM)** | Type of action: **EURATOM Cofund Actions**

Severe Accidents: vision beyond the WP 2026-27

- The Euratom Research mandate is to fund research on the safety of nuclear installations, the existing ones and the ones to come
- Severe Accidents consideration is crucial part of the safety assessment, this especially in the EU considering MS' nuclear regulations
- We note the need to continue funding research on SA for the existing NPPs and for the expected new designs: LW large-size, LW-SMRs, AMRs GEN-IV.

  - For the established technologies experimental data preservation should be considered
  - For the incoming new technologies experimental activity and code validation should be considered

The next Euratom Research and Training Programme 2028-2032

Proposal for a COUNCIL REGULATION
establishing the research and training programme of the European Atomic Energy Community for the period 2028-2032, complementing Horizon Europe, the Framework Programme for **Research and Innovation, and providing for the Community's** contribution to the ITER project, and repealing Regulation (Euratom) 2025/1304

- For the next MFF 2028-34 the EC proposed to double the Euratom Research budget from EUR 2 billion to EUR 4 billion for fusion and fission research.

Thank you for your attention!

Euratom research multilateral cooperation with international organizations IAEA and NEA-OECD

The 12th European Review Meeting on Severe Accidents Research
May 18-22, 2026
Madrid, Spain

Outline

- Coordinated Research Projects (CRPs)
- Platforms, databases, publications
- Technical meetings
- AI for Nuclear

Division of Nuclear Power

Nuclear Power Engineering Section

The Section supports countries operating nuclear power plants or expanding their existing programmes to improve engineering, performance, management systems, human resource management, stakeholder involvement and technical infrastructure. It shares best engineering practices and innovations consistent with the global objectives of nuclear safety, security and non-proliferation. Read more →

Nuclear Power Technology Development Section

Fostering information exchange and collaborative research and development for advanced nuclear reactor technologies, this Section provides information to the IAEA's Member States on technology status and development trends for advanced reactor systems and their applications. Read more →

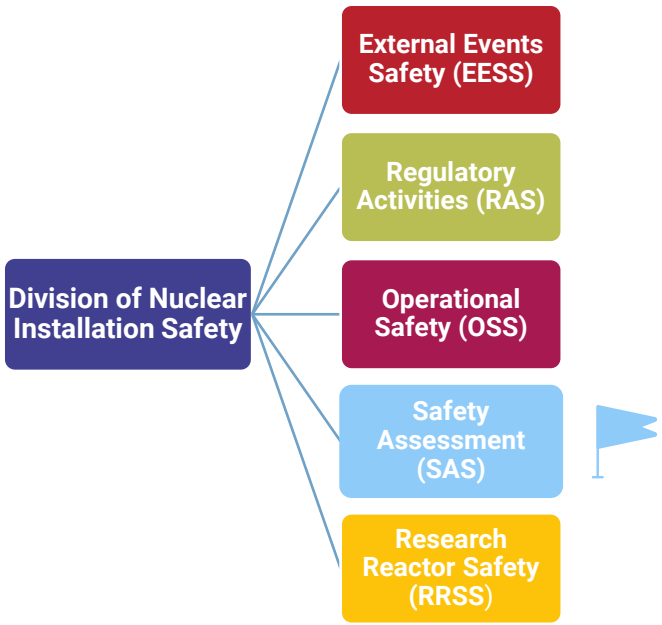
Nuclear Infrastructure Development Section

This Section is responsible for coordinating IAEA assistance to Member States considering or embarking on nuclear power programmes. It supports capacity-building, conducts review missions and offers guidelines, standards and workshops on developing the infrastructure for a safe, secure and sustainable nuclear power programme. Read more →

International Project on Innovative Nuclear Reactors and Fuel Cycles Section

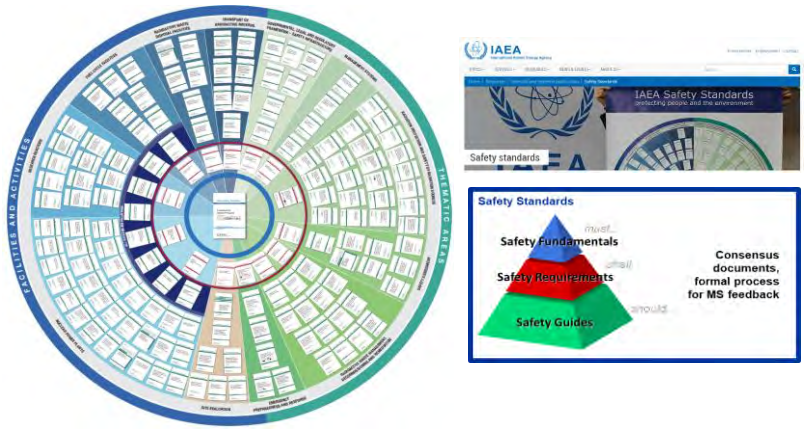
The Section coordinates the activities of the membership-based International Project on Innovative Nuclear Reactors and Fuel Cycles (INPRO) to increase international cooperation on global nuclear energy sustainability, long term strategies and institutional and technical innovations for nuclear energy development and deployment. Read more →

Division Of Nuclear Installation Safety (NSNI)



Three key missions:

- Development of **safety standards** for nuclear installations, and supporting publications
- Provision of **safety reviews and advisory services** to support the effective application of the safety standards
- Support to Member States in building and sustaining **capability and capacity** in nuclear safety



https://www.iaea.org/resources/safety-standards

A **new cycle of revision of the safety standards** under SAS responsibilities **has started** to cover:

- **All technologies of reactor designs** (water-cooled, non water-cooled, SMRs, microreactors, land-based or not, transportable reactors)
- **New applications used for civil purposes** (e.g. other than only electrical generation, as process heat, desalination, marine propulsion)
- **Interfaces between safety** and **security**, and safety and **safeguards**

Coordinated Research Activities

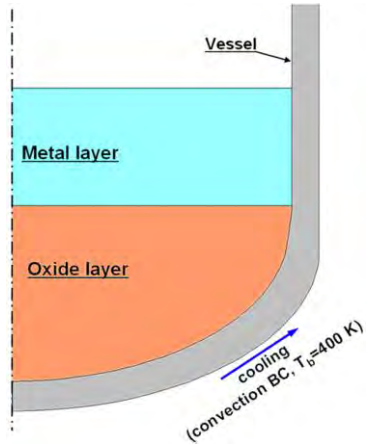
- Provide opportunities to engineers and scientists in developing and developed Member States to ***collaborate on research topics of common interest***
- ***Results of research activities supported by the Agency are disseminated to all Member States*** through national, international and IAEA scientific and technical publications, and other communications media
- ***118 active CRPs***

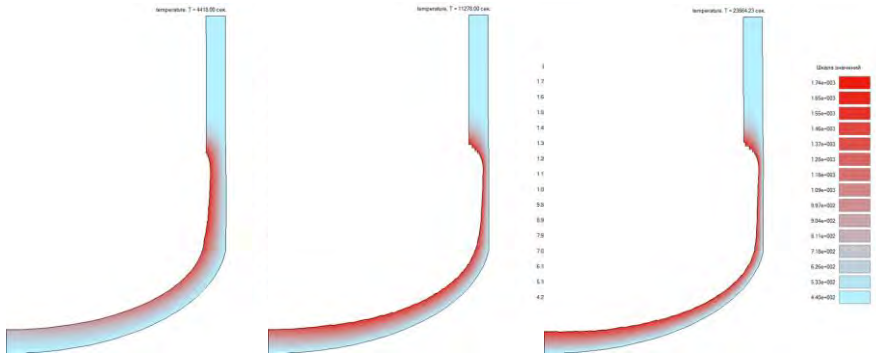
http://cra.iaea.org/cra/index.html

Completed in 2025: CRP on Developing a Phenomena Identification and Ranking Table (PIRT) and a Validation Matrix, and Performing a Benchmark For In-Vessel Melt Retention

CRP outputs:

- **TECDOC** aimed to harmonize the international understanding of scientific and technological bases underpinning crucial parts of the **safety demonstration of IVMR** (2026)
- **Technical Meeting** on the *Development of a Phenomena Identification and Ranking Table and a Validation Matrix, and Performing a Benchmark for In-Vessel Melt Retention* organised on **16–20 June 2025** to disseminate the outcomes





t = 200 s *t* =4 400 s *t* =23 500 s
Sequential states of heated/ablated vessel (start of loading from *t* =0)

CRP on IVMR: Key Messages, Conclusions, Future Work

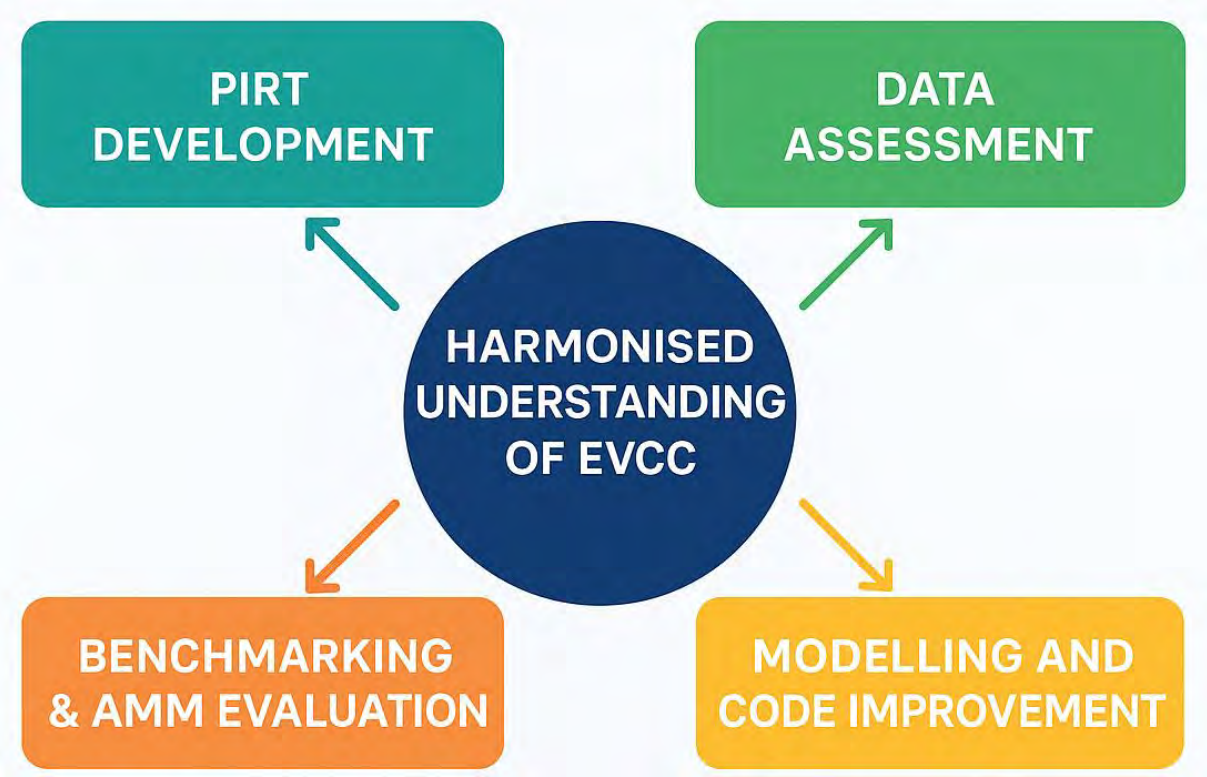
- Significant progress achieved in the **harmonization of IVMR understanding, modelling, and validation**
- Strong integration of PIRT, VM, code benchmarking and reactor simulations
- Reactor design strongly impacts IVMR behaviour
  - Geometry, power level, and internal structures change dominant phenomena
- Current SA/CFD/FE codes show **good maturity for "standard" stratification cases**
- Uncertainty Propagation proved **highly valuable** and led to the concept of **Sensitive PIRT (SPIRT)** for quantitative ranking of phenomena
- Priority R&D needs:
  - Oxide–metal interaction kinetics during stratification inversion
  - Mechanical strength of ablated vessel wall under external cooling
- Additional model improvements needed:
  - Corium thermochemistry
  - Focusing effect in thin metal layers
  - Heat transfer in flat oxide pools
  - Radiative heat transfer modelling
  - Corium oxidation & steel corrosion
  - Debris bed melting / molten pool formation

New CRP on Ex-Vessel Corium Behaviour and Cooling (2026–2030)

- **Characterize state-of-the-art knowledge:** to assess key phenomena in EVCC, evaluate the robustness of current understanding for ex-vessel mitigation strategies, and identify R&D priorities to address uncertainties in initial and boundary conditions
- **Review experimental data:** assess available experimental data for model validation and identify gaps, including recent findings post-Fukushima Daiichi accident
- **Benchmark exercices:** comparing experimental data to models, focusing on key phenomena to identify deviations. The two-step approach involves:
  - Analysing open results under Fukushima-specific conditions to optimize parameters
  - Applying those parameters in a Fukushima-based scenario with spreading and MCCI phases, followed by sensitivity analyses
- **Organise training course:** develop a training course on applying severe accident codes to ex-vessel accident scenarios
- **Call for proposals open.** First RCM meeting planned on 3–6 November 2026.

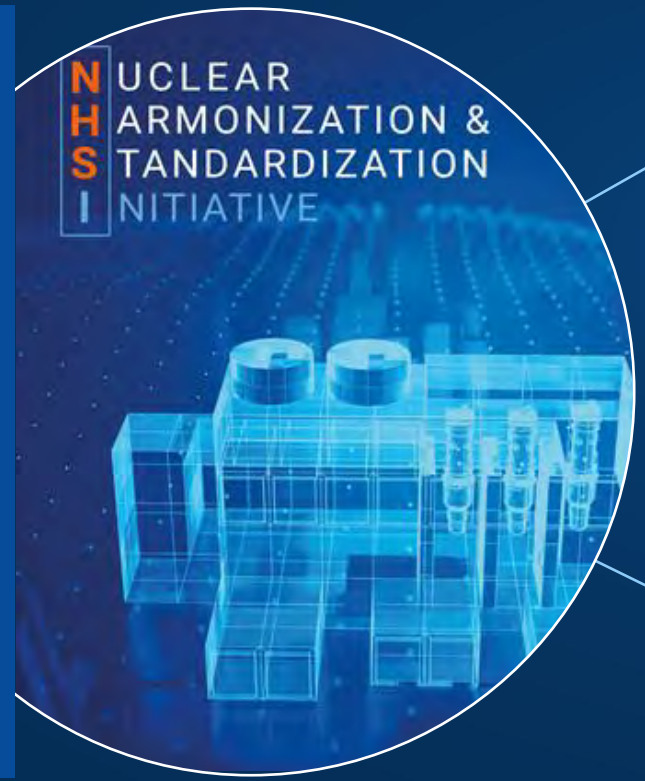
CRP Expected Outcomes

1. **Harmonised understanding** of EVCC phenomena through a consensus-based PIRT.
2. **Consolidated experimental and plant data** for model validation and identification of remaining gaps.
3. **Improved modelling and simulation capabilities** and shared methodologies among Member States.
4. **Coordinated benchmark exercises**, including scenarios with accident management measures and a Fukushima-type accident case.
5. **Training and capacity-building materials** to support Member State application of severe accident codes to ex-vessel scenarios.



Background: Nuclear Harmonization and Standardization Initiative (NHSI)

Effective Global Deployment of **Safe and Secure** Advanced Nuclear Reactors



Harmonization of Regulatory Approaches Track

Advance the development of a Global Framework for Advanced Reactors Reviews (GFARR)

[Nuclear Harmonization and Standardization Initiative (NHSI)]

Harmonization and **S**tandardization of Industrial Approaches Track

Develop more standardized industrial approaches for SMR manufacturing, construction and operations to reduce licensing efforts, costs and deployment timelines.

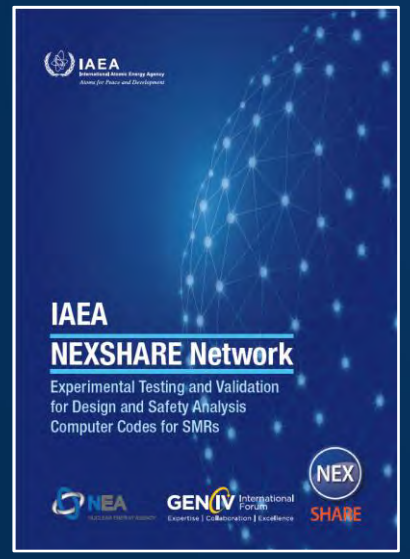
- Governments
- Technology Holders
- Operators and other end-users
- International Organisations and Associations

Experimental Testing and Validation for Design and Safety Analysis Computer Codes - NEXSHARE Network

SMRs may require extending the validated boundaries of existing codes or include physical phenomena for which the experimental data lacks. The significant resources for validation or experimentation is a challenge to a safe and secure timely deployment of SMRs.

To address these challenges, the IAEA established **NEXSHARE**, a technical forum for global cooperation and resource sharing for experiments and code validation.



The Network is a collaboration with the **NEA**, the **Gen-IV Forum** and the **European Commission**.

- ✓ **Members**: Vendors, Experimental Facilities, TSO, International Organizations.
- ✓ **Events**: Workshops, webinars, SC meetings and Focus-Groups meetings.
- ✓ **Web interface**: Information on the topic, opportunity for collaborations, **Experimental Facility Catalogue.**
- ✓ **Focus Groups**: Work specific to a reactor family.

IAEA NEA NUCLEAR ENERGY AGENCY GEN IV International Forum European Commission

NEXSHARE's Mission and Objectives:

- Information Sharing on Experimental Facilities and Programmes.
- Enhance utilization of existing experimental facilities.
- Resources optimization for SMR code validation and experiments.
- Greater confidence on data and codes used in safety cases.

Experimental Facility Catalogue & Focus Groups

Experimental Facility Catalogue: Through filtering and search, members can find facilities that can be contacted to access existing data or generate new data needed for code validation of SMRs and Advanced Reactors.

Focus: Thermalhydraulics (separate & integral effects), neutronics, component/feature, severe accident & containment

LW-SMR

HTGR

LMFR

MSR

Integration of SANIS in NEXSHARE and Collaboration with SEAKNOT:

- In order to ensure maintenance and upgrade, it has been decided to integrate the SANIS database in NEXSHARE.
- Facilities will have to provide concurrence and additional information.
- In parallel, SEAKNOT is updating its Severe Accident Facility Catalogue.
- To avoid duplication of effort and requests to facilities, collaboration between SEAKNOT and NEXSHARE is ongoing for EU facilities.

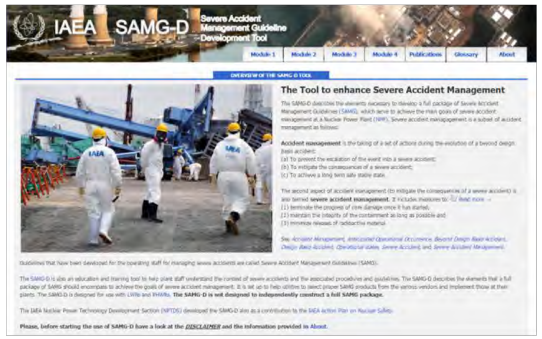
IAEA SAMG-D toolkit

SAMG-D
Severe Accident Management Guideline Development toolkit

- **Module 1** Fundamentals of reactor safety
- **Module 2** Severe accident challenges and mitigation strategies
- **Module 3** Severe accident management guidelines
- **Module 4** Implementation, requirements and infrastructure



Nine Training Workshops

Toolkit revision planned in 2026-2027 (jointly with NSNI)

- Ensuring coherency with IAEA Specific Safety Guide SSG 54
- Information for BWRs, including practical examples of SAMG for BWRs
- Include additions or changes regarding CANDU reactors
- Review and update the sections focusing on computer codes used for the accident analysis
- Update the toolkit based on advances in the state-of-the-art revision of the list of references

10th SAMG-D Toolkit training workshop: 30 November – 4 December 2026, IAEA (in-person)

Publications

- Analysis and Modelling of Severe Accidents for Liquid Metal Fast Reactors, IAEA-TECDOC-2079 (2025)
- Progress in the Performance Assessment and Regulation of Passive Systems in Advanced Nuclear Power Plant Designs, TECDOC, jointly with NSNI (2026)
- Ex-vessel Phase of Severe Accidents in Water Cooled Reactors, TECDOC (2026)
- Artificial Intelligence Methods and Research Needs for the Design and Qualification of Advanced Reactors, TECDOC (2027)

TECDOC Ex-Vessel Phase of Severe Accidents in Water-Cooled Reactors

Publication and scope

- Comprehensive IAEA reference on ex-vessel severe accident phenomena in water-cooled reactors (PWR, BWR, CANDU).
- Covers accident progression after RPV failure, corium behaviour, containment challenges and mitigation strategies.
- Integrates experimental evidence, modelling tools, plant applications and lessons from Chernobyl and Fukushima.

Main objectives

- Consolidate current state of knowledge on ex-vessel corium behaviour.
- Review analytical codes, experiments and validation approaches.
- Support severe accident management and containment protection strategies.
- Identify remaining uncertainties and R&D priorities.

Structure

- Severe accident progression and transition to ex-vessel phase
- Forensic insights from Chernobyl and Fukushima accidents
- Key phenomena: melt release, FCI, debris beds, spreading, MCCI, FP behaviour
- Experimental programmes and large-scale testing databases
- Numerical tools and integrated severe accident codes
- Plant implementation examples and SAM measures
- Remaining issues, modelling gaps and future research needs

Some key messages from conclusions

- Fukushima investigations continue to reveal new issues and improve understanding of ex-vessel corium behaviour.
- Further coordinated international R&D, experiments and model validation are required to reduce uncertainties in corium cooling and containment protection.

Planned Schedule

The safety standards → below will incorporate a **new definition of severe accidents** (DEC-B), that will apply to all technology designs (w/o impact for WCRs)

Requirements and Safety guides	2025				2026				2027				2028				2029				2030				2031				2032				2033				2034				2035

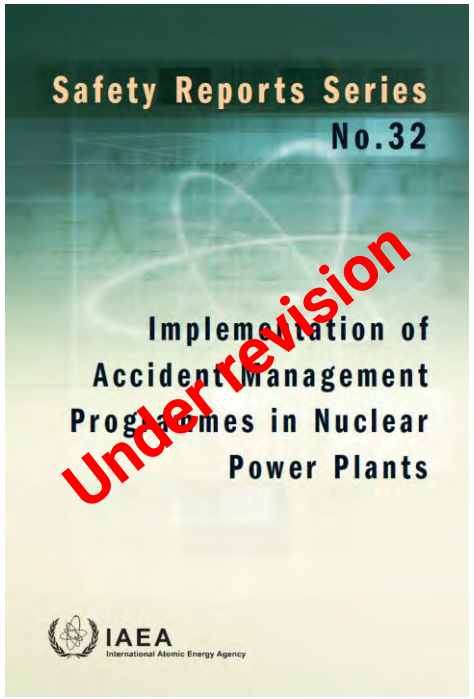
Revision of SAFETY REPORTS SERIES No. 32 (2004) (in pre-print)

Revision 1, entitled "**Development and Implementation of Severe Accident Management Programmes for NPPs**":

- **Integrates lessons learned from Fukushima Daiichi accidents** (external events and common cause failures, review training and continuous improvement, multi-units and SFP, containment integrity, H2 management, I&C systems, heat removal and power supply systems)
- Safety Standards used as inputs for revising the report: **SSR-2/1 (Rev.1)**, **SSR-2/2 (Rev.1)**, **SSG-54** and **Member States enhanced AMPs**
- **Significant enhancements** in the report:
  - Consideration of multi-unit sites and spent fuel pool, inclusion of non-permanent equipment
  - Equipment and instrumentation reliability for accident conditions
  - Guidelines for transition between EOPs and SAMGs
  - Periodic Review and revision of Accident Management Programme
  - Rules for usage of SAMGs
  - Role of Regulatory Body in the development and implementation of SAMGs



2024–2025 Technical Meetings

- Technical Meeting on Capitalizing on Artificial Intelligence Analysis to Accelerate the Technological Development of Evolutionary and Innovative Reactor Designs (4–7 November 2024)
  - 107 registered participants from 46 Member States, 33 technical presentations
- Technical Meeting on Progress in the Performance Assessment and Regulation of Passive Safety Systems in Advanced Nuclear Power Plant Designs (10-14 March 2025)
- Technical Meeting on Advancements and New Developments in Water Cooled Reactor Designs (6–9 May 2025)
- Technical Meeting on the Development of a Phenomena Identification and Ranking Table and a Validation Matrix, and Performing a Benchmark for In-Vessel Melt Retention (16–20 June 2025) to disseminate the outcomes of a CRP

2026–2027 Technical Meetings

- Technical Meeting on Policies and Strategies for the Long-Term Operation of Nuclear Power Plants, NPES (IAEA, 16–18 June 2026)
- Technical Meeting on Considerations for the Deployment of AI, NPES (IAEA, 27–31 July 2026)
- Technical Meeting on Artificial Intelligence Integration in Nuclear Operations: Bridging Intelligence and Operations for a Safe, Secure, and Resilient Nuclear Power Industry, NPES (IAEA, 5 Nov–4 Dec 2026)
- Technical Meeting on Application of Advanced Computational Methods and Codes for Design and Analysis of Advanced WCRs (IAEA, Q2/2027)
  - To share advances in computational methods (high-fidelity simulations, reduced-order models, system-CFD coupling, AI tools) for analysing and optimizing advanced WCRs, with emphasis on validation, integration, and experimental support.

IAEA Collaborating Centre on AI (CSOI, Purdue University, USA) 2023-2027

Facilitate programmatic activities and knowledge sharing in AI for nuclear power (AI4NP) to advance reactor designs and support industrial deployment of AI solutions at operating NPPs

Develop validation approaches for AI concepts in reactor technology, real-time operation, maintenance, design optimization, safety analysis, and accident management

Support human capacity building with training and educational courses on AI basics, opportunities, challenges, and applications for nuclear power software development, safety analysis and accident management

Joint IAEA-ICTP Workshop on Artificial Intelligence and Machine Learning in Advancing Nuclear Engineering and Technology: from Theory to Practice

- Comprehensive understanding of AI and ML concepts and applications in nuclear engineering
- Knowledge-based and data-based AI, ML paradigms, and decision support for optimal design, operation, maintenance, safety analysis, and risk assessment in nuclear technology
- Various ML approaches, including decision trees, tree ensembles, artificial neural networks, and data analytics
- Hands-on exercises with datasets to apply AI and ML in nuclear engineering problems
- 10–14 March 2025, ICTP, Trieste, Italy
- Planned in 2027

TECDOC Artificial Intelligence Methods and Research Needs for the Design and Qualification of Advanced Reactors

Objective:

- Identify key R&D areas where AI can accelerate advanced and FOAK reactor design
- Define technical gaps in modelling, validation, and data
- Propose benchmarking, uncertainty, and evidence-building approaches
- Provide a roadmap to support Member States in prioritizing AI integration

Scope:

- How AI R&D outputs should be structured to enable subsequent deployment work (deployment considerations covered in the NES No. NR-T-1.26)
- Targets the upstream technical R&D required for reactor design
- Education and capacity building
- Will provide the essential technical basis that directly enables and complements the downstream deployment guidance

Structure (Preliminary Table of Contents):

- Introduction (background, objectives, scope)
- Overview of AI methods for advanced reactor R&D
- Modelling and simulation (complexity reduction, multi-scale coupling)
- Inference and uncertainty quantification for FOAK validation
- Digital twin and document intelligence (use cases, limitations)
- Design optimization and automation
- Materials and fuel reload/management applications
- Data governance for R&D workflows
- Benchmarking and community exercises
- Education and training needs
- Recommendations and roadmap
- Conclusions

Resolutions Adopted at the 69th IAEA General Conference (2025)

Page 8, Point (s): Stressing the importance of…strengthening long-term research **programmes to learn about severe accidents**…

Page 13, Point (i): … activities for enhancing Member State capabilities in modelling, predicting and improving the **understanding of the behaviour of current and advanced nuclear fuel in normal operation and under accident conditions**.

P.14, Point 73: Encourages the Agency to facilitate the **exchange of results of research and development on severe accident management strategies** for nuclear power plants

P.14, Point 75: Encourages Member States to develop as necessary and implement **severe accident management guidelines** taking into account, inter alia, lessons learned from the Fukushima Daiichi nuclear power plant accident, and **requests the Secretariat to support their efforts through training workshops.**

1. **New CRP** on Ex-Vessel Corium Behaviour and Cooling.

2. **Yearly training workshops with the IAEA SAMG-D toolkit** are being organised by the IAEA to facilitate the development of severe accident management guidelines in Member States accounting lessons learned from Fukushima accident.

ABSTRACT

CALPHAD-based corium thermodynamic modelling is impaired by the lack of activity or calorimetric experimental measurements for such liquids at very high temperatures. It relies almost exclusively on phase equilibrium data. As such, when the associated thermodynamic databases (e.g. NUCLEA, TAF-ID) are used to evaluate the liquid properties (e.g. chemical potential) out of equilibrium, their values come with a very large (and unquantified) uncertainty. This was clearly highlighted in recent thermodynamic evaluations (based on the Butler equation) of the interfacial tension between the oxide and metal liquid phases of the U-O-Zr-Fe system under equilibrium conditions. In particular, a strong sensitivity to the chemical potentials evaluated at the interface composition (that differs from the bulk liquids' compositions) was noticed. Indeed, for such out-of-equilibrium conditions, NUCLEA and TAF-ID predictions significantly differ while they are in rather good agreement at the bulk phases' equilibrium compositions. Based on this observation, a proof of concept was recently made regarding the use of gas/liquid surface tension data in the CALPHAD assimilation process (in the framework of Bayesian inference). Indeed, for such interfaces, some experimental data are available, even for high-temperature corium. It was shown on the well-assessed Cu-Mg system that gas/liquid surface tension data can effectively replace activity data for the assessment. These results are summarized in this paper where this proof of concept is extended to the binary U-O system and a path forward for the actual re-assessment of the liquid phase corium thermodynamic models is discussed.

KEYWORDS

liquid thermodynamic modelling, surface tension, corium, U-O, CALPHAD, Butler equation

1. INTRODUCTION

When considering multicomponent materials at very high temperatures (typically above 2700K), the knowledge of thermodynamic properties is very often impaired by the lack of calorimetric or activity experimental measurements for such liquids. As a consequence, when the associated thermodynamic databases are used to evaluate the liquid properties (e.g. enthalpy, chemical potential) out of equilibrium, the values of these properties come with a very large (and unquantified) uncertainty. Hence, numerical simulations of the behaviour of systems involving such liquids (e.g. multiphase thermalhydraulics) cannot be fully predictive. This is particularly true in the area of severe nuclear reactor accidents where such experimental data for liquids associated with the reactor core meltdown are almost non-existent. Considering the two main databases internationally used for corium systems, namely NUCLEA [1, 2, 3] and TAF-ID (Thermodynamics of Advanced Fuels-International Database) [4], this trend was highlighted in [5] where a renovated Butler equation-based model [6, 7] was used to evaluate the interfacial energy between the two liquids at equilibrium in the miscibility gap of the binary U-O and quaternary U-O-Zr-Fe systems. It was shown that the large differences in interfacial tension predictions depending on the database are to be attributed to the extrapolation of the chemical potentials out of global equilibrium conditions. For the sake of illustration, Figure 1 depicts the behaviour of the Uranium and Oxygen chemical potentials as a function of composition for the binary U-O system in the liquid miscibility gap range at $T = 2800$K. It can be observed that the two liquid phases predicted at equilibrium (in terms of compositions and chemical potentials) by the two databases are in good agreement but that the amplitude of the variations of the chemical potentials w.r.t. the equilibrium values is significantly larger with TAF-ID when compared with NUCLEA. Such differences are consistent with the fact that only one tie-line has been measured in the U-O miscibility gap region [8] and highlights the large uncertainty that is associated with the liquid phase Gibbs energy model calibration in these databases. It also points out that interfacial energies, as modelled through a Butler approach, are very sensitive to the Gibbs energy model extrapolation at the interface composition (that differs from the bulk phases compositions).

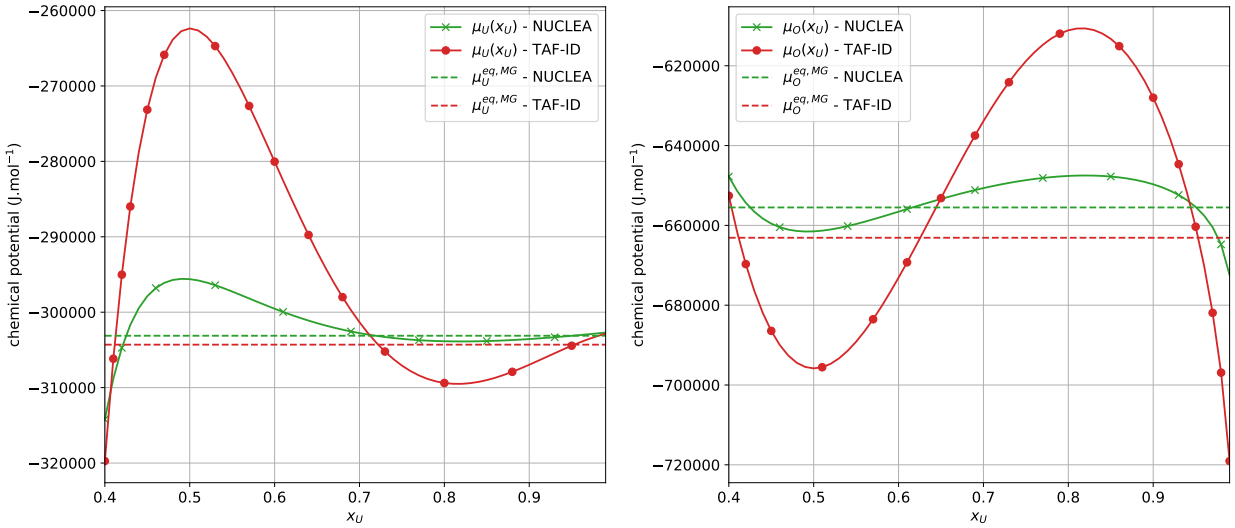

Figure 1. Liquid phase chemical potential (μ_U on the left and μ_O on the right) vs. x_U (molar fraction of Uranium) for the U-O system at $T = 2800$K as evaluated using the NUCLEA version 19.1 and TAF-ID version 10 databases – Equilibrium values in the miscibility gap are plotted in dashed lines – Figure reproduced from [5].

These databases are constructed using the CALPHAD method [9]. In this framework, improving the Gibbs energy model calibration for the liquid corium phase requires new data in the sub-stoichiometric range of composition but acquiring such data is very challenging. On the one hand, developing new experimental capabilities for calorimetric measurements at high temperature is a research avenue with many technical challenges to be tackled [10]. On the other hand, very good results have been obtained using classical molecular dynamics simulations for the properties of stoichiometric liquid (U,Zr)O_2 oxides [11] and metallic (U,Zr) melts [12] but accurate evaluation of sub-stoichiometric melts properties with such an approach is still an open issue.[1]

In this context, considering the fact that measuring surface tension between molten corium and an inert atmosphere is an existing experimental capability in the frame of the VITI facility at CEA Cadarache [14], a third way to improve the liquid corium phase Gibbs energy model has been recently investigated.[2] The idea pursued in the A. Tourneix Ph.D. thesis [15] consists in introducing liquid-gas surface tension data in the CALPHAD assessment process to improve the liquid phase model calibration. To this end, two questions have to be successively addressed. First, a thermodynamic model of surface tension was chosen and tested for its compatibility with the CALPHAD representation of the liquid phase and its *a priori* relevance. Following the work reported in [5] for liquid-liquid interfaces, a model based on different formulations of the Butler equation was considered and tested [16]. Its sensitivity to the underlying CALPHAD model was demonstrated and its predictions compared to experimental measurements of liquid-gas surface tension for the U-O-Zr system [17]. From there, a proof of concept on the binary Cu-Mg system was established for the integration of these data, through the Butler model, into the CALPHAD data assimilation process. In this paper, the main results of this proof of concept are presented and discussed with some additional results regarding the application of such an approach to the binary U-O system.

The paper is structured as follows. Section 2 introduces the Gibbs energy models for the liquid phase of both Cu-Mg and U-O systems along with the Butler-based surface tension model. The numerical method and associated tools considered for the data assimilation are summarized in Section 3. Numerical results are then presented and discussed in Section 4. Section 5 finally draws conclusions and presents perspectives of this work.

2. MODELS

2.1. Liquid phase Gibbs free energy model

For the thermodynamic modelling of the liquid phase, a non-ideal associate model, typically used in the NUCLEA database, is considered in the present work. Such a model is a special case of the general Compound Energy Formalism (CEF) where only one sublattice is considered and where, consequently, constituents and endmembers (in this case, the stoichiometric compounds) are one and the same. A full description of the different models describing the Gibbs energy in the CALPHAD framework is given in [9].

In order to present this model, the following notations are first introduced:

- $\underline{x}_{\mathcal{E}} = \{x_i\}_{i\in\mathcal{E}}$ are the component molar fractions and $\mathcal{E}$ the set of components;
- $\underline{y}_{\mathcal{S}} = \{y_j\}_{j\in\mathcal{S}}$ are the constituent molar fractions and $\mathcal{S}$ the set of constituents;
- T is the temperature.

[1] In this context, if *ab initio* molecular dynamics simulations are very promising, their application to non-stoichiometric composition is not trivial [13].

[2] It should be noted that an ambitious 5-year OECD/NEA project (Properties for reactor Simulation and uncertainties – COPS) has started in April 2024 and will largely increase the amount of surface tension data for corium mixtures.

The following transformation from $\underline{y}_{\mathcal{S}}$ to $\underline{x}_{\mathcal{E}}$ is then defined:

$$\mathtt{C} : \underline{y}_{\mathcal{S}} \longmapsto \left\{ x_i = \frac{\sum\limits_j b_{ij} y_j}{\sum\limits_k \sum\limits_j b_{kj} y_j} \right\}_{i \in \mathcal{E}} \tag{1}$$

where b_{ij} is the stoichiometric factor of component i in constituent j.

The non-ideal associated model represents the Gibbs energy per mole of constituents [J·mol^{-1}] according to the following decomposition:

$$\mathcal{G}_M : T, \underline{y}_{\mathcal{S}} \longmapsto \sum_{j \in \mathcal{S}} y_j \, {}^0\mathcal{G}_j(T) + RT \sum_{j \in \mathcal{S}} y_j \ln y_j + {}^E\mathcal{G}_M\left(T, \underline{y}_{\mathcal{S}}\right) \tag{2}$$

where ${}^0\mathcal{G}_j$ is the molar Gibbs energy of formation for pure constituent j [J·mol^{-1}], R is the universal gas constant [J·mol^{-1}·K^{-1}] and ${}^E\mathcal{G}_M$ is the excess contribution, the key ingredient of such model that takes into account the departure from ideality (the second term in Eq. 2 being associated with the ideal entropy of mixing). Considering the Redlich–Kister binary excess model, it is written as:

$${}^E\mathcal{G}_M : T, \underline{y}_{\mathcal{S}} \longmapsto \sum_{j \in \mathcal{S}} \sum_{l \in \mathcal{S} | l > j} y_j y_l \sum_{k=0}^{K_{j,l}} {}^kL_{j,l}(T) \left(y_j - y_l\right)^k \tag{3}$$

with $K_{j,l}$ the expansion order and ${}^kL_{j,l}(T)$ the interaction parameter, a function of temperature. From there, the Gibbs energy per mole of components can be obtained as:

$$\mathcal{G}_m : T, \underline{y}_{\mathcal{S}} \longmapsto \frac{\mathcal{G}_M\left(T, \underline{y}_{\mathcal{S}}\right)}{\mathcal{N}\left(\underline{y}_{\mathcal{S}}\right)} \tag{4}$$

where $\mathcal{N}$ is the total amount of components per mole of constituents *i.e.* $\mathcal{N}\left(\underline{y}_{\mathcal{S}}\right) = \sum\limits_k \sum\limits_j b_{kj} y_j$.

On one hand, in the general case, $\mathtt{C}$ is not invertible (in other words, $\mathrm{card}\,\underline{y}_{\mathcal{S}} > \mathrm{card}\,\underline{x}_{\mathcal{E}}$)) and, to make the link with measurable thermodynamic quantities for the modeled phase, it is needed to introduce the following Gibbs energy per mole of components:

$$\tilde{\mathcal{G}}_m : T, \underline{x}_{\mathcal{E}} \longmapsto \min_{\underline{y}_{\mathcal{S}} \,|\, \mathtt{C}\left(\underline{y}_{\mathcal{S}}\right) = \underline{x}_{\mathcal{E}}} \left(\mathcal{G}_m\left(T, \underline{y}_{\mathcal{S}}\right)\right) \tag{5}$$

that represent the "local" minimization of $\mathcal{G}_m$ for a given component composition $\underline{x}_{\mathcal{E}}$. For instance, the chemical potential of component k is obtained from $\tilde{\mathcal{G}}_m$ by $\mu_k = \frac{\partial \tilde{\mathcal{G}}_m}{\partial x_k}(T, \underline{x}_{\mathcal{E}})$. On the other hand, in the special case where $\mathcal{S} = \mathcal{E}$, this model is simplified into the substitutional model and the component chemical potentials can be evaluated analytically without any numerical minimization.

The activity of component k is defined by

$$a_k = \exp\left(\frac{\mu_k - \mu_k^\star}{RT}\right) \tag{6}$$

where $\mu_k^\star$ is the reference chemical potential of pure component k under the same p and T conditions.

We now restrict our presentation to the liquid phase of two binary systems: U-O and Cu-Mg. More precisely, we consider the non-ideal associated model for U-O of the NUCLEA database and the substitutional model for Cu-Mg considered in [18]. Focusing on the interaction parameters only, the parametrization of both databases is summarized in Table I. In both cases, four parameters associated with the description of the binary excess terms are considered in the assessment process for this work.[3]

[3]Note that the order of these expansions has not been questioned in this work; the interested reader is referred to [15] for further discussion concerning the Cu-Mg system.

Table I. Description of the interaction terms parametrization for the two binary systems.

System	$\mathcal{E}$	$\mathcal{S}$	Interaction terms' expansions
U-O	$\{U,O\}$	$\{UO_2,U,O\}$	${}^0L_{UO_2,U}(T) = {}^0c_0 + {}^0c_1T$
			${}^1L_{UO_2,U}(T) = {}^1c_0$
			${}^2L_{UO_2,U}(T) = {}^2c_0$
Cu-Mg	$\{Cu,Mg\}$	$\{Cu,Mg\}$	${}^0L_{Cu,Mg}(T) = {}^0c_0 + {}^0c_1T$
			${}^1L_{Cu,Mg}(T) = {}^1c_0 + {}^1c_1T$

2.2. Liquid/gas surface tension model

For modelling the surface tension between a liquid phase and a gas phase, a Butler-based model is considered. In this sharp interface framework, the zero-volume surface Γ at the interface between the liquid and gas phases is treated as an additional phase fully characterized by its component chemical potentials $\mu_k^\Gamma\left(T^\Gamma,\underline{x}_\mathcal{E}^\Gamma\right), \forall k \in \mathcal{E}$ as a function of its average temperature T^Γ and composition $\underline{x}_\mathcal{E}^\Gamma$. The chemical potential of component k is expressed as follows:

$$\mu_k^\Gamma : T^\Gamma, \underline{x}_\mathcal{E}^\Gamma \longmapsto \bar{\mu}_{k,\Gamma} - \sigma_\Gamma \omega_{k,\Gamma} \tag{7}$$

where σ_Γ is the surface tension, $\omega_{k,\Gamma}$ the partial molar surface associated with component k and $\bar{\mu}_{k,\Gamma}$ is the reduced chemical potential. Considering a planar surface under equilibrium conditions (uniform temperature T in particular), the general form of the Butler equation is then obtained from the uniformity of the chemical potentials over the system as follows: $\forall k \in \mathcal{E}$,

$$\sigma_\Gamma = \frac{\bar{\mu}_{k,\Gamma} - \mu_k}{\omega_{k,\Gamma}} \tag{8}$$

where μ_k is, in particular, the value of the chemical potential of component k in the liquid phase.

From there, if both the liquid and surface chemical potentials are decomposed, in analogy with a substitutional model of the Gibbs energy (see Eq. 2), by distinguishing a pure component term, a configurational entropy term and an excess term, one obtains the Butler equation under its classical form: $\forall k \in \mathcal{E}$,

$$\sigma_\Gamma = \sigma_{k,\Gamma}^\star \frac{\omega_{k,\Gamma}^\star}{\omega_{k,\Gamma}} + \frac{RT}{\omega_{k,\Gamma}} \ln\left(\frac{x_{k,\Gamma}}{x_k}\right) + \frac{{}^E\mu_{k,\Gamma}\left(T,\underline{x}_\mathcal{E}^\Gamma\right) - {}^E\mu_k\left(T,\underline{x}_\mathcal{E}\right)}{\omega_{k,\Gamma}} \tag{9}$$

where $\sigma_{k,\Gamma}^\star$ is the surface tension of pure component k, $\omega_{k,\Gamma}^\star$ the associated partial molar surface and ${}^E\mu_{k,\Gamma}\left(T,\underline{x}_\mathcal{E}^\Gamma\right)$ (resp. ${}^E\mu_k\left(T,\underline{x}_\mathcal{E}\right)$) the excess term for the surface (resp. the liquid phase).

While all the different terms associated with the liquid phase can readily be obtained from a CALPHAD-based Gibbs energy model (as introduced in the previous section), additional closures are needed for the surface terms. The surface tension of pure components are taken from the literature and are summarized in Table II.

Table II. Pure component surface tension laws as a function of temperature under the form $\sigma(T) = a - b\,(T - T_0)$ – For the Oxygen, in the temperature range of interest, it is supposed to be null.

Component	a [J.m^{-2}]	b [J.m^{-2}.K^{-1}]	T_0 [K]	Reference
U	1.675	$3.4 \cdot 10^{-4}$	1405.45	[19]
Cu	1.303	$2.3 \cdot 10^{-4}$	1356.0	[20]
Mg	0.559	$3.5 \cdot 10^{-4}$	924.0	[20]

Regarding the excess energy term, the standard assumption that it can readily be obtained from the liquid

model considering a proportionality relationship is made *i.e.*

$$^{E}\mu_{k,\Gamma}\left(T,\underline{x}_{\mathcal{E}}^{\Gamma}\right) = k_{\Gamma}\,{}^{E}\mu_{k}\left(T,\underline{x}_{\mathcal{E}}^{\Gamma}\right) \tag{10}$$

where the coordination number ratio k_{Γ} is introduced (see for instance [21]).

From there, Eq. 9 represents a non-linear set of equations whose unknown is the interface composition $\underline{x}_{\mathcal{E}}^{\Gamma}$.

3. NUMERICAL METHODS AND TOOLS

Regarding surface tension modelling, the Butler equation is solved using the in-house pyButler python module that is based on the OpenCalphad software [22] to handle the CALPHAD databases and perform Gibbs energy minimization. This module uses the same numerical approach as discussed in [5] and implements different forms of the Butler equation for both liquid/liquid and liquid/gas interfaces (see [16] for more details).

For the CALPHAD parameter calibration, a Bayesian inference framework was considered for this proof of concept in order to correctly treat uncertainty. To do so, the ESPEI software was used as a starting point [18]. It makes use of an affine-invariant ensemble sampler for Markov chain Monte Carlo (MCMC) [23] as implemented in the emcee python module [24]. Such a method was considered in this work for two main reasons. First of all, it makes no assumption on the dependency between the input parameters (from the CALPHAD model in the present case) and the output quantities (that can be obtained from the CALPHAD model and compared with available data) in the data assimilation process (in contrast with a linear model for instance [25]). Secondly, it is readily possible with such a method to marginalize over nuisance parameters. A nuisance parameter is a parameter that, in addition to the input parameters, is required in order to evaluate an output quantity and compare it with the corresponding data, but is otherwise of little interest. In other words, considering the set of input (resp. nuisance) parameters $\mathbf{c}$ (resp. $\mathbf{n}$) and the set of data $\mathbf{d}$, the probability density function (pdf) of interest is $p(\mathbf{c}|\mathbf{d})$ that is formally given by:

$$p(\mathbf{c}|\mathbf{d}) = \int p(\mathbf{c},\mathbf{n}|\mathbf{d})\, p(\mathbf{n})\, d\mathbf{n} \tag{11}$$

In practice, MCMC-generated sampling of values $(\mathbf{c}_t,\mathbf{n}_t)$ for the input and nuisance parameters from the joint distribution $p(\mathbf{c},\mathbf{n}|\mathbf{d})$ automatically provides a sampling of values $\mathbf{c}_t$ from the marginalized pdf $p(\mathbf{c}|\mathbf{d})$.

To draw samples $(\mathbf{c}_t,\mathbf{n}_t)$ from the posterior pdf $p(\mathbf{c},\mathbf{n}|\mathbf{d})$, an MCMC algorithm makes use of the Bayes' theorem:

$$p(\mathbf{c},\mathbf{n}|\mathbf{d}) = \frac{p(\mathbf{d}|\mathbf{c},\mathbf{n})\, p(\mathbf{c},\mathbf{n})}{Z} \tag{12}$$

where $p(\mathbf{d}|\mathbf{c},\mathbf{n})$ is the so-called likelihood pdf, $p(\mathbf{c},\mathbf{n})$ the prior distribution and $Z = p(\mathbf{d})$ the normalization independent of $\mathbf{c}$ and $\mathbf{n}$ (that is not evaluated). It consists in an iterative procedure based on Markov chains that converges to a stationary set of samples from the posterior distribution. The inverse convergence rate can be estimated by the integrated autocorrelation time that estimates the number of steps needed in the chain in order to draw independent samples from the target density. The affine-invariant ensemble sampler of the MCMC method implemented in emcee has been devised to reduce this time especially for strongly anisotropic distributions.

Within this framework, assuming that all data are independent, the likelihood pdf is decomposed as:

$$p(\mathbf{d}|\mathbf{c},\mathbf{n}) = \prod_{d_i \in \mathbf{d}} p(d_i|\mathbf{c},\mathbf{n}) \tag{13}$$

and, for each likelihood contribution $p(d_i|\mathbf{c},\mathbf{n})$, a maximum likelihood estimation strategy is followed assuming that the residuals are normally distributed and centered on zero *i.e.*

$$p(d_i|\mathbf{c},\mathbf{n}) = p_{\mathcal{N}_{0,\sigma_i}}(r_i) \tag{14}$$

where $p_{\mathcal{N}_{0,\sigma_i}}$ is the normal distribution centered on zero with standard deviation σ_i and $r_i = \tilde{d}_i(\mathbf{c},\mathbf{n}) - d_i$ is the residual associated with the estimation $\tilde{d}_i(\mathbf{c},\mathbf{n})$ of d_i. The ESPEI software was extended in such a way that, through an interface with the pyButler module, surface tension data predicted by the Butler model of Eq. 9 can be considered in $\mathbf{d}$ in addition to activities, mixing enthalpies and so on.

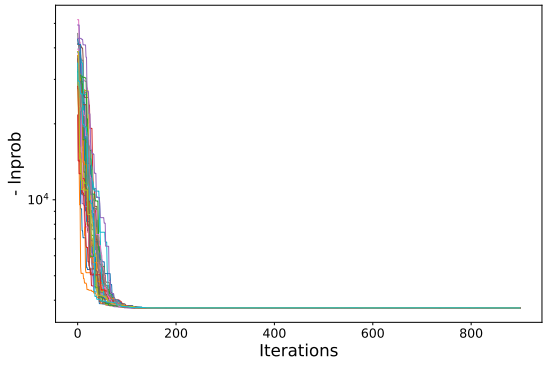
In the remainder, $\mathbf{c}$ will be the set of interaction parameters for the liquid phase model *i.e.* $\left\{{}^{i}c_{j}\right\}_{i,j}$ (see Table I) while $\mathbf{n}$ will be either $\{k_\Gamma\}$ or $\emptyset$ depending if k_Γ is calibrated and marginalized or not. This aspect will be further discussed in Section 4.

4. NUMERICAL RESULTS

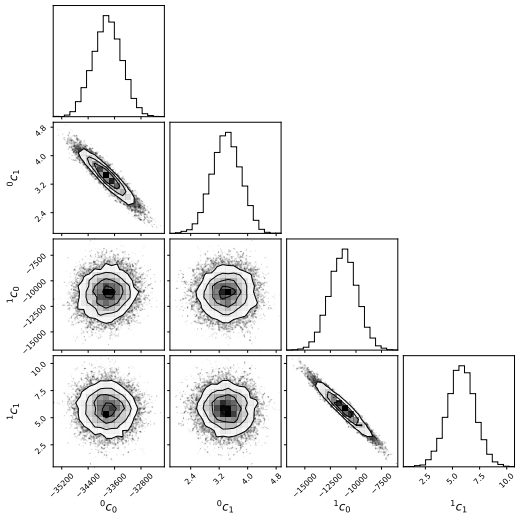
4.1. Proof of concept on the Cu-Mg system

This section summarizes and illustrates the main results obtained in [15] where the introduction of surface tension data in the CALPHAD assimilation process was tested on the liquid phase of the Cu-Mg system.

The starting point of this incremental proof of concept was to create a reference assessment of the liquid Cu-Mg phase from Mg activity, enthalpy of mixing and liquidus data. From [26], 34 mixing enthalpies, more than 200 liquidus temperatures and 95 Mg activities were considered for the re-assessment of the liquid phase only.[4] In any case, a relative uncertainty $2\sigma_i/d_i$ of 15% was considered along with an improper prior (in such a way that the posterior is informed entirely by the data). 900 iterations with 40 chains have been performed as illustrated in Figure 2a in terms of the evolution of $-\ln\left(p\left(\mathbf{d}|\mathbf{c},\mathbf{n}\right)p\left(\mathbf{c},\mathbf{n}\right)\right)$ for the different chains. Accordingly, discarding the 200 first iterations (so-called burn-in), the maximum likelihood estimate of the parameters $\bar{\mathbf{c}}$ along with ± 1.94 standard deviation is shown in Table III while their distributions are illustrated in the corner plot of Figure 2b that displays the marginalized univariate distributions along the diagonal and the covariance between pairs of parameters below the diagonal.



(a) Opposite of $\ln\left(p\left(\mathbf{d}|\mathbf{c},\mathbf{n}\right)p\left(\mathbf{c},\mathbf{n}\right)\right)$. Each line corresponds to the log probability of the accepted parameters for a single chain.



(b) Corner plot of the sampled posterior parameter distributions.

Figure 2. Reference assessment of the liquid Cu-Mg phase considering liquidus temperature, mixing enthalpy and Mg activity data – 900 iterations with 40 chains – $2\sigma_i/d_i = 15\%$ and improper prior.

[4] For the different solid phases in equilibrium with the liquid one depending on the composition, the original ESPEI assessment [18] was used.

Table III. Assessed parameters of the liquid Cu-Mg phase – maximum likelihood estimate ± 1.94 standard deviation.

	${}^0c_0$	${}^0c_1$	${}^1c_0$	${}^1c_1$
this work	$(-3.38 \pm 0.09) \cdot 10^4$	3.4 ± 0.9	$(-1.1 \pm 0.3) \cdot 10^4$	6 ± 3
[18]	$(-3.46 \pm 0.09) \cdot 10^4$	3 ± 6	$(-1.1 \pm 0.3) \cdot 10^4$	5 ± 9

In Table III, the results of the assessment performed in [18] are also presented for the sake of comparison. Both assessments well agree with a noticeable reduction of the uncertainty on ${}^0c_1$ and ${}^1c_1$ in our case that is attributed to the fact that activity data were not considered in [18].

From there, activity and surface tension were compared in terms of the information they give on parameters **c**. To do so, for a same composition and temperature grid, data were generated for both types of physical quantities considering the previously calibrated liquid phase model and a given value of k_Γ of 0.83 (the value estimated in [21] for metallic systems). These data are given in Tables IV and V for surface tensions and Cu activities respectively while the different datasets constructed from these data are summarized in Table VI. These datasets were used for performing assessments of parameters **c** for various values of the data relative standard deviation σ_i/d_i. In any case, for each parameter, the prior distribution was arbitrarily taken as a normal law of unit relative standard deviation with following mean values: $-8 \cdot 10^4$ for ${}^0c_0$, $-3 \cdot 10^1$ for ${}^0c_1$, $1.5 \cdot 10^4$ for ${}^1c_0$ and $6 \cdot 10^2$ for ${}^1c_1$.

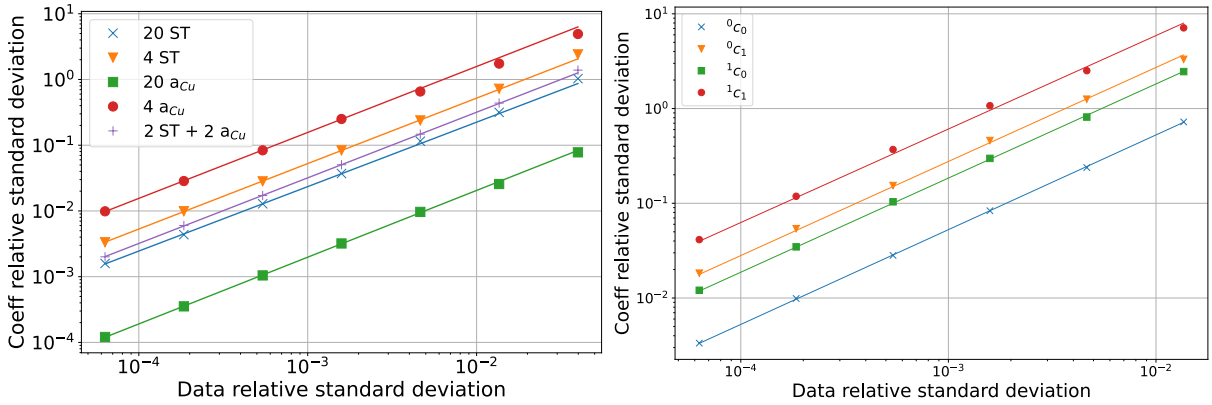
4 a_{Cu}	–	data in red and blue
2 ST + 2 a_{Cu}	data in blue	data in blue
5 ST	data in red, blue and green	

In a first batch of assessments, the parameter k_Γ was not calibrated and was kept constant at its reference value. The results of these assessments are summarized in Figure 3 where the relative standard deviation of

the parameters posterior distribution is depicted as a function of σ_i/d_i. In Figure 3a, the different datasets are compared focusing on parameter ${}^0c_0$. Below a threshold σ_i/d_i value of about 10^{-1}, all assessments are successful and ${}^0c_0$ relative standard deviation decreases when σ_i/d_i decreases following a linear law (in all cases, the fit of a power-law $a \times (\sigma_i/d_i)^b$ gives $b \approx 1$). Because of the first-order dependency in both temperature and composition of the Gibbs energy model (see Table I), two temperature points along with two composition points are required when surface tension data or activity data are considered separately. In such "minimal" configurations, it can be seen that the assessments with surface tensions and activities (datasets (4 ST) and (4 a_{Cu}) respectively) gives similar results. Interestingly, because the surface tension through the Butler equation depends on both the bulk liquid composition and the interface composition, surface tension data and activity data at a same unique composition point can be combined to ensure a successful assessment. This is illustrated with the (2 ST + 2 a_{Cu}) dataset calculation in Figure 3a. As expected, when the number of data points is increased (datasets (20 ST) and (20 a_{Cu}) respectively), the parameter relative standard deviation is decreased; while this decrease is limited for surface tension data (a factor of 2 approximately), for activity data, it is more pronounced (a factor of 100 approximately). The same trends are exhibited for all **c** parameters as illustrated by Figure 3b that depicts the relative standard deviation convergence for the four parameters ${}^ic_j$ for dataset (4 ST).

On the overall, these numerical results demonstrate that surface tension data, as modelled through the Butler equation, play a very similar role to activity data in the calibration process of the Cu-Mg liquid phase Gibbs energy model.



(a) Comparison of various datasets **d** for parameter ${}^0c_0$.

(b) Comparison of the four parameters ${}^ic_j$ for dataset (4 ST).

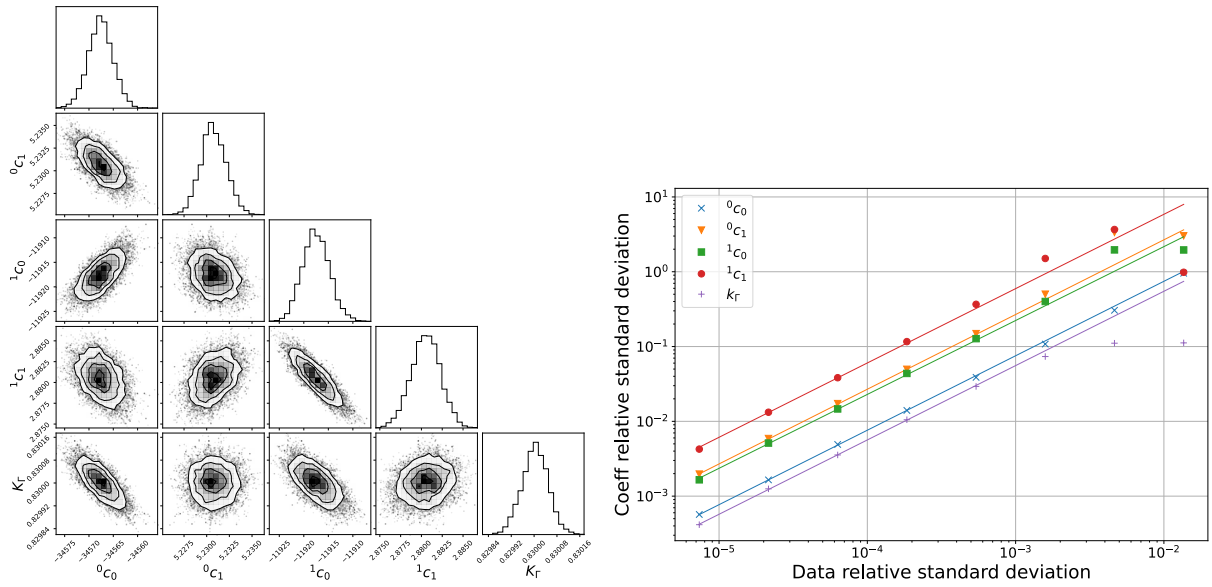
Figure 3. Evolution of the relative standard deviation of $p\left({}^ic_j|\mathbf{d}\right)$ as a function of σ_i/d_i considering various datasets (see Table VI) – Cu-Mg liquid phase.

However, the Butler equation introduces additional parameters that, in principle, should be considered as uncertain. In particular, different values of the coordination number ratio k_Γ can be found in the literature depending on the system under consideration and surface tension as evaluated through Eq. 9 is very sensitive to this parameter.[5] Accordingly, in the remainder of this proof of concept, this parameter has been considered as a nuisance parameter and was calibrated and marginalized. Doing so, the minimum number of data points for a proper MCMC convergence is increased by one. The successful assessment with dataset (5 ST), constructed from dataset (4 ST) by adding a single surface tension value, is illustrated in the corner plot of Figure 4a where, in particular, it can be seen that the marginalized univariate distribution of k_Γ

[5]The reader is refered to [16] for more details. The other parameters of Eq. 9 could also considered but, because of their uncertainty and/or the associated sensitivity of surface tension, their impact is more limited.

follows a Gaussian law centered on its reference value.[6] In Figure 4b, the relative standard deviation of the parameters posterior distribution is depicted as a function of σ_i/d_i. The same trends as with dataset (4 ST) and k_Γ kept constant (see Figure 3b) are observed with, in particular, a linear dependency of the relative standard deviation of $p\left({}^{i}c_j|\mathbf{d}\right)$ below a threshold σ_i/d_i value. It can be noted that this threshold value is decreased to about 10^{-3} while, in the asymptotic linear region, introducing k_Γ in the calibration process leads to a very limited increase of the **c** relative standard deviation (by a factor lower than 2).

Taking into account the uncertainty of the interface parameter k_Γ in the assimilation process (by adjusting and marginalising it) does not call into question the results obtained previously without taking this uncertainty into account. The information that surface tension data can provide on the liquid phase Gibbs energy is confirmed. In A. Tourneix Ph.D. thesis [15], this analysis on the Cu-Mg system with generated data was followed by assessments considering actual experimental measurements (including surface tension data measured in the VITI facility) that have confirmed their similar role and the complementarity of surface tension and activity data in calibrating the liquid phase model. For the sake of conciseness, they are not presented here.



(a) Corner plot of the sampled posterior parameter distributions – $\sigma_i/d_i = 10^{-6}$ case.

(b) Evolution of the relative standard deviation of $p\left({}^{i}c_j|\mathbf{d}\right)$ and $p\left(k_\Gamma|\mathbf{d}\right)$ as a function of σ_i/d_i.

Figure 4. Assessment considering the calibration and marginalization of parameter k_Γ for dataset (5 ST) (see Table VI) – Cu-Mg liquid phase.

4.2. First results for the U-O system and the possible path forward

Considering the positive outcome of the proof of concept on the Cu-Mg system, tentative simulations were made on the U-O system. Following the same approach as for Cu-Mg, surface tension data were generated considering a k_Γ value of 0.94 (the value estimated in [21] for oxidic systems) and **c** values extracted from the NUCLEA database: $6.2 \cdot 10^4$ for ${}^0c_0$, $-1.1 \cdot 10^1$ for ${}^0c_1$, $-6.1 \cdot 10^4$ for ${}^1c_0$ and $-2.1 \cdot 10^4$ for ${}^2c_0$. These data are given in Table VII. An important difference w.r.t. the Cu-Mg system is that the U-O system exhibits

[6] The prior distribution for k_Γ was arbitrarily taken as a $[0,1]$-truncated normal law of 10% relative standard deviation with 0.8 mean value.

a liquid miscibility gap over an extended composition and temperature range. Accordingly, the composition points considered in Table VII were selected out of the miscibility gap region *i.e.* in conditions where the equilibrium between a unique liquid and an inert gaseous atmosphere is possible. This dataset was then used for performing an assessment of parameters $\mathbf{c}$ for various values of the data relative standard deviation σ_i/d_i. In any case, for each parameter, the prior distribution was arbitrarily taken as a normal law of unit relative standard deviation with following mean values: $-3.2 \cdot 10^4$ for ${}^0c_0$, $-7.1 \cdot 10^1$ for ${}^0c_1$, $1.1 \cdot 10^4$ for ${}^1c_0$ and $2.1 \cdot 10^4$ for ${}^2c_0$. The results in terms of relative standard deviation evolution are depicted in Figure 5a while Figure 5b shows the corner plot for the assessment with $\sigma_i/d_i = 10^{-4}$. On the overall, the same trends as for the Cu-Mg system are observed with an asymptotic linear regime below a below a threshold σ_i/d_i value. Additional assessments with k_Γ calibration (not shown) were also performed: the impact of this additional nuisance parameter was found similar as in the Cu-Mg case.

Considering these positive results, carrying out actual surface tension measurements of a sub-stoichiometric U-O melt (out of the miscibility gap range) could be a short-term way to improve the CALPHAD assessment of the associated liquid phase.

5. CONCLUSIONS AND PERSPECTIVES

In this paper, we have presented the positive outcomes of a proof of concept regarding the use of surface tension data to improve a liquid phase thermodynamic modelling in the frame of the CALPHAD method.

To do so, surface tension was modeled through the Butler equation and parameter calibration was made in the frame of Bayesian inference (with an MCMC approach) for an adequate uncertainty treatment. It was shown, through a detailed analysis with generated data on the well-assessed Cu-Mg system, that surface tension plays a role very similar to activities in the assessment process. Calibration and marginalization of the coordination number ratio, an additional uncertain parameter introduced in the Butler equation, was also carried out without impairing the CALPHAD assessment. Additional results on the U-O system were provided to confirm that this approach could be a viable short-term approach to improve the liquid phase description for corium systems for which data are very scarce.

Pursuing this research direction, the next steps would be the following. Carrying out surface tension measurements of sub-stoichiometric U-O melts (for compositions out of the miscibility gap range) in the VITI facility would provide data in such a way that the approach promoted here could be actually tested to improve the CALPHAD assessment of the associated liquid phase. To do such an assessment, while the Bayesian inference framework should be kept, the results of this paper suggest that the costly MCMC method could be replaced by a simpler (and approximate) linear model (as used in the CALPHAD assessment framework in [25]).

Outline

Introduction

Problem Statement

Models & methods

Proof of concept on the Cu-Mg system

Possible path forward with U-O system

Conclusions & Perspectives

1. Introduction

Context and problem statement

Context

Thermodynamic properties of corium phases

- Associated knowledge under the form of databases constructed by the CALPHAD method, in particular: NUCLEA [Bar21], TAF-ID [GDK+21]
- Algebraic models for the Gibbs energy of the different phases calibrated on experimental and atomistic simulation data
- These databases: very useful for constructing closure laws for the models describing corium associated phenomena in SA codes

The CALPHAD method goes beyond (global) equilibrium calculations

> *"These [Gibbs energy] functions can be extrapolated also outside the equilibrium state and thus, when they are included in a simulation model, provide information about values and gradients of the thermodynamic properties in space and time outside the range of stability of a phase."*
>
> *(H. Lukas, S. G. Fries, and B. Sundman, [LFS07], pp. 2)*

But "high-fidelity" databases are required to do so

Context

Status of corium databases through the example of the U-O binary system

- From OECD/NEA project TCOFF-2 System Identification and Ranking Table:
  "A system like (O,Zr,U) has now a good knowledge (average marks of 3.3 and 3.5) due to the considerable work that have been conducted in the past years on this system."
  (C. Journeau et al., [JBK+24])

- **Is it so?**

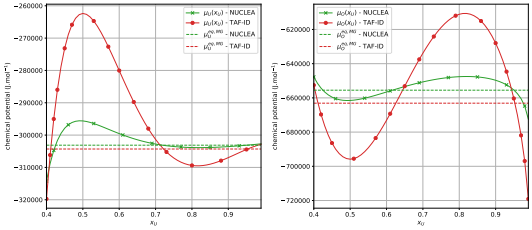

FIGURE 1: Liquid phase chemical potential (μ_U on the left and μ_O on the right) vs. x_U (molar fraction of Uranium) for the U-O system at $T = 2800$K – Equilibrium values in dashed lines

- Comparison of NUCLEA version 19.1 and TAF-ID version 10 in the liquid miscibility gap region:
  - Fairly good agreement at global equilibrium points
  - Large difference in the chemical potentials away from these equilibrium points
  - E.g. leads a factor 6 on the interfacial energy (at T_{liq}) as evaluated by the Butler equation [GLT22]

How can we move forward?

Problem Statement

Acquiring thermodynamic data for sub-stoichiometric melts is a challenge

- Developing experimental capabilities for calorimetric measurements at high temperature
  → many technical challenges to be tackled [Cro22]
- Good results obtained with classical molecular dynamics simulations for the properties of stoichiometric liquid $(U,Zr)O_2$ oxides [BBR21] and metallic (U,Zr) melts [TNBB24]
  → evaluation of sub-stoichiometric melts properties is an open issue
- *Ab initio* molecular dynamics simulations are very promising
  → their application to non-stoichiometric composition is an open issue [CBB23]

Measuring surface tension data for such melts is ongoing

- In particular in the VITI facility at CEA Cadarache [DPC$^+$22, DTD$^+$25]
- *cf.* ongoing OECD/NEA COPS project

Can we use surface tension data for improving the corium liquid Gibbs energy model?

This work

Proof of concept (PoC) regarding the use of liquid-gas surface tension data in the CALPHAD assessment of the liquid phase model

1. Choose a thermodynamic model of surface tension compatible with the CALPHAD representation of the liquid phase
   - ✓ Different formulations of the Butler equation tested [TDLT+24] on U-O-Zr system with comparison to experimental measurements [DTD+25]
     → Sensitivity to the underlying CALPHAD model and predictive capability demonstrated
2. Perform comparative assessments introducing liquid-gas surface tension data
   1. Choose a simple binary system → Cu-Mg system
   2. Assess how much information surface tension data can bring → comparison with activity data
   3. Correctly take into account uncertainty → Bayesian inference framework
   4. Start with “generated” data to put aside the issue of data-model adequacy
   5. Continue with actual experimental data

   - ✓ Done in the frame of A. Tourneix Ph.D. thesis [Tou25]

This presentation: analysis with “generated” data on Cu-Mg and U-O

2. Models & methods

Models - Liquid phase Gibbs free energy model

- Non-ideal associated model for U-O (as in NUCLEA)
- Substitutional model for Cu-Mg [CAL$^+$91, BOE$^+$19]
  - Gibbs energy per mole of constituents $\mathcal{G}_M : T, \underline{y}_{\mathcal{S}} \longmapsto \sum_{j\in\mathcal{S}} y_j \, {}^0\mathcal{G}_j(T) + RT \sum_{j\in\mathcal{S}} y_j \ln y_j + {}^E\mathcal{G}_M\left(T, \underline{y}_{\mathcal{S}}\right)$
  - Redlich–Kister binary excess model ${}^E\mathcal{G}_M : T, \underline{y}_{\mathcal{S}} \longmapsto \sum_{j\in\mathcal{S}} \sum_{l\in\mathcal{S}|l>j} y_j y_l \sum_{k=0}^{K_{j,l}} {}^k L_{j,l}(T) \left(y_j - y_l\right)^k$

System	$\mathcal{S}$	Interaction terms' expansions		
U-O	$\{UO_2, U, O\}$	${}^0L_{UO_2,U}(T)$	$=$	${}^0c_0 + {}^0c_1 T$
		${}^1L_{UO_2,U}(T)$	$=$	${}^1c_0$
		${}^2L_{UO_2,U}(T)$	$=$	${}^2c_0$
Cu-Mg	$\{Cu, Mg\}$	${}^0L_{Cu,Mg}(T)$	$=$	${}^0c_0 + {}^0c_1 T$
		${}^1L_{Cu,Mg}(T)$	$=$	${}^1c_0 + {}^1c_1 T$

- Gibbs energy per mole of components

$$\mathcal{G}_m : T, \underline{y}_{\mathcal{S}} \longmapsto \mathcal{G}_M\left(T, \underline{y}_{\mathcal{S}}\right) / \mathcal{N}\left(\underline{y}_{\mathcal{S}}\right)$$

$$\tilde{\mathcal{G}}_m : T, \underline{x}_{\mathcal{E}} \longmapsto \min_{\underline{y}_{\mathcal{S}} \mid \mathfrak{C}\left(\underline{y}_{\mathcal{S}}\right) = \underline{x}_{\mathcal{E}}} \left(\mathcal{G}_m\left(T, \underline{y}_{\mathcal{S}}\right)\right)$$

  - Chemical potential of components $\mu_k = \frac{\partial \tilde{\mathcal{G}}_m}{\partial x_k}(T, \underline{x}_{\mathcal{E}})$ and activity $a_k = \exp\left(\frac{\mu_k - \mu_k^\star}{RT}\right)$
- **Four parameters to be calibrated in both cases**

Models - Liquid/gas surface tension model: Butler equation

- Interface Γ separating two phases = an additional phase $(T^\Gamma, \underline{x}^\Gamma_{\mathcal{E}})$
  - Chemical potentials $\mu^\Gamma_k : T^\Gamma, \underline{x}^\Gamma_{\mathcal{E}} \longmapsto \bar{\mu}_{k,\Gamma} - \sigma_\Gamma \omega_{k,\Gamma}$
  - Reduced chemical potentials $\bar{\mu}_{k,\Gamma}$, surface tension σ_Γ and partial molar surfaces $\omega_{k,\Gamma}$
- Equilibrium conditions for a planar interface: $\forall k \in \mathcal{E}$

$$\sigma_\Gamma = \frac{\bar{\mu}_{k,\Gamma} - \mu_k}{\omega_{k,\Gamma}} \text{ with } \mu_k \text{ the chemical potentials in both phases}$$

  $\rightarrow$ Non-linear equation system (size = $\mathrm{card}\,(\mathcal{E}) - 1$) for unknown $\underline{x}^\Gamma_{\mathcal{E}}$
- Adapted formulation for a liquid/gas interface
  - CALPHAD-like decomposition of $\bar{\mu}_{k,\Gamma}$ and introduction of the pure component surface tensions $\sigma^\star_{k,\Gamma}$

$$\sigma_\Gamma = \sigma^\star_{k,\Gamma} \frac{\omega^\star_{k,\Gamma}}{\omega_{k,\Gamma}} + \frac{RT}{\omega_{k,\Gamma}} \ln\left(\frac{x_{k,\Gamma}}{x_k}\right) + \frac{{}^E\mu_{k,\Gamma}\left(T, \underline{x}^\Gamma_{\mathcal{E}}\right) - {}^E\mu_k\left(T, \underline{x}_{\mathcal{E}}\right)}{\omega_{k,\Gamma}}$$

  - Closure by standard assumption ${}^E\mu_{k,\Gamma}\left(T, \underline{x}^\Gamma_{\mathcal{E}}\right) = k_\Gamma \, {}^E\mu_k\left(T, \underline{x}^\Gamma_{\mathcal{E}}\right)$ with coordination number ratio k_Γ
  - ${}^E\mu_k$ function obtained from μ_k (CALPHAD liquid model)

Methods and codes

Butler equation

- in-house pyButler python module [TDLT$^+$24]
- OpenCalphad [SKPF15] for CALPHAD databases and Gibbs energy minimization

CALPHAD parameter calibration

- Bayesian inference framework (input parameters **c**, nuisance parameters **n** and data **d**)
  - Posterior pdf $p(\mathbf{c}, \mathbf{n}|\mathbf{d})$ using Bayes' theorem: $p(\mathbf{c}, \mathbf{n}|\mathbf{d}) \propto p(\mathbf{d}|\mathbf{c}, \mathbf{n})\, p(\mathbf{c}, \mathbf{n})$
  - Maximum likelihood (with $\tilde{d}_i(\mathbf{c}, \mathbf{n})$ estimation of d_i): $p(\mathbf{d}|\mathbf{c}, \mathbf{n}) = \prod_{d_i \in \mathbf{d}} p_{\mathcal{N}_{0,\sigma_i}}\left(\tilde{d}_i(\mathbf{c}, \mathbf{n}) - d_i\right)$
  - Markov chain Monte Carlo (MCMC) sampling: no assumption on the dependency between the input and output, straightforward marginalization over nuisance parameters (e.g. k_Γ)
- ESPEI software [BOE$^+$19] extended to consider surface tension data in **d** (in addition to activities...) by an interface with pyButler

3. Proof of concept

The Cu-Mg system

Starting point: reference assessment for the liquid phase

- 34 mixing enthalpies, more than 200 liquidus and **95 Mg activities** from [CAL+91]
- $2\sigma_i/d_i = 15\%$ and improper prior – 900 iterations with 40 chains
- Discarding the 200 first iterations (so-called burn-in), maximum likelihood estimate of $\bar{\mathbf{c}}$ along with ± 1.96 standard deviation:

	${}^0c_0$	${}^0c_1$	${}^1c_0$	${}^1c_1$
this work	$(-3.38 \pm 0.09) \cdot 10^4$	3.4 ± 0.9	$(-1.1 \pm 0.3) \cdot 10^4$	6 ± 3
[BOE+19]	$(-3.46 \pm 0.09) \cdot 10^4$	3 ± 6	$(-1.1 \pm 0.3) \cdot 10^4$	5 ± 9

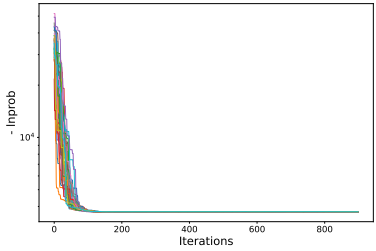

FIGURE 2: Opposite of $\ln\left(p\left(\mathbf{d}|\mathbf{c},\mathbf{n}\right)p\left(\mathbf{c},\mathbf{n}\right)\right)$. Each line corresponds to the log probability of the accepted parameters for a single chain.

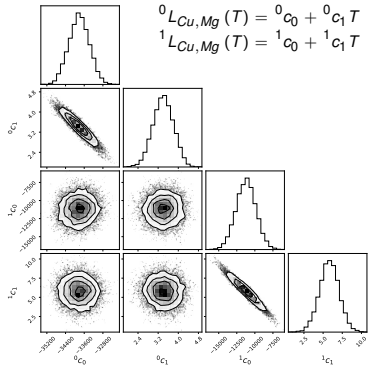

FIGURE 3: Corner plot of the sampled posterior parameter distributions.

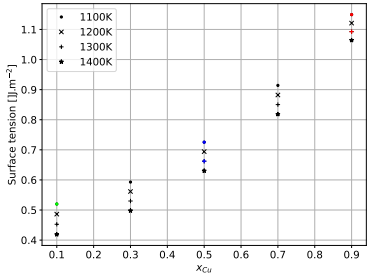
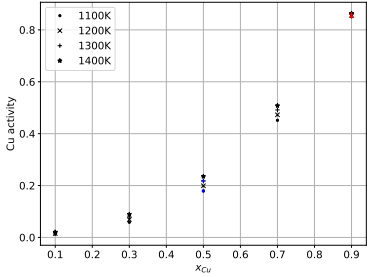
Comparing activity and surface tension based assessments

Generated data from the reference assessment

- $k_\Gamma = 0.83$ ([THIH96], metallic systems)
- Datasets for comparing different assessments:

	surface tension	Cu activity
20 ST	all data	–
4 ST	data in red and blue	–
20 a_{Cu}	–	all data
4 a_{Cu}	–	data in red and blue
2 ST + 2 a_{Cu}	data in blue	data in blue
5 ST	data in red, blue and green	–





→ **compare activity and surface tension in terms of the information they give on parameters c**

Comparing activity and surface tension based assessments

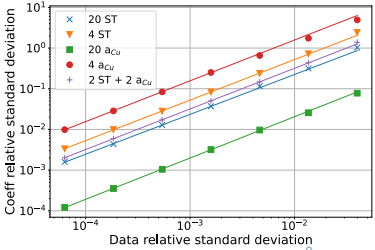
Assessments with different datasets

- Varying the data relative std σ_i / d_i

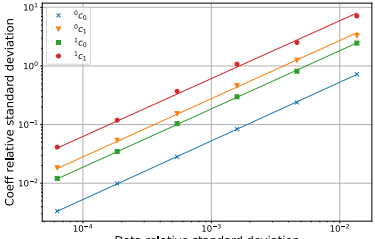
N.B. Prior distribution arbitrarily taken as a normal law with mean values very far from the actual $\bar{\mathbf{c}}$ and unit relative std

Key observations

- All assessments are successful for $\sigma_i / d_i < 10^{-1}$
- Relative std of $p\left({}^{i}c_j | \mathbf{d}\right) \propto \left(\sigma_i / d_i\right)$
- Activity (or surface tension) data alone: two temperature points with two composition points needed because of first-order dependency of $\mathcal{G}_M$ in both T and composition
- Surface tension data play a very similar role to activity data
- Surface tension data combined with activity data: a single composition point is sufficient (*cf.* Butler equation)



(A) Various datasets $\mathbf{d}$ for parameter ${}^{0}c_0$.



(B) Four parameters ${}^{i}c_j$ for dataset (4 ST).

Comparing activity and surface tension based assessments

About k_Γ in Butler equation

- An "uncertain" parameter (different values found in the literature, surface tension evaluation very sensitive to it)
- $\mathbf{n} = \{k_\Gamma\}$ so that k_Γ calibrated and marginalized

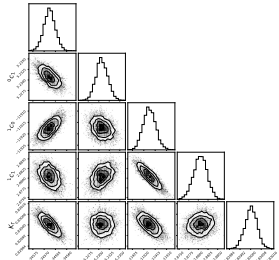
N.B. Prior distribution of k_Γ arbitrarily taken as a $[0, 1]$-truncated normal law of 10% relative std with 0.8 mean value

Key observations

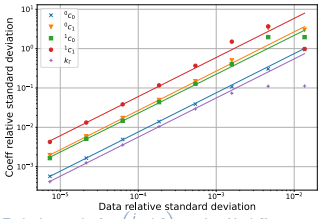
- Minimum number of data points for a proper MCMC convergence increased by one $\rightarrow$ (5 ST) dataset
- Same trends as with dataset (4 ST) and k_Γ constant with:
  - Convergence threshold value σ_i/d_i decreased to about 10^{-3}
  - In the linear region, very limited increase of the **c** relative std

Positive outcome of the PoC on Cu-Mg

(incl. assessments with actual experimental data [Tou25])



(A) Corner plot – $\sigma_i/d_i = 10^{-6}$ case.



(B) Relative std of $p\left({}^{l}c_j|\mathbf{d}\right)$ and $p\left(k_\Gamma|\mathbf{d}\right)$ vs. σ_i/d_i.

3. Possible path forward

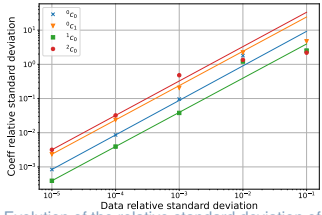
First results on U-O

First results for the U-O system

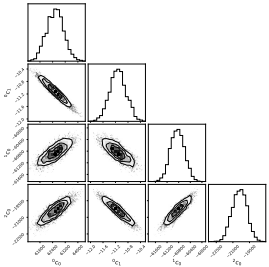
- Same approach as for Cu-Mg with “generated” data
- k_Γ value of 0.94 – *cf.* [THIH96] for oxidic systems – and **c** values from the NUCLEA
- Main difference: liquid miscibility gap over extended composition and T range
  $\rightarrow$ composition points such that equilibrium between a unique liquid and an inert gaseous atmosphere is possible
- e.g. results with 3 temperatures points and 4 composition points

Key observations

- Same trends as for Cu-Mg system
- Incl. k_Γ marginalization (not shown)



(A) Evolution of the relative standard deviation of $p\left({}^{i}c_j|\mathbf{d}\right)$ as a function of σ_i/d_i.



(B) Corner plot of the sampled posterior parameter distributions – $\sigma_i/d_i = 10^{-4}$ case.

Conclusions & perspectives

- Proof of concept about the use of surface tension data to improve liquid phase thermodynamic model in the frame of CALPHAD
- Key points:
  - Analysis carried out in the frame of Bayesian inference in order to adequately treat uncertainties
  - Butler-based modelling of surface tension
  - Detailed analysis with generated data on the well-assessed Cu-Mg system
  - Additional results on the U-O system to strengthen the analysis
- Main findings:
  - Surface tension data can advantageously replace or supplement activity data
  - k_Γ in Butler equation can be calibrated and marginalized without impairing the assessment
- Perspectives:
  - Measure surface tension of sub-stoichiometric U-O melts (out of the miscibility gap range) and revise the U-O liquid phase assessment with such data
  - Replace MCMC method by a simpler (and approximate) linear model (as used in the CALPHAD assessment framework in [Law20])

ABSTRACT

Estimating the cooling rate of fuel debris formed during the accident at the Fukushima Daiichi Nuclear Power Station (FDNPS) is essential for understanding accident progression phenomena. In this study, we propose a method to estimate the cooling rate of U–Zr–Fe–Cr–O particles based on microstructural observations and a diffusion-based scaling model. Simulated U–Zr–Fe–Cr–O debris samples were fabricated under rapid- and slow-cooling conditions, and their phase-separated microstructures were characterized by scanning electron microscopy and transmission electron microscopy.
The results revealed that the phase-separation spacing of the interpenetrating microstructure varied with the cooling rate. By applying a diffusion-based scaling model to the measured spacing, the cooling rate of particles collected from the operating floor of Unit 2 at FDNPS was estimated to be on the order of 10^3 K/s. Furthermore, the feasibility of the estimated cooling rate was examined using a simplified heat-transfer model assuming a freely flying spherical molten droplet, demonstrating that the estimate is not thermally inconsistent. The relationship between cooling rate and equivalent droplet size was also evaluated.
This study provides a quantitative approach to infer the cooling conditions of U–Zr–Fe–Cr–O fuel-debris particles from phase-separated microstructures and is expected to contribute to a deeper understanding of accident progression behavior.

KEYWORDS
Accident Progression, Cooling rate, Phase separation

1. INTRODUCTION

At the Fukushima Daiichi Nuclear Power Station (FDNPS), an accident occurred in which cooling functions were lost due to the tsunami, leading to core melting. Deepening our understanding of accident progression is essential for safe decommissioning and for the design of nuclear reactors with improved safety; however, the situation remains highly uncertain. In this context, samples and debris collected from FDNPS are considered to contain information relevant to the formation processes of fuel debris. Accordingly, analyses of such samples and debris have been conducted to contribute to understanding accident progression. Previous analyses have reported particles containing high-temperature stable phases and particles exhibiting phase separation [1]. These particles are considered to retain the information on the fuel-debris formation process, including the cooling conditions during solidification. Specifically, the persistence of high-temperature stable phases suggests rapid cooling, whereas the observation of phase separation in systems with slow diffusion (e.g., in solids) implies slow cooling. However, these assessments remain qualitative and have not yielded numerical estimates of cooling rates.

Therefore, our research group has been exploring methods to infer formation-process information such as cooling rates from the information obtained through analyses of samples collected from FDNPS. We have previously investigated the relationships between cooling rate and the crystal structure and microstructure of $(U,Zr)O_2$ [2]. In the $(U,Zr)O_2$ system, cooling at rates on the order of 10 °C/min or lower results in phase separation and crystal-structure transformations, indicating sensitivity to slow cooling rates. In contrast, methods to infer higher cooling rates remain a challenge.

To address this, we focus not only on $(U,Zr)O_2$ but also on quinary U–Zr–Fe–Cr–O particles containing Fe and Cr [1, 3]. As shown in Fig. 1, particles collected from the operating floor of Unit 2 reactor building—specifically from the cover sheet (hereafter, the "2u OF particle")—and particles from a deposit fragment at the Unit 2 X-6 penetration (hereafter, the "2u X-6 PEN particle") consist of a U–Zr–O phase and a Cr–Fe–O phase. These particles are considered to have formed via phase separation of a U–Zr–Fe–Cr–O melt during cooling. Because such precipitation/phase-separated microstructures are presumed to arise via rapid diffusion in the liquid phase, they are expected to be sensitive to higher cooling rates, and the precipitate size may depend on cooling rate.

In this study, we perform microstructural observations of U–Zr–Fe–Cr–O simulated debris cooled at different cooling rates, and explore an approach to estimate the cooling rates of FDNPS samples.

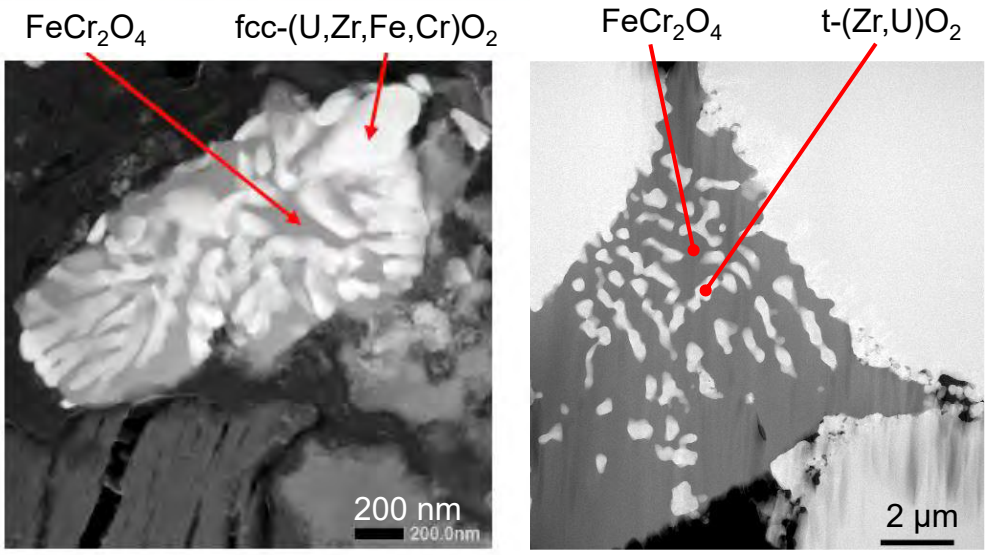

Figure 1. TEM images of 2u OF particle (left) [1] and 2u X-6 PEN particle (right) [3]

2. METHODS

2.1 Thermodynamic calculations for experimental condition design

To set the experimental conditions, thermodynamic calculations were performed using Thermo-Calc 2025b [4] with the Thermo-Calc Software IRSN Nuclear Alloys-Oxides Database v20 [5], assuming the approximate composition of the 2u OF particle. The metal-element ratio of the 2u OF particle was estimated from the compositions and area fractions of the $(U,Zr)O_2$ phase and the $FeCr_2O_4$ phase, yielding U:Zr:Fe:Cr = 20:15:25:40. The oxygen content was set by assuming that the analyzed products were oxides [1, 3] and that the atmosphere inside Unit 2 during the accident was not strongly oxidizing [6]. Accordingly, U and Zr were treated as dioxides, Fe as FeO, and Cr as $CrO_{1.5}$, corresponding to the oxide-component composition summarized in Table I. The results are shown in Fig. 2. The calculation indicated that the assumed composition becomes fully molten at slightly below 1900 °C, forming an oxide liquid phase.

Table I. Assumed oxide-component composition used for thermodynamic calculation and powder mixing

Component	UO_2	ZrO_2	FeO	$CrO_{1.5}$
Amount (mol%)	20	15	25	40

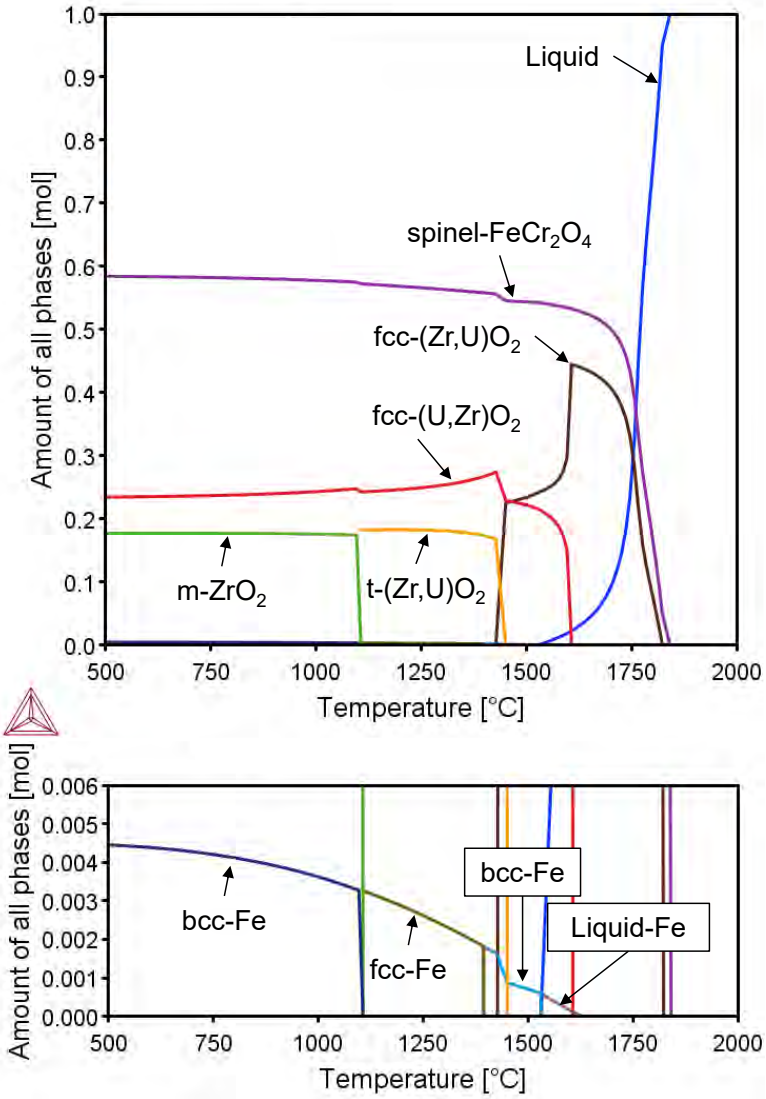

Figure 2. Thermodynamic calculation results with the approximate composition of the 2u OF particle. The lower panel shows an enlarged view of the vertical-axis range near 0–0.006.

2.2 Solidification experiments under different cooling rates

To examine the effect of cooling rate on the solidified microstructure, powders of UO_2, ZrO_2 (purity 98%, Kojundo Chemical Lab. Co., Ltd.), FeO (purity 99.5%, Kojundo Chemical Lab. Co., Ltd.), and Cr_2O_3 (purity 99.9%, Kojundo Chemical Lab. Co., Ltd.) were mixed to match the oxide-component composition shown in Table I. The mixture was heated at 1900 °C for 10 min in a yttria-stabilized zirconia (YSZ) crucible under an Ar (G2) flow. The Ar gas was passed through an oxygen-removal purifier before introduction into the furnace. The sample was then subjected to either rapid cooling (cooling rate: approximately 700 °C/min from 1900 to 1200 °C) or slow cooling (cooling rate: 5 °C/min). The measured temperature in this test was the value recorded by a radiation thermometer directed at the

bottom surface of the tungsten crucible containing the YSZ crucible and sample. The indicated temperature was calibrated using the melting points of pure metals, such as Pt and Rh, under the same optical configuration. A simplified one-dimensional heat-conduction calculation was then performed to estimate the thermal lag from the tungsten crucible to the U–Zr–Fe–Cr–O melt. The calculation indicated that the cooling of the melt center was delayed relative to that at the bottom surface of the tungsten crucible. Nevertheless, the cooling rate of the melt center around 1600–1500 °C, where the phase-separated microstructure is considered to have formed, was estimated to be approximately 600–800 °C/min, which is of the same order as the above cooling rate of 700 °C/min.

The obtained samples were mounted in resin, sectioned, and polished. The polished surfaces were then examined by scanning electron microscopy - energy dispersive X-ray spectroscopy (SEM-EDS) and transmission electron microscopy (TEM)-EDS, and electron diffraction.

3. RESULTS AND DISCUSSION

3.1 Results

Fig. 3 shows SEM (backscattered electron, BSE) images for the slowly cooled and rapidly cooled specimens. Phase-separated microstructures were observed in both specimens. No clear macroscopic stratification into oxide-rich and metal-rich layers was observed in the polished cross sections examined by SEM-EDS. In the slowly cooled specimen, the phase-separated microstructure was coarser than that in the rapidly cooled specimen.

Fig. 4 shows enlarged SEM-EDS maps of the rapidly cooled specimen. The bright regions in the SEM (BSE) image clearly coincided with U- and Zr-rich regions. Regions with lower U and Zr were Cr-rich. The dark regions in the SEM (BSE) image corresponded to Cr-rich regions. The Cr-rich regions could be further classified into Fe-rich areas and areas with low Fe. Oxygen was distributed throughout the specimen. Therefore, the presence of U–Zr–O, Cr–O, and Cr–Fe–O phases is suggested. The interpenetrating microstructure of the U–Zr–O phase and the Cr–Fe–O phase was similar to that observed in the 2u OF particle. The phase-separation spacing between U–Zr–O phase regions within this interpenetrating microstructure was on the order of 1 μm.

Fig. 5 shows an SEM (BSE) image of the slowly cooled specimen. Similar to the rapidly cooled specimen, it consisted of dark and bright regions. Interpenetrating microstructures were also observed; however, the phase-separation spacing was on the order of 10 μm, i.e., approximately one order of magnitude larger than that in the rapidly cooled specimen.

Fig. 6 shows TEM images of the rapidly cooled specimen (left) and the slowly cooled specimen (right). Based on TEM-EDS point analyses and electron diffraction, the rapidly cooled specimen contained fcc-$(U,Zr)O_2$ and spinel-$FeCr_2O_4$, while the slowly cooled specimen additionally contained bcc-(Fe,Cr). Table II summarizes a comparison among the 2u OF particle, the rapidly cooled specimen, and the slowly cooled specimen, including TEM results. For compositional data, multiple TEM-EDS point analyses were performed for each phase and averaged. For the U–Zr–O phase, all specimens exhibited an fcc structure, and the U:Zr ratio was approximately 6:4; thus, the simulated debris specimens were consistent with the 2u OF particle. TEM-EDS point analyses did not indicate significant Fe dissolution in the fcc-$(U,Zr)O_2$ phase within the resolution and quantification limits of the present analysis. For the Fe–Cr–O phase, the crystal structure was consistent (spinel), whereas the composition showed some deviation between the simulated debris and the 2u OF particle. However, thermodynamic calculations at 1500 °C (immediately after completion of solidification) for the (Fe,Cr):O = 3:4 system, using Cr/(Cr+Fe) as a parameter, indicate that the dominant phase remains spinel over a wide range of Cr/(Cr+Fe) = 0–0.77; therefore, such compositional differences are plausible. Notably, the Cr fraction in the Fe–Cr–O phase of the simulated debris approached the upper bound of this range.

Table II also lists the phase-separation spacing of the phase-separated interpenetrating region obtained from SEM observations. The spacing was approximately 1 μm for the rapidly cooled specimen and approximately 10 μm for the slowly cooled specimen. These spacings are larger than that of the 2u OF particle (approximately 0.1 μm). The experimentally identified solid phases were compared with the thermodynamic calculation shown in Fig. 2. The calculation predicted that fcc-$(U,Zr)O_2$ and spinel-$FeCr_2O_4$ phases remain stable down to lower temperatures after solidification, which is broadly consistent with the TEM results. The bcc-(Fe,Cr) phase observed in the slowly cooled specimen is also qualitatively consistent with the calculated appearance of a bcc Fe-rich phase at lower temperatures. However, the experimentally observed bcc phase contained both Fe and Cr, whereas the calculation assumes global equilibrium. In addition, the Fe content in the fcc-$(U,Zr)O_2$ phase may depend on the oxygen potential assumed in the thermodynamic calculation. Therefore, the comparison between the calculated and observed phase compositions should be regarded as qualitative.

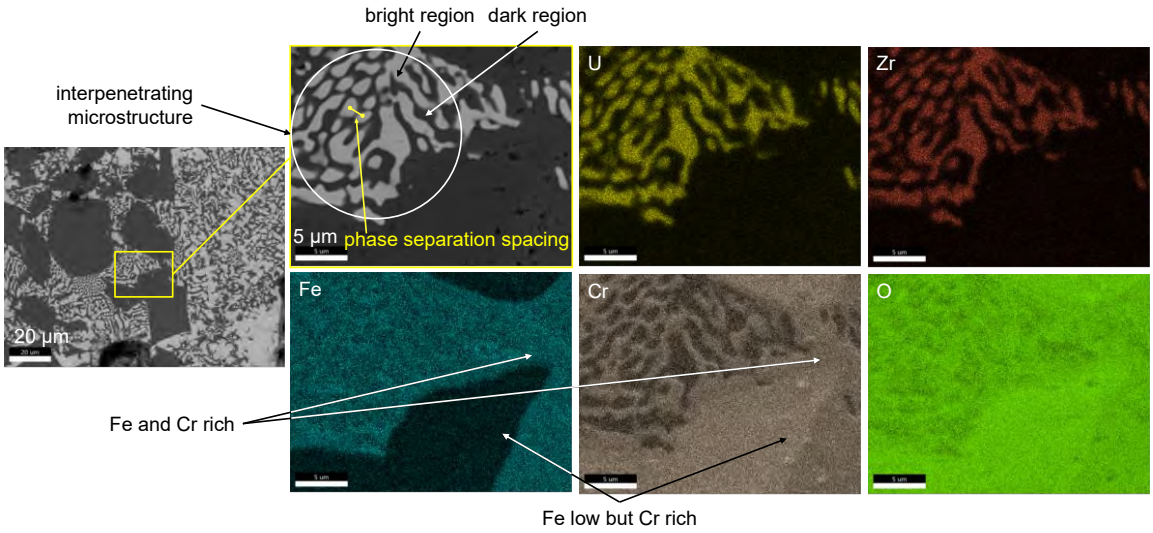

Figure 4. SEM-EDS maps of rapidly cooled simulated fuel debris

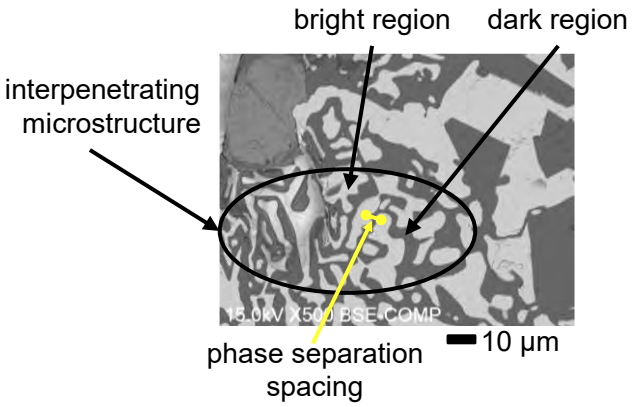

Figure 5. SEM image of slowly cooled simulated fuel debris

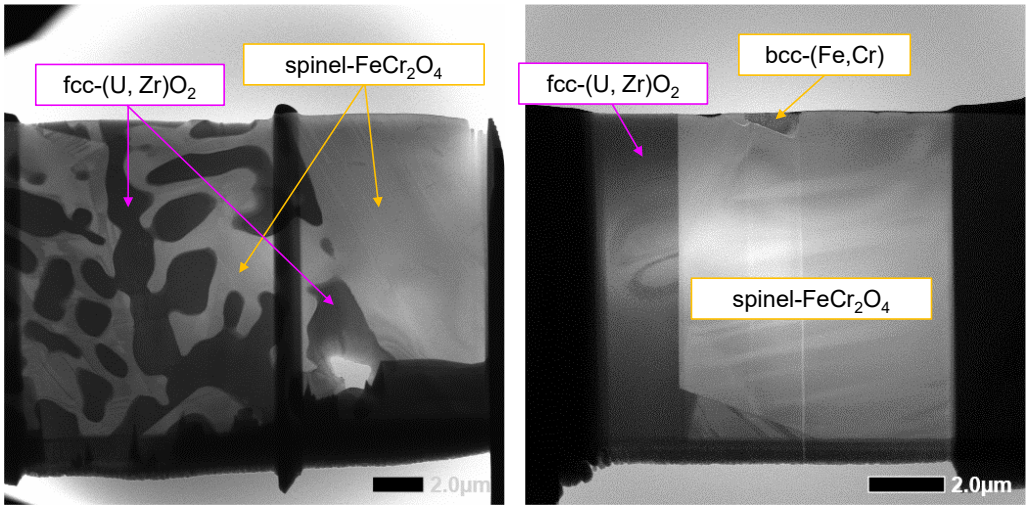

Figure 6. TEM images of rapidly (left) and slowly (right) cooled simulated fuel debris

Table II. Comparison among the 2u OF particle and the rapidly and slowly cooled simulated fuel debris specimens

Sample	Phase	Crystal structure	Composition (at%)	Phase-separation spacing
2u OF particle	U-Zr-O	fcc	U/(U+Zr)≈60	0.1 μm
	Fe-Cr-O	spinel	Cr/(Cr+Fe)≈60	
Rapid cooling	U-Zr-O	fcc	U/(U+Zr)≈64	1 μm
	Fe-Cr-O	spinel	Cr/(Cr+Fe)≈73	
Slow cooling	U-Zr-O	fcc	U/(U+Zr)≈53	10 μm
	Fe-Cr-O	spinel	Cr/(Cr+Fe)≈77	

3.2 Estimation of the cooling rate of the FDNPS particles

Using the phase-separation spacing in the interpenetrating region of the simulated debris microstructure as shown in the schematic image of Fig. 7, we attempted to estimate the cooling rate during formation of an FDNPS particle. Let the phase-separation spacing between adjacent bright regions in the interpenetrating phase-separated microstructure be L (cm), the characteristic formation time of this region be t (s), and the apparent diffusion parameter be D (cm^2/s). Assuming that diffusion follows Fick's law, the relationship can be expressed as:

$$L = \sqrt{Dt} \tag{1}$$

Let the temperature drop during formation of the interpenetrating region be ΔT (K) and the cooling rate be v (K/s). Because t=$\Delta T/v$, substitution yields:

$$D = \frac{vL^2}{\Delta T} \tag{2}$$

According to the thermodynamic calculation results in Fig. 2, the U–Zr–Fe–Cr–O melt is fully molten above approximately 1900 °C (oxide liquid phase). Upon cooling, crystallization of $(U,Zr)O_2$ and $FeCr_2O_4$ begins at slightly above 1800 °C and ends at approximately 1500 °C. Here, D should be regarded as an apparent diffusion parameter representing the characteristic mass transport associated with the formation of the interpenetrating phase-separated microstructure. It is not a tracer diffusion coefficient of a specific element. In this study, D was treated as constant over the temperature interval in which the interpenetrating microstructure formed. Although the absolute value of this apparent parameter depends on the assumed temperature interval ΔT, ΔT cancels out in the derivation of Eq. (3). Therefore, the present analysis does not require assigning a literature diffusion coefficient to a specific element.

Using the average apparent diffusion parameter $\overline{D}$ obtained from the rapidly cooled and slowly cooled specimens, the cooling rate v (K/s) for an FDNPS particle can be expressed as:

$$v_{\mathrm{p}} = \frac{\overline{D}\Delta T}{{L_{\mathrm{p}}}^2} = \frac{v_{\mathrm{R}}{L_{\mathrm{R}}}^2 + v_{\mathrm{S}}{L_{\mathrm{S}}}^2}{2\Delta T} \cdot \frac{\Delta T}{{L_{\mathrm{p}}}^2} = \frac{v_{\mathrm{R}}{L_{\mathrm{R}}}^2 + v_{\mathrm{S}}{L_{\mathrm{S}}}^2}{2{L_{\mathrm{p}}}^2} \tag{3}$$

where subscripts p, R, and S denote an FDNPS particle, the rapidly cooled specimen, and the slowly cooled specimen, respectively.

Fig. 7 plots the relationship between the cooling rate and the spacing of the interpenetrating microstructure. The region between the rapidly cooled and slowly cooled data points corresponds to interpolation and is shown by a solid line, whereas extrapolated regions are shown by dashed lines. The phase-separation spacing in the interpenetrating region is approximately 0.1 μm for the 2u OF particle and approximately 1 μm for the 2u X-6 PEN particle. The corresponding cooling rates are estimated to be on the order of 10^3 K/s and approximately 10 K/s, respectively. Because the present model is intended for order-of-magnitude estimation, the estimated cooling rates should be interpreted as order-of-magnitude values rather than precise numerical values.

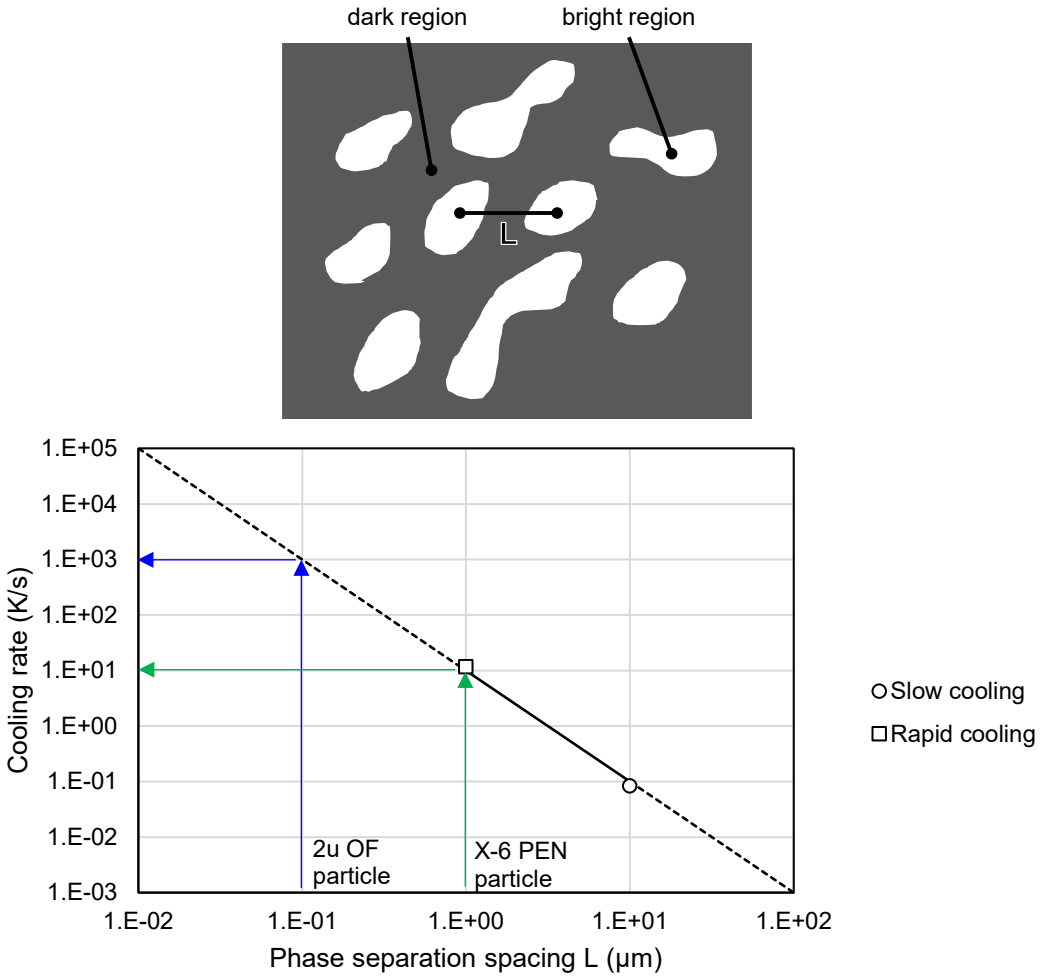

Figure 7. Schematic illustration of the phase-separation spacing L (upper panel) and relationship between phase-separation spacing and cooling rate (lower panel).

3.3 Estimation of the solidification scale from the estimated cooling rate of U–Zr–Fe–Cr–O melt droplets

The energy balance of a droplet can be expressed based on Newton's law of cooling [7] as:

$$\rho V c \frac{\mathrm{d}T}{\mathrm{d}t} = -A[h(T - T_\infty) + \varepsilon\sigma(T^4 - {T_\infty}^4)] \tag{4}$$

where ρ and c are the density and specific heat of the droplet, respectively; V is the volume; A is the surface area; T is the droplet temperature; T_∞ is the ambient temperature; h is the convective heat transfer coefficient; ε is the emissivity; and σ is the Stefan–Boltzmann constant.
For a spherical droplet with radius r,

$$\frac{A}{V} = \frac{3}{r} \tag{5}$$

therefore, the cooling rate is:

$$\frac{\mathrm{d}T}{\mathrm{d}t} = -\frac{3}{\rho c r}[h(T - T_\infty) + \varepsilon\sigma(T^4 - {T_\infty}^4)] \tag{6}$$

This equation allows estimation of the solidification scale (r) from the cooling rate (dT/dt) estimated by the diffusion model.

Because physical properties (ρ, c) of U–Zr–Fe–Cr–O melt droplets and parameters (h, ε) for the relevant system have not been reported, they were set as follows. The density ρ was calculated as a weighted average based on the densities of the input oxides: UO_2 (10.97), ZrO_2 (5.68), FeO (6.0), and Cr_2O_3 (5.22) [8], yielding $\rho=8\times10^3$ kg/m^3. This value is a weighted average of solid densities. Although density generally decreases in the liquid phase compared to the solid phase, the reduction is typically on the order of several tens of percent; thus, the order of magnitude remains unchanged. Because the purpose here is an order-of-magnitude evaluation, the weighted average of literature solid densities was used. If a lower melt density were assumed, the estimated solidification scale would become larger.

The specific heat c was set based on reported values for molten UO_2 and molten ZrO_2, approximately 380 J/kg/K and 815 J/kg/K, respectively [9]. In addition, based on NIST-JANAF data [10], the specific heats of molten FeO and molten Cr_2O_3 are approximately 949 J/kg/K and 1032 J/kg/K, respectively. Although the oxides other than FeO are not molten at the test temperature (1900 °C) as pure substances, the temperature dependence of specific heat in the molten state is small; therefore, these values were adopted. A weighted average yields $c=7\times10^2$ J/kg/K.

For h, it is known that the convective heat transfer coefficient for spherical droplets moving in a gas phase is on the order of $h\sim10^2$ W/m^2/K for mm-scale particles [7]; therefore, $h=100$ W/m^2/K was used. For emissivity ε, uranium oxides exhibit values of 0.70–0.90 [11], and emissivity of molten slag during steelmaking is reported as 0.75–0.87 [12]; therefore, $\varepsilon=0.8$ was assumed.

Using these values, and back-calculating the radius required to satisfy the cooling rate of 10^3 K/s estimated for the 2u OF particle, the radius is approximately 0.6 mm under $T=2000$ °C and $T_\infty=1000$ °C. Considering that the 2u OF particle was collected from the operating floor above the primary containment vessel, it may have solidified at a size range that could be released into the atmosphere, and the present model is not inconsistent with such a scenario. In contrast, the observed size of the 2u OF particle is less than approximately 1 μm, which is markedly smaller than the back-calculated droplet radius (0.6 mm). It is possible that a sub-millimeter droplet, once released into the atmosphere and solidified, was subsequently fragmented during processes prior to sampling.

Thus, this formulation enables estimation of the droplet size at solidification from a cooling rate estimated by the diffusion model. Fig. 8 shows the relationship between the cooling rate and droplet size. In the above equation, ρ and c contribute inversely (power of −1) to the cooling rate, while h and ε contribute linearly; in contrast, T and T_∞ contribute through the fourth-power radiation term, indicating high sensitivity to T and T_∞. Therefore, using $T=2000$ °C and $T_\infty=1000$ °C as a benchmark, cases of $T=2400$ °C and 1600 °C and cases of $T_\infty=1500$ °C and 500 °C are also shown. For the same droplet radius, the influence of droplet temperature is larger than that of ambient temperature.

From the cooling rate–size relationship, the 2u OF particle with an estimated cooling rate of 10^3 K/s corresponds to a droplet radius of approximately 0.3–1.5 mm, whereas the 2u X-6 PEN particle with an estimated cooling rate of 10 K/s corresponds to a droplet radius of approximately 30–150 mm. Considering that the 2u X-6 PEN particle was a particle in a deposit collected during hatch opening at the X-6 penetration, it is unlikely that it solidified as a droplet of such a large size. In this model, the internal temperature of the droplet is assumed uniform when estimating the solidification scale. In practice, the thermal conductivity of oxide melts is low; therefore, particularly for large particles, a temperature gradient between the surface and the interior is expected. If internal temperature distribution is considered, the surface temperature may decrease faster than predicted by this model, while the interior temperature may decrease more slowly. Such effects due to low thermal conductivity may contribute to uncertainty in estimating the solidification scale of the 2u X-6 PEN particle. This case is intentionally shown here to indicate the limitation of applicability. Defining the applicable range of the present model remains a subject for future work.

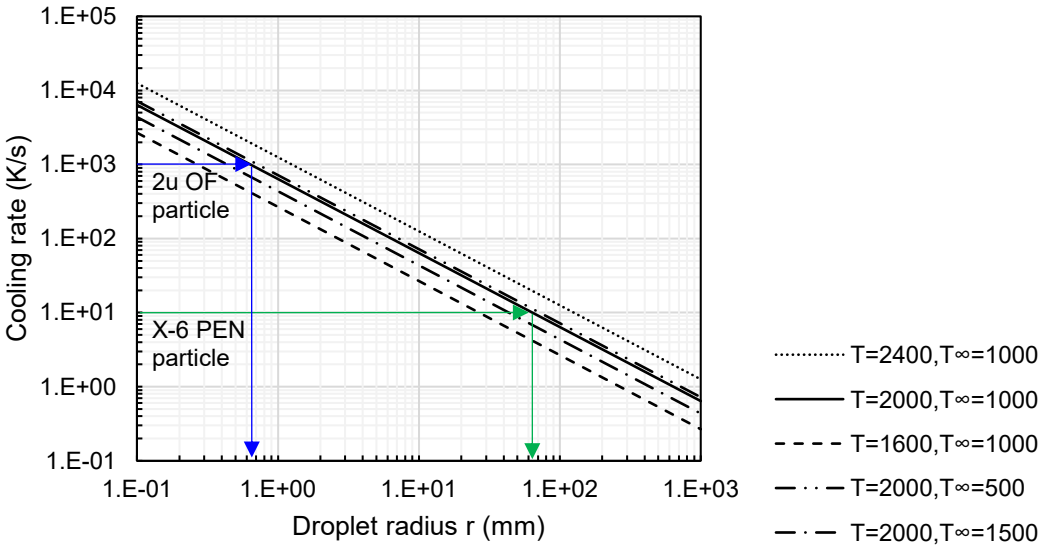

Figure 8. Relationship between droplet radius and cooling rate

4. CONCLUSIONS

In this study, we attempted to estimate the cooling rate of U–Zr–Fe–Cr–O system samples collected from FDNPS. Two types of U–Zr–Fe–Cr–O simulated debris specimens were fabricated under different cooling rates. A finely phase-separated microstructure consisting of fcc-$(U,Zr)O_2$ and spinel-$FeCr_2O_4$, similar to that observed in the FDNPS sample, was successfully obtained.

Using the phase-separation spacing in the finely phase-separated interpenetrating region of the simulated debris, the cooling rate of the 2u OF particle was estimated by a diffusion-based scaling model to be on the order of 10^3 K/s. This estimated cooling rate is not inconsistent from the viewpoint of heat transfer. Thus, this study demonstrates a method to estimate cooling conditions quantitatively from phase-separation spacing.

In addition, we proposed a heat-transfer-based model to estimate the droplet size at solidification from the estimated cooling rate. However, further investigation is required to define the range of applicability of this model. Overall, this study provides a framework for quantitatively estimating cooling conditions from phase-separated microstructures and is expected to contribute to reducing uncertainty in inferring the formation processes of fuel debris.

Motivation: Convert FDNPS* fuel debris observations into accident-progression information

Power the Future

Accident progression

Molten fuel debris formation → Cooling & solidification → Debris observation → Cooling rate inference

FDNPS fuel debris

https://fukushima.jaea.go.jp/debris/images/pict-20250529_4.png

Proposing estimation framework

- **Fuel debris can retain information on accident progression.**
- **Debris microstructures can record cooling and solidification histories.**
- **However, current interpretations are often qualitative.**

Purpose

- **Estimate the cooling rate of FDNPS fuel-debris particles from phase-separation spacing and check its thermal plausibility.**

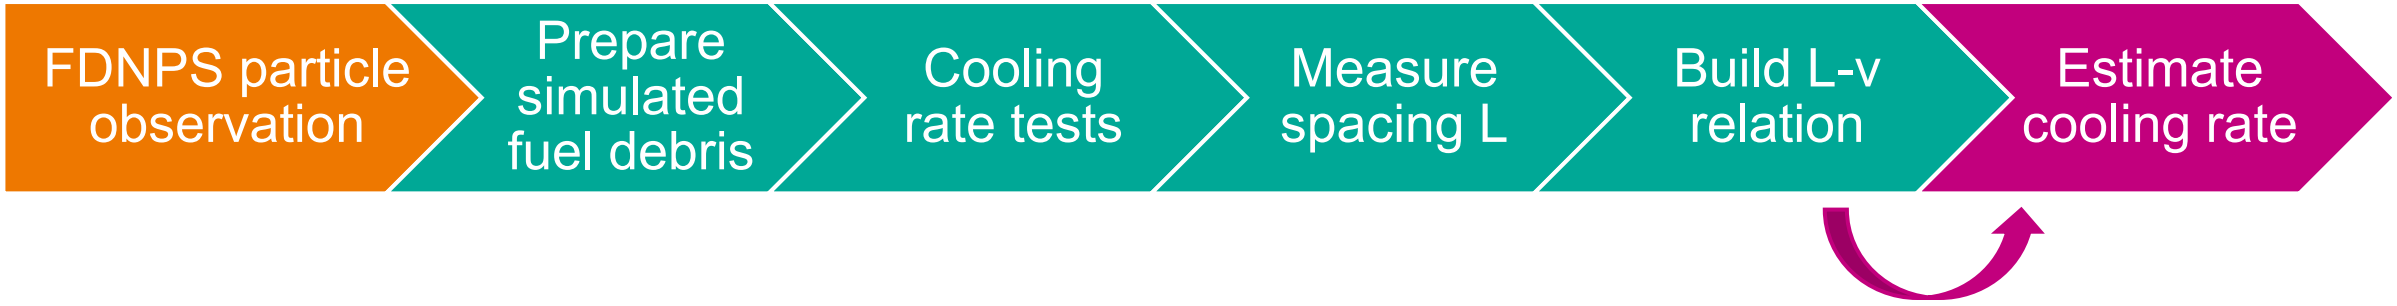
Research question and strategy

Can phase-separation spacing (L) be calibrated against cooling rate (v) and applied to FDNPS particles?



Simulated debris is not expected to match the FDNPS particle's spacing exactly; the spacing difference is used as the signal.
The model is deliberately presented as an order-of-magnitude cooling-rate estimate.

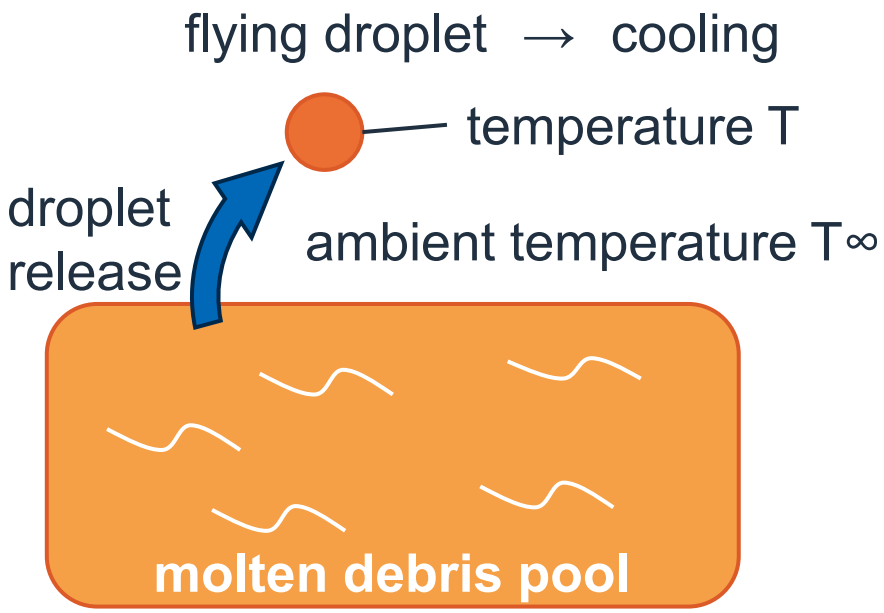
Heat-transfer consistency check: Model

A simplified flying-droplet cooling model was used to check the plausibility of the microstructure-based cooling-rate estimate.



Simplified flying-droplet model

- **spherical molten droplet**
- **radius r**
- **temperature T**
- **ambient temperature T∞**
- **heat loss by convection and radiation**

$$\rho V c \frac{dT}{dt} = -A\left[h(T - T_\infty) + \varepsilon\sigma(T^4 - T_\infty^4) \right]$$

$$A/V = 3/r$$

smaller r → larger A/V → faster cooling

(ρ: density, c: specific heat, V: volume, A: surface area, h: convective heat-transfer coefficient, ε: emissivity, σ: Stefan–Boltzmann constant)

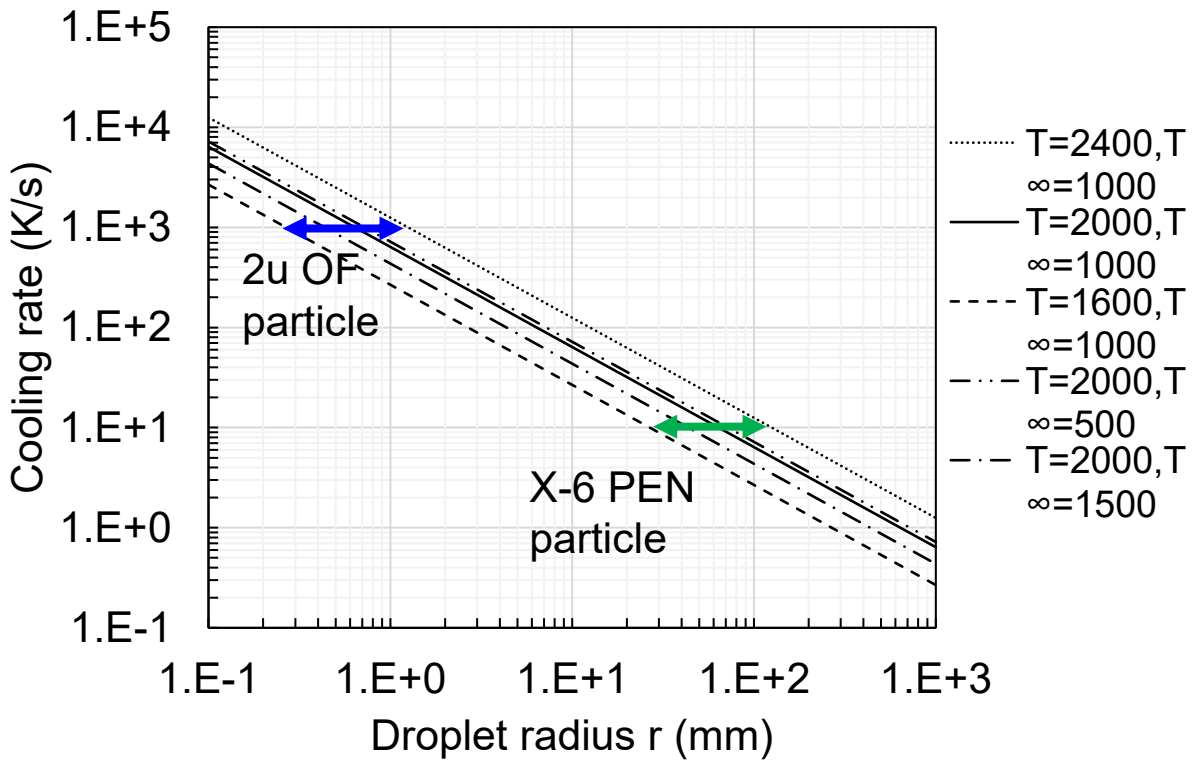
This model does not independently determine the cooling rate; it evaluates whether the microstructure-based cooling-rate estimate is physically plausible from a heat-transfer viewpoint.

Copyright© NIPPON NUCLEAR FUEL DEVELOPMENT Co., Ltd. 2026. All rights reserved.

Heat-transfer consistency check: Result

The 2u OF estimate corresponds to a sub-mm to mm-scale equivalent droplet, supporting the plausibility of the microstructure-based cooling-rate estimate.

Droplet cooling model



Key readout

- **2u OF particle:**
  Cooling rate estimated from microstructure:
  ~ 10^3 K/s
  - → **equivalent droplet radius: sub-mm to mm scale**
  - → **not thermally inconsistent with a flying-droplet scenario**
- **X-6 PEN particle:**
  Cooling rate estimated from microstructure:
  ~ 10^1 K/s
  - → **much larger equivalent droplet radius**
  - → **likely beyond the simple flying-droplet assumption**

Conclusions / Outlook

Conclusions

- Simulated U–Zr–Fe–Cr–O debris reproduced the major phases of the target FDNPS particles.
- Phase-separation spacing decreased with increasing cooling rate.
- A first-order framework was proposed to estimate cooling rate from phase-separation spacing.
- The 2u OF particle was estimated to have cooled on the order of 10^3 K/s.
- The heat-transfer check supports that this estimate is not thermally inconsistent.

Outlook

Future work will refine spacing statistics, sample temperature-history evaluation, and the applicability limits of the diffusion-based and heat-transfer models.

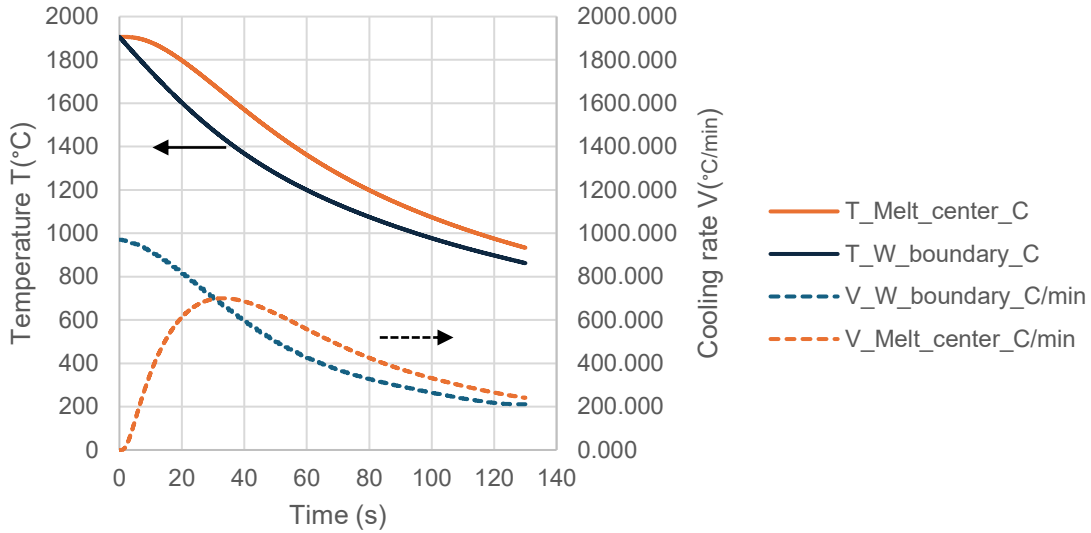
Effect of thermal lag on the cooling-rate calibration



- The cooling-rate calibration was based on the measured temperature history at the bottom of the W crucible.
- Strictly, the relevant cooling rate for phase separation is the local cooling rate inside the oxide melt.
- A simplified 1D heat-conduction calculation was therefore performed to estimate the thermal lag between the W crucible bottom and the melt center.
- The melt-center cooling rate shows a delayed response and reaches a peak at around 35 s.
- This thermal lag represents a possible uncertainty when using the W crucible temperature as a proxy for the melt temperature.

ABSTRACT

In-Vessel Melt Retention (IVMR) is a strategy employed in several design of new nuclear reactors (e.g., AP1000, HPR1000, APR1400, CAP1400 …), and is also considered by some utilities to support lifetime extension of existing operating reactors. A prerequisite for the successful implementation of this strategy is that, at any time and location, the maximum heat flux at the outer surface of the reactor vessel wall remains below the critical heat flux (CHF). For medium- and high-power reactors (>1 GWe), the efficiency of external heat removal is generally enhanced through passive flow circulation, which increases CHF by raising the superficial velocity. This requires optimization of the flow path between the outer vessel wall and the thermal insulator acting as a liner, to maximize superficial velocity at critical locations. In contrast, for low-power reactors, heat removal can be achieved under pool boiling conditions, which do not require flow channel optimization. This article presents a comprehensive literature review of CHF experiments in pool boiling conditions applicable to external reactor vessel cooling (ERVC), primarily involving 'smooth' outer vessel walls (e.g., copper, stainless steel, or aluminum). In addition, it discusses the latest CHF measurements obtained on the THS-15 facility, which features an oxidized RPV steel outer vessel wall. These recent tests were conducted within the framework of the EU-funded EASI-SMR project, which addresses safety issues related to light water small modular reactor (LW-SMR) technology to support its deployment.

1. INTRODUCTION

The Critical Heat Flux (CHF) is defined as the maximum heat flux that can be transferred from a specified region of the reactor vessel's external surface to the water surrounding the RPV, beyond which the onset of a boiling crisis occurs. The boiling crisis corresponds to the formation of a continuous vapor film on the heated surface, which drastically reduces the heat transfer coefficient between the vessel wall and the coolant. This phenomenon inhibits the removal of thermal energy generated by the corium pools inside the vessel, leading to progressive wall overheating and ultimately structural failure. On a local scale, CHF increases with water subcooling, RPV wall inclination (0° at the vessel bottom of the RPV and 90° at the cylindrical part), superficial velocity of the water (in $kg/m^2/s$), and hydrostatic pressure. Also, at low pressure —typical of reactor building pressure during a severe accident— CHF increases with roughness and wettability of the material. Using RPV steel increases CHF compared to stainless steel or copper commonly used in experimental setups.
For low-power reactors (< ~ 500 MWe), the necessity of vessel cooling by circulating water can be questioned, since the thermal loads from the corium pools to the vessel and their impact on the heat flux from the vessel to the surrounding water remain limited. Moreover, pool boiling cooling is simpler to implement than thermosiphon cooling, as it does not require optimized insulation to maximize superficial velocity. Under pool boiling conditions, the superficial velocity is virtually zero.

The objective of this article is to conduct a literature review on critical heat flux (CHF) values under pool boiling conditions and to fill existing data gaps in order to establish, to the extent possible, bounding CHF values that can be applied for any type of LWR design.

2. LITERATURE SURVEY OF CRITICAL HEAT FLUXES IN POOL BOILING SITUATIONS FOR ERVC APPLICATIONS

2.1. In-Vessel Retention in nuclear industry

Demonstrations of IVR feasibility for commercial reactors have primarily focused on low and medium-power units (VVER-440 at Lovisaa, AP600), and were extended to mid-size units (AP1000, HPR1000) and high-power units (APR1440, CAP1400) when a water circulation is implemented to enhance critical heat flux. However, due to the limited water volume available to flood the reactor cavity and establish a closed-loop circulation, some VVER-440 reactors (such as Paks NPP) do not employ water circulation but rely solely on pool boiling. While numerous references exist on CHF studies under natural or forced circulation conditions, literature on pool boiling scenarios is much scarcer and mainly relates to the early stages of IVR research.

To detect experimentally the CHF, a reference heat flux profile is progressively scaled until boiling crisis occurs, which is detected by a monotonic increase in wall temperature above the saturation point. Heat flux profiles were initially derived from corium pool experiments using simulant materials intended to cover all reasonable scenarios and provide a realistic bounding case with respect to thermal loading. In current practice, heat flux profiles applied in CHF test loops are generated by lumped parameter code calculations (MAAP, ASTEC, …) that rely on heat transfer correlations derived from such experiments. Corium-to-vessel wall heat flux increases monotonically with inclination and peaks in the upper region, generally where the metallic layer above the oxide pool induces a focusing effect (~90° inclination). Maximum residual power occurs under large-break loss of coolant accident (LOCA) scenarios, which generally yield the highest heat flux. In cases of partial vessel bottom filling, stratified corium pools and focusing effect may occur at less favorable inclination for steam removal (lower CHF). But generally, smaller corium oxyde pools have smaller residual power, reducing heat transfer to vessel wall.

2.2. Main CHF experiments in pool boiling

In pool boiling situation, full-scale height experiments which are reviewed here and discussed in the next chapter are CYBL facility [1], ULPU (configuration I) facility [2], and THS-15 facility [3]. The SBLB facility from Penn State University (PSU) is also discussed (3D vessel geometry, 1/8th) [1]: For reduced-scale 2D or 3D vessel geometries, caution is required due to distortion between hydrostatic pressure and inclination of the RPV wall. However, the same basic principle remains: as the focusing effect is in the upper region, maintaining residual power in the lower region consistent with the studied geometry allows CHF studies at the top of the corium pool.

2.3.1. CYBL (Cylindrical Boiling) facility

The CYBL facility is the forerunner of all In-Vessel Retention (IVR) experimental loops. It was constructed in the United States at Sandia National Laboratories to investigate originally the feasibility of an external RPV cooling in the 1990s. In particular, the program aimed to assess whether steam generated in the area near the 0° inclination (i.e., at the bottom head of the vessel) could be passively removed under pool-boiling conditions, and in the absence of any natural-circulation driving head. The test vessel used in CYBL is a full-scale (1:1) three-dimensional representation of a reactor pressure vessel. The only significant deviation from an actual RPV concerns the use of stainless steel for the mock-up, instead of RPV steel.

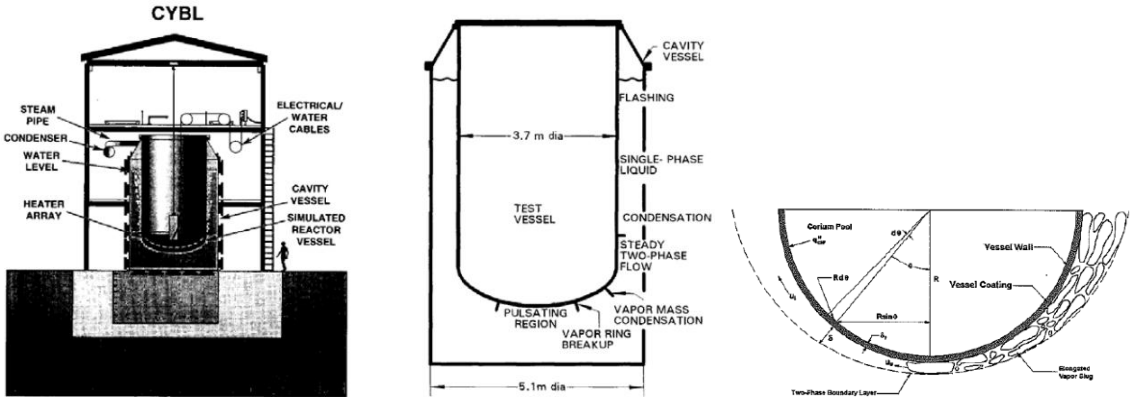

Figure 1. CYBL facility and 3D flow patterns

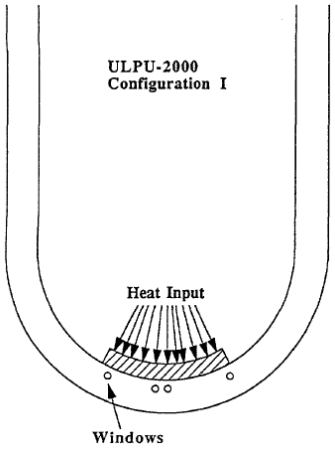
The thermal power of 6 MW was sufficient to reach the critical heat flux at very low inclination. For the experimenters, the observation of rapid, periodic, and asymmetric bubble bursts provided clear evidence that the local critical heat flux was not as low as initially expected. Indeed, the measured critical heat flux at 0° inclination, under saturated water conditions (i.e., without subcooling), was 500 kW/m², which remains a significant value. The horizontal gap between the vessel wall and the cavity wall was 70 cm [4].

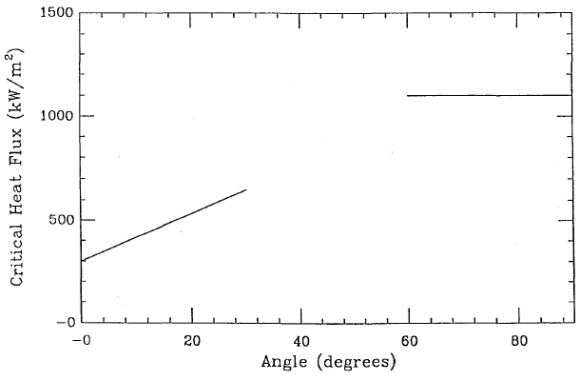
2.3.2 ULPU facility (configuration I)

The ULPU facility was hosted at the University of California, Santa Barbara (UCSB) to support the certification of the AP600 and AP1000 reactors. The present discussion focuses on Configuration I, for which a series of experiments was conducted under pool-boiling conditions. This configuration is a 2D slice at 1:1 scale in height, and the SF-1 test series used copper heating blocks that could be positioned either

between 0° and 30°, or between 60° and 90°. In the reference [2], there is no data on the gap thickness. However, based on the schematics provided in the document, this gap appears to range between approximately 15 cm and 22 cm.

With "no" water height above the measurement location (i.e., saturation temperature which is a bounding condition with respect to CHF), the CHF values increase quasi-linearly with the inclination (in degrees, over the 0–30° range), rising from approximately 0.3 MW/m² to 0.69 MW/m², with very good reproducibility. A CHF value at 0° is observed to be lower (~ 0.32 MW/ m²) than the 0.5 MW/m² measured in CYBL. This can be explained by the greater difficulty for steam to escape in the more constrained 2D geometry of ULPU, compared with the 3D geometry of CYBL. Between 60° and 90° inclination, the CHF values obtained under pool-boiling and saturation conditions are around 1.1 MW/m².





Figre 3.2. Critical heat flux as function of position on the lower head; from ULPU, in pool boiling.

Figure 2. CHF values measured in ULPU I (pool boiling, DI water at saturation, copper wall) [2]

2.3.3. THS-15 facility

In 2015, construction of the large-scale experimental facility THS-15 (Thermo-Hydraulic Stand 2015) was initiated at UJV. The facility is designed to assess the limits of coolability of a VVER-1000 RPV with respect to full length of the flow path (gravity head), using reactor axisymmetric geometry. As for ULPU experiments, it uses a a slice geometry (1/95th). The heat flux generated within the RPV by molten corium during a severe accident is simulated using electrically heated copper elements, with a maximum applied heat flux of 2.3 MW·m^{-2}. However, the cooled copper segments are coated with a 3-mm-thick V354 steel layer (which chemical composition is intented to be representative of VVER RPV steel) in order to provide surface conditions more representative for CHF measurements.

Figure 3. THS-15 facility

UJV performed some a series of tests for the Czech State Office for Nuclear Safety (SÚJB) in the frame of a Czech national project [3]. The thermal loading from the corium pools to the RPV wall was calculated using ASTEC code in Temelin VVER 1000/320 conditions. The CHF were measured with different surface treatments. Without any treatment (ie. RPV steel naturally oxidized), the obtained values are summarized in the table below, with a water gap of 50 cm and about 3 m of water height above the semi-ellipsoidical and cylindrical junction of the vessel. These values are compared with ULPU and CYBL CHF values (thought with different HFF, lower head RPV shape and water level).

	CHF [MW/m2] for 1:1 scale in height experiments		
RPV inclination	THS-15 (2D, RPV steel)	CYBL (3D, stainless steel)	ULPU I (2D, copper)
[0-10°]	0.42	~ 0,5	~ 0.3
15°	0.53	No data	~ 0,5
25°	0.65	No data	~ 0.6
45°	1	No data	No data
70°	1.35	No data	1.1
90°	1.92	No data	1.1

Table 1. Comparison of CHF values between THS-15, ULPU and CYBL experiments in pool boiling conditions at saturation temperature (with differents HF profiles) and atmospheric pressure

2.4. SBLB experiment

This facility was built at Pennsylvania State University (PSU) in the United States. It consists of a pressurizable water tank filled with DI water, equipped with a condenser, and capable of accommodating a reduced-scale (1/8th) 3D RPV mock-up built either in aluminium or stainless steel. The heat-flux distribution is defined according to five vertical zones. The observation of the different flow regimes was possible through an optical viewing window. The critical heat-flux (CHF) measurements obtained in pool boiling configuration are summarized in the following table and compared with the CYBL and ULPU data under saturated conditions. PSU provides an interpolation correlation for CHF values as a function of subcooling between 0 and 10 K and inclination between 0° and 90°.

Table 3 Comparison of the Local Critical Heat Fluxes Measured at Various Test Facilities Under Saturated and Subcooled Boiling Conditions

Local Angle of Inclination* θ	Local Critical Heat Flux, MW/m²				
	SBLB at PSU		CYBL at SNL	ULPU at UCSB	
	Saturated Boiling	Subcooled Boiling**	Saturated Boiling+	Saturated Boiling	Subcooled Boiling++
0°	0.40	0.59	0.50	0.28	0.50
30°	0.61	0.86	--	0.65	0.89
60°	0.85	1.05	--	--	1.18
90°	(1.00)	(1.35)	--	--	1.50

* θ = 0° corresponding to the bottom center and θ = 90° corresponding to the upper edge of the test vessel
** Pool boiling with a subcooling of 10 °C
\+ Based largely on small-scale quenching data
++ Natural convection boiling with a subcooling of 14 °C at the bottom center

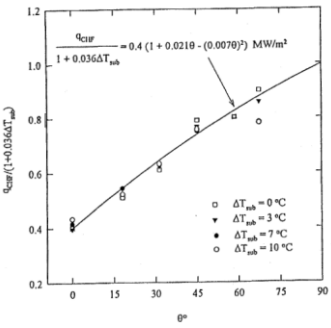


Table 2. Comparative table of CHF values measured in CYBL, SBLB, and ULPU – from [1]

In loops representing the vessel at reduced height, a geometric distortion occurs: the hydrostatic head (water height above the measurement point) does not vary with inclination in the same manner as for a given water level in the actual vessel. However, this effect results only in a few degrees of subcooling within the ranges covered by SBLB and ULPU I. Similar CHF values are observed in the 0–30° inclination sector for both SBLB (3D, 1/8th scale) and ULPU (2D, full height). No comparison is possible between 30° and 60° due to the absence of ULPU measurements.

3. SCALING FOR REACTOR APPLICATION

3.1. Effect of the RPV shape

When determining the critical heat flux (CHF), it seems logical to consider the influence of flow history: A CHF value recorded at an inclination of 90° is theorically affected by the cumulative energy absorbed by the fluid throughout the entire hemispherical—or semi-ellipsoidal—portion of the vessel. The HF profile is intended to represent the net thermal loading on the vessel wall from corium pools, after accounting for conduction through the vessel thickness. In practical, the CHF values obtained with different HF profiles or even at reduced scale are not significantly different in pool boiling situation, when considering only smooth surfaces (cleansed copper, stainless steel). PSU proposed an upscaling law, which it validated on ULPU over the 0–30° and 60–90° ranges.

3.2. Effect of gap size

The annular gap is defined as the distance between the vessel and the insulation (or liner) and is filled with water. From an industrial standpoint, the larger the annular gap, the greater the water inventory shall be to fill the reactor cavity.
From a phenomenological standpoint, experiments using inclinable test sections under forced-flow conditions (for thermosiphon applications) have shown either a weak influence of the gap size [5] and a very limited two-phase boundary-layer development [6]. In addition, the capillary length below which the gap width would start to perturb boiling is only on the order of ~2.5 mm. Therefore, a gap of 10 cm, 15 cm, or 20 cm should not to disturb the escape of bubbles. Recent experiments carried out by KAERI and Seoul National University [7] investigated the influence of gap size under pool-boiling conditions in the 1-10 mm range and in a “no-gap” (meaning “infinite gap” actually) configuration. Under saturation conditions, with a gap of 1 cm, the measured CHF was between 1 MW/ m² (@45° inclination) and 1.2 MW/m² (@90° inclination). Without any gap, these values increases up to 1.2 MW/ m² (@45° inclination) and 1.3 MW/m2

@90° inclination). Interestingly, the CHF values obtained for very small gaps (< 1 cm) are higher than those measured for a 10 mm gap. According to the authors, this effect is associated with flow induced by bubble detachment, leading to a local enhancement of heat transfer. However, such small gaps are not encountered in ERVC for commercial reactors.

Regardless of the size of the vapor bubbles and how they escape from the gap, the gap width may also influence the flow induced by natural convection. For sufficiently large gaps (on the order of several tens of centimeters), a convection loop may develop, generating a significant near-wall superficial velocity and thereby enhancing heat removal. Consequently, for gap sizes typical of commercial reactors (15 cm and above) under pool boiling conditions, it remains difficult to draw firm conclusions regarding the impact of the gap size on the critical heat flux (CHF) based on the currently available data.

3.3. Effect of surface material

At low pressure, surface effects of the heated wall have a significant influence on the critical heat flux (CHF). The MIT/EDF experiments quantified these surface effects under water circulation (350 to 1000 kg/m^2/s), as a high wettability is correlated to a high CHF. Experimental measurements conducted on oxidized 18MND5 samples indicate a superhydrophilic surface behavior, which leads to a ~ ×1.5 increase in the CHF relative to stainless steel under water circulation conditions [6]. Applying the CHF correlation to the local thermohydraulic conditions computed with Neptune_CFD for the ULPU IV loop (which uses copper heating blocks) reproduced the CHF values defended by Westinghouse [8]. Unfortunately, this correlation cannot be applied to pool-boiling situations, where the superficial velocity is virtually zero.

In an “upward-facing” pool-boiling configuration (ie. stagnant fluid above the heated wall), the use of oxidized RPV steel in the BETA experiment at UCSB [9] led to a gain of approximately ×1.7 in CHF[1] compared with cleansed copper.
A comparison between the ULPU-I and THS-15 results presented in the previous chapter (without any consideration of the applied HF profile) also shows an increase in the CHF (~ ×1.5 in the range 70°-90°).

Regarding the VVER V354 steel which is used to cover the THS-15 heater blocks (and intented to be similar to VVER RPV steel), no specific data on wettability are available. Given the similar chemical compositions of 16MND5 and V354 steels, comparable surface oxidation behavior is expected. Owing to its slightly higher chromium content, V354 steel may exhibit increased corrosion resistance, making the associated CHF results possibly bounding[2] with respect to PWR vessel steels.

	Typical Chemical Composition (wt.%)			
Element	**16MND5 (PWR RPV steel)**	**V354 (THS-15)**	**15Kh2NMFA (VVER RPV steel)**	**Stainless steel (304L)**
Carbon (C)	0.16 – 0.20	0.12 – 0.18	0.12 – 0.18	≤ 0.03
Manganese (Mn)	1.20 – 1.60	0.80 – 1.10	0.30 – 0.60	≤ 2.00
Silicon (Si)	0.15 – 0.35	≤ 0.20	0.17 – 0.37	≤ 1.00
Nickel (Ni)	0.40 – 1.00	—	1.00 – 1.50	8.0 – 12.0
Molybdenum (Mo)	0.45 – 0.60	0.80 – 1.00	0.40 – 0.70	—

[1] “Effect of surface material and aging by exposure to air and to boiling (…) leads to an increase of the CHF (typically from ~750kW/m^2 to over ~1300kW/m^2 in pool boiling configuration)” [9]

[2] The potential improvement in critical heat flux (CHF) would most likely be masked by the inherent uncertainties associated with CHF measurement.

Chromium (Cr)	≤ 0.30	1.25 – 1.50	1.80 – 2.30	18.0 – 20.0
Vanadium (V)	—	0.20 – 0.30	0.10 – 0.30	—
Copper (Cu)	≤ 0.25	—	≤ 0.10	—
Phosphorus (P)	≤ 0.020	≤ 0.020	≤ 0.015	≤ 0.045
Sulfur (S)	≤ 0.010 – 0.020	≤ 0.015	≤ 0.015	≤ 0.030
Iron (Fe)	Balance	Balance	Balance	Balance

Table 3. Typical chemical composition (in wt.%) of 16MND5, 15Kh2NMFA,V354 and stainless steels

3.4. Effect of water chemistry

The water chemistry (presence of dissolved boron or buffering agents) may also influence the critical heat flux (CHF), although its effect is less significant than that of the wall material surface, and experimental trends have not been clearly established.
In the BETA facility (pool-boiling in an up-facing configuration) [9], the use of TSP appears to decrease the CHF on SA508, although UCSB considers that the available data are insufficient to draw a definitive conclusion. However, the CHF obtained with SA508 and TSP nevertheless remains far higher than the CHF obtained with copper in demineralized water or with TSP. The impact of adding boric acid alone did not allow clear trends to be established. No tests were performed with the combination of boric acid and TSP.
Under thermosiphon-representative conditions with 18MND5 samples [6], the impact of boron and STB on the CHF measured with demineralized water only were also unclear, but overall, the discrepency was at max < 14% (superficial velocity of 500 and 1000 kg/m2/s ; inclination of 45° and 90°).

3.5. In summary

The vessel size does not appear to have a significant effect on the critical heat flux, provided that the system remains in a pool-boiling configuration. In contrast, the natural oxidation that develops on the external surface of the vessel has a pronounced impact on the critical heat flux, both under thermosiphon and pool-boiling in an up-facing conditions. The CHF values measured on copper (ULPU) or stainless steel (SBLB) surfaces are considered bounding, since under identical conditions, a CHF measured on oxidized RPV steel would be higher. This chapter also highlighted a lack of experimental data, particularly for covering the full range of inclinations relevant to IVR applications.

4. DEFINITION OF A CHF METHODOLOGY IN POOL BOILING SITUATION INDEPENDENT OF THE THERMAL HEAT FLUX PROFILE

4.1. Objectives

In this context, an experimental program has been proposed within the EASI SMR European Project to establish a pool-boiling CHF correlation representative of naturally oxidized RPV steel, making use of the existing THS-15 facility operated at UJV. The resulting correlation is intended to remain broadly applicable—independent of reactor design—and robust even in situations where the detailed thermal loading imposed by corium pools on the vessel wall is not precisely known.

4.2. Heat flux profile

4.2.1. “Bounding” HF profile

In general, thermal-flux distribution profiles may be taken directly from simulant-corium experiments (e.g., COPO or ACOPO), which provide the heat flux imposed on the inner vessel wall by molten corium pools. However, the preferred approach is to apply the heat-flux profile from the vessel toward the coolant, as this inherently accounts for thermal diffusivity through the vessel wall thickness.
That said, when the various scenarios of corium relocation into the lower head are insufficiently characterized, a bounding thermal-flux profile can be employed to encompass the full spectrum of plausible thermal loadings. This approach enables the determination of an envelope critical heat-flux curve. This is the methodology we propose to discuss here.

Corium pools configuration

In PWRs, the upper metallic layer above the oxidic pool (containing ~90% of the decay heat) is responsible for dissipating the highest heat fluxes, leading to the so-called “focusing effect.” In contrast, VVER reactors, which contain a relatively larger in-vessel metallic inventory, may exhibit maximum heat fluxes localized in the upper region of the oxide layer[3]. In certain transient configurations, a three-layer stratification can develop. From bottom to top, this configuration consists of a heavy metallic pool, an oxide pool, and a light metallic pool. However, reactor calculations performed using severe accident codes such as ASTEC or MAAP have not identified situations leading to higher thermal loads than those associated with a two-layer configuration (e.g., a top light metallic layer over a heavy oxidic layer). The oxide pool is dominated by natural-convection phenomena, and the overall angular distribution of the thermal load as a function of the inclination is well established. The overlying metallic layer generates a localized peak in the heat flux along the inclination corresponding to its position. Representing the whole system using a linearized envelope profile provides a conservative estimate of the heat transferred to the coolant, as illustrated in the schematic figures below. Thus, the critical heat fluxes determined using this envelope loading remain valid for any realistic pool configuration.

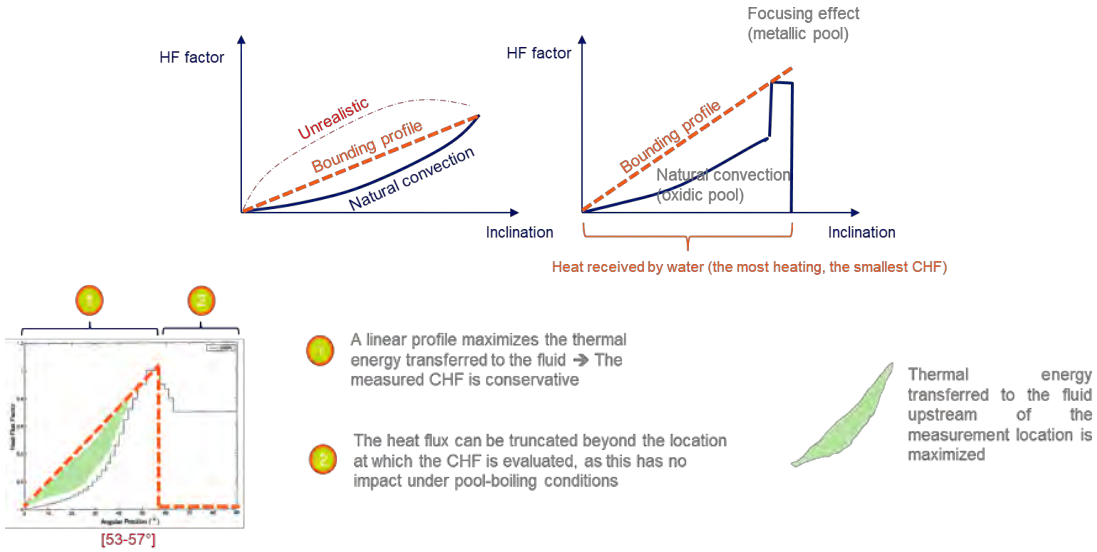

Figure 4. Simplified and bounding heat flux profile (in orange)

[3] The peak heat flux is dissipated in the upper region of the oxide layer as a result of natural convection. Thanks to the thickness of the overlying metallic layer due to the relatively high in-vessel metal inventory, this peak heat flux is not necessarily located within the metallic phase, in contrast to typical PWR configurations

4.2.2. "ELSMOR" HF profile

As a sensitivity heat-flux profile, the following ASTECv3 results from IRSN are proposed. These results were generated for an SMR design as part of a benchmark exercise involving the MAAP and ASTEC codes within the ELSMOR European Project [10] for an station blackout (SBO) scenario.

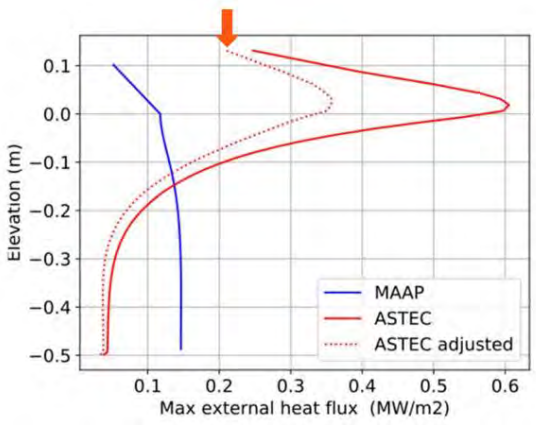

Figure 5. ELSMOR profile ("ASTEC adjusted") used as a sensitivity HF profile (from [10])

4.4. Experimental procedure applied to THS-15

To determine the CHF, the slope of the heat flux profile is increased incrementally until critical boiling conditions are reached. The retained value is the heat flux corresponding to the increment immediately preceding the onset of boiling crisis. The same procedure is applied for all inclinations of the test matrix.

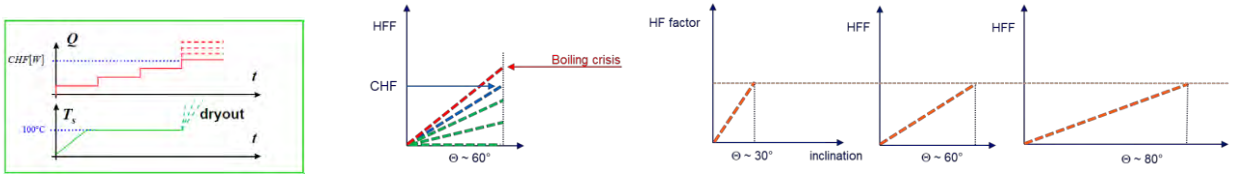

Figure 6. CHF detection for linear HFP (left: standard protocol to detect CHF ; center: protocol applied for 60° of inclination; right: HFF applied at each inclination if interest). The same protocol is applied for ELSMOR profile.

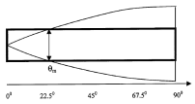
The following power shaping correction proposed by Theofanous et al. [2] is applied for the heat-flux profiles used on THS-15 experiment in order to account for the specificity of slice configuration (singularity at 0° inclination) vs sector configuration (reactor case):

$$HFF_{Slice}(\theta) = HFF_{prototypical} \times \frac{\sin\theta}{sin\theta_m} \text{ for } \theta < \theta_m$$



where θ_m is the location under consideration for CHF measurement.

4.5. Experimental matrix

In order to fulfil the objective of defining bounding critical-heat-flux data capable of covering a broad spectrum of scenarios and designs, the parameters listed below are hereby designated as reference:

- Ambient pressure : atmospheric (bounding)
- Water temperature and chemistry : saturated (bounding), DI water
- Water submergence : as low as reasonnably possible (bounding) – a sensitivity is done to check and quantify in pool boiling the increase of CHF with water height (hydrostatic pressure) ;
- Coating: as it is (naturally oxidized RPV steel)
- Gap size: 50 cm

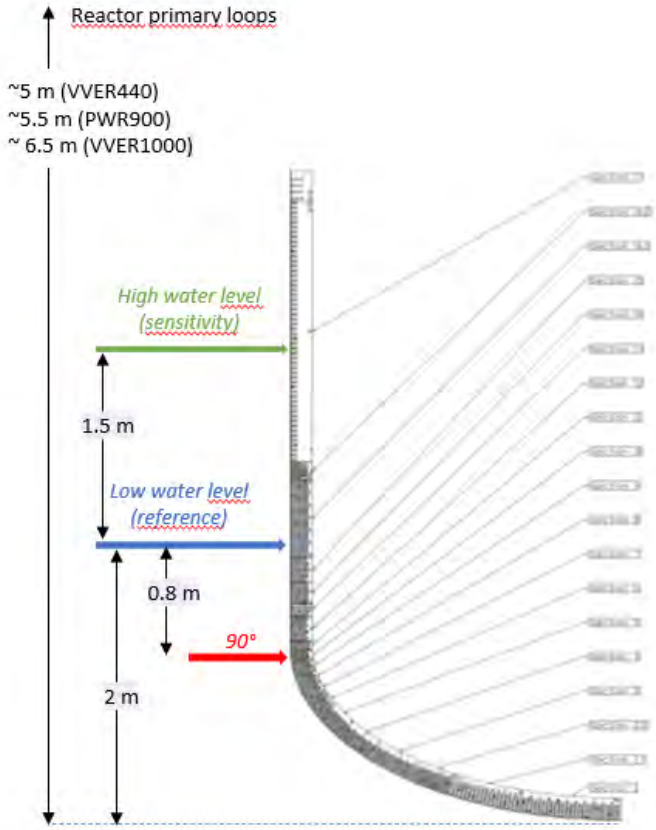


Figure 7. Water levels

4.6. Thermal losses

During the tests, it was important to maintain saturated water conditions in the region close to the RPV surface (approximately 0–15 cm from the RPV wall). Eight temperature measurement points are installed inside the cavity to monitor the thermal conditions, as shown in the figure below.

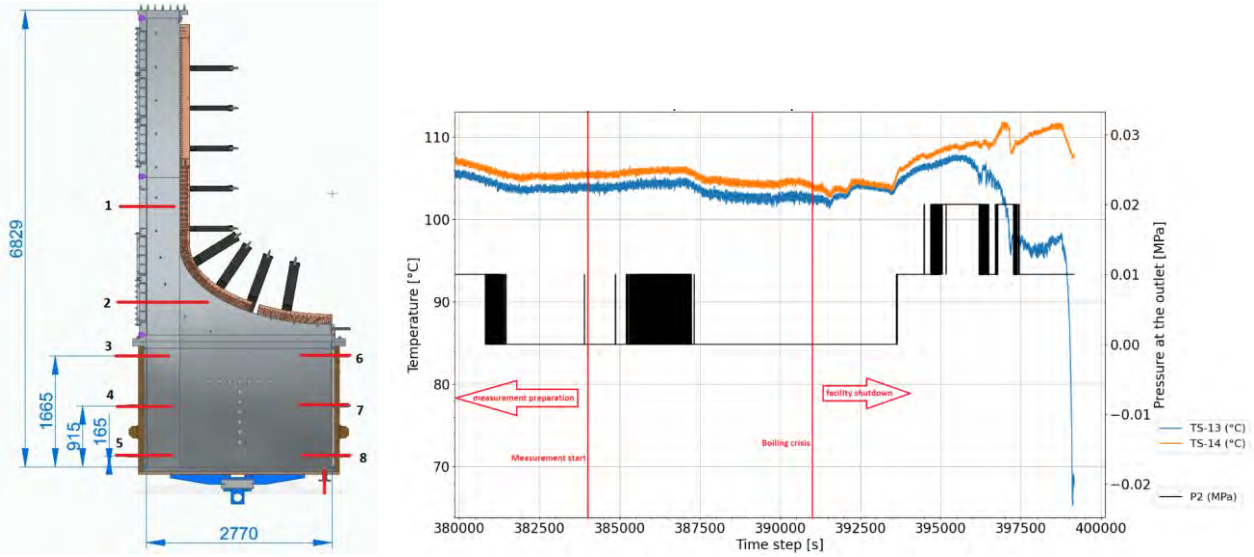

Figure 8. Location of the 8 thermocouples in the flooded cavity and example of water temperature

Thermocouples labeled 1 in fig. 8 (“TS-13” on the graph) and 2 in fig. 8 (“TS-14”) reach saturation temperature when heat flux is generated from the RPV (see examples in the graph on Fig. 8). The other thermocouples (labeled 3 to 8) are generally not at saturation level during the tests due to thermal stratification of the water. In this case, the water volume in the lower part of the cavity does not significantly contribute to heat transfer.

4.7. Results of CHF tests on THS-15 facility

At 90°, the degradation of the heaters on THS-15 facility limits the maximum achievable heat flux to approximately 1.7 MW/m², whereas at 80° the heaters are still intact. Therefore, the maximum inclination where CHF is recorded is 80°. All CHF measurements are duplicated.

Linear (bounding) HF profile (50 cm gap)				
RPV inclination	Low water level		High water level (+ 1.5 m)	
	1st Measurement [MW/m^2]	2nd Measurement [MW/m^2]	1st Measurement [MW/m^2]	2nd Measurement [MW/m^2]
30°	0.82	0.82	0.87	0.92
45°	1.05	1.09	1.37	1.22
60°	1.26	n/a		
80°	1.67	1.71		
90° (limited power)	> 1.76 (maximum heat flux)	> 1.58 (maximum heat flux)	> 1.71 (maximum heat flux)	> 1.63 (maximum heat flux)

Table 4. CHF values for bounding linear HF profile, 50 cm gap

e-SMR HF profile (50 cm gap)				
RPV inclination	Low water level		High water level (+ 1.5 m)	
	1st Measurement [MW/m^2]	2nd Measurement [MW/m^2]	1st Measurement [MW/m^2]	2nd Measurement [MW/m^2]
30°	0.97	0.92	0.97	0.97
45°	1.17	1.07	1.27	1.17
60°	1.31	n/a		
80°	1.8	1.76		
90° (limited power)	> 1.71 (maximum heat flux)			

Table 5. CHF values for ELSMOR e-SMR HF profile, 50 cm gap

4.8. Discussion

The measured critical heat flux values are generally consistent with those reported in the literature, and the observed trends are in line with the understanding of boiling crisis phenomena regarding surface properties of the wall. Surprisingly, the thermal flux profile has only a low influence on the critical heat flux values. The application of a maximized thermal loading, intended as an envelope for any possible thermal configuration, did not lead to a collapse of the critical heat flux values; on the contrary, these values remain high in absolute terms. This indicates that comparing CHF value between 2 facilities with different applied HFF makes sense. As anticipated, the use of reactor vessel steel, rather than a copper wall, results in an increase in critical heat flux across all tested inclinations (30° to 80°).

	Effect of HF profile (RPV steel				Effect of material surface		
RPV inclination [degree]	Linear (bounding)	ELSMOR	Δ%		Copper (ULPU)	RPV Steel	Δ%
	Mean CHF [MW/m^2]	Mean CHF [MW/m^2]			Mean CHF [MW/m^2]	Mean CHF [MW/m^2]	
30°	0.82	0.95	+16%		0.67	0.82	+22%
45°	1.07	1.12	+4%		-	-	-
60°	1.26	1.31	+4%		1.1	1.26	+14%
80°	1.69	1.78	+5%		1.1	1,69	+53%

Table 6. Effect of Heat Flux Profile and surface material on the CHF

As expected, increasing the water level leads to a higher CHF (+20% at a 45° inclination). In a real NPP, the water level typically reaches the elevation of the primary circuit loops, which is significantly higher than in the experimental configuration. This would further increase the CHF.

4.9. Correlation

For gap size of 50 cm, the following empirical bounding correlation is proposed:

$$CHF\ (MW/m2) = 0{,}0156.\theta + 0{,}3694$$

where θ is the angular position expressed in degrees (0° corresponding to the bottom of the vessel).

The validity range is proposed for this bounding correlation:

- RPV vessel steel (15Kh2NMFA or 16MND5) as it is (naturally oxidized);
- Gap size : 50 cm;
- Water level: higher than ~ 250 cm above the height of bottom of the vessel;
- Water chemistry and water temperature: DI water, saturated;
- Thermal heat profile from corium pool: any realistic profile.

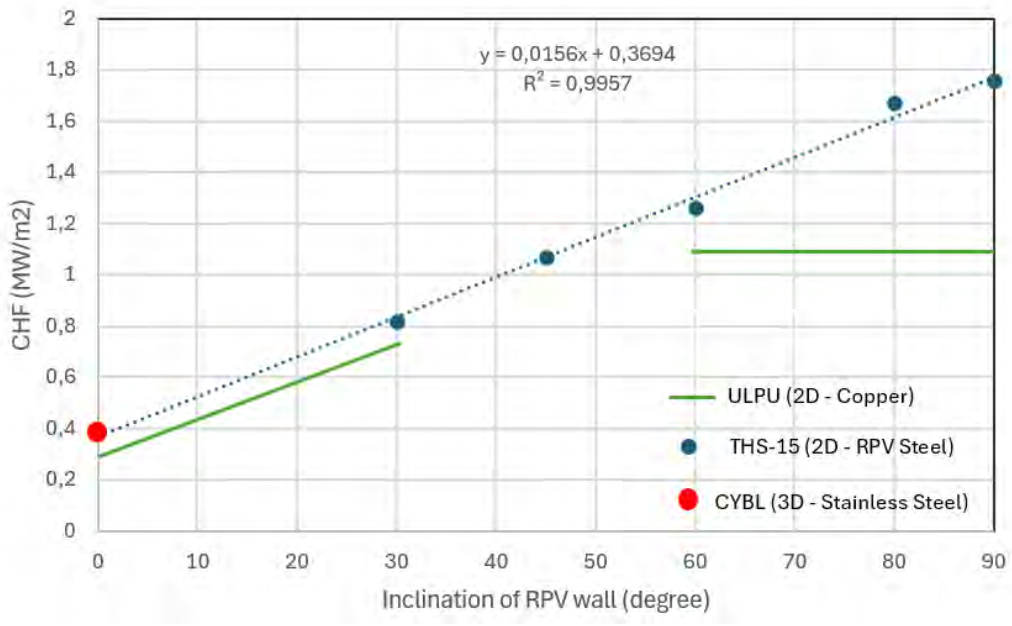

Figure 9. THS-15 results using bounding HFF profile (compared to ULPU-1 and CYBL data)

5. CONCLUSIONS AND PERSPECTIVES

A correlation for the Critical Heat Flux (CHF) under pool boiling conditions has been developed in the context of studies supporting the In-Vessel Retention (IVR) strategy. The correlation is intended to provide pragmatic and bounding CHF values that may be applicable to a range of Light Water Reactor (LWR) designs, without requiring detailed prior knowledge of the external heat flux distribution along the reactor pressure vessel (RPV) wall. The associated experimental programme was designed using a bounding heat flux profile, together with conservative assumptions regarding water height in the cavity, water temperature and ambiant pressure, consistent with severe accident conditions.

The proposed correlation contributes to the existing CHF database for pool boiling on RPV-like geometries, which remains limited. In particular, it complements previous full-scale CYBL and full-height ULPU-I experimental programmes by considering a more representative RPV surface material and by extending the available data over a broad range of wall inclinations relevant to IVR applications.

The relatively high measured values of CHF are mainly attributed to the use of RPV steel, which exhibits enhanced wetting properties compared with copper or stainless steel surfaces commonly used in full-scale in height IVR loop. This effect has been previously observed in earlier dedicated separate-effects experiments.

The influence of water chemistry (e.g. demineralized water with buffering agents and/or boric acid) was not addressed in the present study. From a safety assessment perspective, such effects may warrant further consideration if the coolability margins for a specific reactor design are found to be limited. Where sufficiently large margins are demonstrated, additional investigations of water chemistry effects are not expected to be a priority.

As a next step, the impact of the RPV–insulation annular gap will be examined by reducing the gap width from 50 cm to 15 cm. In the current configuration, a gap of 50 cm may allow the development of a natural convection cell in the THS-15 facility, potentially leading to a non-zero local superficial velocity at the RPV wall. Such effects could influence the measured CHF and should be quantified to confirm the conservatism and applicability of the proposed correlation.

AKNOWLEDGEMENT

The tests whose results are presented in Tables 4 and 5 were financially supported by the European Commission within the framework of the EASI-SMR project.

12th CONFERENCE ON
SEVERE ACCIDENTS RESEARCH
May 18-22, 2026 - Madrid, Spain
ERMSAR 2026

1. Introduction
2. Literature Survey
3. Experimental parameters
4. CHF results
5. Conclusions and perspectives

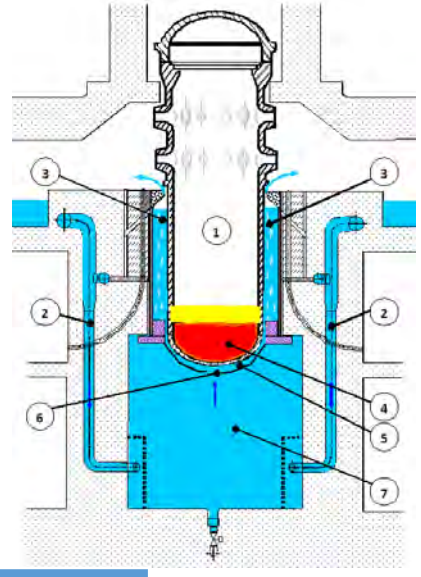
Introduction

- In the framework of the In-Vessel corium Retention (IVR) strategy for commercial nuclear reactor, two external cooling modes are considered
  - Pool boiling configuration
  - Water circulation around the vessel
    - ✓ Either by natural circulation (thermosiphon loop) or forced circulation (pumps)

- For low power reactor (typically < ~500 MWe), pool boiling configuration may have the following advantages
  - Robustness (no need to optimize the gap geometry)
  - Stable flow (not concerned by hydraulic instabilities, or flow oscillations)
  - Simpler than thermosiphon and probably more forgiving in degraded situation (do not depend on the baffle behavior …)

- Objective of this work
  - To attempt to determine a bounding critical heat flux correlation for pool boiling conditions in PWRs, applicable regardless of design-specific parameters such as thermal loading from the corium pools to the vessel wall
  - May be useful-during pre-conceptual design phase to evaluate margins for vessel coolability when IVR strategy is considered

Literature survey



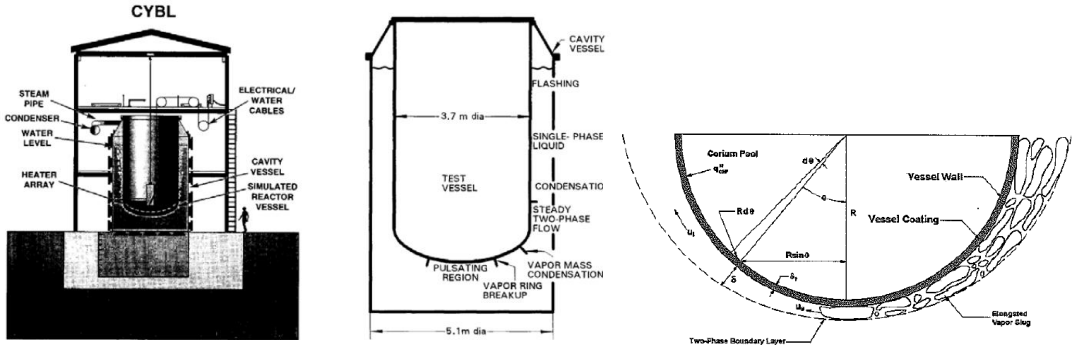
- Few commercial reactors use pool boiling to remove decay heat
  - Example : Paks VVER-440 units (implemented as a post-design modification)
- Few experiments were done in pool boiling configuration for severe accident applications. Experimental facilities and programs examined in this study are:

	CYBL (Cylindrical BoiLing facility- Sandia National Lab)	ULPU I (UCSB)	SBLB (Penn State Univ.)
Scale	3D, 1:1	2D slice, 1:1 in height	3D, 1:8
Vessel shape	Semi-ellipsoidal	Hemispherical (slice)	Hemispherical
Material	Stainless steel	Copper	Stainless steel or aluminium

- None of these facilities use reactor vessel steel (low-alloy ferritic steel)
  - Past separate effect tests have shown that roughness and wettability is enhanced when using vessel steel (e.g. 16/18/20MND5 or SA508/SA533), then increasing critical heat flux

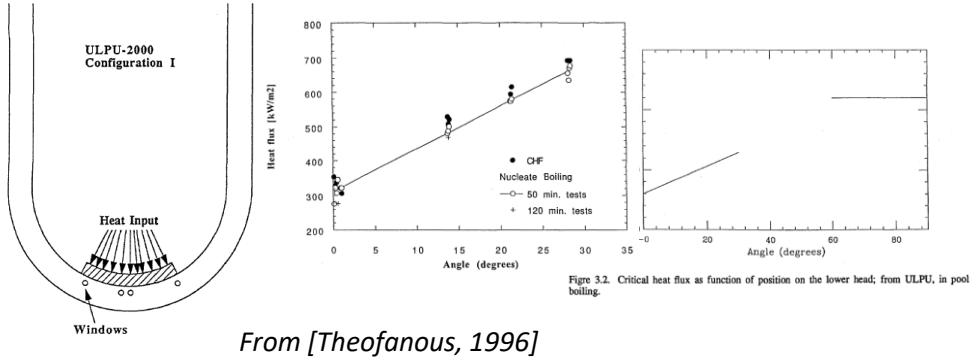
Literature survey: CHF values

- CYBL (saturated water data)
  - 400 kW/m^2 obtained at low inclination (~ 0°)
  - ☹ No data for other inclinations (power limitation)



From [Chu, 1994]

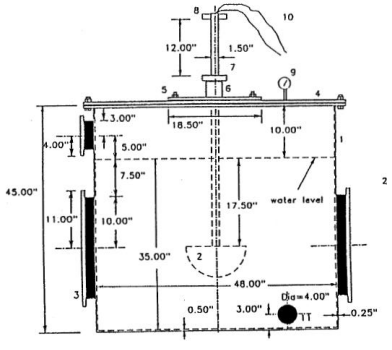
- ULPU I (saturated water data)
  - 0°-30° of inclination: CHF linearly raises from 320 to 670 kW/m^2
  - 60°-90° : CHF ~ 1.1 MW/m^2 (no detailed data published)
  - ☹ No data in the range 30°-60°



Figre 3.2. Critical heat flux as function of position on the lower head; from ULPU, in pool boiling.

From [Theofanous, 1996]

- SBLB (saturated water data)
  - CHF increases constantly from 0.5 MW/m^2 (@20°) to 0.9 MW/m^2 (@70°)
  - PSU proposed a scaling law for full-size vessel applications



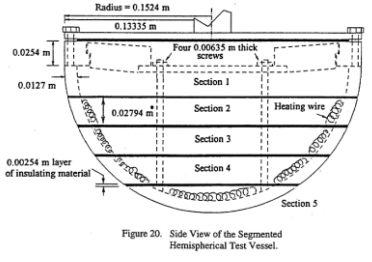


Figure 20. Side View of the Segmented Hemispherical Test Vessel.

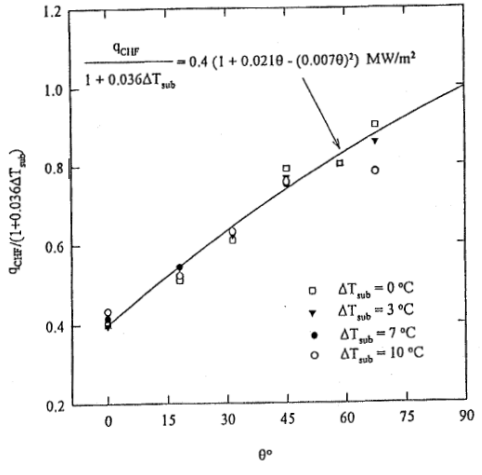
From [Cheung, 1997]



Literature survey: Key findings

- Typical values at saturated water
  - 0.3-0.4 MW/m^2 @0°
  - 0.6 – 0.65 MW/m^2 @30°
  - 0.85 – 1.1 MW/m^2 @60°

- These values were obtained for different heat flux profiles, but sensitivity to these profiles has not been investigated

- Questions that arise:
  - Which CHF in the range 30° to 90° ?
  - What if using vessel (i.e. low-alloy ferritic) steel ?
  - How significantly does the HFF impact the CHF ?

Table 3 Comparison of the Local Critical Heat Fluxes Measured at Various Test Facilities Under Saturated and Subcooled Boiling Conditions

Local Angle of Inclination* θ	Local Critical Heat Flux, MW/m^2				
	SBLB at PSU		CYBL at SNL	ULPU at UCSB	
	Saturated Boiling	Subcooled Boiling**	Saturated Boiling+	Saturated Boiling	Subcooled Boiling++
0°	0.40	0.59	0.50	0.28	0.50
30°	0.61	0.86	--	0.65	0.89
60°	0.85	1.05	--	--	1.18
90°	(1.00)	(1.35)	--	--	1.50

* θ = 0° corresponding to the bottom center and θ = 90° corresponding to the upper edge of the test vessel
** Pool boiling with a subcooling of 10 °C
\+ Based largely on small-scale quenching data
++ Natural convection boiling with a subcooling of 14 °C at the bottom center

From [Cheung, 1997]

Effect of surface material

- Experimental evidence of an increase of CHF at low pressure, when using vessel steel instead of copper / stainless steel
  - Pool boiling on an upward-facing heated surface: BETA Experiment
    - **0.75 → 1.3 MW/m²** when switching from cleansed copper to oxidized steel
  - Under circulating flow: for example, EDF/MIT tests
    - **1,6 →2.3 MW/m²** @500 kg.m^{2}.s^{-1}, 90° inclination, and ~ 12 K subcooling
  - ➢ No clear physical explanation, but measurements indicate increased surface roughness and wettability when using vessel steel

Increase of roughness and porosity – Wickability tests (MIT/EDF program, from [Trojer 2018])

2024 : Opportunity through EASI-SMR project to perform some CHF test in pool boiling situation on THS-15 facility at UJV using vessel steel

THS-15 facility at UJV

- Main characteristics
  - 2D-slide, 1:1 in height (VVER1000 geometry)
  - Naturally oxidized vessel steel covering the heaters
  - Can be configurated for pool boiling situation

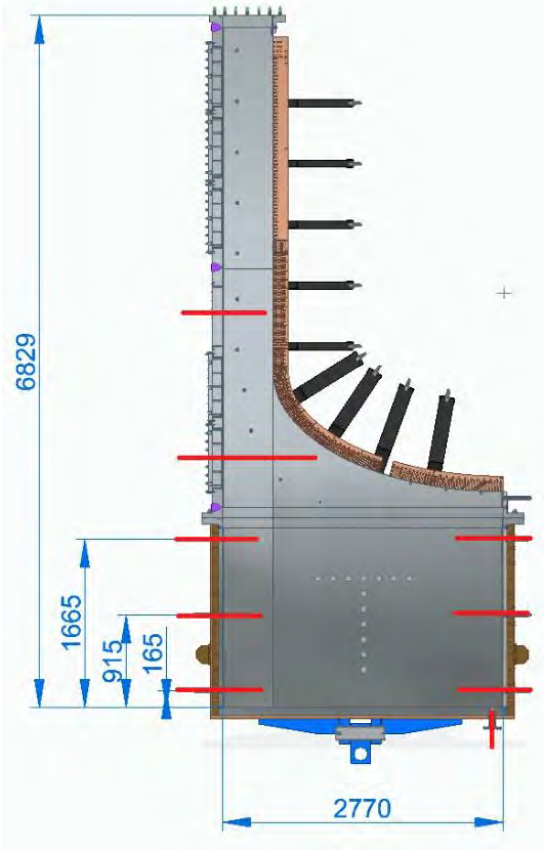
THS-15 facility - from [Batek, 2024]

- Heater surface material : V354

	Typical Chemical Composition (wt.%)			
Element	16MND5 (PWR RPV steel)	V354 (THS-15)	15Kh2NMFA (VVER RPV steel)	Stainless steel (304L)
Carbon (C)	0.16 – 0.20	0.12 – 0.18	0.12 – 0.18	≤ 0.03
Manganese (Mn)	1.20 – 1.60	0.80 – 1.10	0.30 – 0.60	≤ 2.00
Silicon (Si)	0.15 – 0.35	≤ 0.20	0.17 – 0.37	≤ 1.00
Nickel (Ni)	0.40 – 1.00	—	1.00 – 1.50	8.0 – 12.0
Molybdenum (Mo)	0.45 – 0.60	0.80 – 1.00	0.40 – 0.70	—
Chromium (Cr)	≤ 0.30	1.25 – 1.50	1.80 – 2.30	**18.0 – 20.0**
Vanadium (V)	—	0.20 – 0.30	0.10 – 0.30	—
Copper (Cu)	≤ 0.25	—	≤ 0.10	—
Phosphorus (P)	≤ 0.020	≤ 0.020	≤ 0.015	≤ 0.045
Sulfur (S)	≤ 0.010 – 0.020	≤ 0.015	≤ 0.015	≤ 0.030
Iron (Fe)	Balance	Balance	Balance	Balance

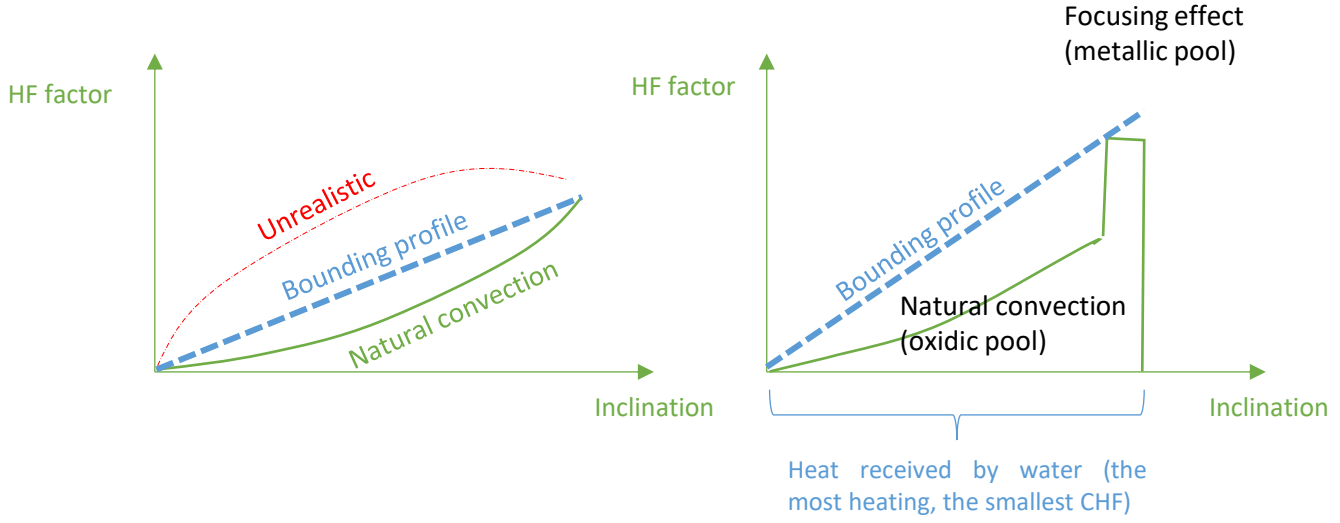
Objective of the experimental program / test parameters

- Choice of bounding parameters
  - Ambient pressure: atmospheric
  - Water level: as low as possible (low submergence)
  - Water temperature: at saturation
  - Coating: as it is (no treatment)
- Gap size
  - “No gap” (~ 50 cm)
- Water chemistry
  - None (De-Ionized water)

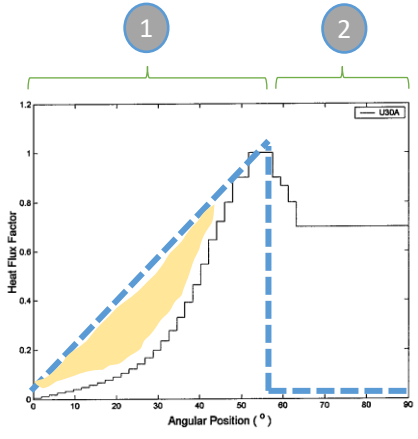


Test parameters (con't)

- Heat Flux Profile
  - **"Linear":** for a given inclination, bounding profile can be set so that the amount of energy that heats the water before CHF location is maximized



✓ *Example on a ULPU HFP*



[53-57°]

1 *A linear profile maximizes the thermal energy transferred to the fluid ➔ The measured CHF is conservative*

2 *The heat flux can be truncated beyond the location at which the CHF is evaluated, as this has no impact under pool-boiling conditions*

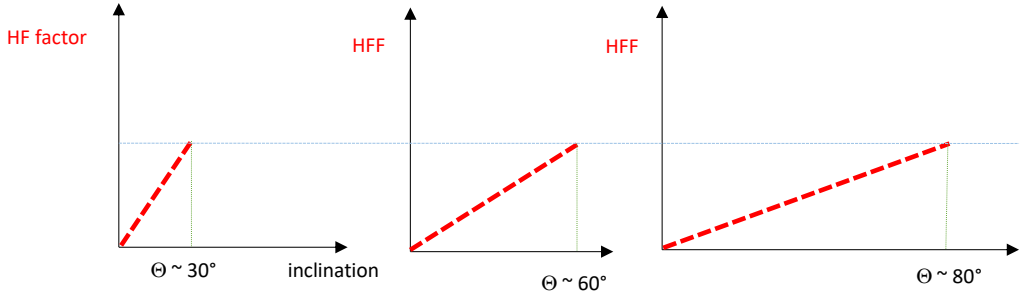
Thermal energy transferred to the fluid upstream of the measurement location is maximized

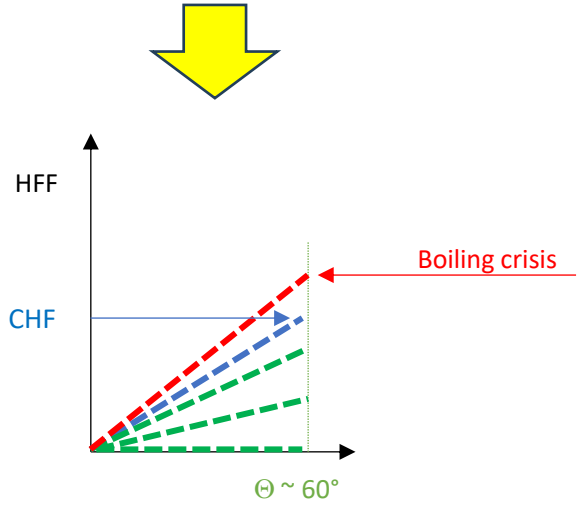
Test parameters (con't)

- Inclinations
  - 30°, 45°, 50°, 60°, 80°, 90°
    - ✓ depending on the condition of the heating cartridges
- Methodology for CHF measurement
  - For each inclination of the test matrix, HFF is set linear
  - Theofanous' correction [Theofanous, 1996] is then applied to take into account slice geometry

$$HFF_{Slice}(\theta) = HFF_{prototypical} \times \frac{\sin\theta}{sin\theta_m} \text{ for } \theta < \theta_m$$

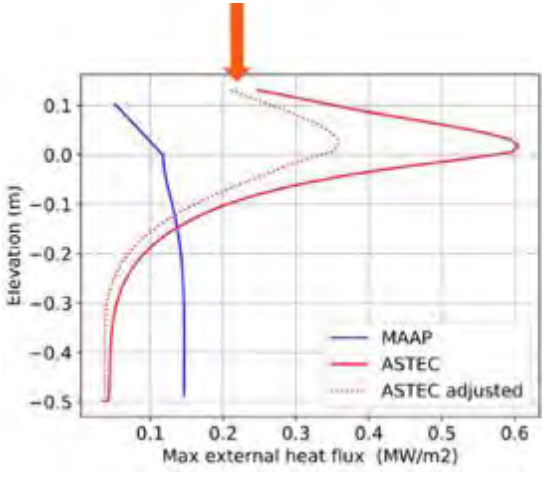
  - To detect the CHF, the HF slope is increased until a rapid increase in temperature is detected by the thermocouples located near the surface of the heaters



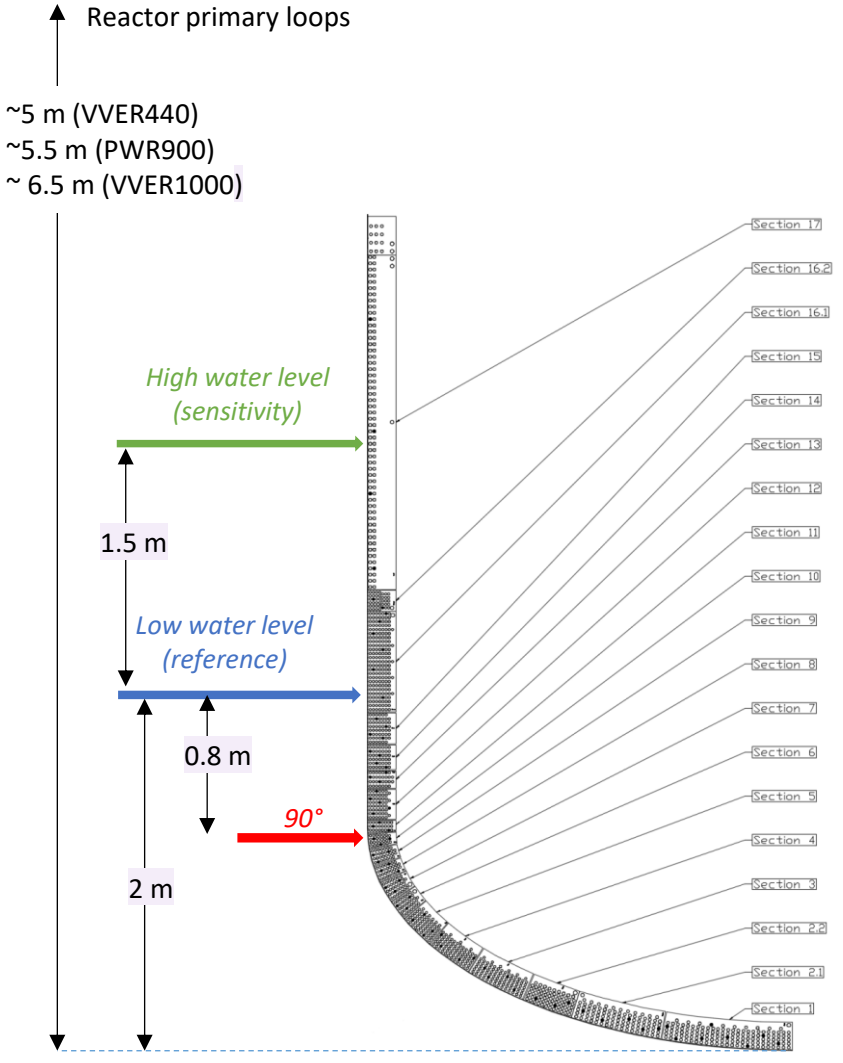


Test parameters (con't) - Sensitivity

- Sensitivity studies
  - On water level
    - ✓ Reference level is set at low level
    - ✓ Sentivity : higher water level (+ 1.5 m)
    - ✓ In reactor situation, the water level would reach the primary loop
  - On the heat flux profile
    - ✓ a HFF from ASTEC calculation on E-SMR design (from ELSMOR European Project) is used



from [Bittan, 2024]

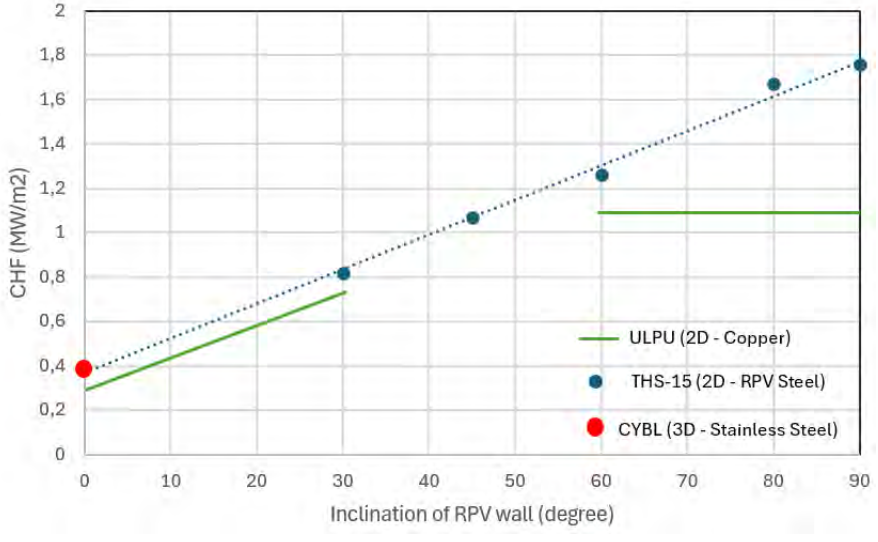


CHF results

- Reference parameters (linear HFF)
  - At ~90° inclination, the heating cartridges did not dissipate enough heat to reach critical heat flux

Linear (bounding) HF profile		
RPV inclination	Low water level	
	1st Measurement [MW/m²]	2nd Measurement [MW/m²]
30°	0.82	0.82
45°	1.05	1.09
60°	1.26	n/a
80°	1.67	1.71
90° (limited power)	> 1.76 (maximum heat flux)	> 1.58 (maximum heat flux)

- Comparison with literature
  - Heat Flux Factor used for CHF detection are different
    - ✓ bounding (“linear”) for THS-15 (hemi-ellipsoidal)
    - ✓ depending on the reactor design considered for ULPU (hemispherical)
  - ✓ Bounding curve may be approached by *CHF (MW/m²) = 0.0156Θ (degree) + 0.3694*



CHF results (sensitivity)

- Effect of Heat Flux Factor profile and effect of surface material

	Effect of HFF profile (RPV steel)		
RPV inclination [degree]	Linear (bounding) Mean CHF [MW/m²]	ELSMOR Mean CHF [MW/m²]	Δ%
30°	0.82	0.95	+16%
45°	1.07	1.12	+4%
60°	1.26	1.31	+4%
80°	1.69	1.78	+5%

	Effect of surface material		
RPV inclination [degree]	Copper (ULPU) Mean CHF [MW/m²]	RPV Steel Mean CHF [MW/m²]	Δ%
30°	0.67	0.82	+22%
45°	-	-	-
60°	1.1	1.26	+14%
80°	1.1	1,69	+53%

  - o "Realistic" HFF logically provides slightly higher CHF than the bounding HFF, though not significantly
  - o Effect of surface material has a more significant impact on CHF

- Effect of water level
  - o Higher water level increases logically the CHF
  - ✓ Higher CHF are expected if the cavity is flooded until the primary loops

Effect of water level					
RPV inclination	Low water level Mean CHF (linear) [MW/m²]	Low water level Mean CHF (ELSMOR) [MW/m²]	"High" water level (+ 1.5 m) 1st Measurement [MW/m²]	"High" water level (+ 1.5 m) 2nd Measurement [MW/m²]	Δ%
30°	0.82	0.95	0.90	0.97	+10% ; + 5%
45°	1.07	1.12	1.30	1.32	+21% ; +17%
60°	1.26	1.31			
80°	1.69	1.78			

Conclusion

- Main insights
  - CHF values with bounding assumptions are provided for ERVC under and IVR strategy when pool boiling is considered, especially considering bounding heat flux profile and very low water submergence compared to reactor situation
  - The study addresses a gap in the literature by providing critical heat flux data
    - ✓ for inclinations between 30° and 60°
    - ✓ specifically for reactor vessel steel
  - These values are significant, with heat fluxes reaching at least 1 MW/m² at 45° and about 1.7 MW/m² at 80° inclination for a 50 cm gap size.
  - These values can be used to assess reactor vessel coolability margins when the design is not well defined (e.g., safety system architecture and corium loading)
- Perspectives
  - The effect of the gap still needs to be assessed. A narrower gap is advantageous for designers, as it reduces the water volume needed to initially flood the reactor cavity
  - The effect of vessel shape (semi-ellipsoidal or hemi-spherical) has also to be assessed

NB : effect of water chemistry cannot be assessed in THS-15 facility. Past studies ([Dinh, 2003], [Trojer, 2018]) did not show a clear tendency of the impact of boron and/or alkaline buffering agent on the CHF, either under pool boiling or circulating flow.

Thank you
Any question ?

ABSTRACT

Internal investigations at the Fukushima Daiichi Nuclear Power Station (1F) have been conducted by Tokyo Electric Power Company Holdings (TEPCO HD); however, the condition of the reactor pressure vessel (RPV) has not yet been confirmed. To clarify the RPV damage progression during the accident, a simulation test (ELSA-3) was conducted using the LEISAN test facility owned by JAEA, focusing on the interaction between a zirconium-containing liquid metal (304SS-83wt% Zr alloy) that discharged to the bottom of the RPV lower head and the lower head structural components, forming a liquid metal pool and potentially causing failure through eutectic reactions.

The test results showed that at the lower head penetration region, the eutectic reaction (approximately 1250°C) between the simulated metal debris and the lower structural components (CRD housings and CRD stub tubes) caused melting of the structural components, allowing the simulated metal debris to flow into the CRD housings. This eutectic reaction temperature is below the melting point of the individual structural materials, indicating that failure can occur due to inter-material eutectic reactions even without reaching the melting point. These results suggest that for Zr-rich molten materials, damage may occur through eutectic reactions between materials even below their melting points.

KEYWORDS
Reactor Pressure Vessel, Eutectic reaction, CRD

1. INTRODUCTION

Internal investigations of the Fukushima Daiichi Nuclear Power Station (1F) are being conducted by Tokyo Electric Power Company Holdings (TEPCO HD); however, the condition of the reactor pressure vessel (RPV) has not yet been sufficiently confirmed.

To clarify the damage status of the RPV associated with accident progression, a simulated experiment (ELSA-3: Experiment on Late In-vessel Severe Accident Phenomena) was conducted, focusing on failure caused by material interactions (eutectic reactions) between the lower structural components of the RPV and a molten metal pool formed at the bottom of the lower head, resulting from the relocation of zirconium-containing liquid metal. In the previous ELSA series, the ELSA-1[1] teste focused on the local failure behavior of the RPV structure caused by zirconium (Zr)-rich simulated metal debris. Conversely, the ELSA-2[2][3] test was conducted under conditions with high stainless steel content, which provided the insight that failure remains limited under such compositions.

2. FAILURE MODES OF THE LOWER HEAD

When the reactor pressure vessel (RPV) is not under high-pressure conditions, failure of the lower head (LH) during a severe accident (SA) in a boiling water reactor (BWR) occurs as a result of molten core

materials relocating to the lower plenum. LH failure is caused by mechanical factors, thermal factors, and eutectic melting that depends on the composition of the molten pool.
Examples of mechanical factors include plastic deformation, creep damage, and buckling. Thermal failure occurs when LH structural materials are heated beyond their melting points. When eutectic melting occurs between the LH structural materials and the relocated core materials, failure can take place at temperatures lower than the melting point of the LH materials.
The dominant failure mechanism of the LH depends on the condition of the core during slumping. If most of the core fuel is molten during the slumping process, thermal damage caused by high-temperature molten oxide fuel becomes dominant. In contrast, if a large portion of the fuel remains unmelted, mechanical damage or eutectic melting-induced failure is more likely to occur.
In addition to fuel materials, metallic core components such as fuel cladding, control rods, and channel boxes undergo eutectic melting and relocate to the lower plenum. In BWRs, Ni/Zr, Fe/Zr, UO_2/Zry, and Fe/B systems are among the first materials to relocate. The molten metals initially solidify in the lower plenum, but are subsequently reheated by falling solid fuel fragments, forming a molten metal pool.
In mechanically dominated failure, heating due to the amount and height of accumulated debris within the RPV leads to vessel deformation and eventual rupture. When eutectic melting is dominant, partial liquefaction of LH structural materials occurs due to eutectic reactions between the molten metal pool and the LH structures, resulting in damage. Because the LH consists of structural components and welds made of stainless steel and nickel-based alloys, eutectic interactions between these materials and the molten metal pool can cause damage at the boundary regions.
Furthermore, the LH of a BWR contains many components such as control rod drive (CRD) housings, which are thinner than the RPV shell and therefore more susceptible to eutectic melting-induced failure. The material configuration around the CRD housing is shown in Figure 1. As shown in the Figure 2, when the weld between the CRD housing and the CRD stub tube is lost, the CRD housing is designed to rest on the grid clamp.

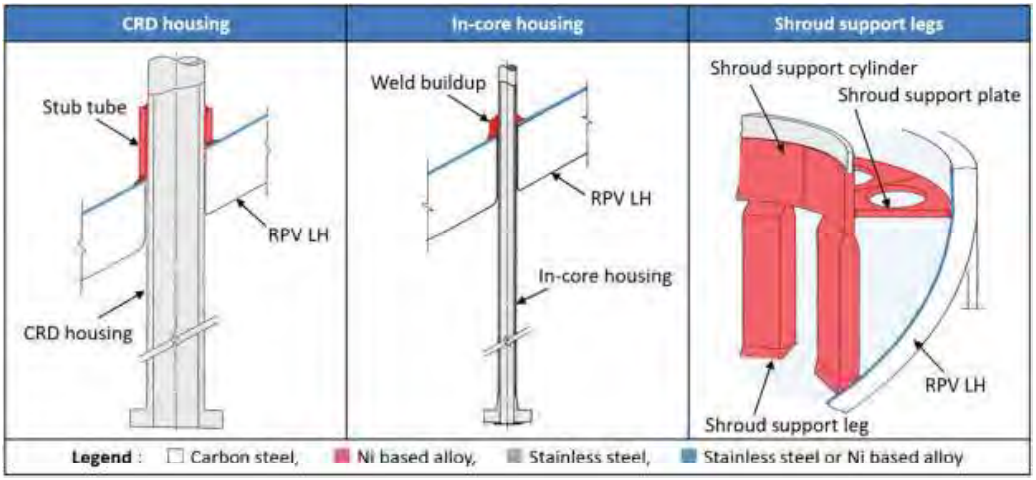

Figure 1 Material composition around the CRD housing [1]

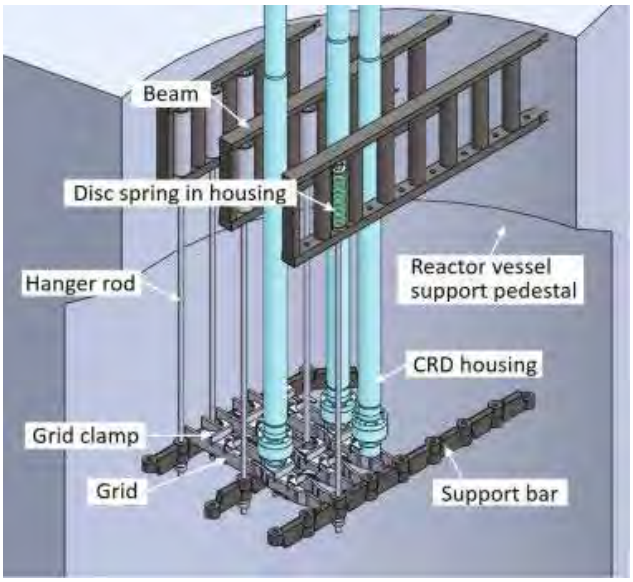

Figure 2 Structural layout around the grid clamp [1]

3. EXPERIMENT

3.1. EXPERIMENTAL OVERVIEW

This experiment was conducted using a test specimen that simulates the lower head of the reactor pressure vessel (RPV) and the control rod drive (CRD) system of Unit 2 at the Fukushima Daiichi Nuclear Power Station (1F2).

To simulate metallic debris relocating from the reactor core to the lower head during a severe accident, surrogate metal debris composed of SUS304–83 wt.% Zr was loaded into the specimen. This composition was selected based on a pseudo-binary phase diagram, as it becomes liquid at a relatively low temperature of approximately 1080°C. The selected ratio was determined with reference to the results of the CMMR tests [4], which simulated fuel melting behavior during slumping in Unit 1F2.

After the surrogate metal debris flowed into and blocked the CRD housings, the liquid level was set to allow observation of interactions between the remaining molten metal debris at the bottom of the RPV lower head and the lower head structural materials (Figure 3). The test was performed using the large-scale experimental facility LEISAN (Large-scale Equipment for Investigation of Severe Accidents in Nuclear Reactors) owned by JAEA/CLADS (Collaborative Laboratories for Advanced Decommissioning Science). The debris was heated and melted to form a molten metal pool, and failure caused by eutectic reactions with the CRD housings and CRD stub tubes in the lower plenum was investigated.

It should be noted that uranium was not used in this experiment because the facility was not designed for hot testing. The external views of the test apparatus and specimen are shown in Figure 4.

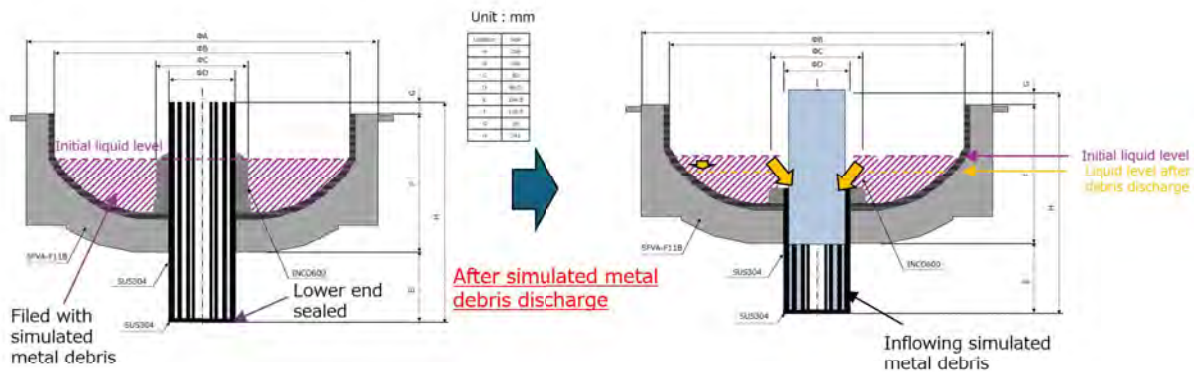

Figure 3 Liquid level setting

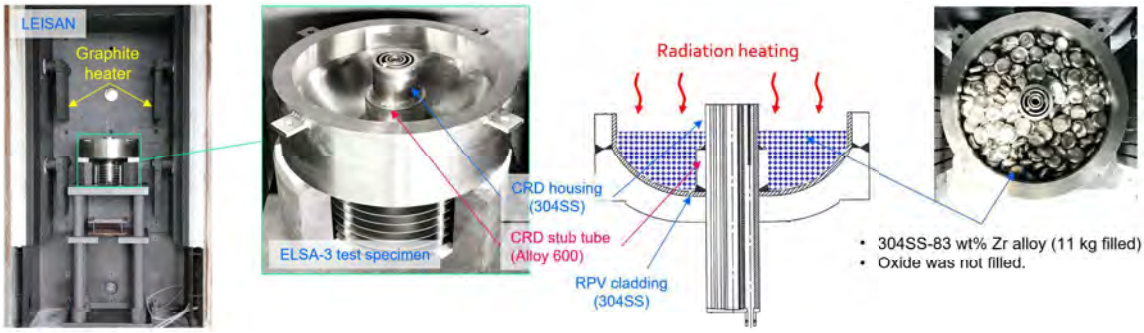

Figure 4 The ELSA-3 test apparatus and specimen

3.2. ACCIDENT PROGRESSION OF UNIT 2

Figure 5 presents an overview of the accident progression in Unit 2[1]. Immediately before failure of the lower head (LH), a decrease in RPV pressure was observed at 4:10 on March 15, accompanied by a reduction in steam generation within the RPV. This behavior suggests that the depletion of liquid water in the lower plenum led to a decline in steam production.

In Unit 2 (1F2), the formation of a large molten fuel pool was limited; therefore, the fuel debris that relocated to the lower plenum was likely in particulate form. In this situation, metallic debris that fell during the early stage of core damage was reheated and remelted by heat from the oxide fuel particles. The remelted metallic debris is considered to have formed a molten metal pool by filling the voids between the solid particulate oxide fuel.

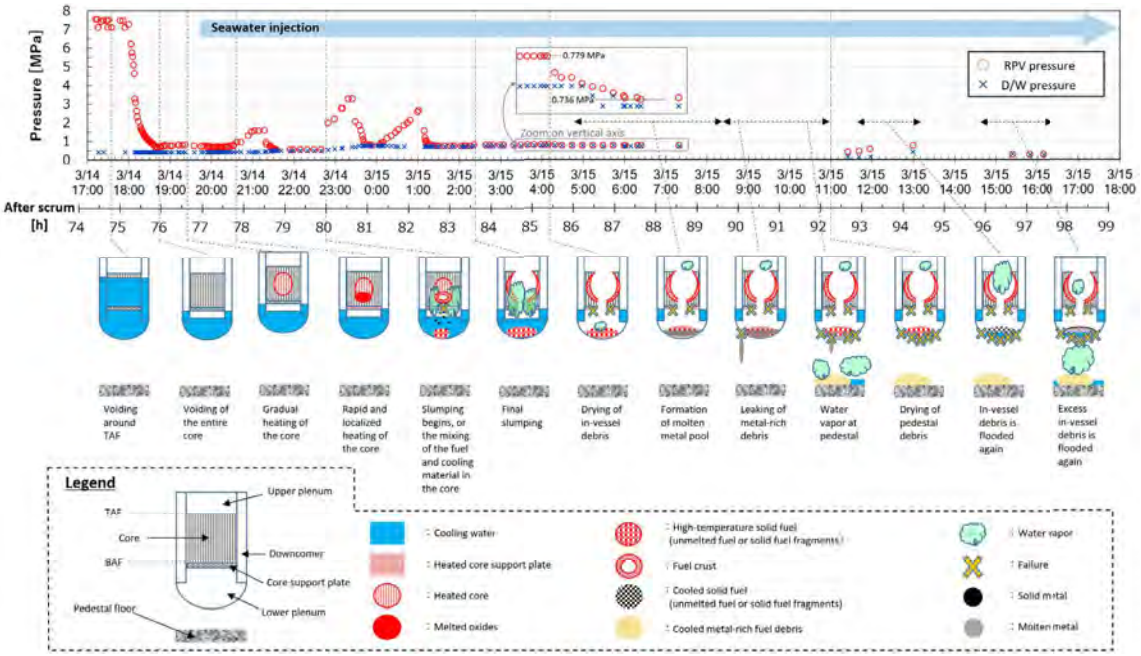

Figure 5 1F2 accident progression (2011) [1]

3.3. EXPERIMENTAL CONDITIONS

The experimental conditions were established based on the accident progression analyses and evaluations described above. The objective of this experiment was to clarify the failure behavior inside the CRD housings when debris accumulated in the lower plenum melts under steam-starved conditions.

In an actual reactor, a molten metal pool is formed through heating by oxide fuel; however, this process cannot be directly reproduced in the LEISAN facility. Therefore, surrogate debris was melted using radiative heat transfer from graphite heaters.

The test atmosphere consisted of argon gas with a purity of 99.99%. The test temperature was controlled by adjusting the output of the graphite heaters so that the temperature history of the specimen met the prescribed conditions, based on the results of thermal-hydraulic analyses from the RPV PJ [5]. During the test, temperatures were measured using thermocouples installed at various locations, and the behavior was observed using cameras mounted on the experimental apparatus.

3.4. EXPERIMENTAL RESULTS

The experimental results confirmed that eutectic reactions between the surrogate metal debris and the lower structural components—namely the CRD housings and CRD stub tubes—caused damage to these components at the lower head penetrations. The temperature history during the test is shown in Figure 6. The temperatures of the CRD housings and stub tubes at the time of failure were approximately 1300°C. Figures 7 and 8 present the pseudo-binary phase diagrams for the stainless steel (74%Fe–18%Cr–8%Ni)–zirconium system and the stainless steel (74%Fe–18%Cr–8%Ni)–zirconium–Alloy 600 (74%Ni–16%Cr–10%Fe) system, respectively. In this study, tungsten-rhenium thermocouples were employed to accommodate temperature measurements in the high-temperature range exceeding 1300°C. The measurement uncertainty is based on the ASTM E230/E230M-17 standard. At the failure temperature observed in this test (approximately 1300°C), the measurement error of the thermocouples is evaluated to be ±13°C.

From these phase diagrams, the eutectic reaction temperature between the 304SS–83 wt.% Zr alloy and the CRD housings and stub tubes is approximately 1250°C. The observed failure temperature in this experiment closely corresponds to this eutectic temperature, indicating that the structural components failed at temperatures below their respective melting points.

Because no external loads or constraints were applied to the specimen, mechanical effects can be neglected. After the failure of the CRD housings and stub tubes, the inflow of surrogate metal debris into the CRD housings was also observed.

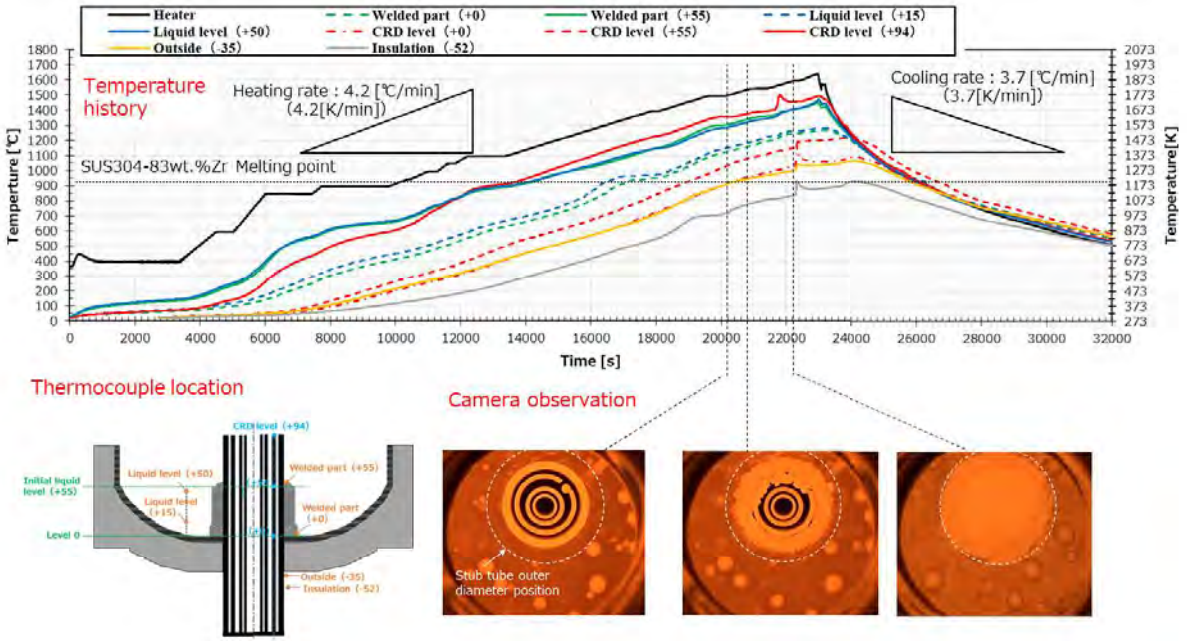

Figure 6 The temperature history during the test

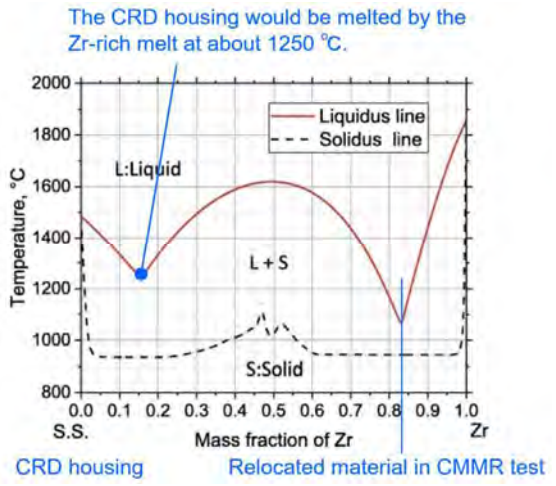

Figure 7 Quasi-binary phase diagram of stainless steel (74%Fe-18%Cr-8%Ni)-Zirconium–

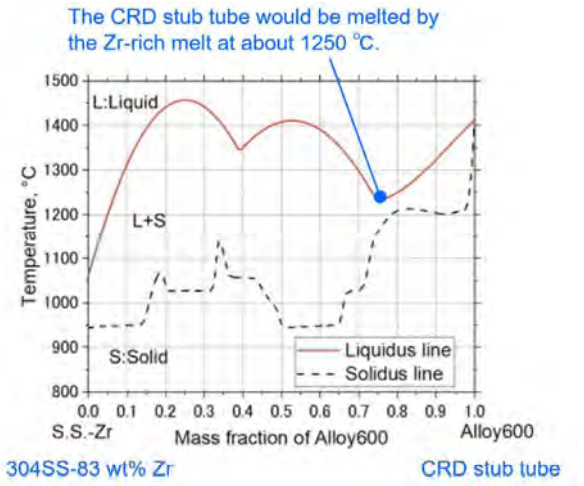

Figure 8 Quasi-binary phase diagram of stainless steel (74%Fe-18%Cr-8%Ni) – Zirconium-Alloy600 (74%Ni-16%Cr-10%Fe) [1]

3.5. POST-TEST OBSERVATIONS

Figure 9 shows the cutting position of the specimen, and Figure 10 shows the cross-sections of the specimen after cutting. EPMA analyses targeting Fe, Ni, O, and Zr were conducted in the region indicated by the blue box in the figure, and the results are presented in Figure 11. The specimens were mounted in epoxy resin alongside standard samples (Inconel, SUS304, SUS310S, SFVA, and Fe-Zr pellets) and

mirror-polished prior to analysis. The Ni distribution confirms that the upper portion of the CRD stub tube had disappeared, which is attributed to the diffusion of Ni into the molten surrogate debris.
The Zr distribution further indicates that Zr-rich material, namely the surrogate debris, flowed into the region where the stub tube had been lost. Furthermore, the molten metallic debris that rose along the CRD housing nearly obstructs the upper opening. However, the formation of a Laves phase at this opening restricts the amount of material flowing into the CRD housing.
The molten material was observed to have flowed out from the locations where the CRD housing and stub tube had melted. These results demonstrate that the Zr-rich molten material was capable of melting the CRD housing and stub tube at approximately 1300°C.
Based on the test results, the experiment is considered to have progressed through the following behaviors (Figure 12).

Step 1 First, the test specimen was filled with simulated metallic debris, and heating was initiated using a heater based on radiative heat transfer.

Step 2 Due to radiative heating from the heater, the surface began to melt, with nickel from the stub tube diffusing into the molten metal, while iron from the CRD housing surface diffused into the molten metal.

Step 3 Subsequently, a phenomenon in which the molten metal climbed up along the CRD housing occurred.

Step 4 The surface of the CRD housing became covered, and a thin oxide layer and the Laves phase were formed. Part of the molten metal that climbed up flowed into the interior of the CRD housing.

Step 5 Due to the formation of the oxide layer, dripping was limited. The upper part of the stub tube disappeared owing to eutectic reactions, eroding the CRD housing, and molten metal flowed into the interior of the CRD housing from the side of the stub tube.

Step 6 Similarly to the climbing behavior along the side of the CRD housing, molten metal also climbed up outside the test specimen and flowed out of the vessel, with dripping still being limited, as described in Step 5.

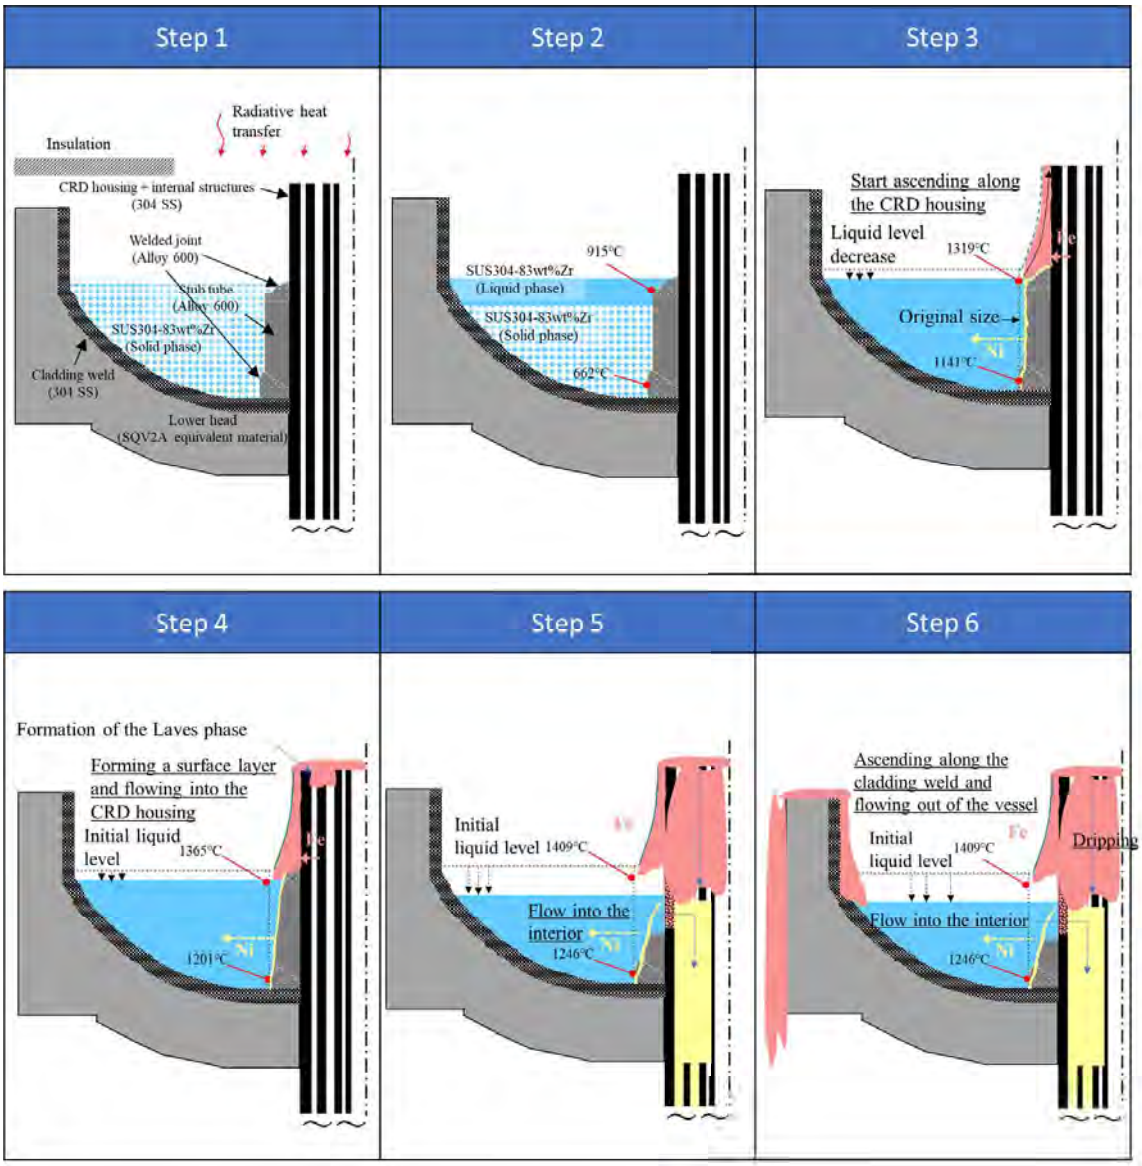

Figure 12 Schematic illustration of the test progression

4. ANALYSIS OF THE RESULTS

Based on the results of the ELSA-3 experiment, the failure of the CRD housings and stub tubes in Unit 2 (1F2) is estimated to have progressed through the following Steps 1 to 4. The conditions at each step are illustrated in Figure 13.

1. Zr-rich molten material relocated to the lower plenum and was reheated by fuel debris.
2. Some CRD housings and stub tubes failed due to eutectic reactions at temperatures below their respective melting points.
3. The molten material flowed into the CRD housings through the damaged regions.
4. As the stub tubes melted, the load previously supported by the weld joints between the CRD housings and stub tubes was transferred to the support bars.

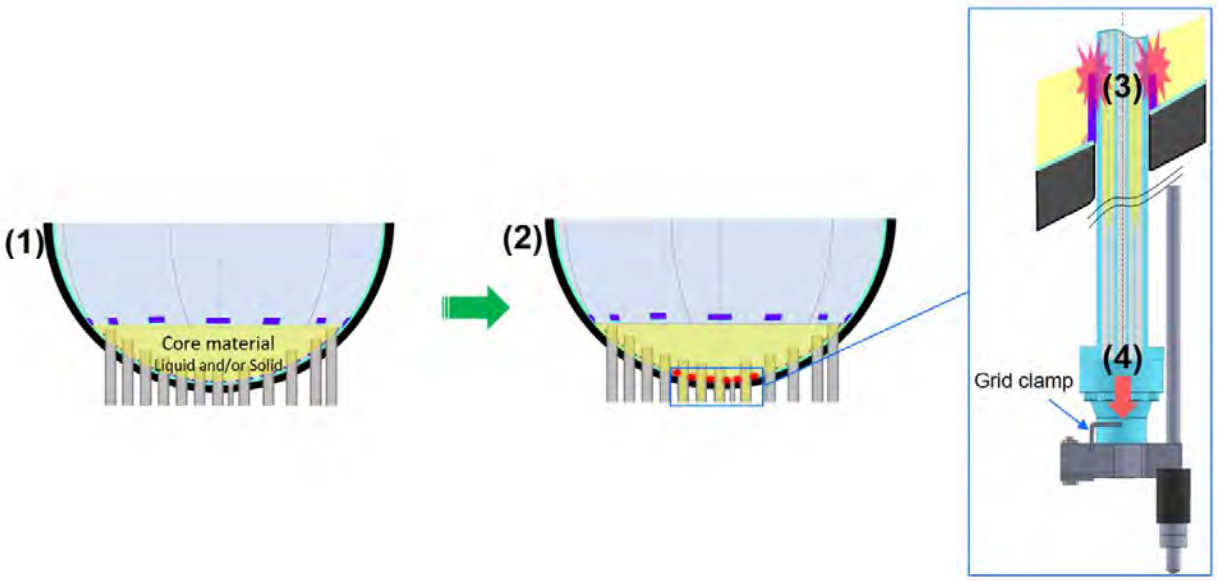

Figure 13 Estimation of the 1F2 accident progress

5. Conclusions

To clarify the accident progression at Unit 2 of the Fukushima Daiichi Nuclear Power Station, tests were conducted focusing on eutectic melting as part of the investigation into failure behaviors at the bottom of the Reactor Pressure Vessel (RPV).To understand the failure mechanisms caused by the eutectic reaction between the zirconium (Zr)-rich molten metallic debris accumulated in the lower plenum and lower internal structures (such as Control Rod Drive (CRD) housings), simulated metallic debris (SUS304-83wt.%Zr) was radiatively heated using graphite heaters in an argon atmosphere within the large-scale test facility LEISAN. The test results demonstrated that the CRD housing and stub tubes failed at approximately 1300°C, a temperature significantly lower than the melting points of the individual materials. Consequently, it is estimated that many of the CRD stub tubes in the actual reactor have melted, and the CRD housings are likely seated on and supported by the CRD housing support components.

1. Introduction

- Estimated Diagrams of Internal Conditions of Units 1–3 at Fukushima Daiichi Nuclear Power Station (1F)

- Based on past evaluations, it is estimated that the Reactor Pressure Vessel (RPV) has been breached (holes have formed).

- Current focus is placed on damage caused by material interaction (eutectic reaction) among various RPV failure modes

  - Damage due to material interaction (eutectic reaction) between liquid metallic core materials (Zr) and lower structural components at the RPV lower head.

To investigate the damage status of the RPV bottom and the inflow of molten material into the Control Rod Drive (CRD) housings under conditions where metallic debris is present at the bottom of the RPV, tests are conducted using specimens simulating the RPV lower head section (ELSA: Experiment on Late In-vessel Severe Accident phenomena). These tests demonstrate the possibility of damage resulting from material interactions (eutectic reactions) between the RPV lower head components and the metallic debris.

3. Experiment

3.1 Experimental overview

- Test specimens simulating the RPV lower head (including weld cladding), CRD housings, and CRD stub tubes were fabricated.
- "SUS304-83wt.%Zr" was selected as the simulated metallic debris to be filled into the specimens. This composition was chosen based on the SUS304-Zr pseudo-binary phase diagram as a Zr-rich ratio that liquifies at low temperatures, reflecting CMMR (Core Material Melting and Relocation) test results where Zr-rich materials were found to melt preferentially.

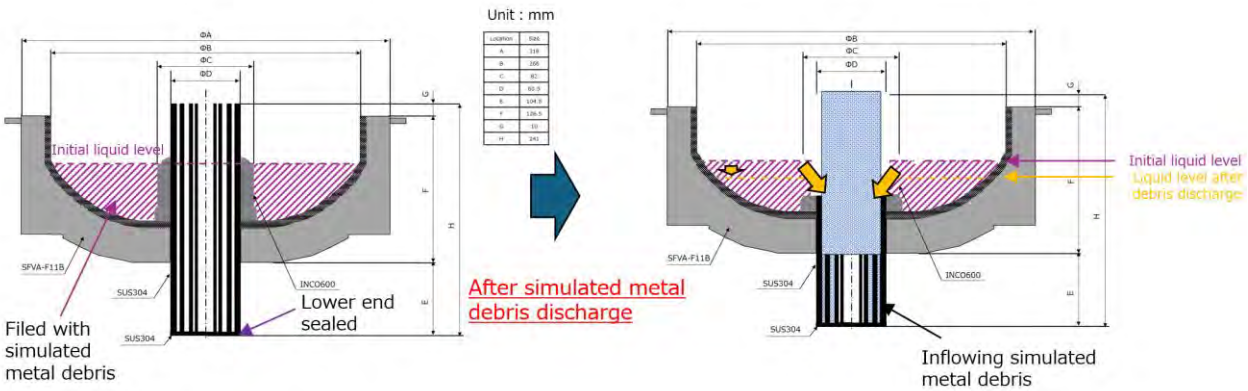
3.2 Experimental conditions

- To observe the reaction between the simulated metallic debris and the lower head structural components after the debris has flowed into and blocked the CRD housing, the liquid level height was established to ensure that the debris remaining in the lower head would react with those lower head components .
- Using the large-scale test facility (LEISAN facility) owned by JAEA/CLADS, the materials were heated and melted with graphite heaters to form a liquid pool. Damage caused by eutectic reactions with the CRD housing and CRD stub tubes was then observed. Following the test, the specimen was cut for cross-sectional observation and analysis.

Liquid level height setting



LEISAN Facility

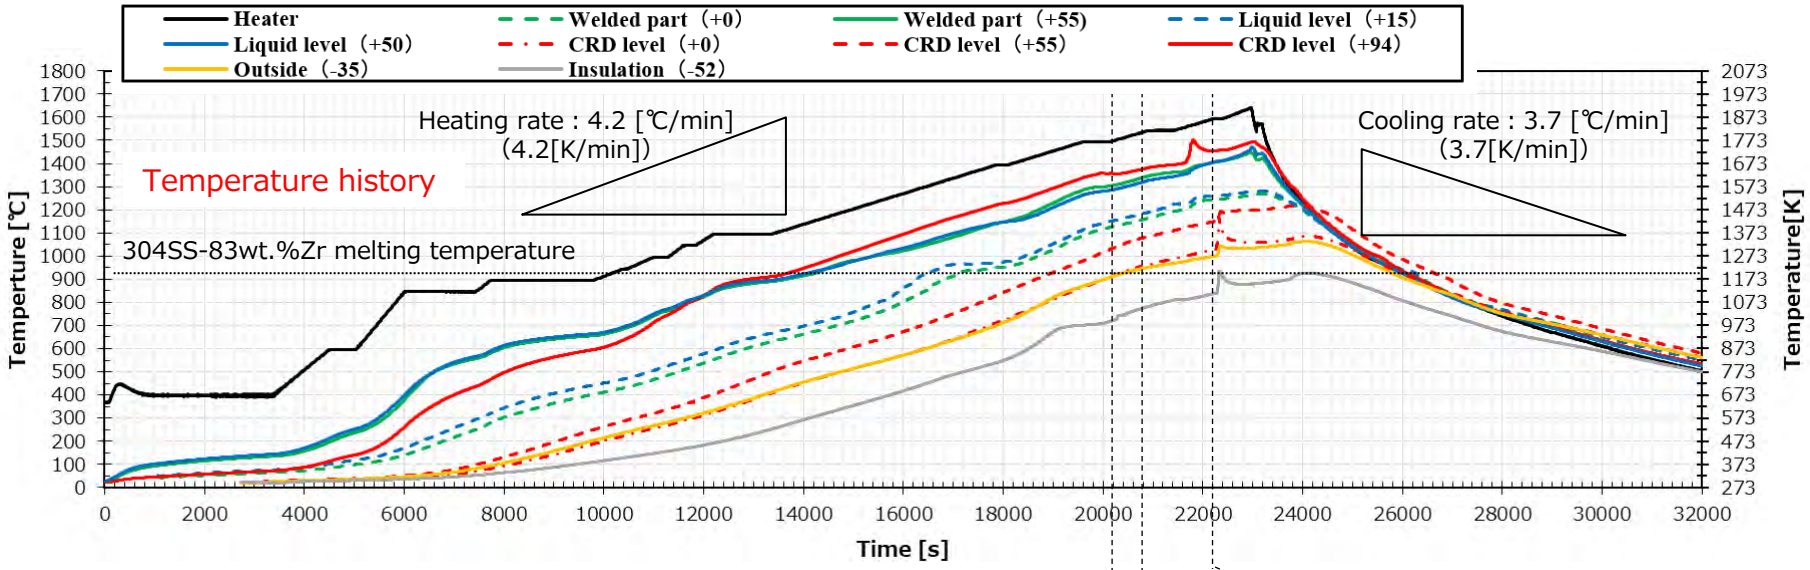
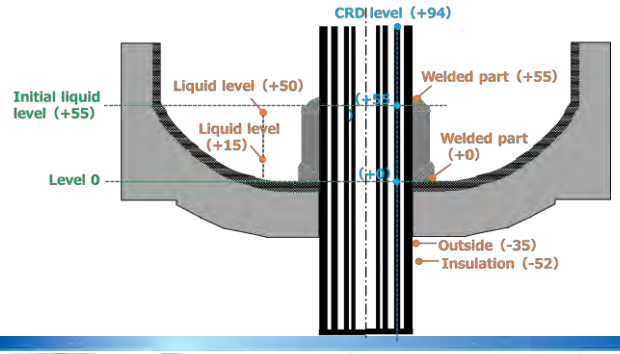
3.3 Experimental results

- During the test, temperature measurements were conducted using thermocouples installed at various locations, and observations were made using cameras installed in the test apparatus.
- The heating rate was established based on the temperature history obtained from a thermal-hydraulic analysis* of the actual reactor (Unit 2). The heating rate was set to 4.2° C/min. During the cooling phase, the temperature was reduced with a target rate of 3.7° C/min, considering the constraints of the test apparatus.



Thermocouple locations



Camera observation

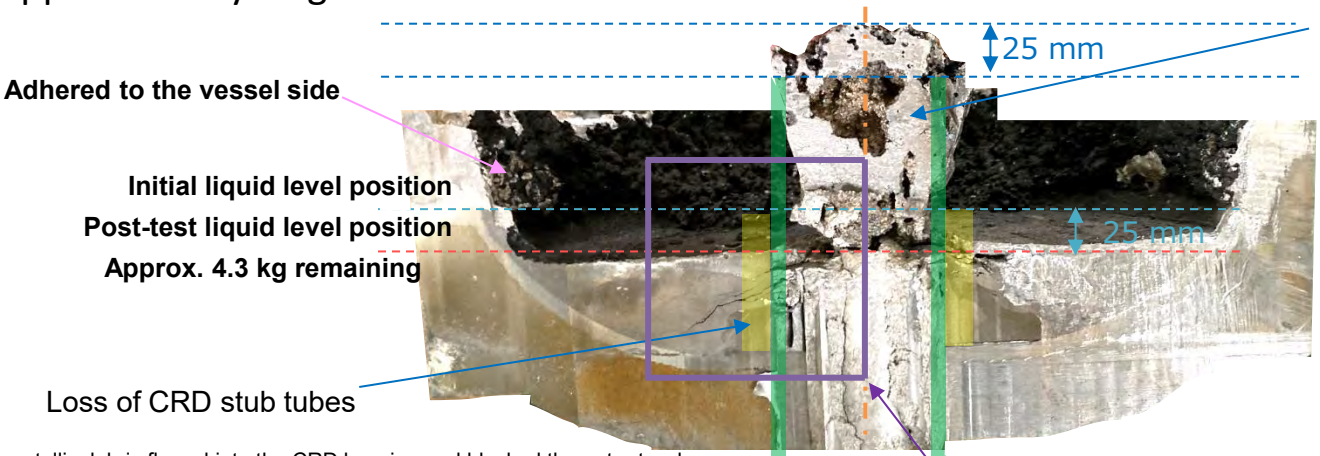
3.4 Post test observations

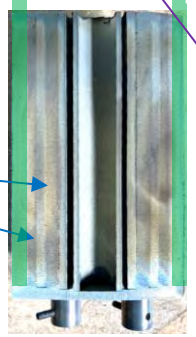
- The specimen was sectioned after the test, and the cross-sections were observed. The loss (disappearance) of the CRD stub tubes and the inflow of molten metallic debris into the CRD housings were confirmed. Additionally, it was observed that the molten metallic debris climbed the sides of the CRD housings and the specimen walls, resulting in inflow into the CRD housings and outflow from the vessel.
- The total amount of simulated metallic debris filled into the specimen was 11 kg. Based on the amount found inside the CRD housings (approx. 1.7 kg [upper part: ~0.8 kg, lower part: ~0.9 kg]) and the residual amount remaining in the vessel (approx. 4.3 kg), the amount that adhered to the vessel sides or flowed out of the vessel was approximately 5 kg.



Molten metallic debris climbed the side of the CRD housing and flowed into it. (Upper part: Approx. 0.8 kg of molten metallic debris flowed in.)

Cutting position

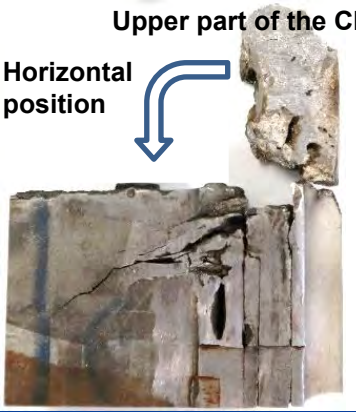
・Molten metallic debris flowed into the CRD housing and blocked the outer two layers. (Approximately 0.9 kg of molten metallic debris flowed into the lower part.)
・The temperature of the molten metallic debris at the time of outflow (thermocouple: Welded part (+55)) was approximately 1300° C (1573.15K).
・The temperature of the CRD housing (thermocouple: CRD level (+0)) was approximately 930° C (1203.15K), which is comparable to the melting temperature of the simulated metallic debris.



- Analysis was conducted over an 8 cm × 8 cm area (refer to the next page for analysis results).The upper part of the CRD housing was analyzed in a horizontal position (laid on its side) due to the constraints of the analytical equipment.

Upper part of the CRD housing

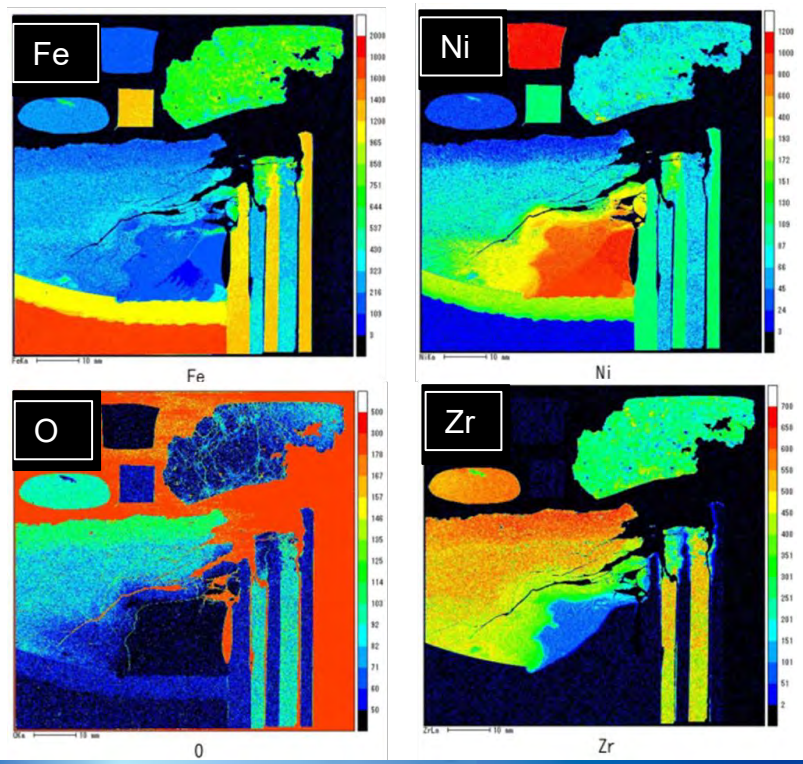
Horizontal position



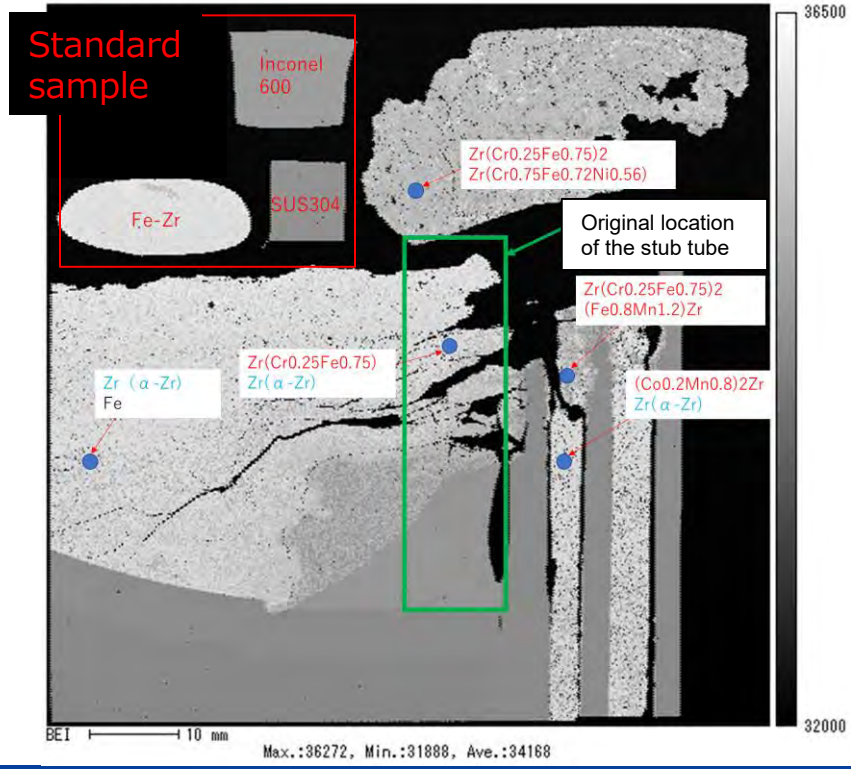
3.4 Post test observations

- EPMA analysis (target elements: Fe, Ni, O, and Zr) was performed on an 8 cm × 8 cm area of the specimen cross-section. Following the EPMA analysis, XRD analysis was conducted on the same cross-section.
- The molten metallic debris that crept up the CRD housing blocked most of the upper opening; however, the inflow from the upper opening into the CRD housing was limited due to the formation of the Laves phase at the opening.
- The upper part of the CRD stub tube melted through reaction with the molten metallic debris, leading to the migration of the molten metallic debris from the melted section.

EPMA analysis

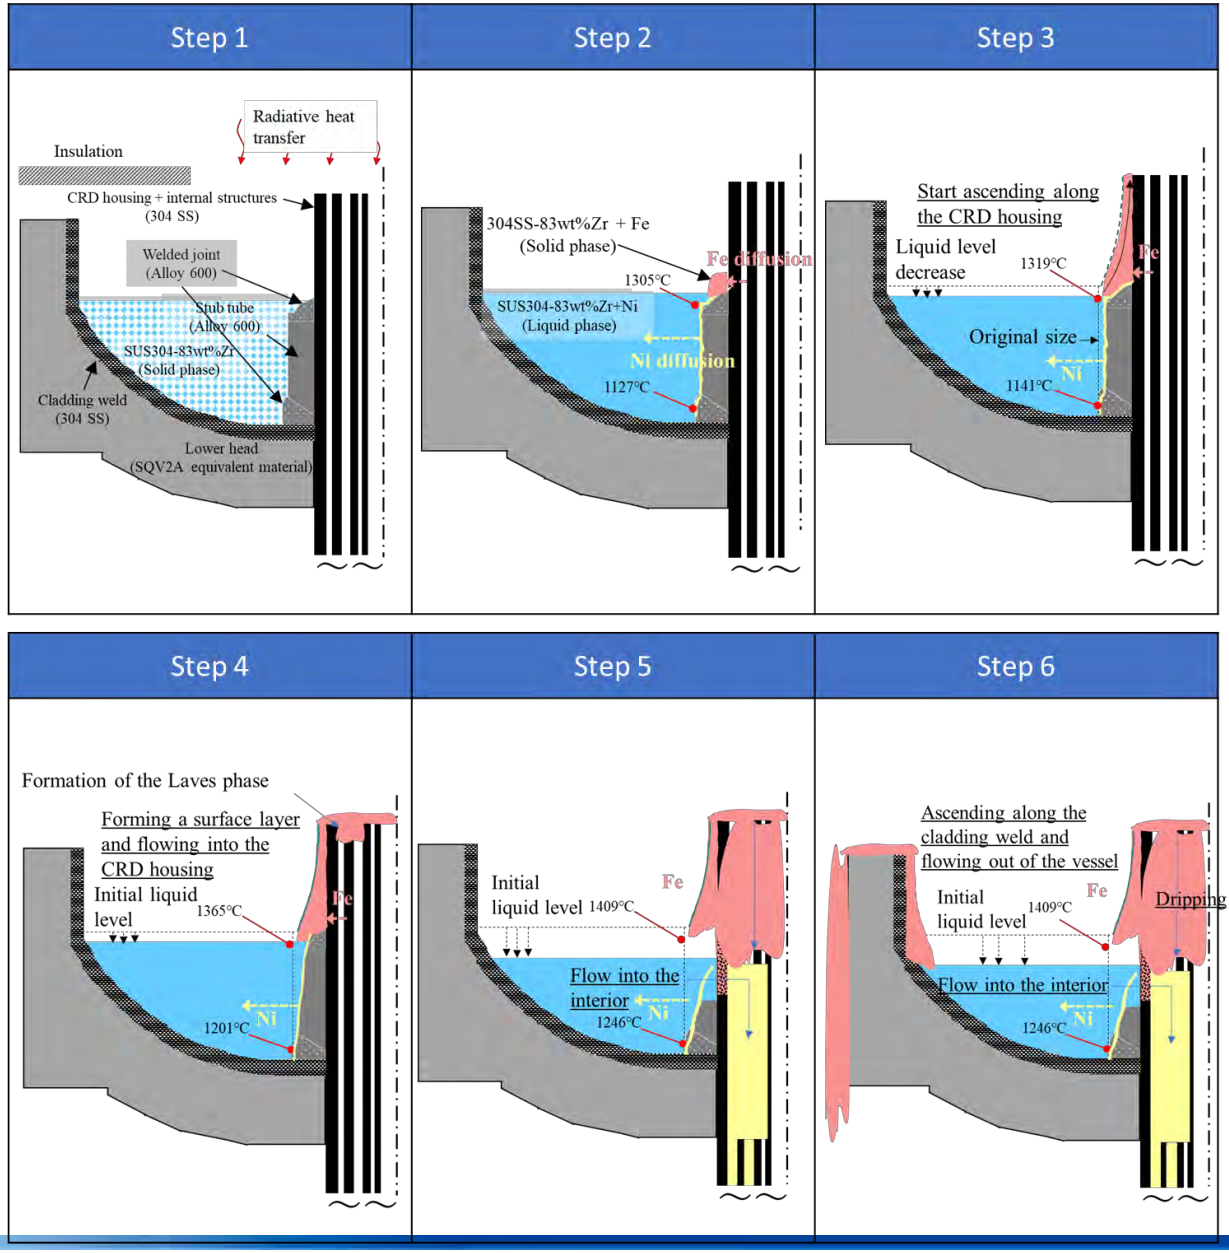


XRD analysis



4. Analysis of the results

4 Analysis of the results



5. Conclusions

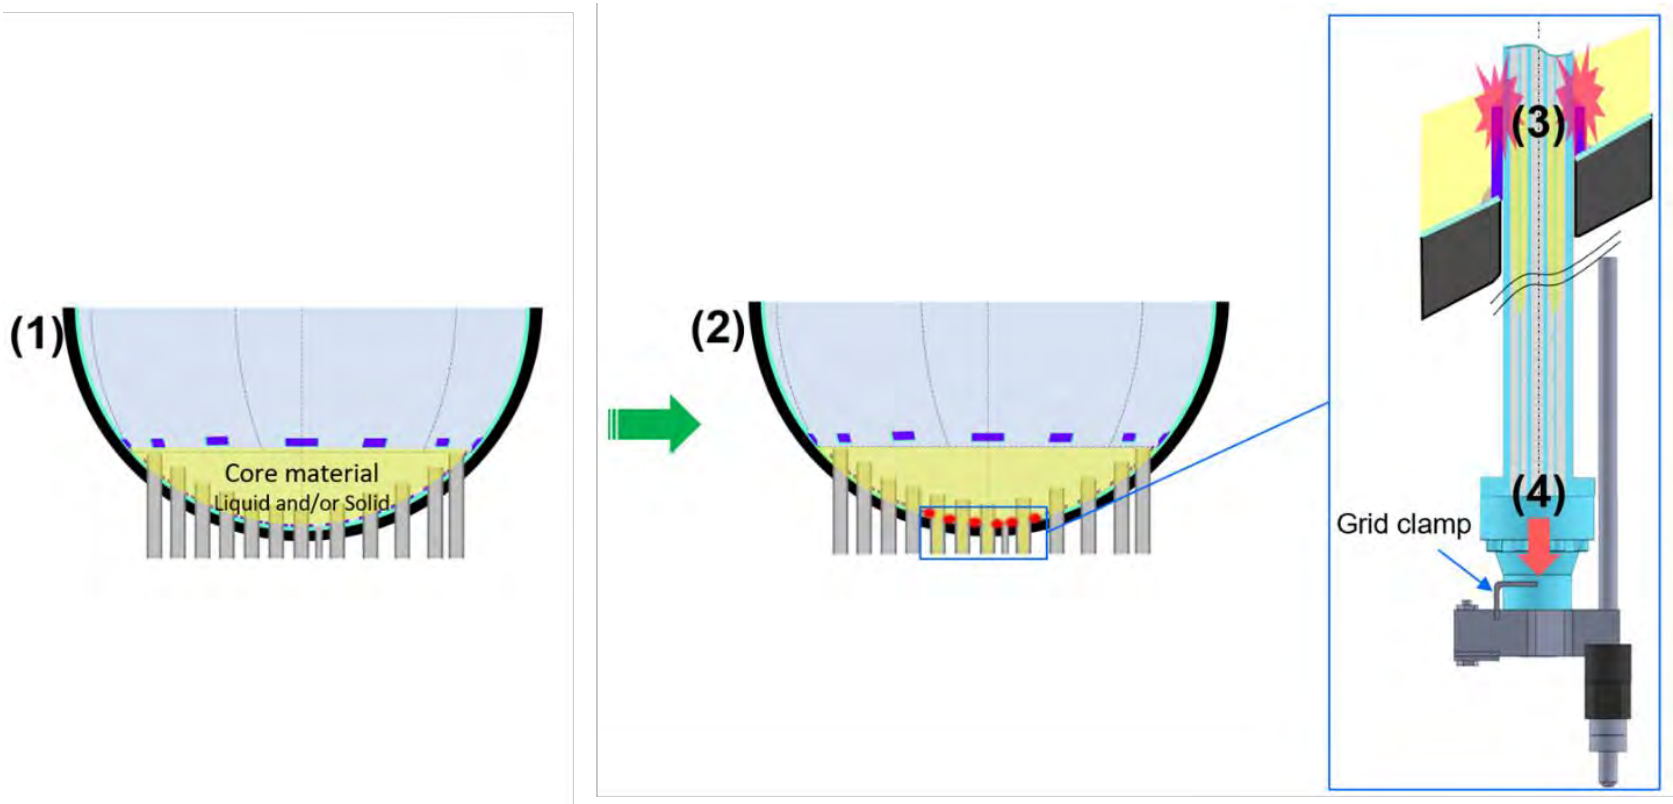
Conclusions

In addition to RPV failure modes caused by temperatures exceeding the melting point and creep rupture, it was found that the melting of internal structures at lower temperatures can lead to an RPV boundary breach.

5 Conclusions

Estimation of 1F Accident Progression

1. Zr-rich molten material relocated to the lower plenum and was reheated by fuel debris.
2. Some CRD housings and stub tubes were severely damaged due to eutectic reactions at temperatures below their respective melting points.
3. The molten material flowed into the CRD housings through the breached regions.
4. As the stub tubes melted, the load previously supported by the weld joints between the CRD housings and stub tubes was transferred to the support bars.



6. Latest topics

The internal drone investigation of Unit 3 confirmed a breach of the RPV. At the breached bottom part of the RPV, the CRD stub tubes had disappeared, and the CRD housings were found to have cleanly detached. This is considered to be due to a phenomenon similar to that observed in the ELSA-3 test.

ABSTRACT

Supercritical Water-cooled Reactor (SCWR) is the Generation IV water-cooled reactor, which adopts unique once-through direct cycle plant system. Namely, the core is cooled with once-through coolant flow as in PWR and the entire core coolant is directly fed to the turbine as in BWR, because the coolant does not exhibit liquid / gas phase change. The Reactor Pressure Vessel (RPV) is like that of PWR with no flow bypasses in the upper core and the Primary Containment Vessel (PCV) is like that of BWR with suppression chamber (S/C). Stainless-steel or other advanced materials are being considered for the fuel cladding, channel boxes. This study addresses the fast reactor concept (Super FR), which has minimal coolant inventory in RPV.

The basic safety principle of the once-through direct cycle system is that the core cooling is ensured by keeping the core flow rate at supercritical pressure and the core is effectively cooled by depressurizing RPV in managing design basis accidents (DBAs) including the Loss-of-Coolant Accident (LOCA). However, the plant concept has not been established for managing Beyond-Design Basis (BDB) accidents, such as BDB-LOCA, where all means of water injections are assumed to fail.

This study investigates the in-vessel phase of the plant behavior of Super FR during BDB-LOCAs. Following a single line break, the initial blowdown phase from supercritical pressure (25 MPa) to subcritical pressure is analyzed with ASYST code based on point kinetics and node-junction models. Then, the plant parameters were transferred to MELCOR code for the subsequent core heat-up, oxidation, degradation, slumping, up to the moment of RPV failure. Different scenarios are analyzed with focus on managing non-condensable hydrogen gas generation and PCV pressurization.

1. INTRODUCTION

As the main contribution of cost of fossil fueled fire power plants is the fuel cost, coal-fired power plants have evolved to operate at higher pressure and temperature above the critical point of water (22.1 MPa and 374℃) to improve the thermal efficiency and compensate for the large fuel cost since the 1970s. In contrast, the main contribution of cost of nuclear power is the costs of construction, operation and maintenance. Hence, the main benefit of operating water-cooled reactors at supercritical pressure is reducing such costs by simplifying and downsizing the plant system. More specifically, the nature that supercritical water does not exhibit phase change (i.e., boiling) enables elimination of all systems and components associated with separation of steam from water [1] [2].

Supercritical Water-cooled Reactors (SCWRs) are being researched and developed in Japan, the EU, Canada, China, and Russia including small modular reactor scale designs [3]. The Canadian designs adopt the pressure-tube type designs like CANDU reactors [4] while most other designs adopt the pressure-vessel type designs like BWR / PWR. Both the thermal neutron spectrum reactor and fast reactor concepts are being developed [5] [6]. The average core outlet coolant temperatures range from 400°C [7] to over 600℃ [4]. Advanced stainless steel, Oxide Dispersion Strengthened (ODS) steel, and nickel-based alloys and other high temperature alloys and corrosion resistant materials are considered as candidate materials for core structures such as fuel cladding [8].

The Balance Of Plant (BOP) of SCWR is basically the same as that of the existing supercritical coal fired power plant and the basic design concepts have been developed including startup, control, stability, transient management, Design Basis Accident (DBA) management (including Loss Of Coolant Accident (LOCA)), and Anticipated Transient Without Scram (ATWS)[1] [2]. The design concepts with passive safety systems have also been developed [9]. The Primary Containment Vessel (PCV) and Emergency Core Cooling System (ECCS) are like those in BWRs while many designs adopt PWR-like Reactor Pressure Vessel (RPV) and control rod designs [10].

Since SCWR is a pressurized system, LOCA is defined as DBA and the system must prevent large-scale core degradation and maintain a coolable core geometry during such events [10]. The key characteristics of LOCA of SCWR arise from the nature of supercritical water-cooling that water / steam separation is not needed and the system becomes once-through direct cycle, where the entire core coolant is fed directly to the turbine. As the result, there is no core bypass of coolant and large coolant flow is induced through the core in LOCA, leading to no / minimal core heat-up during the blowdown phase. Subsequently, the core is reflooded without large-scale damage when ECCS operation is assumed [11] [12].

However, studies on Beyond Design Basis LOCA (BDB-LOCA), assuming failures of all means of water injections, are limited. The preceding study on BDB-LOCA with total core meltdown developed the concept of In-Vessel Retention (IVR) of the fuel debris by flooding the RPV bottom exterior [13]. The key identified issue was managing the PCV pressure by efficient condensation of excess steam by the suppression chamber (S/C). More specifically, the key issues were reducing and evaluating the in-vessel non-condensable hydrogen gas generation due to oxidation of the core structure materials (e.g., stainless-steel fuel cladding) by steam at elevated temperature [13]. However, the preceding study mainly focused on the long-term plant behavior and did not investigate the blowdown phase and the differences between the hot-leg and cold-leg breaks.

Hence, this study aims to clarify the key characteristics and potential issues of in-vessel phase of a BDB-LOCA for a supercritical water-cooled fast reactor (Super FR). More specifically, the differences in the blowdown phase for different break locations (hot-leg break and cold-leg break) with respect to in-vessel hydrogen generation and the PCV pressure history are investigated. The ASYST code [14] was utilized to analyze the blowdown phase from the supercritical pressure to subcritical pressure. Moreover, the plant

parameters at the end-of-calculations by ASYST were transferred to MELCOR [15] code analysis to evaluate the post blowdown core heat-up phase.

2. DESIGN FEATURES AND ANALYSIS MODELS AND SCENARIOS

2.1 Core and Plant Design Features and Specifications

Super FR with operating pressure of 25 MPa and core thermal power of 2867 MWth [16] was selected as the reference design. The in-vessel design specifications were determined by referring to the earlier core design study [16] as summarized in **Table Ⅰ**. The core consists of 349 fuel assemblies with 631 fuel rods arranged in hexagonal lattice. The fuel mass and the structure (stainless-steel) mass were estimated from the available information in reference [16]. **Figure 1** describes the reactor system configurations. The compact PCV is equipped with S/C. During RPV depressurization, steam is discharged into the water of the suppression chamber (S/C) via safety relief valve (SRV) lines for condensation. The volume ratio between the drywell (D/W) and the suppression chamber (S/C) is about the same as that of ABWR [13].

Table Ⅰ. Specifications of the plant (RPV and PCV)

In-vessel design parameters [16]	
Pressure [MPa] / power [MWth] / core flow rate [kg/s]	25 / 2867 / 1906
Core inlet / outlet temperatures [°C]	295 / 433
Active height[mm]/equivalent diameter [mm]	1400 / 4840
Fuel rod diameter [mm] / gap [mm] / lattice	9.05 / 0.50 / hexagonal
In-vessel structure material / mass [kg]	Stainless steel (SS) / 21256
Doppler reactivity [10^{-4}%Δk/k/K] / coolant density [%Δk/k/(g/cc)]	-0.11 / 6.20
Other design parameters	
Line cross-section area (cold-leg / hot-leg) [m^2]	0.092 [13] / 0.27 [13]
PCV total volume / D/W volume / S/C volume [m^3]	7900 [1] / 2530 [13]/ 5370 [13]

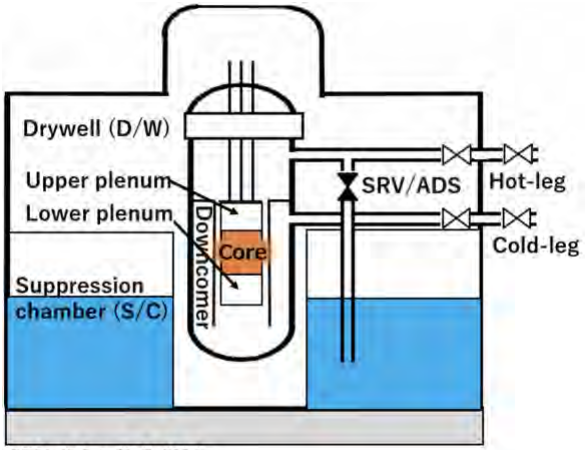

Figure 1. Configurations of the reactor system.

2.2 ASYST Analysis Models

The LOCA blowdown phase of Super FR from supercritical pressure was analyzed with ASYST code to evaluate the reactor pressure, flow rate, temperature, and power. ASYST [14] is a thermal-hydraulic analysis code based on point kinetics approximation and the node-junction method, primarily for in-vessel phase of the accident. **Figure 2** describes the in-vessel node and junctions for Super FR, where PCV is represented by a single large volume.

The critical flow from the break was evaluated using the standard Ransom-Trapp model based on the non-equilibrium gas-liquid two-fluid model [17] to consider the choking phenomena as the supercritical fluid rapidly expands and transitions into a subcritical two-phase flow at the break. In the meantime, the Dittus-Boelter correlation for single-phase forced convection heat transfer was utilized to evaluate the fuel cladding temperature at supercritical pressure and different correlations were applied under subcritical pressure depending on different heat transfer regimes, such as nucleate boiling, transition boiling, and film boiling, based on the boiling curve of the ASYST/RELAP5 code [17].

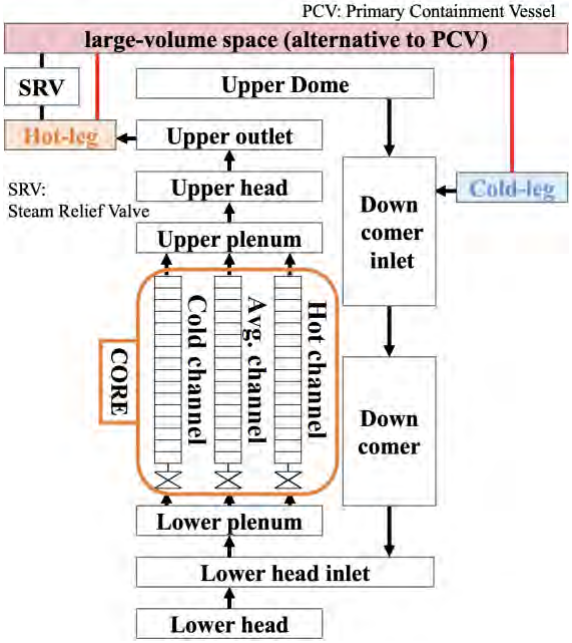

Figure 2: In-vessel node junction model (ASYST).

2.3 MELCOR Analysis Models

The thermal responses within RPV and PCV during the post blowdown phase was analyzed using the severe accident analysis code MELCOR-2.2 (Version 9541) [15]. The initial conditions for the MELCOR analysis were prepared by transferring the end of blowdown phase in-vessel thermal parameters calculated by ASYST code. Specifically, these parameters included core power, RPV pressure, fuel cladding temperature distributions, reactor water level, and reactor water temperature.

Figure 3 illustrates control volumes (CVs), flow paths (FLs) of PCV and RPV, and cell divisions of RPV used in the analysis. The active fuel length of the core was divided into 7 axial cells and 4 radial rings and one bypass ring. The lower plenum was also divided into cells as shown in **Figure 3**.

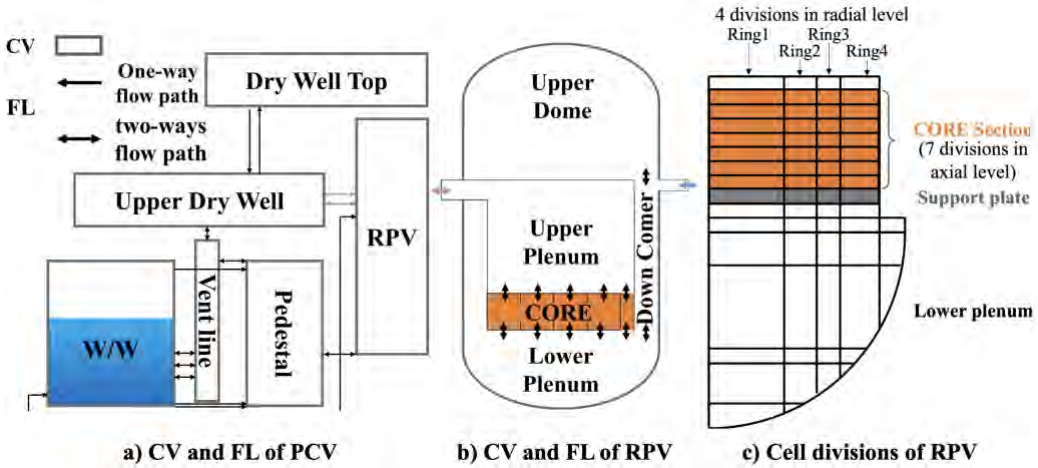

Figure 3: CV, FL and Cell divisions of PCV and RPV (MELCOR).

The oxidation reaction between stainless steel and steam during core heat-up was considered with the standard Arrhenius type rate constant above temperature (T) 1100 K as shown below.

$$K(T) = 2.42 \cdot 10^9 \exp\left(-\frac{42400}{T}\right) \quad (1700\ K > T > 1100\ K) \tag{1}$$

Then, due to lack of sufficient evidence to define specific failure conditions of the stainless steel cladded core, the default MELCOR core collapse models for stainless steel cladded fuel were adapted [15]. Namely, the intact fuel was converted to particulate debris when:
(a) the unoxidized cladding metal wall thickness reduced to the minimum threshold of 0.1 mm, or:
(b) the fuel temperature exceeded the maximum threshold of 1700 K.

Similarly, the core support plate was assumed to fail at the default MELCOR setting temperature of 1273 K [15], which would determine the moment of the slumping of the core ring being supported by the corresponding ring of the core support plate. The influences of changing failure criteria of the core and core slumping on the PCV pressure and temperature management of Super FR may be considered in future studies.

Following the core slumping, the default MELCOR quench model was applied. In this study, the hydraulic diameter of particulate debris was set to the default value of 2 mm. In the default settings, the quench heat transfer coefficient is 2000 W/m²/K until the leading edge of the falling debris reached the bottom of the lower plenum. For stationary particulate debris beds in the plenum water pool, the Lipinski zero-dimensional correlation was applied with the dry out heat flux, q_d given by the following relationships:

$$q_d = 0.756 h_{lv} \left[\frac{\rho_v(\rho_l - \rho_v) g d \varepsilon^3 (1 + \lambda_c/L)}{(1-\varepsilon)[1 + (\rho_v/\rho_l)^{1/4}]^4}\right]^{\frac{1}{2}} \tag{2}$$

where, h_{lv} is the latent heat of water, ρ_l is the water density, ρ_v is the vapor density, g is the gravitational acceleration, d is the debris particle diameter, ε is the debris bed porosity, L is the total debris bed depth, and $\lambda_c$is the liquid capillary head in the debris bed.

3. PLANT BEHAVIOR OF SUPER FR DURING BDB-LOCA

In this study, a 100% large break in the hot-leg (0.27 m²) and the cold-leg (0.0916 m²) were assumed as the two representative initiating events. Following the actuation logics of the safety systems adopted by preceding studies [18], the reactor scram signal was assumed by either flow rate low level-1 (90%) or pressure low level-1 (24.0 MPa). The signal to actuation delay of 0.55 s was assumed and scram was assumed to complete by 2.8 s after the initial break. In LOCA, the reactor scram is governed by the pressure low criterion. Then, the reactor is further depressurized by actuation of the Automatic Depressurization System (ADS), which opens all the Steam Relief Valves (SRVs) with total opening area of 0.27 m^2 when the reactor pressure has decreased to 23.5 MPa. In the standard design basis LOCA, high pressure and low-pressure injection systems are actuated with flow rate low level-2 (20%) and flow rate low level-3 (6%) or pressure level low level-2 (23.5 MPa). However, in this study, all means of water injection were assumed to fail to evaluate BDB-LOCA.

3.1. Hot-Leg / Cold-Leg Breaks

3.1.1 Blowdown Phase (ASYST)

The blowdown phase analysis results with ASYST are presented in this section. The simulation covered the period from the initial break through the reactor scram, the RPV depressurization to the subcritical pressure until 7 seconds after the break as the changes of the plant thermal parameters (power, pressure, coolant flow rate and reactor water level) with time became moderate. More specifically, the transfer timing had to have sufficient delay after the initial break so that the pressure had fallen below the critical pressure (22.1 MPa) and rapid power fluctuations due to void and Doppler effects were no more significant, because MELCOR could not treat such short-term reactivity feedbacks. By referring to the pressure and power histories shown in **Figure 4**, it seemed that the transfer timing had to be later than 3 seconds after the initial break. In this study, some extra margin was considered to wait for the plant thermal parameters to stabilize until 7 seconds after the break.

Figure 4 shows the histories of the reactor power, the RPV pressure, the reactor water level, and the core flow rate for the hot-leg and cold-leg break scenarios. Although the break area of the hot-leg was approximately three times larger than that of the cold-leg, the coolant density in the hot-leg was about one-sixth that of the cold-leg. Consequently, the results indicate that the cold-leg break leads to faster depressurization and a more rapid decrease in the reactor water level than the hot-leg break for the initial short period (less than one second) after the break.

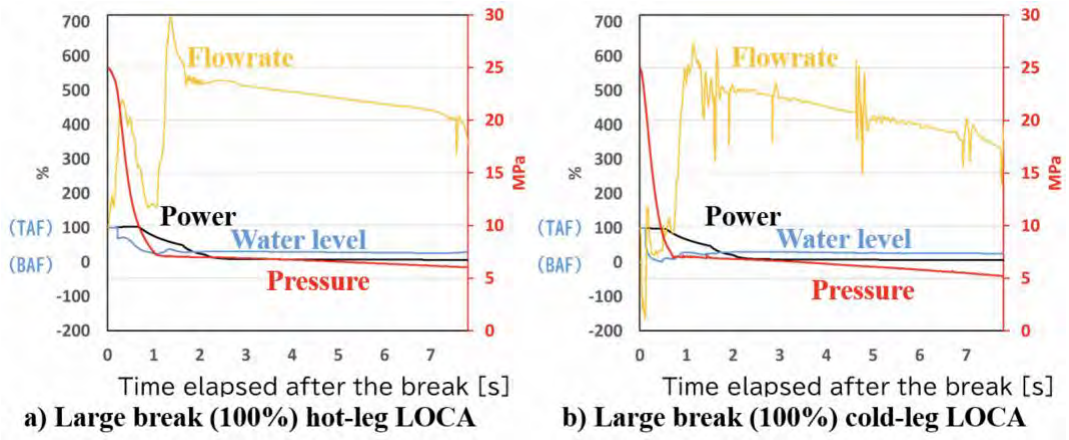

Figure 4: Core power, pressure, collapsed water level, and flow rate histories (blowdown phase).

Figure 5 shows the peak temperature histories (temperature of the 10th axial segment out of 14 divisions) of the hot channel up to 7 seconds after the break. The reactor power changes immediately after the breaks were governed by the negative coolant void reactivity coefficient resulting from the decrease in the core water level and the negative fuel Doppler reactivity coefficient resulting from fuel temperature changes. In the hot-leg break, the coolant flowed towards the break point induced a significant core flow rate (466% as can be seen from **Figure 4**), which led to reduction of the fuel temperature. Consequently, positive reactivity was inserted by the negative Doppler effect, which dominated the effect of the negative reactivity insertion by the negative void reactivity effect. As a result, the reactor power increased temporarily to approximately 103% of the rated power. Conversely, in the cold-leg break, the coolant flow towards the break point led to temporal reverse flow and flow stagnation in the core as can be seen from **Figure 4**, which led to core heat-up. Consequently, the combined Doppler and void reactivity feedback led to moderate change in the reactor power until the reactor scram. Following the reactor scram, the core temperatures in both the hot-leg and cold-leg breaks continuously decreased as the core flow rate was kept high by the reactor depressurization.

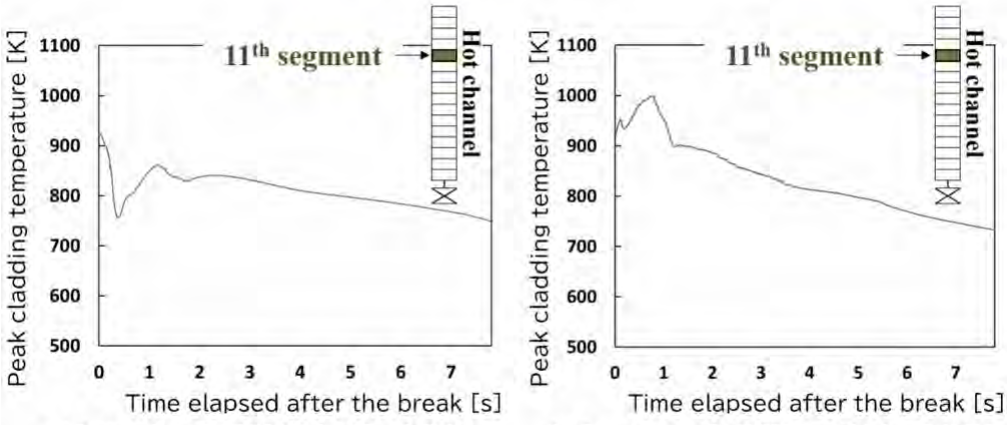

Figure 5: Fuel cladding peak temperature histories (blowdown phase).

Table Ⅱ summarizes the parameters relating ASYST results and MELCOR input at 7 s after the break. The in-vessel parameters, such as the core power, the RPV pressure, the fuel cladding temperatures, the core water level and the core water temperature were transferred from ASYST to MELCOR. However, ex-vessel

parameters, such as the energy and H_2O mass released from RPV to PCV during the 7 seconds and the initial D/W filler gas (N_2) mass swept from D/W to S/C could not be transferred or evaluated. The integrals of the in-vessel fuel decay power until the time of the RPV failures for the cold / hot-leg breaks (about 4.6 hours after the break) were about 433 / 439 GJ, while the corresponding energy transfers from RPV to PCV by MELCOR analyses were about 230 / 270 GJ. The ASYST analyses indicated that the energy released from RPV to PCV during the initial 7 seconds were about 36.0 GJ / 18.1 GJ for the cold / hot-leg breaks, respectively (corresponding to about 13.5% / 6.3% of the energy transferred from RPV to PCV from the initial line break to the RPV failure for the cold and hot leg-breaks, respectively).

Thus, the current study has obvious limitations regarding evaluation of the short-term PCV management. Namely, the current study cannot evaluate the rapid pressurization and heat-up of PCV immediately after the break. Moreover, the initial release of water / steam from the break is expected to sweep the initial D/W filler gas (N_2) to S/C. Consequently, accumulation of the non-condensable gas (N_2) is expected to reduce the S/C capability to manage PCV pressurization. The N_2 gas sweeping may be dependent on the break flow, which in tern may depend on the flow rate of the ADS line from RPV to S/C through SRVs. Since current ASYST code cannot model S/C and therefore cannot evaluate the flow rate splits between the break and the ADS line, evaluation of N_2 sweeping is not possible. Sensitivity analyses with different assumptions of post blowdown N_2 distributions among D/W and S/C may be a possible alternative evaluation for future study.

Table Ⅱ. Parameters relating ASYST results to MELCOR input (7 s after the break)

	Hot-leg break	Cold-leg break
Transferred from ASYST to MELCOR		
Core power [%]	6.71	6.67
RPV pressure [MPa]	6.18	5.51
Fuel cladding temperatures	As shown in Fig. 5(a)	As shown in Fig. 5(b)
Core water level [m]	BAF+1.16	BAF+1.20
In-vessel water temperature (saturated) [℃]	278.95	271.85
Not transferred from ASYST to MELCOR		
Energy released from RPV to PCV [GJ]	18.1	36.0
H_2O mass released from RPV to PCV [kg]	8,454	28,358
N_2 mass swept from D/W to S/C [kg]	Not evaluated	Not evaluated

3.1.2 Post Blowdown Phase without Water Injection (MELCOR)

This section presents the post blowdown phase analysis results by MELCOR using the initial parameters listed in **Table Ⅱ** (Section 3.1.1). **Figure 6** shows the core temperature histories for the hot-leg and cold-leg break scenarios at the core locations corresponding to those of the ASYST analyses (i.e., at the peak temperature elevation during the blowdown phase). As discussed in Section 3.1.1, during hot-leg break, the steam generated in the vessel flows through the core towards the break. In contrast, during cold-leg break, most of the steam generated in the vessel flows to the break without passing through the core. As the result, the post blowdown phase core heat-up rate of the cold-leg break was higher than that of the hot-leg break. Consequently, the core collapse of the cold-leg break was earlier than that of the hot-leg break.

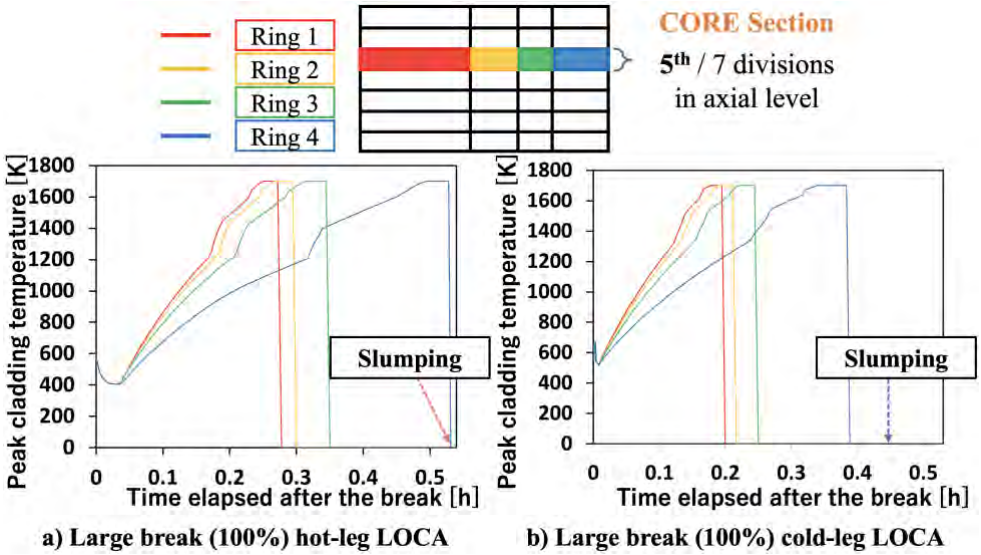

Figure 6: Fuel cladding temperature histories (post blowdown phase).

Figure 7 shows the changes in the drywell (D/W) pressure and hydrogen (H_2) partial pressure, as well as the suppression chamber (S/C) pressure and hydrogen partial pressure. As was discussed in Section 3.1.1, during the hot-leg break, the steam generated in the vessel flows through the core towards the break. Such high temperature steam flow through the core promoted oxidation of the metals (e.g., fuel cladding) within the core, increasing the H_2 partial pressure in D/W until the core slumping. Following the core slumping, large steam generation in the vessel swept H_2 from D/W to S/C. In contrast, during cold-leg break, most of the steam generated in the vessel flows through the break without passing through the core. As a result, H_2 generation before the core slumping was limited in the cold-leg break LOCA. However, following the core slumping, H_2 partial pressure in D/W increased significantly.

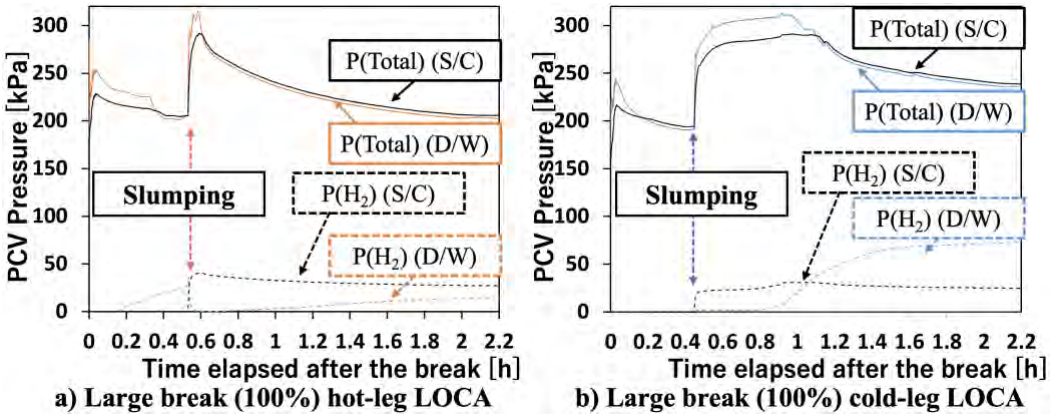

Figure 7: D/W and S/C pressures (post blowdown phase).

As shown in **Figure 8**, H_2 generation was limited after the core slumping in the hot-leg break, while significant H_2 generation is seen after the core slumping in the cold-leg break. The difference between the two cases can be understood from the histories of the H_2 generation (**Figure 8**) and the downcomer water volume (**Figure 9**). By correlating the two figures, it can be understood that in the cold-leg break, significant

amount of water is temporarily kept in the downcomer, which gradually flows down to the lower plenum, where hot fuel debris bed is oxidized between 0.45 h- 1.12 h.

The temporal reservation of the downcomer water and gradual flow down to the lower plenum may be understood from the major and minor flow paths during the cold-leg break LOCA as shown in **Figure 10**. As can be seen from Figure 10, the steam generated in the lower plenum by the core slumping has effectively no other alternatives but to flow through the downcomer, pushing the in-vessel residual water in the downcomer volume. As the lower plenum water is depleted and steam generation rate decreases, the water being pushed up in the downcomer volume may gradually flow back to the lower plenum, where hot fuel debris bed is available for water-metal oxidation reactions. Such hold-up of water inventory in the downcomer does not occur in the hot-leg break, because the steam generated in the lower plenum bypasses the downcomer to the break. Therefore, the prolonged H_2 generation after the core slumping is a unique feature of the cold-leg break LOCA of the once-through direct cycle plant system.

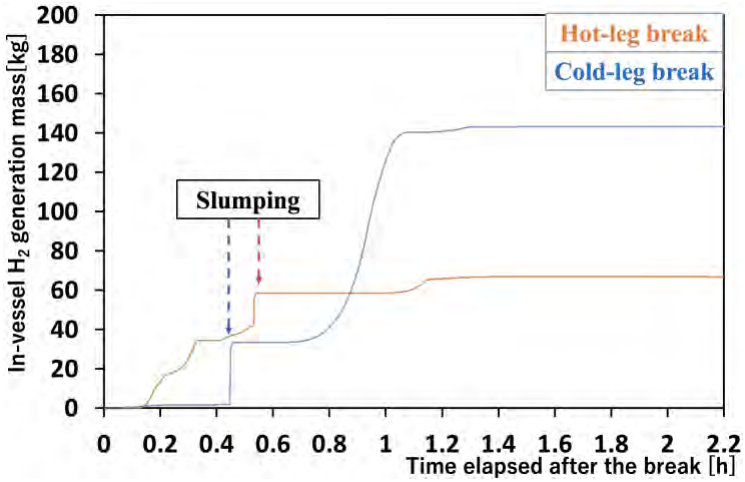

Figure 8: In-vessel H_2 generation (post blow down phase).

4. CONCLUSIONS AND FUTURE WORKS

The in-vessel phase of BDB-LOCA plant behavior of Supercritical Water-cooled Fast Reactor (Super FR) was analyzed by dividing the accident to the blowdown phase from the supercritical to the subcritical pressure and the subsequent post blowdown phase, assuming failures of all means of water injections. ASYST code was utilized to analyze the blowdown phase and the plant parameters (core power, RPV pressure, fuel cladding temperature distributions, reactor water level, and reactor water temperature) at the end-of-calculations by ASYST were transferred to MELCOR code analysis to evaluate the post blowdown core heat-up phase. The blowdown phase analysis results confirmed the same features of the once-through direct cycle plant system as identified in the preceding studies. Namely, the hot-leg break was featured with rapid core cooling as strong core flow was induced by the coolant flow to the break point through the core. In contrast, the cold-leg break was featured with moderate core heat-up until the reactor scram as the flow to the break point did not induce such large core flow rate.

The following features of the once-through direct cycle plant system have been newly identified through post blowdown phase analyses of BDB-LOCA. In the hot-leg break, H_2 generation was mainly prior to the core slumping as the steam generated in the vessel passed through the core and oxidized the core structural materials. Such H_2 generation was terminated by the core slumping. In the cold-leg break, H_2 generation prior to the core slumping was limited as the steam generated in the vessel did not flow through the core. In the cold-leg break, H_2 generation was significant in the post-core slumping phase, as the lower plenum water was pushed and held-up in the downcomer by the steam flow from the lower plenum to the break point through the downcomer. Consequently, as the lower plenum water depleted and the steam generation rate decreased, the downcomer water flowed back to the lower plenum, leading to significant H_2 generation due to oxidation of the debris bed.

Future works include investigating the effects of accident scenarios, design parameters, and analytical models on the hydrogen generation history and long-term plant pressure management. For example, it is necessary to clarify how core slumping history, break size, rated thermal power, and critical flow models affect the break flow behavior and hydrogen generation characteristics in BDB-LOCA of the once-through direct cycle plant system.

ABSTRACT

Major achievements have been made in severe accident (SA) research in the last decades. However, there is still a need for further research mainly driven by remaining gaps, new scenarios brought up by upcoming technologies (i.e., advanced technology fuels, ATF, and small modular reactors, SMR), more stringent safety requirements and optimization of SA management. At the same time, an efficient use of available resources (analytical/experimental knowhow, experimental facilities and advanced modeling approaches) should be pursued to make the most out of it. Under the frame of the EU SEAKNOT (Severe Accident research and KNOwledge ManagemenT for LWRs) project, the PIRT (Phenomena Identification and Ranking Table) methodology has been adapted to fit the full-scope SA field, based on a phenomenon pre-screening by domain (i.e., in-vessel, ex-vessel, containment and source term) sequentially coupled with a phase-PIRT process, both led by source term as top-level objective. Such an adaptation is described in this paper. From more than 400 phenomena initially, about 10% have been finally recommended as issues requiring further investigation based on their poor knowledge and their safety significance. Among them, issues related to Fukushima Daiichi accidents and associated to new upcoming technologies have been considered. This paper identifies and succinctly discusses the bases for their selection.

KEYWORDS
Severe Accidents; R&D priorities; PIRT; database and modelling.

1. INTRODUCTION

Severe accidents are known to dominate the risk associated to the commercial production of nuclear power. A vast amount of research has been done in this field after the TMI2 accident in 1979. Preservation of knowledge and know-how gathered, though, might be at stake at present because of the retirement of senior scientists and engineers and the loss of access to old archives. At the same time, innovation in nuclear technologies (i.e., SMRs and ATFs) and in severe accident analysis, i.e., Uncertainty and Sensitivity

Analysis (UaSA) and Artificial Intelligence (AI), might mean a change in the SA analysis paradigm. These factors, along with the progressive reduction of resources in SA, stand out the timeliness of critically reviewing the knowledge acquired to project a SA research roadmap that result in an enhanced understanding of accident unfolding and, consequently, an optimization of AM. A key element to achieve the goal is to involve and enable young scientists and engineers by conducting a proper transfer of both knowledge and knowhow. These are the major drivers underneath the EURATOM SEAKNOT project (GA 101060327 [1]), which is coordinated by CIEMAT and participated by a total of 16 European organizations plus 1 associated partner.

One of the instruments used to outline a SA research roadmap for the coming decade has been the PIRT methodology, which origin dates back to the times when the USNRC developed the Code Scaling, Applicability and Uncertainty (CSAU) evaluation methodology to support the application of the BEPU (Best Estimate Plus Uncertainty) methods in safety analyses of commercial Nuclear Power Plants (NPPs) (Boyack B., 1989). A PIRT is a table in which phenomena within a defined topic and scope are identified and ranked according to their importance. Soon, the PIRT proved to be useful in numerous applications (Wilson G.E., 1998), mostly within the domain of Design Basis Accidents (DBAs).

At the beginning of this century, the EU EURSAFE project (1998–2002) conducted the first-of-a-kind PIRT on SAs with a full scope. More than 1000 phenomena were identified, and a few more than 100 were considered worth of investigation, their safety significance being substantial and the knowledge about them lacking [4]. More recently, in 2015, a Source Term (ST) PIRT based on findings from the Fukushima Daiichi NPP accident identified almost 70 phenomena and ranked at the top the radionuclide release from molten fuel in the early phase of the accident and the Molten Core Concrete Interaction (MCCI) and iodine chemistry in the late phase [5]). Three years later, in 2018, the results of a PIRT dedicated to Spent Fuel Pool (SFP) related accidents were published; out of the eighteen phenomena highlighted as having priority for research, roughly half were related to fuel rod performance under SA conditions [6]. In 2020, the PIRT approach was employed to identify the relevant physical phenomena that computer codes should include for a proper representation of In-Vessel Retention (IVR) of corium during SAs [7]. The most recent research priority ranking conducted in Europe, with a marked qualitative nature, addressing the full SA domain dates back on 2019 [8]; nevertheless, this study cannot be considered a PIRT exercise.

The next sections describe the major outcomes of the PIRT application to the entire domain of SAs, including new technologies like Water-Cooled SMRs (WC-SMRs) and ATFs, under the frame of the SEAKNOT project. For a better contextualization, a synthesis of the methodology adaptation is given before presenting the results.

2. THE PIRT APPROACH

The PIRT is the backbone of SEAKNOT. Along with a database collection (WP2) and a European experimental infrastructure mapping and critical analysis, the PIRT is one of the essential ingredients to write up a research roadmap for the short- and mid-term (5-10 years) on SA. Generally speaking, the PIRT has been grounded on State Of the Art (SOAR) reports recently issued, previous global and partial PIRT exercises mentioned above, and the outcomes of open research projects since practically the beginning of this century (see the extensive list of references in this paper).

2.1. PIRT Adaptation

The first step when facing a PIRT on SA is to adapt the work initially proposed in the field of thermal-hydraulics and Design Basis Accidents (DBA) [2] to the SA domain. Even if a few applications in the SA domain have been already reported (as mentioned above), most of them were restricted to specific systems

and scenarios. The SEAKNOT PIRT extends over the entire SA domain, including in-vessel, ex-vessel, containment, and source term areas. Likewise, WC-SMRs and near-term ATFs are being also considered.

The specific problem this PIRT addresses is the identification of the SA issues which research would lead to better characterize and, if possible, reduce uncertainties, as well as to efficiently enhance mitigation of SA consequences. The focus is on the potential effect of the issues on source term (i.e., radiological releases from the Nuclear Power Plant, NPP). The specific variables monitoring such an effect are: onset time, rates and composition of the releases to the environment of a selection of radionuclides (I131; I132; Cs137; Ru106; Te132; Kr88; Xe133; Xe135). In other words, those variables for the given isotopes were the bases of the evaluation criteria.

The drastic difference expected in source term between the in-vessel and the ex-vessel phases recommends to split accident sequences accordingly. The PIRT was developed in two sequential steps: domain-PIRT and phase-PIRT. In the domain PIRT, the SA domain was split into sub-domains: in-vessel core degradation; ex-vessel corium behavior; containment and source term. The first task in each of them was the phenomenon identification, which on purpose was separated from the ranking process. Note that in the case of containment and source term, some phenomena were dealt with twice in case they played a role in both accident phases (i.e., in-vessel, in-V; and ex-vessel, ex-V). Once all the phenomena considered relevant were listed, the ranking stage was launched.

Ranking consisted in assessing the relative importance of phenomena (sometimes processes) with respect to the evaluation criteria noted above. The research priority was assessed based on existing knowledge and safety significance of each phenomenon; each of these concepts split into three levels (i.e., low, L; medium, M; high, H). Knowledge was weighed on data availability and representativeness, and modeling maturity; as in the case of priority, three levels were set to both data and models. Figure 1 shows how knowledge and safety significance were combined to define priority. It was high priority (H) whenever knowledge was poor (L) and safety significance was high. Low priority was attributed whenever safety significance was low and/or existing knowledge was high. The rest of cases (3) was given a medium ranking level but ordered by priority: the maximum (M1) given to high safety significance and the minimum (M3) to mid-impacting phenomena on which there was some knowledge.

		Safety Significance		
		Low	Medium	High
Knowledge	Low	L (Poor understanding; irrelevant)	M2 (Poor understanding; mild effect)	H (Poor understanding; impacting)
	Medium	L (Some understanding; irrelevant)	M3 (Some understanding; mild effect)	M1 (Some understanding; impacting)
	High	L (Sound understanding; irrelevant)	L (Sound understanding; mild effect)	L (Sound understanding; impacting)

Figure 1. PIRT ranking

In Figure 2 the structure of the table used to list and rank phenomena is displayed. Even if minor differences might exist between the four sub-domains, all of them included this minimum information: a reference number; a phenomenon name; a short description; its potential link to a system or a component; the accident phase, since some phenomena might be present only in one of the accident phases (i.e., in-V and ex-V) of the accident or even if they extend over both phases the boundary conditions might be notably different; the ranking boxes; and, very important, the references supporting the associated ranking.

					Knowledge		Safety Significance	Priority		
Ref. Number	Phenomenon	Short Description	Comp/ Sub-system	Accident Phase	Data	Model			Refs.	
C-1	Homogeneous steam condensation	Phase change of steam in a gas atmosphere driven by a local oversaturation	N.A.	In-v	H	M	L	L	D M	[1], [2] [3]
ST-1									D M	

C-Containment; ST- Source Term; In-v – In-vessel; Ex-v – Ex-vessel; N.A. – Not Applicable

Figure 2. Basic PIRT template

At the end of the domain-PIRT, the results coming from each specific sub-domain were merged into the accident phase perspective (the phase-PIRT stage). To do so, the ranking given in each sub-domain was reviewed to make sure each phenomena considered H-ranked, still kept that condition when examined from the accident phase perspective. This allowed cross-checking the previous rankings and gave the opportunity for a more uniform ranking over the different sub-domains. To practically articulate this phase-PIRT, the final ranking was done through a specific template which main inputs, once the phenomena shortly described, were: information still lacking; connection with source term; and, safety significance. Needless to say, for each of them credited references were requested.

Figure 3 displays the whole flowchart described in the previous paragraphs showing at the top the source term integral equation as the final objective of the SEAKNOT PIRT.

As a very last step, the final set of H-ranked phenomena were submitted to an external revision. The reviewer group consisted mostly of regulators and TSO (Technical Support Organization) experts on SA, but also representatives of international organizations, like NEA (Nuclear Energy Agency) and IAEA (International Atomic Energy Agency), with activities on SA and nuclear safety. They were supposed to raise criticism on each specific phenomenon they do not agree with for any reason, and were also requested to support their rationale with credited references.

2.2. PIRT limitations

The PIRT methodology is a structured way to identify and prioritize phenomena based on the existing knowledge and safety importance, which makes it a useful tool for the final purpose of the SEAKNOT project: to outline a SA research roadmap for the next 5-10 years. However, the best use of PIRT outcomes requires not just to know its potential but also to be aware of its limitations:

- Correctness of PIRT outcomes is conditioned by the field it is applied to. PIRT is heavily based on knowledge. While it is true that a vast knowledge has been grasped on SA since the first accident in a commercial NPP (TMI-2), it is not less true that SA scenarios are intrinsically uncertain and the more the scenario evolves the less known the NPP state. Therefore, the accuracy of PIRT outcomes in SAs are by far more questionable than those coming from other domains, like DBA. Awareness of this is indispensable for the right consideration of the SA PIRT results.
- Accuracy of PIRT outcomes decreases with extension of its scope. In other words, the more focused the PIRT on a specific scenario, the better assessment should be expected. However, at the same time, addressing “individual pieces of a puzzle” hinders a cross-comparison of phenomena importance among SA sub-domains, which is the purpose of this PIRT. Hence, one should be aware that a broad scope hinders an accurate assessment of the relative importance. In terms of scenario scope, SEAKNOT dig down to sub-domains, but not any deeper. This conditioned its accuracy.

- Expertise is not “a cheap commodity to get”. Expertise is the main working tool of a PIRT. Two key pillars of a PIRT are associated to it: knowledge level and perspective diversity. SEAKNOT paid attention to both from the very beginning. The level of expertise depended mostly on the project partners (17 organizations, all of them familiar with SA) and they were responsible for appointing individual experts of their staff to each specific sub-domain panel. Diversity was given a major importance since the project conception. Bringing entities with different perspectives and mind-sets (i.e., academia, research, industry, regulators, …) into the project and ensuring their involvement, were the ways devised to achieve a sound critical assessment, unbiased by the lack of sufficient background or by the “research inertia” of keeping “business-as-usual” (i.e., SA research).

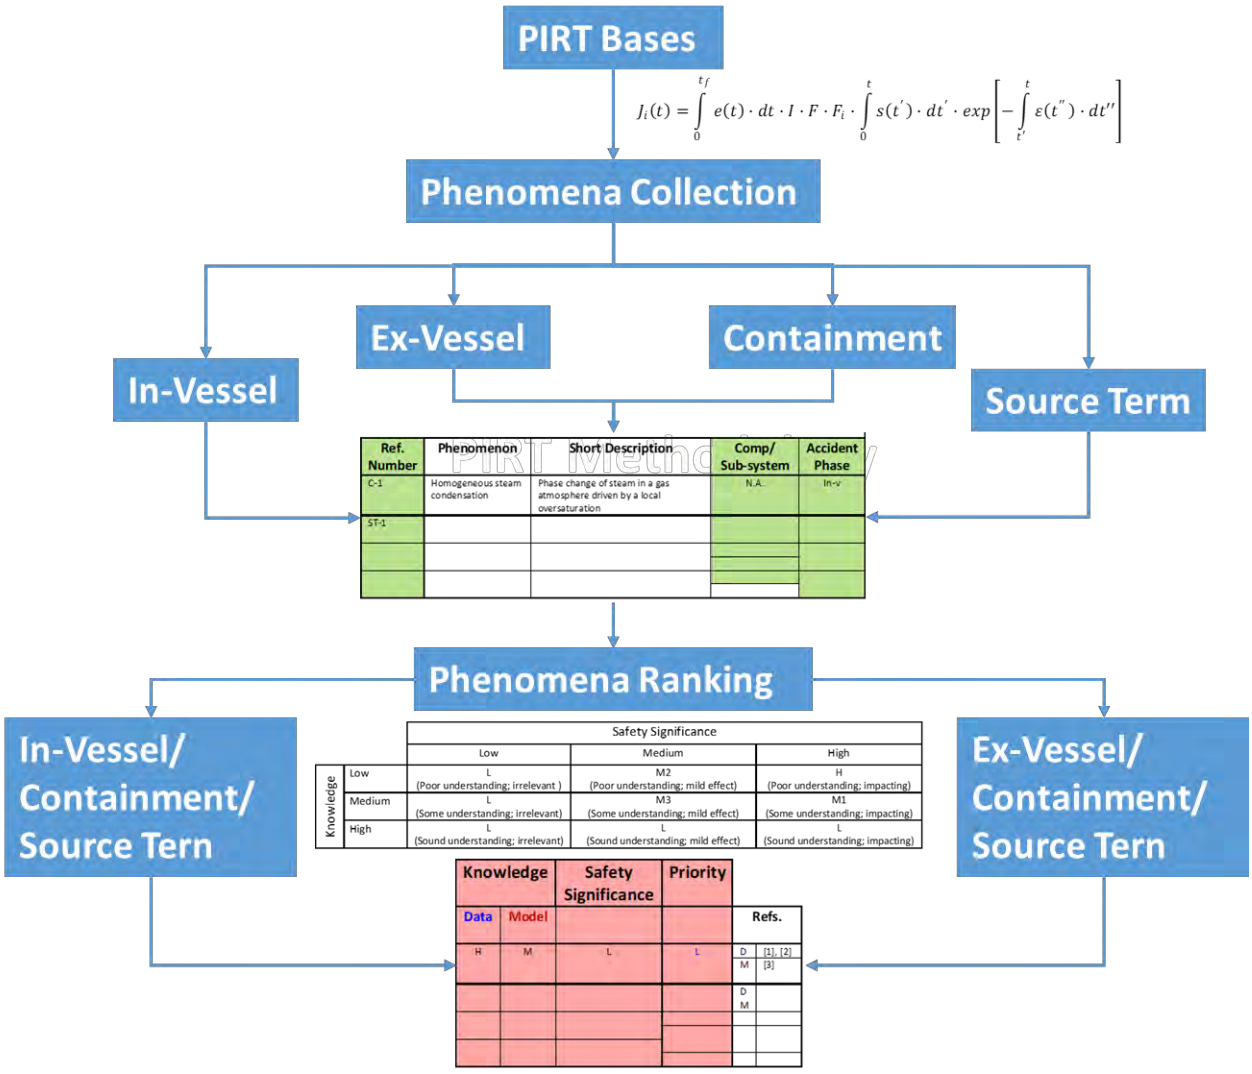

Figure 3. Flowchart of the SEAKNOT PIRT

- Practicalities in the application of the PIRT methodology adaptation. No matter how accurate and thoroughly described the methodology is, different interpretations in its application always come up whenever PIRT needs expert grouping. SEAKNOT suffered from this heterogeneity and that was one of the reasons behind the double review in the phase-ranking step. Nevertheless, some of that heterogeneity persisted to the end. Just an example, some sub-domains accepted new phenomena (coming with new technologies or recent observations from Fukushima) as a driver for investigation, even if there was not any proof of their potential impact. This was due to the misconception that anything outside the PIRT would be excluded from the final SA research roadmap.

In short, important limitations have been experienced when applying the PIRT methodology in SEAKNOT. Nevertheless, two main instruments have been used to deal with them: awareness, which did allow reducing their impact as much as feasible while developing the PIRT; and, flexibility in the PIRT reading, which will guide the integration of the outcomes in the final research roadmap to be produced within the SEAKNOT project.

3. PRELIMINARY OUTCOMES

According to the last phase of the PIRT process, the major outcomes will be split into in-vessel and ex-vessel phases. Whenever the same phenomena were selected in both phases, the new features will be highlighted in the ex-vessel section. Note that the word “preliminary” is added in the title of this section because at the time this paper is written the external review of the PIRT process is still pending.

3.1. In-Vessel phase

The In-Vessel phase aims at ranking the physical phenomena/processes mainly affecting source term occurring in the Reactor Pressure Vessel (RPV), containment, and source term domains’ path. As described in Chapter 2, just those phenomena/processes ranked high are described next.

3.1.1. In-Vessel domain

Initially, this sub-domain was divided to list the phenomena to consider into: core degradation, reflooding, corium behavior in RPV (Reactor Pressure Vessel) bottom head, RPV integrity and RIA (Reactor Initiated Accidents). A total of almost 200 phenomena were listed. By applying the PIRT methodology, as described in section 2, only 4 H-ranked phenomena were finally considered (Table I).

Table I. In-Vessel domain: High-ranked phenomena

#ID	In-vessel scenario	Phenomena
InV-1	Reflooding of a degraded core	Geometrical configuration of the degraded core (in between rod-like and molten pool)
InV-2	Lower head molten pool	Kinetics of segregation & stratification of materials
InV-3	Lower head molten pool	Crust thermal-mechanical behavior
InV-4	RPV failure under ERVC	Mechanical resistance of RPV wall

The beneficial impact of reflooding a massively degraded core might be compromised by channels blockage. Integral experiments to support thorough model validation are lacking, and scaling up from small tests to reactor cores is uneasy [9]. There are still discrepancies on some key phenomena for accident unfolding, like quenching efficiency [10-14]. In the same scenario, some codes predict a fast and complete quenching,

while others highlight the existence of non-coolable regions in the core. The effect on source term is associated with the extension and kinetics of metal oxidation [13,14], whose corresponding enthalpy release would entail higher in-core temperatures and a larger and faster fission product release from the core [9,15]. Additionally, from a safety perspective the amount and kinetics of hydrogen released and the entire in-core evolution (amount of molten corium reaching the lower head) might affect the containment and RPV bottom head integrity, respectively.

High temperature (over oxide melting temperature) molten pools in the RPV bottom head involve two immiscible liquid phases of oxides and metals. Their stratification is heavily impacted by the migration kinetics of the quaternary system U-O-Zr-Fe elements. Despite the analytical developments [16,17] and experimental work (e.g., MASCA [18], CORDEB [19], and CORDEB2 [20]), there is still a lack of high-temperature prototypical experimental data. Despite the indirect impact on source term, a more accurate description of these molten pools might largely affect the thermal-mechanical behavior of the integrity of the lower head (high safety relevance), affecting both the onset of the ex-vessel phase of the accident (if it happens) and the magnitude and kinetics of material downloaded in the reactor cavity, if RPV eventually fails.

The TMI-2 post-accident investigations revealed the significance of the crust thermal-mechanical behavior [21, 22]. Crust modelling is accounted for in mechanistic codes and in some LP integral codes like ASTEC and MELCOR [23, 24]. Nevertheless, crust effects on core degradation dynamics are not considered due to the lack of integral experimental data. A key issue is the molten steel relocation and the interaction of species through the oxide crust, which directly impact the maximum heat flux in transient situations in the lower plenum, so affecting the RPV wall degradation and the RPV integrity. The potential of a crust breach and a massive in-vessel corium relocation into the lower plenum would lead to a pressure peak, a sudden increase of hydrogen production and additional fission product release [25].

Behavior of thinned out RPV lower head walls under large temperature gradients (ex-vessel cooling, ECVR) is highly uncertain, as concluded in the H2020 IVMR project [10, 26] and the subsequent IAEA CRP J46002 one [27]. There is still a lack of integral experimental data and predictive modelling of partially ablated walls under ECVR conditions. The safety significance is related to the loss of RPV integrity and, as a consequence, the onset of the ex-vessel phase of the accident. In other words, any potential source term resulting from the ex-vessel phase of an accident would be prevented if the IVMR-ERVC strategy would support considering RPV failure practically eliminated in flooded cavity conditions.

3.1.2 Containment domain

The containment domain mostly deals with thermal-hydraulics, which is a field vastly addressed by investigation since the onset of nuclear power back in the 1960s. In other words, it is hard to find out issues where no experimentation or modeling have been attempted over the past decades. Given the condition for an H-rank knowledge (i.e., no “representative” data and no “capable” model available), that were apparently not considered as being fulfilled by the majority of the contributors, the phenomena considered here strictly correspond only to the M1 (“medium high”) classification (but are still referred as “high priority” compared to other phenomena). Thus, phenomena considered highly safety relevant with some necessary knowledge still missing have been brought up (Table II). Out of more than 50 phenomena, the ones considered worth for further investigation boiled down to 4.

Table II. Containment domain: Highly ranked physical phenomena

#ID	Accident phase	Physical phenomenon
Ct-1	In-Vessel, Ex-Vessel	Gas combustion
Ct-2	In-Vessel, Ex-Vessel	Spray mass and energy exchange
Ct-3	In-Vessel, Ex-Vessel	Buoyancy/heating from structures
Ct-4	In-Vessel	Filtered containment venting system dynamics

In-containment combustion of hydrogen [28] generated in the reactor core by oxidation of core materials (mostly Zr alloys) would increase pressure [29]. Under certain conditions (fast deflagrations and detonations), the resulting dynamic pressure loads may have the potential to damage safety systems or even containment structures. If pressure increases beyond the containment design threshold, containment integrity might be even compromised (loss of final barrier of the defense-in-depth concept). The direct effect on source term would be through the paths opened between containment atmosphere and environment, in case of loss of containment integrity; and, indirectly, if combustion affects the performance of some mitigation systems and vice versa within the containment. Experiments conducted so far were not as representative as needed: initial homogeneous atmospheres (not likely in severe accidents) and lack of systematic variation of conditions (hydrogen and steam concentration, atmosphere structure), except in the THAI programs [30]; very few tests explored the transition from deflagration to detonation (DDT) (the effect of realistic geometry characteristics on flame acceleration was only generically investigated) [31, 32]. Existing models provide satisfactory results in terms of pressure and temperature, but a poor characterization of spatial flame propagation. This is the main reason for the high-priority ranking of this process.

Even though, in-containment combustion might happen during in-vessel and ex-vessel phases, major differences do exist:

- Combustible gas generation rate (due mostly to molten core-concrete interaction - MCCI) during the ex-vessel phase is much slower, although it usually lasts much longer.
- In addition to hydrogen, carbon monoxide (CO), which is also a flammable gas, is being generated due to MCCI.
- In case of PARs installed within the containment, oxygen starvation might happen in the ex-vessel phase and prevent combustion from occurring.

Containment sprays are a source of coolant droplets, dispersed from a high elevation in the containment over the maximum possible fraction of the containment atmosphere and then freely falling down due to gravity [29]. Sprays might be actuated following discharge from the primary system to depressurize the atmosphere by steam condensation on droplets (mass exchange) and to cool the atmosphere (energy exchange). Momentum exchange also plays a role, as the downward motion of droplets causes mixing of the containment atmosphere. Finally, the washing down of aerosols from the containment atmosphere decreases the maximum amount that may eventually leave the containment, thus influencing the source term. On the other hand, condensation of steam caused by sprays may cause such a decrease in steam concentration in the containment that the atmosphere becomes flammable due to corresponding increase of hydrogen and air concentration. The reason for the high-priority ranking of this process is the deficient theoretical modelling [33-36] as perceived by the contributors, in spite of various performed experiments [36, 37]. Apparently, there is a lack of systematic experimental parametric studies within the same facilities, where the spray mass flow rate and the spray droplet parameters would be varied, and which would be suitable for further model development.

In the ex-vessel phase, sprays are more likely to be used, as a significant amount of fission products in the containment atmosphere is expected. However, as an excessive increase of flammable gas concentration may also occur due to intense steam condensation, such options should be studied individually case by case.

In any containment, there are some systems with relatively elevated temperature due to the operation of the plant, resulting in "hot" structures in contact with the atmosphere. This may heat the atmosphere locally, first inducing transport due to buoyancy and then circulation in the entire containment volume. Also, the containment atmosphere might become (locally or globally) superheated. In general, gas transport within the containment may mix the containment atmosphere and prevent the formation of regions with high concentrations of flammable gases (the opposite case, that is that gas transport within the containment could lead to formation of regions with high local hydrogen concentration, which increases the probability of combustion, is theoretically possible but not likely). Superheated gas may also cause degrading of in-containment sensors, cables and safety systems. The reason for the high-priority ranking of this process is that the agreement between experimental [38, 39] and theoretical (simulation) [40, 41] results is not as good as could have been expected (as buoyant flow is a basic phenomenon that has been modelled since the beginning of research in fluid mechanics). At present, the main reason seems to be the deficient modelling of turbulence. This phenomenon is expected to become gradually less significant during the ex-vessel phase due to the gradual cooling of structures.

Venting of the containment through the Filtered Containment Venting System (FCVS) causes an outbound flow from the containment, which in turn induces circulation of the containment atmosphere. Gas transport within the containment, induced by venting, may lead to mixing and prevention of the formation of regions with high local hydrogen concentration (as already stated before, the opposite effect is not likely). However, due to lack of specific experiments, flow dynamics induced by the venting are mostly speculations [42-44]. This, as well as the perceived lacking in theoretical modelling, are the reasons for this process to have been assigned a high priority. This priority was assigned in the in-vessel accident phase, probably as this is the phase during which the highest hydrogen concentration is expected, eventually leading to hydrogen combustion (as occurred in the Three Mile Island-2 accident in the USA in 1979), so that venting would be most beneficial in preventing hydrogen explosion (which is related to safety and source term as described earlier).

3.1.3. Source Term domain

Within the source term domain, a total list of 56 phenomena has been identified, most of which related to both the In-vessel and Ex-vessel phase. These phenomena link to the release of gaseous and particulate fission products from the intact and deteriorated fuel (in-vessel), their transport, chemical reactions and aerosol behavior within the RCS and the containment as well as their potential release via containment leaks and breaches. By applying the PIRT methodology, 2 H-ranked phenomena were considered (Table III).

Table III. Source Term domain: High-ranked phenomena

#ID	In-vessel scenario	Phenomena
ST-1	Full/partial core degradation	High-burnup and MOX FP release characteristic
ST-2	FP release by intact geometry	FP release from Fuel – ATF

High-burnup UO_2 and MOX fuels show significantly enhanced release of semi-volatile and low-volatile fission products compared to standard UO_2, as demonstrated by the VERCORS/VERDON programs [45,46,47]. Altered release kinetics have also been observed for volatile fission products, indicating a strong dependence on fuel composition during in-vessel severe accident conditions from early to late phases. Available data are scarce and limited to a few dedicated programs, many of which are not publicly

accessible. Current models are mainly developed and validated for standard UO_2 fuels and only poorly address MOX and high-burnup effects, resulting in notable uncertainties [48]. The phenomenon is relevant for both current and advanced reactor designs and may also indirectly affect residual decay heat through the release of specific fission products.

Fission product release from doped UO_2 accident-tolerant fuels (ATF) in intact geometry during the early in-vessel phase is of high safety relevance. While several dopants (e.g. Cr, Al, Si, Ti, Mo) are known to improve fuel performance, experimental data on FP release, speciation, and chemistry remain scarce, particularly under accidental conditions. Existing databases are limited, and most models are developed for standard UO_2 and are poorly validated for doped fuels [49,50]. OECD/NEA FORESEEN will focus on the Cr dopant behavior and might impact the PIRT rating in future [51]. Key knowledge gaps include the lack of systematic data on dopant effects on FP retention and release, limited understanding of FP–dopant chemical interactions, and insufficient coverage of normal and accident conditions. Chromium-doped fuels are a particular focus of ongoing and future OECD/NEA activities, but current experimental evidence on volatile FP behavior (e.g. Cs, I) is very limited. Indirect effects on the source term are expected through altered FP chemistry, aerosol formation, and transport, potentially affecting cesium and iodine behavior.

3.2. Ex-Vessel phase

As the previous chapter did with the In-Vesssel phase, this one aims at ranking phenomena heavily impacting source term once RPV integrity has been lost. Next, just the H-ranked phenomena are succinctly described along with the rationale supporting their consideration.

3.2.1. Ex-Vessel domain

A total of almost 48 phenomena were listed. By applying the PIRT methodology, as described in section 2, 5 H-ranked phenomena were considered (Table IV).

Table IV. Ex-Vessel domain: High ranked physical processes

#ID	Ex-Vessel scenario	Phenomena
ExV-1	"Wet" RPV failure location (bottom vs. side)	Fuel Coolant Interaction (FCI) and steam explosion: oxidation & solidification during corium premixing & fragmentation
ExV-2	"Wet" RPV failure (water in the reactor pit)	"Stratified" Steam Explosion (SSE)
ExV-3	Molten corium concrete interaction (MCCI)	MCCI at large scale (~5 m reactor pit)
ExV-4	Long term MCCI	Vertical/horizontal melt through (radiological consequences)
ExV-5	Degraded reactor pit after MCCI	Concrete disappearance (standing rebars)

During FCI, the premixing/jet fragmentation step remains partially known whereas it strongly impacts steam explosion energetics and even, in case of no steam explosion, corium debris bed formation and its coolability [52,53]. Oxygen sub-stoichiometric or metallic corium melt might strongly impact steam explosions energetics and corium debris bed formation and coolability [52,53,54], during the premixing and jet fragmentation phases of the Fuel Coolant Interaction (FCI). While their knowledge is incomplete, its effect on accident scenarios might be substantial, as it fosters oxidation and fast hydrogen generation and corium solidification [54,55,56]. From one hand, the impact on possible containment damage with a stronger steam explosion and from the

other hand the fission products release from the corium droplet during FCI in these conditions are today not well known.

Stratified Steam Explosion (SSE) can occur if a corium melt is released in a limited amount of water (i.e., in case of partially reflooded cavity or underwater corium spreading) [52,53]. Interaction dynamics between corium and water largely differs from that expected in case of a jet immersed in a large mass of deep water [57,58,59]. The high energetic interaction generates a shock wave pressurization and propagation. What is specifically missing is a pool of representative (i.e., prototypic corium composition) experimental data that enable both model development and validation. A possible consequence would be the motion/displacement of heavy components such as the vessel or the steam generator with possible consequences on containment and so possible fission products release outside of the containment.

MCCI [60,61] is a critical phenomenon that results in specific threats for containment integrity [21]: basemat penetration, over-pressure, combustible gas generation. Even though investigated over decades, there are still some key issues that are needed to investigate:

- The effect of scale in the MCCI phenomenology. MCCI is expected to occur in reactor pits (even 5-6 m diameter) in case of RPV failure or later in even larger spreading chambers for some reactor designs. Most experiments carried out so far have been conducted at a substantially smaller scale than the large dimensions of some reactor pits (MACE tests were done at a 1.2x1.2 scale [62], rather smaller yet [63]). Given that the dominant phenomena (thermochemistry, thermal-hydraulic, heat transfer, degassing, ablation, thermomechanical properties of degraded concrete) are strongly sensitive to scaling, large scale data would be of primary relevance to scale-up existing data and to support model validation. The absence of modelling to explain a more rapid ablation in vertical or horizontal directions according to the nature of the concrete implies uncertainties [63], especially for vertical ablation with risk for the ground waters. Both MCCI topics are crucial to assess reliably the delay of possible failure of the containment and so the possible release of radioactivity outside of the containment.
- Long term behaviour. Under the frame of OECD/NEA projects addressing Fukushima (i.e., BSAF, ARC-F and FACE) the MCCI-related observations in the long-run have brought up major discrepancies with the current MCCI understanding encapsulated in MCCI models. On one side, a large difference has been reported between models' predictions and data from the site after more than 5 days of the accident [64,65]. Even if some hypotheses have been formulated to explain them, still some long-term data would be needed to support variable settings, like concrete ablation temperature, or the effect of some processes, like through-concrete conduction. On the other, video recordings of pedestal vertical walls showing intact rebars with no concrete cover did strike all expectations. At present such concrete removal under the harsh prevailing conditions anticipated in the pit during the accident, cannot be plausibly explained.

3.2.2. Containment domain

As noted in section 3.2.1., the same containment phenomena, although under different prevailing conditions, were H-ranked for the ex-vessel phase, except for Ct#4 (gas dynamics induced by FCVS operation).

3.2.3. Source Term domain

The following phenomena in the source term domain are related to the Ex-Vessel domain, only. By applying the PIRT methodology, 5 H-ranked phenomena were considered (Table V).

Table V. Source Term domain: High-ranked phenomena

#ID	Ex-vessel scenario	Phenomena
ST-3	Steam condensation conditions	FP transport onto surfaces under condensing conditions (non-soluble)
ST-4	FP in sumps	Gaseous mass-transfer at gas/water surfaces and in liquid films
ST-5	FP in CNT with organics	Iodine reactions with organics other than paints
ST-6	FCVS operation	Gaseous and particulate FP retention by FCVS
ST-7	Non-hermetic CNT	Liquid release from containment via cracks and leakage paths

FPs transport onto surfaces due to steam condensation is significant, and an accurate quantification may reduce the uncertainties on the safety margins [66]. The published PIRT regarding the Fukushima Daiichi NPP accident [67] suggested also high importance of the phenomenon in the ST assessment. Validated models predicting aerosol behavior inside the CNT relate primarily to the gas phase [66,67,68] but not to the liquid phase. An adequate description of aerosol transport downwards the wall by the condensate is complex and corresponding validation data that include concentration and particle size data measurements are very rare [69]. Most of existing models do not allow FP product transport in any other component except the vapor phase [66,67].

Aqueous organic iodide production is one of the main sources for gaseous organic iodides inside the CNT which are strongly related to the potential source term to the environment due to corresponding high radiotoxicity [70,71,72]. The capture, transport and release of iodine species by the CNT sump water is still insufficient for a comprehensive understanding of chemistry and mass transfer kinetics [73]. Gaseous contaminants present in the CNT during an accident, e.g. nitric acid, may affect the pH of liquid water films which subsequently can affect the iodine release rate [71,74] and High Molecular Weight organic iodine compounds (HMWI) reactions owe very limited validation [74].

Iodine speciation in the CNT is of primary importance to assess radiological consequences in case of outside releases. Feedback on SA accident (TMI2, Fukushima) concerning iodine speciation of outside releases shows large uncertainties due to rapid decay heat and possible evolution in the atmosphere. Even if there are uncertainties, large presence of Org-I is still suspected [75], also supported by a less efficient trapping of FVCS in case of filtering releases [76]. The identification of potential sources of Org-I, in addition to epoxy paints, would directly impact the ST from the CNT. ESTER project data highlights that some other reactive pathways must be considered in SA simulations [77] and potential sources of Org-I must be experimentally evaluated to confirm these findings and validate improved models.

Particulate and gaseous retention by FCVS involves gaseous absorption, chemical reaction and physical separation of solid and aerosol-borne radioactive particles from a high-energy, steam-non-condensable gas mixture through a combination of thermodynamic, hydrodynamic, and filtration mechanisms. Even though knowledge is accessible via literature and FCVS vendor, sub-micron aerosol retention (e.g., <0.3 μm) is not consistently validated across systems including performance drops in some designs without deep-bed filtration [78,79]. Long-term retention stability under high radiation and thermal loads is insufficiently characterized and such conditions might include the risk of re-suspension or re-volatilization. Decay heat

impact on filter media and aerosol re-release is underexplored, especially for extended venting cycles [80]. There exists data related to adsorbents materials or compounds that may enhance the retention of FP and iodine in FCVS, such as, Ag in zeolites [81] or Na_2SO_3 in wet scrubbing systems [82]. However, a more exhaustive database is required to support the design of FCVS in terms of types of materials, operating conditions, mechanism of retention, and performance. New models are required to design FCVS systems with new material candidates [83,84], and a broader set of operating conditions needs to be included.

During Fukushima accident, direct discharge of water to the ocean has been observed, and radiological consequences evaluated [85] Contaminated water has also been found in the auxiliary building. This behaviour could have a very strong impact on the source term transferred to the environment. The EU project SOCRATES shall contribute to an enhanced understanding of liquid source term as well as corresponding model development [85].

4. KEY INSIGHTS

The material here presented will be used to build a roadmap on SA research which was conceived to efficiently articulate the available resources for the coming decade. The full-scope PIRT exercise conducted under the frame of the EC SEAKNOT project settled key insights that are worth highlighting:

- PIRT (Phenomena Identification and Ranking Table) is a systematic methodology that can guide a deep review of research needs in SA. Nonetheless, even if providing a sound basis, a SA research roadmap should go beyond the PIRT outcomes by accounting the drawbacks of the method and by adding other information sources, like new observations made in real SA transients.
- Out of roughly 400 phenomena/processes critically reviewed, about 20 remain seen most relevant investigating based on the poor knowledge existing and their potential safety impacts. However, contrary to knowledge level, which assessment was strongly supported, safety relevance was not so deeply and specifically done. It is likely that after feedback from expert external groups (AB and EUG) the final list of phenomena of interest might change.

ACKNOWLEDGMENTS

The work presented in this communication was done under the frame of the SEAKNOT project. This project has received funding from the Euratom Research and Training Programme 2021-2023 under grant agreement No 101060327. The content of this paper reflects only the authors' view. • Nat. & Int. (SAMHYCO; IPRESCA; AIRSFP; ...)
RESEARCH ROADMAP
- Issues ("what").
- Approach ("how" & "where")

Objective & Scope

- **Identify the major SA issues worth new R&D activities**

  Critically assess existing SA knowledge by

  - Identifying SA issues by sub-domains (In-V; Ex-V; Cont.; ST).
  - Assessing the knowledge gaps (data & models).
  - Evaluating their safety significance.

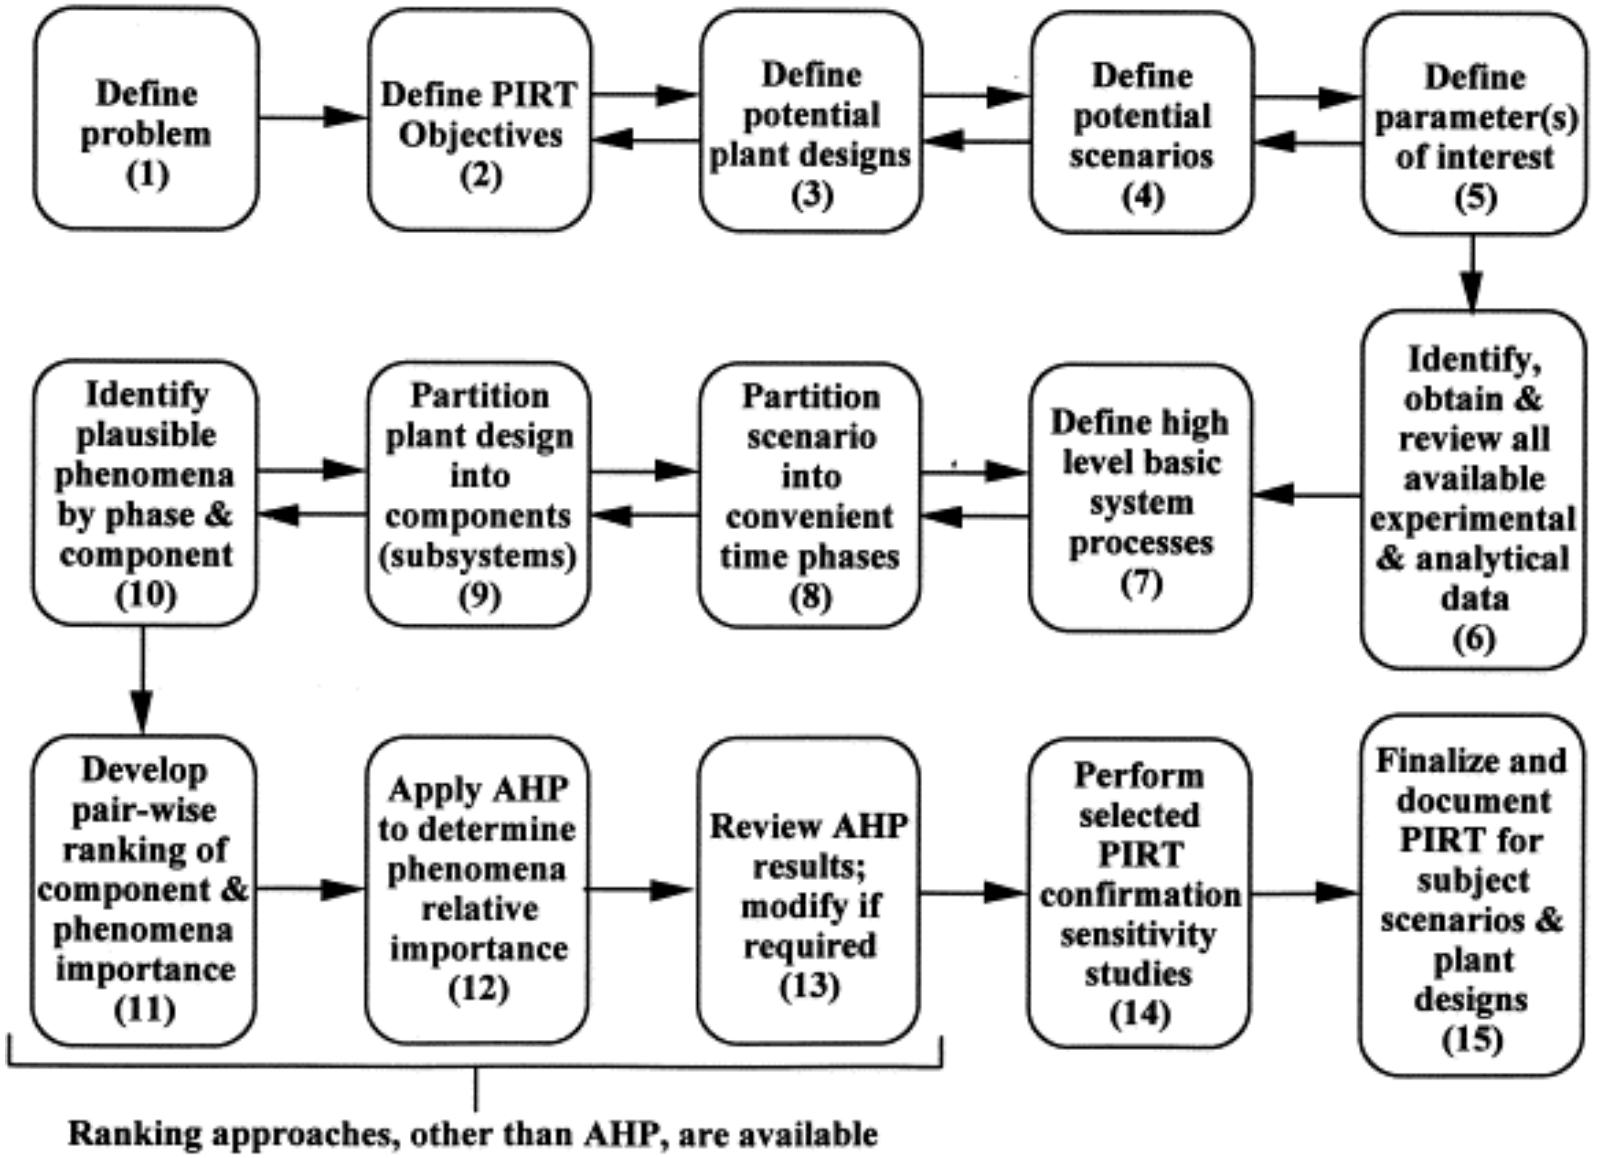
- **Focus on water-cooled reactors (LWRs +** WC-SMRs & ATFs)
- **5-10 years time horizon.**

02 The PIRT Approach

The PIRT Background

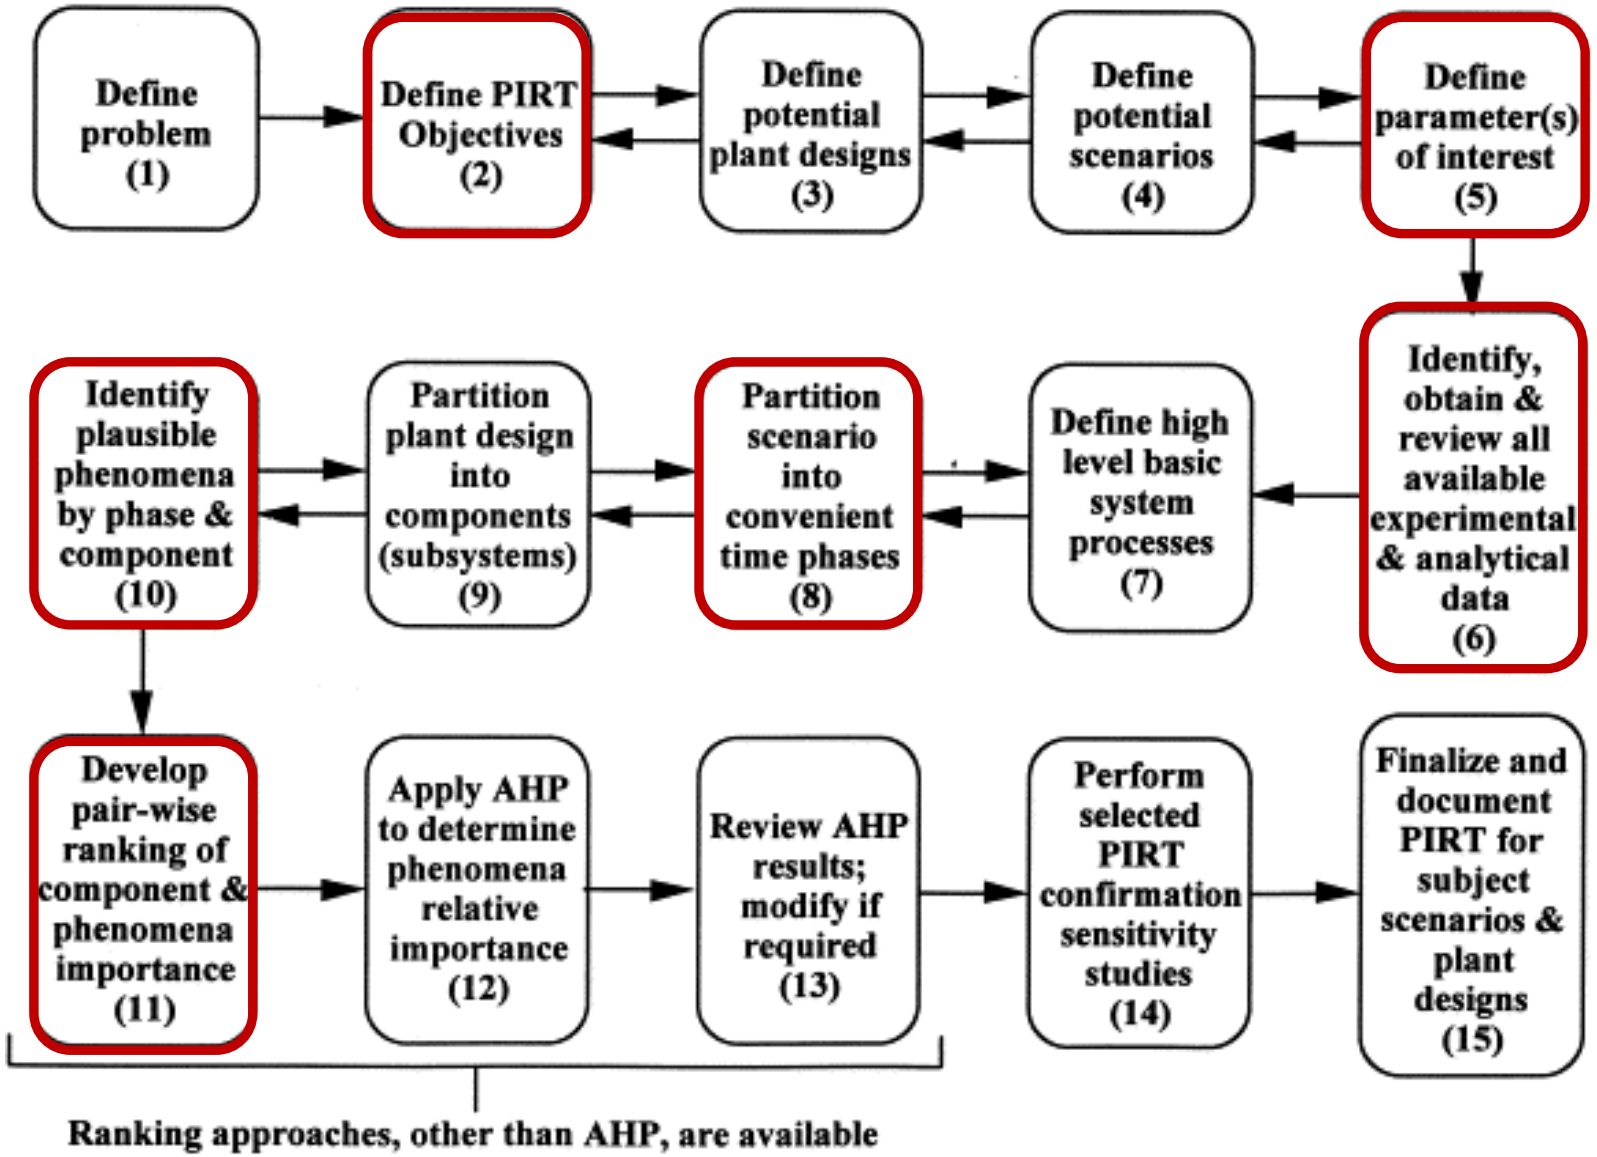
- PIRT: Step 3 in CSAU (Code Scaling, Applicability and Uncertainty) Method. (BEPU application in safety analysis; USNRC,1988).
- PIRT: A way to set technical basis for experimental programs.
- PIRT: A means to establish computer codes phenomenological requirements.
- PIRT: A methodology broadly used in SA (… but adaptation required!).
  - "Development of the source term PIRT based on findings during Fukushima-1 NPPs accident", 2015.
  - "PIRT: R&D Priorities for Loss-of-Cooling and Loss-of-Coolant Accidents in SNF Pools", 2018.
  - "Elaboration of a PIRT for the modelling of In-Vessel Retention", 2020.

The PIRT Structure

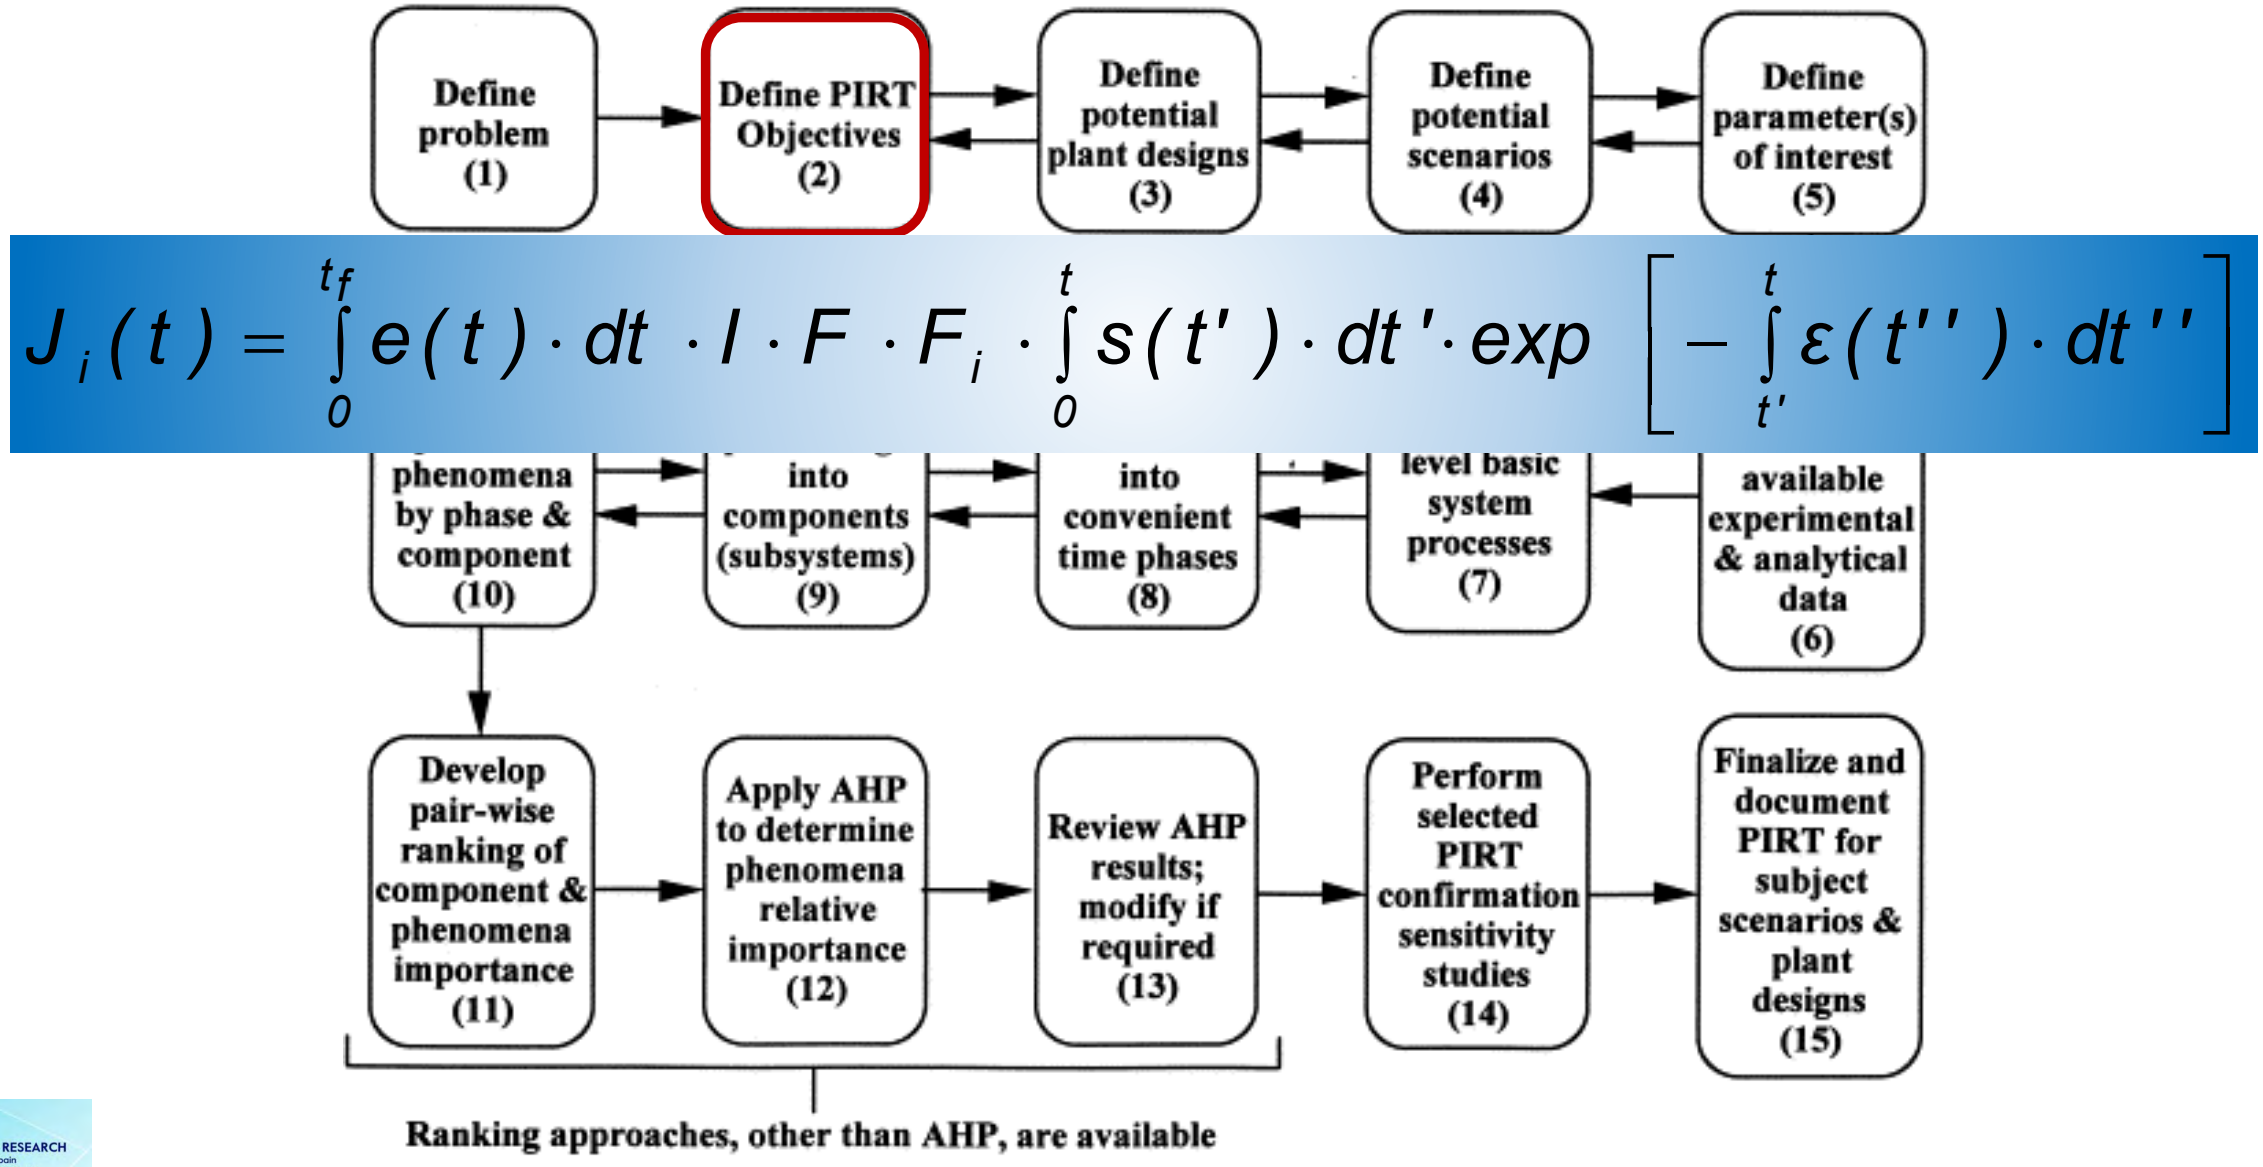


Wilson et al., 1998

The PIRT Essential Steps

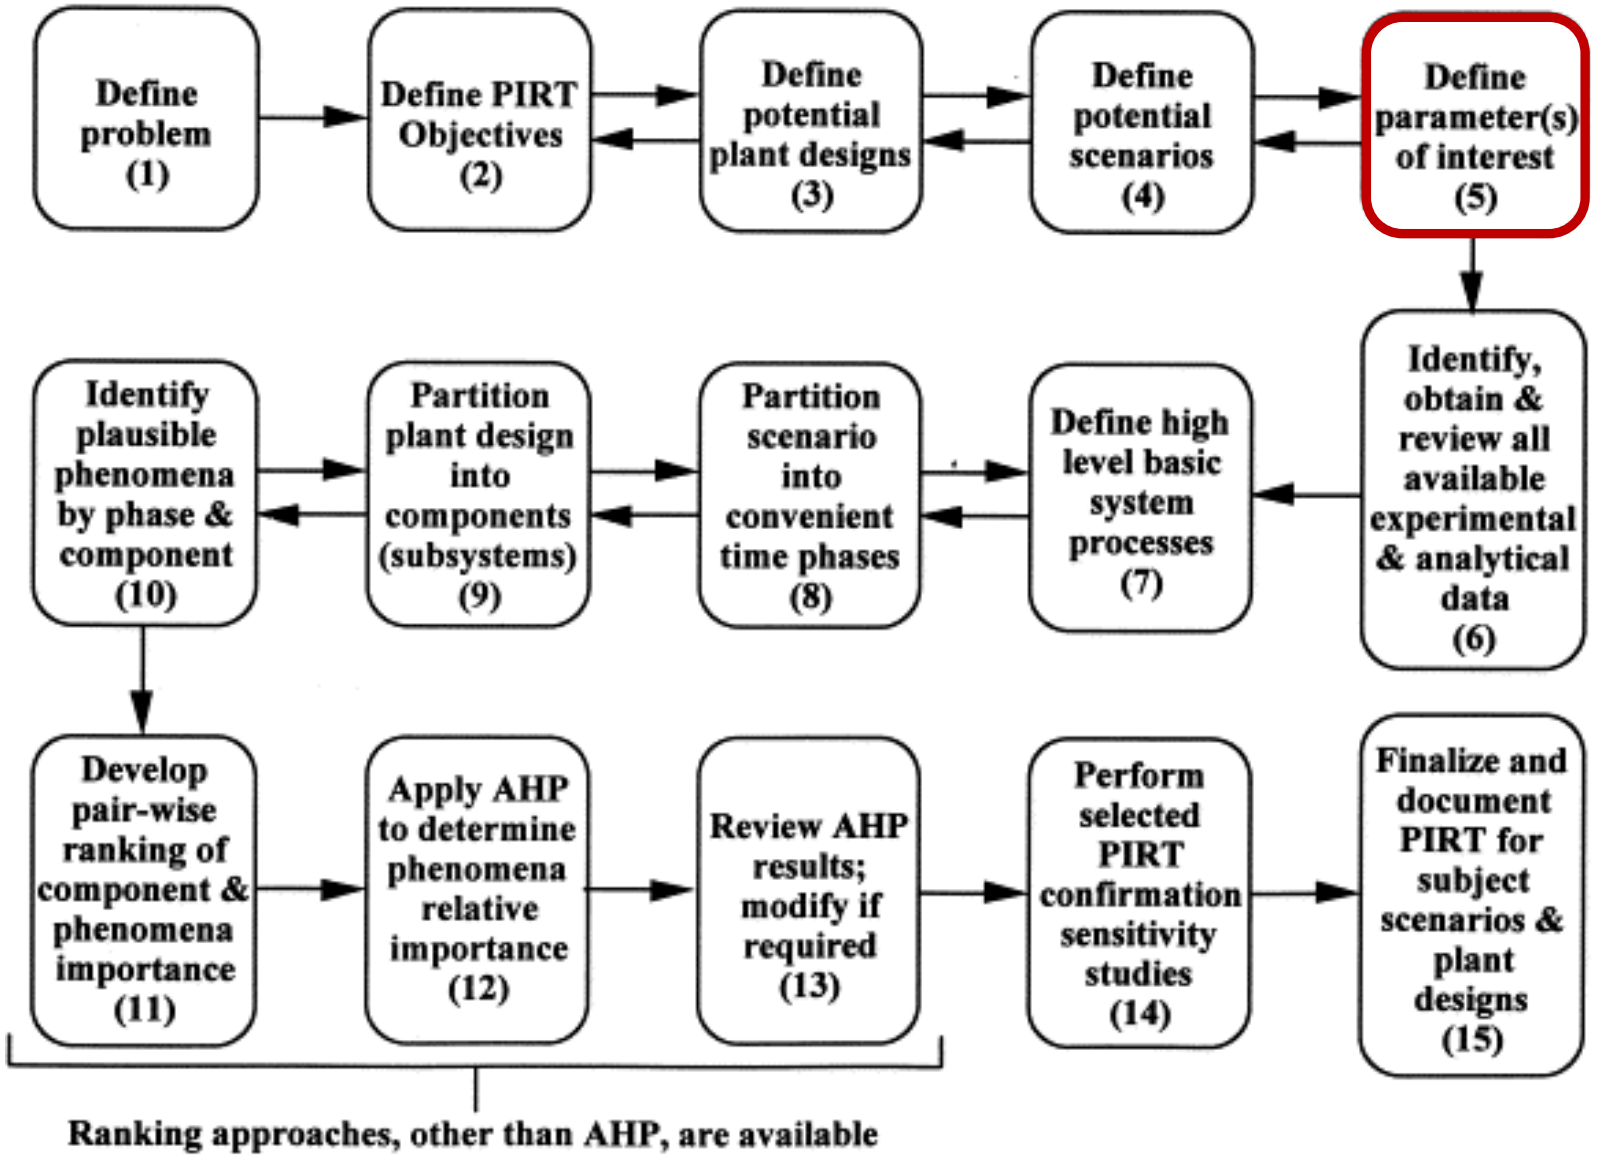


The PIRT Essential Steps



$$J_i(t) = \int_0^{t_f} e(t) \cdot dt \cdot I \cdot F \cdot F_i \cdot \int_0^{t} s(t') \cdot dt' \cdot \exp\left[-\int_{t'}^{t} \varepsilon(t'') \cdot dt'' \right]$$

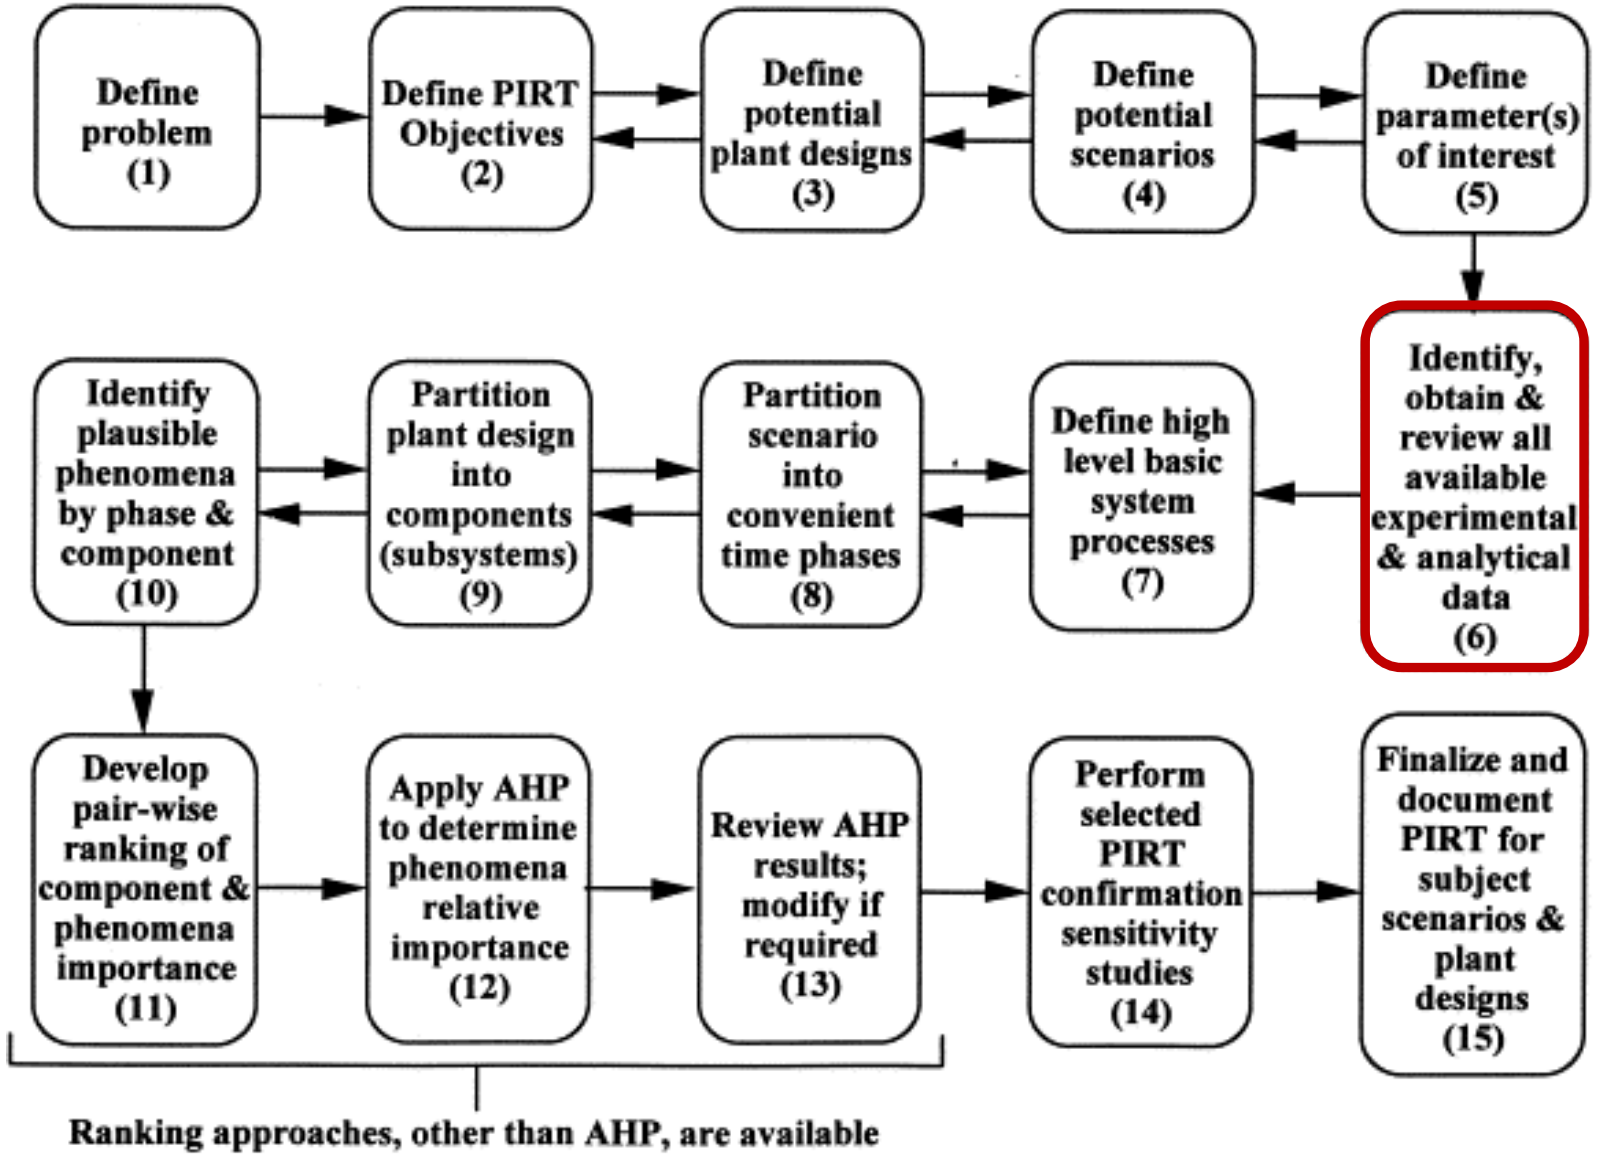
The PIRT Essential Steps



I; Cs; Te; Ru; Kr; Xe

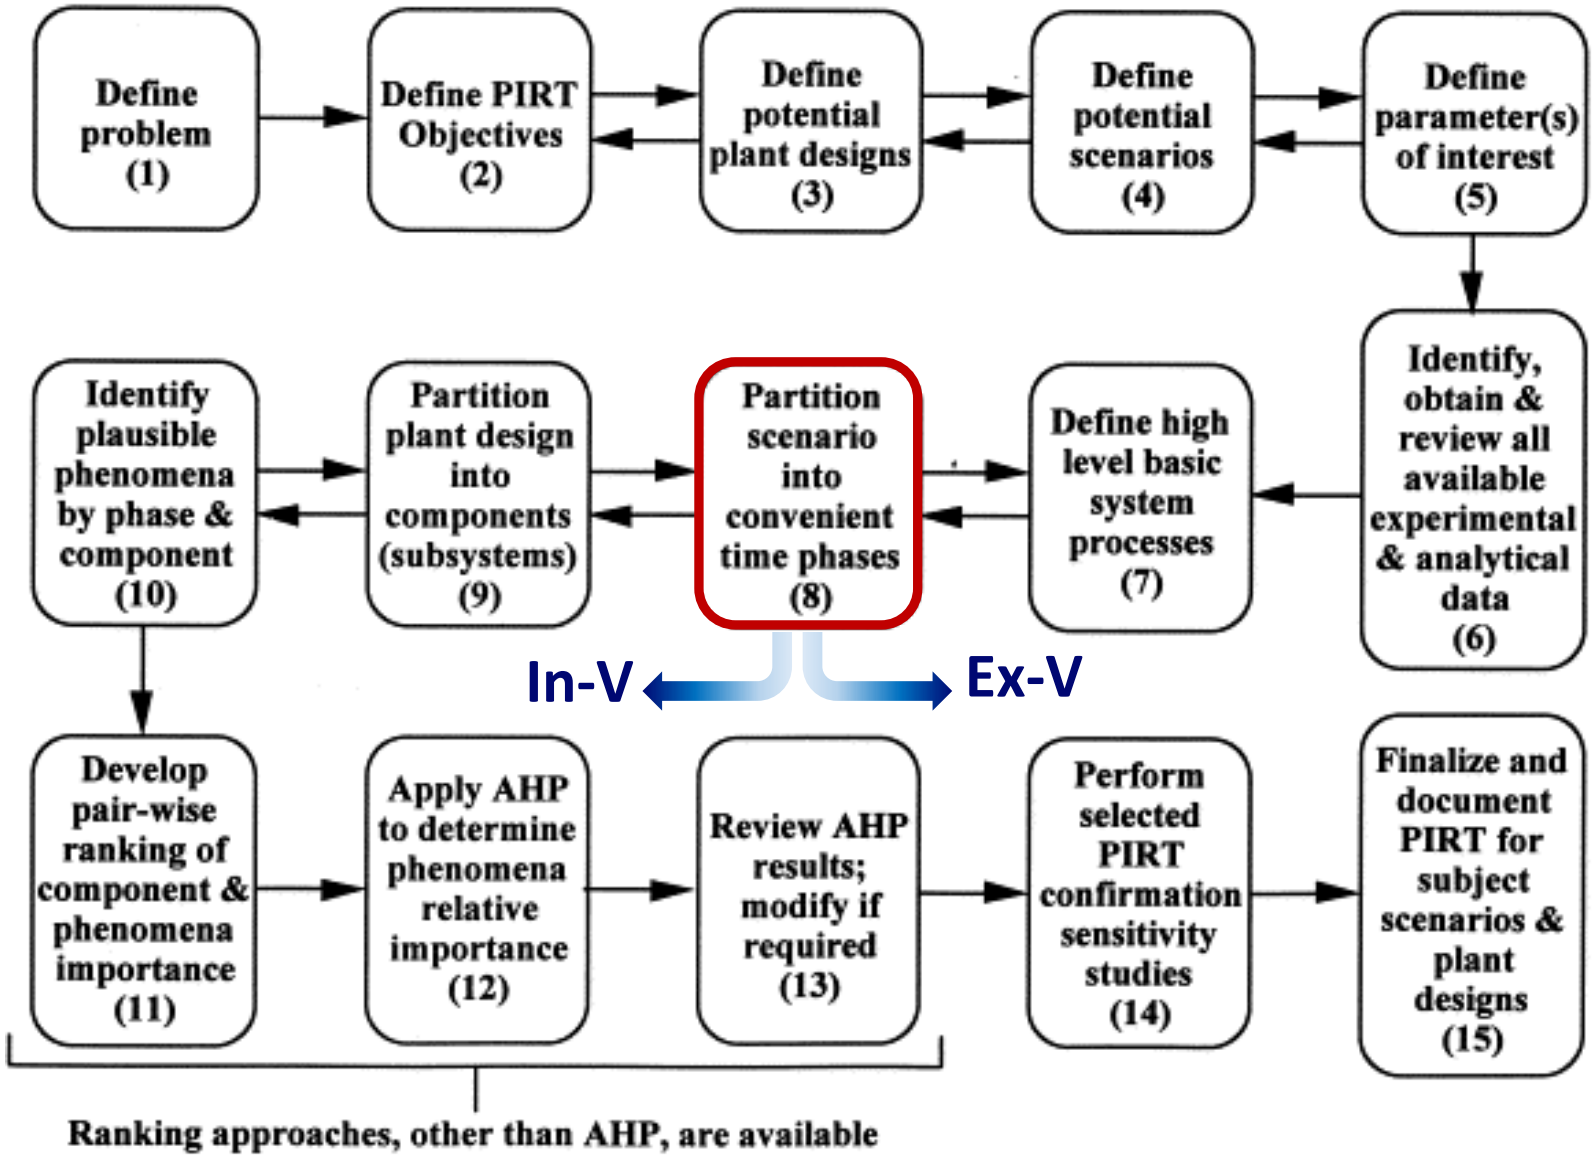
- **Onset time**
- **Release rates**
- **Composition**

The PIRT Essential Steps

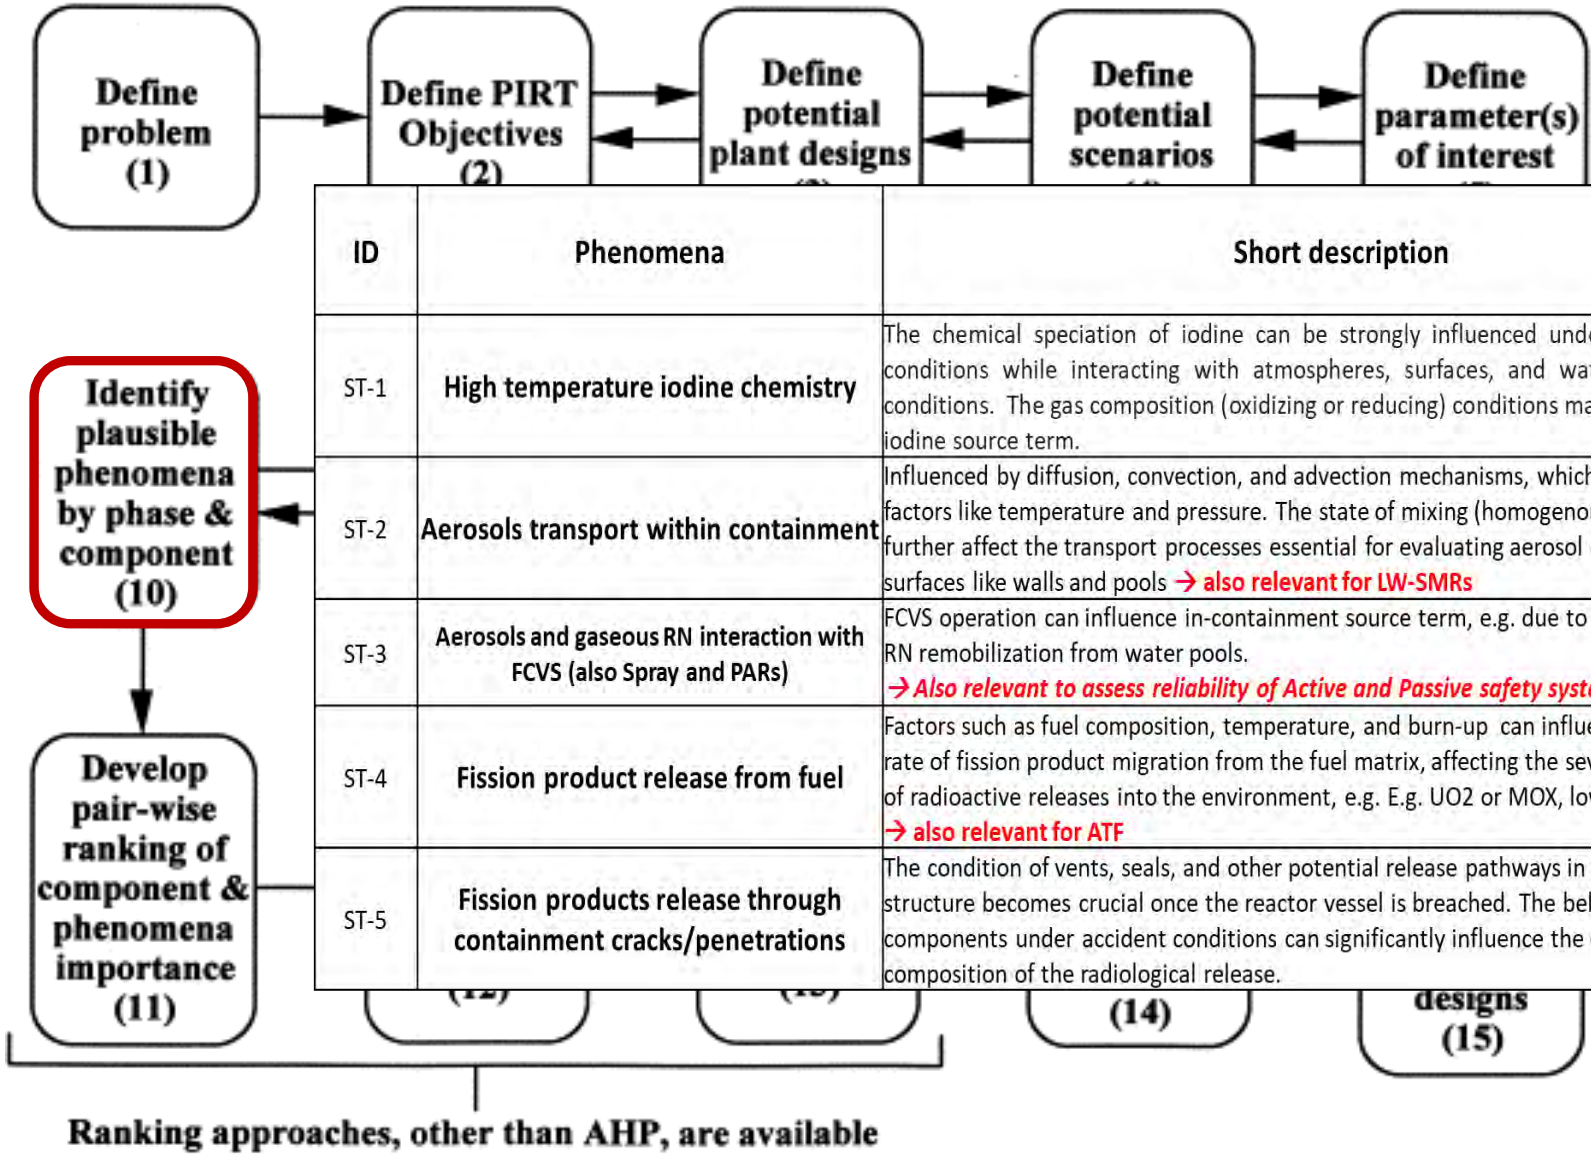


- **EURSAFE PIRT to SARP**.
- High-level American PIRT (SBO-focused).
- AEAJ PIRT on Source Term (Fukushima-based).
- USNRC PIRT on ATFs (NUREG/CR-7283).
- EURATOM (SARNET2, CESAM, ALISA, PASSAM, SAFEST, IVMR, …)
- HORIZON-2020 (MUSA, R2CA, AMHYCO; …)
- OECD/NEA (BIP; STEM; BSAF; ARCF; THAI; ESTER; THEMIS; FACE; QUENCH; …)
- IAEA/CRPs …
- Other nat. & int. projects (SAMHYCO; IPRESCA; AIRSFP; …)

The PIRT Essential Steps

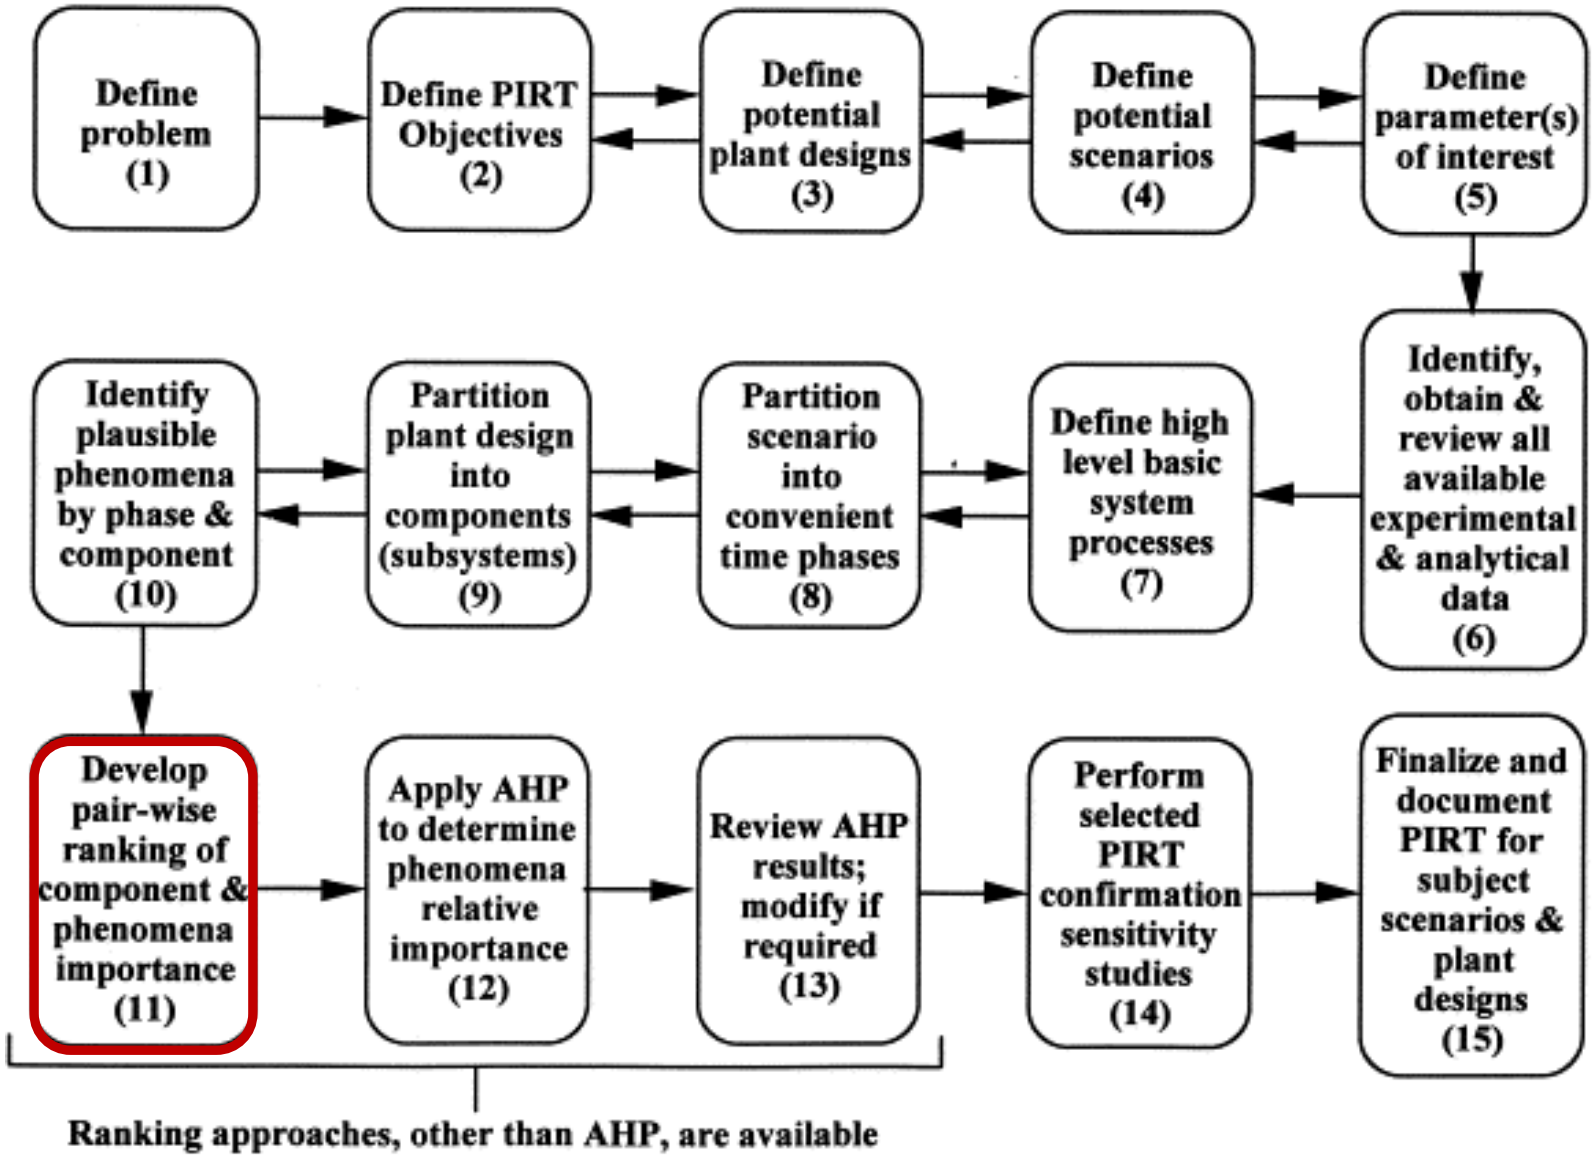


The PIRT Essential Steps



ID	Phenomena	Short description	Accident Phase (In-V, Ex-V)
ST-1	High temperature iodine chemistry	The chemical speciation of iodine can be strongly influenced under high-temperature conditions while interacting with atmospheres, surfaces, and water pools under SA conditions. The gas composition (oxidizing or reducing) conditions may further impact the iodine source term.	In-V
ST-2	Aerosols transport within containment	Influenced by diffusion, convection, and advection mechanisms, which are affected by factors like temperature and pressure. The state of mixing (homogenous or stratified) can further affect the transport processes essential for evaluating aerosol deposition on surfaces like walls and pools → also relevant for LW-SMRs	In-V, Ex-V
ST-3	Aerosols and gaseous RN interaction with FCVS (also Spray and PARs)	FCVS operation can influence in-containment source term, e.g. due to aerosols or gaseous RN remobilization from water pools. *→ Also relevant to assess reliability of Active and Passive safety systems*	In-V, Ex-V
ST-4	Fission product release from fuel	Factors such as fuel composition, temperature, and burn-up can influence the extent and rate of fission product migration from the fuel matrix, affecting the severity and duration of radioactive releases into the environment, e.g. E.g. UO2 or MOX, low or high burn-up → also relevant for ATF	In-V, Ex-V
ST-5	Fission products release through containment cracks/penetrations	The condition of vents, seals, and other potential release pathways in the containment structure becomes crucial once the reactor vessel is breached. The behavior of these components under accident conditions can significantly influence the extent and composition of the radiological release.	Ex-V

The PIRT Essential Steps



The PIRT Essential Steps

The Knowledge Ranking

	Low	Medium	High
Data	No data available	Data available, but not directly applicable	Data available & qualified for validation
Model	No model available	Model available but highly uncertain	Model validated & implemented in codes

		Data		
		Low	**Medium**	**High**
Model	**Low**	L (Unknown)	L (Qualitative understanding)	M (Bases for “known” set)
	Medium	L (Uncertain approximation)	M (Qualitatively assessed approximation)	M (Soundly assessed approximation)
	High	L (Uncertain model)	M (Qualitatively assessed model)	H (“Known”)

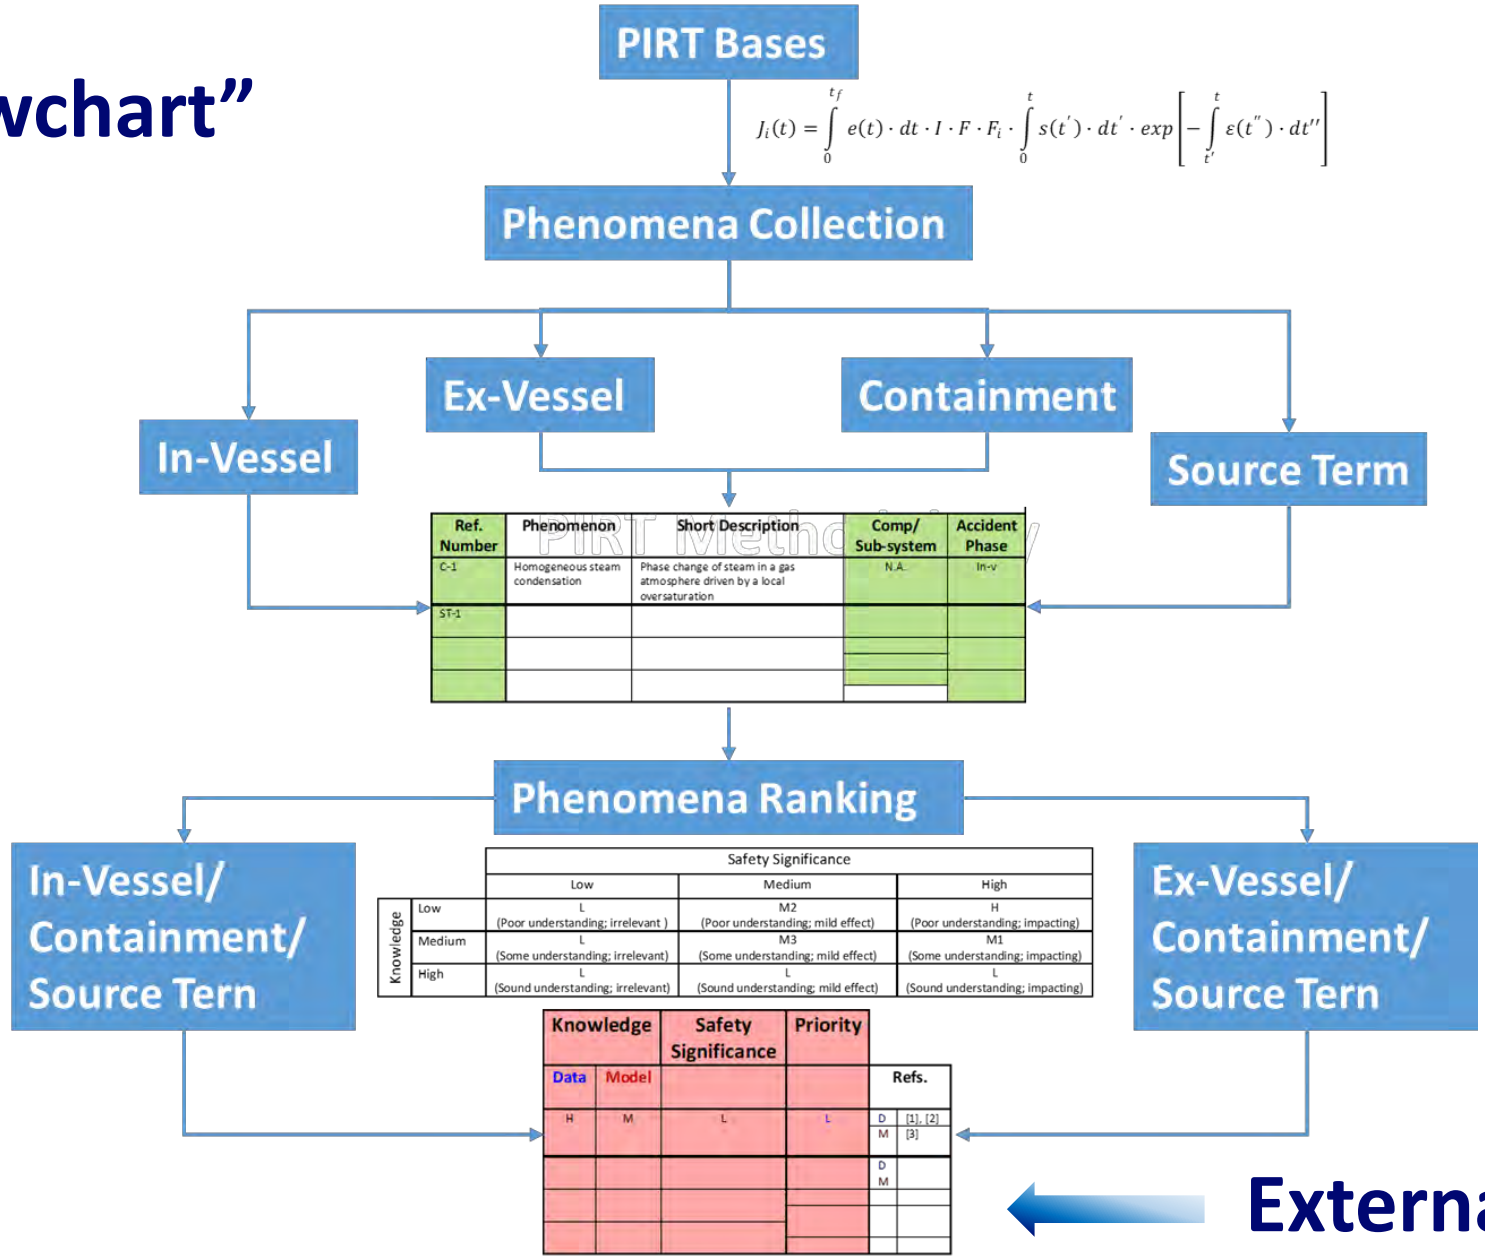
The PIRT Essential Steps

The Final Ranking

		Safety significance		
		Low	**Medium**	**High**
Knowledge	**Low**	L (Poor understanding; irrelevant)	M2 (Poor understanding; mild effect)	H (Poor understanding; high impact)
	Medium	L (Some understanding; irrelevant)	M3 (Some understanding; mild effect)	M1 (Some understanding; high impact)
	High	L (Sound understanding; irrelevant)	L (Sound understanding; mild effect)	L (Sound understanding; high impact)

The PIRT Essential Steps

PIRT "Flowchart"



External review!

The PIRT Challenges

- PIRT is a knowledge-based method. SA are intrinsically uncertain.

  Awareness!

- The larger the PIRT scope, the less accurate outcomes.

  Awareness!

- Expertise (knowledge & perspective diversity) is the PIRT main asset.

  Partnership & diversity & External review groups (AB&EUG).

- Practicalities in the application of the PIRT methodology.

  Understanding & Phase PIRT.

The PIRT Practicalities

- To “adapt” the agreed **methodology.**
- To achieve **a uniform application of the methodology** in domains.
- To **integrate** the input from domains.

- To **stretch the boundaries** to WC-SMRs and ATFs (WP1.2-.5).
- To keep the **safety-focus** throughout the work.

Trade-off between resources and efforts!

MORE THAN TWO DECADES OF ACTIVITIES ON SEVERE ACCIDENT MANAGEMENT GUIDELINES (SAMGs) IN TECNATOM AND WESTINGHOUSE

Tanarro Onrubia, Agustin
Tecnatom / Westinghouse
agustin.tanarroonrubia@westinghouse.com

Giner Gonzalez, Amparo
Westinghouse
amparo.ginergonzalez@westinghouse.com

ABSTRACT

The Severe Accident Management Guidelines (SAMGs) provide guidance to operators and designated support staff for use if accident conditions progress beyond the prevention capabilities described in Emergency Operating Procedures (EOPs).

SAMGs are designed to fill the void beyond the EOPs with respect to formalized guidance for responding to an accident which progresses beyond limited core or spent fuel overheating due to inadequate core cooling (i.e., a Severe Accident). These guidelines employ strategies intended to arrest the progression of fuel damage, maintain the capability of the containment as long as possible, and minimize radiological releases.

For more than two decades, Tecnatom, currently owned by Westinghouse, has continued to carry out different activities associated with SAMGs for the Spanish Westinghouse design Nuclear Power Plants (NPPs).

With the integration of Tecnatom into Westinghouse in November 2023, the merged company's capabilities and field of action have increased with the contribution of Westinghouse experts in the development and maintenance of the generic PWROG SAMGs and access to related projects in other countries.

This paper presents the above activities in Tecnatom and Westinghouse, with special attention to those associated with the development, validation and implementation of plant-specific SAMGs.

KEYWORDS

Severe Accident Management Guidelines, PWR

1. INTRODUCTION

Since 2001, in a close collaboration with the engineering and operation staff of Spanish Westinghouse design Almaraz, Ascó and Vandellós NPPs, Tecnatom has participated in the development and validation of the specific SAMGs for these plants, based on the generic guidelines of the owners' group of the technology supplier, Westinghouse Owners' Group (WOG), currently PWR Owners' Group, (PWROG).

Following the integration of Tecnatom into Westinghouse, the company scope of action in the SAMGs field has extended to other countries with the currently underway development of the plant specific SAMGs for Framatome design Koeberg NPP in South Africa.

Other activities associated with the Severe Accident Management (SAM) carried out at Tecnatom include:

- The design of training plans and delivery of courses on phenomenology and management of severe accidents for operation crews and Emergency Response Organization (ERO) personnel in Spanish NPPs and abroad (United Arab Emirates, China, etc.)
- The development of Technical Support Center (TSC) computer aiding tools for using SAMGs in real or simulated severe accident scenarios.
- The implementation of severe accident codes (MAAP) into Full Scope Replica Simulators (Laguna Verde NPP, Mexico) and Interactive Graphic Simulators (Almaraz NPP, Spain)
- The development of severe accident simulation tools based on IA surrogate models. The company is currently involved in the ASSAS (Artificial intelligence for Simulation of Severe Accidents) European Union project, which is presented in another paper within this meeting.

2. HISTORY OF THE DEVELOPMENT OF THE WOG/PWROG GENERIC SAMGs

The Three Mile Island accident in 1979 showed that, although highly unlikely, accidents seriously affecting the fuel in the core or Spent Fuel Pool of a NPP can have very serious consequences for the plant itself and its surroundings.

Consequently, the need arose to broaden the objectives of nuclear safety, which until then had been basically focused on preventing such accidents, to provide plants with the means to mitigate their consequences in the event of a severe accident, including equipment and organisational and procedural frameworks designed for this purpose.

As a result, the so-called Severe Accident Management Guidelines (SAMG) were developed to cover the void beyond the Emergency Operating Procedures (EOPs) for operating staffs by adopting the existing safety systems and technical support under severe accident conditions. It was expected that the SAMG can extend significantly the Defence in Depth (DiD) concept providing strategies to mitigate the consequences of severe accidents.

In 1992, the Electric Power Research Institute (EPRI) published the Severe Accident Management Guidance Technical Basis Report (TBR) (References 1 and 2) which included an extensive description of severe accident involved phenomena and identified Candidate High-Level Actions (CHLA) based on the analysis of accident scenarios.

These actions and technical information became the cornerstone of generic SAMGs for Light Water Reactors (LWRs). In line with the design features of the different LWRs owner groups, generic SAMGs were developed by the owner groups by adapting the suggested CHLAs in the EPRI TBR report. This set of generic guidelines were used afterwards by individual plants as the basis for their plant specific SAMGs.

The WOG SAMG is a well-known generic SAMGs set which, through their several revisions, has been widely applied to Westinghouse design PWRs, and adapted also to other PWR designs including VVER and CANDU reactors. It encompasses guidelines for operators in the Main Control Room (MCR), and diagnostic tools and guidelines for the Technical Support Center (TSC).

While the MCR is responsible for EOPs, the TSC would be in charge of identifying the plant damage states and direct actions to MCR staffs during SAM. This means that the operational authority shifts from MCR to TSC with the transition from EOPs to SAMGs.

The initial **WOG SAMG Revision 0** (Reference 3), published in 1994, was intended to provide an initial generic basis for individual Westinghouse PWR plant owners to develop a first guide specific to their plants, based on a structured decision-making process and use of stepwise structured guidelines and flowcharts. This approach minimised training requirements and provided a tool for mitigating the consequences of the severe accident under potentially high stress conditions

The components of the WOG SAMG Revision 0 are shown in Figure 1

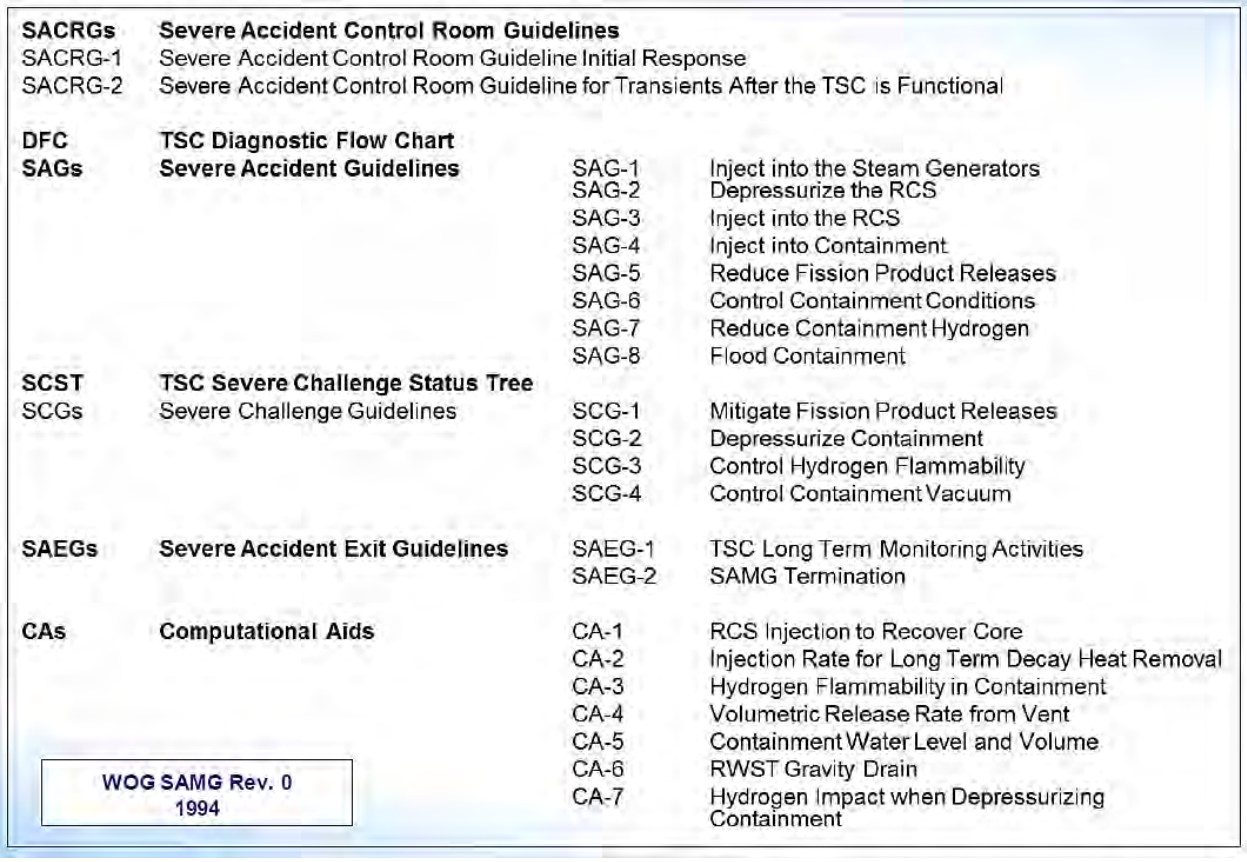

Figure 1: WOG SAMG Rev.0 Components

Revisions to the generic guidance were performed when improvements were made to the understanding of severe accident phenomena, plant modifications were introduced to facilitate mitigation of severe accidents, and lessons were learned from implementation and performance of drills and exercises.

In this way, the generic **WOG SAMG Revision 1** (Reference 4), published in 2001, incorporated significant improvements to the SAMGs, arising from several years of experience in training, validation and exercises on the specific guidelines of the different plants.

The Fukushima Daiichi Nuclear Power Plant (NPP) accident, that took place on 11 March 2011, initiated a significant number of activities at the international level to reassess the safety of existing NPPs, evaluate the sufficiency of technical means and administrative measures available for emergency response, and develop recommendations for increasing the robustness of NPPs to withstand extreme External Events (EE) and Beyond Design Basis Accidents (BDBA).

One of the lessons learned from the Fukushima Daiichi NPP accident was that the scope of SAM needed to be extended to consider important aspects as: plant shutdown conditions, multi-unit events, loss of instrumentation and control, long-duration events, accidents initiated in spent fuel pools, devastated site and surrounding conditions, harsh environments and widespread contamination.

In addition. critical for the successful implementation of the strategies during an emergency is to ensure appropriate training of responders on the procedures and guidelines to be followed.

The EPRI TBR report was also updated in 2012 (References 5 and 6), not only accounting for the initial lessons learned from the Fukushima accident, but also reflecting the enhanced understanding of severe accident behaviour gained from research and analyses conducted in the 20 years after the publication of the original report.

Generic **WOG SAMG Revision 2** (Reference 7) was issued for implementation in February 2013, following the Fukushima accident. This revision was intended to address short term post-Fukushima modifications to the SAMGs, addressing specific issues raised by the revised TBR.

In Europe and other countries outside the US, WOG type SAMGs have been used as the basis for plant specific SAMGs in many Westinghouse PWRs (eg Beznau, Ringhals, Asco, Vandellos, Almaraz, Tihange and others), at Framatome/AREVA plants (eg Koeberg), at Siemens/AREVA plants (eg Borssele) and in VVER reactors in Central Europe (Bohunice, Mochovce, Temelin, Dukovany).

However, the approach to systems upgrades for the mitigation of severe accidents has been different in the US and Europe (Reference 16), with European plants generally opting to backfit mitigation systems such as Hydrogen Passive Autocatalytic Recombiners (PAR) and Filtered Containment Venting Systems (FCVS). In addition, certain issues such as severe accidents occurring from shutdown initial condition have always received more attention in Europe than in the US. This has led to specific needs for international plants implementing SAMGs which were originally developed in the US.

To address some of these issues, in 2012-2013, a European PWROG project **PA-PSC-1081** (Reference 8) was performed This project addressed several issues and updates to guidance for the systems upgrades and backfits that were implemented across the industry to enhance severe accident mitigation capabilities. It also addressed severe accidents occurring from initial shutdown states. Main items accounted for by this project and addressed in several WENX documents (References 8.1 to 8.7). included:

- Passive Autocatalytic Recombiner (PAR) hydrogen control systems
- Filtered Containment Venting Systems (FCVS)
- Plants without containment hydrogen monitoring system,
- Guideline for a severe accident combined with loss of all DC power and instrumentation
- Shutdown initial plant condition
- Simultaneous severe accidents in multiple units at a single site

Other owners' groups of PWRs in the US have also developed generic SAMGs with considerations of their reactor designs, including the Combustion Engineering Owners' Group SAMG (CEOG SAMG), Babcock & Wilcox Owners' Group SAMG (B&WOG SAMG).

Since 2013 a consolidated PWROG SAMG project **PA-PSC-0932** was developed by combining the SAMG approaches with operating experiences of WOG, CEOG and B&WOG. The main framework of the consolidated PWROG SAMG was based on the WOG approach and enhanced and adapted to new insights, including lessons learned from the Fukushima accident, feedback from exercises/drills, human factors, and benefits from other SAMG approaches.

As a result, in February 2016 the official revision of the generic **PWROG-15015-P Revision 0** SAMGs (Reference 9), applicable to Westinghouse, Babcock & Wilcox and Combustion Engineering design PWRs, was issued. This revision included very significant changes in the structure and rules of use of the generic SAMGs, to the point of considering it the beginning of a new line of development of the guidelines and therefore designating it as Revision 0.

The basic structure and components of the PWROG consolidated SAMG are shown in Figure 2.

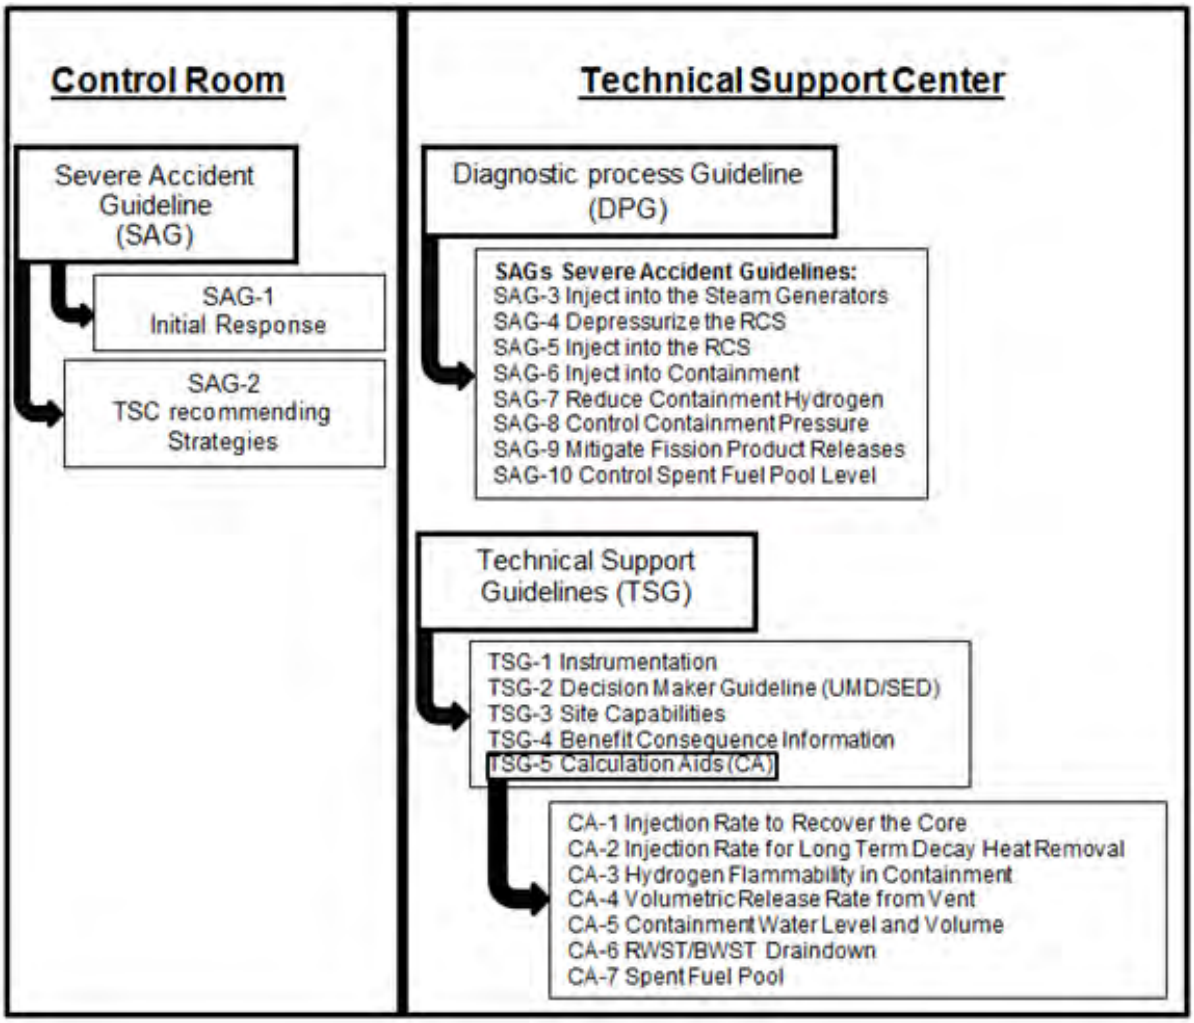

Figure 2: Main Components of the PWROG SAMG

The main new features of this review were

- New set of guidelines:
  - 2 Control Room Guides (SAG-1 and SAG-2) replace SACRG-1 and SACRG-2.
  - Diagnostic Process Guideline (DPG) replaces the DFC and SCST of previous versions and identify, by means of a colour code, the priority for the implementation of the guidelines based on two criteria: the severity of the threat to the specific barrier associated to each guide and the expected chronology of these threats.
  - 8 Technical Support Center guides (SAG-3 to SAG-10) replace previous versions of SAGs and SCGs.
  - 5 Technical Support Guides (TSGs).

- New structure of the TSC guidelines to increase the level of proceduralizing by means of a pre-established selection of the strategy to be implemented based on the existing conditions (positive and negative impacts associated with the existing conditions are implicitly considered in the guidelines). With this structure the TSC 'decision-making' burden associated to the assessment of positive and negative impacts is greatly reduced.
- Supplemental Base Information on Left Page (TSC guidelines).
- Introduction of 'Priority Actions' in Control Room SAG-1.
- Independent management for accidents affecting only fuel in the Spent Fuel Pool (SFP).

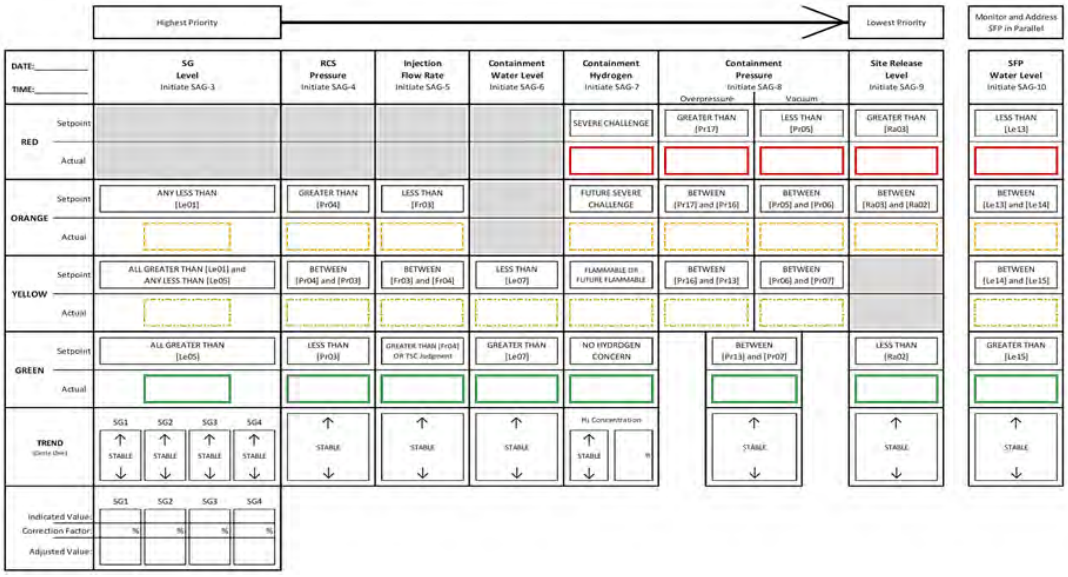

Figure 3 Diagnostic Process Guideline (DPG) Parameter Sheet

The differences between the US and European approaches can have a major impact on SAMGs and have meant that developing and maintaining plant specific SAMGs based on US generic reference guidelines has become more and more complex for European plants. While the international PWROG project PSC-1081 described above addressed many of these differences, it did not produce a new dedicated set of generic guidelines for plants with additional severe accident mitigation features.

To address this, in December 2016, under project **PSC-1413**, a new PWROG generic SAMGs **PWROG-16059-P, Revision 0** (Reference 9) was issued specifically for international plants, based on a reference plant design typical in Europe (with large dry containment, PARs, filtered vent, etc), and taking into account the Revision 1 and 2 changes to the initial WOG SAMG Revision 0, the changes from project PSC-1081, and also certain selected features of the revised consolidated PWROG-15015-P Revision 0 SAMGs developed for the US plants under project PSC-0932 (e.g., the Diagnostic Process Guideline, DPG).

However, to minimize changes and reduce training and SAMG writing burden, some aspects of the original WOG SAMG Revision 2 were retained, maintaining the content and format of the Severe Accident Guidelines (SAGs) and Severe Challenge Guidelines (SCGs) (though they will be called from the new DPG), Computational Aids (CAs) and Severe Accident Control Room Guidelines (SACRGs) (though modified) for control room use

Finally, in March 2021, under **PA-PSC-1844** project (Reference 9), the PWROG initiated an effort to integrate an International Reference Plant (IRP) design into the Generic PWROG-15015-P SAMGs for US

plants. The resulting generic SAMG revision will increase access to the latest PWROG SAMG features for additional PWROG member plant designs with PARs and FCVS and will address severe accidents arising from shutdown initial conditions.

Although several features from PWROG-15015-P such as the Diagnostic Process Guideline (DPG) were already added to PWROG-16059-P, some beneficial features were not added, including the new structure of the TSC guidelines to increase the level of proceduralizing by means of a pre-established selection of the strategy to be implemented based on the existing conditions.

Combining to a single PWROG SAMG volume, applicable to all members, will increase efficiencies in the generic SAMG maintenance program. Moving to a consistent format will also help with regulatory inquires or other questions related to SAMG differences between international member SAMGs and the generic PWROG SAMG. A multidisciplinary team undertook the effort to update and verify every PWROG SAMG guideline, basis document and computational aid impacted by the IRP addition.

A preliminary version of the PWROG-15015-P SAMGs with the changes approved prior to January 1, 2022 to integrate the IRP features has been developed in 2024 with the name **PWROG-15015-P Revision 0-Plus**. A validation of the SAMG changes for the IRP design was completed and is documented in PWROG-23003-P (Reference 13).

The official updated revision will be referred to as **PWROG SAMG Revision 1**, and is scheduled to be published in April 2028.

A general scheme of the WOG/PWROG SAMGs history is given in Figure 4

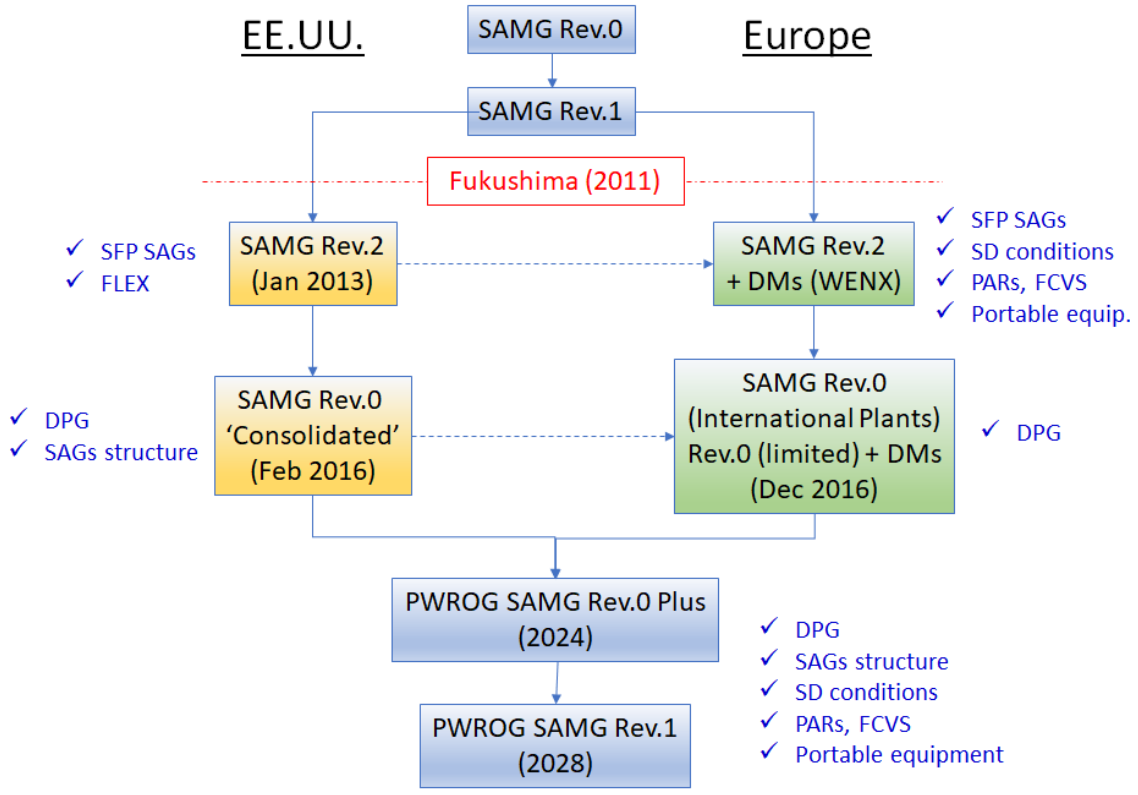

Figure 4 WOG/PWROG generic SAMGs history

3. SPANISH WESTINGHOUSE DESIGN NPPs SPECIFIC PLANT SAMGs DEVELOPMENT

Since 2001, in close collaboration with the engineering departments of the Spanish PWR Westinghouse design Almaraz, Ascó and Vandellós NPPs, Tecnatom has developed the successive revisions of the plant-specific SAMGs, with the generic guidelines of the owner groups (WOG/PWROG), as references. Tecnatom tasks in these developments also included the validation of the specific guidelines and the training of the involved plant personnel.

The initial development of the plant specific SAMGs of Almaraz, Ascó and Vandellós NPPs was developed in 2001, taking as a reference the generic WOG SAMGs Revision 0 (Reference 3). Therefore, the components and structure of these plant specific SAMGs are the same than that of the generic reference shown in Figure 1 above.

In 2011, Revision 1 of the plants-specific SAMGs was approved based on the generic WOG SAMG Revision 1 (Reference 4).

In 2016, Revision 2 of the plant-specific SAMGs, based on the generic WOG SAMG Revision 2 (Reference 7) was approved, which was a major update to the plant-specific SAMGs in the wake of the lessons learned from the Fukushima accident. Thus, the main modifications implemented were the introduction of strategies based on the use of portable equipment and the incorporation of two additional guidelines (SAG-9 and SCG-5) for the mitigation of accidents with damage to the fuel stored in spent fuel pools.

However, as noted, Revision 2 of the generic reference SAMGs did not consider the additional severe accident mitigation capabilities introduced in many plants outside the United States through certain design modifications, in particular:

- Hydrogen Passive Autocatalytic Recombiners (PAR).
- Filtered Containment Venting Systems (FCVS).
- Direct Reactor Cavity Injection capability (only implemented in Ascó and Vandellós NPPs).

Therefore, during 2015 and 2016, the Spanish Westinghouse design NPPs implemented strategies to take advantage of these capabilities in their plant specific guides by applying the basic generic guidelines generated in the European PWROG project PA-PSC-1081 (Reference 8), to extend the scope of the guides to accidents initiated at shutdown conditions and implement the post-Fukushima design modifications introduced in the plants, generating Revision 2A of the SAMGs.

Subsequently, Ascó and Vandellós NPPs plants contracted Tecnatom again to develop a new revision of their plant-specific SAMGs based on the generic PWROG-15015-P, Revision 0 for US plants (Reference 9). The components and structure of these plant specific SAMGs are the same than that of the generic reference shown in Figure 2 above.

Among the most relevant changes, the new Revision 0 includes a new TSC diagnostic tool, the Diagnostic Process Guideline (DPG), which replaces the diagnostic trees (Diagnostic Flowchart, DFC, and Severe Challenge Status Tree, SCST) of the previous revisions. The DPG introduces a new scheme to diagnose the level of threats to the different fission product barriers based on the ranges of selected basic parameters associated to these threats. Such ranges are represented by a colour code that allows to establish the priority of the guidelines to be implemented by the TSC at all times.

By replacing the DFC and SCST diagnostic trees from previous revisions, the two groups of TSC guidelines for potential damage (SAGs) or severe challenges (SCGs) to which diagnostic these trees directed have also been unified into a single group of Severe Accident Guides (SAG) to which the DPG directs.

In this latest revision, the structure of the TSC guidelines themselves was also substantially modified in order to increase their 'proceduralisation', reducing the demand for decision-making by the TSC to select the strategies to be implemented based on their positive effects and potential negative impacts. To this end, in the development of the guidelines, the positive and negative impacts of the available strategies based on the existing conditions were already implicitly considered, and based on this each guide leads directly to the strategy considered most appropriate for such conditions, exempting the TSC from the need to decide on the strategy to be implemented.

Another important new feature of Spanish W-PWR SAMGs Revision 0 was the incorporation of 5 Technical Support Guides (TSGs) with supporting information, including Calculation Aids to complement the information provided by the instrumentation, or alternative means of measurement in case of loss of instrumentation or uncertainties about the reliability of their readings.

As described in the previous section, the new generic PWROG SAMGs Revision 0 for US plants did not include the strategies associated with the design modifications introduced in European plants, and the PWROG-16059-P Revision 0 issued later for plants outside the US only partially implemented the changes in the structure of the guidelines to provide them with a greater proceduralization.

Consequently, the Spanish Westinghouse design NPPs decided to include into their plant specific SAMGs, currently in force, all the changes in the structure and use of the generic PWROG SAMGs Revision 0 for US plants, and to an undertake additional developments to introduce the strategies associated with the design modifications implemented in the plants. Asco and Vandellós plants once again entrusted this development to Tecnatom.

Figure 5 represents the development of the plant specific SAMGs for the Spanish Westinghouse design NPPs.

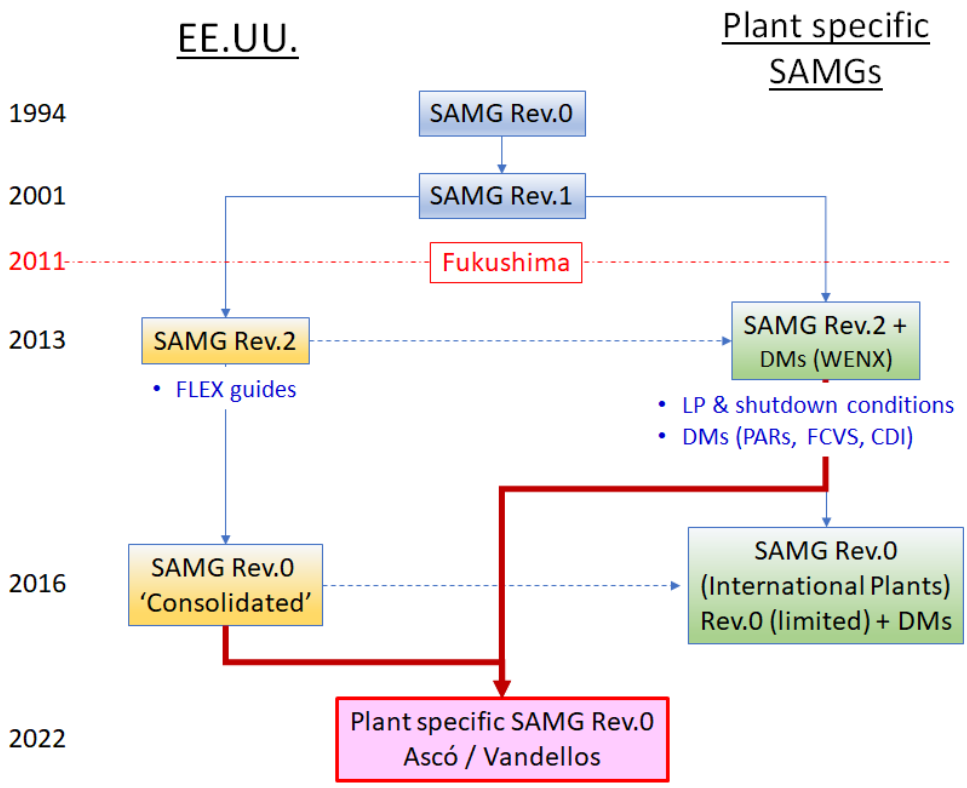

Figure 5 Spanish W-PWR plant specific SAMGs development

Prior to the approval and entry into force of the new plant specific SAMGs, training programs were carried out for all personnel involved in their use, both the MCR operation crews and all the TSC groups, including exercises on their use in postulated scenarios.

Finally, the approval and implementation of the new plant specific SAMGs required their prior verification and validation process, in accordance with the requirements of the IS-36 Safety Instruction of the Nuclear Safety Council (CSN, Spanish Regulatory Body) (Reference 15) and following the indications of the plants Severe Accident Management Guidelines (PG-SAMG) Generation Plans. The validation consisted of tabletop exercises on postulated severe accident scenarios in order to verify the ability for the correct use of the SAMGs by the personnel involved in the management of severe accidents in the plant, especially the TSC teams and MCR operation crews, evaluating the ease of reading, the consistency and homogeneity of the guides and the identification of the information.

4. KOEBERG NPP (SOUTH AFRICA) SPECIFIC PLANT SAMGs DEVELOPMENT

Subsequent to the Fukushima Daiichi NPP accident in 2011, the South African National Nuclear Regulator (NNR) directed Koeberg Nuclear Power Station (KNPS) to perform an External Events Safety Re-assessment to identify vulnerabilities and to devise likely modification measures, and technical features required to enable the plant to mitigate the consequences of an extreme External Event (EE).

To comply with NNR's requirements, Eskom (Koeberg NPP utility) developed an extensive review of the existing accident procedures, and identified plant vulnerabilities which were required to be addressed. These vulnerabilities included shortcomings in the existing KNPS procedures and guidance to cope with Beyond-Design Basis Accidents (BDBA) and External Events (EE).

In November 2024, Eskom and Westinghouse signed a contract for the development of a project to resolve the vulnerabilities detected in the Koeberg NPP procedures. The project scope covered a wide range of procedures enhancements to ensure that the plant is adequately covered to provide guidance on how to deal with an Extended Loss of Alternating Current Power (ELAP), respond in the event of an external hazard and manage severe accidents.

The project, currently under development, is divided into four Work Packages (WPs) that will cover the required procedures and document updates and developments. Westinghouse provides the qualified and competent resources to support the scope of all four WPs.

In particular, WP4, “Updates to the Severe Accident Management Guidelines (SAMGs)”, consists in the revision and adaptation of the SAMGs currently in force in Koeberg to the structure and contents of the generic PWROG-15015-P Revision 0-Plus SAMGs (Reference 12).

A post-Fukushima update of the generic WOG SAMG Revision 2 (Reference 7) on which the current Koeberg-specific SAMG are based, was released in 2013. This followed the 2012 revision of the EPRI Technical Basis Report (References 5 and 6), which forms the technical basis of the WOG/PWROG generic SAMGs.

Koeberg specific SAMGs were reviewed and updated against this released generic SAMGs, and related background documents were generated. The purpose of these updates was to keep the Koeberg SAMG aligned with international best practices. These updates are in addition to an earlier 2012 update of the Koeberg-specific SAMG that followed an internal Eskom post-Fukushima review.

The base scope of the ongoing project will develop an updated set of plant specific SAMGs in compliance with generic PWROG-15015-P Revision 0-Plus (Reference 12). As explained above, this update to the original PWROG-15015-P, Revision 0 (Reference 9) includes all the features of PWROG-16059-P, Revision 0 (Reference 10) which were developed for an “International Reference Plant”. It is now the single

reference PWROG generic SAMG and will become the PWROG supported version (for example for generic maintenance).

To develop the final plant-specific SAMGs for Koeberg Units 1 and 2, the first step was to collect the applicable plant data

- Current version of the Koeberg Plant-Specific SAMGs, Setpoints & CAs
- Plant Design features
- Instrumentation information
- Spent Fuel Pool characteristics
- Details of Instrumentation for Key SAMG Parameters
- Details of plant equipment and mitigating system resources

In parallel with these data package development a process to systematically identify plant changes has been required due to Koeberg specific design features.

In January 2026, the Revision 0-A draft of the new Koeberg specific guidelines has been delivered for Eskom comments and feedback. In Table I, the relation between current Koeberg and Rev 0-A SAMGs are shown.

Once Eskom's comments are analysed and discussed, the resulting modifications will be incorporated to generate Revision 0-B, which will also be sent to Eskom for further comments. The modifications resulting from the analysis of this new feedback will be incorporated into the Revision 0-B to generate the Revision 0-C on which the verification and validation processes will be carried out.

Finally, after implementing the modifications resulting from the validation, Revision 0 will be generated and must be approved by Eskom and the Regulatory Body.

Following the approval of the new Koeberg specific SAMGs Revision 0 and prior to their entry into force, Westinghouse will conduct an initial training process for personnel involved in their use, including MCR operation and TSC personnel.

The project is scheduled to close by the end of 2027.

Prior to this project, Westinghouse has participated in other development projects or post-Fukushima updating of plant specific SAMGs taking as reference the generic PWROG SAMGs in other plants, such as Ringhals (Sweden) or Sizewell B (UK) NPPs.

In addition, Westinghouse actively participates from its formation in PWROG activities for the development and maintenance of both the generic Emergency Response Guidelines (ERGs), basis of the plant-specific EOPs, and the generic SAMGs, reference of the plant-specific guidelines.

Table I: Current Koeberg and Rev 0-A specific SAMGs

PWROG 15015-P Rev.0 Plus SAMGs			Current Koeberg SAMGs		
TSC Diagnostic Tool	DPG	Diagnostic Process Guideline	DFC	Diagnostic Flow Chart	TSC Diagnostic Tools
			SCST	Severe Challenge Status Tree	
			SAEG-1	Long Term Monitoring	TSC Exit Guidelines
			SAEG-2	SAMG Termination	
MCR Guidelines	SAG-0	Loss of DC and/or Instrumentation			
	SAG-1	Initial Response	KWB-SACRP-1	Severe Accident Control Room Procedure - Initial Response	MCR Guidelines
			KWB-SACRP-3	Severe Accident Control Room Procedure - Initial Response for RRA aligned for service	
	SAG-2	TSC Recommending Strategies	KWB-SACRP-2	Severe Accident Control Room Procedure for Transients after TSC is Functional	
TSC Guidelines	SAG-3	Inject Into Steam Generators	SAG 1	Inject into the Steam Generators	TSC Guidelines • Severe Accident Guidelines (SAGs) • Severe Challenge Guidelines (SCGs)
	SAG-4	Depressurize RCS	SAG 2	Depressurize the RCP	
	SAG-5	Inject Into RCS	SAG 3	Inject into the RCP	
	SAG-6	Inject Into Containment	SAG 7	Inject into the Containment	
	SAG-7	Reduce Containment Hydrogen	SAG 6	Reduce Containment Hydrogen	
			SCG 3	Mitigate CCI Concerns	
	SAG-8	Control Containment Pressure	SAG 5	Control Containment Conditions	
			SCG 2	Depressurize Containment	
			SCG 4	Control Containment Vacuum	
	SAG-9	Mitigate Fission Product Release	SAG-4	Reduce Fission Product Releases	
			SCG 1	Mitigate Fission Product Releases	
	SAG-10	Control SFP Level	SAG 8	Mitigate Fuel Building Challenges	
TSC Technical Support Guidelines	TSG-1	Instrumentation			
	TSG-2	Ultimate Decision Maker			
	TSG-3	Site Capabilities			
	TSG-4	Benefit Consequence			
	TSG-5	Computational Aids			
	CA-1	Injection Rate To Recover the Core	CA-1	RCP injection to recover core	Computational Aids
	CA-2	Injection Rate for Long Term Decay Heat Removal	CA-2	Injection rate for long term Decay Heat Removal
