Proceedings of the 12th European Review Meeting on Severe Accidents Research (ERMSAR2026)

Universidad Carlos III de Madrid, Madrid, Spain

May 18-22, 2026

ERMSAR 2026 was organized under the frame of the SEAKNOT project. This project has received funding from the Euratom Research and Training Programme 2021-2023 under grant agreement No 101060327.

The content of the papers reflects only the authors' views and do not necessarily reflect those of the European Union or EURATOM. Neither the European Union nor EURATOM can be held responsible for them.

DOI: 10.5445/IR/1000196279

FOREWORD

The 12th edition of the ERMSAR (European Review Meeting on Severe Accident Research) Conference was held from 18 to 22 May 2026 in Madrid, hosted and locally organized by CIEMAT, two years after the 11th edition in Stockholm. ERMSAR 2026 was organized within the framework of the EURATOM SEAKNOT project and NUGENIA Technical Area 2 of the SNETP Association, in cooperation with the International Atomic Energy Agency and the OECD Nuclear Energy Agency.

The conference brought together 223 participants, including 35 students, from 27 countries. Scientific contributions originated from 84 institutions located in 26 countries, while 23% of the participants represented non-European Union institutions. The programme comprised 112 oral papers and 43 posters, making ERMSAR 2026 the largest edition in the historical series and confirming its role as a reference international forum fully devoted to severe accident research.

The technical programme was organized into eight thematic tracks:

No.	Technical topic	Papers	Posters
1	Analysis, management, and consequences of severe accidents for Gen I-III reactors	16	12
2	Containment behaviour, including hydrogen explosion risk	15	5
3	Ex-vessel corium interactions and coolability	17	6
4	In-vessel corium and debris coolability	15	5
5	Source-term issues	20	4
6	Severe accidents in Small Modular Reactors (SMRs)	16	4
7	Severe accidents in Generation IV concepts	7	5
8	Other applications, including fusion reactors, interim spent nuclear fuel storage and Accident Tolerant Fuels (ATFs)	6	4
ERMSAR 2026 total		**112**	**43**

The meeting combined parallel technical sessions with plenary lectures, expert panels and round-table discussions. It addressed severe accident phenomenology, hydrogen behaviour, corium management, source-term assessment, risk and uncertainty methodologies, simulation tools, and the safety of operating reactors, SMRs, Generation IV systems, advanced fuels, fusion applications and other nuclear installations.

As major conclusions from ERMSAR 2026, it is possible to highlight:

- Fundamental severe accident phenomenology and mitigation remain major research priorities, particularly for corium coolability, containment and hydrogen behaviour, and source-term assessment.
- SMRs and Generation IV systems require credible safety demonstrations, extensions of current code capabilities, and new experimental evidence for verification and validation.
- Severe accident assessments are becoming more integrated, linking accident progression and management with uncertainty analysis, radiological consequences and emergency response.
- International cooperation and the preservation and transfer of expertise remain essential; the participation of 35 students supported direct interaction between young researchers and senior experts.

These open-access proceedings, published by the KIT Library with an international Digital Object Identifier, provide a durable record of the scientific work presented at ERMSAR 2026. They complement the selected extended papers prepared for the Annals of Nuclear Energy Virtual Special Issue.

ERMSAR 2028 will take place in Bled, Slovenia, continuing more than two decades of scientific exchange and cooperation within the international severe accident community.

Editors: Fabrizio Gabrielli, Luis E. Herranz, and Sandro Paci

Celebrating Excellence in European Severe Accident Research Communication & Dissemination

The Opening Session of ERMSAR 2026 included the first recognition ever given to the contribution done over decades to Communication and Dissemination of European Severe Accident research, as one of the activities with visible and specific achievements. Among them it is worth highlighting:

- The Severe Accident Phenomenology course (SAP), which has become the international reference in severe accident education.
- The ERMSAR conference series, once born as a European Review Meeting and now turned into the worldwide topical conference on severe accident research.
- The distinctive Textbook on severe accident phenomenology and nuclear safety, a must-reading for all newcomers and professionals.
- The Severe Accident Summer Camp, for the first time came to light in 2025 with an excellent reception in the Community.

On behalf of the entire European Severe Accident Community, upon the approval of the NUGENIA/TA2 Coordination Team, Prof. Luis E. Herranz, NUGENIA/TA2 Leader at the time, delivered such a recognition to:

***Professor Sandro Paci of the University of Pisa**, for the continuous and relentless role played in these outstanding achievements through his relevant participation in EC projects and distinctive leadership of the Education and Training activities within the SNETP/NUGENIA Technical Area 2 (Severe Accidents).*

An outstanding ovation became the soundtrack of the event in the Auditorium of the Campus Puerta de Toledo of the Carlos III University.

The 12th European Review Meeting on Severe Accidents Research

May 18-22, 2026, Universidad Carlos III de Madrid, Madrid, Spain

Conference Program

MONDAY, MAY 18th, 2026

PLENARY SESSION: WELCOME AND OPENING

Chairs: S. Paci (University of Pisa), F. Gabrielli (KIT)

Welcoming Addresses

Félix Barrio, Head of the International Relations Division at CIEMAT

Santiago Aleza, Deputy Director for Engineering Nuclear Safety Directorate, CSN

Opening of the ERMSAR2026 Conference

L. E. Herranz (CIEMAT); Coordinator of the SEAKNOT Project

PLENARY SESSION: SINGULAR CAREERS IN THE SEVERE ACCIDENT RESEARCH

Chair: T. Lind (PSI)

30 years of materials science for nuclear safety. From unexpected findings to improved severe accident codes
M. Steinbruck (KIT)

Research, Insights, and Lessons Learned During a Career Focused on Ex-Vessel Severe Accident Behavior
M. Farmer (ANL)

Technical Session 3.1: Severe Accident Scenarios - Small Modular Reactors

Chairs: M. Garcia Martin (CIEMAT), F. Mascari (ENEA)

ID062	**Analysis of Postulated Severe Accidents in Generic Integral PWR Small Modular Reactors: Outcomes on Integral Codes' Modelling Capabilities from the Horizon Euratom SASPAM-SA Project** M. E. Cazado (KIT)	**Paper** **Presentation**
ID157	**Rolls-Royce SMR 3D Hydrogen Combustion Assessment Approach**	**Paper** **Presentation**

J. Fowles (Rolls-Royce SMR Limited), A. Meredith (Rolls-Royce SMR Limited), J Butterworth (Gexcon)

ID065 **Severe accident analysis of SASPAM-SA Design II LW-SMR dry containment using containmentFOAM** — Paper, Presentation
S. C. Vázquez-Rodríguez (FZJ)

ID131 **Analysis of LDR Lite Reactor's Resistance to Design Extension Conditions** — Paper, Presentation
A. Kaliatka (LEI)

Technical Session 2.1: In-vessel Corium and debris coolability

Chairs: L. Carénini (ASNR), M. Braun (Framatome)

ID143 **Reflooding of a damaged core in case of severe accident: synthesis of experimental results, modelling and consequences for the reactor scale** — Paper, Presentation
F. Fichot (ASNR)

ID013 **Simulation of the low Prandtl metallic layer of a corium pool** — Paper, Presentation
N. Seiler (CEA)

ID053 **Analysis of In-Vessel Retention in a VVER-1000 Reactor Design using AC2** — Paper, Presentation
P. Pandazis (GRS)

ID105 **Towards a High fidelity numerical simulation of In-vessel corium pool under severe accident scenarios** — Paper
A. Alasif (King Fahd University of Petroleum and Minerals)

Technical Session 1.1: Severe Accident Scenarios

Chairs: M. Angelucci (University of Pisa), D. Luxat (Sandia National Lab)

ID021 **Analysis of dose rates in the containment during the Fukushima accident** — Paper, Presentation
T. Sevón (VTT)

ID054 **Preliminary Analytical Justification of Long-Term Containment Cooling System with Steam Condensing Heat Exchanger for NPPs with VVER-1000 Reactors** — Paper, Presentation
Y. Vorobyov (Energy Safety Group LLC)

ID091 **ASTEC Modelling of the AP1000 and Cold-Leg Small-Break LOCA Simulations with Long-Term Cooling Cut-off** — Paper, Presentation
D. Zhao (National University of Singapore)

ID080 **Instrumentation survivability Assessment during a Severe Accident; Incorporating radiation monitoring in MELCOR to evaluate the impact on SAMGs** — Paper, Presentation
K. Fernandez-Cosials (Universidad Politécnica de Madrid)

Technical Session 6.1: Source term

Chairs: A.-C. Grégoire (ASNR), T. Kärkelä (VTT)

ID198 **Extension of Fission Product Transport Modeling in MELCOR** — Presentation
D. Luxat (SNL)

ID187 **Severe Accident Source Term Analyses for VVER-1000 Focused on Iodine Speciation: Sensitivity Studies with Derived Best-Practices Using ASTEC/SOPHAEROS** — Paper, Presentation
Štěpán Tichý (UJV)

ID184 **Evaluation of the effect of different transport path modelling on FP behaviour in AC2/ATHLET-CD** — Paper, Presentation
L. Tiborcz (GRS)

ID058 **Development of Evaluation Technology for Radiological Source Term in the Containment Using CINEMA Code During Severe Accidents** — Paper, Presentation
D. Son (KAERI)

Technical Session 5.1: Hydrogen risk and Containment behavior

Chairs: M. Malicki (PSI), K. Dieter (Becker Technologies GmbH)

ID096 **AMHYCO Project Outcomes and Lessons Learned** — Paper, Presentation
G. Jiménez (Universidad Politécnica de Madrid)

ID097 **CFD Analysis of the Containment Behavior during a TLAP Sequence in a Generic KWU PWR with containmentFOAM** — Paper, Presentation
S. Kelm (FZJ)

ID126 **ETSON-AMHYCO Benchmark Exercise on Flame Propagation in Representative Reactor Containment Atmosphere in Case Severe Accident Late Phases** — Paper, Presentation
A. Bentaib (NEA)

ID038 **Suppression Pool Modelling with the CESAR Thermal-Hydraulic Module of ASTEC** — Paper, Presentation
J.-A. Zambaux (ASNR)

Technical Session 4.1: Ex-vessel Corium and debris coolability

Chairs: S. Bechta (KTH), P. Piluso (CEA)

ID134 **Development of the SAFARI Code for Comprehensive Severe Accident Analysis in Nuclear Reactors: Steam Explosion Analysis Module** — Paper
K. Ju Bin (Seoul National University)

ID018 **Effect of Corium Properties Uncertainties on a PWR SBO Severe Accident** — Paper, Presentation
L. E. Herranz (CIEMAT)

ID011 **Consideration on Floating Crusts During Molten Core Concrete Interaction** — Paper, Presentation
C. Journeau (CEA)

Technical Session 3.2: Severe Accident Scenarios: Small Modular Reactors

Chairs: M.E. Cazado (KIT), S. Brumm (JRC)

ID180 **SASPAM-SA WP5: Source Term Estimation of Generic SMR Designs** — Paper, Presentation
T. Hollands (GRS)

ID048 **Gas phase iodine release from iPWR pool based on MELCOR and IMPAIR calculation** — Paper, Presentation
M. Malicki (PSI)

ID185 **MELCOR DEC-B Transient analysis in a generic integral Pressurized Water Reactor** — Paper, Presentation
F. Giannetti (University of Rome ‘La Sapianza’)

Technical Session 7.1: Spent Fuel Pools

Chairs: A. Stakhanova (KIT), S. Paci (University of Pisa)

ID111 **Recent Activities at Canadian Nuclear Laboratories on LOCA Progression in CANDU Spent Fuel Pools** — Paper, Presentation
B. Dastvareh (CNL)

ID073 **Validation of the Theoretical Approach for Modelling of the Hydride Morphology with Experimental Data for Zircaloy-4 obtained from SPIZWURZ bundle Test** — Paper, Presentation
M. Kolesnik (KIT)

TUESDAY, MAY 19th, 2026

Technical Session 1.2: Severe Accident Scenarios - Uncertainty and Sensitivity Analyses

Chairs: L. Tiborcz (GRS), F. Giannetti (University of Rome 'La Sapienza')

ID006	**Employment of relative time scale in the U&S analysis of the MBLOCA scenario in a generic KONVOI NPP** A. Stakhanova (KIT)	Paper Presentation
ID009	**Calibration of the Postulated Scenario of Fukushima-Daiichi Unit 1 through the Application of Uncertainty Quantification** L. E. Herranz (CIEMAT)	Paper Presentation
ID026	**Integrated Severe Accident Analysis for a VVER-1000: Accident Progression, Uncertainty Quantification, and Radiological Consequences Assessment** M. Angelucci (University of Pisa)	Paper Presentation

Technical Session 2.2: In-vessel Corium and debris coolability

Chairs: X. Gaus-Liu (KIT), F. Fichot (ASNR)

ID066	**Direct numerical evaluation of core equivalent conductivity: a comparative analysis of open rod and flat plate assemblies** R. Le Tellier (CEA)	Paper Presentation
ID151	**Experimental Investigation of Debris-Bed Formation for Optimizing Core-Catcher Design** T. Mashiko (University of Tokyo)	Paper Presentation
ID115	**A comparison of EATF and Zircalloy-4 cladding behaviour under severe accident conditions from 1600°C till 1970°C in steam/argon atmosphere** P. Piluso (CEA)	Paper Presentation

Technical Session 3.3: Severe Accident Scenarios - Small Modular Reactors

Chairs: F. Mascari (ENEA), M. Malicki (PSI)

ID117	**Investigation of Severe Accident Progression in Integral PWR SMRs** G. Acharya (KTH)	Paper Presentation
ID107	**Evaluation of Hypothetical Severe Accident Progression with ATF Cladding in Generic Integral PWR Designs in the Frame of the SASPAM-SA Project** M. E. Cazado (KIT)	Paper Presentation
ID164	**Comparative Analysis of Containment Behavior in a Generic iPWR Design under Postulated BDBA Conditions Using ASTEC v3.1.2 and MELCOR v2.2 codes** E. Cilia (ENEA)	Presentation
ID046	**SASPAM-SA: Assessment of existing experimental data in WP3** T. Lind (PSI)	Paper Presentation

Technical Session 3.4: Severe Accident Scenarios - Small Modular Reactors

Chairs: S. Brumm (JRC), F. Rocchi (ENEA)

ID148	**Assessment of Emergency Planning Zone for iPWRs within the Horizon Euratom SASPAM-SA Project**	Paper Presentation

M. Ilvonen (VTT)

ID191	**Performance Assessment of Passive Safety Systems and Identification of Conditions Leading to Design Extension Scenarios** E. Cilia (University of Bologna)	Paper Presentation
ID119	**Effect of Delayed Recovery of ECCS during Severe Accidents in Integral PWR SMRs** G. Acharya (KTH)	Paper Presentation
ID181	**Investigation of In Vessel Melt Retention by a stand-alone Lower Plenum ASTEC model of integral-PWR design#1 in the SASPAM-SA project** S. Brumm (JRC)	Paper Presentation

Technical Session 5.2: Hydrogen risk and Containment behavior

Chairs: S. Kelm (FZJ), G. Jiménez (Universidad Politécnica de Madrid)

ID092	**PARs for Hydrogen Measurement in Nuclear Containments in Severe Accidents** L. Gardner (CNL)	Paper Presentation
ID093	**Development of a database for PAR model validation based on THAI experiments and its application in the framework of the AMHYCO project** E.-A. Reinecke (FZJ)	Paper Presentation
ID069	**Fission product behavior and Source Term Impacts in Ex-Vessel Phase using THAI Test Data: the OECD/NEA THEMIS Project** K. Dieter (Becker Technologies GmbH)	Paper Presentation
ID078	**Development status of the flammability risk monitoring system in severe accidents** Y. Na (KAERI)	Paper Presentation

Technical Session 6.2: Source term

Chairs: T. Lind (PSI), T. Kärkelä (VTT)

ID195	**Developing a Concept for the Prediction of Long-Term Radionuclide Leaching from Corium in Post-Accident Scenarios** T. Jankowski (RUB)	Paper Presentation
ID031	**FissiOn pRoducts bEhavior under SeverE accident with New fuel concepts The OECD/NEA FORESEEN Project** A.-C. Grégoire (ASNR)	Paper Presentation
ID201	**Scaling Effects in Iodine Retention for Filtered Containment Venting: Experimental Findings and Safety Implications** S. Gupta (Framatome GmbH)	Paper Presentation
ID182	**A Deep Learning Surrogate Model for Rapid Prediction of Atmospheric Radioisotope Dispersion** O. Murat (KIT)	Paper Presentation

PLENARY SESSION: EXPECTATIONS FROM SA R&D (ROUND TABLE)

Chair: A. Bentaib (NEA)

Expectations from SA R&D. A Regulator Point of View — Presentation

M. Sánchez (CSN)

Notes to the Severe Accident Research Community Based on the Experience of the Fukushima Daiichi Accident — Presentation

T. Fuketa (NDF; NRA)

L. Borondo Arribas (Iberdrola) — Presentation

Severe Accident in NPP Research and Application — Presentation

A. Giner (Westinghouse)

Poster Session

ID015	**MAAP5 Analysis of High-Pressure Severe Accidents in a Small Modular Reactors** Byung Jo Kim (KEPCO E&C)	Abstract Poster
ID019	**Development and Evaluation of an Ablation-Resistant Basemat Concrete for Severe Accident Mitigation in LWRs** E. Chen (CNPE)	Abstract Poster
ID023	**Aerosol Removal Behavior by Containment Spray** B. Lee (KAERI)	Abstract
ID025	**Development of performance verification test methodology for passive radioactive material filtration system** K.H. Park (KAERI)	Abstract Poster
ID027	**Experimental analysis of molten salt aerosol in tank of confined volume: evaporation, airborne and deposition.** Jun-young Kang (KAERI)	Abstract
ID029	**Additional primary depressurized line (APDL) for NPP Units with VVER-440/V-213** O. Mykhailenko (ES Group LLC)	Abstract Poster

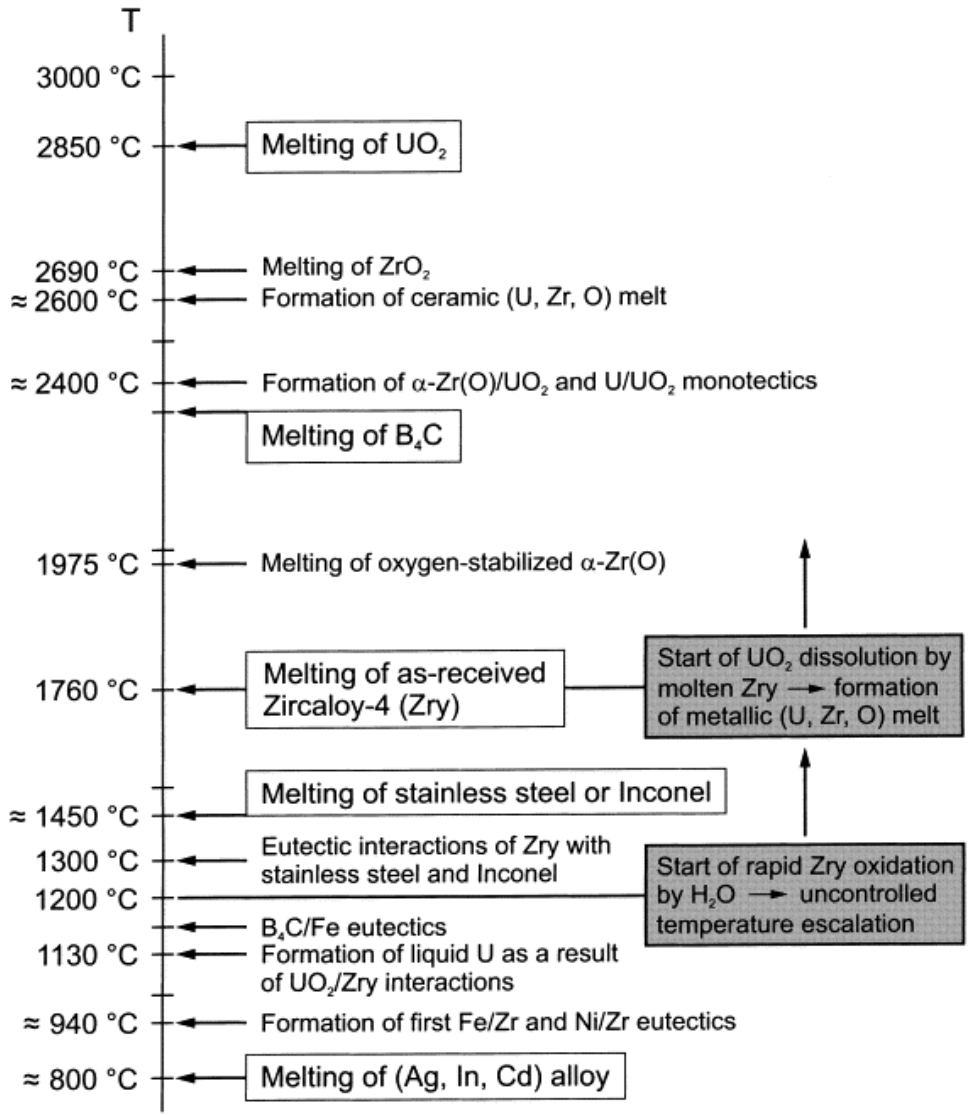
12th Confenece on Severe Accident Research (ERMSAR 2026)

May 18-22, 2026 – Madrid, Spain

IAM-AWP

Background

- Intensive research into severe accidents worldwide and at Karlsruhe following the TMI-2 accident (1979)
- At KfK/FZK, large-scale experiments on many in-vessel and ex-vessel phenomena
- QUENCH program initiated by Peter Hofmann after completion of the CORA program
  - Determination of the hydrogen source term during reflood of an overheated reactor core
- Intensive research on ATF worldwide and at Karlsruhe after Fukushima Daiichi (2011)
  - KIT presentation at ERMSAR 2024
- My carrier at Karlsruhe started with the commissioning of the QUENCH facility



P. Hofmann, JNM 270 (1999) 194

Content

1. Background
2. The “quench effect” on hydrogen source term
3. The effect of nitrogen on cladding oxidation and degradation
4. The effect of B_4C-SS eutectic interactions on accident progression
5. Takeaways

The “quench effect” on hydrogen source term

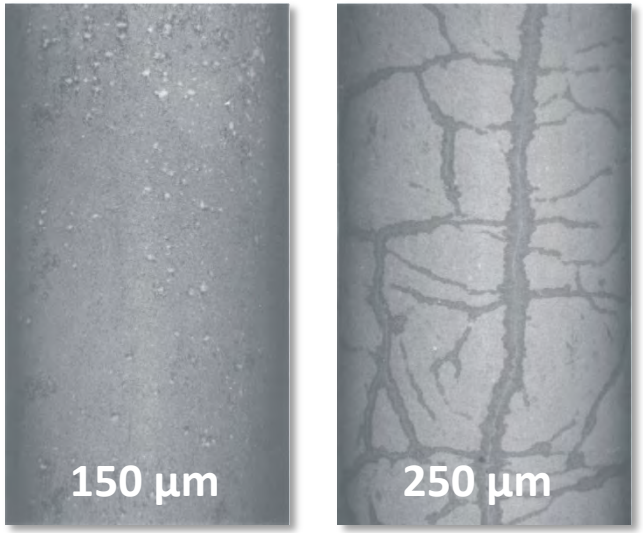
In search of the "quench effect"

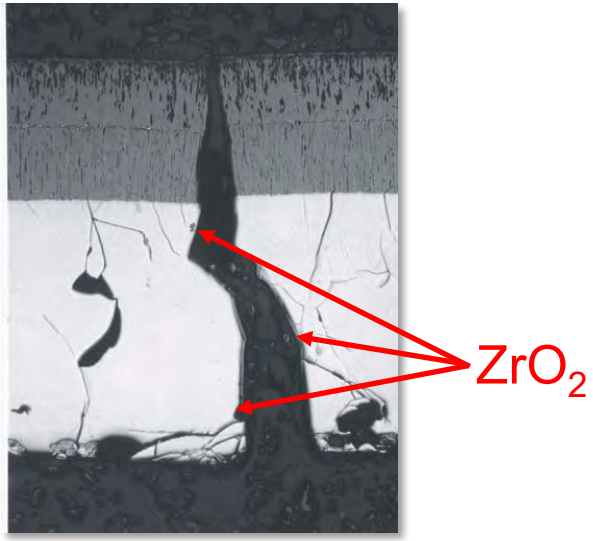
- Water injection is the primary AMM for cooling an uncovered core during a severe accident scenario
- Analysis of the TMI-2 accident as well as subsequent integral in-pile and out-of-pile experiments (PBF, LOFT, PHEBUS, CORA) has shown that water injection can result in temperature runaway, which is connected with intense hydrogen release
- The QUENCH program was designed to understand this phenomenon and to provide quantitative data on the hydrogen source term
- Initially we looked for a single “quench effect”

Sepold et al., NED204 (2001) 205–220:

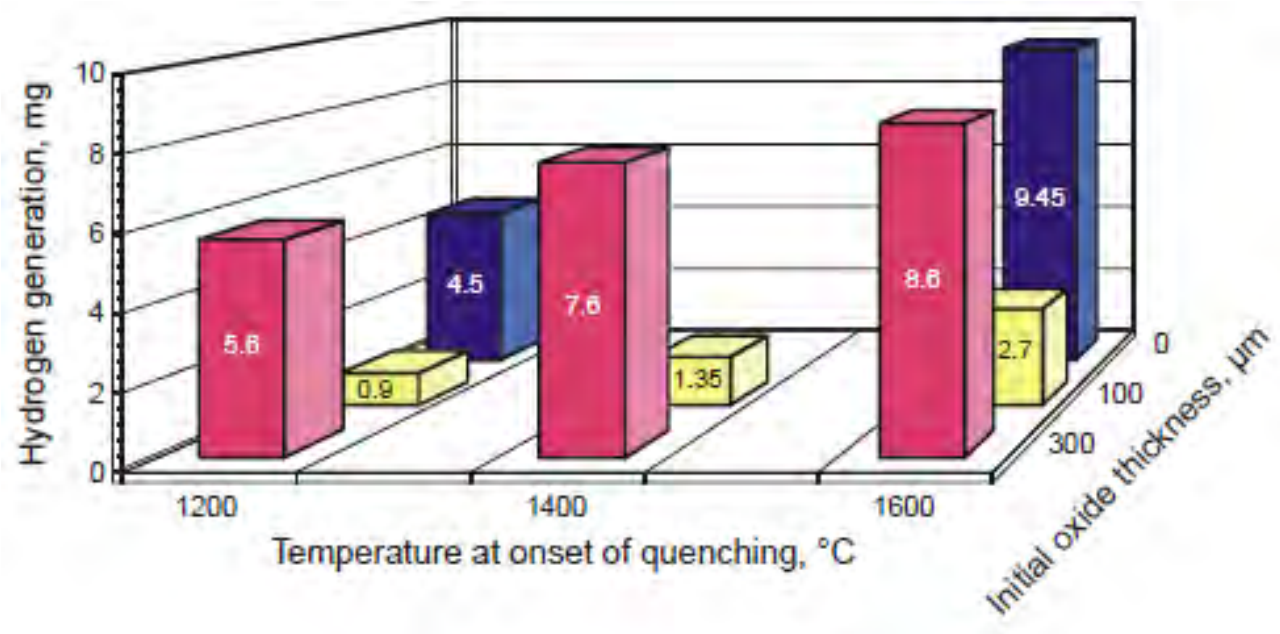
However, before the water succeeds in cooling the fuel elements, water injection can trigger a renewed enhanced oxidation of the Zircaloy cladding and, at the same time, cause a rapid increase in temperature and hydrogen generation.
This phenomenon was demonstrated by analyses of the TMI-2 accident and in results of out-of-pile (CORA) and in-pile LWR bundle experiments (LOFT, Phebus). It was explained as being due to the generation of new metal surfaces by cracking and fragmentation of the oxygen-embrittled cladding tubes during flooding, and to enhanced exothermal oxidation of the newly formed metal surfaces *(Hofmann et al., Report FZKA 5846, 1997)*.

Single-rod QUENCH tests – Main results



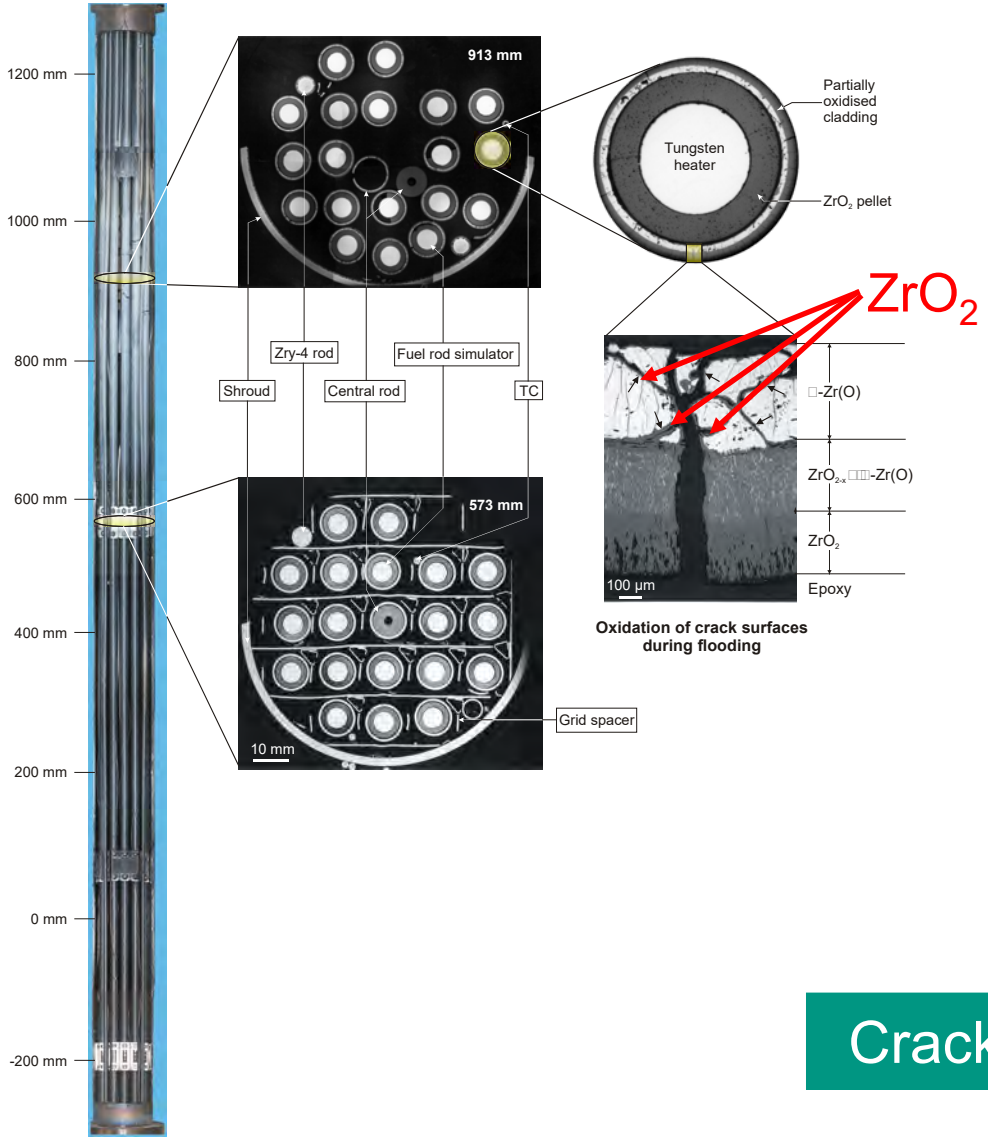


- Through-wall crack for pre-oxidation >200 µm with a density of 0.5 mm/mm^2
- Oxidation of crack surfaces connected with hydrogen generation and partly absorption by the metal



Hydrogen generation vs. oxide thickness

Crack formation in QUENCH-01 bundle test



- Estimation of hydrogen production by crack oxidation gives only ca. 1-2 g for the whole bundle
- This could not explain temperature runaway during reflood

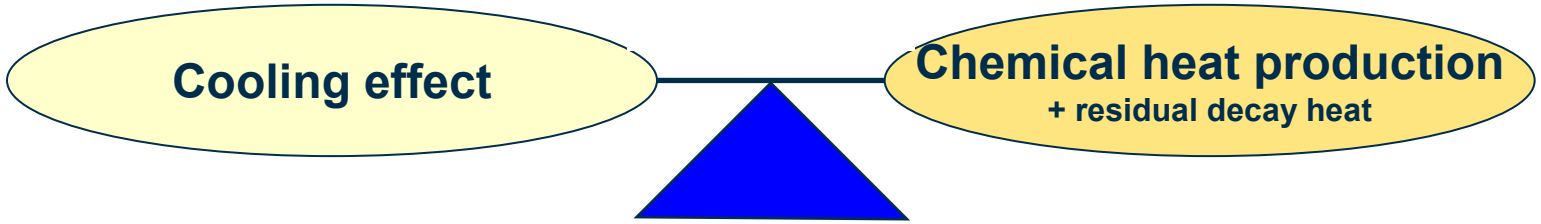
However:

- *Solution enthalpy of 1 g H_2 in 1 kg Zr increases temperature by 200 K*

Crack formation and oxidation are only minor effects

Successful reflood depends on many parameters

Reflood
Water injection → steam production



$Q_c \sim h\,(T_{Zr} - T_c)$

$Q_R \sim \Delta_R H\,(K(T)/t)^{0.5}$

$Zr + 2\,H_2O \rightarrow ZrO_2 + 2\,H_2 + 580\ kJ$

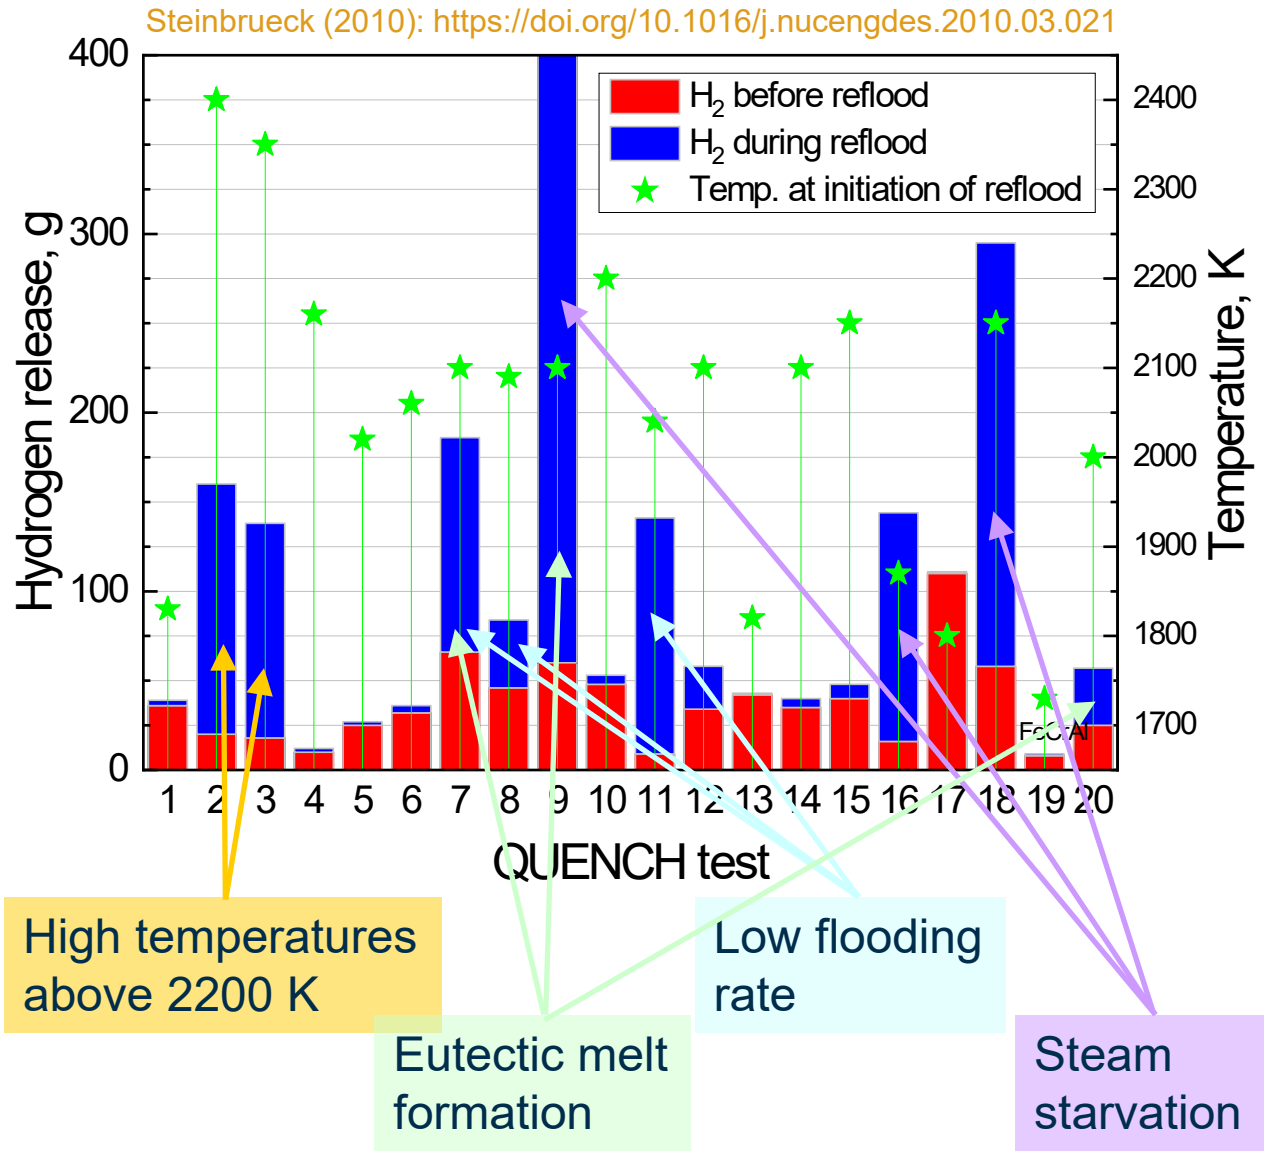
Influenced by

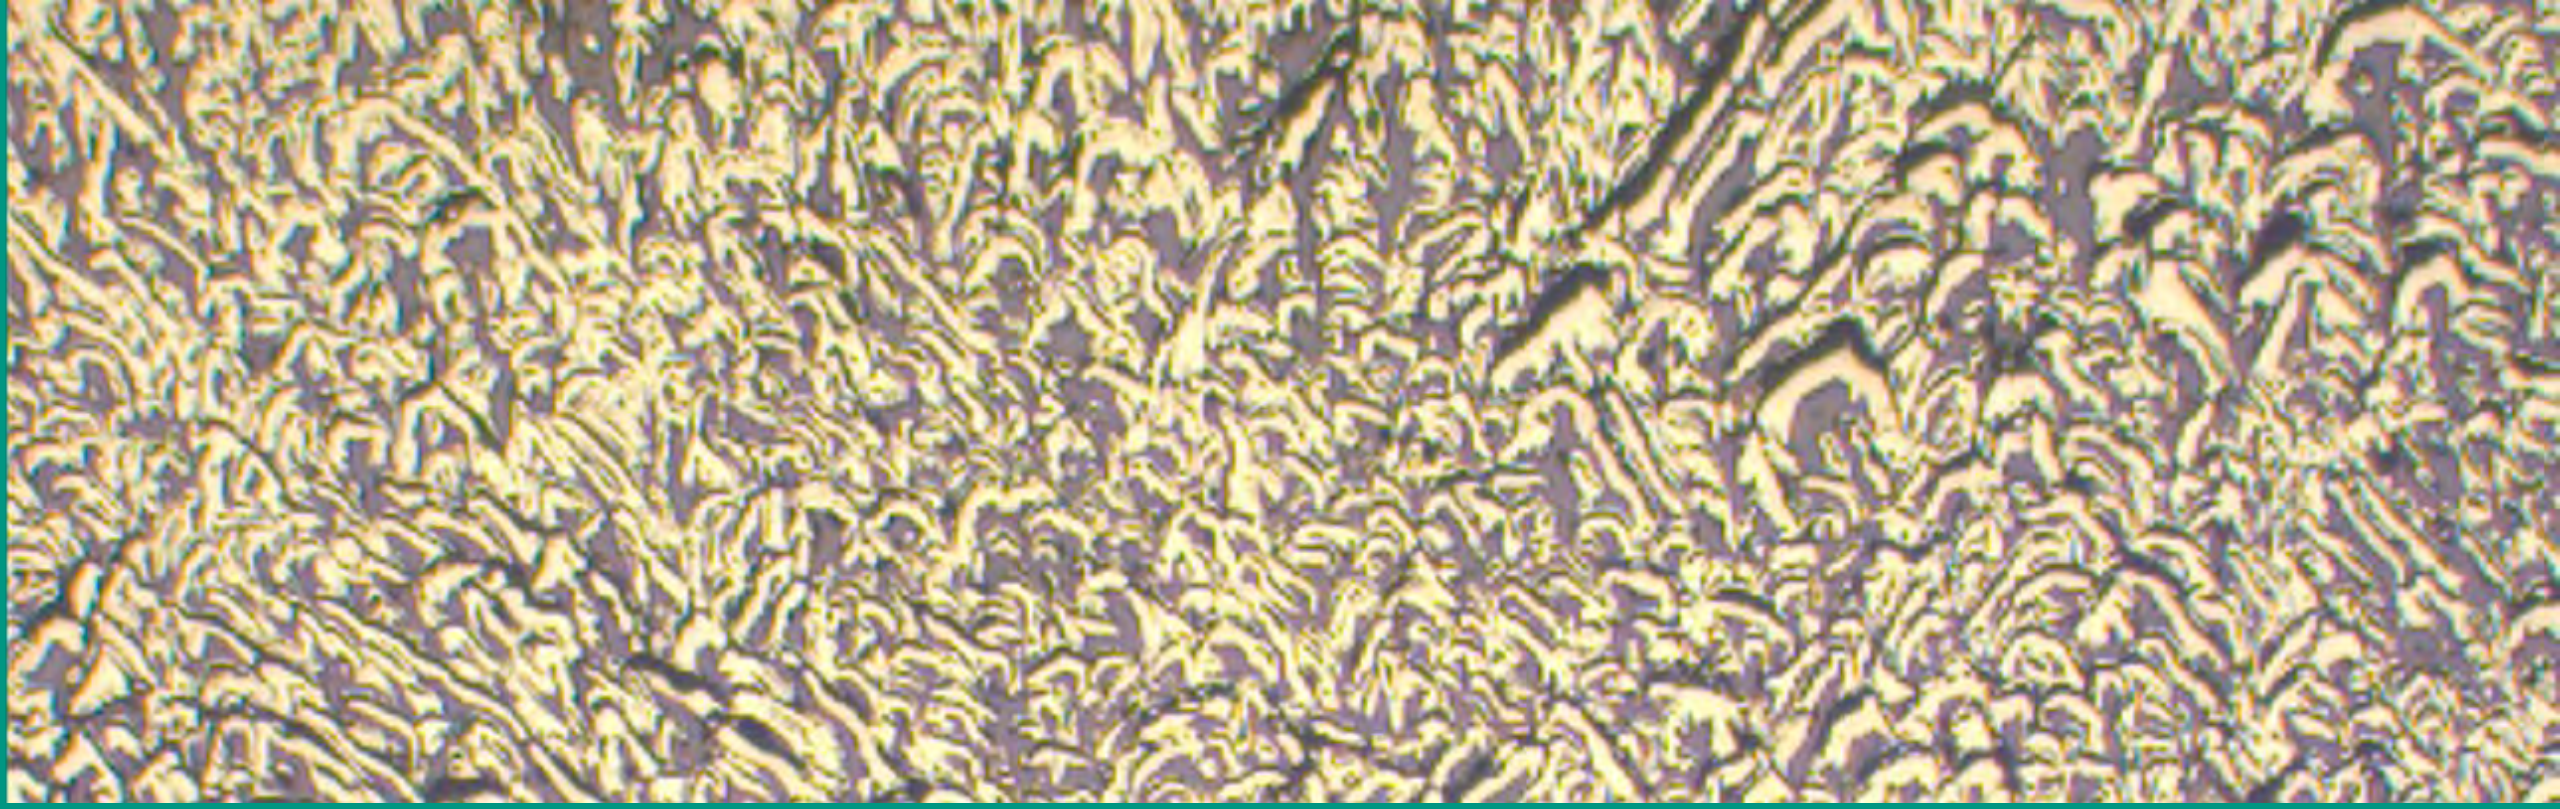
- **ΔT**
- Flooding rate
- Cooling medium
- Pressure
- Hydraulic diameter
- …

- **Oxidation kinetics**
- Temperature (Arrhenius type)
- Degree of pre-oxidation
- Surface available for oxidation
- Material composition
- **Steam availability**

Summary of QUENCH bundle tests

- Depending on the energy balance after reflood initiation, there will be a cooldown or temperature escalation
- Successful reflood if
  - Less chemical (and residual decay) energy is produced than can be eliminated by cooling
  - Cooling water rate is > 1 g/s rod
  - No oxidizable melt in contact with steam
- Ultimately, we discovered that a variety of factors must be considered
- QUENCH experiments are used for validation of many SA codes

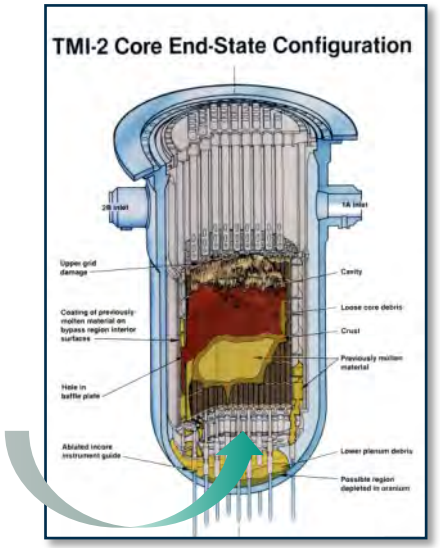


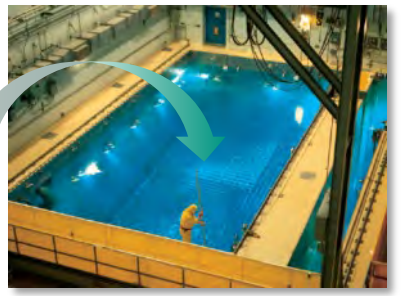


The effect of nitrogen on cladding oxidation and degradation

Nitrogen in LWRs

- The “inert” gas nitrogen is used to inertize BWR containments and in ECCS pressurizers
- Air contains nitrogen and ingress may occur into reactor core, spent fuel pond, or transportation cask
- Typically, nitrogen comes into contact with the cladding after steam oxidation, mixing with the steam

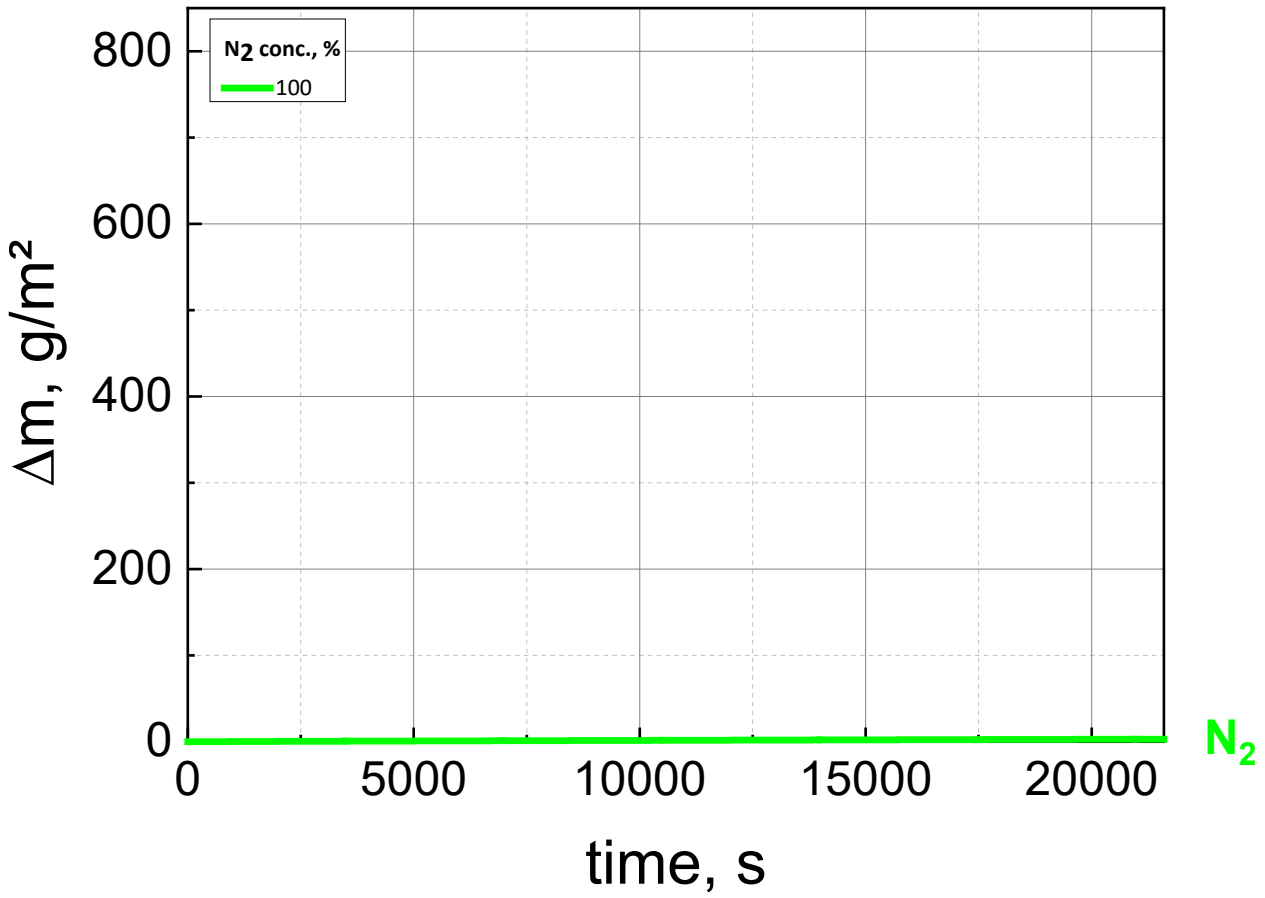




What are the consequences on hydrogen source term and cladding degradation?

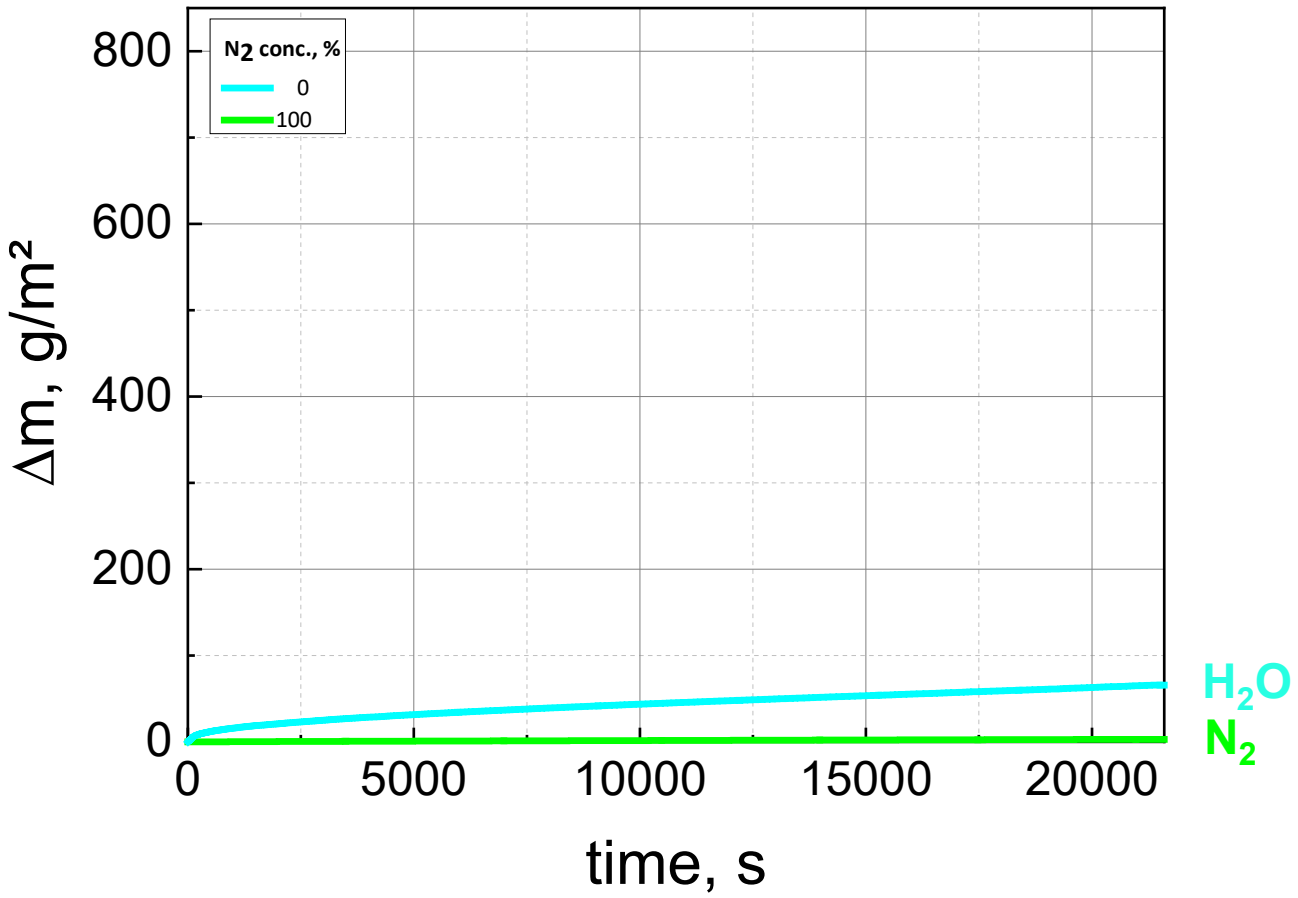
The effect of nitrogen on the oxidation and degradation of Zr alloys

6 hours at 800°C

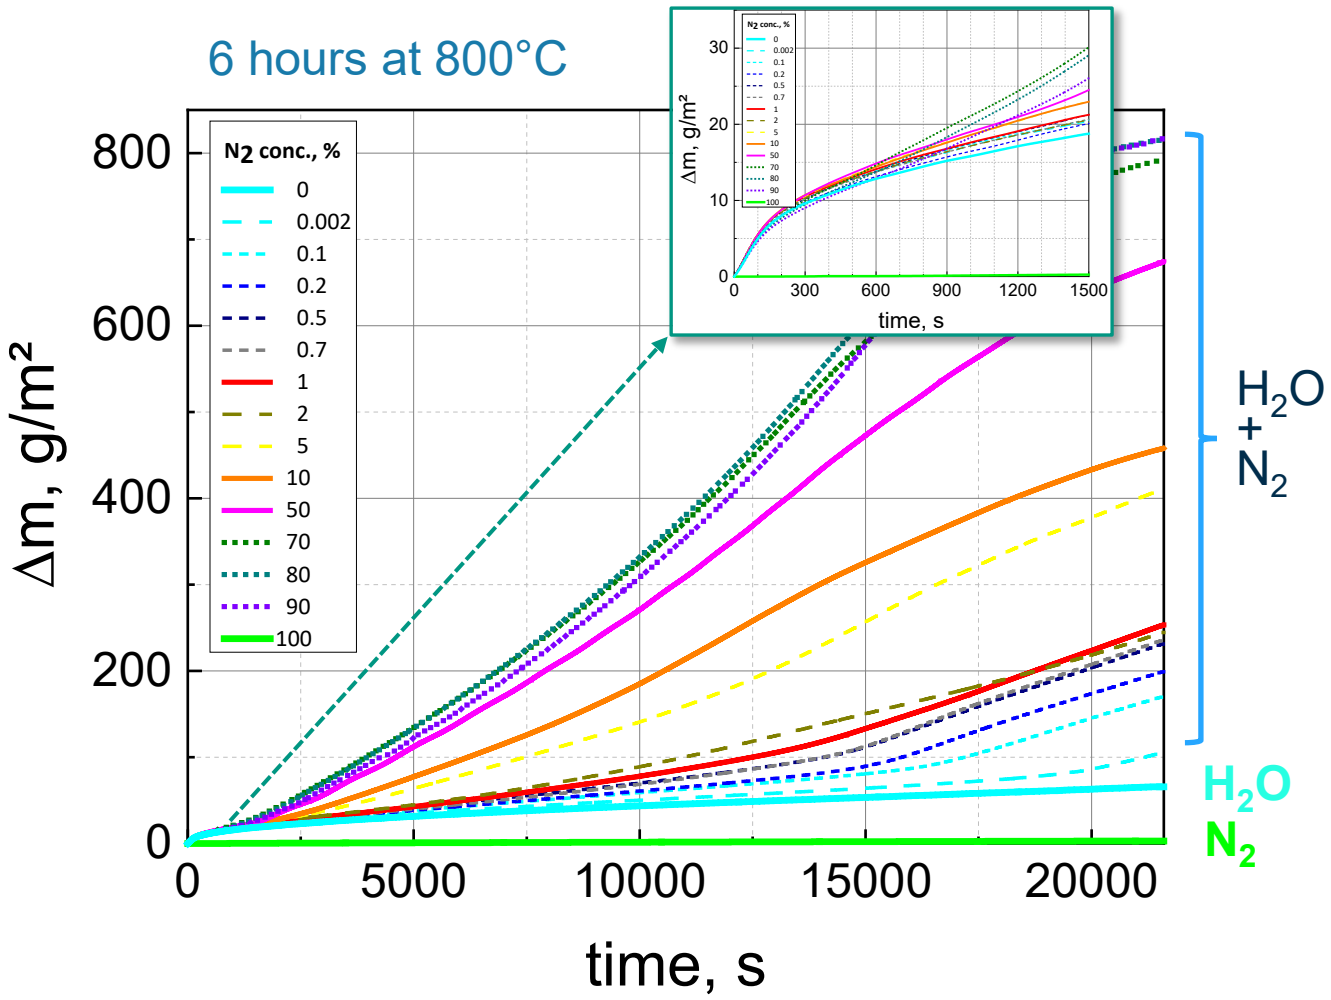


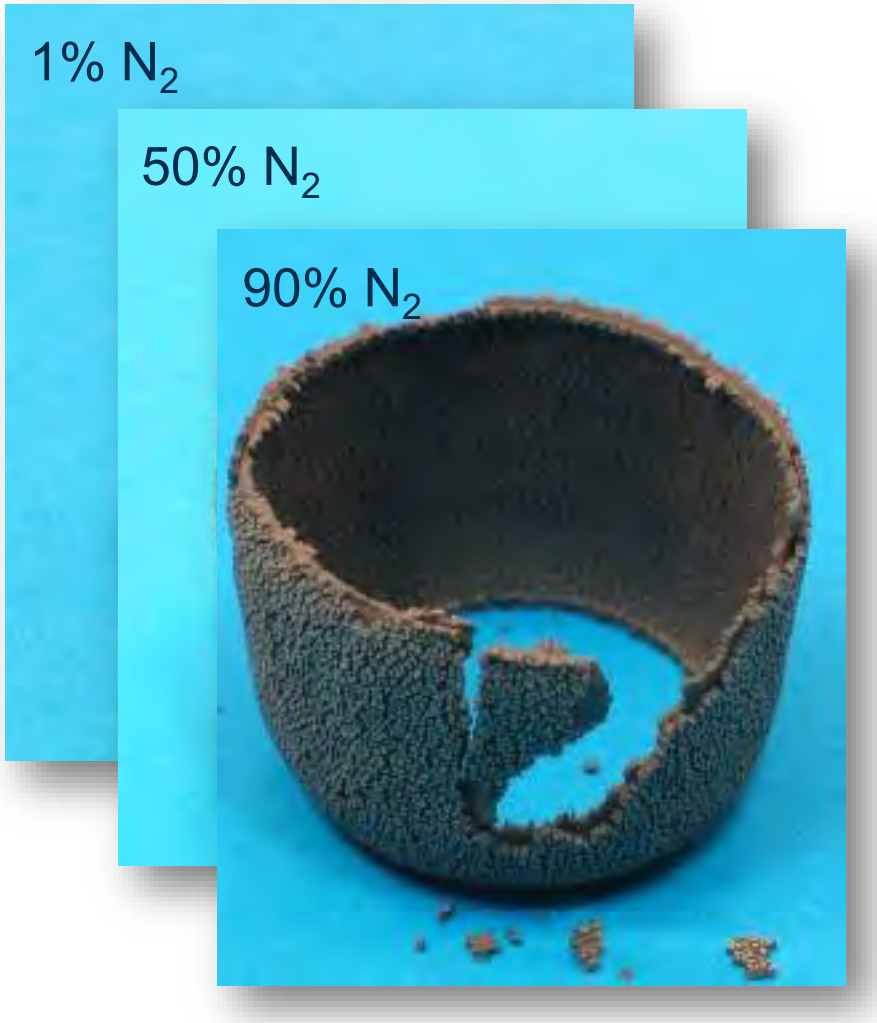
The effect of nitrogen on the oxidation and degradation of Zr alloys

6 hours at 800°C



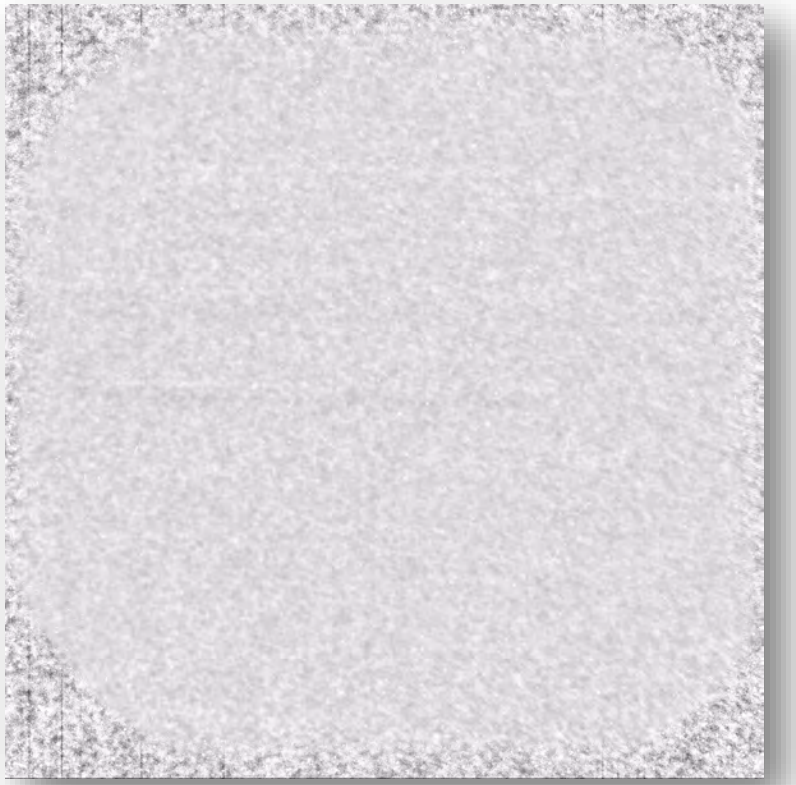
The effect of nitrogen on the oxidation and degradation of Zr alloys



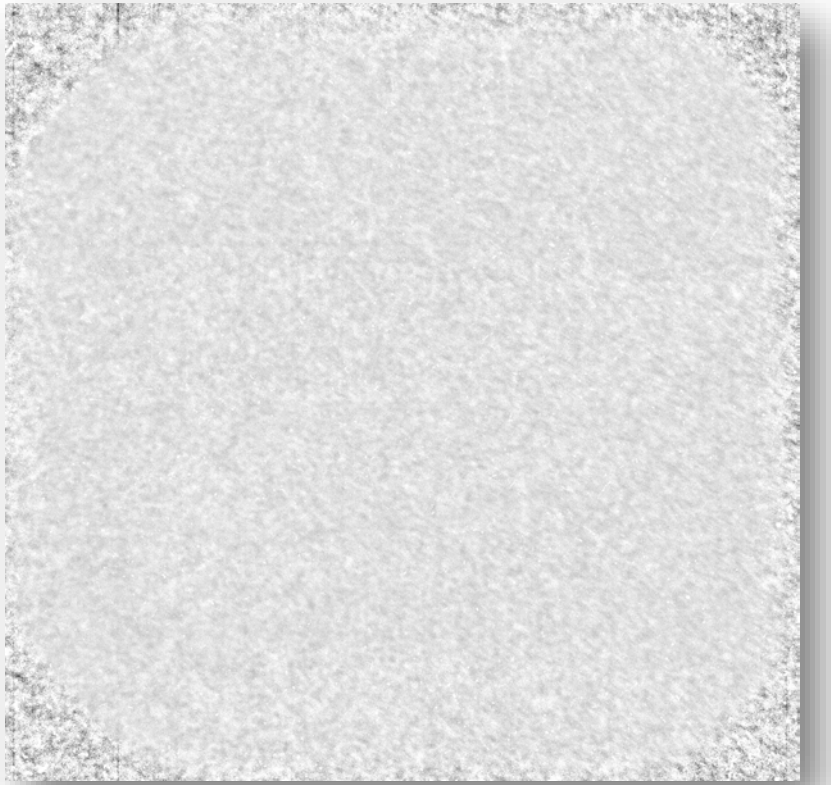


In-situ Neutron imaging

Example: 2h oxidation of Zry-4 at 900 °C in steam and steam/N_2



Steam



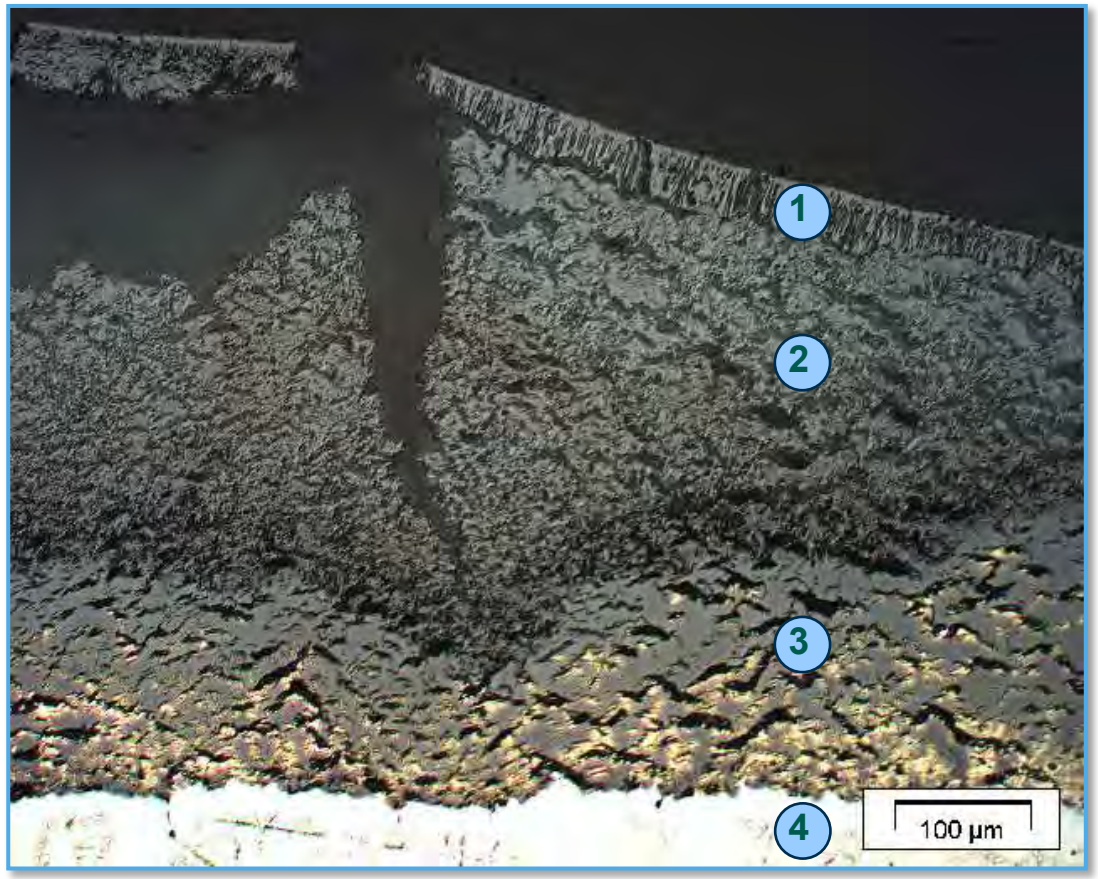
Steam + nitrogen

Grosse (2018): https://doi.org/10.1016/j.physb.2018.03.030

Mechanism of air oxidation

- Diffusion of the gas mixture through imperfections in the oxide scale to the metal/oxide interface
- Consumption of oxygen/steam
- Remaining nitrogen reacts with zirconium and forms ZrN
- ZrN is re-oxidized by fresh air with continuing reaction, associated with a volume increase by 48%

➢ Formation of porous and non-protective oxide scales



1 – initially formed dense oxide ZrO_2

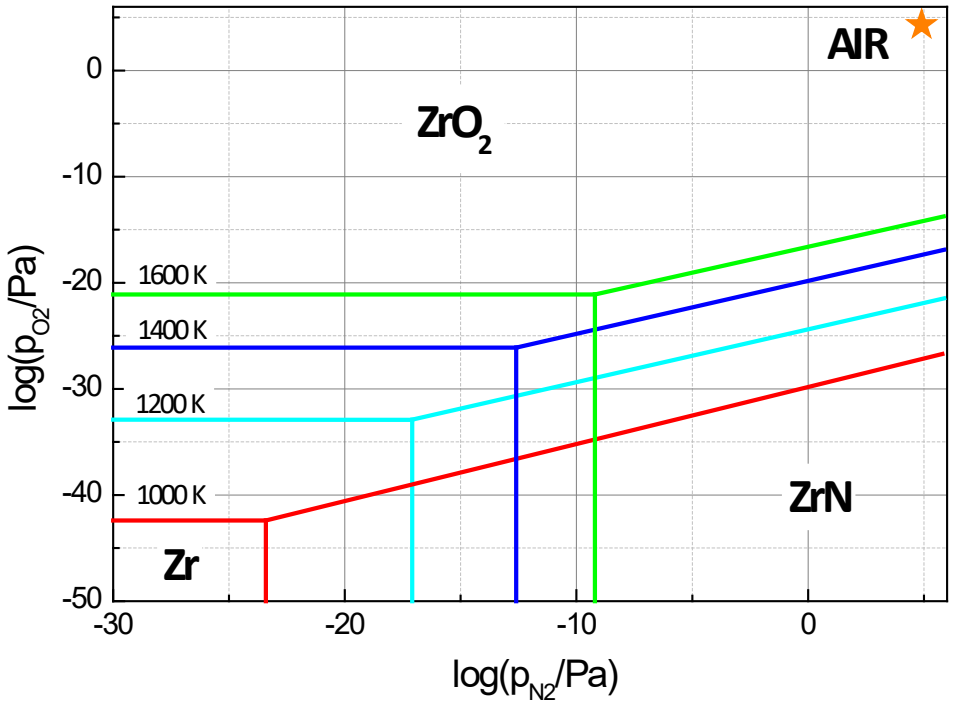
2 – porous oxide after oxidation of ZrN

3 – ZrO_2 / ZrN mixture

4 – α-Zr(O)

Mechanism of air oxidation

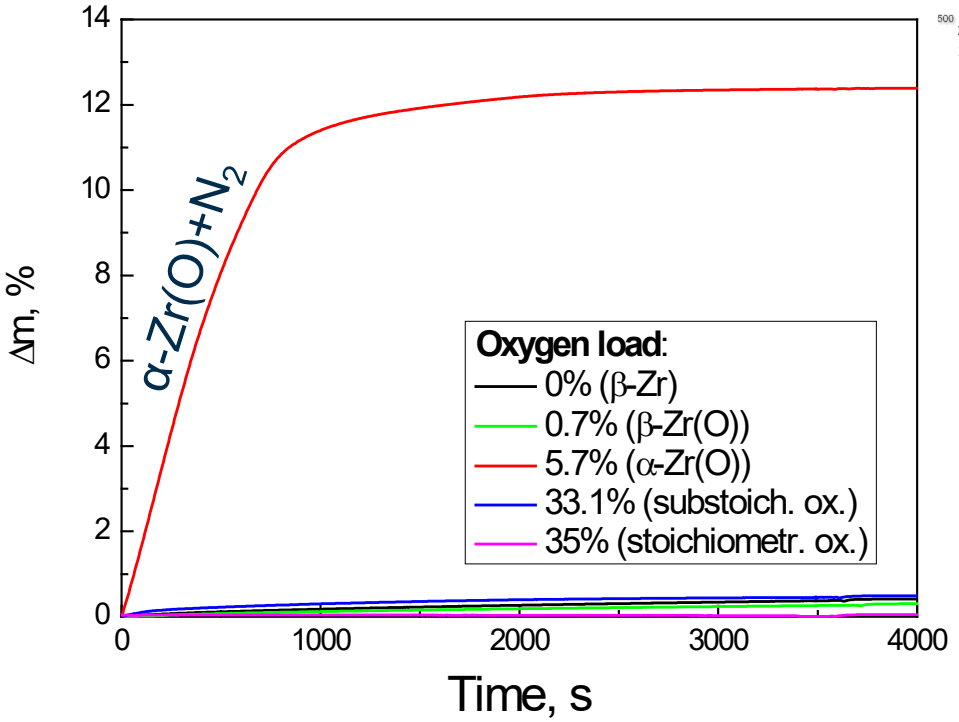
Thermodynamic view



Stability diagram Zr-O-N

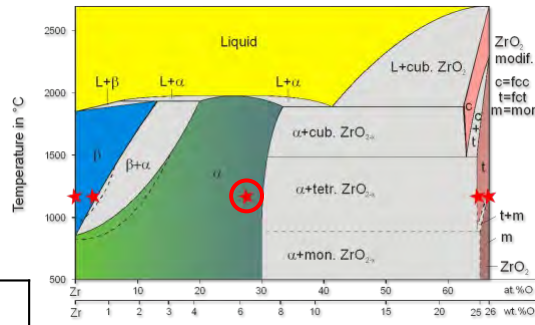
- ZrN only stable at very low oxygen partial pressure

Kinetic view



Reaction of ZrO_x with nitrogen (1200°C)

- Fast reaction of oxygen-stabilized Zr with nitrogen



Both conditions are present locally at the metal-oxide interface

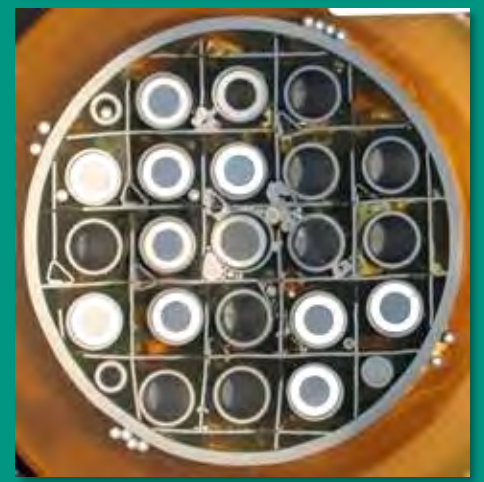
More information, see paper from Steinbrück
https://doi.org/10.1016/j.jnucmat.2009.04.018
http://dx.doi.org/10.1016/j.jnucmat.2013.12.024

Summary of oxidation in N_2 containing atmosphere

- Oxidation of zirconium alloys in atmospheres containing air or nitrogen is a very complex process, strongly dependent on experimental boundary conditions
- Local conditions (i.e. at M/O interface) may be different from ambient conditions
- Nitrogen causes early loss of barrier effect against FP release and contributes to enhanced hydrogen source term
- The effect of nitrogen (“air ingress”) has been considered in the severe accident codes, using experimental data from KIT and other laboratories

Nitrogen is not an inert gas under the conditions of a nuclear accident!

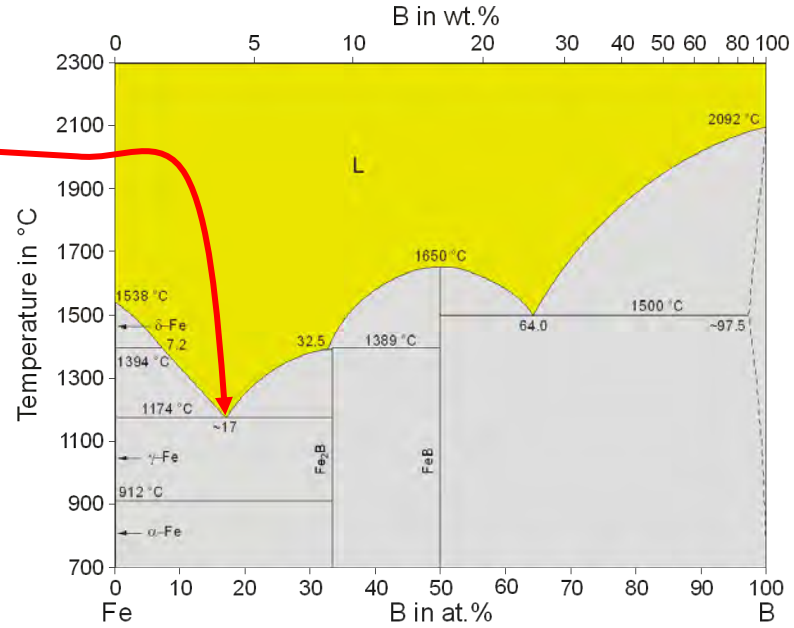
The effect of B_4C-Fe eutectic interaction on accident progression

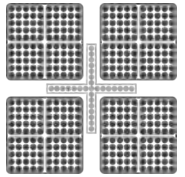


B_4C control rods in LWRs

- Boron carbide is used in boiling water reactors (BWR), VVERs, some pressurized water reactors (PWR)
- Oxidation of B_4C (containing melts) in steam produces large amounts of hydrogen, C+B containing gases, and heat
- Surrounded by stainless steel (cladding, blades) and Zry (guide tubes, canisters)

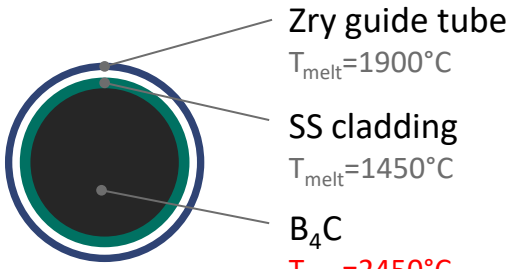
T_{eut} < 1200°C





BWR control blade

B_4C pellet



BWR control rod

Eutectic interaction of stainless steel with B_4C

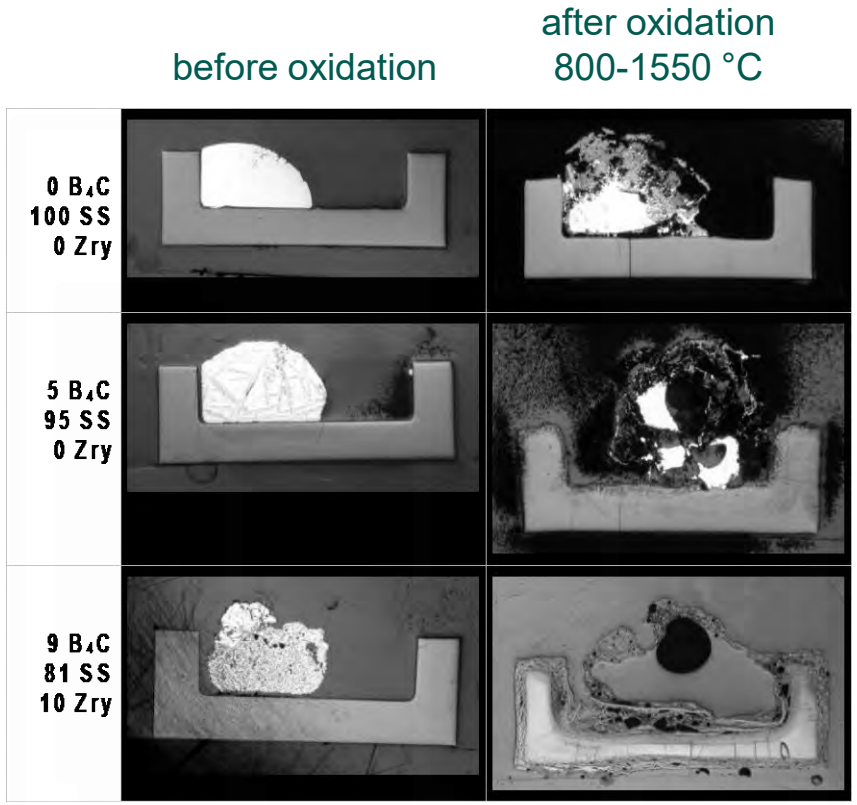
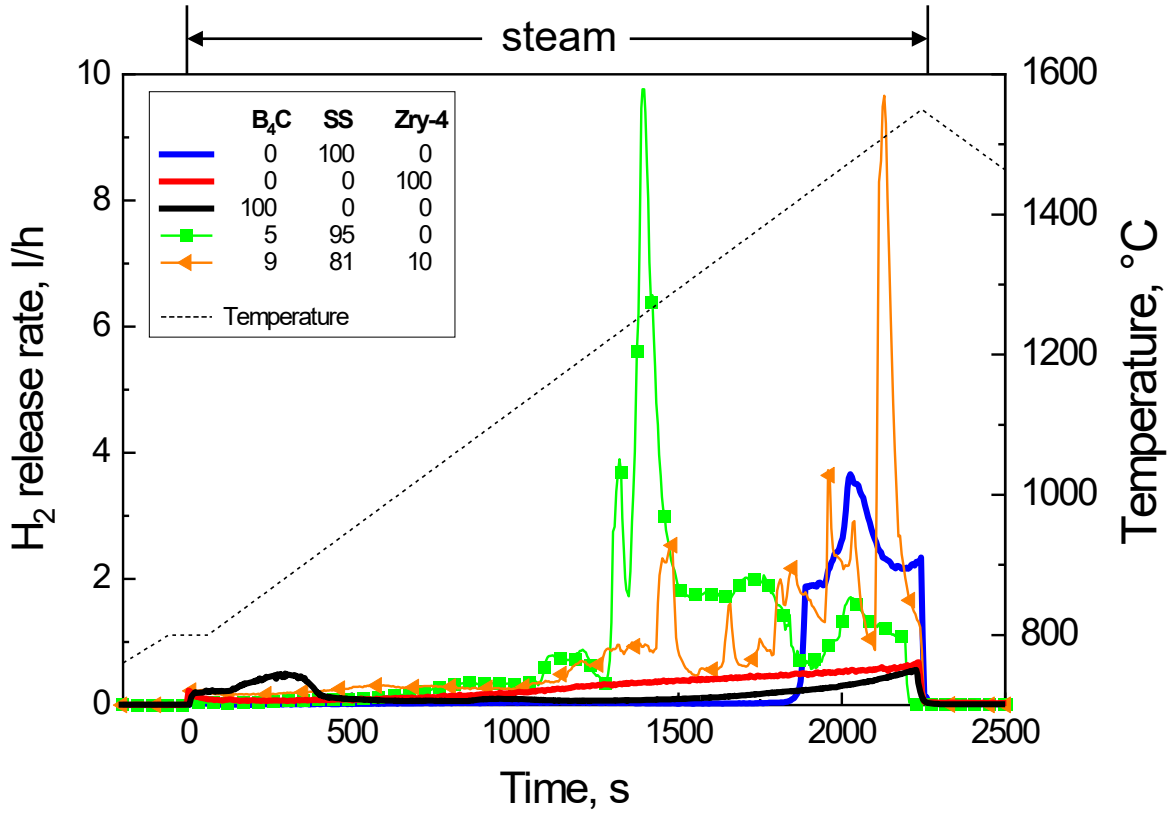
- Dissolution of cladding and fuel
- Massive melt relocation (SS, Zry, UO_2)

16-01 (110mm), top view

Oxidation of eutectic melts



Strong interaction of oxidized melt with ZrO_2 crucible



High oxidation rates beyond melting temperature

Summary of B_4C effects in severe accidents

- Low-temperature eutectic melts form at temperatures several hundred Kelvin below the melting temperatures of the materials involved
- These chemically aggressive melts may attack surrounding core structures including fuel, thus influencing corium behavior and the FP source term
- Oxidation of B_4C and B_4C-containing melts results in the release of large amounts of hydrogen and heat
- Further reaction products (CO, CO_2, boric acids) have to be taken into account for accident analyses as well
- No methane (relevant for FP chemistry) is produced during high-temperature oxidation of B_4C

Takeaways

- Not everything is as it seems at first glance
- Experiments must be designed to be as prototypical as possible
- Equilibrium thermodynamics (also locally!) and kinetics must be considered
- The key to the success of the QUENCH program lies in the interlocking of large-scale bundle experiments, separate-effects tests, modelling, and code validation and application

RESEARCH, INSIGHTS, AND LESSONS LEARNED DURING A CAREER FOCUSED ON LWR EX-VESSEL SEVERE ACCIDENT BEHAVIOR

MITCH FARMER
Manager, LWR Programs
Nuclear Science & Engineering Division
Argonne National Laboratory

Presentation at 12th European Review Meeting in Severe Accidents Research (ERMSAR) Conference
Madrid, Spain, May 18, 2026

PRESENTATION BACKGROUND & OBJECTIVES

Background:

- Over the last 30+ years, Argonne has conducted various test programs focused on improving the understanding ex-vessel severe accident behavior (ACE/MCCI, COMET, MACE, OECD/MCCI, ROSAU…)
- To successfully execute these programs, there was a need to evolve the technology for producing core-melts to meet test objectives.
  - Due to the complexity of this work (principally related to core melt production techniques) a few ‘bumps in the road’ were encountered along the way.

Objectives:

- Provide a high-level overview of the evolution of core melt production technology.
- Present a few case studies illustrating difficulties encountered along the way, the resultant lessons-learned, and steps taken to address them in subsequent tests.

APPROACH

1. Summarize the overall evolution of core melt production technology and its application in tests (2 viewgraphs).
2. Provide video examples of ‘good day’ and ‘bad day’ test outcomes.
3. Discuss three tests where difficulties were encountered and what was done to address lessons learned in subsequent experiments.

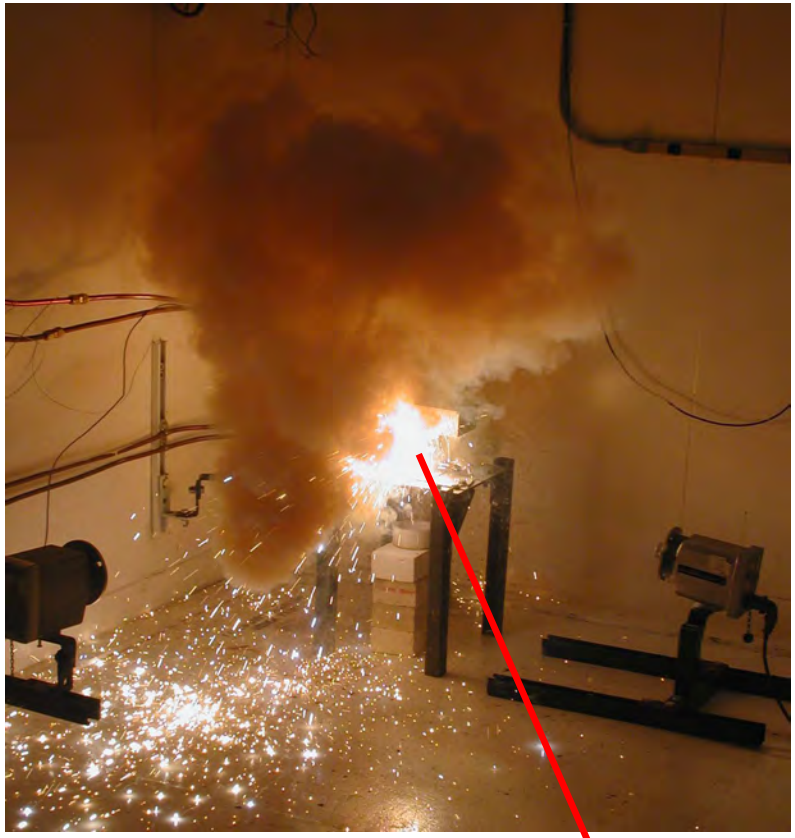
EVOLUTION OF CORE MELT PRODUCTION TECHNOLOGY

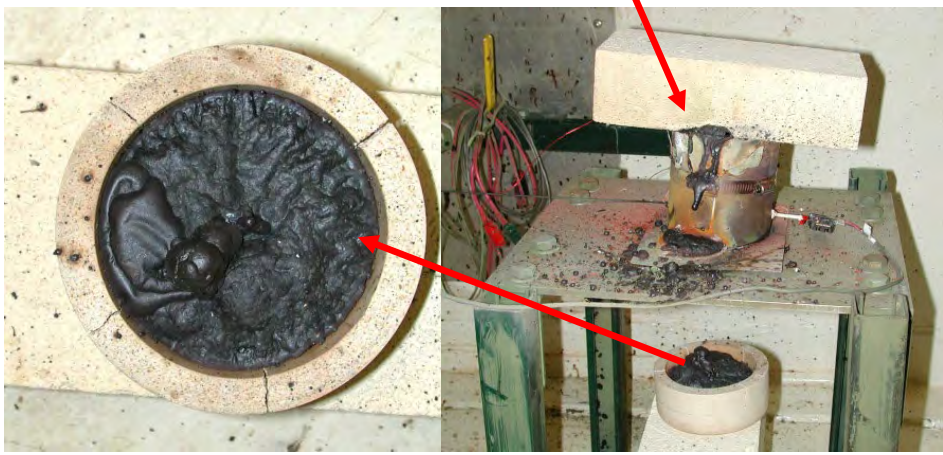
A long road….

- Early ACE/MCCI tests focused on studying fission product release during MCCI under dry cavity conditions.
  - Used ‘Direct Electrical Heating (DEH)’ to produce core melt.
  - Tungsten starter coils were embedded in crushed UO_2 pellets near the top of the powder bed.
  - Pellets heated until onset of melting; subsequent growth of melt zone to encompass the entire melt mass.
  - Process took several hours to melt a few hundred kg *in-situ* before ‘the test’ could start.
- During the follow-on MACE program, focused on debris coolability, decision made to switch from DEH to exothermic chemical reactions to produce melt.
  - Several motivating factors, but primary reason was that testing & analysis indicated a need for very large melt mass ($\geq$ 2000 kg) to achieve ‘prototypic’ conditions for coolability testing.
  - DEH approach impractical for producing this amount of melt.

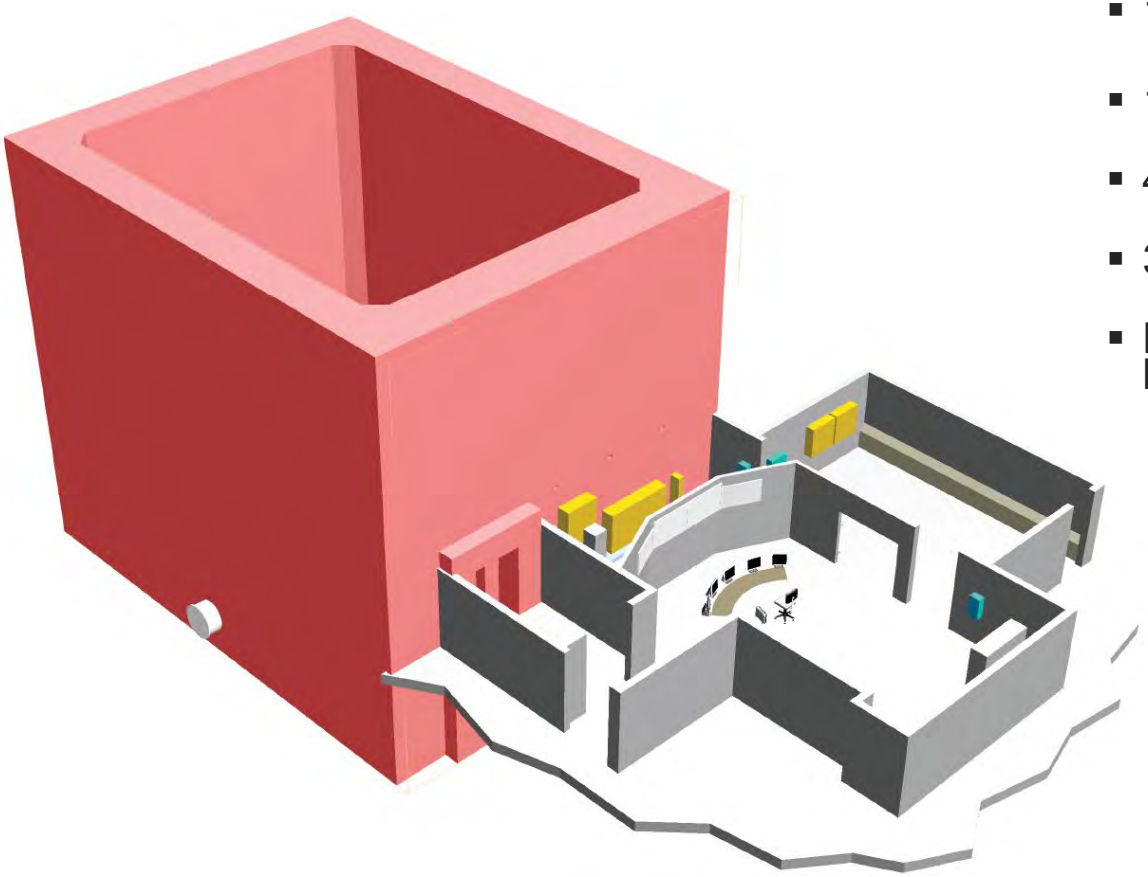
MELT PRODUCTION VIA EXOTHERMIC CHEMICAL REACTIONS

- Methodology:
  1. Heat of reaction calculations performed to define candidate mixtures to produce a target melt composition (UO_2, ZrO_2, steel, concrete oxides).
  2. Samples ignited to verify melt pool formation & reaction temperature
  3. Mixture adjusted as needed & test is repeated.
- Results for 1 kg test producing a 70 % oxidized PWR melt at 2400˚C is shown.
- This technology used in large scale tests up to 2 metric ton scale.





REACTOR CONTAINMENTS AS TEST FACILITIES AT ARGONNE (CELLS 4 & 5, BLDG. 315)



- Formerly housed ZPPR 6 & 9 reactors
- 1.2 m thick walls
- 12 x 9 x 9 m high (1000 m^3)
- 45 kg TNT explosion rating
- 3.4 bar pressure rating
- Potential test hazards include fires, hydrogen and steam explosions

GOOD DAY VIDEO CLIPS…

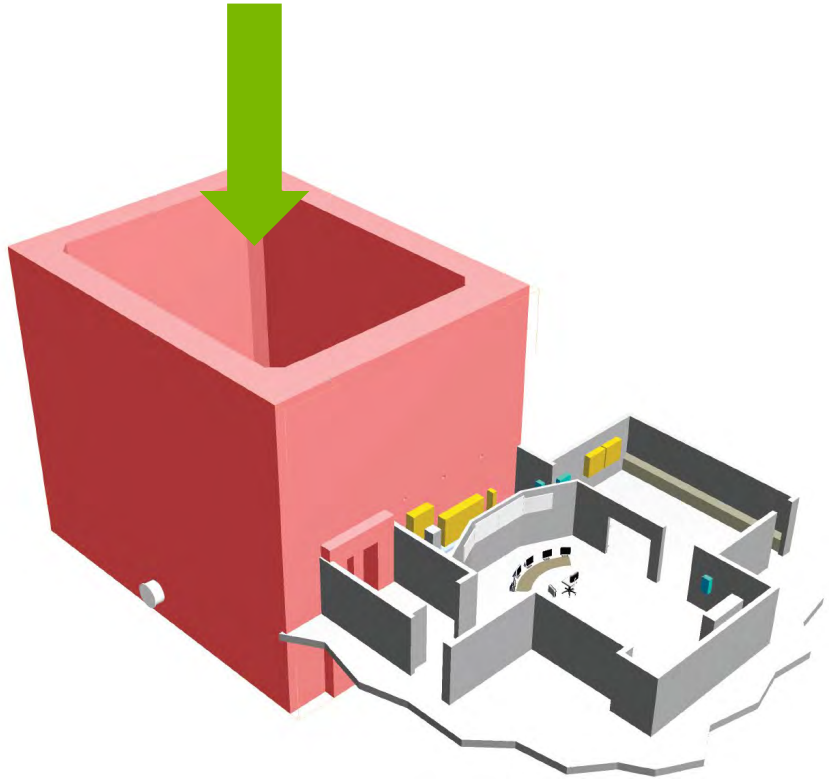
Argonne NATIONAL LABORATORY

BAD DAY VIDEO CLIPS…

- Recorded by surveillance cameras mounted at various locations within the test cell.



CASE STUDIES ON LESSONS LEARNED

Experiments discussed herein:

1. MACE M1b/M2: Experiments investigating debris coolability using limestone/common sand and siliceous concrete basemats, respectively.
2. MACE M3: Large scale experiment intended to investigate coolability for the case of a limestone/common sand concrete basemat.
3. COMET-U: Tests investigating debris coolability via water injection at the melt-substrate interface.

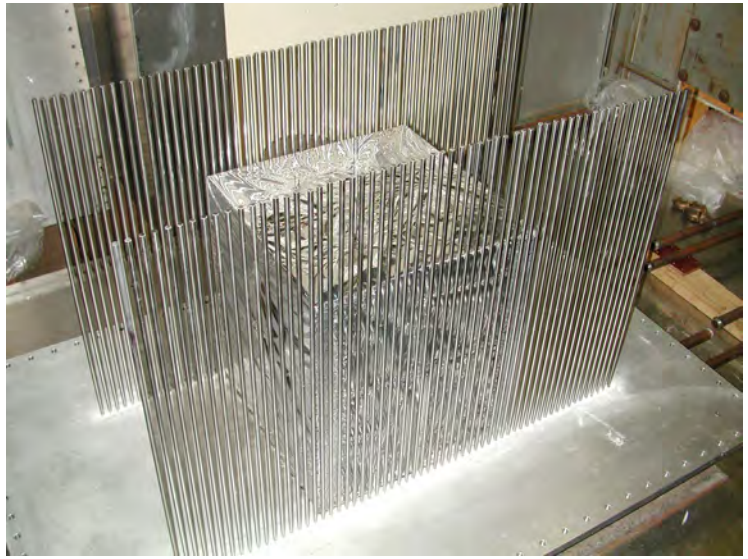
- Much of the information shared in this presentation is unpublished as it describes non-successful test outcomes and the associated corrective actions, as opposed to successful test outcomes that are routinely published.

1. MACE M1B/M2

- These tests used DEH to produce the melt.
  - M1b: LCS concrete basemat
  - M2: SIL basemat
- Featured a 'new' monolithic test section design made from castable refractory MgO.
  - Castable MgO used as a liner in steel industry furnaces/ladles.
  - No additional protective layer applied over MgO surfaces in contact with melt.
  - Tungsten electrodes sat immediately adjacent to opposing MgO sidewalls.
- M1b: operationally successful.
- M2: *not* successful. East electrode sidewall (~ 30 cm thick) failed by melt-through after 2.5 hours of powder melting via DEH.
- Subsequent posttest examination of M1b indicated that sidewall melt-through nearly occurred in that test also.

MgO sidewalls

Typical tungsten electrode installation

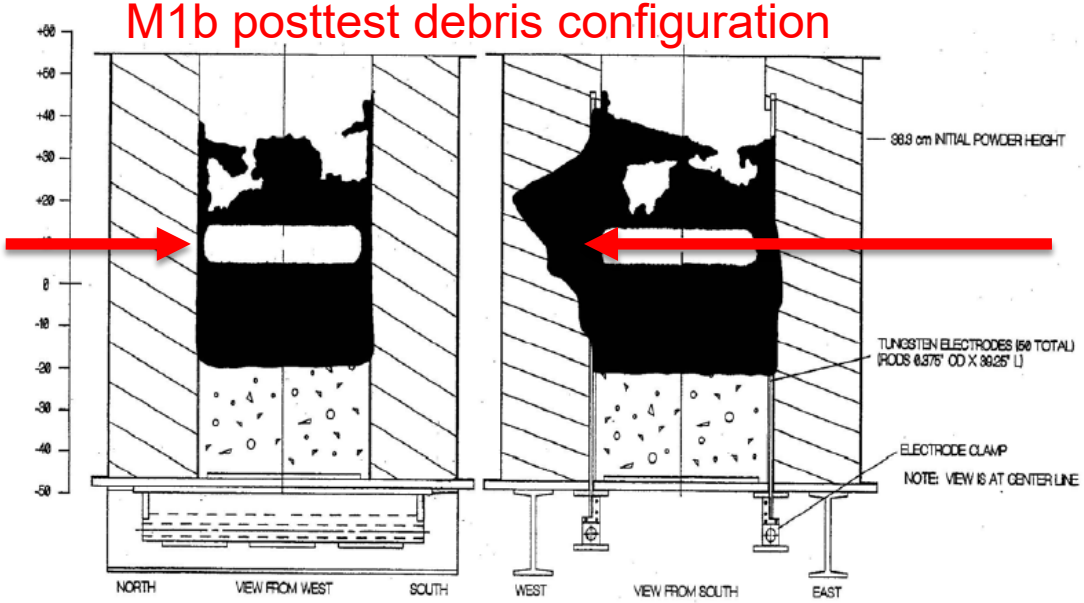


M2: WHAT HAPPENED?

- Investigation carried out by internal committee (featuring chemists) to identify failure mechanism and to recommend corrective actions.
- Culprit: rapid SiO_2 reaction with MgO forming silicates [forsterite (Mg_2SiO_4) and enstatite ($MgSiO_3$)] at temperatures > 800°C.
  - Observed in steel industry for high silica slag; not widely reported in literature.
  - M2 powder charge contained ~ 6 wt% SiO_2; M1b ~ 2 wt%
- Result: test section re-designed to prevent reoccurrence (see next page).
- **Lesson learned**: chemistry plays a key role in high temperature testing, so get to know your local chemist well!!

M1b posttest debris configuration

Little erosion of non-electrode sidewalls



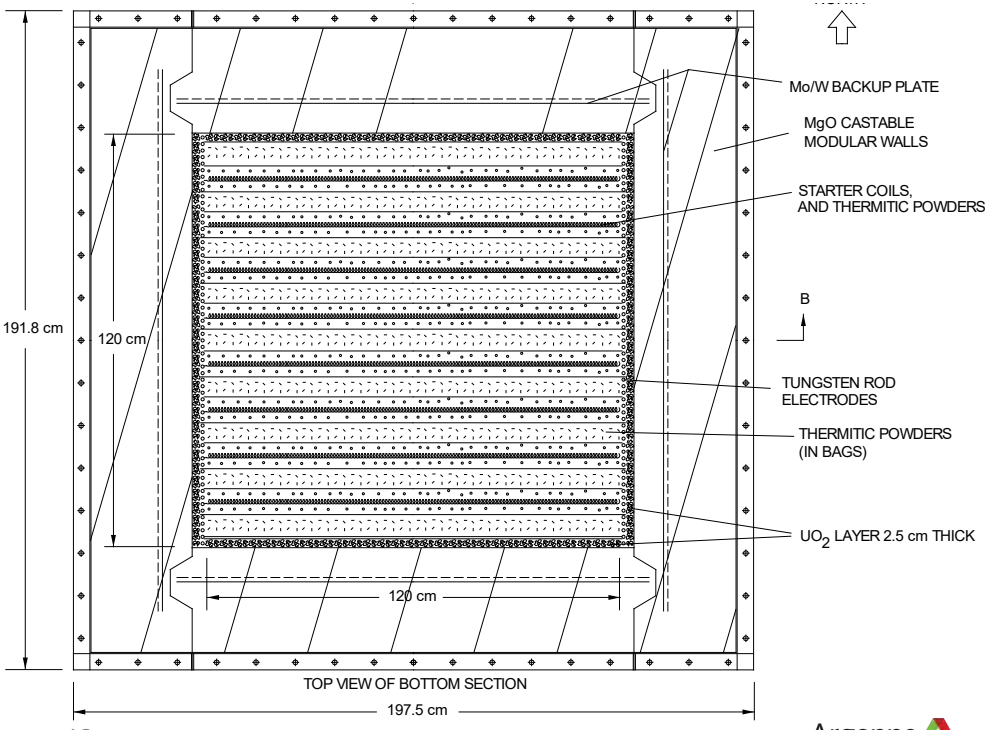
Heavy erosion of west electrode sidewall

Argonne NATIONAL LABORATORY

CORRECTIVE ACTIONS BASED ON M1B/M2

- Test section redesigned to accommodate protective layer of UO_2 or U_3O_8 powder/pellets covering sidewall inner surfaces to chemically protect MgO.
  - Required adding metal forms for electrodes to keep UO_2/U_3O_8 from covering (electrically insulating) powder-facing surfaces during loading.
- Instrumented W backup plates added to detect melt contact; monitored during test.
- Additional thermocouples added to monitor exterior test section exterior temperatures.
- Lower section redesigned to be modular so that walls could be removed and examined posttest. Benefit: enabled better PTE plus parts could be reused.
- **Once these changes were implemented, no MgO sidewall attack occurred in the balance of tests conducted**.

M3 lower section design

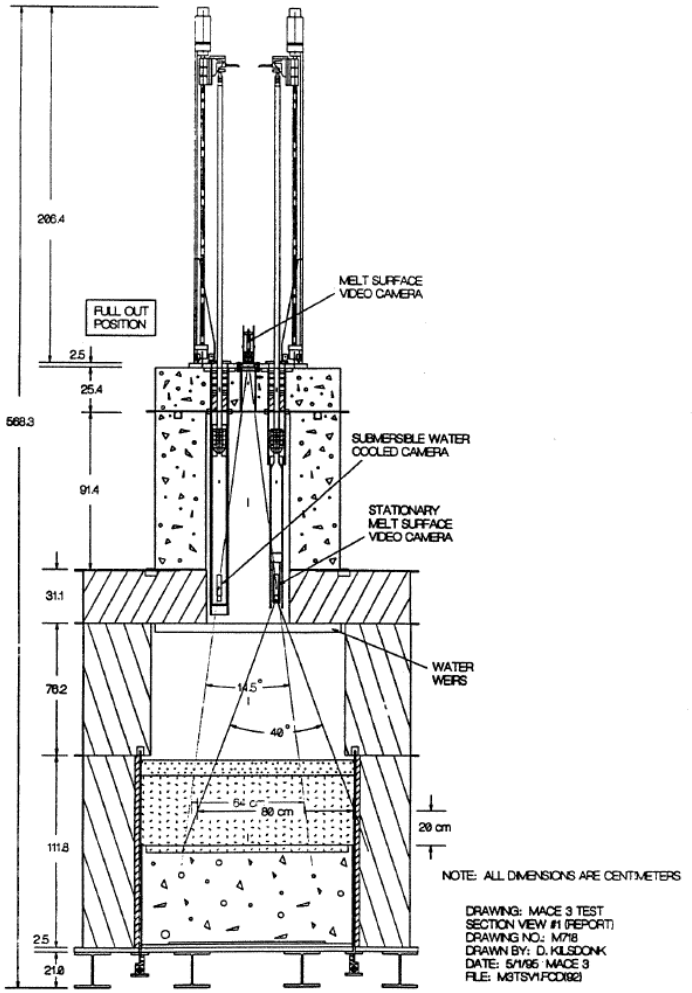


Argonne NATIONAL LABORATORY

2. MACE M3

- After M2, project review group (PRG) requested test scale increase to as large as possible to approach ‘prototypic’ test conditions. Result: 120 cm x 120 cm test section cross-sectional area; 2000 kg melt mass.
- Involved extensive R&D to develop an exothermic chemical mixture (‘thermite’) for large scale melt production.
- Mixing & loading of 2000 kg powder charge performed, and final facility preps were underway.
- PRG member raised concern that thermowells for melt temp measurements would act as ‘table legs’ supporting crust and undermining scale-up basis.
- → test section disassembled, thermite unloaded, thermowells cut down *in situ*, loading/assembly repeated, and test executed after 8-month delay following thermite mixing.

M3 test section design



- Result: test aborted at startup due to failures at flange locations leading to discharge of gases (including H_2) into the test cell (video)

M3: WHAT HAPPENED?

- Investigation committee formed (included chemical and structural specialists, others) to identify cause(s) and recommend corrective actions.
- Failure mechanism: excessive non-condensable gas release during thermite burn led to test section over-pressurization.

Root causes:

- Moisture uptake by the thermite during 8 month time interval between mixing and test initiating.
  - Led to excessive gas release during the burn.
- Bagging material inadequate for long-term storage of hygroscopic material to prevent moisture uptake.
  - Simple plastic bags were used to store/load the thermite.

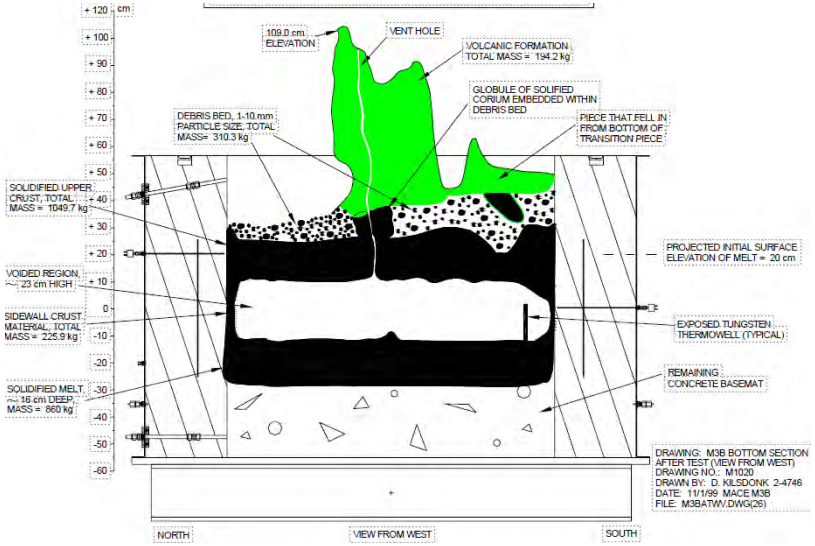
Top view of M3 powder bed after loading

CORRECTIVE ACTIONS BASED ON M3

- To minimize moisture absorption, candidate bagging materials tested (with thermite) based on weight gain method.
  - Aluminized Saran bags selected.
- Gas sample test (GST) procedure developed to characterize impurity content of thermite (based on ideal gas law).
- Based on system ΔP calcs, established a criterion for maximum allowable 'moisture' content to start test (0.3 wt%).
- Procedure developed to monitor thermite moisture uptake internal to the test section.
- Test section continuously purged with Argon during pretest preparations.
- Safety plan updated and revised.
- **Repeat test M3b successful!!**
- **Lesson re-learned**: chemistry plays a key role in high temperature testing, so get to know your local chemists well!!

Top view of M3b powder bed after loading

M3b posttest debris distribution

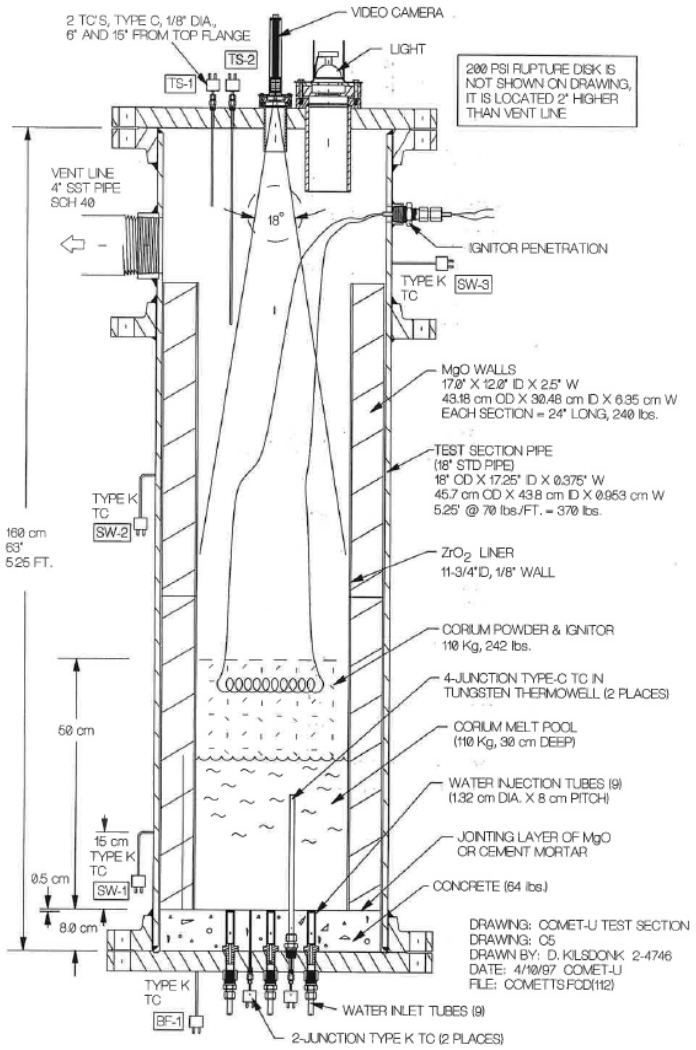


Argonne NATIONAL LABORATORY

3. COMET-U

- KIT (FZK) developed a novel coolability concept based on bottom water injection through an array of tubes cast in the basemat.
- Reactor material tests (-U series) carried out to supplement simulant material tests at KIT.
- Target melt composition to be produced by thermite reaction (specified by KIT) included core and concrete oxides, plus B_2O_3.
  - Boria a concrete additive for criticality control in case of an ex-vessel accident.
  - Present at a level of 1.3 wt% in the thermite.
- Test operationally successful, showing positive coolability attributes for this concept.
- *However,* thermite reaction was extremely vigorous, leading to melt through of main steam-line during burn phase.

COMET-U test section



Argonne NATIONAL LABORATORY

COMET-U: WHAT HAPPENED?

- Tests carried out to develop a thermite to produced target melt composition.
  - Principally based on GST's to check reaction temperature and to verify an acceptable level of *noncondensable* gas production.
- Subsequent analysis of thermite constituents revealed that B_2O_3 has a relatively low boiling point range of 1500-1860 °C, significantly less than thermite reaction temperature of ~ 2000 °C.
- Thus, B_2O_3 likely boiled during the thermite burn, leading to excessive voiding in the melt located over the downward-progressing burn front.
- Entrained core debris led to rapid thermal attack in the vent/steamline adjacent to the test section top flange and subsequent meltthrough.
- B_2O_3 present in the thermite at a level of 1.3 wt% can be compared to the test initiation criterion of $\leq$ 0.3 wt% H_2O based on M3 corrective actions.
- Note that B_2O_3 is a *condensable* burn gas byproduct, vs. *non-condensable* gas products identified as part of GST's.

CORRECTIVE ACTIONS BASED ON COMET-U

- Thermite development procedures modified to include a screening based on normal boiling point temperature vs. expected thermite reaction temperature.
- Aside from GST's, additional developmental test(s) at larger scale (typically 1-2 kg) are carried out to verify acceptable burn behavior.
- **Over-arching lesson-learned**: testing with high temperature reactor materials featuring exothermic chemical reactions to produce core melt are difficult and complex. Consult your local chemist on a regular basis as part of the development process!!

SUMMARY

- Severe accident experiments are a complex and difficult undertaking and are not always successful.
- When tests don’t go right, it is critically important to investigate the process to determine contributing factors so that corrective actions can be taken.
- IMO, the evolution of melt production technology from DEH to exothermic chemical reaction technology was a critical step required to enable large scale severe accident experiments.
- Although there were several bumps in the road, this technology has enabled many successful and high-value experiments to be conducted, both in the US and abroad.
- The tests have led to improved understanding of severe accident phenomenology and have informed the development of industry accident management guidelines.

ACKNOWLEDGEMENTS

- Thanks to the ERMSAR organizing committee for the opportunity to attend and present at this conference!
- The work performed in this area at Argonne was and continues to be a team effort, and special thanks go to Jeremy Licht, Steve Lomperski, Nathan Bremer (active), and Bob Aeschlimann, Dennis Kilsdonk, and Lou McUmber (retired). All are highly skilled laboratory specialists, and this work would not be possible without their efforts!

ABSTRACT

The HORIZON-EURATOM SAPSAM-SA project, coordinated by ENEA (Italy), was launched in 2022 aiming at investigating applicability and transfer of knowledge and expertise gained from operating large-LWR reactors to innovative iPWRs, in view of the European licensing needs with respect to severe accident (SA) and EPZ. Two generic iPWR concepts are considered in SASPAM-SA: the iPWR Design 1 (submerged containment, ~60 MWe) and the iPWR Design 2 (~300 MWe), which employs several passive systems and a dry containment. In the framework of the WP2 (coordinated by KIT, Germany) of the project, three hypothetical SA scenarios have been postulated for each design and analyzed by means of the AC2, ASTEC, EdF-MAAP, MAAP, and MELCOR codes. Additionally, CFD models have been developed to evaluate containment thermal hydraulics using ANSYS CFX and containmentFOAM. The primary objective was

assessing the ability of state-of-art SA codes to predict the key physical phenomena occurring during such postulated scenarios in the selected generic iPWRs. The paper presents the results of such large calculation campaigns. The results show a general consistency among the different codes in predicting the key physical phenomena and events characterizing the progression of the postulated SA scenarios, e.g., H_2-onset, beginning of the core degradation and the absence of RPV failure in all the scenarios. Furthermore, the SASPAM-SA WP2 user's feedback are provided aiming at assessing preliminary best practice and lessons learned regarding the modelling capabilities of the codes employed.

KEYWORDS
SMR, iPWR, Severe Accident, EU project

1. INTRODUCTION

Small Modular Reactors (SMRs) are innovative nuclear power plants expected to be deployed worldwide in the near term. In Europe, particular interest has been focused on Integral Pressurized Water Reactors (iPWRs), owing to their enhanced safety features largely based on passive systems. While these features significantly strengthen the first three levels of the Defence-in-Depth (DiD) concept, a systematic demonstration of iPWR capabilities for preventing and managing Severe Accidents (SAs), corresponding to DiD levels 4 and 5, is still required [1].

To address this need, the HORIZON-EURATOM project 'Safety Analysis of SMR with Passive Mitigation Strategies – Severe Accidents' (SASPAM-SA), coordinated by ENEA, was launched in 2022 and involves 23 partners from 13 European countries [2–6]. The project aims to assess the applicability of knowledge gained from large Light Water Reactors (LWRs) to iPWRs, supporting licensing and siting activities and contributing to a European, independent perspective on iPWR safety for DiD levels 4 and 5 [1]. A key focus is the evaluation of Reactor Pressure Vessel (RPV) and containment behavior under postulated SA scenarios.

Two generic iPWR concepts are considered: a ~60 MWe design with submerged containment (Design-1) and a ~300 MWe design with dry containment and multiple passive safety systems (Design-2). Without assessing the designs themselves, SASPAM-SA evaluates the capability of integral SA codes and Computational Fluid Dynamics (CFD) tools to simulate the key phenomena occurring in iPWRs. These reactors are characterized by integral configuration and strong thermal-hydraulic coupling between the primary system, containment, and safety systems, posing challenges to current modelling approaches. Relevant phenomena include natural circulation in the integral RPV, thermal stratification in large pools, primary–containment interactions, and in-vessel melt retention [7].

Within this framework, an extensive calculation campaign was conducted in WP2 of the project, involving 16 institutions and employing state-of-the-art European and non-European integral codes (AC2, ASTEC, EdF-MAAP, MAAP, and MELCOR), together with CFD tools (ANSYS CFX and containmentFOAM). The activity included the development and assessment of generic but representative datasets for both iPWR designs, as well as the postulation and analysis of hypothetical Design Basis Accidents (DBAs) and SAs. Since the study is based on generic designs and no Probabilistic Safety Analysis (PSA) was performed, SA scenarios were selected according to severity rather than probability of occurrence.

This paper presents the main results of the calculation campaign, together with preliminary best practices and recommendations for the application of integral codes to iPWRs, derived from the lessons learned by the SASPAM-SA WP2 participants. The ultimate objective is to provide a preliminary assessment of the capability of the considered codes to simulate the dominant phenomena driving accident progression, with particular emphasis on the behavior and interaction of passive safety systems in an SMR configuration.

Specifically, the analysis addresses passive decay heat removal, primary automatic depressurization, passive high- and low-pressure safety injection, containment pressure suppression, and passive flooding of the reactor cavity. It is emphasized that this activity was not intended as a classical benchmark. Instead, starting from common specifications for the two generic designs—based on open literature and engineering judgment—each participant was allowed to explore different modelling approaches (e.g., decay heat assumptions, nodalization strategies, and physical models). This approach enabled both a quantitative

evaluation of the impact of modelling choices on selected figures of merit and a qualitative assessment of the codes' ability to reproduce the key physical phenomena occurring during the postulated scenarios.

2. THE GENERIC iPWR DESIGN-1 AND DESIGN-2

The generic iPWR Design-1 and Design-2 considered in the SASPAM-SA project are shown in Figure 1. Their specifications were defined in WP2 based on open literature [8] and reflect the main features of the most promising European iPWR concepts. These generic designs are used to broadly assess the capability of SA and Computational Fluid Dynamics (CFD) codes to simulate phenomena and processes typical of iPWRs.

The investigated Design-1 (Figure 1, left) is a natural-circulation iPWR with an integral RPV housing a shrouded core and riser, an integrated pressurizer (PRZ), and a helical-coil steam generator. The RPV is enclosed in a steel containment largely submerged in a water pool acting as the ultimate heat sink. The Emergency Core Cooling System (ECCS) relies on passive coolant circulation between the RPV and containment through Reactor Vent Valves (RVVs) and Reactor Recirculation Valves (RRVs), while the Chemical and Volume Control System (CVCS) is connected to the downcomer above the core.

The investigated Design-2 (Figure 1, right) features a dry containment and several passive safety systems. The reactor operates in forced circulation under normal conditions and switches to passive mitigation during accidents. Its integral RPV contains the core, eight helical-coil steam generators, eight primary pumps, the control rod drive mechanisms, and the pressurizer, with hot coolant flowing upward through a circular riser to the pump suctions located above the steam generators.

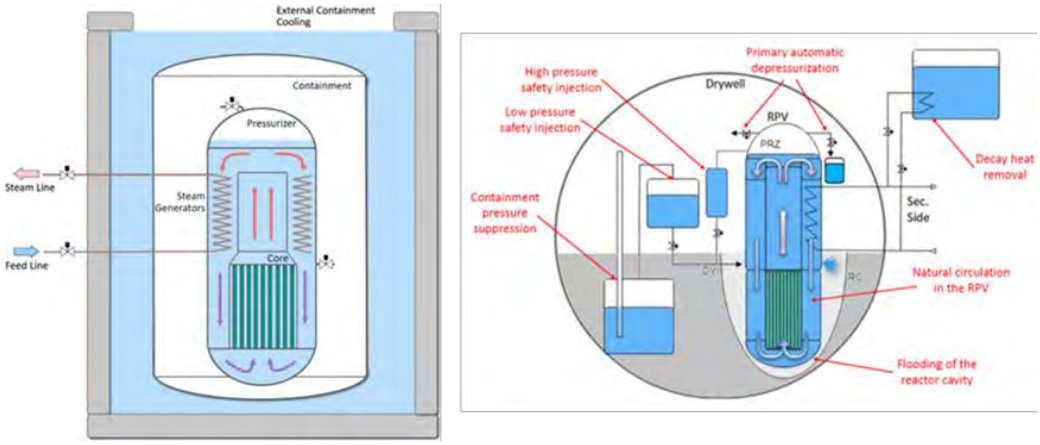

Figure 1. Layout of the generic iPWR Design-1 (left) and Design-2 (right) [9].

In addition to the design specifications, a database of decay heat and isotopic inventories covering burnups from 20 to 60 MWd/kgU, with a 2.5 MWd/kgU step, was generated using the CASMO code, developed by Studsvik, and is hereafter referred to as WP2data. To assess the impact of different decay heat assumptions, two additional datasets were considered: the 1973 ANS standard data (ANS73) and the same data increased by 20% (ANS73+20%). The results indicate that, following scram, the decay power predicted by WP2data is approximately 30% lower than that of the 1973 ANS standard [9]. Note that the WP2data have been computed by employing generic core model for both iPWR designs characterized by a lower power density than in the 1973 ANS standard, usually based on large reactors.

3. DEVELOPMENT OF THE DATASETS OF INTEGRAL AND CFD CODES

The full list of the partners and of the integral and CFD codes employed are given in Table I for the iPWR Design-1 and Design-2, respectively. In order to increase the efficiency of the activities, some partners joined the project by sharing their own datasets, upon request. Such sharing allowed a sensible acceleration of the activity. As shown in Table I, Tractebel and PSI made available the ASTECv2.2 and MELCORv2.2

datasets, respectively, of the iPWR Design-1. Similarly, ENEA and ENEA/UNIROMA1 made available the ASTECv3.1 and MELCORv2.2 datasets, respectively, of the iPWR Design-2. Furthermore, ASNR and GRS, as ASTEC and AC2 developers, respectively, supported the users. New datasets of the EdF-MAAP and AC2 codes have been developed for the iPWR Design-1 by EdF and RUB, respectively. Similarly, for the iPWR Design-2, new datasets of the MAAPv5.06 and AC2 codes have been assessed by JRC and LEI, respectively. Concerning CFD codes, new datasets using ANSYS CFX and containmentFOAM were developed by SSTC NRS and FZJ for the iPWR Design-1 and Design-2, to be mainly employed in the SASPAM-SA WP devoted to the CNMT analyses.

Table I. iPWR designs: codes, partners, and contributions

Code	Partners Design-1/Design-2	Contribution/Role	Design
ASTECv3.1	KIT / ENEA	Contribution to a new dataset /sharing	1–2
ASTECv2.2/v3.1	Tractebel / ENEA	Dataset sharing	1–2
MELCORv2.2	KTH, PSI / CIEMAT, KTH, UNIROMA1	Dataset use/sharing	1–2
MAAPv5.06	— / JRC	New dataset	2
EdF-MAAP5.04	EdF / —	New dataset	1
AC2	RUB / LEI	New dataset	1–2
ANSYS CFX	SSTC NRS / —	New dataset (CFD)	1
CAD/containmentFOAM	— / FZJ	New dataset (CFD)	2
AC2	GRS / GRS	AC2 user support	1–2
ASTEC	ASNR / ASNR	ASTEC user support	1–2
—	RATEN / RATEN	Support in the definition of the scenarios	1–2

4. ANALYSIS OF THE POSTULATED SEVERE ACCIDENTS IN THE GENERIC DESIGN-1

Three SA scenarios are postulated for the generic iPWR Design-1. In all scenarios, the ECCS is assumed to actuate when both of the following conditions are met: the containment (CNMT) water level exceeds ~5.8 m and the pressure difference between the reactor pressure vessel (RPV) and the CNMT falls below ~6.2 MPa or ~6.9 MPa, depending on the modelling choices of the code user.

SA-1 is initiated by a break in the CVCS make-up line combined with a loss of AC power. The RVVs are assumed to be operational, while the RRVs are assumed to be stuck closed. The break discharges directly into the CNMT. To investigate the effect of coolant reverse flow following ECCS activation, the break height was varied in the datasets, and reverse flow was either allowed or suppressed depending on the modelling approach.

SA-2 is initiated by the inadvertent opening of one RVV (~12.7 cm) at the top of the pressurizer, also combined with a loss of AC power. The remaining two RVVs are assumed to be available and actuated as in SA-1, while both RRVs are unavailable. This configuration prevents water recirculation from the CNMT to the RPV, leading to progressive core degradation.

SA-3 is initiated by a smaller break (~4.3) in the pressurizer vent line, again combined with a loss of AC power. As in SA-2, the remaining RVVs are available and actuated as in SA-1, while the RRVs are unavailable. Owing to the smaller break size compared to SA-2, a slower accident progression is expected.

4.1. Results: accident progression

The results by the different integral codes using the decay heat power ANS73+20% are presented. The behavior of the water level in the RPV and in the CNMT predicted by the AC2, ASTECv3.1, EdF-MAAP, and MELCOR codes is shown in Figure 2 (left) during the postulated SA-1.

Following the accident initiator, the RPV depressurizes while the pressure in the CNTM increases and does reach ~0.1 MPa at the end of the scenario. Because RRVs are stack, the core is isolated and the water level decreases below the top of active fuel (TAF) quite early and it is completely uncovered at ~25,000 s. The results concerning the water level in the containment at the end of the transient show a deviation of ~1 m, the final value being 9 m ± 0.5 m. The results show a quite good agreement among the codes. Furthermore, the ASTECv3.1 and EdF-MAAP results for all the postulated SAs are shown in Figure 2 (right). One may observe a good agreement between the two codes and, as expected, a slower accident progression going from the SA-1 to the SA-3.

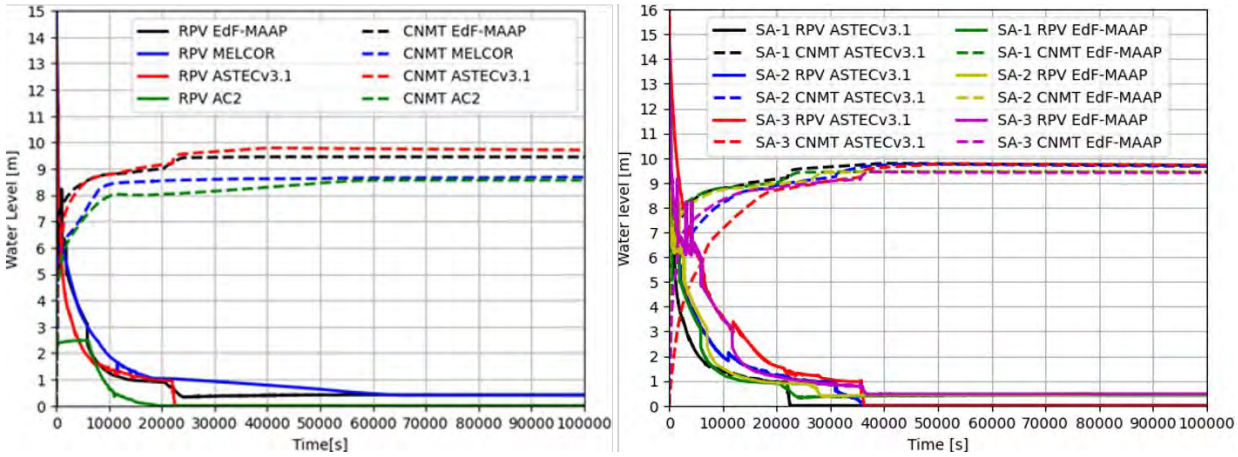

Figure 2. Water level in the RPV and in the CNMT in the SA-1 (left) and in all the SAs (right).

The results for selected key events during the progression of the postulated SA-1 (black), SA-2 (blue), and SA-3 (green) are summarized in Table II. As previously mentioned, starting from the common design specifications, each participant explored the code capabilities using different modelling options, leading to a spread of results.

In particular, deviations in the timing of ECCS activation are observed due to differences in the break height and in the set point of the RPV–CNMT pressure difference adopted by the partners. Earlier ECCS activation is predicted in simulations employing a lower break height (7.3 m instead of 9 m) and a lower pressure difference set point (6.2 MPa instead of 6.9 MPa), resulting in a shorter time to reach the CNMT water level of 5.8 m. For instance, MELCOR predicts ECCS activation at 339 s when the break is set at 7.3 m and no reverse flow is imposed, in agreement with ASTECv3.1 and EdF-MAAP using the same assumptions. Conversely, when higher values are adopted for both parameters, ECCS activation is delayed, as observed in AC2 and ASTECv3.1 (CPA), where it occurs at ~950 s. Two different CNMT modelling approaches and code versions for ASTEC have been adopted: ASTECv2.2 (CESAR) and ASTECv3.1 (CPA). Further details on the modelling options and results are provided in [10, 11] for ASTECv2.2 and ASTECv3.1, [10] for EdF-MAAP, [12–15] for MELCOR v2.2, and [16, 17] for AC2.

For SA-1, the deviation in hydrogen onset among ASTEC, EdF-MAAP, and AC2 is approximately 2,000 s, increasing to ~5,000 s in MELCORv2.2, likely due to the earlier ECCS activation. Nevertheless, the sequence of major phenomenological events related to core degradation shows reasonable agreement among the codes, considering modelling uncertainties. Core damage is predicted to start at ~10,000 s by all codes, with ASTECv3.1 and EdF-MAAP showing good agreement on the timing of the first corium slump with Fission Products (FP) to the Lower Plenum (LP), while in MELCOR simulations core damage begins later, at ~15,000 s. For SA-2 and SA-3, ASTECv3.1 (CPA) and EdF-MAAP show reasonable qualitative agreement on hydrogen onset and on the timing of the first corium slump to the lower plenum, whereas ASTECv2.2 (CESAR) predicts a delayed response in SA-2.

Despite the observed deviations arising from both modelling choices and uncertainties in core degradation and relocation models, no RPV failure is predicted by any of the codes in any scenario up to 70 h after the initiating event, owing to the effectiveness of External Reactor Vessel Cooling (ERVC).

Table II. Progression of the postulated SA scenarios (ANS73+20% decay heat data)

Event	ASTECv3.1 (CPA)	ASTECv2.2 (CESAR)	EdF-MAAP	MELCORv2.2	AC2

4.2. Results: core degradation

The time-dependent evolution of the corium mass in the core and relocated to the LP for the postulated SA-1, as predicted by AC2, EdF-MAAP, MELCORv2.2, ASTECv2.2 (CESAR), and ASTECv3.1 (CPA), is shown in Figure 3 (left and right, respectively). In the SA-1, the codes show a reasonable agreement on the timing of material relocation in the LP, the max deviation being of ~6,000 s when AC2 is compared with the other codes.

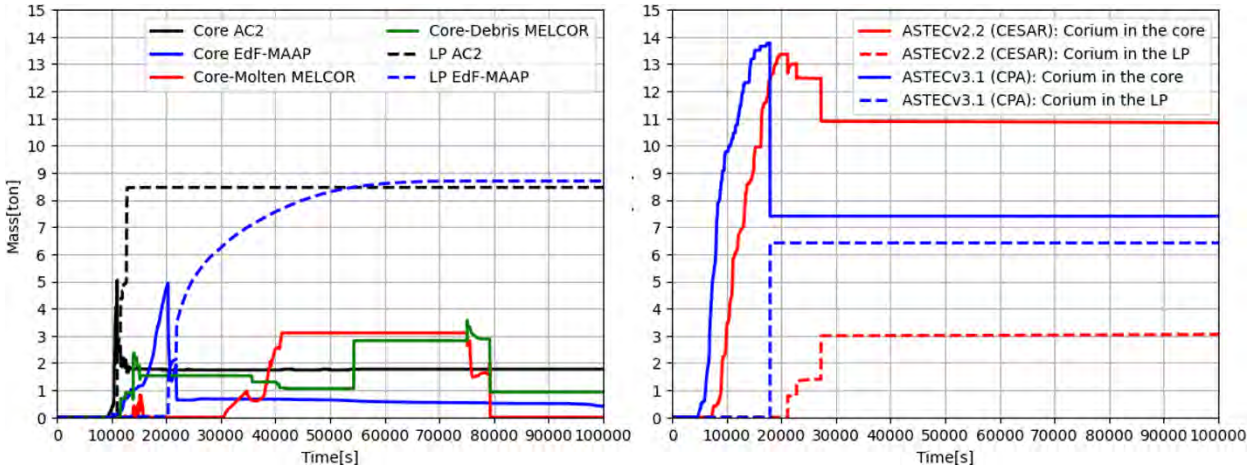

Figure 3. SA-1: Mass of molten material and debris in the core and relocated in the LP (SA-1).

For the molten material remaining in the core, ASTECv3.1 predict a range of ~7.5-10 t depending on the module employed for the CNMT behavior (Figure 3, right). With respect to LP relocation, AC2, EdF-MAAP, and ASTECv3.1 (CPA) show reasonable agreement (~9 t, with ASTEC slightly lower), whereas ASTECv2.2 (CESAR) predicts a significantly smaller relocated mass (~3 t). ASTECv3.1 (CPA) generally predicts a larger amount of molten material remaining in the core than EdF-MAAP, reflecting differences in core relocation modelling, as EdF-MAAP tends to relocate most of the corium to the LP. Similarly, for AC2. MELCORv2.2 predicts ~6 t relocated to the LP (drops in (Figure 3, left), with debris accounting for approximately 50% of the total mass. Nevertheless, it must be noted that the parametric analyses performed at PSI indicate a wide range of core damage (~17–100%), of corium remaining in the core, and amount of material relocated in the LP, depending on the modelling assumptions [13].

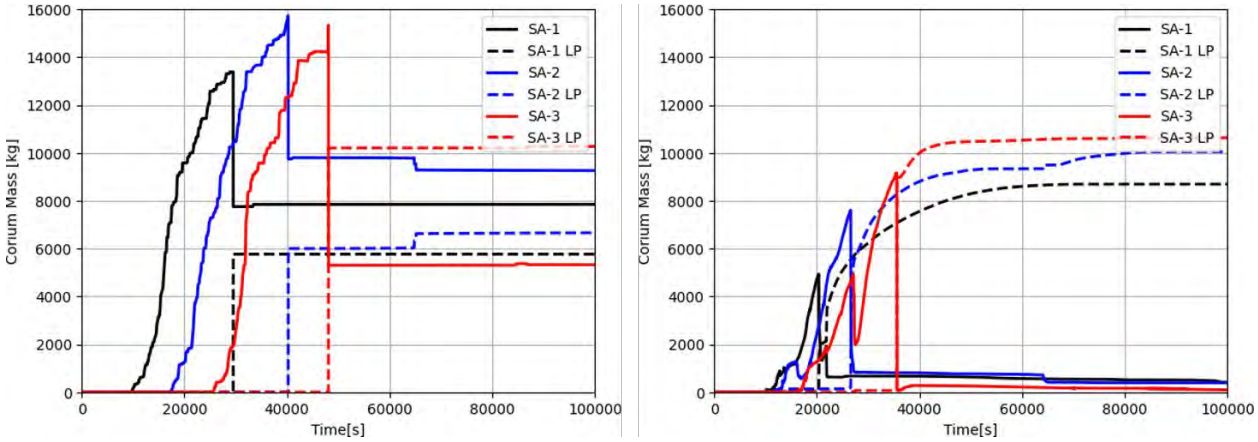

Figure 4. Core degradation: ASTECv3.1 (WP2data) left and EdF-MAAP (ANS73+20%) right.

To assess the impact of different decay heat data, ASTECv3.1 (CPA) simulations were performed for all postulated scenarios using WP2data, with results shown in Figure 4 (left). Comparison with the ASTEC v3.1 (CPA) SA-1 results in Figure 3 (right) confirms that the lower decay heat leads, as expected, to a delayed progression of core degradation. EdF-MAAP results for all postulated scenarios obtained using the ANS73+20% decay heat are shown in Figure 4 (right). Despite the different decay heat assumptions, ASTECv3.1 (CPA) and EdF-MAAP show qualitative agreement on the corium mass relocated to the LP in SA-3, while deviations of ~3-4 t are observed for SA-1 and SA-2. The results in Figure 4 also reveal the slowing of the progression from the SA-1 to the SA-3, the latest being also characterized by a large amount of corium relocated in the LP.

4.3. Hydrogen generation

The time-dependent behaviour of the in-vessel H_2 production computed by the codes by employing the ANS73+20% decay heat data is shown in Figure 5 (left).

The results show that the final total amount of hydrogen produced by the codes lies in the band of ~70 ± 10 kg. Furthermore, the results relevant to the total amount of the in-vessel H_2 produced from the parametric analyses performed by considering the effects of different modelling options (see, e.g. [10-17]) is shown in Figure 5 (right).

It may be observed that the maximum deviation among the results is ~25-35 kg in the SA-1. In the SA-2, ASTECv3.1 (CPA) and EdF-MAAP show a reasonable agreement, while a larger deviation is observed in the SA-3. Note that the steel oxidation conservative approach in EdF-MAAP, lead to higher values than ASTEC (CPA), as discussed in [18]. Finally, ASTECv2.2 (CESAR) provides significantly larger values.

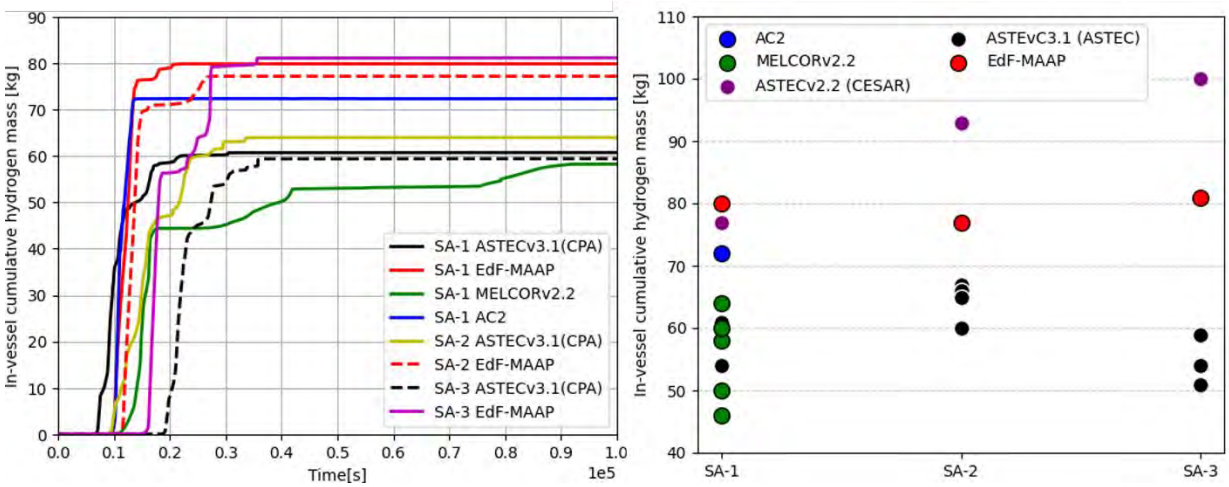

Figure 5. In-vessel H_2 production.

5. ANALYSIS OF THE POSTULATED SEVERE ACCIDENTS IN THE GENERIC DESIGN-2

Three SA scenarios are postulated for the generic iPWR Design-2, assuming a progressive increase in the failure of safety systems from SA-1 to SA-3.

In SA-1, a guillotine break of one Direct Vessel Injection (DVI) line (Figure 1) is assumed, together with the unavailability of the EHRS due to failure of the corresponding valves to open. SA-2 assumes the same guillotine DVI break, combined with the unavailability of both the EHRS and the Automatic Depressurization System (ADS-1), again due to valve failure. In SA-3, the same DVI break is assumed, together with the unavailability of all safety systems as a result of the failure of the associated valves to open.

Regarding modelling options, the WP2data set was adopted for all analyses. The CNMT design pressure was set to ~1.4 MPa in the ASTEC v3.1 and AC2 models, ~1.2 MPa in the MELCOR v2.2 datasets, and to ~2.4 MPa in the MAAP v5.06 model. These non-homogeneous hypotheses for containment response to high pressures induced large difference in the pressure evolution, determinately affecting the SA progression. To investigate the accident progression without containment failure, a drywell-to-environment leak was modelled in one of the two MELCOR v2.2 datasets used for the SA-1 and SA-3 analyses, with the leak area increasing as a function of the pressure difference between the two volumes. This modelling option, hereafter referred to as MELCOR v2.2-leak, is currently under further investigation within the work package dedicated to CNMT behavior. More details on the modelling options and results are in [19] (ASTECv3.1) and [20] (MELCORv2.2). Even if CFD analyses are not discussed here, details of the analysis of the SA-1 in Design-2 by means of containmentFOAM can be found in [21].

5.1. Results: accident progression

The behavior of the pressure in the RPV and in the CNMT (dots) as well as the water level in the cavity predicted by the ASTECv3.1 and MELCORv2.2 codes in all the postulated scenarios is shown in left and right sides of Figure 6, respectively. The DVI break leads to a fast depressurization of the RPV, and a slower pressurization trend occurs in the CNMT, while the SCRAM is performed after a short delay. The failure of the EHRS triggers a fast pressurization of the CNMT, which reaches the design value (1.4 MPa) rather soon.

Regarding the SA-1, the comparison of the ASTECv3.1 and MELCORv2.2-leak results show a different behavior of the CNMT pressure. The MELCORv2.2-leak results show that the CNMT pressure remains constant at ~1.2 MPa. A massive reverse flow from the Pressure Suppression System (PSS) tanks is predicted by ASTECv3.1 after CNMT failure, while not by MELCOR v2.2-leak and MAAP v5.06 leading to a fast increase of the water level above the DVI line in the ASTECv3.1 and not in MELCORv2.2 and MAAPv5.06 (not shown) analyses.

Due to the failure of the ADS-1 in the SA-2, the results show, as expected, slower depressurization of the RPV and of the CNMT. At the same time, the rapid decrease in CNMT pressure forces water from PSS tanks to the reactor cavity. As a result, the water level in the cavity rapidly increases (Figure 6), the ASTECv3.1 and MELCORv2.2 results showing a reasonable agreement (~2 m difference).

The failure of all the safety systems in the SA-3 leads to a much slower RPV and CNMT depressurization than in the SA-1 and SA-2 scenarios as shown in Figure 6 by the ASTECv3.1 and MELCORv2.2 results, as well as in AC2 and MAAPv5.06 (not shown). As expected, the MELCORv2.2 dataset with the drywell/environment leak modelled predicts constant CNMT pressure of ~1.2 MPa. As observed in the SA-1 and SA-2, water rapidly fills the reactor cavity. Because of both the CNMT depressurization and the postulated failure of the Long term Gravity Make-up System (LGMS), the water level in the cavity predicted by ASTECv3.1, the MELCORv2.2 dataset w/o the leak modelled in Figure 6 (right) and MAAPv5.06 (not shown) decreases, while it remains constant in the MELCOR v2.2-leak simulations.

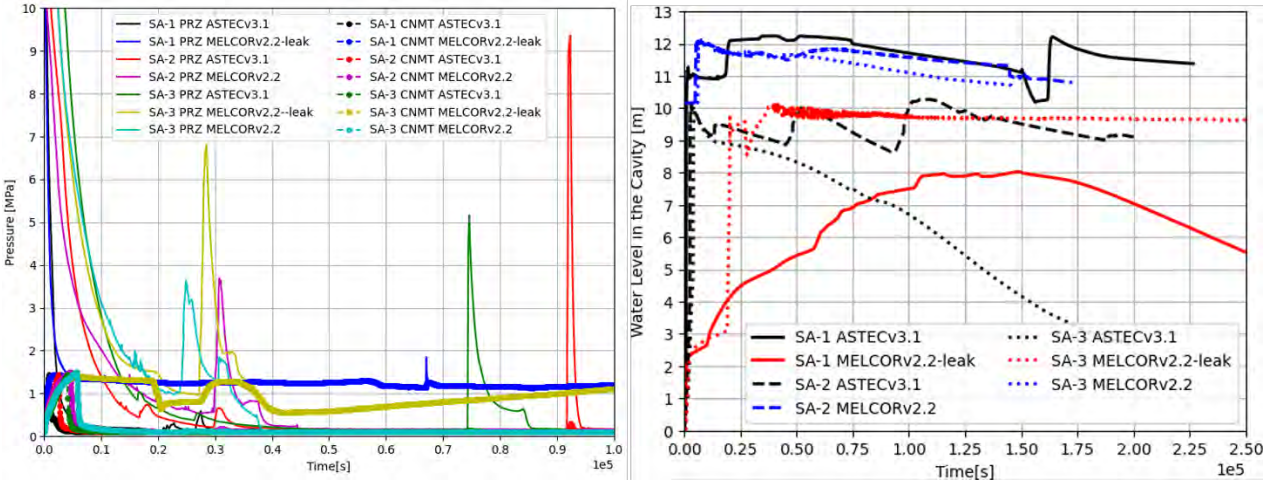

Figure 6. Pressure in the RPV and in the CNMT (left) and water level in the cavity (right).

The results for selected key events during the progression of the postulated SA-1 (black), SA-2 (blue), and SA-3 (green) are shown in Table III, where 'NA' indicates 'Not Activated', while '–' denotes unavailable results. Overall, all codes predict, as expected, a faster accident progression from the SA-1 to the SA-3.

For SA-1, ASTECv3.1 and MELCOR v2.2-leak show reasonable agreement up to the time at which the TAF level is reached. Beyond this point, H_2 onset and the start of core degradation occur earlier in ASTEC v3.1 than in MELCORv2.2-leak. MAAPv5.06 predicts earlier for most events compared to ASTEC v3.1 and MELCOR v2.2-leak, mainly due to the higher containment design pressure adopted (2.4 MPa versus 1.4 MPa), which avoids containment failure. Such discrepancies due to the different modelling of the CNMT further prove the larger impact of the tight coupling between RPV and CNMT on the SA progression in iPWRs than in large PWRs, which will be more extensively studied in another WP focused on the CNMT behavior in the SASPAM-SA project. A major discrepancy among the codes concerns corium relocation to the lower plenum: while ASTEC v3.1 predicts no corium slump due to water injection in the vessel, both MELCORv2.2-leak and MAAP v5.06 predict corium relocation, as discussed in the following section. Note that the degraded core is stabilized up to 70 h from the accident initiator.

For SA-2, ASTECv3.1 and MELCORv2.2 show reasonable agreement in the timing of the main accident phases, although ASTECv3.1 predicts a significantly slower decrease of the core water level. The main differences concern the H_2 onset, predicted by MELCORv2.2 ~4,000 s later than by ASTECv3.1, and the first corium slump, which occurs ~60,000 s earlier in MELCORv2.2. MAAPv5.06 again shows deviations for several events, largely attributable to the higher containment design pressure. Nevertheless, reasonable agreement with MELCORv2.2 is observed for the time to reach the BAF level (~4,000 s) and for the onset of upper core failure. In contrast, H_2 onset is predicted by MAAPv5.06 ~4,000 s earlier than ASTECv3.1.

For SA-3, ASTECv3.1, MELCOR v2.2, and AC2 show overall qualitative agreement up to CNMT failure, with maximum differences of ~2,000 s. Large discrepancies are observed for the timing of the low pressure difference (DP) RPV–containment signal, which is predicted by AC2 ~27,000 s and 40,000 s earlier than by MELCOR v2.2 and ASTEC v3.1, respectively. As in SA-1 and SA-2, the MAAP v5.06 results exhibit a slight faster progression due to the higher containment design pressure. In ASTECv3.1, both the attainment of the BAF level and the first corium slump to the LP occur later than in the other codes.

As for Design-1, no RPV failure is predicted by any of the codes in any scenario up to 70 h after the initiating event, owing to the effectiveness of the ERVC.

Table III. Progression of the postulated SA scenarios

Event	ASTECv3.1	MELCORv2.2	MAAPv5.06	AC2

RPV failure	No	No	No	No

5.2. Results: core degradation

Figure 7 shows the time-dependent evolution of the corium mass in the core and relocated to the LP for the postulated SAs as predicted by ASTEC v3.1 and MELCOR v2.2. The results indicate an increasing severity of accident progression from SA-1 to SA-3.

For SA-1 (Table III), corium relocation to the LP is predicted by MELCORv2.2-leak but not by ASTECv3.1. In ASTECv3.1, a quasi-steady state is reached between 50,000 s and 150,000 s. At~19,000 s, the RPV pressure approaches the CNMT pressure, water then flows in the RPV through the break, and a fast steam generation occurs (peak pressure in Figure 6). ~60 t of molten material form in the core is stabilized by the water injected in the vessel and no relocation to the LP occurs.

In contrast, MELCORv2.2-leak predicts an initial corium slump to the LP at 67,060 s, followed by partial reflooding until LGMS depletion and two additional slumps at later times (at ~145,700 s and ~159,000 s, Figure 7), resulting in ~95 t of mostly debris relocated to the LP by the end of the simulation. MAAPv5.06 predicts limited relocation (~13 t, not shown) and a stable LP configuration w/o ablation [18].

For SA-2, ASTECv3.1 predicts relocation of ~100 t of molten material to the LP starting at 92,900 s, while MELCORv2.2 predicts relocation of mostly debris (~70 t) beginning at approximately 29,800 s. MAAPv5.06 predicts relocation of ~50 t starting at 10,200 s.

In SA-3, ASTECv3.1, MELCORv2.2, and MAAPv5.06 (not shown in Figure 7) show reasonable agreement on the onset of core degradation and on the total relocated mass in the LP (~91 t, ~70 t, and ~74 t, respectively), although significant discrepancies remain in the predicted timing of relocation.

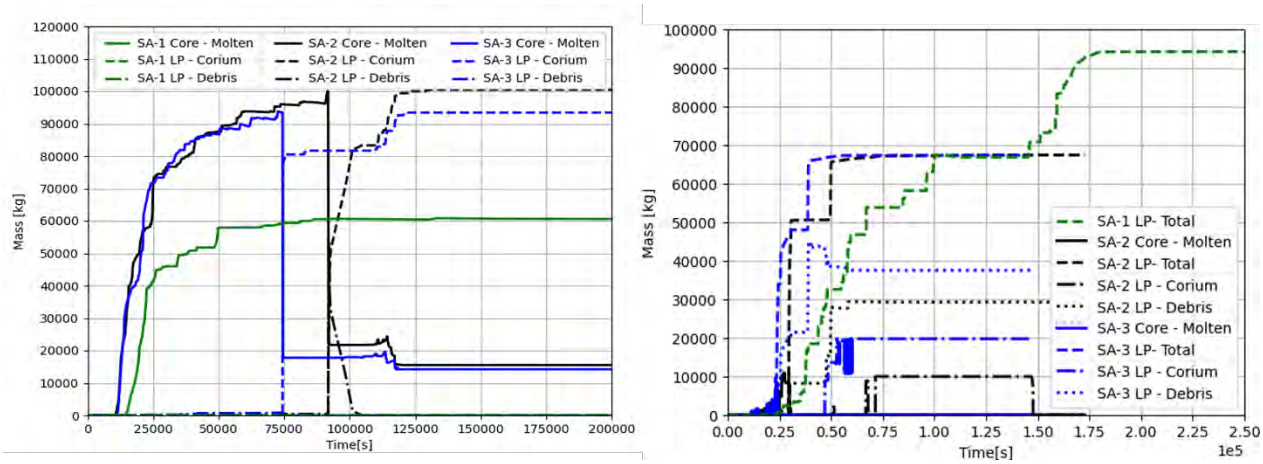

Figure 7. Core melting and material relocation in the LP: ASTECv3.1 (left), MELCORv2.2 (right).

5.3. Hydrogen generation

The time-dependent behaviour of the in-vessel H_2 production computed by the ASTECv3.1, MELCORv2.2, and MAAPv5.06 codes in the postulated SAs are show in Figure 8.

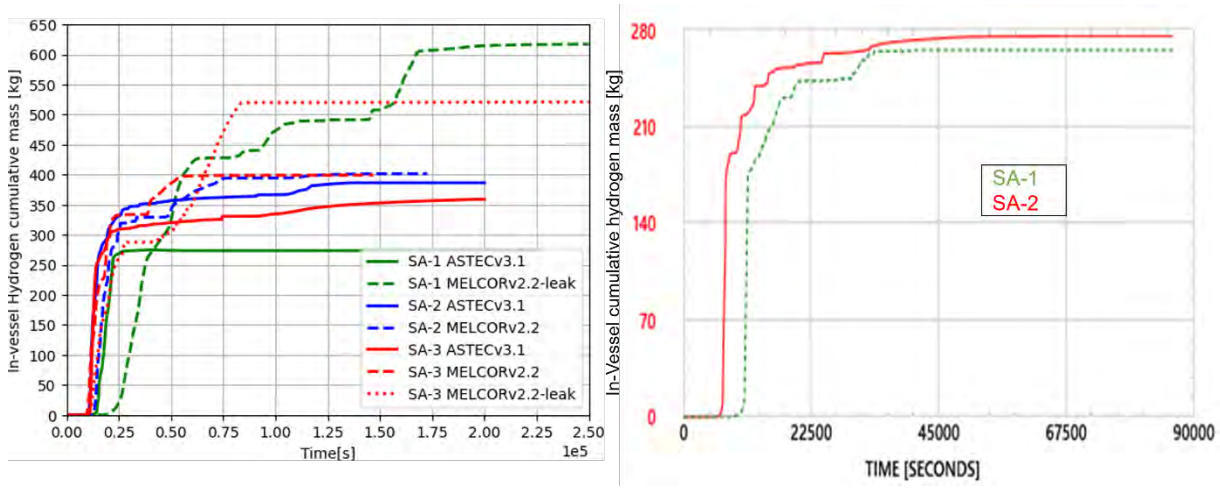

Figure 8. In-vessel H_2 production: ASTECv3.1 and MELCORv2.2 (left) and MAAPv5.06 (right).

In the SA-1, the ASTECv3.1 and MAAPv5.06 results show a good agreement on the maximum amount of H_2 (~280 kg), while the value predicted by the MELCOR v2.2-leak is almost the double (~600 kg) due to the occurrence of three slumps in the LP, which are responsible of the increase of the H_2 production, a significant contribution coming from the steel oxidation. The results relevant to the SA-2 show a quite good agreement between ASTECv3.1 and MELCORv2.2, a deviation of ~20 kg being observed. Furthermore, the MAAPv5.06 simulation predicts a value of ~280 kg, namely ~100 kg lower than ASTECv3.1 and MELCORv2.2. Regarding the SA-3, the ASTECv3.1 and MELCOR v2.2 results show a reasonable agreement, the deviation on simulated H_2 production being ~50 kg, while MAAP v5.06 (not shown in Figure

8) predicts a lower amount (~280 kg). Finally, the MELCOR v2.2-leak simulation shows a much larger value (~525 kg), the increase at ~50,000 s mainly due to the stainless-steel oxidation.

6. PRELIMINARY TAKEAWAYS

The capabilities of the state-of-art integral codes to predict key thermal-hydraulics and core degradation phenomena in the two generic iPWR designs selected in the SASPAM-SA project have been analyzed. Furthermore, an additional goal of the WP2 was providing the necessary data for more detailed investigations in the other WPs of the project regarding in-vessel melt retention, CNMT behavior, and source term.

With respect to the performance of the integral codes, the strong thermal–hydraulic coupling between the different components and passive systems characterizing the iPWR designs (compared with large water-cooled reactors), represents a major challenge for such tools.

The results reveal that the integral codes are capable to predict the key phenomena occurring in the postulated SAs. Despite modelling differences, the codes generally show qualitative agreement on accident progression trends, while quantitative discrepancies are observed in timing and mass inventories.

The following preliminary lessons learned summarize the main findings and best practices applicable across codes, designs, and accident classes:

- As in LWR accident simulations, nodalization of the RPV, core, containment, reactor pool, and safety systems play a key role. Particular sensitivity has been found to axial and radial core nodalization, as expected. Same thing might apply to passive safety systems. Hence, sensitivity studies on nodalization are highly recommended before adopting a final model;
- ERVC modelling is recommended for both DBA and SA analyses, while simplified correlations may underestimate cooling effectiveness. For example, the AIDA module in AC2 is recommended;
- Uncertainty and sensitivity analyses are indispensable to grasp a better assessment of safety margins, to identify dominant parameters, to quantify modelling uncertainty, to support the interpretation of results, and to assess code capabilities;
- In water-cooled SMRs, heavily based on natural circulation, core coolability parameters, e.g., heat-transfer coefficients, and steam flow patterns have a significant impact on core degradation (at least for MELCOR code, for which the study was performed) and must be explicitly considered during input-deck development and may play a stronger role than in large PWRs. In particular, MELCOR analyses looks showing a possible cooling of the core due to natural convection with steam for iPWR Design-1, which does represent a significant difference with large power PWR and seems to be an interesting point for the further analyses in the future;
- Long accident timelines increase computational demands: reduced decay heat and corium mass in SMRs lead to slow SA progression, requiring long simulation times and careful resource management.

There are not reference calculations that allow concluding that the deviations found are larger than in LWR scenarios. Besides, rooting the source of discrepancies might require cross-comparison of input decks, which was beyond this WP scope. Even so, there are some efforts ongoing to identify potential sources in the differences of code modeling approaches.

SASPAM-SA Project: Motivation and Goals

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- 'Safety Analysis of SMR with PAssive Mitigation strategies - Severe Accidents' (SASPAM-SA) project (2022-2026), coordinated by ENEA (F. Mascari) - 23 partners from 13 European countries

- **Systematic demonstration of Integral Pressurised Water Reactors (iPWRs) ability to prevent and to manage Severe Accidents (SA) (DiD levels 4-5) for licensing**

- Project goals:
  - transfer LWR safety knowledge to iPWRs
  - investigating the key elements to create a European independent point of view on the safety of iPWRs with respect to DiD levels 4-5

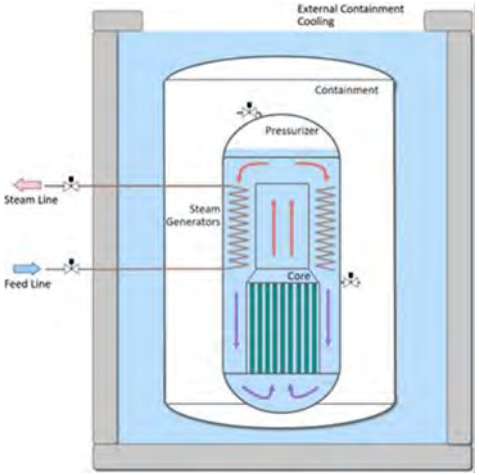
SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorization is strictly prohibited.

Generic iPWR Designs

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

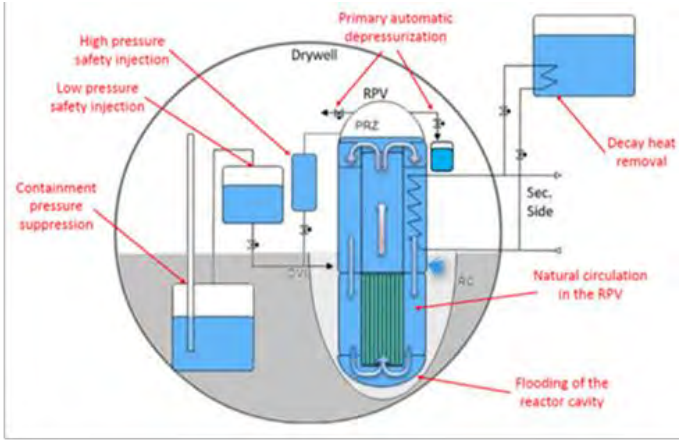
iPWR Design-1

Submerged containment, P~60 MWe



iPWR Design-2

Dry containment, several passive systems, P~300 MWe



- The designs incorporate the main safety features of the most promising concepts ready for deployment in the European market
- It is not the project's objective to assess the design of such concepts

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorization is strictly prohibited.

Objectives of the WP2 (SCENARIOS)

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- **Evaluating the capabilities of state-of-art European and non-European integral SA codes and Computational Fluid Dynamics (CFD) tools to simulate the key phenomena occurring in generic iPWR designs**

- Methodology:
  - Development of the iPWR Design-1 and Design-2 database (generic designs, decay heat) based on open-literature
  - Assessment of generic, but representative, SA and CFD codes' datasets
  - Postulating DBA and SA sequences
  - Analysis the postulated DBA and SA scenarios
  - Feedback/recommendations from the codes' users

Methodology

- Keyword: Sharing
  - The datasets are shared among the partners upon request

- **No PSA assessments employed** (generic designs) → SA scenarios selected in terms of severity and not of probability to occur

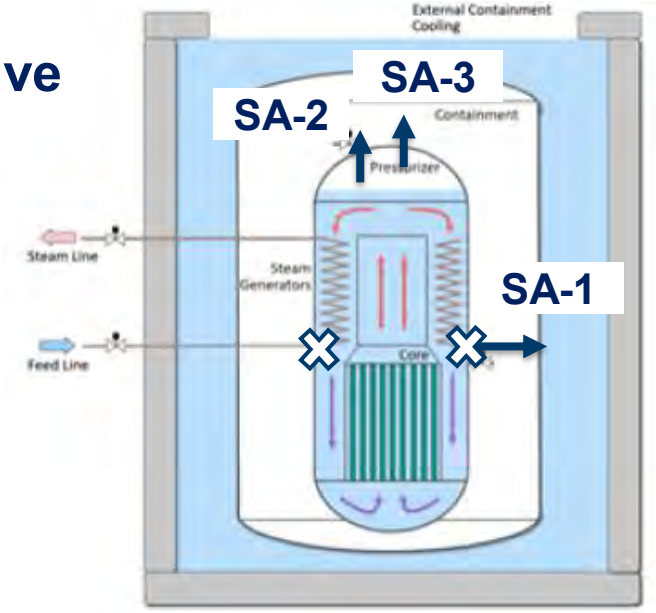
- Having in mind the goal ('*Evaluating the SA codes capabilities in iPWR applications..*') → **No 'classical' code-to-code benchmarks**
  - Each partner free to perform sensitivity analyses (e.g., height of the break, inverse flow modelling, decay heat, …)
  - Three sets of decay heat and fuel inventories available: WP2 (computed by CASMO), ANS73, and ANS73+20%

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorization is strictly prohibited.

iPWR Design-1: Postulated SA Scenarios

- **Initiators**
  - **SA-1**: 100% **break** on the CVCS **makeup line**
  - **SA-2**: Inadvertent opening of **1 RVV valve**
  - **SA-3:** 100% **break** on the **Venting line**

- **Accident progression:**
  - Loss of AC @t = 0 s
  - Loss of FDW and Reactor SCRAM
  - Isolation of the MSL
  - Activation of the ECCS



SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorisation is strictly prohibited.

iPWR Design-1 SA Scenarios: Modelling Parameters

- ECCS activation
  - CNMT water level ≈ 5.8 m
  - RPV-CNMT pressure difference ≈ 6.2–6.9 MPa
  - Opening of 3 RVVs and failure of 2 RRVs
- Break-height (7.3 m vs 9 m) influences ECCS timing
- Reverse-flow allowed/suppressed in some datasets
- ASTEC: CNMT modelled by using CPA (v3.1) or CESAR (v2.2)

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorisation is strictly prohibited.

iPWR Design-1: SA-1 Accident Progression

Event	ASTECv3.1 (CPA)	ASTECv2.2 (CESAR)	EdF-MAAP	MELCORv2.2	AC2
ECCS signal [s]	318-950	259	349	339-495	4,537

- Deviations due to differences on the break height and on the set point of the RPV–CNMT pressure difference assumed, e.g.:
- Earlier ECCS activation in MELCOR (break is set at 7.3 m, no reverse flow, RPV-CNMT pressure 6.2 MPa) in agreement with ASTECv3.1 and EdF-MAAP using the same assumptions
- Conversely, when higher values adopted (break is set at 9 m, RPV-CNMT pressure 6.9 MPa), ECCS activation is delayed, as observed in AC2 and ASTECv3.1 (CPA), where it occurs at ~950 s

iPWR Design-2: Accidents' Progression

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

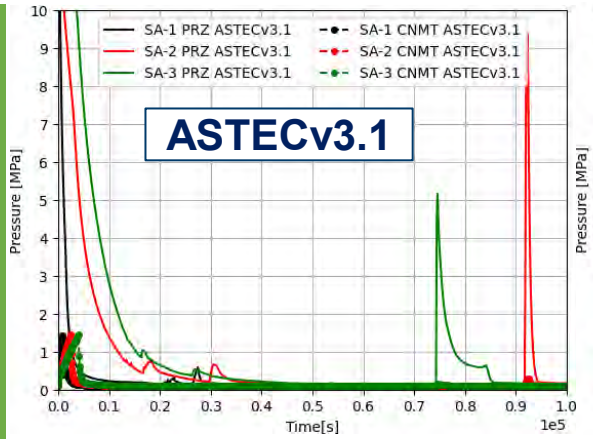
	Event	ASTEC v3.1	MELCOR v2.2	MELCOR v2.2	MAAP v5.06	AC²
SA-3 unavailability of all safety systems	**Containment failure***	**4,020**	**3,090**	**5,730**	**13,327**	**2,504**
	Core uncover (TAF)	5,280	4,250	1,690	2,675	3,600
	H2 onset	**7,294**	**12,290**	**9,070**	**3,980**	**7,000**
	Start of FPs release	10,386	-	-	-	7,000
	Core uncover (BAF)	72,960	23,800	18,680	12,411	11,000
	First core failure	10,386	14,630	10,270	9,955	13,500
	First corium slump	**74,610**	**27,300**	**24,300**	**9,955**	**-**

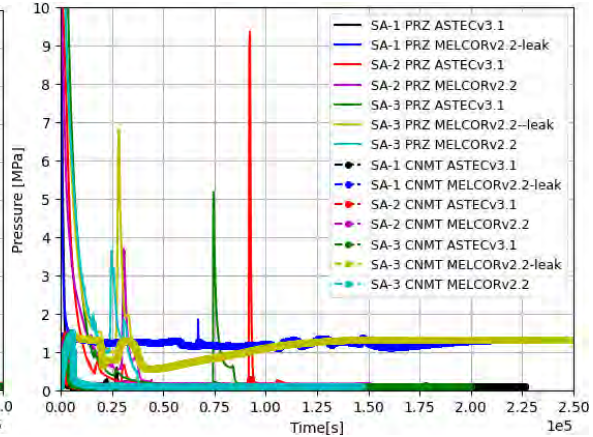
- **No lower head vessel failure up to 70 h due to the ERCV**
- The codes are able to predict key thermal-hydraulics and core degradation phenomena
- General good agreement on the timing of the main events
- Large deviation on the timing of the relocation to the LP

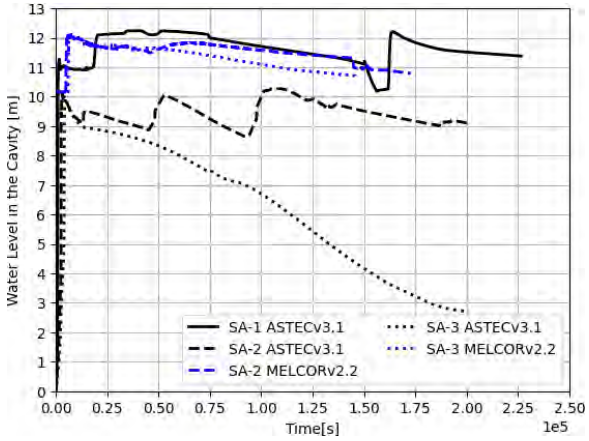
SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorization is strictly prohibited.

iPWR Design-2: Accidents' Progression

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT







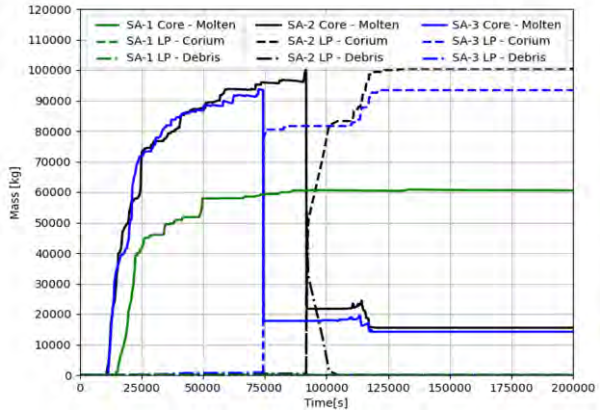
- DVI break → fast depressurization of the RPV and slower CNMT pressurization
- SA-1 (EHRS failure) → fast CNMT pressurization (different CNMT behaviour depending on the design pressure modelling) → after CNMT failure (ASTEC), water level increase in the cavity
- SA-2 (+ADS-1 failure) and SA-3 all systems fail) → slower progression → rapid increase on the cavity water level
- All the codes able to identify the progression of the key TH phenomena

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorization is strictly prohibited.

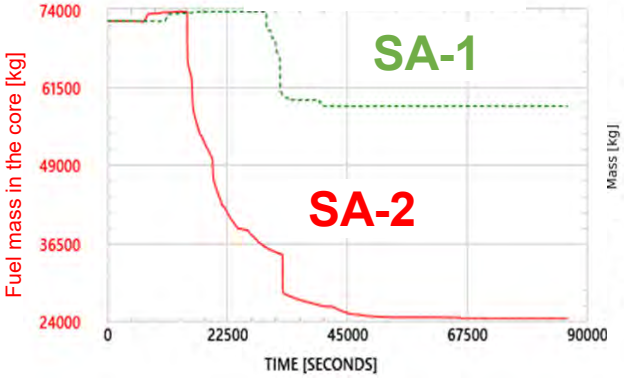
iPWR Design-2: Core Degradation Results

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

ASTECv3.1

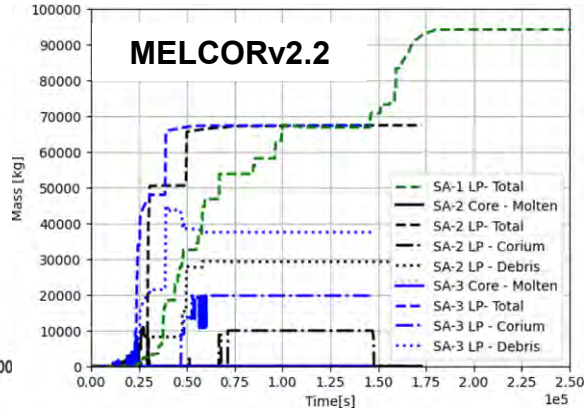


MAAP v5.06



(courtesy of J. C. de la Rosa Blul, JRC)

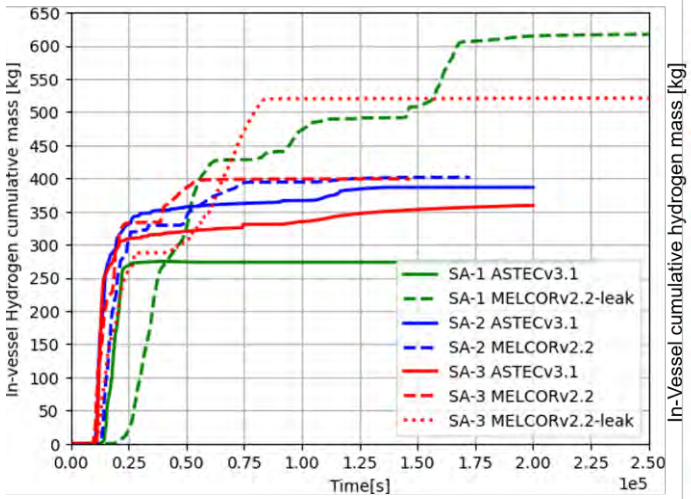
MELCORv2.2

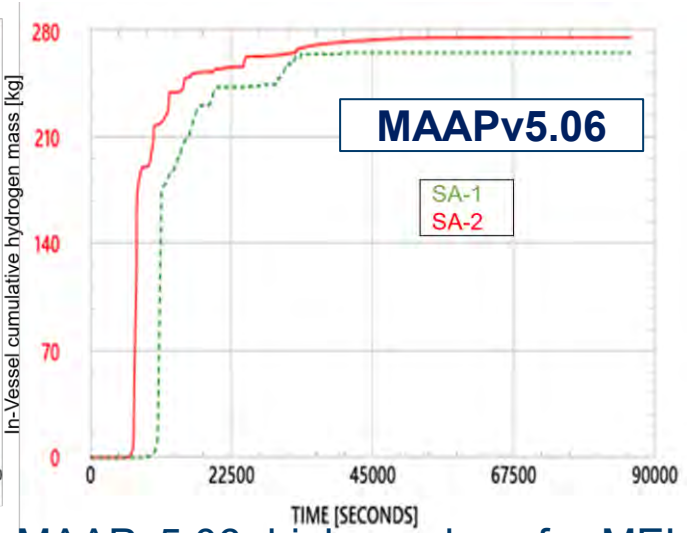


- Increase of the systems unavailability (SA-1 to SA-3) → Increase of the severity of the core degradation conditions
- **No RPV failure in any scenario**
- Deviation on mass relocated in the LP (SA-2 and SA-3) ~20-50 ton
- SA-1: different prediction on the relocation in the LP

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorization is strictly prohibited.

iPWR Design-2: Hydrogen Production





- SA-1: good agreement ASTECv3.1 and MAAPv5.06, higher values for MELCORv2.2 due to the occurrence of three slumps in the LP
- SA-2: good agreement ASTECv3.1 and MELCORv2.2 (deviation of ~20 kg); larger deviation against MAAPv5.06 (~100 kg)
- SA-3: similar deviations as in SA-2

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorization is strictly prohibited.

Preliminary Lessons Learned

- **Sensitivity studies on nodalization** are highly recommended before adopting a final model
- **ERVC modelling** is recommended
- **Uncertainty and sensitivity analyses** are indispensable
- **Core coolability parameters and steam flow patterns may play a stronger role than in large PWRs**, e.g. MELCOR analyses show a possible core cooling due to natural convection with steam for iPWR Design-1 → significant difference with large power PWR
- Reduced decay heat and corium mass in SMRs lead to slow SA progression → **large wall-clock time and careful resource management necessary**

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use or disclosure to third party without express authorization is strictly prohibited.

Preliminary Takeaways and Outlook

- Integral codes are able to predict the key TH phenomena occurring in iPWRs in the postulated SA scenarios
- Despite modelling differences, the codes generally show qualitative agreement on accident progression trends
- There are not reference calculations that allow concluding that the deviations found are larger than in LWR scenarios
- Efforts ongoing:
  - identifying potential sources in the differences of code modelling approaches
  - Generic small BWR (from CNL): SAs‘ postulation and MELCOR analyses

ABSTRACT

Rolls-Royce SMR has developed a three step analysis process for assessing the risk arising from hydrogen build-up in the containment building of a pressurised water reactor. The process uses MAAP5 to predict the severe accident evolution, fuel clad oxidation rate, and hydrogen and steam release rates into the containment atmosphere. 3D GOTHIC predictions are used to assess the localised gas composition in regions of the containment, and estimate the risk of energetic hydrogen combustion using the sigma (σ) and lambda (λ) correlations for flame acceleration and deflagration to detonation transition. Boundary conditions are then transferred to the FLACS-CFD code to perform combustion assessments, including predictions of overpressures if the conditions for flame acceleration or deflagration to detonation transition are met.

KEYWORDS
Containment Gas Mixing, Hydrogen, DDT, Combustion

1. INTRODUCTION

During the extremely unlikely event of a Severe Accident (SA) occurring on a Pressurised Water Reactor (PWR) such as the Rolls-Royce SMR, the interaction of high temperature steam and zirconium fuel cladding leads to oxidation and the rapid production of large quantities of hydrogen. Hydrogen is also generated from other sources such as hydrolysis, steel and boron carbide oxidation and molten core concrete interaction. This hydrogen is released into the containment atmosphere with the potential formation of combustible gas mixtures.

The integrity of the containment vessel and essential safety equipment could be challenged by the onset of energetic combustion modes, such as flame acceleration and deflagration to detonation transition (DDT) that can result in significant increases in containment pressure and temperature. The possibility of these combustion modes is highly dependent on the relative gas concentrations of hydrogen, oxygen and any dilutants (e.g. steam), on both a global and local scale.

Mitigative safety measures such as Passive Autocatalytic Recombiners (PARs) and ignitors are therefore deployed to remove hydrogen from the containment atmosphere and prevent the occurrence of energetic combustion that could challenge the integrity of the containment vessel or any Systems, Structures or Components (SSCs) delivering essential safety functions.

Analysis of the accident evolution, and local containment conditions, is used to determine the risk arising from hydrogen combustion in containment, support the design substantiation of safety systems and provide evidence to support safety case claims. The three-step assessment approach deployed by Rolls-Royce SMR to support these key objectives is described here.

2. Hydrogen Assessment Approach

A three step assessment approach has been developed by Roll-Royce SMR. The intention is to identify limiting credible SA scenarios that may pose a risk to containment integrity from slow deflagration, and assess the possibility of localised accumulation of hydrogen that could lead to flame acceleration and DDT. The steps are summarised as follows, and described in detail in the following sub-sections:

1. Global Risk Evaluation: scenarios of interest are identified from analysis of a range of SAs with an integral SA code (e.g. MAAP, MELCOR, ASTEC, etc). A survey of credible conditions is performed to identify the most limiting scenarios for subsequent assessment. Figures of merit such as total hydrogen production, hydrogen release rate, and average hydrogen concentration in containment are used to quantify and compare the relative severity of accident sequences.
2. Flame Acceleration/Detonation Risk Evaluation: 3D containment gas mixing analysis is performed on a local scale to evaluate the potential for conditions favourable for flame acceleration and DDT using the sigma (σ) and lambda (λ) indices respectively. Source term boundary conditions are provided from assessments performed in Step 1, and a detailed representation of containment geometry and key phenomena impacting gas mixing, steam generation and condensation are included. Predictions of localised gas mixture concentration, temperature, pressure are used as inputs to the σ and λ assessments. If the occurrence of flame acceleration or DDT cannot be excluded, then subsequent combustion analysis is recommended.
3. Localised Combustion Assessment: Gas mixture and turbulence predictions from Step 2 are supplied as boundary conditions to a combustion code to perform detailed analysis of turbulent flame propagation, possibility of DDT, and resultant localised pressure loadings throughout containment.

The resultant temperature and pressure loadings from Step 3 can be compared against safety acceptance criteria to determine the possibility of failure of the containment vessel or SSCs within containment. Alternatively, transient pressure loadings can be used as boundary conditions to subsequent dynamic structural integrity assessments to assess the containment vessel response to a specific accident sequence.

3. Global Risk Evaluation

The first step of the assessment process is to identify the scenarios of interest for hydrogen management. Initially knowledge of the SA physical phenomena and engineering judgement is used to postulate scenarios that could lead to more onerous conditions for hydrogen generation and release to containment.

Typically the severity of scenarios will depend upon the following three aspects:

1. The overall hydrogen generation in the core and the rate of release into the containment. A sustained period of high fuel temperature and fuel clad/steam oxidation will lead to rapid oxidation and hydrogen generation, and high hydrogen concentrations in containment.
2. The overall steam generation in core and the rate of release into the containment. Steam generated in the core (e.g. due to safety water injection), will be available for fuel clad oxidation and hydrogen generation. Steam release into the containment reduces the relative hydrogen concentration, and further acts as a dilutant to hydrogen combustion. Typically LOCA scenarios that balance the coolant circuit depressurisation rate with injection of safety water lead to the greatest sustained steaming of the core and hydrogen generation.
3. The location of hydrogen release into the containment. Releases into the confined regions of containment (e.g. through a reactor coolant system breach) are expected to be more onerous for localised flame acceleration.

Public – Not Listed – Not Subject to Export Controls

It is difficult to ascertain the exact combination of these aspects that could lead to the most onerous hydrogen conditions through engineering judgement alone. Furthermore, the prediction of hydrogen generation in SA codes is known to be highly sensitive to relatively small changes to the in-core transient progression and conditions, which can be impacted by the relative balance of competing thermal hydraulic phenomena.

Therefore, it is recommended that a large survey of calculations is used to determine the general trends in hydrogen generation and dependency on system functionality/timing. For LOCA scenarios this includes a survey of all credible coolant circuit break sizes to identify the limiting break size that maximises hydrogen generation. For scenarios where high levels of hydrogen generation are predicted, a larger number of calculations with a refined parameter space should be performed to reduce the overall uncertainty. However, it is acknowledged that within the large domain of calculation parameters it is unlikely to be able to fully resolve all dependencies and identify the most limiting conditions.

To identify scenarios of interest the following figures of merit are recommended:

- Total hydrogen production during the in-core accident phase. During this phase, rapid oxidation of fuel cladding, and therefore hydrogen production is expected. Scenarios with greater hydrogen production during this phase would be expected to present a more significant risk of hydrogen combustion. However, this metric does not consider other important factors, such as the rate of release and the balance against hydrogen removal rates, as well as local dependencies relating to release location.
- Peak hydrogen concentration in containment. High hydrogen concentration typically indicates a higher risk of energetic combustion. Hydrogen concentration above 10% typically indicates a possible risk of conditions that could lead to flame acceleration/DDT but does not resolve local dependencies. A volume average hydrogen concentration below 10% could also lead to a localised risk of flame acceleration.
- Steam concentration at the time of peak hydrogen concentration. Peak hydrogen concentration is a good indicator of risk, but if coincident with a high steam concentration, then the overall risk of combustion may be low. For steam concentrations greater than ~50-60%, the mixture will become inert and combustion will not be possible.

It is acknowledged that no single parameter can be used to fully determine hydrogen risk, particularly on a local scale that the coarse containment nodalisation typically adopted by integral codes cannot resolve. Therefore, the identified figures of merit alongside engineering judgement are used to rank scenarios of interest.

When performing the global assessment to identify the most limiting scenarios, the inclusion of the mitigative safety measures, and modelling approach, should be justified based the capability of the code/model to adequately predict hydrogen removal so as not to impair scenario identification. For example, the performance of an individual PAR unit is subject to the localised gas conditions that cannot be resolved by coarse nodalisation. However, reduced hydrogen removal of a unit in one location is expected to be balanced by a unit located elsewhere with more favourable conditions and the overall impact on global average conditions will not be significantly impacted. Therefore, it is considered appropriate to include the effects of PARs within this assessment step. Whereas ignitors are expected to remove hydrogen at a much faster rate, and therefore the potential impact on containment conditions during the phase of hydrogen release is more significant. Furthermore, the coarse nodalisation typically adopted in integral codes may be expected to overpredict the hydrogen burn, which can impair the scenario identification process. Therefore, ignitors are typically not represented in this analysis step unless their inclusion can be appropriately justified.

Public – Not Listed – Not Subject to Export Controls

Scenarios will be considered for detailed analysis if the following are met:

- Global hydrogen concentration exceeds 10%,
- Rapid release of hydrogen would be expected into a confined region of containment,
- PARs as the sole mitigation are not expected to be effective in mitigating the release rate of hydrogen.

The outcome of this step is the identification of a subset of limiting accident scenarios for both local hydrogen conditions and global hydrogen conditions. A global slow deflagration assessment can be conservatively performed by evaluating the Adiabatic Isochoric Complete Combustion pressure attained.

For Roll-Royce SMR this step is performed using the MAAP 5.06 SA code [2], and typically several hundred LOCA analyses are used to identify those that are most limiting for containment conditions.

4. Flame Acceleration/Detonation Risk Evaluation

Scenarios of interest identified from the previous step are evaluated with a detailed 3D representation of containment to assess the possibility of flame acceleration or detonation. Therefore, localised gas mixing analyses are performed to predict the localised gas concentrations and conditions throughout the containment. This enables the assessment of the σ and λ criteria to predict the likelihood of flame acceleration and detonation respectively [1].

To provide confidence in gas mixing predictions, a structured approach using a Phenomena Identification and Ranking Table (PIRT) and Test and Assessment Matrix (TAM) is used to determine the phenomena and features that need to be included, such as:

- Accurate representation of the containment layout, including potential coolant circuit depressurisation safety systems and coolant circuit break locations (if relevant) and their release orientation, on a length scale/nodalisation sufficient to resolve relevant phenomena for hydrogen combustion.
- Inclusion of source term information (steam/hydrogen release) from MAAP analysis.
- Representation of heat removal mechanisms from containment.
- Representation of heat sources that could influence containment conditions (e.g. PARs exhaust).
- Adequate representation of thermal hydraulic phenomena within containment to accurately predict gas mixing and mixture concentration.
- Representation of mitigative measures such as PARs.

The localised mixing assessments are performed for the duration of interest where there is judged to be a risk, and this will be used to identify local regions of risk if the σ and λ criteria are for flame acceleration and DDT are met.

It is noted that σ and λ are empirically derived correlations that largely rely on experimental data derived from tests of combustion of homogeneous clouds in simple geometries. The application in the analysis approach to potentially inhomogeneous gas mixtures and complex geometries introduces uncertainty. An appropriate break-down of the regions over which they are assessed must be used. For example, the calculation of the σ and λ-indices based on the global average conditions and gas concentrations, would not be appropriate for assessing the localised risk within potentially confined regions around the coolant circuit pipework and steam generators. Whilst both criteria are necessary conditions for the onset of flame acceleration and detonation respectively, they do not guarantee occurrence.

As illustrated in the previous section, there is considerable uncertainty in SA sequence evolution that could lead to differences in hydrogen generation. Furthermore, there are uncertainties associated with

Public – Not Listed – Not Subject to Export Controls

predictions of gas mixing and therefore localised conditions and gas concentrations. A common approach to bound the uncertainties associated with hydrogen generation is to scale the hydrogen generation of the most limiting cases to the equivalent generation of 100% fuel clad oxidation. Additional sources of hydrogen generation in the period of interest (e.g. oxidation of B_4C control rods) may also be added to this scaled value. Nonetheless, a balanced approach must be used to ensure excessive conservatism is not represented, for example scaling of scenarios where it is physically impossible to reach 100% fuel clad oxidation would be inappropriate.

Sensitivity analysis should be used to understand the impact of uncertainties in the mixing analysis or features that cannot be adequately captured in the precursor global analysis. In particular, this may relate to the specific location and orientation or gas release from the coolant circuit which could impact mixing and local hydrogen concentration.

The following figures of merit are used to aid judgement in identifying the most limiting accident sequences and periods of risk:

- Volume of gas clouds within combustion limits can be used to estimate the possibility of flame propagation and burn completeness.
- Timing within the accident sequence that σ and λ criteria are met.
- Duration that σ and λ criteria are met. The period of risk of flame acceleration/detonation may be significant in combination with consideration of ignition sources.
- Volume of containment where σ and λ criteria are met. A larger volume meeting the criteria means that more potential ignition sources could lead to flame propagation across containment.
- Concentration of hydrogen when σ and λ criteria are met. The possibility of highly energetic combustion occurring is believed to be low when hydrogen concentration is close to the flammability limit [1].

The outcome of this analysis step allows the down-selection of scenarios, and proposal for limiting scenarios, times, and approximate containment locations for subsequent combustion analysis.
For Roll-Royce SMR this step is performed using the 3D GOTHIC containment code [3]. GOTHIC is a thermal-hydraulic software package that solves the conservation equations for mass, momentum and energy for multicomponent, multi-phase compressible flow in lumped parameter and/or multi-dimensional geometries. GOTHIC is well-established within the nuclear industry for performing containment thermal hydraulic analysis, including for hydrogen distribution during SAs.

5. Localised Combustion Assessment

For the scenario(s) of interest assessed by the previous step that indicate a possibility of flame acceleration based on the σ-criterion, detailed combustion analysis can be performed. The aim of the combustion analysis is to calculate the consequences of deflagration in terms of the resultant temperature and pressure loading, including the effects of flame acceleration due to turbulence generation. The σ and λ criteria, as assessed in Step 2, are necessary conditions for flame acceleration and detonation, and detailed combustion analysis can be used to further resolve the risk posed.

The combustion assessment incorporates the following features:

- Accurate representation of the containment layout on a length scale/nodalisation sufficient to resolve relevant phenomena for hydrogen combustion, including turbulence generation.
- Inclusion of relevant boundary conditions such as gas mixture, temperature, pressure and turbulence prior to deflagration.
- Representation of an ignition source at a selected location.

Public – Not Listed – Not Subject to Export Controls

The output of analysis includes:

- Magnitude and duration of temperature and pressure loadings due to deflagration at selected monitor points (e.g. equipment and/or the containment vessel).
- Global pressure response during and following deflagration.
- The likelihood of DDT.

For the assessments of relevant scenarios of interest, combustion is initiated at a time and location within containment considered to be the most onerous. The identification of appropriate times relies upon the figures of merit (σ- and λ-criteria) assessed in analysis Step 2, and engineering judgement. The outcome of initial combustion assessments, and sensitivity studies considering alternative ignition locations or model parameter settings can improve understanding of the relative severity and output uncertainty associated with the accident scenario. Alternative ignition locations may also be more onerous for different target SSCs requiring assessment.

The overall objective of the Roll-Royce SMR SA containment safety measure (including hydrogen reduction measures) is to prevent combustion leading to flame acceleration that could challenge containment vessel or SSC integrity. When considering uncertainty in the end to end approach, it may be unfeasible to demonstrate deterministically that flame acceleration can be prevented in totality for every plausible SA sequence. Therefore, if flame acceleration cannot be excluded by design provision, it may be necessary to demonstrate that the design of the containment vessel and relevant SSCs can withstand the predicted dynamic loadings. The outputs of detailed combustion analysis can be supplied to finite element code analysis to predict the structural response of the containment vessel and associated structures. The analysis steps are iterative, with refined analyses performed to ensure the lowest risk position is reached where practicable through optimisation of the mitigative safety measure design.

For Roll-Royce SMR localised combustion analysis is performed by the combustion code FLACS-CFD. FLACS-CFD is an advanced tool for performing engineering calculations for safety applications related to combustion of flammable gases. The software includes a 3-dimensional CFD code that solves Favre-averaged transport equations for mass, momentum, enthalpy, turbulent kinetic energy, rate of dissipation of turbulent kinetic energy, mass-fraction of fuel and mixture-fraction on a structured Cartesian grid using a finite volume method. One of the key features that distinguishes FLACS-CFD from most commercial CFD codes is the use of the distributed porosity concept for representing complex geometries on relatively coarse computational meshes [4]. This improves calculation time for assessments of large problem domains, such as a nuclear power plant containment building.

6. Verification, Validation and Uncertainty Quantification

Rolls-Royce SMR deploy the PIRT and TAM approach to ensure that all relevant phenomena in the problem domain are identified and that analysis code capability in representing the phenomena is reviewed and demonstrated to be adequate in the domain of interest. The approach allows the identification of the most significant phenomena for assessments and prioritisation of verification, validation and uncertainty quantification (VVUQ) activities.

The objectives of the analysis should always be used to guide the prioritisation of VVUQ activities. Often validation for hydrogen relates to peak pressure attained following combustion (slow deflagration, flame acceleration and detonation), however if the safety case objective is to prevent the occurrence of energetic combustion then the focus of validation should be to enable accurate prediction of the onset of flame acceleration and DDT rather than the resultant peak pressure.

The three-step assessment approach outlined herein intends to utilise the advantages of fast solving analysis codes where possible, acknowledging that there are inherent shortfalls and utilising successive

Public – Not Listed – Not Subject to Export Controls

steps with more detailed analysis as required. The following fundamental limitations guide the assessment approach, and also elicit areas where additional validation would be advantageous to improve confidence in predictions:

- Integral codes (e.g. MAAP) with coarse containment nodalisation are unlikely to be sufficient to resolve localised gas concentrations and the risk of flame acceleration and DDT on a local scale. To address this, the Roll-Royce SMR approach incorporates GOTHIC to perform 3d localised gas mixing assessments with appropriate application of the σ and λ criteria.
- The σ and λ criteria are necessary conditions for the occurrence of flame acceleration and detonation respectively, however are derived from experimental data predominantly representing uniform gas clouds in simple geometries. The application to complex containment geometries and inhomogeneous gas clouds introduces uncertainty to the approach for identifying scenarios that could lead to flame acceleration/DDT. To address this, the Roll-Royce SMR approach incorporates FLACS-CFD to perform detailed combustion load assessments and is used to support substantiation of the chosen application of the σ and λ criteria.
- The prediction of peak pressure resulting from flame acceleration/DDT is subject to high uncertainty. There is limited validation evidence for atmospheres with high hydrogen concentration and steam dilutant, particularly for complex geometries with increased potential for turbulence-induced flame acceleration, applicable to PWR containments. This limitation becomes more significant when considering containment scale geometry. Ultimately, the objective of the Roll-Royce SMR hydrogen reduction system is to prevent the occurrence of flame acceleration. Therefore, the aim of the analysis is to adequately predict the occurrence of flame acceleration through application of the σ criterion, minimising the reliance on peak pressure predictions, and the associated uncertainties.

Rolls-Royce SMR is supportive of the THEMIS-2 test programme, as a key source of further validation data in this area.

7. Summary

A three step assessment approach has been developed by Roll-Royce SMR. The intention is to identify limiting credible SA scenarios that may pose a risk to containment and SSC integrity from slow deflagration, and assess the possibility of localised accumulation of hydrogen that could lead to flame acceleration and DDT. The assessment approach utilises fast solving codes for coarse evaluation of a large number of scenarios, and optimised utilisation of detailed analysis methods to evaluate the possibility of occurrence of flame acceleration/DDT for limiting scenarios and the potential consequences. The advantages of each analysis step/code are utilised whilst acknowledging limitations and uncertainties in each step. The overall aim is to provide demonstration that containment safety measures and hydrogen reduction systems are able to reduce the risk associated with hydrogen deflagration during a SA as far as possible.

Rolls-Royce SMR 3D Hydrogen Combustion Assessment Approach

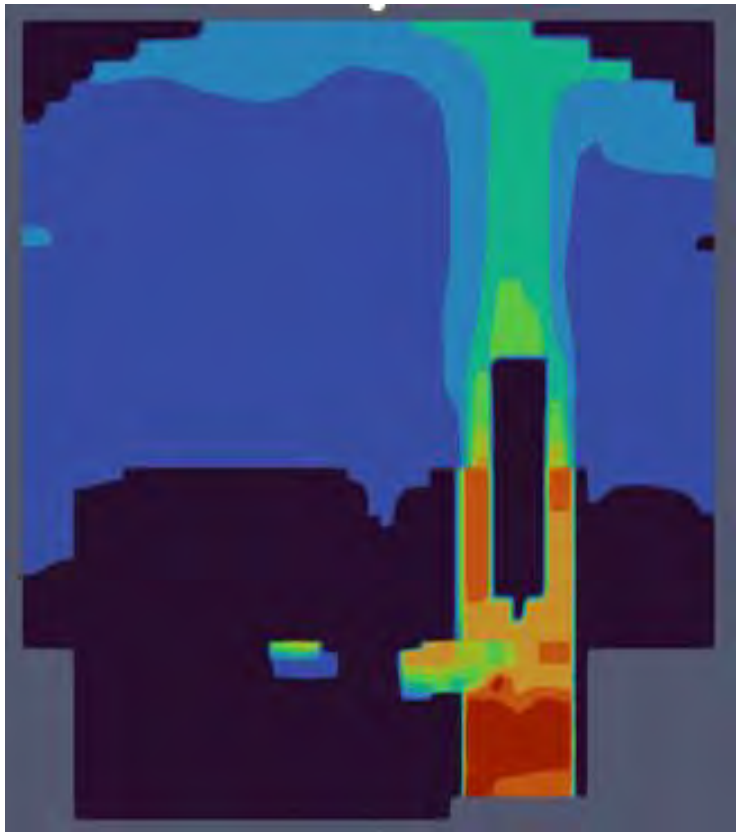
Jonathan Fowles, Alex Meredith, Joe Butterworth (Gexcon)

 © 2026 Rolls-Royce SMR Ltd

Public – Not Listed – Not Subject to Export Controls

Introduction

- Hydrogen release during a Severe Accident poses a risk to containment integrity in the event of combustion.
- Assessments should effectively identify and analyse limiting accident scenarios.
- This presentation describes the process developed by Roll-Royce SMR and Gexcon to identify limiting credible scenarios that may pose a risk to containment.
- The assessments utilise fast solving codes for coarse evaluation of a large number of scenarios, and optimised use of detailed analysis methods for energetic combustion modes.



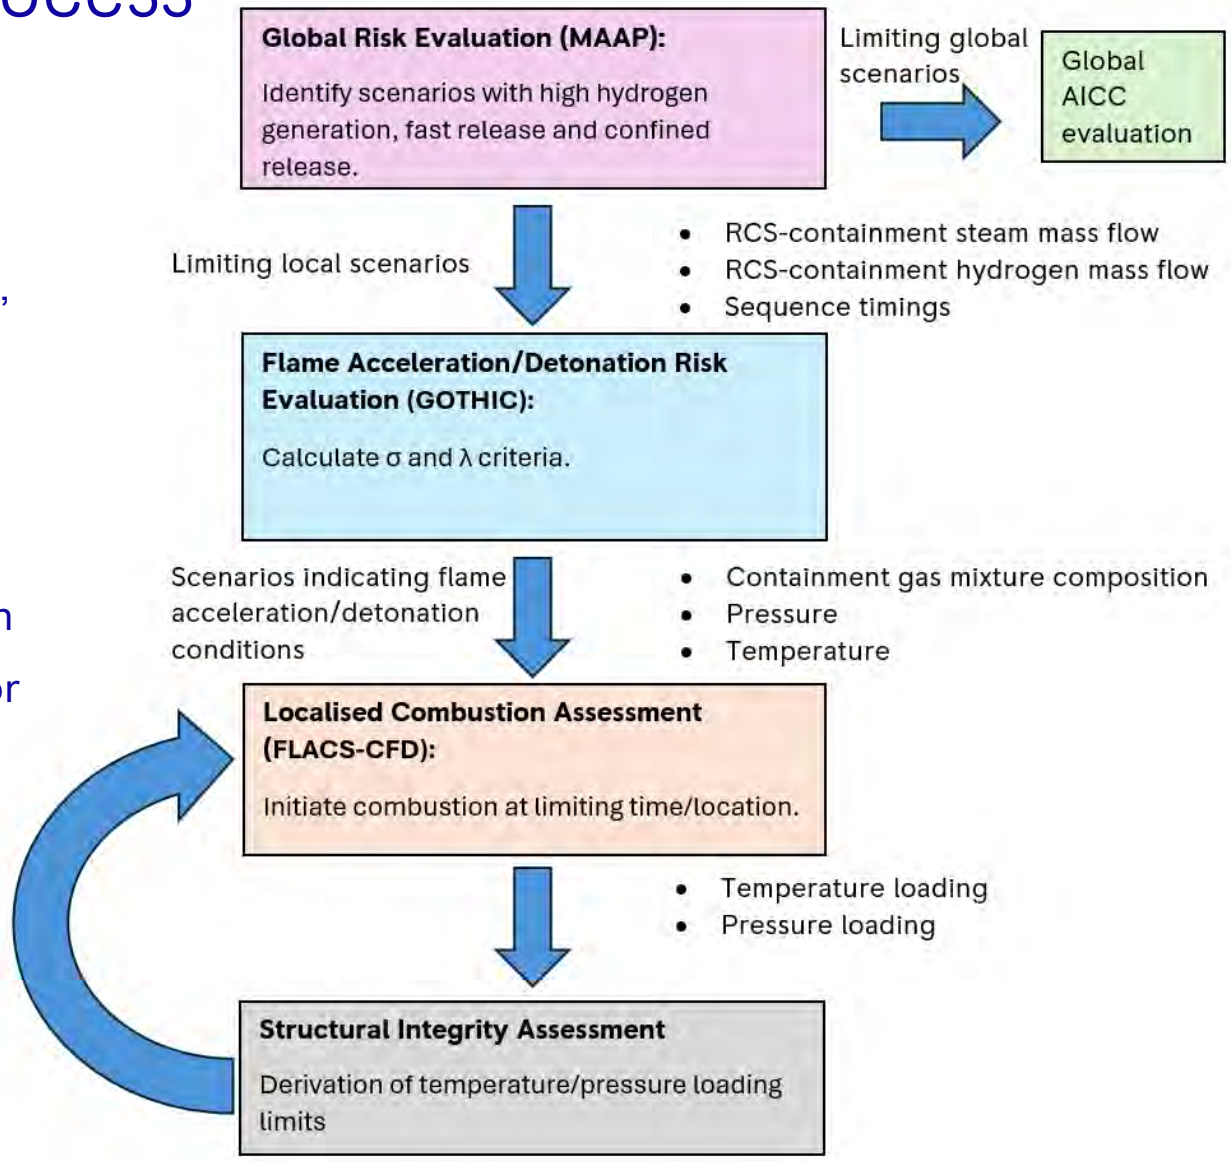
Public – Not Listed – Not Subject to Export Controls

Assessment Process

Public – Not Listed – Not Subject to Export Controls

Risk Assessment Process

- Identification of limiting credible SA scenarios that may pose a risk to containment integrity from slow deflagration,
- Assess the possibility of localised accumulation of hydrogen that could lead to flame acceleration/DDT.
- Evaluate consequences of energetic hydrogen combustion
- Provide boundary conditions for structural integrity assessments



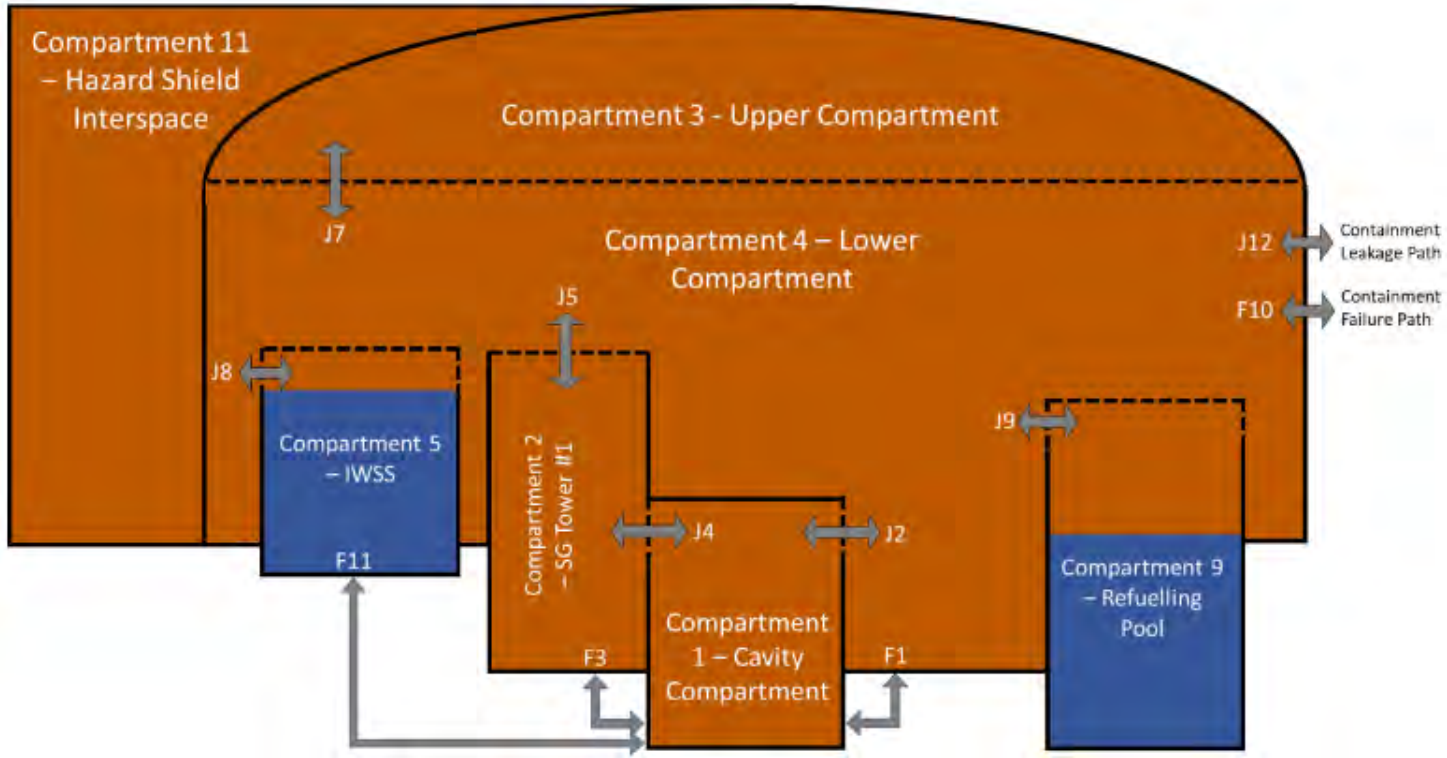
Public – Not Listed – Not Subject to Export Controls

Global Risk Evaluation

Public – Not Listed – Not Subject to Export Controls

Global Risk Evaluation - MAAP

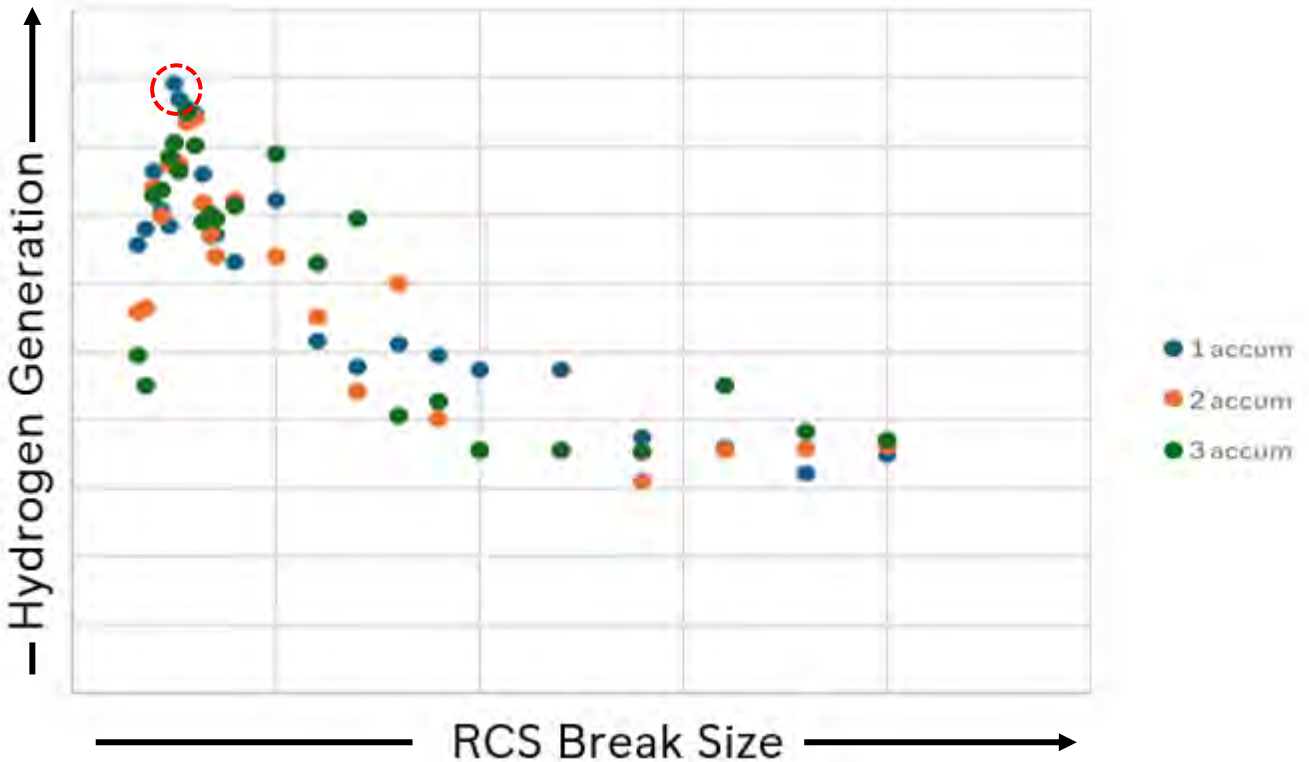
- Integral SA code (e.g. MAAP) is used to identify the most limiting SA scenarios on a global basis.
- Representation of core and RCS allows predictions of hydrogen generation and release into containment
- Coarse containment nodalisation provides good representation of global gas concentrations.
- Adiabatic Isochoric Complete Combustion (AICC) pressure, conservatively represents the pressure rise due to slow deflagration.
- Due to the coarse containment nodalisation, it is not considered suitable for the assessment of localised combustion risk.



Public – Not Listed – Not Subject to Export Controls

Global Risk Evaluation - MAAP

- Fast solving integral codes allow the evaluation of a large number of SA scenarios.
- E.g. LOCA scenarios typically maximise the duration of fuel clad/steam interaction by varying:
  - Break size.
  - Safety injection water sources.
  - RCS depressurisation timing.
- Figures of merit (FoM) used to estimate localised conditions, including:
  - Total hydrogen generation.
  - Peak hydrogen concentration in containment/compartments.
  - Steam concentration during hydrogen release.
- Source terms for the most onerous scenarios are transferred to the next step for localised assessment.



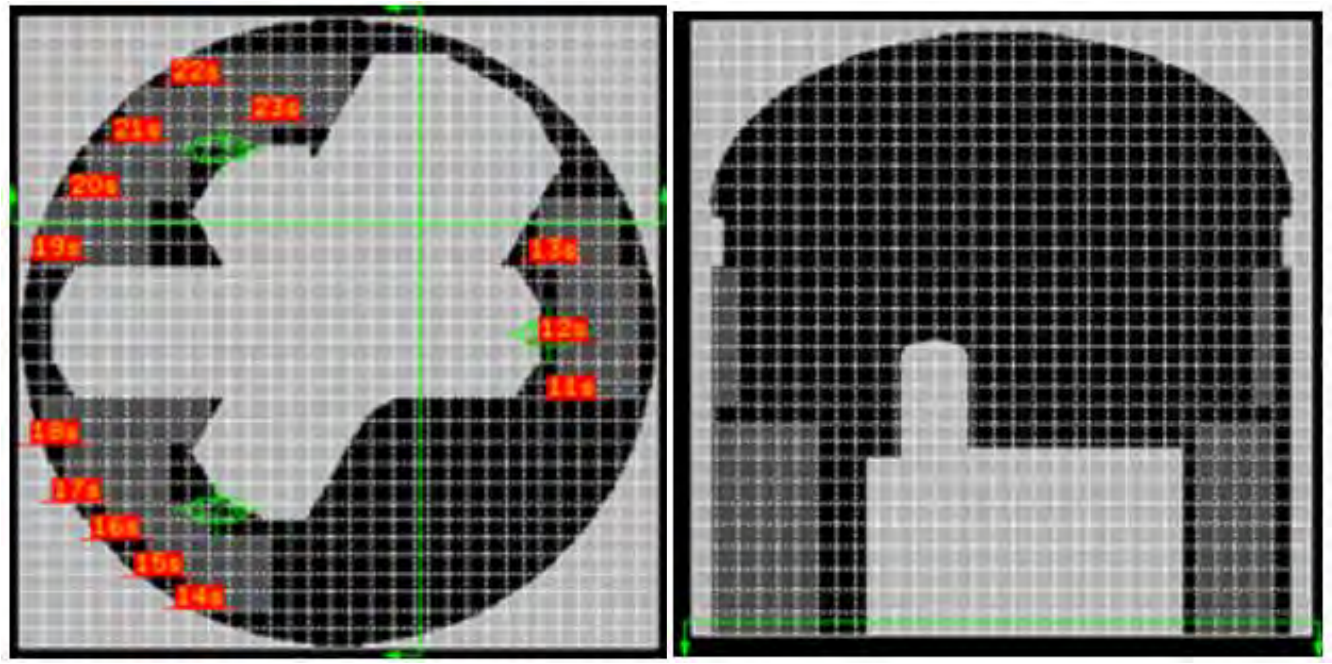
Public – Not Listed – Not Subject to Export Controls

Flame Acceleration & Detonation Risk Evaluation

Public – Not Listed – Not Subject to Export Controls

Flame Acceleration & Detonation Risk Evaluation - GOTHIC

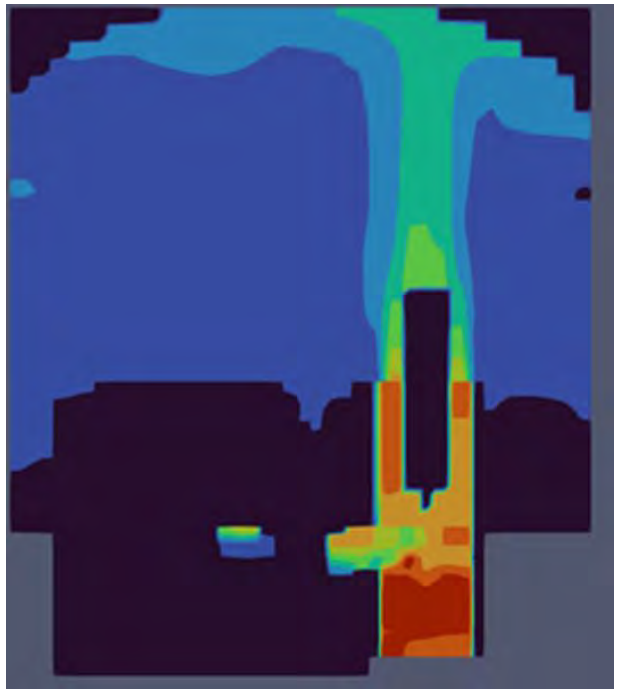
- Detailed assessments of “scenarios of interest” are performed using code capable of modelling 3D gas mixing and heat transfer (e.g. GOTHIC).
- Detailed containment geometry model is used, with a target cell size of ~1m^3.
- Heat sinks represented by thermal conductors spanned across blockage surfaces/cells.
- MER/hydrogen source terms are injected at the cell faces representative of release location/direction.
- To bound uncertainty in hydrogen generation, the hydrogen mass flow rate is scaled to achieve the equivalent of 100% fuel clad oxidation.
- Mitigative safety measures, such as PARs, can be included in assessment.



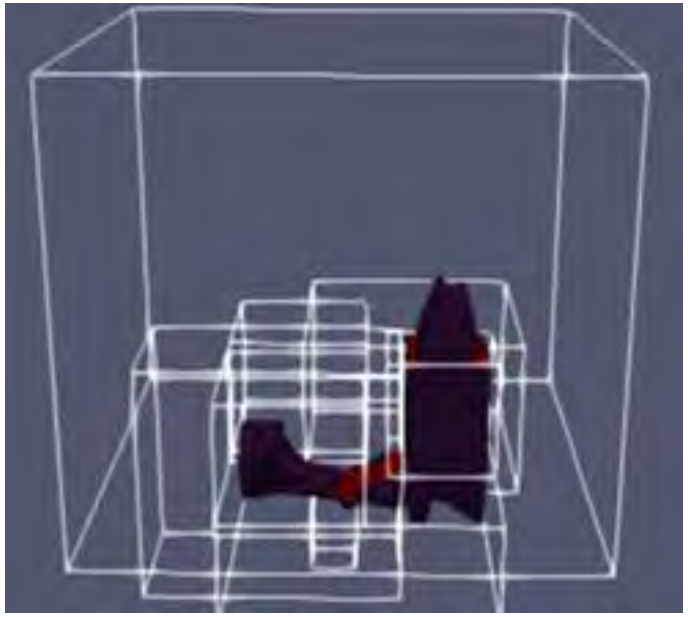
Public – Not Listed – Not Subject to Export Controls

Flame Acceleration & Detonation Risk Evaluation - GOTHIC

- The 3D mixing results are used to assess the likelihood of FA and DDT through the Sigma (σ) and Lambda (λ) criteria:
  - Regional/room assessments performed based on cell average conditions.
  - Cell-by-cell assessment can be used to inform on “cloud size”.
- If the σ and λ criteria are met, the following FoM are reviewed:
  - Volume of gas clouds exceeding combustion limits/criteria.
  - Timing within accident that criteria are satisfied.
  - Time duration criteria are satisfied or “time at risk”.
  - Relative concentration of hydrogen and steam.
  - Location of clouds, considering potential for turbulence.



Localised Hydrogen Concentration

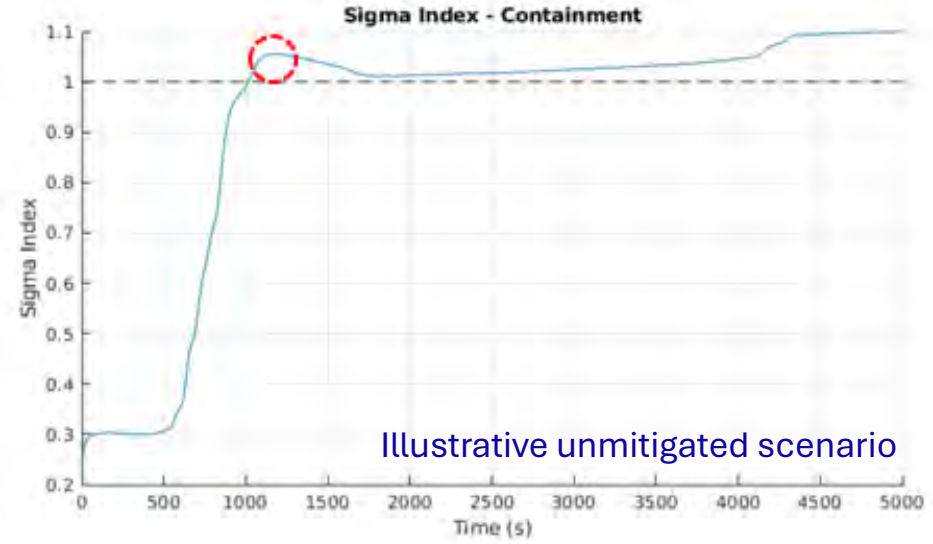


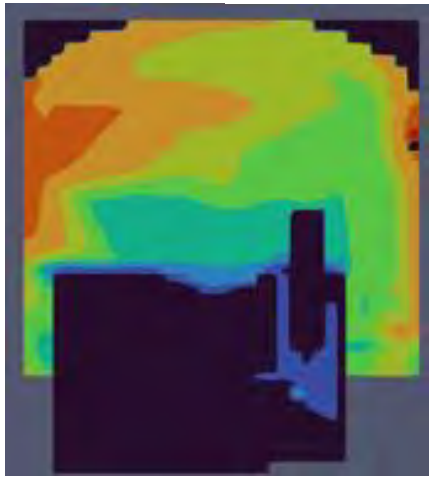
Gas Volume Satisfying σ Criterion

Public – Not Listed – Not Subject to Export Controls

Flame Acceleration & Detonation Risk Evaluation - GOTHIC

- The outcome of this analysis step allows identification of scenarios with the greatest potential for flame acceleration.
- The limiting scenarios, time within scenario, and approximate containment locations are taken forward for subsequent combustion analysis.
- Cell-by-cell conditions at the selected time are extracted, processed and used as the initial conditions for the combustion assessment (FLACS-CFD):
  - Gas Concentrations (e.g. H2, O2, Steam)
  - Temperature
  - Pressure
  - Turbulent Kinetic Energy

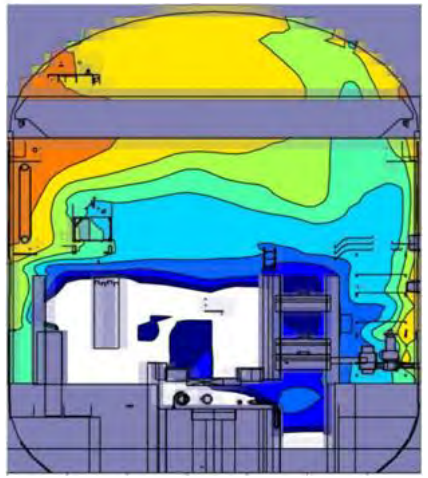




GOTHIC

Pre-processor

Localised Hydrogen Concentration



FLACS-CFD

Public – Not Listed – Not Subject to Export Controls

Localised Combustion Assessment

Public – Not Listed – Not Subject to Export Controls

Localised Combustion Assessment – FLACS-CFD

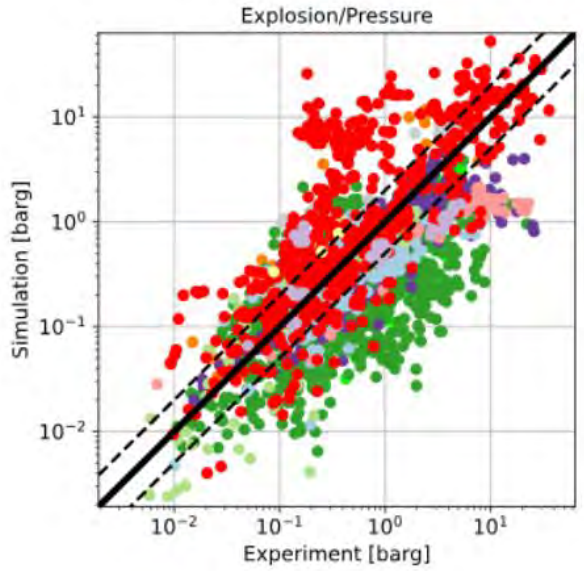
FLACS-CFD simulates vapour cloud explosions for 60+ fuels including hydrogen, accounting for the effect of contributing and mitigating effects (such as confinement and congestion due to realistic geometry).

Relevant models:

- Flame propagation and pressure build-up
- Propagation of blast waves
- Porosity Distributed Resistance model

Extensive validation:

- Many cases relevant for hydrogen
- Hydrogen Balloon, Sandia FLAME, etc.
- Confined and congested cases are relevant for both hydrocarbon industry and containment
- Generally good performance, some spread



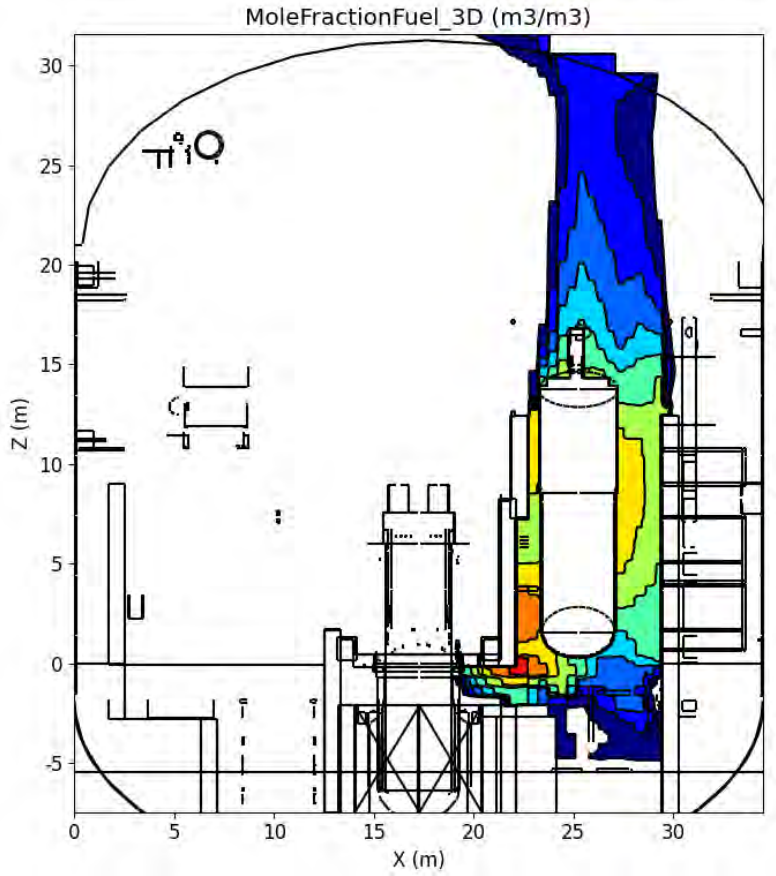
Public – Not Listed – Not Subject to Export Controls

Localised Combustion Assessment – FLACS-CFD

FLACS-CFD uses input data from GOTHIC analysis to predict the consequences of containment combustion and predict flame acceleration and detonation based on local conditions.

Overview of method:

- Set up FLACS-CFD grid
- Interpolate data from GOTHIC to FLACS-CFD
- Select ignition locations
- Simulate
- Check velocities for flame acceleration
- Automatic detection of detonation based on spatial pressure gradient
- Output overpressures and pressure-time curves at monitor points to determine loading on containment shell



Slice through containment showing initial hydrogen concentrations above a threshold for hydrogen released in a steam generator compartment

Public – Not Listed – Not Subject to Export Controls

Localised Combustion Assessment – FLACS-CFD

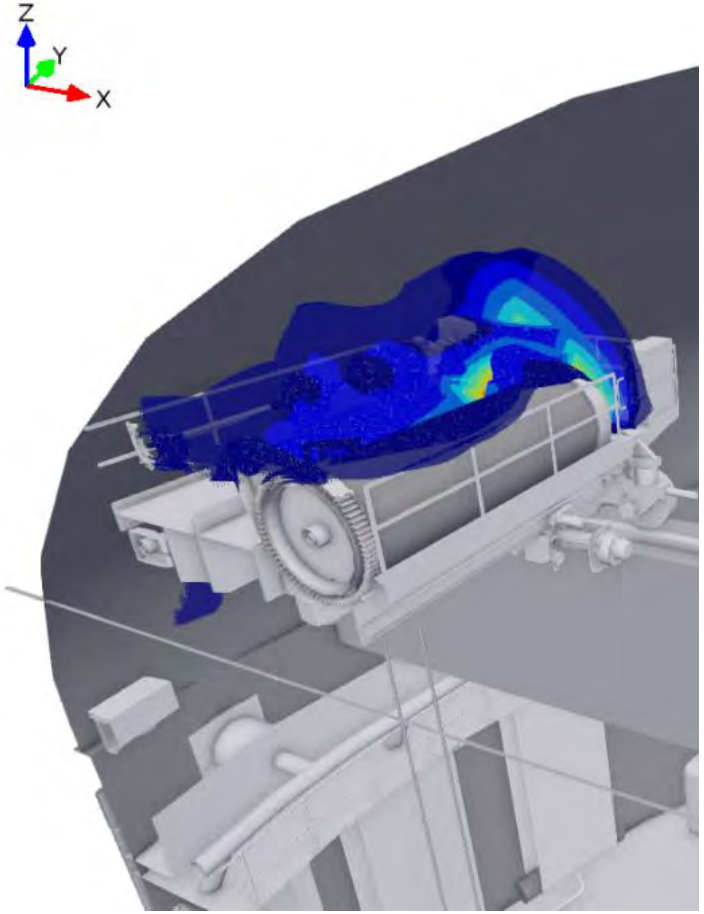
FLACS-CFD can predict local flame acceleration where sigma criteria are not met according to a global analysis, especially where higher hydrogen concentrations intersect with small-bore pipework and other blockages.

The solver accounts for:

- Inerting
- Spatial distribution of hydrogen
- Confinement and congestion
- Laminar, wrinkled, and turbulent burning regimes

Example explosion simulation:

- Sigma criteria not met globally
- Localized flame acceleration around crane structure
- Local loading on containment



Slice through containment showing velocity magnitude as flame accelerates around crane structure

Public – Not Listed – Not Subject to Export Controls

Localised Combustion Assessment – FLACS-CFD

FLACS-CFD calculates the spatial pressure gradient and automatically triggers the Deflagration-to-Detonation Transition (DDT) when this exceeds a specified value.

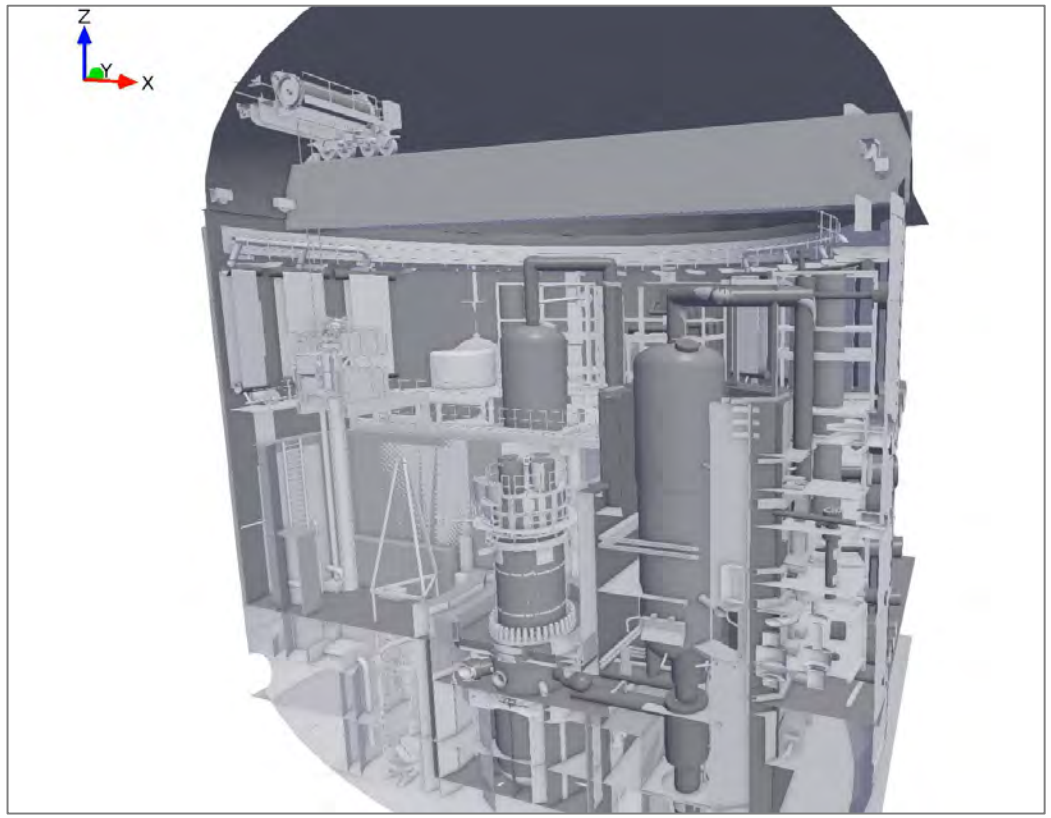
Comparing to lambda criteria:

- Spatial pressure gradient criterion set to give slightly conservative prediction of DDT compared to validation cases
- When lambda criterion met, simulations show high likelihood of DDT
- Simulations will be targeted at times where the lambda criterion is close to being met, to show whether DDT is predicted for borderline cases

Following DDT prediction:

- Dedicated burning model for detonation
- Can be disabled to investigate development of spatial pressure gradient over time

Slice through containment showing pressure development



Public – Not Listed – Not Subject to Export Controls

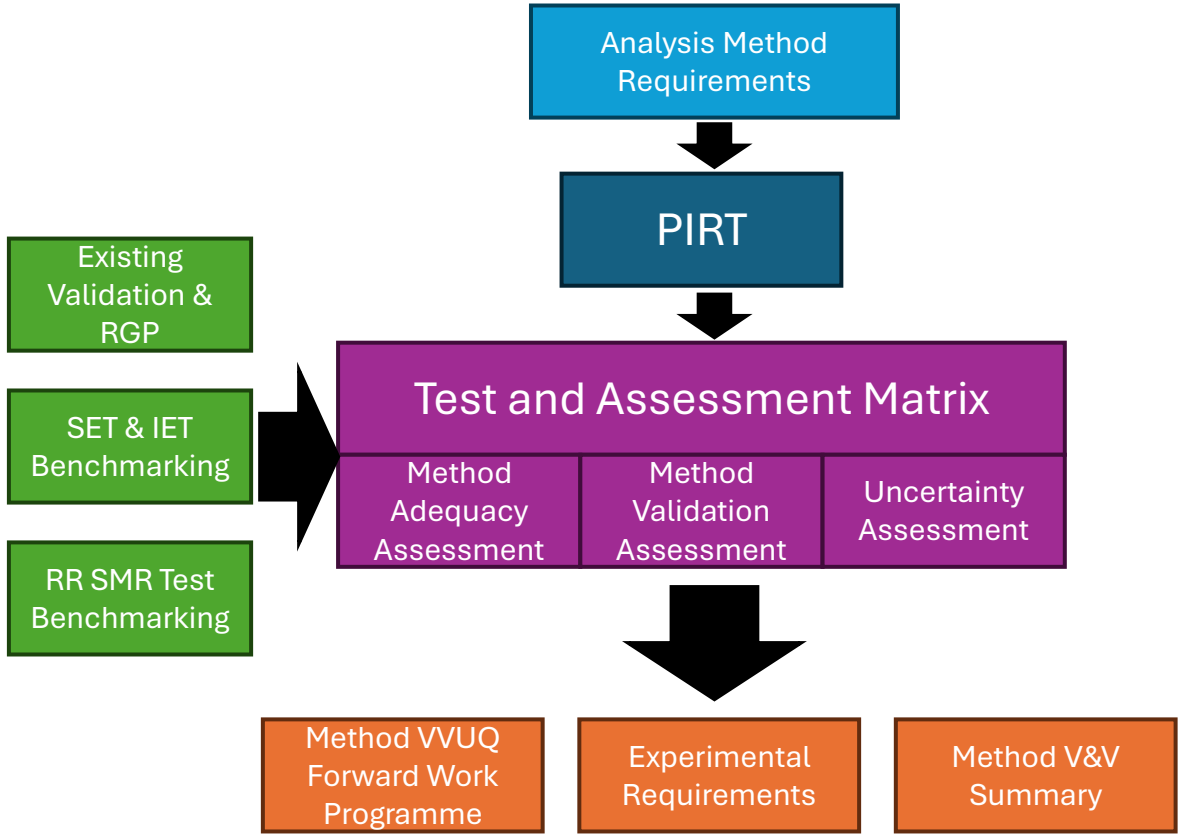
Verification, Validation and Uncertainty Quantification

Public – Not Listed – Not Subject to Export Controls

Verification, Validation and Uncertainty Quantification (VVUQ)

- Rolls-Royce SMR deploy the PIRT and TAM approach:
  - Identify all relevant phenomena in the problem domain.
  - Assess analysis code capability in representing phenomena according to importance.
- Allows identification of the most significant phenomena/modelling limitations and prioritisation of VVUQ.
- The objectives of the analysis should always be used to prioritise VVUQ activities.

For example:
Validation for hydrogen combustion often prioritises accurate peak pressure prediction, whereas if the safety case objective is to prevent the occurrence of energetic combustion then the priority is to adequately predict the onset of FA/DDT.



Public – Not Listed – Not Subject to Export Controls

Summary

Public – Not Listed – Not Subject to Export Controls

Summary

- A three-step process has been developed for the assessment of SA hydrogen risk.
    1. Global Assessment in MAAP.
    2. Localised gas mixing assessment in GOTHIC.
    3. Localised combustion assessment in FLACS-CFD.
- The approach allows identification and assessment of limiting credible scenarios for the Rolls Royce SMR and provides conditions for detailed finite element assessments of the containment vessel.
- Iterative approach allows optimisation of safety systems to manage hydrogen release and development of a robust safety case for severe accidents.

SEVERE ACCIDENT ANALYSIS OF SASPAM-SA DESIGN II LW-SMR DRY CONTAINMENT USING CONTAINMENTFOAM

Carlos Vázquez-Rodríguez, Stephan Kelm
Forschungszentrum Jülich (FZJ)
Wilhelm-Johnen-Straße, 52428 Jülich, Germany
c.vazquez-rodriguez@fz-juelich.de; s.kelm@fz-juelich.de

ABSTRACT

The Horizon Euratom SASPAM-SA Project investigates the transferability of severe-accident knowledge and methods developed for large LWRs to Light-Water SMRs. While most SASPAM-SA partners rely on lumped-parameter tools (MELCOR, ASTEC, AC2), this work uses *containmentFOAM*, an open-source CFD add-on to OpenFOAM®-11, to complement those calculations with 3D, high-fidelity insight into the containment response of SASPAM-SA Design II, which features a containment with several passive safety systems. With that purpose, and using MELCOR data as boundary conditions, two different time windows of one of the SA sequences postulated in SASPAM-SA are analysed with *containmentFOAM*.

The first window covers the blowdown phase, where the large mass and energy release drives a rapid displacement and redistribution of the initial gases, with nitrogen transport to the Passive Suppression System (PSS) as the central aspect. The second window targets a later stage of the transient including the first significant hydrogen release, during which the hydrogen molar fraction rises from zero to about 0.1 and the flow field is governed by weak buoyancy-driven motions. In both windows, the local transport of non-condensables to the PSS end up determining the pressurization of the containment, that ultimately affect the severe accident progression. *containmentFOAM's* simulations indicate that the blowdown phase quickly approaches a well-mixed atmosphere, suggesting that the added value of resolving 3D details is limited. In contrast, during the later time window, the weak buoyancy-driven flows sustain gas stratification, affecting the hydrogen distribution and its transport to the PSS.

KEYWORDS
SMR, CFD, *containmentFOAM*, OpenModelica

1. INTRODUCTION

The most recent energy outlooks published by the International Atomic Energy Agency (IAEA) postulates the deployment of up to 162 GW of Small Modular Reactors (SMRs) by 2050 [1]. Among the concepts under consideration, Light Water SMRs (LW-SMRs) are the most likely ones to be deployed in the near term. They generally share key characteristics with currently operating large LWRs, while incorporating evolutionary design features that provide safety benefits and reinforce the first three levels of the Defence-in-Depth (DiD) principles [2,3]. Nevertheless, the path from conceptualization [4] to the licensed concept [5] of an reactor is complex, effort-intensive, and time-consuming, always involving numerous interactions between designers and regulators. Moreover, even for plants with advanced features strengthening DiD levels 1–3, regulators require independent provisions for Severe Accident (SA) prevention and mitigation to be incorporated in the design (DiD level 4). Consequently, scenarios that could lead to a SA must be postulated and studied deterministically (see [2] for details). In this context, the Horizon Euratom SASPAM-SA project [6], coordinated by ENEA (Italy), addresses the identification of potential postulated SA

sequences for two generic concepts representative of a range of LW-SMRs. The SASPAM-SA Design-I features a generic integral Pressurised Water Reactors (i-PWR) of about 60 MWe embedded in a containment submerged in a pool, whereas Design-II consists of a generic 300 MWe i-PWR with a containment and several passive systems. The postulated SA sequences for each design are summarised in [6] for completeness.

Aligned with SASPAM-SA evaluation of the applicability of large PWR know how to LW-SMR, the postulated sequences calculated with Lumped Parameter (LP) codes were used in previous work [7] as a screening exercise to identify how LW-SMR specific phenomena required targeted upgrades of the *containmentFOAM* model library. *ContainmentFOAM* is a CFD toolbox —developed at Forschungszentrum Jülich as an add-on for OpenFOAM (currently v11)— with a modelling basis originally consolidated for the phenomenology prevailing in dry large-PWR containments. It is focused on multi-species transport and condensation-driven heat transfer and aiming at technical-scale safety analyses. Among the different upgrading needs, the stronger coupling between the containment atmosphere and the Pressure Suppression System (PSS) motivated the main development effort, since the transport and accumulation of non-condensables at the PSS is the driving phenomenon for the containment pressurisation. A fully high-fidelity, two-phase CFD representation of containment and PSS was discarded, as it would be computationally prohibitive. The proposed solution was a multi-fidelity coupling framework where *containmentFOAM* resolves the containment space while the PSS is treated at system level, with data exchanged through an Functional Mock-up Interface (FMI) based coupling to OpenModelica [7]. This coupling was validated against experiments with comparable coupled phenomena and tested with a preliminary application at the technical scale [7,8].

Within SASPAM-SA, most partners rely on LP SA codes (MELCOR, ASTEC, AC2) with empirical models to replicate the severe accident phenomenology at an affordable computational cost for simulating transients of several days. Within SASPAM-SA, *containmentFOAM*'s role was to complement those calculations with high-fidelity, 3D insights into the containment response of Design II for selected time windows. The objective of the present work is not to replace the LP analyses, but to identify and simulate phases of the SASPAM-SA sequences where local heterogeneities, not resolved in 0D/1D models, can become safety-relevant. In particular, the 3D transport and accumulation of non-condensable gases (N_2 and H_2) to the PSS. Following this scope, Section 2 introduces the selected SASPAM-SA transient and defines the two analysed time windows, Section 3 presents the Design II *containmentFOAM* model, and Section 4 discusses the results for the blowdown phase (Section 4.1) and for the later phase dominated by hydrogen transport (Section 4.2).

2. SEVERE ACCIDENT TIME WINDOWS FROM SASPAM-SA SEQUENCES

SASPAM-SA Design-II is a generic ~300 MWe integral PWR concept with a dry, inertised containment integrating several passive safety systems, including a PSS coupled to the drywell. This section is intended to describe the main characteristics of the SASPAM-SA Design-II SA postulated sequences simulated with SA codes, which will be necessary to better understand the containment analyses that will be presented in Section 4. A more comprehensive description of the Design Basis Accident (DBA) and all the SA postulated in SASPAM are available in [9] and [6,10], respectively.

For the response the DBA (Direct Vessel Injection (DVI) break) the different systems —Reactor Pressure Vessel (RPV-P_1), Containment/Drywell (P_2) and PSS (P_3)— are expected to behave as a closely coupled thermal-hydraulic system driven by natural circulation. In the initial pressure-suppression stage (see Figure 1, containing all the needed acronyms), ADS actuation rapidly couples the RPV and containment pressures, limiting the coolant inventory discharged thanks to the faster pressure equalization ($P_1 = P_2$). The resulting pressure rise in the drywell promotes venting to the PSS, where steam is efficiently condensed in the subcooled pool and the pressure increase becomes dominated by the progressive accumulation of non-

condensables in the PSS gas space. After the drywell peak, P_1 and P_2 decrease due to primary-side cooling and wall condensation, and since P_3 decreases more slowly the pressure gradient then reverses ($P_3 > P_2$), pushing water from the PSS into the drywell and flooding the reactor cavity. When the cavity water level rises above the break elevation, the long-term cooling loop is closed and stable cooling is established (right sketch in Figure 1), with the coupled system approaching $P_1 \approx P_2 \approx P_3$ while decay heat is removed by the passive Emergency Heat Removal System (EHRS).

As already concluded at [10], SASPAM-SA confirmed that the pivotal safety system was the EHRS (the combined failure of all the other safety systems still resulted in a successful long-term cooling of the core). Therefore, SASPAM-SA sequences combined the failure of the EHRS with additional safety systems (ADS-Automatic Depressurization System, LGMS-Long Term Gravity Make-up System, EBT-Emergency Borated Tank) [6]. From the containment-analysis perspective, one evident time window to investigate is the blowdown phase, since the SA codes predict a pressure increase above 11 bar during the first 1000 s. In this early transient, containment phenomenology is dominant: wall condensation rates and the transport of non-condensable gases to the PSS are expected to be at their maximum. And evaluation of the 3D flows should also confirm the nearly homogeneous containment conditions usually assumed for blowdown, or whether the coupling with the PSS can still generate safety-relevant local heterogeneities. In addition, the rapid evolution of the containment conditions is reinforced by ADS actuation, which motivated the selection of the SA sequence including ADS-1 actuation (SA3). Figure 2 summarizes the corresponding pressure evolution (P_1, P_2 and P_3), the main system actuations, and the associated phenomenological windows.

A second time window of interest was selected between 30,000 s and 50,000 s, at the beginning of the core-degradation phase (between PhW2 and PhW3 in Figure 2). In this period, after the first Filtered Containment Venting System (FCVS) actuation, core oxidation starts and hydrogen is released to the containment. With the ADS-1 valve open, the more elevated release favours the hydrogen stratification. The potential 3D heterogeneities can affect hydrogen transport to the PSS and the non-condensable distribution, which in turn influence steam condensation and containment pressure evolution. A proper prediction of the pressure response in this phase is particularly relevant because it is linked to the observed FCVS cycling in Figure 2, and therefore to the timing of venting actions and the associated source-term evolution.

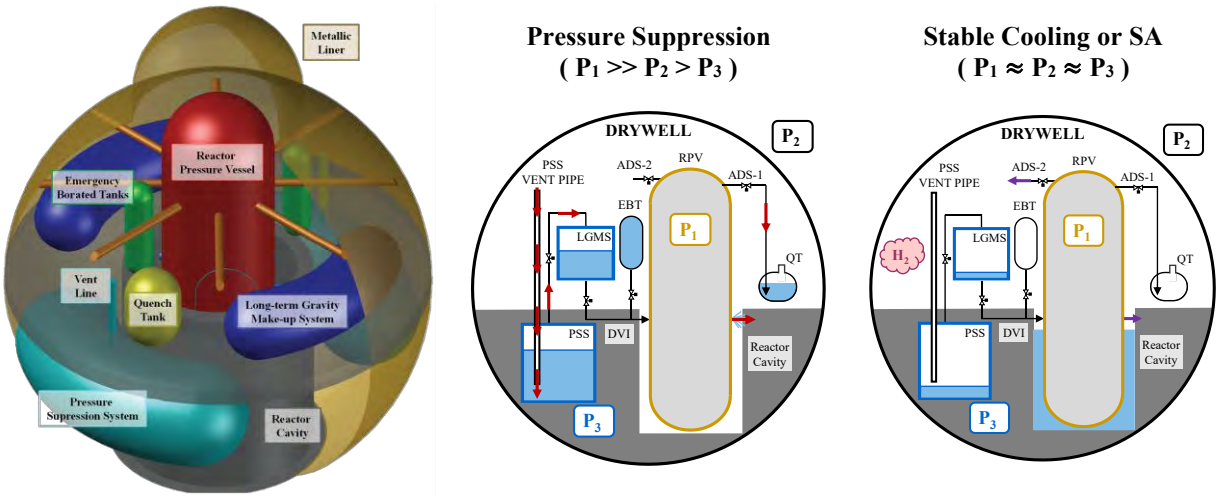

Figure 1. On the left, 3D CAD representation of Design-II containment. The additional 2D sketches represent the status of passive safety tanks in different stages of DBA and SA

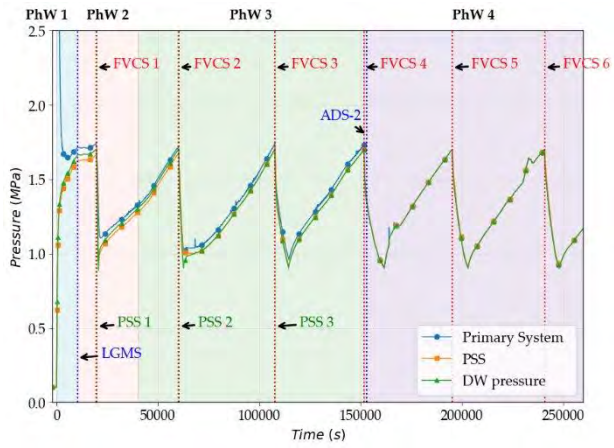

Phenomena Windows	Phenomena	Duration
PhW1 - Thermal-hydraulic phase	Blowdown, ADS-1, EBT ,LGMS, PSS reverse flow, onset of oxidation	10300 s
PhW2 - Core degradation phase	Onset of oxidation, FCVS, PSS Reverse flow, Onset of core damage	30000 s
PhW3 - Containment phenomena	FCVS, PSS reverse flow	110000 s
PhW4 - Reflood	ADS-2, Reflood, FCVS	11000 s

Figure 2. P_1, P_2 and P_3 pressure evolution for the selected SA with colour codes for phenomena windows. The figure is produced and table is adapted from the work of Sapienza University of Rome [11]

3. SASPAM-SA DESIGN-II containmentFOAM MODEL

The CFD model is based on the geometry shown on the left of Figure 1. The containment consists of a steel shell with an inner diameter of about 25 m and an upper removable head for outage requirements. Compared with conventional large-PWR containments, the internal layout is simpler and less compartmentalised. According to the available design information, the containment should be evaluated as two main halves with different pressure evolutions, separated by a concrete floor: an upper half containing the RPV, QT, LGMS and EBT, and a lower half containing the PSS tanks, connected to the upper region through the vent lines.

The geometric information was taken from the common SASPAM-SA database developed as reference input for the LP analyses [12]. Since the level of detail required for a 3D CFD model is significantly higher than for a 0D control-volume representation, missing geometric data had to be completed by engineering judgement. This process led to a detailed CAD model of Design-II, which was then used as the basis for the *containmentFOAM* model, and also helped identify and correct inconsistencies in the initial geometry database used by the LP modellers. To preserve consistency with the SA-code models, the final 3D geometry was checked against the common database, yielding relative deviations below 1.2% for free volume and 2.8% for wall surface. Minor adaptations were then introduced to facilitate meshing, the main ones being a local modification of vent-line thickness, and the non-inclusion of the feed and main steam lines.

The containment model was subdivided into three regions: the containment gas space (FLUID), the concrete cavity (CONCRETE), and the containment shell (STEEL). As shown in Figure 3, a hybrid meshing strategy was adopted: automatic unstructured meshes were used for the FLUID and CONCRETE domains, while the STEEL was kept as a block-structured hexahedral mesh. The FLUID domain was discretised with 2.3 million predominantly hexahedral cells using cfMesh (cut-cell approach with cubic base cells), with a base cell size of 0.4 m and up to two local refinement levels (0.2 and 0.1 m) around relevant geometric features (e.g., vent lines, QT and LGMS), as illustrated in Figure 3. The CONCRETE region was meshed with about 0.37 million unstructured cells (cfMesh), whereas the STEEL was represented by a block-structured mesh of about 0.36 million hexahedral cells generated with ICEM. Wall condensation was only modelled on the concrete surfaces and on the STEEL shell, with all other internal structures treated as adiabatic. Boundary-layer resolution was applied on condensing walls (Figure 3), with average y^+ below 2, while thicker near-wall layers were accepted on non-condensing adiabatic structures due to less restrictive wall functions without condensation. For the FLUID mesh, the main quality indicators were satisfactory for the present calculations (maximum skewness 1.18, maximum non-orthogonality 55 with average ≈5, average cell volume ratio 0.85). A formal mesh sensitivity analysis was, however, not yet performed.

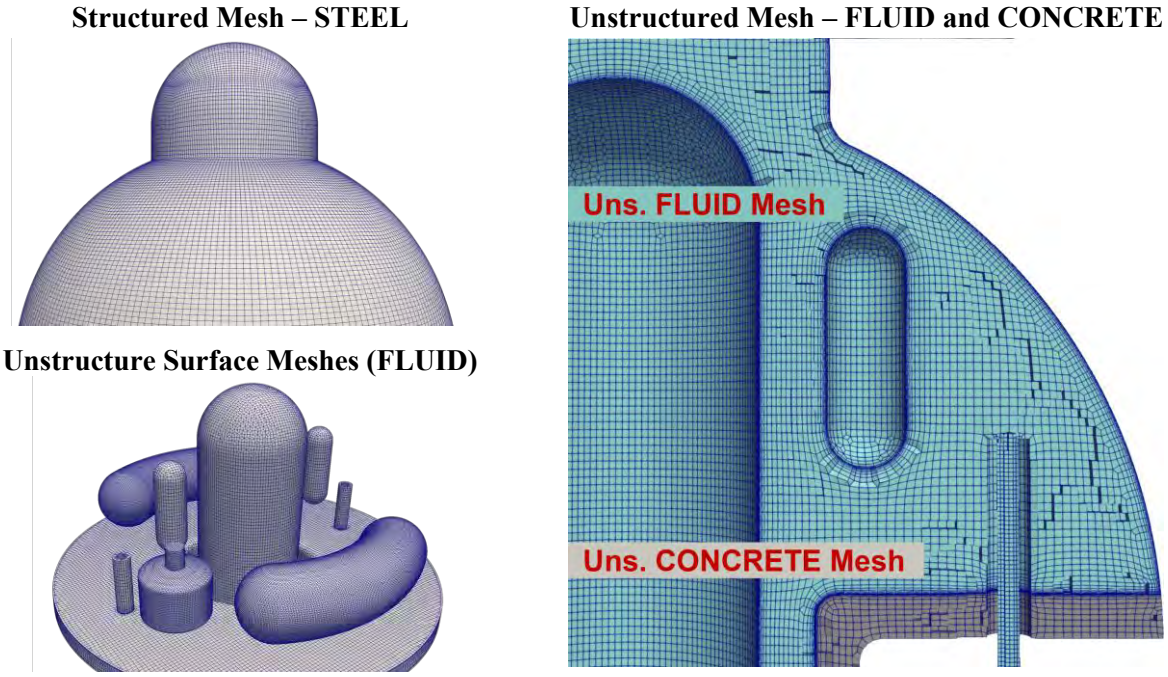

Figure 3. Hybrid meshing: structured steel-shell mesh and unstructured fluid/concrete meshes

The 'baseline model set' for *containmentFOAM* technical scale analysis, which was intensively validated before (e.g., [8,13–15]), was employed. Its main characteristics are summarized and described in Table I. Essentially, it founds on a single-phase simplification of the containment atmosphere, where wall condensation is modeled using a diffusion layer approach [16] and bulk condensation a homogeneous equilibrium model [17]. Solids use a simpler approach only solving for the energy equation to represent heat diffusion. All structures allowing condensation are represented by a conjugate heat transfer (CHT) approach.

A key enabling element of the present model is the *containmentFOAM*-OpenModelica multi-fidelity coupling implemented through the FMI-2 standard, where the containment is resolved in 3D CFD and the PSS is represented by a system-level model exchanged as an Functional Mock-up Unit (FMU). The main rationale for using OpenModelica was its flexibility and the availability of reusable components and modelling libraries that can be readily adapted to the needs of the coupling. FMI then provides a code-agnostic framework for information exchange and coupled simulation. This approach was introduced and validated in previous work [7], so only the main hypotheses of the PSS-FMU are recalled here: the PSS is represented by a lumped 0D two-phase single-node model with complete steam condensation into a subcooled pool, non-condensable bypass of the pool, user-defined heat transfer coefficients, and no pool-surface evaporation. PPOOLEX was selected as validation benchmark because it also involves a containment and a pressure-suppression pool with two closely coupled gas spaces, where the pressure evolution is strongly driven by non-condensable transport. For the evaluated PPOOLEX tests, the validation demonstrated both qualitative and quantitative accuracy of the coupling framework. The impact of the PSS-FMU simplifications, mostly the neglected evaporation, on the present Design-II calculations is discussed in the Results section.

The boundary conditions were taken from the MELCOR calculations for SASPAM-SA Design-II provided by Sapienza University of Rome (UniRoma) and detailed in [6]. Three injection sources were considered in the CFD model (the two sides of the DVI break and the ADS-1 discharge above the QT). For each source, the release rate, composition and temperature were directly imposed from the MELCOR injection tables. Steam, hydrogen and enthalpy releases were applied as volumetric sources (order of 1 m^3), with a simplified averaged representation of directional momentum.

Table I. Physical Models (adapted from [18])

Physics	Model
governing equations	Unsteady Reynolds-averaged Navier-Stokes equations, total energy equation, transport equation for species mass fraction
turbulent transport	k-ω based Shear Stress Transport (SST) model, including production and dissipation terms for buoyancy based on SGDH; Turbulent heat and mass transport: SGDH, Pr_t=Sc_t=0.85
multi-species transport	Ideal mixture approach. Each individual set of gas transport, properties (heat capacity, viscosity, conductivity) is implemented by tables, being temperature dependent for H_2 and N_2, and pressure and temperature dependant for H_2O. Effective binary diffusion model with pressure and temperature diffusion coefficients (Fuller model)
wall treatment and condensation	Wall condensation: single phase 'diffusion-layer' approach, continuous wall functions
thermal radiation	P_1 model, gray participating mixture, (κ_{H2O}=10 $bar^{-1}m^{-1}$, NCG transparent), ε_{wall} = 0.6
system models	PSS: Single node lumped two phase model built with OpenModelica. Complete condensation of steam into subcooled water, and no surface evaporation

4. SIMULATION RESULTS

4.1. SASPAM-SA3: Blowdown phase

For the blowdown case, the set-up illustrated in Figure 4 preserves the same modelling basis introduced in Section 3. The PSS coupling is treated implicitly through the FMI interface located at the end of the vent lines. There, *containmentFOAM* provides the local pressure, temperature and gas composition at the outlet patch, and the OpenModelica PSS FMU returns the mass flow rate imposed at the CFD boundary as a function of the counter-pressure (water column plus non-condensables in the PSS gas space). In addition, Figure 4 shows the three release locations (DVI-1, DVI-2 and ADS-1) and flow rates used for the blowdown. For the DVI break sources, MELCOR's liquid discharge (initially at 155 bar) cannot be injected directly into the single-phase CFD containment model, which is at near-atmospheric conditions. Therefore, an isenthalpic expansion correction was applied to estimate the available energy for flashing liquid into a steam flow for *containmentFOAM* (from the LP-code break conditions to the CFD saturation conditions).

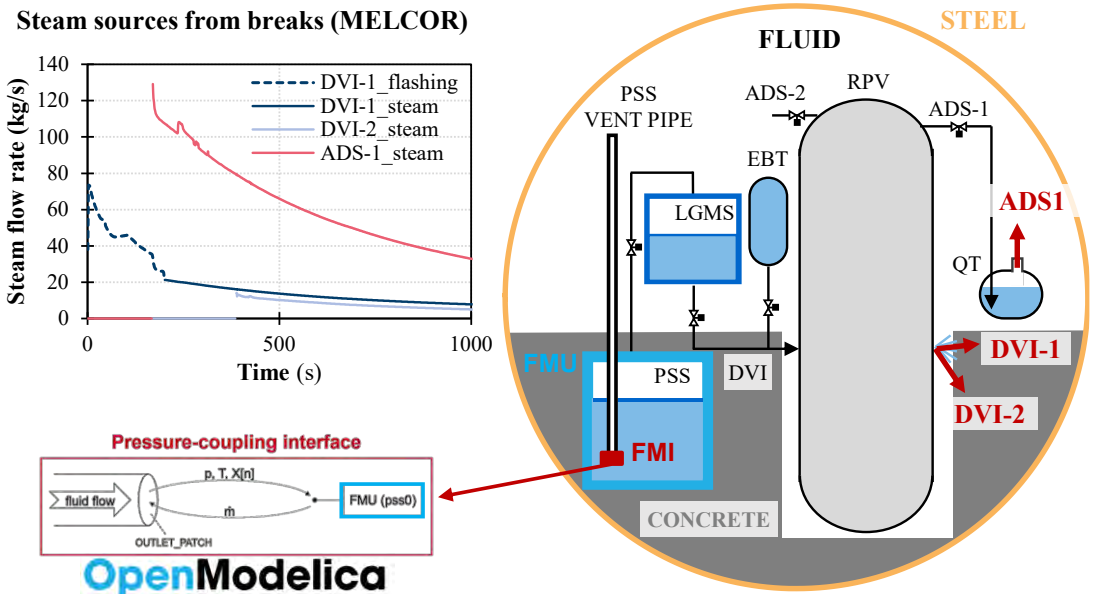

Figure 4. Sketch of case set-up: FMI coupling, location and flow rate of volume sources, and mesh regions

A constant time-step strategy was adopted to improve the stability of the FMI coupling in this first time window, starting from Δt=0.001 s and increasing up to 0.003 s toward the end of the transient. The calculations were run on 96 cores, with a wall-clock time of about 140 h (13 440 core-h), which corresponds to roughly 170 s of simulated transient per day. The time step control kept the maximum CFL number below 2, with a maximum of 5 outer PIMPLE iterations and all residuals below 10^{-4} (generally below 10^{-5}). It should also be noted that the highest local velocities of the blowdown are not fully represented because the releases are imposed as volumetric sources (not surface/patch injections). However, these very fast transients remains a challenge for high fidelity codes, and the authors are not aware of comparable CFD simulations of the containment blowdown phase in the open literature.

Figure 5 compares the blowdown results from MELCOR, the *containmentFOAM* base case, and a parametric *containmentFOAM* case with modified energy transfer from the PSS liquid to the PSS gas ("colder PSS"), just included to complement the interpretation of the results. The four graphs are shown together to support a consistent reading of the blowdown response. In fact, although the global containment-pressure evolution remains comparable between cases, other quantities that are usually considered relevant in containment analyses (e.g., wall condensation and transport to the PSS) can differ significantly.

Before ADS-1 actuation (≈ 200 s), the *containmentFOAM* base case reproduces the MELCOR pressure increase with good qualitative and quantitative agreement. After ADS-1 opens, both curves keep a similar trend but progressively diverge, reaching at 1000 s about 1.2 MPa in MELCOR and about 1.4 MPa in the *containmentFOAM* base case. This difference is not straightforward to interpret from the other graphs, since the CFD/FMU calculation predicts both higher steel-liner condensation and higher transport to the PSS,

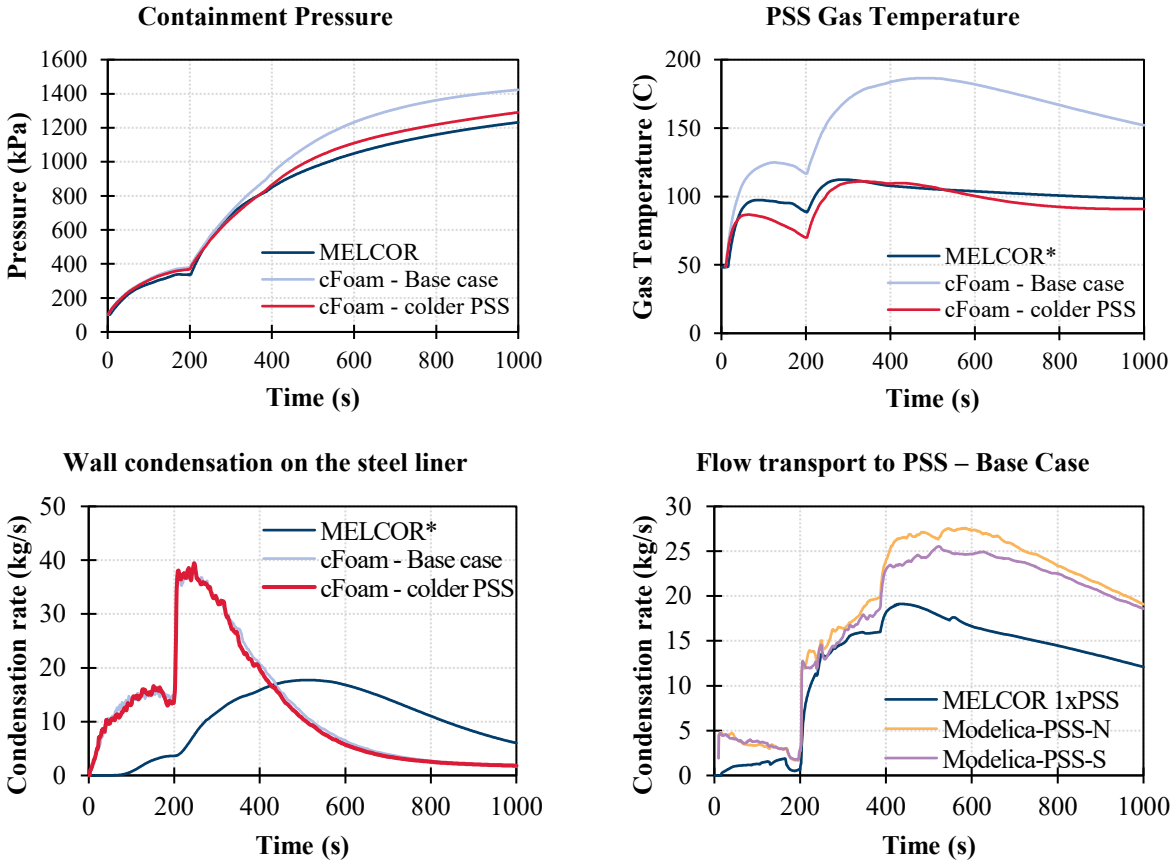

Figure 5. MELCOR (UniRoma) vs *containmentFOAM* blowdown calculations comparison

which would a priori suggest a lower containment pressure. The key point is that the additional transport to the PSS is largely associated with steam (which condenses in the pool), while the transported nitrogen inventory (not shown here) is comparatively similar. Therefore, the understanding of the pressure evolution should be mainly based on the higher gas temperature in the PSS gas space predicted by the OpenModelica PSS model, which increases the PSS counter-pressure and, consequently, the containment pressure.

This interpretation motivated the parametric "colder PSS" case, where the effective heat-transfer coefficient (including natural convection and evaporation effects) used in the PSS FMU in all PPOOLEX validation experiments was increased from 30 to 130 W/m^2 K. The latter value was estimated just to replicate the MELCOR PSS gas temperature evolution, and not as a realistic figure. As shown in Figure 5, this adjustment strongly reduces the difference in PSS gas temperature after ADS-1 actuation (peak values of about 185 °C in the base case, versus about 110 °C in MELCOR and in the colder-PSS case), and the containment pressure correspondingly moves much closer to MELCOR (at 1000 s, from about 1.4 MPa in the base case to about 1.28 MPa, compared with about 1.2 MPa in MELCOR). Having closer backpressures from the PSS, allowed to investigate how the pressure equalization affected the containment phenomena. Interestingly, the wall-condensation curve and the transport-to-PSS flow rates remain of the same order as in the base case, which reinforces that the improved pressure comparability is mainly linked to the PSS gas-space conditions, rather than to changes in the main containment-side mechanisms. The remaining code-to-code differences are still under investigation and cannot be resolved further with the currently available comparison data.

Regarding 3D effects, no additional plots are included at this sub section because the containment atmosphere is mostly homogeneous after ADS-1 actuation. The present minor heterogeneities —see the asymmetry seen in Figure 5 for the flow rates to PSS-N (North) and PSS-S (South) in the base case— indicate some 3D influence on the transport processes, but no safety-relevant impact on the global blowdown response. Overall, for the blowdown time window, the results indicate that the pressure build-up is mainly controlled by the state of the non-condensables accumulated in the PSS gas space (especially N_2 inventory and gas temperature). So, as an insight for LP codes, the detailed representation of PSS physics seems to be more influential than a more detailed 3D resolution (or complex nodalization) of the containment atmosphere.

4.2. SASPAM-SA3: Late phase with hydrogen transport

Similarly to Section 4.1, the evaluation of the second time window of interest is introduced by presenting a sketch of the case set-up (Figure 6). Apart from the evident variation of the mass source flow rates, now also including the hydrogen mass flow rate in a secondary axis, one clear visual difference is that now the cavity is mostly occupied by water, which has been included in the model to actuate as an additional condensing surface. To keep the single-phase approach, the water pool is represented by a thin solid region that allows the water surface to reach the containment steam saturation temperature while the bulk is maintained at the liquid temperature estimated by MELCOR. However, the main difference with the previous case set-up is the replacement of the FMU-FMI coupling by a pressure boundary condition representing the containment pressure predicted by MELCOR. This replacement was motivated by preliminary tests showing that, in this late window, the simplified PSS-FMU (without pool-surface evaporation) lead to unphysically high flow rates from the containment to the PSS. Due to this limitation —combined with 100% steam in the containment: conditions beyond the current validation basis of the FMU— the PSS pressure can only increase by the heat transferred by a hotter water pool, and not by the increasing steam partial pressure. Consequently, the missing steam build-up in the PSS gas space was artificially compensated by excessive steam/enthalpy transport to heat up the pool and pressurise the PSS gas. Therefore, a MELCOR pressure boundary was imposed to evaluate the effect of 3D transport vs the MELCOR reference data under equivalent pressures.

The time step control followed the same criteria described in Section 4.1, but with significantly larger time steps due to the lower velocities of this time window. The time step was automatically adjusted to keep the maximum CFL below 1, typically reaching ≈ 0.008-0.01 s. The calculation was run on 256 cores of FZJ's

high performance computing facility JURECA, and advanced about 1550 s of transient per day. This corresponds to about 12.9 days of wall-clock time (≈310 h), i.e., approximately 80 000 core-h.

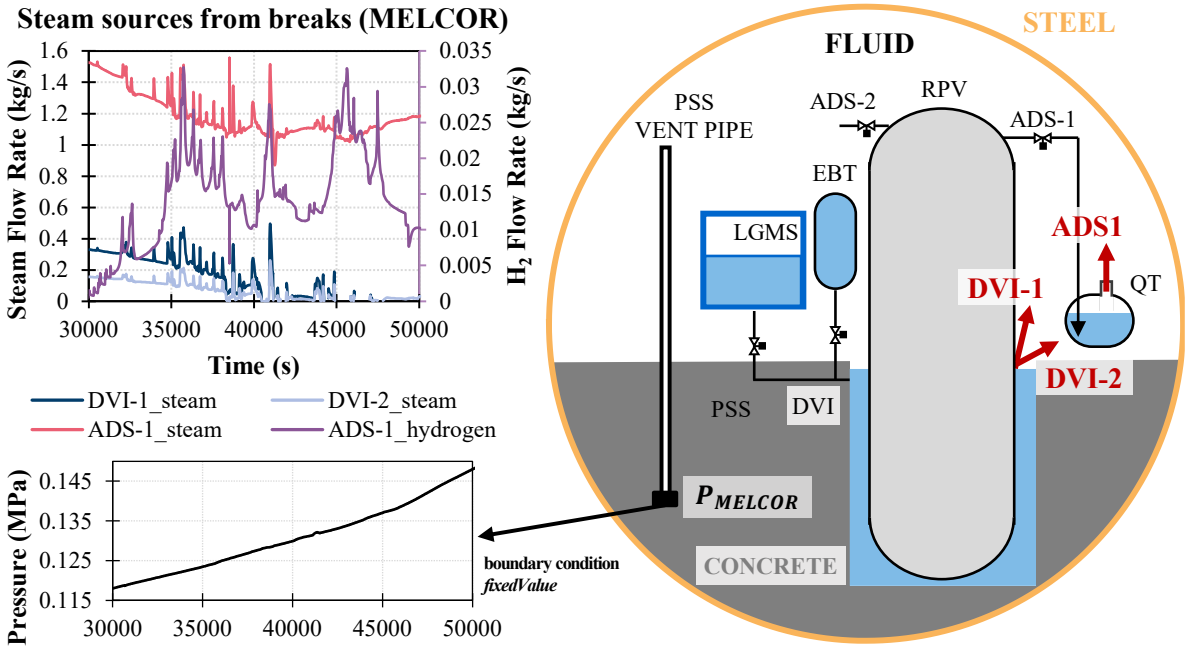

Figure 6. Sketch of case set-up: Outlet pressure, location and flow rate of volume sources, and mesh regions

To assess the hydrogen distribution and its transport from the containment to the PSS during PhW2-3, two complementary types of results are presented. First, Figure 7 compares *containmentFOAM* and MELCOR by means of two global variables: (i) the containment averaged hydrogen volume fraction; and (ii) the integral mass transported from the containment to the PSS, shown separately for steam and hydrogen. Then, to interpret the origin of the differences in these global trends, Figure 8 provides selected 3D CFD visualizations of the identified heterogeneities, focusing on the temperature field and on the hydrogen distribution in the upper containment and at the vent line connecting containment and PSS. The plotting times of Figure 8 are chosen to highlight the heterogeneities.

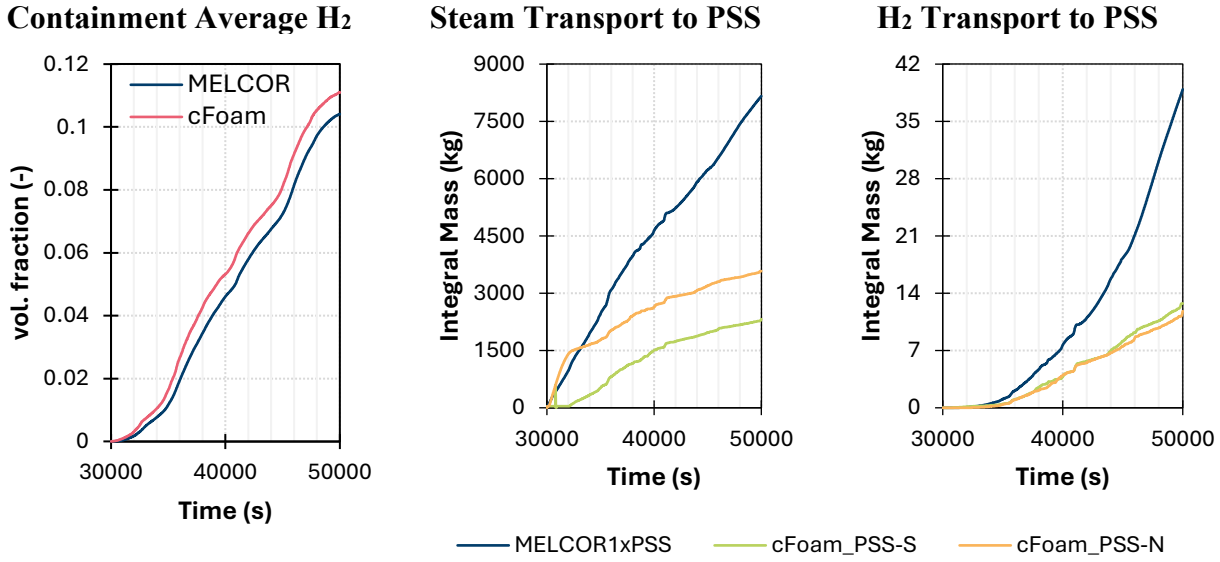

Figure 7. MELCOR (UniRoma) vs *containmentFOAM* hydrogen distribution comparison

Figure 7 shows that both calculations predict a similar global build-up of hydrogen, with *containmentFOAM* consistently higher and reaching 11.1% at the end of the transient, compared with 10.1% in MELCOR. At the same time, the integral steam and hydrogen mass transported to the PSS is lower in *containmentFOAM*. A more complete interpretation of this LP-CFD comparison (including wall condensation rates and gas temperature) is currently being performed. However, even with that information, a consolidated quantitative explanation of the code-to-code differences has not yet been reached yet. In principle, since both codes use the same mass sources and *containmentFOAM* reproduces the MELCOR pressure evolution, the lower transport to the PSS should imply higher wall-condensation rates in *containmentFOAM*, but this point cannot yet be demonstrated rigorously with the currently available MELCOR output and will require further exchanges with UniRoma.

Even if any interpretation should remain qualitative, Figure 7 and Figure 8 show that the containment conditions are no longer homogeneous, unlike the blowdown phase of Section 4.1. Figure 7 indicates a clear asymmetry in the transport to PSS-N and PSS-S, especially for steam during the first part of the window. The non-integrated mass-flow data (not shown here) confirmed that the dominant vent line changes during the transient. Figure 8 represents the heterogeneities behind these differences. The temperature field exhibits a vertical stratification, with the upper region hotter than the lower one and top-to-bottom differences reaching up to about 40 °C, with the stratification growing as the transient progresses. The hydrogen field shows a similar behaviour, with higher volume fractions in the upper containment and different hydrogen concentrations at the two vent-line entrances. These heterogeneities are sufficient to create different conditions in the flow transported to PSS-N and/or PSS-S.

It is important to underline that this analysis remains limited by the simple outlets based on MELCOR's pressure used at the CFD side. The lack of a PSS model able to store and track the effects of the different mass and composition histories coming from each side does not allot to evaluate the feedback of these heterogeneities on the thermodynamic state of each PSS gas space. Improving the current analysis will require a more advanced PSS model, with a modelling basis able to represent the relevant PSS physics and evaluating the impact of the identified 3D differences into a quantitative system response.

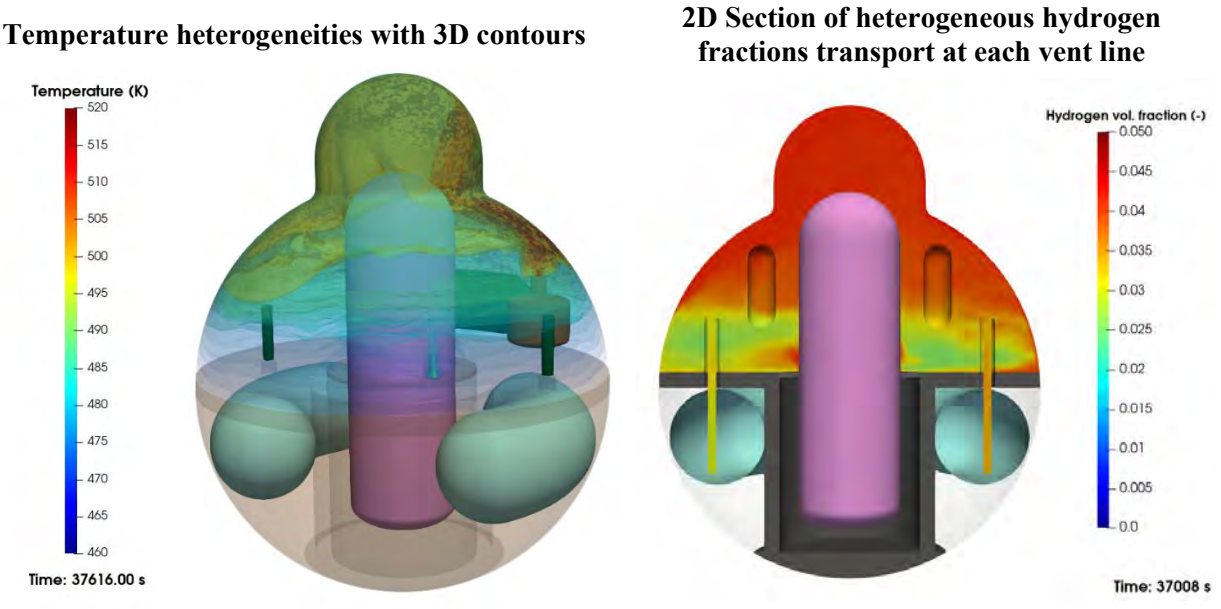

Figure 8. Insights on the identified 3D heterogeneities for the simulations of PhW2 time window

5. CONCLUSIONS

This work, developed in the framework of SASPAM-SA, moved from the conceptual exploration of *containmentFOAM* application to LW-SMR severe-accident analysis —identifying on the way a list of model development needs— to the technical scale safety evaluation presented in this work. The main enabling step was the implementation of the *containmentFOAM*-OpenModelica multi-fidelity coupling, which allowed the containment response and the PSS feedback to be simulated in a coupled manner at an affordable computational cost. Within this framework, two complementary time windows (PhW1 and PhW3) were analysed for SASPAM-SA Design-II: the fast-changing blowdown case, which is particularly demanding for CFD in terms of stability and computational cost, and a later hydrogen-transport window, closer to the original modelling basis of *containmentFOAM*. Despite the known limitations of the current set-up (discussed below), the blowdown calculation with flashing correction and coupled PSS feedback constitutes a relevant step forward with respect to the current open literature on CFD containment analyses.

The role of CFD analysis in SASPAM-SA is to complement the integral calculations of LP codes, with the objective of identifying when 3D effects add safety-relevant information and when simpler representations are sufficient. In this sense, the two analysed windows provide different messages:

- Blowdown window (PhW1): the CFD results confirm that the containment atmosphere rapidly evolves towards nearly homogeneous conditions after ADS-1 actuation. The observed 3D heterogeneities are limited and do not appear to produce a significant safety-relevant impact on the global blowdown response. For this phase, the results indicate that the dominant modelling challenge is not the 3D containment resolution itself, but the adequate representation of the PSS response, since the pressure evolution is mainly controlled by the species partial pressures in the PSS gas space (inventory, composition, and temperature).
- Late hydrogen-transport window (PhW3): *containmentFOAM* predicted a non-homogeneous distribution of temperature and gas composition at different points of this 20.000 second window characterised by low momentum sources and buoyancy driven flows. The heterogeneities induced differences in the mass and composition of each containment-PSS vent lines. However, the quantitative impact of the heterogeneities could not be quantified since the CFD domain is closed by a MELCOR-based pressure outlet and not by a PSS model able to store and evolve the different mass and composition histories reaching each PSS. Whether these heterogeneities accumulate or compensate each other in the actual PSS response remains to be evaluated.

Therefore, the current limiting factor of the multi-fidelity framework is the simplified physics of the PSS FMU. The PSS model was initially conceived mainly as a computationally efficient system-level closure providing counter-pressure feedback to the *containmentFOAM* high-fidelity model. However, in the present Design-II applications, its simplification of the physics, particularly the too simple modelling of the pool surface heat and mass transfer, proved to be a limiting factor for the global accuracy of the analyses. Therefore, the priority to advance these first application of *containmentFOAM* to LW-SMR safety analysis —where our CFD toolbox even proved its ability to simulate a blowdown— is to extend the current PSS FMU modelling basis and, in parallel, to investigate similar couplings with validated established codes.

ACKNOWLEDGMENTS

This work has been partially funded by the European Union through the SASPAM-SA project, HORIZON-EURATOM-2021-NRT-01 under grant agreement No. 101059853. Views and opinions expressed are, however, those of the author(s) only and do not necessarily reflect those of the European Union or the European Commission-Euratom. Neither the European Union nor the granting authority can be held responsible for them. We acknowledge the valuable technical discussions within the SASPAM-SA consortium. In particular, we thank Sapienza University of Rome (UniRoma), led by Fabio Giannetti, for the MELCOR simulations used in this work, and especially Marcello Principiato for his continuous support and prompt feedback during the iterative exchanges and model adaptations required for a consistent comparison with the *containmentFOAM* calculations.

We gratefully acknowledge the support of the German Federal Ministry for the Environment, Climate Action, Nature Conservation and Nuclear Safety (BMUKN) for funding code maintenance and integration of *containmentFOAM* within the national CFD reference package CF2REF (Fkz 150 1633B). Preparatory work for adapting *containmentFOAM* to LW-SMR applications was supported by the Innovation Pool of the Helmholtz Research Field Energy within the project "Safety assessment of generic SMR" (2021–2024). We thank the John von Neumann Institute for Computing (NIC) for computing time on the supercomputer JURECA at Jülich Supercomputing Centre (JSC) under project 'va4cf'.

Background

EU Euratom SASPAM-SA Project:

- Applicability of SA know-how to LW-SMR
- Generic designs based on Open Literature
- Most of partner using Lumped Parameter codes (ASTEC, MELCOR, AC-2, MAAP)
- **CFD to complement LP codes**

Phenomenological differences:

- Higher pressures (film-condensation)
- Closer coupling RCS and containment
- Central role of containment response for SA progression in the primary

Code upgrades towards LW-SMR analysis:

- Based on SASPAM-SA sequences
- All ongoing. Preliminary experimental-scale testing performed, and known future improvements
- Coupling framework main priority for SASPAM-SA

Coupling validated with available data:

- Code agnostic: FMI Standard
- Multi-Fidelity approach (Modelica FMU)
- Validated with PPOOLEX MIX Series

4. SASPAM-SA: Late phase H_2 Transport
5. Conclusions

5. Conclusions

Takeaway messages

- **CFD** insights for the blowdown phase:
  - It is confirmed that the **blowdown produced homogeneous conditions** in the containment (good for LP)
  - The small **heterogeneities appear to have no significant safety impact**
  - Message for LP: **PSS modelling is crucial to model the blowdown** and currently need to be improved
- **CFD** insights for the late SA time windows:
  - Buoyancy-driven flows cause **stratification and local heterogeneities**
  - Heterogeneities may affect containment wall condensation and PSS pressure build-up
  - The safety relevance of the observations **cannot be evaluated without improving the PSS** modelling
- SASPAM-SA revealed modelling challenges to simulate LW-SMRs with containmentFOAM
  - The code upgrades implemented in parallel to the project make it **ready to support SMR safety analysis**
  - **See #97 S. Kelm (Today 14:25, A.01)** for the most advanced technical scale application of the code
- Many upgrades (film condensation, two-phase flows, PCCSs, etc.) towards LW SMR safety analysis currently under validation. If interested, **let's discuss over the week!**

Severe accident analysis of SASPAM-SA Design-II LWR SMR containment using containmentFOAM

ABSTRACT

Passive safety features without requiring an active power source have been in use in nuclear power plants to accomplish safety functions for many decades. However traditionally, the use of such passive features was of limited extent. The situation is different with the LDR-50 reactor, designed at VTT since 2020 for low temperature heat production applications, which exclusively leverage the physical laws to initiate safety functions.

Within the frame of HORIZON EUROPE EURATOM project "Ensuring Assessment of Safety Innovation for SMR" (EASI-SMR) the safety justification of LDR Lite reactor is performed. LDR Lite is an "academic", simplified and publicly available version of LDR-50. In this paper the analysis of typical initiated events, leading to design extension conditions (loss of offsite power supply, loss of coolant and imbalance between heat generated in the reactor and heat demand) are presented. The system thermal-hydraulic computer code RELAP5 was used for the analysis. The developed RELAP5 model is tested comparing the calculation results with VTT (Centre for Nuclear Safety in Finland) calculation results. The analysis results, presented in this paper, demonstrated the resilience of LDR Lite reactor concept to design extension conditions. It is shown that in LDR Lite case the natural circulation of coolant and self-pressurizing of primary circuit allows us to avoid overheating of reactor core.

KEYWORDS
LDR Lite, natural circulation, self-pressurizing

1. INTRODUCTION

LDR-50 design was developed at VTT since 2020 and is now being commercialized by Steady Energy. The LDR Lite is a public version of the LDR-50 reactor design for low temperature heat production applications. The main specifics of this 50 MW_{th} integrated pressure water reactor are boron less operation, natural circulation driven primary circuit, self-pressurization and passive decay heat removal through a dual vessel design [1, 2]. Reactor operates at 150 °C temperature and 0.8 MPa pressure and must be connected to district heating network via intermediate (secondary) water loop and heat exchangers. In normal operation, heat is extracted through the main heat exchangers. The reactor module is comprised of two nested pressure vessels:

* Footnote, if necessary, in Times New Roman font and font size 10

(1) inner reactor vessel, and (2) outer containment vessel (Figure 1). The reactor with containment is submerged into big water pool. The intermediate space between the reactor and containment vessels is partially filled with water, which assures the decay heat transfer from the rector into water pool. This pool can receive decay heat for several weeks without any cooling or operator action.

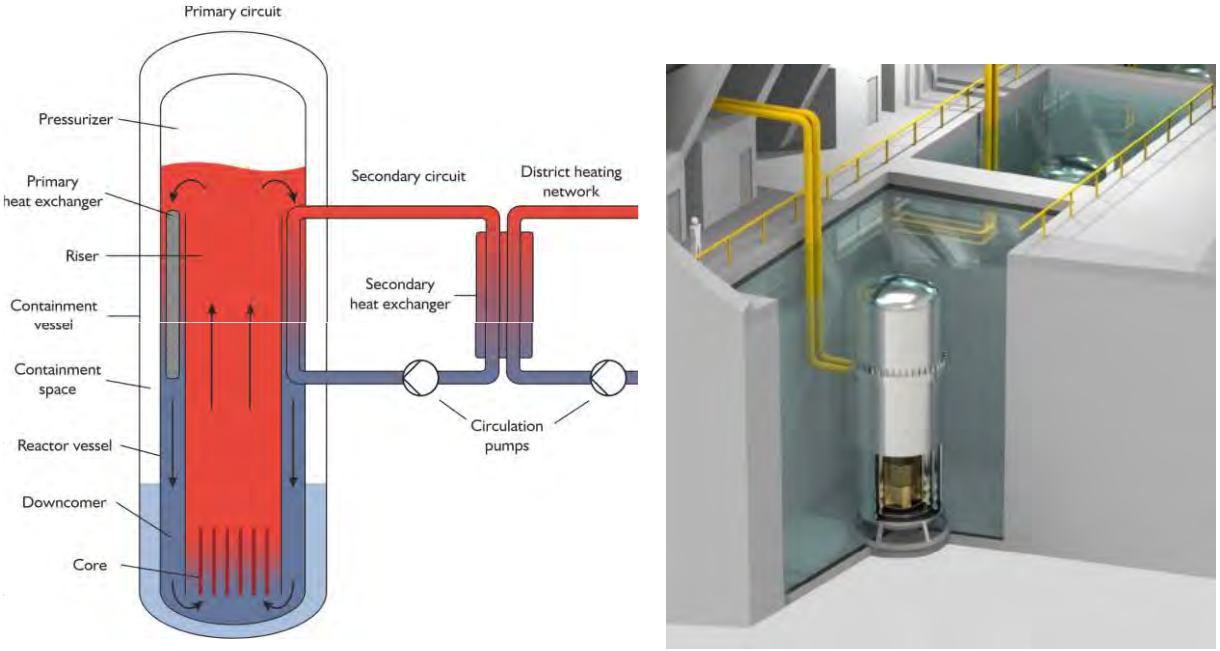

Figure 1. The LDR-50 reactor design [1, 2].

Within the frame of HORIZON EUROPE EURATOM project "Ensuring Assessment of Safety Innovation for SMR" (EASI-SMR) the safety justification of LDR Lite reactor is performed. This paper deals about the work performed in parallel to this EASI- SMR project. To analyse the resilience of LDR Lite reactor three initiating events, which can cause design extension conditions, were modelled:

1. Station Blackout (SBO);
2. Loss of coolant (LOCA);
3. Reduction of coolant flow in secondary circuit.

2. LDR LITE MODEL DEVELOPED USING RELAP5 CODE

The LDR Lite thermal-hydraulic model was developed using RELAP5 code. The RELAP5 code has been developed by Idaho National Engineering Laboratory [3] for best estimate transient simulation of light water reactor during design basis accidents. The code models coupled behaviour of the reactor coolant system and the core for loss-of-coolant accidents, and operational transients. RELAP5 code in Lithuanian Energy Institute (LEI) is used since 1995. For the analysis of thermal-hydraulic processes in LDR Lite reactor, the simplified model for RELAP5 code is developed (Figure 2):

- The reactor core was simplified and only thermal-hydraulic (no reactor neutronics) was modelled. The reactor core is modelled by four flow paths (max, min, average power and core bypass).
- The secondary circuit is modelled only with boundary conditions.
- Heat transfer from bottom and top in axial direction from the reactor vessel into containment are not modelled.
- Containment and water pool are modelled as two pipe elements with crossflows each. This allows to model the heat transfer in containment and water pall using convection of coolant.
- The containment and water pool are modelled as a group of concentric cylindrical rings.

- In the RELAP5 model the outside walls of water pool are not modelled (adiabatic condition is assumed).

The impact of modelling simplifications is following:

a) Impact of secondary circuit as boundary conditions. The detailed modelling of heat exchanger in secondary circuit and secondary thermal inertia will add additional heat removal. Thus, the approach without detailed modelling of secondary circuit leads to conservative results, which is fully justified when evaluating the safety of reactor.

b) No axial heat transfer at top/bottom of reactor vessel and containment. The additional heat transfer area will provide greater heat dissipation from reactor core into water pool. The very significant influence of heat loses into the water pool was presented in sensitivity analysis (answer to the comment No. 1). Thus, the approach without axial heat transfer at top/bottom of vessel and containment slightly decreases heat loses to final heat sink and gives more conservative results.

c) Adiabatic pool outer walls. The approaches with adiabatic pool outer wall enable the heat removal from water pool, which leads to a conservative result.

In conclusion, we can say that all simplifications allow us to obtain conservative results.

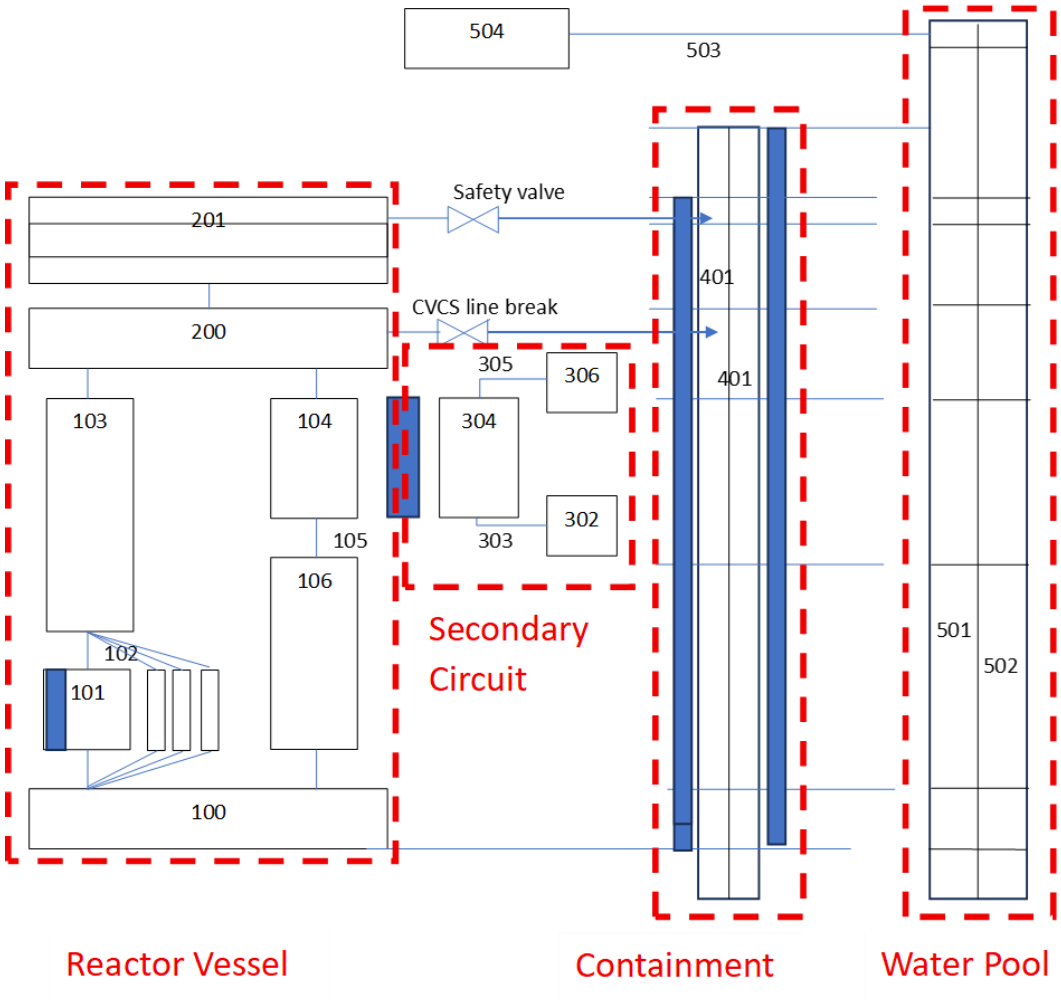

Figure 2. LDR Lite reactor model nodalization scheme, developed for RELAP5 code

The volume of primary circuit in the reactor vessel is ~ 41 m^3. The volume of containment is ~ 27.5 m^3, while the water mass is ~ 5000 kg. The water pool volume is 1000 m^3 (mass is 10E+05 kg) [1]. Initially, at cold state (at zero reactor power) the pressure in pressurizer and containment is atmospheric, water temperature in reactor and containment is 20°C. The water level in pressurizer is 7.02 m, and containment water level – 1.7 m, when the bottom of reactor lower plenum is at elevation 0.0 m.

At the hot full power steady state conditions, the reactor power is 50 MW, the pressurizer pressure is 0.65 MPa, core inlet and outlet temperatures are 109 and 157 °C respectively. The total primary mass flow is 244 kg/s. Secondary circuit inlet and outlet temperatures are 77 and 125 °C respectively. Secondary circuit mass flow is 245 kg/s at 1.5 MPa pressure. The water temperature in containment increases from 20 up to 67 °C, pressure – increases from 0.1 up to 0.132 MPa. The heat loss to water pool is about 190 kW. Because it is assumed adiabatic condition on the water pool outer walls, the water temperature in pool is continuously increasing (it is assumed, that at beginning of accident the water temperature is 24°C.

3. STATION BLACKOUT. COMPARISON OF LEI AND VTT CALCULATION RESULTS

In this section the LEI calculation results are compared to the VTT calculation [4], performed using APROS code (developed by VTT and Fortum). In case of station blackout, the pump in secondary circuit is stopped, what stops the heat removal from the reactor. At the same time, the reactor shutdown system is activated and heat release from fuel assemblies decreases from nominal power 50 MW down to decay power (Figure 3). After reactor shutdown, the fuel temperature decreases (Figure 4). This leads to the decrease of coolant flow rate in primary circuit from 244 kg/s don to ~ 10 kg/s (Figure 5). Pressure in pressurizer decreases also from 0.70 MPa down to ~ 0.30 MPa (Figure 6). The decay heat in reactor core is utilised transferring the heat to the water pool through containment; thus, the containment water temperature is slightly increasing (Figure 7) as well as temperature of water in pool (Figure 8). In summary, it can be noted that LDR Lite reactor is equipped with water pool, which plays a role of huge heat sink and decay heat from reactor core is transferred into water pool (Figure 9). This ensures safety of this reactor.

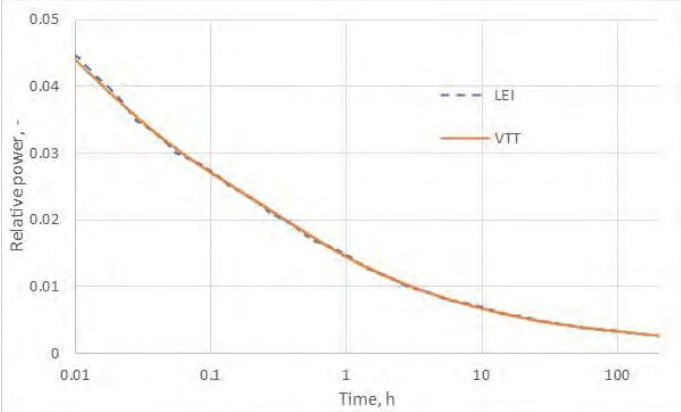

Figure 3. SBO. Reactor power.

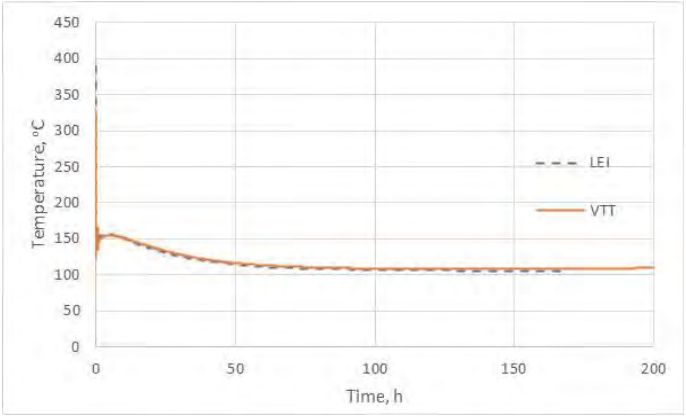

Figure 4. SBO. Maximum fuel temperature.

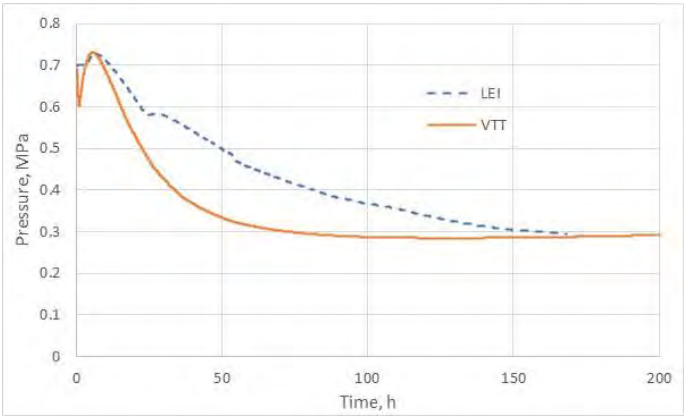

Figure 6. SBO. Pressurizer pressure.

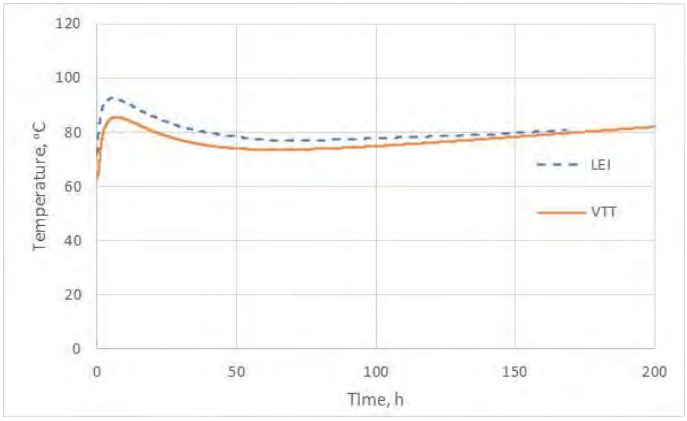

Figure 7. SBO. Containment water temperature.

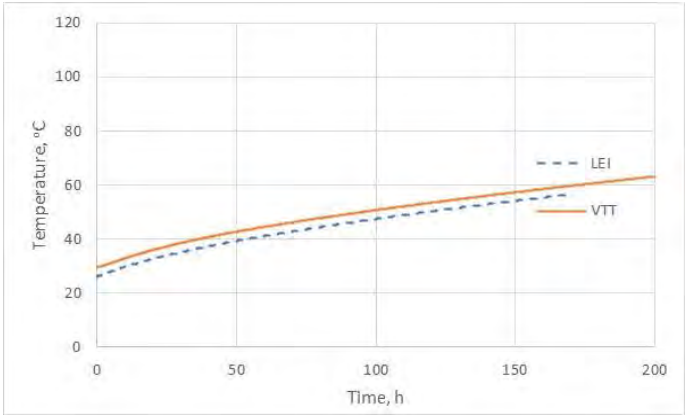

Figure 8. SBO. Pool water temperature.

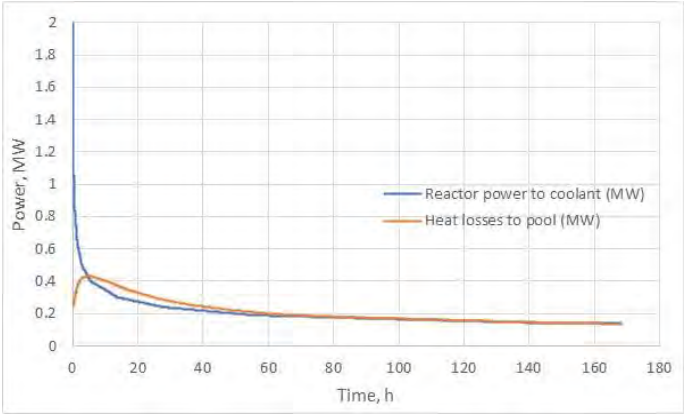

Figure 9. SBO. Comparison of decay heat released in reactor core and heat absorbed by the water pool.

Figure 9 demonstrated that the heat losses to water pool are very important. To analyse the influence of heat transfer from containment into water pool, two cases were compared. In first case, the coolant convection in the gap between the reactor vessel and containment vessel was without limitation. This increases the heat transfer coefficient from containment into water pool. In second case it was evaluated that the mentioned gap is narrow, thus could be some limitations for the coolant convection – this could lead to the decreased heat transfer coefficient from containment into water pool (see Figure 10). The differences in to heat transfer

leads to the significant difference in pressure behaviour in the pressurizer (Figure 11), while remaining parameters are not changing.

The comparison of VTT and LEI results for SBO scenario calculation demonstrated qualitative and quantitative compliance of parameters. Small discrepancies of some parameters are caused by slightly different nodalization.

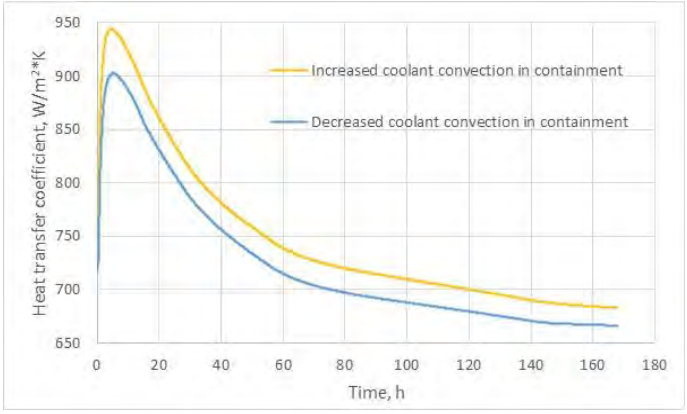

Figure 10. SBO. Two cases of heat transfer coefficient from containment into water pool.

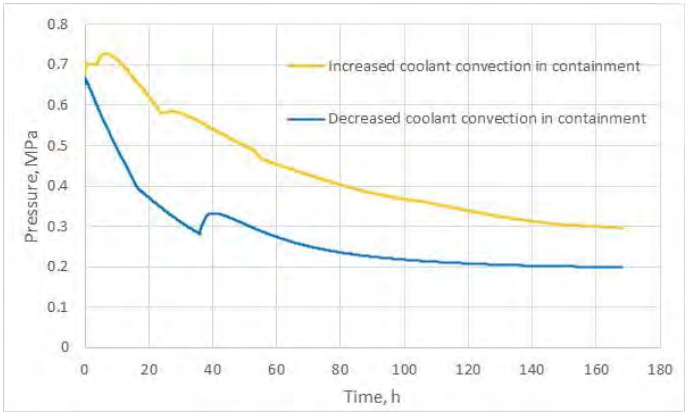

Figure 11. SBO. Two cases of heat transfer coefficient from containment into water pool. Pressurizer pressure.

4. LOSS OFF COOLANT ACCIDENT

The Chemical and Volume Control System (CVCS) pipes are only pipes connecting primary reactor circuit with the system outside reactor containment. Thus, break of CVCS line (0.025 m diameter) with discharge into containment was selected as LOCA scenario. This line is connected to the upper reactor plenum at elevation 7.045 m, when initial water level in pressurizer at nominal reactor power is at elevation 8.21 m. There is a check valve installed in the CVCS system; thus, the discharge is possible only from the reactor primary circuit side. In RELAP5 model the Henry Fauske choked flow model is applied for break discharge and two-phase critical flow treatment modelling.

The water and steam mixture through the break is discharged into the containment (Figure 12). The reactor shutdown system is activated immediately due to pressure increase in the containment (Figure 13). The reactor power decreased from nominal power 50 MW down to decay power, the pump in secondary circuit is stopped and the heat is not removed through the reactor heat exchangers. The pressure in reactor vessel after the break is decreased and equalizes with the pressure in containment (Figure 13). Due to significant

pressure decrease and start of water boiling, the coolant flow rate through reactor core starts to fluctuate around zero (Figure 14). The coolant temperatures in reactor vessel decreases (Figure 15). As it is seen from this figure, the water temperature in upper plenum (which is connected to the break) is equal to saturated temperature, what indicates that the water is starting to boil in upper part of the reactor. Fuel and cladding temperatures decrease down to coolant temperature (Figure 16). This is because the water level in reactor vessel remains much higher than location of fuel assemblies (Figure 17). The water level in containment increases, however, within 25 hours after the accident, the water level in the containment did not reach the water level in the reactor vessel. Figure 18 demonstrated that after the reactor shutdown the reactor decay heat is transferred into water pool, which ensures complete safety of the reactor.

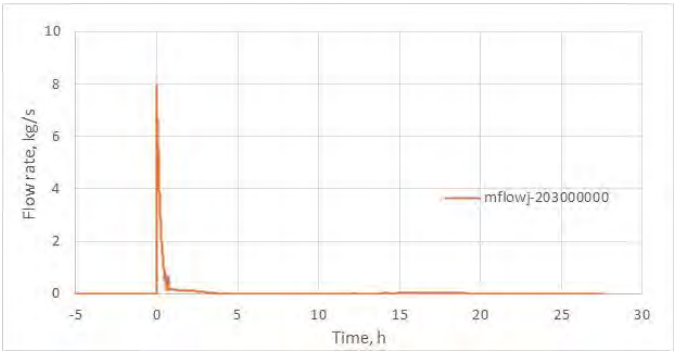

Figure 12. LOCA. Release of coolant from the break.

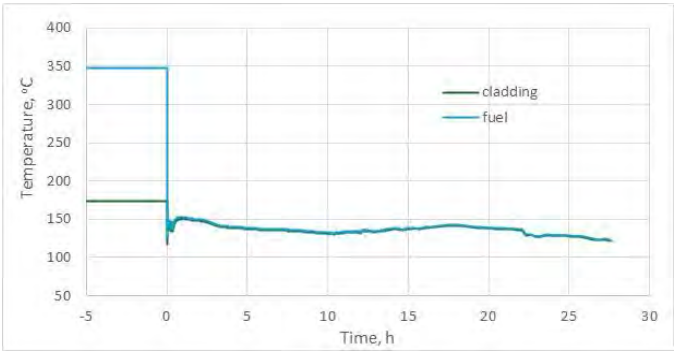

Figure 16. LOCA. Reactor fuel and cladding temperature behaviour.

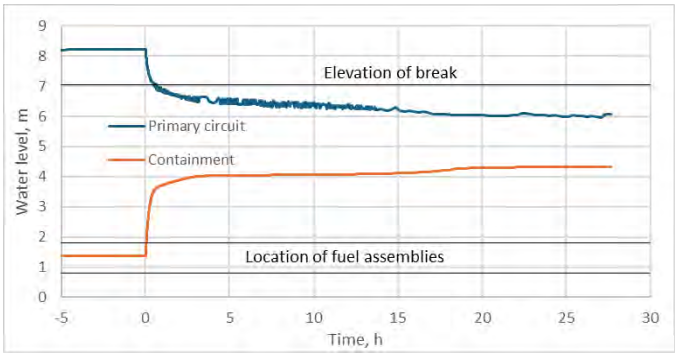

Figure 17. LOCA. Behaviour of water level in primary circuit and containment.

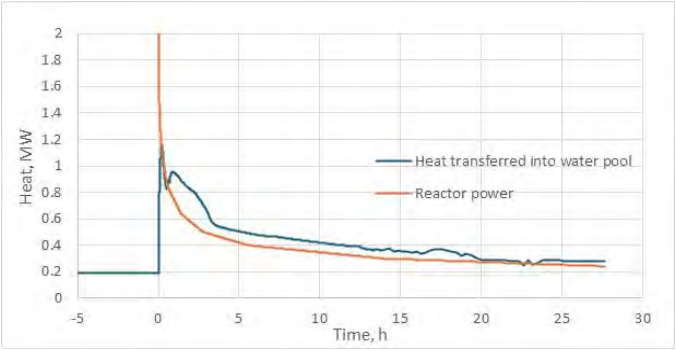

Figure 18. LOCA. Comparison of decay heat from reactor with heat removal through heat exchanger of secondary circuit.

The investigation of nodalization influence on calculation results was carried out by changing the pressurizer simulation. The pressurizer is 1.5 m height and 7.3 m^3 volume element, placed in the reactor vessel top. In the simplified model case this pressurizer is modelled as single volume, while in the modified model – this element was divided into 3 identical volumes. The performed analysis showed, that in case of simplified model the initial (steady state) pressure in pressurizer is slightly higher than in in three volumes case (see Figure 19). This slightly higher pressure leads to slightly higher release of steam through the break within first seconds after break initiation. However, this practically does not lead to differences in containment pressure and further behaviour of pressure in pressurizer and containment remains practically identical.

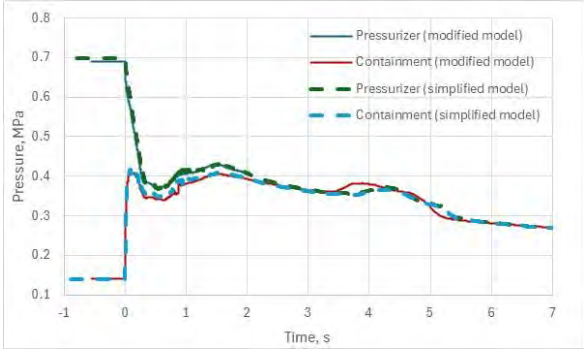

Figure 19. LOCA. The pressure behaviour in pressurizer and containment using different pressurizer models.

5. DECREASE OF SECONDARY WATER FLOW

The LDR Lite reactor is designed specifically for low-temperature district heating, not electricity, aiming for safe, simple, featuring passive safety, self-pressurization, and boron-free operation. The previously sections demonstrate that in case of SBO and LOCA, after the reactor shutdown, the reactor decay heat is transferred into huge water pool, which ensures cooling of fuel assemblies and safe cooldown of the reactor. In the following section it is shown that the passive safety and self-pressurization systems ensure reactor resilience to design extension conditions even when the heat removal from the reactor to become unbalanced.

It is assumed that for unknown reasons (for example due to a pump failure) the flow rate through secondary circuit decreases from 245 down to 150 kg/s (Figure 20). At the same time, it is assumed that none of the safety systems are activated and reactor power remains constant (50 MW). The decreased flow rate causes an increase of water temperature at the heat exchanger outlet from 125 up to 155 ºC (Figure 21). Hoverer, the pressure in secondary circuit is 1.5 MPa, the water remains subcooled. Such change in secondary water temperature leads to short term disbalance in heat removal through reactor heat exchangers (Figure 22). As is seen from presented figure, a few minutes after the accident the heat transfer returns to the initial value. At the same time the coolant temperatures in primary circuit are increasing also (Figure 23). The temperatures of fuel and cladding increases by 15 – 20 ºC as well. This leads the increase of coolant flow rate through reactor core (Figure 24). The increase of coolant temperature leads to increase of pressure in reactor vessel – the pressure in pressurizer reaches the safety valve actuation set-point (Figure 25). The overpressure protection system is actuated at 1 MPa pressure and steam from the pressurizer is released into containment (Figure 26). This leads to the increase of pressure in containment from 0.132 up to 0.22 MPa (Figure 27). Water temperature in containment increases by ~ 15 ºC, but the saturation temperature is not reached. Due to steam release from the pressurizer, the water level in primary circuit is decreased, while in containment – increases (Figure 28). The water level in reactor vessel remains much higher than location of fuel assemblies. At the same time, the loss of coolant leads to slight decrease in pressure and within approximately 10 hours the new steady state is reached. As the water temperatures in the primary circuit and in containment increased, heat transfer into water pool increased also (Figure 29). As is seen from this

figure, after reaching a new steady state, heat transfer to the water pool begins to gradually decrease, which proves that automatic self-pressure maintenance and mode regulation are achieved, and the reactor is operating safely.

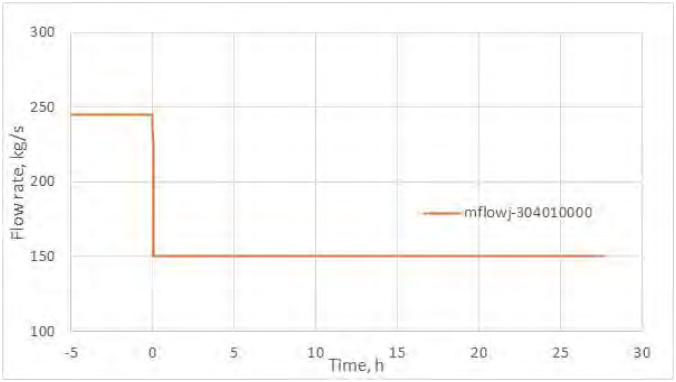

Figure 20. Decrease of secondary water flow. Water flowrate in secondary circuit.

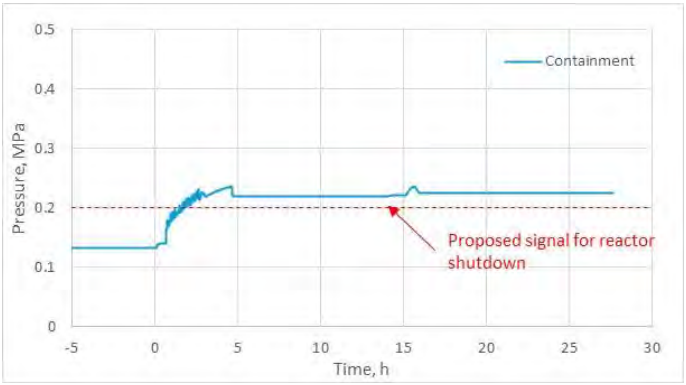

Figure 27. Decrease of secondary water flow. Increase of pressure in containment.

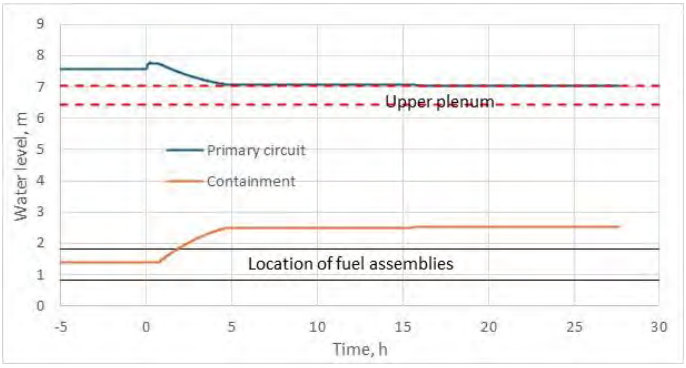

Figure 28. Decrease of secondary water flow. Behaviour of water level in primary circuit and in containment.

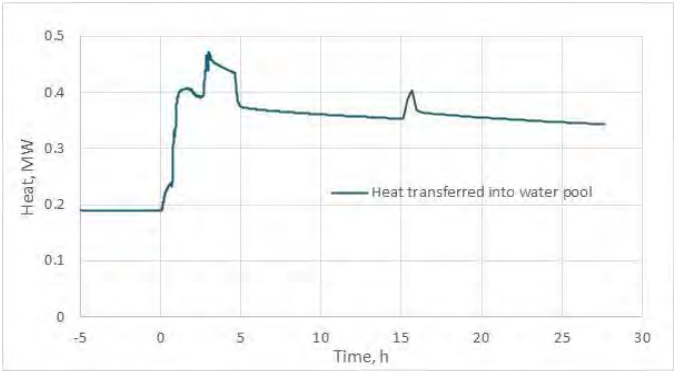

Figure 29. Decrease of secondary water flow. Heat transfer into water pool.

The investigation of nodalization influence on calculation results was carried out by changing the pressurizer simulation (in the same case as for LOCA case). In the simplified model case this pressurizer is modelled as single volume, while in the modified model – this element was divided into 3 identical volumes. The changes in nodalization only insignificantly change the behaviour of pressure in pressurizer and containment (see Figure 30), while remaining parameters are not changing.

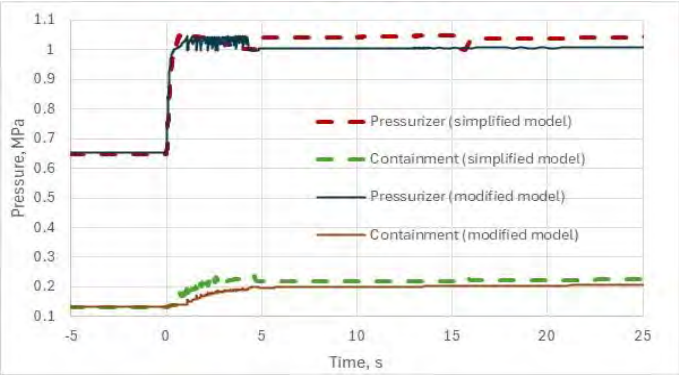

Figure 30. Decrease of secondary water flow. The pressure behaviour in pressurizer and containment using different pressurizer models.

The LDR Lite reactor is under development, thus we did not meet the acceptance criteria used in open literature. On the other hand, the performed safety justifications allowed us to propose acceptance criteria:
Peak cladding temperature. The performed analysis of selected accidents shows that fuel and cladding temperatures are decreasing after reactor shutdown. In the case of coolant flow in secondary circuit reduction the reactor power remains constant, and the fuel and cladding temperatures increased up to 5%. The recommended acceptance criteria for fuel could be the same as for PWR plants with analogical fuel assemblies. However, it is necessary to evaluate, that LDR Lite reactor will be located in the city are, therefore the acceptance criteria may be stricter – for example peak cladding temperature should be below 900 ºC (related to steam – zirconium oxidation reaction risk).
Minimum liquid level above core. In LDR Lite reactor this criterion is related to the maintenance of natural circulation in primary circuit. In the coolant flow in secondary circuit reduction case, it was shown that water level should be not below elevation 7.00 m (see Figure 28) – the upper plenum should be filled by water.
Maximum containment pressure. In LDR Lite reactor the containment is protected by containment overpressure protection valve, which actuation pressure is 1.00 MPa. Thus, acceptance criterion related containment pressure is 1.10 MPa (plus 10% from overpressure protection valve). It is recommended to shutdown reactor if pressure in containment is higher as 0.2 MPa (see Figure 27).
Long-term pool temperature margin to boiling. Recommended value - 90 ºC.

6. CONCLUSIONS

To analyse the resilience of LDR Lite reactor three initiating events, which can cause design extension conditions, were modelled:

- SBO
- LOCA
- Reduction of coolant flow in secondary circuit

The comparison of VTT and LEI results for SBO scenario demonstrated qualitative compliance of parameters and confirms the suitability of the created model. The performed analyses of SBO and LOCA demonstrated that after the reactor shutdown the reactor decay heat is transferred into water pool, which ensures safe cooldown of the reactor. The analysis of decrease of secondary water flow demonstrated that selected LDR design ensures resilience to interference. Even without activation of safety systems, the automatic self-pressurization and mode adjustment is achieved, new steady state is reached, and the reactor is safely operating. Thus, the design of reactor, low core power and availability of water pool as an ultimate heat sink, assures the resilience of LDR Lite reactor concept to design extension conditions.

ABSTRACT

This paper presents the conclusions of experimental and analytical investigations of the bottom reflooding of debris (particle) beds at high temperature. Particle beds are assumed to be representative of the configuration of a PWR core in the late stages of a severe accident in PWR reactors, as observed after TMI-2 accident. Large scale experiments were performed in the PEARL facility of IRSN (now ASNR), to investigate the effects of water injection flow rate, pressure, particle size and presence of a possible bypass at the periphery. As a complement to experimental measurements, numerical simulations were performed to interpret measured data and experimental observations. One of the important results is the evidence that the coolant flow is not uniform across the debris bed and that the quench front does not propagate uniformly: regions with smaller particles or higher temperature are quenched at a lower rate than other parts of the debris bed and a part of the injected water flows around those critical regions. This may lead to significant delay to quench such zones which may eventually melt before being quenched. In such situations, the coolability of the whole core would be questionable and it may be followed by a progression of the molten pool, even under water. Some criteria leading to unsuccessful reflooding are identified in the paper.

KEYWORDS
Reflooding; damaged core; severe accident; molten pool; debris bed

1. INTRODUCTION

Reflooding of a nuclear reactor core after a Loss of Coolant Accident (LOCA) may occur at different stages of the accident. In case of temporary failure of the safety injection systems, the fuel elements may be strongly damaged or even molten (severe accident) when reflooding occurs. The impact of reflooding on a severely damaged core is quite different from the impact in LOCA situations: temperatures are much higher (above 1500 K and up to 2800 K) and the geometry of fuel elements is lost (the cylindrical rod geometry may have disappeared completely). Both aspects play a significant role during reflooding. First we discuss the geometry of the severely damaged core.

1.1 Geometry of an in-vessel debris bed

When the reactor core is extremely damaged, fuel rods are transformed into debris beds after their collapse. This may result from the quenching of very hot rods during the reflooding of the core, as it was assumed in TMI-2 reactor, above the core molten pool, with debris size of the order of several millimeters (Tolman et al., 1988, Broughton et al., 1989). In those studies, the uncertainties about the thermal hydraulic behavior in the debris bed and the time that was necessary to cool it down were underlined. However, the accurate knowledge of the geometry of the debris bed could never be determined from later experiments, although

debris formation was observed in tests such as LOFT-LP-FP2 (Coryell et al., 1994) and PBF-1.4. The range of variation of the size of the TMI-2 in-core debris and their porosity could be estimated by (Akers et al, 1989). Recently, an analytical approach was used by (Nguyen et al. 2017) who were able to simulate the collapse of a fuel rod assembly which was pre-cracked into fragments. The number of fragments was varied in a range that may be expected for fuel rods with a standard average burn-up. They found that, for loose debris beds, the porosity was near 0.41. It corresponds to the upper parts of 'in-core' debris beds such as the ones observed in TMI-2 or in LOFT-LP-FP2 experiment. When additional damaged structures accumulate above an existing bed, the contact force network changes, the fragments rearrange and the porosity decreases. The calculated cases where compression was applied demonstrated that it is possible to reach a "dense" porosity value of 0.32. Similar values for porosity could be found in lower parts of debris beds (Akers et al., 1986). Together with the decrease of the porosity, the rearrangement of fuel fragments also implies a decrease of the surface in contact with the coolant flow, due to a greater proportion of face-face contacts. It was found that the specific surface area can be reduced by about 5% by compression, which is not much. In addition, the work of (Nguyen et al. 2017) made a link between the variations in geometry which were calculated here and the coolability of the debris bed. A model was used to correlate directly the parameters such as porosity and mean Sauter diameter to the fluid behavior in the porous medium. The model gave average values for permeability of 7.10^{-9} m^2, with an uncertainty range of 30% and values for the passability of 14.10^{-5} m, with an uncertainty range of 15%. If the debris bed is compressed, both values are divided by 2, approximately. Considering that, in a damaged core, assemblies with different burn-up and lineic power would be present, those results indicate that a large debris bed will be non-homogeneous in permeability and passability and that it is reasonable to consider that the uncertainties on those parameters correspond to the range estimated above. But the most significant non-homogeneity is the possible presence of intact rods, as observed at the periphery of the TMI-2 core (Tolman et al., 198, Broughton et al., 1989). This corresponds to regions where the permeability/passability would be approximately 100 times larger than in the particle bed: this is a very large contrast which has a direct impact on the flow, as it will be shown in the next sections of this paper.

1.2 Objectives of the paper

The objective of this paper is to make a synthesis of experimental and analytical results obtained in situations of reflooding of a debris bed and, from that understanding, to analyze some trends that can be expected at the reactor scale. This brings conclusions about the efficiency or success of reflooding, depending on the stage of degradation (porosity, homogeneity, timing) and on the available water sources to inject water (flow rate). It is important to mention that the details of derivation of models and their validation are not presented in this paper but are extensively provided in the papers and reports indicated in references. This paper just recalls them in order to address the extrapolation to reactor scale with credibility.

In the first part, we examine the simplest configuration of a homogeneous debris bed (porosity, particle diameter), from analytical and experimental points of view. This brings first conclusions about the efficiency of reflooding and about the existence of spatial instabilities which appear spontaneously and lead to reduce the efficiency of cooling. In the second part, we investigate a more realistic configuration of a debris bed divided in two zones with different porosities and particle diameters. This shows that a significant part of the inlet water flow may be diverted to the most porous debris bed, reducing significantly the efficiency of cooling in the less porous debris bed. This is observed both experimentally and in models/calculations. Finally, using the validated modelling approach, we examine the situation of a debris bed surrounded by intact rods, over a significant height of the reactor core. Series of calculations provide some trends for the time to completely quench the debris bed before it reaches the melting temperature: this gives the range of conditions for which an in-vessel reflooding could be considered as successful. A short discussion about the generalization of those results is added as a conclusion.

2 HOMOGENEOUS DEBRIS BED: ANALYSIS OF 1D REFLOODING AND

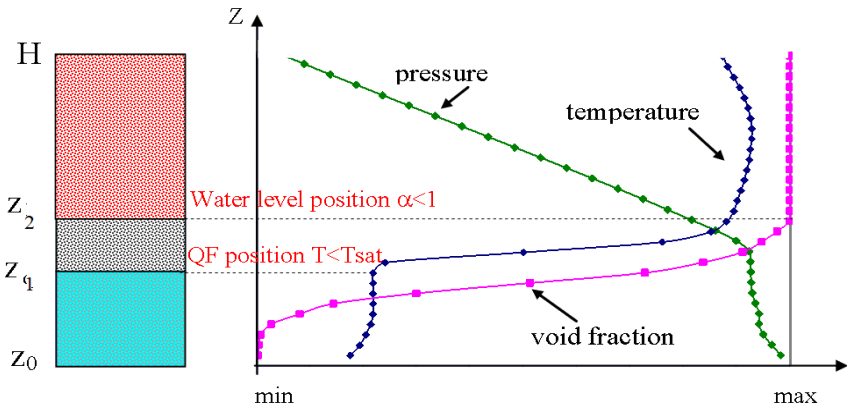
EXPERIMENTAL RESULTS

Reflooding tests with homogeneous debris beds were carried out in the PRELUDE facility of IRSN at atmospheric pressure. Published experimental results and analyses with the ICARE/CATHARE code can be found in (Fichot et al. 2012, Repetto at al. 2013 and Bachrata et al. 2013). The phenomenology of PRELUDE tests with water injection from below a homogeneous debris bed (no bypass or more compact zone) was analyzed in (Fichot et al. 2012) and more details can be found in (Bachrata 2012, Ph.D. thesis). The main learnings and conclusions of those studies are provided in this section. There are two important characteristics of the quench front progression:

- The quench front is flat (1D) in several cases, within the range of experimental parameters tested, but several cases also show a curved front (2D). When the front is curved, it moves faster at the periphery than at the center.
- Despite the spatial non-uniformity of the front, the progression seems to remain quasi-steady overall, and an average speed of progression can be determined. A relatively short unsteady phase is observed at the beginning. This is particularly visible in steam production.

This rather simple behaviour when the front is 1D allows the derivation of a simple model which is presented in the next subsection.

2.1 Mass and energy balances for a simplified 1D model



Integrating the mass and energy equations between the bottom (z_1) and the top (z_2) of the two-phase zone, that is to say, by taking a balance over the height, and assuming that this zone propagates in a quasi-steady manner (velocity U_q and height (z_2- z_1) constant), we arrive at the following two relations:

$$\rho_g\left(j_g(z_2) - U_q\right) = \rho_l\left(j_l(z_1) - U_q\right)$$

$$\rho_g\left(j_g(z_2) - U_q\right)\left(h_g^{\{sat\}} + Cp_g\Delta T_g\right) + (1-\varepsilon)U_q\rho_s Cp_s\Delta T_s = \varepsilon\rho_l\left(j_l(z_1) - U_q\right)\left(h_l^{\{sat\}} + Cp_l\Delta T_l\right)$$

This amounts to verifying the conservation of water mass in the frame of reference moving at velocity U_q and stating that all the energy lost by the particles is used to evaporate the liquid and raise the gas temperature to T_{max} (we could also have assumed that the gas exits at T_{sat}, which slightly alters the balance). In what follows, we will neglect the effect of water subcooling (the term $Cp_l\Delta T_l$ is negligible compared to Δh_{sat}).

Combining these two equations gives a relationship between the velocity of the front U_q and the injection velocity $j_l(z_1)$:

$$U_q = j_{inj} \frac{\varepsilon\rho_l\left(\Delta h_{sat} + Cp_g\Delta T_g\right)}{(1-\varepsilon)\rho_s Cp_s\Delta T_s + \varepsilon\rho_l\left(\Delta h_{\{sat\}} + Cp_g\Delta T_g\right)}$$

We thus see the emergence of an essential parameter of reflooding, which we denote γ_E, the ratio between the energy initially stored in the solid and the maximum energy that the surrounding fluid can remove (if it does not move).

$$\gamma_E = \frac{(1-\varepsilon)\rho_s Cp_s\Delta T_s}{\varepsilon\rho_l\left(\Delta h_{sat} + Cp_g\Delta T_s\right)}$$

We can then simply express the equation which relates the front velocity to the injection velocity:

$$\gamma_u = \frac{U_q}{u_{inj}} = \frac{1}{1+\gamma_E}$$

In the preceding expression, we assumed that $j_{inj} = u_{inj}$, that is, that the void fraction $\alpha \approx 0$ upstream of the front, which is not necessarily the case when the residual power is not negligible (especially when the quench front is slow).
Combining this with the mass conservation equation, we find the proportionality relationship between the inlet water flow rate and the outlet steam flow rate:

$$\rho_g\, j_{g(z_2)} = \frac{\rho_l u_{inj}\,\gamma_E}{1+\gamma_E}\left(1-\frac{\rho_g}{\rho_l}\right)$$

Thus we get an expression for the ratio γ_Q between the produced steam and injected water flow rates:

$$\gamma_Q = \frac{\gamma_E}{1+\gamma_E}\left(1-\frac{\rho_g}{\rho_l}\right)$$

Figure 1 shows the values given by the equation for γ_Q by varying the initial temperature difference of the particles relative to the saturation temperature. Two assumptions are made: either $T_g = T_{max}$ at the two-phase zone exit, or $T_g = T_{sat}$. The latter assumption is less realistic because the vapor reaches thermal equilibrium with the particles quite quickly. With the first assumption, it is clear that the conversion rate tends towards an asymptotic value and that the results obtained from tests at 2500 °C would give a conversion rate only slightly higher than that obtained for tests at 900 °C. Therefore, PRELUDE tests are representative of much higher temperature cases (from a thermal hydraulic point of view).

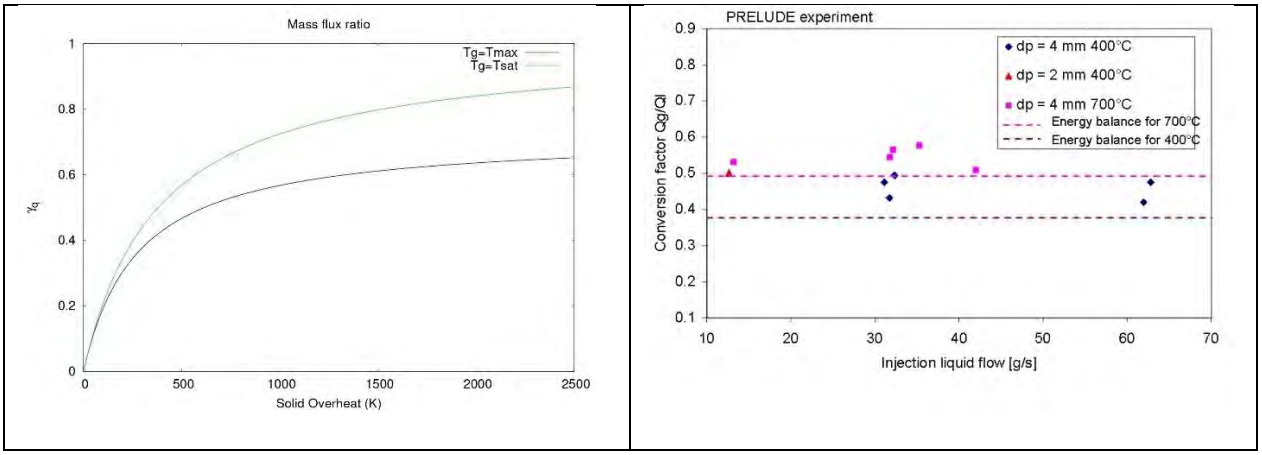


Figure 1: Ratio of steam produced to water injected, as a function of initial overheat of particles	*Figure 2: Conversion rate as a function of inlet flow rate (experimental data and model prediction)*

2.2 Steam production

The equation for γ_Q shows that, to a first approximation, the water-to-steam conversion rate does not depend on the debris diameter, nor, more generally, on the permeability or passability of the debris bed. This result appears to be partially confirmed by experimental measurements of the steam flow rate for particles of different diameters, as shown in (Bachrata et al., 2012), when comparing to the maximum value reached. However, for small particles (2mm and 1mm), there was no plateau observed after reaching the maximum value, which therefore limits the interpretation made with a steady-state model. The absence of a plateau may be due to the presence of water above the bed shortly after the start of reflooding.
The conversion rate given by the simplified approach is also independent of the water injection rate. This is confirmed by the experimental results in Figure 2. However, it can also be seen that the measured conversion rate is higher than the theoretical conversion rate. A similar discrepancy had already been observed in experiments conducted at Brookhaven National Laboratory (BNL) by (Tutu et al., 1984). This means that some of the assumptions made are not verified. In particular, it cannot be verified that the thickness of the two-phase zone is constant or that the gas exits this two-phase zone at T_{max}.
Calculations with a more detailed model implemented in ICARE/CATHARE (and presented in (Fichot et al. 2012) show that the proportionality to the injection rate and the quasi-steady-state behavior with a plateau are indeed observed for some tests. However, not all tests exhibit a well-defined plateau. As the speed increases, the peak produced during the initial phase has a predominant effect, especially as the duration of the plateau phase decreases.

2.3 Velocity of progression of the quench front

The relation for γ_u is shown in Figure 3. Two assumptions were again made regarding the steam temperature at the outlet of the two-phase zone. As with the flow rate ratio γ_q, the velocity ratio does not tend towards zero but towards an asymptotic value and varies very little beyond $T_{max} = 1000$°C. Therefore, the figure is limited to the temperature range corresponding to the tests performed.

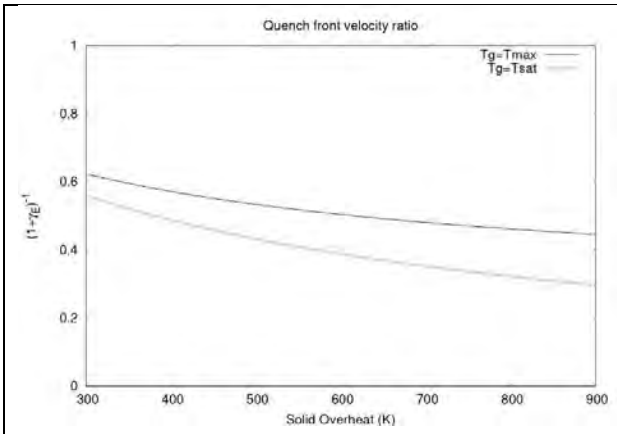

Figure 3: Ratio of quench front to inlet velocities as a function of initial overheat of particles

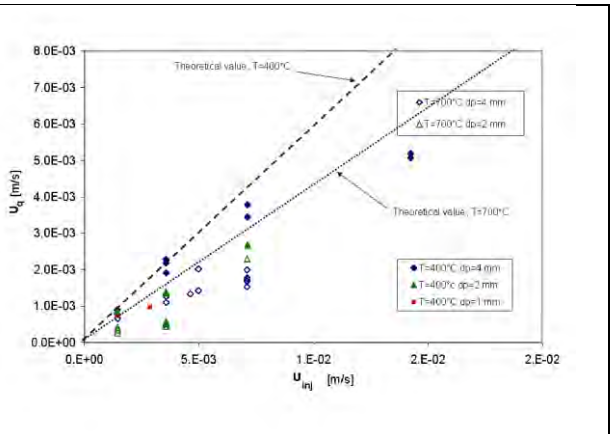

Figure 4: Quench front velocity as a function of inlet velocity (experimental data and 1D model predictions

From experimental measurements, the propagation speed of the quenching front can also be estimated. This is done by measuring the time interval between the arrival of water at the bottom of the bed and the moment

a thermocouple measures the value T_{sat} plus a few degrees. The results presented in Figure 4 show the degree of uncertainty in the evaluation of this speed. The ratio between the two speeds differs quite significantly from the theoretical value given above. This can be explained firstly by the uncertainty of the evaluation based on the thermocouple measurements. It may also indicate that the boundaries z_1 and z_2 of the two-phase zone do not progress at the same speed (which was assumed to be identical to the quench front speed U_q)

The quasi-steady progression is a remarkable result. However, it provides little information for modeling, since we have seen that it leads to finding the solution to the problem simply from the fluid mass balance and the energy balance of the debris bed. To go further in the analysis and in the validation of the models, it is necessary to study transient phases or more complex geometries such as non-homogeneous particle beds, which is done in the next section.

To conclude, **the 1D approximation of the front moving at constant speed is a valid representation when seeking a rapid assessment of the front progression and its consequences on steam production and on the pressure gradient in the debris bed**. In particular, it allows assessing the potential for fluidization of the debris bed.

The 1D approximation of the front moving at constant speed has its limitations. Among these limitations, we have already mentioned the curvature of the front (which increases with the pressure gradient generated by the steam flow). Some of those limitations disappear when using the two-phase flow model, as in (Bachrata et al., 2012).

3 NON-HOMOGENEOUS DEBRIS BED: ANALYSIS OF 2D REFLOODING AND EXPERIMENTAL RESULTS

2D reflooding was investigated in the PEARL facility (Chikhi & Fichot, 2017, Chikhi et al., 2017) at IRSN. The damaged part of the core is represented by a bed of spheres which are heated in order to simulate residual power. This debris bed is surrounded by an area representing a less damaged zone, such as remaining fuel assemblies. The scale of the experiment was approximately 1/8 of the reactor scale. The main results obtained from those experiments are presented below.

One of the main results is the effect of water entrainment in the bypass channel, which occurs under some conditions and affects the timing of quenching as well as the temperature of steam at the outlet. Indeed, the direct application of the 1D model for the conversion rate shows that it provides a good prediction only when the injection flow rate is low or when the temperature of the bed is low. If the temperature is higher or the injection velocity is higher, the conversion ratio is over predicted. This, together with temperature measurements indicated that the increase in steam production leads to a deviation of a part of the injected liquid into the bypass, where it is not converted into steam and flows up to the top of the particle bed, as observed in the temperature measurements in the bypass (which remains at saturation temperature).

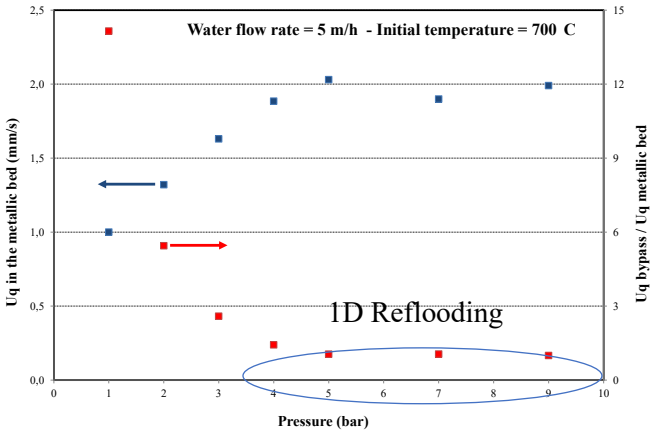

Figure 5: Effect of pressure on the quench front velocity (experimental data, Mutelle et al. 2017)

The quench front velocity in the heated bed and the ratio of QF velocities in the bypass and in the metallic bed are plotted as a function of pressure in Figure 5. It shows that the reflooding time tends first to decrease with increasing pressure then is rather constant when the pressure is above 4-5 bar. At high pressure, the QF velocities in the bypass and in the central bed are identical, indicating that the upward flow of water is one-dimensional. Conversely, when the pressure decreases below 4-5 bar, the ratio between the QF velocities increases. Thus, the reflooding switches from one-dimensional to two-dimensional. In 2D cases, the water outflow from the bypass, before the end of complete quenching is confirmed by the video recordings.
Despite the presence of water above the bed, it is worth noticing that the flow rate of steam is large enough to maintain a counter-current flow limitation and thus to preclude water ingression from the top of the bed. From the experimental data and the calculations, it appears that the entrainment of water probably depends on a threshold value of the axial pressure gradient generated in the debris bed by the intense flow of steam. Below this threshold, the progression of the quench front is uniform across the section and the phenomenon is 1D. Above this threshold, water submitted to a large pressure gradient is able to move at a faster velocity than the injection velocity, in the bypass region. This leads to an accumulation of water above the debris bed before its complete quenching. It is interesting to notice that the bypass actually emphasizes the instability of the quench front velocity already observed in the 1D tests (PRELUDE).

According to these results, the exact values of the thresholds could not be yet exactly identified (neither from the experimental data nor from the calculations) because it depends on several coupled parameters: the injection velocity, the maximum temperature in the debris bed, the pressure, and the aspect ratio of the bed and bypass. But the existence of two different reflooding situations, the 1D and the 2D, is clear from the experiment and is confirmed by the calculations.

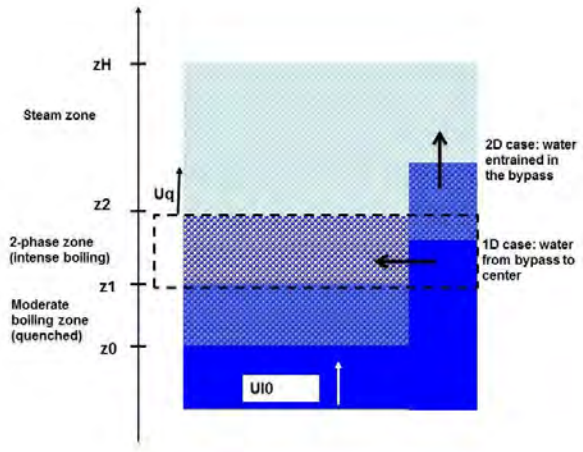

Figure 6: scheme of the liquid flow distribution with a lateral bypass

In order to adapt the simplified 1D approach to the 2D cases, we consider the schematical flow represented in Figure 6: the central bed and the bypass are considered as parallel 1D channels. Mass transfers of steam or water are possible between the channels and are calculated from radial pressure differences. We introduce a parameter characterizing the relative cross section of the center bed, weighted by the permeabilities:

$$R_{lb} = \frac{S_c + S_b}{S_c \frac{K_c}{K_b} + S_b}$$

At this point, we introduce also an empirical parameter k_{ent} representing the fraction of water flow entrained in the bypass. In 1D cases, this parameter is set to 0 and for 2D cases, it is assumed to increase linearly when the pressure decreases or when the velocity increases. The threshold for 1D/2D transition is

taken from experimental data. Obviously, this parameter has more complex variations than the proposed empirical variations, but the purpose of the approach presented in this paper is to remain simple and address only the main effects of the presence of the bypass.
In a similar way as for the 1D case, the quench front velocity ratio γ_u is derived:

$$\gamma_u = \frac{U_q}{u_{inj}} = \frac{1}{1+\gamma_u} + \frac{(1 - R_{lb}k_{ent})}{1+\gamma_u}\frac{S_b}{S_c}$$

From that equation, it appears that **the quench front is faster than without bypass when the entrained fraction of water in the bypass is low (high pressure cases)** because some water flows from the bypass into the central bed. But **it may become slower if the entrained fraction is high**. This evaluation was compared favorably with experimental data in (Mutelle et al, 2017), where the linear decrease of QF velocity was also found in the experiment. The maximum QF velocity ratio predicted by the model is 0.52 which corresponds to a velocity of 1.8mm/s, close to the experimental measurement (2mm/s).
For the conversion ratio, we get:

$$\gamma_q = \frac{\rho_g u_{gc}(z_2)S_c + \rho_g u_{gb}(z_2)S_b}{\rho_l u_{inj}(S_c + S_b)} = \frac{\gamma_u}{1+\gamma_u}\left(1 - k_{ent}R_{lb}\frac{S_b}{S_c + S_b}\right)$$

From that equation, it appears that **the conversion ratio is always lower than or equal to the value without bypass** because of the entrained fraction of water in the bypass. If we apply this formula over the range of parameters corresponding to PEARL experiments, the maximum conversion ratio starts at 0.64 (at highest pressure and lowest temperature) and it decreases down to 0.38 (at 1bar and highest temperature). This is close to the experimental results obtained in the PEARL tests, as presented in (Mutelle et al., 2017).
In parallel with those simple evaluations, intensive validation of the 2D two-phase model were made, by comparison with PEARL data. Validation was made for ICARE/CATHARE model (Chikhi et al. 2017) and for MC3D model (Mutelle et al. 2017, Raverdy et al. 2017). Both models are rather similar. Validation of a comparable 2D model in ASTEC code was made by (Gómez et al., 2021)

Those observations and conclusions are important to evaluate the consequences of accident management by injection of water in the core. **The 1D reflood is more efficient** because all the water entering the central bed is used to cool down the debris whereas, **in case of 2D reflood**, a part of that water is diverted into the bypass and accumulated at the top of the bed. However, **the presence of water on top of the debris bed before complete quenching leads to decrease the temperature of steam above the bed which is a good point** for the integrity of the top part of the vessel and of the hot leg of the primary circuit.
At this point, it is possible to also draw some conclusions about the analytical approaches that can be used to evaluate the impact of reflooding at the reactor scale. From the analyses of the reflooding experiments with homogeneous debris beds (PRELUDE) and non-homogeneous debris beds (PEARL), two main outcomes were obtained on the analytical side: (i) a simple model to predict the quench front velocity and conversion ratio (water to steam) and (ii) the validation of a general multi-dimensional model for two-phase flow in a debris bed (implemented in ICARE/CATHARE code). The simple model catches the effect of inlet flow redistribution into higher permeability bypass and helps explain this process, which is driven partly by the imbalance of pressure between the central debris bed and the bypass and partly by the interfacial friction between water and steam flowing at high velocity. Nevertheless, the simple approach has a limited accuracy and requires an empirical parameter: it cannot be used in all configurations. **Therefore, the recommended approach for reactor scale evaluations is to use a 2D two-phase model**.

4 APPLICATION TO REACTOR SCALE

The flowrates considered in PEARL cover a range of water velocity from 2 to 20m/h. In a reactor where the vessel diameter is typically 4m, this corresponds to a volumetric flowrate of 24m3/h to 240m3/h or a mass

flowrate of 6kg/s to 60kg/s. Those are rather low flowrates compared to a low-pressure safety injection but are comparable to injection flow rates of mobile devices that are currently considered for "ultimate" SAM actions, for which the maximum flow rate is higher than 100kg/s. The pressures considered in PEARL cover a range from 1 to 9bar which is typical of the ranges of pressure reached in severe accident sequences when the pressure release valves are open. The temperature of the bed in PEARL is lower than in the reactor where debris would be in the range 1500K-2500K. The melting of debris occurs between 2500 and 2900K. A debris bed formed in the core could have a height between 1m (TMI2 case) and up to 2m if we consider that the top half of the core is severely damaged before reflooding.
In order to define a realistic reactor case, it is considered that fuel rods have collapsed into a debris bed at the upper part of the assemblies (1m high), over a cross section representing 85% of the total area of the core. Therefore, there is a bypass at the periphery, covering 15% of the total area (compared to 30% in PEARL). The permeability of that bypass is more than 10 times higher than the permeability of the central bed. We assume a rather high residual power of 200 W/kg, and a porosity of 0.39. The rest of the reactor conditions are specified in Table 1.

To investigate the coolability limits of a debris bed formed inside the core region, the ICARE/CATHARE code was used, describing the debris bed and the bypass as 2D, axisymmetric zones. Sensitivity studies are made for 4 parameters. For each calculation, we compare the time to reach total quenching with the "virtual" time to reach melting in the debris bed (in the calculations, debris can reach temperatures above their melting point)
The impact of debris temperature on the coolability limit is shown in Figure 7. The dependency is almost linear: a higher temperature decreases the velocity of the quench front (almost linearly, as in the 1D model) and strongly decreases the time to reach melting. In the present case, the threshold temperature is 2500K. Even if the debris are initially at a rather low temperature (around 1500K), the margin for cooling is only 1 hour. Therefore, it appears that **the main issue with the quenching of debris beds is not necessarily their low permeability but, first of all, their high temperature which lets very little time margin to reflood the core**.

The impact of injection velocity on the coolability limit is shown in Figure 8. It shows that there is a critical value below which the flow rate is insufficient to quench the debris bed before melting: this is quite obvious. But it also shows that **there is not much benefit increasing the flow rate up to high values** because it does not reduce significantly the quenching time: this result was confirmed experimentally in (Chikhi et al. 2017). The critical value, in the present case, is around 5mm/s which corresponds approximately to a mass flow rate of 200 t/h for a high power PWR. **Such flow rate can be delivered easily** by a low-pressure safety injection pump or by the Chemical and Volume Control System (CVCS) or a by fire pump.

The impact of porosity on the coolability limit is shown in Figure 9. In the present case, the threshold porosity is around 25-30%: this is close to the value that can be reached if the debris bed is strongly compressed (i.e. 28% in the study of (Nguyen et al., 2017)), Such low porosity could exist at the bottom of the debris bed, and it might even be lower if relocated metal melt is present. The dependency with porosity is very non linear and we see that it is almost impossible to quench a region where the porosity is lower than 15% (2h would be necessary). **As a conclusion, we may expect that some regions of the debris bed, in particular the bottom part, may melt before quenching (even if the top part iss quenched).**

The impact of the relative cross-section of the central bed on the coolability limit is shown in Figure 10. It shows that if the central bed occupies less than 50% of the total area, it cannot be quenched before melting. This is amplified as the relative cross section decreases. This result may seem unphysical at first sight but it is explained by the decrease of the pressure gradient in the bypass when the central bed cross-section decreases: for a central bed with a small radius, the vertical pressure gradient becomes close to hydrostatic (0.1 bar/m) which is small compared to the pressure gradient generated by a direct injection with a pump (in case of homogeneous debris bed covering the whole cross section of the core). This shows that, **in case**

of a debris bed occupying only a limited part of the total cross section, the permeability becomes the limiting parameter for the quenching time. It is the effect of the parameter that we defined as R_{lb}.

5 CONCLUSIONS

The large series of experiments performed at IRSN, for homogeneous debris bed in the PRELUDE facility and for non-homogeneous debris bed in the PEARL facility, have provided data to validate two-phase flow models able to simulate the reflooding of 2D debris bed.
In parallel, the analysis of results with simple approaches and with 2D simulations have provided an understanding of the behavior of water and steam during reflooding, in particular the phenomena of water entrainment between regions with different porosities/permeabilities.
Extrapolations at the reactor scale and for severe accident conditions lead to the following conclusions:

- The time to successfully quench the whole damaged core, at a late stage where debris have formed, is quite short: approximately 20 to 60 minutes in the realistic case studied in this paper, which

means that the probability of recovering a safety injection during this time frame is very low (considering that a severe core damage occurs only when all water sources are lost for some time)

- A minimum injection flow rate is necessary but increasing this flow rate does not lead to a significant reduction in total quenching time: low porosity/permeability regions are not sensitive to the flow rate. This means that it is very likely that some parts of the core would be quenched while other parts would melt, in spite of the core reflooding.
- It is likely that the core region would be covered by water quickly after reflooding starts (even if some parts remain unquenched): the benefit of this situation is that steam entering the hot leg would be rather cold. This means that reflooding would not induce heating and mechanical failure in the circuit or steam generator tubes.

As a conclusion, if water is injected in the core at a late stage, when the core is already severely damaged, it is expected that only a part of the core can be quenched while other parts will melt. Nevertheless, this will have several benefits and very few drawbacks. The drawbacks are: a hydrogen production peak (likely to be comparable to the early degradation phase) and a containment pressure peak, comparable to what is expected in a LOCA sequence. The benefits are: a decrease of temperatures in the hot leg (preventing mechanical failure) and the stabilization of some part of the fuel within the core region. This last point makes it easier to stabilize the molten corium, either in the lower plenum of the vessel, or ex-vessel.

6 NOMENCLATURE and REFERENCE VALUES

Table 1: List of variables and their values in experiments and reactor case

description	variable	Exp. range	Reactor case
water velocity at inlet	u_{inj}	2-20 mm/s	11 mm/s
quench front velocity	U_q	m/s	m/s
volumetric flow rate	j	2-20 mm/s	mm/s
initial temperature of particles	T_s	400-900 °C	2000 °C
Residual power per unit of mass	Q_{res}	100-300 W/kg	200 W/kg
porosity of the bed	ε	0.39	0.39
permeability of the bed	K	10^{-9} -10^{-8} m^2	10^{-8} m^2
outlet pressure	P_{ext}	1-9 bar	3 bar
height of debris bed	H	0.2-0.5m	1m
diameter of particles	d_p	1-2-4 mm	3 mm
Density of particles	ρ	7800 kg/m3	8000 kg/m3
heat capacity of particles	Cp	J/kg/K	J/kg/K
latent heat of vaporization of water	Δh_{sat}	J/kg	J/kg

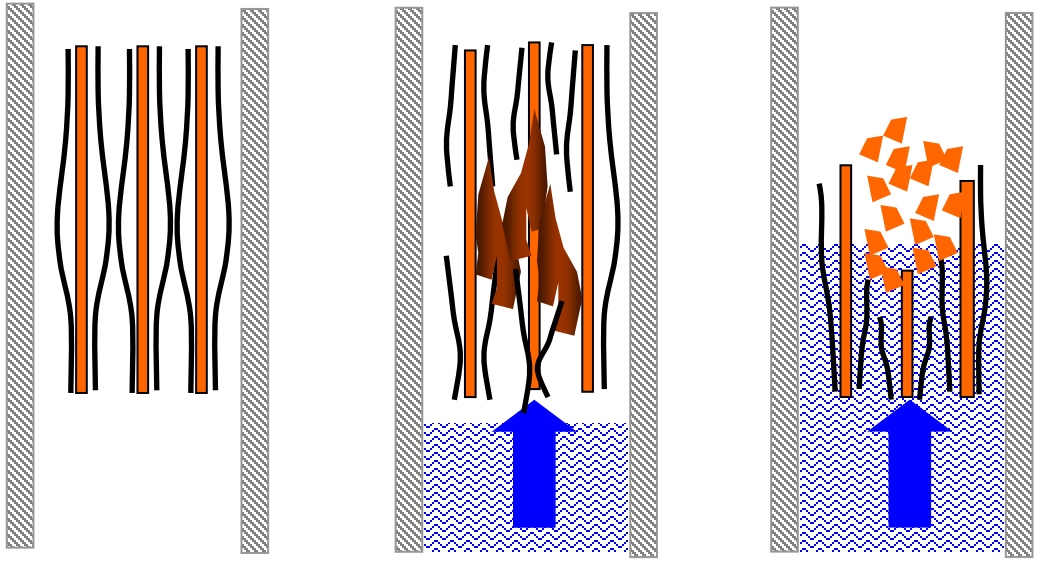
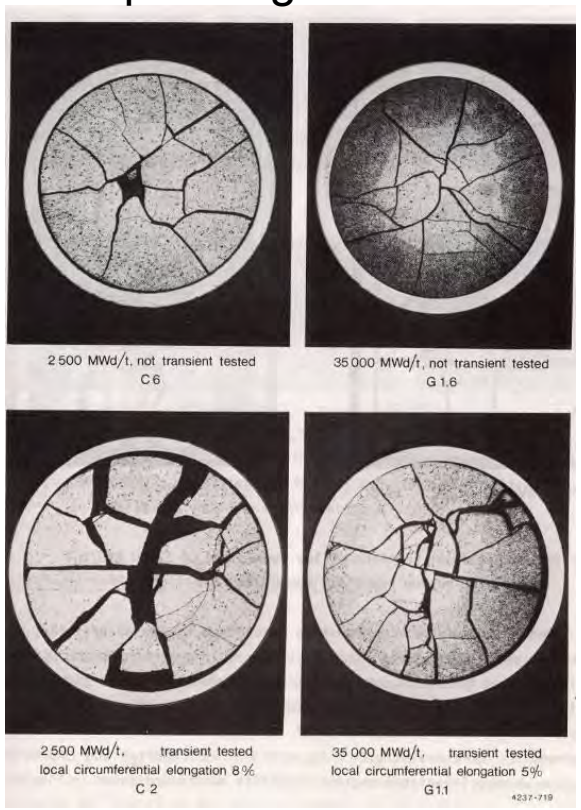
DEBRIS BED FORMATION IN A DAMAGED CORE (1)

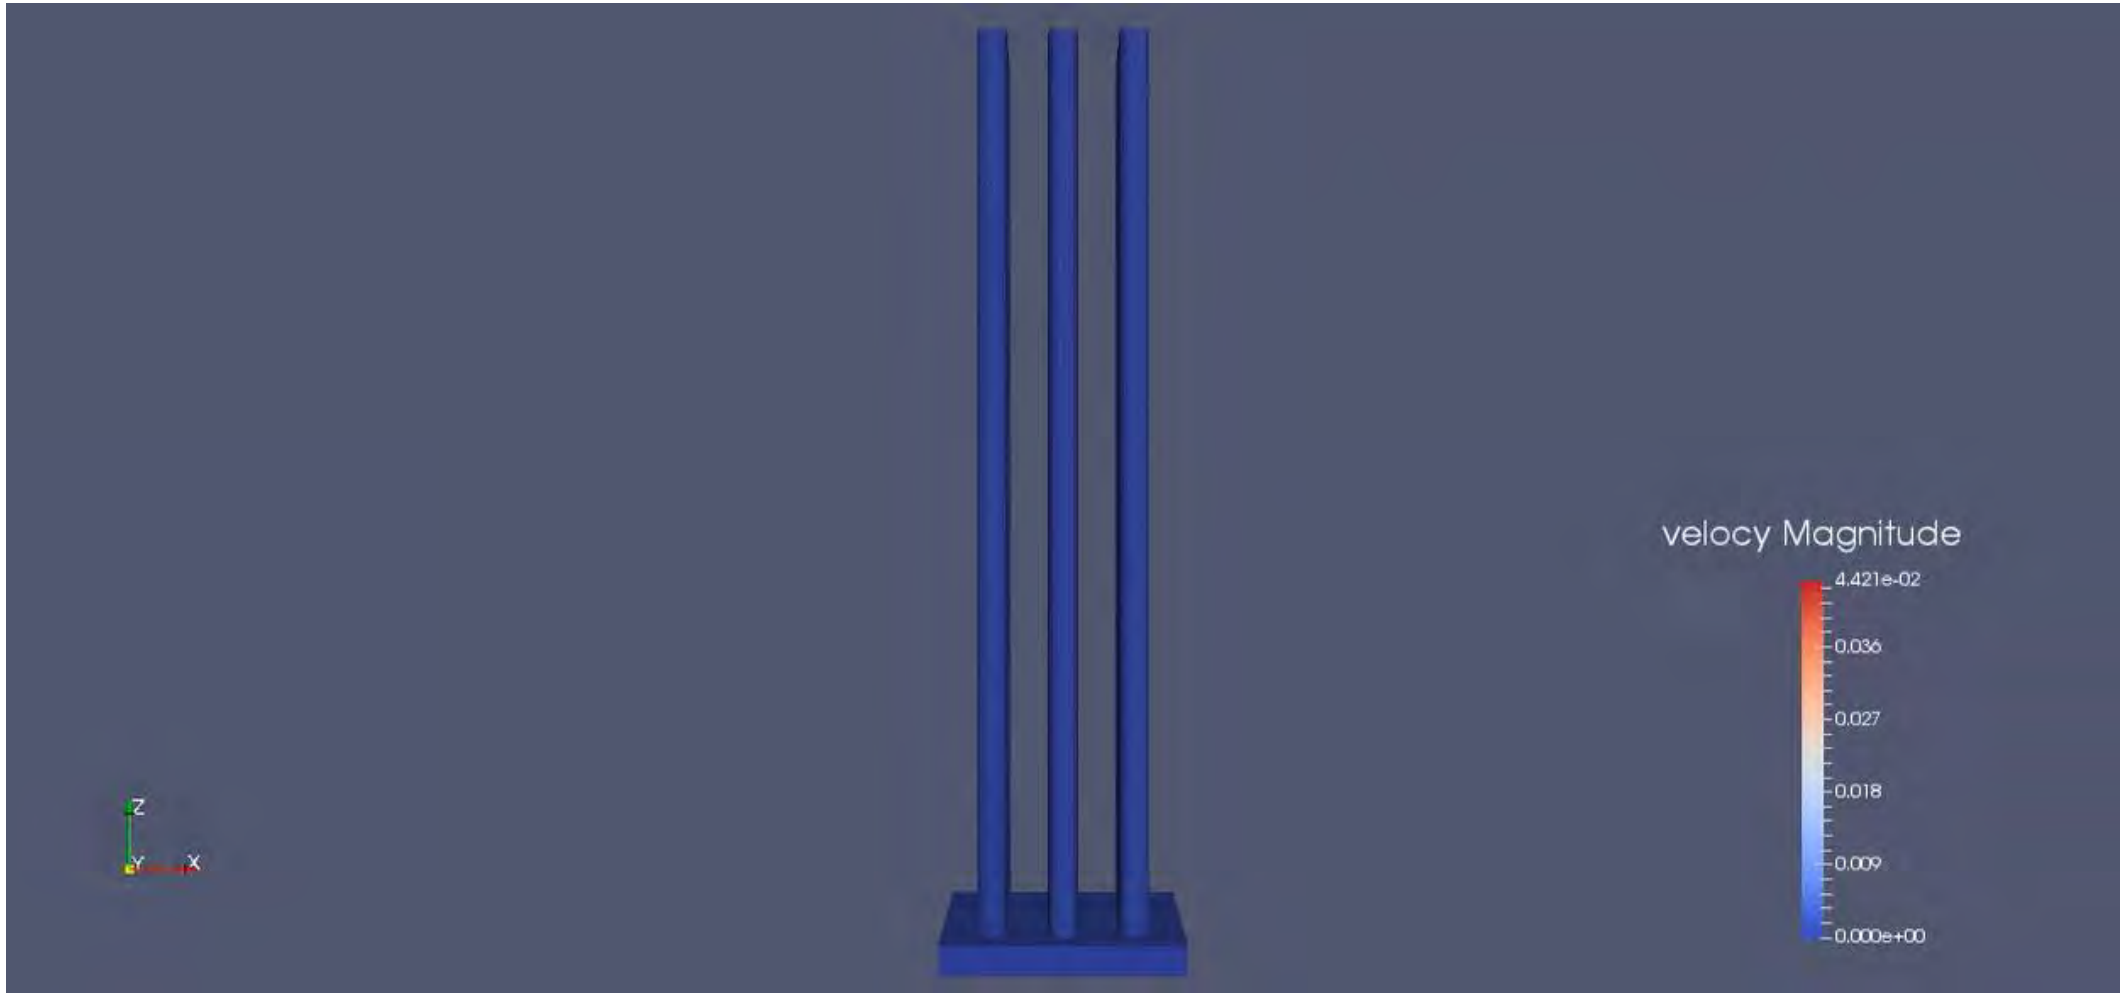


Large fragments (≈ 3 mm) resulting from fuel fragmentation under operating conditions



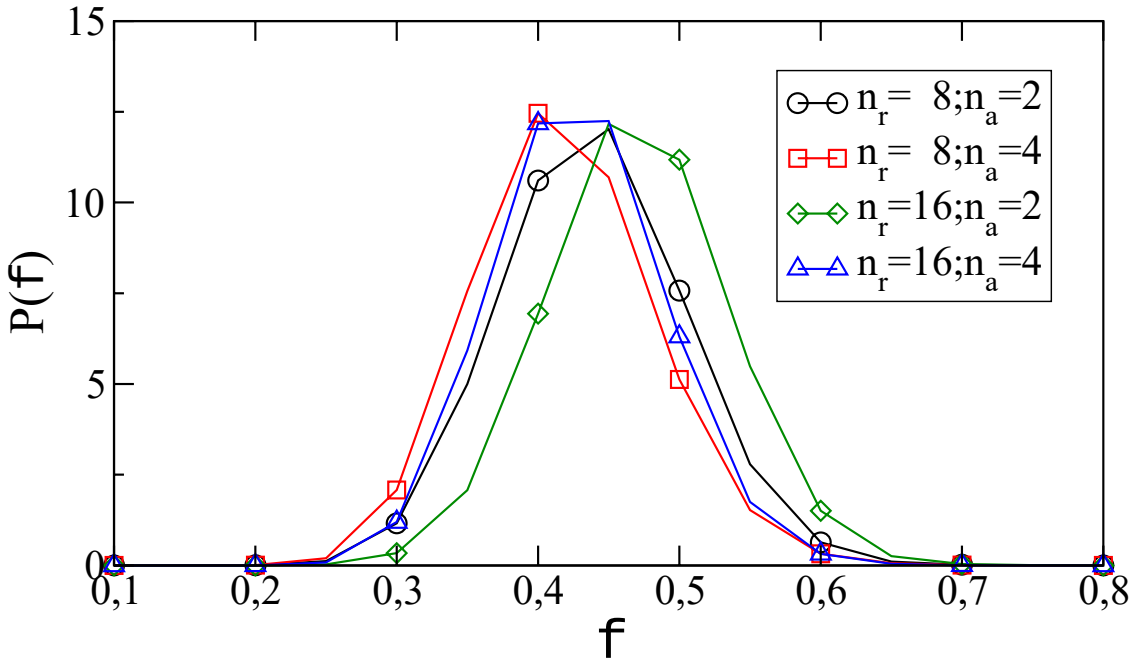
E.H. Karb et al. 1983, LWR fuel rod behavior in the FR2 in-pile tests simulating the heatup phase of a LOCA

DEBRIS BED FORMATION IN A DAMAGED CORE (2)



Calculations of debris collapse from fragmented fuel columns (with Contact Dynamics granular approach)

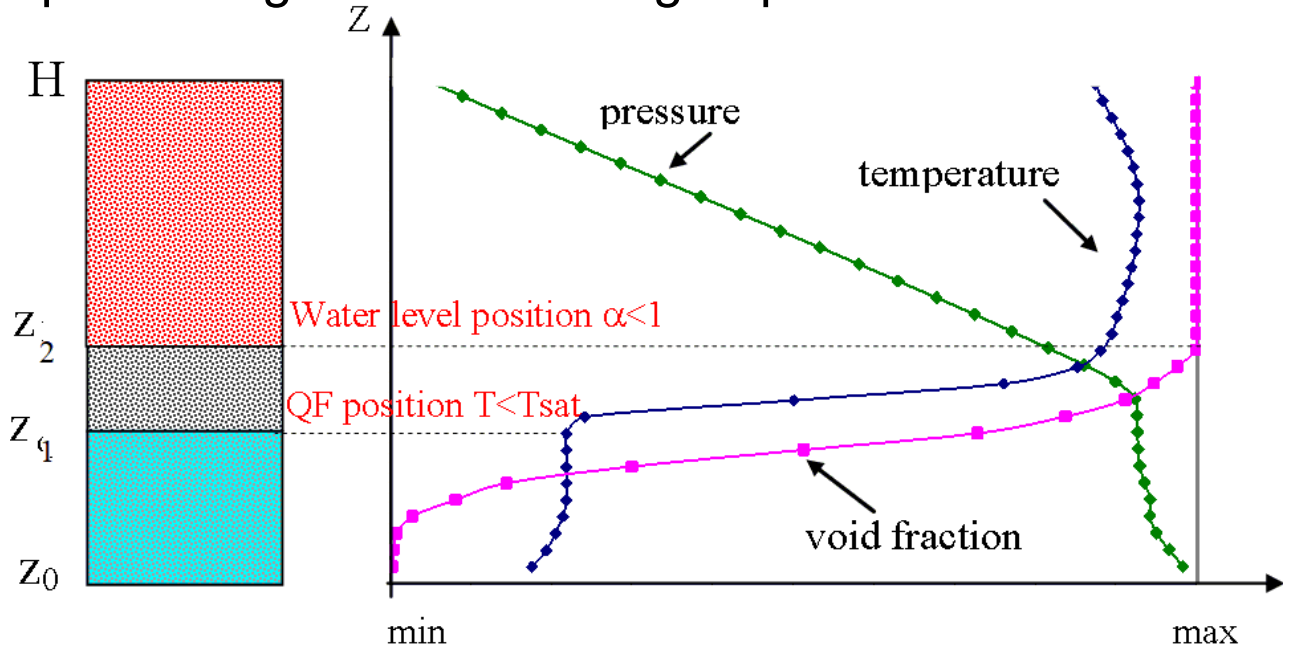
DEBRIS BED FORMATION IN A DAMAGED CORE (3)

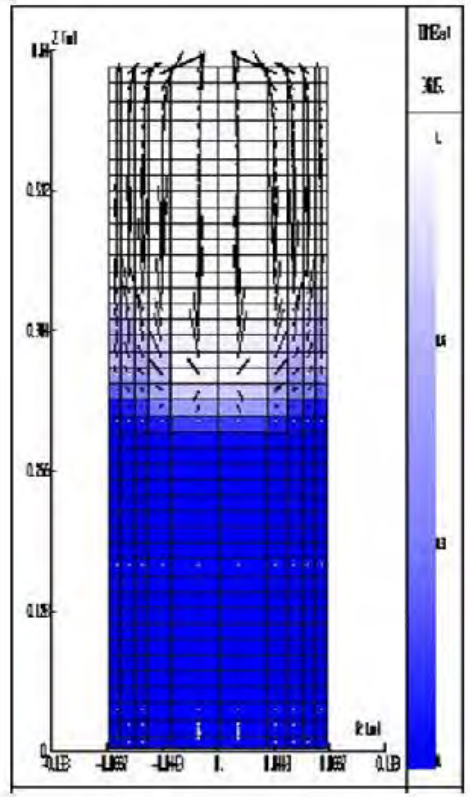


Distributions of porosity for various fragmentations of fuel pellets → rather large average porosity and significant statistical variations

1D REFLOODING (PRELUDE FACILITY)

- Quasi-steady progression of quench front
- High velocity of steam flow → steep pressure gradient
- Results are consistent with earlier tests performed at Brookhaven NL (Tutu et al. 1984)
- If pressure gradient is too high: quench front becomes 2D (instability)





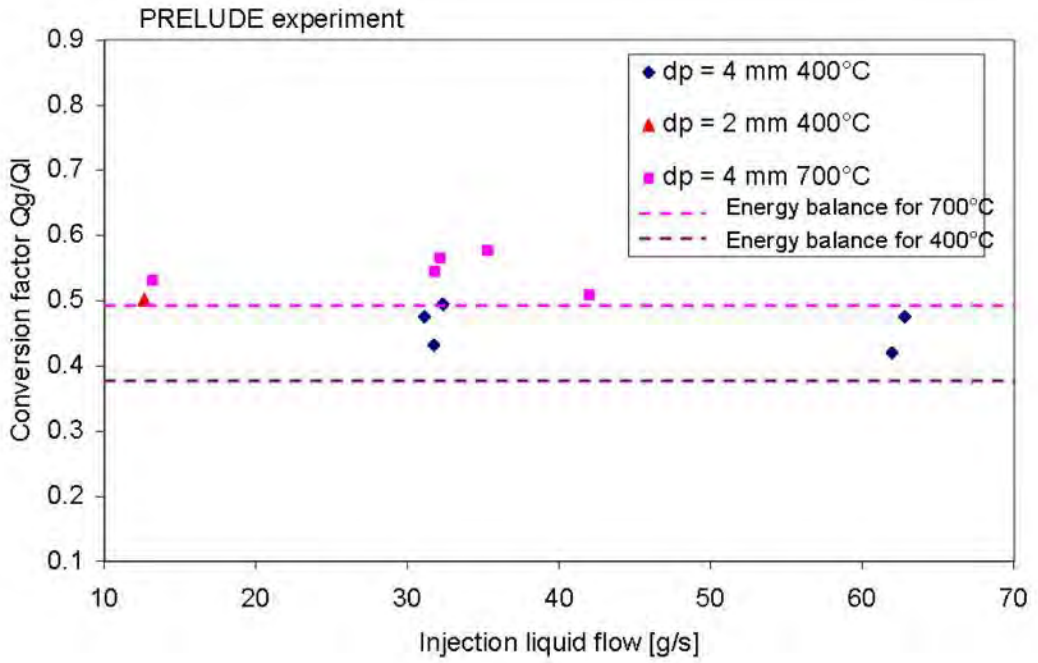
Calculated void fraction → 2D deformation of quench front, as observed experimentally

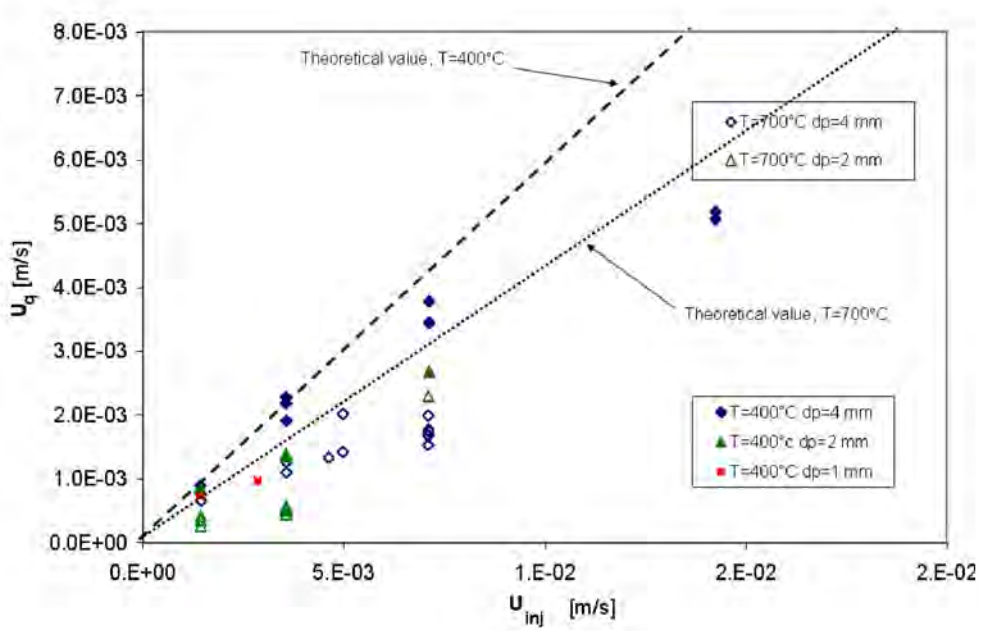
N.K. Tutu, T. Ginsberg, J. Klein, J. Klages, and C.E. Schwarz. “Debris bed quenching under bottom flood conditions”, technical report NUREG/CR-3850, Brookhaven National Labs., 1984.

1D REFLOODING

A SIMPLIFIED 1D STEADY-STATE APPROACH PROVIDES

- Constant quench front velocity
- Conversion ratio water → steam





Accuracy of 1D steady-state model = +/-15%

CONCLUSIONS ON 1D REFLOODING

Quasi-steady progression of QF is observed in all cases

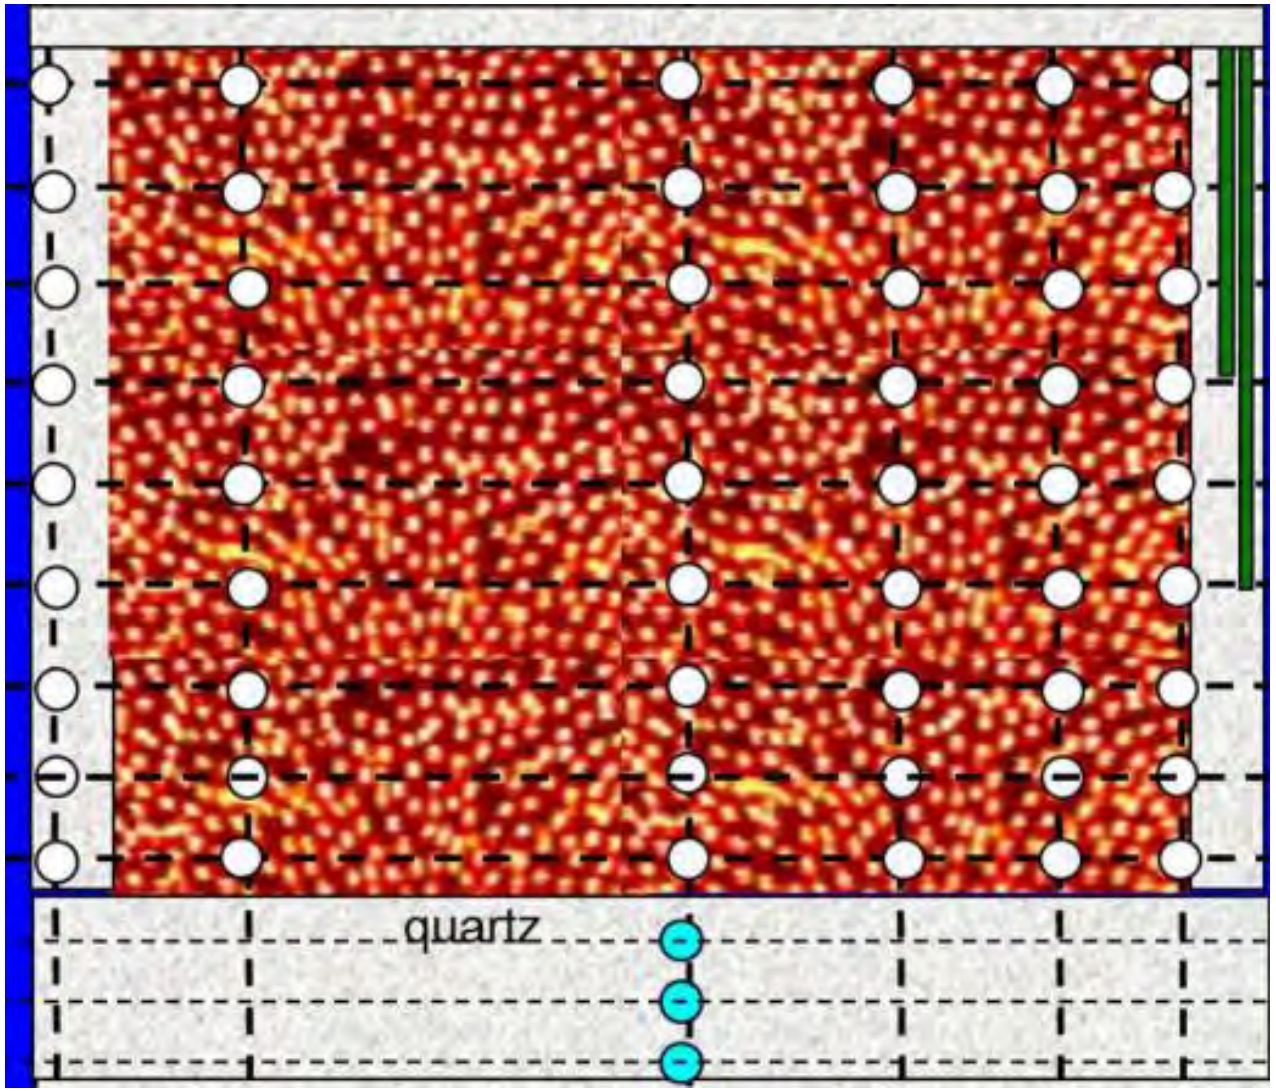
QF may be 2D with entrainment of water at the periphery

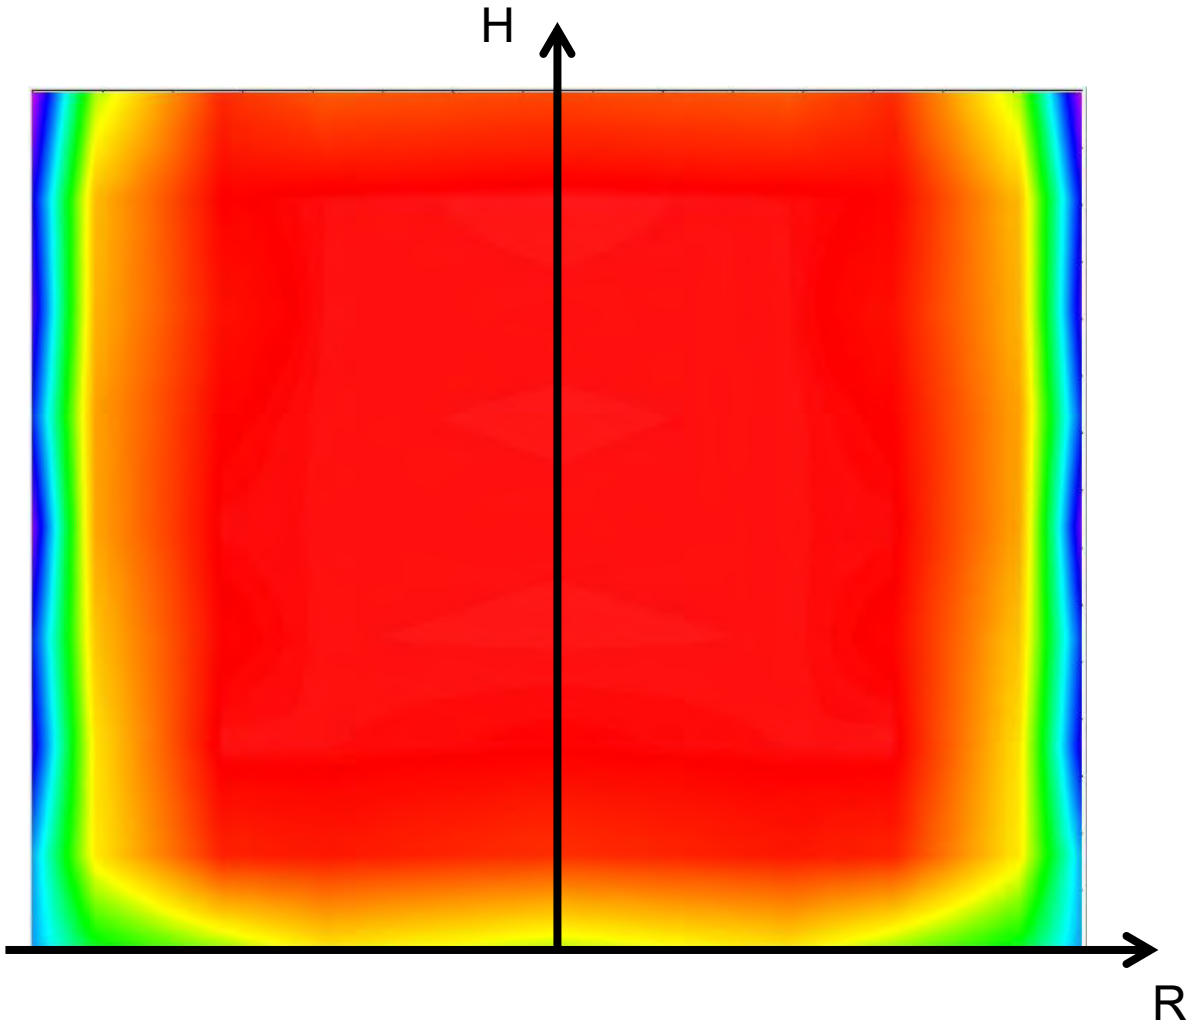
The overall behaviour can be predicted with a 2D 2-phase numerical model

1D approximation of the front moving at constant speed is a valid representation when seeking a rapid assessment of the front progression and its consequences on steam production and on the pressure gradient in the debris bed

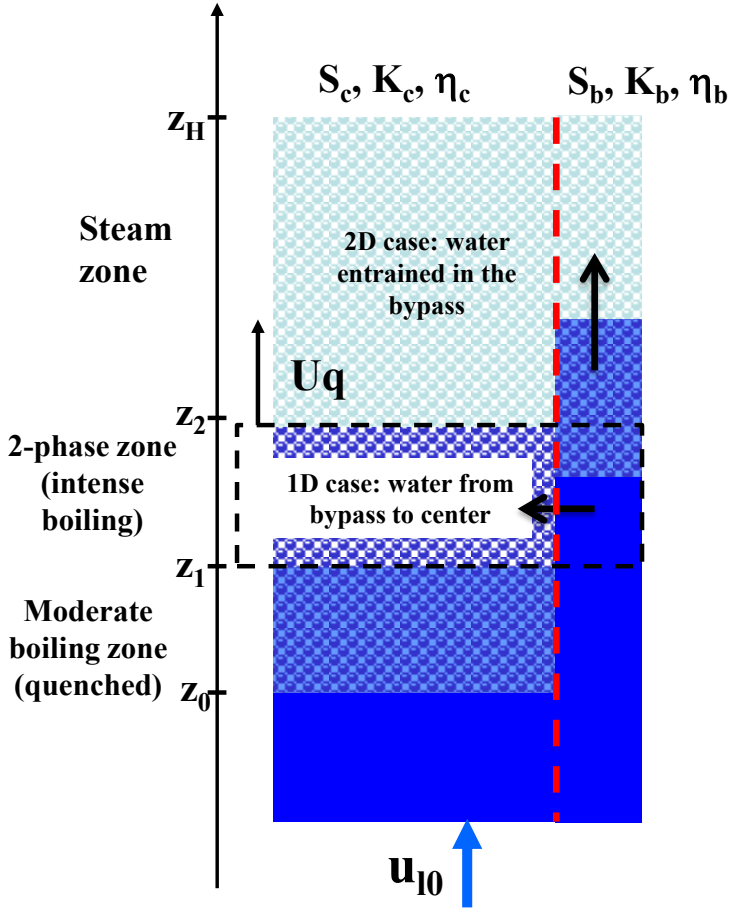
- It gives a relatively good approximation at steady-state, within +/- 15% uncertainty range
- It is inaccurate in the transient phases (quench front entering or leaving the core)

2D REFLOODING (PEARL FACILITY)





ANALYTICAL MODEL FOR 2D STEADY-STATE PROGRESSION



- Assumptions :
  - 3 different zones with steady velocity (= Uq)
  - No heat losses and no heat exchange in the bypass
  - A fraction of water is entrained from the central bed to the bypass: parameter k_{ent}

- Mass balance in each zone and energy balance for the whole system give :

Quench front velocity ratio

$$\frac{U_q}{u_{l0}} = \frac{1}{1+\gamma}\left[1+\frac{S_b}{S_c}(1-R_{lb}k_{ent})\right]$$

with :

$$R_{lb} = \frac{u_{lb}(z_1)}{u_{lo}} = \frac{(S_c+S_b)}{(S_c\frac{K_c}{K_b}+S_b)} = 2.1$$

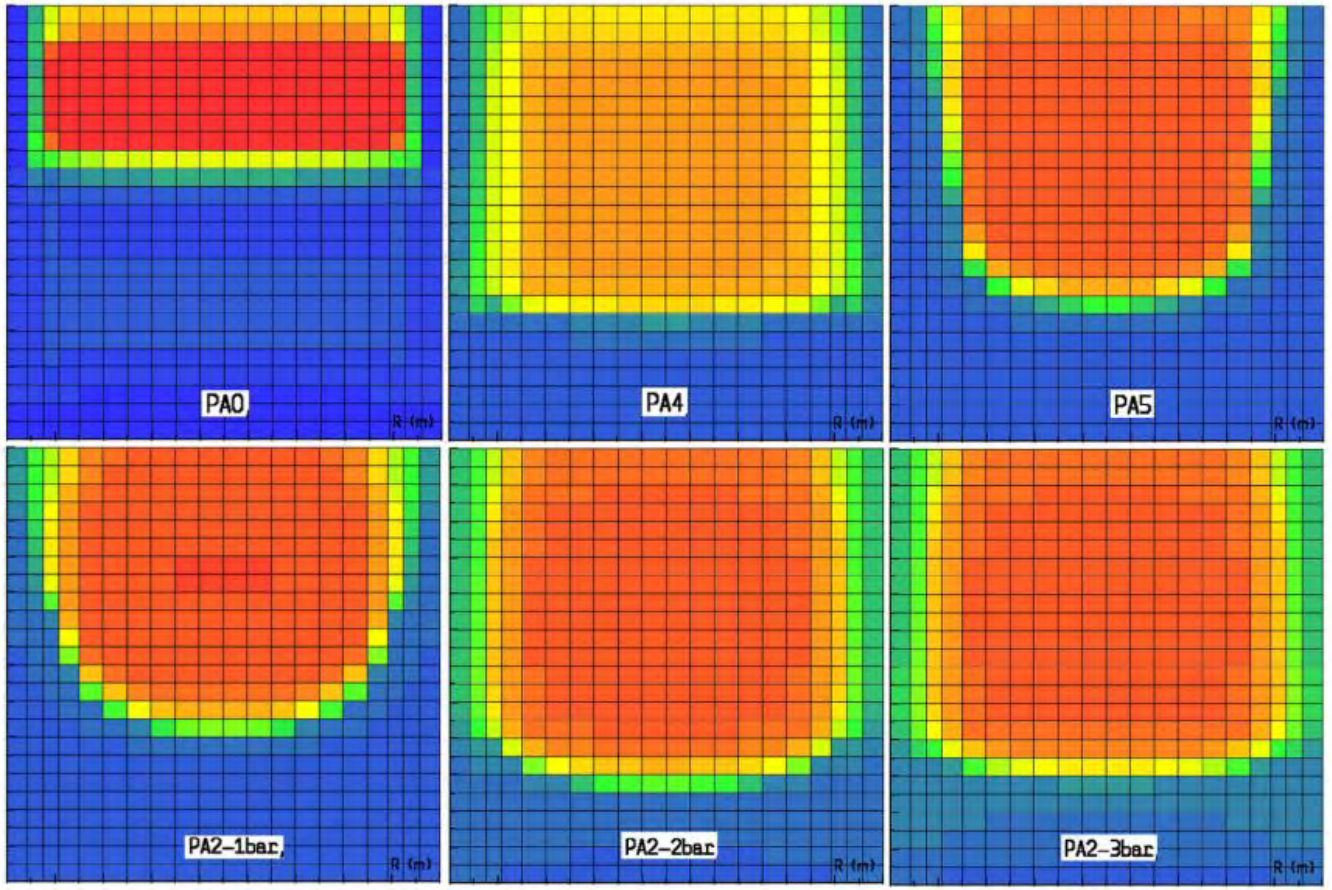
$$\gamma = \frac{(1-\varepsilon)\rho_s Cp_s \Delta T_s}{\varepsilon \rho_l (\Delta h^{sat} + Cp_g \Delta T_g)}$$

- The QF is faster in the presence of bypass than without bypass when k_{ent} is low (1D mode) because some water flows from the bypass to the central bed. It may become lower if the entrained fraction is high.

- Maximun QF velocity ratio = 0.52 corresponding to 1.8 mm/s close to the experimental value (= 2 mm/s)

2D 2-PHASE MODEL

A TWO-PHASE FLOW MODEL WAS DEVELOPED AND FITTED TO EXPERIMENTAL DATA:

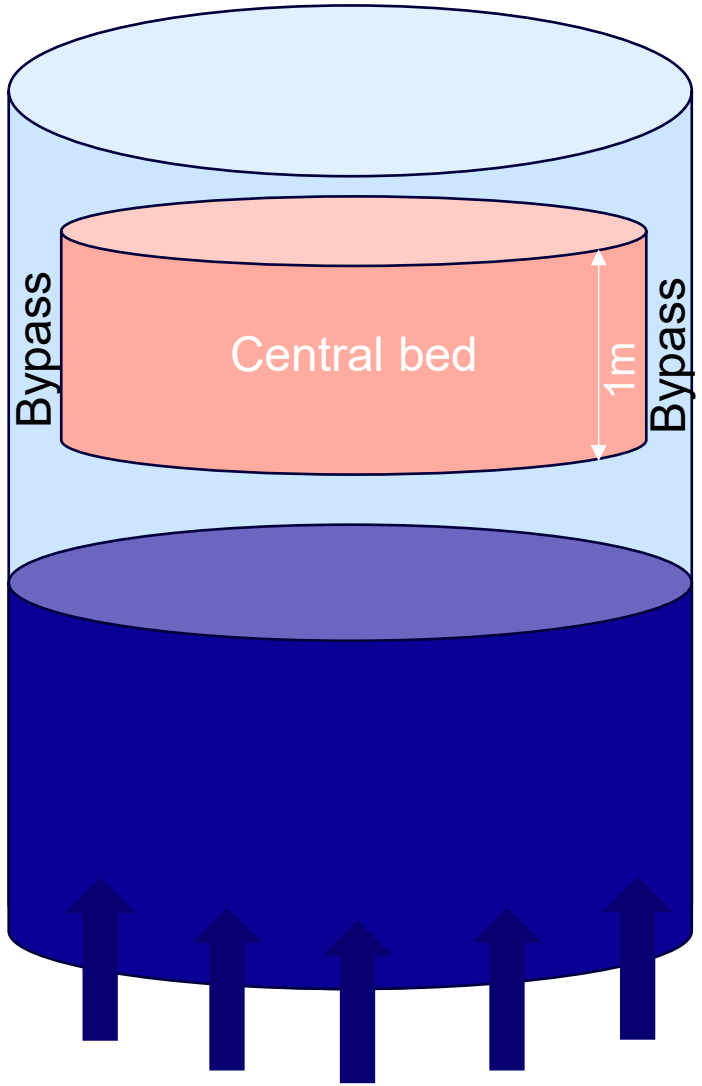


- It is able to reproduce experimental data, including the 2D behaviour of quench front
- It uses only local closures (friction terms, HF) → it can be extrapolated to reactor scale

APPLICATION TO REACTOR CASES

- A 1m high debris bed is generated near the top of the core
- It is surrounded by non damaged rods (bypass)

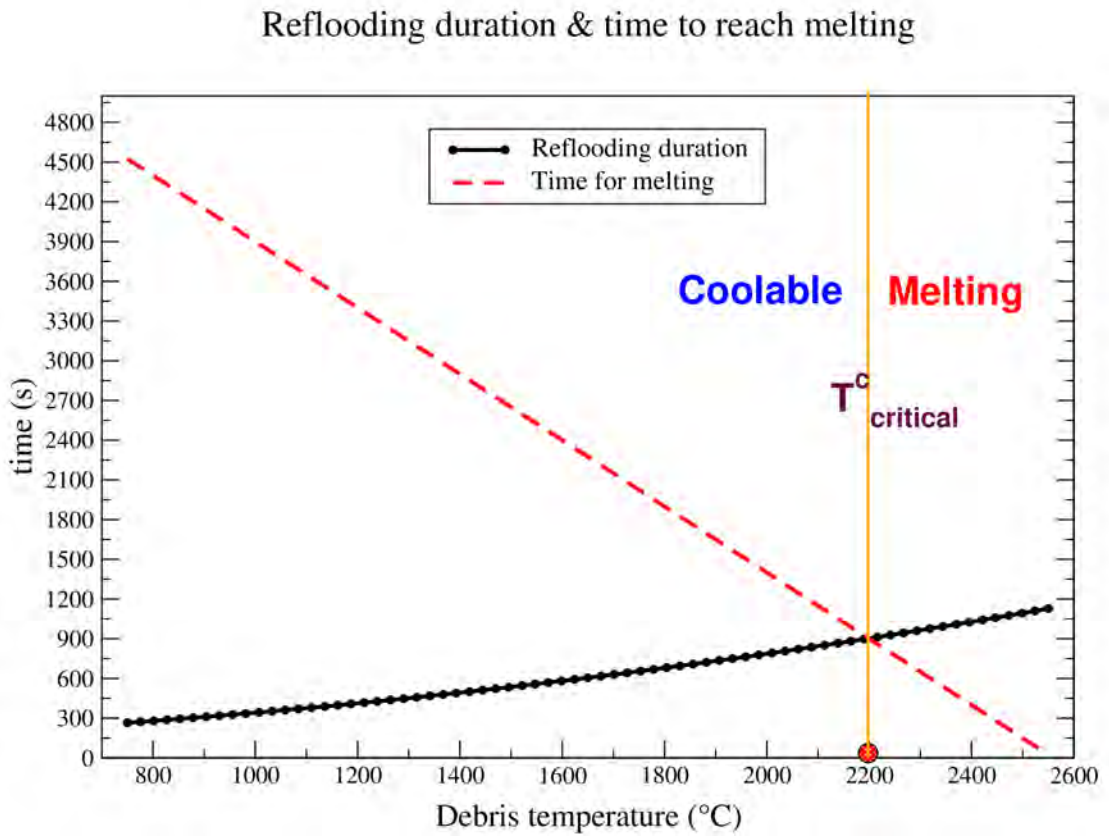
description	variable	Exp. range	Reactor case
water velocity at inlet	u_{inj}	2-20 mm/s	11 mm/s
volumetric flow rate	j	2-20 mm/s	2-30 mm/s
initial temperature of particles	T_s	400-900 °C	**2000 °C**
Residual power per unit of mass	Q_{res}	100-300 W/kg	200 W/kg
porosity of the bed	ε	0.39	0.39
permeability of the bed	K	10^{-9} -10^{-8} m^2	10^{-8} m^2
outlet pressure	P_{ext}	1-9 bar	3 bar
height of debris bed	H	0.2-0.5m	**1m**
diameter of particles	d_p	1-2-4 mm	3 mm
Density of particles	ρ	7800 kg/m3	8000 kg/m3



COOLABILITY LIMITS IN A REACTOR CORE (1)

EFFECT OF CORE TEMPERATURE:

- A higher temperature decreases the velocity of the quench front and strongly decreases the time to reach melting
- Even if the debris are initially at a rather low temperature (around 1500K), the margin for cooling is only 1 hour
- If BDBA conditions are reached, the main SAM issue is to recover a water source in a short time



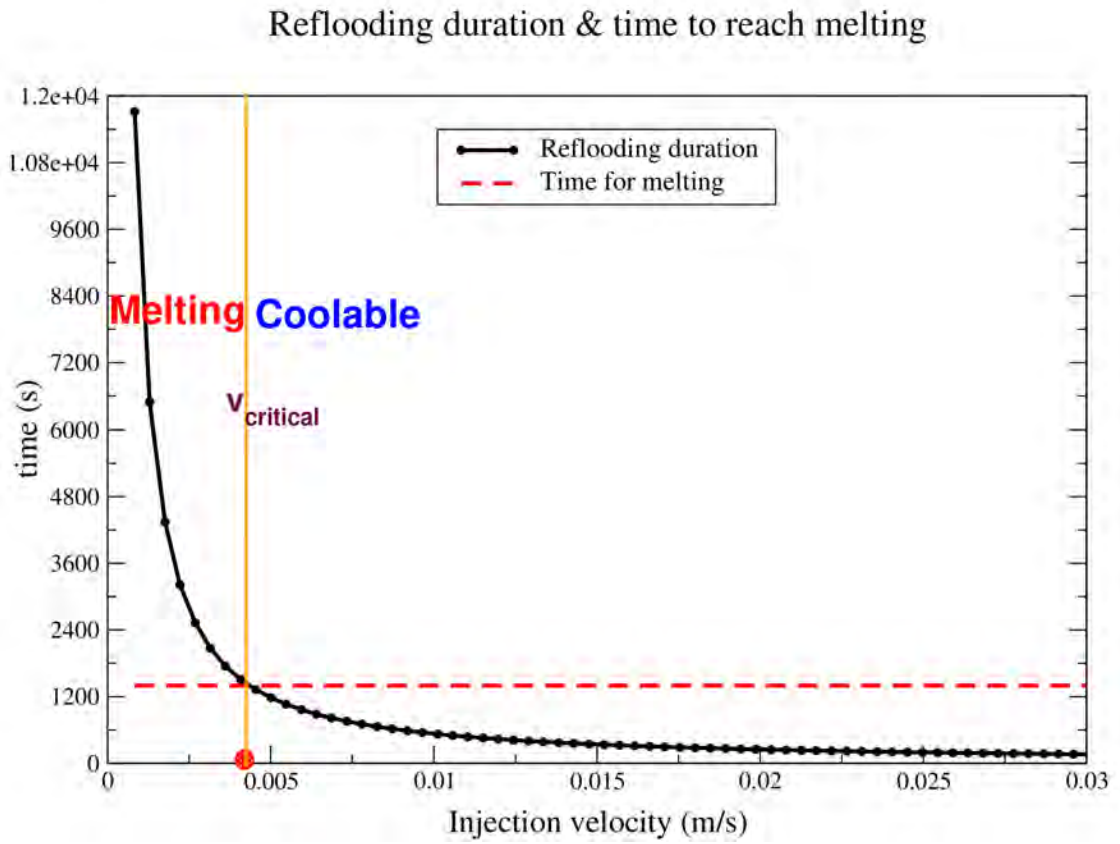
COOLABILITY LIMITS IN A REACTOR CORE (2)

EFFECT OF INJECTION VELOCITY:

- The critical value is around 5mm/s which corresponds approximately to a mass flow rate of 200 t/h for a high power PWR

- A high flow rate may reduce significantly the total quenching time but … would it be available?

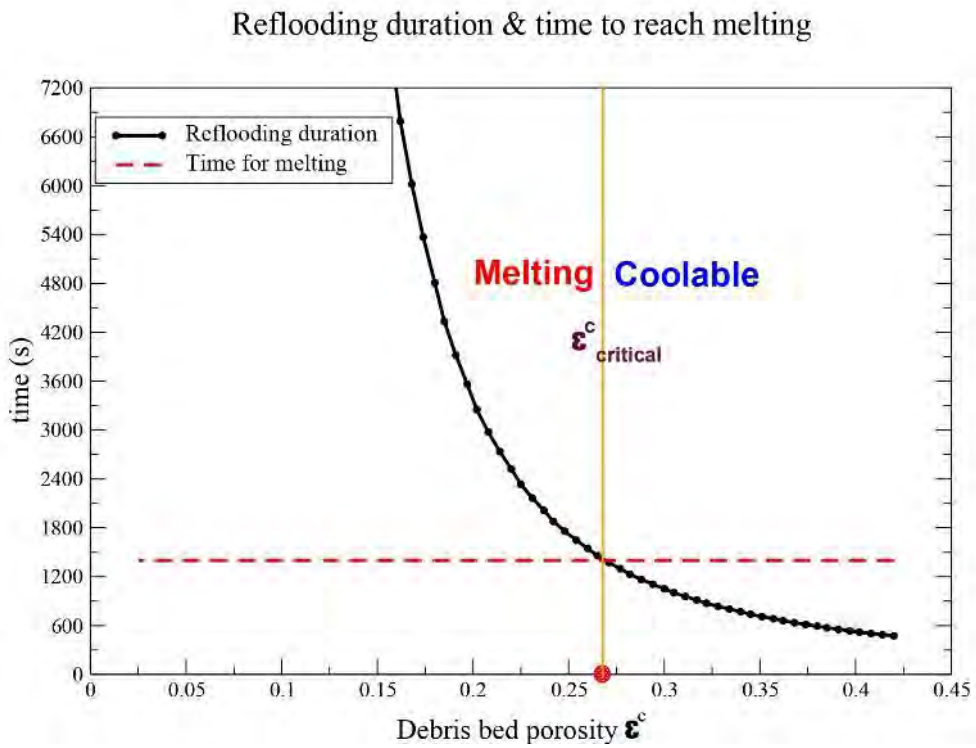
- Low flow rates lead to debris melting

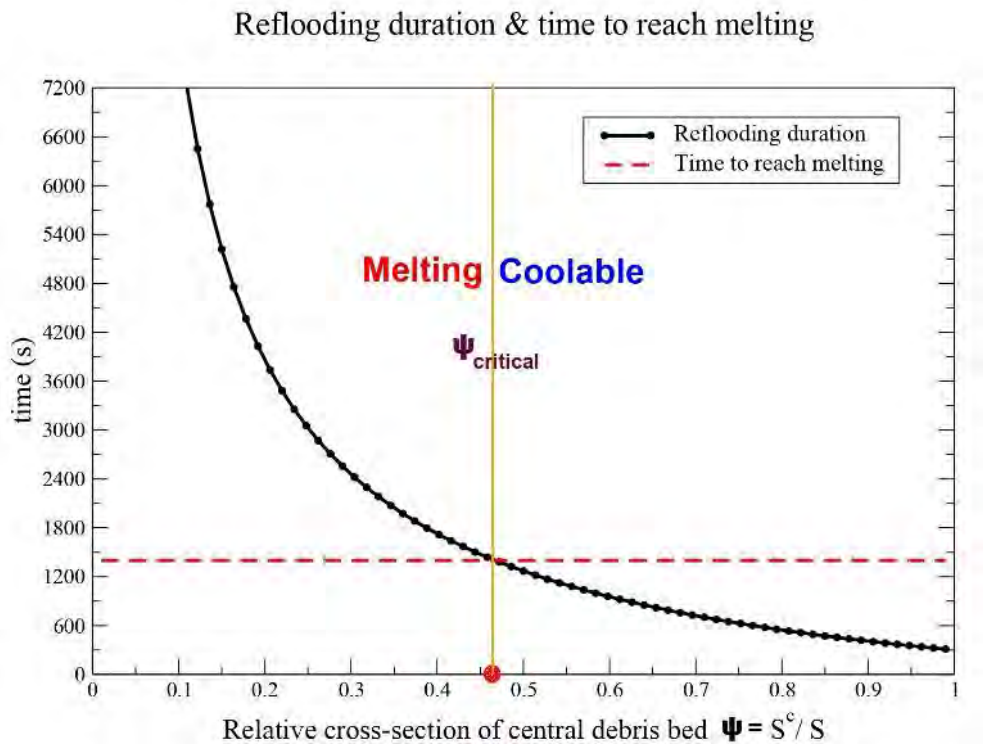


COOLABILITY LIMITS IN A REACTOR CORE (3)

EFFECTS OF POROSITY AND BYPASS CROSS SECTION:

- threshold porosity is around 25-30% (strongly compressed bed)
- if central bed occupies less than 50% of total area, it cannot be quenched before melting (= gravitational flooding)





CONCLUSIONS FOR ACCIDENT MANAGEMENT

Extrapolations at the reactor scale and for severe accident conditions lead to the following conclusions:

- The time to successfully quench the whole damaged core, at a late stage where debris have formed, is quite short: approximately 20 to 60 minutes in the realistic cases studied in this paper, which means that the **probability of recovering a safety injection during this time frame is very low** (reflooding may be successful for longer sequences, with lower residual power)

- A minimum injection flow rate is necessary but increasing the flow rate does not lead to significant reduction of quenching time → **Low porosity/permeability regions are not sensitive to the flow rate**. This means that it is very likely that **some parts of the core would be quenched while other parts would melt**, in spite of the core reflooding.

- **It is likely that the core region would be covered by water quickly after reflooding starts** (even if some parts remain unquenched): the benefit of this situation is that steam entering the hot leg would be rather cold. This means that reflooding would not induce heating and mechanical failure in the circuit or steam generator tubes.

- → **it is necessary to implement a strategy for corium stabilization**, either in the lower head or in the containment (core catcher or backfitting for corium spreading and flooding)

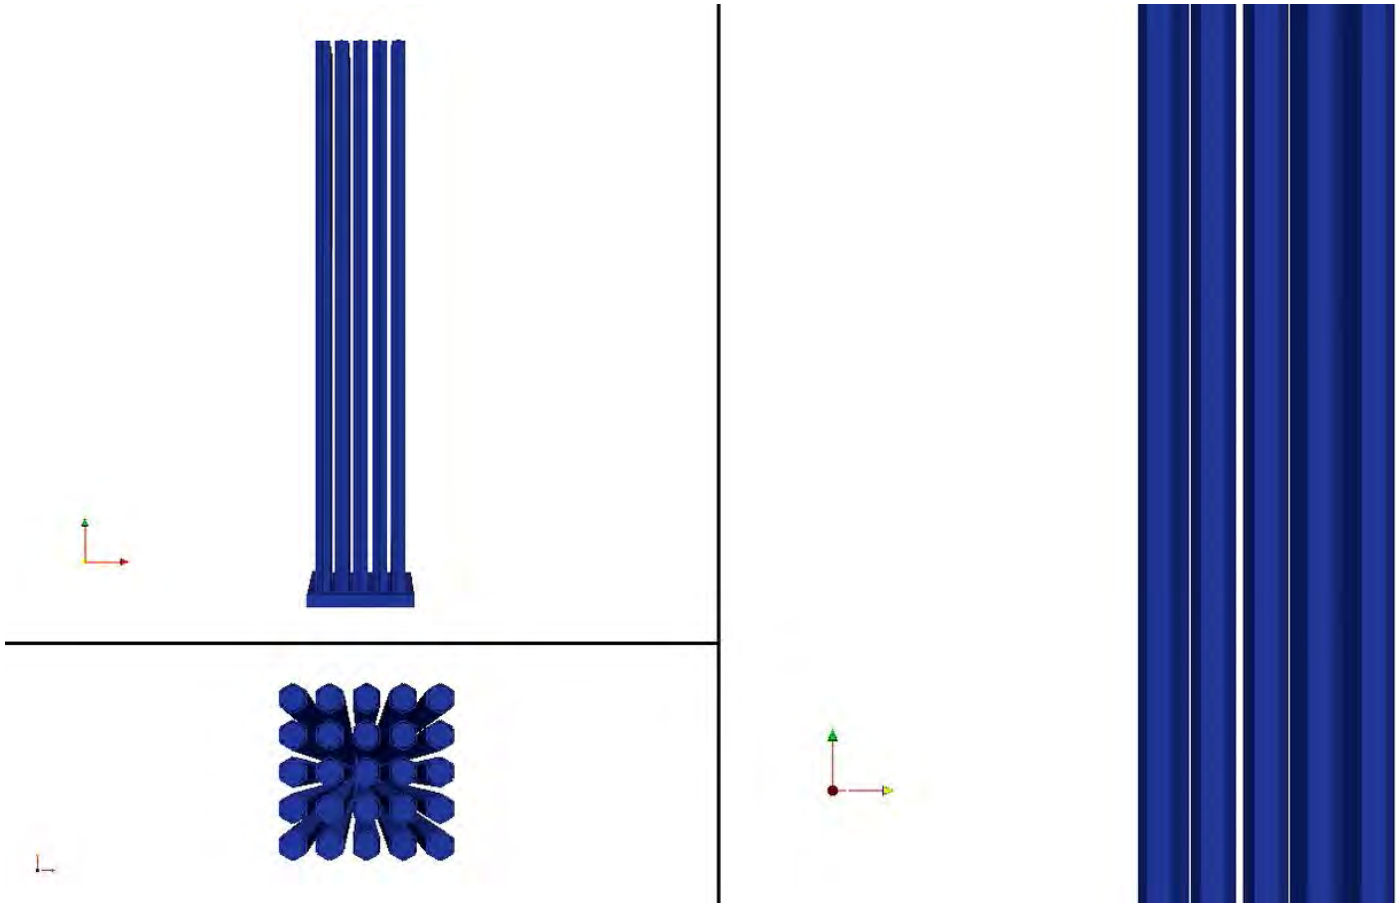
DEBRIS BED FORMATION IN A DAMAGED CORE (2)

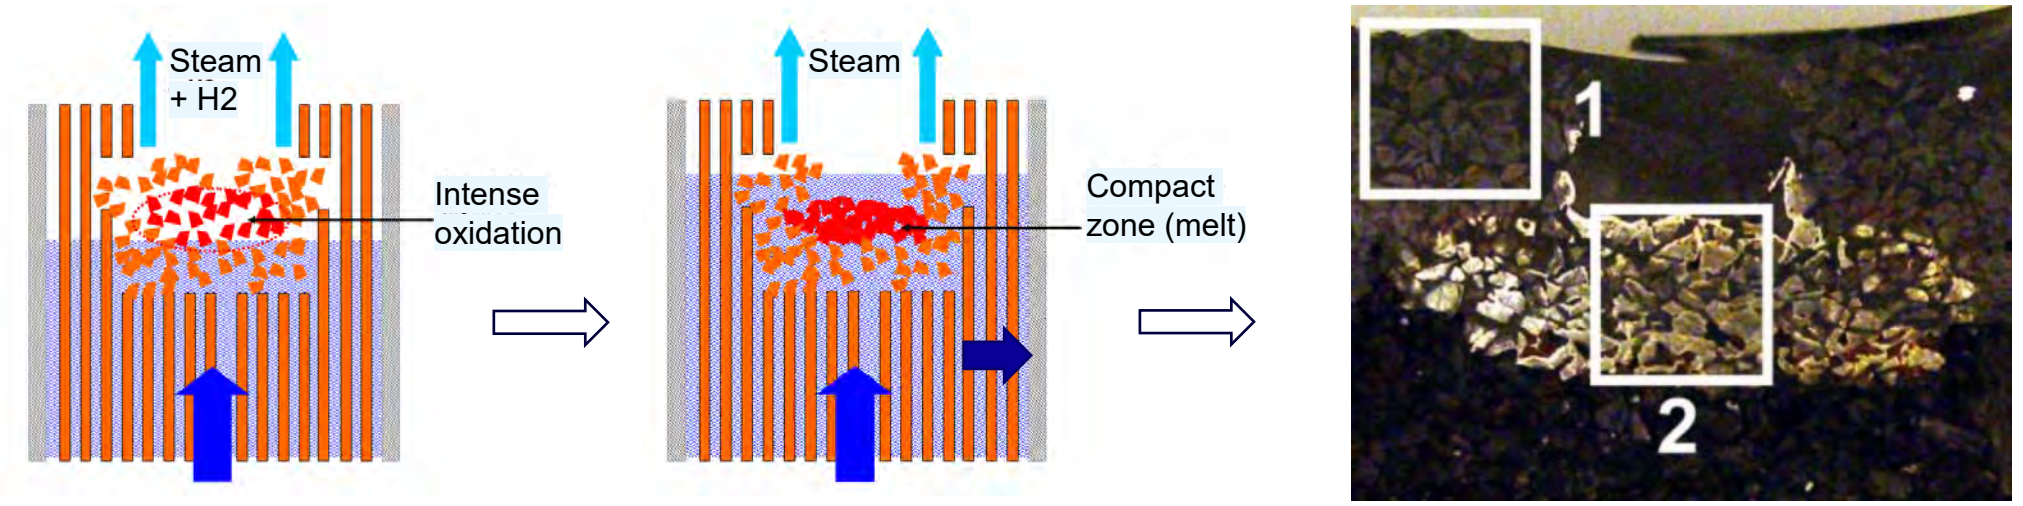


The presence of large fragments of claddings and confined space limits the compaction of debris → rather large porosity and non-isotropic porous medium, with larger axial permeability

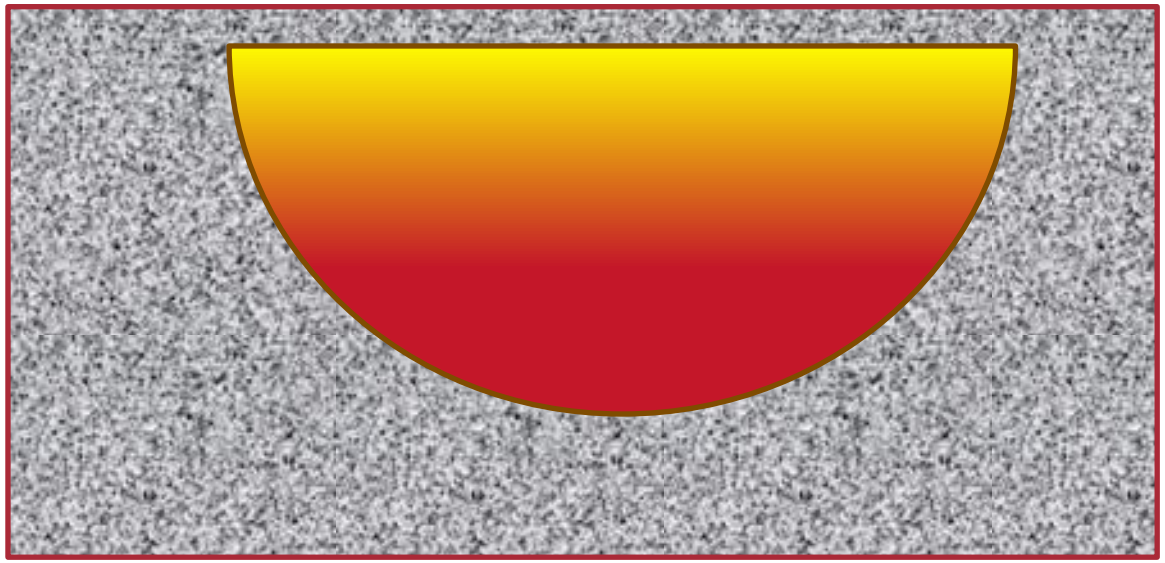
OXIDATION: MELTING OF ZR IN DEBRIS

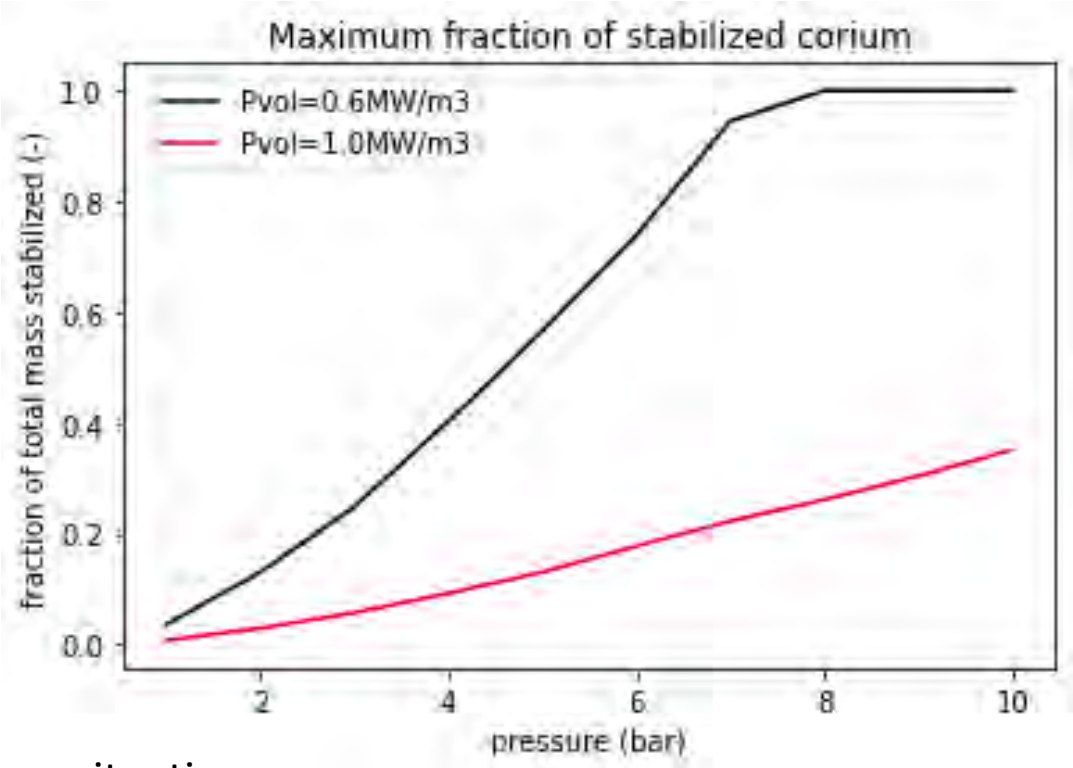
- If Zr is present in the debris bed: strong oxidation will lead to melting of Zr and relocation → reduction of porosity

- If porosity below 25/30% → probable melting UO_2 eventually



STABILIZATION OF A MOLTEN POOL SURROUNDED BY DEBRIS





- Mass of stabilized corium increases with pressure

- Stabilization of a large fraction of the core may be reached in some situations:
  - Late melting of core (more than 12h after scram)
  - High primary pressure (as in TMI-2: near 100bar)

- Otherwise, only a limited fraction of the core may be stabilized → relocation to lower plenum

SIMULATION OF THE LOW PRANDTL LAYER OF A CORIUM POOL

ABSTRACT

As part of the In-Vessel Retention strategy, it is necessary to maintain the local heat flux from the corium pool onto the reactor wall below the critical heat flux. In the stratified configuration of the corium pool, the maximum flux is observed at the level of a highly conductive steel-rich shallow light metal layer, referred to as the focusing effect. Two LES WALE simulations are presented of natural convection in a low Prandtl number fluid (Pr≈0.11) heated from below ($Ra_\Phi = 10^8$) where 10 % and 90 % of thermal losses occur at the upper boundary respectively, mimicking different modes of heat dissipation from the free surface. Strong cooling at the upper boundary produced fluid dynamics broadly consistent with Rayleigh-Bénard convection. Weak cooling of the upper surface revealed an important localized focusing effect, with a local lateral heat flux of around three times the magnitude of heat injection from below, close to the free surface. The dominant lateral heat dissipation produced four large convection cells, demarcated by branches of elevated radial velocity, which rotated in the $r - \theta$ plane. A mild increase in lateral heat dissipation is observed in the proximity of the high velocity branches. The simulations demonstrate very good agreement with corresponding spectral-DNS simulations indicating that the LES WALE approach may offer a computationally feasible solution to extending existing correlations for natural convection in the light metal layer into a higher Rayleigh number regime ($Ra_\Phi > 10^8$), which may be observed in the early stages of a severe accident.

focusing effect, In-Vessel Retention, natural convection, LES

1. INTRODUCTION

In the event of a severe accident within a Pressurised Water Reactor (PWR), and the transfer of very high-temperature molten core materials (corium) to the lower part of the reactor pressure vessel (RPV), the In-Vessel Retention (IVR) mitigation strategy aims to safely dissipate the decay heat generated within the corium in order to prevent the loss of RPV integrity [1]. Safety studies often focus on a stratified corium pool configuration [2], whereby a dense oxide-rich pool containing most of the fuel and fission products dissipates heat to an overlying shallow 'light-metallic' layer, rich in molten stainless steel, uranium and zirconium. An assumption of a stable oxidic crust at the interface between the stratified layers enables each molten layer to be investigated independently [3]. The shallow cylindrical light metal layer is thereby subject to an imposed heat flux from the underlying oxidic corium pool, dissipating heat from its free surface and laterally towards the reactor wall.
The fluid dynamics in the light metal layer are the subject of significant research interest due to the implications of a potential 'focusing effect' [4] [5]. The focusing effect relates to an intensification of the lateral

heat flux imparted from the shallow, highly conductive light metal layer toward the reactor wall. A significant focusing effect could pose a high risk of RPV failure if the lateral heat flux at the reactor wall exceeds the critical heat flux [6]. For severe accident integral codes, such as ASTEC [7], the 0D representation of the light metallic layer requires robust empirical models [8] to accurately describe the heat dissipation within a computationally efficient framework necessary to simulate the transient in close to real time.
To this end, a recent international benchmark exercise on the prediction of the lateral heat flux profile observed during the BALI-Metal experiment [9] was undertaken within the IAEA CRP J46002 framework [5]. Experimental observations of the fluid dynamics were generally well predicted by various CFD approaches. The test case in a thin cuboidal geometry (Figure 1), in which ~42-47 % of the heat injected from below is released at the upper boundary, exhibits significant concurrent heat dissipation from both the upper and lateral boundaries. This results in relatively complex fluid dynamics from the superposition of two convection regimes, Rayleigh-Bénard convection driven by heat transfer in the vertical direction, and larger convection cells produced by buoyancy in the fluid subject to rapid cooling adjacent to the lateral wall and heating along the lower boundary. Depending on the ratio of heat dissipation at the upper and lateral surfaces, either of these competing convection regimes may become dominant. The hybrid fluid dynamics of the light metal layer under different cooling conditions at the upper boundary have been thoroughly characterized by both spectral-DNS simulations [8] and experimentally [10].
Simulations of a prototypic light metal layer with a Rayleigh number of $Ra_{\Phi} = 8.5 \times 10^{11}$ and radiative heat loss at the upper boundary [5] revealed fluid dynamics consistent with the dominant lateral thermal losses, resulting in downward acceleration of cool fluid along the reactor wall, expulsion of a cold jet from the base of the lateral wall along the lower boundary, and detachment of warm fluid from the lower boundary close to the center of the reactor, as illustrated in Figure 1.

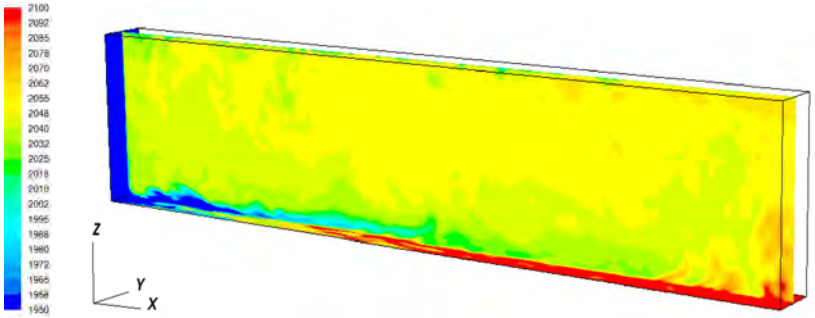

Figure 1: An instantaneous temperature field at steady state from an LES WALE simulation of a prototypical light metal layer with radiative heat loss from the upper boundary [5].

The IAEA CRP J46002 benchmark enabled assessment of different numerical approaches to simulating the fluid dynamics of the light metal layer, including different sub-grid turbulence models, near-wall treatments and different resolutions of spatial discretization. The benchmark also highlighted a number of issues requiring further research:

- The BALI-Metal experiments were performed using water (Pr ≈ 7) as a simulant. Additional experimental data in more representative low-Prandtl number fluids closer to metallic corium (Pr ≈10^{-2}), would be valuable.
- Simulations performed using a representative shallow cylindrical geometry, in order to observe the global 3D fluid dynamics, are required to in addition to those in a quasi-2D, or thin cuboidal, geometry representing a thin slice through the metal layer in the $r - z$ plane, as employed for the BALI-Metal experiments.
- Severe gradients in the lateral heat flux profile are observed both at the base of the lateral wall, below the cold jet, and close to the free surface where the maximum focusing effect is observed

(see Figure 2, [5]). The heterogeneity in the localized focusing effect at the lateral wall, particularly close to the free surface, should be considered during safety studies, rather than simply the surface-averaged lateral heat dissipation from the metal layer onto the reactor wall.

- Simulations should take particular care to ensure sufficient mesh refinement within the critical zones at the lower and upper extremes of the lateral boundary. The benchmark revealed some departure between numerical approaches within the corner between the heated lower boundary and the base of the cold lateral wall (Figure 2). Some approaches identified a significant spike in lateral heat flux below the cold jet, which was not clear from simulations with less near-wall mesh refinement. Further validation was deemed to be required regarding the local heat flux observed at the top and bottom of the lateral wall.

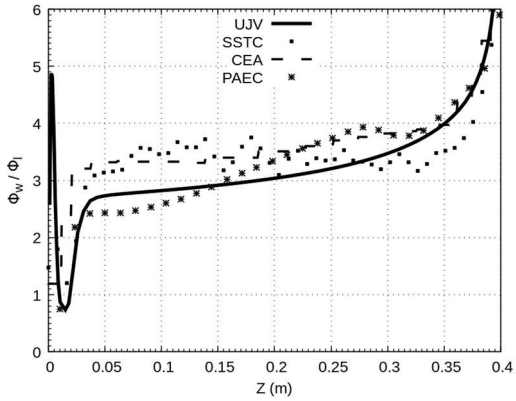

Figure 2: Distribution of the predicted dimensionless lateral heat flux profiles (the ratio of lateral heat flux to the heat flux injected from below) for a prototypic test case [5].

Following the IAEA CRP J46002 benchmark, the CEA is expanding its investigation into the fluid dynamics of the light-metallic layer by validating its CFD code TrioCFD with simulations of a low-Prandtl number fluid in a representative cylindrical geometry. The selected test cases are taken from a study by [8], which presents an extensive investigation of the fluid dynamics for conditions of $10^2 \leq Ra_\Phi \leq 10^9$; with Ra_Φ, the Rayleigh number based heat flux, $4 \leq \Gamma = \mathrm{R}/H \leq 16$; R and H being the radius and height, respectively, $0.1 \leq \widehat{\Phi}_u = -\frac{\Phi_u}{\Phi_l} \leq 0.9$ (the ratio of upper and lower heat flux) and $Pr = 0.1$ using a spectral-DNS code [11]. This investigation has enabled significant progress in the understanding of the complex convection behaviour resulting from the superposition of flow fields characteristic of Rayleigh-Bénard convection ($\widehat{\Phi}_u \to 1$) and convection induced by lateral cooling ($\widehat{\Phi}_u \to 0$). Spectral-DNS simulations were validated using experimental data acquired using air and air-SF_6 mixtures as low-Prandtl number fluids [12] with particle image velocimetry (PIV) characterisation of the velocity field. The current study presents a numerical investigation of two test cases, pertaining to a prototypic corium test fluid with a Prandtl number of $Pr = 0.11$, an external Rayleigh number of $Ra_\Phi = 10^8$, an apect ratio of $\Gamma = 4$, and upward heat flux ratios of $\widehat{\Phi}_u = \{0.1, 0.9\}$. Simulations are performed using a finite volume discretisation and an LES WALE [13] sub-grid turbulence closure model. Results are compared with corresponding simulations undertaken using spectral-DNS [8].

2. NUMERICAL METHODS

The dimensions of the cylindrical light metal layer are reduced by a factor of around 5 in comparison with the radius of a typical PWR. The simulation scale was chosen for consistency with the dimensions of an

experimental rig used to investigate the natural convection fluid dynamics in low Prandtl number fluids [12][14].

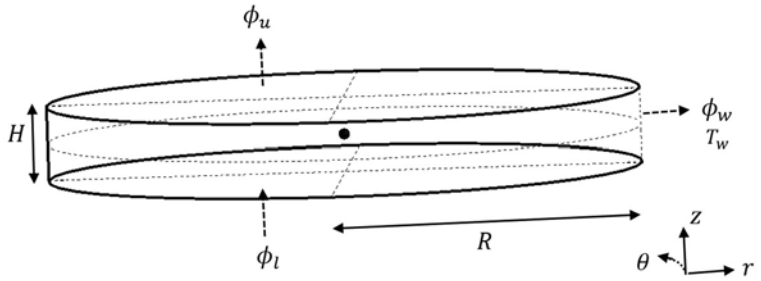

Figure 3: Schematic of the cylindrical fluid layer of depth H and radius R with heat flux of ϕ_l, ϕ_u and ϕ_w and the lower, upper and lateral walls respectively.

The light metal later is represented as a shallow cylinder 0.11 m in depth and 0.44 m in radius, corresponding to an aspect ratio of $\Gamma = R/H = 4$. The fluid layer is heated from below by a uniform flux of $\Phi_l = 2.1\ 10^5$ W m^{-2}, corresponding to an external Rayleigh number of $Ra_\Phi = 10^8$. Heat is dissipated from the upper boundary, with a uniform heat flux of Φ_u, and from the lateral wall with a heterogeneous heat flux, $\Phi_w(\theta, z)$. Hereafter, heat flux data at surface $i \in u, w, l$, for the upper, lateral and lower boundaries respectively, will be presented in dimensionless form, $\widehat{\Phi}_i = -\Phi_i/\Phi_l$. Thus, heat dissipation from the upper and lateral boundaries will present with a positive dimensionless heat flux. In the present investigation, two test cases are simulated with $\widehat{\Phi}_u$ = 0.1 and 0.9 respectively. The vertical lateral boundary is considered to be isothermal, with a wall temperature fixed at the melting point of the fluid, thereby mimicking a crust of the same composition at the lateral wall of the reactor vessel. The velocity boundary conditions at all three boundaries are modelled as no-slip.

The prototypic light metallic corium to be simulated is assumed to be composed largely of stainless steel with non-negligible concentrations of uranium and zirconium. The fluid is assumed to be incompressible, using a Boussinesq approximation to account for the density variation with temperature. The assumed physical properties the light metal layer are detailed in Table I. The Prandtl number of the fluid is 0.11, enabling comparison with corresponding spectral-DNS simulations using a fluid with a Prandtl number of 0.10 [8].

Table I. Estimated physical properties of the prototypic light metallic corium, assumed to be independent of temperature.

Density (kg m^{-3})	Dynamic viscosity (Pa s)	Thermal conductivity (W m^{-1} K^{-1})	Specific heat capacity (W kg^{-1} K^{-1})	Linear expansion coefficient (m^{-1})	Thermal diffusivity (m^2 s^{-2})	Melting point (K)
7000	5×10^{-3}	20	450	3×10^{-5}	6.3×10^{-6}	1700

The natural convection fluid dynamics in the light metal layer are resolved numerically by large eddy simulation (LES), using the TrioCFD code [15]. LES can offer a significant reduction in computational cost in comparison with direct numerical simulations (DNS) by low-pass filtering the Navier-Stokes equations. Larger scales are directly resolved, as with DNS, while the smallest length scales of the energy cascade, which are computationally intensive to resolve, are modelled. Here, the low-pass filter is applied at the mesh resolution and thus the mesh was constructed at a resolution sufficient to directly resolve at least 80 % of the turbulence energy spectrum. The discretisation of the fluid was informed by results of the spectral-DNS simulations of Rein [12]. The domain-averaged turbulence kinetic energy and dissipation rate indicated

Taylor scales of 9.4 mm and 10.1 mm at $\widehat{\Phi}_u = 0.1$ and 0.9 respectively. An unstructured mesh of tetrahedral elements was constructed with a 9 mm resolution in the bulk, refined through the boundary layer to a resolution of 900 μm at the walls, comparable to the Kolmogorov length scale. The resulting mesh consisted of around 9 million tetrahedral elements.

In the filtered Navier-Stokes equations, LES uses a turbulent eddy viscosity, ν_t, to model the sub-grid stress tensor. The Wall-Adapting Local Eddy-viscosity (WALE) implementation [13] uses a spatiotemporal operator to model the eddy viscosity derived from both the strain and rotation of the flow, rather than simply the former as in the case of classical Smagorinky approaches [16]. Furthermore, the operator reproduces realistic asymptotic decay in the eddy viscosity towards the wall without implementation of a near-wall filter [13]. LES WALE simulations have previously shown promise [5] in accurately simulating natural convection driven by an imposed heat flux at the lower boundary within the quasi-2D geometry employed for the BALI-Metal experiments [9]. Closure of the energy conservation equation is treated similarly as in [5], using a turbulent thermal diffusivity to resolve the sub-grid turbulent heat flux. The Simple Gradient Diffusion Hypothesis (SGDH) assumes proportionality between the turbulent shear stress and turbulent heat flux, which enables the turbulent thermal diffusivity to be approximated as $\alpha_t = \nu_t/\mathrm{Pr}_t$, where the coefficient of proportionality, Pr_t, is the turbulent Prandtl number. The turbulent Prandtl number is estimated in the 0.85-0.9 range for many engineering fluids with molecular Prandtl numbers close to unity [17] and close to 2 in liquid metals [18]. The two test cases presented are simulated using a turbulent Prandtl number of 2.

The two simulations were tracked until the thermal losses reached an apparent equilibrium with the heat injection from below and the mean and maximum fluid temperatures converged to a steady state. They achieved a pseudo-steady state after around 500 s of simulation time. Statistical analysis of the turbulent fluctuations in the resolved variables was then performed.

2.1. Non-dimensionalisation and nomenclature

In order to facilitate comparison with corresponding spectral-DNS calculations [8], results will be presented using the same non-dimensionalisation scheme, where the dimensionless temperature, $\hat{T}$, time, $\hat{t}$, length, $\hat{l}$, and heat flux, $\widehat{\Phi}_i$, are expressed as follows:

$$\hat{T} = \left(T - T_{mp}\right)\frac{\lambda}{\Phi_l H},\ \hat{t} = \frac{H^2}{\alpha},\ \hat{l} = \frac{l}{H},\ \widehat{\Phi}_i = -\frac{\Phi_i}{\Phi_l} \quad (1)$$

where T_{mp} is the melting point. Temporal-averages of variable 'x' are presented as $\bar{x}$ and fluctuations are $x' = x - \bar{x}$ respectively. Domain-averages over all spatial dimensions are denoted $\langle x \rangle$, while spatial-averages over dimensions i and j are expressed $\langle x \rangle_{i,j}$.

3. RESULTS AND DISCUSSION

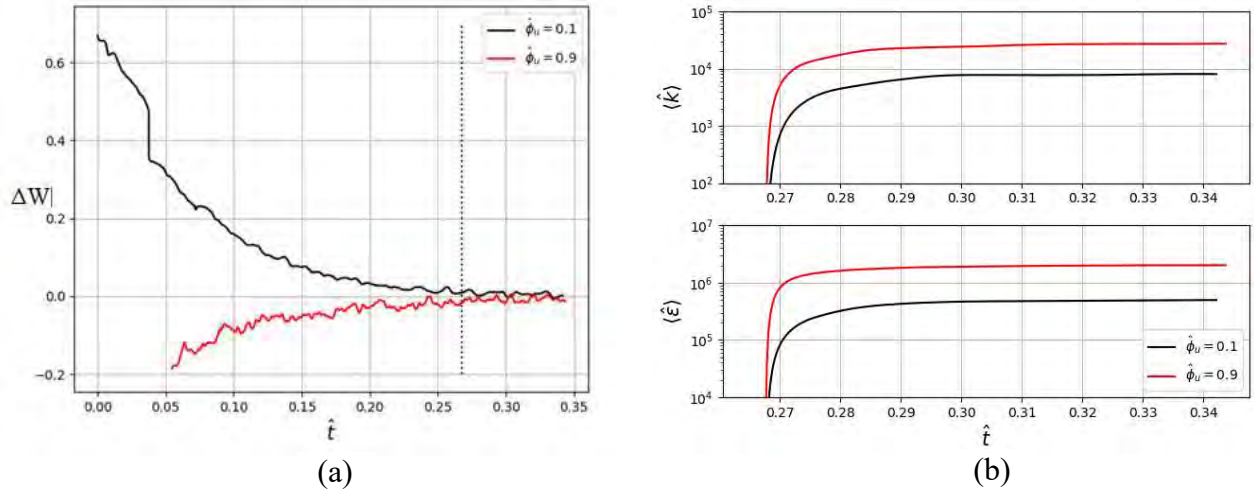
The following sections discuss the structure of the convective flow observed during the two test cases, through the distribution of the mean temperature and velocity fields, the turbulence kinetic energy and its dissipation rate, as well as the distribution of the thermal losses from the lateral wall. An initial transient period was simulated. The calculation was deemed to have achieved a pseudo-steady state when the heat dissipation from the upper and lateral walls reached equilibrium with the heat injection from below. The rate of energy accumulation in the fluid normalized by the rate of energy input at the lower boundary is expressed as $\Delta W = 1 - \widehat{\Phi}_l - \frac{1}{\pi R^2}\int_0^H \int_0^{2\pi} \widehat{\Phi}_l \, d\theta \, dz$.

From $\hat{t} = 0.265$ (or 505 s), both test cases converged to $|\Delta W| < 0.023$ (Figure 4a), indicating that the energy accumulation/dissipation rate, including temporal fluctuations, was less than 2.3 % of the energy injection rate. At pseudo steady-state, statistical analysis of the stationary and transient components of the resolved fields was performed. The turbulence kinetic energy ($\hat{k}$) and dissipation rate ($\hat{\varepsilon}$) are estimated from half the

sum of the variance in the velocity components and the gradients of the fluctuating components of the velocity as follows:

$$\hat{k} = \left(\frac{H^2}{\alpha^2}\right)\frac{\overline{(u_i')^2}+\overline{(u_j')^2}+\overline{(u_k')^2}}{2}\ ;\quad \overline{(u_i')^2} = \frac{1}{t_2-t_1}\int_{t_1}^{t_2}(u_i(t)-\bar{u}_i)^2\,\mathrm{d}t\ ;\qquad \hat{\varepsilon} = \left(\frac{H^4}{\alpha^3}\right)\frac{\nu}{2}\overline{\left(\frac{\partial u'_\iota}{\partial x_J}+\frac{\partial u'_J}{\partial x_\iota}\right)^2} \quad (2)$$

With H the height of the domain, α and ν the thermal and dynamic viscosity, respectively
The evolution of the domain average turbulence kinetic energy and dissipation rate during the post-processing period shows that both metrics had converged to constant values from $\hat{t} > 0.34$ ($t > 650$ s) for the two test cases (see Figure 4b).



(a) (b)

Figure 4: (a) Normalised heat accumulation rate in the fluid and (b) convergence of the estimated domain average turbulent kinetic energy (top) and dissipation rate (bottom) during statistical post-processing at steady state.

3.1 Convective flow behaviour where lateral thermal losses are dominant ($\hat{\Phi}_u = 0.1$)

Two planar views of the instantaneous temperature field, superposed with the instantaneous velocity vectors, are presented at $\theta = 0°$ and $\hat{z} = 0.9$ in Figure 5a and b respectively for the test case with dominant lateral heat loss.
The fluid accelerates downwards along the cold lateral wall and a high velocity cold jet is expelled from the base of the lateral wall towards the centre of the fluid layer. As fluid increases in temperature along the heated lower boundary, warm metal eventually detaches, close to the centre of the fluid layer, and rises towards the free surface in a high temperature 'chimney'. This recirculation is observed as a convection cell in the $r - z$ plane occupying the full radius and height of the metal layer. From the $r - \theta$ plane at $\hat{z} = 0.9$, four high velocity 'branches' are observed demarcating four roughly equivalent convection cells. The rotational pattern and number of branches are consistent with observations from spectral-DNS simulations [8] and experiments using air ($Pr = 0.7$) as a low-Prandtl number simulant [14] above a threshold Rayleigh number, required to establish the rotating flow, in the order of $Ra_\Phi \sim 10^5$.
Animation of the temperature and velocity fields indicated that the high-temperature, high-velocity branches rotated in an anticlockwise direction through an angle of around 65° during a period of $\hat{t} = 0.022$, corresponding to a dimensionless rotation time of $\hat{t}_{360°} = 0.122$, or just under 4 minutes. Given the relatively

slow rotation, simulating several rotational cycles at steady state entails significant computational expense, and thus it remains unclear whether a constant rotational velocity has been established.

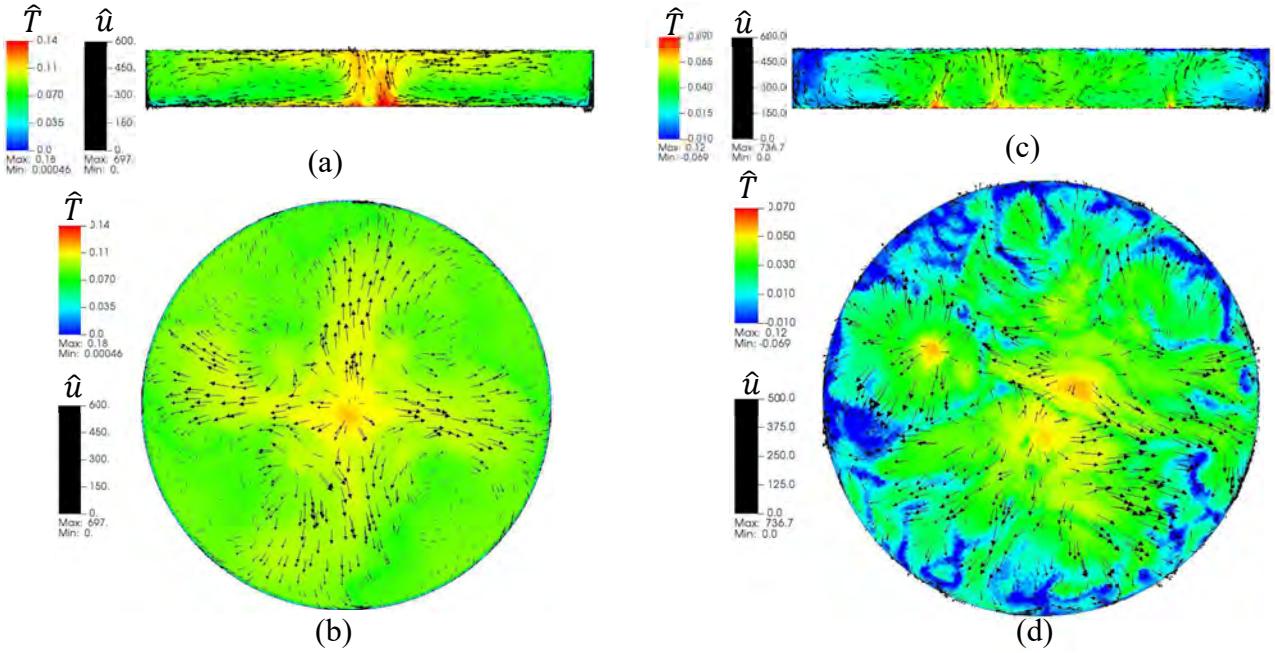


Figure 5: Visualisation of the dimensionless instantaneous temperature field superposed with the dimensionless instantaneous velocity vectors for the $\widehat{\Phi}_u = 0.1$ (a,b) and $\widehat{\Phi}_u = 0.9$ (c,d) test cases in (a,c) the $r - z$ plane at $\theta = 0°$ and (b,d) the $r - \theta$ plane at $\hat{z} = 0.9$

3.2 Convective flow behaviour where thermal losses at the upper boundary are dominant ($\widehat{\Phi}_u = 0.9$)

Two equivalent planar views of the instantaneous temperature field, superposed with the instantaneous velocity vectors, are presented for the $\widehat{\Phi}_u = 0.9$ test case at $\theta = 0°$ and $\hat{z} = 0.9$ in Figure 5c and d respectively. Downward acceleration of fluid is observed at the outer boundary; however, given the reduced lateral heat dissipation, this acceleration is less significant than the $\widehat{\Phi}_u = 0.1$ test case. Rather than generating very large permanent convection cells occupying the full radius of the fluid later, the weaker acceleration drives smaller outer convection cells. These outer convection cells remain larger in radial dimension than the axial direction, but are significantly less large in radial dimension than those observed during the $\widehat{\Phi}_u = 0.1$ test case.

Towards the centre of the fluid layer, multiple convection cells comparable in dimension to the depth of the fluid layer are observed. Hot plumes of fluid detach from the lower boundary at various locations rather than in a single chimney close to the centre of the fluid layer. The hot plumes detach, rise towards the free surface. These fluid dynamics at the centre of the fluid layer appear consistent with Rayleigh-Bénard convection. Relatively mild lateral heat dissipation from the fluid layer appears sufficient to drive larger, less axisymmetric convection cells adjacent to the outer boundary and a departure from conventional Rayleigh-Bénard convection in the outer radial zone. In the case of especially poor cooling at the upper boundary, or below a threshold dimensionless upward heat flux, $\widehat{\Phi}_u$, the non-axisymmetric outer convection cells occupy

the full radius of the fluid layer and the rotating permanent convection cell configuration is established. The fluid dynamics appear consistent with those observed by [8].

3.3 The mean temperature and turbulence fields

A two-dimensional representation of the stationary component of the temperature field was obtained from a temporal average of the temperature field in the $0.26 < \hat{t} < 0.34$ period, averaged in the theta axis ($0 \leq \theta \leq 360°$). This 2D mean temperature field, $\langle \hat{\tilde{T}} \rangle_\theta$, was then interpolated at regular intervals in the $\hat{z}$ axis and averaged to obtain a depth averaged radial temperature profile, $\langle \hat{\tilde{T}} \rangle_{\theta,z}$, for comparison with spectral-DNS results from [8] (see Figure 6). The LES and spectral-DNS predictions superpose very closely for the $\widehat{\Phi}_u = 0.1$ test case, with only a marginally elevated temperature in the hot chimney at the centre of the metal layer ($\hat{r} < 0.3$) predicted by the LES WALE simulation. The LES WALE simulation predicts a marginally lower bulk temperature for the $\widehat{\Phi}_u = 0.9$ case, but the two numerical approaches appear to exhibit excellent agreement in their predictions of the temperature field.

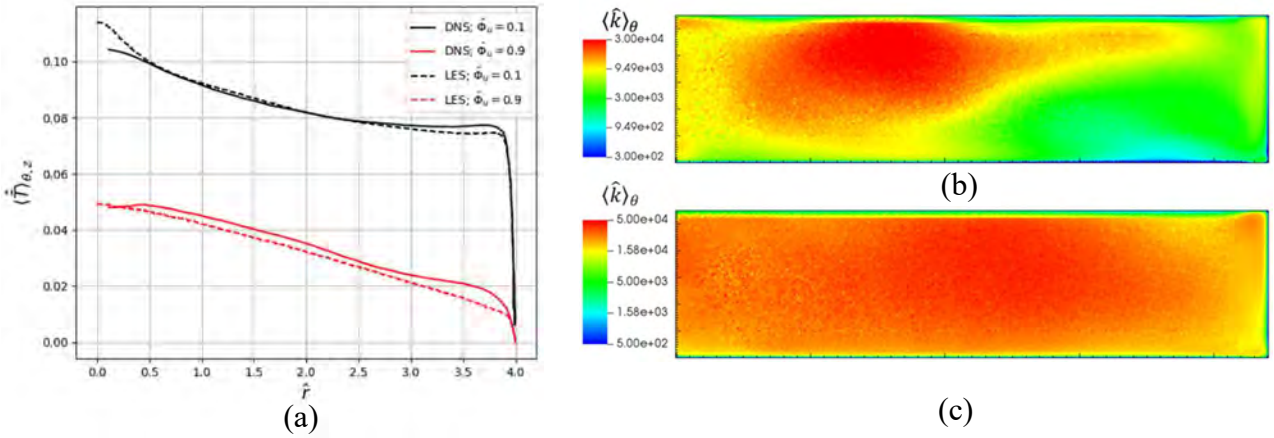

Figure 6: (a) Comparison of the radial profiles of the depth averaged mean temperature between the LES WALE and spectral-DNS [8] simulations, and the theta-averaged turbulence kinetic energy fields, $\langle \hat{k} \rangle_\theta$, for the (b) $\widehat{\Phi}_u = 0.1$ and (c) $\widehat{\Phi}_u = 0.9$ test cases (increasing in $\hat{r}$ from left to right).

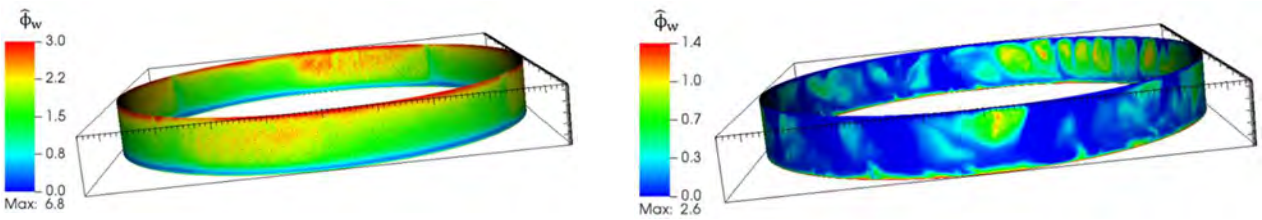
The theta-averaged turbulence kinetic energy fields are presented (using a logarithmic scale) for the two test cases in Figure 6b-c. For the $\widehat{\Phi}_u = 0.1$ test case, elevated turbulence kinetic energies are observed at the centre of the large rotating convection cells previously observed in Figure 5 with a concentration of turbulence kinetic energy closer to the centre of the fluid layer, $\hat{r} < \Gamma/2$. The turbulence kinetic energy dissipates rapidly within the upper and lower boundary layers. For the $\widehat{\Phi}_u = 0.9$ test case, the multiple, more axisymmetric convection cells of shorter duration, more consistent with Rayleigh-Bénard convection, produce a more homogeneous distribution of turbulence kinetic energy in the $r - z$ plane through the bulk, while also dissipating rapidly through the boundary layers.

3.4 Distribution of the thermal losses from the lateral wall

The spatial distribution of the dimensionless instantaneous heat flux at the lateral wall, $\widehat{\Phi}_w$, is presented for the two test cases in Figure 7. For the $\widehat{\Phi}_u = 0.1$ test case, a relatively uniform band of elevated heat dissipation is observed at the top of the lateral wall, revealing the focusing effect. The heat flux is around 3-times

the magnitude of the rate of heat injection from below. Diminished thermal losses are observed at the base of the lateral wall, in the region from which the cold jet is propelled along heated lower boundary. At intermediate depths ($0.2 < \hat{z} < 0.9$) focusing effects in the order of $1.4 < \hat{\phi}_w < 2.4$ are observed, with elevated heat dissipation in the proximity of the high velocity 'branches' previously observed in Figure 5.
For the $\widehat{\Phi}_u = 0.9$ test case, negligible heat losses are observed over much of the lateral boundary, $\hat{\phi}_w < 0.3$, punctuated by zones of elevated heat dissipation in the vicinity of the outer convection cells. Maximum local heat flux values comparable in magnitude to the rate of heat injection from below are observed. Unlike the significant, permanent lateral heat dissipation at the top of the fluid layer in the $\widehat{\Phi}_u = 0.1$ test case, the zones of elevated local heat dissipation ($\hat{\phi}_w > 0.7$) are transient in nature, presenting over the timescale of near-wall convection cells. By contrast, a very thin permanent layer adjacent to the lower boundary exhibits heat dissipation in excess of the rate of heat injection, $\hat{\phi}_w < 1.4$.



(a) (b)

Figure 7: Instantaneous dimensionless heat flux from the lateral wall, $\widehat{\Phi}_w$, for the (a) $\widehat{\Phi}_u = 0.1$ and (b) $\widehat{\Phi}_u = 0.9$ test cases.

The steady-state component of the lateral heat flux is approximated by the non-dimensional heat flux field, averaged over time and the theta-axis, $\left\langle \widehat{\Phi}_w \right\rangle_\theta$, which is presented for the two test cases as a function of axial position in Figure 8. Corresponding results of spectral-DNS simulations [8] are presented for comparison. The LES demonstrates particularly good agreement with the spectral-DNS for depths of $\hat{z} < 0.8$. The elevated heat dissipation immediately adjacent to the heated lower boundary and the reduction in heat dissipation at the base of the cold jet are in particularly good agreement between LES and spectral-DNS.
For the $\widehat{\Phi}_u = 0.9$ test case with dominant heat dissipation from the free-surface, the LES prediction of the lateral heat flux in the vicinity of the free surface ($\hat{z} > 0.9$) exhibits some departure from the spectral-DNS. For both simulations, the dimensionless lateral heat flux becomes negative in this region, implying local fluid temperatures below the corium melting point. This is an artefact of approximating the corium-crust interface at a fixed location in order to avoid the computational expense of modelling the transient displacement of the solidification front. The negative dimensionless lateral heat flux predicted by both LES and spectral-DNS approaches indicates a likelihood of some crust development at the confluence of the lateral wall and the free surface. The mild departure between the LES and spectral-DNS in the region where the metal is anticipated to solidify is not of significant concern.
The LES simulation of the test case with dominant lateral heat dissipation, $\widehat{\Phi}_u = 0.1$, exhibits a more significant departure from the spectral-DNS close to the free surface ($\hat{z} > 0.9$). This region is of particular interest since the maximum focusing effect is observed very close to the free surface. While the spectral-DNS indicates a continuous increase in lateral heat dissipation up to a maximum of $\langle \hat{\phi}_w \rangle_\theta \approx 3.5$ very close to the free surface, the LES peaks at $\langle \hat{\phi}_w \rangle_\theta \approx 2.8$ marginally below the free surface with a very mild reduction in the immediate proximity of the free surface. The disparity is considered to be a numerical artefact of the spatial discretisation employed for the LES simulation close to the free surface. The significant refinement of the unstructured mesh over a narrow upper boundary layer results in a relatively large ratio in characteristic mesh dimension between neighbouring cells, which poses a challenge for the finite volume element (VEF) discretisation scheme [15].

The axial profile of the lateral heat dissipation for the $\widehat{\Phi}_u = 0.1$ test case qualitatively resembles the thin cuboidal simulation results of a prototypic test case [5], where $\widehat{\Phi}_u = 0.34$, $\Gamma = 5$ and $Ra_\Phi = 8.5 \times 10^{11}$, presented in Figure 2. The reduction in lateral heat dissipation in the vicinity of the base of the cold jet, the progressive increase in heat dissipation towards the free surface at intermediate depths, and the rapid escalation of the focussing effect close to the free surface are common features of the two simulations and can be considered characteristic of test cases with poor cooling at the upper boundary. However, for the thin cuboidal simulation at an elevated Rayleigh number, the weak lateral dissipation zone at the base of the cold jet is shallower, the magnitude of the lateral heat dissipation from intermediate depths and the severity of the focussing effect are greater in the thin cuboidal simulation. Care should be taken when comparing the magnitude of heat losses from the lateral wall between the thin cuboidal and cylindrical geometries as the cylindrical geometry offers a much greater surface for lateral heat dissipation. Consequently, $\langle \widehat{\Phi}_w \rangle = \Gamma(1 - \widehat{\Phi}_u)$ for the thin cuboidal geometry, while $\langle \widehat{\Phi}_w \rangle = \frac{\Gamma}{2}(1 - \widehat{\Phi}_u)$ for cylindrical geometries. It is reassuring that simulations in both the cylindrical and thin cuboidal geometry produce consistent trends in the lateral heat flux profiles for cases which poorly dissipate heat at the upper boundary. However, the heterogeneity in lateral heat flux as a function of angular coordinates identified in Figure 7, driven by the rotation of large persistent convection cells, demonstrates a clear advantage of simulating the full cylindrical domain and averaging heat flux for cases where the required computational resources are not prohibitive.

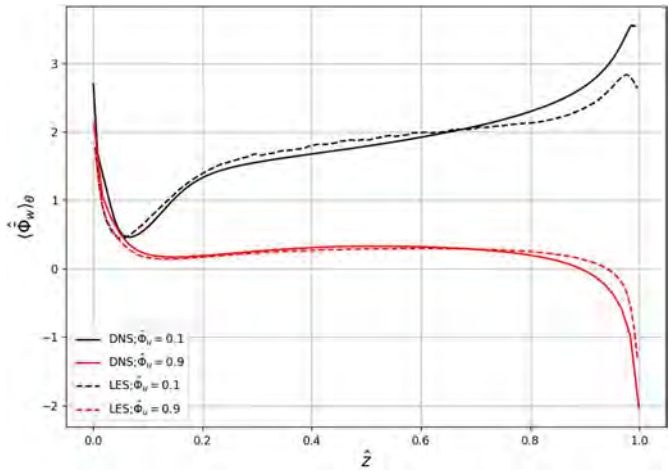


Figure 8: Comparison of the theta-averaged dimensionless heat flux at the lateral wall between LES (present study) and spectral-DNS [8].

4. CONCLUSIONS

Maintaining a local lateral heat flux from a stratified corium pool below the critical heat flux is an essential component of the In-Vessel Retention strategy. A maximum flux is observed at the level of a highly-conductive steel-rich shallow light metal layer, referred to as the focusing effect. Two LES WALE simulations were performed to assess the lateral heat flux distribution from a cylindrical pool of low Prandtl number fluid ($Pr = 0.11$), heated from below with an external Rayleigh number of $Ra_\Phi = 10^8$, with strong and weak cooling at the upper surface (90% and 10% of the rate of heat injection from below respectively, or $\widehat{\Phi}_u = 0.9$ and 0.1). Simulations demonstrated very good agreement with corresponding spectral-DNS simulations [8] in terms of the steady state temperature and lateral heat flux distributions. The LES WALE approach to modelling the smallest length scales of the turbulent energy cascade may therefore offer a computationally feasible solution to extending existing correlations for natural convection in the light metal layer into a higher Rayleigh number regime ($Ra_\Phi > 10^8$), taking into account lateral profile.

In the case of dominant heat dissipation at the upper surface was characterized by more axisymetric and shorter-lived convection cells away from lateral boundary comparable in dimension with the depth of the fluid layer, consistent with Rayleigh-Bénard convection. Slightly larger, les axisymmetric convection cells were observed adjacent to the lateral boundary. The simulations indicate that additional metallic crust is likely to develop at lateral wall in the vicinity of the upper surface. The case of weak heat dissipation at the upper surface was characterized by significant downward acceleration of fluid at the lateral boundary, ex-pulsion of a cold jet from the base of the lateral wall and recirculation of warm fluid in a chimney at the center of the fluid layer. These phenomena resulted in the formation of four[1] large permanent convection cells, demarcated by branches of elevated radial velocity, occupying the radius and depth of the fluid layer, which were observed to rotate in an anticlockwise direction. The maximum local heat dissipation from the lateral boundary was in the order of three times the magnitude of heat injection from below.
The lateral heat flux profile and convective flow behaviour in the $r-z$ plane observed for the case of limited heat dissipation at the upper boundary appear consistent with simulations of a prototypic test case, with a significantly elevated Rayleigh number of $Ra_{\Phi} = 8.5 \times 10^{11}$ and radiative heat dissipation at the upper surface, performed within the IAEA CRP J46002 framework [5]. The prototypic test case was simu-lated using a quasi-2D geometry, representing a thin slice through the $r-z$ plane. While the quasi-2D geometry appears sufficient to predict the mean heat dissipation behaviour at the lateral boundary, the tran-sient peaks in local heat flux in the vicinity of the rotating branches is only captured by simulating the full cylindrical geometry. Work is ongoing to smooth the near-wall mesh refinement to determine whether better agreement with the spectral-DNS can be achieved in a small zone of elevated heat dissipation adjacent to the lateral and upper boundaries. Future work includes plans to couple LES WALE simulations with an enthalpy-porosity model to account for steel solidification.

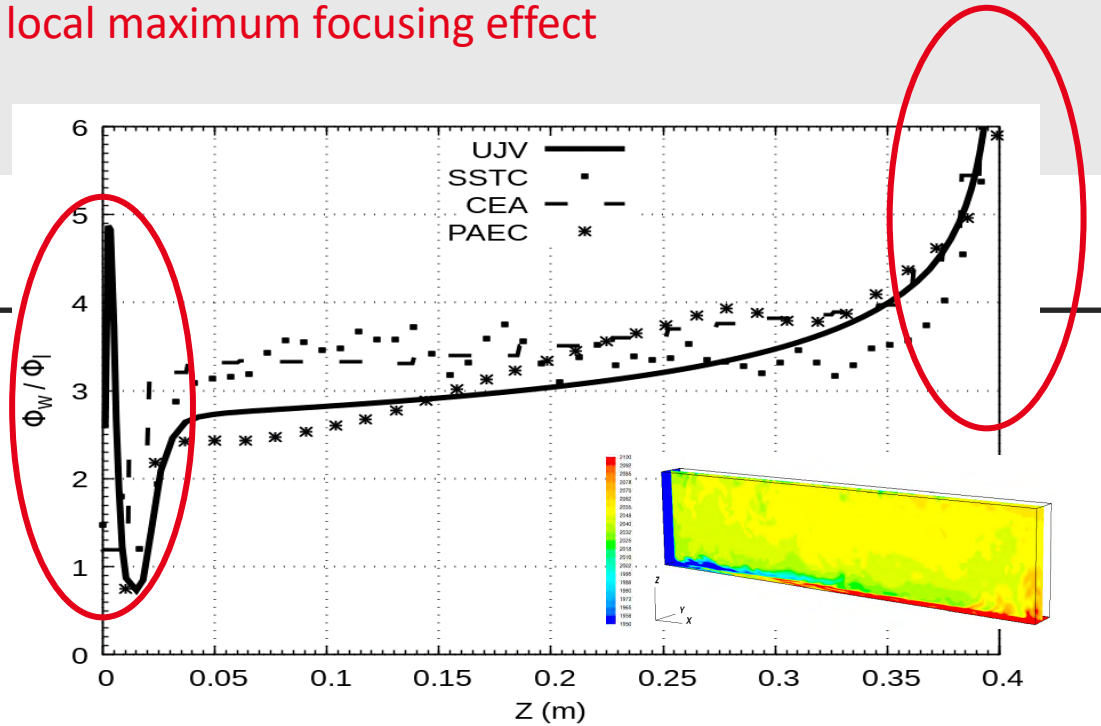
- a representative cylindrical geometry



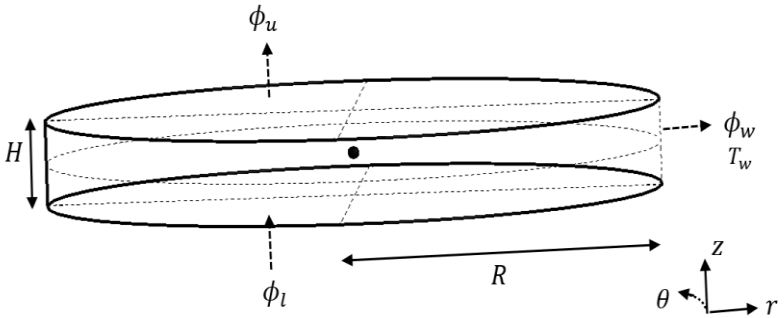
Evolution of lateral heat flux over lower one along the height (vessel surface)

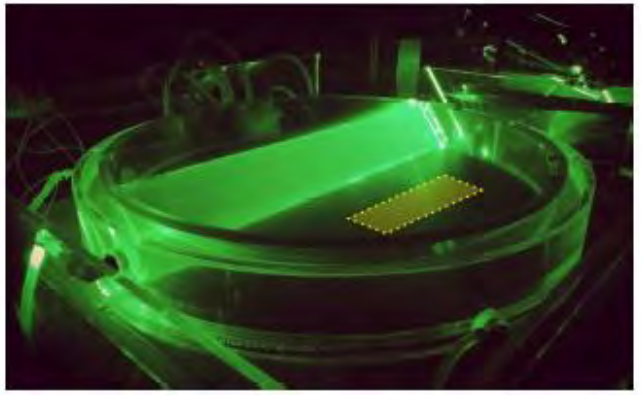
Test case & Numerical method (1/2)

Representative test case : Rein et al. 2025, 10.1017/jfm.2025.2. hal-05177850

FOCUS experiment *(data not available)*
- Cylindrical ($\Gamma = R/H = 4$) ; R=0.44 m
- Seeded SF6 – low Prandtl

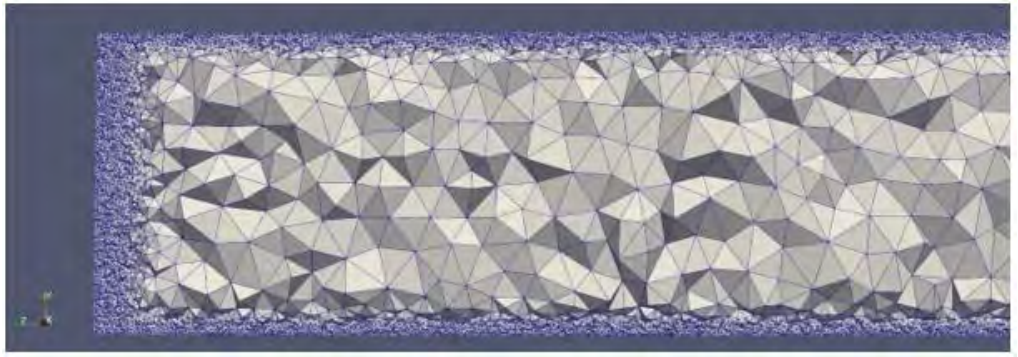
Prior to experiment : **DNS NEK 5000 simulations**
- Pr=0.11 - $Ra_\Phi = 10^8$
- $\Phi_l = 2.1\ 10^5$ W m^{-2} - uniform
- 2 cases : $\widehat{\Phi}_u = \frac{\phi_u}{\phi_l} = 0.1$ and 0.9 - ϕ_u uniform, $\phi_w(\theta, z)$
- Vertical boundary, $T_w = cst$ - melting point (mimicking a crust)
- Velocity boundary conditions at all three boundaries as no-slip





Our simulation (same methodology than in **CRP J466002**):
- Geometry $\Gamma = R/H = 4$) ; R=0.44 m
- Pr=0.11
- Same boundary conditions as DNS NEK 5000 simulations
- Incompressible TrioCFD code - Boussinesq approximation
- LES simulations :
  - Wall-Adapting Local Eddy-viscosity (WALE) – near wall turbulence
  - Simple Gradient Diffusion Hypothesis (SGDH) Pr_t=2 (liquid metal)
- Meshing respecting turbulent length scale : 900 μm near walls- 9mm in bulk
  → ~ 36 million tetrahedral elements

Density (kg m^{-3})	Dynamic viscosity (Pa s)	Thermal conductivity (W m^{-1} K^{-1})	Specific heat capacity (W kg^{-1} K^{-1})	Linear expansion coefficient (m^{-1})	Thermal diffusivity (m^2 s^{-2})	Melting point (K)
7000	5×10^{-3}	20	450	3×10^{-5}	6.3×10^{-6}	1700

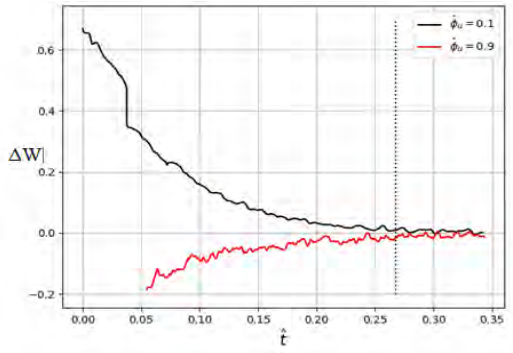


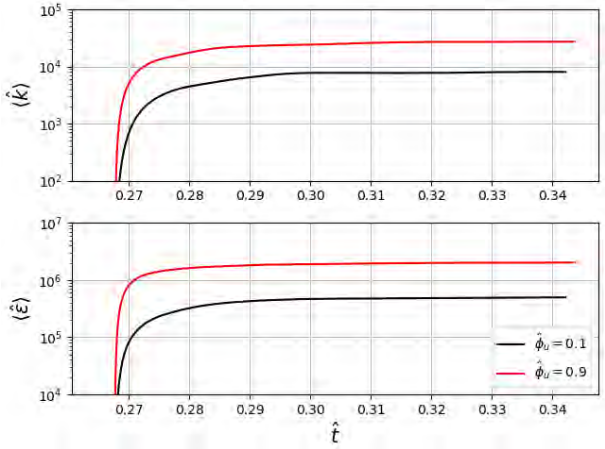
Test case & Numerical method (2/2)

Establishment of **pseudo-steady state**, following :

- Energy balance $\Delta W = 1 - \hat{\Phi}_u - \frac{1}{\pi R^2}\int_0^H \int_0^{2\pi} \hat{\Phi}_w \, d\theta \, dz$
- Different metrics

Steady-state $\hat{t} = t\frac{\alpha}{H^2} > 0.34$ i.e. 650 s





Some results

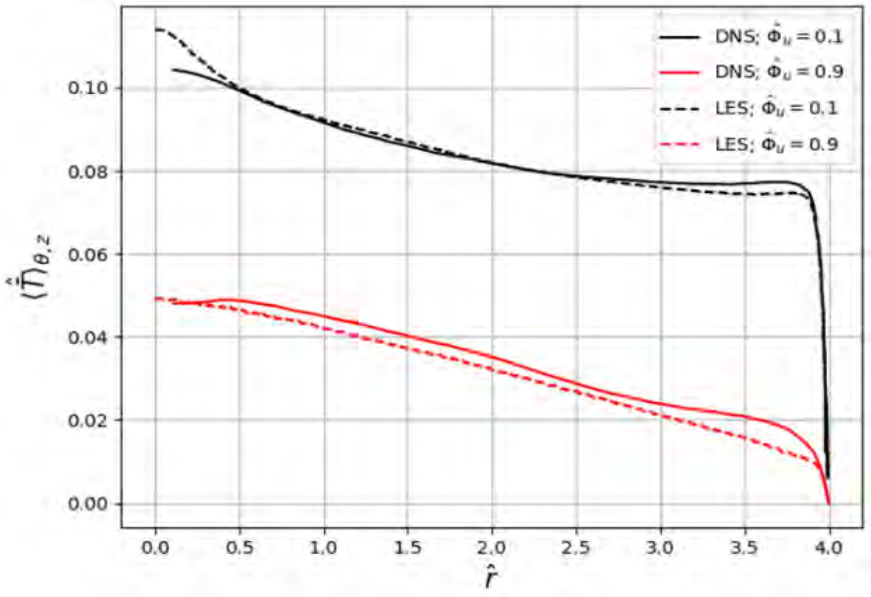
Temporal and azimuthal and then axial averages

Good agreement with DNS results

- $\hat{\Phi}_u$ =0.1 – LES overestimation in the hot chimney (pool centre- $\hat{r} < 0.3$)
- $\hat{\Phi}_u$ =0.9 – LES marginally lower bulk temperature prediction

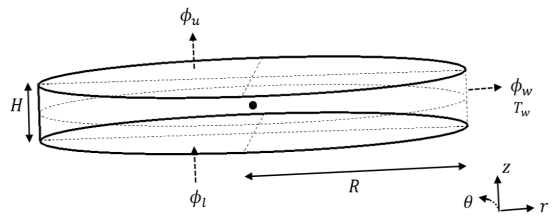
$$\hat{T} = \frac{T}{T_{ad}}$$

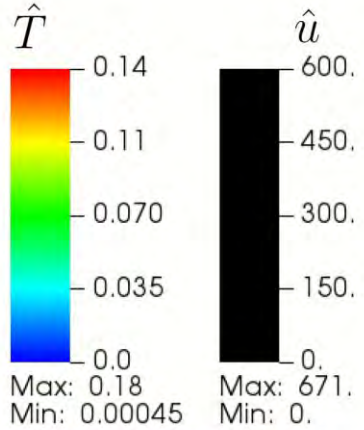
$$T_{ad} = (T - T_{mp})\frac{\lambda}{\Phi_l H}$$



Results

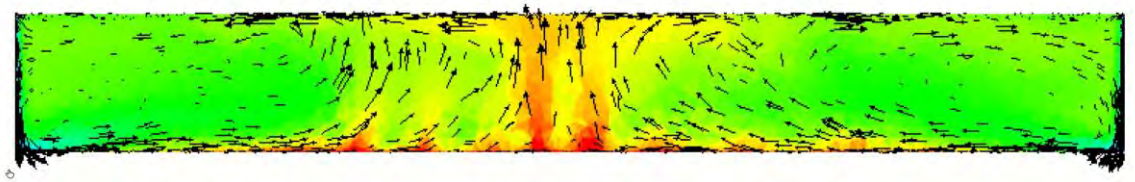
$\hat{\Phi}_u = 0.1$



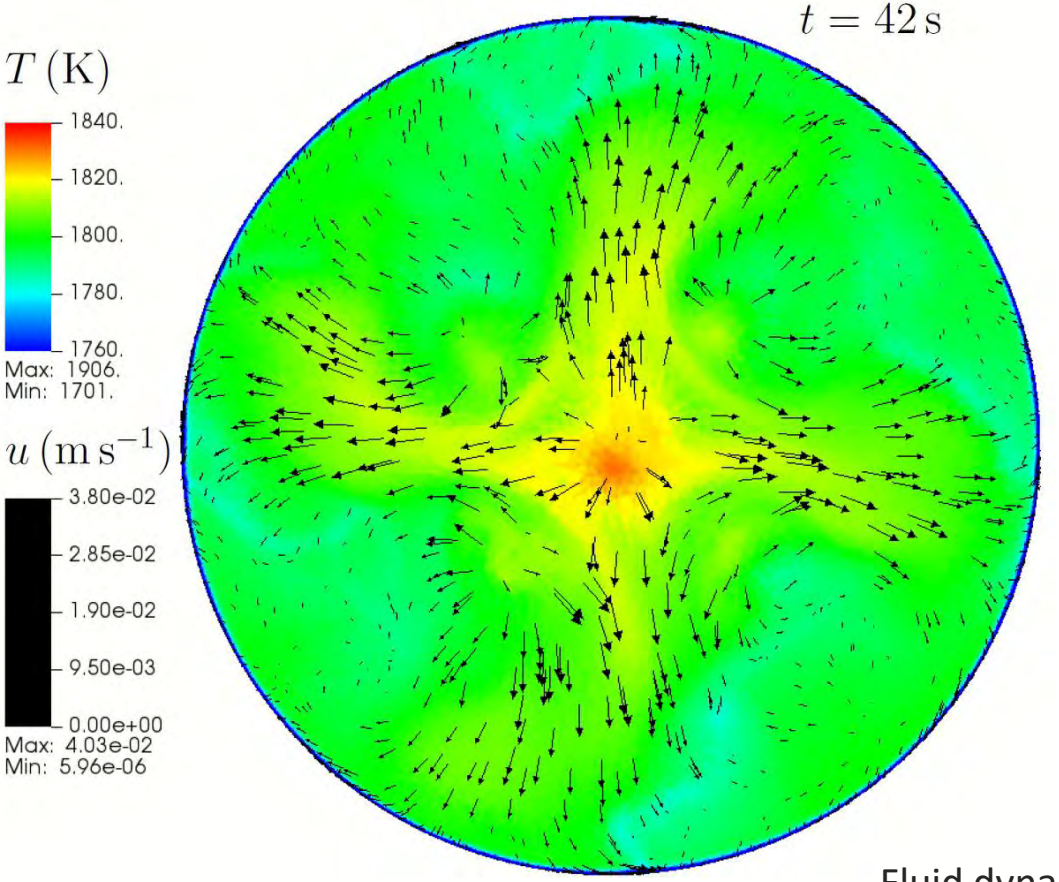


$\hat{t} \times 10^3 = 0$

r-z plane, θ=0°



$t = 42\,\mathrm{s}$



- Large convection cell in the $r - z$ plane
- Four high velocity ‘branches’
- Rotation pattern (anticlockwise and period ~4 min) and number of branches consistent with DNS simulations

Fluid dynamics constistent with DNS results of Rein et al.

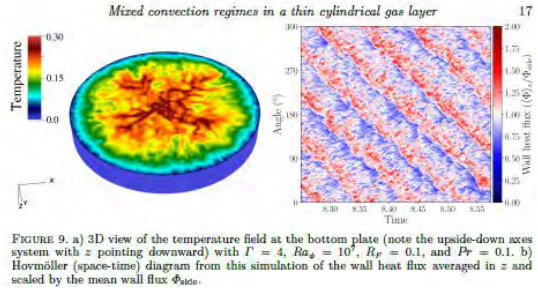


FIGURE 9. a) 3D view of the temperature field at the bottom plate (note the upside-down axes system with z pointing downward) with $\Gamma = 4$, $Ra_\Delta = 10^7$, $R_P = 0.1$, and $Pr = 0.1$. b) Hovmöller (space-time) diagram from this simulation of the wall heat flux averaged in z and scaled by the mean wall flux Φ_{wide}.

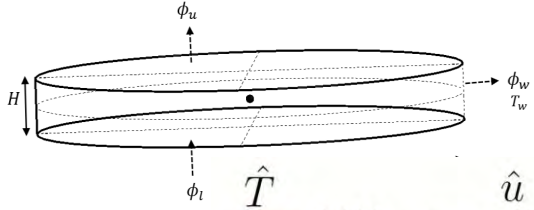
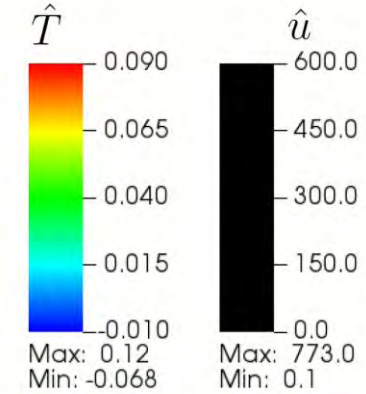
Results

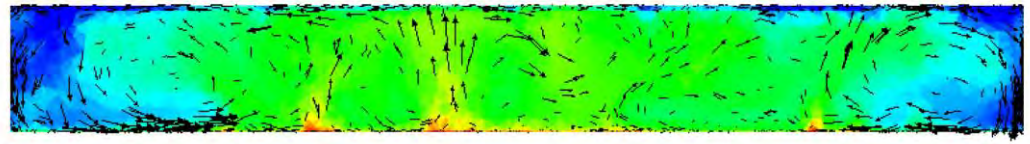
$\hat{\Phi}_u = 0.9$

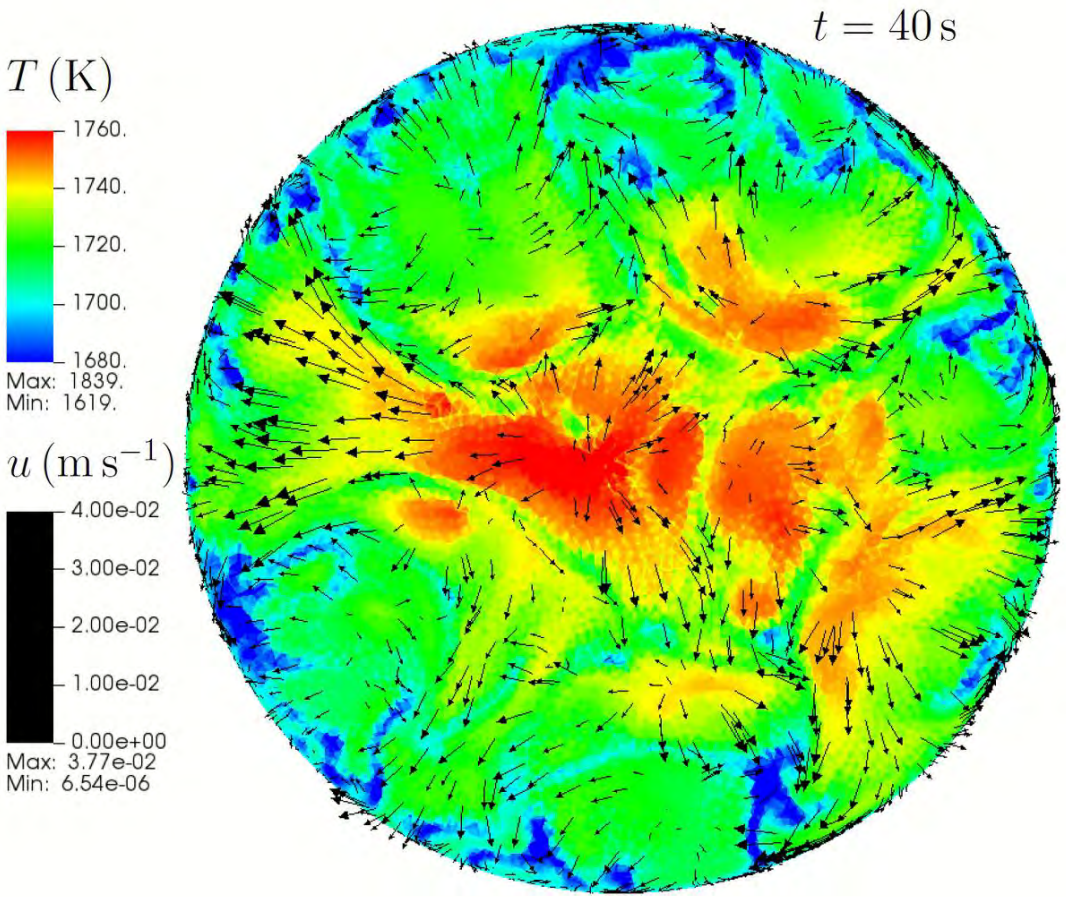




$\hat{t} \times 10^3 = 0$

r-z plane, θ=0°





- Weaker acceleration → smaller outer convection cells (larger radially than axially)
- Fluid dynamics at the center ~ Rayleigh-Bénard cells.

Fluid dynamics constistent with DNS results of Rein et al.

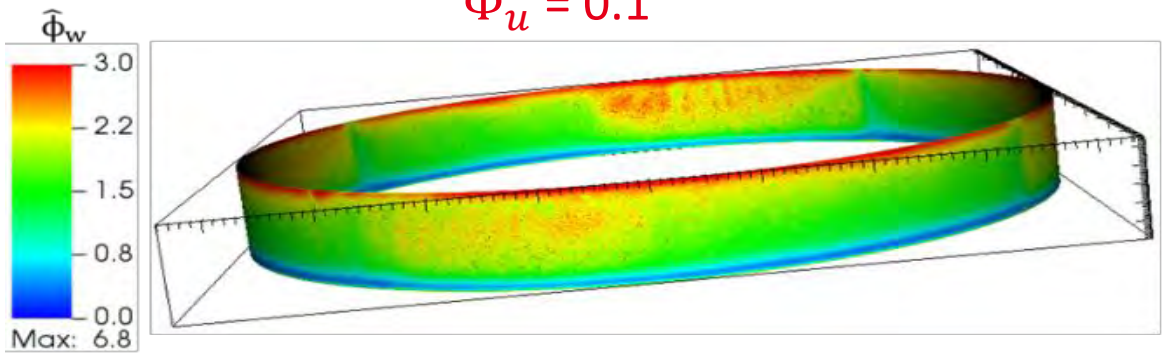
Results – lateral heat flux

Spatial distribution of dimensionless instantaneous heat flux

$\hat{\Phi}_u$ =0.1

- Uniform band of elevated heat dissipation at the top of the lateral wall → the focusing effect (× 3 Φ_l).
- Elevated heat dissipation in the proximity of the high velocity 'branches'

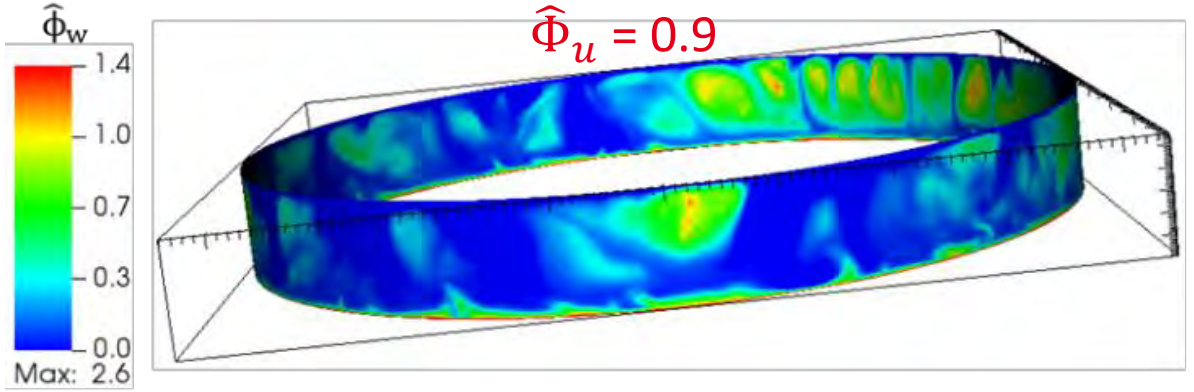
$\hat{\Phi}_u$ = 0.1



$\hat{\Phi}_u$ =0.9

- Negligible heat losses (~Φ_l) , punctuated by transient zones of elevated heat dissipation in the vicinity of the outer convection cells,
- More dissipation in a thin permanent layer adjacent to the lower boundary

$\hat{\Phi}_u$ = 0.9



Results – lateral heat flux

θ-averaged dimensionless heat flux

Good agreement with DNS for $\hat{z} < 0.8$ (pool top)

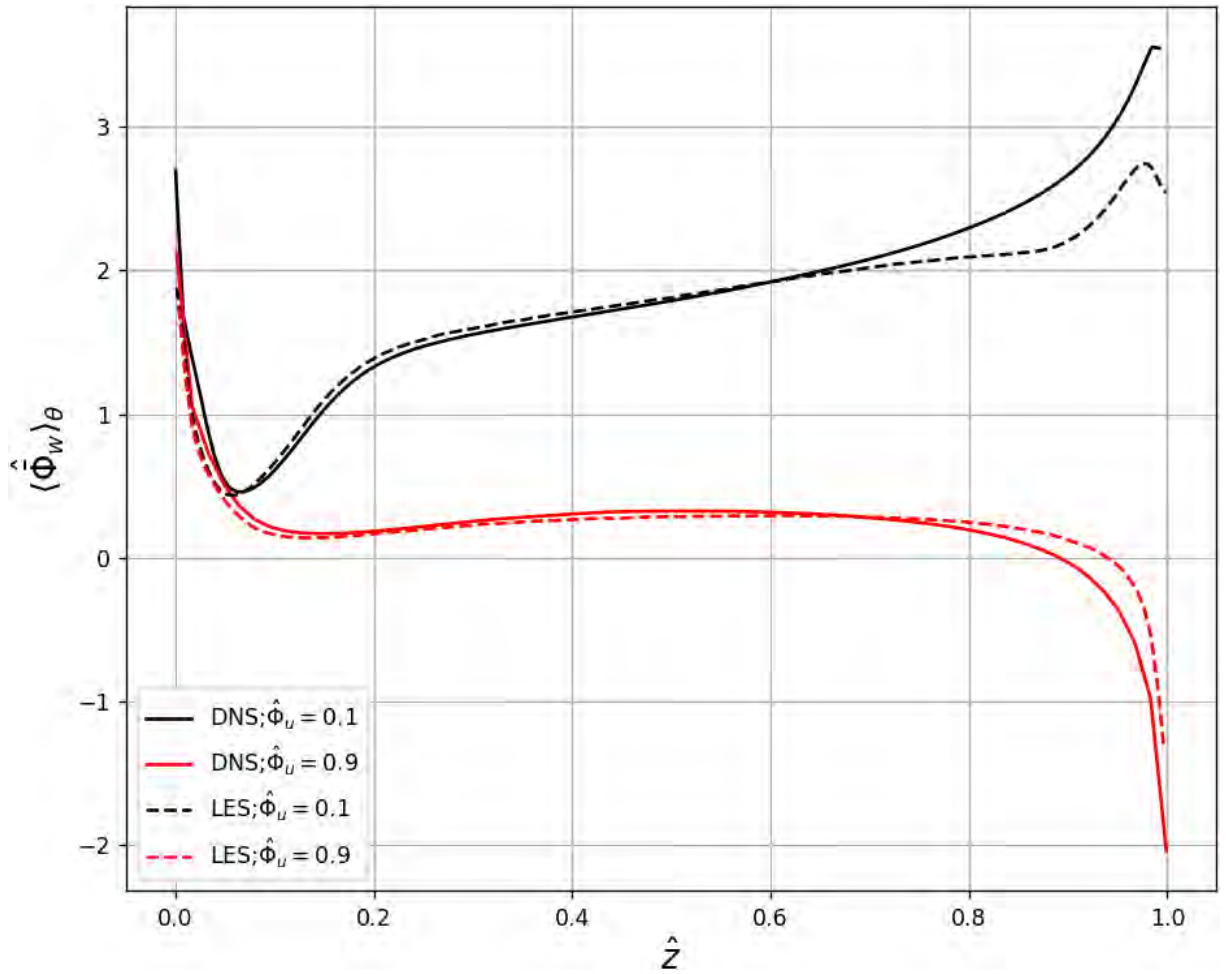
$\hat{\Phi}_u$ =0.1

- lower heat flux at the bottom and at the top with the LES model than with the DNS model,
- At the top, very low speeds are very difficult to simulate accurately in both DNS and LES.

$\hat{\Phi}_u$ =0.9

- Higher heat flux at the bottom
- Negative in the top region, implying local fluid temperatures below the corium melting point (curst solidification should be considered)

Such areas with right angles not representative of the reactor geometry ; ablation or formation of crusts

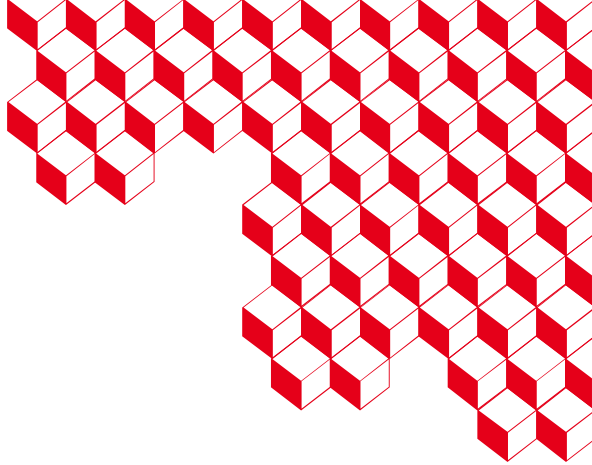


Conclusions and perspectives

- CFD simulations help to derive reliable lateral axial profile of heat flux on the reactor vessel.
- Validation of the LES simulation against DNS results for a low-Prandtl-number cylindrical case showed :
  - The adapted turbulence model is valid for Prandtl numbers <<1
  - 3D geometry affects flow dynamics, leading to the formation of rotating convection cells

- The thermal-hydraulics of a metal pool under IVR conditions are complex and can vary significantly depending on the ratio of the heat flux released from the top.
  - If this ratio is high, the flow exhibits small Rayleigh–Bénard convection loops and weak lateral flows, which can even lead to crust formation at the top of the pool;
  - In the case of a weak ratio, a large convection loop, spanning the width of the pool, dominates the flow. Azimuthally, these loops are separated, leading to warm branches that exhibit a rotational motion. This situation can lead to significant local heat fluxes at the top of the pool.

- **Perspectives** :
  - It would be interesting to take the axial flow profile into account in macroscopic codes – instead of an average value.
  - couple LES WALE simulations with an enthalpy-porosity model to account for steel solidification.



Thank you for your attention

Analysis of In-Vessel Retention in a VVER-1000 Reactor Design using AC²

ABSTRACT

Use of In-Vessel Retention (IVR) through External Reactor Vessel Cooling (ERVC) is a widely considered severe accident management strategy for light water reactors. Its objective is to prevent reactor pressure vessel (RPV) failure during severe accidents with core melt and relocation into the lower plenum. Once design specific criteria are met, the reactor cavity is flooded, enabling external vessel cooling to transfer the decay heat of the relocated corium to the containment. While IVR is not implemented as a standard accident management strategy in VVER-1000 reactors, extensive research and benchmarking over the past decade have investigated its feasibility.
Due to the complexity of the underlying phenomena, the effectiveness of this strategy should be assessed using integral calculations with lumped parameter codes. In this study, the latest version of the German code system package AC² is applied to analyse a hypothetical IVR scenario in a VVER-1000 reactor. The thermal-hydraulics is modelled with ATHLET, the severe accident phenomena in the reactor coolant system (such as core degradation, and late-phase processes) are simulated with ATHLET-CD, while the containment response is modeled in a simplified manner using COCOSYS. In recent years, several new models and methods have been implemented in the lower plenum module of ATHLET-CD to improve its capability for simulating IVR scenarios as well as modelling the lower plenum of VVER reactor designs.
This paper presents the current modeling capabilities of AC², highlighting the newly implemented features, and demonstrates their applicability through the simulation of a station blackout combined with a large-break LOCA in a VVER-1000/320 reactor equipped for hypothetical IVR. The analysis covers the full progression of the accident, from the initiating event to the stabilization of corium within the RPV lower plenum with a focus on the heat transfer during ERVC.

1. INTRODUCTION

In case of a severe accident in a light water reactor, the core dries out, heats up, and starts to melt. In a later phase, the molten core material (corium) relocates into the lower plenum (LP) of the reactor pressure vessel (RPV). The hot corium starts to heat-up and ablate the vessel wall and, without any countermeasure, the thermal load could lead to RPV failure, releasing corium into the containment. Severe accident management (SAM) strategies for mitigating the radiological consequences of severe accidents have received increased attention since the Fukushima Daiichi accident. One common SAM strategy for new plant designs as well as for retrofitting existing nuclear power plants is the in-vessel retention (IVR) of corium by external reactor vessel cooling (ERVC) [1].

The IVR concept aims to maintain RPV integrity by ensuring successful removal of decay heat from the relocated corium through external RPV cooling, thus limiting damage to the RPV wall. For this purpose, the outer surface of the RPV needs to be flooded—if possible before corium relocation—by dedicated safety provisions once a specific criterion is met during accident progression. The coolant evaporates at the RPV surface, and the resulting steam–water mixture returns to the containment, where it condenses, enabling long-term operation. The key points of the IVR strategy are the cooling efficiency (often limited by the critical heat flux, CHF) and the thermal load. The thermal load largely depends on the relocated corium mass and composition as well as on the decay heat. These, in turn, depend on the course of the accident and on the reactor size and design [2].

The IVR strategy was originally developed in the mid-1990s for mid-size reactors such as the AP-600 and the VVER-440 design [1]. Since then, the concept has been extended and adopted for new large Generation III/III+ reactor designs with electrical outputs exceeding 1000 MWe. Since high-power new designs such as the AP-1000, APR-1400, and HPR-1000 are already in operation with the IVR concept, IVR has also been intensively investigated over the past decades for retrofitting the VVER-1000/320 design [3], [4].

Severe accident system codes are commonly used to investigate IVR scenarios and to support the safety demonstration of the concept. In this work, the latest version of the German severe-accident code system AC^2 is applied. In recent years, several code improvements relevant to IVR and VVER reactor applications have been introduced, supported by international research projects and benchmark exercises. The present paper describes VVER design-specific model improvements relevant to IVR simulations. Furthermore, the applicability of the approach is demonstrated by simulating a large-break LOCA scenario with a concurrent station blackout (SBO) in a generic VVER-1000/320 reactor equipped with a hypothetical IVR concept.

2. APPLIED CODE SYSTEM AND MODEL IMPROVEMENTS

The code system AC^2, developed by GRS, is dedicated for the analysis of the whole spectrum of operational transients, design-basis accidents and beyond design-basis accidents [5], [6]. It includes the code ATHLET to model thermal-hydraulics in the primary circuit, ATHLET-CD to model severe accident phenomena and COCOSYS to model containment phenomena. The investigation of an IVR scenario requires a complete AC^2 simulation involving all three code parts. ATHLET-CD has a modular architecture including ATHLET for simulation of the complete thermal-hydraulic part [7]. The central core degradation module is ECORE, which defines the core section with fuel assemblies and structures and models the oxidation and the core degradation processes. The fission product inventory of the core and the total decay heat after SCRAM is calculated with the modules OREST/FIPISO. The module FIPREM calculates the fission product release of dedicated elements as a function of the partial pressures and the module SAFT simulates the fission product transport. The late phase phenomena in the LP are simulated with the module AIDA.

The key ATHLET-CD module for IVR simulation is AIDA. Fig 1. shows an overview of the current modelling scheme of this module. AIDA simulates the corium thermal behaviour, the heat conduction and damage to the LP wall and the external cooling. In the current version of AIDA, the relocated corium instantaneously forms a contiguous molten pool at the bottom of the LP. The MASCA experiments have revealed the existence of two immiscible liquid phases at equilibrium in the corium pool, one metal and another consisting of oxides [8]. The current code version provides the conventional representation of the stratified pool with two corium layers, a heavier oxide in the bottom and a lighter metal layer above of it, without considering the complex thermochemical stratification processes. The corium pools are each modelled as one-dimensional. The crust formation, dependent on the boundary conditions, is modelled around and in between the corium layers.

The heat transfer between melt and the external cooling is calculated in two dimensions. This includes the calculation of crust formation at the wall, the heat transfer between melt and crust as well as crust and wall,

heat conduction in the wall and also the heat transfer between wall and reactor pit volumes. Heat conduction in the vessel wall is solved with an explicit finite-difference scheme that accounts for progressive wall ablation. When a wall nodes melt, it is filled immediately by corium, while the effect of crust insertion is considered. Assuming molten metal pushed up by the crust into the metal layer, the node mass is added directly to the metallic layer. Crust formation at the layer interfaces depends on the layer temperatures and strongly influences the interlayer heat transfer.

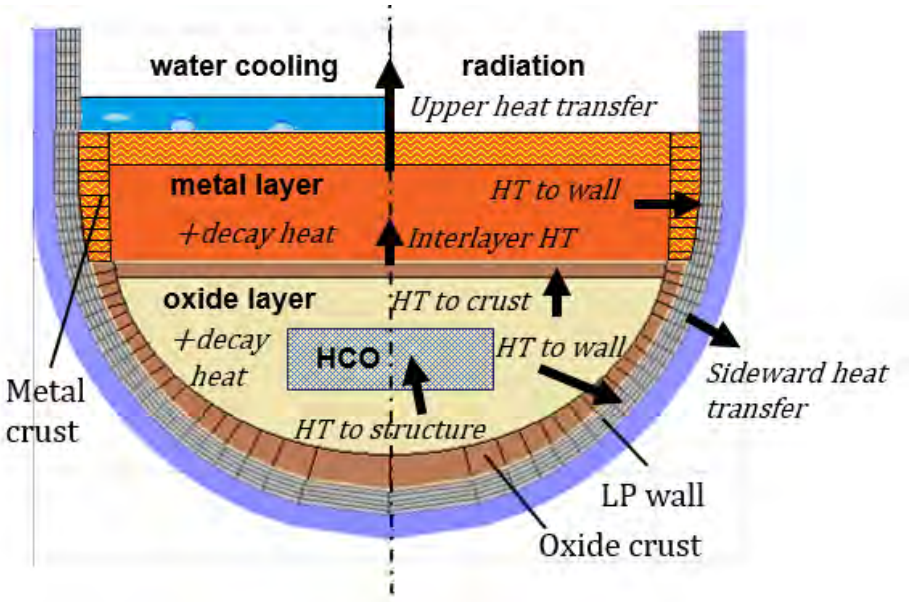

Figure 1. Modelling scheme of AIDA adapted from [9]

In recent years, several modelling improvements have been implemented in AIDA to enhance its capability to simulate IVR in VVER-1000 reactors. The following section briefly describes these.

2.1 Model improvements in AIDA

2.1.1 Metal layer modelling

The VVER-1000 geometry leads to significant amount of metal in the corium pool, which results in a thick metal layer above the oxide. The material properties of the metal layer can differ significantly from those of the vessel wall due to differences in material type, composition, and thermal history, which limits the heat transfer between them. The temperature difference between the molten metal layer and the wall (which can exceed 1500 degree) promotes solidification at the interface, forming a solidified metal crust. These crusts introduce additional thermal resistance. Accurate modelling of this crust is therefore particularly important in the case of a thick metal layer with a large heat-transfer area, as it strongly influences the heat transfer from the metal layer to the vessel wall.

Therefore, a new metal layer crust model has been introduced in AIDA. The thickness and the temperature of the sideward crust is calculated for every wetted wall node in every timestep. The heat transfer between metallic melt and crust is calculated using a Nusselt number based on the Chawla–Chan correlation [10]:

$$\mathrm{Nu}_{\text{metal layer}} = 0.508\ \mathrm{Pr}^{0.25}\ \mathrm{Ra}^{0.25}\ \left(\frac{20}{21}+\mathrm{Pr}\right)^{-0.25} \quad (1)$$

The heat transfer between crust and wall is calculated as conduction. With this, the heat balance is solved for the crust elements in every timestep, taking phase changes into account, calculating crust thickness

(evolution, melting) and from that crust temperature. Upper metal crust forms when the surface temperature drops below the solidification point due to significant heat loss through radiation or flooding of the LP. The upper crust is modeled as a single node with constant thickness above the metal layer's upper surface, using volume-averaged material properties. The heat flux from the metal layer to the crust is calculated assuming a thermal boundary layer, due to the comparatively large upper surface area and weaker convection. The thickness and the temperature is solved in the same way as for the sideward crust [9].

2.1.2 Consideration of internal structures

The LP of the VVER-1000 contains a considerable number of internal structures within the lower head (see Fig. 2). These include the lower core barrel (~14 t) and the fuel assembly (FA) supports (~ 7 t). After corium relocation, the corium gets in contact with the internals and starts to heat them up and melt them. In the new AIDA model, the internal structures are defined as standard ATHLET heat conduction objects (HCO). AIDA reads the volume and surface area of the coupled HCO and derives an equivalent cylindrical structure. Depending on the position of the structure, the wetted area and the heat transfer for both layers will be calculated separately. The heat transfer between oxide layer and the HCO is calculated similarly to the heat transfer between oxide layer and LP wall, using a Nusselt correlation selected by user. The heat transfer between metal layer and the HCO is calculated using the Bonnet-Seiler correlation [15]. Crust formation is taken into account in a simplified manner as a heat resistance. The transferred heat is considered in the corium layer balance equations as well as in the ATHLET model. After the HCO is completely molten, its mass will be automatically added to the metal layer [9]. Progressive ablation of the HCO is not considered in the current code version.

2.1.3 Improvements in geometry modelling

A large part of the decay heat is contained in the oxide layer. This heat is transported through the upper surface (via interlayer crust and metal layer) to the inner RPV area and through the sideward crust and wall to the cavity (possibly filled with water). This causes a geometry-dependent natural circulation in the molten pool, except in the bottom region, which is characterized by stratification. Also, the external cooling represents a complex, geometry-dependent three-dimensional multiphase flow process [1]. This implies that the heat transfer is strongly dependent on the LP shape.

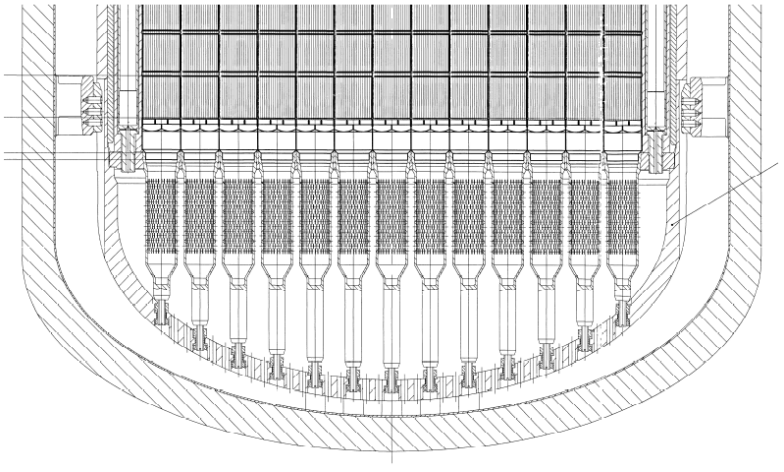

Figure 2. Lower plenum geometry of VVER-1000 [3]

The improved AIDA model simulates the VVER-1000 (see Fig. 1) LP wall with an ellipsoid shape and a non-constant wall thickness. The transition between the bottom and the cylindrical cross-section is modelled continuously. The shape of the LP wall is also considered in the heat transfer distribution along the inner wall. The heat transfer is calculated with a Nusselt correlation using the averaged parameters of the corium

layer. In AIDA, a simplified geometrical factor is introduced to transform this into more realistic two-dimensional heat transfer distribution at the inner wall surface considering the fluid flow patterns in the molten pool [9]. This factor has been optimized based on new benchmark simulations and experimental calculations.

3. POSTULATED SCENARIO

To demonstrate the new code capabilities, a large-break LOCA scenario with a simultaneous station blackout was chosen to obtain an early core meltdown with a large decay-heat level. A DN 850 mm break opens on the cold leg of loop 1. The break is located close to the RPV. At break initiation, the reactor is in normal operation at an up-rated thermal power of 3120 MW (104%) at end-of-cycle. The primary coolant mass flow is 84,800 m³/h, and the core outlet temperature is 320 °C. The coastdown of the main coolant pumps starts immediately after break opening. No active safety systems are available; therefore, only the passive hydro accumulators and the pressurizer inject water into the primary circuit during the transient.

The containment is equipped with a hypothetical system that starts injecting water into the reactor cavity once the core outlet temperature reaches 650 °C. This system is assumed to have enough water inventory to provide coolant for more than 24 hours. The initial water temperature is 60 °C. External cooling of the RPV is assumed to occur via natural circulation. Please note that to date no IVR system has been developed and approved for VVER-1000 reactors. The investigated scenario is intended for demonstration purposes only.

The calculation has been done from the transient initialization until corium stabilization (more heat transfer from corium than decay heat in the corium and no more wall ablation happens).

4. SIMULATION MODEL

The code system AC^2 version 2025.0 has been used for investigations with the improved AIDA module. The VVER-1000 input deck for these calculations has been developed over many years at GRS [11], [12] and has been adapted for a recent IAEA benchmark on IVMR [4], [13].

4.1 Thermal-hydraulic model

The primary and the secondary circuit are modelled with ATHLET, based on a two-fluid model with fully separated balance equations for liquid and vapor. The model represents the primary circuit and, partially, the secondary circuit of a VVER-1000 reactor. The primary circuit includes the RPV, the pressurizer, four hydro accumulators, and four loops modelled separately with their steam generators (see Fig. 2). The hydro accumulators, each containing 50 m³ of boron water, inject into the reactor when the pressure drops below 5.9 MPa: two inject into the upper plenum and two into the downcomer. The RPV model consists of the core region divided into five channels and a bypass (cross connected), the downcomer, the upper plenum, and the LP. The downcomer is divided into four parallel segments to accurately simulate asymmetric flow.

The LP structures, the bottom part of the barrel and the fuel assembly supports are modelled together as one horizontal cylindrical plate, representing their average dimension and mass. The structure is connected to the two representative lower-plenum thermo-fluid objects. The structure failure is modelled using a simple melting criterion.

The secondary circuit is modelled with the horizontal steam generators and the main steam lines up to the turbines. The pressure relief system of the secondary side, the so called BRU-A is modelled with VVER BOP model.

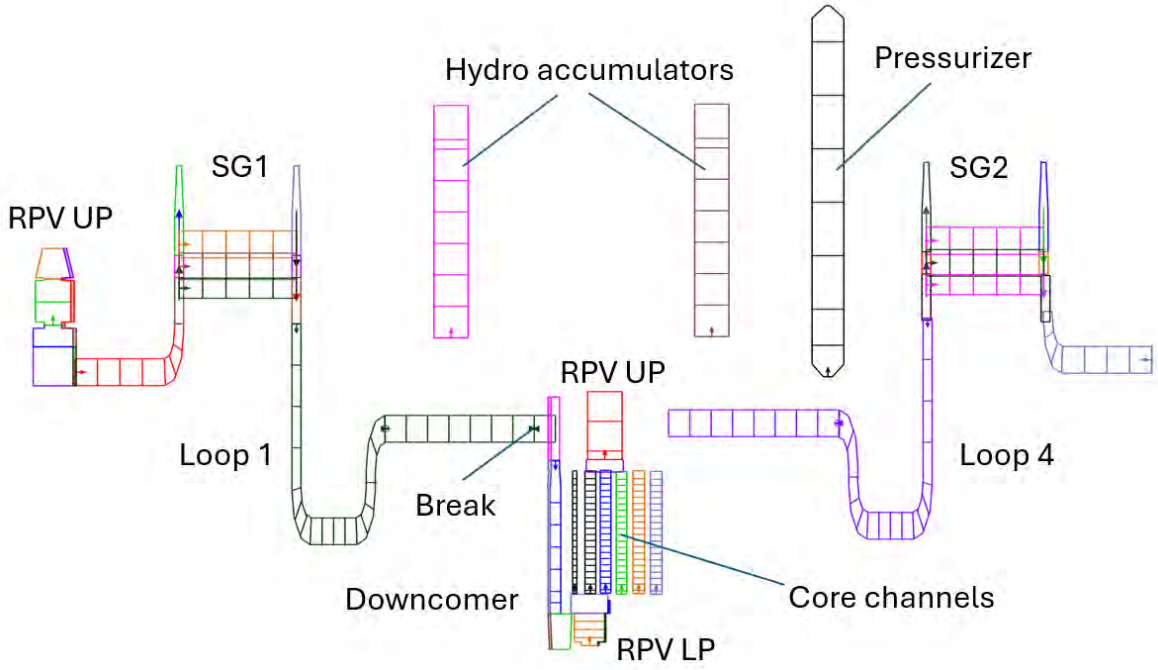

Figure 3. Schematic view of the PC thermal hydraulic model (RPV and loop 1 & 2) with nodalisation

The containment processes are modelled with COCOSYS. The present investigation focuses on the effectiveness of IVR; therefore, a simplified VVER-1000 containment model has been applied. The containment model provides the backpressure for the break discharge flow and the coolant properties in the reactor cavity for external cooling modelling. The heat transfer from the LP to the cavity is calculated by AIDA and is introduced into the containment cavity. Accordingly, the containment model consists of only three compartments, the cavity, the upper dome and the rest of the containment.

4.2 Severe accident model

To model severe accident phenomena, the ATHLET model has been extended with the ATHLET-CD modules, ECORE, OREST/FIPISO, FIPREM and AIDA. The present investigation is not focused on the source term, therefore the fission product transport module SAFT was not activated. The module ECORE simulates the core oxidation and core degradation processes such as ballooning and melting of the fuel and control rods. In the present model, hexagonal VVER-type fuel has been applied. The 163 fuel assemblies and the 18x163 B_4C control rods are divided into five groups which are assigned to five concentric core sections. The core channels are divided into 18 vertical nodes [12], [13].

The initial thermal reactor power is 3120 MW. The decay heat after SCRAM is calculated from fission product inventor with the modules OREST/FIPISO and the fission product release with the module FIPREM. The oxidation of the cladding is calculated with the Cathcart correlation under consideration of possible steam starving phenomena [9].

In the early phase of the accident, molten corium relocates and accumulates on the core support (grid) plate. Further relocation into the LP can only occur after failure of the grid plate or failure of the core barrel. In the present simulation, grid plate failure is assumed. Failure is assumed to occur when the grid plate reaches its melting temperature and when at least 45 t of molten oxide has already accumulated on it. This criterion is based on achieving reasonable relocation time [14].

AIDA starts after grid plate failure. The LP geometry has a horizontal inner radius of 2.046 m and a vertical inner radius of 0.958 m. The wall has a thickness of 0.241 m at the bottom and 0.194 m at the cylindrical region. The wall thickness between these two points is calculated using a continuous transition. The cylindrical part of the LP is modelled with a height of 1.6 m to ensure that all molten material fits within the AIDA simulation domain. The RPV wall has been nodalized with 20 nodes in radial and with 124 nodes in axial direction. As mentioned in Section 2.1.2, about 20 t of LP internal structures is considered via ATHLET HCO with a distance of 0.3 m from the LP bottom. For the temperature dependent LP wall properties (density, heat capacity and heat conduction) the built-in VVER steel (15X2HMFA) model was used.

The relocated melt instantaneously forms a stratified molten pool with a light metal layer on the top and with an oxide layer at the bottom. In the model 15 % of the decay heat is assumed to be generated in the metal layer. Heat transfer between the oxide layer and the crust is modelled using the Bonnet–Seiler correlations [15]. The heat transfer in the metal layer has been modelled as described in Section 2.1.1.

The external cooling is modelled with a simplified, AIDA built-in ERVC model [9]. The inlet and the outlet of the ERVC channel is coupled to the COCOSYS domain for the rest of the containment. Therefore, the inlet parameters; temperature and mass flow are provided by COCOSYS since AIDA calculates the heat transfer into the cavity cooling channel and thus cooling effectiveness. In the present simulation a constant heat transfer coefficient of 20,000 W/(m^{2}K) has been applied along the external wall, based on relevant, previous benchmark calculations [3].

5. SIMULATION RESULTS

The postulated large break causes a rapid pressure decrease in the primary circuit and triggers an immediate SCRAM. The pressurizer empties after approximately 20 s, and the passive injection from the hydro accumulators stops at about 55 s. After that, no further water is injected into the primary circuit. The time points of the key events of the transient are shown in Table I.

Table I. Key accident events

Event	Time [s]
Initial event of the accident	0.1
End of water supply from HA-1	55
Fuel rod burst	466
Core dry out	480
Intense hydrogen generation	1,200
Start of fuel melting	1,529
Corium relocation to the lower head	1,859
LP structure failure	4,496
Corium stabilization	~12,000

The core degradation phase starts shortly before total core dry-out, with fuel rod bursting at 466 s. Runaway oxidation, accompanied by intense hydrogen generation, starts about 1,200 s after the initiating event. The core begins to melt and corium relocates onto the grid plate. After 1,859 s, a total of 70 t of corium has

already accumulated on the grid plate, leading to its collapse and subsequent corium relocation into the LP. Fig. 4 shows the oxide melt and crust volume and the metal layer volume in the LP. The evolution of the oxide volume shows that corium continues to relocate into the LP thereafter, up to approximately 7,000 s. During this period, about 70 t of oxide corium is present in the LP. Interaction of the corium with the cold vessel wall initially leads to intense crust formation. Later, as the lower-plenum wall heats up, the crust begins to remelt and thin. After corium stabilization (around 12,000 s), the crust starts to grow slowly again. The LP wall starts to ablate at ca. 3,000 s. Wall ablation lasts until approximately 10,000 s and stabilizes at a minimum wall thickness of 50 mm. The 29.5 t of ablated wall material is added to the metal layer, which has a mass of about 120 t at the end of the calculation.

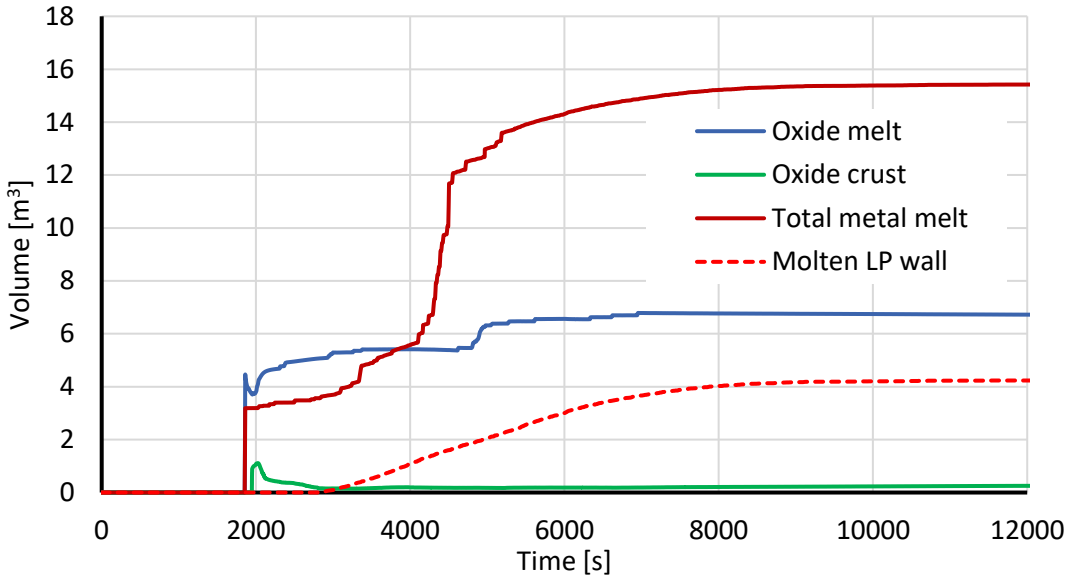

Figure 4. Volumes of relocated corium component

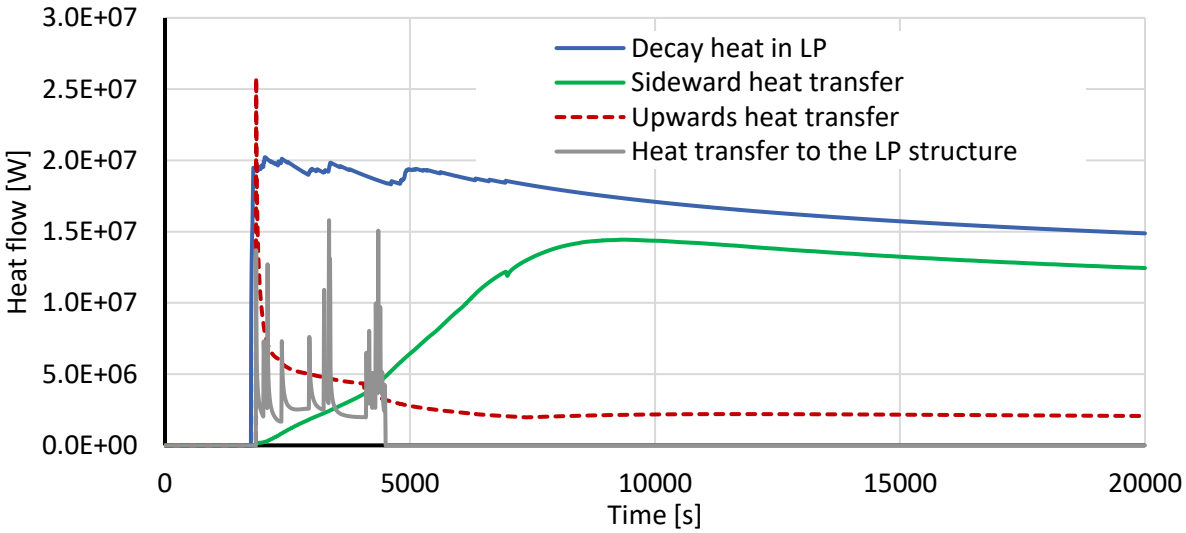

Figure 5. Heat balance of the corium pool

The heat balance of the corium pool shows Fig. 5. The corium mixture has a temperature of 2,500 K at relocation. Since the separation of corium phases is modelled as immediate, the still hot metal layer faces the remaining water in the LP, which leads to a large upper heat transfer immediately after relocation. At the same time, the upper metal layer crust starts to develop, which leads to a significant decrease of the

upper heat flux. At about 4,100 s the LP dries out and the upper heat transfer changes to radiation causing a strong decrease of the heat flux. The stepwise increase in decay heat also indicates further corium relocation (blue curve in Fig. 5). The grey curve shows the heat transfer from the corium pool to the coupled lower-plenum internal structure. The evolution of the layer heights influences the heat-transfer area to the structure. For example, when further oxide relocation occurs, the oxide layer height increases suddenly, leading to a larger heat-transfer area and larger temperature differences. This can cause transient peaks in the heat transfer. The approximately 20 t of lower-plenum structure melts completely up within ca. 2630 s, at about 4496 s after the initiating event. Without modelling the lower-plenum structures, the corresponding enthalpy of fusion would be redirected and could lead to non-negligibly higher lateral and upward heat transfer during this phase. The heat-balance figure shows that, at approximately 12,000 s, the decay heat becomes equal to the transferred heat, and since no further wall ablation occurs, the corium begins to stabilize.

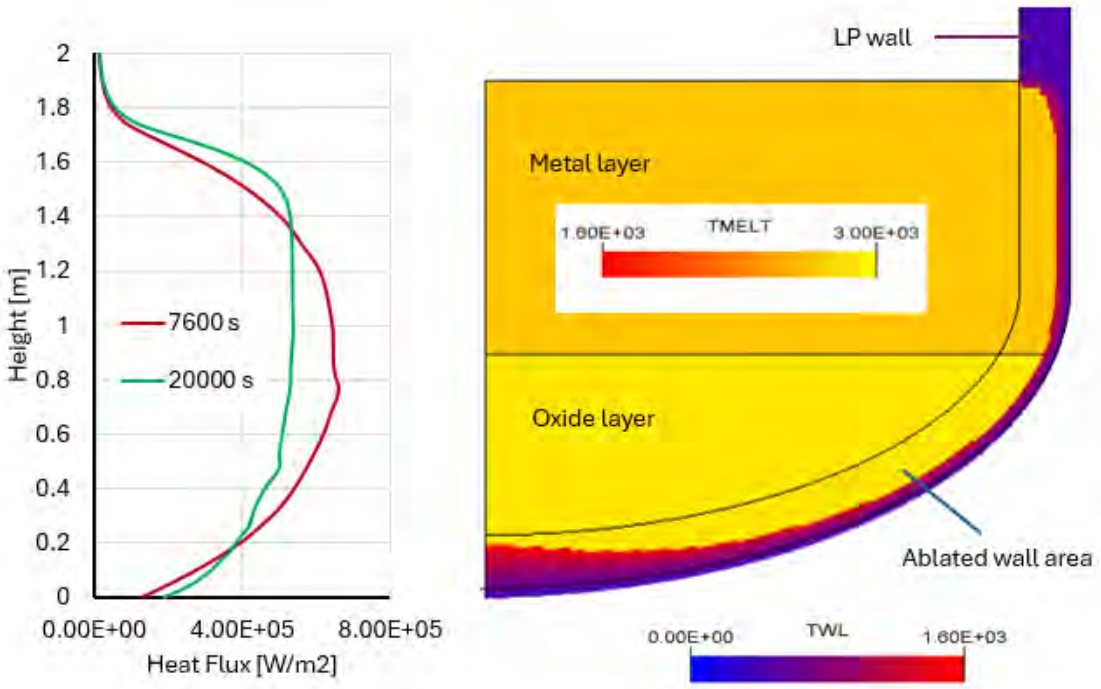

Figure 6. Left: Heat flux from corium to ERVC at maximum (7600 s) and at the calculation end (20000 s). Right: Wall ablation and corium composition at the end of the calculation.

During the simulations a maximal sideward heat flux of 0.66 MW/m^2 has been calculated at 7,600 s after accident initiation. At this time, a metal layer crust thickness of approximately 66 mm upward and an average of 28 mm sidewards has been calculated. At the end of the simulation, the upper crust thickness slowly decreased to 48 mm, while the average sideward thickness increased to 43 mm, forming together a nearly homogeneous crust around the metal layer. The heat flux evolution along the wall is shown in Fig. 6 left at 7,600 s and at the end of the simulation. As expected for a thick metal layer, the maximum heat flux is reached at the upper edge of the oxide layer. This result is consistent with the literature and indicates that the improved metal-layer model achieves improved physical predictions without overrepresenting the focusing effect [3].

The right side of Fig. 6 shows the wall ablation and the corium pool configuration at the end of the simulation. In the simulation, the corium layers fill the ablated wall nodes. The wall ablation profile shows that significant ablation occurs in the region of the metal layer and in the upper part of the oxide layer, while

the wall at the bottom remains nearly intact. These results are consistent with corium pool physics and with findings reported in the literature [3].

6. CONCLUSIONS

The lower plenum module AIDA of ATHLET-CD has been equipped with new models which improve its applicability to safety demonstration of IVR in case of VVER-1000 reactor designs. The new modelling approach considers the LP wall geometry of a VVER-type reactor more realistically. Furthermore, AIDA has also been equipped with a model to simulate the LP internal structures, which are also considered in the heat-balance calculations of the corium layers. In addition, the metal-layer modelling has been extended to calculate crust formation at the sideward and upper interfaces of the metal layer.

The model improvements have been successfully demonstrated with the investigation of a hypothetical IVR scenario in a generic VVER-1000 reactor. The consideration of the LP structures implies a larger heat-transfer area for the layers and simultaneously consumes decay heat from the corium. In addition, crust formation around the metal layer has an insulating effect, which avoids overpredicting the focusing effect for thick metal layers. These improvements lead to lower lateral and upper heat fluxes and, consequently, to a larger remaining wall thickness. Overall, the results are more realistic for IVR scenario behaviour.

The development, verification, and validation of AC^2 codes are ongoing. Further improvements of the lower plenum model are planned, including an improved representation of LP structures and relocation paths, as well as the consideration of thermochemical processes, to provide a more realistic representation of the corium pool. In addition, in the framework of international cooperation, the new modelling approach will be further verified through code-to-code benchmark exercises.

ACKNOWLEDGMENTS

The development and the validation of AC^2 is sponsored by the German Federal Ministry for the Environment, Climate Action, Nature Conservation and Nuclear Safety (BMUKN) on the basis of decisions by the German Bundestag within several projects.

Analysis of In-Vessel Retention in a VVER-1000 Reactor Design using AC²

P. Pandazis, L. Lovasz, A. Wielenberg

Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) gGmbH

Madrid, Spain, May 18-22, 2026

Outline

- Background
- Applied code and model improvements
- AC^2 model of the VVER-1000 reactor
- Simulation of IVR in VVER-1000 reactor
- Summary

Background – In-Vessel Retention

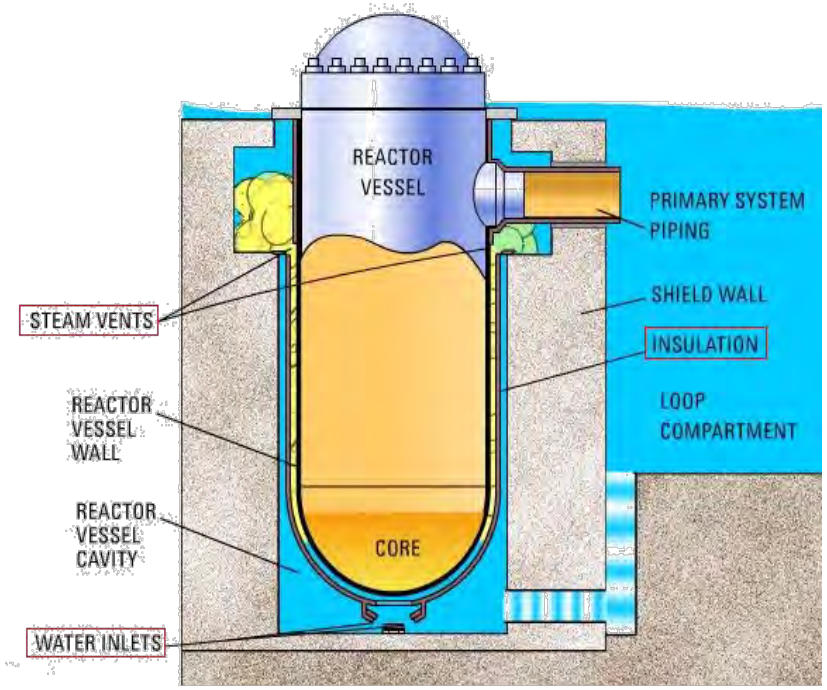
Severe Accident Management Strategy with the aim:

Stabilizing corium in lower plenum via external RPV cooling to prevent vessel failure

- Developed for AP600/1000 and VVER-440
- Licensed in several countries
- Considered for different reactor types

Key points are:

- Thermal load to wall (reactor size and design)
- Cooling efficiency



Scheme of IVR by AP1000

Source: AP1000 Brochure, Westinghouse

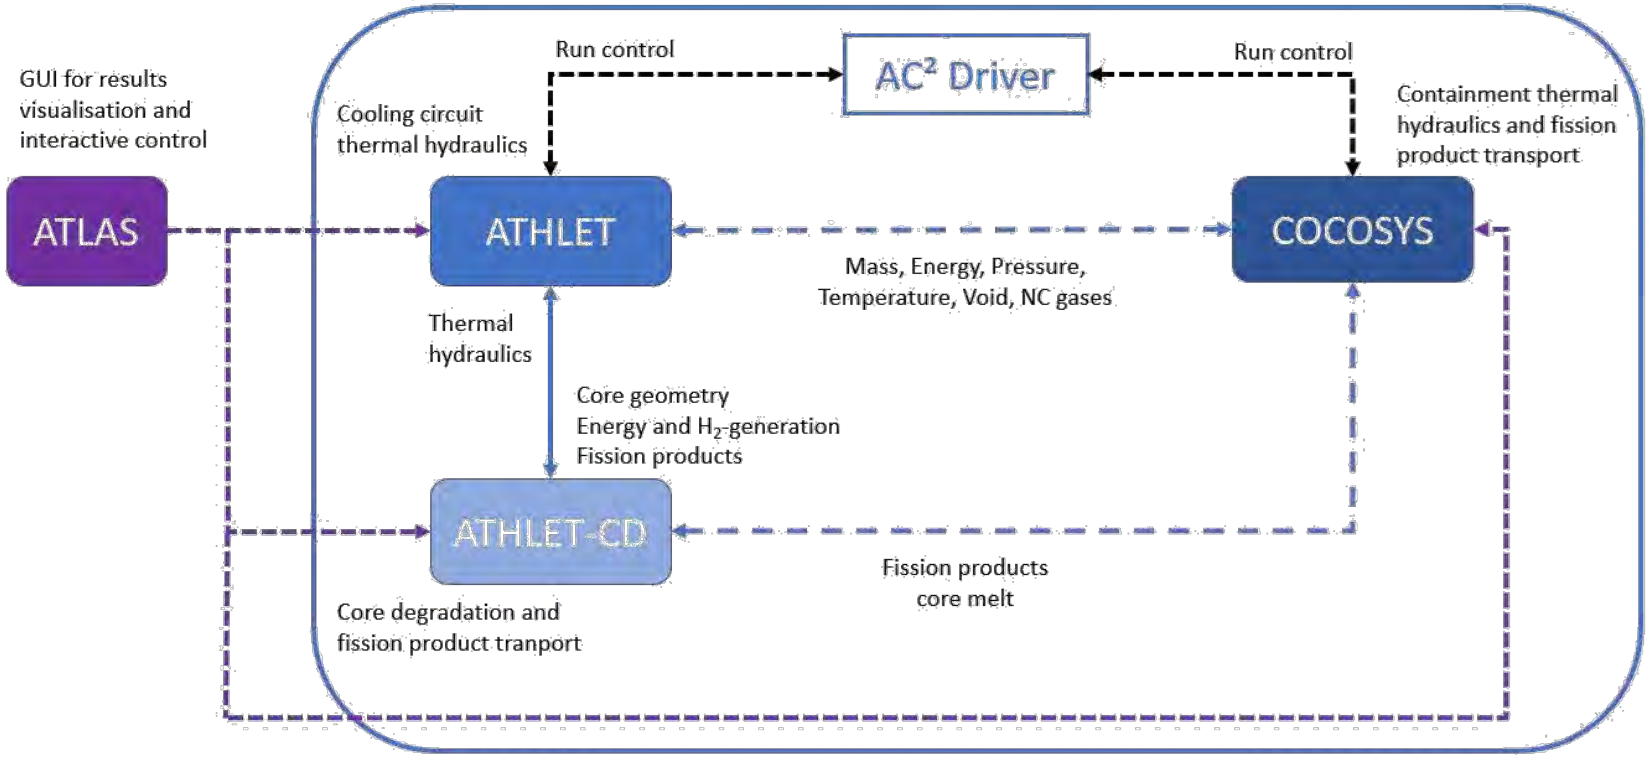
Several investigations in the last years for retro-fitting the **VVER-1000/320** design ⟹ using AC² to investigate the IVR concept

Applied code system – AC²

- Using the German code package **AC² 2025.0** (developed by GRS)
- Modular architecture, ATHLET: thermal hydraulics, ATHLET-CD: severe accident phenomena, COCOSYS: containment phenomena

ATHLET-CD modules:

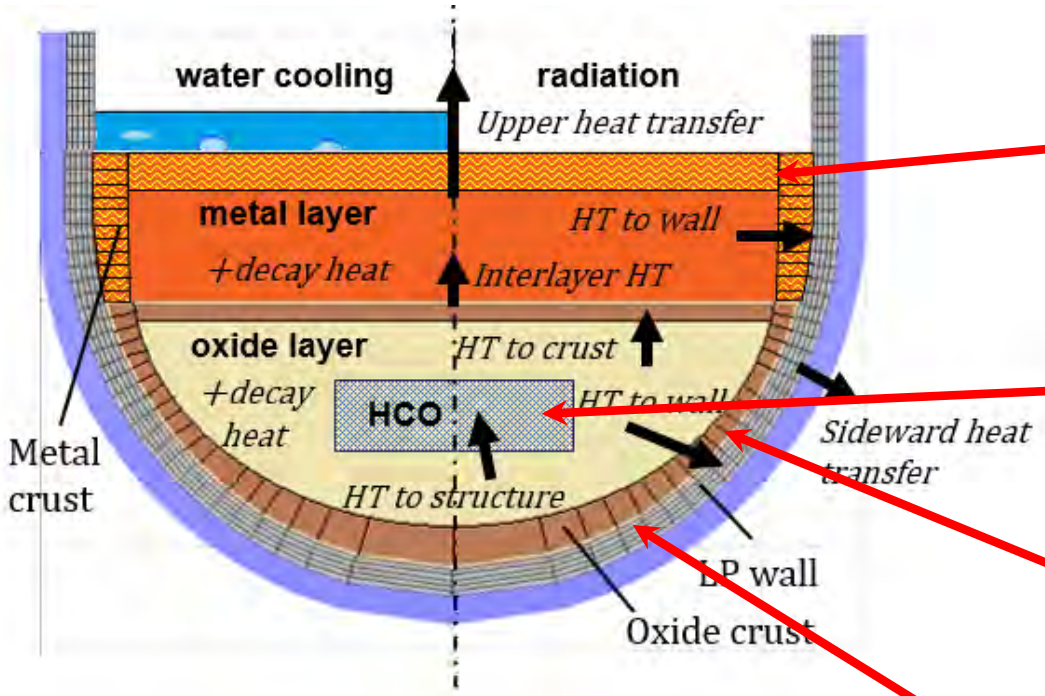
- Core degradation
- Fission product inventory
- Fission product release
- Fission product transport
- Lower plenum behaviour



Applied code system – lower plenum module AIDA

Lower plenum module:

- Stand Alone
- Instantaneous melt segregation
- Two-layer model
- Molten pools (1D)
- Crust formation (2D)
- Wall model with ablation (2D)
- Top and lateral cooling
- ERVC model



Modelling scheme of AIDA

Recent AIDA improvements relevant to VVER-1000:

- Modelling of upper and sideward metal layer crust formation
- Internal structure modelling
- New heat flux distribution factor to model shallow lower plenum geometries
- Update of 15Kh2NMFA RPV (VVER) steel properties

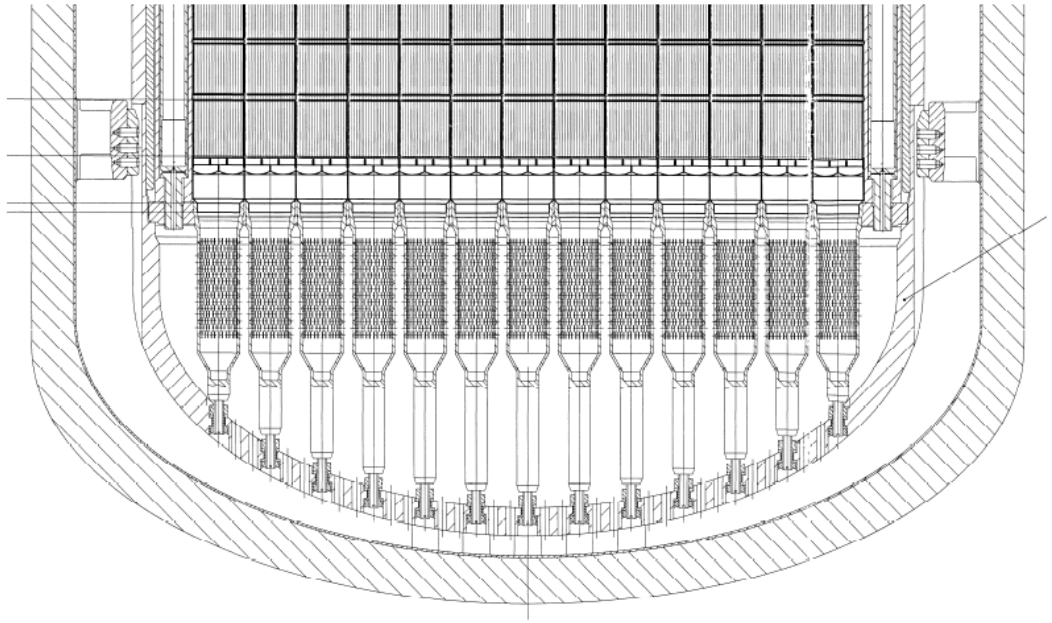
AIDA modelling improvements

LP geometry has a significant effect on the effectiveness of ERVC. VVER-1000 LP has:

- Shallow, ellipsoid shape
- Transition in thickness from bottom to cylindrical part
- Significant amount of lower plenum internal structures (core barrel, FA supports, over 20 t)

1. Improvement in geometry modelling:

- Pool characteristics for external and upper cooling: stratification (lower part) + convection (upper part)
- Improved transition of 1D to 2D heat flux distribution
- LP wall shape modelling with different wall thickness



Lower plenum of VVER-1000/320*

*M. Sangiorgi, A. Grah, G. Pascal, In-Vessel Melt Retention (IVMR) Analysis of a VVER-1000 NPP, 2016.

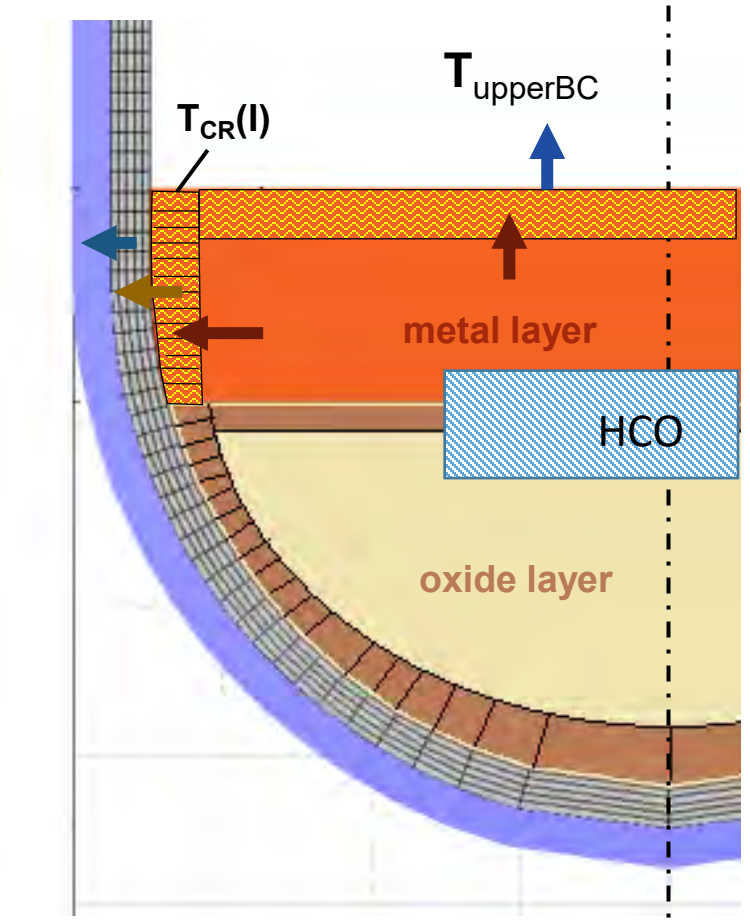
AIDA modelling improvements

2. Improvement in metal layer modelling

- Thick metal layer in VVER-1000
- Solidification at interface (temperature gradient)
- Crust acts as a thermal resistance
- Heat balance is solved for every crust elements incl. phase change

3. Consideration of internal structures

- Modeling with standard ATHLET HCOs
  - Currently one horizontal plate
- Consideration in pool heat balances and volume
- ATHLET failure modelling
- After failure, the melt is added to the metal layer



AIDA model

Simulation of IVR in VVER-1000

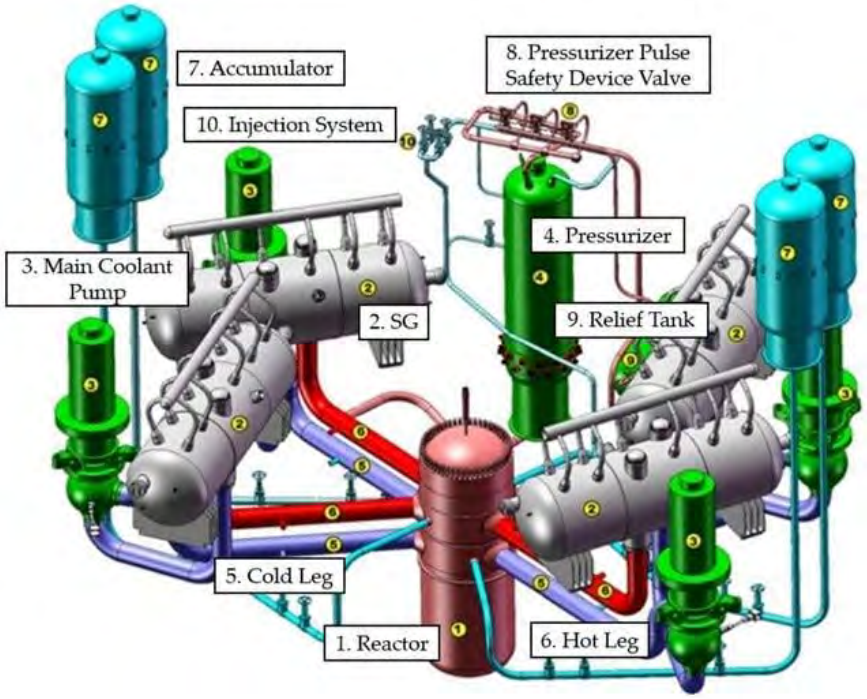
Postulated scenario:

- LOCA by normal reactor operation at 3120 MW
- Core mass flow: 84,800 m^3/h
- Core outlet temperature: 320 °C
- DN850 mm break in the cold leg of loop 1 + simultaneous SBO
  → only passive hydro-accumulator and pressurizer injection
- Simulation until corium stabilization

The hypothetical IVR system:

- Water injection into the cavity starts once the core outlet temp. reaches 650 °C
- Initial ERVC water temperature is 60 °C
- Enough water is assumed for more than 24 h
- External cooling via natural circulation

Simulation done with AC^2 2025.0



Primary circuit of VVER-1000*

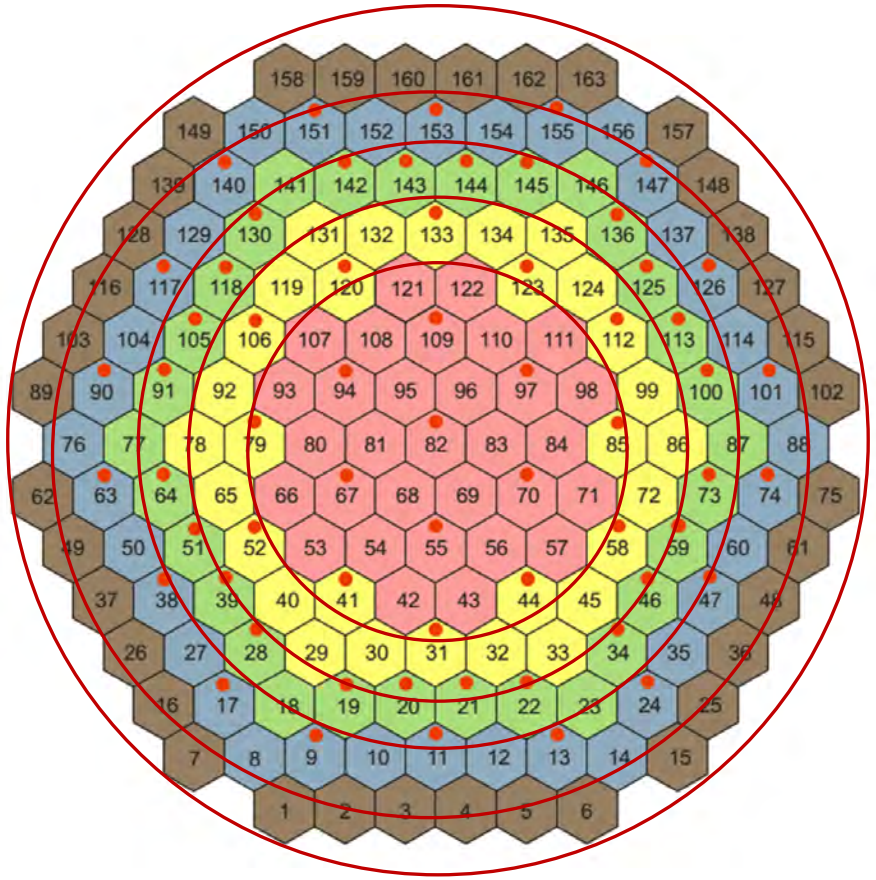
Simulation of IVR in VVER-1000 – ATHLET-CD model

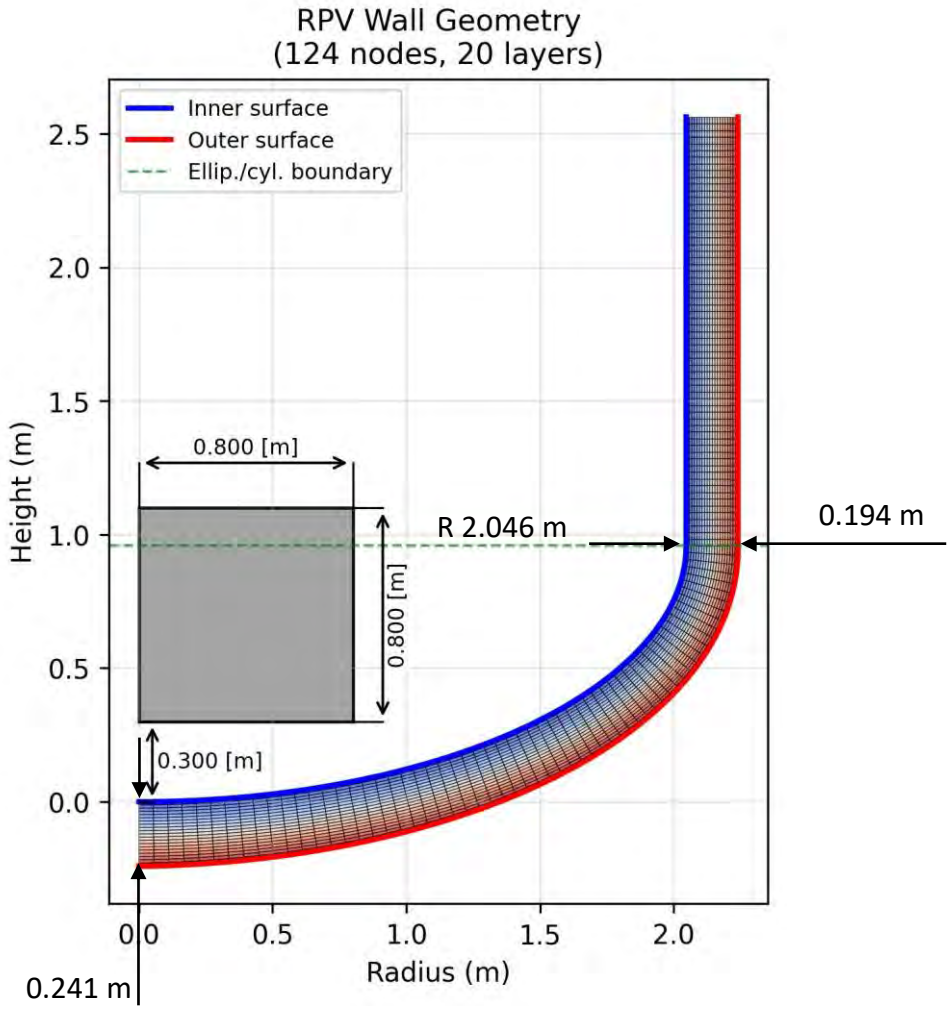
- Calculated fission product inventory, release and decay heat after SCRAM
- Oxidation modelled with Cathcart correlation, incl. steam starvation
- Without modelling of fission product transport
- Five concentric core channels (defined in TH model)
- 163 fuel assemblies divided in 5 groups
- 18x163 B_4C control rod
- VVER fuel type (hexagonal)
- Molten corium accumulates on the grid plate → start of relocation: grid plate failure (mass & temp. criterion)



FA groups in the 5 core section

Simulation of IVR in VVER-1000 – ATHLET-CD AIDA model

- Start after grid plate failure
- Wall nodalisation: 124 axial x 20 radial nodes
- Two-layer model
- 15% of the decay heat is assumed in metal layer
- Bonnet-Seiler correlation for heat transfer between melt-pool and crust
- VVER steel model
- Constant outer wall HTC of 20,000 (W/m^2K)
- Heat transfer is calculated by AIDA
- ERVC parameters are coupled to COCOSYS



AIDA geometry model

Simulation of IVR in VVER-1000 - Results

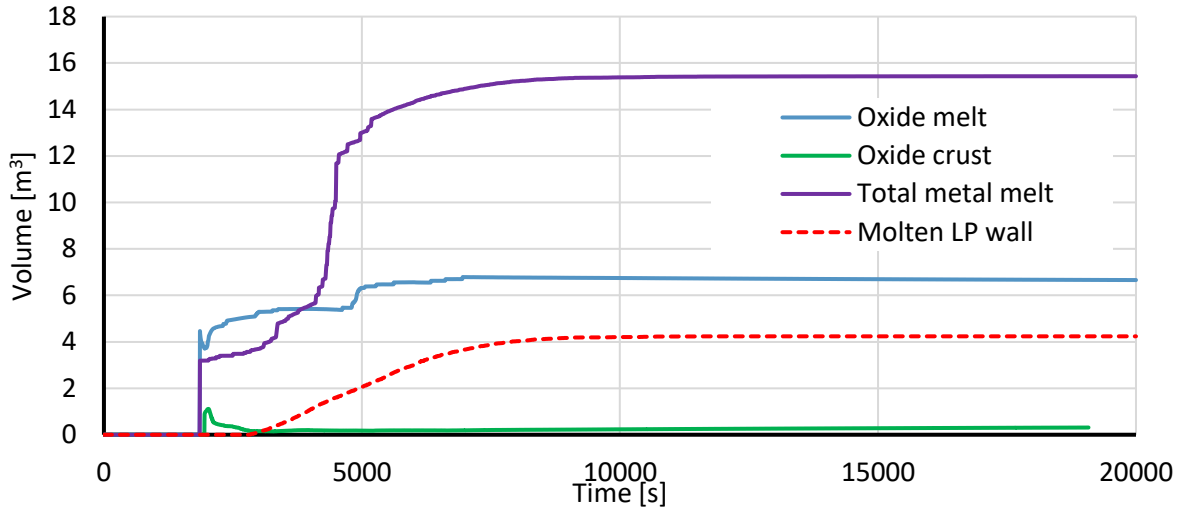
- Immediate SCRAM because of rapid pressure decrease
- Pressurizer is empty after 20 s
- HA stops at 55 s
- After that no more water injection
- Underestimation of hydrogen generation, about 150 t at the simulation end, steam starvation

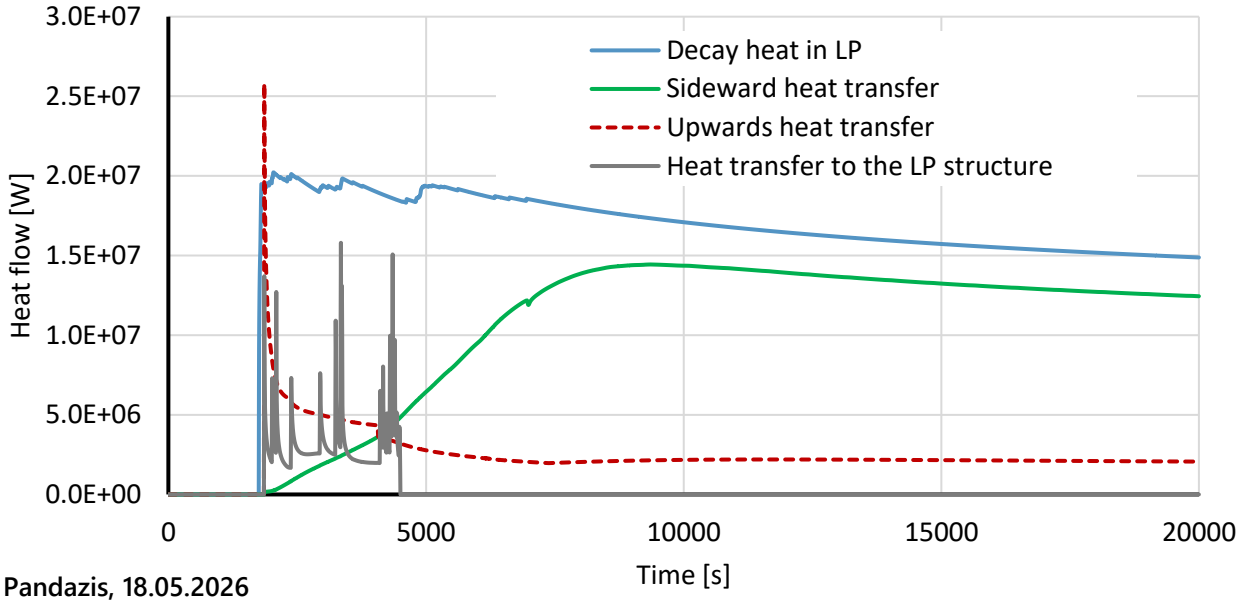
Event	Time [s]
Initial event of the accident	0.1
End of water supply from HA-1	55
Fuel rod burst	466
Core dry out	480
Intense hydrogen generation	1,200
Start of fuel melting	1,529
Corium relocation to the lower head	1,859
LP structure failure	4,496
Corium stabilization	~12,000

Key accident events

Simulation of IVR in VVER-1000 - Results

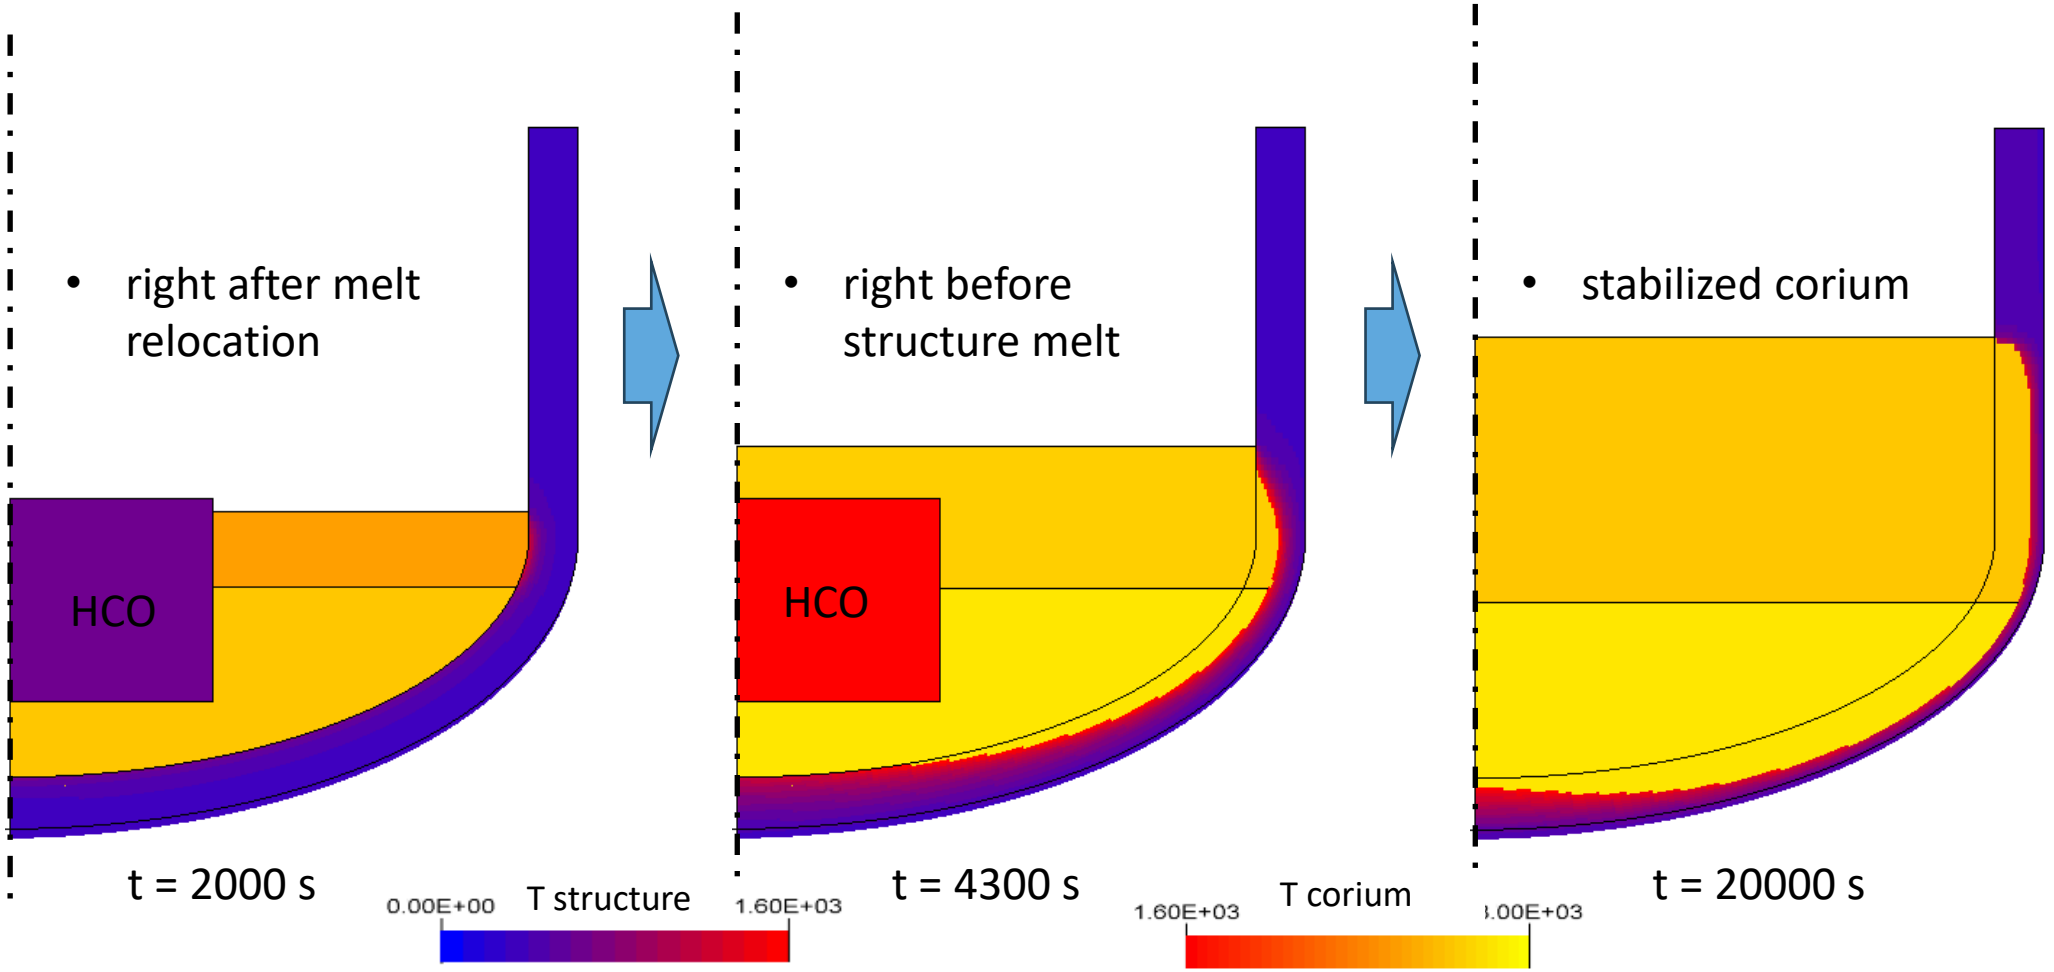
- LP dry out at ~4100 s
  → switch to radiation
- Peaks in heat transfer to LP structure → layer evolution affects the heat transfer area
- At the calculation end:
  - ~70 t of oxide
  - ~120 t of metal
- Wall ablation from 3000 – 10000 s (ca 29.5 t in total)
- Corium stabilization at ~ 12000 s
  - no further wall ablation
  - decay heat < transferred heat





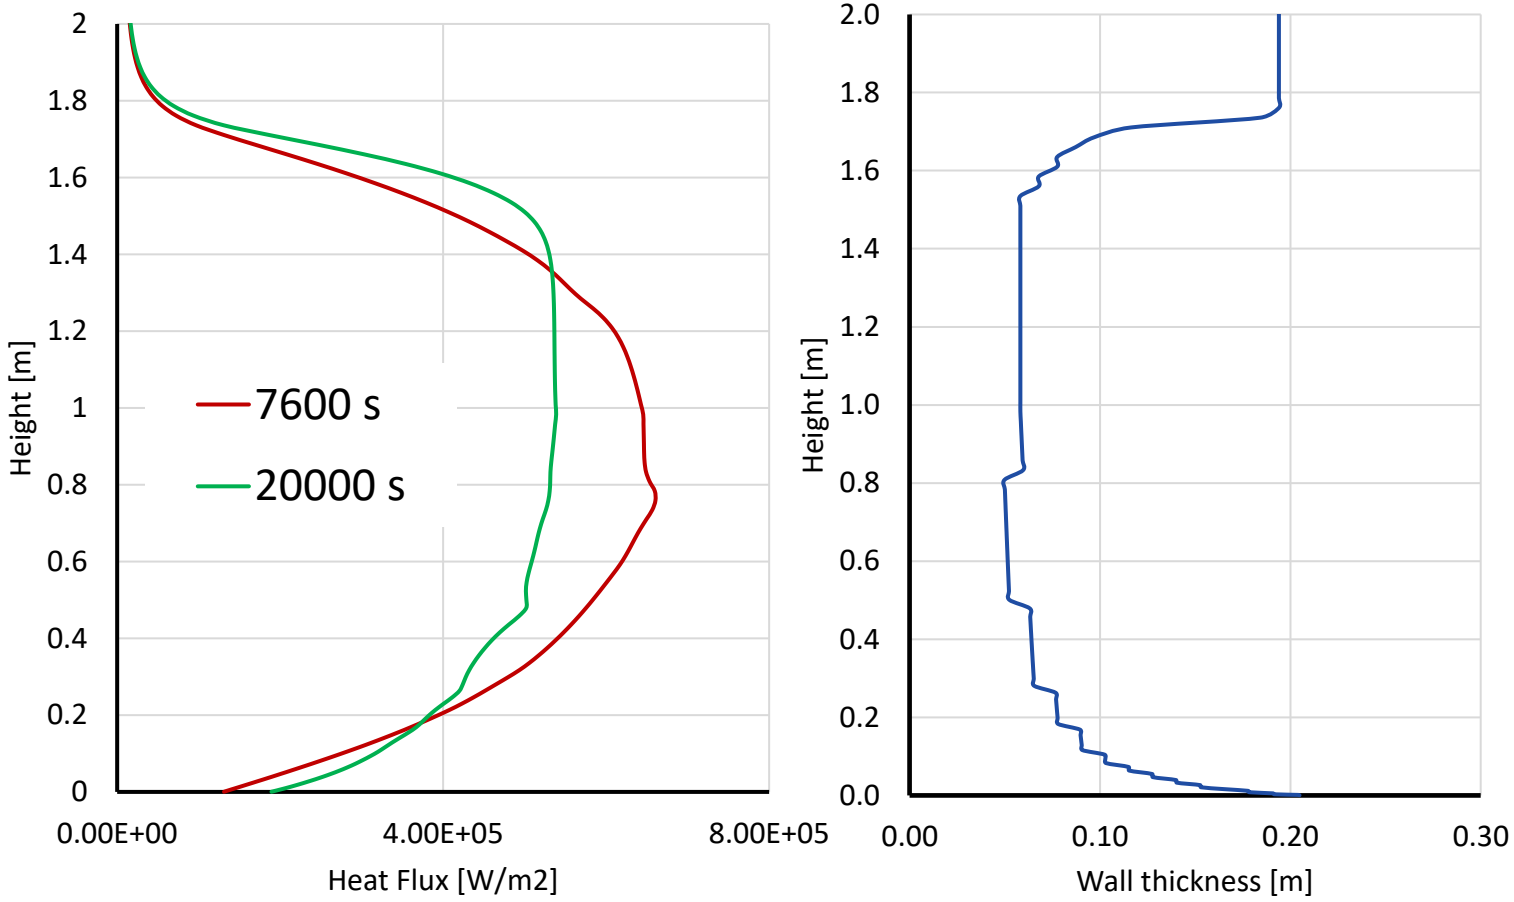
Simulation of IVR in VVER-1000 – lower plenum

Corium pool evolution



Simulation of IVR in VVER-1000 - Results

- Maximum sideward heat flux: 0.66 MW/m^2
- Max. ablation at the upper edge of the oxide layer
- Bottom wall remains intact
- Min. wall thickness: ~50 mm



Heat flux along the wall

Residual wall thickness

Conclusion

- AC^2, ATHLET-CD lower plenum module improved for IVR safety assessment in VVER-1000 reactors
  - More realistic lower plenum wall geometry and shallow pool heat transfer modelling
  - Extension of the metal layer modelling with crust formation
  - More realistic modelling of lower plenum internal structures
- Demonstration by simulation of a hypothetical IVR scenario in generic VVER-1000
  - LP structures increase heat transfer area and absorb part of the corium decay heat
  - Metal layer crust reduces the focusing effect and avoids upper heat transfer overprediction
  - Results show lower heat fluxes and more realistic heat flux distribution at the LP wall
- Ongoing development, verification and validation of the modelling approach
- Improved representation of the lower plenum structures are planned

ABSTRACT

Predicting the flow and heat transfer of in-vessel corium pools poses a significant challenge. Internally heated natural convection induced by the decay heat of fission products is extremely difficult to predict with standard numerical models. This difficulty can hinder the development of accurate severe-accident integral codes and limit the advancement of In-Vessel Retention (IVR) safety systems designed to protect reactor pressure vessel (RPV) integrity in the event of severe accidents. Computational Fluid Dynamics (CFD) is commonly categorized into three approaches: Direct Numerical Simulation (DNS), Large Eddy Simulation (LES), and Reynolds-Averaged Navier-Stokes Simulation (RANS). While DNS provides the highest accuracy at a substantial computational cost, RANS offers the most efficient but least precise results. LES strikes a well-balanced tradeoff between accuracy and computational cost. This work investigates corium pool flow and heat transfer using RANS, validating the results against a new DNS benchmark at a high Rayleigh number (Ra = 1.6 x 10^6). Various turbulence closure models, including SST k-ω, Low-Re k-ε, Two-Layer Cubic k-ε, AHFM-CC, and GEKO, are evaluated. The results indicated that while all models capture the generic flow structure, the k-ω based models provide superior flow predictions but inaccurate thermal fields. Conversely, the Cubic k-ε model improves flow profile accuracy over linear models, and the AHFM-based model yields precise temperature prediction in the stratification region, despite overpredicting velocity.

1. INTRODUCTION

In a severe accident scenario (e.g., Loss of Coolant Accident - LOCA), the reactor core may overheat and melt due to decay heat, forming a molten mixture known as corium. Containing this corium pool within the Rector Pressure Vessle (RPV) is essential to prevent the corium pool from penetrating the vessel, and subsequent contamination of soil and groundwater with radioactive material [1], [2]. To prevent such a scenario, a safety system has been proposed: External Reactor Vessel Cooling (ERVC). A schematic view of the system is shown in Figure 1 [3]. Advancing the design of such systems requires a comprehensive understanding of the flow and heat transfer in corium pools. In the event of a meltdown, the corium pool will be heated internally by the decay heat generated by radioactive material in the core. This heat will drive the molten corium to circulate through the pool because of the density difference created by the fluid's temperature difference, a phenomenon called Internally Heated Natural Circulation (IHNC).

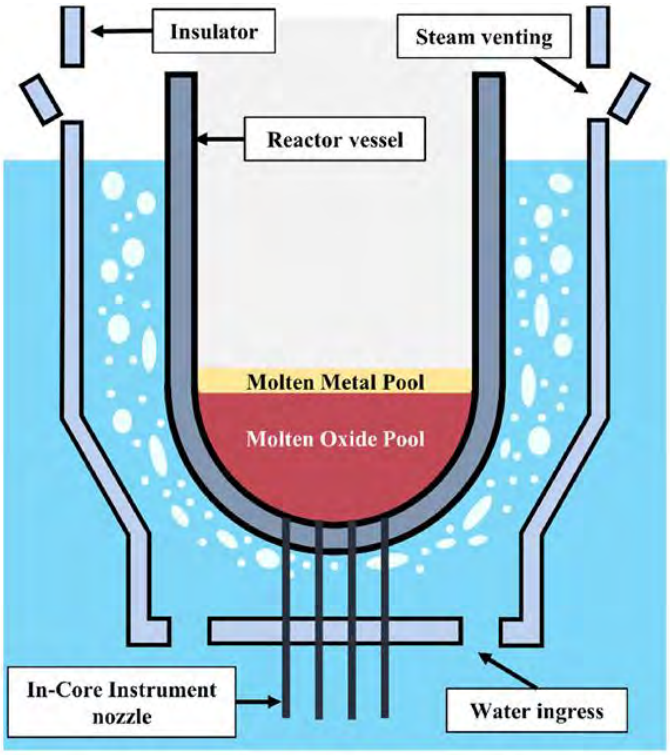

Figure 1. Schematic of the External Reactor Vessel Cooling System [3]

As shown in Figure 1, a corium pool generally consists of two layers: a low-density molten metal pool and a heavier pool of molten oxides, where heat is generated by radioactive decay. The flow behavior of corium pools during cooling has been extensively investigated. Numerous experiments using surrogate materials under various conditions have been conducted, with the resulting data sets available in the literature. A comprehensive list of such experiments was reported by Bian et al. [4]. However, these experiments were typically conducted at low temperatures using materials with relatively high Prandtl numbers (Pr), whereas corium exhibits a significantly lower Pr number of approximately 1 as per Smirnov et al. [5].

A remedy for the difficulties of experimental setups is the utilization of Computational Fluid Dynamics (CFD). Unlike physical experiments, CFD and other numerical methods offer the flexibility to investigate phenomena under extreme conditions. However, since CFD approximates real-life physics by numerically solving the governing equations, numerical error remains a constant concern. CFD is primarily categorized into three approaches: Reynolds-Averaged Navier-Stokes (RANS), Large Eddy Simulation (LES), and Direct Numerical Simulation (DNS). While RANS models all turbulent scales, making it computationally efficient but less accurate, DNS and LES resolve varying degrees of theses scales [6]. Specifically, DNS resolves all turbulence scales, providing the highest accuracy and offering insights into turbulence-related quantities that are often inaccessible through experiments. Consequently, DNS data is extremely valuable for validating lower order methods such as RANS.

Numerous studies available in the literature have investigated and validated numerical models of internally heated corium pools under cooling conditions. In 2018, Shams [7] evaluated the thermal fields of the corium pool using RANS models. Specifically, the Reynold Stress Model with Elliptic Blending (RSM-EB), the Low Reynolds k-ε, and the Low Reynolds k-ε coupled with an Algebraic Heat Flux Model (AHFM) were validated against BALI experimental data. The AHFM-based model (hereafter referred to as AHFM-CC (Calibrated Coefficients) yielded the most accurate results and was specifically calibrated for highly buoyant flows.

Sharma et al. [8] followed a similar approach to Shams [7], utilizing Unsteady RANS (URANS) to test various AHFM formulations with the low-Reynolds k-ε framework. Their findings showed good agreement with the BALI experimental data for the AHFM-based models. In addition, the complex geometries of the lower plenum of Pressurized Water Reactors (PWR) and Boiling Water Reactors (BWR) were investigated. However, the researchers lacked proper validation for these geometries, as the BALI experimental setup - a quarter of a circular slice – does not fully represent the three-dimensional (3D) hemispherical geometry characteristic of a reactor vessel's lower plenum.

In 2025, Guo et al. [9] investigated Detached Eddy Simulation (DES), Wall-Modified Large Eddy Simulation (WMLES), and URANS methods using ANSYS Fluent. The results were validated against the LIVE-3D experimental thermal fields data. The study concluded that WMLES provided the most accurate results, followed by the Realizable k-ε and Generalized Energy k-ω (GEKO) models.

Recently, Bian et al. [4] performed a DNS study of a hemispherical, internally heated corium pool. This study is highly valuable for validating lower-order methods, such as RANS, as it provides detailed data on heat transfer quantities, including: temperature, temperature variance, turbulent heat flux, and heat fluxes. In addition, flow parameters, such as velocity, turbulent kinetic energy, and the buoyancy production term, were reported. Dovizio et al. [1] utilized these DNS results to validate several RANS turbulence models, including the Low-Reynolds k-ε with Yap correction, the Shear Stress Transport (SST) k-ω, the Realizable k-ε, and RSM-EB. While the iteration-averaged temperature profiles showed acceptable agreement with the DNS data; the flow-field predictions were notably less accurate across all models. This discrepancy is likely related to the assumption that an inherently unsteady phenomenon is treated with a steady-state approach and averaging across iterations.

From a qualitative perspective, nearly all models reported in the literature successfully captured the fundamental flow behavior of internally heated corium pools. The characteristic behavior, established through both experimental and DNS studies, is illustrated in Figure 2.

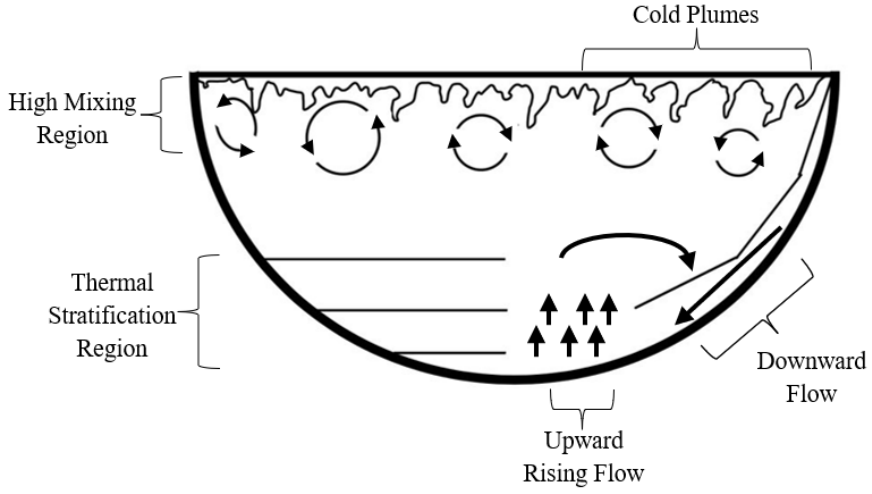

Figure 2. Flow regions inside an internally heated corium pool.

This study aims to investigate the performance of different turbulence models by adopting a URANS approach. Specifically, the Low-Reynolds k-ε with Yap correction, SST k-ω, k-ε cubic, AHFM-CC, and GEKO models are evaluated. All numerical results are validated against the DNS data reported by Bian et al. [4].

2. METHODOLOGY

This section describes the numerical methods and modelling techniques used to simulate the internally heated corium pool.

2.1. Geometry

The adopted geometry is a direct replica of the hemispherical geometry simulated by Bian et al. [3] in their DNS study, featuring a 2 m radius representing the lower plenum of a Light Water Reactor (LWR). A schematic of the geometry and locations chosen for data extraction are shown in Figure 3 below. To analyze the results, a vertical midline was established to capture flow and thermal profiles. Furthermore, 50 horizontal planes were utilized to extract flow and thermal field data, with each plane's data being spatially averaged to ensure a robust comparison with the benchmark.

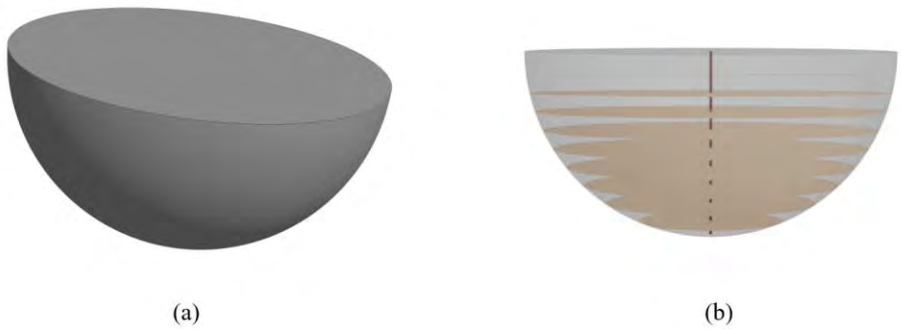

Figure 3. Geometry considered (a) and measurement locations (b).

2.2. Numerical Setup

Two finite-volume codes were employed in this study, namely STAR-CCM+ (Version 19.04.009-R8) and Ansys Fluent 2025 R2. Both codes were used with the SIMPLE algorithm for velocity-pressure coupling. In addition, the second-order upwind scheme was used for spatial discretization. Since the case considered is inherently an unsteady physical phenomenon, an unsteady approach was adopted. Unlike the previously mentioned studies, the authors found that considering a steady-state solution for this case produces results with high uncertainty, especially for the flow fields. Consequently, an implicit unsteady numerical scheme with second-order temporal discretization was utilized. The simulation used a time step (Δt) of 5 seconds with 10 inner iterations per step, ensuring that the average Courant-Friedrichs-Lewy number (CFL) remained below 1. A total flow time of 55 150 seconds was simulated, with parameters being temporally averaged over the final 8 000 seconds.

2.3. Turbulence Modeling

The numerical codes employed in this study utilize the finite volume method (FVM) to solve the Navier-Stokes equations. A RANS-based approach is used, where instantaneous variables, such as velocity, pressure, and temperature, are decomposed into mean and fluctuating components via Reynolds decomposition. This approach simplifies the governing equations, utilizing the eddy viscosity hypothesis to account for the Reynolds stresses. These stresses are resolved by introducing two additional transport equations: one for turbulent kinetic energy (k) and another for the dissipation rate (ϵ) or specific dissipation rate (ω). For the sake of brevity, only the most essential equations are highlighted here. The reader may refer to the Ansys Fluent or STAR-CCM+ theory guides for more detailed information about the models [10], [11]. A summary of the governing equations for incompressible fluids is provided below [12]:

The continuity equation:

$$\frac{\partial \overline{u_i}}{\partial x_i} = 0 \tag{1}$$

The momentum equation:

$$\frac{\partial(\rho\overline{u_i})}{\partial t} + \frac{\partial}{\partial x_j}\left(\rho\,\overline{u_i}\,\overline{u_j}\right) = -\frac{\partial \overline{P}}{\partial x_i} + \frac{\partial}{\partial x_j}\left[\mu\left(\frac{\partial \overline{u_i}}{\partial x_j} + \frac{\partial \overline{u_j}}{\partial x_i}\right) - \rho\,\overline{u_i' u_j'}\right] + F_i \tag{2}$$

The Reynolds stress is defined as:

$$\tau_{ij} = -\rho\,\overline{u_i' u_j'} \tag{3}$$

The energy equation:

$$\rho c_p\left(\frac{\partial \overline{T}}{\partial t} + \overline{u_j}\frac{\partial \overline{T}}{\partial x_j}\right) = k\frac{\partial^2 \overline{T}}{\partial x_j^2} - \frac{\partial}{\partial x_j}\left(\rho c_p\,\overline{T' u_j'}\right) \tag{4}$$

To solve Reynolds Stresses, the eddy viscosity approach is considered:

$$\tau_{ij} = 2\mu_t S_{ij} + \frac{2}{3}\rho k \delta_{ij} \tag{5}$$

$$\mu_t = \rho C_\mu \frac{k^2}{\varepsilon} \tag{6}$$

Four baseline turbulence models are considered: the Low Reynolds linear k-ε model, the two-layer standard cubic k-ε model, the SST k-ω model, and the GEKO model. The transport equations for turbulent kinetic energy (k) and the turbulent dissipation rate (ε) in the standard k-ε framework are given by [13]:

$$\frac{\partial(\rho k)}{\partial t} + \frac{\partial(\rho \overline{U_j} k)}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_j}\right] + P_k - \rho\varepsilon \tag{7}$$

$$\frac{\partial(\rho\varepsilon)}{\partial t} + \frac{\partial(\rho \overline{U_j}\varepsilon)}{\partial x_j} = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_j}\right] + C_{1\varepsilon}\frac{\varepsilon}{k}P_k - C_{2\varepsilon}\rho\frac{\varepsilon^2}{k} \tag{8}$$

In the cubic formulation, the Reynolds stresses are calculated as [14]:

$$\rho\overline{u_i' u_j'} = 2k\rho\left(C_1 S_{ij} + C_2(S^2)_{ij} + C_3(S\Omega - \Omega S)_{ij} + C_4(\Omega^2)_{ij}\right) + \frac{2}{3}\rho k\delta_{ij} \tag{9}$$

The Low Reynolds formulation of the k-ε equations are given in [15].
The basic equations of the SST k-ω model from STAR-CCM+ are [11]:

$$\frac{\partial(\rho k)}{\partial t} + \frac{\partial(\rho k u_i)}{\partial x_i} = \frac{\partial}{\partial x_j}\left(\Gamma_k \frac{\partial k}{\partial x_j}\right) + G_k - \rho f_{\beta^*}\beta^*(k\omega - k_0\omega_0) + G_b \tag{12}$$

$$\frac{\partial(\rho\omega)}{\partial t} + \frac{\partial(\rho\omega u_i)}{\partial x_i} = \frac{\partial}{\partial x_j}\left(\Gamma_\omega \frac{\partial \omega}{\partial x_j}\right) + G_\omega - \rho f_\beta \beta(\omega^2 - \omega_0^2) + D_\omega \tag{13}$$

The GEKO model is a k-ω-based model with coefficients that can be tuned for specific applications. The full description of the model is not published yet. The default settings of the GEKO model are considered with the full buoyancy effect option enabled.
All aforementioned models account for the turbulent heat flux using the Simple Gradient Diffusion Hypothesis (SGDH). An alternative approach is the Algebraic Heat Flux Model (AHFM) to account for the turbulent heat flux. As previously demonstrated by Shams [7], a calibrated AHFM model can yield high accurate results for internally heated corium pools. In this approach, the turbulent heat flux is calculated as follows:

$$\overline{T' u_i}' = -C_{t0}\frac{k}{\varepsilon}\left(C_{t1}\overline{u_i' u_j}'\frac{\partial \overline{T}}{\partial x_j} + C_{t2}\overline{T' u_j}'\frac{\partial \overline{u_i}}{\partial x_j} + C_{t3}\beta g_i \overline{T'^2}\right) + C_{t4}a_{ij}\overline{T' u_j}' \tag{15}$$

Table I. Coefficients for the AHFM-CC

C_{t0}	C_{t1}	C_{t2}	C_{t3}	C_{t4}
0.2	0.25	0.6	$-4.5 * 10^{-9}(\log(RaPr))^7 + 2.5$	0

2.4. Mesh

Three different meshes were generated using the Automated Mesher of STAR-CCM+, utilizing a three-dimensional polyhedral mesh with prism layers applied at the walls. A grid convergence study was conducted in accordance with the method proposed by Eca and Hoekstra [16] for Grid Convergence. The characteristics of the considered meshes are summarized in Table II.

Table II. Details of Different Types of Mesh

Mesh	Number of cells (In Million)	Base Size (mm)	Number of Prism Layers	Average CFL	Maximum y+	Φ (maximum velocity in m/s)
Mesh C	0.62	37.8	16	0.08	0.180	0.000758
Mesh B	1.2	30	20	0.09	0.04	0.000760
Mesh A	2.4	23.8	25	0.1	0.007	0.000759

The grid convergence study was conducted using the SST k-ω in STAR-CCM+. From the measured variable values, an oscillatory convergence behavior was observed. Figure 4 illustrates the velocity profile across 50 horizontal planes for various mesh densities. The Grid Convergence Index (GCI) between Mesh A and B was 0.184%. To minimize numerical error in the subsequent validation study, Mesh A (shown in Figure 5) was selected.

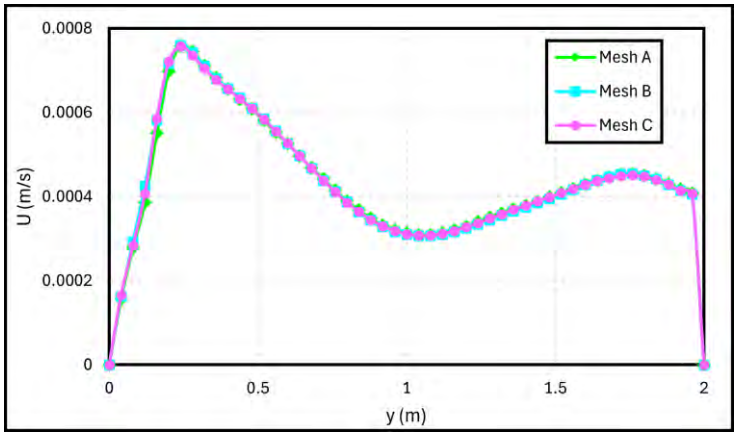

Figure 4. Mean velocity across the 50 horizontal planes for different types of mesh

Figure 5. Final adopted mesh (Mesh A)

2.5. Boundary Conditions

For boundary conditions, no-slip isothermal walls are assumed for all walls of the hemisphere. The wall temperature is 2623.15 K. An internal volumetric heat source of 6.11 W/m^3 is applied. The thermophysical properties of the material are given in Table III [17].

Table III. Material Properties [17].

Density (kg/m^3)	Thermal Conductivity (W/m.K)	Viscosity (Pa.s)	Specific heat (J/kg.K)	Thermal Expansion coefficient (1/K)
7588.4	3	0.0027	540	6.71x10^{-5}

3. RESULTS

This section presents the results obtained from the six different turbulence models. A detailed analysis of the flow physics is provided, followed by a comparative discussion of the predictive accuracy of each model.

3.1. Physics of the Flow

As mentioned in the previous section, the turbulence models with the adopted methodology were applied to the selected test case. Due to the low heat generation rate, the observed changes in temperature and velocity remain relatively small, hence two normalized values are used for comparison with the DNS data [17]. The normalization for velocity and temperature are defined in equations (16) and (17), respectively:

$$U^* = \frac{UH}{\alpha} \tag{16}$$

$$T^* = \frac{(T-T_0)\,\alpha}{H^2\, Q_{\mathrm{vol}}\, \rho c_p} \tag{17}$$

Where U is the velocity magnitude, H is the radius of the hemisphere, α is the thermal diffusivity, Q_{vol} is the volumetric heat source, T is the temperature, T_0 is the temperature of the wall, ρ is the density c_p is the specific heat.

Figure 6 shows the mean velocity contours for the different models on a vertical mid-plane section. All tested models reproduced the main flow behavior of internally heated corium pools, consistent with the reference as shown in Figure 2. Specifically, each model predicted an accelerated downward flow near the side wall, albeit with varying intensities. It is also worth noting that the laminar and the low-Re k-ε models

exhibited nearly identical flow patterns. This observation is particularly interesting as the laminar approach neglects Reynold stresses entirely. Furthermore, it was observed that k-ω-based models predict lower turbulence in the upper high-mixing region than the other models.
Figures 7 and 8 present the instantaneous and mean normalized temperature distribution, respectively. The k-ω based models predicted fewer cold plumes, while all models captured some degree of thermal stratification in the lower region of the pool. This stratification was more pronounced in the laminar and k-ε-based models than in the k-ω-based ones.

3.2. Quantitative Assessment

Quantitative comparison across the different models are presented in Figures 9 and 10. As previously mentioned, data were sampled along the vertical midline and across 50 horizontal planes, with a spatial average computed for each plane. Figure 9 reports the normalized mean velocity; it is evident that none of the tested RANS models fully captured the flow field of this specific case with high accuracy. In addition, it was found from Figure 9(b) that the velocity profiles of the laminar, low-Re k-ε, and the low-Re k-ε with AHFM-CC yield almost identical velocity profiles. This is an interesting finding, as it is quite uncommon for the low-Re k-ε model to laminarize the flow across the whole domain. A similar finding was reported by Dovizio et al. [17]where the turbulent kinetic energy (k) was almost zero for the low-Re k-ε model results tested on the same case. This behavior may be attributed to the damping function of the low-Re k-ε model. One possible explanation is the activation of the damping function across the whole domain, which enforces low values of the turbulent viscosity and treats the case as a laminar one. A further investigation is required to verify the main underlying reason of the exact mechanism. Results also indicate that the k-ω-based models can produce more accurate flow results than linear low-Re k-ε models. In addition, the cubic formulation of the k-ε model yields more accurate results than the linear low-Re k-ε models.

As illustrated in Figure 10, the laminar, low-Re k-ε model and the AHFM-CC models accurately predicted the temperature profile within the stratification region. However, all investigated models overpredicted the temperature in the high-mixing region near the top wall. This discrepancy suggests that the models underpredict the turbulence intensity in this zone, resulting in insufficient mixing and reduced heat transfer, which ultimately leads to higher predicted temperatures. Consequently, a model with good prediction capabilities for turbulence should be considered.

A classical approach to improving accuracy is the use of LES, however, this entails a significant increase in computational cost. An alternative remedy for such complex flows is the use of non-linear eddy-viscosity models, which account for turbulence anisotropy and typically offer better predictions in high-mixing zones. In this study, however, the cubic k-ε model failed to accurately capture the physics in the stratification region. This suggests that a non-linear approach, coupled with a robust closure for turbulent heat flux such as AHFM, may be necessary to achieve higher accuracy. Such a combination could facilitate the development of a tailored turbulence model for specifically optimized for internally heated flows.

4. CONCLUSIONS

In this study, the flow and heat transfer of internally heated corium pools have been investigated. A URANS approach with different turbulence models has been evaluated and validated against high-fidelity DNS data. The results indicated that all tested models successfully reproduce the fundamental flow patterns expected in such systems. Specifically, k-ω-based models provided superior flow field predictions but exhibited inaccuracies in thermal distribution. Conversely, the non-linear cubic k-ε model demonstrated improved velocity profile accuracy compared to linear formulations. While the AHFM-based model yielded precise temperature prediction in the stratified region, it tended to overpredict the velocities. As a final recommendation for future work, combining AHFM closures for turbulent heat flux with higher-order eddy-viscosity models is suggested to achieve better predicted thermal and flow-field results for internally heated corium pools.

ANALYSIS OF DOSE RATES IN THE CONTAINMENT DURING THE FUKUSHIMA ACCIDENT

Tuomo Sevón
VTT Technical Research Centre of Finland
Kivimiehentie 3, Espoo, Finland
tuomo.sevon@vtt.fi

ABSTRACT

Dose rates that were measured during the Fukushima accident using the CAMS (Containment Atmosphere Monitoring System) were analyzed. Distributions of Kr, Xe, I and Cs in the containment drywell and wetwell, calculated with the MELCOR code, were converted to dose rates using conversion factors published by Uchida et al. The calculated dose rates were then compared with the measurements. While the wetwell dose rates were reproduced reasonably well, significant discrepancies were observed in the drywell dose rates, particularly for units 2 and 3. The calculated peak drywell dose rates occurred much too early, and the long-term dose rates were significantly underestimated. Several possible reasons for these discrepancies were identified, including missing models of iodine chemistry, wash-off of deposited aerosols by condensed water, desorption of chemisorbed CsOH, complex structures and piping in the drywell, three-dimensional effects, debris spreading from the pedestal to the drywell, and absence of conversion factors for certain nuclides.

KEYWORDS
Fukushima, MELCOR, dose rate, CAMS

1. INTRODUCTION

Simulation results of the Fukushima accident are typically compared with the measured pressures and water levels, as they are directly available as outputs of accident analysis codes. In addition to these parameters, dose rates in the drywell and wetwell were measured during the accident using the CAMS (Containment Atmosphere Monitoring System). However, accident analysis codes do not directly calculate dose rates. Recently, Uchida et al. [1] published conversion factors that enable the conversion of becquerels of Cs, I, Xe and Kr in the drywell and wetwell to dose rates, accounting for the detector geometry.

This paper analyses results of VTT's MELCOR calculations of the Fukushima accident at units 1, 2 and 3. The calculated fission product distributions are converted to dose rates and compared with the measured dose rates during the accident. The analysis considers magnitudes of the dose rates, their trends, and the timing of sudden changes.

A similar analysis was previously conducted in the OECD Nuclear Energy Agency BSAF project (Benchmark Study of the Accident at the Fukushima Daiichi Nuclear Power Station); see figures 2.7, 3.6 and 4.6 of reference [2]. Very large differences among the benchmark participants were found, but their reasons were not analyzed in detail.

2. METHODS

2.1. MELCOR Models

The dose rate analysis is based on the MELCOR simulations published in references [3], [4] and [5]. The models were developed with the objective of reproducing the measured pressures and water levels as accurately as possible. The drywell was modeled with three control volumes: pedestal, drywell, and a small "drywell hot" volume that receives the assumed leaks from the steam line before mixing the gases with the entire drywell volume. The gas space of the wetwell was modeled with a single control volume. Both the drywell and wetwell were modeled with cylindrical symmetry, so possible azimuthal asymmetry of the fission product distributions was not represented.

One of the main uncertainties in the accident modeling is the timing and flow rate of water injections with the fire engines. At unit 1, there is consensus that a significant amount of water did not reach the reactor before 270 h [6]. At unit 2, attempts to pump seawater to the reactor began 77 h 11 min after the earthquake (March 14, 19:57) [7]. When the accident was modeled with the injection starting at that time, the Reactor Pressure Vessel (RPV) did not fail. However, camera inspections of the drywell have shown that the RPV has failed and debris has been discharged to the pedestal. The RPV failure could be reproduced by assuming that water could be injected only when the pressure was below 0.3 MPa. In this scenario, the injection started at 91 h 11 min. The debris ejection to the pedestal was calculated to begin at 94 h 6 min. In the unit 3 simulation, the first water injection took place at 42 h 39 min (March 13, 9:25), but the injection was stopped several times [8].

Three pressure peaks were measured at the unit 2 reactor between 77 and 83 h. The first and the third peaks were assumed to be caused by Safety Relief Valve (SRV) closing and reopening. At the time of the second peak, the model calculated core plate failure, dropping hot debris into the water in the lower plenum and increasing the pressure. The pressure decrease after 89 h was assumed to have been caused by a leak from the drywell to the reactor building. A 40 cm^2 leak area provided the best match to the measurements.

The water level measurement systems at all three units were distorted by boiling of water in the measurement system, causing the indicated water level to be much higher than the actual level. This boiling was caused by leaks of superheated steam from a steam line to the drywell, heating the measurement system pipes. The measurement systems were added to the MELCOR models, and the leak area and timing that best matched the measurement data were determined. At unit 1, a small 1.7 cm^2 leak was opened at 6.5 h [3]. At unit 2, the best agreement with the measurements was obtained by assuming an 8 cm^2 leak at 78.5 h [4]. And at unit 3, a 20 cm^2 leak was opened at 42.2 h, coinciding with the actuation of the Automatic Depressurization System [5].

2.2. Converting MELCOR Results to Dose Rates

The locations of the CAMS detectors are shown in Fig. 1. Uchida et al. [1] provide conversion factors χ_{ik} from activity to dose rate for nuclide i at location k, taking into account the geometry of the containment and the detector locations. The unit of the conversion factors is (Sv/h) / PBq. Conversion factors are provided for 8 nuclides: Cs-134, Cs-136, Cs-137, I-131, I-132, I-133, Xe-133 and Kr-88. For the wetwell CAMS, conversion factors are available for three locations: water, gas, and deposited on the wall. For the drywell CAMS, conversion factors are available for five locations: gas in the spherical part, wall of the spherical part, drywell floor, and the outer surface of the biological shield (separating the pedestal from the drywell), separately for lower and upper parts of the shield. The conversion factors for the drywell floor were not available in tables, but were estimated from Fig. 11 of [1]. Uchida et al. estimate that the uncertainty of the conversion factors is a factor of two.

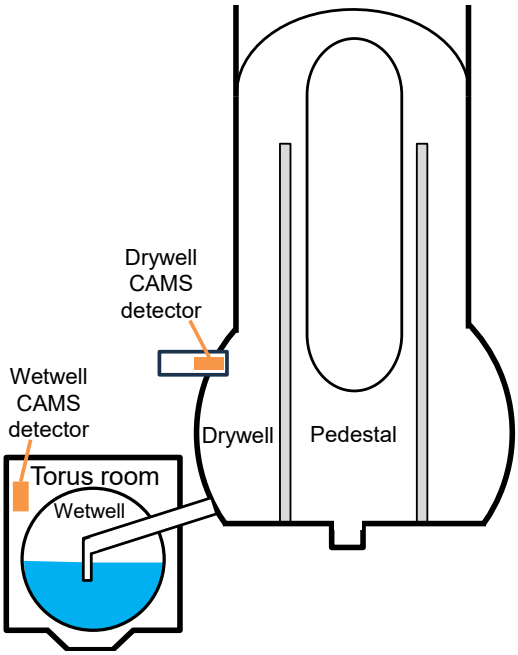

Figure 1. Locations of the CAMS detectors.

For the wetwell, Uchida et al. [1] provide three correction factors that account for the changing water level of the suppression pool. A rising water level increases the conversion factors for the gas phase and wall deposition because the gas volume and wall area decrease, so the same total activity in the gas or on the wall corresponds to a higher concentration. Conversely, a rising water level decreases the conversion factor for the water phase because the concentration of fission products in the water decreases. Private communication with S. Uchida indicated that reference [1] contains typos in the correction factor equations (4-9) and (4-10). The correct forms of the wall and gas correction factors are

$$w_{wall} = 0.24 \cdot [1 - exp\{-4 \cdot (h_s/R_s + 1)\}] + 0.76 \quad (1)$$
$$w_{gas} = 0.4 \cdot [1 - exp\{-4 \cdot (h_s/R_s + 1)\}] + 0.6 \quad (2)$$

Here h_s is the water level measured from the center of the wetwell, and R_s is the smaller radius of the wetwell torus. The effects of the water level correction factors on the dose rates were small, less than 30 %. Another error in reference [1] is that in table A1b, the gas and wall columns have been swapped.

The MELCOR simulations provide the amount of fission product i at location k as a function of time t: $\Phi_{ik}(t)$. The unit of $\Phi_{ik}(t)$ is fraction of core inventory. The dose rate (Sv/h) is then calculated as

$$\Gamma(t) = \sum_k \sum_i \chi_{ik} exp(-\lambda_i t) S_i \Phi_{ik}(t) \quad (3)$$

Here λ_i is the decay constant of nuclide i, and S_i is the core inventory (PBq) of nuclide i at the time of the reactor shutdown [9]. In addition, the water level correction factors were applied for the wetwell dose rates.

The drywell control volume in the MELCOR model includes both the spherical and cylindrical parts. Because the conversion factor was provided only for the spherical part, and the detector does not see the cylindrical part, $\Phi_{ik}(t)$ for $k = gas$ was multiplied by the volume of the spherical part divided by the total volume. Effectively, it was assumed that the fission product concentration is uniform in the drywell gas space. When water was present on the drywell floor, fission products in the water were taken into account using the drywell floor conversion factor.

3. RESULTS

3.1. Unit 1

The wetwell and drywell dose rates at unit 1 are plotted in Figs 2 and 3, respectively. For reference, the measured reactor pressure is also shown. The measurement data was taken from [10]. The MELCOR calculation ends at 168 h because, at that time, the model predicts melt-through of the concrete biological shield between the pedestal and the drywell. Camera inspections have confirmed that this did not occur, so it was not reasonable to continue the calculation further. Overestimation of the long-term concrete ablation is a known issue with severe accident codes [11]. The −50 % and +100 % curves of the calculation results are shown because the estimated uncertainty of the conversion factors is factor of two [1]. The peak value of the wetwell MELCOR CAMS curve (277 Sv/h at 5.2 h) is not visible because the scale was adjusted to better display the measured dose rates. The measured dose rates become available at 63 h, while the core degradation and RPV failure occurred much earlier.

The wetwell dose rates are reproduced reasonably well from 63 to 144 h, considering the factor-of-two uncertainty in the conversion factors. However, the measured wetwell dose rate increases steeply at 144 h, without any apparent reason. The measured pressure does not show any changes at this time, and no significant events were recorded at the plant.

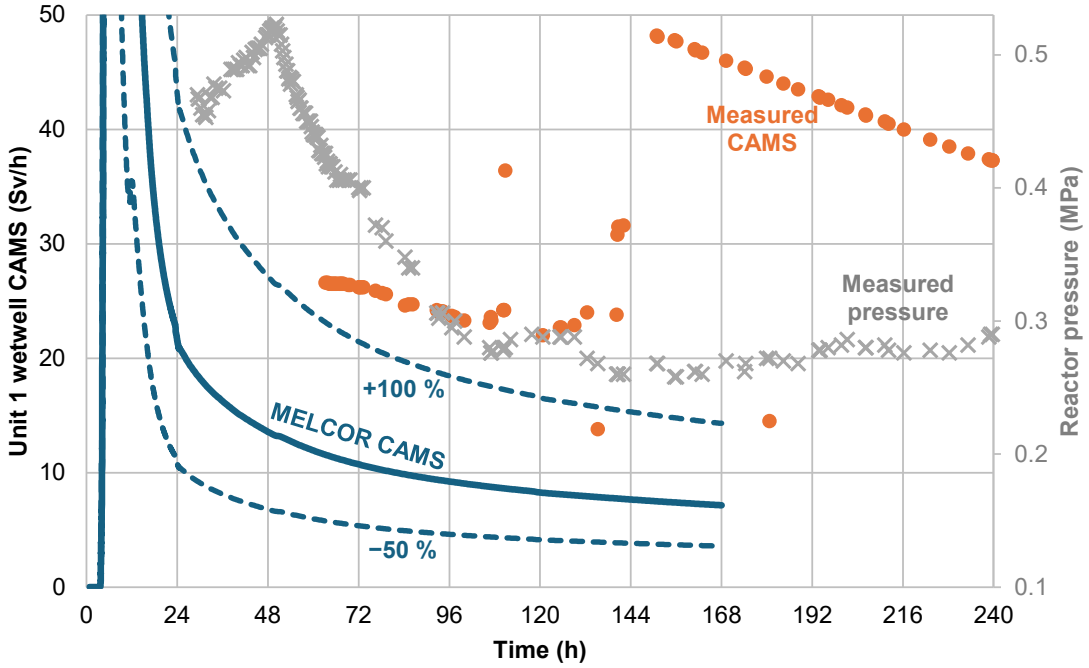

Figure 2. Wetwell dose rate at unit 1.

The decreasing trend of the drywell dose rate of unit 1 from 63 to 84 h is captured quite well by the calculation (Fig. 3). However, the measured dose rate starts increasing at 84 h, again for no apparent reason. After 125 h, the measured dose rate drops to a few millisieverts per hour. Although the figure appears to show a good match, the calculated dose rate is actually around 500 mSv/h during that period. The very low measured dose rates are suspected to be erroneous [6]. Then, at 194 h, the measured dose rates suddenly increase, again with no apparent reason.

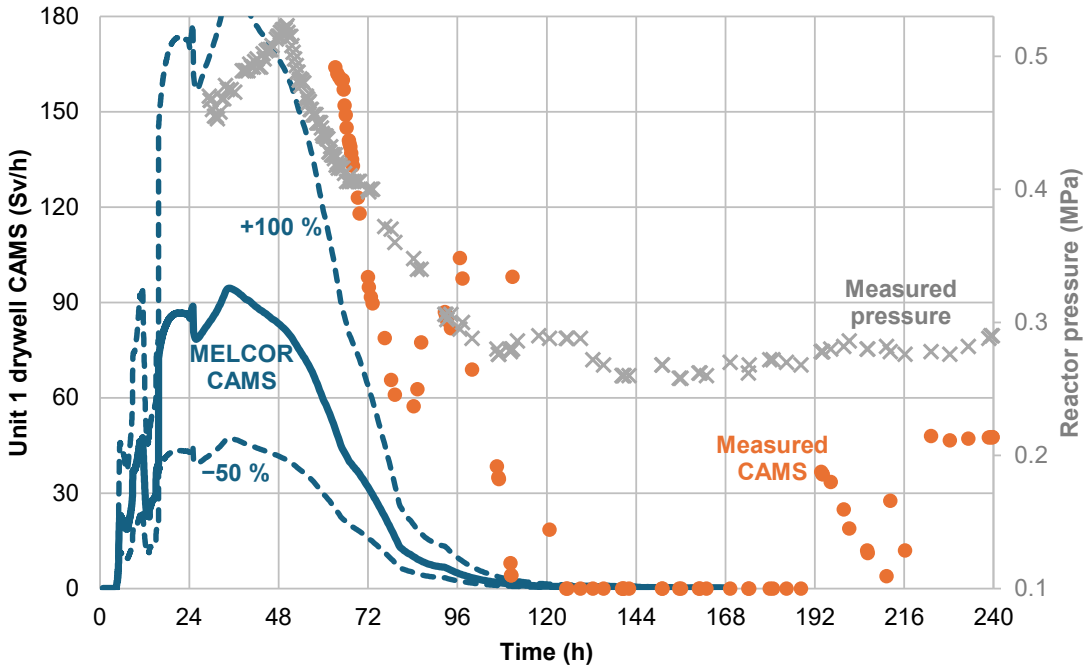

Figure 3. Drywell dose rate at unit 1.

3.2. Unit 2

Unit 2 is the most interesting case because dose rate measurements are available during the time when the core degradation was taking place. The wetwell dose rate at unit 2 is plotted in Fig. 4. For reference, the measured drywell pressure is also shown. The dose rate is calculated quite well, again taking into account the factor of two uncertainty in the conversion factors. Both the measured and the calculated dose rates jump at 78.5 h, when a SRV was opened and a gasket leak from a steam line to the drywell assumed. This event is visible also as a rapid increase of the drywell pressure.

At the peak, 73.5 % of the calculated dose in the wetwell is caused by fission products in the gas phase, 26 % in the water, and only 0.5 % deposited on the wall. The situation changes over time, as aerosols deposit and gases leak out of the containment. At 163 h, only 0.4 % of the calculated wetwell dose is caused by fission products in the gas phase, 80.5 % in the water, and 19.1 % deposited on the wetwell wall.

The drywell dose rate at unit 2 is plotted in Fig. 5. Both the measured and the calculated dose rates start increasing at 78.5 h, but the calculated peak dose rate occurs 18 h too early. Also in the BSAF-2 benchmark, almost all participants calculated the peak dose rate at an earlier time than measured (Figure 3.6 of [2]). (Note that the VTT results shown in [2] were calculated with an earlier version of the model, which did not predict RPV failure at unit 2.) The long-term drywell dose rate is underestimated by a factor of about 24.

At the peak, 96.1 % of the calculated dose in the drywell is caused by fission products in the gas phase, 3.2 % on the floor, and only 0.7 % deposited on the walls. The situation changes over time, as aerosols deposit and gases leak out of the containment. At 163 h, only 0.2 % of the calculated drywell dose is caused by fission products in the gas phase, 1.1 % on the floor, and 98.7 % deposited on the walls.

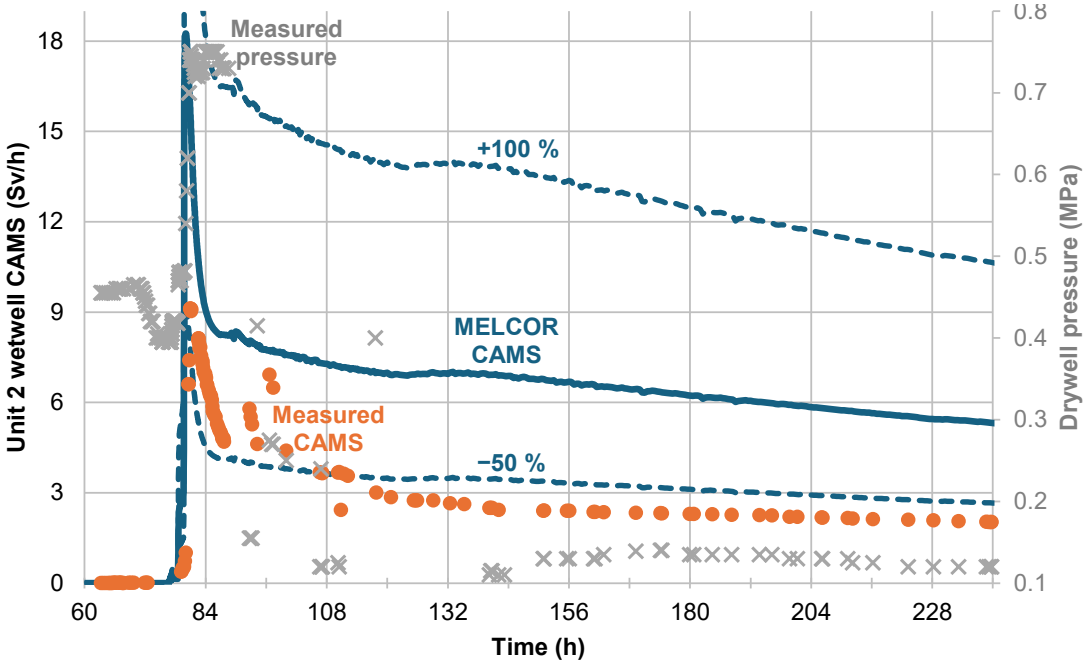

Figure 4. Wetwell dose rate at unit 2.

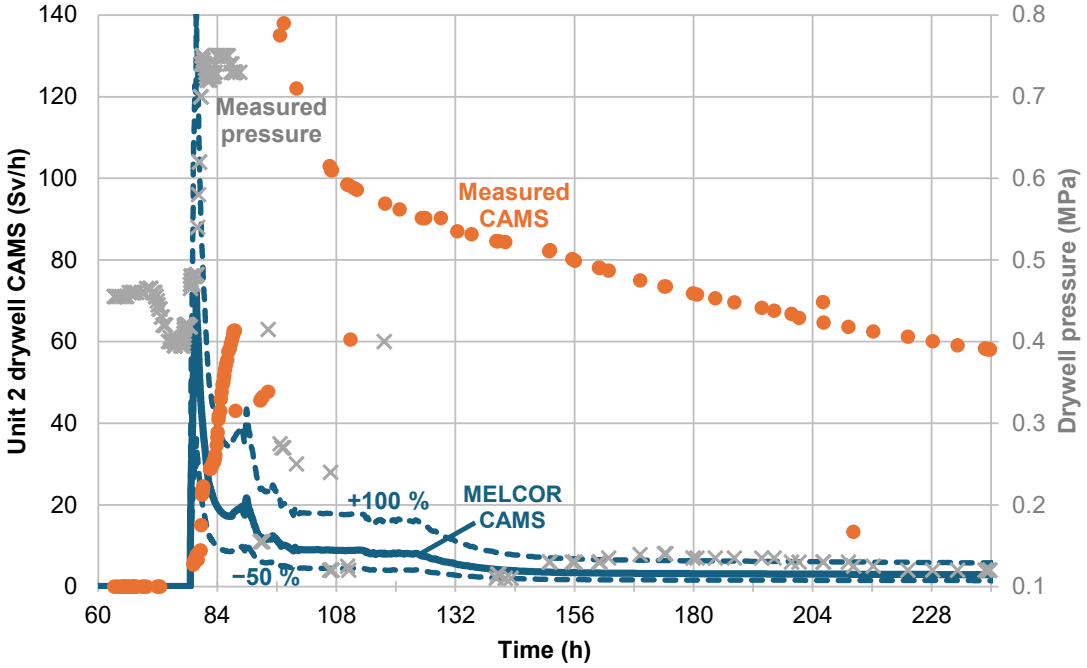

Figure 5. Drywell dose rate at unit 2.

3.3. Unit 3

At unit 3, the dose rates measurements are available from 61 to 68 h, and again starting at 161 h. Similarly to unit 1, the core degradation period was already over when the CAMS became available. The calculation reproduces the wetwell dose rates well, as shown in Fig. 6. The MELCOR calculation ends at 141 h, but simple extrapolation shows that the dose rate is at the same level as the measurements beyond 161 h. There

were two CAMS detectors, A and B, and the B detector showed about 30 % lower readings than the A detector. The detectors may be located at different angular positions, but the exact locations are unknown.

The unit 3 drywell dose rates are presented in Fig. 7. The measured dose rate peaks at 64 h, but the measurement was not available during the time when the calculation predicts the highest dose rate (45 h, soon after the ADS actuation and assumed steam line leak). The results look similar to unit 2 (Fig. 5): the peak value is calculated much too early, and the long-term dose rate is significantly underestimated.

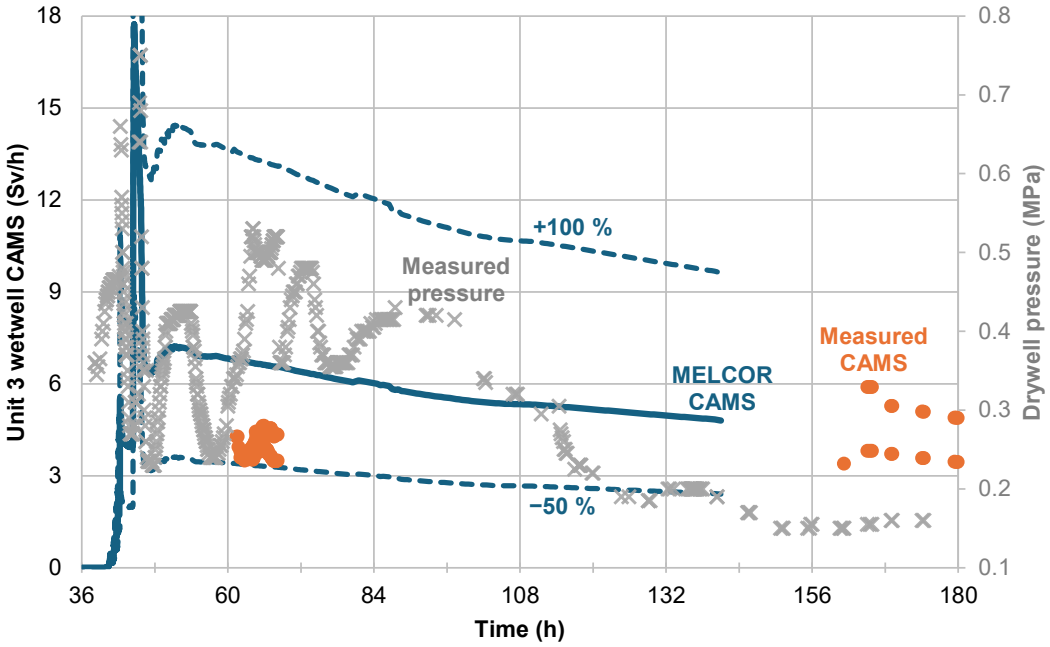

Figure 6. Wetwell dose rate at unit 3.

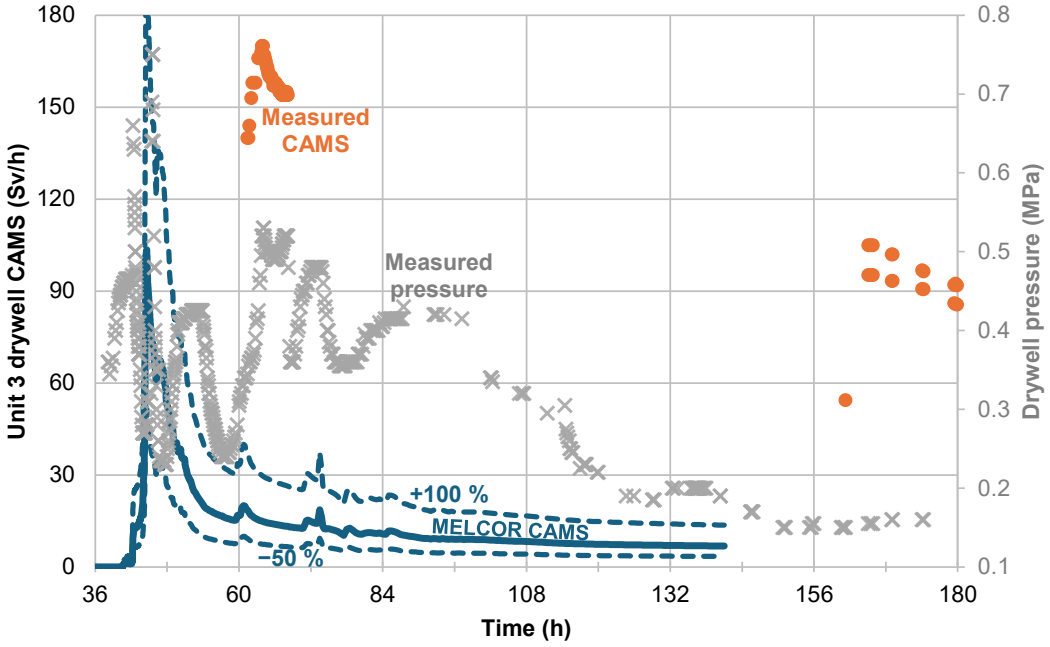

Figure 7. Drywell dose rate at unit 3.

4. DISCUSSION

The measured dose rates seem to follow exponential decay curves at late phases of the accident. Fig. 8 shows decay curves fitted to the unit 2 dose rates after 100 h. The drywell dose rate decreases with an effective half-life of 8.2 d, while the wetwell dose rate follows the effective half-life of 7.9 d. Similar curves can be fitted to the other units' dose rates, yielding effective half-lives between 7.7 and 11.6 d.

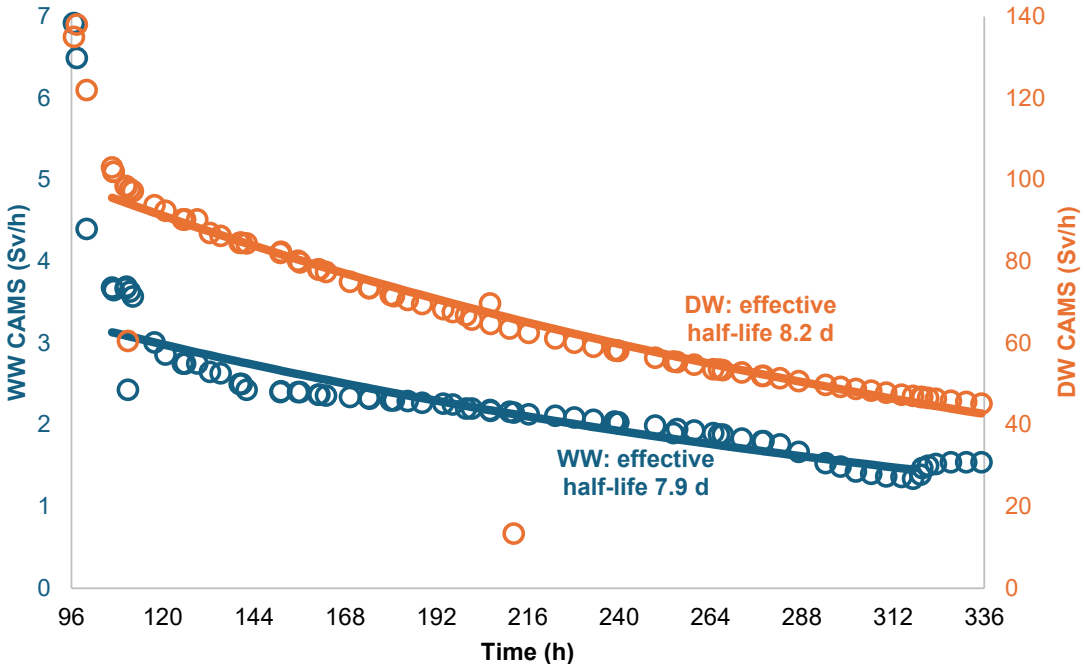

Figure 8. Exponential decay curves fitted to unit 2 dose rates after 100 h.

Half-lives of all the nuclides considered in the analysis are presented in Table I. The effective half-lives of the measured dose rates (7.7–11.6 d) are very close to I-131. This suggests that iodine was the main source of the containment dose rate during the first few days of the accident. The half-life of Xe-133 is also close to the measured values, but the conversion factors from becquerels to dose rates are so small for Xe-133 that its contribution to the dose rate was very small, despite its large inventory. If cesium was a significant contributor to the dose rates, the measured effective half-life should be much longer.

Table I. Half-lives of the considered nuclides.

Nuclide	Half-life
Kr-88	2.8 h
Xe-133	5.3 d
I-131	8 d
I-132	2.3 h
I-133	21 h
Cs-134	2.1 a
Cs-136	13 d
Cs-137	30 a

A source or uncertainty is that conversion factors for tellurium are not available. Te-132 has the half-life of 3.2 d, so it may reduce the effective half-life. Another uncertainty is that radioactive decay is not the only phenomenon that reduces the dose rate. The release of fission products from the containment to the environment also plays a role, as well as wash-off of deposited fission products from the walls by condensed water.

Cesium has a significant effect on the calculated dose rates. For example at unit 2 at 163 h, Cs causes 55.5 % of the calculated wetwell dose rate and 59.1 % of the calculated drywell dose rate. The corresponding numbers for iodine are only 44.2 % and 40.9 %.

Using unit 2 drywell at 163 h as an example, the measured dose rate was 77.4 Sv/h, while the calculated dose rate was only 3.3 Sv/h. For the calculated dose rate to reach the measured value, additional 9 % of the Cs inventory, or alternatively 14 % of the I inventory, would have to move to the lower part of the biological shield outer surface (which has the highest conversion factors). The distribution of the Cs and I at the selected instant is presented in Table II. More than half of the Cs and I is in the wetwell water. Possible overestimation of the retention in the water could explain the significantly underestimated drywell dose rate and the somewhat overestimated wetwell dose rate (Fig. 4). Alternatively, desorption of the CsOH that is calculated to be chemisorbed in the RPV could rise the calculated dose rate to the measured level. Possible underestimation of the release of Cs and I from the fuel could also explain the underestimated dose rate. However, if more fission products were released from the fuel or desorbed from the reactor, all of them would not be deposited in the drywell.

Table II. Distribution of Cs and I at unit 2 at 163 h.

	% of inventory	
	Cs	I
Fuel	12.5	18.8
RPV	19.4	0.3
Steam lines	0.8	0.7
Pedestal	4.8	4.7
Drywell outside pedestal	3.0	3.3
Wetwell	57.0	67.5
Reactor building	0.4	0.8
Environment	2.1	3.9

Nine possible causes were identified for the underestimated drywell dose rates at late phases of the accident:

1. The model may underestimate aerosol deposition in the drywell, possibly due to missing deposition surfaces, such as small piping of auxiliary systems, supporting structures, and maintenance platforms and walkways.
2. The detector may measure radiation coming from inside of pipes that contain highly radioactive materials. This effect could not be modeled.
3. There may be 3-dimensional effects. The drywell is modeled with a cylindrical symmetry, but the fission product deposition may be asymmetric, with more fission products deposited close to the detector. [12] Asymmetry could also explain why the calculated peak occurs earlier than the measured peak, if the leak from the steam line to the drywell was located at another side of the drywell than the detector.

4. MELCOR assumes that condensed water washes off all deposited fission products from heat structure surfaces, but this may not be a correct assumption, especially for species that are not water soluble.
5. Possible overestimation of the fission product retention in the wetwell water can explain the discrepancy.
6. MELCOR assumes that a significant amount of CsOH vapor is chemisorbed on steel structures in the reactor. For example at unit 2 at 163 h, 19.4 % of the Cs inventory is retained in the reactor. MELCOR assumes that the chemisorbed CsOH is never desorbed. If this assumption is incorrect, desorption of the chemisorbed CsOH from the reactor could explain the high dose rates in the drywell during the late phases.
7. If fuel debris has spread from the pedestal to the drywell, the detector may directly "see" the debris. This effect was not taken into account in the analysis.
8. The effective half-lives of the measured dose rates suggest that I-131 was the main source of the containment dose rate. Iodine has a very complicated chemistry that is not modeled by MELCOR. For example, adsorption of gaseous iodine on the drywell wall could explain the high dose rates.
9. The analysis considered the eight nuclides listed in Table I because the conversion factors have been published only for them. Other nuclides, such as tellurium, may have caused significant dose rates in the drywell.

One of the objectives of the analysis was to find opportunities for improving the MELCOR models. This objective was not reached. Discrepancies between the calculated and measured dose rates were found, and possible reasons for the discrepancies were identified. But the identified reasons remain speculative because fixing any of them is beyond reach. It would require changing the MELCOR source code (e.g. iodine chemistry, or desorption of chemisorbed CsOH), or modeling phenomena for which sufficient information is not available (e.g. radiation from inside of pipes or directly from debris, or nuclides for which conversion factors have not been published).

5. CONCLUSIONS

Results of MELCOR calculations of the Fukushima accident at units 1, 2 and 3 were analyzed. The calculated distributions of Kr, Xe, I and Cs in the wetwell and drywell were converted to dose rates using conversion factors published by Uchida et al. [1] and compared with the measured dose rates during the accident.

The results of the unit 2 and 3 analyses are similar. For both units, the dose rates in the wetwell are reproduced reasonably well, taking into account uncertainties in converting becquerels to dose rates. However, the drywell results are not so good. The calculated peak dose rates in the drywell occur much too early (even though the timing of the measured peak at unit 3 is uncertain, as it may have occurred at a time when measurement data was not recorded). And the calculated drywell dose rates in the late phases of the accident are significantly underestimated.

The unit 1 results are somewhat different. The wetwell dose rates are reproduced reasonably well from 63 to 144 h. But the measured dose rate increased steeply at 144 h, without any apparent reason. The decreasing trend of the drywell dose rate from 63 to 84 h is captured quite well by the calculation. However, the measured dose rate started increasing at 84 h, again for no apparent reason.

During late phases of the accident, the measured dose rates decreased with effective half-lives between 7.7 and 11.6 d. This suggests that I-131 (half-life 8 d) may have been the main source of the containment dose rate during the first few days after the accident. Uncertainties in iodine chemistry and adsorption may have caused the discrepancies in the calculated drywell dose rates.

Several other possible causes for the underestimated drywell dose rates in the late phases of the accident were identified. These include complex structures and piping in the drywell, 3-dimensional effects, models for wash-off of deposited fission products due to condensed water, desorption of chemisorbed CsOH from the reactor, debris spreading from the pedestal to the drywell, and other nuclides besides Kr, Xe, I and Cs. Testing the possible causes was beyond reach of this work.

Analysis of dose rates in the containment during the Fukushima accident

Tuomo Sevón

ERMSAR, Madrid, Spain, 18–22 May 2026

Introduction

- Measurement data available from the Fukushima accident:
  - Pressures in reactor and containment
  - Water level in reactor
  - Dose rates in containment ("CAMS data")
- Simulation results usually compared with pressures and water level because direct outputs of severe accident codes
- Dose rates not directly calculated by codes
  - ➢ Conversion factors (Bq → Sv/h) published:

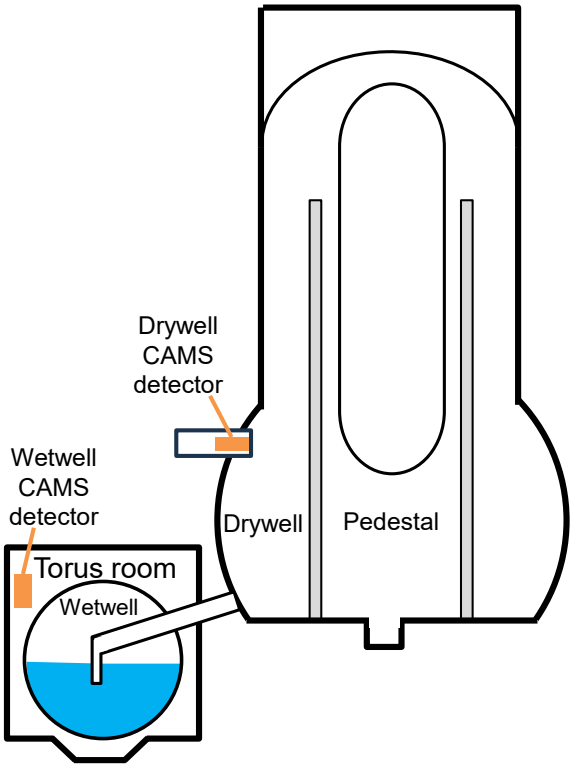
  Uchida, S., Pellegrini, M. & Naitoh, M., Nuclear Engineering and Design 380 (2021)
- This presentation: Convert MELCOR results of unit 1, 2 and 3 accidents to dose rates, compare with measured dose rates

MELCOR models of units 1, 2 and 3

- Developed by VTT, results published in 2020–2023
- Tuned to reproduce measured pressures and water levels as well a possible
- Assumptions of water injection with fire engines:
  - Unit 1: injection unsuccessful until 270 h
  - Unit 2: injection rate restricted so that RPV failure calculated
  - Unit 3: injection as reported by TEPCO
- Assumed leaks of superheated steam from steam line to drywell at all units:
  - Timing: when the water level measurement system "went crazy"
  - Leak sizes: tuned to match the measurement data as well as possible

Nuclides and locations

- Conversion factors available for 8 nuclides: Cs-134, Cs-136, Cs-137, I-131, I-132, I-133, Xe-133, Kr-88
- Source locations:
  - Wetwell: water, gas, deposited on wall
  - Drywell: spherical part gas; deposited on wall, floor, and biological shield surface
- Correction factor depending on wetwell water level
- Uchida et al. estimate uncertainty of the conversion factors: factor of two



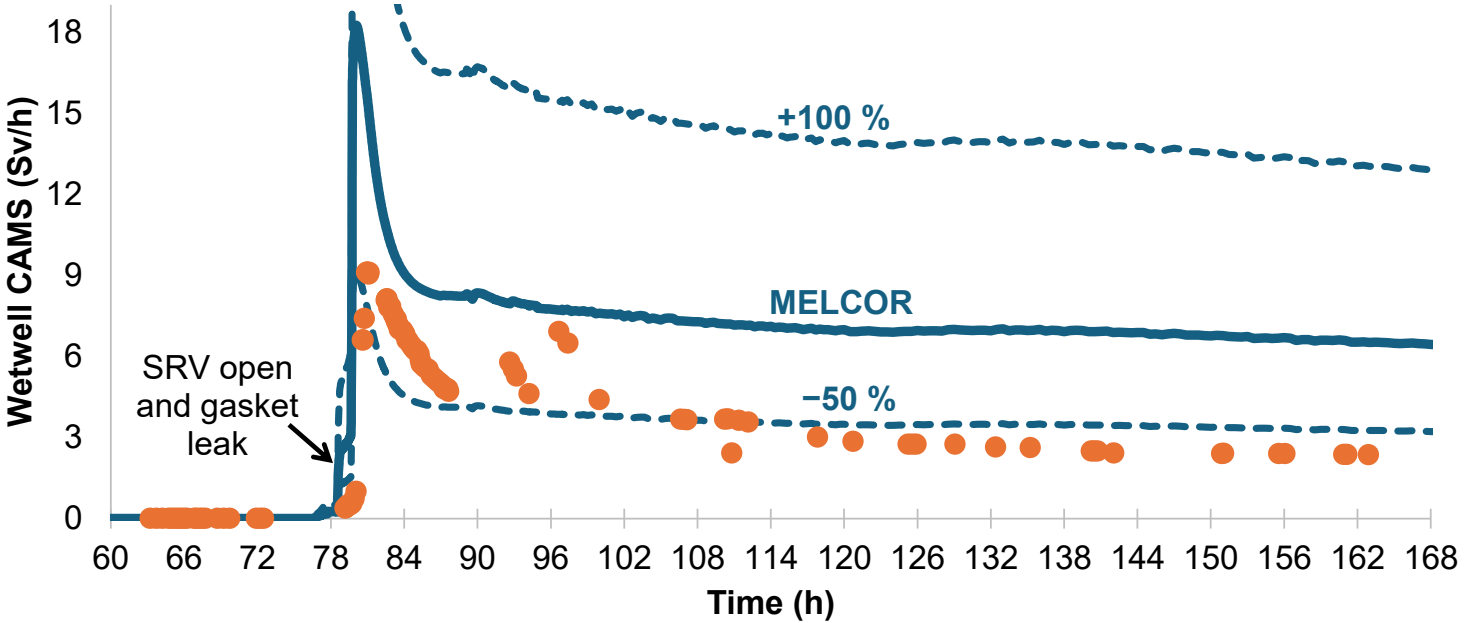
Converting MELCOR results to dose rates

$$\Gamma(t) = \sum_k \sum_i \chi_{ik}\, e^{-\lambda_i t}\, S_i\, \Phi_{ik}(t)$$

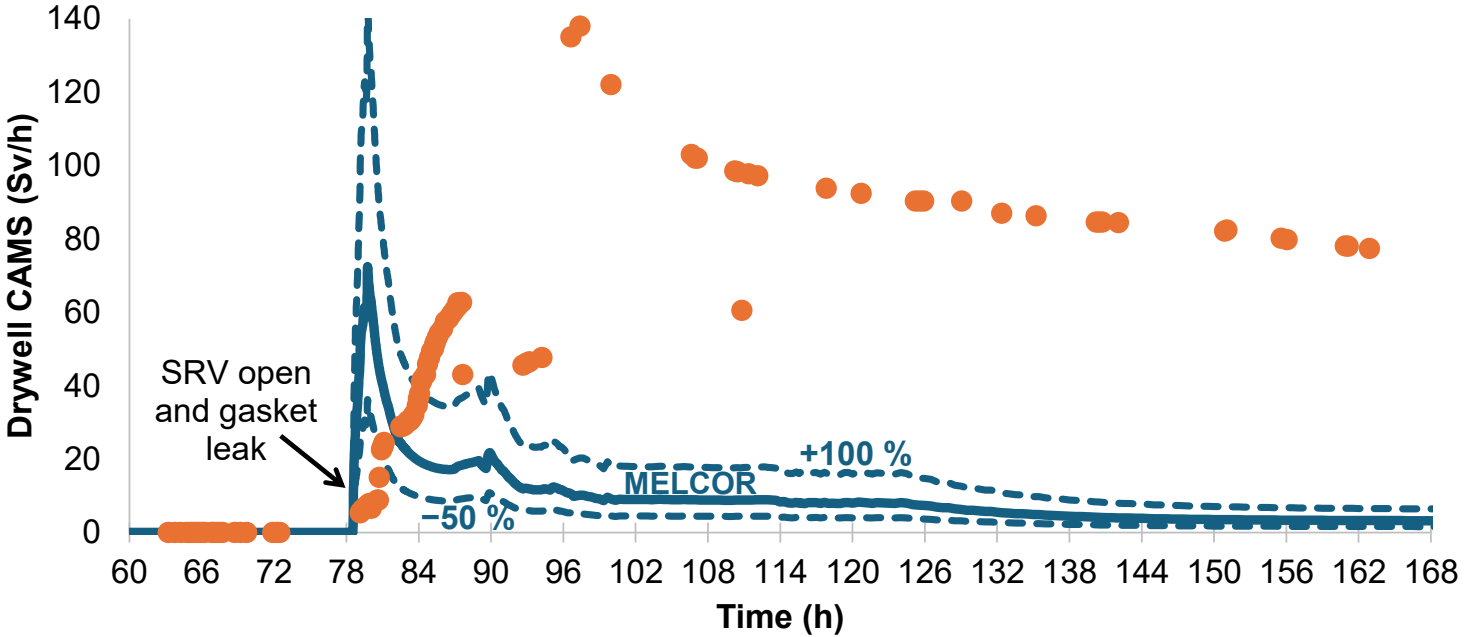
- Γ = dose rate (Sv/h)
- χ_{ik} = conversion factor (Sv/h / PBq) for nuclide *i*, location *k*, from Uchida et al.
- λ_i = decay constant for nuclide *i* (1/s)
- S_i = inventory of nuclide *i* at reactor shutdown (PBq), from JAEA-Data/Code 2012-018
- $\Phi_{ik}(t)$ = amount of nuclide *i* at location *k* at time *t* (fraction of inventory), from MELCOR

Results

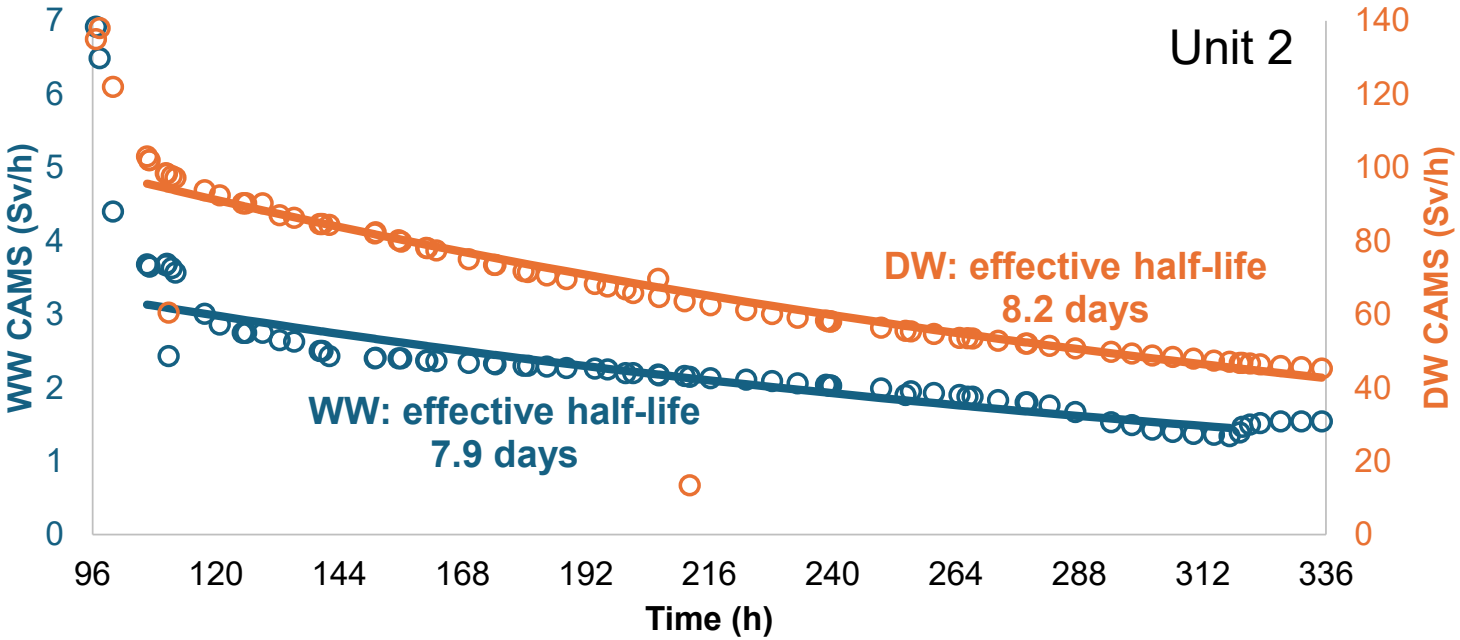
Unit 2 wetwell dose reproduced quite well



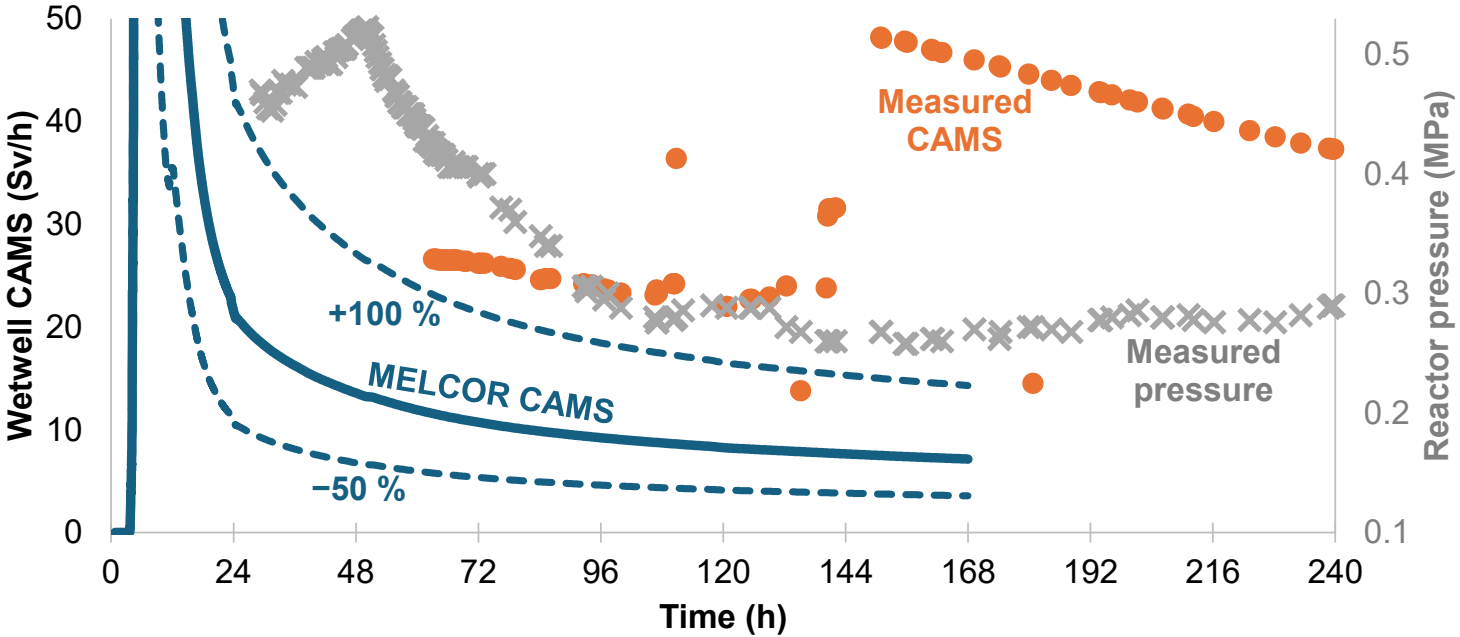
Unit 2 drywell CAMS: Peak 18 h too early, long-term dose rate grossly underestimated



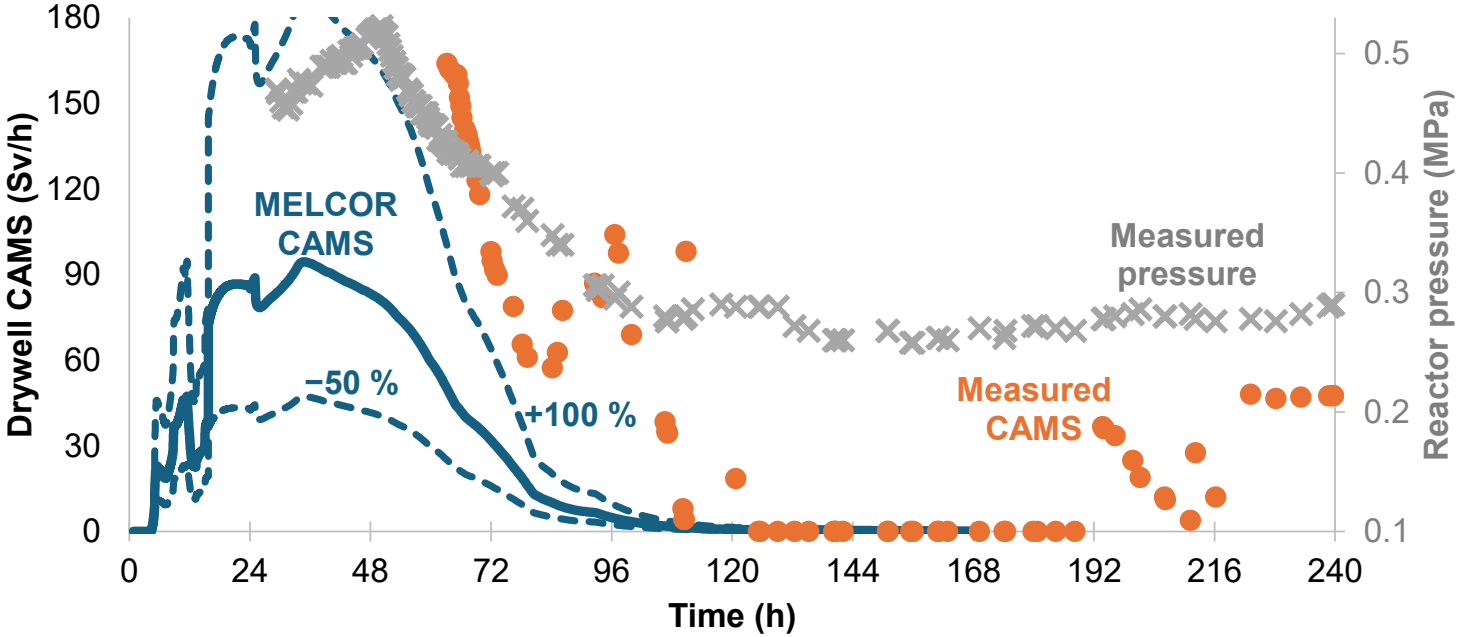
Measured dose rates suggest the main source was I-131 (half-life 8 days)



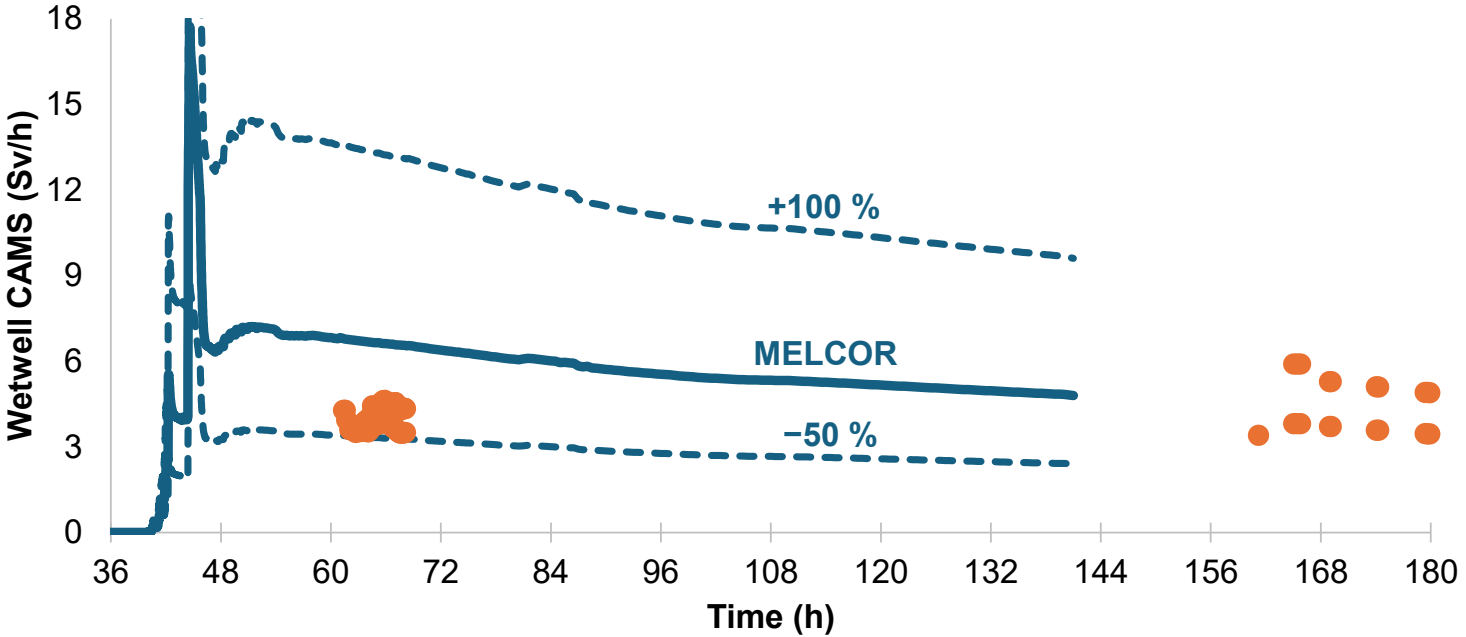
Unit 1 wetwell CAMS: OK until 144 h, then reason for increase unknown



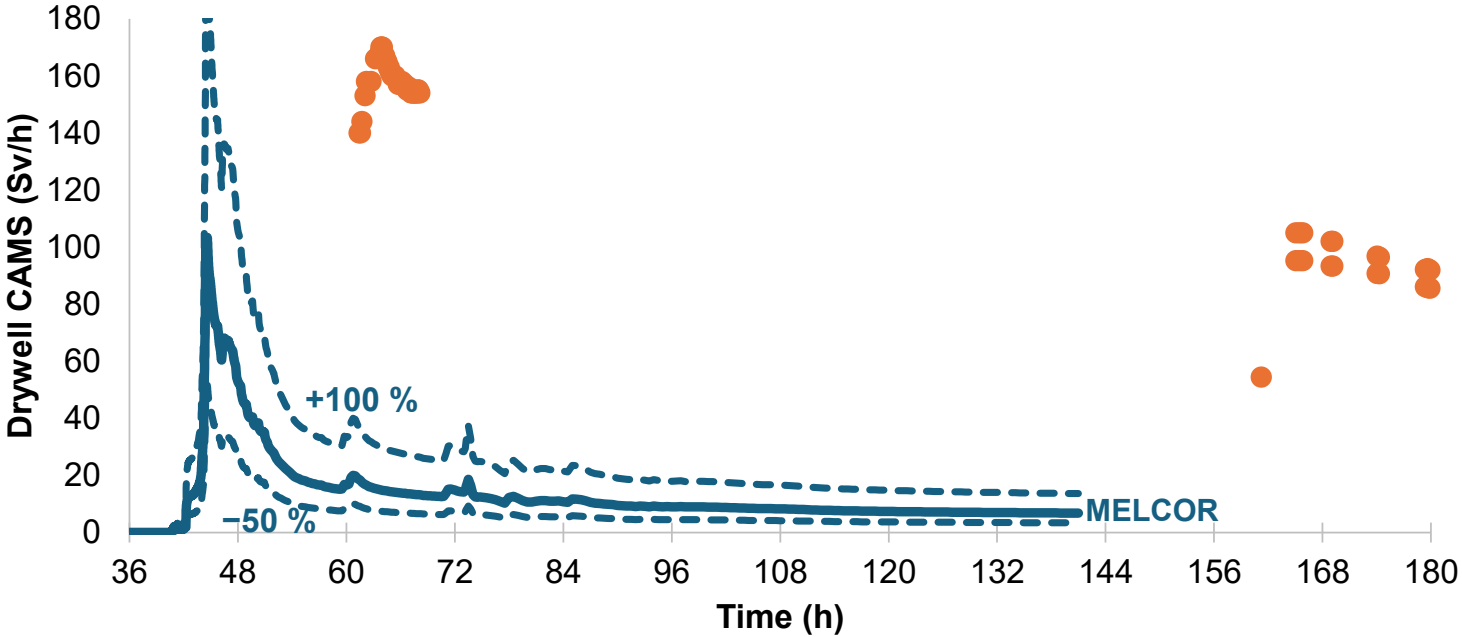
Unit 1 drywell CAMS: OK until 84 h, then reason for increase unknown



Unit 3 wetwell CAMS reproduced quite well



Unit 3 drywell CAMS: grossly underestimated



Discussion

Summary of results

- Units 2 and 3:
  - Wetwell dose rates reproduced quite well
  - Drywell dose rates: calculated peaks much too early, dose rates in late phases significantly underestimated
- Unit 1:
  - Wetwell dose rate reproduced quite well from 63 to 144 h
  - Drywell dose rate reproduced quite well from 63 to 84 h
  - Measured dose rates increased steeply at 144 h (wetwell) and 84 h (drywell), without any apparent reason

Possible causes for underestimated drywell dose rates at late phases

- Deposition surfaces missing from model
- Detector may measure radiation coming from inside of pipes
- Detector may "see" debris that has spread from pedestal to drywell
- MELCOR assumes condensed water washes off deposited aerosols
- Missing model of CsOH desorption from steel structures in RPV
- Iodine chemistry
- Nuclides for which conversion factors unavailable, e.g. tellurium

Photo: TEPCO

Conclusions

- MELCOR-calculated distributions of Kr, Xe, I, Cs in Fukushima wetwell and drywell converted to dose rates
- Wetwell dose rates reproduced quite well
- Drywell peak dose rates calculated much too early
- Drywell dose rates in late phases significantly underestimated
- Several possible reasons for discrepancies identified, but difficult to test their contributions
- One of the objectives was to find opportunities for improving the MELCOR models, but that was found difficult

PRELIMINARY ANALYTICAL JUSTIFICATION OF LONG-TERM CONTAINMENT COOLING SYSTEM WITH STEAM CONDENSING HEAT EXCHANGER FOR NPPS WITH VVER-1000 REACTORS

ABSTRACT

Severe accidents in VVER-1000 reactors involve a high probability of molten core material leaving the reactor and spreading in the containment. Achieving a stable safe state during such accidents requires effective containment heat removal to minimize the release of fission products and liquid radioactive waste into the environment.

To preserve containment integrity, a Long-Term Containment Cooling System (LTCCS) with steam-condensing and water-water heat exchangers is proposed for VVER-1000 plants. The concept was developed and patented by Westinghouse in cooperation with its subcontractor, ES Group. This paper presents preliminary analytical results and expected phenomena associated with this concept. Modeling of reactor system and LTCCS was performed using MELCOR code.

The LTCCS design guarantees containment pressure/temperature reduction and stabilization below design limits. LTCCS with total heat removal capacity of ~10-18 MW is sufficient to reduce containment pressure to near-atmospheric levels and water temperature below saturation. The steam generated by boiling of water covering the molten core materials is condensed, while the containment water is circulated by turbine-driven pump (RTS Pump™ by KSB)[1] and cooled in water-water heat exchanger. The condensate returns to the containment by gravity drainage.

LTCCS operation also enables continuous long-term venting of non-condensable gases, including hydrogen, through the Containment Filtered Venting System (CFVS). This gradually decreases the fraction of non-condensables (NC) in the containment atmosphere while increasing the steam fraction, that improves condenser efficiency and eliminates the late hydrogen hazard. In addition, the LTCCS eliminates multiple CFVS venting cycles. Preliminary calculations confirm the effectiveness of the proposed LTCCS concept.

1. INTRODUCTION

The analysis of severe accidents (SA) for VVER-1000 reactors indicates a high probability of core melt/fragments leaving the reactor pressure vessel (RPV) with spreading in the containment. The issue of long-term slow containment pressure buildup and floor melt-through for ex-vessel phase should be addressed by special cooling actions as one of the back-fitting measures for Gen. II reactors [9]. The ex-vessel corium cooling measures are continuously analyzed for VVER-1000 reactors [10-14]. Safe end-state requires reliable heat removal from debris to minimize releases. To ensure the containment integrity under such conditions implementation of the long-term containment cooling system (LTCCS) is proposed.

The objective of the present study is to justify that the proposed LTCCS can maintain containment pressure below 5 kgf/cm² (abs) and average temperature below 150 °C under representative SA scenarios. The work forms part of the Analytical Justification Report prepared by ES Group LLC in cooperation with Westinghouse Electric Germany GmbH and ES Group Europe s.r.o. within Energoatom's safety-improvement program for operating VVER-1000 units in Ukraine. Previous analytical and experimental studies confirmed the technical feasibility of the LTCCS concept for VVER-1000. However, plant-specific justification was required to quantify its performance margins. This paper summarizes study of LTCCS with steam condenser [1], focusing on expected phenomena, consequences and system performance.

2. METHODOLOGY

2.1. VVER-1000 LTCCS layout and system concept description

The LTCCS layout for VVER-1000 V-320 and V-302 (338) designs is similar (Fig. 1). The system consists of two containment circuits (steam and water) and cooling water loop. During ex-vessel phase of SA the corium spread on the containment floor is flooded with cooling water. Boiling of this water produces steam that rises to the upper containment part. In the steam circuit the gas mixture is directed through LTCCS ducts to condenser, where it is cooled and condensed into a tank. This condensate is returned to the containment via condensate turbine-driven pump or by gravity depending on the system layout. This keeps the containment water balance, ensures the corium remains covered and creates a closed-loop circulation of the water-steam inventory.

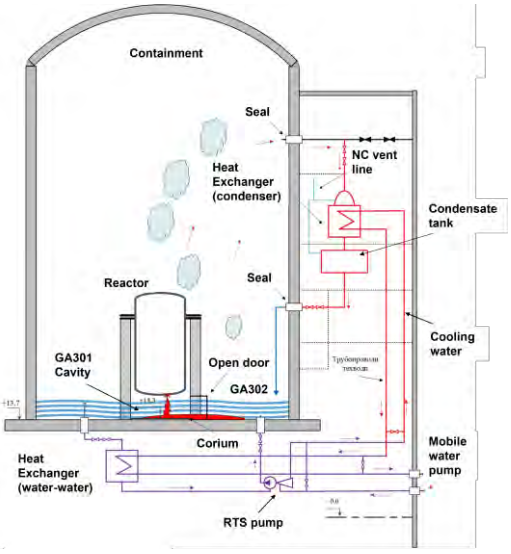

Figure 1. VVER 1000 V-320 LTCCS concept layout.

The water circuit circulates containment water through water-water heat exchanger by turbine-driven RTS pump. Both circuits can operate separately from each other, or in the base version they operate together. External cooling water pump (e.g. mobile diesel pump) first supplies water to the condenser. Cooling water also drives the RTS pump turbine. Then heated cooling water passes to water-water heat exchanger and exits outside the Reactor Building. Cooling water loop pressure is designed to be higher than containment, thereby preventing any transfer of contaminated water outside. LTCCS is designed to avoid containment vacuum conditions and requires no containment entry during SA. The system can operate in conjunction with other SAM systems, such as CFVS and Passive Autocatalytic Recombiners (PAR). LTCCS operation prevents containment pressure buildup, thereby avoiding additional filtered venting cycles. System does not require external power supply and needs external mobile water source (regular pumping unit).

Advantages of LTCCS for VVER-1000:

- Closed-loop water recirculation: Steam is condensed, returned to the containment, and water is cooled in recirculation mode preventing accumulation of contaminated water.
- Containment pressure management: External flexible cooling (FLEX) system ensures stable containment pressure control.
- Corium stabilization: Returned condensate ensures water coverage over molten materials.
- Functional independence: Separation from Defense-in-Depth (DiD) Levels 1,2,3 systems.
- Diverse heat removal path: Independent from Design Basis Accident (DBA) systems.
- Safe condensation: No risk of clogging or direct contact with corium cooling water (steam circuit).

Condenser capacity is preliminarily sized to match decay heat at 72 hours after the Initiating Event (IE). The operation of the system is expected to begin no later than 72 hours after the IE. Once the accident progresses to the ex-vessel phase, the containment is flooded with borated water to create a corium cooling pool.

The LTCC system concept accounts for:

- The removal of NC gases (to support condensation).
- Integration with the CFVS.
- Ensuring dry reactor cavity prior RPV failure to prevent steam explosions.
- Capability to remove heat both from the corium and the spent fuel pool (SFP).
- Long-term containment floor water cooling

2.2. General approach to computational analysis

The computational analysis consisted of sequential steps:

- LTCCS modeling.
- Determination of LTCCS flow rates and condensation capacity.
- Assessment of impact on SA progression.
- Assessment of release to the environment.

Thermal-hydraulic analysis of the LTCCS, RCS and containment is performed using the MELCOR code. After model preparation, representative SA sequences were analyzed to assess LTCCS performance and interaction with CFVS. Acceptance criteria from the CFVS justification [3] and LTCCS-specific criteria were applied.

2.3. Calculation model of VVER-1000/V-320 for MELCOR

MELCOR code version 1.8.5 RL [2] is used to perform the analyses. The South-Ukraine NPP (SUNPP) Unit 3 MELCOR model (VVER-1000/V-320) from analytical justification for the CFVS [3] is taken as start one. This model is modified from Zaporizhzhya NPP model [4] and consists of primary and secondary circuits, reactor core, containment, CFVS, LTCCS and associated systems, other systems and control functions.

RPV is modeled by 7 control volumes (CV001 - CV007) including downcomer (DC), core and upper plenum (UP) (see Fig.2). Four circulation loops are modeled with hot legs, cold legs, reactor coolant pumps (RCPs) and steam generators (SGs). The pressurizer and piping are represented by 5 control volumes. Pressurizer (PRZR) safety valves are modeled as flow paths FL440,441,442 connecting the PRZR dome with pressure relief tank (PRT). The rupture membrane is modeled by flow path (FL443) connecting PRT with containment (CV629). Emergency core cooling systems (ECCS) of low pressure (LP) and high pressure (HP) injection are modeled as water-energy sources. The model is equipped with control systems and controllers.

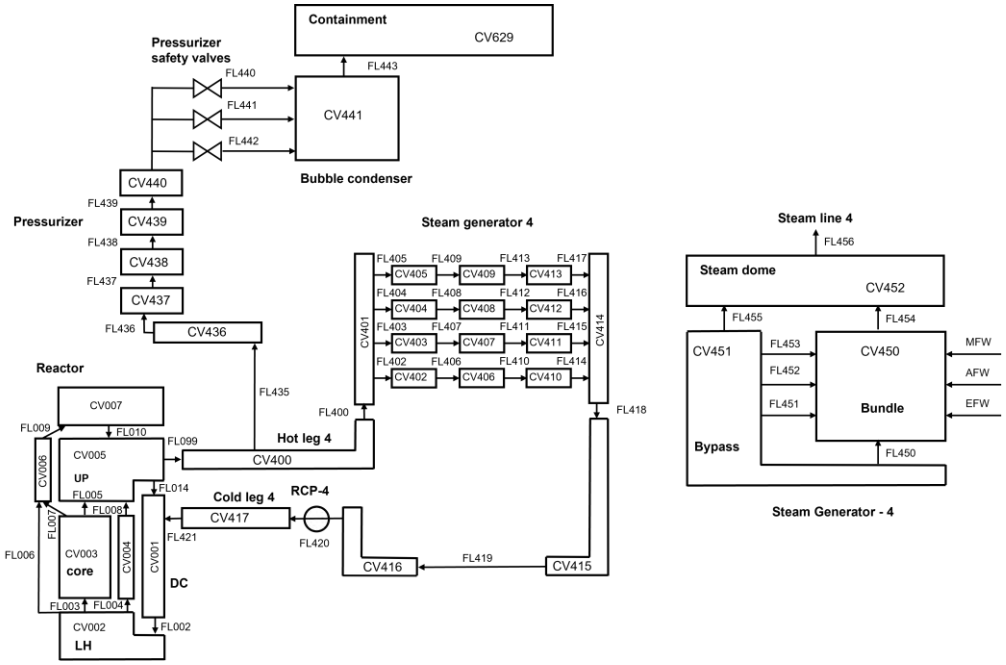

Figure 2. Nodalization scheme of the reactor, primary circuit and SG of Loop 4.

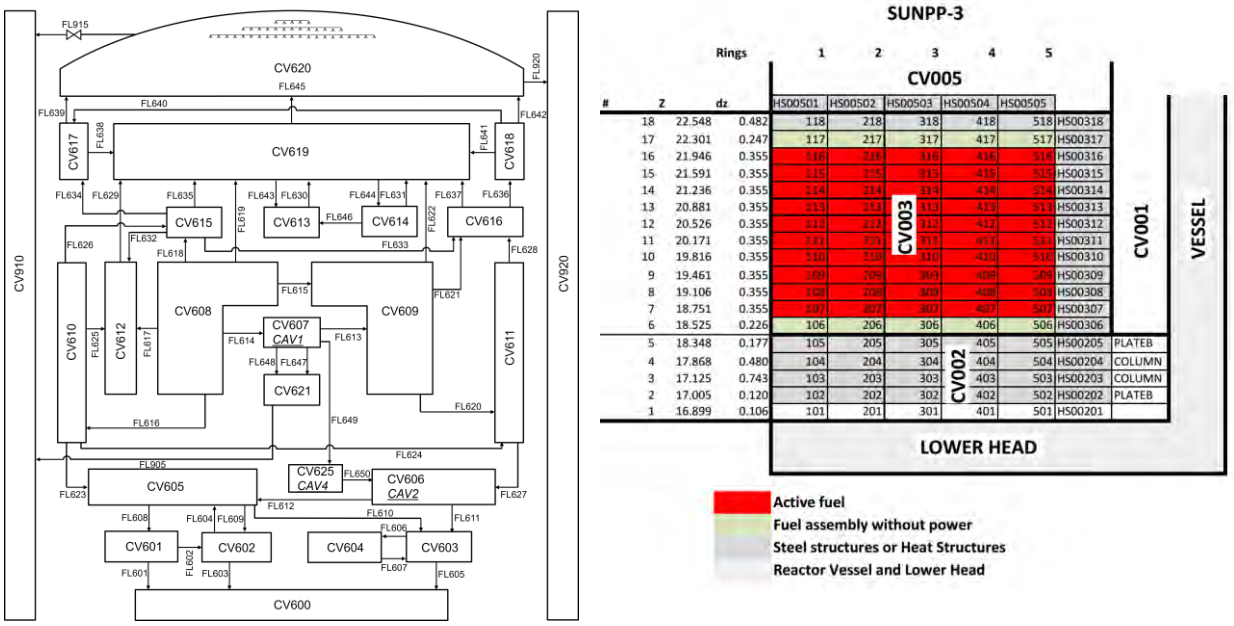
Secondary circuit comprises 32 control volumes and 66 flow paths. Each SG contains three control volumes for the secondary side (see Fig.2) with steam lines and steam dump valves to condenser (BRU-K) and atmosphere (BRU-A). Each SG has two safety valves (SVs). Feedwater systems (normal/auxiliary/emergency) are represented as water sources. The containment model consists of 23 control volumes connected by 46 flow paths. To represent natural convection and hydrostatic pressure gradient, the reactor hall is divided into four control volumes: dome (CV620) and cylindrical part (CV617, 618 and 619). CV617 and 618 represent the wall area, and CV619 models the central part (see Fig.3a).

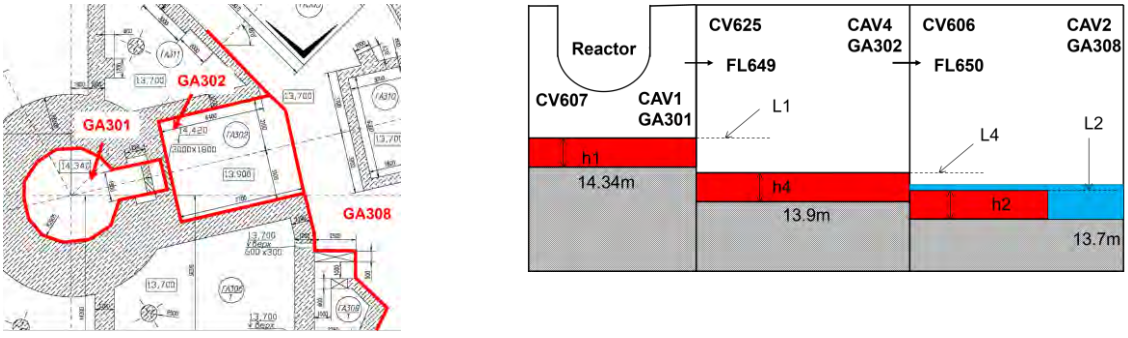


a) b)

Figure 3. Nodalization of the containment (a) and core model (b).

The core model includes 5 radial rings and 18 axial segments. Core is bounded by heat structures in the radial direction. In the axial direction, the core is bounded by the lower plate of guide tubes unit. The first axial section includes reactor lower plenum (segments 1-6). Second section models the reactor core itself, which is divided into 10 axial segments of equal height. Third section models the upper part of unheated core and guide tubes unit lower plate (Fig.3b).

The reactor cavity model includes rooms GA301 (beneath the reactor), room GA302 and part of room GA308 beyond the reactor cavity door [5] (Fig.4). The main cavity door is assumed to open after melt discharge enabling corium spreading on containment floor. Document [6] recommends overflow height 0.15m for a melt with liquidus temperature, and 0.5m with solidus. The analysis assumes 0.15m overflow thickness and uses Control Functions (CF) to model melt overflow, considering relative melt thickness and concrete erosion (see Fig.4). It is assumed that the presence of water does not interfere with corium spreading.



a) b)

Figure 4. Reactor cavity compartments (a) and approach to cavity modeling in MELCOR (b).

The model is equipped with 90 units (RVK-1000) of passive autocatalytic hydrogen recombiners (PARs). CFVS model includes pipes, scrubber, nitrogen system and discharge orifice (Fig. 5). SFP energy source 2.587 MW is added to CV614 corresponding nominal state [7]. SFP is supposed to be leak tight during SA.

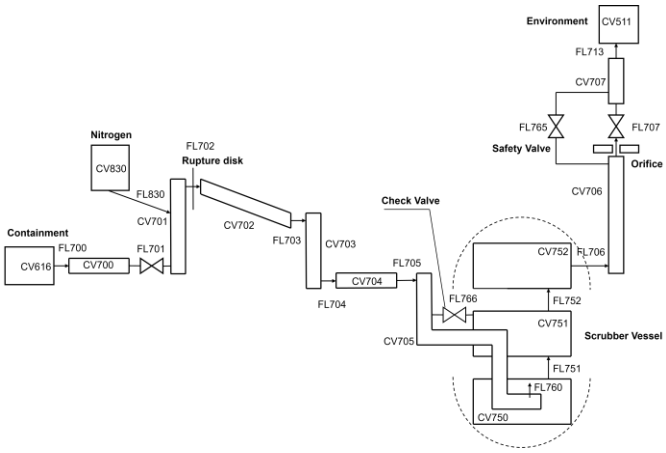


Figure 5. Nodalization of CFVS model.

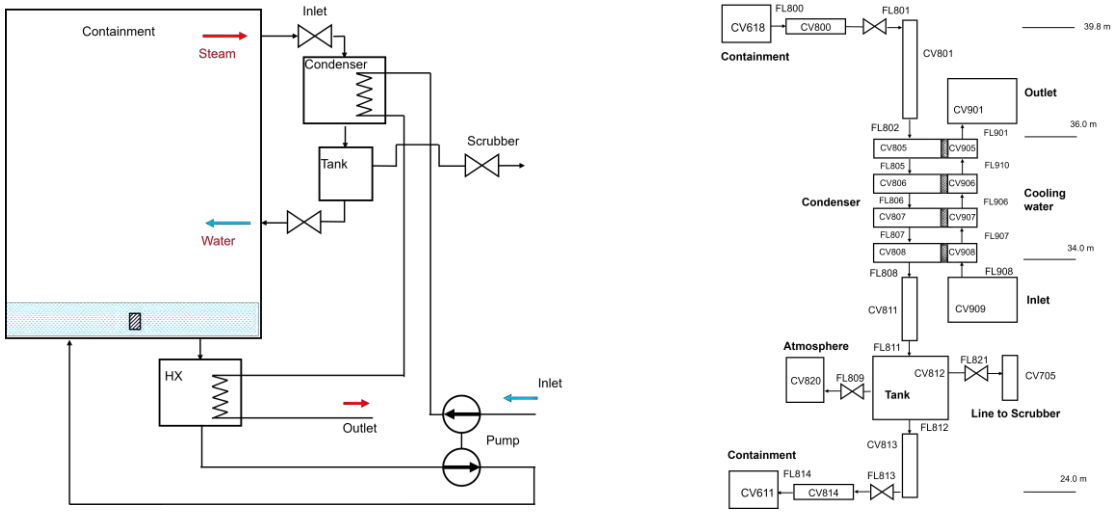
2.4. LTCCS model

Preliminary parameters of LTCCS are taken from [8]. Based on the preliminary conceptual design (Fig.1) the MELCOR model is developed (Fig. 6). LTCCS steam part pipeline is modeled by a series of volumes CV800-801, 811, 813, 814 with 0.5m inlet diameter and 0.25m at the outlet of the condenser. The condenser is represented by vertical volumes CV805-808 with total height of 2m, and 4000 heat exchange tubes with internal cross-section of 1.018m^2 and heat exchange area 503m^2. Such condenser has margin to adjust condensing power in analysis. CV812 models a 10m^3 volume condensate collection tank. Flow paths connect the system to the scrubber model (CV705) and to environment (CV820). Venting path to the scrubber FL821 (diameter 0.050m) removes NC gases behind the condenser. FL813 with 0.030m diameter ensures passive condensate drain to containment.



a) b)

Figure 6. LTCCS simplified scheme (a) and its MELCOR model nodalization (b).

The LTCCS water circuit is modeled by control variables with countercurrent heat exchange scheme. The power of water-water heat exchanger is chosen equal to 10 MW at 320 m^3/h cooling water flow rate (high pressure) and a water flow rate of 320 m^3/h for low pressure side (containment). The cooling water pipeline is modeled by volumes CV901, 909 and condenser volumes CV905-908. The condenser model is tested to obtain condensing power for 320 m^3/h cooling water flow rate with temperature of 20°C (Table I). The scrubber NC venting line is fully open, scrubber level is nominal. The model reproduces condensation power 10.5 MW at 3 kgf/cm^2 (abs.) with 98% steam mole fraction meeting 10 MW requirement from [8]. This power corresponds approximately to core decay heat at 5-7 days after the IE (without SFP). The maximum condenser capacity 28.7 MW is chosen with a margin.

Table I. Condensation capacity of the LTCCS condenser model

№	Pressure, kgf/cm^2 (abs.)	Mole fraction of steam, %	Capacity, MW
1	3	95	5.3
2	3	98	10.5
3	3	99	18.0
4	3	99.9	28.7
5	2	99.9	10.9

2.5. Identification of scenarios, initial and boundary conditions

Station blackout (SBO) is selected as a representative initiating event. Primary breaks sequences exhibit generally similar containment conditions at later SA phases. Three scenarios are analyzed:

- Scenario 1. SBO with SAM actions (without LTCCS)
- Scenario 2. SBO with SAM actions and LTCCS start (steam circuit, condenser capacity limited to 15 MW)
- Scenario 3. SBO with SA management actions and LTCCS start (steam and water circuit, condenser capacity limited to 10 MW)
- Scenario D1. SBO with SAM actions and LTCCS start (steam circuit, condenser capacity limited to 10 MW).

After core exit (CE) temperature rises above 450°C personnel open 3 pressurizer SVs according to SAM. CFVS operates by the containment pressure (open-close) setpoints 5 kgf/cm^2 - 3 kgf/cm^2 (abs.). After the 1st CFVS cycle, containment flooding to 0.9m level is started. LTCCS cooling water flow rate 320 m^3/h with 20° C temperature is assumed.

LTCCS start is assumed after active in-vessel and ex-vessel phase main events and aerosols settling. Start requires water level in the containment; therefore, it is assumed after containment filling to +0.3m above the floor after 1st CFVS venting cycle. The start conditions need future refinement. The condensing capacity is controlled by changing NC gas venting behind the condenser. Condensing power might be monitored via cooling water flow and exit temperature. The analysis covers time intervals of 72 hours (3 days), 7 days (600000s) or 10 days (900000s) and assumes initial nominal power state.

2.6. Acceptance criteria

Acceptance criteria from CFVS justification [3]:

- Containment pressure is limited by 5 kgf/cm^2 (abs.) (short peak < 6 kgf/cm^2 (abs) permitted).
- Scrubber level stays in the range 0.75 - 2.1 m.
- Steam-gas mixture is outside of detonation region on Shapiro-Moffetti diagram.

LTCCS operation criteria:

- Containment pressure approaches to atmospheric and stabilizes.
- Containment water/steam temperature is stabilized or steadily decreases.
- Containment water temperature is stabilized at less than 100ºC for compartments without debris.
- LTCCS thermal total capacity is equal to or consistently greater than decay heat.

3. RESULTS OF ANALYSIS

3.1. Scenario timelines

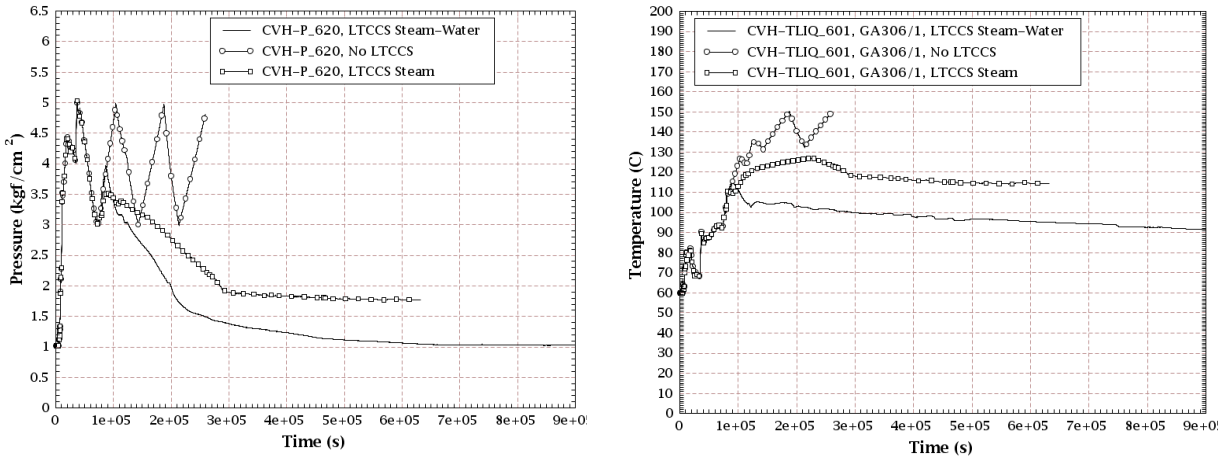
The main Scenario 3 events are presented in Table II.

Table II. Sequence of main events for Scenario 3

Time, s	Event	Description
0	Station blackout	Postulated IE and failures
2020	Pressurizer SVs periodic opening	RCS pressure above 192 kgf/cm^2
7220	Containment pressure above 1.3 kgf/cm^2 (abs.)	Spray setpoint reached, no spray available
10000	Opening of 3 Pressurizer SVs	SAM action, CE temperature > 450ºC
10530	Hydroaccumulators (HA) injection	RCS pressure below 60 kgf/cm^2
20000	Fuel elements collapse	Core damage starts
25300	Complete damage of all fuel assemblies	
34940	RPV lower head failure	MCCI and melt spreading begins
35900	Opening of CFVS venting	Containment pressure > 5 kgf/cm^2 (abs.)
73000	Closure of CFVS venting	Containment pressure < 3 kgf/cm^2 (abs.)
75500	Containment flood from the external source	SAM action, flow rate 15 kg/s
86500	Start of the LTCCS (steam and water circuit)	SAM action, containment level 0.3 m
86500	Containment pressure 3.97 kgf/cm^2 (abs.)	Maximum value after LTCCS start
120000	Termination of containment flood	SAM action, containment level 0.9 m
300000	Containment water temperature <100ºC	For compartments without debris
650000	Containment pressure 1.04 kgf/cm^2 (abs.)	Containment pressure close to atmospheric
750000	Water level in CFVS scrubber 0.75 m	Less than criterion, make-up needed
900000	End of calculation	Containment pressure 1.03 kgf/cm^2 (abs), water temperature 85-92ºC (without debris) and 100ºC (with debris), steam temperature 93-127ºC

3.2. Pressure and temperature in the containment

Timely LTCCS activation reduces and stabilizes containment pressure below the design limit of 5 kgf/cm^2 (abs.). LTCCS operation with only steam circuit allows stabilizing containment pressure above atmospheric at the level of 1.7-1.8 kgf/cm^2 (abs.). Stabilization occurs once LTCCS condensation power matches decay heat, typically within 3–5 days depending on system condenser capacity. The duration of stabilization phase is unlimited. In contrast, combined operation with water circuit allows reduce containment pressure nearly to atmospheric value 1.03 kgf/cm^2 (abs.). Figure 7a compares containment pressure with and without LTCCS operation. Containment pressure stabilization corresponds to the balance of LTCCS power and total heat released in the containment (melt, aerosols, SFP) without CFVS venting cycles.



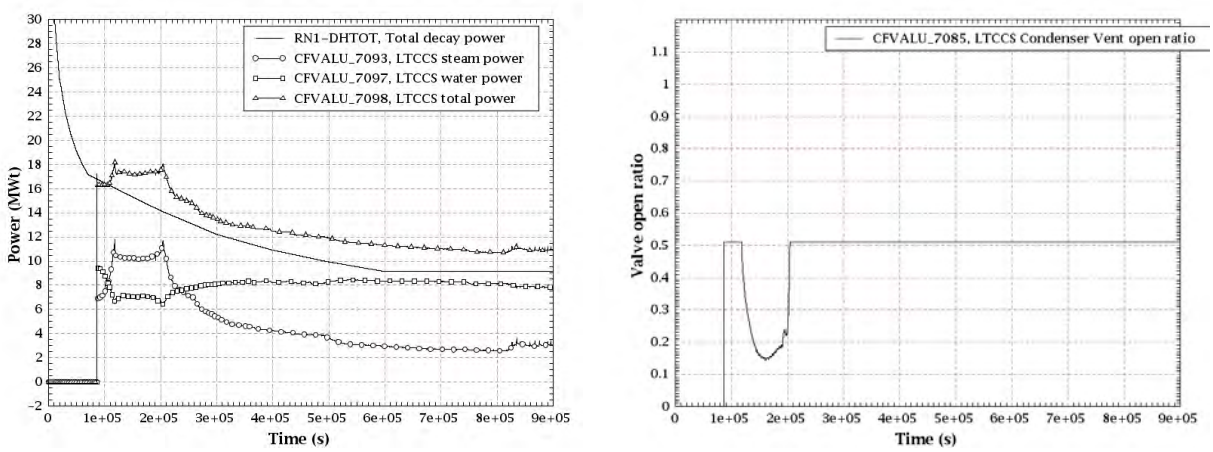
a) b)

Figure 7. Pressure (a) and water temperature (b) in the containment with LTCCS operation (steam and water circuit, Scenario 3), with LTCCS operation (steam circuit, Scenario 2) and without LTCCS operation (Scenario 1).

Containment water and steam temperature follow similar trends (Fig. 7b). Some temporary gas temperature stratification persists because LTCCS does not mix containment atmosphere. Water covering the corium remains saturated while sump water may be cooler.

3.3. LTCCS thermal heat removal capacity

Condensing capacity depends on condenser design (heat transfer area, geometry) and inlet conditions. A condenser with margin is selected to allow condensing capacity adjustment by NC venting control. This effectively decreases condensing surface area while NC present in the mixture. Figure 8a compares condensing capacity and heat removed from the water with decay power. NC venting valve open ratio for Scenario 3 is provided at Figure 8b. Total LTCCS power constantly exceeds core decay heat by 10-15% at any containment pressure. When NC gases are present, the system condensing capacity can be effectively controlled. For the analyzed range (10-15 MW), LTCCS ensures successful stabilization while lower condensing capacity may result in additional CFVS cycles.

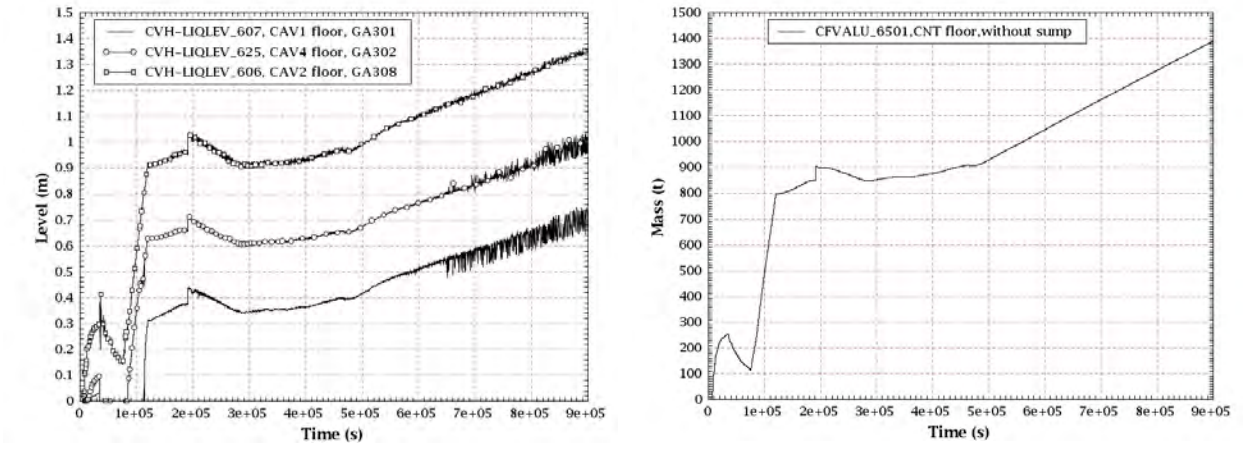


a) b)

Figure 8. Condensing, water circuit and total LTCCS power (a) and NC venting valve open ratio (b) (steam and water circuit, Scenario 3).

3.4. Containment floor flooding and level

Successful LTCCS performance relies on the water covering corium on containment floor. Containment is flooded by personnel actions to a level of 0.9m providing ~0.3m coverage above the melt locations. Flooding requires ~600-650 tons of additional water, yielding a total containment floor pool inventory of ~750-780 tons. This inventory remains inside the containment to maintain the closed cooling loop (Fig. 9) while sump water resides below the floor elevation. Containment level increases with time due to return of boiled off water from SFP to the floor. Technical solutions will be proposed during LTCCS implementation that will allow stabilizing and redistributing such a water flow in a long term.



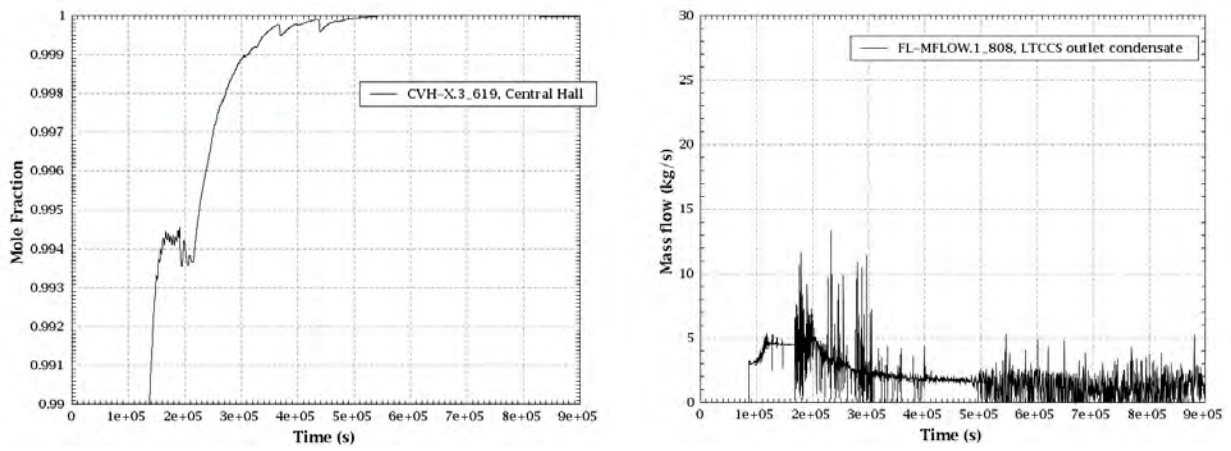
a) b)

Figure 9. Water level (a) and water mass (b) on containment floor for Scenario 3.

3.5. Containment atmosphere and condensate flow

Venting of NC gases downstream of condenser reduces mole fraction and progressively replaces containment atmosphere with steam. This solves the late phase hydrogen problem by discharging it to the

environment (Fig. 10a). This containment atmosphere state requires additional SAM guidance if safety systems (e.g., spray system) become available later. The pressure drop driving steam-gas mixture flow into the LTCCS is created by condensation ("suction" effect). Condensation occurs at approximately containment pressure, vacuum formation is prevented by low inlet resistance. Iterative analysis of various system layouts showed that the condensate gravity drainage is feasible through 30 mm diameter pipe (Fig. 10b). Final drain line routing to containment will depend on available penetrations and LTCCS layout.

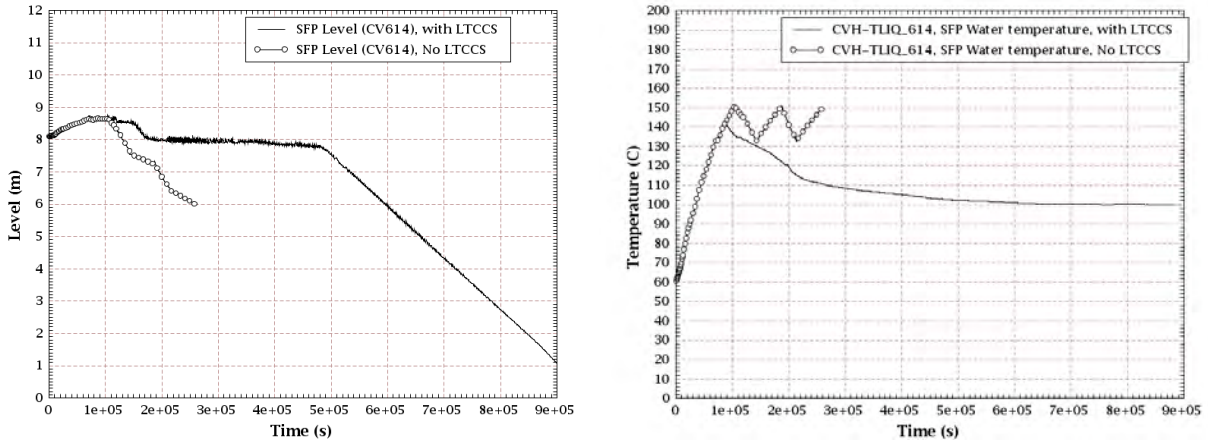


a) b)

Figure 10. Mole fraction of steam in the containment (a) and condensate flow rate (b) for Scenario №3.

3.6. Impact on SFP

The presence of fuel in the SFP results in gradual heating and boiling of SFP water during SA. LTCCS operation delays SFP boil-off by reducing the number of CFVS cycles giving time gain before SFP make-up. With LTCCS operating, the SFP level decreases with water remaining near saturation temperature (Fig. 11). Long-term containment water balance needs further evaluation. Possible partial return of the water from containment floor back to SFP by RTS pump is under analysis.

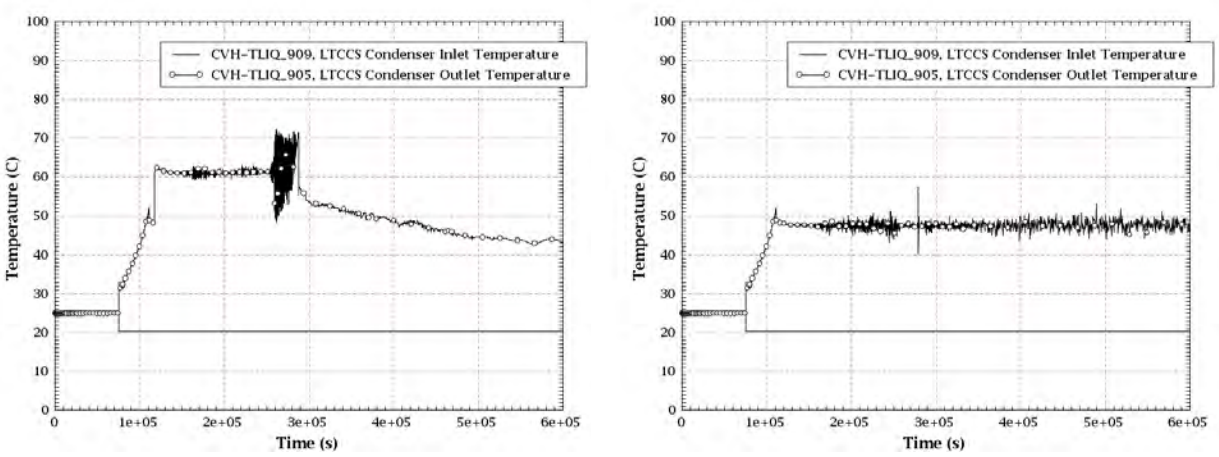


a) b)

Figure 11. Water level (a) and temperature (b) in the SFP for Scenario 3.

3.7. LTCCS cooling water flow rate and temperature

Selected LTCCS cooling water flow rate of 320 m^3/h is adequate for both of 10MW and 15MW condensation capacity. The water heating on the condenser is equal to 40° C for 15MW and 30° C for 10MW (Fig. 12). Therefore, flow rates in the range of 300-400 m^3/h are acceptable for the system.



a) b)

Figure 12. Cooling water temperature at the inlet/outlet of the LTCCS condenser for 15MW power (a) and 10MW power (b)

3.8. Radioactivity release and hydrogen safety

Activity release to the environment is reduced with LTCCS operation. Main reasons for the reduction are the absence of CFVS subsequent venting and decreased containment pressure. The 3 days cumulative aerosols mass of Cs class that entered CFVS is changed from 6% (% of core content) to 4% and for containment leaks from 0.0039% to 0.0032% for the sequence without LTCCS operation (Scenario 1) and with LTCCS (Scenario 3). The deflagration conditions in the containment volumes are not reached due to the high steam concentration. The maximum hydrogen concentration in and behind LTCCS condenser is calculated to be 5%. However, there are no ignition initiators in these locations and the temperatures are low. Therefore, hydrogen safety is not critical for LTCCS path. In the later phase due to the almost complete removal of NC gases from containment, the hydrogen safety problem is completely resolved.

3.9. Melt/debris spreading and criticality of fission materials

To maintain containment integrity, corium must spread effectively after RPV failure. The analysis indicates a dry state of subreactor cavity for V-320 and V-302/V-338 reactor designs (VVER-1000) at melt ejection. Melt overflow through the cavity door and further spreading takes place under low water level (0.1-0.2 m) or without water. Ensuring rapid melt overflow and spreading in coolable geometry requires further spreading analysis, including MCCI and water flooding. The criticality of core materials is more dangerous in the state of debris, when the moderator can penetrate between fuel parts in the reactor. However, given the presence of control rod absorbers and boron in HA water, this is unlikely. Outside the reactor, the concrete oxides are mixed and the melt configuration does not allow water penetrating deeply inside. The criticality in such states seems practically impossible.

4. CONCLUSIONS

Implementation of LTCCS for VVER-1000 reactors significantly enhances plant's capability to achieve and maintain safe stable state during SA. The analysis demonstrates that LTCCS concept reliably reduces and stabilizes containment pressure and temperature below the design limits of 5 kgf/cm^2 (abs.) and 150ºC. Stabilization pressure remains nearly atmospheric with steam condensation supported by continuous boiling over core materials and containment water is cooled to temperatures less than saturation in LTCCS water circuit. Total LTCCS power (steam and water circuits) exceeds decay heat power for all containment pressures. Analysis assumes coolable state of core materials after spreading over the containment floor.

Hydrogen safety is not adversely affected by delayed LTCCS activation. By the time of LTCCS operation, a significant amount of hydrogen and oxygen has been recombined by PARs. As LTCCS progressively removes non-condensable gases, the containment atmosphere becomes increasingly steam-dominated, eliminating late-phase hydrogen risks. Lower stabilized containment pressure reduces radiological release by decreasing leak-path flows and minimizing CFVS actuation. Joint LTCCS–CFVS operation is feasible and may be advantageous in certain accident-management scenarios.

Extended post-accident operation of LTCCS is required to reduce containment parameters towards near-normal operating conditions. Final containment water level management will require additional technical provisions. Sizing of the water circuit flow, heat exchangers and piping might be changed. Recommendations for optimized accident management will be further developed.

Heat removal basis

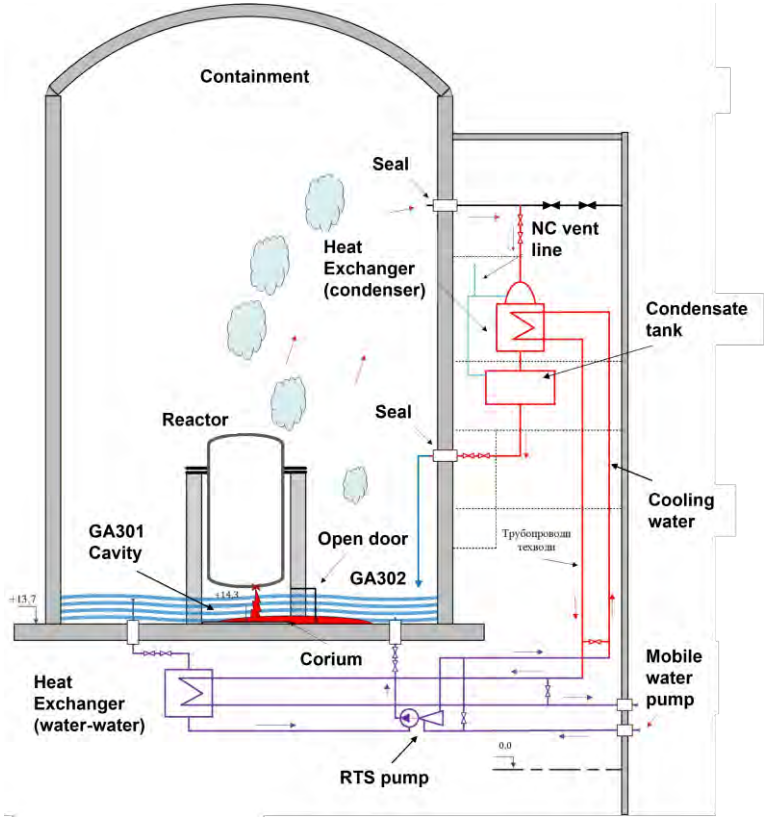
- Ex-vessel corium spreading in **C**onta**i**N**m**en**T** (**CNT**)
- Corium cooling by water pool (boiling)
- Steam condensation in condenser
- Water pool is cooled in heat exchanger

System layout

- Main steam circuit (contaminated)
- Auxiliary water circuit (contaminated)
- Cooling water external circuit (clean)
- Common cooling circuit for condenser and heat exchanger

System layout feature

- Turbine-driven water pump (RTS pump)
- Sequential cooling for condenser and heat exchanger
- First condenser cooling
- Second heat exchanger cooling



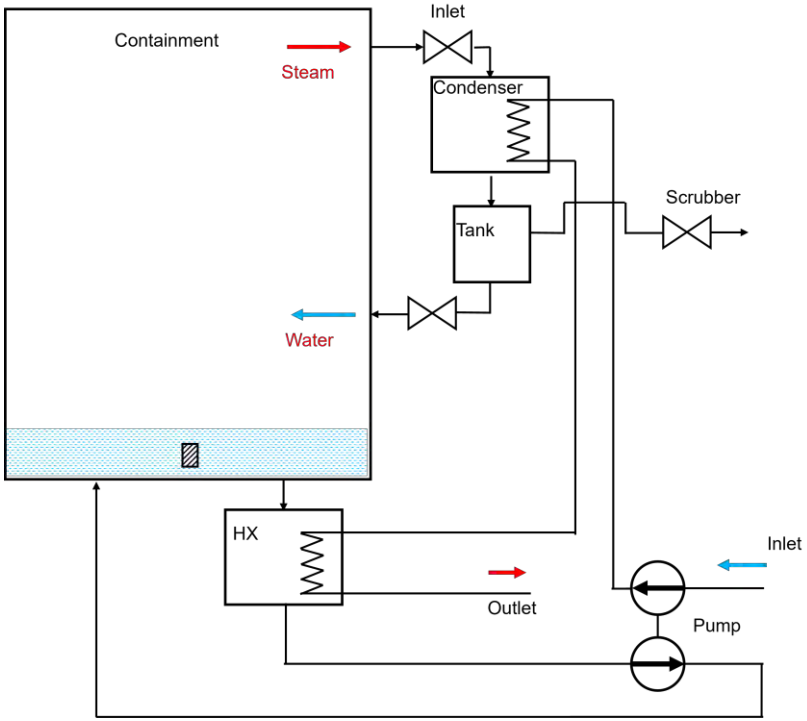
LTCCS VVER-1000 general layout

Advantages

- efficiency due to boiling-condensation
- corium stabilization
- pressure decrease to atmospheric
- water temperature decrease less than 100 ºC
- functional independence from DBA equipment
- long-term water retention within containment
- no need of water evacuation from containment
- no need of external electric supply

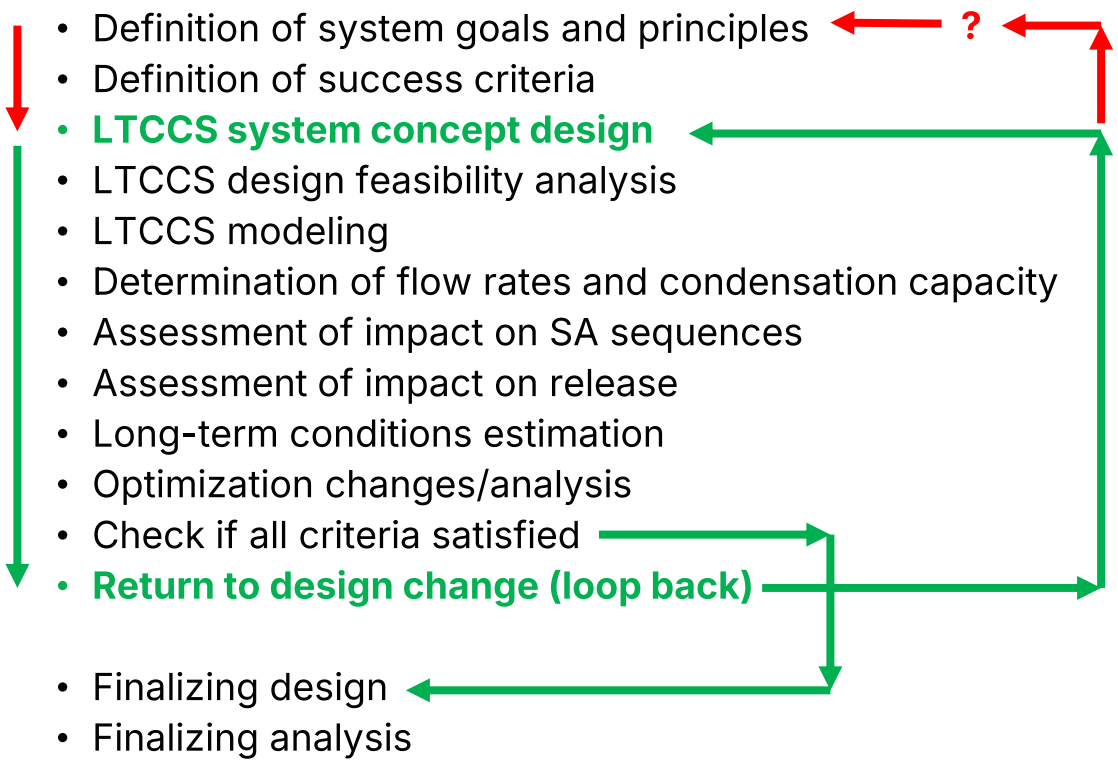
Concept covers:

- removal of non-condensable (NC) gases with H_2
- integration with filtered venting (CFVS)
- dry reactor cavity prior RPV failure
- heat removal from spent fuel pool (SFP)
- long-term containment floor water cooling
- reducing effects of corium on the base slab



LTCCS VVER-1000 general layout workflow

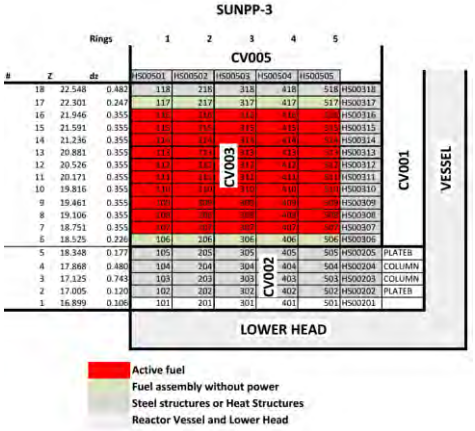
Approach



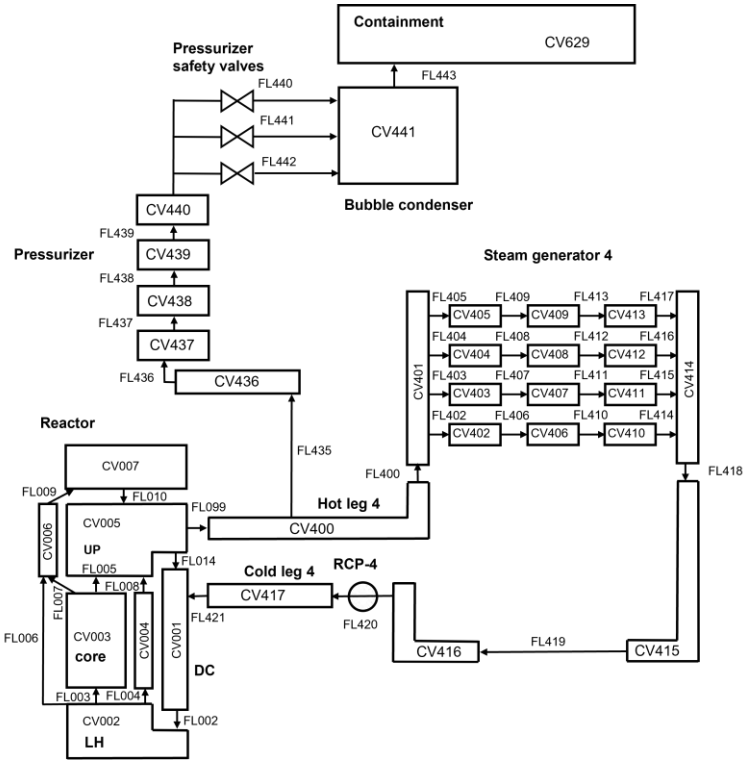
!!! Even small problem CAN loop back the Process !!!

RCS Model

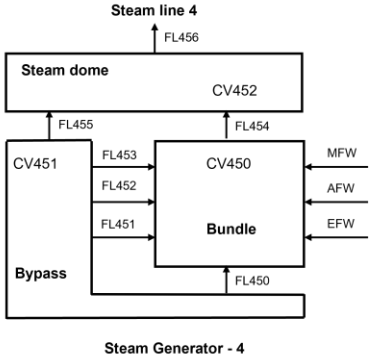
- 4 loop MELCOR model
- Simple reactor TH modeling
- SG primary detailed
- SG secondary with bypass
- Core 18 axial levels



MELCOR core nodalization



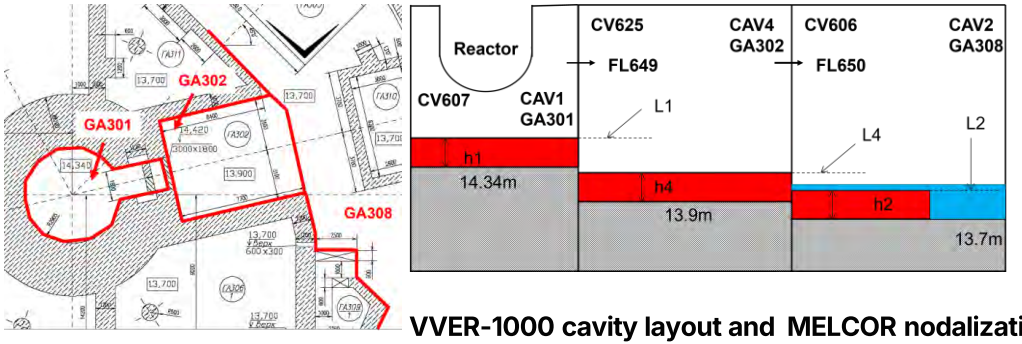
VVER-1000 primary MELCOR nodalization (loop #4)



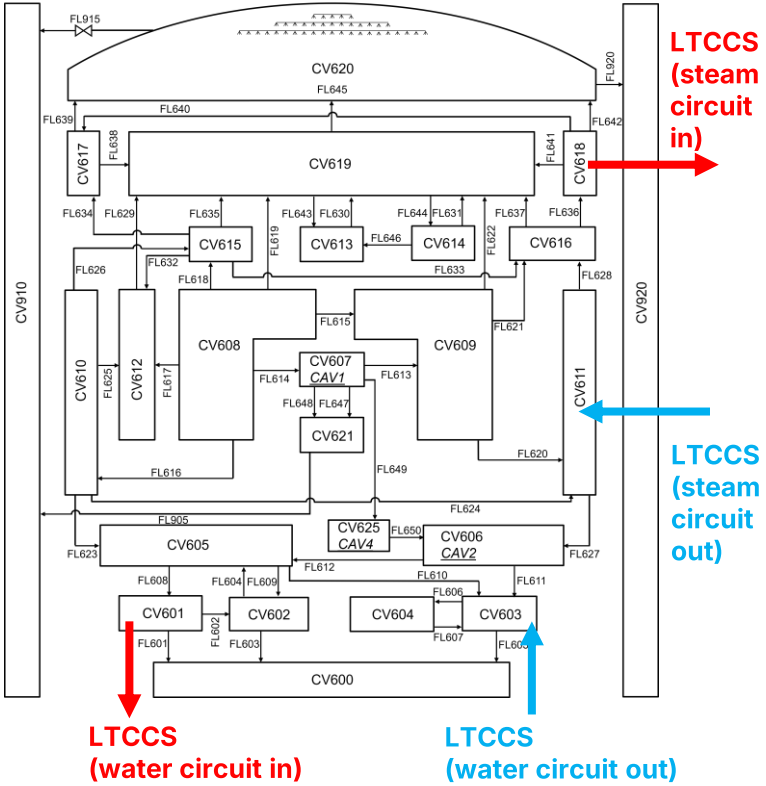
Steam Generator - 4

Containment and Cavity Model

- Detailed containment model
- Axial compartments levels
- Cavity detailed model (3 cavities)
- Melt overflow and height dynamic approach (radius(t))
- CAV1 overflow height 0.2m
- CAV2, CAV4 overflow height 0.15m
- SFP (CV614) heat power 2.6 MW



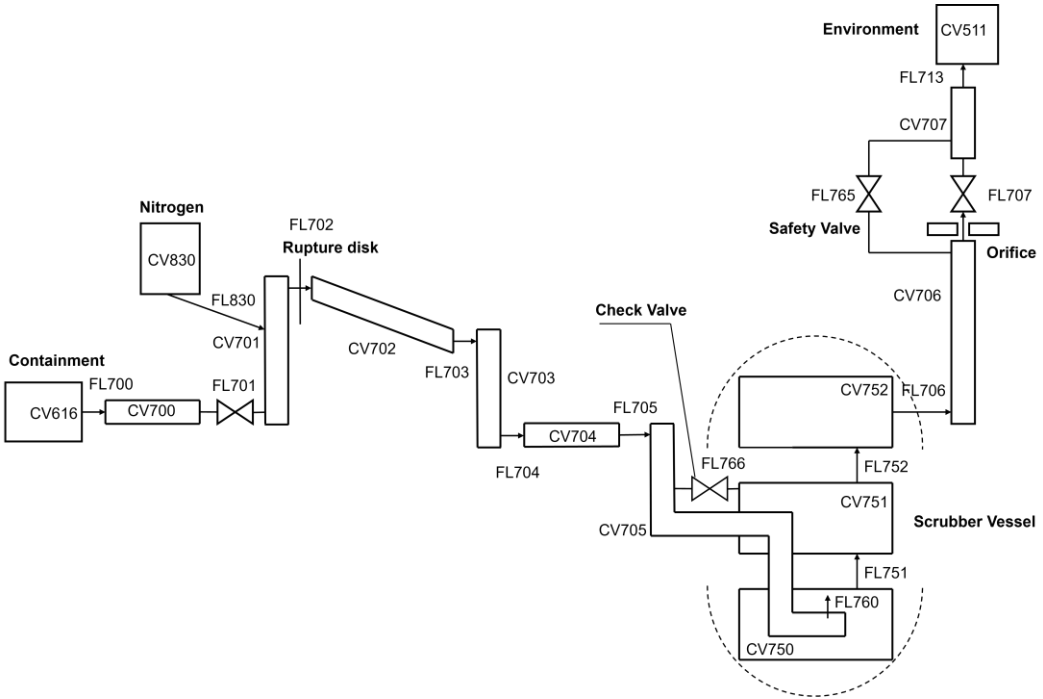
VVER-1000 cavity layout and MELCOR nodalization



MELCOR containment nodalization

CFVS model

- Detailed model with scrubber
- Open – close setpoints 5 – 3kgf/cm^2
- Passive rupture disk opening
- Initial scrubber water level
- Filled with nitrogen
- Flow is based on real tests (at plant)



CFVS MELCOR nodalization

LTCCS model (steam circuit)

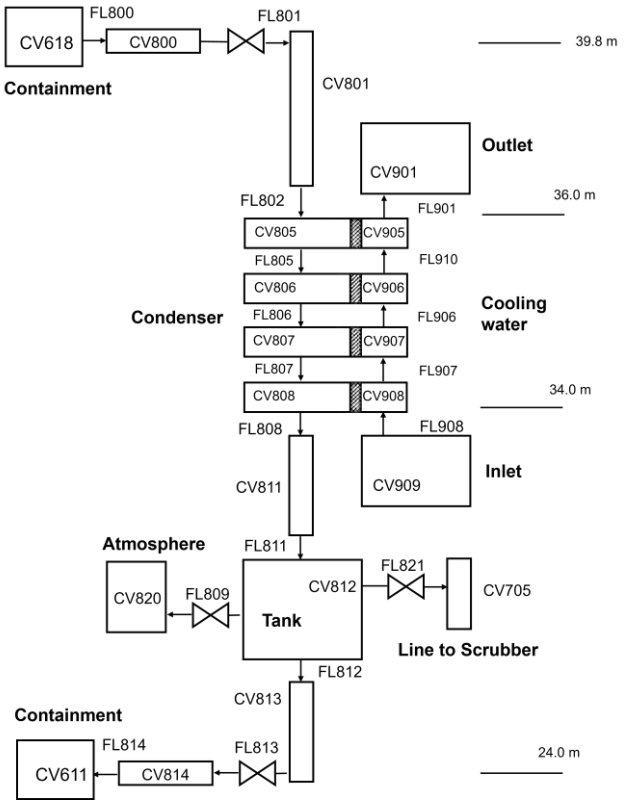
- Detailed model with condenser
- Condensate drain to containment
- NC venting after condenser to scrubber (FL821)

Condenser model

• Inlet diameter	0.5m	
• Heat transfer area	503m^2	
• Cooling water flow (external)	320t/h	
• Temperature of cooling water	20°C	
• Condenser power (3bar, 98% steam)	10.5 MW	
• Condensate flow		4.9kg/s
• NC venting flow (50mm diam.)	0.23kg/s	

LTCCS model (water circuit, control functions)

• Heat exchanger power	~10.0 MW
• RTS (turbine-driven) pump flow	320t/h



LTCCS MELCOR nodalization

Condenser model power

- Pressure 3bar (abs.), 95% steam — 5.3 MWt
- Pressure 3bar (abs.), 98% steam — 10.5 MWt (**Base**)
- Pressure 3bar (abs.), 99% steam — 18.0 MWt
- Pressure 3bar (abs.), 99.9% steam — 28.7 MWt (**Max**)
- Pressure 2bar (abs.), 99.9% steam — 10.9 MWt

Condenser power control (initial phase)

- Need of NC venting
- NCs can be used for condensing power control
- NC venting valve open control to scrubber (FL821)
- Possible for initial phase with NCs in containment

Scenarios

- **Scenario 1**. SBO with SAM actions (without LTCCS)
- **Scenario 2**. SBO with SAM actions and LTCCS start (steam circuit, condenser capacity limited to 15 MW)
- **Scenario 3. (Base analysis)** SBO with SA management actions and LTCCS start (steam and water circuit, condenser capacity limited to 10 MW)

SAM actions

- SAMG enter on core exit > 450°C
- Open of 3 PORVs

LTCCS related actions

- Start of containment flood to +0.9m level
- LTCCS start at +0.3m containment level

LTCCS activation basis

- After CFVS 1st cycle
- After active core damage and melt spreading (aerosols settling)
- Not later than 72h

SFP related actions

- No SFP external make-up (action is possible)

Acceptance criteria

- Containment pressure is limited by 5 kgf/cm^2 (abs.) (short peak < 6 kgf/cm^2 (abs) permitted)
- Scrubber level stays in the range 0.75 - 2.1 m
- Steam-gas mixture is outside of detonation region on Shapiro-Moffetti diagram
- **Corium is in coolable state***
- **SFP fuel is in coolable condition***
- **Containment water balance is constant***

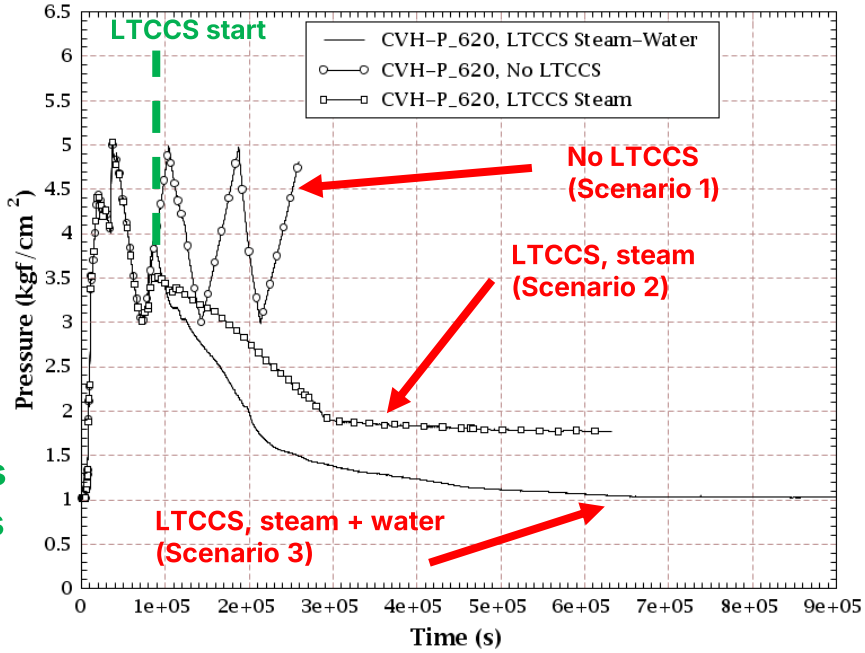
*** - needs adaptation or special measures**

LTCCS acceptance criteria

- Containment pressure approaches to atmospheric and stabilizes
- Containment water/steam temperature is stabilized or steadily decreases
- Containment water temperature is stabilized at less than 100ºC for compartments without debris
- LTCCS thermal total capacity is equal to or consistently greater than decay heat

Events and actions (Scenario 3)

• Loss of power, DGs failure	0s
• PRZ SVs open (CE temp > 450ºC)	10000s
• RV failure, debris/melt spreading	34940s
• CFVS open, pressure > 5 kgf/cm^2	35900s
• CFVS closed, pressure < 3 kgf/cm^2	73000s
• CNT flood external source start (15kg/s)	75500s
• LTCCS start (steam and water circ.)	**86500s**
• CNT flood external source stop	120000s
• CNT water temperature **< 100ºC**	**300000s**
• CNT pressure **1.04 kgf/cm^2** (abs.)	**650000s**
• End of calculation (10.4days)	900000s



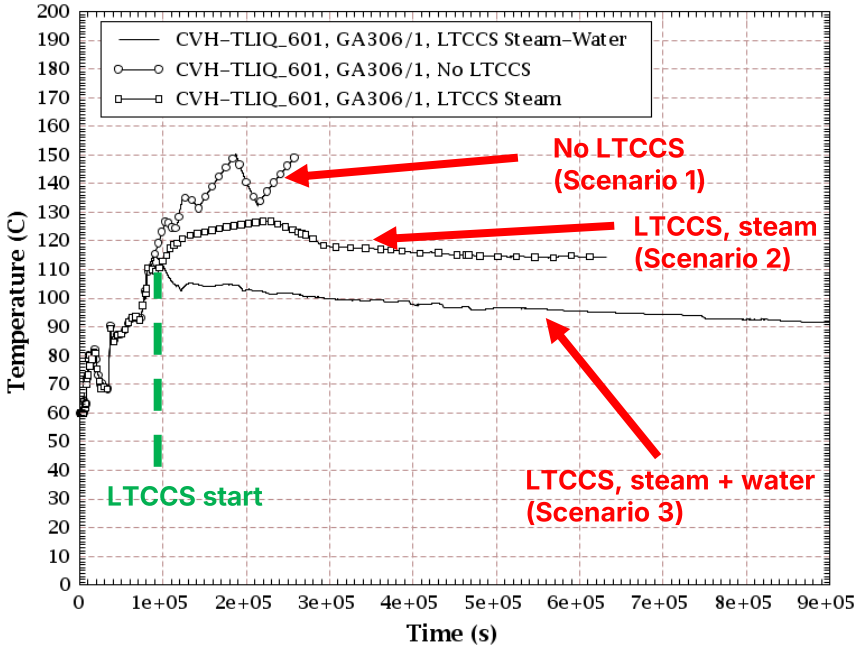
Containment pressure (comparison)

CNT pressure

- Stabilizes at **1.7-1.8** kgf/cm^2 (abs.) if only **steam** circuit in operation
- Stabilizes at **1.03-1.04** kgf/cm^2 (abs.) if **steam + water** circuits in operation

End state (Scenario 3)

- CNT pressure (abs.) 1.03 kgf/cm^2
- CNT water temp. (no debris) 85-92ºC
- CNT water temp. (debris) 100ºC
- CNT steam/atm. temp. 93-127ºC
- CNT steam fraction 99.999% vol.
- H2 fraction 0 - 0.1% vol.
- Steam circuit power ~3.2MW
- Water circuit power ~7.9MW
- Core decay heat ~9.2MW
- SFP decay heat ~2.6MW



Containment water temperature (comparison, no debris compartment)

CNT water/steam temperature

- Stabilizes at 114-115ºC >100ºC if only **steam** circuit in operation
- Decreases Twater < **100ºC** if **steam + water** circuits in operation
- Steam dome temperature 127ºC and decreasing

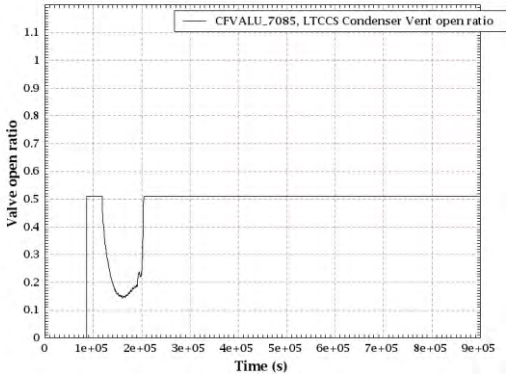
LTCCS thermal power (Scenario 3)

- Steam circuit power is controlled max ~10MW
- Steam power controlled by venting (initial phase
- Steam power is defined by HE area (late phase)

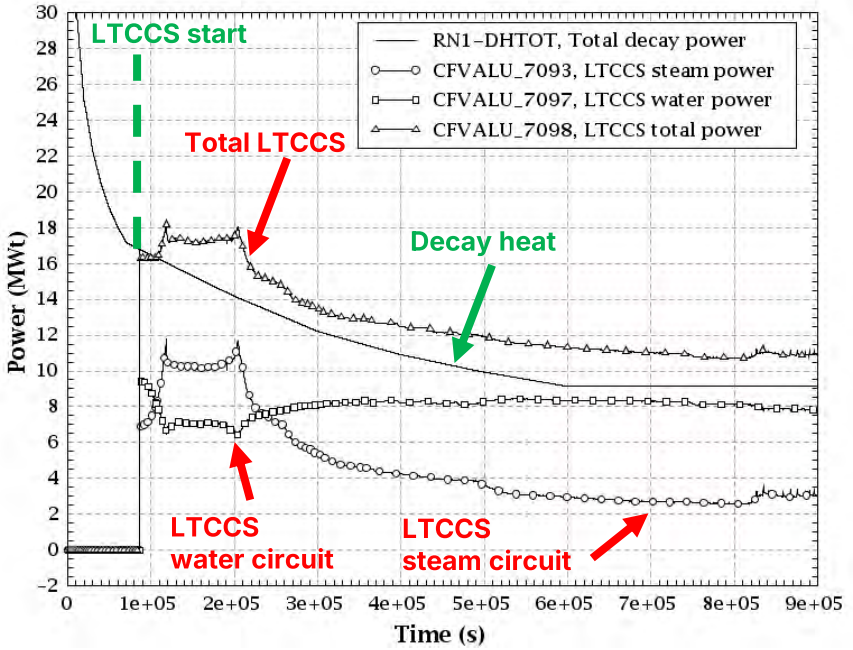
- Water circuit power ~6 - 10MW
- Water circuit power increases (late phase)
- Total LTCCS power > decay heat
- Decay + SFP ~ Total LTCCS

Condenser power control

- NC venting after condenser
- Valve position operation



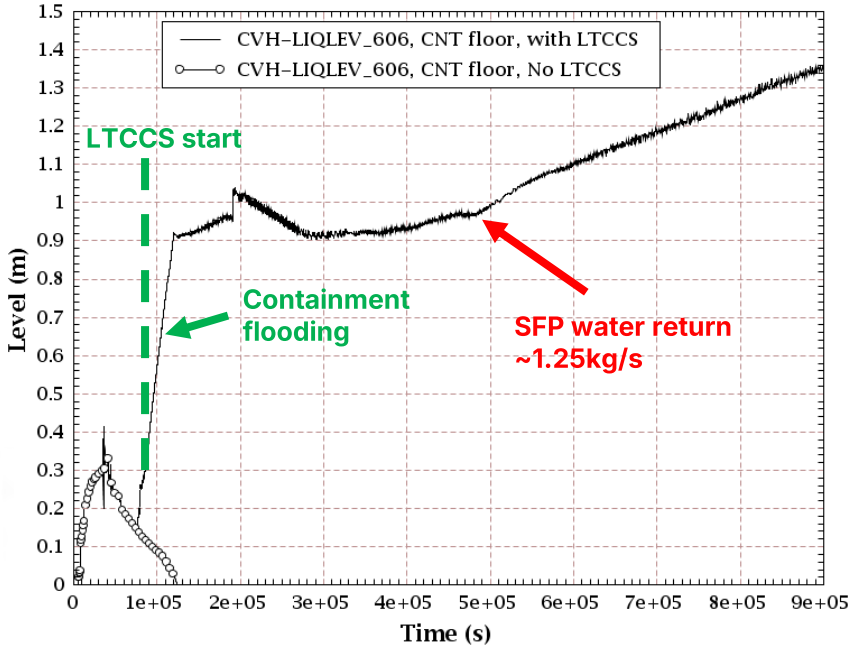
LTCCS NC venting valve position after condenser



Core total decay heat and LTCCS thermal power (extracted)

Containment water level (Scenario 3)

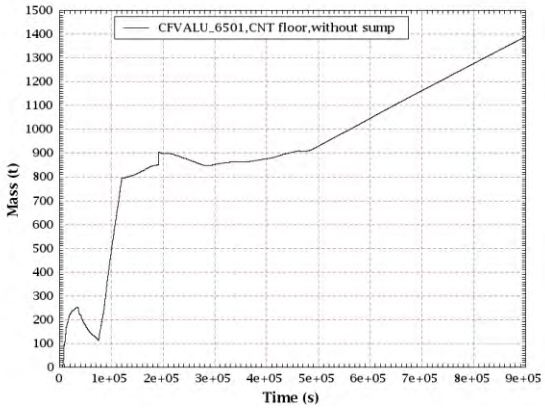
- Flooded to cover all debris ~0.9m
- Added ~500-600t to flood containment (CNT)
- Start of increase after SFP intense boiling
- Needs stabilization



Containment floor water level

Containment floor water mass

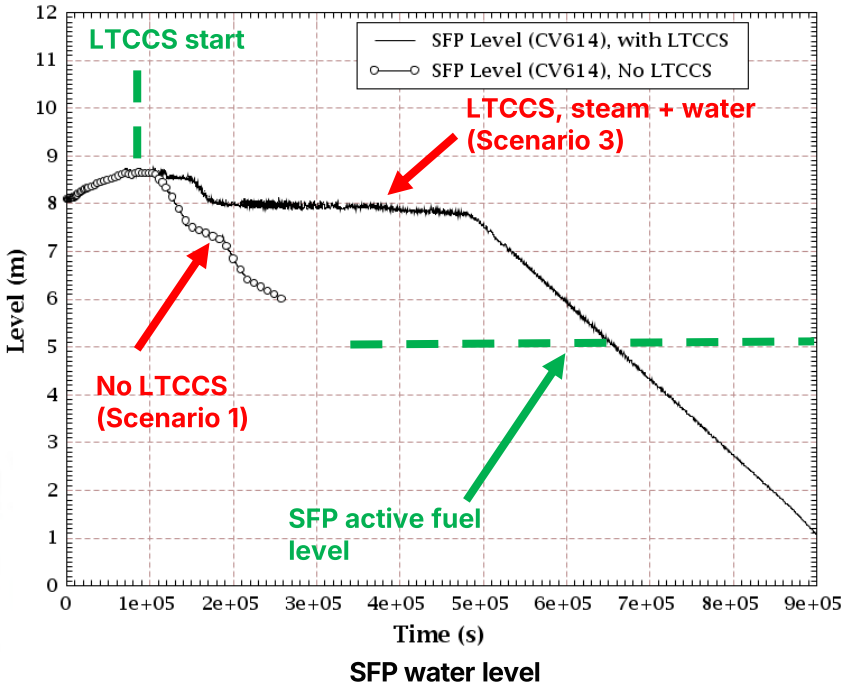
- Needs stabilization



Containment floor water mass (without sump)

SFP water level (Scenario 3)

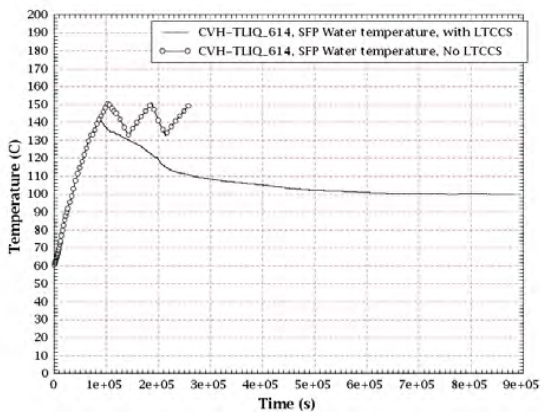
- After CNT pressure decrease SFP -> boil
- Evaporated SFP water returns to CNT floor
- SFP balance needed
- No fuel damage in SFP is accounted for



SFP water level

SFP water temperature

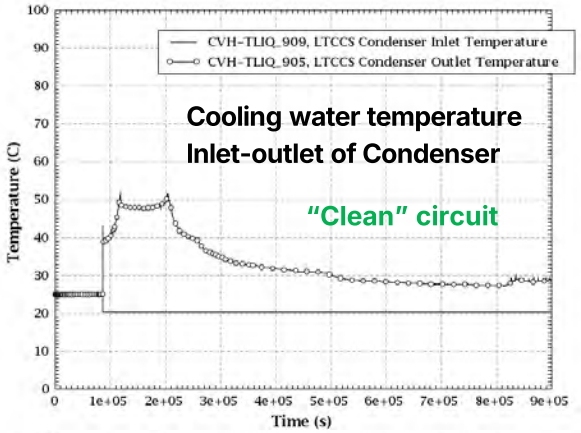
- Needs cooldown

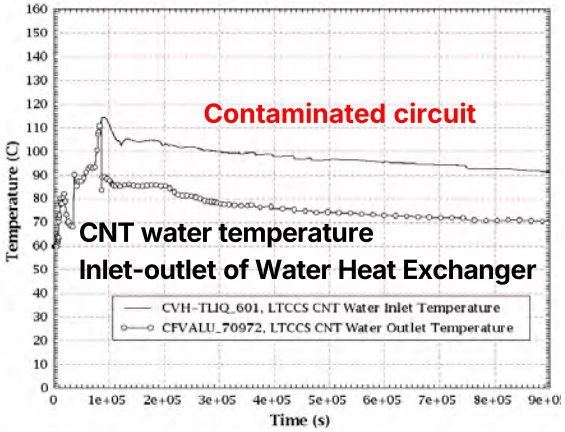


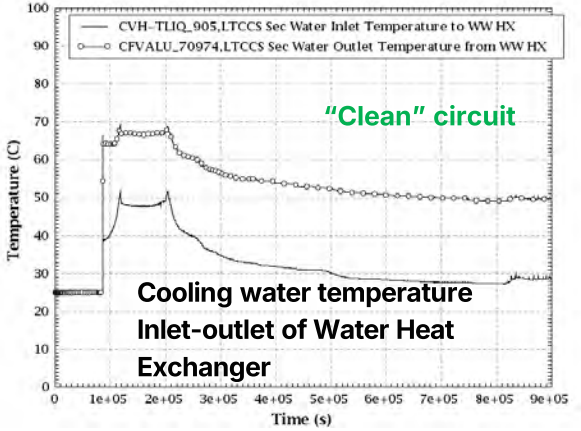
SFP water temperature

LTCCS water temperatures (Scenario 3)

- Max cooling “clean” circuit temperature <70ºC
- Inlet cooling “clean” circuit temperature 20ºC
- No outlet water boiling





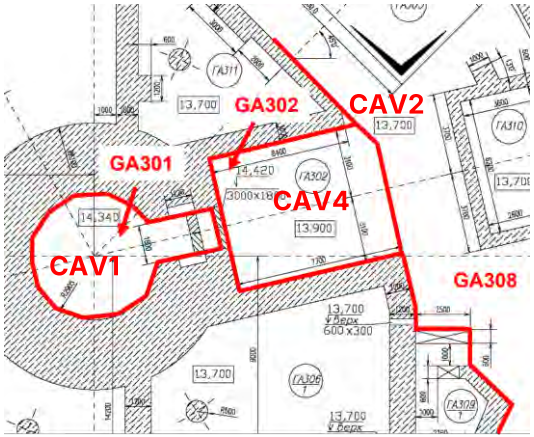


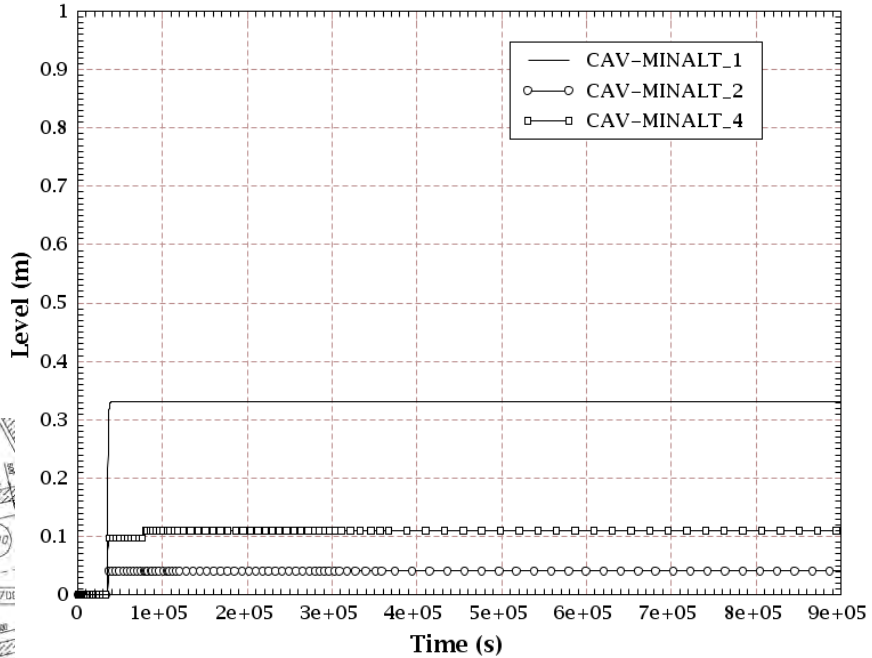
Cavity MELCOR analysis

- CAV1 ablation depth 0.33m, level 0.2m
- CAV4 ablation depth 0.11m, level 0.15m
- CAV2 ablation depth 0.04m, level 0.19m
- Corium is in coolable geometry

Corium mass distribution (CAV1, CAV4, CAV2):

- After RPV failure: 18%, 44%, 38%
- End of analysis: 18%, 32%, 50%





Cavities ablation depth

Hydrogen safety

Containment

- H_2 generated in-vessel 402kg
- H_2 generated ex-vessel 240kg
- Dome max H_2 fraction 2.1-2.9% (vol.)
- End of analysis H_2 fraction 0%
- Not globally flammable

LTCCS

- Inside LTCCS H_2 fraction <5%
- No detonation in LTCCS

Activity release to environment

- Aerosol CFVS activity release decrease 33%
- Containment leak release decrease 18%

Containment long-term

- Containment openable conditions
- Needs NC inlet procedure (very late)

Issues to consider (in process)

- Detailed melt spreading analysis
- Detailed melt impact analysis in cavities
- Estimation of MCCI/spreading success probability (from ejection to coolability)
- Long-term TH analysis (half year)
- Long-term water balance analysis
- LTCCS interruptions analysis
- LTCCS failures analysis
- LTCCS condenser aerosols load
- Sump boiling possibility analysis
- Detailed criticality analysis
- Analysis of refuel and shutdown states
- Cavity door thermal/accident analysis
- Cavity isolation thermal radiation analysis
- Etc...

Optimization issues (in process)

- Common or separate cooling circuits
- System detailed specifications
- System start conditions
- SFP cooling line
- Number of RTS pumps and heat exchangers
- Improve cavity melt spreading from CAV1
- Shielding measures to containment (melt attack)
- Bound or not the melt spreading area?
- Optimize containment flooding
- Optimize water circuit flow
- Increase cavity door open probability
- Etc ...

Melt spreading analysis (Example)

Oxide only, 0-3600s, T(ini)=2700 ºC, Vol(ini)=12m^3 , water elev. 14m, impact opposite door, special developed calculation program (MSP)

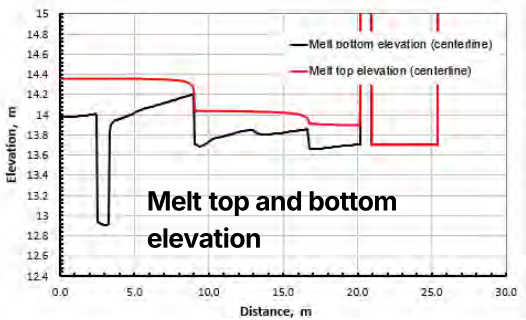
Preliminary estimations

- Melt final thickness is not uniform
- Melt final thickness depends on flow time
- Central sump, ducts and isolation are in analysis

Fast (flow time 200s)

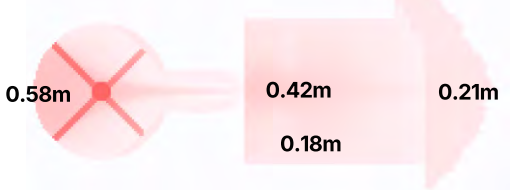
Vol(end)=24.6m^3, Area(end)=100.3m^2

Melt thickness

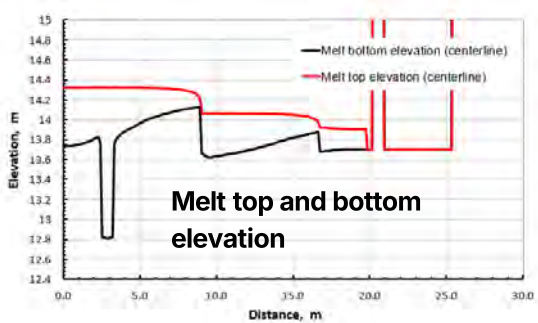


Middle (flow time 600s)

Vol(end)=25.1m^3, Area(end)=97.2m^2

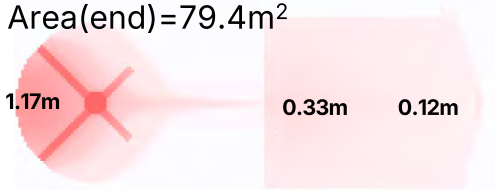


Melt thickness

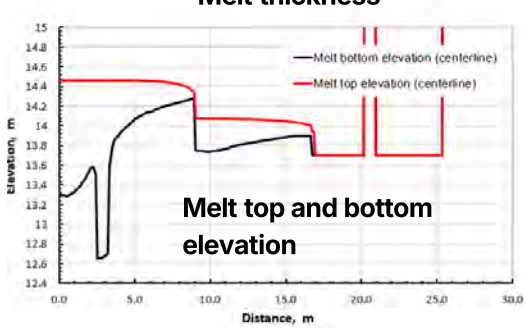


Slow (flow time 1200s)

Vol(end)=25.1m^3, Area(end)=79.4m^2



Melt thickness



Melt spreading analysis (Example)

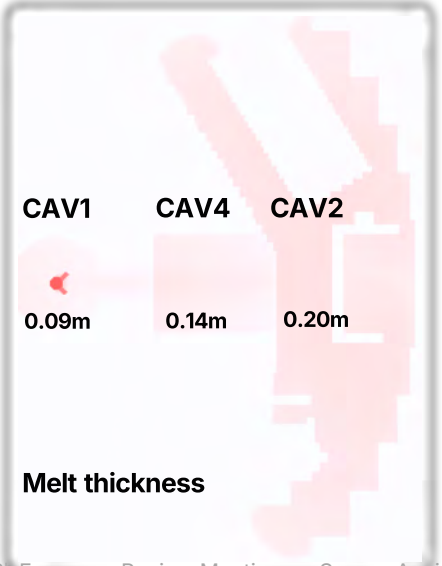
Oxide-metal mixture, 0-3600s, T(ini)=2700ºC, Vol(ini)=21m^3 , water elev. 14m, impact opposite door

Preliminary estimations

- CAV4 tends to low level and “rivers”
- CAV2 tends to agglomerate
- Slower flow -> more nonuniformity

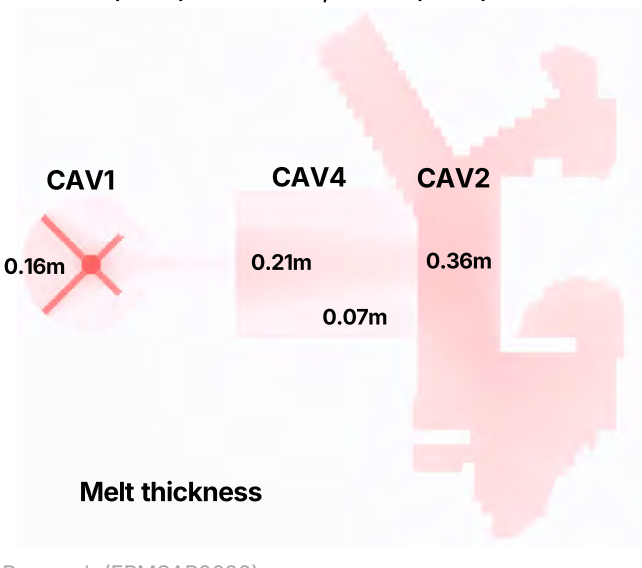
Fast (flow time 200s)

Vol(end)=39.7m^3, Area(end)=295.3m^2



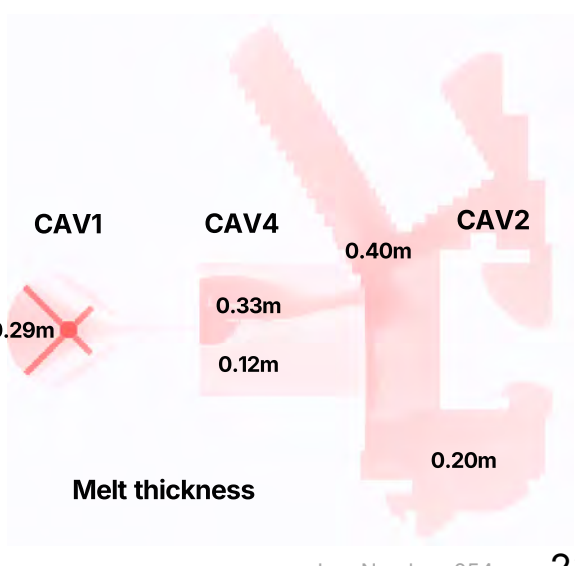
Middle (flow time 600s)

Vol(end)=40.3m^3, Area(end)=203.4m^2



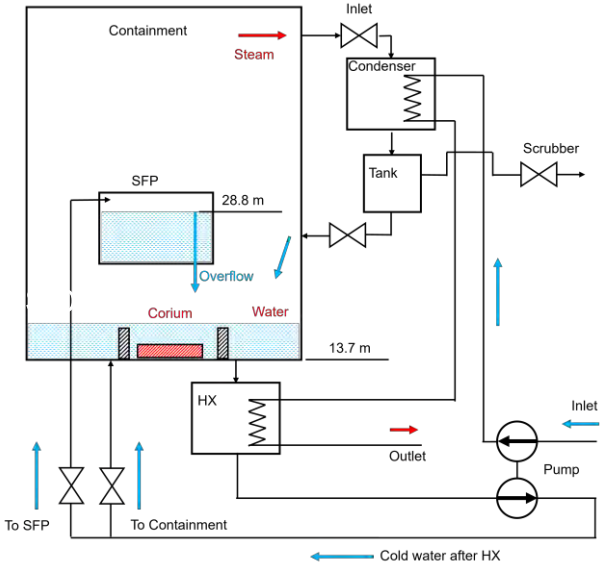
Slow (flow time 1200s)

Vol(end)=40.2m^3, Area(end)=216.7m^2



LTCCS with common cooling circuit

- Longer piping
- SFP line added

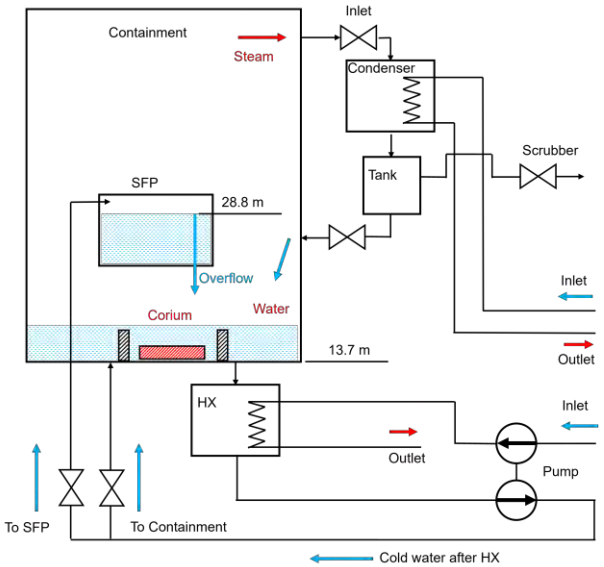


LTCCS layout with common cooling circuit

Combine?

LTCCS with separate cooling circuits

- Two or one external source?
- Simpler?



LTCCS layout with separate cooling circuits

LTCCS function

- LTCCS is successful in achieving safe stable end state for SA with ex-vessel phase
- Containment pressure and temperatures are decreased
- Late hydrogen problem in containment is resolved
- Contaminated water is circled inside containment

Analysis scope

- Basis to increase containment survivability
- Justification analysis
- Optimization analysis
- System specifications as a result of analysis
- Iterative process

Design

- Compromising between success probability, simplicity and feasibility
- Sizing, number of pumps and scheme is under development

ASTEC MODELLING OF THE AP1000 AND COLD-LEG SMALL-BREAK LOCA SIMULATIONS WITH LONG-TERM COOLING CUT-OFF

ZHAO Dawei, GUO Zhexi, XIAO Sicong

ABSTRACT

In this study, the AP1000 reactor pressure vessel (RPV) and reactor coolant system (RCS), including their passive safety systems, are modelled using the ICARE and CESAR modules in ASTEC, respectively. A 10-inch small-break loss-of-coolant accident (SB-LOCA) is simulated to evaluate the thermohydraulic performance of the passive residual heat removal (PRHR) system and three passive water injection systems: the core makeup tank (CMT), the accumulators (ACC), and the in-containment refuelling water storage tank (IRWST). Heat removal by the PRHR and the emergency water injections from the CMT, ACC, and IRWST show reasonable agreement with NOTRUMP results reported in the AP1000 Design Control Document [1] and another CESAR/ASTEC work by Di Giuli et al. [2]. These passive safety systems, in combination with the ADS, guarantee continuous emergency core cooling from less than 15 seconds after pipe-break initiation to approximately 25,000 seconds (~7 hours). Under the hypothetical condition that condensation on the containment vessel inner surface for long-term core cooling and lower head external cooling are unavailable, the in-vessel core degradation process is simulated and the potential radiological source term is estimated using the ICARE module.

KEYWORDS
AP1000, ASTEC, Small-Break LOCA, Passive safety, In-vessel degradation

1. INTRODUCTION

Despite increasing popularity and interest in novel nuclear reactor technologies and small modular reactors, large pressurised water reactors (PWRs) remain the most widely deployed around the world with a long history of operation. This means there is a wealth of operational experience and data, on which past analyses and computer codes were based, and efforts by the global scientific community to improve safety and performance of large PWRs are still ongoing. One such example is the AP1000 by Westinghouse [1], which is the subject of this study. Like many new designs, the AP1000 tries to incorporate passive safety systems designed to keep the plant within safe physical margins without external electricity and human intervention for extended periods of time, a concept strongly highlighted after the Fukushima accident. Even in the event of severe accidents (SAs) where the reactor core is damaged or melted, these systems are supposed to keep the release of radioactive material at low levels to minimise impact on human health and the environment.

To aid in the siting and overall planning of reactor deployment, prediction of the quantity and extent of these releases is of importance. To this end, SA simulations enable quantitative assessment of the radiological source term based on a chain of complex and diverse physical processes. A couple of widely recognised SA codes have been in use across the world, one of which is MELCOR [3] developed in the U.S. This work is performed with the other SA code—ASTEC (Accident Source Term Evaluation Code)—developed by the Autorité de sûreté nucléaire et de radioprotection (ASNR) in France [4].

The transient progression of a 10-inch small-break loss-of-coolant accident (SB-LOCA) had been simulated and analysed in the AP1000 Design Control Document [1] using NOTRUMP, which is a specific SB-LOCA system thermal-hydraulic (TH) code that incorporates passive safety features developed for AP600 safety analysis, and it had been verified against applicable plant test data [5]. Another work [2] also simulated the 10-inch SB-LOCA using the CESAR module in ASTEC instead. These two sets of results form the basis for comparison in this work, where the ICARE module is used in addition to CESAR in ASTEC to model TH and post-degradation phenomena in the reactor pressure vessel (RPV). A hypothetical scenario without long-term cooling is simulated to give preliminary insights into the roles of various structural components and safety systems in the management of source term release.

2. AP1000 RPV AND RCS MODEL

The reactor core models for fuel and vessel structures in the RPV beneath the upper core plate are built with the ICARE module of ASTEC. The reactor core simulation covers TH performance, reactor core degradation progression including cladding and steel structure oxidations, fuel rod embrittlement or melting, corium mixing and relocation, and corium behaviour in the lower plenum etc. In Fig.1, the reactor core area is split into 3 concentric core flow channels from reactor core centre to baffle inner surface, which contains 25, 68 and 64 fuel assembles, respectively. In the fuel area, each core flow channel is split into 15 meshes in the axial direction. Each fuel assembly includes 264 UO_2 fuel rods with Zr cladding, 24 AgInCd (AIC) control rods and 1 instrument guide tube. 15 spacer grids are set along the axial direction of the fuel assembly. The reactor core power is set at 3400 MW. The core axial power profile from Figure 4.3-16 in [1] is used. The reactor core decay heat is calculated from the inventory of fuel and fission products by the FP_HEAT Structure in ASTEC. From baffle outer surface to barrel inner surface is the reactor core bypass flow channel. The downcomer flow channel is set between barrel outer surface and reactor vessel inner wall. The bottoms of the downcomer, bypass and the 3 core flow channels are connected to the top of the lower plenum.

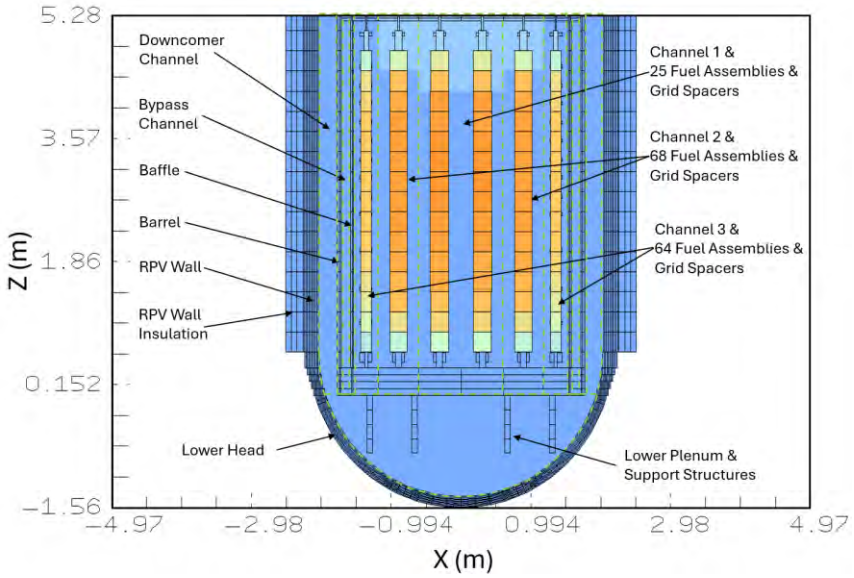

Figure 1. Reactor Core Nodalisation Scheme in ICARE.

In Fig. 2, the models for the reactor coolant system (RCS), including the primary and secondary loops, are built via the CESAR modules in ASTEC. The RCS primary loop is composed of RPV upper plenum structures, two coolant loops and one pressuriser (PZR). In each RCS primary loop, one hot leg (HL) links

the RPV upper plenum and the hot box of a steam generator (SG). Two reactor coolant pumps (RCPs) are set at the bottom of the SG cold box driving the coolant to RPV downcomer via two cold legs (CLs). The pump coast-down curve in [6] is adopted when the RCP shuts down.

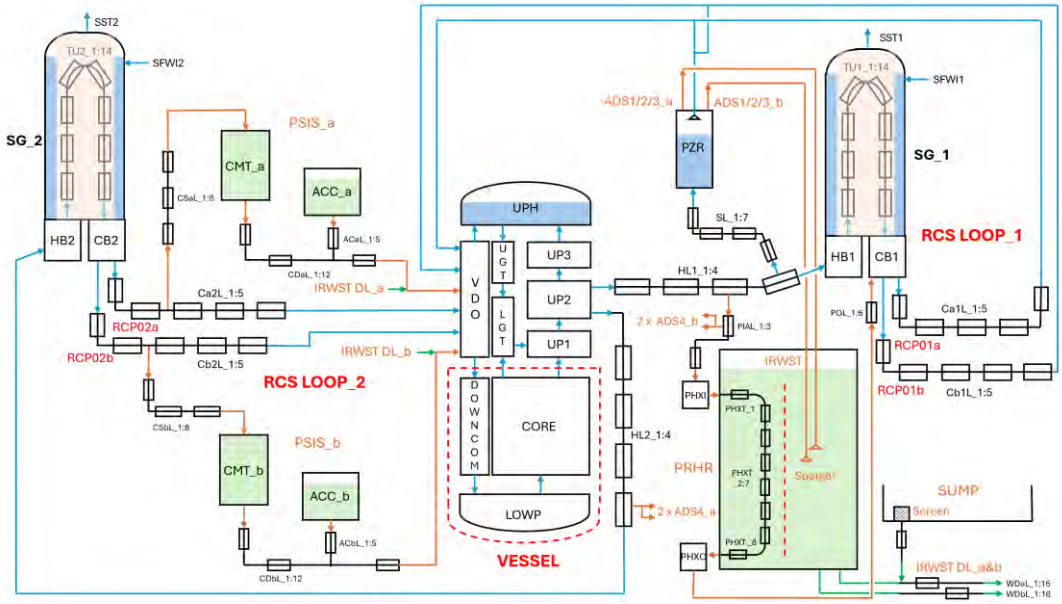

Figure 2. RCS Nodalisation Scheme in CESAR.

The primary loop and secondary loop in the RCS are coupled at the U-tube heat exchange area in the SGs. The RCS secondary loop is composed of SG feedwater pump, downcomer, riser, separator, steam dome and main steam line. The SG feedwater pump provides feedwater at defined pressure and temperature that serve as boundary conditions. The SG riser in the secondary loop shares the U-tube wall in the primary loop for heat transfer. A 'CONNECTI' structure of type 'BREAK' with constant back-pressure is set at the end of the SG main steam line to attain the correct main steam outlet pressure without modelling the unknown piping configuration to the steam turbine.

3. AP1000 PASSIVE SAFETY SYSTEM MODELS

In the AP1000 design, PZR, passive residual heat removal system (PRHR) and automatic depressurisation systems (ADSs) are located on RCS LOOP_1. The core makeup tank (CMT) and accumulator (ACC) are set in each cold leg of RCS LOOP_2.

The PZR is modelled by a 'swollen' type volume with sprays and heaters for maintaining RCS pressure. At the top of the PZR, there are 2 parallel groups of ADS_1/2/3 valves with discharge lines connected to the In-containment Refuelling Water Storage Tank (IRWST). The IRWST is modelled as 3 axial layers with one volume at the bottom and one volume at the top, while the middle layer is split into 2 parallel pipes connecting the bottom and top volumes, forming a loop within the IRWST. The heat exchange tube of the PRHR is coupled with one of the IRWST parallel pipes. When the PRHR is actuated, natural circulation could be generated in the IRWST.

The CMT is modelled by a 'swollen' type volume with a suction line connecting its top to the RCP downstream of the SG cold leg. Downstream of the CMT, a discharge line from the CMT bottom is extended to the direct vessel injection (DVI) nozzle on the RPV downcomer. Even under high pressure conditions,

borated water in the CMT could be driven by gravity and natural circulation for emergency water injection. The ACC is modelled by an 'Accumulator' type 'SYSTEM' component connected to the CMT discharge line. The gas pressure of compressed nitrogen at the ACC top is 4.8 MPa. Gas expansion coefficient is set at 1.3 with isotherm expansion at 1.0 and adiabatic expansion at 1.4. From the bottom of the IRWST, 2 discharge lines with check valves are connected to 2 CMT discharge lines, separately, for water injection under low pressure conditions. On each cold leg of RCS LOOP_2, the CMT, ACC and IRWST discharge lines share one common DVI on the RPV downcomer.

The reactor trip and safety systems actuation signals have been modelled according to Table 15.0-4a&b and Table 15.6.5-10 of the AP1000 Design Control Document [1].

4. STEADY STATE CALCULATION

Before transient calculation of the accident scenario, the initial steady-state NPP operation condition is calculated. The 'REGU' structures in ASTEC are used to adjust initial settings like local flow resistances, initial water loading, PZR heater power or spray flow etc., for aligning the steady state simulation to some representative parameters during normal operation, like PZR pressure and water level, reactor core water flow and bypass flow, reactor core inlet and outlet temperatures, steam produced, and pressure drops. This runs for 20,000 s to achieve the required steady-state initial conditions. Steady-state calculations and nominal AP1000 operation parameters are listed in Table I.

Table I. Comparison of ASTEC Steady State Simulations with reference nominal values [1]

NPP representative operating parameter	ASTEC simulations	Design values[1]
Pressuriser pressure (MPa)	15.5997	15.6
Vessel flow (kg/s)	15169.95	15170.14
Reactor core bypass flow (kg/s)	378.82	378.82
Bypass flow to reactor core upper head (kg/s)	227.25	227.25
Average core inlet temperature (°C)	282.17	280.67
Average core outlet temperature (°C)	323.88	323.3
Steam flow from SG (kg/s)	938.85	943.1
Steam pressure from SG (MPa)	5.753	5.760
Reactor core pressure drop (kPa)	294.97	275.1±27.58
RPV pressure drop (kPa)	441.43	429.5±42.75
SG pressure drop (kPa)	340.71	~343.0

5. 10-INCH SB-LOCA SIMULATION

A 10-inch SB-LOCA is assumed to occur at the bottom of a cold leg connected to CMT_a. The simulation results are compared with NOTRUMP simulations in the AP1000 design control document [1] and CESAR results [2]. In addition, the reactor core degradation progression is analysed when post-LOCA long-term cooling is unavailable due to exclusion of the containment and its cooling system models in this simulation.

5.1. Emergency reactor core cooling

The AP1000 passive safety systems actuations in this 10-inch SB-LOCA simulation follows 3 variables in emergency reactor core cooling progression: RZR pressure, CMT water level and IRWST water storage

with pre-set setpoint and time delays listed in Table II. The event times for the emergency reactor core cooling progressions of the 10-inch SB-LOCA are shown in Table II.

Table II. Safety Systems Sequence in AP1000 10-inch SB-LOCA Transient

Event	Setpoints and Delays	CESAR [2]	NOTRUMP [1]	CESAR + ICARE (this work)
Break initiation		0.0	0.0	0.0
Reactor trip signal	PZR pressure < 12.41 MPa + 0.2 s	4.3	5.2	5.2
Safeguards signal ('S' signal)	PZR pressure < 11.72 MPa + 2 s	5.4	6.4	8.8
PRHR & CMT actuation	'S' signal + 5 s			13.8
Steam turbine isolation	'S' signal + 6 s	12.5	11.2	14.8
Reactor coolant pumps trip	'S' signal + 6 s	10.5	12.4	14.8
Accumulator injection starts		102.2	85.0	94.6
ACC_a empties		477.8	418.2	806.7
ACC_b empties		478.3	425.5	806.8
ADS_1 actuation	67.5% CMT level + 32 s	817.0	750.0	580.2
ADS_2 actuation	ADS_1 actuation + 48 s	877.0	820.0	630.2
ADS_3 actuation	ADS_2 actuation + 120 s	997.0	940.0	750.2
ADS_4a actuation	20% CMT level & ADS_3 actuation + 128 s	1535.0	1491.0	1215.2
IRWST injection starts		1650	~1800	1245.2
ADS_4b actuation	ADS_4a actuation + 120 s			1275.2
CMT_b empties		1830	1800	1510.2
CMT_a empties		~2000	1900	1510.2

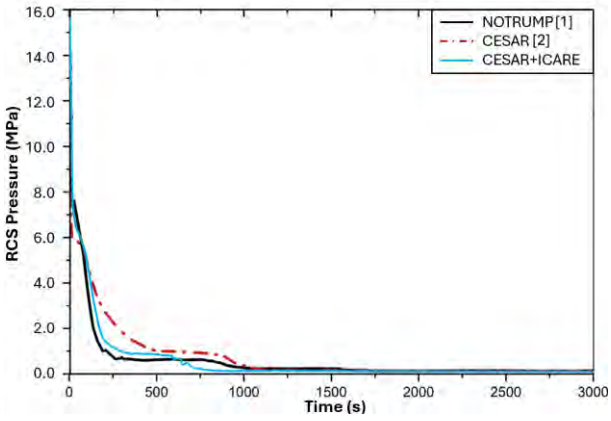

Figure 3. RCS pressure drop curve.

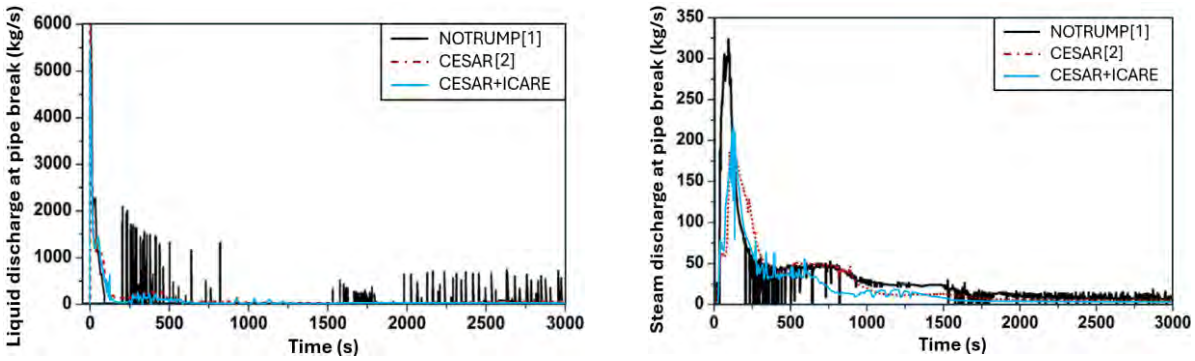
The event times for reactor trip, 'S' signal and ACC injection in the present study show a reasonable agreement with NOTRUMP results in the blowdown phase and in the early stage of the natural circulation phase. The pressure drop speed is dominated by discharge flow rates from the pipe-break. In the first 100 s after the pipe is broken, the discharge liquid flow rates in Fig. 4a agree quite well in all 3 simulations. Even

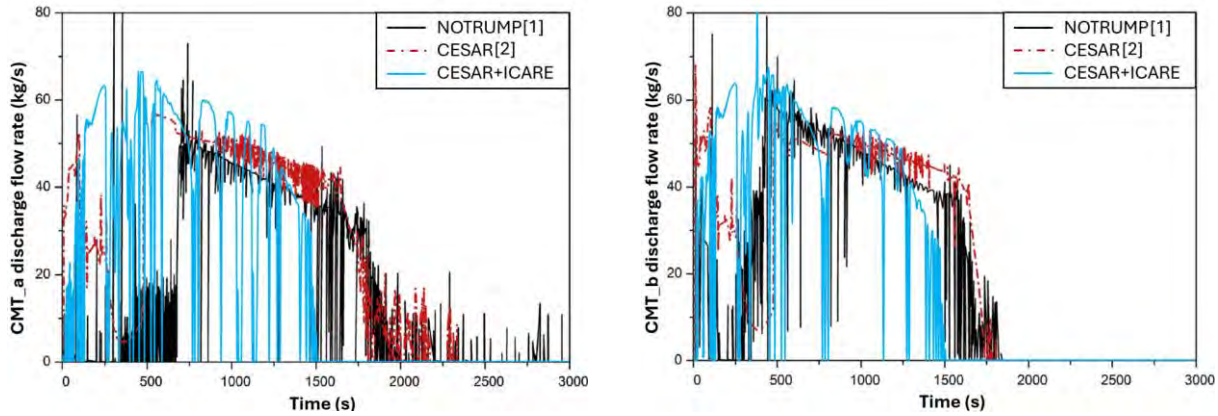
though there are slight deviations in discharge gas flow rates in Fig. 4b, the RCS pressure drop shows nearly the same decline rate till the ACC injection actuation pressure of 4.8 MPa.



(a) **(b)**

Figure 4. (a) Liquid and (b) Steam Discharge Flows at Pipe-Break.

In the natural circulation phase, the emergency water injection flow to the RPV from the DVI is dominated by natural circulation in the CMT loop and pressure difference between ACC compressed gas and RCS system. In Fig. 5a&b, natural circulation is quickly set up in the CMT loop within 6 s after 'S' alarm. When ACC is triggered as RCS pressure drops below 4.8 MPa, CMT natural circulation flow is suppressed by ACC discharge flow. After ACC is emptied, CMT natural circulation flow rate firstly recovers to a higher level and then slips down till CMT water is depleted. The natural circulation flows in CMT_a and CMT_b loops are almost the same as in the other 2 simulations.

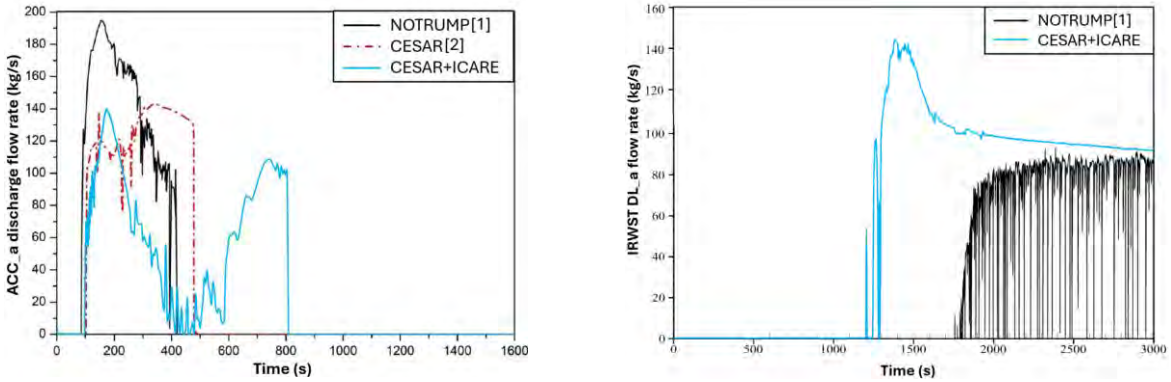


(a) **(b)**

Figure 5. (a) CMT_a and (b) CMT_b Discharge Flows.

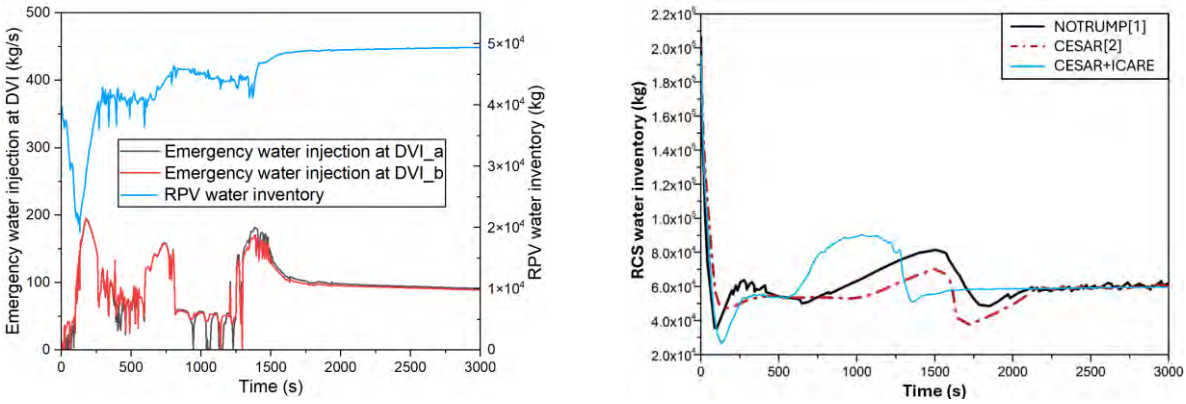
In Fig. 6a, the ACC discharge flow in the present study shows a different trend. The ACC discharge flows are generally suppressed, which leads to a longer ACC discharge period. From Fig. 3, RCS pressure decline rate is significantly reduced after ~250 s. The decrease of pressure difference between ACC and RCS system induces suppression of ACC discharge flows. However, the CMT discharge flow rate is shortly recovered during this ACC discharge flow suppression period. As water level in CMT decreases to 67.5 %, ADS_1 is triggered much earlier at ~580.2 s than in the other 2 simulations. The series of ADS_1/2/3 actuations re-accelerates RCS pressure drop and ACC discharge flow rate starts to increase. When the water level in the

CMT reaches 20 %, additional RCS depressurisations by ADS_4 a&b start from 1215.2 s in Table II, which guarantee the long-term cooling water injection from IRWST is triggered at ~1245.2 s in Fig. 6b before CMT water is depleted at ~1510.2 s in Fig. 5 a&b.



(a) **(b)**

Figure 6. Discharge Flows from (a) ACC_a and (b) IRWST_a.



(a) **(b)**

Figure 7. (a) DVI Injection Flows & RPV Water Inventory and (b) Water Inventories in RCS.

In Fig. 7a, the CMT, ACC and IRWST work together with ADS_1/2/3/4 to guarantee continuous emergency water injection from the DVI after pipe-break. The first DVI flow peak brought about by ACC actuation successfully reverses the RCS and RPV water inventory decrease as shown in Fig. 7a & b. The second DVI flow peak following ACC injection after ADS_1 is triggered at ~580.2 s contributes to the RCS and RPV water inventory step. The third DVI flow peak at the beginning of IRWST discharge compensates for the massive water loss due to ADS_4a/b ruptures.

Besides continuous emergency water injection, heat transfer in the PRHR system also contributes to preventing reactor core overheating, especially in the early stages of the LOCA as shown in Fig. 8. In Fig. 9, fuel cladding temperature is well controlled with maximum temperature remaining below 650 K. However, the temperature peaks on the declining fuel cladding temperature curve in the present simulation indicate that the fuel claddings are shortly exposed to steam. The first two fuel cladding temperature peaks are triggered in the early blowdown phase of the LOCA. The prompt ACC discharge actuation effectively increases RPV water inventory and re-wets the fuel cladding surface. The DVI flow peak brought about by ACC discharge guarantees the reactor core safely transits to the long-term cooling stage.

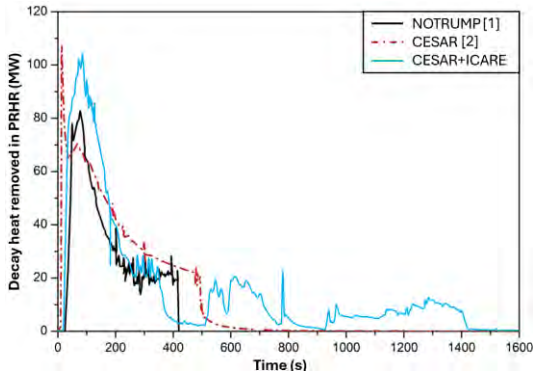


Figure 8. Heat Discharge in PRHR.

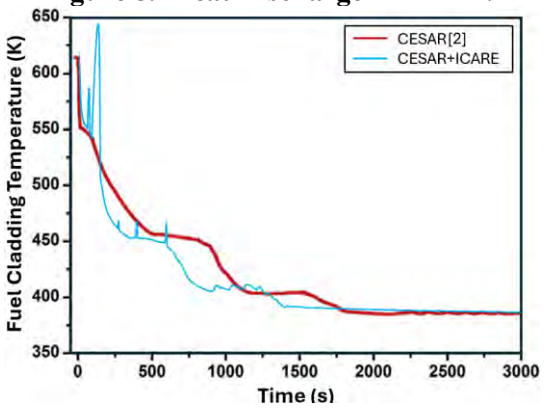

Figure 9. Max. Cladding Temperature Curve.

5.2. In-vessel core degradation with long-term cooling cut-off

In the long-term cooling stage, water discharged from the IRWST compensates for water loss in the reactor core. In the AP1000 design, steam leaking through ADS_1/2/3/4 and the piping break will be cooled and condenses on the steel containment vessel inner surface by the passive containment cooling system for at least 72 hours. Driven by gravity, the condensate collected in the sump flows back to the RPV via the IRWST discharge line. The steel containment vessel works as the third barrier—both in retaining radioactive materials and in serving as the ultimate heat sink, which could provide long-term cooling water for a submerged reactor core as shown in Fig. 10.

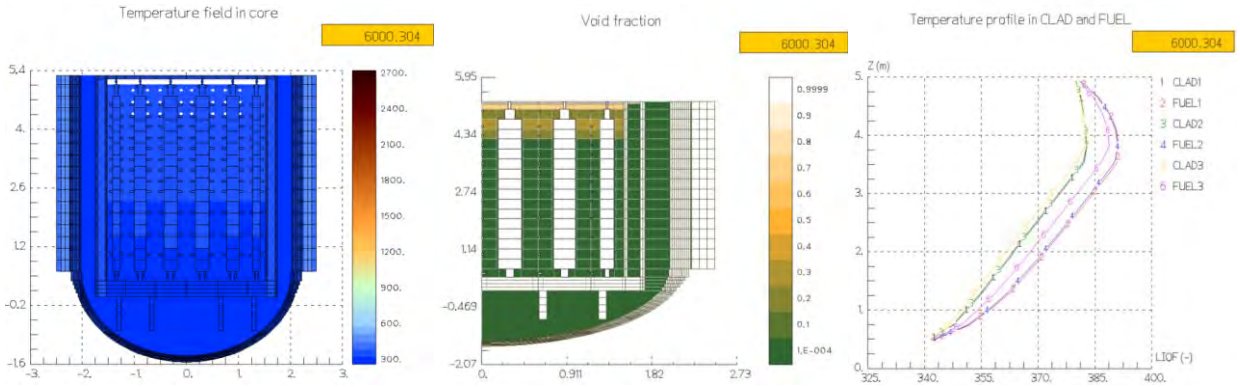

Figure 10. Temperature & Void Fraction Fields in Core, and T_{Clad} and T_{Fuel} Profiles at 6000.3 s.

In the present study, we removed the containment and its passive containment cooling system. After IRWST water is depleted, the water source for long-term cooling is cut off to simulate the reactor core degradation process using ICARE module. In Fig. 11, IRWST discharge flow drops abruptly at ~22000 s as IRWST water inventory approaches zero without supply from containment condensation. Without sufficient cooling water supply, water temperature in the reactor core gradually increases. As shown in Fig. 11 and Fig. 12, the fuel and cladding temperatures at reactor core bottom increase from ~340 K to 374 K due to the surrounding water temperature increase. The significant void fraction increase in reactor core upper section in Fig. 12 indicates there is violent boiling on cladding surfaces. The nucleate boiling on cladding wall in reactor core upper section suppresses the fuel and cladding temperatures on the top of fuel and cladding temperatures profile in Fig. 12. However, when the IRWST discharge flows cannot compensate for the water loss via evaporation, the increasing void fraction will trigger boiling crisis on cladding surfaces.

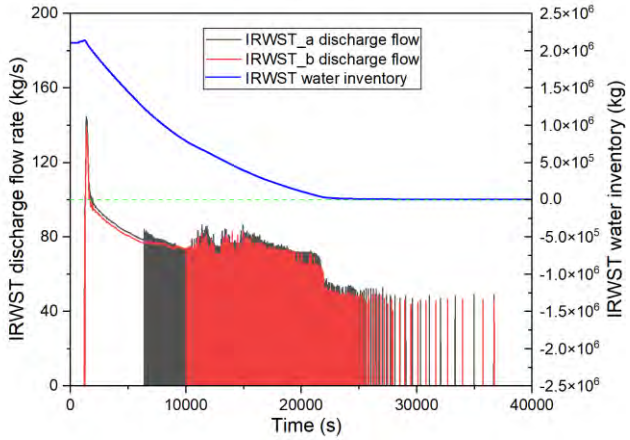

Figure 11. IRWST Inventory and Discharge Flows in Long-term Cooling Period.

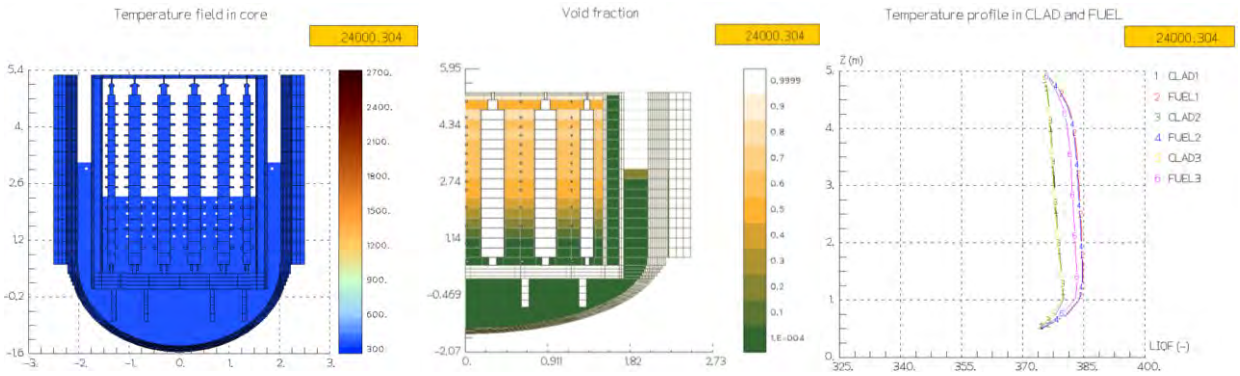

Figure 12. Temperature & Void Fraction Field in Core and T_{Clad} & T_{Fuel} Profiles at 24000.3 s.

In Fig. 11, the water inventory in IRWST is almost depleted at ~25000 s, around 7 hours after the pipe is broken. After wetting by steam flow and entrained water droplets are lost, cladding temperatures in the reactor core upper section increase to ~850 K at 26630.3 s as shown in Fig. 13 and Fig. 14. Oxidation starts on high-temperature Zr cladding surfaces and steel vessel structure surfaces with hydrogen generation as shown in Fig. 15a. The exothermic reaction between Zr and steam aggravates fuel cladding failure.

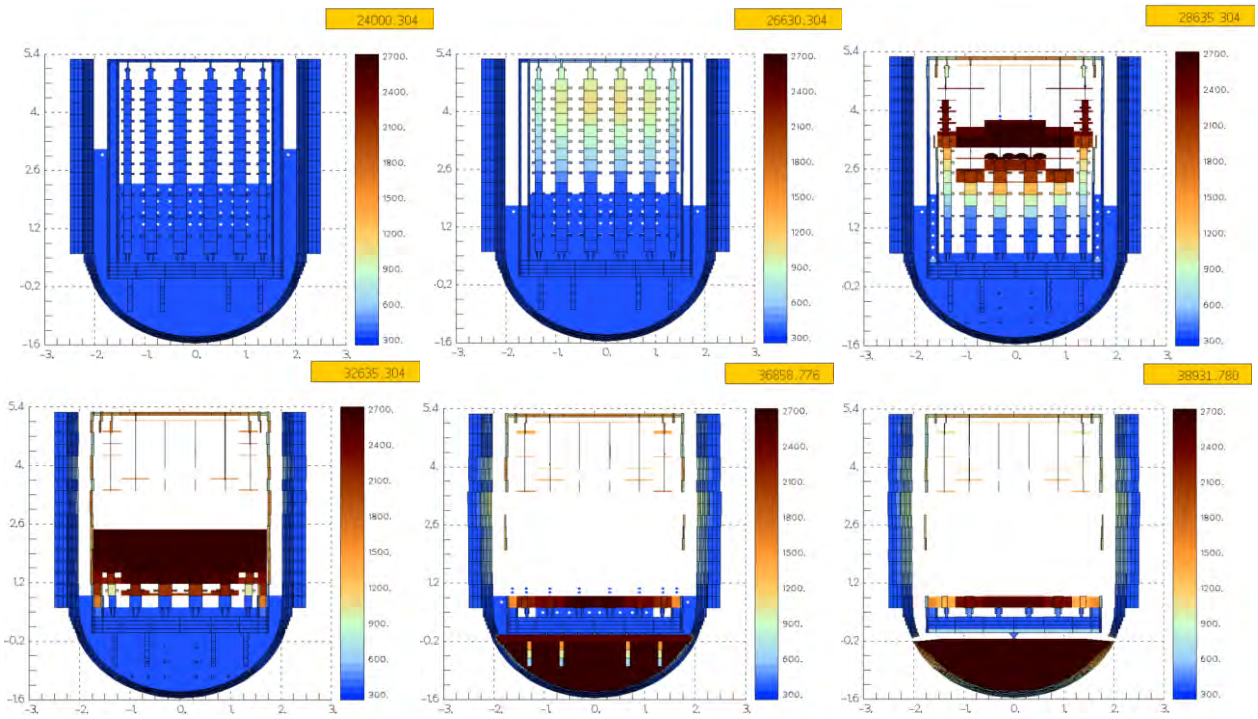

Figure 13. Reactor Core Temperature Field.

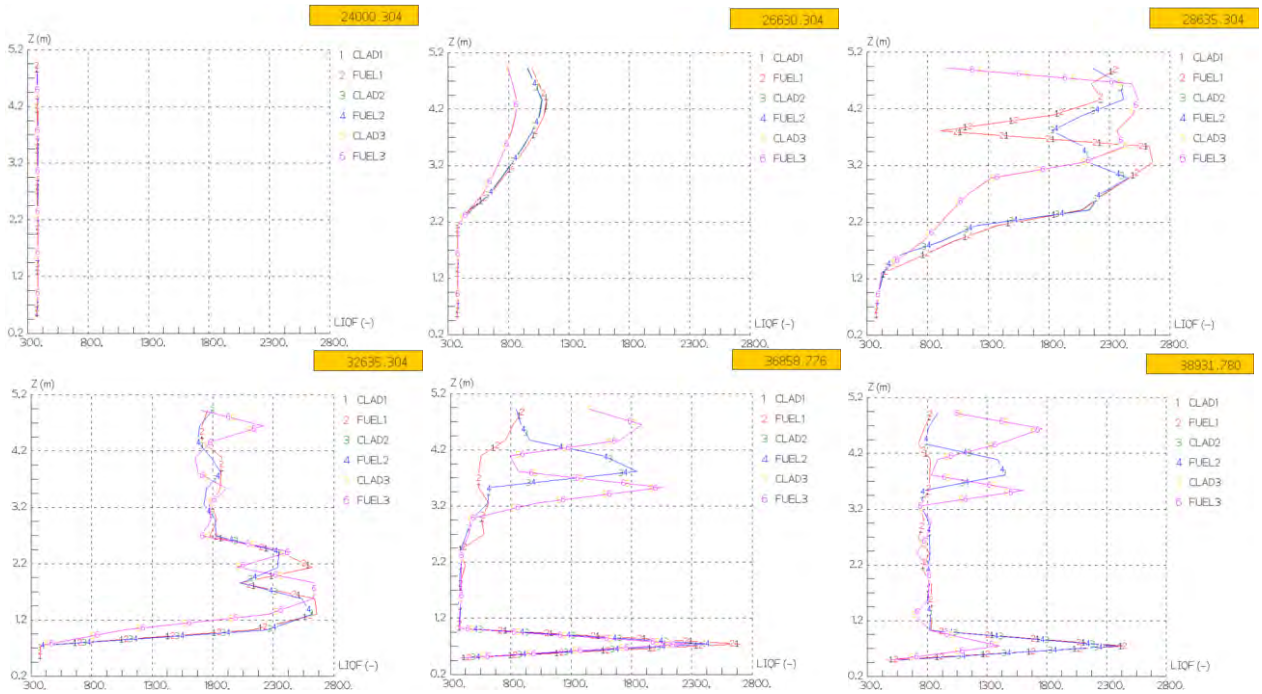

Figure 14. Fuel and Cladding Temperature Profiles.

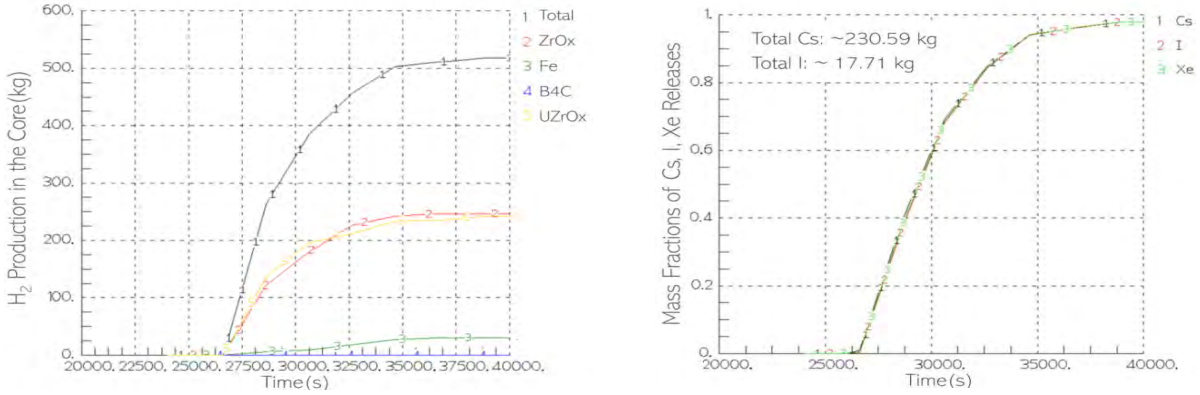
At 28635.3 s in Fig. 13, most of the fuel, cladding and vessel structures in the reactor core upper section are liquefied and relocated to the lower section, which leads to massive radioactive material release as shown

in Fig. 15b. With molten corium gradually slumping to the lower plenum, a molten corium pool is formed at ~36635.3 s with a light metal layer on the top in Fig. 13.



(a) **(b)**

Figure 15. Hydrogen Production and Radioactive Material Release.

As lower head external cooling is excluded in the present study, the lower head wall suffers from high heat flux from light metal layer and its deadweight, which induces vessel rupture near the molten corium pool surface level referring to ductile failure based on Oeuf model, a mechanical model to describe the behavior of a reactor vessel lower head loaded by thermal, pressure and weight loads under severe conditions in ICARE [7]. Partial corium above lower heat rupture elevation (-0.147 m) flows out of the lower head. Lower head (LH) collapses at 38931.8 s, around 4 hours after IRWST water depleted, marks the final stage of the in-vessel accident progression in ICARE calculation. The in-vessel core degradation progression and estimated source term releases are listed in Table III.

Table III. Safety Systems Sequence in AP1000 10-inch SB-LOCA Transient

Time (s)	Event
26630.3	First cladding creep rupture
26630.3	Start of FPs release from fuel pellets
26915.3	Start of structural material release
27990.3	First material slump in lower plenum
36858.8	Lower head vessel failure • Ductile failure based on Oeuf model [7] • H_2 mass produced during in-vessel phase = 510.926 kg • Aerosol mass produced during in-vessel phase = 9086.69 kg Corium flows out of the lower head • Corium mass transferred from the lower head = 14431.6 kg • Remaining corium mass in the lower plenum = 97678.6 kg
38931.8	Lower head collapse

6. CONCLUSIONS

The AP1000 RCS and its safety systems, including the PRHR system, ADS and 3 passive water injection systems—CMT, ACC and IRWST, are modelled by the CESAR module in ASTEC. The thermohydraulic

performance of those passive safety systems in the 10-inch SB-LOCA are simulated. Heat removal driven by natural circulation in the IRWST pool, and emergency water injections from CMT, ACC and IRWST, driven respectively by natural circulation, compressed gas and gravity, show reasonable agreement with NOTRUMP results in the AP1000 design control document [1] and another CESAR/ASTEC work by [2]. The ADS depressurisation design plays an important role in maintaining ACC discharge flow rate and actuating IRWST injection before CMT water is depleted. The 3 passive water injection systems, in combination with the ADS, guarantee continuous emergency core cooling from less than 15 seconds after the pipe-break until approximately 25,000 seconds (~7 hours), effectively slowing down reactor core water level decline rate and preventing fuel and cladding from overheating.

The containment and passive containment cooling system in the AP1000 design are intentionally removed for demonstrating the in-vessel core degradation process by the ICARE module in ASTEC. Without containment providing condensation water for reactor core long-term cooling and lower head external cooling, reactor core melt-down along with massive hydrogen and radioactive material release is inevitable. The in-vessel core degradation simulation underscores the critical role of the containment as the third barrier in the AP1000 design, both in retaining radioactive materials and in serving as the ultimate heat sink for long-term cooling.

AP1000 & Typical Passive Safety Systems

The AP1000 reactor is the first operating Gen III+ reactor with fully passive safety systems, modular construction design and one of the most compact footprints among Gen-III+ NPPs. Those advanced design philosophy have been adopted in many innovative LW-SMR designs.

- Passive Core Cooling System (PXS)
- High Pressure Safety Injection with Core Makeup Tanks (CMTs)
- Medium Pressure Safety Injection with Accumulators
- Low Pressure Reactor Coolant Make from the IRWST
- Automatic Depressurization System
- Passive Residual Heat Removal

- Containment Isolation
- Passive Containment Cooling System (PCS)
- Main Control Room Emergency Habitability System

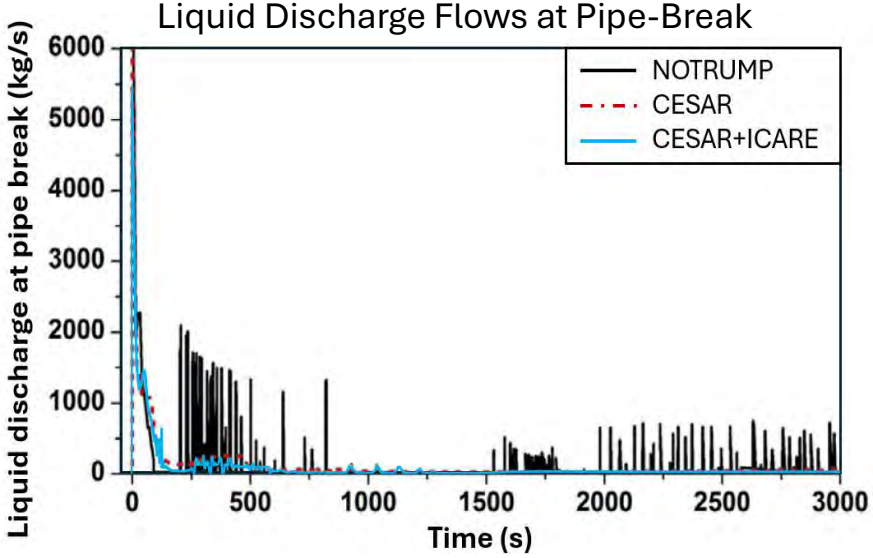
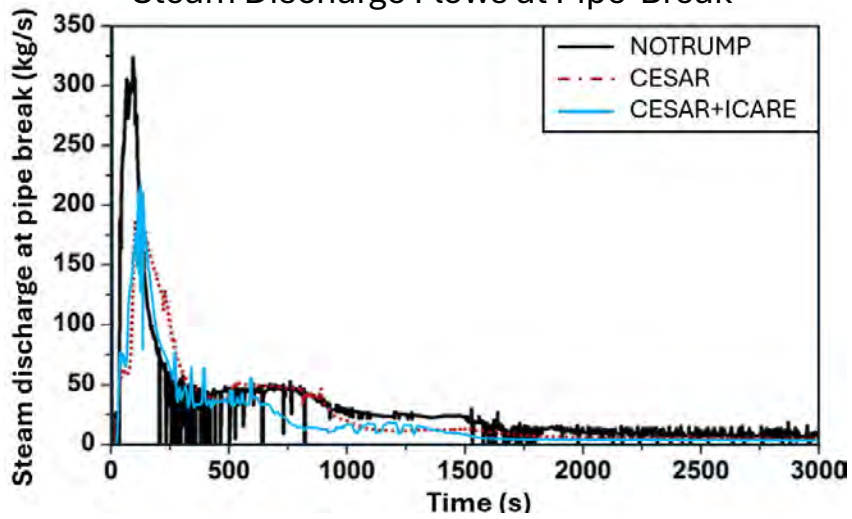
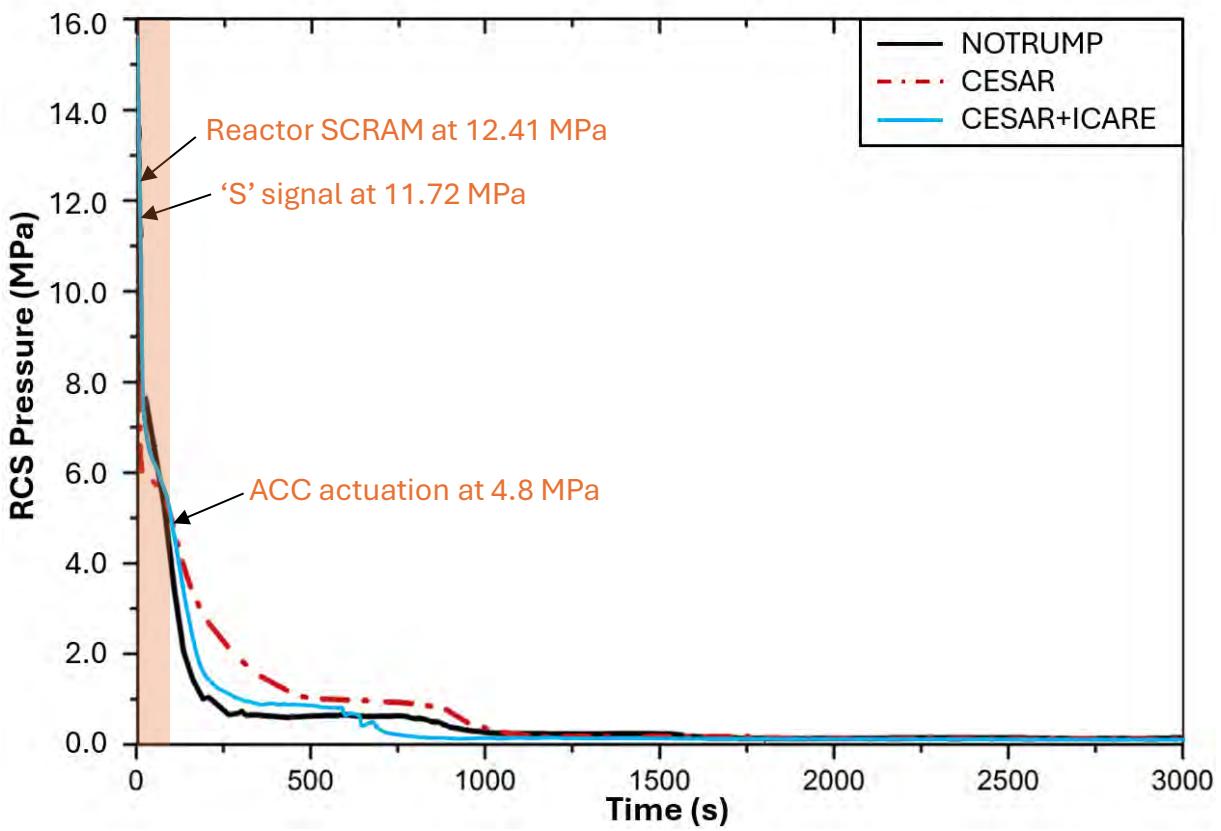
AP1000 SB-LOCA Simulation: RCS Depressurization

Liquid Discharge Flows at Pipe-Break



Steam Discharge Flows at Pipe-Break

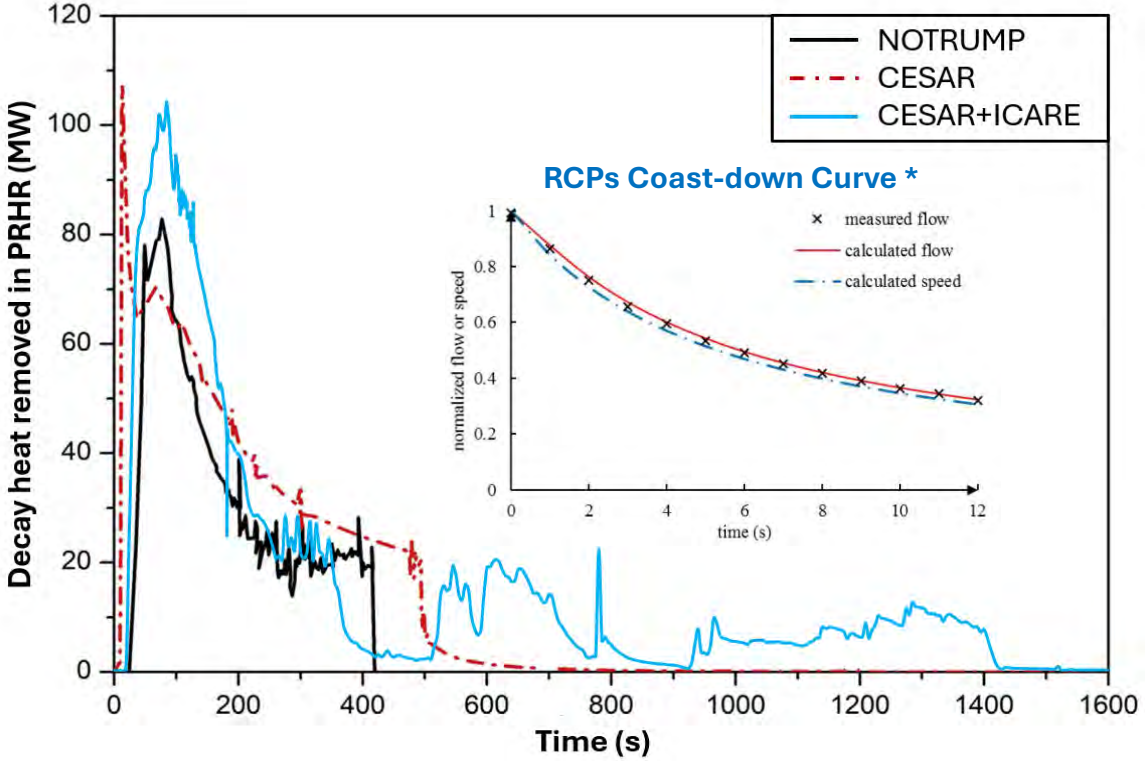




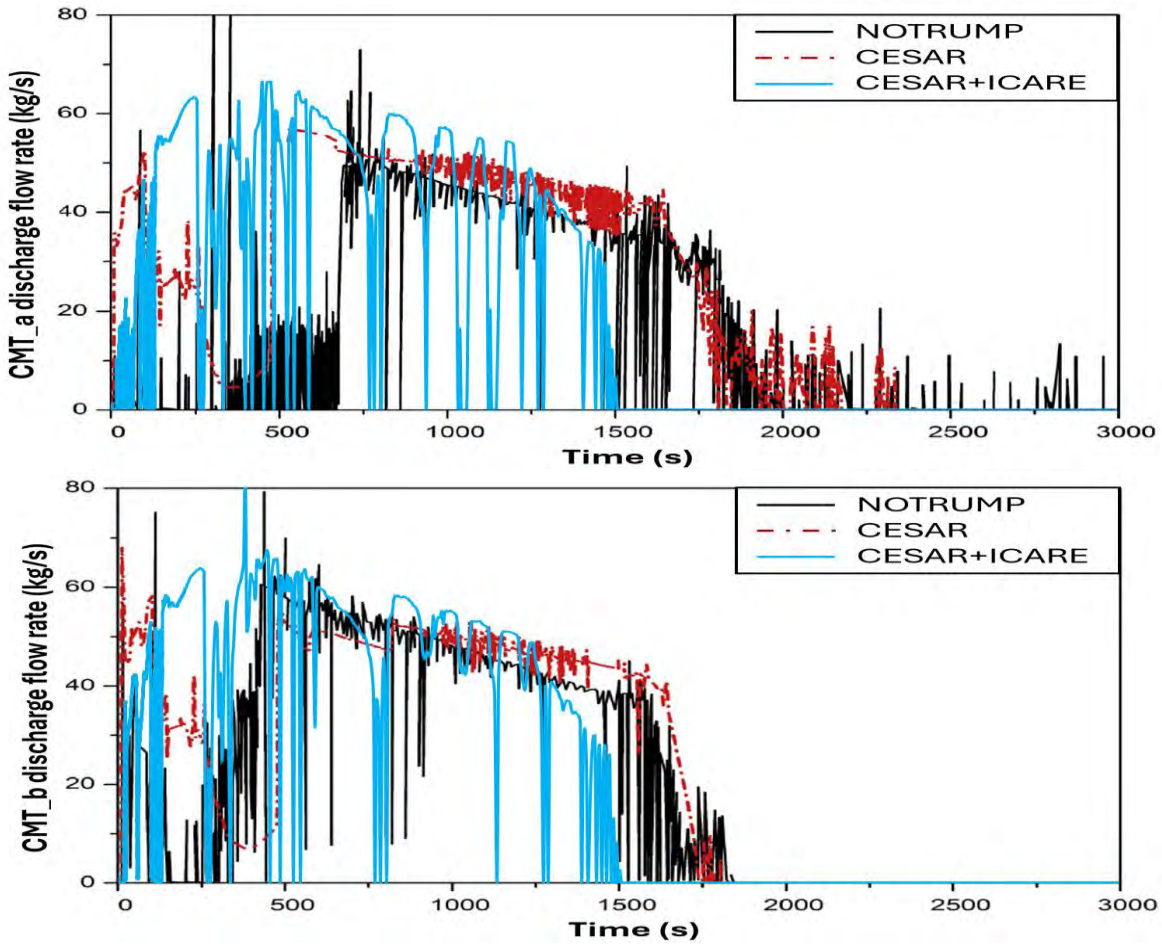
In the first 100 s after the pipe is broken, the discharge liquid flow rates agree quite well in all 3 simulations. Even though there are slight deviations in discharge steam flow rates, the RCS pressure drop shows nearly the same decline rate till the ACC injection actuation pressure(4.8 MPa).

AP1000 SB-LOCA Simulation: Flow Circulations in PRHR & CMT Loops

The isolation valves on CMT & PRHR are opened at 5s after 'S' signal. As RCPs trip 1s later, the residual pump head during RCP coast-down drives the flow circulations in the PRHR loop and CMT loops in the following few seconds.



The partial reactor core decay heat is transferred through PRHR loop and dispersed to refueling water via the C-type heat exchanger submerging in IRWST water pool.

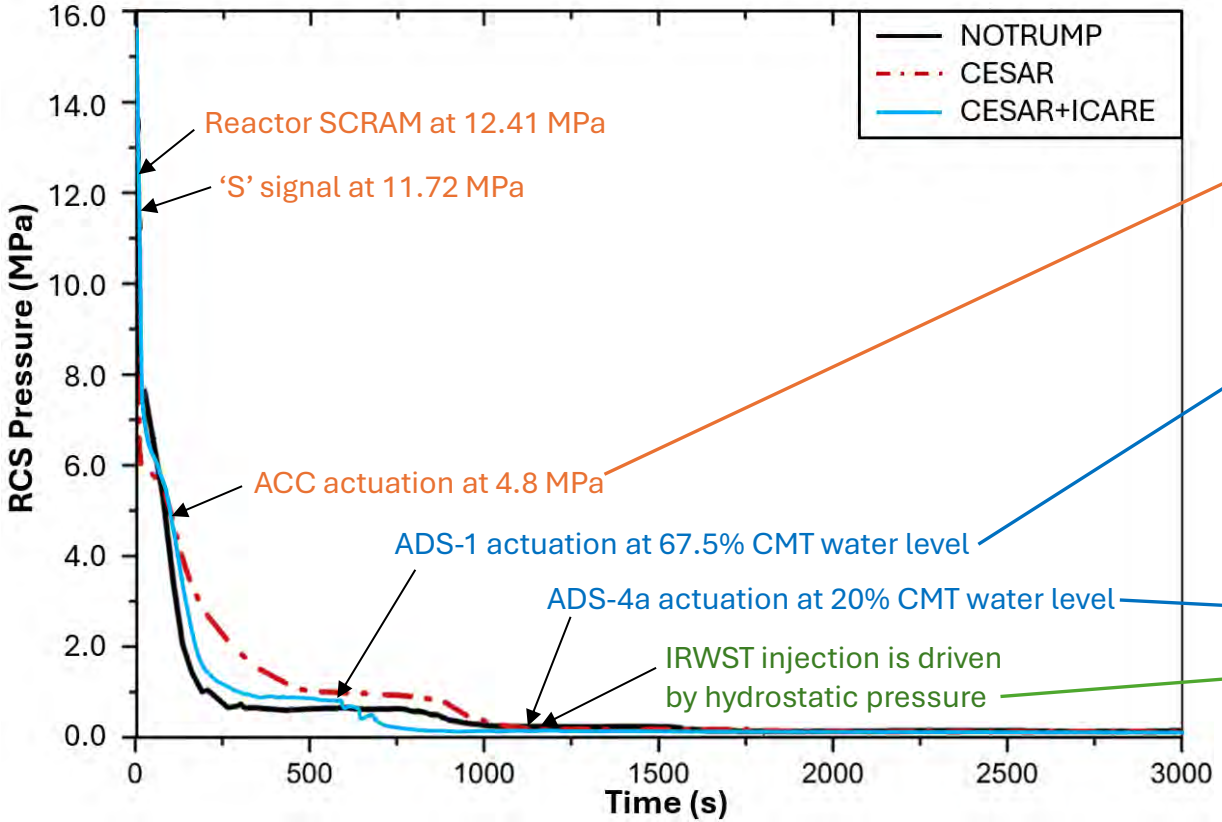


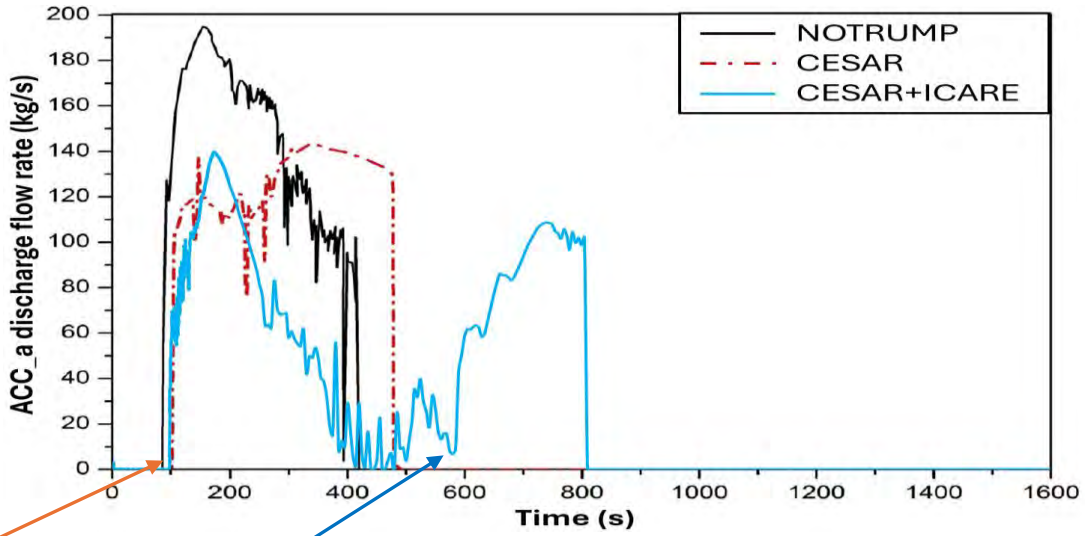
The flow circulations in CMT_a & b loops start the emergency water injection in the first few mins before RCS pressure drop to ACC actuation pressure.

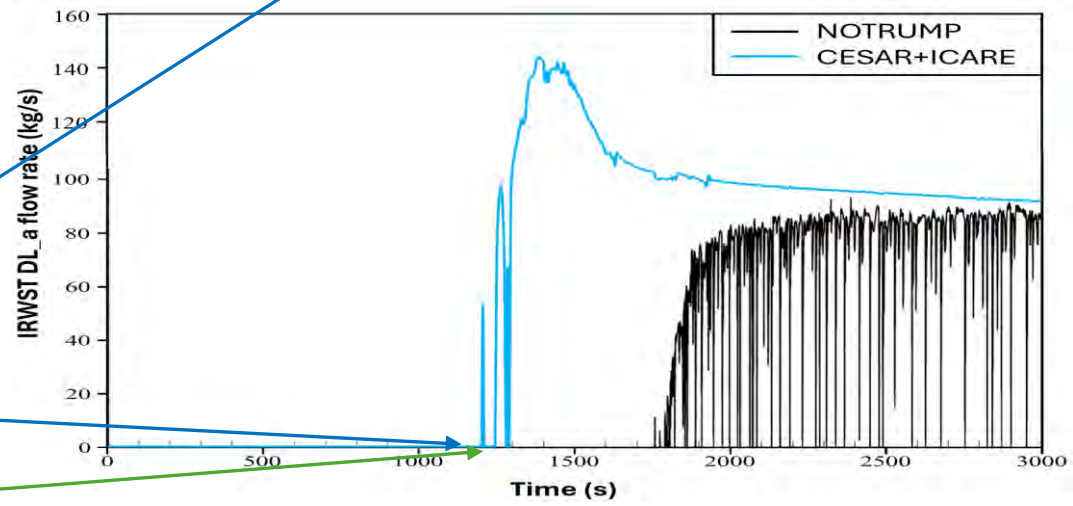
* Extended Study of Reactor Coolant Pump Coastdown Phenomenon with RELAP/Mod3

AP1000 SB-LOCA Simulation: ACC & IRWST Injections and ADS

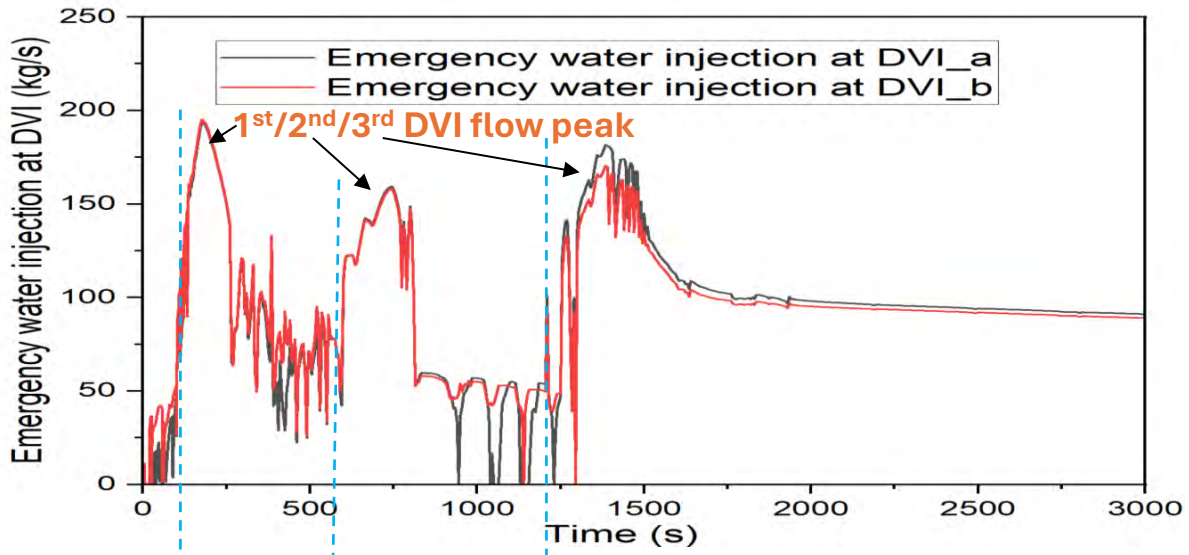
- The series of ADS_1/2/3 actuations at 67.5% CMT water level re-accelerates RCS pressure drop and ACC discharge flow rate starts to increase.
- When the water level in the CMT reaches 20 %, additional RCS depressurizations by ADS_4, which guarantee the long-term cooling water injection from IRWST is triggered before CMT water is depleted.

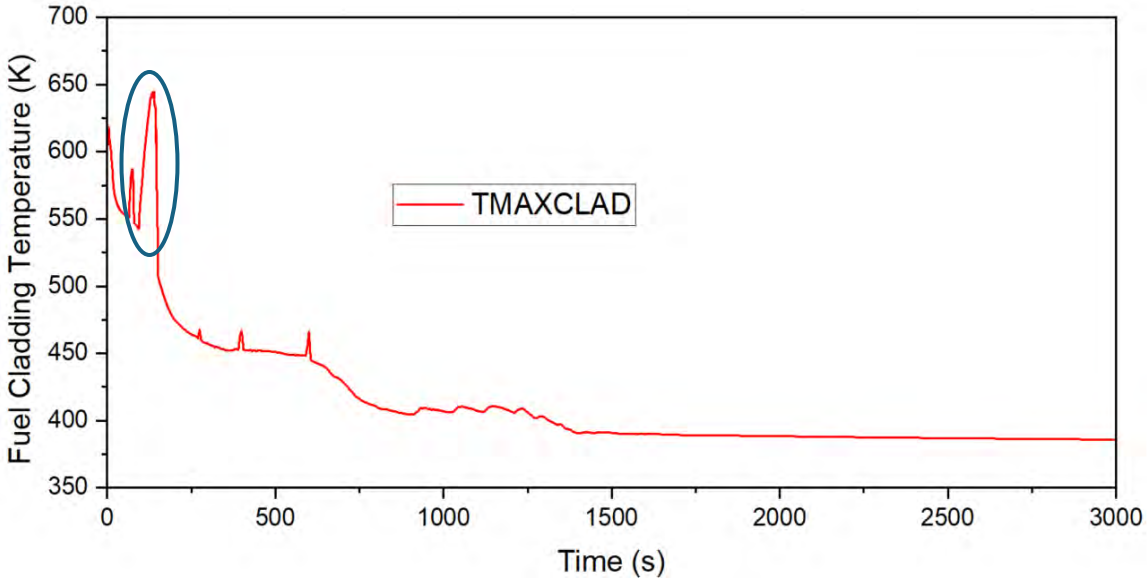


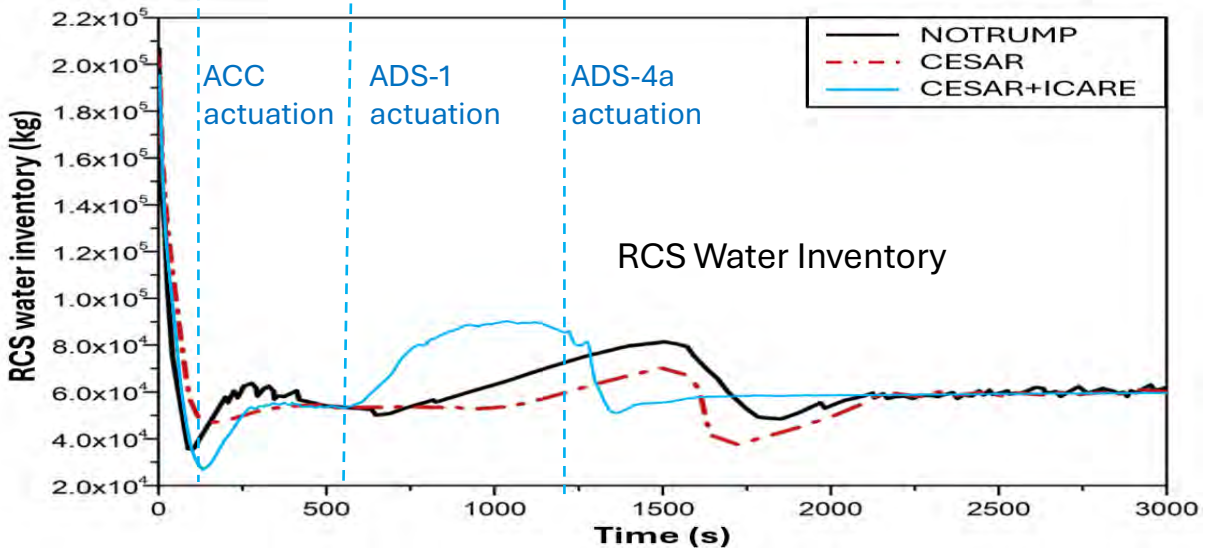




AP1000 SB-LOCA Simulation: DVI Injection







The CMT, ACC and IRWST work together with ADS_1/2/3/4 to guarantee **continuous water injection** from the DVI after pipe-break. The fuel cladding temperature is well controlled with maximum temperature remaining **below 650 K**.

- The **1st DVI flow peak** brought about by ACC actuation successfully reverses the RCS water inventory decrease and re-wets the fuel cladding surface.
- The **2nd DVI flow peak** following ACC injection after ADS_1 is triggered at ~580.2 s contributes to the RCS water inventory step.
- The **3rd DVI flow peak** at the beginning of IRWST discharge compensates for the massive water loss due to ADS_4a/b ruptures.

NUS National University of Singapore | Singapore Nuclear Research and Safety Institute

AP1000 PCS and Long-term Cooling Cut-off

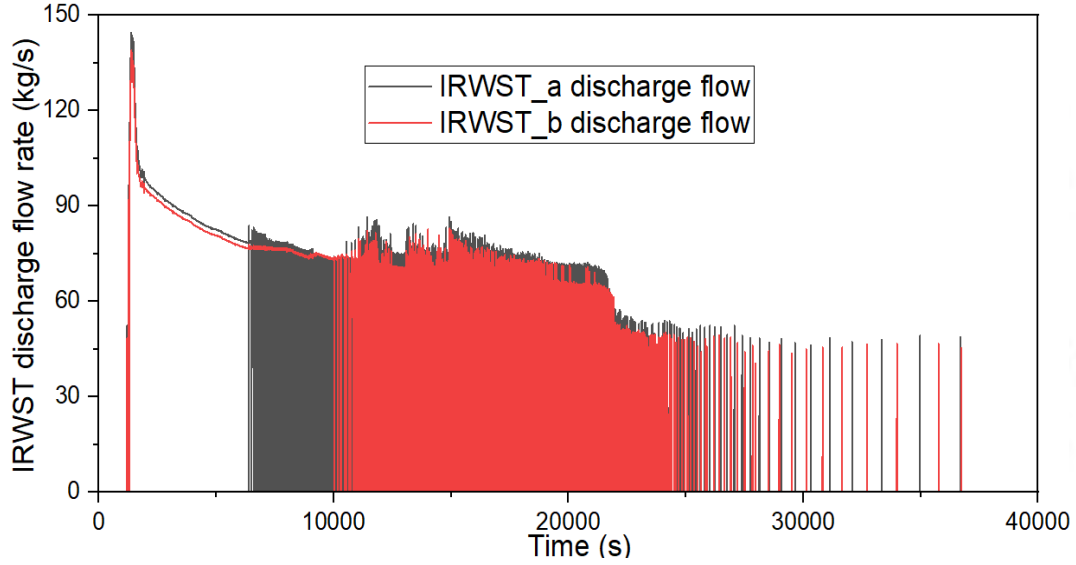
* Status of dynamic water film model development in 3-D CFD code GASFLOW-MPI for analysis of passive containment cooling system

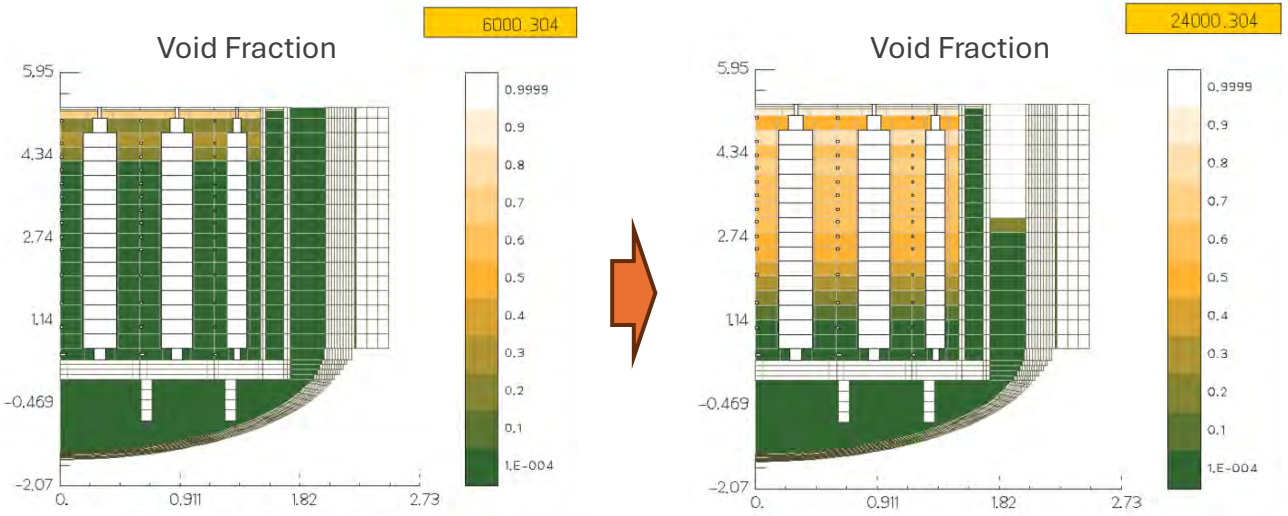
- In the AP1000 design, steam leaking through ADS_1/2/3/4 and the piping break will be cooled and condenses on the steel containment vessel inner surface by the passive containment cooling system(PCS) for at least 72 hours. Driven by gravity, the condensate collected in the sump flows back to the RPV via the IRWST discharge line.
- The steel containment vessel(Thk: 41.2~44.5mm) works as the 3rd barrier—both in retaining radioactive materials and in serving as the ultimate heat sink, which could provide long-term cooling water for a submerged reactor core.
- A shield building with reinforced concrete structure is designed surrounding the steel containment vessel to provide structural protection against severe weather or aircraft impacts(withstand a large commercial aircraft crash), and passive cooling functionality.
- Some security conditions, such as **drone attacking**, should be given more attention as it may bypass the shield building and directly attack at the weak points from inside, such as the water distribution system and air baffle of PCS.

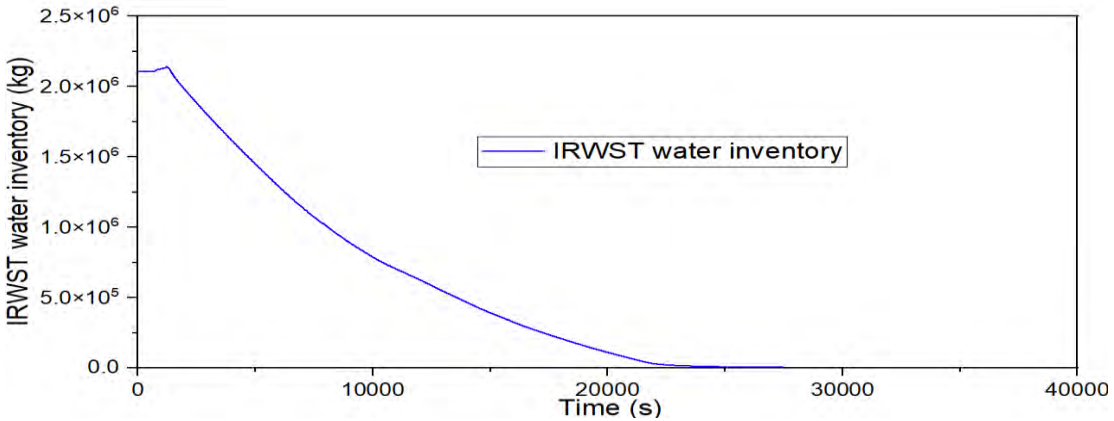
NUS National University of Singapore | Singapore Nuclear Research and Safety Institute

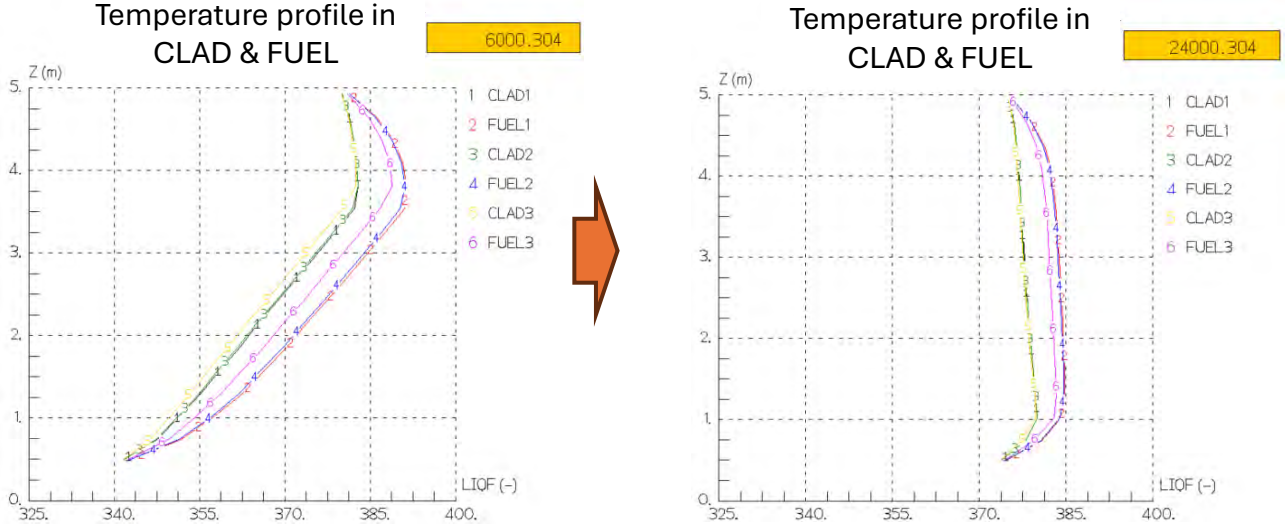
AP1000 SB-LOCA Simulation: Long Term Core Cooling Cut-off

Assuming PCS malfunctioning and IRWST water supply from containment condensation is completely cut-off, the IRWST water storage could maintains 6~7 h injection. As IRWST water injection flow decline, water temperature in the reactor core gradually increases. The boiling region spreads towards reactor core bottom and void fractions in reactor core upper section approaches to 1.



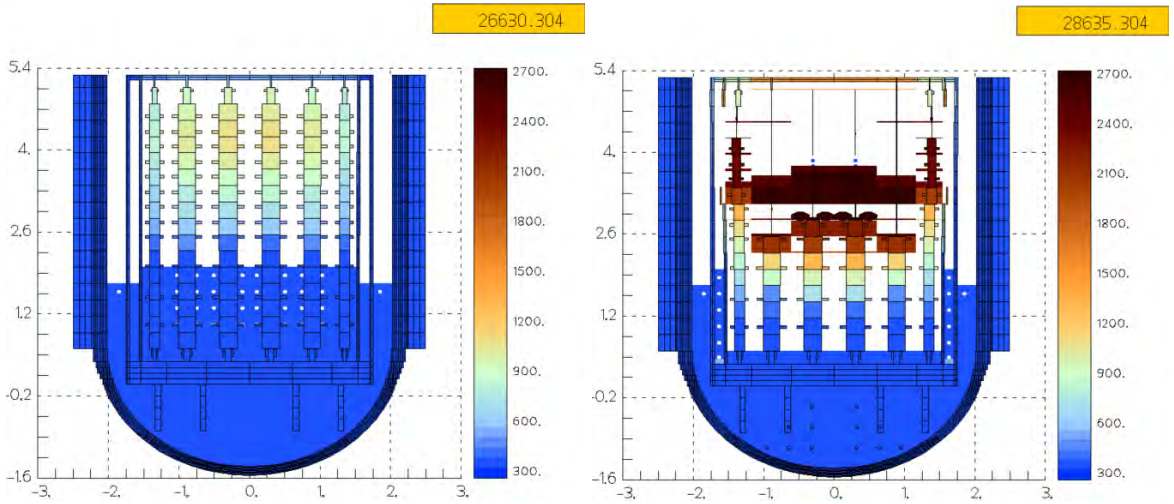




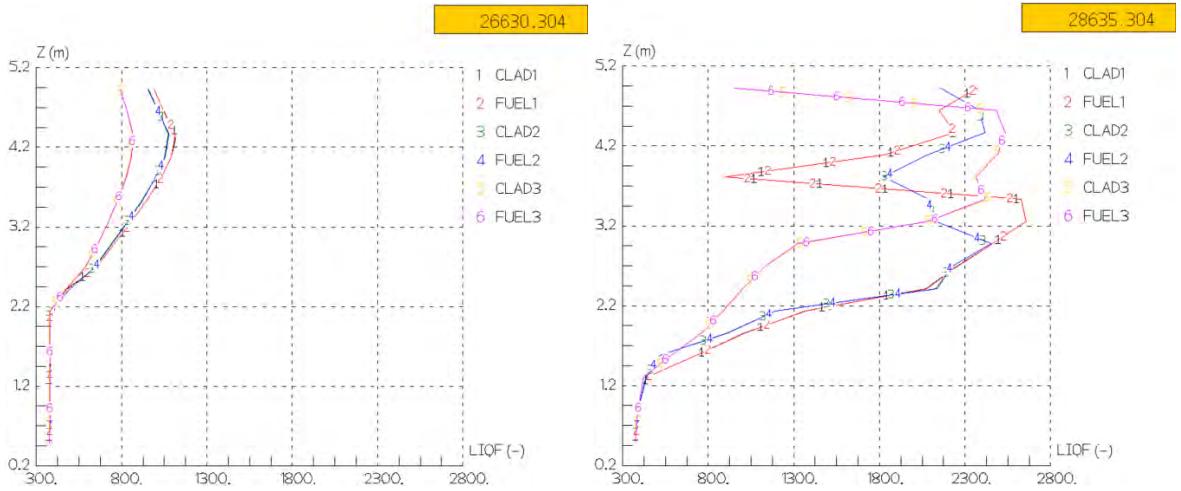


AP1000 SB-LOCA Simulation: In-vessel core degradation

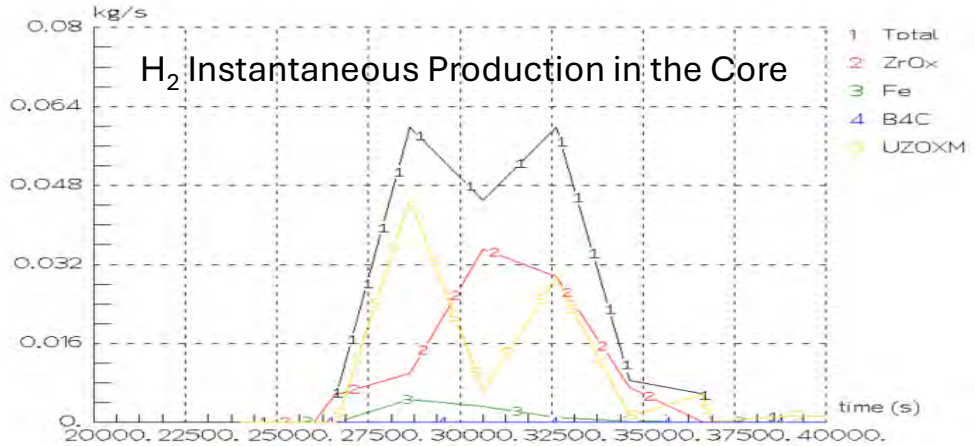
Temperature Field in Core



Temperature Profile in CLAD and FUEL



Time (s)	Event
26630.3	First cladding creep rupture Start of FPs release from fuel pellets
26915.3	Start of structural material release
27990.3	First material slump in lower plenum



Sump water injection is not considered in current Calc. The reactor core water level decreasing is irreversible after IRWST water depleted. The upper section of the core begins to overheat due to reduced heat transfer with diminishing steam flow and fewer entrained water droplets. Oxidation reaction speeds up on high-temperature Zr cladding and steel vessel structure surfaces when fuel cladding and vessel structure temperatures exceed ~1200 K. The exothermic reaction between Zr and steam aggravates fuel cladding failure and generates massive hydrogen.

AP1000 SB-LOCA Simulation: In-vessel core degradation

In this study, lower head external cooling by water in cavity is excluded. With molten corium gradually slumping to the lower plenum, a molten corium pool is formed with light metal layer on the top. The lower head wall suffers from high heat flux from light metal layer and its deadweight, which induces vessel rupture at the molten corium pool surface level, ~4h after IRWST water depleted.

Time (s)	Event
32635.3	First slump of corium with FPs in lower plenum
36858.8	Lower head vessel failure Corium flows out of the lower head
38931.8	Lower head vessel collapse

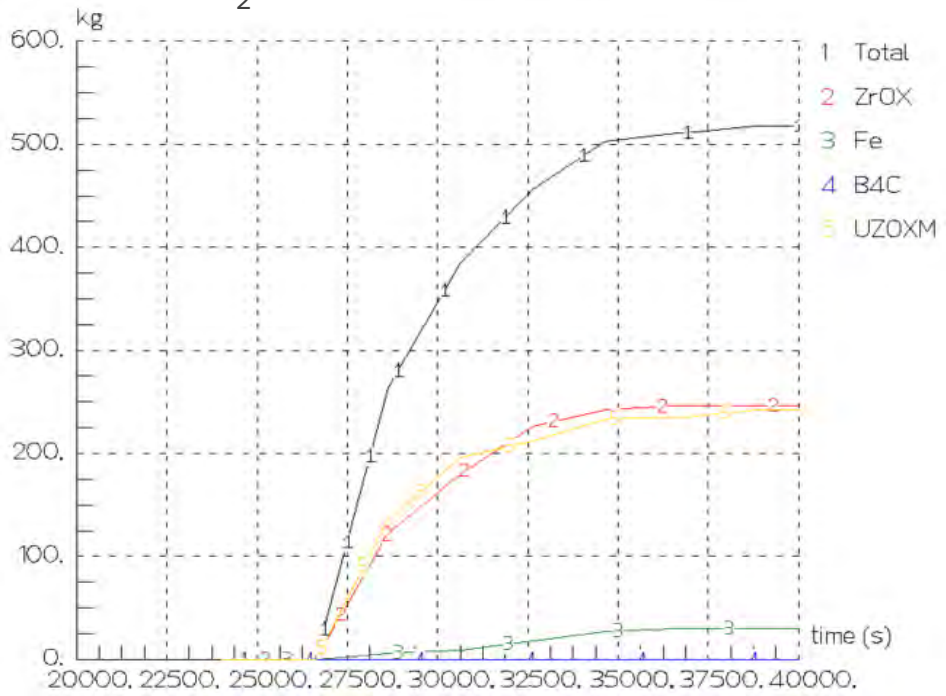
AP1000 SB-LOCA Simulation: Source Term

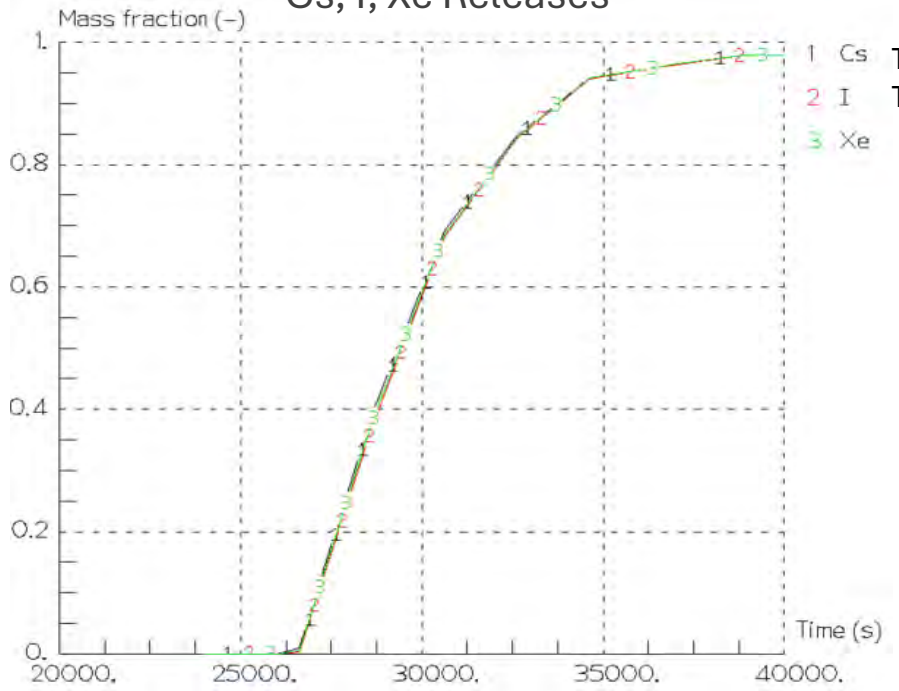
Source Term Analysis
Lower head vessel failure • **Ductile failure based on Oeuf model** • **H_2 mass produced during in-vessel phase = 510.926 kg** • **Aerosol mass produced during in-vessel phase = 9086.69 kg**

- If the drone attack disrupted the integrity of steel containment vessel, massive radioactive material released from the reactor core would easily bypass the steel containment vessel and disperse into environment.

H_2 Production in the Core



Cs, I, Xe Releases



Total Cs: ~230.59 kg
Total I: ~ 17.71 kg

Conclusions

- The AP1000 and its safety systems are modelled in ASTEC. The thermohydraulic performance of passive safety systems in the 10-inch SB-LOCA are simulated, which shows reasonable agreement with NOTRUMP results in the AP1000 DCD Rev. 19 and CESAR/ASTEC work by M. Di Giuli.
- The ADS depressurization design plays an important role in maintaining ACC discharge flow rate and actuating IRWST injection before CMT water is depleted. The PXS in combination with the ADS guarantee continuous emergency injection from less than 15 s after the pipe-break until ~7 h, effectively slowing down reactor core water level decline rate and preventing fuel and cladding from overheating.
- In case the passive cooling functionality of shield building was seriously destroyed, the IRWST long-term cooling water supply from containment condensation would be cut-off and the reactor core meltdown progress would not be terminated w/o SAMP. The possibility and risk of drone attacking on AP1000 PCS from shield building inside should be given more attention.

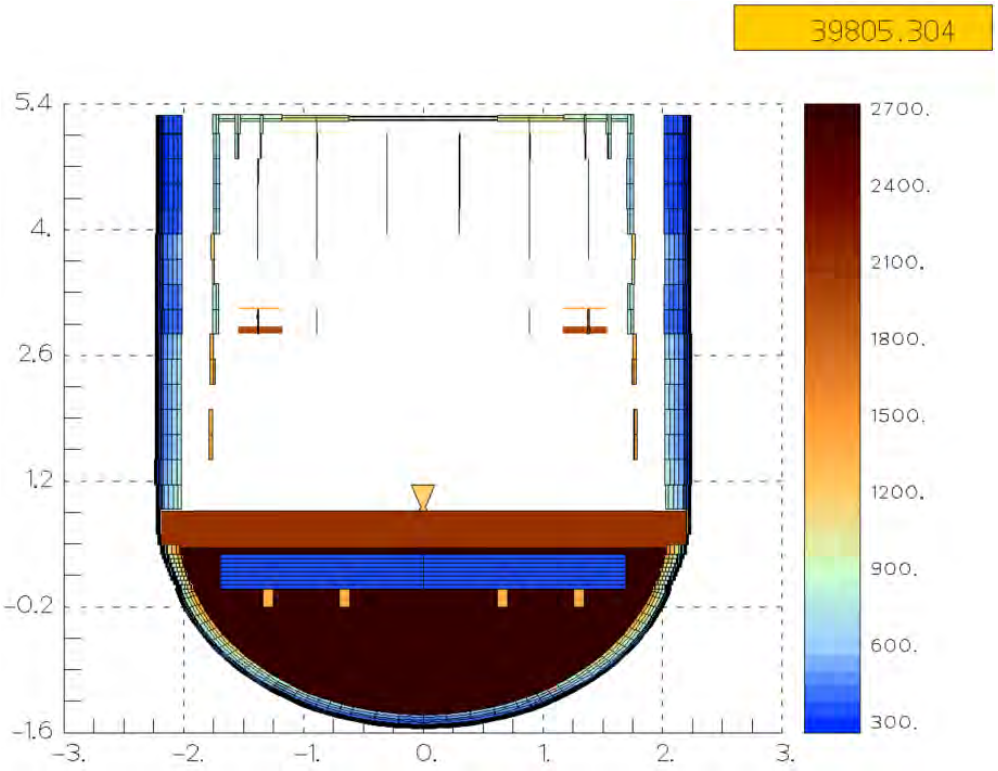
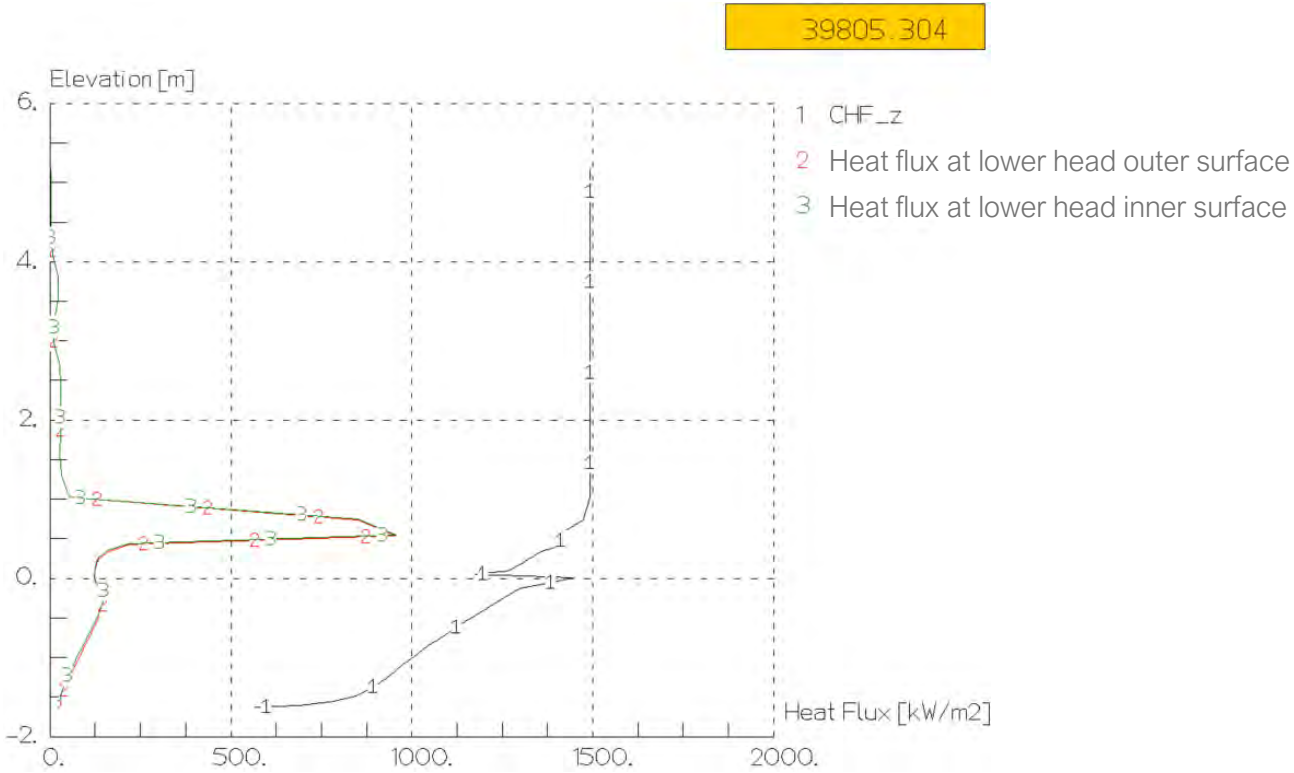
AP1000 SB-LOCA Simulation: Lower Head Failure w Ex-Vessel Cooling





With Ex-Vessel cooling water flow rate setting at 200 kg/s in the ERVC channel, the lower head failure is postponed for ~ 1 h.

INSTRUMENTATION SURVIVABILITY ASSESSMENT DURING A SEVERE ACCIDENT; INCORPORATING RADIATION MONITORING IN MELCOR TO EVALUATE THE IMPACT ON SAMGs

Fernández-Cosials K.*, Rivilla R. and Queral C.

ABSTRACT

The instrumentation of a nuclear power plant is a vital element in the management of any accidental sequence, as its wrong behavior can lead control and protection systems or plant operators to take non-optimal or even incorrect actions. This makes the analysis of the instrumentation performance under severe accident (SA) conditions, as well as other SSC (Structures, Systems and Components), currently one of the most relevant aspects of nuclear safety. In Generation-II plants, the instrumentation is licensed using a pressure and temperature profile as expected during design basis accidents. After core degradation, the SA phenomena are not considered on its design limits. During a SA, it is likely that the pressure, temperature or dose rate range and physical limits of the instrumentation is exceeded, and therefore, their measurements may not be reliable throughout the remaining accident development. As those measurements may be used to mitigate the consequences of the SA, its correct use or interpretation can make a difference in the accident management.
For this reason, a methodology for instrumentation survival and assessment is proposed. It consists of the identification of the mitigation actions to perform together with the parameters that trigger its initiation and the instrumentation required for its development. The damage condition of the instruments is assessed in a continuous manner during the accident, rather than a binary state (function/not function). As a continuation of a previous study the monitoring of radiation is included in a continuous manner, besides thermal-hydraulic parameters extracted from the MELCOR output. The radiation monitoring program used will be released as an open source for other MELCOR users. The impact of the instrumentation degradation is then applied to a Station Black-Out simulation, identifying sources of measurement errors and its effect on the performance of Severe Accident Guidelines actions.

KEYWORDS
Instrumentation Survivability; Dose damage; SAMGs.

1. INTRODUCTION

During a Severe Accident (SA), the correct functioning and interpretation of the instrumentation plays a vital role in the evolution of such [1]. It can be argued that in both, TMI-II and Fukushima Unit-1, the correct interpretation of faulty instrumentation would have modified the accident pace, [2]. During an accident progression, while initially applying Emergency Response Guidelines (ERG), the harsh containment conditions are taken into account in the instrumentation values and additional uncertainties due to accident-induced factors such as elevated temperature, pressure, and radiation are incorporated. These adverse-condition uncertainties are conservatively combined to represent limiting instrument deviations. The use of separate normal and adverse setpoint minimizes unnecessary uncertainty during normal operation while ensuring conservatism under post-accident conditions. In particular, a recalibration procedure normally

occurs after an accumulated certain dose in the instruments to account for a higher uncertainty. The transition between these regimes is plant-specific and is determined by the environmental sensitivity of qualified equipment.

Nevertheless, if the accident progresses to core damage and into the Severe Accident Management Guidelines (SAMGs) the instrumentation is assessed in a survivability approach as the environmental conditions exceed those of the design basis. The most common manner to approach instrumentation survivability is to divide the severe accident in different phases and assume a binary status for the instrumentation, failed-not failed. Assessment of temperature, pressure, humidity limits and other casuistic are taken into account. Previous survivability analysis applied to different technologies of such can be found in [3], [4], [5], [6], [7].

Other more complex approaches, evaluate the status of the instrumentation in a continuous manner along the transient, as well as including a range of failures by the instruments, instead of a binary approach, [8]. Nonetheless, this last methodology lacked the dose rate as important parameter affecting the instrumentation performance [9].

The dose received by the instrumentation during a SA could reach very large values. The environmental qualification of instrumentation already takes the dose into account as a limiting value for Design Basis Events, [10], [11]. Typical values for these doses rates can range between 10 to 10^6 Rads/h (0.1 to 10^4 Gy/h), [12]. As mentioned, radiation generates degradation of electronics which is attributed to mainly total ionizing dose, and ionizing dose-rate due to gamma rays. The displacement damage and total ionizing dose effect are both accumulated effects on the electronics, whereas dose-rate effects are typically of a transient nature but can cause permanent damage to devices.

The assessment of the in-containment dose during a SA is not commonly shown in SA research studies. Many conventional SA codes do not directly calculate this dose and post-processing of data must be done. In the study of [13], the gamma dose is calculated using MELCOR, reaching 1-100 MRads (10^4 to 10^6 Gy); but the procedure for such calculation is not entirely provided. Other studies using ASTEC code which has a specific module for dose calculation do show the activity but they do not the in-containment dose, [14], [15].

In this study, a comprehensive methodology to assess the instrumentation survivability during a severe accident that incorporates radiation damage will be presented. The detailed calculation of the instrumentation dose rate will be described, and the code used will be made available for the general public to use. The methodology will be applied to a Station Black-Out (SBO) scenario in a Boiling Water Reactor (BWR) using the MELCOR code.

The paper proceeds as follows: first, a short introduction to the state of the art is made (Section 1). Second, a description of the MELCOR BWR model and Dose calculation tool is provided in Section 2. Third, a summary of the SAMGs applied to a BWR is reported (Section 3). Then, the results of the methodology applied to a SBO are described in Section 4. Finally, conclusions are drawn (Section 5).

2. MELCOR Model and Dose Calculation

2.1. MELCOR BWR modelling

The MELCOR code is a fully integrated, engineering level computer code, capable of modeling accident phenomena in Light Water Reactors (LWRs). Sandia National Laboratories (SNL) developed it for the U.S. Nuclear Regulatory Commission for SA analysis, initially for Probabilistic Safety Assessment level 2. The MELCOR capabilities include the simulation of thermal-hydraulic behaviors of Reactor Coolant System

(RCS) and containment, core damage process, relocation, molten core concrete interaction, behavior of fission products or hydrogen generation, among others, [16]. Currently, MELCOR and other SA codes, are subject of research such as SOARCA, MUSA, SASPAM-SA [17] and IAEA CRP "Advancing the State-of-Practice in Uncertainty and Sensitivity Methodologies for Severe Accident Analysis in Water-Cooled Reactors" projects which are focused on identifying and quantifying uncertainty sources in SA analyses, [18], [19].

The model reproduced in MELCOR is a BWR/6 Mark III generic reactor. The model has been used in previous research, [20]. It includes control volumes for RCS as the recirculation pumps and loops (RCL), core bypass, channel, separators, upper head (UH), lower head (LH), annulus (AN) and core active region among others, the nodalization can be seen in Figure 1. The RCS coolant is initially at 562 K and the initial RPV level is 14.1 m. The containment model is separated into 8 control volumes including the reactor cavity (CA), drywell (DW), wetwell (WW), Weir Annulus, Compartment A of containment (CTA, which corresponds to the Containment Rooms) and Compartment B of containment (CTB, including Upper Pool and near Dome), Upper Dome (UD) [21], and an external volume for the environment, Figure 1. The Auxiliary Building (AB) is not included in the model, and the instrumentation located there is not expected to suffer any damage in this analysis. The main instrumentation of the plant is located in its correspondent control volume and are modelled with a small thermal conductor to account for thermal inertia.

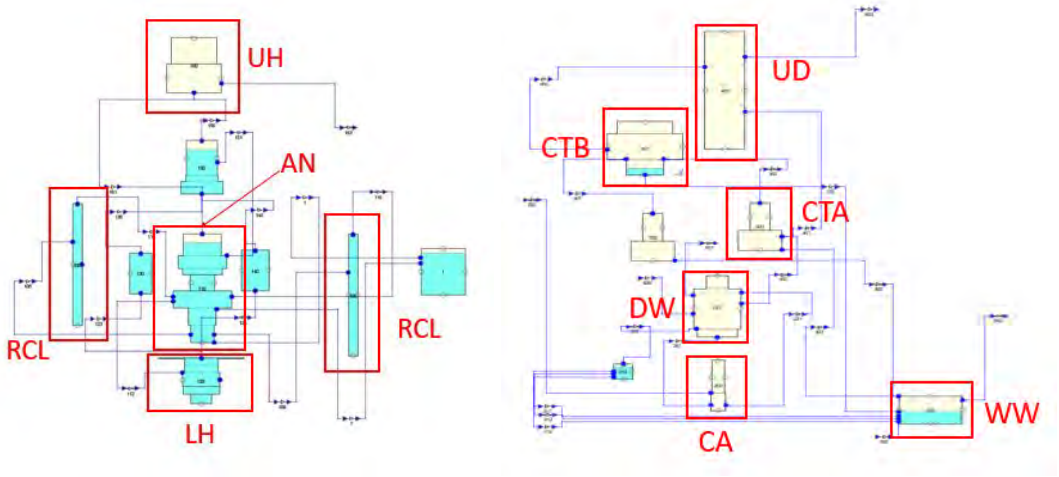

Figure 1. MELCOR Nodalization of the BWR/6 RCS (left) and Mark-III containment (right)

2.2. In-containment Dose Calculation with MELCOR: RadSim development

In order to calculate amount of each radioisotope in containment, the MELCOR code can be supposedly standalone used to provide a result. Based on an initial fission products inventory (provided by the user), the BONUS module can provide with the activities [22]. Nonetheless, utilization of such features is absent in the open literature and therefore, the authors tried to develop a user-friendly post-processing tool that uses open materials for radioactive chains, radiation energy and fission products inventory; this program has been named "RadSim" and is set as an open-source python code. The length limit of this paper prevents for a very detailed description of the code.

The objective of RadSim is to use the amount of a RN class provided by the MELCOR output file, and then directly calculate the dose found in the different control volumes, either in the RCS or containment, as seen in Figure 1. The flowchart of the working procedure of RadSim is shown in Figure 2. Initially, the initial proportion of isotopes the JEFF 3.3 nuclear data library, available through the JANIS platform, has been used as a reference [23]. From this database, only those isotopes whose thermal uranium-235 fission yield

is greater than 0.008 were selected. Based on this criterion, a total of 180 isotopes were identified and included in the analysis. The new proportions for each class are calculated by dividing the yield of each isotope by the sum of the yields of all isotopes belonging to the same class. In this way, it is ensured that the sum of proportions within each class equals 1, and that the initial distribution realistically reflects the relative contribution of each isotope according to experimental fission data. Once these proportions are determined, the mass of each class, which is directly imported from MELCOR, is distributed according to these coefficients.

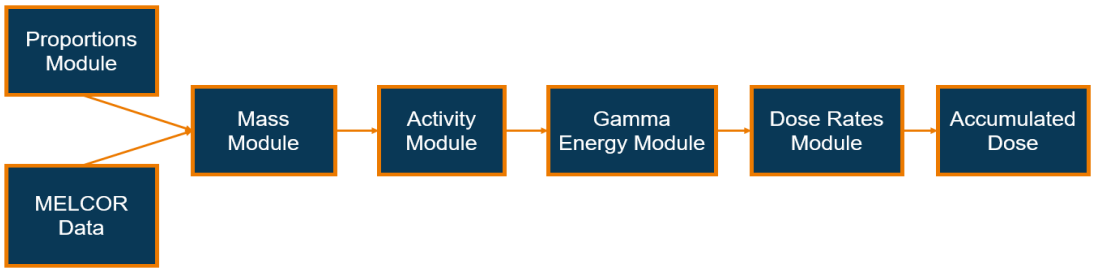

Figure 2. RadSim working scheme

The decay calculation starts from the moment when the chain reaction is terminated. If the reactor shutdown is successful, the neutron flux is interrupted, and the proportions at that instant evolve only through radioactive decay processes until the end of the simulation. For this process, the Python open source library "*radioactivedecay*" is used, which makes it possible to calculate with precision the evolution of masses and isotopic composition over time [24]. The isotopes that appear due to decay but also belong to another class in the list remain in the class where their precursors appeared, in order to avoid overlaps between classes and simplify the processing. This is an assumption that is done by MELCOR in different calculations, and it is maintained in RadSim. A dictionary is created assigning a gamma energy to each isotope. The gamma energy is the value in MeV that corresponds to the gamma emission of each radionuclide. This energy is the characteristic value of the gamma rays emitted by that nucleus. The values have been taken directly from the JEFF 3.3 library available in JANIS. Similar procedure is made for beta emissions.

For the dose calculation, the beta emissions due to their low penetration capability, their contributions are associated with the bremsstrahlung rays created during its scattering. The photonic dose rate will be defined as in [22]:

$$D^{\gamma}{}_{i} = (5.77 \cdot 10^{-5})\emptyset_i E_i \left(\frac{\mu_{a,i}}{\rho}\right)_{air}$$

Where $D^{\gamma}{}_{i}$ is the absorbed gamma dose rate of isotope i (Rads/h), $\emptyset_i$ is the gamma flux of isotope i (1/ (cm^2 s)), E_i is the gamma ray energy of the isotope i (MeV) and μ is the mass absorption coefficient for air to energy E_i, it is defined as follows, as in [22]:

$$\left(\frac{\mu_{a,i}}{\rho}\right)_{air} = a + bE + c[\ln(E)]^2 + d\sqrt{E} + e[\ln(E)]$$

For the mass attenuation coefficient, the coefficient will be defined as:

$$\left(\frac{\mu_{s,i}}{\rho}\right)_{air} = f + gE^h$$

To calculate the gamma flux on the different control volumes, four different geometrical approaches are provided: homogeneous sphere, circular source, shielding and point source. In the homogeneous sphere hypothesis, the volume where the isotopes are distributed uniformly is equivalent to the control volume from MELCOR. Different distances can be defined in the script for the different hypothesis. The intent of the shielding approach is to simulate a cable so thick polymer layer has been used to simulate it, and the mass attenuation coefficients for that material have been taken from [25].

The code will be available in an open-source repository in GitHub and it is expected that MELCOR user's community engage with the tool for further enhancements or improvements.

3. SAMGs feasibilities and Instrumentation in a BWR

The Severe Accident Management Guidelines (SAMGs) are a structured set of guidelines developed to support decision-making during severe accidents, when the plant is no longer within the scope of normal or emergency operating procedures. In conventional Boiling Water Reactors (BWRs), the SAMGs are organized around the control of specific variables in defined plant areas.

In general, two main Severe Accident Guidance (SAG) are defined [26], [27], [28]: SAG-1 (RPV and Primary Containment Flooding), dedicated to vessel and containment flooding strategies, and SAG-2 (Containment and Radioactivity Release control), focused on containment control and fission product release management. Each includes several sub-guides addressing specific conditions or parameters to be monitored. The SAMGs are supported by the Technical Support Guidelines (TSGs), which provide detailed data, limit values, and technical references to justify and document the decisions taken during accident management.

When a BWR accident enters SA, control is formally transferred from the main control room to the Technical Support Center (TSC). This transition marks the activation of the SAMGs. TSC becomes responsible for assessing plant conditions and determining the most appropriate recovery strategies. Within this framework, Candidate High-Level Actions (CHLAs) are evaluated as potential measures to mitigate the consequences such as vessel flooding, containment venting, or boron injection, depending on the plant state [29]. To implement SAMGs effectively, it is essential to have an accurate understanding of the plant condition at every stage of the accident. This requires the continuous availability and reliability of the instrumentation, which provides the critical data needed to support decision-making within the SAMGs. As seen during the Fukushima accident, not having access to plant variables, or being that information corrupted, can lead to worst outcomes [30].

In this work, a detailed analysis of all SAMGs was carried out to identify the variables required for the correct CHLA implementation. In some cases, the need for certain variables is explicit within the guide itself, while in others it becomes evident through the TSGs that appear at specific steps of the procedure. These supporting documents introduce additional information or criteria that depend on variables not directly mentioned in the main guide but still necessary for decision-making.

By considering both levels of information, it was possible to determine the complete set of parameters that must be known simultaneously to assess the evolution of the plant and the capability to follow each guide. In total, sixteen key variables were identified as necessary for the proper application of the SAMGs, namely: DW temperature, DW pressure, containment radiation, containment hydrogen concentration, boron tank level, injected flow to the RPV, RPV level, RPV pressure, RPV temperature, containment pressure, containment (suppression pool) level, suppression pool pressure, suppression pool temperature, SRV position, reactor power, and containment temperature.

In SAG-1, these variables are used in the generic sub-guides (RC/F-1, RC/F-2, RC/F-3, RC/F-4, RC/F-5, RC/P and RC/Q), while in SAG-2 they support the decision-making process in other sub-guides (CN/T, DW/T, PC/H, PC/P, PC/R, SP/L and SP/T).

For this study, a review of SAG sources [31], [32], [33], [34] was carried out to identify the instrumentation typically available in a BWR Mark III. Based on this information, the location of each instrument was established in a reference plant and then linked to the corresponding control volumes of the BWR model implemented in MELCOR, which was used for the analysis. From this mapping, the instruments considered relevant for severe accident conditions were selected, identifying those capable of providing the measurements required to follow the SAMGs.

The following table presents the variables to be monitored, the corresponding instruments that could measure them, and the control volume of the model where each would be located. These control volumes represent real plant locations. Instrumentation assigned to the auxiliary building correspond to devices that, according to the reviewed sources, are located outside the containment. It should be noted that some instruments identified as potentially useful do not measure the variable directly but can provide indirect indications or allow their estimation, which under SA conditions can still offer valuable information for decision-making.

VARIABLES	INSTRUMENTATION	VARIABLES	INSTRUMENTATION
DW TEMPERATURE	DW Thermocouples (DW) CTA Thermocouples (CTA) SP Thermocouples (WW)	RPV TEMPERATURE	UH Vessel Thermocouples (UH) LH Vessel Thermocouples (LH) FW Thermocouples (LH) Suction Pipes Thermocouples (RCL)
DW PRESSURE	DW Pressure Transmitters (DW/CTA) CTA Pressure Transmitters (CTA)	CONTAINMENT PRESSURE	CTA Pressure Transmitters (CTA) DW Pressure Transmitters (DW/CTA)
CONTAINMENT RADIATION	CTA Radiation Detectors (CTA) DW Radiation Detectors (DW)	CONTAINMENT LEVEL	SP Level Transmitters (AB) SP Thermocouples (WW)
CONTAINMENT HYDROGEN	Containment Hydrogen Concentration Analyzer (AB) DW Hydrogen Concentration Analyzer (AB)	SP PRESSURE	SP Thermocouples (WW) CTA Pressure Transmitters (CTA) DW Pressure Transmitters (DW/CTA)
BORON TANK LEVEL	Boron Tank Level Transmitter (CTA) Boron Injection Pressure Transmitters (CTA)	SP TEMPERATURE	SP Thermocouples (WW) DW Thermocouples (DW) CTA Thermocouples (CTA)
INJECTED FLOW RPV	Feedwater Flow Transmitters (DW) HPCS Flow Transmitter (AB) Boron Injection Pressure Transmitters (CTA) Vessel Level - Wide Range (DW/CTA) Vessel Level - Fuel Range (DW/CTA) Feedwater Pressure Transmitters (AB)	SRV POSITION	SRV Position Indicators (DW)
REACTOR POWER	Average Power Range Monitors (AN) Control Rods Position (DW)	CONTAINMENT TEMPERATURE	CTA Thermocouples (CTA) DW Thermocouples (DW) SP Thermocouples (WW)
RPV LEVEL	Vessel Level (Wide Range) (DW/CTA) Vessel Level (Fuel Range) (DW/CTA)	RPV PRESSURE	Vessel Pressure Transmitters (DW/CTA) RCP Pressure Transmitters (RCL)

Table 1. Necessary or useful variables identified in SAMGs with the instrumentation and its location assignation

The assessment of instrumentation damage in a BWR during a severe accident requires a clear framework for characterizing the degradation of measurement capabilities as environmental conditions worsen. For this purpose, the present work adopts as reference the methodology established in the study presented in [8], where instrumentation performance in a PWR was evaluated under a SA. Five Damage Conditions (DC) were defined to classify the ability of each instrument to provide meaningful information as the accident progresses. These categories are fundamentally based on the concept of Environmental Qualification (EQ), and other relevant phenomena. EQ values, based on IEEE standards, define the boundary between normal

operating capability and progressive degradation, and constitute the basis upon which the DC classification is constructed.

The five Damage Conditions adopted in this study are presented in Table 2, which summarizes the meaning of each category and the corresponding degree of degradation in the instrumentation.

Instrument Damage Condition	Description
DC-1 (Normal Operating Conditions)	Normal operating conditions, suitable for measurement. They are within the EQ (Environmental Qualification) range and the readings are fully reliable.
DC-2 (Anomalous Operating Conditions I)	Challenging conditions or slightly above the EQ design, but the measurements are still useful both in trend and in value.
DC-3 (Anomalous Operating Conditions II)	The design limit has been significantly exceeded; the measurements are no longer valid in absolute value, although the information on trends and orders of magnitude is still useful.
DC-4 (Damaged Operating Conditions)	The measurements are only reliable in terms of trend, not quantitative or order magnitude information. In this state, the instrument cannot be recalibrated, and therefore, once level DC-4 is reached, it cannot decrease.
DC-5 (Destruction Conditions)	The measurements of such instrument have no value at all. Instrument is completely unusable, and it cannot and should not be employed for any measurement.

Table 2. Damage Conditions defined for the instrumentation

For pressure and temperature instrumentation, the DC used in this work were defined using the same environmental limits as in the reference study mentioned before [8]. The present analysis applies those same limits and thresholds to the instrumentation in the BWR, so that the Damage Conditions for these two variables are defined in a consistent and coherent way with the methodology presented in [8]. Other issues for instrumentation failure have also been considered, like the possibility of the evaporation of the reference column of water for the RPV level transmitters [30], or the failure of the hydrogen monitors due to the condensation that could led to a blockage on its sample line. This series of hypotheses has been established based on the methodology followed in [8].

In addition to those variables, this study includes radiation as an additional factor affecting instrumentation performance. To define the radiation-related damage levels, the environmental qualification values specified by IEEE standards 1974 for this variable have been used as the reference [10], [11]. Based on these values, five categories are established: DC-1, for doses below the IEEE qualification value; DC-2, for exposures between 1 and 4 times that value; DC-3, for doses between 4 and 7 times the IEEE limit; DC-4, for 7 to 10 times that value; and DC-5, for conditions exceeding 10 times the IEEE qualification value. This criterion is consistent with previous studies [35], [36], [37], which indicate that instrumentation operability is significantly degraded when the Total Integrated Dose (TID) reaches values on the order of several MGy (i.e., several hundreds of Mrads).

Table 3 shows the EQ values stablished by IEEE for radiation mentioned before [10], [11]. It represents the cumulative dose that instrumentation is design or qualified to support during a Design Basis Event (DBE) in the containment of a nuclear power plant. This values are expected to appeared in a DBE in a PWR. For BWR, the cumulated dose expected in the accident is 26 MRads according to IEEE but as the instrumentation available in both technologies is similar, and should resist both DBE, the most descriptive limits (the ones for PWR) have been selected to define EQ values and stablish DC.

Time	1h	12h	1 day	10 days	1 month	6 month	1 year
Cumulative Dose (Mrads)	4	20	24	40	55	110	150

Table 3. Environmental Qualification generic values for radiation stablished by the IEEE [ref]

4. Application to a Station Black-Out scenario

In this study, a severe accident scenario corresponding to a SBO has been simulated using the MELCOR code applied to a BWR Mark III. The Radionuclide (RN) MELCOR package, which performs the tracking of radionuclei classes throughout the control volumes of the model, has been used as input for RadSim. In this way, the rate and accumulated dose received by the different instrumentation in the different can be determined, see for example Figure 3. Using dose values together with the pressure, temperature and other conditions of the same volumes, the damage level of the instrumentation can be assessed. This allows the evaluation of SAMG decision paths according to the ability to monitor the parameters required in each guideline.

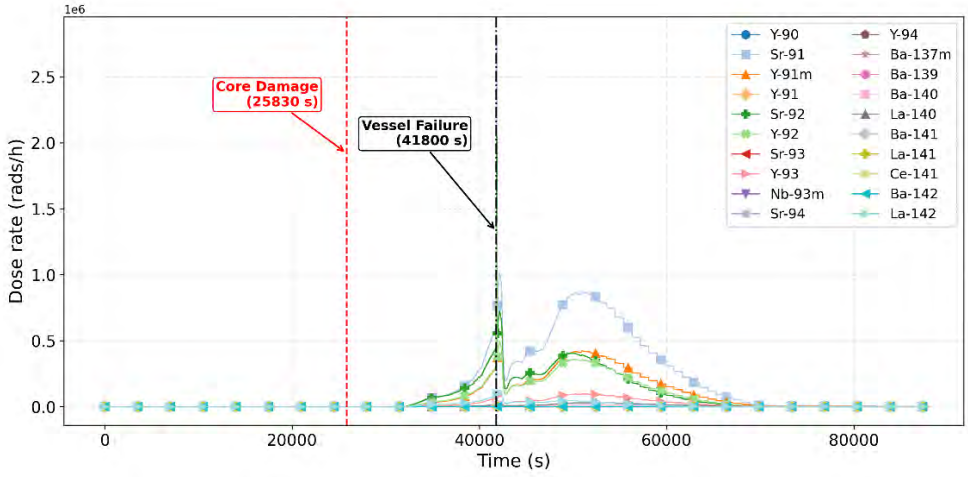

Figure 3. Dose Rate evolution of Class 3 isotopes at CTA considering the Point Source Hypothesis

The simulated sequence corresponds to a SBO case, in which the reactor loses all onsite and offsite power and relies initially on the Reactor Core Isolation Cooling (RCIC) system to control vessel inventory. Following reactor shutdown with residual decay heat, the RCIC system operates from the beginning of the event and maintains water injection until its failure is supposed at 15,000 s (e.g. due to battery discharge and loss of control of the RCIC). From that moment, with no further vessel makeup flow, the vessel water level begins to decrease and the core becomes progressively exposed, with initial uncovery occurring at approximately 22,000 s, marking the start of a rapid temperature escalation. As heat removal is no longer available, core temperatures rise sharply, and cladding temperature exceed 1477 K at around 27,000 s, indicating the onset of core damage. The degradation intensifies until 28,500 s, when conditions reach those associated with core melting. Due to restrictions in the article length, no detailed description of the accident is possible.

4.1 Instrumentation damage levels during the SBO sequence

The instrumentation will suffer degradation during the accident provoke by the extremely harsh condition that can be reached in different locations of the plant. The thresholds usually stablished are the EQ values defined for instrumentation [10], [11] in containment for these variables (422K and 0.41MPa), and it is assumed that if they are exceeded, those instruments will enter DC-2. Most instruments will fail once the vessel failure occurs, as the temperatures and pressures that will be reached in the environment will be so high that its failure is unavoidable. Although those conditions are temporary, caused by temporary peaks in those variables, they caused the instrumentation to reach DC-5 and no recovery of its operability is considered, as mentioned before.

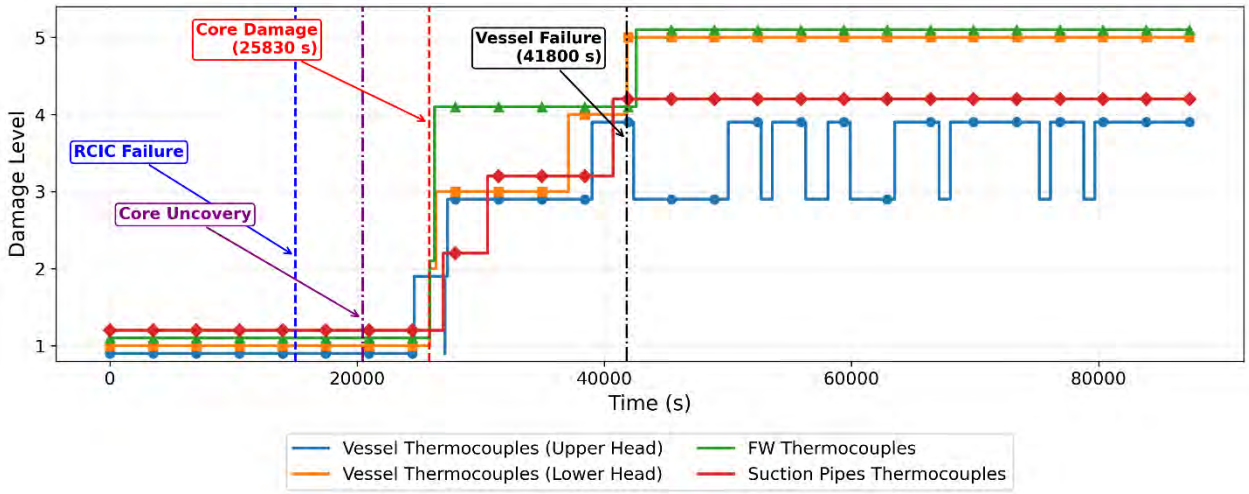

Figure 4. DC evolution of the instrumentation used to measure RPV Temperature considering temperature and pressure as the limiting variables

The main new feature of this analysis consists on the consideration of radiation as a new variable for evaluating the survivability of instrumentation. With the thresholds mentioned previously for defining instrumentation damage conditions in this study, radiation has resulted to be the most limiting variable during this sequence for many instruments, see Figure 4. Once the core melts and later on, vessel failure occurs, the accumulated doses reached in the different locations of the containment provoke the rapidly failure of all the instrumentation located in there (Figure 5).

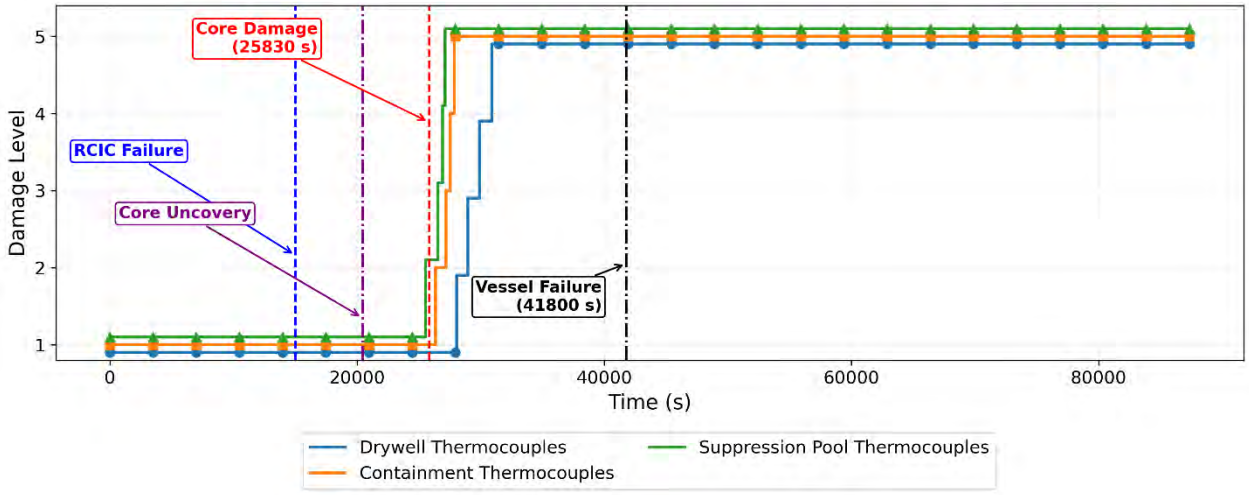

Figure 5. DC evolution of the instrumentation used to measure DW Temperature considering radiation as the limiting variable

4.2 Severe Accident Management Guidelines Availability assessment

In order to mitigate the consequences, the guides established to control in-vessel phenomenology during SA are located first in the priority scale. Actions in this guide (SAG-1) are developed for avoiding or controlling aspects like cladding oxidation and deformation, or core melting and relocation. If vessel failure is identified (RPV depressurization), the next group of guidelines (SAG-2) must be applied, which are responsible to mitigate the consequences of the containment phenomenology. The actions applied in these guides are designed to control the effects of phenomena like molten core relocation, molten core-concrete interaction, and, ultimately, containment integrity and fission products release. Their primary objective is to halt fuel degradation if it has already begun. If this cannot be achieved, the next goal is to preserve containment integrity for as long as possible, thereby increasing the available time to implement additional actions and strategies aimed at preventing the release of fission products. If these objectives also cannot be achieved, the SAMGs then focus on minimizing radioactive releases to the environment and reducing the overall impact of the accident.

For evaluating the availability to obtain the different measurements identified for the correct execution of the mitigating strategies, a classification method on the availability state of the instrumentation is defined. The availability states are established according to the Damage Condition (DC) reached by the instruments associated with each variable. A measurement is considered “Good” when all related instruments remain at DC-1, meaning they operate under normal conditions and provide reliable information. The state “Careful” is assigned when at least one instrument has reached DC-2, indicating initial degradation, although the measurement is still usable. The state “Warning” corresponds to situations in which one or more instruments have reached DC-3 or DC-4; in this case, the information may be affected, but it can still provide useful indications. Finally, the measurement is classified as “Blind” when all associated instruments reach DC-5, implying complete failure and total loss of information for that variable. See the availability state in Figures 6 and 7 for Pressure in the RPV and SP as examples. The intervals of time for which the availability state is identified as Careful or Warning are also shown in the figures.

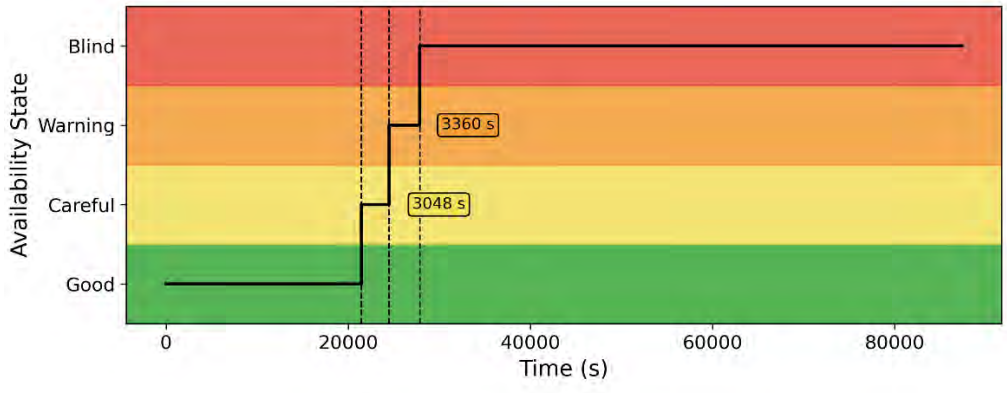

Figure 6. Availability to measure RPV Pressure considering all limiting variables

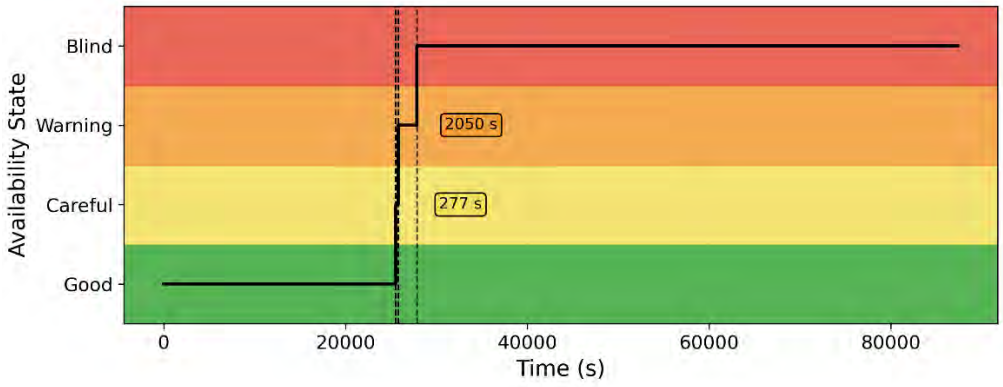

Figure 7. Availability to measure Suppression Pool Pressure considering all limiting variables

5. Conclusions

The main objective of this study was to develop a complete evaluation of the instrumentation survivability during severe accidents in BWR, adding full radiation assessment as the novelty, and the impact that its failure can provoke for the correct execution of the mitigation strategies that are stablished to overcome this accidental scenario.

For pursuing this analysis, the RadSim program was developed. This open-source python code has multiple capabilities that lead to the SAMGs availability evaluation during the severe accident. Furthermore, RadSim has other features like dose rates calculation for different geometrical hypotheses or evaluating the decay of the multiple isotopes present in the nuclear power plant, making it a state-of-the-art tool.

The output of this analysis is a code which is capable of developing an assessment of the applicability of the SAMGs. This assessment can help to identify the state of the instrumentation and the possibility to perform the different measurements needed. Precisely, radiation dose has been identified as the most limiting variable in the analysis, highlighting the importance of considering this variable as crucial when performing this kind of evaluations.

Future work includes dose assessment of the instrumentation in other containment and reactor designs, as well as the evaluation of the SAMGs based on that input.

ACKNOWLEDGMENTS

The work has been performed in the framework of the CSARP agreement between UPM and CSN. Additionally, the authors would like to thank the comments from an anonymous reviewer which have enhanced the quality of the work.

2. Development and Capabilities

3. Application to a SBO in a BWR/6 Mark III

1. Motivation

- **Motivation**: Instrumentation Survivability during a Severe Accident
  - Requirements of Environmental Qualification rely on Pressure, Temperature, Humidity and … **Radiation Dose.**
  - **MELCOR** does not provide *an easy method* to obtain Doses in-containment during the SA.
  - In order to obtain instrumentation damage in a continuous manner during a Severe Accident and help TSC crew with EOPs/SAMGs, **rad-doses should be taken into account**.
- **Objectives**:
  - Develop a script that takes as Input MELCOR RN Data, and Outputs Doses for instrumentation located in each CV.
  - Apply a **complete Instrumentation survivability** assessment to a SBO in a BWR Mark III.

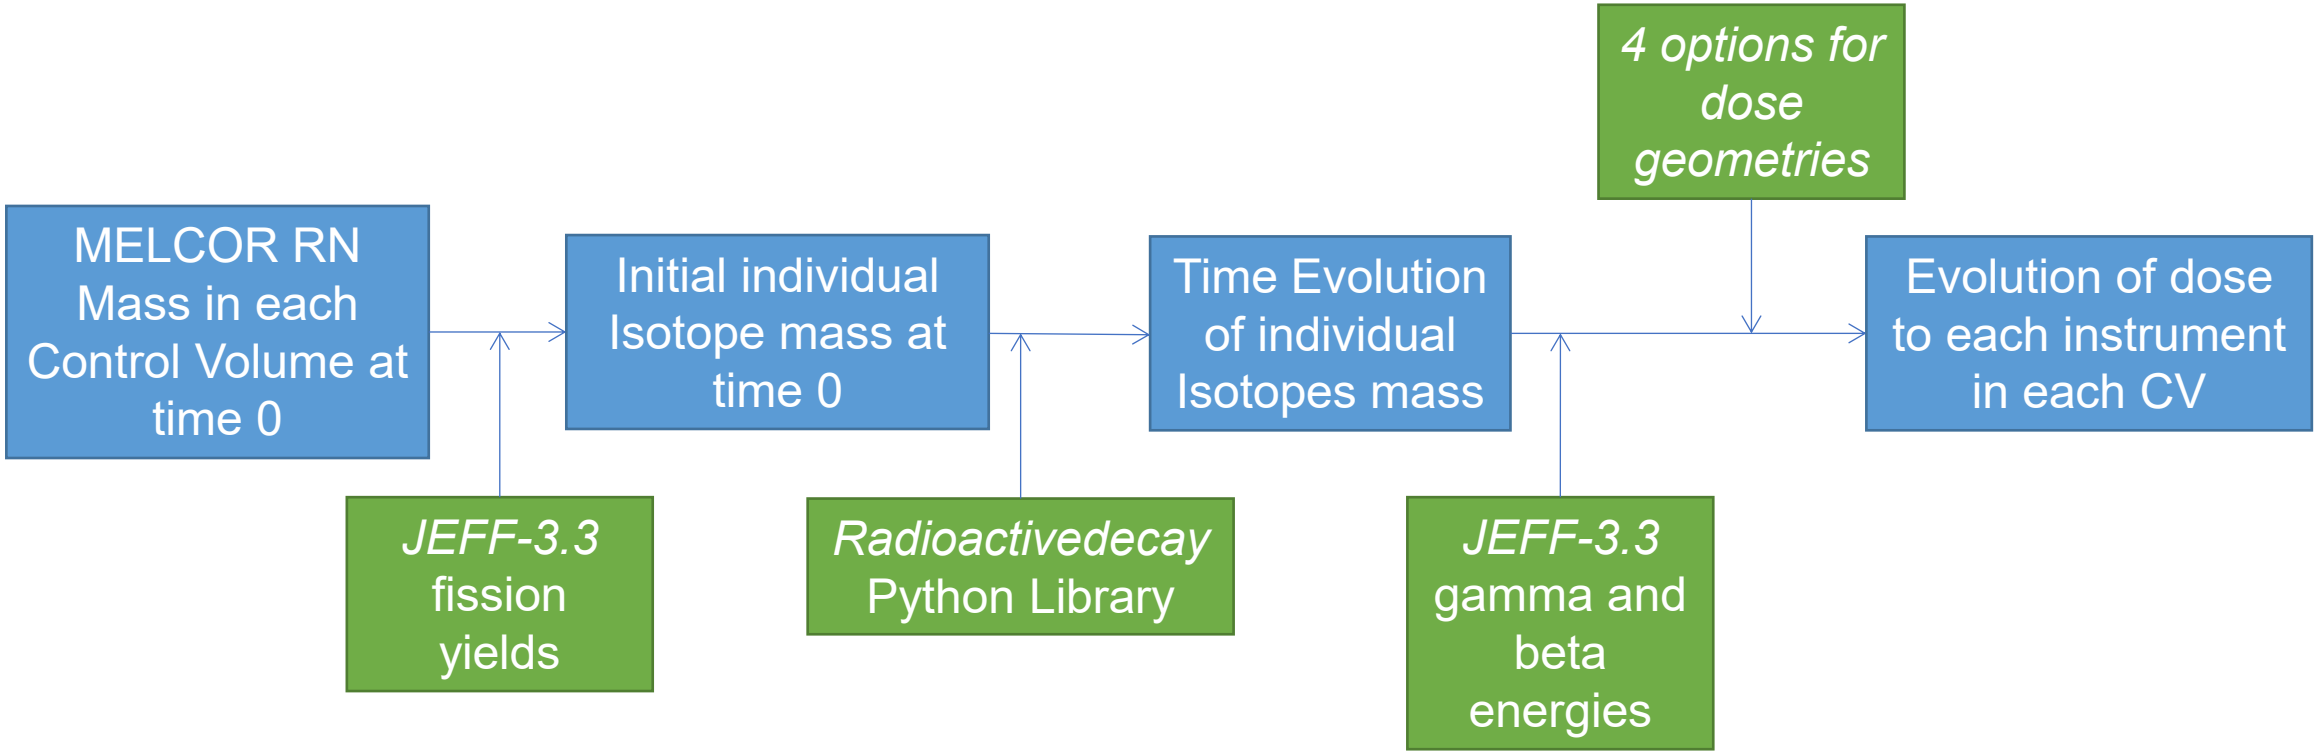
2. Capabilties and Development

- **Input**:
  - MELCOR outputs RN classes mass in each containment Control Volume.
  - MELCOR outputs Pressure, Temperature and Humidity of each Containment Control Volume.
  - MELCOR outputs temperature of HS and volumes of CV.

RN Classes	Representative	Isotopes
1. Noble Gases	Xe	He, Ne, Ar, Kr, Xe, Rn, H, N
2. Alkali Metals	Cs	Li, Na, K, Rb, Cs, Fr, Cu
3. Alkaline Earths	Ba	Be, Mg, Ca, Sr, Ba, Ra, Es, Fm
4. Halogens	I	F, Cl, Br, I, At
5. Chalcogens	Te	O, S, Se, Te, Po
6. Platinoids	Ru	Ru, Rh, Pd, Re, Os, Ir, Pt, Au, Ni
7. Early Transition Elements	Mo	V, Cr, Fe, Co, Mn, Nb, Mo, Tc, Ta, W
8. Tetravalent	Ce	Ti, Zr, Hf, Ce, Th, Pa, Np, Pu, C
9. Trivalents	La	Al, Sc, Y, La, Ac, Pr, Nd, Pm, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, Am, Cm, Bk, Cf

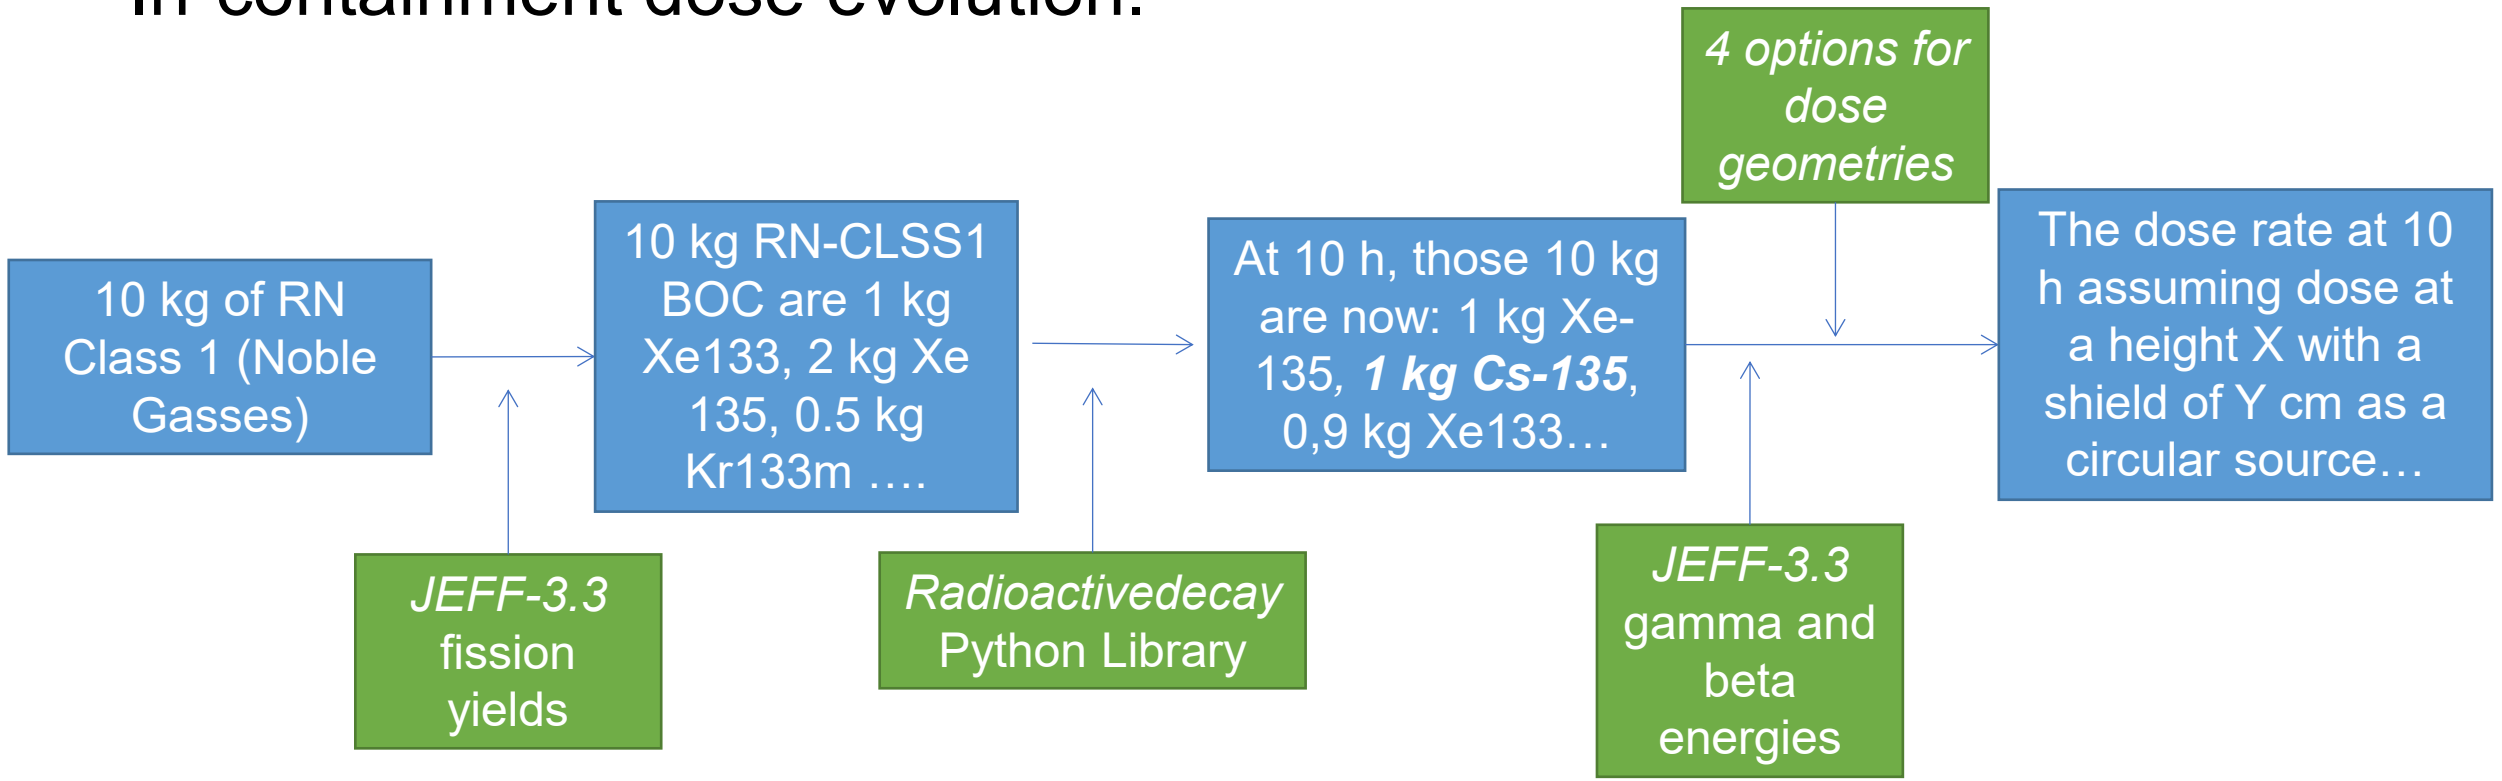
2. Capabilties and Development

- **Transformation**:
  - RN masses → Isotope Masses → Isotope decay chains evolution → In-containment dose evolution.



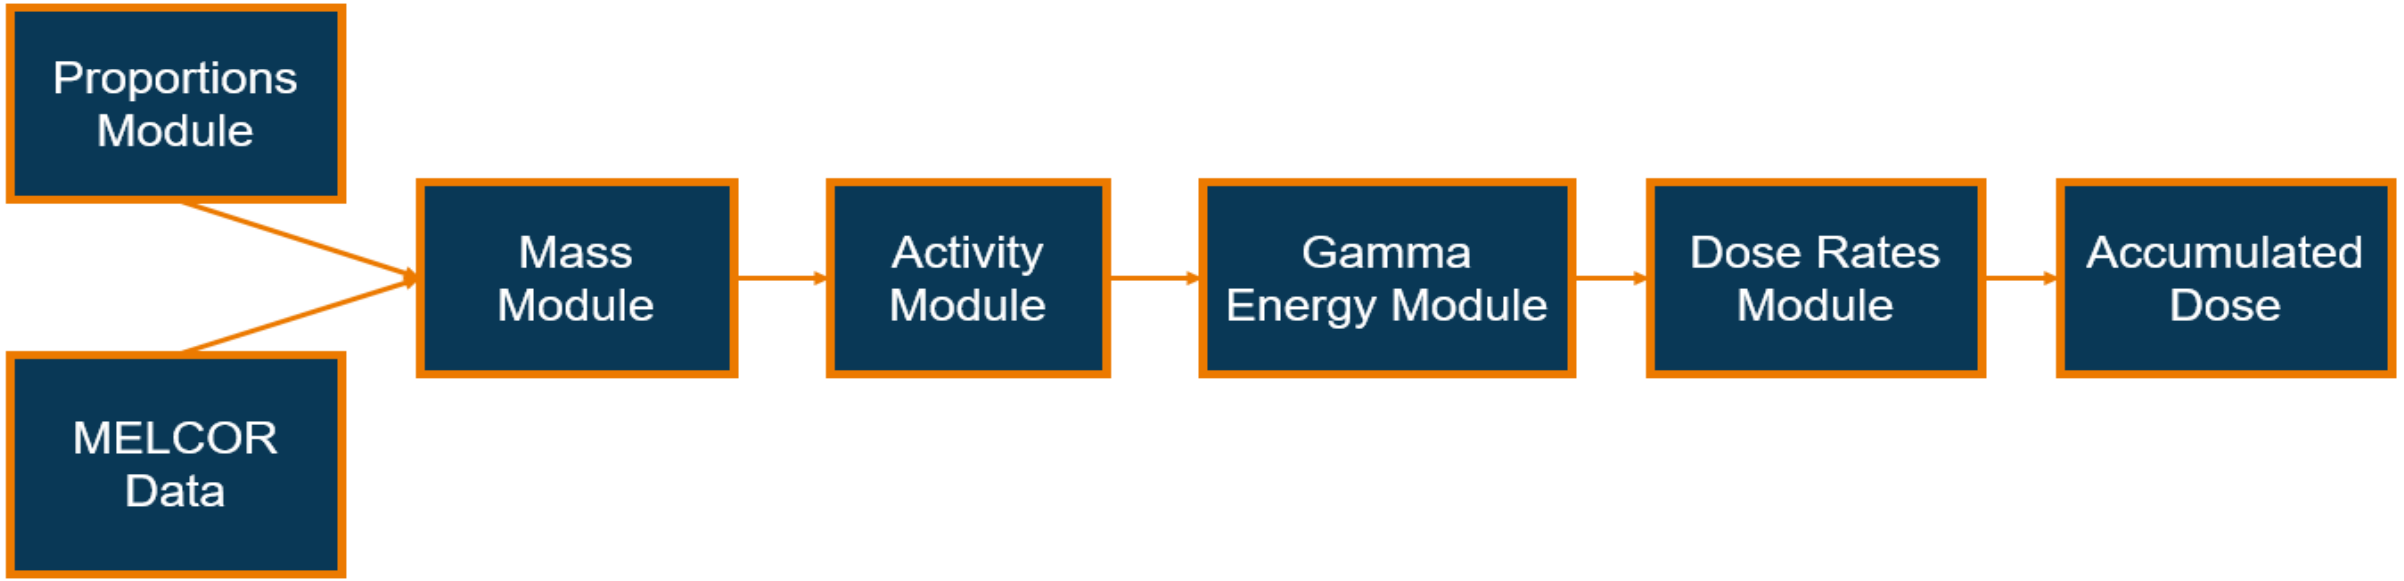
2. Capabilties and Development

- **Transformation**:
  - RN masses → Isotope Masses → Isotope decay chains evolution → In-containment dose evolution.



2. Capabilties and Development

- **Module-based approach of RADSIM**:



- **Open-Source code. Can be found in Github.**

2. Capabilties and Development

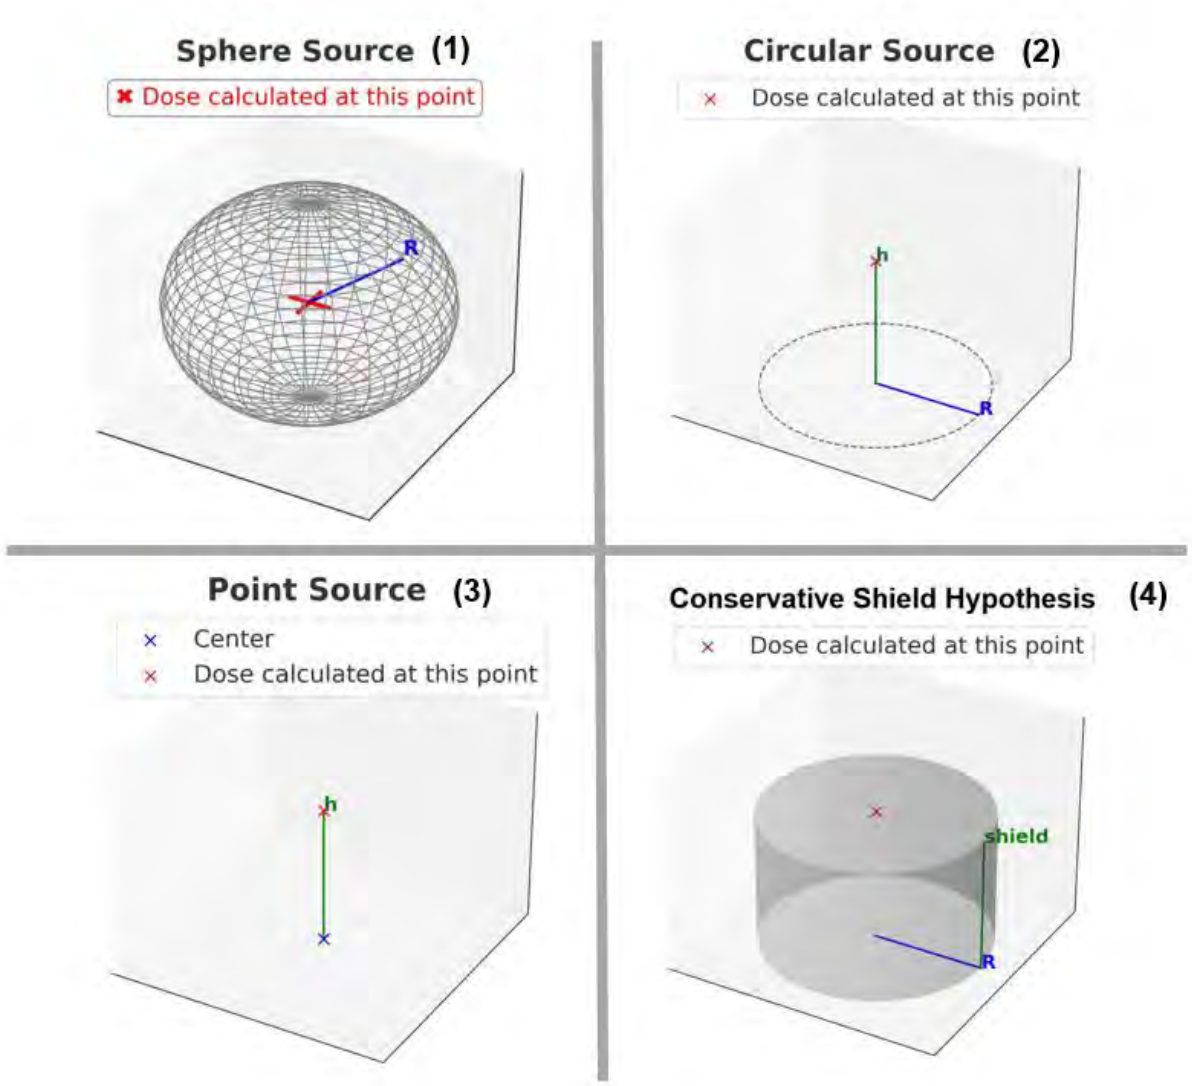
- **Geometry Calculation Options**:

$$D^{\gamma}{}_i = (5.77 \cdot 10^{-5}) \emptyset_i E_i \left(\frac{\mu_{a,i}}{\rho}\right)_{air}$$

$$\left(\frac{\mu_{a,i}}{\rho}\right)_{air} = a + bE + c[\ln(E)]^2 + d\sqrt{E} + e[\ln(E)]$$

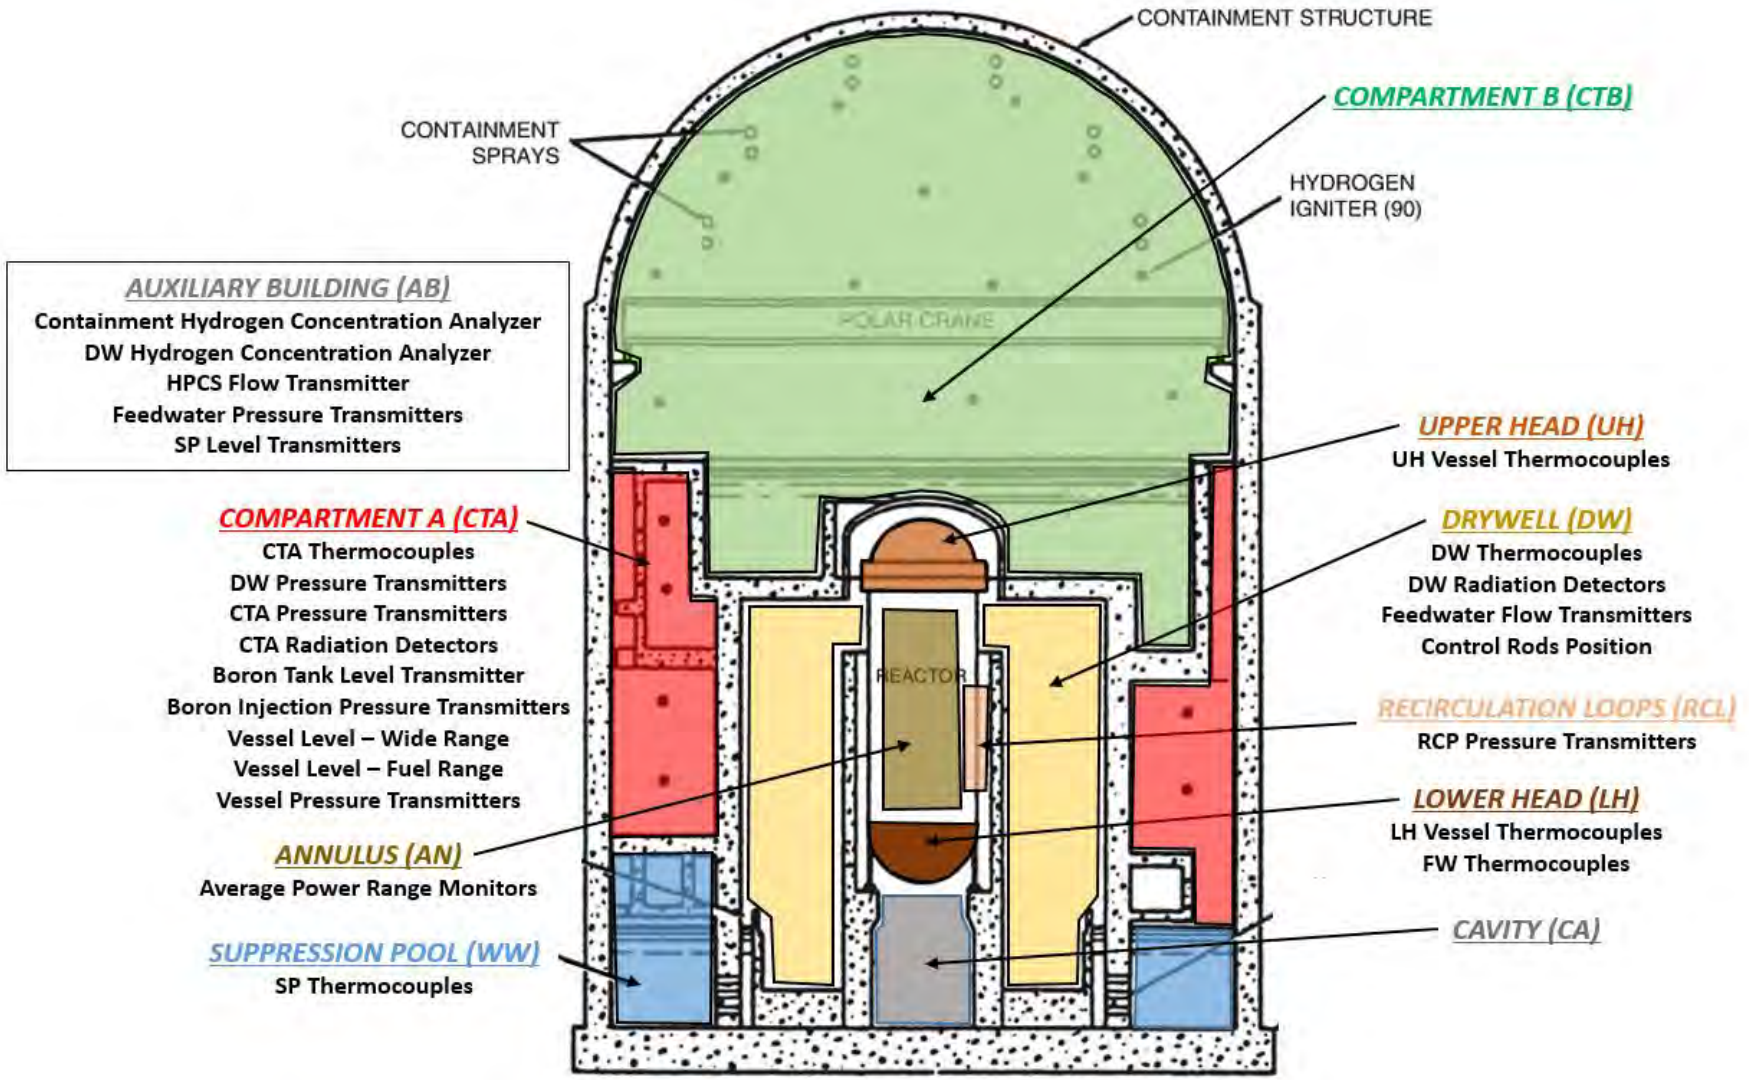
$$\left(\frac{\mu_{s,i}}{\rho}\right)_{air} = f + gE^h$$

Methodology based on L. L. Humphries, “MELCOR Dose Rate Calculations,” presented at the Workshop on Operational Experience and Advances in MELCOR Modeling, Shenzhen, China, Nov. 19, 2012.



3. Example of Application SBO on BWR. Steps

- 1. Identification of all containment instrumentation.
- 2. Identification of physical Variables required in Specific SAMGs.
- 3. Define Degradation Level
- 4. Evaluation of Instrumentation & SAMG blindness along the SA.



3. Example of Application SBO on BWR. Existing Methodology

3. Example of Application SBO on BWR. Existing Methodology

Instrument Damage Condition	Description
DC-1 (Normal Operating Conditions)	Normal operating conditions, suitable for measurement. They are wit hin the EQ (Environmental Qualification) range and the readings are f ully reliable.
DC-2 (Anomalous Operating Conditions I)	Challenging conditions or slightly above the EQ design, but the measurements are still useful both in trend and in value.
DC-3 (Anomalous Operating Conditions II)	The design limit has been significantly exceeded; the measurements are no longer valid in absolute value, although the information on trends and orders of magnitude is still useful.
DC-4 (Damaged Operating Conditions)	The measurements are only reliable in terms of trend, not quantitative or order magnitude information. In this state, the instrument cannot be recalibrated, and therefore, once level DC-4 is reached, it cannot decrease.
DC-5 (Destruction Conditions)	The measurements of such instrument have no value at all. Instrument is completely unusable, and it cannot and should not be employed for any measurement.

3. Example of Application SBO on BWR. Damage Conditions

Scoping Study Investigating PWR Instrumentation during a Severe Accident Scenario

Joy L. Rempe, Rempe and Associates, LLC

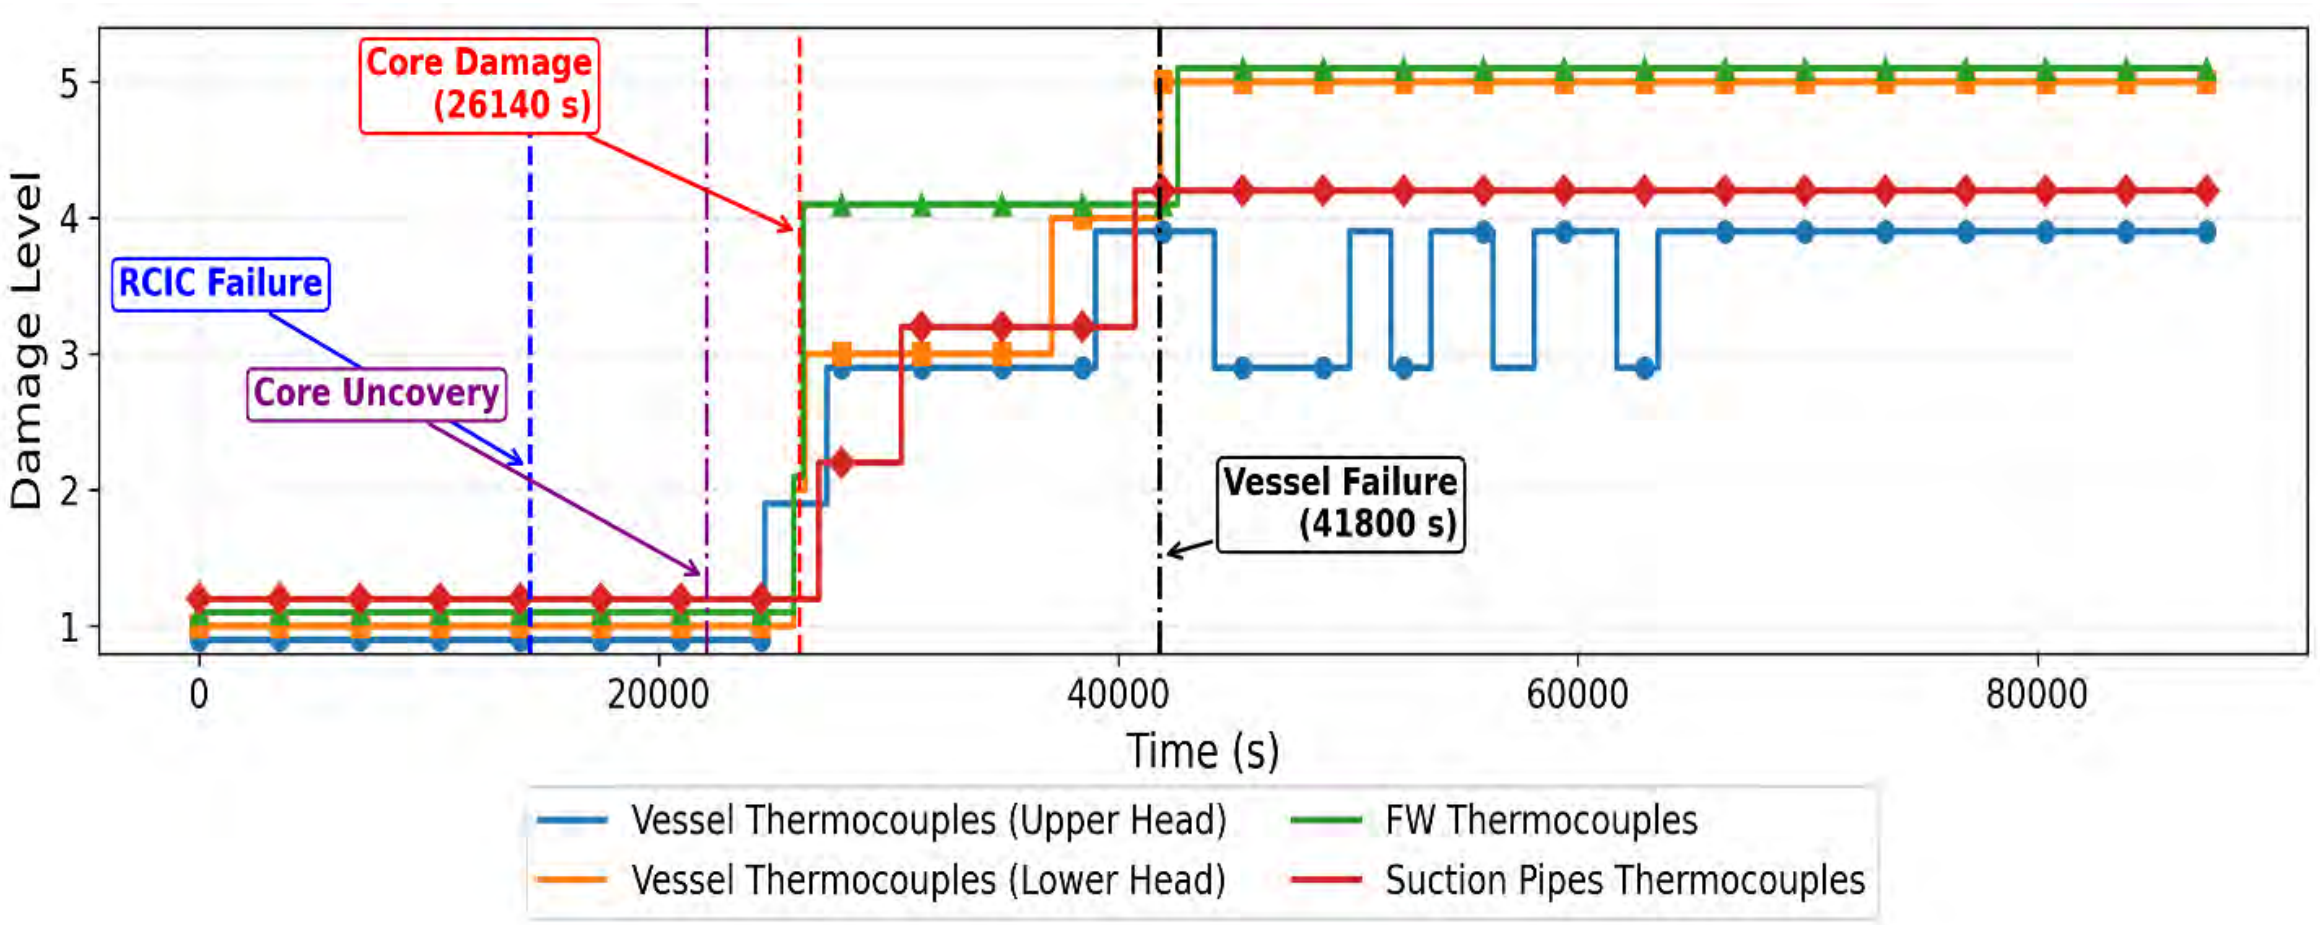
Darrell L. Knudson, Idaho National Laboratory

Robert J. Lutz, Lutz Nuclear Safety Consultant, LLC

September 2015

Results obtained are in the same order of magnitude that Rempe et al.'s SBO 2015 study.

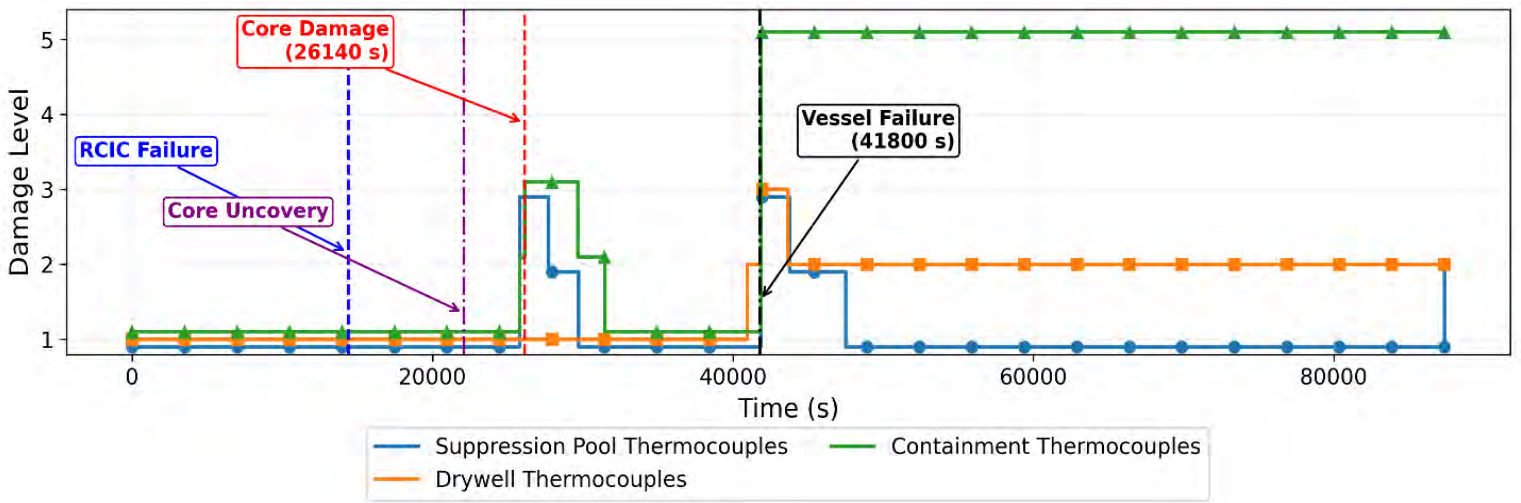
3. Example of Application SBO on BWR. Full Instrumentation damage survivability.



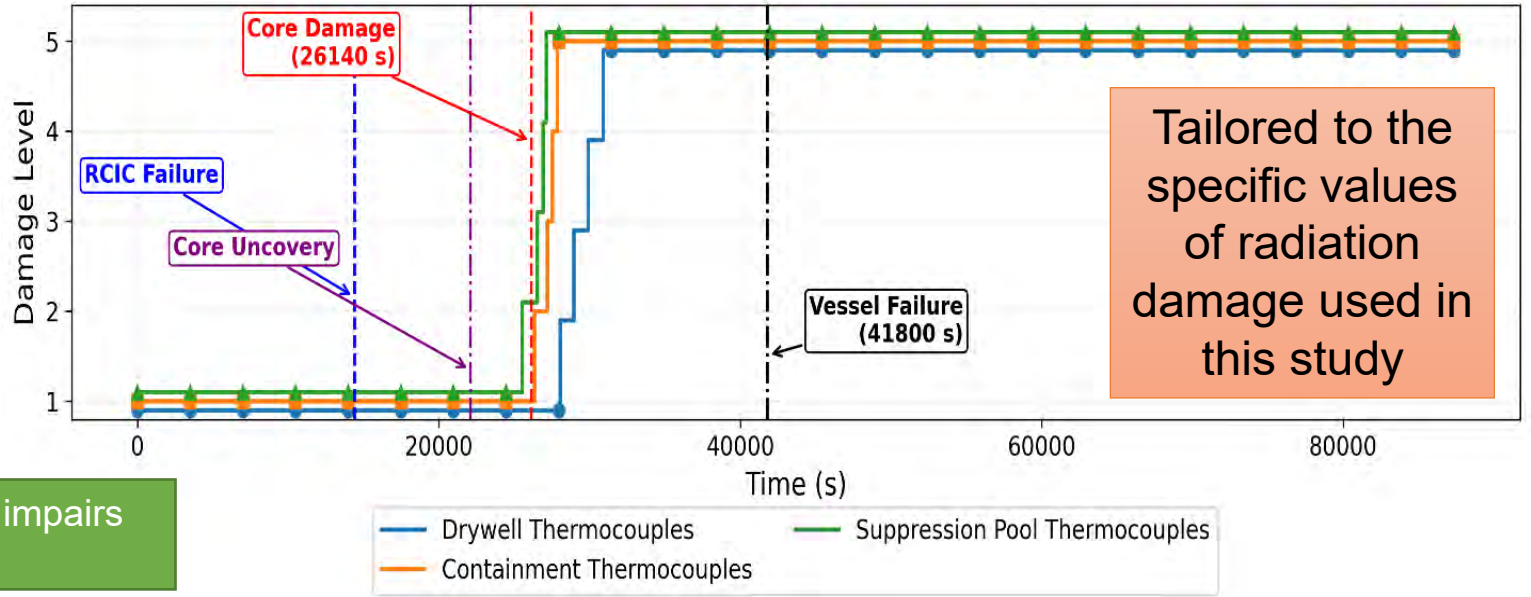
A Survivability Analysis that takes into account Temperature, Pressure and Dose in a continuous manner

3. Example of Application SBO on BWR. Full Instrumentation damage survivability.

Without Taking into account radiation



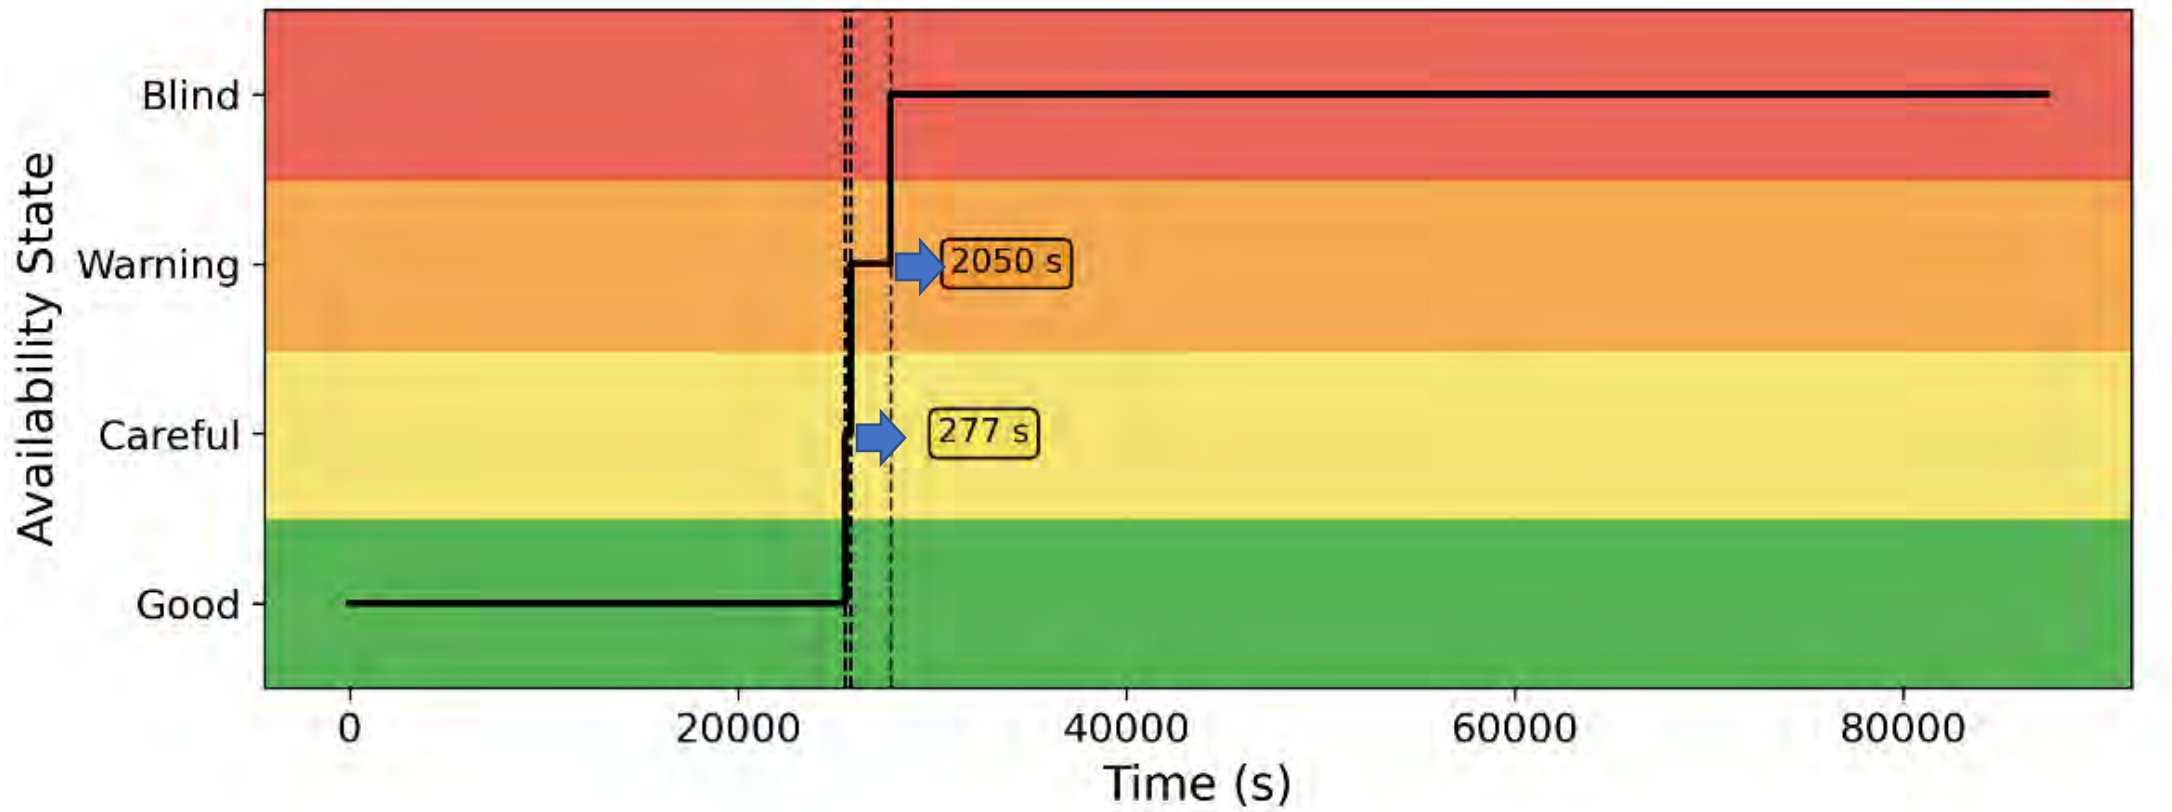
Taking into account radiation



Tailored to the specific values of radiation damage used in this study

Radiation Damage (set at ~ 100 Mrads) impairs more instruments than expected

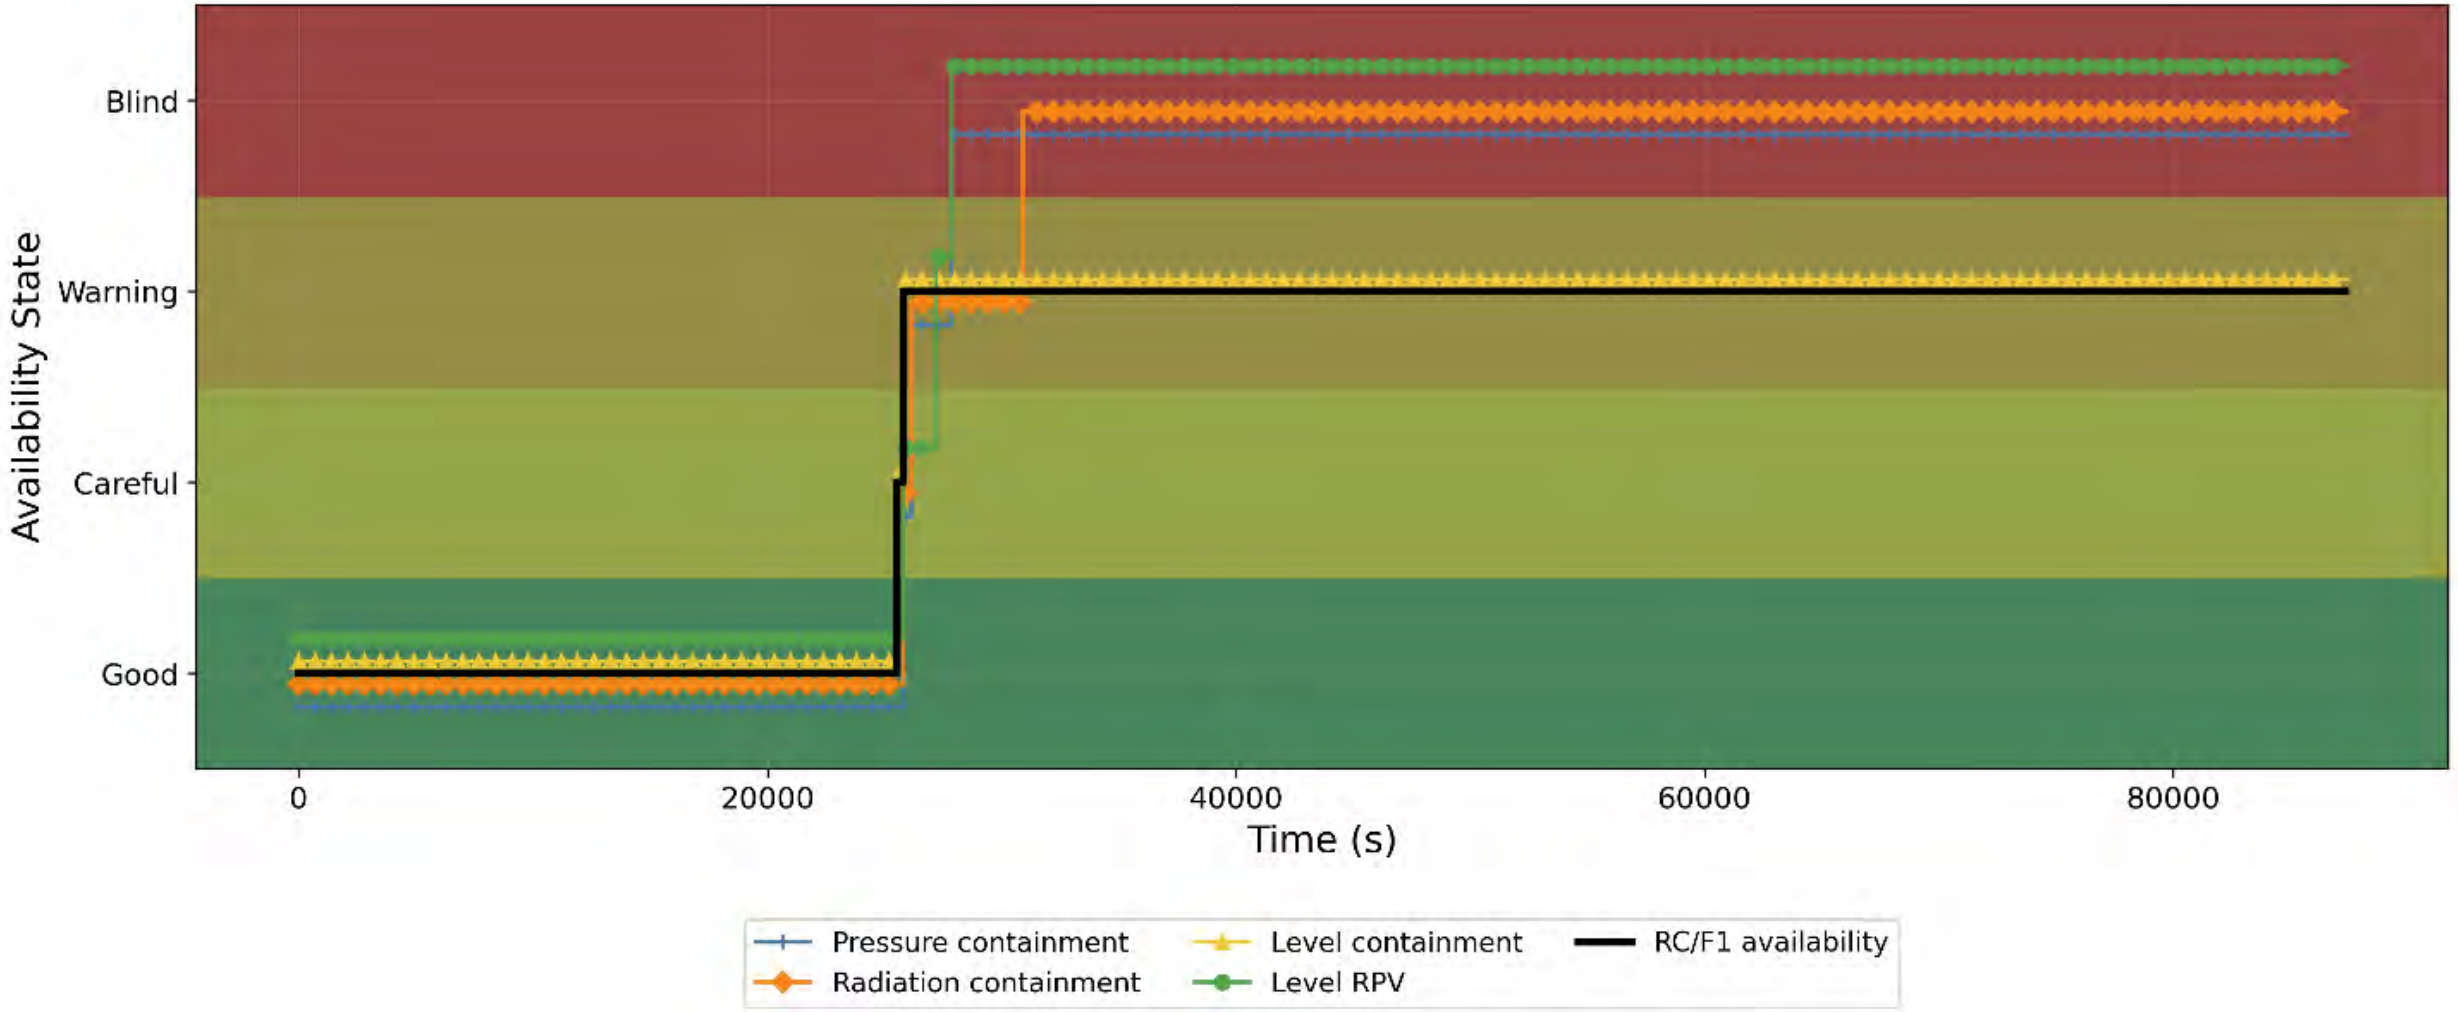
3. Example of Application SBO on BWR. Full Instrumentation damage survivability.



Availability to measure Suppression Pool Pressure

Radiation Damage (set at ~ 100 Mrads) impairs more instruments than expected

3. Example of Application SBO on BWR. Full Instrumentation damage survivability.



Conclusions

- A post-processing application to calculate dose rates in-containment during a Severe accident has been developed. RADSIM. Uses JEFF 3.3 Data and a full radioactive chain calculation, and provides more flexibility to dose calculation than other counterparts.
- Code-to-code comparison of results appear to be adequate.
- A full assessment of BWR Mark III instrumentation and SAMGs dependence has been developed.
- Core Damage and Vessel Failure dominate instrumentation survivability in consonance with other instrumentation survivability methodoloties.
- Radiation Damage can dominate Instrumentation damage under certain hypothesis.

Want to test?

- If you want to test the RADSIM tool or contribute, feel free to scan the code.

ADVANCING NUCLEAR SAFETY TECHNOLOGY

Extension of Fission Product Transport Modeling in MELCOR

David L. Luxat · Lucas Albright · Brad Beeny · Troy Haskin · Dallin Keesling
Dept. 8852 · Nuclear Energy Safety Technologies · Sandia National Laboratories

SAND2026-XXXXP

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Bottom line up front

Where the work stands

- Modernized architecture running alongside the established baseline — one simulation manager, one time loop
- Original MELCOR unchanged — packages, input decks, source
- Three generic engines for FP transport: species transport, particle balance, chemistry
- Each engine is configuration-driven — reads species, reactions, materials from the input deck
- New physics enters at any granularity: correlation, fluid or material, submodel, integrator, external code

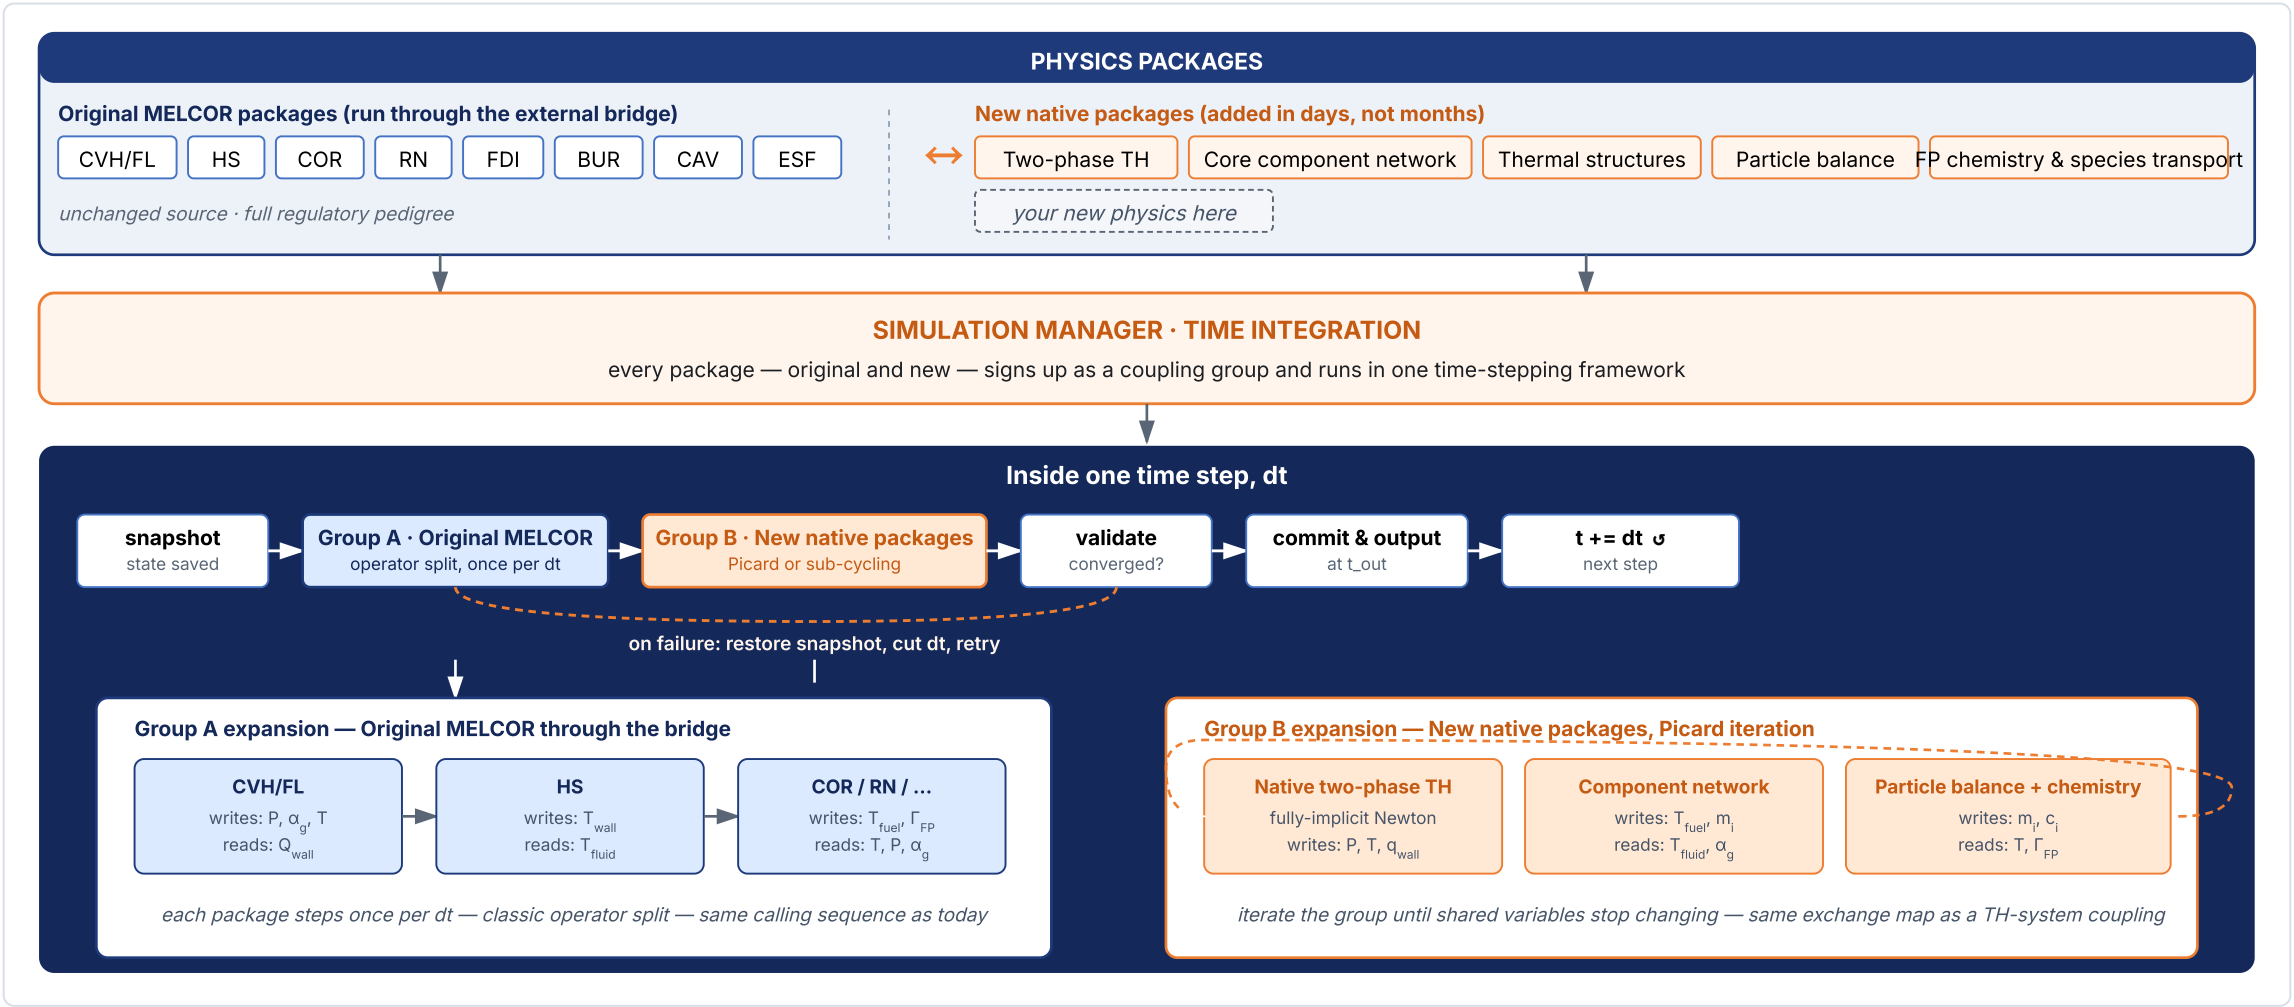
What this opens up

- A common platform for continued FP-modeling evolution — baseline preserved underneath
- Contributions from the community without forking: national labs, regulators, vendors, universities
- Open-ended validation campaigns — new models in the same harness as the built-ins
- Every addition named, versioned, and recorded in the run log
- Auditability MELCOR is trusted for, preserved end to end

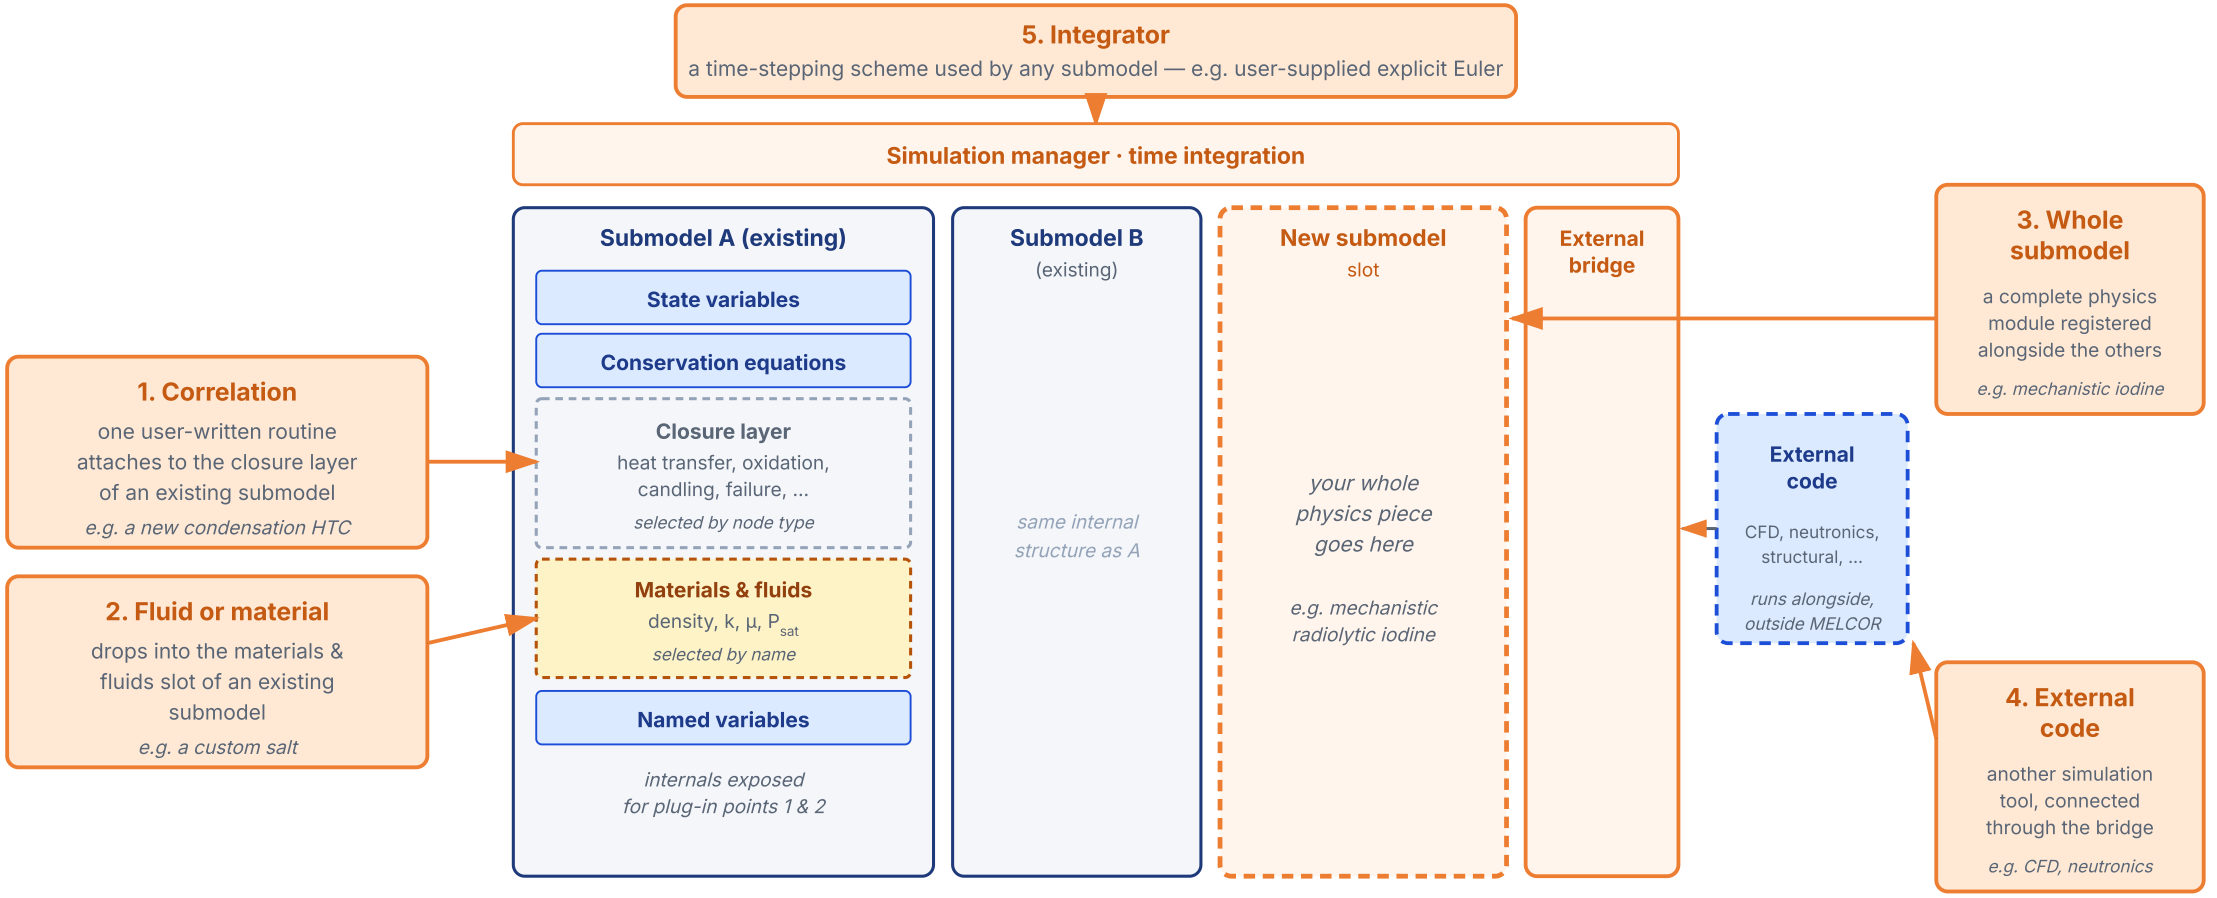
The architecture extends MELCOR's fission-product modeling without modifying the original packages. The existing validation basis for those packages is unaffected.

Original MELCOR and new physics in one time loop

Not a replacement — an enabler. Every validated package from the original MELCOR runs underneath in the same time loop as the new native packages.



Five places extensions plug in



the rest of the deck walks through points 1 and 3, with two worked examples

Writing a plugin — what the engineer has to define

The same three steps for every kind of plugin: name the new piece, declare what it reads and writes, and supply the physics. What changes by plugin type is the kind of physics being written.

1. Name the new piece
the input deck will reference it by name

→

2. Declare its inputs & outputs
the named quantities it reads and writes

→

3. Supply the physics
the equations or property functions

→

Compile
to a shared module

What "the physics" means — depending on which kind of plugin you are writing:

1. Correlation

A single closure relation: heat-transfer coefficient, friction factor, oxidation rate.

Inputs to declare
the dimensionless groups or local conditions it consumes — Re, Pr, void fraction, wall temperature

Output to declare
the value returned at each call — e.g. h, f, k(T)

The physics
the formula or tabulated form — pure point-wise evaluation, no time stepping

2. Fluid or material

A new working fluid for the thermal-hydraulics, or a new structural material for the walls.

Inputs to declare
temperature, pressure, and composition where the properties depend on them

Outputs to declare
fluid: density, specific heat, conductivity, viscosity, vapor pressure. Solid: k(T), ρ(T), creep law

The physics
the property correlations — from a reference compilation or your own data fits

3. Whole submodel

A complete piece of physics with its own state and its own time evolution.

State to declare
the variables this submodel owns — masses per species, temperature, phase fraction

Coupling to declare
which named quantities it consumes from the rest of MELCOR and which it exposes back

The physics
the conservation equations and the closure relations that feed them

4. External code

Another simulation tool (CFD, neutronics, structural) coupled in alongside MELCOR.

Boundary conditions to declare
what the external code reads from MELCOR — T, P, void fraction, source rates

Source terms to declare
what it returns — wall heat flux, species generation, deformation

The physics
already exists — you supply the wrapper that exchanges data each timestep

5. Integrator

An alternative time-stepping scheme for submodels that need one.

Inputs to declare
the named state vector to advance and the time interval

Outputs to declare
the advanced state plus convergence and step-control diagnostics

The algorithm
the time-stepping logic itself — explicit, implicit, predictor-corrector, sub-cycling

PART 1

Fission-Product Transport Capabilities

Three pillars — species, particles, chemistry

Source-term calculations need three capabilities running together. The modernized path treats each one as a generic engine that accepts user-supplied configuration — from the input deck or from a plugin.

Activation today is through integration with the modernized thermal-hydraulic submodule: it provides the volumes, the flow fields, and the boundary conditions that all three engines consume.

Species transport

How dissolved and gas-phase species move through the system — convection, diffusion, deposition, and trap kinetics.

- Fick + Soret diffusion in fluids; advection from the thermal-hydraulics
- Mass transfer across interfaces (Sherwood correlations: laminar/turbulent plate, Dittus–Boelter, packed bed)
- Diffusion + Oriani / McNabb–Foster trap kinetics in metal walls
- Permeation barriers (Al_2O_3, Er_2O_3, Cr_2O_3)

tritium permeation, deposited FP plateout, structural permeation

Particle balance (sectional PBE)

How particles are born, grow, agglomerate, and deposit — in **any** carrier phase: vapor plenum, liquid pool, or frozen layer.

- Sectional bins (1 nm to 1 µm, log-spaced), multi-species, multi-component
- Classical-nucleation theory; agglomeration; breakup; deposition
- Heterogeneous nucleation on solid seeds; crust-face plateout; melt-back resuspension
- Coupling to species transport for wall deposition flux

aerosol source term, noble-metal precipitation, debris-bed plateout

Chemistry

How species transform into one another — radiolytic, kinetic, equilibrium — expressed as a reaction network read from the input deck.

- Generic chemistry engine: species list + reaction list
- Rate-law types: unimolecular, bimolecular, radiolysis source
- Phase-transfer via Henry's law / two-film mass transfer
- Same engine hosts a 3-species fast option or a ~35-species mechanistic model

iodine speciation, organic iodide, FP–radical interactions

Particle balance — one engine, three carrier phases

The sectional particle-balance engine is carrier-agnostic. The same machinery counts and advances particles in a gas plenum, a salt pool, or a freezing crust — only the carrier-specific closures change.

Common machinery, registered once and dispatched by carrier type:
nucleation · agglomeration · breakup · condensation/evaporation · deposition · resuspension

Vapor carrier

Classical aerosol PBE in the gas plenum or cover-gas system.

- **Nucleation** — classical-nucleation theory driven by supersaturation
- **Agglomeration** — Brownian + turbulent shear
- **Deposition** — gravitational settling, thermophoresis, diffusiophoresis, wall plateout
- **Data** — CsI, CsOH, NaI from JANAF tables; surface tension and saturation pressure built in

e.g. containment aerosol source term; off-gas to charcoal bed

Liquid carrier

Particulates suspended in a coolant, salt pool, or sump.

- **Nucleation** — same classical form, driving force now dissolved-species supersaturation
- **Agglomeration** — DLVO-modulated: Hamaker constant, zeta potential, ionic strength
- **Deposition** — Sherwood-based wall mass transfer; settling under gravity
- **Application** — noble-metal precipitation in molten salt (Mo, Ru, Pd); pool-scrubbing capture

e.g. molten-salt-reactor noble-metal source; liquid-phase iodide carryover

Solid (frozen) carrier

Particles entrained in a freezing layer or debris bed.

- **Heterogeneous nucleation** — on existing solid seeds in the bulk: $J_{het} = J_{hom}(1 + \gamma\, \alpha_{sp})$
- **Crust deposition** — particulate flux onto the growing freezing front
- **Resuspension** — on melt-back, frozen-trapped inventory returns to the liquid carrier
- **Coupling** — reads α_{sp} and freeze/melt rates from the solidification submodel

e.g. freeze-plug trapped inventory; crust-face plateout in molten salt

Generalized chemistry — the species mole balance

Each control volume integrates a species mole balance for every tracked species. The same equation shape applies whether the network has three species or three hundred — only the stoichiometry tables and the rate-constant functions change.

Per-volume species mole balance

$$\mathrm{d}n_i/\mathrm{d}t = V \cdot \Sigma_r \nu_{i,r} \cdot R_r + J_i^{\mathrm{phase}} - \lambda_i n_i$$

Terms

- $\mathrm{d}n_i/\mathrm{d}t$ — moles of species i in the control volume
- $V \cdot \Sigma_r \nu_{i,r} \cdot R_r$ — net production/consumption from all reactions: the stoichiometric coefficient $\nu_{i,r}$ picks up species i in each reaction r, weighted by the volumetric rate density R_r [$\mathrm{mol \cdot m^{-3} \cdot s^{-1}}$]
- J_i^{phase} — aqueous↔gas exchange (covered next slide)
- $-\lambda_i n_i$ — radioactive decay of species i

The integrator sees N coupled ODEs per control volume

- N species ⇒ N coupled ODEs per volume; reactions are the off-diagonal coupling terms
- Jacobian assembled automatically from the stoichiometry table and the rate-constant derivatives
- Fast scoping networks: N ≈ 3 (iodine baseline). Mechanistic networks: N ≈ 35–50 (radiolytic chemistry)
- Stiff in radiolysis regimes — same fully-implicit integrator path used elsewhere in the modernized layer

The user does not write the ODE solver, the Jacobian assembly, or the time integration. Only the stoichiometry and rate-constant functions are user-supplied — through the species and reaction lists.

Generalized chemistry — rate-law forms and phase transfer

Three rate-law forms cover essentially every reaction class in containment chemistry. Phase transfer between aqueous and gas-phase species uses Henry's-law two-film relaxation.

Three rate-law forms — one per reaction entry

Unimolecular — first-order in one reactant

$$R_r = k_r(T, \mathrm{pH}, \dot{D}) \cdot c_A$$

radiolytic oxidation/reduction, hydrolysis, dissociation

Bimolecular — second-order, two reactants

$$R_r = k_r(T) \cdot c_A \cdot c_B$$

radical–radical recombination, radical–iodine reactions, scavenging

Radiolysis source — zero-order in species

$$R_r = G_r \cdot \dot{D} \cdot \rho_{\mathrm{liquid}}$$

water radiolysis from gamma/beta dose; G-values per Elliot & Bartels compilation

Phase transfer — Henry's-law two-film

$$J_i^{\mathrm{phase}} = -(1/\tau_{\mathrm{relax}}) \cdot (c_i^{\mathrm{aq}} - c_i^{\mathrm{aq,eq}})$$

$$c_i^{\mathrm{aq,eq}} = p_i^{\mathrm{gas}} / H_i(T)$$

The aqueous concentration relaxes toward Henry's-law equilibrium with the gas-phase partial pressure on a timescale τ_{relax}. The user names the aqueous/gas pair, supplies the partition coefficient $H_i(T)$, and supplies a numerical value of τ_{relax} for each pair — the code does not derive it. Typical choice: a film-theory estimate $\tau \sim V_{\mathrm{liq}}/(k_L A)$, or an empirical fit.

Generalized chemistry — couplings into the modernized code

All chemistry inputs and outputs are named exchange variables. The chemistry engine reads boundary conditions and drivers from other modernized modules each timestep, and writes back the quantities those modules consume.

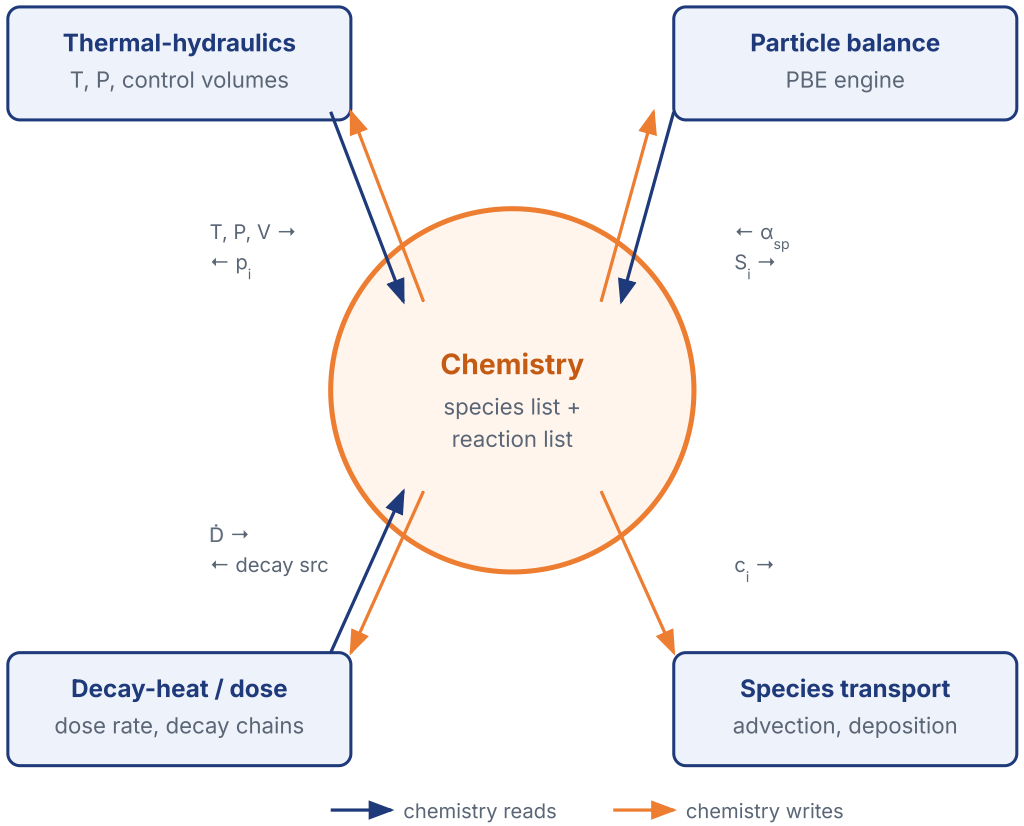
Reads (boundary conditions, drivers)

- **T, P, control-volume V** — from the modernized thermal-hydraulics
- **pH** — from a pH-tracking model or as a user-supplied field
- **dose rate $\dot{D}$** — from the decay-heat / dose-source module
- **solid particle volume fraction α_{sp}** — from the particle balance, when heterogeneous nucleation applies

Writes (back into the coupled state)

- **dissolved-species inventories c_i** — to species transport for advection, deposition, wall plateout
- **gas-phase partial pressures p_i** — to thermal-hydraulics for the cover-gas mass balance
- **supersaturation drivers $S_i = c_i/c_i^{sat}$** — to particle balance for nucleation and condensation
- **radioactive decay source** — to the decay-heat module

Every exchange variable is named in the input deck and recorded in the run log. The chemistry engine has no implicit dependencies on the rest of the code.



PART 2

Replacing Rate Correlations

Pool release — the rate-correlation library

Four mass-transfer kernels for pool → cover-gas release. Each species in the input deck declares which kernel applies; the plugin evaluates it each timestep and writes the per-species release rate.

Henry's-law mass transfer — aqueous pools

$$dm_i/dt = -k_l \cdot A_{pool} \cdot (c_{aq} - p_i/H_i(T))$$

Supplied per species: liquid-side mass-transfer coefficient k_l, Henry constant $H_i(T)$.

I_2, CsI, CsOH, TeO_2 in water.

Raoult's-law mass transfer — multi-component liquids

$$dm_i/dt = -h_m \cdot A_{pool} \cdot (P_i^{liq} - P_i^{gas}) \cdot M_i/RT$$

$P_i^{liq} = \gamma_i\, x_i\, P_{sat,i}(T)$; Antoine form. Supplied per species: A, B, γ_i.

CsF, LiI, Li_2Te, TF in salt; Cs in sodium.

Bubble degassing — dissolved gases

$$dm_i/dt = -k_b \cdot A_{pool} \cdot m_i$$

First-order depletion. Supplied per species: k_b.

Xe, Kr in every coolant; T_2 in salt.

Aerosol entrainment — non-volatile species

$$dm_i/dt = -e_{ent} \cdot A_{pool} \cdot (m_i/m_{pool})$$

Mechanical droplet entrainment from the pool surface; rate scales with surface mass-fraction.

NaI, Na_2Te in sodium.

Worked example — FLiBe pool with thermal transient, 7 days

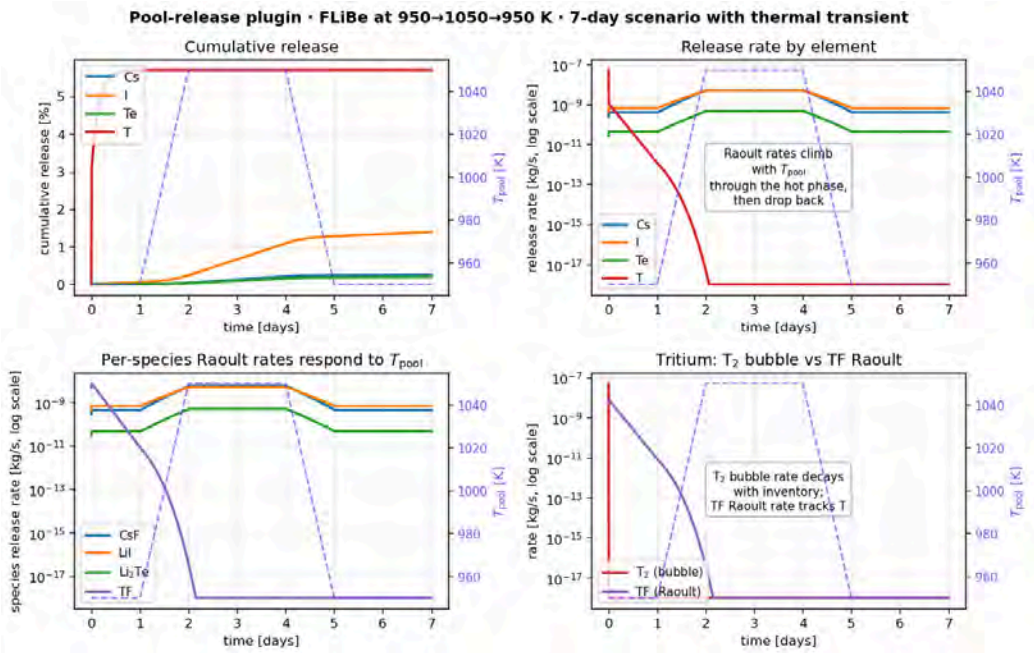
A molten-salt drain-tank pool driven through a temperature ramp from nominal 950 K up to 1050 K and back. The plugin's Antoine vapor-pressure response is exercised by the transient; the bubble path is set by inventory rather than T, and the two behaviours appear side by side in one plugin.

Scenario

- FLiBe (66 mol% LiF / 34 mol% BeF_2); pool volume 10 m^3, surface 5 m^2, off-gas plenum 100 m^3
- T_{pool} transient: 950 K (1 day) → ramp to 1050 K → 2 days at 1050 K → ramp back to 950 K → final 2 days nominal
- 7-day total, 10-minute output cadence
- Seven species: CsF, LiI, Li_2Te, TF (vapor-Raoult); T_2, Xe, Kr (bubble)

What the temperature transient brings out

- Raoult release rates climb roughly one order of magnitude through the 1050 K plateau, then relax back when T_{pool} returns to 950 K
- Cumulative Cs, I, Te release inflects upward during the hot phase — the integrated fraction depends strongly on the high-temperature dwell
- Each Raoult species responds differently — CsF, LiI, Li_2Te, TF have different Antoine slopes
- T_2 bubble rate is set by remaining inventory, not by T_{pool}; TF Raoult tracks the temperature transient instead



Worked example — sodium pool with thermal transient, 30 days

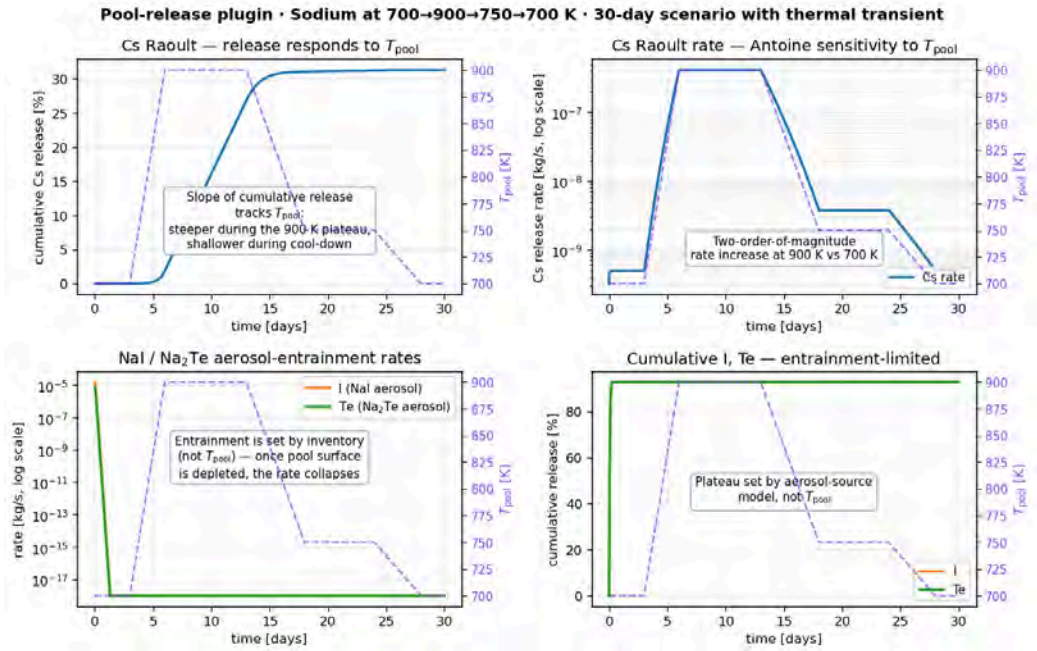
A liquid-sodium primary pool driven through a 30-day temperature transient: 700 K → 900 K (hot phase) → 750 K (intermediate) → 700 K. The plugin's vapor-Raoult and aerosol-entrainment modes respond to T_{pool} in qualitatively different ways — one tracks the transient closely, the other does not.

Scenario

- Liquid sodium; pool volume 50 m^3, surface 25 m^2, cover-gas plenum 500 m^3
- T_{pool} transient: 700 K (3 days) → ramp to 900 K → 7 days at 900 K → ramp to 750 K → 6 days at 750 K → ramp back to 700 K
- 30-day total, 30-minute output cadence; 4321 adaptive timesteps
- Five species: Cs (vapor-Raoult); NaI, Na_2Te (aerosol entrainment); Xe, Kr (bubble)

What the temperature transient brings out

- Cs Raoult rate swings two orders of magnitude as T_{pool} rises to 900 K and returns — the Antoine vapor pressure is the dominant sensitivity
- Cumulative Cs release shows distinct slopes per temperature plateau: steep through the 900 K phase, shallower in the 750 K phase, baseline at 700 K
- NaI and Na_2Te aerosol entrainment is set by the inventory and pool-surface model — effectively T-independent on this scale, so the I and Te dynamics is decoupled from the transient
- Two physically distinct release modes, one set of inputs — the deck visibly separates the responses

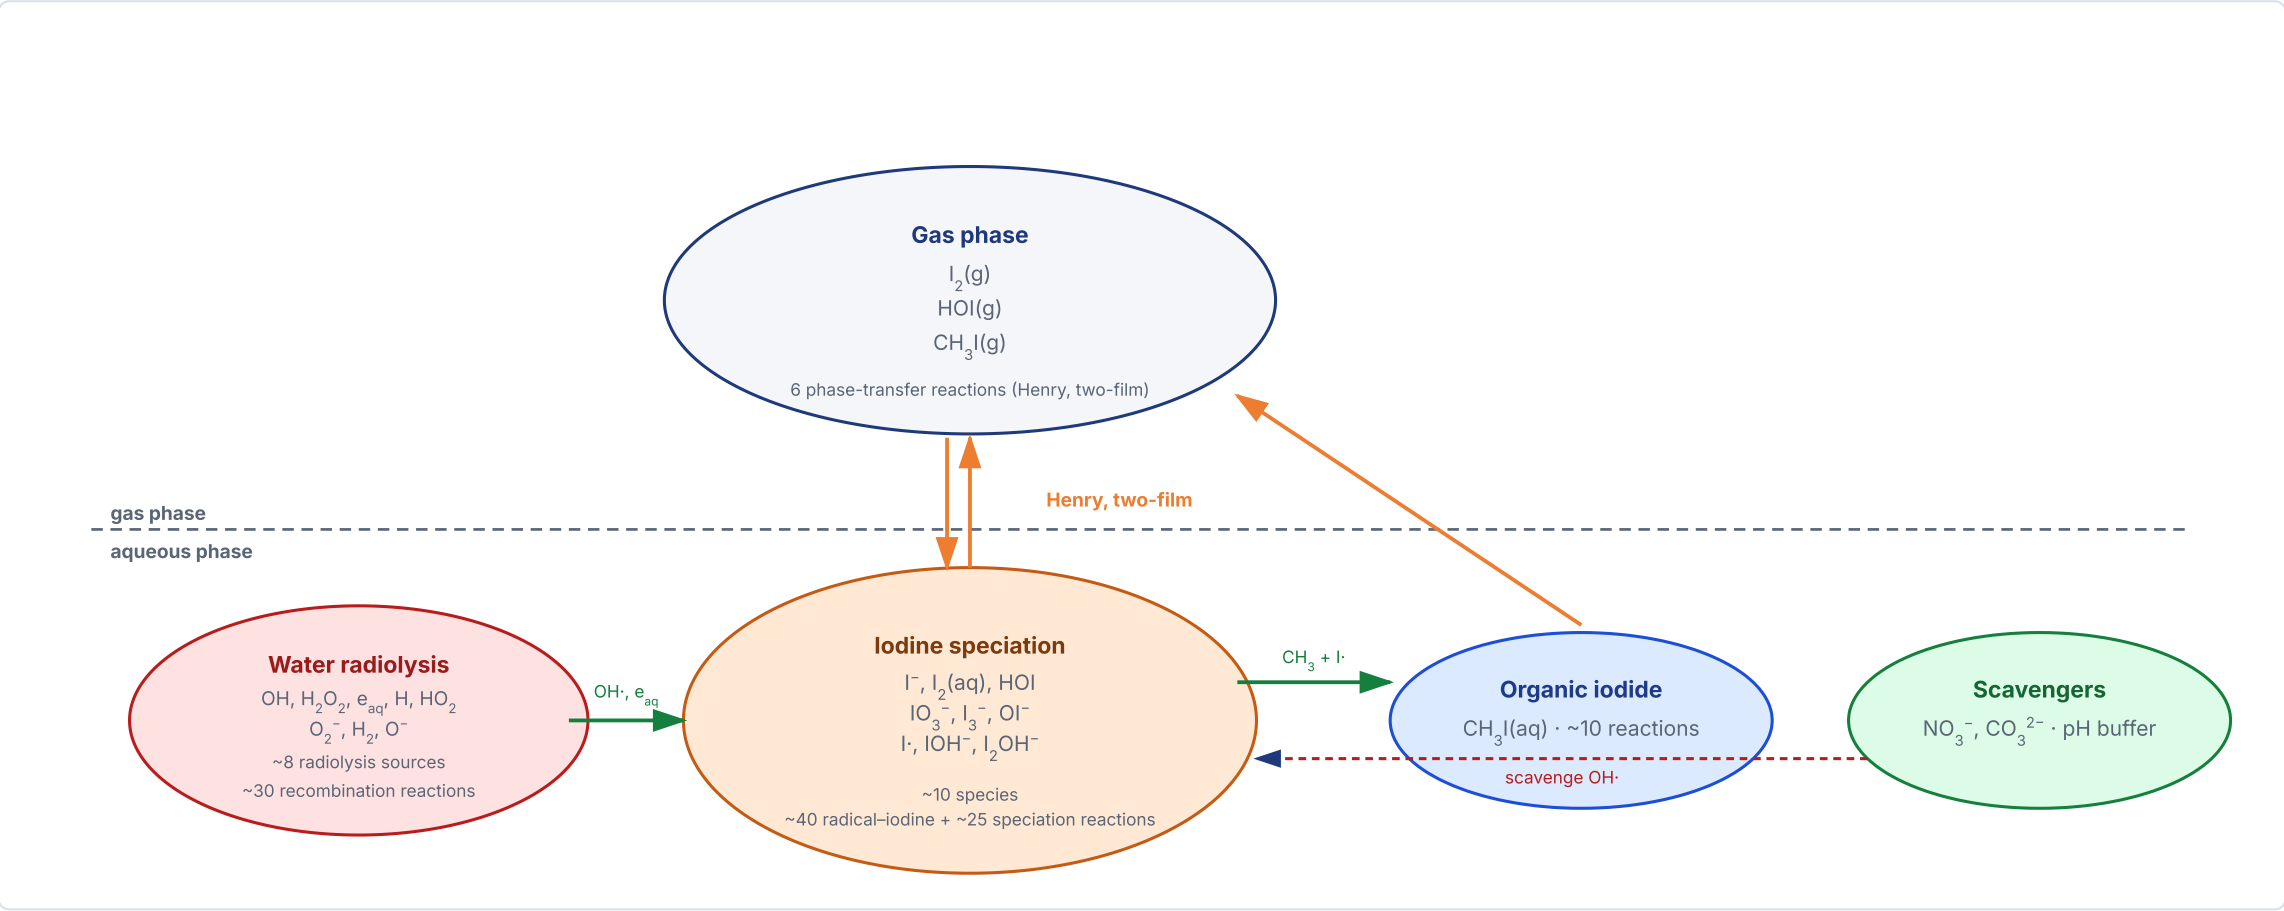


PART 3

Replacing a Whole Submodel

A LIRIC-style mechanistic iodine model — implemented in the modernized submodule

A mechanistic radiolytic iodine model is currently implemented in the modernized submodule. It tracks roughly 35 species and 180 reactions, including water radiolysis, the full iodine speciation chain, organic-iodide formation, radical scavenging, and aqueous↔gas phase partition.

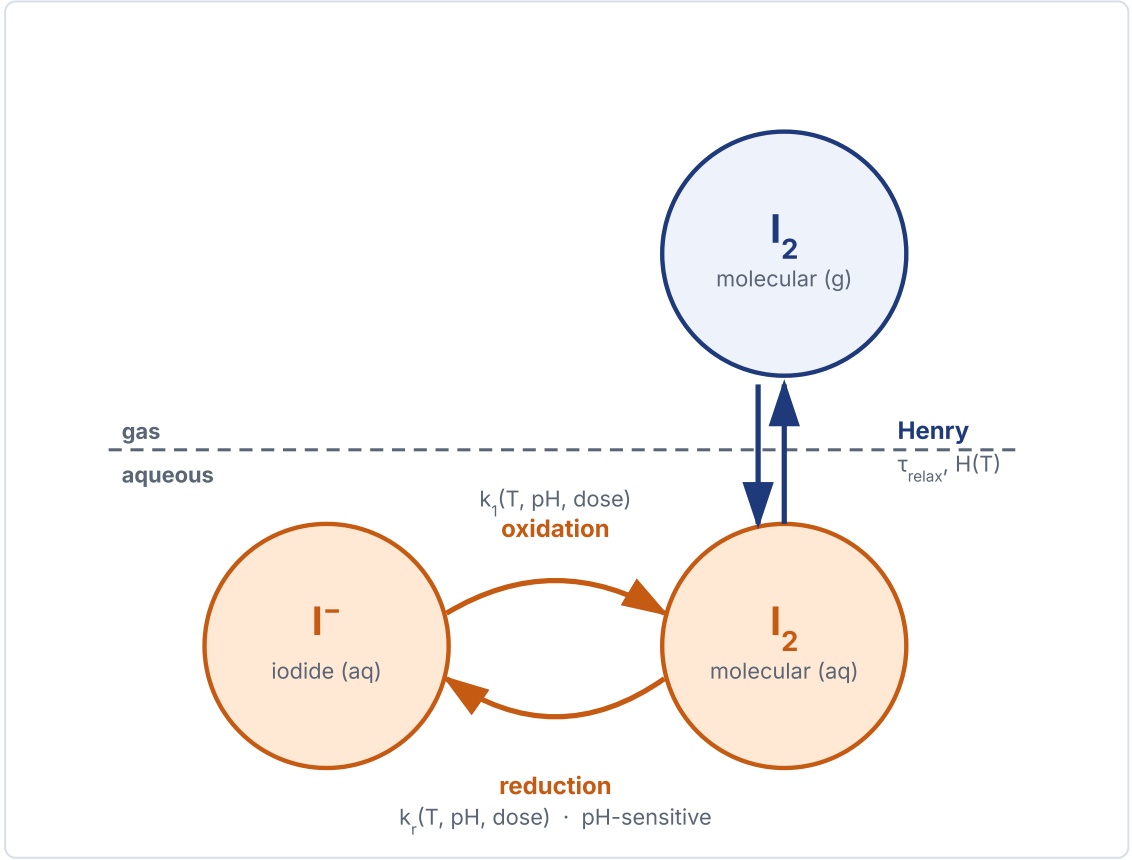


Simplified iodine modeling plugin

A 3-species, 3-reaction network of the IMOD class. The forward radiolytic oxidation drives iodide toward I_2; the reverse radiolytic reduction returns I_2 to iodide. Together they set a pH-dependent kinetic steady state rather than monotonically exhausting iodide.

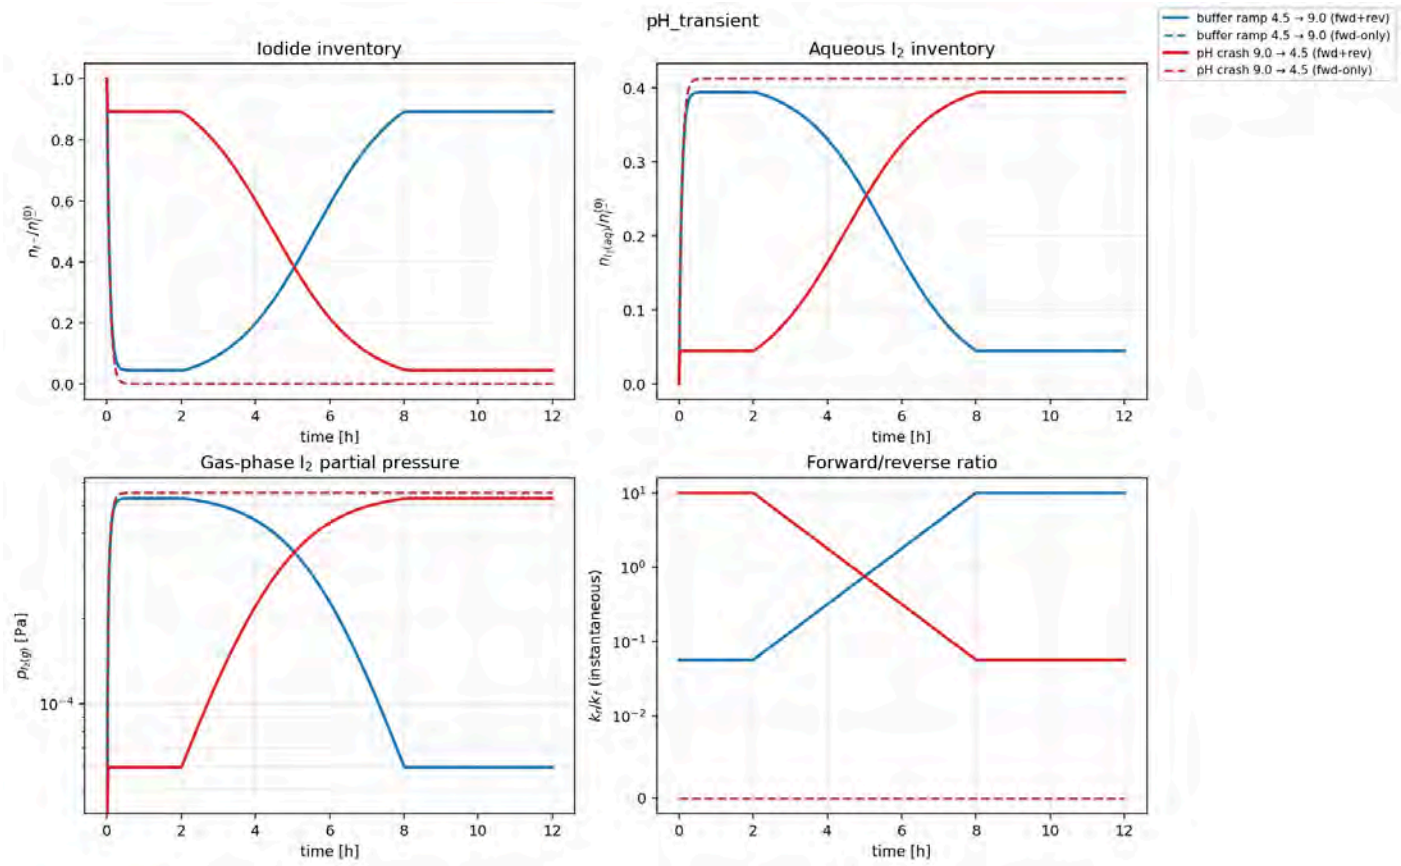
- **Species.** I^-(aq), I_2(aq), I_2(g)
- **Radiolytic oxidation.** $I^- \rightarrow \frac{1}{2} I_2$, first-order in iodide. Native form $k_1 = \alpha \cdot$ dose rate.
- **Radiolytic reduction.** $I_2 \rightarrow 2\ I^-$, first-order in I_2, **pH-dependent**. Captures the O_2^- / H_2O_2-mediated reduction pathway from Wren et al., **Nucl. Tech.** 129(3), 2000 (§II.B.2, §II.C.2).
- **Henry's-law transfer.** I_2(aq) ↔ I_2(g) at a relaxation timescale τ against a partition coefficient.

Not modelled in this network: organic-iodide formation (I_2 + RH → RI), AgI precipitation, I_2 hydrolysis.



Result — iodine chemistry tracks a buffered pH ramp

12-hour transient. The pool buffer ramps pH between 4.5 and 9.0 (and back). Chemistry equilibrates fast; the question is whether the source term **follows** the pool when conditions move — or stays stuck.



Ramp ↑ pH 4.5 → 9.0 (red)

Iodide regenerates as the pool becomes alkaline; gas-phase I_2 falls **three orders of magnitude** over the 6-hour ramp; forward/reverse ratio swings from ~0.1 to ~10.

Ramp ↓ pH 9.0 → 4.5 (blue)

Mirror image — iodide is re-oxidized; gas-phase I_2 climbs three orders of magnitude. Reversibility is in the kinetics, not just thermodynamics.

Forward-only twins (dashed)

No response to pH at all. Once iodide is exhausted there is no path back — the dashed gas-phase I_2 sits at the ceiling for the entire transient.

ABSTRACT

Severe accident management and source term evaluation are essential for nuclear safety, especially in large light-water reactors such as the VVER-1000. This paper presents best-practice methodologies and sensitivity analyses using the ASTEC code, focusing on iodine chemistry and transport processes in the containment. Iodine is of particular concern because of its volatile forms, complex speciation, and sensitivity to containment thermohydraulic conditions. The analyses use the SOPHAEROS module to model fission product deposition, re-volatilization, and chemical transformations across multi-compartment containment geometries. Special attention is given to iodine speciation among gaseous molecular iodine (I_2), organic iodides, and aerosols, and to the effects of temperature, humidity, and radiation on interconversion mechanisms.

Sensitivity studies emphasize the importance of boundary conditions, especially thermodynamic parameters that control iodine volatility and long-term retention within the containment. In total, over 80 reactions with iodine in the containment are considered in the ASTEC code, among which those happening in the sump are of major importance. Those reactions are radiation, temperature, pH and I^- concentration dependent and govern thus iodine retention and re-volatilization.

Results of the sensitivity analyses indicate that containment thermodynamic conditions, together with sump acidity and iodine mass transfer – reflected by changes in iodide (I^-) concentration due to entrainment by droplets from an operating containment spray system – are decisive factors in predicting the iodine source term to the environment. These findings underscore the need for harmonized best-practice approaches in ASTEC applications and offer valuable guidance for developing improved accident management strategies not only for VVER-1000 type reactors.

1. INTRODUCTION

Iodine is a key contributor to radiological risk during severe accidents (SA) because it appears in several volatile forms and can be transported efficiently to the environment, especially in its gaseous forms, if not retained by in-vessel or containment processes. European R&D programs such as PHEBUS FP [1] and the

associated state-of-the-art report on iodine chemistry [2] have established that iodine behavior in containment (CTMT) is governed by a complex interplay between aqueous chemistry, gas-phase reactions, radiolytic effects, and interactions with CTMT surfaces.

In parallel, the ASTEC [3] integral severe-accident code has been developed and validated as the European reference for source-term evaluation, including the SOPHAEROS module for fission-product (FP) transport and iodine chemistry.

In this work, the ASTEC code, with the simulations centered around the SOPHAEROS module is applied to an integral model of a VVER-1000 nuclear power plant subjected to a cold-leg guillotine break leading to loss of coolant accident (G-LOCA) scenario. The study focuses on the sensitivity of iodine speciation to the pH variation in the CTMT sump with sump pH values spanning from 5 to 9. For each analyzed variant, the evolution of iodine amount retained in the CTMT sump and the total amount of gaseous forms of iodine in the CTMT atmosphere was evaluated, with particular attention to molecular iodine (I_2). In addition to pH variation, selected calculations also included the activation of the CTMT spray system, which significantly alters the thermodynamic conditions in the CTMT atmosphere – namely the atmosphere pressure, temperature, and relative humidity. These changes influence both the production of I_2 in the sump and the mass-transfer processes controlling the release of volatile iodine species into the gas phase.

The objective of this sensitivity study is to study the influence of sump pH and CTMT thermodynamic conditions on iodine speciation, with emphasis on the resulting quantity of total mass of gaseous iodine in CTMT atmosphere. The results provide insights relevant for SA management, modelling best practices, and the interpretation of iodine-related uncertainties in source-term assessments.

2. COMPUTATIONAL FRAMEWORK AND MODELLING APPROACH

The analyses presented in this study were performed using ASTEC V3.1.2 applied to an integral model of a VVER-1000 plant. The simulations cover the full sequence from in-vessel degradation accompanied with FPs release and their transport within the primary circuit. Focus is then placed on physical processes, mass transfer, and the subsequent chemical and radiolytic transformations of fission products within the CTMT.

2.1. ASTEC Code and SOPHAEROS Module

The integral code ASTEC covers all relevant phenomena occurring during a SA progression and namely couples primary/secondary circuit thermal-hydraulics (module CESAR [4]), core degradation phenomena (module ICARE [5]), FP release, transport and chemical reactions in the circuits and in the CTMT, the state of which is evaluated using the CPA module [6]. Radiological dose rates are automatically calculated by the DOSE module [7], based on FP decay heat and activity inventories provided by the ISODOP module [8].

For the present study, emphasis is placed on the SOPHAEROS module [9] within the ASTEC code, which models FP transport and iodine chemistry in multi-volume circuits and CTMT. The model accounts for a wide range of transport and interaction processes, including deposition, condensation, agglomeration, physical and chemical sorption, resuspension, evaporation, aerosol dynamics, and mass-transfer reactions across several domains (liquid, atmosphere, walls). FPs are treated in both aerosol and gaseous forms, encompassing condensable vapors and non-condensable gases, and are tracked through six distinct physicochemical states: airborne gases, condensed vapors, suspended aerosols, deposited aerosols, gases sorbed on structures, and FPs dissolved in sump water. These states apply to all FPs. In addition, six iodine-specific states are considered, describing iodine compounds sorbed on painted, concrete, and steel surfaces under dry, submerged, or wetted (water-film) conditions.

These reactions, along with liquid-gas, wall-gas and wall-liquid mass-transfer pathways, are summarized in Fig 1, which illustrates the large number of potential reactions (more than 80) that may occur within the CTMT. The module thus enables direct assessment of how sump conditions (pH, radiation field), CTMT thermodynamic states and mass-transfers influence the partitioning of iodine between the aqueous and gaseous phases.

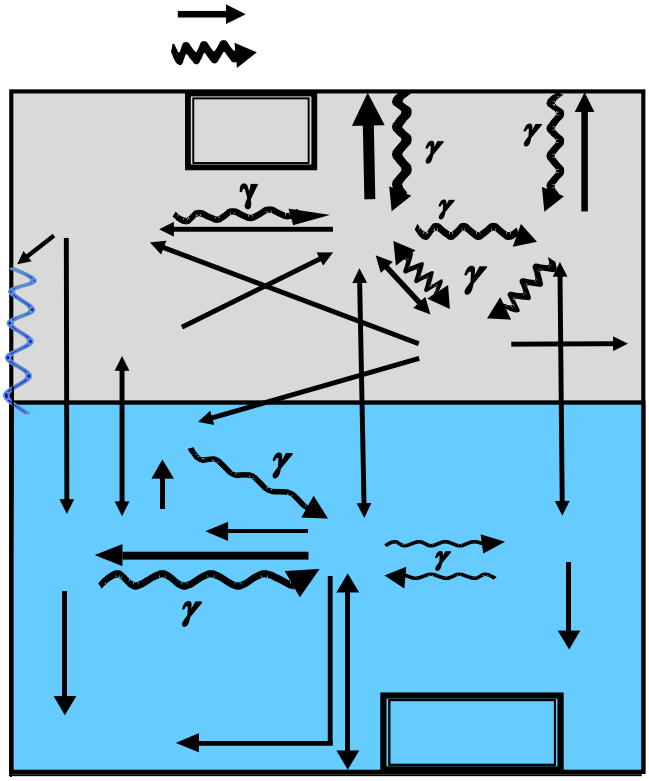

Figure 1. Thermal, radiolytic and mass transfer reactions of iodine considered in SOPHAEROS [10]

2.2. VVER-1000 Plant and Containment Model

The integral model represents a NPP with reactor VVER-1000 including core, primary circuit and a CTMT that includes a water sump, located at the very bottom of the CTMT, which collects liquid from the CTMT compartments. In addition, coolant leakage from the primary circuit into the CTMT leads to the formation of smaller local water pools within the steam generator compartments. Model of CTMT includes distinct surface families (painted, concrete, steel). As the focus of this article is on the forms and speciation of iodine in CTMT, the input model description limits to the nodalization scheme of the core/reactor pressure vessel (RPV) on Fig. 2. The primary circuit is represented by a 1+2+1 loop configuration, providing pathways for FP transport from the reactor to the CTMT.

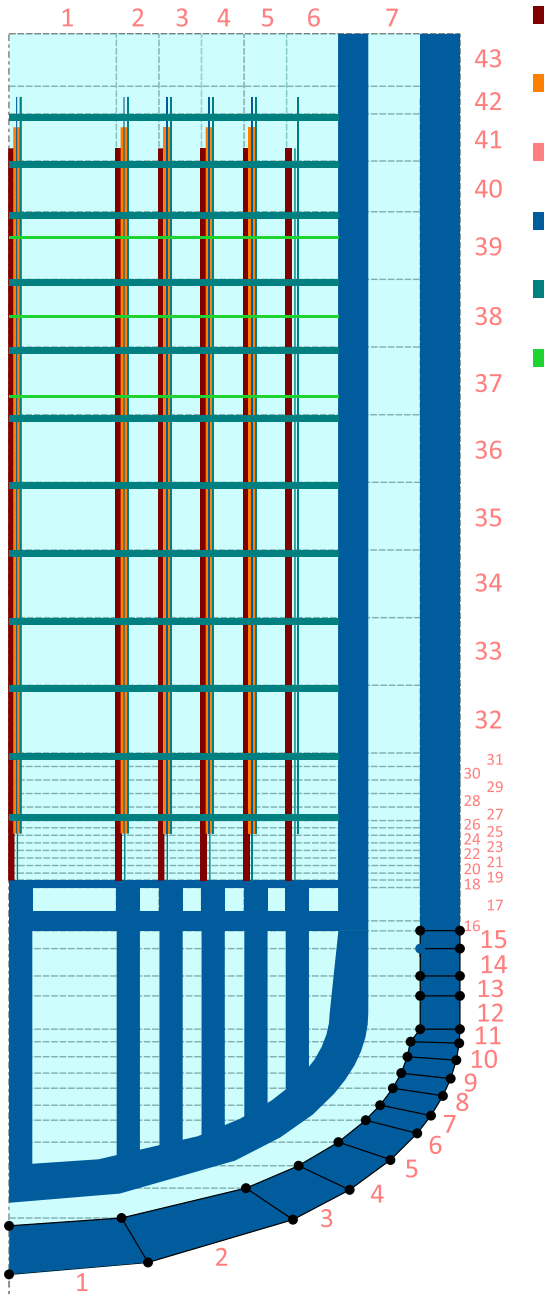

Figure 2. Nodalization scheme of the RPV

The CTMT is modelled using a 36-zone nodalization that represents individual compartments, CTMT water sump and characteristic surface groups. Its layout is shown in Fig. 3. This level of discretization enables the model to capture spatial variations in gas concentrations, temperature and relative humidity that influence iodine partitioning between aqueous, gaseous and other possible phases. During the G-LOCA sequence, the model enables proper tracking of materials and FPs and thermal-hydraulic loads into the CTMT, allowing the assessment of how evolving conditions affect iodine behavior. In selected simulations, the CTMT spray system is activated to assess how spray-induced cooling and substantial decrease of pressure and humidity modify the CTMT atmosphere and the resulting distribution of iodine between the sump and atmosphere.

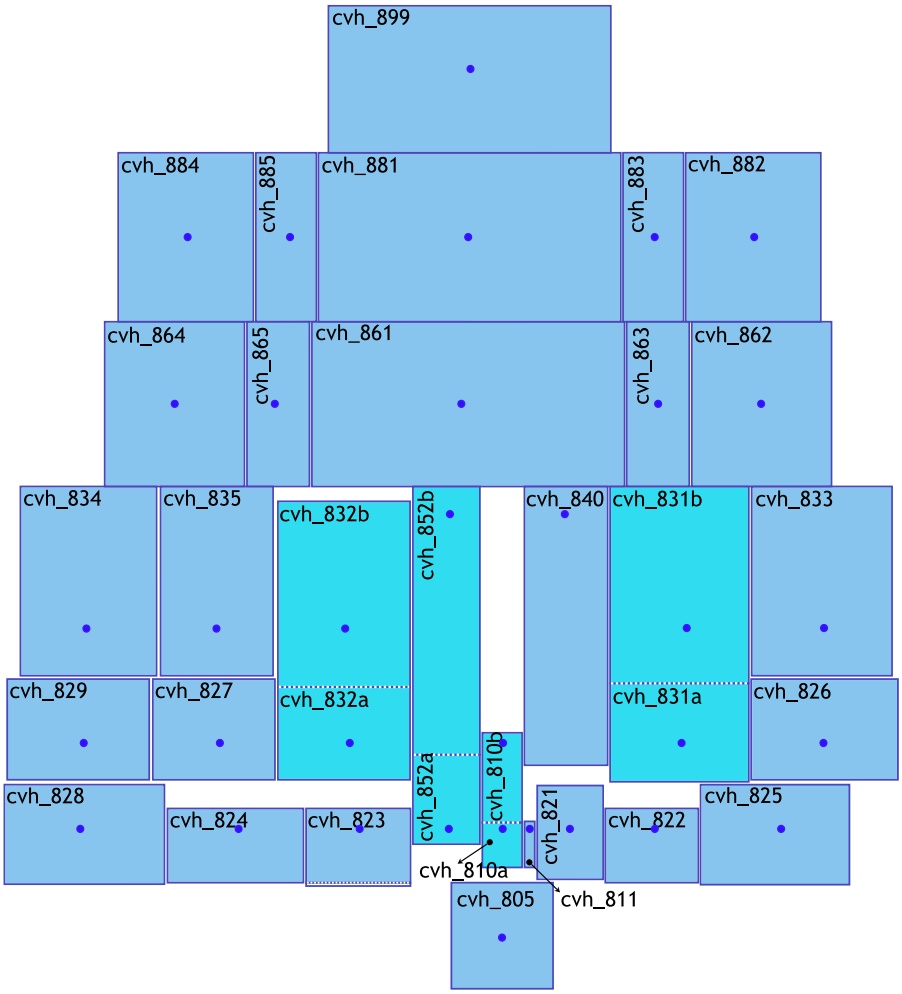

Figure 3. CTMT nodalization for the iodine speciation ASTEC/SOPHAEROS analysis. Reactor shaft is in volume cvh_810. Primary break is modeled in cvh_831b and CTMT sump is in cvh_805.

3. SENSITIVITY ANALYSIS METHODOLOGY

The sensitivity analysis was designed to quantify how selected chemical and thermodynamic conditions in the CTMT influence iodine behavior during a cold-leg G-LOCA sequence. The only parameter varied in the study was the pH of the CTMT sump. Since the default chemistry of the sump reflects the presence of boric acid originating from primary coolant leakage, the pH was adjusted over the range of 5 to 9, representing conditions achievable through the natural buffering capacity of the system as well as through potential operator-initiated additives such as KOH or hydrazine (N_2H_4). This range ensures that both slightly acidic and slightly alkaline environments are represented, allowing evaluation of chemical pathways that are strongly pH dependent. For each pH variant, ASTEC tracked the evolution of dissolved iodine species, with particular focus on iodide (I^-) and molecular iodine (I_2) in the sump, as well as the total amount of gaseous iodine present in the CTMT atmosphere.

Lower pH enhances radiolytic oxidation of I^- through the governing equation (1) and increases the formation of volatile iodine species. It is therefore expected that lower pH would lead to a higher I_2 concentration in the sump (but not necessarily in the CTMT atmosphere; that would depend on mass-transfer from sump) whereas more alkaline conditions favor retention of iodine in non-volatile aqueous forms such as I^-.

$$2I^- + 1/2\ O_2 + 2H^+ \rightarrow I_2 + H_2O \quad (1)$$

To assess the additional influence of CTMT thermodynamic conditions, two additional cases included activation of the CTMT spray system, namely the simulations with pH 5 and pH 9. These spray-assisted variants were chosen to represent the two extreme chemical conditions in the study and to allow a clear comparison of how pH, together with spray-induced changes in pressure, temperature, and relative humidity, modulates mass-transfer from the sump and thus the formation of gaseous iodine in the CTMT atmosphere.

The radiation level, influencing mainly the creation of OH radicals and thus contributing to I^- oxidation, was left to be calculated by the DOSE module, working in close coupling with the ISODOP module. Additionally constant organic concentration was set on the walls as boundary condition.

4. RESULTS OF SENSITIVITY ANALYSIS

A total of seven integral ASTEC simulations were performed to evaluate the influence of CTMT sump chemistry and thermodynamic conditions on iodine behavior during a cold-leg G-LOCA (2x850 mm) sequence. Five calculations covered the pH variation study, with fixed sump pH values of 5, 6, 7, 8 and 9. Two additional simulations were conducted with activation of the CTMT spray system, applied only to the boundary cases at pH 5 and pH 9 to provide a clear contrast between the chemical extremes. This set of simulations forms the basis for the following evaluation of both the in-vessel progression and the subsequent iodine behavior in the CTMT.

4.1 Results of the in-vessel phase of the integral ASTEC calculation

Illustration of the G-LOCA progression through the SA phase up to RPV failure is provided in Fig. 4 to Fig. 6; those 3 graphs summarize the in-vessel progression for all seven simulations, while the timing of main events and selected values at the instant of lowerhead failure are summarized in Table I. Up to the onset of core degradation, all seven simulations evolve indistinguishably; the cold-leg break depressurization and early heat-up proceed in the same manner across the pH-only variants and the two spray-assisted cases, in which the spray systems were activated within the first seconds of the simulation after the CTMT absolute pressure reached 120 kPa, with no activation delay assumed, and remained activated until the end of the simulation.

The initial FPs release from fuel occurs at a comparable instant for all simulations, with a slight advance in the non-spray runs relative to the spray-activated cases. Once rapid degradation of the core begins, small divergences appear that are attributable to numerical noise associated with solving and updating a large, coupled matrix in the integral calculation. The scatter of results indicates rather the inherent sensitivity of integral SA codes to the input parameters. A consistent, scenario-relevant deviation is the earlier timing of vessel failure in the spray-activated variants, where the RPV fails tens of minutes sooner than in the corresponding non-spray cases. Integrated releases from the primary to CTMT differ only marginally – at the level of a few percent.

The pressure evolution in the CTMT shows that the activation of the spray systems results in a noticeable pressure reduction and a subsequently more moderate pressurization rate, as seen in Fig. 6. First small pressure peaks correspond to first relocation of corium to lower plenum. The change in the pressurization trend observed between the third and fourth hour is attributable to the failure of the hermetic doors separating the reactor cavity – into which the corium relocated following RPV failure – from the CTMT.

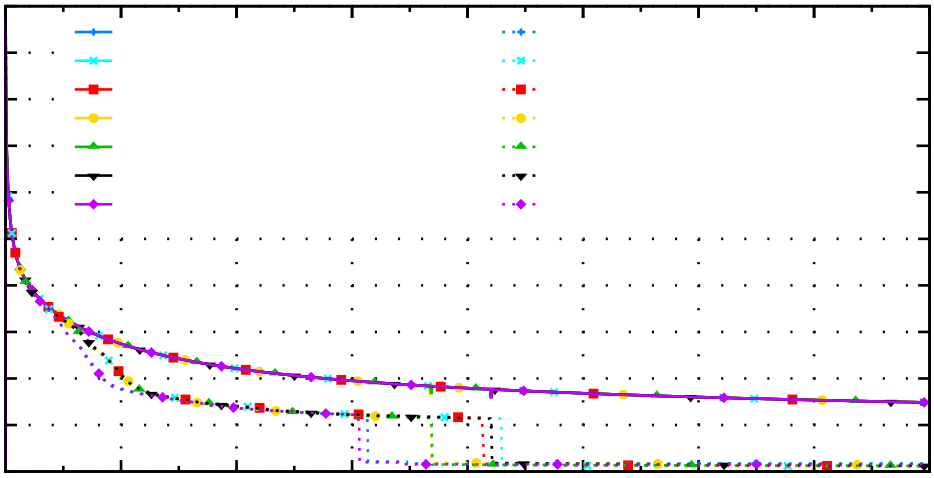

Figure 4. Decay power indication cladding rupture and FPs release, as well as RPV failure.

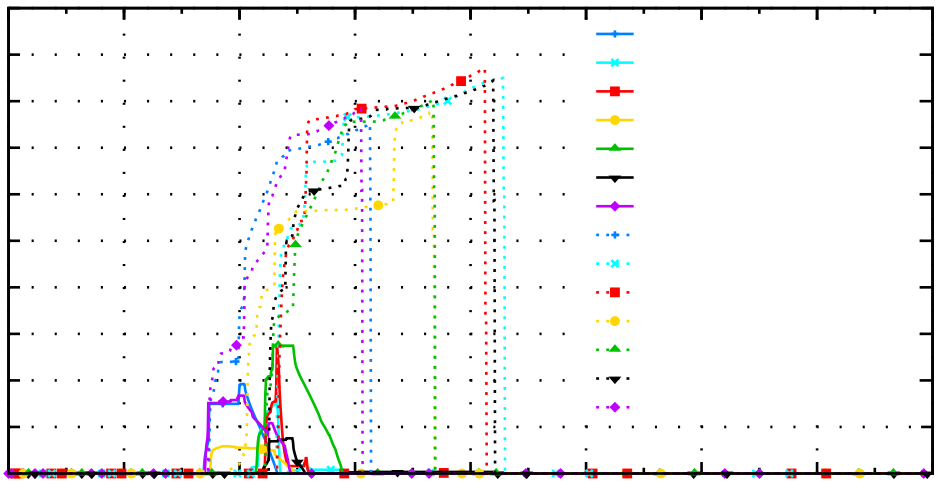

Figure 5. Mass of solid debris (PD) and molten corium (MAG) in the lower plenum.

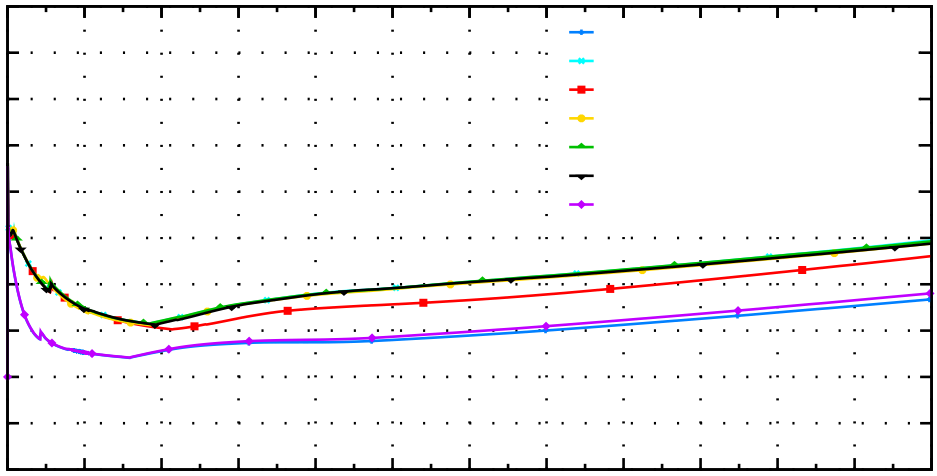

Figure 6. CTMT pressure (absolute).

Table I. Timing of main events and evaluation of iodine release at time of RPV lower head failure

Event	pH 5	pH 6	pH 7	pH 8	pH 9	pH 5 SPRAY	pH 9 SPRAY
Initial event (G-LOCA)	0 s						
Start of FP release	48 s					53 s	
1st material slump in lower plenum	3556 s	3617 s	2869 s	3473 s	3584 s	3037 s	3055 s
Lower head failure	7706 s	7432 s	6605 s	6631 s	7558 s	5634 s	5498 s
Total mass of iodine leaked into CTMT	3381 g	3380 g	3385 g	3588 g	3401 g	3799 g	3522 g

4.2 Results of the CTMT-phase of the integral ASTEC calculation

The CTMT-phase iodine behavior is shown in Fig. 7 to Fig. 10 , covering I^- and I_2 in the CTMT sump and the total gaseous iodine in the atmosphere for all seven simulations. Across the pH-only variants (no spray), the total mass of gaseous iodine (Fig. 10) remains relatively similar despite the chemically driven increase of dissolved I_2 in the sump at lower pH, with only minor run-to-run scatter attributable to numerical noise. Fig. 7 confirms the expected decrease of I^- with decreasing pH for the spray-variation cases. For the no-spray variations, the differences are not discernible due to the selected scale. The slight deviation observed for the pH 8 case results from the higher iodine release compared with the other no-spray simulations. Fig. 8 shows the corresponding increase of dissolved I_2, consistent with enhanced radiolytic oxidation in more acidic conditions. However, this shift in sump speciation does not translate into higher total gaseous iodine mass in the CTMT atmosphere when sprays are not active. The prevailing thermodynamic conditions during G-LOCA – elevated pressure and high relative humidity – limit the liquid-to-gas mass transfer of I_2.

Toward the end of the transient, cyclic rises and drops of gaseous iodine are observed, driven by alternating heating and cooling of small sump that developed within the steam-generator compartments as a consequence of primary coolant depletion. These temperature oscillations periodically enhance or suppress I_2 transfer across the water–atmosphere interface, producing the small late-time fluctuations.

When the CTMT spray system is activated, the thermodynamic state of the CTMT is markedly altered and the iodine response changes accordingly. The spray-induced wash-down of airborne aerosols provides a continuous pathway for transferring iodine species from the containment atmosphere to the sump, resulting in substantially higher I^- inventories (Fig. 7) in the CTMT sump in the spray-assisted scenarios than in the corresponding non-spray variants. This leads to a higher dissolved I^2 inventory in the sump (Fig. 9). In parallel, spray operation leads to a decrease of pressure and increase of mass transfer from the sump to the gas phase resulting in higher amount of total gaseous iodine compared to the non-spray cases, with the effect most prominent at pH 5 (Fig. 10).

The spray cools the atmosphere, decreases pressure, and lowers relative humidity, thereby increasing the driving force for I_2 volatilization and enhancing mass transfer from the sump to the gas phase; at the same time, spray wash-down redistributes aerosol-borne iodine to the sump, reinforcing the coupling between chemistry and transport. In the paired spray simulations at pH 5 and pH 9, the pH-dependent chemistry remains evident – greater radiolytic oxidation at pH 5 yields more dissolved I_2 and, under spray-modified conditions, a higher gaseous-iodine level – highlighting the combined influence of sump chemistry, CTMT thermodynamics and resulting FP mass transfers on the iodine source term.

Overall, the CTMT-phase results confirm the expected pH-dependent shift in sump chemistry, characterized by decreasing I^- and increasing dissolved I_2 at lower pH, while also demonstrating that these chemical changes do not, under non-spray conditions, lead to a higher total gaseous iodine mass in CTMT atmosphere. The higher CTMT pressure without spraying limits liquid–gas transfer. When sprays are activated, the modified conditions enhance I_2 volatilization due to decreased pressure in the CTMT, and the concurrent wash-down redistributes aerosol-borne FPs increasing the sump iodine inventory, resulting in a clearer rise in gaseous iodine, particularly at low pH.

5. CONCLUSIONS

This work employed the integral code ASTEC V3.1.2 to assess iodine behavior in a VVER-1000 CTMT during a cold-leg G-LOCA (2x850 mm) scenario, with a focus on sump chemistry and on the thermodynamic evolution of the CTMT during spray operation, together with the associated FP mass transfer mediated by the spray droplets. Seven integral simulations were performed: five with fixed sump pH values (5–9) and two spray-assisted with fixed values pH 5 and pH 9. The analysis targeted I^- and I^2 in the CTMT sump and the total gaseous iodine inventory in the CTMT atmosphere.

The results confirm the expected pH dependence of sump speciation: as pH decreases, radiolytic oxidation shifts iodine from I^- toward dissolved I^2. However, in non-spray configurations this chemical shift does not translate into a larger total iodine gaseous mass in the CTMT atmosphere. Under G-LOCA conditions, elevated pressure and high relative humidity constrain liquid–gas mass transfer of I_2, thereby stabilizing the gaseous iodine level across pH-only variants.

Activation of the CTMT spray system markedly changes the iodine response. Spray-modified pressure – temperature–humidity conditions enhance I_2 volatilization and interfacial mass-transfer, while spray wash-down increase the sump-borne iodine inventory (notably I^-). The combined effect is a clear rise in gaseous iodine present in the CTMT atmosphere (relative to the non-spray cases), most pronounced at pH 5, consistent with stronger radiolytic production of I_2 at lower pH. These findings highlight that the gaseous iodine source term is co-controlled by sump chemistry, together with CTMT thermodynamics and iodine mass transfer – reflected by changes in iodide (I^-) concentration due to entrainment by droplets from an operating containment spray system rather than by chemistry alone.

The author is aware of the uncertainties present in the study of ASTEC integral simulations. Variations between runs are limited to differences in timing of RPV failure in the order of tens of minutes and leak magnitudes at the percent level. These differences in timing and leak magnitudes reflect numerical scatter inherent to large coupled integral calculations but do not alter the qualitative accident course. In line with

previous observations, the scatter of results indicates rather the inherent sensitivity of integral SA codes to the input parameters, underlining the value of complementary uncertainty and sensitivity analyses when interpreting source-term outcomes.

To further reduce the influence of numerical scatter and to better isolate CTMT-phase phenomena, it is therefore advisable to perform stand-alone CTMT (module CPA) calculations with SOPHAEROS module, using as boundary conditions the coolant, hydrogen, and fission-product releases to the CTMT, together with the thermodynamic evolution, obtained from the in-vessel phase computed by the integral model.

From a modelling and severe-accident-management perspective, the study supports three practical best-practice messages. First, representing sump chemistry alone is insufficient to project gaseous iodine; accurate prediction requires concurrent, time-consistent treatment of CTMT thermodynamic states that govern liquid-gas mass-transfer and possible FPs mass transfers, linked e.g. spray operation. Second, when sprays are credited, their dual role – thermodynamic modification of the CTMT atmosphere and relocation of aerosol-borne FPs to the sump – should be modelled explicitly, as it can both increase gaseous iodine via enhanced I_2 volatility and simultaneously increase sump inventories via wash-down. These conclusions provide a consistent basis for refining ASTEC applications not only to VVER-type plants and for prioritizing measurements and operator guidance related to CTMT thermodynamics and sump chemistry in late-phase accident management.

Third, even though Fig. 7 shows a pronounced increase in I^- concentration in the sump when sprays are operating under alkaline conditions (which should be the high-priority mitigation measure), Fig. 10 demonstrates that the gaseous iodine level in the CTMT atmosphere remains low regardless of spray operation, owing to the basic additives present in the sump. This finding clearly indicates that spray operation does not adversely affect the iodine source term as long as the sump is maintained sufficiently alkaline.

NOMENCLATURE

CTMT	Containment

COMPUTATIONAL FRAMEWORK

Code

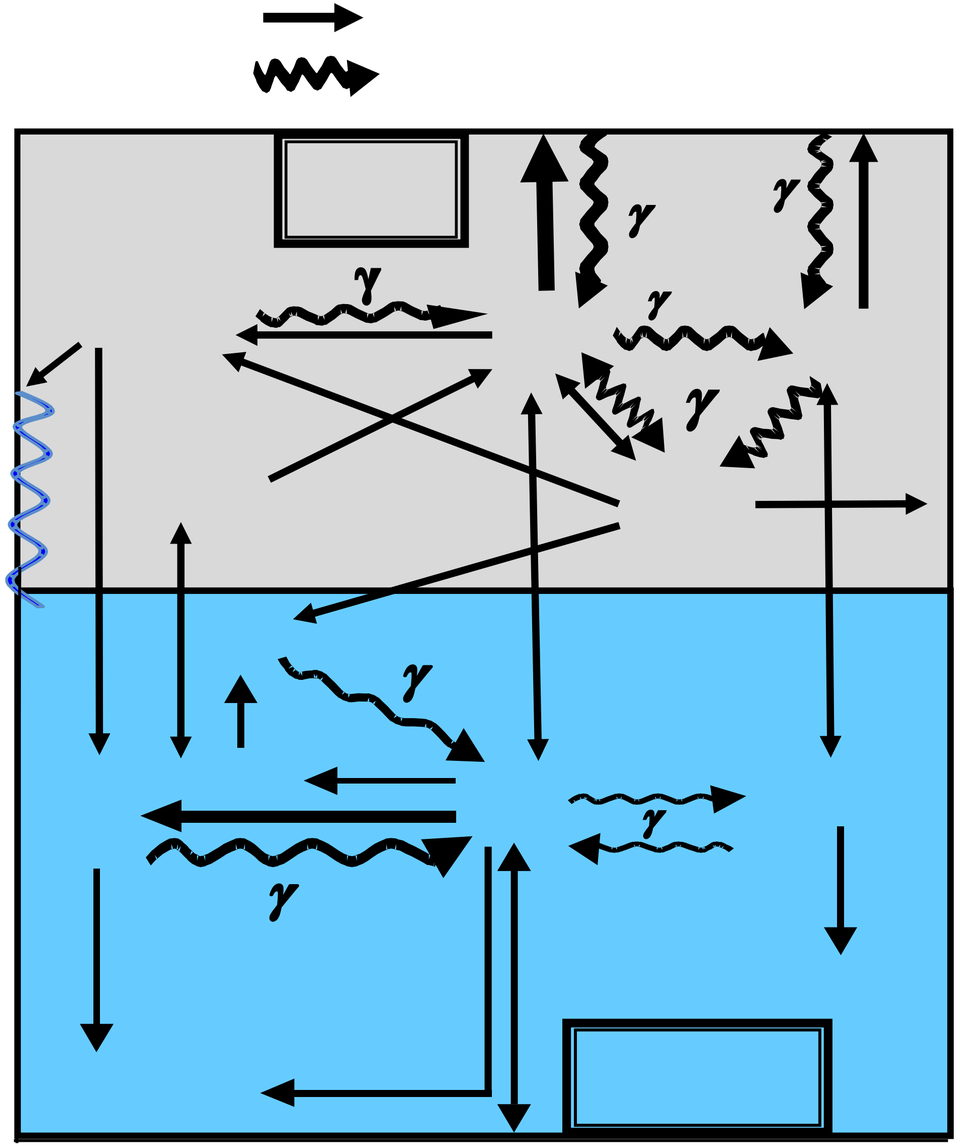
- ASTEC Code V3.1.2
- Used modules includes: ICARE, CESAR, CPA, DOSE, ISODOP, MEDICIS and SOPHAEROS

UJV model

- Integral model of NPP with VVER-1000 reactor including core, primary circuit and a CTMT that includes a water sump, located at the very bottom of the CTMT
- Simulations cover the full G-LOCA on cold leg sequence from in-vessel degradation with fission product (FP) release and transport within primary circuit
- Focus is placed on physical processes, mass transfer, and the subsequent chemical and radiolytic transformations of FPs within the containment (CTMT)

SOPHAEROS MODULE

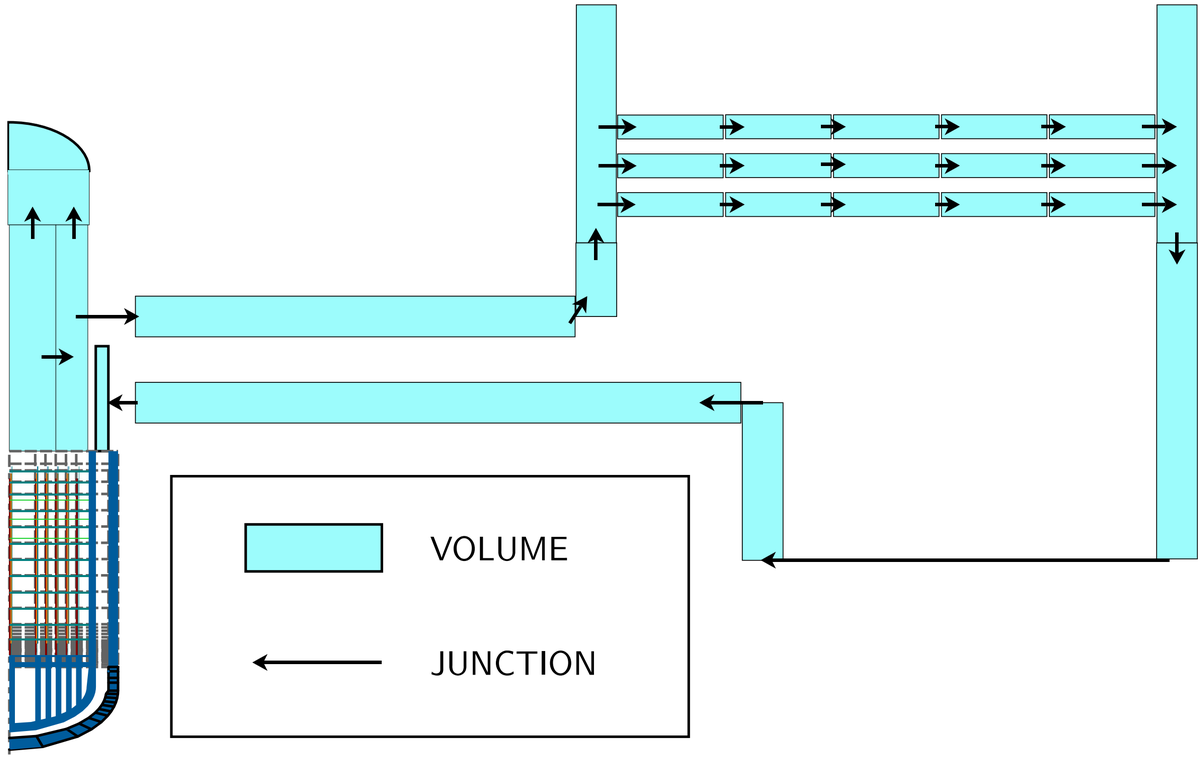
- The model accounts for a wide range of transport and interaction processes that may occur within CTMT including:
  - Deposition
  - Condensation
  - Agglomeration
  - Physical and chemical sorption,
  - Resuspension
  - Evaporation
  - Aerosol dynamics
  - Mass-transfer reactions across several domains (liquid, atmosphere, walls).

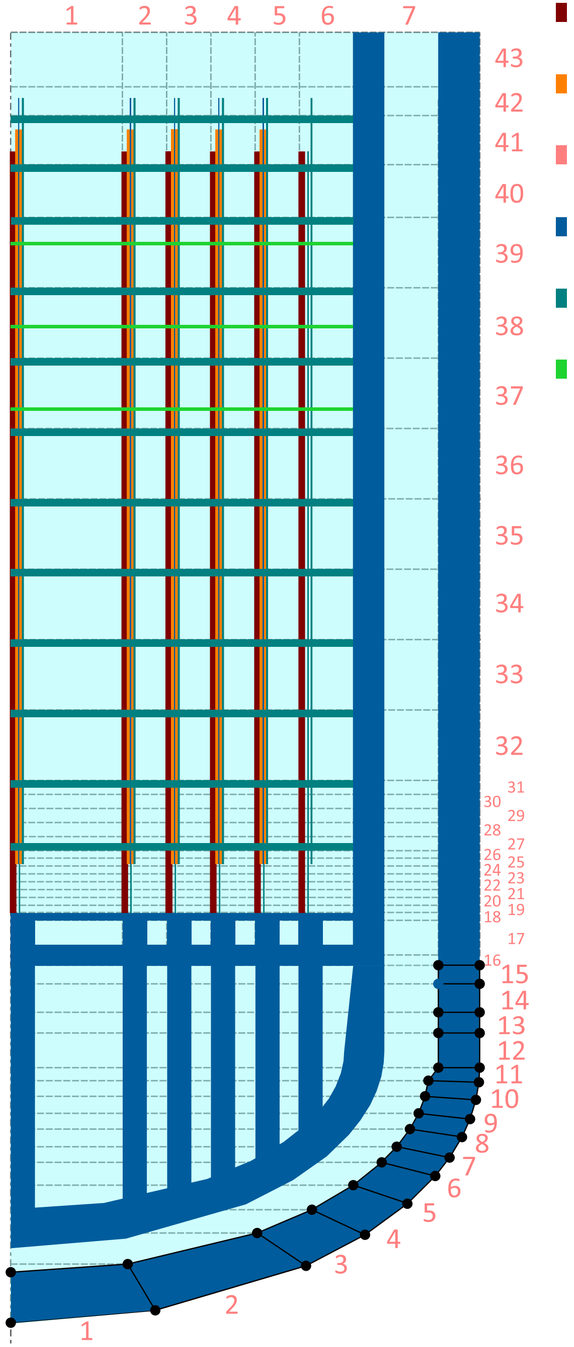


Thermal, radiolytic and mass transfer reactions of iodine considered in SOPHAEROS: O. Coindreau and F. Kremer, *ASTEC SOPHAEROS module: User manual,* IRSN, Paris, France (2021)

REACTOR VESSEL MODEL

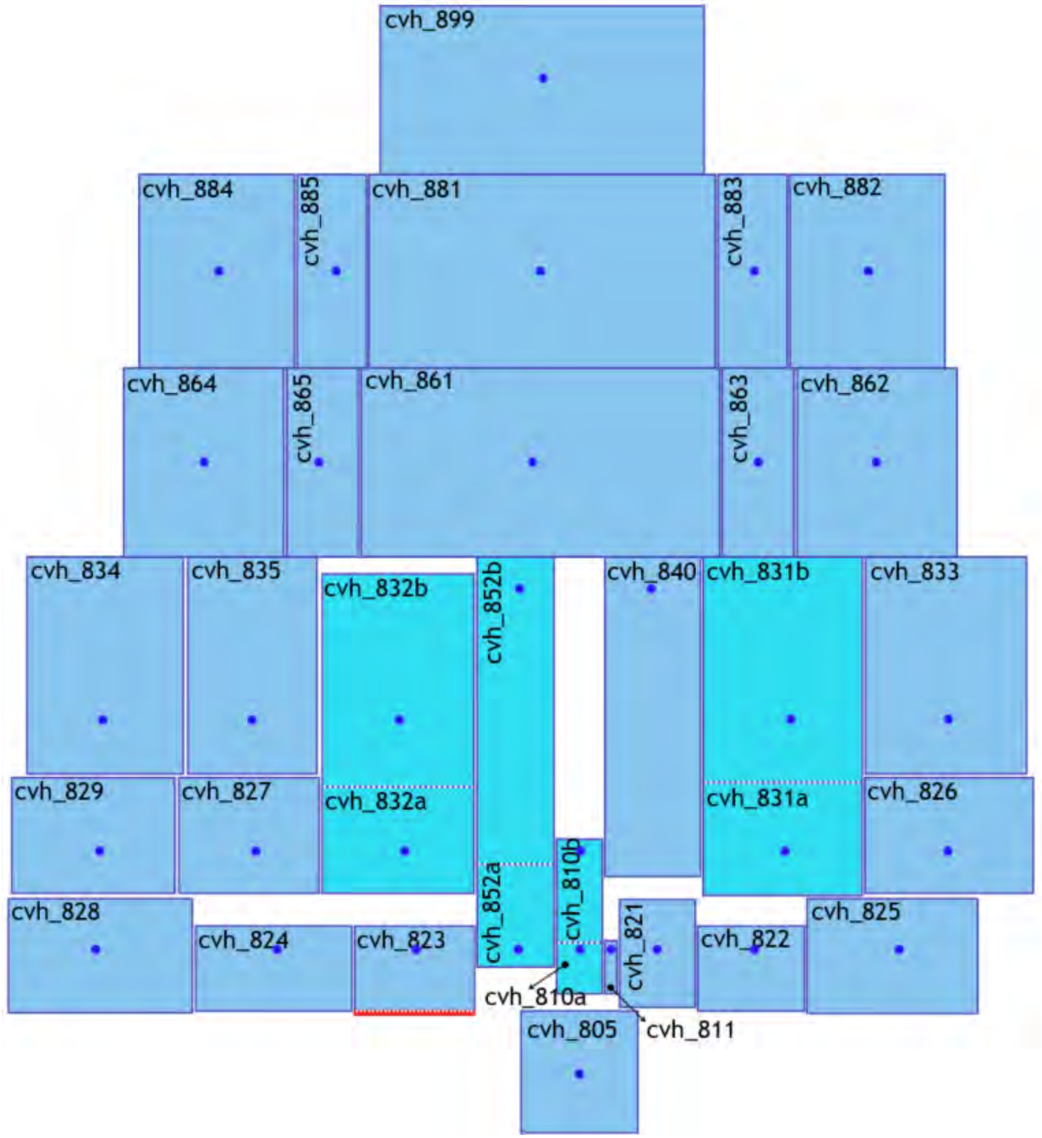
- Core is divided in 6+1 radial channels and 32 axial levels
- Primary circuit is represented by a 1+2+1 loop configuration, providing pathways for FP transport from the reactor to the CTMT





CONTAINMENT MODEL

- CTMT model is made of 36 zones
- Model includes CTMT spray system and water sump, located at the very bottom of the CTMT (cvh_805), which collects liquid from the CTMT compartments
- In addition, coolant leakage from the primary circuit into the CTMT leads to the formation of smaller local water pools within the steam generator compartments.
- Model of CTMT includes distinct surface families (painted, concrete, steel)



SENSITIVITY ANALYSIS METHODOLOGY

NUCLEAR RESEARCH INSTITUTE

- **Speciation**: distribution of an element among defined chemical species (oxidation states, compounds, complexes) in a system
- Assesment of chemical forms is importat for Source Term prediction
- Chemical speciation of FP (especially iodine) is highly sensitive to containment conditions

Key influencing parameters:

- **Temperature, Pressure and Relative humidity**– affect condensation, volatility, and mass transfers.
- **pH and Redox Potential** – influence solubility and chemical transformation (e.g. I- to I_2).
- **FP Concentrations** – determine reaction pathways and product stability.
- Due to system complexity, predictions are uncertain; experimental data (e.g., from the Phebus program) provide essential validation

SENSITIVITY ANALYSIS FOCUSED ON IODINE SPECIATION

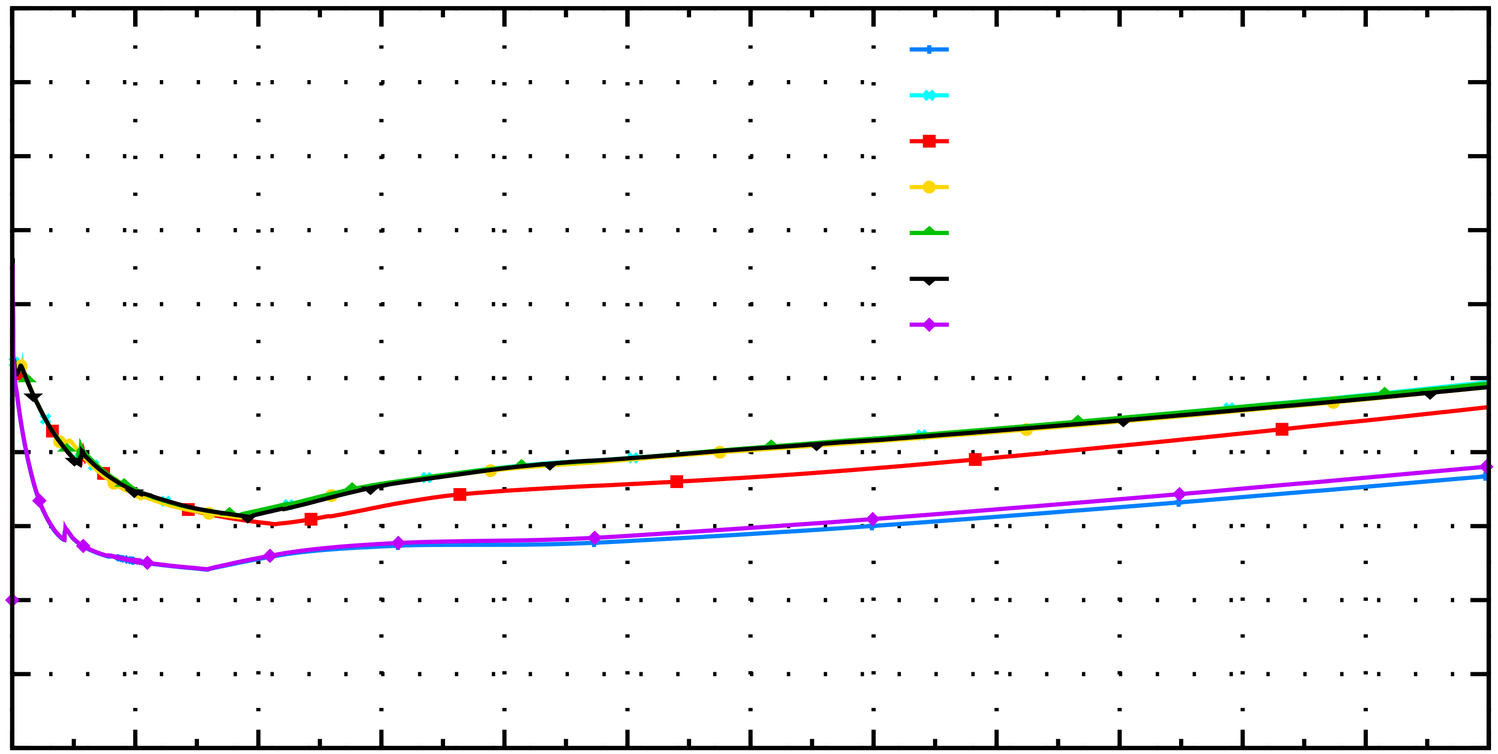
NUCLEAR RESEARCH INSTITUTE

- UJV model of VVER-1000 in ASTEC integral code was used for the analysis
- The only varied parameter was **pH of the CTMT sump**

- Total of **7** ASTEC simulations were performed to evaluate the influence of CTMT sump chemistry and thermodynamic conditions on iodine speciation during G-LOCA scenerio
  - **5** calculations covered the pH variation in CTMT Sump in Range 5–9
  - pH varied within range of achievable conditions through presence of boric acid (H_3BO_3) and potential operator-initiated additives such as KOH or hydrazine (N_2H_4).
  - **2** additional simulations were conducted with activation of the CTMT spray system, applied only to the boundary cases at pH 5 and pH 9 to provide a clear contrast

- Expected increase in gaseous iodine with decreasing pH
- Expected increase in I_2 and CH_3I and decrease in I^- in sump water due to radiolytic oxidation ($I_2 \leftrightarrow I^-$) in more acidic environment (lower pH)
- Expected decrease in pressure and temperature in CTMT with spray system activated

CTMT PRESSURE (ABSOLUTE)



TIMING OF MAIN EVENTS AND EVALUATION OF IODINE RELEASE AT TIME OF LOWER HEAD FAILURE

Event	pH 5	pH 6	pH 7	pH 8	pH 9	pH 5 SPRAY	pH 9 SPRAY
Initial event (G-LOCA)	0 s						
Start of FP release	48 s					53 s

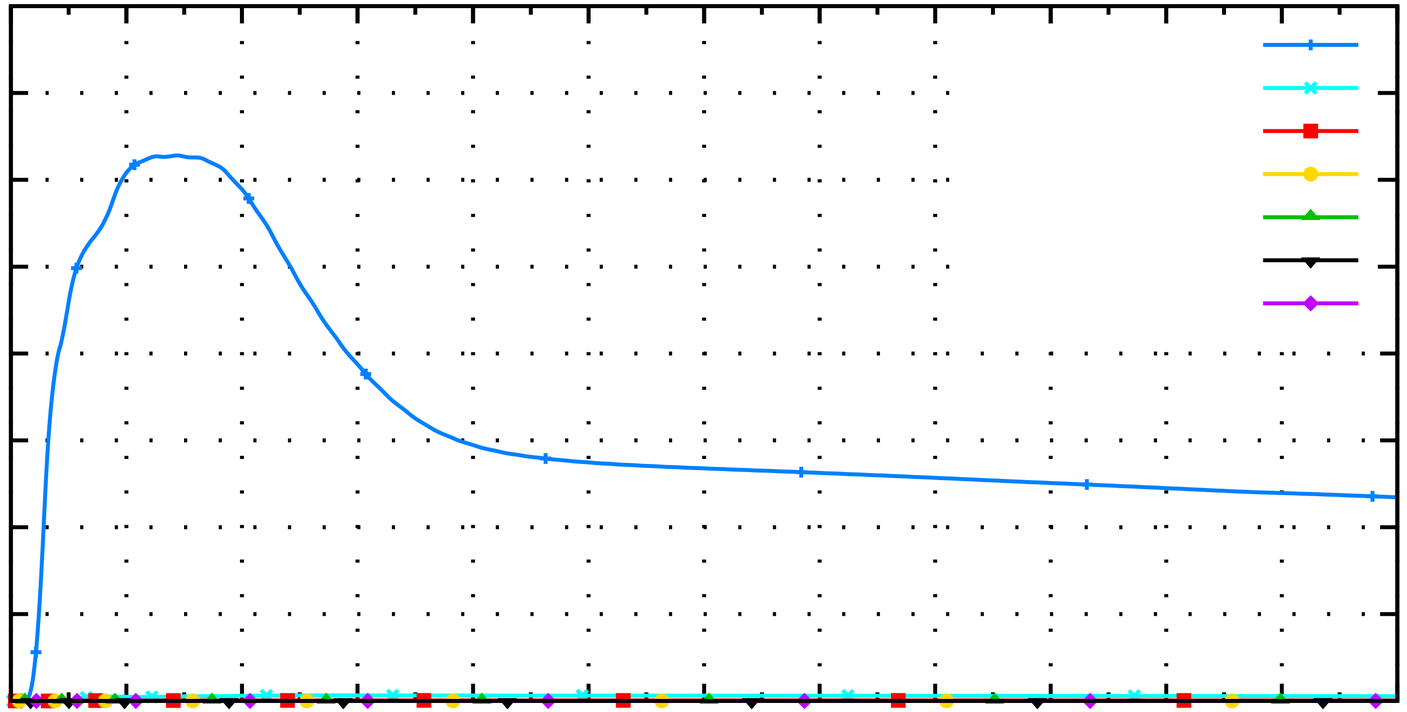
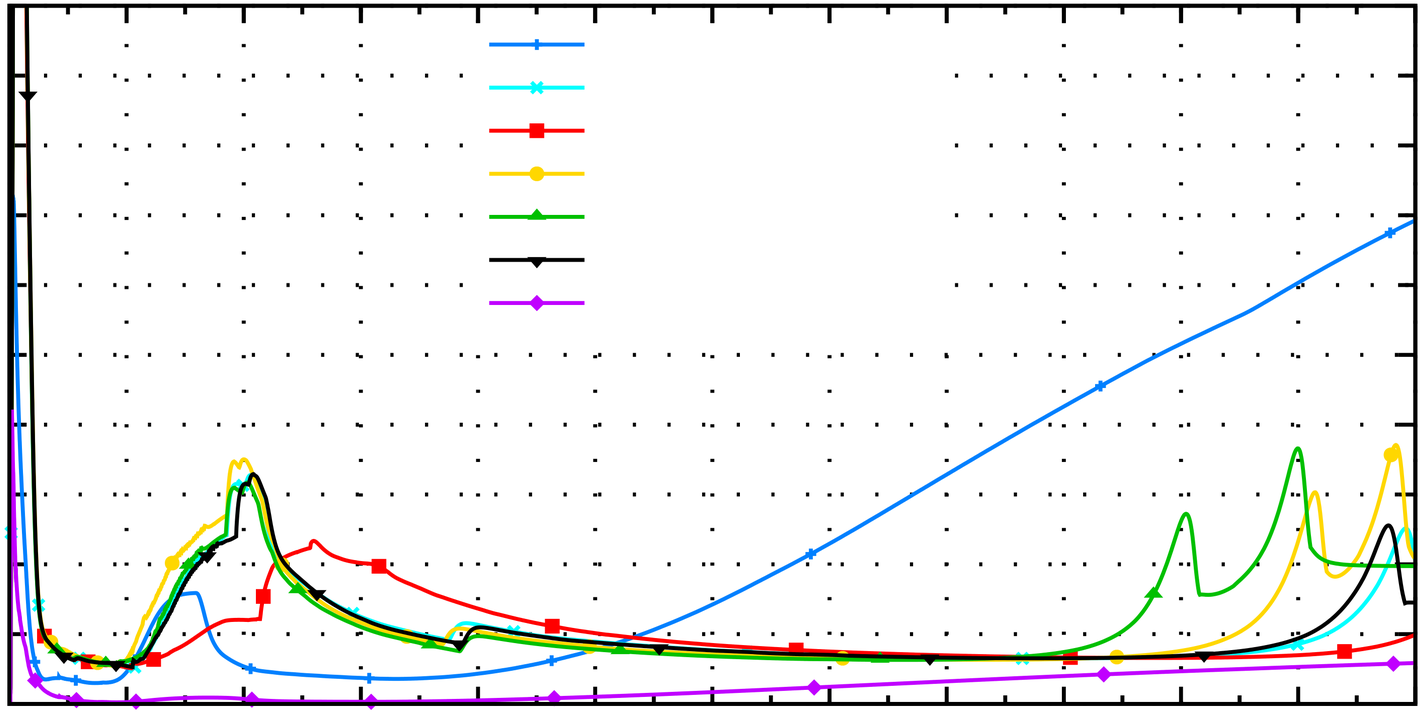
NUCLEAR RESEARCH INSTITUTE

MASS OF I_2 IN THE SUMP OF CTMT INCLUDING SIMULATIONS WITH SPRAY SYSTEM ACTIVATED



NUCLEAR RESEARCH INSTITUTE

TOTAL MASS OF GASEOUS IODINE (MAINLY I_2 AND CH_3I) IN CTMT



SENSITIVITY ANALYSIS CONCLUSION (1/2)

NUCLEAR RESEARCH INSTITUTE

Sump chemistry effect confirmed

- With pH decrease, radiolytic oxidation shifts iodine from I^- toward dissolved I_2

Non-spray configurations

- In non-spray configurations this chemical shift does not translate into a larger total iodine gaseous mass in the CTMT atmosphere
- Under G-LOCA conditions, elevated pressure and high relative humidity constrain liquid–gas mass transfer of I_2, thereby stabilizing the gaseous iodine

Spray configurations

- Activation of the CTMT spray system alters thermodynamic conditions and enhance I_2 volatilization and interfacial mass-transfer
- Spray wash-down increase the sump-borne iodine inventory (notably I^-)
- Combined effect is a clear rise in gaseous iodine present in the CTMT atmosphere (relative to the non-spray cases), most pronounced at pH 5

SENSITIVITY ANALYSIS CONCLUSION (2/2)

NUCLEAR RESEARCH INSTITUTE

Uncertainties

- Analysis showed variations between simulation runs
- Differences are mainly observed in RPV failure timing (tens of minutes) and leak magnitudes (percent level).
- These differences reflect numerical scatter inherent to large coupled integral calculations but do not alter the qualitative accident course

→ Uncertainty and sensitivity analyses are essential for reliable interpretation of source-term predictions

→ To further reduce the influence of numerical scatter and to better isolate CTMT-phase phenomena, it is therefore advisable to perform stand-alone CTMT calculations using boundary conditions obtained from the in-vessel phase computed by the integral model

CLOSING REMARKS

- Accurate prediction of gaseous iodine requires coupled modelling of sump chemistry and CTMT thermodynamic conditions.
- Spray systems have a dual effect: they modify CTMT atmospheric conditions and relocate aerosol-borne fission products to the sump.
- Under alkaline conditions, spray operation does not significantly increase the iodine source term in the CTMT atmosphere.
- Maintaining sufficiently alkaline sump conditions is a key mitigation measure for limiting gaseous iodine release.
- To reduce the influence of numerical scatter it is advisable to perform stand-alone CTMT calculations using boundary conditions obtained from the in-vessel phase.

EVALUATION OF THE EFFECT OF DIFFERENT TRANSPORT PATH MODELLING ON FP BEHAVIOUR IN AC²/ATHLET-CD

L. Tiborcz, T. Hollands
Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) gGmbH
Boltzmannstr 14, Garching, Germany
livia.tiborcz@grs.de; thorsten.hollands@grs.de;

ABSTRACT

One of the main foci of a severe accident analysis is the fission product (FP) and aerosol behaviour needed for the evaluation of a possible source term. The models implemented in system codes are highly complex, derived from limited available data and must rely on several other modules (like thermal-hydraulic) for their BC/IC. Therefore, it is of high importance to assess their capabilities, to identify possible limitations and to ensure their reliability. Within AC²/ATHLET-CD, a new modelling approach is under development and verification in order to be able to include the full core and consequently to close the transport path modelling within the RCS. This is expected to have an effect on the FP behaviour simulation particularly in cold leg break scenarios, during which transport through the reverse flow direction with lower expected retention rates can impact the amount of FP predicted to reach the containment.
In this paper a postulated cold leg LOCA concurrent with an SBO in a generic German PWR is investigated. Next to the traditional modelling the new developments are tested and compared to the standard modelling approach. The focus is on the FP behaviour in the RCS and subsequently the release into the containment.

1. INTRODUCTION

One of the main questions during a potential severe accident concerns the radiological impact on the environment. Even before the accident at the TMI-2 nuclear power plant, probabilistic safety assessments were carried out to evaluate the radiological consequences of a possible release of radioactive material into the environment [1,2]. At the time, however, a lot of experts considered studies of severe accidents to be largely theoretical. After the accident advanced research programs were started to investigate and better understand the phenomena during a severe accident scenario. Ever since the accident in the Fukushima Daichii NPP a special focus is put on severe accident analysis and source term evaluation.

Severe accident system codes such as AC², MELCOR, or ASTEC model highly complex phenomena using empirical and semi-empirical approaches. Their objective is to deliver dependable results within a reasonable computational time for the analysis of accident evolution, covering both in-vessel and ex-vessel processes up to the determination of the source term [3]. These code use simplifications both in their physical models as well as in their geometrical representation of the facility in order to keep computational time manageable.

In the present paper, an advanced modelling approach under development within SAFT (module responsible for simulating fission product (FP) and aerosol behaviour in the reactor cooling system AC²/ATHLET-CD) is presented. The approach extends the representation of transport paths to be able to include the core region, thereby enabling the closed representation of the reactor cooling system (RCS) loop including the possibility of reverse flow. This is expected to increase the consistency of the modeling (e.g. mass balance of FPs) also to better represent scenarios during which there is a reverse flow or where transport and deposition processes within the core region could significantly impact the predicted source term. This modelling approach, though with a slightly older AC² version, has been investigated in a coupled scenario (with explicit modelling of the containment), focusing on source-term uncertainty analysis [4]. In this paper, we provide a detailed comparison between the simple and advanced modelling approaches while applying only ATHLET-CD.

2. MODELLING APPROACH

2.1. ATHLET-CD and SAFT

The AC² code system [5,6], developed by GRS, integrates the system codes ATHLET, ATHLET-CD, and COCOSYS together with the numerical toolkit NUT. It provides a best-estimate analysis framework for the comprehensive simulation of nuclear power plant behaviour across the full range of operating transients, design-basis accidents, and design extension conditions up to severe accidents, including the evaluation of the source term.

SAFT is the module responsible for the simulation of transport and deposition of fission products within the RCS. The module is simulating the main vapour-phase (e.g. homogenous/heterogenous nucleation, condensation/evaporation, sorption, etc.) and aerosol phenomena (e.g. different agglomeration processes, Brownian diffusion, settlings, thermophoresis, diffusiophoresis, remobilisation processes, etc.) with the help of mechanistic and semi-empirical models. The basis of the chemical modelling is the calculation of thermodynamic chemical equilibrium utilizing a transient approach based on the deviation from the equilibrium. Changes in carrier gas mass due to chemical reactions or decay as well as the energy involved in chemical reactions are neglected. The chemical speciation is influenced by temperature, carrier gas composition, and concentration of the different gaseous species. The required boundary conditions, such as thermohydraulic parameters, surface temperatures, and release data, are supplied by various ATHLET and ATHLET-CD modules.

In the currently accepted modelling approach for SAFT [7], modelling within the core region is not recommended and is provided only for test purposes. In the thermal-hydraulic (TH) module, the core region is modelled using a multi-channel approach, usually interconnected via so-called cross-connection objects (CCOs), yielding a quasi-3D representation of the core [8]. This is highly important and beneficial for thermal-hydraulic calculations, but it requires careful consideration from the SAFT network point of view. This issue is addressed by taking cross-connection objects (CCO) into account. These objects are essentially a series of junctions without any physical volume that connect the control volumes (CVs) of different thermal-fluid objects (TFOs). At the same time, if cross-connection objects are present at other locations in the SAFT network, they are also automatically taken into account. This can lead to “dead-ends” within the SAFT network: a thermal-hydraulic connection exists, but no fission product (FP) transport modelling is considered (as shown in Figure 1). This situation is similar to an open-ended SAFT loop, where the SAFT network is not closed and, consequently, at least one thermal-hydraulic connection is not accounted for in the FP transport modelling. This might cause issues such as FP accumulation in the last CV or mass-balance errors due to mass losses. These cases are handled in the same way as previous dead-ends: an artificial outlet is created for information purposes. This information can then be used by the user to decide whether the representation of the transport paths should be modified to include the neglected parts of the network (note

that this strongly depends on the thermal-hydraulic conditions). These considerations underline the need for correct and comprehensive modelling of the transport network and a solid thermal-hydraulic representation.

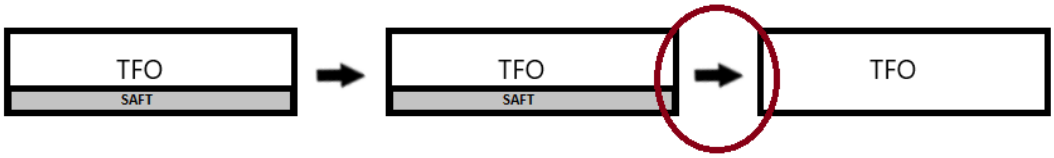

Figure 1 Dead-End in SAFT transport path [9]

Another important aspect when considering the core region is the location of the fission product (FP) source. In the recommended modelling approach (without the core region) FPs are assumed to appear in the upper plenum and are subsequently transported further through the system. This approach may overestimate the amount of FP entering the upper plenum/hot leg, however, it is considered conservative. In the proposed advanced approach, an algorithm is implemented in SAFT to extract the exact location of cladding and fuel failure(s) within the core region (based on dedicated clad and fuel failure models in ATHLET-CD), accounting for both axial and radial positions. Moreover, the approach is not limited to the initial cladding burst; subsequent failures are also identified and included as additional FP source locations. At the moment, however, the melting of structures within the core region is not yet taken into account. The melting and relocation of structures affect both the available surface area and its position, on which deposition could occur. It is planned to address these effects in the future, not only using the concentric core region approach (traditional TH modeling approach of the core), but also the more advanced one subdividing the core rings into radial slices for better representation of local effects [10].

2.1. Postulated Accident Scenario

As the proposed modelling approach is expected to affect the predicted source term under cold-leg LOCA conditions, a cold-leg medium-break LOCA has been selected as the reference scenario. The analysis is performed for a generic German PWR (Konvoi) concurrent to a station blackout (SBO). The plant has a four-loop configuration, as illustrated in Figure 2, with nominal parameters summarized in Table I. No active severe accident management measures are assumed. Due to the SBO, all active heat removal systems are unavailable, and only the hydro-accumulators are assumed to operate as designed. The break is assumed to occur at the lowest point of the loop seal in Loop 1, which also contains the pressurizer, with a break area of 200 cm^2.

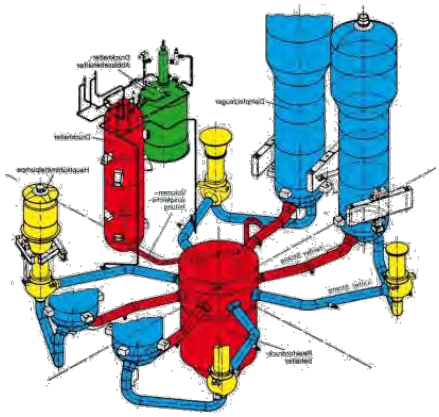

Figure 2 Schematic representation of generic German PWR [11]

Table I Nominal operational conditions [11]

Parameter	Nominal value
Reactor Power	3750 MW_{th}
Operational pressure	157 bar/65 bar
Core inlet/outlet temperature	292°C/325°C
# of fuel assemblies	193
Coolant mass flow rate	19.8 t/s

The ATHLET-CD model of the reactor contains a detailed representation of all loops, including the steam generators (SG) and their secondary sides (Figure 3). The core region is represented by four parallel channels, to each a concentric core ring with a rod object is assigned. The rings have outer diameters of 0.8 m, 1.15 m, 1.49 m, and 1.72 m, representing 14,700 rods in the innermost ring and 14,400 rods in each of the three outer rings. The number of control rods per ring, from innermost to outermost, is 312, 768, and 384, with no control rods placed in the outermost ring. Axially, the active core is divided into 20 nodes. Critical discharge is calculated using ATHLET's built-in CDR1D model. The fission product release is described by Arrhenius-type correlations, which for certain elements account for the partial pressure as well. Transport and deposition of the fission products are modelled within the SAFT module. Previous versions of the input deck have been used successfully in other investigations with earlier AC^2 versions, see e.g. [4,12].

In case of the basis calculation ("simple") the transport path is modelled starting from the upper plenum. From here Loop1 (loop with the break location) is only represented up to the break position in the SAFT network: upper plenum → hot leg →SG → cold leg → break location. In this case five SAFT-Loops are defined due to the representation of the SG (different length U-tubes are grouped into three sets to better represent the heat exchange between the primary and secondary sides) and the upper plenum. The model comprises 19 TFO-objects, 81 control volumes and 87 junctions.

In case of the advanced approach, the core region, lower plenum and downcomer are also taken into account in the SAFT network, allowing the transport paths to be fully closed. The resulting transport network include a forward direction—upper plenum → hot leg → steam generator (SG) → cold leg → break location—and a reverse direction—core → lower plenum → downcomer → cold leg → break location. Within the core region, the bypass channel is also included in order to preserve mass balance. In total, ten SAFT loops are defined, accounting for multiple core channels, the aforementioned SG modelling, and a detailed representation of the upper plenum. The model comprises 27 TFO-objects, 191 control volumes and 270 junctions. In this configuration, there is no thermal-hydraulic dead-end from SAFT point of view, unlike in the simple approach, where at the break position the fluid might flow in the direction of the core (or from it), which is not considered in the FP transport, thus resulting in a sink/neglected source. (Note: A handling mechanism is implemented in SAFT to address such dead-end situations in the simplified approach by providing an estimate of the associated losses.)

Figure 4 shows the schematic representation of the two modelling approaches. In the simple version only the path indicated in orange is included, whereas in the advanced approach the path shown in purple is additionally taken into account, together with the explicit representation of the core region.

Simulations have been carried out with a developer version based on the current release AC^2-2025 [6]. Altogether 30,000 s have been simulated including a 5,000 s steady-state normal operation at the beginning to ensure stable initial conditions prior to the initiation of the transient.

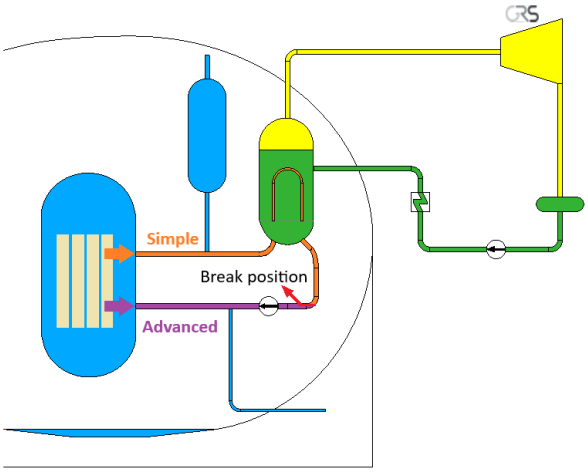

Figure 4 Schematic view of the FP transport modelling

3. RESULTS

As the FP and aerosol transport module heavily relies on the thermal-hydraulic conditions provided by several other ATHLET modules, establishing a robust base-case simulation is essential. It is worth mentioning that, thanks to the modular nature of AC^2, the models describing the severe accident phenomena can be introduced in a stepwise manner. Consequently, both the development of the input deck and the required preparation time can be significantly reduced by avoiding the simultaneous inclusion of all models. This approach facilitates input verification, shortens the time required to identify input errors, and helps prevent compensating modelling errors.

The timing of the main events predicted by ATHLET-CD is summarized in Table II. Following the initiation of the break, the SCRAM signal leads to an almost immediate shutdown of nuclear power generation. The resulting loss of coolant causes a quick primary side depressurization (Figure 5.), while the secondary side depressurization is much slower. This is due to the limited heat transfer caused by the nearly stagnant vapor filling the primary-side U-tubes. The initially single-phase liquid discharge under critical flow conditions is followed by two-phase flow; at later stages of the accident, single-phase vapor flow becomes dominant. Given the assumption of a station blackout (SBO), active emergency core cooling systems, such as high- and low-pressure injection systems, are unavailable, leaving only the hydro-accumulators operational. At the same time, due to the severity of the initiating event, the accumulators are rapidly depleted without having a noticeable effect on the system pressure. The results are consistent with those reported in [4].

Table II Accident sequence

Event	Time [s]
Break opening	5,000
Start of ACC	5,884
1st clad failure	8,859
1st CR failure	9,207
1st fuel rod failure	9,842/10,068*
Start of relocation to LP	10,106/10,181*
LP failure	13,613/13,557*

*simple/advanced

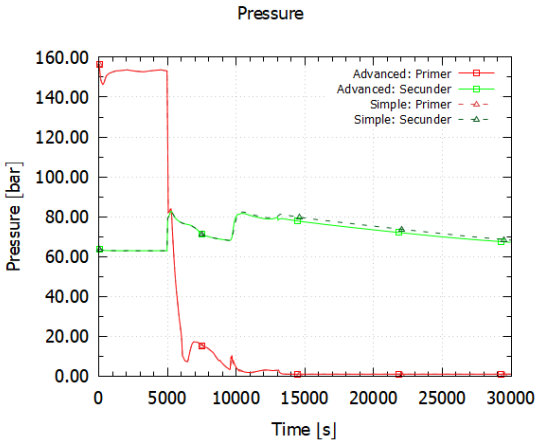

Figure 5 Pressure in RCS

The temperature within the core region initially decreases (no heat generation, but sufficient coolant) but gradually increases as the accident progresses due to the decreasing core liquid levels. The cladding oxidation excursion occurs at approximately ~9,200 s, quickly producing almost all the predicted hydrogen of about ~600 kg, corresponding to about 11.5% of the cladding being oxidised. As shown in Figure 6 slight differences are observed between the predictions obtained with the two modelling approaches. These differences arise because SAFT not only receives information from other thermal-hydraulic modules but also feeds back calculated quantities (e.g. deposition), into the system. These quantities form the basis, for example, for determining the location and distribution of the decay heat source within the RCS. This, in turn, affects the thermal-hydraulic response, which then influences fission product behaviour, and so on.

As the core progressively melts, the molten material is eventually relocated to the lower plenum (LP). This relocation first occurs at about ~10,100 s, based on a corium mass criterion as shown in Figure 7. The lower plenum is predicted to fail at around ~13,600 s, releasing the accumulated molten material into the containment. Continued core melting results in additional relocation of material to the lower plenum, which is then instantaneously relocated into the containment. The containment is not modelled in detail in this study (i.e. no COCOSYS model); it is only represented as a pressure-enthalpy boundary condition at the break location.

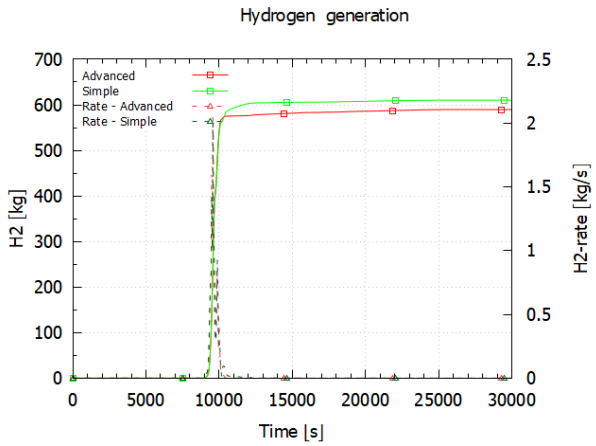

Figure 6 Hydrogen production

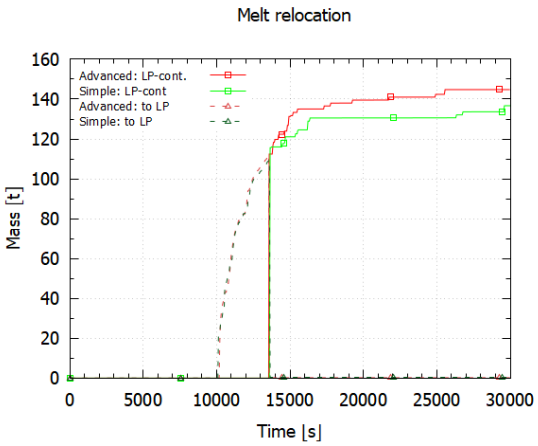

Figure 7 Melt relocation to LP/containment

The FP release starts with the first cladding failure, which occurs in both modelling approaches at the same time at 8,859 s. As shown in the thermal-hydraulic results, the simulation results are identical for both modelling approaches up until the 1st cladding burst occur, after which the FP and aerosol module is activated. At this stage, the release is dominated by the gap release (fill gas and highly volatile fission product in gaseous form).
The release from the core is calculated by the module FIPREM based on Arrhenius type correlations. In case of the simple modelling approach all FP and aerosol released from the core are assumed to enter the upper plenum and are then transported through the hot leg, SG, and cold leg to the break location. Depending on the thermal-hydraulic conditions, this assumption may lead to an overestimation of the actual amount of FPs and aerosols reaching the upper plenum.

In the advanced modelling approach, the release occurs at the exact position of the cladding failure within the core region, as determined by the mechanical models predicting cladding rupture. In this scenario, the first failure occurs in the innermost core ring (hottest) at the 18th axial position, which corresponds to ~3.2 m within the active core. This approach allows an exact localization of each FP source within the core region and enables the consideration of local thermal-hydraulic conditions for potential retention or reverse flow. Furthermore, by closing the FP and aerosol transport loop possible circulation within the RCS can be accounted for. In the simulation results, we see that there was intermittent flow reversal in core channels. In addition, we also observe retention of fission products in core regions, at least temporarily, and even for volatile FPs such as caesium and iodine.

From a radiological point of view the two most important FPs are iodine and cesium, therefore in the following we will focus on these two. Figure 8 shows the iodine and cesium mass balances within the RCS. Both being highly volatile, the release amounts to almost the entire initial inventory (i.i.) in case of iodine, and about ~90 i.i.% for cesium. As can be seen, the release from the core shows no difference in case of iodine, whereas in case of cesium a slightly smaller amount is released when applying the advanced modelling approach. This is not the case when considering the overall behavior within the RCS. A much higher retention is predicted with the simple modelling approach compared to the advanced one. Consequently, higher release rates into the containment are predicted using the advanced modelling approach. For iodine 60 i.i% is predicted to reach the containment with the advanced modelling approach, compared to about 45 i.i% with the simple approach. In case of cesium this difference is even more pronounced: 52 i.i% reaches the containment as opposed to 22 i.i%. These differences have a significant impact on the potential radiological consequences to the environment.

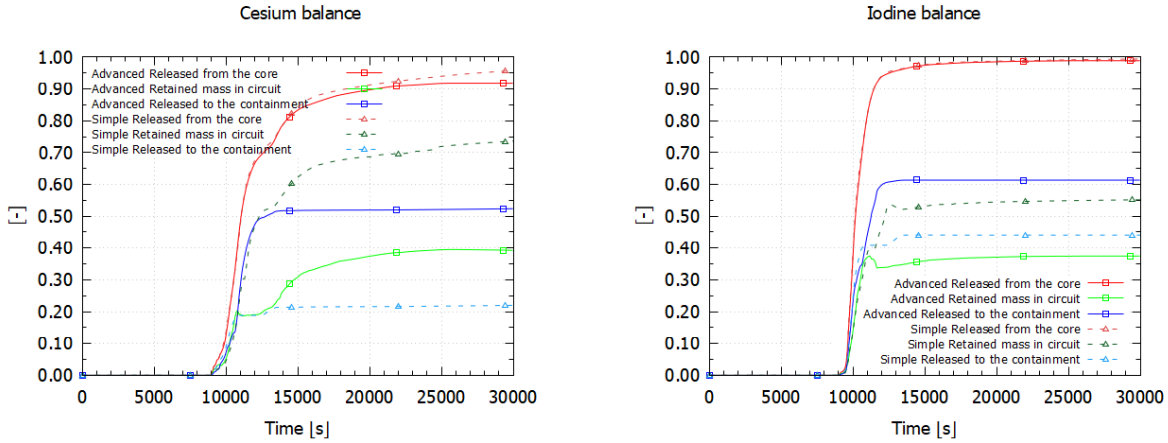

Figure 8 Cs and I balance

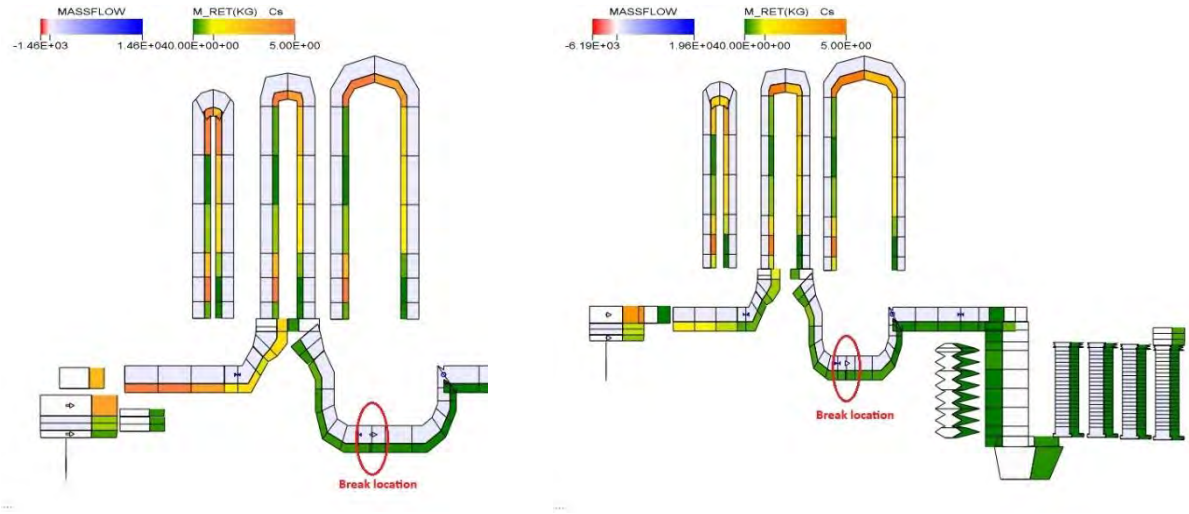
Figure 9 depicts the mass flow rates and retained caesium masses within the RCS for both the simple as well as for the advanced modelling approaches (qualitative predictions for iodine are similar, therefore only caesium is shown here). The scale for the retention on the figures is the same in both cases for easier comparison. In Figure 9 the highest deposition can be observed within the SG and at the beginning of the hot leg in both cases. This is due to the geometrical features (bends) and the temperature distribution (high ΔT). In the advanced approach, however, the absolute retention values are lower, while additional retention is observed within the core region, including the lower plenum and downcomer. This underlines the complex nature of FP transport phenomena and their modelling. On the one hand the advanced modelling approach leads to lower predicted deposition in the hot leg/SG area (partially due to the fact, that less FPs reach the hot leg, as some are directly transported in the other direction through the downcomer into the cold leg), on the other hand deposition is predicted to also occur in regions previously neglected (core region). Which aspect is more dominant is determined by the thermal-hydraulic conditions, underlining once again the importance of TH-modelling.



simple advanced

Figure 9 Mass flow rate and retained Cs mass at 30,000s - simple vs advanced modelling

Figure 10 depicts the global retention mechanism for all FPs within the SAFT-network. In both cases thermophoresis and settling are predicted to be responsible for the majority of FP retention. However, their relative importances differ between the two approaches. Applying the simple approach thermophoresis initially dominates, particularly during the oxidation excursion, but its importance rapidly decreases and settling accounts for approximately 80% of retention After the LP failure, the significance of settling gradually decreases but remains the dominant mechanism, contributing roughly 55% of the total retention by the end of the simulation time.

Applying the advanced modelling approach, no such dominance of settling can be observed. Thermophoresis remains the dominant mechanism throughout the oxidation period and continues to govern FP retention until the LP failure, although its absolute contribution is lower than in the simplified approach. Even after this time point, settling, though predicted to be the more dominant mechanism, never reaches the same relative significance it showed in case of the simple modelling approach. This is mainly due to the relevance of temperature gradients in the core region and in the downcomer facilitating thermophoretic processes. It's interesting to note that by the end of the simulation the relative dominances are the same, but as seen in Figure 9, the actual predicted retention values are significantly different.

Bend and eddy impaction also contribute, particularly in the advanced modelling approach due to the presence of geometrical bends when taking into account the core region/down-comer. Nevertheless, their overall significance is much lower, even negligible on the long run.

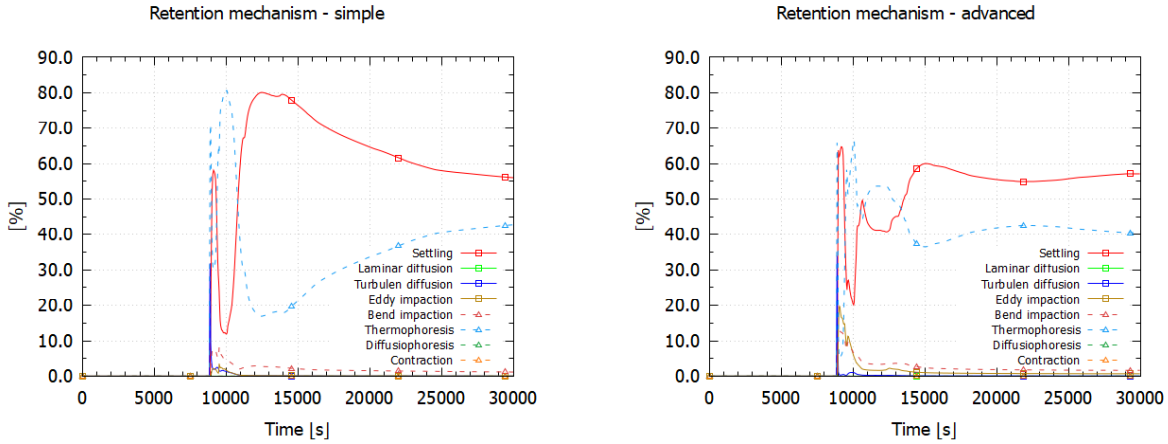


Figure 10 Retention mechanism - simple vs advanced modelling

Figure 11 shows the void fraction and the retained cesium within the core region and downcomer at 14,000 s using the advanced modelling approach. This illustrates the previously discussed retention within the lower plenum and downcomer. At certain times, retention can also be observed within the core region, however, due to remobilization processes, these are later transported further. Nevertheless, this retention within the core region affects both the timing and the composition of the source term. Additionally, depending on the thermal-hydraulic conditions, FPs can reach the break location via the downcomer, a pathway neglected in the simplified modelling approach.

The ratio of fission products (FPs) reaching the break location in each direction (forward through the hot leg and reverse through the downcomer) is another important question. Unfortunately, at the moment, no standard SAFT module output provides this information directly. However, when looking at the normalized carrier fluid rates (1/s) derived based on thermal-hydraulic conditions and directly used in the transport calculation to determine the FP mass transport (kg/s) between consecutive control volumes and through the outlet(s) we can get an idea. Figure 12 shows the normalized carrier gas flow rates in SAFT-Volume #37, where the break is located. The red line indicates the junction on the left side (SG side), the green line the junction on the right side (downcomer side), while the blue line represents the outlet. The positive flow rate in each junction corresponds to the direction indicated by the arrows (left → right, outlet). The negative value of the green line indicates a significant reverse flow rate from the direction of the downcomer, which contributes substantially to the break flow rate up to approximately the LP failure time. It should be noted that this only demonstrates the source term contribution from this reverse flow direction but does not provide a direct measure of the actual FP mass transported through this direction. Nevertheless, when combined with the retention information shown in Figure 9, it can be concluded that the reverse flow contributes significantly to the source term entering the containment

At later times, no reverse flow is predicted. However, in the simplified modelling approach, FPs transported from the normal flow direction through the cold leg back into the core region would be neglected (and lost), whereas this is accounted for in the advanced modelling approach.

The LP failure introduces a new challenge, as it creates an additional opening from the RCS into the containment. It should be noted that by the time LP fails most volatile and semi-volatile FPs have already been released, leaving predominantly low-volatile FPs in the RCS and the core melt. This dynamic change in the transport path is currently not modelled and should be addressed in future work. This would also be useful e.g. when coupling AC^2 with structure-mechanic codes determining the failure position and area within the RCS. Additionally, at present, no release from the molten material is calculated, which further contributes to the uncertainty of the results. These modelling limitations should be addressed in future developments work.

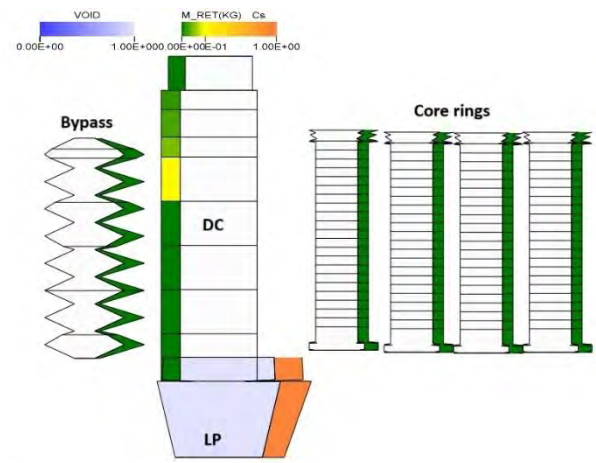

Figure 11 Advanced modelling - void and retained Cs mass in the core region at 14,000s

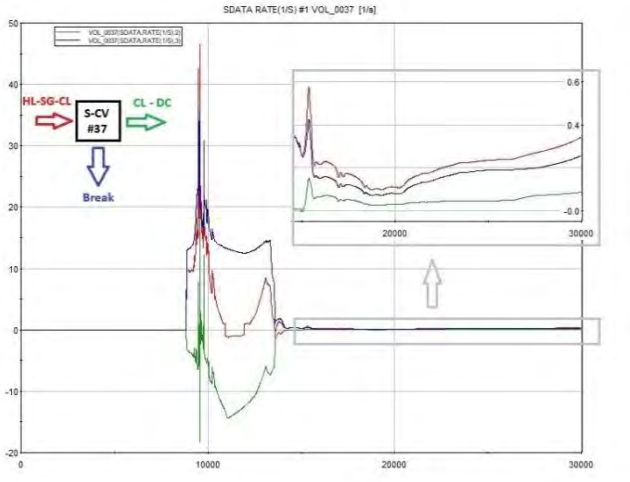

Figure 12 Rate (1/s) values in Saft CV#37 (break location)

Another limitation of the current modelling is the inability to simulate remobilization and transport in fully water-filled CVs. At the moment, only soluble compounds are transported in water. Future developments should address remobilization and entrainment processes in fully water-filled CVs. This limitation is only relevant when the void fraction is zero, as occurs at certain time points in the lower plenum (LP) in our study. Nevertheless, in other scenarios involving reflooding, severe accident management (SAM) measures, or similar conditions, this will be a significant factor in determining the release to the containment and thus the possible source term to the environment.

4. SUMMARY AND OUTLOOK

In the present study, the application of a new advanced modelling approach for FP and aerosol transport within the RCS has been shown. The advanced approach enables explicit modelling of the core region, allowing the SAFT loop to be fully closed. This is expected to have a non-negligible impact on source term evaluation in specific accident scenarios. As a demonstration, a medium-size cold-leg LOCA concurrent with a SBO has been selected and successfully simulated using both the simplified and advanced modelling approaches for a SAFT network.

The results showed a significant influence on the FP and aerosol behaviour between the two approaches. Not only did the dominant retention mechanism change, but the quantitative prediction of the source term is also affected. Applying the advanced approach in the given scenario, a substantially higher release into the containment has been simulated compared to previous calculations [13,14], while thermophoresis played a more significant role in retaining FPs.

At the same time, some shortcomings in code capabilities have also been identified, which should be addressed in the future. The first is the availability of output information: currently, no direct data are provided to determine the exact value of the source term from each flow direction. Another important area for future development is the modelling of remobilization and transport of non-soluble FPs in fully water-filled CVs.

Finally, it should be noted that including the core region significantly increases the number of SAFT loops and CVs, leading to higher computational demand. In our case, applying the advanced modelling approach (with all other modelling assumptions unchanged) resulted in a 70% increase in required computational resources. Therefore, the use of such an approach should always be weighed against the potential gain in the accuracy of predicted results. However, GRS is currently integrating core degradation models, including SAFT, into ATHLET, which enables the use of parallelization for these models as well and will impact the feasibility of such detailed analyses.

ACKNOWLEDGMENTS

The development and the validation of AC^2 is sponsored by the German Federal Ministry for the Environment, Climate Action, Nature Conservation and Nuclear Safety (BMUKN) on the basis of decisions by the German Bundestag within several projects.

Evaluation of the effect of different transport path modelling of FP behavior in AC^2/ATHLET-CD

L. M.-Tiborcz, T. Hollands

ERMSAR 2026 - The 12th European Review Meeting on Severe Accidents Research, Madrid, Spain, 18-22.05.2026

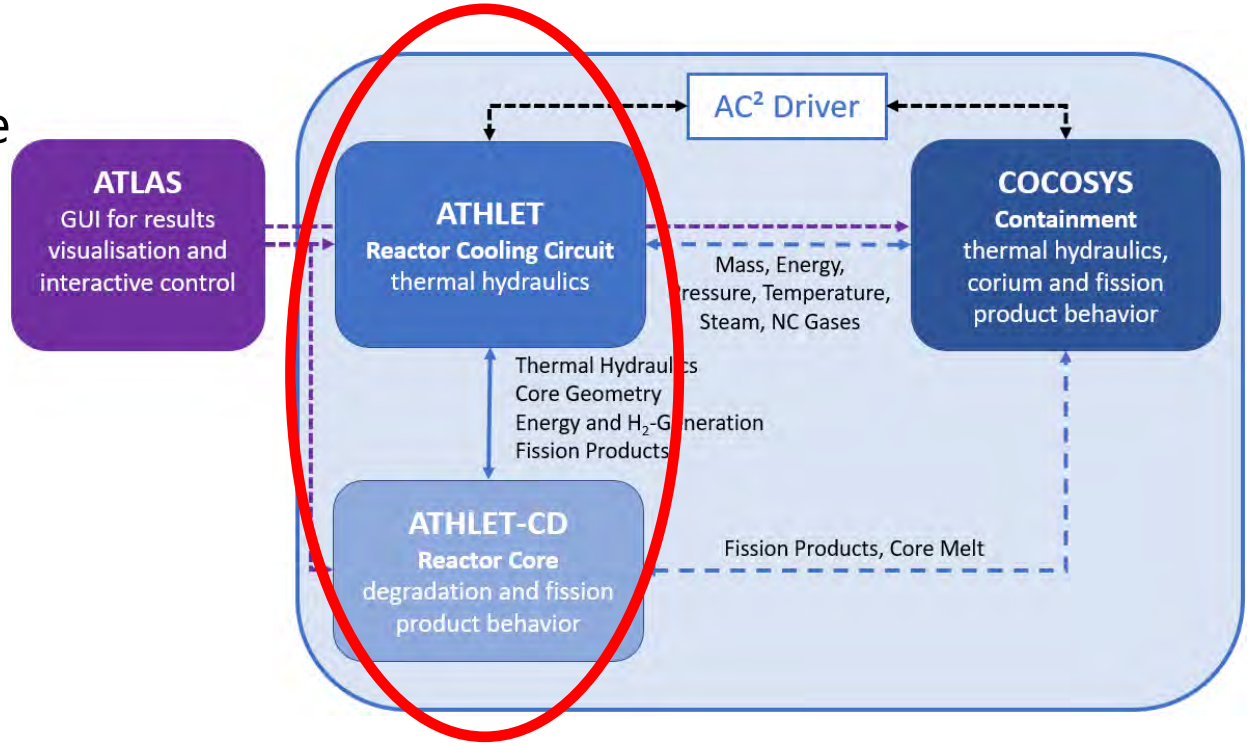
AC² – Severe Accident System Code

General Features:

- complex systems and phenomenology
- empirical, semi-empirical models
- reliable data vs reasonable time frame

AC² - in- and ex-vessel phenomena
- normal operation → severe accidents

Importance of code evaluation and V&V



The transport module SAFT (Simulation of Aerosol and Fission Product Transport)

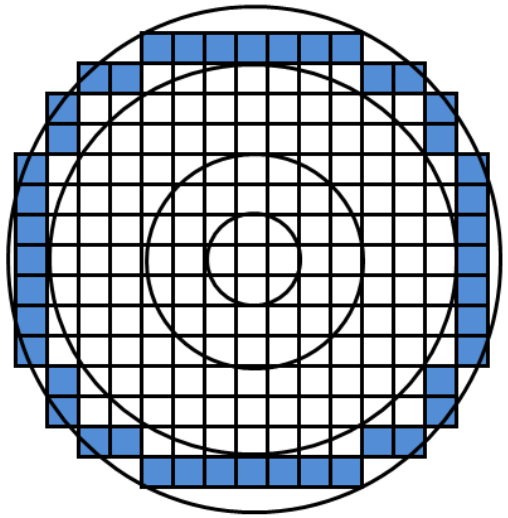
- FP and Aerosol behaviour within the RCS
- Vapour phase and aerosol phenomena
- Mechanistic; semi-empirical modelling
- Simplified chemical modelling
- Boundary conditions (TH params, surface T/material, etc.) ← ATHLET, ATHLET-CD

Aerosol	Vapour
• Agglomeration: gravitational, Brownian diffusion, turbulent diffusion • Deposition mechanism: Brownian diffusion, turbulent diffusion, eddy impaction, sedimentation, thermophoresis, diffusiophoresis, impaction in bends, deposits in flow contractions • Remobilization: revaporisation, mechanical resuspension • Dedicated pool scrubbing model for SG flooded secondary side	• homogeneous nucleation • heterogeneous nucleation • condensation/revaporisation • wall sorption • vapour phase chemistry • preliminary model for kinetics of gas chemistry

Modelling the core region in SAFT

- AC2 2025.0 – recommendation is to start from the UP
- Development and verification work: to include the Core region

→ possibility to close the FP transport loop

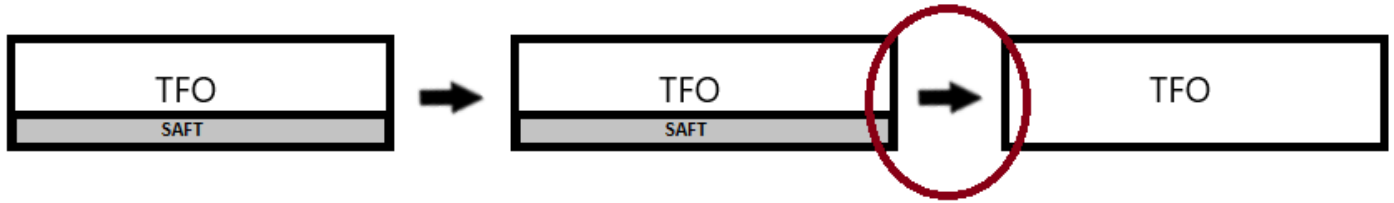


Subdivision into concentric rings

Source: Lovasz, L. 2026. *Further development of ATHLET-CD for simulations of accidents with asymmetrical characteristics. Dissertation - submitted*. PSS.

- TH: concentric core rings + Cross Connection Objects
- SAFT: modelling based on TH (ATHLET) modelling

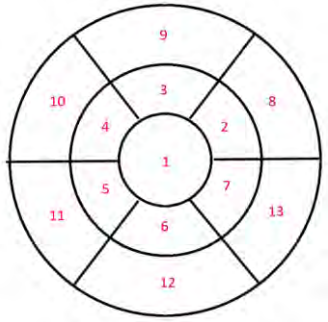
- CCO can be included all/nothing approach
  - All/None Core rings
  - CCO outside the core region



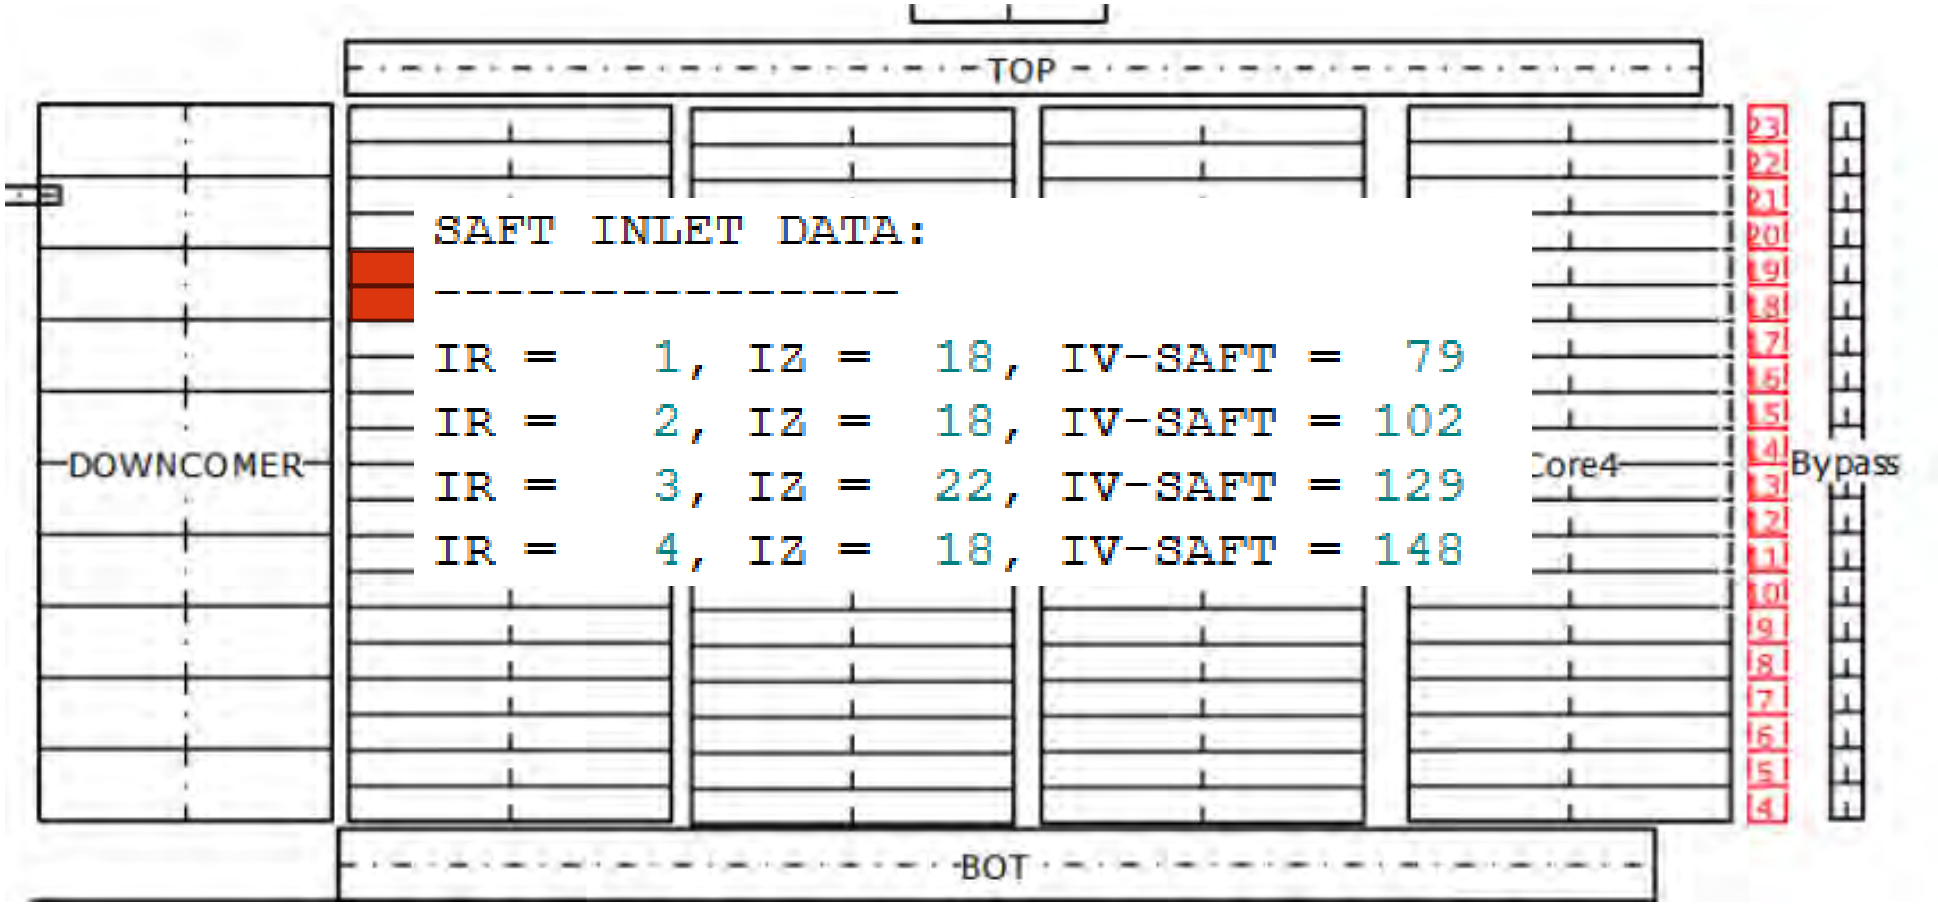
SAFT “Dead End”

Source term positioning

- Traditional modelling approach:
  - All FP appears in the 1st SAFT CV (based on TH modelling)
  - Some overestimation may be present, but generally “conservative”
- New modelling approach:
  - Separate routine to find exact position of FP release
  - Exact axial/radial position
  - Based on cladding failure (dedicated model within ATHLET-CD)
  - Not only initial, but subsequent failures are also identified
- Missing:
  - Consideration of the melting of structures
    - Planned to be addressed in the future
    - Not only for concentric rings, but also for more flexible nodalisations



Source term positioning



Postulated Accident Scenario

- Cold leg medium break LOCA with SBO (200 cm^2)
- Generic German PWR (Konvoi)
- No SAM actions

Parameter	Nominal value
Reactor Power	3 750 MW_{th}
Operational pressure	157 bar/65 bar
Core inlet/outlet temperature	292 °C/325 °C
# of fuel assemblies	193
Coolant mass flow rate	19.8 t/s

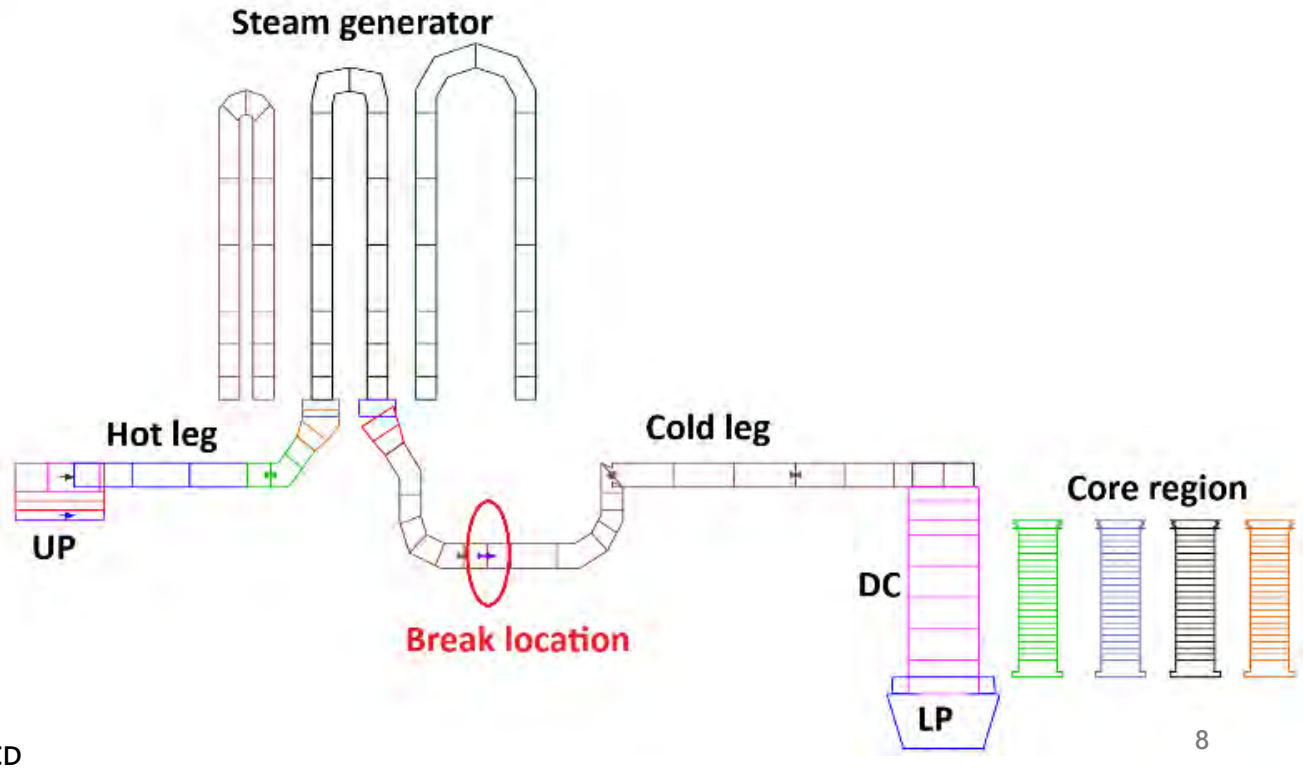
Modelling approach in AC²/ATHLET-CD

- Model based on previous simulations
- Full, 4 loop TH reactor model
- 4 core rings/rods with realistic radionuclide inventory
- FP release: Arrhenius type correlation f(T, p_p*)
- SAFT – 2 options
  - Simple
  - including core region with
    fully closed SAFT-Loop
- 217 TFOs, over 600 junctions



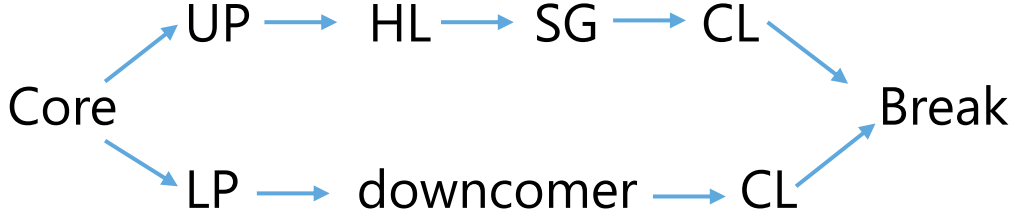
Different transport path modelling approaches

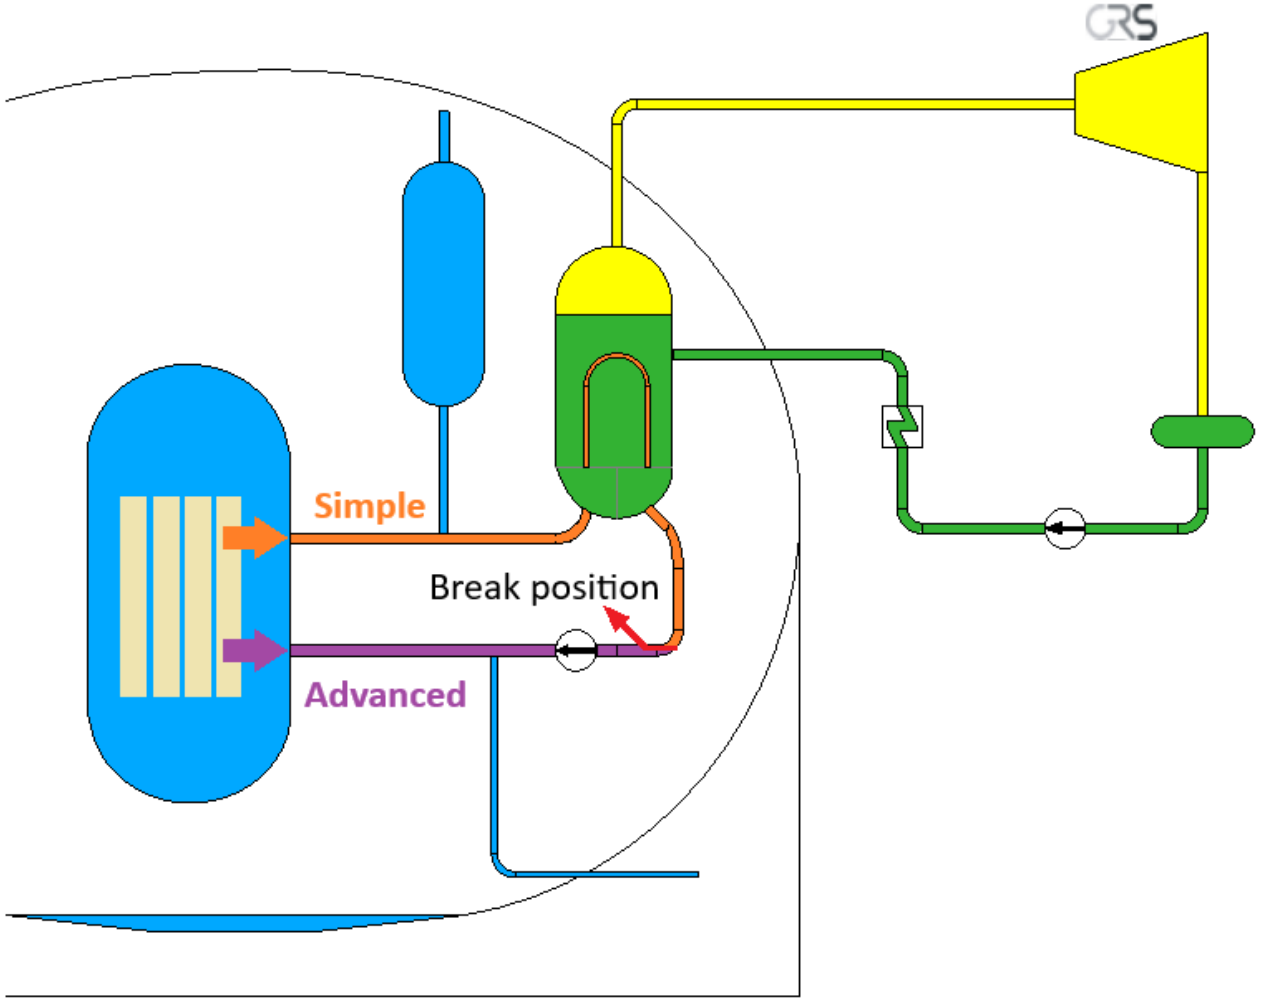
Old modelling approach (simple):

UP → HL → SG → CL → Break

New modelling approach (advanced)

includes also the core region

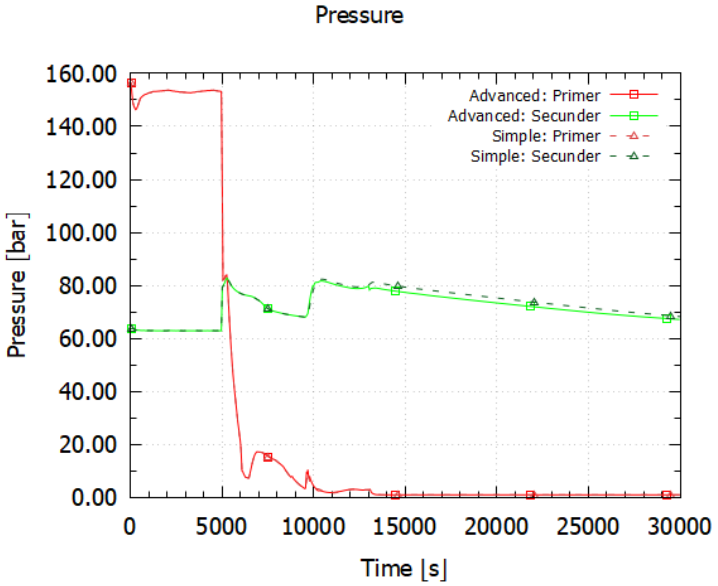


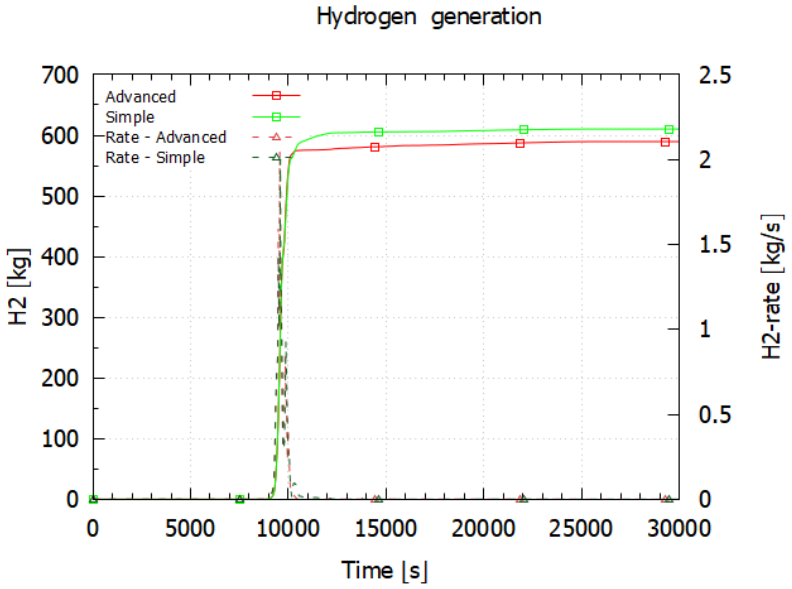


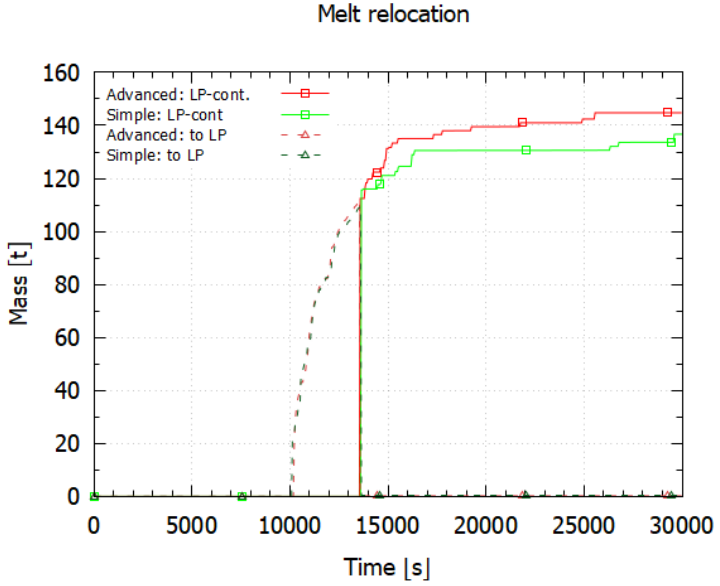
Simulation results

Event	Time [s]
Break opening	5,000
Start of ACC	5,884
1st clad failure	8,859
1st CR failure	9,207
1st fuel rod failure	9,842/10,068*
Start of relocation to LP	10,106/10,181*
LP failure	13,613/13,557*

*simple/advanced







FP behavior

1st FP release ~8,859s in both cases

Traditional modelling approach:

higher retention in RCS

FP → starts in UP

Advanced modelling approach

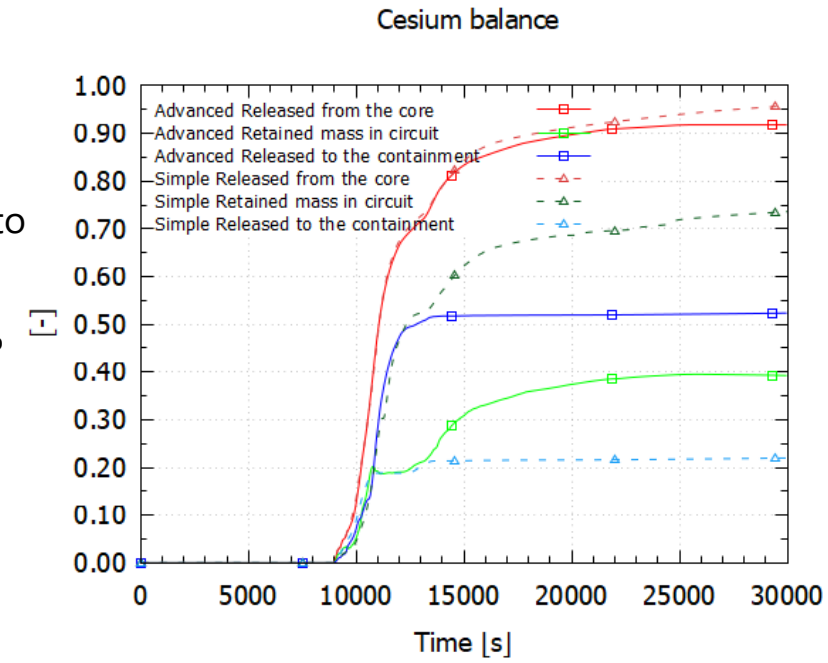
higher release

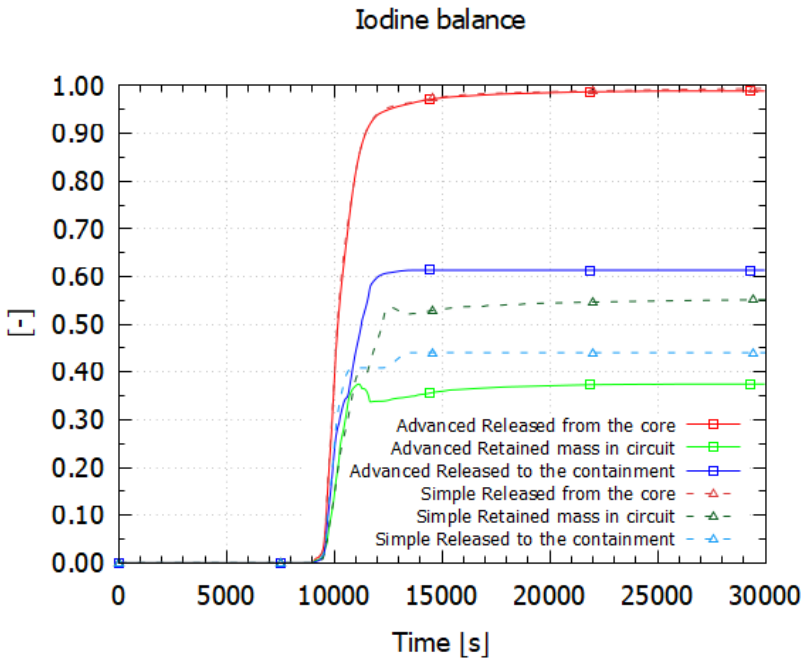
1st burst: Rod 1., node 18

~3.2m within the active core

Cesium release into containment

22 i.i.% vs 52 i.i%



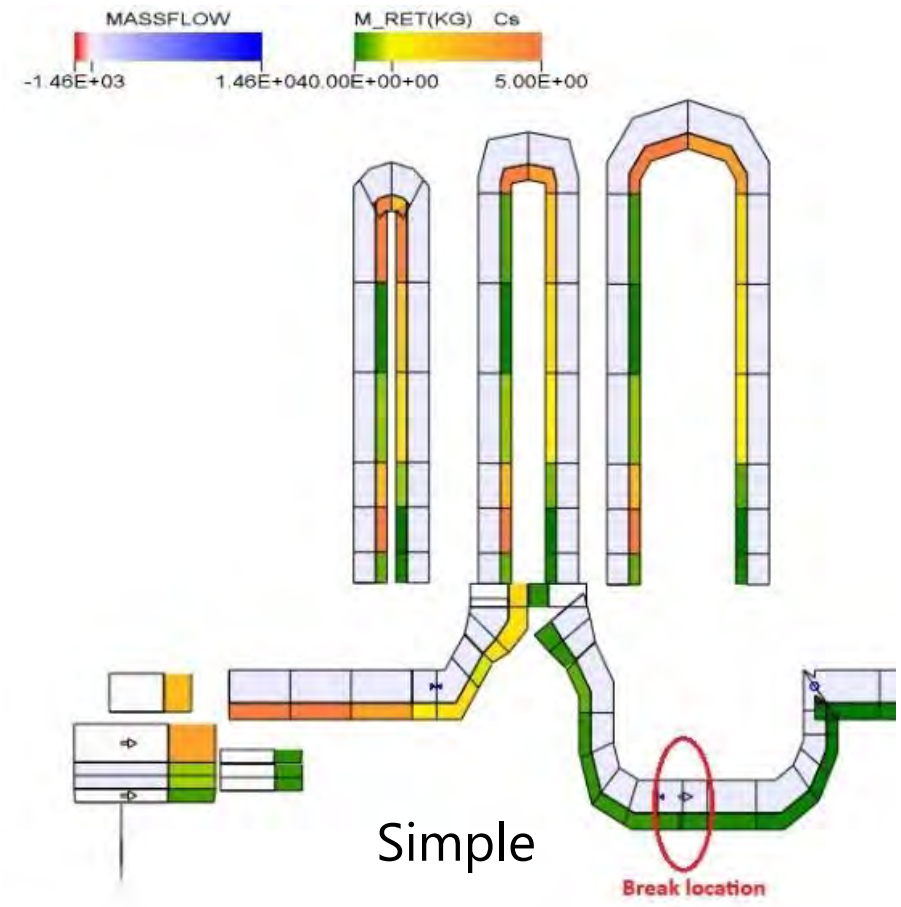


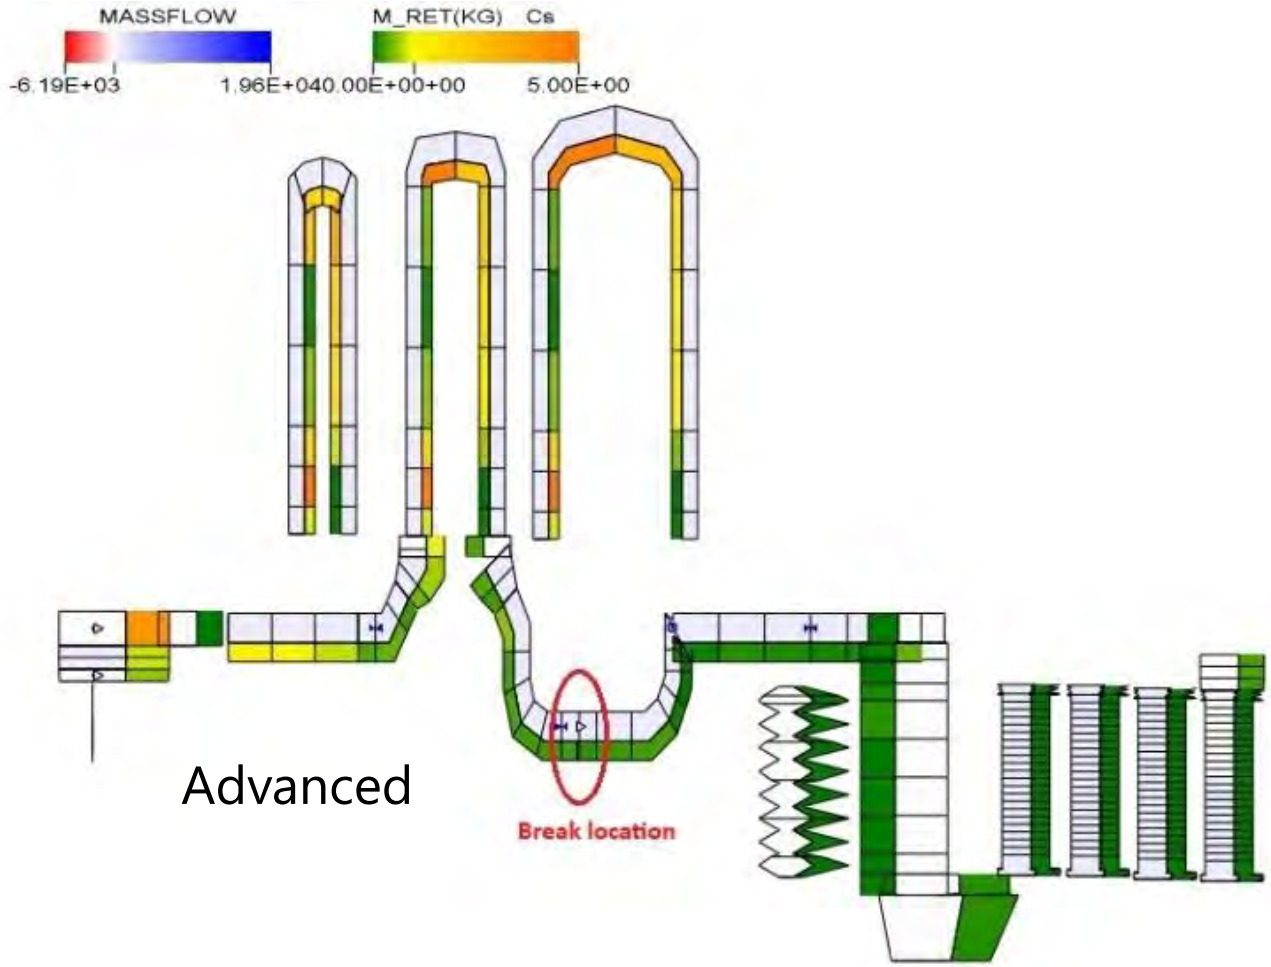
Iodine release into containment

45 i.i.% vs 60 i.i%

FP behavior – retention: Cesium @ 30,000s

Retention: mainly within SG, beginning of hot leg

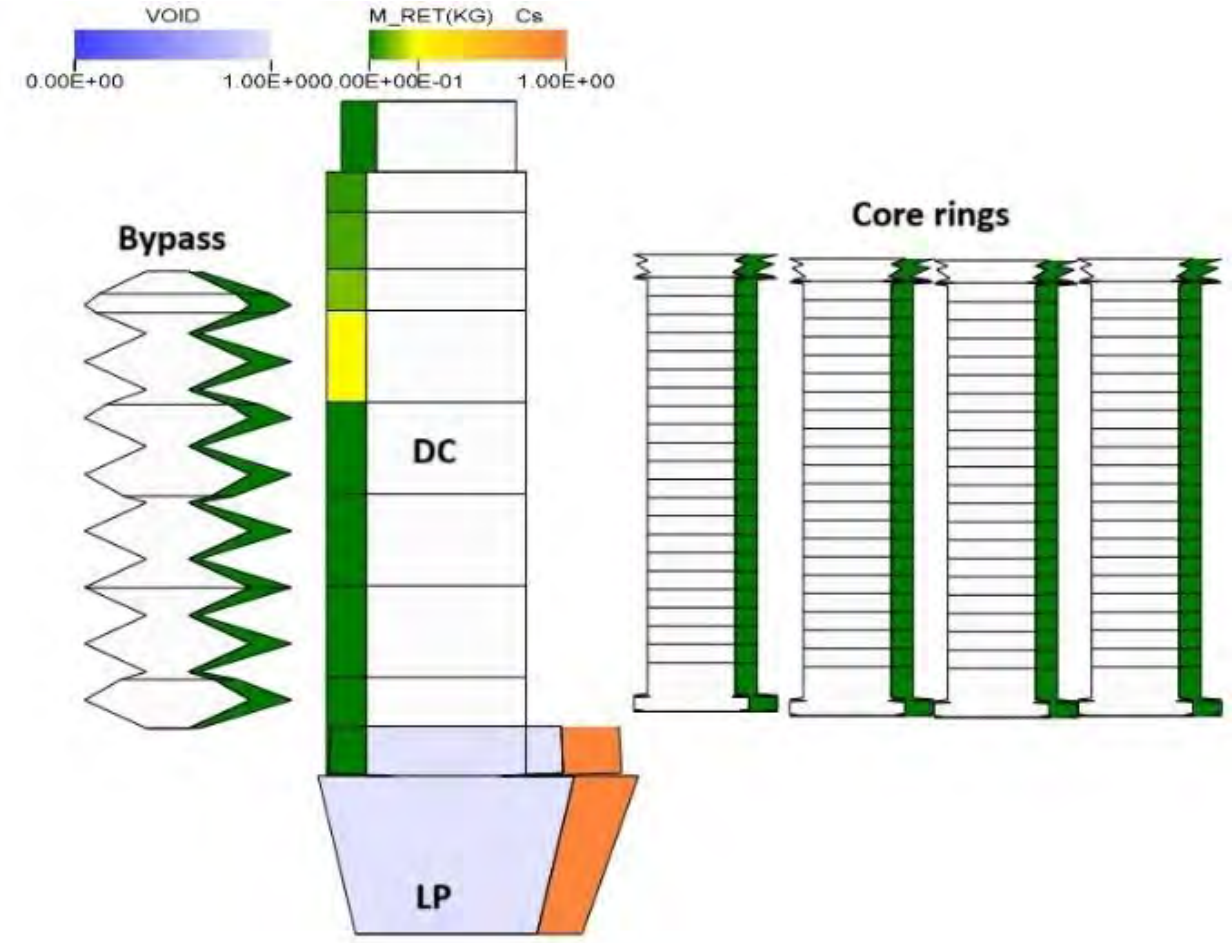




FP behavior – Cs retention @ 14,000 s in the advanced modelling approach

- additionally: core region/LP/CL
- neglected in the simple modelling
- reverse flow
- remobilization is strong in the core/LP regions

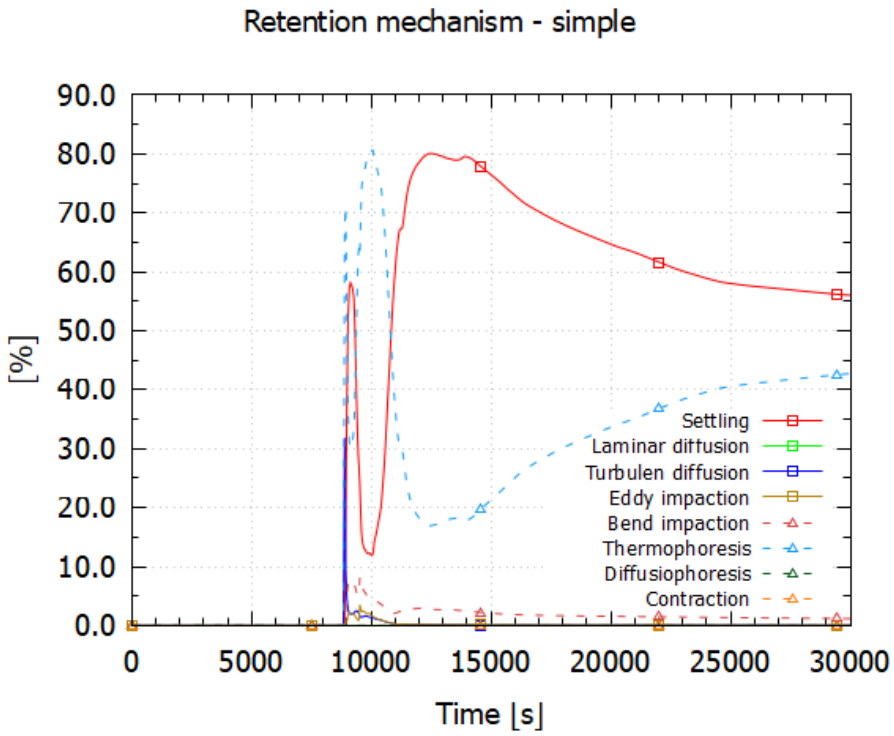
affects timing/composition of the source term into the containment

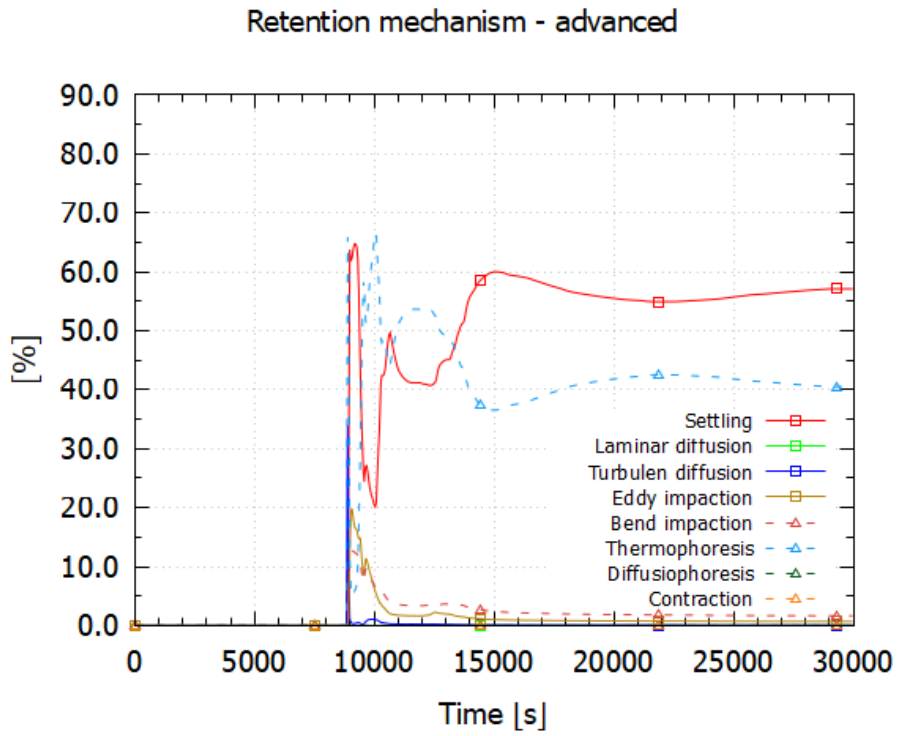


FP behavior - retention

Dominant retention mechanism

- thermophoresis and settling
- relative importance differs

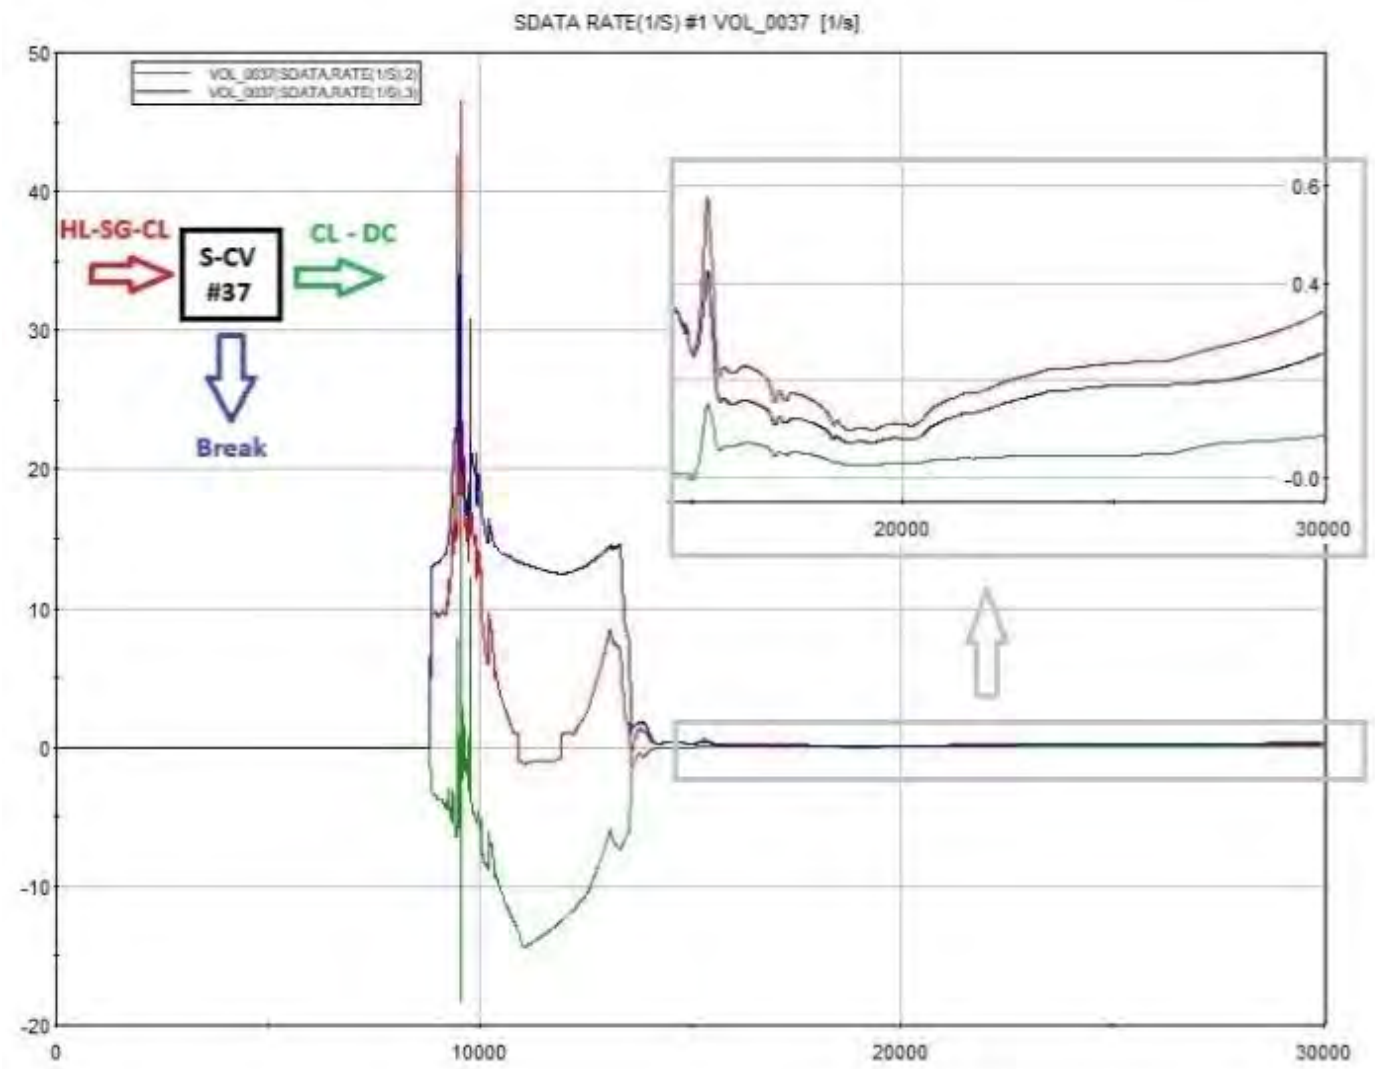




FP behavior – release

- ST release from both direction
- At the moment no separate value
- Normalized rate values give some orientation, combined with retention values
- Significant contribution from reverse direction

Future development work: save explicit values from each direction



Challenges, future work

- Explicit outlet values from each direction
- Dynamic handling of SAFT-outlets (e.g. LP failure)
- Fully water filled CVs → no aerosol/vapor transport
  - void=0, can be relevant in e.g. LP
  - Reflooding, SAM measures
- Extension of V&V

Summary

- Introduction of new, advanced modelling approach
  - explicit modeling of the core region
  - limitations/recommendations
- Demonstration of simulation capabilities on postulated reactor severe accident
- Results show significant influence of modelling approach (importance of underlying TH)
- Identification of future development and V&V needs
- Need for numerical overview for possible computational time reduction
  - advanced modelling approach needed in this case +70%
  - Note: integration of ATHLET-CD modules into ATHLET → parallelization possibilities

Thank You for your attention!

The development and the validation of AC^2 is sponsored by the German Federal Ministry for the Environment, Climate Action, Nature Conservation and Nuclear Safety (BMUKN) on the basis of decisions by the German Bundestag within several projects.

DEVELOPMENT OF EVALUATION TECHNOLOGY FOR RADIOLOGICAL SOURCE TERM IN THE CONTAINMENT USING CINEMA CODE DURING SEVERE ACCIDENT

ABSTRACT

Quantitative evaluation of the radiological source term (ST) inside the containment during a severe accident is essential for plant-specific severe accident management guidance (SAMG), emergency response planning, and the design of mitigation systems. However, widely used deterministic Alternative Source Term approaches (e.g., U.S. reactor-based methodologies) may not fully represent the design characteristics and severe accident phenomenology of Korean pressurized water reactors, including OPR1000 and APR1400. This paper presents recent advances to the domestically developed integrated severe accident analysis code CINEMA (Code for INtegrated severe accident Evaluation and MAnagement) to enable plant-specific assessment of containment source term for OPR1000. The fission product (FP) behavior module SIRIUS (SImulation of Radioactive nuclide Interaction Under Severe accident) was improved and applied to nine representative severe accident scenarios selected from Level 2 PSA insights and deterministic considerations, including SBO, TLOCCW, LOCA classes, and SGTR. CINEMA predictions were compared against MAAP5 results under consistent boundary and initial conditions to assess credibility of thermal-hydraulic trends, major event timing, and the containment inventory of key radionuclide groups, with particular emphasis on iodine and cesium. In addition, uncertainty and sensitivity analyses were performed using MELCOR to identify dominant contributors to ST variability; the aerosol shape factor (CHI) was found to be the most influential parameter affecting iodine and cesium release through its impact on aerosol transport and deposition. Code performance was also benchmarked against the PHEBUS FPT-1 international experiment, demonstrating prediction capability within the experimental error band for key quantities. Finally, this work introduces the Fission Product Evaluation Module (FPeval) v2.0 as a post-processing tool to quantify mass distribution by containment nodes, release mechanisms, and radionuclide decay from CINEMA outputs. The resulting severe accident “big data” is expected to support improved SAMG strategies and future AI-assisted real-time accident response and mitigation facilities for Korean reactors.

Severe Accident; Source Term; CINEMA; OPR1000

1. INTRODUCTION

A severe accident (SA) in a nuclear power plant involves complex, coupled phenomena such as core heat-up and degradation, fission product release, transport and deposition in the reactor coolant system, and multi-compartment containment thermal-hydraulics with aerosol behavior. A central objective of SA analysis is the evaluation of the radiological source term (ST) [1], i.e., the time-dependent quantity and chemical/aerosol form of radionuclides that are released into the containment and potentially to the environment, which directly supports emergency planning, habitability assessment, and mitigation strategy development.

Historically, licensing and safety evaluations have relied on conservative Alternative Source Term (AST) [2] methodologies originally developed for U.S. reactor designs. While such approaches provide standardized assumptions, limitations have been recognized when applying them to reactors with different design and operational characteristics. In the Korean context, OPR1000 and APR1400 include plant-specific features that can influence severe accident progression and containment retention (e.g., large containment volume and wet cavity-related phenomena). Therefore, a plant-specific, mechanistic evaluation capability is required to support domestic SAMG and to provide credible source-term data for engineered mitigation concepts.

To address this need, the integrated severe accident analysis code CINEMA [3] has been developed and continuously advanced. CINEMA integrates modules for in-vessel progression, system thermal-hydraulics, ex-vessel and containment behavior, and fission product/aerosol behavior. This paper focuses on the development and application of CINEMA for quantitative containment ST evaluation for OPR1000 severe accident scenarios.

The objectives of this paper are as follows:

1. Present the CINEMA code architecture and key modeling features for source term evaluation, with emphasis on the SIRIUS [4] fission product module and the post-processing tool FPeval v2.0 [5].
2. Describe the selection and modeling of nine representative OPR1000 severe accident scenarios [5].
3. Demonstrate credibility via comparative assessment against MAAP5 results for thermal-hydraulics and radionuclide inventories [5].
4. Identify dominant uncertainty contributors to iodine and cesium release using MELCOR-based uncertainty and sensitivity analysis, and discuss implications [5].
5. Summarize key findings and expected applications to SAMG enhancement and future real-time/AI-assisted decision support.

2. METHODOLOGY

2.1. Overview of CINEMA Code Architecture

CINEMA (Code for INtegrated severe accident Evaluation and MAnagement) is a domestically developed, integrated severe accident analysis framework designed to simulate coupled in-vessel, ex-vessel, and containment phenomena while enabling mechanistic evaluation of fission product release and aerosol behavior.

CINEMA consists of the following main components:

- CSPACE [6]: In-vessel and primary/secondary system severe accident thermal-hydraulics and core damage progression (coupling of COMPASS [7] and SPACE-SAM [6]).
- SACAP [3]: Containment thermal-hydraulics and ex-vessel severe accident phenomena (e.g., MCCI, hydrogen combustion, DCH), including mitigation features.
- SIRIUS: Fission product release, transport, chemistry, aerosol generation and deposition within the RCS and containment.

- MASTER [3]: An integration/coupling framework to exchange boundary conditions and state variables among modules. Figure 1 shows the conceptual architecture and information flow.

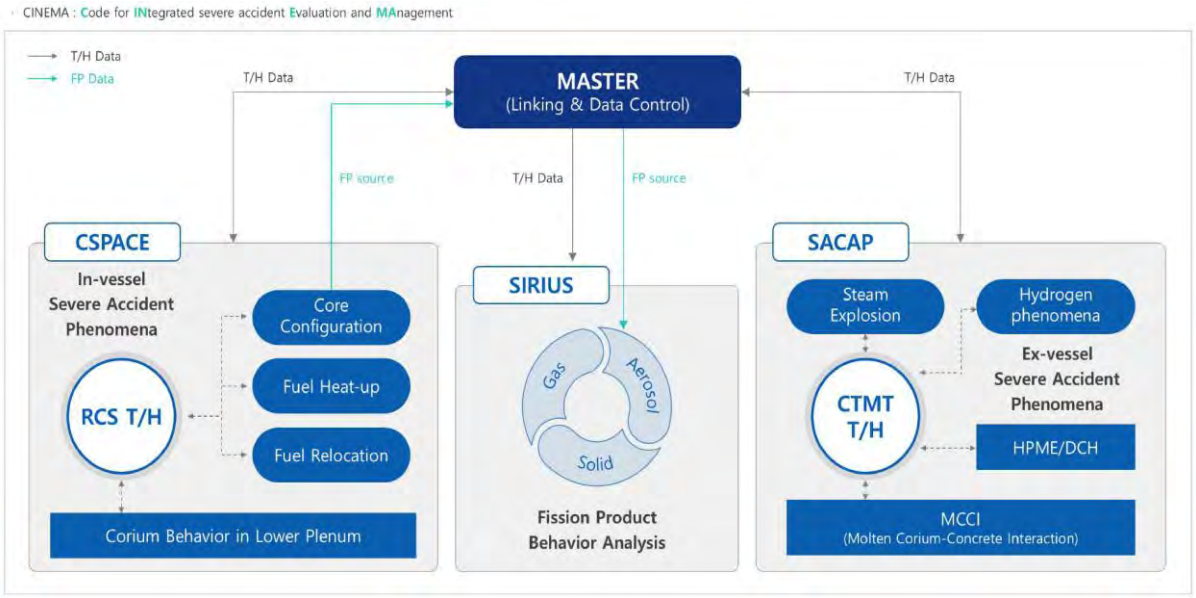

Figure 1. CINEMA architecture and coupling among CSPACE, SIRIUS, SACAP, and MASTER.

2.2. In-vessel and System Thermal-Hydraulics: CSPACE (COMPASS + SPACE-SAM) Module

CSPACE is a coupled code system combining:
- SPACE-SAM: An enhanced system thermal-hydraulic code to simulate severe accident conditions, including improvements such as time-step control for rapid hydrogen generation, refined metastable property models, improved non-condensable gas treatment, critical flow model enhancement, and internal energy equation refinements.
- COMPASS: A core degradation and melt progression module representing initial core configuration, heat-up under uncover, fuel relocation, debris bed and molten pool formation, and lower head integrity evaluation.

CSPACE provides time-dependent thermal-hydraulic boundary conditions (temperatures, pressures, flows, steam/non-condensable compositions) required by SIRIUS for fission product and aerosol transport calculations.

2.3. Containment and Ex-vessel Phenomena: SACAP Module

SACAP evaluates thermal-hydraulic behavior in containment compartments and models major severe accident phenomena such as steam explosion, molten corium–concrete interaction (MCCI), hydrogen combustion, and direct containment heating (DCH), as well as mitigation systems (e.g., igniters, PARs) if applicable. Conservation equation fidelity is designed to be comparable to, or higher than, integral severe accident codes commonly used for containment analyses. SACAP provides containment conditions (pressure, temperature, compartment flows, aerosol removal conditions) to SIRIUS and receives radionuclide/aerosol source terms for multi-compartment tracking.

2.4. Fission Product and Aerosol Behavior: SIRIUS Module

SIRIUS (SImulation of Radioactive nuclide Interaction Under Severe accident) predicts:
- In-core fission product release into the RCS (gas phase),

- Transport through the RCS and associated retention mechanisms,
- Aerosol formation and evolution, and
- Release and behavior inside containment compartments.

Key aerosol processes include condensation, evaporation, adsorption, impaction, gravitational settling, diffusion, and thermophoretic deposition. Since SIRIUS does not directly simulate core melt thermal-hydraulics, it relies on boundary conditions from CSPACE and SACAP. This structure enables consistent coupling between severe accident progression and radionuclide behavior.

2.5. Scenario Selection for OPR1000 Severe Accident Evaluation

Nine representative severe accident scenarios were selected based on:
- Review of Level 2 PSA results to identify dominant accident sequences contributing to risk, and
- Deterministic considerations to cover a spectrum of initiating events and system availability conditions.

The scenario set includes: SBO (Station Blackout), TLOCCW (Total Loss of Component Cooling Water), LOCA classes (SLOCA/LLOCA/MLOCA), and SGTR (Steam Generator Tube Rupture). Table 1 provides the scenario list and main characteristics used for analysis.

Table 1. Representative OPR1000 severe accident scenarios considered in this study (nine cases). [8]

Index	Sequence name	Remarks
1	SBOR _S38	(SBO)(TDAFW for 8 hours)(Late Recovery of AC Power)(Recirculation Spray)
2	TLOCCW_S 10	(TLOCCW) (TDAFW failed) (Bleed Operation failed)
3	MLOCA _S3	(MLOCA)(HPSI) (Recirculation failed)
4	LLOCA_BE _BASE	(LLOCA)(SIT)(SI failed)(CS failed)
5	LLOCA_BE _MACST	(LLOCA)(SIT)(SI failed)(CS failed)(IVI)(Late Recovery of CS) (Recirculation Spray)
6	SLOCA_BE _BASE	(SLOCA)(SIT)(SI failed)(Bleed Operation failed)(CS failed)
7	SLOCA_BE _MACST	(SLOCA)(SIT)(SI failed)(Bleed Operation failed)(CS failed) (IVI)(Late Recovery of CS) (Recirculation Spray)
8	SGTR_BE_ BASE	(SGTR)(Broken SG Isolation)(SIT)(Bleed)(Feed failed)(CS failed)
9	SGTR_BE_ MACST	(SGTR)(Broken SG Isolation)(SIT)(Bleed)(Feed failed)(CS failed) (IVI)(Late Recovery of CS) (Recirculation Spray)

2.6. Post-processing and Quantification of Source Term: FPeval v2.0 Module

To support systematic and reproducible ST quantification from CINEMA runs, the Fission Product Evaluation Code (FPeval) v2.0 was developed as a post-processing tool operating on CINEMA output files (e.g., log/output/rsplt).

FPeval v2.0 performs:
- Quantification of radionuclide mass distribution by containment node/compartment,
- Evaluation of release amounts by release mechanism categories (e.g., gap release, in-vessel release, ex-vessel release, late in-vessel release),
- Nuclide-specific radioactive decay tracking, and
- Automatic recording of key accident progression times (e.g., core uncovery, relocation, vessel failure).

This framework enables consistent comparison among scenarios and between codes, and it supports generation of structured datasets suitable for further analysis and visualization.

2.7. Code Credibility Assessment and Benchmarking Strategy

Two complementary approaches were used to assess credibility:

1. Code-to-code comparison: CINEMA results were compared to MAAP5 simulations under equivalent conditions to verify trends in key thermal-hydraulic variables, major event timings, and containment inventories of major radionuclide groups (with emphasis on iodine and cesium).
2. Experimental benchmark: CINEMA was benchmarked against the PHEBUS FPT-1 [9] international experiment to evaluate the capability to reproduce representative severe accident source-term behavior within experimental uncertainty.

2.8. Uncertainty and Sensitivity Analysis Using MELCOR [9]

Uncertainty and sensitivity analyses were conducted using MELCOR to:
- Identify key uncertain parameters affecting containment ST,
- Quantify the variability range of iodine and cesium releases, and
- Provide insight for prioritizing model improvements and instrumentation/mitigation strategies.
Uncertain variables were selected following criteria widely used in severe accident uncertainty studies, covering in-vessel progression (e.g., fuel failure criteria), ex-vessel/containment parameters (e.g., leakage, failure pressure), aerosol parameters, and FP chemistry-related variables. Particular attention was given to the aerosol shape factor (CHI) due to its influence on aerodynamic behavior and deposition.

3. RESULTS AND DISCUSSION [5]

3.1. Severe Accident Progression Characteristics for the Nine Scenarios of OPR1000 [8]

CINEMA simulations were executed for the nine OPR1000 scenarios to quantify severe accident progression, including:
- Timing of core uncovery and heat-up,
- Onset of significant fission product release,
- Core relocation to the lower plenum,
- Lower head failure timing (if predicted), and
- Transition to ex-vessel phase and containment pressurization behavior.

The scenario set produced differentiated progression patterns consistent with expected initiating event characteristics. For example, LOCA-driven sequences generally exhibit rapid depressurization and different retention/removal behaviors compared to SBO-driven sequences where prolonged heat-up and hydrogen generation can dominate.

SOE	MAAP5 (s)	CINEMA (s)	Description for CINEMA
SGTR(SG#1) start	0	0

Figure 2. Example timeline of key severe accident events for representative scenarios (core uncovery, relocation, vessel failure).

3.2. Comparison of Thermal-Hydraulic Trends: CINEMA vs. MAAP5

To confirm that CINEMA properly reproduces the RCS and containment thermal-hydraulic response, key metrics were compared with MAAP5, including:
- Primary system pressure evolution,
- Core heat-up indicators and major event timings,
- Containment pressure rise and stabilization behavior.

Across the nine scenarios, CINEMA predicted the timing of major events (e.g., core uncovery and vessel failure indicators) and containment pressurization trends consistent with MAAP5 when equivalent inputs were applied. Agreement in thermal-hydraulic behavior is a prerequisite for meaningful source term comparison because fission product release, transport, and deposition strongly depend on temperature, steam flow, and non-condensable gas conditions.

3.3. Comparison of Containment Radionuclide Inventories (I and Cs Groups)

The principal target of this study is the quantitative evaluation of radiological ST within containment, focusing on major contributors to early and intermediate dose and contamination concerns: iodine (I) and cesium (Cs) groups. For the nine scenarios, CINEMA predicted the distribution of iodine and cesium within containment compartments in strong agreement with MAAP5, typically within approximately 10–20% difference under the study's comparison basis. This level of agreement supports the conclusion that SIRIUS improvements allow CINEMA to achieve prediction performance comparable to established severe accident codes for the considered metrics.

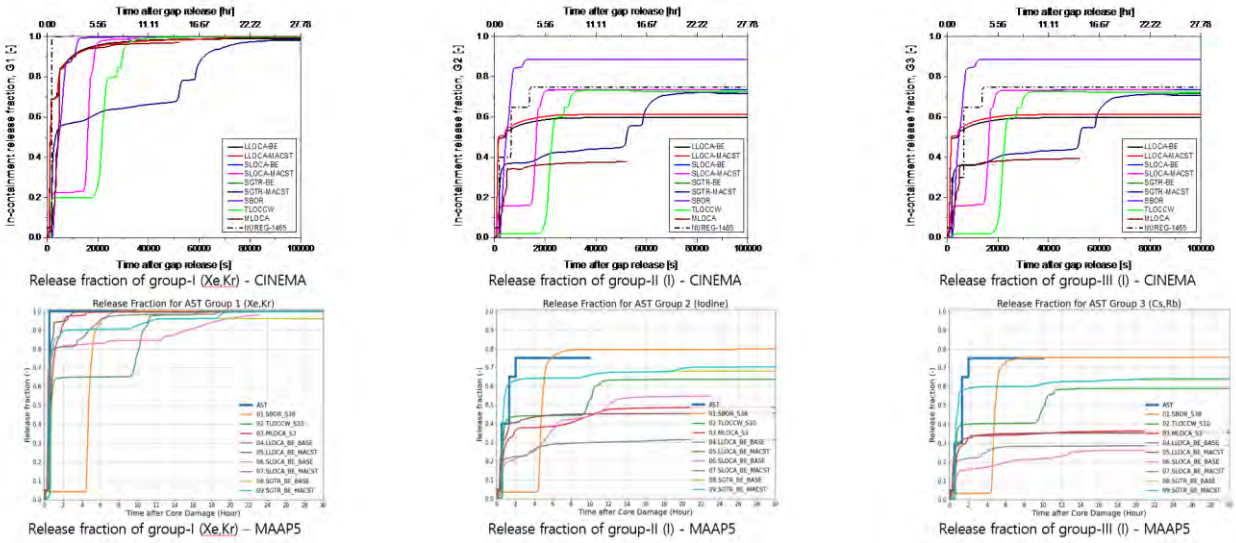

Figure 3. Comparison of key release fraction of FP groups between CINEMA and MAAP5.

3.4. Plant-Specific Effects Reflected in CINEMA Results

A key motivation for CINEMA-based ST evaluation is to reflect Korean reactor design characteristics. Two notable impacts were observed:
1. Large containment volume effect: Larger volume tends to reduce concentration peaks, influence aerosol dynamics, and alter deposition/removal behavior.
2. Wet cavity-related scrubbing/retention effect: The presence of water pools and relevant flow paths can enhance aerosol and soluble radionuclide removal depending on accident sequence and transport route.

CINEMA produced differentiated results consistent with these plant-specific features and showed enhanced mitigation capabilities compared with simplified standardized methodologies.

3.5. Source Term Trends by Accident Type

Clear qualitative differences were observed among accident categories:
- LOCA-series accidents generally produced relatively higher containment release fractions or release rates for iodine and cesium, driven by rapid changes in thermal-hydraulics, direct transport paths, and aerosol behavior under high steam flow.
- SGTR cases exhibited more limited containment release in the evaluated metrics, attributed to scrubbing/retention effects associated with secondary-side transport pathways.
These differentiated trends are important for SAMG because they influence prioritization of containment spray strategies, hydrogen control considerations, and monitoring needs.

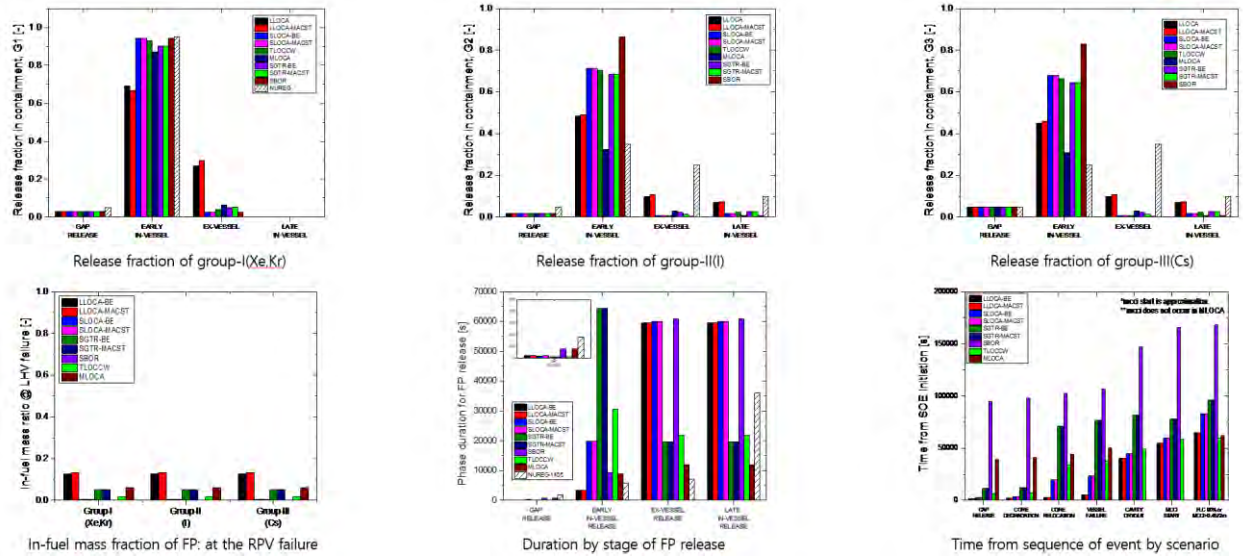

Figure 4. Release fraction of FP groups: by phases of FP release

3.6. Spatial Distribution of Radionuclides in Containment Compartments

Using CINEMA outputs and FPeval v2.0, radionuclide mass distribution across containment nodes (e.g., upper compartments, wet cavity region) was quantified. This provides:
- A basis for evaluating compartment-specific dose and contamination drivers,
- Guidance for instrumentation placement (e.g., where aerosol loading or iodine concentration may be highest), and
- Input for targeted mitigation concepts such as filtered venting or localized aerosol removal.

3.7. Uncertainty and Sensitivity Analysis: Dominant Role of Aerosol Shape Factor (CHI) [9]

The MELCOR-based uncertainty and sensitivity analyses indicated that the aerosol shape factor (CHI) is the most influential parameter affecting iodine and cesium release in the evaluated set. CHI governs the aerodynamic behavior of aerosols, impacting deposition rates and removal from the containment atmosphere; therefore, it significantly affects the airborne fraction and time-dependent availability for leakage or venting pathways.

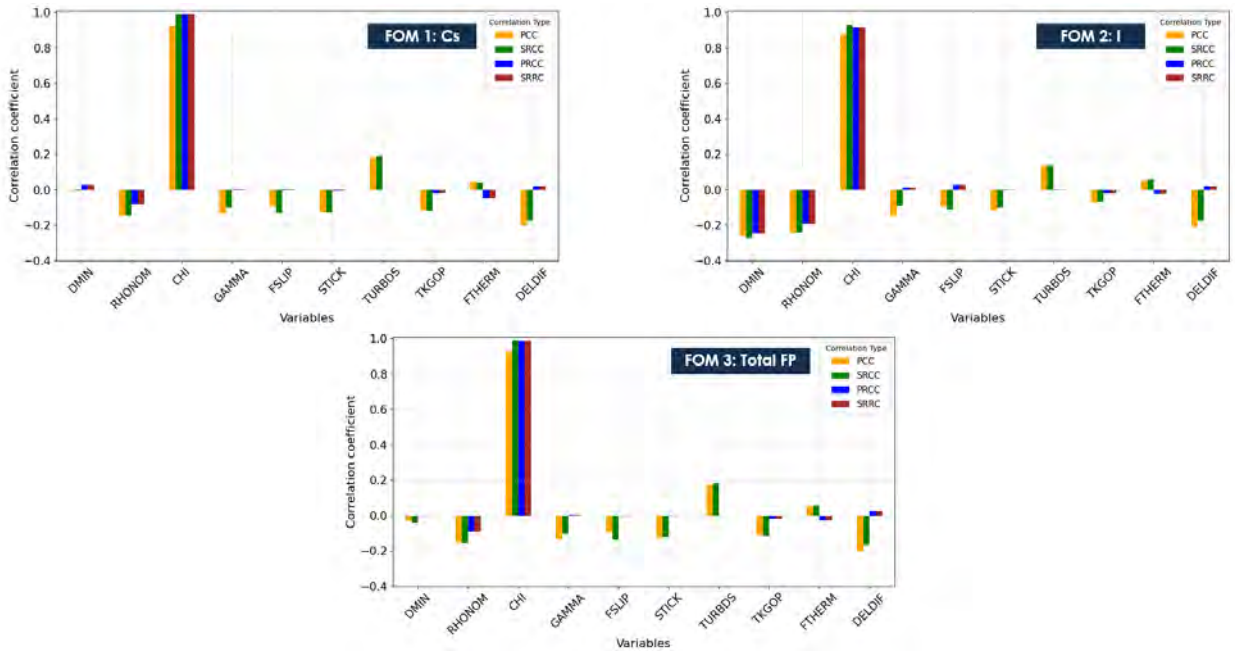

Figure 5. Sensitivity ranking of uncertainty parameters for iodine and cesium release.

3.8. Benchmark Against PHEBUS FPT-1 Experiment The MELCOR [9]

Benchmarking against the PHEBUS FPT-1 international experiment was conducted to assess the ability of CINEMA to represent key behaviors relevant to source-term analysis. The results showed that CINEMA predictions for important variables such as fuel temperature and source term release were within the experimental error band (approximately 30% for the considered comparison basis). This provides additional support for the reliability of CINEMA/SIRIUS modeling for severe accident ST applications.

3.9. Implications for SAMG and Future Applications

The developed CINEMA-based ST evaluation framework and the generated severe accident dataset can contribute to:
- Strengthening plant-specific SAMG strategies for OPR1000 and APR1400,
- Supporting the design and performance assessment of radioactive material mitigation facilities,
- Enabling development of AI-assisted real-time severe accident response systems by providing high-volume, structured analysis data.

4. CONCLUSIONS

This study advanced the domestically developed integrated severe accident analysis code CINEMA to enable quantitative evaluation of radiological source term within the OPR1000 containment during severe accidents, with an emphasis on iodine and cesium behavior.
The main conclusions are:
1. Nine representative OPR1000 severe accident scenarios (including SBO, TLOCCW, LOCA classes, and SGTR) were selected based on Level 2 PSA insights and deterministic coverage considerations, and were analyzed using CINEMA.
2. CINEMA thermal-hydraulic behavior and fission product release predictions showed strong agreement with MAAP5 under equivalent conditions, with iodine and cesium containment inventory metrics typically within a 10–20% difference.

3. The post-processing tool FPeval v2.0 was developed to quantify radionuclide mass distribution by containment node, categorize release mechanisms, track nuclide decay, and automatically record key severe accident event times from CINEMA output files.
4. Uncertainty and sensitivity analyses using MELCOR identified the aerosol shape factor (CHI) as the dominant contributor influencing iodine and cesium release behavior via aerosol deposition and removal processes.
5. Benchmarking against the PHEBUS FPT-1 experiment indicated CINEMA prediction performance within the experimental uncertainty range for key comparison quantities, supporting its applicability to mechanistic source term evaluation [10, 11, 12, 13, 14, 15].
Overall, the proposed CINEMA-based evaluation technology provides a foundation for plant-specific SAMG enhancement and for future development of AI-assisted real-time severe accident response and mitigation applications for Korean reactors.

Why Plant-Specific Source Term Evaluation?

- Limitations of Alternative Source Term (AST) methods for Korean PWR designs

Current Practice & Limitations

U.S. PWR based AST (NUREG-1465)

Conservative, standardized assumptions — not tailored to Korean OPR1000 / APR1400 design features

Large containment volume

Korean PWRs have larger free volumes → different aerosol dynamics, concentration peaks

Wet cavity configuration

Enhanced scrubbing / retention effects via water pool pathways — not in generic models

Fission product transport paths in containment

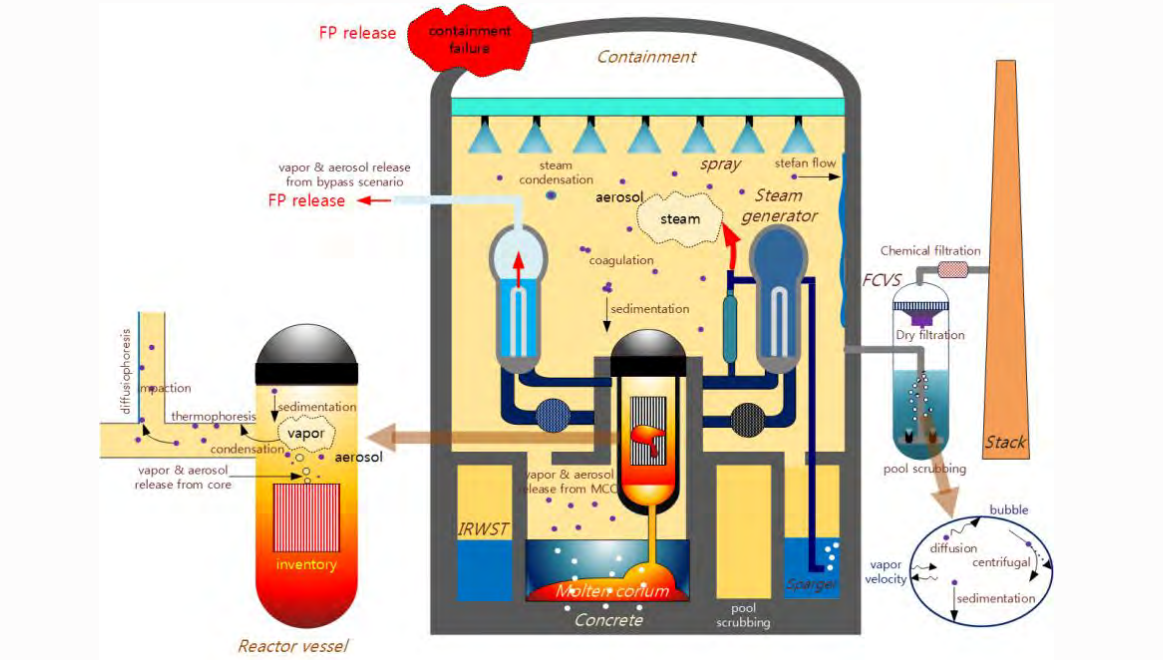

Fig. 1 Schematic of fission product release, transport and deposition in containment

Objectives of This Study

CINEMA for Korean PWR Analysis

- OPR1000: CINEMA / MAAP5 nodalization comparison

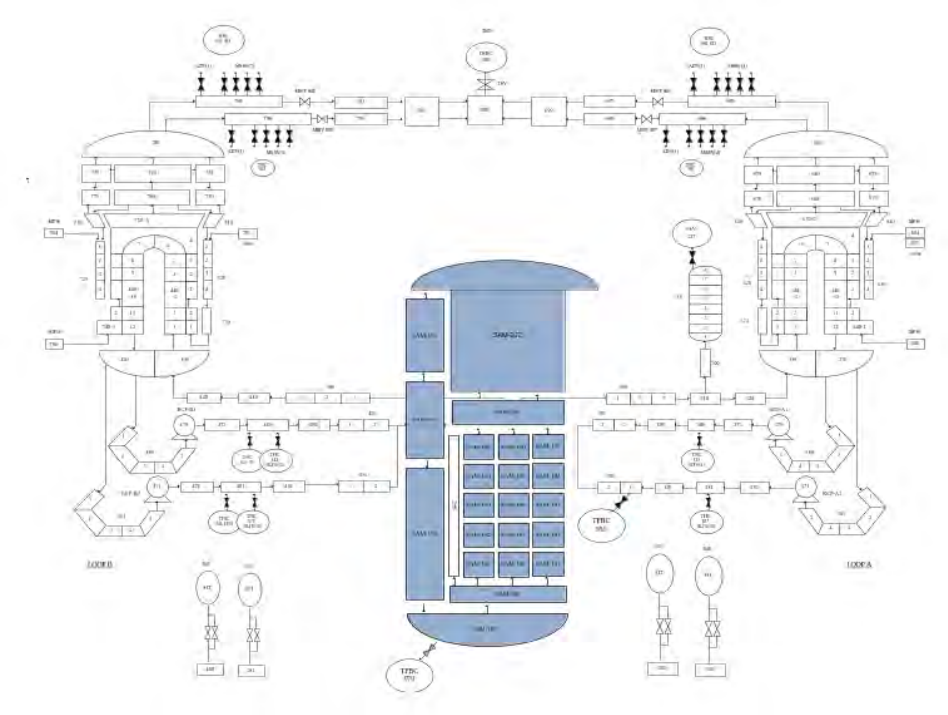

Fig. A CINEMA nodalization — OPR1000 primary system

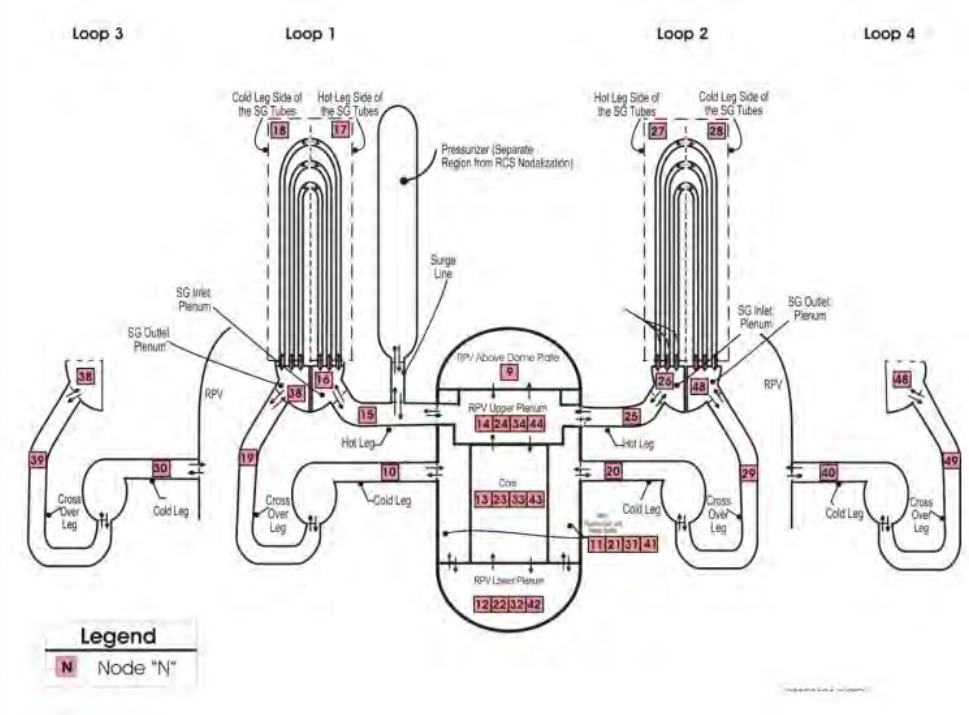

Fig. B MAAP5 nodalization — OPR1000 primary system

OPR1000	CINEMA	MAAP5	Purpose
Korean standard PWR — 2-loop / 4-loop nodalization	Mechanistic SA code — detailed core degradation model	Industry SA code — fast-running lumped parameter	Cross-validation of SA progression predictions

CINEMA vs. MAAP5: Thermal-Hydraulic, FP release fraction comparison

- Consistent boundary & initial conditions — 9 scenarios · Major event timings & Severe accident phenomena & FP release to containment

Objects of comparison

Primary system pressure

Evolution under accident progression — depressurization, injection, steam behavior

Core heat-up indicators

Onset of fuel damage, core relocation timing

Major event timings

Core uncovery · Vessel failure → prerequisite for ST comparison

In-vessel, in containment physics

RPV failure by corium attack
Pressure rise and stabilization under FP/steam/H_2 release

In-containment release fraction: CINEMA vs. MAAP5

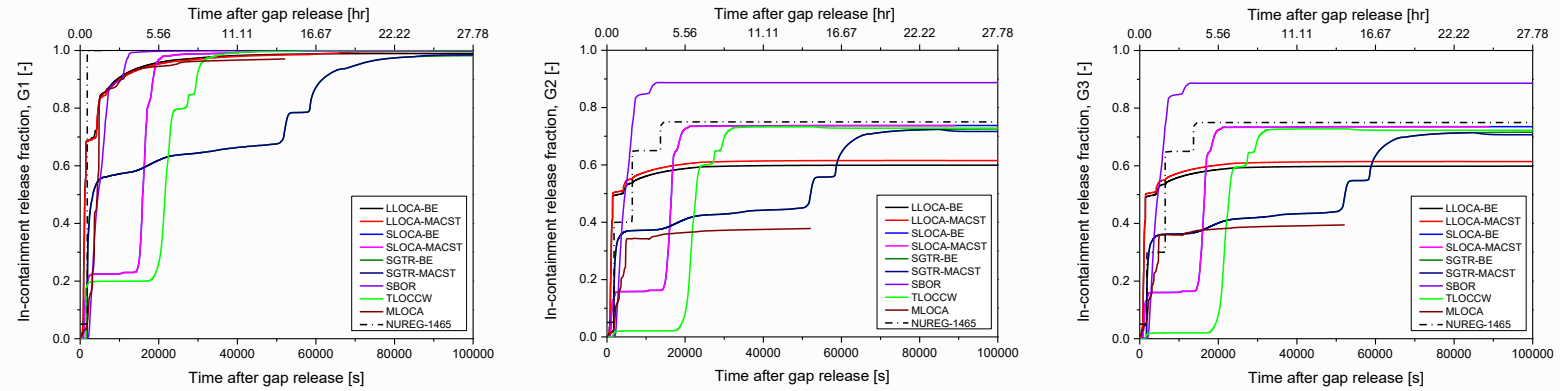

Fig. 3a Group-I (Xe, Kr), II (I), III (Cs) in-containment release fraction — CINEMA (9 scenarios)

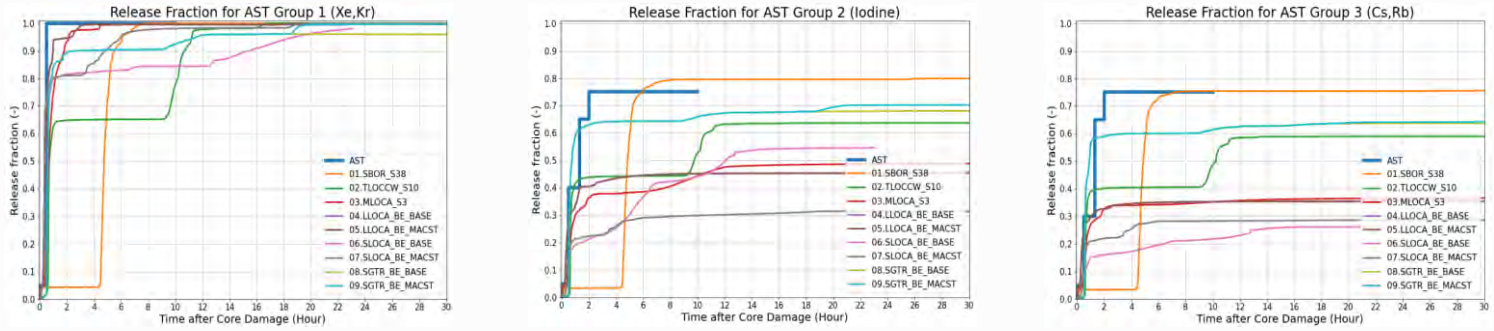

Fig. 3b Group-I (Xe, Kr), II (I), III (Cs) in-containment release fraction — MAAP5 (9 scenarios)

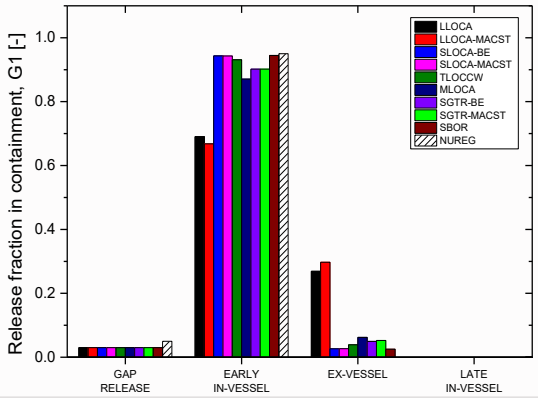
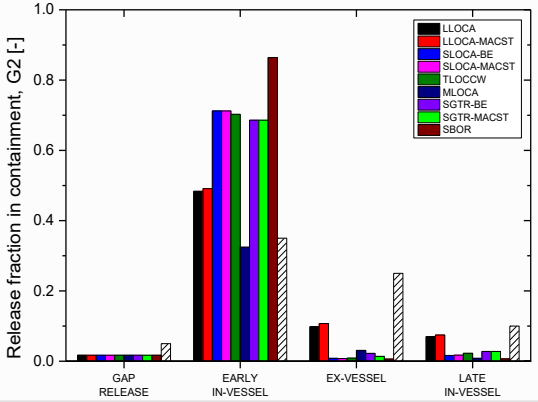
Key finding: CINEMA reproduces MAAP5 major event timings and containment pressurization trends under equivalent inputs across all **9** scenarios — prerequisite confirmed for meaningful ST comparison. CINEMA–MAAP5 iodine & cesium inventory agreement typically within 10–20% under consistent inputs.

Radiological Source Term Evaluation for OPR1000

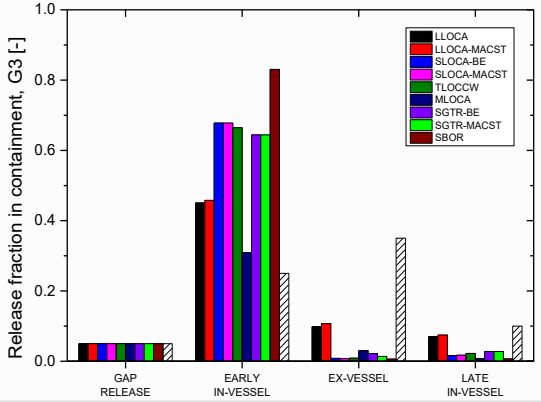
- Source term evaluation results by CINEMA, as compared to that by alternative source term.



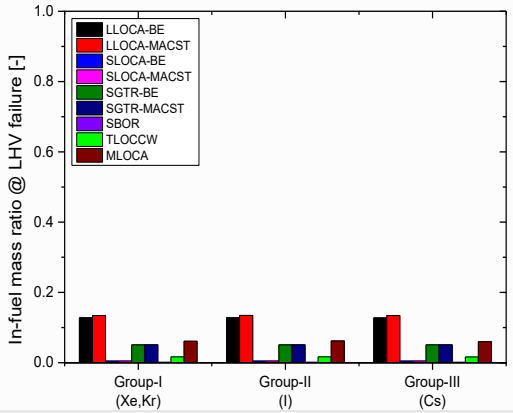
Release fraction of group-I(Xe,Kr)



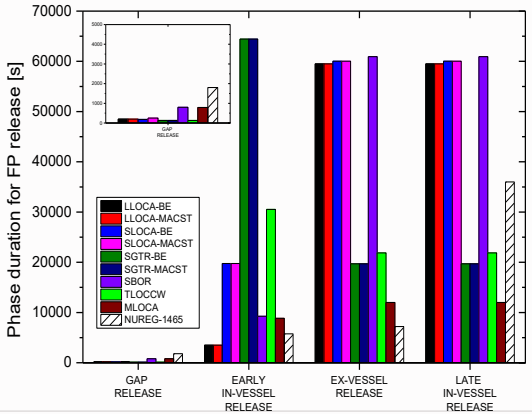
Release fraction of group-II(I)



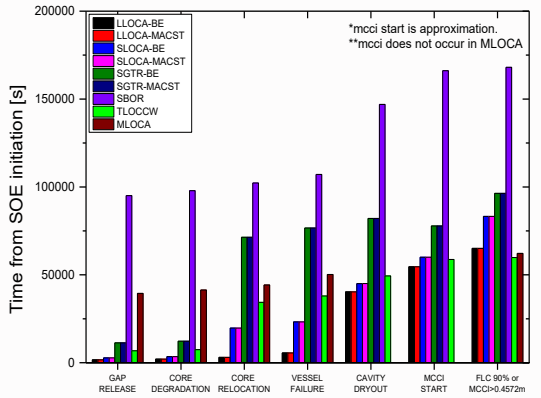
Release fraction of group-III(Cs)



In-fuel mass fraction of FP: at the RPV failure



Duration by stage of FP release

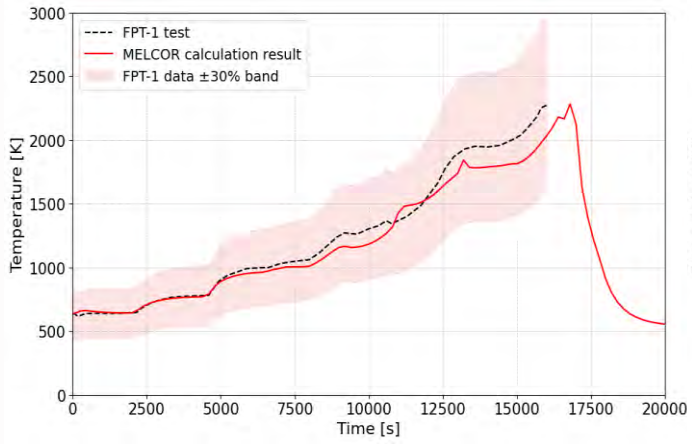


Time from sequence of event by scenario

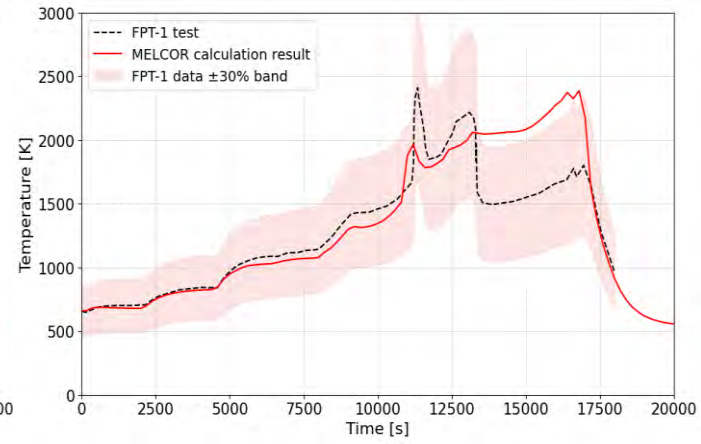
Key finding: In general, for the severe accident scenarios of the OPR1000, source term release to the containment mainly occurred at Early in-vessel phase.
In our results, duration of FP release stages show big difference by accident scenarios. That leads to necessity of mechanical source term (MST) evaluation.

Experimental Benchmark: PHEBUS FPT-1

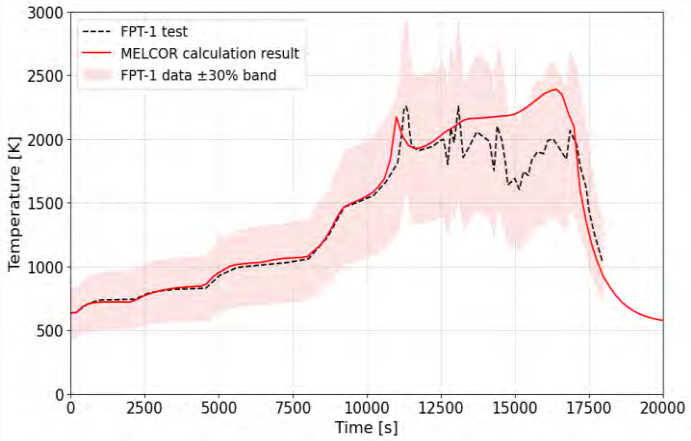
- CINEMA / MELCOR predictions vs. international experimental data — within ±30% uncertainty band



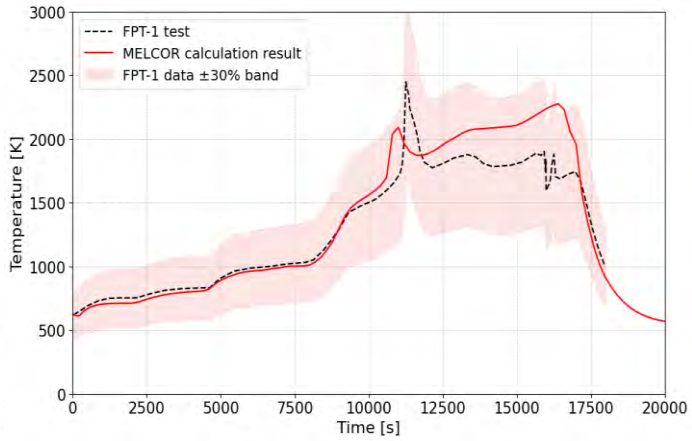
<Fuel temperature at 300 mm>



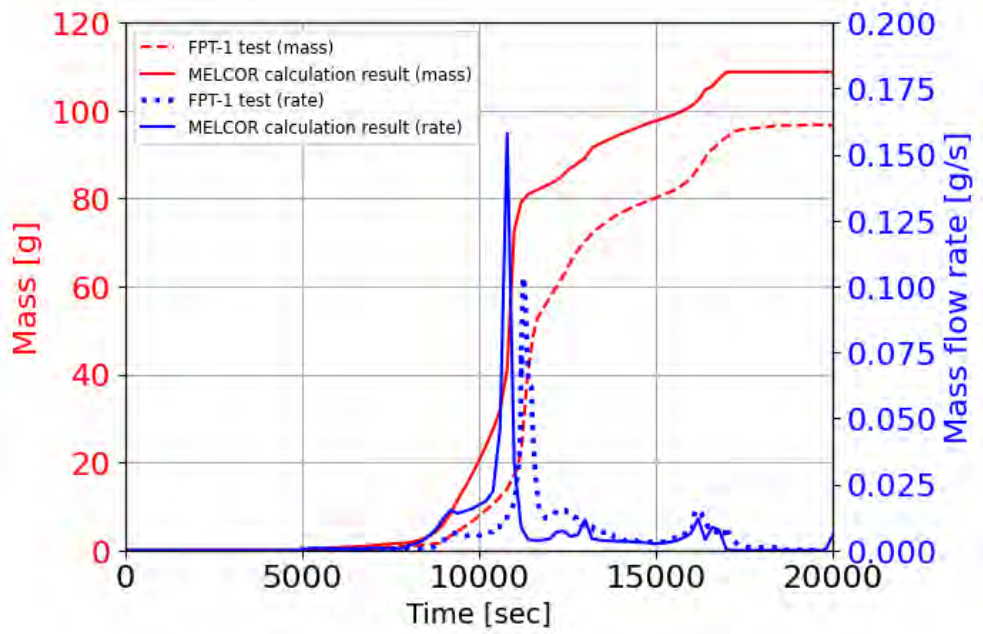
<Fuel temperature at 400 mm>



<Cladding temperature at 600 mm>



<Cladding temperature at 700 mm>



<Accumulated hydrogen mass and generation rate>

Dominant Role of Aerosol Shape Factor (CHI)

- MELCOR uncertainty & sensitivity analysis — iodine and cesium release variability

UA variables

RHONOM	*Nominal density of aerosol*
CHI	*Dynamic shape factor of aerosol*

① Brownian diffusion velocity $v_{diff} = \frac{\sigma T C_m}{3\pi\mu\chi d_p \Delta}$

② Gravitational settling velocity $v_{grav} = \frac{d_p^2 \rho_p g C_m}{18\mu\chi}$

③ Thermophoretic deposition velocity

$$v_{therm} = \frac{3\mu C_m (c_t Kn + k_{gas}/k_p)}{2\chi\rho_{gas} T (1 + 3F_{slip} Kn)(1 + 2c_t Kn + k_{gas}/k_p)} \nabla T$$

As CHI increases, the deposition rate decreases, leading to an increase in the transport fraction to the containment vessel.

CHI dominates iodine and cesium release variability via aerosol deposition rate → prioritize **aerosol measurement instrumentation**

Cs/I release fraction uncertainty band (MELCOR)

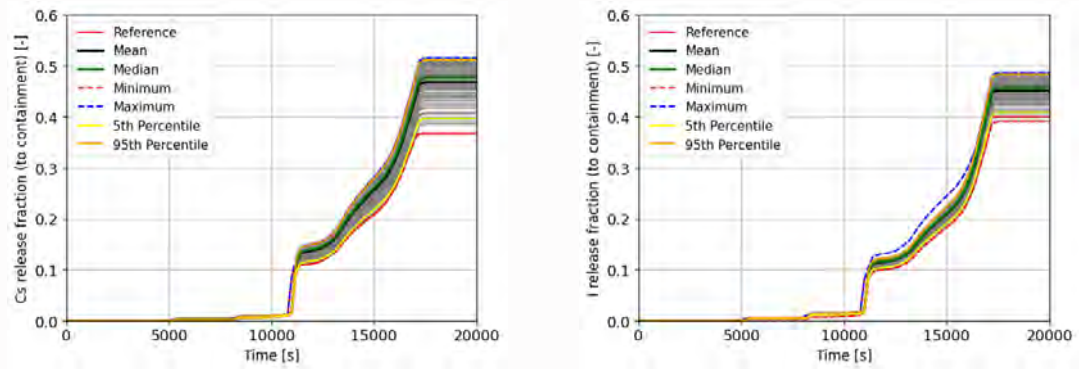


Fig. 5a Cs/I release fraction — uncertainty band (5th/50th/95th percentile)

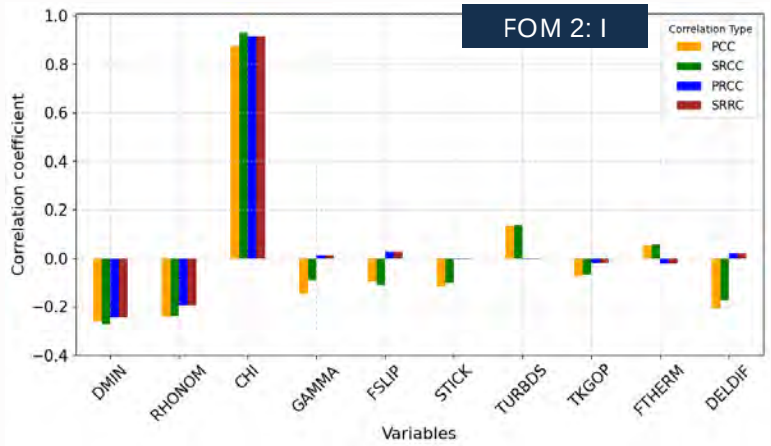

Fig. 5b Sensitivity ranking — CHI (aerosol shape factor) dominant contributor for I

Applications: SAMG Enhancement & AI-Assisted Response

- CINEMA-based ST evaluation as foundation for next-generation accident management

01

Plant-Specific SAMG Enhancement

· OPR1000 / APR1400 — differentiated ST data per accident type

· Containment spray strategy prioritization by accident category

· Quantified influence of wet cavity and large containment volume

· Source for updating severe accident event trees in L2 PSA

ABSTRACT

During a severe accident, one of the potential threats to the containment is the release of flammable gases leading to combustion risk. Severe Accident Management Guidelines (SAMGs) as well as dedicated hardware are in place to mitigate this combustion risk and protect the containment integrity. Advancements in SAMGs are the focus of AMHYCO, an EU-funded Horizon2020 project (Euratom 2019/2020, GA No 945057) conducted between October 2020 and March 2025. In this paper, the main outcomes and lessons learned from the AMHYCO project are presented. A comprehensive bibliographic review was conducted, providing a common foundation to build the knowledge gained during the project. An extensive set of accident transients was simulated, covering in-vessel as well as ex-vessel phenomena. Based on these simulations, a set of challenging accident sequences was selected for further assessment from the combustion risk perspective across the different power plant types (PWR-KWU, PWR-W, PWR-VVER). At the same time, three generic containment models for the three considered reactor designs were created to enable full containment analysis using lumped parameter (LP) models, 3-dimensional (3D) containment codes, and CFD simulations. To further consolidate the modelling base, combustion experiments and performance tests on passive auto-catalytic recombiners (PARS) in H_2/CO atmospheres were performed at CNRS, France, and FZJ, Germany, respectively. Based on these experiments, a new PAR correlation, referred to as AMHYCO PAR correlation, was proposed. Additionally, several accident sequences were simulated using LP, 3D, and CFD approaches for the three PWR containment types, assessing the impact of the installment of PAR, the effects of filtered containment venting, and (re-)activation of containment cooling systems on the global and local combustion risk. Finally, a set of recommendations to the SAMGs developers and NPP operators was developed, outlining the importance of mitigation systems and especially proper management of the containment cooling systems.

KEYWORDS
AMHYCO, combustion risk, in-vessel phase, ex-vessel phase, passive auto-catalytic recombiners, containment response, SAMGs

1. INTRODUCTION

The risk associated to combustible gases generated during a severe accident are among the most relevant threats to containment integrity. An appropriate management of the associated risk is paramount to protect the containment and, thus, prevent the uncontrolled release of radioactive material into the environment. This management of combustible gases includes, on one side, suitable hardware like, e.g., Passive Autocatalytic Recombiners (PARs), and, on the other side, elaborated guidance to operate the plants in case of a core damage accident. These procedures are referred to as Severe Accident Management Guidelines (SAMG).

2. MAIN OUTCOMES OF THE PROJECT

The main objective of the AMHYCO project is to extend the knowledge about the presence and the mitigation of combustible gases, especially in the late stage of a severe accident where not only hydrogen from the core oxidation is present but also possible carbon monoxide, generated by a molten corium-concrete interaction (MCCI). Based on the examinations, the AMHYCO project makes recommendations concerning hardware backfitting as well as updates to SAMG. The project utilized a methodology that is organized in five different technical work packages (WPs). These WPs are at the same time successive and

interlinked. In the next sections, the AMHYCO technical WPs and the tasks therein will be briefly described, and the main outcomes and lessons learned are summarized.

2.1. WP1: Critical review

The WP1 aims at reviewing the status of existing methodologies and practices related to gas combustion risk management in the late phase of severe accidents. Most of the combustible gas mitigation strategies adopted in European countries are based on the use of PARs. Therefore, a critical assessment of the PAR behaviour, especially in the up-to-now lesser explored late phases of a severe accident, is performed. Similarly, a survey of the available experimental data and engineering combustion models is provided. In addition, a review of the safety equipment qualification criteria and gas monitoring systems, as well as the existing SAMGs is established with the aim to pave the way towards the SAMGs enhancement. The main outcomes of the WP1 are gathered in the AMHYCO (public) deliverable D1.1 "Critical assessment of key elements of combustible gases management in containment." (Bentaib, 2022) and can be summarized as follows:

- The literature review showed that despite the extensive research performed in the last decades, additional experimental and theoretical investigations are needed to fill the knowledge gaps regarding the PARs behaviour in representative conditions of late phase of the severe accidents.
- The literature review showed that the H_2/CO combustion in representative conditions of severe accident late phases is rarely investigated. Additional experimental and theoretical investigations are needed to fill the observed knowledge gaps.
- Regarding the existing PWR SAMGs concerning containment risk management, the literature review showed that the adopted requirements address in-vessel conditions; therefore, their extension to ex-vessel conditions needs to be established for the containment and the auxiliary buildings connected to the containment. It was also identified that all the adopted requirements aim to preserve the containment integrity; the availability of the safety systems, such as sprays or venting line, needed for severe accident late phases, needs to be addressed in extended requirements. It should be pointed out that only a few countries adopt quantitative criteria for the requirement, and only a few existing SAMGs contain instructions about the usage of safety systems (containment sprays and air coolers) in the late phase of a severe accident.
- It was also identified that the existing monitoring systems do not measure carbon monoxide content separately (hydrogen gas detectors using gas heat conductance measurements are insensitive to CO while hydrogen detectors using catalytic recombination measure CO as hydrogen).

2.2. WP2: Characterization of sequences with relevant combustion risk

Given the current European nuclear reactor fleet, three PWR reactor designs are modelled (PWR-W: Western: French and Westinghouse; PWR-KWU; PWR-VVER) and the most relevant sequences are chosen according to a set of agreed criteria: high molar fractions of combustible gases (H_2 + CO) in control volumes whose conditions are within flammability limits; a large total mass of combustible gas (H_2 + CO) within the containment; and high combustible gas (H_2 + CO) release rates. Besides, a qualitative assessment was needed.

This WP has been structured consistently with the reactor types addressed, and it includes a specific task (2.1) to produce a "Generic Containment (GC)" of each PWR type. The individual databases were built based on open information on each containment design, which was then used to build three CAD (Computer Aided Design) models. From each containment CAD model, different proposals were made for both Lumped Parameter (LP) codes and 3D codes nodalization. Additional information about the process as well as the generic containments data for the three PWR types can be found in the AMHYCO (public) deliverable D2.1 "Data for the generic containment analysis (PWR-W, PWRVVER, PWR-KWU)" (Serra et al., 2024) and in open publications (Vázquez-Rodríguez et al., 2025; Serra et al., 2025).

The second objective of the AMHYCO work package 2 (WP2) was to identify bounding accident sequences in which the combustible gases (H_2 and CO) could jeopardize containment integrity (tasks 2.2 to 2.4). The simulations of different accident sequences with integral codes provided relevant estimations of the behaviour of the combustible gases in the containment. Therefore, one of the main tasks of this work package was the identification of the most challenging accident sequence regarding the gas combustion risk based on selection criteria previously set. Different sequences of the three PWR reactor types were simulated with different codes and hypotheses, starting with the nodalization used by each organization before the start of AMHYCO (therefore, not coming from the generic containment nodalization), as a difference of what was done in WP4, as it will be seen later.

Partner	Reactor type	Code	Number of plant nodes	Number of cont. nodes
IRSN/ASNR	PWR-900 (Framatome)	ASTEC v2.1	~160	14
IRSN/ASNR	PWR-1300 (Framatome)	ASTEC v2.1	~160	18
JSI	PWR-700 (Westinghouse)	MELCOR 2.2	158	13
CIEMAT	PWR-1000 (Westinghouse)	MELCOR 2.2	157	19
Framatome	KWU-1300	MELCOR 2.2	69	30
RUB	KWU-1300	AC^2 2019.1	283	23
Energorisk	VVER	MELCOR v1.8.5	126	21

Table 1. WP2 reactor type, code, and nodalizations

The detailed analyses of the results obtained for each design, as well as the hypotheses and approximations made in the simulations, were reported in the AMHYCO (public) deliverable D2.2 “Identification and analysis of accident sequences posing high H_2/CO combustion risk (PWR-W, PWR-VVER, PWR-KWU)” (Herranz et al., 2023) and synthesized in open publications (Herranz et al., 2022; 2025). The analysis was mostly focused on the gas composition in different compartments (particularly those taking a high share of the total containment building, i.e., upper compartment and dome) and its corresponding Shapiro diagram. The main outcomes of these tasks 2.2 to 2.4 can be summarized as follows:

- The severe accident sequences that posed a higher risk of gas combustion (H_2 and CO) were SBLOCA (20 cm^2) and LBLOCA, for PWR-W, LOCA (80 cm^2) for PWR-KWU, and SBO with sprays for PWR-VVER.
- A key factor heavily conditioning sequence selection is the availability of containment cooling systems. Their capability of condensing steam during the ex-vessel phase results in a boost of combustible gas molar fraction. In this respect, the partial restoration of sprays after an SBO can pose a threat to the containment integrity.
- As expected, the largest gas accumulation (as long as PARs are not modelled) is found in the ex-vessel phase. The composition of the concrete greatly influences the amount of released gas and the CO fraction.
- Whenever PARs are modelled, O_2 starvation in the ex-vessel phase (low oxygen situation due to the consumption of oxygen by the PARs in the in-vessel phase) makes gas composition exit the flammable region of the Shapiro diagram, even if the combustible gas fraction well exceeds 9 vol%. Even though a lack of oxygen prevents an in-containment combustion in the late phase of an accident, the hydrogen and carbon monoxide stored within the containment still represents a combustion risk in case a containment leakage occurs.

- The presence of a PAR system can significantly reduce the size and magnitude of possible combustible gas clouds within the containment.
- Cavity flooding partially quenches the core melt and thus reduces the release rate of combustion gases resulting from MCCI. Additionally, the strong release of steam during the quenching leads to a fast dilution of the combustible gases.
- Sequences evolving with high in-containment pressure normally do not imply a high risk for hydrogen and CO combustion because of the high steam concentration of these sequences, (e.g., SBO).

The characterization of the highest risk scenarios found (initial and boundary conditions) was reported in detail and passed onto WPs 3 and 4, as a basis for experimental matrices and benchmarking containment analysis approaches, respectively.

2.3. WP3: Experimental investigations

The objective of WP3 was to experimentally investigate phenomena related to hydrogen and carbon monoxide combustion and mitigation, which were still not covered by existing numerical models. The focus was set on the combustion of hydrogen/carbon monoxide/steam mixtures, as well as on the operational behaviour of PARs under boundary conditions representative of the late phase of a severe accident. Hence, following the conclusions of the review performed in WP1 and the scenarios selected in WP2, WP3 provided specific experimental data to assess and enhance the numerical tools used in WP4. WP3 was organized in two major tasks: Task 3.1 (combustion) and Task 3.2 (PARs). The experimental program was conducted in two laboratories: investigations on the H_2/H_2O and $H_2/CO/CO_2/H_2O$ combustion under different conditions were performed at CNRS/ICARE in Orléans/France (see Section 2.3.1), while the operational behaviour of PARs under conditions of the ex-vessel phase of a severe accident was investigated at FZJ in Juelich/Germany (see Section 2.3.2).

2.3.1 Task 3.1: Combustion

The major outputs of this task were related to (i) flammability domain, (ii) laminar and turbulent flame speed, (iii) fundamental flame parameters, and (iv) combustion regimes of H_2/CO mixtures in air or in oxygen starvation conditions and with or without diluents, mainly water vapor and carbon dioxide.

The flammability limits were determined using two different criteria: (a) a visual criterion using a high-speed imaging system, (b) a pressure criterion using a high-frequency piezo-electric pressure transducer. For each condition in terms of initial temperature and initial pressure, ignition energy (Ciccarelli and Dorofeev, 2008; Grosseuvres et al., 2019), the upper and lower flammability limits were determined by performing hundreds of runs to establish a probability of ignition from which the upper and lower flammability were deduced. The combustible gas composition was, on a molar basis: 50% CO + 50% H_2. The major results, Figure 1, showed that:

- the initial pressure had nearly no effect on the LFL and induced a decrease of UFL from 72.4±0.6% at 1 bar and 23°C to 69.3±0.4% at 3.5 bar.
- Raising the initial temperature from 23 to 90°C induced a decrease of the flammability limits from 6.9±0.4% to 5.8±0.3%.
- For oxygen starvation, the LFL was not affected, but a strong drop of the UFL was found from 72.4±0.6% for normal air conditions to 45.7±0.9%.
- Finally, the inerting point of a stoichiometric {50% H_2 + 50% CO}/ air by carbon dioxide was determined to be 52±1 % at 1 bar and 22°C.

The ternary diagram of $H_2/CO/Air/CO_2$ was determined, as a supplementary work for WP4, at an initial pressure of 1 bar and 25°C (Figure 2). The major result was that with this additional diagram, the

flammability limits were known over different ratios of CO_2 (from 0 to 60%). And it has also shown that the inerting point was not obtained for the stoichiometric mixture but on the rich side.

The dynamics of laminar flames have been investigated, from which the laminar flame speed, the Markstein length, and the combustion overpressures have been determined. These detailed experiments showed that reducing the O_2 content in the air had no significant effect both on S_b^0 (unstretched burning flame speed) and L_b (Markstein length of the burnt gases), this is not surprising since the studied mixtures remained on the lean side. The negative L_b indicates that the flame is enhanced by stretch and curvature of the flame. This is an important feature when considering the effect of the turbulence on the increase of the burning rate. The increase of the initial temperature to 60°C led to an increase of the laminar flame speed. The predominance of the thermo-diffusive instabilities, for the range of the studied conditions, illustrates that they must be considered by the 3D and CFD codes as the laminar flame speed is increased by a factor close to 2 depending on the size of the flame and on the exact composition without any turbulence. The measured combustion overpressure showed that for mixtures containing less than 13% of {50%H_2 + 50% CO}, the combustion is incomplete as the flames are dominated by buoyancy. This limit is not modified by the depletion of oxygen.

The detailed experimental and numerical results of Task 3.1 can be found in the AMHYCO (public) deliverable D3.1 “Synthesis and outcomes of performed experiments and numerical results related to H_2/CO/H_2O combustion” (Chaumeix et al., 2024).

2.3.1 Task 3.2: Passive Auto-catalytic Recombiners

The main objective of AMHYCO Task 3.2 was to ensure that the impact of the challenging boundary conditions of a severe accident on the PAR performance is properly addressed in numerical PAR models, which are to be used in full containment accident simulations in the work program of WP4. For this purpose, experimental studies and model development activities have been performed to improve the predictive capabilities of the following four numerical models used to assess the efficiency of PARs as hydrogen mitigation measures: Framatome correlation (correlation-based model for the specific Framatome-PAR type); REKO-DIREKT (mechanistic PAR model involving diffusion-controlled reaction kinetics), developed by FZJ (Reinecke et al., 2016); SPARK (mechanistic PAR model involving full surface and gas-phase chemistry), developed by IRSN (Meyet et al., 2014) and PARUPM (mechanistic PAR model involving surface chemistry), developed by UPM (Jiménez et al., 2007).

The experimental program was addressing knowledge gaps on PAR operation in the presence of hydrogen and carbon monoxide, which could be divided into three different regimes: Regime I: Undisturbed parallel reaction of hydrogen and carbon monoxide with oxygen (oxygen-rich atmosphere); Regime II: Constrained parallel reaction of hydrogen and carbon monoxide with oxygen (oxygen-lean atmosphere) and Regime III: Interruption of reaction due to catalyst deactivation (poisoning).

The experimental program was conducted in the REKO facilities at FZJ, enabling well-defined boundary conditions for single catalyst sheets (REKO-1 flow channel), catalyst sections (REKO-3 flow channel) and down-scaled PARs (REKO-4 pressure vessel). The test program was complemented by results from national and international THAI programs provided by Becker Technologies through the SAMHYCO-NET project, the precursor to the AMHYCO project. For the first time, the experimental program has investigated the effect of carbon monoxide on both platinum- and palladium-based catalysts, to obtain information on the differences in behaviour.

The results of the AMHYCO experimental program have elucidated the behaviour of recombiners in all three operating states mentioned previously. The processes in regime I are well understood and mechanistic approaches for the different PAR models exist. For the transition from regime I to regime II the approach of diffusion-controlled reaction kinetics has been successfully applied to provide a criterion that is applicable for both correlation models as well as detailed codes. This approach is independent of the type of catalyst (Pt or Pd). The experimental data obtained for Regime III from the catalyst poisoning tests suggest that gas temperature and oxygen concentration are the most relevant parameters to describe PAR

poisoning for both catalyst types. The results allowed for the derivation of empirical criteria for catalyst poisoning with sufficient (if necessary, conservative) precision, which are based on easy-to-obtain parameters (gas temperature and oxygen concentration) even for those PAR models that don't involve surface chemistry.

The Framatome correlation is used by most of the AMHYCO partners participating in WP4. Improvements of the correlation based on the laws of diffusion-controlled reaction kinetics have been implemented and validated, which allow for a more consistent transition from oxygen-rich to oxygen-lean PAR operation. The improved model, called the "AMHYCO correlation" (Braun and Reinecke, 2025) has been transferred for testing and implementation in the corresponding thermo-hydraulic codes within the WP4 framework.

Within the AMHYCO project, the PARUPM code has been proposed as an appropriate tool for assessing the performance of PARs in full containment simulations. In the framework of Task 3.2, the PARUPM code has been further developed and validated (Domínguez-Bugarín et al., 2022; 2025). Most relevant enhancements include the implementation of a chimney model as well as a diffusion-based reaction model. The results obtained demonstrate that the physico-chemical strategy used in the PARUPM model can simulate the behaviour of the recombiner under various conditions, from typical concentrations and settings to more extreme ones such as oxygen starvation, catalyst poisoning, or elevated inlet temperatures. Furthermore, the code can reproduce the behaviour of a PAR in transient conditions, where pressure, temperature, and gas concentrations are constantly changing at the recombiner inlet. The PARUPM code has been implemented in the 3D thermo-hydraulic analysis code GOTHIC in WP4.

The further development of the SPARK code includes an update of the surface reaction mechanisms for platinum-based catalysts as well as an approach to implement a surface mechanism for palladium-based catalysts. The new Pt mechanism allows PAR simulation during deactivation conditions in the presence of carbon monoxide. The enhanced SPARK code has been used for post-calculations of both REKO-1 and REKO-3 data to verify that the SPARK code can reproduce the experimental results. The numerical results are consistent with the experimental results for all the cases, confirming that the SPARK code can predict the catalyst temperature for rich-oxygen conditions, oxygen starvation conditions, and in the presence of steam.

Advancements of the REKO-DIREKT code concern the implementation of different poisoning criteria for both catalyst types (Pt and Pd) based on the findings from REKO-3 poisoning experiments. The status of the PAR model has been validated against the new THAI database developed in Task 3.2. General good agreement was obtained, specifically regarding the catalyst temperature, which is one of the specific features of the code.

The detailed experimental and numerical results of Task 3.2 can be found in the AMHYCO (public) deliverable D3.2 "Synthesis and outcomes of performed experiments and numerical results related to PAR behaviour" (Reinecke et al., 2023).

2.4. WP4: Full containment analysis

The main objective of WP4 was to employ the results obtained in WPs 1-3 to define and conduct a comprehensive analytical assessment and finally provide the insights for a review and potential extension of the SAMGs and EOPs within WP4. Following the approach of WP2, an analysis was conducted for the European PWR concepts, W(estern), KWU and VVER. However, while WP2 used the available plant specific models and nodalization schemes, in WP4 generic containments and partly scaled input tables (from WP2) were employed to prepare a common open basis of the analysis, enable a better comparability of the simulation results.

Full containment analyses were conducted in a consecutive analysis chain, consisting of three levels of increasing detail: As a basis, the identified sequences were simulated completely with lumped parameter containment models e.g., built in ASTEC or MELCOR. On this basis, the most penalizing cases were

additionally investigated by 3D models developed in GOTHIC to address potential asymmetric / 3D conditions that may lead to higher combustion risk. As a last step, relevant compartments and/or time frames identified in the 3D analysis were simulated in detailed CFD-grade local containment studies (e.g., using containmentFOAM or ANSYS Fluent) to substantiate GOTHIC analysis and answer remaining open issues. The increasing level of spatial details achieved with the different codes was also utilized to assess the view on the accident from the control room (available sensors) against the full insights provided by the simulations to propose an upgrade of the SA instrumentation.

To ensure comparability of the simulation results, a common generic containment database (D2.1) was utilized (Serra et al., 2024) to develop the containment models within the different codes. The demonstrated agreement of the different codes and models paved the way for a detailed and systematic assessment of the effectiveness or impact of mitigative measures like PARs, fan coolers, sprays, and filtered containment venting systems regarding the in-containment combustion risk. The latter was evaluated in terms of the evolution of the flammable gas cloud as well as its potential of developing flame acceleration conditions, rather than by conducting combustion analyses to exclude the definition of ignition source and timing from the parameter space.

The simulations of the unmitigated reference simulations consistently show that without any hydrogen mitigation measures (no PARs), the containment atmosphere always has pockets where ignition and flame acceleration could occur. In some scenarios, the containment atmosphere even became globally flammable, with the potential of having fast dynamic combustion processes. Furthermore, the mass of combustible gas increases with time due to the ongoing MCCI. This emphasizes the need for combustible gas control hardware to protect the containment integrity and prevent potential loads resulting from a flame acceleration during both the in- and ex-vessel phases for all containment designs.

The experimental work as well as the comparison of the improved ‘AMHYCO PAR correlation’ (Braun and Reinecke, 2025) against the established manufacturer’s correlation (in this case, the Framatome correlation) confirm that PAR operation in the late phase is impaired more strongly by oxygen starvation and parallel recombination of CO. The ‘AMHYCO PAR correlation’ revealed to be conservative compared to the existing manufacturers’ correlation, i.e., resulting in a slower depletion of H_2, CO and O_2 in the late phase.

Besides limiting the H_2 mass in containment, the main effect of PARs was the consumption of O_2 and thus the inertisation of the containment atmosphere in the late phase. The capacity and efficiency of the PAR system primarily affected the peak concentration of H_2 and CO and the time until this inertisation was reached, but PAR systems could deplete the combustible mixtures effectively even with reduced capacities (cf. Figure 3). In all studied scenarios and for all the containment designs, the implementation of PARs prevented the global formation of a gas mixture, which could lead to flame acceleration conditions, while local flame acceleration conditions partially remained possible.

Furthermore, thanks to the O_2 removal, PWR-W and PWR-VVER cooling actions (i.e., spray and containment coolers) to decrease the containment pressure in the late phase of the accident can be taken without increasing the risk of combustion. Considering the steam concentration in the containment, it is clear that for all options, the steam concentration is far below the steam inertisation limit, and thus, the effects of different cooling means on the flammability are small.

The reactivation of the PWR-KWU’s Emergency Core Cooling System did not further increase the combustion risk, since it was primarily cooling the melt pool and not globally the containment atmosphere. In the specific case of containment venting in the PWR-KWU, the combustion risk was further reduced by the removal of combustible gases by the PARs. The later the FCVS is operated, the more the inertisation of the containment atmosphere due to PAR operation also reduces the risk of a combustion event in the first or subsequent operations of the FCVS system.

Equipment survivability (here according to IEEE 323-1974: $T_{gas} > 149.8$ °C, $P < 4.82$ bar) can be challenged in scenarios without containment cooling and with high pressures, i.e. SBO sequences. 3D simulations

revealed a strong heterogeneity of the gas temperature, in particular when PARs are considered. They should be used in future to substantiate LP code analysis and allow quantifying thermal stratifications.

While the 3D and CFD analysis generally showed well-comparable trends for the CV-averaged quantities to the system code analysis, local stratifications and stagnation zones (e.g., dead-end compartments) were identified. Those can result in locally flammable conditions, or e.g., standing flames, which cannot be identified by using the coarse system code nodalization. Furthermore, pointwise evaluation of possible sensor locations showed stronger oscillations with high peak values compared to the rather smooth monotonous evolution of the CV mean values. Consequently, for decision making, it should be accounted for that sensor readings might be affected by local heterogeneities and/or cannot capture local accumulations (e.g., dead-end compartments). While a global combustion event is most likely prevented by PARs, a local combustion (e.g., in dead-end compartments) is possible and should be evaluated or conservatively treated, e.g., by checking the availability of the equipment in these areas under a combustion event.

To conclude, it is important to note that the established approach to combustion risk and flame acceleration assessment, that is considering CO as additional H_2, is quite conservative and should be re-evaluated when improved experimental data and correlations becomes available. In particular, the assessment of flammability and potential flame acceleration of arbitrary mixtures of H_2-CO-O_2 mixtures, including large amounts of diluting gases, obtained in WP3, became available too late to be employed on the evaluation. Nevertheless, these correlations substantiate the findings achieved so far based on a conservative treatment of CO as additional H_2.

Future investigations should substantiate the conclusions taken so far by addressing further scenarios, operator actions and further exploiting 3D / CFD analysis tools to get insight into localized phenomena. The generic containment database (D2.1) and input decks created in WP4 proved to be a well-suited basis for this work and can be refined based on 3D simulation results. Also, sensitivities and propagation of uncertainties should be considered to identify crucial input parameters and modeling choices.

The detailed lessons learned from WP4 can be found in the AMHYCO (public) deliverable D4.3 “Lessons Learned during the Full Containment Analysis of KWU, Western and VVER PWRs and Quality Assurance Measures” (Kelm et al., 2025) and in open publications (Serra et al., 2025; Kelm et al., 2026).

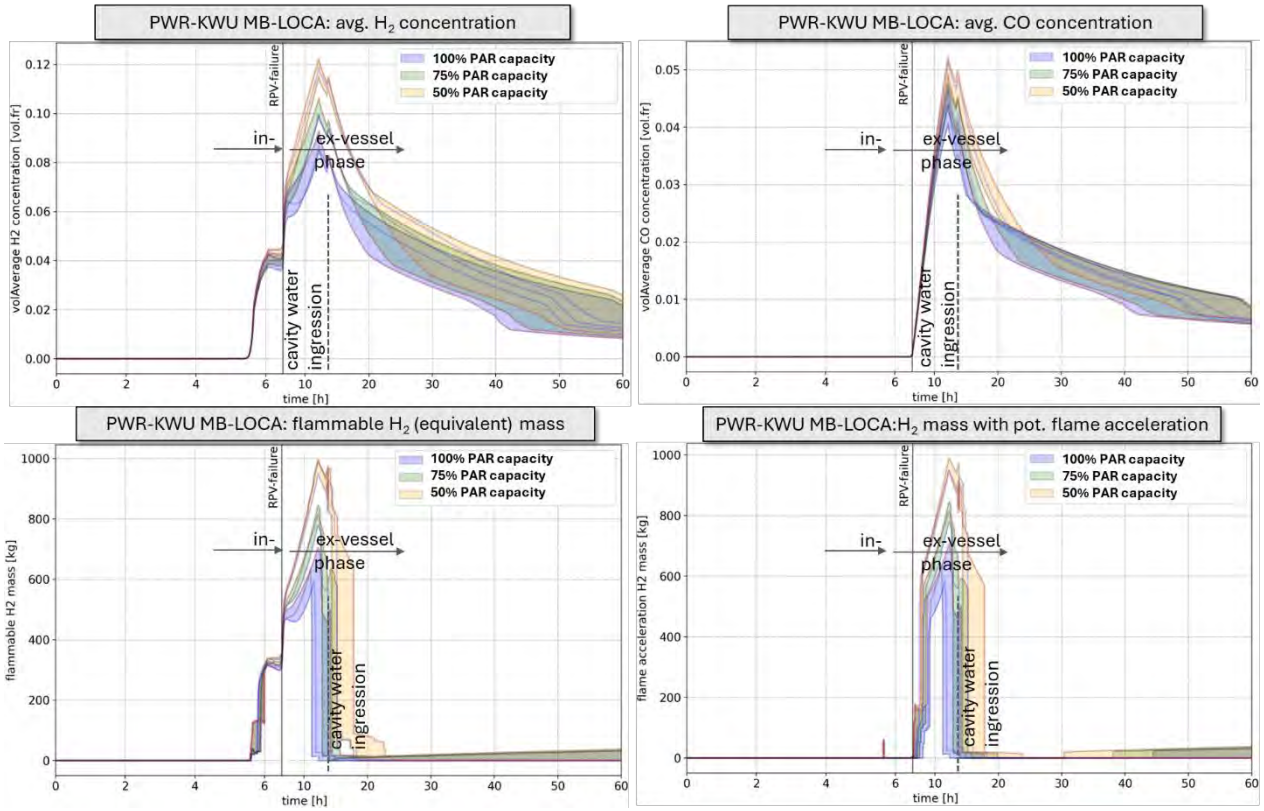

Figure 3. Average H_2 and CO concentrations in the containment and integral flammable H_2 equivalent mass for the PWR-KWU MBLOCA sequences for different PAR system capacities.

2.5. WP5: Enhancement of Severe Accident Management Guidelines

WP5 aimed to identify room for improvement of SAMGs regarding the management of combustible gases, on the basis of the experimental and computational efforts carried out in the above-mentioned WPs. Thereby, the insights from the calculations, including the late phase with CO present in the containment, are transferred into SAMGs considerations. Additionally, recommendations are given concerning possible hardware backfitting.

To make these recommendations, WP5 analyses the results of all the preceding work packages, especially the numerical analyses carried out in WP4, and the experimental results obtained within WP3. From this database, relevant aspects are pointed out, motivated and described, and the applicability to existing European pressurized water reactor types (Western-type, KWU-Type, and VVER-Type) confirmed, and the results are presented in a language commonly used in the nuclear industry framework.

In this way, WP5 formed the interface from academic research and numerical simulations into industrial application. Its outcome was documented in the AMHYCO (public) deliverable D5.1 “Generic Guidelines for SAMG Development, Minimizing the H_2/CO Combustion Risk in a Containment. Lessons learned of the AMHYCO project” (Braun et al., 2025) and can be summarized in these three fields:

a) <u>Gain in knowledge concerning simulating H_2 within a reactor containment</u>

The comparison of simulations performed on different length scales allowed to make statements concerning the connection between the gas cloud distribution within the containment and the singular point values. These findings can support the interpretation of actual measurements as displayed in the main control room, regarding the identification of a containment risk condition. The modelisation of passive autocatalytic recombiners was significantly improved, based on the experimental campaigns with PARs in WP3. Thus, in the future, they can be incorporated in

containment simulations in a much more physically accurate way. The new description includes the consumption of hydrogen as well as carbon monoxide by the PAR, the transition from oxygen-rich into oxygen lean operating conditions, the poisoning of the PAR by CO, as well as the PAR-induced ignition of the containment atmosphere by an extremely high concentration of combustible gases.

b) Improvements in severe accident management guidelines

In the simulations, a strongly negative impact of an early spray (by automatic activation) or a late re-activation of a spray (e.g., due to re-establishment of electric power) on the in-containment combustion risk was identified. Based on the WP4 simulations, the following recommendations were deduced in WP5: In case the spray is already operating, then keep it operating to at least keep the containment pressure prior to ignition low. Concerning a late reactivation, the operators shall have a mean to manually control the spray system to prevent an automatic start of the spray by re-establishing AC power, and the plant shall have appropriate means to characterize the containment atmosphere by suitable gas measurement equipment prior to manually activating the containment spray.

In the frame of WP4, numerical simulations of the PWR-KWU were performed on how the containment atmosphere, and especially its flammability, changes in case of an early and a late venting activation. The insights then were transferred to the other reactor designs. After evaluating the advantages and disadvantages of a filtered venting of the containment, it was concluded in WP5 to not recommend using the filtered containment venting system for hydrogen mitigation. The main reasoning was that a venting affects the containment atmosphere slower than a hydrogen control system based on PARs. Thus, it is beneficial to wait until the PARs have improved the hydrogen risk by consuming both H_2 and O_2 instead of activating the venting system. The results were documented in Deliverable D5.1 Chapter 5.3 and 6.4.

c) Recommendations for backfitting of hardware for long-term operation

Concerning PARs, it was shown that they are greatly beneficial regarding the mitigation of combustible gases. Even in case they would operate only with a reduced efficiency, for whatever unforeseen reason, a suitably designed system can still cope with a wide variety of accident sequences. Concerning the surveillance of the PAR operation, it turned out that often a measurement of oxygen may reveal key information about the containment atmosphere concerning a possible combustion risk state that is needed to complement the measurement of combustible gases.

Furthermore, the backfitting of a filtered venting system (FCVS) can be unconditionally recommended. Within AMHYCO WP5, it was deduced how a FCVS should be operated in the presence of combustible gases, and at which stages high-concentration of combustible gases may get in contact with oxygen-rich atmospheres.

Containment cooling systems like spraying or fan coolers are so strongly interconnected to the containment design itself that there is a low likelihood of backfitting an entirely new system. Instead, possible selective works and upgrades of the systems were evaluated. In some plant designs, the containment cooling is initiated automatically. Especially for accident sequences with a late recovery of the system, the need for manual inhibition of the system activation was identified. Further, it is strongly recommended that if a containment cooling system shall be used in accident management, then a suitable containment surveillance system shall be in place to confirm that the activation of the containment cooling system does not unnecessarily endanger the containment itself by making the atmosphere flammable.

About monitoring, AMHYCO significantly strengthened the knowledge of how to interpret point data measurements in the main control room (see Chapter 5.1) and how these relate to a containment failure risk state. Further, the optimal measurement range of a combustible gas monitoring system

was determined, and the need for such a system was deduced, depending on the plant design and anticipated usage of containment cooling systems.

3. FINAL REMARKS

The AMHYCO project went beyond the state-of-the-art of combustible gas control under severe accident conditions in several aspects. Thereby, the special focus was on closing knowledge gaps concerning combustion mixtures in the late phase of a nuclear accident. Within the scope of AMHYCO were the three dominant containment designs of pressurized water reactors in Europe: the KWU-type, the Western-type (French and Westinghouse), and the VVER-type.

The first work package established the knowledge basis, both numerically and experimentally, to understand the combustion risk of H_2, H_2O and CO mixtures in realistic severe accident conditions. Work Package 2 on one side explored the boundary conditions to be experimentally and numerically explored thereafter, as well as established a common reference plant model for the three considered PWR designs (Western, KWU-type, and VVER). In short, two different databases resulted from WP2: a database of "generic containments" for the three types of reactors and another one with more than 40 accident sequences that closely looked at the combustion risk in containment.

In Work Package 3, experimental campaigns helped, on one side, to increase the understanding of the combustion properties of H_2-CO mixtures, and, on the other side, how passive autocatalytic recombiner operate in atmospheres containing H_2 as well as CO, building an extensive database of experiments with ex-vessel representative conditions.

With improved modelling techniques based on the experimental insights in WP3 and the standardized generic plant models from WP2, in WP4 systematic containment simulations were performed by numerous codes, establishing a broad database of accidental sequences for different code approaches (LP, 3D, and CFD). This database provided insight into the numerical differences of the different codes as well as a more profound understanding of the containment atmosphere during a severe accident and the impact of existing containment cooling systems and backfitted severe-accident-related hardware. A special interest was the comparison of LP, 3D, and CFD numerical codes and how the stimulation of the hydrogen distribution on different length scales affected the results.

Finally, in WP5, all preceding experimental, theoretical, and numerical works were evaluated and condensed into proposals to improve the severe accident mitigation guidelines as well as to recommend back-fitting in existing European pressurized water reactors. The deliverable of this work package shall bring the research results into industrial application.

In the end, AMHYCO provided the community with extensive databases that broadened the knowledge as stated before the project, fulfilling and often exceeding its initially set objectives.

AMHYCO objectives

The AMHYCO project main objective is **to propose innovative enhancements on the way combustible gases are managed in case of a severe accident in currently operating reactors.**

To reach this main objective, the AMHYCO project has three main specific objectives:

Objective 1: To experimentally investigate phenomena that are difficult to predict theoretically: H2/CO combustion and PARs (Passive Autocatalytic Recombiners) behavior under realistic accidental conditions, taking into account their interaction with safety systems.

Objective 2: To improve the predictability of analysis tools - Lumped Parameter (LP), 3D and Computational Fluid Dynamic (CFD) codes - used for explosion hazard evaluation inside the reactor containment and providing support to SAMGs design and development.

Objective 3: To improve the Severe Accident Management Guidelines for both in-vessel and ex-vessel phases with respect to combustible gases risk management, using theoretical, simulation and experimental results.

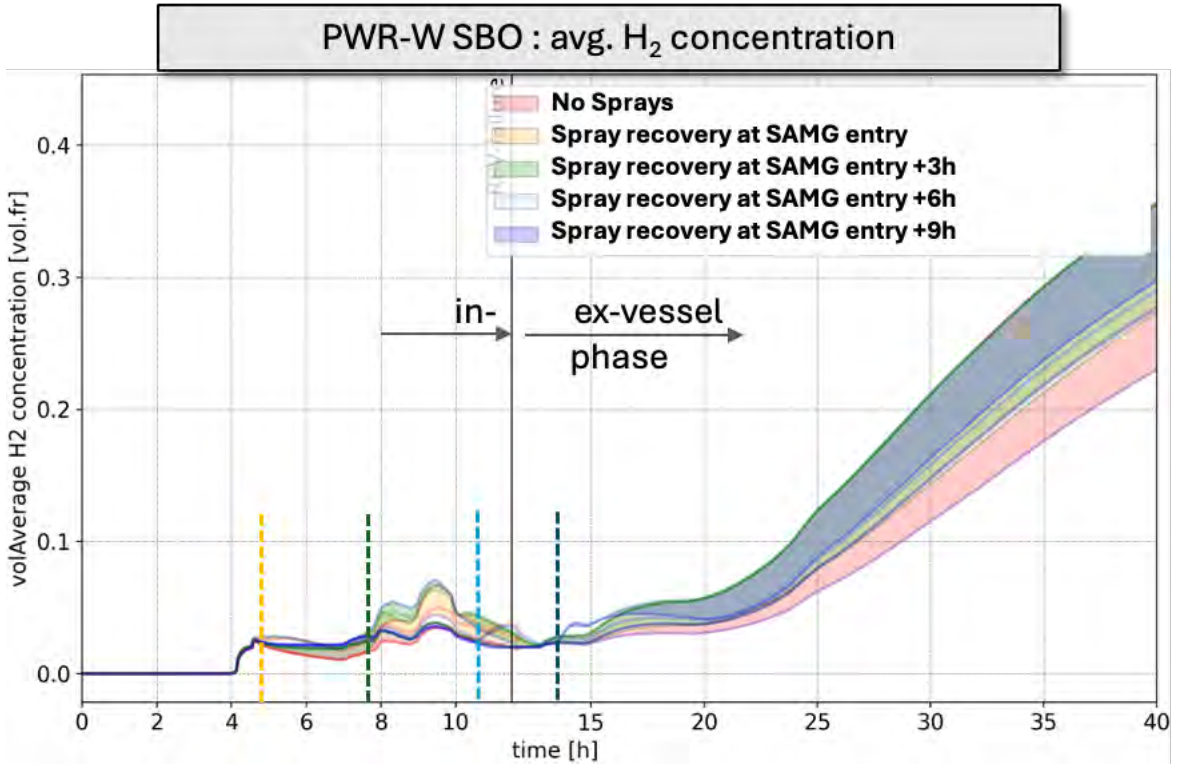
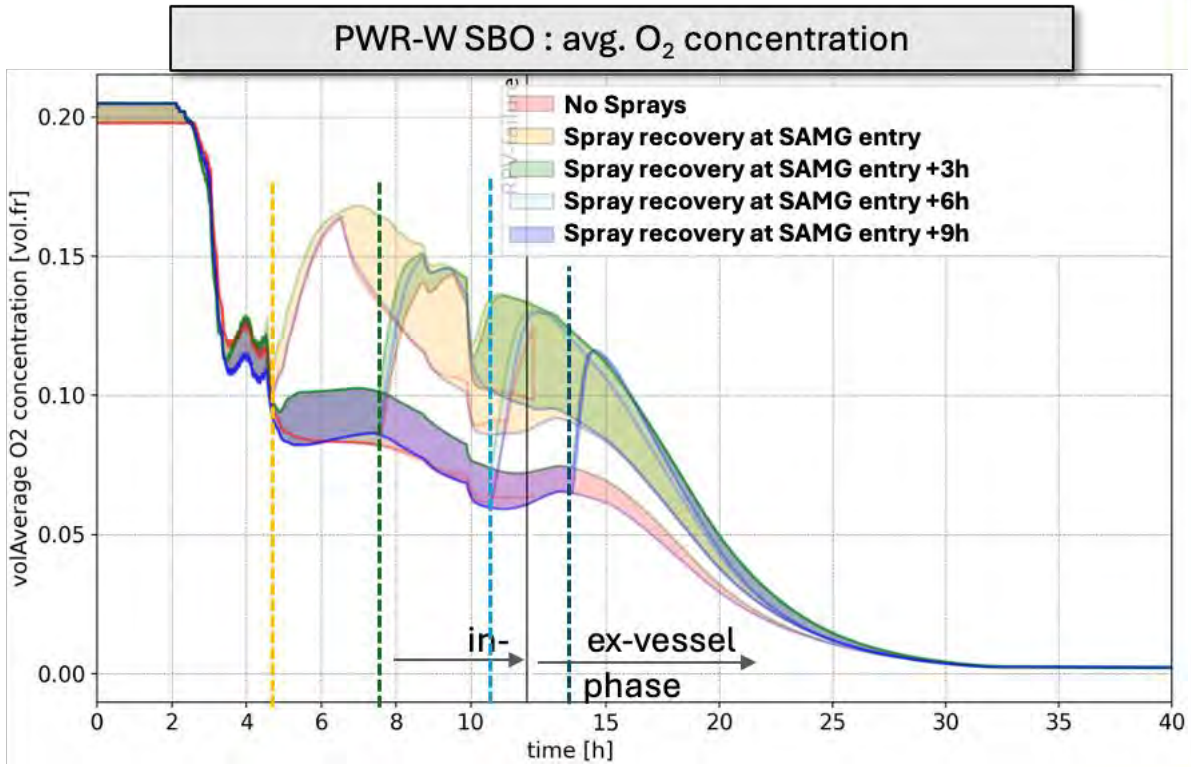
WP4-WP5: a proper spray/fan coolers operation criteria is needed for limiting the H2/CO combustion risk

- recovery of AC power enables operators to activate the sprays for pressure reduction





- Steam concentration mostly below inertization limit
- For late spray recovery, O_2 is consumed by the PARs (but still above O_2 limit).

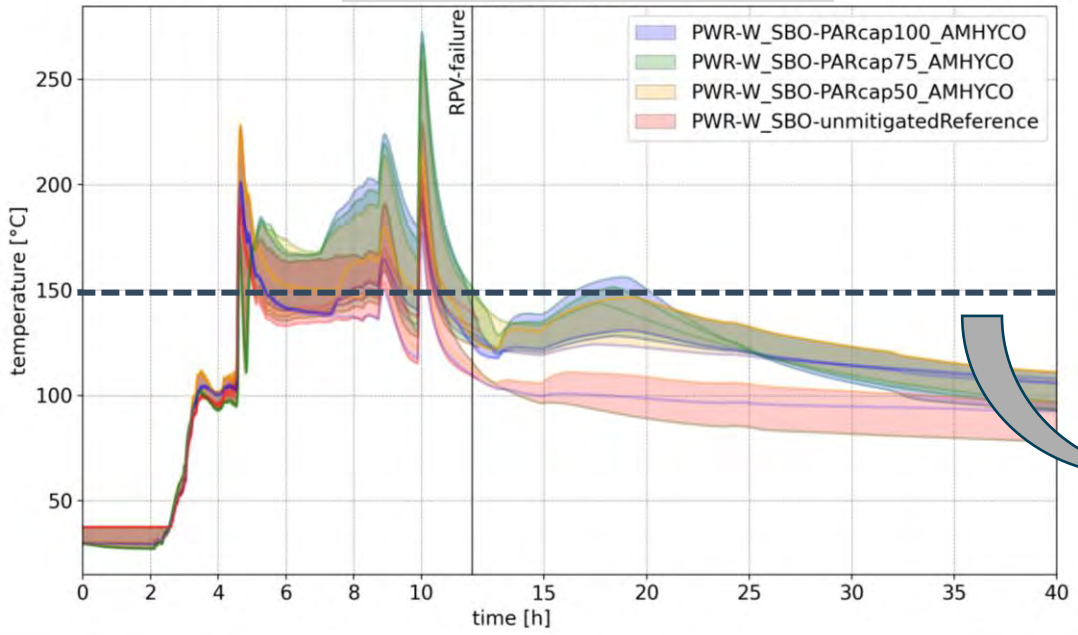
*SAMG entry: depressurization of the primary system

REF: Braun, M et al. (2025). *D5.1 – Generic guidelines for SAMG development, minimizing the H2/CO combustion risk in a containment. Lessons learned of the AMHYCO project*. AMHYCO project

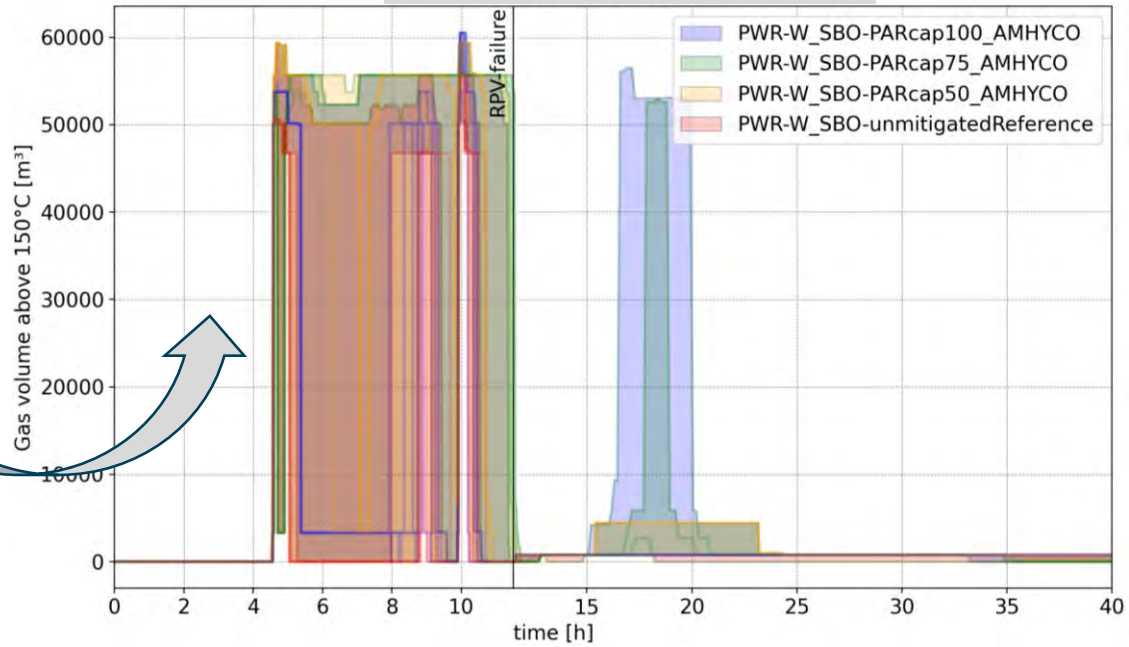
WP4-WP5: the equipment qualification limits should take into account 3D/CFD simulations

- EQ criterion: Evaluation of gas cloud hotter than T = 149°C, e.g. PWR-W SBO:

Dome temperature



´hot cloud´



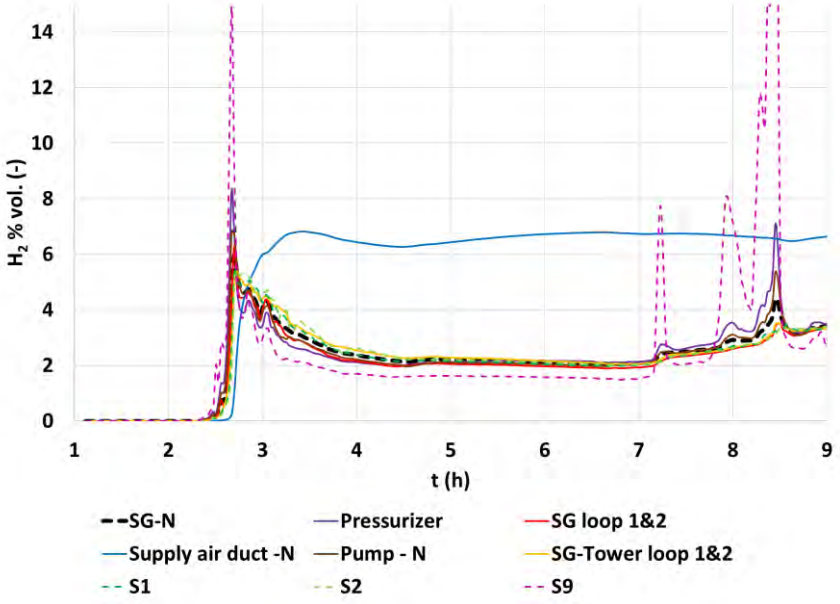
- Without containment cooling means, T_{gas} can exceed T_{lim}.in the late in-vessel and ex-vessel phases. PARs promote ‚overheating'!
- Early failures in PWR-W SBO, late failures (+50h for PWR-KWU MBLOCA and TLAP)

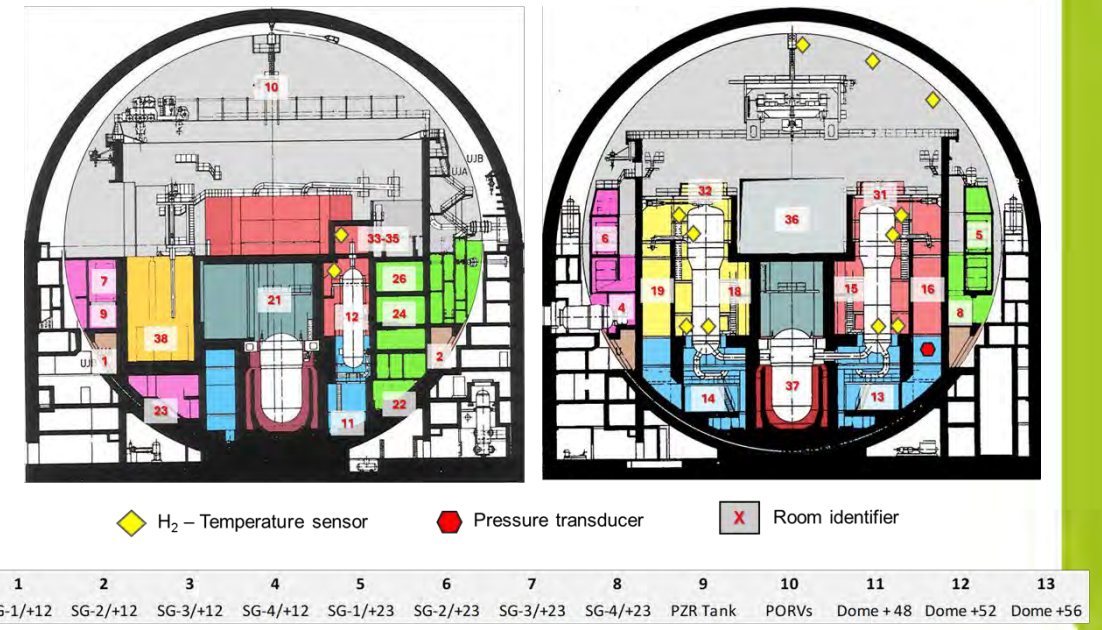
REF: Braun, M et al. (2025). *D5.1 – Generic guidelines for SAMG development, minimizing the H2/CO combustion risk in a containment. Lessons learned of the AMHYCO project*. AMHYCO project

WP4-WP5: containment instrument readings could bring a not totally clear idea of the global combustion risk

- Complementary 3D / CFD analysis were performed to assess heterogenities and evaluate the representativeness of available containment instrumentation
- E.g. GOTHIC analysis of PWR-KWU TLAP

O2 and CO measurements are needed!!!





- local ‚hot spots' and temporal H_2 peaks observed near release locations and dead-ends which can cause high and fluctuating sensor readings or not be visible at all

REF: Braun, M. et al. (2025). *D5.1 – Generic guidelines for SAMG development, minimizing the H2/CO combustion risk in a containment. Lessons learned of the AMHYCO project*. AMHYCO project

CFD ANALYSIS OF THE CONTAINMENT BEHAVIOR DURING A TLAP SEQUENCE IN A GENERIC KWU PWR WITH CONTAINMENTFOAM

Stephan Kelm, Carlos Vázquez-Rodríguez, Michael Klauck

Forschungszentrum Jülich GmbH

ABSTRACT

The European AMHYCO project (Euratom 20192020, GA No 945057) aimed at enhancing the understanding of the H_2/CO combustion risk within the containment of a nuclear power plant during a severe accident. The goals of the project were to incorporate the gained knowledge into severe accident mitigation guidelines (SAMGs) and recommend long-term operation upgrades. The analytical work comprised a consecutive analysis chain, consisting of three levels with increasing detail (system codes, 3D GOTHIC, and CFD) to assess containment pressurization, PAR efficiency, and options of individual mitigation measures regarding H_2/CO combustion risk and equipment and instrumentation survivability for three generic European PWR containment designs, namely KWU, Western (Westinghouse and French designs) and VVER.

The paper focuses on the *containmentFOAM* modeling of a KWU-PWR containment. Along with a brief introduction of the *containmentFOAM* CFD package built on OpenFOAM-11, the modeling assumptions and simplifications of the full-scale model are discussed. On this basis, the gas distribution in the containment is simulated for a Total Loss of AC Power (TLAP) sequence. The results are discussed in comparison with the system code COCOSYS also employed within AMHYCO. Due to its ability to consider momentum transfer, the CFD model reveals a different mixing mechanism close to the break. Because of the high elevation of the release location at the pressurizer relief tank, this leads to a less complete mixing in the equipment rooms and gas transport within the containment dome. While the global pressurization is not significantly affected by heterogeneous steam distribution, the evolution of a locally flammable cloud reveals a different mechanism in both approaches and the relevance of local conditions and 3D flow in the global quantification of combustion risk. To conclude, the paper summarizes the lessons learned from the full-scale CFD application and needs for further model development.

KEYWORDS

containment mixing, combustion risk, CFD, containmentFOAM

1. INTRODUCTION

The containment structure constitutes the last barrier against the release of fission products during severe nuclear accidents. Its integrity can be challenged by continuous pressurization from steam and non-condensable gas releases or by dynamic events such as combustion. Three-dimensional characteristics of the containment can influence the transport and mixing processes, and thus pressurization, combustion risk, and overall structural response to dynamic loads. Understanding these interactions is essential for accurately assessing the containment behavior under severe accident conditions.

To address these challenges, the open-source Computational Fluid Dynamics (CFD) package *containmentFOAM* has been developed since 2017 to provide highly resolved 3D simulations of the containment phenomena in large dry PWR containments [1], [2], [3]. Currently, it is extended to study containment phenomena and the effectiveness of passive safety features, e.g., for containment cooling or pressure limitation in Light-Water cooled Small Modular Reactors (LW-SMR) [4], [5].

Aligned with the conceived application of *containmentFOAM*, the European AMHYCO project (Euratom 2019–2020, GA No. 945057) [6] provided a framework dedicated to improving the understanding of hydrogen and carbon monoxide combustion risks in nuclear power plant containments during severe accidents, with the objective of supporting severe accident management guidelines and long-term operation upgrades. The project employed a hierarchical analysis approach of increasing fidelity —system codes, 3D GOTHIC, and CFD— to evaluate containment pressurization, mitigation measure effectiveness, and equipment survivability for three representative European PWR containment designs [7], [8].

Building on the AMHYCO analysis framework, this paper focuses on CFD simulations of a KWU PWR containment using *containmentFOAM*. After outlining the modeling assumptions and simplifications of the full-scale containment model, the study analyzes the distribution of condensable and non-condensable gases and investigates containment atmosphere mixing during a total loss of AC power (TLAP) with delayed depressurization, a special kind of station blackout (SBO) sequence. Results are compared with predictions obtained with the system code COCOSYS [9] to discuss plausibility of the overall transient progression but also additional insights and limitations of the CFD approach. Thus, this study complements the recent analysis done by Serra et al. [10] using the 3D 'coarse grid' CFD tool GOTHIC^{TM}. The paper concludes by summarizing key insights from the full-scale CFD application and identifying needs for further model development.

2. FULL CONTAINMENT MODELING

2.1. Accident Sequence

In this study, a total loss of AC power (TLAP) is considered as initiating event, leading to reactor scram (cf. Table 1). After the SCRAM, the decay heat is first removed by a vaporization of the secondary side steam generator (SG) inventory. Once the SG dried out after approximately one hour, pressure in the reactor cooling system (RCS) rises and the pressurizer safety valve starts cycling leading to a continuous loss of coolant to the pressurizer release tank (PRT) and, after opening of its burst discs, to the containment (steam release indicated by blue curve in Figure 1).

Time [h]	Event
0	TLAP and SCRAM
<1	SG dry-out
>1	Pressurizer safety valve cycling
1.8	Core uncovery
2.1	COT > 650°C (SAMG entry)
2.5	Onset of H_2 production
2.7	RCS depressurization (delayed)
>2.7	Hydro accumulator injection
9.1	RPV failure

Table 1: Event chronology

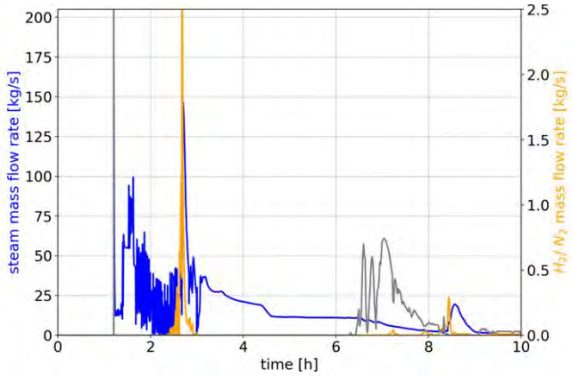

Figure 1: Mass release rates during the in-vessel phase

Later on, the continuous heat release and loss of coolant lead to core uncovery. With reaching the criterion "core outlet temperature (COT) > 650 °C", the operators switch from preventive (here assumed ineffective) accident management into mitigative accident management. However, it is assumed that they cannot proceed directly with the depressurization of the RCS as defined by the EOPs/SAMGs. Thus, when the core oxidation starts, the released H_2 initially accumulates within the RCS. After around 2.7 h, operators finally manage to initiate RCS depressurization, leading to a strong release of H_2 to the containment (orange curve in Figure 1). Along with the depressurization, the accumulators start injecting water for about 3 hours before also their N_2 inventory is injected (gray curve in Figure 1). After about nine hours, the RPV fails. However, the subsequent ex-vessel phase is not considered in this study. Energy and mass source terms are obtained from a MELCOR analysis, kindly provided by Framatome Germany within AMHYCO [11].

Before RPV failure, steam, and hydrogen are released from the RCS only via the rupture disk of the PRT. In KWU-type of containments, this tank is installed at a relatively high elevation, directly below the operating floor, see Figure 2. Considering the relatively high release location (~ +25m) in the containment and the comparably low injection momentum (compared to a MB/LB LOCA), a limited mixing in the containment and atmospheric stratification is expected and thus motivates a closer look using the CFD approach.

2.1. Geometric Model

The containment of a German KWU-type PWR consists of a spherical, free-standing steel containment with an inner diameter of ~56 m and a design pressure of 6.3 bar. Within the steel shell is a complex internal concrete structure, see Figure 2. The containment is split into two main compartments, the inner 'equipment rooms', housing the components of the RCS, and the outer rooms (e.g., service floor, dome, pipeline duct) which are accessible by plant personnel during power operation. These two compartments are primarily connected via burst foils on top of the steam generator towers, which open once a differential pressure of 30 mbar is reached. Furthermore, there are multiple doors connecting both compartments, which, however, have considerably higher opening pressure and will only be blown out during large break loss of coolant (LOCA) sequences with fast containment pressurization. In the TLAP sequence investigated in this paper, the pressurization is comparably slow, and it is assumed that only a part of the burst foils (here those on top of the northern steam generator tower 'SG-N') open. This leads to a reduced mixing in the containment compared to the sequence studied with in the AMHYCO project.

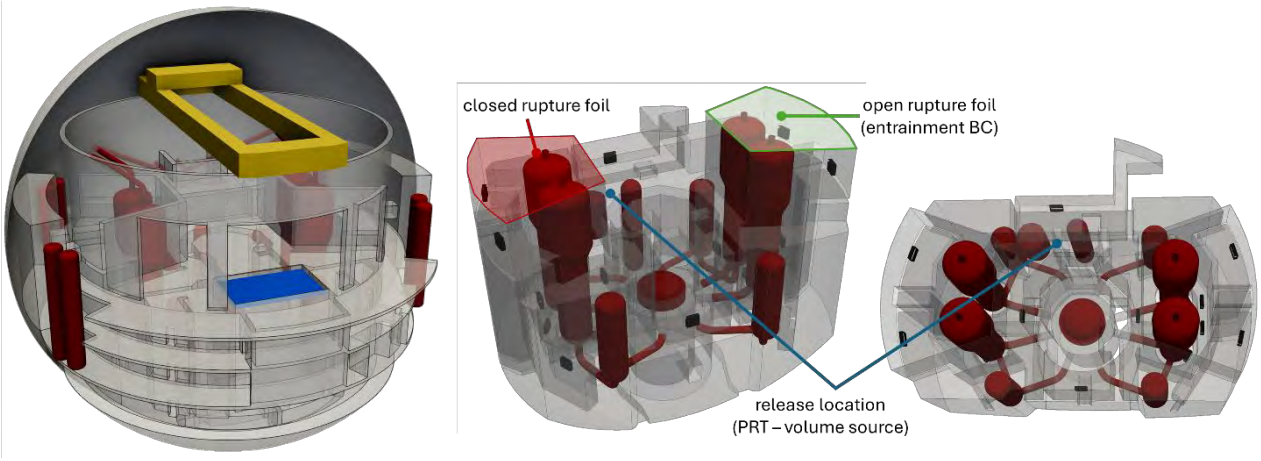

Figure 2: Full containment geometry (left), separated equipment rooms (middle/right). Black boxes represent PARs (adapted from [12])

Within AMHYCO, detailed Computational Aided Design (CAD) models have been prepared by Universidad Politécnica de Madrid (UPM) and used as a basis to derive comparable nodalisation schemes and 3D models. Furthermore, a generic system of 40 passive auto-catalytic recombiners (PAR) has been implemented [10], [12]. This 3D geometry was slightly adapted to ease meshing (e.g., removing small geometric features, thickening thin structures), while its overall heat capacity (mass * spec. heat capacity) and surface area were maintained. The nodalisation scheme used for COCOSYS corresponds to the one defined within AMHYCO and is illustrated in Figure 3 (right). It should be stressed that the nodalisation scheme was intentionally kept simple within AMHYCO, involving a limited number of control volumes (CVs), to facilitate a better comparison among the results.

2.3. Mesh

The mesh was created with the commercial software cfMesh+, which relies on the cut-cell method with cubic base cells. It uses a base mesh spacing of 40 cm and is refined towards geometric features using up to two refinement levels of 20 and 10 cm edge length. Wall shear layers near structures were resolved by five layers of prismatic cells. This proved to be an optimal mesh resolution to resolve the relevant geometric characteristics and flow features and maintain a sufficient mesh quality. A formal mesh sensitivity analysis was, however, not performed yet. The total mesh consists of approximately 10 million cells in the gas space and is illustrated in Figure 3.

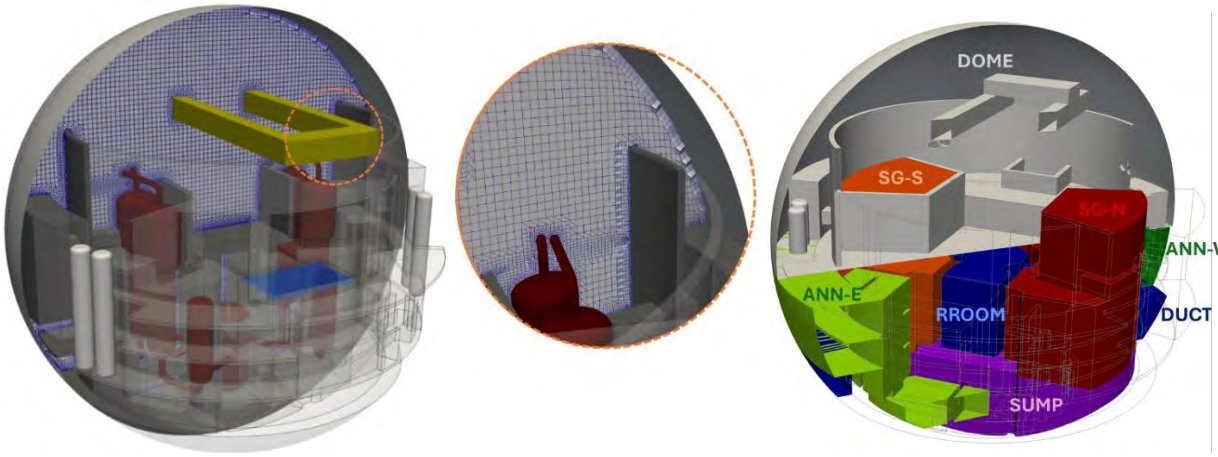

Figure 3: Discretization of the containment volume in *containmentFOAM* (left), generic nodalisation of the containment employed with COCOSYS within AMHYCO (right)

The concrete structures as well as the steel shell and polar crane are also resolved by the mesh, while other steel structures are either represented by a boundary condition (e.g., RCS components by a Robin-type boundary) or assumed to be in equilibrium with the gas phase and ignored (smaller structures such as walking grids).

2.4. Physical and Numerical Modeling

The 'baseline model set' for large dry PWR containment analysis, which was intensively validated before (e.g., [1], [2], [3], [13]), was employed. Its main characteristics are summarized in Table 2. Basically, it is based on a single-phase simplification of the containment atmosphere, where wall condensation is modeled using a diffusion layer approach [14] and bulk condensation a homogeneous equilibrium model [15]. Turbulence production and dissipation due to buoyancy forces is considered [16] and thermal radiation is simply modeled using the P_1 model, assuming the containment atmosphere to be optically thick. The rupture foils on top of the SG towers are represented by a conditional mesh connection which opens based on the

pressure difference between both sides. PARs are represented by the detailed mechanistic model *REKO-DIREKT*, developed at FZJ [17]. It was wrapped into a Functional Mockup Unit and coupled with *containmentFOAM* through its in-built Functional Mockup Interface (FMI) 2.0 interface using a domain decomposition approach.

The steam, non-condensable gases, and heat release from the PRT are efficiently treated as a volumetric source ($V \sim 1\ m^3$) without directional momentum. This is conservative since it minimizes momentum-driven mixing in the containment. The release rate, composition, and temperature are directly specified from the injection tables provided by a MELCOR simulation. All structures are represented by a conjugate heat transfer (CHT) approach and allow for condensation heat transfer except for the RCS components, which are defined as 'hot' boundaries at elevated temperature obtained from COCOSYS.

Table 2: Physical models

Physics	Model
governing equations	unsteady Reynolds-averaged Navier-Stokes equations, total energy equation, transport equation for species mass fraction
turbulent transport	k-ω based Shear Stress Transport (SST) model, including production and dissipation terms for buoyancy turbulence based on SGDH; Turbulent heat and mass transport: SGDH, Pr_t=Sc_t=0.85
multi-species transport	temperature dependent transport properties, constant specific heat capacity, ideal mixture, effective binary diffusion model, pressure and temperature dependent diffusion coefficients (Fuller model)
wall treatment and condensation	wall condensation: single phase 'diffusion-layer' approach, continuous wall functions bulk condensation: single phase homogeneous equilibrium approach, passive scalar drift-flux transport equation for fog
thermal radiation	P_1 model, gray participating mixture properties (κ_{H2O}=10 $bar^{-1}m^{-1}$, non-condensables transparent), ε_{wall} = 0.6
system models	PARs: coupling with mechanistic model REKODIREKT

The numerical schemes and settings are summarized in Table 3.

Table 3: Numerical schemes and settings

Aspect	Setting
Time step	Adaptive: 10^{-5}s ... 10^{-1}s (mean $\Delta t \sim 5e^{-3}$s)
PIMPLE loop	2 inner pressure correction loops, 2 non-orthogonality corrections, max. 10 outer loops
Convergence criteria	All equations PIMPLE residuals < 10^{-4}
Schemes	Gradients: least squares incl. gradient limiters Divergence: 2nd order with limiters Laplacian: 2nd order with limiter for non-orthogonal corrections
Time step	Adaptive: 10^{-5}s ... 10^{-1}s (mean $\Delta t \sim 5e^{-3}$s), CFL< 10
Parallelization	1024 partitions, scotch partitioner

The spatial discretization is mostly of 2nd order, while local blending towards 1st order accuracy was required for stability or boundedness. Discretization in time was 2nd order using a Crank-Nicholson scheme with 10% off-centering for stability. The time step was automatically adapted to maintain a max. CFL number below 10 and max. 5 outer PIMPLE iterations. This strategy allowed for a stable simulation of around 100 to 1500 s/day, depending on the release rate, using 1024 cores of FZJ's high-performance computing facility JURECA.

3. RESULTS

At the time of writing the paper, a simulation of the first 3 hours (11,000 s) of the accident sequence was conducted. To investigate the efficiency of the PAR system, two simulations, one with and one without PARs, were performed. Considering the mass and energy release (cf. Figure 1), the first H_2 release occurs relatively late at ~2.6 h (9,300 s). Consequently, the following discussion focuses on the steam release and pressurization as well as the distribution of H_2 and formation of a flammable gas cloud.

3.1. Steam Distribution and Pressurization

To compare *containmentFOAM* (3D) results with *COCOSYS* (1D), a volume weighted average is calculated per CV. A first impression of the results is given in Figure 4 for the DOME, which is the largest CV in the containment. Generally, the mean values obtained with *COCOSYS* and *containmentFOAM* reveal comparable trends. The wide blue bands representing min/max *containmentFOAM* values in the DOME CV showing the high local variability indicate that the gas / heat in the dome is not well mixed. Considering the two completely different code approaches to the problem, *containmentFOAM* (3D) and *COCOSYS* show a surprisingly good agreement of (averaged) results. However, the local differences in heat transfer and condensation contribute to the differences that can be observed for the mean pressure evolution.

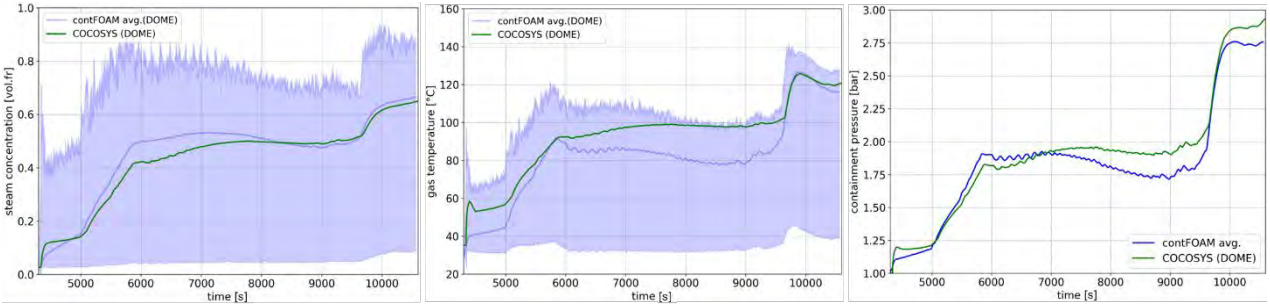

Figure 4: Comparison of steam concentration (left), gas temperature (middle) and pressure (right) in the DOME compartment

While the DOME compartment is involved in the main gas convective loop, there is less exchange with the SUMP region in the bottom of the equipment rooms during this transient in the *containmentFOAM* analysis compared to the LP model. Figure 5 illustrates this difference between both simulations. While in *COCOSYS* the predicted mean gas temperature and the steam concentration are comparable to the ones in the DOME, *containmentFOAM* predicts a considerably reduced transport of hot steam to the lower containment.

This is related to the high release elevation, the missing downward momentum, and the strong buoyancy of the released hot gases, which immediately ascend to the dome through the open rupture foils after being released. Thus, in the *containmentFOAM* analysis, the release of gases inside the equipment rooms primarily leads to a displacement of the initial atmosphere above the release location and only limited mixing below. In contrast, the coarse 1D-LP nodalisation results in a more pronounced downwards transport of steam due to the averaging along the height of the CVs ('numerical diffusion'). This is a known limitation of lumped-parameter codes.

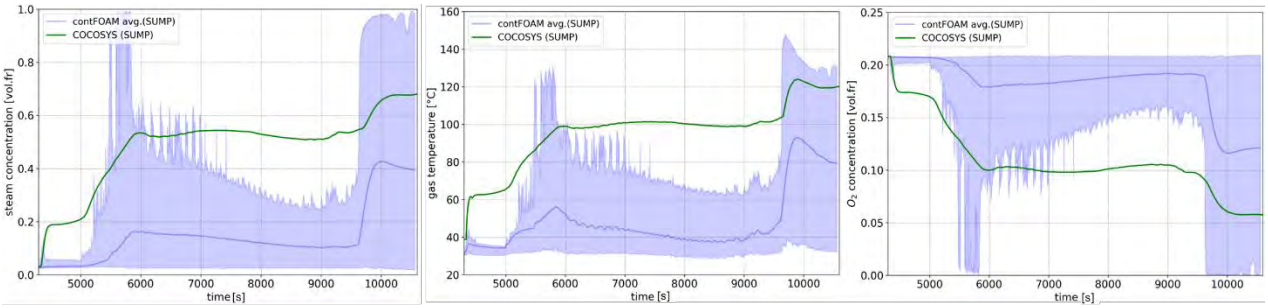

Figure 5: Comparison of steam concentration (left), gas temperature (middle) and oxygen concentration (right) in the SUMP compartment

Figure 6 illustrates the 3D distribution of steam in the containment and resulting condensation rates on the containment structures.

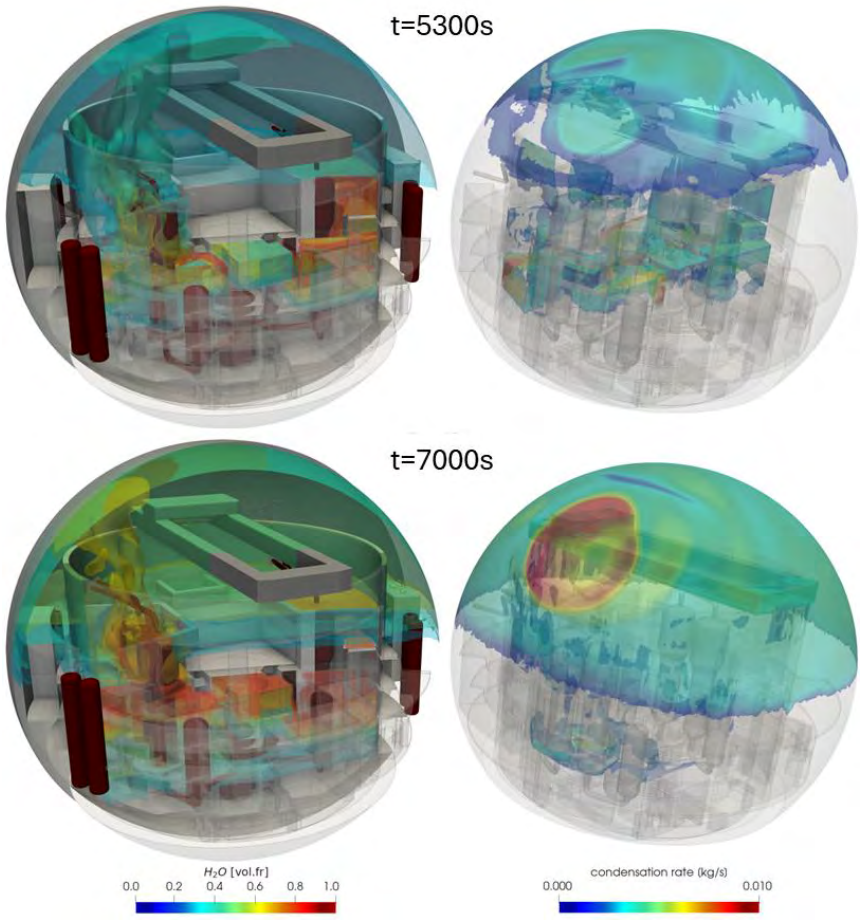

Figure 6: Steam distribution (left) and local condensation rates on structures (right)

Within the equipment rooms, a steam stratification is formed above the elevation of the PRT. Outside, in the DOME region, the stratification extends down to the upper opening of the steam generator towers. Only in these regions, significant steam condensation (>0.01 kg/m²s) occurs. Comparing the two time frames, it becomes obvious that the major condensation, which limits the pressure in the early accident phase, occurs on the containment shell, while the concrete surfaces inside the equipment rooms are heated up quickly and allow only for low condensation rates in the longer term, limited by the low heat conductivity of concrete.

3.2. H_2 Distribution and Formation of a Flammable Cloud

The observations made for steam can be extended to H_2. Primarily, in the break compartment and the DOME above, the CV averaged distribution simulated by *containmentFOAM* compares quite well with *COCOSYS* results, while the min/max band already indicates heterogeneous distribution inside the CVs. Into the region below the release elevation (SUMP) or into dead-end compartments (e.g. ANN-E) only limited transport is predicted by *containmentFOAM* and the volumetric average values are below those, obtained with the LP simulation, as illustrated in Figure 7.

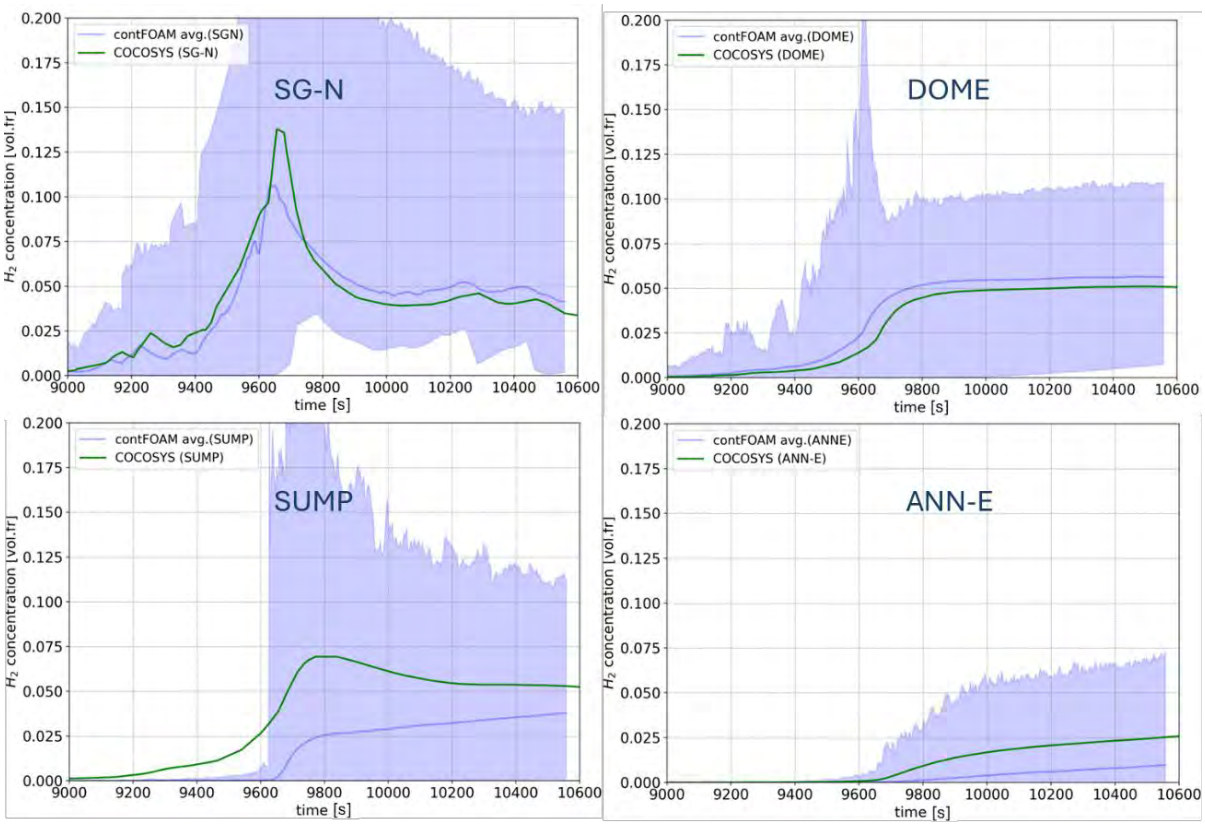

Figure 7: Comparison of H_2 distribution between different compartments: Main convective loop (top), dead-ends (bottom)

The broad blue bands indicate a heterogeneous distribution of gases within the CVs, which likely has an impact on the formation of flammable clouds. In the following, the flammable cloud was characterized using the extended flammability limits determined by CNRS within the AMHYCO project [18]. For the *containmentFOAM* analysis, the flammable cloud was both evaluated based on volumetric averages for the CVs, obtaining a LP-like quantification, as well as 'local' cell-by-cell values. The resulting evolution of the flammable volume and mass following the first H_2 release peak is compared in Figure 8. While the evolution of the flammable clouds is visibly different for the different approaches, one can stress a common point, i.e., flammability is limited to few CV's or regions. Besides, it is obvious that (i) the cell-wise and CV-wise integration of the flammable volumes does not reveal comparable trends. Furthermore, the CV-wise integration of the *containmentFOAM* results differs from *COCOSYS*. While *COCOSYS* predicts flammability in the SG-S and SUMP CV's, *containmentFOAM* reaches flammable conditions within SG-N and RROOM CVs. Looking at the cell-wise integration, the total flammable cloud(s) volume is much larger as it involves parts of the dome and sump regions, which are not globally flammable. It is also apparent that in the 'local' cell-wise integration, the flammable cloud exists for a longer duration than for the 'global' CV-wise consideration.

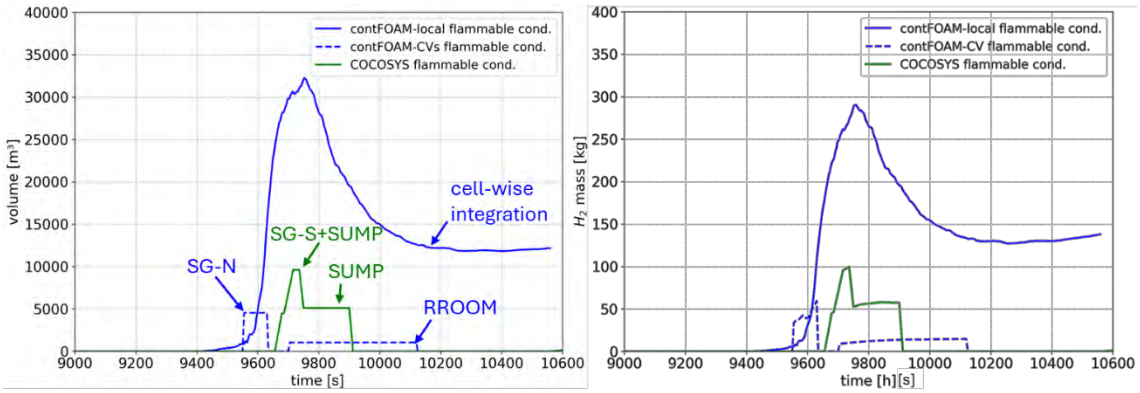

Figure 8: Comparison of flammable cloud volume (left) and H_2 mass (right)

Considering the flammable H_2 mass, considerable differences can be observed, which underlines the uncertainty associated with such a metric, evaluated by volumetric averaging for a large CV. This finding substantiates the observation made by Serra et al. [10]

The detailed build-up process of the flammable cloud is illustrated in Figure 9. Shortly after beginning of H_2 release (t = 9.600 s), the lower flammability limit (LFL) is not reached in the containment and limits the extent of the flammable cloud to a plume rising from the PRT into the dome. After a while (t = 9.900 s) the LFL is exceeded in the SG towers and DOME, but the continuous release of steam leads to a dilution of O_2 and forms an inert stratified cloud in the upper DOME.

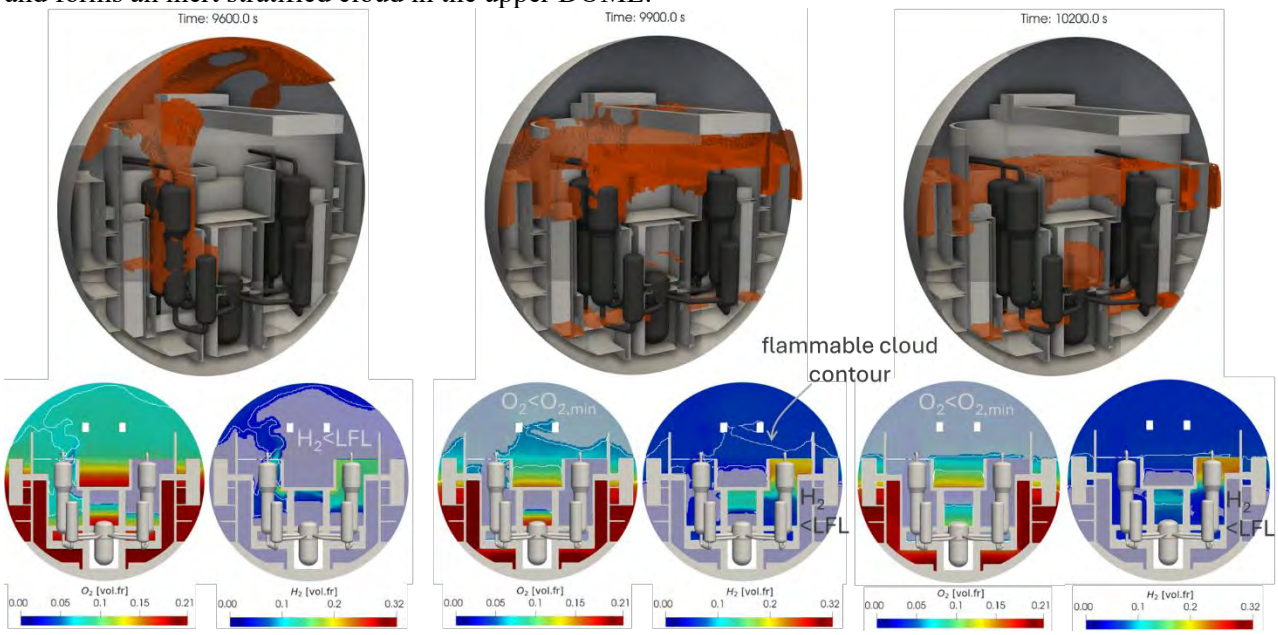

Figure 9: Visualization of flammable cloud built-up and evolution

Soon after (t=10200 s), the H_2 concentration is above the LFL in a large area of the containment, but sufficient O_2 is only available in the annular compartments and the SUMP. The resulting flammable clouds are formed in between the 'inert' O_2 lean cloud of hot injected gases and the H_2 lean initial gas mixture present in the stagnant zones. The small 2D slices at the lower half of Figure 9, coloring the areas of the containment where O_2 and H_2 are within the flammability bounds, clearly illustrate that flammable cloud (in orange) appears only where both gases are within the flammable bounds.

This situation can exist for a longer time (t > 10200 s), since the slow mass exchange between both volumes maintains flammable conditions. Looking at the same situation from the perspective of volumetric averages in large CVs, however, likely leads to 'averaging out' local flammable conditions from an 'all or nothing' viewpoint. An effect that could be potentially reduced by a refined nodalisation scheme. However, the 3D simulation also revealed considerably reduced transport of released gas to lower regions in the containment, which is difficult to reproduce using LP codes. This will affect the available O_2 concentration and thus the long-term flammability.

The implementation of a generic PAR system, consisting of 40 units, was performed in parallel to the discussed simulation and is still under investigation. It turned out that PARs, being slow-acting thermal devices, do not affect the initial peak of the flammable cloud but introduce additional local buoyancy-driven flows that enable enhanced mixing of the lower dead-end regions and the lower DOME region. Thus, the containment atmosphere mixing is promoted and O_2 is removed more effectively, leading faster to inert / O_2 lean conditions.

4. CONCLUSIONS AND FUTURE WORK

This paper presents work performed in the aftermath of the EU AMHYCO project, representing the first full-scale containment analysis based on a station blackout (SBO) sequence conducted with *containmentFOAM*. The selected sequence was chosen for detailed CFD investigation due to the elevated release location and, in comparison to LOCA scenarios, lower release mass flow rates. Consequently, pronounced stratification effects and deviations from lumped-parameter (LP) simulations were anticipated. In addition, one rupture foil on the steam generator (SG) towers remained closed during the sequence, further limiting mixing within the containment.

The applied spatial mesh resolution of approximately 10 million cells in the gas space is unprecedented for such analyses and enabled a detailed assessment of the three-dimensional distribution of steam, associated condensation phenomena, and containment pressurization. Furthermore, the distribution of hydrogen (and oxygen) was investigated, allowing to evaluate the build-up and temporal evolution of the flammable cloud.

The *containmentFOAM* results indicate that the coarse nodalisation and large control volumes used in system-level simulations tend to promote the transport of steam and non-condensable gases towards the lower sump region and annular dead-end compartments. In contrast, the resolved flow field obtained from the CFD analysis shows a significantly stronger buoyancy-driven flow towards the dome, leading to: (i) pronounced stratified conditions above the release location within the equipment rooms and above the upper openings of the SG towers in the containment dome; and (ii) visibly lower steam concentrations in the lower compartments when compared to LP results. While these differences substantially affect the local steam distribution, the resulting global containment pressurization remains in good agreement with the LP simulation. Accordingly, although wall condensation rates exhibit strong local heterogeneities, their integral effect is well comparable to the averaged rates obtained from the LP representation.

More pronounced discrepancies were observed in the hydrogen distribution and in the formation and evolution of flammable gas clouds. These result from localized mass transfer between two initially non-flammable regions, one rich in oxygen (dead-end compartment) and the other rich in hydrogen (main convective loop). Such mechanisms are difficult to represent using a coarse system-code nodalisation and therefore motivate the application of three-dimensional CFD tools such as *containmentFOAM*. It is expected that similar observations can be made for situations where dead-end compartments exist.

Nevertheless, despite notable differences in local details, both approaches yielded largely comparable results, particularly in regions characterized by sufficient mixing. Given the high computational cost of the present CFD analysis, approximately 0.5 million core-hours for 2 hours of simulated problem time, the use of CFD remains a complementary element in containment analysis. To enhance its applicability, a coupling

strategy between CFD and system codes at the compartment or control-volume level is foreseen. A first step was made within the AMHYCO project, where a one-way coupling was already successfully demonstrated, in which the dome and annular compartments were modeled at the system level and imposed as boundary conditions for a resolved CFD analysis of the equipment rooms. Furthermore, the local gas composition near the release from the pressurizer relief tank (PRT) was found to consist of pure steam, indicating the need for further development of the diffusion-layer-based wall condensation model in *containmentFOAM*. In addition, considering the phenomenology in the sump region, the current single-phase treatment should be extended to adequately represent heat and mass transfer processes involving water pools, which were found relevant within the GOTHIC™ analysis by UPM. For LP modeling, insights gained from the three-dimensional analysis should be systematically employed to refine the nodalisation scheme, reducing evaluation uncertainties regarding locally flammable conditions. While this paper only considers the LP code COCOSYS, the conclusions are transferable to other LP codes.

ACKNOWLEDGMENTS

This work is based on results obtained within the EU project AMHYCO, funded by the European Commission (Euratom 20192020, GA No 945057). We particularly thank Luis Serra-Lopez, Araceli Domínguez-Bugarín and Gonzalo Jiménez (UPM) for their efforts in creating the generic containment database and associated CAD models. Furthermore, we thank Matthias Braun (Framatome) for sharing the TLAP/SBO sequence analyzed in the paper.

We gratefully acknowledge the support of the German Federal Ministry for the Environment, Climate Action, Nature Conservation and Nuclear Safety (BMUKN) for funding code maintenance and integration of *containmentFOAM* within the national CFD reference package CF2REF (Fkz 150 1633B). We thank the John von Neumann Institute for Computing (NIC) for the computing time supercomputer JURECA at Jülich Supercomputing Centre (JSC) under projects ‘cf2app’ and ‘va4cf’. The LP simulation results were obtained using COCOSYS v2.4. COCOSYS is developed and kindly provided by GRS gGmbH, Germany.

APPLICATION TO CONTAINMENT ANALYSIS

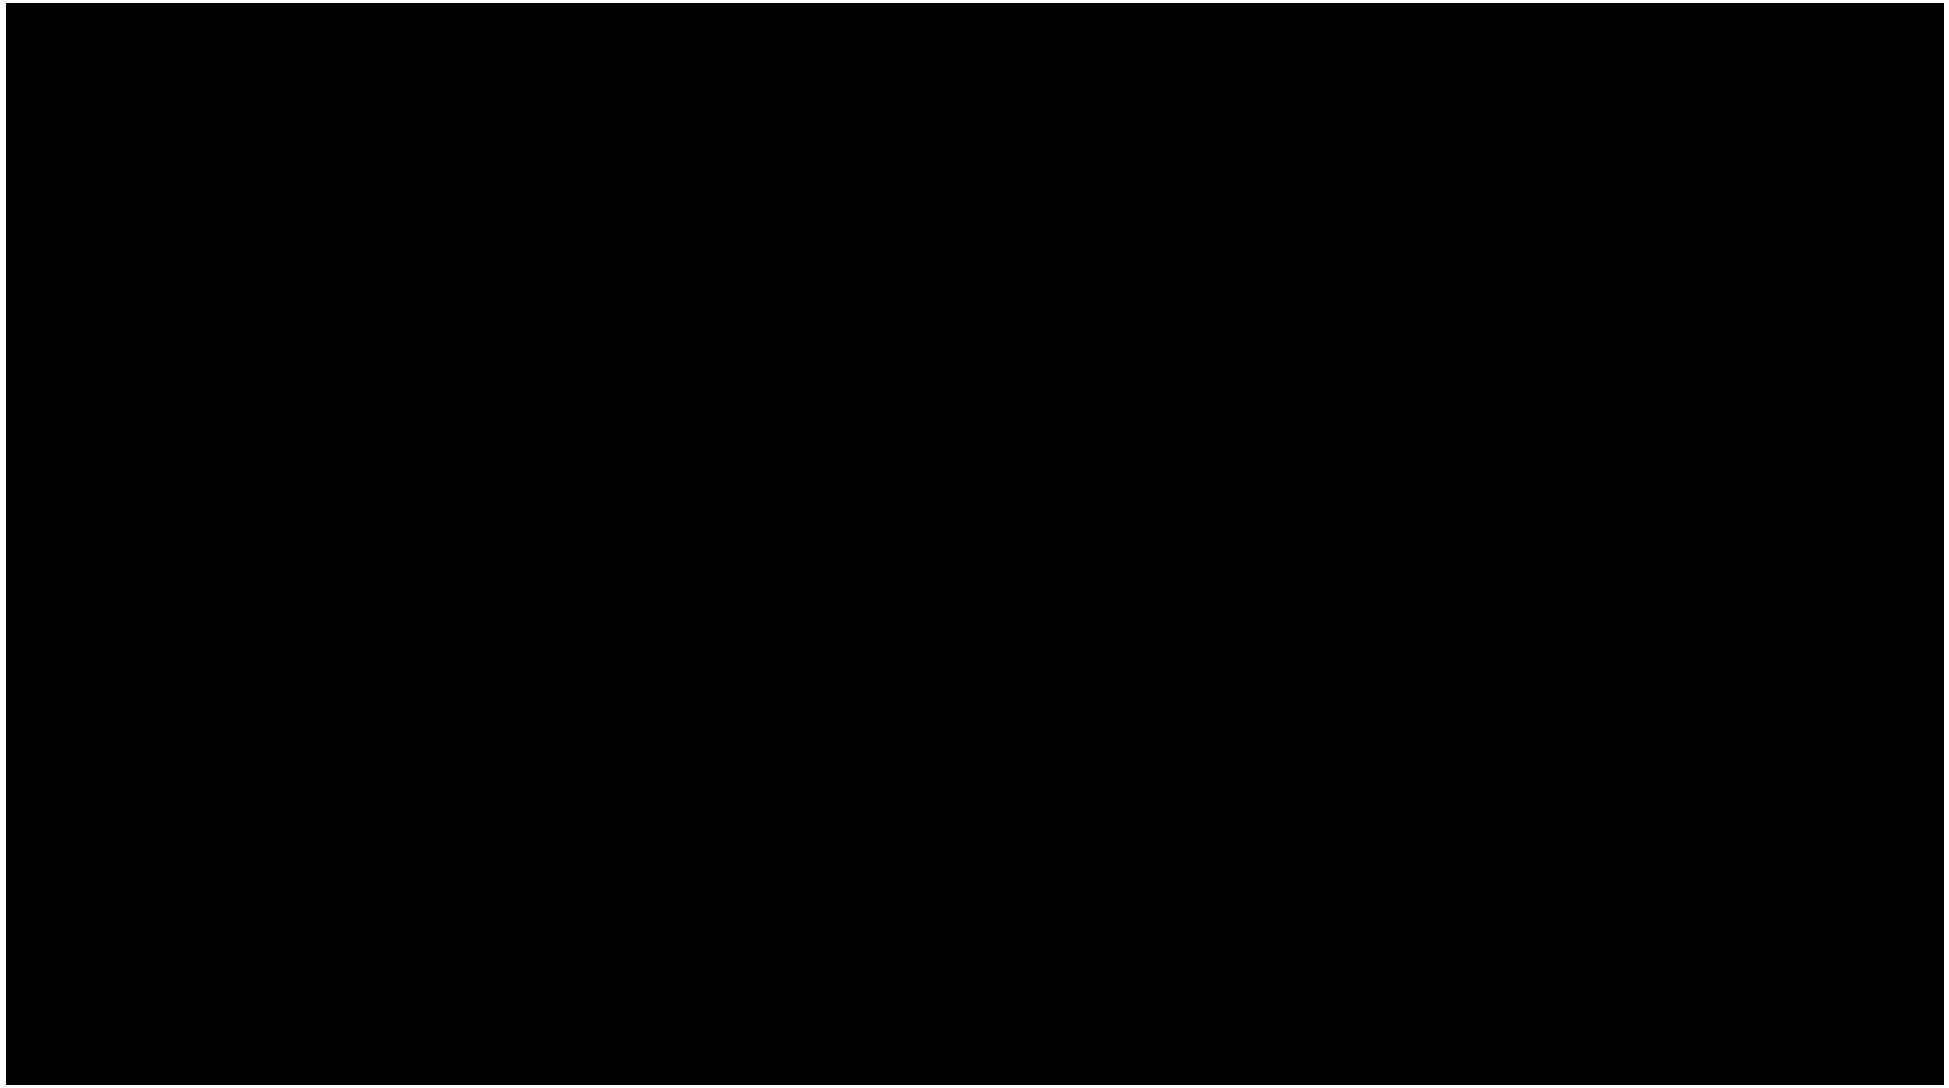
Full containment - overview

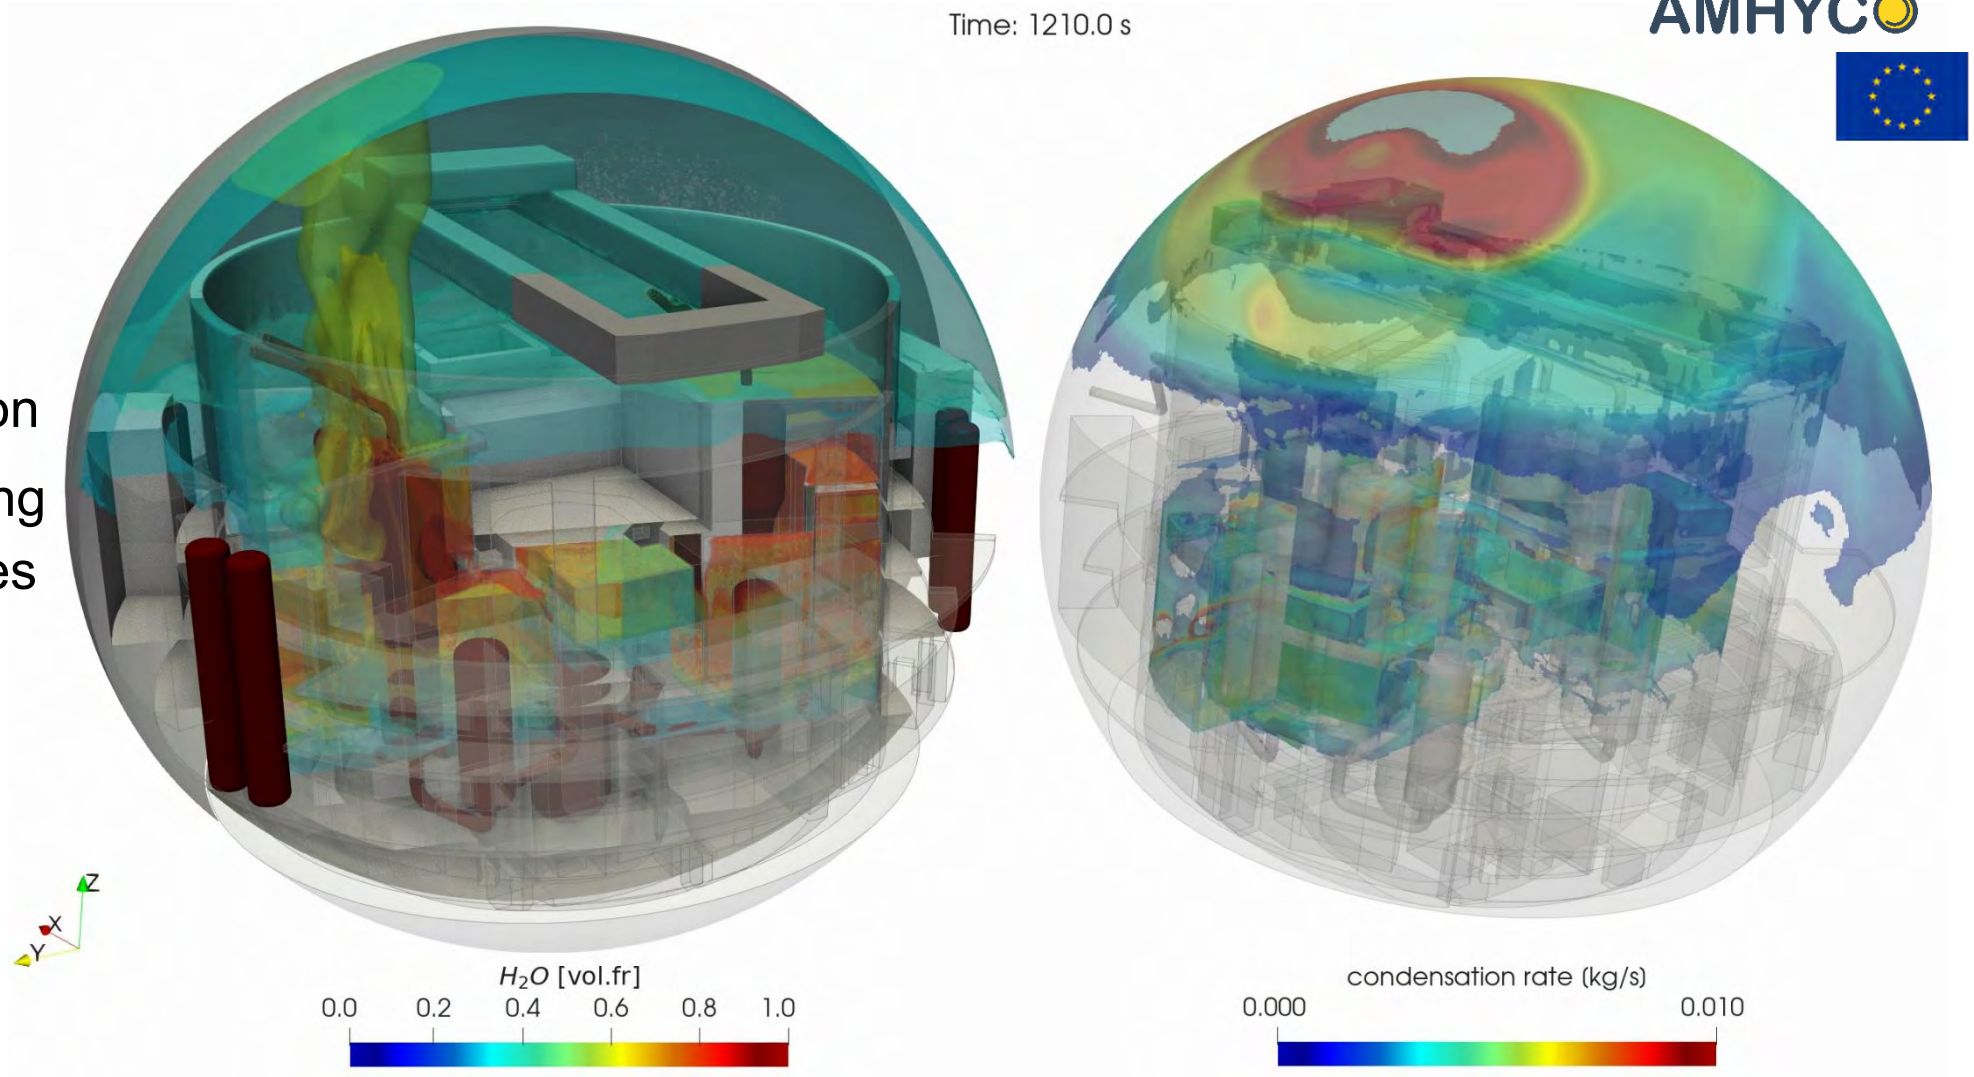
- Sequence start with PRT burst disc rupture (t_0~4300s)



APPLICATION TO CONTAINMENT ANALYSIS

Full containment - overview

- Sequence start with PRT burst disc rupture (t_0~4300s)
- Steam stratification
- Spatially fluctuating condensation rates
  - ➢ difference to LP?

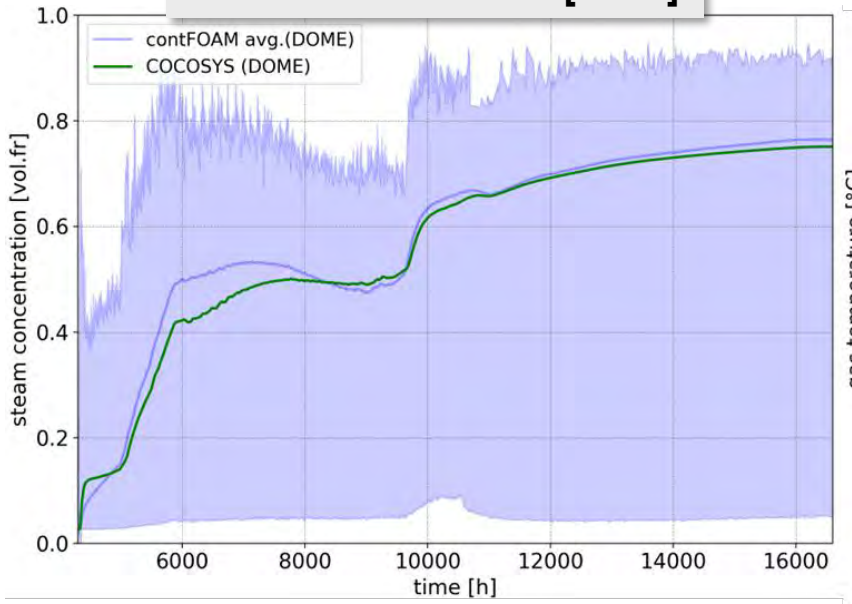


APPLICATION TO CONTAINMENT ANALYSIS

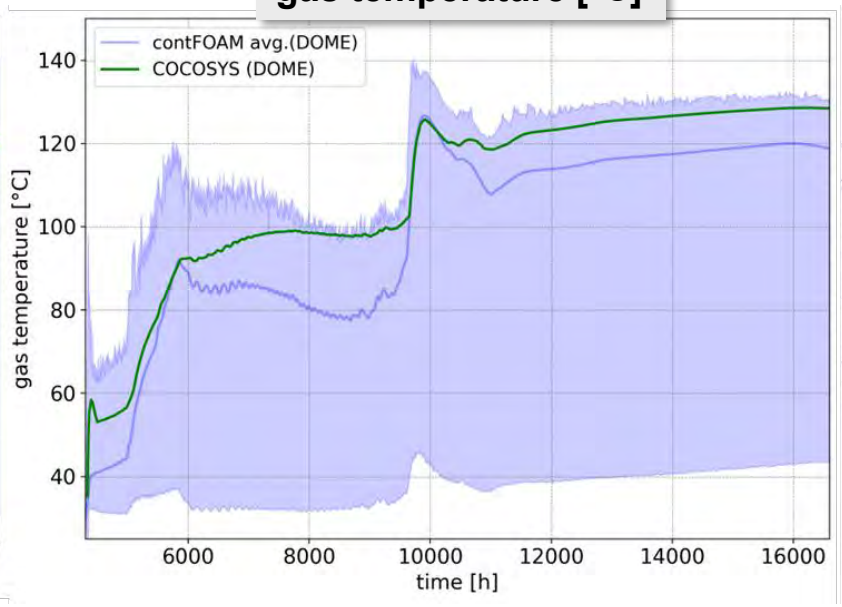
Full containment - pressurization

- Containment dome conditions

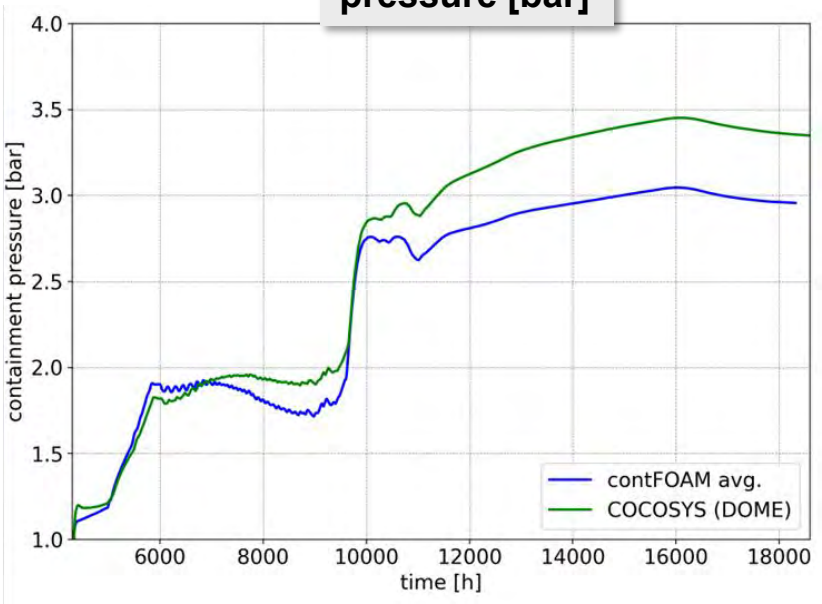
Steam concentration [vol.fr]



gas temperature [°C]



pressure [bar]



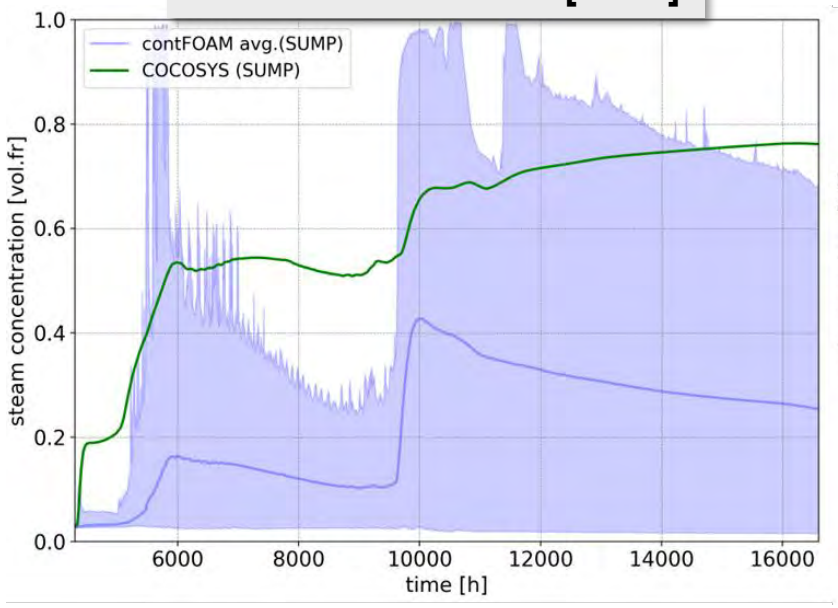
- ➢ Average CV trends well comparable with LP (COCOSYS).
- ➢ Bandwidth (min/max) indicates strong spatial heterogeneity affecting e.g., heat and mass transfer

APPLICATION TO CONTAINMENT ANALYSIS

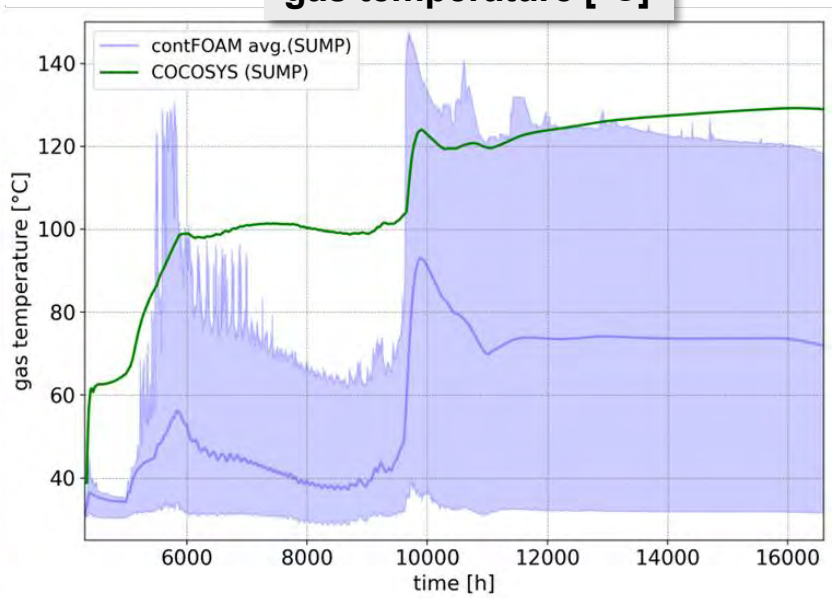
Full containment - pressurization

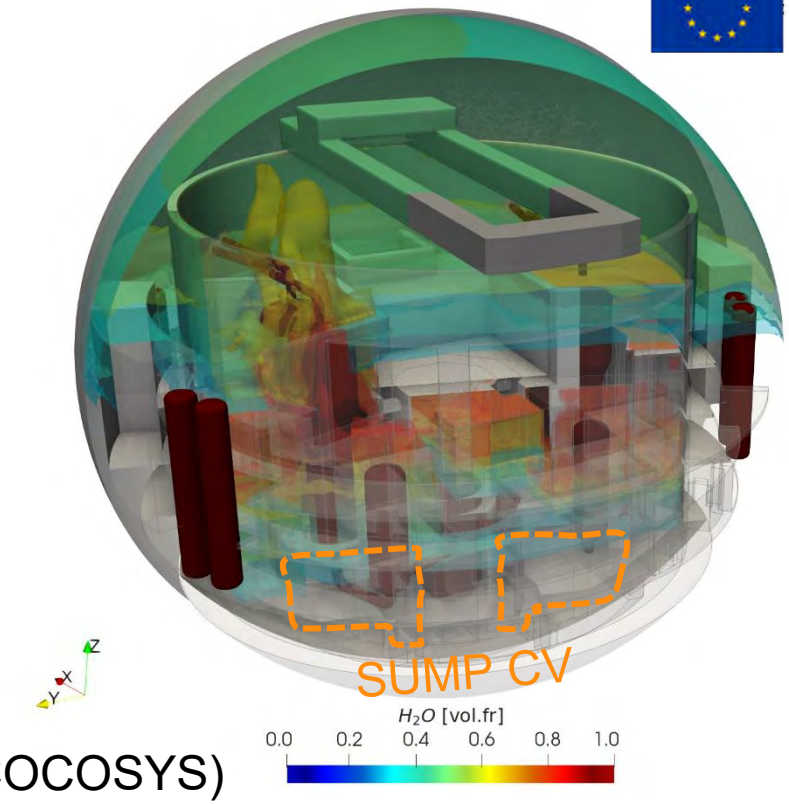
- Equipment rooms stratification

Steam concentration [vol.fr]



gas temperature [°C]



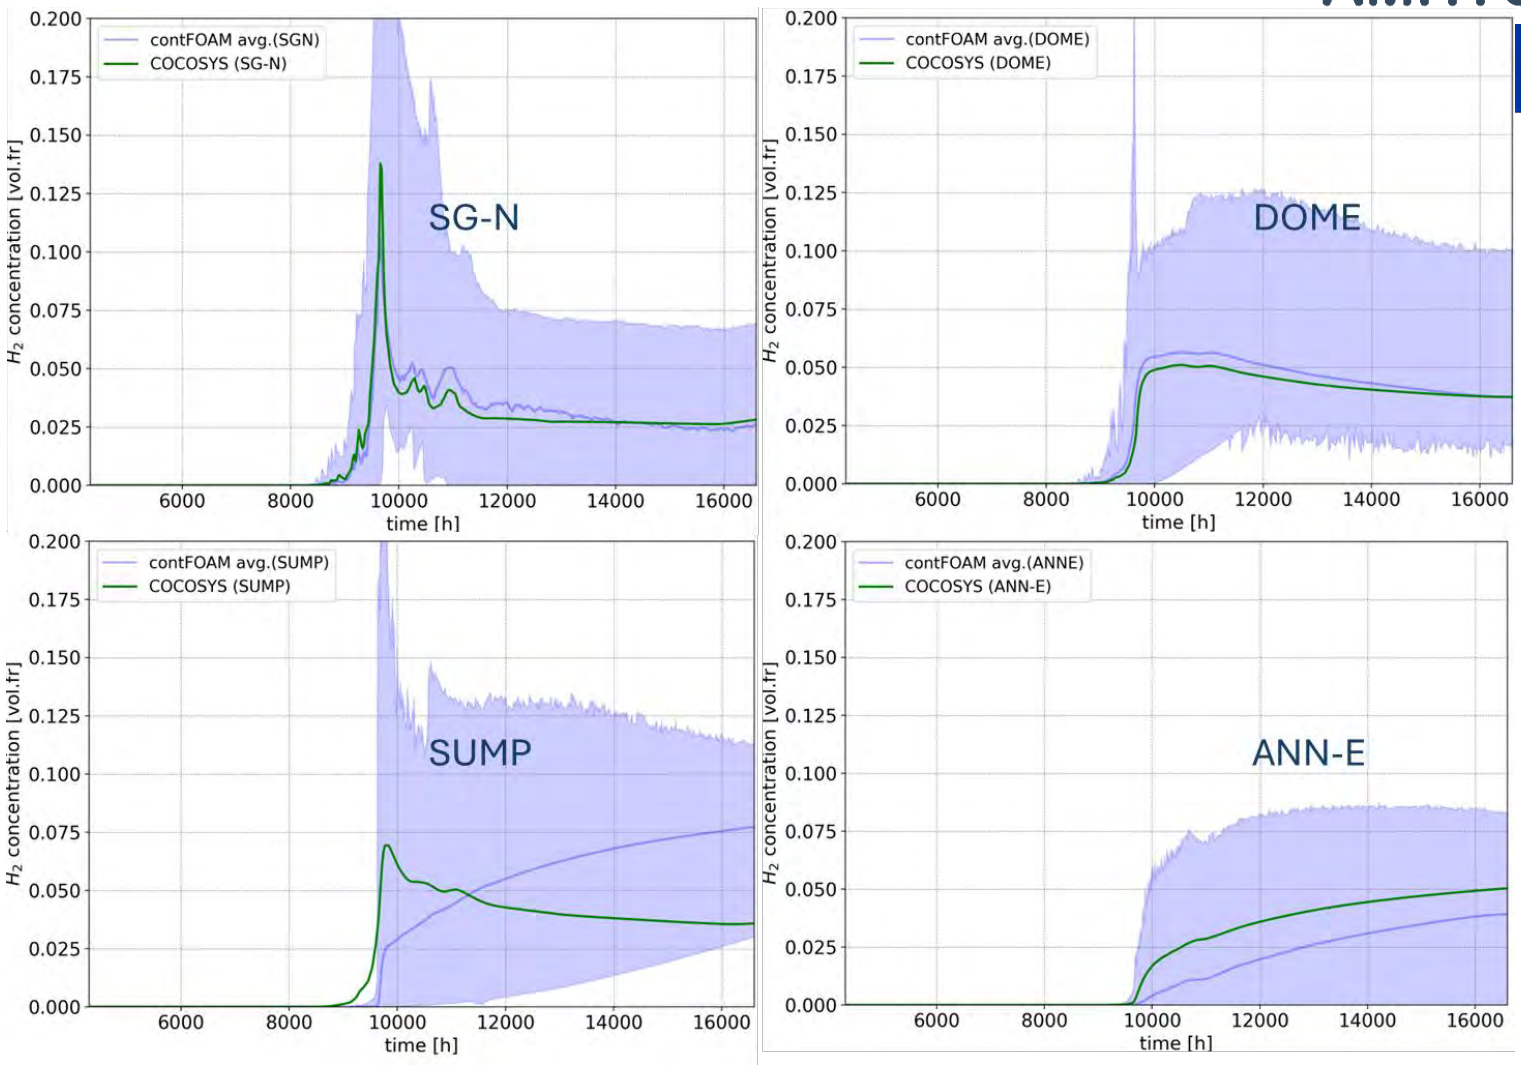


- Less transport to SUMP region and other ‘dead-end’ CVs than with LP (COCOSYS)
- Little effect on pressure (comparably small volume)
- Effect on later H_2 injection?

APPLICATION TO CONTAINMENT ANALYSIS

H_2 distribution

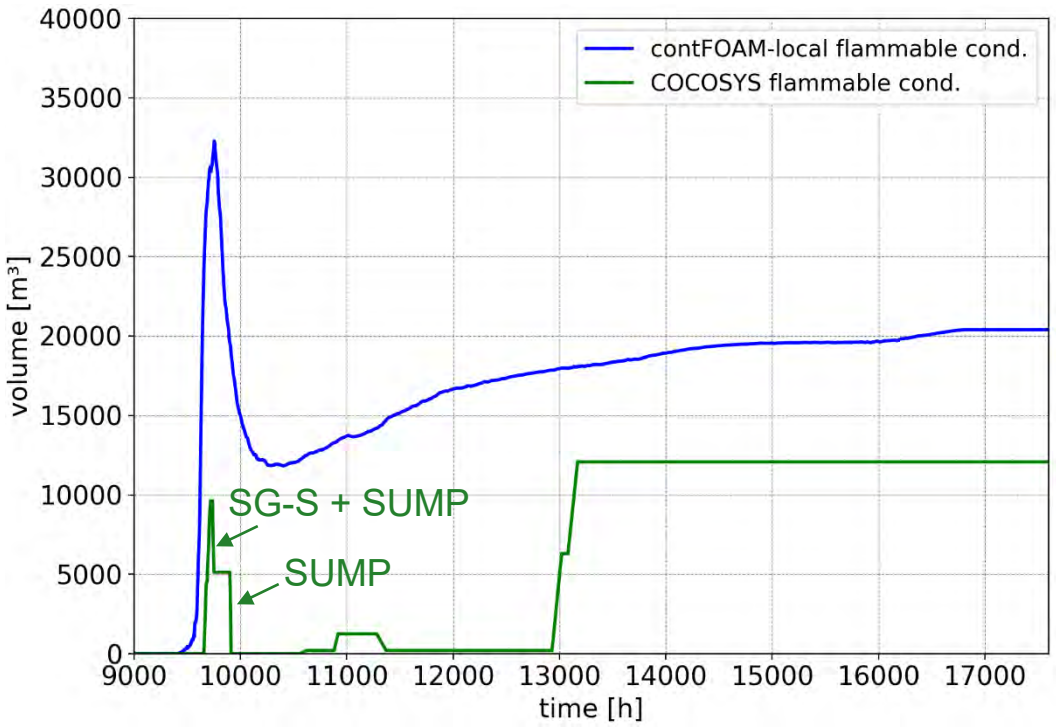
- Well comparable along main convective loop, but
- Deviating transport into the dead-ends / stagnant zones

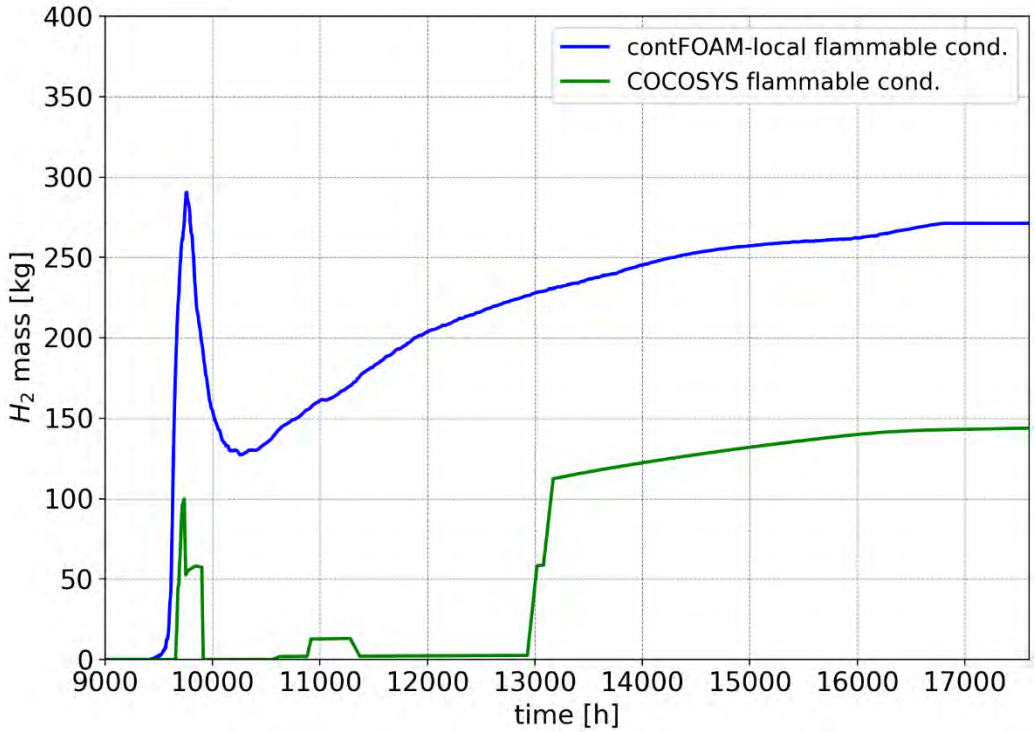


APPLICATION TO CONTAINMENT ANALYSIS

Flammability

- Cell-wise vs. CV-wise (‘all-or-nothing’) evaluation of the flammable cloud



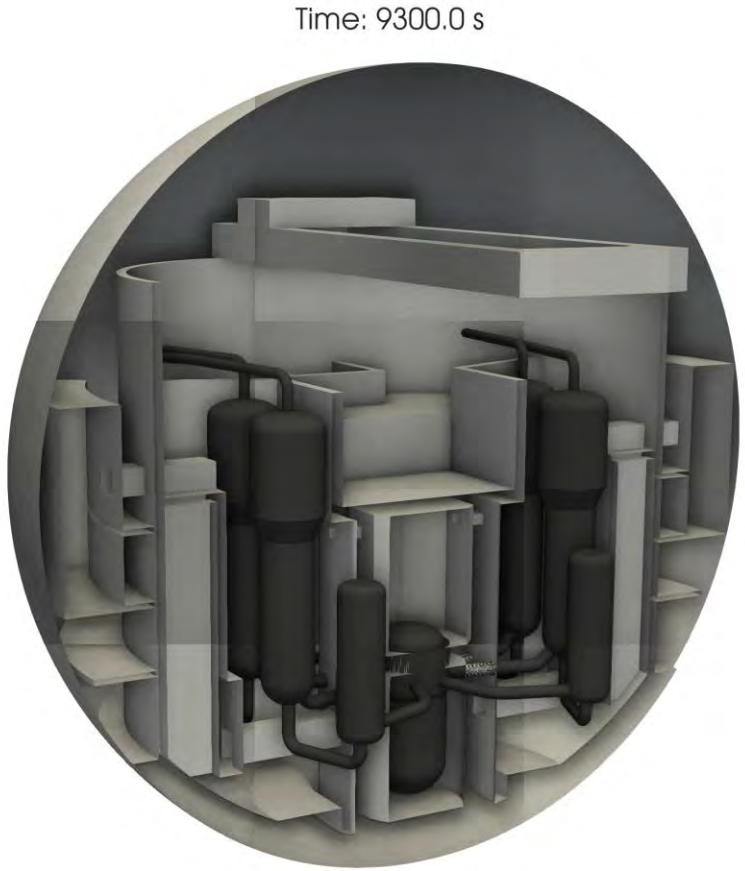


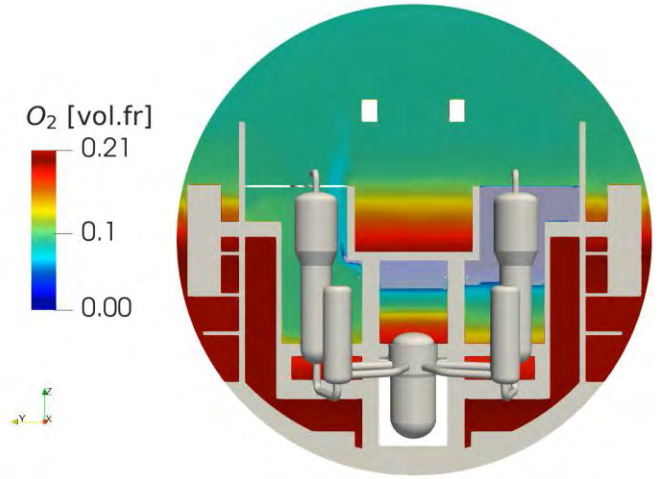
- Both codes predict no global flammability, but differences appear due to coarse nodalization

APPLICATION TO CONTAINMENT ANALYSIS

Combustion Risk

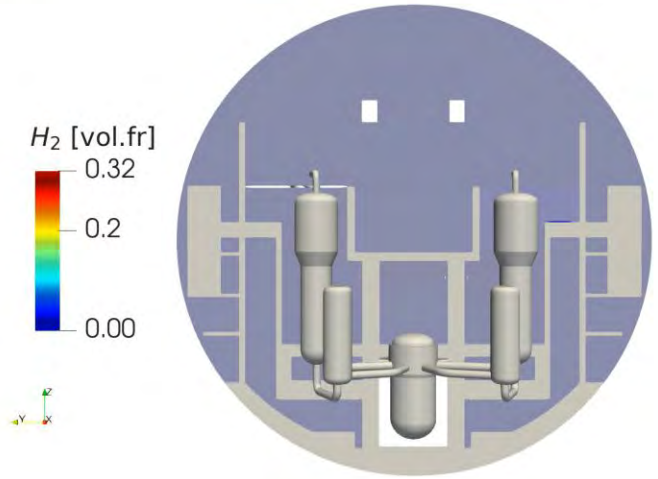
- Insights to the formation of flammable clouds





Opacity

$O_2 < O_{2,min}$

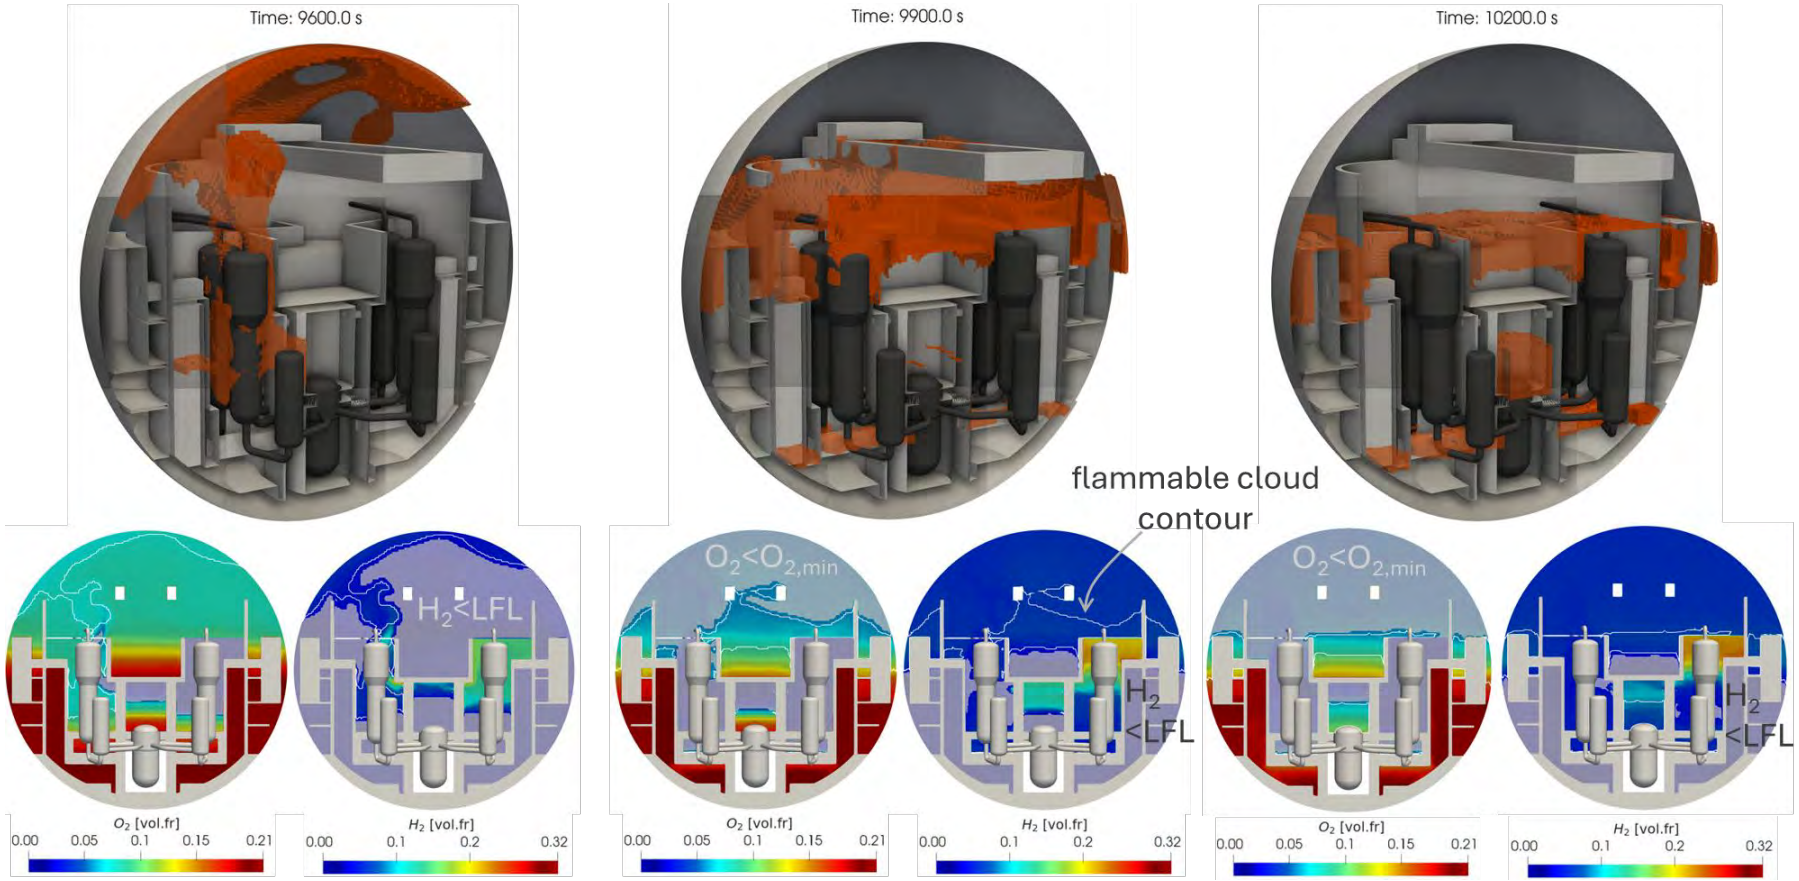


$H_2 < H_{2,min}$

APPLICATION TO CONTAINMENT ANALYSIS

Evolution of the flammable mixture

- Insights to the formation of flammable clouds..



➢ ..in the transition between main convective loop (H_2 rich) and stagnant zones (O_2 rich)

SUMMARY

- Prototypic application of containmentFOAM to the in-vessel phase of a SBO sequence
  - despite notable differences in local details, both approaches yielded largely comparable results, particularly in regions characterized by sufficient mixing
  - The coarse nodalisation used in system-level simulations tends to promote the transport of steam and non-condensable gases towards the lower sump region and annular dead-end compartments
  - Flammable gas clouds are formed at the boundary between H_2 rich (main convective loop) and O_2 rich gas mixtures (stagnant regions), which is hard to capture with coarse lumped volumes
  - Full containment CFD analysis is feasible: 1024 cores, ~0.5 Mcore-h/1h transient, ~100..1500 s/day .. but still significant simplifications required (e.g., geometry, single-phase formulation) !

➢ Simulation including PARs in progress

- Needs for further model development:
  - Sump heat and mass transfer, condensation at high steam mass fractions
  - Two-way system code coupling

THE END..

ABSTRACT

During a severe accident in a nuclear power plant (NPP), hydrogen (H_2) can be produced from the oxidation of fuel cladding or fuel assembly canisters and other hot metallic components. In case of failure of in-vessel corium retention, a large amount of carbon monoxide (CO) in addition to H_2 and other gases may be produced during molten corium-concrete interaction in the reactor pit. As a consequence, local concentrations of H_2 and CO can exceed the flammability limit of the gas mixture. Subsequent combustion would induce high dynamic pressure loads which could threaten the containment structures and technical equipment. Therefore, accurate and trustworthy combustion simulation is a task of primary importance in NPP accident analysis to determine local and global blast and heat loads. In particular, investigations are still necessary to increase the knowledge regarding turbulence effects on flame propagation.
In the framework of the European AMHYCO project, an experimental test campaign had been conducted with the aim to investigate the flame propagation in gaseous mixtures representing LWRs containment atmosphere during severe accident late phases. The experiments were performed on the highly instrumented ENACCEF2 facility, operated by the Institut de Combustion Aérothermique Réactivité et Environnement (ICARE) of the Centre National de la Recherche Scientifique (CNRS) in Orléans (France).
At the initiative of the AMHYCO project consortium and the European Technical Safety Organisation Network (ETSON), a code benchmark on hydrogen-carbon monoxide combustion was organised with the goal to identify the current level of the computational tools in the area of combustion simulation under conditions typical for safety considerations for NPP.
In the proposed paper, the simulation results obtained by participating organisations, using both Computational Fluid Dynamics and Lumped-Parameter computer codes, are compared to experimental results and analysed.

AMHYCO, ETSON, COMBUSTION, ENACCEF2, HYDROGEN, CARBON MONOXIDE

1. INTRODUCTION

During a severe accident (SA) in a nuclear power plant, hydrogen (H_2) can be produced from exothermic oxidation of fuel cladding or fuel assembly canisters and other hot metallic components. In case of failure of in-vessel corium retention, a large amount of carbon monoxide (CO) in addition to H_2 and other gases may be produced during molten corium-concrete interaction (MCCI) in the reactor pit. Therefore, local

concentrations of H_2 and CO can exceed the flammability limit of the gas mixture and induce strong dynamic pressure loads which may threaten the containment structures and technical equipment's, including important safety systems (SISs). The use of passive autocatalytic recombiners (PARs) considerably reduces the flammability risk of the containment atmosphere during the accidental transient. However, analyses of accidental scenarios in reactor cases show that, even in the presence of PARs, the flammability risk cannot be totally excluded during the whole accidental transient and particularly during the phases of high hydrogen production rate, which are affected by high uncertainties.

Therefore, accurate and trustworthy combustion simulation is a task of primary importance in NPP accident analysis to determine local and global blast and heat loads. Following the recommendations made in the SOAR R(99)16 [4] and the outcomes of the OECD/CCVM expert group discussions and the conclusions of ISP49 [5] and SARNET benchmarks [6], investigations are still needed to increase the knowledge regarding the effect of parameters such as turbulence level, initial temperature, initial and pressure, presence of CO, or lack of oxygen on flame propagation. In the framework of the MITHYGENE project and to this end, the new highly instrumented ENACCEF2 facility was built to address the above-mentioned issues.

To identify the current level of the computational tools in hydrogen combustion simulation under conditions typical for safety considerations for NPP, a first benchmark on hydrogen combustion was organised at the initiative of the MITHYGENE project consortium and the European Technical Safety Organisation Network (ETSON). This benchmark consisted of simulating experiments, performed in the ENACCEF2 facility, in which a homogeneous hydrogen-air mixture (for three different concentrations of hydrogen) was ignited at the tube bottom, and the subsequent flame and pressure wave propagation were measured. The benchmark blind results show that most of the used codes are able to predict qualitatively the pressure evolution inside the vessel [2]. Nevertheless, the flame speed maximum value is generally predicted with a significant deviation from the experimental results. This indicates that there are still limitations and weaknesses in the combustion models used in the different codes. These limitations concern the chemistry part, the turbulent combustion model and the coupling between the two models. An improvement of the combustion models is necessary to obtain consistent agreement between the flame regime and the pressure build-up predicted for a given configuration.

A second benchmark was organised in the framework of the SAMHYCO-NET and with the support of ETSON, as a continuation of the previous benchmark by considering more representative gas mixtures [3]. Here also, the benchmark blind results show the code's ability to predict qualitatively the pressure evolution inside the vessel and their difficulty to predict accurately the flame speed maximum. Therefore, further investigations are still needed.

Moreover, the outcomes of the international workshop on hydrogen management in NPP, held at IRSN in April 2019, underlined the need to improve the combustion models for both low hydrogen concentrations and for stratified mixtures which are more relevant for the reaction applications. Similarly, the SAMHYCO-Net outcomes pointed out the need of improving combustion models to simulate flame propagation in mixtures representative of late phases of a severe accident.

To this end, the European project AMHYCO was launched in 2020 with the objective to propose innovative enhancements on the combustible gas management procedures in case of a severe accident by addressing open issues related to the understanding of H_2 and CO phenomena involved in such an accident. To achieve this goal, an extensive experimental study has been conducted addressing different combustion phenomena including flammability limits determination, laminar and turbulent flame speed measurements and flame regime investigation the large closed ENACCEF-II facility considering different initial conditions.

From the performed experiments, three tests were selected to organize the ETSON-AMHYCO benchmark with the aim to evaluate the existing models, identify gaps in current knowledge, and derive significant

improvements in the quality and accuracy of numerical predictions of flame propagation in representative mixtures of a severe accident late phase.

The ETSON-AMHYCO benchmark was established within three main phases: STEP0, STEP1, and STEP2. STEP0 was organized as an open benchmark, while STEP1 and STEP2 were conducted as blind exercises. It is important to note that STEP2 is optional. The benchmark was started in October 2024 and lasted until February 2025. During this period, meetings were held to discuss the results and derive conclusions. This article presents and discusses the results of the submitted calculations for STEP1 and provides the main conclusions issued from the discussion during the final meeting.

2. ENACCEF2 facility

ENACCEF2 is a vertical acceleration tube of 7.65 m height and 23 cm inner diameter composed of nine cylindrical modules as shown in Figure 1. Two of these modules are equipped with large sapphire windows for imaging of the flame propagation using high speed camera.

Each module is equipped with different detectors to measure flame position and the pressure build-up during the combustion. For the benchmark needs, 2 visualization sections (sapphire windows, Figure 1-left), 27 photomultipliers (Hamamatsu), 10 pressure sensors (Kistler and PCB) and 27 shock detectors (Metal Process) were used (Figure 1-center). The initial combustible gas content along the facility is monitored using a micro-gas chromatographer (SRA instruments). Sampling of the fresh gases prior to ignition is done at 4 different heights along the facility (Figure 1-center). The gas mixture is introduced in the facility, initially under vacuum, using mass flow meters (Bronkhorst). The initial temperature is monitored using several thermocouples located at different heights along the tube. To enhance the turbulence, the lower part of ENACCEF2 is equipped with 9 annular obstacles (Figure 1-right) having a blockage ratio BR of 0.63, the separation distance between 2 consecutive obstacles was fixed to be 23 cm.

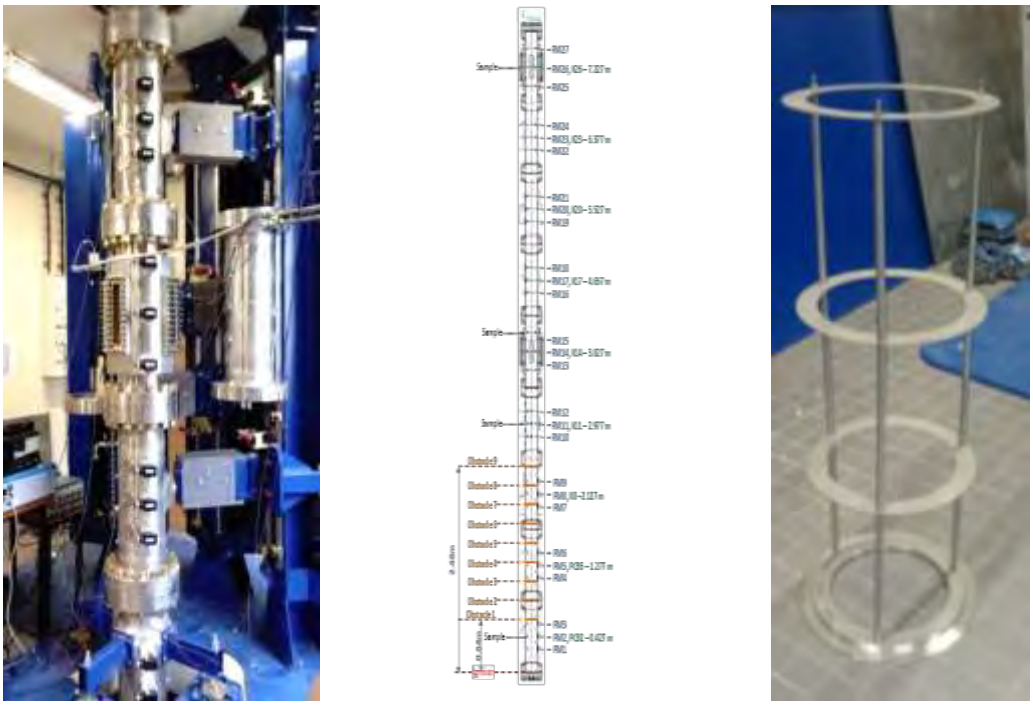

Figure 1. ENACCEF2 - left: photo, center: schematics, right: internal obstacles

3. EXPERIMENTAL RESULTS

As mentioned above, the ETSON–AMHYCO benchmark was organized in three steps based on experimental tests carried out within the AMHYCO project, using representative gas compositions and thermodynamic conditions of ex-vessel severe accident phases. The initial conditions considered are summarized in the following Table 1:

Table 1. Initial conditions of the experiments

	T_{ini} (°C)	P_{ini} (bar)	H_2O_{vap} (%mol)	CO_2(%mol)	H_2 (%mol)	CO(%mol)
STEP0	100	1	30	0	12.6±0.03	12.58±0.02
STEP1	88	2.47	20.3	16.05±0.09	7.90±0.08	7.45±0.06
STEP2	83	1.71	21.9	0	9.92±0.012	1.30±0.01

Based on the sigma criterion, all three tests fall into a flame acceleration regime, as the maximum flame velocity exceeded half the sound speed in the burned gas. Ignition is always initiated at the bottom of the facility, and the flame propagates upward through a homogeneous gas mixture. To characterize the flame propagation regime, measurements focused on flame position and pressure. Each test was performed at least three times each. The average of the recorded flame position as a function of time was then used to determine the flame velocity along the facility height, allowing the identification of acceleration and deceleration regimes. The following Figure 2 shows the flame position versus time (left graph) and the corresponding flame velocity (right), each time averaged over three experimental runs.

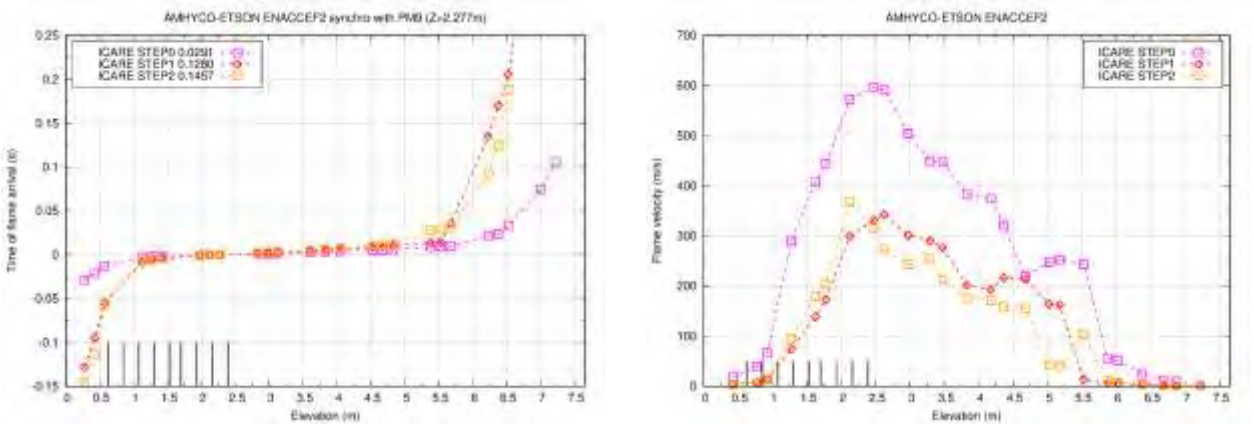

Figure 2: STEP0, STEP1 and STEP2 - average measured flame position versus time (left) and corresponding flame velocity along the facility elevation (right)

For all tests, four flame propagation phases can be distinguished:

- The first phase corresponds to the flame propagation between the ignition point and the first obstacle. During this phase, the flame propagates in a smooth tube with a maximum velocity of ~10 m/s.
- The second phase corresponds to flame propagation in the area between the first and the last obstacle. Due to turbulence induced by those obstacles, the flame front accelerates and reaches values between 340 m/s for STEP1 and 600 m/s for STEP0.
- The third phase corresponds to the flame propagation in the area just past the last obstacle. Due to the decrease of turbulence level past the last obstacles, the flame speed decreases. When the flame

becomes sub-sonic, the pressure wave detaches from the flame front and travels with speed of sound along the ENACCEF2 tube upwards. At the end of the tube, the shock wave gets reflected and starts travelling downward again. The third phase of the experiment is defined that the downward-traveling reflected shock wave did not reach the upward-traveling flame front.

- The fourth phase corresponds to the flame propagation in the upper part of the facility, after the flame front encountered the reflected shockwave. During this phase, the flame velocity is drastically slowed down due to its interaction with the reflected shockwave. The flame travels the last meter at velocities between 2 and 40 m/s.

The relative position of the shockwave can be identified in the recordings of the pressure sensors located along ENACCEF2, see Figure 3**Erreur ! Source du renvoi introuvable.**. The small black lines along the y-axis indicate the position of the obstacles in the facility. The pressure recordings are plotted in arbitrary units at the corresponding elevation of the sensor position. The upward traveling shockwave is highlighted by blue triangles, the first reflection of the shockwave by green triangles, and a secondary reflected wave by light-blue triangles. Additionally, the flame position is shown by circle-markers. When the first reflected shockwave meets the flame position, a dramatic decrease in flame velocity can be observed.

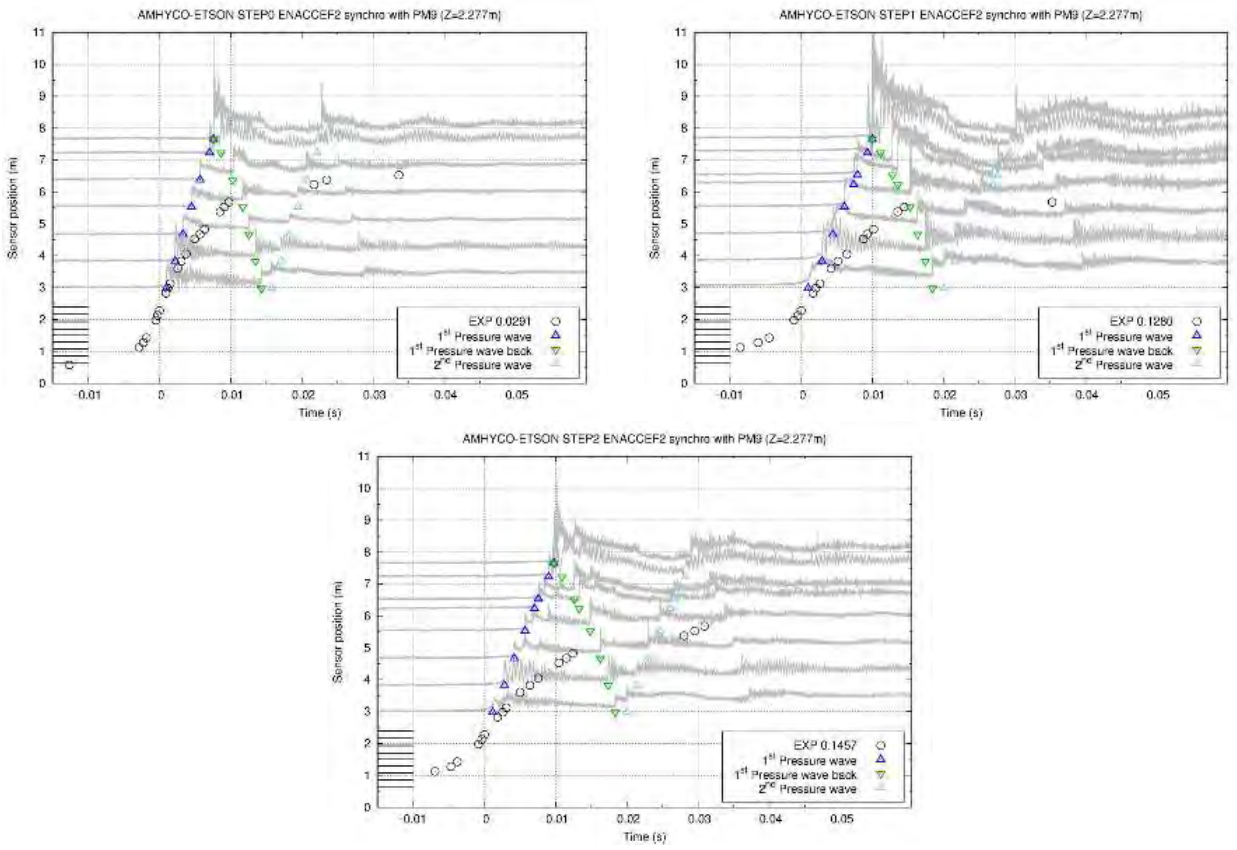

Figure 3: Pressure records in the experiment STEP0 (top-left), STEP1 (top-right), and STEP2 (bottom). The circles indicate the flame position. The blue triangles indicate the location of the pressure shock ahead the flame front, the green triangles represent the reflected shockwave.

From the experimental results presented above, we can conclude that the higher the initial fuel (CO and H_2) concentration the higher is the maximum flame velocity and the later the flame front interacts with the reflected pressure shock.

4. NUMERICAL CODES AND APPROACHES

There were eleven submitted results from nine participating organizations from 6 countries. Seven Computational Fluid Dynamics (CFD) and four Lumped-Parameter (LP) code contributions were then received. The following Table 2 presents the participating organizations and used codes.

Table 2: List of participating organizations and codes

Participants	Country	Code	Code Type	Label for graph
CNRS-ICARE	France	Experiments		ICARE-EXP
UPCT	Spain	OPENFOAM	CFD	UPCT_OPENFOAM
NRG	Netherlands	OPENFOAM	CFD	NRG_OPENFOAM
CNSC	Canada	Fluent	CFD	CNSC_Fluent
CIEMAT	Spain	MELCOR	LP	CIEMAT_Melcor
GRS	Germany	OPENFOAM	CFD	GRS_OPENFOAM
RUB	Germany	COCOSYS	LP	RUB_COCOSYS
FRG	Germany	MELCOR	LP	FRG_Melcor
ASNR	France	Fluent	CFD	ASNR_Fluent
ASNR	France	CALIF3S	CFD	ASNR_Calif
ASNR	France	ASTEC	LP	ASNR_Astec
LEI	Lithuania	OPENFOAM	CFD	LEI_OPENFOAM

The codes mentioned in Table 2 use different approaches for combustion modelling. Most of CFD combustion models are based on the burning velocity combustion approach: the flame front is then supposed to be thin, and the flame speed is obtained as a function of turbulence level and the laminar flame as for Fluent, OPENFOAM and CALIF3S codes where the burning Velocity Model (BVM model) based on a turbulent flame closure (as Zimont correlation for Fluent) is used. The chemical reaction rate is then built using the flame velocity V_{flamet}, the gas density $\bar{\rho}$ and progress variable gradient $|\nabla\tilde{c}|$ as follow: $\overline{\omega} = \bar{\rho} V_{flame} |\nabla\tilde{c}|$. The flame velocity is given by: $V_{flame} = Au' Da^{1/4}$, where A is constant. u' stands for turbulence intensity and Da for Damkhöler number [1]. However, specific modifications were incorporated into some of the models to accurately capture the Darrieus–Landau flame instability in slow combustion regime and to account for the additional effects of the Lewis number and pressure in fast flames.

As is customary in LP codes, the turbulence is not modelled, but its effects must be taken into account in flow-loss coefficients, the LP combustion models, as for ASTEC and COCOSYS codes, the correlations used to evaluate the turbulence intensity are based on the gaseous flow velocities in the atmospheric junctions between nodes (zones) (see Figure 4).

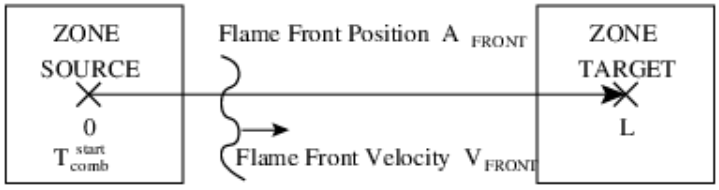

Figure 4. CPA-FRONT flame propagation principle.

The flame front burning speed is then obtained as sum of gas speed and turbulent flame speed:

$$V_{FRONT} = S_t + U_{gas}$$

where U_{gas} stands for the gas velocity in the junction and S_t represents the turbulent flame speed issued from the Peters correlation [11]:

$$S_t = S_l\,(1 + \sigma_{Peters}) \quad \text{with} \quad \sigma_{Peters} = \frac{\sqrt{\left(0.39\frac{l_t}{\delta}\right)^2 + 8\times 0.39\frac{l_t u'}{\delta S_l}} - 0.39\frac{l_t}{\delta}}{2}$$

S_l is the laminar flame speed for which several correlations are available in the ASTEC code:

- Liu-McF for the classical Liu Mac Farlane model [12]
- Liu-CNRS for the correlation developed by CNRS [13]
- USER option offering the possibility to use different correlations

u' represents the root-mean-square (RMS) velocity fluctuations given by the correlation below:

$$u' = \left|U_{gas}\right| REYFAC\ Re^{REYEXP}$$

where $Re = \frac{\rho|U_{gas}|\sqrt{S_{junc}}}{\mu}$ stands for the Reynolds number while REYFAC and REYEXP are user parameters. l_t represents the turbulence integral scale estimated based on the zone floor and the junction section area S_{junc} and δ stands for the flame thickness and μ for the dynamic viscosity.

In MELCOR [14], the flame velocity V is computed with the BURN package using the HECTR code. For a cell with characteristic length L, the combustion time associated with flame propagation is given by:

$$t_{\text{comb}} = \frac{L}{V}.$$

To account for flame acceleration and deceleration due to flame–turbulence interactions, this combustion time is modified with a user-defined factor, Frac, such that

$$t_{\text{comb,adj}} = \text{Frac} \times t_{\text{comb}}$$

The parameter Frac was calibrated along the facility height to reproduce the STEP0 experimental data, with values (from bottom to top) of 0.22, 0.04, and 0.50. By modifying Frac, the code user imposes a multiplicative increase of the internally calculated flame velocity.

For the CFD contributions, the following Table 3 summarizes the information related to numerical models, turbulence and combustion models as well as heat transfer models:

5. RESULTS OF THE SIMULATIONS AND DISCUSSIONS

Both STEP0 and STEP1 were simulated by all participants; STEP0 as an open exercise and STEP1 as a blind one. STEP2 was optional and was analyzed by few participants. For this reason, only STEP0 and STEP1 submitted results are addressed in the following sections. Following the benchmark specifications, the comparison of experimental and simulation results is performed based on:

- the flame arrival time,
- the flame velocity,
- pressure – time histories.

The STEP0 test results were provided to the participants to calibrate their models before the blind phase in STEP1 and STEP2. Figure 5 present the flame position and the flame velocity profile along the facility elevation for the STEP0 test. The small vertical lines at the bottom of the graphs indicate the position of the internal obstacles (see Figure 1). The black line represents the experiment, and the coloured lines are the simulation results of the benchmark participants.

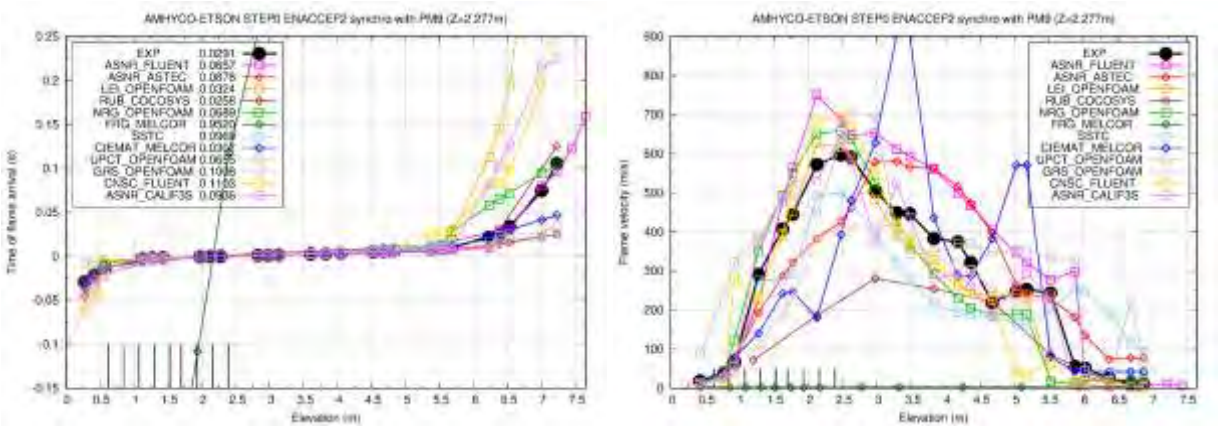

Figure 5: STEP0 - Flame position versus time (left) and flame velocity along facility elevation (right)

All codes, except one contribution with MELCOR code without time combustion calibration, are able to reproduce the main features of the combustion regimes in ENACCEF2: a 1st phase of flame acceleration before the obstacles, the very steep acceleration leading to the maximum flame speed at the end of the obstacles field and the subsequent flame deceleration. Nonetheless, large discrepancies are observed in predicting the maximum reached flame speed value and location.

In the region of flame acceleration, a pressure shock wave is created. While CFD codes can at least predict this shock wave reflection, the interaction between the flame front and the reflected shocks is not well reproduced. Figure 6**Erreur ! Source du renvoi introuvable.** compares the measured (straight black lines) and the by codes predicted pressures (straight coloured lines) at different facility elevations. The shockwave and its reflection can be observed by the relative time position of the pressure peaks. Further, in the figure also the flame front is shown as markers. The respective coloured lines represent code predictions, for a LP code on the left and for a CFD code on the right.

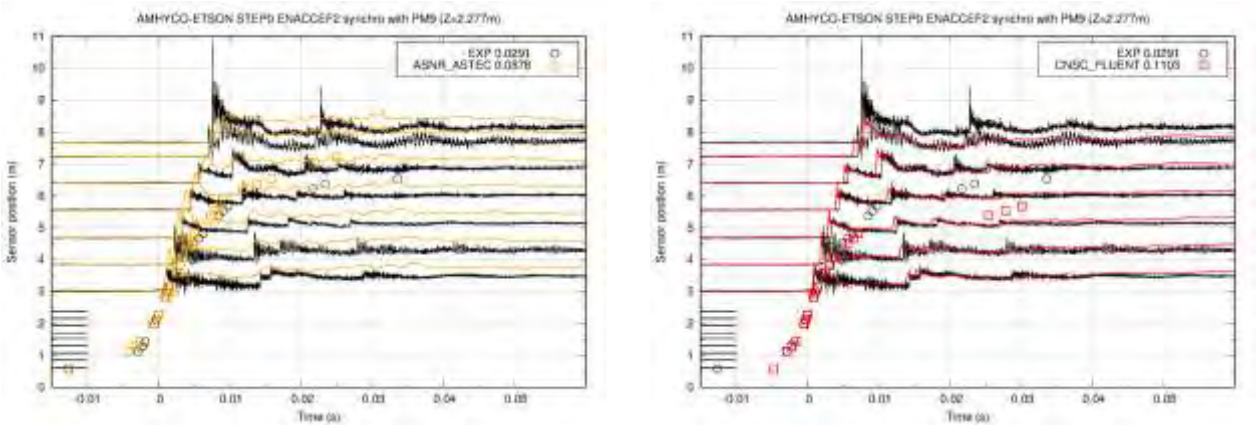

Figure 6: STEP0 - Pressure signals at different elevations (straight lines) and flame front position (markers) - comparison between experiment (black) and ASNR_ASTEC results (left, yellow) as well as CNSC_Fluent results (right, red)

The insights gained from the STEP0 test allowed participants to adjust their models in preparation for the blind STEP1 exercise. Despite this calibration phase, and because STEP1 involved different initial conditions from STEP0, discrepancies between the simulations and the experimental results persist. Nevertheless, as shown in Figure 7, most codes were able to reproduce both the acceleration and deceleration phases of the flame. The position of the peak flame speed (left figure) is reasonably well captured by most contributions. The flame speed magnitude (right figure) is still either under- or over-predicted.

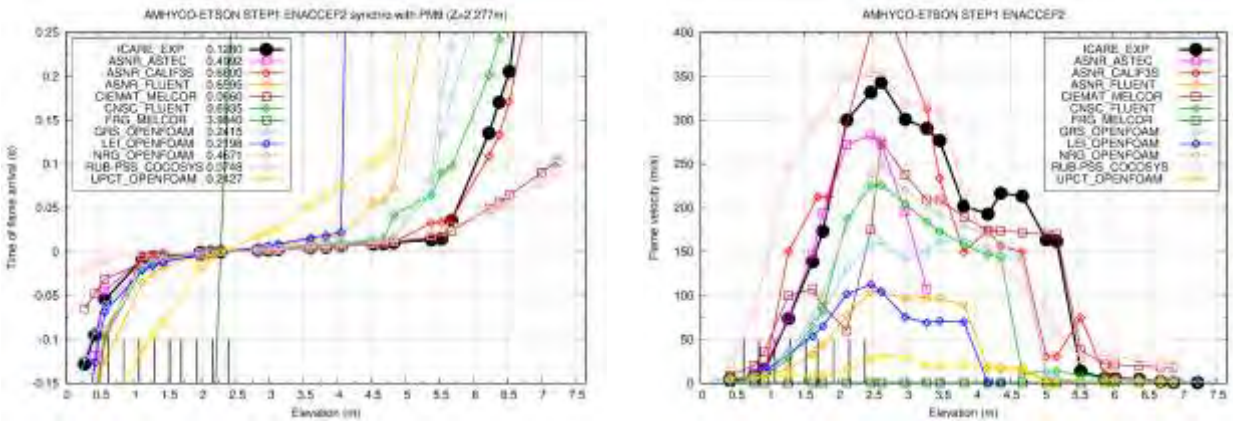

Figure 7: STEP1 - Flame position versus time (left) and flame velocity along facility elevation (right)

Moreover, the contributions that overpredict the maximum flame speed generally provide a reasonable estimate of the flame front–pressure shock interaction location. In contrast, those contributions that significantly underpredict the flame speed also predict the flame–pressure shock interaction to occur at a lower position. The pressure histories in Figure 8 below illustrate this trend for the CFD contributions.

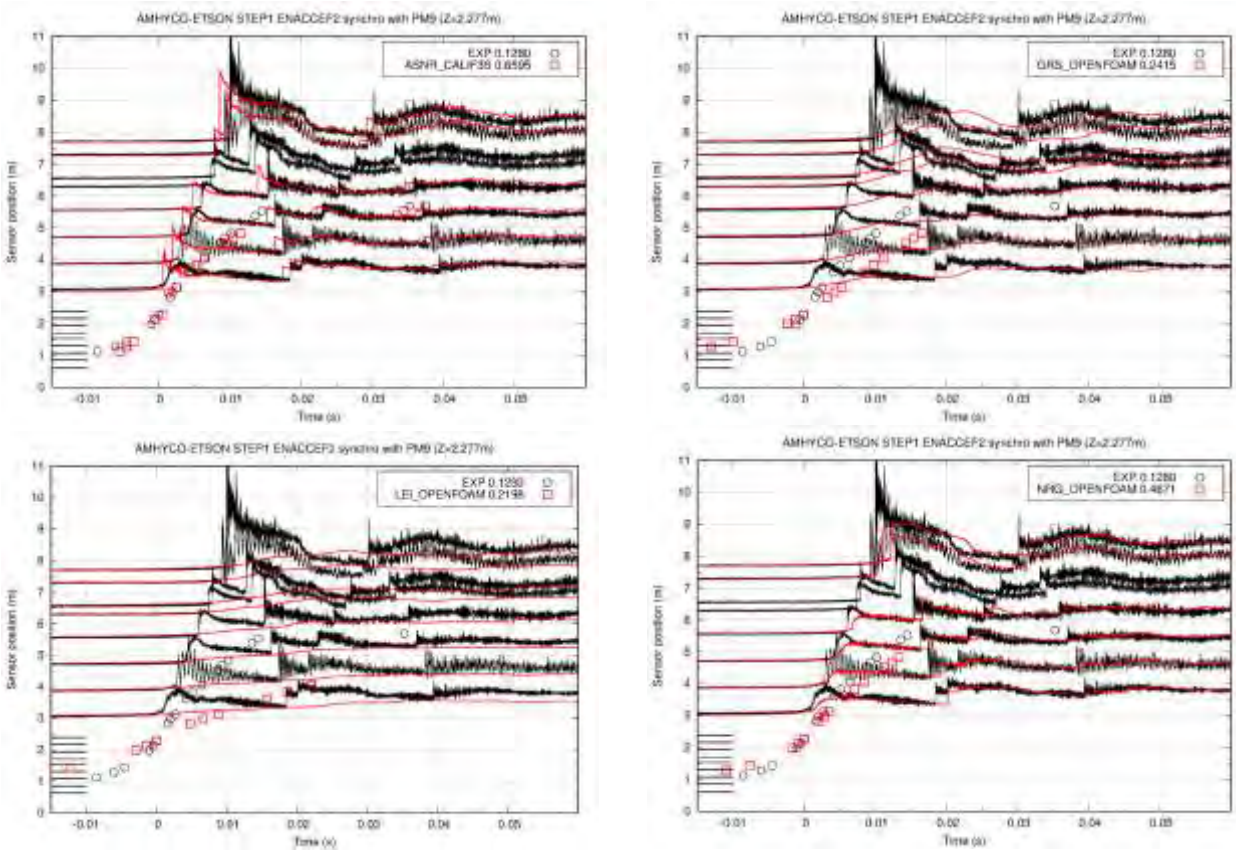

Figure 8: STEP1 - Pressure signals at different elevations (straight lines) and flame front position (markers) - comparison between experiment (black) and ASNR_CALIFS results (top-left), GRS-OPENFOAM results (top-right), LEI_OPENFOAM results (bottom-left), and NRG_OPENFOAM results (bottom-right)

6. CONCLUSIONS

The benchmark highlighted several key findings and recommendations regarding both the numerical solvers and the physical models. For the numerical solvers, it was recommended that, in addition to using an appropriate discretization scheme, pressure-based solvers should, when applicable, be corrected to account for compressibility effects. Numerical solvers, including pressure correction methods, need to be proven applicable to compressible flow; consistency and stability for compressible Euler equations, including shock solutions, should be numerically assessed. Furthermore, the use of adaptive time-stepping strategies and high-order numerical schemes was noted to improve simulation results and numerical convergence studies are necessary to reliably link results to the physical model

Regarding turbulence modelling, URANS provided acceptable predictions for the configurations considered. However, the initial turbulence level prior to ignition must be carefully specified, as it can significantly influence the overall flame behaviour.

For combustion modelling, burning velocity models (BVM) were found to yield satisfactory results, while the inclusion of detailed chemistry with CO offered no added benefit for STEP1 at the considered mesh resolution. Additionally, for lean H_2/CO mixtures, the impact of H2 and CO mass diffusivities on flame behaviour warrants further discussion.

Based on partner experience, thermal radiation is expected to have a significant influence on flame dynamics and should be investigated in future studies.

ABSTRACT

In case of a hypothetic severe accident in a light water nuclear reactor, hydrogen could be produced during reactor core degradation and released into the reactor building. This could subsequently raise a combustion hazard. A local ignition of the combustible mixture may generate standing flames or initially slow propagating flames. Depending on geometry, mixture composition and turbulence level, the flame can accelerate or be quenched after a certain distance from the ignition point. The loads generated by the combustion process (increase of the containment atmosphere pressure and temperature) may threaten the integrity of the containment building and of internal walls and equipments. Turbulent deflagration flames may generate high pressure pulses, temperature peaks, shock waves and large pressure gradients which could seriously damage specific containment components, internal walls and/or safety equipment. The evaluation of such loads relies on codes, which in turn should be used with a high level of confidence.

Currently, turbulence effect on flame acceleration, flame deceleration and flame quenching mechanisms has not been completely well understood and further model development and validation are needed. For this purpose, hydrogen deflagration benchmark exercise had been organized in frame work of the French MITHYGENE project. This benchmark was focused on turbulence effect on flame propagation:three tests performed in the ENACCEF facility had been considered. They concern vertical flame propagation in an initially homogenous mixture with 13% hydrogen content and different geometrical configurations : 5, 9 and 16 annular obstables having the same blockage ratio (64%) to generate different levels of turbulence. This paper aims to present the Benchmark conclusions regarding the ability of CFD combustion models to predict the effect of turbulence on flame acceleration.

ABSTRACT

In case of a core melt-down accident in a light water nuclear reactor, hydrogen is produced during reactor core degradation and released into the reactor building. In case of failure of in-vessel corium retention, a large amount of carbon monoxide (CO) in addition to H2 and other gases may be produced during molten core concrete interaction (MCCI). This subsequently creates a combustion hazard. A local ignition of the combustible mixture may generate standing flames or initially slow propagating flames. Depending on geometry, mixture composition and turbulence level, the flame can accelerate or be quenched after a certain distance. The pressure and temperature loads generated by the combustion process may threaten the integrity of the containment building and safety equipment. The evaluation of such loads requires validated codes which can be used with a high level of confidence. Currently, turbulence and steam effect on flame propagation mechanisms are not well reproduced by combustion models usually implemented in safety tools and further model enhancement and validation are still needed. For this purpose and at the initiative of the SAMHYCO-NET project consortium and of the European Technical Safety Organization Network (ETSON), a benchmark on hydrogen combustion was organized with the goal to identify the current level of the computational tools in the area of hydrogen combustion simulation under conditions typical for safety considerations in a Nuclear Power Plant (NPP). This benchmark is composed by four main steps with increasing difficulty starting from flame propagation in homogenous dry atmosphere and finishing with more representative conditions with (H2/H2O/O2/N2) stratified mixtures. In this paper, only experiments related to flame propagation in homogenous atmosphere are considered. The simulation results obtained by participating organizations, using both Computational Fluid Dynamics (CFD) and lumped-parameter computer codes, are compared to experimental results and analyzed. The main outcomes and lessons learned are also provided.

ETSON-AMHYCO: Lessons learned

Most computational codes are able to predict the phases of flame acceleration and deceleration

Combustion modelling

- Burning Velocity Models (BVM) produced satisfactory results.
- Detailed chemistry including CO did not provide additional benefits for STEP1 at the mesh resolution used.
- For lean H_2/CO mixtures, the influence of H_2 and CO mass diffusivities on flame behavior requires further discussion.

ETSON-AMHYCO: Lessons learned

Turbulence modelling

- URANS approaches provided acceptable predictions for the configurations considered.
- The initial turbulence level prior to ignition must be carefully defined, as it strongly influences overall flame behavior.

Thermal radiation

- Based on partner experience, thermal radiation is expected to significantly affect flame dynamics.
- Its influence should be examined in future studies.

ETSON-AMHYCO: Lessons learned

Numerical solvers

- Appropriate discretization schemes are essential.
- Pressure-based solvers should be corrected for compressibility effects whenever applicable.
- Numerical solvers, including pressure-correction methods, must be demonstrated to be applicable to compressible flows.
- Consistency and stability for the compressible Euler equations, including shock solutions, should be numerically verified.
- Adaptive time-stepping strategies and high-order numerical schemes were found to improve simulation accuracy.
- Numerical convergence studies are required to reliably relate simulation results to the underlying physical models.

ABSTRACT

Free convection is a cornerstone passive safety feature of spent fuel pools and small modular reactors; thus, the adequate modelling of the related phenomena gains more and more attention to facilitate the design maturation and licensing of such nuclear units. The French Authority for Nuclear Safety and Radiation Protection (ASNR) has initiated development activities considering the CESAR thermal-hydraulic module of the ASTEC code to improve its capabilities. During the ELSMOR project potential development paths were identified with respect to containment behaviour, where direct contact condensation (DCC) was hindered as the code assumed an unsuitable (annular) flow regime in the pool. A preliminary code assessment was carried out using the results of a steam blowdown test, performed at the Blowdown and Condensation pool facility (Korea Atomic Energy Research Institute (KAERI), Republic of Korea). The conclusions of this work highlighted the need for a better depiction of DCC considering closed and open (atmospheric) volumes, along with bubble hydrodynamics. Focusing on former topic, experimental data from the SUPERCLAUDIA suppression pool facility (French Alternative Energies and Atomic Energy Commission (CEA), France) was used to reassess DCC and liquid stratification in an open tank with vertical downward steam injection in two tests. It was shown that during longer transients the blowdown pipe can play an important role in the stratification of the liquid volume of the pool. Correcting the applied flow regime in such applications, an additional model was implemented which utilizes bubbly flow instead of annular at low void fraction, enabling a more adequate depiction of DCC. An option to simplify the thermal coupling of the outer surface of pipes to the surrounding liquid volume was also added to CESAR. A modified CESAR model of interphase heat and mass exchanges was also deployed for big 0D swollen water level volumes with improved results in presence of non-condensable gas. This latter update underlined the benefits of having two separate gas temperatures in a single volume, one below the swollen water level and another above.

1. INTRODUCTION

Recent years have seen new light-water small modular reactor (LW SMR) projects emerging on the global stage. The design processes and anticipated regulatory reviews necessitate a rigorous review of safety analysis tools, especially with respect to passive heat removal systems. Large pools of water in which steam direct contact condensation (DCC) will occur can be found in different auxiliary and safety apparatuses, e.g. fuel storage pools and pressure suppression pools. The characteristics of these systems raise questions regarding the modelling adequacy of the related phenomena such as pool stratification, mixing and steam flow regime (jet or bubbly flow). Wang et al. [1] identified various condensation regimes during low-

pressure (< 7 bar) steam blowdown into a wet well with 28-85 °C subcooling using the high-speed video footage of bubble formation and collapse. Compiling the data allowed the researchers to define classification criteria for the different condensation regimes, however, the work covered only low steam mass flux cases. Kang & Song [2] and Choo & Song [3] investigated vertical and horizontal jets in an open pool using particle image velocimetry and a movable Pitot tube, respectively, to map the velocity field of the pool with the purpose of computational fluid dynamics (CFD) code validation. Wang et al. [1] characterized the internal circulation in the pool, driven by vertical jets, nonetheless the pressures and steam mass fluxes were once again low compared to engineering applications. Choo & Song [3] noted that the turbulent intensity around the nozzle determines the jet boundary through a momentum diffusion process in the radial direction, yet their research also relied on relatively low steam mass fluxes and small geometry hence the results are not directly applicable to larger cases. Norman & Revankar [4] conducted tests at the PUMA suppression pool facility using single or multiple horizontal jets to study the thermal mixing and stratification of the water tank. The results revealed that thermal stratification can occur under certain air flow rates, steam flow rates and pool temperature. The phenomena of mixing-to-stratification transition and vice versa were observed depending on the subcooling and steam and air flow rates. Okawa & Furuva [5] showed that lumped-parameter codes like TRACE still struggle to capture the stratification in their work considering the toroidal suppression pool of a Mark I BWR. Implementing an additional pressure loss coefficient (K-factor) on node boundaries improved the global trends albeit local effects of steam flow and condensation remained a challenge. A. Oliva et al. [6] used the CATHARE code to model transients at the SUPERCLAUDIA facility using the classic 0D approach for the water tank. Average liquid temperatures showed very good agreement with experimental trends, on the other hand, the liquid mass variation highlighted discrepancies related to DCC modelling and free surface evaporation.

The Accident Source Term Evaluation Code (ASTEC) has been developed by ASNR for severe accident analyses in various nuclear installations. This modular code can model transient scenarios from the initiating event to fission product (FP) release in the environment. The sequence of events can cover thermal-hydraulics, core degradation along with FP chemistry and transport in the containment. Due to its versatility, the code has been employed in numerous domestic and international projects by regulatory bodies, technical support organizations and industrial affiliates [7]. CESAR is the thermal-hydraulics module of ASTEC dedicated to the modelling of the reactor coolant system. During the ELSMOR Euratom project, potential development points were identified as a result of benchmark activities featuring ASTEC and MAAP [8], among which DCC in a suppression pool was noted. Addressing these modelling needs, the development of CESAR capabilities regarding this particular phenomenon has been underway and are presented here.

2. CESAR MODELLING FOR SUPPRESSION POOL

Pressure suppression pool systems are typically constituted by a big pool of water in which an injection pipe is plunged. Such devices are used to depressurize the primary circuit of a reactor by condensation of the steam injected into the water pool through the pipe. The CESAR module calculates 1D in circuits or 2D in vessel two-phase flows, with one liquid coolant and a homogeneous mix between steam and non-condensable (NC) gases. The code solves $6+n$ equations (mass balance equations for liquid, steam and n number of NC species, along with energy and momentum balance equations for each phase). To better depict large volumes where a water level is expected, e.g. in pressurizers, steam generator cavities or suppression pools, a 0D swollen water level volume can also be considered. In these big volumes, the same total pressure is assumed below and above the water level. Although there is only gas in the dry top part of the volume, there can be dispersed gas also below the water level. An additional state variable, the void fraction below the water level (α_l) in the swollen sub-volume can then be introduced. This approach still assumes that the dispersed gas is in thermal equilibrium with the continuous gas in the upper volume, which can result in unphysical gas temperatures in the tank in presence of non-condensable gas. Recent developments in the code (available from released ASTEC version 3.2) have improved this modelling by also assuming different energy and mass balance for the gas above and below the water level. This improvement is suitable for

suppression pools applications where the upper dry region can be expected to be mainly cold air while saturated steam can be expected below the water level.

In addition to the 0D pool, a 1D element is used to model the injection pipe. The wall of the pipe is also considered to be in contact with the water pool. This connection can enable condensation inside the injection pipe and boiling on the external, submerged surface of the pipe wall. In CESAR, mass transfer between liquid and steam is calculated through the interfacial heat transfers evaluated for both phases. The heat transfer is assessed between the considered phase *k* and the liquid-gas interface *i*:

$$Q_{i,k} = h \cdot A_i \cdot (T_k - T_{int}) \quad (1)$$

where h is the heat transfer coefficient, A_i is the interfacial area, T_k and T_{int} are the bulk and interface temperatures respectively (interface temperature is usually taken at saturation conditions). The heat transfer coefficient (through Nusselt number correlations) and the interfacial area are evaluated by the code depending on the flow configuration. Since the flow regimes in CESAR are mainly based on a 1D pipe configuration, the solution for large quiescent volumes might be distorted depending on the boundary conditions. In a subcooled water pool, the liquid to interface heat transfer is expected to be quite important and have a big impact on the condensation process. By default, in CESAR, in particular for low void fractions, the liquid to interface heat transfer is evaluated using the assumption of an annular flow configuration. In this case, the heat transfer coefficient is calculated using the Nusselt formula given by Shah et al. [9] while the interfacial area is given by the D_h volume hydraulic diameter as:

$$A_i = \frac{4}{D_h} \quad (2)$$

In the case of a large tank of water, as in suppression pool applications, a very small interfacial area can be expected, far from the presumed flow configuration. From the release version 3.2 of ASTEC, a new option can be applied, modifying the flow configuration detected by the code when the void fraction is small. In volumes where the option is activated, the flow is now assumed to be in the bubbly regime for low void fractions (< 0.3). The liquid to interfacial heat transfer is then evaluated using the Ranz-Marshall Nusselt number correlation for the heat transfer coefficient, and the interfacial area density is calculated using:

$$A_i = \frac{6\alpha}{d_{bub}} \text{ , where } d_{bub} = 1.73 \cdot \sqrt{\frac{\sigma}{g(\rho_{liq} - \rho_{steam})}} \quad (3)$$

where α is the void fraction and d_{bub} is the bubble diameter, σ is the surface tension, g is the gravitational acceleration, ρ_{liq} and ρ_{gas} are the liquid and gas densities, respectively.

3. TRANSIENT ANALYSES WITH CESAR

3.1. Suppression pool validation cases selection and CESAR model

The code development work revolved around two experimental facilities to cover a wider range of boundary conditions, including closed and open pools. Three tests from the literature were analyzed with CESAR:

- two long tests at ambient pressure: SUPERCLAUDIA facility [10]
- one short, pressurized test: Blowdown and Condensation (B&C) facility [11]

Heat losses were neglected in both models either due to the brief nature of the blowdown or assuming adequate insulation around the tank. The two selected facilities shared the general topology of a water tank

thus the same spatial discretization strategy was used in both cases; Fig. 1 illustrates the nodalization schemes of the models. The sparger pipe had 5 axial nodes in each case, connected to 5 wall heat structures. In the B&C model the sparger had a horizontal nozzle, and the tank was closed, whereas in the SUPERCLAUDIA model the injection was downward and the pool was open to the atmosphere. It is worth mentioning that the B&C facility employed a perforated sparger head i.e. multiple small jets along its circumference. Song et al. [12] noted that in such configurations individual jets can be lumped together, as substituting several condensation regions by one does not incur penalties in terms of steam-to-liquid momentum transfer. Air (nitrogen and oxygen) constituted the atmosphere in the tanks while no residual gas was considered in the swollen sub-volume.

Each test was run with four different water tank configurations to highlight the impact of the different modelling choices:

- *case 1*: using the standard 0D swollen water level volume with a single NC mass and gas energy balance equation for the whole water tank
- *case 2*: using the newly developed 0D volume for the water tank (with different NC mass and gas energy balance equations for both sub-volumes)
- *case 3*: case 2 with thermal coupling between the pipe and the volume
- *case 4*: case 3 with the new option modifying the flow configuration activated in the pool

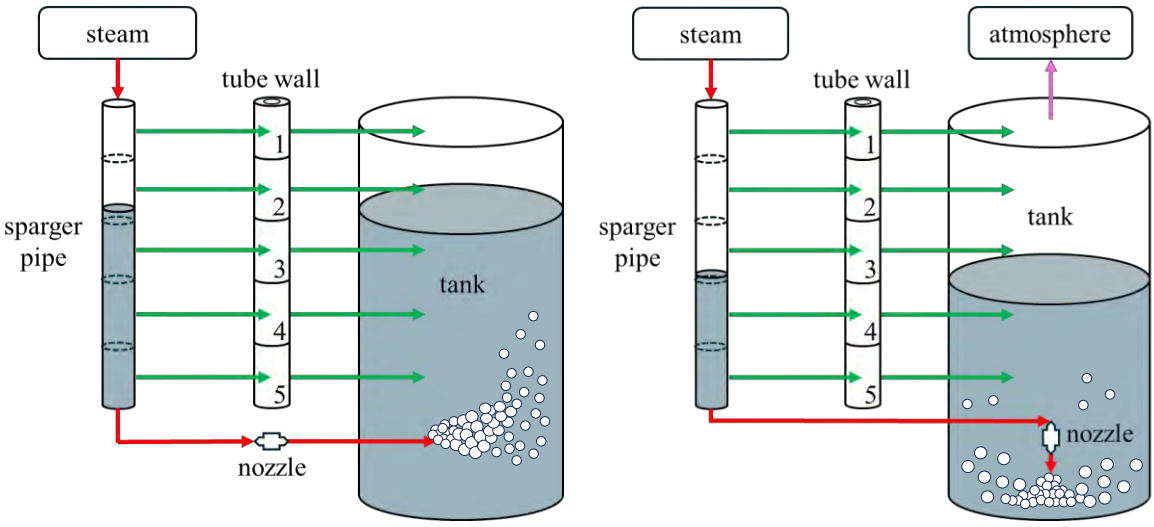

Figure 1. CESAR models of B&C KAERI (left) and SUPERCLAUDIA (right).

3.2. Pool stratification tests of the SUPERCLAUDIA facility

Avakian et al. [10] conducted steam blowdown experiments at the SUPERCLAUDIA facility of French Alternative Energies and Atomic Energy Commission (CEA). The test rig included an open and relatively small water tank. Three campaigns incorporated nine tests with varying steam pressures, nozzle diameters and nozzle head configurations. Since ref. [10] reported data on tests #3 and #5, only these two experiments were modelled in CESAR. Both runs used a constant saturated steam flow rate that slowly saturated the liquid in the atmospheric tank. The transients were terminated when the average liquid temperature reached ≈95 °C. Relevant facility parameters and test conditions are summarized in Table I.

Table I. Facility parameters and initial conditions [10].

Parameter	Value	Test conditions	Test #3 / #5
Tank inner diameter	2500 mm	Tank pressure (p_{tank})	1 bar
Tank height	1600 mm	Pressurizer pressure	45 / 100 bar
Tank free volume	7.85 m^3	Initial liq. temp. (T_{liq})	10 °C
Sparger length	1000 mm	Water level	1.03 m
Sparger elevation from tank bottom	600 mm	Liquid inventory (M_{liq})	5025 kg
Nozzle flow area on the sparger head	1.96x10^{-3} m^2	Steam flow rate ($\dot{m}_{steam}$)	76 / 167 g/s
		Transient duration	13000 / 5240 s

Fig. 2 depicts the liquid mass inventory evolution for test #3 and #5 along with the theoretical (theo.) and experimental (exp.) curves. The theoretical trend refers to full condensation while the experimental curve shows the weight measurements. In test #3, the growing discrepancy between theory and observation can be associated with the intensifying natural evaporation on the free water surface and the diminishing condensation potential of the liquid. Concerning test #5, ref. [10] called attention to the unintuitive experimental M_{liq} curve, the authors explained the surprising mass increase by the 'jet effect', the larger steam mass flux exerted an additional downward force on the bottom of the water tank, skewing the weight measurement. In case 1, condensation was very weak, whereas after switching to case 2 both tests started to show improvements compared to case 1, increasing the liquid inventory by 47 % and 135 % in tests #3 and #5, respectively. Coupling the sparger pipe with the pool (case 3) further increased condensation rates, still, quantitatively speaking the condensed steam mass was underestimated at the end by 2 % and 12 % in tests #3 and #5, respectively. Finally, by modifying the interfacial area density evaluation i.e. increasing the condensation mass transfer, the code could capture some additional inventory gain in case 4. It should yet be noted that in both tests, results are closer to the theoretical curve than to the measurement data until liquid saturation.

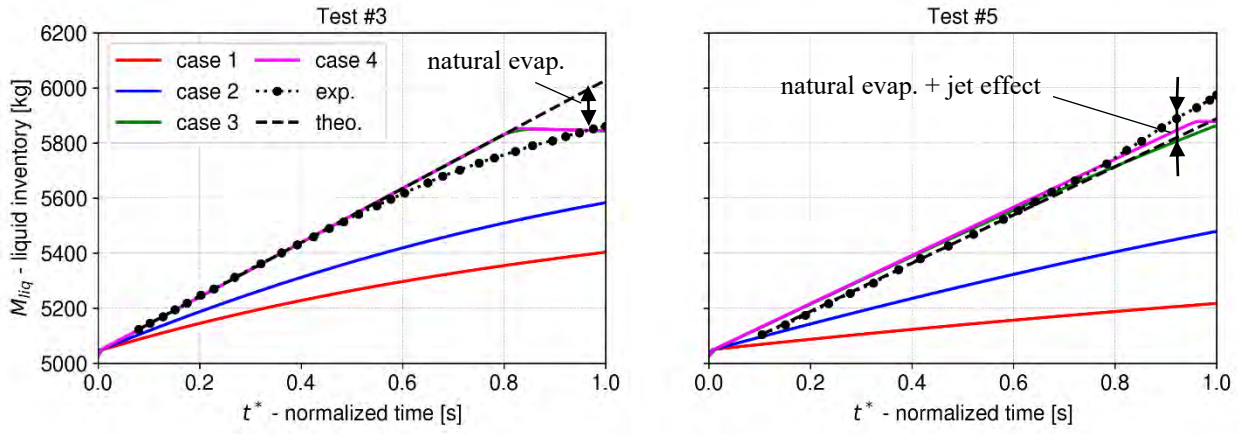

Figure 2. Liquid inventory variations in the tank.

The average liquid temperature trends are depicted in Fig. 3, where the experimental curve is the average reading of the thermocouple chain closest to the tank wall. Even though this chain was farthest from the

nozzle, its average reading can be regarded as a pool-representative T_{liq} as the variation in temperatures on all chains along the tank radius remained below 1.5 °C [10].

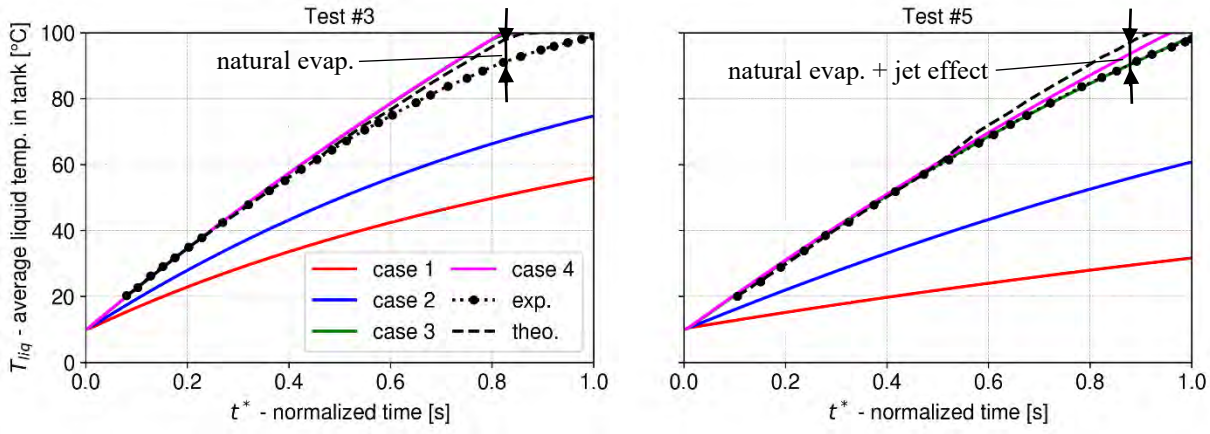

Figure 3. Liquid temperature variations in the tank.

It is interesting to note that the impact of the condensation in the sparger pipe was quite pronounced due to the length of the transients and the size of the pipe. Fig. 4 presents the total mass flow rate from vapour to liquid (positive for vaporization and negative for condensation) in the injection pipe for both experiments. The thermal coupling of the sparger pipe with the tank, when taken into account, was responsible for condensing ~87-96 % and ≈82 % of the total steam flow in tests #3 and #5, respectively. Without the coupling no condensation could take place in the pipe. The initial condensation rates could further increase as the wetted surface area of the pipe on the tank side grew, thanks to the rising water level. In test #5 the relative condensation rate was slightly lower than in test #3, this can be attributed to the higher wall temperatures of the sparger pipe due to the higher steam pressure.

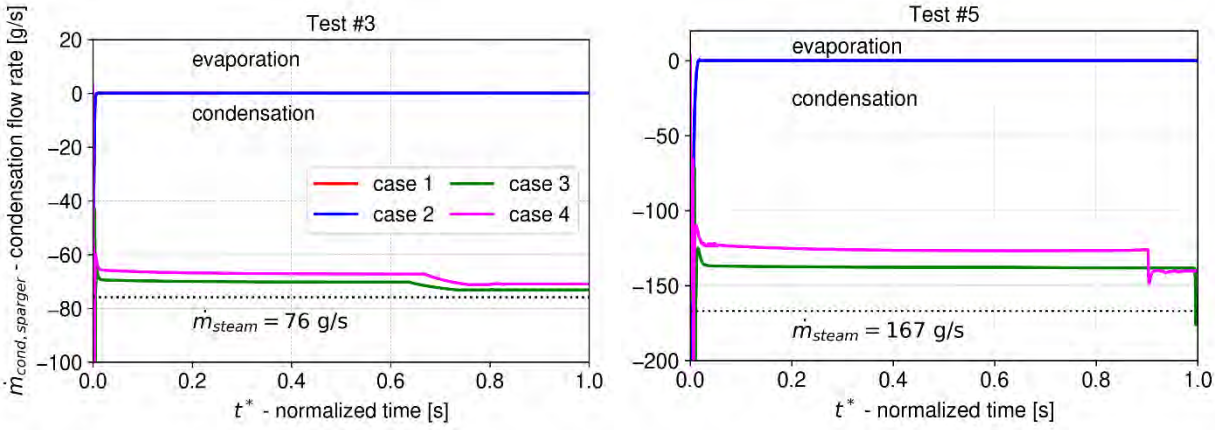

Figure 4. Condensation rates in the sparger pipe.

During the experiment the observers reported perfect condensation for the larger part of the transients, that is confirmed by the water temperature theoretical and experimental curves in Fig. 3. In the real scenario, the liquid temperature began to deviate from the ideal, nearly linear curves before the midpoint and at the

halfway point of tests #3 and #5, respectively, due to the intensifying natural evaporation on the water surface [10]. Fig. 5 depicts the phase change mass flow rates in CESAR occurring below the water level in the swollen pool volume. Case 1 showed a 0.0-1.8 g/s evaporation rate meaning that no condensation took place below the water level. Having a separate T_{gas} in the swollen volume enabled DCC to some extent, nonetheless the efficacy of this heat transfer remained unsatisfying in case 2. Due to the very efficient condensation in the sparger pipe, i.e. pipe-to-pool thermal coupling, case 3 had a much lower condensation rate in the tank compared to the previous case, as little remaining steam reaches the pool. Using the modified flow configuration in case 4 the code could capture DCC in the pool. It should be noted that the discrepancy between the steam inlet flow and the case 4 curve, until bulk saturation, corresponds to the in-pipe condensation rates given in Fig. 4, meaning complete condensation of the steam is observed in this case. Upon reaching saturation temperature in the tank, the steam started to evaporate the liquid inventory as the condensation potential dropped to zero.

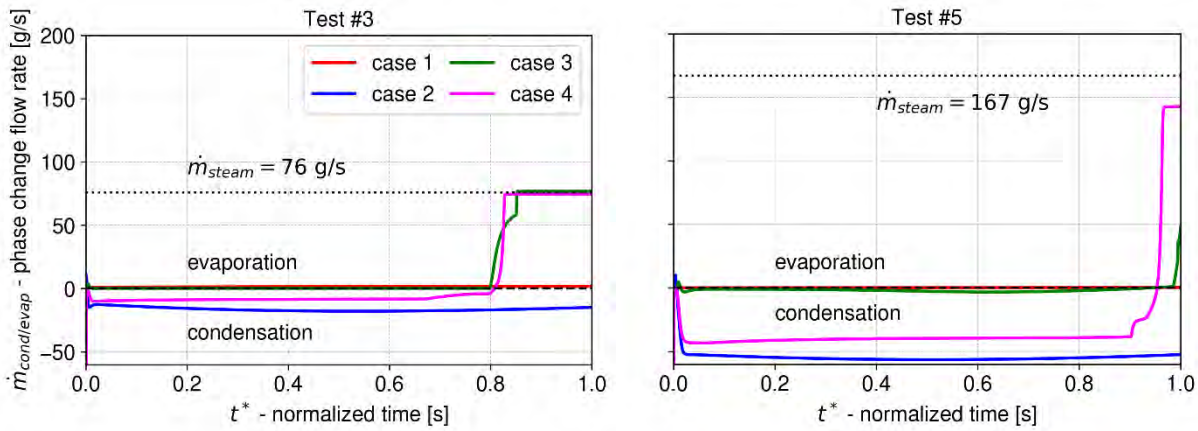

Figure 5. Phase change rates in the swollen sub-volume of the tank.

Fig. 6 shows the phase change mass flow rate at the water level in the pool. This mass flow rate is associated with the heat transfer between the free surface and the gas above the water level in the tank. The negative phase change rates in cases 1-3 (complementing the weak condensation below the water level) explain the liquid inventory gains that can be seen in Fig. 2. The cold free surface could condense some of the steam mass that broke through the water. In case 4, in the absence of steam above the water level, no substantial condensation could take place. After saturation, evaporation did occur (positive value for the phase change mass flow rate in Fig. 6). However, the flow rates only reached 1.4-1.3 g/s in tests #3 and #5, respectively, this inventory loss could not play a meaningful role in the mass balance of the tank. The liquid inventory loss due to evaporation ($\dot{m}_{evap}$) was evaluated based on M_{liq} from the experimental and theoretical curves given in ref. [10] using the following formula:

$$\dot{m}_{evap} = \frac{\Delta M_{liq,theo} - \Delta M_{liq,exp}}{\Delta t} \quad (4)$$

where $\Delta M_{liq,theo}$ and $\Delta M_{liq,exp}$ are the theoretical and experimental mass changes during Δt window. For test #3 only, the evaporation mass flow rate assessed is shown in Fig. 6 (the jet-effect observed in test #5 makes it complicated to give an estimate of the evaporation). From the experimental data, evaporation was shown to play a much more important role than what is assessed by CESAR and could explain the discrepancies observed. In order to better calculate the SUPERCLAUDIA experiments, improving the free surface evaporation model seems to be an interesting direction for further code developments.

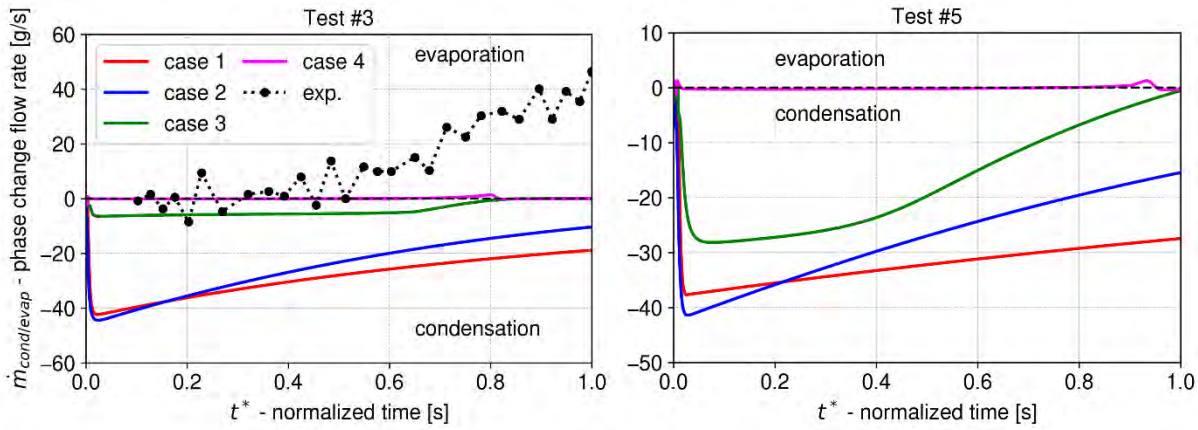

Figure 6. Free surface phase change rates in the tank.

3.3. Blowdown transient of the B&C facility of KAERI

The B&C facility of the Korea Atomic Energy Research Institute (KAERI) is a representative of the in-containment refueling water storage tank of the APR1400 [11]. Compared to the SUPERCLAUDIA facility, the pool is bigger and can pressurize. The test loop comprises a pressurizer, a piping system with a sparger and a water tank, the main parameters and initial conditions are given in Table II. The purpose of the pool mixing test was to provide input for subsequent CFD validation activities, building upon earlier research e.g. condensation regime maps and multi-hole sparger head modelling. The test procedure had two main steps: first the pressurizer was heated to produce saturated steam at 150 bar, afterwards the control valve was opened to release the steam into the water via a perforated sparger head. The calculated 60 s sequence covered a brief steady state of 4.5 s prior to injection, followed by the blowdown of 55.5 s. Transient considered here is way shorter than for the previous facility.

Table II. Facility parameters and initial conditions [11].

Parameter	Value	Initial conditions	Value
Tank inner diameter	3000 mm	Tank pressure (p_{tank})	1 bar
Tank height	4000 mm	Pressurizer pressure	150 bar
Tank free volume	28.22 m^3	Tank temperature (T_{liq})	25.60 °C
Sparger inner diameter	152.40 mm	Water level	3.02 m
Sparger length	3100 mm	Liquid inventory (M_{liq})	21244 kg
Sparger elevation from tank bottom	900 mm	Liquid volume	21.31 m^3
Nozzle flow area on the sparger head	5.52x10^{-3} m^2	Gas volume	6.91 m^3

Fig. 7 shows that, in CESAR, for cases 1-3, the water had practically no suppressive impact on the pressure balance between the tank and the pressurizer as the curves saturated around 150 bar, far above the observed experimental values provided by the pressure transducer of the tank (PT207). The liquid temperatures were underestimated for these three cases compared to thermocouple (TC635, TC705 above the sparger head in the tank). On the other hand, modification of the flow regime map in the pool volume displayed a large

impact on the results. In case 4 the maximum tank pressure was 1.30 bar, which indicated extremely efficient condensation, the injected steam could not break through the water to pressurize the tank.

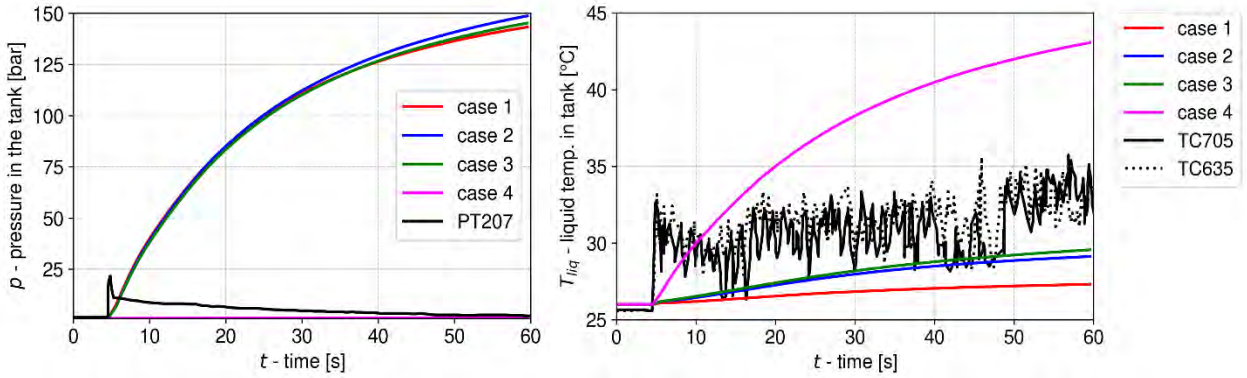

Figure 7. Pressure (left) and liquid temperature trends (right) in the tank.

Fig. 8 illustrates the phase change mass flow rates in the different parts of the system. It can be seen here that the sparger had a relatively small importance compared to SUPERCLAUDIA, only ~9.8 % of the total condensed steam mass was captured in the pipe. Free surface evaporation was a negligible factor in this case as well, as the increase of 17 °C in liquid temperature evaporated ~0.28 kg water.

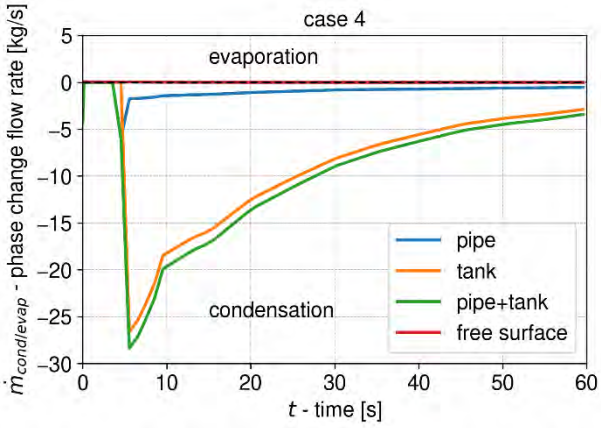

Figure 8. Phase change rates in case 4.

In case 4, due to the modification of the interfacial area evaluation, bubbles diameter becomes one of the most important parameters for the DCC. Fig. 9 illustrates this bubble diameter evolution during the test. This diameter is evaluated according to Eq. (3) and resembled rather a constant as the pressure did not vary during the transient and the water density reduction due to the warm-up was negligible. Focusing on case 4, the largest discrepancies between calculation and measurement data appeared at the beginning of the transient. Due to the large steam mass fluxes, the experiment featured a continuous vapour jet, which could raise the steam up to the free surface with small interfacial area density. With a decreasing mass flux, the jet and the bubbles could break up thereby increasing the interfacial area and the efficiency of DCC. Fig. 9 suggests that the nearly constant bubble diameter led to the overestimation of the condensation rates in the tank which prevented the pressure peak shown in the PT207 readings in Fig. 7. In other words, modelling a

jet with an approach based on the bubbly flow configuration results in the misrepresentation of the interfacial area density i.e., unrealistic heat transfer and pressure trends. The issue of wrong estimation of interfacial area could be improved by substituting the formula of d_{bub} in Eq. (3) with a model that considers jets e.g., relying on the approaches of Zeitoun [13] or Hibiki et al. [14]. Such improvements will be considered in future code developments.

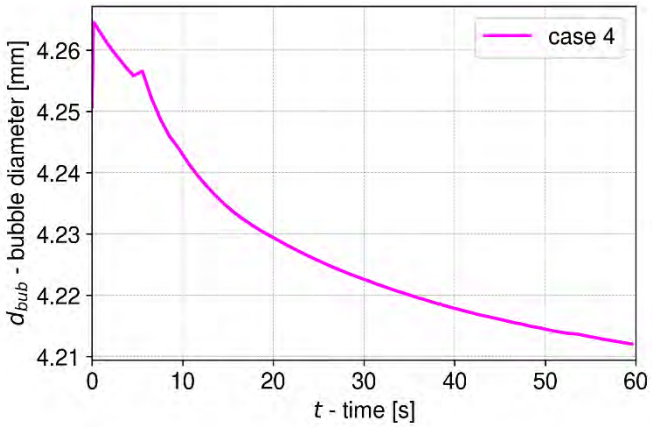

Figure 9. Bubble diameter evolution with the bubbly flow configuration in the pool.

Another point to consider is the evaluation of the heat transfer correlation used to assess the interfacial heat transfer coefficient. In case 4 the Ranz-Marshall correlation was utilized to compute the Nusselt number, which has been a popular choice in similar engineering applications yet has a very limited validity range ($Re_{bub} < 200$), most importantly; unfit for jetting. A better depiction of the heat transfer coefficient could be achieved by complementing the Ranz-Marshall correlation with other formulae, e.g. covering the transitional ($200 < Re_{bub} < 10^4$) and turbulent bubble Reynolds region ($Re_{bub} > 10^4$) with Chen & Mayinger [15] and Yang et al. [16] correlations, respectively.

4. CONCLUSIONS

Steam blowdown experiments were modelled with the CESAR thermal-hydraulic module of ASTEC, considering closed and open suppression pool facilities. The classic 0D approach with a single gas temperature in the control volume failed to capture heat transfer trends in the tank, whereas the introduction of additional state variables to distinguish the gas temperature and composition above and below the swollen water level, improved the solution profoundly. Both open- and closed-pool simulations highlighted the importance and positive impact of the flow regime correction of bubbly flow with respect to DCC. The results also underlined the impact of the thermal coupling between the injection pipe and the pool, notably during longer transients.

Concerning the SUPERCLAUDIA tests, the free surface evaporation model of CESAR was identified as a potential topic of future development. In the B&C test the pressure trend could be improved by adopting an interfacial area density or bubble diameter correlation that is fit for vapor jets in subcooled water. The turbulent nature of such applications motivates the extension of the bubble heat transfer coefficient model, which is exclusively based on the Ranz-Marshall formula. Along with these improvements of the model to be able to cover a wider range of diphasic flow configurations in the pool, additional validation work will also be pursued.

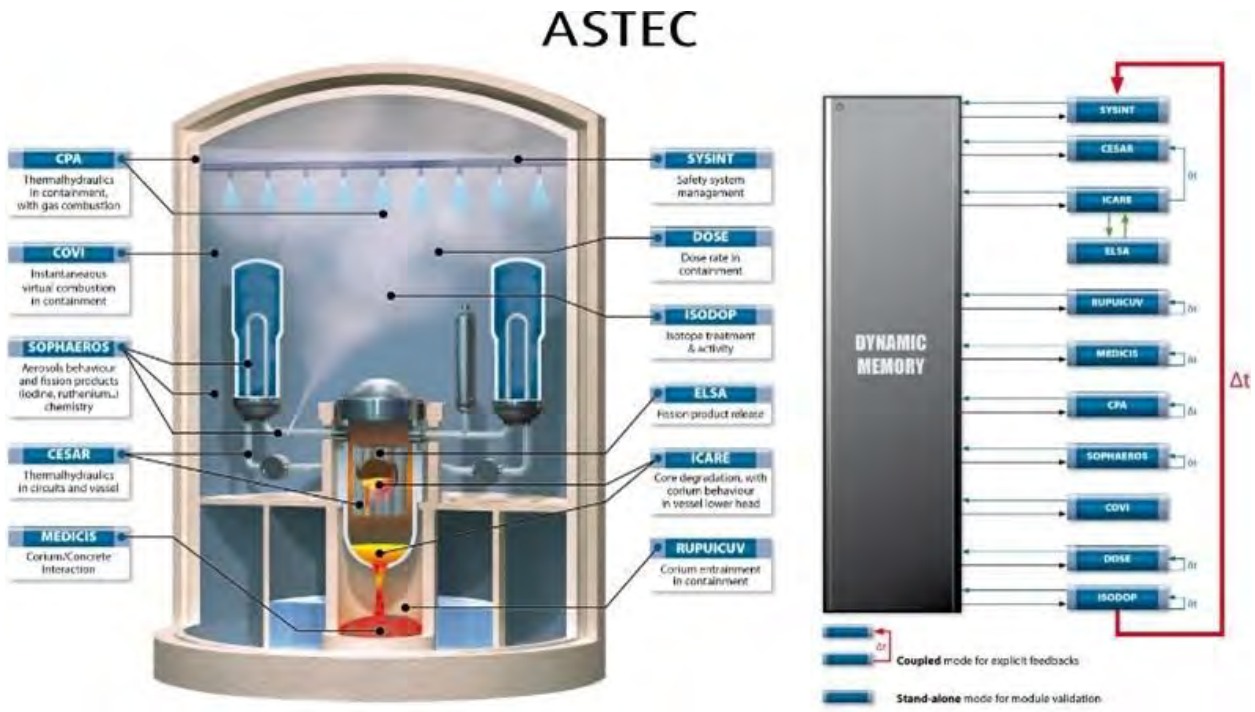
01. INTRODUCTION AND CONTEXT

- Direct contact condensation
  - Spent fuel pools
  - Suppression pools → BWR, SMR (ELSMOR E-SMR, SASPAM iPWR)…

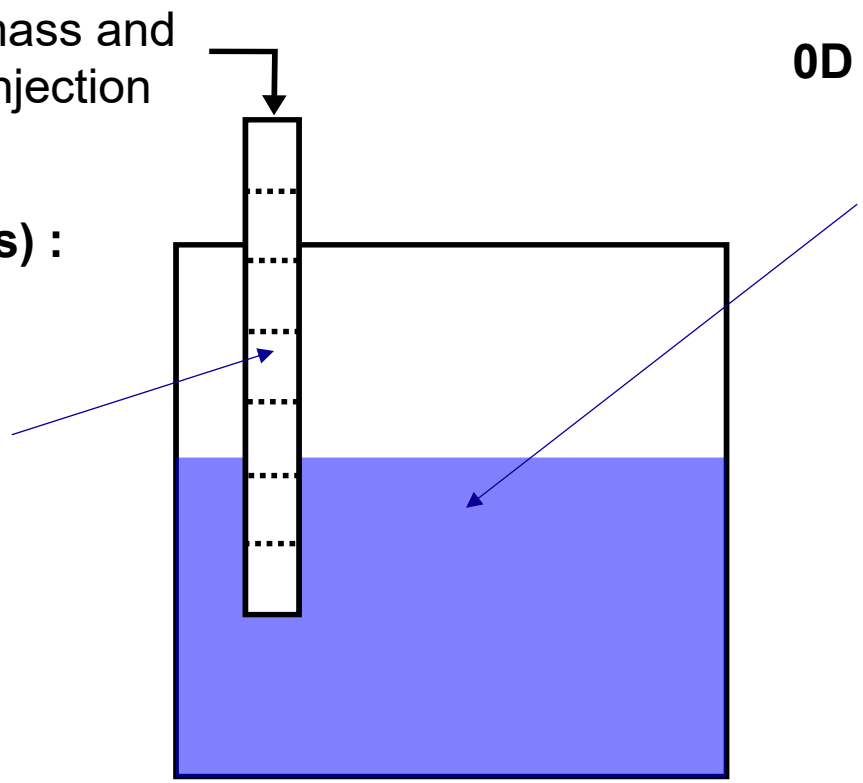
- ASTEC severe accident code for safety analysis
  - CESAR module
    - TH in RCS
    - Some containment applications → ERVC, SMR containment…
  - Previous studies have shown CESAR tends to under-estimate the pool condensation (ELSMOR project [1])
    - ➔ Improvement presented in the paper are all included in the latest ASTEC released version (v3.2)



[1] Bittan et al., *Ann. Nucl. Energy (2025)*

02. SUPRESSION POOL MODELLING

❑ **Case 1** : Default modelling in CESAR using a 1D pipe and a 0D swollen water level volume



1D pipe (6 (+n) balance equations) :

- Liquid mass
- Steam mass
- Each NC gas mass
- Liquid energy
- Gas energy
- Liquid momentum
- Gas momentum

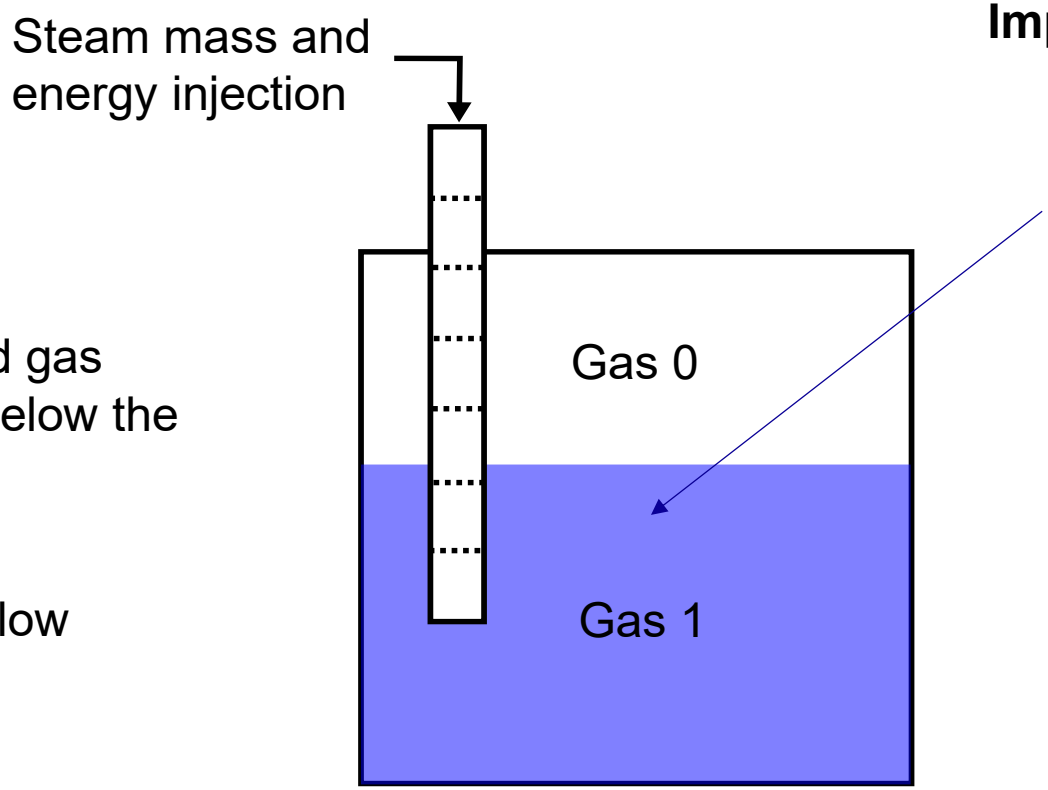
0D pool volume (5(+n) equations) :

- Liquid mass
- Global steam mass
- Global NC gas mass for each species
- Liquid energy
- Global gas energy
- Total gas mass below the water level

02. SUPRESSION POOL MODELLING

❑ **Case 2** : Application of recent CESAR improvement of the 0D swollen level volume model

- Different temperature and gas composition above and below the water level
  - → Cold air above
  - → Saturated vapour below



Improved 0D pool volume :

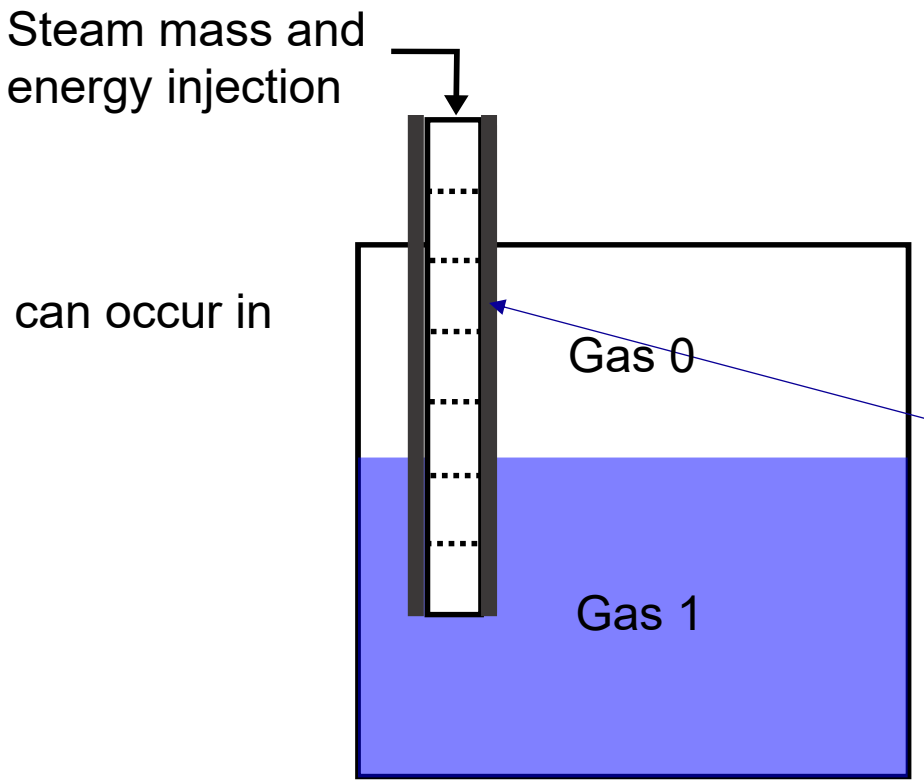
- Liquid mass
- Global steam mass
- Global NC gas mass for each species
- Liquid energy
- **Gas energy above the water level**
- **Gas energy below the water level**
- **Each NC gas mass below the water level**

➔ **6(+2n) equations**

02. SUPRESSION POOL MODELLING

❑ **Case 3** : Taking into account the thermal coupling between the pipe and the pool

- Part of the condensation can occur in the injection pipe

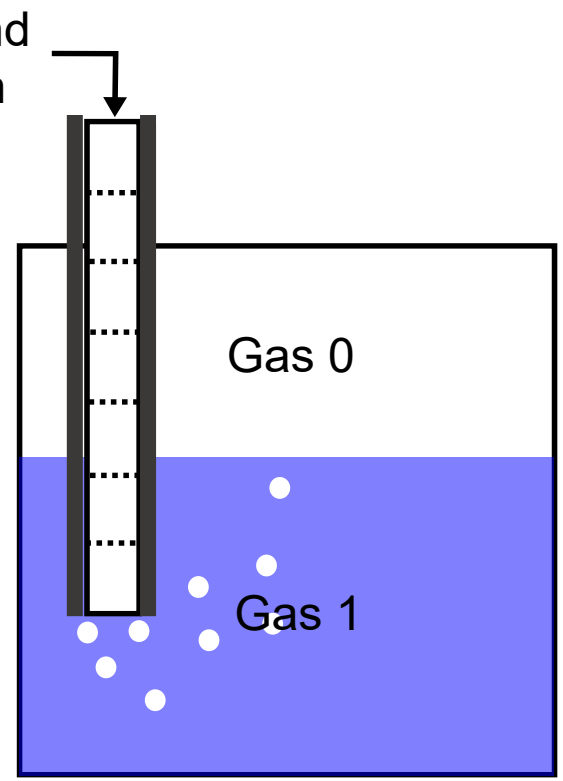


Solid wall modelling :

- Energy balance in the wall
- Heat exchange with the 1D pipe volumes and the 0D pool

02. SUPRESSION POOL MODELLING

❑ **Case 4** : Modification of the interfacial exchange below the water level in the 0D pool



- Condensation below the water level is calculated from interfacial heat transfer evaluation

$$Q_{ik} = h\, A_i (T_i - T_k)$$

- CESAR has been written for circuit application and uses corresponding flow maps for A_i and h
- Annular configuration assumed for Q_{il} calculation in default CESAR

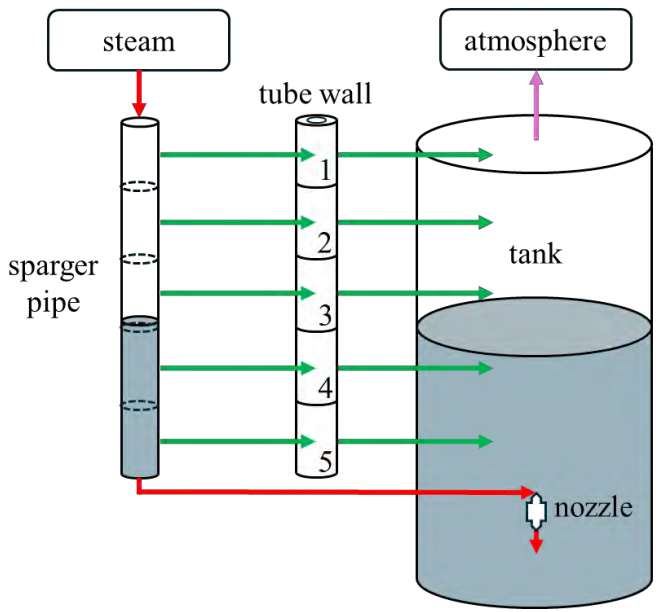
- Modification of the flow regime map for the pool volume :
  - ➔ Bubbly flow assumed below the water level for void fraction <0.5

	Default	New
Interfacial area Ai	$\frac{4}{D_h}$	$\frac{6\alpha}{d_{bub}}$
Heat transfer correlation	Shah [2]	Ranz and Marshall

[2] Shah, *Int. J. Heat Mass Transfer* (1979)

03. VALIDATION ON THE SUPERCLAUDIA EXPERIMENT

❑ Experiment from CEA : open tank, small volume and long transient [3]



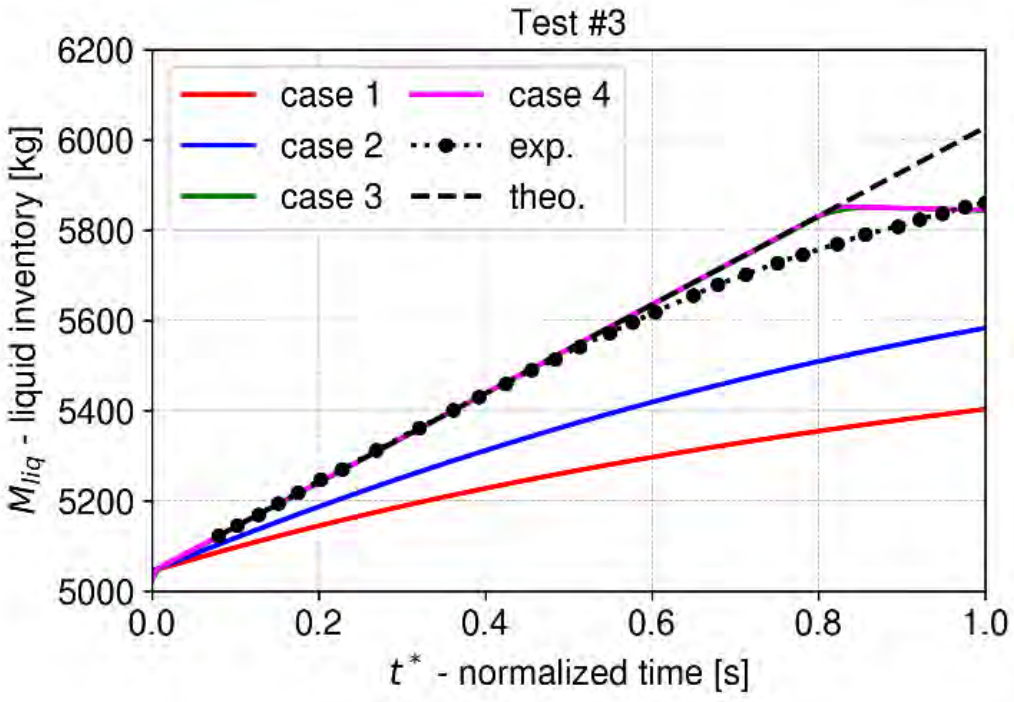
Parameter	Value	Test conditions	Test #3
Tank inner diameter	2500 mm	Tank pressure (p_{tank})	1 bar
Tank height	1600 mm	Pressurizer pressure	45 bar
Tank free volume	7.85 m^3	Initial liq. temp. (T_{liq})	10 °C
Sparger length	1000 mm	Water level	1.03 m
Sparger elevation from tank bottom	600 mm	Liquid inventory (M_{liq})	5025 kg
Nozzle flow area on the sparger head	1.96x10^{-3} m^2	Steam flow rate ($\dot{m}_{steam}$)	76 g/s
		Transient duration	13000 s

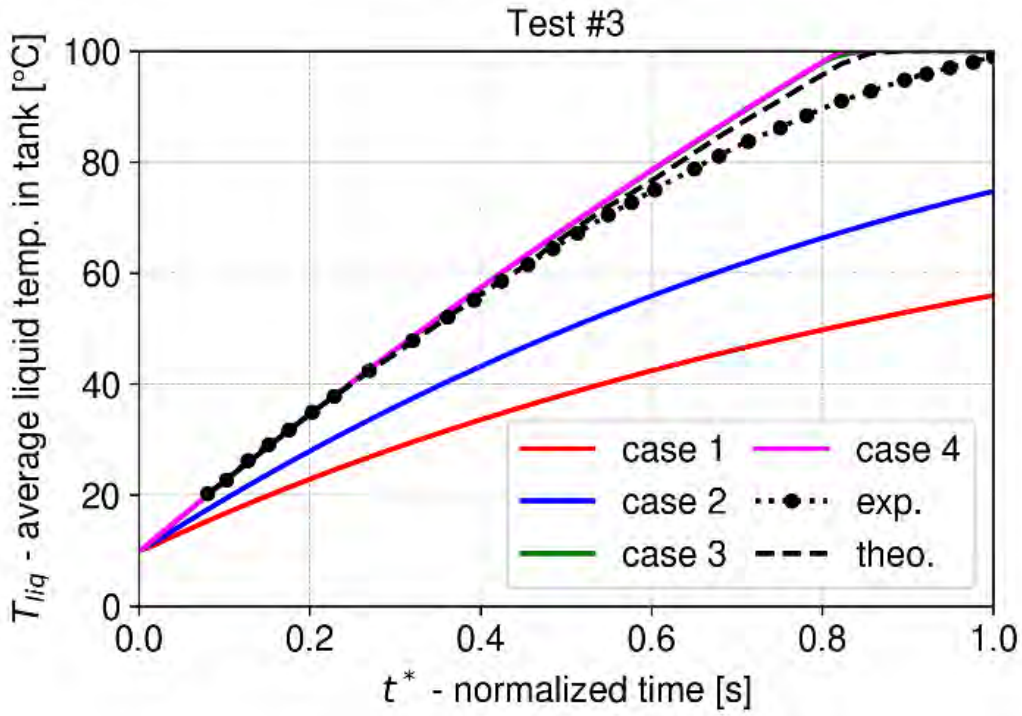
[3] Avakian et al., *ICONE6* (1998)

03. VALIDATION ON THE SUPERCLAUDIA EXPERIMENT

case 1 : default
case 2 : + improved 0D pool model
case 3 : case 2 + pipe/pool thermal coupling
case 4 : case 3 + corrected condensation

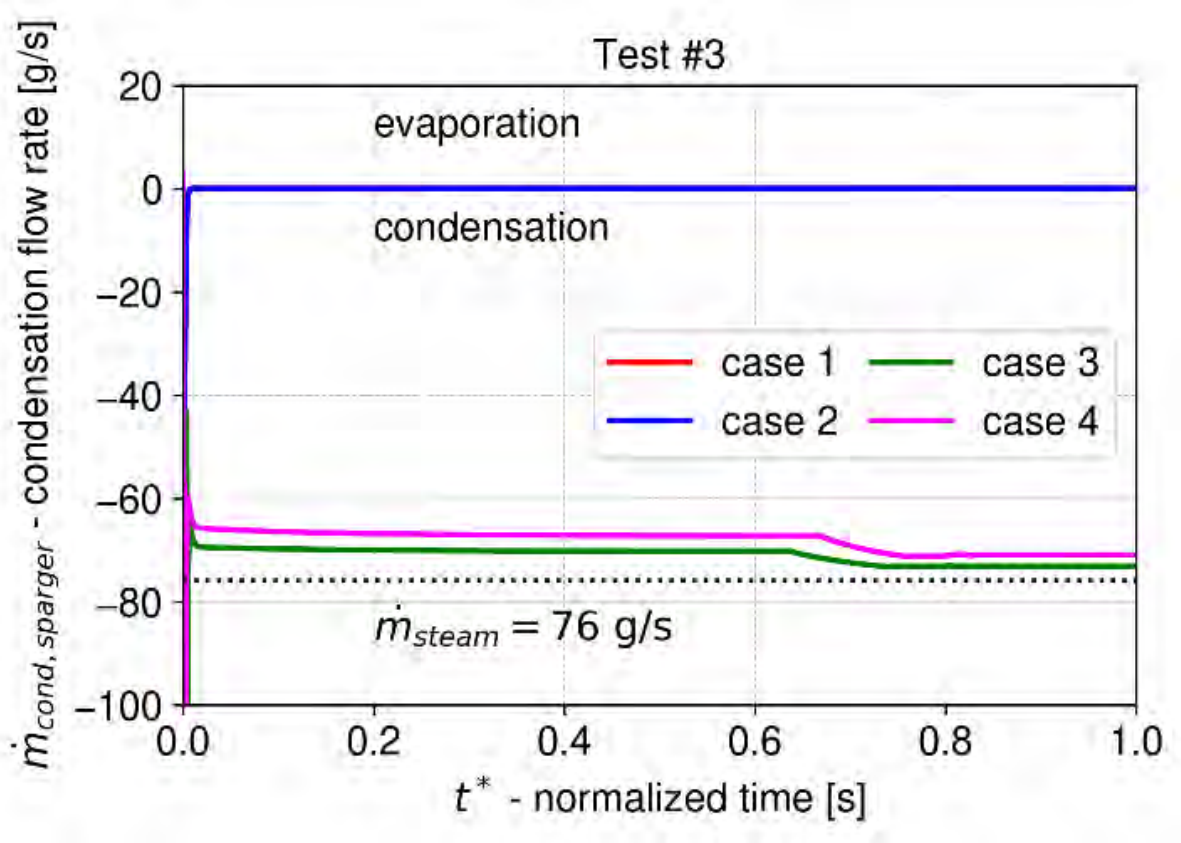
- With case 1, strong under-estimation of the condensation
- Thermal coupling between the pipe and the pool has a strong influence → where most of the condensation occurs in this case in the calculations (~90%)





03. VALIDATION ON THE SUPERCLAUDIA EXPERIMENT

- Condensation inside the injection pipe → where most of the condensation occurs in this case in the calculations (~90%)

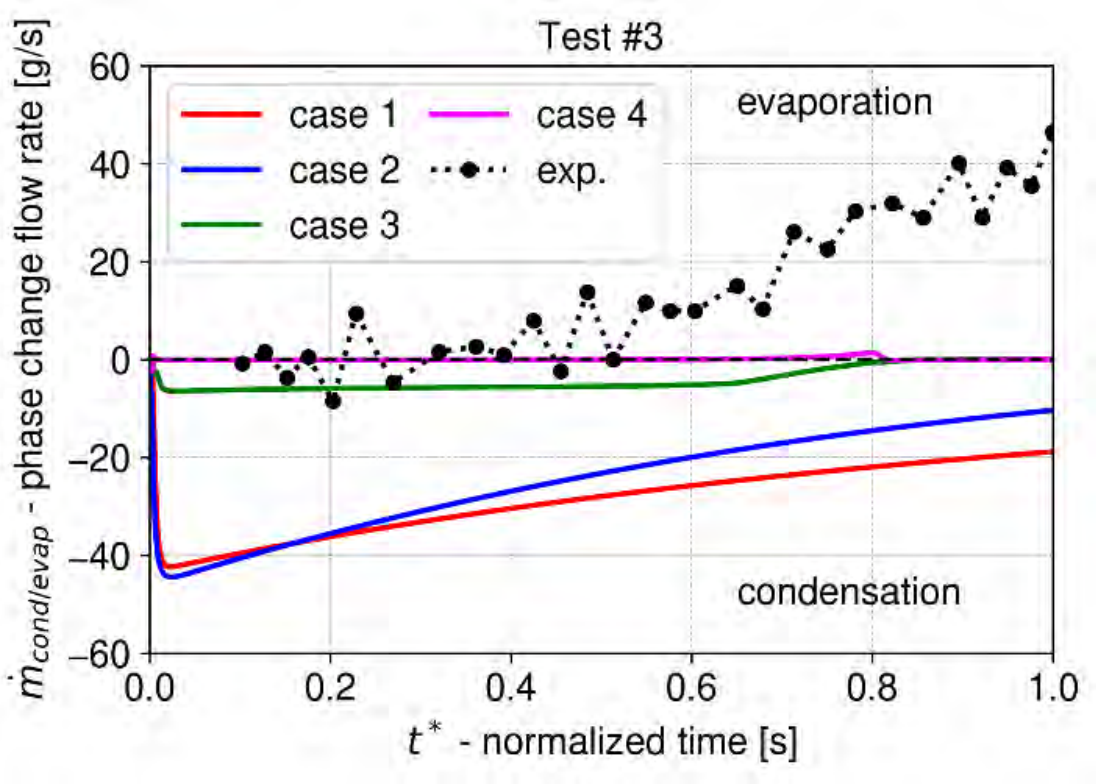


case 1 : default
case 2 : + improved 0D pool model
case 3 : case 2 + pipe/pool thermal coupling
case 4 : case 3 + corrected condensation

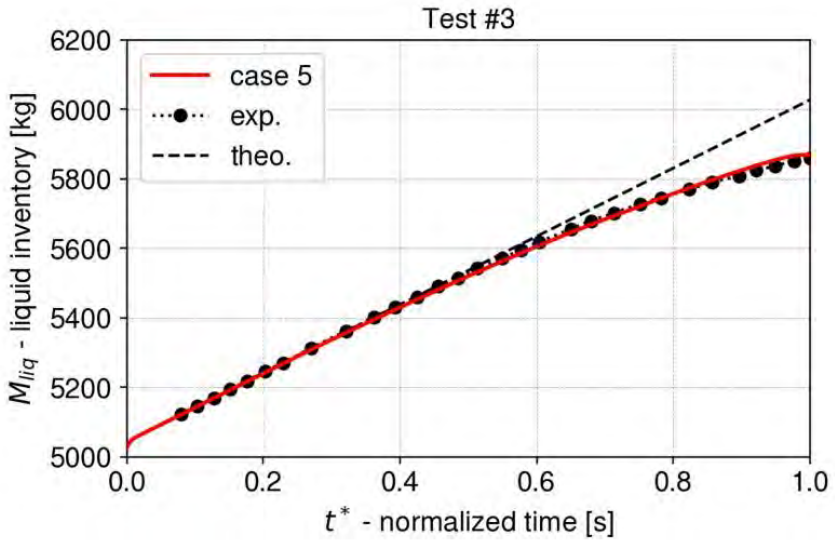
03. VALIDATION ON THE SUPERCLAUDIA EXPERIMENT

case 1 : default
case 2 : + improved 0D pool model
case 3 : case 2 + pipe/pool thermal coupling
case 4 : case 3 + corrected condensation
case 5 : case 4 with improved free surface heat transfer model

- End of the transient : deviation assumed to be due to evaporation at the free surface (long transient)
  - Strongly under-estimated in the calculation

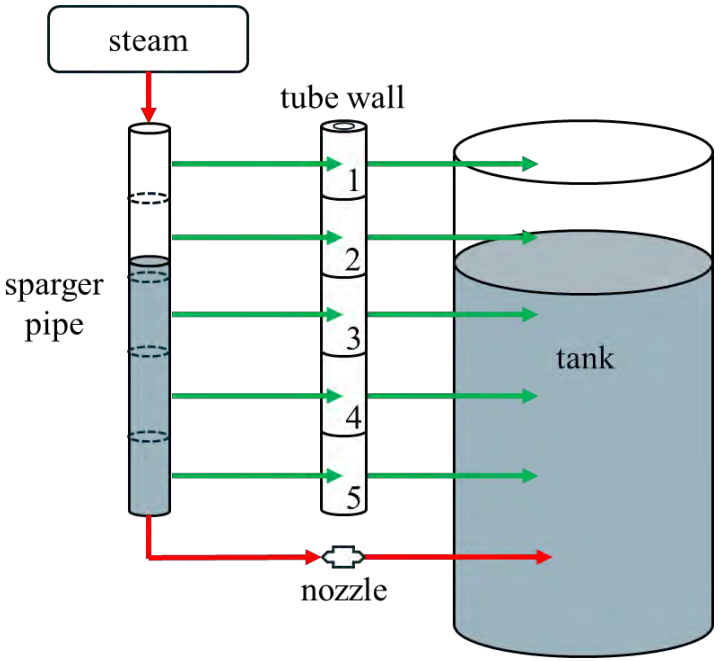


Recent development and improvement of the heat transfer model at the free surface have confirmed this hypothesis



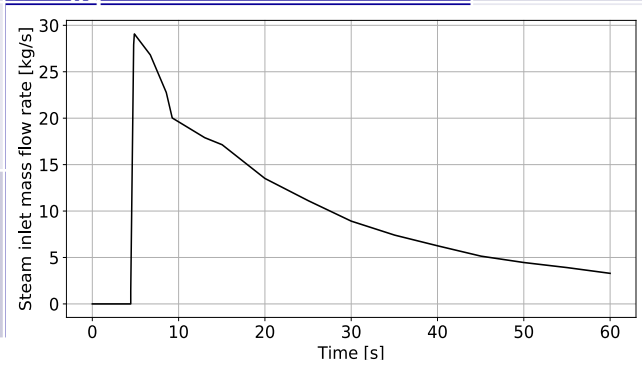
04. VALIDATION ON THE B&C EXPERIMENT

❑ Experiment from KAERI : closed tank with higher mass flow rate and smaller transient time [4]



[4] Kang and Song, *Nucl. Eng. Des.* (2008)

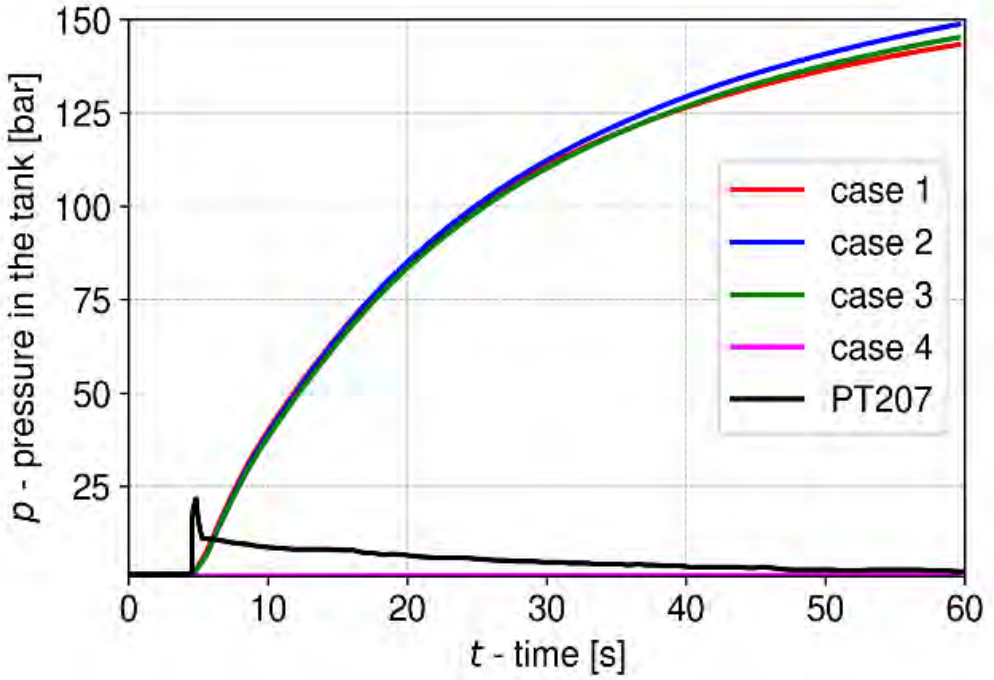
Parameter	Value	Initial conditions	Value
Tank inner diameter	3000 mm	**Tank pressure (p_{tank})**	1 bar
Tank height	4000 mm	**Pressurizer pressure**	150 bar
Tank free volume	28.22 m^3	**Tank temperature (T_{liq})**	25.60 °C
Sparger inner diameter	152.40 mm	**Water level**	3.02 m
Sparger length	3100 mm	**Liquid inventory (M_{liq})**	21244 kg
Sparger elevation from tank bottom	900 mm		
Nozzle flow area on the sparger head	5.52×10^{-3} m^2		

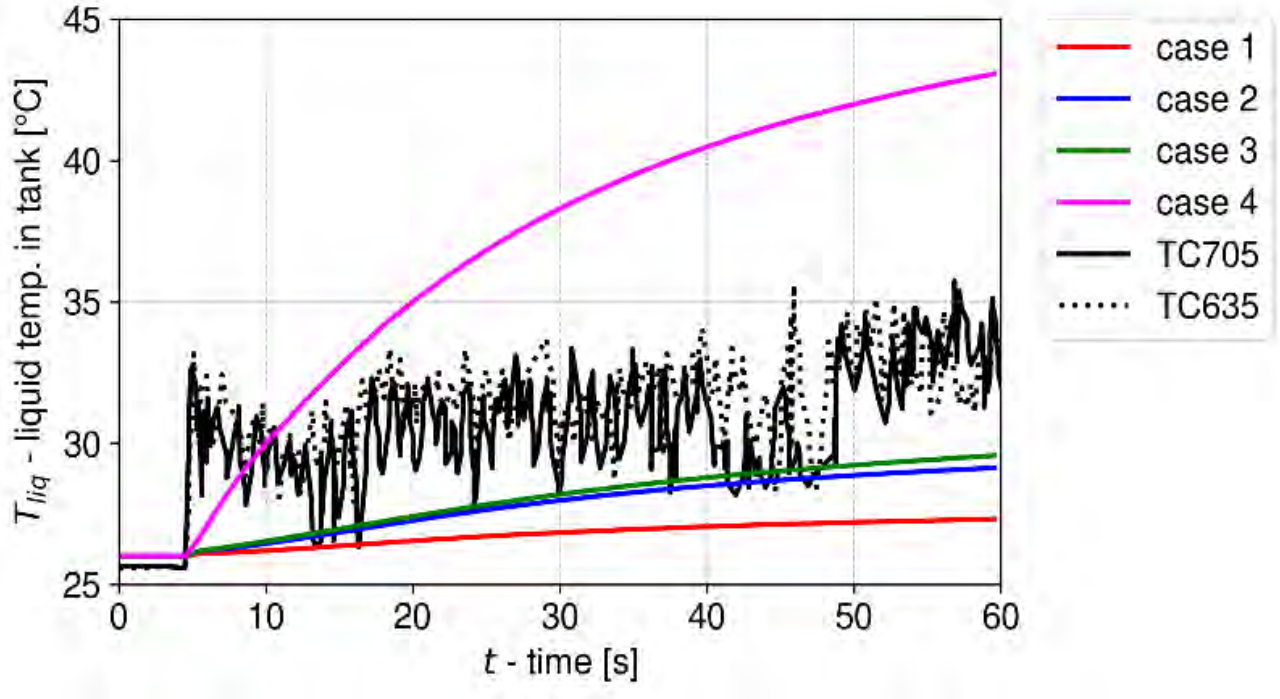


04. VALIDATION ON THE B&C EXPERIMENT

case 1 : default
case 2 : + improved 0D pool model
case 3 : case 2 + pipe/pool thermal coupling
case 4 : case 3 + corrected condensation

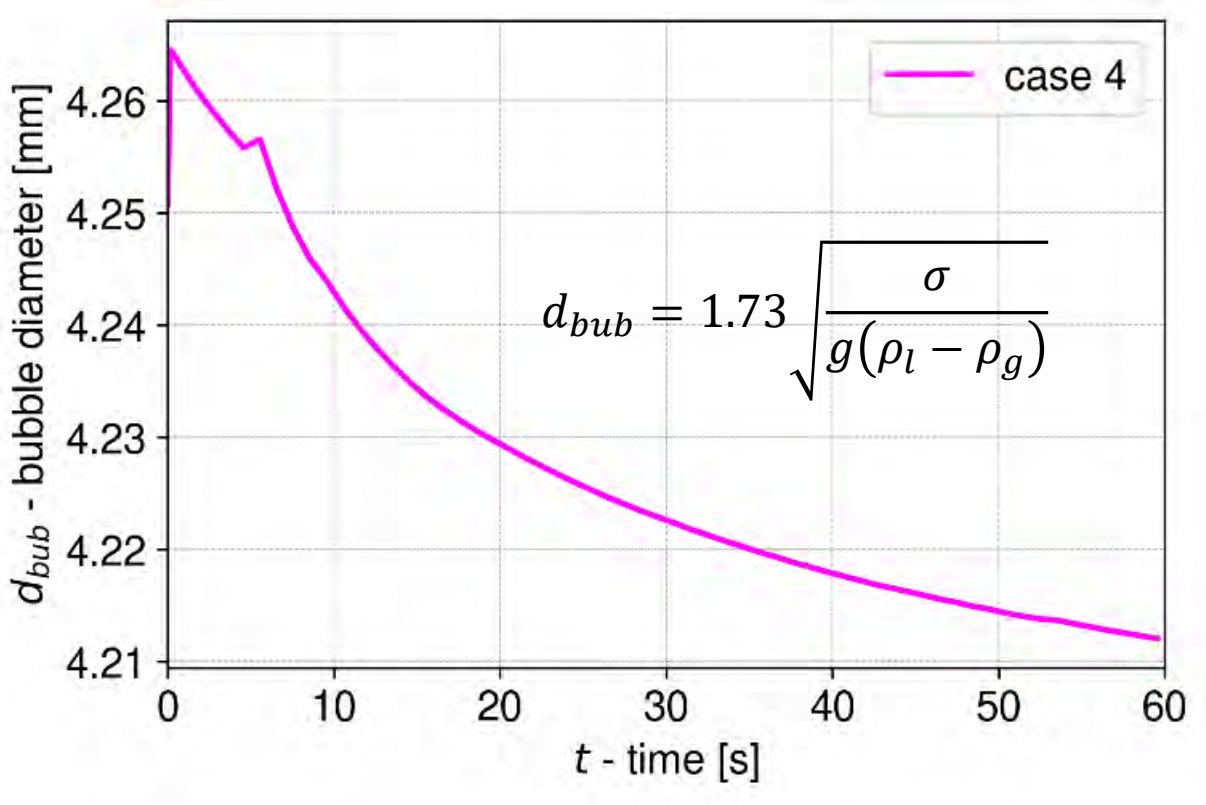
- Very high under-evaluation of the condensation with case 1-3
- Not much influence of the thermal coupling between the pipe and the pool → not much condensation in the pipe for this case
- Very high impact for case 4





04. VALIDATION ON THE B&C EXPERIMENT

❑ Case 4 : Bubbles size around mm ➔ Ai from ~1 m^{-1} in annular configuration to ~10^3 m^{-1}



❑ Improvements planned :

- ❑ At the transient beginning, a vapour jet is expected ➔ reduction of the interfacial area
- ❑ Introduction of a more complete flow map for jet and bubbly regime
- ❑ Nusselt correlation improvement

05. CONCLUSIONS AND PERSPECTIVES

- CESAR default model does under-estimate direct contact condensation in pool configuration
  - A correct evaluation of the diphasic flow configuration and corresponding interfacial area is necessary,
  - New pool specific CESAR option available in latest released version to properly assess the liquid to interface heat transfer in bubbly flow configuration,
  - Further improvements needed to complete the flow map, including jet regime.

- In some configurations, an important part of the condensation can occur in the injection pipe : thermal coupling between the pipe and the pool should be taken into account.

- For long transients at atmospheric conditions, evaporation at the pool free surface can play an important part and should be also correctly evaluated.

THANK YOU FOR YOUR ATTENTION

ABSTRACT

Steam explosions occur when molten corium comes into sudden contact with coolant during severe accidents. The resulting pressure waves can endanger containment integrity and must be assessed in accident analysis. The SAFARI project develops an integrated regulatory framework for such evaluations. It includes modules for Fuel-Coolant Interaction (FCI), Steam Explosion (SE), Molten Core-Concrete Interaction (MCCI), and Containment Thermal-Hydraulics. This paper presents the SE module.
The SE module adopts a lumped parameter model that solves mass and energy conservation equations. The thermodynamic state is determined from specific internal energy and volume, which are inverted through steam tables to obtain pressure and temperature. Near the critical point, steep nonlinear property gradients often cause instability and oscillations. To overcome this limitation, a ResNet-based deep learning surrogate was developed and integrated into the framework. It provides accurate and stable predictions of pressure and temperature in the critical region. This approach enables the code to maintain the efficiency of tabulated methods while ensuring robustness under challenging conditions.
The SE module receives initial conditions and transient mixing parameters from the FCI module to directly estimate peak pressure and impulse. Validation was performed against three benchmark steam explosion experiments: KROTOS K44, FARO L33, and TROI 13. These tests cover diverse conditions, including variations in melt composition, coolant subcooling, and geometry. The module reproduced key features such as peak pressure and impulse. This consistency across different scenarios demonstrates its robustness and versatility. Compared with mechanistic codes, it provides similar predictive accuracy with significantly lower computational cost. These results confirm that the SE module offers a reliable and efficient tool for regulatory safety evaluations. It also contributes to the establishment of an integrated severe accident analysis framework.

1. INTRODUCTION

1.1. Motivation

Severe accidents in power reactors can involve core melting and relocation, potentially leading to vessel failure. Under such conditions, fuel heat up and melting may lead to relocation of molten core materials and eventual vessel failure. When molten corium is released into a wet cavity during an accident progression in ex-vessel accident, it can interact violently with the coolant. This fuel-coolant interaction, commonly referred to as FCI, involves jet breakup, premixing, and debris formation, and it can create conditions under which a steam explosion may occur [1-3]. A steam explosion is a rapid energetic event driven by fine fragmentation of molten fuel, intense heat transfer, and explosive vapor generation. The associated pressure pulse and impulse can impose high dynamic loads on surrounding structures, and therefore steam explosions remain an important issue for containment integrity and severe accident management.

Reliable assessment of steam explosion loads is required for regulatory safety evaluations and for the quantitative comparison of accident management strategies such as ex-vessel cooling. However, the steam explosion process is strongly dependent on the premixing state at the time of triggering, including fuel temperature and inventory, fragment size distribution, coolant subcooling, void fraction, and the geometric configuration of the interaction region. These parameters evolve over time during the coolability transient, and the most challenging cases are often associated with short time intervals and rapidly changing thermohydraulic conditions. Fully mechanistic multiphase codes can represent many detailed phenomena, but their computational cost and input requirements make them difficult to apply repeatedly for large parametric studies or for integration into broader severe accident analysis frameworks. This motivates the development of efficient steam explosion analysis tools that can estimate pressure and impulse over a wide range of transient conditions while maintaining physically consistent modeling assumptions.

1.2. SAFARI Project

In South Korea, the SAFARI project was initiated to establish an integrated and regulatory-oriented severe accident analysis capability. SAFARI develops a modular framework that couples key ex-vessel severe accident phenomena, including fuel-coolant interaction, steam explosion, molten core-concrete interaction, and containment thermal-hydraulics, within a consistent set of modeling assumptions and data interfaces [4]. Within this effort, the steam explosion module has been developed to provide fast and robust predictions of explosion loads using a lumped parameter approach that can accept time-dependent premixing information from the FCI module named HIPPO. The primary motivation of this development is to support systematic verification against representative benchmark experiments and to enable practical regulatory evaluations of steam explosion loads under realistic accident progression scenarios within the SAFARI framework.

2. METHODOLOGY

2.1. Model Overview

The steam explosion module called SCORPION is built on a non-equilibrium model and a lumped parameter model. The objective is to capture the mass and energy conservation equations that control pressure load generation during the short explosion transient, while keeping the computation fast enough for repeated analyses. The overall formulation is inspired by the one-dimensional lumped modeling philosophy developed in the University of Wisconsin fuel-coolant interaction program (UWFCI) [5]. Instead of resolving detailed multiphase momentum fields, the model represents the system with a small number of control volumes and tracks the time evolution of the key material masses and energies.

The coolant region is divided into a mixing zone and a slug zone as shown in Figure 1. The mixing zone is where molten fuel, fine fragments, coolant, and vapor coexist and exchange mass and energy. Fine fragmentation and rapid vapor generation are treated in this zone, and the thermodynamic state of the vapor region is determined from the evolving vapor mass, energy, and volume. The slug zone represents the upper water column that is accelerated by the pressure rise. Direct fuel-coolant interaction is not assumed in the slug zone, but mass and energy exchange with the mixing zone can occur through coolant redistribution.

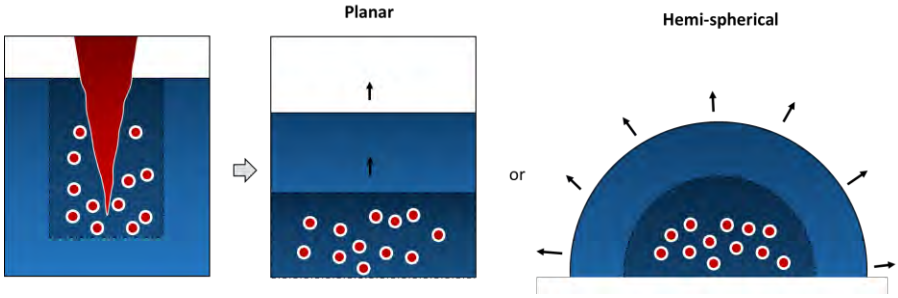

Figure 1. Conceptual illustration of mixing zone and slug zone [4].

The model tracks the masses and energies of molten fuel, fine fragments, coolant, vapor, and the slug, and it advances these quantities in time. Figure 2 provides a conceptual picture of the fragmentation process that motivates the source terms and heat transfer terms used in the conservation equations. As fragmentation proceeds, interfacial area increases and heat transfer intensifies, which accelerates vapor production and drives the pressure rise. The model is structured to reflect this causal chain in a compact form.

Time integration is performed by solving the coupled ODE system with the LSODA algorithm [7]. Pressure and temperature are obtained from the vapor specific internal energy and specific volume computed from the conserved vapor mass, energy, and volume. Momentum equations are not solved explicitly. Slug motion and the effective fragmentation process are represented using simplified kinematic relations and constraint concepts such as slug breach and acoustic limits. With this formulation, SCORPION aims to reproduce the key energetics that control pressure and impulse while maintaining computational efficiency.

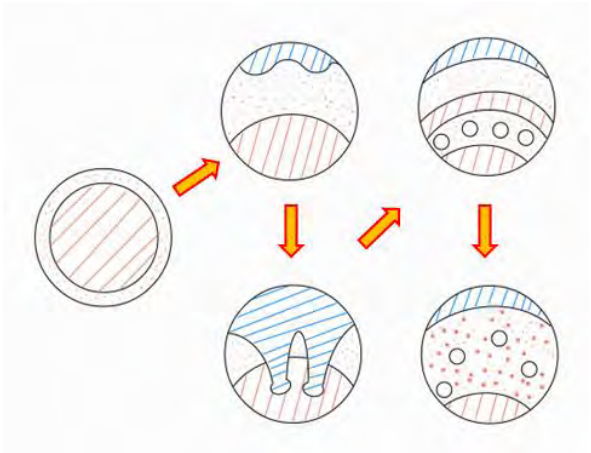

Figure 2. Conceptual illustration of fine fragmentation [6].

2.2. Governing Equations

The governing equations are written as coupled ordinary differential equations for mass and energy in the mixing and slug regions. In Eq. (1)-(10), subscripts f, fr, c, g, and s denote the molten fuel, fragmented fuel, coolant, vapor (gas), and slug-region respectively. Interfacial heat-transfer terms are written as $\dot{Q}_{lj}$, where the first subscript identifies the donor and the second the receiver. The mass conservation equations are written in Eq. (1)-(5). The mass balances represent the main conversion and exchange mechanisms. Molten fuel is converted into fine fragments by a fine fragmentation source term. Coolant is converted into vapor by rapid vaporization driven by heat transfer from the fuel and fragments. In addition, coolant can be exchanged between the mixing zone and the slug zone as the pressure driven motion redistributes coolant inventory during the transient.

$$\frac{dm_f}{dt} = -\dot{m}_{fr} \tag{1}$$

$$\frac{dm_{fr}}{dt} = \dot{m}_{fr} \tag{2}$$

$$\frac{dm_c}{dt} = -\dot{m}_g + \dot{m}_s \tag{3}$$

$$\frac{dm_g}{dt} = \dot{m}_g \tag{4}$$

$$\frac{dm_s}{dt} = -\dot{m}_s \tag{5}$$

$$\frac{dE_f}{dt} = -\dot{Q}_{fg} + \dot{m}_{fr} V_f P - \dot{m}_{fr} h_{fn} \tag{6}$$

$$\frac{dE_{fr}}{dt} = -\dot{Q}_{frg} - \dot{m}_{fr} V_f P + \dot{m}_{fr} h_{fn} \tag{7}$$

$$\frac{dE_c}{dt} = \dot{Q}_{fc} + \dot{Q}_{frc} - \dot{m}_g c_{pc}\left(T_c - T_{ref}\right) + P\dot{V}_c + \dot{m}_s c_{pc}(T_s - T_{ref}) \tag{8}$$

$$\frac{dE_g}{dt} = \dot{Q}_{fg} + \dot{Q}_{frg} - \dot{Q}_{fgc} - \dot{Q}_{frgc} + \dot{m}_g(h_{fg} + c_{pc}\left(T_c - T_{ref}\right)) - P\dot{V}_g \tag{9}$$

$$\frac{dE_s}{dt} = -\dot{m}_s c_{pc}\left(T_s - T_{ref}\right) + P\dot{V}_s \tag{10}$$

The energy conservation equations are given in Eq. (6)-(10). Heat transfer from molten fuel and fine fragments supplies energy to the coolant and vapor, while phase change introduces enthalpy transport associated with vapor generation. The expansion of the vapor region performs pressure volume work, which is included to represent the driving mechanism of the pressure pulse. These terms determine how quickly thermal energy is converted into vapor energy and how the resulting expansion produces the pressure load.

The vapor state is evaluated using variables that are naturally available in the lumped formulation. The model updates vapor mass, vapor energy, and vapor volume in time. From these conserved quantities, the vapor specific internal energy and specific volume are obtained and used to determine pressure and

temperature. This structure keeps the property evaluation consistent with the conservation equations and allows stable tracking of the thermodynamic state even when the highly energetic transients.

Overall, the conservation set provides a clear link from fragmentation and heat transfer to vapor generation and pressure loading. The equation structure is compact enough for parametric studies, yet it retains the key energetic couplings needed to predict peak pressure and impulse. This balance between physical consistency and computational simplicity is the basis for using the module in verification studies and broader severe accident analyses.

2.3. Fine Fragmentation Model

Fine fragmentation is a central process in steam explosions because it controls how much melt participates in rapid heat transfer. When coarse melt droplets or jets are broken into small particles, the total interfacial area between fuel and coolant increases sharply. This accelerates heat transfer, promotes rapid vapor generation, and amplifies the pressure load. If fragmentation is weak or ends quickly, only a limited fraction of the melt contributes to vapor production during the effective time interval, and the resulting peak pressure and impulse are reduced.

Fragmentation is commonly interpreted from two perspectives. In the hydrodynamic perspective, breakup is driven by external mechanical loading such as shock waves, strong shear, and large relative motion between phases. The breakup rate is often described using slip velocity and dimensionless groups that reflect the balance between inertia and stabilizing effects such as surface tension. In the thermal perspective, breakup is driven by thermally induced instabilities at the interfaces between melt, vapor film, and coolant. Collapse of the vapor film, local coolant penetration, and rapid rewetting can strip melt from the surface and generate fine fragments even without strong bulk acceleration.

SCORPION is implemented to allow different fragmentation options so that different assumptions can be tested under the same governing equation structure. Hydrodynamic and thermal viewpoints are both supported through alternative rate models that define the conversion of molten fuel mass into fine fragment mass. This design is useful for sensitivity studies and for comparisons against other steam explosion codes that emphasize different breakup mechanisms.

$$\frac{dm_{fr}}{dt} = 6C_{fr}m_f\sqrt{\frac{\Delta P_{fr}}{\rho_c {R_f}^2}}f(\alpha)g(\tau_{fr}) \tag{11}$$

The Tang model in the TEXAS is adopted as the default option, and the corresponding fine fragmentation rate is expressed by Eq. (11). The cutoff functions $f(\alpha)$ and $g(\tau_{fr})$ are introduced to terminate fragmentation at large void fractions and after the prescribed fragmentation time scale. The model provides a compact rate expression for the conversion of molten fuel to fine fragments and includes termination criteria that limit fragmentation when conditions become unfavorable. The fragmentation rate computed by this model directly supplies the mass source term in the governing equations, and it therefore controls the effective intensity of vapor generation and pressure loading within the lumped parameter framework.

2.4. ResNet-Based Model for Thermodynamic Property Prediction Near the Critical Point

Accurate evaluation of thermodynamic properties from specific internal energy and specific volume is essential for predicting steam explosion loads. In the original implementation, pressure and temperature were obtained by inverting the IAPWS steam tables using the vapor energy, mass, and volume from the governing equations [8]. This approach is efficient in most regions, but it becomes numerically sensitive

near the critical point, where small perturbations in state variables produce large nonlinear changes in pressure and temperature. As a result, the inversion may require very small time steps and can introduce oscillatory or nonphysical behavior, particularly when the state approaches the edge of the tabulated domain.

To overcome these limitations, a residual neural network (ResNet) surrogate was developed and integrated into SCORPION [4]. Figure 3 summarizes the architecture, which maps specific volume and specific internal energy to pressure and temperature through input normalization, a fully connected layer, and stacked residual blocks. The surrogate was trained on high resolution IAPWS-IF97 data with dense sampling in the near critical region, with normalized variables and removal of nonphysical states [8].

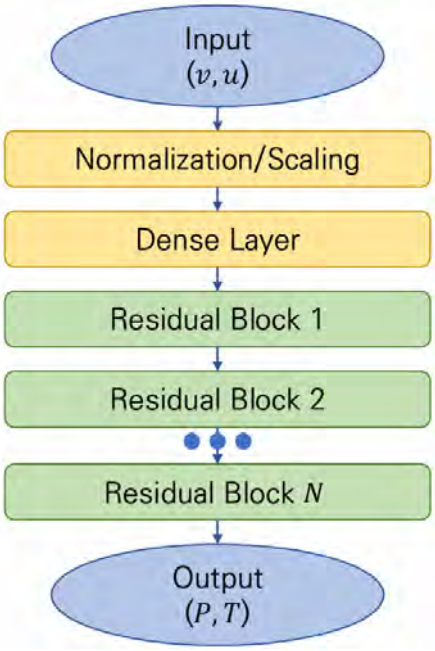

Figure 3. Network structure of the ResNet-based surrogate mapping specific volume and internal energy to pressure and temperature.

Early tests with a multilayer perceptron showed degraded accuracy in the near critical region due to steep gradients. A ResNet architecture was therefore adopted to improve both accuracy and training robustness. The network consists of an input normalization followed by multiple residual blocks with nonlinear activations and skip connections that add the block input to the block output. This residual formulation helps the network learn incremental corrections and improves convergence in deep models.

The loss function is designed to balance absolute and relative accuracy across the entire training domain. It combines mean squared error, mean absolute error, and relative error terms, with tunable weights assigned to each component. Because accurate prediction at high pressure is particularly important for severe accident analysis, an additional weighting factor is applied to samples with pressures above a specified threshold, increasing the penalty for errors in this region. The learning rate is controlled using a scheduler that reduces the rate when the validation loss stagnates, allowing coarse exploration in early epochs and fine adjustment near convergence.

Once trained, the ResNet model is incorporated into the steam explosion module through a hybrid property evaluation strategy. For states well away from the critical region, pressure and temperature are obtained from standard IAPWS steam table interpolation to retain efficiency and consistency with established data.

In the near critical region, the module evaluates pressure and temperature using the ResNet surrogate based on the current specific volume and internal energy. A smooth blending procedure is applied across the interface of the two methods to prevent abrupt changes in predicted properties. In addition, basic thermodynamic consistency checks are applied to the surrogate outputs, and table-based values are used as a safeguard when the predicted state is outside the physically admissible range.

This hybrid strategy improves numerical robustness near the critical point while preserving computational efficiency. Standalone tests confirm that the surrogate reproduces IAPWS steam table values in the near critical range with small errors. When integrated into the steam explosion calculations, the hybrid evaluation yields smoother pressure transients and more stable time integration, especially for cases with rapid energy release and high energetic cases. Overall, the combined use of conventional tables and a ResNet surrogate provides reliable property prediction in challenging near critical conditions without increasing the cost of large parametric studies.

2.5. Coupling with the FCI Module

In the SAFARI framework, the SCORPION module is coupled to the HIPPO module. HIPPO module simulates ex-vessel melt jet breakup, premixing, and debris formation in a flooded cavity, and it provides the thermohydraulic conditions that define the initial state for a potential steam explosion. This coupling enables the sequence from melt release to premixing and the subsequent explosion phase to be evaluated using consistent geometry and property assumptions.

The coupling is implemented as a one-way interface from the HIPPO module to the SCORPION module. The FCI calculation is performed first, and key premixing quantities are recorded as time-dependent outputs. These include the interacting melt mass, coolant inventory and subcooling in the mixing region, void fraction, characteristic fragment size, pool depth, and slug mass and cross-sectional area. The outputs are stored at selected times in a tabular file and used to define the initial conditions for SE calculation.

To maintain consistency between the two modules, the transferred variables are defined with clear physical meaning. Only the melt fraction that remains liquid and is in direct contact with coolant is transferred as the participating fuel, while solidified material and debris bed inventory are excluded. The mixing and slug control volumes are constructed from the pool depth and slug geometry provided by the HIPPO module so that coolant volumes and inventories remain consistent. Fragment size and void fraction are passed to the fine fragmentation and heat transfer models, and background pressure and ambient conditions are applied as boundary conditions.

This coupling strategy improves consistency and usability compared with workflows that rely on external premixing tools and manual input processing. Using premixing results directly from the HIPPO module preserves the causal link between the premixing state and explosion energetics and avoids inconsistencies caused by mismatched assumptions. The one-way interface also reduces computational cost, because the premixing calculation is performed once and its time-dependent outputs are used to define the initial and boundary conditions for the SCORPION calculation. As a result, the coupled HIPPO-SCORPION capability provides a practical and reliable basis for estimating ex-vessel steam explosion pressure and impulse.

3. RESULTS

3.1. Verification Experiments: KROTOS K44, FARO L33, TROI 13

Three OECD SERENA experiments were selected: KROTOS K44, FARO L33, and TROI 13 [1-3]. These benchmarks represent the main conditions controlling pressure and impulse generation, including melt

composition, melt inventory, melt temperature, coolant subcooling, system pressure, facility geometry, and the triggering mechanism.

KROTOS K44 provides tightly controlled initial conditions and a comparatively simple geometry, which is useful for examining how the explosion phase models reproduce peak pressure and impulse under well-defined boundary conditions [2]. FARO L33 is conducted with a prototypic corium composition under pressurized conditions and high coolant subcooling [10]. The test includes an external trigger and non-condensable gas in the cover region, which challenges the prediction of pressure rise and impulse in a deep pool. TROI 13 also employs prototypic corium, but it is characterized by a much larger melt release height and a spontaneous explosion without an external trigger [11]. This case supports an assessment of model performance under different premixing development and triggering conditions. Overall, the three benchmarks confirm the applicability of the module across a wide range of steam explosion scenarios within a unified framework.

3.2. Initial Conditions of Simulation

Table I lists the initial and boundary conditions adopted for the simulations of KROTOS K44, FARO L33, and TROI 13 [2, 10-12]. The calculations were defined to be consistent with the reported melt composition, released mass, jet diameter, system pressure, coolant subcooling, and geometric scale of each facility. For FARO L33, the released mass is reported together with the melt mass at the triggering time, and this information is used to define a representative participating inventory for the explosion phase. Using a consistent set of initial and boundary conditions enables a direct comparison of predicted peak pressure and impulse across experiments with different scales and operating conditions.

Table I. Initial and boundary conditions of experiments: KROTOS K44, FARO L33, TROI 13

Experiment	KROTOS K44	FARO L33	TROI 13
Melt Composition	Al_2O_3	80 $wt\%$ UO_2 + 20 $wt\%$ ZrO_2	70 $wt\%$ UO_2 + 30 $wt\%$ ZrO_2
Released Mass [kg]	1.45	100/25 [1)]	7.7
Release Diameter [m]	0.03	0.05	0.02

Water Temperature [K]	363	294	292
Water Subcooling [K]	10	124	81
Pressure [MPa]	0.1	0.41	0.1
External Trigger	Yes	Yes	No

1) For FARO L33, "100/25" denotes the released melt mass and the melt mass at the triggering time, respectively.

3.3. SCORPION Simulation Results

Table II and Figures 4 to 6 summarize the SCORPION predictions for the three benchmark experiments. Rather than focusing only on peak values, the results are interpreted in the context of the defining experimental characteristics outlined in Section 3.1, including melt composition, thermohydraulic boundary conditions, facility geometry, and the triggering condition. This approach allows the verification to assess

whether the module reproduces not only the magnitude of the loads but also the expected trends and response characteristics across substantially different experimental regimes.

Table II. SCORPION analysis results for the experiments: KROTOS K44, FARO L33, TROI 13

Experiment	KROTOS K44	FARO L33	TROI 13
Peak Pressure [MPa]	27.94	9.50	6.53
Peak Impulse [kPa·s]	53.64	25.94	29.77

KROTOS K44 yields the highest predicted peak pressure and impulse among the three cases, with a peak pressure of 27.94 MPa and a peak impulse of 53.64 kPa·s. This result is consistent with the KROTOS K44 configuration, which employs a simulant alumina melt, operates under a relatively low system pressure environment, and uses a well-defined external triggering procedure in a simplified planar geometry. Under such conditions, the explosion energetics are dominated by rapid fine fragmentation and intense vapor generation within a short time interval. As a result, the pressure response rises sharply to a pronounced peak and accumulates a large impulse. The ability of SCORPION to reproduce this distinctly energetic behavior supports that the governing conservation equations and the fine fragmentation model can represent highly explosive scenarios without requiring detailed multiphase momentum resolution.

FARO L33 shows a moderated load response compared to KROTOS K44, with a predicted peak pressure of 9.50 MPa and a peak impulse of 25.94 kPa·s. FARO L33 differs from KROTOS K44 in several major aspects that directly affect steam explosion. The experiment is conducted at elevated system pressure, involves a deep pool, and uses a prototypic corium composition. Although the total released melt mass is large, the melt inventory at the triggering time can be reduced due to premixing development and solidification processes, resulting in a less concentrated energy release than in the KROTOS case. These conditions lead to a lower peak pressure and impulse. The SCORPION results follow this expected tendency by predicting a significantly reduced peak pressure relative to KROTOS K44, while still yielding a clearly developed impulse response.

TROI 13 produces the lowest peak pressure among the three cases, 6.53 MPa, while yielding a relatively large peak impulse of 29.77 kPa·s. This combination reflects the distinctive features of the TROI benchmark, which is performed with prototypic corium without an external trigger and with a larger free fall height and facility scale than the other two experiments. These factors influence premixing development and the spatial distribution of the interacting melt and coolant, often resulting in a less abrupt but more sustained pressure evolution. In such cases, the peak pressure can remain moderate while the impulse grows due to the extended duration of overpressure. The SCORPION prediction captures this qualitative behavior by producing the lower peak pressure among the three cases, while accumulating an impulse. This is an important verification point, as it indicates that the model can represent cases where the impulse is driven primarily by load duration rather than by a single extreme peak.

SCORPION shows consistent performance across the three benchmarks by reproducing distinct pressure and impulse responses that reflect the underlying differences in experimental conditions. The KROTOS K44 case exhibits a strongly energetic response representative of a low-pressure, triggered configuration with an alumina simulant melt. FARO L33 yields a more moderated load level under pressurized, deep-pool conditions with a prototypic corium melt and a limited participating inventory at the trigger. TROI 13 produces a lower peak pressure but a comparatively large impulse, consistent with its large-scale geometry, long free-fall release, and spontaneous initiation. Taken together, the results demonstrate that SCORPION can capture the relative severity and characteristic load behavior over a wide range of melt compositions,

facility scales, pressures, and triggering conditions, supporting its versatility as a steam explosion analysis tool.

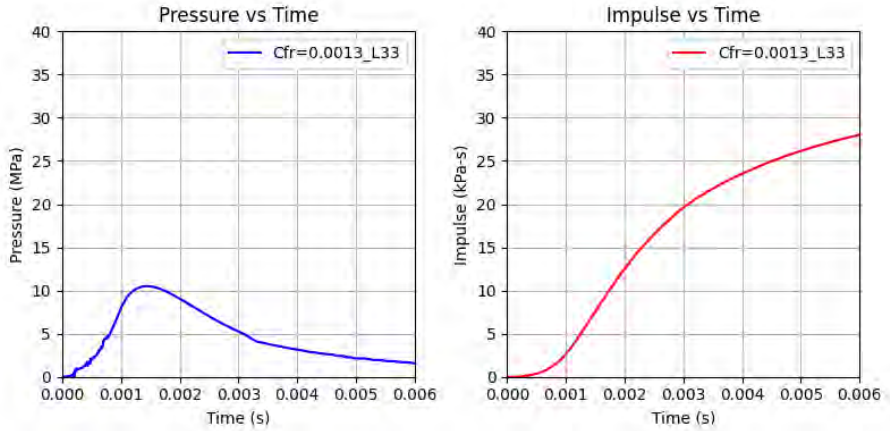

Figure 5. SCORPION simulation results for FARO L33: pressure and impulse.

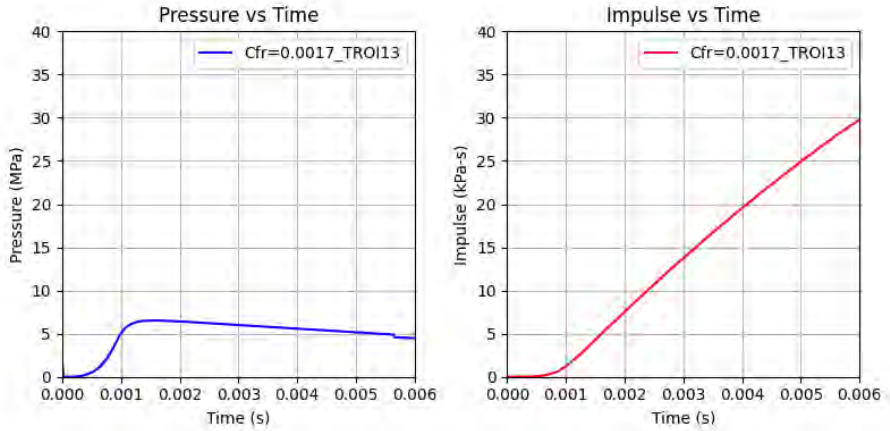

Figure 6. SCORPION simulation results for TROI 13: pressure and impulse.

3.4. Discussion on the Fragmentation Constant C_{fr}

In SCORPION, the fine fragmentation process is modeled using a lumped rate expression in which the fragmentation constant C_{fr} determines how rapidly the melt inventory is converted into fine fragments during the fragmentation time. Because fine fragmentation controls the interfacial area for heat transfer and rapid vapor generation, C_{fr} becomes a major parameter linking the premixing state to the intensity of the explosion phase. In a lumped parameter framework, C_{fr} should be interpreted as an effective parameter rather than a directly measurable material property. It represents the integrated outcome of unresolved mechanisms, including fragmentation initiation efficiency, the effective rate of droplet size reduction, and the coupling between evolving void conditions and heat transfer in the mixing region.

The case dependent C_{fr} values estimated in this study reflect that each benchmark experiment combines different melt compositions, hydrodynamic environments, and triggering conditions, which influence the effective fragmentation intensity. KROTOS K44 shows a highly energetic response under low pressure, externally triggered condition with an alumina simulant melt, while FARO L33 and TROI 13 employ prototypic corium under different system pressures and facility scales. As a result, the same fragmentation model can require different effective C_{fr} values to reproduce the observed pressure and impulse response, because the unresolved mechanisms controlling fragmentation and rapid vaporization are activated differently across experiments. C_{fr} provides a practical way to parameterize effective fragmentation rate within a consistent modeling structure, enabling systematic comparisons while preserving computational efficiency.

Although C_{fr} is empirical in nature, it does not vary arbitrarily in the present verification. The results indicate that SCORPION produces stable and physically consistent predictions within a limited band of C_{fr} values. Within this band, the pressure rise behavior and impulse accumulation trends remain qualitatively realistic, supporting the use of C_{fr} as a bounded calibration parameter for verification and sensitivity studies. Once a representative C_{fr} range is identified for a given class of experiments or accident scenarios, SCORPION can be applied efficiently to assess uncertainties and to estimate conservative envelopes of peak pressure and impulse for regulatory assessments.

4. CONCLUSIONS

In this study, the SCORPION steam explosion module within the SAFARI framework was verified using three OECD SERENA benchmark experiments, KROTOS K44, FARO L33, and TROI 13, which cover main operating conditions relevant to ex-vessel fuel-coolant interaction events. SCORPION employs a lumped parameter formulation that solves mass and energy conservation with a modular fine fragmentation treatment. It is designed to interface with the HIPPO module through a one-way coupling scheme so that time-dependent premixing information can be used as consistent initial conditions for the explosion phase. To improve numerical robustness near the thermodynamic critical point, a ResNet-based surrogate was integrated into a hybrid property evaluation scheme with the IAPWS steam tables. These initial verification results indicate that SCORPION reproduces the main pressure load characteristics of the selected experiments, including peak pressure levels, impulse trends, and transient pressure rise behavior, with consistent performance across different melt compositions, facility scales, system pressures, and triggering conditions.

Overall, the agreement obtained for the selected benchmarks suggests that SCORPION provides a computationally efficient tool for estimating steam explosion loads within an integrated severe accident analysis. The one-way coupling concept enables systematic assessments over varying premixing states without changing the core modeling structure, which is beneficial for applications requiring repeated calculations. The present results support the use of SCORPION within SAFARI for sensitivity studies and

for load estimation under representative accident progression scenarios, while additional coupled validation and code-to-code comparisons are planned to broaden the validation and benchmarking scope.

NOMENCLATURE

P : Pressure
T : Temperature
V : Volume
α : Void fraction
R_f : Radius of fuel

ABSTRACT

During the ex-vessel phase of a severe accident in a nuclear power plant, containment integrity might be jeopardized by three main mechanisms: concrete erosion (epsilon mode), over-pressurization (delta mode), combustible gas detonation (gamma mode). All of them are tightly related to molten core-concrete interaction. This study investigates the impact of uncertainties in corium properties on key variables describing the containment scenario (i.e., pressure, gas composition, and radial and axial ablation) during a station blackout accident in a 1000 MWe pressurized water reactor. The properties analyzed are viscosity, conductivity, specific heat, density and emissivity. A stand-alone containment Best Estimate Plus Uncertainty analysis has been conducted using the MELCOR v.2.2 2025.0 code and in-house Python scripts for sampling, propagation and results processing. The Order Statistics (95/95) was used and uniform probability density functions adopted for each property. The initial and boundary conditions were taken from a MELCOR full-scope plant analysis. Under the assumption of instantaneous melt-spreading within the cavity, the results indicate a small/moderate effect of corium properties uncertainties on concrete erosion and combustion risk. Containment pressure, though, shows an observable influence, which uncertainty band ranged from -17% to +33% with respect to the best estimate value. A complementary sensitivity analysis highlighted the specific heat uncertainties as the main driver of the band scatter noted in containment pressure.

1. INTRODUCTION

Severe Accidents (SA) are low-probability, high-consequence events in which the failure of multiple safety systems can lead to the loss of core cooling and, in the most critical scenarios, to the partial or complete meltdown of the reactor core. In such conditions, molten core material (corium) may relocate to the Lower Head (LH) of the Reactor Pressure Vessel (RPV), threatening its integrity by thermal creep. In case of LH failure, the corium slumps into the cavity beneath the RPV, and it comes into contact with the pedestal and basemat concrete, leading to a Molten Core-Concrete Interaction (MCCI). As a consequence of MCCI, three major threats can jeopardize containment integrity: concrete erosion (epsilon mode); over-pressurization

(delta mode); combustible gas detonations (gamma mode) [1]. Therefore, a reliable assessment of the ex-vessel phase of a SA is of utmost relevance in nuclear safety.

To analyze these complex SAs-related scenarios, integral codes, such as MELCOR ([2], [3]) are widely used. Nevertheless, the reliability of these simulations is strongly affected by uncertainties, which may originate from physical modelling assumptions, numerical approximations, and lack of precise knowledge of boundary conditions. In this framework, the Uncertainty and Sensitivity Analysis (UaSA) approach has emerged as a fundamental instrument, as it allows combining Best Estimate (BE) simulations with a systematic quantification of uncertainties, thus providing a more comprehensive and robust basis for safety assessments [4].

The uncertainties of the corium properties reaching the pedestal in case of RPV failure, heavily associated with the materials mixture and the harsh prevailing conditions, might be substantial and affect accuracy of containment characterization during the ex-vessel phase of a SA.

The relevance of the ex-vessel phase of a SA became evident during the Fukushima Daiichi accidents and discrepancies between the forensic analysis and the in-situ observations, particularly in Unit 1, emphasized the need for better understanding ([5], [6]). International projects like ROSAU [7] (Reduction of Severe Accident Uncertainties, 2019-2024) and COPS [8] (Corium Properties for reactor Simulation and uncertainties) intended to fill existing gaps. Interestingly, the latter investigates the influence of thermo-physical properties of corium melts on SA modelling and on the analyses of corium melt stabilization strategies in a reactor.

This paper presents the major results obtained in the investigation of the influence of uncertainties in corium properties uncertainties on containment integrity in a 1000 MWe Pressurized Water Reactor (PWR) Station Blackout (SBO). Corium viscosity, conductivity, specific heat, density and emissivity have been studied, and their effect on key safety-relevant target variables (hereafter, Figures Of Merit, FOMs), including containment pressure, concrete ablation and gas flammability, have been quantitatively determined. The uncertainty and sensitivity evaluation is performed using the MELCOR v.2.2 2025.0 code in combination with in-house Python scripts for sampling, input decks creation and post-processing.

2. SCENARIO MODELLING

2.1. Containment Model

A stand-alone PWR containment model is adopted. This modelling approach is easier to handle and significantly reduces computational time, as the simulation is initiated right from the beginning of the ex-vessel phase. In this setup, corium spreading is assumed instantaneously spread over the cavity basemat at the onset of the calculation. The corium mass and energy are defined as initial conditions in the containment input deck. This approach allows excluding the complex in-vessel phenomena, which would burden the computational cost, and allowing a direct focus on the purpose of the study. The initial and boundary conditions resulting from these phenomena are imported from the corresponding full-plant MELCOR model [9]. The containment model is schematically represented in Figure 1 [10]. It consists of 11 Control Volumes (CVs), with a total volume of 61,300 m³, of which the dome CV accounts for the 76%. Further details can be found in [10].

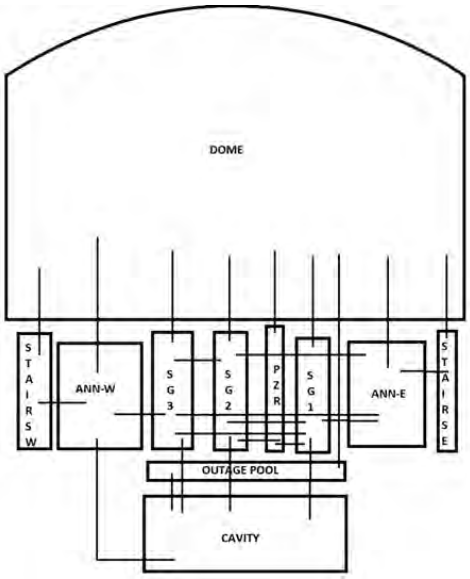

Figure 1. PWR Containment model.

2.2. Cavity Model

The cavity (CAV) package [2], derived from the CORCON Mod3 code [11], is used to set initial conditions of the corium pool and to define the cavity geometry. A 135 tons corium pool consisting of initially 78 % of oxides and 22 % of metals lay down in the cavity at the start of the simulation at 26,400 seconds (7.3 hours). Corium is treated as a single layer, according to the recommendations made by the MELCOR developers. The dimensions of pedestal walls and basemat correspond to the design parameters of a 1000 MWe Westinghouse PWR. The basemat concrete is a limestone aggregate-common sand mixture (Table I).

Table I. Limestone aggregate-common sand concrete composition in mass fraction.

SiO_2	35.80
TiO_2	0.18
MnO	0.03
MgO	0.48
CaO	31.30
Na_2O	0.082
K_2O	1.22
Fe_2O_3	1.44
Al_2O_3	3.60
Cr_2O_3	0.014
CO_2	21.15
H_2O chem	2.00
H_2O evap	2.70

The cavity is modeled as a flat-bottom cylinder. Its geometry is discretized in a set of fewer than 100 body points distributed along rays emanating from an origin located on the cavity axis. The number and position of these points were determined in accordance with the guidelines provided in the MELCOR and CORCON manuals and subsequently refined through a dedicated sensitivity analysis. The center of the reference coordinate system (R0, Z0) was defined in the middle of the eroded cavity to ensure a consistent description of the ablation profile.

Initial cavity geometry, number and position of body points are reported in Figure 2 and Table II.

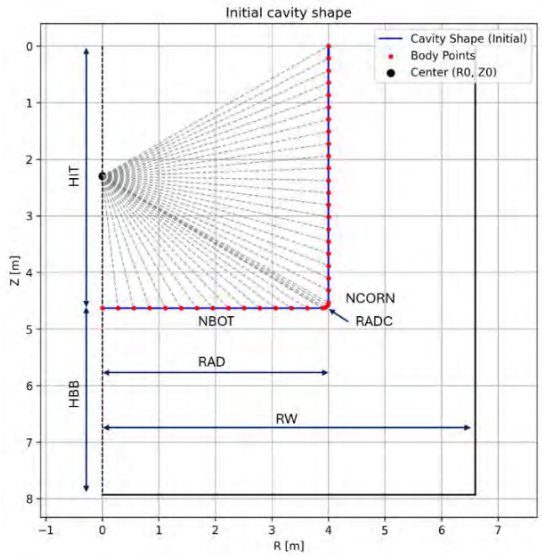

Figure 2. Cavity with body points and rays.

Total number of body points	40

RADC	0.1 m
HBB	3.3 m
RAD	4 m
HIT	4.6 m
RW	6.6 m

Table II. Cavity geometry and body points.

3. CORIUM PROPERTIES

The corium pool consists of a mixture of oxides and metals, mainly including UO_2, ZrO_2, FeO, Fe_2O_3, SiO_2, Al_2O_3, Zr, Fe, Cr, and Ni. Its mass and composition evolve during MCCI as a consequence of concrete ablation and chemical oxidation of metallic phases. The thermophysical properties of corium are therefore dependent on several factors, such as composition, temperature, time, corium configuration and the averaging method used to derive the overall properties from those of the individual components.

To define a consistent range for each property, the following hypotheses were introduced:

- Two representative compositions considered, a fully oxidic mixture (100% oxides) and a partially metallic mixture (containing 12% metals) ([12], [13]);
- Three characteristic temperatures considered to evaluate properties (1,700 K, 2,250 K, 2,800 K), which cover the temperature range expected during an SBO;
- No major changes in MCCI composition are assumed, which means the same corium composition is considered at the three reference temperatures;
- Corium is homogeneous. This simplification is particularly relevant for properties, such as thermal conductivity, which are strongly influenced by the configuration of the melt;
- Properties averaging was performed by applying mole fraction, mass fraction or molar volume averaging consistently with the CORCON formulation.

Table III shows the ranges found for each property.

Table III. Corium properties range.

	Averaging method	Unit of measurement	Lower bound	Upper bound
μ	Mole fraction	$kg/m \cdot s$	0.1	10

k	Mole fraction	$W/_{m \cdot K}$	1	12
$\mathbf{c_p}$	Mass fraction	$J/_{kg \cdot K}$	500	1,300
$\boldsymbol{\rho}$	Molar volume	$kg/_{m^3}$	2,800	8,000
$\boldsymbol{\varepsilon}$	Molar volume	-	0.5	1

4. UaSA METHODOLOGY

The primary objective of UaSA is to quantify the effect of input uncertainties on model outputs, and to identify the parameters that most strongly influence the system's behavior.

In this study, the uncertainty evaluation is performed using a random sampling strategy, where uncertain input parameters are sampled according to a uniform Probability Distribution Function (PDF) [14]. This assumption ensures that all values within the specified range are equally likely, given the lack of knowledge about the true PDFs of the input parameters. The uncertainty parameters are the five corium properties reported in the previous section: viscosity, conductivity, specific heat, density and emissivity. MELCOR is not enabled to change directly corium properties (except for emissivity, for which the user can set a value that remains constant throughout the simulation). However, through *ad-hoc* multipliers (M) the user can modulate property ranges as desired. In this study, Ms have been set to fit the ranges presented in Table III.

To characterize the uncertainty in the simulation outcomes, multiple code runs are required. In each run, all uncertain parameters are varied simultaneously. The minimum number of required simulations depends on the probability content and confidence level associated with the statistical tolerance limits adopted for Uncertainty Quantification (UQ). For this purpose, the Wilks non-parametric method is applied [15]. According to the Wilks' formula for a two-sided tolerance interval, at least 93 independent simulations are necessary to estimate the 95th percentile of the output distribution with a 95% confidence level. Strictly speaking, given that in the study multiple FOMs are targeted, the Wald extension [16] should be used, which yields a minimum requirement of 260 runs. Nevertheless, some scoping calculations conducted confirmed that the results coming from 93 realizations were consistent with those coming out from 260 ones. In this study the Wilk's approach was embraced to relieve the computational burden.

To evaluate the influence of input parameter values on the results, two Correlation Coefficients (CCs) are employed: Pearson and Spearman CCs. Pearson CC quantifies the linear relationship between each input parameter and the FOM, while Spearman CC measures the strength of a monotonic correlation. Both range from -1 (indicating a perfect negative linear/monotonic correlation) to +1 (indicating a perfect positive linear/monotonic correlation), while a value of 0 denotes the absence of a relationship. The p-value concept is used as well: a p-value lower than 0.05 suggests that the computed correlation between the input parameter and the output one has statistical significance.

5. RESULTS

5.1 Once-At-A-Time (OAT) Sensitivity Analysis

In this type of analysis, only one corium property is varied at a time. This approach makes it possible to determine the most appropriate value of the multiplier M to apply for each property and provides a first insight into which parameter might have the greatest influence on FOMs. However, it misses the effect of the potential interaction among different properties. Table IV displays the ranges of the individual

properties, the properties domains resulting from the BE, and the multiplier interval corresponding with the uncertainty range. As noted, uncertainty ranges encompass BE ones.

Table IV: Ranges for each property.

	Uncertainty range	Best Estimate range	Multiplier range
Viscosity [kg/ms]	0.1 – 10	0.7 – 5	0.2 – 7
Conductivity [W/mK]	1 – 12	4.5 – 12	0.33 – 1
Specific heat [J/kgK]	500 – 1,300	575 – 1,095	0.88 – 1.13
Density [kg/m^3]	2,800 – 8,000	3,300 – 7,400	0.83 – 1.07
Emissivity	0.5 – 1	-	-

The OAT sensitivity analysis showed that the corium property with the greatest influence on the dome pressure, cavity erosion and gas flammability is the specific heat, while both thermal conductivity and viscosity also appear to affect the erosion behavior. Table V summarizes these preliminary insights. To encapsulate the qualitative nature of this sensitivity analysis, a color code is chosen to reflect what has high influence (red circle), from what just makes a mild (blue circle) or no influence at all (green circle).

Table V. Corium properties influence on FOMs.

	Dome pressure	**Cavity Erosion**	**Gas Flammability**
μ	🟢	🔵	🟢
k	🟢	🔵	🟢
c_p	🔴	🔴	🔴
ρ	🟢	🟢	🟢
ε	🟢	🟢	🟢

5.2 Uncertainty Analysis (UA)

In this section, the UA for the selected three FOMs is reported: containment dome pressure, cavity erosion (through maximum cavity radius and minimum cavity altitude) and the Shapiro diagram, to assess the combustion risk.

Containment pressure (Figure 3a) displays a cumulative effect of uncertainties along time that ends up in a (-17%, 33%) interval after 2 days since the accident onset (172,800 s as calculation ending time). It is worth noting that there is a strong linear and monotonic correlation with the corium specific heat (Figure 3b). The Pearson and Spearman coefficients, evaluated at the end of the simulation, are associated with extremely low p-values (<<0.05), confirming the statistical significance of the correlation. This is interpreted as the result of a counterbalance effect of c_p on the corium temperature. On one side, a high c_p would mean a lower T_{corium}, which will result initially in less concrete erosion. But, on the other side, the amount of energy stored in the corium would be the same (regardless of its temperature) and the temperature decrease rate due to the heat transfer to concrete would be slower and last over longer time, which might eventually result in further concrete erosion and gas generation.

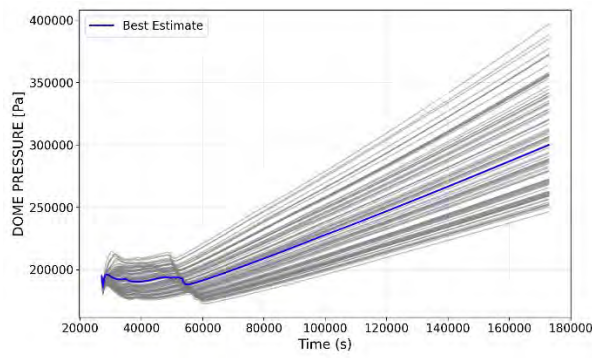

Figure 3a. Dome pressure.

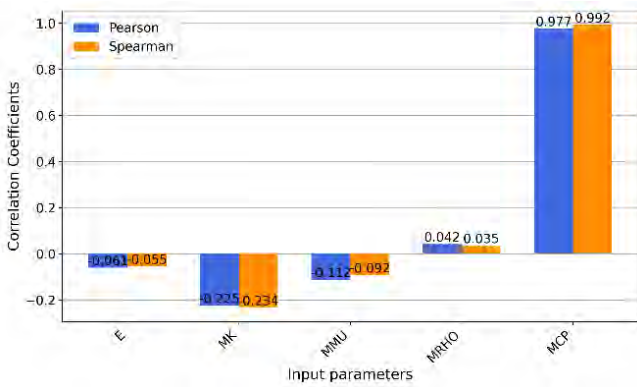

Figure 3b. CCs.

Concrete erosion scattering also shows a growing monotonically increase with time, both axially and radially, as shown in Figure 4a and Figure 5a. In both cases, the uncertainty band extends over time, although in a narrower interval with respect to the dome pressure: (5%, -5%) radially; (11%, -7%) axially. As for the sensitivity analysis, c_p seems to have the highest influence also on this FOM. The associated p-values for the Pearson and Spearman coefficients are in both cases much smaller than 0.05, confirming the statistical significance of the correlation. So, the same discussion as before might be brought up. However, it is observed that uncertainties in corium density also play a role on radial erosion with p-values of 3.4×10^{-5} (Pearson) and 1.8×10^{-4} (Spearman). While for the axial one, corium conductivity shows a statistically significant effect too with p-values of 2.9×10^{-7} (Pearson) and 7.6×10^{-8} (Spearman). The latter is consistent with a fast uniform distribution of stored thermal energy in the concrete, which would make heat transfer losses from the corium top surface more efficient and cause a faster fall of corium-concrete interfacial temperature.

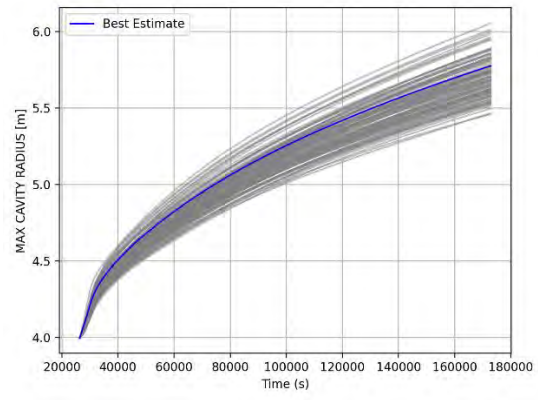

Figure 4a. Maximum cavity radius.

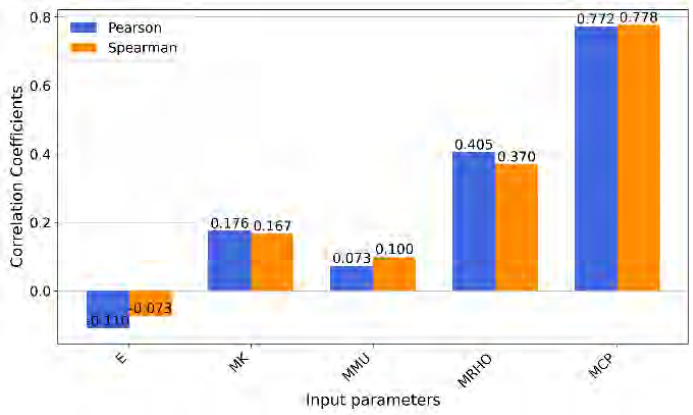

Figure 4b. CCs.

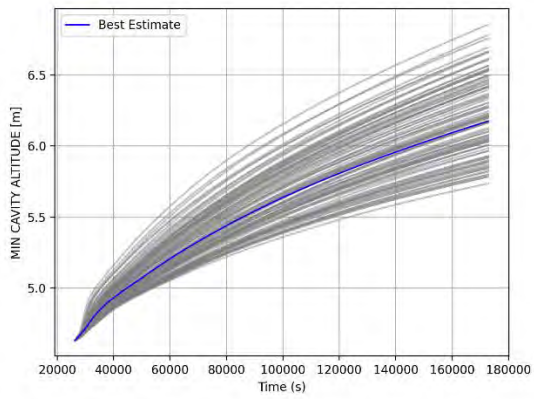

Figure 5a. Minimum cavity altitude.

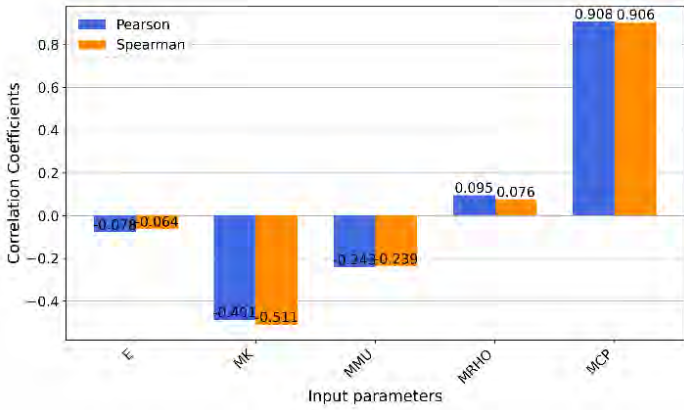

Figure 5b. CCs.

Combustion risk (Figure 6a) is observed not to change substantially due to corium properties uncertainties. At all times and in all calculations, the atmosphere gas mixture is far from the detonation limits in the diagram. If "time within flammability limits" is used as an indicator of the effect of properties uncertainties (Figure 6b), it is noted that the effect is, as in the case of erosion, pretty mild. The distribution of the time spent in the flammable region obtained from the simulations shows a negative skewness normal distribution over the range 9,000 s to 15,000 s. Almost 75% of the data points are between 12,000 s and 14,000 s: the weighted average being 12,427 s and the standard deviation is 935 s. This indicates a very moderate effect of corium properties uncertainties in the combustion risk.

6. MAJOR INSIGHTS

The ability of UaSA to investigate the potential effect of knowledge uncertainties on SAs footprints has been explored in this work by focusing in a specific study: the influence of uncertainties in corium thermo-physical properties on the in-containment progression of an SBO SA accident in a 1000 MWe PWR. The

insights gained are inherently associated, of course, to the NPP and scenario modelling (i.e., instantaneous melt spreading) by using a lumped parameter code (MELCOR v.2.2 2025.0) and the order statistics in the realization campaigns:

- Cavity erosion and gas flammability risk are mildly sensitive to uncertainties in corium properties. In-containment pressure, though, showed a visible effect that would translate in potential shortening of time-to-reach a given threshold;
- Among all the properties investigated, uncertainties in corium specific heat dominated any other property's effect by far.

In all the cases, the findings have been discussed to be physical grounded.

The methodology used in this work should be further proved in other scenarios and plant designs before settling down generic conclusions on the matter investigated. Nevertheless, as a high-level conclusion, the study conducted showed the usefulness of UaSA to explore areas where further research might or might not be needed.

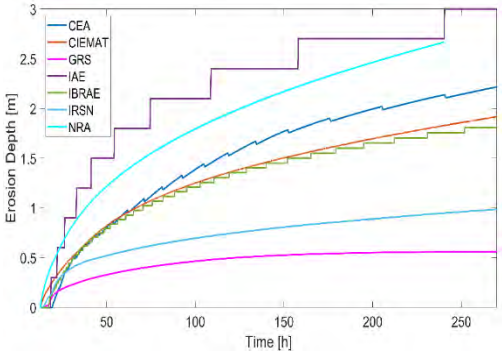
Background

Motivation

- Containment integrity might be jeopardized in SA ex-vessel phase:
  - Concrete erosion.
  - Over-pressurization.
  - Energetic combustion (fast deflagration & detonation).

- Fukushima observations, far from “expectations”.
- Codes major discrepancies in the long run.

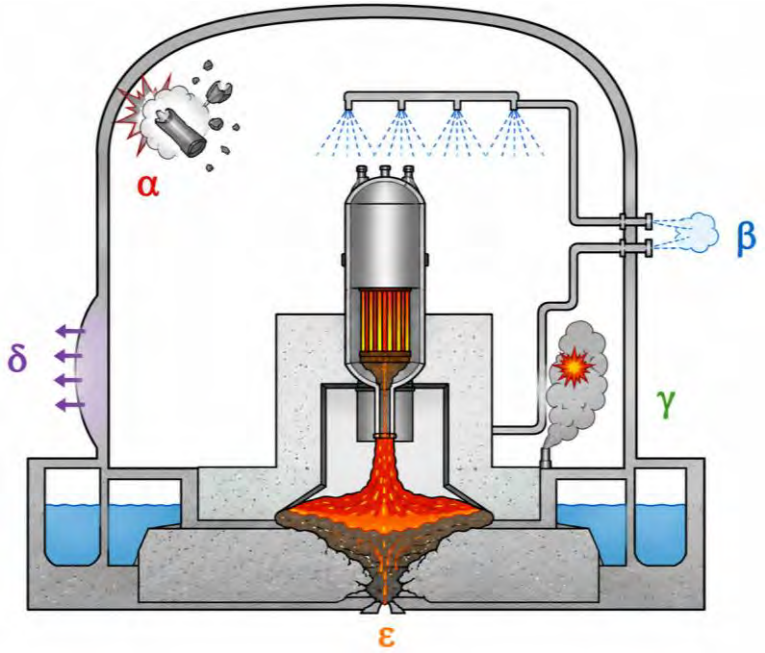


- Intl. projects on ex-vessel corium (ROSAU; **COPS**; …).
- UaSA in SA … is phasing UQ an option?

Background

Objectives & Scope

- Investigate the influence of corium properties on the containment SA scenario during the ex-vessel phase:
  - Cavity erosion
  - Pressure
  - Gas composition



- PWR “dry cavity” (MCCI).
- UaSA approach (MELCOR + in-house Python scripts)

02 Accident Scenario

Accident Scenario

A Snapshot

- 1000 MWe W-PWR.
- Mitigated SBO.
- Dry cavity
- Corium pool: 78% ox.; 22% mtls.
- Corium total mass: 135 tons
- Limestone concrete
- Initial conditions (26,400 s = 7.3h):

P (Pa)	Tgas (K)	RH	H_2 (%)
2.66E5	457.95	0.102	8.0

SPECIES	Limestone aggregate/common sand concrete (mass%)
SiO_2	35.80
TiO_2	0.18

05

Major Insights

Preliminary Insights

- **A methodology** proposed to explore the relevance of corium properties on SA containment scenario in the ex-V phase.
- **Major hypos** made to set the basis of the UaSA analysis.
- A "**small/mild" effect of corium properties uncertainties** on erosion & combustion risk found.
- **Containment pressure significantly affected**, though.
- **Uncertainties in specific heat,** a big player!

Future Steps

- To consolidate the results (sensitivity to assumptions).
- To extend to other scenarios (wet cavity; Fukushima-like).

CONSIDERATIONS ON FLOATING CRUSTS DURING MOLTEN CORE CONCRETE INTERACTION

Christophe Journeau

ABSTRACT

In the case of Molten Core Concrete Interaction, it is commonly accepted that an anchored crust cannot remain stable at reactor pit/pedestal scale (~5-6m). Floating crust hypothesis is thus considered to study long term ex-vessel coolability by water top-flooding. Typical characteristics from Fukushima Daiichi MCCI modelling have been used to estimate crust characteristics, as well as published data from a typical PWR scenario. Melt Eruption is an important phenomenon contributing to ex-vessel coolability in flooded MCCI configuration as ejected debris are considered to be quenched and remain cooled by water pool.
Heat conduction considerations provide estimates of crust thickness (which are consistent with the 3-4 cm thickness estimated for the observed Fukushima Daiichi unit 1 pedestal shelves. A crust floatability study provides the possible floating crust potential characteristics in terms of density and porosity. It shows that a floating crust cannot withstand a large mass of ejected debris without sinking in the molten pool and remelting its lower part. This value is then compared with the ejected debris rate estimated from Ricou and Spalding model. Ejected debris cooling mode would then be limited to a short-term cooling followed by refusion (quenched at ~100°C then reintroduced in melt pool) instead of a long-term cooling by ~100°C boiling water. a new scenario can be proposed, which is currently not modelled in MCCI codes, for concretes with high gas contents as limestone-rich ones: a floating crust is formed on the top of the corium pool interacting with concrete; due to gas releases, melt eruption occurs and “volcanic vents” are formed; erupted debris droplets (typically of centimetric size) are quench in water and deposited above the crust; as the debris bed weight increases, the crust progressively sinks, remelts and is incorporated again to the molten pool.

KEYWORDS

MCCI, Crust, Melt Eruption, Coolability, Long term

1. INTRODUCTION

Terminating Molten Core Concrete Interaction (MCCI) [1] [2] is an important goal in the management of the Ex-Vessel phase during a Severe Accident. In the absence of external cooling, MCCI would continue ablating the basemat concrete for a very long time period [3]. Top flooding by water the corium concrete molten pool is considered as a means to enhance melt cooling used as a generic severe accident management strategy for ex-vessel melt stabilization in many existing plants [1].
Three main processes [1][4] have been considered that favors melt cooling even though corium thermal conductivity is relatively low and would limit cooling heat transfer:

- Water ingression in the crust [4, 5];
- Melt eruption forming particulate debris bed above the top crust [6];
- Bulk cooling in case of sudden breach of a suspended crust.

At experimental scale, crust generally anchors to the sidewall and a cavity may form between the molten pool and the crust that largely reduces upwards heat transfer in the presence of top cooling [4] even with relatively large (1.5 m) span between walls. Nevertheless, it is expected that at reactor scale, with a typical

6-meter diameter reactor pit, the crust strength would not be sufficient for it to remain in an anchored geometry for most plausible configurations [7], as the stress caused by the crust weight varies with the square of the ratio of radius over thickness. Therefore, the most expected configuration during MCCI with top flooding is that of a floating crust.
Between December 2021 and March 2022, a series of remotely operated investigations have been conducted in the pedestal of Fukushima Daiichi unit 1 [8, 9] that has shown the presence of so-called "shelves" or "terraces" [10] on the concrete wall that can be assumed to be partially anchored crust, as well as structures that are likely to be broken crusts that have fallen above the deposits that lie above the concrete substrate (Figure 1). Observing these structures that are interpreted as corium crusts, lead to reconsidering some issues about floating crusts that will be developed in this paper.

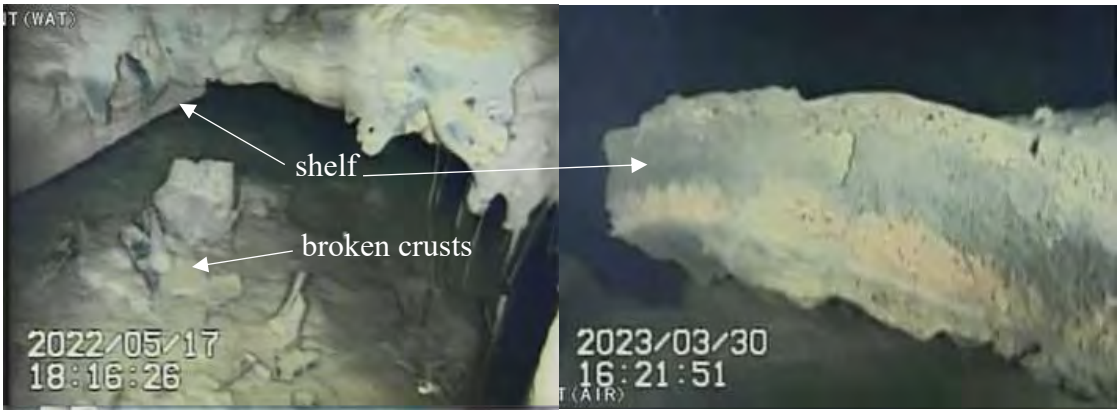

Figure 1. Remains of crusts observed during remote-operated investigation of Fukushima Daiichi unit 1. Left: "shelf" or piece of anchored crust at top, broken crusts visible at bottom ***https://photo.tepco.co.jp/en/date/2022-e/202205-e/220519-02e.html*** **;**
Right: zoom on "shelf" ***https://photo.tepco.co.jp/en/date/2023-e/202304-e/230404-01e.html***

In a first section, crust characteristics will be analysed and their floatability will be discussed. Then a section will be devoted to applications to melt eruption scenarios and a final section will focus on crust floatability during melt eruptions.

2. CRUST CHARACTERISTICS AND FLOATABILITY

Figure 2 schematically describes MCCI with water top-flooding and melt eruption. In this configuration, a floating crust is being considered, even though some small portions of an original crust at higher elevation may remain and form shelves.
From Fukushima Daiichi unit 1 MCCI benchmark [11], the melt temperature rapidly falls between 1500 and 2000 K during Molten Core Concrete Interaction, due to the mixing of the initial corium composition with molten concrete. Neglecting the effects of water ingression and of decay heat in the crust, Equation (1) determines the crust thickness by considering conductive heat transfer of the heat flux φ imposed by convection in the corium-concrete pool, between crust lower interface at a temperature in the 2000 -1500 K and its upper surface which would be around 400 K if covered by water.

$$h = \frac{k\Delta T}{\varphi} \quad (1)$$

With the thermal conductivity k of the order of 1-2 W/m²/K and an upwards heat flux in the 340- 50 kW/m² range [11], this leads to crust thicknesses between 5 and 60 mm. Actually, Cibula et al. [9] estimated from robotic observations the "shelf" (part of the crust remaining attached to the wall) thickness to 3-4 cm, which is in agreement with the simplified calculation above. Equation (1) neglects the contribution of the decay

heat present in the crust [12], which is acceptable due to the crust small thickness compared to that of the pool. Anyhow, these values must be considered as orders of magnitude, as it is difficult to estimate the actual crust thickness.

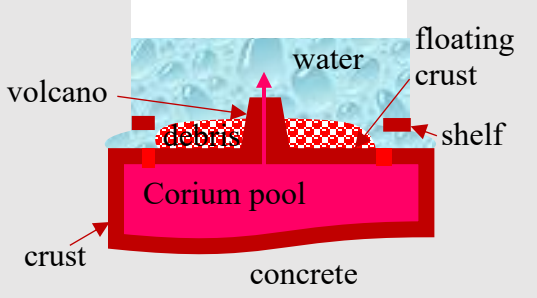

Figure 2. Schematic view of crust overlying an MCCI pool

The density of solid MCCI material is higher than that of the liquid material, as all of its constituent materials are denser in solid state compared to the corresponding liquid phases. For instance, there is about 7.5 vol% shrinkage at solidification for UO_2 [13] and 10 ±2 vol% for ZrO_2 [14, 15].
Moreover, the crust upper surface will be near water boiling point if it has been flooded by water while its lower surface will be at a temperature close to the crust-liquid interface temperature (somewhere between melt solidus and liquidus depending on model assumptions [1]). Anyhow, the crust will be colder than the molten pool and thus have a higher density due to thermal contraction.
Finally, the pool composition will evolve with the progression of concrete ablation, as concrete will mix with the oxidic phase of corium. Through this process, as molten concrete is much lighter than molten corium, there will be a continuous decrease of the molten pool density during concrete ablation.
Therefore, it is necessary to have more than 20 vol% of closed porosity in the crust than in the melt for crust to be lighter than the melt and effectively float on the pool. Indeed, open porosity would be filled by overlying water and the corresponding volume would not be accounted in considering Archimedean floatability.
These 20 vol% are quite plausible: The VB-U6 benchmark calculations [16] estimated the void fraction in the melt in the 30-50 % range at the initial minutes of the molten core-concrete interaction, so it is plausible that after solidification, similar void fractions are achieved. In less than one hour of test, the void fraction falls below 10%, implying a significant reduction of the pool height, the formation of a cavity and of an anchored crust, until it falls creating some “shelf” structures and floating crust.

3. ORDERS OF MAGNITUDE ABOUT MELT ERUPTIONS

The floating crust approach is in particular considered in the study of melt eruption in relation with concretes having a large gas content, as Limestone Common Sand concretes [1, 6] for which it is calculated to be an efficient contribution to coolability. In this approach, it is considered that thanks to entrainment by concrete-decomposition gases, corium debris are ejected through “volcanic eruptions”. The ejected droplets are then quenched in the overlying boiling water pool and accumulate as a porous particle bed atop the crust [4]. These eruptions have been observed in MCCI experiments such as e.g. ECOKATS-2 [20], MACE M3B [4] or VULCANO VBS-U1 [21] (Figure 3).
Based on Ricou and Spalding [17] correlation, Farmer [18] assumes that the superficial gas velocity j_m of the entrained melt is proportional to the superficial gas velocity j_g with a proportionality factor (entrainment rate) linked to the square root of the ratio between gas and melt densities:

$$j_m = 0.08 \left(\frac{\rho_g}{\rho_m}\right)^{1/2} j_g \qquad (2)$$

The superficial gas velocity is linked to the concrete ablation rate v by:

$$j_g = \sum_i \frac{f_i}{M_i} \cdot \varrho v \, RT/P \quad (3)$$

Figure 3. A corium "volcano" from VULCANO VBS-U1 test [21] © CEA, 2006

For a typical limestone-rich concrete such as that reported by Hengra et al. [19], f_{CO2} = 21.154 wt% and f_{H2O}=4,7 wt% while ρ = 2340 kg/m^3. At a typical corium pool temperature of 2000 K under a pressure of 3 bars, Equation (2) yields $j_g \approx 960$ v

Table I. Gas released from Limestone concrete in [19]

	CO_2	**H_2O**	**Total**
Mass fraction	21.15%	4.70%	25.85%
Density (kg/m^3)	0.79	0.32	0.63
	CO	**H_2**	**Total**
Mass after reduction (wt%)	13.5 %	1.0%	0.145
Density (kg/m^3)	0.50	0.07	0.35

In the presence of metals, steam can be reduced to hydrogen and carbon dioxide to carbon monoxide, but that would not change the superficial gas velocity as there is the total number of moles does not change during this RedOx reaction. Nevertheless, gas densities would be changed in this case. Table I synthesizes the gas densities for this case. The average gas density varies between 0.35 and 0.63 kg/m^3 in this typical case. For a typical liquid melt density of 5000 to 8000 kg/m^3, applying Equation (1) indicates that the entrainment rate j_m/j_g is typically in the 5-7.10^{-4} range and is thus consistent with coolability according to Bonnet and Seiler approach [22]. Equation (2) gives:

$$j_m \sim 0.5\text{-}0.7 \text{ v} \quad (4)$$

Ablation rates have been calculated for numerous reactor cases and reported in various publications [19, 23-27]. Table II present the range of estimated average axial ablation rates. It lies between 0.003 and 0.2 m/h. Applying (4) gives a range of melt superficial velocity between 2.10^{-3} and 2.10^{-1} m/h.
In the first hours of interaction, the superficial gas velocity is generally in the 2.5-10 cm/h range.
The surface of interaction lies between 24 m² (corresponding to a Ø5.5 m reactor pit) and 70-80 m² (corresponding to spreading from pit into a nearby compartment). Over one hour, between 5 and 60 t of debris would be forming a debris bed over the floating crust.

Table II. Ablation rates estimated from published reactor MCCI calculations with limestone-rich concretes.

Period over which estimation has been made in indicated under brackets.

Reference	Conditions	Minimum ablation rate (m/h)	Maximum ablation rate (m/h)
Cranga et al. 2010 [23]	Median value of homogeneous pool	0.01 (96-240 h)	0.08 (0-2 h)
	Median value of stratified pool	0.035 (48-96 h)	0.07 (0-48 h)
Vaitova & Stemberg 2015 [24]	VVER with limestone concrete	0.04 (32-45 h)	0.09 (0-1 h)
Yu et al. 2015 [25]	EPR with limestone concrete	----------	0.1 (0-3 h) Only published data
Stefanova et al. 2015 [26]	VVER with 26 wt% $CaCO_3$	----------	0.12 (14-30 h)
Na et al. 2021[27]	Dry MCCI	0.004 (60-330 h)	0.2 (0-1.7 h)
	Underwater MCCI	0.003 (0-6.7 h)	
Hengra et al. 2023 [19]	Dry Limestone Common Sand cavity	0.01 (28-56 h)	0.05 (0-14 h)
Fichot 2025 [12]	Limestone concrete	0.003 (60-80 h; with water ingression and eruptions)	0.015 (0-10 h; dry)

The formed debris beds have a large porosity and the debris particles have a size in the order of one centimetre that is considered coolable by boiling water [4, 22]. Termination of the concrete ablation is considered achievable when most of the corium pool is transformed into a coolable debris bed, which is possible with entrainment rates in the 10^{-4}-10^{-3} range. It has thus been suggested that addition of a thin layer of limestone concrete would accelerate stabilization [12].
This would not be operating if there were an anchored crust, because a cavity would form at between the melt surface and the anchored crust that would prevent melt eruptions from reaching above the crust. This has often been observed at laboratory scale [1, 4, 21], especially with limestone-rich concretes due to loss of volume of limestone aggregates during decarbonation. But such cavities are generally considered to be extremely unlikely at reactor scale due to the large spans for which crusts are not strong enough to stay. Broken crust are likely to have been observed at scale 1 in Fukushima Daiichi unit 1 (Figure 1 left).

4. CRUST FLOATABILITY DURING MELT EJECTION

As the crust is assumed to be floating (Figure 4), it is then necessary to estimate the quantity of debris that may lie on the crust without sinking. Let's assume a porosity of 50 vol%, which is clearly a bounding case reduces the risk of crust sinking under the weight of debris bed. It must be stressed that this porosity should also decrease thermal conductivity and thus crust thickness, but this effect is neglected here.
Taking into account shrinkage and thermal contraction, we may assume an intrinsic initial crust density of the order of 7000 kg/m^3 (i.e. 3500 kg/m^3 taking into account 50% closed porosity) and a pool density of the order of 6000 kg/m^3. In this case, about 60 % of the crust will be submerged, considering Archimedes' principle.
For a typical 35-mm thick crust, it would correspond to about 20 mm submerged and 15 mm above the molten pool level. These 15 mm will sink in the molten pool if sufficient weight is applied on top of it. This weight corresponds to the weight of displaced pool. Therefore, sinking would occur for a typical surfacic density ρ_A of 0.015 x 6000 = 90 kg/m² (i.e., a few tons over the whole MCCI area). Submersion will arrive quite rapidly in the order of 1 hour of interaction and anyhow before a significant fraction of the melt mass (of the order of 100 t). In the case of a very porous debris bed, Archimedes's force should be taken into account, reducing the apparent density of the debris by $(\rho_{debris}-\rho_{water})/\rho_{debris}$ which corresponds to 20% of added mass for the same sinking depth.

Table III: Sensitivity analysis of sinking added mass with respect to closed porosity
(Crust density : 7000 kg/m^3, Pool density: 6000 kg/m^3, pedestal diameter: 5 m)

Closed porosity	10%	20%	30%	40%	50%	60%
Porous crust density (kg/m^3)	6300	5600	4900	4200	3500	2800
Emerged height (mm) for 35-mm crust	0	2	6	11	15	19
Added mass (t) for sinking (taking into account floatability)	0	0.3	0.9	1.5	2.1	2.6

Table III presents the sensitivity of these calculations with respect to the crust porosity. It confirms that even with very high porosities, the initial crust cannot carry a significant fraction of the corium inventory without sinking. Table IV similarly presents the sensitivity of sinking with respect to the crust density. Even with crust and liquid pool having the same density (i.e., neglecting material shrinkage due to solidification and thermal contraction) and a crust closed porosity of 50%, the total mass that can be taken on the c rust without sinking is below 3 t.

Table IV: Sensitivity analysis with respect to the crust density (for a 50% closed porosity), taking the same other hypotheses than in Table III

Crust intinsic density (kg/m^3)	6000	6300	6600	7000	7500
50%-porosity crust density (kg/m^3)	3000	3150	3300	3500	3750
Emerged height (mm) for 35-mm crust	18	17	16	15	13
Added mass (t) for sinking (taking into account floatability)	2.5	2.4	2.2	2.1	1.9

Mixing of the melt pool with ablated concrete has not been considered in this order of magnitude calculation. It will reduce the melt density (but not the crust density, as crust was formed earlier) and thus increase

submersion. Independently of the exact timing of this event, it occurs that a significant fraction of the corium inventory (in the 100-ton order of magnitude) cannot stay on a floating crust without making it sink.

Figure 4. Schematic view of floating crust supporting a mass dm of debris
Arrows mark the forces applied to the floating crust

To study the behaviour of a sinking crust, it is first assumed that the system (crust + ejected debris) remains in stable horizontal position (as a raft) and debris do not roll down into the pool. The crust will thus progressively sink into the pool. In this simplified approach, the decay heat generated in the crust and the debris will be neglected, as it concerns a thickness of a few centimeters of heat-generating corium, which is negligible compared to the multi-decimeter deep pool.

At the start of the ejection process, there is an upward heat flux at the crust lower interface φ_0 following Equation (1). If a mass dm is added, it will lead to a sinking of $dh=dm/(\rho_{pool}.S.h)$. If changes of heat flux and of thermal conductivity are neglected, the flux $d\varphi$ is available to melt a mass dm' at the bottom surface of the crust in order to reach again equilibrium between convection from the pool and conduction in the crust:

$$d\varphi = k\Delta T\left[\frac{1}{h} - \frac{1}{h+dh}\right] \approx k\Delta T\frac{dh}{h^2} = \frac{k\Delta T dm}{\rho_{pool}h^2 S} \qquad (5)$$

This is valid as long as the characteristic remelting time τ is shorter than the characteristic time of mass increase due to melt eruption. Remelting of $dm'=\rho_{crust}.S.dh$ to return to the initial thickness is characterized by:

$$\tau \sim \frac{L.dm'}{d\varphi.S} = \frac{L\,\rho_{crust}\,h^2}{k\,\Delta T} \qquad (6)$$

Considering crust latent heat of the order of L= 300 kJ/kg, ρ= 7000 kg/m^3, h= 3 cm, k=1.5 W/m/K and $\Delta T \sim 2000$ K, the characteristic time is of the order of 10 minutes. This is well shorter than ejection characteristic times, so the floating crust is expected to progressively melt when it sinks because of the arrival of erupted debris.

Another plausible alternative scenario, in which there is no crust sinking, would be that, due to an uneven repartition of debris on the crust, there would be floatation instabilities and tilting of the floating crust leading to the fall of most of the debris in the pool. In this case also, there would be a rather quick return of the debris into the molten pool.

In both scenarios, heat-generating material will be temporarily removed from corium pool, (partly) quenched by water and will eventually return to the melt pool and be remelted. This will indeed provide some enhanced heat removal compared to top flooding without melt ejection. A simple way to assess the contribution of these phenomena to the overall heat balance has not been found and it is expected that more mechanistic modelling shall be carried out to determine its efficiency.

5. CONCLUSIONS

Remote-controlled investigation in Fukushima Daiichi unit 1 containment have shown the presence of structures that have been interpreted as broken crusts having fall over solidified fuel debris and of small partly-broken crusts attached to the walls (shelves). These observations have been the basis for a renewed interest in the fate of crusts during ex-vessel phases of a severe accident, in particular during top flooding with melt eruption.

Top crusts above an MCCI pool are expected to have a thickness of the order of a centimeter and must have significant porosity in order to float over the melt pool. Melt eruptions over a floating crust are considered to be an efficient way to quench a large part of the MCCI inventory as coolable particulate debris bed.

Considering typical ablation rates from reactor scale MCCI calculations reported in the literature, it occurs that the crust would sink due to the weight of the debris bed as soon as a mass of the order of a few tons (out of typical a total mass of the order of 100 t) has been deposited on the floating crust. Moreover, characteristic remelting time indicate that the remelting of the sinking crust will be significantly more rapid than that of the deposition of debris.

Therefore, a new scenario can be proposed, which is currently not modelled in MCCI codes, for concretes with high gas contents as limestone-rich ones:

- A floating crust is formed on the top of the corium pool interacting with concrete;
- Due to gas releases, melt eruption occurs and “volcanic vents” are formed;
- Erupted debris droplets (typically of centimetric size) are quench in water and deposited above the crust;
- Due to weight increase, the crust (and the overlying debris bed) progressively sinks and remelts.
- A variant would be that, instead of sinking, the crust is subject to tilting until the added debris roll out of the crust and fall back into the corium pool.

In this scenario, ejected debris cooling mode would then be limited to a short-term cooling followed by refusion (quenched at ~100°C then reintroduced in melt pool) instead of a long-term cooling of a large debris bed by ~100°C boiling water of a significant part of the inventory. Moreover, with this scenario the crust characteristics will continuously vary with composition, which may affect water ingression, as this cooling phenomenon is less efficient at high silica fractions [9].

It is thus recommended to introduce this crust sinking phenomenon in wet MCCI modelling codes to estimate the evolution of pool cooling during this plausible scenario.

NOMENCLATURE

Symbol	Variable	unit
f	Mass fraction	-
h	thickness	m
i	Gas species identifier	-
j	Superficial velocity	m/s
k	Thermal conductivity	$W.m^{-1}.K^{-1}$

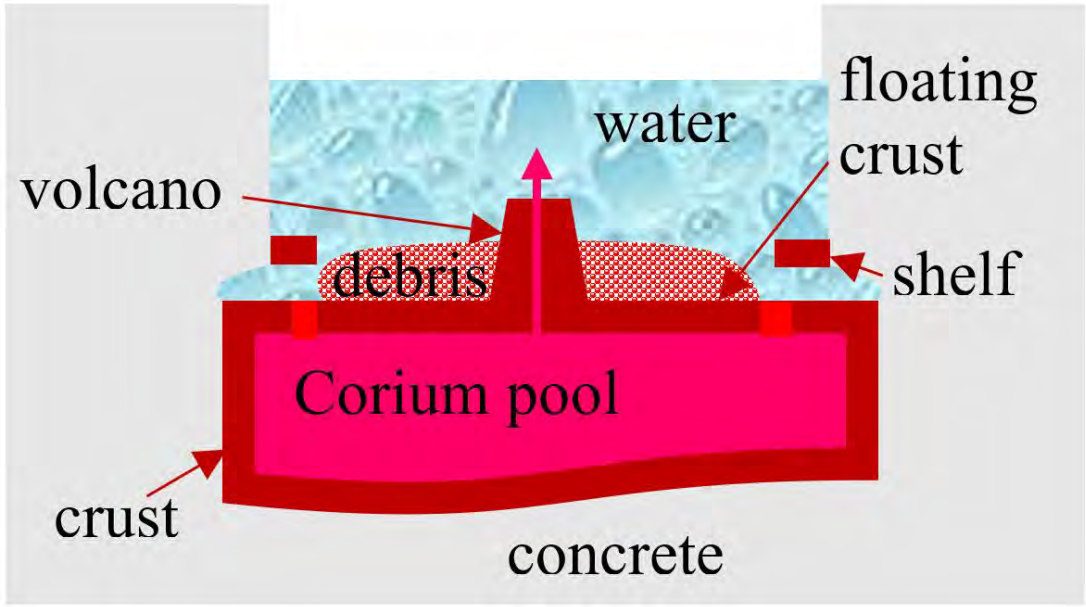
Outline

1. Introduction and Context
2. Observations at Fukushima Daiichi unit 1
3. Crust Characteristics and Floatability
4. Melt Eruptions
5. Crust Floatation in presence of Melt Ejection
6. Conclusions

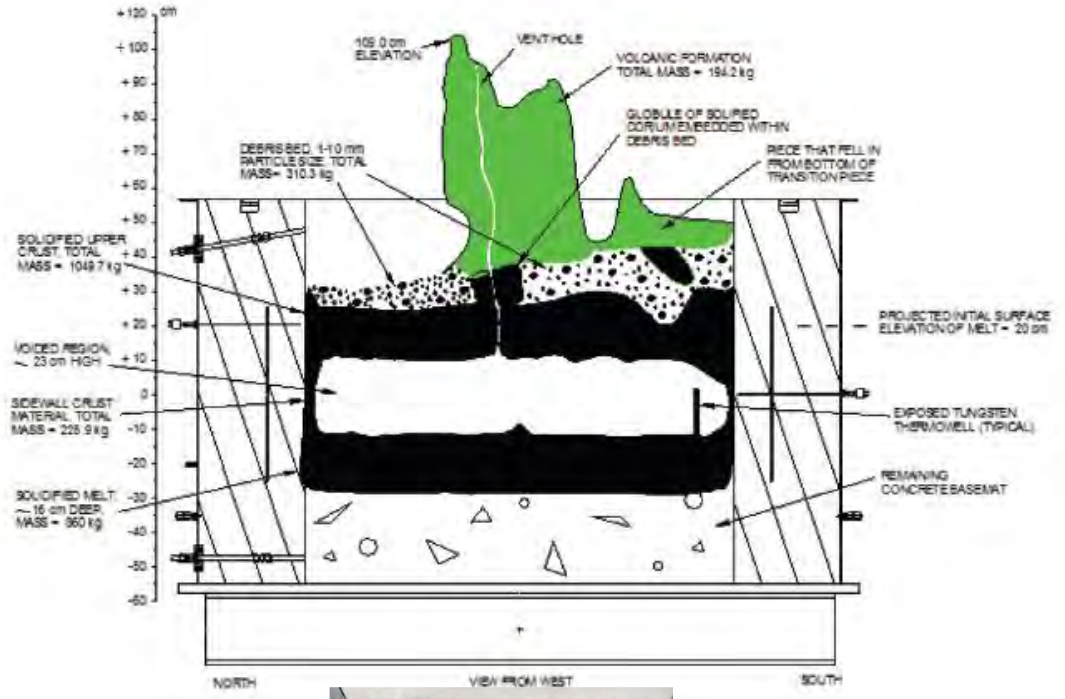
Introduction: Top-cooling during MCCI

- Ex-vessel phase of a Severe Accident
- Molten Core Concrete Interaction
  - Powered by decay heat
  - Ablation of concrete is to be arrested before concrete layer melt-through
- Top flooding is an accident management strategy that has been implemented in some reactors
  - Potentially after spreading (to reduce heat density)
  - Heat transfers can be enhanced by
    - Water ingression
    - Melt ejection on a floating crust
      - Ejected debris are expected to be easily coolable
        - *See Farmer, Nucl. Eng. Tech. 211 (2009) 575-602 and ICAPP2006 for more details*



Experimental issues with crust anchoring

- At laboratory scale, during experiments, top crust often anchors to the walls
  - When gas rate decreases, pool level becomes lower and a gap appears that is reducing upwards heat transfers.
  - Top cooling efficiency is estimated during periods without this gap.
- As crust resistance varies with 1/thickness², such behavior is believed to be impossible at reactor pit/pedestal scale (5-6 m typical diameter).

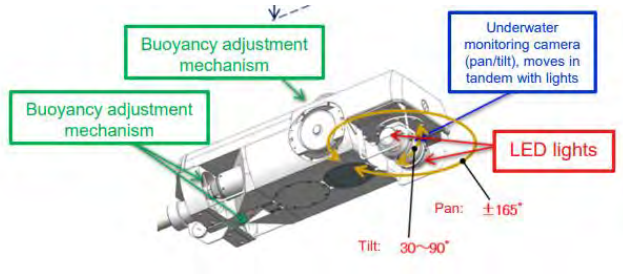


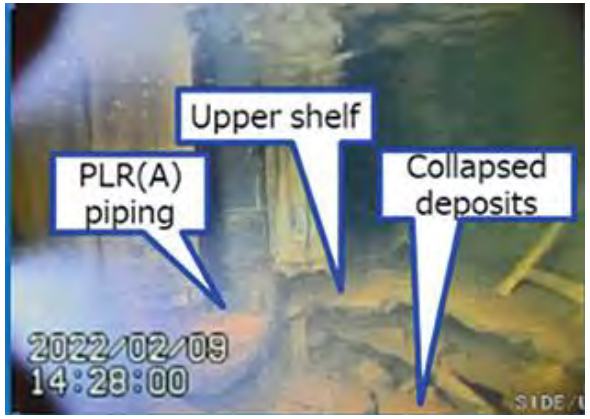
From NEA/CSNI/R(2016)15

2. Observations at Fukushima Daiichi Unit 1

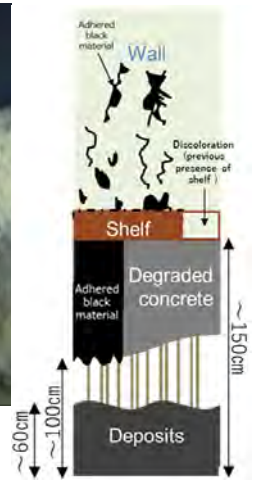
Investigations between December 2021 and May 2022

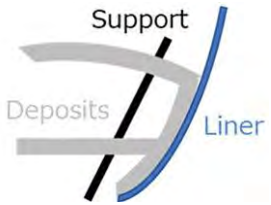
- Remotely-Operated underwater Vehicle observations





- Structures “collapsed deposits” have been found on top of deposits (likely remains of a corium spread) which have been considered to be broken crusts
- Structures called “shelves” or “terraces have been found at higher elevations that are attached to the walls
  - Interpreted as the remains of a broken anchored crust close to the walls or liner
  - Thickness 3-4 cm





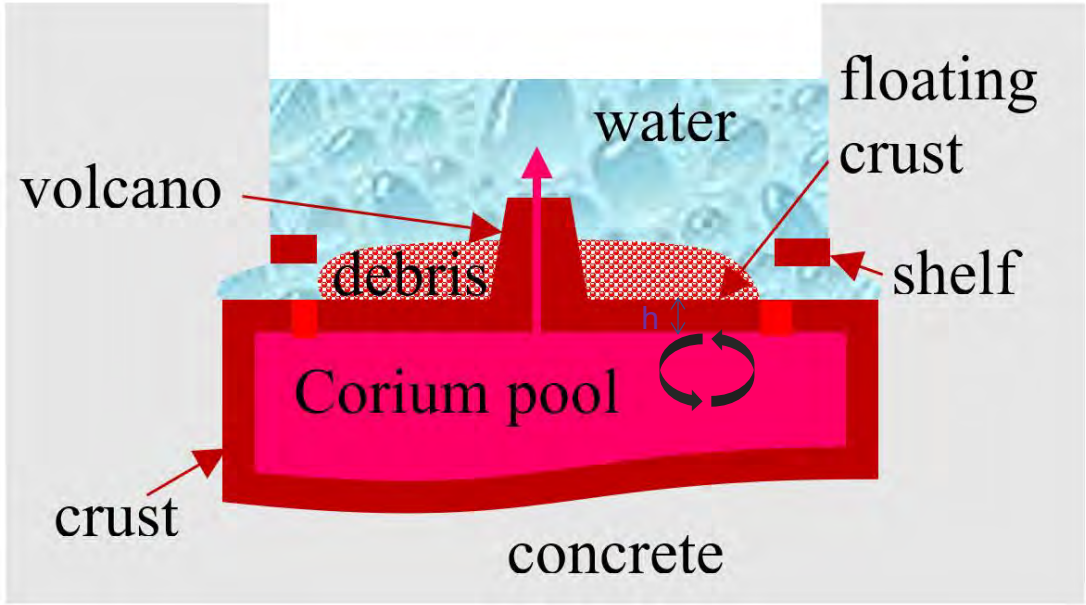
- *Images from TEPCO video archives and from Cibula et al., J.Nucl. Sci. Technol., 211 (2025) 513-530.*

3. Crust Characteristics and Floatability

Crust thickness

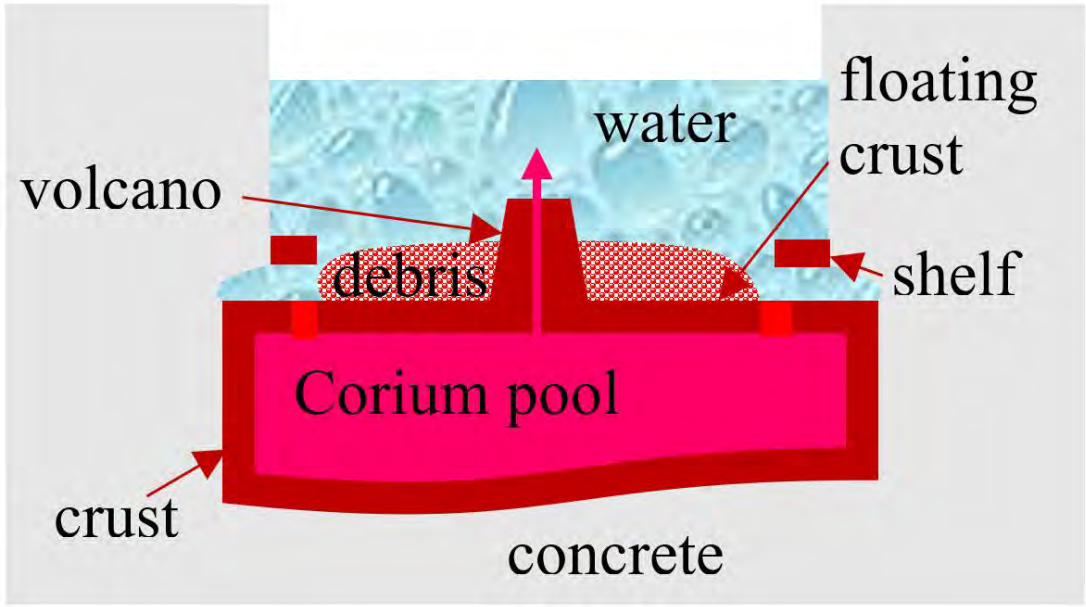
- Heat conduction in the crust subjected to
  - Convective heat flux at bottom
  - Imposed temperature, close to boiling point at its top surface
  - Neglecting decay heat in the crust gives:

    Thickness $h = \frac{k\Delta T}{\varphi}$
- Application:
  - Conductivity~1-2 W/m²/K
  - upwards heat flux in the 340- 50 kW/m² range [from ARC-F benchmark on 1F1]
  - Crust lower interface~2000K
  - Crust upper interface: ~430K
  - h between 5 and 60 mm
    - Fits with observed 30-40 mm



Floatability

- Solid fuel debris have a higher density than liquid pool
  - Shrinkage of 7 to 12 vol% between liquid and solid phases
  - Thermal contraction from melting point to boiling water interface temperature.
  - Liquid pool progressively mixes with lighter-density concrete
    - Affects crust and “older” ejected debris
    - Not newer eruptions
- Only solution to keep a crust afloat is to consider
  - Closed porosity in the crust
    - max ~50 vol%
    - ~20 vol% necessary
    - Calculated void fractions (are initially in the 30-50 vol%. Journeau et al, ERMSAR 2012
  - Archimedian force on particulate debris that will reduce their apparent density.



Numerical Application

- Intrinsic crust density : 7000 kg/m^3
- Crust closed porosity: bounding case of 50 vol% => Apparent density 3500 kg/m^3
- Corium pool density: 6000 kg/m^3 (taking into account mixing with some more concrete)
- Crust thickness: typically 35 mm

- Archimedes' principle
  - About 60% of the crust will be submerged
    - 20 mm below corium pool level
    - 15 mm above corium pool level

Closed porosity	10%	20%	30%	40%	50%	60%
Porous crust density (kg/m^3)	6300	5600	4900	4200	3500	2800
Emerged height (mm) for 35-mm crust	0	2	6	11	15	19

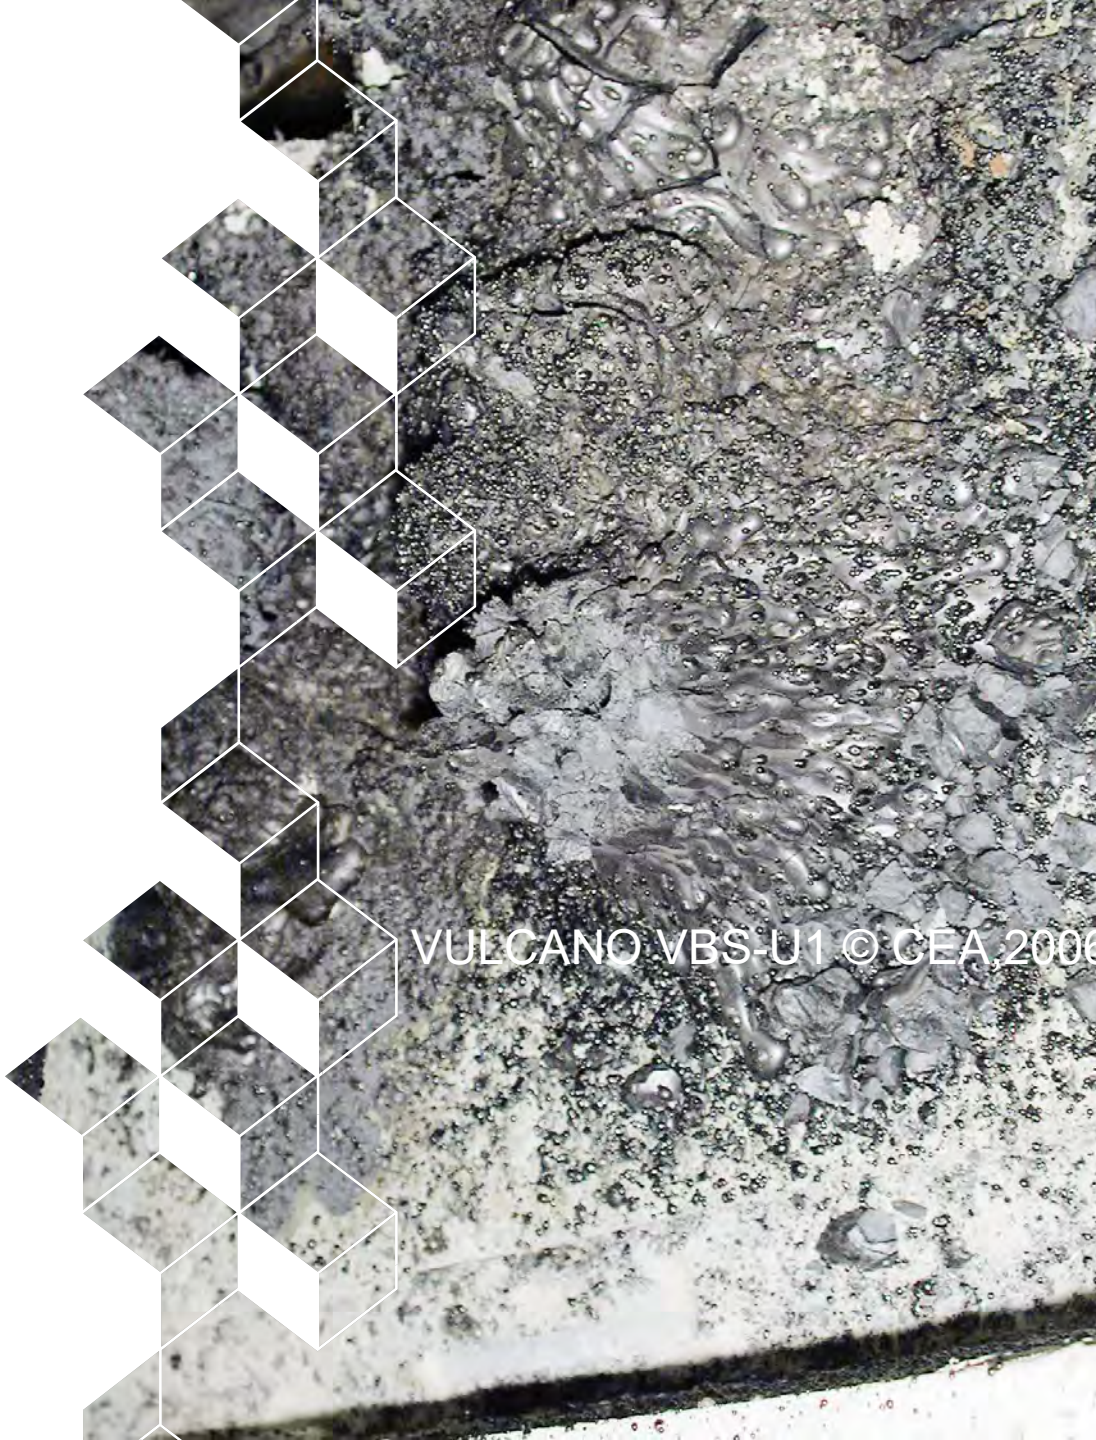
4. Melt eruptions

Melt eruptions

- Farmer adapted Ricou & Spalding correlation

$$j_m = 0.08 \left(\frac{\rho_g}{\rho_m}\right)^{1/2} j_g \qquad \text{with} \quad j_g = \sum_i \frac{f_i}{M_i} \cdot \varrho v \, RT/P$$

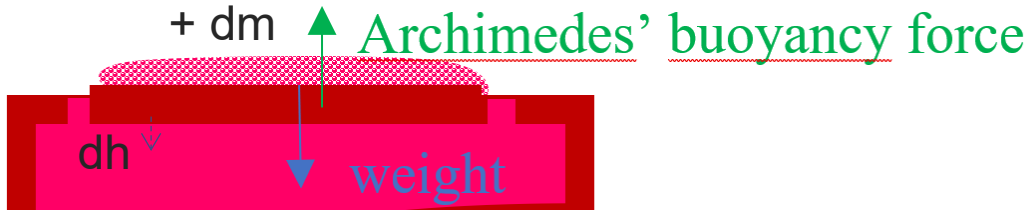
  - v being the concrete (average) ablation rate
  - For a typical limestone concrete, with corium at 2000 K under 3 bars, it gives j_g ~1000 v
  - For a typical corium density (5000-8000 kg/m^3) it gives
    - j_m ~ 0.5-0.7 v
- Typical ablation rates (from literature survey) in the 0.03-0.2 m/h
  - 2.5-10 cm/h generally in the first hours, then reducing.
- Considering a surface of interaction between 24 m² (Ø5 m) and 70 m² (spreading compartment) lead to formation of 5-60 t of particulate debris bed / solid volcanoes during the 1st hour.



5. Crust floatation during melt ejection

Crust floatation

- Like any raft, adding a mass dm (or an equivalent mass dm' taking into account debris buoyancy) on the floating crust will make it sink of a depth dh
- Depending on the crust density and porosity, it typically takes 0.3 t to 2.6 t to completely sink the crust due to the added mass.

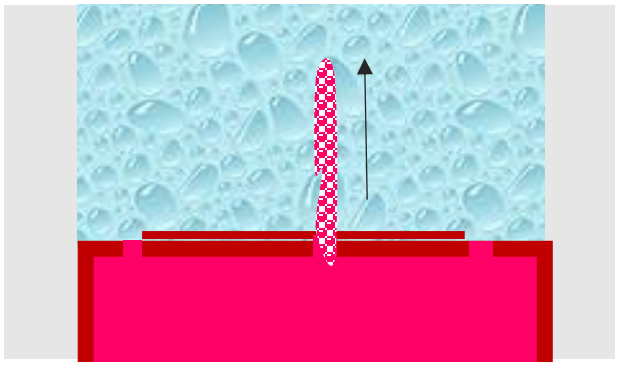


Crust intinsic density (kg/m^3)	6000	6300	6600	7000	7500
50%-porosity crust density (kg/m^3)	3000	3150	3300	3500	3750
Emerged height (mm) for 15 mm crust	18	17	16	15	13
Added mass (t) for sinking (taking into account debris floatability)	2.5	2.4	2.2	2.1	1.9

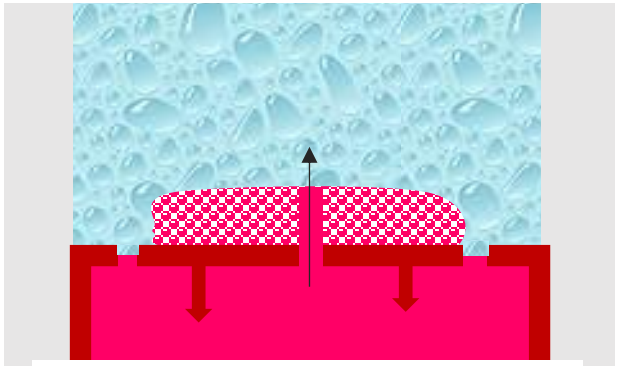
Remelting of the newly submerged crust

- Let's assume that the crust remains in stable horizontal position (as a raft with uniform distribution of added debris weight).
  - Decay heat in the crusts and debris is neglected, as well as change of heat conductivity due to the debris bed vs. crust.
- Due to increased thickness, there is an extra thermal resistance, so a flux dφ is available to remelt the extra thickness, in order to have again the thickness/thermal resistance adapted to the imposed heat flux from the pool
  - $d\varphi = k\Delta T\left[\frac{1}{h} - \frac{1}{h+dh}\right] \approx k\Delta T\frac{dh}{h^2} = \frac{k\Delta T dm}{\rho_{pool} h^2 S}$
- It is thus possible to estimate the characteristic remelting time:
  - $\tau \sim \frac{L.dm\prime}{d\varphi.S} = \frac{L\,\rho_{crust}\,h^2}{k\,\Delta T}$
  - Considering crust latent heat of the order of L= 300 kJ/kg, ρ= 7000 kg/m^3, h= 3.5 cm, k=1.5 W/m/K and ΔT ~ 2000 K, the characteristic time is of the order of 10 minutes.
    - Well shorter than the characteristic time of debris ejection.
    - Floating crust are thus expected to remelt faster than they are sinking into the corium pool so that their (thermal equivalent) thickness remains almost constant.

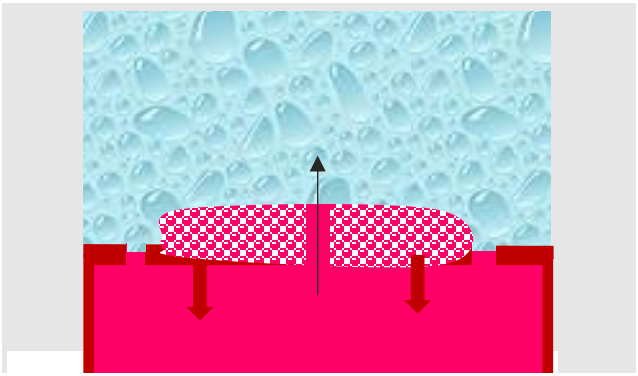
Scenario for uniform debris piling



- Floating crust
- Melt eruption
- Debris are flown out of pool and quenched by the boiling water



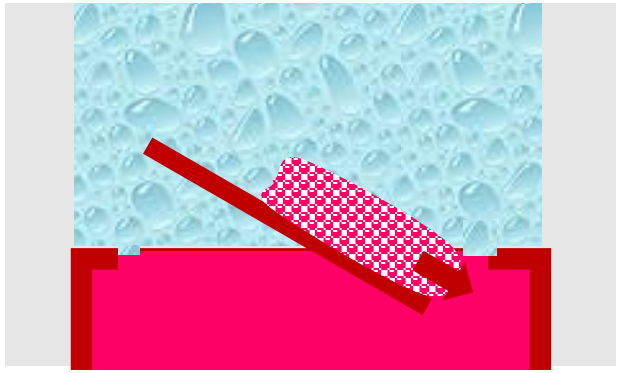
- A bed of quench particulate debris is forming above the floating crust
- Due to this extra weight, the crust progressively sinks in the molten pool



- The extra depth of submerged crust is remelted rapidly after sinking into the pool.
- The quenched debris will thus continuously remelt and reenter the molten pool.

Alternative scenario in case of non-uniform piling of particular debris

- In case of non-uniform weight distribution, the crust will not remain horizontal
  - Free particulate debris may slide/roll on the crust and fall back inside the corium pool
  - Otherwise the crust may partly remelt in an oblique geometry.
- Anyhow, as in previous scenario, after quenching in boiling water pool, the erupted debris will not remain indefinitely on the floating crust.



6. Conclusions

Summary - Perspectives

- Remotely-operated investigations at Fukushima Daiichi unit 1 have shown 3-4 cm thick structures that are likely to be broken solid corium crusts.
  - This has been the cause of my renewed interest in the fate of top crusts during top-flooding sequences of MCCI.
- Expected crust thickness of a few centimeters.
  - Expected to float on molten pool with typically more than 50% of crust submerged below pool surface.
- With gas-releasing concretes (e.g. limestone-rich), melt ejection above a floating crust is considered as an efficient way of cooling the MCCI melt.
- But, a floating crust will sink (or tilt) after a few tons are deposited on it.
- New scenario has been proposed in which melt eruption creates debris that are quenched and continuously remelted in the corium pool.
  - These scenarios differ from classical modelling in which the debris permanently remained cooled by the overlying water
  - More detailed modelling is now necessary to better quantify the effect of these “transient ejection” processes on the MCCI coolability, compared to the classical “permanent ejection”.

ABSTRACT

Small Modular Reactors (SMR) are equipped with several especially passive safety systems to avoid severe accidents as a consequence of transients and incidents. Nevertheless, under specific initial and boundary conditions, severe accidents cannot be excluded a priori. In such cases, core degradation up to melting and relocation including fission product release possibly leading to a source term into the environment have to be taken into account.
In the frame of the EU-funded project SASPAM-SA (Safety Analyses of SMR with Passive Mitigation strategies – Severe Accident) specific severe accident scenarios were identified for two different generic SMR designs, one with a small and one with a large containment. As a consequence of the accident scenarios a specific source term can be estimated for each scenario and SMR design. Therefore, different severe accident codes like AC², ASTEC, MAAP and MELCOR were applied by several organizations. The results of the simulations are compared to evaluate the capabilities of the codes to predict a plausible accident evolution and source term estimation. Based on this comparison, representative source terms were derived for each reference scenario and SMR design, providing valuable input for the definition of emergency planning zone.

KEYWORDS
Generic SMR, Severe Accident, Source Term, Simulation Codes

1. INTRODUCTION

Small Modular Reactors (SMRs) represent a class of the innovative Nuclear Power Plants (NPP) designs to be deployed worldwide in the near future. In Europe, the technological and economical interest for SMRs has been growing in recent years. Activities are going on in several member states aiming at supporting the licensing of such systems. Among the different concepts, the Integral Pressurized Water Reactors (iPWRs) are of particular interest. They are ready to be licensed as new builds, since they integrate several evolutionary features, particularly relying in passive systems, to enhance even further the already high inherent safety. In spite of the advantageous impact of passive safety systems on the first three levels of the Defence-in-Depth (DiD) approach, a systematic a demonstration of iPWR ability to prevent and to manage Severe Accidents (SA) needs to be done (DiD levels 4-5) [1, 2].
In order to fill this gap, the HORIZON-EURATOM 'Safety Analysis of SMR with PAssive Mitigation strategies - Severe Accidents' (SASPAM-SA) project, coordinated by ENEA (Italy), was launched in 2022 and takes the contribution of 23 partners from 13 European countries [3-6]. The main objective of the SASPAM-SA project is to investigate the applicability and transfer of knowledge and know-how accumulated on the operating large-LWR reactors to the iPWRs. These activities are performed in view of European licensing needs relevant to SA and Emergency Planning Zone (EPZ) analyses. SASPAM-SA therefore aims at investigating the key elements to create a European independent point of view on the safety of iPWRs with respect to DiD levels 4 and 5 [1, 2, 3]. The expected project's outcome is to support and speed-up the licensing and siting process of iPWRs in Europe. The pillars of the SASPAM-SA project are topics not addressed in other on-going iPWR initiatives. In particular, the determination of the conditions prevailing in the Reactor Pressure Vessel (RPV) and containment under postulated SA scenarios is an essential element to support any other ongoing investigation within the project.
Two generic design-concepts are considered in SASPAM-SA. The iPWR Design-1 is characterized by a submerged containment and electric power output of ~60 MWe and the iPWR Design-2 of ~300 MWe, which employs several passive systems and a dry containment. Note that it is not the project's objective to assess the design of such concepts. One of the primary goals of SASPAM-SA is the evaluation of the capabilities of integral SA codes and Computational Fluid Dynamics (CFD) tools to simulate the key phenomena occurring in generic iPWR designs. There are differences between iPWRs and the running reactors fleet, like the tighter interaction between the different systems of iPWRs (e.g., primary, containment, and safety systems), which might question the capability of the integral codes to predict such strong thermal-hydraulic (TH) coupling. To name a few: single and two-phase natural circulation in integral RPV, thermal stratification in large pools, primary/containment coupling, in-vessel melt retention, etc. [7-10].
The SASPAM-SA results are documented in several deliverables to which this summary refers to [11]

2. GENERIC SMR DESCRIPTION

The generic iPWR Design-1 and Design-2 considered in the SASPAM-SA project are shown in Figure 1 and Figure 2 and summarized in [11]. The specifications of both designs were determined in the WP2 based on open literature and engineering judgment [7]. Such generic reactor concepts include the main iPWR design features considered in the most promising designs in the European market. Therefore, their employment in the project aims to assess more broadly the capability of codes (SA and CFD) to simulate the SA phenomena typical of iPWR.
The generic IPWR Design-1 reactor here investigated consists of a natural circulation iPWR composed of a shrouded reactor core and riser, an integrated Pressurizer (PRZ), and Helical coil Steam Generators (HSGs) within an integral RPV housed inside a steel containment. The containment is largely immersed in a large pool of water, serving as the Ultimate Heat Sink (UHS). The Emergency Core Cooling System (ECCS) in the iPWR Design-1 consists of two groups of valves allowing the coolant circulation between

RPV and containment during accident conditions: the Reactor Vent Valves (RVV) located at the top of the PRZ and Reactor Recirculation Valves (RRVs) located slightly above the active core.
The iPWR Design-2 Figure 3 is characterized by the use of several passive systems and by a dry containment. The reactor operates in forced circulation during normal operation and employs a passive mitigation strategy in accidental conditions. It consists of an integral RPV, containing the core, HSGs, primary pumps, the Control Rod Drive Mechanism (CRDM), and the PRZ. The hot water at the core outlet flows upwards in a circular riser up to the primary pumps suction located above each HSGs 4.
As mentioned above, the objective of SASPAM-SA is not the assessment of the selected generic iPWR designs. On the contrary, the goal of the project is to investigate and assess the applicability of the state-of-art computation tools to reproduce SA conditions in generic iPWRs and identify code development needs.

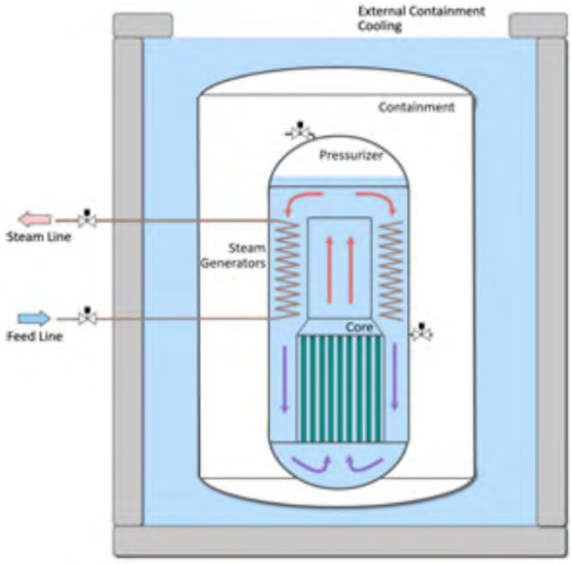

Figure 1. Design 1 layout.

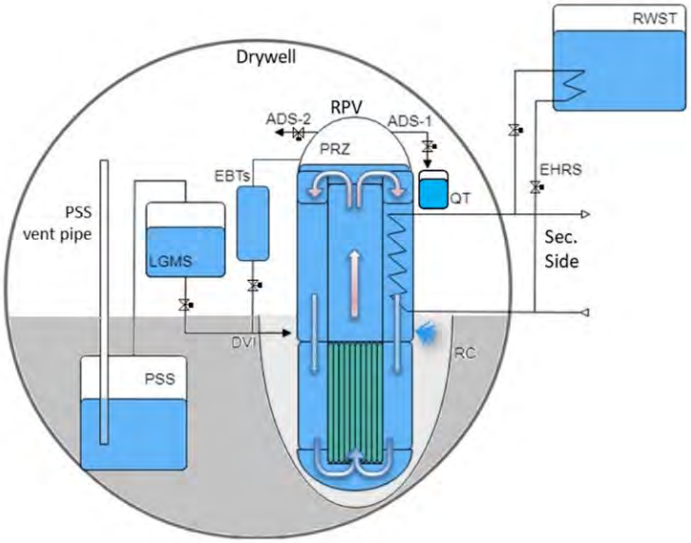

Figure 2. Design 2 layout.

3. INVESTIGATED SCENARIOS

In the following sub-chapter one scenario for each generic design will be described and the main initial and boundary conditions will be summarized.

3.1. Design 1 Scenario

A break is assumed to open at time $t_0 = 0$ s located on the Chemical and Volume Control System (CVCS) discharge line as presented in Figure 3 below.

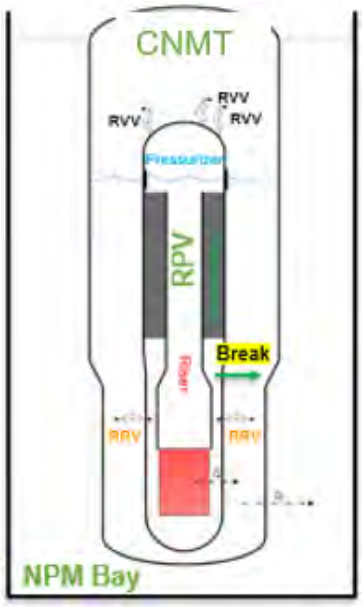

Figure 3. D1-SA1 break localization in the RCS

The break elevation is 3.5 m above the Top of Active Fuel (TAF). The break is discharging from the RCS directly into the Containment (CNMT).

The following events are assumed to happen:

- Loss of AC:
  - Loss of Feedwater (t0 + 5s – valve is open, 5s-10s valve is closing linearly),
  - Loss of CVCS (t0))
- MSIV closure (t0 + 5s – valve is open, 5s-10s valve is closing linearly)

Regarding the systems' availability and actuation:

- ECCS is activated on:
  - Pressure RPV– Pressure CNMT < 62.05 bar
  - AND CNMT Level (collapsed level in EDF MAAP5.04) >5.8 m
- 3 RVVs available (3*0.01266 m²) – Delay between threshold and signal 5s – Opening time 10s (linearly),
- 2 RRVs unavailable

Leakages

From CNMT to Reactor Building

A design leakage of $l = 0.2\%$ of volume/day is considered at P_{CNMT} = 69 bar and T_{CNMT} = 298 K. This is reasonable for this type of metallic containment.
The CNMT volume is assumed VCNMT = 200 m³. The leakage is assumed to be at the top of the CNMT above the level of water in the Reactor Building.

From Reactor Building to Environment

A break at the top of the Reactor Building (RB) is considered to allow fission products to be released into the environment. Sensitivity analyses indicate that, if the break is sufficiently large, its size does not significantly influence the magnitude of the releases to the environment.
The default considered break is 5 m².

3.2. Design 2 Scenario

The selected SA scenario is initiated by the guillotine rupture of the DVI line, along with the failure of all passive systems (Figure 4):

- EBTs,
- LGMSs,
- EHRS, and
- ADS-1.

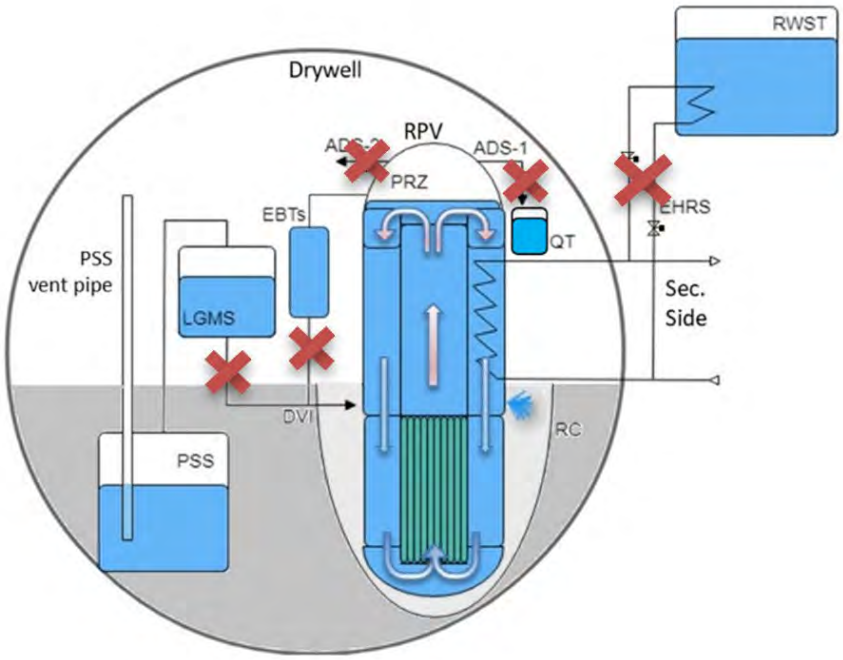

Figure 4. Schematic Scenario of Design 2.

Leakages

From DW to Environment due to design leakages
The design leakages from the containment (DW) have been modeled by "Leak" with flow area of 2.E-07 m2 (equivalent diameter of 0.504 mm) at height of 8,8885 m from the containment bottom floor. This "Leak" is modeled as an open junction with length 1.0 m.
The "Leak" has been modeled as 0.1% containment gas leaked per day at the design pressure.

From the DW Safety Valve and the Filtered Containment Venting System (FCVS) to the Environment
To avoid enormous pressure increasing in the containment it has been modeled a Safety Valve on the DW at relative elevation 10 m. The SV opens at 16 bars and closes at 8 bars. To reach the initial volumetric gas flow rate of 1.9 m^3/s, the cross-section area 0.129 m2 has been adjusted. We developed a filter system with some specific losses. As a result, the initial flow rate is around 1.9 m^3/s. The discharge loss coefficient of 0.75 is assumed. The length of the filter is 50 m.

4. Simulation Results

The progress of simulations and their analyses and evaluation differ for both designs due to complexity and variations in the systems and phenomena considered. Due to that, for design 1 core degradation as well as fission product behavior can be discussed, while for design 2 only a short comparison and evaluation for the thermal hydraulic and core degradation behavior is given.

4.1. Design 1 Results Comparison and First Evaluation

4.1.1. Core Degradation Behavior

This section provides comparison of the main phenomenological event timings obtained by the six partners (EDF, SURO, Tractebel, VTT, RUB, KIT and PSI) for the reference Severe Accident scenario. Although all partners applied the same initiating event and global boundary conditions, the results exhibit noticeable dispersion (Table I). These differences are attributed to variations in system actuation logic, nodalisation detail, code-specific modelling approaches, and assumptions regarding containment–primary coupling. Also, user experience in applying the codes can have an influence on the code performance.

Table I. Key timings – Design 1

Parameter	EDF	SURO	Tractebel	VTT	RUB	KIT	PSI
Start (t0)	0	0	0	0	0	0	0
Scram	2.9	30	3.8	3.6	–	4.3	38
RVVs opening	354	530–545	222	512	1349	297	1886
Core uncover (TAF)	6493	4555	5234	3764	–	1904	2315
H_2 onset	7949	8620	8004	7500	7057	4933	6580.32
Core completely uncovered (BAF)	20908	14190	27500	10920	–	18362	10115
First corium slump	11888	10085	27609	23671	10588	23235	8460

Vessel failure	–	–	–	–	–	-	-

4.1.2. Fission Product Release

Most of the volatile FP are released into the containment (Figure 5 and Figure 6). The overall trends are similar among partners; however, it can be observed that KIT predicts releases approximately one order of magnitude lower than the other participants.
It should also be noted that RUB and SURO report cumulative releases without accounting for radioactive decay, which may partly explain the differences in their trends.
For almost all partners, the predicted releases fall within a similar range, except for Tractebel, whose values are also around one order of magnitude lower compared to the main group.

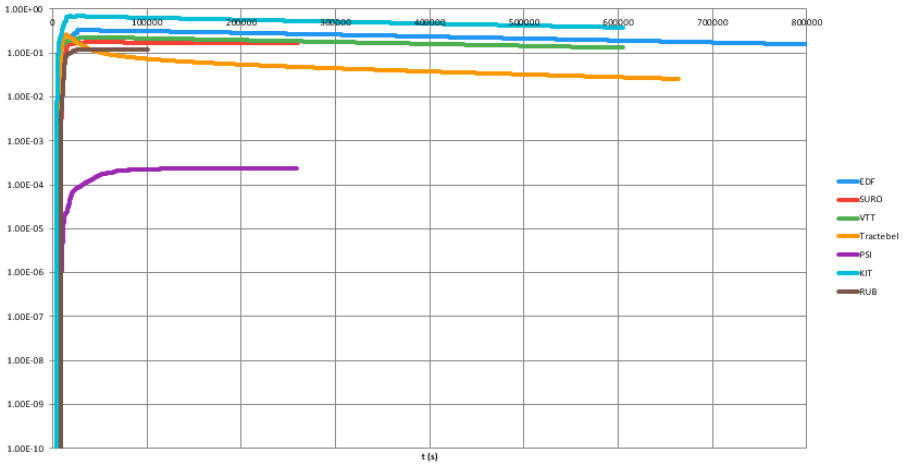

Figure 5. I131 released in Containment – Design 1.

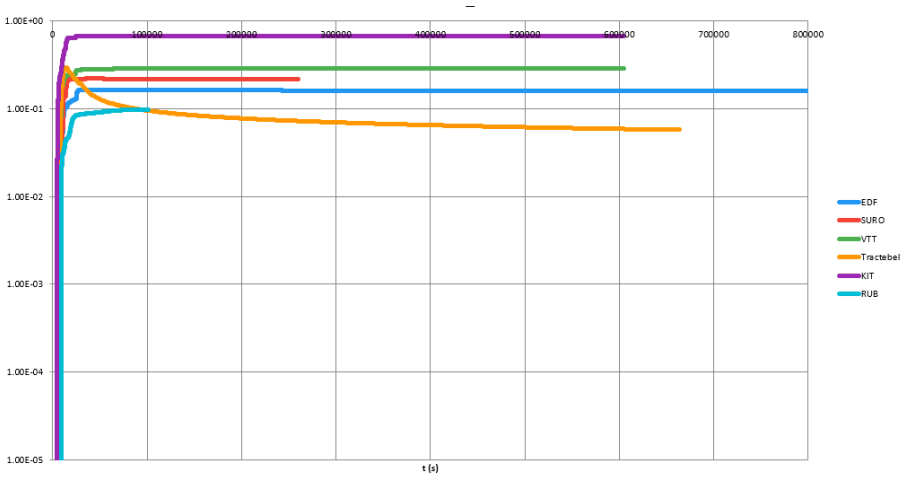

Figure 6. Cs137 released in Containment – Design 1.

Due to the very small leakage rate, the amount of fission products (FP) released to the reactor building (RB) and subsequently to the environment remains low (Figure 7 and Figure 8). For the volatile FP, most codes predict that only a few percent of the initial inventory are released to the environment. For the less volatile FP, the predicted release is on the order of 10^{-3} to 10^{-5} of the initial inventories.
It should be noted that there are significant discrepancies – sometimes several orders of magnitude – between partners regarding releases to the environment. This discrepancy did not appear for releases within

the containment. The leakage flow itself is driven by the CNMT pressure, which differs significantly between partners.

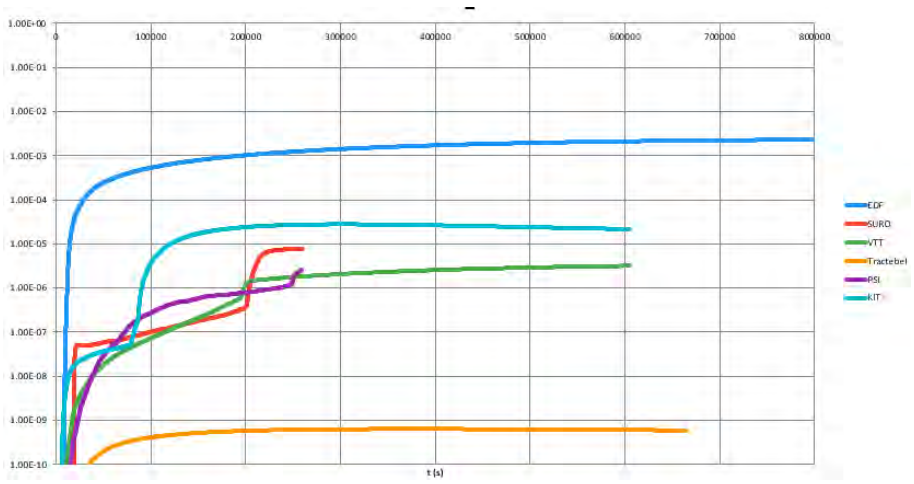

Figure 7. I131 released in Environnement – Design 1.

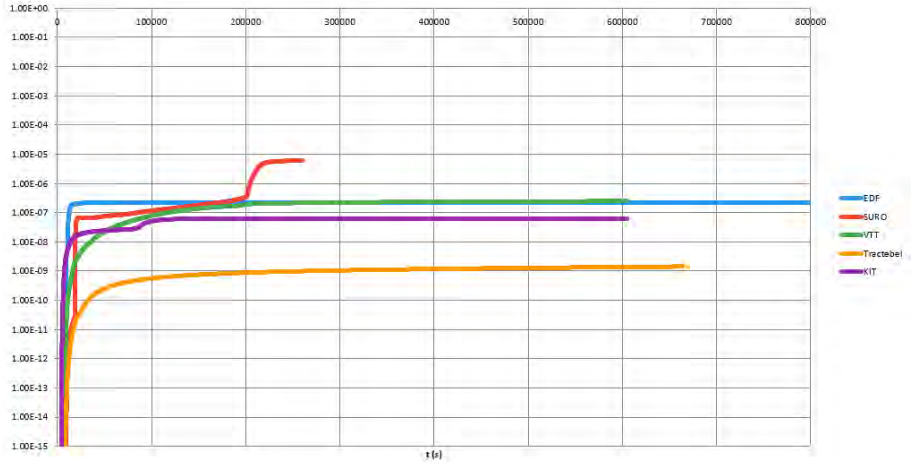

Figure 8. Cs137 released in Environnement – Design 1.

4.2. Design 2 Results Comparison and First Evaluation

The comparison of the results provided by the different partners highlights that, although some results are consistent, others exhibit significant discrepancies. The calculated RPV and containment pressure evolution (Figure 9 and Figure 10), confirming the overall alignment of the simulation approaches. However, noticeable discrepancies emerge in specific time windows, particularly during transient phases. These differences are likely related to variations in modelling assumptions, nodalization schemes, and code-specific correlations (for example the pressure's spike in primary system due to corium slump, or the peak that occurs in INRNE results at approximately 120,000). In the early phase of the transient, most partners' show a similar pressure increase rate, for containment indicating comparable initial conditions and boundary treatments. Some partners predict slightly higher peak pressures, while others exhibit a more damped response, suggesting differences in heat transfer or mass release modelling. For the maximum cladding temperature, Figure 11 shows a similar trend across all partners' calculations, with a similar heat-up phase followed by stabilization. Differences mainly appear in peak values and timing. At the end of the simulation, hydrogen production shows some variability among the partners (Figure 12), although the results remain

within the same order of magnitude, ranging approximately between 270 kg and 430 kg. An exception is observed for ENEA, whose calculation predicts significantly higher hydrogen production, reaching about 660 kg.

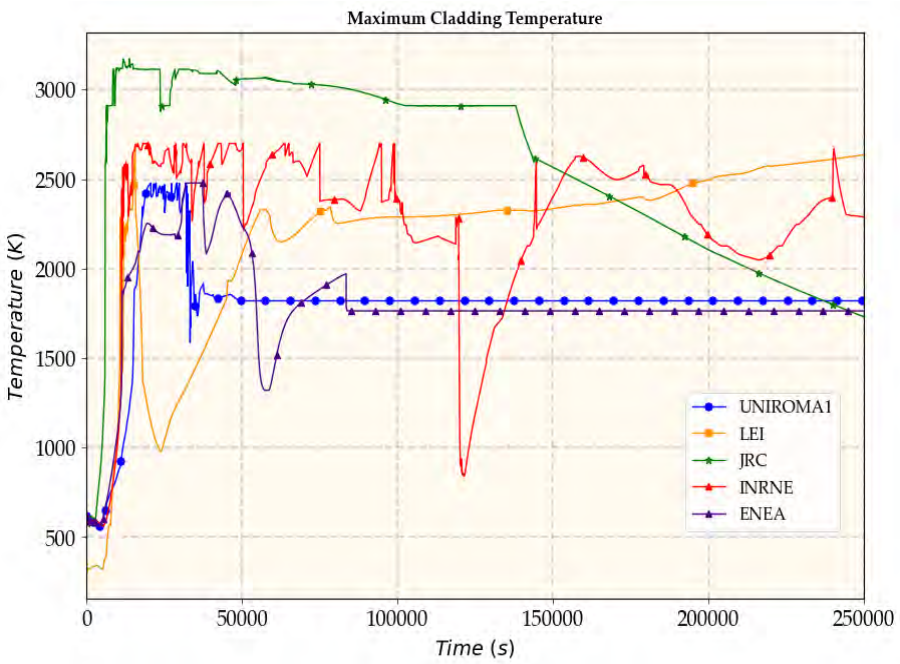

Figure 11. Maximum Cladding Temperature – Design 2.

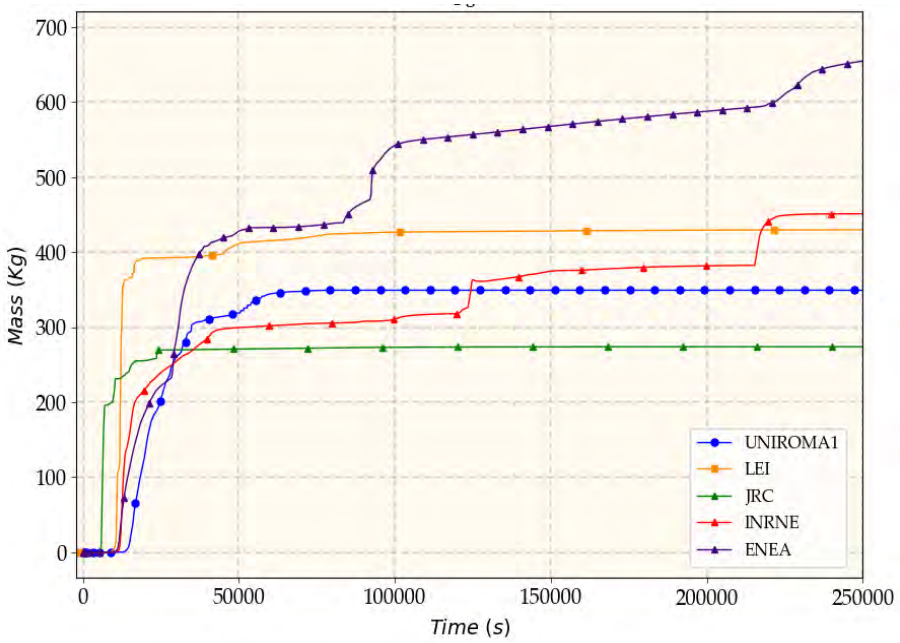

Figure 12. Hydrogen Generation – Design 2.

5. CONCLUSIONS

Design1
All partners reproduce a slow accident progression, with no vessel failure and only limited releases to the environment. Differences in predicted containment pressure and leakage modelling explain the observed variability in environmental releases. Three progression profiles clearly emerge: fast, intermediate, and slow. Overall, these results demonstrate the qualitative robustness of the simulated severe accident sequences while emphasizing the influence of modelling assumptions on quantitative outcomes. They also underscore the importance of continued efforts toward understanding and reducing inter-code differences to improve modelling consistency and enhance confidence in severe accident predictions.

Design 2
The results of the simulations show that although some results are consistent, others exhibit significant discrepancies. This can mainly be explained by different model approaches of the codes even in the core degradation and core relocation phase which has a strong impact on the containment behavior. Additionally, the detail of passive system modelling affects the containment pressure evolution and venting. Further analysis will be carried out regarding fission product behavior and source term estimation.

SASPAM-SA WP5: SOURCE TERM ESTIMATION OF GENERIC SMR DESIGNS

Thorsten Hollands, Jeremy Bittan, Fabio Giannetti

The 12h European Review Meeting on Severe Accident Research (ERMSAR2026)
Madrid, Spain, May 18-22, 2026

Outline

- Introduction to SASPAM-SA Project
- Generic Design Description
- Design-1
  - Investigated Scenario
  - Results
- Design-2
  - Investigated Scenario
  - Results
- Conclusion and Outlook

Introduction to SASPAM-SA Project (I)

- Small Modular Reactors (SMRs) represent a class of the innovative Nuclear Power Plants (NPP) designs to be deployed worldwide in the near future.
- In Europe, the technological and economical interest for SMRs has been growing in recent years. Activities are going on in several member states aiming at supporting the licensing of such systems.
- Among the different concepts, the Integral Pressurized Water Reactors (iPWRs) are of particular interest.
- They are ready to be licensed as new builds, since they integrate several evolutionary features, particularly relying in passive systems, to enhance even further the already high inherent safety.
- In spite of the advantageous impact of passive safety systems on the first three levels of the Defence-in-Depth (DiD) approach, a systematic a demonstration of iPWR ability to prevent and to manage Severe Accidents (SA) needs to be done (DiD levels 4-5)

Introduction to SASPAM-SA Project (II)

- In order to fill this gap, the HORIZON-EURATOM 'Safety Analysis of SMR with PAssive Mitigation strategies - Severe Accidents' (SASPAM-SA) project, coordinated by ENEA (Italy), was launched in 2022 and takes the contribution of 23 partners from 13 European countries [3-6].
- The main objective of the SASPAM-SA project is to investigate the applicability and transfer of knowledge and know-how accumulated on the operating large-LWR reactors to the iPWRs. These activities are performed in view of European licensing needs relevant to SA and Emergency Planning Zone (EPZ) analyses.
- SASPAM-SA therefore aims at investigating the key elements to create a European independent point of view on the safety of iPWRs with respect to DiD levels 4 and 5.
- The pillars of the SASPAM-SA project are topics not addressed in other on-going iPWR initiatives. In particular, the determination of the conditions prevailing in the Reactor Pressure Vessel (RPV) and containment under postulated SA scenarios is an essential element to support any other ongoing investigation within the project.

Structure of SASPAM-SA Project

- Three generic design-concepts are considered in SASPAM-SA:
  - The iPWR Design-1 is characterized by a submerged containment and electric power output of ~60 MW_e.
  - The iPWR Design-2 of ~300 MW_e, which employs several passive systems and a dry containment.
  - The BWR Design-3 of ~300 MW_e

Introduction to SASPAM-SA Project (III)

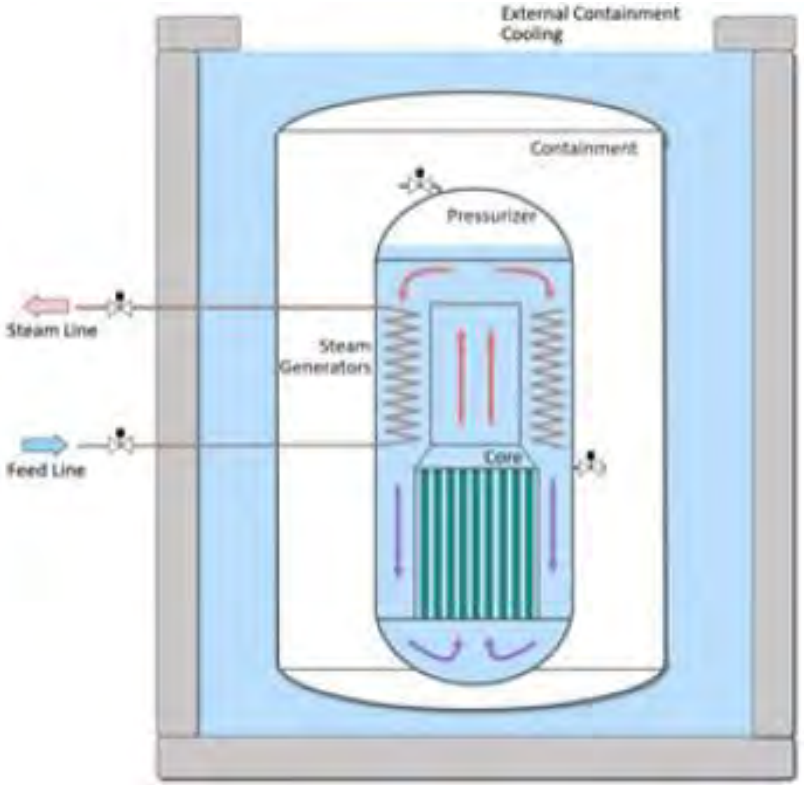
- Three generic design-concepts are considered in SASPAM-SA:
  - The iPWR Design-1 is characterized by a submerged containment and electric power output of ~60 MW_e.
  - The iPWR Design-2 of ~300 MW_e, which employs several passive systems and a dry containment.
  - The BWR Design-3 of ~300 Mw_e.

- This paper focuses only on the Designs-1 and -2 due to project progress.

- Focus of WP5 is the investigation of the containment behaviour and the source term evaluation to the environment.

Structure of SASPAM-SA Project

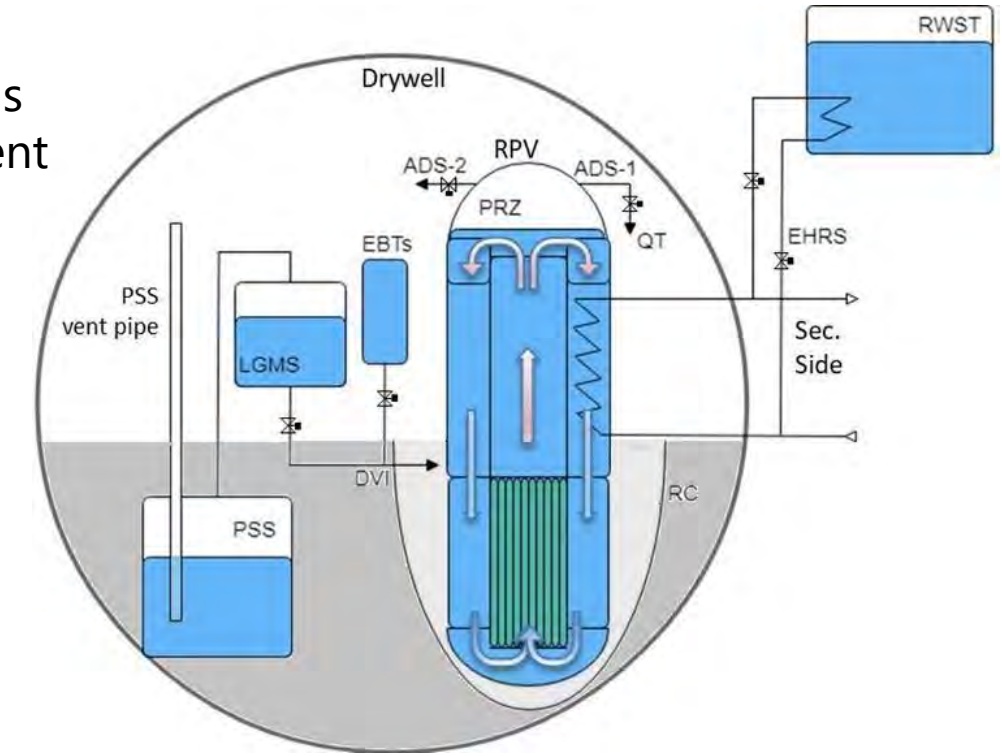
iPWR Design-1
Submerged containment, P~60 MWe



Currently generic only

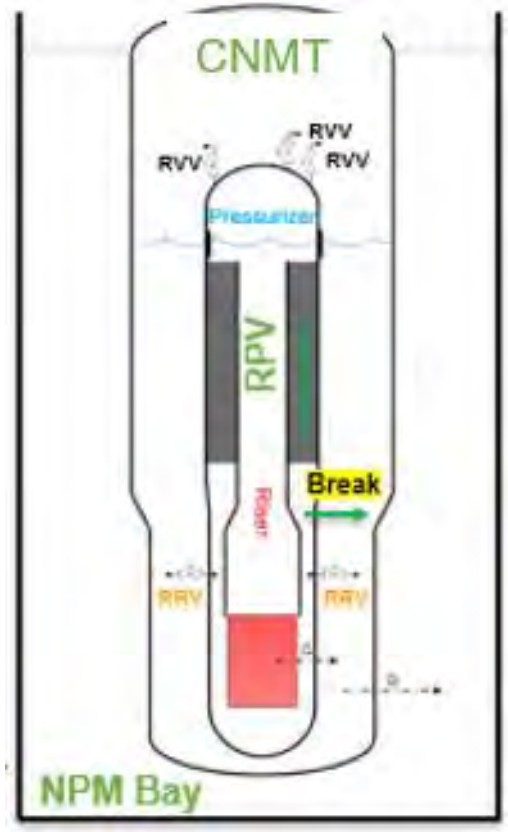
Both iPWR designs **but** e.g containment safety measures differ clearly, e.g. Pressure Suppression System vs. Water Wall.

iPWR Design-2
Dry containment, several passive systems, P~300 MWe



Design-1: Investigated Scenario (I)

- A break is assumed to open at time t0 = 0 s located on the Chemical and Volume Control System (CVCS) discharge line
- The break elevation is 3.5 m above the Top of Active Fuel (TAF). The break is discharging from the RCS directly into the Containment (CNMT).
- The following events are assumed to happen
  - Loss of AC
    - Loss of Feedwater (t0 + 5s – valve is open, 5s-10s valve is closing linearly),
    - Loss of CVCS (t0)
  - MSIV closure (t0 + 5s – valve is open, 5s-10s valve is closing linearly)



Design-1: Investigated Scenario (II)

- Regarding the systems' availability and actuation:
  - ECCS is activated on:
    - Pressure RPV– Pressure CNMT < 62.05 bar
    - AND CNMT Level (collapsed level) >5.8 m
  - 3 RVVs available (3*0.01266 m^2) – Delay between threshold and signal 5s – Opening time 10s (linearly),
  - 2 RRVs unavailable
- Leakages
  - From CNMT to Reactor Building

    A design leakage of l=0.2%" of volume/day
  - From Reactor Building to Environment

    A break at the top of the Reactor Building (RB) is considered to allow fission products to be released into the environment

ABSTRACT

The HORIZON-EURATOM SAPSAM-SA project, coordinated by ENEA (Italy), was launched in 2022 aiming at investigating the applicability and transfer of knowledge and know-how accumulated on the operating large-LWR reactors to the iPWRs, in view of the European licensing needs with respect to severe accident and Emergency Planning Zone (EPZ). Two generic iPWR concepts are considered in SASPAM-SA: the iPWR Design 1 is characterized by a submerged containment and electric power of approx. 60 MWe and the iPWR Design 2 of approx. 300 MWe, which employs several passive systems and a dry containment.
The analytical efforts by PSI were focused on Design 1. For this reactor, we investigated several DBA and severe accident scenarios. For the present work, a containment by-pass scenario was selected. In this, transport of iodine from the core to the reactor pool and subsequent potential release of gas phase iodine from the reactor pool were analysed. In the containment by-pass scenario, a break was assumed in a line below the water level of the reactor pool. Iodine concentration in the reactor pool was simulated with MELCOR, and used as an initial condition for iodine chemistry analysis using the IMPAIR code. IMPAIR accounts for formation of elemental iodine and organic iodides from iodide in water, and their subsequent release to the gas phase. In beginning of the IMPAIR calculation, all iodine in the reactor pool water was assumed in the form of iodide I-. The releases of iodine I2 and CH3I from the water to the reactor building atmosphere were analysed.

1. INTRODUCTION

One of the key challenges in best-estimate severe accident analyses is the evaluation of the iodine source term. Due to iodine's high reactivity and complex physico-chemical behaviour during release and transport, predicting its speciation and the fraction ultimately discharged to the environment is associated with high uncertainty and remains key subject of study [1][2][3][4]. At the same time, iodine remains one of the most safety-relevant radionuclides in nuclear accidents, since it largely determines early off-site radiological consequences and directly influences emergency and mitigation measures implemented during and shortly after the accident. Under severe accident conditions, iodine released into containment/reactor pool/reactor building water may undergo complex radiation-induced chemistry. In particular, iodide can be oxidized to volatile molecular iodine (I_2) under radiolytic conditions, while the presence of organic materials may promote the formation of volatile organic iodides such as methyl iodide (CH_3I)[1]. These processes strongly affect iodine volatility, transport, and the fraction ultimately released to the environment, and therefore represent a major source of uncertainty in source term evaluation.

The SASPAM-SA project focuses on the applicability and usability of analytical methods developedfor classic Nuclear Power Plant (NPP) designs to SMRs (small modular reactors), and specifically, iPWRs (integrated pressurized water reactors) [5]. In SASPAM-SA, two designs of iPWRs are addressed, Design 1 which is characterized by a submerged containment and electric power of approx. 60 MWe and the iPWR Design 2 of approx. 300 MWe, which employs several passive systems and a dry containment. Due to unique features of iPWRs, and differences between the considered Design1 and Design2 concepts and modern Generation III/III+ reactor technologies, additional modelling approaches should be tested and assessed. One of the key distinctive features of iPWR Design1 is the presence of a Reactor Pool (RP), in which the reactor vessel is submerged. This pool may act as an Ultimate Heat Sink (UHS) and, importantly, it can also contribute to radionuclide retention if releases occur underwater. Therefore, understanding iodine behaviour in the pool is essential for realistic source term evaluation and for assessing the mitigation potential provided by this design feature.

To evaluate potential releases from a hypothetical severe accident scenario to the reactor pool, a bypass-type scenario was selected and analysed (described in the following chapters). Integral severe accident codes such as MELCOR apply a lumped-parameter approach to represent the reactor systems and containment, which enables efficient simulations but inherently limits the spatial resolution of key phenomena governing fission product transport, deposition, and resuspension. Although MELCOR includes mechanistic models for aerosol behaviour and radionuclide class transport, the prediction of iodine source term remains particularly challenging due to the complex coupling between phase transfer, water chemistry, and radiolytic reactions controlling iodine speciation and volatility [6]. As a consequence, iodine release fractions and transport predictions may remain affected by significant modelling uncertainty, especially for scenarios involving releases into water pools where, as mentioned, iodine chemistry plays a dominant role.

In this paper, the authors evaluate iodine behaviour following releases from the Reactor Coolant System (RCS) of SASPAM-SA Design 1 into the reactor pool, and subsequently through the Reactor Building (RB) towards the environment, with a particular focus on the influence of water chemistry in the pool on the overall iodine source term. To address these challenges, the European code IMPAIR was implemented to model iodine behaviour in the reactor pool, including speciation and key chemical processes similar to previous work on MELCOR and iodine behaviour [6][7]. The iodine releases are planned to be used in a follow-up work as input for atmospheric dispersion and consequence assessment using the winMACCS code. This combined, more comprehensive approach allows the pool chemistry effects to be explicitly taken into account, which is crucial for iPWR-Design1 where underwater releases and retention mechanisms may play an important role in mitigating environmental consequences.

2. MODEL AND SCENARIO DESCRIPTION

2.1. Codes

In this work two codes were applied in a sequential manner, a) MELCOR to calculate severe accident progression in iPWR (SASPAM-SA Design1), b) IMPAIR to evaluate Iodine behaviour in the reactor pool.

a) MELCOR [8][9]

MELCOR is an integral severe accident analysis code developed by Sandia National Labolatories in USA to simulate the progression of severe accidents in nuclear reactors, including thermal-hydraulic response, core degradation, reactor vessel failure, fission product release, transport, containment

behaviour. The code applies a lumped parameter approach, representing the reactor coolant system and containment as interconnected control volumes and flow paths, which enables efficient calculation of a wide range of accident scenarios. MELCOR includes models for aerosol behaviour and radionuclide class transport, however the representation of iodine chemistry and detailed pool-scrubbing mechanisms is limited, which may contribute to uncertainties in iodine speciation and source term predictions.

MELCOR input deck used in this study is adapted input deck utilized in previous SASPAM-SA work see in Figure 1 [10][11]. The iPWR is characterized by an integrated reactor pressure vessel (RPV), in which the reactor core, pressurizer, and two helicoidal steam generator loops are housed within a single vessel, eliminating the need for reactor coolant circulation pumps. The RPV is enclosed within a second pressure vessel that serves as the primary containment and is maintained under near-vacuum conditions during normal operation. The entire reactor module is located inside a reactor pool and the reactor building, providing additional passive safety features and heat removal capabilities. Main updates are added design leakage from the top of the containment pressure vessel to the reactor pool (not underwater) and updated initial inventory based on the SASPAM-SA project deliverables.

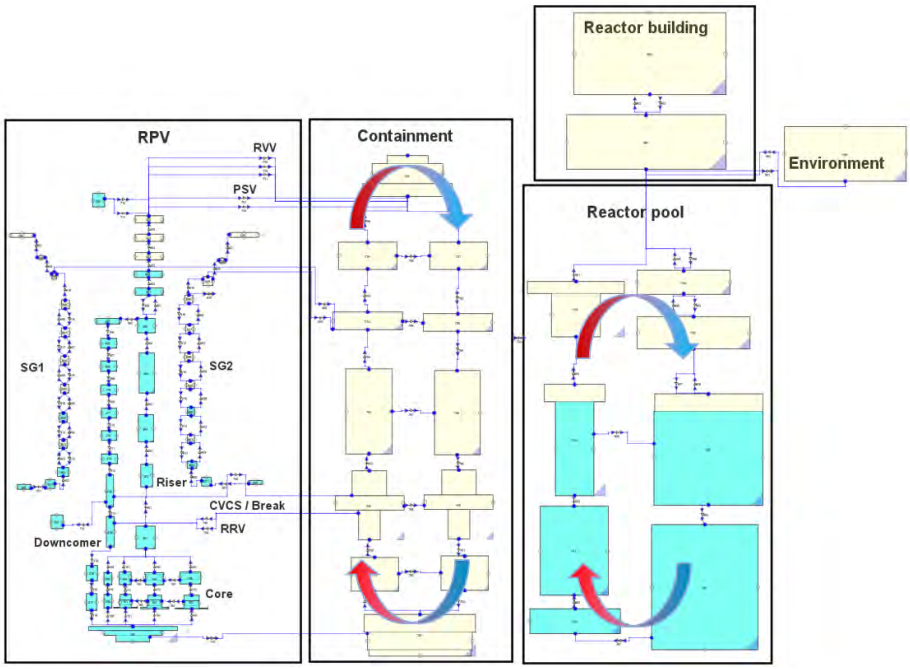

Figure 1 Schematic MELCOR nodalization of Design 1 - iPWR

b) IMPAIR [12][13]

The European iodine chemistry code Iodine Matter Partitioning And Iodine Retention (IMPAIR) is code dedicated to modelling iodine behaviour in aqueous pools under severe accident conditions, with emphasis on chemical speciation, phase partitioning, and processes governing iodine volatility [12]. Compared to MELCOR, IMPAIR allows a more mechanistic treatment of iodine transformations in water, including the influence of water chemistry and relevant reaction pathways. IMPAIR was used to calculate the release of I2 and CH3I from the reactor pool water. This code is designed to simulate iodine chemistry in a light water reactor containment under severe accident conditions, including the sump, deposition processes, and the containment atmosphere. As mentioned in [12] the model is based on 29 coupled differential equations and 69 kinetic rate constants, which describe the time dependent behaviour of multiple iodine species in both the aqueous sump and the gas phase. In addition to chemical reactions and equilibrium processes, the code accounts for key transport mechanisms such as aerosol

dynamics, mass transfer of elemental and organic iodine, and droplet carry-over during pressure relief and venting operations [12].

In this study, IMPAIR was used to evaluate iodine retention and speciation in the iPWR Reactor Pool following releases from the RCS and containment pressure vessel due to containment by-pass type scenario, providing refined source term information for subsequent transport and consequence assessment. Iodine chemistry, considering the reactions and rate constants as *given in Table I was* modeled.

2.2. Scenario description

The scenario implemented in MELCOR calculation is a chemical volume control system (CVCS) line break between Reactor Pressure Vessel (RPV) and reactor pool at around 7 m from the bottom of containment, which is followed by SCRAM with a partially functioning emergency core cooling system (ECCS). Only Reactor Ventilation Valves (RVV) on the top of the pressurizer were activated, which allowed some steam to condense in the containment. The break discharged the rest of the RCS coolant directly into the reactor pool. Steam condenses in the reactor pool, which heats up till saturation temperature. The reactor building filled up with steam, and as it is open to the environment (defined as

a constant control volume), exchanges the atmosphere freely. The whole scenario is calculated for 70 h.

3. RESULTS AND DISCUSSION

The accident could be divided into three phases, i) core degradation which ends with total corium relocation to the Lower Plenum (LP) at 43995 s, ii) in-vessel corium cooling when corium stays in lower plenum till 216800 s, when it is cooled by steam circulation inside RCS and outside by condensate water in the containment, and iii) vessel failure phase when corium relocates to containment pressure vessel, see Table II. After RPV failure water from the pool floods RCS and Containment.

Table II List of main events during the analysed accident scenario.

event	Time [s]	Time [h]
CVCS break	0	0.00
SCRAM	40	0.01
ECCS activation (only RVV)	514	0.14
Onset of active core uncovery	516	0.14
Onset of H2 generation	2566	0.71

RPV failure	216800	60.22
RPV and containment reflooding	239040	66.4

Seevere accident progession

In the first phase due to core uncovery and compromised cooling of RCS, core peak cladding temperature (PCT) reaches ~2500K. The core degrades entirely in less than 12.5 h (PCT drop in Figure 2). Even with the corium fully relocated to LP, one can see that vapour is extracting a significant amount of energy as the difference between inlet and outlet temperature is around 500 K until vessel failure at ~60 h when this difference decreases rapidly. The mass flow rate through the break after the flow peak at verry beginning of the transient, fluctuates during the degradation phase and the fluctuation in the circulation pattenrs cause minor back flow from pool to the RCS, see Figure 3. The natural circulation disturbance seen in Figure 4 are on the downcomer side until around 6-7 h of the transient, when the lower plenum is still under water, which blocks circulation patterns which lead to a decrease of cooling efficiency and extensive oxidation, see Figure 5. At around 6 h, corium starts to relocate to the lower plenum which cause water level in LP rapidly decreasing and opening the RCS circulation patterns. During this period, main fraction of H2 and radionuclide releases occur, see Figure 5. After ~60 h when vessel fails, rest of the water in the containment evaporates and around 66 h back flow from the pool is flooding RPV and Containment cooling down the system.

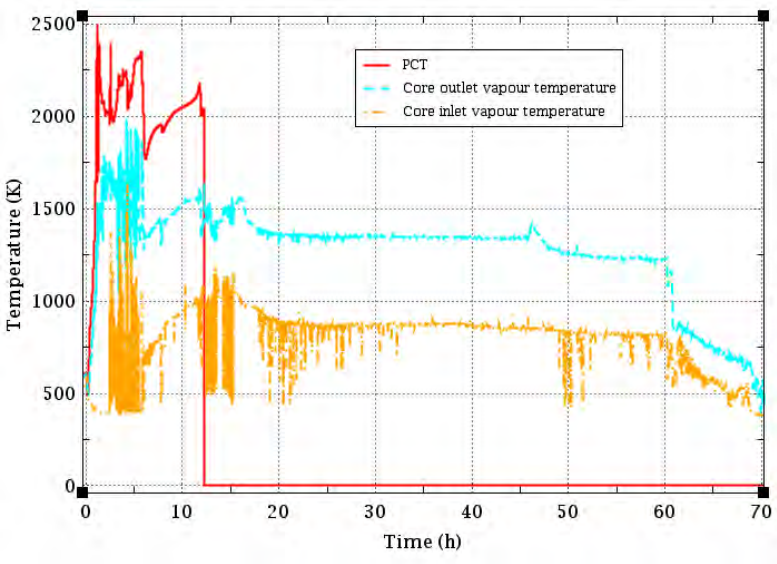

Figure 2 Temperature evolution during accident simulation, PCT, core inlet and outlet vapour temperature

This hypothetical transient was designed to provide a radionuclide source term to the reactor pool to estimate releases to the environment through the pool. The release path from RCS is a CVCS line break but besides this, there is also design leakage from containment to reactor pool (above water surface), however, as main RCS depressurization is going through the break, design leakage releases are negligible (but still added to the presented results). In this paper, the main focus is on I2 and CsI, which are modeled in MELCOR as separate classes. CsI is generated by combining I2 class and Cs class when they are released in the same core cell and timestep. In MELCOR, we can plot parameter RN1_TYCLT (Radioactive mass of a given radionuclide RN class in all control volumes of a certain type, including mass deposited on heat structures associated with the control volumes). In Figure 6, the mass of RN class 4,– I2, and RN class 16; CsI; is presented for all CVHs outside of RCS. This means it is conservatively all mass of RNs from Reactor Pool, Reactor Building and Environment. One can see that mass of I2 is extremely small as most of I2 reacted with Cs; thus it was released from the RCS as CsI. Comparing Figure 5 and Figure 6, it is clear that there is no late releases from fuel/corium but vessel failure causes additional releases to the reactor pool due to evaporation of residual water in containment and refooding of the RCS and Containment by water from the pool.

In Figure 6, the iodine released from the containment to the reactor pool as % of initial inventory (ii) is presented for I2, CsI and the total iodine. One can see that around 30% of ii is released outside of the containment pressure vessel, and the majority of those releases is done through the underwater break. In these MELCOR calculations, pool scrubbing was not turned on as the assumption was to use maximum releases for IMPAIR calculations.

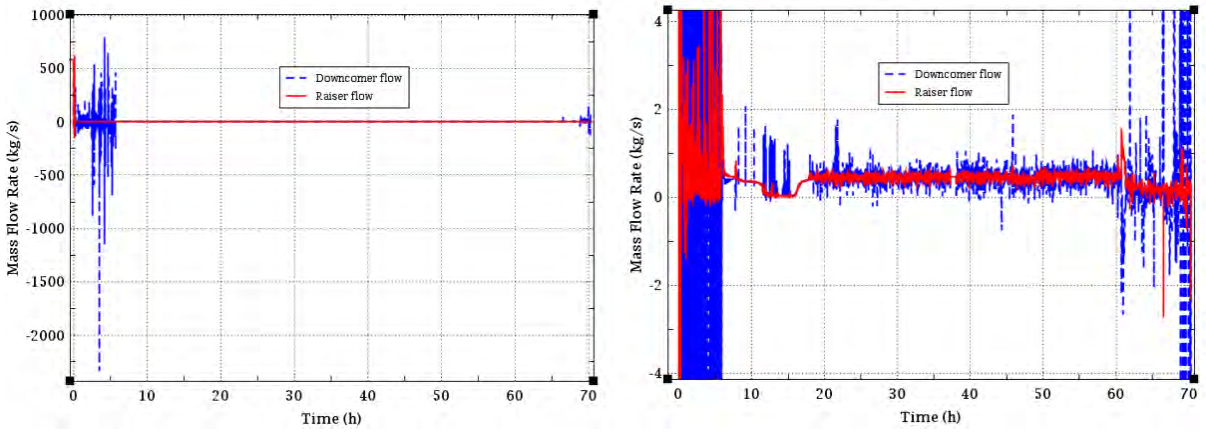

Figure 4 Mass flow rate thorught riser and downcomer (positive value - flow in design direction), full scale on the left zoom on the right.

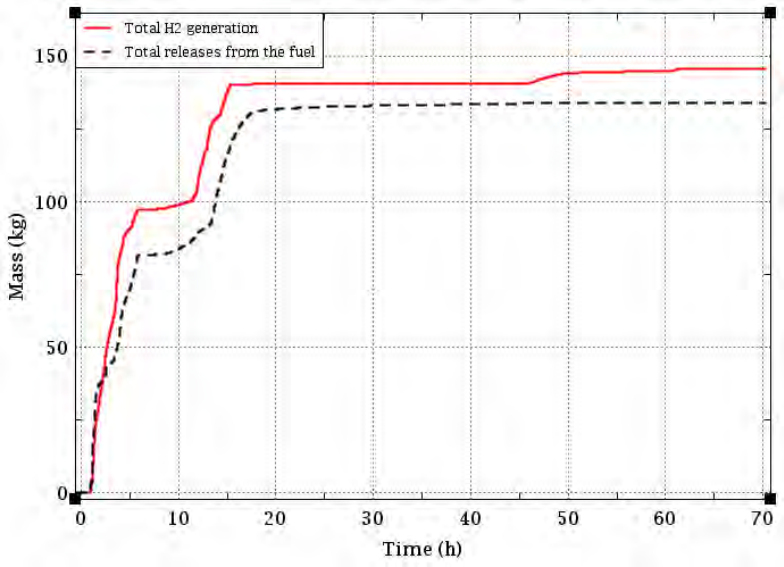

Figure 5 H_2 generation and radionuclide releases in simulated scenario.

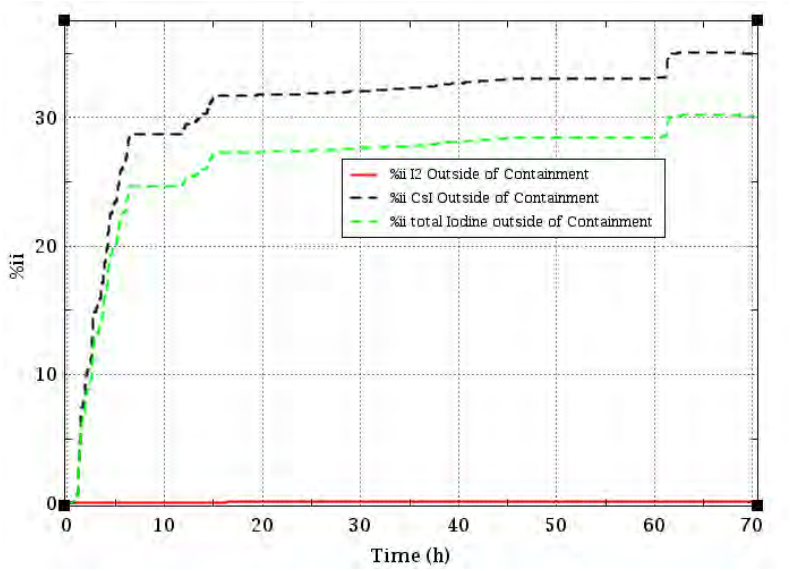

Figure 6 The % of initial inventory released from Containment for I2 and CsI and total Iodine (I2 plus I from CsI).

IMPAIR analyses

The iodine concentration in the pool water was taken from the MELCOR analysis as total iodine transported to the reator pool. The containment by-pass was assumed below the pool water level, enabling all the flow from the reactor to enter the pool. To calculate water phase reactions leading to the formation of gas phase iodine, approximately 30% of initial inventory of iodine was assumed in the pool water as shown in the above MELCOR analysis. Note that this corresponds to the total iodine mass at the end of MELCOR calculation from two RN classes, I2 and the calculated fraction of iodine from class CsI, see Figure 6 – total iodine outside of the containment. The major fraction of iodine is in the form of CsI.

Decontamination by pool scrubbing is not calculated in this first analysis, instead, all the iodine species are assumed to be scrubbed by the pool water. This assumption gives a slightly higher iodine concentration in the pool water than a best estimate using a realistic decontamination factor (DF) for iodine in the pool water which could be on the order of DF=10-100.

All iodine in the water was assumed to be in the form of iodide I- in the beginning of the calculation. This assumption is justified as the major fraction of iodine enters the pool as CsI which is soluble in water. The IMPAIR calculations were performed for 107 s (2778 hours; 114 days).

The following initial and boundary conditions were assumed:

- Water volume: 1618 m3
- Air volume: 538 m3
- Pool and air temperature T: 353 K
- Iodide in the pool water: 4.14 x 10-6 mol/l (0.30 i.i.)
- Low molecular weight organic iodides in the pool water: 1 x 10-5 mol/l
- pH = 5.0, 7.0, 9.0

- Dose rate = 3.0 kGy/h (water and air)
- Surface painted steel
- Reactor building/pool open to the environment with the leak rate of 0.0455 kg/s

The time evolution of the total gas phase iodine mass assuming pool building walls as painted steel surfaces was calculated at three pH values, 5.0, 7.0 and 9.0, Figure 7**Error! Reference source not found.**. As expected, pH had a major effect on formation of gas phase species. It is noticed that within the calculated timeframe, only a small amount of iodine is released from the pool water as gas phase species.

The main iodine species in the pool water were I- and IO3-, Figure 8. The pH dependence is observed in the rapid decrease of I- in the pool water with a low pH of 5.0 whereas with higher pH, after a rapid decrease of I- in the water, the concentration decreases only slowly, Figure 9.

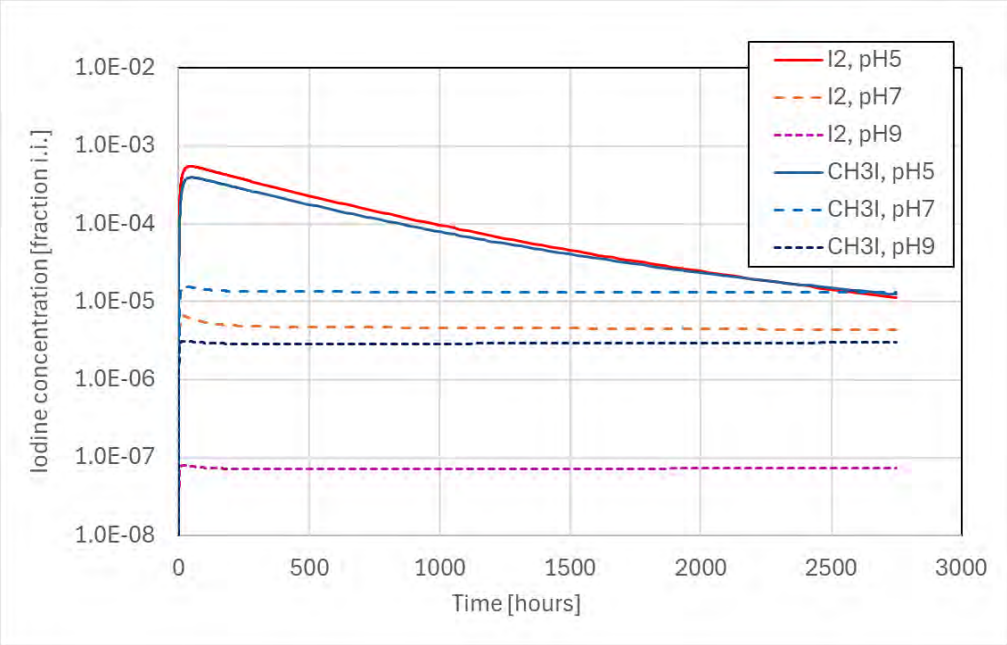

Figure 7 Evolution of Iodine concentration depends on pool pH.

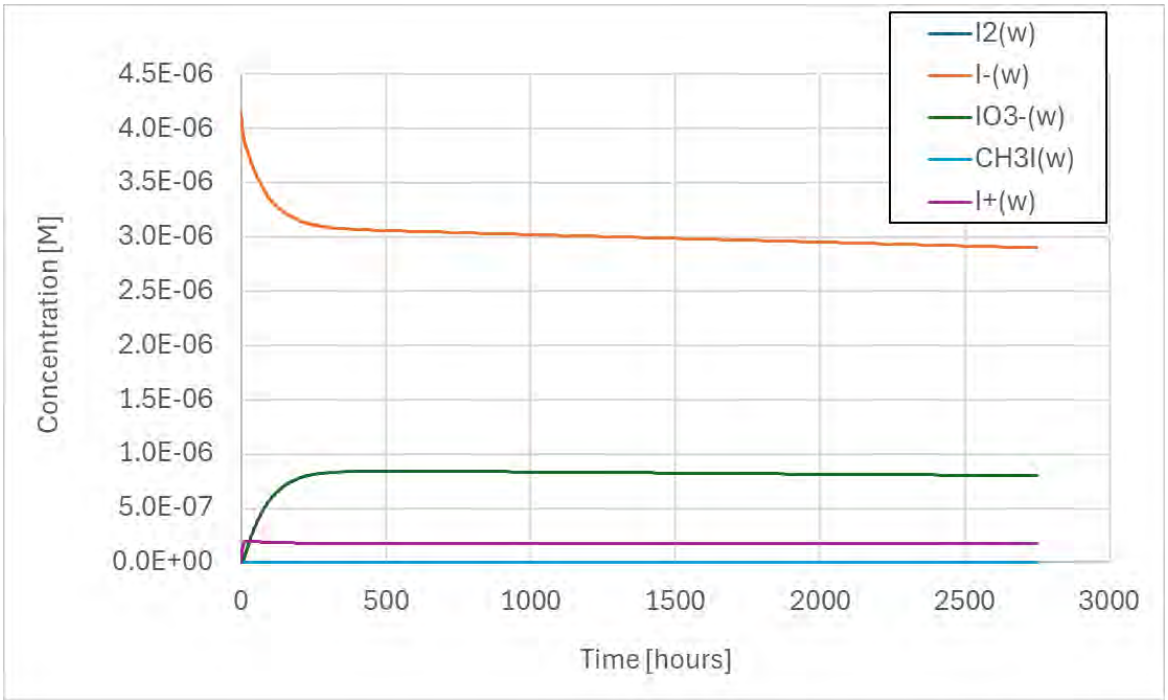

Figure 8. The main iodine species in the pool water with pH=7.0

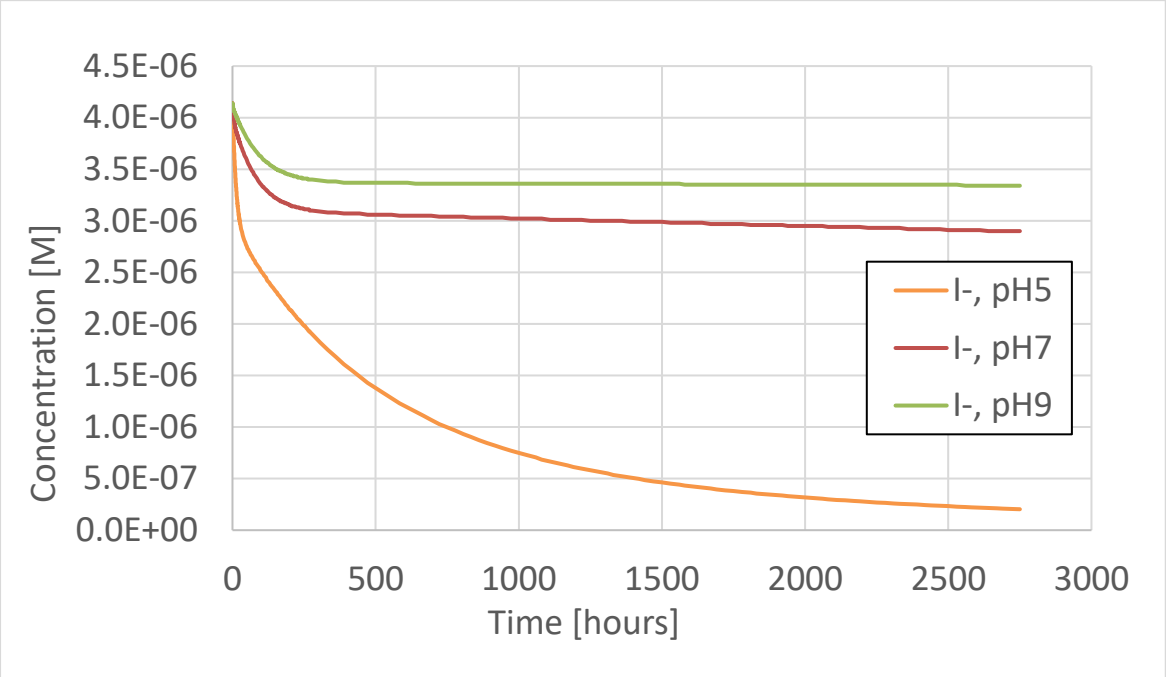

Figure 9. Time evolution of I- as the main iodine species in the pool water with pH = 5, 7 and 9

4. CONCLUSIONS

The presented analyses of a hypothetical severe accident scenario implement a bypass-type configuration in which RCS coolant is released directly into the reactor pool. The results demonstrate that MELCOR is capable of simulating this rapid accident progression and provides reasonable predictions for core degradation, in-vessel cooling, and vessel failure phases. Natural circulation within the RCS contributed to corium cooling even after core uncovery; however, due to flow blockages and unstable circulation, cooling was insufficient, ultimately leading to full core degradation and relocation

of molten material to the lower plenum. Extensive core degradation resulted in significant hydrogen and radionuclide releases, with the majority transported out of the RCS by the steam flow.

The molten pool in the lower plenum after approximately 45 h (from ~5-60h of transient) led to reactor vessel failure as a consequence of insufficient cooling caused by limited water inventory in the containment pressure vessel. Following relocation of the molten material into the containment, evaporation of the remaining condensate occurred, and after approximately 6 hours the pressure in the RCS decreased sufficiently to allow backflow from the reactor pool into the RCS. This backflow resulted in reflooding of both the RCS and the containment, effectively cooling the system.

This hypothetical scenario was used to estimate iodine releases into the reactor pool and to assess the applicability of the IMPAIR code in the evaluation of gas phase iodine release from the pool to the reactor building and the environment. In this initial analysis, all iodine released to the containment at the end of the MELCOR simulation was assumed by IMPAIR in the form of iodide (I^-) in the pool water. IMPAIR calculations were performed for three pH values (5, 7, and 9). Long-term simulations (114 days) demonstrate a strong pH dependence of iodine behaviour; however, only a small fraction of iodine was released to the gas phase within the analysed timeframe. Iodide and iodate (IO_3^-) were the dominant aqueous species, with a faster depletion of iodide observed at pH 5 compared to neutral and alkaline conditions.

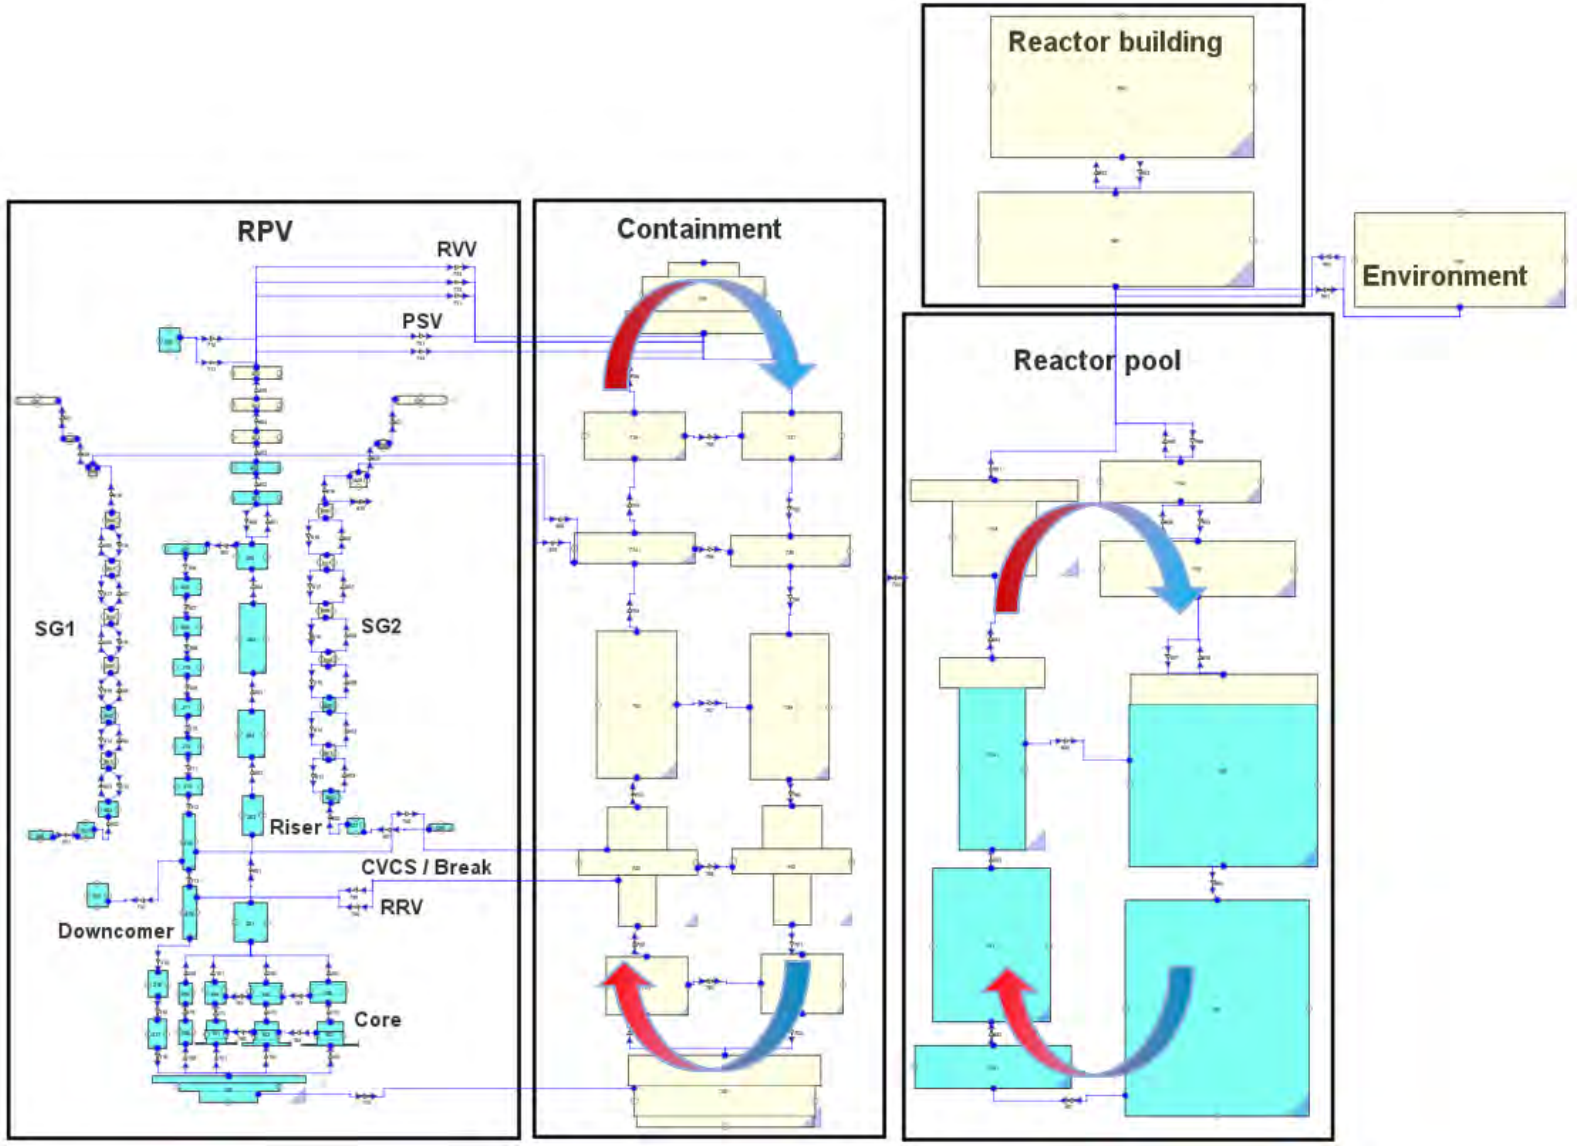
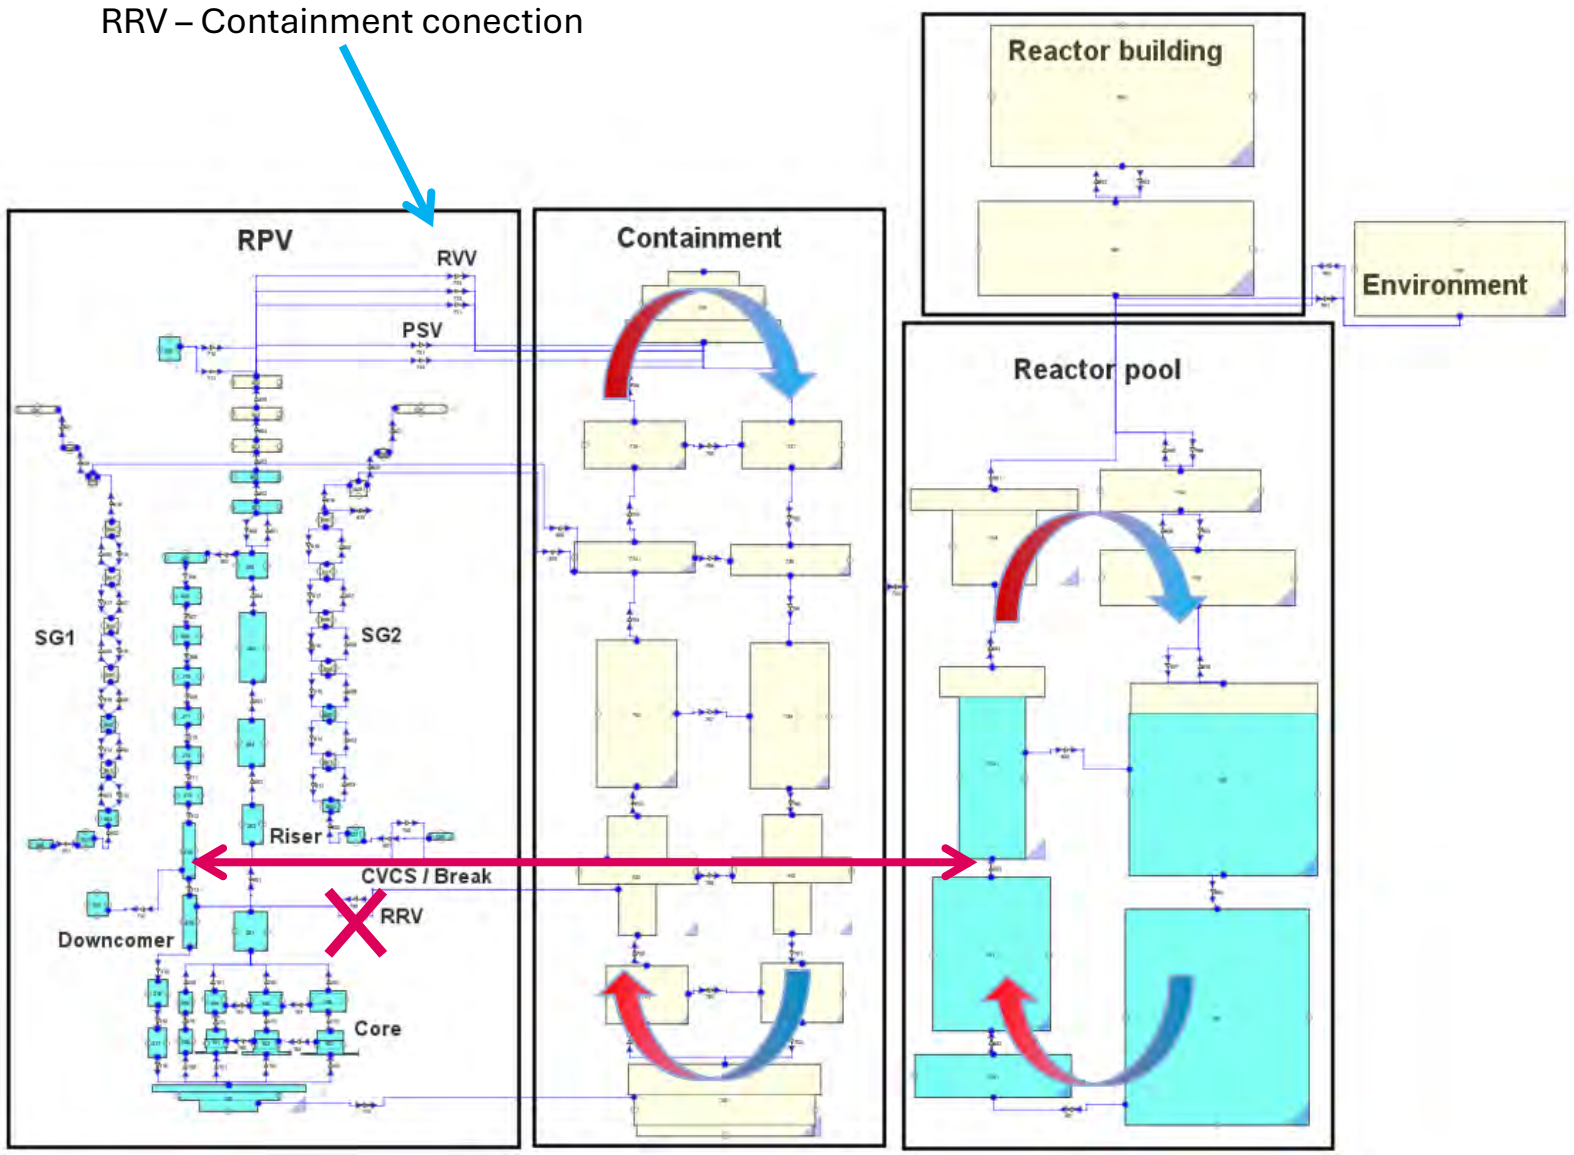
SASPAM-SA - Design 1

- Main objective of this task was to evaluate relases from iPWR to asses potential EPZ.
- To do so, we needed to assume hipotetical bypass accident.
  - Releases directelly to the reactor pool.
  - All iodine transportet to the water

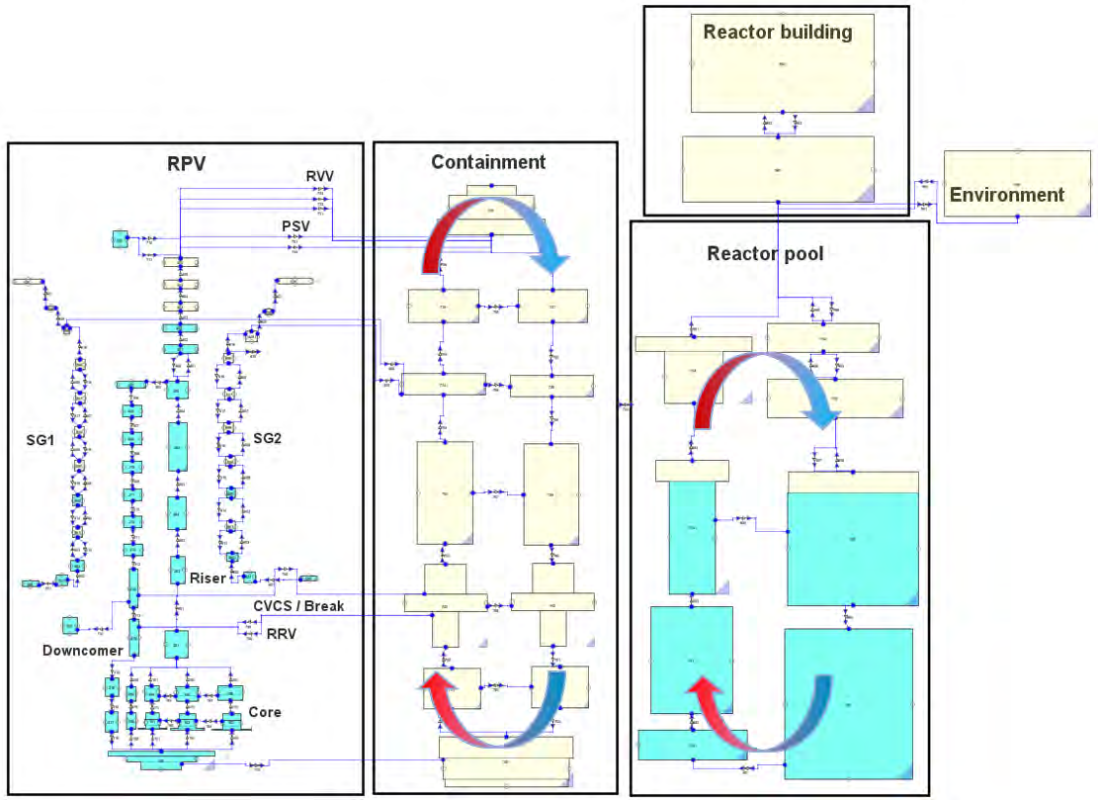


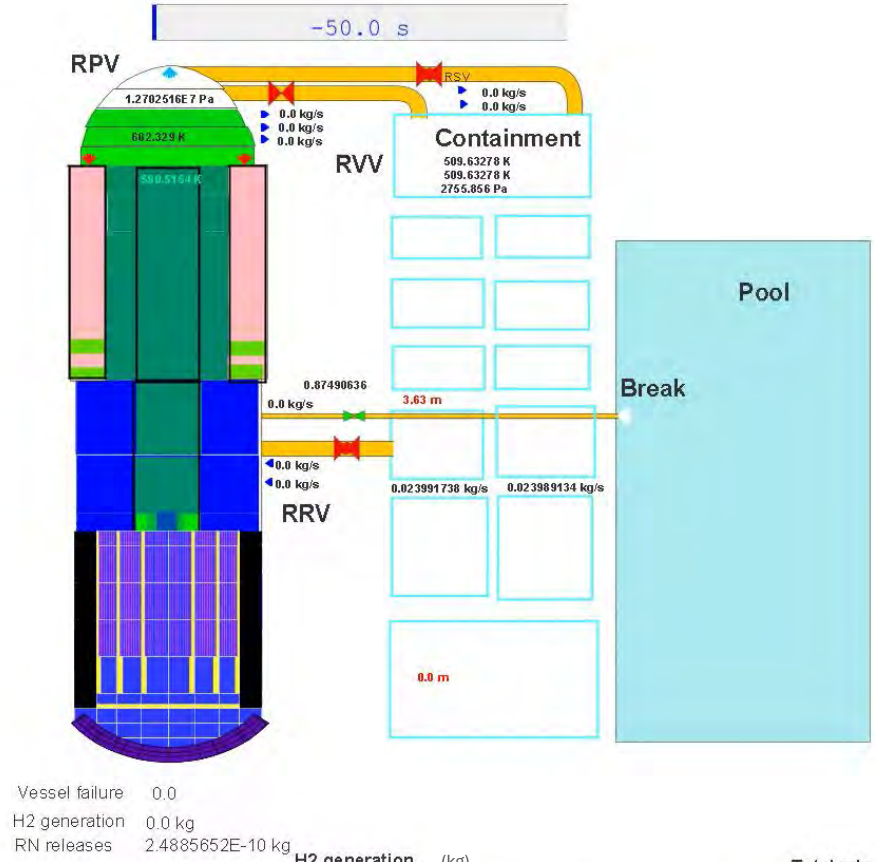
SASPAM-SA - Design 1

- Design 1 – iPWR:
  - Integral design
  - Passive safety systems
  - Submerged containment vessel
- Scenario – SBLOCA:

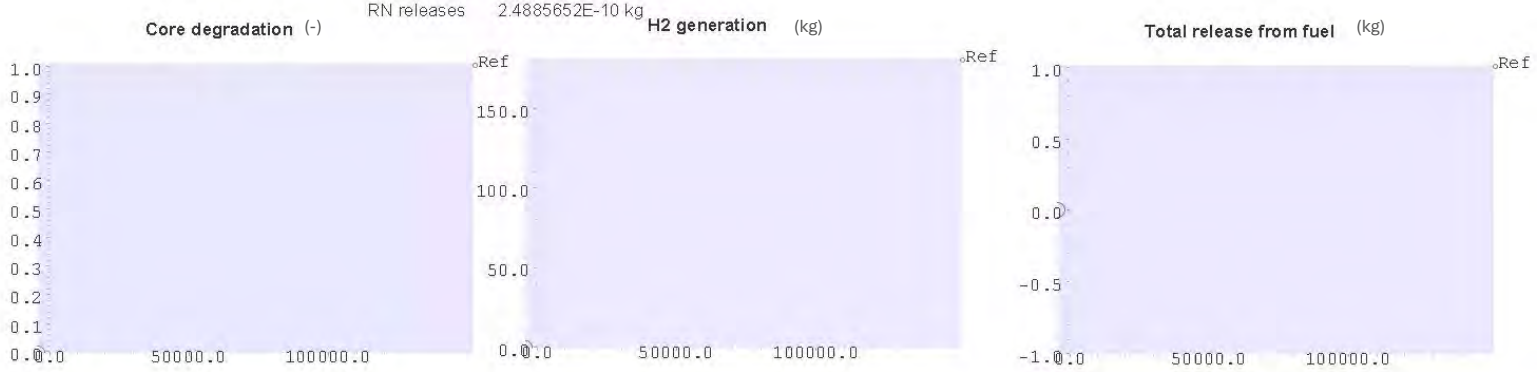


SASPAM-SA Design 1 bypass type scenario simulation



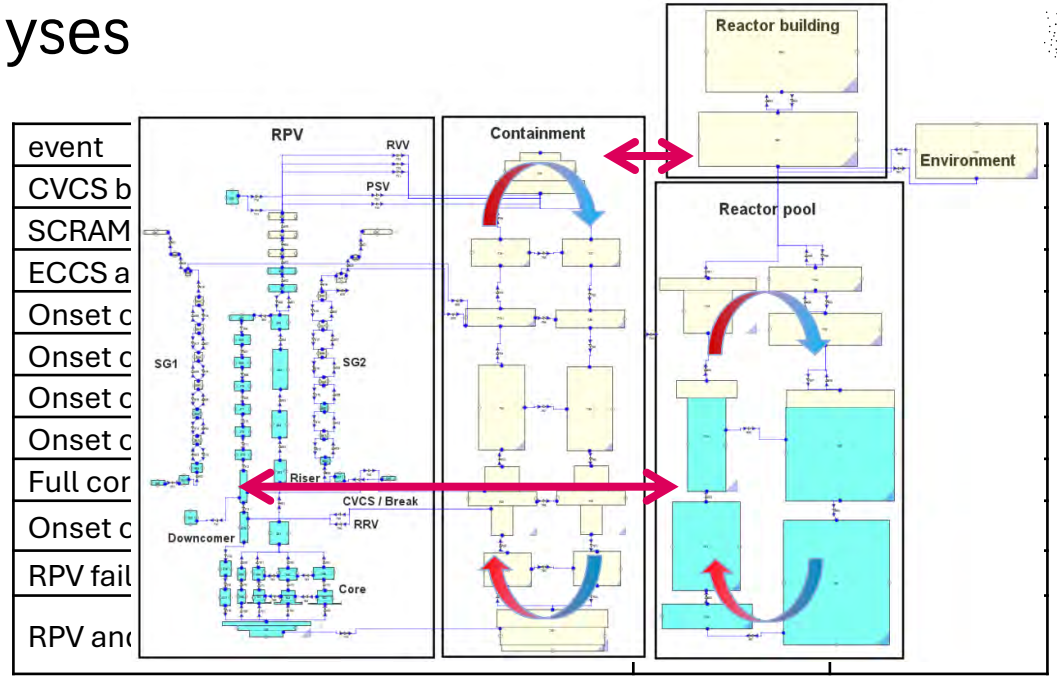


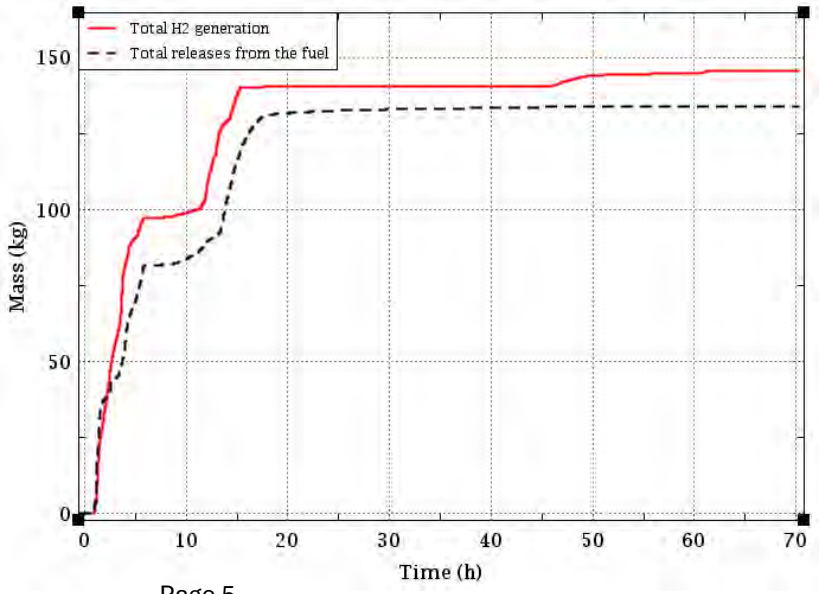
- Scenario – SBLOCA:
  - Bypass type CVCS line break from the downcomer to the reactor pool
  - RVV available
  - RRV not available

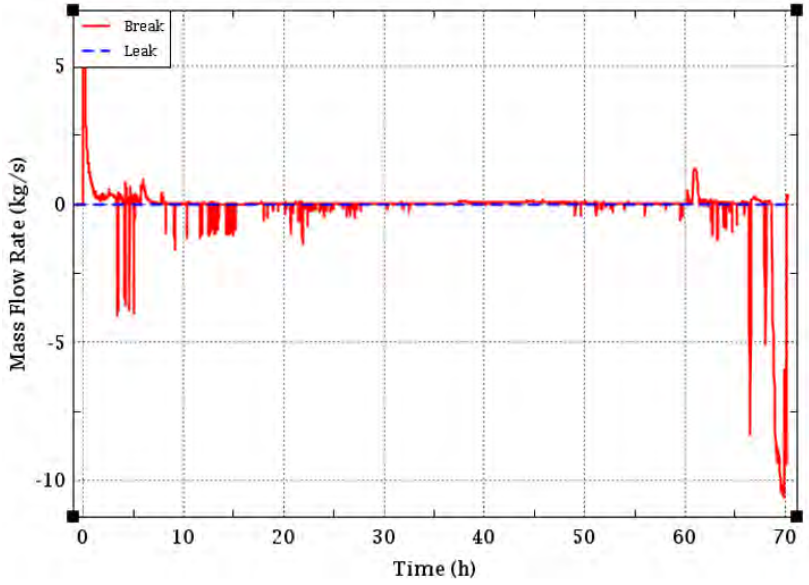


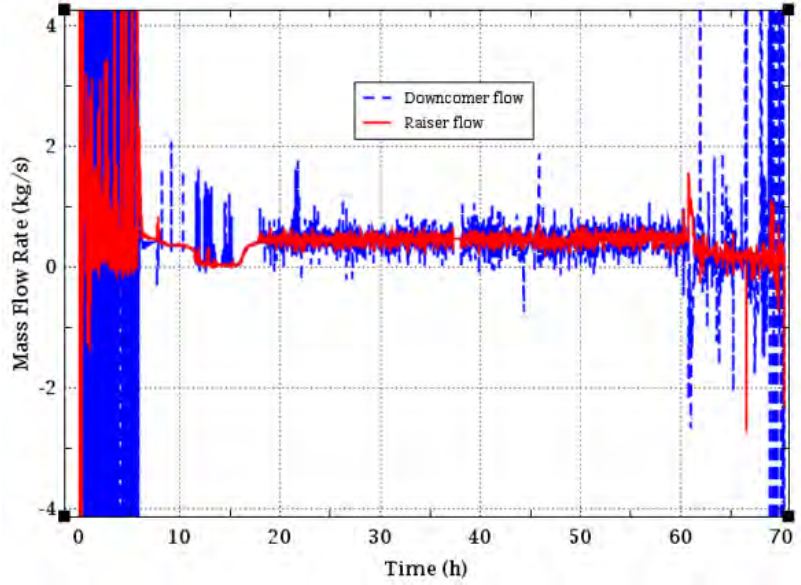
SASPAM-SA - Design 1 scenario analyses

- Scenario – SBLOCA:
  - Bypass type CVCS line break from the downcomer to the reactor pool
  - RVV available
  - RRV not available









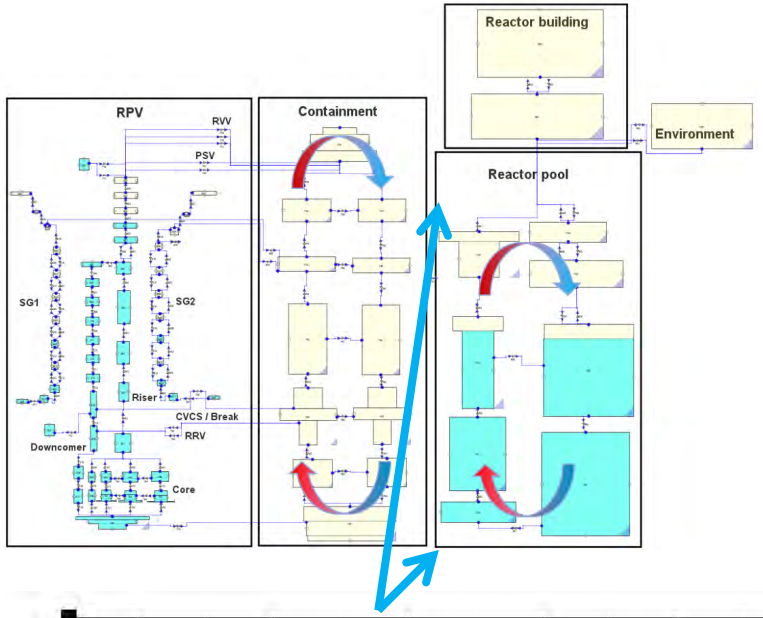
SASPAM-SA Design 1 – release analyses

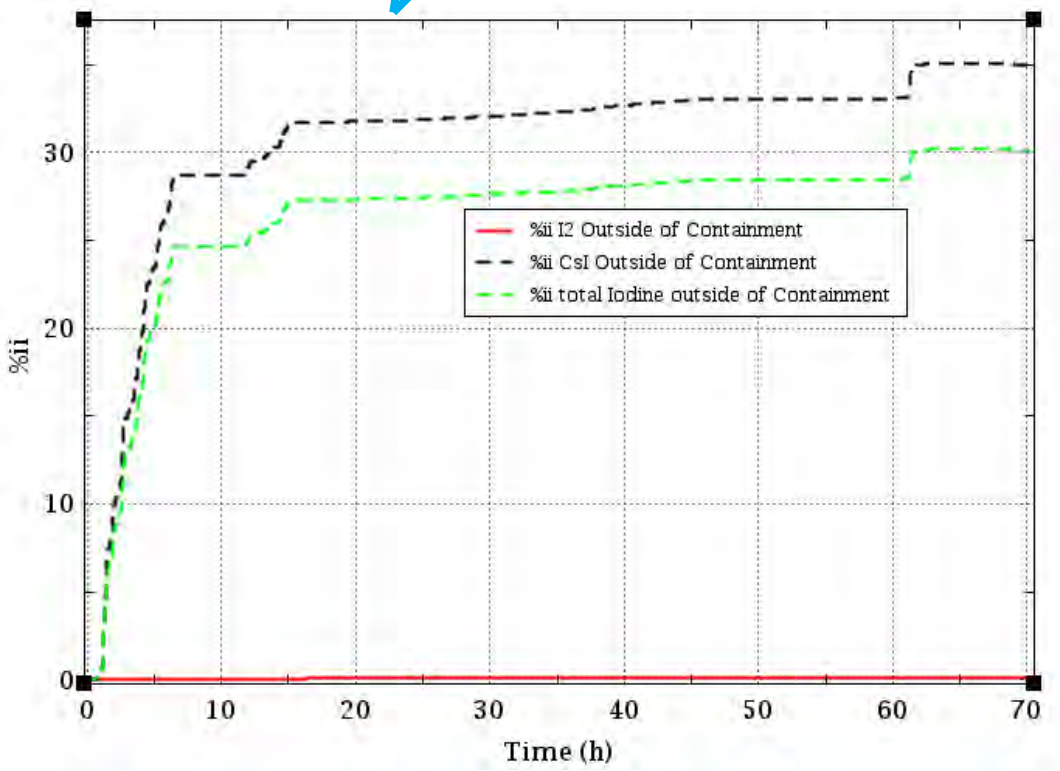
IMPAIR code assumptions:

- Water volume: 1618 m^3
- Air volume: 538 m^3
- Pool and air temperature: T = 353 K
- Iodide in the pool water: 4.14×10^{-6} mol/L, corresponding to 0.30 of the initial iodine inventory
- Low-molecular-weight organic iodides in the pool water: 1×10^{-5} mol/L
- pH = 5.0, 7.0, 9.0
- Dose rate = 3.0 kGy/h in water and air
- Surface: painted steel
- Reactor building/pool open to the environment with a leak rate of 0.0455 kg/s
- Calculation time: 2778 hours, **114 days**

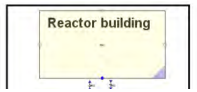
Scenario assumptions:

- No pool scrubbing was modeled in MELCOR; all iodine species were assumed to be scrubbed by the pool water.
- The containment bypass was assumed to be below the pool water level.
- Approximately **30%** of the initial iodine inventory was assumed to be in the pool water at the end of the transient.
- At the beginning of the IMPAIR calculation, all iodine in the water was assumed to be in the form of iodide I^-.





SASPAM-SA – IMPAIR analyses



PSI

IMPAIR enables a more mechanistic simulation of iodine transformations in water by accounting for water chemistry effects and the relevant reaction pathways.

The code is designed to simulate iodine chemistry in light-water-reactor containment under severe accident conditions, including aqueous-phase processes in the sump, deposition phenomena, and iodine behavior in the containment atmosphere.

In this work, IMPAIR was used to calculate the release of I_2 and CH_3I from the reactor pool water.

The time evolution of the total gas-phase iodine mass was calculated for three pH values: 5.0, 7.0, and 9.0, assuming that the pool/building walls were painted steel surfaces.

Gas phase wall reactions

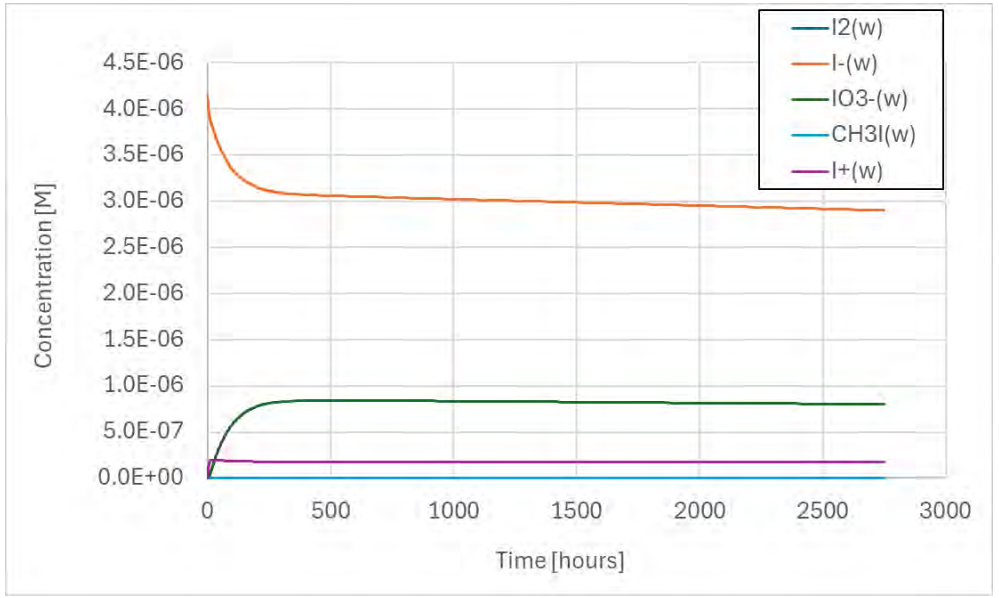
k_{58} = 1.0E-02	Dissolution from immersed wall: I_2(dep_concrete) -> $I^-(w)$
k_{69} = 1.0E-05	Dissolution from immersed wall: I_2(dep_paint) -> $I^-(w)$

SASPAM-SA – IMPAIR analyses

IMPAIR – iodine species:

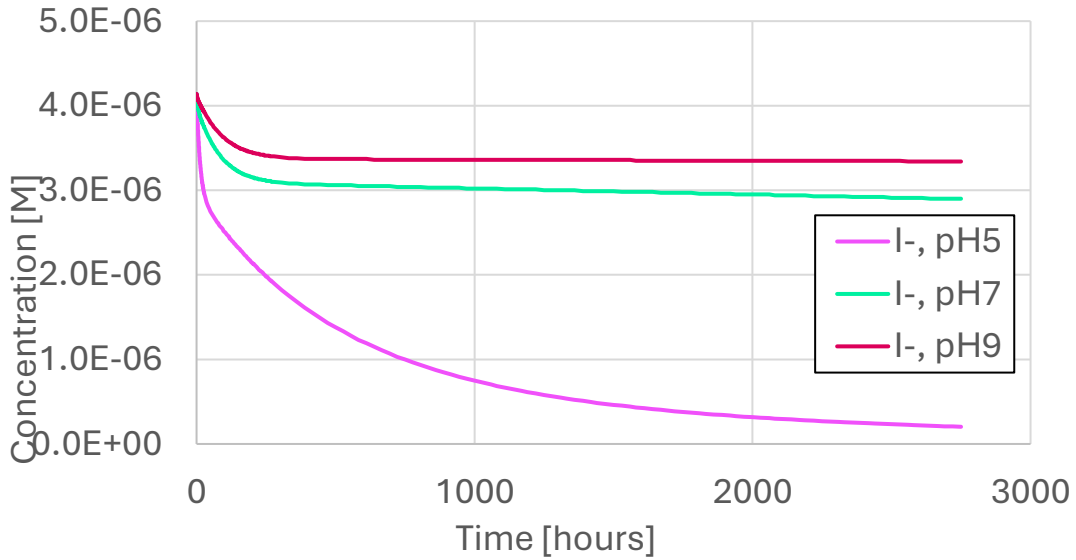
- The main iodine species in the pool water were I^- and IO_3^-



The main iodine species in the pool water with pH=7.0

IMPAIR – evolution of I^- concentration depending on pH:

- The pH dependence is observed through the rapid decrease in I^- concentration
- At a low pH of 5.0, I^- rapidly decreases in the water
- At a higher pH of 9.0, the concentration decreases only slowly



Time evolution of I- as the main iodine species in the pool water with pH = 5, 7 and 9

Conclusions

- MELCOR successfully simulated the rapid progression of the bypass-type severe accident scenario.
  - Natural circulation supported in-vessel cooling, but was insufficient to prevent full core degradation and vessel failure.
  - Reactor pool backflow after pressure reduction led to RCS and containment reflooding and effective long-term cooling.
  - The scenario provided boundary conditions for assessing iodine behaviour in the reactor pool using IMPAIR.

- IMPAIR calculations assumed iodine initially present in the pool water as iodide I^- and were performed for pH values of 5, 7, and 9.
  - IMPAIR results showed strong pH dependence of iodine chemistry, with faster I^- depletion at low pH.
  - Only a small fraction of iodine was released to the gas phase; I^- and IO_3^- remained the dominant aqueous iodine species.

ABSTRACT

Within the framework of the Euratom project SASPAM-SA Work packages 2 and 5, a MELCOR input deck for a generic integral Pressurized Water Reactor (iPWR) has been developed. The generic Design 2 is an iPWR, characterized by electric power of 300 MW_e, a dry containment and protected by passive safety systems. Three main Design Extended Conditions were considered, all initiating from the rupture of a Direct Vessel Injection line, causing a small break LOCA. The investigations suggested that the scenario postulate different passive systems unavailability, to investigate MELCOR capability to simulate severe accident conditions in iPWR, which is the main aim of the SASPAM-SA project. The MELCOR input deck has been developed by the Sapienza University of Rome (DIEE, NERG research group) according to best practices. The results of the analysis demonstrate that MELCOR can qualitatively replicate the expected dominant phenomena that drive the severe accident sequences. In particular, an accurate evaluation of the containment response and the adequacy of the Filtered Containment Venting System in these scenarios was also investigated.

1. INTRODUCTION

Light water Small Modular Reactors (SMRs), and Integral Pressurized Water Reactors (iPWRs), are currently considered among the most mature SMR concepts for near-term deployment in Europe [1]. Their design evolution originates from large Light Water Reactors (LWRs), benefiting from extensive operational experience while introducing enhanced, largely passive safety features. Despite the improvements achieved at the early Defence-in-Depth (DiD) levels, the demonstration of iPWR robustness with respect to Severe Accident (SA) prevention and mitigation, corresponding to DiD levels 4 and 5 [2], remains a central aspect of the European licensing process. Consequently, the identification and deterministic analysis of representative SA scenarios is required to support both reactor design evaluation and regulatory review. Within this context, the Horizon Euratom Safety Analysis of SMR with PAssive Mitigation strategies-Severe Accident (***SASPAM-SA)*** project, addresses the transferability of SA knowledge, experimental data and analytical methodologies developed for large LWRs to iPWR configurations [3,4,5,6], with specific attention to European requirements for SA and Emergency Planning Zone (EPZ) analyses; SASPAM-SA is coordinated by ENEA (Italy) and involves twenty-three organizations from fourteen countries, with a total

duration of four years. Two generic iPWR reference concepts are considered in the project to support its objectives:

- *Design 1*: a low-end power iPWR configuration (about 60 MW_e) with a submerged containment.
- *Design 2*: a high-end power iPWR configuration (about 300 MW_e) characterized by a dry containment and the extensive use of passive safety systems.

These generic designs are not intended for design assessment; rather, they provide representative platforms to investigate the capability of integral SA codes and Computational Fluid Dynamics (CFD) tools to reproduce key iPWR-specific phenomena under postulated Design Basis Accident (DBA) and SA conditions. Particular attention is devoted to phenomena associated with strong thermal–hydraulic coupling between the primary system, containment and safety systems, including natural circulation, heat transfer in helicoidal steam generators, thermal stratification in large pools, and in-vessel melt retention, which may challenge the applicability of codes primarily developed for the current large LWR fleet. Given the complexity of the SASPAM-SA project and the range of its objectives, the work is structured into seven dedicated Work Packages (WPs), each addressing a specific technical or organizational aspect. Within this framework, the present paper is specifically connected to WP2, coordinated by KIT (Germany), focused on the input deck development and definition and assessment of hypothetical SA scenarios, and to WP5, coordinated by GRS (Germany), which addresses the capability of integral codes to simulate iPWR containment behavior and to evaluate the effectiveness of accident mitigation measures. The objective of this paper is to present the selected SA scenarios and to discuss the main results of containment analyses performed for the reference iPWR Design 2, highlighting key phenomenological aspects and modelling challenges.

2. iPWR DESIGN 2

The MELCOR input deck developed by Sapienza University of Rome is based on the Design 2 reference configuration adopted within the Horizon Euratom SASPAM-SA project [7,8]. This configuration represents an integral Pressurized Water Reactor with an electric output of about 300 MW_e and based on the passive safety systems considered, it is inspired by the IRIS (International Reactor Innovative and Secure) concept [8]; this configuration permits the elimination of the occurrence of some accidental sequences. The integral Reactor Pressure Vessel houses the reactor core, helical coil steam generators, the primary pumps, and the pressurizer within a single vessel; the absence of large-diameter penetrations in the vessel effectively eliminates the possibility of Large Loss-of-Coolant Accidents. The primary system is enclosed in a spherical dry containment filled with nitrogen at atmospheric pressure and subdivided into two main regions: the Drywell and the Reactor Cavity. The safety and mitigation strategy relies exclusively on passive systems that do not require external power, nevertheless, the performance of these systems is strongly governed by complex thermal–hydraulic phenomena, may still involve active initiation, and is characterized by limited operational experience; in **Errore. L'origine riferimento non è stata trovata.**, in addition to the overall reactor layout, the main safety systems are highlighted, including:

- **Emergency Heat Removal System** (EHRS), which consists of four independent natural circulation loops connected to external refueling Water Storage Tanks (RWST). Once active, it removes core power through the SGs.
- **Automatic Depressurization System** (ADS); consists of two stages, **Stage 1** includes two identical redundant trains connected to the pressurizer head through check valves, which depressurize the system by venting steam into a quench tank located in the drywell, and **Stage 2** allows pressure equalization between the containment and the RPV, located at the pressurizer top.

- **Emergency Boration Tanks** (EBT); are located in DW and inject borated water into the core by gravity via direct vessel injection (DVI, two independent lines are connected to the vessel above the core's upper plate).
- **Long-Term Gravity Make-up System** (LGMS); two tanks, located in the DW, connected to the DVI via check valves.
- **Riser-Downcomer Valves** (RI-DC): the eight connections between the riser and the downcomer are designed to allow the primary water to flow along a shorter path, bypassing the pump suction plenum, which facilitates the establishment of natural circulation in accidental phases.

For SA management, the Pressure Suppression System (PSS) plays a key role in limiting containment pressurization and supporting mitigation. The PSS enables a reverse flow mechanism that is activated when the Drywell pressure decreases below the PSS tank pressure, resulting in flooding of the reactor cavity. This facilitates external cooling of the RPV lower head and supports the In-Vessel Retention (IMVR) strategy adopted for the reference iPWR design.

2.1. MELCOR input description

The input deck has been developed with **MELCOR v2025.0.0** [9], for the creation of the input deck and for the preparation of the project database, the main geometric information has been determined by scaling the data available from the SPES-3 facility [10], by engineering evaluation or public general data available from the IRIS reactor [7,8,11] and the studies carried out by ENEA with the ASTEC code [12]. The objective of the model is to reproduce the reactor behavior under normal and accidental conditions, with a detailed thermal-hydraulic nodalization to study in depth the thermal-hydraulic phenomena related to passive systems and the phenomenology of SAs such as core degradation, radionuclide transport of radionuclides, etc [9]. Most of the structures in Design-2 will be modelled with the support of the *CVH* package, the fluid paths represented with the *FL* package will be coupled to the control volumes of the reactor, the *HS* package will be used to simulate the thermal response of the containment structures, tanks and piping; the union of these three packages represents the thermal hydraulic nodalization of the reactor. The behavior of the core and its internal structures such as fuel rods or lower head will be modeled using the *COR* package, instead with the RN package initial inventories of radionuclides in the core, cavity, and control volumes are simulated. A reactor schematization is depicted in **Figure *1* (b)** : *RPV & primary circuit*, *Secondary circuit & EHRS*, *In-containment Safety Systems and Containment (DW+RC).*

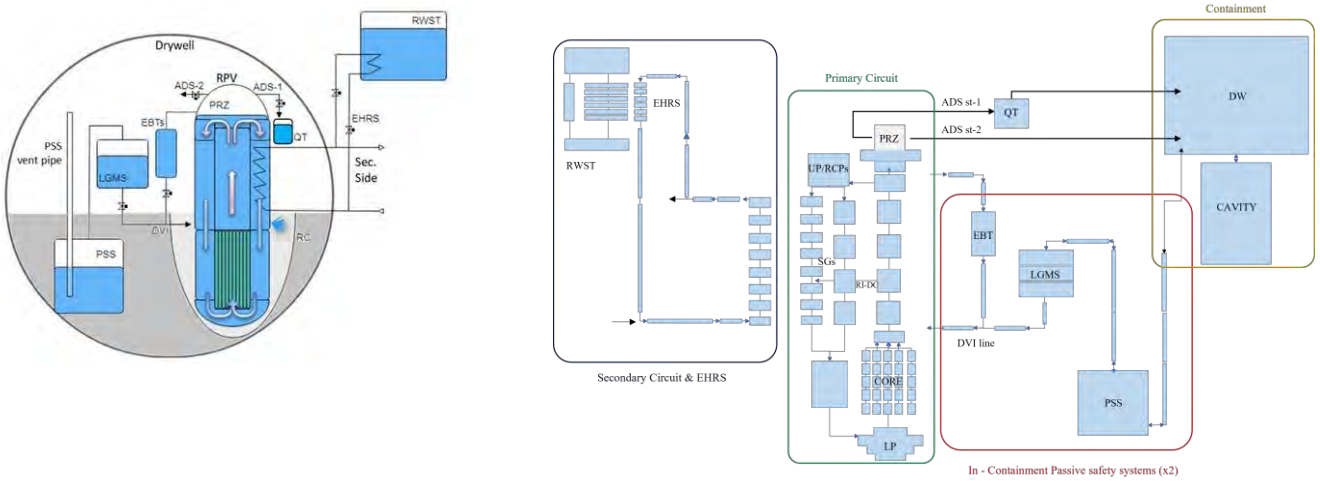

Figure 1. Design 2: conceptual scheme (a), thermal-hydraulic nodalization (b)

The iPWR reactor and its systems are represented through a slice-based nodalization strategy. The primary circuit is subdivided into 44 control volumes covering the core, bypass regions, lower plenum, downcomer, riser, pressurizer, upper plenum, and the primary side of the steam generators, including bypass zones. Passive systems such as the EBT, LGMS, PSS, and the ADS with quench tank are nodalized with dedicated control volumes, valves, and SPARC model enabled flow paths to simulate injection, venting, condensation, and radionuclide retention during accident scenarios; for the transport and deposition of radionuclides in the core, primary circuit, and containment, the RN and DCH packages are used, including the simulation of pool scrubbing and aerosol filtration processes. The stainless steel drywell, and the concrete cavity are modeled as separate single control volumes, while the containment heat structures are linked to an external volume, representing the surrounding reactor environment; to improve the simulation of condensation on the steel containment liner, the thermal structure corresponding to the DW steel liner was modified, with its geometry changed from rectangular to a spherical form; a node was added to represent the paint layer on the steel and the Film Tracking [9] model was activated to simulate the drainage of condensation, with liquid distributed between the drywell pool and the spray package (50% each). In the spray package, part of the drained liquid falls as droplets (diameter ~4 mm) into the containment volume, contributing to internal heat exchange. In addition, a venting system connected to the DW was modelled: FCVS (Filtered Containment Venting System) it provides filtered venting of the containment to mitigate radioactive releases during severe accident scenarios. The system operates when containment pressure exceeds a predefined threshold, allowing controlled release while maintaining structural integrity, the FCVS ensures that venting reduces overpressure while limiting environmental contamination.

3. SEVERE ACCIDENT ANALYSIS

The accident scenarios investigated in this work are based on a Small Break Loss of Coolant Accident (SB-LOCA) caused by a double-ended rupture of a DVI line, due to the low elevation of the break, this event constitutes a particularly demanding condition for reactor safety systems [7,8]. The injection system layout includes two independent and redundant DVI lines, identified as DVI-A and DVI-B, each connected to the corresponding safety subsystems. In the analyzed cases, DVI-A is broken, depending on the availability of the remaining safety systems, the transient may either remain within DBA conditions or evolve to a SA, which is the focus of this study. The three SAs are classified as [8]:

- SA-1: Postulated failure of **ADS-1** and **EHRS**
- SA-2: Postulated failure of **all** safety systems
- SA-3: Postulated failure of **EHRS**

The results discussed in the following sections are structured according to a sequence of *Phenomenological Windows* (PhWs), each window represents a distinct phase of the transient, characterized by the overall reactor conditions and, in particular, by the state and evolution of the core. An overview of the defined PhWs for the three analyzed transients is provided in **Table I**.

Table I. SA-1, SA-2, SA-3 Phenomenological Windows

Severe Accident	***PhW***	***Main Phenomena***	***Start** (s)*	***End** (s)*
SA-1	*PhW 1*	***Blowdown, EBT injection, Oxidation onset***	0	16364
	PhW 2	***Core Degradation, IVMR, ADS-2, Reflood***	16364	54154
	PhW 3	***FCVS operation, PSS***	54154	260000

SA-2	*PhW 1*	***Blowdown, EBT injection, Oxidation onset***	0	17645
	PhW 2	***Core Degradation, Corium Slump***	17645	42360
	PhW 3	***IVMR, FCVS operation***	42360	260000
SA-3	*PhW 1*	***Blowdown, ADS-1, EBT, LGMS, PSS***	0	10370
	PhW 2	***Oxidation onset, Core Damage, PSS***	10370	40031
	PhW 3	***FCVS operation, Core Degradation, PSS***	40031	151777
	PhW 4	***ADS-2, Reflood, FCVS***	151777	260000

3.1. SA-1

The SA-1 sequence starts with the rupture of the DVI line, which evolves into a small-break LOCA, the break triggers the SCRAM only after 27 seconds. The first phase of the SB-LOCA, known as blowdown, marks the beginning of the first phase (PhW 1) of the accident, where it is characterized by a sudden increase in pressure, leading to RCP coastdown and the opening of the RI-DC valves.

Table II. SA-1 chronological sequence

Event	*Time (s)*	*Time (h)*
Start of Transient (SoT)	0	0
SCRAM	27.98	0.01
RCP coastdown and RI-DC valves opening	109.76	0.03
EBT line opening	160.23	0.04
Water level below TAF	375	0.10
EBT-B empties	2520	0.7
Containment Design Pressure reached	2653	1.09
Time of onset H_2 production	14523	4.03
1st PSS reverse flow	16364	4.54
Onset of Core damage	21860	6.07
Water level below BAF	38920	10.81
LGMS line opening	39080	10.85
Total core degradation	40319	11.19
Molten Core Relocation in LP	41181	11.43
1st FCVS actuation	41764	11.60
2nd PSS reverse flow	42225	11.72
1st FCVS deactivation	44025	12.22
ADS-2	54154	15.04
2nd FCVS actuation	80529	22.36
3rd PSS reverse flow	80920	22.47
2nd FCVS deactivation	89032	24.73
3rd FCVS actuation	114750	31.87
3rd FCVS deactivation	123680	34.35
4th FCVS actuation	153110	42.53

4th FCVS deactivation	161020	44.72
5th FCVS actuation	194636	54.06
5th FCVS deactivation	202007	56.11
6th FCVS actuation	240297	66.74
6th FCVS deactivation	247487	68.84
End of Transient (EoT)	260000	72

As shown in **Table II**, the first EBT is actuated after only 160 seconds, since it is directly connected to the ruptured DVI line, it constitutes an additional water source for the LOCA.

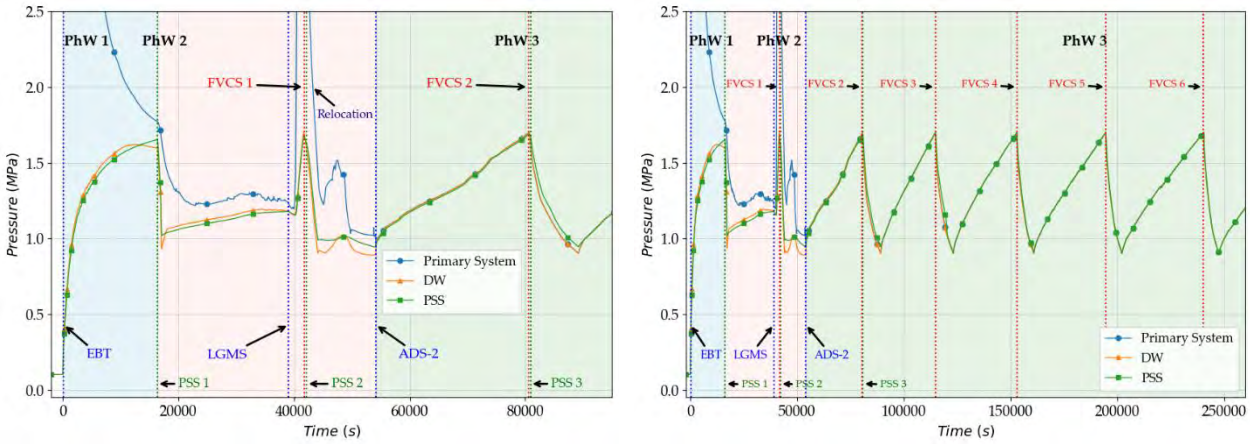

Figure 2. Pressure trends PhW 1 and PhW 2 (a), Entire simulation (b) (SA-1)

As illustrated in the figures above, the containment pressure rises, reaching the design pressure within one hour from the SOT. The steam generated inside the DW is partially sent to the PSS tanks, where it is condensed through direct liquid–steam interactions, thereby increasing the pressure in their atmosphere. This condition leads to a reverse flow from the PSS tanks back to the containment through the PSS vent pipe [7]. In this accident, three reverse flow events occur, which periodically reduce the containment pressure and contribute to flooding the reactor cavity; the first reverse flow marks the end of PhW 1. At the same time, the liquid level in the core drops dramatically, leading to PhW 2 (*cladding rupture*) only 6 hours after the DVI rupture.

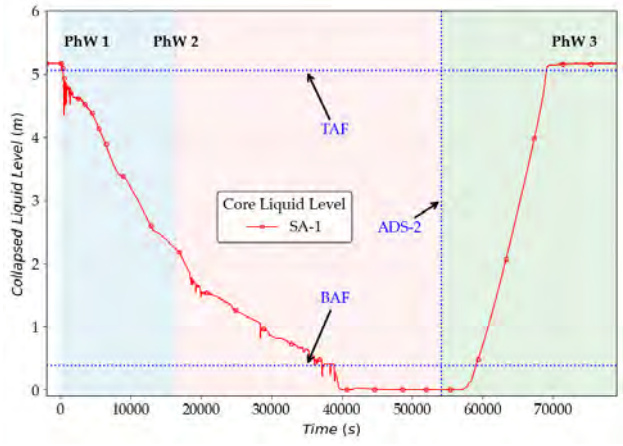

Figure 3. Core collapsed liquid level (SA-1)

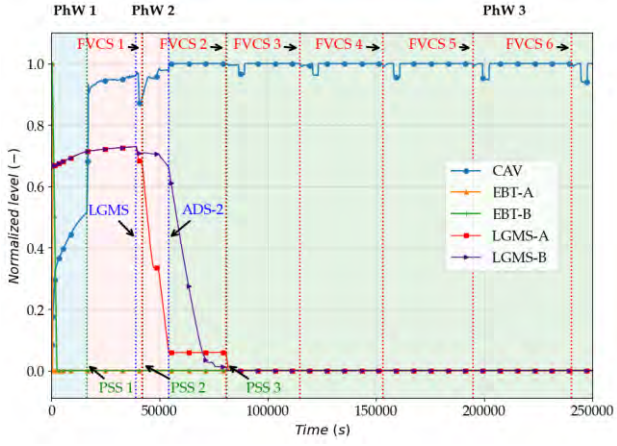

Figure 4. Collapsed normalized liquid level for EBT, LGMS and CAV (SA-1)

In PhW 2, due to the lack of ADS-1 and EHRS, the activation of the *LDPC* signal (*low RPV–containment differential pressure* [6,7]) and the consequent opening of the LGMS valves occur with a significant delay, when the core liquid level is already below the BAF (**Figure 3**) and the core is partially molten. The LGMS water injection takes place rapidly (**Figure 4**); however, this does not prevent complete melting and the relocation of the molten corium into the lower plenum (as demonstrated by the general pressure increase shown in **Figure 2**). Due to the presence of residual water in the lower plenum, the relocation causes a pressure spike in the drywell, activating the FCVS for the first time at 1.69 MPa, the venting system reduces the pressure in the DW and in the vessel, leading to a second PSS reverse flow; the valve remains open for less than one hour, until the DW pressure drops to a value of 0.85 MPa; in the final moments of PhW 2, the IVMR is achieved. The rapid emptying of the LGMS tanks activates the Low LGMS Mass signal (two LGMS tanks < 8%), which concomitantly commands the opening of the ADS-2 valves. This configuration enables controlled steam circulation between the RPV and the DW and marks the beginning of PhW 3. With the activation of the second stage of the depressurization system, the vessel is fully reflooded with water, effectively cooling the molten corium. PhW 3 is characterized by the transient behavior of the FCVS, the overall system pressures fluctuate between the two setpoint values of the FCVS. Notably, as in the first phase of the accident, the opening of the venting system valve causes the 3rd PSS reverse flow, though less pronounced than the previous two.

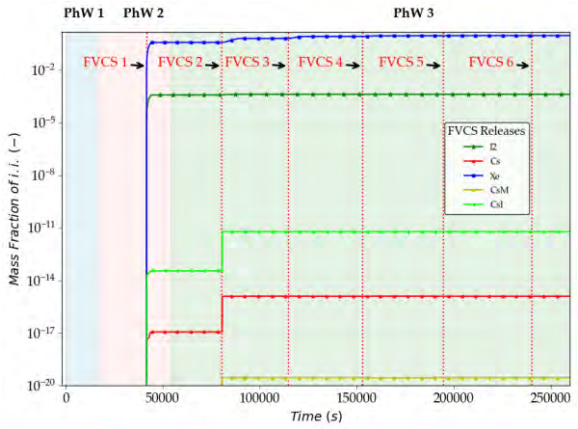

Figure 5. FCVS releases in mass fraction of initial inventory (SA-1)

The analysis of the released mass fractions respect to the initial inventory of certain classes, considering only the FCVS contribution, shows that halogen class releases are higher than those of the remaining classes because of the lower decontamination factor for elemental iodine in the FCVS. Releases are summarized in **Figure *5***, while the noble gases class (Xe) is completely released, due to their high volatility. The source term results are presented on a logarithmic scale to better highlight differences between the various classes.

3.2. SA-2

The second scenario analyzed is the more unlikely of the three. Indeed, the unavailability of all safety systems is postulated. In the **Table *III*** the main events occurring in SA-2 are listed.

Table III. SA-2 chronological sequence

Event	*Time (s)*	*Time (h)*
SoT	0	0
SCRAM	26.22	0.01

RCP coastdown and RI-DC valves opening	108.88	0.03
Water level below TAF	680	0.18
Containment Design Pressure reached	3935	1.09
Time of onset H_2 production	12803	3.55
1st PSS reverse flow	17645	4.90
Onset of Core damage	18110	5.03
Water level below BAF	31750	8.81
Corium Slump	34900	9.69
2nd PSS reverse flow	42360	11.77
Total core degradation	49636	13.78
FCVS actuation	177580	49.32
FCVS deactivation	186297	51.74
EoT	260000	72

PhW 1 starts with the rupture of DVI-A, this event triggers the SCRAM signal and the opening of the recirculation valves; the blowdown phase is very fast and similar to the one in previous case, the only source of water discharge is the vessel side broken DVI. This results in a reduction of the primary system pressure from the initial 15 MPa and produces a slightly less pronounced peak in the DW pressure (***Figure 6***) compared to the previous scenario.

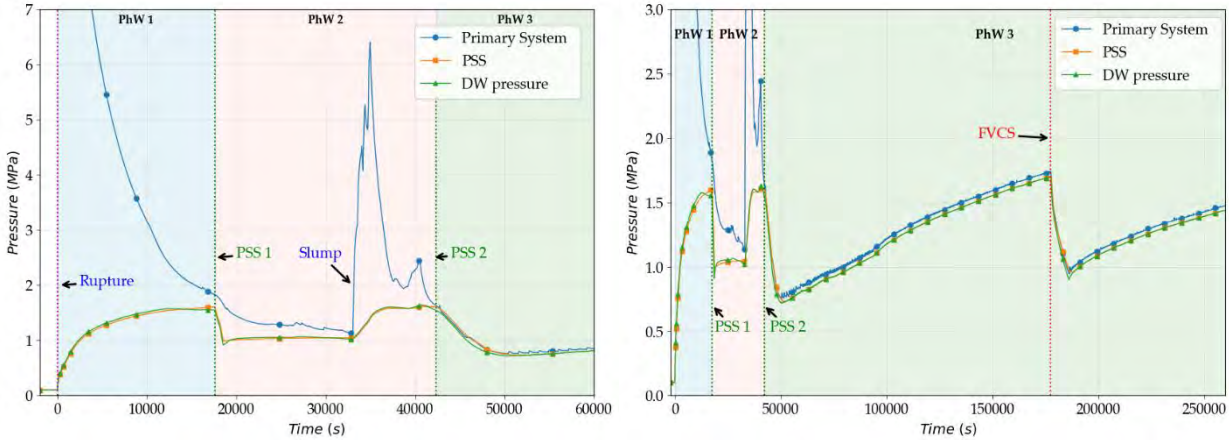

Figure 6. Pressure trends PhW 1 and PhW 2 (a), Entire simulation (b) (SA-2)

The first PSS reverse flow marks the transition to the second phase, PhW 2, of the accident: the liquid level inside the core gradually drops, leaving the core uncovered in just 9 hours: this fact, combined with the increase in cladding temperature, leads to the onset of degradation (5 hours after SOT). At the end of PhW 2, the core is completely molten and relocated within the lower plenum, from **Errore. L'origine riferimento non è stata trovata.**: we can see the presence of a corium slump, which causes a sudden pressure spike, marked in the case of the primary system (6.22 MPa). This pressure peak has a reduced impact on both the containment and the PSS, in fact, the pressure increase does not reach the threshold value required to trigger the opening of the FCVS system valve. At the conclusion of PhW-2, a second PSS reverse flow takes place, resulting in an overall pressure reduction and ensuring that the cavity remains completely flooded. This is one of the key conditions to ensure IVMR into the lower plenum. In PhW 3, the corium is already relocated to the lower plenum, and water injection into the primary system is provided solely by the flooded cavity.
After 50 hours from the onset of the transient, the thermal-hydraulic conditions of the reactor lead to an

increase in the DW pressure and to the opening of the FCVS, resulting in the release of steam and radionuclides to the environment. Compared to the previous case, releases are reduced for all the classes analyzed.

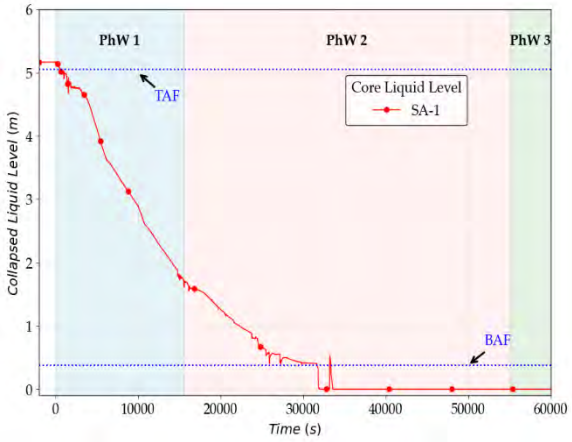

Figure 7. Core collapsed liquid level (SA-2)

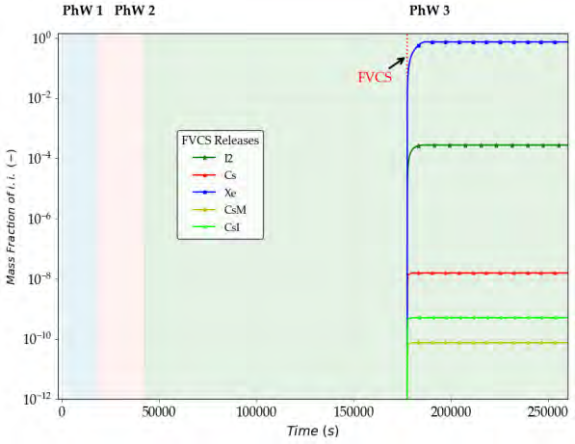

Figure 8. FCVS releases in mass fraction of initial inventory (SA-2*)*

3.3. SA-3

The last analyzed sequence postulates the failure of EHRS; the transients starts as the rupture occurs and the RCP coastdown and RI-DC valves opening is triggered. Following **Table IV**, the ADS-1 is opened and the EBT starts injecting water, the containment design pressure of 12 bar is reached earlier with respect to the other two scenarios, thanks to the triple early pathway from the vessel to the DW: the double guillotine rupture and the ADS-1. The pressurization of the containment is significantly faster, due to ADS-1 venting steam into the quench tank.

Table IV. SA-3 chronological sequence

Event	*Time (s)*	*Time (h)*
SoT	0	0.00
SCRAM	28.00	0.01
RCP coastdown and RI-DC valves opening	112	0.03
ADS-S1/EBT	166	0.04
Water level below TAF	185	0.05
Containment Design Pressure reached	918	0.25
LGMS	10370	2.88
1st FCVS actuation	19641	5.46
1st PSS reverse flow	19960	5.54
1st FCVS deactivation	20745	5.76
Time of onset H2 production	29779	8.27
Onset of core damage	40031	11.11
2nd FCVS actuation	60247	16.74
2nd PSS reverse flow	60449	16.79
2nd FCVS deactivation	62776	17.44
3rd FCVS actuation	107713	29.92

3rd PSS reverse flow	107802	29.94
3rd FCVS deactivation	114687	31.86
4th FCVS actuation	151777	42.16
ADS-S2	153000	42.50
4th FCVS deactivation	161816	44.95
5th FCVS actuation	195335	54.26
LGMS-A empty	197048	54.73
5th FCVS deactivation	203228	56.45
6th FCVS actuation	240931	66.93
6th FCVS deactivation	248364	68.99
EoT	260000	72

During PhW 1 the containment keeps pressurizing and the 1st PSS reverse flow occurs only after the 1st FCVS actuation. This system will be activated six times throughout the entire simulation (**Figure 9**). Around 3 hours after the SOT, when the primary and containment pressures are close (triggering of *low RPV-Containment differential pressure* signal), the LGMS valves open, this event marks the transition to PhW 2. In this phase's first moments, the pressure trends inside the primary, the drywell and the PSS undergo a steady state period of 3 hours, thanks to the injection of the LGMS. When the downcomer pressure becomes greater than the pressure in the LGMS, the overall system pressure gradually grows, until the value of 1.6 MPa that is the set-point for FCVS actuation; this causes a series of phenomena: the pressure in the main system drops, mass flows from the break and ADS-1 have a significant peak and the 1st PSS reverse flow is triggered, filling the reactor cavity; after this moment, the injection phenomena and pressure trends follow the opening and closing cycles of the FCVS

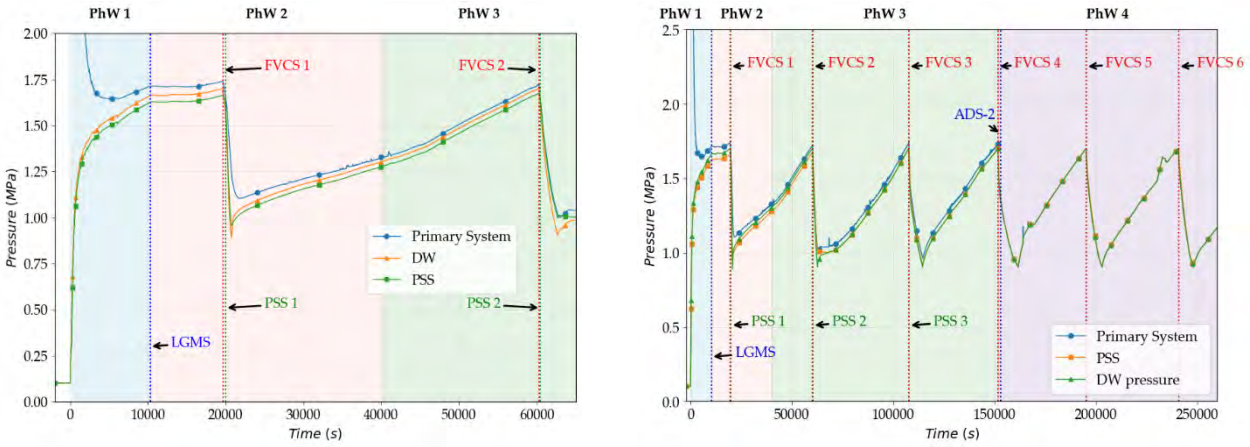

Figure 9. Pressure trends: PhW 1 (a), Entire Simulation (b) (SA-3)

Continuous FCVS cycling, as seen in 3.1, causes pressure fluctuations, which can negatively impact the reliability of the entire system, therefore, scaling of this system is considered. The **Figure 10** shows the LGMS-B tanks intermittent injection during the whole transient, following the FCVS trend, due to their pressure. Despite the operability of the injection systems and the reactor cavity contribution, the level in the core decreases, causing the core melting approximately 11 hours after SOT, beginning PhW 3 of the transient. PhW 3 is characterized by FCVS oscillations due to pressure increases caused by the greater amount of steam in the DW coming from the quench tank. The core doesn't melt completely, about 22% of the total, unlike the two previous cases, because in this phase the FCVS actuation leads to injection of LGMS

and CAV, which result in a partial reflooding of the reactor core, bringing its collapsed level to almost half the total height.

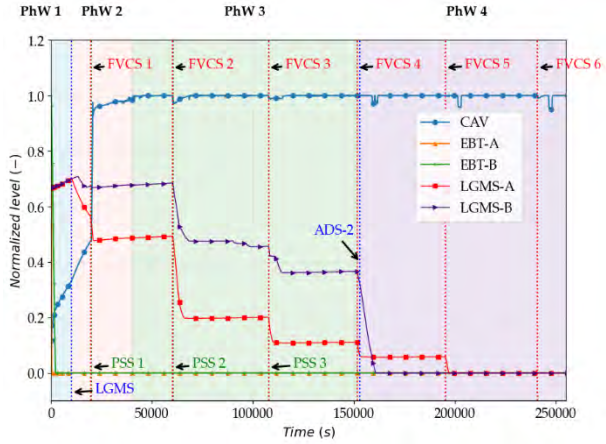

Figure 10. Collapsed normalized liquid level for EBT, LGMS and CAV (SA-3*)*

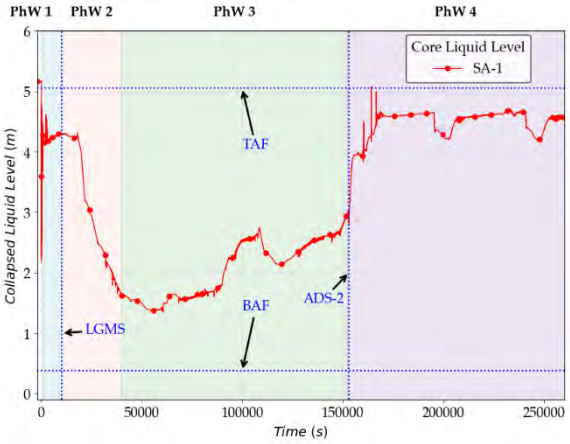

Figure 11. Core collapsed liquid level (SA-3)

When the liquid level in the LGMS-B tank reaches its minimum threshold, the ADS-2 signal is triggered, establishing a direct connection between the reactor vessel and the containment, starting PhW 4. This action leads to a substantial vessel complete reflooding, thereby restoring the core liquid level to a value close to that observed prior to the DVI line break. From this point onward, the water injections associated with the final two FCVS actuations are supplied exclusively through the cavity. The resulting collapsed liquid level, as illustrated in **Figure *11***, is sufficient to prevent further core damage for the remainder of the simulation period, extending up to 72 hours. In **Figure 12** the source term is shown. For halogens, releases are lower than SA-1 but higher than SA-2, while noble gases exhibit an overall lower release. The remaining classes, as in previous cases, show negligible releases.

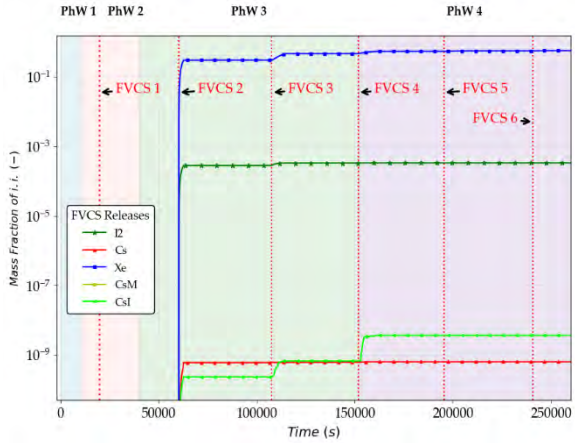

Figure 12. FCVS releases in mass fraction of initial inventory (SA-3)

4. CONCLUSION

This work presents the development and application of a MELCOR input deck for a generic iPWR Design 2 within the Horizon Euratom SASPAM-SA project. Three SA scenarios initiated by a small-break LOCA due to a DVI line rupture were analyzed, considering different configurations of passive safety system unavailability. The results indicate that MELCOR is capable of qualitatively simulating

the main phenomena expected during SA progression in an iPWR, including core degradation, corium relocation, and containment pressurization; however, quantitative assessment is currently limited by the lack of experimental validation. The analysis primarily focused on the containment response and on the role of the PSS and the FCVS, highlighting the strong coupling between depressurization, cavity flooding and pressure control; future developments will include multi-volume containment modeling to investigate these phenomena. Radionuclide releases through the FCVS were analyzed, showing that halogens are partially retained, while noble gases experience the highest release; other classes remain negligible. In addition, the potential cliff-edge effect associated with reverse flow in the PSS emerged as an aspect of interest and represents a promising topic for further investigation. Future work will therefore focus on model refinement, sensitivity analyses, a more detailed evaluation of radionuclide behavior, and comparisons with other integral and CFD codes, providing a reference for iPWR safety assessment within the SASPAM-SA framework.

ACKNOWLEDGEMNTS

The research activity is carried out by Sapienza DIAEE with the code MELCOR, in the framework of the DIAEE -ISIN agreement signed on 05/13/2020 as part of the General Arrangement between the United States Nuclear Regulatory Commission (US-NRC) and the Italian National Inspectorate for Nuclear Safety and Radiation Protection (ISIN).

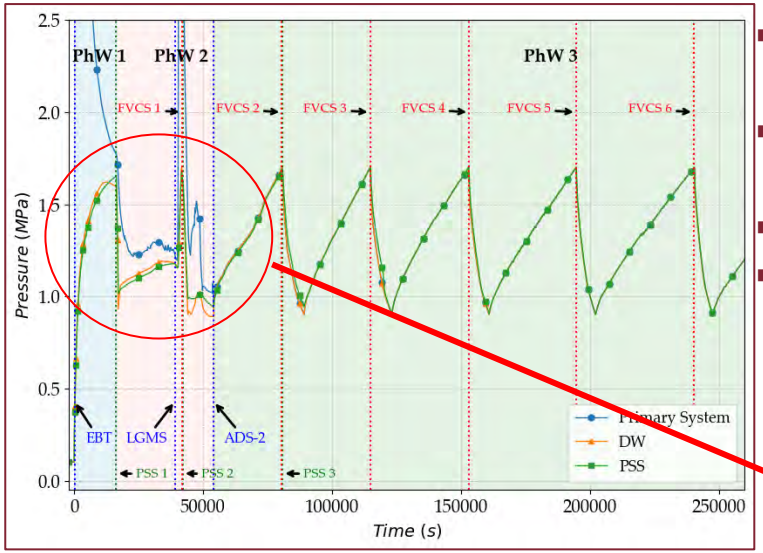
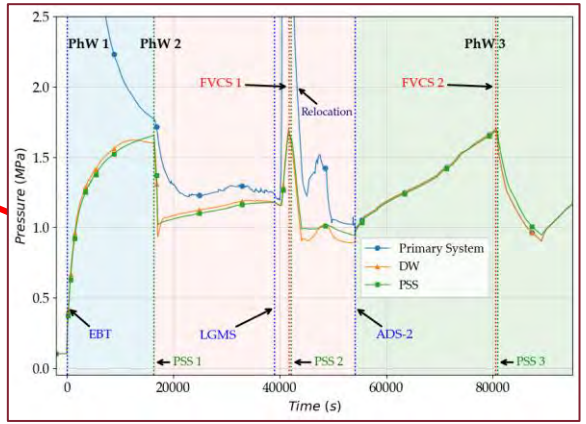
	PhW 3	FVCS operation, PSS reverse flow, Core degradation	40191	151777
	PhW 4	ADS-2, Reflood, FVCS operation	151777	260000

Severe Accident Scenarios – SA1



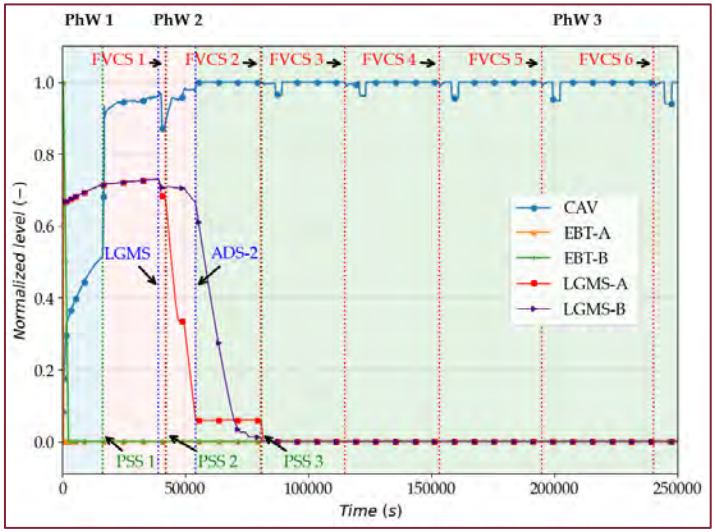
Pressure Trends

- The ADS-1 and EHRS combined failure produces a Severe Accident.
- The PSS reverse flow contributes to In-Vessel Melt Retention (IVMR) by flooding the cavity early in the transient.
- 6 FVCS actuations.
- After 15h from SOT, ADS-2 equalizes ***primary*** and ***drywell*** pressures.

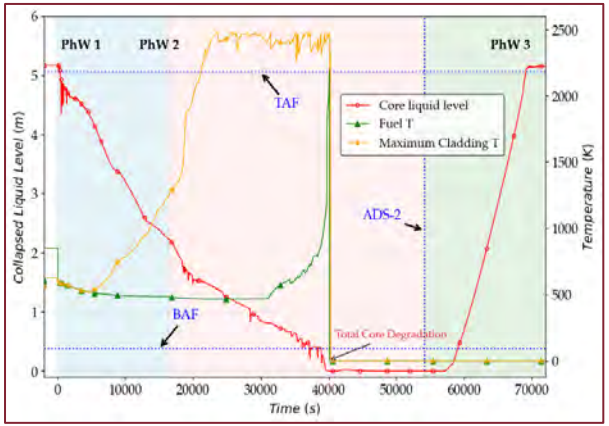


- **3 PSS reverse flows:** control the *DW pressure* contribute to flooding the *reactor cavity.*

SA1 water levels and temperature



Collapsed normalized liquid level for EBT, LGMS and cavity



Core collapsed liquid level/Fuel and Maximum Cladding T

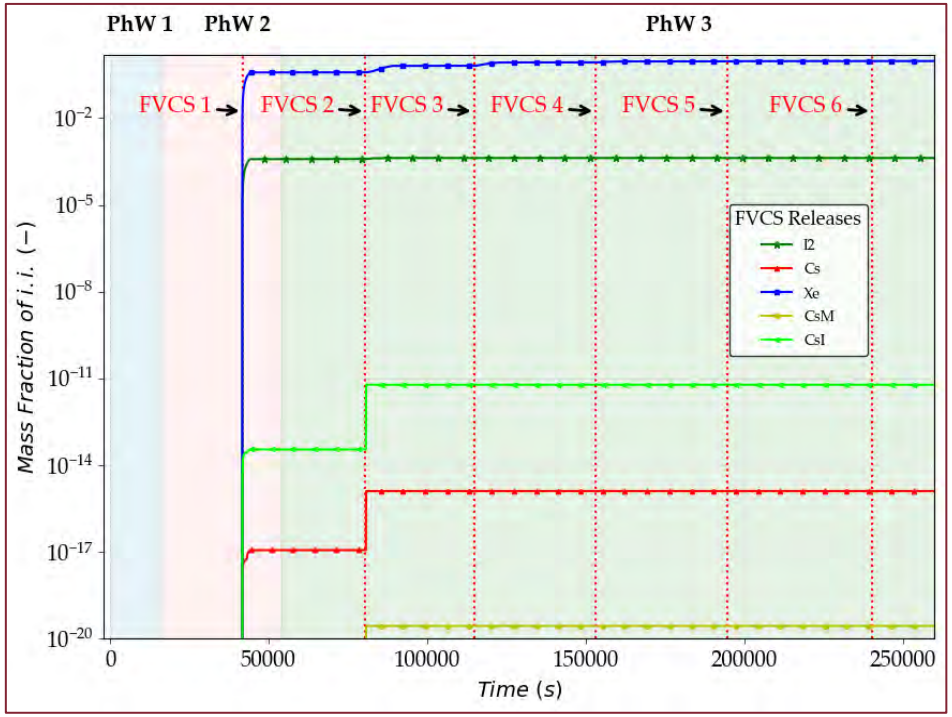
- At the end of simulation (72 h), the ***core level*** is above the **TAF**.

- **Reactor Cavity** results completely flood (*in all 3 scenarios*).

- **LGMS *water injection*** takes place rapidly; however, this does not prevent complete melting and the relocation of the molten corium into the lower plenum.

SA1 release frations

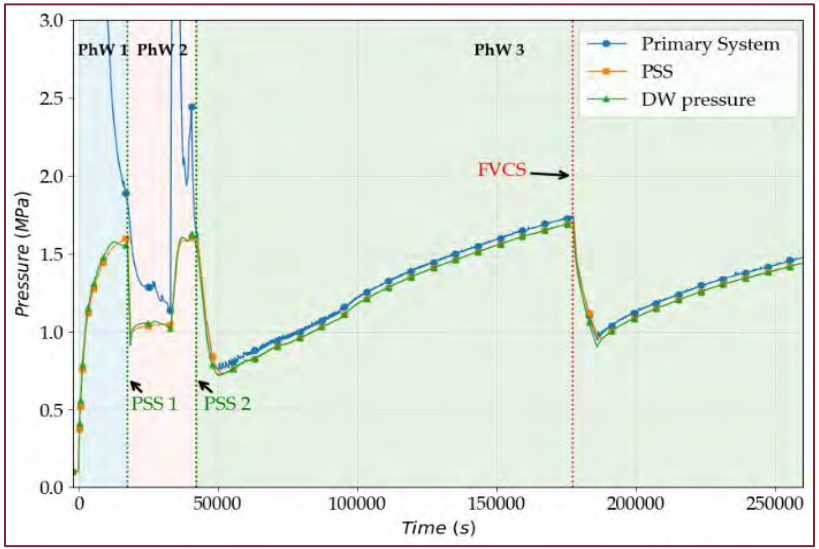
- The noble gases class (Xenon) are fully released.



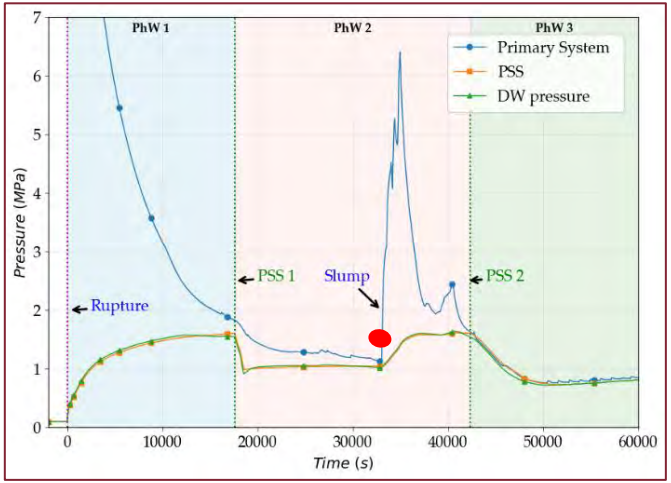
FVCS releases in mass fraction of initial inventory

- The halogen class (Iodine) releases are higher than those of the remaining classes

Severe Accident Scenarios – SA2



Pressure Trends

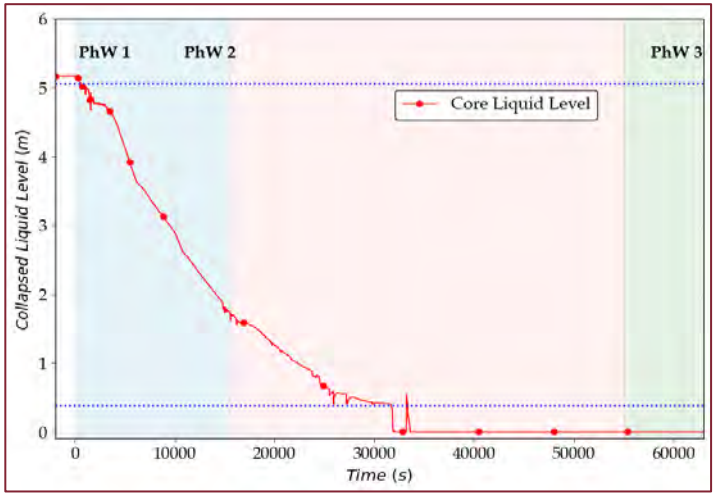


Corium Slump = spike of 6.22 MPa on Primary System pressure

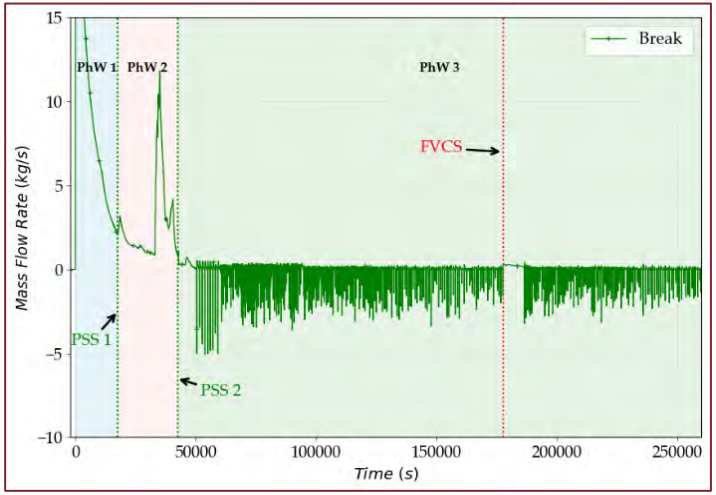
(*reduced impact on DW and PSS pressures)

- The 2 PSS reverse flows reducing the DW pressure before FVCS actuation.
- 1 FVCS actuation, after 50 hours from SOT (***core is already totally molten***).

Severe Accident Scenarios – SA2



Core collapsed liquid level



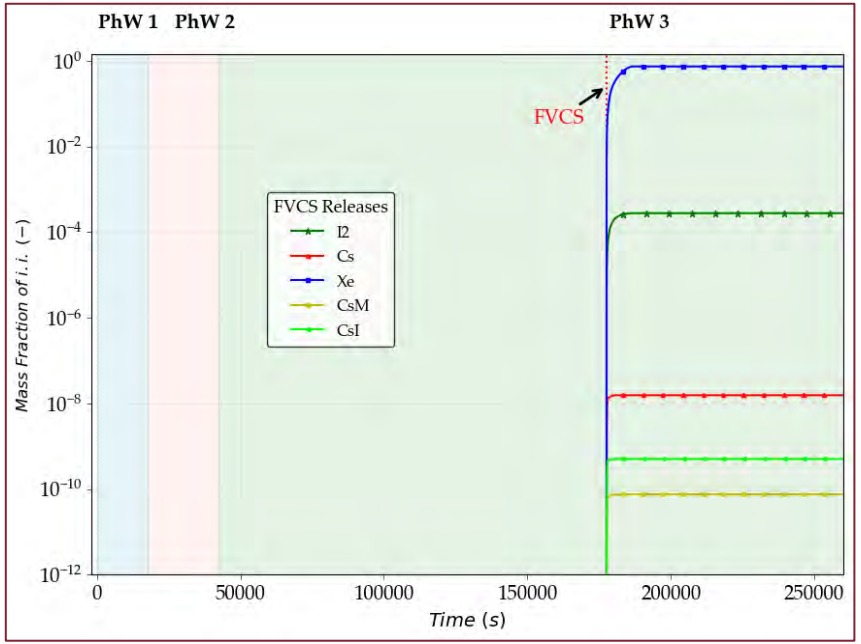
Break mass flow rate

- The ***core level*** decrease rapidly under the critical lower level (BAF), leading to *complete core degradation* in less than 7 hours from SOT.

- Water injection into the primary circuit/RPV is provided solely by the flooded **Reactor Cavity** ***(negative values on this picture)***

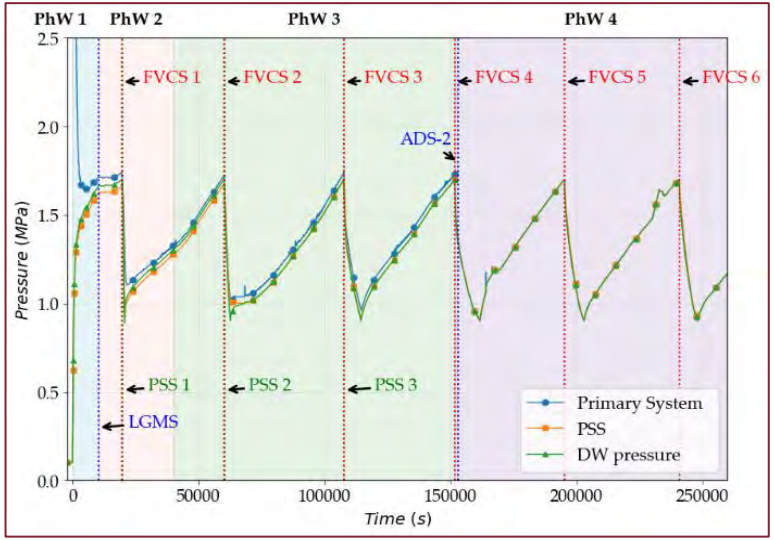
Severe Accident Scenarios – SA2

- Releases are reduced respect previous case; there is only one FCVS actuation.



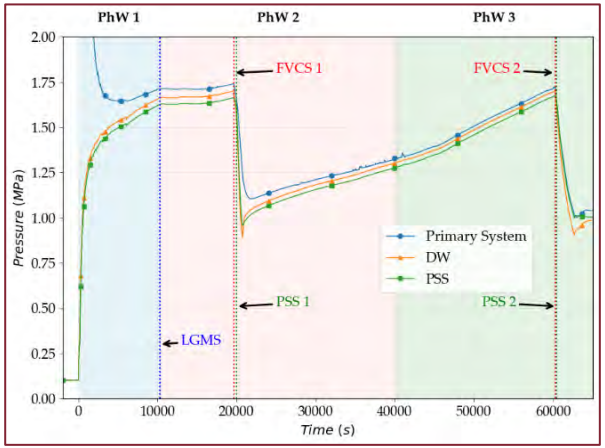
FVCS releases in mass fraction of initial inventory

Severe Accident Scenarios – SA3



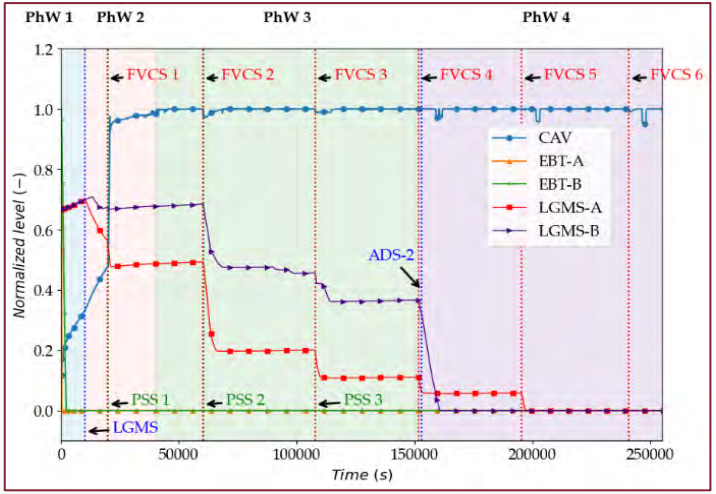
Pressure Trends

- **SA-3** has a different phenomenology; safety injection from EBT, LGMS and **Reactor Cavity** injection prevent complete core degradation.
- 6 FVCS actuations

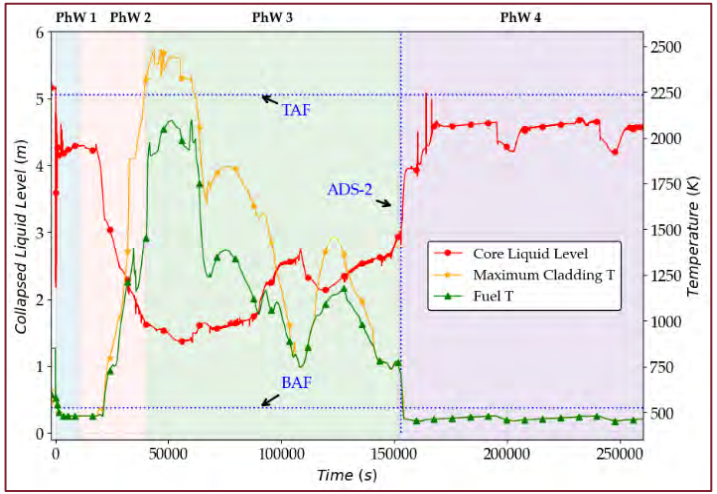


- The first FCVS actuation causes a series of phenomena: the pressure in the main system drops, mass flows from the break and ADS-1 have a significant peak and the 1st PSS reverse flow is triggered, filling the reactor cavity.

Severe Accident Scenarios – SA3



Collapsed normalized liquid level for EBT, LGMS and cavity

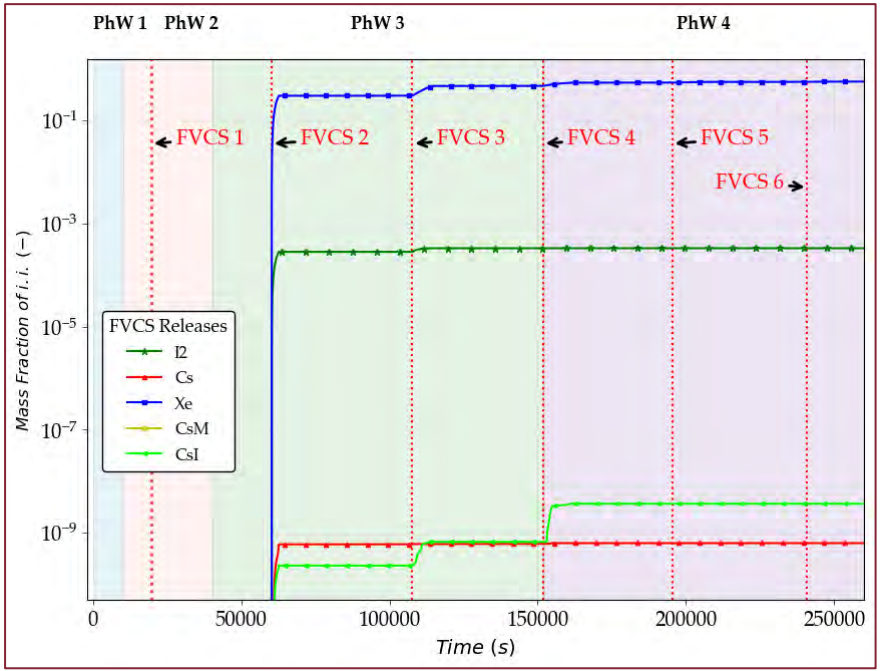


Core collapsed liquid level/Fuel and Maximum Cladding T

- The *injection* of LGMS follows the opening and closing cycles of the FCVS.
- ADS-2 actuation is delayed respect SA-1 (42.50 h).
- The water level inside the *core* ensures that only **22%** of the core is damaged.

Severe Accident Scenarios – SA3

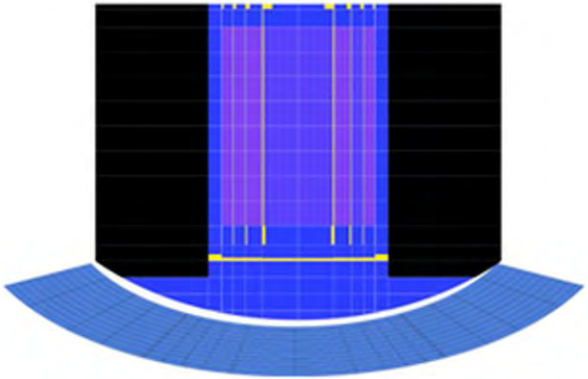
- For halogen, releases are lower than SA-1 but higher than SA-2, while noble gases exhibit an overall lower release.

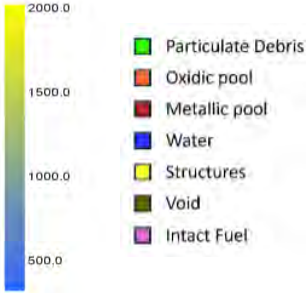


FVCS releases in mass fraction of initial inventory

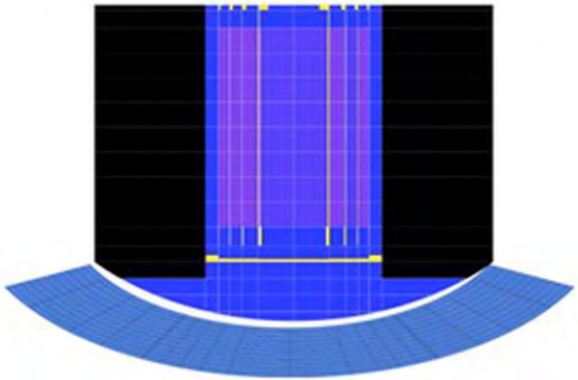
Core degradation sequences

SA-1

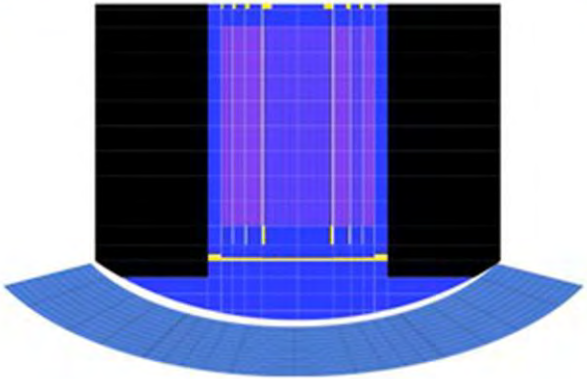




SA-3



SA-2



Comparative Core Degradation

Metric	SA-1 (Delayed ADS-2)	SA-2 (All failed)	SA-3 (ADS-1 active)
Time to Core Damage	6.07 hours	5.03 hours	11.11 hours
Core State	Total Melting - IVR	Total Melting -IVR	22% Damage
Corium Relocation	Yes (Lower Plenum)	Yes (Lower Plenum)	Partial (No slump)
Final Core Level	Above TAF (at 72h)	Water from break	Restored to pre-break

Problems and open issues

- The FCVS design parameters for Design-2 were adopted from a large dry containment *PWR* venting system.
- Multiple openings are observed; "large PWR" vent on a "small iPWR" containment means the pressure drops too fast when the valve opens, causing it to slam shut immediately, leading to rapid cycling: design requires iPWR-specific scaling.
- A sensitivity and uncertainty analysis is required to explore the results.

Conclusions and Future Activities

- The expected containment phenomenology in a Severe Accident Scenario are predicted using MELCOR, also using a simple containment nodalization.
- The main *passive safety* system was simulated as expected.
- *Radionuclide releases* through the FCVS showing that halogens are partially retained, while noble gases experience the highest release; other classes remain negligible.
- Potential cliff-edge effect associated with reverse flow in the PSS. The containment volumes are much smaller than a standard PWR. A slight error in predicting containment pressure could mean the difference between the cavity flooding or remaining dry.

- Future new analyses, coupling dose evaluations using HYSPLIT/WinMACCS.

ABSTRACT

This paper presents the calibration and assessment of two complementary simulation tools using new experimental data on hydride morphology in zirconium alloy fuel cladding. The first tool is based on the numerical solution of a system of ordinary differential equations, predicting averaged microstructural quantities including the radial hydride fraction, hydride length and hydride volume density. The second, MORPHYD explicitly simulates the nucleation and diffusion-controlled growth of disc-shaped hydrides within a virtual 3D domain. In the present work, MORPHYD is applied only to 100 wppm cases because its current version is limited to precipitation-only simulations of small, non-overlapping hydrides. MORPHYD also enables the evaluation of hydride network connectivity metrics and their statistical distributions based on the Monte Carlo method, repeating the simulations a statistically significant number of times. In both approaches, hydride nucleation is described within a classical heterogeneous framework in which the defect energy for nucleation sites is defined by the user-specified distribution. Both modelling approaches were calibrated using new experimental data obtained from the SPIZWURZ bundle test on cladding tubes manufactured from Zircaloy-4 and opt. ZIRLO. The SPIZWURZ included long-term hydride reorientation experiments conducted at the LICAS facility of the Karlsruhe Institute of Technology. The test bundle consisted of 21 hydrogen-charged cladding tubes, each 2.5 meters long, which were subjected to slow, stepwise cooling over 250 days to reproduce as close as possible dry storage conditions for spent nuclear fuel. The following morphological parameters were measured experimentally across a spectrum of hydrogen concentrations and applied stresses: radial hydride fraction, hydride length and surface density, hydride continuity coefficient (HCC) and radial hydride continuity path (RHCP). The results show that, after calibration, both simulation tools reproduce the main experimental trends in hydride morphology and connectivity, supporting their further development and application for assessing hydride embrittlement of fuel rod cladding under dry storage conditions.

hydride embrittlement, zirconium alloys, dry storage, spent nuclear fuel, modelling

1. INTRODUCTION

Hydride embrittlement of zirconium claddings can pose a risk to the integrity of cladding tubes, especially during post-operational storage [1], [2]. Hydrides are capable of providing low energy brittle crack pathways, which determine the influence of hydride morphology on the degree of embrittlement [3]. Macroscale hydride morphology is the result of the agglomeration (or stacks) of microscale ones, forming a complex "cornflake" 3D surface [4], [5]. In simplified form, macroscale hydrides can be approximated as plates and specified by their length, thickness, volume density and orientation. The entire hydride network can also be characterized by its connectivity. Hydride connectivity shows the strongest correlation with the

degree of hydride embrittlement among other metrics [6]. The ductile to brittle transition is associated with percolation of brittle crack through hydrides and corresponds to the threshold of the connectivity [3].

The morphology of hydrides is determined by the alloy texture, hydrogen concentration and thermomechanical conditions during hydride precipitation and growth. The orientation of hydrides at low stresses is determined by the texture and microstructure of the alloy. However, when external stresses exceed the threshold, hydrides tend to nucleate and grow perpendicular to the external tension [7]. Temperature is another parameter that can theoretically influence the orientation of precipitating hydrides [8]. The density, length and thickness of the hydrides are strongly determined by the cooling rate. Slow cooling rates increase length and thickness and decrease number density [9].

Temperature regimes for long-term dry storage (DS) and transport of spent nuclear fuel (SNF) include the drying of fuel assemblies in storage or transport casks. During drying, the temperature of the fuel assemblies can rise to about ~ 400 °C due to decay heat in the fuel pellets, resulting in dissolution of all or a significant part of the hydrides. The hydrides will later reprecipitate as the temperature slowly decreases with the natural reduction of decay power. Meanwhile, the cladding is loaded by the internal gas pressure, creating hoop tension. These conditions can potentially lead to the precipitation of long radially oriented hydrides, increasing the degree of embrittlement. The safety assessment of DS regimes should include the prediction of hydride morphology, based on experimental investigations of embrittlement mechanisms and simulations adapted to particular conditions. Research in both directions is currently being carried out at the Karlsruhe Institute of Technology (KIT) within the framework of the SPIZWURZ project [10]. This paper presents the results of the calibration of two theoretical approaches developed for the simulation of hydride morphology in zirconium alloys on new experimental data.

2. EXPERIMENTAL CONDITIONS. SPIZWIRZ BUNDLE TEST

The experimental SPIZWURZ bundle consisted of 21 cladding tubes with a length of 2.5 m, manufactured from Zircaloy-4, opt. ZIRLO, and the duplex alloy DX-D4 and hydrogen-charged to one of two target concentrations, 100 or 300 wppm. The spatial arrangement of the rods within the bundle is shown in Fig. 1. A detailed analysis of the experimental results concerning hydride morphology, as well as a description of the SPIZWURZ experiment, can be found in [11].

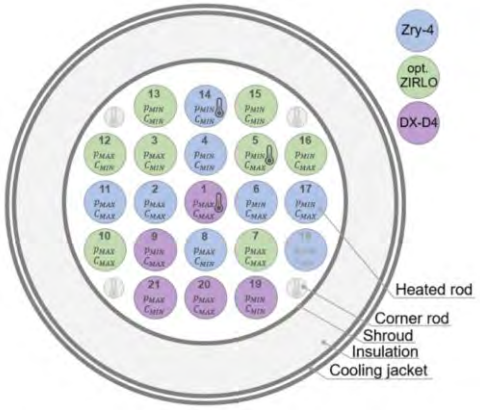

Figure 1: Schematic cross-section of the SPIZWURZ bundle. Rod arrangement

At the present stage, eight rods were selected for simulation and comparison with experimental data. These included rods 2, 4, 6, and 8 manufactured from Zircaloy-4 and rods 10, 12, 15, and 16 manufactured from opt. ZIRLO. For each alloy, the selected rods represent all combinations of the two target hydrogen

concentrations and two target internal gas pressure levels. The internal gas pressure histories applied in the simulated rods are shown in Fig. 2. Two target pressure levels, 106 and 146 bar, corresponding to approximate hoop stresses of 68 and 93 MPa, respectively.

The thermal scenario of the bundle consisted of heating up to approximately 400 °C, followed by slow, stepwise cooling. The axial temperature profiles measured by thermocouples in three instrumented rods are shown in Fig. 3*a*, where the axial coordinate of 0 mm corresponds to the beginning of the actively heated region. Fig. 3*b* presents the temperature history in the hottest axial position of rod 1 (at an elevation of 520 mm). Several abrupt temperature drops (Fig. 3*b*) are associated with unexpected power blackouts during the experiment. For the numerical simulations, smoothed temperature histories were applied, Fig. 3*b*.

The rods selected for simulations were not equipped with thermocouples; therefore, their temperature histories had to be inferred. Rods 2, 4, 6, and 8 are located symmetrically in the second layer of the bundle. Consequently, their temperature scenarios were assumed to be identical and were defined as the average of the thermocouple readings from rods 1 and 5. Rods 10, 12, 15, and 16 are located in the outer layer of the bundle; for these rods, the temperature histories were assumed to be identical to each other and equal to the thermocouple measurements obtained from rod 14, which belongs to the same layer. All temperature scenarios assumed in the simulations were smoothed in a similar way to that shown in Fig. 3*b* for the hottest zone of rod 1. These smoothed profiles remove abrupt temperature drops, short-term fluctuations of about 5 °C during holding periods, and minor non-monotonic variations, while preserving the overall thermal history and the effective cooling rates of the main cooling steps for calibration and assessment.

3. A SIMULATION TOOL BASED ON ODE SYSTEM SOLUTION

3.1. The description of the tool

The first approach is based on the numerical solution of the system of ordinary differential equations (ODE). The simulation tool used here is based on the concept described in [12] after modernization. The ODE system has four independent variables: the hydrogen concentration in solid solution (C_s), the fraction of hydrides elongated in the radial direction (θ) and the volume density of the radial and circumferential hydrides (n_r and n_r).

The kinetics of hydrogen concentration in solid solution C_s during dissolution and precipitation of hydrides is described as the relaxation of supersaturation with a characteristic time τ_0, by analogy with [13]:

$$\frac{\mathrm{d}C_s}{\mathrm{d}t} - \frac{C_s - C_e}{\tau_0} = 0 \tag{1}$$

where C_e denotes the equilibrium hydrogen solubility, which is different for dissolution and precipitation; the characteristic time τ_0 is estimated as $\tau_0 = V_{per\ hydride}/(d \cdot D_{\mathrm{H}})$, where $V_{per\ hydride} = n^{-1}$ is the volume per hydride (n is the mean hydride concentration), and dD_{H} characterizes the diffusional-controlled sink efficiency of an average hydride, with d being the average hydride diameter and D_{H} the hydrogen diffusion coefficient.

The fraction of radially oriented hydrides θ is assumed to be constant during dissolution of hydrides and can be written as follows for precipitation [12], [13]:

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = -\frac{f_r - \theta}{C_{tot} - C_s} \cdot \frac{\mathrm{d}C_s}{\mathrm{d}t} \tag{2}$$

where C_{tot} is the total hydrogen concentration (both in solid solution and in hydride phase), and f_r is the fraction of hydrogen precipitating as a component of radially oriented hydrides at the current step [12], [13]:

$$f_r = \frac{1}{1 + f_0 \cdot \exp(-\sigma \cdot \Delta\Omega/kT)} \tag{3}$$

where f_0 and $\Delta\Omega$ are model parameters, determined the susceptibility of hydrides to reorientation.

The process of nucleation of new hydrideы on crystal lattice defects is simulated in the classical heterogeneous approximation, where the nucleation rate R is [12]:

$$R = n_0 Z j^* \cdot \exp(-\Delta G^*/kT) \tag{4}$$

where n_0 is the volume density of the nucleation sites, j^* is the hydrogen flow to the critical nucleus of the hydrides, Z is the Zeldovich factor and ΔG^* is the Gibbs energy change after the hydride nucleation, which can be written as [12]:

$$\Delta G^* = \Omega^*(g_m - \Delta\mu/v_{\mathrm{H}}) + S^*\gamma - E_d \tag{5}$$

where g_m is the mechanical deformation energy due to the volume dilatation [12], $\Delta\mu$ is the chemical energy change per unit volume, v_{H} is the atomic volume of hydrogen, γ is the metal/hydride interphase energy, Ω^* and S^* are the volume and surface area of the critical hydride nucleus, E_d is the defect energy of the nucleation sites. The defect energy of the particular nucleation site depends on the defect type and its specific features and is assumed here to be a random value with a normal distribution. The nucleation kinetics of hydride stacks at the precipitation stage is estimated as the integral over all vacant nucleation sites of the nucleation frequency from Eq. (4), [12]:

$$\frac{\mathrm{d}n}{\mathrm{d}t} = \int_{E_{d,min}}^{E_{d,max}^{frei}} Gauss(E_d) \cdot R(E_d) \cdot \mathrm{d}E_d \tag{6}$$

Gauss denotes a normal distribution over energies, with the mean value E_{d0} and standard deviation $\bar{\sigma}$. Nucleated hydrides are radial with probability equal to f_r and circumferential with probability $(1 - f_r)$:

$$\frac{\mathrm{d}n_r}{\mathrm{d}t} = f_r \cdot \mathrm{d}n, \quad \text{and} \quad \frac{\mathrm{d}n_c}{\mathrm{d}t} = (1 - f_r) \cdot \mathrm{d}n \tag{7}$$

It is assumed, that the nucleation sites with maximum defect energy are filled first, and therefore the maximum defect energy of vacant nucleation sites $E_{d,max}^{frei}$, required for the integration in Eq. (6), is [12]:

$$\frac{1 + \mathrm{erf}\left(\left(E_{d,max}^{frei}, -E_{d0}\right)/\sqrt{2} \cdot \bar{\sigma}\right)}{2} = \frac{n_r + n_c}{n} \tag{8}$$

The ODE system, including Eqs. (1), (2) and (7), is solved numerically. The main model parameters are presented in Table I in the Appendix.

3.2. Calibration and assessment of the approach based on the ODE solution

Fig. 4 present the comparison of calculated RHF on experimental data for Zircaloy-4. Two sets of numerical results are shown: blind pre-test and post-test simulations. The pre-test simulations systematically overestimate the RHF, whereas the post-test simulations exhibit significantly improved agreement with the experimental data. This discrepancy can be attributed to two main factors. First, the actual hydrogen concentrations were determined only after the experiments by destructive hot-gas extraction, which data were not available for pre-test simulations. Second, different parameter sets governing hydride reorientation (f_0 and $\Delta\Omega$ in Eq. (3)) were used in the pre-test and post-test simulations. In the pre-test simulations, these parameters were fitted using the most conservative values reported in the literature (Fig. 8*a* in [14]), which resulted in an over-conservative prediction of RHF. For the post-test simulations, the model parameters were calibrated using a larger experimental database, including the new results obtained within the SPIZWURZ experiment, leading to a substantially improved model–experiment agreement. Since SPIZWURZ data were included in calibration, these post-test simulations are used to assess calibrated model performance and identify remaining deviations and trends, rather than as fully independent validation. A noticeable deviation is seen only for rod 8. We attribute this to a likely contact between the cladding and the pellet imitator, which is supported by the abnormal deformation pattern of this tube.

Fig. 5 shows the model–experiment comparison for RHF in opt. ZIRLO. In contrast to Zircaloy-4, opt. ZIRLO exhibits a lower propensity for hydride reorientation. This behavior is captured in the model through a single alloy-dependent parameter controlling the sensitivity of hydride reorientation to applied stresses ($\Delta\Omega$ in Eq. (3)). The calculated mean absolute error (both alloys) for RHF is 0.04.

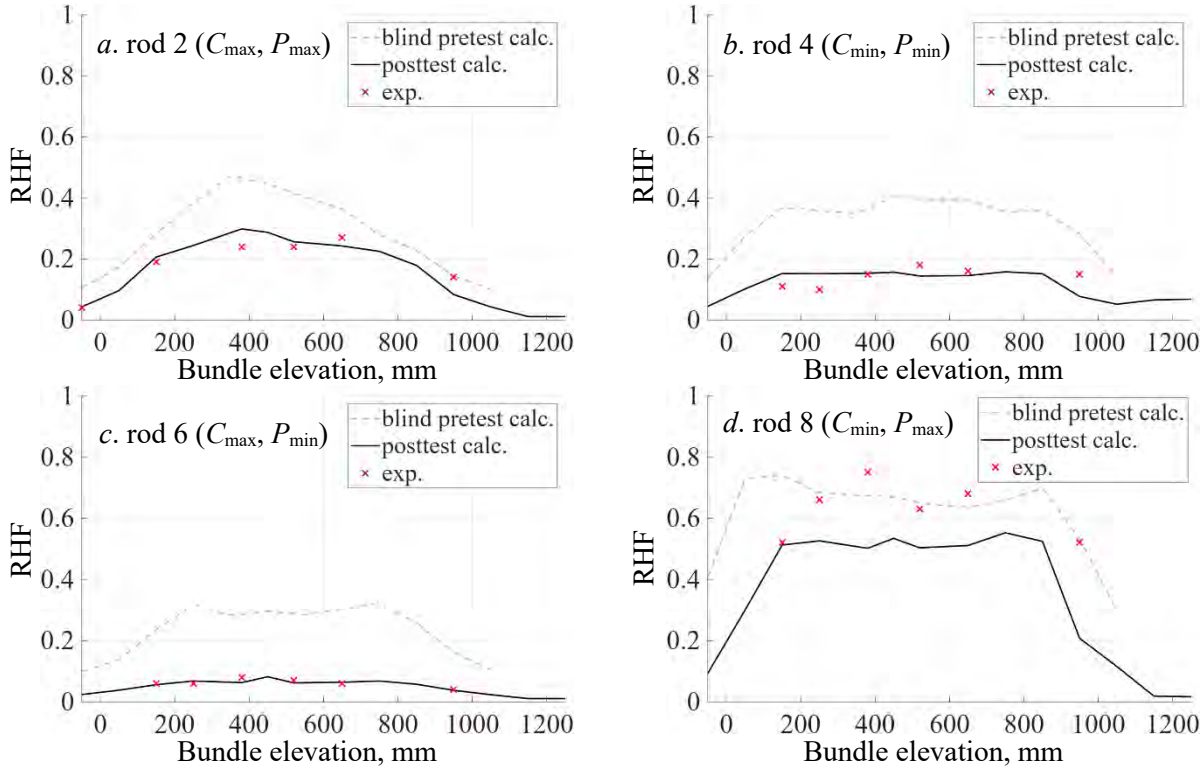

Figure 4. RHF in Zircaloy-4, model-experiment comparison; C_{max}/C_{min} corresponds to 300/100 ppm, (target concentration), P_{max}/P_{min} corresponds to 146/106 bar (target internal pressure)

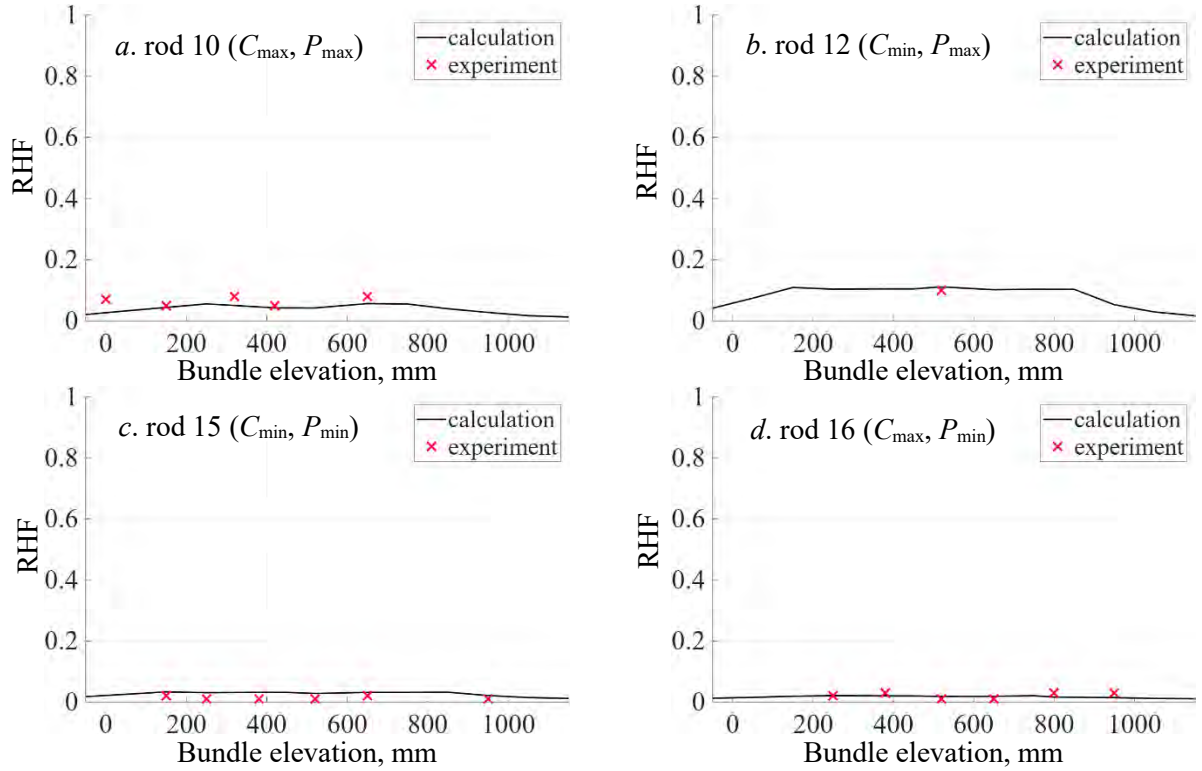

Figure 5. RHF in opt. ZIRLO, model-experiment comparison; C_{max}/C_{min} corresponds to 300/100 ppm, (target concentration), P_{max}/P_{min} corresponds to 146/106 bar (target internal pressure)

Figs. 6 and 7 compare the mean hydride length and hydride surface density for Zircaloy-4 and opt. ZIRLO. The simulated and experimentally measured values may differ by up to a factor of two, which is considered acceptable at the current stage of tool development. The calculated relative RMSE values for hydride length and hydride density are 25% and 20%, respectively. Hydride length and density are governed by the balance between the nucleation rate and the supersaturation relaxation rate and are therefore highly sensitive to uncertainties in key model parameters, including hydrogen solubility, hydrogen content, and defect-related energies. The present results were obtained using a smoothed temperature scenario (Fig. 3*b*). Compared to Zircaloy-4, opt. ZIRLO exhibits longer hydrides and a lower hydride surface density. This alloy-dependent behavior is captured in the model by assuming different densities of nucleation sites (n_0 in Eq. (4)), which may be associated with differences in crystallographic texture and in the density of high-energy grain boundaries with large misorientations.

4. MORPHYD SIMULATION TOOL

4.1. The description of the tool

The numerical tool MORPHYD (an acronym of MORPHology of HYDrides), described in [15], [16], is another approach used to simulate the morphology of hydrides under the conditions of the SPIZWURZ bundle test. The physical basis of MORPHYD is very similar to the model described above; however, the

numerical realization is different. The fundamental difference is that MORPHYD simulates the nucleation and growth of disc-shaped hydrides in a virtual 3D domain. Nucleation occurs at uniformly distributed nucleation sites (defects in the crystal lattice) with a probability at the current time step τ equal to $r \cdot \tau$, where $r = R/n_0$ and R is given by Eq. (4). The orientation of the nucleated hydride is the stochastic value: the probability for radial orientation is f_r, and for circumferential orientation is $(1 - f_r)$, where f_r is determined by the Eq. (3). The growth of hydrides is determined by the diffusive flow from the solid solution to the end of the edge of the disk-shaped hydride [15], [17]. Another assumption is that each hydride can only absorb hydrogen from the space where it is the nearest hydride (in its Voronoi cell) [16]. This assumption takes into account the "clustering effect", i.e. that randomly closely related hydrides are expected to be shorter, than isolated ones due to "competition" for the hydrogen in the solid solution, needed for their growth during cooling.

Fig. 8*a* shows the MORPHYD simulation result for the hydride morphology in rod 4 at an elevation of 520 mm. Fig. 8*b* presents a cross-section of the simulated domain shown in Fig. 8*a*, which can be directly analyzed by analogy with the corresponding experimental micrographs. All MORPHYD simulation results are stochastic in nature. By repeating the simulations a statistically significant number of times, the statistical distributions of hydride morphology parameters can be evaluated using a Monte Carlo approach.

At its current stage of development, the model is limited to the simulation of the precipitation phase and is applicable only to small, non-overlapping hydrides, whose characteristic size remains smaller than the inter-hydride spacing. Consequently, MORPHYD was applied exclusively to samples with a hydrogen content of 100 ppm.

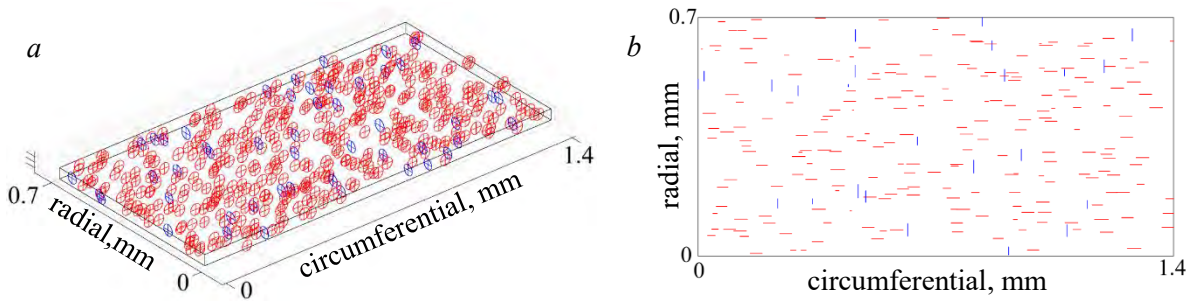

Figure 8: A single MORPHYD simulation result for rod 4 at 520 mm: *a*) disk-shaped hydrides with two orientations in a 3D domain; *b*) cross-section of the domain used for morphology analysis

4.1. Calibration and assessment of the MORPHYD

The following metrics were simulated with MORPHHYD and compared with experimental data: hydride length, hydride continuity coefficient (HCC, the sum of hydride length projected in radial direction in a 110 μm wide band, [6]) and radial hydride continuity path (RHCP, estimated as the relative reduction in calculated fracture energy for a given morphology compared to the samples without hydrides [6], [18]). By repeating the simulations at least 100 times, the statistical distribution of these morphology metrics can be estimated based on the Monte Carlo method. The calculated probability density functions (PDF) for the hydride morphology metrics in rods 4, 8, 12 and 15 at elevation 520 mm (the hottest axial zone) are compared with the experimental results on Figs. 9 – 11.

As shown in Fig. 9, the mean value and the width of the hydride length distributions obtained from simulations are in good agreement with the experimental data for both Zircaloy-4 and opt. ZIRLO. A notable

deviation is observed for rod 12, for which the simulated mean and distribution width are approximately a factor of two lower than the experimental values. Nevertheless, this discrepancy is considered acceptable at the current stage of tool development. In both experiments and simulations, the hydride length distributions are well described by a lognormal function characterized by a long-length tail [11]. In the simulations, this tail arises from the merging of several neighboring hydrides located at mutual distances smaller than approximately 5 μm, which are represented as a single elongated hydride.

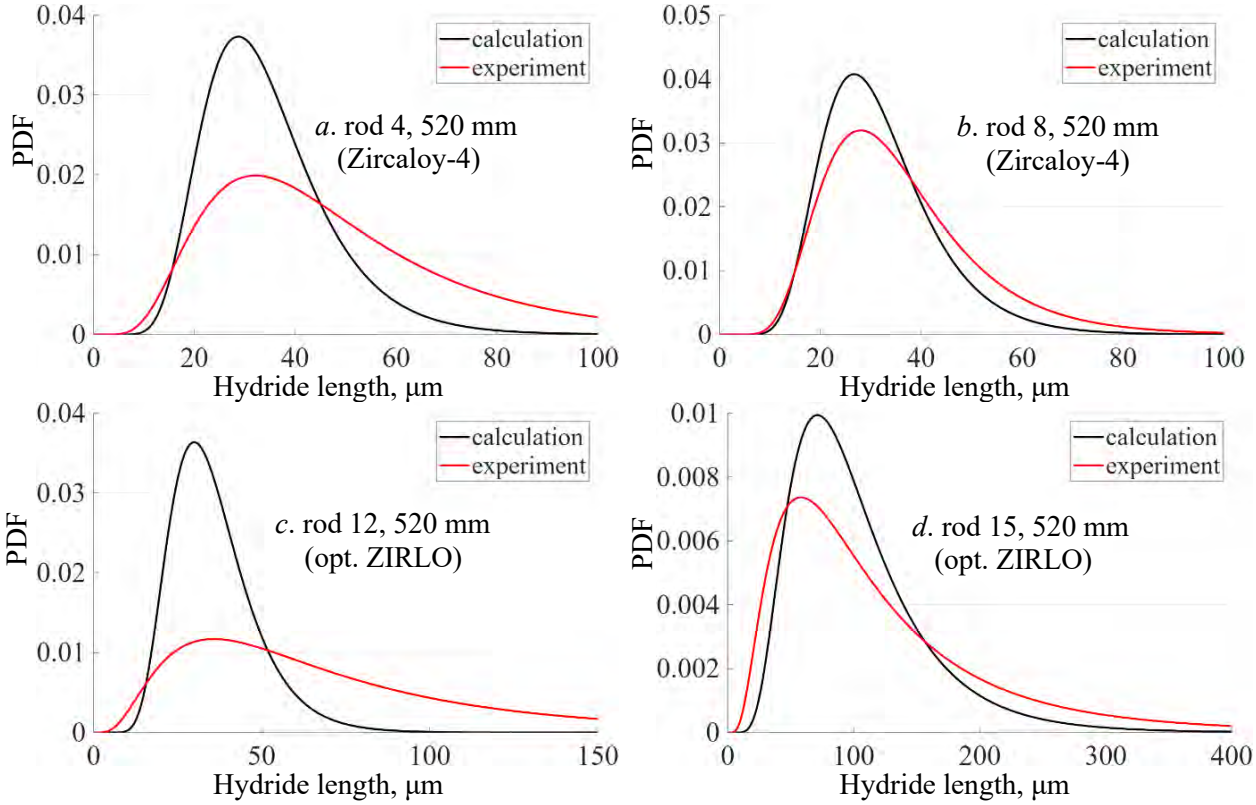

Figure 9. Statistical distributions of hydride lengths: comparison of experiment and calculation;

The calculated statistical distributions of the HCC and the RHCP are shown in Figs. 10 and 11, respectively. These distributions are compared with the corresponding experimental values obtained for the same cross-sections, which are indicated by dotted lines. The experimental HCC values are systematically higher than the mean values of the simulated distributions, whereas the experimental RHCP values are consistently lower than the corresponding simulated means. Nevertheless, when the finite width of the simulated distributions is taken into account, the experimental values remain comparable to the calculated results. The experimental value lies within the central 90% interval of the simulated distribution. Overall, the agreement between simulations and experiments is considered acceptable at the current stage of model development. Both HCC and RHCP exhibit the correct qualitative trends with increasing internal pressure and attain physically reasonable absolute values.

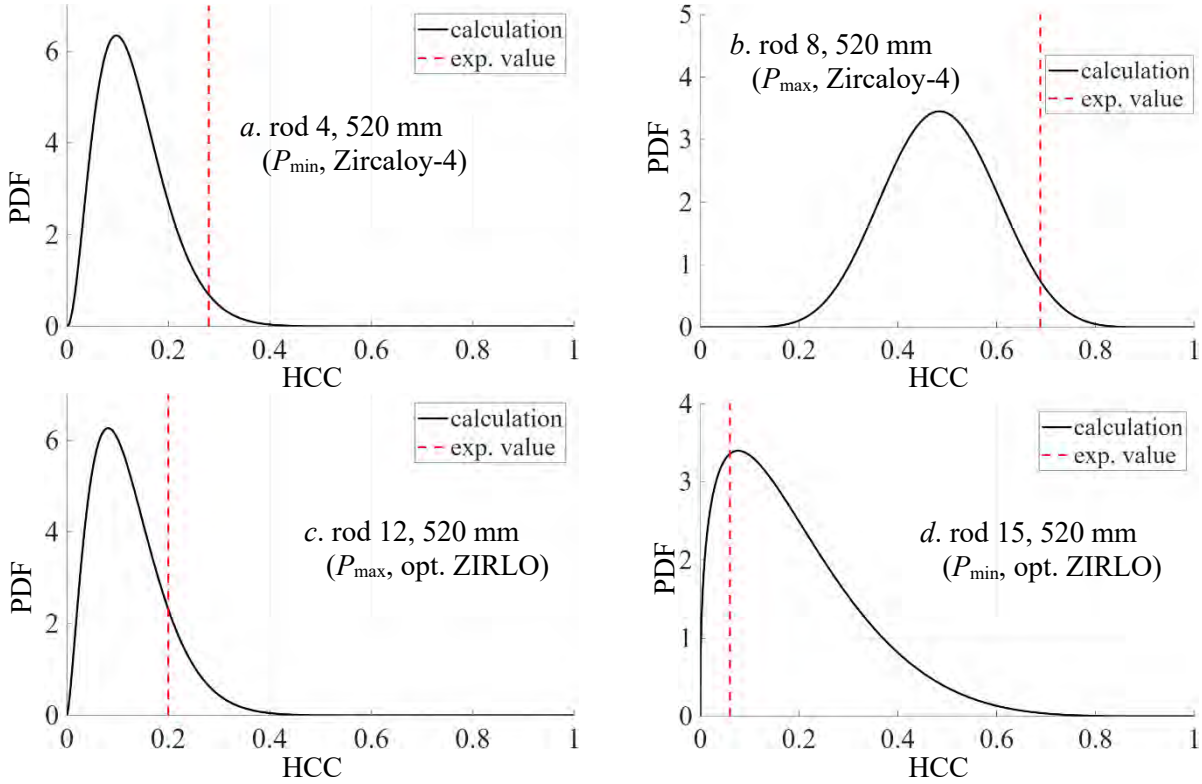

Figure 10. Calculated statistical distributions of HCC, compared with a single measurement

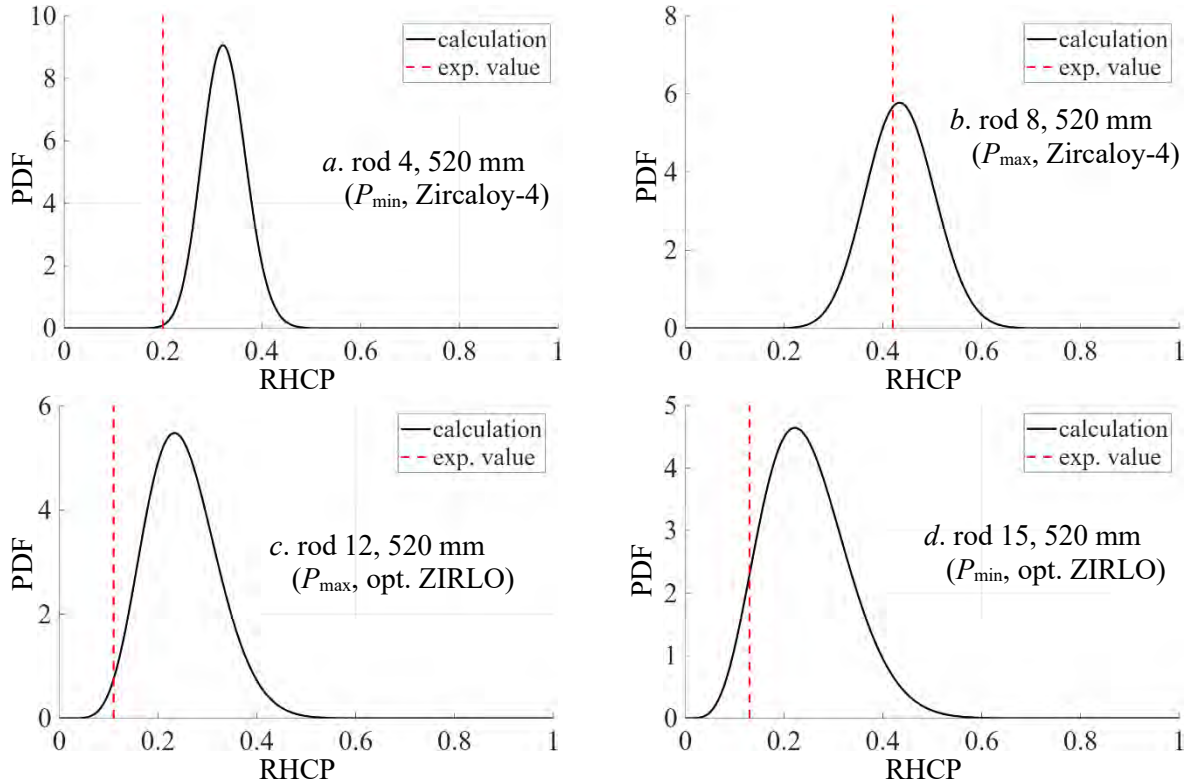

Figure 11. Calculated statistical distributions of RHCP, compared with a single measurement

5. CONCLUSION

Two numerical tools developed for the simulation of hydride morphology in zirconium alloys have been calibrated using new experimental data for Zircaloy-4 and opt. ZIRLO obtained in the SPIZWURZ test. Both numerical tools are complementary and can be used in tandem for advanced simulations.

The tool, based on the solution of the ODE system, is able to simulate the mean values of RHF, hydride length and density. The mean absolute error for RHF is 0.04, while the relative RMSE values for hydride length and density are 25% and 20%, respectively. A more systematic sensitivity analysis with respect to thermal-history assumptions and selected model parameters, including calculations with non-smoothed temperature histories, will be reported separately.

The MORPHYD tool showed the satisfactory agreement of the statistical distributions of hydride length, HCC and RHCP. The current limitations of MORPHYD are related to its precipitation stage only, the simplified description of hydride growth, and the restriction to small, non-overlapping hydrides. Therefore, the present MORPHYD assessment is limited to the 100 wppm cases.

Response to Reviewer#1

Accepted with no revisions

Author's response: *We sincerely thank the reviewer for the positive evaluation of our manuscript and for recommending acceptance without further revisions. We appreciate the reviewer's time and consideration.*

Response to Reviewer#2

Accepted with minor revisions

Reviewer's comment: I see several strengths. First, the topic is important and timely for dry-storage safety. Second, the two-model strategy is well motivated: the ODE tool is suitable for mean quantities along the rod, while MORPHYD addresses statistical distributions and connectivity, which are physically more relevant to embrittlement. Third, the figures on pp. 6–10 show that the models reproduce the main qualitative trends, including weaker reorientation in opt. ZIRLO and sensible pressure effects on HCC/RHCP. The manuscript is also commendably honest about current limitations: the ODE tool reaches about ±0.1 for RHF, while hydride length and density may differ by up to a factor of two, and MORPHYD is limited to precipitation-only simulations of small, non-overlapping hydrides and was applied only to 100 wppm cases.
Author's response: *We sincerely thank the reviewer for the careful and constructive evaluation of our manuscript. We are grateful for the positive comments which helped us to improve the manuscript. The detailed responses for comments are below.*

Reviewer's comment: My main concern is that the strongest "validation" result is not fully independent. The manuscript states that the post-test ODE parameter set was calibrated using a larger database that included the new SPIZWURZ results, whereas the blind pre-test simulations systematically overpredicted RHF. This is important. The paper should distinguish clearly between blind prediction and post-test calibration. As written, the term "validation" is somewhat too strong unless the authors reserve an independent subset of the data or at least tone down claims such as "reliably predict."
Author's response: *The authors are grateful to the reviewer for this important comment and agree that the present paper largely describes the calibration and assessment of the models using new experimental data rather than a fully independent validation. The manuscript has been revised accordingly. Following the reviewer's recommendation, the term "validation" has been replaced throughout the text by "calibration and assessment", where appropriate. The only exception is the title of the paper, which has been retained because it has already been included in the conference program in its current form, in order to avoid any confusion with the title used in the published conference proceedings and the conference program. Additionally, the conclusion has been corrected and the following phrase has been added to the manuscript (in the end of Page 5):*
"Since SPIZWURZ data were included in calibration, these post-test simulations are used to assess calibrated model performance and identify remaining deviations and trends, rather than as fully independent validation."

Reviewer's comment: A second concern is that the agreement assessment is still mostly qualitative. Statements such as "acceptable agreement," "±0.1 for RHF," or "factor of two" are useful, but a validation paper would be much stronger with formal error metrics: MAE/RMSE, mean relative error, bias, and perhaps confidence bands. This is especially important for MORPHYD. On pp. 9–10, the simulated HCC and RHCP distributions are compared with single experimental values, and the manuscript itself notes a systematic pattern: experimental HCC tends to be above the simulated mean, while RHCP tends to be below it. A broad simulated distribution can make a single measured value look "comparable," but that is weaker evidence than agreement in central tendency and spread.

Author's response: *We thank the reviewer for this helpful suggestion. We agree that the assessment of the model performance should be supported by quantitative error metrics where possible. In the revised manuscript, we have added quantitative metrics for the ODE-based tool. The mean absolute error for RHF is 0.04, while the relative root mean square errors for mean hydride length and hydride surface density are 25% and 20%, respectively. The corresponding comments have been added to the manuscript text in Section 3.2 and in the Conclusion.*

For MORPHYD, a direct calculation of MAE or RMSE is less straightforward because the simulations provide statistical distributions obtained from repeated Monte Carlo runs, whereas the available experimental comparison consists of single measured values for individual cross-sections. We have therefore clarified in the manuscript (above Figure 10) that the experimental value lies within the central 90% interval of the simulated distribution.

Reviewer's comment: A third issue is uncertainty propagation. The temperature histories for most rods were inferred rather than directly measured and were smoothed to remove abrupt drops and fluctuations. Because hydride precipitation is sensitive to thermal history, the paper would benefit from at least a short sensitivity analysis showing how RHF, hydride length, HCC, and RHCP change when the smoothing assumptions are varied. Likewise, several parameters in Table I appear to be fitted or user-defined rather than independently measured. The calibration workflow and uncertainty ranges should be made more explicit; otherwise it is difficult to judge how much of the agreement is physically predictive and how much comes from compensating parameter choices.

Author's response: *We thank the reviewer for this important comment. We agree that the uncertainty associated with the inferred and smoothed temperature histories is an important aspect of the present assessment. In the revised manuscript, we have clarified the purpose and limitations of the smoothing procedure (above Figure 2). The smoothing was applied to remove short-term temperature fluctuations of approximately 5 °C during the holding periods and minor non-monotonic variations, while preserving the overall thermal history and the effective cooling rates of the main cooling steps used in the experiment.*

We also agree that a systematic sensitivity analysis with respect to the temperature scenario and model parameters is highly relevant. Such an analysis has been performed as a separate follow-up study, including calculations with the original, non-smoothed temperature histories and an updated version of the model with reduced sensitivity to short-term thermal fluctuations. These results are beyond the scope of the present conference paper and will be presented at the TopFuel conference later this year. In the revised manuscript (Conclusion), we have added a short statement to make this limitation and the ongoing follow-up work explicit.

Reviewer's comment: I also think the scope limitations of MORPHYD should be stated earlier and more prominently. Page 8 explains clearly that the model is limited to the precipitation phase, to small non-overlapping hydrides, and therefore to the 100 wppm cases analyzed here. That limitation is acceptable at this stage, but it narrows the generality of the conclusions and should be visible already in the abstract and in the final take-home message."

Author's response: *We thank the reviewer for this helpful comment. We agree that the current limitations of MORPHYD should be stated more prominently. In the revised manuscript, we have added a sentence to the Abstract clarifying that the present version of MORPHYD is limited to precipitation-only simulations of small, non-overlapping hydrides and was therefore applied only to the 100 wppm cases. We have also revised the Conclusion to make this limitation visible in the final take-home message and to clarify that further model development is required before applying MORPHYD to higher hydrogen concentrations and dissolution–precipitation scenarios.*

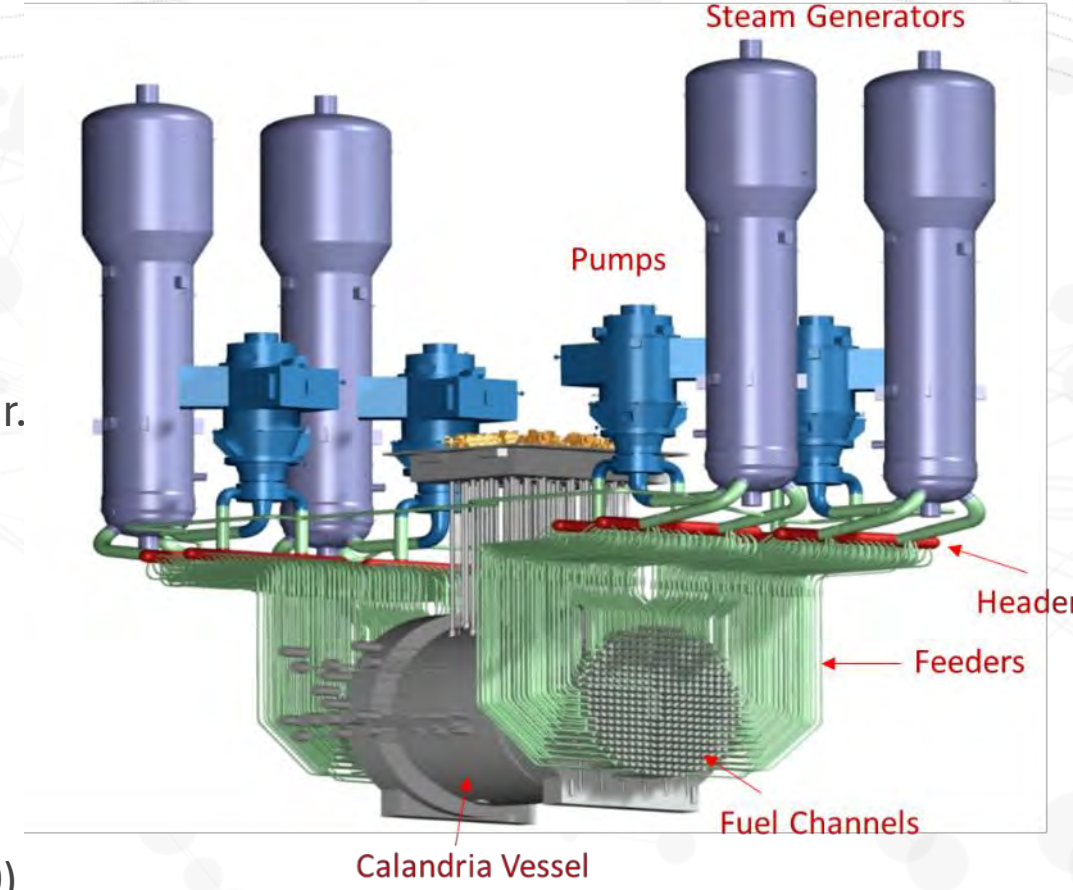
SECTION 1

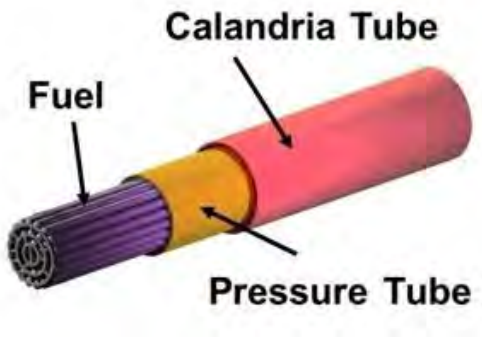
Introduction

Overview of CANDU

Key Features:

- Uses natural uranium (not enriched).
- Employs heavy water (D_2O) as the coolant and moderator.
- Reactor core is a horizontal pressure tube design rather than a pressure vessel design.
- On-power refueling—fuel can be replaced without shutting down the reactor.
- Generates tritium (a rare isotope) as a byproduct, valuable for medical research and fusion energy.
- Allows to produce medical radioisotopes (such as Cobalt-60) simultaneously with electricity, due to low-temperature moderator.





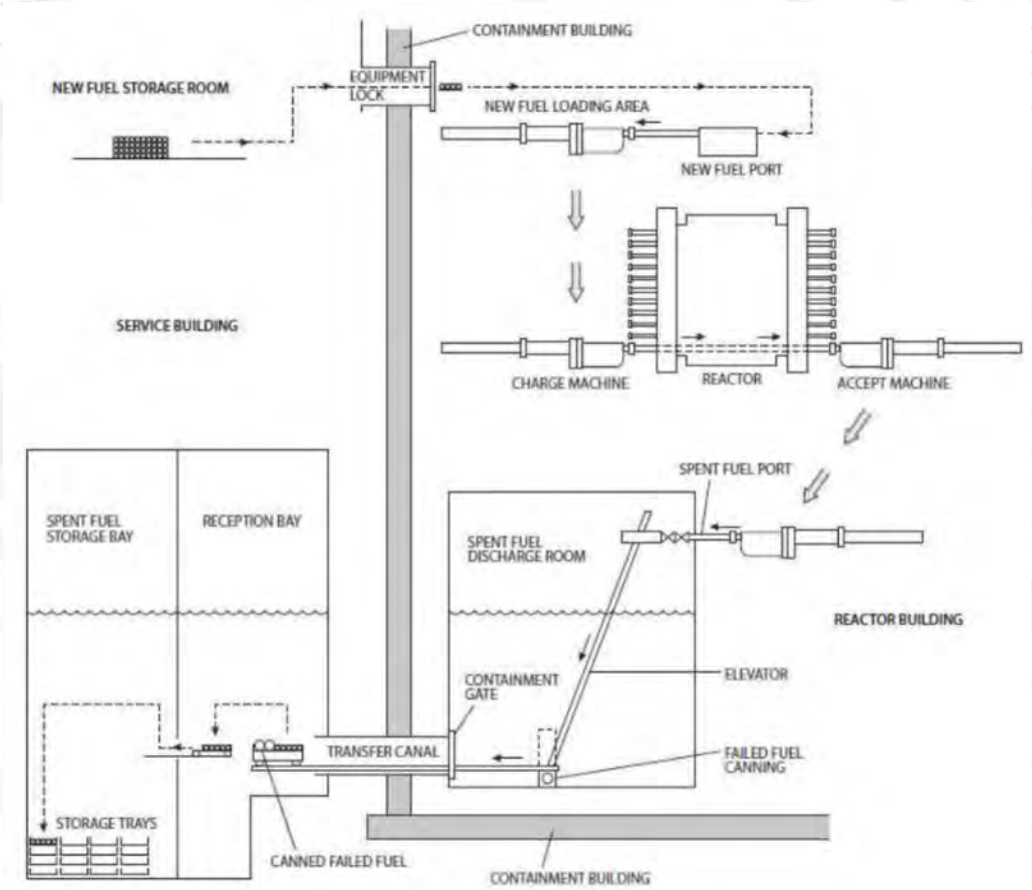
Source: Canteach.CANDU

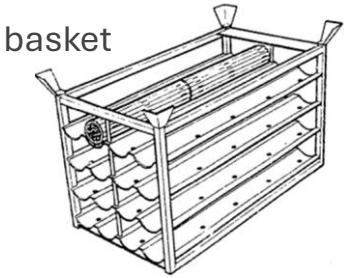
CANDU Spent Fuel Pools (SFPs)

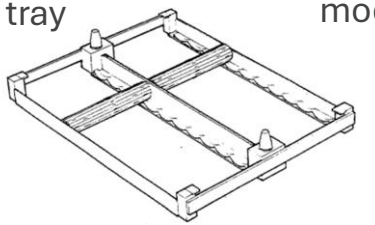
- CANDU fuel bundles are ~50 cm long, weigh 25 kg, and are ~10 cm in diameter
- CANDUs are refueled daily (~12-16 fuel bundle/day).
- Spent fuels continue to generate decay heat and requires cooling.
- Fuel taken from reactor is transferred to:

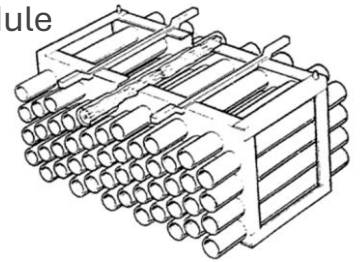
discharge room → reception bay → spent fuel storage bay

- In the reception bay, fuel bundles are placed in baskets
- After ~1-2 weeks, the fuel is relocated to the storage bay where bundles are transferred into trays/modules
- Criticality concerns are negligible, allowing for flexible bundle spacing.









Source: The essential CANDU textbook

Motivation for SFP Accident Studies

- **SFP safety depends on active cooling**

  Prevents fuel overheating, hydrogen buildup, and radionuclide release

- **Fukushima highlighted vulnerabilities**

  water levels dropped, but emergency makeup preserved fuel coverage

- **International response**

  IAEA called for reassessment of plant resilience to extreme natural hazards, including SFPs

- **Regulatory actions**

  Global regulators, including the CNSC, addressed identified gaps

- **CNL contribution**

  ✓ Developed a PIRT [1] to identify key accident phenomena

  ✓ Initiated SFP accident analysis studies, focused on CANDU reactors

SECTION 2

CNL's Efforts in SFP Accident Analysis for CANDU Reactors (2022-2025)

Fuel Bay Heater Apparatus (FBHA) Experiments

Overview

Objective

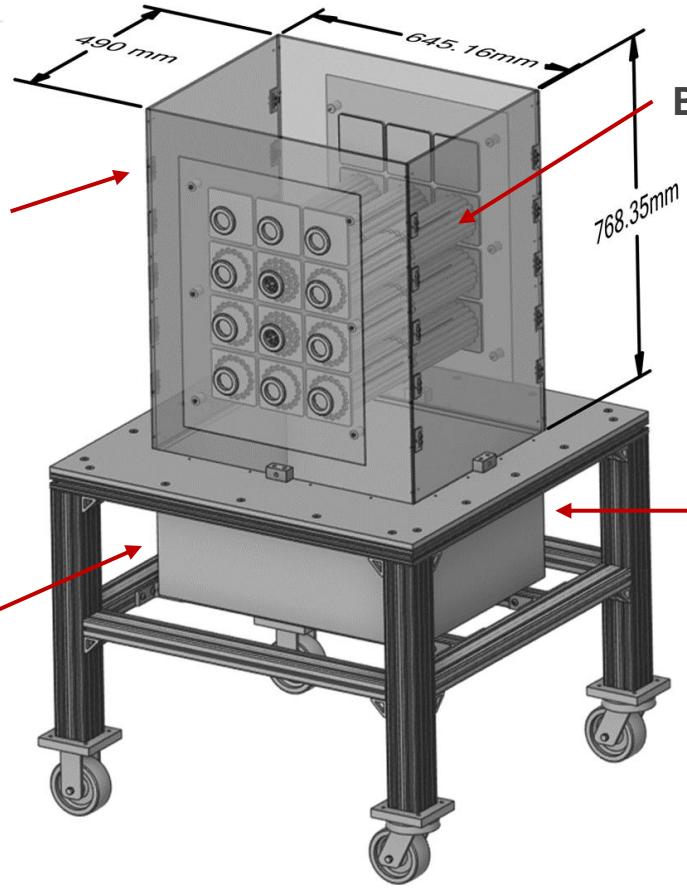
- To measure the **surface temperature** of irradiated CANDU fuel bundle simulators across different power levels and under various environments (representative of LOCA [2] scenario).

Bundle Power & Test Conditions

- Typical CANDU bundle decay power decreases to ~2.6 kW after 1 days, and further to ~62 W after a year in the pool [1].
- Experiments were conducted over a range of simulated bundle power levels (500 W to 3 kW) under three environmental conditions:
  - Stagnant dry air
  - Forced dry air (flow rate of 0.013 m^3/s)
  - Steam environments (low/high steam generation rates)

2 Loss of Coolant Accident

Apparatus Design

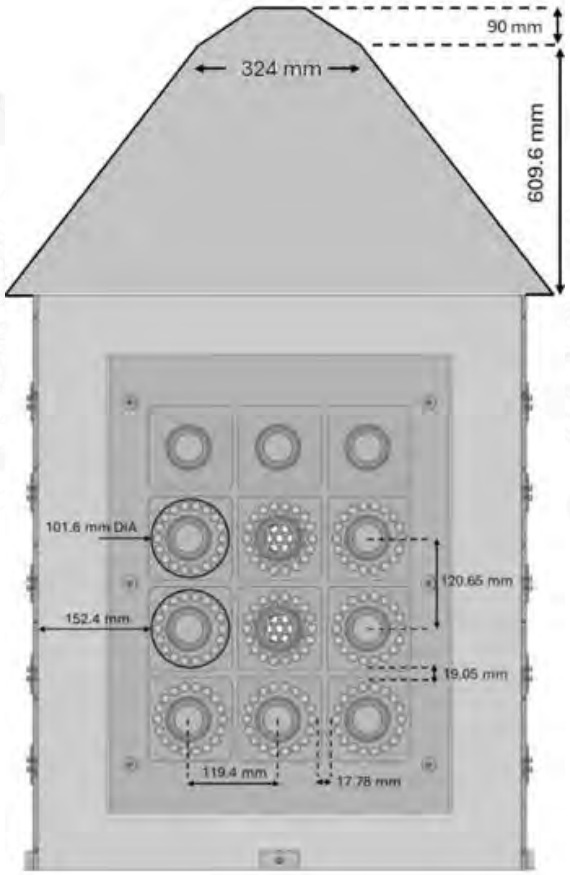


Stainless-Steel Enclosure

Bundles

Water Tank

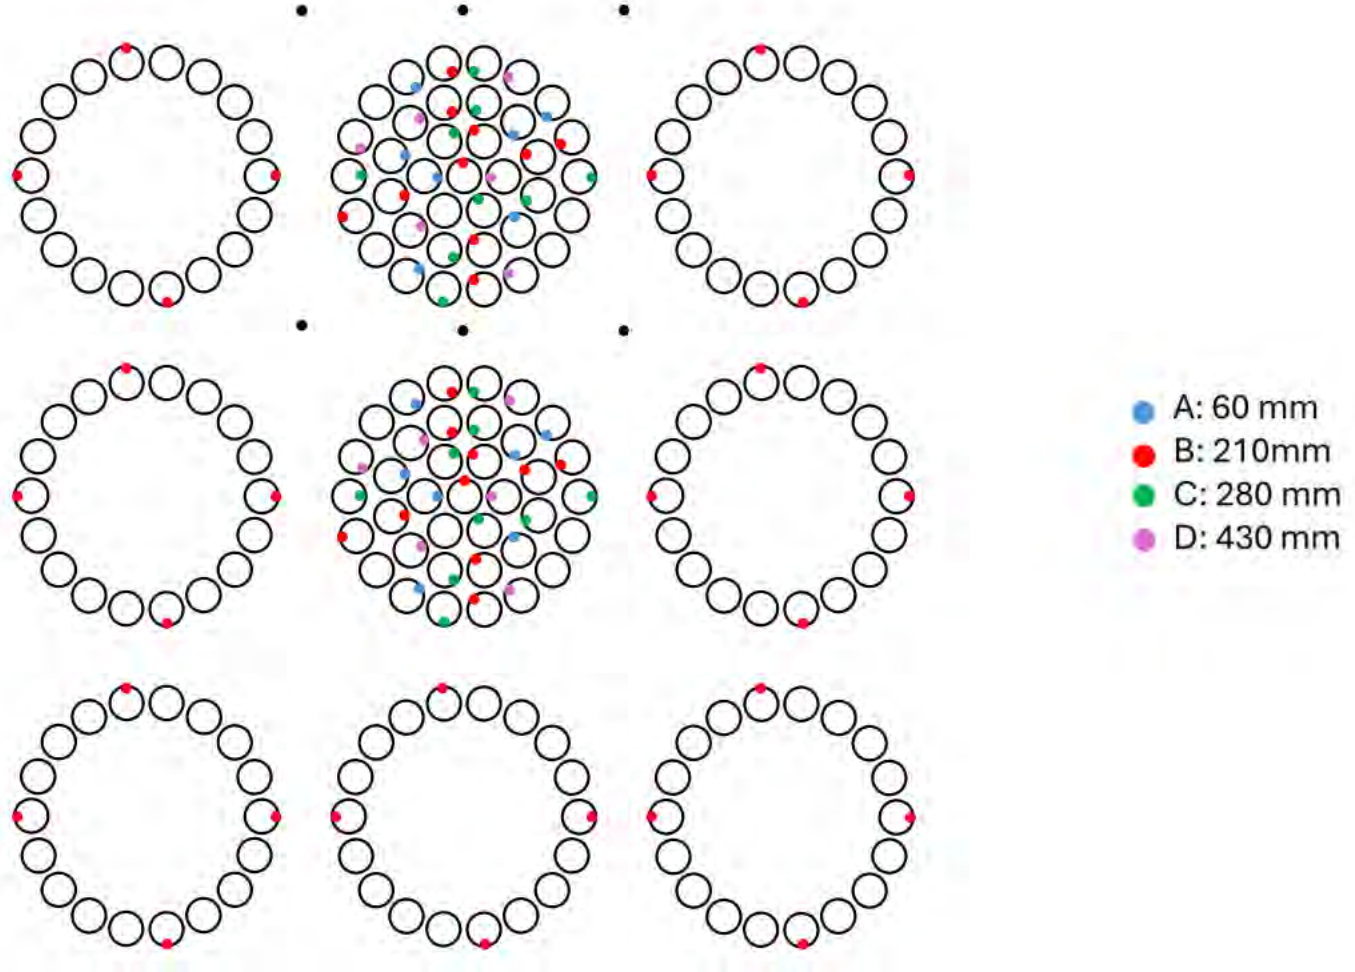
Forced Air Supply (not shown)



Bundles: Cartridge-heater–based simulator used to reproduce bundle heating profiles

Thermocouple Placement

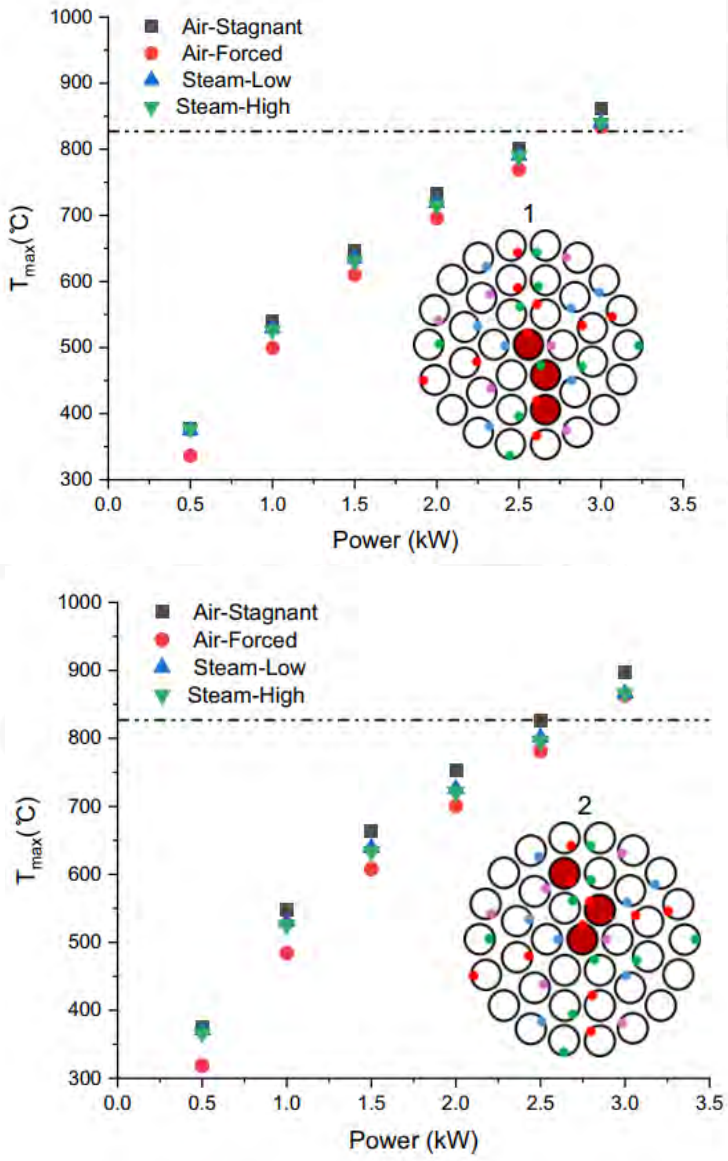
- **92** TCs were embedded ~1 mm beneath the **outer surface** of the elements to measure surface temperatures of the simulated fuel elements.
- **24** TCs were deployed to monitor inter-bundle **gas** (air/steam) temperatures.
- **8** thermocouples assessed the interior apparatus **wall** temperatures.



Locations of bundle (coloured) and gas (black) thermocouples. The inset illustrates the distances of thermocouples from the front edge of the bundle.

Selected Results

- The highest sheath temperatures occurred in the **stagnant air environment**, whereas the lowest were observed in the forced air environment.
- The steam generation rate had a negligible effect on sheath temperature.
- In the **top** full bundle peak temperatures were recorded at the **central element and its immediate lower vicinity**.
- In the **bottom** full bundle peak temperatures were observed at the **central element and its upper vicinity**.
- The maximum sheath temperature approached the hydrogen generation threshold (~827 °C) **at bundle power levels exceeding 2.5 kW** in the evaluated three row bundle configuration.



Maximum sheath temperature as a function of bundle power: (top) top full bundle; (bottom) bottom full bundle

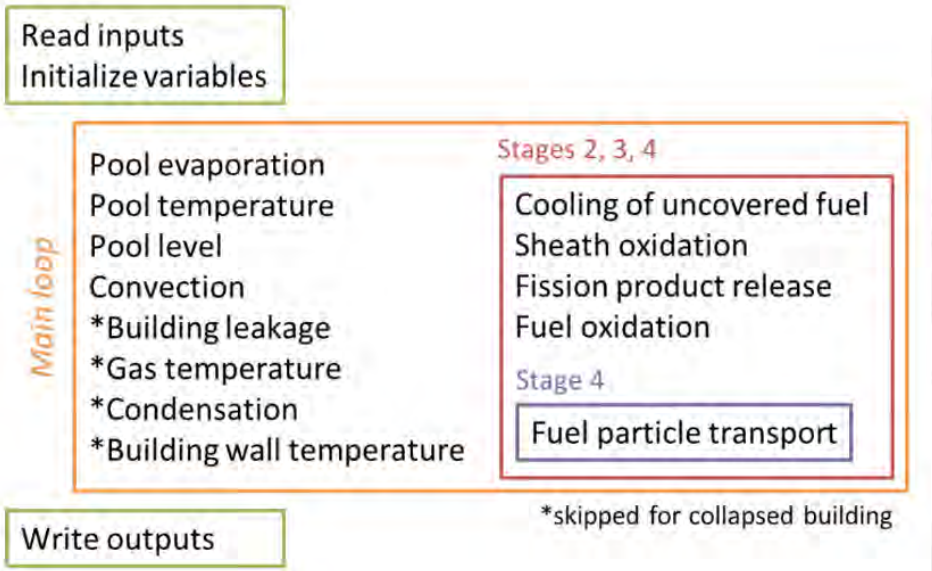
Assessment of BAYLOCA SFP Accident Analysis Code

BAYLOCA Code Overview

- **BAYLOCA** is a fast-running, lumped-parameter accident analysis code developed for the CNSC to evaluate CANDU SFP LOCAs.
- Designed to simulate all phases of SFP accident progression, **from loss of cooling to recovery**.
- Accident evolution modeled in **four stages**:

1. Loss of pool makeup; fuel remains fully submerged
2. Pool level decreases; partial fuel uncovering begins
3. Complete loss of pool water due to boil-off or leakage
4. Cooling water restoration (can occur from any prior stage)

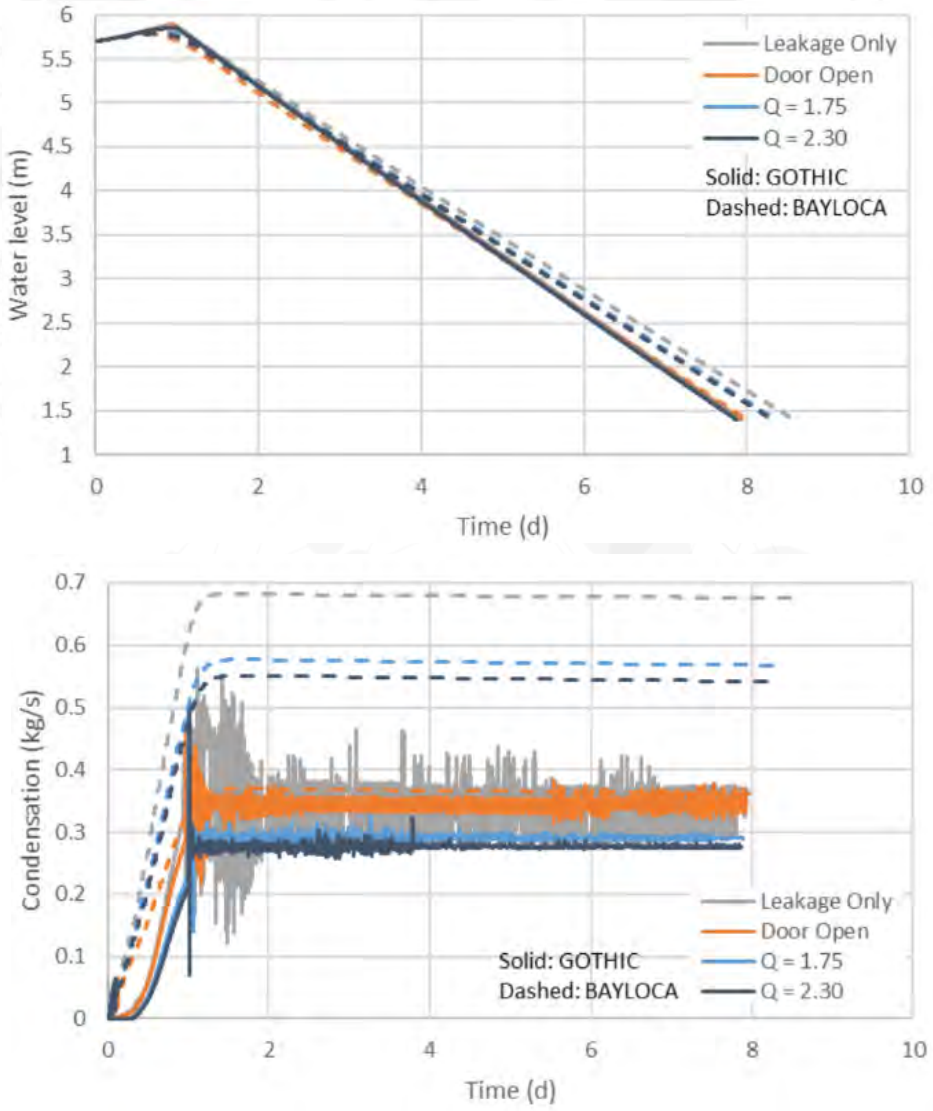
- User inputs include decay heat, fuel and pool geometry, building characteristics, and boundary conditions.
- Key outputs include **pool water level and temperature, fuel and gas temperatures, oxidation progression, and fission product release histories.**



Overall view of an accident simulation

Code Assessment and Benchmarking

- Benchmarking performed against GOTHIC and CFD simulations demonstrated generally good agreement in predicted thermal-hydraulic behavior.
- Identified further refinement in:
  - ✓ convective fuel cooling
  - ✓ fission product transport
  - ✓ deposition models

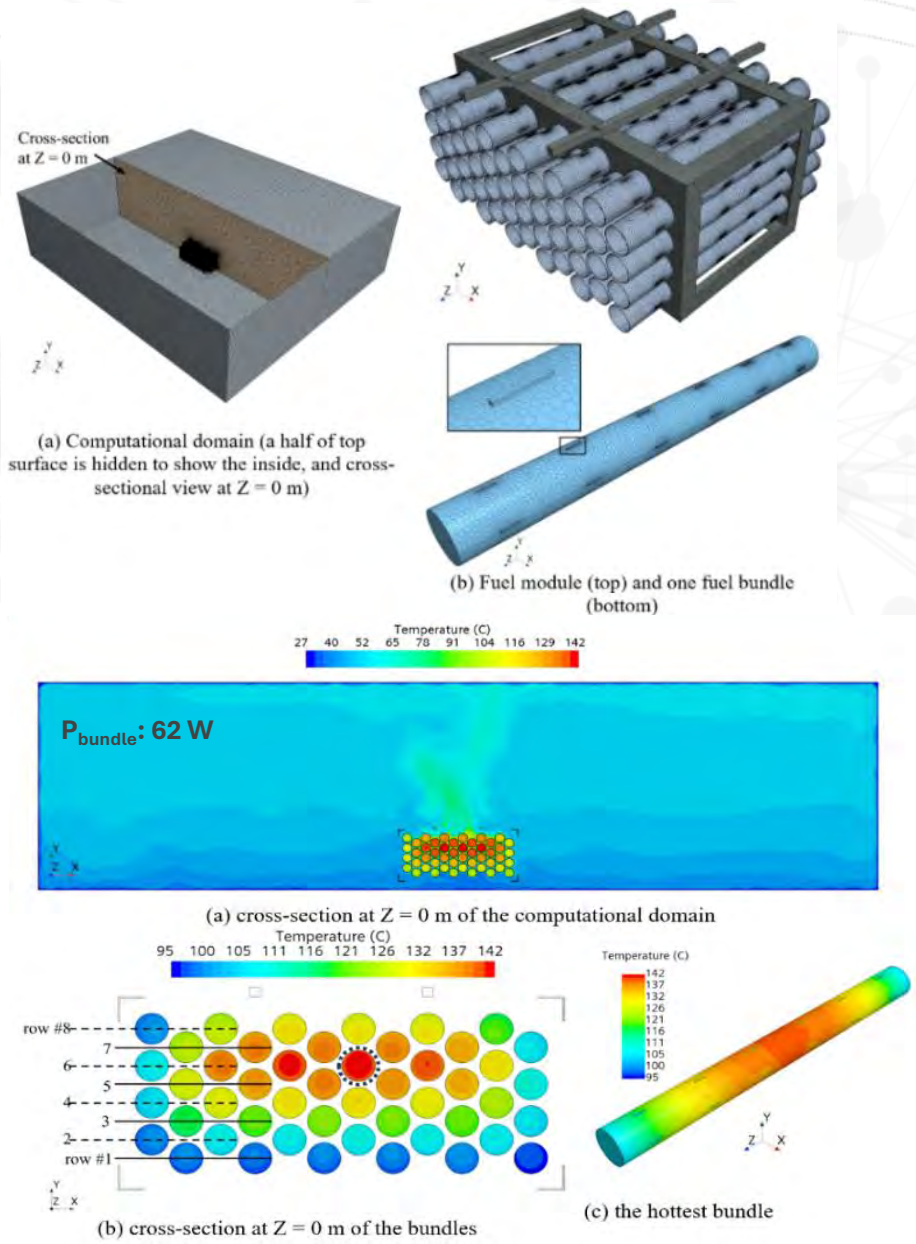


Comparison of the results between GOTHIC and BAYLOCA with similar input parameters: (top) water level in the pool, (bottom) rate of condensation

CFD Analysis of SFP Accidents

Overview and High-Level Results

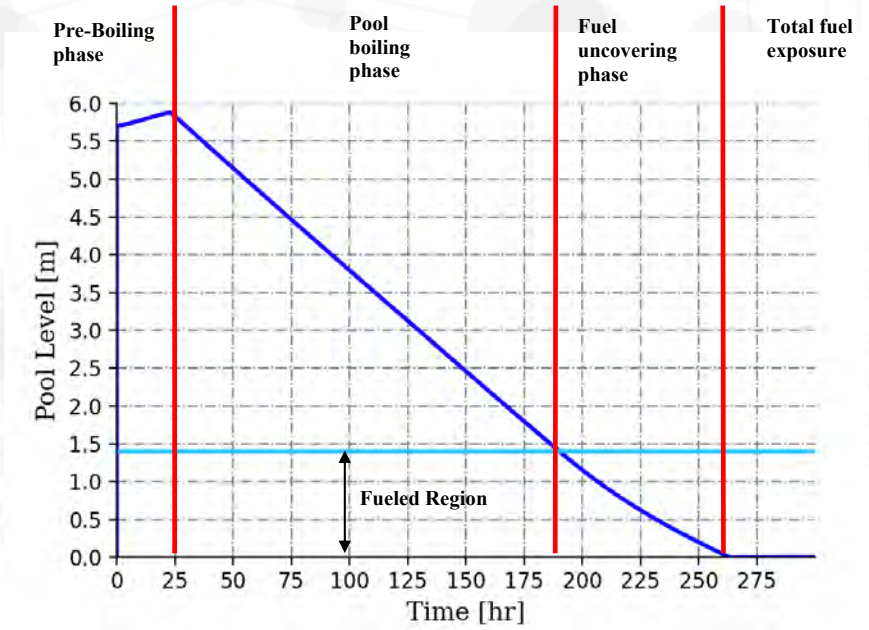
- A CFD modelling capability was developed to estimate peak sheath temperatures in a CANDU SFP during a complete LOCA.
- It was intended to support the development of reduced-order, fast-running models for the BAYLOCA analysis code, and to guide experimental design.
- Simulations performed using Simcenter STAR-CCM+.
- The model represents a CANDU spent fuel module and resolves: **natural convection**, **radiative heat transfer**, and **solid conduction** within fuel bundles and structures
- Results show non-uniform temperature distributions, with the **central bundles** at row #6 experiencing the highest sheath temperatures [2].

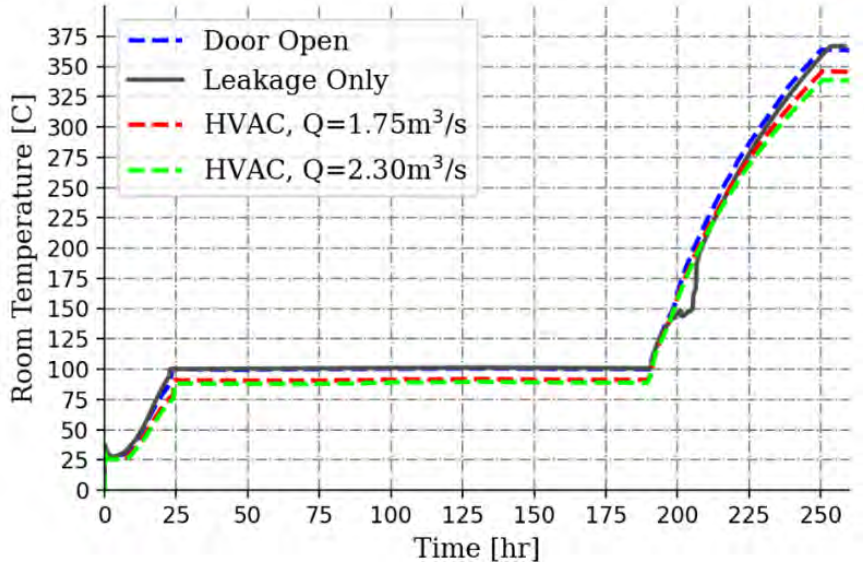


GOTHIC Analysis of SFP Accidents

GOTHIC Modelling of SFP Accident Scenarios

- GOTHIC is originally developed for containment analysis; adapted here to predict:
  - ✓ pool drainage and boil-off behaviour
  - ✓ building temperature
- Transient initiated with ~8.6 MW decay heat, decreasing with time.
- Outputs used to inform and support BAYLOCA thermal-hydraulic models.
- Model later extended to include aerosol and fission product transport:
  - ✓ Results indicate ~60% of released fission products remain inside the building, mainly deposited in liquid
  - ✓ Highlighted the conservatism of BAYLOCA's primary release assumptions (i.e. full release to environment)





Model Insights and Identified Limitations

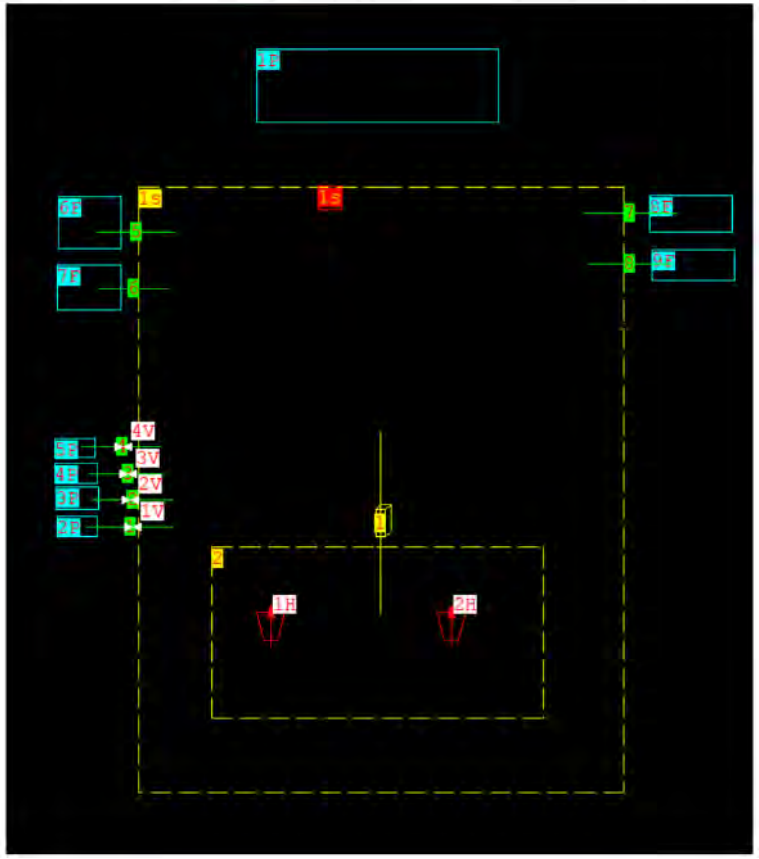
- Single lumped pool volume does not fully capture fuel-region porosity and internal convection.

  ➡ multiple vertically stacked pool control volumes instead of single lumped pool with.

- However, the moving liquid–vapor interface crossing the boundaries between these pool volumes during water evaporation triggers numerical instabilities.

- Current decay-heat treatment artificially returns heat from gas to the pool, suppressing gas temperatures.

  ➡ surface-based heat input above the pool as fuel becomes uncovered yielded more credible predictions.



GOTHIC model of the SFP

Participation in OECD-NEA POLCA Project

OECD/NEA Pool during Loss of Cooling Accident (POLCA)

- The OECD/NEA [3] POLCA project examines the behaviour of SFPs during situations of loss of cooling through experimental analysis.

- Objectives:

✓ Enhance knowledge of SFPs in an accident scenario

✓ Improve the physical understanding of large-scale pools to provide thermal hydraulics data

✓ Support the thermal-hydraulics model development and validation for SFP during a LOCA

- Given the strong alignment with CNL objectives, CNL decided to participate in the POLCA project.

3 Economic Co-operation and Development / Nuclear Energy Agency

Summary

- **Motivation:**

Vulnerabilities of SFPs demonstrated during Fukushima accident

- **Experimental work:**

FBHA designed and commissioned. Tests measured sheath and gas temperatures under dry air, forced air, and steam conditions

- **Modeling & code development:**

✓ BAYLOCA reviewed and improved; benchmarked against GOTHIC and CFD models

✓ GOTHIC and CFD models developed to study accident progression in CANDU SFPs

- **International collaboration:**

Participation in OECD/NEA POLCA project

ABSTRACT

Spent fuel pools (SFPs), located within reactor buildings, rely on active cooling systems to prevent overheating, hydrogen accumulation, and potential environmental contamination from radionuclide release. The Fukushima accident underscored the vulnerability of SFPs when cooling systems are compromised. In response, the International Atomic Energy Agency (IAEA) called on Member States to conduct national assessments of nuclear power plant designs against site-specific extreme natural hazards, explicitly including SFP structures and fuel behavior. In accordance with this guidance, Canadian Nuclear Laboratories (CNL) has undertaken studies to predict the progression of loss-of-coolant accidents (LOCA) in CANDU SFPs. This paper summarizes CNL's recent efforts in this area and presents high-level findings from these investigations.

KEYWORDS
CANDU, spent fuel pools (SFPs), loss-of-coolant accident (LOCA)

1. INTRODUCTION

1.1 Background

Spent fuel pools (SFPs), also known as irradiated fuel bays (IFBs), provide temporary storage for spent fuels removed from the reactor core until its residual heat decreases enough for safe transfer to longer-term facilities. These pools, located within or directly adjacent to reactor buildings, are typically used for temporary storage of freshly discharged fuel before transferring them to longer-term dry storage. The fuel assemblies are submerged under 5–8 meters of water, which ensures cooling and radiation shielding [1]. Figure 1 shows a typical SFP for CANDUs, which are located in connected buildings to the reactor containment and used to store spent fuel for 5-10 years of wet storage before moving to longer term dry-storage.

During a prolonged loss of coolant accident (LOCA) in SFPs, however, cladding temperatures can rise significantly and high temperature steam may interact with the cladding, accelerating oxidation and potentially leading to breakaway oxidation, an event that increases the oxidation rate by more than an order of magnitude [1]. This condition greatly raises the likelihood of fission product release, posing an immediate safety risk to both the environment and nearby populations.

The Fukushima disaster underscored the critical need for understanding the behaviour of spent fuels when cooling is lost. In response, regulators across the world, including the Canadian Nuclear Safety Commission (CNSC) made efforts to address these gaps. In support of CNSC efforts, Canadian Nuclear Laboratories (CNL) compiled a Phenomena and Identification and Ranking Table (PIRT) to identify the accident phenomena and corresponding key parameters in CANDU SFPs. The PIRT informed the development of a computer code for the CNSC called BAYLOCA (BAY Loss Of Coolant Accident) designed for SFP accident analysis [2], and laid the foundation for the series of studies on spent fuel pool

accident analysis, mainly on CANDU reactors, under the Atomic Energy of Canada Limited (AECL) Federal Nuclear Science and Technology (FNST) program. This paper summarizes CNL's efforts under the latest FNST project in this area over the last three years (2022-2025) and presents high-level findings from these investigations. For simplicity, we refer to this initiative as the SFP accident analysis project.

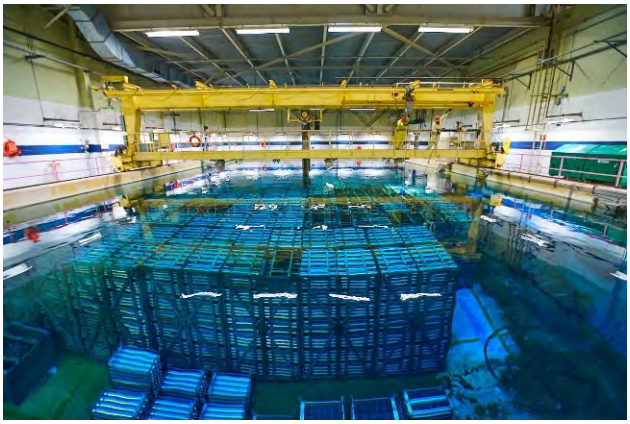

Figure 1. Spent nuclear fuel is stored in a pool at the Pickering Nuclear Generating Station in Pickering, Ontario. (Photo: Ontario Power Generation - Brian Pieters, Corporate Visuals)

1.2 Objectives and Goals of SFP Accident Analysis Project

The objective of the project was to advance the understanding of accident phenomena in CANDU SFPs and to improve insight into accident progression and its consequences. The project also aimed to enhance experimental capabilities, integrated with advanced modeling and simulation, to enable detailed analysis of accidents in CANDUs, and to support testing, benchmarking, and further development of BAYLOCA. Finally, the project sought to contribute to the global understanding of SFP accidents through active participation in international research initiatives. These objectives were pursued through several focused activities, each of which is described in the subsequent sections.

2. FUEL BAY HEATER APPARATUS (FBHA) EXPERIMENTS

CANDU fuel bundles are ~50 cm long, weigh 25 kg, and are ~10 cm in diameter. Every day during normal operation about 12-16 spent fuel bundles are received from a reactor core and stored in SFPs [3]. In response to the risk of spent fuel overheating when cooling is compromised in an accident scenario in CANDU SFPs, the FBHA was constructed, and series of experiments were conducted. As shown in Figure 2, the apparatus consists of a stainless-steel enclosure, a water tank beneath the enclosure, electrically heated simulated bundles in three rows and columns, and a hood. Inside the water tank heaters are used to generate steam.

The experiments aimed to approximate sheath and surrounding air or steam temperatures to determine heat transfer between bundles within a representative CANDU SFP tray configuration. Tests were carried out across a range of simulant bundle power levels, from 500 W to 3 kW, under stagnant dry air, blowing dry air, and steam environments. The results showed that peak sheath and gas temperatures occurred in the stagnant air environment in the middle bundle, while the lowest temperatures were observed under forced air condition. Tests conducted in steam, even over different generation rates, produced sheath temperatures that were similar to those measured under stagnant air conditions.

The maximum sheath temperature approached the hydrogen generation threshold (~827 °C) only at bundle power levels exceeding 2.5 kW. This suggests a negligible risk of hydrogen production in the evaluated three row bundle configuration, as bundle power in a CANDU SFP during the fuel uncovering phase is expected to remain significantly below 2.5 kW [4].

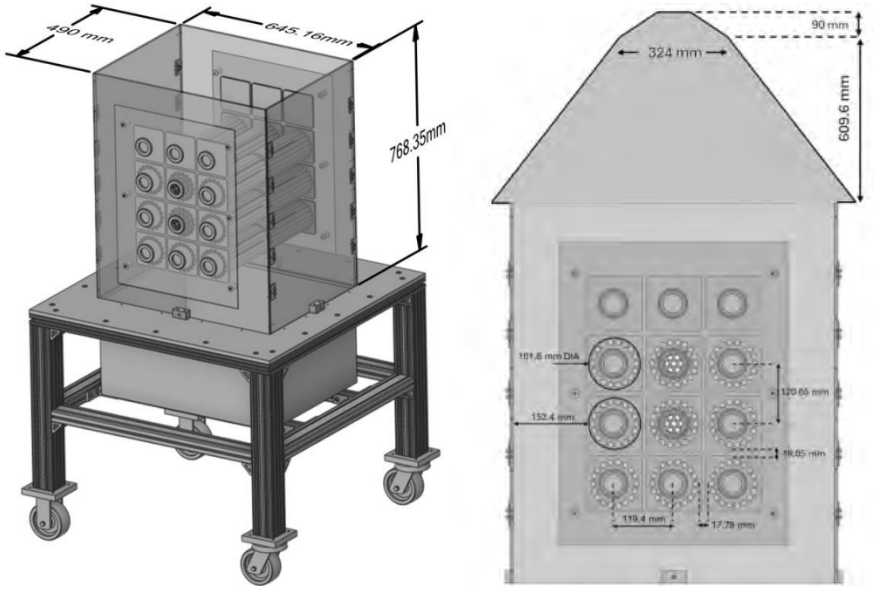

Figure 2. Schematic representation of the FBHA, illustrating its dimensions, including the stainless-steel enclosure, water tank, simulated bundles, and hood.

3. ASSESSMENT OF BAYLOCA SFP ACCIDENT ANALYSIS CODE

BAYLOCA is an independent computational tool developed for the CNSC to evaluate the progression and consequences of severe accidents in the SFPs of CANDU reactors in Canada. The code is designed for rapid execution, relying primarily on lumped-parameter models, and is capable of simulating all phases of an SFP accident. BAYLOCA represents accident evolution through four distinct stages:

Stage 1: Pool makeup is interrupted, although the spent fuel remains fully submerged.
Stage 2: The water level recedes sufficiently so that the fuels begin to be exposed to the atmosphere. In this stage some fuel assemblies are partially uncovered while others remain submerged.
Stage 3: The pool becomes completely devoid of water, either through boil-off or leakage.
Stage 4: Cooling water is restored to the pool. This stage may be entered directly from any of the preceding stages.

An overall schematic of a representative accident simulation is provided in Figure 3. User-defined inputs include initial decay heat conditions, fission product inventories, geometric and structural characteristics of the fuel stacks, pool, and building, accident-specific parameters, and ambient environmental conditions. All material properties, apart from those assigned to the building walls and roof, vary with temperature. Time-dependent outputs such as decay power, pool water temperature and height, fuel and tray temperature, gas temperature, temperature of building components, sheath and fuel oxidation, and fission product release are written to external files for subsequent post-processing. Additional detail is available in reference [2] and [5].

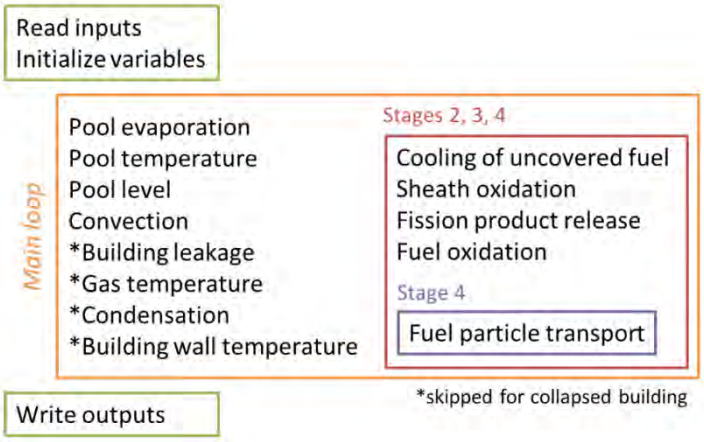

Figure 3. Overall view of an accident simulation

As part of the SFP accident analysis project, several areas for enhancement to BAYLOCA were identified, spanning phenomenological models, overall code architecture, and usability. A number of these issues have since been resolved through updates to the BAYLOCA code. Benchmarking exercises comparing BAYLOCA results with those from GOTHIC and CFD simulations demonstrated generally good agreement in thermal-hydraulic behavior, while also highlighting areas requiring further refinement, particularly with respect to fission product transport, convective fuel cooling, and deposition models within the building. Figure 4 illustrates a representative comparison between BAYLOCA predictions and GOTHIC results.

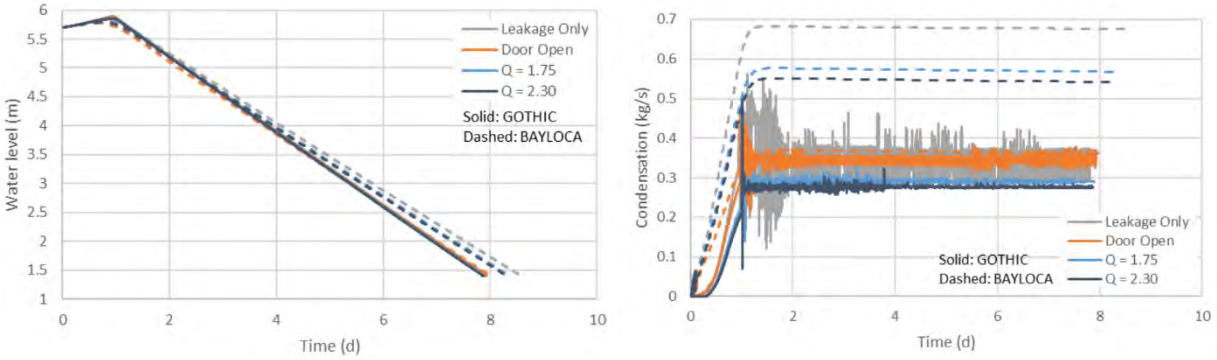

Figure 4. Comparison of the results between GOTHIC and BAYLOCA with similar input parameters: (a) water level in the pool, (b) rate of condensation.

4. CFD ANALYSIS OF SFP ACCIDENTS

A CFD modelling capability was developed in this project to estimate the peak sheath temperature in a CANDU SFP during a complete LOCA (stagnant air cooling only) [6]. Peak sheath temperature is a key indicator of accident progression and helps identify conditions under which breakaway oxidation may occur. Such conditions could threaten the integrity of the irradiated fuel bundle or lead to severe fuel damage.

A mechanistic CFD model was created using the geometric features of a CANDU spent fuel module. The model simulates flow and heat transfer within an irradiated fuel storage facility, accounting for natural convection, radiation, and solid-body conduction. The CFD simulations were performed using Simcenter STAR-CCM+. The CFD models were quantitatively evaluated and shown to capture the complex thermal-hydraulic behaviour expected in the SFP geometry at the specified decay powers.

The resulting CFD model was intended to support the development of reduced-order, fast-running models for the BAYLOCA analysis code for use in emergency response. It can also help guide experimental design by identifying conditions that warrant detailed measurement.

Figure ***5*** presents the mesh and temperature contours for a representative fuel module containing 96 irradiated fuel bundles, each decaying at 62 W in the SFP. The figure shows that the central bundles in row #6 attain the highest temperature levels within the module [6].

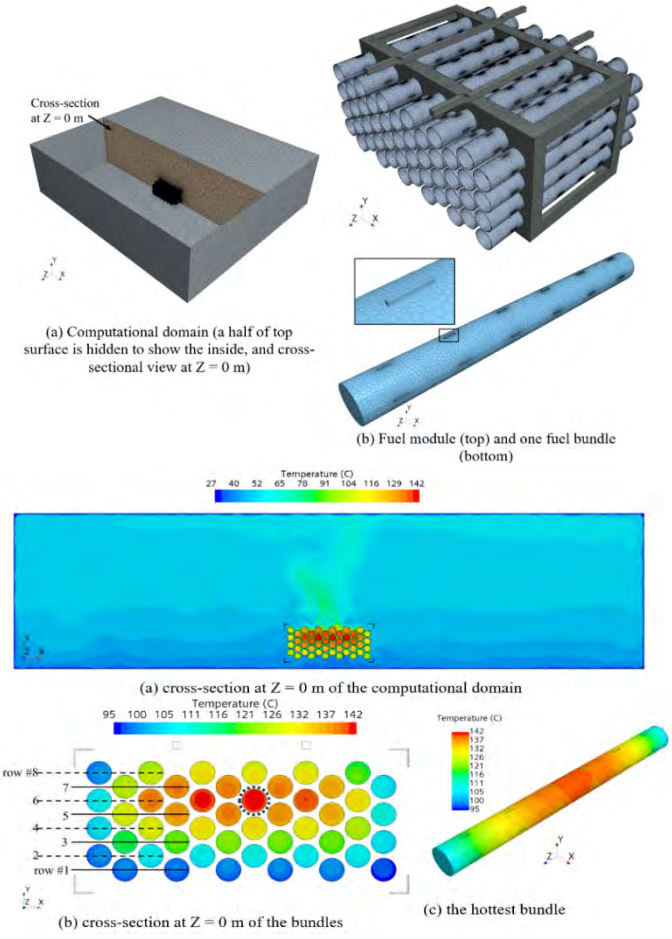

Figure 5. Mesh and temperature contours of the simulation domain, showing the pool and a fuel module containing 96 irradiated CANDU bundles, each with a decay power of 62 W [6].

5. GOTHIC ANALYSIS OF SFP ACCIDENTS

This task focused on applying the GOTHIC software, typically used for containment analyses, to simulate SFP accident scenarios and generate thermal-hydraulic data such as pool drainage behavior and building temperature responses. The results were intended to support improvements to the thermal-hydraulic models in BAYLOCA. Figure 6 presents the GOTHIC model and the predicted average building temperature for an accident scenario in a representative CANDU SFP. The building and pool dimensions were 46 × 15 × 9 m and 46 × 10 × 6 m, respectively. The analysis began with an initial decay power of approximately 8.6 MW, decreasing over time.

During the study, several limitations in GOTHIC's capability for modelling this type of scenario became evident and recommendations were made to mitigate these issues and to enhance the physical realism of future simulations. First, replacing the current single lumped pool with multiple vertically stacked pool control volumes would better capture fueled-region porosity and internal convection. However, in the version used here (GOTHIC 8.2) the moving liquid–vapor interface crossing the boundaries between these pool volumes during water evaporation triggers numerical instabilities. The issue was shared with developers to consider it for later versions. Second, the present method for applying decay heat to the gas above the pool artificially returns heat to the liquid, depressing predicted gas temperatures. Adopting a surface-based heat input just above the pool avoids this artefact and yields more credible predictions as fuel becomes exposed. Finally, because wall temperatures reach ranges where radiation becomes significant, adding radiative heat-transfer treatment to building surfaces would improve accuracy during high-temperature late phase of the accident.

The GOTHIC model was later expanded to include aerosol transport processes involving fission products. This update enabled a comparison with assumptions related to these phenomena embedded in BAYLOCA, especially those related to the conservatism of its primary release estimates. The enhanced GOTHIC simulations indicated that roughly 60% of the released fission products would remain inside the building, largely deposited in liquid accumulations. BAYLOCA 1.0 was unable to reproduce this outcome because it was designed with a conservative bias and did not include a model for fission product deposition.

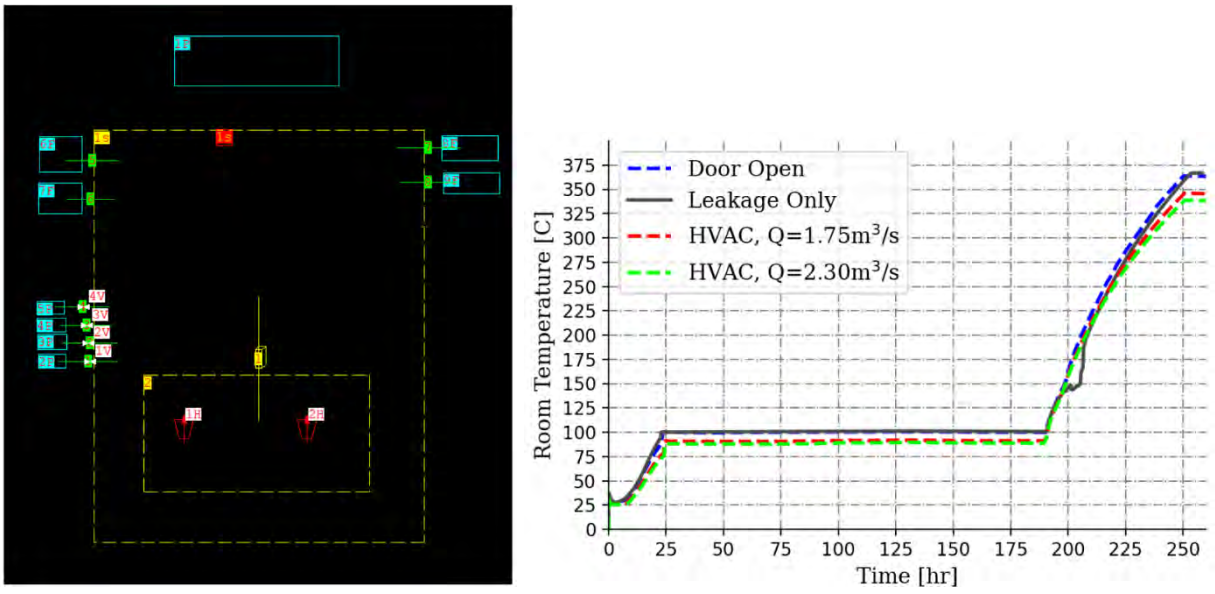

Figure 6. GOTHIC model of the SFP (left), and temperature of the building during a transient under different boundary conditions (right).

6. PARTICIPATION IN OECD-NEA POLCA PROJECT

In alignment with the objectives of the SFP accident analysis project, an international research connection was included to leverage the research and understanding of the broader community studying SFP severe accidents. This involved Canada's participation in the OECD-NEA POLCA project, which is focused on understanding LOCA scenarios in light water reactor SFP, while also generating broader insights applicable to common phenomena found in CANDU SFPs. This project aims to generate data for SFP thermal-hydraulic under accident conditions that can be used to benchmark and refine numerical modelling tools for SFP accident analysis.

7. CONCLUSION

Following the vulnerabilities revealed in SFPs during the Fukushima accident, many countries conducted research efforts in this area. As part of Canada’s response, and with the support of the CNSC, CNL initiated research efforts to improve the understanding of accident progression and consequences in SFPs, with emphasis on CANDU facilities.

As part of this effort, the FBHA was constructed to study bundle level behavior in a tray type configuration. A series of experiments were carried out to measure sheath and gas temperatures over a range of bundle powers in dry air, blowing air, and steam environments.

A comprehensive review of the BAYLOCA SPF accident analysis code was also completed, identifying several areas for improvement, including potential enhancements to phenomena models, updates to the code architecture, and improvements in the user experience. The updated code was benchmarked against results from both GOTHIC and high fidelity CFD models.

The CFD model, developed to estimate peak sheath temperatures during a complete LOCA in CANDU SFPs, demonstrated the complex heat transfer and flow patterns expected at the examined decay powers.

A thermal-hydraulic GOTHIC model was developed to simulate a LOCA scenario in a simplified SFP configuration. Several limitations in GOTHIC’s treatment of fuel exposure to air steam mixtures were identified. The model was later expanded to include aerosol and fission product transport, enabling an assessment of the conservatism of the BAYLOCA primary release assumptions.

Finally, in alignment with these efforts CNL is participating in the OECD-NEA POLCA joint project, which is designed to generate valuable data on thermal-hydraulic phenomena in a SFP under accident conditions thereby strengthening understanding and improving international capabilities for SFP safety analysis.

Model based on ODE system solution
model description

1. Diffusion growth of hydrides:
H concentration in solution C_s tends to its equilibrium value C_e with characteristic time τ_0

$$1)\quad \frac{\mathrm{d}C_s}{\mathrm{d}t} - \frac{C_s - C_e}{\tau_0} = 0$$

$$\tau_0 = \frac{\Delta}{\alpha^2 D_{\mathrm{H}}}$$

2. Orientation of hydrides:
Accumulated radial hydride fraction θ evolution is determined by the instantaneous fraction of radially-oriented hydrides precipitated on the current time step f_r

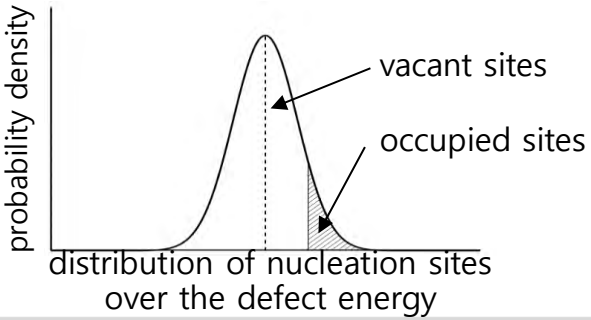
$$2)\quad \frac{\mathrm{d}\theta}{\mathrm{d}t} = \frac{\theta - f_r}{C_{tot} - C_s} \cdot \frac{\mathrm{d}C_s}{\mathrm{d}t}$$

$$f_r = \frac{1}{1 + f_0 \cdot \exp\left(-\sigma \cdot \Delta\Omega / kT\right)}$$

3 and 4. Nucleation of hydrides:
Approximation of classical heterogeneous nucleation theory on predefined nucleation sites with normally distributed defect energies.

$$3)\quad \frac{\mathrm{d}n_r}{\mathrm{d}t} = f_r \cdot \frac{\mathrm{d}n}{\mathrm{d}t}$$

$$4)\quad \frac{\mathrm{d}n_t}{\mathrm{d}t} = \left(1 - f_r\right) \cdot \frac{\mathrm{d}n}{\mathrm{d}t}$$



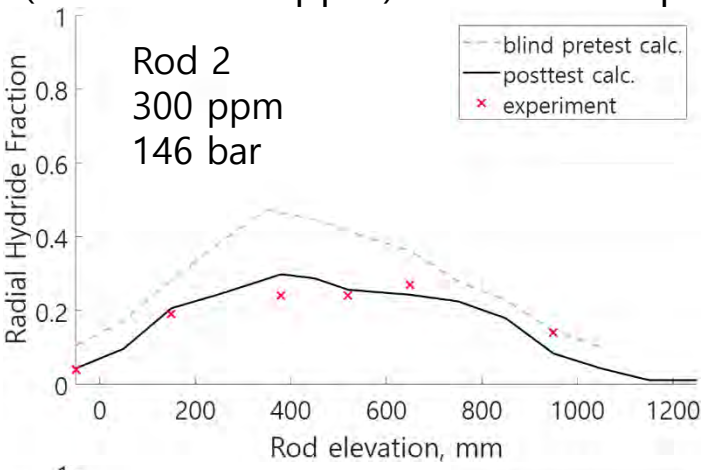
$$\frac{\mathrm{d}n}{\mathrm{d}t} = \int_{E_{d,\min}}^{E_{d,\max}^{frei}} \varphi\left(E_d\right) \cdot n_{\max} \cdot R\left(E_d\right) \cdot \mathrm{d}E_d$$

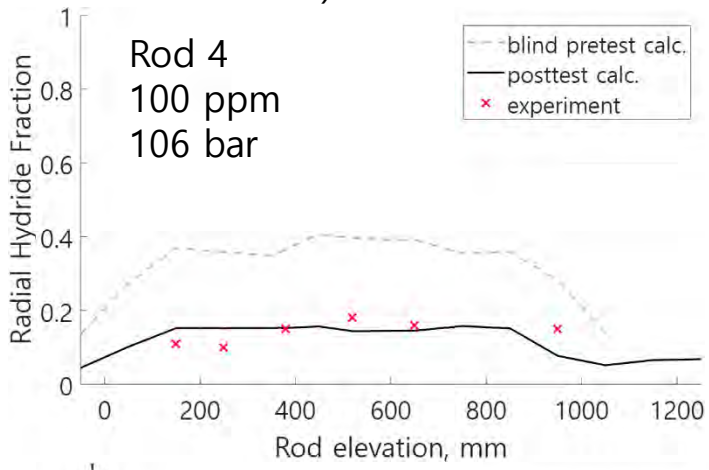
$$R\left(E_d\right) = Zj^* \cdot \exp\left(-\Delta G\left(E_d\right)^* / kT\right)$$

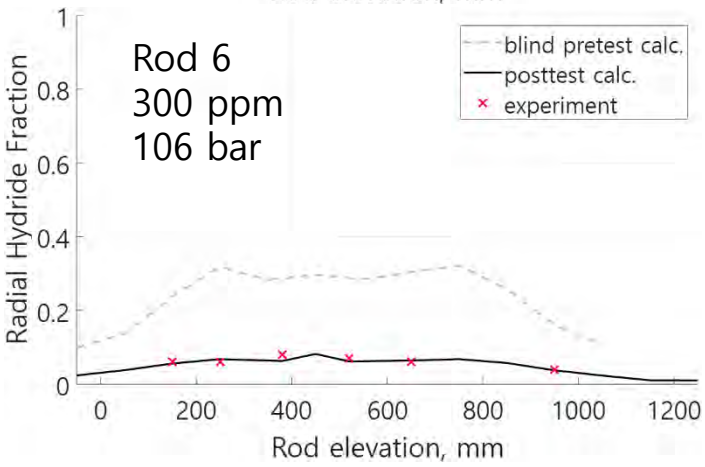
$$\Delta G\left(E_d\right) = \Omega_n \left(g_m - \Delta\mu / v_{\mathrm{H}}\right) + S_n \gamma - E_d$$

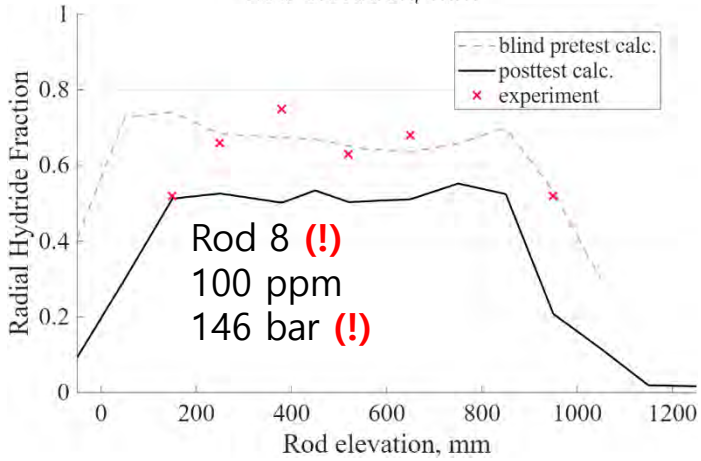
Model based on ODE system solution
simulation results 1

Rods 2, 4, 6 and 8 (Zircaloy-4):
located symmetrically within the bundle and have all possible combinations of hydrogen content (100 and 300 ppm) and internal pressure (106 and 146 bar)





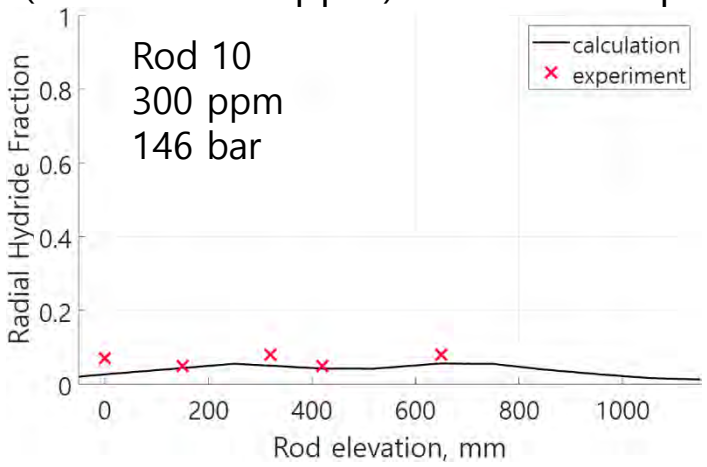


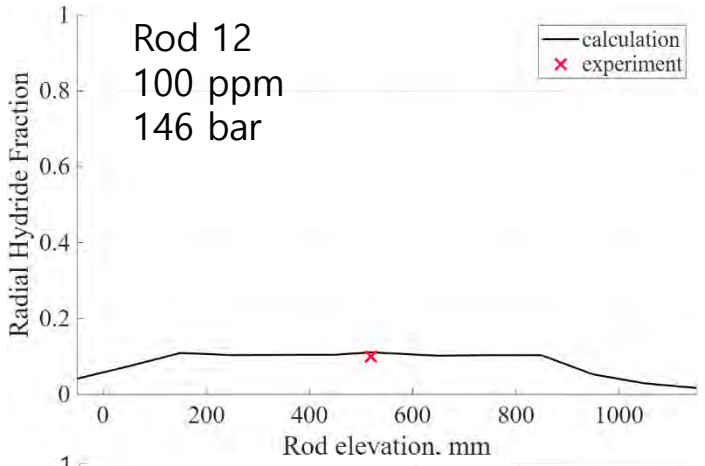


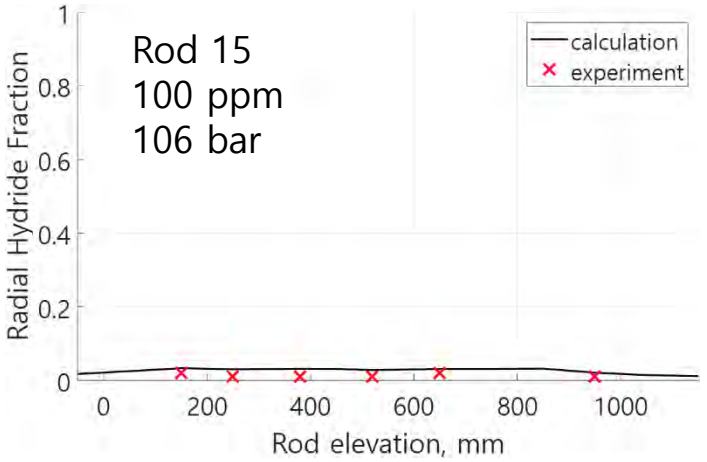
The difference in pre- and post-simulations originates from:
(i) the actual H concentration and (ii) the datasets used to fit the model parameters

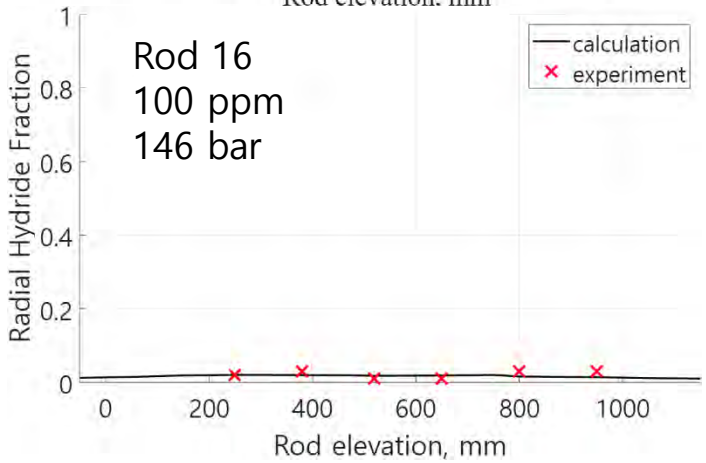
Model based on ODE system solution
simulation results 2

Rods 10, 12, 15 and 16 (opt. ZIRLO):
located symmetrically within the bundle and have all possible combinations of hydrogen content (100 and 300 ppm) and internal pressure (106 and 146 bar)





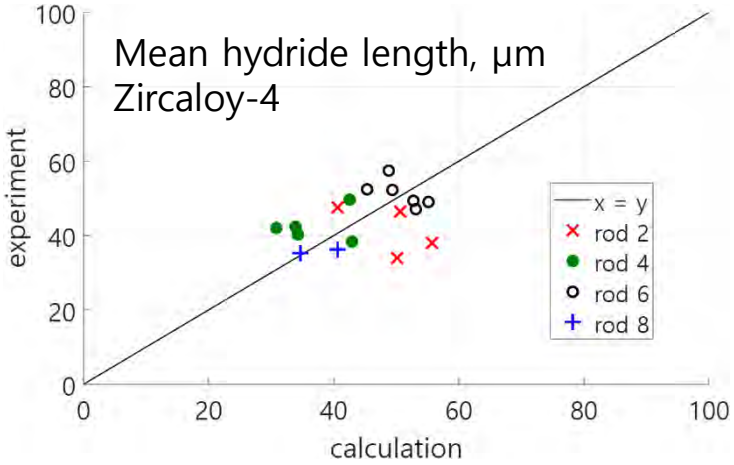


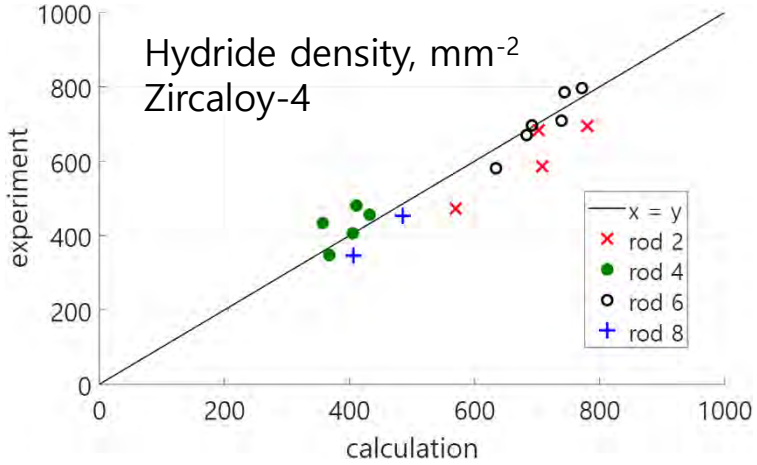


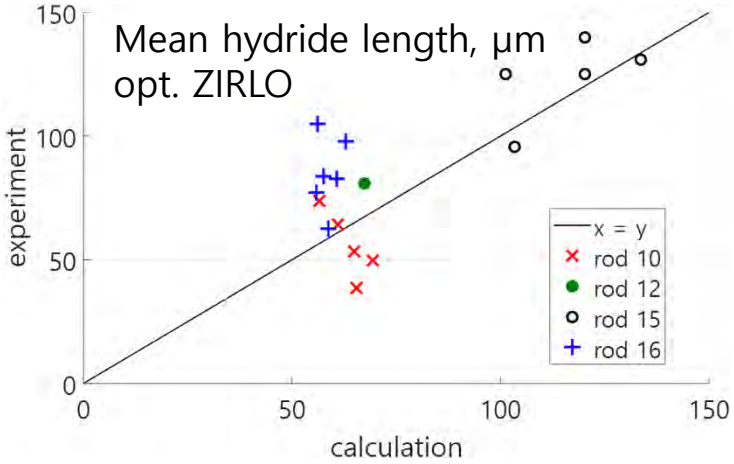
Tendency to reorientation in opt. ZIRLO is lower than that in Zircaloy-4. Possible explanation is the difference in texture and grain structure

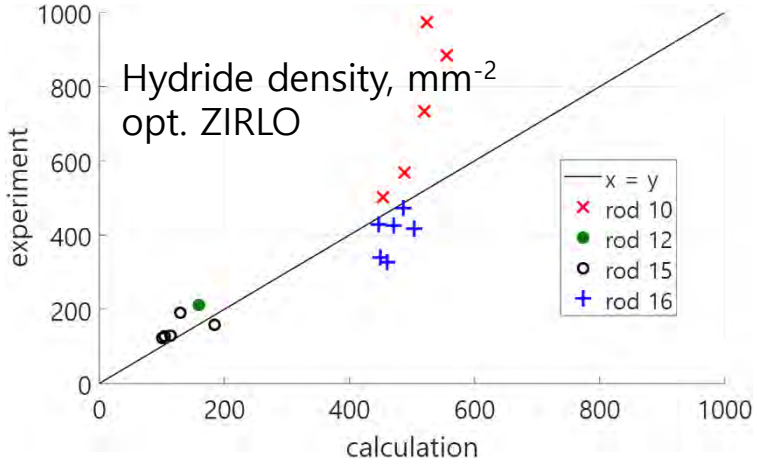
Model based on ODE system solution
simulation results 3

Experiment-to-calculation comparison:
mean hydride length and surface density of hydrides









Mean hydride length in Zircaloy-4 is lower and hydride density is higher than in ZIRLO

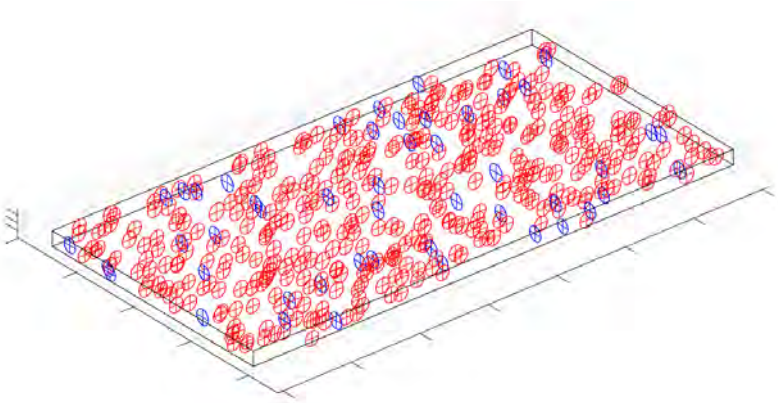
MORPHYD module
the model description

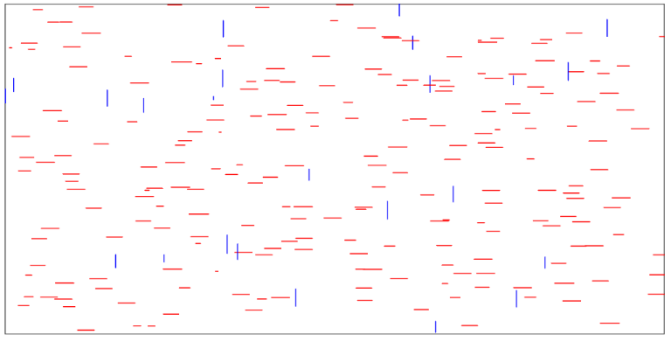
Nucleation and growth of hydrides

- disk-shaped hydrides
- pre-defined nucleation sites
- classical nucleation theory
- diffusional growth
- competition of neighboring hydrides for the hydrogen in solid solution

Cross-section analysis

- morphology analysis as with experimental cross-sections
- any hydride morphology metric
- statistical analysis of metrics





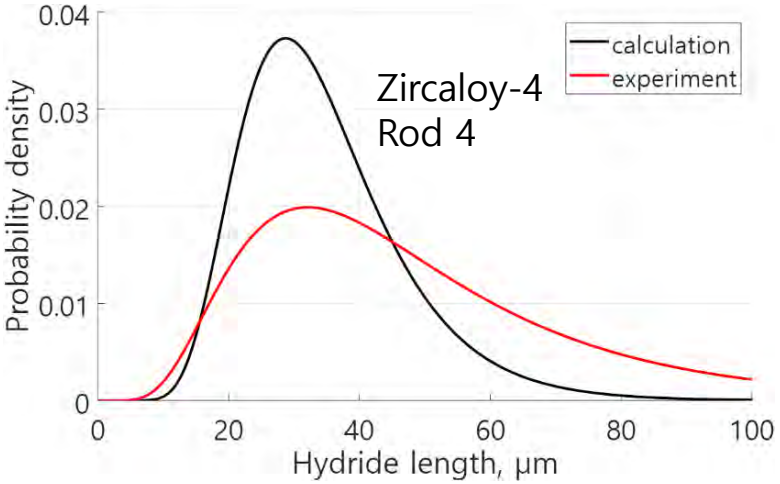
Current limitations of the MORPHYD module:

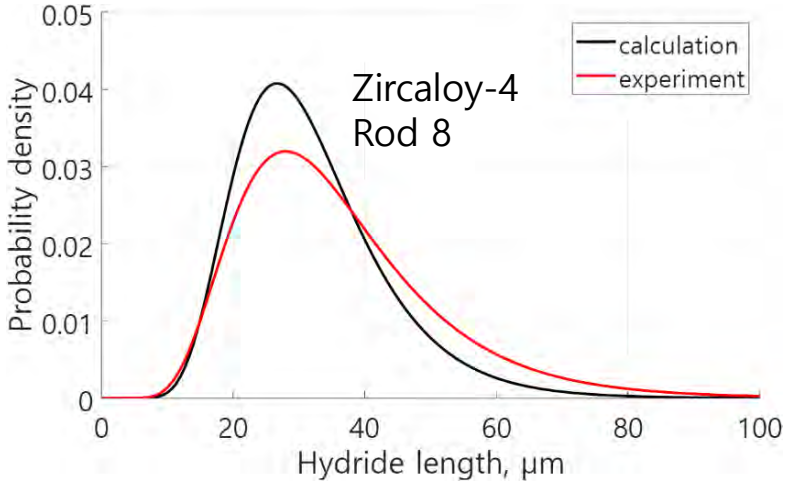
(i) precipitation only (no dissolution), (ii) valid for small hydrides

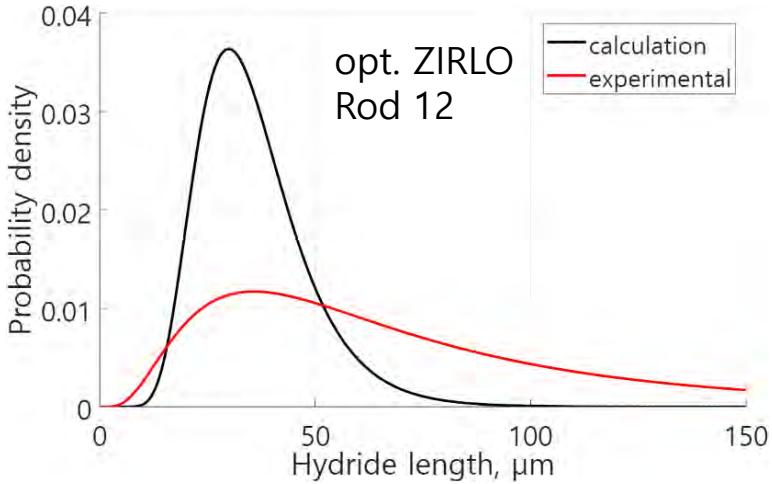
[1] M. Kolesnik and T. Aliev, *Phys. of Met. and Metal.* 104 (2023) 1414-1425, DOI: 10.1134/S0031918X22602074
[2] T. Aliev and M. Kolesnik, *Let. on Mater.* 13 (2023) 143-148, DOI: 10.22226/2410-3535-2023-2-143-148

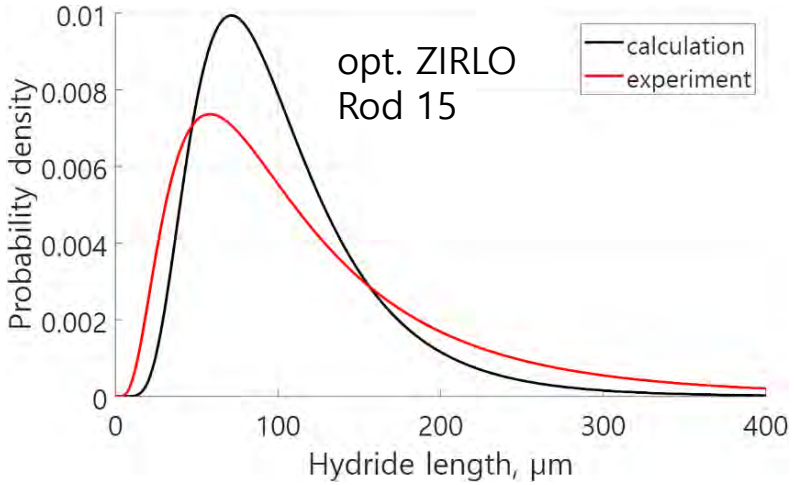
MORPHYD module
comparison with experiment 1

Hydride length distribution (at elevation 520 mm in the hottest axial zone)



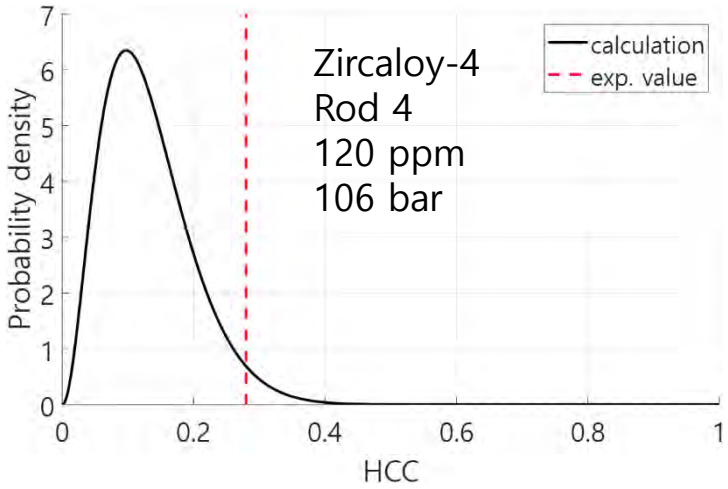


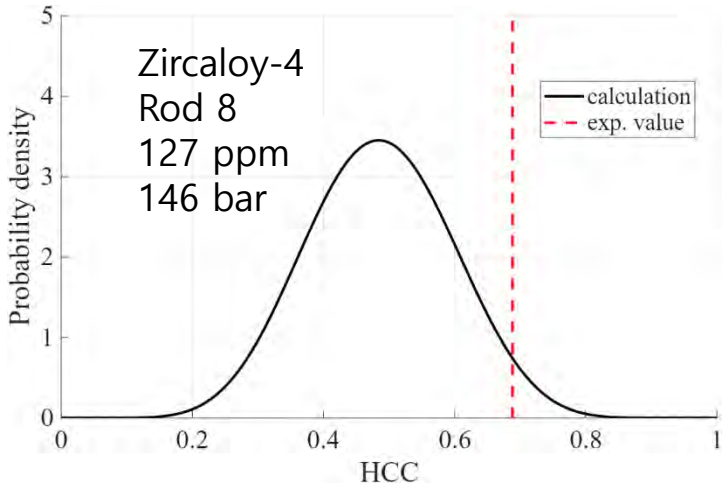


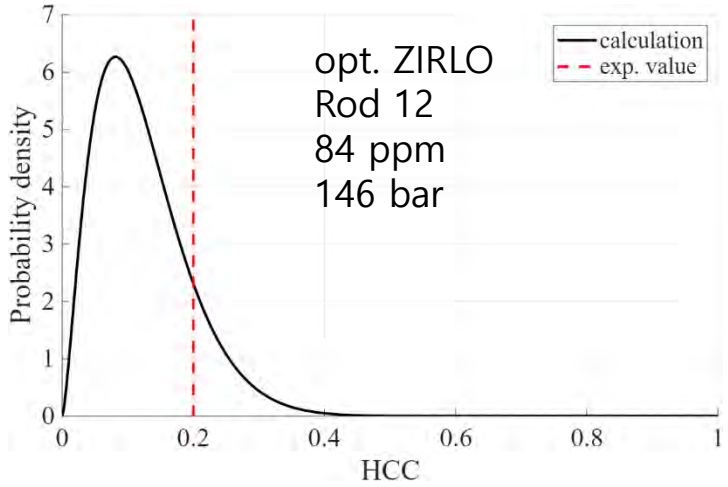


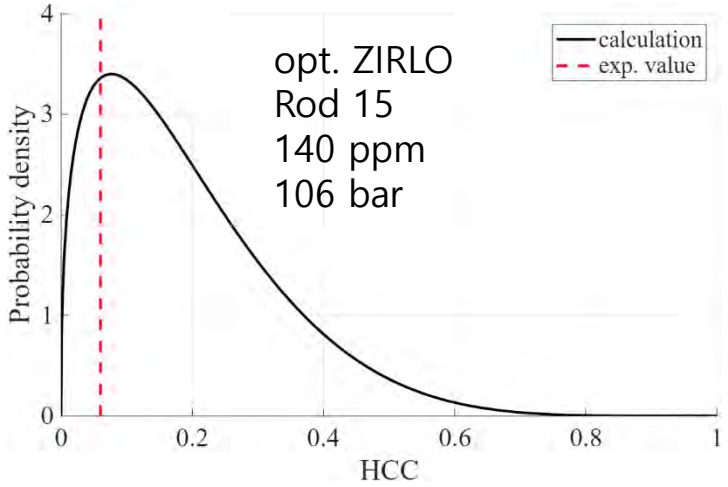
MORPHYD module
comparison with experiment 2

Hydride Continuity Coefficient (HCC) – the total projection of hydride lengths on radial direction in a 110-μm band (at elevation 520 mm in the hottest axial zone)



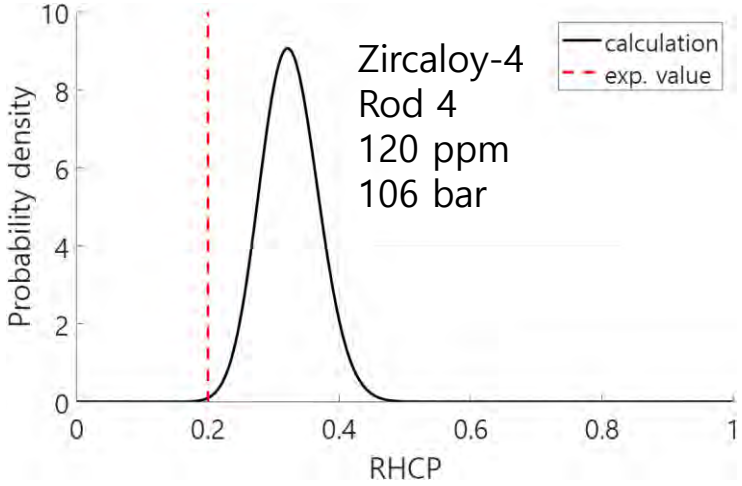


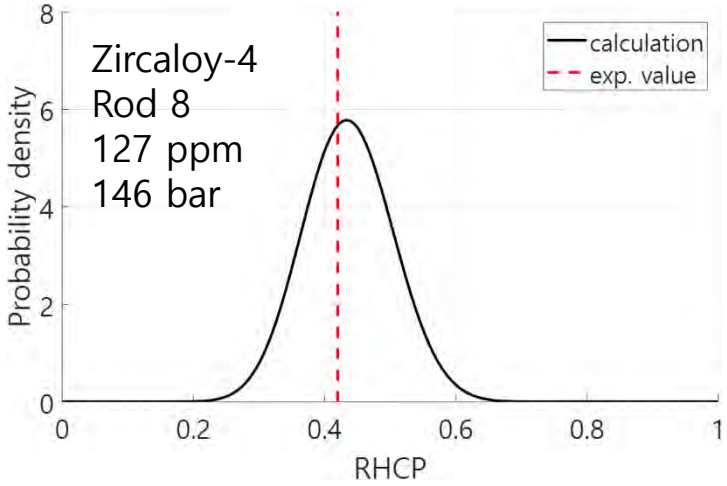


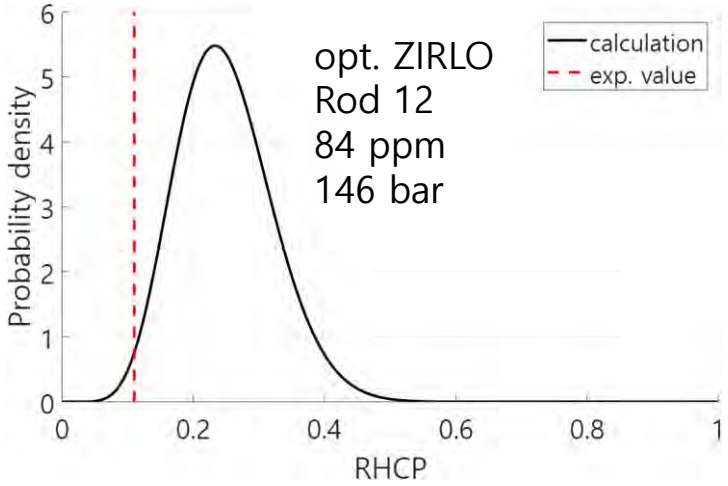


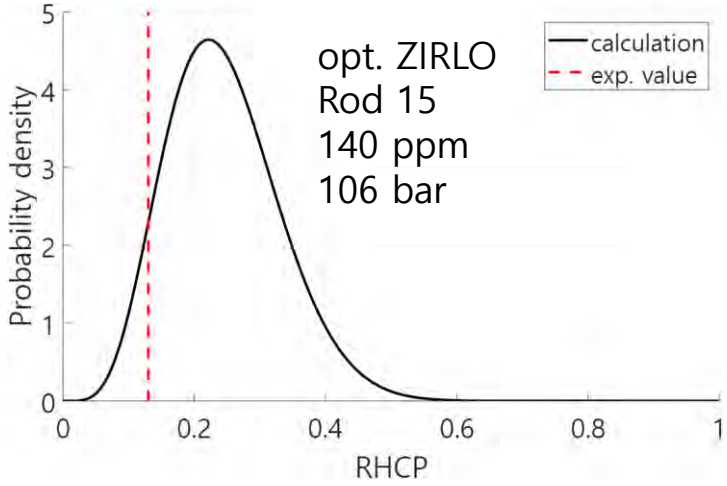
MORPHYD module
comparison with experiment 3

Radial Hydride Continuity Path (RHCP) – the estimated relative reduction of the fracture energy (at elevation 520 mm in the hottest axial zone)









Conclusion

- Two complementary numerical tools have been calibrated using new data from SPIZWURZ experiment for Zircaloy-4 and opt. ZIRLO.
- The ODE-based tool reasonably predicts mean morphology parameters: RHF, hydride length and hydride density.
- MORPHYD reproduces statistical distributions of hydride length and integral hydride morphology metrics.
- Safety-relevant assessment can be supported by the tandem use of both approaches, with MORPHYD applied within its current validity limits.

ABSTRACT

Spent fuel pools (SFPs), located within reactor buildings, rely on active cooling systems to prevent overheating, hydrogen accumulation, and potential environmental contamination from radionuclide release. The Fukushima accident underscored the vulnerability of SFPs when cooling systems are compromised. In response, the International Atomic Energy Agency (IAEA) called on Member States to conduct national assessments of nuclear power plant designs against site-specific extreme natural hazards, explicitly including SFP structures and fuel behavior. In accordance with this guidance, Canadian Nuclear Laboratories (CNL) has undertaken studies to predict the progression of loss-of-coolant accidents (LOCA) in CANDU SFPs. This paper summarizes CNL's recent efforts in this area and presents high-level findings from these investigations.

KEYWORDS
CANDU, spent fuel pools (SFPs), loss-of-coolant accident (LOCA)

1. INTRODUCTION

1.1 Background

Spent fuel pools (SFPs), also known as irradiated fuel bays (IFBs), provide temporary storage for spent fuels removed from the reactor core until its residual heat decreases enough for safe transfer to longer-term facilities. These pools, located within or directly adjacent to reactor buildings, are typically used for temporary storage of freshly discharged fuel before transferring them to longer-term dry storage. The fuel assemblies are submerged under 5–8 meters of water, which ensures cooling and radiation shielding [1]. Figure 1 shows a typical SFP for CANDUs, which are located in connected buildings to the reactor containment and used to store spent fuel for 5-10 years of wet storage before moving to longer term dry-storage.

During a prolonged loss of coolant accident (LOCA) in SFPs, however, cladding temperatures can rise significantly and high temperature steam may interact with the cladding, accelerating oxidation and potentially leading to breakaway oxidation, an event that increases the oxidation rate by more than an order of magnitude [1]. This condition greatly raises the likelihood of fission product release, posing an immediate safety risk to both the environment and nearby populations.

The Fukushima disaster underscored the critical need for understanding the behaviour of spent fuels when cooling is lost. In response, regulators across the world, including the Canadian Nuclear Safety Commission (CNSC) made efforts to address these gaps. In support of CNSC efforts, Canadian Nuclear Laboratories (CNL) compiled a Phenomena and Identification and Ranking Table (PIRT) to identify the accident phenomena and corresponding key parameters in CANDU SFPs. The PIRT informed the development of a computer code for the CNSC called BAYLOCA (BAY Loss Of Coolant Accident) designed for SFP accident analysis [2], and laid the foundation for the series of studies on spent fuel pool

accident analysis, mainly on CANDU reactors, under the Atomic Energy of Canada Limited (AECL) Federal Nuclear Science and Technology (FNST) program. This paper summarizes CNL's efforts under the latest FNST project in this area over the last three years (2022-2025) and presents high-level findings from these investigations. For simplicity, we refer to this initiative as the SFP accident analysis project.

1.2 Objectives and Goals of SFP Accident Analysis Project

The objective of the project was to advance the understanding of accident phenomena in CANDU SFPs and to improve insight into accident progression and its consequences. The project also aimed to enhance experimental capabilities, integrated with advanced modeling and simulation, to enable detailed analysis of accidents in CANDUs, and to support testing, benchmarking, and further development of BAYLOCA. Finally, the project sought to contribute to the global understanding of SFP accidents through active participation in international research initiatives. These objectives were pursued through several focused activities, each of which is described in the subsequent sections.

2. FUEL BAY HEATER APPARATUS (FBHA) EXPERIMENTS

CANDU fuel bundles are ~50 cm long, weigh 25 kg, and are ~10 cm in diameter. Every day during normal operation about 12-16 spent fuel bundles are received from a reactor core and stored in SFPs [3]. In response to the risk of spent fuel overheating when cooling is compromised in an accident scenario in CANDU SFPs, the FBHA was constructed, and series of experiments were conducted. As shown in Figure 2, the apparatus consists of a stainless-steel enclosure, a water tank beneath the enclosure, electrically heated simulated bundles in three rows and columns, and a hood. Inside the water tank heaters are used to generate steam.

The experiments aimed to approximate sheath and surrounding air or steam temperatures to determine heat transfer between bundles within a representative CANDU SFP tray configuration. Tests were carried out across a range of simulant bundle power levels, from 500 W to 3 kW, under stagnant dry air, blowing dry air, and steam environments. The results showed that peak sheath and gas temperatures occurred in the stagnant air environment in the middle bundle, while the lowest temperatures were observed under forced air condition. Tests conducted in steam, even over different generation rates, produced sheath temperatures that were similar to those measured under stagnant air conditions.

The maximum sheath temperature approached the hydrogen generation threshold (~827 °C) only at bundle power levels exceeding 2.5 kW. This suggests a negligible risk of hydrogen production in the evaluated three row bundle configuration, as bundle power in a CANDU SFP during the fuel uncovering phase is expected to remain significantly below 2.5 kW [4].

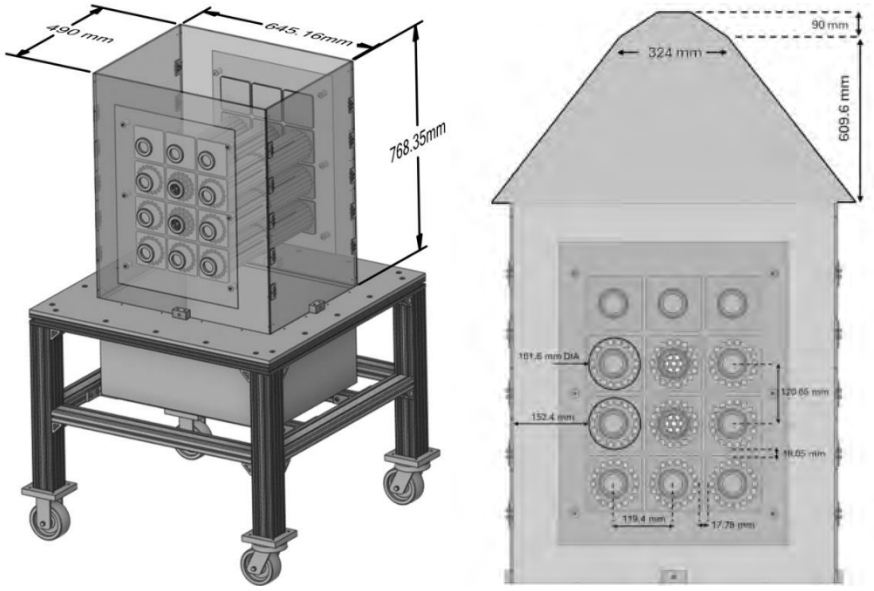

Figure 2. Schematic representation of the FBHA, illustrating its dimensions, including the stainless-steel enclosure, water tank, simulated bundles, and hood.

3. ASSESSMENT OF BAYLOCA SFP ACCIDENT ANALYSIS CODE

BAYLOCA is an independent computational tool developed for the CNSC to evaluate the progression and consequences of severe accidents in the SFPs of CANDU reactors in Canada. The code is designed for rapid execution, relying primarily on lumped-parameter models, and is capable of simulating all phases of an SFP accident. BAYLOCA represents accident evolution through four distinct stages:

Stage 1: Pool makeup is interrupted, although the spent fuel remains fully submerged.
Stage 2: The water level recedes sufficiently so that the fuels begin to be exposed to the atmosphere. In this stage some fuel assemblies are partially uncovered while others remain submerged.
Stage 3: The pool becomes completely devoid of water, either through boil-off or leakage.
Stage 4: Cooling water is restored to the pool. This stage may be entered directly from any of the preceding stages.

An overall schematic of a representative accident simulation is provided in Figure 3. User-defined inputs include initial decay heat conditions, fission product inventories, geometric and structural characteristics of the fuel stacks, pool, and building, accident-specific parameters, and ambient environmental conditions. All material properties, apart from those assigned to the building walls and roof, vary with temperature. Time-dependent outputs such as decay power, pool water temperature and height, fuel and tray temperature, gas temperature, temperature of building components, sheath and fuel oxidation, and fission product release are written to external files for subsequent post-processing. Additional detail is available in reference [2] and [5].

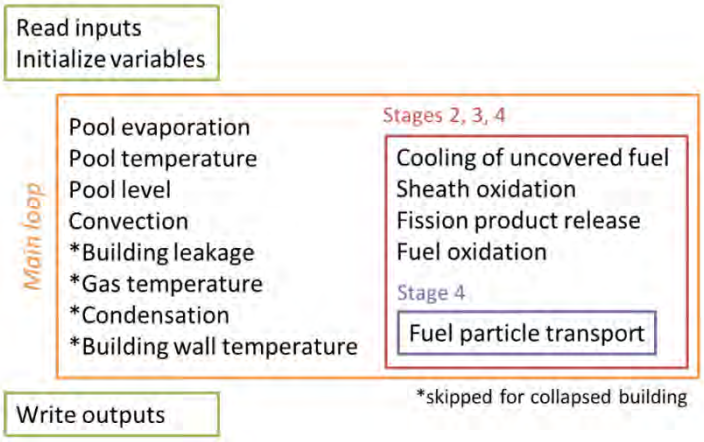

Figure 3. Overall view of an accident simulation

As part of the SFP accident analysis project, several areas for enhancement to BAYLOCA were identified, spanning phenomenological models, overall code architecture, and usability. A number of these issues have since been resolved through updates to the BAYLOCA code. Benchmarking exercises comparing BAYLOCA results with those from GOTHIC and CFD simulations demonstrated generally good agreement in thermal-hydraulic behavior, while also highlighting areas requiring further refinement, particularly with respect to fission product transport, convective fuel cooling, and deposition models within the building. Figure 4 illustrates a representative comparison between BAYLOCA predictions and GOTHIC results.

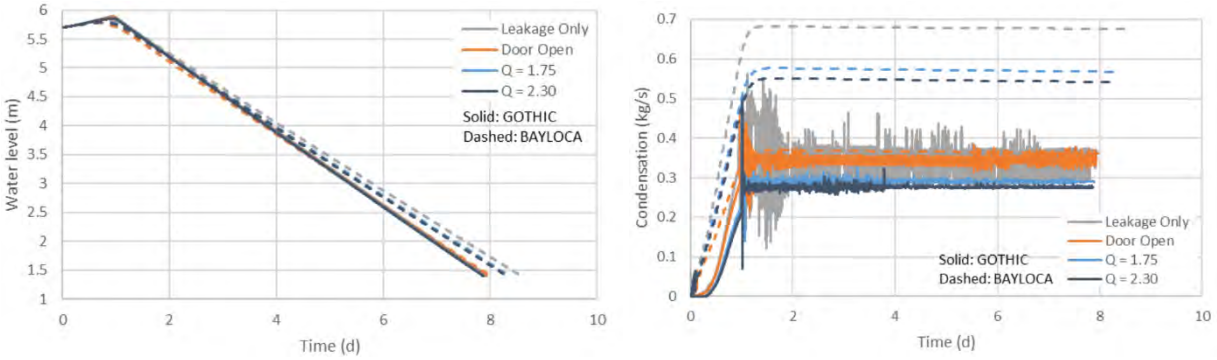

Figure 4. Comparison of the results between GOTHIC and BAYLOCA with similar input parameters: (a) water level in the pool, (b) rate of condensation.

4. CFD ANALYSIS OF SFP ACCIDENTS

A CFD modelling capability was developed in this project to estimate the peak sheath temperature in a CANDU SFP during a complete LOCA (stagnant air cooling only) [6]. Peak sheath temperature is a key indicator of accident progression and helps identify conditions under which breakaway oxidation may occur. Such conditions could threaten the integrity of the irradiated fuel bundle or lead to severe fuel damage.

A mechanistic CFD model was created using the geometric features of a CANDU spent fuel module. The model simulates flow and heat transfer within an irradiated fuel storage facility, accounting for natural convection, radiation, and solid-body conduction. The CFD simulations were performed using Simcenter STAR-CCM+. The CFD models were quantitatively evaluated and shown to capture the complex thermal-hydraulic behaviour expected in the SFP geometry at the specified decay powers.

The resulting CFD model was intended to support the development of reduced-order, fast-running models for the BAYLOCA analysis code for use in emergency response. It can also help guide experimental design by identifying conditions that warrant detailed measurement.

Figure ***5*** presents the mesh and temperature contours for a representative fuel module containing 96 irradiated fuel bundles, each decaying at 62 W in the SFP. The figure shows that the central bundles in row #6 attain the highest temperature levels within the module [6].

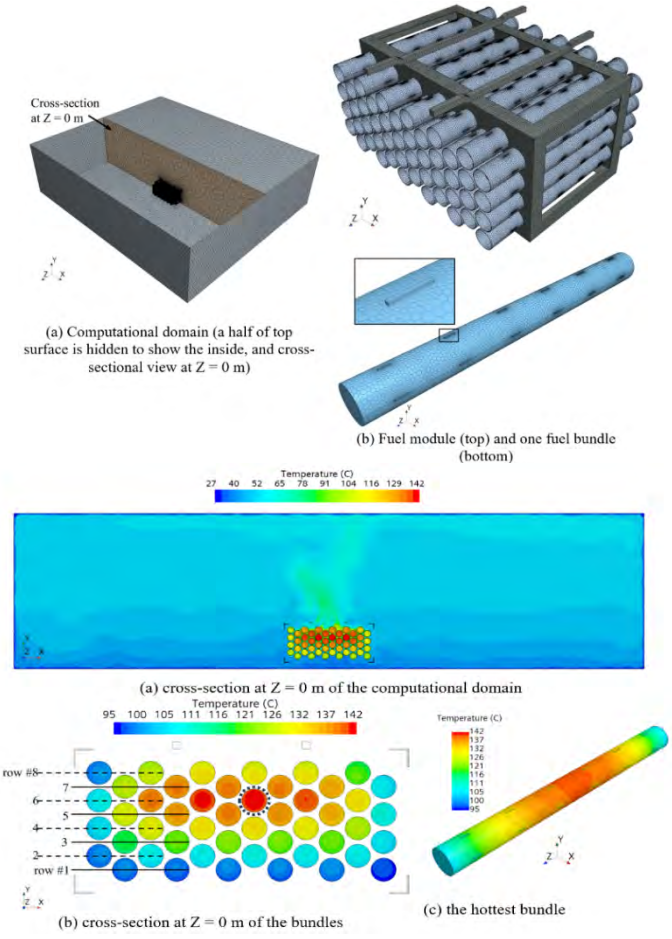

Figure 5. Mesh and temperature contours of the simulation domain, showing the pool and a fuel module containing 96 irradiated CANDU bundles, each with a decay power of 62 W [6].

5. GOTHIC ANALYSIS OF SFP ACCIDENTS

This task focused on applying the GOTHIC software, typically used for containment analyses, to simulate SFP accident scenarios and generate thermal-hydraulic data such as pool drainage behavior and building temperature responses. The results were intended to support improvements to the thermal-hydraulic models in BAYLOCA. Figure 6 presents the GOTHIC model and the predicted average building temperature for an accident scenario in a representative CANDU SFP. The building and pool dimensions were 46 × 15 × 9 m and 46 × 10 × 6 m, respectively. The analysis began with an initial decay power of approximately 8.6 MW, decreasing over time.

During the study, several limitations in GOTHIC's capability for modelling this type of scenario became evident and recommendations were made to mitigate these issues and to enhance the physical realism of future simulations. First, replacing the current single lumped pool with multiple vertically stacked pool control volumes would better capture fueled-region porosity and internal convection. However, in the version used here (GOTHIC 8.2) the moving liquid–vapor interface crossing the boundaries between these pool volumes during water evaporation triggers numerical instabilities. The issue was shared with developers to consider it for later versions. Second, the present method for applying decay heat to the gas above the pool artificially returns heat to the liquid, depressing predicted gas temperatures. Adopting a surface-based heat input just above the pool avoids this artefact and yields more credible predictions as fuel becomes exposed. Finally, because wall temperatures reach ranges where radiation becomes significant, adding radiative heat-transfer treatment to building surfaces would improve accuracy during high-temperature late phase of the accident.

The GOTHIC model was later expanded to include aerosol transport processes involving fission products. This update enabled a comparison with assumptions related to these phenomena embedded in BAYLOCA, especially those related to the conservatism of its primary release estimates. The enhanced GOTHIC simulations indicated that roughly 60% of the released fission products would remain inside the building, largely deposited in liquid accumulations. BAYLOCA 1.0 was unable to reproduce this outcome because it was designed with a conservative bias and did not include a model for fission product deposition.

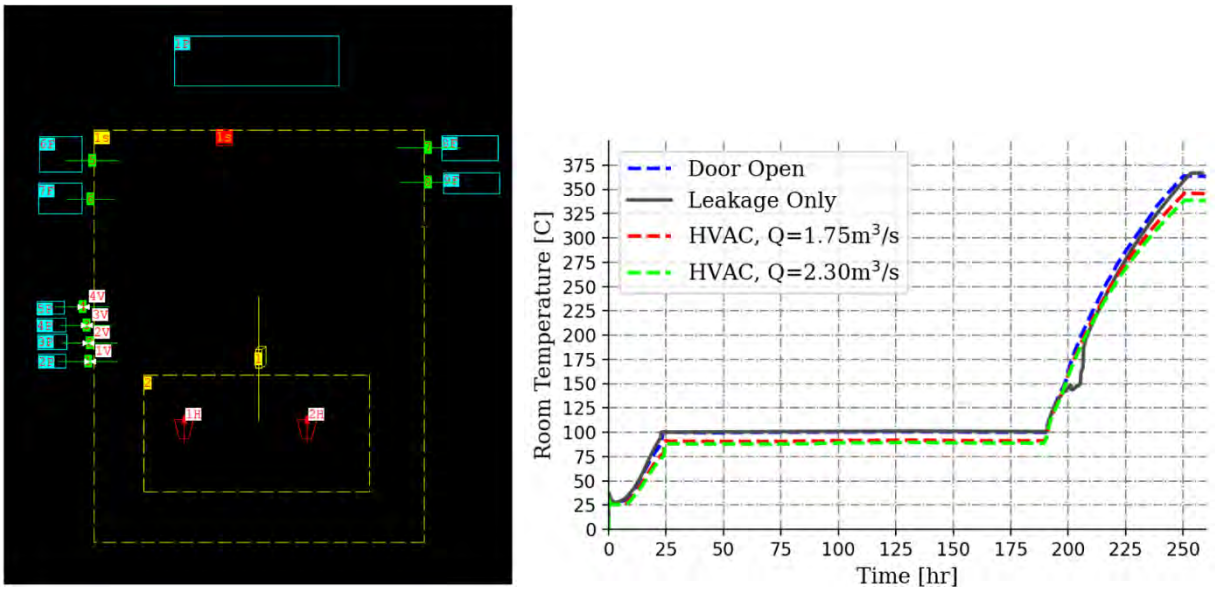

Figure 6. GOTHIC model of the SFP (left), and temperature of the building during a transient under different boundary conditions (right).

6. PARTICIPATION IN OECD-NEA POLCA PROJECT

In alignment with the objectives of the SFP accident analysis project, an international research connection was included to leverage the research and understanding of the broader community studying SFP severe accidents. This involved Canada's participation in the OECD-NEA POLCA project, which is focused on understanding LOCA scenarios in light water reactor SFP, while also generating broader insights applicable to common phenomena found in CANDU SFPs. This project aims to generate data for SFP thermal-hydraulic under accident conditions that can be used to benchmark and refine numerical modelling tools for SFP accident analysis.

7. CONCLUSION

Following the vulnerabilities revealed in SFPs during the Fukushima accident, many countries conducted research efforts in this area. As part of Canada’s response, and with the support of the CNSC, CNL initiated research efforts to improve the understanding of accident progression and consequences in SFPs, with emphasis on CANDU facilities.

As part of this effort, the FBHA was constructed to study bundle level behavior in a tray type configuration. A series of experiments were carried out to measure sheath and gas temperatures over a range of bundle powers in dry air, blowing air, and steam environments.

A comprehensive review of the BAYLOCA SPF accident analysis code was also completed, identifying several areas for improvement, including potential enhancements to phenomena models, updates to the code architecture, and improvements in the user experience. The updated code was benchmarked against results from both GOTHIC and high fidelity CFD models.

The CFD model, developed to estimate peak sheath temperatures during a complete LOCA in CANDU SFPs, demonstrated the complex heat transfer and flow patterns expected at the examined decay powers.

A thermal-hydraulic GOTHIC model was developed to simulate a LOCA scenario in a simplified SFP configuration. Several limitations in GOTHIC’s treatment of fuel exposure to air steam mixtures were identified. The model was later expanded to include aerosol and fission product transport, enabling an assessment of the conservatism of the BAYLOCA primary release assumptions.

Finally, in alignment with these efforts CNL is participating in the OECD-NEA POLCA joint project, which is designed to generate valuable data on thermal-hydraulic phenomena in a SFP under accident conditions thereby strengthening understanding and improving international capabilities for SFP safety analysis.

ABSTRACT

This work presents the results of uncertainty and sensitivity analysis (U&Sa) performed using a modified approach – introducing a relative time scale instead of an absolute time scale. All simulations have been done with the European reference Accident Source Term Evaluation Code (ASTEC) **[1]**, developed by ASNR (formerly IRSN) and representing a Medium Break Loss of Coolant accident (MBLOCA) with the activation of the Filtered Containment Venting System (FCVS) in a generic KONVOI NPP **[2]**. The U&Sa was performed with KArlsruhe Tool for Uncertainty and Sensitivity Analysis (KATUSA) **[2]**, developed by KIT. The paper shows the modified approach to perform U&Sa of the SA simulations, discuss the results and remaining questions. The simple statistics for the fission product (FP) release into the containment and environment as well as correlation coefficients between the release values and the selected uncertain input parameters (UPs) are presented in the paper. The difference in the correlation coefficients values as a result of using the different time scale types is discussed.

KEYWORDS

ASTEC, KATUSA, Sensitivity analysis, Severe accident, Uncertainty analysis

1. INTRODUCTION

U&Sa in the nuclear safety field plays important role in analyzing the potential consequences **[3, 4, 5]** of severe accidents and allows a closer look on the variations in the SA progression and the release to the environment. The SA codes used to perform such simulations have a lot of uncertainties **[6, 7]** in their models of various physical processes. In addition to it, other uncertainties exist, for example, related to the reactor model. All this leads to significant differences in the simulations output, which should be analyzed and taken into account.

Currently, the standard approach **[8]** in the field includes the following steps:

- Identifying the uncertain input parameters and the output of interest;
- Sampling input parameters inside the defined range of values;
- Running certain number of simulations with the selected code;
- Computing the correlations between input and output parameters.

Often the output of interest is a single value like, for example, peak cladding temperature or final release value of a given fission product, but it could be also a parameter changing over time, when the goal is to look at changes of the selected parameter over time and how the uncertain input parameters can influence those changes at the different stages of the severe accident progression.

This paper focus at one particular issue that SA simulation results have quite different progression in time depending on the values of the uncertain input parameters, which could require different way of how these results are approached and analyzed.

The analyzed data is the results of the MBLOCA SA scenario simulations with the ASTEC code, which were obtained earlier and presented **[2]**, where in some cases the conditions of activating the FCVS were fulfilled. That subset of simulations – with the activated FCVS – is analyzed in the current work. This group of simulation is particularly interesting due to the very late activation of the FCVS – for some simulations it happens at time point, when other simulations have already reached the time of a basemat rupture. That makes U&Sa quite tricky, raising the question, how to analyze correctly such ensemble of simulations at the same time keeping as much data as possible for analysis.

This work tries to answer this question introducing the so-called "relative time scale" option, where data from different simulations is aligned on the time scale from 0 to 1. This allows to analyze the results not between given time points t_1 and t_2, removing all data lying outside of this time window, but to look at the data between two selected events – one of them will be always located at 0 point at the relative time scale, and the other – at 1.

The paper is organized in the following way:

- ***Chapter 2*** provides a shortened description of the computational framework – ASTEC KONVOI NPP model and the KATUSA tool. For a more detailed description, see the previous works **[2, 9]**;
- ***Chapter 3*** describes the idea of the relative time scale approach;
- ***Chapter 4*** at the beginning shows how much data could be lost in case of using the standard approach with the absolute time scale, then presents the results of the U&Sa obtained with using the relative time scale option and comparing them with the previous ones;
- ***Chapter 5*** discusses the results of the performed analysis and the differences in the results obtained with two different approaches.

2. COMPUTATIONAL FRAMEWORK

The same computational framework described here has been used for our previous works **[2, 9]**. For this paper no new simulations have been made, the data presented in **[2]** has been re-used instead. All simulation results were acquired using the ASTEC code and KATUSA tool. The generic KONVOI-1300 NPP model has been used as input for the ASTEC code.

The ASTEC model of the KONVOI-1300 NPP is shown at ***Figure 1***. The reactor core in ASTEC model is divided in six cylindrical rings plus two additional channels representing the downcomer and the bypass. Each core channel consists of fuel rods, control rods, grid spacers and plates. The containment is divided into 26 rooms plus an auxiliary building. The containment and the annulus are connected with each other and with the environment by means of fans. Two filtering systems are modelled - the annulus air extraction system (AAES) connects the annulus to the environment and is always available; the Filtered Containment Venting System (FCVS) connects the containment and the environment. The FCVS is activated as Severe Accident Management (SAM) action when the absolute pressure in the containment reaches 6.3 bar, and it is deactivated when the absolute pressure in the containment is equal to 3.65 bar. The goal of this SAM is the containment depressurization aiming at avoiding containment rupture.

The KATUSA tool developed at KIT **[2, 9, 10]** consists of the following six modules:

- *Sampling*: Two algorithms are available - Simple Random Sampling (SRS) or Latin Hypercube Sampling (LHS). The uncertain input parameters can be pre-correlated;

- *Organize simulations*: This part of the tool run multiple ASTEC simulations using the number of cores provided by the user. Each simulation has its own input deck with a corresponding set of uncertain input parameters values;
- *Identify failed simulations*: Failed runs are identified to be exclude from further analysis;
- *Collect data from non-failed simulations*: User provides the list of figure-of-merit (FoM), which will be extracted from all non-failed samples and stored in a database;
- *Adjust time grid and interpolate the data*: The collected data are interpolated onto a common time grid for further U&Sa and then stored in the database;
- *Perform U&Sa*: For each selected FoM, simple statistics (minimum, mean, maximum, 5th, 50th, and 95th percentiles values) and time-dependent correlation coefficients can be computed.

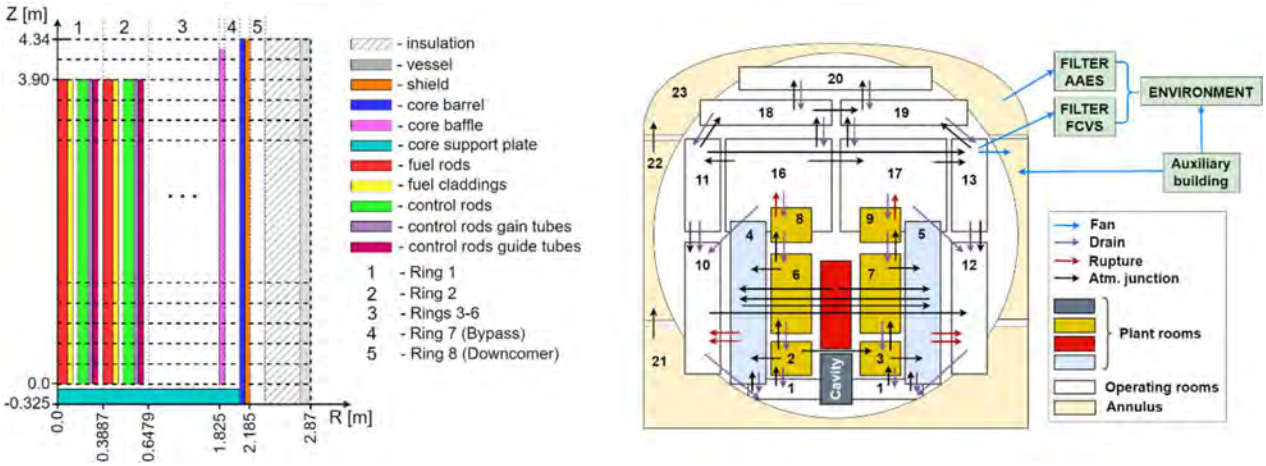

Figure 1. Core (left) and containment (right) nodalization of the ASTEC model of a generic KONVOI NPP (dimensions not in scale) [11, 12].

All details about the selected uncertain input parameters are provided in the ***Appendix A*** to avoid unnecessary repetitions.

3. ABSOLUTE AND RELATIVE TIME SCALE

This section explains the current approach to perform U&Sa used in KATUSA tool and how it could be changed. On ***Figure 2*** is shown how the data extracted for U&Sa in the current version of KATUSA tool. During the adjusting time grid and interpolating the data step (see above in the ***Section 2***) it is specified between which characteristic events the data should be extracted. For example, one wants to analyze the data between the start of fission product (FP) release and up to the basemat rupture – in that case, the starting point of the data extraction will be the maximum time of the start of FP release and the minimum time of the basemat rupture among all considered simulations. This leads to the exclusion some of the data from analysis – namely, all the data after the minimum time of the basemat rupture will not be taken into account, because this particular simulation is finished, and analysis couldn't be continued.

Figure 2. Current approach for data extraction implemented in KATUSA.

In addition to it, at every given time step the simulations considered in U&Sa are experiencing the different stages of the SA progression. For example, see on ***Figure 3*** – "Sample 1" hasn't yet reached the time point, when 20 tons of corium are relocated to the lower plenum, while the "Sample 2" has already passed the lower head vessel failure event.

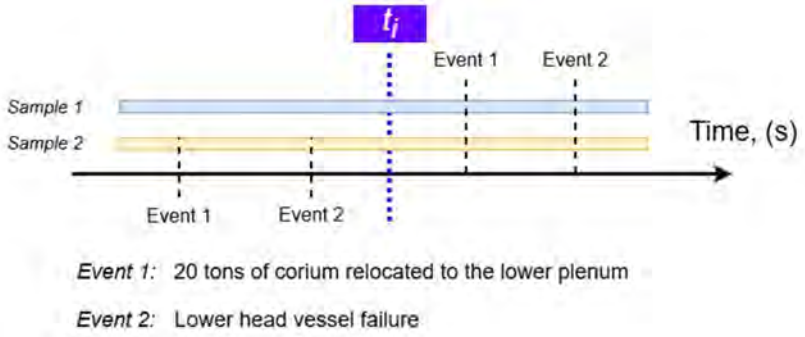

Figure 3. Samples with the different SA progression used in U&Sa.

On the idea of the relative time scale ***Figure 4*** is illustrated. For example, firstly the data between "Event 1" and "Event 2" is taken for analysis. Instead of using the approach shown on the ***Figure 2***, here the data between two considered events is taken from each sample and interpolated on one time scale from 0 to 1. After that, the data between "Event 2" and "Event 3" could be analyzed in the same manner. Therefore, any number of the characteristic events could be considered in the analysis.

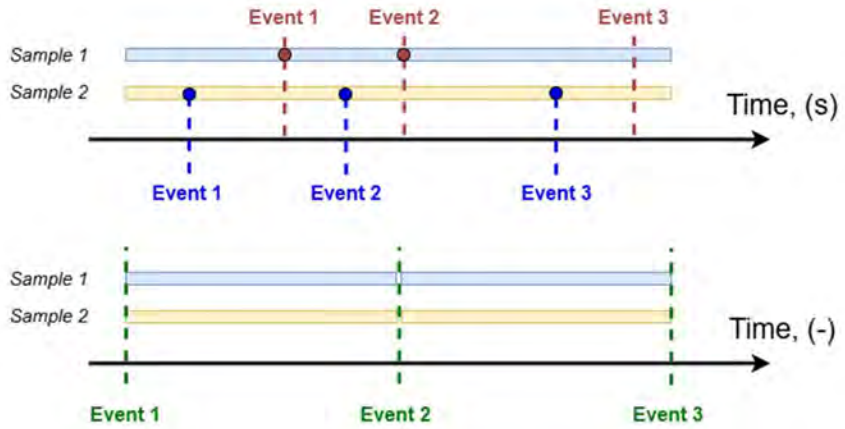

Figure 4. Absolute and relative time scale schemes.

4. RESULTS OBTAINED WITH THE RELATIVE TIME SCALE

Initially for our previous work **[2]** the two sets of the MBLOCA scenario simulations with the activation of the FCVS were performed with the 300 simulations in each set. For the current analysis these sets were combined and divided into two sub-sets by the presence of the FCVS activation. As a result, there are 97 simulations with the activated FCVS and 477 simulations where conditions of FCVS activation haven't been reached – these two sub-sets are analyzed separately. From initial 600 simulations 26 have failed and are not considered in the U&Sa.

On ***Figure 5*** is shown how time of characteristic events is distributed for two sub-sets of simulations (with and without FCVS activation). Start of FP release usually happens between ~450 s and ~700 s, most likely closer to 500 s. The time of LHVF has a wider spread – mostly it happens between ~17 000 s and 30 000 s, but there are couple of samples in the set (without FCVS activation) with much shorter degradation phase. The FCVS activation time is spreading from ~170 000 s up to ~370 000 s. Time of the basemat rupture mostly lying between ~220 000 s and ~360 000 s, and couple of samples have much shorter and much longer SA progression time.

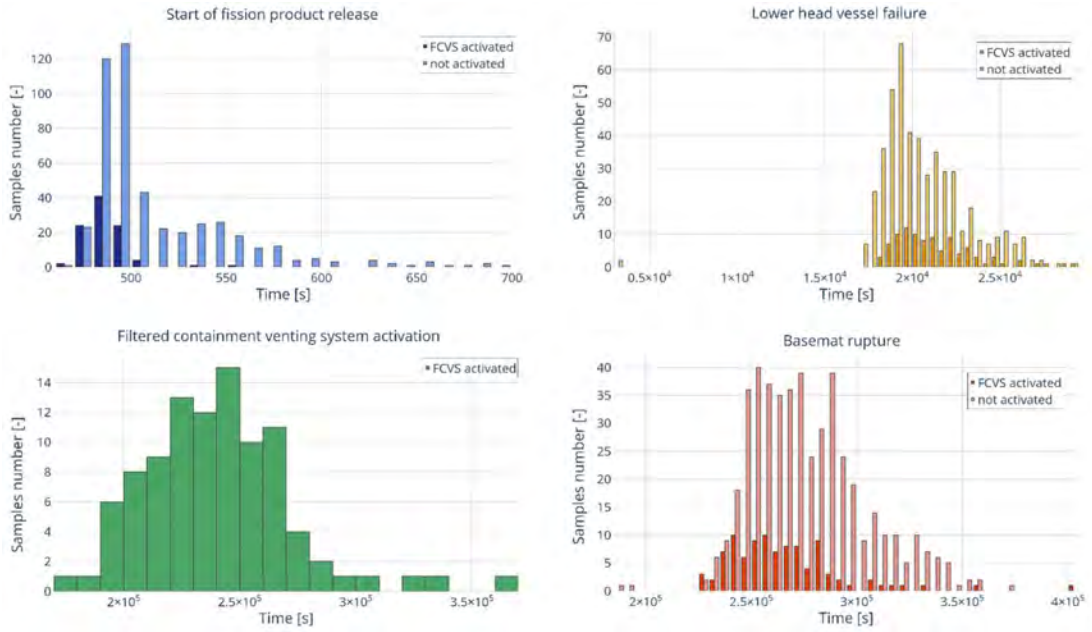

Figure 5. Distribution of the characteristic events in time for simulations with and without FCVS activation.

In this paper the main focus will be on the subset of simulations with the activated FCVS due to the following reasons:

1) Time of the FCVS activation in our simulations could be very close to the time of basemat rupture;
2) After FCVS activation, the changes in FP release (for example, Xe release into the environment) happens very fast (see example on the left upper part of the ***Figure 8***), which in combination with 1) makes U&Sa more complicated.

On ***Figure 6*** is shown how the basemat rupture time and time of FCVS activation are distributed. For subset of simulations without FCVS activation couple of samples could be excluded (see two marked samples on the left), due to their particularly short SA progression time, leaving majority of the samples for further analysis. On the contrary, for the subset with FCVS activation, the minimum basemat rupture time is marked with the vertical line, and one can see that only part (not even half) of the samples with be used for further analysis in that case. All other data will be lost if U&Sa is performed with absolute time scale.

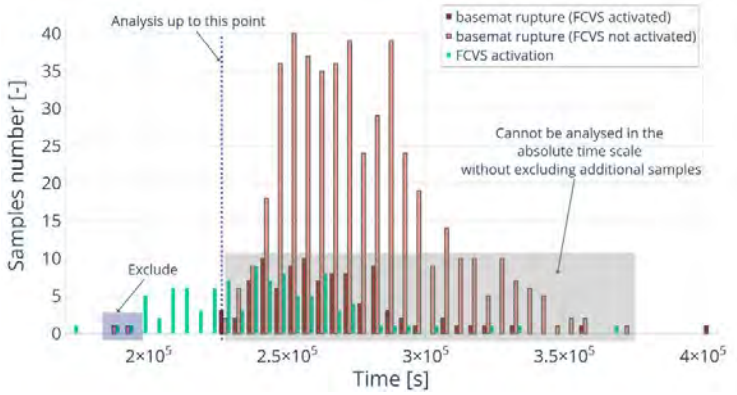

Figure 6. Distribution of the basemat rupture time and time of FCVS activation. Data not included in analysis with absolute time scale option is marked.

According to what is presented above on the ***Figure 6***, the amount of lost data will be quite significant, which is shown on ***Figure 7***. Therefore, the attempt was made to perform U&Sa in a different way without losing the data.

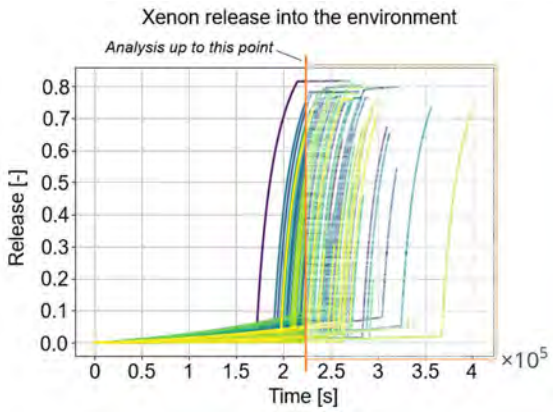

Figure 7. Data lost in the U&Sa with the absolute time scale for set of simulations with the FCVS activated.

Below the results of the U&Sa for the subset of simulations with activated FCVS will be presented. The Spearman correlation coefficients for this set are calculated for the Xenon, Cesium and Barium release using absolute and the relative time scales options.

On ***Figure 8*** all 97 simulations, where FCVS was activated, are shown on one plot. Thin solid lines represent the simulations used for analysis. The thick dashed lines are the excluded simulations. The reason for exclusion was that the activation of the FCVS in these cases happened on the last or one to the last time

step leaving to room for analyzing separately the time window between the FCVS activation and the basemat rupture. The details for the excluded samples are presented in ***Table 1***.

Table I. Excluded samples with the FCVS activation shortly before the basemat rupture

Sample index (from 97 samples set)	FCVS activation time, (s)	Basemat rupture time, (s)
6	238603.0	239803.0
21	238765.0	240065.0
37	269791.0	271591.0
56	244093.0	245393.0
69	243824.0	244524.0
70	257986.0	258286.0
75	264649.0	266149.0
83	330874.0	331674.0

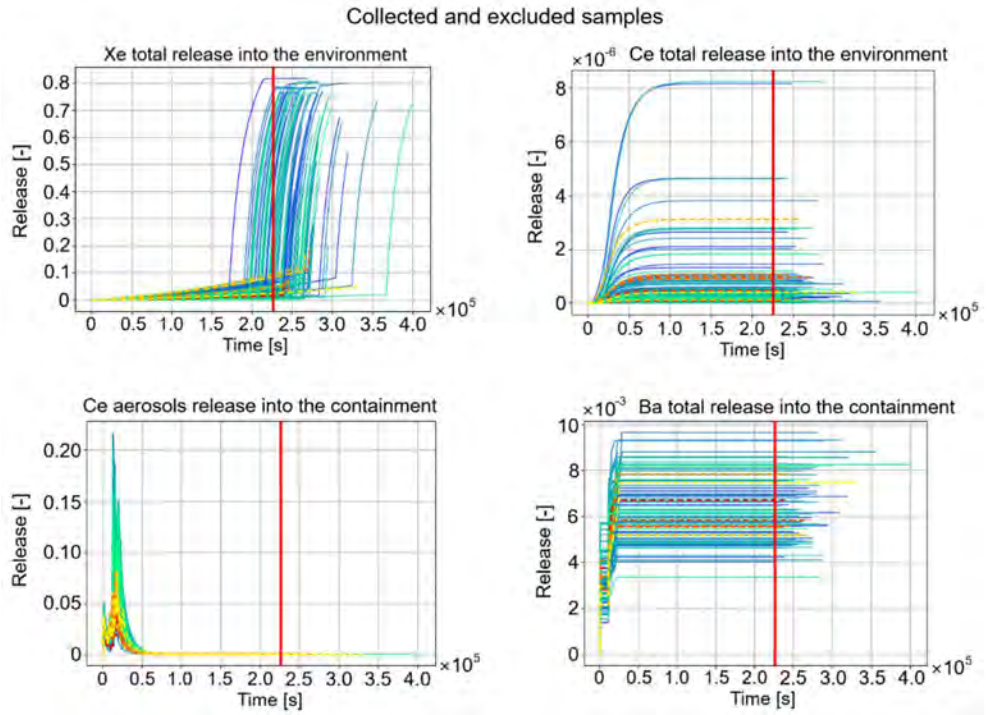

Figure 8. Xe, Cs, Ba release into the containment in time. Analyzed and excluded samples.

To check the effect from exclusion some of the simulations from the set, the comparison of the Spearman correlation values has been done between the case, where no samples were excluded and the case where 8 samples were excluded. The results are shown on the ***Figure 9***. As a results, no significant changes have been observed for the Spearman correlation values between the considered FP release and the most important uncertain input parameters.

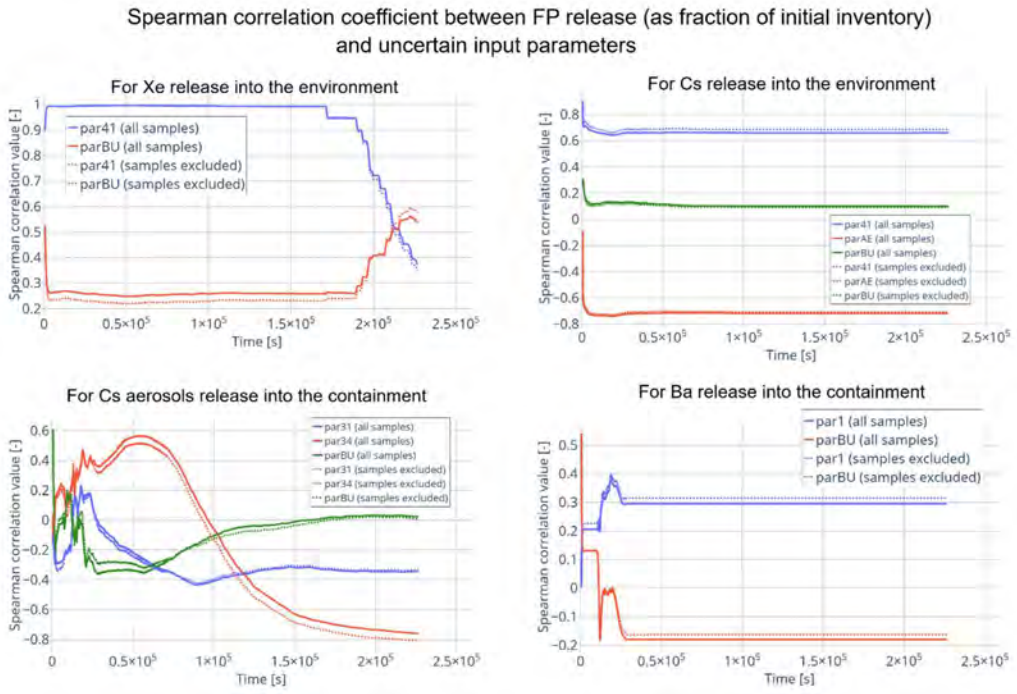

Figure 9. The Spearman correlation values in time for Xe, Cs and Ba release. With and without samples exclusion.

After confirming that exclusion of particular small group of simulations will not lead to any significant changes in the results, the Spearman correlation values were calculated both on the absolute and relative time scales. Below, on ***Figures 10 – 13*** results are shown for Xe, Cs and Ba release. The figures are presented in the following manner:

- Left subplot: correlation values are calculated on the absolute time scale from start of FP release up to basemat rupture. The time zones where LHVF, FCVS activation and basemat rupture can happen are colored and highlighted with text. The analysis on the absolute time scale performed up to the minimum time of the basemat rupture (see the scheme on ***Figure 2***).
- Right subplot: the relative time scale option is used for analysis. The start of FP release for every considered simulation is considered as "0", and the basemat rupture time – as "1" (see the scheme on the ***Figure 4***). The time zones where LHVF and FCVS activation can happen are colored and highlighted with text.

In addition, the time scale could be divided into zones to investigate the influence of the uncertain input parameters on the FP release inside each zone. These results are not presented here due to the paper size limit.

Moving to the relative time scale allows to avoid losing of the data (as it was shown on the ***Figure 7***) and to analyze the time period between the FCVS activation and the basemat rupture time for all simulations.

Xenon release into the environment according to our previous analysis **[2]** is mostly governed by the two UPs – *par41* related to the leakage rate between containment and environment and *parBU* related to the burnup level. From the ***Figure 10*** one can see that correlation coefficient values for *par41* computed with the relative time scale option show the same pattern as for the absolute time scale. But for *parBU* the rising effect closer to the end of the process is not observed anymore.

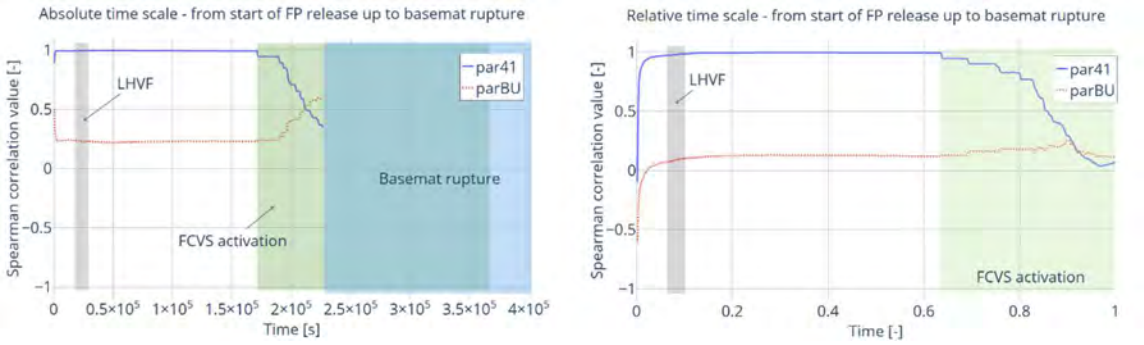

Figure 10. Spearman correlation values for the Xe release into the environment on the absolute and relative time scales.

For Cesium aerosols release into the containment was found that the most influencing parameters are *par31* and *par34* related to the aerosol behavior, and *parBU* related to the burnup level. It could be seen from ***Figure 11***, that Spearman correlation values for *par31* and *par34* for absolute and relative time scale options are quite similar, while for *parBU* the relative time scale option gives higher values up to FCVS activation region.

For Cesium release into the environment three UPs play a role – *par41*, *parBU* which were mentioned already, and *parAE* related to the filter efficiency for aerosols. For these parameters no significant changes in values has been observed between the relative and absolute time scales options, which is depicted on the ***Figure 12***.

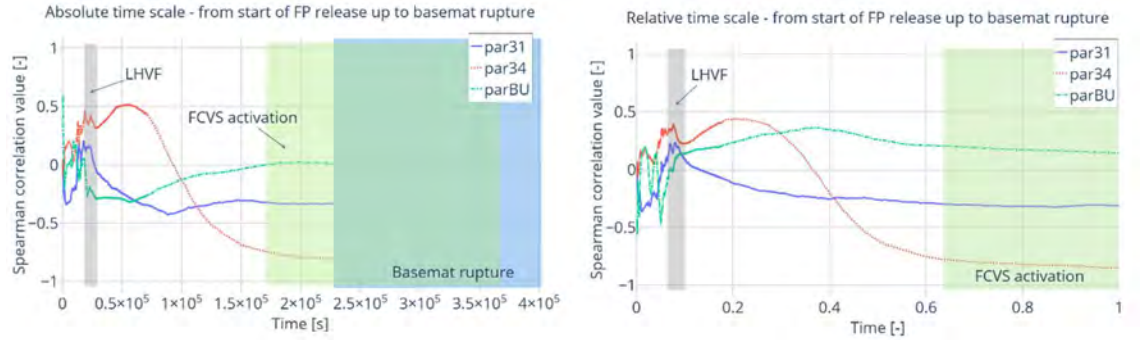

Figure 11. Spearman correlation values for the Cs aerosols release into the containment on the absolute and relative time scales.

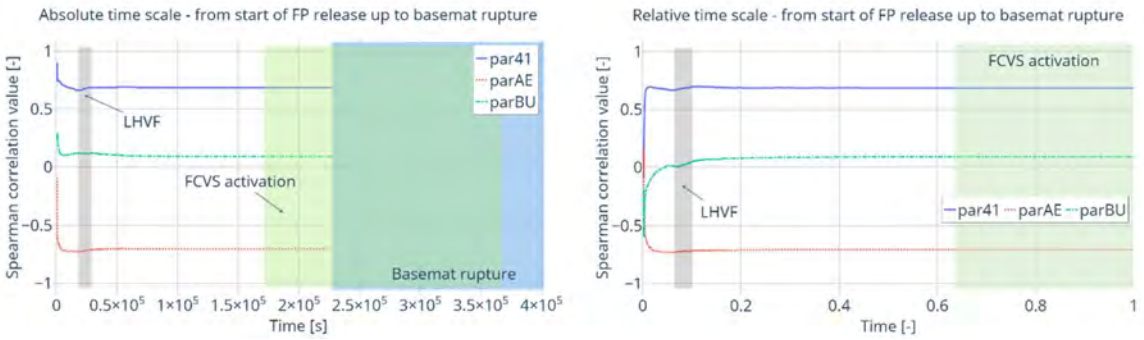

Figure 12. Spearman correlation values for the Cs release into the environment on the absolute and relative time scales.

For Barium release into the containment the main parameters as were found previously are the *parBU* and *par1* related to the model governing release from the fuel pellets. In this analysis also no significant differences have been found between the two different time scale options, at least after the LHVF event.

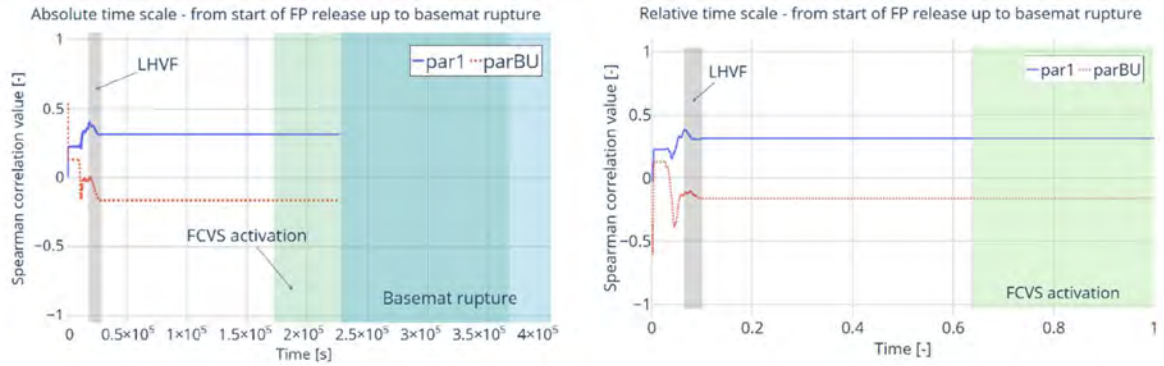

Figure 13. Spearman correlation values for the Ba release into the containment on the absolute and relative time scales.

5. CONCLUSIONS

In this paper the new "relative time scale" option for performing the U&Sa is introduced. This approach, comparing to the one used in our previous works, allows to reduce to the minimum exclusion of the data. This is quite relevant for the U&Sa of the SA simulations, which could have significant differences in the SA progression and timing of the main characteristic events. In this work the different option to look at such type of data is tested on the previously acquired set of the simulations of the MBLOCA SA scenario with the activation of FCVS. The activation of that system happens very late in the course of the SA progression, and some simulations could already reach the basemat rupture, while the others are still haven't reached the FCVS activation time. All these make U&S analysis quite tricky and lead potentially to exclusion a lot of samples from already not very large set of simulations (just 97 samples in total). That lead to the idea to look at this data at the different angle and to introduce the so-called "relative time scale", where the time of one characteristic event is set to "0", the time of the other event – to "1", and all the data interpolated to this time scale, helping to preserve as much data as possible.

To illustrate this approach the Spearman correlation coefficients have been calculated for the Xe, Cs and Ba release into the environment and containment, and comparison of the results between the "relative" and "absolute" time scale option have been made. Mostly the data are in a very good agreement, except maybe the very first time steps, which could have just numerical reasons, due to the very small release values at the beginning of the time scale. In addition to it, the Spearman correlation values for the *parBU* (related to the burn-up level) show some difference for the Xe release into the environment, and also for the Cs aerosols release into the containment. In these cases, the difference is observed along the whole SA progression and could not be attributed to the small release values.

APPENDIX A

In this Appendix the detailed information about eighteen selected UPs is provided. Their meaning and corresponding PDFs, as well as the links to the literature are given in ***Table A-I***. The UPs could be divided into following group according to their meaning:

- *par1*, *par2*, *par5*, and *par5a* are related to the ASTEC code ELSA model for simulation of the the fission product release;
- *par14*, *par15*, and *par16* are related to the fuel cladding integrity criteria;
- *par31* - *par37* are from ASTEC SOPHAEROS and CPA calculation models simulating the behavior of the aerosols in the reactor coolant system and in the containment;
- *par41* governs the uncertainty of the leakage rate from the containment to the annulus;
- *parBU* related to the fuel burnup level, namely the number of effective full power days;
- *parAE* and *par12* characterize the performance of the FCVS: filter efficiency for aerosols and filter efficiency for gaseous iodine, respectively.

On ***Figure A-1*** the correlations between UPs are shown.

Uncertainty and Sensitivity Analysis of the ASTEC Source Term Results of a MBLOCA Scenario with the Activation of Severe Accident Management Actions in a Generic Konvoi Plant. *Nuclear Technology*, pp.1-18. https://doi.org/10.1080/00295450.2025.2544372

A:

- Set of 300 MBLOCA simulations (with 48 simualtions where FCVS was activated) analyzed as a whole – ERMSAR-2024 conference
- Results between MBLOCA and MBLOCA+FCVS activation were compared

B:

- Relative time scale is introduced
- Relative time scale is applied to the FP release in environment and containment results
- Results between MBLOCA and MBLOCA+FCVS activation were compared

Computational framework

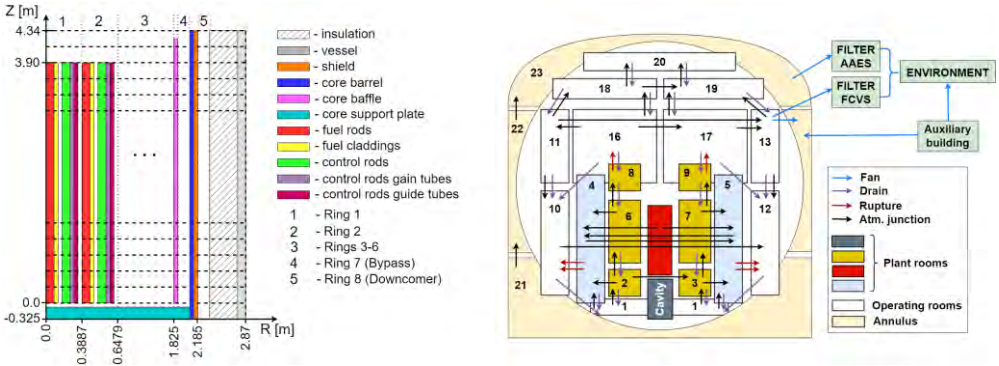

Figure 1. Core (left) and containment (right) nodalization of the ASTEC model of a generic KONVOI NPP

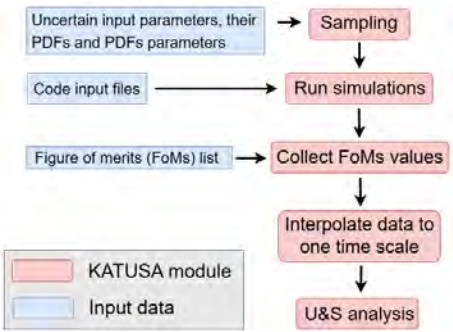

Figure 2. KATUSA tool scheme

- ASTEC code
- KATUSA tool for U&S analysis
- KONVOI-1300
- MBLOCA scenario
- 600 simulation in total -> 97 with FCVS activation are analyzed
- 18 uncertain input parameters, some of them are correlated

Problem description

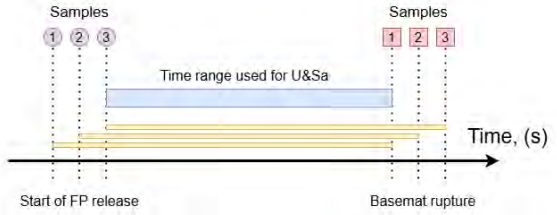

Figure 3. Approach for data extraction used in previous works

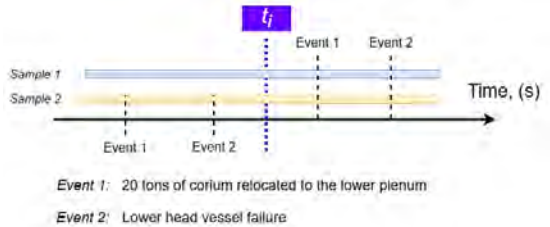

Figure 4. Samples with the different SA progression used in U&Sa

- In the previous works the U&S analysis was made on the absolute time scale.
- Between two considered events the data analysed as it is shown on the ***Figure 3***.
- For any time point different realisations of the SA scenario could be at the different stages of the SA progression – ***Figure 4***.

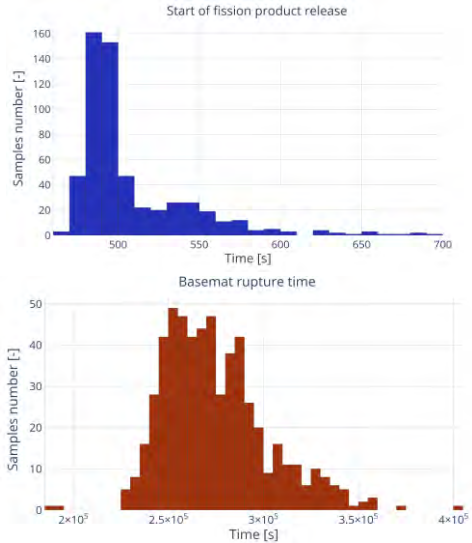

Figure 5. Distribution of the characteristic events in time

- The range between the earliest and the latest start of FP release – usually in our simulations [400, 700] s
- The range for the time of basemat rupture is much broader - ***Figure 5.***

Problem description

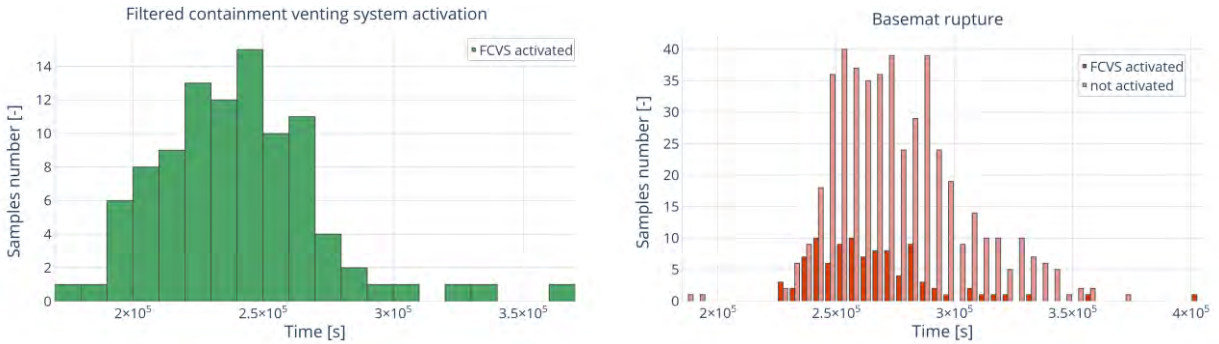

Figure 6. Distribution of the characteristic events in time

Due to the late activation of the filtered containment venting system (FCVS) – ***Figure 6***:

1) Stop analysis, for example, at ~ 250 000 s – it will lead to loss of the part of the time scale, where FCVS is activated for significant number of samples – ***Figure 7***

2) Extend the time range for analysis – exclude a lot of sample (including onces with FCVS activation)

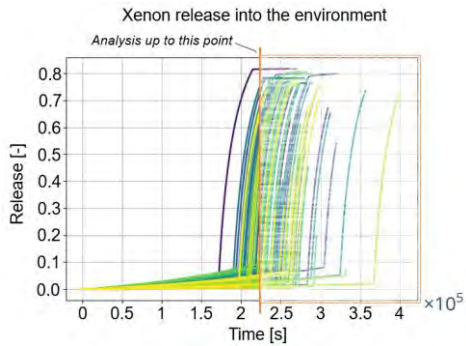

Figure 7. Data lost in the U&Sa with the absolute time scale for set of simulations with the FCVS activated.

Proposed solution

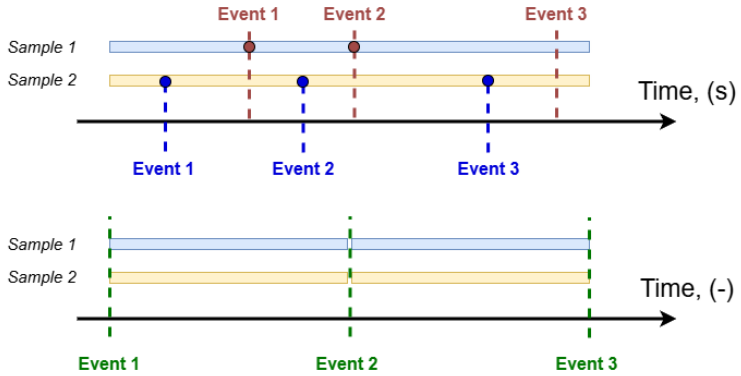

Figure 8. Absolute and relative time scales schemes

Proposed solution is to align all simulated SA progressions to the common relative time scale – ***Figure 8***.

- Take start of FP release as time point „0“ and basemat rupture as time point „1“
- Divide time scale into parts. For example, analyze first the part between start of FP release and lower head vessel failure (LHVF), then between LHVF and basemat rupture

Results of U&S analysis

- In total 600 MBLOCA simulations were performed to collect enough cases with FCVS activation
- 97 cases with FCVS
- 8 cases (from 97) were excluded due to the FCVS activation happened right before the basemat rupture - ***Figure 9***
- Spearman correlation coefficients were calculated on the absolute time scale to check the effect from excluded samples - ***Figure 10***

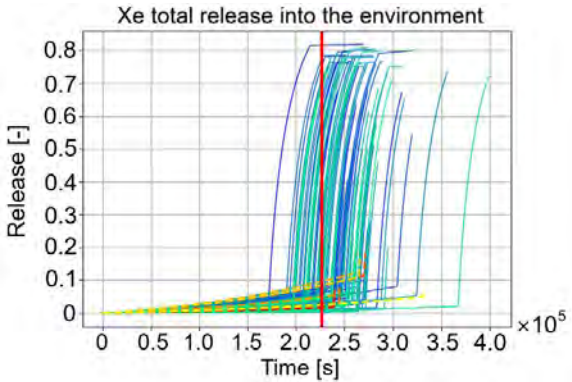

Figure 9. Xe release into the containment in time. Analyzed and excluded samples.

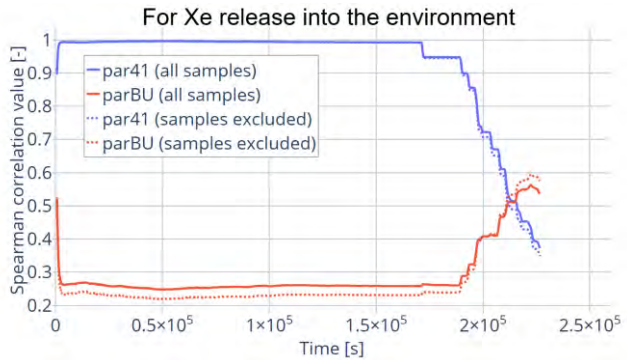

Figure 10. The Spearman correlation values in time for Xe, release. With and without samples exclusion.

Results of U&S analysis

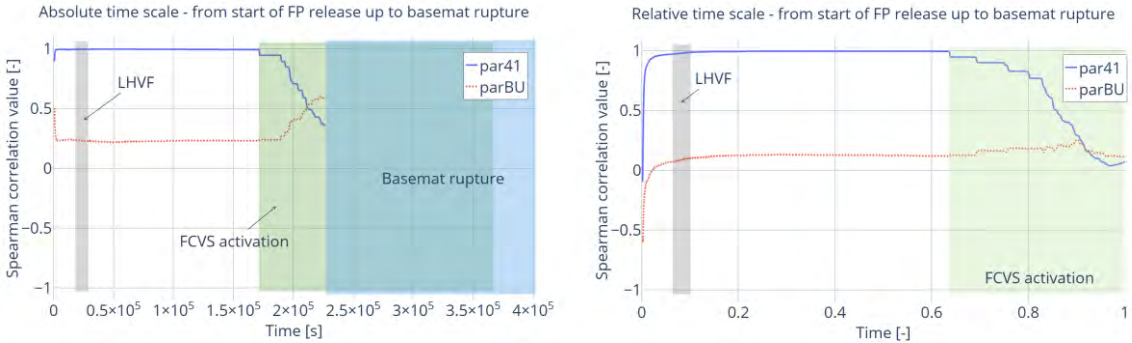

Figure 11. Spearman correlation values for the Xe release into the environment on the absolute and relative time scales.

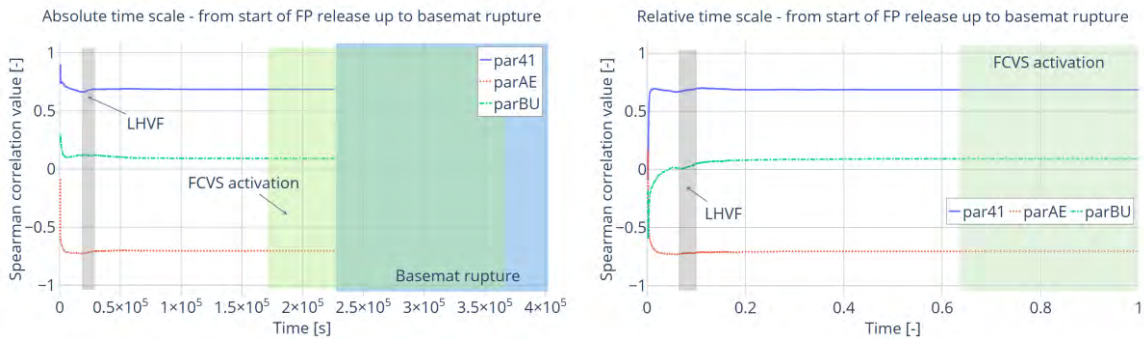

Figure 12. Spearman correlation values for the Cs release into the environment on the absolute and relative time scales.

Results of U&S analysis

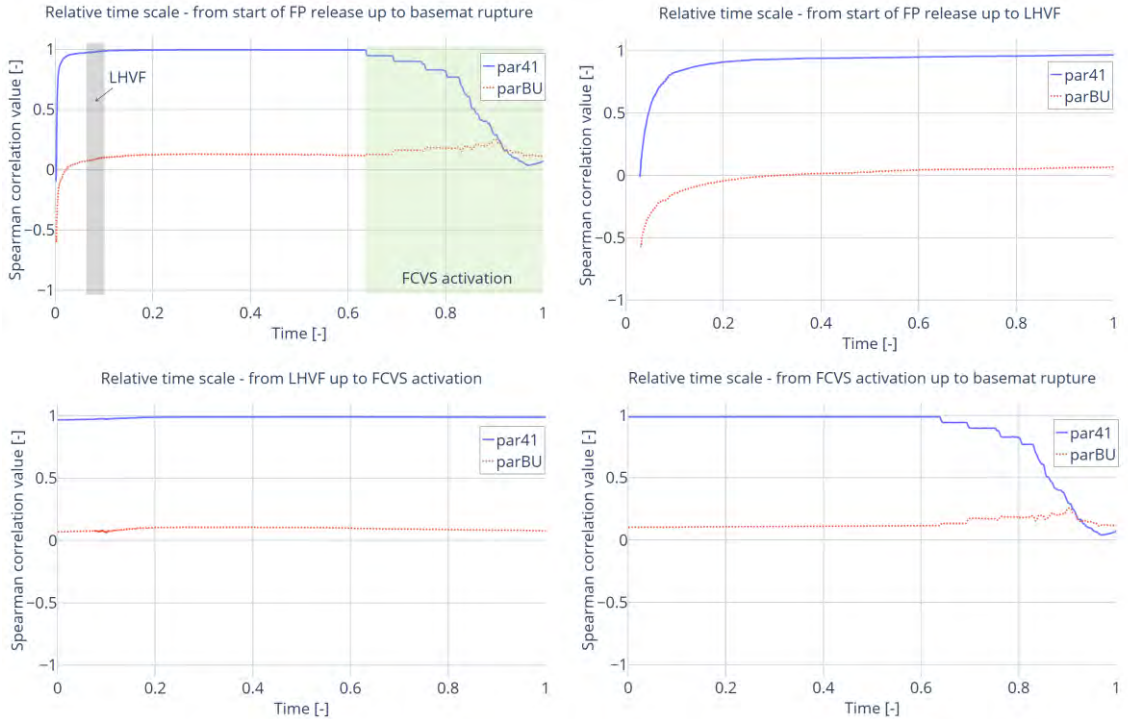

Figure 13. Spearman correlation values for the Xe release into the environment on the relative time scale. Example of dividing time scale into parts between characteristic events

Conclusions and outlook

- Previous work of analyzing results of MBLOCA SA scenario with FCVS activation is continued
- Relative time scale option is used to perform U&S analysis
- Focus on the simulations where FCVS was activated to show the need of the relative time scale option
- Time scale could be divided into zones between characteristic events

- Relative time scale option could be further tested
- Other options of time scales alignment could be considered

Thank you for your attention!

ABSTRACT

A thorough understanding of the accidents unfolding at the Fukushima Daiichi site in Japan on March 11th 2011, is a sound path to optimize accident management. This has been the ultimate goal of the BSAF, ARC-F and FACE projects, conducted under the OECD frame. CIEMAT focused on the Unit 1 accident and postulated a scenario that fitted the in-Reactor Pressure Vessel (RPV) and in-Primary Containment Vessel (PCV) pressure footprints with MELCOR 2.2.9607 (2017). Further code versions, though, caused significant changes in the estimates and raised the need to re-build a plausible scenario. Based on MELCOR 2.2.r2024 (2024), this paper describes the rationale underneath the scenario postulated and how an *ad-hoc* application of Uncertainty and Sensitivity Analysis (UaSA) turned it into a valuable tool to assess its consistency. Even though the hypotheses made in the scenario resulted in trends consistent with data, their magnitude and timing did not capture them, even if uncertainty bands are considered. An interpretation of consistencies and differences is included in this paper.

KEYWORDS
Forensic Analysis, Severe Accident, Uncertainty Quantification, Fukushima-Daiichi

1. INTRODUCTION

The Fukushima Daiichi accident, occurred in Japan on 11 March 2011, has revived the interest for the analysis of severe accidents. Despite the low probability of this type of events, Fukushima Daiichi has brought forward two irrefutable facts: the occurrence of highly unlikely accidents is possible; and, in the event of such an accident, their consequences might be long lasting and of sizeable dimensions, with worldwide impact in many regards. Consequently, grasping a thorough understanding of the accident unfolding has been in the spotlight as a way to gain insights for mitigation and prevention of these accidents.

Since 2012, the international OECD/BSAF project [1] adopted a forensic approach to find out defensible scenarios that could explain the evolution of the accident at the units 1 through 3 of the Fukushima Daichii Nuclear Power Plant. In this frame, CIEMAT focused on the Unit 1 accident and chased postulated malfunctions and failures in equipment and components that resulted in variables evolutions consistent with the data recorded, particularly in-RPV and in-PCV pressure footprints. MELCOR 2.2.9607 (2017) was used at the time [2].

The continuous code development, however, has entailed changes that resulted in significant differences in the MELCOR estimates with respect to the previous versions. This triggered a new campaign of calculations to test how the postulated scenario should be modulated (i.e., keeping the major assumptions and hypotheses, but varying some of the parameter settings) to keep a data-predictions match at least as good as in earlier calculations: a scenario re-calibration. This paper describes the rationale underneath the scenario

postulated and how an *ad-hoc* application of Uncertainty and Sensitivity Analysis (UaSA) turned into a valuable tool to assess its consistency.

2. BEST ESTIMATE CALCULATIONS

2.1. MELCOR basic model

The plant is modelled with the MELCOR 2.2. code [3], [4] through 109 control volumes, 215 flow paths and 137 heat structures. The model is completed with around 180 user functions describing aspects like valves and safety systems operation or water injection along the sequence.

The RPV nodalization includes the steam-dome, dryers, separators, shroud dome, annulus and the lower plenum whereas the core is split axially in 7 nodes and radially in 4 rings giving 56 control volumes, which account for the corresponding channels and bypasses. The in-shroud region is set with 4 radial nodes and 8 axial nodes, the core plate is defined with 1 node and 3 nodes describe the lower plenum (LP) (Fig. 1a).

The PCV nodes have been distributed as follows (Fig. 1b): 9 nodes for the Dry Well (DW), 8 circumferential nodes for the Wet Well (WW) and 8 nodes for the vents between DW and WW. Cavity is modelled through 2 interconnected cavities (one for the pedestal region and the other to the DW floor outside the pedestal) (Fig. 1c). Finally, the reactor building is modeled through 19 control volumes, 25 flow paths and 58 heat structures (Fig. 1d). A detailed description of the model can be found at [2].

Given the analytical nature of this paper, it is worth highlighting that the plant model has been kept with no changes in all the calculations reported.

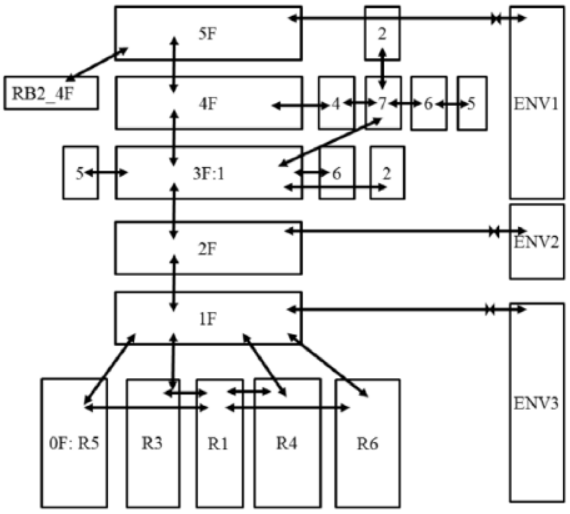
c) Cavity.



d) Reactor building.

Figure 1. 1F1 MELCOR nodalization.

2.2. Key Scenario Hypothesis

Scarcity of data along the first 12 h since the accident onset is crucial. During this time interval core extensively degraded and resulted in RPV and PCV failures. The information available is not enough to identify neither timing nor the mechanisms responsible for the RPV failure, which eventually determined to a good extent the in-containment pressure evolution and final failure. In other words, a forensic approach (i.e., building a full scenario out of few footprints) is indispensable to ascertain defensible scenarios that could explain the accident unfolding. This forensic approach was based on two variables recorded during this period: in-RPV pressure and in-PCV pressure. Some other signals did complement these two variables, like in-core water level or dose rates in PCV. However, their accuracy limited their use to qualitative comparisons.

The main fundamental hypotheses considered in the proposed scenario are as follows [2], [5]:

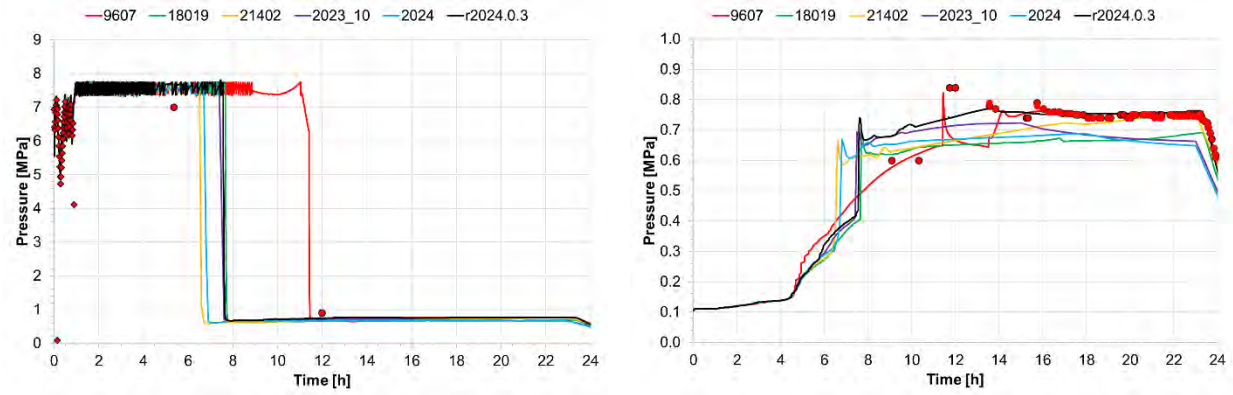
- The isolation condenser is modelled as an energy sink with an imposed efficiency to fit the RPV pressure oscillations reported during the first 50' of the accident.
- The 4 SRVs are modelled as valve-controlled flow paths (just one SRV operated during the accident).
- Two RPV leaks are considered: through the SRV gaskets when the SRV location reaches 723 K (steam and hydrogen) and from the LP (water), as a collateral damage of the quake.
- A DW flange failure is assumed at high containment pressure and a temperature (> 755 K).
- PCV venting (~24 h).
- Reactor building major failure imposed right after the venting.
- A "perfect" vertical stratification in the suppression pool under the injection point is assumed.
- No water injection is modelled during the first 24 h of the accident.

Given the goal of this work, the calculation time was restricted to the first 24 h since the quake event.

2.3. Results across MELCOR versions

The continuous MELCOR code development [6], [7], [8] has meant internal changes in models and settings that has correspondingly resulted in changes in predictions. Figs. 2a and 2b synthesize the estimates coming

from different versions of MELCOR for the in-RPV and the in-PCV pressures during the first 24 h of the accident. As observed, there are major differences with respect to the "reference version" (9607 in the plots). First, RPV failure time (sharp pressure drop down to less than 1 MPa) has been brought forward at least 4 h (Fig. 2a). As a consequence, the in-PCV evolution (Fig. 2b) has moved up as well and the tendency shown by the reference calculation has been lost both in timing and in the magnitude of pressure spike, at approx. 12 h in the reference calculation, caused by the RPV failure. Note that only the version r2024.0.3 was capable to describe the quasi steady-state drawn by data after 12 h (around 0.75 MPa); the 21402 version got there too, but at much later times (20 h).



a) in-RPV pressure. b) in-PCV pressure.

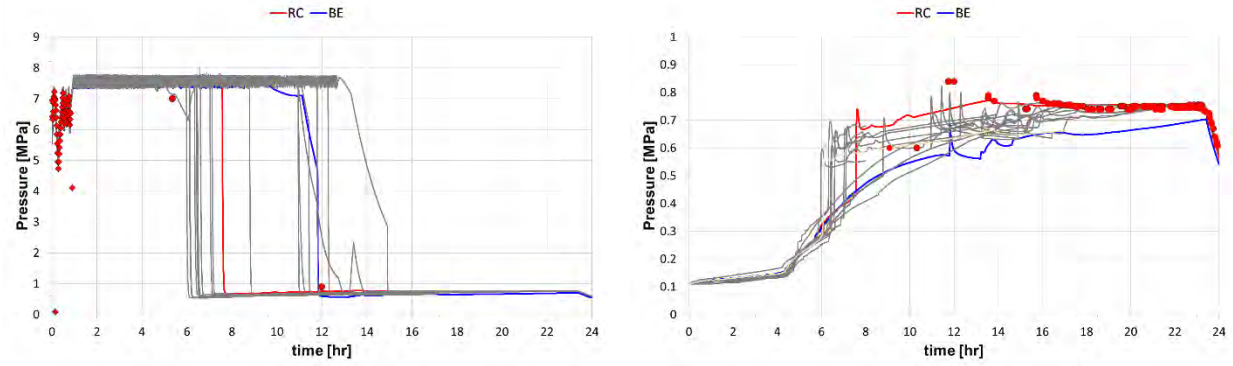
Figure 2. MELCOR versions update.

2.4. MELCOR Latest Version´s Best Estimate

As a result of the differences found, a re-calibration of the postulated scenario has been proposed by using the last code version released at the time these calculations were made (MELCOR 2.2.r2024.0.3). Three factors have been explored in these studies (Table I): the dimensions of the leaks from the primary system; the thermal setpoint failure limit of RPV lower plenum penetrations; and the description of the materials interactions while core degradation. Given the complex in-core phenomenology, the parametric results of each of the three factors explored (neither their combination) showed a clear non-linear effect on the in-PCV pressure. In Figure 3, the MELCOR calculation with the above version for the parameters as set in the reference case (RC, red line) and in the Best Estimate (BE, blue line) case are shown; in grey, some of the intermediate parametric calculations done are displayed for completeness.

Table I. Parameters of the scenario re-calibration.

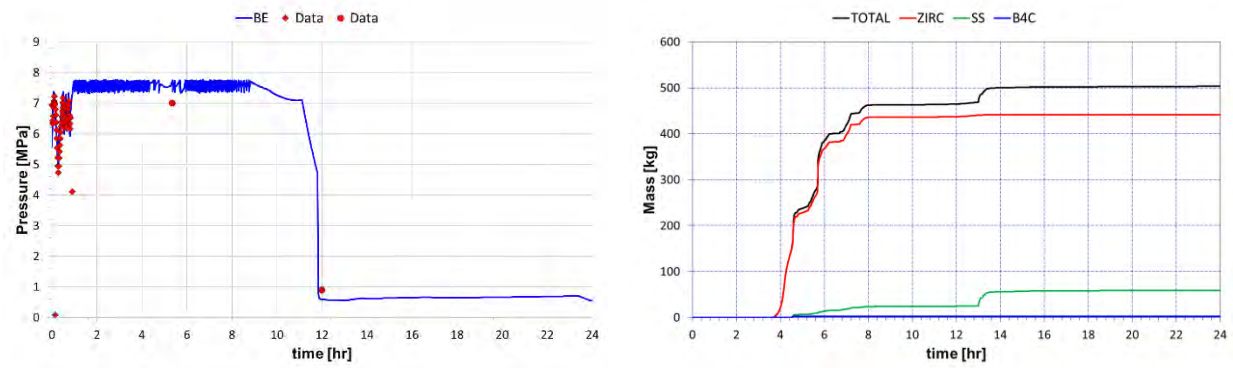
Parameter	Value range	RC	BE
Time of LP leakage (h)	0-1	1	0
LP leakage diameter (m)	$0 - 5 \cdot 10^{-3}$	$2 \cdot 10^{-3}$	$3.5 \cdot 10^{-3}$
Gasket failure diameter (m)	$10^{-2} – 3 \cdot 10^{-2}$	$2 \cdot 10^{-2}$	$2 \cdot 10^{-2}$
Penetrations failure setpoint (K)	1153 – 1673	1153	1400
Materials-interaction modelling	INT/EUT	INT	EUT



a) in-RPV pressure. b) in-PCV pressure.

Figure 3. Scenario re-calibration.

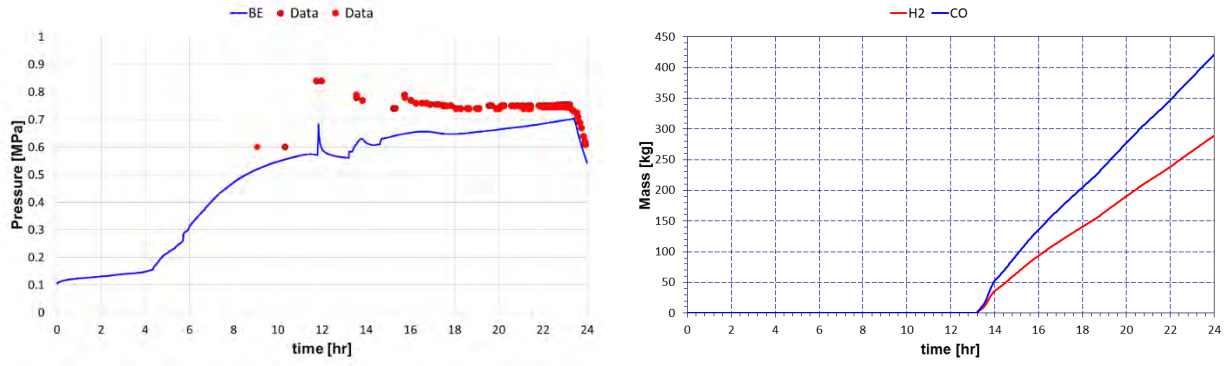
In-RPV pressure is shown in Fig. 4a. After the IC operation for about 45' since the quake, the data recorded does not allow a true comparison with estimates, since just a couple of data points, at around 5 h (7 MPa) and at 12 h (less than 1 MPa) were recorded. Namely, primary system depressurization occurred in between 5 and 12 h, which is a broad "blind-interval" from the in-RPV perspective. According to the MELCOR estimates, during the in-vessel phase, more than 500 kg of H_2 were produced (Fig 4b), mostly via Zr oxidation (87.7%), the remaining coming from SS oxidation (11.8 %) (Fig. 4b).



a) In-RPV pressure. b) In-vessel H_2 production.

Figure 4. Core degradation.

As for the in-containment P evolution (Fig. 5a), no data existed for 9 h and, then, from about 12 h on, recordings allow a thorough description of the variable. A pressure spike of about 0.25 MPa occurred from 10.5 h to a bit earlier than 12 h. At that moment, the loss of PCV tightness slightly depressurized the DW which slowly moved down to a steady state high pressure (at around 0.75 MPa), where it got quasi-steady because of the continuous generation of gases from the molten corium interaction with concrete (MCCI). Figure 5b shows the continuous additional generation of about 300 kg of H_2 until 24 h, and more than 400 kg of CO, from the oxidation of remaining metals in the corium deposited in the reactor cavity.



a) In-PCV pressure. b) Ex-vessel gases generation from MCCI.

Figure 5. In-PCV evolution.

Assuming BE predictions reasonably capture the data trends available, the Fukushima Daiichi Unit 1 scenario evolved as follows: after reactor scram (earthquake time), RPV was initially controlled by IC cooling for about 45' and, once the SBO occurred and the IC is lost, RPV pressure oscillated around the lowest setting of one of the SRV (7.5 MPa) for about 11 h. At 11.8 h, in-RPV pressure sharply decreased due to the RPV lower head rupture through penetrations. A small leak of water from RPV into the DW makes in-PCV rise slowly during the first 4 h and, then, faster when steam leaks into the DW through the SRV gasket leaking (723 K setting) makes in-PCV rise steadily from about 4 h to near 12 h, where the RPV failure causes a sudden pressure increase.

Two major deviations, though, weaken this scenario as a plausible one to explain the accident unfolding: the containment pressure peaks at a value 0.15 MPa below the data recorded and decreases fast, while data shows a sort of plateau held for a few tens of minutes; the steady state value drawn by data after 15 h is never reached in MELCOR estimates. Nevertheless, it might be worth investigating how uncertainties in the postulated scenario might affect the data-estimates comparison.

3. UaSA APPLICATION

3.1. Input Parameters

Based on previous forensic and sensitivity analyses, the chosen uncertain input parameters and their characterization are shown in the next table (Table II).

Table II. Uncertain parameters.

Parameter	Short description	Reference value	Range of Variation	PDF Type	Ref.
$Area_{LP_BREAK}$ (m^2)	Area of the LP break	$9.62 \cdot 10^{-6}$	$7.85 \cdot 10^{-7}$/$1.96 \cdot 10^{-5}$	Uniform	Sensitivity studies
$Area_{GASKT_LEAK}$ (m^2)	Area of the gasket leak	$3.14 \cdot 10^{-4}$	$1.77 \cdot 10^{-4}$/$3.14 \cdot 10^{-4}$	Uniform	Sensitivity studies
$T_{solidus}$ (Zr/SS EUT) (K)	Solidus temperature of the eutectic pair	1210	1100/1400	Uniform	[4]
$T_{solidus}$ (Zr/INC EUT) (K)	Solidus temperature of the eutectic pair	1210	1100/1400	Uniform	[4]
$T_{solidus}$ (UO_2/ZrO_2 EUT) (K)	Solidus temperature of the eutectic pair	2450	2200/2650	Uniform	[4], [9]

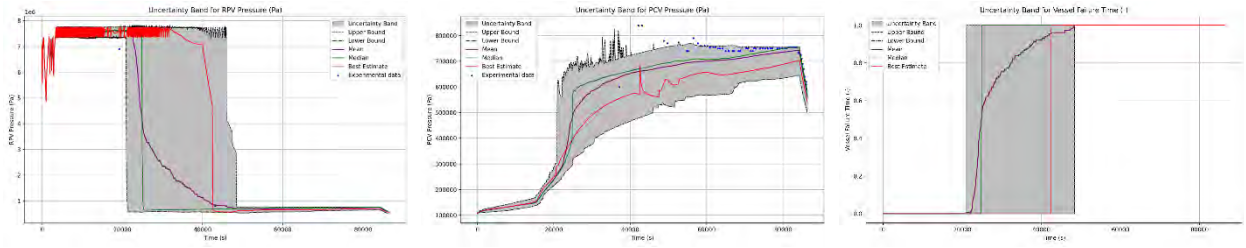
Parameter	Short description	Reference value	Range of Variation	PDF Type	Ref.
T_{P_FAIL} (K)	Penetration failure temperature	1273	1000/1671	Uniform	[4], [10]
STRAIN	Total strain assumed to cause failure in the LP	0.18	0.15/0.3	Uniform	

Note that the Probability Density Function (PDF) was subject to a parametric analysis. A second realization campaign was carried out with a triangular PDF to check the sensitivity to the uniform approximation, and no major differences resulting. Because of that, we decided to apply the uniform PDF according to the principle of maximum entropy.

3.2. Realization Campaigns

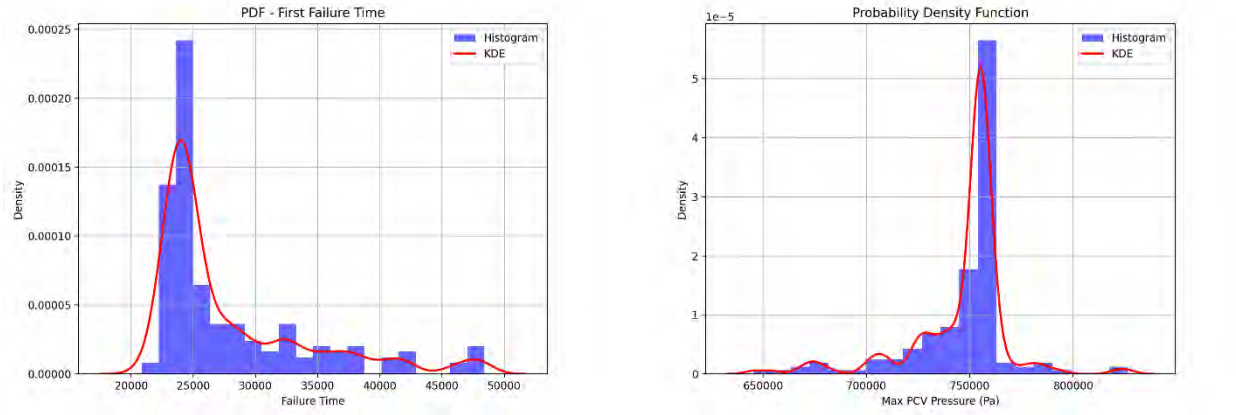
The methodology used for UQ is based on the Wilks's order statistics method [11]. Each FOM (Figure of Merit) is evaluated independently assuming it is a scalar variable (neglecting time dependence). Thus, for a tolerance interval with a 95% coverage and 95% confidence, it is necessary a sample of at least 93 code runs. To achieve this, a campaign was carried out with 250 samples, of which 180 run successfully (crash rate of 28%).

The selected FOMs in this study are the in-RPV pressure, the in-PCV pressure and the time of the vessel failure; the ending time of calculation is 24 h after the accident. Even though the main uncertainty analysis is carried out at 24 h, it is interesting to look at the time evolution of the considered FOMs. As can be seen from the dispersion plots (Fig. 6), all calculations follow the same global trends but with substantial differences in the timing of vessel failure, which heavily conditions the transient evolution in the PCV. In the case of in-PCV pressure it is noted that the upper bound of the uncertainty band covers the steady state after 15 h and there are some calculations peaking over 0.8 MPa, although at different times than the data records. This is also displayed in the PDF distributions of RPV time failure and in PCV maximum pressure (Fig. 7). In other words, uncertainties in the dimensions of leaking points, temperature settings for RPV failure and thermal thresholds describing the materials interactions might respond to some of the deviations noted, making the postulated scenario still defensible, although the most favorable scenarios seem not to have a high probability.



a) In-RPV pressure. b) In-PCV pressure. c) Time of vessel failure

Figure 6. Dispersion plots for selected FOMS.

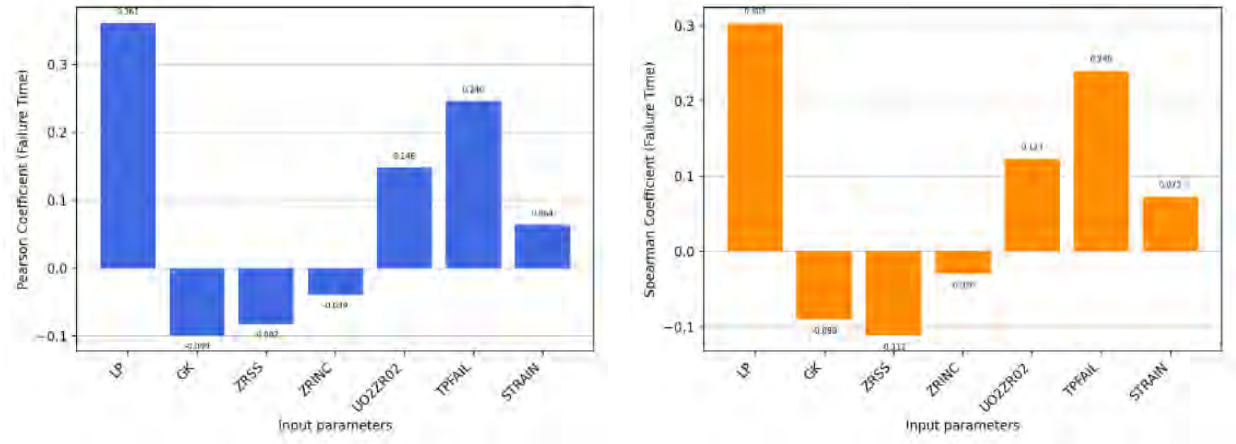


a) RPV failure time b) Maximum PCV pressure

Figure 7. Probability Density Functions key FOMS.

3.3. Sensitivity Analysis

Pearson's and Spearman's CCs have been considered as a first approach for sensitivity analysis of the RPV failure time (Fig. 8) and the in-PCV pressure at the ending time (Fig. 9). From the analysis, it is noted that RPV failure is notably affected by the size of the LP leak and, to less extent, by the temperature set for the lower head temperature and the UO_2-ZrO_2 eutectic temperature. In the case of the PCV maximum pressure, a high sensitivity to the LP leak size is found too, with the UO_2-ZrO_2 eutectic temperature also affecting.



a) Pearson b) Spearman

Figure 8. Correlation coefficients of RPV failure time.

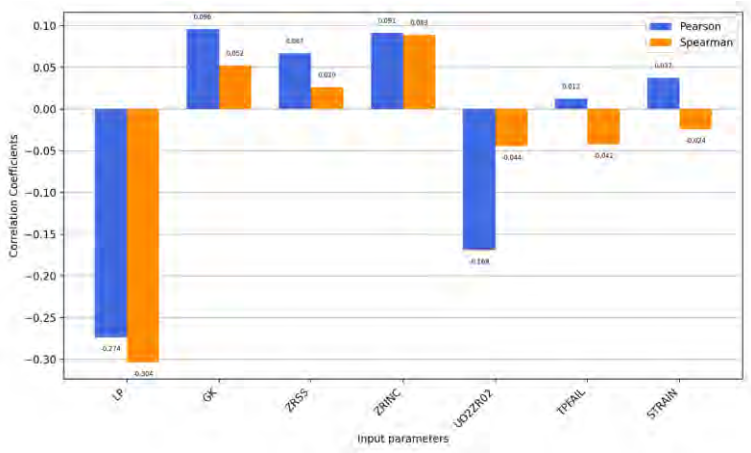


Figure 9. Pearson & Spearman coefficients for maximum in-PCV pressure.

In short, further studies should set reasonable values for the rest of uncertain variables in this study and focus on the liquid leak from the cooling system to the drywell and the eutectic temperature of UO_2-ZrO_2.

4. MAIN INSIGHTS

The existing footprints recorded during the Fukushima Daiichi accident during the first 24 h after the earthquake in Unit 1 pose a forensic challenge to SA analysts. However, capturing the main features of the scenario might provide valuable insights into SA management. The results shown in previous section allow reaching the following conclusions:

- The MELCOR code is mature enough to become a useful "forensic analytical tool". The integration of multiple phenomena, the thorough models and code validation done over years and the enhancement of the numerical robustness achieved, do support this statement. However, as any other SA code, the analyst should be aware that MELCOR has also drawbacks and limitations that are inherent to the extreme complexity of the SA scenarios, particularly when used as a forensic tool in search for the prevailing boundary conditions.
- Recalibration of the initially postulated SA scenario of Fukushima Daiichi Unit 1 highlighted that such a scenario might still be defensible based on the tendencies observed in the PCV, not so much on quantitative terms. The UaSA application reinforced this idea by exploring over 100 combinations of the uncertain variables consider key for the scenario postulated.
- The size of the liquid leak between the cooling system and drywell, the eutectics modeling (particularly, UO_2-ZrO_2 interactions) during core degradation and, to less extent, the size of the SRV gasket failure, are the factors that might influence more in the postulated scenario.

By no means, the work described above intends to conclude that the scenario postulated is the right one for Unit 1. Alternative scenarios that meet the same accident footprints have been proposed by other authors [12].

ACKNOWLEDGMENTS

The authors are grateful to partners in Fukushima OECD related projects for the insightful discussions; particularly to Marco Pellegrini, who led some of the earliest studies on forensic analysis. The authors wish to thank CSN for the support given to this work through the collaboration set for severe accident research (APIAS project).

ABSTRACT

Nuclear safety aims at the protection of people, society and environment from the consequences of hypothetical accidents in Nuclear Power Plants (NPPs). This is particularly true in the case of Severe Accidents (SAs) with partial or complete core meltdown and potential radioactive release to the environment. In such conditions, a rigorous assessment of accident progression, Source Term (ST), and radiological consequences is essential for the development of accident management strategies guidelines and for emergency preparedness.
The present study investigates a hypothetical Large Break Loss of Coolant Accident (LBLOCA) in the hot leg during a Station Blackout (SBO) sequence for a generic VVER-1000 reactor. The analysis relies on the integral SA code ASTEC (v3.1.1) to simulate accident progression, fission products release from the core, and ST to the external environment. The KATUSA tool and the JRODOS decision support system are then used for uncertainty and sensitivity analysis and for radiological dispersion and consequence evaluation under different meteorological conditions, respectively. As a case-study, the radiological consequences analysis has been performed taking into consideration the location of Zaporizhzhia NPP area in southeastern Ukraine.
The integrated use of a SA code, an Uncertainty Analysis (UA) tool, and a consequence assessment system provides a comprehensive computational framework for SAs analysis. The results from the UA reveal that the uncertainty band for the total activity released to the environment is not negligible. In a complementary way, sensitivity analysis points out containment leakage area and fuel burnup as the factors driving the ST variability. Moreover, atmospheric dispersion and consequences analyses indicate limited off-site radiological consequences, in both winter and summer seasons, under maximum release conditions.

1. INTRODUCTION

Nuclear safety aims at the protection of people, society and the environment from the consequences of hypothetical accidents occurring in Nuclear Power Plants (NPPs) [1]. This objective becomes especially relevant in the case of Severe Accidents (SAs), characterized by partial or complete core melting and potential release of radioactive material to the environment.

In such scenarios involving core degradation and possible radioactive release, the timely and reliable estimation of the Source Term (ST) represents a key element to support decision-making by the emergency teams. In fact, the ST determines magnitude, composition and timing of radioactive releases, which, in turn, affect atmospheric dispersion, radiological consequences and the effectiveness of the protective actions.

In this context, simulation tools capable of evaluating the progression of the accident itself and the resulting ST, together with the assessment of the off-site radiological impact, play a fundamental role. However, despite the significant progresses achieved in the development and advancement of integral SA codes, some uncertainties still remain and affect the prediction of a SA sequence evolution and the ST release [2]. On this account, Uncertainty and Sensitivity Analysis (UaSA) represents an essential complement to Best-Estimate (BE) SA simulations. By quantifying the variability of key output variables and identifying the parameters driving the associated uncertainty, this type of analysis provides a more robust basis for scenario interpretation and for strengthening emergency preparedness and response capabilities.

The present work proposes and applies an integrated analysis framework that systematically combines SA simulations, Uncertainty Quantification (UQ), and radiological consequences assessment. More precisely, the framework integrates the capabilities of the European Accident Source Term Evaluation Code (ASTEC) [3], developed by ASNR, the KArlsruhe Tool for Uncertainty and Sensitivity Analysis (KATUSA) [4], and the Java Real-Time On-line Decision Support (JRODOS) system [5], the last two being developed by KIT. The calculation platform is applied to a hypothetical Large Break Loss of Coolant Accident (LBLOCA) on the hot leg occurring in conjunction with a Station Blackout (SBO) in a generic VVER (Vodo-Vodyanoi Energetichesky Reaktor)-1000 NPP. The selected scenario is representative of high-risk sequences [6] and is characterized by rapid system depressurization and challenging conditions for accident management.

The objectives of this study are threefold: to simulate the progression of the selected SA and to estimate the corresponding radiological ST using an updated version of the ASTEC model of a generic VVER-1000 NPP assessed at KIT [7]; to quantify uncertainties and sensitivities affecting key Figures of Merit (FoMs), with particular emphasis on the activity released to the environment; and to evaluate the off-site radiological consequences for a representative site by coupling the ST results with atmospheric dispersion calculations performed with JRODOS. Through this integrated approach, the work aims to provide a comprehensive assessment of SA consequences and to highlight the added value of uncertainty-informed analyses for emergency preparedness and radiological risk evaluation.

2. ACCIDENT SCENARIO AND METHODOLOGY

2.1. Reference Plant and Accident Scenario

VVERs are Pressurized Water Reactors (PWRs) of Soviet design, in which light water is used both as coolant and neutron moderator, operating according to principles similar to those of Western PWRs. They constitute a significant fraction of the global nuclear reactor fleet, with numerous units currently in operation and more than 20 under construction worldwide. In particular, more than 30 VVER-1000 units are in operation nowadays, mainly in Russia, China and Eastern Europe [8].

Given their widespread deployment and their relevance within the international nuclear fleet, the analysis of SAs scenarios for VVER-1000 reactors is of particular interest. For this reason, the analyses presented in this work refer to a generic VVER-1000/V320 NPP, representative of generation II VVER designs currently in operation.

The selected accident sequence is a LBLOCA (more specifically, a double ended guillotine break) occurring on the hot leg, combined with a SBO condition (hereafter, LBLOCA+SBO). The SBO assumption implies

the loss of both off-site and on-site AC power supplies, resulting in the unavailability of active safety systems and significantly challenging the removal of decay heat from the reactor core. In addition, no Severe Accident Management (SAM) actions and no Filtered Containment Venting Systems (FCVS) are considered in the analysis. This choice represents a conservative assumption, aimed at evaluating the potential ST and radiological consequences in the absence of mitigation measures.

The LBLOCA+SBO sequence has been selected based on Probabilistic Risk Analysis (PRA) insights, which identify LOCA combined with SBO conditions among the sequences associated with the highest core damage frequencies for VVER-1000 reactors [6]. Such scenarios are characterized by rapid system depressurization, early core uncover, and limited opportunities for operator intervention, making them particularly relevant for SA analysis and emergency preparedness assessments.

2.2. Integrated Computational Framework

The assessment of SA progression, ST and associated uncertainties, as well as off-site radiological consequences, is performed by means of an integrated computational framework that combines three complementary tools: the SA code ASTEC, the UaSA tool KATUSA, and the decision-support system JRODOS. Each tool addresses a specific stage of the analysis chain, ensuring continuity from the starting of the accidental sequence to the evaluation of the radiological impact.

ASTEC is an integral code developed to model a SA, from the initiating event up to the release of radioactive material to the environment. The code addresses both in-vessel and ex-vessel phenomena, including core heat-up and degradation, Fission Products (FPs) release and transport, containment thermal-hydraulics, and ST evaluation. In this work, the ASTEC code (v3.1.1) is mainly used to carry out a BE simulation, with the prediction of the timing, magnitude, and isotopic composition of the radiological ST associated with the LBLOCA+SBO scenario.

KATUSA is a tool developed at Karlsruhe Institute of Technology (KIT) for performing UaSA through the propagation of input uncertainties. The tool manages the entire process, from initial input parameters' sampling and input deck preparation, through the automatic execution of multiple ASTEC calculations, to the post-processing of the results, including the computation of simple statistics and Correlation Coefficients (CCs) [9]. In the present study, KATUSA is employed to quantify the uncertainty affecting key ST-related FoMs when varying several input parameters. In addition, the tool is also used to identify the parameters that influence the most the variability of the predicted ST, thus providing insights into the dominant drivers of uncertainty.

JRODOS is a system dedicated to the assessment of atmospheric dispersion and radiological consequences following an accidental radioactive release. It uses the isotopic release data as input to simulate radionuclide transport, deposition, and dose to the population, accounting for site characteristics and meteorological conditions. This allows the evaluation of off-site radiological impact in terms of environmental contamination and effective doses. While JRODOS is typically applied in combination to ST data derived from a BE ASTEC simulation, in present work the effective dose assessment is performed using the maximum activity release, as resulting from the UaSA analysis.

Further details on each step and the corresponding results are provided in the next sections.

The overall analysis workflow is schematically represented in Figure 1.

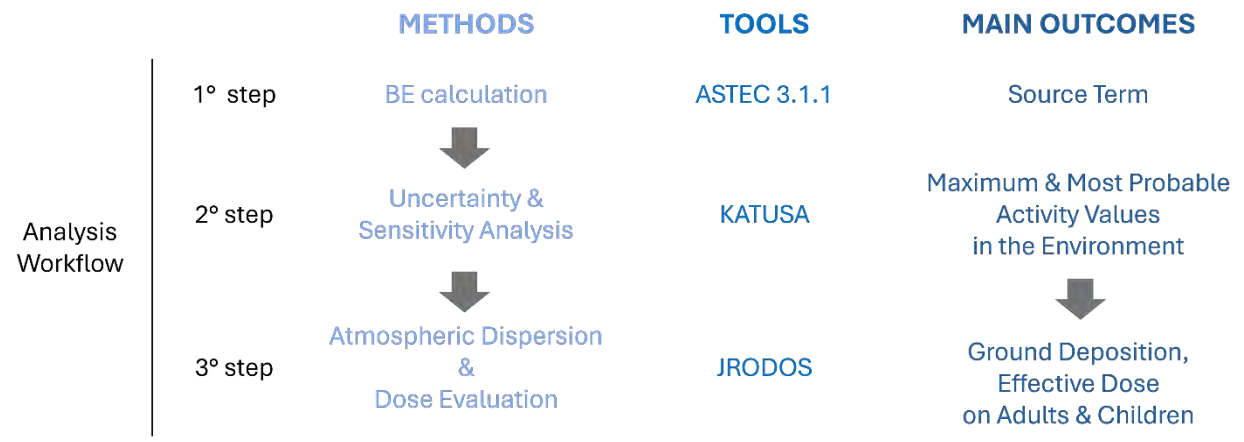

Figure 1. Analysis Workflow

3. SEVERE ACCIDENT PROGRESSION AND SOURCE TERM

3.1. Accident Progression

As introduced in the previous sections, the SA scenario investigated in this work is a hypothetical LBLOCA+SBO occurring on the hot leg of a VVER-1000 reactor. The accident sequence has been simulated using ASTEC v3.1.1, starting from an integral plant nodalization originally developed for ASTEC v2.2 [7] and subsequently adapted to a more recent version of the code.

The accident is initiated by the instantaneous double-ended guillotine break on the hot leg, which causes a rapid depressurization of the primary circuit and the discharge of coolant into the containment. The reactor is assumed to scram at the initiation of the event, while the SBO condition leads to the loss of off-site and on-site AC power and, consequently, to the unavailability of active safety systems. Main coolant pumps coast down shortly after the initiating event, resulting in the early loss of forced circulation.

Following the primary pressure decrease, water injection from the hydro-accumulators partially compensates for the coolant inventory loss and temporarily delays core heat-up. However, after the depletion of accumulator inventory, heat removal from the core becomes inadequate. As a consequence, the core progressively uncovers, and a rapid increase in fuel and cladding temperatures take place. Therefore, cladding oxidation starts, accompanied by significant hydrogen generation and FPs release from the fuel.

With the progression of the accident, extensive core degradation occurs, with molten materials relocating downward through the core region and accumulating in the lower plenum. The interaction between molten materials and residual coolant contributes to additional oxidation processes and further hydrogen production. The continued heat-up of the lower head ultimately leads to reactor pressure vessel failure, allowing the relocation of corium into the containment cavity.

After vessel failure, ex-vessel phenomena dominate the transient. Molten Core Concrete Interaction (MCCI) takes place in the cavity, generating additional thermal power and non-condensable gases, which affect containment pressure and composition. The progressive ablation of the concrete of the cavity eventually leads to basemat failure.

The main events characterizing the accident progression and their corresponding occurrence times are summarized in Table 1.

Table I. Main events characterizing the accident progression - timing

Event	Time (s)
Large break on the hot leg	0.0
Reactor scram	0.0
Main coolant pumps' coast down	0.0
Turbine trip	1.6
Accumulator injection - starting	5.1
Accumulator injection - ending	111.8
Onset of FPs release	456.2
First material slump in the lower plenum	1081.8
Lower head failure	3377.9
Basemat failure	106705.0

3.2. Source Term Results

The conducted BE analysis resulted in the evaluation of the ST, both in-containment and in the environment. Figure 2 shows the time evolution of the total activity transported to the containment and the one released to the environment during the accident progression.

Following core heat-up and fuel degradation, FPs are released from the fuel and transported through the primary system and to the containment. Due to the location of the break on the hot leg, the steam generator is effectively bypassed. As a consequence, a significant fraction of the released FPs is transported directly into the containment. Nevertheless, partial retention occurs within the primary system and the containment. As a result, the activity in the containment atmosphere reaches approximately 1.0E+19 Bq at the end of the transient.

Part of the activity transported to the containment is subsequently released into the environment. Retention mechanisms within the containment, including deposition on containment walls and internal structures, limit the activity available for release. Nevertheless, since no FCVS is considered, the activity released to the environment directly depends on the containment inventory and on the leakage characteristics. A total activity of around 6.0E+15 Bq is released to the environment.

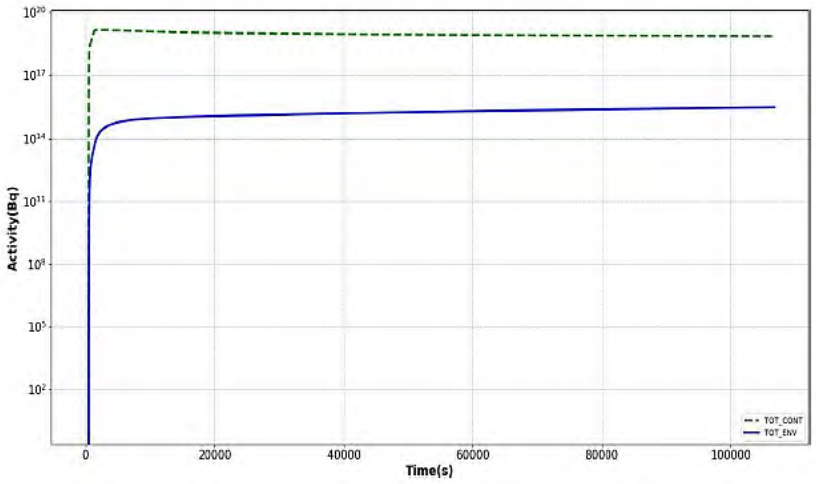

Figure 2. Activity transported to the containment and released to the environment

The resulting environmental ST is characterized by an early release dominated by noble gases, following by the release of volatile radionuclides, such as cesium and iodine, which are particularly relevant for radiological consequences. More specifically, following inhalation or ingestion, iodine accumulates in the thyroid increasing cancer risk, while cesium contributes to long-term contamination and both external and internal exposure.

The isotope-wise activity released in the environment at the end of the transient is shown in Figure 3. As it can be seen, xenon and iodine exhibit the dominant activity levels among the represented radionuclides.

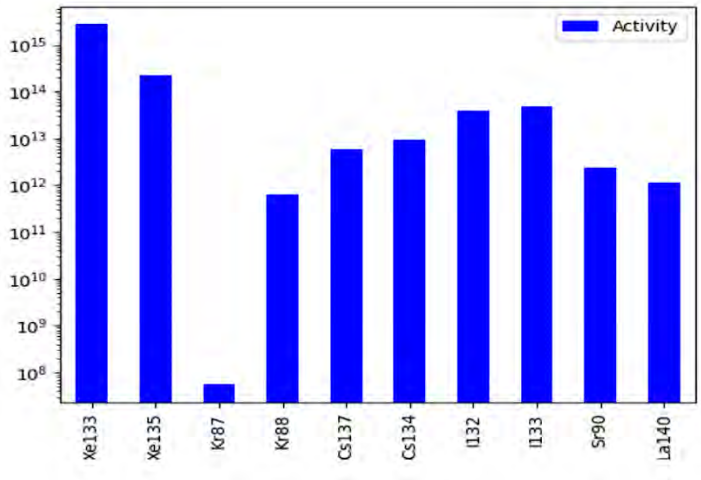

Figure 3. Isotope-wise activity in the environment

4. UNCERTAINTY AND SENSITIVITY ANALYSIS

4.1. Uncertainty Analysis Setup

In order to account for uncertainties affecting the prediction of the ST, an UaSA is performed using KATUSA, coupled with ASTEC, with particular emphasis on ST-related FOMs.

The Uncertainty Analysis (UA) is carried out by means of a total of 150 ASTEC simulations, generated through a random sampling of selected input parameters. For each run, KATUSA automatically prepares the corresponding ASTEC input deck, executes the calculation, and extracts the relevant output variables.

A set of uncertain input parameters is selected based on their relevance to FPs release, transport and behavior in the containment under SA conditions. More specifically, the selected parameters include quantities related to aerosol behavior, containment leakage, and fuel burnup. For each parameter, an appropriate variation range as well as a Probability Distribution Function (PDF) are defined. Their characterization is mainly based on literature review, engineering judgement, and the experience gained from the MUSA project [2], [10], [11].

The list of selected input parameters, together with their corresponding variation ranges and PDFs, is reported in Table II.

Table II. Input parameters - characterization

Parameter	Description	Reference Value	Variation Range	PDF
frho	Particle mean density (kg/m3)	3000.0	2610.0 10000.0	Triangular Mode: 3000.0
fR_max	Particle max radius (m)	1.995E-5	5.0E-6 2.0E-5	Triangular Mode: 1.995E-5
fR_min	Particle min radius (m)	1.1E-8	1.0E-8 2.0E-7	Triangular Mode: 1.1E-8
fspheat	Particle mean specific heat (J/kgK)	840.0	71.0 960.0	Uniform
fv_stks	Shape factor relative to Stokes velocity	1.0	1.0 3.0	Beta Alpha: 1.0 Beta: 5.0
p_bu	Effective full power days	164.0	10.0 320.0	Uniform
f_leak	Containment leakage area (multiplier)	1.0	0.8 1.2	Uniform

4.2. Uncertainty Analysis Results

The UA results are presented in terms of activity released to the environment, which is selected as primary FoM. This FoM is directly relevant for the assessment of the radiological consequences, since it constitutes a key input for dispersion and dose calculations.

Figure 4 shows the uncertainty band associated with the total activity released to the environment as obtained from the UA runs. The results show that the predicted ST exhibits a non-negligible variability, which reflects the combined effect of the selected uncertain input parameters. In particular, the activity released to the environment spans over a range between a minimum value of 3.9E+15 Bq and a maximum value of 7.2E+15 Bq.

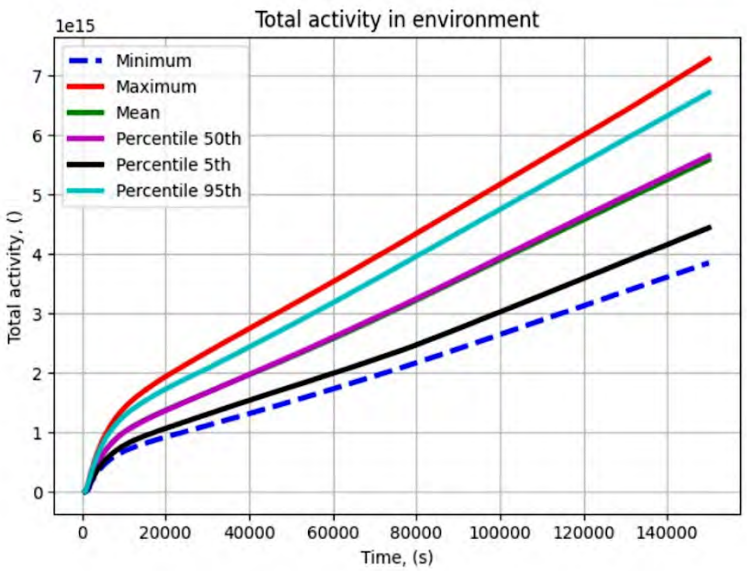

Figure 4. Activity Released to the environment – uncertainty band

Focusing on the final step of the UQ, it is additionally possible to derive a probability distribution of the total activity in the environment. As it can be observed in Figure 5, the distribution is asymmetric, and it is characterized by a clear peak, which identifies the most probable value, while the upper tail corresponds to less frequent but more severe release scenarios.

It is worth noting that the BE simulation result (≈ 6.0E+15 Bq), as presented in Section 3.2, lies close to the most probable value of the uncertainty distribution (6.18E+15 Bq), indicating a good representativeness of the BE calculation within the uncertainty space explored. On the other hand, the maximum release scenario exceeds the BE value to some degree, underlining the importance of accounting for uncertainty when evaluating potential radiological consequences.

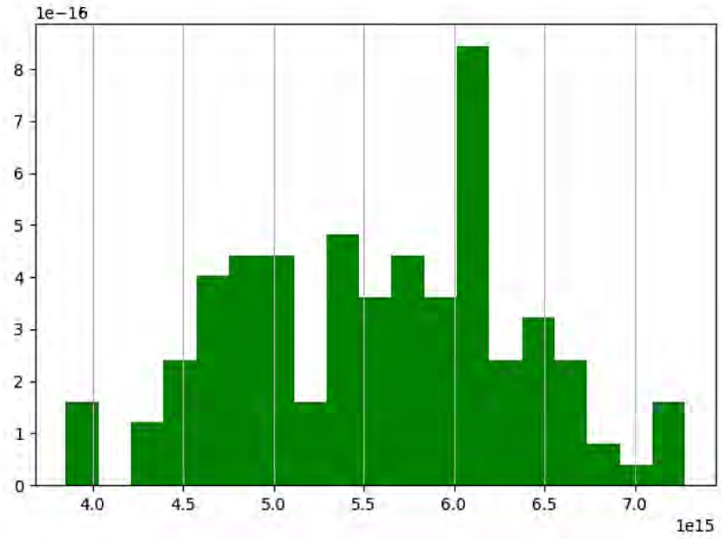

Figure 5. Probability distribution of the total activity in the environment at the last step pf the UA

4.3. Sensitivity Analysis Results

In complement to the UA, a sensitivity analysis is performed with the aim of identifying the input parameters with the strongest influence on the studied FoM, namely the activity released to the environment. For this purpose, a correlation-based sensitivity metric is employed. In particular, the Spearman CC is adopted to account for monotonic relationships between each uncertain input parameter and the FoM.

The sensitivity analysis indicates that the containment leakage area and the fuel burnup play a dominant role in driving the variability of the environmental ST, whereas the influence of the remaining parameters is comparatively limited. The strong sensitivity associated with the containment leakage area reflects its direct role in governing the transfer of radioactive material from the containment to the environment once containment integrity is lost. Similarly, fuel burnup directly affects the initial FPs inventory in the core and, consequently, the amount of radioactive material available for release during a SA scenario. The combined influence of these two parameters explains the majority of the spread observed in the UA results.

Figure 6 presents the Spearman CC obtained by considering the activity released to the environment as the FoM and the containment area leakage as input parameter. Figure 7 shows the Spearman CC for the same FoM when accounting for the fuel burnup as input parameter.

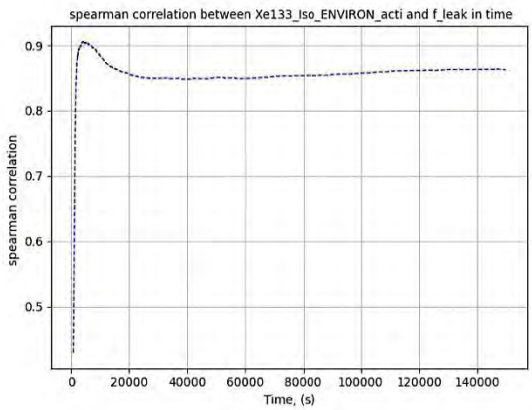

Figure 6. Spearman CC – activity to the environment vs containment leakage area

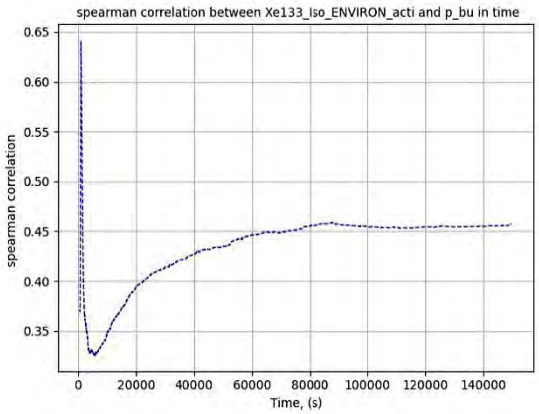

Figure 7. Spearman CC – activity to the environment vs fuel burnup

5. RADIOLOGICAL CONSEQUENCES ASSESSMENT

5.1. Dispersion Analysis Setup

Based on the results of the UA presented in Section 4.2, two representative ST scenarios are identified: the most probable release and the maximum release of activity to the environment. While both scenarios are worthy of further investigation and provide valuable information, the present radiological consequence assessment focuses on the maximum release scenario, which represents a bounding case and ensures a conservative evaluation of off-site radiological impact.

The analysis is carried out using the JRODOS decision-support system. The time-dependent, isotope-wise ST associated with the maximum release scenario, as obtained from the ASTEC-KATUSA coupling, is provided as input to JRODOS for the simulation of atmospheric dispersion, radionuclide deposition, and population exposure.

In addition to ST-related data, JRODOS requires detailed geographical and demographic information for the considered NPP site. As a case-study, the location of Zaporizhzhia NPP (ZNPP), located in southeastern Ukraine, is selected as a representative site. Moreover, to account for the influence of atmospheric conditions on radionuclide transport and deposition, two different meteorological scenarios are considered, representative of summer and winter conditions, respectively.

The JRODOS calculations are performed over a domain covering approximately 640000 km^2, with a total population of about 37.6 million inhabitants. The dispersion simulations are carried out over a time window of 42 hours starting from the onset of radioactive release. No emergency countermeasures, such as sheltering, evacuation, or administration of KI pills, are assumed in the simulations, in order to maintain the conservative analysis framework. For reference, the adopted intervention criteria consider sheltering when the effective dose exceeds 10 mSv and evacuation when the effective dose exceeds 50 mSv, while KI administration is considered when thyroid dose thresholds of 100 mSv for adults and 10 mSv for children are exceeded.

5.2. Radiological Impact Results

The radiological consequences assessment results for the maximum release scenario are presented in terms of ground deposition of aerosol and effective doses to the adult population, considering both summer and winter meteorological conditions.

Figure 8 shows the spatial distribution of the total aerosol distribution at the end of the calculation, in summer conditions. The deposition reached a maximum value of 1.89E+4 Bq/m^2, with decreasing values at increasing distance from the release point. The estimated lifetime effective doses to the population, evaluated considering cloud shine, ground shine, and inhalation pathways, remain limited over the considered area. As shown in Figure 9, the estimated lifetime effective dose for adults is well below the adopted intervention thresholds, showing a maximum value of 2.49E-1 mSv.

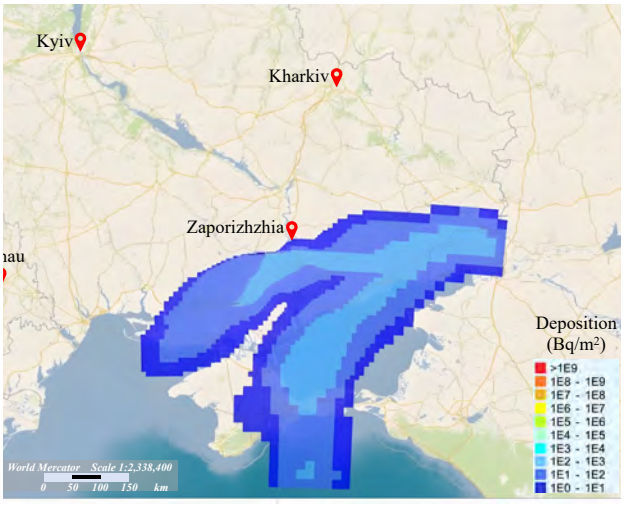

Figure 8. Ground deposition of aerosol at the end of the calculation – summer

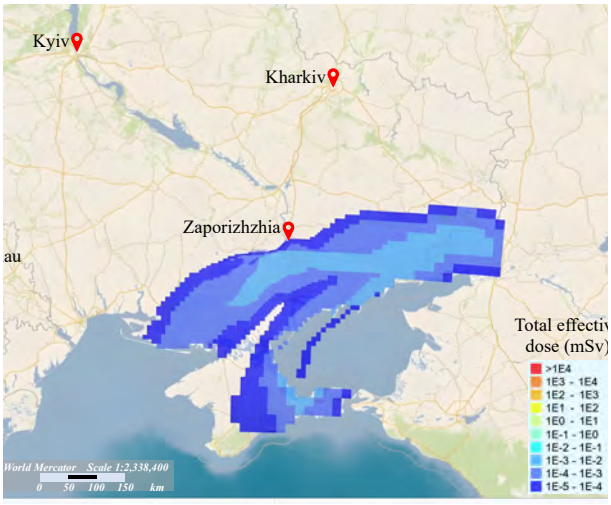

Figure 9. Effective dose for adults - summer

In winter, the deposition pattern differs (Figure 10), consistently with a more stable atmosphere, and resulting in a plume that follows the wind direction more clearly. In this case, the aerosol ground deposition reaches a higher maximum value of 7.7E+4 Bq/m^2. A corresponding increase is observed for the lifetime effective dose for the adult population, that reaches a value of 9.69E-1 mSv (Figure 11). Nevertheless, even considering these less favorable conditions, the calculated effective dose remains below the criteria for sheltering and evacuation.

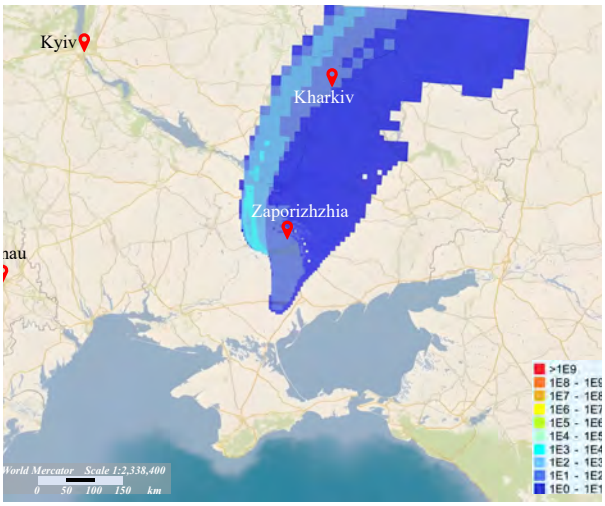

Figure 10. Ground deposition of aerosol at the end of the calculation – winter

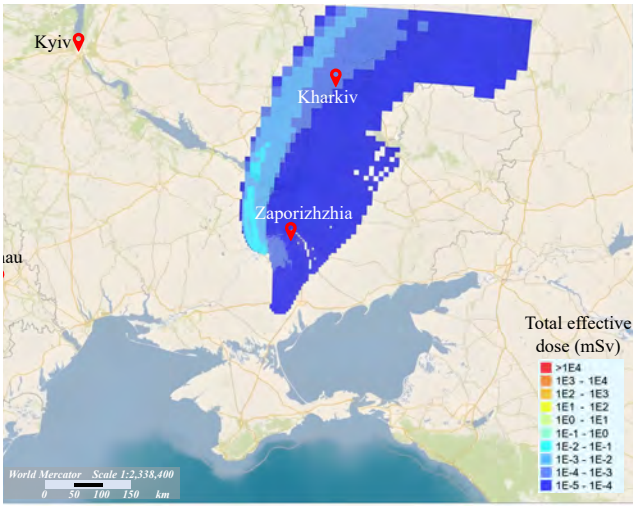

Figure 11. Effective dose for adults - winter

6. CONCLUSIONS

In this work, an integrated computational framework combining SA simulation, UaSA, and radiological consequence assessment has been applied to a hypothetical LBLOCA+SBO scenario in a generic VVER-1000 NPP, under conservative assumptions (no mitigation measures and FCVS have been modeled). The results demonstrate the consistency and robustness of the adopted framework, which allows the systematic evaluation of accident progression, radiological ST, and off-site consequences within a unified and coherent analysis chain.

The integrated analysis provides some meaningful insights:

- The study demonstrates the importance of UaSA in SA ST evaluation. The uncertainty propagation highlights a non-negligible variability in the activity released to the environment and shows that BE results, while representative of the most probable outcome, do not fully capture the range of possible releases. The identification of containment leakage area and fuel burnup as the dominant contributors to ST variability provides valuable physical insight and underlines the need to explicitly account for these parameters when assessing radiological risk;
- The radiological consequence assessment, performed under conservative assumptions and focusing on the maximum release scenario, indicates that the off-site radiological impact remains limited, with effective doses to the population staying below intervention thresholds even under unfavorable meteorological conditions.

In short, the integrated approach adopted in this work is relevant for emergency preparedness and planning, as it provides not only BE predictions but also uncertainty-informed results that can be directly used in decision-support tools. Moreover, the framework offers a flexible basis for future analyses. Possible extensions of the present work include the modeling of SAM strategies and containment mitigation systems, the application to different site locations and with meteorological conditions, and the investigation of additional accident scenarios and alternative FoMs. Such developments would further enhance the applicability of the computational framework and its value for safety analysis and emergency response support.

ABSTRACT

Radiation is an important mode of heat transfer when investigating loss of coolant accidents in light water nuclear reactors. For small reactors, it plays a decisive role as a mode of heat exchange in some phases of accidents, even overtaking gas convection. However, modelling radiative heat transfer in a reactor core is not straightforward because of its complicated geometry. Accordingly, in codes that simulate the accident sequence, approximate lumped parameter models are used. In very general terms, they are built from a combination of net radiation enclosure models and equivalent conductivity models. Regarding the latter homogenization approach, valid for an optically thick medium, different approximate models have been proposed in the literature with a specific focus on open rod geometries (typical of Pressurized Water Reactors). Little interest have been shown in cores composed of closed flat plate assemblies despite the fact that they can be found in various reactor designs ranging from material testing reactors to space thermal propulsion reactors. In the present work, the equivalent conductivity is evaluated by direct numerical simulations of conjugate radiative and conductive heat transfer modes on spatial domains representative of both types of core geometries. A comparison is provided, taking also into account the approximate model in use in the RADR model of the ASTEC code. In addition, the effects of the lattice heterogeneities due to guide tubes and control rods in the open rod case are analyzed.

Radiative heat transfer, conduction, equivalent conductivity

1. INTRODUCTION

Loss-of-Coolant Accidents (LOCAs) represent critical design-basis events for light water nuclear reactors. During such accidental transients, radiative heat transfer becomes a pivotal mechanism for heat dissipation, as the liquid coolant can no longer effectively remove heat from the core. For small reactors, currently under active development all over the world, this mode of heat transfer is especially significant as its relative importance in comparison with heat removed by gas convection is increased. Because of the complex

dependency of Zircaloy cladding oxidation to temperature (with a strong escalation typically above 1800K), bifurcations in the core degradation transients can be observed depending on the heat removal; accordingly, it is sensitive to radiative heat transfer as illustrated, for instance, in [1].

Modeling radiative heat transfer in a reactor core is not straightforward because of its complicated geometry that can evolve with time during core degradation. Accordingly, in codes that simulate the accident sequence, approximate lumped parameter models are used. In very general terms, they are built from a combination of net radiation enclosure models (e.g. total exchange surface method [2]) and effective conductivity models (such as Rubiolo model proposed in [3, 4] and implemented in the RADR model of the ASTEC code [5]). While the former are used to describe the radiation between opaque and diffuse surfaces through a fluid for well-defined geometrical configurations, the latter are diffusion models based on a porous medium approach. Regarding the net radiation enclosure models, in thermalhydraulics system codes and severe accident codes, they are based on lumped surfaces and can yield highly inaccurate results because of the uniform surface temperature approximation on the one hand and the uniform radiosity surface assumption on the other hand. While the latter bias can be mitigated by correction factors [6] or suppressed by the Gebhart method [7], the former one remains and, as further analyzed in [8], can be predominant when the solid conductivity is low. Regarding the effective conductivity approach, it is valid for an optically thick medium (at the scale of the representative volume element used for homogenization). If this condition is met in reactor cores, its accuracy is dependent on the modelling of the equivalent conductivity $\underline{\underline{Ke}}$ associated with the anisotropic Fourier law $\boldsymbol{q} = -\underline{\underline{Ke}}\boldsymbol{\nabla} T$ with $\boldsymbol{q}$ the total heat flux vector and T the temperature field. It should also be noted that such an approach can be inadequate when the boundary effects are important *i.e.* the temperature jump between the porous medium and the enclosing boundary is large [3].

On the one hand, different approximate models for $\underline{\underline{Ke}}$ have been proposed in the literature with a specific focus on open rod geometries (typical of Pressurized Water Reactors – PWR) in the context of nuclear cores. Little work has been reported for cores composed of closed flat plate assemblies despite the fact that they can be found in various reactor designs ranging from Material Testing Reactors (MTR) (e.g. [9]) to space thermal propulsion reactors (see, for instance [10]). One noticeable exception is the work reported in [11] where Rubiolo model has been partially extended to such geometries.

On the other hand, a "brute force" approach to evaluate this conductivity is to simulate conjugate radiative and conductive heat transfer modes on a spatial domain representative of the core geometrical pattern under investigation. While this method is computationally intensive, it can be considered as a "reference" method useful for the validation of approximate algebraic models. It was used in [3] for instance.

The present work is focused on the comparison of $\underline{\underline{Ke}}$ radial component (*i.e.* in the plane perpendicular to the extrusion axis of the prismatic core) between a standard PWR (open rod geometry) and a plate assembly-based MTR. The equivalent conductivity is evaluated by direct numerical simulations on spatial domains representative of both cores. This analysis is supplemented by results obtained with Rubiolo model and its partial extension to the case of closed flat plate assemblies in [11]. The paper is organized as follows. First, numerical models and tools are introduced in Section 2 and illustrated on a validation test case taken from [3] in Section 3. Then, the configurations of interest associated with the two core types under consideration are presented in Section 4. The corresponding numerical results are discussed in Section 5. Finally, Section 6 gives short conclusions and perspectives.

2. METHODS

In this section, the two different methods that have been used to evaluate the equivalent conductivity of a 2D porous medium composed of opaque and grey solids (conductivity K_s, total emissivity ε_s) in a transparent

fluid (conductivity λ_g) are introduced. The "reference" method is based on the direct numerical simulation of conjugate radiative and conductive heat transfer modes on a spatial domain representative of the porous medium; in the remainder, the conductivity obtained with such an approach will be referred to as an apparent conductivity and denoted *Ka*. The Rubiolo model is an approximate algebraic model proposed in [3, 4] for a regular Cartesian lattice of cylindrical rods and partially extended to the case of closed flat plate assemblies in [11]; in the remainder, the associated equivalent conductivity is denoted *Ke*.

2.1. Direct numerical simulation approach

In order to evaluate the apparent conductivity, simulations of both radiative and conductive heat transfers on a 2D rectangular two-phase spatial domain $\mathcal{D}$ (see Figure 1) are performed considering the following boundary conditions:

$$\begin{aligned} T &= T_0 - \frac{\delta T}{2} \text{ and } \varepsilon = 1 && \text{on } \Gamma_L \\ T &= T_0 + \frac{\delta T}{2} \text{ and } \varepsilon = 1 && \text{on } \Gamma_R \\ \boldsymbol{\nabla} T \cdot \boldsymbol{n} &= 0 \text{ and specular reflection} && \text{on } \Gamma_U \cup \Gamma_B \end{aligned}$$

where T is the temperature, ε the emissivity, and $\boldsymbol{n}$ the outward normal on the domain boundary. With such symmetry boundary conditions at the top and the bottom, an infinite lattice along the *y*–axis is simulated in such a way that the apparent conductivity along the *x*–axis can be evaluated as:

$$Ka(T_0) = \frac{L_X \int_{\Gamma_L \cup \Gamma_R} |\boldsymbol{q} \cdot \boldsymbol{n}| \, ds}{2 L_Y \delta T} \tag{1}$$

where $\boldsymbol{q}$ is the total heat flux (conduction and radiation accounted in), L_X (resp. L_Y) is the domain length along the *x*–axis (resp. *y*–axis). In this approach, $\mathcal{D}$ is associated with a solid-fluid geometrical pattern deemed representative of the porous medium under consideration. Taking a unit emissivity on Γ_L and Γ_R (black boundaries), the boundary effect on the temperature gradient, in comparison with an infinite medium along the *x*–axis, is mitigated. This is the approach that was used for the partial validation of Rubiolo model presented afterwards in [3].

The coupled conduction-radiative heat transfer calculations were performed with the TrioCFD code [12], an open-source code (`https://triocfd.cea.fr/`) based on the TRUST numerical platform [13] (`https://cea-trust-platform.github.io/`), referred to as TRUST/TrioCFD. For our present applications, it couples conduction in the fluid and solid phases to radiation between the solid surfaces (considered as opaque, grey and diffuse) through the transparent fluid. The heat conduction equation is solved over triangular meshes considering a first order finite volume-element discretization. For radiative heat transfer, the radiosity equations are solved for a given partitioning of the solid surfaces. The associated view factors are obtained either from exact formulas (for the simple case of a rectangular cavity) or using the pyMCRAD numerical tool based on a Monte-Carlo Ray-Tracing method [8]; they are provided to TRUST/TrioCFD as input parameters. In practice, from a unique description of the geometry and the associated surface partitioning, the view factors are calculated (with pyMCRAD in the general case) and a meshing of the volumes is carried out with the gmsh tool [14]. From there, TRUST/TrioCFD calculations are performed. For more detail, the reader is referred to [8] where such calculations with these numerical tools have been first reported.

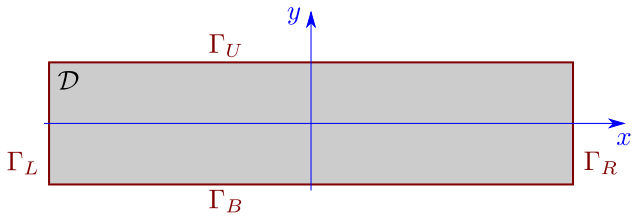

Figure 1. Notations associated with the geometrical domain $\mathcal{D}$ considered for coupled radiation-conduction calculations.

2.2. Rubiolo model

This algebraic model is based on a thermal resistance formalism where the possible coupling between radiative and conductive heat transfer modes is taken into account (contrarily to simpler models where they are supposed to act independently). For the sake of conciseness, the formulation of Rubiolo model is presented in Appendix A. For the purpose of this paper, the following model features should be kept in mind:

- This model is obtained considering a homogeneous solid phase in such a way that, when this phase is heterogeneous, it should be first replaced by an equivalent homogeneous medium characterized by an equivalent conductivity K_s. Considering the heterogenous nature of a fuel pin or a flat plate assembly, this homogenization step is crucial. To do so, a model was proposed and validated in [3] for a typical fuel pin geometry (a fuel rod in a clad with a gaseous gap, taking into account radiation through the gas). In [11], the same thermal resistance approach based on an electrical analogy was followed for flat plate assemblies and 2×2–arrangement of such assemblies; no validation was proposed.
- While this model formulation is rather general and does not depend directly on the porous medium structure, it requires closure laws that, in principle, should be defined on a case-by-case basis depending on the phase topology. In [3], the different closures were obtained for a regular Cartesian lattice of identical cylinders. If some closures are simply algebraic laws (some obtained under simplifying hypotheses), the closures associated with the equivalent conductive Kt and radiative Kr conductivities have been obtained in a precise way from the numerical simulations of closure problems. In the extension of this model to a regular Cartesian lattice of identical squares (for the flat plate assemblies) in [11], the associated closure problems were not solved to obtained new laws; the closure laws for the cylinders case were transposed.

In the case of open rod geometries (where all the rods are identical), the validation in [3] showed that the bias introduced by this model is lower than 10%. It is worth noting that, in the frame of this model, the difference in conductivity between an infinite lattice and a finite lattice can also be estimated.

3. VALIDATION TEST CASE

In order to validate the use of the pyMCRAD and TRUST/TrioCFD tools for evaluating the apparent conductivity of a geometric pattern, the case of a 10–rod pattern reported in [3] has been revisited. The associated analysis is summarized in this section.

For the evaluation of view factors, the surfaces of the rods are partitioned into 16, while the surfaces Γ_L and Γ_R are partitioned into 8. For TRUST/TrioCFD, the triangular mesh was generated considering a uniform characteristic mesh size of 0.2mm.

Before presenting the comparison results, several remarks should be made:

- First, it should be noted that in [3], as the tool used (CASTEM2000) did not allow for the treatment

of specular reflection conditions (for the evaluation of view factors), the geometric pattern considered had 4 rows of rods along the y–axis to minimize boundary effects (associated with the isotropic nature of the reflection on Γ_U and Γ_B) without significantly increasing the domain size. The associated bias (not present in our simulations with specular conditions) is said to be less than 2% in [3].

- In terms of boundary conditions for evaluating Ka at temperature T_0, in [3], it is considered $T = T_0$ on Γ_L and $T = T_0 + \delta T$ on Γ_R, which leads to an offset of $\delta T/2$ compared to our results where a centered difference was favored.
- In [3], the partitioning of the surfaces is comparable to the one used in the present paper, while the mesh is significantly coarser (about 3.5 times) but for second-order finite elements. The discretization error is said to be less than 1% in [3]. Our calculations suggest that this is indeed the case when the temperature (and conductivity) is sufficiently high, with a bias increasing as T_0 decreases.

Considering $\delta T = 50$K and varying T_0 in a range between 400K and 2800K (as in [3]), the apparent conductivity obtained with pyMCRAD and TRUST/TrioCFD is illustrated in Figure 2b in comparison with the results from [3] and the equivalent conductivity Ke of the infinite lattice calculated with Rubiolo model. If we compare the apparent conductivities, we can see that the relative difference is less 2%, except for the lowest temperature (below 1200K) where it increases to approximately 5%. Given the previous remarks on the calculations performed in [3] and adding the fact that the results from [3] were extracted by digitizing Figure 3.18 from [3] in PDF format, these results are deemed satisfactory and validate the combined tools pyMCRAD and TRUST/TrioCFD. The relative difference w.r.t. Rubiolo model is, at the most, of about 10% with an underestimation (resp. overestimation) of the conductivity for the highest (resp. lowest) temperature. It is worth noting that, in this case, the relative difference between the finite-size geometric pattern and an infinite lattice, as evaluated in the frame of Rubiolo model, is about -5% at 1900K and tends to be reduced when the temperature increases.

λ_g [W.m^{-1}.K^{-1}]	K_s [W.m^{-1}.K^{-1}]	ε_s [–]

4. APPLICATION TEST CASES

For the intended comparative analysis between open rod and closed flat plate assemblies, the two considered assemblies are depicted in Figure 3. In terms of geometry, while the 17×17–rod open assembly (see Figure 3a) is a standard PWR assembly, the 24–flat plate closed assembly is taken from the fictitious MTR core proposed in [15] (previously considered for radiative heat transfer analysis in [8]). The pins and plates that compose theses two assemblies are depicted in Figure 4. In the case of the 17×17–rod open assembly,

two cases will be considered afterwards regarding the guide tube pins: either the guide tube is empty or an AgInCd pin is inserted inside.

In terms of materials, for the sake of comparison, in the 24–flat plate closed assembly, the same UO_2 and Zircaloy materials as in the 17×17–rod open assembly have been considered for the fuel and cladding of the plates.[1] The UO_2, Zircaloy and steel conductivity laws (as a function of temperature) are depicted in Figure 5a while AgInCd conductivity was taken constant equal to $60\text{W.m}^{-1}\text{.K}^{-1}$; all these data were taken from [16].

For the calculations performed afterwards, the different assembly elements have been homogenized following a thermal resistance approach based on an electrical analogy. For the cylindrical pins, the approach proposed in [3] (where radiative heat transfer through the gas gaps is taken into account) was followed and the conductivity laws obtained for the equivalent homogenized pins are illustrated in Figure 5b. For the plates (considered to be composed of layered infinite slabs), the analogy is very straightforward but, contrarily to the cylindrical pins where the equivalent conductivities can be considered isotropic, one has to distinguished between the conductivity parallel to the plate axis (denoted "fuel plate $\|$") and the one perpendicular to the plate axis (denoted "fuel plate $\perp$") as they significantly differ (see Figure 5b). Accordingly, in all subsequent calculations where plates are involved and can be oriented vertically or horizontally, an anisotropic thermal conductivity $\underline{\underline{K_s}}$ is considered with diagonal components $\underline{\underline{K_{s,xx}}} \neq \underline{\underline{K_{s,yy}}}$.

The different geometric patterns that have been considered for apparent conductivity calculations are depicted in Figure 6. For the open rod assembly, because of the guide tube pins location in the assembly, a pattern limited to three layers of pins was deemed sufficient for this study where the guide tube impact is studied. Regarding the closed plate case, different patterns have been studied in order to study the impact of the assemblies orientation in the core. The different test cases are summarized in Table I. The $2 \times 2-$ assembly case with a checkerboard arrangement is the one studied in [11]. This limited set of cases has been constructed in order to:

- Assess the effect of the heterogeneities introduced in the open rod lattice because of the guide tubes, either empty or with an AgInCd pin inserted.
- Assess the anisotropy effect for patterns of flat plate assemblies.
- Compare, for both types of assemblies, the evaluated apparent conductivities to the equivalent conductivities obtained with Rubiolo model.

In all cases, an emissivity ε_s of 0.8 has been taken, a value representative of oxidized Zircaloy.

■ ***Nota Bene*** In the remainder, the apparent and equivalent conductivities are evaluated over the $[250, 2750]$K temperature range for comparison purpose. Obviously, during a core heat-up transient, many important phenomena occur in such a way that geometrical configurations of Table I are not maintained over such a large temperature range as materials degrade and melt (typically above 1800K). In addition, AgInCd melting point is about 800°C. Accordingly, the quantitative results that have been obtained here should not be transposed directly to an actual accident transient. ■

In terms of meshing, a characteristic mesh size of 1mm has been used in all cases. For the view factors evaluation was considered as follows. The external surface of all rods (resp. square assemblies and flat plates) was partitioned in 16 (resp. 4×4). Γ_L and Γ_R were partitioned accordingly in such way that all partitioned surfaces have approximately the same area. A limited parametric analysis on these discretization parameters, not reported here, was carried out in such a way that the associated bias was found limited (to about 2% at the most).

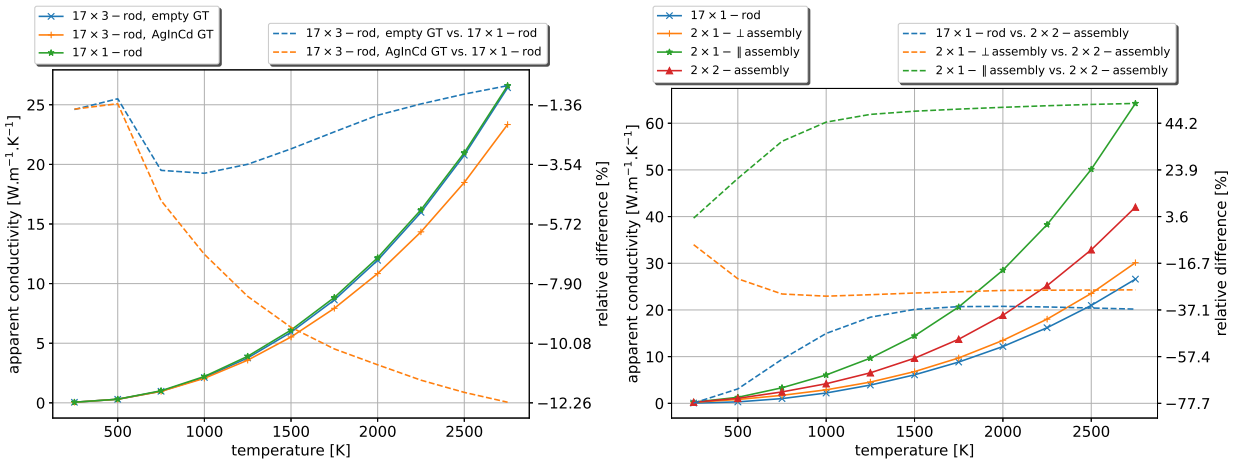
5. NUMERICAL RESULTS AND DISCUSSION

In Figure 7a, the apparent conductivity, as calculated with the pyMCRAD and TRUST/TrioCFD tools, is illustrated as a function of temperature for the three open rod cases. First, it is observed that the heterogeneity associated with the empty guide tubes (case $17 \times 3 -$ rod, empty GT) has a limited impact on the conductivity, with a variation between -3.5% and -1% compared to the homogeneous lattice case $17 \times 1 -$ rod. This effect is actually the combination of two opposing trends: if the guide tubes have a significantly higher conductivity than the fuel rods, they also have a larger radius that reduces heat transfer by radiation through

the gas. Next, when considering AgInCd pins in the guide tubes (case $17 \times 3 - \text{rod, AgInCd GT}$), a more significant decrease in Ka is observed compared to the case $17 \times 1 - \text{rod}$ (up to -12% at 2750K). Indeed, as seen in Figure 5b, the presence of AgInCd pins in the guide tubes drastically reduces the conductivity of the equivalent rod such that, compared to a fuel rod, there is both a lower conductivity of the solid phase and a reduced direct heat exchange by radiation through the gas. It is worth comparing these variations to the effect associated with the lattice size that, in the $17 \times 1 - \text{rod}$ case, can be estimated in the frame of Rubiolo model as discussed previously. It is found that the relative difference between the finite lattice and an infinite lattice is about -5% at 500K with a reduction to -2% at 2750K.

On the overall, considering that AgInCd melts at about 800°C, one may conclude that the lattice heterogeneities due to guide tubes and control rods in such an open rod configuration have a limited impact and that the use of Rubiolo model in such cases does not introduce a significant additional bias in comparison with the homogeneous lattice case.



(a) Open rod cases.

(b) Flat plate assembly cases.

Figure 7. Apparent conductivities as a function of temperature for the different test cases.

The conductivity results for the flat plate assembly cases are depicted in Figure 7b where Ka in the $17 \times 1 - \text{rod}$ case has also been plotted for the sake of comparison. In any cases, the flat plate assembly patterns exhibit a significantly higher conductivity than the open rod pattern: in the upper temperature range (above 1500K), the conductivity relative increase between the $17 \times 1 - \text{rod}$ case and the $2 \times 2 - \text{assembly}$ case is about 35%. Then, comparing the $2 \times 1 - \parallel$ assembly and $2 \times 1 - \perp$ assembly cases, as expected, it is observed that when the plates are parallel to the heat flux, the apparent conductivity is higher. The difference increases when the temperature increases in such a way that, at 2750K, the conductivity of the $2 \times 1 - \parallel$ assembly case is 50% higher than in the $2 \times 1 - \perp$ assembly case. As expected again, the conductivity in the $2 \times 2 - \text{assembly}$ case is somewhere in between the parallel and perpendicular plate cases. It is worth comparing these variations to the effect associated with the number of assemblies considered in the geometric pattern. To do so, an additional calculation of a 4×2–pattern (the 2×2– plate assembly pattern being replicated along the x–axis) has also been performed. A noticeable conductivity increase was observed above 750K when the pattern x–axis length is doubled, reaching about 6% at 2750K.

Finally, the apparent conductivity for the homogeneous open rod case and the different flat plate assembly cases are compared to the equivalent conductivities obtained with Rubiolo model (and its adaptation to flat plate assembly cores in [11]) for the associated configurations in Figure 8b. The solid phase equivalent conductivities Ks used in Rubiolo model in the different plate assembly cases are depicted in Figure 8a.

Regarding the open rod lattice, the difference between Ka and Ke follows a consistent trend w.r.t. the observations made in the verification case (see Figure 2b in Section 3) *i.e.* Ke is lower (resp. greater) than Ka for $T_0 > 750$K (resp. $T_0 < 750$K) with an underestimation in the high temperature range that is slightly more severe (about 16% at 2750K). When considering the plate assembly cases $2 \times 1-\parallel$ assembly and $2 \times 1-\perp$ assembly, Ke is higher than Ka over the whole temperature range and the trends are differents. In the $2 \times 1-\parallel$ assembly case, the overestimation is maximum at 500K (about 30%) and largely decreases when the temperature is increased. In the $2 \times 1-\perp$ assembly case, while the overestimation is comparable in the low temperature region, the bias steadily increases when the temperature increases above 1000K to reach about 35% at $T_0 = 2750$K. In the $2 \times 2-$ assembly case, error compensation is at play with Rubiolo model in such a way that Ke underestimates Ka for $T_0 < 2250$K with a difference that decreases when the temperature increases in such a way that it is almost zero at $T_0 = 2250$K. Accordingly, the difference in conductivity between the open rod and flat plate assembly configurations in the high temperature range is higher when Ke is considered in comparison to Ka estimation.

On the overall, one may conclude that Rubiolo model's partial extension to flat plate assembly configurations in [11], while giving the correct trends, introduces a noticeable additional bias in comparison with the open rod case. To reduce it (to a level comparable to the open rod case), the closure laws for equivalent conductive Kt and radiative Kr conductivities should be improved by solving the associated closure problems in the actual geometry of such configurations (a regular Cartesian lattice of identical squares).

6. CONCLUSIONS AND PERSPECTIVES

In this study, we have evaluated and compared the equivalent thermal conductivity in open rod and closed flat plate assemblies, two types of geometries commonly found in nuclear reactors. To do so, direct numerical simulations and the approximate Rubiolo model were considered. Our results show that the apparent conductivity varies significantly between these two types of assemblies, with higher conductivities observed in flat plate assemblies. Additionally, we found that the heterogeneities introduced by guide tubes in open rod assemblies have a limited impact on conductivity, except in the presence of AgInCd rods inside, which significantly reduces conductivity. In flat plate assembly configurations, it was shown that the partial extension of Rubiolo model (initially proposed for open rod cores) from [11] gives the correct trends but that the associated bias is noticeably increased in comparison with the open rod case.

A direct perspective to this work would be to construct, for flat plate assembly configurations, closure laws for the equivalent conductive and radiative conductivities at play in Rubiolo model in order to reduce this bias. It could be achieved through numerical simulations performed with the same pyMCRAD and TRUST/TrioCFD tools used in this study. From a broader perspective, the validation of lumped parameter models using an equivalent conductivity approach should now be tackled considering core-wise stationary calculations. Once again, pyMCRAD and TRUST/TrioCFD tools could be used for obtaining "reference" solutions. It should be noted that, because of performance issue, the pyMCRAD is limited to 2D configurations for the time being. Another tool, based on the Intel® Embree library, is under development for calculating view factors in 3D [17]. Performing such coupled conduction and radiation transport calculations in 3D is also a strong perspective.

APPENDIX A. Equivalent conductivity model for a porous medium

In order to evaluate the equivalent conductivity Ke along a direction $\vec{e}$, Rubiolo model proposed in [3] starts from a representative layer of the porous medium as depicted in Figure 9. The conductivity of the solid (resp. gas) phase is denoted K_s (resp. λ_g) while the solid surface emissivity is denoted ε_s. The porosity of the layer is p and its average temperature T. From there, the layer equivalent conductivity Ke is expressed in terms of the equivalent conductive Kt and radiative Kr conductivities as follows:

$$Ke = K_g + Kr^0 + \left(R_s + \left(\frac{Kr - Kr^0}{1 - R_s\left(Kr - Kr^0\right)} + \frac{Kt - K_g}{1 - R_s\left(Kt - K_g\right)} \right)^{-1} \right)^{-1} \tag{2}$$

with $K_g = \lambda_g \frac{S_g}{S}$, $Kr^0 = \lim_{K_s \to 0} Kr$ and $R_s^{-1} = \lim_{T \to +\infty} \left(Kr - Kr^0\right)$. This expression is general and is *a priori* applicable to any geometry where the heat exchanges can be described considering the following modes acting in parallel: thermal conduction through the gas phase alone (K_g term in Eq. 2), radiation through the gas phase alone (Kr^0 term in Eq. 2), conduction in the radiative solid and coupled conduction and radiation through the gas (the third term in Eq. 2).

Regarding radiative heat transfer, in [3], the following expression have been proposed for Kr:

$$Kr = 4\left(\frac{2 - (\hat{a} + 2\hat{r})}{\hat{a} + 2\hat{r}} \right) \sigma T^3 L \tag{3}$$

with $\hat{a} = a(1-\varphi)$, $\hat{r} = r + \varphi(r_0 - r)$, $r_0 = \lim_{\varepsilon_s \to 0} r$. Function φ takes into account the solid temperature inhomogeneity in the layer under the assumption that, at any point $\vec{r}$ in the solid phase, $T_s(\vec{r}) = \varphi T_s^0(\vec{r}) + (1-\varphi) T_s^\infty(\vec{r})$ where $T_s^0(\vec{r}) = \lim_{K_s \to 0} T_s(\vec{r})$ and $T_s^\infty(\vec{r}) = \lim_{K_s \to +\infty} T_s(\vec{r}) = T$. Accordingly, it should enforce $\lim_{K_s \to 0} \varphi = 1$ and $\lim_{K_s \to \infty} \varphi = 0$. Accordingly, one has:

$$Kr^0 = 4\left(\frac{1 - r_0}{r_0} \right) \sigma T^3 L \tag{4}$$

From there, in order for R_s^{-1} to remain finite when $T \to +\infty$, φ should be such that: $\exists \alpha > 0$,

$$\varphi = 1 - \frac{\alpha}{4\sigma T^3} + o\left(\frac{1}{4\sigma T^3} \right) \tag{5}$$

Under these conditions, R_s can be expressed as:

$$R_s = \frac{2\left(r_0\right)^2}{\alpha\left(2(r - r_0) - a\right)} \tag{6}$$

This model is general and can be applied to any geometry provided that the four following closures are obtained: $\frac{S_g}{S}$, Kt, φ and associated α, (a, r) and associated r_0. Moreover, the following asymptotic behaviours are enforced:

- $\lim_{K_s \to +\infty} Ke = Kt + Kr$ provided that $\lim_{K_s \to +\infty} R_s = 0$

- $\lim_{K_s \to 0} Ke = \lambda_g + Kr^0$ provided that $\lim_{K_s \to 0} R_s = +\infty$ and $\lim_{K_s \to 0} Kt = \lambda_g$
- $\lim_{\varepsilon_s \to 0} Ke = Kt + Kr^0$ provided that $\lim_{\varepsilon_s \to 0} Kr = Kr^0$ *i.e.* $\lim_{\varepsilon_s \to 0} \varphi = 0$
- $\lim_{T \to 0} Ke = Kt$

For a uniform Cartesian arrangement of cylindrical (resp. square) solids, $\frac{S_g}{S} = 1 - \sqrt{\frac{4}{\pi}(1-p)}$ (resp. $\frac{S_g}{S} = 1 - \sqrt{(1-p)}$).

For φ, under simplifying hypotheses, [3] proposes to use for a cylinder of diameter d (or a slab of thickness d):

$$\varphi = \left(1 + \frac{2K_s}{4 + \varepsilon_s \sigma T^3 d}\right)^{-1} \tag{7}$$

in such a way that $\alpha = \frac{2K_s}{\varepsilon_s d}$.

For K_t, a correlation has been proposed in [3] from the numerical simulation of conductive heat transfer in the 2D-unit cell associated with the cylinder lattice for various porosity and conductivity ratio K_s/λ_g values. In a similar way, correlations for a, r have been obtained from numerical simulation of radiative heat transfer in the gas phase of a 2D-unit cell varying ε_s and p (and imposing a zero solid temperature).

Conclusions & Perspectives

1. Introduction

Context and problem statement

Context

Radiative heat transfer crucial for heat dissipation during LOCA in LWRs

- For small reactors, the accident progression can be very sensitive to the heat removal from the core [MDL24]
- Bifurcations in the core degradation transients because of the complex dependency of Zircaloy cladding oxidation to temperature

Its modeling is complex due to the intricate geometry of reactor cores

- Approximate lumped parameter models are used in accident simulation codes
- Built from a combination of net radiation enclosure models and effective conductivity models
- Equivalent conductivity $\underline{\underline{Ke}}$ associated with the anisotropic Fourier law $\boldsymbol{q} = -\underline{\underline{Ke}}\boldsymbol{\nabla} T$
  (N.B. valid for an optically thick medium – at the scale of the representative volume element used for homogenization)

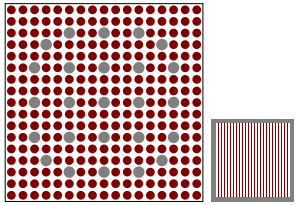
Problem Statement

- Different models in the literature for $\underline{\underline{Ke}}$ mainly focused on open rod geometries (PWRs)
- In particular, Rubiolo model [Rub00, RG02] as implemented in the RADR model [ZFR06] of the ICARE module of the ASTEC code
  - Rather general formulation that requires geometry-dependent closures
  - Obtained in practice only for a regular Cartesian lattice of identical cylinders

→ **In a standard 17×17 PWR assembly, what is the impact of the guide tubes on $\underline{\underline{Ke}}$?**

- Little work for closed flat plate assemblies
  - Found in various designs ranging from material testing reactors to space thermal propulsion reactors
  - Rubiolo model partially extended to such geometries [Zab08] but no validation

→ **How $\underline{\underline{Ke}}$ varies for closed flat plate assemblies?**



Nota Bene

- Focus here on the radial component of $\underline{\underline{Ke}}$ to investigate these two questions
- Radiation between opaque solids through a transparent medium

2. Methods

Direct numerical simulation approach and Rubiolo model

Methods - Direct Numerical Simulation Approach

- "Reference" approach for evaluating the equivalent conductivity
- Simulate radiative and conductive heat transfer modes in two-phase spatial domain $\mathcal{D}$:

$$T = T_0 - \frac{\delta T}{2} \text{ and } \varepsilon = 1 \quad \text{on } \Gamma_L$$

$$T = T_0 + \frac{\delta T}{2} \text{ and } \varepsilon = 1 \quad \text{on } \Gamma_R$$

$$\nabla T \cdot \boldsymbol{n} = 0 \text{ and specular reflection} \quad \text{on } \Gamma_U \cup \Gamma_B$$

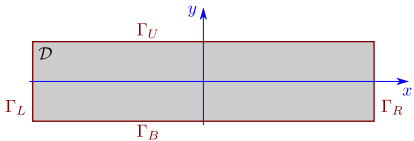


FIGURE 2: Geometrical domain $\mathcal{D}$: L_X (resp. L_Y) is the domain length along the x–axis (resp. y–axis)

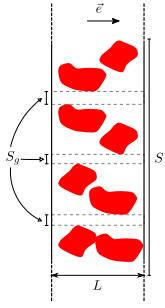
- Evaluate the apparent conductivity (Ka) along the x–axis from $\boldsymbol{q}$ the total heat flux on $\Gamma_L \cup \Gamma_R$:

$$Ka(T_0) = \frac{L_X \int_{\Gamma_L \cup \Gamma_R} |\boldsymbol{q} \cdot \boldsymbol{n}| \, ds}{2 L_Y \delta T}$$

- TRUST/TrioCFD code [SBLB25] for conduction/radiation coupled calculation
  - Triangular meshes, finite volume-element discretization with anisotropic conductivity handling
  - View factors obtained by Ray-Tracing Monte-Carlo method [LTCSB25] or analytical formulas

Methods - Rubiolo Model

- Algebraic model based on thermal resistance formalism for describing a porous medium
  - Opaque homogeneous solid (conductivity K_s, emissivity ε_s)
  - Transparent fluid (thermal conductivity λ_g)
  - Porosity p
- Requires: K_s (solid homogenization) and closures laws that depend on the phase topology
  - S_g/S
  - Equivalent conductive Kt and radiative Kr conductivities
- Kt and Kr closures laws + validation $\rightarrow$ available for a regular Cartesian lattice of identical cylinders (RADR model in ASTEC)
- For closed flat plate assemblies: partial adaptation (only K_s) [Zab08] and no validation



Methods - Verification test case (adapted from [Rub00])

- *Ka* evaluated in [Rub00] with CASTEM2000

λ_g [W.m^{-1}.K^{-1}]	K_s [W.m^{-1}.K^{-1}]	ε_s [–]
0.01	10.0	0.5

FIGURE 3: 10 × 1– homogeneous rod pattern – fuel pins in red – length is 5.01cm, pitch is 0.50cm

- Very good agreement between both *Ka* evaluations
- *Ke* with Rubiolo model vs. *Ka*: a limited underestimation ($\approx$ 10%)

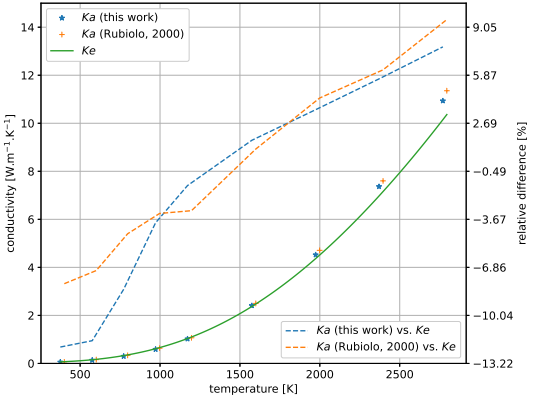


FIGURE 4: Apparent and equivalent conductivities as a function of temperature

3. Application Test Cases

Assemblies - Geometries and Materials

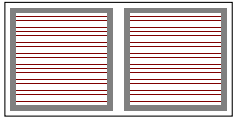
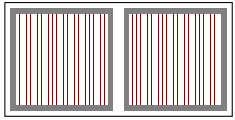
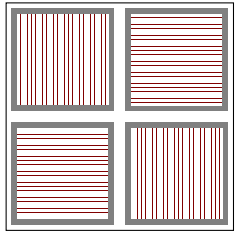
(B) 17×3– heterogeneous rod pattern



(C) 2×1– plate $\parallel$ assembly pattern



(D) 2×1– plate $\perp$ assembly pattern



(E) 2×2– plate assembly pattern

3. Numerical Results

Numerical Results - Open Rod Cases

Ka in the open rod cases: what is the impact of the guide tubes?

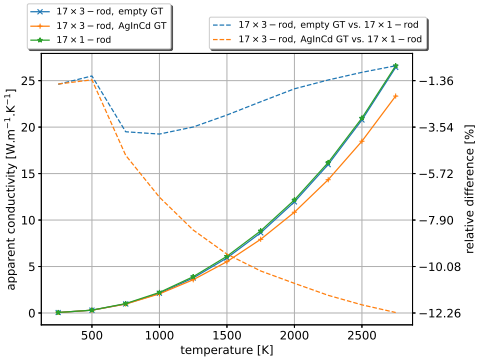


FIGURE 9: Apparent conductivities as a function of temperature: open rod cases

- Heterogeneities due to empty guide tubes
  → a very limited impact on conductivity (-3.5% to -1%)
- AgInCd pins in guide tubes
  → a more significant decrease in *Ka* (down to −12%)
- Taking into account that AgInCd melts at about 800 °C
  → lattice heterogeneities have a limited impact

→ considering the homogeneous lattice case probably sufficient in accident scenario codes

Numerical Results - Flat Plate Assembly Cases

Ka in plate assemblies: how does it compare with the open rod case?

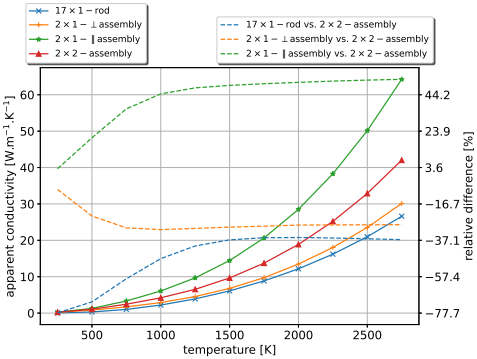

FIGURE 10: Apparent conductivities as a function of temperature: flat plate assembly cases

- Higher conductivity compared to open rod cases
- Strong anisotropy effect: conductivity is higher when plates are parallel to the heat flux
- $2 \times 2 - \mathrm{assembly}$ somewhere in between the parallel and perpendicular plate cases

N.B. Pattern size effect $4 \times 2 - \mathrm{assembly}$ (not shown) vs. $2 \times 2 - \mathrm{assembly}$: limited increase (a few %) in *Ka*

Numerical Results - Comparison with Rubiolo model

Ke (Rubiolo model) vs. *Ka*

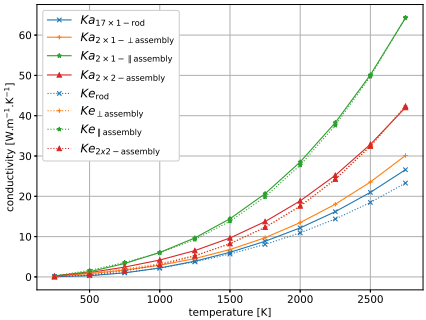

FIGURE 11: Apparent and equivalent conductivities – $Ke_{\perp\text{ assembly}}$ and $Ke_{2\times2\text{ assembly}}$ almost indistinguishable

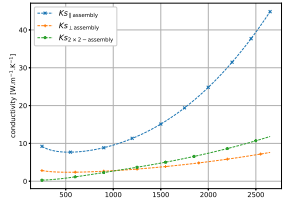
- Open rod lattice: same trend as in the verification case with an underestimation slightly more pronounced (up to $\approx$ 16%)
- K_s as used in Rubiolo model for evaluating *Ke* in the plate assembly cases (following [Zab08])

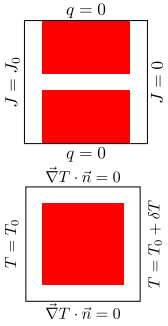


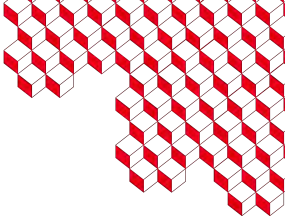
- $2\times1-\parallel\text{assembly}$ and $2\times1-\perp\text{assembly}$:
  - *Ke* $>$ *Ka* over the whole temperature range
  - at 500K: about 30% bias
  - above 1000K: bias $\nearrow$ (resp. $\searrow$) in $\perp$ (resp $\parallel$) case
- in $2\times2-\text{assembly}$ case: error compensation at play with *Ke* very close to $2\times1-\perp\text{assembly}$ case

$\rightarrow$ correct trend but noticeable additional bias in comparison with the open rod case

Conclusions & perspectives

- Evaluation and comparison of equivalent conductivity in open rod and closed flat plate assemblies using direct numerical simulations and Rubiolo model
- Main findings:
  - Limited impact of heterogeneities introduced by guide tubes in open rod assemblies
  - Flat plate assemblies compared to open rod assemblies: higher conductivity and strong anisotropy
  - Partial extension of Rubiolo model in [Zab08]: noticeable additional bias in comparison with the open rod case
- Perspectives:
  - Improve Rubiolo model application to flat plate assemblies: construct closure laws for K_t and K_r conductivities in such a configuration
  - Use direct numerical simulations for the thorough validation of lumped parameter models that describe radiative heat transfer in accident codes
  - Extend the direct numerical simulation approach to 3D configuration: tool for calculating view factors in 3D under development [BCSLT26] using the Intel® Embree library





Thanks! Any questions?

ABSTRACT

Large-scale three-dimensional experiments were performed to investigate debris-bed formation during underwater sedimentation of sub-millimeter particles under conditions relevant to sodium-cooled fast reactor (SFR) core disruptive accidents. Solid particles with different diameters and densities were released into a water pool through nozzles of varying diameters, and their settling, spreading, and deposition behaviors were recorded using high-speed imaging.
The resulting debris-bed shape was quantified using several geometrical indicators, including inner diameter, fan diameter, outer diameter, maximum height, outer slope angle and inner slope angle. Dimensionless parameters representing granular-jump intensity, particle–fluid coupling, and momentum injection were introduced to interpret the observed trends. A clear transition in the dominant formation mechanisms was identified around a Stokes number of unity, separating fluid-coupled and inertia-dominated regimes.
Based on these findings, regime-wise empirical correlations were developed for key geometrical indicators. The proposed framework embeds experimentally observed physical tendencies into invariant dimensionless parameters and provides quantitative insight into debris-bed formation behavior, contributing to debris-bed study and core-catcher design for SFR safety evaluation.

1. INTRODUCTION

In a core disruptive accident (CDA) of a sodium-cooled fast reactor (SFR), molten core materials are fragmented through melt–sodium interaction and subsequently relocated to the lower plenum by passing through internal flow paths such as control rod guide tubes [1]. Due to the high boiling point and thermal conductivity of liquid sodium, stable film boiling is unlikely; instead, direct liquid–liquid contact is expected, leading to rapid quenching and fragmentation into fine debris with characteristic sizes on the order of 0.1–1.0 mm [1].
The fragmented debris particles settle and accumulate on the core-catcher system installed at the bottom of the reactor vessel [2]. The final debris bed shape strongly affects coolability, recriticality risk, and in-vessel retention performance [3,4]. Therefore, understanding debris-bed formation mechanisms and identifying governing parameters are essential for SFR safety evaluation.
Previous experimental studies have investigated debris-bed formation using sedimentation experiments. The Japan Atomic Energy Agency (JAEA) and Kyushu University conducted a series of three-dimensional experiments focusing on the effects of nozzle diameter, particle density, and drop height [5–7]. Cheng et al. performed large-scale quasi-two-dimensional experiments and identified multiple flow regimes based on

particle–fluid interaction mechanisms [8]. However, limitations in experimental scale, particle size range, and dimensionality reduce the applicability of these studies to realistic SFR accident scenarios.
Motivated by these gaps, the present study conducts large-scale three-dimensional sedimentation experiments using sub-millimeter particles to clarify debris-bed formation mechanisms and to construct physically interpretable empirical correlations based on dimensionless analysis.

2. MATERIALS AND METHODS

2.1 Experimental apparatus and simulant materials

Figure 1 shows a schematic of the experimental apparatus. Experiments were conducted in a transparent acrylic tank with internal dimensions of 60 cm × 60 cm × 120 cm. Solid particles were released from a hopper through nozzles with diameters of 24 mm and 30 mm into a quiescent water pool with a fixed water depth of 90 cm.
Three types of particles—stainless steel, zirconia, and alumina—were used as debris simulants. Particle diameters ranged from 0.3 to 2.0 mm. Particle properties and experimental conditions are summarized in Table **1** and Table **2**. In all experiments, a constant bulk particle volume of 3.0 L was used.
High-speed cameras were installed near the nozzle and near the bottom of the tank to capture particle entry and deposition processes. Additional cameras recorded the global spreading behavior and final debris-bed shape.

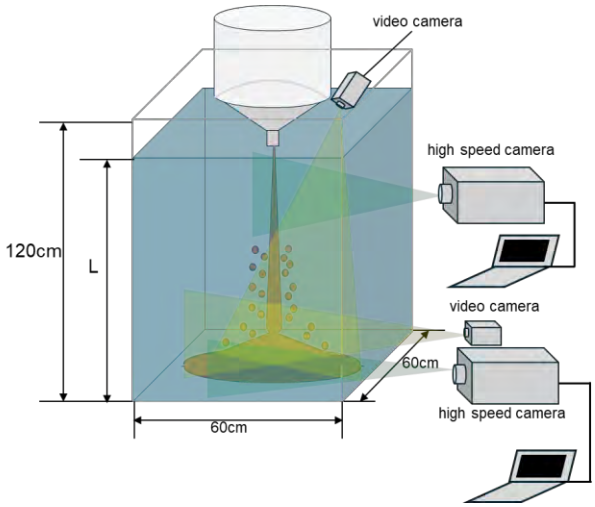

Figure 1. The schematic of the experimental apparatus

Table 1. Particle properties

Materials	Density ρ_p [kg/m³]	Particle diameter d [mm]
Al_2O_3	3600	2.0
		1.0
		0.5
ZrO_2	6000	2.0
		1.0
		0.5
SS	7800	2.0
		1.0
		0.3

Table 2. Experimental conditions

Particle volume V [L]	Nozzle diameter D_{nozzle} [mm]	Water height H [cm]
3.0	24, 30	90

2.2 Experimental procedure and characteristic velocities

Particles were released instantaneously by removing a retaining pin at the hopper outlet. After entering the water as a coherent group, particles settled through the water column, spread radially near the bottom, and accumulated to form a debris bed. Selected test conditions were repeated to confirm experimental repeatability. The Mean Absolute Percentage Error (MAPE) in the measured geometrical indicators were within approximately ±5.21–17.4%, depending on the parameter, as summarized in Table 3. Based on this assessment, the systematic trends discussed in the following sections are significantly larger than the experimental scatter.
The initial exit velocity at the nozzle, $\mathbf{v}_i$, was estimated using the continuity equation,

$$\mathbf{v}_i = \frac{4Q}{\pi D_{\text{nozzle}}^2}, \tag{1}$$

where Q is the average discharge flow rate.
A terminal velocity $\mathbf{v}_t$was defined as a characteristic velocity scale describing particle motion near the bottom region. This velocity scale was used consistently in the definition of dimensionless parameters without attempting detailed modeling of the settling process.

Table 3. Experimental uncertainty of the measured geometrical indicators, quantified by MAPE from repeated test conditions.

Geometrical indicator	MAPE [%]
D_{inner}	14.2
D_{fan}	7.95
D_{outer}	6.14
h_{max}	5.21
θ_{out}	17.4
θ_{in}	15.0

3. RESULTS AND DICUSSIONS

3.1 Debris bed morphology and geometric indicators

Figure **2** shows representative debris-bed shapes observed in the experiments. Three typical morphologies were identified: volcano, concave, and flat-topped beds, depending on particle size, density, and injection conditions.
To quantitatively characterize these shapes, five geometrical indicators were defined as shown in Figure 3: inner diameter D_{inner}, fan diameter D_{fan}, outer diameter D_{outer}, maximum height h_{max}, inner slope angle θ_{in} and outer slope angle θ_{out}. These indicators were selected to separately represent impact-induced spreading near the center region, lateral particle transport, and stabilization behavior at the bed periphery.
To enable comparison across different experimental conditions and to extract physically meaningful trends, the characteristic lengths were nondimensionalized using $V^{1/3}$, where V is the total particle volume released in each experiment, as defined previously. Since $V^{1/3}$ represents the characteristic length scale of the deposited debris volume, this normalization allows the geometrical indicators to be evaluated independently of the absolute amount of released particles.
Accordingly, the diameters D_{inner} , D_{fan} , and D_{outer} were normalized as $D^*_{\text{inner}} = D_{\text{inner}}/V^{1/3}$, $D^*_{\text{fan}} = D_{\text{fan}}/V^{1/3}$, and $D^*_{\text{outer}} = D_{\text{outer}}/V^{1/3}$. The maximum bed height was similarly nondimensionalized as $h^*_{max} = h_{\text{max}}/V^{1/3}$. The outer slope angle θ_{out}, the inner slope angle θ_{in} are inherently dimensionless geometrical quantities and were therefore used directly without normalization.

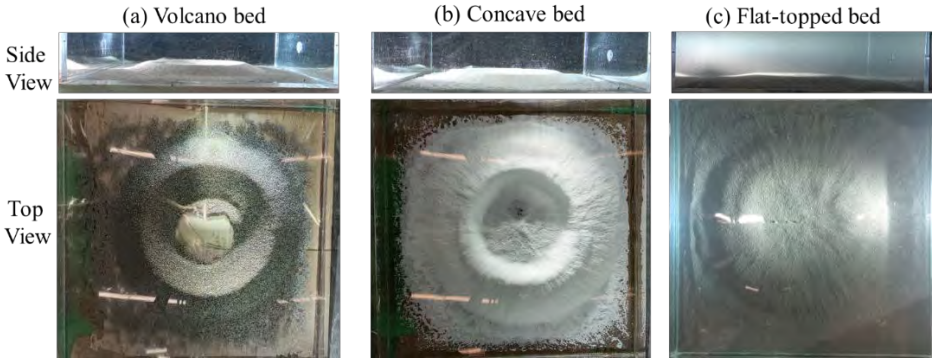

Figure 2. Representative debris bed shape observed in the present experiments. The upper figures show side views, and the bottom figures show top views on each debris bed shape. (a) volcano-shaped bed (material: SS, $\boldsymbol{d = 1.0}$mm, $\boldsymbol{D}_{\text{nozzle}} = \boldsymbol{24}$mm), (b) concave bed (material: ZrO_2, $\boldsymbol{d = 0.5}$mm, $\boldsymbol{D}_{\text{nozzle}} = \boldsymbol{24}$mm), and (c) flat-topped bed (material: SS, $\boldsymbol{d = 0.3}$mm, $\boldsymbol{D}_{\text{nozzle}} = \boldsymbol{20}$mm).

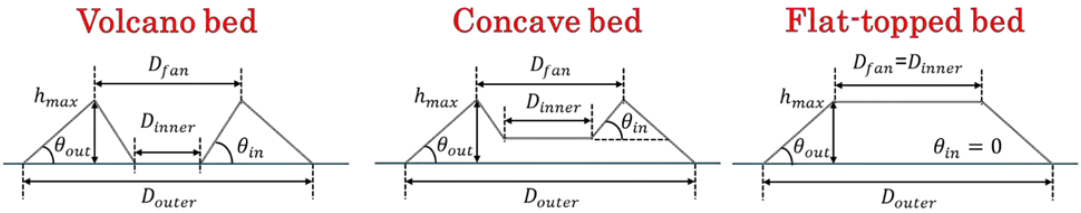

Figure 3. The geometrical definition of each debris bed shape ($\boldsymbol{D_{inneer}, D_{fan}, D_{outer}, h_{max}, \theta_{in}, \theta_{out}}$)

3.2 Inner diameter $\boldsymbol{D}_{\text{inner}}$

After particle impact on the bottom surface, a clear radial spreading pattern was observed, leaving a central cavity as shown in Figure 4. This behavior is characteristic of a granular jump, in which the vertical momentum of the particle group is abruptly converted into horizontal motion upon interaction with the bottom surface [9]. The resulting cavity defines the inner diameter D_{inner}, which represents the spatial extent of this momentum conversion process.

To quantify the intensity of the granular jump, a Froude number was introduced as

$$Fr_t = \frac{\mathbf{v}_t}{\sqrt{gD_{\text{nozzle}}}}, \tag{2}$$

where D_{nozzle} represents the characteristic length scale of momentum injection and $\mathbf{v}_t$ is a representative particle velocity near the bottom region. From a physical perspective, Fr_t expresses the ratio between particle inertia and the restoring effect of gravity during bottom impact.

In addition, a Stokes number was defined to characterize particle–fluid coupling during impact,

$$St_i = \frac{\rho_p d}{C_d \rho_l D_{\text{nozzle}}}, \tag{3}$$

where the drag coefficient C_d was evaluated using the Schiller–Naumann correlation [10]. This parameter reflects the relative importance of particle inertia compared with fluid drag during rapid deceleration and redirection at the bottom surface.

Figure 5 (a) shows the relationship between the normalized inner diameter D^*_{inner} and Fr_t. The data exhibits two distinct regimes separated around $St_i \approx 1$, as summarized in Figure 5(b). Within each regime, D^*_{inner}

increases monotonically with increasing Fr_t, indicating that the cavity size is governed primarily by the strength of the granular jump.
In the low-St_i regime, particle motion remains strongly coupled to the surrounding fluid, and the extent of radial spreading is controlled by fluid-driven momentum redistribution. In contrast, in the high-St_i regime, particle inertia dominates the impact process, leading to a more direct conversion of vertical momentum into lateral motion. Despite the difference in dominant mechanisms, D_{inner} consistently reflects the magnitude of momentum conversion at bottom impact.
These results demonstrate that D_{inner} is a sensitive geometrical indicator that directly captures the dominant momentum-conversion mechanism during the granular jump.

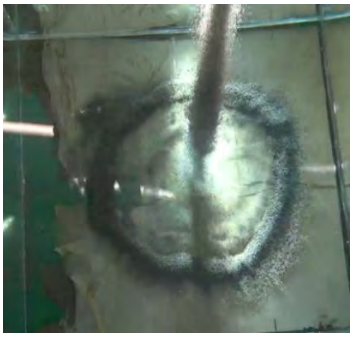

Figure 4. Top-view visualization of particles spreading near the bottom surface 2.5 sec after release. The granular jump causes lateral expansion of the particle group and leaves a central cavity that defines the inner diameter D_{inner} (material: SS, d=1.0mm, D_{nozzle}=24mm).

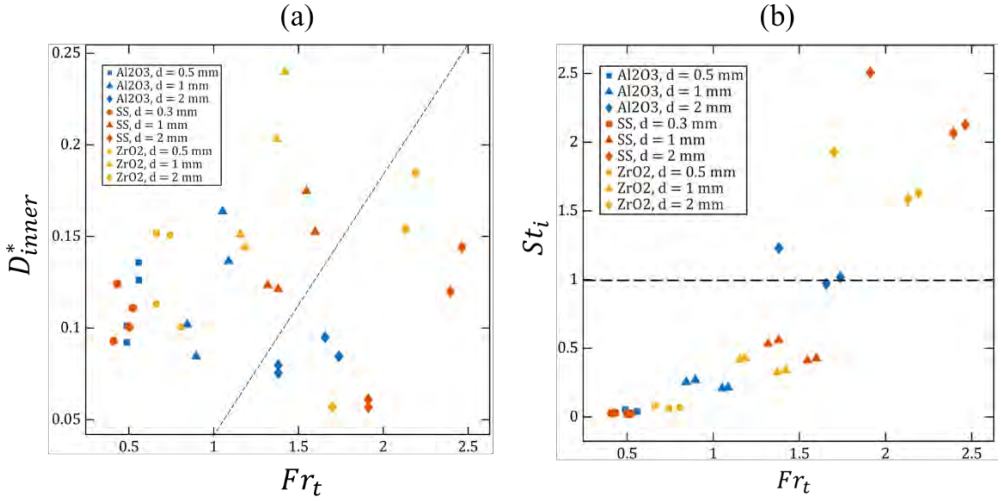

Figure 5. (a) Relationship between the normalized inner diameter $D^*_{\text{inner}}$and the Froude number Fr_t. (b) Relationship between the Stokes number St_i and Fr_t, indicating a regime transition around $St_i = 1$. Symbols represent experimental data for different particle materials and diameters.

3.3 Fan diameter D_{fan}

Figure 6 (a) shows a strong correlation between the normalized fan diameter D^*_{fan} and the normalized inner diameter D^*_{inner}, indicating that cavity formation and upper region spreading are closely linked phenomena. This correlation suggests that the granular jump not only determines the size of the central cavity but also controls the subsequent redistribution of particles above the cavity region.

Figure 6 (b) presents the relationship between D^*_{fan} and Fr_t. Like D^*_{inner}, two distinct regimes are observed. In the low-St_i regime, D^*_{fan} increases strongly with Fr_t, reflecting fluid-coupled momentum redistribution. In this regime, particles redirected by the granular jump remain strongly influenced by the liquid flow, resulting in enhanced spreading in the upper region.
In the high-St_i regime, D^*_{fan} continues to increase with Fr_t, although the underlying mechanism changes. Here, particle–particle interactions play a more dominant role, and the spreading reflects a combination of direct inertial motion and subsequent collisions rather than fluid-driven transport alone.
These observations indicate that D_{fan} serves as a complementary geometrical indicator to D_{inner}, capturing the extent to which the granular jump influences particle redistribution beyond the immediate impact zone.

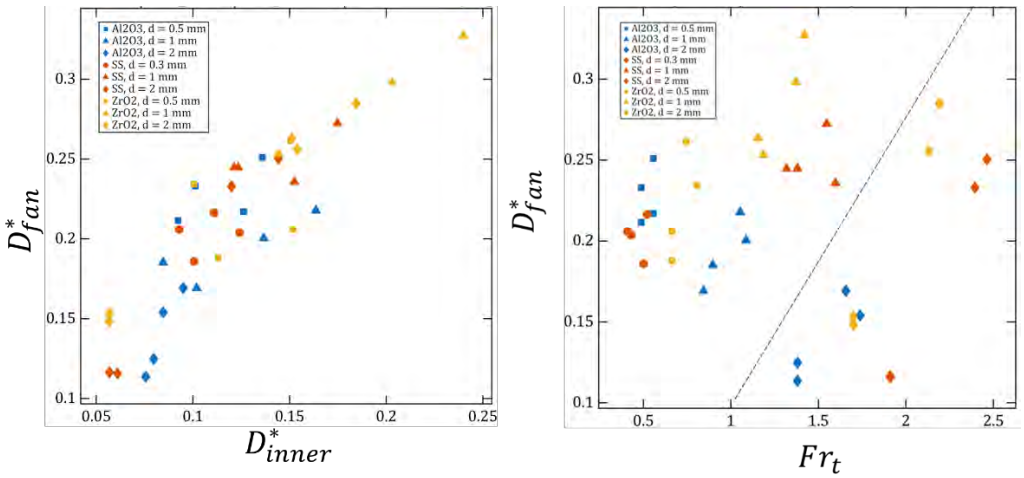

Figure 6. (a) Relationship between the normalized fan diameter D^*_{fan} and the normalized inner diameter D^*_{inner}. (b) Relationship between D^*_{fan} and Fr_t. Symbols represent experimental data for different particle materials and diameters.

3.4 Outer diameter D_{outer}

To clarify the dominant velocity scale governing the lateral extent of the outer region, two Reynolds numbers were examined. Previous debris-bed studies have emphasized the role of particle inertia in lateral spreading behavior [8]. Following this perspective, a Reynolds number based on particle settling motion near the bottom was first considered.
This Reynolds number is defined using the representative settling velocity $\mathbf{v}_t$ as

$$Re_{Dt} = \frac{\rho_l \mathbf{v}_t D_{\text{nozzle}}}{\mu_l}, \tag{4}$$

which characterizes the relative importance of inertial and viscous effects associated with particle motion in the near-bottom region.
In addition to settling inertia, the initial momentum of the particle jet acts as a driving source for both particle motion and the surrounding liquid flow. During injection, a portion of the particle momentum is transferred to the liquid, generating a large-scale flow field that can significantly influence lateral particle transport. To account for this particle–flow coupling, a second Reynolds number based on the initial momentum injection near the nozzle was introduced and defined as

$$Re_{Mi} = \frac{\sqrt{\frac{M_i}{\rho_l}}}{\nu}, \tag{5}$$

where ν is the kinematic viscosity of water. Here, M_i denotes the initial momentum of the particle jet, given by

$$M_i = \rho_p \mathbf{v}_i^2 \, \pi \left(\frac{D_{\text{nozzle}}}{2} \right)^2 . \tag{6}$$

Figure 7 compares the dependence of the normalized outer diameter D^*_{outer} on these two Reynolds numbers. In Figure 7(a), where the data are organized using Re_{Dt}, substantial scatter remains and no clear systematic trend is observed. Notably, the largest lateral spreading occurs at smaller Re_{Dt}, corresponding to weaker terminal settling inertia. This behavior indicates that the lateral extent of the outer region cannot be explained solely by particle settling dynamics near the bottom.

In contrast, Figure 7(b) presents D^*_{outer}as a function of Re_{Mi}, revealing a much clearer data collapse. This indicates that the lateral extent of the outer deposition region is governed primarily by the momentum injected near the nozzle rather than by the terminal behavior of individual particles.

The improved collapse with Re_{Mi}suggests that the spreading of the outer region is driven by the flow field generated through particle–fluid momentum transfer during the injection process. The initial particle jet imparts momentum to the surrounding liquid, inducing a radial flow that transports particles laterally toward the periphery. Consequently, the outer region spreading is not controlled by terminal settling inertia characterized by Re_{Dt}, but is instead dominated by flow-induced transport associated with the initial momentum injection, as represented by Re_{Mi}.

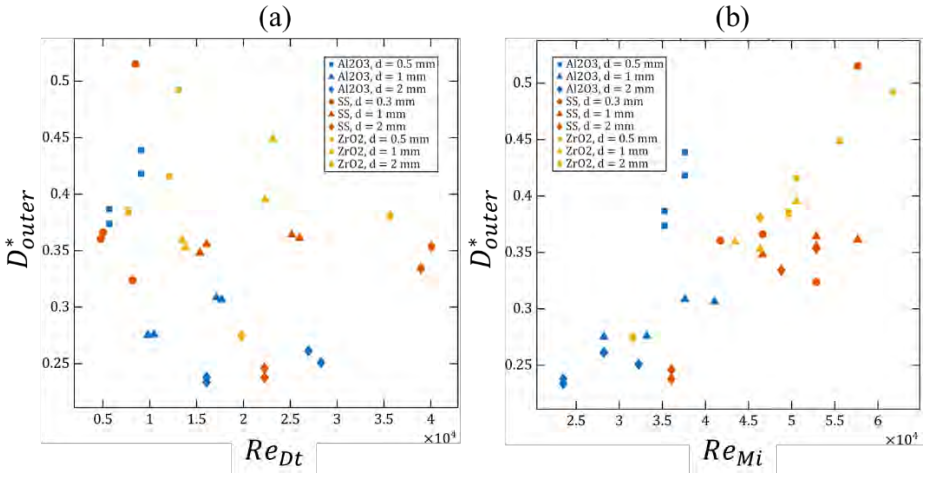

Figure 7. Relationship between the normalized outer diameter $\boldsymbol{D^*_{\text{outer}}}$ and Reynolds numbers based on (a) the representative terminal velocity, $\boldsymbol{Re_{Dt}}$, and (b) the initial jet momentum, $\boldsymbol{Re_{Mi}}$.

3.5 Maximum height h_{max}

Figure 8(a) and (b) show the relationship between the normalized maximum bed height $h_{\text{max}}$and the Stokes number $St_i$for two nozzle diameters. For both cases, a clear transition is observed around $St_i \approx 1$, indicating a change in the dominant mechanism governing vertical bed development.

In the low-St_i regime, h_{max}increases with increasing St_i. Particle motion in this regime remains strongly coupled to the surrounding fluid, and increasing particle inertia reduces the effectiveness of flow-induced lateral redistribution after bottom impact. As a result, particles tend to accumulate near the central region, promoting vertical piling and leading to an increase in the maximum bed height.

In the high-St_i regime, granular-jump dynamics dominate, and the evolution of $h_{\text{max}}$is governed by how particle momentum is redistributed near the bottom. As particle inertia increases, granular-jump-induced collisions occur closer to the bed center, enhancing particle–particle interactions and promoting lateral redistribution toward the fan region. For conditions in which particle supply and momentum injection are

spatially distributed over a wider area, this redistribution limits further central accumulation, resulting in plateau or decreasing trends in $h_{\max}$.
Overall, $h_{\max}$reflects a balance between inertia retention during bottom impact and the scale-dependent redistribution of particle mass near the bed. Its evolution is therefore controlled not only by particle dissipation, but also by how the spatial distribution of particle momentum governs the partitioning between vertical piling and lateral spreading.

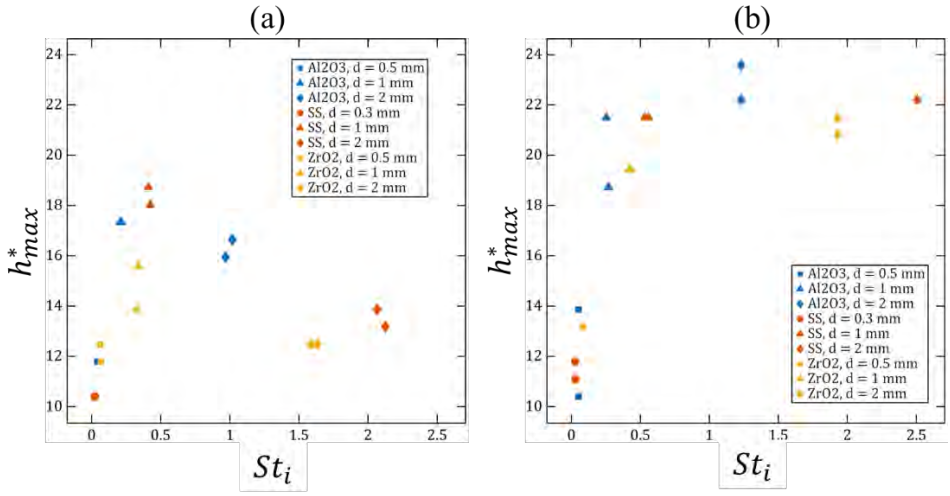

Figure 8. Relationship between the normalized maximum bed height h^*_{max} and the Stokes number St_i for (a) $D_{\text{nozzle}} = 24$mm and (b) $D_{\text{nozzle}} = 30$mm. In both cases, two regimes are observed around $St_i \approx 1$, indicating a transition in the dominant bed-formation mechanism.

3.6 Outer slope angle θ_{out}

Figure 9 (a) and (b) show the relationship between the outer slope angle θ_{out} and the Stokes number St_i for two nozzle diameters. The similarity of the trends for different nozzle diameters indicates that θ_{out} is a relatively robust geometrical indicator with weak dependence on injection scale.
In the low-St_i regime, θ_{out}increases with increasing St_i. As particle inertia becomes more significant relative to viscous forces, particles arriving at the outer region are less easily rearranged by the surrounding fluid. Consequently, steeper slopes can be maintained without significant fluid-induced reworking.
In the high-St_i regime, θ_{out} decreases with further increases in St_i. Under these conditions, collision-driven redistribution and inertial avalanching dominate near the bed periphery. Particles arriving at the outer region retain sufficient momentum to destabilize local packing, leading to enhanced rearrangement and gentler slopes.
These results indicate that θ_{out} captures the stabilization mechanism at the bed periphery and reflects the competition between fluid-induced reworking and inertia-driven redistribution.

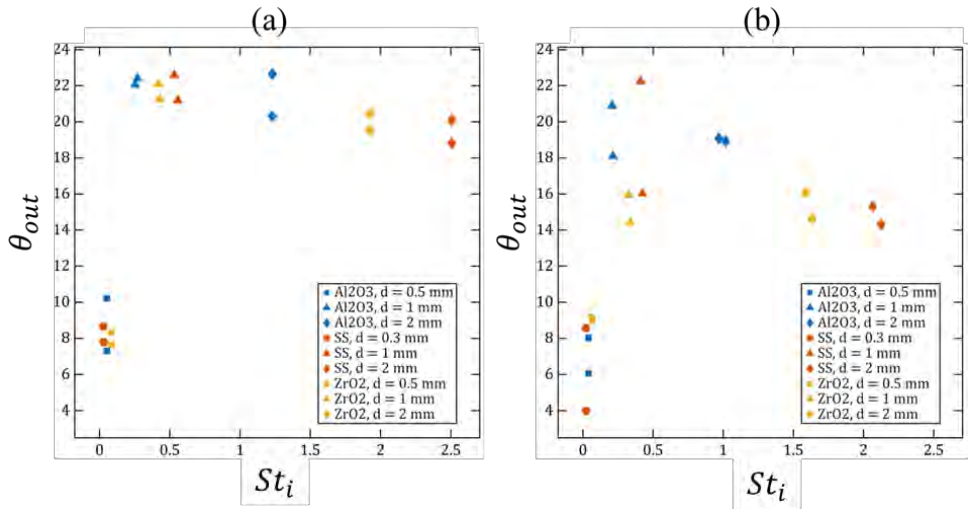

Figure 9. Relationship between the outer slope angle θ_{out} and the Stokes number St_i for (a) $D_{\mathrm{nozzle}} = 24\mathrm{mm}$ and (b) $D_{\mathrm{nozzle}} = 30\mathrm{mm}$. In both cases, two regimes are observed around $St_i \approx 1$.

3.7 Inner slope angle θ_{in}

Figure 10 (a) and (b) show the dependence of the inner slope angle θ_{in} on the Stokes number St_i for two nozzle diameters. For both cases, θ_{in} increases in the low-St_i regime ($St_i < 1$), where particle motion remains strongly coupled to the surrounding fluid. As St_i increases, particles increasingly retain vertical momentum during settling, enabling weak granular jumps at bottom impact. Consequently, a larger fraction of particles contributes to inner-slope formation near the center, leading to a gradual increase in θ_{in}.
Around $St_i \approx 1$, a transition in the dominant formation mechanism of the inner slope is observed, beyond which the behavior of θ_{in} depends strongly on the nozzle diameter. For the larger nozzle diameter, θ_{in} decreases monotonically in the high-St_i regime. In this case, particle supply and momentum injection are spatially distributed over a wide area, and granular-jump-induced particles are preferentially redistributed laterally rather than accumulating near the center. As a result, inner-slope geometry is governed primarily by lateral redistribution, and the effect of spreading leads to a progressive reduction in θ_{in}.
In contrast, for the smaller nozzle diameter, θ_{in} exhibits a non-monotonic trend in the high-St_i regime. Immediately above $St_i \approx 1$, energetic particle impacts concentrated near the bed center disrupt the formation of a stable inner slope, resulting in a sharp decrease in θ_{in}. With further increases in St_i, the inward displacement of the granular-jump location becomes more pronounced, and particle collisions occur while a larger fraction of inertia is retained. Under these conditions, enhanced particle accumulation and collision-induced rearrangement promote packing and frictional stabilization near the center, leading to a recovery and subsequent increase in θ_{in}.
Overall, these results indicate that θ_{in} reflects a regime-dependent balance between lateral redistribution and central stabilization, analogous to the behavior observed for the maximum bed height. While inner-slope formation is dominated by redistribution for the larger nozzle diameter, scale-dependent collision inertia and packing effects play an increasingly important role for the smaller nozzle diameter, making θ_{in} a sensitive indicator of granular-jump onset and particle redistribution geometry.

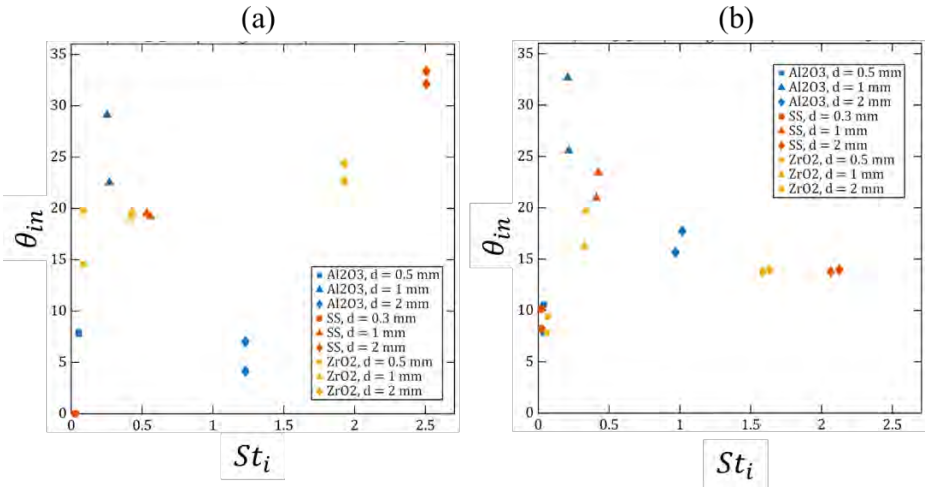

Figure 10. Relationship between the inner slope angle $\boldsymbol{\theta_{in}}$ and the Stokes number $\boldsymbol{St_i}$ for (a) $\boldsymbol{D_{nozzle}} = \mathbf{24}$mm and (b) $\boldsymbol{D_{nozzle}} = \mathbf{30}$mm.

4. EMPRICAL CORRELATIONS

Based on the detailed analysis in Section 3, this section examines whether the dominant tendencies governing debris-bed formation can be quantitatively embedded into a predictive description of the outer slope angle θ_{out} as a physically meaningful and condition-independent quantity.

As discussed in Section 3, θ_{out} is established through granular-jump-induced momentum conversion near the bottom, subsequent particle transport toward the outer region, and particle rearrangement and stabilization at the bed periphery. To represent these mechanisms in a dimensionless framework, Fr_t is adopted to characterize granular-jump intensity, Re_{Mi} to account for flow-driven particle transport, and the Stokes number St_i to describe particle–fluid coupling. In addition, a buoyancy parameter $Bu = (\rho_p - \rho_l)/\rho_l$ is introduced to represent the effect of density difference driving sedimentation.

The results in Section 3 revealed a clear regime transition around $St_i \approx 1$. Since the dominant physical mechanisms differ across this boundary, separate empirical correlations were constructed for the low- and high-St_i regimes. The resulting correlations are given as follows:

$$\theta_{\text{out}} = 2.23 \times 10^9 \, Fr_t^{0.77} \, Re_{Mi}^{-1.80} \, St_i^{0.16} \, Bu^{0.51} (St_i < 1), \tag{7}$$

$$\theta_{\text{out}} = 6.34 \times 10^4 \, Fr_t^{0.13} \, Re_{Mi}^{-0.82} \, St_i^{-0.016} \, Bu^{0.20} (St_i \gtrsim 1). \tag{8}$$

Figure 10 shows that the proposed correlations reproduce the experimental values of $\theta_{\text{out}}$with small errors, yielding a mean absolute percentage error of 12.1% in the low-St_i regime and 3.16% in the high-St_i regime, both smaller than the experimental repeatability.

The fitted exponents provide a consistency check between the proposed correlations and the experimentally observed trends discussed in Section 4. The Stokes number shows a positive exponent in the low-St_i regime and a near-zero to slightly negative exponent in the high-St_i regime, reflecting the transition from particle–fluid interaction–dominated behavior to particle–particle interaction–dominated redistribution.

The nozzle-based Reynolds number Re_{Mi} exhibits a negative dependence in both regimes, indicating that enhanced flow-driven lateral spreading reduces the outer slope angle irrespective of the dominant interaction regime. The buoyancy parameter Bushows a positive dependence, consistent with the role of density contrast in promoting inertia-driven particle rearrangement.

The influence of the Froude number Fr_t is pronounced in the low-St_i regime due to granular-jump-induced momentum conversion but becomes weak in the high-St_i regime, suggesting a secondary role once particle

motion is inertia-dominated. Overall, although empirical, the correlations capture the dominant physical mechanisms governing the outer slope formation in a physically consistent manner.

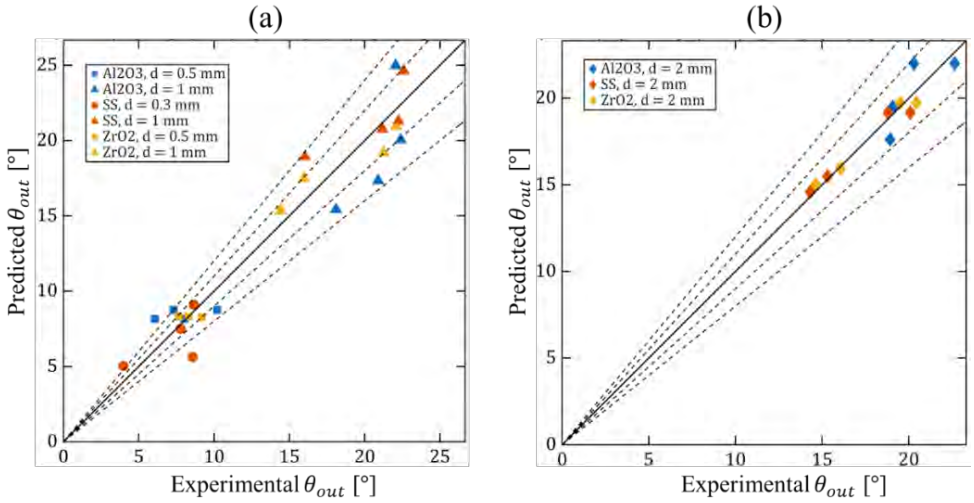

Figure 11. Comparison between predicted and experimental values of the outer slope angle $\boldsymbol{\theta_{out}}$ obtained from the regime-wise empirical correlations; (a) data points with $\boldsymbol{St_i < 1}$and (b) data points with $\boldsymbol{St_i \gtrsim 1}$. Solid lines indicate the parity line, while dashed lines represent ±10% and ±20% deviation from the experimental values. MAPE on each graph is 12.12% in (a), 3.16% in (b).

5. CONCLUSIONS

Large-scale three-dimensional experiments were conducted to investigate debris-bed formation during underwater sedimentation of fine particles under conditions relevant to CDA in sodium-cooled fast reactors. By systematically analyzing debris-bed shape together with appropriate dimensionless parameters, the dominant formation behaviors and their underlying physical mechanisms were identified.

The experiments showed that debris beds can be classified into three representative morphologies—volcano, concave, and flat-topped—and that debris-bed formation is governed by regime-dependent mechanisms with a clear transition around a Stokes number of unity. At low Stokes numbers, particle motion is strongly coupled to the surrounding fluid, and granular-jump-induced momentum conversion promotes lateral particle transport, leading to central cavity formation and influencing both bed height and outer slope geometry. At high Stokes numbers, particle inertia dominates, particle–particle interactions and inertial redistribution become more important, and the influence of fluid-driven transport diminishes.

Among the geometric indicators examined, the outer slope angle $\theta_{\mathrm{out}}$was identified as a relatively robust characteristic with weak dependence on experimental scale and debris volume. Based on this regime distinction, empirical correlations for θ_{out}were developed, reproducing the experimental data within approximately ±13%, which is smaller than the experimental repeatability error. The fitted exponents are consistent with the experimentally observed trends in each regime, supporting the physical relevance of the selected dimensionless parameters.

Although direct extrapolation to reactor conditions is limited by the simplified experimental configuration, the proposed framework provides a physically consistent and scalable basis for debris-bed assessment. Future work should extend the approach to more realistic conditions, including non-spherical particles, modified bottom geometries, and forced or background convection, which are expected to affect granular-jump behavior and near-bottom momentum redistribution. The present findings contribute to the refinement of predictive models and to the design and safety assessment of core catcher systems in SFRs.

$$D^*_{inner} = \frac{D_{inner}}{V^{\frac{1}{3}}} \quad D^*_{fan} = \frac{D_{volcano}}{V^{\frac{1}{3}}} \quad D^*_{outer} = \frac{D_{outer}}{V^{\frac{1}{3}}} \quad h^*_{max} = \frac{h_{max}}{V^{\frac{1}{3}}}$$

$V = initial\ particles\ volume$ (3.0L)

Discussion ~θ_{out}~

$St < 1$ (**particle-fluid interaction** dominated)

$\theta_{out} \uparrow$ = particles become **less influenced by the fluid** maintaining the steeper slope

$St > 1$ (**particle-particle interaction** dominated)

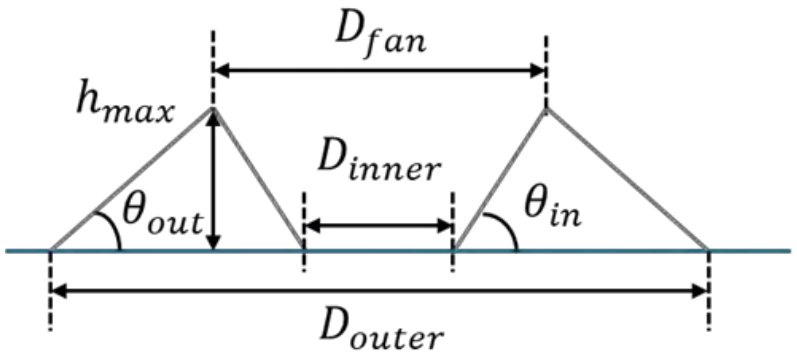
$\theta_{out} \downarrow$ = promoting **rearrangement by particle interaction** relaxing the slope

θ_{out} is controlled by particle mobility under fluid and particle forces governed by St

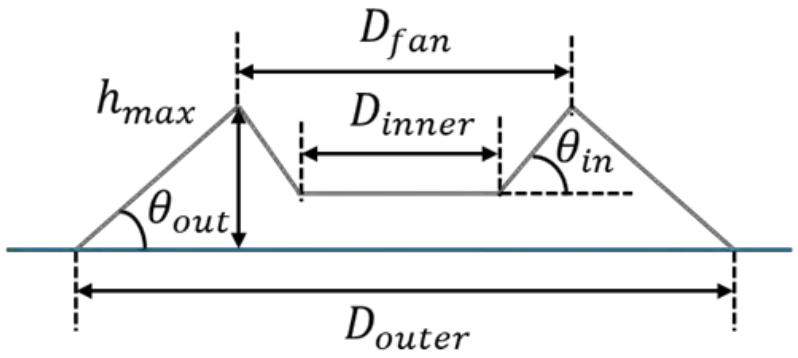
Fig. The relationship between St and θ_{out}

Summary of the discussion

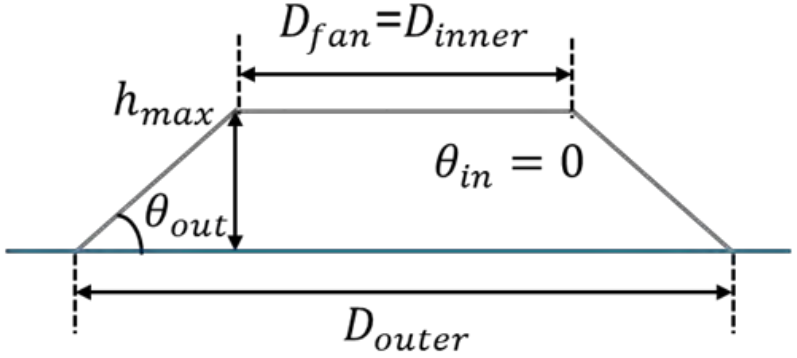
Volcano



Concave bed



Flat-topped



D_{inner}

- D_{inner} is generated by "**Granular jump**" and **its intensity is determined by Fr**
- **St governs the dominant forces** and the momentum conversion process during Granular jump

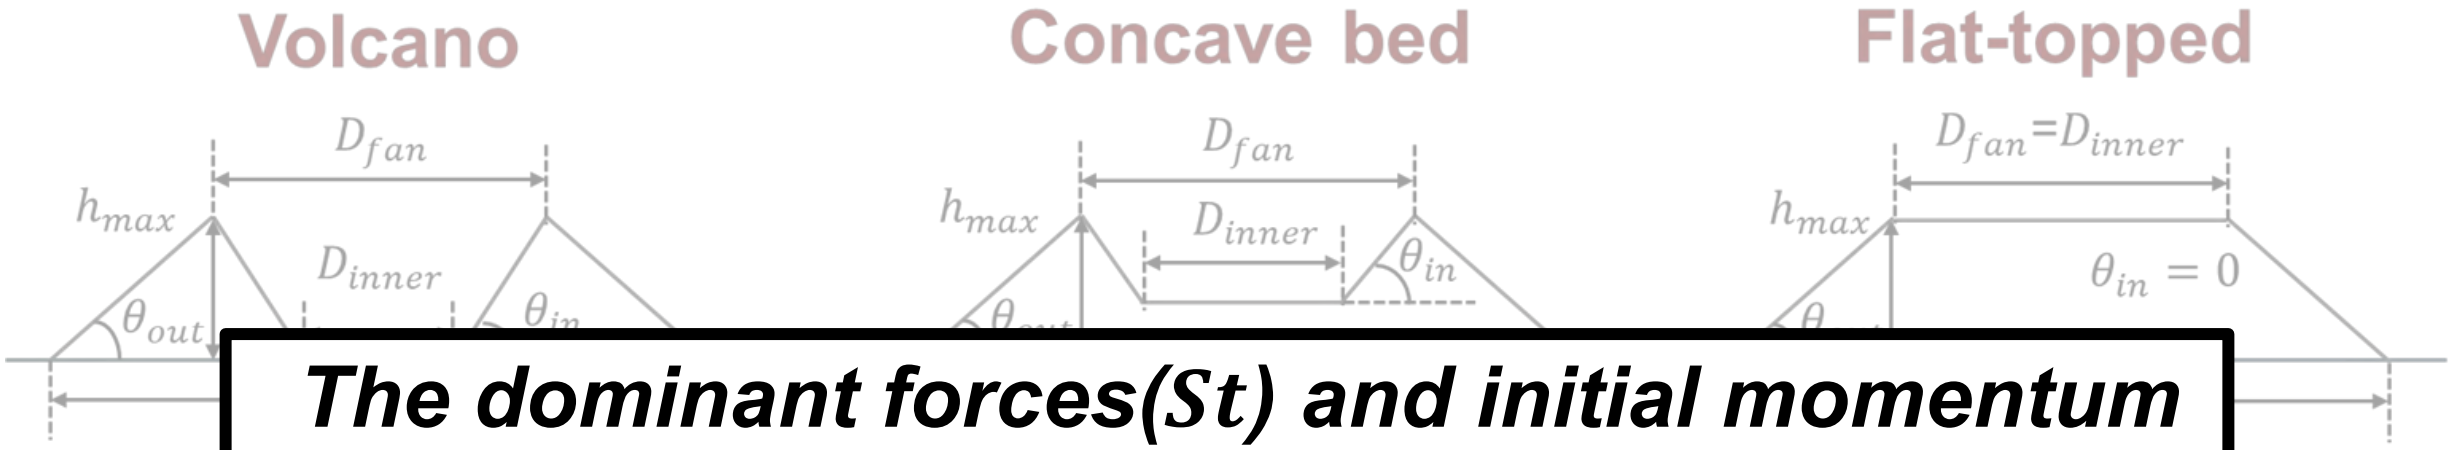
D_{outer}

- D_{outer} is affected by the balance **"flow", inertia and fluid viscosity,** which is governed by **Re_{M0}**

θ_{out}

- θ_{out} is controlled by **particle mobility under fluid and particle forces** governed by **St**

Summary of the discussion



The dominant forces(St) and initial momentum influence the DBF behavior (e.g., granular jump)

D_{inner}

- St **governs the dominant forces** and the momentum conversion process during Granular jump

D_{outer}

- D_{outer} is affected by the balance **"flow", inertia and fluid viscosity,** which is governed by Re_{M0}

θ_{out}

- θ_{out} is controlled by **particle mobility under fluid and particle forces** governed by St

6. Summary

Summary

Background
- In severe accidents of SFRs, molten core materials relocate and solidify on the core-catcher, **forming a debris bed**
- **Understanding its formation mechanism** is essential for designing core-catcher system **with optimal coolability**

Previous Studies
- 2D experiments highlighted the importance of **particle diameter** and the balance between **inertia** and **convection**
- However, their applicability to **3D configurations** remained unclear

This Study
- Conducted **3D debris bed formation experiments** with various particle sizes, densities, and nozzle conditions.
- Observed three typical bed shapes: **volcano**, **concave**, and **flat-topped**, depending on parameters

Summary

Discussion

- $\boldsymbol{D_{inner}}$ is dominated by **granular jump** and two regimes exist due to the **different conversion mechanism**
- $\boldsymbol{D_{outer}}$ is governed by the balance between **flow, inertia and fluid resistance**
- $\boldsymbol{\theta_{out}}$ is governed by **particle mobility under fluid and particle forces**, governed by $\boldsymbol{St}$

Empirical correlation

- Empirical correlation for θ_{out} was developed using dimensionless parameters representing **underlying physics**
- The proposed correlations reproduce the experimental data with **small prediction errors**.

Future Work

- Effects of realistic initial conditions (**polydispersity, surface roughness, convection**)
- Detailed analysis of **falling jet** and **granular jump**
- Simulating DBF behavior **with elastoplastic model**

ABSTRACT

In the frame of Severe Accidents studies, different ways of mitigation are currently proposed all over the world by the nuclear community. One possible way of mitigation concerns the use of new cladding concepts: the Enhanced Accident Tolerant Fuel (E-ATF) could avoid severe accidents thanks to the increase of a supplementary coping time in comparison with the current cladding such as zircalloy-4. Among the different EATF cladding under development and qualification, the chromium coated zircalloy has shown a high interest for the nuclear industry. The formation of a chromium oxide protective layer has been presented as being very resistant under steam conditions at high temperature.
The VITOX facility-PLINIUS severe accident facility at CEA-Cadarache has been recently developed in order to perform experiments simulating severe accidents conditions representative of reactor case from 1600°C till 1970°C under steam non starvation conditions. This paper presents experimental tests, calibration, instrumentation, results and analyses performed in the VITOX facility for EATF (chromium coated zircalloy) and zircalloy-4. Mechanistic oxidation behaviors of both cladding EATF and zircalloy-4 are presented, oxidation kinetics and hydrogen production laws are proposed and discussed.

KEYWORDS
EATF, zircalloy-4, oxidation by steam, hydrogen production, oxidation kinetics

1. INTRODUCTION

After the severe accidents that occurred in the three reactors of the Fukushima-Daiichi nuclear power plant in Japan in 2011, the development of new fuels Accident Tolerant Fuels (ATF) has become a priority worldwide to improve on the one hand safety and on the other hand increase the performance of the fuel in the reactor under normal conditions, notably the burn-up [1-3].
To meet these objectives, several strategies have been developed for the ATF either around the UO_2 nuclear fuel or around the cladding. For the ATFs with new cladding concepts, several ways have been explored:

change the cladding (for example replace it with a silicon carbide cladding), make surface deposits on the zircalloy cladding either on the inner side or on the external side [4]. For the external layer, several material solutions have been proposed from pure metallic phases till full oxidic phases [5].
In this paper, only the so-called E-ATF (Enhanced Accident Tolerant Fuel) cladding with chromium on zircalloy-4 is presented. Indeed, the latter offer a very good compromise: a minor modification of the fuel cladding with a specific surface treatment that will produce E-ATF. This option offers no drastic changes for the operation of the reactor but with a high potential gain considering the burn-up.
Classical zircalloy-4 and E-ATF claddings have been used for this study in order to better understand and qualify their respective behavior under severe accident conditions, i.e at high temperature between 1600°C and 1970°C under steam and non-starvation conditions, especially regarding oxidation kinetics and hydrogen production. In a first part, the main oxidation phenomena involved for zircalloy alloys are shortly reminded. In the second part, VITOX facility is described and then in the last part, some results are presented for zircalloy-4 and E-ATF claddings.

2. BEHAVIOR UNDER NORMAL, INCIDENTAL AND ACCIDENTAL CONDITIONS FOR ZIRCALLOY CLADDING AND EATF

Under normal conditions, the zirconium alloy will oxidize (stress corrosion, 330°C, 155 bars) and a thin oxide layer will form on the surface.
There are typically two oxidation regimes [6]:

- A first so-called pre-transient regime where a layer of black, adherent zirconium oxide will form. The oxidation law is a parabolic law, governed by the diffusion of oxygen through the formed oxide layer. At the beginning of oxidation, the zirconia grains are equiaxed. Then, during the anionic growth of the oxide layer, the zirconia grains grow into an elongated shape perpendicular to the metal/oxide interface.
- A second post-transient regime occurs when the zirconium oxide layer undergoes compressive stresses due to differences in bulk density (zirconium, zirconium oxide) causing the formation of cracks. Oxygen can then penetrate more quickly at the oxide/metal interface through the cracks formed and thus access the metal/oxide interface more quickly. A second layer of protective oxide is then formed and a new parabolic kinetics begins again, and so on.

The kinetics of oxidation presents itself as a succession of parabolic regimes (Figure 1), each parabolic domain ending on the cracking of the oxide layer. In all cases, the oxidation reaction at the water/cladding interface is as follows:

$$Zr_{(s)} + 2H_2O_{(liq)} \rightarrow ZrO_{2(s)} + 2xH_{2(g)} + 4(1-x)\,H \qquad \text{(Equation 1)}$$

Under LOCA conditions for a PWR fuel, two distinct kinetic regimes depending on the temperature domain are identified:

- **Temperature below 1800 K:** ***"slow" process of oxidation***
  - Swelling of the zircaloy cladding by creep due to overpressure inside the fuel
  - Phenomenon of «ballooning»
  - Risk of local rupture (1200K)
  - Beginning of oxidation at 1300K-1400K, strongly exothermic reaction aiding the rise of thermal runaway (*breakaway*):

$$Zr(s) + 2\,H_2O_{(g)} \rightarrow ZrO_2\,(s) + 2\,H_2 \quad (\Delta H = -555\text{kJ/mol}) \qquad \text{(Equation 2)}$$

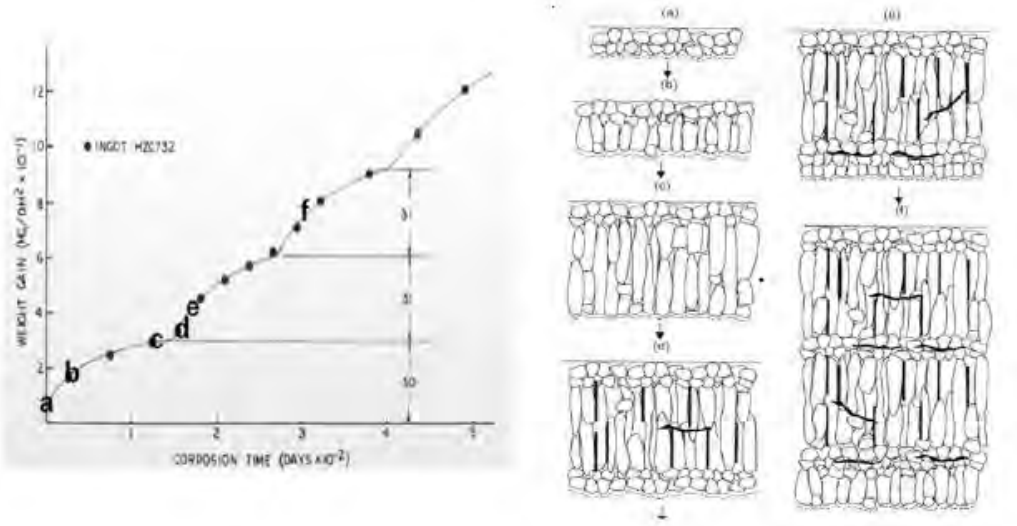

Figure 1: Oxidation regimes of the zirconium alloys cladding- Normal PWRs conditions [7].

The oxidation kinetics of zircaloy, after a transient phase, follows a parabolic type distribution expressed as [8]:

$$\mathbf{e = k_{ox}\sqrt{t}} \qquad \text{(Equation 3)}$$

- e: oxide thickness (m)
- k_{ox}: parabolic oxidation constant ($m/sec^{0.5}$)
- t: time

It has to be stressed that the parabolic constant can be expressed according to an oxidized thickness (ex-situ measurement), but usually the oxidized thickness can be non-uniform and can vary in a large manner of several tens %, hence a difficulty to estimate correctly k_{ox}. For these reasons, in the frame of this work, another approach to describe parabolic behavior is proposed to avoid this source of uncertainties.

- **For temperatures above 1800 K:** ***a "rapid" external oxidation promoting a "thermal runaway" of the zircalloy oxidation reaction***
  - Acceleration of oxidation kinetics with a factor 10 to 20 for the oxidation constant
  - Zirconia layer rupture beyond 2300 -2500 K

At the end, we can note that only extrapolation are proposed for the parabolic constant above 2000K with 2 laws with high differences as it ca be seen on the figure 2.

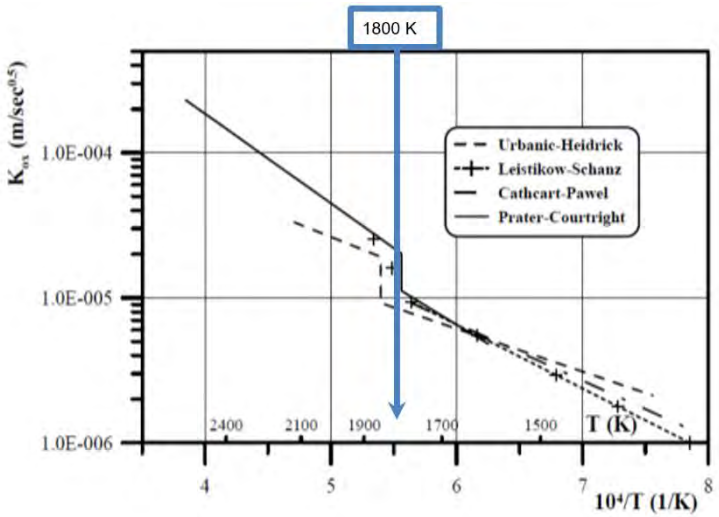

Figure 2: Oxidation parabolic constants for the zirconium alloys cladding- LOCA PWRs conditions [8].

Under normal conditions, E-ATF chromium protected cladding seem to provide an obvious benefit, notably by blocking the oxidation of the cladding thanks to the formation of Cr_2O_3 thin layer which stops oxidation phenomena of zircaloy alloys at low temperatures (360°C, 150 bars). This gain should eventually allow new features to be added to nuclear fuel, notably with higher burn-ups [9-10].
In incidental conditions, the primary objective for E-ATF is to demonstrate improved performance against current fuels up to the threshold temperature of 1500K (1200°C), qualification criterion for BDBA studies (Beyond Design Basis Accident).
Beyond incidental conditions, it would be possible with the ATF not to reach the thermal runaway temperature by "*sufficiently slowing down the oxidation and hydrogen production and assuming to recover means of water injection into the vessel after a "certain time*" as shown in Figure 3 proposed by [11].
In this ideal vision of ATFs, the entry into severe accidents with corium formation and significant hydrogen production would therefore be excluded for LOCA scenarios.

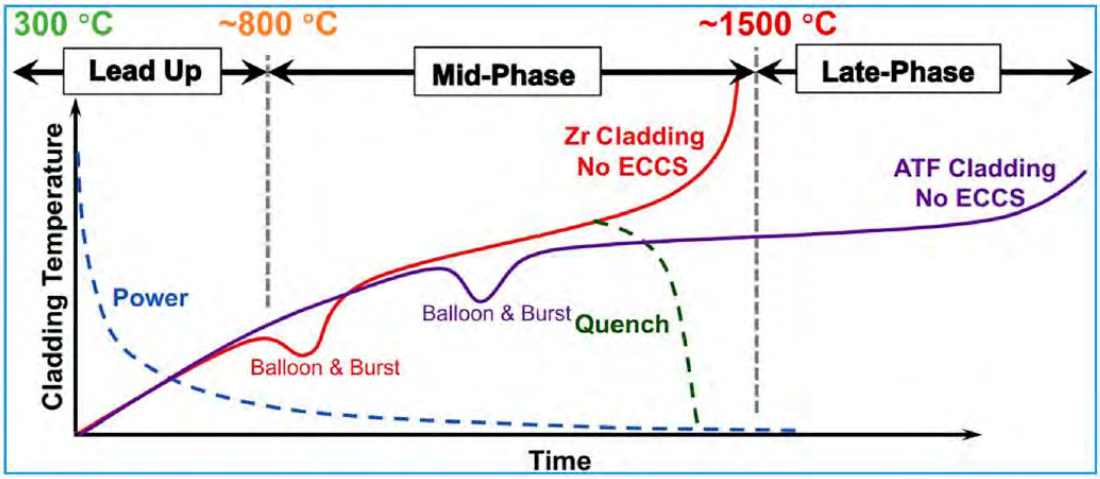

Figure 3: General overview of coolant–limited accident progression inside an LWR core [11].

For nuclear safety demonstration, the determination of the coping time to be able to recover cooling and water injection after a LOCA is crucial: if effective cooling can be recovered within this time, the accident will not escalate into a severe accident. However, if effective cooling cannot be restored regardless of the coping time, as in the Fukushima Daiichi accident, the severe accident will continue to progress. Under these conditions, - as it was the case for Fukushima-Daiichi severe accident- the severe accident will go on. Under these conditions, it is essential to assess whether chromium-coated E-ATF claddings perform better or worse than zircaloy-4 claddings.
Above 1600K (1300°C), the Cr-Zr interdiffusion is highly activated with the formation at the Cr/Zr interface of $Zr(Cr,Fe)_2$ intermetallic compounds [12]. Between 1600K and 1800K, the existence of an eutectic at low temperature at 1613K between Cr and $Zr(Cr,Fe)_2$ will generate a liquid phase [12]. This liquid phase, even if it represents a limited quantity, will modify surface properties and could accelerate candling-type phenomena at low temperatures. However, available data remain very limited at higher temperatures, and no studies are available to our knowledge on E-ATF behavior above 1900K under non–steam-starvation conditions.

3. EXPERIENCES

3.1. VITOX experimental facility

Steam oxidation experiments on Zircaloy alloys and E-ATF were conducted in the VITI facility, part of the PLINIUS Severe Accident Platform at CEA Cadarache. The VITI facility features an induction-heated furnace capable of reaching temperatures up to 2700 °C.
The VITOX (**VITI-OX**idation) configuration [13,14] has been especially develop in order to perform analytical oxidation experiments on different families of alloys at solid and liquid states with oxygen or steam and measuring on line hydrogen production and oxygen (see figure 4). For solid configuration, the sample is placed inside the crucible with the possibility to use different geometries from plates to cylinders. The design of the high-temperature cell ensures a convenient exposure of the sample to steam flow.
This assembly is confined within a so-called separating tube, all components being made of yttria-stabilised zirconia, which prevents oxidation especially of the susceptor from steam exposure. These protected components surrounding the separating tube are the susceptor and the thermal shield, made of tungsten and porous graphite, respectively. The susceptor is electromagnetically coupled to the inductor, and is heated by the resulting Joule effect in link with eddy currents. In turn, the susceptor heats the high-temperature cell up to the target temperature by radiative heat transfer. The thermal shield ensures thermal homogeneity at sample scale, by limiting thermal losses.

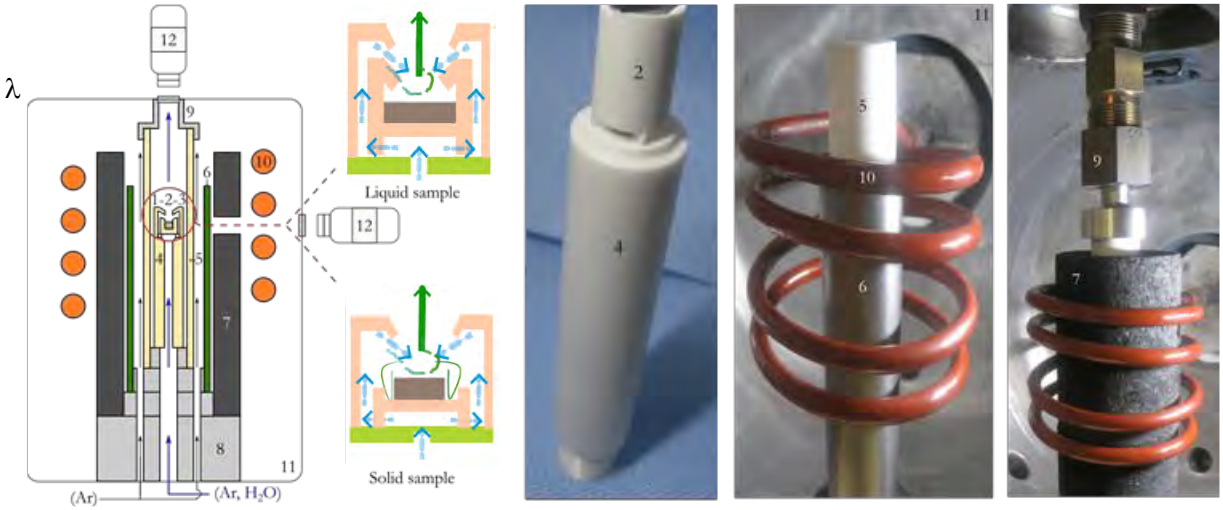

Figure 4: Experimental layout of VITOX facility. Labels: 1) 316Nb Sample, 2) Crucible, 3) Lid, 4) Support, 5) Separating tube, 6) Susceptor, 7) Thermal shield, 8) Injector, 9) Sampling rod, 10) Inductor, 11) Confinement vessel, 12) Video-pyrometers.

All the experiments are carried out inside a water-cooled confinement vessel, for the sake of controlling working atmosphere quality. Steam is generated by means of a Controlled Evaporation Mixing (CEM) unit, and flows through heated and insulated gas lines up to the injector in the lower (and cooler) part of the experiment. This injector also allows for argon gas circulation around the separating tube, providing an additional and dynamic confinement of potential steam leaks through the separating tube. The residual gases after interaction with the sample are collected downstream by means of a sampling rod connected to the separating tube. At the exhaust, a cold trap condensates residual steam, followed by hydrogen analyser. Video-pyrometers (bi-chromatic,λ_1= 0.95µm and λ_2= 1.05µm) are located either on top or on the side of the vessel and focus on the sample or on the susceptor wall, respectively. They allow for sample and susceptor monitoring during the tests, along with temperature measurements by infrared thermometry.

The instrumentation used in VITOX experiments is detailed Table I, along with related features.
The confinement vessel is first placed under primary vacuum by pumping. Argon is then injected into the furnace until 1.3 bar (absolute pressure), with a flow rate of 2 L/min. This preliminary step is cycled until the initial oxygen concentration is reduced below 30 vol.ppm to limit initial oxidation during the heating process. Heating is then initiated under a static argon atmosphere at a rate of approximately 20 ◦C/ min. Above 800°C, residual oxygen within the vessel is pumped by the graphite of the thermal shield. Once the working temperature reached and stabilized, a molar composition of 10 % H_2O and 90 % Ar for steam oxidation tests is injected in the test tube. The injection flow rate for both oxidant mediums is set at 2.60 L/min (see Figure 5).

Table I. VITOX Instrumentation

Denomination	Measurement range and accuracy
CEM Unit Bronkhorst® W-303B	Ar flow-rate $Q_{Ar} \in [1.2; 60]$ L/min. H_2O flow-rate $Q_{H_2O} \in [12; 600]$ g/h. Temperature $T_{CEM} \in [20; 200]$ °C. Manufacturer accuracy: 1% reading.
Videopyrometers Keller® PA40	Temperatures T_{K1} (susceptor) and T_{K2} (sample) $\in [800; 3000]$ °C. Two-colour pyrometers. Manufacturer accuracy: 1% reading.
Hydrogen analyzer AP2E® Proceas	Hydrogen concentration $[H_2](t) \in [0 ; 5]$ % vol. LOD = 5 ppm vol. Manufacturer accuracy : 1% reading.
Precision scale Sartorius® MCA524P -2S00-U QP99	Mass $m \in [0; 520]$ mg. Manufacturer accuracy: 0.1 mg.

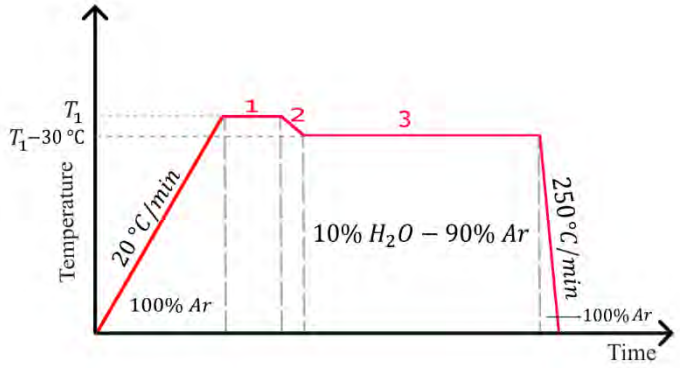

Figure 5: Thermal treatment for VITOX-test - Heating up (20°C/min) till the temperature plateau - 1 Stabilization under Ar 2- Steam injection 3- Oxidation plateau under steam

The weight gain during VITOX oxidation tests is obtained by tracking the mass balance of the gas injected into and the gas leaving the oxidation chamber. This approach allows indirect measurement. The tracking of the weight gain, standardized to the reactive surface and measured in g/cm², is established as a function of an adjustment factor k, set to align the in-situ mass reading at time "tf " with the actual mass, measured after a "tf " duration test.
For oxidation tests under steam atmosphere, it is assumed that one mole of oxygen adsorbed at the surface of the sample is equivalent to one mole of hydrogen released out of the sample.
One could define the weight gain per reactive surface unit as in equation 4:

$$W(t) = {}^{k}/_{S} \times \int_0^t C(H_2)(u).du \quad ; \quad k = \frac{m_{t_f} - m_i}{\int_0^{tf} C(H_2)(u).du} \qquad \text{(Equation 4)}$$

- W(t): weight gain of the sample, (g/cm²)
- C(H_2): volumetric concentration of in-situ released hydrogen at "t" instant, (vol.%)
- S: reactive surface of the sample, (cm²)
- t: time, (s)
- k: adjustment factor, (g/s.vol. %)
- m_i: initial mass of the sample, (g)
- m_{tf}: final mass of the sample, weighed after a "tf " duration test, (g)

Hydrogen mass release can be deduced from Eq. (4), taking the following form as formulated with Eq. (5):

$$m_{H_2}(t) = \frac{M_{H_2}}{M_o} \times W(t) \qquad \text{(Equation 5)}$$

- M_O: molar mass of oxygen, (g/mol)
- M_{H2} : molar mass of hydrogen, (g/mol)

3.2. VITOX experimental grid

In order to determine oxidation kinetics under Ar-H_2O gas of zircalloy-4 and E-ATF at solid state, different temperature representative of severe accident conditions have been chosen.

Table II. VITOX experimental grid for zircalloy-4 and E-ATF at solid state

Cladding	Temperature (°C)	Duration (sec.)	Gas composition (mol.%)
Zircalloy-4 (Cylinder, thickness 2 mm)	1600	1800	Ar (90%)-Steam (10%)
	1700	1800	Ar (90%)-Steam (10%)
	1800	1800	Ar (90%)-Steam (10%)
E-ATF (Plate, thickness 0,67 mm)	1600	600	Ar (90%)-Steam (10%)
	1700	600	Ar (90%)-Steam (10%)
	1800	600	Ar (90%)-Steam (10%)

4. RESULTS AND DISCUSSION

4.1. Zircalloy-4 oxidation at solid state

In order to compare the results obtained in this study with those of the literature regarding steam oxidation of zircaloy-4 alloy, the parabolic constant k_p has been chosen as reliable parameter. The reaction rate constants were determined using a modified parabolic model, which accounts for a 200-second threshold corresponding to an "incubation phase".The description of the parabolic law is carried out according to equation 6:

$$W(t) = \sqrt{(t - t_i) \cdot k_p + b}, \qquad \text{(Equation 6)}$$

- W(t): weight gain of the sample, (g/cm²)
- t_i: incubation period (s)
- k_p: parabolic constant (g^2/cm^4.sec.)

- b: square of the mass at the establishment of the parabolic regime (g^2/cm^4)

The experimental kinetics obtained using this approach are shown in Figure 6. In the first instants of reaction, oxidation does not follow parabolic behavior, hence the need to introduce an incubation time t_i. Moreover, oxidation kinetics increase significantly with rising temperature. At 1800 °C, complete oxidation of the sample occurs approximately 400 seconds earlier than at 1700 °C.

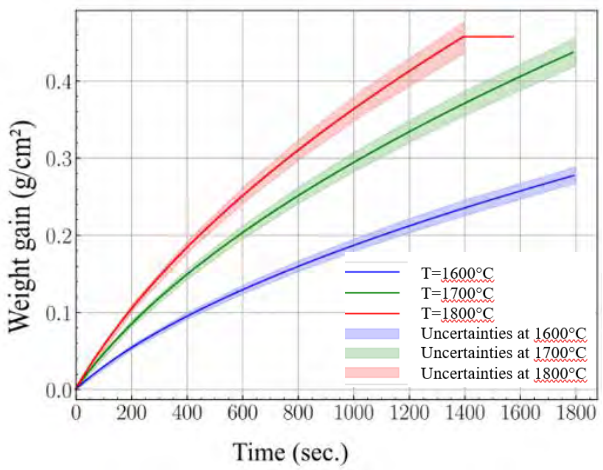

Figure 6: Weight gain for zircalloy-4 under steam at 1600, 1700, 1800°C in VITOX facility

The temperature dependence of the parabolic rate constant is shown in Figure 7, highlighting differences between the VITOX experiments and literature data [15,16]. The uncertainty in the parabolic constants k_p reported by Prater et al. [16] and Urbanic et al. [15] was calculated by accounting for the contribution of temperature, as proposed by the respective authors. The same approach was similarly applied to the VITOX data, indicating a substantial reduction in uncertainties and a more precise determination of the parabolic rate constants. The newly proposed values for the zircaloy-4 oxidation parabolic constants are higher than those reported in the literature [15,16], indicating faster oxidation kinetics.

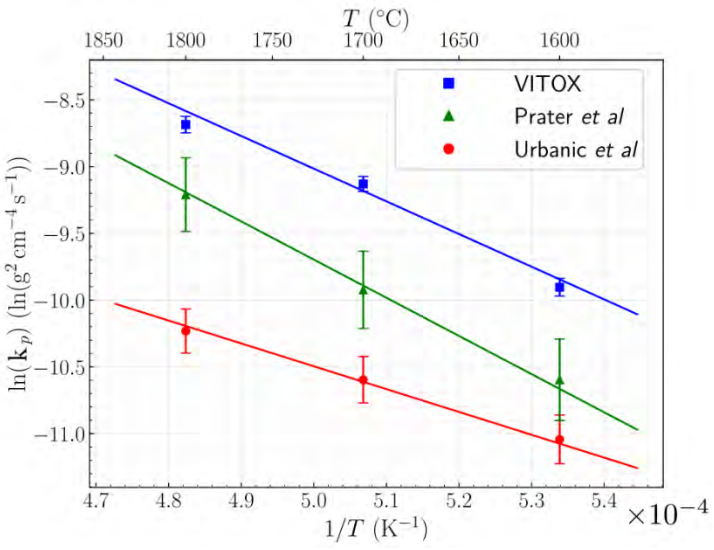

Figure 7: Evolution of the parabolic constants for zircalloy-4 for VITOX and Urbanic et al. [15] and Prater et al. [16].

In the first study reported by Prater *et al.*[16], the parabolic rate constant may be affected by the non-uniform oxide/metal interface, which can disturb the accurate determination of the effective oxide thickness. In the second study by Urbanic *et al.*[15], the total weight gain was calculated assuming the only formation of zirconia, thereby neglecting the contribution of the Zr(O) phase. Moreover, steam-starvation conditions are likely to have occurred in this experiment [15]. These methodological and experimental limitations can provide a plausible explanation to the deviation of the parabolic rate evolution between VITOX data and those of the literature [15,16].
The activation energy obtained from the VITOX data exhibits a reduced uncertainty range compared to the literature [15,16], showing a difference of approximately 55 % relative to Urbanic *et al.* [15] and about 10 % relative to Prater *et al.* [16]. (Table III).

Table III. Activation energy and their uncertainties for zircalloy-4 steam oxidation

	Urbanic et al. [15]	**Prater et al. [16]**	**VITOX**
Activation energy (J/mol)	200 300	224 000	131 000
Relative uncertainty (%)	8	19	32

4.2. E-ATF oxidation at solid state

The steam oxidation of the E-ATF alloy follows parabolic kinetics from the early instants of reaction over the temperature range 1600°C - 1800 °C. The maximum oxide weight gain is consistent across all temperatures, reaching approximately 0.16 g/cm². This value is obtained after 600 seconds at 1600 °C, 260 seconds at 1700 °C, and 150 seconds at 1800 °C (Figure 8).

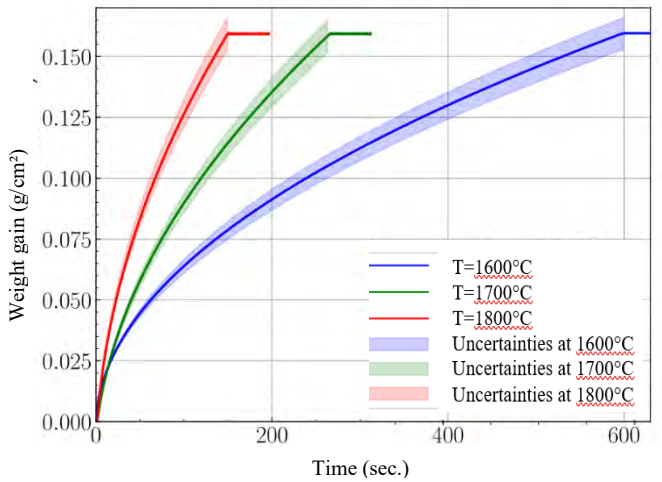

Figure 8: Weight gain E-ATF under steam at 1600, 1700, 1800°C in VITOX facility

In order to investigate the oxidation mechanism of E-ATF under steam conditions, a blank test was first conducted under argon atmosphere to characterize the distribution of metallic phases prior to steam injection. SEM–EDS analyses revealed the formation of a zirconium-rich dendritic phase and an inter-dendritic chromium-rich phase. The atomic fraction of chromium at the external interface was approximately 30.26 %. The presence of such microstructure indicates the complete consumption of chromium to form a Zr–Cr eutectic phase at 1600 °C [12]. Upon steam injection, oxidation of the Zr–Cr

eutectic phase induces the formation of an α-Zr(O) layer at the external interface, along with inward migration of the remaining eutectic into the bulk of the sample. Subsequent oxygen diffusion leads to progressive consumption of α-Zr(O) and the formation of zirconia throughout the sample. Chromium released during oxidation of the Zr–Cr eutectic precipitates within the internally formed zirconia, ultimately leading, after complete zirconium consumption, to a biphasic layer composed of chromia Cr_2O_3 and zirconia ZrO_2 (Figure 9).

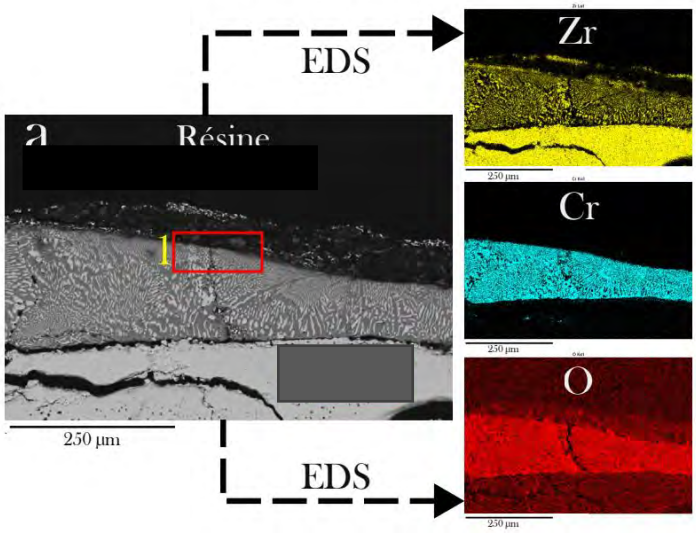

Figure 9: BSD image of the upper part of the E-ATF sample after oxidation under steam at 1800 °C and EDS acquisitions of the elements Zr, Cr and O-Eutectics-Upper part

At both 1700 °C and 1800 °C, oxidation of the E-ATF alloy results in the formation of a lamellar microstructure and spherical inclusions of both zirconia and chromia phases, likely indicating the formation of a Zr-Cr-O eutectic phase (Figure 10). Final state is slightly different at 1600°C.

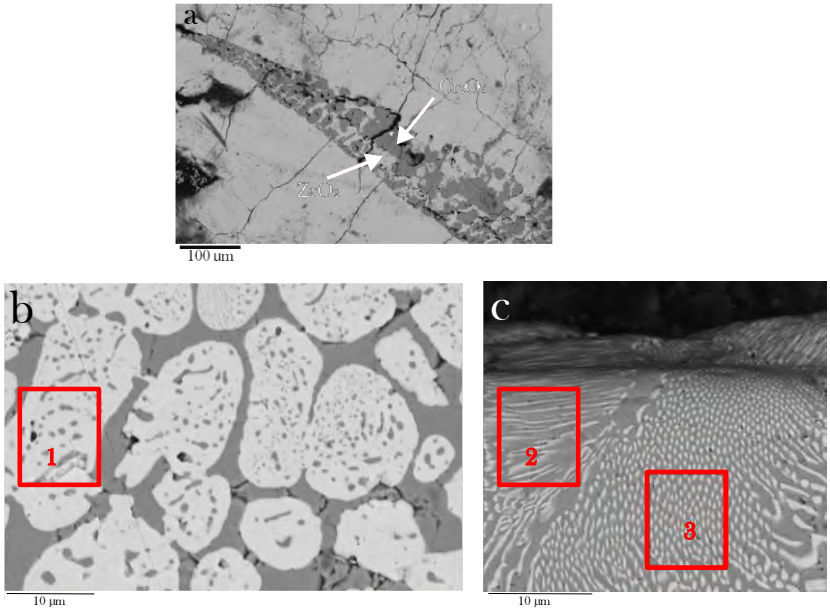

Figure 10: (a) - BSD image of biphasic layer of zirconia and chromia. (b-1) – BSD image of submicrometric inclusions of chromia within zirconia cells. (c-1) – lamellar microstructure of zirconia in chromia layer. (c-2) – inclusions of zirconia in chromia layer-

4.3. Comparison Zircalloy-4/E-ATF oxidation at solid state

For the first time, it has been possible to study the oxidation of E-ATF at temperature representative of severe accident conditions. As seen in the previous section, E-ATF oxidation kinetic follows a parabolic trend between 1600 °C and 1800 °C. It is possible to do a direct comparison between E-ATF and zircalloy-4. Figure 11 presents the activation energies established from parabolic constants. The activation energy of the E-ATF alloy corresponds to a value of 220.000 kJ/mol whereas it is about 203.000 kJ/mol for zircalloy-4.

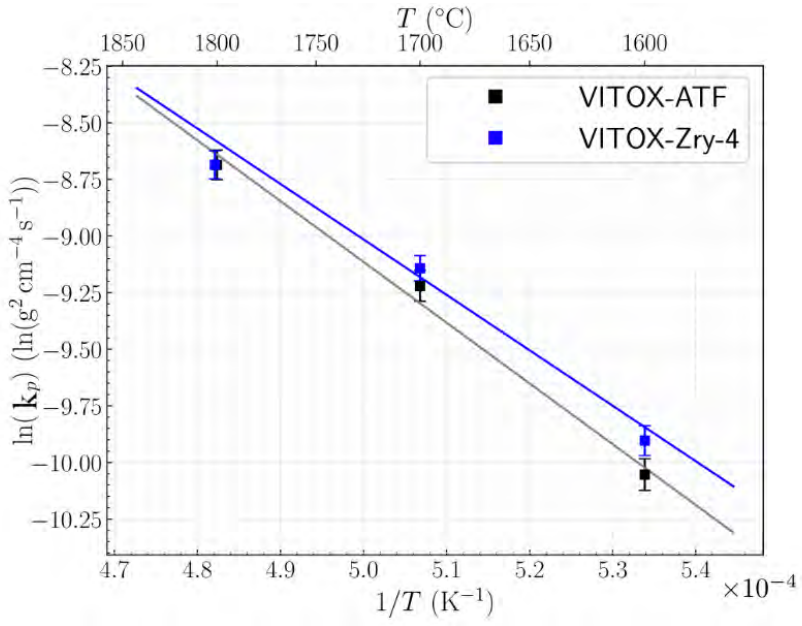

Figure 11: evolution of the oxidation parabolic constants for zircalloy-4 and E-ATF

These new results show that the coupling between the steam oxidation and the formation of an eutectic liquid phase for EATF leads to a macroscopic behavior close to zircaloy 4 at temperature above 1600°C, the activation energy being the same order of magnitude for both cladding. The impact of the formation of a liquid phase on the mechanical behavior of the cladding pin is not today clearly understood and will need complementary studies to assess if it moderates or accelerates the degradation and delocalization phenomena.

5. CONCLUSIONS

After Fukushima accidents, a lot of efforts has been done all over the world to develop and qualify new tools for mitigation in the frame of severe accident management. One important way of mitigation concerns the E-ATF for which different concepts have been proposed. One concept concerns the chromium coating protective layer on zircalloy. This new family of E-ATF cladding should offer a coping time to manage the severe accident.

In order to quantify the steam oxidation effect on both zircalloy-4 and E-ATF, a specific facility has been developed, the VITOX facility (**VIT**I-**Ox**idation), to follow on-line hydrogen production and oxidation kinetics under non steam starvation conditions. The new methodology proposed more reliable results for zircalloy-4 steam oxidation studies. A more rapid kinetic of zircalloy-4 above 1600°C is proposed in this work in comparison with the previous literature [16].

The behavior of E-ATF shows above 1600°C in isothermal conditions a behavior close to zircalloy-4 under steam non starvation conditions, meaning the total disappearance of the chromium protective effect. The

impact of formation of a liquid phase due to the formation of a eutectic seems to play an effect at second order on the oxidation mechanism.
The process of E-ATF manufacturing seems to play a negligible effect on oxidation phenomena and hydrogen production.
Transitory conditions for zircalloy-4 and E-ATF have to be studied and compared to complete the knowledge concerning the oxidation and hydrogen production mechanism at temperature above 1600°C and in non-starvation conditions.

ACKNOWLEDGMENTS

The authors gratefully thank Martin Steinbrueck (KIT) for the E-ATF materials and for the very fruitful discussion on steam oxidation of zircalloy-4 and EATF.

ABSTRACT

The development and deployment of Small Modular Reactors (SMRs), specifically integral Pressurized Water Reactors (iPWRs), promise enhanced safety and flexibility in nuclear power generation. However, understanding the behavior of these reactors during severe accidents, particularly the core degradation and source term — the release and transport of radioactive materials — remains a critical area of investigation. This study focus on the core degradation phenomena in iPWR SMRs. Unlike large traditional reactors, the integrated design of iPWR SMRs, with their smaller cores, compact primary systems, and passive safety features, introduces unique factors that affect the progression of core degradation and the resulting source term. MELCOR v2.2.r2023.0 is used to model severe accident scenarios in a 160MWth submerged containment natural circulation PWR. A Design Basis Accident (DBA) involving loss of coolant accident (LOCA) occurring in the chemical volume control system (CVCS) discharge line inside the CNT, with expected functioning of emergency core cooling system (ECCS) is analyzed. Progression during additional design extension conditions were also assessed. The role of LOCA break sizes is analyzed to assess its impact on mitigating core degradation. Preliminary results reveal that the compact design and passive features of iPWR SMRs can significantly alter the dynamics of core degradation and fission product behavior compared to traditional reactors. These findings provide valuable insights for refining source term models specific to iPWR SMRs and contributes to the broader understanding of severe accident phenomena in advanced reactor designs and supports the development of safety guidelines tailored to SMRs.

1. INTRODUCTION

There is growing interest in deploying Small Modular Reactors (SMRs) to cater to growing energy demands by large data centers and industries, and to replace energy sources with large carbon footprint increasingly due to their ability in meeting flexible power needs [1]. SMRs enjoy better safety features, including inherent, passive, integral safety features, than conventional reactors, drawing to its appeal [2]. SMRs also promise simplification and standardization making it economically feasible. Among over 70 designs of SMRs available from the last 60 years of development [2], Integral Pressurized Water Reactors (iPWRs) are of interest. These are designs where the reactor primary circuit is housed together as an integral component [4]. This integral design, with a smaller core, promises “safety by design” and when scaled can effectively cater to flexible power demands with load-following operability. Although advancements have been made in different SMR technologies , with a few reactors already in operation or under construction in Russia and China, certain technical aspects are in focus pertaining, but not limited to, instrumentation, control and human factor engineering, development of new codes and standards for license and operation, source term for multiple module plants and establishment of emergency planning zones during accidents [3]. Discussions with regulators regarding elimination of public evacuations are ongoing.

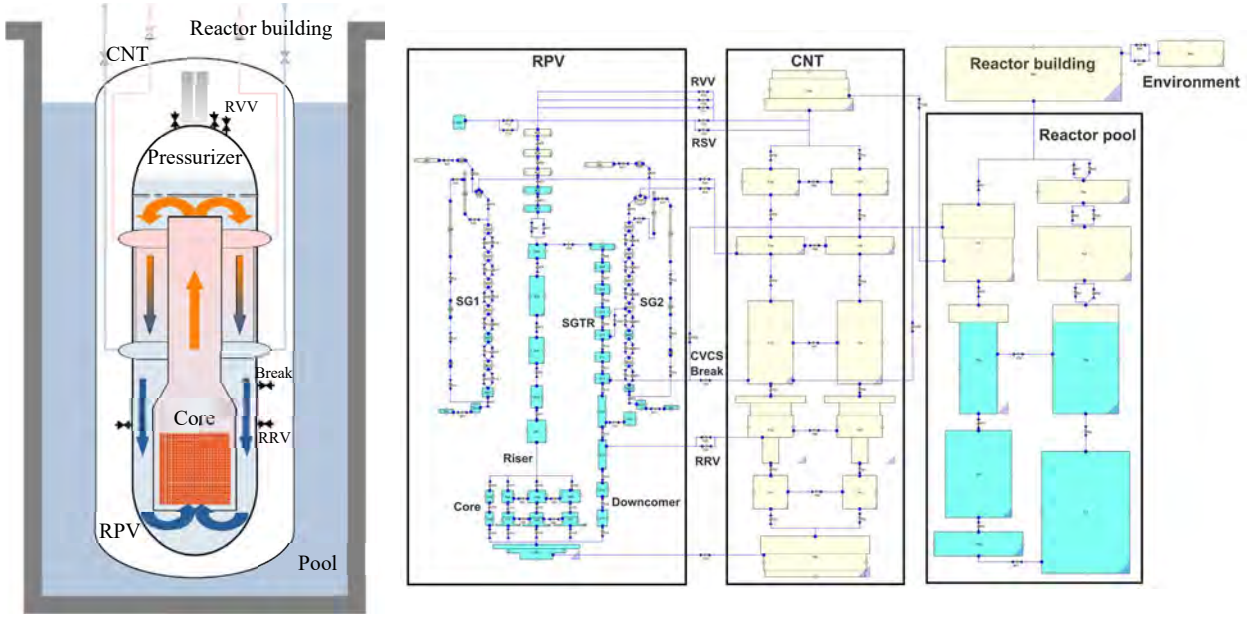
With international interest in the technology and technical aspects needing more knowledge, EURATOMs SASPAM-SA project, the frame under which this study is undertaken, commenced in 2022 in order to address these challenges and support European licensing needs relevant to analysis of severe accidents (SA) and emergency planning zones (EPZ) [5]. Due to certain uniqueness of the designs of iPWRs, the capability of system codes and analytical tools to analyze the complex phenomenon in the reactor during an adverse event is a challenge that is being addressed by many studies [11][12][13][14]. Hydrogen explosions [6], forced and natural circulation passive safety [7][8], in-vessel cooling and debris retention [9], containment phenomena and behaviour [10] are some of the aspects in focus for SMR design analysis. Typically, SA codes such as MELCOR or ASTEC, are used in modelling accidents and are validated against experiments. These integral codes were designed for use in large reactor analysis. When new phenomena, such as in SMRs, where extensive experimental data are unavailable, use of system codes may include uncertainties based on modelling or design choices. This requires adequate knowledge of code capabilities and shortcomings, motivating current research.

Recently, generic designs of iPWRs were analyzed where a design basis accident (DBA) and some design extension conditions (DEC) were simulated [5][15][16]. The thermal-hydraulic characterization during the accident progression, conditions of vessel and containment, show counter intuitive behaviour of peak cladding temperature (PCT) when compared to large-PWRs. Capability of MELCOR in stable and accurate simulation of iPWR during loss of coolant accident (LOCA) was demonstrated [17][18]. The conservative source term behaviour in iPWR during severe accidents was recently analyzed in a complementary study [19]. In this study, SA analysis for a generic iPWR design is performed for accident scenarios with focus on core degradation and further T/H characterization, as part of activities in the SASPAM-SA project.

2. iPWR MODEL DESCRIPTION

The generic iPWR design under consideration is of the submerged containment type, where the integral reactor vessel is housed inside a larger containment which is submerged inside a pool of water, shown in Figure 1(a). The MELCOR model is a development of input deck developed by [15][16]. The specifications were based on available open literature. The iPWR is a 160MWth, naturally cooled integral reactor with 2 helical tube steam generators (HTSG). The reactor pressure vessel (RPV) is contained inside a containment vessel (CNT) to maintain core cooling in case of potential loss of reactor vessel integrity. The primary system operating pressure is 8.3MPa and CNT is almost a vacuum. In case of accidents the, steam generators (SGs) are isolated and emergency core cooling system (ECCS), comprising of 3 reactor ventilation valves (RVVs) at the top of RPV and 2 reactor recirculation valves (RRVs) at elevation above top of active fuel (TAF), is activated which opens the RVVs to vent steam into the containment, and the RRVs which establishes coolant circulation between the reactor coolant system (RCS) and the containment side transferring decay heat to the reactor pool (RP) acting as the ultimate heat sink (UHS). The core has 37 17x17 fuel assemblies, about half the height of typical PWR assemblies located at the bottom of the RPV. Above the core, a cylindrical riser tube terminates in the pressurizer (PRZ). The downcomer, an annular region surrounding the riser, houses the two HTSGs in the upper part and the core in the lower part. The HTSG consists of a set of tube bundles with separate feedwater inlet and steam outlet lines. The MELCOR model of the iPWR, shown in Figure 1(b), comprises of control volumes (CVs) representing parts of RPV, SGs, CNT, RP, reactor building and the environment, and flowpaths (FLs) representing connections between CVs. Details of packages used to develop inputs in MELCOR can be found in the guides [15][16].

The T/H behaviour is dependent on the assumptions and choices made in nodalization of these CVs and properties of FLs. Here, the RPV has 5 CVs for the riser, 5 CVs for the PRZ, 7 CVs for SG primary side, 5 CVs for the downcomer, 8 CVs for the core channel and bypass, and 1 CV for the lower plenum (LP). Heat structures (HS) transfer heat between CVs, here, cylindrical HS are defined between RPV and CVN axially, and hemispherical HS are defined at top and bottom of RPV.



(a) Generic design. (b) MELCOR nodalization.

Figure 1. Schematic of the generic iPWR design (based on [15]).

The CNT is defined by 12 CVs, separately for the cold and hot side to support natural convection, to reduce instabilities in simulations, while RP has 8 CVs. The SG is a bundle of once through HTSG, whose secondary side has 2 sets with 7 CVs each. The heat transfer inside is modelled using HelicalSG HS in MELCOR. HSs also exist for the CNT designed to support natural convection in the pool. FLs exist between CVs in the core, riser, downcomer, SGs and CNT. A leakage FL is added to the top of CNT with the top of RP, and the flow rate is controlled by a tabular depending on pressure differences. The core is modelled in the COR package, as 4 rings radially and 10 levels axially. Active core is in the central 3 rings and levels 6-9, the lower plate in level 4 and lower plenum in levels 1-3. 2 reactor safety valves (RSV) are included to protect RPV from over-pressure. Decay heat tables based on ANS73 standard are implemented. The radionuclide transport is handled by the RN package, where hygroscopic and chemisorption models are activated. Revised CORSOR-Booth high burnup model is used for fission product (FP) release.

2.1. Accident Scenarios

The DBA and DEC scenarios studied here are given in Table 1 below. The SA identified in SASPAM-SA were based on potential severity of consequences and not on probability of occurrence. A LOCA in chemical volume and control system (CVCS) discharge line, 1.6” diameter, is assumed to be the initiator in DBA, with fully functioning ECCS. Postulated DECs, referenced as in the table, include spurious opening of the RVV and RRV either with fully or partially functioning ECCS. In order to analyze non-LOCA type scenarios in the CNT, a 13mm tube rupture in the SG and loss of feedwater leading to loss of heat sink (LOHS) are included. Unavailability of RRVs during an accident voids natural circulation in the CNT.

The conditions for activation of the ECCS (ECCS signal) are as follows. RVVs and RRVs open simultaneously after 15s of both these conditions being met:

1. High containment water level – above 5.8m,
2. Low RCS pressure – pressure difference between PRZ and CNT is below 6.2MPa.

Table I. Accident scenarios considered for analysis.

Scenario ID	Initiator	ECCS availability		Comments
		RVV	RRV	
DBA	CVCS discharge LOCA	Yes	Yes	1.6” LOCA in CVCS discharge to CNT
DBAN	CVCS discharge LOCA	No	No	1.6” LOCA in CVCS discharge to CNT
SA1	CVCS discharge LOCA	Yes	No	1.6” LOCA in CVCS discharge to CNT
SA1o	CVCS discharge LOCA	Yes 1	No	1.6” LOCA in CVCS discharge to CNT
SA2	Spurious opening of 1 RVV	Yes 2	No	2.5” RVV opening of 1 RVV
SA2N	Spurious opening of 1 RVV	No	No	2.5” RVV opening of 1 RVV
SA3	Spurious opening of 1 RRV	No	Yes 1	2.5” RRV opening of 1 RRV
SA3N	Spurious opening of 1 RRV	No	No	2.5” RRV opening of 1 RRV
SA4	CVCS discharge LOCA	Yes	Yes	1.6” LOCA in CVCS to RP
SA4N	CVCS discharge LOCA	No	No	1.6” LOCA in CVCS to RP
SA5	CVCS discharge LOCA	Yes	Yes	1.6” LOCA in CVCS to CNT, breach in CNT to RP
SA5N	CVCS discharge LOCA	No	No	1.6” LOCA in CVCS to CNT, breach in CNT to RP
SA6	SG tube rupture (SGTR)	Yes	Yes	No steam line isolation, feedwater line isolated
SA6N	SG tube rupture (SGTR)	No	No	No steam line isolation, feedwater line isolated
SA7	Loss of heat sink (LOHS)	Yes	Yes	Steam line and feedwater line isolated

In open literature (for instance NuScale), activation of RRVs have inadvertent actuation block (IAB), wherein RRVs open only after IAB clears (pressure difference between PRZ and CNT is < 6.2MPa). While in LOCA type situation this may imply RRVs open almost simultaneously with RVVs, in actuality that may not be the case. The sensitivity of timing of RVV and RRV activation on the accident progression is performed in a separate study, where RRVs open only after RVVs open with set delay time and low RCS condition is met. In this study, the sensitivity of accident progression on size of break is analyzed by considering 12 CVCS break size diameters from 0.1cm to 4.4cm in the absence of ECCS. On a spectrum, DBAN scenario would be the 11th case with 4cm diameter LOCA and LOHS would be the 0th case with no LOCA. In the case of SGTR accident (SA6), where there is no loss of coolant to the CNT, condition 1 is not satisfied. Hence, it is assumed ECCS is activated upon fulfilling condition 2.

From the perspective of FP release pathway to the environment: DBA/DBAN, SA1/SA1o, SA2/SA2N, SA3/SA3N, SA7 cases have a leakage FL from the containment to the reactor building, SA4/SA4N, SA5/SA5N cases have, in addition to leakage, direct/indirect FL from the RPV to the reactor building, and in the case of SA6/SA6N FPs trace a pathway from RPV into the turbine CVs through ruptured SG tube, which in this study is considered to be outside the containment pressure boundary and hence part of the environment.

3. RESULTS

Here, results of MELCOR simulations are presented with timing of events, T/H considerations, and core behaviour. All accident scenarios were run using MELCOR v2.2.r2023 for 72h. In some of the figures presented, the range is shortened for better readability. Table 2 shows the timing of reactor trip signal, ECCS signal, core uncovery and core damage process.

3.1. Thermal-hydraulic Behaviour

DBA and DBAN: In LOCA type scenarios where coolant is lost directly to CNT (CVCS line break or spurious opening of valves), reactor trips between 4 and 44s. In the case of DBA, once the reactor trips,

depressurizes into and fills the CNT, ECCS is activated at 520s. This initiates circulation of coolant between RPV and CNT, enabling removal of decay heat. The elevation of CVCS break is at 9m, and RRV at 5.6m. Water fills the containment, subsequently, decay heat boils the water and steam produced escapes majorly through the RVVs and the break, see Figure 2(a). The released steam condenses on the CNT walls and collects adding to circulating pool below. In the RRVs, Figure 2(b), both positive and negative flow are observed, indicating convection of the coolant. Figure 2(c) shows the collapsed liquid levels in the RPV and the CNT, where at ~10.5m after the start of accident, levels on either side of the RPV are stabilized. One can observe the heat transfer rates, Figure 2(d), from the core to the water (in blue) coinciding with decay heat (in yellow), indicating successful cooling and expected behaviour of ECCS. The fuel and cladding temperature during this scenario can be observed in Figure 3(a).

Table II. Timing of events during the accident scenarios.

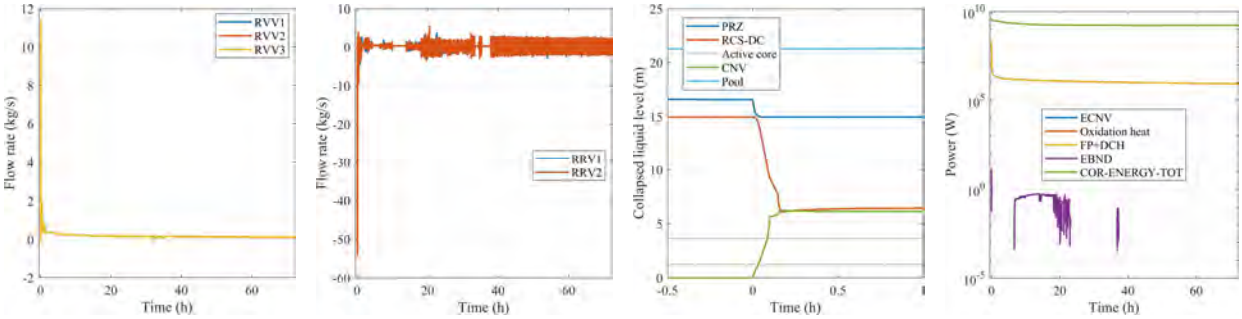
SA7	23	-	-	-	-	-	-	-	-

SCRAM - safety control rod axe man/reactor trip; PD - particulate debris; LH - RPV lower head.

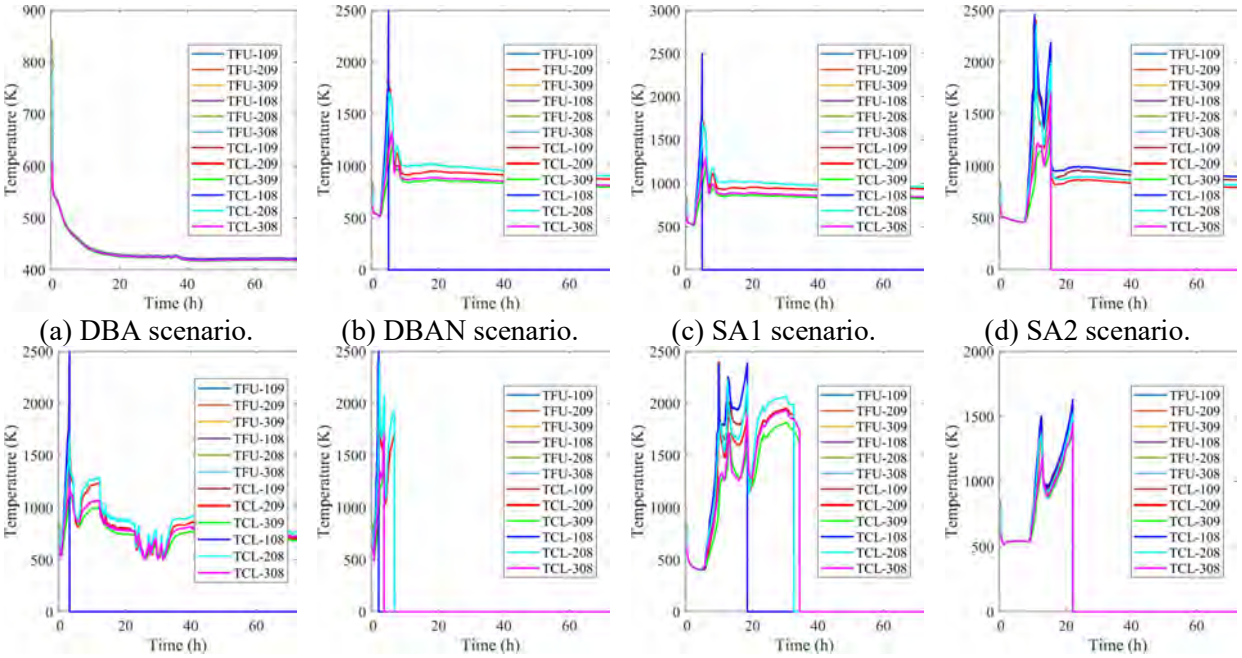
With absence of ECCS, in DBAN, circulation of water is not established, steam mainly flows outwards, till level in RPV reaches the break elevation that is filling the CNT. Then the water surrounding the core boils off slowly, because steam can only escape from the break (not through RVVs). Core starts uncovering at 4950s. Subsequently, (i) once the level falls below the core in the LP, it takes a longer time to boil into steam, (ii) there is no direct core cooling by water, and (iii) the heat from the core is removed by steam and by conduction across lower head (LH) to water in CNT. The cladding is exposed to steam, undergoing oxidation and generating hydrogen and oxidation heat in the process. This further accelerates degradation of the fuel rods, ultimately leading to failure of cladding due to high temperature, see Figure 3(b) the first failure of cladding occurs around 5h. When this happens, irrespective of the axial level where the failure occurs, FPs in the entire fuel-cladding gap are released, at 12782s. Formation of particulate debris (PD) – resulting from collapse of fuel rods and other components – follows at 13728s.

Fuel and cladding in the upper levels start melting and relocating downwards by gravity (candling). If the molten mass is cooled, it may refreeze onto other intact material forming conglomerate debris (DC). With insufficient cooling, more such intact material degrades, relocating downwards. This mixture of molten material, particulate debris and conglomerate debris would then relocate onto the core support plate.



(a) RVV flow rate. (b) RRV flow rate. (c) Collapsed liquid levels. (d) Rate of heat transfers.

Figure 2. Evolution of T/H properties during DBA scenario. ECNV: convective heat transfer, FP+DCH: fission power and decay heat, EBND: conductive heat transfer (to HSs), COR-ENERGY-TOT: total energy handled in COR package.



(a) DBA scenario. (b) DBAN scenario. (c) SA1 scenario. (d) SA2 scenario.

(e) SA3N scenario. (f) SA4 scenario. (g) SA5 scenario. (h) SA6N scenario.

Figure 3. Fuel and cladding temperature in the top 2 axial levels. TFU: cell fuel temperature, TCL: cell cladding temperature.

SA1 and SA1o scenarios. SA1/SA1o scenario have progressions similar to DBAN, except that with the availability of RVVs, loss of coolant inventory from the reactor vessel is accelerated. In DBAN, SA1 and SA1o, the opening at RVVs and the break, create a circulation pattern of steam around the core, cooling it for a longer period preventing degradation, without large relocation to the LH, see Figure 4(a) and (b) for mass of steam in the core and LP regions.

SA2, SA2N, SA3 and SA3N scenarios. In the case of SA2, SA2N, SA3 and SA3N, the loss of coolant occurs via the opening of larger ECCS valves (2.5" v/s 1.6" of CVCS) – SCRAM is quicker. However, with opening of RVV loss of RCS is through steam escaping out at top of RPV, whilst with opening of RRV, loss is through water flowing out at just above active core level: latter case sends faster ECCS signal at 61s compared to 8640s of the former scenarios. It is observed, quiet expectedly, that core uncovery in SA2 and

SA2N happens much later than SA3 and SA3N, see Figure 5(a), when boiling of water in RPV starts there is smaller quantity of water inside RPV so uncovery is faster. Irrespective of availability of ECCS, during SA2/SA2N, failure of the core support plate and debris collection in the LP is observed.

With twice the larger area in SA3 compared to SA3N for escaping steam, uncovery is almost twice as fast. One thing to be noted here is that, if the total inventory of RCS were to be transferred to the CNT, it would fill to a level above RRV elevation (lower than CVCS break elevation). Therefore, when water starts collecting in CNT, there is counter-current flow of escaping steam and incoming water in the RRVs. This can be sensitive to accident progression, because any slight change in T/H conditions can lead to large change in water level inside the RPV, subsequently causing variations in core cooling. Between SA3 and SA3N, a variation of flow area is shown to either induce debris relocation to LH (at 12830s in SA3N) or not (in SA3), suggesting a limiting area of flow that avoids relocation of debris. Figure 6(a) and (b) show the mass of steam in RPV during SA3 and SA3N. Unavailability of ECCS, for a brief period at ~3.5h during SA3N accident causes sufficient cooling deficit conditions in the LP and core regions leading to debris relocation to LP, see Figure 3(e) the drop of cladding material temperature in the innermost ring of the top axial level of the core.

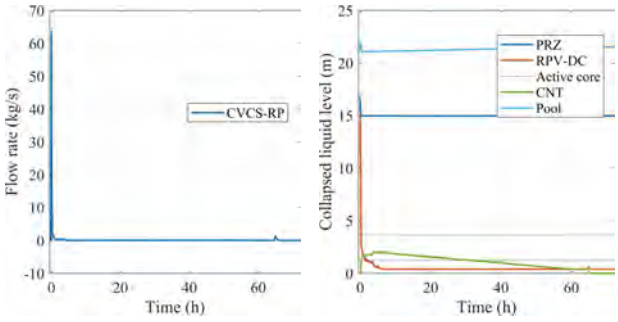
Figure 6. Mass of steam inside RPV.



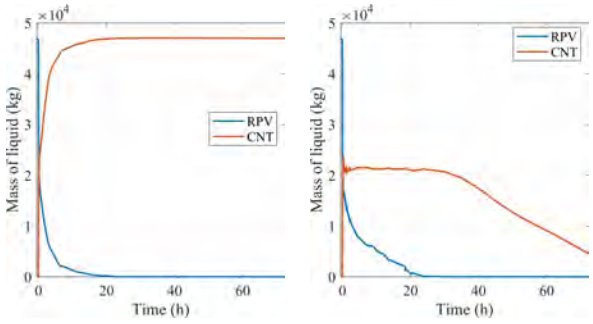
(a) Flow rate. (b) Collapsed liquid level.

Figure 7. Flow rate of the break and liquid level during SA4 scenario.

SA4 and SA4N scenarios. In these scenarios, the containment is bypassed and the coolant is lost directly from the downcomer to the reactor pool. The flow rates through the break and the liquid level are shown in Figure 7(a) and (b). SA4 has the fastest complete core uncovery, by 2h liquid level is below bottom of active fuel (BAF). As seen in Table II, these scenarios have the earliest onset of debris formation and gap releases amongst all the cases considered. As seen in Figure 7(b), before ECCS activation level at 815s, CNT is

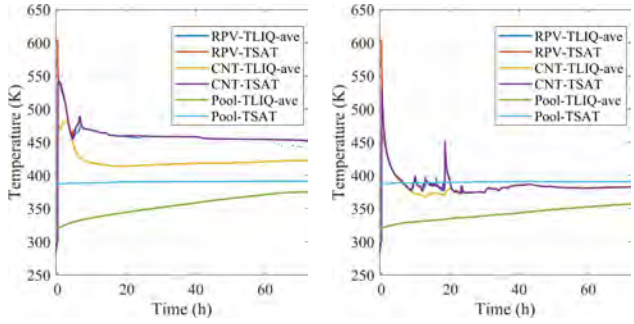
filled due to steam escaping the RPV through safety valves by overpressure. After ECCS activation, CNT is filled by water, and the liquid inventory in the RPV and CNT has reached such low levels that activating ECCS does not establish circulation through the RRVs. ECCS is therefore unable to prevent the eventual core degradation and relocation at 10426s. Subsequently, the support plate fails at 12057s. In the case of SA4N, this relocation is observed at 13071s, instantly followed by support plate failure. Expectedly, this scenario leads to a failure of the LH 232843s for SA4 and 33682s for SA4N due to insufficient cooling of the debris pool. This is one of the most severest of scenarios, where time period from core uncovery to vessel failure is less than 10h.

SA5 and SA5N scenarios. In these two scenarios, the core is partially covered with water for most of the 72h, and the natural circulation inside RPV is restricted. In the case of SA5, a break in CVCS line causes LOCA and simultaneously a flow is established from the CNT to the reactor pool, so that coolant can escape as steam directly to the reactor building, leading to loss of coolant inventory in the reactor, see Figure 8(b). Until 20h, the coolant from the RPV flows into the CNT, post which, total mass of liquid water (that could sustain core cooling) in the CNT starts reducing. Compared to DBAN scenario, the coolant temperatures inside the CNT in SA5 is lower, see Figure 9(a) and (b) (where TLIQ: liquid temperature, TSAT: saturation temperature of the liquid). Because in the case of DBAN, the containment pressure boundary is not breached, the pressure in the CNT is high compared to SA5, where the pressure is almost atmospheric, see Figure 5(b) (red line). Correspondingly, in Figure 9(a), the water saturation temperature in the CNT is higher (purple line) and the water in CNT does not boil (yellow line). However, in the case of SA5, saturation temperature of water in CNT is lower, accelerating conversion to steam and loss to the RP. The flow rate of the pathway leading out of the CNT is shown in Figure 10(a). A maximum of 6kg/s flow rate of steam is initially observed, due to high CNT pressure, which gradually reduces to atmospheric. A small peak at ~18h is observed due to pressure spike caused by core degradation.



(a) DBAN scenario. (b) SA5 scenario.

Figure 8. Mass of coolant inside the CNT boundary.



(a) DBAN scenario. (b) SA5 scenario.

Figure 9. Water temperature in RPV, CNT and RP.

SA6 and SA6N scenarios. In the case of SA6 and SA6N, with rupture of a single tube of the SG and opening a containment bypass pathway to the turbines, SCRAM occurs late at 30s, because the depressurization caused in RPV is slow (also the pressure in the CNT is unaffected as it is bypassed, similar to SA4/SA4N case) to trigger reactor trip. Another point to note is that in SA6N, since CNT is bypassed, water does not accumulate there, just as in the case of SA4N. The flow rate of steam through the tube rupture is shown in Figure 10(b). Negative values indicate flow into the SG. Flow rate peaks to ~9.3kg/s initially due to high primary side pressure, see Figure 5(b) (light green line). The depressurization due to flow into SG is insufficient to balance pressure generated by superheated steam, the reactor safety valves are triggered at 14.75MPa pressure. This causes steam to flow into the CNT, that condenses and flows to the bottom (which is why liquid temperature increase in CNT is observed in Figure 11(a) (purple line)). The RSV closes once primary reaches 14.7MPa. Once the primary side is sufficiently depressurized, boiling water in the core increases the pressure, sufficiently higher than in other SA cases, at ~5.5MPa. Core uncovery starts at 27350s, the longest it takes amongst all SA cases where core is uncovered, because of the time needed for

evaporation of entire RCS inventory and RPV dryout. Gap release occurs at 40220s and relocation of debris to LH at 72145s. The core support plate fails at 79230s and roughly 1.2h later at 84320s the LH fails. Once the LH fails, the CNT is instantly pressurized and water inside is vaporized.

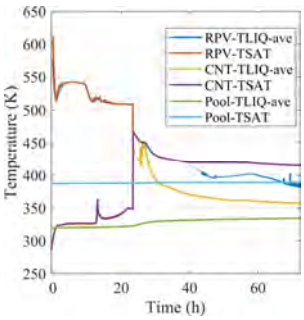
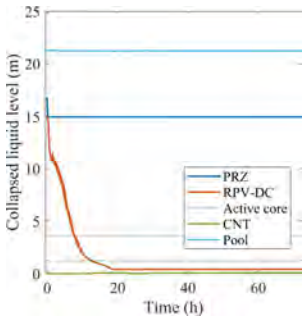
(b) SA6 scenario.

Figure 10. Flow rate of the break pathways.



(a) Water temperatures.

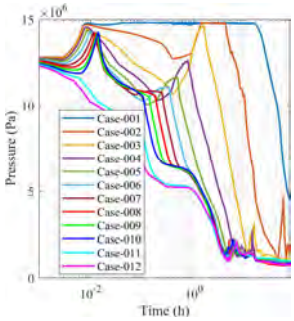


(b) Collapsed liquid level.

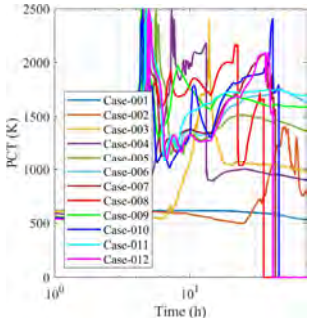
Figure 11. T/H properties during SA6N scenario.

SA7 scenario. In the case where no LOCA or SGTR event occurs, and only the feedwater flow is stopped leading to loss of heat sink (LOHS), the primary pressure increases once the reactor trips at 23.2s. There is no vent for the steam being generated by the boiling of water, and the RPV pressure increases beyond 14.75MPa, triggering the RSV, see Figure 5(b) (dark blue line). This vents out steam continuously for >10h as liquid level in the RPV drops and in the CNT increases. Once the CNT water level surrounds the active fuel region (after ~10h), this creates stronger direct heat transfer from the core to the RP, which hitherto was filled with air and steam, thus a weaker heat transfer. Once this happens, the temperatures of the fuel gradually reduce because of higher rate of removal of decay heat, and the pressure inside the RPV reduces further, and eventually venting in the RSV stops. No core uncovery is observed until the end of 72h at which time the primary pressure is about 10MPa. This scenario is similar in many ways to a very small sized LOCA at the top of RPV.

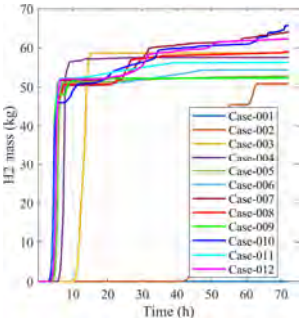
Effect of LOCA break sizes. To analyze effect of break sizes, a spectrum of scenarios is considered with 12 sizes uniformly spaced between 0.1cm and 4.4cm (Case-001 to Case-012). Firstly, the effect in DBAN is presented, followed by SA4N and SA5N. The ECCS is assumed unavailable in all scenarios. The reference scenarios (DBAN, SA4N and SA5N) would be equivalent to 11th case with a break size of 4cm. The T/H and accident progression parameters for these accident scenarios are shown in Figure 12, Figure 13 and Figure 14.



(a) RPV pressure.



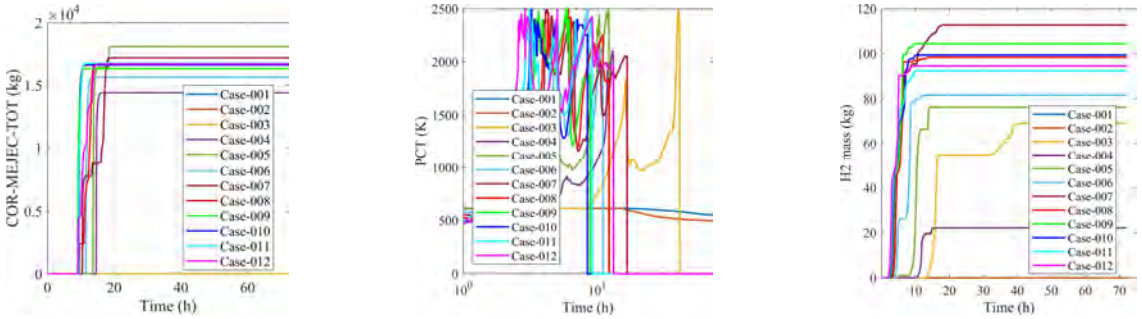
(b) PCT.



(c) H_2 generation.

Figure 12. SA characterization for DBAN cases with varying break sizes.

For varying sizes during DBAN, reactor trip causes the RCS pressure to increase, and in cases lacking sufficient break flow area, pressure does not fall. The smaller size of the LOCA break does not lead to loss of pressure in the RPV, as does larger LOCA. This leads to initial venting via RSV. In the case of 001 the RSV does not close until sufficient loss of steam into the CNT. In the case of 002 and 003, after closing of RSV, the rising pressure by the boiling of water and insufficient loss of water to CNT for circulation, reactivates the RSV briefly. Other cases lead to higher depressurization and subsequent uncovery of the core is expectedly faster with increasing size. Core degradation phenomenon is not linear. Cases 010, 008 and 007 lead to complete damage of the core (indicated by the vertical drop in PCT signal in the plot). Case 009 leads only to ~10% damaged core. In the former cases, complete dryout and steam starvation is observed. However, the size of break in Case 009 (diameter of 3.275cm) is sufficient to circulate steam inside the RPV and transfer the decay heat to the water in the CNT. PCT is also lower in 009, than 010 and 008 for instance. Such non-trivial behavior needs to be verified by further analysis and experimental observations.

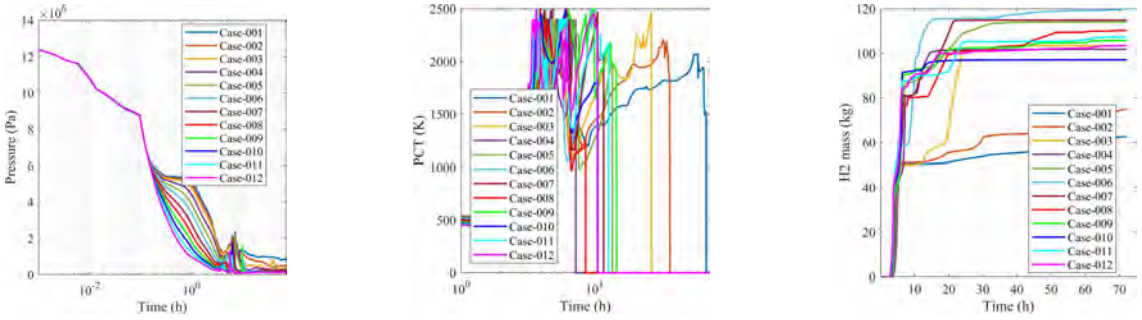


(a) Core debris mass ejection. (b) PCT. (c) H_2 generation.

Figure 13. SA characterization for SA4N cases with varying break sizes.

In the case of SA4N with varying break flow sizes, pressure trends match the case of DBAN, however the downstream control volume is the reactor pool instead of the CNT, which leads to loss of debris cooling capacity with empty CNT. Consequently, what is observed is that Cases 001 and 002 because of small break size, retains sufficient coolant inventory saving the core from uncovery. All other larger break sizes lead to complete uncovery and core degradation, and except for Case 003, lead to RPV failure and debris ejection to the CNT at 9-15h after onset of LOCA. Between Case 003 and Case 004 corresponding to break size 0.89cm and 1.29cm lies the limiting size that can avoid complete RPV failure. Roughly 14-18tons of debris is ejected from the RPV to the CNT. Largest debris ejection is observed for Case 005 at ~18tons where almost all debris formed is ejected, whereas in other cases, some conglomerate and particulate debris remain in the core. Total H_2 generation for Case 007 is the largest at ~113kg. Generally SA4N cases lead to almost twice the amount of H_2 generation compared with DBAN. However, in DBAN the hydrogen accumulates inside the CNT whereas in SA4N cases it flows out to the reactor building.

In the case of SA5N with changing the break sizes, it is seen from Figure 14(b) that all considered sizes lead to complete core damage. The RPV pressure follows a typical evolution as seen from DBAN case, with the variations arising from subsequent loss of steam from the varying sized break CNT to the RP. Because there is an intermediate control volume between RPV and the RP enough steam circulation is possible to maintain debris cooling to prevent RPV failure, even in Case 012 with the largest break size. Similar to SA4N cases, total H_2 generation extends from ~62kg for Case 001 to a maximum of ~120kg for Case 006. Largely, all the hydrogen is transferred along with steam into the reactor building and very small amounts are retained in the CNT itself. Complete core uncovery is observed to occur between ~3.5h to ~5.5h and correspondingly, complete core damage between ~7.2h to ~70h. This indicates a double-sided LOCA break inside the CNT is able to retain the debris inside the RPV without failing the LH for 72h irrespective of the size of break, unlike a break inside the RPV itself (SA4N). A similar analysis on the effect of size of tube rupture during SGTR (SA6N) is in progress and will be presented in the future.



(a) RPV pressure. (b) PCT. (c) H_2 generation.

Figure 14. SA characterization for SA5N cases with varying break sizes.

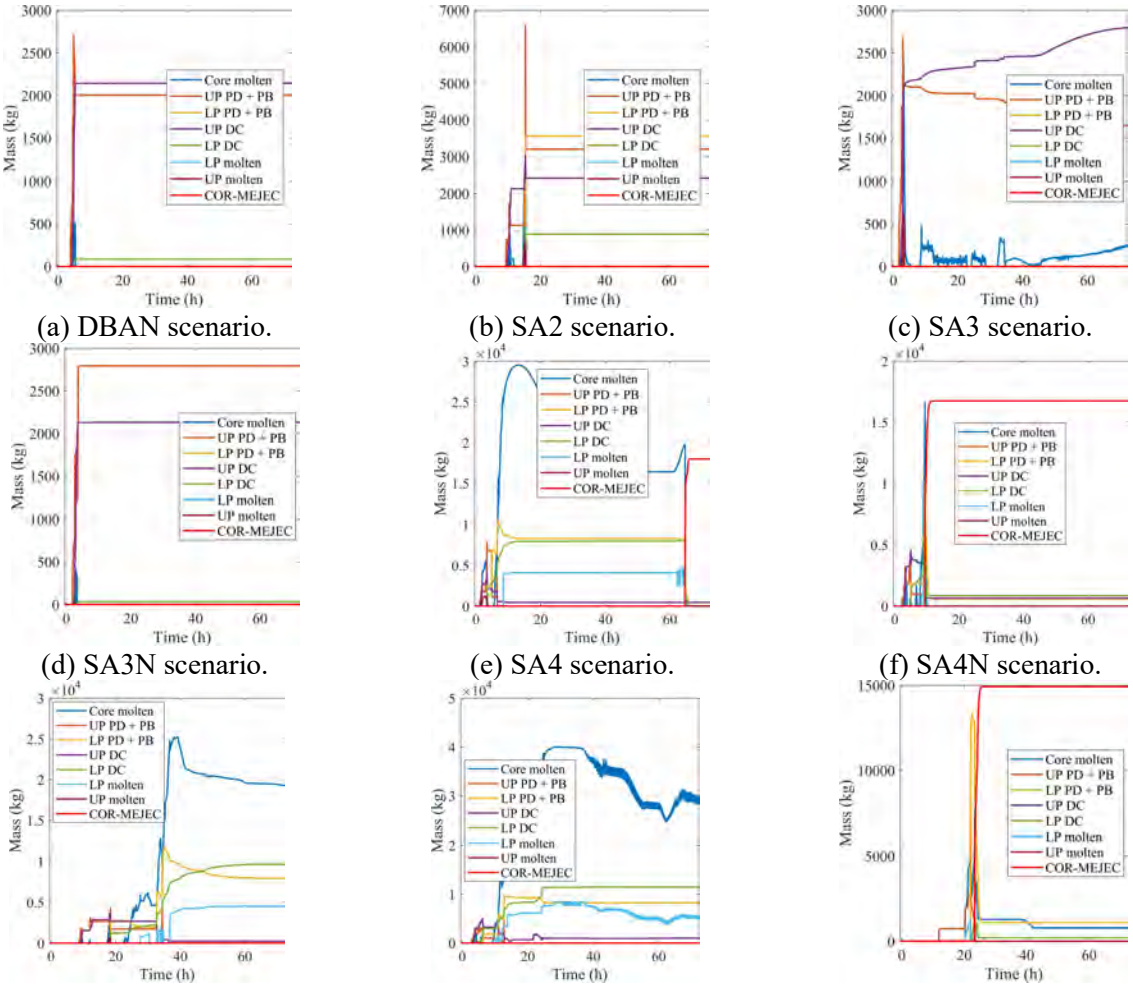
3.2. Core Degradation

The mass of solid and molten debris for scenarios with uncovery and damaged core (DBAN, SA2, SA3, SA3N, SA4, SA4N, SA5, SA5N and SA6N) are presented in Figure 15. As mentioned before, following uncovery, the cladding is oxidized and ultimately fails in absence of cooling. This starts fuel oxidation and, with increasing temperature of the fuel-cladding (UO_2/ZrO_2) eutectic mixture, can melt and candle. Presence of oxide layer in the cladding can contain the molten ZrO_2 inside the shell. Any failure of material component forms particulate debris that slumps to the bottom of core. The overall damage fraction of the core (defined as fraction of fuel that is no longer intact due to loss of support, liquefaction or melting) for all scenarios is shown in Figure 17(a). In the case of DBAN, since the commencement of PD formation, 2200kg of DC and 2000kg of PD are formed in the core region. Until 72h, this debris is oxidized slowly without reaching component failure temperature, as the circulating steam cools the core without further degradation. When the core support plate fails, the falling debris (if water exists in the LP) can be quenched. Oxidation of the core components generates about 60kg of H_2 at the end of 72h. SA1 has similar magnitudes and behaviour of debris masses and is not shown in the figure, however it generates the least H_2 among the cases considered, about 55kg.

In the cases of SA2, SA3 and SA3N, initial damage of core is similar (~10% damage fraction), resulting in the formation of 3000kg, 2100kg and 2750kg of PD and 2100kg, 2750kg and 2100kg of DC in the core region respectively. It is also interesting to note that in SA3, the total damage fraction is 10%, the top 2 axial levels of the central ring have failed, whereas in SA3N, the damage fraction is 0.2%, with major failure in any of the core cells. However, in both the cases, comparable PD and DC are formed, mainly due to damage of the cladding. This is the effect of, as noted earlier, limiting area of the RRV that keeps the core partially covered with counter-current flow in partially activated ECCS. SA2 generates about 70kg, SA3 59kg and SA3N slightly higher 68kg of H_2 at the end of the simulation. Due to failure of the support plate, about 4500kg and 80kg debris are relocated to the LP in SA2 and SA3N respectively.

By 10h due to insufficient cooling of the core, about 16tons of PD+DC have relocated to the lower plenum and around 4tons form a molten pool during SA4 generating about 110kg of H_2. The debris remain as such without any further relocation due to sufficient water in the CNT transferring the decay heat until about 65h when the CNT is dry around the LP region effectively removing major heat transfer. Subsequent to RPV failure all debris, around 18tons, is ejected to the CNT vessel. In the case of SA4N at 10h, due to unavailability of water in the CNT, any debris relocation to LP almost instantly fails the RPV and ejects about 17tons of debris. This scenario generates about 92kg of H_2 by oxidation. In the case of SA5, at ~10h about 10tons of PD+DC forms in the core region which relocates to the LP at ~20h. Some of the debris is quenched forming almost forming about 2tons of DC in the LP. From about 32h onwards the water in the CNT falls below TAF and due to insufficient cooling more debris relocation occurs, forming 4.5tons molten pool in the LP and an additional 18tons of PD+DC generating about 165kg H_2. The, now rapidly evaporating, water in the CNT keeps extracting decay heat until 72h preventing further degradation.

With SA6, ECCS is activated upon satisfaction of the ECCS low pressure condition. However, the loss of coolant inventory through the tube rupture is slow that core is never uncovered by 72h. In SA6N, with high pressure conditions – about 5MPa until 10h (full core uncovery) followed by about 3MPa, which is the highest among all cases considered in this study during early core degradation – water inventory in the RPV is lost completely by 20h forming about 1000kg of PD in the core. Once the core plate fails at 72145s, further core damage is observed reaching 100% by 22h, which drives relocation to the LP forming about 14.2tons of PD+DC. This is massive relocation causes instant lowerhead failure ejecting 15tons of debris to the CNT with a breach area of 0.045m^2, which subsequently cooled by the reactor pool. In total, during this accident about 64kg of H_2 is generated.



(a) DBAN scenario. (b) SA2 scenario. (c) SA3 scenario.

(g) SA5 scenario. (h) SA5N scenario. (h) SA6N scenario.

Figure 15. Solid and molten debris mass formation during the postulated accident scenarios.

A point of observation is that, with the failure of LH in this design as observed during SA4, SA4N and SA6N, the distance between LH and CNT vessel is small, ~0.4m. This can cause plugging of the breach by the ejected debris. Experimental evidence may be necessary to accurately describe the porosity of the debris and flow characteristics of molten material through the breach. Once the LH fails, pressure in the CNT equalizes with the RPV in cases with unavailable ECCS. The ejected debris may interact with the CNT support structures, melting the steel. At the moment the CAV package in MELCOR that represents the CNT is setup in the Design 1 deck as concrete and will be upgraded to include other appropriate material. The water that is retained or relieved through safety valves in CNT, quenches the hot debris and decay heat is transferred to the RP eventually. The temperature evolution of the RP is shown in Figure 16. The pool

temperature, acting as the UHS, is indicative of effective core cooling. It can be observed that 3 different "type" of behaviour is observed. First, CNT is filled with no out-flow: either due to LOCA (or SGTR) or activation of ECCS and there is no flow path from the CNT (DBA, DBAN, SA1, SA1o, SA2, SA2N, SA3, SA3N, SA6, SA7). Second, CNT is filled with out-flow: either due to LOCA (SA5 and SA5N) or activation of ECCS (SA4) and open flow path to the pool. Third, CNT is completely bypassed: either due to LOCA directly to the pool (SA4N) or SGTR with no ECCS activation (SA6N). Since the last 2 types have cases with RPV failure, it can be expected that SA5 and SA5N that do not lead to failure within 72h may indeed fail beyond this period without accident management strategies. Furthermore, analysis on the effect of delayed activation of ECCS during these accidents is underway.

4. CONCLUSIONS

The work presented in this study aimed to demonstrate capability of system SA code MELCOR in successfully simulating postulated DBA and severe accidents in a submerged containment type generic iPWR. In the DBA scenario, the code demonstrates its ability to simulate passive safety (natural circulation) to prevent core uncovery. Several DEC scenarios involving spurious opening of RVV or RRV, loss of heat sink, and SG tube rupture were simulated with MELCOR. The code can qualitatively and quantitatively address specific phenomena affecting SMRs. The need to verify code accuracy in simulating natural convection with flow constraints, and behavior of debris accumulation in the vessel lower head were identified. Largely, all SA scenarios behave similarly in 3 groups, for their ability to transfer decay heat from the core to the reactor pool. The delay in activating ECCS, and filling of the containment vessel can affect this transfer, leading to severe core damage (DBA with ECCS v/s DBAN without ECCS, SA2 with ECCS v/s SA2N without ECCS). When the break of the primary system is closer to the core, fraction of core damage also depends on the area of the break (SA3N vs SA3, latter with twice the area). Together with delay, the capacity of ECCS can induce non-linear effects on SA phenomena. Non-LOCA accidents such as SGTR can be a challenge for iPWR, that have design and size constraints. The helical tube SGs are susceptible to inadvertent operational degradation leading to rupture. Under such a scenario, the behavior of the reactor systems was shown to be non-trivial. STR and cases with CNT bypassed almost certainly lead to full core damage with high likelihood of RPV failure. This necessitates analysis of severe accident measures in mitigating ex-vessel accident progression.

The size of break in the CVCS was shown to affect core degradation. In regions with extreme, coupled interactions in the core, the accident may progress differently with minor changes in the conditions (Case 009 v/s Case 008 and 010). The presence of small amounts of circulating steam inside the RPV significantly altered the reactor conditions. MELCOR code's capability to handle such situations needs to be addressed with further sensitivity and uncertainty studies. As was demonstrated with counterintuitive behavior of LOCA break sizes, advanced search algorithms could be employed to identify input domains that can lead to a SA. These results support further tasks of SASPAM-SA in best estimate analysis and assessments of emergency planning zones.

EU SASPAM-SA Project

- Increasing global interest in deploying SMRs has necessitated activities in support of licensing such reactors – particularly iPWRs.
- There is also a need for demonstrating ability of iPWRs to prevent and manage SAs.
- Can knowledge and experience in operating large LWRs be applied to iPWRs?
  - Main objective of HORIZON-EURATOM '**S**afety **A**nalysis of **S**MR with **PA**ssive **M**itigation strategies - **S**evere **A**ccidents' project launched in 2022.
- Key Outcomes:
  - Support iPWR licensing process by demonstration needed for the safety.
  - Speed up the licensing and siting process of iPWRs in Europe.
- Key Highlights:
  - Applicability of large LWR reactor knowledge and know-how to the near-term deployment iPWR, in view of SA and EPZ analyses, will be assessed and consolidated.
  - Identify the research priorities in terms of methodology, code development and experimental needs.
  - Support regulators in decision-making as well as Industry and TSOs in assessing the applicability of iPWR safety features.

Work Packages: KTH Contributions

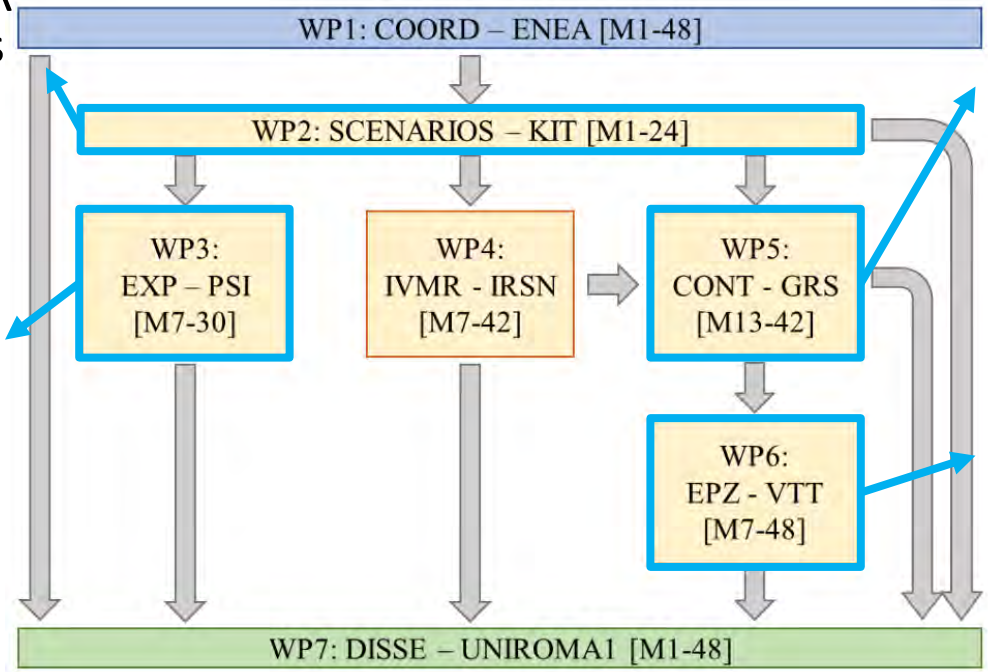
Current

Develop and assess generic but representative iPWR SA code input-decks and to identify plausible SA scenarios.

2.1

Review the existing experimental database, to assess its applicability to iPWR, to propose methods to apply existing data to iPWR, and to identify new experimental needs.

3.1, 3.2



Assess the codes to simulate the main containment behaviour (TH, FP and aerosol) and characterize the efficiency of passive measures for accident mitigation.

5.1, 5.2

Provide EPZ size and extension for selected SA scenarios coupling the results of ST codes to radiological consequences tools.

6.2, 6.3, 6.4

Core damage fraction

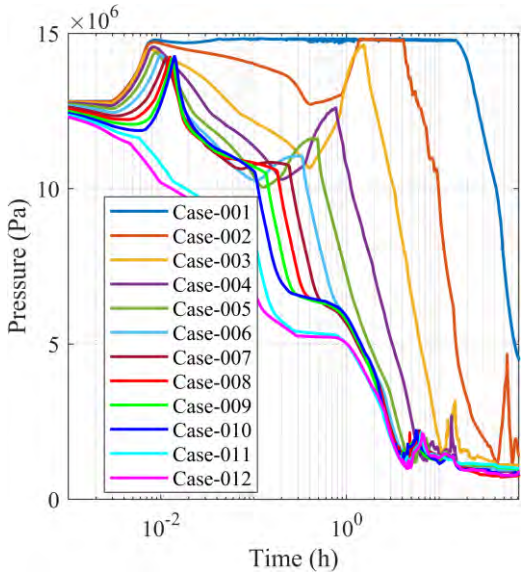
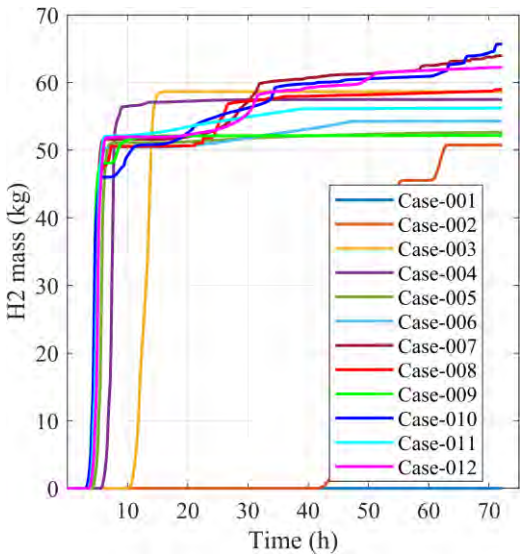
Pressure



Hydrogen generated



- Very small sizes cause activation of RSV, as LOCA does not cause sufficient depressurization.
  - In 002 and 003, after closing of RSV, the rising pressure by the boiling of water and insufficient loss of water to CNT for circulation, reactivates the RSV.
- Cases 012, 010, 008 and 007 lead to complete damage of the core.
  - Cases 009 and 010 lead to only 10% core damage, with the break sizes allowing for sufficient steam circulation that prevents complete core damage. In other cases, complete dryout of the core is observed.

Hydrogen generated

- Enough steam circulation is possible to maintain debris cooling to prevent RPV failure, even in case 012.
- Hydrogen mass generated is similar to SA4N cases.

Summary and Outlook

- As contribution to SASPAM-SA project MELCOR is used to simulate postulated accidents.
- Several scenarios leading to SA were simulated. The code can qualitatively and quantitatively address specific phenomena affecting SMRs.
- The need to verify code accuracy in simulating natural convection with flow constraints, and behavior of debris accumulation in the vessel lower head were identified.
- Largely, all SA scenarios behave similarly in 3 groups, for their ability to transfer decay heat from the core to the reactor pool.
  - The delay in activating ECCS, and filling of the containment vessel can affect this transfer, leading to severe core damage (DBA with ECCS v/s DBAN without ECCS, SA2 with ECCS v/s SA2N without ECCS).
- SGTR and cases with CNT bypassed almost certainly lead to full core damage with high likelihood of RPV failure.
- The size of break in the CVCS was shown to affect core degradation. In regions with extreme, coupled interactions in the core, the accident may progress differently with minor changes in the conditions.
- Advanced search algorithms could be employed to identify input domains that can lead to a SA – under development.
- Further parametric analysis for DBAN, SA4N, SA5N are in progress – feeds to WP6 assessment of emergency planning zones.

ABSTRACT

Small Modular Reactors (SMRs), particularly integral Pressurized Water Reactor (iPWR) designs, are emerging as a viable option for providing flexible, scalable and inherently safer nuclear power generation to meet the global energy demand. To further enhance the safety margins of these systems in the event of an accident, Advanced Technology Fuel (ATF) materials have been proposed as alternative to traditional

zirconium-based fuel cladding. Specifically, FeCrAl alloys are gaining interest due to their superior high-temperature oxidation resistance and ability to reduce the hydrogen generation, as demonstrated in separate effect experiments and in the QUENCH-19 bundle test conducted at the Karlsruhe Institute of Technology (KIT) in 2018.

In this framework, the HORIZON-EURATOM SASPAM-SA project, initiated in 2022 and coordinated by ENEA (Italy), aims to address fundamental knowledge gaps in the modelling and understanding of severe accident (SA) progression in generic iPWR designs. Among the tasks within the project, one focuses on assessing the performance of integral codes to simulate postulated SA scenarios involving FeCrAl as a cladding material. Within Work Package 2, coordinated by KIT (Germany), numerical analyses were conducted using the ASTEC, AC^2 and MELCOR codes to investigate the behaviour of two generic iPWR designs under SA conditions, comparing the performance of FeCrAl with conventional Zircaloy.

All codes demonstrated an overall capability to simulate the reduction of H_2 production in the early stage of the SA scenarios associated to the use of FeCrAl as cladding material. The incorporation of FeCrAl also led to delays in the onset of high-temperature transients. Although some differences were observed across the codes based on each model implementation, and the current models available for FeCrAl present limitations and uncertainties at advanced degradation stages, the general trends consistently highlight the potential of FeCrAl to mitigate risk and enhance safety.

Severe Accident Analysis, Small Modular Reactors, Advanced Technology Fuels (ATF), FeCrAl Cladding

1. INTRODUCTION

Small Modular Reactors (SMRs) have been gaining significant attention as a next-generation nuclear option due to their modular deployment strategies, versatile markets applications, such as remote or industrial settings, and improved safety features [1]. Alongside plant-level innovations, enhancements to the fuel system are being explored to strengthen safety margins during beyond-design-basis conditions. Advanced Technology Fuels (ATFs), previously termed Accident-Tolerant Fuels, represent an important component of this effort as they are designed to delay core degradation and maintain the overall reactor integrity during Severe Accident (SA) scenarios, thus providing extended time for emergency and operator actions [2]. Fe-based alloy, such as FeCrAl, are among the most promising concepts (along with Cr-coated Zr and SiC) due to their superior oxidation resistance in high-temperature steam environment and balanced mechanical properties when compared to Zircaloy [3-5].

Many SMR designs, particularly Integral Pressurized Water Reactors (iPWRs), feature passive safety functions that reinforce the initial levels of the defense-in-depth (DiD) principle. However, regulatory expectations also require the demonstration of independent safety analysis prevention and mitigation capabilities (DiD level 4) and adequate support for offsite emergency response (DiD level 5). This requires dedicated analytical studies under postulated SA conditions [6, 7]. Within this context, the EU-funded SASPAM-SA project (Safety Analysis of SMRs with PAssive Mitigation Strategies - Severe Accidents), which was initiated in 2022 and is being coordinated by ENEA (Italy), is addressing this need by evaluating how knowledge from large commercial LWRs can be transferred to iPWR concepts [8-10]. As part of the SASPAM-SA project, a specific study was conducted to evaluate the influence of ATF cladding on SA progression in two generic iPWR configurations. The main objective of this research is not to assess the designs or to stablish a formal benchmark, but rather to evaluate modelling capabilities and how integral codes simulate critical in-vessel phenomena. This particular study involved the collaborative efforts of six international organizations (ENEA, KIT, LEI, RUB, UNIROMA1 and VTT) using three system codes (ASTEC, AC^2 and MELCOR).

This paper summarizes the results of the comparative study of SA sequence simulations using FeCrAl and Zircaloy as cladding materials. This work highlights the different modelling approaches and code implementations used for the ATF cladding, and discusses the key finding in terms of hydrogen generation and timing of events in the two generic SMRs designs analyzed.

2. GENERIC iPWR DESIGNS DESCRIPTIONS

The evaluation conducted within the SASPAM-SA project considered two representative iPWR concepts. These generic designs were defined using publicly available data and expert engineering judgment to cover the main design features considered in the most promising concepts to be deploy in the near-term future [11, 12]. Both selected concepts integrate the reactor core, steam generators, and pressurizer within a single Reactor Pressure Vessel (RPV). This integral configuration enhances safety by eliminating large-diameter external loop piping, thereby removing the possibility of Large Break Loss-of-Coolant Accidents (LB-LOCA) common in traditional PWRs. While the project goal is not to evaluate these specific designs, they serve as the reference cases to assess the capabilities of integral codes in simulating key phenomena during hypothetical accidents. In Figure 1, schematic representations of Design-1 and -2 are presented.

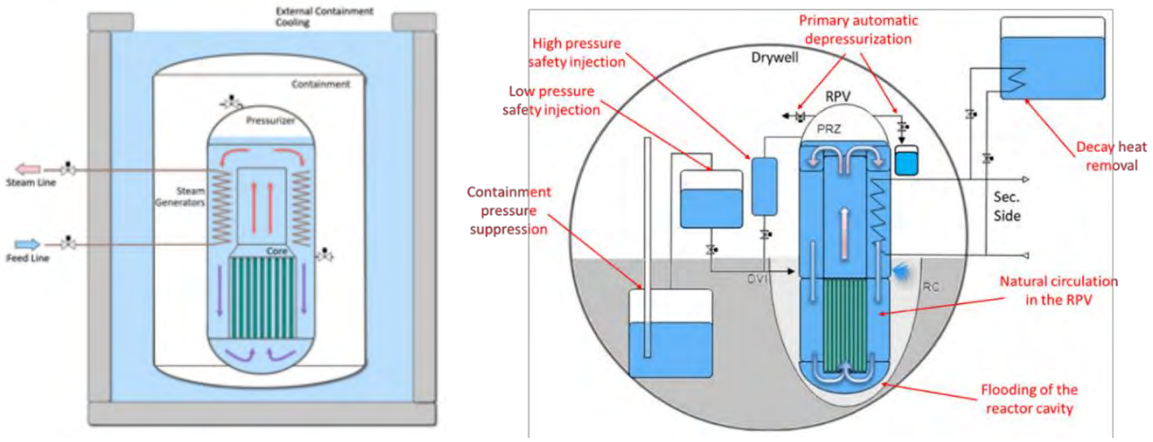

Figure 1. Representation of the generic iPWR Design-1 (left) and Design-2 (right).

2.1. Generic iPWR Design-1

The generic Design-1 is a 160 MWth natural circulation iPWR, characterized by a submerged containment. The generic design studied consists on an integral RPV housing a shrouded core, a riser, a pressurizer, and two helical tube steam generators. The core consists of 37 fuel assemblies arranged in a 17×17 configuration with an active height of approximately 2 m. Finally, the RPV is within a steel containment vessel that is submerged in a large external pool of water, which serves as the ultimate heat sink. The interior of the containment is maintained at a near-vacuum atmosphere to promote steam condensation in the event of steam release from the RPV.

The primary passive safety system is the Emergency Core Cooling System (ECCS), which improves heat removal in case of accident by using the Reactor Vent Valves (RVs) located at the top of the RPV and Reactor Recirculation Valves (RRs) positioned in the downcomer above the core level. During an accident sequence, these valves establish a natural circulation flow path: steam is vented to the containment, condensed on the walls cooled by the external pool, and then returned to the RPV through the RRs.

2.2. Generic iPWR Design-2

The generic Design-2 represents a larger power generation unit with a thermal output of 1000 MWth. Unlike Design-1, this reactor operates under forced circulation during normal conditions, using primary coolant pumps integrated within the RPV alongside the core, steam generators, control rod drive mechanisms, and pressurizer. Design-2 employs a dry containment concept and incorporates passive mitigation strategies to manage design basis and severe accidents. The main passive features are described below:

- After the primary pump trip, coolant flow is sustained by **Natural Circulation** in the RPV, with riser-downcomer connections ensuring flow even at reduced coolant levels;
- **Decay Heat Removal** is achieved via natural circulation between the steam generators and a submerged heat exchanger in an elevated pool;
- The Primary **Automatic Depressurization System** (ADS) reduces the RPV pressure to enable the activation of passive safety injection systems;
- **High-Pressure Safety Injection** uses a natural circulation loop between the RPV and dedicated tanks of borated water, while **Low-Pressure Safety Injection** relies on gravity-driven flow from elevated tanks through direct vessel injection (DVI) lines;
- **Containment Pressure Suppression** mitigates the pressure buildup by directing steam into a large pool of water through the DryWell (DW) connections;
- **Flooding of the Reactor Cavity** is automatically initiated under SA conditions to provide external cooling of the lower head, thereby supporting in-vessel melt retention.

3. ATF MATERIAL AND MODELLING STRATEGIES

The development of ATF cladding materials has become a critical area of research to improve safety margins in the event of a SA. Under off-normal conditions, such as LOCAs, the reactor core may become exposed to high-temperature steam, triggering several degradation mechanisms [13, 14]. Even though zirconium-based alloys are still an effective material under normal operating conditions, they show certain limitations at high temperatures. Zircaloy cladding can experience ballooning and bursting between 973 K and 1373 K due to internal pressurization, and undergo fast exothermic oxidation reactions in steam environment. These reactions generate substantial heat, accelerating further temperature increase, and produce large quantities of hydrogen, thus increasing the risk of combustion or detonation [3, 13-15]. Following the Fukushima-Daiichi accident, significant efforts have been directed towards identifying cladding concepts that can mitigate these phenomena by delaying the onset of rapid oxidation and reducing hydrogen release during core degradation.

ATF developments for cladding can be broadly classified into three main categories:

- **Surface-modified zirconium alloys**, including metallic and ceramic coatings, which improve early-phase oxidation behaviour while retaining the Zircaloy substrate;
- **Non-zirconium metallic alloys**, such as FeCrAl, which rely on protective and adherent oxides that show higher oxidation resistance;
- **Ceramic-based composite**, mainly SiC/SiC, which offer excellent chemical stability but face mechanical, joining and manufacturing challenges at industrial scale.

Among these options, FeCrAl alloys have emerged as a promising metallic ATF cladding due to their balanced formability, mechanical strength and demonstrated performance in high-temperature steam. Their superior oxidation resistance comes from the formation of a dense, adherent Al_2O_3 scale, which maintains oxidation rates several orders of magnitude lower than Zircaloy below 1673 K. However, at higher temperatures, scale failure triggers the rapid formation of Fe-rich oxides with accelerated kinetics [3]. Although there are some challenges with FeCrAl, such as higher thermal neutron absorption, these can be mitigated by reducing the thickness of the cladding or increasing the fuel enrichment. Current optimization

focuses on balancing the content of chromium and aluminium to prevent embrittlement while retaining the high oxidation resistance [3, 4, 13, 14]. This has led to the development of several specific candidates, such as the B136Y3 alloy, which was selected as the reference material for this study, as it has been extensively studied through separate-effect and bundle tests at the QUENCH facility at the Karlsruhe Institute of Technology in Germany [3, 16].

A key aspect of the modelling task was that each partner had full autonomy over the level of detail included in the modelling and implementation strategies within each code framework. Three integral codes were used for testing ATF in the two generic iPWRs: ASTEC, AC² and MELCOR for Design-1 by KIT, RUB and VTT respectively, and for Design-2 by ENEA, LEI and UNIROMA1 respectively. The modelling approaches adopted for each code and partner are briefly described below.

3.1. ASTEC Modelling Strategy

At the time of the study, ASTEC V3.1 did not include a dedicated FeCrAl model; however, efforts are currently underway to its development [17]. To perform the simulations, partners used the MDB structure to overwrite the Zr oxidation correlation with the temperature-dependent parabolic FeCrAl law derived from experimental data [3]. The kinetics rate of the parabolic law presents an Arrhenius form $A \times \exp(-Q/RT)$, in which $R = 8.31446$ J/molK, and the A and Q constants are listed in Table I. Two variants were applied:

- **Oxidation-only substitution**, retaining default zirconium thermophysical and thermodynamic properties to isolate the effect of oxidation kinetics;
- **Extended substitution**, including FeCrAl thermophysical and thermodynamic updates [4], while still relaying on Zr-based corium oxidation models in late degradation phases.

Table I. Arrhenius constants for FeCrAl oxidation kinetics.

Temp. Range	A [$\mathrm{kg^2/m^4 s}$]	Q [$\mathrm{J/mol}$]	comments
873 K ≤ T < 1173 K	5.376×10^{-3}	1.847×10^{5}	θ-alumina kinetics
1173 K ≤ T < 1273 K	4.692×10^{-12}	0.0	-
1273 K ≤ T < 1648 K	5.018	2.877×10^{5}	α-alumina kinetics
T ≥ 1648 K	2.4×10^{8}	3.527×10^{5}	Fe-oxide kinetics

Both implementations of Design-1 were tested by KIT. For Design-2, ENEA used the oxidation-only approach. In all cases, the core geometry remained unchanged.

3.2. AC² Modelling Strategy

ATF modelling capabilities were included into AC² since version 2023.1. This implementation assumes the formation of a single protective α-Al_2O_3 layer during FeCrAl oxidation, i.e., Fe-rich oxide formation after alumina scale failure is not explicitly represented in the current study. The reaction kinetics follow a parabolic rate law analogous to zirconium oxidation models and are calculated using an Arrhenius-type equation incorporating a reduction factor to account for the effects of steam starvation. Different modelling options are available:

- **Option 20**: kinetics based on KANTHAL material. Arrhenius constants: $A = 3.1\ \mathrm{kg^2/m^4 s}$ and $Q = 2.785 \times 10^5\ \mathrm{J/mol}$;
- **Option 21**: identical formulation as option 20 with empirically increased constants;
- **Option 22**: user-defined oxidation parameters.

In addition to these release-version capabilities, recent AC^2 developments [18] introduced multi-component oxidation models to further improve the physical representation of FeCrAl oxidation under SA conditions, including the transition at 1648 K. However, evaluations with the new models are not included in this work.

Material property data must be user-defined if other than the standard Zircaloy is used. Design-1, modelled by RUB, was tested using Option 21, adopting fuel rod geometries and specific FeCrAl parameters from literature [19] while missing data were derived from Zircaloy or iron databases. In contrast, LEI applied Option 20 to Design-2, keeping cladding properties identical to the reference zirconium case.

3.3. MELCOR Modelling Strategy

In MELCOR, a generalized oxidation model based on Arrhenius equations is used. For this model, user-defined constants must be specified for each temperature range. The properties of both the FeCrAl alloy and a unified FeCrAl oxide are provided in the MELCOR Material Properties. However, these can be overwritten by the user in the input interface.

In the simulations conducted by VTT for Design-1, experimental data from Kim et al. [3] was used to fit an Arrhenius equation for two temperature ranges. Nevertheless, the oxidation heat release remained based on the default MELCOR Zr oxidation framework. Since the heat release associated with Zr oxidation is expected to be larger than that of FeCrAl oxidation for early degradation regime, this assumption may conservatively overestimate the local heat generation and, as a consequence, the cladding temperature.. The Arrhenius constants used are:

- $T \leq 1573\ K$: $A = 1.66 \times 10^{-2}$ $\mathrm{kg^2/m^4 s}$ and $Q/R = 22334$ K;
- $T \geq 1673\ K$: $A = 2.48 \times 10^{8}$ $\mathrm{kg^2/m^4 s}$ and $Q/R = 39282$ K;
- The code performs an interpolation between the two temperature limits for which the coefficients are undefined.

For Design-2, simulated by UNIROMA1, FeCrAl properties for both the metallic and oxide phases were implemented from Field et al. [19], and oxidation kinetics rate constants were applied based on experimental data [3]. For both designs, the cladding thickness was the same as the Zr reference material in order to keep the core geometry.

4. POSTULATED ACCIDENT SCENARIOS

To evaluate the performance of the integral codes when implementing ATF cladding materials, hypothetical accident sequences were postulated for the two generic iPWR designs used in this study. These scenarios involve system failures leading to core uncovery and subsequent heat-up, thereby initiating the oxidation processes relevant to the study of FeCrAl performance.

Regarding the core conditions, the partners adopted two different assumptions. Some used the SASPAM-SA database [20] that includes decay heat data and isotopic inventories for 60 MWd/tU, while others considered a fission product inventory derived from a scaled PWR core and applied a decay heat curve based on the ANS73 standard [21] with or without a 20% power increase.

4.1. Hypothetical Scenario for Design-1

The postulated SA sequence consists of a break in the Chemical and Volume Control System (CVCS) discharge line, combined with a loss of AC power. The break, which had a diameter of ~0.04 m, was located above the top of the active fuel (TAF), creating a path between the downcomer and the containment vessel. The elevation was set to between 3.5 and 6.5 m above the TAF, depending on the modelling assumptions adopted by each participant.

The postulated sequence begins with a loss of AC power, followed by the Main Steam Line closing after 5 s. The ECCS actuates when the pressure difference between the containment and the RPV falls below 6.2–6.9 MPa (depending on the partner), and when the containment water level exceeds about 5.8 m, i.e., above the elevation of the RRs. The RVs remain functional, whereas both RRs are assumed to be unavailable and remain closed.

4.2. Hypothetical Scenario for Design-2

For Design-2, the initiating event of the SA sequence is a guillotine break of one Direct Vessel Injection (DVI) line, combined with the failure of the Emergency Heat Removal System (EHRS), while all other safety systems remain available. Following the DVI break, the increase in the containment pressure rises the plant safety signal. About 5 s later, the reactor scrams, the secondary system is isolated, and the primary pressure control system is shut down. As the pressurizer (PRZ) level decreases below its low-level set-point (< ~14%), a signal initiates reactor coolant pump (RCP) coastdown and RI-DC valve opening. Continued depressurization leads to a low-pressure signal (PRZ pressure < ~11.7 MPa), triggering Emergency Boration Tank (EBT) injection and ADS Stage-1 actuation.

When the pressure difference between the RPV and the containment falls below ~0.05 MPa, the Long-term Gravity Make-up System (LGMS) activates. If the mass in one LGMS tank drops below about 8%, a low-mass signal triggers ADS Stage-2. The sequence leads to sustained primary depressurization and safety injection, while the failed EHRS prevents decay-heat removal, enabling a SA progression.

5. SELECTED RESULTS AND DISCUSSIONS

The selected results of the SA transients performed using the ASTEC, AC² and MELCOR codes for Designs -1 and -2 are presented below. The results primarily focus on hydrogen production and peak cladding temperature evolution. These quantities were selected because the FeCrAl implementations currently used in this study still rely, to different extent, on Zr-based degradation models, which are expected to be more applicable during the initial degradation phase, when oxidation kinetics dominate the response and the cladding preserves its rod-like geometry. However, after cladding failure, FeCrAl-specific effects on melting, relocation, and interactions with UO_2 and other core materials are not yet fully represented in the SA codes. Therefore, late-phase results should therefore be interpreted with caution.

5.1. Results for iPWR Design-1

For all codes, the initial thermohydraulic progression of the SA sequence follows the same overall dynamics for FeCrAl and the Zircaloy reference cases during the initial phase of the transient. Following the break initiation, the primary coolant is discharged into the containment vessel. However, even when the ECCS signal is triggered, the unavailability of the RRs prevents coolant recirculation, leading to progressive core uncovery, increasing the cladding temperature, and ultimately initiating core degradation. A detailed description of the accident progression can be found in [12, 22]. Key sequence parameters are provided in Table II.

The timing of the ECCS signal varied across the codes, primarily due to the modelled break elevations. AC² showed activation ~360 seconds earlier, while the FeCrAl implementation in ASTEC and MELCOR produced no significant differences on the ECCS timing or on key parameters such as the maximum water level and pressure in containment. The deviations observed in AC² are attributed to geometric modifications and to the conservative decay heat assumption (ANS-73 +20%) applied to the specific input deck, whereas the core geometry remained unchanged in the ASTEC and MELCOR models. Despite some differences, the impact of FeCrAl on the initial thermohydraulic sequence is not significant.

Core uncovery begins as the coolant is discharged into the containment and the RRs stuck closed. While MELCOR and ASTEC show small differences for TAF and BAF (Top and Bottom of Active Fuel) timings, AC² reports earlier occurrences by approximately 640 s and 3730 s, respectively. Following the onset of core uncovery, a gradual temperature increase is observed among all codes up to approximately two hours. After this period, a rapid escalation in temperature is triggered; however, the timing of this escalation's onset and subsequent evolution depends on the cladding material and the code-specific implementation. In ASTEC, the oxidation-only substitution (FeCrAl-1) delays the time at which the cladding reaches 1648 K by ~28 min compared to the Zr case. When both the oxidation kinetics and the material properties are modified (FeCrAl-2), the delay increases to approximately 35 min. A similar behaviour is observed with MELCOR, in which the FeCrAl case presents a delay of ~20 min. This delay occurs despite the conservative Zr-like oxidation enthalpy assumed in MELCOR (Section 3.3), suggesting that slower reaction kinetics dominate the thermal escalation during this phase. In contrast, AC² shows a near-linear FeCrAl temperature increase, reaching 1648 K ~3 min earlier than in the Zr case. This difference in behaviour is likely to be influence by the specific AC² modelling assumptions and input-deck conditions, including the FeCrAl oxidation kinetics implementations

Table II. iPWR Design 1: Progression of the postulated SA sequence with FeCrAl and Zircaloy.

Event/Parameter	ASTEC – KIT			AC2 – RUB		MELCOR – VTT	
	FeCrAl-1	FeCrAl-2	Zr	FeCrAl	Zr	FeCrAl	Zr
Scram time (s)	4.3	4.3	4.3	0	0	4	4

Pmax in Cont. (MPa)	2.65	2.65	2.65	4.94	4.83	4.68	4.67
TAF uncovered (s)	3817	3833	3851	5493	6130	3960	4050
BAF uncovered (s)	23000	22382	22483	11519	15254	10290	10920
Clad at 1648 K (s)	11090	11510	9400	10000	10180	9480	8280
Total H_2 gen. (kg)	48.9	28.1	64.0	10.95	72.4	69.0	90.0
1st corium slump in the LP (s)	29350	30460	29515	15521	11050	25245	23671
Corium in the LP (kg)	7630	9020	5771	6585	8460	3112	2967

The most significant effect of FeCrAl concerns the hydrogen generated during core degradation, in particular during the early degradation phase. The hydrogen has multiple sources, including the oxidation of cladding, corium, and structural materials. Figure 2 (left) presents a comparison for the total H_2 generated in the core during the first 30000 s of the transient for FeCrAl and Zr claddings. Compared to the Zr case, the implementation of FeCrAl cladding results in a reduction in hydrogen production. In both ASTEC and MELCOR, the onset of rapid hydrogen escalation is delayed by approximately 35 (FeCrAl-2) and 20 min, respectively. This is consistent with the delayed temperature escalation. However, AC² does not show a rapid hydrogen escalation phase for FeCrAl. Although an overall reduction in hydrogen production is achieved with FeCrAl, the late-phase results should be interpreted with caution due to the modelling limitations when cladding integrity is lost. Since corium oxidation models are Zr-based (e.g., UZOXMAG in ASTEC), their application to iron-based alloy such as FeCrAl is uncertain. Thus, Figure 2 (right) shows the cumulative hydrogen generated only before the cladding reaches 1648 K, when the modelling results are more reliable. As can be seen in this figure, implementing FeCrAl results in a 72% reduction in hydrogen for ASTEC FeCrAl-2 (compared to 67% with FeCrAl-1), a 95% reduction for AC², and an 81% reduction

for MELCOR. The observed reductions are consistent with the superior steam oxidation resistance of FeCrAl. Its kinetics are orders of magnitude slower than those of Zircaloy while the protective alumina scale remains intact. Following the alumina scale failure, the behaviour is governed by rapid iron oxidation. Although the cladding retains a rod-like geometry at 1648 K, the subsequent degradation process differs from that of Zircaloy due to FeCrAl's different melting temperature and melt interaction behaviour. This affects the timing and kinetics of material relocation into the melt, significantly impacting late-phase evolution. As previously mentioned, no model dedicated to FeCrAl was developed in the SA codes for advanced degradation phase. This should be addressed in future studies.

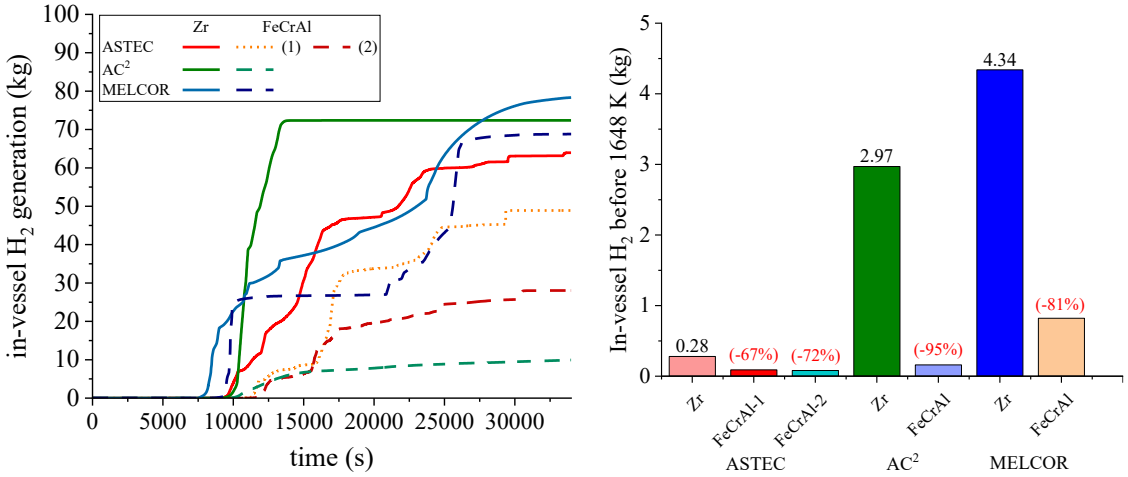

Figure 2. Selected results for Design-1. *Left*) Total H_2 generation during SA sequence. *Right*) Cumulative H_2 before reaching a peak cladding temperature of 1648 K.

It is worth noting that none of the simulations performed with either FeCrAl or Zr cladding led to vessel failure.

5.2. Results for iPWR Design-2

As previously mentioned, the scenario evaluated for Design-2 is initiated by a guillotine break of one of the DVI lines with the unavailability of the EHRS while all other safety systems operate normally. Early safety actions, such as SCRAM, RCP coastdown, opening of the RI-DC valves, actuation of the EBT and ADS-1 show no or negligible difference between the FeCrAl and Zr simulations. The main results are summarized in Table III.

Once the event is initiated, the pressure in the containment experiences a rapid increase, reaching the design pressure at ~670–800 s, depending on the code. In ASTEC and MELCOR, containment failure is assumed, whereas in AC², a venting valve modelled on specific threshold values is used. As the RPV depressurizes, the water level gradually decreases while the cavity accumulates water. The core uncovers and reaches the TAF at ~1715–5830 s, triggering degradation and hydrogen generation. No significant differences between FeCrAl and Zr simulations were observed in ASTEC or AC², while MELCOR predicts the TAF to be reached ~24 minutes earlier for FeCrAl. Notable differences in the timing of the temperature escalation are observed depending on the cladding material used. In general, it was observed that FeCrAl delays the temperature escalation dynamics. In ASTEC, the use of FeCrAl introduces a significant delay of about 4900 s (1.4 hours) before the 1648 K cladding temperature onset is reached. In contrast, in AC², the delay is much smaller (less than 500 s). In MELCOR, the Zircaloy case shows a clear rapid escalation starting at ~24900 s (6.9 hours), whereas the FeCrAl case shows a nearly linear temperature increase without a sudden jump. It reaches 1648 K roughly 8800 s (2.4 hours) later than the Zircaloy case.

Figure 3 shows the FeCrAl and Zr comparisons of total H_2 generated in the vessel during the transient on the left, and the H_2 mass accumulated before reaching 1648 K on the right. In all cases, the use of FeCrAl results in a delayed onset of rapid oxidation and lead to notable reductions in the hydrogen generated. These differences are associated with the dynamics of temperature escalation and the slower kinetics of steam oxidation of FeCrAl during the early to intermediate phases. As mentioned above for Design-1, significant uncertainties arise as the core degradation progresses and FeCrAl interacts with other core materials, for which no dedicated models are applied yet. To highlight the effects of the cladding in the early phase, prior to cladding loss of integrity, the right-hand plot presents the in-vessel H_2 mass at the time the PCT reaches 1648 K. While ASTEC and AC² predict reductions exceeding 95% in the early phase, MELCOR shows a significantly more conservative reduction of only 17%. For ASTEC and AC², the reduction up to this transition temperature exceeds 95%, whereas in MELCOR it is about 17%. This deviation could be attributed to each specific ATF implementation and core degradation modelling strategies.

Table III. iPWR Design 2: Progression of the postulated SA sequence with FeCrAl and Zircaloy.

Event/Parameter	ASTEC - ENEA		AC2 - LEI		MELCOR-UNIROMA1	
	FeCrAl	Zr	FeCrAl	Zr	FeCrAl	Zr
Scram time (s)	25	25	45	45	27	27
RCP-Coastdown (s)	105	105	162	162	157	157

Containment Design Pressure reached (s)	800	800	801	801	670	670
TAF uncovered (s)	5830	5830	5260	5360	1720	3130
BAF uncovered (s)	-	-	-	-	113400	63000
Cladding at 1648 K (s)	18170	13250	14020	13550	33670	24880
LGMS Actuation (s)	21880	18590	10270	10270	11320	10350

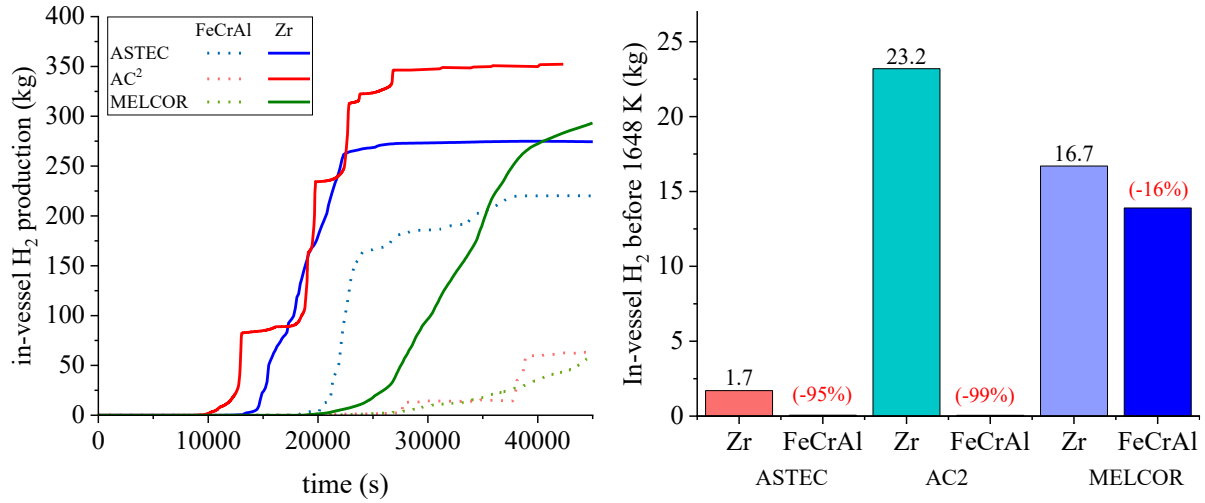

Figure 3. Selected results for Design-2. *Left*) Total H_2 generation during SA sequence. *Right*) Cumulative H_2 before reaching a peak cladding temperature of 1648 K.

Despite the existing uncertainties and the differences in codes and FeCrAl implementations, there is consistent indication that this material can provide a delay the onset of core degradation and reduce the associated hydrogen generation to some extent.

6. CONCLUSIONS

As part of the SASPAM-SA project, SA analyses were performed for two generic iPWR configurations to assess the impact of ATF cladding based on FeCrAl alloys in comparison with conventional Zircaloy. The integral codes ASTEC, AC², and MELCOR were employed to simulate postulated scenarios and quantify FeCrAl effects on key phenomena, such as hydrogen generation, cladding temperature escalation, and the timing of early core degradation processes.

Overall, the codes demonstrated the capability to implement different FeCrAl modelling approaches and to reproduce the main thermal-hydraulic phenomena of SA progression in both designs. Replacing Zircaloy with FeCrAl had no major impact on global thermal-hydraulic variables during the early stage of degradation, aside from minor discrepancies attributed to modelling assumptions such as break elevation, nodalization, or boundary conditions. The main differences between the Zircaloy and FeCrAl cases were observed in the oxidation-driven phenomena, where FeCrAl led to reduced hydrogen production, delayed onset of rapid temperature increase, and a slower transition into early degradation phases. These effects are consistent with the superior steam oxidation resistance of FeCrAl during the period in which the protective alumina layer remains intact.

The performance of each code depended on the modelling strategy adopted. ASTEC and MELCOR mainly implemented the oxidation kinetics of FeCrAl, with optional updates to selected material properties, AC² offered several oxidation formulations based on a single temperature range in the version used. In addition, a common limitation of the codes is their reliance on Zr-based models for late degradation phases, reducing result reliability once cladding integrity is lost due to the lack of dedicated FeCrAl models for high-temperature thermomechanical phenomena, relocation, and corium interaction. Despite these limitations, the simplified implementations were adequate for demonstrating the potential benefits of FeCrAl. The analyses suggest that, while it does not prevent core damage, FeCrAl behaves as an accident-delaying cladding material by extending the time period before severe degradation and significantly reducing hydrogen production during the early phase.

Although recent developments have aimed to improve high-temperature behaviour, further development and validation of dedicated FeCrAl models for late in-vessel degradation are needed to strengthen safety assessments and simulation capabilities, including UO_2 interaction and melt formation.

Introduction & Motivation

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- **SMRs** are a promising innovation, offering modular deployment, versatile applications, and clean and reliable energy solutions.
- **iPWR** are based on well-proven and established LWR technology, with enhanced safety features.
- **SA analysis** are still required to support:
  - Defense-in-Depth assessment,
  - Accident Management strategies, and
  - Emergency Planning considerations.
- ATF concepts aim to improve safety margins during off-normal and accident conditions.

Delay degradation

Reduce H_2 generation

Introduction & Motivation

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

Several activities to support possible license need:

SASPAM-SA: Safety Analysis of SMR with Passive Mitigation strategies – Severe Accident

- Investigates SA progression in generic iPWR concepts,
- Evaluates the transferability of knowledge from large LWR to iPWR,
- Dedicated task on ATF

Scope of the present ATF study: Integral-code assessment of FeCrAl vs. Zircaloy in-vessel behavior

Partners	KIT	RUB	VTT	ENEA	LEI	UNIROMA1
Design	1			2		
Code	ASTEC	AC2	MELCOR	ASTEC	AC2	MELCOR

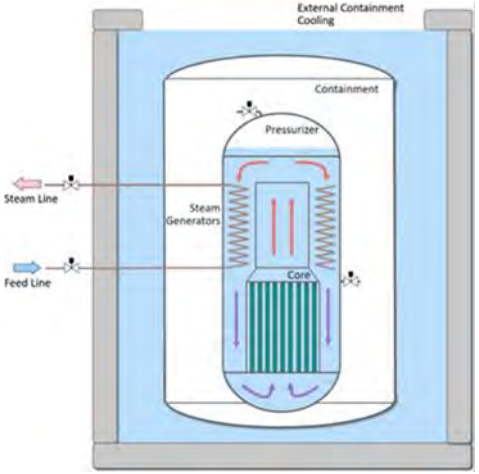
Generic iPWR Designs

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

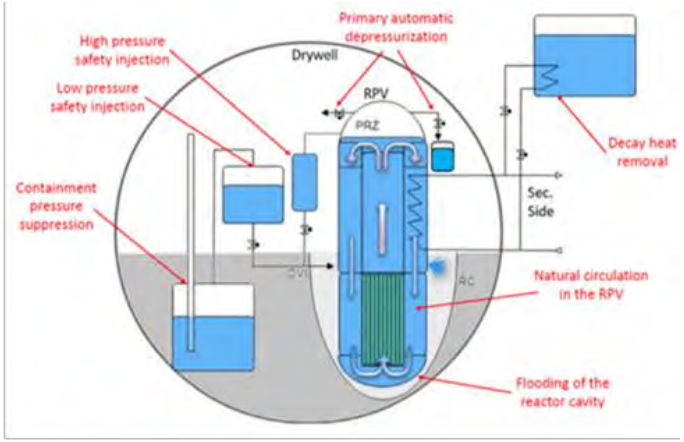
iPWR Design-1

Submerged containment, P~60 MWe



iPWR Design-2

Dry containment, several passive systems, P~300 MWe



- The designs incorporate the main safety features of the most promising concepts ready for deployment in the European market
- It is not the objective of the task to assess the design of such concepts

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use of disclosure to third party without express authorization is strictly prohibited.

ATF Concept: FeCrAl

FeCrAl alloys

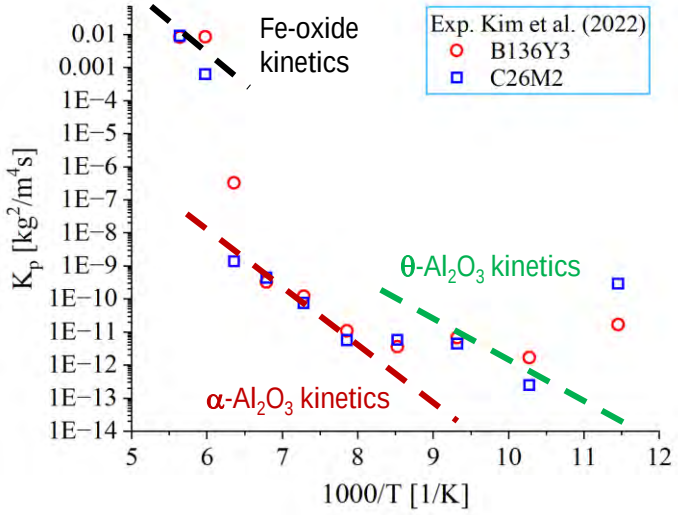
Nuclear grade FeCrAl: 10 – 13 wt% Cr and 5 – 6 wt% Al. Additional additives to improve oxidation resistance and mechanical properties: Mo and Y.

Advantages

- Superior mechanical properties compared to Zr alloy.
- Superior oxidation resistance at high temperatures: formation of protective Al_2O_3
- Lower hydrogen generation under steam oxidation.

Challenges

- Higher neutron absorption cross-section than Zircaloy: cladding thickness must be reduced.
- Tritium permeability due to lack of hydrogen isotopes trapping, but lower than pure Fe.
- FeCrAl with high Cr content is susceptible to irradiation embrittlement.
- Interaction between UO_2 and FeO forming an Eutectic at ~1335°C



Parabolic rate constants of B136Y3 and C26M2 as a function of temperature with the parabolic constants of Fe-oxide , α-alumina and θ-alumina (Kim, 2022).

≤1300°C: Aluminum oxidation
>1400°C: Iron oxidation dominates the reaction

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use of disclosure to third party without express authorization is strictly prohibited.

ATF Modelling Strategies

Each Partner had full autonomy over the level of detailed included in the modelling and implementation strategies within each code framework: ASTEC, AC^2 and MELCOR.

ASTEC

- No FeCrAl built-in models in the version used (under development by KIT and ASNR – See Presentation by Z. Balbuena - KIT).
- MDB structure used to implement FeCrAl properties in place of Zr-based properties: Oxidation kinetics and material properties.

AC^2

- Formation of a single protective α-Al_2O_3 layer during FeCrAl oxidation. Fe-rich oxide formation after alumina failure not explicitly treated in the version used.
- Different options for oxidation kinetics of FeCrAl. Material property data is user-defined.

MELCOR

- Generalized oxidation model.
- Default FeCrAl and FeCrAl oxide properties that can overwritten.

Late phase degradation still rely, to different extent, on Zr-based models

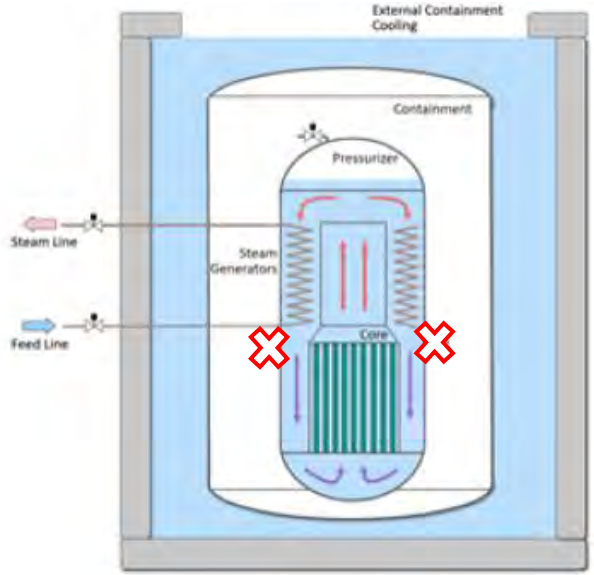
SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use of disclosure to third party without express authorization is strictly prohibited.

Accident Scenarios Selected

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

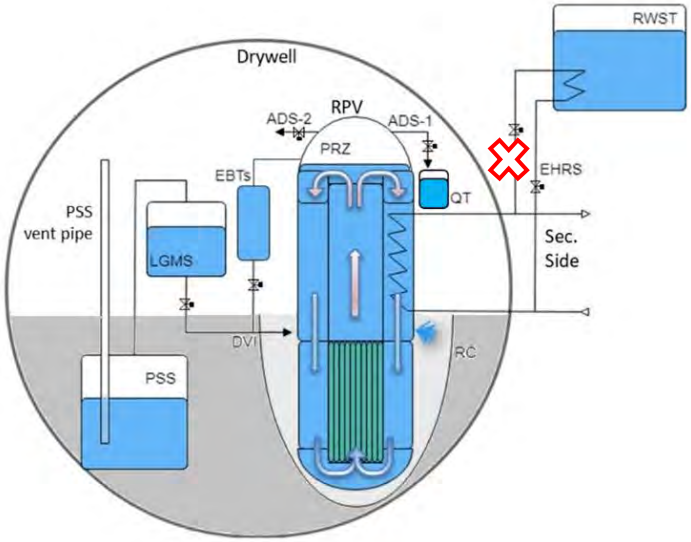
Design 1

SA-1: 100% break on the CVCS makeup line (high elevation to avoid reverse flow)



Design 2

SA-3: Unavailability of EHRS system



SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use of disclosure to third party without express authorization is strictly prohibited.

Accident Scenarios Selected

Main FoM

- Hydrogen generation
- Peak Cladding Temperature
- Timing of key degradation event

✓ FeCrAl implementation mainly affects oxidation kinetics.

✓ A reference temperature of 1648 K was used for early-phase comparison, corresponding to the transition in FeCrAl oxidation behaviour.

✓ After cladding failure, FeCrAl-specific melting, relocation, and interactions with UO_2 are not fully represented → Simulations still rely on Zr-based models.

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use of disclosure to third party without express authorization is strictly prohibited.

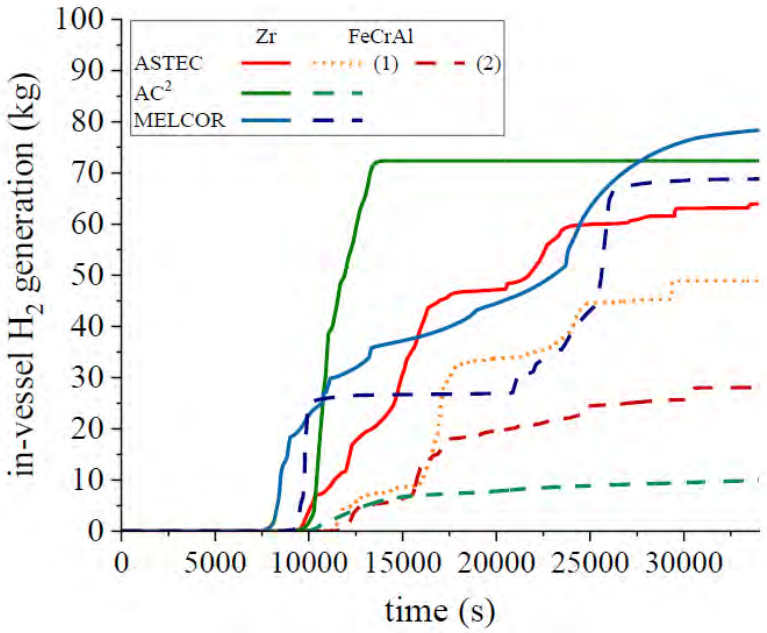
Results – Design 1

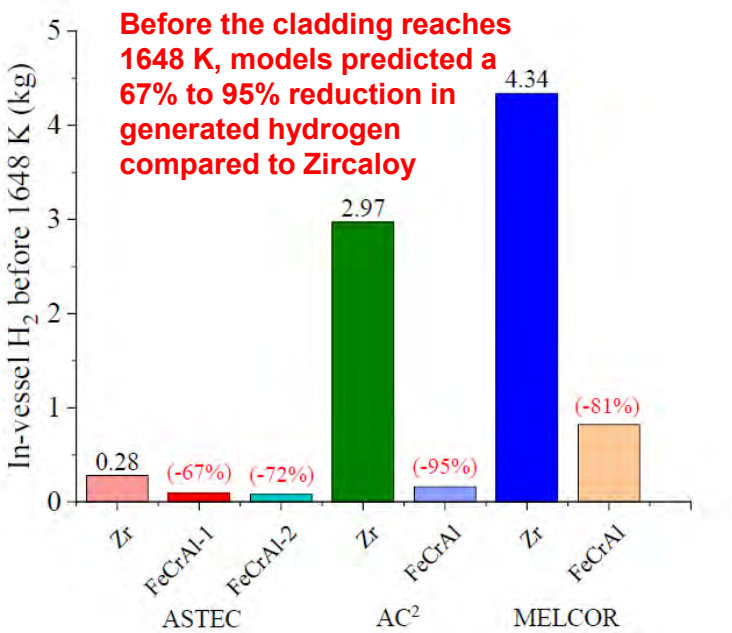
- Initial thermal-hydraulic progression is similar for FeCrAl and Zircaloy.
- FeCrAl has no major effect on: ECCS signal timing, Maximum containment water level and pressure.

Partners /Code	**KIT - ASTEC**			**RUB - AC2**		**VTT - MELCOR**	
Cladding	Zr	FeCrAl1	FeCrAl2	Zr	FeCrAl	Zr	FeCrAl
Clad at 1648 K (s)	9400	11090	11510	10180	10000	8280	9480
Delay -1648 K	~28 – 35 min			Slightly earlier		~ 20 min	
Total H_2 (kg)	64	48.9	28.1	72.4	10.95	90	69
H_2 reduction	~23 – 56%			~85%		~23%	

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use of disclosure to third party without express authorization is strictly prohibited.

Results – Design 1





Selected results for Design-1. *Left*) Total H_2 generation during SA sequence. *Right*) Cumulative H_2 before reaching a peak cladding temperature of 1648 K.

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use of disclosure to third party without express authorization is strictly prohibited.

Results – Design 2

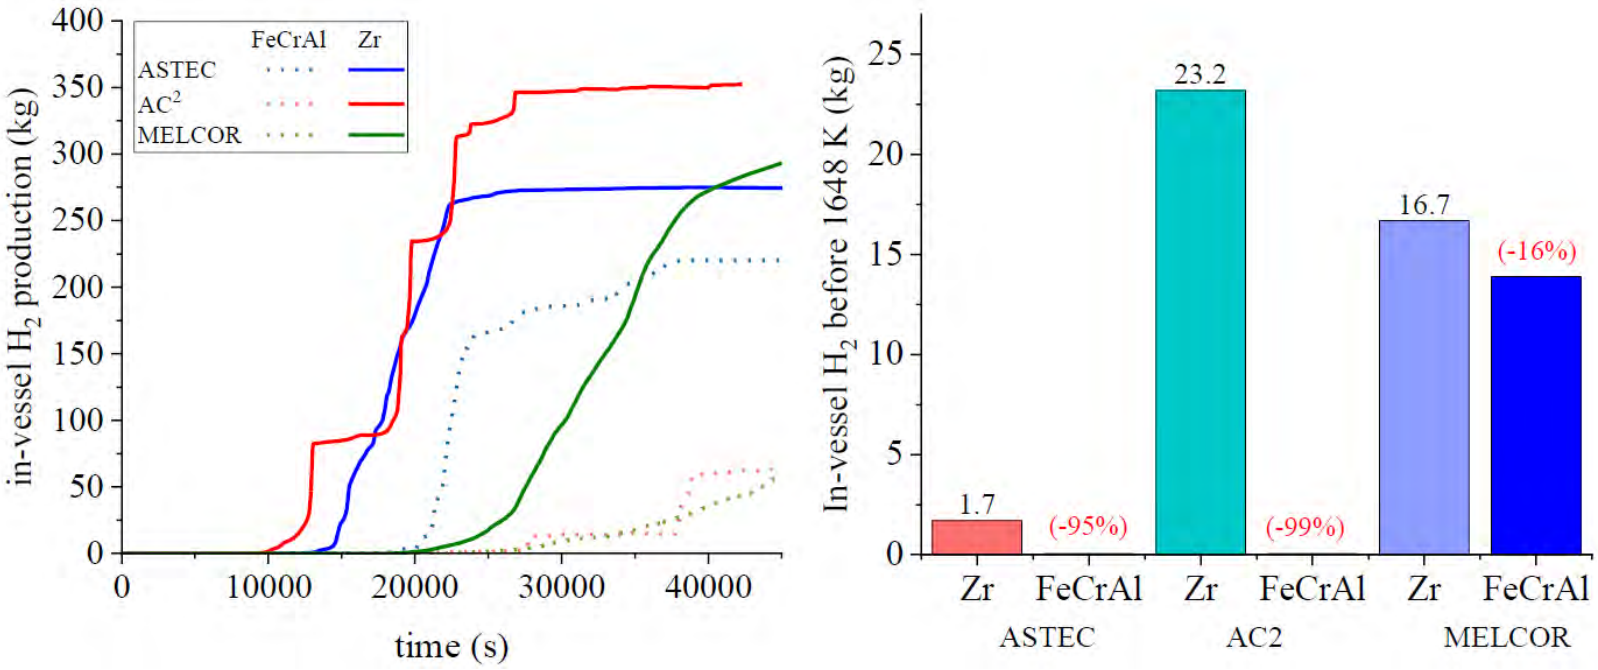
- Early safety actions show negligible differences between FeCrAl and Zircaloy.
- Similar to Design-1, FeCrAl significantly delayed the temperature escalation dynamics

Partners /Code	ENEA - ASTEC		LEI - AC2		UNIROMA1 - MELCOR	
Cladding	Zr	FeCrAl	Zr	FeCrAl	Zr	FeCrAl
Clad at 1648 K (s)	13250	18170	13550	14020	24880	33670
Delay -1648 K	~82 min		~8 min		~ 146 min	

For Design 2, depending on the code, the time taken to reach the 1648 K threshold was delayed by up to 2.4 hours when using FeCrAl

SASPAM-SA Consortium reserves all rights in this document and in the information contained therein. Reproduction, use of disclosure to third party without express authorization is strictly prohibited.

Results – Design 2



Selected results for Design-2. *Left*) Total H_2 generation during SA sequence. *Right*) Cumulative H_2 before reaching a peak cladding temperature of 1648 K.

Conclusions

- Within SASPAM-SA, SA analyses of two generic iPWRs assessed FeCrAl ATF cladding against Zircaloy.
- Overall, the codes implemented different FeCrAl approaches and reproduced the main SA thermal-hydraulic trends: **FeCrAl had limited impact on early global TH behaviour**, with expected differences mainly due to modelling assumptions.
- The performance of each code depended on the modelling strategy adopted.
- The implementations were adequate for demonstrating the potential benefits of FeCrAl: **reduction of H_2 production and delay of rapid temperature rise before cladding failure**.
- Dedicated FeCrAl late-degradation models, including UO_2 interaction and melt formation, require further development and validation.

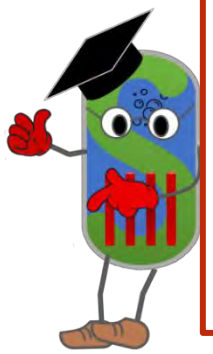
COMPARATIVE ANALYSIS OF CONTAINMENT BEHAVIOR IN A GENERIC IPWR DESIGN UNDER POSTULATED BDBA CONDITIONS USING ASTEC V3.1.2 AND MELCOR V2.2 CODES

M. Savini, G. Grippo, E. Cilia*, F. Mascari

UNIBO – Department of Industrial Engineering

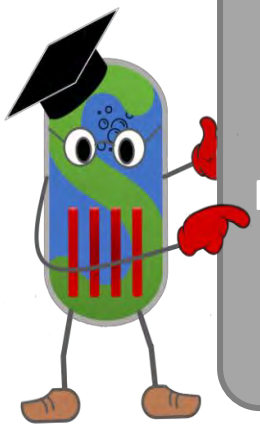
ENEA - Research Center



The present **activity** has been **conducted in the framework of the Horizon Euratom SASPAM-SA project**. The project is coordinated by ENEA and 23 organization from 14 countries are involved.

SASPAM-SA

Funded by the European Union



TARGET OF THE PROJECT

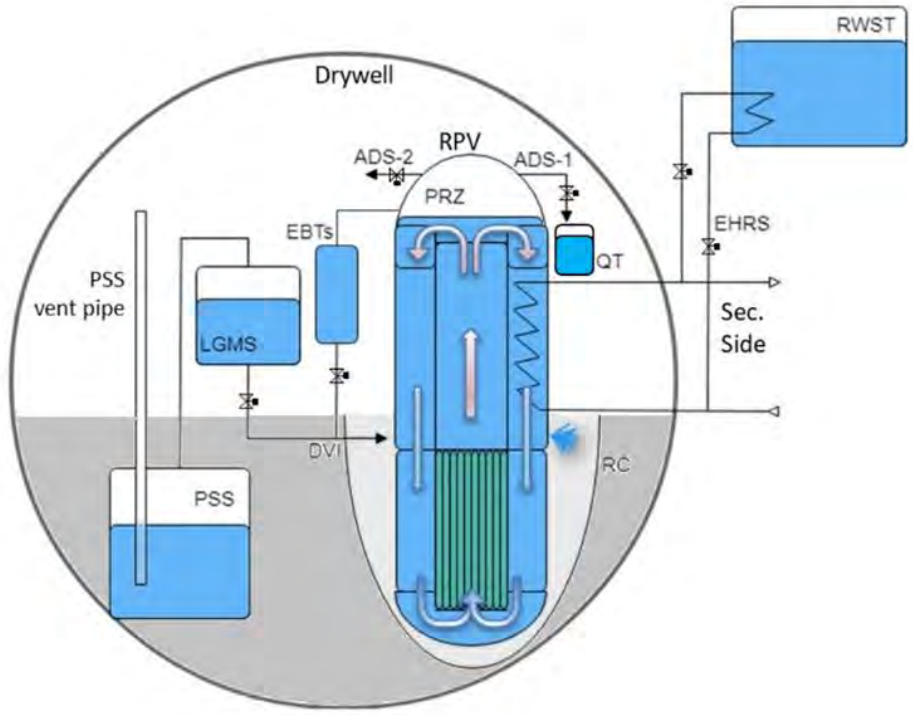
- Identification of **plausible postulate SA scenarios** for **iPWR** designs;
- Identification of the **conditions** in the **vessel** and in the **containment** that **characterize iPWR scenarios** and differ significantly from those in large-LWRs;
- Study the **applicability** of the **existing experimental database** to **iPWR** and identify **new experimental needs**;
- Assess the **capability** of internationally recognized **European and Non-European computational tools** (largely used in Europe) to **describe the behaviour** of the most promising **iPWR designs** during **SA scenarios** and to **predict** the resulting **radiological impact** on- and off-site.

ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

Generic iPWR Design2 and selected sequences

Design 2

Several passive systems, a dry containment (with a RC) and an electric power of about 300 MWe.



- The reactor operates in **forced circulation during normal operation** and employs a **passive mitigation strategy in accidental transients**.
- It consists of an **integral RPV**, which contains the core, a compact SG, the Control Rod Drive Mechanism (CRDM), the primary pumps and the **pressurizer included in the upper head**.

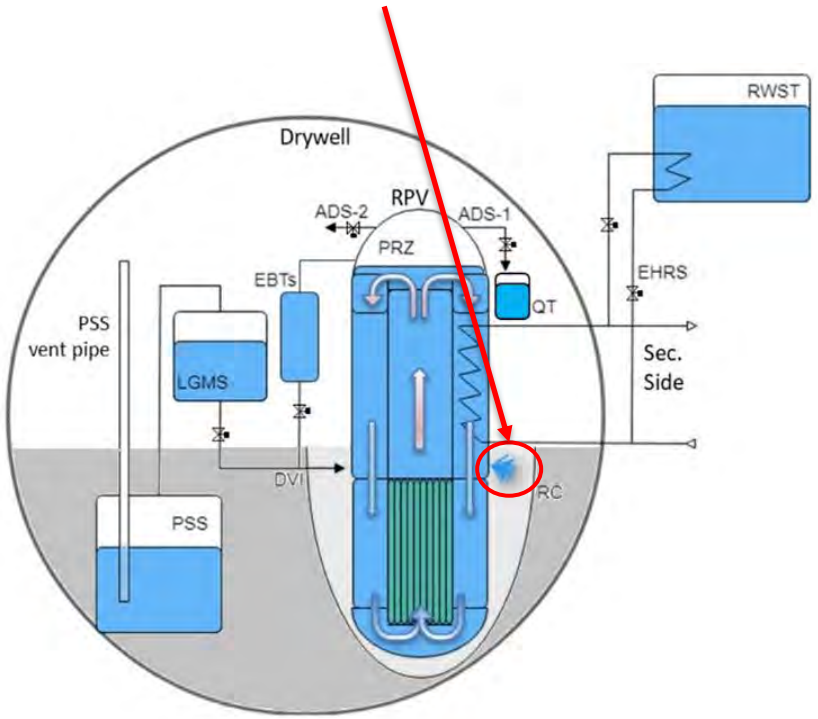
- To develop the **ASTEC and MELCOR input-deck**, a **reference database** was needed.
- Considering the **characteristics of Design 2 reactor type** and the selected passive systems, a **generic IRIS SMR type has been considered as reference** for this analysis.
- During the development of the MELCOR and ASTEC nodalization, **no proprietary data have been used.**
- The **main geometric information** has been **determined by scaling the data available from the SPES-3 facility**, by engineering evaluation or public general data available for the IRIS reactor.

ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

Generic iPWR Design2 and selected sequences

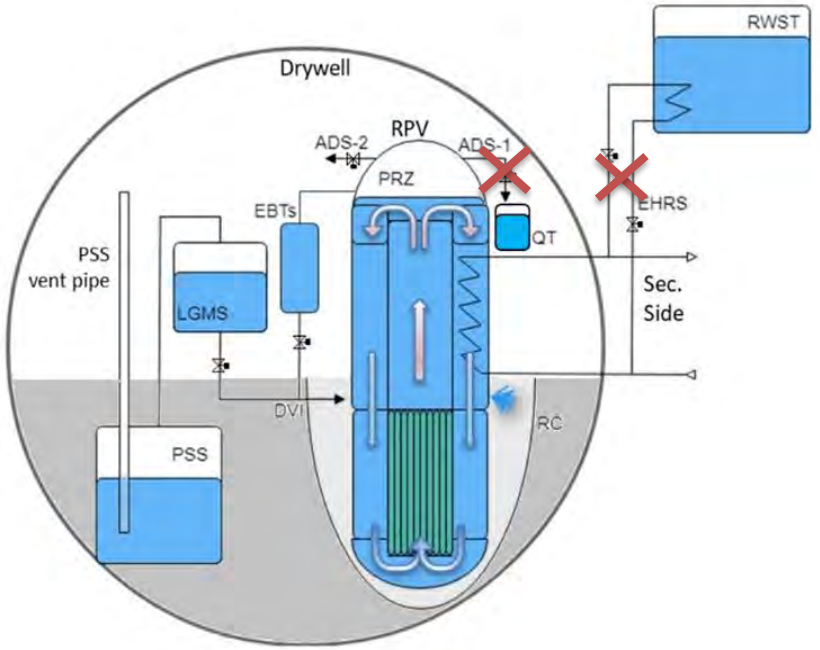
DBA

After the qualification of the steady state, the DBA scenario selected is the guillotine break of one Direct Vessel Injection (DVI) line, considering the availability of all safety systems.



SA1

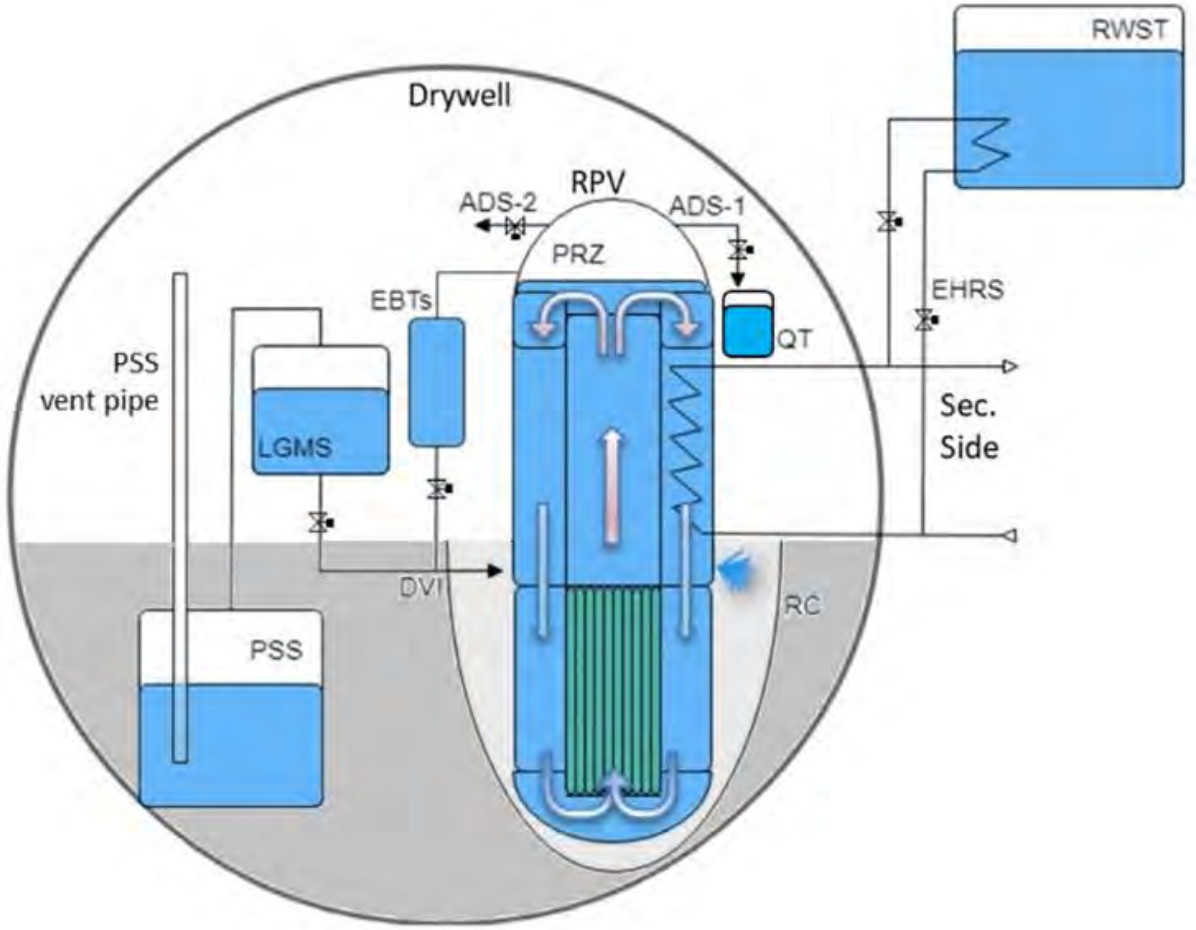
The first SA scenario postulated is the guillotine break of one Direct Vessel Injection (DVI) line, considering the postulated unavailability of EHRS and ADS-1 systems (through the assumed not opening of the related actuation valves).



ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

Why containment modelling matters for iPWR SA analysis

- **The considered Integral PWRs** (iPWRs) **rely on a strong thermal-hydraulic coupling** between **RPV, containment and passive safety systems**.
- In the new advanced passive reactor designs**, it is not possible to consider the RCS as a boundary condition for the containment**; instead, it is necessary to consider the physical behavior of the containment coupled with the physical behavior of the RCS during the transient evolution:
    - the containment is not simply a receiving volume for mass and energy released from the primary system. It actively influences the pressure evolution, liquid redistribution, steam condensation.



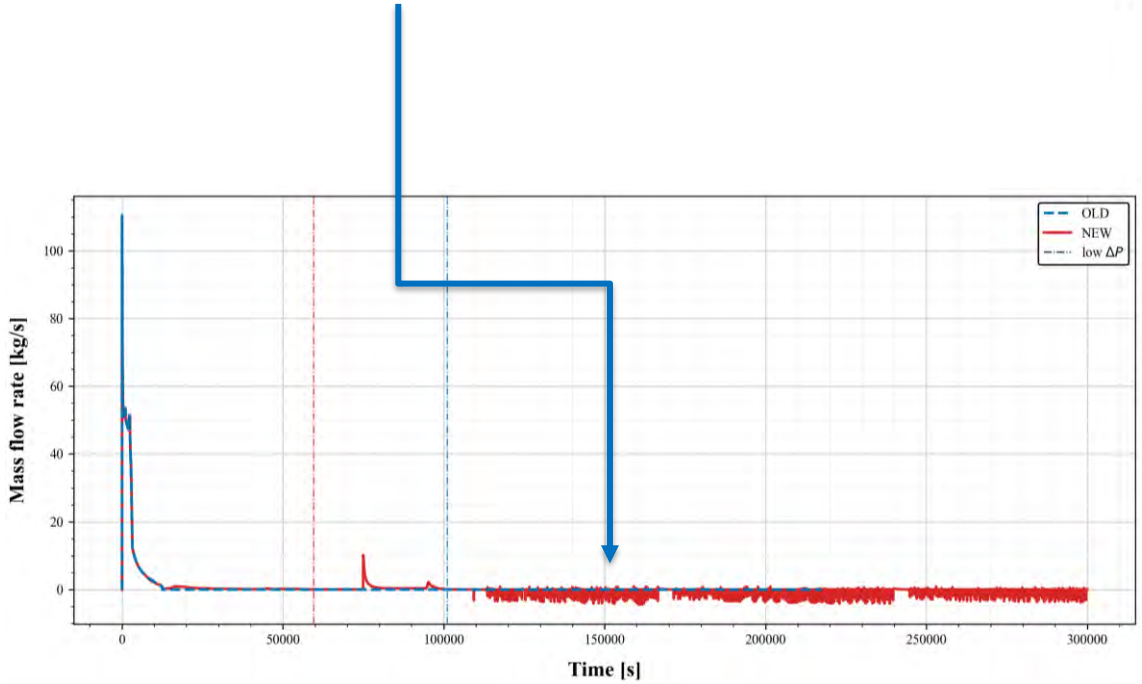
ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

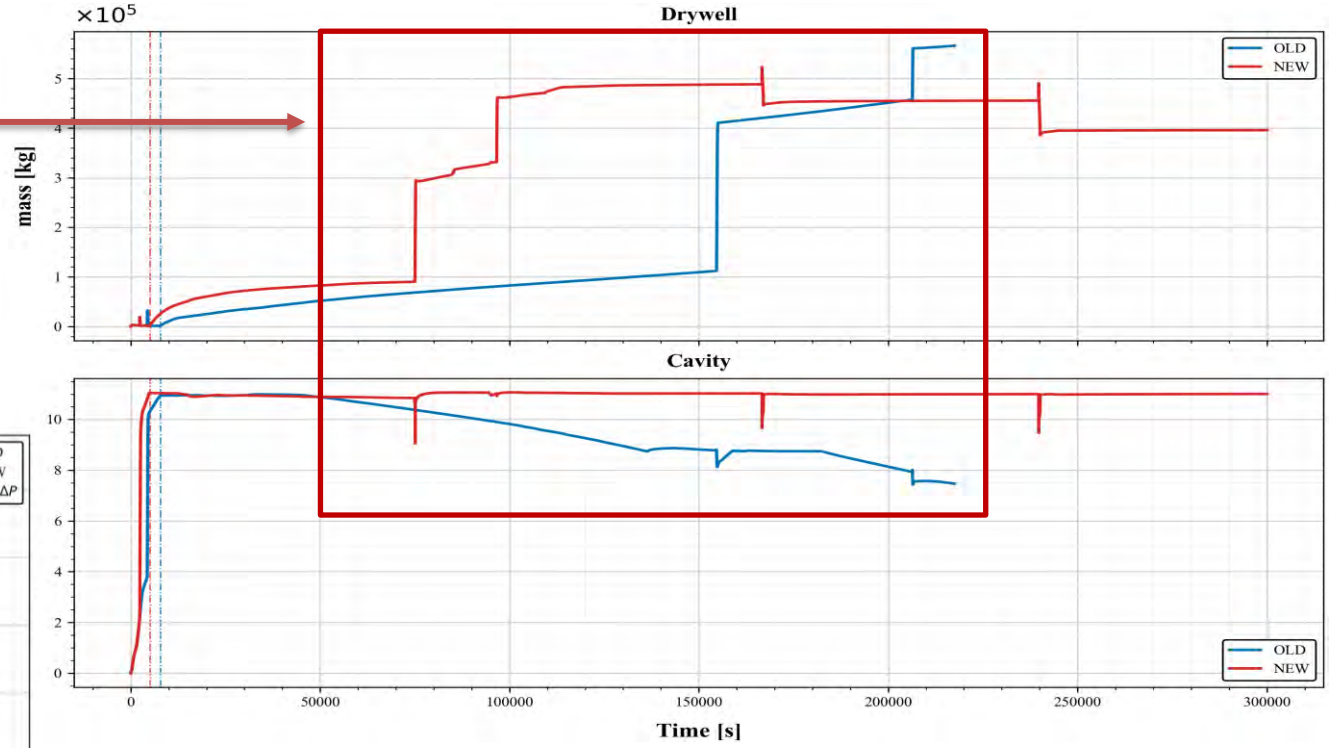
Previous ASTEC containment nodalization: limitation identified in first analyses

Calculations with the previous ASTEC nodalization showed a limitation in predicting the draining of water from the DW to the RC due to **liquid hold-up in DW** regions.

This nodalization limitation in liquid redistribution affected:

- **RC level**
- **DW liquid inventory**
- **Break reverse flow**

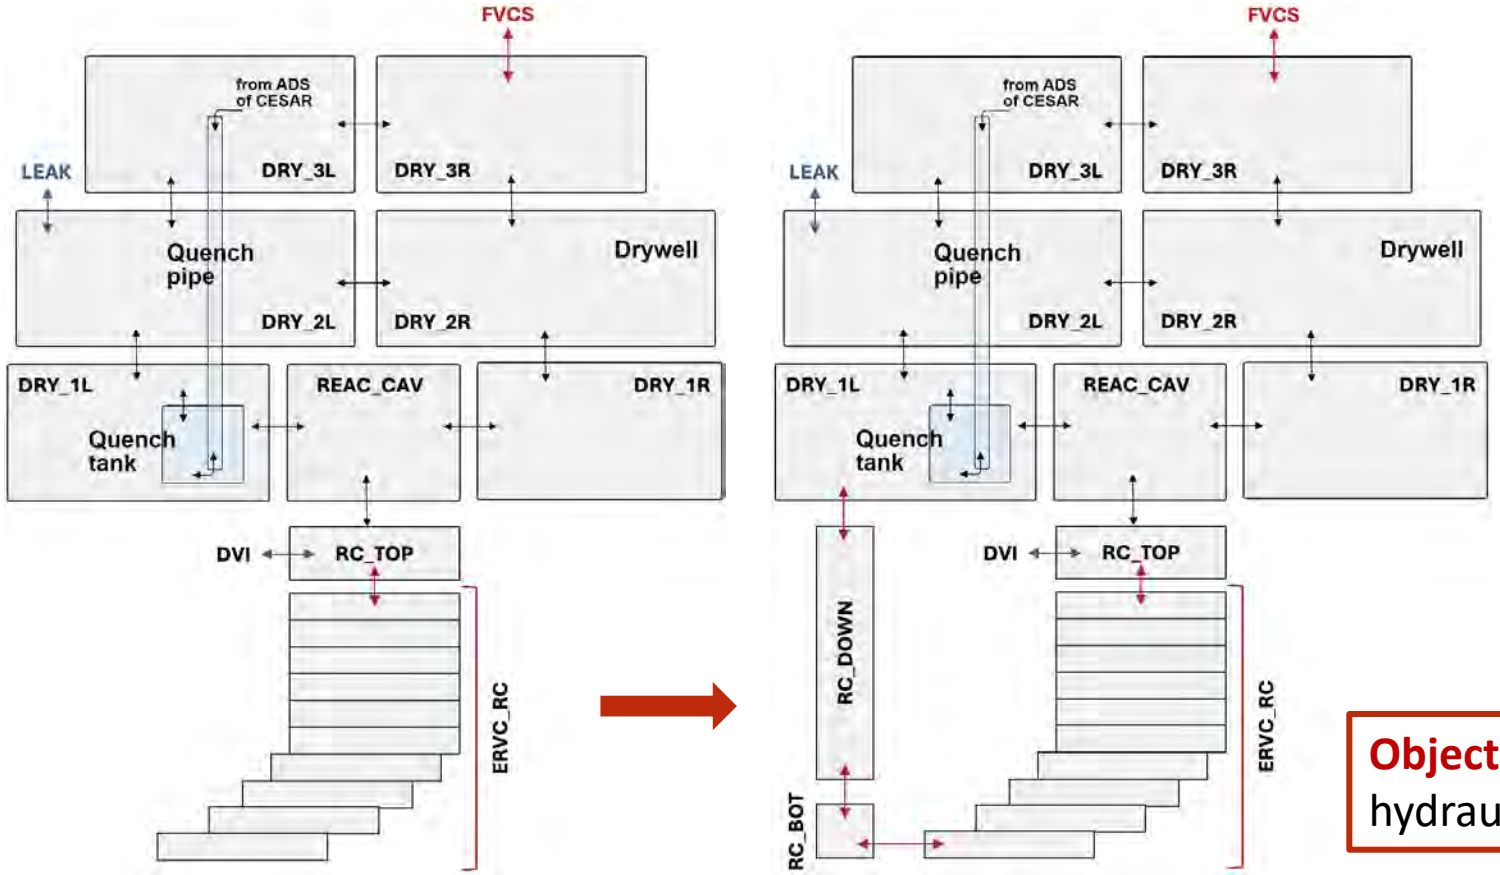




ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

Updated RC–DW hydraulic representation

A gravity-driven path has been added between the DW and the lower RC region.



Added CESAR volumes:

- RC_BOT;
- RC_DOWN.

RC_DOWN is connected to DRY_1R, providing a downcomer-like drainage path.

The modification preserves the global RC capacity while allowing water accumulated in the DW to be redistributed toward the cavity more consistently.

Objective: correct containment-side thermal hydraulics prediction

ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

DBA consistency check

The updated input cannot be used directly for SA1 without checking its impact on the **reference DBA response**.

The DBA check **verifies whether the RC–DW update**:

- **improves liquid redistribution**;
- **preserves** primary **depressurization behaviour**;
- **preserves EHRS heat removal (not directly connected)**
- **preserves final core cooling**;

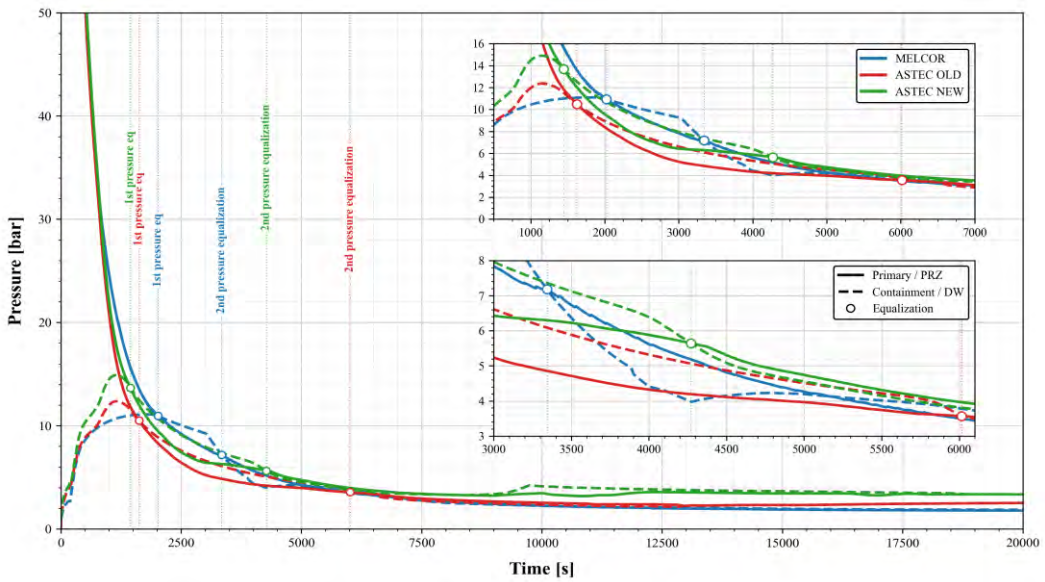
Comparison was performed **among**:

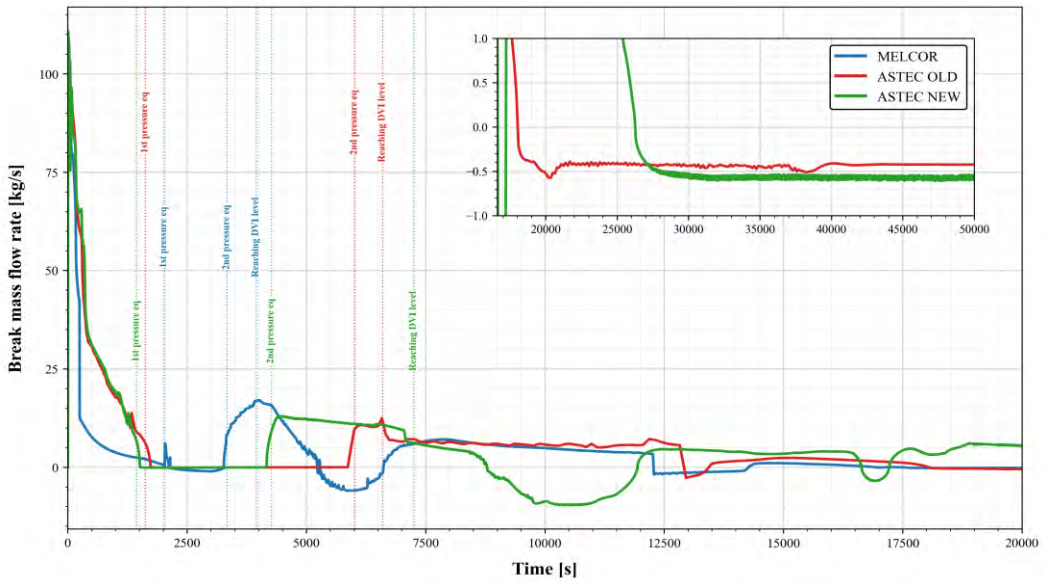
- MELCOR;
- previous ASTEC input (v0);
- updated ASTEC input (v1).

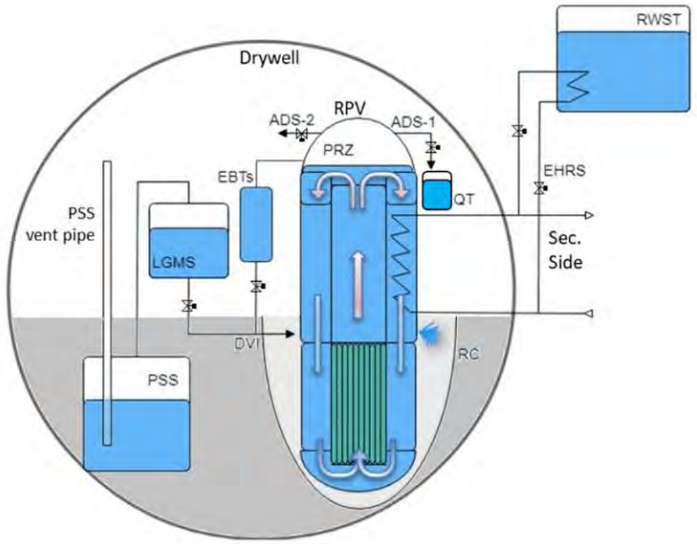
Event	MELCOR	ASTEC_v0	ASTEC_v1
High DW pressure signal	41.0	20.0	17.7
Low PRZ level signal	122.0	65.0	67.5
Low PRZ pressure signal	148.0	158.0	158.8
Low DP RPV–containment signal	1884.0	1398.0	1320.7
1st RPV–DW pressure equalization	2000.0	1584.0	1486.3
1st PSS vent injection	3010.0	5534.0	4038.2
2nd RPV–DW pressure equalization	3315.0	6606.0	4283.6
2nd PSS vent injection	5405.0	n.a.	n.a.
Core level reaches TAF	3000.0	5500.0	8950.0
Cavity level reaches DVI elevation	3950.0	6600.0	7278.1
Low LGMS mass signal	12265.0	12902.0	13179.2

ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

DBA check: pressure equalization and break-flow reversal







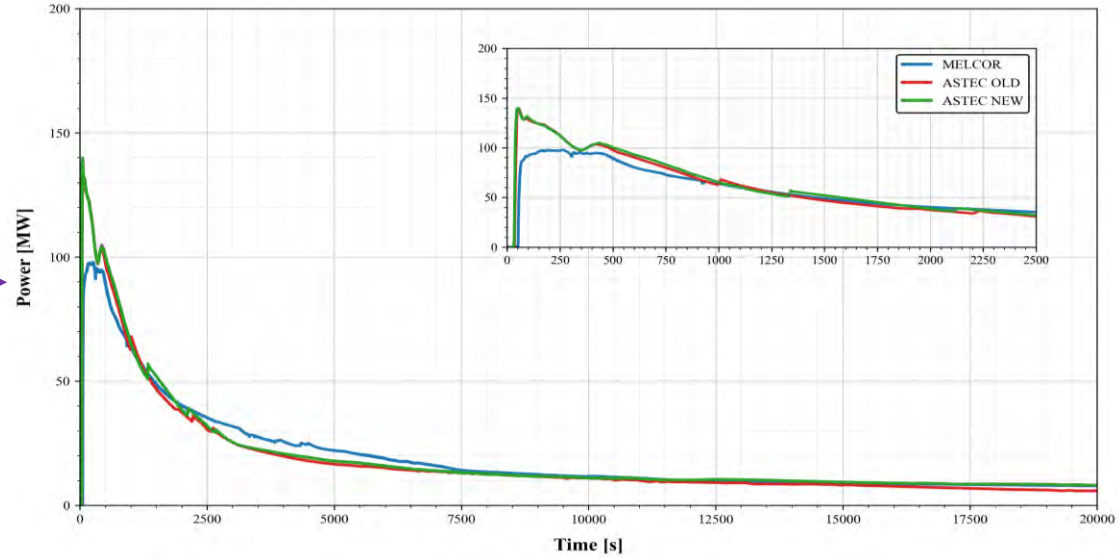
- Updated ASTEC nodalization preserves the global DBA pressure response.
  - First RPV–DW pressure equalization: ~1490s in updated ASTEC.
  - Second pressure equalization: ~4280s in updated ASTEC.
- Break reverse flow occur after the second pressure equalization and RC level rise.
- Compared with the previous ASTEC input, the updated input improves the prediction of
  - cavity filling;
  - Break reverse flow.
- It is to note that the second equalization is anticipated with respect to the previous analyses

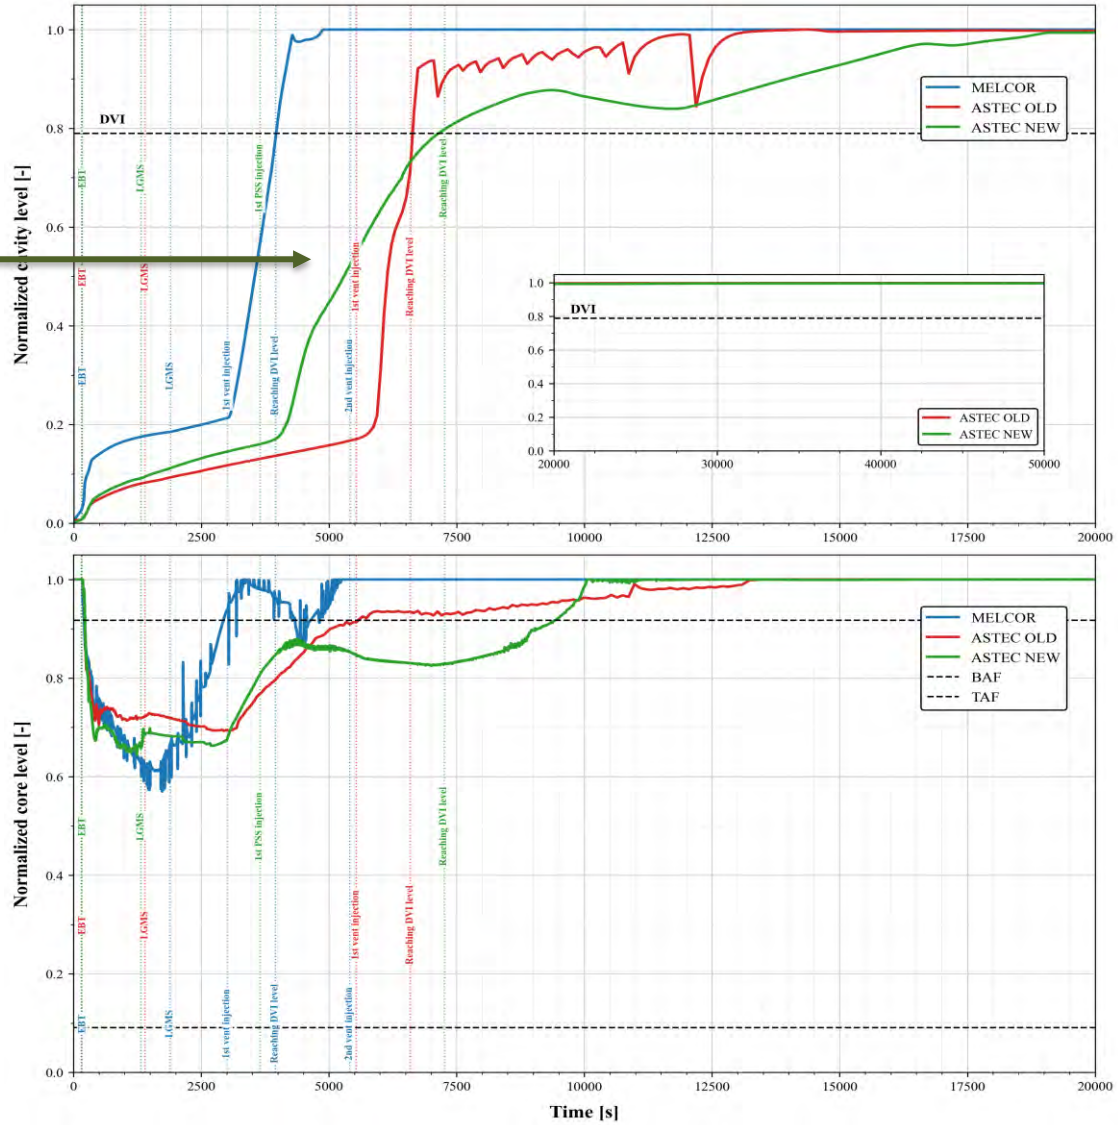
ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

DBA check: final safety outcome is preserved

ASTEC v1 predicts a **slower and more progressive RC filling**.

- Cavity level reaches DVI elevation at ~7280s.
- Core level reaches TAF later, at ~8950s.





However, **the final DBA outcome is unchanged**:

- core remains sufficiently cooled;
- no SA progression occurs;
- **EHRS heat removal** is essentially **unaffected**.

The update acts mainly **on containment liquid redistribution, not on the heat removal function of the EHRS**.

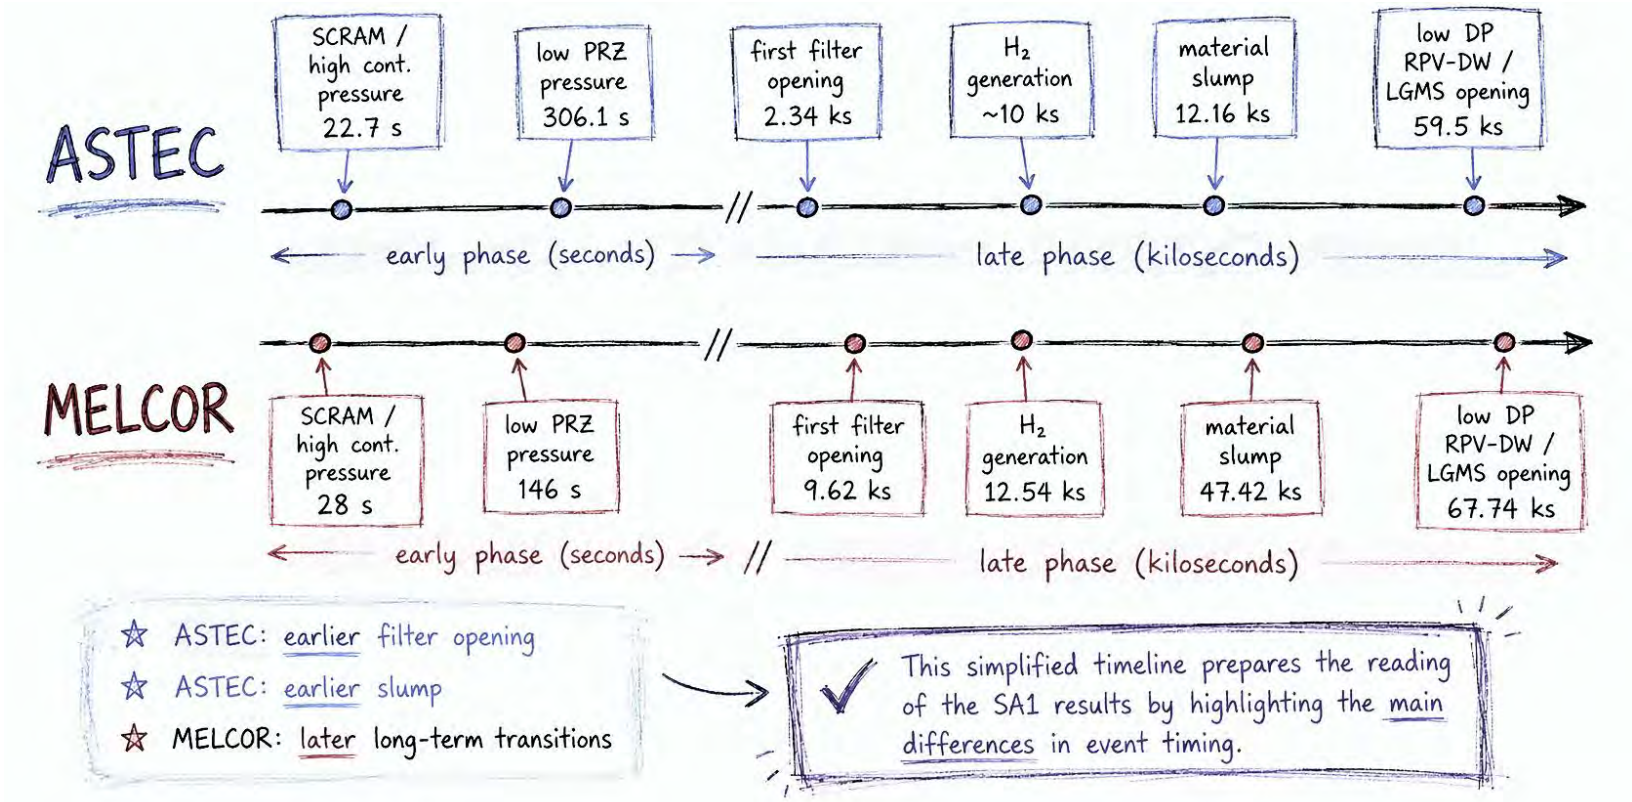
ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

SA1 BDBA sequence: dominant phenomenology

- **SA1 SoT** from the same **DVI guillotine break**
- **EHRS unavailable**: decay heat is not effectively removed through the secondary side.
- **ADS-1 unavailable**: affect primary depressurization.

Transient governed by:

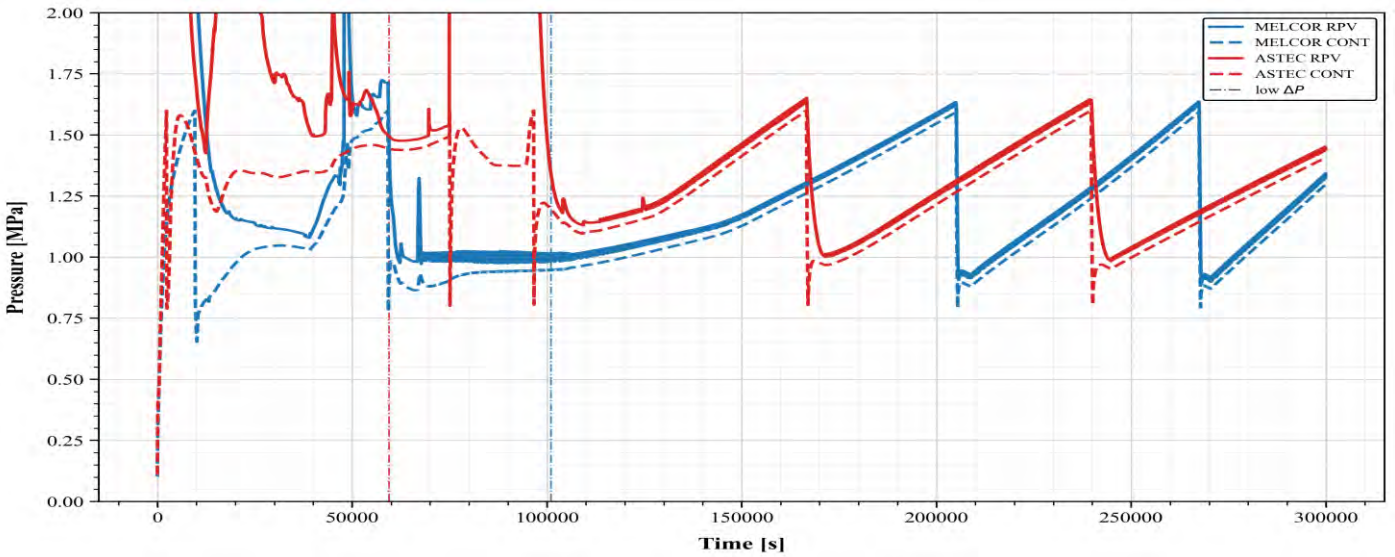
- the **break discharge**
- RPV–DW pressure coupling;
- passive injection availability;
- core heat-up and oxidation;

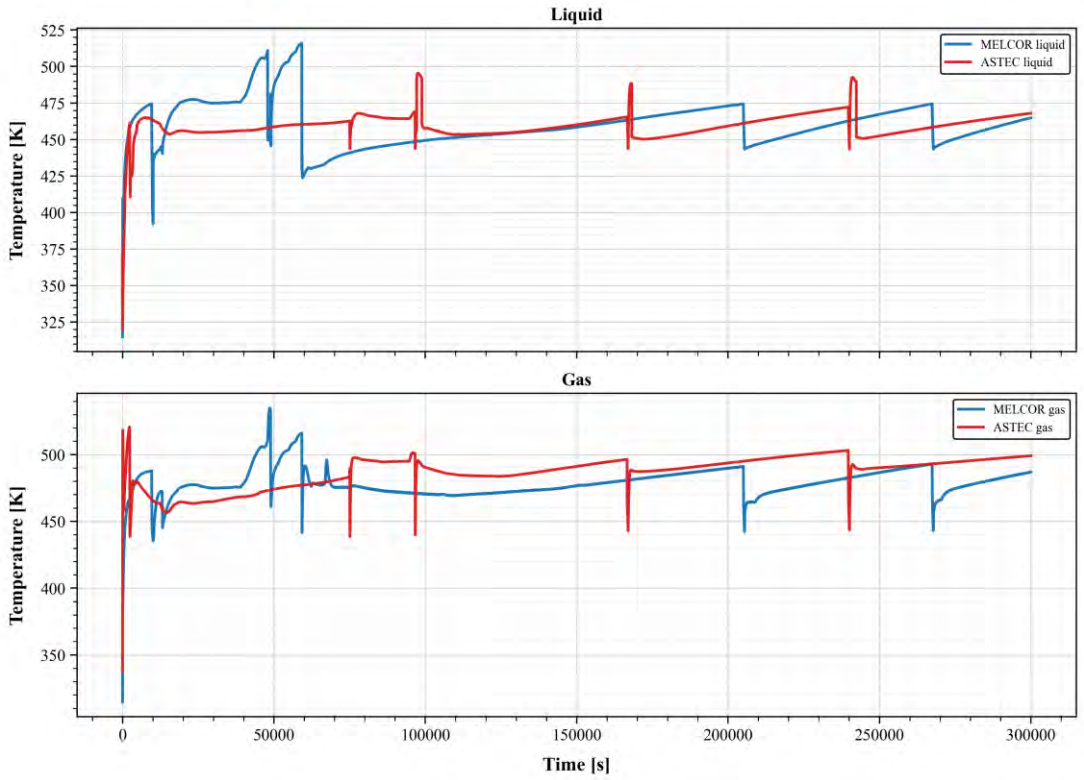


ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

SA1: RPV–DW pressure coupling

- Both codes predict rapid containment pressurization after the DVI break. Pressure cycling is associated with filter actuation
- Both codes predict the long term RPV/containment coupling



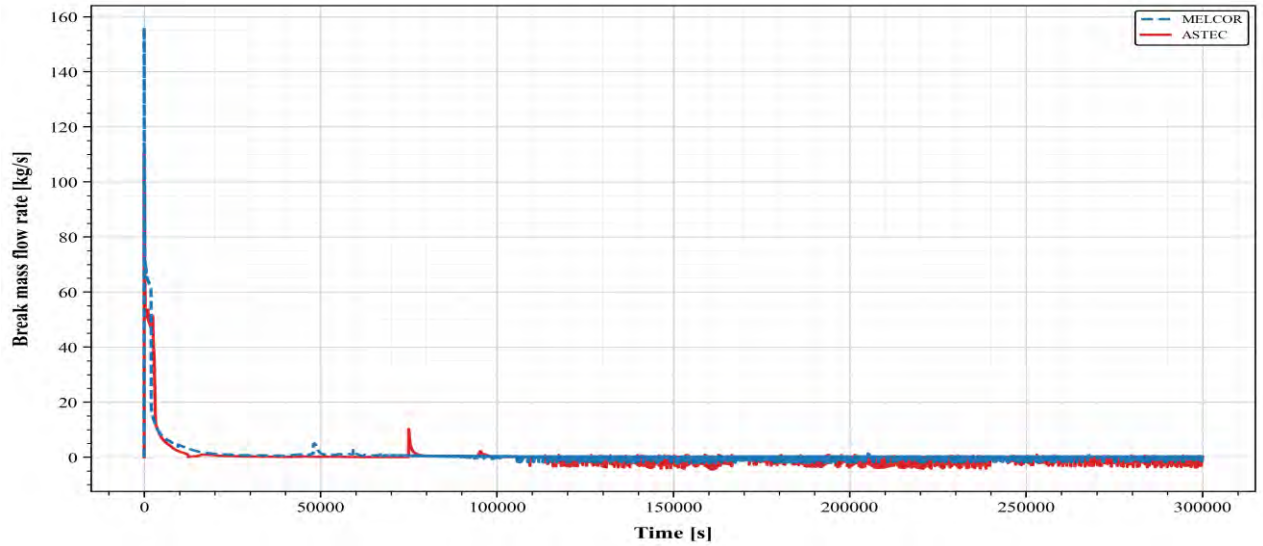


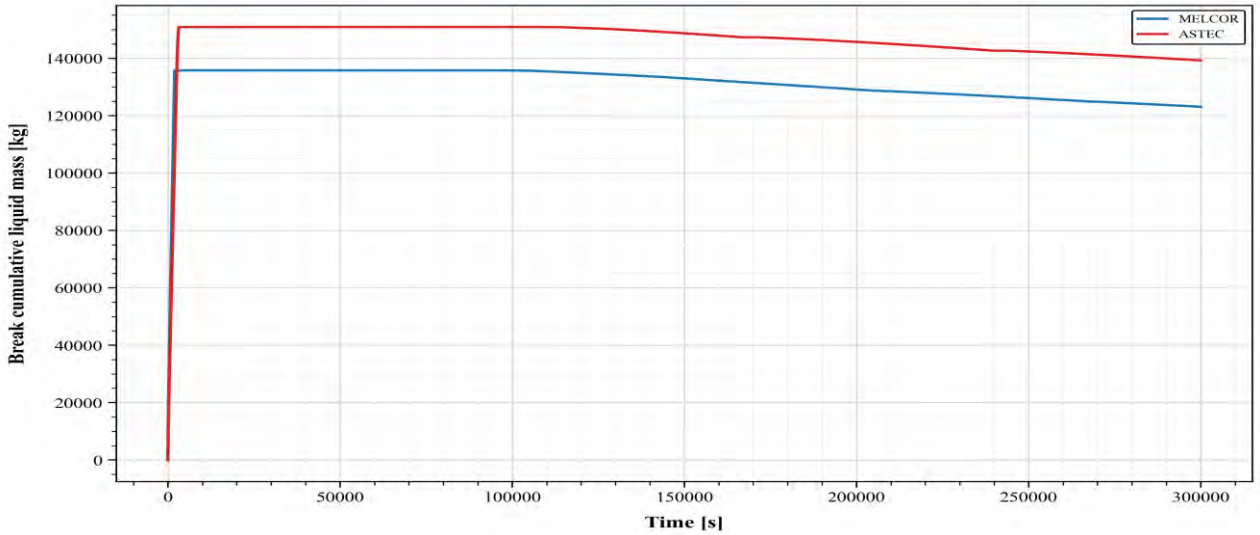
- Gas and liquid temperatures remain broadly in the 450–500 K range for both the code with some quantitaive discrepancies

ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

SA1: water redistribution and core uncovery

- Both codes predict an **initial break discharge followed by low/oscillating flow and reverse-flow** phases.
- **The updated ASTEC** input **avoids** the previous **DW liquid hold-up**.
- **The full filling of the RC allow reverse flow through the DVI break over the long term**.

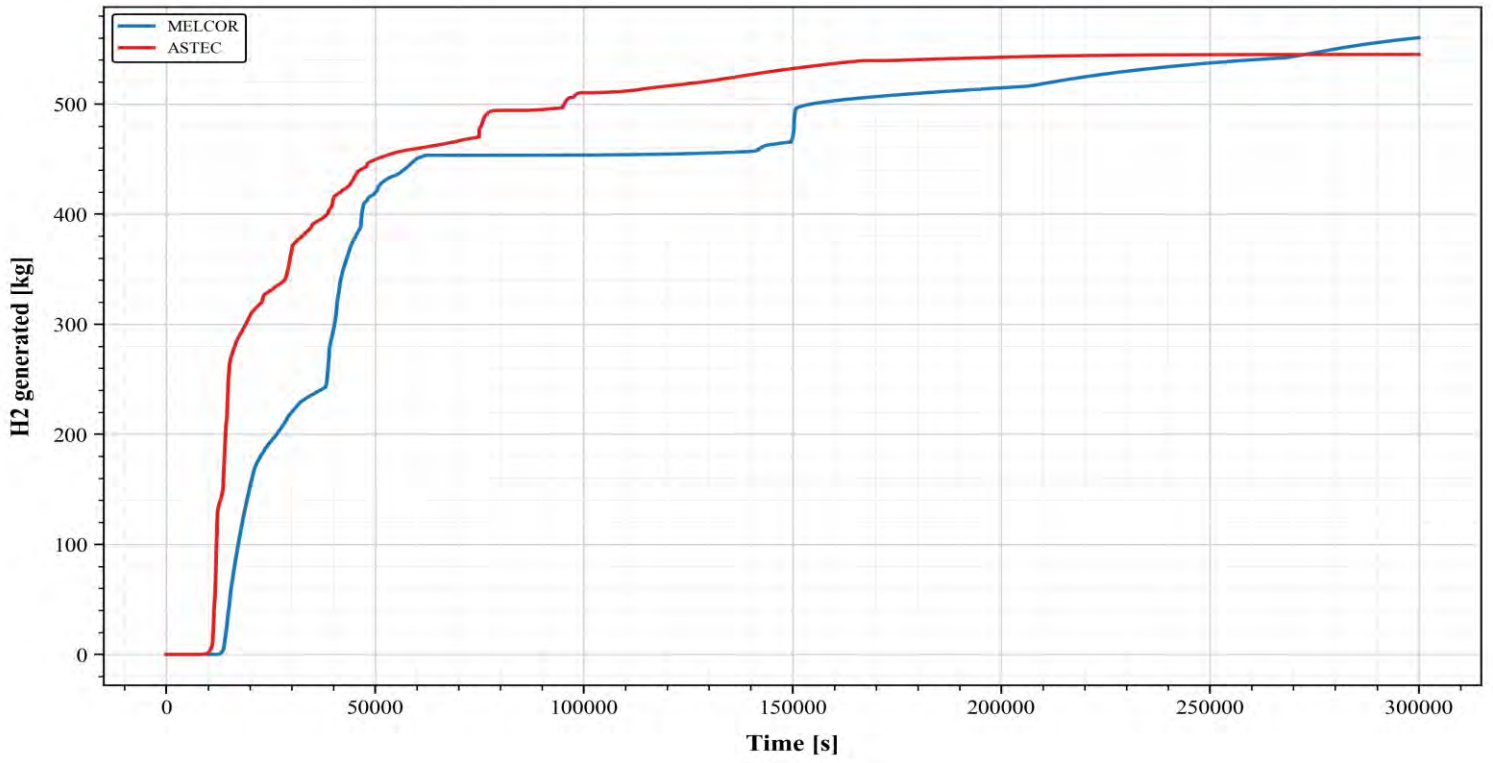




ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

SA1: degradation timing and hydrogen production

- Both codes predict the **same qualitative progression in terms of degradation phenomena:** core uncovery; heat-up; oxidation; material degradation; H_2 generation.
  - **ASTEC anticipates** cladding failure/**degradation** and **H_2 production**.
  - **MELCOR** predicts a **delayed degradation** sequence.



- Despite these differences the final cumulative H_2 mass is comparable, above 500 kg.

ALMA MATER STUDIORUM
UNIVERSITÀ DI BOLOGNA

Conclusions and future remarks

- The previous ASTEC input showed a containment-RC liquid-redistribution limitation under SA1-like conditions.
- The updated RC–DW hydraulic path restores a more physical consistent gravity-driven transfer of water toward the reactor cavity.
- DBA consistency check confirms that the update modifies some timing (of thermal-hydraulic phenomena within the containment) but preserves global DBA safety outcome.

ASTEC and MELCOR are in qualitative agreament in reproducing SA1 progression, but with quantitative discrepancy in:

- Containment-RPV coupling timing;
- liquid redistribution;
- Degradation behaviour timing;

Future work:

- extend the comparison to other BDBA sequences;
- more detailed studies on the condensation behaviour.

ABSTRACT

The HORIZON-EURATOM SAPSAM-SA project, coordinated by ENEA (Italy), was launched in 2022 aiming at investigating the applicability and transfer of knowledge and know-how accumulated on the operating large-LWR reactors to the iPWRs, in view of the European licensing needs with respect to severe accident and Emergency Planning Zone (EPZ). Two generic iPWR concepts are considered in SASPAM-SA: the iPWR Design 1 is characterized by a submerged containment and electric power of approx. 60 MWe and the iPWR Design 2 of approx. 300 MWe, which employs several passive systems and a dry containment.

Extensive scientific test programs have been carried out for today's LWRs over the past few decades, which have contributed to understanding and assessing the phenomena associated with postulated severe reactor accidents. One of the key objectives of SASPAM-SA is to evaluate the relevance and applicability of the existing experimental database to iPWR. The emphasis was on SASPAM-SA Designs 1 and 2, but for specific phenomena, considerations were extended to generic light-water iPWRs. The applied methodology relies on i) determining the main phenomena to be assessed, ii) identifying available experimental facilities and data for the identified phenomena, iii) using data from WP2 for the geometry of Designs 1 and 2, as-well-as for severe accident scenarios and relevant boundary conditions, iv) comparing the experimental data with the data for iPWR, and v) assessing the applicability to iPWR analysis.

Based on the review, the applicability of the data for iPWR analysis has been assessed. Experimental data needs from previous tests, or from new investigations, are identified for phenomena for which no applicable data are available or for which the database is not sufficient, but are considered of significant importance for iPWR analysis. This work is conducted in collaboration with the EU-SEAKNOT project. Recommendations for future experimental data needs are given.

Introduction

Safety assessments of nuclear power plants need reliable, validated analysis methods. Typically, those analysis methods involve the use of accident analysis codes, which can have different levels of scale and detail in the modelling of the phenomena involved. For Severe Accidents (SA), the complex, interconnected, and interdisciplinary phenomena during the accident progression typically require a certain amount of empirism to be applied in the modelling. For validation of the models, experimental data from separate effect scale to integral effect scale all the way to real accident data are used. For this validation, an extensive database has been generated over decades of

experimental efforts. Most of the available data have been produced to represent large Light-Water Reactor (LWR) features and conditions. Recent development of various Small-Modular Reactor (SMR) concepts, many of them using LWR technology, has brought with it the need to validate the codes developed for large-LWRs for use to carry out safety analysis of light-water SMRs.

To assess if the data generated for large LWRs are applicable to SMRs, the experimental facilities and conditions need to be compared to the design features and accident conditions in SMRs. SASPAM-SA project addressed this issue by first developing a methodology for assessment of the applicability of the data and then by reviewing data for different SA phenomena using the methodology (Lind et al., 2024). The focus was on two selected generic iPWR (integrated Pressurized Water Reactor) designs. The main SA phenomena for investigation were selected to be: 1) in-vessel, 2) ex-vessel, 3) containment, and 4) source term topics. Once the work was started, it was decided to include natural circulation in the investigation as its own topic due to its decisive importance in many light-water small modular reactor designs.

Natural circulation is not, strictly speaking, a SA phenomenon; however, it significantly affects the SA progression, especially during the initial phase of the transient. It is treated here as many of the light-water SMR designs increasingly use natural circulation during normal operation and / or in safety systems. The present activity aimed to assess if the existing experimental data for natural circulation are applicable to iPWRs; in order to achieve such goals, both Integral Effect Test Facilities (IETF) and Separate Effects Test Facilities (SETF) have been considered and, moreover, several open access experiments have being reviewed focusing on the thermal-hydraulic of integral Reactor Pressure Vessel (RPV), the primary/containment coupling and the passive systems operation that affect the SA progression As most of the safety analysis tools have been developed for active systems using experimental data for active systems, the validity of the tools for passive systems needs to be assessed. As natural circulation is generally driven by small forces caused by temperature and density differences, it is also highly dependent on the particular geometries and Thermal-Hydraulic (TH) properties. Thereby, the experimental data used for code validation should be produced under conditions closely resembling specific SMR geometries and TH conditions.

In-vessel phenomena. For in-vessel phenomena, reflooding of a rod-like geometry, as well as several phenomena related to core degradation, debris bed, melt formation and lower head failure were reviewed. Many light-water SMR designs foresee fuel rods and assemblies closely resembling large LWR designs, but many times with shorter length of the fuel rods. The different length has mainly an effect on the TH behaviour of the core, including cooling of an over-heated core. The core degradation phenomena at later stages of core heat-up can be expected to be rather similar to large LWRs as long as similar fuel is used. In the later stages of the core degradation, the large amount of structures consisting of stainless steel would affect debris melting and melt pool characteristics.

Ex-vessel phenomena. Ex-vessel phenomena were included in the analysis to a limited extent even though no ex-vessel scenarios were identified in WP2 analyses. SMRs are typically designed for in-vessel retention of the melt. Therefore, ex-vessel phenomena are not expected to be of significant importance. However, adopting a conservative defence-in-depth approach, selected ex-vessel phenomena were included in this work. The containment designs in different light-water SMRs differ considerably. In many designs, the containment is a steel structure in which, therefore, molten-core concrete interaction would not take place. Instead, challenge to the containment would be more similar to the reactor pressure vessel lower head with a molten pool or debris in which the hot corium will react with the stainless steel. In the SMR, the steel content would be expected to be high.

Containment. Gas distribution with focus on hydrogen can be affected by several factors associated with the thermal hydraulics of the containment. Firstly, the effects of inertia (forced convection) and buoyancy (natural convection), which accompany the release of gas, need to be quantified to

estimate the amount of gas mixed by the release and the possible development of a stratified atmosphere in the dome region of the containment. Secondly, the mixing process depends on sink/source terms of mass and/or energy, condensation in bulk and on the walls and evaporation in the sump and on the walls. Both can induce a natural convection flow that transports the gases and enhances mixing. The geometry of the containment can also play an important role in gas distribution. Depending on the design, there may be dead-end compartments that can impede mixing and induce stratification. Finally, accident management systems such as sprays, venting and coolers can also influence gas distribution.

For containment phenomena with focus on hydrogen risk, inert and steam rich containment atmospheres as well as high containment pressures pose distinctly different boundary conditions compared to large LWRs. During a SA in a LWR, large amounts of hydrogen can be generated and released into the containment during reactor core degradation. Additional burnable gases (H_2 and CO) may be released into the containment in case of corium/concrete interaction. This could subsequently raise a combustion hazard. As the Fukushima Daiichi accidents revealed, hydrogen combustion could cause high pressure spikes that could challenge the reactor buildings and lead to the failure of surrounding buildings. To prevent the gas explosion hazard, most of the mitigation strategies adopted by European countries are based on the implementation of Passive Autocatalytic Recombiners (PARs). Thereby, their experimental validation space was assessed in this work.

Finally, data for hydrogen combustion risk was assessed. The hydrogen release can form a combustible mixture depending on different parameters, namely: (i) the H_2 content compared to the oxidant, (ii) the thermodynamic conditions, (iii) the ignition source that could lead to the combustible mixture. When a flammable mixture is ignited, several regimes of combustion can be reached, each of these regimes is characterized by the flame speed which in turns will lead to an overpressure in a confined environment. The phenomena of interest for safety analysis are:

- the flammability limits and their variation with the thermodynamic conditions and the presence of diluents
- Flame propagation and the impact of the environment through well-characterized initial turbulence
- Flame propagation in confined vessel laden with obstacles to characterize flame acceleration in a complex environment and determine the propensity of a given mixture to undergo a fast combustion regime responsible of substance pressure loads on equipment and infrastructures.

Assessment in this work was carried out with the focus on these phenomena.

Source term. Finally, source term issues ranging from aerosol characteristics to aerosol transport, pool scrubbing and iodine chemistry were reviewed and analysed. The containments in light-water SMRs are many times much smaller than in larger LWRs, and are planned for much higher pressures. At the same time, there is typically a large amount of water present compared to the reactor power. Many containments are either at a very low pressure or inertized. These features will result in containment conditions distinctly different from large LWRs with a large pressure range, high humidity and reducing conditions. The small geometrical dimensions would also affect the formation and transport of radionuclides.

Designs and SA scenarios

The main objectives of this work were to assess the relevance and applicability of the existing experimental database to iPWR, and to identify the need for new experiments. The emphasis of the review was on SASPAM-SA Designs 1 and 2 (Mascari et al., 2024; Herranz et al, 2025), Figure 1, but for specific phenomena, considerations were extended to generic light-water iPWRs.

The generic iPWR Design-1 investigated consists of a natural circulation iPWR composed of a shrouded reactor core and riser, an integrated Pressurizer (PRZ), and two Helical coil Steam Generators (HSGs) within an integral RPV housed inside a steel containment. The containment is largely immersed in a large pool of water, serving as the ultimate heat sink. The Emergency Core Cooling System (ECCS) in the iPWR Design-1 consists of two groups of valves allowing the coolant circulation between RPV and containment during accident conditions: the Reactor Vent Valves (RVV) located at the top of the PRZ and Reactor Recirculation Valves (RRVs) located slightly above the active core.

The generic iPWR Design-2 investigated is characterized by the use of several passive systems and by a dry containment. The reactor operates in forced circulation during normal operation and employs a passive mitigation strategy in accident conditions. It consists of an integral RPV, containing the core, eight HSGs, eight primary pumps, the Control Rod Drive Mechanism (CRDM), and the PRZ. The hot water at the core outlet flows upwards in a circular riser up to the primary pumps suction located above each HSGs.

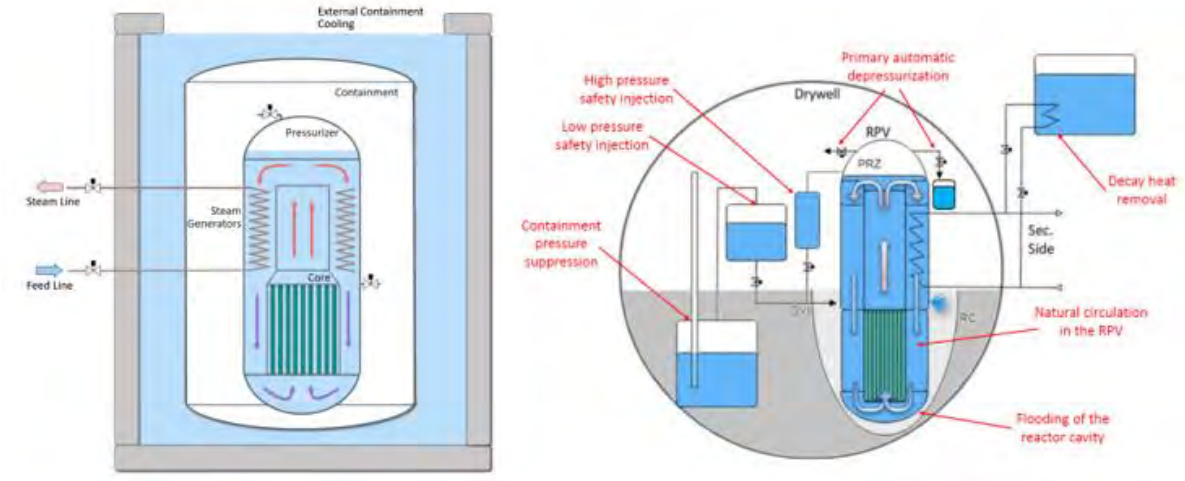

Figure 1. The designs 1 (on the left) and 2 (on the right) used in the SASPAM-SA project (figure from SASPAM-SA)

Several design basis and beyond design basis accident scenarios were postulated in two designs, Design-1 and Design-2 (Gabrielli et al., 2024; Gabrielli et al., 2026). The main parameters relating to the phenomena selected to be investigated were extracted from the analyses and compared to those in the experiments. The reader is referred to Habrielli et al., 2026 for further details of the accident scenarios.

Experimental data analysis

Natural circulation

As most of the safety analysis codes have been developed based on data for active safety systems, the applicability of the data and existing models for passive systems and natural circulation needs to be assessed. Several main parameters affect natural circulation behavior: 1) geometry: e.g. elevation between the source and sink or piping diameters; 2) phases: single phase/two phase; 3) conditions: pressure and temperature fields; 4) pressure losses and heat losses; 5) non-Condensable gas content (NCG).

In both Design 1 and 2, natural circulation is adopted:

- Design 1: During normal operation and accident conditions in the RPV and in the primary/containment coupling

- Design 2: During accident conditions in the RPV and in passive safety systems while in normal operation the plant works in forced circulation.

For review of natural circulation data, the OSU-MASLWR facility (Mascari et al., 2012) was selected based on scaling and other design criteria. In the selected facility, several experimental tests have been performed investigating different types of phenomenology. For the present work, the test DOE OSU-MASLWR-001 and DOE OSU-MASLWR-003B were analysed for primary-containment coupling, . In first instance, the experimental data range has been verified to evaluate the applicability to the design, considering the selected figures of merit (containment and primary pressure), and, subsequently, the dimensionless number conservation for the phenomenon of interest has been evaluated.

For passive systems, existing data for natural circulation from test 7 in the PERSEO facility (in-Pool Energy Removal System for Emergency Operation) (Mascari et al, 2023) was selected. The analysis methodology applied to the PERSEO test data follows the same approach used for the OSU-MASLWR tests. The work has been focused on comparing the EHRS operation in Design 2 during DBA conditions with the experimental data from PERSEO facility. The SA sequences have not been considered in this analysis since they are characterized by EHRS unavailability.The analysis highlights the general applicability of the OSU-MASLWR experimental data for characterizing Design 1, and of PERSEO data for characterizing in-pool decay heat removal systems as in Design 2. At the same time, it underlines the limited transferability of OSU-MASLWR data to Design 2, due to the fundamentally different system configuration and decay heat removal mechanisms.Needs for future testing to improve the accuracy of code results have been identified. Increasing the instrumentation to locally characterize the phenomena of interest, such as condensation, is crucial. For instance, the addition of wall thermocouples to measure in/out containment wall temperatures and parametric oxygen analyzers to estimate non-condensable gas concentrations would provide more detailed insights into the physical processes occurring during natural circulation. These measurements are particularly important for ensuring that the observed phenomena are accurately captured, especially in scenarios where, even if there is a geometrical similarity, the physical interactions are not fully replicated. . On the other hand, considering the existing experimental databases, the analysis'results underscores the importance of careful scaling considerations when applying such data to advanced reactor designs. While current experimental databases provide valuable insights, their application requires a thorough understanding of their limitations, particularly regarding the representation of passive safety features and natural circulation phenomena under various operating conditions.

In-Vessel phenomena

Rod-like geometry. To assess the applicability of existing data for in-vessel hydrogen generation, oxidation behaviour, cladding failure, temperature data, and the influence of reflooding of a rod-like geometry to iPWRs, data from the QUENCH facility were compared with iPWR SA conditions with focus on test QUENCH-06. The experimental data obtained from QUENCH-06 were found to be directly applicable to iPWR SMR. There are no major differences between the fuel assemblies of large PWR and iPWR. The hydrogen production, oxidation behavior, cladding failure, temperature data, and the influence of reflooding may be used in the current limits of uncertainties (experimental, simulation models).

The need of new experiments is rather necessary for a more detailed understanding of the phenomena and their correlations than to obtain basic knowledge (that is the same for large reactors and iPWR). The future efforts for the experimental work will support both cases.

The reflooding case is of interest especially for the large values of the flowrate since QUENCH-06 does not offer data for such case. The existing data may be extrapolated for reasonable range of the parameters both in case of large PWR and iPWR.

Particulate debris bed spreading and coolability. The debris bed coolability is among the critical factors for the integrity of the RPV. Therefore, the main goal of the experimental work in PDS tests at KTH was to provide data for model development for the assessment of uncertainty in the debris self-spreading for achieving a coolable state of the debris bed. Phenomena of particulate debris spreading caused by upward two phase (water and gas) flow was of interest. The analysis showed that the experimental data for particulate debris bed spreading and coolability from PDS tests can be used for the development of a model to predict self-leveling of a non-agglomerated debris bed. The data are relevant to a limited set of scenarios where such beds can be formed either inside the primary vessel or inside the containment vessel. In conventional LWR ex-vessel debris bed coolability is dependent on debris be agglomeration and particle size distribution. There is no obstruction for water access to the debris bed. In case of Design 1 iPWR, the reactor vessel lower head and reactor support skirt are positioned directly on top of and around the debris bed, effectively obstructing water recirculation through the debris bed.

Melt propagation in a porous bed. The REMCOD experiments studied melt propagation through debris beds of different morphologies (e.g., ceramic, metallic, glass particles) and with different thermal properties. The tests show that melt penetration into debris is influenced by particle size, material, and morphology. Solidification (crust formation) was a significant factor in halting melt penetration, and different materials (glass, ceramics, metal) had different effects on the melt behavior. The REMCOD data for melt propagation in a porous bed was found to be relevant in understanding how debris mixtures in iPWRs might behave under severe accident conditions, including the remelting and potential plugging of coolant channels. In addition, the REMCOD experiments were found to provide data on how molten material can remelt and spread through cold debris beds, which is relevant for predicting how molten core material might spread across containment structures or through the reactor cavity in iPWRs.

Melt jet underwater. The goal of DEFOR-MG experiments was to provide an experimental study on underwater phenomena of melt jet structure interaction, breach ablation, plugging, melt jet release and fragmentation. The DEFOR-MG tests highlight different modes of vessel breach, including variations in breach size, melt composition (oxidic vs. metallic), and melt superheat. These failure modes are relevant to both large LWRs and SMRs, as they can lead to varying melt discharge rates and debris bed configurations that influence cooling and the potential for containment failure.

The DEFOR-MG test results highlight key phenomena such as melt fragmentation, nozzle ablation, and debris bed coolability, which are crucial in the confined and integrated structure of SMRs. The findings offer essential data for the optimization of passive safety features, the prevention of containment failure, and the mitigation of SAs in iPWRs. The findings on potential energetic steam explosions due to inadequate quenching are relevant to both LWRs and iPWRs. SMRs with smaller containment volumes could be more vulnerable to pressure spikes if effective melt quenching does not occur.

In-vessel melt pool formation. The data and results related to the in-vessel melt pool formation were reviewed from the LIVE-L1 and LIVE-L3 experiments performed within the LACOMERA project. The LIVE experiments provided significant information on the melt pool behavior during cooling of the outer RPV surface with air followed by the flooding of the lower head.

Materials. In the series of LIVE experiments, the test vessel wall was made of stainless steel (AISI316Ti, material number X6CrNiMoTi17-12-2). Similar material (stainless steel) was adopted in the Design-1 and Design-2 (also confirmed by the material properties section on the input deck of the facilities).

Size. In the series of LIVE experiments, test vessel has outer diameter equal to 1 m, with wall thickness 0.025 m. The geometry differences between Design 1, 2 and LIVE vessel showed that results of experiments cannot be directly applied for Design 1 and 2 from the point of view of melt in-vessel coolability.

Range of parameters. The results of the performed analyses demonstrated that the parameter range of the LIVE-L1, L3, L3A experiments may be partially applicable for in-vessel coolability analysis of Designs 1 and 2.

Ex-Vessel phenomena

As already mentioned, a limited review and assessment of ex-vessel data was conducted despite the fact that no ex-vessel scenarios were identified in SA analyses in SASPAM-SA. The data and results related to the debris coolability and Molten Core Concrete Interaction (MCCI) were assessed from experiments carried out in the OECD-MCCI project. The primary goal of the experiments was to provide data on the behavior of molten corium interacting with concrete under various conditions, focusing on the ability to cool the corium using water flooding, and the effects of corium and concrete interaction on containment structures. Additional goals were to investigate different cooling strategies during SAs, crust break-up and debris cooling after the crust break-up.

Related to iPWRs, the experimental data from MCCI-1, MCCI-2, and MCCI-6 tests were found to provide a solid foundation for understanding core-concrete interactions and coolability in nuclear reactors. For iPWR-specific applications, the data would need to be supplemented with additional experiments with prototypical materials and geometries, or scaled appropriately to account for the differences in design, operational parameters, and advanced safety features of iPWRs.

Containment phenomena

The main containment phenomena considered in this work were related to hydrogen risk: hydrogen distribution, flammability, and mitigation using PARs. In the following, this work is described.

Hydrogen distribution

Several experimental programs have been carried out to investigate the effect of the main phenomena on the hydrogen distribution considering different scales. The data from TOSQAN (e.g., Pocheron et al., 2007; Lemaitre and Pocheron, 2008, Malet et al., 2010) THAI (e.g., OECD/NEA, 2014)), MISTRA (e.g., Studer et al., 2006), and PANDA (e.g., Auban et al., 2004; Paladino et al., 2008) facilities have been reviewed. In these facilities, various experimental programs were performed under OECD/NEA auspices or in the framework of European or national projects.

The data issued from the experimental programs mentioned above covers a large domain of representative conditions of SA in large LWRs. The range of the addressed conditions in the performed tests can be summarized as follow:

- Temperature between 20°C and 150°C,
- Steam concentration between 0 and 70%vol
- Hydrogen concentration between 0 and 20%vol
- Pressure between 0.1 and 0.4 MPa.

iPWR containments with design conditions with pressures above 1.0 MPa, temperatures above 150°C, and steam contents above 70 vol-% are foreseen. These conditions have not been covered in the past experimental programs.

Hydrogen mitigation with PARs

Starting in the 1980s, PAR performance has been studied in a series of test campaigns over the years. Based on these investigations, the PAR response to different pressures, gas mixtures, humidity, temperature and the presence of inhibitors has been broadly assessed.

The following test series were considered for this review noting that for most of these programs, full data sets are not publicly available:

- CTF and LSVCTF (AECL, Canada): Fundamental and qualification tests with AECL PARs (1983-2018) [Koroll et al., 1996]

- KALI-H2 (CEA/EPRI/EDF, France): Fundamental and qualification tests with Areva and NIS PARs (1995-1998) [Braillard et al., 1997]
- H2PAR (IPSN/EDF, France): Impact of core melt aerosols and catalyst poisons with AECL, Areva, and NIS PARs (1995-1999) [Rongier and Studer, 1996]
- Surtsey Vessel (Sandia NL, USA): Fundamental and qualification tests with NIS PARs (1997-1998) [Blanchat and Malliakos, 2000]
- BMC (Battelle, Germany): Several aspects of PAR performance with Areva and NIS PARs (1991-1996) [Kanzleiter, 1997]
- REKO (FZJ, Germany): Single-effect and reaction kinetics tests with generic catalysts/PARs (since 2001) [Reinecke et al., 2010]
- THAI (Becker Technologies, Germany): Several aspects of PAR performance with AECL, Areva, and NIS PARs (since 2003) [Gupta et al., 2013]

The review showed that, in general, the operating behavior of PARs can be considered to be well understood. Furthermore, a comprehensive experimental database is available, which is specifically relevant to large LWR containments with state-of-the-art recombiner models and the accident conditions to be expected there. However, a conclusive statement on the applicability of the existing PAR knowledge and the available test data to iPWR is not yet possible without reservation. If, for example, air ingress into the containment is postulated in the course of the accidnt, significantly different accident conditions would have to be expected compared to large LW-PWRs. Depending on the point in time of the air ingress, the change in atmospheric gas composition would follow different paths, so that a combustible gas composition may also develop under certain circumstances (see Figure 2).

For these possible transients, experimental data for PAR operation at pressures > 0.5 MPa, for the startup behavior under extremely humid conditions and/or oxygen depletion, as well as for fast H_2 feed rates into comparatively small containment volumes are not available. Furthermore, it should be noted that, due to geometric constraints, significantly more compact PAR models may have to be developed for iPWRs and that a substantial database exists so far mainly for rather large-scale PARs. The release of H_2 and O_2 by radiolysis could also play a more significant role in smaller containments and might necessitate different PAR designs.

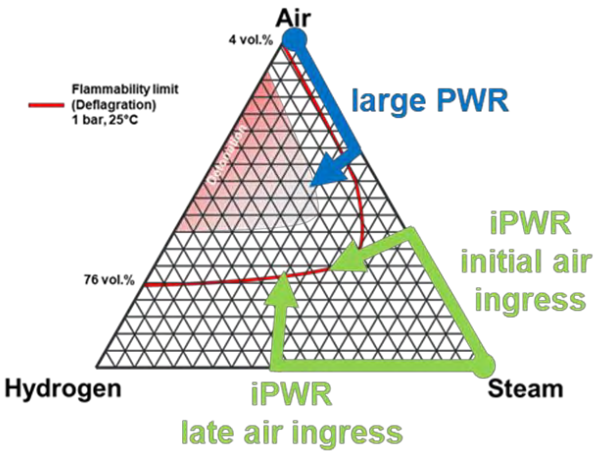

Figure 2. Qualitative progression of gas compositions for different accident scenarios

Combustion risk

The hydrogen risk in LWRs has been addressed over roughly 2 decades through both experimental and simulation investigations. To conduct the analysis of the available data, the following programs have been considered and for which part of the data is publicly available:

- Integral large-scale experiments on hydrogen combustion for SA code validation-HYCOM, a joint research project was carried out in the EU Fifth Framework Programme, concerning hydrogen risk in a nuclear power plant [Breitung et al. 2005],
- IRSN/CNRS research programs on experimental investigation of flammability domain [Cheikhravat et al. 2015], impact of water spray [Joseph-Auguste et al. 2009] and solid particles (graphite and tungsten) [Sabard et al. 2013]
- IRSN/CNRS research programs on H2 safety criteria [Bleyer etal. 2012], [Bentaib et al. 2014]
- PIA-MITHYGENE, a national program on post-Fukushima accident [Bentaïb et al. 2014b]
- THAI, run by Becker Technology with some combustion activities (ISP 49: H2 combustion based on OECD THAI hydrogen deflagration tests)
- Several benchmarks SARNET, ETSO-MITHYGENE, ETSON-SAMHYCO-NET [Bentaib et al., 2014, 2018, 2022]

The description of the flammability limits and the behavior of the flame close these limits are very important for the analysis of the combustion risk applicable to iPWRs. If the temperature domain is close to iPWRs, the pressure is rather limited. From the literature data, the flammability limit of H_2-air diluted or not with steam does not vary linearly with the pressure and data are needed by extending these studies to higher pressures > 1.0 MPa. For iPWR, Fig. 2 illustrates that the mixture will be close to the upper flammability limit. In this case, the flame will lead to a complete combustion with pressure peaks that are substantially higher than the ones reached when the mixture is close to the lower flammability limit.

The codes may use turbulent combustion models that have been validated for lean mixtures. However, rich mixtures behave differently when submitted to turbulence. Indeed, lean mixtures are prone to thermo-diffusive instabilities that enhance the burning speed while rich mixtures are not. Moreover, the increase of the initial pressure is responsible for the occurrence of the hydrodynamic instabilities that modify substantially the burning rate in presence of turbulence.

Regarding combustion regimes, most of the research has focused on lean mixtures (H_2 lean, O_2 rich) for a limited range of temperatures (25 to 140°C) and limited to 0.1 MPa. When considering the Beyond Design Basis Accident (BDBA) in an iPWR, if an air ingress is possible leading to the formation of rich H_2 mixtures (lean O_2), the flame dynamic is completely different, and only limited data is available in the literature. Moreover, the initial pressure can be more than 1.0 MPa and can reach 2.0 MPa during the transient. In this domain of pressure, there is no data in the literature.

Source term

Experimental data for source term were reviewed in the area of aerosol characteristics, aerosol transport in humid / condensing atmosphere, pool scrubbing, and iodine chemistry.

Aerosol characteristics

Aerosol characteristics have a decisive influence on the transport of fission products. This has been investigated in primary circuit conditions covering temperatures from 300 K to 1700 K (e.g., Gouëllo et al., 2020; Kärkelä et a., 2014; Kärkelä et al., 2017). The work has resulted in a unique database describing also the shape of particles, which usually differs from the spherical shape – often assumed (as a simplification) in computer code calculations.

The importance of particle dynamic shape factor on fission product transport and mitigation is similarly applicable to conventional large LWRs as well as to the innovative LW-SMRs (iPWR). In general, the computer codes used for safety analysis assume spherical particles. Particle shape can typically be accounted for by using a shape factor. Accurate knowledge of the particle shape at various stages of accident is difficult to obtain, thus it is a notable source of uncertainty related to particle transport. It is likely that at least insoluble particles differ from the spherical shape during a SA, and therefore, dynamic shape factor higher than 1.0 (spherical particle) should be considered in the analysis work.

Aerosol transport in humid atmosphere

Experimental data for aerosol transport and mitigation were reviewed with the focus on high-humidity, condensing conditions and hygroscopic aerosols. A brief summary of the findings is given below.

Aerosol transport in the containment was investigated in the experimental programs in the AHMED (Mäkynen et al., 1997) and DIANA facilities (Kalilainen et al., 2016). The main aim of the AHMED experimental program was to determine the depletion of both inert and hygroscopic aerosols in the containment under high humidity conditions to understand the reasons for the observed large discrepancies between the results from model calculations and measurements carried out in large scale experiments. The experiments demonstrated the influence of humidity and hygroscopic growth of particles on depletion from the containment atmosphere emphasizing the importance of these phenomena in iPWR containments.

Aerosol deposition in heat exchangers, both in-tube and outside of them, as addressed in the experimental programs in AIDA (no references found in the open literature) and CESANE (Friesen et al., 2001) facilities was shown to have a significant detrimental effect on the heat transfer and on the flow patterns in the heat exchanger. Unfortunately, experimental data from the AIDA program are not available in sufficient detail. CESANE data have limited applicability as the geometrical and other design parameters have a decisive impact on the aerosol deposition and thereby its effect on the heat transfer. Due to the importance of natural circulation and the potential aerosol effects on it, the aerosol deposition in condensing atmosphere is of considerable importance.

The ARTIST experiments for aerosol retention in the U-tube steam generator during steam generator tube rupture SAs were found not to be applicable to present iPWR designs which employ helical coil once-through steam generators.

Pool scrubbing

Fission product retention in water ponds, i.e., pool scrubbing, is known to be an efficient way to mitigate potential source term to the environment. A vast investigation has been done over decades to thoroughly understand the multi-physics that govern this complex process. As a result, a large database has been produced under the anticipated conditions in large LWRs (Herranz et al., 2022). In this work, the database was complemented with additional recent experimental data. The experimental data were found to be sufficient to cover the SA conditions as analysed in the SASPAM-SA project. However, it was observed that experimental data at high injection gas temperatures and velocities, as well as with light non-condensable gases would be beneficial to cover future data needs. Particular attention should be paid to the scaling issues in the pool scrubbing experiments.

Iodine chemistry in the containment

An extensive program has been carried out in the EPICUR facility to provide experimental data for the development and validation of iodine chemistry models in a reactor containment in an accident situation.

Approximately thirty tests were performed by IRSN between 2005 and 2010 as part of the ISTP. The aim of these tests was to study the behavior of iodine in the containment and the effect of irradiation on i) the volatile iodine released from the sump; ii) the formation of organic iodides from the iodine deposited on the painted surfaces of the containment, whether submerged or above ground; iii) the formation of iodine oxides from gaseous iodine and their stability.

About thirty tests were performed by the IRSN as part of the international STEM AND STEM2 programs for the period 2011-2019. In particular, the effects of irradiation on i) the stability of iodine aerosols (CsI, AgI, iodine oxides, etc.) (e.g., Bosland and colombani, 2020); ii) the interactions between iodine and aged paints (e.g., Bosland and Colombani, 2020), taking into account the extension of reactor life; iii) revolatilisation of iodine in the long term after an accident.

In the MiRE and PASSAM (Albiol et al., 2018) programs with the aim of improving the management of radioactive releases in the event of a nuclear accident, around fifteen tests were carried out. The MiRE program (2013-2022) focused on the study of materials capable of trapping radioactive iodine in conditions close to those of an accident, while PASSAM (2013-2016) evaluated existing filtration systems, focusing on gaseous iodine. Together, these projects have made it possible to strengthen filtration solutions to limit the consequences of nuclear accidents.

Finally, eight tests were carried out by the IRSN as part of the international ESTER program. The aim of these tests was to identify additional sources of organic iodine formation, in particular i) in the presence of volatile organic compounds (VOCs): methane, acetone and ethylene; and ii) on different substrates: cables, quartz coupons, galvanized steel and stainless steel.

These tests provide an extensive database of iodine behaviour in the containment of a large-LWR. However, the expected reducing conditions in the containment of a iPWR have not been addressed in these tests. As chemistry of fission products is known to be strongly affected by the gas atmosphere, iodine chemistry data under reducing conditions would be of great importance.

Concluding words

In this work, the applicability of existing experimental data from large LWRs to be used for safety analysis of iPWRs was assessed. The emphasis was on SASPAM-SA Designs 1 and 2, but for specific phenomena, considerations were extended to generic light-water SMRs. The methodology relies on i) determining the main phenomena to be assessed, ii) identifying available experimental facilities, including scaling considerations, and data for the identified phenomena, iii) using data from analyses made in SASPAM-SA for the severe accident scenarios to determine the boundary conditions, iv) comparison of the experimental data with the data for iPWR, and v) classification of the data based on their applicability to iPWR analysis.

Based on the analysis, the data which can be used for iPWR analyses were assessed for natural circulation, in-vessel phenomena, ex-vessel phenomena (limited extent due to absence of such scenarios in WP2 analyses), containment, and source term. Experimental data needs are identified for the phenomena to which no applicable data are available or to which the database is not sufficient, but which are considered of significant importance for iPWR analysis.

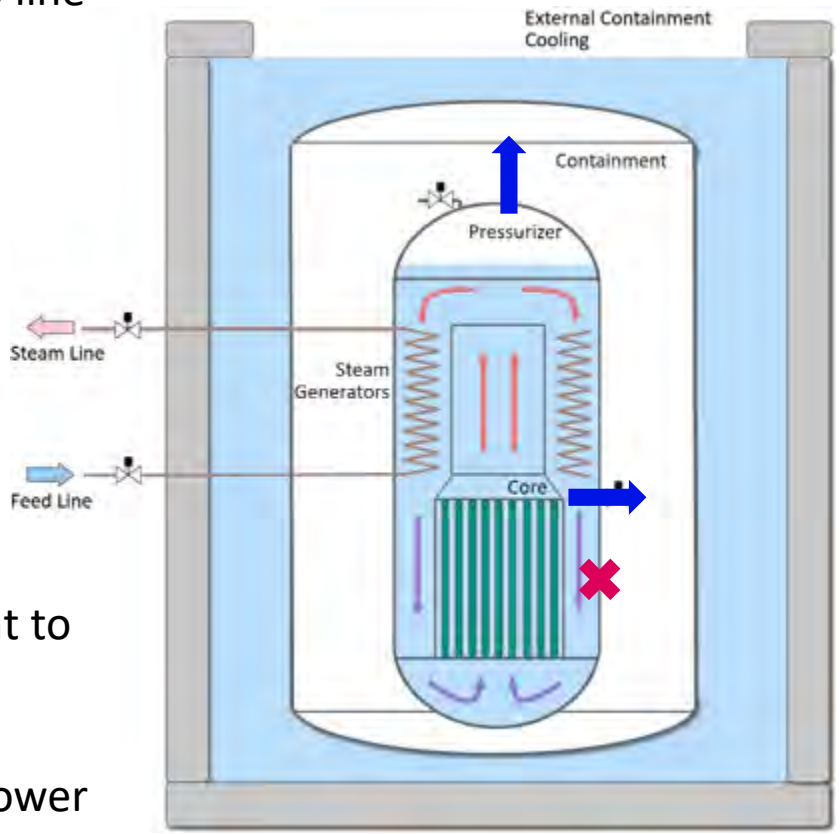
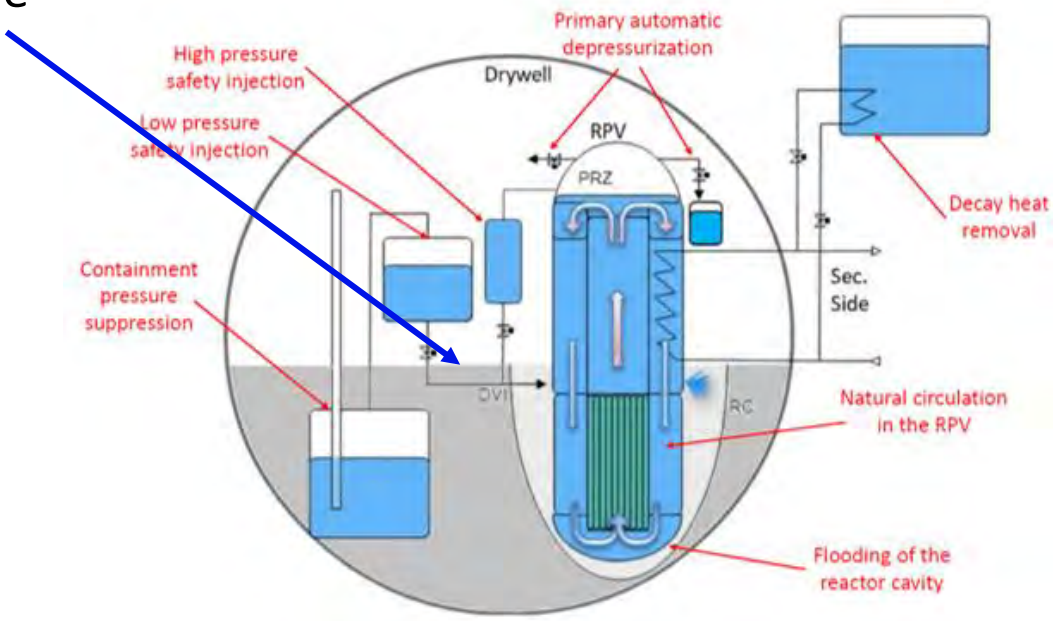
SASPAM-SA Design 1

- **SA-1:**
  - A break in the Chemical and Volume Control System (CVCS) make-up line combined with a loss of AC power
  - The Reactor Vent Valves (RVVs) are operational
  - The Reactor Relief Valves (RRVs) stuck closed. The break discharges directly into the containment
  - The break height was varied, and reverse flow was either allowed or suppressed depending on the modelling approach
- **SA-2:**
  - Inadvertent opening of one RVV (5”) and loss of AC power
  - Two RVVs are available and actuated as in SA-1
  - Both RRVs are unavailable
  - This configuration prevents water recirculation from the containment to the RPV
- **SA-3:**
  - A smaller break (1.7”) in the pressurizer vent line with a loss of AC power
  - The remaining RVVs are available and actuated as in SA-1
  - The RRVs are unavailable



SASPAM-SA Design 2

- **SA-1:**
  - A guillotine break of one Direct Vessel Injection (DVI) line together with the unavailability of the Emergency Heat Removal System (EHRS) due to failure of the corresponding valves to open.
- **SA-2:**
  - DVI break, combined with the unavailability of both the EHRS and the Automatic Depressurization System (ADS) due to valve failure
- **SA-3:**
  - DVI break together with the unavailability of all safety systems as a result of the failure of the associated valves to open



Natural circulation

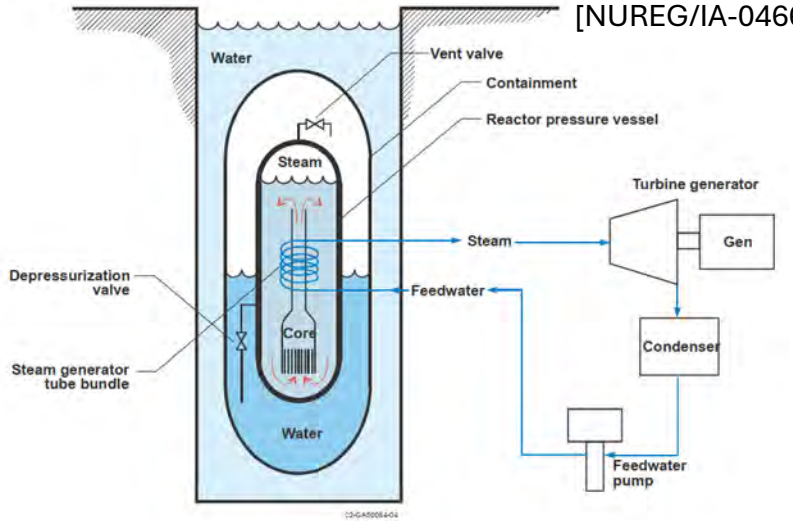
- **Design 1:**
  - During normal operation and accidental conditions
  - In the Reactor Pressure Vessel (RPV) and in the primary/containment coupling (MASLWR-001, 003B)
- **Design 2:**
  - During accidental conditions (PERSEO)
  - In the RPV and in the passive systems (e.g., decay heat removal system)

- MASLWR facility for primary/containment coupling
- PERSEO facility passive safety systems

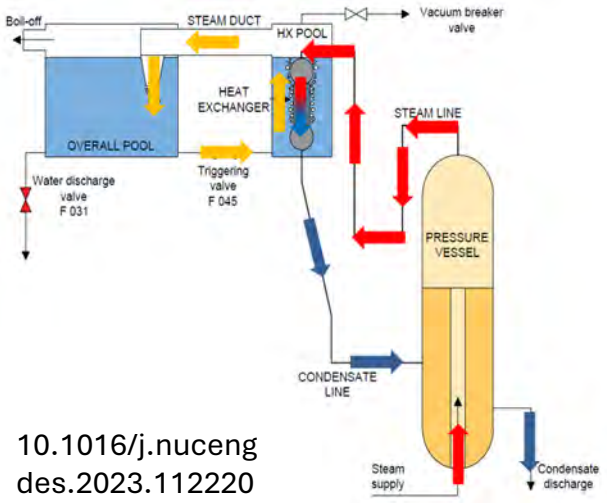
- Primary containment coupling with different SBLOCA dimensions
- Compact steam generator in different operating conditions
- Natural circulation in an integral PWR at low flow rates
- EHRS at different accidental conditions

OSU-MASLWR facility

[NUREG/IA-0466]



PERSEO facility – In-operation layout



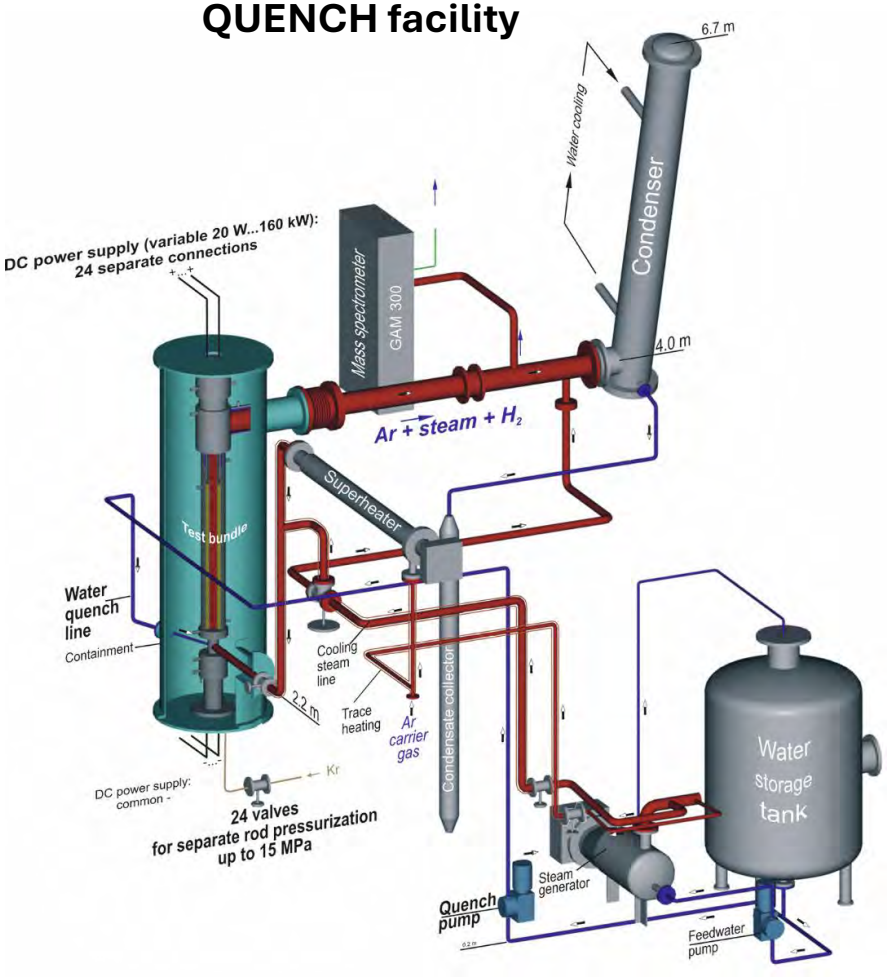
10.1016/j.nucengdes.2023.112220

In-vessel – oxidation and coolability of rod-like geometry

- **QUENCH-06 test**
  - The core heat-up and reflooding at temperatures above 2000 K
  - Pre-oxidation behavior without severe damage to the rods due to reflooding with water
  - Cladding oxidation and hydrogen generation
- **Applicability**
  - **No major differences** between the fuel assemblies of large PWR and iPWR
  - Hydrogen production, oxidation behavior, cladding failure, temperature data, and the influence of reflooding may be used in the current limits of uncertainties (experimental, simulation models)

Reflooding data at large flowrates may not be readily available

QUENCH facility

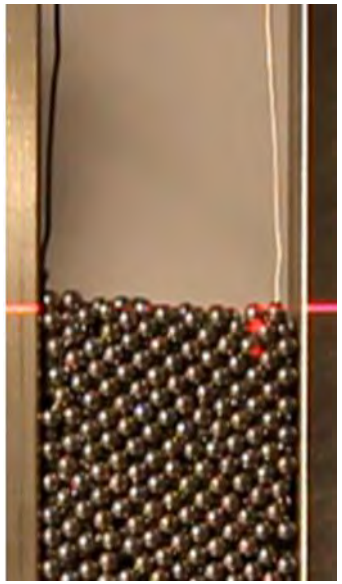


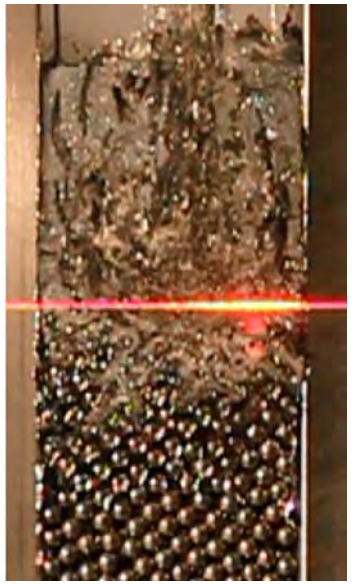
https://www.iam.kit.edu/awp/english/163.php

In-vessel – debris bed, melt propagation and FCI

- **KTH experiments:**
  - Debris formation and agglomeration – DEFOR facility
  - Particulate debris spreading – PDS facility
  - Melt propagation in a porous debris bed – REMCOD facility
  - Lower head failure, breach ablation and plugging during melt release – DEFOR-MG facility
  - Steam explosion in stratified melt-coolant configuration
- Parametric tests with simulant materials for phenomenological understanding and model development

REMCOD





- Underwater melt release and debris bed formation (agglomeration) in a shallow water pool
- Debris coolability with obstructions to water circulation
- Remelting and melt relocation into a dry lower head at low volumetric power
- The effect of steam explosion in a small containment

Pictures: KTH

In-vessel – melt pool formation

- **LIVE experiments:**
  - For lower plenum phenomena related to in-vessel cooling of a molten core LIVE (Large-scale Tests on In-vessel Melt Relocation and Retention), i.e., LIVE-1, -2, -L3A, L4 and L5L
  - LIVE-L1: melt pour is central
  - LIVE-L3: melt pour is lateral near to wall
  - The LIVE3D test facility simulates the lower plenum of a water-cooled reactor pressure vessel and investigates the transient and steady state thermal-hydraulics and heat transfer of solid and liquid corium under various accident scenarios.

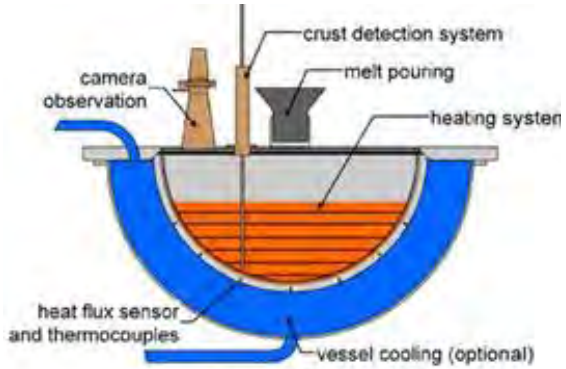


Figure 1: LIVE test vessel

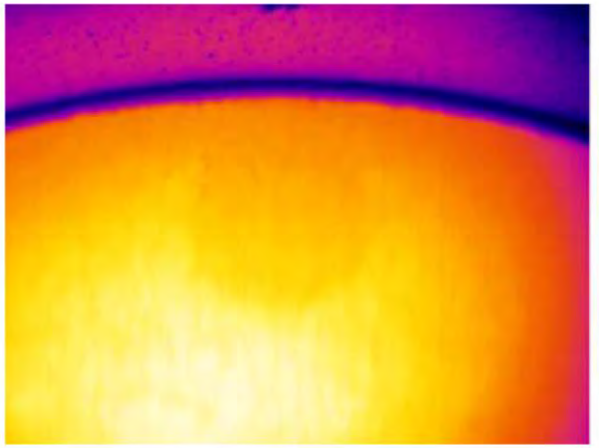


Thermal image of the melt surface in LIVE-L1

Parametric understanding, not aiming to replicate SMR conditions: confined geometry, large amount of steel, abundant water cooling, etc.

Pictures: KTH

Containment – hydrogen distribution

- **Facilities**
  - TOSQAN (e.g., Pocheron et al., 2007; Lemaitre and Pocheron, 2008, Malet et al., 2010)
  - THAI (e.g., OECD/NEA, 2014))
  - MISTRA (e.g., Studer et al., 2006)
  - PANDA (e.g., Auban et al., 2004; Paladino et al., 2008)
- **The range of addressed conditions:**
  - Pressure 0.1-0.4 MPa
  - Temperature 20-150°C,
  - Steam content 0-70%vol
  - Hydrogen concentration 0-20%vol
- **iPWR containments with design conditions:**
  - Pressures > 1.0 MPa
  - Temperatures > 150°C
  - Steam contents > 70 vol-%

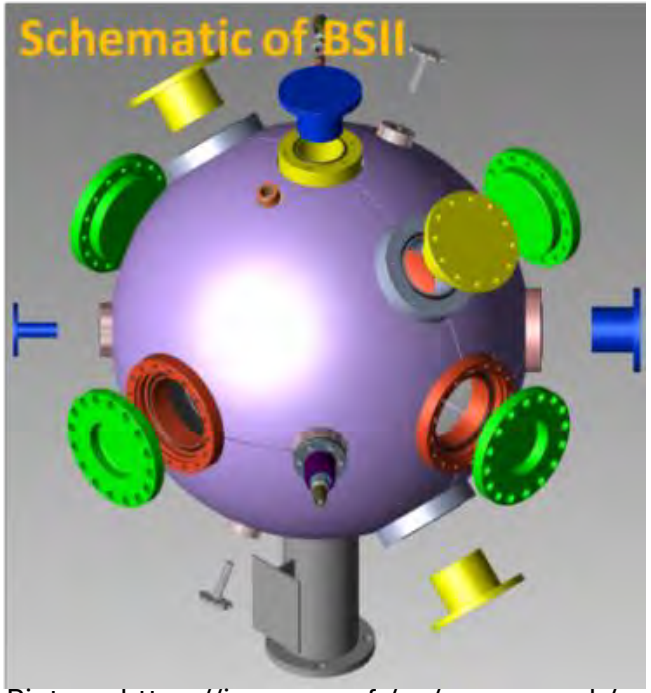
MISTRA

THAI+

Containment – hydrogen combustion risk

- Research programs at **IRSN (ASNR) and CNRS**:
  - Fundamental flame properties of H_2-Air-diluents (steam, He, CO_2)
  - Self-acceleration of H_2 based flames
  - Acceleration of the flame in a turbulent medium
  - Safety criteria for H_2 based mixtures applicable to nuclear power plant

- Different configurations:
  - Homogeneous mixtures
  - Homogeneous gradients (positive and negative)
  - Upward and downward propagation
  - Initial H_2= 4-20 mol-%
  - Initial T= 25-140°C
  - Initial p = 1 bar
  - Water vapor = 0-30%
  - He-CO_2 = 0-40%
  - Effect of water spray

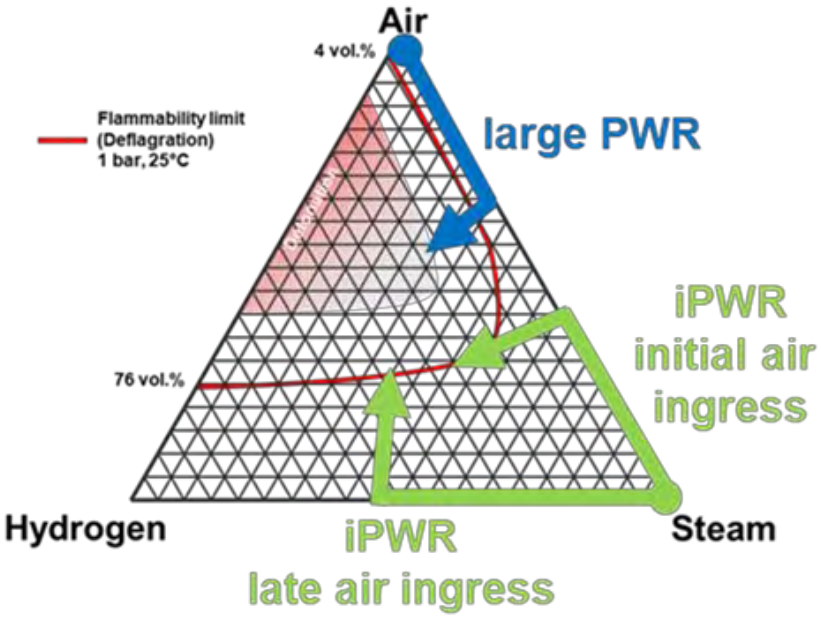


Picture: https://icare.cnrs.fr/en/en-research/en-facilities/en-ct-spherical-bombs/

- Potential air ingress leading to formation of **fuel-rich** mixtures (lean O_2)
  ⇒ Different flame dynamic
  ⇒ Only scarce data available
- **Initial pressure from10 bar to 20 bar** during the transient
  ⇒ At this pressure, no data in the literature

Containment – hydrogen mitigation with PARs

- **Facilities**
  - **CTF and LSVCTF** (AECL, Canada): [Koroll et al., 1996]
  - **KALI-H2** (CEA/EPRI/EDF, France): [Brailard et al., 1997]
  - **H2PAR** (IPSN/EDF, France): [Rongier and Studer, 1996]
  - **Surtsey Vessel** (Sandia NL, USA): [Blanchat and Malliakos, 2000]
  - **BMC** (Battelle, Germany): [Kanzleiter, 1997]
  - **REKO** (FZJ, Germany): [Reinecke et al., 2010]
  - **THAI** (Becker Technologies, Germany): [Gupta et al., 2013]
- In general, the operating behavior of PARs can be considered to be well understood
- A comprehensive experimental database available, specifically relevant to large LWR containments and the accident conditions to be expected there



iPWR containments:

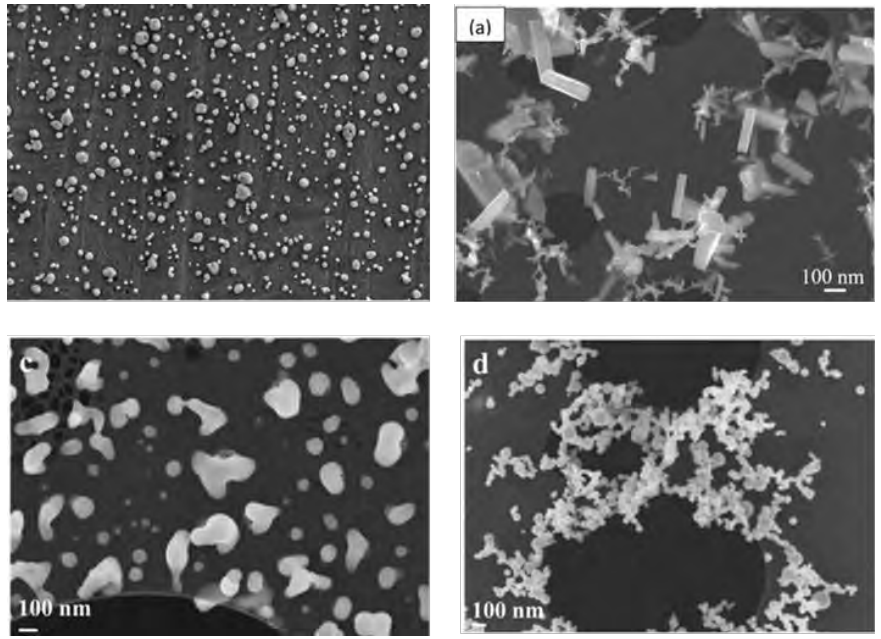
- Pressures > 0.5 MPa
- Startup under extremely humid conditions and/or oxygen depletion
- Fast H_2 feed rates into small containment volumes
- Significantly **more compact PAR models** may have to be developed for iPWRs

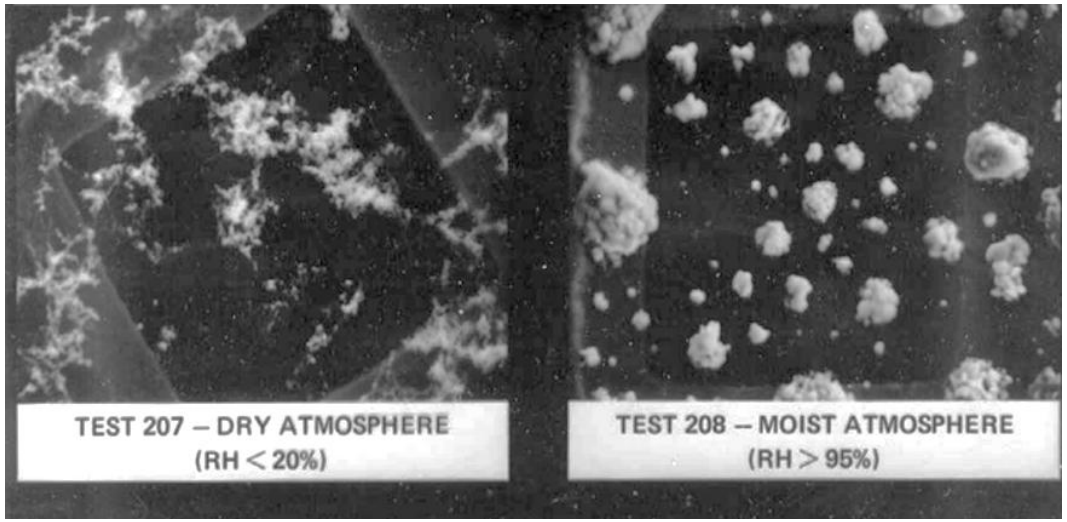
Note: Air ingress!

Source term – aerosol characteristics

- **VTT experimental programs for aerosol characteristics**
  - Primary circuit experimental studies simulated fission product behavior when transporting from high temperatures to low temperatures (from primary circuit to containment conditions)
  - Various shapes in primary circuit conditions
  - Effect of humidity on particle shape

- iPWRs high humidity and small containments
  - Collapse of chain-like agglomerates
  - Particle hygroscopic growth
  - Transport in confined geometries dependent on particle characteristics: size, density, shape





Pictures: VTT and NEA/CSNI/R(2009)5

Source term – aerosol transport in condensing conditions

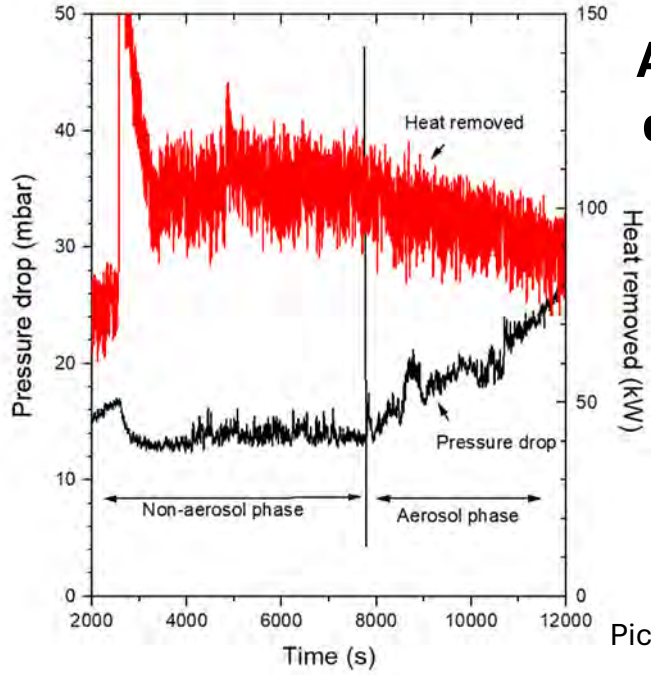
- **AIDA:** Effect of aerosol deposition in PCCS
- **CESANE:** Effect of aerosol deposition on heat transfer, influenced by:
  - Aerosol characteristics: size, shape, composition, concentration
  - Gas atmosphere (steam and NC content)
  - Temperature gradient, heat exchanger power
  - Heat exchanger geometry, esp. entry effects
- **PCC-VTT:** In-tube diffusio-phoresis in condensing conditions
- **AHMED:** Aerosol deposition in containment under humid conditions
- **DIANA:** Aerosol transport in natural circulation – dry conditions
- **ARTIST:** Aerosol deposition during SGTR severe accident
- **FCVS projects:** Large containment conditions

AIDA and CESANE showed that aerosol deposition had a significant effect on:

- Heat transfer
- Pressure drop in the heat exchanger → Flow distribution

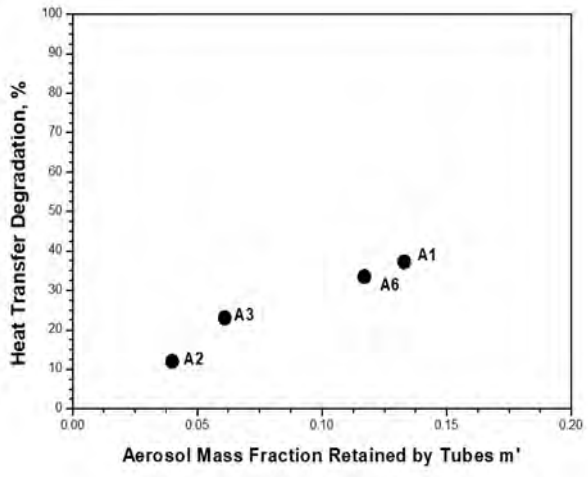
Data not readily available

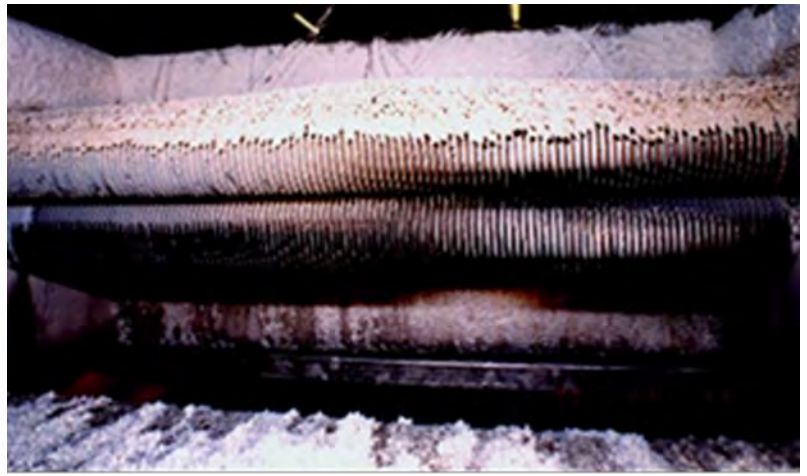
AIDA data



Pictures: PSI

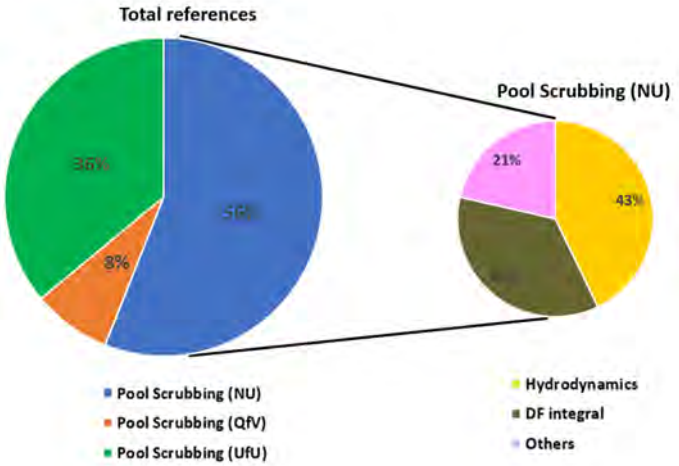
CESANE data





Source term – pool scrubbing

- **Data from over 20 experimental programs in 1960-2016 (Herranz et al., 2022)**
- **Extended by experiments in 2016-2024**
  - 27 additional references, > 350 experiments
  - 8% of the total number of tests are considered qualified for validation and about 36% are seen as useful for understanding
    - FCVS performance oriented (36%)
    - Hydrodynamics oriented (43%)
    - Other Factors (21%). For example, vapor scrubbing or incomplete test characterization



Picture: CIEMAT

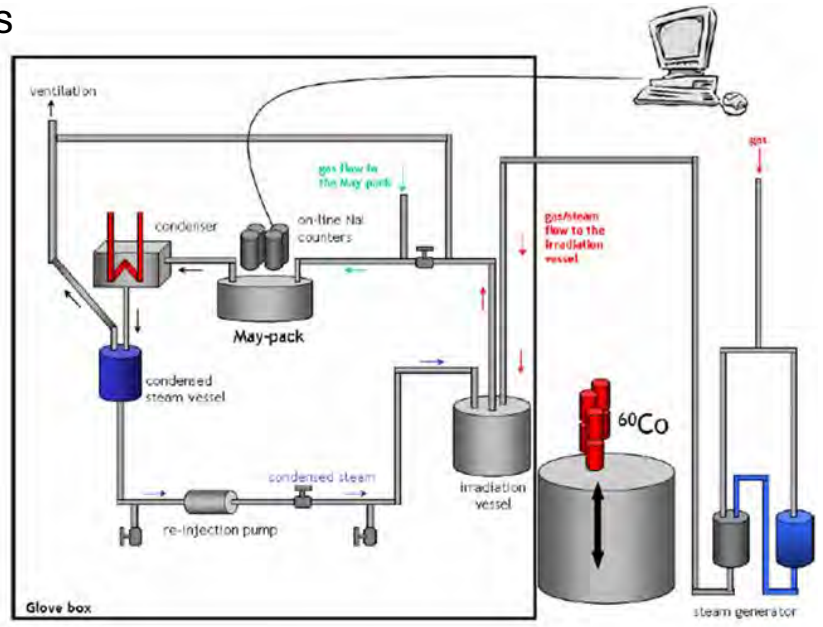
Data base might be needed to be extended:

- **Higher gas injection temperatures**. The hot condition would enhance thermo-phoretic depletion at the pool inlet region
- Presence of **light non-condensable gases** (i.e., H_2 or He as a surrogate gas). Inner bubble hydrodynamics might be affected by the substantial difference in terms of molecular weight of NC. *This observation applies to both iPWRs and LWRs*
- ***Facility scaling should be paid attention to***

Source term – iodine chemistry

- **Data from:**
  - ISTP – 30 tests in 2005-2010
    - volatile iodine released from the sump
    - formation of organic iodides from the iodine deposited on the painted surfaces (submerged and not)
    - formation of iodine oxides from gaseous iodine and their stability
  - STEM and STEM2 – 30 tests in 2011-2019
    - stability of iodine aerosols (CsI, AgI, iodine oxides, etc.);
    - interactions between iodine and aged paints for LTO
    - revolatilisation of iodine in the long term after an accident
  - MiRE and PASSAM – 15 tests in 2013-2022
  - ESTER – 8 tests in 2020-2025, sources for organic iodine formation
    - in the presence of volatile organic compounds (VOCs): methane, acetone and ethylene
    - on different substrates: cables, quartz coupons, galvanized steel and stainless steel

EPICUR facility



Iodine behaviour under reducing or low-oxygen conditions of iPWR containments has not been investigated

Concluding words

- Experimental data were reviewed by 11 organizations for:
  - Natural circulation (1 partner)
  - In-vessel and ex-vessel (ex-vessel limited) (4 partners)
  - Containment (3 partners)
  - Source term (4 partners)
- **LWR data are applicable in most of domains addressed**. Some prevailing boundary conditions would require extensions of the existing databases
- Those experimental data needs for iPWR were identified

ABSTRACT

The Horizon Euratom SASPAM-SA project (Safety Analysis of SMR with PAssive Mitigation strategies – Severe Accidenft) analyzes the applicability of current state-of-the-art severe accident codes against hypothetical generic iPWR designs in the view of the needs of the European licensing processes. In addition to work packages related to code analysis capabilities, current experiments' applicability to iPWRs, and containment analyses, WP6 (on Emergency Planning Zone – EPZ) considers the offsite dispersion and doses caused by radioactive releases from postulated severe accidents, thus representing the last phase of calculations. Twelve partners are working to achieve numerical, quantitative results about the geographic extent of off-site dose consequences, affecting the final decision on EPZ.

Initially, a set of varyingly conservative calculations were performed, based on atmospheric source terms ranging from maximum possible quantities down to smaller release estimates from pure 'expert judgement' or some quite simple analytical work. The codes used included JRODOS, MACCS, HotSpot, RASCAL, GENII and ARANO. The first phase mainly served to test the calculation capabilities of the codes used at the participating institutions.

In the current phase, more refined 'BE' STs produced within WP5 ('Containment') are being used to avoid exceedingly conservative results due to lack of release knowledge, i.e. detailed data about actual nuclide content, activities, temporal release rate trend, effective release height etc.

Generally, it is expected that SMR smaller inventories and longer delays before any atmospheric release might lead to smaller dose consequence footprints than those for existing large LWR plants. That could facilitate the acceptance of SMR plant sites near densely populated areas. Finally, it is expected, at the end of the project, that results from WP6 can be used to understand limits, if any, of the current codes and/or methods and approaches in producing sound and reliable data for EPZ extents of iPWRs.

KEYWORDS
EPZ, Severe Accident, SMR, atmospheric dispersion, offsite doses

1. INTRODUCTION TO WP6 (EPZ)

The Horizon Euratom SASPAM-SA project (Safety Analysis of SMR with PAssive Mitigation strategies – Severe Accident) [1,2,3], coordinated by ENEA (Italy), analyzes the applicability of current state-of-the-art Severe Accident (SA) codes against hypothetical generic integral Pressurized Water Reactor (iPWR) designs in the view of the needs of the European licensing processes. In addition to Work Packages (WP) related to code analysis capabilities [4,5], current experiments' applicability to iPWRs [6], and containment analyses [3], WP6 (Emergency Planning Zone, EPZ), considers the offsite dispersion and doses caused by radioactive releases from postulated SAs, thus representing the last phase of calculations. In order to maximize the knowledge transferability and impacts of the project, two generic design-concepts, characterized by different evolutionary innovations in comparison with larger operating reactor, were selected for analyses.

The overall objective of WP6 is to provide evaluations of size and extension of EPZ for selected SA scenarios, eventually (during latter half of SASPAM-SA project) coupling the results of BE Source Term (ST) codes to radiological consequences tools. One of the most important features of iPWRs is the possibility of their siting near densely populated areas thanks to the (claimed) increased inherent safety, the assumedly lower radiological impact, and possibly reduced size of the region affected by releases (dose consequences footprint). The need to demonstrate these features using quantitative results is addressed by WP6 which attempts to provide a sound basis for the assessment of EPZ. WP6 will produce recommendations on rigorous and justified methodology for iPWR EPZ 'right-sized' determination. However, the size is not necessarily universally the same in all countries due to domestic regulations, for all kinds of plants or for all sites. Furthermore, for the EPZ, SASPAM-SA is strictly considering radiological consequences only ('off-site doses footprint area'), leaving out any possible social, political, logistics etc. factors. It can be postulated that the EPZ cannot be smaller than the area defined by the purely radiological considerations.

The structure of WP6 is the following:
- Task 6.1: Critical review of existing EPZ methodology
- Task 6.2: Preliminary conservative offsite dose assessments
- Task 6.3: Offsite doses & EPZ by Best Estimate (BE) approach
- Task 6.4: Conclusions on iPWR EPZ & recommendations on methodology

This paper considers mainly the first two tasks of WP6, specifically the review of current methodologies (Task 6.1) and the conservative assessments of EPZ (Task 6.2). VTT (Finland) is leading the work in WP6.

Task 1 (methodology review) is devoted to the analyses of the methods already available for large Light Water Reactors (LWR) to understand their applicability to iPWR. It included also preparatory work in relation to the following task such as an analysis of the suitability of codes linked to the problem of near range atmospheric dispersion and the effect of nearby buildings.

Task 2 (preliminary / conservative dose calculations) was devoted to develop first estimates of STs relying on publicly available data or conservative hypothesis based on initial inventory evaluated in WP2, and to calculate EPZs using simplified and conservative methods. This provides background technical results to be used as a comparison set for the BE tasks.

2. CRITICAL REVIEW OF THE EXISTING METHODOLOGY FOR EPZ DETERMINATION

The work carried out within Task 6.1 focused on a comprehensive review of the existing methodologies, relevant to the definition of EPZs for integral iPWR. The activities were jointly conducted by ENEA, JRC, LEI, POLIMI, SSTC NRS, TUS, Università di Roma, and VTT, combining expertise from multiple European and international institutions.

The review work included the following subtopics:

- Analysis of the methods already available for large-LWR to understand their applicability to iPWR.
- Preparatory work in relation to the following task such as an analysis of the suitability of codes linked to the problem of near range atmospheric dispersion and the effect of nearby buildings.
- Study of country-specific regulations on EPZ & protective measures, IAEA guidelines on those & outcomes of the SMR Regulators' Forum [13], and outcomes of relevant IAEA CRP projects.
- Analysis of current EPZ approaches (large PWR or other) and their applicability to smaller iPWRs.
- Review of simulation tools and recommendations for suitable, possibly harmonized methods for iPWR SMR EPZ.
- Overview of short range dispersion special approaches & phenomena.
- Consideration of risk-informed methodology for the calculation of the EPZ size for an iPWR SMR.

The activities by WP6 partners included examination of the features of several available dispersion and dose projection tools, including their near-range capability which is important for SMRs, if exceedance of dose limits is only expected in the near-range. Current regulations and methodologies for EPZ were studied to serve as groundwork both for the quantitative calculations and the expected methodology recommendations.

The review of EPZ-related regulations covered e.g. Bulgaria, Finland, Lithuania, Ukraine, and the USA. The implications of the International Atomic Energy Agency (IAEA) and European Union (EU) standards and directives for several EU countries were considered. The codes for release through water volumes (like reactor pool) were SPARC-90 for pool scrubbing and IMPAIR for iodine chemistry and release. For the atmospheric dispersion and dose calculations, e.g. JRODOS, MACCS, HotSpot, or the VTT in-house code ARANO were used.

2.1. Current regulations on EPZ & protective measures

SASPAM-SA WP6 performed a comprehensive review of EPZ[1] regulations and methodologies across multiple countries and international frameworks. In the EU, the bases are directives (Basic Safety Standards 2013/59/Euratom [7] and European Nuclear Safety Directive 2014/87/Euratom [8]) which set overarching goals for emergency management but do not prescribe specific EPZ distances. Instead, member states define zones based on national policies, laws and risk assessments.

Country-specific approaches vary significantly. Belgium mandates evacuation planning within 10 km and sheltering/iodine prophylaxis within 20 km, while Bulgaria uses a tiered system (Precautionary Action Zone[2] – PAZ – 2 km, Urgent Protective Actions Zone[3] – UPZ – conditionally 30 km, and a long-term zone, without fixed outer boundary because its extent is determined by monitoring results and conditions after an event) integrated into the disaster protection legislation. Finland used to prescribe 5 km precautionary and

[1] **Emergency Planning Zone (EPZ)**: The precautionary action zone (PAZ) and the urgent protective action planning zone (UPZ) [10].

[2] **Precautionary Action Zone (PAZ)**: An area around a facility for which emergency arrangements have been made to take urgent protective actions in the event of a nuclear or radiological emergency to avoid or to minimize severe deterministic effects off the site. Protective actions within this area are to be taken before or shortly after a release of radioactive material or an exposure, on the basis of prevailing conditions at the facility [10].

[3] **Urgent Protective Actions Zone (UPZ)**: An area around a facility for which arrangements have been made to take urgent protective actions in the event of a nuclear or radiological emergency to avert doses off the site in accordance with international safety standards. Protective actions within this area are to be taken on the basis of environmental monitoring — or, as appropriate, prevailing conditions at the facility [10].

20 km planning zones, supported by STUK regulations and detailed rescue plans, but shifted to a flexible scheme with the STUK Emergency Decree Y/2/2024 [12]. France in 2019 expanded its EPZ for sheltering and iodine pills from 10 km to 20 km to improve public preparedness. Other European nations (Czech Republic, Hungary, Lithuania, Slovakia, Slovenia, Spain) adopt similar concentric-zone models, typically ranging from 3–5 km for immediate actions to 30 km or more for extended measures, often aligned with IAEA guidance. Ukraine is in the process of harmonizing national rules with EU and IAEA standards.

Internationally, Canada applies flexible, case-by-case EPZ sizing, while the U.S. has shifted to a performance-based, risk-informed approach for SMRs and new technologies, formalized in updated NRC regulations (final new rule 2023). This method considers accident scenario likelihoods, together with the STs, potentially reducing EPZs to very small distances for advanced designs.

Overall, trends indicate some movement towards risk-informed, site-specific EPZ sizing, especially for SMRs, balancing safety, practicality, and societal factors. For example, the UK Nuclear Regulatory Review by Fingleton, 2025 [11], strongly emphasizes simplification of regulations together with management and proportionality of risks. Protective actions, such as evacuation, sheltering, iodine prophylaxis, and food restrictions, are most universally planned based on dose criteria and operational intervention levels.

2.2. Future development – Finland example

Finland's regulations are evolving related to SMRs, starting with the determination of EPZ (consisting of PAZ and UPZ). STUK emphasizes that SMR safety should be assessed case by case, as their lower power and passive safety features can reduce risks compared to traditional nuclear power plants. This flexibility may allow SMRs to be located closer to urban areas, provided safety is demonstrated.

A major legislative reform is underway, but EPZ rules were updated earlier through STUK Regulation Y/2/2024 (effective February 2024) [12] to support urban planning. Previously fixed EPZ distances — PAZ at 5 km and UPZ at 20 km — are now flexible, based on dose criteria. For PAZ, radiation dose outside the zone must remain below 1 Sv within 10 hours. Inside PAZ, efficient precautionary evacuation is planned to prevent early deterministic health effects. Outside UPZ, dose remaining below 10 mSv within 48 hours is required, to not necessitate sheltering indoors there. Licensees must demonstrate compliance using realistic SA scenarios, though probabilistic risk assessment is not required. SASPAM-SA WP6 is facing the same fundamental problem: How to choose the accident scenarios for EPZ determination purposes? However, a further step towards risk-informed approach may be expected with the recent STUK information that the accident and release scenario for UPZ may be less severe than that for PAZ. The approach prioritizes safety performance regarding emergency preparedness rather than prescribing reactor design / technology, actually so aligning with IAEA EP&R high-level guidelines and STUK emergency regulations ('VAL' guides).

2.3. IAEA and the SMR Regulators' Forum

WP6 outlined IAEA guidelines for emergency preparedness and response planning, with protective measures for nuclear facilities, which are not yet specifically focusing on SMRs. The IAEA defines five Emergency Preparedness Categories (EPC), with Category I posing the highest offsite health risks. SMRs generally fall between Categories I–III, suggesting potential for reduced emergency planning compared to large LWRs, though enhanced safety needs to be demonstrated.

Key standards include GSR Part 7 (2015; possibly to be updated) [10], which sets 26 requirements for preparedness and response, covering hazard assessment, protective actions, public communication, and medical response [10]. It applies to all reactor types, including small or next-generation designs. Supporting documents such as EPR-NPP-PPA (2013) [9] provide practical guidance on protective actions and EPZ

sizing, though currently presented methods remain deterministic and rather simplified, often based on worst-case scenarios.

The IAEA recommends concentric EPZ zones called PAZ near the plant for immediate measures once release is expected and UPZ for rapid protective actions. Post-Fukushima, recommended planning area increased significantly, with Extended Planning Distances (EPD)[4] up to 100 km and Ingestion and Commodities Planning Distance (ICPD)[5] up to 300 km.

The SMR Regulators' Forum (2015–2018) [13] addressed challenges in applying EPZ concepts to SMRs, advocating a graded, site-specific approach that considers design features and possible accident scenarios with smaller inventories, passive safety features and possibly slower accident progression. While smaller EPZs for SMRs are possible, current IAEA methodologies are mainly those for large reactors, lacking adaptation for SMR-specific safety innovations. Future guidance should integrate lessons from modern studies, emphasizing optimization and justification principles.

2.4. IAEA CRP projects

WP6 reviewed results from two IAEA Coordinated Research Projects (CRPs) focused on EPZs for SMRs. The earlier CRP (I25001, 2010) [14] examined small reactors without on-site refueling, producing TECDOC-1652 [15], which addressed reactor characteristics and emergency planning, proposing a methodology to redefine EPZs using Probabilistic Risk Assessment (PRA) and deterministic dose evaluations. The approach aimed to reduce EPZ size for innovative SMRs while maintaining safety level.

The later CRP (I31029, 2018–2021) [16] involved participants from 12 countries, aiming to establish technical bases for EPZ sizing for SMRs, particularly relevant for urban or industrial heat applications. Objectives included:

1. defining criteria for EPR based on SMR safety features (e.g. smaller STs, enhanced safety systems),
2. developing methodologies linking SMR design to offsite arrangements, and
3. contributing to future IAEA guidance on EPZ determination.

Research focused on modelling radioactive inventories, STs, and off-site dose assessments to compare against national and international protective action levels. While most participants calculated reference accident cases for specific SMR designs, broader methodological discussions also occurred. A TECDOC summarizing these findings is still pending publication.

2.5. Different safety approaches: risk-informed, generic vs. specific etc.

WP6 also discussed the characterization and classification of various methodologies for determining EPZs for nuclear installations, particularly with regard to their applicability for SMRs. Two main categories can be described as generic and specific. Generic approaches apply fixed distances based on conservative assumptions without considering plant-specific details, relying on bounding calculations for STs and atmospheric dispersion. These methods are simple and widely used but often overly conservative and

[4] **Extended Planning Distances (EPD)**: The extended planning distance is the distance within which arrangements at the preparedness stage (before an emergency) need to be made to monitor the dose rates from deposition [9].

[5] **Ingestion And Commodities Planning Distance (ICPD)**: distance at which urgent restrictions are placed on the consumption and distribution of local produce, wild-grown products (e.g. mushrooms and game), milk from grazing animals or rainwater that need to be implemented before or shortly after a release in order to: (a) significantly reduce the risk of an increase in the thyroid cancer incidence due to radiation induced cases, and (b) to reduce doses in excess of the generic criteria given in Table 23 of [9].

misaligned with smaller inventories and advanced safety features of modern SMR designs. Specific methodologies, by contrast, incorporate plant-specific safety analyses, accident scenarios, and plant PRA, offering tailored EPZs that reflect actual design and safety features. Within specific approaches, deterministic methods use bounding SA scenarios, while probabilistic methods employ Level 2 PRA results to estimate accident frequencies together with consequences. Hybrid or risk-informed approaches combine deterministic dose calculations with probabilistic insights to balance conservatism and practicality.

WP6 also attempted to classify some national and international EPZ practices, including IAEA guidelines, UK's REPPIR 2019 [17] framework, and examples from France, Belgium, Slovakia and the Netherlands. Probabilistic and mixed approaches can significantly reduce EPZ size, potentially to site boundaries, by leveraging SMR safety features. However, these methods are computationally demanding and require regulatory maturity and ultimately, for best acceptance, harmonized probability thresholds across jurisdictions. WP6 work includes a SWOT analysis for deterministic (see Table I), probabilistic, and mixed approaches, highlighting trade-offs in implementation complexity, exploitation of SMR inherent safety features, conservatism, and alignment with EU and global practices. While deterministic methods remain straightforward and widely understood, probabilistic and mixed approaches, though challenging, offer opportunities for optimized EPZs and broader SMR deployment, provided harmonization and technical capability are achieved.

Table I. SWOT Analysis for the Deterministic Approach (ENEA)

	Strengths +	**Weaknesses -**
Internal Factors	• Easy to implement (no need for PSA-2) • Easy to check and verify • Well known and established	• Not exploiting, in ST use, the inherent safety features of some SMRs • Over-conservative in results
	Opportunities +	**Threats -**
External Factors	• Depends only on Intervention Levels, which should be harmonized in EU • Easy to implement in different EU countries, even in those with lower background in PSA	• Results not supportive of SMR non-electric uses • Not aligned with USA, UK or Canada practice • Considered too much old-fashioned? • Perhaps not reaching the goal of EPZ harmonization in EU for a given design

2.6. SMR-specific dispersion and exposure considerations

If expecting to find exceedance of dose limits in SMR cases nearer to the plant than currently typical for large LWRs, it is more important than before to have physically realistic modelling of atmospheric dispersion in the near-field, with still a lot of influence from ST parameters and possible building etc. obstacles. For larger plants, such distances have been included in the EPZ anyway. Some particularities of near-field dispersion that were identified in WP6 work can be listed as follows:

- Many SMR designs locate the reactor underground, or at least the size of the building is smaller than for large NPPs. Possibly the initial heat content is smaller. These factors will make the effective release height smaller, meaning a more concentrated radioactive cloud in the nearby areas. Furthermore, the possible offsite adverse effects are inherently located more pronouncedly in the

nearby areas only, because of the small source. Potential siting near population centres makes it very important to study those near-field effects in great detail.
- Building wake: Turbulent eddies around buildings provide more initial spread.
- Stack-tip downwash (buildings and other structures causing downwards transfer of activity concentrations)
- Cloud rise (plume rise): Initial upward momentum and heat content make the release rise higher than stack height right at the starting point. Even when iPWR plants are not expected to have tall stacks, the effect may not be negligible, depending on how the release enters the atmosphere.
- Near-field dispersion parameters: Weather mast measurements may be more reliable near the source than NWP (numerical weather prediction) model, but more masts than one single would make the data even more reliable and complete.
- Very narrow plume: It takes some time for the release to spread in the lateral and vertical directions, and when e.g. using the Gaussian model, choice of appropriate parameters is very important.
- Urban / industrial terrain: Terrain roughness may decrease wind speeds locally and induce turbulence. Furthermore, spread directions may favour street 'canyons' etc.

In many dose pathways (exposure modes), there are potentially some specific considerations to perform an accurate assessment of doses, originating specifically from the siting and small size of SMR plants:
- Cloudshine: In many codes, the so-called 'semi-infinite uniform' approximation of the radioactive cloud is used. Then the radiation source is a uniformly distributed concentration [18] in a half-space (or practically, a half-sphere). With SMR plants, we are interested in the close surroundings, and it is important to consider the cloudshine source in all of its possible physical reality / realizations: In some cases, a long, narrow plume extending as such relatively far (even several kilometers) from the source (cf. the LINCON code used to generate cloud gamma dose conversion coefficients for ARANO). In urban environment, big buildings may provide considerable shielding effect against external radiation.
- Groundshine: In population centers and in industrial settings, deposition will not accumulate only on ground surface and vegetation, but to a relatively large extent also on the surfaces of buildings. They will become an additional source of radiation. Their decontamination is usually laborious. On the other, buildings provide some shielding for more faraway radiation source.
- Inhalation: In urban environment, with a large population in a large number of buildings, the inhalation dose caused by inhaled radionuclides indoors is a particularly important consideration. Air-tightness and ventilation systems of the buildings determine how much activity will be inhaled indoors. Depending on the systems, it may be possible to considerably reduce the internal dose commitment.
- Ingestion: Traditionally, and with regard to usually defined representative person, the conservative assumption of all consumed foodstuff being produced locally, very near the target population, has been used. However, this is seldom true in today's world, where foodstuff are routinely transported over great distances before being offered to consumers. It is even less true for SMR surrounding environment which may be urban or industrial, and in any case the area affected by significant deposition is expected to be smaller.

3. OFFSITE DOSE ASSESSMENTS BEFORE CONTAINMENT CALCULATIONS

In the SASPAM-SA project, two hypothetical generic iPWR designs were defined to be considered in detail in all WPs and phases of the project:
- Design 1: A generic iPWR characterized by a submerged containment and electric power of about 60 MWe;
- Design 2: A generic iPWR characterized by the use of several passive safety systems, a dry containment and an electric power of about 300 MWe.

Several SASPAM-SA project partners working in WP6 (ENEA, JRC, KIT, KTH, LEI, POLIMI, SSTC NRS, TUS, UNIROMA, VTT) selected one of the designs to study with regard to potential atmospheric radioactive releases and offsite doses. In the conservative phase of the project, detailed SA code calculations of the phenomena in reactor core and containment were in most cases not used.

Each partner had the freedom to select representative accident scenarios to study, including both Design Basis Accidents (DBAs) and SAs. The selection of scenarios common to the project was defined by WP2 and had various postulated breaks in piping, malfunctions of valves and failures of safety systems. The scenarios enable performing varied assessments of radionuclide behaviour and containment performance, which is the topic of WP5. The diversity of cases ensured that the study so far captured a broad spectrum of released amounts of radionuclides. The selection of scenarios is crucially important for EPZ determination purposes. In WP6, it was concluded that some consideration should be paid to the probabilities of the scenarios, in order to not use e.g. only extremely unlikely cases to calculate the dose consequence footprint areas.

STs are affected by assumed fuel burnup, which was available from WP2 for 20 to 60 MWd/kg in steps of 2.5 MWd/kgU; higher burnup means more accumulation of long-lived isotopes. From WP2, there was the inventory of 304 nuclides available [19]. Fractions of inventory released to the atmosphere usually depend on nuclide chemical group. The atmospheric release may happen at temporally variable release rates. Simple offsite dose codes typically only accept a uniform rate; more sophisticated codes can use any temporal evolution. Obviously, released amounts of activity have a very big and direct effect on off-site doses, the exact effect depending on nuclide. For final phases of SASPAM-SA, the releases will come from WP5 results. In previous studies it was typically found that the biggest uncertainty in offsite doses (and so also in the EPZ sizing) is coming from the (poor) knowledge of the ST, while also other, subsequent uncertainties do exist.

The preliminary / conservative analyses by WP6 partners considered a broad range of input parameters, like the variability in ST evaluations. Fuel burnup values ranged from 15 to 60 MWd/kgU, representing conditions from early to extended core reloading. Radionuclide inventories used included 2 – 71 species, mostly ensuring coverage of key fission products and activation products relevant to safety assessments. Atmospheric release fractions were highly dependent on chosen scenario and expert judgement by partner, spanning from fraction 1e-5 to whole inventory, depending on nuclide, reflecting both conservative (or even extremely conservative) SA release assumptions and more realistic ones, and also more probable design-basis accident conditions. These ranges provided a good readiness basis for evaluating containment performance and radiological consequences under diverse accident scenarios.

As an example of the initial conservative phase of WP6, the atmospheric source term used in the LEI analyses was developed by applying a simplified large PWR methodology consistent with U.S. NRC RG 1.183 [20] and with the source term evaluation approaches discussed by Mitrakos, 2022 [21]. In this LEI specific approach, a prompt LOCA driven release without delay was assumed, using standard PWR release fractions for noble gases, iodines, and aerosols. Radionuclide behaviour in the containment was calculated through a time dependent balance of release, decay, deposition, and a conservative leakage rate of 0.65 % d^{-1}. This methodology produced nuclide specific released fractions like in Fig. 1 below.

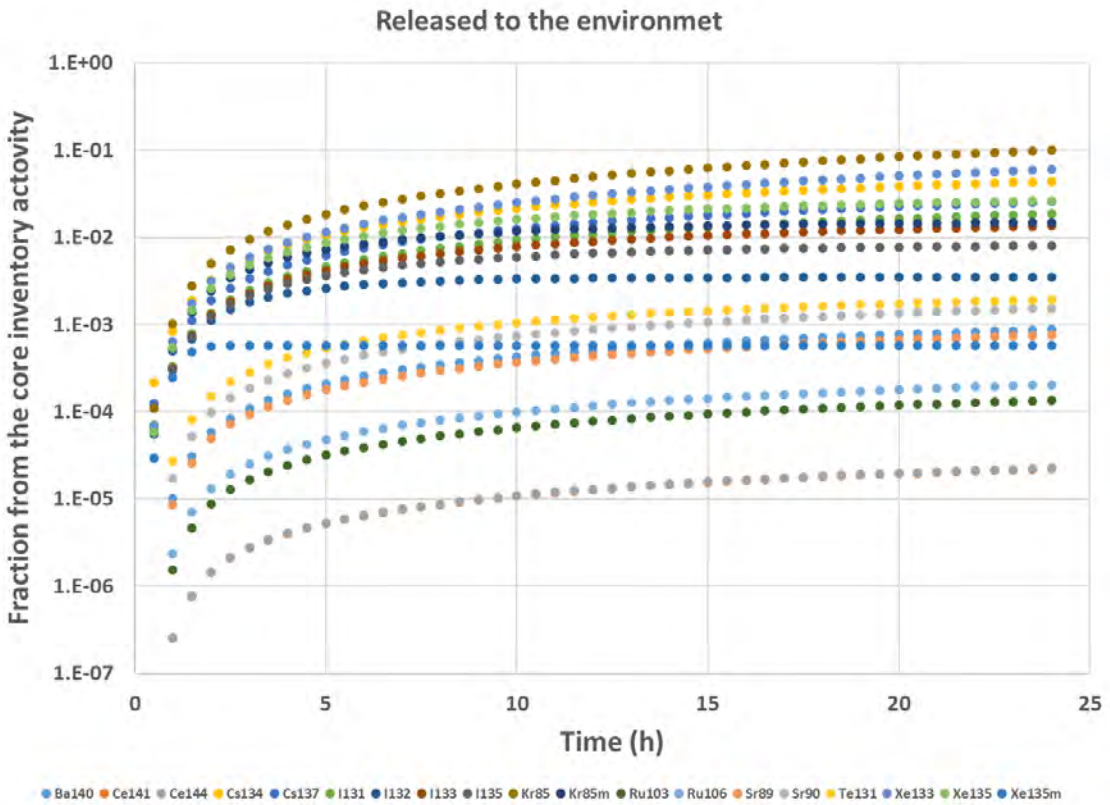

Figure 1. Nuclide-specific cumulative released fractions to the environment of the core inventory of Design-2. A sample case from the initial conservative phase approach by LEI, to illustrate some of the source term features needed for the subsequent atmospheric dispersion modelling.

In addition to released amounts of activity, STs must be described by also a number of other release parameters, like effective release height (or distribution on various atmospheric transport starting heights), and release duration, with possible temporal variations of nuclide-specific release rates. Effective release height is typically defined by height of stack or containment breach hole, increased by the effect of plume rise by momentum and buoyancy. Several off-site dose codes use the inventories at reactor shutdown time, corrected by the so-called delay time (time for radioactive chain decay and various other decontaminating processes between shutdown and start of atmospheric release). Decay inherently continues also during release duration and atmospheric dispersion. All the mentioned release parameters have a major effect on off-site doses; their increase leads to doses decreasing).

The modelling of atmospheric ST in WP6 incorporated a wide range of temporal and spatial release parameters, reflecting different assumptions on possible accident progression. Release delay times varied from the unrealistic zero to more than one day, depending on assumptions made about containment integrity and safety systems response. Effective release heights ranged from ground level for containment bypass or venting scenarios to more than 100 m for stack discharges with cloud rise, influencing the subsequent atmospheric dispersion patterns. Release durations spanned from rapid emissions lasting for one hour to prolonged releases over several days, corresponding to severe accident conditions with only a gradual leakage. These variations represent coverage of potential off-site radiological consequences on many levels of severity.

Assumed iPWR site in WP6 could be anything from operating NPP site to proposed newbuild site and a completely hypothetical one. The partners mostly selected representative locations within their countries, typically existing nuclear sites or candidate SMR deployment areas, while also ensuring realistic dispersion and population data. Off-site doses generally depend on site-specific environment and weather conditions. As the source of weather data, both Numerical Weather Prediction (NWP) reanalysis (data assimilation of past prediction data with observations) and site mast measurements were used, with the size of the data set chosen according to the needs of deterministic or statistical study. For near field calculations (as expectedly most interesting and typical for small iPWR), local weather mast measurements may be better representative than numerical data with large grid cells. Meteorological inputs for WP6 work were obtained from national weather services, site-specific historical datasets, or publicly available databases such as ERA5 reanalysis, providing wind speed, direction, temperature, and stability classes (one point or 3D) for dispersion modelling.

The code tools of WP6 implement physical models for atmospheric dispersion and off-site dose projection. They typically have a large number of possibly user-tunable parameters, like dry deposition velocity, washout coefficient, dose and dose rate conversion factors, shielding factors, breathing rates etc. Partners used their chosen set of dose criteria, i.e. limits of projected (or averted) dose, above which actions should be implemented to reduce doses to people. When using statistical / long-term weather data, also confidence levels are chosen, meaning the fractile (percentile), e.g. 95 %, of all values such that the dose was lower (or EPZ smaller) in 95 % of all cases, called P95 in short. In WP6 so far, the partners used a mix of established calculation tools for ST and dispersion modelling, including RODOS, MACCS, RASCAL, GENII, HotSpot, ARANO, and as well as some in-house / national methodologies. As for the radiation dose criteria, evaluations were based on standard IAEA or national regulatory limits for public exposure, typically expressed in terms of e.g. effective dose (mSv) for short-term health effects. With statistical weather, meteorological sampling applied percentile-based confidence levels, most commonly 95%, to ensure conservative enough estimates of doses under varying atmospheric conditions.

4. CONCLUSIONS

Generally SASPAM-SA WP6 on iPWR EPZ was, even in the conservative assessments phase, able to demonstrate that the EPZ for iPWR could potentially be reduced from that of large LWRs. Conservative and deterministic assessment of off-site doses is basically usable also for SMRs. Also the IAEA SMR Regulators' Forum Pilot project report [13] concludes about EPZ that '*the IAEA safety requirements and methodology for determining the EPZ size are effective in establishing an emergency preparedness and planning program*'. After the conservative assessments phase of SASPAM-SA WP6, the calculations using a BE ST will show if further reduction of iPWR EPZ seems feasible. This will depend on assumed mitigative strategies to reduce the emissions from the containment to outside atmosphere. If only very near-range doses turn out to be decisive for EPZ size, then probably some improvements to near-field dispersion and dose models would be recommended.

A possibly justifiable way to further reduce the iPWR EPZ size (even with conservative STs) is to replace the so far most used deterministic worst-case methodology, to a risk-informed approach. This is however outside the scope of the present SASPAM-SA project, in lack of the full spectrum of STs and their associated probabilities from PSA level 2. For future projects, some knowledge of the order of magnitude of Design Extension Condition (DEC)-A and DEC-B frequencies / probabilities could be useful. Some nuclear regulators are considering or going to consider a risk-informed methodology, meaning to take into account also the probabilities of accident sequences and the associated offsite consequences, not only their magnitudes.

In future projects, creating an EPZ database for DEC-A and DEC-B can be recommended. The US 'traditional' EPZ distances (10 / 50 miles) originate in part as kind of generalization of the results of the

influential WASH-1400 study (1975) [22] where several NPPs and also SA sequences for them were considered. Likewise for the EPZ determination of present iPWR (and other SMRs) it would be beneficial that several plant types and SA releases be considered. Also, there is no one single 'correct' off-site consequence code that calculates the most reliable results. To draw conclusions that are useful for regulators and operators willing to site their plant, it would be good to have much more results than just single plant type – single accident scenario – single ST – single approach to EPZ calculation.

Co-location of SMRs presents many cases: colocation of several modules / units, siting reactor(s) in a populated city, or reactor(s) in industrial area (like oil refinery, hydrogen production, fertilizers, steel, etc). There are events like common cause failure, or e.g. industrial accident affecting nuclear plant, or nuclear radioactive release affecting the industry, thus also the possibility of simultaneous conventional and nuclear emergency. Too high dose rates and contamination may slow down emergency management efforts. Also there are some new considerations to calculate dispersion, deposition and external / internal doses when accidents happens in built environment. Those would be good to study more in more detail.

WP6 (EPZ) introduction

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- Assessment of EPZ zones for iPWRs within the Horizon Euratom SASPAM-SA Project
- SASPAM-SA project (Safety Analysis of SMR with PAssive Mitigation strategies – Severe Accident)
- Applicability of current state-of-the-art severe accident codes against hypothetical generic iPWRs
- WP6 (EPZ) considers the offsite dispersion and doses caused by radioactive releases from SA.
- Initially, a set of varyingly conservative calculations were performed.
- The codes used in WP6 included JRODOS, MACCS, HotSpot, RASCAL, GENII and ARANO.
- In the current phase, more refined Best Estimate BE source terms from WP5 ('Containment') are being used to avoid exceedingly conservative results.
- Detailed SA code (WP5) data about actual nuclide content, activities, temporal release rate trend, effective release height etc.
- General expectation is that SMR smaller inventories and longer delays before any atmospheric release might lead to smaller dose consequences.
- Acceptance of SMR plant sites near (or even in) densely populated areas?
- WP6 attempts to understand limits, if any, of the current codes and/or methods and approaches in producing sound and reliable data for EPZ extents of iPWRs.

SASPAM-SA (2022-2026) WP connections

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

Safety Analysis of SMR with PAssive Mitigation strategies – Severe Accidents

Adapt existing LLWR safety knowledge to iPWRs in Europe

- **Experiments, SA codes, dispersion & off-site doses**

Two generic iPWR designs:

- **D1: Characterized by a sub-merged containment and ~60 MWe**
- **D2: Several passive systems, dry containment, ~300 MWe**

WP5: From mechanistic modelling of containment phenomena to atmospheric releases

WP6: Study capability to assess extent of EPZ zones (PAZ and UPZ) needed for iPWR site

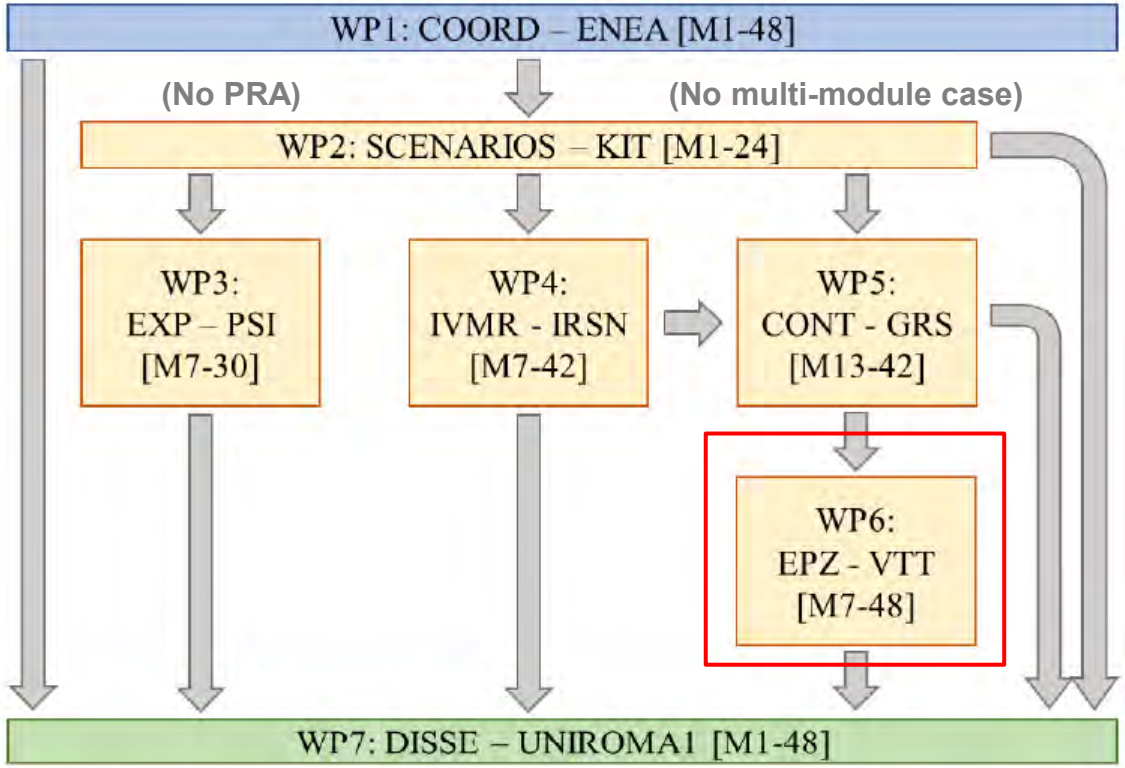

Figure 5 SASPAM-SA project diagram and WP interconnections.

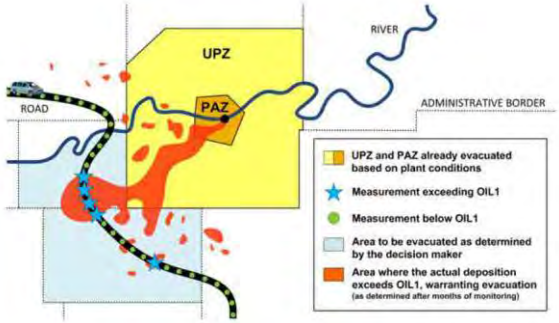
EPZ: Emergency planning zone

(IAEA)



- PAZ (precautionary action zone): smaller, inner zone
- UPZ (urgent protective actions planning zone): larger, outer zone
- Avoid or minimize severe deterministic effects / avert doses offsite

- Why important to determine?
  - PAZ: Urban planning (in city plan area) starts well in advance
  - EPZ will affect actual siting decision
  - EP&R (Emergency preparedness & response) planning
  - DiD Level 5, independently: Off-site emergency response to mitigate radiological impact
  - People want to know their potential radiological risks (not technical details)
- Benefits from potentially reduced EP&R / EPZ:
  - Siting closer to densely populated areas, particularly important for heat
  - Overall decreased cost of maintaining emergency preparedness
- Potential justification:
  - Small inventory, potentially easier heat transfer, advanced safety features (often passive)
  - With various time delays, Early Release unlikely

Tasks of WP6 (SMR EPZ)

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- SASPAM-SA, 2022-2026, possible extension to 31 March 2027, coordinator ENEA
- Structure of SASPAM-SA WP6 (EPZ), Task lead VTT / Ilvonen
  - Task 6.1: Critical **review** of existing EPZ methodology
    - Partners: ENEA, LEI, POLIMI, SSTC NRS, TUS, UNIROMA1, VTT, JRC
  - Task 6.2: Preliminary **conservative offsite dose** assessments
    - Partners: ENEA, CIEMAT, KIT, KTH, LEI, POLIMI, PSI, SSTC NRS, TUS, UNIROMA1, VTT, JRC
  - Task 6.3: Offsite doses & EPZ by **best estimate (BE)** approach
    - Partners: ENEA, KIT, KTH, LEI, PSI, SSTC NRS, TUS, UNIROMA1, VTT
  - Task 6.4: Conclusions on iPWR EPZ & **recommendations on methodology**
    - Partners: ENEA, KIT, KTH, LEI, POLIMI, PSI, SSTC NRS, TUS, UNIROMA1, VTT, JRC
  - CNL (Canada) joined during project by amendment

WP6 review of EPZ methodologies

Relation of IAEA documents with EPZ determination – by ENEA, JRC, TUS, VTT

1. GSR Part 7 (2015): 'Preparedness and Response for a Nuclear or Radiological Emergency'
   - Establishes requirements for an adequate level of preparedness and response for a nuclear or radiological emergency, irrespective of its cause; "**What should be achieved**"
   - Appendix II has tables of generic limits expressed as doses
2. GS-G-2.1 (2007): 'Arrangements for preparedness for a nuclear or radiological emergency'
   - Recommendations on implementation of specific safety requirements
   - "**What should be done and how**"
3. EPR NPP PPA (2013): 'Actions to Protect the Public in an Emergency due to Severe Conditions at a Light Water Reactor' – IAEA EPR Series publication
   - Basic information and criteria needed by a decision maker in order to protect the public during an emergency involving SA in LWR); applies to reactors with power > 100 MWth
   - Appendix I: Basis for the suggested size and protective actions within the emergency zones and distances: "Zone size calculations are very uncertain and based on very simple assumptions"

WP6 review of EPZ methodologies

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

Relation of IAEA documents with EPZ determination – by ENEA, JRC, TUS, VTT

- IAEA guidelines and examples of methodologies to estimate the EPZ are suited for large LWRs.
- For SMR guidance on practical implementation, focus should be put on specific technologies.
- Technology neutrality should be foreseen for higher-level documents, like Safety Requirements.
- Information from MSs to start discussion: Consultancy Meetings, CRPs and the production of TECDOCs
- TECDOC from CRP I31029 (2018-21, 'SMR EPZ methods') has been in preparation.
- Not considering the principles of justification and optimization >> national, site/society dependent
- Possible differences in STs between SMRs and large LWRs >> effectiveness of countermeasures?

- The IAEA EPZ reference approach can be found in IAEA document EPR-NPP PAA 2013, Appendix I:"Basis for Suggested Size and Protective Actions within the Emergency Zones and Distances".
- In this approach plant-specific feature as well as meteorological conditions, presence of buildings, terrain complex morphology are not taken into account.
- It is based on a deterministic safety analysis postulating conditions for a Severe Accident (SA) and Radiological Consequences (RC) event.

Country review: Still mostly fixed EPZ sizes

- **Country-specific EPZ regulations – by ENEA, JRC, LEI, SSTC NRS, TUS, VTT, CNL**
- **Considered 17 countries & EU level**

EU (Directives 2013/59 and 2014/87)
Belgium regulation (10 / 20 km)
Bulgaria emergency planning system
Canada regulation
Czech regulation (5-10 / 13-20 km)
Finland offsite dose limits and EPZ size
France regulation (5 / 20 km)
Hungary regulation (30 km)
Italy
Lithuania current regulations on EPZ (5 / 30 km)
Netherlands regulation (5 / 10 / 20 km)
Romania regulation (10 km)
Slovakia regulation (5-10 / 20-30 km)
Slovenia regulation (10 km)
Spain regulation (10 km)
Sweden (5 / 25 km)
Ukrainian requirements for EPZ sizing
USA

- Mostly fixed EPZ zone sizes, made for large LWR.
- Flexibility can be found in USA, Canada, UK and Finland.

Finland's EPZ in new (2024) regulations

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- 2. The precautionary action zone (PAZ) shall be defined in such a way that, in the event of an accident, there is a high probability that there will be no need to evacuate the population beyond the PAZ and that the necessary evacuation measures can be effectively carried out inside the PAZ in order to prevent or limit severe deterministic effects of ionising radiation. In order to enable effective evacuation, the PAZ shall be subject to land use restrictions.
- 3. When determining the size of the PAZ, it shall be demonstrated that, in the event of an accident, the radiation dose of an unprotected person outside the PAZ will not exceed 1 Sv within 10 hours of the start of exposure.
  - (Note: 1 Sv in 10 h appears in Table II.1 of IAEA GSR Part 7 for red bone marrow.)
- 4. The emergency planning zone (EPZ) shall be determined in such a way that, in the event of an accident, there is a high probability that there will be no need for the population to shelter indoors outside the EPZ.
- 5. When determining the size of the EPZ, it shall be demonstrated that, in the event of an accident, the radiation dose of an unprotected person outside the EPZ will not exceed 10 mSv within 48 hours of the start of exposure. The EPZ can be limited to a maximum distance of approximately 20 km.
  - (Note: 10 mSv in 2 d has long been the threshold for sheltering in STUK VAL regulations.)

- How to practically implement the new flexibility of STUK Y/2/2024 (Feb 2024) ?
  - Licence applicant must present and justify the size of EPZ for their plant.
  - Flexible scheme facilitates early start of urban planning for SMR projects.
  - For the EPZ size, possible assumptions (What should be the accident scenarios ?):
    - Large amount of released radioactive material is in the containment
    - There is some breach or by-pass of the containment
  - That is clearly, multiply failing management of a severe accident.
  - More detailed 'lower-level' regulations are expected to appear later during the legislation reform process – 2026?

New Decree (2026) additionally states:

- Early releases: Must have 5 h from accident start for protective measures
- Outside PAZ, Cs-137 deposition must remain less than 400 kBq/m2 (suffices to avoid evacuation, i.e. 20 mSv/week)

Choices for flexible EPZ approaches

- Probabilistic (cf. PSA levels 1-2-3) vs. deterministic ('worst plausible / maximum credible' scenario & possibly 'worst weather case, with stable atmosphere and low wind speed'
  - Probabilistic approach to atmospheric source term (ST) has all the release parameters (nuclide-specific activities etc.) but also some information of the expected frequency of such a release to happen.
  - Probabilistic approach to dispersion uses a large number of weather conditions, e.g. site hourly measurements for several years, and uses each of them to calculate offsite doses resulting from one given source term >> result is probability distribution of dose (or rather, doses, via pathway, at distance & integration time).
  - The combined approach could be completely deterministic, completely probabilistic, or hybrid (mixed) of the two.
  - IAEA IEC: 'Probabilistic can be used as complementary to deterministic'
- Consequence based (dose / health effect)
  - Predicted – averted – residual dose (as basis for choosing protective measures) ?
  - Look at only individual doses (STUK / Finland), or make a difference by using population dose (manSv, based on population distribution), even when individual doses the same?
- Risk-informed (US NRC new ruling 2023); Risk based (probability x consequence)

Deterministic / probabilistic approaches

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

Comparison of different approaches to NPP offsite safety – by JRC, ENEA in WP6

-- SWOT analysis for the deterministic approach, by ENEA:

	Strengths +	Weaknesses -
Internal Factors	• Easy to implement (no need for PSA-2) • Easy to check and verify • Well known and established	• Not exploiting, in source term used, the inherent safety features of some SMRs • Over-conservative in results
	Opportunities +	Threats -
External Factors	• Depends only on Intervention Levels, which should be harmonized in EU • Easy to implement in different EU countries, even in those with lower background in PSA	• Results not supportive of possible SMR non-electric uses, like small district heat-only reactor • Not aligned with USA, UK or Canada practice • Considered too much old-fashioned? • Perhaps not reaching the goal of EPZ harmonization in EU for a given design

-- SWOT analysis for the probabilistic approach (full-scope PSA-3), by ENEA:

	Strengths +	Weaknesses -
Internal Factors	• Full exploitation of declared improved and inherent features of some SMRs • Proper estimation of safety margins • Possible limitation of EPZ to site boundaries	• Difficult to implement • Enormously time-demanding, especially if considering the use of microscale ATM dispersion • Too little experience among EU regulators?
	Opportunities +	Threats -
External Factors	• Possible important role in SMR massive deployment • In line with USA, UK and Canada practice	• Are EU regulatory bodies ready for it? • Depends on decision on probability thresholds: is EU harmonized on this?

Practical work: Off-site doses footprint area

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- Out of scope of SASPAM-SA:
  - (Comprehensive hazard assessment, internal / external)
  - (Comprehensive listing of initiating events, or PIEs in PSA terminology)
- Preceding work packages of SASPAM-SA:
  - WP2: Selection of accident scenarios to consider
  - WP5: Containment phenomena, atmospheric source term, release parameters
- WP6 (iPWR EPZ):
  - Atmospheric physics of dispersion and offsite doses (external / internal pathways)
  - Computer codes for dispersion and offsite doses chosen in WP6
  - Site data, weather data (data source, location, time span, resolution)
  - exposure pathways, target organs, age groups, breathing rates, shielding factors, etc. etc.
  - Looking at projected, averted, or residual dose; Confidence level (e.g. P95 = 95 %)
  - Generic dose limits, protective actions, EPZ (PAZ and UPZ) sizes proposed
  - ‘Validation’ by code inter-comparisons; Uncertainties, ‘unknown unknowns’

Phenomena affecting an atmospheric release and off-site doses

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

IAEA-TECDOC-379 (Atmospheric dispersion models for application in relation to radionuclide releases)

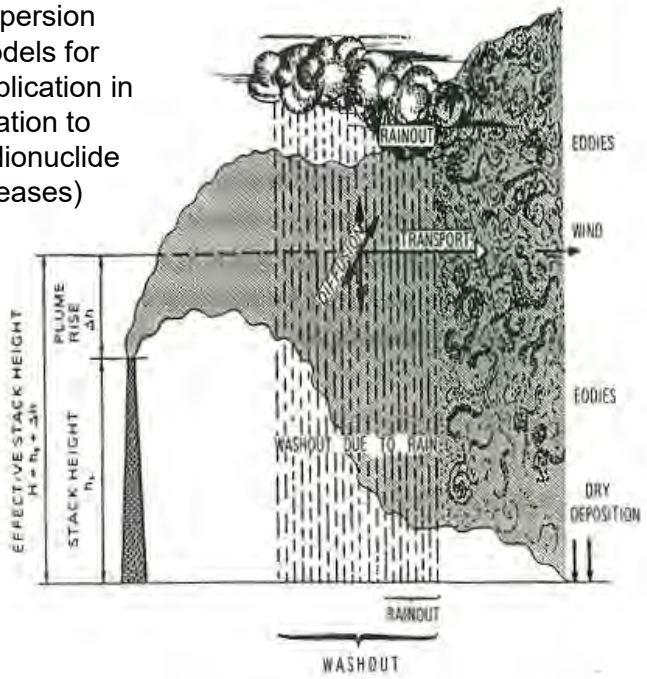


FIG.1. Behaviour of effluents released to the atmosphere.

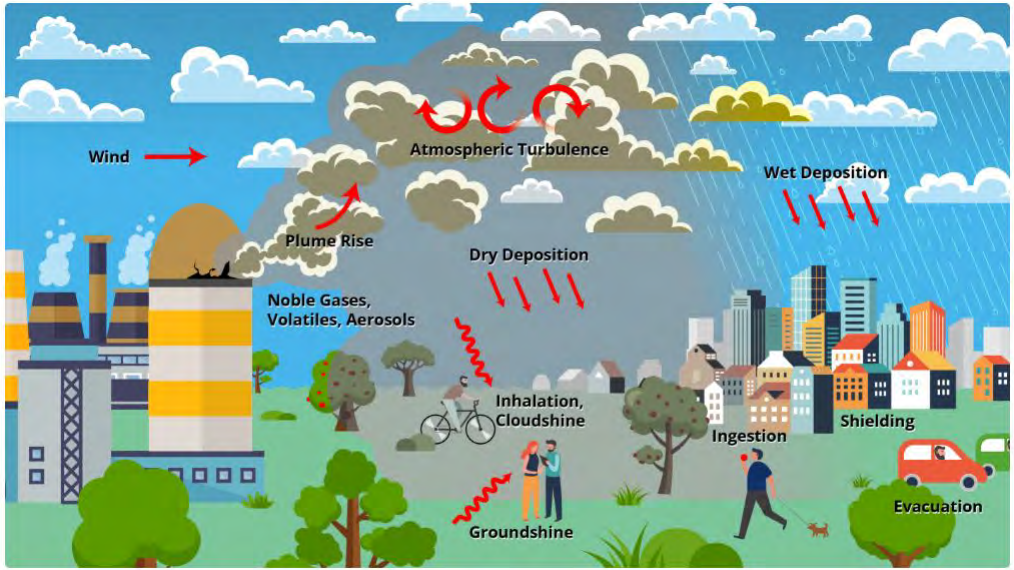
Sandia National Laboratories: MACCS Accident Consequence Model



MACCS Data Flow

For EPZ in WP6, we consider: cloudshine, groundshine and inhalation

Near-field dispersion is very important

- Small initial heat content of release, small reactor building, possibly underground >> Effective release height smaller, meaning a more concentrated radioactive cloud in the near range.
- Small core >> Possible adverse offsite effects are inherently located pronouncedly in the near range.
- Siting in or near population centers makes it very important to study near-field effects in more detail.
- Building wake and stack tip / building downwash: Structures may cause immediate downwards transfer of activity, while turbulent eddies around buildings also provide more initial spread.
- Cloud rise (plume rise): Initial upward momentum, heat content >> How much rise by buoyancy?
- Near-field dispersion parameters: Weather mast measurements may be more reliable near the source than analysis fields from NWP (numerical weather prediction) model. Single point sufficient very near.
- Very narrow plume cases: It takes some time for the release to spread in the lateral and vertical directions, and when e.g. using the Gaussian model, choice of appropriate parameters is important.
- Cloudshine source is not uniform. Dry deposition and inhaled concentrations when touching ground.
- Urban / industrial terrain: Terrain roughness may decrease wind speeds locally and induce turbulence. Furthermore, spread directions may favor street ‘canyons’ etc.

- In SASPAM-SA WP6, detailed study of some of these done by SSTC NRS and CNL

WP6 collects a calculation database

- Other SASPAM-SA WPs, like WP2 and WP5, also collect calculation parameters / Key Figures of Merit from the cases calculated by all partners
- For the Conservative calculations phase (Task 6.2), WP6 partners could use their own estimates of the atmospheric source term and release parameters.
- Therefore, various choices appeared, ranging from pure expert judgement or literature-based release fractions to simple analytical calculations or actual mechanistic modelling by dedicated SA codes
- For the Best Estimate phase (BE, Task 6.3, on-going), all WP6 partners are using source term data from WP5 (Containment): The chosen scenarios and mechanistically calculated releases as function of time, for specific dose-relevant nuclides.
- The calculation databases will remain as a valuable asset for future projects as a comprehensive reference.

WP6 Task 6.2: Chosen designs & scenarios

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- Design-1: iPWR characterized by a submerged containment and electric power of about 60 MWe
- Design-2: iPWR, several passive systems, dry containment, electric power of about 300 MWe

Listing of scenarios, available from SASPAM-SA WP2:

iPWR Design-1:

DBA-1: Loss of AC (Feedwater, DHRS, CVCS), ECCS activated, Break on CVCS discharge line (10%)
DBA-2: Loss of AC (Feedwater, DHRS, CVCS), ECCS activated, Break on CVCS discharge line (20%)
DBA-3: Loss of AC (Feedwater, DHRS, CVCS), ECCS activated, Break on CVCS discharge line (35%)
DBA-4: Loss of AC (Feedwater, DHRS, CVCS), ECCS activated, Break on CVCS discharge line (100%)
SA-1: break on CVCS, Loss of AC, partial ECCS activation (both RRVs fail)
SA-2: spurious opening of 1 RVV, Loss of AC, partial ECCS activation (both RRVs fail)
SA-3: high venting break, Loss of AC, partial ECCS activation (both RRVs fail)

iPWR Design-2:

DBA-1: Guillotine break of one Direct Vessel Injection (DVI) line, considering the availability of all safety systems
SA-1: guillotine break of one Direct Vessel Injection (DVI) line, considering the unavailability of EHRS and ADS-1 systems
SA-2: guillotine break of one Direct Vessel Injection (DVI) line, considering the unavailability of all safety systems
SA-3: guillotine break of one Direct Vessel Injection (DVI) line, considering the unavailability of EHRS system

WP6 Task 6.2: Chosen designs & scenarios

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

Design-1: iPWR characterized by a submerged containment and electric power of about 60 MWe

Design-2: iPWR, several passive systems, dry containment, electric power of about 300 MWe

- SA-2: Guillotine break of one Direct Vessel Injection (DVI) line, unavailability of all safety systems

Partner	Design	Scenario
KIT	Design-1	Total release (whole inventory) of selected FPs
LEI	Design-2	NUREG 1.183 LOCA
SSTC NRS	Design-1	3 cases, varying inventory & release fractions
TUS	Design-2	DBA-1, SA-2
JRC	Design-2	SA-2
VTT	Design-1	108 ‘artificial cases’, separately for nuclide groups, vary release fractions
ENEA	Design-2	SA-2 (= ‘R11’)
POLIMI	Design-2	SBLOCA (inside / outside containment)
KTH	D1, BWR	D1: DBAN, SA1, SA2, SA2N, SA3, SA3N, SA5, SA6
UNIROMA	Design-2	DBA-1, SA-2

WP6 Task 6.2: Nuclides & activities (Bq)

Source terms (for Task 6.3 BE, from WP5):

- Burnup: Available from WP2 for from 20 to 60 MWd/kg in steps of 2.5 MWd/kgU
- Nuclides: WP2 / 304 nuclides available (spreadsheet format)
- Fractions of inventory released to atmosphere: Should usually depend on nuclide chemical group
- Release rates: Simple codes only accept uniform rate; more sophisticated, temporal evolution

- Obviously, released activities have very big & direct effect on off-site doses (depending on nuclide).
- Over the years, in usual cases, it was found that the biggest uncertainty in offsite doses (and so the EPZ sizing) is actually coming from the (poor) knowledge of the source term, while also other, subsequent uncertainties do exist.

WP6 Task 6.2: Nuclides & activities (Bq)

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

Source terms chosen by WP6 partners in the Conservative phase (Task 6.2)

- Partners were completely free to choose their own degree of conservativeness when creating the source terms for atmospheric dispersion. (Some also just tested their code tools with some ST.)
- For on-going Task 6.3 BE (Best Estimate), source terms come from WP5 (Containment).

Partner	Burnup	Nuclides	Atm. release fractions
KIT	60 MWd	22	1.0 (whole inventory)
LEI	20, 40, 60	19	1e-5 < fraction > 0.1 (depending on nuclide)
SSTC NRS	15+30+45	26	6.8e-5 < fraction < 0.988 (depending on nuclide)
TUS	20, 40, 60	40	Kr, Xe 100 %, less volatiles 10 % or 1 %
JRC	N/A	I-131, Cs-137	(2e16 Bq, 2e14 Bq)
VTT	40	29	2.08e-4 < fraction < 0.32 (depending on nuclide)
ENEA	45	< 60	2e-5 < fraction < 2e-2 (depending on nuclide)
POLIMI	40	17	(to CNT) Kr, Xe 100 %, halogens 0.4, others 0.002-0.3
KTH		MELC. classes	For Cs and I, up to 10 % / 12 %
UNIROMA		71 (CR-7270)	(time-dependent rate)

WP6 Task 6.2: Delay, duration, h_{eff}

Release parameters (for Task 6.3 BE, from WP5):

- Delay time: Time for chain decay & decontaminating processes between reactor shutdown and start of atmospheric release
    - (Of course, decay continues also during release duration and atmospheric dispersion.)
- Effective release height: Height of stack / breach hole + plume rise by momentum / buoyancy
- Release duration; possibly temporally variable release rates for each specific nuclide
- All these release parameters have major effect on off-site doses (increase >> doses decrease).

WP6 Task 6.2: Delay, duration, h_{eff}

Release parameters chosen by WP6 in the Conservative phase (for Task 6.3 BE, from WP5):

Partner	Delay time	Eff. release height	Duration
KIT	(no delay)	100 m	24 h
LEI	< 60 min	10 m	24 h
SSTC NRS	16.2 h	Ground / 10 m	10 min / 6 h
TUS	1 h	Ground level	1 h
JRC	4.77 h (37 h)	20 m	5 h (23 h)
VTT	1 h – 10 d	20 / 60 / 120 m	1 h – 10 d
ENEA	6.5 h	10 / 50 m	5 h
POLIMI	1.7 / 24 (+ 8 h)	1 m	24 h
KTH	(dep. on scen.)	5 – 34 m	Up to 70 h
UNIROMA		0 m and 20 m	

WP6 Task 6.2: Site and weather

Site: Could be anything: operating NPP, proposed for iPWR, or completely hypothetical

- However, off-site doses generally depend on site-specific environment & weather conditions

Weather data: source can be NWP or mast; choice of data set size for deterministic or statistical study

- For near field, local weather mast measurements may be better than numerical with large grid cells
- Note: 1° = appr. 100 km (east-west depending on latitude)
- Reanalysis = data assimilation of past prediction data with observations

WP6 Task 6.2: Site and weather

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

Partner	Site	Weather data
KIT	KIT campus	NOMAD (NOAA), 1 year (2021), resolution 0.5°
LEI	Kaunas / thermal	single point, 5 distinct cases
SSTC NRS	3 (near Kyiv)	single point (2019-2022); WRF 0.05° 2023-2024
TUS	Kozloduy VVER site	D; NIMH (Bulgaria), Kozloduy met. stations, Meteoblue (US)
JRC	(fictitious)	ECMWF reanalysis, hi-res 10x10 km, 30 d (June 2022), n=120
VTT	(no specific)	single point, 84 different combinations
ENEA	(Arkansas Unit 1)	single point, 2 cases (A-1.8 m/s and C-3.6 m/s-rain)
POLIMI	NW Italy	default values from on-site data 1959-2013, stab. A to F
KTH	3 sites in Sweden	2020, hourly (SMHI, Vattenfall, Copernicus data)
UNIROMA	Southern Europe	One year, hourly (8760 sequences)

WP6 Task 6.2: Codes, criteria, conf. level

Code tools: Implement physical model(s) for atmospheric dispersion and off-site dose projection

- Lots of parameters: v_{dry}, $c_{washout}$, DCFs, shielding factors, breathing rates, …

Dose criteria: Limits of projected (or averted) dose, above which actions should be implemented to reduce doses to people

- TEDE = Total Effective Dose Equivalent
- Generic dose limits may also be specified as organ-specific doses

Confidence levels: (with statistical / long-term weather data): The fractile (percentile), e.g. 95 %, of all values such that the dose was lower (or EPZ smaller) in 95 % of all cases; called P95.

WP6 Task 6.2: Codes, criteria, conf. level

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

'Conservative analyses of iPWR EPZ extent'

WP6 partner	Code	Dose criteria	Confidence levels
KIT	JRODOS (main developer)	TEDE 10/100 mSv (SSK)	(365 days considered)
LEI	RODOS	TEDE 100 mSv	N/A (deterministic cases)
SSTC NRS	JRODOS, HotSpot	(several, from NRBU-97)	P90, P95, P99
TUS	Excel / PC-CREAM	Red m. 1 Gy, inh. 100 mSv	N/A
JRC	JRODOS	10 / 50 mSv (GS-G-2.1)	'boundary method' (max_{cell})
VTT	ARANO (in-house devel.)	STUK UPZ 10 mSv / 48 h	P95 shown from cum.distr.
ENEA	RASCAL	IAEA GSR Part 7, App. II	N/A
POLIMI	GENII FRAMES	Evacuation (by 5 countries)	N/A
KTH	MACCS	SSM: UPZ 0.1 Sv, PAZ 1 Gy	95 / 99.5 %
UNIROMA	MACCS	IAEA shelt / evac / ITB	95 %

VTT: Parametric study, ARANO code

Seen in a 'wishlist' of SASPAM-SA End User Group (EUG):

- Harmonize methods for defining the EPZ
- How to properly select the source term from a range of accident analyses?
- How to define conditions for spreading of radioactive materials in the environment?
- Treatment of several years of weather data with a resolution of one hour

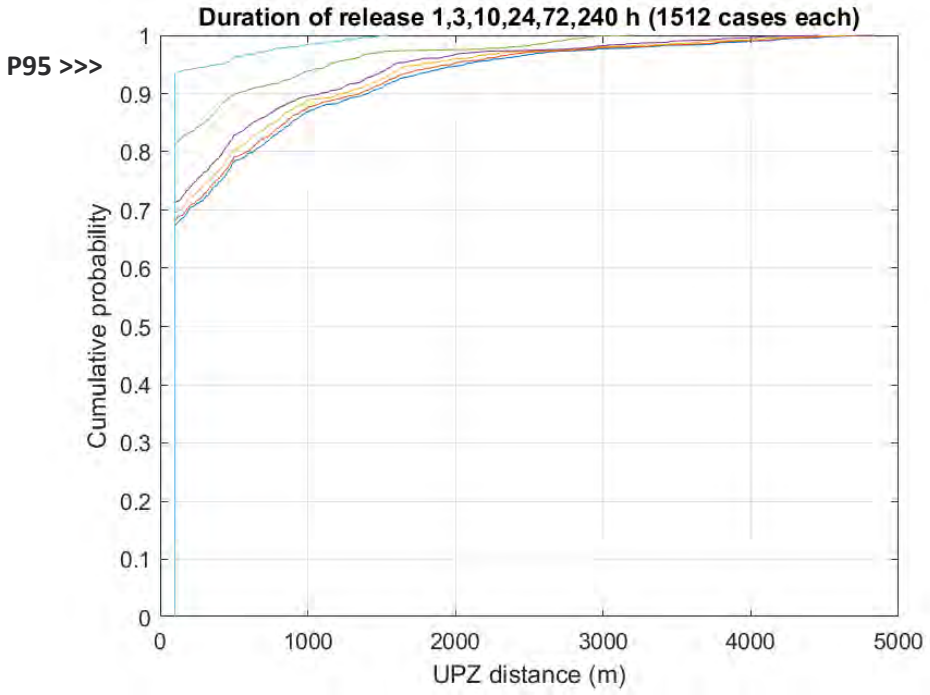
Attempt to 'partially answer' these questions: Start with a kind of sensitivity study.

How to choose relevant / plausible values for release parameters? Customarily (FI / large LWR):

- Time from initiating event to off-site alert: 30 min
- Time from initiating event to start of release could be 0.5 h – 4 h – or more
- Duration of release: hours - days (highest release rate most usually during the first hours)
- In highest-consequence weather, distance of 5 km could usually be reached in 15 – 60 min
- Exposure time to cause deterministic effects off-site: worst case, a few hours; usually more

For the ARANO study, for iPWR, extened these assumptions also towards the less conservative.

VTT: Iodine isotopes, effect of duration



Design-1, 0.1 % of iodine isotopes (of D1 inventory)

Cumulative probability distributions of EPZ distance (Finland STUK limit 10 mSv / 48 h)

Duration of release 1 / 3 / 10 / 24 / 72 / 240 h. Other release parameters and weather may take on range of values >> probability distribution of EPZ. (Results would change with site-specific weather.)

Guide to ordering of curves:

1. **blue (blue): 1 h**
2. **red (red): 3 h**
3. **yellow (yellow): 10 h**
4. **magenta (magenta): 24 h**
5. **green (green): 72 h**
6. **cyan (cyan): 240 h**

Figure. Dependence of the Design-1 UPZ (i.e. EPZ outer bound) distance on release duration (DU), when release contains only iodine (atmospheric release fraction 0.001 of core shutdown inventory). STUK (Finland) 10 mSv criterion was used. Shown are the cumulative probability distributions of EPZ distance for each DU. The 95 % percentiles (P95 values) of UPZ distance are: **2060 m, 1976 m, 1760 m, 1579 m, 1143 m, 375 m**

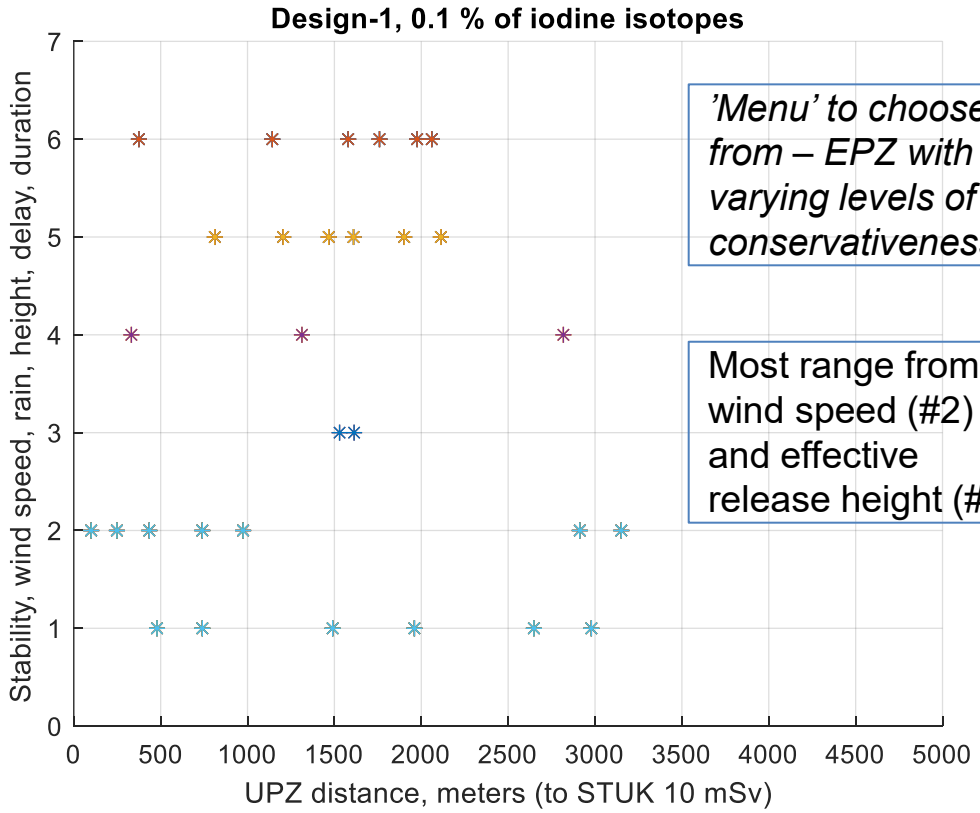
VTT: Iodine isotopes, P95 EPZ (m) for iodine

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

In this plot, we show (for each value of the six varied parameters) the 95 % percentile value of the EPZ distance, as extracted from the previously shown cumulative probability distributions.

Important to note:

- The '0.1 % of iodine' is completely hypothetical, but assumed to be a conservative fraction for Design-1 with large water pool.
- The '95 %' is a confidence choice.
- However, weather here is not for any real site, and the P95 values would change for real site-specific weather (will be in BE phase).



'Menu' to choose from – EPZ with varying levels of conservativeness…

Most range from wind speed (#2) and effective release height (#4).

Release data from WP5 (Containment)

- Responsibilities:
  - WP5: GRS (Hollands); cf. ERMSAR2026 presentation #180 (Monday pm)
  - Design-1: EDF (Bittan)
  - Design-2: UNIROMA (Giannetti)
- STs (corium > containment > atmosphere) for the BE phase (Task 6.3) available:
  - PSI (Malicki), Design-1 SA-1 (MELCOR)
  - Tractebel (Di Giuli), Design-1 Case-1 (ASTEC)
  - VTT (Sevón), Design-1 SA-1 and SA-2 (MELCOR)
  - KIT (Gabrielli), D1 (ASTEC)
  - EDF (Bittan), Design-1 Case-1 (MAAP)
  - SURO, D1 (MELCOR)
  - KTH, D1 (MELCOR)
- For each accident scenario considered, a consolidated ‘best estimate’ source term for WP6 (EPZ)
- Scenario selection (likelihood?) for EPZ might depend on country-specific risk acceptance
- In WP6, we emphasize a plausible scenario (and not very improbable ones)

Release data from WP5 (Containment)

D1 SA-1: Break on CVCS, loss of AC, partial ECCS activation (both RRVs fail)

WP5, Design-1 scenarios considered:

1. SA-1 (as defined in WP2): Reference case, featuring a leakage from the containment (CNMT) to the reactor building (RB) at 0.2% of volume per day (under 69 bar and 298K), and a break from the RB to the environment (5 m²)
2. Bypass scenario, based on SA-1, but with the break occurring directly into the RB. It assumes the availability of reactor recirculation valves (RRVs) and reactor vent valves (RVVs), leading to CNMT dry-out and eventual vessel failure.

- Regarding Figures of Merit, the activity of key isotopes like Cs, I, Xe, Kr and the total activity released to the environment as primary metrics
- Expressed in Bq or as a fraction of the initial inventory (burnup chosen)
- Most important for doses, include iodine and cesium (at least ^{131}I and ^{137}Cs)

Releases, VTT MELCOR calculations for D1

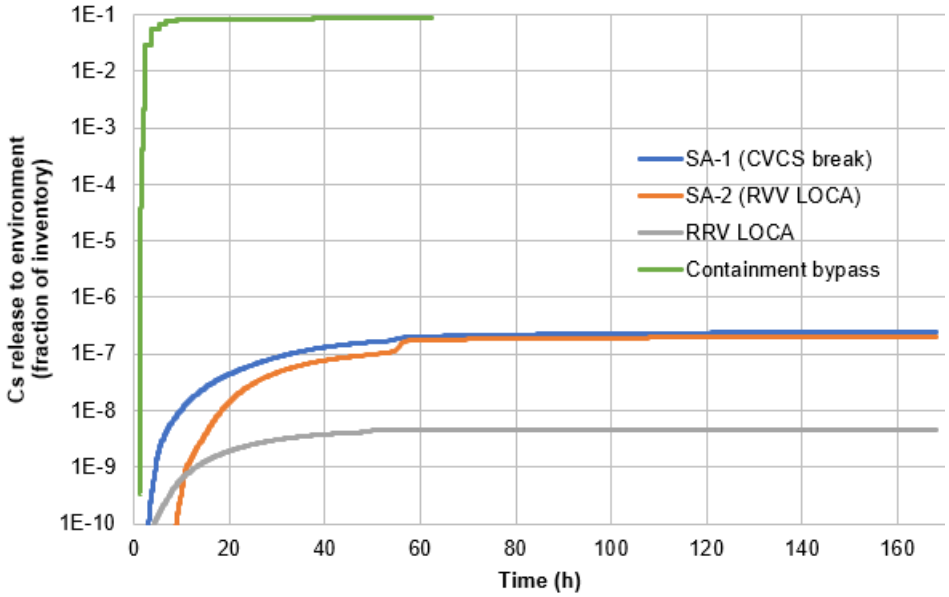
SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

SA-1: break on CVCS, both RRVs fail
SA-2: spurious opening of 1 RVV, both RRVs fail
Opposite of SA-2: spurious opening of 1 RRV, all RVVs fail
Containment bypass through broken CVCS line, RRVs and RVVs operate normally:

- Almost 10 % of cesium escaped in first 10 h (HUGE RELEASE, even when smaller inventory)

- Scenarios' VTT results plotted (Tuomo Sevón) >>>
- Cs release into the environment

- VTT D1 SA-1 result chosen:
  - WP5 >> WP6 (EPZ)



D1 bypass releases, ARANO, 10 % alkali

- Offsite doses and EPZ (VTT ARANO code)

- Fraction 0.1 of D1 core inventory alkali metals
- Cs-137 inventory = 4.184e+16 Bq
- HUGE RELEASE with bypass case, even when small reactor inventory

- ARANO parametric study results
- Parameters 1-3: stability class, wind speed, rain
- Parameters 4-6: release height, delay after shutdown, duration of release (Very little effect from height, because large distances.)
- This was with hypothetical weather; Task6.3 will be real site weather

- Dose criterion: 10 mSv / 48 h (cloudshine, groundshine, inhalation commitment)
- == Finland STUK criterion for UPZ, found in regulation STUK/Y/2024

- What is the realistic frequency (1 / reactor-year) that such a case (with containment bypass through broken CVCS line) would happen at all?

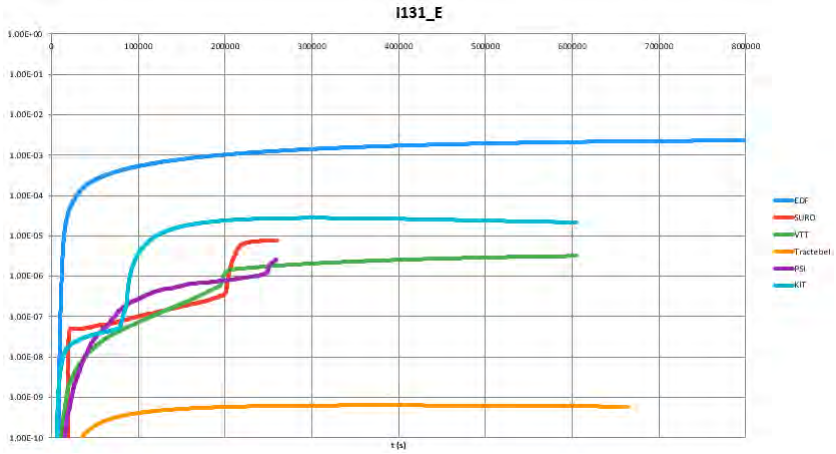
Comparison of partner calculations for D1

Design 1 is generic iPWR with a submerged containment and electric power of about 60 MWe

Scenario SA-1: break on CVCS, both RRVs fail

- Atmospheric environment source terms for: Kr-85, Xe-131m, Xe-133, Xe-135, I-131, I-133, I-135, Cs-134, Cs-136, Cs-137, Te-127, Te-129m, Te-132, Sr-90, Ba-140
- Comparison plots of partners' SA-1 results (by EDF / Bittan)
- Design 1, SA-1: ^{131}I released into the environment >>>
- VTT D1 SA-1 result (green) chosen:
  - Transfer from WP5 >> WP6 (EPZ)
  - VTT mostly close to the mean values
- WP6: Reference scenario and possibly BE + sensitivity



- Releases: Orders of magnitude differences
- Modelling in codes, assumptions made
- Condensation models, nodalisation etc.
- 'User effect', even when same code ?

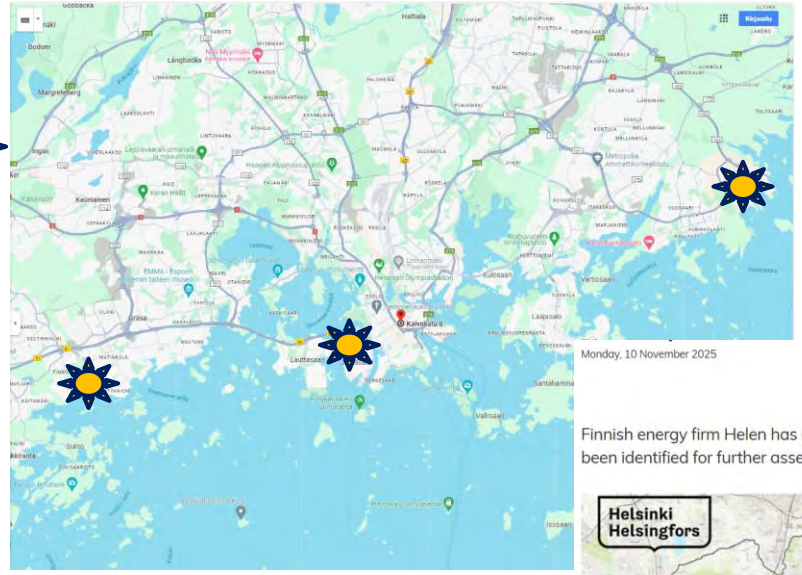
- SASPAM-SA is interfacing with another current EU project (EASI-SMR)
- Our WP5 results help in defining atmospheric release fractions in EASI-SMR

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

WP6 T6.3: Sites, Helsinki metropolitan area

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- Industrial / fossil plant locations
- Inland: Ämmässuo
- Coastal: Suomenoja, Salmisaari, Vuosaari
- (Sites hypothetical at the moment)



Monday, 10 November 2025

Finnish energy firm Helen has announced that three potential sites in Helsinki have been identified for further assessment for locating a small nuclear power plant.

(image: Helen)

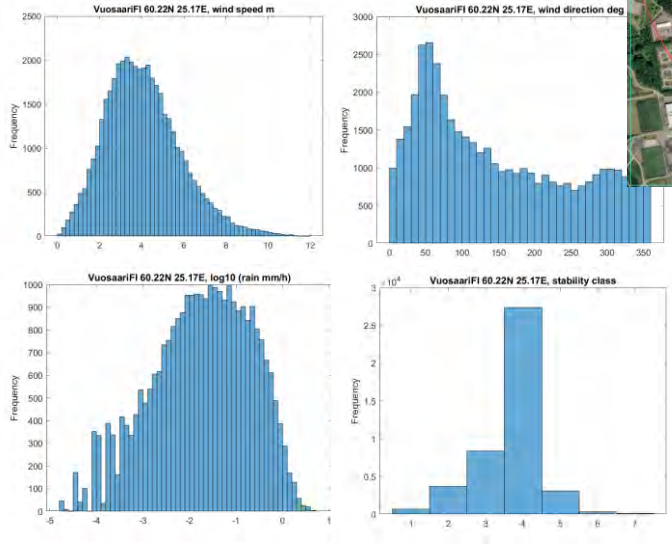
- However, Helen (Helsinki Energy) announced in 2025 three prospective sites for their SMR project >>>

WP6 T6.3 VTT: Vuosaari, Helsinki

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- One of Helen tentative sites is Vuosaari in eastern Helsinki:
- 60.220 N, 25.171 E (a current fossil power plant site) >>>

- Weather data from observations or analysis?
- Weather data from FMI for 5 years (2020-2024), total 43848 hourly conditions, from model analysis fields
- Top: Wind speed & direction
- Bottom: Rain and stability class distributions
- Parameters usable in codes ARANO, VALMA and MACCS.



WP6 conclusions: Regulatory frameworks

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- Suitability of overall procedures in WP6, regulatory framework etc. (those reviewed or the one work was based on): Technically mostly fairly reasonable, but most regulators still fix EPZ.
- Clearly, small / advanced reactors deserve flexible, consequence-oriented approach.
- Regulatory frameworks already with risk metrics are better applicable to passive SMR.

- What is 'safe enough'? >> Suffice it to show that final risk level the same or lower than LLWR ?
- EPZ is ultimately a political / societal / regulator decision, with enough margins
- What we calculated in WP6 should rather be called e.g. 'off-site doses footprint area'

- Can nuclear EP&R ever be harmonized even within the EU? (Cf. IAEA NHSI)
- Urge / trigger international organizations to consider SMR in more detail, more practical level (IAEA, EU Industrial Alliance; regulator side HERCA, WENRA, ENSREG)

- What is the 'share' of each DiD level in achieving the final offsite safety level?
- Frequent comment from IAEA colleagues: EP&R (DiD level 5) / EPZ is not a design issue, but by definition, 'beyond what was ever considered explicitly during design'

WP6 conclusions: Probabilities and risk

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- Probability of DEC-A and DEC-B (i.e. just order of magnitude) is important because many regulators are going to consider some risk-informed methodology.
- In SASPAM-SA, however, full spectrum of STs and their PSA-2 probabilities can not be available.
- CNL: SASPAM is missing accident likelihood assessments. Maybe we can give it a shot as call our guesses 'expert judgement' ?
- An accident scenario with multiple failures of systems can be extremely unlikely to ever happen! So is it then appropriate to be used as basis for emergency planning?

- ENEA: Even in a very conservative manner and with a purely deterministic, worst-case method, the EPZ could be reduced a lot w.r.t. large LWRs, e.g. in some cases to about 1-3 km.
- The calculations using a BE Source Term and a refined atmospheric ATM code (JRODOS) will indicate whether the EPZ size could be further reduced or not.
- The overall EPZ methodology might be shifted from a deterministic, worst-case approach, to a risk-informed one.
- On the use of PRA: Passive systems may be more difficult; sometimes partially functioning; very low probabilities are usually most uncertain.

WP6 conclusions: Uncertainties

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- The 'Conservative' phase quantitative values (distances) are preliminary and very conservative.
- There are obvious reasons for spread of results & possible outliers.

- Uncertainties exist at every step: Source term, atmospheric dispersion, dose assessment.
  - Uncertainties regognized qualitatively; quantification practically not possible.
  - Most probably the source term uncertainties dominate over dispersion and doses.
- Release is decisive: large or not, early or not? Precautionary, or urgent protection needed?
- ENEA: For example, a mitigative strategy to protect the containment (passive FCV) in Design-2, could lead to substantial reduction of source term.

WP6 conclusions: Number of cases

- WP6 can answer the main question: The current dispersion and off-site dose codes and methodologies are generally applicable, provided that no built area or very near range.
- More cases should be calculated to better answer the quantitative question 'SMR EPZ size'.
- We cannot say anything nearly certain about iPWR EPZ extent (numbers, km) based on the 'Conservative phase' work; better after the BE phase.

- 'SMR EPZ size' cannot be generic; must be plant- or design-specific
- Generic EPZ does not exist. SASPAM-SA has shown that a realistic source term is critical. Realistic reactor & containment design and environment are needed.

- Recommended follow-up: Create a 'generic' but representative EPZ database under key DECA and DECB conditions, applying the best practices and recommendations identified in SASPAM-SA, including the iPWR designs, a generic BWR and LDR Lite
- After current SASPAM-SA, there is much better readiness to do more cases, as people already have set up their calculation systems – then for EPZ, we could basically 'plug in' more different DEC-A and DEC-B release source terms.

Conclusions: Codes, Built environments

SAFETY ANALYSIS OF SMR WITH PASSIVE MITIGATION STRATEGIES - SEVERE ACCIDENT

- WP6 was generally satisfied with SMR EPZ methodology used:
  - Choices of codes, calculation parameters, practical steps followed, etc.
- To answer the main questions of SASPAM-SA: The codes were mostly found to be appropriate. Current dispersion & dose codes are applicable when the EPZ is still relatively large.
