REVIEW OF PARTICLE PHYSICS*

Particle Data Group

Abstract

The *Review* summarizes much of particle physics and cosmology. Using data from previous editions, plus 3,200 new measurements from 903 papers, we list, evaluate, and average measured properties of gauge bosons and the recently discovered Higgs boson, leptons, quarks, mesons, and baryons. We summarize searches for hypothetical particles such as supersymmetric particles, heavy bosons, axions, dark photons, etc. Particle properties and search limits are listed in Summary Tables. We give numerous tables, figures, formulae, and reviews of topics such as Higgs Boson Physics, Supersymmetry, Grand Unified Theories, Neutrino Mixing, Dark Energy, Dark Matter, Cosmology, Particle Detectors, Colliders, Probability and Statistics. Most of the 118 reviews are updated, including many that are heavily revised.

The *Review* is divided into two volumes. Volume 1 includes the Summary Tables and 96 review articles. Volume 2 consists of the Particle Listings and contains also 22 reviews that address specific aspects of the data presented in the Listings.

The complete *Review* (both volumes) is published online on the website of the Particle Data Group (pdg.lbl.gov) and in a journal. Volume 1 is available in print as the *PDG Book*. A *Particle Physics Booklet* with the Summary Tables and essential tables, figures, and equations from selected review articles is available in print, as a web version optimized for use on phones, and as an Android app. The PDG API (Application Programming Interface) provides access to the data published in the *Review* in machine-readable format.

The 2026 edition of the *Review of Particle Physics* should be cited as:

HIGHLIGHTS OF THE 2026 EDITION OF THE REVIEW OF PARTICLE PHYSICS

All PDG data and review articles are available online at **pdg.lbl.gov**.

903 new papers with 3,200 new measurements

- 339 new measurements from *LHC* experiments (ATLAS, CMS and LHCb).
- Extensive *Higgs boson* coverage: 92 new papers and 250 measurements, including the latest results on mass, couplings, decay width, constraints on the Higgs self-coupling, and searches for other new scalar bosons.
- *Supersymmetry*: 40 new papers with 143 measurements with major exclusions.
- *Top quark*: 32 new papers with 71 measurements provide latest results on mass, coupling, and the discovery of quantum entanglement between pairs of top quarks at LHC.
- *W mass and Electroweak measurements*: The LHC-Tevatron M_W Working Group reports a new combination that provides a more precise world average. New measurements for the leptonic effective electroweak mixing angle are also reported.
- *c-, b-hadron physics*: 170 papers and 717 measurements provide world-leading data on lifetimes, mixing, CP violation, CKM angles, semileptonic and hadronic branching fractions, including rare processes, and constraints on new physics.
- *Neutrino Physics*: 58 new papers with 126 measurements on neutrino mass, mixing, and CP-violation.
- *Meson resonances*: 171 papers with 618 measurements provide substantial improvements, including new cross particle fits involving $J/\psi(1S)$, $\psi(2S)$ and $\eta_c(1S)$; emerging evidence for existence of additional scalar mesons in the 1700 - 1800 MeV region led to revamping of the $f_0(1710)$, $f_0(1810)$ entries; complex pole positions quoted when available in addition to Breit-Wigner masses and widths; many decay branching fractions re-adjusted with current PDG values; and recently observed states now considered established added to Summary Tables.
- Data from both Summary Tables and Particle Listings are now available in machine-readable format via the PDG API.

118 reviews (most are revised)

- New review on Muon Anomalous Magnetic moment (g-2), covering the latest experimental and theoretical results.
- Major revision of *Higgs Physics* review with a renewed focus on the SM Higgs theory and phenomenology.
- Major revision of *EWK* review includes a pedagogical introduction to the renormalization procedure, updated *EWK* fits based on the HEPFit and GFitter frameworks, and the addition of an SMEFT fit to electroweak precision observables.
- Major revision of *Top Quark* review summarizes latest LHC results and constraints on new physics from top quark.
- Major revision of *Machine Learning* review, with new discussions of self-supervised learning, foundation models, and other recent developments.
- Major revision of various sections in the Particle Detectors for:
  - Accelerator physics in particular on *Gaseous detectors*, *Low-noise detector readout*, and *Semiconductor detectors*.
  - Non-accelerator physics in particular on *Atmospheric fluorescence detectors*, *Atmospheric Cherenkov telescopes*, and *Deep liquid detectors*.
- Major revision of the *Statistics* review, which has been updated and restructured for clarity.
- *Semileptonic B Hadron Decays, Determination of V_{cb} and V_{ub}* summarizes the latest results and discusses long-standing issues with inclusive and exclusive measurements.
- The *Quark Model* review has been updated to include new charmed baryons observed by LHCb and CMS.
- The *Monte Carlo Particle Numbering Scheme* has been extended to better incorporate tentative states, tetraquarks, and pentaquarks.

Introduction

1 Overview

The *Review of Particle Physics* is a comprehensive review of the field of Particle Physics and of related areas in Cosmology. It is divided into two volumes. Volume 1 includes the "Summary Tables" and "Reviews, Tables, and Plots". Volume 2 consists of the "Particle Listings".

The *Review* is updated each year and made available on the PDG website (pdg.lbl.gov). In even-numbered years, the *Review* is also published in a journal and printed as the *PDG Book* together with an abridged *Particle Physics Booklet* containing Summary Tables and essential tables, figures, and equations from selected review articles. This edition is an updating through January 2026.

The Summary Tables give our best values and limits for particle properties such as masses, widths or lifetimes, and branching fractions, as well as an extensive summary of searches for hypothetical particles and a summary of experimental tests of conservation laws.

The 94 review articles in Reviews, Tables and Plots cover a wide variety of theoretical and experimental topics. Together with the Summary Tables they provide an exhaustive reference for the practicing particle physicist. Two more review articles, Online Particle Physics Information and Tests of Conservation Laws, can be found in the introduction and Summary Tables, respectively.

The Particle Listings are a compilation/evaluation of data on particle properties. They contain all the data used to get the values given in the Summary Tables. They also give information on unconfirmed particles and particle searches. In this edition, the Particle Listings include 3,200 new measurements from 903 papers, in addition to the 49,555 measurements from 13,778 papers that first appeared in previous editions [1]. 22 review articles are part of the Particle Listings and address specific aspects of the data presented in the Listings. Because of the large quantity of data, the Particle Listings are not an archive of all published data on particle properties. We refer interested readers to earlier editions for data now considered to be obsolete.

We organize the particles into six categories:

- Gauge and Higgs bosons
- Leptons
- Quarks
- Mesons
- Baryons
- Searches not in other sections

The last category only includes searches for particles that do not belong to the previous groups. For example, it includes searches for supersymmetric particles, compositeness and extra dimensions, while searches for heavy charged leptons are with the leptons.

In Sec. 2 of this Introduction, we list the main areas of responsibility of the authors of the Particle Listings. Our many consultants, without whom we would not have been able to produce this *Review*, are acknowledged in Sec. 3. In Sec. 4, we mention briefly the naming scheme for hadrons, and in Sec. 5, we discuss our procedures for choosing among measurements of particle properties and for obtaining best values of the properties from the measurements.

The accuracy and usefulness of this *Review* depend in large part on interaction between its users and the authors. We appreciate comments, criticisms, and suggestions for improvements of any kind. Please send them to pdg@lbl.gov from where they will be forwarded to the appropriate author according to the list of responsibilities in Sec. 2 below.

In addition to the online publication at pdg.lbl.gov, the *Review* is available in different formats:

- The printed *PDG Book* includes volume 1 only, *i.e.* it contains the Summary Tables and most review articles. Since the 2016 edition [2] the detailed tables from the Particle Listings are no longer printed.
- The *Particle Physics Booklet* includes the Summary Tables plus essential tables, figures, and equations from selected review articles. Starting with the Booklets of the 2018 edition, we have excluded most text and explanations in order to revert back to a more pocket-sized format. The Booklet is available in print, as a web version optimized for use on phones, and as an Android app (see pdg.lbl.gov/booklet).
- *pdgLive* (pdgLive.lbl.gov) is a web application giving more interactive access to PDG data than the static web pages and PDF files that are also available.
- Files that can be downloaded from the PDG website include a table of masses, widths, and PDG Monte Carlo particle ID numbers; PDF files of volume 1 (PDG Book), volume 2 (Particle Listings) and Booklet; individual review articles; all figures; and an archive file containing the complete PDG website (except for pdgLive).
- The data published in the *Review of Particle Physics* is available in machine-readable format through the PDG API (Application Programming Interface). See pdg.lbl.gov/api for details.

Copies of the *PDG Book* or the *Particle Physics Booklet* can be ordered from our website or directly at pdg.lbl.gov/order. For special requests only, please email pdg@lbl.gov in North and South America, Australia, and the Far East, and pdg-products@cern.ch in all other areas.

This *Review* is considered to be a single comprehensive review of particle physics and related areas. Therefore we prefer that it be cited as a whole, rather than citing *e.g.* an individual review article that is part of this *Review*. For the 2026 edition, the proper citation is:

F. Takahashi *et al.* (Particle Data Group), Int. J. Mod. Phys. A **41**, 2630011 (2026).

If you wish to refer to a specific part of the *Review*, for example to the Higgs boson review article, the following form should be used:

"Status of Higgs Boson Physics" in F. Takahashi *et al.* (Particle Data Group), Int. J. Mod. Phys. A **41**, 2630011 (2026).

2 Particle Listings responsibilities

* Asterisk indicates the people to contact with questions or comments about Particle Listings sections. Please contact them by e-mail to pdg@lbl.gov.

- Gauge and Higgs bosons

γ	A. Bettini, D.E. Groom*
Gluons	R.M. Barnett,* A.V. Manohar
Graviton	A. Bettini,* D.E. Groom
W, Z	M. Grünewald,* A. Gurtu*, J. Kretzschmar
Higgs bosons	S. Heinemeyer,* K. Hikasa, J. Tanaka
Heavy bosons	R. Bonventre,* K.A. Olive, M. Tanabashi
Axions	C. O'Hare, K.A. Olive, F. Takahashi

- Leptons

Neutrinos	C.-J. Lin,* K.A. Olive, A. Piepke, M. Yokoyama
Double-β decay	A. Bettini*, A. Piepke
e, μ	A. Bettini,* C. Grab
τ	A. Lusiani, K. Mönig*

- Quarks

Quarks	R.M. Barnett,* A.V. Manohar
Top quark	Y. Sumino, W.-M. Yao*
b', t'	Y. Sumino, W.-M. Yao*
Free quark	A. Bettini,* C.-J. Lin

- Mesons

π, η	A. Bettini,* C. Grab
K (stable)	G. D'Ambrosio, C.-J. Lin*
D (stable)	G. Casarosa, J. Rademacker, D. Robinson*
B (stable)	A. Cerri,* P. Eerola, M. Kreps, Y. Kwon, W.-M. Yao*

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Unstable mesons	C. Amsler,*, S. Giovannella, T. Gutsche, C. Hanhart, J.J. Hernández-Rey, C. Lourenco, A. Masoni, M. Mikhasenko, R.E. Mitchell, S. Navas, C. Patrignani, K. Peters, C. Schwanda, S. Spanier, G. Venanzoni, C.Z. Yuan

- Baryons

Stable baryons	C. Grab, D. Robinson*
Unstable baryons	V. Crede, U. Thoma, L. Tiator, R.L. Workman*
Charmed baryons	G. Casarosa, J. Rademacker, D. Robinson*
Bottom baryons	A. Cerri,* P. Eerola, M. Kreps, Y. Kwon, W.-M. Yao*

- Miscellanoues searches

Monopole	A. Bettini,* D. Milstead
Supersymmetry	H.K. Dreiner,* A. de Gouvêa, I.-A. Melzer-Pellmann, K.A. Olive, I. Vivarelli
Technicolor	K. Agashe,* K.A. Olive, M. Tanabashi
Compositeness	M. Tanabashi, J. Terning*
Extra Dimensions	T. Gherghetta, K.A. Olive, D. Robinson*
WIMP, DM, Other	H. Baer, A. Bettini,* W.-M. Yao*

3 Consultants

The Particle Data Group benefits greatly from the assistance of hundreds of physicists who are asked to referee review articles and verify every piece of data entered into this *Review*. Of special value is the advice of the PDG International Advisory Committee, which meets biennially and thoroughly reviews all aspects of our operation. The members of the 2026 committee are:

S. Demers (Yale)
D. d'Enterria (CERN)
J. Frieman (FNAL)
S. Gori (UCSC)
M. Ishitsuka (Tokyo)

We have especially relied on the expertise of the following people for advice on particular topics:

- I. Abt (MPP, Garching)
- M. Achasov (Budker Inst., Novosibirsk)
- S. Adachi (Kyoto U.)
- C. Adams (Columbia U.)
- D. Adan (RWTH Aachen U.)
- E. Adli (Oslo U.)
- Y. Afik (Chicago U.)
- S. Alderweireldt (Edinburgh U.)
- M. Aleksa (CERN)
- M. Alpízar (IF-UNAM)
- G. Alves (USP; FNAL)
- A. Antognini (ETH Zurich)
- E. Aprile (Columbia U.)
- S. Arguedas Cuendis (ICC, U. of Barcelona)
- M. Artuso (Syracuse U.)
- N. Asbah (CERN)
- P. Athron (Nanjing U.)
- E. Auffray (CERN)
- G. Azuelos (U. de Montreal)
- S. Bahinipati (IIT Bhubaneswar)
- X. Bai (Yale U.)
- A.B. Balantekin (Wisconsin U.)
- A. Baldini (INFN, Pisa)
- A. Barabash (ITEP)
- E. Barriga (Florida State U.)
- V. Baru (Ruhr U. Bochum)
- R. Battiston (Trento U.)
- G. Bell (Siegen U.)
- J. Bellido Caceres (Adelaide U.)
- V. Belyaev (ITEP)
- J. Bendavid (CERN)
- X. Benhou (IHEP Beijing)
- J. Bennett (Mississippi U.)
- F. Betti (INFN, Bologna)
- F. Bianchini (SLAC)
- T. Biekotter (KIT)
- P. Bisio (INFN, Genova)
- F. Blanc (CERN)
- P. Blasi (GSSI)
- M. Blaskiewicz (BNL)
- O. Boente (CERN)
- M. Bona (QMUL)
- A. Bondar (Budker Inst., Novosibirsk)
- C. Bonifazi (ICAS and ICIFI, UNSAM)
- M. Boonekamp (CEA/IRFU Saclay)
- M. Borsato (CERN)
- S. Bressler (Weizmann Inst.)
- F. Brizioli (CERN)
- R. Bruce (CERN)
- O. Bruning (CERN)
- J. Butter (Cavendish Lab.)
- M. Cadeddu (INFN, Cagliari)
- C. Caillol (CERN)
- R. Camacho (CERN)
- S. Camarda (CERN)
- F. Caola (Rudolf Peierls, Oxford U.)
- L. Capriotti (INFN, Ferrara)
- A. Caputo (CERN)
- B. Carlo (INFN, LNGS)
- V. Carretero (IFIC, Valencia)
- G. Cavoto (Rome U.; INFN, Rome)
- S. Cebrian Guajardo (U. de Zaragoza)
- M. Cermeno (UAM/CSIC, U. Autónoma de Madrid)
- R. Cervantes (FNAL)
- C. Chen (CPPM Marseille)
- D. Chen (SEU)
- M. Chen (Queen's U.)
- Y. Chenghui (IHEP Beijing)
- G. Chiarelli (INFN, Pisa)
- V. Chobanova (CERN)
- J. Choi (Seoul National U.)
- I. Cholis (Oakland U.)
- V. Cirigliano (U. Washington)
- S. Clayton (LANL)
- G. Colangelo (U. Bern)
- J.I. Collar (Chicago U.)
- L. Corpe (Clermont-Ferrand U.)
- A. Cortes Gonzalez (Physik, Humboldt U.)
- P. Crivelli (ETH Zurich)
- A. Czarnecki (Alberta U.)

4 Naming scheme for hadrons

We introduced in the 1986 edition [3] a new naming scheme for the hadrons. Changes from older terminology affected mainly the heavier mesons made of u, d, and s quarks. Otherwise, the only important change to known hadrons was that the $F^{\pm}$ became the $D_s^{\pm}$. None of the lightest pseudoscalar or vector mesons changed names, nor did the $c\bar{c}$ or $b\bar{b}$ mesons (we do, however, now use χ_c for the $c\bar{c}$ χ states), nor did any of the established baryons. The Summary Tables give both the new and old names whenever a change has occurred.

In the 2018 edition [4], the naming scheme was extended to address the naming of charmonium and bottomonium states that were commonly referred to as X, Y, or Z states in the literature. The further discovery of various exotic hadron states — including in particular tetraquarks and pentaquarks containing $qq\bar{q}\bar{q}$ and $q\bar{q}qqq$ minimal quark content, respectively — rendered the 2018 extension insufficient. In the 2024 edition, the naming scheme was again revised and extended to cover all experimentally-known states. The current scheme is described in "Naming Scheme for Hadrons" (p. 155) of this *Review*. A table details the correspondence between the names newly adopted by the PDG and those that have previously appeared in the literature.

We give here our conventions on typesetting style. Particle symbols are italic (or slanted) characters: e^-, p, Λ, π^0, K_L, D_s^+, b. Charge is indicated by a superscript: B^-, Δ^{++}. Charge is not normally indicated for p, n, or the quarks, and is optional for neutral isosinglets: η or η^0. Antiparticles and particles are distinguished by charge for charged leptons and mesons: τ^+, K^-. Otherwise, distinct antiparticles are indicated by a bar (overline): $\overline{\nu}_\mu$, $\bar{t}$, $\bar{p}$, $\overline{K}^0$, and $\overline{\Sigma}^+$ (the antiparticle of the Σ^-).

5 Procedures

5.1 *Selection and treatment of data*

The Particle Listings contain all relevant data known to us that are published in journals. With very few exceptions, we do not include results from preprints or conference reports. Nor do we include data that are of historical importance only (the Listings are not an archival record). We search every volume of 30 journals through our cutoff date for relevant data. We also include later published papers that are sent to us by the authors (or others).

In the Particle Listings, we clearly separate measurements that are used to calculate or estimate values given in the Summary Tables from measurements that are not used. We give explanatory comments in many such cases. Among the reasons a measurement might be excluded are the following:

- It is superseded by or included in later results.
- No error is given.
- It involves assumptions we question.
- It has a poor signal-to-noise ratio, low statistical significance, or is otherwise of poorer quality than other data available.
- It is clearly inconsistent with other results that appear to be more reliable. Usually we then state the criterion, which sometimes is quite subjective, for selecting "more reliable" data for averaging. See Sec. 5.4.
- It is not independent of other results.
- It is not the best limit (see below).
- It is quoted from a preprint or a conference report.

In some cases, *none* of the measurements is entirely reliable and no average is calculated. For example, the masses of many of the baryon resonances, obtained from partial-wave analyses, are quoted as estimated ranges thought to probably include the true values, rather than as averages with errors. This is discussed in the Baryon Particle Listings.

For upper limits, we normally quote in the Summary Tables the strongest limit. We do not average or combine upper limits except in a very few cases where they may be re-expressed as measured numbers with Gaussian errors.

As is customary, we assume that particle and antiparticle share the same spin, mass, and mean life. The Tests of Conservation Laws table, following the Summary Tables, lists tests of CPT as well as other conservation laws.

We use the following indicators in the Particle Listings to tell how we get values from the tabulated measurements:

- OUR AVERAGE —From a weighted average of selected data.
- OUR FIT —From a constrained or overdetermined multiparameter fit of selected data.

- OUR EVALUATION —Not from a direct measurement, but evaluated from measurements of related quantities.
- OUR ESTIMATE —Based on the observed range of the data. Not from a formal statistical procedure.
- OUR LIMIT —For special cases where the limit is evaluated by us from measured ratios or other data. Not from a direct measurement.

An experimentalist who sees indications of new a particle will of course want to know what has been seen in that region in the past. Hence, we include in the Particle Listings all reported states that, in our opinion, have sufficient statistical merit and that have not been disproved by more reliable data. However, we promote to the Summary Tables only those states that we feel are well-established. This judgment is, of course, somewhat subjective and no precise criteria can be given. For more detailed discussions, see the reviews section on Particle Properties.

5.2 *Averages and fits*

We divide this discussion on obtaining averages and errors into three sections: (1) treatment of errors; (2) unconstrained averaging; (3) constrained fits.

5.2.1 *Treatment of errors*

In what follows, the "error" δx means that the range $x \pm \delta x$ is intended to be a 68.3% confidence interval about the central value x. We treat this error as if it were Gaussian. Thus, when the error *is* Gaussian, δx is the usual one standard deviation (1σ). Many experimenters now give statistical and systematic errors separately, in which case we usually quote both errors, with the statistical error first. For averages and fits, we then add the two errors in quadrature and use this combined error for δx.

When experimenters quote asymmetric errors $(\delta x)^+$ and $(\delta x)^-$ for a measurement x, the error that we use for that measurement in making an average or a fit with other measurements is a continuous function of these three quantities. When the resultant average or fit $\overline{x}$ is less than $x - (\delta x)^-$, we use $(\delta x)^-$; when it is greater than $x + (\delta x)^+$, we use $(\delta x)^+$. In between, the error we use is a linear function of x. Since the errors we use are functions of the result, we iterate to get the final result. Asymmetric output errors are determined from the input errors assuming a linear relation between the input and output quantities.

In fitting or averaging, we usually do not include correlations between different measurements, but we try to select data in such a way as to reduce correlations. Correlated errors are, however, treated explicitly when there are a number of results of the form $A_i \pm \sigma_i \pm \Delta$ that have identical systematic errors Δ. In this case, one can first average the $A_i \pm \sigma_i$ and then combine the resulting statistical error with Δ. One obtains, however, the same result by averaging $A_i \pm (\sigma_i^2 + \Delta_i^2)^{1/2}$, where $\Delta_i = \sigma_i \Delta [\sum (1/\sigma_j^2)]^{1/2}$. This procedure has the advantage that, with the modified systematic errors Δ_i, each measurement may be treated as independent and averaged in the usual way with other data. Therefore, when appropriate, we adopt this procedure. We tabulate Δ and invoke an automated procedure that computes Δ_i before averaging.

Another common case of correlated errors occurs when experimenters measure two quantities and then quote the two and their difference, *e.g.*, m_1, m_2, and $\Delta = m_2 - m_1$. We cannot enter all of m_1, m_2 and Δ into a constrained fit because they are not independent. In some cases, it is a good approximation to ignore the quantity with the largest error and put the other two into the fit. However, in some cases correlations are such that the errors on m_1, m_2 and Δ are comparable and none of the three values can be ignored. In this case, we put all three values into the fit and invoke an automated procedure to increase the errors prior to fitting such that the three quantities can be treated as independent measurements in the constrained fit. We include a note saying that this has been done.

5.2.2 *Unconstrained averaging*

To average data, we use a standard weighted least-squares procedure and in some cases, discussed below, increase the errors with a "scale factor." We begin by assuming that measurements of a given quantity are uncorrelated, and calculate a weighted average and error as

$$\overline{x} \pm \delta\overline{x} = \frac{\sum_i w_i\, x_i}{\sum_i w_i} \pm \left(\sum_i w_i\right)^{-1/2} , \qquad (1)$$

where

$$w_i = 1/(\delta x_i)^2 .$$

Here x_i and δx_i are the value and error reported by the ith experiment, and the sums run over the N experiments. We then calculate $\chi^2 = \sum w_i(\overline{x} - x_i)^2$ and compare it with $N-1$, which is the expectation value of χ^2 if the measurements are from a Gaussian distribution.

If $\chi^2/(N-1)$ is less than or equal to 1, and there are no known problems with the data, we accept the results.

If $\chi^2/(N-1)$ is very large, we may choose not to use the average at all. Alternatively, we may quote the calculated average, but then make an educated guess of the error, a conservative estimate designed to take into account known problems with the data.

Finally, if $\chi^2/(N-1)$ is greater than 1, but not greatly so, we still average the data, but then also do the following:

(a) We increase our quoted error, $\delta\overline{x}$ in Eq. (1), by a scale factor S defined as

$$S = \left[\chi^2/(N-1)\right]^{1/2} . \qquad (2)$$

Our reasoning is as follows. The large value of the χ^2 is likely to be due to underestimation of errors in at least one of the experiments. Not knowing which of the errors are underestimated, we assume they are all underestimated by the same factor S. If we scale up all the input errors by this factor, the χ^2 becomes $N-1$, and of course the output error $\delta\overline{x}$ scales up by the same factor. See Ref. [5].

When combining data with widely varying errors, we modify this procedure slightly. We evaluate S using only the experiments with smaller errors. Our cutoff or ceiling on δx_i is arbitrarily chosen to be

$$\delta_0 = 3N^{1/2}\, \delta\overline{x} ,$$

where $\delta\overline{x}$ is the unscaled error of the mean of all the experiments. Our reasoning is that although the low-precision experiments have little influence on the values $\overline{x}$ and $\delta\overline{x}$, they can make significant contributions to the χ^2, and the contribution of the high-precision experiments thus tends to be obscured. Note that if each experiment has the same error δx_i, then $\delta\overline{x}$ is $\delta x_i/N^{1/2}$, so each δx_i is well below the cutoff. (More often, however, we simply exclude measurements with relatively large errors from averages and fits: new, precise data chase out old, imprecise data.)

Our scaling procedure has the property that if there are two values with comparable errors separated by much more than their stated errors (with or without a number of other values of lower accuracy), the scaled-up error $\delta\,\overline{x}$ is approximately half the interval between the two discrepant values.

We emphasize that our scaling procedure for *errors* in no way affects central values. And if you wish to recover the unscaled error $\delta\overline{x}$, simply divide the quoted error by S.

(b) If the number M of experiments with an error smaller than δ_0 is at least three, and if $\chi^2/(M-1)$ is greater than 1.25, we show in the Particle Listings an ideogram of the data. Figure 1 is an example. Sometimes one or two data points lie apart from the main body; other times the data split into two or more groups. We extract no numbers from these ideograms; they are simply visual aids, which the reader may use as they see fit.

Each measurement in an ideogram is represented by a Gaussian with a central value x_i, error δx_i, and area proportional to $1/\delta x_i$. The choice of $1/\delta x_i$ for the area is somewhat arbitrary. With this choice, the center of gravity of the ideogram corresponds to an average that uses weights $1/\delta x_i$ rather than the $(1/\delta x_i)^2$ actually used in the averages. This may be appropriate when some of the experiments have seriously underestimated systematic errors. However, since for this choice of area the height of the Gaussian for each measurement is proportional to $(1/\delta\, x_i)^2$, the peak position of the ideogram will often favor the high-precision measurements at least as much as does the least-squares average. See our 1986 edition [3] for a detailed discussion of the use of ideograms.

5.2.3 *Constrained fits*

In some cases, such as branching ratios or masses and mass differences, a constrained fit may be needed to obtain the best values of a set of parameters. For example, most branching ratios and rate measurements are analyzed by making a simultaneous least-squares fit to all the data and extracting the partial decay fractions P_i, the partial widths Γ_i, the full width Γ (or mean life), and the associated error matrix.

Assume, for example, that a state has m partial decay fractions P_i, where $\sum P_i = 1$. These have been measured in N_r different ratios R_r, where, e.g., $R_1 = P_1/P_2$, $R_2 = P_1/P_3$, *etc.* [We can handle any ratio R of the form $\sum \alpha_i P_i / \sum \beta_i P_i$, where α_i and β_i are constants, usually 1 or 0. The forms $R = P_i P_j$ and $R = (P_i P_j)^{1/2}$ are also allowed.] Further, assume that *each* ratio R has been measured by N_k experiments (we designate each experiment with a subscript k, e.g., R_{1k}). We then find the best values of the fractions P_i by minimizing the χ^2 as a function of the $m-1$ independent parameters:

$$\chi^2 = \sum_{r=1}^{N_r} \sum_{k=1}^{N_k} \left(\frac{R_{rk} - R_r}{\delta R_{rk}} \right)^2 , \tag{3}$$

where the R_{rk} are the measured values and R_r are the fitted values of the branching ratios.

In addition to the fitted values $\overline{P}_i$, we calculate an error matrix $\langle \delta\overline{P}_i \ \delta\overline{P}_j \rangle$. We tabulate the diagonal elements of $\delta\overline{P}_i = \langle \delta\overline{P}_i \ \delta\overline{P}_i \rangle^{1/2}$ (except that some errors are scaled as discussed below). In the Particle Listings, we give the complete correlation matrix; we also calculate the fitted value of each ratio, for comparison with the input data, and list it above the relevant input, along with a simple unconstrained average of the same input.

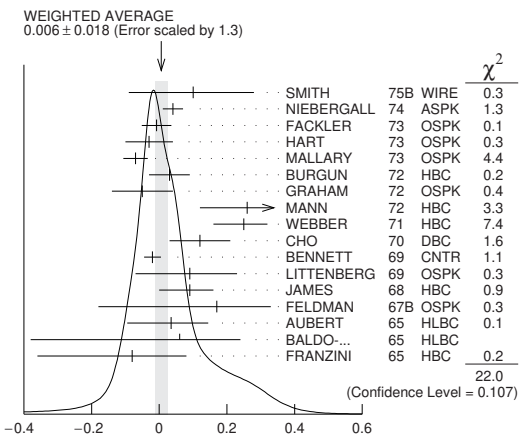

Figure 1: A typical ideogram. The arrow at the top shows the position of the weighted average, while the width of the shaded pattern shows the error in the average after scaling by the factor S. The column on the right gives the χ^2 contribution of each of the experiments. Note that the next-to-last experiment, denoted by the incomplete error flag ($\perp$), is not used in the calculation of S (see the text).

Three comments on the example above:

(1) There was no connection assumed between measurements of the full width and the branching ratios. But often we also have information on partial widths Γ_i as well as the total width Γ. In this case we must introduce Γ as a parameter in the fit, along with the P_i, and we give correlation matrices for the widths in the Particle Listings.

(2) We try to pick those ratios and widths that are as independent and as close to the original data as possible. When one experiment measures all the branching fractions and constrains their sum to be one, we leave one of them (usually the least well-determined one) out of the fit to make the set of input data more nearly independent. We now do allow for correlations between input data.

(3) We calculate scale factors for both the R_r and P_i when the measurements for any R give a larger-than-expected contribution to the χ^2. According to Eq. (3), the double sum for χ^2 is first summed over experiments $k = 1$ to N_k, leaving a single sum over ratios $\chi^2 = \sum \chi_r^2$. One is tempted to define a scale factor for the ratio r as $S_r^2 = \chi_r^2 / \langle \chi_r^2 \rangle$. However, since $\langle \chi_r^2 \rangle$ is not a fixed quantity (it is somewhere between N_k and N_{k-1}), we do not know how to evaluate this expression. Instead, we define

$$S_r^2 = \frac{1}{N_k} \sum_{k=1}^{N_k} \frac{\left(R_{rk} - \overline{R}_r \right)^2}{\langle (R_{rk} - \overline{R}_r)^2 \rangle} . \tag{4}$$

With this definition the expected value of S_r^2 is one. We can show that

$$\langle (R_{rk} - \overline{R}_r)^2 \rangle = \langle (\delta R_{rk})^2 \rangle - (\delta \overline{R}_r)^2 , \tag{5}$$

where $\delta\overline{R}_r$ is the fitted error for ratio r.

The fit is redone using errors for the branching ratios that are scaled by the larger of S_r and unity, from which new and often larger errors $\delta\overline{P}_i'$ are obtained. The scale factors we finally list in such cases are defined by $S_i = \delta\overline{P}_i'/\delta\overline{P}_i$. However, in line with our policy of not letting S affect the central values, we give the values of $\overline{P}_i$ obtained from the original (unscaled) fit.

There is one special case in which the errors that are obtained by the preceding procedure may be changed. When a fitted branching ratio (or rate) $\overline{P}_i$ turns out to be less than three standard deviations ($\delta\overline{P}_i'$) from zero, a new smaller error $(\delta\overline{P}_i'')^-$ is calculated on the low side by requiring the area under the Gaussian between $\overline{P}_i - (\delta\overline{P}_i'')^-$ and $\overline{P}_i$ to be 68.3% of the area between zero and $\overline{P}_i$. A similar correction is made for branching fractions that are within three standard deviations of one. This keeps the quoted errors from overlapping the boundary of the physical region.

5.3 *Rounding*

While the results shown in the Particle Listings are usually exactly those published by the experiments, the numbers that appear in the Summary Tables (means, averages and limits) are subject to a set of rounding rules.

The basic rule states that if the three highest order digits of the error lie between 100 and 354, we round to two significant digits. If they lie between 355 and 949, we round to one significant digit. Finally, if they lie between 950 and 999, we round up to 1000 and keep two significant digits. In all cases, the central value is given with a precision that matches that of the error. So, for example, the result (coming from an average) 0.827 ± 0.119 would appear as 0.83 ± 0.12, while 0.827 ± 0.367 would turn into 0.8 ± 0.4.

In cases where there are asymmetric errors, if these errors differ by less than 10 percent of the average of the two errors, the average is instead used as a symmetric error in the displayed result and the rounding is determined by this average. Otherwise, the narrower of the two asymmetric errors is used to determine the rounding on both.

Rounding of this form is also performed on the value of limits that come from calculations (but not on limits that are directly taken from a single source).

Finally, we should point out that in several instances, when a group of results come from a single fit to a set of data, we have chosen to keep two significant digits for all the results. This happens, for instance, for several properties of the W and Z bosons and the τ lepton.

5.4 *Discussion*

The problem of averaging data containing discrepant values is nicely discussed by Taylor in Ref. [6]. He considers a number of algorithms that attempt to incorporate inconsistent data into a meaningful average. However, it is difficult to develop a procedure that handles simultaneously in a reasonable way two basic types of situations: (a) data that lie apart from the main body of the data are incorrect (contain unreported errors); and (b) the opposite—it is the main body of data that is incorrect. Unfortunately, as Taylor shows, case (b) is not infrequent. He concludes that the

choice of procedure is less significant than the initial choice of data to include or exclude.

We place much emphasis on this choice of data. Often we solicit the help of outside experts (consultants). Sometimes, however, it is simply impossible to determine which of a set of discrepant measurements are correct. Our scale-factor technique is an attempt to address this ignorance by increasing the error. In effect, we are saying that present experiments do not allow a precise determination of this quantity because of unresolvable discrepancies, and one must await further measurements. The reader is warned of this situation by the size of the scale factor, and if they desire can go back to the literature (via the Particle Listings) and redo the average with a different choice of data.

Our situation is less severe than most of the cases Taylor considers, such as estimates of the fundamental constants like $\hbar$, *etc.* Most of the errors in his case are dominated by systematic effects. For our data, statistical errors are often at least as large as systematic errors, and statistical errors are usually easier to estimate. A notable exception occurs in partial-wave analyses, where different techniques applied to the same data yield different results. In this case, as stated earlier, we often do not make an average but just quote a range of values.

A brief history of early Particle Data Group averages is given in Ref. [5]. Our History Plots show the time evolution of some of our values of a few particle properties. Sometimes large changes occur. These usually reflect the introduction of significant new data or the discarding of older data. Older data are discarded in favor of newer data when it is felt that the newer data have smaller systematic errors, or have more checks on systematic errors, or have made corrections unknown at the time of the older experiments, or simply have much smaller errors. Sometimes, the scale factor becomes large near the time at which a large jump takes place, reflecting the uncertainty introduced by the new and inconsistent data. By and large, however, a full scan of our history plots shows a dull progression toward greater precision at central values quite consistent with the first data points shown.

We conclude that the reliability of the combination of experimental data and our averaging procedures is usually good, but it is important to be aware that fluctuations outside of the quoted errors can and do occur.

ACKNOWLEDGMENTS

The publication of the *Review of Particle Physics* is supported by the Director, Office of Science, Office of High Energy Physics of the U.S. Department of Energy under Contract No. DE–AC02–05CH11231; by an implementing arrangement between the governments of Japan (MEXT: Ministry of Education, Culture, Sports, Science and Technology, and KEK: High Energy Accelerator Research Organization) and the United States (DOE) on cooperative research and development; by the Italian National Institute of Nuclear Physics (INFN); and by the European Laboratory for Particle Physics (CERN). Individual collaborators receive support for their PDG activities from their respective institutes or funding agencies.

We thank all those who have assisted in the many phases of preparing this *Review*. We particularly thank the many who have responded to our requests for verification of data entered in the Listings, and those who have made suggestions or pointed out errors.

We are grateful to the staff at CERN, DESY, IHEP Beijing, KEK, LBNL, NISER and UNIFAL who take care of the mailing and distribution of our products.

This work used resources of the National Energy Research Scientific Computing Center, a DOE Office of Science User Facility supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

1 Introduction

Online resources are used in a diverse and expanding set of ways in particle physics. Many of these resources have become central to our collective work. We provide a brief curated selection of the major resources here. An expanded and regularly updated online repository is referred to below and can be found at

`https://github.com/particledatagroup/hep-resources`

By contrast, it is meant to be inclusive and catalog all useful resources related to particle physics. The community is warmly invited to contribute in order to ensure a broad and up to date coverage of relevant resources. Practical details are available online.

2 Particle Data Group (PDG) resources

- **Review of Particle Physics (RPP):** A comprehensive report on the fields of particle physics and related areas of cosmology and astrophysics, including both review articles and a compilation/evaluation of data on particle properties. The review section includes articles, tables and plots on a wide variety of theoretical and experimental topics of interest to particle physicists and astrophysicists. The particle properties section provides tables of published measurements as well as the Particle Data Group's best values and limits for particle properties such as masses, widths, lifetimes, and branching fractions, as well as an extensive summary of searches for hypothetical particles. RPP is published as a large book every two years, with partial updates made available once each year on the web.

  All the contents of the book version of RPP are available online:

  `https://pdg.lbl.gov`

  The printed book can be ordered:

  `https://pdg.lbl.gov/order`

  Of historical interest is the complete RPP collection which can be found online:

  `https://pdg.lbl.gov/publications`

- **Particle Physics booklet:** An abridged version of the Review of Particle Physics, available as a pocket-sized 250-page booklet. It is one of the most useful summaries of physics data. The booklet contains an abbreviated set of reviews and the summary tables from the most recent edition of the Review of Particle Physics.

  The PDF file of the booklet can be downloaded:

  `https://pdg.lbl.gov/current/booklet.pdf`

  The printed booklet can be ordered:

  `https://pdg.lbl.gov/order`

  A mobile version of the booklet is also available:

  `https://pdg.lbl.gov/booklet`

- **PDGLive:** A web application for browsing the contents of the PDG database that contains the information published in the Review of Particle Physics. It allows one to navigate to a particle of interest, see a summary of the information available, and then proceed to the detailed information published in the Review of Particle Physics. Data entries are directly linked to the corresponding bibliographic information in INSPIRE.

  `https://pdglive.lbl.gov`

- **Computer-readable files:** Data files that can be downloaded from the PDG include tables of particle masses and widths, PDG Monte Carlo particle numbers, and cross-section data. The files are updated with each new edition of the Review of Particle Physics.

  `https://pdg.lbl.gov/files`

- **PDG API:** In addition to the fixed-format data files that have been available for many years, PDG is developing new tools to access PDG data in machine-readable format (currently available as beta versions).

  `https://pdg.lbl.gov/api`

3 Particle physics information platform

INSPIRE: INSPIRE serves as a one-stop information platform for the particle physics community, comprising interlinked databases on literature, authors, jobs, seminars, conferences, institutions and experiments (each described in more detail below). Run in collaboration by CERN (which hosts INSPIRE), DESY, Fermilab, IHEP, IN2P3, SLAC and TIB, it has been serving the scientific community for almost 60 years. Previously hosted at SLAC and known as SPIRES, in December 1991 it became the first website outside Europe and the first database on the web. Close interaction with the user community and with arXiv, ADS, HEPData, ORCID, PDG, ROR and publishers is the backbone of INSPIRE's evolution. Since 2020, it is running on a modernized platform that is continually being improved.

`https://inspirehep.net/`

4 Literature databases

Most research articles in the field of high-energy physics are first made available on the arXiv eprint server, where researchers can learn about the latest developments by browsing through the new announcements five days a week. They are indexed, together with all other publications in high-energy physics and related fields, in the INSPIRE literature collection. For neighboring fields such as astrophysics or mathematics, other databases are more exhaustive.

- **ADS:** The SAO/NASA Astrophysics Data System is a Digital Library portal that maintains four bibliographic collections covering astronomy and astrophysics (including heliophysics and planetary science), physics, Earth science, and general science, containing more than 28 million records, including all arXiv e-prints. The ADS search engine also indexes the full-text for many publications in this collection and tracks citations. The system also provides access and links to a wealth of external resources, including electronic articles hosted by publishers and arXiv, data catalogs and a variety of data products hosted by the astronomy archives worldwide. The ADS can be accessed at:

  `http://ads.harvard.edu/`

- **arXiv.org:** A repository of full-text articles in physics, astronomy, mathematics, computer science, statistics, nonlinear sciences, quantitative finance, quantitative biology, electrical engineering and systems science, and economics. Papers are submitted by registered authors to arXiv, often as preprints in advance of submission to a journal for publication; includes postprints, working papers, and other relevant material. Established in 1991, the repository is interlinked with ADS and INSPIRE, among others. Readers can browse subject categories or search by author, title, abstract, date, and other fields. Receive daily update alerts for subfields by email or RSS.

  `https://arXiv.org`

- **INSPIRE Literature:** The literature collection, the flagship of the INSPIRE suite. Its almost 2 million literature records cover high energy physics, astrophysics, gravitation and cosmology, nuclear physics, quantum information science

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

and other related fields. Records offer a growing number of full-text articles attached and metadata including author affiliations, abstracts, references, experiments, keywords as well as links to arXiv, ADS, PDG, HEPData, publisher platforms and other servers. It provides fast metadata searches that can be easily refined using facets, plots extracted from full text, author disambiguation, author profile pages and citation analysis.

`https://inspirehep.net/literature`

- **MathSciNet:** This database of almost 4 million items provides reviews, abstracts and bibliographic information for much of the mathematical sciences literature. Over 125,000 new items, most of them classified according to the Mathematics Subject Classification, and more than 90,000 reviews of the current published literature are added each year. Author identification allows users to search for publications by author and citation data allows users to track the history and influence of research publications.

`https://www.ams.org/mathscinet`

OSTI.GOV: A portal to free, publicly available DOE-sponsored R&D results including technical reports, bibliographic citations, journal articles, conference papers, books, multimedia and data information. It consolidates OSTI's home page and the now-retired primary search tool SciTech Connect. It contains over 4 million records, including records for 2 million journal articles, 1 million of which have digital object identifiers (DOIs) linking to full-text articles on publishers' websites.

`https://www.osti.gov/`

5 Journals

- **CERN Journal List:** This list of journals and conference series publishing particle physics content provides information on Open Access, copyright policies and terms of use for CERN authors.

`https://scientific-info.cern/submit-and-publish/publish-open-access`

- **INSPIRE Journals:** A database of almost 4,000 journals relevant to HEP and related fields. Each entry displays the papers published in the journal that are included in the INSPIRE Literature database.

`https://inspirehep.net/journals`

- **SCOAP^3 Journals:** A list of journals currently financed by the SCOAP^3 consortium. All HEP publications in those journals are made freely available under Open Access conditions at no cost for the authors.

`https://scoap3.org/journals-2025-2027/`

6 Conference and seminars databases

- **INSPIRE Conferences:** The database of more than 31,000 past, present, and future conferences, schools, and meetings relevant to high-energy physics and related fields is searchable by title, acronym, series, date and location. Included are information about published proceedings, links to conference contributions in the INSPIRE HEP database, and links to the conference website when available. New conferences can be submitted from the entry page.

`https://inspirehep.net/conferences`

- **INSPIRE Seminars:** Created to support the surge of online seminars during the COVID-19 pandemic, this database already contains more than 3,400 seminars in high-energy physics and related fields. Seminars can be filtered by date, series and subject and exported to a calendar. Direct links to join the online seminar and external resources are included. All seminars are community-maintained and can be submitted from the entry page.

`https://inspirehep.net/seminars`

- **researchseminars.org:** A list of research seminars and conferences, organized by topic and seminars series or conference.

`https://researchseminars.org/`

7 Research institutions

- **INSPIRE Institutions:** INSPIRE Institutions contains over 12,000 institutes, laboratories, and universities, where research on particle physics and astrophysics is led. Every record includes, whenever possible, as detailed information, such as address, web links, experiments, and links to INSPIRE papers authored by people affiliated to that institution. One can search for a particular institution by name, acronym, and location.

`https://inspirehep.net/institutions`

- **Research Organization Registry (ROR):** The Research Organization Registry (ROR) is a global, community-led registry of open persistent identifiers for research organizations. It includes IDs and metadata for more than 120,000 organizations and counting. Registry updates are curated through a community process and released on a rolling basis.

`https://ror.org/`

8 People

- **INSPIRE Authors:** Searchable worldwide database of more than a hundred thousand active, departed, retired, and deceased people associated with particle physics and related fields. The affiliation history of these researchers, their e-mail addresses, ORCIDs, web pages, experiments they participated in, PhD advisor, information on their graduate students and links to their papers and seminars are provided, as well as a user interface to update this information.

`https://inspirehep.net/authors`

- **ORCID**: Registry providing persistent digital identifiers allowing to unambiguously identify researchers. Through integration in key research workflows such as manuscript and grant submission, it supports automated linkages between scientists and their professional activities ensuring that their work is recognized.

`https://orcid.org`

9 Experiments

- **INSPIRE Experiments:** Contains almost 4,000 past, present, and future experiments in particle physics. It lists and classifies both accelerator and non-accelerator experiments as well as theory collaborations. Includes official experiment name and number, location, and collaboration lists. Simple searches by participant, title, experiment number, institution, date approved, accelerator, or detector, return a description of the experiment, including a complete list of authors, title, overview of the experiment's goals and methods, and a link to the experiment's web page if available. Recently, it has expanded its scope to include particle accelerators besides experiments and to link them together.

`https://inspirehep.net/experiments`

- **Cosmic ray/Gamma ray/Neutrino and similar experiments:** This extensive collection of experiment websites is organized by focus of study and by location. Additional sections link to educational materials, organizations, and other useful resources. The site is maintained at the Max Planck Institute for Nuclear Physics, Heidelberg.

`https://www.mpi-hd.mpg.de/hfm/CosmicRay/CosmicRaySites.html`

- **Wikipedia particle experiments:** A list of particle experiments with Wikipedia pages.

`https://en.wikipedia.org/wiki/Category:Particle_experiments`

10 Jobs

- **AAS Job Register:** The American Astronomical Society publishes once a month graduate, postgraduate, faculty and other positions mainly in astronomy and astrophysics.

`https://jobregister.aas.org/`

- **Academic Jobs Online:** A full-service online recruiting site for academic institutions worldwide in all disciplines and areas.

`https://academicjobsonline.org/`

- **APS Careers:** A gateway for physicists, students, and physics enthusiasts to information about physics jobs and careers. It contains Physics job listings, career advice, upcoming workshops and meetings, and career and job-related resources provided by the American Physical Society.
  `https://www.aps.org/careers`
- **INSPIRE Jobs:** Lists academic and research jobs in high energy physics, nuclear physics, accelerator physics and astrophysics with the option to post a job or to receive email notices of new job listings. Several hundreds of jobs are listed all year round, with more activity during the application season.
  `https://inspirehep.net/jobs`
- **IOP Careers:** Career information and resources primarily aimed at university students are provided by the UK Institute of Physics.
  `https://www.iop.org/careers-physics/your-future-with-physics`
- **Physics Today Jobs:** Online recruitment advertising website for Physics Today magazine, published by the American Institute of Physics. Physics Today Jobs is the managing partner of the AIP Career Network, an online job board network for the physical science, engineering, and computing disciplines. Over 6,000 resumes are currently available, and nearly 5,000 jobs were posted in 2018.
  `https://jobs.physicstoday.org/`
- **Physicsworld Jobs:** A recruitment service run by IOP Publishing that connects employers from different industry sectors with jobseekers who have a background in physics and engineering.
  `https://www.physicsworldjobs.com/`

11 Software packages and repositories

A vast number of software tools are used for various aspects of high-energy physics research. Due to their number, their often specialized purpose and the quickly-changing nature of software, no attempt has been made to present them in this chapter. The accompanying online version contains an extensive categorized list of software.

12 Data repositories and preservation

Initiatives to preserve and disseminate data produced during different stages of research, from Monte Carlo events to machine-readable versions of tables in papers, have grown in recent years. Unfortunately, there currently exists no central resource aggregating all these data as is the case for the more established means of scholarly communication. Instead, there are a number of repositories targeting different types of data and research subjects. They are listed in the online version.

13 Particle physics education and outreach

Particle physics public engagement efforts are widespread, with laboratories, experiments, universities and individual researchers engaged in a range of efforts. The online version of this chapter provides links to resources for particle physicists wanting to become engaged in public education as well as resources that physicists can provide directly to students, teachers or lay people. There are classroom activities, interactive websites, films, and direct links to education offices at institutions and experiments. Many researchers also engage the public via a variety of social media platforms. Additionally, a selection of news sites relevant for experts and for the general public are provided.

14 Regional HEP efforts

The online version of this chapter provides links to summaries of regional HEP activities across Europe, Japan, the US, Africa, Latin America, and other regions that may be classified as developing or emerging. This list of summaries is not exhaustive and is based on the expert knowledge of the authors at the time of information gathering; the narrative was developed in July 2023 and will require periodic updates as the HEP landscape changes.

$m >$ 660 GeV, CL = 95% (2nd gen., single prod., B(μq)=1)
$m >$ 1520 GeV, CL = 95% (3rd gen., pair prod., B(τt)=1)
$m >$ 1280 GeV, CL = 95% (3rd gen., single prod., B(τb)=1)
(See the Particle Listings for assumptions on leptoquark quantum numbers and branching fractions.)

Diquarks

Mass $m >$ 7200 GeV, CL = 95% (E_6 diquark)

Axigluon

Mass $m >$ 6600 GeV, CL = 95%

Axions (A^0) and Other Very Light Bosons, Searches for

See the review on "Axions and other similar particles."

The best limit for the half-life of neutrinoless double beta decay with Majoron emission is $> 7.2\times10^{24}$ years (CL = 90%).

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as S = $\sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S $>$ 1, which often indicates that the measurements are inconsistent. When S $>$ 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] Theoretical value. A mass as large as a few MeV may not be precluded.
[b] This value does not include the AALTONEN 22 measurement by CDF. See the W mass section in the listings for details.
[c] ℓ indicates each type of lepton (e, μ, and τ), not sum over them.
[d] This represents the width for the decay of the W boson into a charged particle with momentum below detectability, p$<$ 200 MeV.
[e] The Z-boson mass listed here corresponds to a Breit-Wigner resonance parameter. It lies approximately 34 MeV above the real part of the position of the pole (in the energy-squared plane) in the Z-boson propagator.
[f] This partial width takes into account Z decays into $\nu\overline{\nu}$ and any other possible undetected modes.
[g] This ratio has not been corrected for the τ mass.
[h] Here $A \equiv 2g_Vg_A/(g_V^2+g_A^2)$.
[i] Here ℓ indicates e or μ.
[j] The value is for the sum of the charge states or particle/antiparticle states indicated.
[k] This value is updated using the product of (i) the $Z \rightarrow b\overline{b}$ fraction from this listing and (ii) the b-hadron fraction in an unbiased sample of weakly decaying b-hadrons produced in Z-decays provided by the Heavy Flavor Averaging Group (HFLAV, http://www.slac.stanford.edu/xorg/hflav/osc/PDG_2009/#FRACZ).
[l] See the Z Particle Listings for the γ energy range used in this measurement.
[n] For $m_{\gamma\gamma}$ = (60 $\pm$ 5) GeV.

$\text{Re}(d_\tau^w) < 0.50 \times 10^{-17}$ $e$cm, CL = 95%
$\text{Im}(d_\tau^w) < 1.1 \times 10^{-17}$ $e$cm, CL = 95%

Weak anomalous magnetic dipole moment

$\text{Re}(\alpha_\tau^w) < 1.1 \times 10^{-3}$, CL = 95%
$\text{Im}(\alpha_\tau^w) < 2.7 \times 10^{-3}$, CL = 95%
$\tau^\pm \to \pi^\pm K_S^0 \nu_\tau$ (RATE DIFFERENCE) / (RATE SUM) = (-0.36 ± 0.25)%

Decay parameters

See the τ Particle Listings for a note concerning τ-decay parameters.

$\rho(e \text{ or } \mu) = 0.745 \pm 0.008$
$\rho(e) = 0.747 \pm 0.010$
$\rho(\mu) = 0.763 \pm 0.020$
$\xi(e \text{ or } \mu) = 0.985 \pm 0.030$
$\xi(e) = 0.994 \pm 0.040$
$\xi(\mu) = 1.030 \pm 0.059$
$\eta(e \text{ or } \mu) = 0.013 \pm 0.020$
$\eta(\mu) = 0.094 \pm 0.073$
$(\delta\xi)(e \text{ or } \mu) = 0.746 \pm 0.021$
$(\delta\xi)(e) = 0.734 \pm 0.028$
$(\delta\xi)(\mu) = 0.778 \pm 0.037$
$\xi(\pi) = 0.993 \pm 0.022$
$\xi(\rho) = 0.994 \pm 0.008$
$\xi(a_1) = 1.001 \pm 0.027$
$\xi(\text{all hadronic modes}) = 0.995 \pm 0.007$
$\xi'(\mu) = 0.2 \pm 1.0$
$\overline{\eta}(\mu) = -1.3 \pm 1.7$
$(\xi\kappa)(e \text{ or } \mu) = 0.5 \pm 0.4$
$(\xi\kappa)(e) = -0.4 \pm 1.2$
$(\xi\kappa)(\mu) = 0.8 \pm 0.6$

τ^+ modes are charge conjugates of the modes below. "$h^\pm$" stands for $\pi^\pm$ or $K^\pm$. "ℓ" stands for e or μ. "Neutrals" stands for γ's and/or π^0's.

τ^- DECAY MODES		Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)
Modes with one charged particle				
particle$^- \geq 0$ neutrals $\geq 0K^0\nu_\tau$ ("1-prong")		(85.24 ± 0.06) %		–
particle$^- \geq 0$ neutrals $\geq 0K_L^0\nu_\tau$		(84.58 ± 0.06) %		–

Lepton Family number (*LF*), Lepton number (*L*), or Baryon number (*B*) violating modes

L means lepton number violation (*e.g.* $\tau^- \to e^+\pi^-\pi^-$). Following common usage, *LF* means lepton family violation *and not* lepton number violation (*e.g.* $\tau^- \to e^-\pi^+\pi^-$). *B* means baryon number violation.

$e^-\gamma$	*LF*	< 3.3	$\times 10^{-8}$	CL=90%	888
$e^-\gamma\gamma$	*LF*	< 2.5	$\times 10^{-4}$	CL=90%	888
$\mu^-\gamma$	*LF*	< 4.2	$\times 10^{-8}$	CL=90%	885

Heavy Charged Lepton Searches

$L^\pm$ – charged lepton

Mass $m >$ 100.8 GeV, CL = 95% [h] Decay to νW.

$L^\pm$ – stable charged heavy lepton

Mass $m >$ 102.6 GeV, CL = 95%

Neutrino Properties

See the note on "Neutrino properties listings" in the Particle Listings.

Mass $m <$ 0.45 eV, CL = 90% (tritium decay)
Mean life/mass, $\tau/m >$ 300 s/eV, CL = 90% (reactor)
Mean life/mass, $\tau/m > 7\times10^9$ s/eV (solar)
Mean life/mass, $\tau/m >$ 15.4 s/eV, CL = 90% (accelerator)
Magnetic moment $\mu < 0.064\times10^{-10}\ \mu_B$, CL = 90% (solar + radiochemical)

Number of Neutrino Types

Number $N = 2.996 \pm 0.007$ (Standard Model fits to LEP-SLC data)
Number $N = 2.92 \pm 0.05$ (S = 1.2) (Direct measurement of invisible Z width)

Neutrino Mixing

The following values are obtained through data analyses based on the 3-neutrino mixing scheme described in the review "Neutrino Masses, Mixing, and Oscillations."

$\sin^2(\theta_{12}) = 0.307 \pm 0.012$
$\Delta m^2_{21} = (7.60 \pm 0.17)\times10^{-5}$ eV^2
$\sin^2(\theta_{23}) = 0.523^{+0.031}_{-0.027}$ (S = 1.3) (Inverted order)
$\sin^2(\theta_{23}) = 0.533 \pm 0.018$ (Normal order)
$\Delta m^2_{32} = (-2.52 \pm 0.04)\times10^{-3}$ eV^2 (S = 1.3) (Inverted order)
$\Delta m^2_{32} = (2.445 \pm 0.023)\times10^{-3}$ eV^2 (Normal order)
$\sin^2(\theta_{13}) = (2.17 \pm 0.07)\times10^{-2}$ (S = 1.4)
δ, *CP* violating phase $= 1.21^{+0.19}_{-0.17}\ \pi$ rad (S = 1.2)
$\langle \Delta m^2_{21} - \Delta\overline{m}^2_{21} \rangle < 1.1\times10^{-4}$ eV^2, CL = 99.7%
$\langle \Delta m^2_{32} - \Delta\overline{m}^2_{32} \rangle = (-0.12 \pm 0.25)\times10^{-3}$ eV^2

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] This is the best limit for the mode $e^- \to \nu\gamma$.

[b] See the review on "Muon Decay Parameters" for definitions and details.

[c] P_μ is the longitudinal polarization of the muon from pion decay. For $V-A$ coupling, $P_\mu = 1$ and $\rho = \delta = 3/4$.

[d] This only includes events with energy of $e > 45$ MeV and energy of $\gamma > 40$ MeV. Since the $e^- \overline{\nu}_e \nu_\mu$ and $e^- \overline{\nu}_e \nu_\mu \gamma$ modes cannot be clearly separated, we regard the latter mode as a subset of the former.

[e] See the relevant Particle Listings for the energy limits used in this measurement.

[f] A test of additive vs. multiplicative lepton family number conservation.

[g] Basis mode for the τ.

[h] $L^\pm$ mass limit depends on decay assumptions; see the Full Listings.

QUARKS

The u-, d-, and s-quark masses are the $\overline{\rm MS}$ masses at the scale μ = 2 GeV. The c- and b-quark masses are the $\overline{\rm MS}$ masses renormalized at the $\overline{\rm MS}$ mass, i.e. $\overline{m} = \overline{m}(\mu = \overline{m})$. The t-quark mass is extracted from event kinematics (see the review "The Top Quark").

u

Free Quark Searches

All searches since 1977 have had negative results.

NOTES

[a] A discussion of the definition of the top quark mass in these measurements can be found in the review "The Top Quark."

[b] Based on published top mass measurements using data from Tevatron Run-I and Run-II and LHC at $\sqrt{s} = 7$ TeV. Including the most recent unpublished results from Tevatron Run-II, the Tevatron Electroweak Working Group reports a top mass of 173.2 ± 0.9 GeV. See the note "The Top Quark' in the Quark Particle Listings of this *Review*.

[c] This limit is for $\Gamma(t \to \gamma q)/\Gamma(t \to Wb)$.

[d] This limit is for $\Gamma(t \to Zq)/\Gamma(t \to Wb)$.

Meson Summary Table

STRANGE MESONS ($S = \pm 1, C = B = 0$)

$K^+ = u\bar{s}$, $K^0 = d\bar{s}$, $\overline{K}^0 = \bar{d}s$, $K^- = \bar{u}s$, similarly for K^*'s

$K^\pm$

$I(J^P) = \frac{1}{2}(0^-)$

Mass $m = 493.677 \pm 0.015$ MeV [o] (S = 2.8)
Mean life $\tau = (1.2380 \pm 0.0020) \times 10^{-8}$ s (S = 1.8)
$c\tau = 3.711$ m

CP violation parameters (Δ = rate difference/sum)

$\Delta(K^\pm \to \mu^\pm \nu_\mu) = (-0.27 \pm 0.21)\%$
$\Delta(K^\pm \to \pi^\pm \pi^0) = (0.4 \pm 0.6)\%$ [p]
$\Delta(K^\pm \to \pi^\pm e^+ e^-) = (-2.2 \pm 1.6) \times 10^{-2}$
$\Delta(K^\pm \to \pi^\pm \mu^+ \mu^-) = 0.010 \pm 0.023$
$\Delta(K^\pm \to \pi^\pm \pi^0 \gamma) = (0.0 \pm 1.2) \times 10^{-3}$
$\Delta(K^\pm \to \pi^\pm \pi^+ \pi^-) = (0.04 \pm 0.06)\%$
$\Delta(K^\pm \to \pi^\pm \pi^0 \pi^0) = (-0.02 \pm 0.28)\%$

T violation parameters

$K^+ \to \pi^0 \mu^+ \nu_\mu \quad P_T = (-1.7 \pm 2.5) \times 10^{-3}$
$K^+ \to \mu^+ \nu_\mu \gamma \quad P_T = (-0.6 \pm 1.9) \times 10^{-2}$
$K^+ \to \pi^0 \mu^+ \nu_\mu \quad \mathrm{Im}(\xi) = -0.006 \pm 0.008$

Slope parameter g [q]

(See Particle Listings for quadratic coefficients and alternative parametrization related to $\pi\pi$ scattering)

$K^\pm \to \pi^\pm \pi^+ \pi^- \; g = -0.21134 \pm 0.00017$
$(g_+ - g_-) / (g_+ + g_-) = (-1.5 \pm 2.2) \times 10^{-4}$
$K^\pm \to \pi^\pm \pi^0 \pi^0 \; g = 0.626 \pm 0.007$
$(g_+ - g_-) / (g_+ + g_-) = (1.8 \pm 1.8) \times 10^{-4}$

$K^\pm$ decay form factors [a,r]

Assuming μ-e universality
$\lambda_+(K^+_{\mu 3}) = \lambda_+(K^+_{e3}) = (2.959 \pm 0.025) \times 10^{-2}$
$\lambda_0(K^+_{\mu 3}) = (1.76 \pm 0.25) \times 10^{-2}$ (S = 2.7)

Not assuming μ-e universality
$\lambda_+(K^+_{e3}) = (2.956 \pm 0.025) \times 10^{-2}$
$\lambda_+(K^+_{\mu 3}) = (3.09 \pm 0.25) \times 10^{-2}$ (S = 1.5)
$\lambda_0(K^+_{\mu 3}) = (1.73 \pm 0.27) \times 10^{-2}$ (S = 2.6)

K_{e3} form factor quadratic fit
$\lambda'_+ (K^\pm_{e3})$ linear coeff. $= (2.59 \pm 0.04) \times 10^{-2}$
$\lambda''_+(K^\pm_{e3})$ quadratic coeff. $= (0.186 \pm 0.021) \times 10^{-2}$

λ'_+ (LINEAR $K^\pm_{\mu 3}$ FORM FACTOR FROM QUADRATIC FIT) $= (24 \pm 4) \times 10^{-3}$
λ''_+ (QUADRATIC $K^\pm_{\mu 3}$ FORM FACTOR) $= (1.8 \pm 1.5) \times 10^{-3}$
M_V (VECTOR POLE MASS FOR $K^\pm_{e3}$ DECAY) $= 890.3 \pm 2.8$ MeV
M_V (VECTOR POLE MASS FOR $K^\pm_{\mu 3}$ DECAY) $= 878 \pm 12$ MeV
M_S (SCALAR POLE MASS FOR $K^\pm_{\mu 3}$ DECAY) $= 1210 \pm 50$ MeV
Λ_+ (DISPERSIVE VECTOR FORM FACTOR IN $K^\pm_{e3}$ DECAY) $= (2.460 \pm 0.017) \times 10^{-2}$
Λ_+ (DISPERSIVE VECTOR FORM FACTOR IN $K^\pm_{\mu 3}$ DECAY) $= (25.4 \pm 0.9) \times 10^{-3}$
$\ln(C)$ (DISPERSIVE SCALAR FORM FACTOR in $K^\pm_{\mu 3}$ decays) $= (182 \pm 16) \times 10^{-3}$
$K^+_{e3} \quad |f_S/f_+| = (-0.08^{+0.34}_{-0.40}) \times 10^{-2}$
$K^+_{e3} \quad |f_T/f_+| = (-1.2^{+1.3}_{-1.1}) \times 10^{-2}$
$K^+_{\mu 3} \quad |f_S/f_+| = (0.2 \pm 0.6) \times 10^{-2}$
$K^+_{\mu 3} \quad |f_T/f_+| = (-0.1 \pm 0.7) \times 10^{-2}$
$K^+ \to e^+ \nu_e \gamma \quad |F_A + F_V| = 0.133 \pm 0.008$ (S = 1.3)
$K^+ \to \mu^+ \nu_\mu \gamma \quad |F_A + F_V| = 0.165 \pm 0.013$
$K^+ \to e^+ \nu_e \gamma \quad |F_A - F_V| < 0.49$, CL = 90%
$K^+ \to \mu^+ \nu_\mu \gamma \quad |F_A - F_V| = -0.153 \pm 0.033$ (S = 1.1)

Charge radius

$\langle r \rangle = 0.560 \pm 0.031$ fm

Forward-backward asymmetry

$A_{FB}(K^\pm_{\pi\mu\mu}) = \frac{\Gamma(\cos(\theta_{K\mu})>0) - \Gamma(\cos(\theta_{K\mu})<0)}{\Gamma(\cos(\theta_{K\mu})>0) + \Gamma(\cos(\theta_{K\mu})<0)} < 0.9 \times 10^{-2}$, CL = 90%

K^- modes are charge conjugates of the modes below.

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K^0_S modes, not as $\overline{K}^0$ modes. Nearly always it is a K^0_S that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\,\Gamma(K^0_S) = \Gamma(\overline{K}^0)$.

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K^0_S modes, not as $\overline{K}^0$ modes. Nearly always it is a K^0_S that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\,\Gamma(K^0_S) = \Gamma(\overline{K}^0)$.

BOTTOM MESONS ($B = \pm1$)

$B^+ = u\overline{b}$, $B^0 = d\overline{b}$, $\overline{B}^0 = \overline{d}b$, $B^- = \overline{u}b$, similarly for B^*'s

B-particle organization

Many measurements of B decays involve admixtures of B hadrons. Previously we arbitrarily included such admixtures in the $B^{\pm}$ section, but because of their importance we have created two new sections: "$B^{\pm}/B^0$ Admixture" for $\Upsilon(4S)$ results and "$B^{\pm}/B^0/B_s^0/b$-baryon Admixture" for results at higher energies. Most inclusive decay branching fractions and χ_b at high energy are found in the Admixture sections. B^0-$\overline{B}^0$ mixing data are found in the B^0 section, while B_s^0-$\overline{B}_s^0$ mixing data and B-$\overline{B}$ mixing data for a B^0/B_s^0 admixture are found in the B_s^0 section. CP-violation data are found in the $B^{\pm}$, B^0, and $B^{\pm}$ B^0 Admixture sections. b-baryons are found near the end of the Baryon section.

The organization of the B sections is now as follows, where bullets indicate particle sections and brackets indicate reviews.

- $B^{\pm}$
  mass, mean life, CP violation, branching fractions
- B^0
  mass, mean life, B^0-$\overline{B}^0$ mixing, CP violation, branching fractions
- $B^{\pm}/B^0$ Admixtures
  CP violation, branching fractions
- $B^{\pm}/B^0/B_s^0/b$-baryon Admixtures
  mean life, production fractions, branching fractions
- B^*, $B_1(5721)$, $B_2^*(5747)$, $B_J(5970)$
  mass, width
- B_s^0
  mass, mean life, B_s^0-$\overline{B}_s^0$ mixing, CP violation, branching fractions
- B_s^*, $B_{s1}(5830)^0$, $B_{s2}^*(5840)^0$
  mass, width
- $B_c^{\pm}$
  mass, mean life, branching fractions
- $B_c(2S)^{\pm}$
  mass

At the end of Baryon Listings:

- Λ_b
  mass, mean life, branching fractions
- $\Lambda_b(5912)^0$, $\Lambda_b(5920)^0$, $\Lambda_b(6070)^0$, $\Lambda_b(6146)^0$, $\Lambda_b(6152)^0$
  mass, width
- Σ_b
  mass
- Σ_b^*, $\Sigma_b(6097)^+$, $\Sigma_b(6097)^-$
  mass, width
- Ξ_b^0, Ξ_b^-
  mass, mean life, branching fractions
- $\Xi_b'(5935)^-$, $\Xi_b(5945)^0$, $\Xi_b(5955)^-$, $\Xi_b(6100)^-$, $\Xi_b(6227)^-$, $\Xi_b(6227)^0$, $\Xi_b(6327)^0$, $\Xi_b(6333)^0$

B^- modes are charge conjugates of the modes below. Modes which do not identify the charge state of the B are listed in the $B^\pm/B^0$ ADMIXTURE section.

The branching fractions listed below assume 50% $B^0\overline{B}^0$ and 50% B^+B^- production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^*, and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, *e.g.*, $B \to D^\pm X$, the values usually are multiplicities, not branching fractions. They can be greater than one.

B^0

$I(J^P) = \frac{1}{2}(0^-)$

I, *J*, *P* need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B^0} = 5279.72 \pm 0.08$ MeV
$m_{B^0} - m_{B^\pm} = 0.31 \pm 0.05$ MeV
Mean life $\tau_{B^0} = (1.5113 \pm 0.0027) \times 10^{-12}$ s
$c\tau = 453.1\ \mu$m
$\tau_{B^+}/\tau_{B^0} = 1.0832 \pm 0.0034$ (direct measurements)

B^0-$\overline{B}^0$ mixing parameters

χ_d (B^0-$\overline{B}^0$ mixing probability) $= 0.1849 \pm 0.0010$
$\Delta m_{B^0} = m_{B^0_H} - m_{B^0_L} = (0.5068 \pm 0.0019) \times 10^{12}\ \hbar\ \mathrm{s}^{-1}$
$= (3.336 \pm 0.013) \times 10^{-10}$ MeV
$x_d = \Delta m_{B^0}/\Gamma_{B^0} = 0.7659 \pm 0.0032$
Re(λ_{CP} / $|\lambda_{CP}|$) Re(z) $= 0.047 \pm 0.022$
$\Delta\Gamma$ Re(z) $= -0.007 \pm 0.004$ ps^{-1}
Re(z) $= (-4 \pm 4) \times 10^{-2}$ (S = 1.4)
Im(z) $= (-0.8 \pm 0.4) \times 10^{-2}$

CP violation parameters

Re(ϵ_{B^0})/(1+$|\epsilon_{B^0}|^2$) $= (-0.5 \pm 0.4) \times 10^{-3}$

$\overline{B}^0$ modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing. Modes which do not identify the charge state of the B are listed in the $B^\pm/B^0$ ADMIXTURE section.

The branching fractions listed below assume 50% $B^0\overline{B}^0$ and 50% B^+B^- production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^*, and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, *e.g.*, $B \to\ D^\pm X$, the values usually are multiplicities, not branching fractions. They can be greater than one.

$\overline{A}_{CP}(B \to K^*\gamma) = (A_{CP}(B^+ \to K^{*+}\gamma) + A_{CP}(B^0 \to K^{*0}\gamma))/2 = -0.009 \pm 0.011$

The branching fraction measurements are for an admixture of B mesons at the $\Upsilon(4S)$. The values quoted assume that $\text{B}(\Upsilon(4S) \to B\overline{B}) = 100\%$.

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ *anything*, the treatment of multiple D's in the final state must be defined. One possibility would be to count the number of events with one-or-more D's and divide by the total number of B's. Another possibility would be to count the total number of D's and divide by the total number of B's, which is the definition of average multiplicity. The two definitions are identical if only one D is allowed in the final state. Even though the "one-or-more" definition seems sensible, for practical reasons inclusive branching fractions are almost always measured using the multiplicity definition. For heavy final state particles, authors call their results inclusive branching fractions while for light particles some authors call their results multiplicities. In the B sections, we list all results as inclusive branching fractions, adopting a multiplicity definition. This means that inclusive branching fractions can exceed 100% and that inclusive partial widths can exceed total widths, just as inclusive cross sections can exceed total cross section.

$\overline{B}$ modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing.

$B^{\pm}/B^0/B_s^0/b$-baryon ADMIXTURE

These measurements are for an admixture of bottom particles at high energy (LHC, LEP, Tevatron, S$p\overline{p}$S).

Mean life $\tau = (1.5673 \pm 0.0029) \times 10^{-12}$ s

Mean life $\tau = (1.72 \pm 0.10) \times 10^{-12}$ s Charged b-hadron admixture

Mean life $\tau = (1.58 \pm 0.14) \times 10^{-12}$ s Neutral b-hadron admixture

$\tau_{\text{charged } b\text{-hadron}}/\tau_{\text{neutral } b\text{-hadron}} = 1.09 \pm 0.13$

$|\Delta\tau_b|/\tau_{b,\overline{b}} = -0.001 \pm 0.014$

The branching fraction measurements are for an admixture of B mesons and baryons at energies above the $\Upsilon(4S)$. Only the highest energy results (LHC, LEP, Tevatron, S$p\overline{p}$S) are used in the branching fraction averages. In the following, the production fractions are provided separately at three different colliders (LEP, $p\overline{p}$ Tevatron, and pp LHC) and are used for the subsequent measurements accordingly.

For inclusive branching fractions, *e.g.*, $B \to D^{\pm}$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

The modes below are listed for a $\overline{b}$ initial state. b modes are their charge conjugates. Reactions indicate the weak decay vertex and do not include mixing.

$\overline{b}$ DECAY MODES	Fraction (Γ_j/Γ)	Scale factor/ Confidence level	p (MeV/c)

PRODUCTION FRACTIONS

The production fractions for weakly decaying b-hadrons at high energy have been calculated from the best values of mean lives, mixing parameters, and branching fractions in this edition by the Heavy Flavor Averaging Group (HFLAV) as described in the note "B^0-$\overline{B}^0$ Mixing" in the B^0 Particle Listings. We no longer provide world averages of the b-hadron production fractions, where results from LEP, Tevatron and LHC are averaged together; indeed the available data (from CDF and LHCb) shows that the fractions depend on the kinematics (in particular the p_T) of the produced b hadron. Hence, we would like to list the fractions at LEP Z decays, at $p\overline{p}$ collision at the Tevatron, and at pp collision at LHC, separately, when they are available.

Values assume:

$\mathrm{B}(\overline{b} \to B^+) = \mathrm{B}(\overline{b} \to B^0)$

$\mathrm{B}(\overline{b} \to B^+) + \mathrm{B}(\overline{b} \to B^0) + \mathrm{B}(\overline{b} \to B_s^0) + \mathrm{B}(b \to b\text{-baryon}) = 100\%$.

The notation for production fractions varies in the literature (f_d, d_{B^0}, $f(b \to \overline{B}^0)$, $\mathrm{Br}(b \to \overline{B}^0)$). We use our own branching fraction notation here, $\mathrm{B}(\overline{b} \to B^0 \text{ at } Z)$ at LEP, $\mathrm{B}(\overline{b} \to B^0 \text{ at } p\overline{p})$ at Tevatron, $\mathrm{B}(\overline{b} \to B^0 \text{ at } pp)$ at LHC. The $\mathrm{B}(\overline{b} \to B_c^+)$ is a placeholder for the future measurements, and is negligible in the $\overline{b}$-production fractions.

Note these production fractions are b-hadronization fractions, not the conventional branching fractions of b-quark to a B-hadron, which may have considerable dependence on the initial and final state kinematic and production environment.

Production fractions at Z

The correlation coefficients between the reported production fractions are:

$cor(B_s^0 \text{ at } Z, b\text{-baryon at } Z) = 0.064$

$cor(B_s^0 \text{ at } Z, B^{\pm}{=}B^0 \text{ at } Z) = -0.633$

$cor(b\text{-baryon at } Z, B^{\pm}{=}B^0 \text{ at } Z) = -0.813$.

B^+ at Z	(40.8 ± 0.7) %		–
B^0 at Z	(40.8 ± 0.7) %		–
B_s^0 at Z	(10.0 ± 0.8) %		–
b-baryon at Z	(8.4 ± 1.1) %		–

Production fractions at $p\overline{p}$

The correlation coefficients between the reported production fractions are:

$cor(B_s^0 \text{ at } p\overline{p}, b\text{-baryon at } p\overline{p}) = -0.429$

$cor(B_s^0 \text{ at } p\overline{p}, B^{\pm}{=}B^0 \text{ at } p\overline{p}) = +0.159$

$cor(b\text{-baryon at } p\overline{p}, B^{\pm}{=}B^0 \text{ at } p\overline{p}) = -0.960$.

as obtained with the Tevatron average of time-integrated mixing parameter $\overline{\chi} = 0.147 \pm 0.011$.

B^+ at $p\overline{p}$	(34.4 ± 2.1) %		–
B^0 at $p\overline{p}$	(34.4 ± 2.1) %		–
B_s^0 at $p\overline{p}$	(11.5 ± 1.3) %		–
b-baryon at $p\overline{p}$	(19.8 ± 4.6) %		–

Production fractions at pp

B^+ at pp	(36.0 ± 0.5) %		–
B^0 at pp	(36.0 ± 0.5) %		–
B_s^0 at pp	(9.04 ± 0.25) %		–
b-baryon at pp	(18.7 ± 1.1) %		–
B_c^+ at pp	(2.7 ± 0.5) $\times 10^{-3}$		–

$\mathrm{Im}(\xi) = 0.004 \pm 0.011$

These branching fractions all scale with $B(\overline{b} \to B_s^0)$.

The branching fraction $B(B_s^0 \to D_s^- \ell^+ \nu_\ell \text{anything})$ is not a pure measurement since the measured product branching fraction $B(\overline{b} \to B_s^0) \times B(B_s^0 \to D_s^- \ell^+ \nu_\ell \text{anything})$ was used to determine $B(\overline{b} \to B_s^0)$, as described in the note on "B^0-$\overline{B}^0$ Mixing"

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

B_s^0 DECAY MODES		Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)

B_s^*

$I(J^P) = 0(1^-)$

I, J, P need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m = 5415.4 \pm 1.4$ MeV (S = 2.6)

$m_{B_s^*} - m_{B_s} = 48.5 \pm 1.4$ MeV (S = 2.6)

B_s^* DECAY MODES	Fraction (Γ_i/Γ)	p (MeV/c)
$B_s\gamma$	seen	48

$B_{s1}(5830)^0$

$I(J^P) = 0(1^+)$

I, J, P need confirmation.

Mass $m = 5828.73 \pm 0.20$ MeV

$m_{B_{s1}^0} - m_{B^{*+}} = 503.98 \pm 0.17$ MeV

Full width $\Gamma = 0.5 \pm 0.4$ MeV

$B_{s1}(5830)^0$ DECAY MODES	Fraction (Γ_i/Γ)	p (MeV/c)
$B^{*+}K^-$	seen	97

$B_{s2}^*(5840)^0$

$I(J^P) = 0(2^+)$

I, J, P need confirmation.

Mass $m = 5839.88 \pm 0.12$ MeV

$m_{B_{s2}^{*0}} - m_{B^+} = 560.48 \pm 0.12$ MeV

Full width $\Gamma = 1.49 \pm 0.27$ MeV

Branching fractions are given relative to the one **DEFINED AS 1**.

$B_{s2}^*(5840)^0$ DECAY MODES	Fraction (Γ_i/Γ)	p (MeV/c)
B^+K^-	**DEFINED AS 1**	252
$B^{*+}K^-$	0.093 ± 0.018	141
$B^0 K_S^0$	0.43 ± 0.11	245
$B^{*0}K_S^0$	0.04 ± 0.04	–

BOTTOM, CHARMED MESONS ($B = C = \pm 1$)

$B_c^+ = c\overline{b}$, $B_c^- = \overline{c}b$, similarly for B_c^*'s

B_c^+

$I(J^P) = 0(0^-)$

I, J, P need confirmation.

Quantum numbers shown are quark-model predictions.

Mass $m = 6274.47 \pm 0.32$ MeV

$m_{B_c^+} - m_{B_s^0} = 907.8 \pm 0.5$ MeV

Mean life $\tau = (0.510 \pm 0.009) \times 10^{-12}$ s

The following quantities are not pure branching ratios; rather the fractions $\Gamma_i/\Gamma \times B(\overline{b} \to B_c)$. B_c^- modes are charge conjugates of the modes below.

Due to the complexity of the $c\overline{c}$ threshold region, in this listing, "seen" ("not seen") means that a cross section for the mode in question has been measured at effective $\sqrt{s}$ near this particle's central mass value, more (less) than 2σ above zero, without regard to any peaking behavior in $\sqrt{s}$ or absence thereof. See mode listing(s) for details and references.

$I^G(J^{PC}) = 0^-(1^{--})$

Mass $m = 4415 \pm 5$ MeV
Full width $\Gamma = 110 \pm 13$ MeV (S = 1.6)

Due to the complexity of the $c\overline{c}$ threshold region, in this listing, "seen" ("not seen") means that a cross section for the mode in question has been measured at effective $\sqrt{s}$ near this particle's central mass value, more (less) than 2σ above zero, without regard to any peaking behavior in $\sqrt{s}$ or absence thereof. See mode listing(s) for details and references.

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] See the review on "Form Factors for Radiative Pion and Kaon Decays" for definitions and details.

[b] Measurements of $\Gamma(e^+\nu_e)/\Gamma(\mu^+\nu_\mu)$ always include decays with γ's, and measurements of $\Gamma(e^+\nu_e\gamma)$ and $\Gamma(\mu^+\nu_\mu\gamma)$ never include low-energy γ's. Therefore, since no clean separation is possible, we consider the modes with γ's to be subreactions of the modes without them, and let $[\Gamma(e^+\nu_e) + \Gamma(\mu^+\nu_\mu)]/\Gamma_{\rm total} = 100\%$.

[c] See the $\pi^\pm$ Particle Listings for the energy limits used in this measurement; low-energy γ's are not included.

[d] Derived from an analysis of neutrino-oscillation experiments.

[e] Forbidden by angular momentum conservation.

[f] C parity forbids this to occur as a single-photon process.

[g] As measured in $e^+e^- \to \rho^0$.

[h] As measured in $e^+e^- \to \pi^+\pi^-\pi^0$ and τ decays.

[i] The $\omega\rho$ interference is then due to $\omega\rho$ mixing only, and is expected to be small. If $e\mu$ universality holds, $\Gamma(\rho^0 \to \mu^+\mu^-) = \Gamma(\rho^0 \to e^+e^-) \times 0.99785$.

[j] Our estimate. See the Particle Listings for details.

[k] See the "Note on $a_1(1260)$" in the $a_1(1260)$ Particle Listings in PDG 06, Journal of Physics **G33** 1 (2006).

[l] See also the $\omega(1650)$.

[n] See also the $\omega(1420)$.

[o] See the note in the $K^\pm$ Particle Listings.

[p] Neglecting photon channels. See, *e.g.*, A. Pais and S.B. Treiman, Phys. Rev. **D12**, 2744 (1975).

[q] The definition of the slope parameters of the $K \to 3\pi$ Dalitz plot is as follows (see also "Note on Dalitz Plot Parameters for $K \to 3\pi$ Decays" in the $K^\pm$ Particle Listings):

$$|M|^2 = 1 + g(s_3 - s_0)/m^2_{\pi^+} + \cdots .$$

[r] For more details and definitions of parameters see the Particle Listings.

[s] See the $K^\pm$ Particle Listings for the energy limits used in this measurement.

[t] Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ's.

[u] Structure-dependent part.

[v] Direct-emission branching fraction.

[x] Violates angular-momentum conservation.

[y] Derived from measured values of ϕ_{+-}, ϕ_{00}, $|\eta|$, $|m_{K^0_L} - m_{K^0_S}|$, and $\tau_{K^0_S}$, as described in the introduction to "Tests of Conservation Laws."

[z] The CP-violation parameters are defined as follows (see also "Note on CP Violation in $K_S \to 3\pi$" and "Note on CP Violation in K^0_L Decay" in the Particle Listings):

$$\eta_{+-} = |\eta_{+-}|e^{i\phi_{+-}} = \frac{A(K^0_L \to \pi^+\pi^-)}{A(K^0_S \to \pi^+\pi^-)} = \epsilon + \epsilon'$$

$$\eta_{00} = |\eta_{00}|e^{i\phi_{00}} = \frac{A(K^0_L \to \pi^0\pi^0)}{A(K^0_S \to \pi^0\pi^0)} = \epsilon - 2\epsilon'$$

$$\delta = \frac{\Gamma(K^0_L \to \pi^-\ell^+\nu) - \Gamma(K^0_L \to \pi^+\ell^-\nu)}{\Gamma(K^0_L \to \pi^-\ell^+\nu) + \Gamma(K^0_L \to \pi^+\ell^-\nu)} ,$$

$$\mathrm{Im}(\eta_{+-0})^2 = \frac{\Gamma(K^0_S \to \pi^+\pi^-\pi^0)^{CP\ \mathrm{viol.}}}{\Gamma(K^0_L \to \pi^+\pi^-\pi^0)} ,$$

$$\mathrm{Im}(\eta_{000})^2 = \frac{\Gamma(K^0_S \to \pi^0\pi^0\pi^0)}{\Gamma(K^0_L \to \pi^0\pi^0\pi^0)} .$$

where for the last two relations CPT is assumed valid, *i.e.*, $\mathrm{Re}(\eta_{+-0}) \simeq 0$ and $\mathrm{Re}(\eta_{000}) \simeq 0$.

[aa] See the K^0_S Particle Listings for the energy limits used in this measurement.

[bb] The value is for the sum of the charge states or particle/antiparticle states indicated.

[cc] $\mathrm{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.

[dd] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K^0_L \to \pi^+\pi^-\gamma$(DE).

[ee] See the K^0_L Particle Listings for the energy limits used in this measurement.

[ff] Allowed by higher-order electroweak interactions.

[gg] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

[hh] See our minireview under the $K_2(1770)$ in the 2004 edition of this *Review*.

[ii] This result applies to $Z^0 \to c\overline{c}$ decays only. Here ℓ^+ is an average (not a sum) of e^+ and μ^+ decays.

[jj] See the Particle Listings for the (complicated) definition of this quantity.

[kk] The branching fraction for this mode may differ from the sum of the submodes that contribute to it, due to interference effects. See the relevant papers in the Particle Listings.

[ll] These subfractions of the $K^-2\pi^+$ mode are uncertain: see the Particle Listings.

[nn] See the listings under "$D \to K\pi\pi\pi$ partial wave analyses" and our 2008 Review (Physics Letters **B667** 1 (2008)) for measurements of submodes of this mode.

[oo] The unseen decay modes of the resonances are included.

[pp] This is *not* a test for the ΔC=1 weak neutral current, but leads to the $\pi^+\ell^+\ell^-$ final state.

[qq] This mode is not a useful test for a ΔC=1 weak neutral current because both quarks must change flavor in this decay.

[rr] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.

[ss] This value is obtained by subtracting the branching fractions for 2-, 4- and 6-prongs from unity.

[*tt*] This is the sum of our $K^-2\pi^+\pi^-$, $K^-2\pi^+\pi^-\pi^0$, $\overline{K}^0 2\pi^+2\pi^-$, $K^+2K^-\pi^+$, $2\pi^+2\pi^-$, $2\pi^+2\pi^-\pi^0$, $K^+K^-\pi^+\pi^-$, and $K^+K^-\pi^+\pi^-\pi^0$, branching fractions.

[*uu*] This is the sum of our $K^-3\pi^+2\pi^-$ and $3\pi^+3\pi^-$ branching fractions.

[*vv*] The branching fractions for the $K^-e^+\nu_e$, $K^*(892)^-e^+\nu_e$, $\pi^-e^+\nu_e$, and $\rho^-e^+\nu_e$ modes add up to 6.17 ± 0.17 %.

[*xx*] This is a doubly Cabibbo-suppressed mode.

[*yy*] Submodes of the $D^0 \to K^0_S\pi^+\pi^-\pi^0$ mode with a K^* and/or ρ were studied by COFFMAN 92B, but with only 140 events. With nothing new for 18 years, we refer to our 2008 edition, Physics Letters **B667** 1 (2008), for those results.

[*zz*] This branching fraction includes all the decay modes of the resonance in the final state.

[*aaa*] This limit assumes the average of $B(D^0 \to K^-e^+\nu_e)$ and $B(D^0 \to K^-\mu^+\nu_\mu)$ for the $B(D^0 \to K^-\ell^+\nu_\ell)$ value.

[*bbb*] Here γ_D stands for massless dark photon.

[*ccc*] This is the purely e^+ semileptonic branching fraction: the e^+ fraction from τ^+ decays has been subtracted off. The sum of our (non-τ) e^+ exclusive fractions — an $e^+\nu_e$ with an η, η', ϕ, K^0, or K^{*0} — is 5.99 ± 0.31 %.

[*ddd*] This fraction includes η from η' decays.

[*eee*] The sum of our exclusive η' fractions — $\eta' e^+\nu_e$, $\eta'\mu^+\nu_\mu$, $\eta'\pi^+$, $\eta'\rho^+$, and $\eta' K^+$ — is 11.8 ± 1.6%.

[*fff*] This branching fraction includes all the decay modes of the final-state resonance.

[*ggg*] A test for $u\overline{u}$ or $d\overline{d}$ content in the D_s^+. Neither Cabibbo-favored nor Cabibbo-suppressed decays can contribute, and $\omega - \phi$ mixing is an unlikely explanation for any fraction above about 2×10^{-4}.

[*hhh*] We decouple the $D_s^+ \to \phi\pi^+$ branching fraction obtained from mass projections (and used to get some of the other branching fractions) from the $D_s^+ \to \phi\pi^+$, $\phi \to K^+K^-$ branching fraction obtained from the Dalitz-plot analysis of $D_s^+ \to K^+K^-\pi^+$. That is, the ratio of these two branching fractions is not exactly the $\phi \to K^+K^-$ branching fraction 0.491.

[*iii*] This is the average of a model-independent and a K-matrix parametrization of the $\pi^+\pi^-$ S-wave and is a sum over several f_0 mesons.

[*jjj*] An ℓ indicates an e or a μ mode, not a sum over these modes.

[*kkk*] An $CP(\pm1)$ indicates the CP=+1 and CP=−1 eigenstates of the D^0-$\overline{D}^0$ system.

[*lll*] D denotes D^0 or $\overline{D}^0$.

[*nnn*] D^0_{CP+} decays into $D^0\pi^0$ with the D^0 reconstructed in CP-even eigenstates K^+K^- and $\pi^+\pi^-$.

[*ooo*] $\overline{D}^{**}$ represents an excited state with mass $2.2 < M < 2.8$ GeV/c^2.

[*ppp*] $\chi_{c1}(3872)^+$ is a hypothetical charged partner of the $\chi_{c1}(3872)$.

[*qqq*] $\Theta(1710)^{++}$ is a possible narrow pentaquark state and $G(2220)$ is a possible glueball resonance.

[*rrr*] $(\overline{\Lambda}_c^- p)_s$ denotes a low-mass enhancement near 3.35 GeV/c^2.

[*sss*] Stands for the possible candidates of $K^*(1410)$, $K_0^*(1430)$ and $K_2^*(1430)$.

[*ttt*] B^0 and B_s^0 contributions not separated. Limit is on weighted average of the two decay rates.

[*uuu*] This decay refers to the coherent sum of resonant and nonresonant $J^P = 0^+$ $K\pi$ components with $1.60 < m_{K\pi} < 2.15$ GeV/c^2.

[*vvv*] $X(214)$ is a hypothetical particle of mass 214 MeV/c^2 reported by the HyperCP experiment, Physical Review Letters **94** 021801 (2005)

[*xxx*] $\Theta(1540)^+$ denotes a possible narrow pentaquark state.

[*yyy*] ψ_{DS} is a GeV-scale dark sector antibaryon (mass range 1–4 GeV/c^2).

[*zzz*] Here S and P are the hypothetical scalar and pseudoscalar particles with masses of 2.5 GeV/c^2 and 214.3 MeV/c^2, respectively.

[*aaaa*] These values are model dependent.

[*bbaa*] Here "anything" means at least one particle observed.

[*ccaa*] This is a $B(B^0 \to D^{*-}\ell^+\nu_\ell)$ value.

[*ddaa*] D^{**} stands for the sum of the $D(1\,^1P_1)$, $D(1\,^3P_0)$, $D(1\,^3P_1)$, $D(1\,^3P_2)$, $D(2\,^1S_0)$, and $D(2\,^1S_1)$ resonances.

[*eeaa*] $D^{(*)}\overline{D}^{(*)}$ stands for the sum of $D^*\overline{D}^*$, $D^*\overline{D}$, $D\overline{D}^*$, and $D\overline{D}$.

[*ffaa*] $X(3915)$ denotes a near-threshold enhancement in the $\omega J/\psi$ mass spectrum.

[*ggaa*] Inclusive branching fractions have a multiplicity definition and can be greater than 100%.

[*hhaa*] D_j represents an unresolved mixture of pseudoscalar and tensor D^{**} (P-wave) states.

[*iiaa*] Not a pure measurement. See note at head of B_s^0 Decay Modes.

[*jjaa*] For $E_\gamma > 100$ MeV.

[*kkaa*] $\Theta(1540)$ is a hypothetical pentaquark state of 1.54 GeV/c^2 mass and a width of less than 25 MeV/c^2.

[*llaa*] Includes $p\overline{p}\pi^+\pi^-\gamma$ and excludes $p\overline{p}\eta$, $p\overline{p}\omega$, $p\overline{p}\eta'$.

[*nnaa*] For a narrow state A with mass less than 960 MeV.

[*ooaa*] For a narrow scalar or pseudoscalar A^0 with mass 0.21–3.0 GeV.

[*ppaa*] For a dark photon U with mass between 100 and 2100 MeV.

[*qqaa*] For a narrow resonance in the range $2.2 < M(X) < 2.8$ GeV.

[*rraa*] J^{PC} known by production in e^+e^- via single photon annihilation. I^G is not known; interpretation of this state as a single resonance is unclear because of the expectation of substantial threshold effects in this energy region.

[*ssaa*] $2m_\tau < M(\tau^+\tau^-) < 9.2$ GeV

[*ttaa*] 2 GeV $< m_{K^+K^-} <$ 3 GeV

[*uuaa*] $X\overline{X}$ = vectors with $m < 3.1$ GeV

[*vvaa*] X and $\overline{X}$ = zero spin with $m < 4.5$ GeV

[*xxaa*] 1.5 GeV $< m_X <$ 5.0 GeV

[*yyaa*] 201 MeV $< M(\mu^+\mu^-) <$ 3565 MeV

[*zzaa*] 0.5 GeV $< m_X <$ 9.0 GeV, where m_X is the invariant mass of the hadronic final state.

[*aabb*] 1.5 GeV $< m_X <$ 5.0 GeV

[*bbbb*] 1.5 GeV $< m_X <$ 5.0 GeV

[*ccbb*] For $m_{\tau^+\tau^-}$ in the ranges 4.03–9.52 and 9.61–10.10 GeV.

See also the table of suggested $q\overline{q}$ quark-model assignments in the Quark Model section.

Baryon Summary Table

This short table gives the name, the quantum numbers (where known), and the status of baryons in the Review. Only the baryons with 3- or 4-star status are included in the Baryon Summary Table. Due to insufficient data or uncertain interpretation, the other entries in the table are not established baryons. The names with masses are of baryons that decay strongly. The spin-parity J^P (when known) is given with each particle. For the strongly decaying particles, the J^P values are considered to be part of the names.

**** Existence is certain, and properties are at least fairly well explored.

*** Existence ranges from very likely to certain, but further confirmation is desirable and/or quantum numbers, branching fractions, etc. are not well determined.

** Evidence of existence is only fair.

* Evidence of existence is poor.

Mean life $\tau > 9 \times 10^{29}$ years, CL = 90% ($p \to$ invisible mode)

See the "Note on Nucleon Decay" in our 1994 edition (Phys. Rev. **D50**, 1173) for a short review.

The "partial mean life" limits tabulated here are the limits on τ/B_i, where τ is the total mean life and B_i is the branching fraction for the mode in question. For N decays, p and n indicate proton and neutron partial lifetimes.

p DECAY MODES	Partial mean life (10^{30} years)	Confidence level	p (MeV/c)
Antilepton + meson			
$N \to e^+\pi$	> 5300 (n), > 24000 (p)	90%	459

Baryon Summary Table

Branching fractions marked with a footnote, e.g. [a], have been corrected for decay modes not observed in the experiments. For example, the sub-mode fraction $\Lambda_c^+ \to p\overline{K}^*(892)^0$ seen in $\Lambda_c^+ \to pK^-\pi^+$ has been multiplied up to include $\overline{K}^*(892)^0 \to \overline{K}^0\pi^0$ decays.

$\Lambda_c(2595)^+$ $I(J^P) = 0(\frac{1}{2}^-)$

The spin-parity follows from the fact that $\Sigma_c(2455)\pi$ decays, with little available phase space, are dominant. This assumes that $J^P = 1/2^+$ for the $\Sigma_c(2455)$.

Mass $m = 2592.25 \pm 0.28$ MeV
$m - m_{\Lambda_c^+} = 305.79 \pm 0.24$ MeV
Full width $\Gamma = 2.6 \pm 0.6$ MeV

$\Lambda_c^+\pi\pi$ and its submode $\Sigma_c(2455)\pi$ — the latter just barely — are the only strong decays allowed for an excited Λ_c^+ having this mass; and the submode seems to dominate.

$\Lambda_c(2595)^+$ DECAY MODES	Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)
$\Lambda_c^+\pi^+\pi^-$	[s] (40±14) %		117
$\Sigma_c(2455)^{++}\pi^-$	(15± 6) %		3
$\Sigma_c(2455)^0\pi^+$	(15± 6) %		3

Ξ_c^+

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

J^P has not been measured; $\frac{1}{2}^+$ is the quark-model prediction.

Mass $m = 2467.79 \pm 0.15$ MeV (S = 1.1)
Mean life $\tau = (453 \pm 5) \times 10^{-15}$ s
$c\tau = 135.8\ \mu$m

Branching fractions marked with a footnote, e.g. [a], have been corrected for decay modes not observed in the experiments. For example, the sub-mode fraction $\Xi_c^+ \to \Sigma^+ \overline{K}^*(892)^0$ seen in $\Xi_c^+ \to \Sigma^+ K^- \pi^+$ has been multiplied up to include $\overline{K}^*(892)^0 \to \overline{K}^0 \pi^0$ decays.

$A_{FB}^{\ell h}$ in $\Lambda_b \to \Lambda \mu^+ \mu^- = 0.25 \pm 0.04$

The branching fractions B(b-baryon $\to \Lambda \ell^- \overline{\nu}_\ell$anything) and B($\Lambda_b^0 \to \Lambda_c^+ \ell^- \overline{\nu}_\ell$anything) are not pure measurements because the underlying measured products of these with B($b \to b$-baryon) were used to determine B($b \to b$-baryon), as described in the note "Production and Decay of b-Flavored Hadrons."

For inclusive branching fractions, *e.g.*, $\Lambda_b \to \overline{\Lambda}_c$anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

b-baryon ADMIXTURE (Λ_b, Ξ_b, Ω_b)

These branching fractions are actually an average over weakly decaying b-baryons weighted by their production rates at the LHC, LEP, and Tevatron, branching ratios, and detection efficiencies. They scale with the b-baryon production fraction B($b \to$ b-baryon).

The branching fractions B(b-baryon $\to \Lambda \ell^- \overline{\nu}_\ell$ anything) and B($\Lambda_b^0 \to \Lambda_c^+ \ell^- \overline{\nu}_\ell$ anything) are not pure measurements because the underlying measured products of these with B($b \to$ b-baryon) were used to determine B($b \to$ b-baryon), as described in the note "Production and Decay of b-Flavored Hadrons."

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

b-baryon ADMIXTURE DECAY MODES (Λ_b,Ξ_b,Ω_b)	Fraction (Γ_i/Γ)	Scale factor	p (MeV/c)
$p\mu^-\overline{\nu}$ anything	($5.8^{+\ 2.3}_{-\ 2.0}$) %		–
$p\ell\overline{\nu}_\ell$ anything	(5.6± 1.2) %		–
p anything	(70 ±22) %		–
$\Lambda\ell^-\overline{\nu}_\ell$ anything	(3.8± 0.6) %		–
$\Lambda\ell^+\nu_\ell$ anything	(3.2± 0.8) %		–
Λ anything	(39 ± 7) %		–
$\Xi^-\ell^-\overline{\nu}_\ell$ anything	(4.6± 1.4) $\times 10^{-3}$	1.2	–

NOTES

This Summary Table only includes established baryons. The Particle Listings include evidence for other baryons. The masses, widths, and branching fractions for the resonances in this Table are Breit-Wigner parameters, but pole positions are also given for most of the N and Δ resonances.

For most of the resonances, the parameters come from various partial-wave analyses of more or less the same sets of data, and it is not appropriate to treat the results of the analyses as independent or to average them together. Furthermore, the systematic errors on the results are not well understood. Thus, we usually only give ranges for the parameters. We then also give a best guess for the mass (as part of the name of the resonance) and for the width. The *Note on N and Δ Resonances* and the *Note on Λ and Σ Resonances* in the Particle Listings review the partial-wave analyses.

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame. For any resonance, the *nominal* mass is used in calculating p. A dagger ("†") in this column indicates that the mode is forbidden when the nominal masses of resonances are used, but is in fact allowed due to the nonzero widths of the resonances.

[a] The masses of the p and n are most precisely known in u (unified atomic mass units). The conversion factor to MeV, 1 u = 931.494 103 72(29) MeV, is less well known than are the masses in u.

[b] The $|m_p - m_{\overline{p}}|/m_p$ and $|q_p + q_{\overline{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\overline{p}}/m_{\overline{p}}|/(q_p/m_p)$.

[c] The limit is from neutrality-of-matter experiments; it assumes $q_n = q_p + q_e$. See also the charge of the neutron.

[d] The μp and ep values for the charge radius are much too different to average them. The disagreement is not yet understood.

[e] There is a lot of disagreement about the value of the proton magnetic charge radius. See the Listings.

[f] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.

[g] Lee and Yang in 1956 proposed the existence of a mirror world in an attempt to restore global parity symmetry—thus a search for oscillations between the two worlds. Oscillations between the worlds would be maximal when the magnetic fields B and B' were equal. The limit for any B' in the range 0 to 12.5 μT is >12 s (95% CL).

[h] The parameters g_A, g_V, and g_{WM} for semileptonic modes are defined by $\overline{B}_f[\gamma_\lambda(g_V + g_A\gamma_5) + i(g_{WM}/m_{B_i})\,\sigma_{\lambda\nu}\,q^\nu]B_i$, and ϕ_{AV} is defined by $g_A/g_V = |g_A/g_V|e^{i\phi_{AV}}$. See the "Note on Baryon Decay Parameters" in the neutron Particle Listings.

[i] Time-reversal invariance requires this to be 0° or 180°.

[j] This coefficient is zero if time invariance is not violated.

[k] This limit is for γ energies between 0.4 and 782 keV.

[l] The decay parameters γ and Δ are calculated from α and ϕ using

$$\gamma = \sqrt{1-\alpha^2}\,\cos\phi\,, \qquad \tan\Delta = -\tfrac{1}{\alpha}\,\sqrt{1-\alpha^2}\,\sin\phi\,.$$

See the "Note on Baryon Decay Parameters" in the neutron Particle Listings.

[n] See the Listings for the pion momentum range used in this measurement.

[o] Our estimate. See the Particle Listings for details.

[p] A theoretical value using QED.

[q] This branching fraction includes all the decay modes of the final-state resonance.

[r] Here γ_D stands for a dark photon.

[s] See AALTONEN 11H, Fig. 8, for the calculated ratio of $\Lambda_c^+\pi^0\pi^0$ and $\Lambda_c^+\pi^+\pi^-$ partial widths as a function of the $\Lambda_c(2595)^+ - \Lambda_c^+$ mass difference. At our value of the mass difference, the predicted ratio is about 4. Using the measured value of $\Lambda_c^+\pi^0\pi^0$ branching fraction and assuming the $\Lambda_c\pi\pi$ branching fractions sum to unity, we derive the $\Lambda_c\pi^+\pi^-$ branching fraction. The derived ratio of the $\Lambda_c\pi^0\pi^0$ to $\Lambda_c\pi^+\pi^-$ partial widths is correspondingly 1.5 ± 0.2.

[t] A test that the isospin is indeed 0, so that the particle is indeed a Λ_c^+.

[u] In the isospin limit, with no other decays, the $\Lambda_c^+\pi^+\pi^-$ branching fraction would be 2/3 and the $\Lambda_c^+\pi^0\pi^0$ branching fraction would be 1/3.

[v] P_c^+ is a pentaquark-charmonium state.

[x] Not a pure measurement. See note at head of Λ_b^0 Decay Modes.

[y] Here h^- means π^- or K^-.

Mass $m_{\widetilde{\chi}_2^0} > 62.4$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}_2^0} - m_{\widetilde{\chi}_1^0}$]

Mass $m_{\widetilde{\chi}_3^0} > 99.9$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}_2^0} - m_{\widetilde{\chi}_1^0}$]

Mass $m_{\widetilde{\chi}_4^0} > 116$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}_2^0} - m_{\widetilde{\chi}_1^0}$]

Mass $m_{\widetilde{\chi}}$ none 200–670 GeV, CL = 95% [R-Parity Violating]
[wino production, $\widetilde{\chi} \to b + \ell/\nu + t/b$ via λ'_{i33} coupling]

$\widetilde{\chi}_i^\pm$ — charginos (mixtures of $\widetilde{W}^\pm$ and $\widetilde{H}_i^\pm$)

Mass $m_{\widetilde{\chi}_1^\pm} > 1170$ GeV, CL = 95% [R-Parity Violating]
[$\chi_1^0 \to b\,t\,\tau$]

Mass $m_{\widetilde{\chi}_1^\pm} > 94$ GeV, CL = 95%
[tan$\beta < 40$, $m_{\widetilde{\chi}_1^\pm} - m_{\widetilde{\chi}_1^0} > 3$ GeV, all m_0]

Mass $m_{\widetilde{\chi}_1^\pm} > 1000$ GeV, CL = 95%
[2ℓ+$\not{E}_T$, Tchi1chi1C, $m_{\widetilde{\chi}_1^0}$=0 GeV]

Mass $m_{\widetilde{\chi}_1^\pm} > 1600$ GeV, CL = 95% [R-Parity Violating]
[Tchi1n2l , $\widetilde{\chi}_1^0 \to \ell^\pm\ell^\mp\nu$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}_1^0} = 1200$ GeV]

$\widetilde{\chi}^\pm$ — long-lived chargino

Mass $m_{\widetilde{\chi}^\pm} > 1300$ GeV, CL = 95%
[$\widetilde{\chi}^\pm \to \widetilde{\chi}_1^0\pi^\pm$, wino LSP, stable, $\tau_{\widetilde{\chi}_1^\pm} > 100$ ns]

Mass $m_{\widetilde{\chi}^\pm} > 1050$ GeV, CL = 95%
[$\widetilde{\chi}^\pm \to \widetilde{\chi}_1^0\pi^\pm$, wino LSP,$\tau$=20 ns]

$\widetilde{\nu}$ — sneutrino

Mass $m > 41$ GeV, CL = 95% [model independent]

Mass $m > 94$ GeV, CL = 95%
[CMSSM, $1 \leq$ tan$\beta \leq 40$, $m_{\widetilde{e}_R} - m_{\widetilde{\chi}_1^0} > 10$ GeV]

Mass $m > 4200$ GeV, CL = 95% [R-Parity Violating]
[$1e + 1\mu$, $\nu_\tau \to e\,\mu$, λ=λ' = 0.1]

$\widetilde{e}$ — scalar electron (selectron)

Mass $m > 107$ GeV, CL = 95% [all $m_{\widetilde{e}_L} - m_{\widetilde{\chi}_1^0}$]

Mass $m > 700$ GeV, CL = 95%
[2ℓ+$\not{E}_T$, $m_{\widetilde{\ell}_R} = m_{\widetilde{\ell}_L}$ and $\widetilde{\ell}$=$\widetilde{e}$, $\widetilde{\mu}$, $m_{\widetilde{\chi}_1^0}$=0 GeV]

Mass $m > 250$ GeV, CL = 95%
[$\ell^\pm\ell^\mp$ + $\not{E}_T$, $\widetilde{e}_R$, $m_{\widetilde{\chi}_1^0} = 0$ GeV]

Mass $m > 410$ GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell^\pm$, $\widetilde{\ell} \to l\widetilde{\chi}_1^0$, $\widetilde{\chi}_1^0 \to \ell^\pm\ell^\mp\nu$]

Mass $m > 1200$ GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}_1^0} = 900$ GeV (m-degenerate $\widetilde{\ell}_L$, $\widetilde{\nu}$)]

$\widetilde{\mu}$ — scalar muon (smuon)

Mass $m > 700$ GeV, CL = 95%
[2ℓ+$\not{E}_T$, $m_{\widetilde{\ell}_R} = m_{\widetilde{\ell}_L}$ and $\widetilde{\ell}$=$\widetilde{e}$, $\widetilde{\mu}$, $m_{\widetilde{\chi}_1^0}$=0 GeV]

Mass $m > 210$, CL = 95%
[$\ell^\pm\ell^\mp$ + $\not{E}_T$, $\widetilde{\mu}_R$, $m_{\widetilde{\chi}_1^0} = 0$ GeV]

Mass $m > 94$ GeV, CL = 95%
[CMSSM, $1 \leq$ tan$\beta \leq 40$, $m_{\widetilde{\mu}_R} - m_{\widetilde{\chi}_1^0} > 10$ GeV]

Mass $m > 410$ GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell^\pm$, $\widetilde{\ell} \to l\widetilde{\chi}_1^0$, $\widetilde{\chi}_1^0 \to \ell^\pm\ell^\mp\nu$]

Mass $m > 1200$ GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}_1^0} = 900$ GeV (m-degenerate $\widetilde{\ell}_L$, $\widetilde{\nu}$)]

$\widetilde{\tau}$ — scalar tau (stau)

Mass $m > 81.9$ GeV, CL = 95%
[$m_{\widetilde{\tau}_R} - m_{\widetilde{\chi}_1^0} > 15$ GeV, all θ_τ, B($\widetilde{\tau} \to \tau\widetilde{\chi}_1^0$) = 100%]

Mass $m > 500$ GeV, CL = 95%
[2 hadronic τ + $\not{E}_T$, $\widetilde{\tau}_{R,L} \to \tau\widetilde{\chi}_1^0$, $m_{\widetilde{\chi}_1^0} = 1$ GeV]

Mass $m > 90$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{\tau}_R$, indirect, $\Delta m > 5$ GeV]

Mass $m > 1200$, CL = 95% [R-Parity Violating]
[$\geq 4\ell$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}_1^0} = 900$ GeV (m-degenerate $\widetilde{\ell}_L$, $\widetilde{\nu}$)]

Mass $m > 286$ GeV, CL = 95% [long-lived $\widetilde{\tau}$]

$\widetilde{q}$ – squarks of the first two quark generations

Mass $m > 1.220 \times 10^3$ GeV, CL = 95%
[jets + $\not{E}_T$, Tsqk1, 1 non-degenerate $\widetilde{q}$, $m_{\widetilde{\chi}_1^0} = 0$ GeV]

Mass $m > 1.600 \times 10^3$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{q} \to q\widetilde{\chi}_1^0$, $\widetilde{\chi}_1^0 \to \ell\ell\nu$, λ_{121},$\lambda_{122} \neq 0$, $m_{\widetilde{g}}$=2400GeV]

Mass $m > 1000$ GeV, CL = 95% [R-Parity Violating]
[jets, $\widetilde{q} \to q\widetilde{\chi}_1^0$, $\widetilde{\chi}_1^0 \to \ell q q$, $m_{\widetilde{\chi}_1^0} = 108$ GeV and $2.5 < c\tau_{\widetilde{\chi}_1^0} < 200$ mm]

$\widetilde{q}$ — long-lived squark

Mass $m > 1340$ GeV, CL = 95% [$\widetilde{t}$ R-hadrons]
Mass $m > 1250$ GeV, CL = 95% [$\widetilde{b}$ R-hadrons]
Mass $m > 1470$ GeV, CL = 95% [$\widetilde{t}$ R-hadrons]

$\widetilde{b}$ — scalar bottom (sbottom)

Mass $m > 1.270 \times 10^3$ GeV, CL = 95%
[b-jets + $\not{E}_T$, Tsbot1, $m_{\widetilde{\chi}_1^0}$=0 GeV]

Mass $m > 307$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{b} \to t\,d$ or $t\,s$, λ''_{332} or λ''_{331} coupling]

$\widetilde{t}$ — scalar top (stop)

Mass $m > 1.310 \times 10^3$ GeV, CL = 95%
[jets + $\not{E}_T$, Tstop1, $m_{\widetilde{\chi}_1^0} < 300$ GeV]

Mass $m > 1900$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{t} \to b\,e$, prompt, Tstop2RPV]

Mass $m > 1800$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{t} \to b\,\mu$, prompt, Tstop2RPV]

Mass $m > 800$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{t} \to b\,\tau$, prompt, Tstop2RPV]

Mass $m > 460$ GeV, CL = 95%
[R-Parity Violating, long-lived $\widetilde{t}$, $\widetilde{t} \to d\overline{\ell}$, 0.01cm < $c\tau$ < 1000 cm]

$\widetilde{g}$ — gluino

Mass $m > 2.300 \times 10^3$ GeV, CL = 95%
[jets + $\not{E}_T$, Tglu1A, $m_{\widetilde{\chi}_1^0} < 200$ GeV]

Mass $m > 2.260 \times 10^3$ GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}_1^0} > 1000$ GeV]

Technicolor

The limits for technicolor (and top-color) particles are quite varied depending on assumptions. See the Technicolor section of the full *Review* (the data listings).

Tests of Conservation Laws

Revised October 2025 by A. Pich (IFIC, Valencia) and M. Ramsey-Musolf (Tsung-Dao Lee Inst.; SJTU; U. Massachusetts).

In keeping with the current interest in tests of conservation laws, we collect together a Table of experimental limits on all weak and electromagnetic decays, mass differences, and moments, and on a few reactions, whose observation would violate conservation laws. The Table is given only in the full Review of Particle Physics (RPP), not in the Particle Physics Booklet, and organizes the data in two main sections: "Discrete Space-Time Symmetries", *i.e.*, C, P, T, CP and CPT; and "Number Conservation Laws", *i.e.*, lepton, baryon, flavor and charge conservation. The references for these data can be found in the Particle Listings. The following text discusses the best limits among those included in the Table and gives a brief overview of the current status. For some topics, a more extensive discussion of the framework for theoretical interpretation is provided, particularly where the analogous discussion does not appear elsewhere in the RPP. References to more extensive review articles are also included where appropriate. Unless otherwise specified, all limits quoted in this review are given at a C.L. of 90%.

DISCRETE SPACE-TIME SYMMETRIES

Charge conjugation (C), parity (P) and time reversal (T) are empirically exact symmetries of the electromagnetic (QED) and strong (QCD) interactions, but they are violated by the weak forces. Owing to the left-handed nature of the $SU(2)_L \otimes U(1)_Y$ electroweak theory, C and P are maximally violated in the fermionic couplings of the $W^\pm$ and (up to $\sin^2\theta_W$ corrections) the Z. However, their product CP is still an exact symmetry when only one or two fermion families are considered. With three generations of fermions, CP is violated through the single complex phase present in the Cabibbo-Kobayashi-Maskawa (CKM) quark mixing matrix. An analogous CP-violating (CPV) phase appears in the lepton sector when non-vanishing neutrino masses are taken into account (plus two additional phases if neutrinos are Majorana particles). The product of the three discrete symmetries, CPT, is an exact symmetry of any local and Lorentz-invariant quantum field theory with a positive-definite hermitian Hamiltonian that preserves micro-causality [1, 2]. Therefore, the breaking of CP implies a corresponding violation of T.

Violations of charge-conjugation symmetry have never been observed in electromagnetic and strong phenomena. The most stringent limits are extracted from C-violating transitions of neutral (self-conjugate) particles such as $\mathrm{Br}(\pi^0 \to 3\gamma) < 3.1 \times 10^{-8}$ [3] and $\mathrm{Br}(J/\psi \to 2\gamma) < 2.7 \times 10^{-7}$ [4]. P (and CP) conservation has been also precisely tested through forbidden decays such as $\mathrm{Br}(\eta \to 4\pi^0) < 6.9 \times 10^{-7}$ [5], but the best limits on P and T are set by the non-observation of electric dipole moments (see section 2). Obviously, the interplay of the weak interaction puts a lower bound in sensitivity for this type of tests, beyond which violations of the corresponding conservation laws should be detected.

1 Violations of CP and T

The first evidence of CP non-invariance in particle physics was the observation in 1964 of $K_L^0 \to \pi^+\pi^-$ decays [6]. For many years afterwards, the non-zero ratio

$$\begin{aligned} |\eta_{+-}| &\equiv |\mathcal{M}(K_L^0 \to \pi^+\pi^-)/\mathcal{M}(K_S^0 \to \pi^+\pi^-)| \\ &= (2.233 \pm 0.012) \times 10^{-3} \end{aligned} \tag{1}$$

could be explained as a K^0–$\overline{K}^0$ mixing effect, $\eta_{+-} = \epsilon$ (superweak CP violation), which would imply an identical ratio $\eta_{00} \equiv \mathcal{M}(K_L^0 \to \pi^0\pi^0)/\mathcal{M}(K_S^0 \to \pi^0\pi^0)$ in the neutral decay mode and successfully predicts the observed CPV semileptonic asymmetry ($A_L(e) \approx 2\,\mathrm{Re}\,\epsilon$)

$$\begin{aligned} A_L(e) &\equiv \frac{\Gamma(K_L^0 \to \pi^- e^+ \nu_e) - \Gamma(K_L^0 \to \pi^+ e^- \bar{\nu}_e)}{\Gamma(K_L^0 \to \pi^- e^+ \nu_e) + \Gamma(K_L^0 \to \pi^+ e^- \bar{\nu}_e)} \\ &= (3.34 \pm 0.07) \times 10^{-3}\,. \end{aligned} \tag{2}$$

A tiny difference between η_{+-} and η_{00} was reported for the first time in 1988 by the CERN NA31 collaboration [7], and later established at the 7.2σ level with the full data samples from the NA31 [8], E731 [9], NA48 [10] and KTeV [11] experiments:

$$\mathrm{Re}(\epsilon'/\epsilon) = \frac{1}{3}\,(1 - |\eta_{00}/\eta_{+-}|) = (1.67 \pm 0.23) \times 10^{-3}\,. \tag{3}$$

This important measurement confirmed that CP violation is associated with a $\Delta S = 1$ transition, as predicted by the CKM mechanism. The Standard Model (SM) prediction, $\mathrm{Re}(\epsilon'/\epsilon) = (1.4 \pm 0.5) \times 10^{-3}$ [12–14], is in good agreement with the measured ratio, although the theoretical uncertainty is unfortunately large.

Much larger CP asymmetries have been later measured in B meson decays, many of them involving the interference between B^0–$\overline{B}^0$ mixing and the decay amplitude. They provide many successful tests of the CKM unitarity structure, validating the SM mechanism of CP violation (see the review on CP violation in the quark sector). Prominent signals of direct CP violation in the decay amplitudes have been also clearly established in several $B^\pm$, B_d^0 and B_s^0 decays, and, more recently, in charm decays [15, 16]:

$$\begin{aligned} \Delta a_{CP}^{\mathrm{dir}} &\equiv a_{CP}^{\mathrm{dir}}(D^0 \to K^+K^-) - a_{CP}^{\mathrm{dir}}(D^0 \to \pi^+\pi^-) \\ &= (-15.7 \pm 2.9) \times 10^{-4}\,. \end{aligned} \tag{4a}$$

$$a_{CP}^{\mathrm{dir}}(D^0 \to \pi^+\pi^-) = (23.2 \pm 6.1) \times 10^{-4}\,. \tag{4b}$$

The first observation of CP violation in baryon decays has been reported recently [17]:

$$\mathcal{A}_{CP}(\Lambda_b^0 \to pK^-\pi^+\pi^-) = (2.45 \pm 0.46 \pm 0.10)\%\,. \tag{5}$$

These direct CP asymmetries necessarily involve the presence of a strong phase-shift difference between (at least) two interfering amplitudes, which makes very challenging to perform reliable SM predictions for heavy-flavored hadrons.

Global fits to neutrino oscillation data provide some hints of a non-zero mixing phase [18, 19]. Although the statistical significance is not yet compelling, they suggest that CP-violation effects in neutrino oscillations could be large (see the review on neutrino masses, mixings and oscillations). The future DUNE and Hyper-Kamiokande experiments are expected to confirm the presence of CP violation in the lepton sector or constrain the phase in the leptonic mixing matrix to be smaller than $O(10^\circ)$.

While CP violation implies a breaking of time-reversal symmetry, direct tests of T violation are much more difficult. The CPLEAR experiment observed longtime ago a non-zero difference between the oscillation probabilities of $K^0 \to \overline{K}^0$ and $\overline{K}^0 \to K^0$ [20]. Initial neutral kaons with defined strangeness were produced from proton-antiproton annihilations at rest, $p\bar{p} \to K^-\pi^+K^0, K^+\pi^-\overline{K}^0$, and tagged by the accompanying charged kaon, while the strangeness of the final neutral kaon was identified through its semileptonic decay: $K^0 \to e^+\pi^-\nu_e$, $\overline{K}^0 \to e^-\pi^+\bar{\nu}_e$. The average asymmetry over the time interval from 1 to 20 K_S^0 lifetimes was found to be different from zero at 4σ [20]:

$$\begin{aligned} &\frac{R[\overline{K}^0\,(t=0) \to e^+\pi^-\nu_e\,(t)] - R[K^0\,(t=0) \to e^-\pi^+\bar{\nu}_e\,(t)]}{R[\overline{K}^0\,(t=0) \to e^+\pi^-\nu_e\,(t)] + R[K^0\,(t=0) \to e^-\pi^+\bar{\nu}_e\,(t)]} = \\ &= (6.6 \pm 1.3 \pm 1.0) \times 10^{-3}\,. \end{aligned} \tag{6}$$

Since this asymmetry violates also CP, its interpretation as direct evidence of T violation requires a detailed analysis of the underlying K^0–$\overline{K}^0$ mixing process [21–23].

The exchange of initial and final states has been made possible in B decays, taking advantage of the entanglement of the two daughter mesons produced in the decay $\Upsilon(4S) \to B\bar{B}$ which allows for both flavor ($B^0 \to \ell^+X$, $\overline{B}^0 \to \ell^-X$) and CP ($B_+ \to J/\psi K_L^0$, $B_- \to J/\psi K_S^0$) tagging. Selecting events where one B candidate is reconstructed in a CP eigenstate and the flavor of the other B is identified, one can compare the rates of the $\overline{B}^0 \to B_\pm$ and $B^0 \to B_\pm$ transitions with their T-reversed $B_\pm \to \overline{B}^0$ and $B_\pm \to B^0$ processes, as a function of the time difference Δt between the two B decays [24–26]. Neglecting the small width difference between the two B_d^0 mass eigenstates, each

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

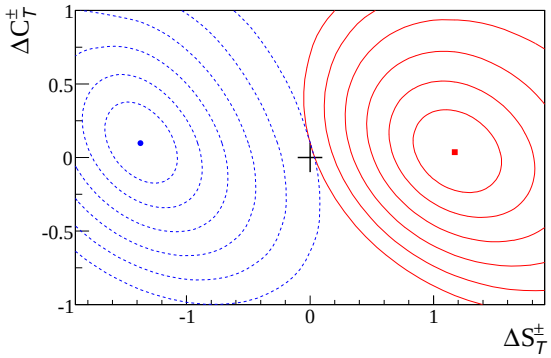

Figure 1: Measured values of ΔS_T^+, ΔC_T^+ (blue point, dashed lines) and ΔS_T^-, ΔC_T^- (red square, solid lines) [27]. The two-dimensional contours correspond to $1-\mathrm{CL} = 0.317$, 4.55×10^{-2}, 2.70×10^{-3}, 6.33×10^{-5}, 5.73×10^{-7}, and 1.97×10^{-9}. The + sign indicates the T-invariant point.

of these eight transitions has a time-dependent decay rate of the form $e^{-\Gamma_d\Delta t}\{1+S^{\pm}_{\alpha,\beta}\sin(\Delta m_d\Delta t)+C^{\pm}_{\alpha,\beta}\cos(\Delta m_d\Delta t)\}$, where Γ_d is the average decay width, Δm_d the B^0_d mass difference, the subindices $\alpha = \ell^+,\ell^-$ and $\beta = K^0_S, K^0_L$ stand for the reconstructed final states of the two B mesons and the superindex + or − indicates whether the decay to the flavor final state α occurs before or after the decay to the CP final state β. Figure 1 shows confidence-level contours for the T-asymmetry parameters $\Delta S_T^{\pm} \equiv S^{\mp}_{\ell^-,K^0_L} - S^{\pm}_{\ell^+,K^0_S}$ and $\Delta C_T^{\pm} \equiv C^{\mp}_{\ell^-,K^0_L} - C^{\pm}_{\ell^+,K^0_S}$, reported by the BABAR experiment [27], which clearly demonstrate a violation of T in $\Delta S_T^{\pm}$, with a significance of 14σ.

2 Electric dipole moments

Among the most powerful tests of CP invariance is the search for a permanent electric dipole moment (EDM) of an elementary fermion or non-degenerate quantum system. The EDM of an elementary spin-1/2 fermion f is defined by the effective, non-renormalizable interaction

$$\mathcal{L}_{\mathrm{EDM}} = -\frac{i}{2} d_f\, \bar{f}\sigma_{\mu\nu}\gamma_5 f\, F^{\mu\nu} \tag{7}$$

where $F^{\mu\nu}$ is the QED field strength tensor. The values for d_f are conventionally expressed in units of $e\,$cm. The interaction (7) is separately odd under T and P. In the non-relativistic limit, Eq. (7) reduces to

$$\mathcal{L}_{\mathrm{EDM}} \to d_f\, \chi_f^{\dagger}\vec{\sigma}\chi_f\cdot\vec{E} \tag{8}$$

where χ is a two-component Pauli spinor and $\vec{E}$ is the electric field. Note the interaction (8) is manifestly T-odd and carries no direct information on CP. The observation of a non-zero EDM of a non-relativistic (and non-degenerate) quantum system, such as the mercury atom (see below) would imply CP violation under the assumption of CPT invariance.

To date, no experimental observation of an EDM of an elementary particle or non-degenerate bound quantum system has been observed. The most stringent limits have been obtained for the EDMs of the electron, mercury atom, and neutron. A selection of the representative, most stringent limits is given in Table 1. The limits on the electron EDM are inferred from experiments involving polar molecules, paramagnetic systems with an unpaired electron spin. In contrast, the neutron and ^{199}Hg atom are diamagnetic. A variety of experimental efforts aimed at improved sensitivities are underway. For reviews of the experimental and theoretical situation, see, *e.g.* [28–31].

EDMs in the Standard Model

The SM provides two sources of d_f: the CPV phase in the CKM matrix and the P- and T-odd 'θ term' in the QCD Lagrangian. The former is characterized by the Jarlskog invariant [38]

$$\mathcal{J} = \mathrm{Im}(V_{us}V_{cs}^*V_{cb}V_{ub}^*) \sim A^2\lambda^6\eta < 10^{-4}\,, \tag{9}$$

Table 1: Most stringent limits on electric dipole moments.

EDM	Limit ($e\,$cm)		Source
Electron	1.1×10^{-29}	(90% C.L.)	ThO [32]
	4.1×10^{-30}	(90% C.L.)	HfF^+ [33]
Muon	1.8×10^{-19}	(95% C.L.)	[34]
Neutron	1.8×10^{-26}	(90% C.L.)	[35]
^{199}Hg Atom	7.4×10^{-30}	(95% C.L.)	[36]
^{129}Xe Atom	1.5×10^{-27}	(95% C.L.)	[37]

while the latter is given by

$$\mathcal{L}_{\bar\theta} = -\frac{g_3^2}{16\pi^2}\,\bar\theta\,\mathrm{Tr}\left(G^{\mu\nu}\tilde{G}_{\mu\nu}\right), \tag{10}$$

where $G_{\mu\nu}$ ($\tilde{G}_{\mu\nu} = \epsilon_{\mu\nu\alpha\beta}\,G^{\alpha\beta}/2$) is the QCD field strength tensor (dual).

The CKM-induced EDMs of quarks and charged leptons arise at three- and four-loop orders, respectively [39–42]. The resulting numerical impact for the experimental observables (see below) falls well below present and prospective experimental sensitivities. The most important impact of $\mathcal{J}$ for the EDMs of the neutron and diamagnetic atoms arise via induced hadronic interactions. The resulting theoretical expectations for the electron, neutron and ^{199}Hg EDMs are

$$|d_e|_{\mathrm{CKM}} \approx 10^{-44}\ e\,\mathrm{cm}\ \ [42], \tag{11a}$$

$$|d_n|_{\mathrm{CKM}} \approx (1-6)\times10^{-32}\ e\,\mathrm{cm}\ \ [43], \tag{11b}$$

$$|d_A(^{199}\mathrm{Hg})|_{\mathrm{CKM}} \lesssim 4\times10^{-34}\ e\,\mathrm{cm}\ \ [28]. \tag{11c}$$

For d_n and $d_A(^{199}\mathrm{Hg})$, the dominant CKM contributions arise from four-quark operators (generated after integrating out the electroweak gauge bosons) rather than from the EDMs of the individual quarks. The corresponding sensitivities to the QCD $\bar\theta$ parameter are given by

$$|d_n|_{\bar\theta} \approx (0.9-1.2)\times10^{-16}\ \bar\theta\ e\,\mathrm{cm}\ \ [43], \tag{12a}$$

$$|d_A(^{199}\mathrm{Hg})|_{\bar\theta} \approx (0.07-8)\times10^{-20}\ \bar\theta\ e\,\mathrm{cm}\ \ [28,29], \tag{12b}$$

where the ranges quoted include the impacts of hadronic, nuclear, and atomic theory uncertainties. The neutron EDM puts then a stringent limit on 'strong' CP violation: $\bar\theta \lesssim 2\times10^{-10}$. The corresponding limit from $d_A(^{199}\mathrm{Hg})$ is weaker due to the large theoretical uncertainty.

EDMs Beyond the Standard Model

It is possible that the next generation of EDM searches will yield a non-zero result, arising from the $\bar\theta$-term interaction and/or physics beyond the SM (BSM). Most of the considered BSM scenarios involve new particles with masses well above the electroweak scale. At energies much lower than the BSM mass scale Λ, the dynamics can be described through an effective field theory (SMEFT) involving an infinite set of non-renormalizable operators $\mathcal{O}_k^{(d)}$, with dimensions $d > 4$, that are invariant under the SM gauge group:

$$\mathcal{L}_{\mathrm{SMEFT}} = \mathcal{L}_{\mathrm{SM}} + \sum_{k,d}\alpha_k^{(d)}\left(\frac{1}{\Lambda}\right)^{d-4}\mathcal{O}_k^{(d)}\,. \tag{13}$$

The operators contain only SM fields, while all short-distance information on the BSM physics is encoded in their Wilson coefficients $\alpha_k^{(d)}$. The $d=4$ term corresponds to the SM Lagrangian.

For the systems of Table 1 and for many BSM scenarios of recent interest, it suffices to consider the leading contributions from $d=6$ operators. Considering only the first-generation SM fermions, there exist 12 independent CPV pertinent operators. For a complete listing, see *e.g.*, Refs. [29, 44]. For a given elementary fermion f, two of these operators reduce to the EDM interaction in Eq. (7). Of the remaining, the most relevant include the chromo-electric dipole moments (cEDMs) of the quarks;

Table 2: Pertinent dimension-six EDM and cEDM sources (first generation fermions only).

System	$d=6$ Source	Wilson Coefficient
Paramagnetic	Electron EDM	Im $C_{e\gamma}$
	Electron-quark	$C_{eq}^{(\pm)}$
Diamagnetic	Quark EDM	Im $C_{q\gamma}$
	Quark cEDM	Im C_{qG}
	Three gluon	$C_{\tilde{G}}$
	Four quark	Im $C_{quqd}^{(1,8)}$
	Quark-Higgs	Im $C_{\varphi ud}$
	Electron-quark tensor*	Im $C_{\ell equ}^{(3)}$

*Applicable only to atoms.

a CP-odd three gluon operator; three semileptonic, four-fermion operators; two four-quark operators; and a CPV interaction involving two Higgs fields and a right-handed quark current. For the dipole operators, it is useful to define a rescaled Wilson coefficient $\alpha_{fV_j}^{(6)} \equiv g_j\, C_{fV_j}$, where V_j ($j=1,2,3$) denote the gauge bosons for the three SM gauge groups with corresponding couplings g_j; for all other $d=6$ operators we correspondingly identify $\alpha_k^{(6)} \equiv C_k$. In this case, one has for the EDM (d_f) and cEDM ($\tilde{d}_q$)

$$d_f = -(1.13\times 10^{-16}\ e\ \text{cm})\left(\frac{v}{\Lambda}\right)^2 \text{Im}\ C_{f\gamma}\,, \tag{14a}$$

$$\tilde{d}_q = -(1.13\times 10^{-16}\ \text{cm})\left(\frac{v}{\Lambda}\right)^2 \text{Im}\ C_{qG}\,, \tag{14b}$$

with $\text{Im}\ C_{f\gamma} = \text{Im}\ C_{fB} + 3I_3^f\,\text{Im}\ C_{fW}$. As the expressions (14a,14b) illustrate, the magnitude of the BSM contributions scales with two inverse powers of the scale Λ. A similar conclusion holds for the contributions from the other $d=6$ operators to the EDMs of Table 1.

It is important to emphasize that if the BSM mediators are light, with masses below the weak scale, the effective field theory description of Eq. (13) does not apply. For recent studies along these lines, see, *e.g.* [45, 46].

EDM Interpretation: From Short Distances to the Atomic Scale

The EDM limits in Table 1 are obtained using composite quantum systems, wherein the relevant dynamics involve physics at the hadronic, nuclear, atomic and molecular scales. The manifestation of a given CPV source (CKM, $\bar{\theta}$ term, BSM) involves an interplay of these dynamics. In all cases, one must first evolve the Wilson coefficients from the weak scale to the hadronic scale, then match onto the relevant low-energy degrees of freedom (electrons, nucleons, pions, *etc.*). At this level, the most straightforward interpretation involves the paramagnetic systems, for which two sources dominate: the electron EDM and the electron spin-dependent semileptonic interaction $\bar{e}\gamma_5 e\,\bar{q}q$. The latter gives rise to an spin-independent Hamiltonian, for an atom with Z electrons/protons and N neutrons,

$$\hat{H}_S = \frac{iG_F}{\sqrt{2}}\,\delta(\vec{r})\left[(Z+N)\,C_S^{(0)} + (Z-N)\,C_S^{(1)}\right]\gamma_0\gamma_5\,, \tag{15}$$

where $C_S^{(0)}$ ($C_S^{(1)}$) is proportional to $C_{eq}^{(+)}$ ($C_{eq}^{(-)}$). The computation of $C_S^{(0,1)}$ is relatively free from theoretical uncertainty since the operator $\bar{q}q$ essentially counts the number of quarks of flavor q in the nucleus. Experimental results for paramagnetic systems, thus, often quote bounds on

$$C_S \equiv C_S^{(0)} + \left(\frac{Z-N}{Z+N}\right) C_S^{(1)} \tag{16}$$

as well as on d_e, assuming only one of these two sources is non-vanishing. Combining results from ThO and HfF^+ (see Figure 2) allows one to obtain the global, 90% C.L. bounds

$$|d_e| < 2.1\times 10^{-29}\ e\ \text{cm}\,, \qquad |C_S| < 1.9\times 10^{-9}\,. \tag{17}$$

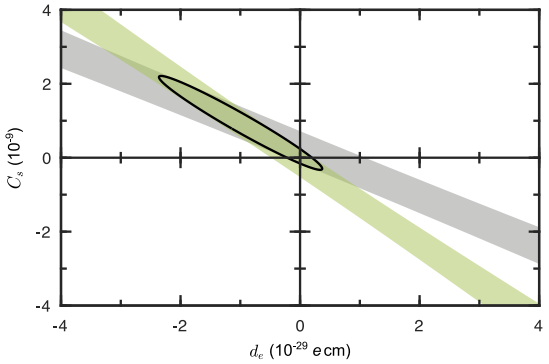

Figure 2: Constraints on d_e and C_S from EDM searches using polar molecules [33]. The green and grey bands are the 90% confidence regions from HfF+ and ThO, while the ellipse shows the 90% CL limits from the global fit. Parameters used in fits are from Ref. [47].

Note that the limits on d_e given in Table 1 have been obtained assuming $C_S = 0$.

For the diamagnetic systems, the situation is considerably more involved. For the neutron, a variety of approaches – including lattice QCD, chiral perturbation theory, QCD sum rules, and the quark model – have been employed to compute the relevant hadronic matrix elements of the CPV sources (see, *e.g.*, [29,30,48,49]). For diamagnetic atoms, the non-leptonic sources of Table 2 give rise to the EDM of the nucleus as well as other P- and T-odd nuclear moments, as allowed by the nuclear spin. However, according to a theorem by Schiff [50], the nuclear EDM generates no contribution to the neutral-atom EDM due to screening by atomic electrons. The leading contribution from these sources, instead, arises via the nuclear Schiff moment, $\vec{S}$, an r^3-weighted moment of the T- and P-odd component of the nuclear charge density. The resulting effective atomic Hamiltonian is

$$\hat{H}_{\text{Schiff}} = -4\pi\,\vec{\nabla}\rho_e(0)\cdot\vec{S}\,, \tag{18}$$

where $\vec{\nabla}\rho_e(0)$ is the gradient of the electron density at the nucleus. To date, computations of the nuclear Schiff moment have assumed that the leading contribution arises from a pion-exchange induced nuclear force, with the P- and T-odd πN interaction given by

$$\mathcal{L}_{\pi N}^{T,P} = \bar{N}\left[\bar{g}_\pi^{(0)}\vec{\tau}\cdot\vec{\pi} + \bar{g}_\pi^{(1)}\pi^0 + \bar{g}_\pi^{(2)}(3\tau_3\pi^0 - \vec{\tau}\cdot\vec{\pi})\right]N\,. \tag{19}$$

Chiral effective field theory power counting implies that in general the magnitude of $\bar{g}_\pi^{(2)}$ is suppressed with respect to the isoscalar and isovector couplings. The CPV sources then generate a diamagnetic atom EDM d_A via the sequence

$$\text{CPV source} \longrightarrow \bar{g}_\pi^{(i)} \longrightarrow \vec{S} \longrightarrow d_A\,. \tag{20}$$

The steps in this sequence involve dynamics at the hadronic, nuclear, and atomic scales, respectively. In addition, d_A may receive contributions from the nuclear spin-dependent interaction generated by the semileptonic tensor interaction listed in Table 2, with the corresponding atomic Hamiltonian

$$\hat{H}_T = \frac{2iG_F}{\sqrt{2}}\,\delta(\vec{r})\sum_N\left[C_T^{(0)} + C_T^{(1)}\tau_3\right]\vec{\sigma}_N\cdot\vec{\gamma}\,, \tag{21}$$

where σ_N is the nucleon spin Pauli matrix and $C_T^{(0,1)} \propto \text{Im}\ C_{\ell equ}^{(3)}$.

Given the large number of CPV sources and existing diagmagnetic EDM limits, it is not possible to obtain a set of global constraints on the former. One may, however, do so for the low-energy effective parameters $\bar{g}_\pi^{(0,1)}$, $C_T^{(0,1)}$ and $\bar{d}_n^{\text{sr}}$, where the latter denotes a 'short-range' contribution to the neutron EDM [28, 51]. In this context, the dominant source of theoretical uncertainty involves computations of the nuclear Schiff moment. From the

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access

bounds on the low-energy parameters, one may then derive constraints on the CPV sources by utilizing computations of the hadronic matrix elements. Reducing the degree of theoretical hadronic and nuclear physics uncertainty is an area of active effort.

3 Tests of *CPT*

CPT symmetry implies the equality of the masses and widths of a particle and its antiparticle. The most constraining limits are extracted from the neutral kaons [52, 53]:

$$\begin{aligned} 2\,\frac{|m_{K^0}-m_{\overline{K}^0}|}{(m_{K^0}+m_{\overline{K}^0})} &< 6\times10^{-19}\,, \\ 2\,\frac{|\Gamma_{K^0}-\Gamma_{\overline{K}^0}|}{(m_{K^0}+m_{\overline{K}^0})} &= (8\pm8)\times10^{-18}\,. \end{aligned} \tag{22}$$

The limit on the K^0–$\overline{K}^0$ mass difference is extracted from the measured CP-violation parameters through the relation [54]

$$m_{\overline{K}^0}-m_{K^0} \approx \frac{2\left(m_{K_L^0}-m_{K_S^0}\right)}{\sin\phi_{\rm SW}}\,|\eta|\left(\frac{2}{3}\,\phi_{+-}+\frac{1}{3}\,\phi_{00}-\phi_{\rm SW}\right), \tag{23}$$

which assumes that there is no other source of CPT violation than this mass difference, where $\phi_{\rm SW}=(43.52\pm0.05)^\circ$ is the superweak angle. An upper bound on CPT breaking in $K_L^0\to2\pi$ has been also set through the measured phase difference of the CPV ratios η_{00} and η_{+-}, $\phi_{00}-\phi_{+-}=(0.34\pm0.32)^\circ$, thanks to the small value of $(1-|\eta_{00}/\eta_{+-}|)$ (see the review on CP violation in K_L^0 decays).

The measured masses and electric charges of the electron, the proton and their antiparticles provide also strong limits on CPT violation [55–58]:

$$\begin{aligned} &2\,\frac{|m_{e^+}-m_{e^-}|}{m_{e^+}+m_{e^-}} < 8\times10^{-9}\,, \qquad \frac{|q_{e^+}+q_{e^-}|}{e} < 4\times10^{-8}\,, \\ &\left|\frac{q_{\bar p}/m_{\bar p}}{q_p/m_p}\right|-1 = (0.3\pm1.6)\times10^{-11}\,. \end{aligned} \tag{24}$$

Worth mentioning are also the tight constraints derived from the lepton and antilepton magnetic moments [59, 60],

$$\begin{aligned} 2\,\frac{g_{e^+}-g_{e^-}}{g_{e^+}+g_{e^-}} &= (-0.5\pm2.1)\times10^{-12}\,, \\ 2\,\frac{g_{\mu^+}-g_{\mu^-}}{g_{\mu^+}+g_{\mu^-}} &= (-0.11\pm0.12)\times10^{-8}\,, \end{aligned} \tag{25}$$

those of the proton and antiproton [61],

$$(\mu_p+\mu_{\bar p})/\mu_p = (2\pm4)\times10^{-9}\,, \tag{26}$$

and the measurement of the 1S-2S atomic transition in antihydrogen which agrees with the corresponding frequency spectral line in hydrogen at a relative precision of 2×10^{-12} [62].

A violation of CPT in an interacting local quantum field theory would imply that Lorentz symmetry is also violated [63]. Signatures of Lorentz-invariance violation have been searched for with atomic clocks, penning traps, matter and antimatter spectroscopy, colliders and astroparticle experiments, with so far negative results [64]. A compilation of experimental bounds is given in Ref. [65], parametrized through the coefficients of the so-called Standard Model Extension (SME) Lagrangian which contains all possible Lorentz- and CPT-violating operators preserving gauge invariance, renormalizability, locality and observer causality [66].

QUANTUM-NUMBER CONSERVATION LAWS

Conservation laws of several quantum numbers have been empirically established with a very high degree of confidence. They are usually associated with some global phase symmetry. However, while some of them are deeply rooted in basic principles such as gauge invariance (charge conservation; local symmetry implies global symmetry) or Lorentz symmetry (fermion number conservation), others appear to be accidental symmetries of the SM Lagrangian and could be broken by new physics interactions.

In fact, if one only assumes the SM gauge symmetries and particle content, the most general dynamics at energies below the BSM mass scale is described by the SMEFT Lagrangian in Eq. (13). All $d=4$ operators (*i.e.*, the SM) happen to preserve the B and L quantum numbers, but this is no-longer true for the gauge-invariant structures of higher dimensionality. There is only one operator with $d=5$ (up to hermitian conjugation and flavor assignments), and it violates lepton number by two units [67], giving rise to Majorana neutrino masses after the electroweak spontaneous symmetry breaking. With $d=6$, there are five operators that violate B and L [68, 69]. Thus, violations of these quantum numbers can be generically expected, unless there is an explicit symmetry protecting them.

4 Electric charge

The conservation of electric charges is associated with the QED gauge symmetry. The most precise tests are the non-observation of the decays $e\to\nu_e\gamma$ (lifetime larger than 6.6×10^{28} yr [70]) and $n\to p\nu_e\bar\nu_e$ (Br $<8\times10^{-27}$, 68% C.L. [71]). The neutrality of matter can be also interpreted as a test of electric charge conservation. Worth mentioning are the experimental limits on the electric charge of the neutron, $q_n/e=(-0.2\pm0.8)\times10^{-21}$, and on the sum of the proton and electron charges, $|q_p+q_e|/e<1\times10^{-21}$ [72].

The isotropy of the cosmic microwave background has been used to set stringent limits on a possible charge asymmetry of the Universe [73]. Assuming that charge asymmetries produced by different particles are not anticorrelated, this implies upper bounds on the photon ($|q_\gamma|/e<1\times10^{-35}$) and neutrino ($|q_\nu|/e<4\times10^{-35}$) electric charges. A much stronger upper bound on the photon charge ($|q_\gamma|/e<1\times10^{-46}$) has been derived from the non-observation of Aharonov-Bohm phase differences in interferometric experiments with photons that have traversed cosmological distances, under the assumption that both positive and negative charged photons exist [74].

5 Lepton family numbers

In the SM with massless left-handed neutrinos there is a separate conservation number for each lepton family. However, neutrino oscillations show that neutrinos have tiny masses and there are sizable mixings among the different lepton flavors. Compelling evidence from solar, atmospheric, accelerator and reactor neutrino experiments has established a quite solid pattern of neutrino mass differences and mixing angles [18, 19]. (see the review on neutrino masses, mixings and oscillations). Nevertheless, flavor mixing among the different charged leptons has never been observed.

If neutrino masses and mixings among the three active neutrinos were the only sources of lepton-flavor violation (LFV), neutrinoless transitions from one charged lepton flavor to another would be heavily suppressed by powers of m_{ν_i} (GIM mechanism), leading to un-observably small rates; for instance [77–82],

$$\mathrm{Br}(\mu\to e\gamma)=\frac{3\alpha}{32\pi}\left|\sum_i U^*_{\mu i}U_{ei}\,\frac{m^2_{\nu_i}-m^2_{\nu_1}}{M^2_W}\right|^2<10^{-54}\,, \tag{27}$$

where U_{ia} are the relevant elements of the PMNS mixing matrix. This contribution is clearly too small to be observed in any realistic experiment, so any experimentally accessible effect would arise from BSM physics with sources of LFV not related to m_{ν_i}. The search for charged LFV (CLFV) remains an area of active interest, which has the potential to probe physics at scales much higher than the TeV.

Among the most sensitive probes are searches for the CLFV decays of the muon, $\mu\to e\gamma$ and $\mu\to3e$, as well as the conversion process $\mu^-+A(N,Z)\to e^-+A(N,Z)$, where $A(N,Z)$ denotes a nucleus with N neutrons and Z protons. Searches for rare τ decays such as $\tau\to\ell\gamma$ ($\ell=e,\mu$) also provide interesting probes of CLFV. A variety of BSM scenarios predict that rates for these CLFV processes could be sufficiently large to be observed in the present or planned searches. To date, no observation has been

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

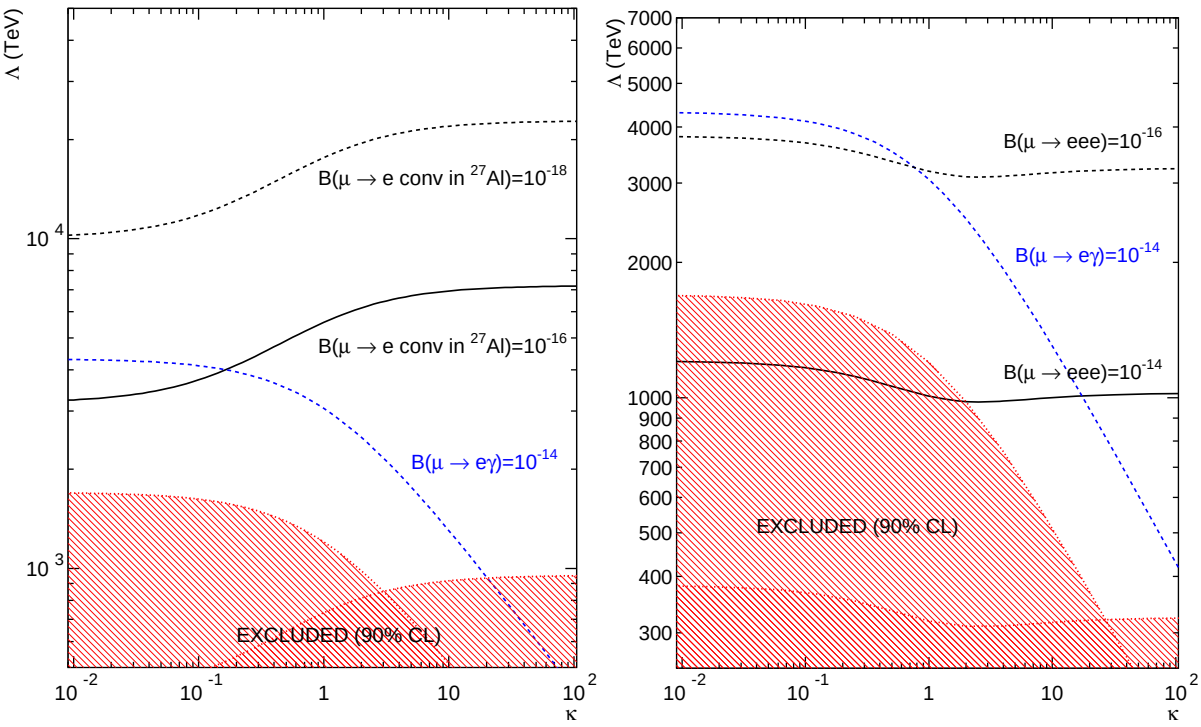

Figure 3: Model-independent CLFV sensitivities based on Eq (33). Left panel shows the comparison of present constraints with prospective future sensitivities for $\mu \to e\gamma$ and $\mu \to e$ conversion. Right panel gives analogous comparison for $\mu \to e\gamma$ and $\mu \to 3e$. Updated by [75] from Ref. [76].

reported, and the resulting null results place strong constraints on BSM scenarios. For extensive reviews of the experimental and theoretical status and prospects, see Refs. [76, 83, 84].

A detailed set of upper bounds on CLFV branching rations is given in the listings for the muon and tau leptons. Here we emphasize those with the strongest limits:

$$\begin{aligned} &\mathrm{Br}(\mu \to e\gamma) < 1.5 \times 10^{-13} \quad [85], \\ &\mathrm{Br}(\mu \to 3e) < 1.0 \times 10^{-12} \quad [86] \end{aligned} \tag{28}$$

and

$$B_{\mu\to e} \equiv \frac{\Gamma(\mu^- + A(N,Z) \to e^- + A(N,Z)}{\Gamma(\mu^- + A(N,Z) \to \nu + A(N+1, Z-1)} \tag{29}$$

with the best limit so far, $B_{\mu\to e} < 7 \times 10^{-13}$ [87], obtained with gold. Several proposed experiments aim to improve these limits by several orders of magnitude with different atoms.

One may interpret both $\mu \to e\gamma$ and $\mu \to e$ conversion in terms of the amplitudes to emit a real or virtual photon:

$$\begin{aligned} \mathcal{M}_{\mu\to e\gamma^{(*)}} = eG_\mu \varepsilon^{\alpha *} \bar{e}(p-q) \Big[\left(q^2\gamma_\alpha - \not{q} q_\alpha\right) \left(\tilde{A}_1^R P_R + \tilde{A}_1^L P_L\right) \\ + i m_\mu \sigma_{\alpha\beta} q^\beta \left(\tilde{A}_2^R P_R + \tilde{A}_2^L P_L\right) \Big] \mu(p) \,, \end{aligned} \tag{30}$$

where it is conventional to normalize the amplitude to the Fermi constant. One then has

$$\mathrm{Br}(\mu \to e\gamma) = 48\pi^3 \alpha \left(|\tilde{A}_2^R|^2 + |\tilde{A}_2^L|^2 \right) . \tag{31}$$

For the conversion process, the virtual photon is absorbed by the quarks in the nucleus, yielding an effective four-fermion operator. In general, the exchange of other particles could lead to similar or alternate Lorentz structures, and it is not possible to distinguish between the exchange of a virtual photon or other particle. It is conventional to write the most general four-fermion amplitude, valid for energies below the electroweak scale as (adapted from Ref. [90])

$$\mathcal{M}_{\mu\to e} = G_\mu \sum_{n,a,q} a_{a,q}^{(n)} \, \bar{e} \Gamma^n P_a \mu \, \bar{q} \Gamma_n q \,, \tag{32}$$

where P_a $(a = L, R)$ denote the left and right-handed projectors and Γ^n denotes 1, γ_5, γ^μ, $\gamma^\mu\gamma_5$, and $\sigma_{\mu\nu}$. If any of the coefficients $a_{a,q}^{(n)}$ are generated by physics at a scale $\Lambda > v$, then their effects would be encoded in the SMEFT Lagrangian (13). For scenarios in which the leading CLFV operators occur at $d = 6$, the $a_{a,q}^{(n)}$ will scale as $(v/\Lambda)^2$. The corresponding decay and conversion rates will then scale as $(v/\Lambda)^4$. Note that the scalar and time component of the vector interactions are coherent over the nucleus, essentially counting the number of quarks. Consequently, these interactions typically yield the greatest sensitivities to high BSM mass scales.

It is sometimes convenient to compare the relative sensitivities of the decay and conversion processes using the following simplified effective Lagrangian [76]:

$$\begin{aligned} \mathcal{L}_{\mathrm{eff}}^{\mathrm{CLFV}} = &\frac{m_\mu}{(\kappa+1)\Lambda^2} \, \bar{\mu}_R \sigma_{\mu\nu} e_L \, F^{\mu\nu} \\ &+ \frac{\kappa}{(\kappa+1)\Lambda^2} \, \bar{\mu}\gamma_\mu e \sum_q \bar{q}\gamma^\mu q + \mathrm{h.c.}\,. \end{aligned} \tag{33}$$

Note that one may replace the second term in Eq. (33) by any one of the other four-fermion interactions given in Eq. (32). An analogous expression applies to the process $\mu \to 3e$ when replacing the sum over quarks by the corresponding electron bilinear. A comparison of the present and prospective sensitivities for various muon CLFV searches in this framework is shown in Figure 3.

Stringent limits have been also set on the LFV decay modes of the τ lepton [91]. As shown in Figure 4, the large τ data samples collected at the B factories have made possible to reach a 10^{-8} sensitivity for many of its leptonic ($\tau \to \ell\gamma$, $\tau \to \ell'\ell^+\ell^-$) and semileptonic ($\tau \to \ell P^0$, $\tau \to \ell V^0$, $\tau \to \ell P^0 P^0$, $\tau \to \ell P^+ P'^-$) neutrinoless LFV decays, and BELLE-II is expected to push these limits beyond the 10^{-9} level [92]. Being a third generation lepton,

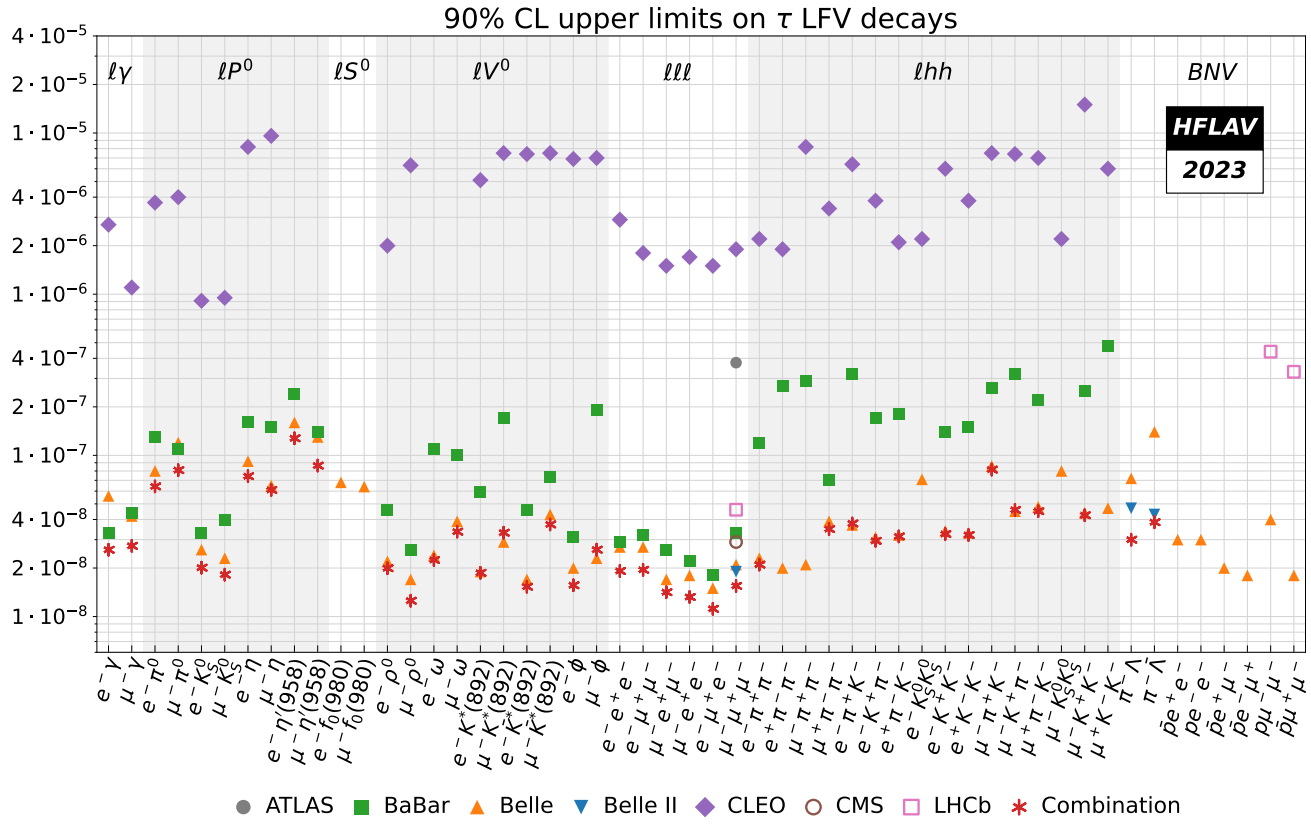

Figure 4: Current experimental limits on neutrinoless LFV τ decays [88]

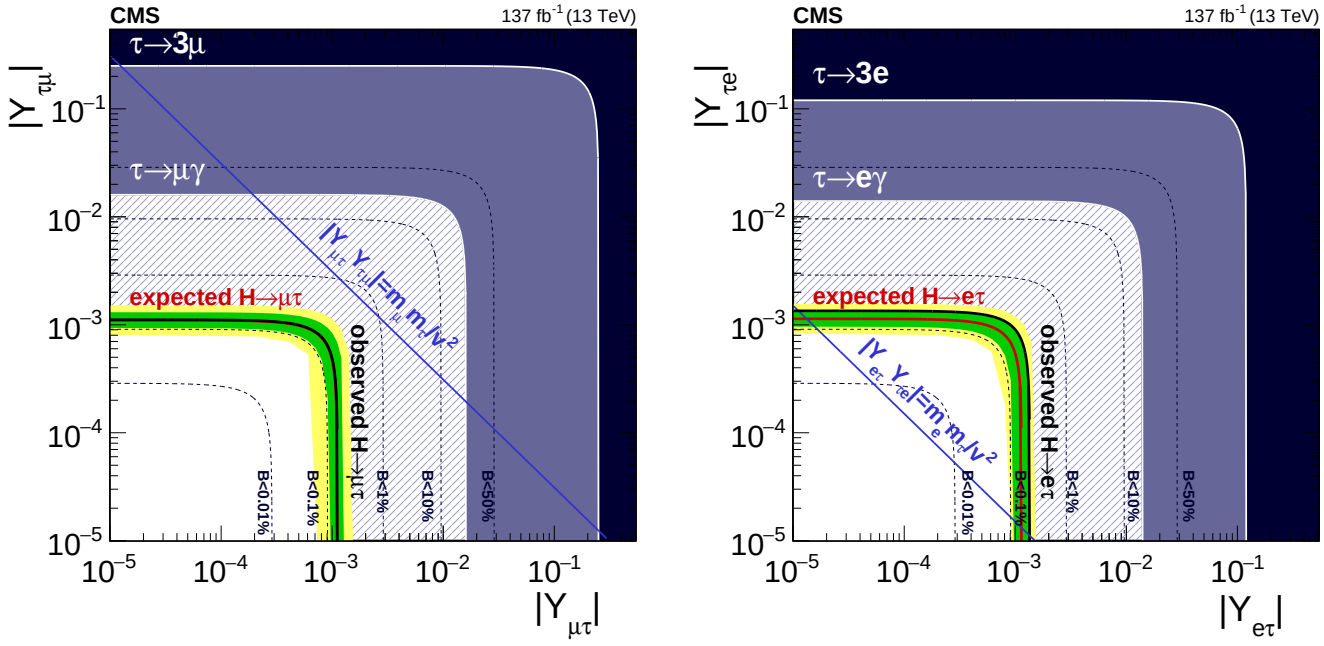

Figure 5: Current limits on the Higgs LFV τ Yukawas from direct $H^0 \to \ell^\pm \tau^\mp$ decays ($\ell = e, \mu$), and indirect constraints from τ decays [89].

the τ could be more sensitive to heavier new-physics scales, which makes his LFV decays particularly interesting. Compared to the muon, the τ decay amplitudes could be enhanced by a chirality ratio $(m_\tau/m_\mu)^2 \sim 280$ and/or by lepton-mixing factors such as $|U_{\tau 3}/U_{e3}|^2 \sim 20$, but the exact relation is model dependent. In any case, the τ LFV decays provide a rich data set that is very complementary to the μ bounds. If LFV is finally observed, the correlations between μ and τ data, and among different LFV τ decays will allow to probe the underlying mechanism of lepton flavor breaking.

Interesting limits on LFV are also obtained in meson decays. The best bounds come from kaon experiments, e.g., $\mathrm{Br}(K_L^0 \to e^\pm \mu^\mp) < 4.7 \times 10^{-12}$ [93], $\mathrm{Br}(K^+ \to \pi^+ \mu^+ e^-) < 1.3 \times 10^{-11}$ [94]. Quite strong limits have also been set in decays of B and D

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

mesons, the best upper bounds being $\mathrm{Br}(B^0 \to e^\pm\mu^\mp) < 1.0 \times 10^{-9}$ [95] and $\mathrm{Br}(D^0 \to e^\pm\mu^\mp) < 1.3 \times 10^{-8}$ [96].

The LFV decays of the Z boson were probed at LEP at the 10^{-5} to 10^{-6} level. Stronger (95% C.L.) limits have been set recently at the LHC by the ATLAS and CMS collaborations [97, 98]:

$$\mathrm{Br}(Z \to e^\pm\mu^\mp) < 1.9 \times 10^{-7}\,, \qquad \mathrm{Br}(Z \to e^\pm\tau^\mp) < 5.0 \times 10^{-6}\,, \qquad \mathrm{Br}(Z \to \mu^\pm\tau^\mp) < 6.5 \times 10^{-6}\,. \tag{34}$$

LHC is now testing LFV in Higgs decays, within the available statistics. From the current (95% C.L.) experimental upper bounds [89, 99–103],

$$\mathrm{Br}(H^0 \to e^\pm\mu^\mp) < 4.4 \times 10^{-5}\,, \qquad \mathrm{Br}(H^0 \to e^\pm\tau^\mp) < 0.20\%\,, \qquad \mathrm{Br}(H^0 \to \mu^\pm\tau^\mp) < 0.15\%\,, \tag{35}$$

one can derive direct limits on the LFV Yukawa couplings of the Higgs boson,

$$\mathcal{L}_Y = -H^0 \sum_{i\neq j} \left(Y_{\ell_i\ell_j}\ \bar{\ell}^i_L \ell^j_R + \mathrm{h.c.}\right)\,. \tag{36}$$

From $H^0 \to e^\pm\mu^\mp$, one obtains $\sqrt{Y^2_{\mu e} + Y^2_{e\mu}} < 1.9 \times 10^{-4}$, which is not yet competitive with the indirect limit set by $\mu \to e\gamma$ through a (one-loop) virtual Higgs exchange:

$$\sqrt{Y^2_{\mu e} + Y^2_{e\mu}} < 3.6 \times 10^{-6}\,. \tag{37}$$

However, the LHC data provide at present the strongest bounds on the LFV τ Yukawas [89, 102]:

$$\sqrt{Y^2_{e\tau} + Y^2_{\tau e}} < 1.3 \times 10^{-3}\,, \qquad \sqrt{Y^2_{\mu\tau} + Y^2_{\tau\mu}} < 1.11 \times 10^{-3}\,. \tag{38}$$

Figure 5 compares the Higgs exclusion limits on the τ Yukawas with the current indirect constraints from LFV τ decays.

6 Baryon and Lepton Number

The transitions discussed in the previous section preserve the total lepton number $L = L_e + L_\mu + L_\tau$. In the SM, conservation of $B - L$ is an accidental symmetry of the Lagrangian. At the classical level, $B + L$ is also conserved, though it is violated at the loop level by the anomaly. The latter is a topological effect that is highly suppressed at zero temperature and, moreover, does not contribute to the processes discussed in the review. Going beyond renormalizable interactions, there exists a tower of operators in the SMEFT Lagrangian (13), containing only SM fields, that break one or both of these symmetries. We briefly review these possibilities in turn.

Lepton Number

The lowest-dimension operator containing only SM fields that breaks baryon or lepton number is the $d = 5$, lepton-number-violating (LNV) 'Weinberg' neutrino-mass operator [67]:

$$\mathcal{L}^{\mathrm{LNV}} = \frac{y}{\Lambda}\,\bar{L}^C H H^T L\,. \tag{39}$$

When the neutral component of the Higgs field obtains its vacuum expectation value, this $\Delta L = 2$ interaction yields a Majorana mass for the light, active neutrinos. The most comprehensive approach for probing this effect is the search for neutrinoless double-beta decay ($0\nu\beta\beta$) of atomic nuclei, $(Z, A) \to (Z + 2, A) + e^- + e^-$ [104, 105] (see the review on neutrinoless double-β decay). The detection of a non-zero $0\nu\beta\beta$ signal could represent a spectacular evidence of Majorana neutrinos. The current best limit, $\tau_{1/2} > 3.8 \times 10^{26}$ yr, has been obtained by the KamLAND-Zen experiment with ^{136}Xe [106].

Theoretically, the interaction (39) can arise from BSM interactions in the well-known see-saw mechanism for neutrino mass (for a review, see [107]). In this context, the conventional choice for the scale Λ is of order the GUT scale, yielding light neutrino masses of order eV and below when the couplings y are of order the charged elementary fermion Yukawa couplings. BSM theories may also give rise to LNV observables in other contexts. In these scenarios, if the LNV scale is of order 1 TeV, one may observe signatures of LNV not only in $0\nu\beta\beta$ but also in collider searches for final states containing same sign dileptons. Searches for same sign dileptons plus a di-jet pair at the LHC have placed constraints on TeV-scale LNV [108, 109] that in some cases complement those obtained from $0\nu\beta\beta$.

Stringent constraints on violations of L have been also set in $\mu^- \to e^+$ conversion in muonic atoms, the best limit being $\sigma(\mu^-\mathrm{Ti} \to e^+\mathrm{Ca})/\sigma(\mu^-\mathrm{Ti} \to \mathrm{all}) < 3.6 \times 10^{-11}$ [110], and at the flavor factories through L-violating decays of the τ lepton and K, D and B mesons. Some representative examples are $\mathrm{Br}(\tau^- \to e^+\pi^-\pi^-) < 2.0 \times 10^{-8}$ [111], $\mathrm{Br}(K^+ \to \pi^-\mu^+\mu^+) < 4.2 \times 10^{-11}$ [112], $\mathrm{Br}(D^+ \to \pi^-\mu^+\mu^+) < 1.4 \times 10^{-8}$ [113] and $\mathrm{Br}(B^- \to \pi^+\mu^-\mu^-) < 4.0 \times 10^{-9}$ (95% CL) [114]. All these $|\Delta L| = 2$ processes could be mediated by a massive Majorana neutrino. They provide useful bounds on the effective Majorana neutrino mass matrix $m_{\ell\ell'} \sim \sum_i U_{\ell i} U_{\ell' i} m_{\nu_i}$ [115], although not as strong as the $0\nu\beta\beta$ constraint on m_{ee}.

Baryon Number

Grand Unified Theories (GUTs) combine leptons and quarks in the same symmetry multiplets and, therefore, predict the violation of the baryon and lepton quantum numbers. Many experiments have searched for B-violating transitions, but no positive signal has been identified so far. Proton decay would be the most relevant violation of B, as it would imply the unstability of matter. The current lower bound on the proton lifetime is 9×10^{29} yr [116]. Stronger limits have been set for particular decay modes, such as $\tau(p \to e^+\pi^0) > 2.4 \times 10^{34}$ yr [117]. For a discussion of proton decay in the context of GUTs, see the review on Grand Unified Theories.

Another spectacular signal would be neutron-antineutron oscillations. Searches have been performed for quasi-free n–$\bar{n}$ oscillations and for $n\bar{n}$ annihilation products in a nucleus. The latter would arise when the $\bar{n}$ produced through oscillations annihilates with another neutron in the nuclear medium. The corresponding best limits, expressed in terms of the free and bound oscillation times, $\tau_{n\bar{n}}$ and τ_m, respectively, are:

$$\tau_{n\bar{n}} > 0.86 \times 10^8 \text{ s} \quad [118], \tag{40a}$$

$$\tau_m > 3.6 \times 10^{32} \text{ yr} \quad [119] \tag{40b}$$

From the latter, one may infer a bound $\tau_{n\bar{n}} > 4.7 \times 10^8$ s, as discussed below. See Ref. [120] for a recent review.

The theoretical interpretation of these bounds starts with an assumed, effective Hamiltonian for the free (anti-)neutron, $\mathcal{H}_{\mathrm{eff}}$ that contains a B-violating part, yielding matrix elements

$$\langle n|\mathcal{H}_{\mathrm{eff}}|n\rangle = \langle \bar{n}|\mathcal{H}_{\mathrm{eff}}|\bar{n}\rangle = m - i\frac{\lambda}{2}\,, \tag{41a}$$

$$\langle n|\mathcal{H}_{\mathrm{eff}}|\bar{n}\rangle = \langle \bar{n}|\mathcal{H}_{\mathrm{eff}}|n\rangle \equiv \delta m\,, \tag{41b}$$

where CPT is assumed to be conserved, the neutron lifetime $\tau_n = 1/\lambda$ and $\tau_{n\bar{n}} = 1/|\delta m|$. The rate for a neutron to oscillate into an antineutron after a time t is given by

$$\mathcal{P}_{n\bar{n}}(t) = \sin^2\left(\frac{t}{\tau_{n\bar{n}}}\right) e^{-\lambda t}\,. \tag{42}$$

For $t << \tau_n << \tau_{n\bar{n}}$, one has

$$\mathcal{P}_{n\bar{n}}(t) \to (t/\tau_{n\bar{n}})^2\,. \tag{43}$$

In realistic experiments, there exist effects, such as background magnetic fields, that split the energies of the neutron and antineutron. One must ensure that the observation time is sufficiently short so that these effects do not overwhelm the small B-violating term δm and that Eq. (42) applies.

In nuclei, the interactions of neutrons and antineutrons with the surrounding medium are sufficiently distinct that one must take the corresponding matter potentials into account. In particular, the matrix elements in Eq. (41a) become

$$\langle n|\mathcal{H}_{\mathrm{eff}}|n\rangle = m + V_n\,, \qquad \langle \bar{n}|\mathcal{H}_{\mathrm{eff}}|\bar{n}\rangle = m + V_{\bar{n}}\,, \tag{44}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access

with V_n being essentially real ($V_n \equiv V_{nR}$) and $V_{\bar{n}} = V_{\bar{n}R} - iV_{\bar{n}I}$. The imaginary part $V_{\bar{n}I}$ characterizes the annihilation of the antineutron with bound nucleons into secondary hadrons. The rate for a bound neutron to disappear is given by

$$\Gamma_m = \frac{2(\delta m)^2 |V_{\bar{n}I}|}{(V_{nR} - V_{\bar{n}R})^2 + V_{\bar{n}I}^2} \equiv \left(R\,\tau_{n\bar{n}}^2\right)^{-1} . \tag{45}$$

For the nuclei of experimental interest, nuclear theory computations yield $R \sim 10^{23} s^{-1}$. Null results of bound n-$\bar{n}$ oscillation searches thus allow one to infer a bound on $\tau_{n\bar{n}}$ via Eq. (45).

From an elementary particle standpoint, n-$\bar{n}$ oscillations involve the conversion of three quarks into three antiquarks (and vice-versa). The lowest-dimension operators mediating such process arise at dimension nine in the SMEFT:

$$\mathcal{L}_{n\text{-}\bar{n}} = \frac{1}{\Lambda^5} \sum_j \alpha_j^{(9)}\, \mathcal{O}_j^{\rm BNV} . \tag{46}$$

Consequently, one expects

$$\delta m \sim \alpha_j^{(9)}\, \frac{\Lambda_{\rm HAD}^6}{\Lambda^5} , \tag{47}$$

where $\Lambda_{\rm HAD}$ is a hadronic scale set by the n-$\bar{n}$ matrix elements in Eq. (41b). Taking $\Lambda_{\rm HAD}$ to be of order the QCD scale and using the present bounds on $\tau_{n\bar{n}}$ yields a lower bound on the B-violating mass scale of ~ 100 TeV.

The search for B-violating decays of short-lived particles such as Z bosons, τ leptons and B mesons provides also relevant constraints. The best limits are $\mathrm{Br}(Z \to pe, p\mu) < 1.8 \times 10^{-6}$ (95% C.L.) [121], $\mathrm{Br}(\tau^- \to \bar{p}\mu^-\mu^+) < 1.8 \times 10^{-8}$ [122] and $\mathrm{Br}(B^0 \to p\mu^-) < 2.6 \times 10^{-9}$ [123]

7 Quark flavors

While strong and electromagnetic forces preserve the quark flavor, the charged-current weak interactions generate transitions among the different quark species (see the review on the CKM quark-mixing matrix). Since the SM flavor-changing mechanism is associated with the $W^\pm$ fermionic vertices, the tree-level transitions satisfy a $\Delta F = \Delta Q$ rule where ΔQ denotes the change in charge of the relevant hadrons. Remember that the flavor quantum number F is defined to be $+1$ for positively charged quarks ($F = U, C, T$) and -1 for quarks with negative charges ($F = D, S, B$). The strongest tests on this conservation law have been obtained in kaon decays such as $\mathrm{Br}(K^+ \to \pi^+\pi^+ e^- \bar{\nu}_e) < 1.3 \times 10^{-8}$ [124], and $(\mathrm{Re}\, x, \mathrm{Im}\, x) = (-0.002 \pm 0.006, 0.0012 \pm 0.0021)$ [125,126] where $x \equiv \mathcal{M}(\overline{K}^0 \to \pi^-\ell^+\nu)/\mathcal{M}(K^0 \to \pi^-\ell^+\nu)$.

The $\Delta F = \Delta Q$ rule can be violated through quantum loop contributions giving rise to flavor-changing neutral-current transitions (FCNCs). Owing to the GIM mechanism, processes of this type are very suppressed in the SM, which makes them a superb tool in the search for new physics associated with the flavor dynamics. Within the SM itself, these transitions are also sensitive to the heavy-quark mass scales and have played a crucial role identifying the size of the charm (K^0–$\overline{K}^0$ mixing) and top (B^0–$\overline{B}^0$ mixing) masses before the discovery of those quarks. In addition to the well-established $\Delta F = 2$ mixings in neutral K and B mesons, $\Delta M_{K^0} \equiv M_{K_L^0} - M_{K_S^0} = (0.5293 \pm 0.0009) \times 10^{10}\ \mathrm{s}^{-1}$, $\Delta M_{B^0} \equiv M_{B_H^0} - M_{B_L^0} = (0.5068 \pm 0.0019) \times 10^{12}\ \mathrm{s}^{-1}$ and $\Delta M_{B_s^0} \equiv M_{B_{sH}^0} - M_{B_{sL}^0} = (17.766 \pm 0.006) \times 10^{12}\ \mathrm{s}^{-1}$, the mixing of the D^0 meson and its antiparticle has been recently observed with a significance of more than seven standard deviations [127], showing that there is a nonzero mass difference between the two neutral charm-meson eigenstates, of the expected size:

$$M_{D_H^0} - M_{D_L^0} = (0.997 \pm 0.116) \times 10^{10}\ \mathrm{s}^{-1}. \tag{48}$$

The SM prediction of the D_H^0–D_L^0 mass difference is dominated by long-distance physics, because it involves virtual loops with down-type light quarks, and has unfortunately quite large uncertainties [128].

The FCNC kaon decays into lepton-antilepton pairs put stringent constraints on new flavor-changing interactions. The measured $K_L^0 \to \mu^+\mu^-$ rate, $\mathrm{Br}(K_L^0 \to \mu^+\mu^-) = (6.84 \pm 0.11) \times 10^{-9}$, is completely dominated by the known 2γ absorptive contribution, leaving very little room for new-physics, and $\mathrm{Br}(K_L^0 \to e^+e^-) = (9^{+6}_{-4}) \times 10^{-12}$ [129] (the tiniest branching ratio ever measured) also agrees with the SM expectation [130]. The experimental K_S^0 upper bounds on the electron, $\mathrm{Br}(K_S^0 \to e^+e^-) < 9 \times 10^{-9}$ [131], and muon, $\mathrm{Br}(K_S^0 \to \mu^+\mu^-) < 2.1 \times 10^{-10}$ [132], modes are still five and two orders of magnitude, respectively, larger than their SM predictions [130]. Another very clean test of FCNCs is provided by the decay $K^+ \to \pi^+\nu\bar{\nu}$. The CERN NA62 experiment has already collected 51 events, with a significance above 5σ, providing the first observation of this decay [133]. This leads to $\mathrm{Br}(K^+ \to \pi^+\nu\bar{\nu}) = (1.30^{\,+\,0.33}_{-\,0.30}) \times 10^{-10}$, in agreement with the predicted SM branching fraction of $(7.73 \pm 0.61) \times 10^{-11}$ [134,135]. Even more interesting is the CP-violating neutral mode $K_L^0 \to \pi^0\nu\bar{\nu}$, expected at a rate of $(2.59 \pm 0.29) \times 10^{-11}$ [134,135] that is still far away from the current upper bound of 2.2×10^{-9} [136]. The KOTO experiment at KEK is expected to substantially increase the sensitivity to this mode.

The strongest bound on FCNC transitions in charm decays is $\mathrm{Br}(D^0 \to \mu^+\mu^-) < 2.1 \times 10^{-9}$ [137], while in B decays the LHC experiments have recently reached the SM sensitivity: $\mathrm{Br}(B_d^0 \to \mu^+\mu^-) < 1.5 \times 10^{-10}$ [138] and $\mathrm{Br}(B_s^0 \to \mu^+\mu^-) = (3.34 \pm 0.27) \times 10^{-9}$.

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

[a] Forbidden by angular momentum conservation.

[b] C parity forbids this to occur as a single-photon process.

[c] See the Particle Listings for the (complicated) definition of this quantity.

[d] Time-reversal invariance requires this to be 0° or 180°.

[e] This coefficient is zero if time invariance is not violated.

[f] Neglecting photon channels. See, *e.g.*, A. Pais and S.B. Treiman, Phys. Rev. **D12**, 2744 (1975).

[g] Allowed by higher-order electroweak interactions.

[h] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

[i] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.

[j] $\text{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.

[k] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K_L^0 \to \pi^+\pi^-\gamma$(DE).

[l] Derived from measured values of ϕ_{+-}, ϕ_{00}, $|\eta|$, $|m_{K_L^0} - m_{K_S^0}|$, and $\tau_{K_S^0}$, as described in the introduction to "Tests of Conservation Laws."

[n] The $|m_p - m_{\overline{p}}|/m_p$ and $|q_p + q_{\overline{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\overline{p}}/m_{\overline{p}}|/(q_p/m_p)$.

[o] The value is for the sum of the charge states or particle/antiparticle states indicated.

[p] A test of additive vs. multiplicative lepton family number conservation.

[q] Derived from an analysis of neutrino-oscillation experiments.

[r] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.

[s] This is the best limit for the mode $e^- \to \nu\gamma$.

[t] The limit is from neutrality-of-matter experiments; it assumes $q_n = q_p + q_e$. See also the charge of the neutron.

[u] See the K_S^0 Particle Listings for the energy limits used in this measurement.

[v] See the K_L^0 Particle Listings for the energy limits used in this measurement.

[x] An ℓ indicates an e or a μ mode, not a sum over these modes.

[y] Here S and P are the hypothetical scalar and pseudoscalar particles with masses of 2.5 GeV/c^2 and 214.3 MeV/c^2, respectively.

[z] This limit is for $\Gamma(t \to Zq)/\Gamma(t \to Wb)$.

Unless otherwise stated, limits are given at the 90% confidence level, while errors are given as ±1 standard deviation.

1. Physical Constants

Table 1.1: Revised May 2026 by D. Robinson (LBNL) and P.A. Zyla (LBNL). Mainly from "CODATA recommended values of the fundamental physical constants: 2022," P.J. Mohr, D.B. Newell, B.N. Taylor, and E. Tiesinga [1]. The electron charge magnitude e, and the Planck, Boltzmann, and Avogadro constants h, k, and N_A, now join c as having defined values; the free-space permittivity and permeability constants ϵ_0 and μ_0 are no longer exact. These changes affect practically everything else in the Table. Figures in parentheses after the values are the 1-standard-deviation uncertainties in the last digits; the fractional uncertainties in parts per 10^9 (ppb) are in the last column. The full 2022 CODATA Committee on Data for Science and Technology set of constants are found at `https://physics.nist.gov/Constants`. The last set of constants (beginning with the Fermi coupling constant) comes from the Particle Data Group. See also "The International System of Units (SI)," 9th ed. (2019) of the International Bureau of Weights and Measures (BIPM), `https://www.bipm.org/utils/common/pdf/si-brochure/SI-Brochure-9-EN.pdf`.

§CODATA recommends that the unit be J/Hz to stress that in $h = E/\nu$ the frequency ν is in cycles/sec (Hz), not radians/sec.

*These are calculated from exact values and are exact to the number of places given (*i.e.* no rounding).

***While e is exact in SI units, in natural units $e = \sqrt{4\pi\alpha}$ is a measured quantity.

**The molar mass of ^{12}C is 12.000 000 0126(37) g.

†CODATA recommended value at $Q^2 = 0$. At $Q^2 \approx m_W^2$ the value is $\sim 1/128$. ‡‡

‡Absolute laboratory measurements of G_N have been made only on scales of about 1 cm to 1 m.

‡‡See the discussion in "Electroweak model and constraints on new physics" review.

††Derived from $\sin^2\theta$ for the effective angle $\bar{s}^2_\ell = 0.23154(6)$.

¶See the "Mass and width of the W boson" and "Electroweak model and constraints on new physics" reviews.

‖See the "Z boson" and "Electroweak model and constraints on new physics" reviews.

§§The ratio $r_{\mu_0} \equiv \sqrt{\mu_0/(4\pi\times10^{-7}\text{ N A}^{-2})} = 0.999\ 999\ 999\ 93(8)$. Prior to the 2019 revision of the SI unit system, $\mu_0 \equiv 4\pi\times10^{-7}$ N A^{-2}.

2. Astrophysical Constants and Parameters

Table 2.1: Revised August 2025 by D.E. Groom (LBNL) and D. Scott (U. of British Columbia). The figures in parentheses after some values give the 1-σ uncertainties in the last digit(s). Physical constants are from Ref. [1]. While every effort has been made to obtain the most accurate current values of the listed quantities, this table does not represent a critical review or adjustment of the constants, and is not intended as a primary reference. The values and uncertainties for the cosmological parameters depend on the exact data sets, priors, and basis parameters used in the fit. Many of the derived parameters reported in this table have non-Gaussian likelihoods and parameters may be highly correlated, so care must be taken in propagating errors. Unless otherwise specified, cosmological parameters are derived from a 6-parameter ΛCDM cosmology fit to *Planck* cosmic microwave background 2018 temperature (TT) + polarization (TE,EE+lowE) + lensing data [2]. For more information see Ref. [3] and the original papers.

Quantity	Symbol, equation	Value	Reference, footnote
Newtonian constant of gravitation	G_N	$6.674\,30(15) \times 10^{-11}\ \mathrm{m^3\,kg^{-1}\,s^{-2}}$	[1]
Planck mass	$M_P = \sqrt{\hbar c/G_N}$	$1.220\,890(14) \times 10^{19}\ \mathrm{GeV}/c^2 = 2.176\,434(24) \times 10^{-8}\ \mathrm{kg}$	[1]
Planck length	$l_P = \sqrt{\hbar G_N/c^3}$	$1.616\,255(18) \times 10^{-35}\ \mathrm{m}$	[1]
tropical year (equinox to equinox, 2020)	yr	$31\,556\,925.1\ \mathrm{s} = 365.242\,189\ \mathrm{days}$	[4]
sidereal year (period of Earth around Sun relative to stars)		$31\,558\,149.8\ \mathrm{s} \approx \pi \times 10^7\ \mathrm{s}$	[4]
mean sidereal day (Earth rotation period relative to stars)		$23^{\mathrm{h}}\ 56^{\mathrm{m}}\ 04\overset{\mathrm{s}}{.}090\,53$	[4]
astronomical unit	au	$149\,597\,870\,700\ \mathrm{m}$	exact [5]
parsec (1 au/1 arcsec)	pc	$3.085\,677\,581\,49\ldots \times 10^{16}\ \mathrm{m} = 3.261\,56\ldots\ \mathrm{ly}$	exact [6]
light year	ly	$0.306\,601\ldots\ \mathrm{pc} = 0.946\,073\ldots \times 10^{16}\ \mathrm{m}$	[7]
solid angle	deg^2	$(\pi/180)^2\ \mathrm{sr} = 3.046\,17\ldots \times 10^{-4}\ \mathrm{sr}$	[8]
Schwarzschild radius of the Sun	$2(\mathcal{G}_N\mathcal{M})_\odot/c^2$	$2.953\,250\,0\ldots\ \mathrm{km}$	exact [9, 10]
Solar mass	$M_\odot$	$1.988\,41(4) \times 10^{30}\ \mathrm{kg}$	[11]
nominal Solar equatorial radius	$\mathcal{R}_\odot$	$6.957 \times 10^8\ \mathrm{m}$	exact [10]
nominal Solar constant	$\mathcal{S}_\odot$	$1361\ \mathrm{W\,m^{-2}}$	exact [10, 12]
nominal Solar photosphere temperature	$\mathcal{T}_\odot$	$5772\ \mathrm{K}$	exact [10]
nominal Solar luminosity	$\mathcal{L}_\odot$	$3.828 \times 10^{26}\ \mathrm{W}$	exact [10, 13]
Schwarzschild radius of the Earth	$2(\mathcal{G}_N\mathcal{M})_\oplus/c^2$	$8.870\,055\ldots\ \mathrm{mm}$	exact [9, 10]
Earth mass	$M_\oplus$	$5.972\,17(13) \times 10^{24}\ \mathrm{kg}$	[11]
nominal Earth equatorial radius	$\mathcal{R}_\oplus$	$6.3781 \times 10^6\ \mathrm{m}$	exact [10]
Chandrasekhar mass	M_{Ch}	$3.097\,972\,\mu^{-2}\,M_P^3/m_H^2 = 1.433\,77(6)\,(\mu/2)^{-2}\,M_\odot$	[14, 15]
Eddington luminosity	L_{Ed}	$1.257\,065\,2\ldots \times 10^{31}\,(M/M_\odot)\ \mathrm{W}$ $= 3.283\,869\,3\ldots \times 10^4\,(M/M_\odot)\,\mathcal{L}_\odot$	[16, 17]
jansky (flux density)	Jy	$10^{-26}\ \mathrm{W\,m^{-2}\,Hz^{-1}}$	definition
luminosity conversion	f_0	$3.0128 \times 10^{28} \times 10^{-0.4\ M_{\mathrm{Bol}}}\ \mathrm{W}$ (M_{Bol} = absolute bolometric magnitude = bolometric magnitude at 10 pc)	exact [18]
flux conversion	$\mathcal{F}$	$2.518\,021\,002 \times 10^{-8} \times 10^{-0.4\ m_{\mathrm{Bol}}}\ \mathrm{W\,m^{-2}}$ (m_{Bol} = apparent bolometric magnitude)	exact [18]
ABsolute monochromatic magnitude	AB	$-2.5\ \log_{10} f_\nu - 56.10$ (for f_ν in $\mathrm{W\,m^{-2}\,Hz^{-1}}$) $= -2.5\ \log_{10} f_\nu + 8.90$ (for f_ν in Jy)	[19]
Solar distance from Galactic center	R_0	$8.275 \pm 0.009(\mathrm{stat.}) \pm 0.033(\mathrm{sys.})\ \mathrm{kpc}$	[20]
local circular angular velocity	Θ_0/R_0	$28.2(10)\ \mathrm{km\,s^{-1}\,kpc^{-1}}$	[21]
circular velocity at R_0	v_0 or Θ_0	$233.4 \pm 0.3(\mathrm{stat.}) \pm 8.0(\mathrm{sys.})\ \mathrm{km\,s^{-1}}$	[22]
local escape velocity from the Galaxy	v_{esc}	$477\ \mathrm{km\,s^{-1}} < v_{\mathrm{esc}} < 502\ \mathrm{km\,s^{-1}}$ (68%)	[23]
local disk density	ρ_{disk}	$6.6(9) \times 10^{-24}\ \mathrm{g\,cm^{-3}} = 3.7(5)\ \mathrm{GeV}/c^2\ \mathrm{cm^{-3}}$	[24]
local dark matter density	ρ_χ	canonical value $0.3\ \mathrm{GeV}/c^2\ \mathrm{cm^{-3}}$ within factor 2–3	[25]
present-day CMB temperature	T_0	$2.7255(6)\ \mathrm{K}$	[26, 27]
present-day CMB dipole amplitude	d	$3.3621(10)\ \mathrm{mK}$	[26, 28]
Solar velocity with respect to CMB	$v_\odot$	$369.82(11)\ \mathrm{km\,s^{-1}}$ towards $(l, b) = (264.021(11)^\circ,\ 48.253(5)^\circ)$	[28]
Local Group velocity with respect to CMB	v_{LG}	$620(15)\ \mathrm{km\,s^{-1}}$ towards $(l, b) = (271.9(20)^\circ, 29.6(14)^\circ)$	[28]
number density of CMB photons	n_γ	$410.73(27)\,(T/2.7255\ \mathrm{K})^3\ \mathrm{cm^{-3}}$	[29]
density of CMB photons	ρ_γ	$4.645(4)\,(T/2.7255\ \mathrm{K})^4 \times 10^{-34}\ \mathrm{g\,cm^{-3}} \approx 0.260\ \mathrm{eV\,cm^{-3}}$	[29]

3. International System of Units (SI)

See D.B. Newell and E. Tiesinga, ed. (2019), "The International System of Units (SI)" (National Institute of Standards and Technology, Gaithersburg, MD), NIST Special Publication **330**, 2019 edition, https://doi.org/10.6028/NIST.SP.330-2019; and A. Thompson and B.N. Taylor (2008), "Guide for the Use of the International System of Units (SI)" (National Institute of Standards and Technology, Gaithersburg, MD), NIST Special Publication **811**, 2008 edition, https://doi.org/10.6028/NIST.SP.811e2008.

SI prefixes

10^{24}	yotta	(Y)
10^{21}	zetta	(Z)
10^{18}	exa	(E)
10^{15}	peta	(P)
10^{12}	tera	(T)
10^{9}	giga	(G)
10^{6}	mega	(M)
10^{3}	kilo	(k)
10^{2}	hecto	(h)
10	deca	(da)
10^{-1}	deci	(d)
10^{-2}	centi	(c)
10^{-3}	milli	(m)
10^{-6}	micro	(μ)
10^{-9}	nano	(n)
10^{-12}	pico	(p)
10^{-15}	femto	(f)
10^{-18}	atto	(a)
10^{-21}	zepto	(z)
10^{-24}	yocto	(y)

Physical quantity	Name of unit	Symbol
Base units		
length	meter	m
mass	kilogram	kg
time	second	s
electric current	ampere	A
thermodynamic temperature	kelvin	K
amount of substance	mole	mol
luminous intensity	candela	cd
Derived units with special names		
plane angle	radian	rad
solid angle	steradian	sr
frequency	hertz	Hz
energy	joule	J
force	newton	N
pressure	pascal	Pa
power	watt	W
electric charge	coulomb	C
electric potential	volt	V
electric resistance	ohm	Ω
electric conductance	siemens	S
electric capacitance	farad	F
magnetic flux	weber	Wb
inductance	henry	H
magnetic flux density	tesla	T
luminous flux	lumen	lm
illuminance	lux	lx
celsius temperature	degree celsius	°C
activity (of a radioactive source)*	becquerel	Bq
absorbed dose (of ionizing radiation)*	gray	Gy
dose equivalent*	sievert	Sv

Table 4.1. Revised March 2024 by D.E. Groom (LBNL). The atomic number (top left) is the number of protons in the nucleus. The atomic masses (bottom) of stable elements are weighted by isotopic abundances in the Earth's surface. Atomic masses are relative to the mass of ^{12}C, defined to be exactly 12 unified atomic mass units (u). The exceptions are Th, Pa, and U, which have no stable isotopes but do have characteristic terrestrial compositions. Relative isotopic abundances often vary considerably, both in natural and commercial samples; this is reflected in the number of significant figures given for the mass. Masses may be found at `https://physics.nist.gov/cgi-bin/Compositions/stand_alone.pl`. If there is no stable isotope, the atomic mass of the most stable isotope known as of June 2019 is given in parentheses.

IUPAC announced verification of the discoveries of elements 113, 115, 117, and 118 in December 2015. The names were approved November 2016. The 7th period of the periodic table is now complete. Attempts to synthesize elements with $Z > 118$ are under way, but as of March 2024 no discoveries have been announced.

PERIODIC TABLE OF THE ELEMENTS

5. Electronic Structure of the Elements

Table 5.1: Reviewed 2022 by A. Kramida (NIST). The electronic configurations, ground state levels, and ionization energies are from A. Kramida, Yu. Ralchenko, J. Reader, and NIST ASD Team (2024), "NIST Atomic Spectra Database" (ver. 5.12), [Online], Available: `https://physics.nist.gov/asd` [2025, Aug 19]. National Institute of Standards and Technology, Gaithersburg, MD. DOI: `https://doi.org/10.18434/T4W30F`. The electron configuration for, say, iron indicates an argon electronic core (see argon) plus six $3d$ electrons and two $4s$ electrons.

		Element	Electron configuration ($3d^5$ = five $3d$ electrons, *etc.*)	Ground state $^{2S+1}L_J$	Ionization energy (eV)
1	H	Hydrogen	$1s$	$^2S_{1/2}$	13.5984
2	He	Helium	$1s^2$	$^1S_0$	24.5874
3	Li	Lithium	(He) 2s	$^2S_{1/2}$	5.3917
4	Be	Beryllium	(He) $2s^2$	$^1S_0$	9.3227
5	B	Boron	(He) $2s^2$ $2p$	$^2P^\circ_{1/2}$	8.2980
6	C	Carbon	(He) $2s^2$ $2p^2$	$^3P_0$	11.2603
7	N	Nitrogen	(He) $2s^2$ $2p^3$	$^4S^\circ_{3/2}$	14.5341
8	O	Oxygen	(He) $2s^2$ $2p^4$	$^3P_2$	13.6181
9	F	Fluorine	(He) $2s^2$ $2p^5$	$^2P^\circ_{3/2}$	17.4228
10	Ne	Neon	(He) $2s^2$ $2p^6$	$^1S_0$	21.5645
11	Na	Sodium	(Ne) 3s	$^2S_{1/2}$	5.1391
12	Mg	Magnesium	(Ne) $3s^2$	$^1S_0$	7.6462
13	Al	Aluminum	(Ne) $3s^2$ $3p$	$^2P^\circ_{1/2}$	5.9858
14	Si	Silicon	(Ne) $3s^2$ $3p^2$	$^3P_0$	8.1517
15	P	Phosphorus	(Ne) $3s^2$ $3p^3$	$^4S^\circ_{3/2}$	10.4867
16	S	Sulfur	(Ne) $3s^2$ $3p^4$	$^3P_2$	10.3600
17	Cl	Chlorine	(Ne) $3s^2$ $3p^5$	$^2P^\circ_{3/2}$	12.9676
18	Ar	Argon	(Ne) $3s^2$ $3p^6$	$^1S_0$	15.7596
19	K	Potassium	(Ar) $4s$	$^2S_{1/2}$	4.3407
20	Ca	Calcium	(Ar) $4s^2$	$^1S_0$	6.1132
21	Sc	Scandium	(Ar) $3d$ $4s^2$	$^2D_{3/2}$	6.5615
22	Ti	Titanium	(Ar) $3d^2$ $4s^2$	$^3F_2$	6.8281
23	V	Vanadium	(Ar) $3d^3$ $4s^2$	$^4F_{3/2}$	6.7462
24	Cr	Chromium	(Ar) $3d^5$ $4s$	$^7S_3$	6.7665
25	Mn	Manganese	(Ar) $3d^5$ $4s^2$	$^6S_{5/2}$	7.4340
26	Fe	Iron	(Ar) $3d^6$ $4s^2$	$^5D_4$	7.9025
27	Co	Cobalt	(Ar) $3d^7$ $4s^2$	$^4F_{9/2}$	7.8810
28	Ni	Nickel	(Ar) $3d^8$ $4s^2$	$^3F_4$	7.6399
29	Cu	Copper	(Ar) $3d^{10}$ $4s$	$^2S_{1/2}$	7.7264
30	Zn	Zinc	(Ar) $3d^{10}$ $4s^2$	$^1S_0$	9.3942
31	Ga	Gallium	(Ar) $3d^{10}$ $4s^2$ $4p$	$^2P^\circ_{1/2}$	5.9993
32	Ge	Germanium	(Ar) $3d^{10}$ $4s^2$ $4p^2$	$^3P_0$	7.8994
33	As	Arsenic	(Ar) $3d^{10}$ $4s^2$ $4p^3$	$^4S^\circ_{3/2}$	9.7886
34	Se	Selenium	(Ar) $3d^{10}$ $4s^2$ $4p^4$	$^3P_2$	9.7524
35	Br	Bromine	(Ar) $3d^{10}$ $4s^2$ $4p^5$	$^2P^\circ_{3/2}$	11.8138
36	Kr	Krypton	(Ar) $3d^{10}$ $4s^2$ $4p^6$	$^1S_0$	13.9996
37	Rb	Rubidium	(Kr) $5s$	$^2S_{1/2}$	4.1771

6. Atomic and Nuclear Properties of Materials

Table 6.1: Abridged from `https://pdg.lbl.gov/current/AtomicNuclearProperties` by D.E. Groom (2023). See web pages for more detail about entries in this table and for several hundred others. Parentheses in the dE/dx and density columns indicate gases at 20° C and 1 atm. Boiling points are at 1 atm. Refractive indices n are evaluated at the sodium D line blend (589.2 nm); values $\gg$1 in brackets indicate $(n-1)\times 10^6$ for gases at 0° C and 1 atm.

Material	Z	A	$\langle Z/A\rangle$	Nucl.coll. length λ_T {g cm^{-2}}	Nucl.inter. length λ_I {g cm^{-2}}	Rad.len. X_0 {g cm^{-2}}	$dE/dx\|_{\rm min}$ {MeV g^{-1}cm^2}	Density {g cm^{-3}} ({g ℓ^{-1}})	Melting point (K)	Boiling point (K)	Refract. index @ Na D

7.1 Impedances (SI units)

ρ = resistivity at room temperature in $10^{-8}\,\Omega$ m:

~ 1.7 for Cu ~ 5.5 for W
~ 2.4 for Au ~ 73 for SS 304
~ 2.8 for Al ~ 100 for Nichrome
(Al alloys may have double the Al value.)

For alternating currents, instantaneous current I, voltage V, angular frequency ω:

$$V = V_0\, e^{j\omega t} = ZI\ . \tag{7.1}$$

Impedance of self-inductance L: $Z = j\omega L$.

Impedance of capacitance C: $Z = 1/j\omega C$.

Impedance of free space: $Z = \sqrt{\mu_0/\epsilon_0} = 376.7\ \Omega$.

High-frequency surface impedance of a good conductor:

$$Z = \frac{(1+j)\,\rho}{\delta}\ , \quad \text{where } \delta = \text{skin depth}\ ; \tag{7.2}$$

$$\delta = \sqrt{\frac{\rho}{\pi\nu\mu}} \approx \frac{6.6\text{ cm}}{\sqrt{\nu\,(\text{Hz})}} \quad \text{for Cu}\ . \tag{7.3}$$

7.2 Capacitors, inductors, and transmission Lines

The capacitance between two parallel plates of area A spaced by the distance d and enclosing a medium with the dielectric constant ε is

$$C = K\varepsilon A/d\,, \tag{7.4}$$

where the correction factor K depends on the extent of the fringing field. If the dielectric fills the capacitor volume without extending beyond the electrodes. The correction factor $K \approx 0.8$ for capacitors of typical geometry.

The inductance at high frequencies of a straight wire whose length ℓ is much greater than the wire diameter d is

$$L \approx 2.0\left[\frac{\text{nH}}{\text{cm}}\right]\cdot \ell\,\left(\ln\left(\frac{4\ell}{d}\right) - 1\right)\ . \tag{7.5}$$

For very short wires, representative of vias in a printed circuit board, the inductance is

$$L(\text{in nH}) \approx \ell/d\,. \tag{7.6}$$

A transmission line is a pair of conductors with inductance L and capacitance C. The characteristic impedance $Z = \sqrt{L/C}$ and the phase velocity $v_p = 1/\sqrt{LC} = 1/\sqrt{\mu\varepsilon}$, which decreases with the inverse square root of the dielectric constant of the medium. Typical coaxial and ribbon cables have a propagation delay of about 5 ns/m.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

The impedance of a coaxial cable with outer diameter D and inner diameter d is

$$Z = 60\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln \frac{D}{d}\,, \tag{7.7}$$

where the relative dielectric constant $\varepsilon_r = \varepsilon/\varepsilon_0$. A pair of parallel wires of diameter d and spacing $a > 2.5\,d$ has the impedance

$$Z = 120\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln \frac{2a}{d}\,. \tag{7.8}$$

This yields the impedance of a wire at a spacing h above a ground plane,

$$Z = 60\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln \frac{4h}{d}\,. \tag{7.9}$$

A common configuration utilizes a thin rectangular conductor above a ground plane with an intermediate dielectric (microstrip). Detailed calculations for this and other transmission line configurations are given by Gunston [1].

7.3 Synchrotron radiation (CGS units)

For a particle of charge e, velocity $v = \beta c$, and energy $E = \gamma mc^2$, traveling in a circular orbit of radius R, the classical energy loss per revolution δE is

$$\delta E = \frac{4\pi}{3}\,\frac{e^2}{R}\,\beta^3\,\gamma^4\,. \tag{7.10}$$

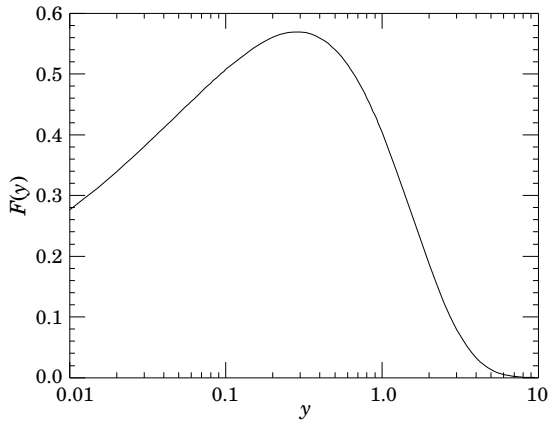

Figure 7.1: The normalized synchrotron radiation spectrum $F(y)$.

For high-energy electrons or positrons ($\beta \approx 1$), this becomes

$$\delta E\ (\text{in MeV}) \approx 0.0885\ [E(\text{in GeV})]^4/R(\text{in m})\,. \tag{7.11}$$

For $\gamma \gg 1$, the energy radiated per revolution into the photon energy interval $d(\hbar\omega)$ is

$$dI = \frac{8\pi}{9}\alpha\,\gamma\,F(\omega/\omega_c)\,d(\hbar\omega)\,, \tag{7.12}$$

where $\alpha = e^2/\hbar c$ is the fine-structure constant and

$$\omega_c = \frac{3\gamma^3 c}{2R} \tag{7.13}$$

is the critical frequency. The normalized function $F(y)$ is

$$F(y) = \frac{9}{8\pi}\sqrt{3}\,y\,\int_y^\infty K_{5/3}\,(x)\ dx\,, \tag{7.14}$$

where $K_{5/3}\,(x)$ is a modified Bessel function of the third kind. For electrons or positrons,

$$\hbar\omega_c\,(\text{in keV}) \approx 2.22\ [E(\text{in GeV})]^3/R(\text{in m})\,. \tag{7.15}$$

For $\gamma \gg 1$ and $\omega \ll \omega_c$,

$$\frac{dI}{d(\hbar\omega)} \approx 3.3\alpha\,(\omega R/c)^{1/3}\ , \tag{7.16}$$

whereas for

$$\gamma \gg 1 \text{ and } \omega \gtrsim 3\omega_c\ ,$$

$$\frac{dI}{d(\hbar\omega)} \approx \sqrt{\frac{3\pi}{2}}\,\alpha\,\gamma\left(\frac{\omega}{\omega_c}\right)^{1/2} e^{-\omega/\omega_c}\left[1 + \frac{55}{72}\frac{\omega_c}{\omega} + \ldots\right]\ . \tag{7.17}$$

The radiation is confined to angles $\lesssim 1/\gamma$ relative to the instantaneous direction of motion. For $\gamma \gg 1$, where Eq. (7.12) applies, the mean number of photons emitted per revolution is

$$N_\gamma = \frac{5\pi}{\sqrt{3}}\alpha\gamma\,, \tag{7.18}$$

and the mean energy per photon is

$$\langle\hbar\omega\rangle = \frac{8}{15\sqrt{3}}\hbar\omega_c\,. \tag{7.19}$$

When $\langle\hbar\omega\rangle \gtrsim \mathrm{O}(E)$, quantum corrections are important [2].[1]

8. Naming Scheme for Hadrons

Revised August 2025 by C. Amsler (Marietta Blau Inst.), E. Pianori (LBNL), D.J. Robinson (LBNL) and R.L. Workman (George Washington U.).

In the 1986 edition [1], the Particle Data Group introduced an extended and systematized naming scheme for mesons and baryons. The extensions were necessary in order to name the new particles containing c or b quarks that were then rapidly being discovered. The 1986 naming scheme has been retained in all subsequent editions, including this one. However, a number of particles were since discovered that could not be accommodated in the 1986 scheme. These include, for example the meson state originally named $Z_c(3900)^+$ (now $T_{c\bar{c}1}(3900)^+$) containing $c\bar{c}$ but with isospin $I = 1$ [2, 3]. Because of such discoveries, in the 2017 edition [4] the 1986 naming scheme was extended to cover $c\bar{c}$ and $b\bar{b}$ states with $I = 1$, including the Z_c and Z_b states.

The further discovery of various exotic hadron states—including in particular tetraquarks and pentaquarks containing $qq\bar{q}\bar{q}$ and $q\bar{q}qqq$ minimal quark content, respectively—has rendered the 2017 extension insufficient. These include, for example: the meson state $T_{cc}(3875)^+$ containing two charm quarks and with unknown isospin [5]; and the baryon state originally named $P_c(4312)^+$ (now $P_{c\bar{c}}(4312)^+$) containing minimal quark content $c\bar{c}uud$ [6]. In this edition, the 2017 scheme is revised and extended to cover all experimentally known states.

The naming scheme as a whole provides a name for each hadron, driven primarily by consideration of its quantum numbers, its minimal quark content—the smallest combination of quarks required to produce a color singlet with the required isospin, parities, strangeness, and open or hidden-heavy flavor—and its mass. While much of the naming scheme has been developed within the context of the naive quark model, a hadron name does *not* designate the internal structure of a state per se: we make no attempt, for example, to distinguish meson states that are "mostly gluonium" from those that are "mostly $q\bar{q}$." (Other reviews within the RPP discuss our current understanding of the nature of various hadron states). While the naming scheme conventions aim to be comprehensive, exceptions to the scheme are occasionally made for historical reasons (e.g. J/ψ, p, or n) or in cases where the spectroscopic identity of a state is considered established (e.g. $\Upsilon(1S)$). Note also the mass label used in particle names is chosen using the best information available when a name is assigned. A more accurate value of a particle mass may become available at a later time. PDG decides on a case-by-case basis whether to revise the mass label, taking into account the updated information.

8.1 Light unflavored, $c\bar{c}$, and $b\bar{b}$ mesons

Unflavored mesons—also referred to as "neutral-flavor" mesons—have zero strangeness and all heavy-flavor quantum numbers are equal to zero. Their minimal quark content is denoted $q\bar{q}$, with the understanding that for $q = u$ or d, such states may carry unit isospin: the "light unflavored" nomenclature is understood to encompass all states furnishing an isospin-1 multiplet that contains a $q\bar{q}$ neutral meson. Mesons composed of $c\bar{c}$ or $b\bar{b}$ are said to have hidden-heavy flavor.

Within the naive quark model, a neutral $q\bar{q}$ bound state has quantum numbers $P = (-1)^{L+1}$ and $C = (-1)^{L+S}$, where $S(= 0, 1)$ and L are the spin and orbital angular momentum of the $q\bar{q}$ system, respectively. The total angular momentum J satisfies $|L-S| \leq J \leq L+S$ as usual. There is thus a selection rule between the angular-momentum state $^{2S+1}L_J$ and the PC configuration, such that

$$PC = -+, \quad +-, \quad --, \quad ++, \tag{8.1}$$

corresponds to

$$^{2S+1}L_J = {}^1(L \text{ even})_L\,, \quad {}^1(L \text{ odd})_L\,, \quad {}^3(L \text{ even})_{|L-1|\leq J\leq L+1}\,, \quad {}^3(L \text{ odd})_{L-1,L,L+1}\,. \tag{8.2}$$

Table 8.1 describes the naming scheme for unflavored mesons. The scheme is categorized by isospin and hidden-heavy flavor (rows) and parity/charge-conjugation configurations (columns); the first few allowed J^{PC} combinations for each column are shown in the header. Note C-parity is only well-defined for neutral unflavored mesons; the states furnishing an isospin-1 multiplet instead have a well-defined G-parity$= (-1)^{L+S+I}$; see the review on the quark model. The angular momentum J is included as a subscript to the base symbol for most unflavored mesons, but is omitted for various pseudoscalar, vector, and axial vector mesons whenever disambiguation by the J subscript is deemed superfluous. The mass is added in parentheses for mesons that decay strongly. However, for some of the familiar mesons (e.g. η', ϕ, ω), we omit the mass.

For light unflavored mesons—i.e. those unflavored mesons formed from u, d, and s quarks—there can be two isospin-0 mesons: a prime is used to distinguish one from the other (e.g. η and η'), with the exception that vector mesons comprised of $u\bar{u} + d\bar{d}$ and $s\bar{s}$ (ideal mixing) are labeled ω and ϕ, respectively. As usual, we assign the spectroscopic name (e.g. $\Upsilon(1S)$) as the primary name to most of those ψ, Υ, and χ states whose spectroscopic identity is known. We use the form $\Upsilon(9460)$ as an alternative, and as the primary name when the spectroscopic identity is not known.

Determination of the quark content (where relevant) and the quantum numbers I, J, P, and C (or G) of an unflavored meson thus determine its symbol. For example, the light unflavored isospin-1 2^{--} meson would be the ρ_2. Conversely, these properties may be inferred unambiguously from the symbol. The name X is used for states with still unknown quantum numbers. In some cases names are assigned when quantum numbers have not been strictly measured but have instead been inferred from a broader context. These cases typically include an explanation in the header, such as "Quantum numbers shown are quark-model predictions." One example is the $\psi_2(3823)$, for which the $I^G(J^{PC}) = 0^-(2^{--})$ assignment needs confirmation. Since the top quark is so heavy that it decays too rapidly to form bound states, no name is assigned to structures like $t\bar{t}$.

The selection rules in Eq. (8.2) impose restrictions on the J^{PC} quantum numbers that are allowed for $q\bar{q}$ states. These do not apply to more complicated structures such as tetraquarks, hybrid mesons, or glueballs. In particular, unflavored mesons with quantum numbers $J^{PC} = 0^{--}$, 0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, ... cannot

Table 8.1: Base symbols for unflavored mesons (zero strangeness and heavy-flavor quantum numbers equal to zero). Each base symbol is uniquely determined by the isospin/hidden-heavy flavor and PC configuration.

$J^{PC} = \left\{ \begin{array}{l} \\ \\ \vdots \end{array} \right.$	0^{-+} 2^{-+} $\vdots$	1^{+-} 3^{+-} $\vdots$	1^{--} 2^{--} $\vdots$	0^{++} 1^{++} $\vdots$
Minimal quark content				
$u\bar{d}, u\bar{u} - d\bar{d}, d\bar{u}$ $(I = 1)$	π	b	ρ	a
$d\bar{d} + u\bar{u}$, $s\bar{s}$ and/or gluons $(I = 0)$	η,η'	h,h'	ω,ϕ	f,f'
$c\bar{c}$ $(I = 0)$	η_c	h_c	ψ *	χ_c
$b\bar{b}$ $(I = 0)$	η_b	h_b	Υ	χ_b

*With the exception of the J/ψ.

be $q\bar{q}$ bound states, but might be glueballs or $q\bar{q}g$ etc. (This is distinct from light unflavored mesons with $I \geq 2$ or hidden-heavy flavor mesons with $I \geq 1$, which could be interpreted as tetraquarks). For such a "manifestly exotic" unflavored meson, the naming scheme nonetheless assigns the same base symbol as solely determined by the isospin/hidden-heavy flavor and PC in Tab. 8.1. For example, an isospin-0 light unflavored 1^{-+} meson would be denoted η_1 while an isospin-1 0^{--} light unflavored meson would be denoted ρ_0. The exotic nature of the meson can be inferred from its PC quantum numbers—given by the symbol—and the spin J—given by the subscript.

8.2 Remarks on "neutral-flavor" mesons with hidden charm or bottom not classified as $q\bar{q}$

In the heavy-quark sector, there are several states with properties – such as masses, decay patterns, and widths – that are in disagreement with predictions from the naive quark model. For example, the vector state at 4230 MeV (the $\psi(4230)$) apparently does not decay into $D\overline{D}$, although within the naive quark model its quantum numbers would call for this decay channel to be dominant. These states were originally named X, Y, or Z, with their masses added in parentheses. This nomenclature differs from the conventions outlined in the previous section, since the meson names are not related to their quantum numbers. However, these states have properties in conflict with the naive quark model and therefore deserve some special labeling.

Since their original discovery, the properties of some of these states have become better understood and it has become possible to include them in the Listings as well as Summary Tables using the name assigned according to this review. The X-, Y-, or Z-based names used at the time of the discovery are also reported in the Listings and Summary Tables from the 2018 edition onwards as a sub-header (listed are only some examples of the particles that appear in the Summary Tables),

- the state originally named $X(3872)$ appears as '$\chi_{c1}(3872)$ also known as $X(3872)$';
- the state originally named $Z_c(3900)$ appears[1] as '$T_{c\bar{c}1}(3900)$ also known as $Z_c(3900)$';
- the state originally named $Y(4260)$ appears[2] as '$\psi(4230)$ also known as $Y(4230)$';

In addition, states with quantum numbers allowed by the naive quark model but showing some peculiarities, such as an unusual decay pattern, will have the following information in the header:

> This state shows properties different from a conventional $q\bar{q}$ state. A candidate for an exotic structure. See the review on ⟨name of the proper review⟩.

8.3 Mesons with nonzero S, C and/or B

Mesons with nonzero strangeness S or heavy flavor C and/or B are not eigenstates of charge conjugation, and in each of them one of the quarks is heavier than the other (as above, states containing top quarks are not considered). The rules have been and remain:

1. The main symbol is an upper-case italic letter indicating the heavier quark as follows:

   $$s \to \overline{K} \qquad c \to D \qquad b \to \overline{B},$$

   We use the convention that *the flavor quantum number and the charge of a quark have the same sign.* Thus the strangeness of the s quark is negative, the charm of the c quark is positive, and the bottomness of the b quark is negative. The effect of this convention is as follows: *any flavor carried by a charged meson has the same sign as its charge.* Thus the K^+, D^+, and B^+ have positive strangeness, charm, and bottomness, respectively, and all have positive I_3. The D_s^+ has positive charm *and* strangeness. Furthermore, the $\Delta(\text{flavor}) = \Delta Q$ rule, best known for the strange kaons, applies to every flavor.
2. If the lighter quark is not a u or a d quark, its identity is given by a subscript. The D_s^+ is an example.
3. When the spin-parity is in the natural series, $J^P = 0^+, 1^-, 2^+, \cdots$, a superscript "$*$" is added.
4. The spin is added as a subscript except for pseudoscalar or vector mesons.

8.4 Baryons with ordinary quantum numbers

All baryons having quantum numbers consistent with a minimal quark content of three quarks are denoted by the symbols N, Δ, Λ, Σ, Ξ, and Ω introduced more than 50 years ago. These symbols are followed by J^P signifying their spin J and parity P. For those where the minimal content involves one or more heavier quarks than the light (u, d, and s) quarks, subscripts are added to their symbols, (c and b) as appropriate. The rules are:

1. Baryons with minimal content of *three* u and/or d quarks are N's (isospin 1/2) or Δ's (isospin 3/2).
2. Baryons with *two* u and/or d quarks are Λ's (isospin 0) or Σ's (isospin 1). If the third quark is a c or b quark, its identity is given by a subscript.
3. Baryons with *one* u or d quark are Ξ's (isospin 1/2). One or two subscripts are used if one or both of the remaining quarks are heavy: thus Ξ_c, Ξ_{cc}, Ξ_b, etc.[3]
4. Baryons with *no* u or d quarks are Ω's (isospin 0), and subscripts indicate any heavy-quark content.
5. A baryon that decays strongly has its mass in parentheses. Examples are the $\Delta(1232)$ $3/2^+$, $\Sigma(1385)$ $3/2^+$, $N(1440)$ $1/2^+$, $\Xi_c(2645)$ $3/2^+$.
6. If individual states of isospin multiplets are addressed, the electric charge is specified as a superscript. The electric charge is not necessary for isospin-0 states (Λ and Ω), as there is no ambiguity, but may still be included.
7. Antibaryons are labeled by an overline (bar) on the base symbol. For example, $\bar{p}$ for the antiproton, or $\bar{\Lambda}_c^-$ for the antiparticle of Λ_c^+. Alternatively, particle and antiparticle can be distinguished by including only a charge-label superscript, so long as the flavor structure of the baryon is defined solely by the base symbol (and subscripts). Thus one may also write Λ_c^- or p^- for the antiparticles of the Λ_c^+ and p^+, but the Σ^- is not the antiparticle of Σ^+, which is called $\bar{\Sigma}^-$.

In short, the minimal number of u plus d quarks together with the isospin determine the main symbol, and subscripts indicate any content of heavy quarks. A Σ always has isospin 1, an Ω always has isospin 0, etc.

8.5 Hadrons with a minimal quark content of $qq\bar{q}\bar{q}$ or $q\bar{q}qqq$

The naming scheme described above does not accommodate various $qq\bar{q}\bar{q}$ mesons and $q\bar{q}qqq$ baryons. In such cases, the 1986 naming scheme must be extended. Following discussion initiated by the proposal made by the LHCb collaboration [7], we adopt the notation

$$T^{(*)}_{\text{quarks}\,J}(\text{mass})^q \qquad \text{for tetraquarks,} \tag{8.3a}$$

$$P_{\text{quarks}}(\text{mass})^q\ J^P \qquad \text{for pentaquarks,} \tag{8.3b}$$

according to the following rules:

1. The basename T or P is chosen in cases where the minimal quark content of a state is $qq\bar{q}\bar{q}$ (tetraquark) or $q\bar{q}qqq$ (pentaquark), respectively.
2. The bottom, charm, and strange quark content (b, $\bar{b}$, c, $\bar{c}$, s, $\bar{s}$) is explicitly listed as a subscript, in order from the heaviest quarks and antiquarks to the lightest and listing quarks before antiquarks. The hidden-flavor $c\bar{c}$ and $b\bar{b}$ combinations

[1] The name $T_{c\bar{c}1}(3900)$ derives from the scheme outlined in a later section.

[2] This is one example where the mass label needed to be shifted given improved experimental information.

[3] See the "Charmed and Bottom Baryons" section of the "Quark Model" review.

Table 8.2: Names used from the 2024 edition onward compared to those in the 2022 edition. Whenever the C-parity of a charged tetraquark is specified in the Particle Listings, it refers to the C-parity of the prospective/observed neutral isospin partner. Only one member per isospin multiplet is shown (see the Listings for more information).

2024 Name	minimal quark content	$I^{(G)}(J^{P(C)})$	2022 Name	2024 Name	minimal quark content	$I^{(G)}(J^{P(C)})$	2022 Name

$T_{c\bar{c}}(4100)^+$	$c\bar{c}u\bar{d}$	$1^-(?^{?+})$	$X(4100)^+$	$P_{c\bar{c}}(4440)^+$	$c\bar{c}uud$	$1/2(?^?)$	$P_c(4440)^+$
$T_{c\bar{c}1}(4200)^+$	$c\bar{c}u\bar{d}$	$1^+(1^{+-})$	$Z_c(4200)^+$	$P_{c\bar{c}}(4457)^+$	$c\bar{c}uud$	$1/2(?^?)$	$P_c(4457)^+$
$T_{c\bar{c}0}(4240)^+$	$c\bar{c}u\bar{d}$	$1^+(0^{--})$	$R_{c0}(4240)^+$	$P_{c\bar{c}s}(4459)^0$	$c\bar{c}uds$	$0(?^?)$	
$T_{c\bar{c}}(4250)^+$	$c\bar{c}u\bar{d}$	$1^-(?^{?+})$	$X(4250)^+$	$P_{c\bar{c}s}(4338)^0$	$c\bar{c}sud$	$0(1/2^-)$	
$T_{c\bar{c}1}(4430)^+$	$c\bar{c}u\bar{d}$	$1^+(1^{+-})$	$Z_c(4430)^+$				

are listed explicitly when their presence can be inferred from production or decay patterns.

3. The approximate mass of a state, in MeV/c^2, is given in parentheses.
4. The electric charge (q) can be specified as a superscript after the mass, for example when referring to a specific member of an isospin multiplet.
5. Antibaryons are marked with an overline ($\overline{P}$). The antiparticle of a meson can be specified either with an overline or by the quark content label (e.g. the charge conjugate of $T_{cc}(3875)^+$ is $\overline{T}_{cc}(3875)^-$, which is equivalent to $T_{\bar{c}\bar{c}}(3875)^-$).
6. For pentaquarks, as in the case of ordinary baryons, when known the spin-parity, J^P, of the state is included as a suffix.
7. For tetraquarks, similarly to the naming scheme for mesons, the spin J is appended as a subscript after the quark content. When the spin-parity is in the natural series, $J^P = 0^+, 1^-, 2^+, \cdots$, a superscript "*" is added.

Table 8.2 summarizes PDG name changes with respect to the 2022 edition [8]. We acknowledge that experiments might choose to add $I^{(G)}J^{P(C)}$ information to hadron names using experiment-specific conventions that differ from the one utilized by the PDG.

9.1 Basics

Quantum Chromodynamics (QCD), the gauge field theory that describes the strong interactions of colored quarks and gluons, is the SU(3) component of the SU(3)×SU(2)×U(1) Standard Model of Particle Physics. The Lagrangian of QCD is given by

$$\mathcal{L} = \sum_q \bar{\psi}_{q,a}(i\gamma^\mu \partial_\mu \delta_{ab} - g_s \gamma^\mu t^C_{ab} \mathcal{A}^C_\mu - m_q \delta_{ab})\psi_{q,b} - \frac{1}{4} F^A_{\mu\nu} F^{A\,\mu\nu}\,, \tag{9.1}$$

where repeated indices are summed over. The γ^μ are the Dirac γ-matrices. The $\psi_{q,a}$ are quark-field spinors for a quark of flavor q and mass m_q, with a color index a that runs from $a = 1$ to $N_c = 3$, *i.e.* quarks come in three "colors." Quarks are said to be in the fundamental representation of the SU(3) color group.

The $\mathcal{A}^C_\mu$ correspond to the gluon fields, with C running from 1 to $N_c^2 - 1 = 8$, so that there are eight kinds of gluons. Gluons transform under the adjoint representation of the SU(3) color group. The t^C_{ab} correspond to eight 3×3 matrices and are the generators of the SU(3) group (*cf.* the section on "SU(3) isoscalar factors and representation matrices" in this *Review*, with $t^C_{ab} \equiv \lambda^C_{ab}/2$), where λ^C_{ab} are the Gell-Mann matrices. They encode the fact that a gluon's interaction with a quark rotates the quark's color in SU(3) space. The quantity g_s (or $\alpha_s = \frac{g_s^2}{4\pi}$) is the QCD coupling constant. Besides quark masses, which have electroweak origin, it is the most fundamental parameter of QCD. Finally, the field tensor $F^A_{\mu\nu}$ is given by

$$F^A_{\mu\nu} = \partial_\mu \mathcal{A}^A_\nu - \partial_\nu \mathcal{A}^A_\mu - g_s\, f_{ABC} \mathcal{A}^B_\mu \mathcal{A}^C_\nu,$$
$$[t^A, t^B] = i f_{ABC} t^C, \tag{9.2}$$

where the f_{ABC} are the structure constants of the SU(3) group.

Neither quarks nor gluons are observed as free particles. Hadrons are color-singlet (*i.e.* color-neutral) combinations of quarks, antiquarks, and gluons.

Ab-initio predictive methods for QCD include lattice gauge theory and perturbative expansions in the coupling. The Feynman rules of QCD involve a quark-antiquark-gluon ($q\bar{q}g$) vertex, a 3-gluon vertex (both proportional to g_s), and a 4-gluon vertex (proportional to g_s^2). A full set of Feynman rules is to be found for example in Refs. [1, 2].

Adopting a standard notation where repeated indices are summed over, useful color-algebra relations include: $t^A_{ab} t^A_{bc} = C_F \delta_{ac}$, where $C_F \equiv (N_c^2 - 1)/(2N_c) = 4/3$ is the color factor ("Casimir") associated with gluon emission from a quark; $f_{ACD} f_{BCD} = C_A \delta_{AB}$, where $C_A \equiv N_c = 3$ is the color factor associated with gluon emission from a gluon; $t^A_{ab} t^B_{ab} = T_R \delta_{AB}$, where $T_R = 1/2$ is the color factor for a gluon to split to a $q\bar{q}$ pair.

There is freedom for an additional CP-violating term to be present in the QCD Lagrangian, $\theta \frac{\alpha_s}{8\pi} F^{A\,\mu\nu} \tilde{F}^A_{\mu\nu}$, where θ is an additional free parameter, and $\tilde{F}^A_{\mu\nu}$ is the dual of the gluon field tensor, $\frac{1}{2}\epsilon_{\mu\nu\sigma\rho} F^{A\,\sigma\rho}$, with $\epsilon_{\mu\nu\sigma\rho}$ being the fully antisymmetric Levi-Civita symbol. Experimental limits on the electric dipole moment (EDM) of ultracold neutrons [3,4] and atomic mercury [5] constrain the QCD vacuum angle to satisfy $|\theta| \lesssim 10^{-10}$. For an overview of current and future experiments measuring EDMs see [6]. Further discussion is to be found in Ref. [7] and in the Axions section in the Listings of this *Review*.

This section will concentrate mainly on perturbative aspects of QCD as they relate to collider physics. Related textbooks and lecture notes include Refs. [1, 2, 8–11]. Aspects specific to Monte Carlo event generators are reviewed in the dedicated section 43. Lattice QCD is also reviewed in a section of its own, Sec. 17, with further discussion of perturbative and non-perturbative aspects to be found in the sections on "Quark Masses", "The CKM quark-mixing matrix", "Structure functions", "Fragmentation Functions", "High Energy Soft QCD and Diffraction", "Passage of Particles Through Matter" and "Heavy-Quark and Soft-Collinear Effective Theory" in this *Review*.

9.1.1 *Running coupling*

In the framework of perturbative QCD (pQCD), predictions for observables are expressed in terms of the renormalized coupling $\alpha_s(\mu_R^2)$, a function of an (unphysical) renormalization scale μ_R. When one takes μ_R close to the scale of the momentum transfer Q in a given process, then $\alpha_s(\mu_R^2 \simeq Q^2)$ is indicative of the effective strength of the strong interaction in that process.

The coupling satisfies the following renormalization group equation (RGE):

$$\mu_R^2 \frac{d\alpha_s}{d\mu_R^2} = \beta(\alpha_s) = -(b_0 \alpha_s^2 + b_1 \alpha_s^3 + b_2 \alpha_s^4 + \cdots)\,, \tag{9.3}$$

where $b_0 = (11C_A - 4n_f T_R)/(12\pi) = (33 - 2n_f)/(12\pi)$ is referred to as the 1-loop β-function coefficient, the 2-loop coefficient is $b_1 = (17C_A^2 - n_f T_R(10C_A + 6C_F))/(24\pi^2) = (153 - 19n_f)/(24\pi^2)$, and the 3-loop coefficient is $b_2 = (2857 - \frac{5033}{9} n_f + \frac{325}{27} n_f^2)/(128\pi^3)$ for the SU(3) values of C_A and C_F. Here n_f is the number of quark flavors. The 4-loop coefficient, b_3, is to be found in Refs. [12, 13], while the 5-loop coefficient, b_4, is in Refs. [14–18]. The coefficients b_2 and b_3 (and beyond) are renormalization-scheme-dependent and given here in the modified minimal subtraction scheme ($\overline{\rm MS}$) [19], by far the most widely used scheme in QCD and the one adopted in the following.

The minus sign in Eq. (9.3) is the origin of "asymptotic freedom" [20, 21], *i.e.* the fact that the strong coupling becomes weak for processes involving large momentum transfers ("hard processes"). For momentum transfers in the 0.1–1 TeV range, $\alpha_s \sim 0.1$, while the theory is strongly interacting for scales around and below 1 GeV.

The β-function coefficients, the b_i, are given for the coupling of an *effective theory* in which n_f of the quark flavors are considered light ($m_q \ll \mu_R$), and in which the remaining heavier quark flavors decouple from the theory. One may relate the coupling for the theory with $n_f + 1$ light flavors to that with n_f flavors through an equation of the form

$$\alpha_s^{(n_f+1)}(\mu_R^2) = \alpha_s^{(n_f)}(\mu_R^2) \times \times \left(1 + \sum_{n=1}^{\infty} \sum_{\ell=0}^{n} c_{n\ell} \left[\alpha_s^{(n_f)}(\mu_R^2)\right]^n \ln^\ell \frac{\mu_R^2}{m_h^2}\right), \tag{9.4}$$

where m_h is the mass of the $(n_f+1)^{\rm th}$ flavor, and the first few $c_{n\ell}$ coefficients are $c_{11} = \frac{1}{6\pi}$, $c_{10} = 0$, $c_{22} = c_{11}^2$, $c_{21} = \frac{11}{24\pi^2}$, and $c_{20} = -\frac{11}{72\pi^2}$ when m_h is the $\overline{\rm MS}$ mass at scale m_h, while

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s except for Open Access articles.

$c_{20} = \frac{7}{24\pi^2}$ when m_h is the pole mass (mass definitions are discussed below in Sec. (9.1.2) and in the review on "Quark Masses"). Terms up to $c_{4\ell}$ with $0 \le \ell \le 4$ are to be found in Refs. [22, 23]. Numerically, when one chooses $\mu_R = m_h$, the matching is a modest effect, owing to the zero value for the c_{10} coefficient. Relations between n_f and (n_f+2) flavors where the two heavy flavors are close in mass are given to three loops in Ref. [24].

Working in an energy range where the number of flavors is taken constant, a simple exact analytic solution exists for Eq. (9.3) only if one neglects all but the b_0 term, giving $\alpha_s(\mu_R^2) = (b_0 \ln(\mu_R^2/\Lambda^2))^{-1}$. Here Λ is a constant of integration, which corresponds to the scale where the perturbatively-defined coupling would diverge. Its value is indicative of the energy range where non-perturbative dynamics dominates. A convenient approximate analytic solution to the RGE that includes terms up to b_4 is given by solving iteratively Eq. (9.3)

$$\alpha_s(\mu_R^2) \simeq \frac{1}{b_0 t}\left(1 - \frac{b_1}{b_0^2}\frac{\ell}{t} + \frac{b_1^2(\ell^2-\ell-1)+b_0 b_2}{b_0^4 t^2} + \right. \\ + \frac{b_1^3\left(-2\ell^3+5\ell^2+4\ell-1\right) - 6b_0 b_2 b_1 \ell + b_0^2 b_3}{2b_0^6 t^3} + \\ + \frac{18 b_0 b_2 b_1^2\left(2\ell^2-\ell-1\right) + b_1^4\left(6\ell^4-26\ell^3-9\ell^2+24\ell+7\right)}{6 b_0^8 t^4} \\ \left. + \frac{-b_0^2 b_3 b_1(12\ell+1) + 2b_0^2\left(5b_2^2+b_0 b_4\right)}{6 b_0^8 t^4}\right), \tag{9.5}$$

with $t \equiv \ln\frac{\mu_R^2}{\Lambda^2}$ and $\ell = \ln t$, again parameterized in terms of a constant Λ. Note that Eq. (9.5) is one of several possible approximate 4-loop solutions for $\alpha_s(\mu_R^2)$, and that a value for Λ only defines $\alpha_s(\mu_R^2)$ once one knows which particular approximation is being used. An alternative to the use of formulas such as Eq. (9.5) is to solve the RGE exactly, numerically (including the discontinuities, Eq. (9.4), at flavor thresholds). In such cases the quantity Λ does not directly arise (though it can be defined, *cf.* Eqs. (1–3) of Ref. [25]). For these reasons, in determinations of the coupling, it has become standard practice to quote the value of α_s at a given scale (typically the mass of the Z boson, m_Z) rather than to quote a value for Λ.

A discussion of determinations of the coupling and a graph illustrating its scale dependence ("running") are to be found in Section 9.4.

9.1.2 *Quark masses*

Free quarks have never been observed, which is understood as a result of a long-distance, confining property of the strong QCD force: up, down, strange, charm, and bottom quarks all *hadronize*, *i.e.* become part of a meson or baryon, on a timescale $\sim 1/\Lambda$; the top quark instead decays before it has time to hadronize. This means that the question of what one means by the quark mass is a complex one, which requires one to adopt a specific prescription. A perturbatively defined prescription is the pole mass, m_q, which corresponds to the position of the divergence of the quark propagator. This is close to one's physical picture of mass. However, when relating it to observable quantities, it suffers from a badly behaved perturbative series which makes it ambiguous to an amount related to Λ (see *e.g.* Ref. [26–28]). An alternative is the $\overline{\rm MS}$ mass, $\overline{m}_q(\mu_R^2)$, which depends on the renormalization scale μ_R.

Results for the masses of heavier quarks are often quoted either as the pole mass or as the $\overline{\rm MS}$ mass evaluated at a scale equal to the mass, $\overline{m}_q(\overline{m}_q^2)$; light quark masses are often quoted in the $\overline{\rm MS}$ scheme at a scale $\mu_R \sim 2\,\text{GeV}$. The pole and $\overline{\rm MS}$ masses are related by a series that starts as $m_q = \overline{m}_q(\overline{m}_q^2)(1 + \frac{4\alpha_s(\overline{m}_q^2)}{3\pi} + \mathcal{O}(\alpha_s^2))$, while the scale dependence of $\overline{\rm MS}$ masses is given at lowest order by

$$\mu_R^2 \frac{d\overline{m}_q(\mu_R^2)}{d\mu_R^2} = \left[-\frac{\alpha_s(\mu_R^2)}{\pi} + \mathcal{O}(\alpha_s^2)\right]\overline{m}_q(\mu_R^2)\,. \tag{9.6}$$

A more detailed discussion is to be found in a dedicated section of the *Review*, "Quark Masses", with detailed formulas also in Ref. [29] and references therein.

In perturbative QCD calculations of scattering processes, it is customary to employ an approximation where the masses of all quarks, whose magnitudes are much smaller than the momentum transfer involved in the process, are neglected or set to zero.

9.2 Structure of QCD predictions

9.2.1 *Fully inclusive cross sections*

The simplest observables in perturbative QCD are those that do not depend on initial-state hadrons and are fully inclusive, disregarding specific details of the final state. An example of such an observable is the total cross section for the process $e^+e^- \to$ hadrons at a center-of-mass energy Q. It can be expressed as follows:

$$\frac{\sigma(e^+e^- \to \text{hadrons}, Q)}{\sigma(e^+e^- \to \mu^+\mu^-, Q)} \equiv R(Q) = R_{\rm EW}(Q)(1 + \delta_{\rm QCD}(Q))\,, \tag{9.7}$$

where $R_{\rm EW}(Q)$ is the purely electroweak prediction for the ratio and $\delta_{\rm QCD}(Q)$ is the correction due to QCD effects.

For the sake of simplicity, we can focus on energies where $Q \ll m_Z$, where the primary contribution to the process comes from photon exchange (while disregarding electroweak and finite-quark-mass corrections) denoted as $R_{\rm EW} = N_c \sum_q e_q^2$, with e_q representing the electric charges of the quarks in units of e. The QCD correction reads

$$\delta_{\rm QCD}(Q) = \sum_{n=1}^{\infty} c_n \cdot \left(\frac{\alpha_s(Q^2)}{\pi}\right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right)\,. \tag{9.8}$$

The first four terms in the α_s series expansion are [30]

$$c_1 = 1\,, \qquad c_2 = 1.9857 - 0.1152 n_f\,, \tag{9.9a}$$

$$c_3 = -6.63694 - 1.20013 n_f - 0.00518 n_f^2 - 1.240\eta\,, \tag{9.9b}$$

$$c_4 = -156.61 + 18.775 n_f - 0.7974 n_f^2 + 0.0215 n_f^3 \\ - (17.828 - 0.575 n_f)\eta\,, \tag{9.9c}$$

with $\eta = (\sum e_q)^2/(N_c \sum e_q^2)$ and $N_c = 3$. For corresponding expressions including also Z exchange and finite-quark-mass effects, see Refs. [31–33].

A related series holds also for the QCD corrections to the W-boson decay or to the hadronic decay width of the τ lepton. The latter essentially involves an integral of $R(Q)$ over the allowed range of invariant masses of the hadronic part of the τ decay (see *e.g.* Ref. [34]). The series expansions for QCD corrections to Higgs-boson hadronic (partial) decay widths in the limit of heavy top quark and massless light flavors up to fifth order are given in Ref. [35].

One characteristic feature of Eqs. (9.8) and (9.9) is that the coefficients of α_s^n increase order by order: calculations in perturbative QCD tend to converge more slowly than would be expected based just on the size of α_s. The situation is significantly worse near thresholds or in the presence of tight kinematic cuts. Another feature is the existence of an extra "power-correction" term $\mathcal{O}(\Lambda^4/Q^4)$ in Eq. (9.8), which accounts for contributions that are fundamentally non-perturbative. All high-energy QCD predictions involve power corrections $(\Lambda/Q)^p$, although typically the suppression of these corrections with Q is smaller than given in Eq. (9.8), where $p = 4$. The exact power p depends on the observable and, for many processes and observables, it is possible to introduce an operator product expansion and associate power-suppressed terms with specific higher-dimension (non-perturbative) operators [36].

Scale dependence. In Eq. (9.8) the renormalization scale for α_s has been chosen equal to Q. The result can also be expressed in terms of the coupling at an arbitrary renormalization scale μ_R,

$$\delta_{\rm QCD}(Q) = \sum_{n=1}^{\infty} \overline{c}_n\left(\frac{\mu_R^2}{Q^2}\right) \cdot \left(\frac{\alpha_s(\mu_R^2)}{\pi}\right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right)\,, \tag{9.10}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

where $\bar{c}_1(\mu_R^2/Q^2) \equiv c_1$, $\bar{c}_2(\mu_R^2/Q^2) = c_2 + \pi b_0 c_1 \ln(\mu_R^2/Q^2)$, $\bar{c}_3(\mu_R^2/Q^2) = c_3 + (2b_0 c_2 \pi + b_1 c_1 \pi^2) \times \ln(\mu_R^2/Q^2) + b_0^2 c_1 \pi^2 \ln^2(\mu_R^2/Q^2)$, *etc.* Given an infinite number of terms in the α_s expansion, the μ_R dependence of the $\bar{c}_n(\mu_R^2/Q^2)$ coefficients will exactly cancel that of $\alpha_s(\mu_R^2)$, and the final result will be independent of the choice of μ_R: physical observables do not depend on unphysical scales.[1]

With just terms up to some finite $n = N$, a residual μ_R dependence will remain, which implies an uncertainty on the prediction of $R(Q)$ due to the arbitrariness of the scale choice. This uncertainty will be $\mathcal{O}(\alpha_s^{N+1})$, *i.e.* of the same order as the neglected higher-order terms. For this reason it is customary to use the scale dependence of QCD predictions as an estimate of the uncertainties due to neglected terms. One usually takes a central value for $\mu_R \sim Q$, in order to avoid the poor convergence of the perturbative series that results from the large $\ln^{n-1}(\mu_R^2/Q^2)$ terms in the $\bar{c}_n$ coefficients when $\mu_R \ll Q$ or $\mu_R \gg Q$. Uncertainties are then commonly determined by varying μ_R by a factor of two up and down around the central scale choice. This is not a rigorous prescription for determining the uncertainty, but is motivated by the requirement that there should not be large logarithms introduced into a calculation by large ratios of scales. A more detailed discussion on the accuracy of theoretical predictions and on ways to estimate the theoretical uncertainties can be found in Section 9.2.4.

9.2.2 *Processes with initial-state hadrons*

Deep-Inelastic Scattering. To illustrate the key features of QCD cross sections in processes with initial-state hadrons, let us consider deep-inelastic scattering (DIS), $e + p \to e + X$, where an electron e with four-momentum k emits a highly off-shell photon (momentum q) that interacts with the proton (momentum p). For photon virtualities $Q^2 \equiv -q^2$ far above the squared proton mass (but far below the squared Z mass), the differential cross section in terms of the kinematic variables Q^2, $x = Q^2/(2p \cdot q)$ and $y = (q \cdot p)/(k \cdot p)$ is

$$\frac{d^2\sigma}{dx dQ^2} = \frac{4\pi\alpha^2}{2xQ^4} \left[(1 + (1-y)^2) F_2(x, Q^2) - y^2 F_L(x, Q^2) \right] , \tag{9.11}$$

where α is the electromagnetic coupling and $F_2(x, Q^2)$ and $F_L(x, Q^2)$ are proton structure functions, which encode the interaction between the photon and the proton. In the presence of parity-violating interactions (*e.g.* νp scattering) an additional F_3 structure function is present. For an extended review, including equations for the full electroweak and polarized cases, see Sec. 18 of this *Review*.

Structure functions are not calculable in perturbative QCD, nor is any other cross section that involves QCD interactions and initial-state hadrons. To zeroth order in α_s, the structure functions are given directly in terms of non-perturbative parton (quark or gluon) distribution functions (PDFs),

$$F_2(x, Q^2) = x \sum_q e_q^2 f_{q/p}(x) , \qquad F_L(x, Q^2) = 0 , \tag{9.12}$$

where $f_{q/p}(x)$ is the non-perturbative PDF for quarks of type q inside the proton, *i.e.* the number density of quarks of type q inside a fast-moving proton that carry a fraction x of its longitudinal momentum.

The result in Eq. (9.12), with PDFs $f_{q/p}(x)$ that are independent of the scale Q, corresponds to the "quark-parton model" picture, in which the photon interacts with point-like free quarks, or equivalently, one has incoherent elastic scattering between the electron and individual constituents of the proton. As a consequence, in this picture also F_2 and F_L are independent of Q [37].

When including higher orders in pQCD, one has

$$F_2(x, Q^2) = x \sum_{n=0}^{\infty} \frac{\alpha_s^n(\mu_R^2)}{(2\pi)^n} \times \\ \times \sum_{i=q,g} \int_x^1 \frac{dz}{z} C_{2,i}^{(n)}(z, Q^2, \mu_R^2, \mu_F^2) f_{i/p}\left(\frac{x}{z}, \mu_F^2\right) + \mathcal{O}\left(\frac{\Lambda^2}{Q^2}\right) . \tag{9.13}$$

Just as in Eq. (9.10), we have a series in powers of $\alpha_s(\mu_R^2)$, each term involving a coefficient $C_{2,i}^{(n)}$ that can be calculated using Feynman diagrams. At variance with the parton model, the PDFs in pQCD depend on an additional scale, the factorization scale μ_F, whose significance will be discussed in the following. Another important difference is the additional integral over z. The parton that comes from the proton can undergo a splitting before it enters the hard scattering. As a result, the $C_{2,i}^{(n)}$ coefficients are functions that depend on the ratio, z, of the parton's momentum before and after radiation, and one must integrate over that ratio. For the electromagnetic component of DIS with light quarks and gluons, the zeroth order coefficient functions are $C_{2,q}^{(0)} = e_q^2 \delta(1-z)$ and $C_{2,g}^{(0)} = 0$. Corrections are known up to $\mathcal{O}(\alpha_s^3)$ (next-to-next-to-next-to-leading order, N^{3}LO) for both electromagnetic [38] and weak currents [39, 40]. For heavy-quark production they are known to $\mathcal{O}(\alpha_s^2)$ [41, 42] (next-to-leading order, NLO, insofar as the series starts at $\mathcal{O}(\alpha_s)$). The current status of the theoretical description of unpolarized and polarized DIS is summarized in Ref. [43].

The majority of the emissions that modify a parton's momentum are collinear (parallel) to that parton, and do not depend on whether the parton will interact with a photon. It is natural to view these emissions as modifying the proton's structure rather than being part of the coefficient function for the parton's interaction with the photon. Technically, one uses a procedure known as *collinear factorization* to give a well-defined meaning to this distinction, most commonly through the $\overline{\text{MS}}$ factorization scheme, defined in the context of dimensional regularization. The $\overline{\text{MS}}$ factorization scheme involves an arbitrary choice of *factorization scale*, μ_F, whose meaning can be understood roughly as follows: emissions with transverse momenta above μ_F are included in the $C_{2,q}^{(n)}(z, Q^2, \mu_R^2, \mu_F^2)$; emissions with transverse momenta below μ_F are accounted for within the PDFs, $f_{i/p}(x, \mu_F^2)$. While collinear factorization is generally believed to be valid for suitable (sufficiently inclusive) observables in processes with hard scales, Ref. [44], which reviews the factorization proofs in detail, is cautious in the statements it makes about their exhaustivity, notably for the hadron-collider processes which we shall discuss below. Interesting considerations on the current status of our understanding of factorization can be found in Refs. [45,46]. While the transverse degrees of freedom have been integrated over for collinear PDFs, it is also possible to produce transverse-momentum dependent (or unintegrated) PDFs where these degrees of freedom remain. For a recent comprehensive review of transverse-momentum dependent parton distribution functions and fragmentation functions see Ref. [47].

For collinear PDFs, the resulting dependence on μ_F is described by the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) equations [48], which to leading order (LO) read[2]

$$\mu_F^2 \frac{\partial f_{i/p}(x, \mu_F^2)}{\partial \mu_F^2} = \sum_j \frac{\alpha_s(\mu_F^2)}{2\pi} \int_x^1 \frac{dz}{z} P_{i \leftarrow j}^{(1)}(z) f_{j/p}\left(\frac{x}{z}, \mu_F^2\right) , \tag{9.14}$$

with, for example, $P_{q \leftarrow g}^{(1)}(z) = T_R(z^2 + (1-z)^2)$. The other LO splitting functions are listed in Sec. 18 of this *Review*, while results up to NLO, α_s^2, and NNLO, α_s^3, are given in Refs. [49] and [50] respectively. At N^{3}LO accuracy, several partial results

[1] With respect to pQCD there is an important caveat to this statement: at sufficiently high orders, perturbative series generally suffer from "renormalon" divergences $\alpha_s^n n!$ (reviewed in Ref. [26]). This phenomenon is not usually visible with the limited number of perturbative terms available today. However, it is closely connected with non-perturbative contributions and sets a limit on the possible precision of perturbative predictions. The cancellation of scale dependence will also ultimately be affected by this renormalon-induced breakdown of perturbation theory.

[2] LO is generally taken to mean the lowest order at which a quantity is non-zero.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo

xcept for Open Access articles.

are currently available [51–65], some of which have been used to derive approximate N^{3}LO PDFs [66, 67].

Beyond LO, the coefficient functions are also μ_F dependent, for example $C_{2,i}^{(1)}(x, Q^2, \mu_R^2, \mu_F^2) = C_{2,i}^{(1)}(x, Q^2, \mu_R^2, Q^2) - \ln\left(\frac{\mu_F^2}{Q^2}\right) \sum_j \int_x^1 \frac{dz}{z} \times C_{2,j}^{(0)}(\frac{x}{z}) P_{j\leftarrow i}^{(1)}(z)$. Progress in higher-order QED and mixed QED-QCD corrections to the splitting functions can be found in Refs. [68, 69].

As with the renormalization scale, the choice of factorization scale is arbitrary, but if one has an infinite number of terms in the perturbative series, the μ_F-dependencies of the coefficient functions and PDFs will compensate each other fully. Given only N terms of the series, a residual $\mathcal{O}(\alpha_s^{N+1})$ uncertainty is associated with the ambiguity in the choice of μ_F. As with μ_R, varying μ_F provides an input in estimating uncertainties on predictions. In inclusive DIS predictions, the default choice for the scales is usually $\mu_R = \mu_F = Q$.

As is the case for the running coupling, in DGLAP evolution one can introduce flavor thresholds near the heavy-quark masses: below a given heavy quark's mass, that quark is not considered to be part of the proton's structure, while above it is considered to be part of the proton's structure and evolves with massless DGLAP splitting kernels. With appropriate parton distribution matching terms at threshold, such a variable flavor number scheme (VFNS), when used with massless coefficient functions, gives the full heavy-quark contributions at high Q^2 scales. For scales near the threshold, it is instead necessary to appropriately adapt the standard massive coefficient functions to account for the heavy-quark contribution already included in the PDFs [70–72]. At sufficiently small x and Q^2 in inclusive DIS, resummation of small x logarithms may be necessary [73, 74].

In situations, in which the center-of-mass energy $\sqrt{s}$ is much larger than all other momentum-transfer scales in the problem (*e.g.* Q in DIS, m_b for $b\bar{b}$ production in pp collisions, *etc.*), each power of α_s beyond LO can be accompanied by a power of $\ln(s/Q^2)$ (or $\ln(s/m_b^2)$, *etc.*). This is variously referred to as the high-energy, small-x or Balitsky-Fadin-Kuraev-Lipatov (BFKL) limit [74–76]. Currently it is possible to account for the dominant and first subdominant [77, 78] powers of such logarithms at each order of α_s, and also to estimate further subdominant contributions that are numerically large (see Refs. [79–82] and references therein). Progress towards NNLO is discussed in Ref. [83].

Physically, the summation of all orders in α_s can be understood as leading to a growth with s of the gluon density in the proton. At sufficiently high energies this implies non-linear effects (commonly referred to as parton saturation), whose treatment has been the subject of intense study (see for example Refs. [84, 85] and references thereto).

The PDFs themselves are primarily determined from data in global fits. PDF sets are available at different orders in perturbation theory (LO, NLO, NNLO and what has been termed approximate N^{3}LO) based on the order at which cross sections used in the fits are calculated. The evolution equations for the PDFs from one scale to another matches the perturbative accuracy of the cross sections. In modern global PDF fits, data are included from DIS, Drell-Yan (DY), jets and $t\bar{t}$ processes, and other LHC collider data, with the global PDF fits using 4000–5000 data points. There is a large change in the PDFs from LO to NLO, with a much smaller change from NLO to NNLO. LO PDFs can be unreliable for collider predictions, especially at low and high x. The uncertainties for the resulting PDFs are determined primarily from the experimental uncertainties of the data that serve as input to the global PDF fits. There is also a component due to the limitations of the parameterizations used, as discussed *e.g.* in Ref. [86], although this may be reduced with the use of more flexible forms. The PDF uncertainties can either be determined through a Hessian approach or through the use of Monte Carlo replicas. It is now relatively straightforward to convert results from one approach to the other. A combination (PDF4LHC21) of the CT18, MSHT20 and (an updated version of) NNPDF3.1 PDFs, each produced from a global PDF fit, serves to provide a more comprehensive view of both the central PDFs and of their uncertainties [87]. The PDF4LHC21 PDFs are often used by the experiments for Monte Carlo generation, as they represent a more realistic representation of the central values and uncertainties of the PDFs.

Theoretical uncertainties related to missing higher orders (MHO) have been included in global PDF determinations [88–91], using scale variations at the fit order as an estimate of the uncertainties at the higher order. The uncertainties are added into the experimental covariance matrix and are treated as uncorrelated with the experimental uncertainties. By tying renormalization scales for related processes, and factorization scales for all processes, together in the global fit, an estimate of the higher order uncertainties can be added to the PDF fit. Another technique, used by MSHT [92], is to create theory nuisance parameters using information from the form of corrections observed at lower orders. The global PDF fit then determines the combination of shapes and sizes of the theory nuisance parameters that allow the best fit to the data.

These two techniques have been used to determine approximate N^{3}LO PDFs [66,67], using the available information at that order. Many of the crucial N^{3}LO cross sections, such as for dijet and top pair production, are not known and so predictions have to rely on the above two techniques, but the evolution at N^{3}LO seems to be under good control [93].

Since the original work of Ref. [94], one of the intriguing questions is whether lattice calculations can provide valuable insights for extracting PDFs. Despite initial debates surrounding the underlying methodologies [95, 96], it is now understood that lattice data in Euclidean space can be connected to light-cone PDFs through factorization theorems, once lattice observables have been renormalized and extrapolated to the continuum limit [97]. Initial determinations based on lattice data have begun to emerge [97–121], see also Refs. [122, 123] for overviews on lattice PDFs, and the comparisons with determinations based on conventional data show great promise. However, the uncertainties in lattice-based determinations are still quite large, therefore, for practical applications, PDFs are currently derived from global fits of experimental data (*cf.* Sec. 18 of this *Review* and also Refs. [124, 125]). It is likely that lattice simulations for light-cone PDFs will have an impact in the short- to medium-term, if they focus on flavor components (strange and charm) and on the kinematic regions that are poorly covered by the experimental data [126]. Similarly, lattice determinations of transverse-momentum dependent PDFs (TMDs), generalized parton distributions (GPDs) and polarized PDFs will be more relevant for phenomenology since the experimental data for these quantities are much less abundant and precise.

Hadron-hadron collisions.

The extension to processes with two initial-state hadrons can be illustrated with the example of the total (inclusive) cross section for W boson production in collisions of hadrons h_1 and h_2, which can be written as

$$\sigma(h_1 h_2 \to W + X) = \sum_{n=0}^{\infty} \alpha_s^n(\mu_R^2) \times \sum_{i,j} \int dx_1 dx_2 \, f_{i/h_1}\left(x_1, \mu_F^2\right) f_{j/h_2}\left(x_2, \mu_F^2\right) \times \hat{\sigma}_{ij\to W+X}^{(n)}\left(x_1 x_2 s, \mu_R^2, \mu_F^2\right) + \mathcal{O}\left(\frac{\Lambda^2}{m_W^4}\right), \tag{9.15}$$

where s is the squared center-of-mass energy of the collision. At LO, $n = 0$, the hard (partonic) cross section $\hat{\sigma}_{ij\to W+X}^{(0)}(x_1 x_2 s, \mu_R^2, \mu_F^2)$ is simply proportional to $\delta(x_1 x_2 s - m_W^2)$, in the narrow W-boson width approximation (see Sec. 51 of this *Review* for detailed expressions for this and other hard scattering cross sections). It is non-zero only for choices of i, j that can directly give a W, such as $i = u$, $j = \bar{d}$. At higher orders, $n \geq 1$, new partonic channels contribute, such as gq, and $x_1 x_2 s \geq m_W^2$ in the narrow W-boson width approximation.

Equation (9.15) involves a collinear factorization between the

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

hard cross section and the PDFs, just like Eq. (9.13). As long as the same factorization scheme is used in DIS and pp or $p\bar{p}$ (usually the $\overline{\rm MS}$ scheme), then PDFs extracted in DIS can be directly used in pp and $p\bar{p}$ predictions [44,127] (with the antiquark distributions in an anti-proton being the same as the quark distributions in a proton).

A number of fully inclusive cross sections have been computed up to N^{3}LO, *i.e.* including corrections up to relative order α_s^3, in recent years. These include inclusive Higgs production through gluon fusion in the large m_t limit, calculated at N^{3}LO in Refs. [128, 129]. Higgs boson pair production via gluon fusion in the same approximation was computed at N^{3}LO in Ref. [130]. Calculations at this order, differential in the Higgs rapidity [131, 132] and fully differential [133] have been presented recently. Bottom-induced Higgs boson production has also been computed at N^{3}LO [134]. Vector-boson fusion single- [135] and double-pair [136] productions are also known to N^{3}LO [135] in the factorized approximation. Neutral [137,138] and charged [139] Drell-Yan processes, as well as associated Higgs production [134] have also been computed at N^{3}LO. Differential rapidity distributions are available, but not yet with fiducial cuts. A number of public codes are now available which allow for phenomenological studies at N^{3}LO [134, 135, 140–142].

The uncertainty band derived by varying the renormalization and factorization scales in the perturbative predictions is not always contained within the corresponding uncertainty band of the previous order, as might be expected from a well-behaved process. For Drell-Yan production, this has been ascribed to cancellations between channels at NNLO that lead to underestimates of the uncertainty at that order. This effect does not seem to be present in other processes, such as Higgs boson production through gluon-gluon fusion. Note that there is currently a mismatch in N^{3}LO calculations in that PDFs at the same order are not yet available. Preliminary approximate N^{3}LO PDFs [66, 67] suggest that N^{3}LO effects can be large, especially as far as heavy-quark distributions and low scales are concerned, as well as the gluon distribution in a region important for Higgs boson production through gluon-gluon fusion. These differences between approximate N^{3}LO distributions do not arise from differences in the data sets being considered in the PDF fits, and need to be studied in further detail. This may have implications for predictions of gluon-gluon fusion Higgs cross sections at the LHC. A comparison of these sets, as well as a preliminary combination, can be found in Ref. [143].

The hard cross sections for several other processes are known to NNLO, [3] for instance, Higgs-boson production in association with a vector boson [144], Higgs-pair production in the large m_t approximation [145], and with full m_t dependence [146], top-antitop production [147, 148], bottom-anti-bottom production [149] and vector-boson pair production [150–152]. For a comprehensive overview on other recent NNLO $2 \to 2$ calculations see Ref. [153, 154]. Other NNLO calculations with fiducial cuts will be discussed in Sec. 9.2.3.

At the level of precision needed/desired at the LHC, electroweak corrections need to be taken into account, both on the relevant matrix elements and on the parton distribution functions. In particular, the proton acquires a photon PDF component, whose magnitude can be precisely calculated [155, 156]. All recent photon PDFs [157–159] are based on the calculation in Ref. [155,156]. A benchmarking exercise of the photon PDFs was carried out in Ref. [160]. The photon component can contribute to new production channels, for example for VBF Higgs boson production. A secondary impact is due to the momentum taken by the photon, and the resultant reduction of the gluon and quark momentum, of the order of 0.3–0.5%. In addition, the re-fit, allowing the photon component, may result in an additional redistribution of the quark and gluon momentum. The net result is a reduction of the gluon-gluon fusion Higgs boson cross section that can vary from 0.6–1.2% [160]. It will be difficult to reduce the PDF uncertainty to the order of 1% if the uncertainty of the electroweak corrections is of that order. More recently, the PDF for leptons has also been computed [161]. The photon PDF has an elastic and an inelastic component, where the photon is generated from the intact proton or from the splitting of quarks inside the proton, respectively, while the lepton PDF is generated by photons splitting into collinear leptons.

Photoproduction.

γp (and $\gamma\gamma$) collisions are similar to pp collisions, with the subtlety that the photon can behave in two ways: there is "direct" photoproduction, in which the photon behaves as a point-like particle and takes part directly in the hard collision, with hard subprocesses such as $\gamma g \to q\bar{q}$; there is also resolved photoproduction, in which the photon behaves like a hadron, with non-perturbative partonic substructure and a corresponding PDF for its quark and gluon content, $f_{i/\gamma}(x, Q^2)$. While useful to understand the general structure of γp collisions, the distinction between direct and resolved photoproduction is not well defined beyond leading order, as discussed for example in Ref. [162].

9.2.3 *Cross sections with phase-space restrictions*

QCD final states always consist of hadrons, while perturbative QCD calculations deal with partons. Physically, an energetic parton fragments ("showers") into many further partons, which then, on later timescales, undergo a transition to hadrons ("hadronization"). Fixed-order perturbation theory captures only a small part of these dynamics. This does not matter for the fully inclusive cross sections discussed in Section 9.2.1: the showering and hadronization stages are approximately unitary, *i.e.* they do not substantially change the overall probability of hard scattering, because they occur long after it has taken place (they introduce at most a correction proportional to a power of the ratio of timescales involved, *i.e.* a power of Λ/Q, where Q is the hard scattering scale).

Less inclusive measurements, in contrast, may be affected by the extra dynamics. For those sensitive just to the main directions of energy flow (jet rates, event shapes, *cf.* Sec. 9.3.1) fixed-order perturbation theory is often still adequate, because showering and hadronization do not substantially change the overall energy flow. This means that one can make a prediction using just a small number of partons, which should correspond well to a measurement of the same observable carried out on hadrons. For observables that instead depend on distributions of individual hadrons (which, *e.g.*, are the inputs to detector simulations), it is mandatory to account for showering and hadronization. The range of predictive techniques available for QCD final states reflects this diversity of needs of different measurements.

While illustrating the different methods, we shall for simplicity mainly use expressions that hold for e^+e^- scattering. The extension to cases with initial-state partons will be mostly straightforward (space constraints unfortunately prevent us from addressing hard diffraction and exclusive hadron-production processes; extensive discussion is to be found in Sec. 20 of this *Review* and in Refs. [163, 164]).

9.2.3.1 *Soft and collinear limits*

Before examining specific predictive methods, it is useful to be aware of a general property of QCD matrix elements in the soft and collinear limits. Consider a squared tree-level matrix element $|M_n^2(p_1, \ldots, p_n)|$ for the process $e^+e^- \to n$ partons with momenta $p_1, \ldots, p_n$, and a corresponding phase-space integration measure $d\Phi_n$. If particle n is a gluon, which becomes collinear (parallel) to another particle i and additionally its momentum tends to zero (is "soft"), the matrix element simplifies as follows,

$$\lim_{\theta_{in}\to 0,\, E_n \to 0} d\Phi_n |M_n^2(p_1, \ldots, p_n)| = d\Phi_{n-1} |M_{n-1}^2(p_1, \ldots, p_{n-1})| \frac{\alpha_s C_i}{\pi} \frac{d\theta_{in}^2}{\theta_{in}^2} \frac{dE_n}{E_n}\,, \qquad (9.16)$$

where $C_i = C_F$ (C_A) if i is a quark (gluon). This formula has non-integrable divergences both for the inter-parton angle $\theta_{in} \to 0$ and for the gluon energy $E_n \to 0$, which are mirrored also in the structure of divergences in loop diagrams. These divergences are important for at least two reasons: firstly, they govern the typical structure of events (inducing many emissions either with low

[3] Processes with light jets or photons in the final state have divergent cross sections unless one places a cut on the jet or (dressed) photon momentum. Accordingly, they are discussed below in Section 9.2.3.2.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
xcept for Open Access articles.

energy or at small angle with respect to hard partons); secondly, they will determine which observables can be calculated within fixed-order perturbative QCD.

9.2.3.2 *Fixed-order predictions*

Let us consider an observable $\mathcal{O}$ that is a function $\mathcal{O}_n(p_1,\ldots,p_n)$ of the four-momenta of the n final-state particles in an event (either partons or hadrons). In what follows, we shall consider the cross section for events weighted with the value of the observable, $\sigma_{\mathcal{O}}$. As examples, if $\mathcal{O}_n \equiv 1$ for all n, then $\sigma_{\mathcal{O}}$ is just the total cross section; if $\mathcal{O}_n \equiv \hat{\tau}(p_1,\ldots,p_n)$ where $\hat{\tau}$ is the value of the thrust for that event (see Eq. (9.22) in Sec. 9.3.1.2), then the average value of the thrust is $\langle\tau\rangle = \sigma_{\mathcal{O}}/\sigma_{\rm tot}$; if $\mathcal{O}_n \equiv \delta(\tau - \hat{\tau}(p_1,\ldots,p_n))$ then one gets the differential cross section as a function of the thrust, $\sigma_{\mathcal{O}} \equiv d\sigma/d\tau$.

In the expressions below, we shall omit to write the non-perturbative power correction term, which for most common observables is proportional to a single power of Λ/Q.

Leading Order. If the observable $\mathcal{O}$ is non-zero only for events with at least n final-state particles, then the LO QCD prediction for the weighted cross section in e^+e^- annihilation is

$$\sigma^{\rm LO}_{\mathcal{O}} = \alpha_s^{n-2}(\mu_R^2) \int d\Phi_n |M_n^2(p_1,\ldots,p_n)|\, \mathcal{O}_n(p_1,\ldots,p_n)\,, \tag{9.17}$$

where the squared tree-level matrix element, $|M_n^2(p_1,\ldots,p_n)|$, including relevant symmetry factors, has been summed over all subprocesses (*e.g.* $e^+e^- \to q\bar{q}q\bar{q}$, $e^+e^- \to q\bar{q}gg$) and has had all factors of α_s extracted in front. In processes other than e^+e^- collisions, the center-of-mass energy of the LO process is generally not fixed, and so the powers of the coupling are often brought inside the integrals, with the scale μ_R chosen event by event, as a function of the event kinematics.

Other than in the simplest cases (see the review on Cross Sections in this *Review*), the matrix elements in Eq. (9.17) are usually calculated automatically with programs such as CompHEP [165], MadGraph [166], Alpgen [167], Comix/Sherpa [168], and Helac/Phegas [169]. Some of these (CompHEP, MadGraph) use formulas obtained from direct evaluations of Feynman diagrams. Others (Alpgen, Helac/Phegas and Comix/Sherpa) use methods designed to be particularly efficient at high multiplicities, such as Berends-Giele recursion [170], which builds up amplitudes for complex processes from simpler ones (see also Refs. [171–173] for other tree-level calculational methods).

The phase-space integration is usually carried out by Monte Carlo sampling or other numerical techniques, because of the high dimensionality of the integration and in order to deal with the possibly involved kinematic cuts that are used in the corresponding experimental measurements. Perturbatively calculable observables should be insensitive to the emission of soft and collinear radiation. Because of the divergences in the matrix element, Eq. (9.16), at lowest order the integral converges only if the observable vanishes for kinematic configurations in which one of the n particles is arbitrarily soft or it is collinear to another particle. As an example, the cross section for producing any configuration of n partons will lead to an infinite integral, whereas a finite result will be obtained for the cross section for producing n deposits of energy (or jets, see Sec. 9.3.1.1), each above some energy threshold and well separated from each other in angle.

At a practical level, LO calculations can be carried out for $2 \to n$ processes with $n \lesssim 6-10$. The exact upper limit depends on the process, the method used to evaluate the matrix elements and the extent to which the phase-space integration can be optimized to work around the large variations in the values of the matrix elements.

NLO. Given an observable that is non-zero starting from n final-state particles, its prediction at NLO involves supplementing the LO result, Eq. (9.17), with the $2 \to (n+1)$-particle squared tree-level matrix element ($|M^2_{n+1}|$), and the interference of a $2 \to n$ tree-level and $2 \to n$ 1-loop amplitude ($2{\rm Re}(M_n M^*_{n,1-{\rm loop}})$),

$$\begin{aligned}\sigma^{\rm NLO}_{\mathcal{O}} = \sigma^{\rm LO}_{\mathcal{O}} &+ \alpha_s^{n-1}(\mu_R^2) \int d\Phi_{n+1} |M^2_{n+1}(p_1,\ldots,p_{n+1})| \\ &\times \mathcal{O}_{n+1}(p_1,\ldots,p_{n+1}) \;+\; \alpha_s^{n-1}(\mu_R^2) \\ &\times \int d\Phi_n \, 2{\rm Re}\left[\, M_n(p_1,\ldots,p_n)\, M^*_{n,1-{\rm loop}}(p_1,\ldots,p_n)\,\right] \\ &\times \mathcal{O}_n(p_1,\ldots,p_n)\,.\end{aligned} \tag{9.18}$$

Relative to LO calculations, two important issues appear in the NLO calculations. Firstly, the extra complexity of loop- relative to tree-level calculations means that automated calculations started to appear only about fifteen years ago (see below). Secondly, loop amplitudes are infinite in four dimensions, while tree-level amplitudes are finite, but their *integrals over the phase space* are infinite, due to the divergences of Eq. (9.16). These two sources of infinities have the same soft and collinear origins and cancel after the integration only if the observable $\mathcal{O}$ satisfies the property of infrared and collinear safety, which means that the observable is non-sensitive to soft emissions or to collinear splittings, *i.e.*

$$\begin{aligned}&\mathcal{O}_{n+1}(p_1,\ldots,p_s,\ldots,p_n) \quad \to \mathcal{O}_n(p_1,\ldots,p_{s-1},p_{s+1},\ldots,p_n) \\ &\qquad\qquad\qquad\qquad \text{if } p_s \to 0 \\ &\mathcal{O}_{n+1}(p_1,\ldots,p_a,p_b,\ldots,p_n) \to \mathcal{O}_n(p_1,\ldots,p_a+p_b,\ldots,p_n) \\ &\qquad\qquad\qquad\qquad \text{if } p_a \,||\, p_b\,.\end{aligned} \tag{9.19}$$

Examples of infrared-safe quantities include event-shape distributions and jet cross sections (with appropriate jet algorithms, see below). Unsafe quantities include the distribution of the momentum of the hardest QCD particle (which is not conserved under collinear splitting), observables that require the complete absence of radiation in some region of phase space (*e.g.* rapidity gaps or 100% isolation cuts, which are affected by soft emissions), or the particle multiplicity (affected by both soft and collinear emissions). The non-cancellation of divergences at NLO due to infrared or collinear unsafety compromises the usefulness not only of the NLO calculation, but also that of a LO calculation, since LO is only an acceptable approximation if one can prove that higher-order terms are smaller. Infrared and collinear unsafety usually also implies large non-perturbative effects.

As with LO calculations, the phase-space integrals in Eq. (9.18) are usually carried out by Monte Carlo integration, so as to facilitate the study of arbitrary observables. Various methods exist to obtain numerically efficient cancellation among the different infinities. These include notably dipole [174], FKS [175] and antenna [176] subtraction.

Thanks to new ideas like the OPP method [177], generalized [178] and D-dimensional [179] unitarity, on-shell methods [180], and on-the-fly reduction algorithms [181], the first decade of the 2000s has seen a breakthrough in the calculation of one-loop matrix elements (for reviews on unitarity based method see Ref. [182, 183]). Thanks to these innovative methods, automated tools for NLO calculations have been developed and a number of programs are available publicly: MadGraph5_aMC@NLO [166] and Helac-NLO [184] provide full frameworks for NLO calculations; GoSam [185], Njet [186], OpenLoops [187] and Recola [188] calculate just the 1-loop part and are typically interfaced with an external tool for a combination with the appropriate tree-level amplitudes. Other tools such as NLOJet++ [189], MCFM [190,191], Vnfnlo [192], the Phox family [193] or BlackHat [194] implement analytic calculations and provide full frameworks to compute NLO cross sections for selected classes of processes. These tools are regularly updated and upgraded to enable more efficient amplitude evaluations, as well as to incorporate electroweak effects and corrections due to beyond-standard-model effects modelled using operators in the Standard Model Effective Theory (SMEFT) [195–206]. Recently, a lot of attention has also been paid to the calculation of NLO electroweak corrections. Electroweak corrections are especially important for transverse

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

momenta significantly above the W and Z masses, because they are enhanced by two powers of $\ln p_t/m_W$ for each power of the electroweak coupling, and close to Sudakov peaks[4], where most of the data lie and the best experimental precision can be achieved. For a review on EW corrections to collider processes see Ref. [207].

Given the progress in QCD and EW fixed-order computations, the largest unknown from fixed-order corrections is often given by the mixed QCD-electroweak corrections of $\mathcal{O}(\alpha_s\alpha)$. These mixed two-loop corrections are often available in an approximate form [208–222]. Complete computations of the mixed QCD–EW corrections to the neutral-current and charged-current Drell–Yan processes are now available [223–225].

NNLO. NNLO is considerably more complicated than NLO as it involves a further order in α_s, consisting of: the squared $(n+2)$-parton tree-level amplitude, the interference of the $(n+1)$-parton tree-level and 1-loop amplitudes, the interference of the n-parton tree-level and 2-loop amplitudes, and the squared n-parton 1-loop amplitude. Each of these elements involves large numbers of soft and collinear divergences, satisfying relations analogous to Eq. (9.16) which now involve multiple collinear or soft particles and higher loop orders (see *e.g.* Refs. [226–228]). Arranging for the cancellation of the divergences after numerical Monte Carlo integration has been one of the significant challenges of NNLO calculations, as has been the determination of the relevant 2-loop amplitudes.

After first differential calculations of $2 \to 1$ processes for hadron colliders, e.g. for vector boson [229] [230] and Higgs boson production in the large m_t limit [231] [232], a large variety of methods have been developed for the cancellation of divergences.

The most common are:

- **Antenna subtraction** [233, 234]: It is a local subtraction scheme with analytically integrated counterterms, removing angular correlations by averaging over azimuthal angles. Extensions of the original method include the generalization to identified jet flavours [235–238], photon fragmentation [239, 240], hadron fragmentation [241, 242], a streamlined antenna construction reducing spurious divergences [243–246], and a color-space formulation to enable a semi-automated computation beyond-leading-color [247,248].
- **q_T subtraction** [232]: This is a slicing method for processes with colourless final states or pairs of massive coloured particles. Extensions to top-pair production [148, 149, 249–251], beyond back-to-back Born kinematics (e.g. $t\bar{t}H$, $t\bar{t}W$) [252–254], mixed QCD–EW corrections [221, 223, 255, 256], power corrections at subleading order [257–259], treatments of fiducial cuts [258, 260–264], as well as to N^{3}LO [265–268] have been formulated recently.
- **Sector-improved residue subtraction** [269–271]: This is a fully local subtraction method combining FKS subtraction [175, 272] with sector decomposition [273–276]. Counterterms are obtained numerically, with improvements in a four-dimensional formulation [277]. Extensions to flavoured jets [278, 279] and B-hadron production [280–282] have been developed recently.
- **ColorFul subtraction** [283, 284]: This is a fully local subtraction method extending the Catani–Seymour dipole method [174] to NNLO, with analytic poles and numerical integration of finite terms. Extensions to colourless final states in hadronic collisions have been formulated [285] and implemented in the code `NNLOCAL` [286].
- **N-jettiness subtraction** [287–289]: This is a slicing method based on the resolution variable τ_N, suited for jet final states. It has been explicitly developed up to one jet at NNLO. Extensions towards N^{3}LO with known zero-jettiness ingredients is work in progress [290–302]. Subleading power corrections to improve the numerical efficiency of the method via SCET [303, 304], direct QCD [305], and for $V+j$ [306] have been computed. A treatment of fiducial and isolation cuts [258], as well as projection-to-Born correction factors to improving numerical stability [303, 307] have also been proposed.
- **Nested soft–collinear subtraction** [308–310]: This is a fully local subtraction method with analytic counterterms, formulated for hadronic initial/final states [311–313]. Extensions include the treatment of arbitrary multi-gluon final states in quark-antiquark annihilation [314], while the treatment of other partonic channels is ongoing.
- **Local analytic sector subtraction** [315–317]: This subtraction method combines FKS [175,272] and dipole subtraction [174], with analytic integration of counterterms. Extensions include the analytic pole cancellation for arbitrary multiplicity in e^+e^- [318], progress toward hadronic initial states [319] as well as first steps towards N^{3}LO [320].
- **Projection to Born** [321]: The method utilizes an inclusive NNLO calculation differential in Born kinematics, as well as a differential NLO cross section for the corresponding process with one extra jet in the final state. It is in principle generalisable to any order. It has been generalized to obtain fully differential N^{3}LO results in DIS jet production, Higgs decays, and gluon-fusion Higgs production [133, 322–324].
- **Locally finite subtraction** [325]: The method employs subtractions expressed as form-factor integrands with known integrals. The resulting subtracted amplitudes can then be evaluated efficiently through numerical integration. This approach exploits the universality of infrared singularities and requires only a relatively small set of subtraction terms.
- **Dual subtractions** [326]: This scheme constructs subtraction terms directly from loop diagrams by exploiting their dual representation, rather than from real-radiation matrix elements. It features built-in exact phase-space factorization and is applicable to both initial and final states, as well as to processes involving either massless or massive particles.

For overviews of NNLO subtraction methods see Ref [327] and Ref [328].

These methods have been applied to compute a large number of processes at NNLO, specifically:

- **Antenna subtraction** was applied to the NNLO calculations of $e^+e^- \to 3j$ [329–332], DIS jets [333–335], $pp \to$ (di-)jets [336–338], $pp \to \gamma\gamma$ [339], $pp \to \gamma + j/X$ [340], $pp \to V + j$ [341–343], $pp \to H + j$ [344], $pp \to VH(+j)$ [235, 345, 346], and Higgs in VBF [347].
- **Sector-improved residue subtraction** was applied to the NNLO calculation of top-quark processes [147, 348–352], $pp \to H + j$ [353, 354], inclusive jets [355], $pp \to 3\gamma$ [356], $pp \to 2\gamma + j$ [357], $pp \to \gamma + 2j$ [358], $pp \to W + j$ [359], $pp \to 3j$ [360] and $Wb\bar{b}$ production [361]. The finite top-mass corrections to inclusive Higgs production have also been computed [362].
- **q_T subtraction** was applied for the NNLO calculations of H [232, 363], V [230, 364], VV' [150, 151, 365–373] in MATRIX [152] or in MCFM [374–376], VH [377–379], HH [380, 381], VHH [382, 383], $t\bar{t}$ [148, 251], $b\bar{b}$ [149], three photons [384], $t\bar{t}H$ [252, 253], and $t\bar{t}W$ [254].
- **N-jettiness** was applied for the NNLO calculations of colour singlet processes [385], $V(+j)$ [288, 386–393], $H + j$ [394], colorless states [385, 395], top decay [396], and single-top s- [397] and t-channel [398, 399].
- **ColorFul subtraction** was applied to $H \to b\bar{b}$ [284] and $e^+e^- \to 3j$ [400–402].
- **Nested soft–collinear subtraction** was applied to VH [403] and VBF [404, 405].
- **Local analytic sector subtraction** was applied to $e^+e^- \to 2j$ [315].
- **Projection-to-Born** was applied to VBF [321], Higgs pair [406], single-top [398, 407], DIS jets [322, 323], and $H \to b\bar{b}$ [324].

Cross sections at the LHC are most often measured with fiducial cuts, for example on the transverse momenta and rapidities

[4] For the definition of Sudakov form factors or Sudakov peaks see e.g. Refs. [1, 2, 11].

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
xcept for Open Access articles.

of the measured objects, restricting the measurement to regions where the objects have a good efficiency to be detected and are well-reconstructed. Ideally, the theoretical predictions should also be constructed at the same fiducial level; the other possibility is to extrapolate the experimental fiducial results to the full phase space. Such an extrapolation, however, requires the extrapolation (typically using a parton shower Monte Carlo) to be accurate over the full phase space.

Comparisons of fixed-order predictions to fiducial measurements can sometimes result in the presence of large logarithms which degrade the accuracy of the prediction. Such is the case, for example, in the calculation of the Higgs rapidity distribution, in the diphoton final state. The imposition of transverse momenta and rapidity cuts on the two photons leads to an uncertainty notably greater at N^{3}LO than at NNLO, due to the presence of these logarithms. One possible solution is to change the form of the kinematic cut on the photons, to a product of the two photon transverse momenta [264], reducing the impact of the logarithms; another solution is to perform a resummation of the logarithms, restoring the expected precision [263]. The product cut is currently being implemented in both the ATLAS and CMS Higgs diphoton analyses.

The Les Houches precision wishlist compiles predictions needed to fully exploit the data that will be taken at the High Luminosity LHC [328, 408]. Most of the needed calculations require accuracy of at least NNLO QCD and NLO EW, and many require the prediction of $2 \to 3$ processes, such as, e.g., $W/Z+ \geq 2$ jets, $H+ \geq 2$ jets, and ttH to NNLO. The latter process has been computed at NNLO in Ref. [252] in the approximation where the Higgs boson in the double-virtual contribution is soft. This calculation considerably reduces the theory uncertainty on this process.

As discussed in this section, calculations at NLO can now be relatively easily generated by non-experts using the programs mentioned above. By now there are also a number of publicly available tools to compute a range of processes at NNLO accuracy in QCD, such as EERAD3 [330] (for e^+e^- collisions), [232], DYNNLO [230], DYTURBO [409], FEHIP [231], FEWZ [410], HTURBO [411], MATRIX [152], MCFM [385], SUSHI [142,412] or NNLOJET [413]. However, in some cases NNLO calculations can be too complex and CPU-intensive to allow such an approach. In these cases, the relevant matrix element information for a specific observable can be stored by means of interpolation grids developed originally for cross sections at NLO [414–416] and recently extended to include electroweak corrections [417]. The application to NNLO has been demonstrated for $t\bar{t}$ and for DIS jet cross sections in Refs. [418,419] and for jet production in hadron-hadron collisions in Ref. [420]. Each such interpolation grid corresponds to one fixed observable with specific selection criteria and binning, but is flexible with respect to the renormalization or factorization scale, the PDF, or the α_s evolution chosen for the cross-section computation. An even more flexible method, at the cost of requiring large amounts of storage space, saves huge numbers of partonic events in the form of ROOT n-tuples, which allow predictions to be generated on-the-fly for many observables of a particular process [421, 422]. Recent developments of both techniques for pp collisions at NNLO are described in Ref. [328].

9.2.3.3 *Resummation*

Many experimental measurements place tight constraints on emissions in the final state. For example, in e^+e^- events, that one minus the thrust should be less than some value $\tau \ll 1$, or, in $pp \to Z$, events that the Z-boson transverse momentum or the transverse momentum of the accompanying jet should be much smaller than the Z-boson mass. A further example is the production of heavy particles or jets near threshold (so that little energy is left over for real emissions) in DIS and pp collisions.

In such cases, the constraint vetoes a significant part of the integral over the soft and collinear divergence of Eq. (9.16). As a result, there is only a partial cancellation between real emission terms (subject to the constraint) and loop (virtual) contributions (not subject to the constraint), causing each order of α_s to be accompanied by a large coefficient $\sim L^2$, where *e.g.* $L = \ln \tau$ or $L = \ln(m_Z/p_t^Z)$. One ends up with a perturbative series, whose terms go as $\sim (\alpha_s L^2)^n$. It is not uncommon that $\alpha_s L^2 \gg 1$, so that the perturbative series converges very poorly if at all.[5] In such cases one may carry out a "resummation", which accounts for the dominant logarithmically enhanced terms to all orders in α_s, by making use of known properties of matrix elements for multiple soft and collinear emissions, and of the all-orders properties of the divergent parts of virtual corrections, following original works such as Refs. [423–432] and also through soft-collinear effective theory [433, 434] (*cf.* also the section on "Heavy-Quark and Soft-Collinear Effective Theory" in this *Review*, as well as Ref. [435]).

For cases with double logarithmic enhancements (two powers of logarithm per power of α_s), there are two classification schemes for resummation accuracy. Writing the cross section including the constraint as $\sigma(L)$ and the unconstrained (total) cross section as $\sigma_{\rm tot}$, the series expansion takes the form

$$\sigma(L) \simeq \sigma_{\rm tot} \sum_{n=0}^{\infty} \sum_{k=0}^{2n} R_{nk} \alpha_s^n(\mu_R^2) L^k, \qquad L \gg 1\,, \tag{9.20}$$

and leading log (LL) resummation means that one accounts for all terms with $k = 2n$, next-to-leading-log (NLL) includes additionally all terms with $k = 2n-1$, *etc.* Often $\sigma(L)$ (or its Fourier or Mellin transform) *exponentiates*,[6]

$$\sigma(L) \simeq \sigma_{\rm tot} \exp\left[\sum_{n=1}^{\infty} \sum_{k=0}^{n+1} G_{nk} \alpha_s^n(\mu_R^2) L^k\right], \qquad L \gg 1\,, \tag{9.21}$$

where one notes the different upper limit on k ($\leq n+1$) compared to Eq. (9.20). This is a more powerful form of resummation: the G_{12} term alone reproduces the full LL series in Eq. (9.20). With the form Eq. (9.21) one still uses the nomenclature LL, but this now means that all terms with $k = n+1$ are included, and NLL implies all terms with $k = n$, *etc.*

For a large number of observables, NLL resummations are available in the sense of Eq. (9.21) (see Refs. [439–441] and references therein). NNLL has been achieved for the DY and Higgs-boson p_t distributions [442–445] (also available in the CuTe [446], HRes [447] and ResBos [448] families of programs and also differentially in vector-boson decay products [262]) and related variables [449], for the p_t of vector-boson pairs [450], for the back-to-back energy-energy correlation in e^+e^- [451], the jet broadening in e^+e^- collisions [452], the jet-veto survival probability in Higgs and Z boson production in pp collisions [453–455],[7] an event-shape type observable known as the beam thrust [456], hadron-collider jet masses in specific limits [457] (see also Ref. [458]), the production of top anti-top pairs near threshold [459–461] (and references therein), and high-p_t W and Z production [462]. Automation of NNLL jet-veto resummations for different processes has been achieved in Ref. [463] (*cf.* also the NLL automation in Ref. [464]), while automation for a certain class of e^+e^- observables has been achieved in Ref. [465]. N^{3}LL resummations are available for the thrust variable, C-parameter and heavy-jet mass in e^+e^- annihilations [466–468], for p_t distribution of the Higgs boson [469,470] and Drell-Yan [471–474,474], also in heavy-quark annihilation [475], and weak gauge bosons [476–479], diphotons [480], for the jet-veto distribution [455, 481], for Higgs- and vector-boson production near threshold [482] and for Z-boson plus jet production using one-jettiness [483]. In order to make better contact with experimental measurements, recent years have

[5] To be precise one should be aware of two causes of the divergence of perturbative series. That which interests us here is associated with the presence of a new large parameter (*e.g.* ratio of scales). It is distinct from the renormalon-induced factorial divergences of perturbation theory discussed above.

[6] Whether or not this happens depends on the quantity being resummed. A classic example involves two-jet rate in e^+e^- collisions as a function of a jet-resolution parameter $y_{\rm cut}$. The logarithms of $1/y_{\rm cut}$ exponentiate for the k_t (Durham) jet algorithm [436], but not [437] for the JADE algorithm [438] (both are discussed below in Sec. 9.3.1.1).

[7] A veto on the jet phase space can be severe, for example by requiring exactly zero jets above a given transverse-momentum cut accompanying a Higgs boson, or relatively mild, for example by placing a transverse momentum cut of 30 GeV on the measurement of the production of a Higgs boson with one or more jets. In general, inclusive cross sections are preferable, as uncertainties on both the theoretical and experimental sides are smaller.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

seen an increasing interest in resummations in exclusive phase-space regions and joint resummations [481, 484–492]. Finally, there has also been considerable progress in resummed calculations for jet substructure, whose observables involve more complicated definitions than is the case for standard resummations, see *e.g.* Refs. [493–497] and references therein (see also Sec. 9.3.1.3).

9.2.3.4 *Fragmentation functions*

Since the parton-hadron transition is non-perturbative, it is not possible to perturbatively calculate quantities such as the energy-spectra of specific hadrons in high-energy collisions. However, one can factorize perturbative and non-perturbative contributions via the concept of fragmentation functions. These are the final-state analogue of the parton distribution functions which are used for initial-state hadrons. Like parton distribution functions, they depend on a (fragmentation) factorization scale and satisfy a DGLAP evolution equation.

It should be added that if one ignores the non-perturbative difficulties and just calculates the energy and angular spectrum of partons in perturbative QCD with some low cutoff scale $\sim \Lambda$ (using resummation to sum large logarithms of $\sqrt{s}/\Lambda$), then this reproduces many features of the corresponding hadron spectra [498]. This is often taken to suggest that hadronization is "local", in this sense it mainly involves partons that are close both in position and in momentum.

Section 19 of this *Review* provides further information and references on these topics, including also the question of heavy-quark fragmentation.

9.2.3.5 *Parton-shower Monte Carlo event generators*

Parton-shower Monte Carlo (MC) event generators like Pythia [499–501], Herwig [502–504], and Sherpa [505][8] provide fully exclusive simulations of QCD events at the level of measurable particles, the so-called "particle level" or "hadron level". Here, "measurable" refers to color-neutral particles with mean lifetimes τ long enough to be associated with tracks or decay vertices in particle detectors. Usually, this requires mean decay lengths $c\tau$ of around 10 mm. As such, MC event generators are a crucial tool for all applications that involve simulating the response of detectors to QCD events. Here we give only a brief outline of how they work and refer the reader to Sec. 43 for a full overview.

In general, we expect parton-shower matched predictions to differ from the underlying fixed-order results in regions where (1) there is a large sensitivity to jet shapes (for instance small R jets), (2) there is a restriction in phase space such that soft gluon resummation effects become important, (3) the observable contains multiple disparate scales, (4) there are perturbative instabilities at fixed order, *e.g.* related to kinematical cuts, and (5) the observable is sensitive to higher multiplicity states than those described by the fixed-order calculation (for an explicit study of some of these effects see *e.g.* [507]).

The MC generation of an event involves several stages. It starts with the random generation of the kinematics and partonic channels of whatever *hard scattering process* the user has requested at some high scale Q_0 (for complex processes and/or higher-order processes, this may be carried out by an external program). This is followed by a *parton shower*, usually based on the successive random generation of gluon emissions (and $g \to q\bar{q}$ splittings). Leading contributions to the shower have emissions that are ordered according to some ordering variable. Common choices of scale for the ordering of emissions are virtuality, transverse momentum or angle. Each emission is generated at a scale lower than the previous emission, following a (soft and collinear resummed) perturbative QCD distribution, which depends on the momenta of all previous emissions. Parton showering stops at a scale of order 1 GeV, at which point a *hadronization model* is used to convert the resulting partons into hadrons. One widely-used model involves stretching a color "string" across quarks and gluons, and breaking it up into hadrons [508, 509]. Another breaks each gluon into a $q\bar{q}$ pair and then groups quarks and antiquarks into colorless "clusters", which then give the hadrons [502]. As both models are tuned primarily to LEP data, the cluster and string models provide similar results for most observables sensitive to hadronization [507]. For pp and γp processes, modeling is also needed to treat the collision between the two hadron remnants, which generates an *underlying event* (UE), usually implemented via additional $2 \to 2$ scatterings ("multiple parton interactions", MPI) at a scale of a few GeV, following Ref. [510]. The parameter values for the MPI models must be determined from fits to minimum-bias and/or underlying-event observables of LHC collision data. As the different MC event generators are adapted to essentially the same measurements, ideally the respective MPI implementations should lead to similar predictions for each program. One complication, however, is some non-universality of the underlying event among different physics processes.

If possible, determinations of the uncertainties encountered in parton-shower Monte Carlo programs should be divided into perturbative and non-perturbative sources, as this will lead to better possibilities for understanding/improving them. If there is a mismatch between the components, then the accuracy obtained by the matrix elements and the parton shower may be compromised (as for example if the parton shower tuning may involve an enhanced strong coupling constant different from that used in the matrix elements). Such a tuned prescription may provide a good description of a particular data set, but it is more of a fit than a prediction. It is not clear if this perturbative tuning can be transferred to other processes or kinematics.

A deficiency of the soft and collinear approximations that underlie parton showers is that they may fail to reproduce the full pattern of hard wide-angle emissions, important, for example, in many new physics searches. It is therefore common to use LO multi-parton matrix elements to generate hard high-multiplicity partonic configurations as additional starting points for the showering, supplemented with some prescription (CKKW [511], MLM [512]) for consistently merging samples with different initial multiplicities. Monte Carlo generators, as described above, compute cross sections for the requested hard process that are correct at LO.

A wide variety of processes are available in MC implementations that are accurate at NLO, using the MC@NLO [513] or Powheg [514] prescriptions, through the MadGraph5_aMC@NLO [166], Powheg-Box [515] and Sherpa [168] programs. Techniques have also been developed to combine NLO plus parton shower (PS) accuracy for different multiplicities of final-state jets [516]. While NLO+PS accurate predictions can now be implemented in the above tools rather easily and are available for a range of processes, given the advances in NNLO calculations it is natural to seek for NNLO+PS accurate Monte Carlos as well. The two main approaches today are the MiNNLO [517] and Geneva [518] ones. NNLO plus shower accuracy was achieved first for Drell-Yan and Higgs production [519–521] and is now available for several $2 \to 2$ color singlet processes [522–538], as well as for heavy-quark pair-production, also accompained by a colour singlet [539–543]. Recently NNLO+PS accuracy for Drell Yan was also obtained using matching conditions at next-to-next-to-leading order in the sectorised VINCIA parton shower [544].

It is important to understand/verify the accuracy of the parton shower predictions in the Monte Carlo programs. A general framework for assessing the logarithmic accuracy of parton-shower algorithms has been formulated, based on their ability to reproduce the singularity structure of multi-parton matrix elements, and their ability to reproduce logarithmic resummation results [545]. The dominant contributions relevant for the extension of parton showers to higher logarithmic accuracy have been computed [546–550] and included in some algorithms.

There exist ways to improve on current parton-shower algorithms [551, 552] and to demonstrate the parton shower accuracy through a comparison to analytic next-to-leading logarithmic calculations for a range of observables [552]. Considerable progress has been achieved in recent years [551–563]. References [552, 555, 556, 559, 560] introduced the first shower implementations towards NLL, but these implementations did not include spin-correlation effects and lacked full color dependence at LL level. Reference [553] incorporated full color effects at

[8] The program ARIADNE [506] has also been widely used for simulating e^+e^- and DIS collisions.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
xcept for Open Access articles.

the NLL level, while spin correlations at NLL were included in Refs. [557, 558], resulting in an NLL accurate parton shower for proton-proton collisions [561, 562]. The modifications necessary for processes such as Deep Inelastic Scattering (DIS) and Vector Boson Fusion (VBF) are addressed in [563]. The novel Alaric parton shower for hadron colliders is introduced in Ref. [564]. First steps towards NNLL parton showers for classes of observables dominantly sensitive to low-energy (soft) emissions have been presented in Ref. [565]. The first public implementation within the PanScales framework is described in Ref. [566]. Finally, a new standard for assessing the logarithmic accuracy of NNLL parton showers is proposed in Ref. [567].

9.2.4 *Accuracy of predictions*

Estimating the accuracy of perturbative QCD predictions is not an exact science. It is often said that LO calculations are accurate to within a factor of two. This is based on experience with NLO corrections in the cases where these are available. In processes involving new partonic scattering channels at NLO and/or large ratios of scales (such as jet observables in processes with vector bosons, or the production of high-p_t jets containing B-hadrons), the ratio of the NLO to LO predictions, commonly called the "K factor", can be substantially larger than two. NLO corrections tend to be large for processes for which there is a great deal of color annihilation in the interaction. In addition, NLO corrections tend to decrease as more final state legs are added.

For calculations beyond LO, one approach to estimate the perturbative uncertainty is to base it on the last known perturbative correction; this may lead to misleading results if new subprocesses are present at the next-higher order. A more widely used method is to estimate it from the change in the prediction when varying the renormalization and factorization scales around a central value Q that is taken close to the physical scale of the process. A conventional range of variation is $Q/2 < \mu_R, \mu_F < 2Q$, varying the two scales independently with the restriction $\frac{1}{2} < \mu_F/\mu_R < 2$ [568]. This constraint limits the risk of misleadingly small uncertainties due to fortuitous cancellations between the μ_F and μ_R dependence when both are varied together, while avoiding the appearance of large logarithms of μ_R^2/μ_F^2 when both are varied completely independently. Where possible, it can be instructive to examine the two-dimensional scale distributions (μ_R *vs.* μ_F) to obtain a better understanding of the interplay between μ_R and μ_F. This procedure should not be assumed to always estimate the full uncertainty from missing higher orders, but it does indicate the size of one important known source of higher-order ambiguity.[9]

As discussed before, several $2 \to 2$ processes at the LHC are now known to NNLO. This typically results in a large reduction in the uncertainty from that obtained at NLO. However, care must be taken in the estimate of the uncertainty in processes containing jets, as accidental cancellations of the scale uncertainties may result in an artificial reduction of the scale uncertainty; for some values of the jet radius R the uncertainty may even be close to zero. There are several possibilities for providing a more realistic estimate of the scale uncertainty for such processes [507], but none have been widely adopted at the LHC. A recent study [576] has carried out a NNLL resummation matched to a NNLO perturbative calculation for inclusive jet production and has found a more realistic scale uncertainty for cross sections involving small-R jets.

Calculations that involve resummations usually have an additional source of uncertainty associated with the choice of argument of the logarithms being resummed, *e.g.* $\ln(2\frac{p_t^Z}{m_Z})$ as opposed to $\ln(\frac{1}{2}\frac{p_t^Z}{m_Z})$, as well as a prescription to switch off resummation effects when the logarithm is not large. In addition to varying renormalization and factorization scales, it is common practice to vary the argument of the logarithm by a suitable factor in either direction with respect to the default argument.

The accuracy of QCD predictions is limited also by non-perturbative (or hadronization) corrections, which typically scale as a power of Λ/Q.[10] For measurements that are directly sensitive to the structure of the hadronic final state, the corrections are usually linear in Λ/Q. The non-perturbative corrections are further enhanced in processes with a significant underlying event (*i.e.* in pp and $p\bar{p}$ collisions) and the impact of non-perturbative corrections is larger in cases where the perturbative cross sections fall steeply as a function of p_t or some other kinematic variable, for example in inclusive jet p_t or dijet mass spectra.

Under high-luminosity running conditions, such as 13 TeV at the LHC, there can be about 50 minimum-bias interactions occurring at each beam-beam crossing. This additional energy needs to be subtracted, and is typically removed by means of a rapidity-dependent transverse-energy density determined on an event-by-event basis [577]. This subtraction usually also removes the underlying event, which must be added back in by means of MC event generator modelling, if one wants to restore the measured event to the particle level.

Non-perturbative corrections are commonly estimated from the difference between Monte Carlo events at the "parton level" and at particle level. Parton level refers to the stage of the parton shower, where the evolution is stopped at an energy scale of typical hadron masses of a few GeV. An issue to be aware of is that "parton level" is not a uniquely defined concept. For example, in a MC event generator such a procedure depends on an arbitrary and tunable internal cutoff scale that separates the parton showering from the hadronization. In contrast, no such cutoff scale exists in an NLO or NNLO partonic calculation. The uncertainties in these corrections are often estimated by comparing different tunes of the various MC event generators. It should be noted that such estimates are not guaranteed to fully cover the true uncertainties.

Alternative methods exist for estimating hadronization corrections that attempt to analytically deduce non-perturbative effects in one observable based on measurements of other observables (see the reviews [26, 578]). While they directly address the problem of different possible definitions of parton level, it should also be said that they are far less flexible than Monte Carlo programs and not always able to provide equally good descriptions of the data.

One of the main issues is whether the fixed-order partonic final state of a NLO or NNLO prediction can match the parton shower in its ability to describe the experimental jet shape (minus any underlying event). Calculations at NNLO provide a better match to the parton shower predictions than do NLO ones, as might be expected from the additional gluon available to describe the jet shape. The hadronization predictions appear to work for both orders, but at an unknown accuracy.

9.3 Experimental studies of QCD

Since we are not able to directly measure partons (quarks or gluons), but only hadrons and their decay products, a central issue for every experimental study of perturbative QCD is establishing a correspondence between observables obtained at the parton and the hadron level. The only theoretically sound correspondence is achieved by means of *infrared and collinear safe* quantities, which allow one to obtain finite predictions at any order of perturbative QCD.

As stated above, the simplest case of infrared- and collinear-safe observables are some inclusive cross sections or including decay widths.

More generally, when measuring fully inclusive observables, the final state is not analyzed at all regarding its (topological, kinematical) structure or its composition. Basically, the relevant information consists of the rate of a process ending up in a partonic or hadronic final state. In e^+e^- annihilation, widely used examples are the ratios of partial widths or branching ratios for the electroweak decay of particles into hadrons or leptons such as Z or τ decays (*cf.* Sec. 9.2.1). Such ratios are often favored over absolute cross sections or partial widths because of large cancellations of experimental and theoretical systematic uncertainties. The strong suppression of non-perturbative effects, $\mathcal{O}(\Lambda^4/Q^4)$, is one of the attractive features of such observables, however, at the same time, the sensitivity to radiative QCD corrections is small,

[9] Various studies have been carried out on how to estimate uncertainties from missing higher orders that go beyond scale variations [569–573], including recently the use of theory nuisance parameters [574, 575].

[10] In some circumstances, the scale in the denominator could be a smaller kinematic or physical scale that depends on the observable.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

which for example leads to a larger statistical uncertainty when using them for the determination of the strong coupling constant. In the case of τ decays not only the hadronic branching ratio is of interest, but also moments of the spectral functions of hadronic τ decays, which sample different parts of the decay spectrum and thus provide additional information. Other examples of fully inclusive observables are structure functions (and related sum rules) in DIS. These are extensively discussed in Sec. 18 of this *Review*.

On the other hand, often the structure or composition of the final state are analyzed, and cross sections differential in one or more variables characterizing this structure are of interest. Examples are jet rates, jet substructure, event shapes or transverse-momentum distributions of jets or vector bosons in hadron collisions. The case of fragmentation functions, *i.e.* the measurement of hadron production as a function of the hadron momentum relative to some hard scattering scale, is discussed in Sec. 19 of this *Review*.

It is worth mentioning that, besides the correspondence between the parton and hadron level, also a correspondence between the hadron level and the actually measured quantities in the detector has to be established. The simplest examples are corrections for finite experimental acceptance and efficiencies. Whereas acceptance corrections essentially are of theoretical nature, since they involve extrapolations from the measurable (partial) to the full phase space, other corrections such as for efficiency, resolution and response are of experimental nature. For example, measurements of differential cross sections such as jet rates require corrections in order to relate, *e.g.*, the energy deposits in a calorimeter to the jets at the hadron level. Note that, while the underlying event energy is part of the event to be measured, particles from additional interactions from other proton-proton collisions are not, and this energy must be subtracted from the jet energy measurement [577]. Typically, detector simulations and/or data-driven methods are used in order to obtain these corrections. Care should be taken here to clearly separate between the parton-to-hadron level and hadron-to-detector level corrections. Finally, for the sake of an easy comparison to the results of other experiments and/or theoretical calculations, it is suggested to provide, whenever possible, measurements corrected for detector effects and/or all necessary information related to the detector response (*e.g.*, the detector response matrix). Any fiducial phase space for measurements should be defined as close as possible to the detector-level selection in order to minimize model-dependent extrapolations. A versatile repository for storing such information is the use of Rivet routines [579].

9.3.1 *Hadronic final-state observables*

9.3.1.1 *Jets*

In hard interactions, final-state partons and hadrons appear predominantly in collimated bunches, which are generically called *jets*. To a first approximation, a jet can be thought of as a hard parton that has undergone soft and collinear showering and then hadronization. Jets are used both for testing our understanding and predictions of high-energy QCD processes, and also for identifying the hard partonic structure of decays of massive particles such as top quarks and W, Z, and Higgs bosons.

In order to map observed hadrons onto a set of jets, one uses a *jet definition*. The mapping involves explicit choices: for example when a gluon is radiated from a quark, establishing for what range of kinematics the gluon should be part of the quark jet, or instead form a separate jet. Good jet definitions are infrared and collinear safe, simple to use in theoretical and experimental contexts, applicable to any type of inputs (parton or hadron momenta, charged particle tracks, and/or energy deposits in the detectors) and lead to jets that are not too sensitive to non-perturbative effects.

An extensive treatment of the topic of jet definitions is given in Ref. [580] (for e^+e^- collisions) and Refs. [581–583]. Here we briefly review the two main classes: cone algorithms, extensively used at hadron colliders before the LHC, and sequential recombination algorithms, more widespread in e^+e^- and ep colliders and at the LHC.

Cone algorithms typically start from a seed particle, summing the momenta of all particles within a cone of radius (R) in rapidity–azimuth space. The cone axis is iteratively updated until stable, and a jet is defined if its transverse momentum exceeds ($p_{t,\min}$). Variants differ in the seed choice and in how they resolve overlapping cones. Seeded algorithms (e.g. JetCLU, MidPoint) suffer from infrared and collinear unsafety, incompatibility with higher-order QCD, and instabilities. They were used at the Tevatron but are deprecated and not employed at the LHC. The modern alternative is the seedless SISCone algorithm [584], which is infrared safe.

Sequential recombination algorithms at hadron colliders (and in DIS) are characterized by a distance $d_{ij} = \min(k_{t,i}^{2p}, k_{t,j}^{2p})\Delta_{ij}^2/R^2$ between all pairs of particles i, j, where Δ_{ij} is their separation in the rapidity-azimuthal plane, $k_{t,i}$ is the transverse momentum w.r.t. the incoming beams, and R is a free parameter. At the LHC, R is typically in the range from 0.4 to 0.8, although analyses can also use jet sizes up to 1.0-1.2. They also involve a "beam" distance $d_{iB} = k_{t,i}^{2p}$. One identifies the smallest of all the d_{ij} and d_{iB}, and if it is a d_{ij}, then i and j are merged into a new pseudo-particle (with some prescription, a recombination scheme, for the definition of the merged four-momentum). If the smallest distance is a d_{iB}, then i is removed from the list of particles and called a jet. As with cone algorithms, one usually considers only jets above some transverse-momentum threshold $p_{t,\min}$. The parameter p determines the kind of algorithm: $p = 1$ corresponds to the (*inclusive-*)k_t algorithm [436, 585, 586], $p = 0$ defines the *Cambridge-Aachen* algorithm [587, 588], while for the *anti-*k_t algorithm $p = -1$ [589]. All these variants are infrared and collinear safe. Whereas the former two lead to irregularly shaped jet boundaries, the latter results in cone-like boundaries, except in situations where there are nearby jets. The *anti-*k_t algorithm has become the de-facto standard for the LHC experiments.

In e^+e^- annihilation the k_t algorithm [436] uses $y_{ij} = 2\min(E_i^2, E_j^2)(1-\cos\theta_{ij})/Q^2$ as distance measure between two particles/partons i and j and repeatedly merges the pair with smallest y_{ij}, until all y_{ij} distances are above some threshold $y_{\rm cut}$, the jet resolution parameter. Q is a measure of the overall hardness of the event. The (pseudo)-particles that remain at this point are called the jets. Here it is $y_{\rm cut}$ (rather than R and $p_{t,\min}$) that should be chosen according to the needs of the analysis. The two-jet rate in the k_t algorithm has the property that logarithms $\ln(1/y_{\rm cut})$ exponentiate. This is one reason why it is preferred over the earlier JADE algorithm [438], which uses the distance measure $y_{ij} = 2\,E_i\,E_j\,(1-\cos\theta_{ij})/Q^2$. Note that other variants of sequential recombination algorithms for e^+e^- annihilations, using different definitions of the resolution measure y_{ij}, exhibit much larger sensitivities to fragmentation and hadronization effects than the k_t and JADE algorithms [590]. Exclusive versions of sequential algorithms recombine objects into a predefined number of jets. Efficient implementations of all the above algorithms are available through the *FastJet* package [591].

While building infrared safe jets is generally considered a solved problem, this is not quite the case when one also wishes to assign a flavor to a jet. In fact, the general experimental definition considers a flavored-jet to be a jet that contains at least one flavor tag (such as a B or D meson) above a given transverse-momentum threshold. Because of collinear or soft wide-angle $g \to q\bar{q}$ splittings, it is easy to see that such a definition is neither collinear nor infrared safe. This problem was addressed in Ref. [592,593] in the context of heavy-flavor production at the Tevatron. However, the jet-algorithm proposed in that work was impractical to implement experimentally because it was based on the k_t-algorithm. Furthermore, it required tagging two nearby flavored hadrons and involved a rather complex beam-distance measure. Since most experimental studies at the LHC instead rely on the anti-k_t algorithm, recent investigations have focused on developing algorithms that preserve the anti-k_t kinematics of the jets while assigning jet flavors in an infrared-safe way [594–596]. It turns out that the problem is more involved than anticipated, and a formulation of infrared-safe anti-k_t-like jets could only be achieved by introducing an interleaved flavor neutralization procedure [597]. For a comparison between these algorithms see Ref. [598].

An unfolding procedure will be necessary to convert experimental measurements of flavor-jets to a form that can be precisely compared to theoretical predictions. In any experimental setting,

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is subject to CC BY except for Open Access articles.

not all gluon splittings into b or c quark pairs can be identified. In addition, the gluon splitting treatment incorporated into the parton shower Monte Carlos does not agree exactly with what is measured in the data. To reach an improved level of precision in the comparison of theory to experiment, an improved understanding of gluon splitting into $b\bar{b}$ and $c\bar{c}$ pairs between data and parton shower Monte Carlos is needed.

9.3.1.2 *Event Shapes*

Event-shape variables are functions of the four momenta of the particles in the final state and characterize the topology of an event's energy flow. They are sensitive to QCD radiation (and correspondingly to the strong coupling) insofar as gluon emission changes the shape of the energy flow.

The classic example of an event shape is the *thrust* [599,600] in e^+e^- annihilations, defined as

$$\hat{\tau} = \max_{\vec{n}_\tau} \frac{\sum_i |\vec{p}_i \cdot \vec{n}_\tau|}{\sum_i |\vec{p}_i|} \,, \tag{9.22}$$

where $\vec{p}_i$ are the momenta of the particles or the jets in the final-state and the maximum is obtained for the thrust axis $\vec{n}_\tau$. In the Born limit of the production of a perfect back-to-back $q\bar{q}$ pair, the limit $\hat{\tau} \to 1$ is obtained, whereas a perfectly spherical many-particle configuration leads to $\hat{\tau} \to 1/2$. Further event shapes of similar nature have been extensively measured at LEP and at HERA, and for their definitions and reviews we refer to Refs. [1, 8, 578, 601, 602]. The energy-energy correlation function [603], namely the energy-weighted angular distribution of produced hadron pairs, and its associated asymmetry are further shape variables which have been studied in detail at e^+e^- colliders. For hadron colliders the appropriate modification consists in only taking the transverse-momentum component [604]. The event shape variable *N-jettiness* has been proposed [605] that measures the degree to which the hadrons in the final state are aligned along N jet axes or the beam direction. It vanishes in the limit of exactly N infinitely narrow jets.

Phenomenological discussions of event shapes at hadron colliders can be found in Refs. [605–609]. Measurements of hadronic event-shape distributions have been published by CDF [610], ATLAS [611–617] and CMS [618–621].

Event shapes are used for many purposes. These include measuring the strong coupling (see *e.g.* Ref. [617]), tuning the parameters of Monte Carlo programs, investigating analytical models of hadronization and distinguishing QCD events from events that might involve decays of new particles (giving event-shape values closer to the spherical limit).

9.3.1.3 *Jet substructure, quark vs. gluon jets*

Jet substructure, which can be resolved by finding subjets or by measuring jet shapes, is sensitive to the details of QCD radiation in the shower development inside a jet and has been extensively used to study differences in the properties of quark and gluon induced jets, strongly related to their different color charges. There is clear experimental evidence that gluon jets have a softer particle spectrum and are "broader" than (light-) quark jets (as expected from perturbative QCD) when looking at observables such as the jet shape $\Psi(r/R)$ (see *e.g.* Ref. [622]). This is the fraction of transverse momentum contained within a subcone of cone-size r for jets of cone-size R. It is sensitive to the relative fractions of quark and gluon jets in an inclusive jet sample and receives contributions from soft-gluon initial-state radiation and the underlying event. Therefore, it has been widely employed for validation and tuning of Monte Carlo parton-shower models. Furthermore, this quantity turns out to be sensitive to the modification of the gluon radiation pattern in heavy ion collisions (see *e.g.* Ref. [623]).

Jet shape measurements using proton-proton collision data have been presented for inclusive jet samples [624–626] and for top-quark production [627]. Further discussions, references and summaries can be found in Refs. [602,628–630] and Sec. 4 of Ref. [631].

The use of jet substructure has also been investigated in order to distinguish QCD jets from jets that originate from hadronic decays of boosted massive particles (high-p_t electroweak bosons, top quarks and hypothesized new particles). A considerable number of experimental studies have been carried out with Tevatron and LHC data, in order to investigate the performance of the proposed algorithms for resolving jet substructure and to apply them to searches for new physics, as well as to the reconstruction of boosted top quarks, vector bosons and the Higgs boson. For reviews of this rapidly growing field, see Sec. 5.3 of Ref. [581], Refs. [496, 497, 631–637] and references therein. One convenient representation for visualizing jet substructure is through the Lund plane [638]. From a theoretical perspective, the Lund plane would be constructed using quarks and gluons, but similar observables can be constructed through the use of jets, as described in detail in Ref. [639].

Neural network techniques and deep learning methods have also been applied to jet and top physics and jet substructure, see *e.g.* Refs. [640–643]. Perhaps no other subfield has benefitted as much from machine learning techniques as the study of jet substructure. As a jet can have O(100) constituents each with kinematic and other information, jet substructure analysis is naturally a highly multivariate problem. Deep learning techniques can use all of the available information to study jets in their natural high dimensionality. Such techniques have not only improved discrimination between different final states/types of jets, but have also improved our understanding of perturbative QCD. For a review see Ref. [495].

9.3.2 *QCD measurements at colliders*

There exists a wealth of data on QCD-related measurements in e^+e^-, ep, pp, and $p\bar{p}$ collisions, to which a short overview like this would not be able to do any justice. Reviews of the subject have been published in Refs. [601, 602] for e^+e^- colliders and in Ref. [644] for ep scattering, whereas for hadron colliders overviews are given in, *e.g.*, Refs. [582, 629] and Refs. [2, 11, 645–647].

Below we concentrate our discussion on measurements that are most sensitive to hard QCD processes with focus on jet production.

9.3.2.1 e^+e^- *colliders*

Analyses of jet production in e^+e^- collisions are mostly based on data from the JADE experiment at center-of-mass energies between 14 and 44 GeV, as well as on LEP collider data at the Z resonance and up to 209 GeV. The analyses cover the measurements of (differential or exclusive) jet rates (with multiplicities typically up to 4, 5 or 6 jets), the study of three-jet events and particle production between the jets, as well as four-jet production and angular correlations in four-jet events.

Event-shape distributions from e^+e^- data have been an important input to the tuning of parton shower MC models, typically matched to matrix elements for three-jet production. In general these models provide good descriptions of the available, highly precise data. Especially for the large LEP data sample at the Z peak, the statistical uncertainties are mostly negligible and the experimental systematic uncertainties are at the percent level or even below. These are usually dominated by the uncertainties related to the MC model dependence of the efficiency and acceptance corrections (often referred to as "detector corrections").

Observables measured in e^+e^- collisions have been used for determinations of the strong coupling constant (*cf.* Section 9.4 below) and for putting constraints on the QCD color factors (*cf.* Sec. 9.1 for their definitions), thus probing the non-Abelian nature of QCD. Angular correlations in four-jet events are sensitive at leading order. Some sensitivity to these color factors, although only at NLO, is also obtained from event-shape distributions. Scaling violations of fragmentation functions and the different subjet structure in quark and gluon induced jets also give access to these color factors. A compilation of results [602] quotes world average values of $C_A = 2.89 \pm 0.03\,(\text{stat}) \pm 0.21\,(\text{syst})$ and $C_F = 1.30 \pm 0.01\,(\text{stat}) \pm 0.09\,(\text{syst})$, with a correlation coefficient of 82%. These results are in perfect agreement with the expectations from SU(3) of $C_A = 3$ and $C_F = 4/3$.

9.3.2.2 *DIS and photoproduction*

Jet measurements in ep collisions, both in the DIS and photoproduction regimes, allow for tests of QCD factorization (as they involve only one initial state proton and thus one PDF function), and provide sensitivity to both the gluon PDF and to the strong

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

coupling constant. Calculations are available at NNLO in both regimes [333, 334]. An N^{3}LO calculation using the Projection-to-Born method was also presented in Ref. [322, 323]. Experimental uncertainties of the order of 5–10% have been achieved, whereas statistical uncertainties are negligible to a large extent. For comparison to theoretical predictions, at large jet p_t the PDF uncertainty dominates the theoretical uncertainty (typically of order 5–10%, in some regions of phase space up to 20%), therefore jet observables become useful inputs for PDF fits.

In general, the data are well described by the NLO and NNLO matrix-element calculations, combined with DGLAP evolution equations, in particular at large Q^2 and central values of jet pseudo-rapidity.

In the case of photoproduction, a wealth of measurements with low p_t jets were performed in order to constrain the photon content of the proton (which is by now determined with percent accuracy thanks to the LUX approach [155, 156]). A few examples of measurements can be found in Refs. [648–652] for photoproduction and in Refs. [653–662] for DIS.

9.3.2.3 *Hadron-hadron colliders*

The spectrum of observables and the number of measurements performed at hadron colliders is enormous, probing many regions of phase space and covering a huge range of cross sections, as exemplified in Fig. 9.1 for a wide class of processes by the CMS (top) and ATLAS (bottom) experiments. In general, the theory agreement with data is excellent for a wide variety of processes, indicating the success of perturbative QCD with the PDF and the strong coupling as inputs. For the sake of brevity, in the following only certain classes of those measurements will be discussed, which permit various aspects of the QCD studies to be addressed. Most of our discussion will focus on LHC results, which are available for center-of-mass energies of 2.76, 5, 7, 8 13, and 13.6 TeV, with integrated luminosities of up to 140 fb^{-1} at 13 TeV, and up to 250 fb^{-1} at 13.6 TeV.

Generally speaking, besides representing precision tests of the Standard Model and QCD in particular, these measurements serve several purposes, such as: (i) probing pQCD and its various approximations and implementations in MC models to quantify the order of magnitude of not yet calculated contributions and to gauge their precision when used as background predictions to searches for new physics, or (ii) extracting/constraining model parameters such as the strong coupling constant or PDFs.

The final states measured at the LHC include single, double and triple gauge boson production, top production (single top, top pair and four top production), Higgs boson production, alone and in conjunction with a W or Z boson, and with a top quark pair. Many/most of these events are accompanied by additional jets. So far only limits have been placed on double Higgs production. The volume of LHC results prohibits a comprehensive description in this *Review*; hence, only a few highlights will be presented [663–667].

Among the most important cross sections measured, and the one with the largest dynamic range, is the inclusive jet spectrum as a function of the jet transverse momentum (p_t), for several rapidity regions and for p_t up to 700 GeV at the Tevatron and $\sim$ 3.5 TeV at the LHC. It is worth noting that this latter upper limit in p_t corresponds to a distance scale of $\sim 10^{-19}$ m: no other experiment so far is able to directly probe smaller distance scales of nature than this measurement. The Tevatron inclusive jet measurements in Run 2 (Refs. [670–673]) were carried out with the MidPoint jet clustering algorithm (or its equivalent) and, in a few cases, with the k_t jet clustering algorithm. Most of the LHC measurements use the *anti-k_t* algorithm, with a variety of jet radii. The use of multiple jet radii in the same analysis allows a better understanding of the underlying QCD dynamics. For example, as discussed earlier, a study of the R-dependence of jet production at NNLO made clear that there are accidental cancellations in the scale dependence. The typical central scale choices used in the theoretical comparisons are related either to the transverse momentum of each jet (p_T^{jet}), or the sum of transverse energies in the event (H_T). Measurements by ALICE, ATLAS and CMS have been published in Refs. [674–685].

In general, we observe a good description of the data by the NLO and NNLO QCD predictions over about 11 orders of magnitude in cross section, as long as care is taken for the functional form of the central scale choice [686]. The experimental systematic uncertainties are dominated by the jet energy scale uncertainty, quoted to be in the range of a few percent (see for instance the review in Ref. [687]), leading to uncertainties of $\sim 5-30\%$ on the cross section, increasing with p_t and rapidity. The PDF uncertainties dominate the theoretical uncertainty at large p_t and rapidity. In fact, inclusive jet data are among the most important inputs to global PDF fits, in particular for constraining the high-x gluon PDF [688–690]. Constraints on the PDFs can also be obtained from ratios of inclusive cross sections at different center-of-mass energies [675, 680]. Ratios of jet cross sections are a means to (at least partially) cancel the jet energy scale uncertainties and thus provide jet observables with significantly improved precision.

Dijet events are typically analyzed in terms of their invariant mass or average dijet p_t and angular distributions, which allows for tests of NLO and NNLO QCD predictions (see *e.g.* Refs. [679, 691, 692] for recent LHC results), and for setting stringent limits on deviations from the Standard Model, such as quark compositeness or contact interactions (some examples can be found in Refs. [682, 693–699]). Furthermore, dijet azimuthal correlations between the two leading jets, normalized to the total dijet cross section, are an extremely valuable tool for studying the spectrum of gluon radiation in the event. The azimuthal separation of the two leading jets is sensitive to multi-jet production, avoiding at the same time large systematic uncertainties from the jet energy calibration. For example, results from the Tevatron [700, 701] and the LHC [616, 702–706] show that the LO (non-trivial) prediction for this observable, with at most three partons in the final state, is not able to describe the data for an azimuthal separation below $2\pi/3$, where NLO contributions (with 4 partons) restore the agreement with data. In addition, this observable can be employed to tune Monte Carlo predictions of soft gluon radiation. Further examples of dijet observables that probe special corners of phase space are those that involve forward (large rapidity) jets and where a large rapidity separation, possibly also a rapidity gap, is required between the two jets. Reviews of such measurements can be found in Ref. [629], showing that no single prediction is capable of describing the data in all phase-space regions. In particular, no conclusive evidence for BFKL effects in these observables has been established so far.

Beyond dijet final states, measurements of the production of three or more jets, including cross section ratios, have been performed (see Refs. [629, 707] for recent reviews), as a means of testing perturbative QCD predictions, determining the strong coupling constant, and probing/tuning MC models, in particular those combining multi-parton matrix elements with parton showers [617, 708]. The calculation of three-jet production to NNLO [360] will allow more precise predictions of the three-jet to two-jet ratio, and thus the extraction of $\alpha_s(m_Z^2)$ from this observable. This calculation also allows for the use of transverse energy-energy correlations (TEEC) for the determination of $\alpha_s(m_Z^2)$ [617].

W and Z production serve as benchmark cross sections at the LHC. The large boson mass stabilizes perturbative predictions, which results in better theoretical accuracy. In terms of experimental precision, measurements of inclusive vector boson (W, Z) production provide the most precisely determined observables at hadron colliders so far. This is because the experimental signatures are based on charged leptons which are measured much more accurately than jets or photons. At the LHC [709–719], the dominant uncertainty stems from the luminosity determination ($\sim$ 1.7%), while other uncertainties (*e.g.* statistical or from lepton efficiencies) are controlled at the $\sim$0.5–3% level. The uncertainty from the acceptance correction of about $\sim$1–2% can be reduced by measuring so-called fiducial cross sections, *i.e.* by applying kinematic cuts also to the particle level of the theoretical predictions. Measurements combining the electron and muon final states were able to achieve a precision a few per mille level in the dilepton final state for the normalized cross section for p_T^{ll} less than 30 GeV [720, 721]. This level of precision can also be achieved by measuring cross section ratios (W/Z or W^+/W^-). On the

theory side, as discussed earlier in this *Review*, the production of these color-singlet states has been calculated to N^{3}LO [137–139]. Since the dominant theoretical uncertainty is related to the choice of PDFs, these high-precision data provide useful handles for PDF determinations.

Further insights are obtained from measurements of differential vector boson production, as a function of the invariant dilepton mass, the boson's rapidity or its transverse momentum. For example, the dilepton invariant mass distribution has been measured [722–727] for masses between 15 and 3000 GeV, covering more than 8 orders of magnitude in cross section. NNLO QCD predictions, together with modern PDF sets and including higher-order electroweak and QED final-state radiation corrections, describe the data to within 5–10% over this large range, whereas NLO predictions show larger deviations, unless matched to a parton shower.

Similar conclusions can be drawn from the observed rapidity distribution of the dilepton system (see *e.g.* Refs. [709, 717, 723]) or, in the case of W production, from the observed charged lepton rapidity distribution and its charge asymmetry. The latter is particularly sensitive to differences among PDF sets [709, 728–730], also thanks to the high precision achieved by the ATLAS and CMS experiments for central rapidity ranges. These measurements are extended to the very forward region, up to 4.5 in lepton rapidity, by the LHCb experiment [715, 716, 731].

An overview of these kinds of measurement can be found in Ref. [629]. There one can also find a discussion of and references to LHC results from studies of the vector boson's transverse-momentum distribution, p_t^V (see also Refs. [720, 732–734]). This observable covers a wide kinematic range and probes different aspects of higher-order QCD effects. It is sensitive to jet production in association with the vector boson, without suffering from the large jet energy scale uncertainties. In the p_t^V region of several tens of GeV to over 1 TeV, the NNLO predictions for V+jet can be used to predict the high-p_t boson production cross section.[11] The NNLO predictions agree with the data to about 10%, and agree somewhat better at high transverse momentum than do the NLO predictions [735]. At transverse momenta below ∼20 GeV, the fixed-order predictions fail and soft-gluon resummation is needed to restore the agreement with data. The soft gluon resummation can either be performed analytically, or effectively using parton showering implemented in Monte Carlo programs. While analytic approaches reach a higher perturbative precision, they typically refer to inclusive measurements without fiducial cuts.

The addition of further jets to the final state extends the kinematic range as well as increasing the complexity of the calculation/measurements. The number of results obtained both at the Tevatron and at the LHC is extensive; summaries can be found in Refs. [629, 736], and more recent results can be found in Refs. [735, 737–741]. The measurements cover a very large phase space, *e.g.* with jet transverse momenta between 30 GeV and ∼ 1.5 TeV and jet rapidities up to $|y| < 4.4$ [735, 741, 742]. Jet multiplicities as high as seven jets accompanying the vector boson have already been measured at the LHC, together with a substantial number of other kinematical observables, such as angular correlations among the various jets or among the jets and the vector boson, or the sum of jet transverse momenta, H_T. Whereas the jet p_t and H_T distributions are dominated by jet energy scale uncertainties at levels similar to those discussed above for inclusive jet production, angular correlations and jet multiplicity ratios have been measured with a precision of ∼ 10%, see *e.g.* Refs. [619, 743].

NLO calculations for up to five jets [744] in addition to the vector boson are in good agreement with the data over that phase space, where the calculations are applicable. Predictions for V+jet at NNLO improve the description of the data for distributions involving the vector boson or the leading jet. MC models that implement parton shower matching to matrix elements (either at LO or NLO) have mixed results.

[11] For these calculations, there is a requirement of the presence of a jet, but the p_t cut is typically small (30 GeV) compared to the high p_t region being discussed here.

The challenges get even more severe in the case of vector boson plus heavy-quark (b, c) production: on the theory side because an additional scale is introduced by the heavy-quark mass, and different schemes exist for the handling of heavy quarks and their mass effects in the initial and/or final state; and on the experimental side because additional uncertainties related to the heavy-flavor tagging must be considered [745] (see also the discussion regarding flavor-jet definition in Sec. 9.3.1.1). A review of heavy-quark production at the LHC is presented in Ref. [746], where the p_t and mass spectra of the pair of b-jets are found to be well modeled within uncertainties by most generators for b-jet production with or without associated W and Z bosons. However, sizable differences between data and predictions are seen in the modeling of events with single b jets, particularly at large b-jet p_t, where gluon splitting processes become dominant, as also confirmed by studies of b-hadron and b-jet angular correlations.

The precision reached in photon measurements is in between that for lepton and jet measurements. The photon energy and angles can be measured at about the same precision as the lepton energy and angles in Drell-Yan production, but there are greater challenges encountered in photon reconstruction (for example isolation) and in purity determination. It should be noted though, that the photon purity approaches unity as the photon p_t increases. At high p_t, it becomes increasingly difficult for a jet to fragment into an isolated neutral electromagnetic cluster, which mimics the photon signature. The inclusive photon cross section can be measured [691, 747–750] as well as the production of a photon accompanied by one or more jets [750–752, 752–756]. The kinematic range for photon production is less than that for jet production because of the presence of the electromagnetic coupling, but still reaches about 2 TeV. Better agreement is obtained with NNLO predictions [238, 240] for photon production than for NLO ones [757, 758], except when the latter are matched to matrix element plus parton shower predictions [759]. Photon production in association with a heavy-flavor jet is a useful input for the determination of the b and c quark PDFs [760].

Electroweak corrections are expected to become more and more relevant in the TeV energy range being explored, and EW corrections can now also be computed automatically [198]. For a comprehensive review on electroweak corrections see Ref. [207]. For example, such corrections were found [761, 762] to be sizable (tens of percent) when studying the ratio $(d\sigma^\gamma/dp_t)/(d\sigma^Z/dp_t)$ in $\gamma\,(Z)$+jet production, p_t being the boson's transverse momentum, and might account for (some of) the differences observed in a CMS measurement [763] of this quantity.

A number of interesting developments, in terms of probing higher-order QCD effects, have occurred in the sector of diboson production, in particular for the WW and $\gamma\gamma$ cases. The statistical reach of the LHC has resulted in the discovery of triple massive gauge boson production [764–766].

In the case of diphoton production, ATLAS [767–769] and CMS [770] have provided accurate measurements, in particular for phase-space regions that are sensitive to radiative QCD corrections (multi-jet production), such as small azimuthal photon separation. While there are large deviations between data and NLO predictions in this region, a calculation [365] at NNLO accuracy manages to mostly fill this gap. This is an interesting example where scale variations can not provide a reliable estimate of missing contributions beyond NLO, since at NNLO new channels appear in the initial state (gluon fusion in this case). These missing channels can be included in a matrix element plus parton shower calculation in which two additional jets are included at NLO. The result exhibits a similar level of agreement as that obtained at NNLO. Three-photon production has also been measured [771] and is in good agreement with NNLO theory predictions [356, 384].

In terms of heaviest particle involved, top-quark production at the LHC has become an important tool for probing higher-order QCD calculations, thanks to very impressive achievements both on the experimental and theoretical side, as extensively summarized in Ref. [772]. Regarding $t\bar{t}$ production, the most precise inclusive cross section measurements are achieved using the dilepton ($e\,\mu$) final state, with a total uncertainty of 4% [773–777].

This is of about the same size as the uncertainty on the most advanced theoretical predictions [147, 148, 251, 349], obtained at NNLO with additional soft-gluon resummation at NNLL accuracy [778]. There is excellent agreement between data and the QCD predictions.

The $t\bar{t}$ final state allows multiple observables to be measured. A large number of differential cross section measurements have been performed at 7, 8, 13 and 13.6 TeV center-of-mass energy, studying distributions such as the top-quark p_t and rapidity, the transverse momentum and invariant mass of the $t\bar{t}$ system (probing the TeV range), or the number of additional jets. These measurements have been compared to a wide range of predictions, at fixed order up to NNLO as well as using LO or NLO matrix elements matched to parton showers. Each of the observables provides information on the high x gluon, and do so in global PDF fits. However, there are tensions among the multiple observables that can lead to difficulties in PDF fits. Quadruple top production has been measured in multi-lepton final states [779] by the ATLAS and CMS collaboration, with results consistent with the standard model prediction [780].

Thanks to both the precise measurements of, and predictions for, the inclusive top-pair cross section, which is sensitive to the strong coupling constant and the top-quark mass, this observable has been used to measure the strong coupling constant at NNLO accuracy from hadron collider data [781, 782] (*cf.* Section 9.4 below), as well as to obtain a measurement of the top-quark's pole mass without employing direct reconstruction methods [781, 783, 784].

The Higgs boson provides a tool for QCD studies, especially as the dominant production mechanism is gg fusion, which is subject to very large QCD corrections. Higgs boson production has been measured in the major decay channels [785]. A measurement of the cross section in the ZZ and $\gamma\gamma$ channels is one of the first measurements at 13.6 TeV to be published [786]. The experimental cross section is now known with a precision approaching 10% [787, 788], similar to the size of the theoretical uncertainty [789], of which the PDF+α_s uncertainty is the largest component. Part of this systematic is the mismatch in orders between the PDF determination (NNLO) and the cross section evaluation (N^{3}LO), as discussed earlier. The experimental precision has allowed detailed fiducial and differential cross section measurements. For example, with the diphoton final state, the transverse momentum of the Higgs boson can be measured out to the order of 650 GeV, with constraints on the Higgs boson cross section up to 1 TeV [790–793], where top quark mass effects become important. The use of the boosted $H \to b\bar{b}$ topology allows probing Higgs boson transverse momenta of the order of 600 GeV and greater [788]. The production of a Higgs boson with up to 4 jets has been measured [788, 790]. The experimental cross sections have been compared to NNLO predictions (for $H+ \geq 1$ jet), NLO for 2 and 3 jets, and NNLO+NNLL for the transverse-momentum distribution. In addition, finite top quark mass effects have been taken into account at NLO.

9.4 Determinations of the strong coupling constant

Assuming zero quark masses, the only free parameter in the QCD Lagrangian is the strong coupling constant α_s. The coupling constant in itself is not a physical observable, but rather a quantity defined in the context of perturbation theory, which enters predictions for experimentally measurable observables, such as R in Eq. (9.7). The value of the strong coupling constant must be inferred from such measurements and is subject to experimental and theoretical uncertainties. The incomplete knowledge of α_s propagates into uncertainties in numerous precision tests of the Standard Model. Here, we present an update of the 2024 PDG average value of $\alpha_s(m_Z^2)$ and its uncertainty [794].

Many experimental observables are used to determine α_s. A number of recent determinations are collected in Refs. [795, 796]. Further discussions and considerations on determinations of α_s can also be found in Refs. [797–799]. Such considerations include:

- The observable's sensitivity to α_s as compared to the experimental precision. For example, for the e^+e^- cross section to hadrons (*cf.* R in Sec. 9.2.1), QCD effects are only a small correction, since the perturbative series starts at order α_s^0; three-jet production or event shapes in e^+e^- annihilations are directly sensitive to α_s since they start at order α_s; the hadronic decay width of heavy quarkonia, $\Gamma(\Upsilon \to \text{hadrons})$, is very sensitive to α_s since its leading order term is $\propto \alpha_s^3$.
- The accuracy of the perturbative prediction, or equivalently of the relation between α_s and the value of the observable. Several observables have been known to NNLO for quite some time. These include, for instance, inclusive observables, as well as three-jet rates and event shapes in e^+e^- collisions, inclusive jet and dijet production in DIS, and inclusive jet, dijet, $t\bar{t}$, W/Z+jet and three-jet production cross sections in pp or $p\bar{p}$ collisions. The e^+e^- hadronic cross section and τ, W and Z branching fractions to hadrons are even known to N^{3}LO, if one denotes the LO as the first non-trivial term. In certain cases, fixed-order predictions are supplemented with resummation. The precise magnitude of the associated theory uncertainties usually is estimated as discussed in Sec. 9.2.4.
- The size of non-perturbative effects. Sufficiently inclusive quantities, like the e^+e^- cross section to hadrons, have small non-perturbative contributions $\sim \Lambda^4/Q^4$. Others, such as event-shape distributions, have typically larger contributions $\sim \Lambda/Q$.
- The scale at which the measurement is performed. An uncertainty δ on a measurement of $\alpha_s(Q^2)$, at a scale Q, translates to an uncertainty $\delta' = (\alpha_s^2(m_Z^2)/\alpha_s^2(Q^2)) \cdot \delta$ on $\alpha_s(m_Z^2)$. For example, this enhances the already important impact of precise low-Q measurements, such as from τ decays, in combinations performed at the m_Z scale.

The selection of results from which to determine the world average value of $\alpha_s(m_Z^2)$ is restricted to those that are

- published in a peer-reviewed journal at the time of writing this report,
- based on the most complete perturbative QCD predictions of at least NNLO accuracy,
- accompanied by reliable estimates of all experimental and theoretical uncertainties.

In order to calculate the world average value of $\alpha_s(m_Z^2)$, we apply, as in earlier editions, an intermediate step of pre-averaging results within the subfields now labeled "Hadronic τ decays and low Q^2 continuum" (τ decays and low Q^2), "Heavy quarkonia decays" ($Q\bar{Q}$ bound states), "PDF fits" (PDF fits), "Hadronic final states of e^+e^- annihilations" (e^+e^- jets & shapes), "Observables from hadron-induced collisions" (hadron colliders), and "Electroweak precision fit" (electroweak) as explained in the following sections. For each subfield, the *unweighted average* of all selected results is taken as the pre-average value of $\alpha_s(m_Z^2)$, and the *unweighted average* of the total uncertainties is assigned to be the respective overall error of this pre-average. Asymmetric total uncertainties are symmetrised beforehand by adopting the larger of the two values as the ($\pm$) uncertainty. For the "Lattice QCD" (lattice) subfield we do not perform a pre-averaging; instead, we adopt for this subfield the $\alpha_s(m_Z^2)$ estimate and uncertainty derived by the Flavour Lattice Averaging Group (FLAG) in Ref. [800].

Assuming that the six subfields (excluding lattice) are largely independent of each other, we determine a non-lattice world average value using a 'χ^2 *averaging*' method. In a last step we perform an unweighted average of the values and uncertainties of $\alpha_s(m_Z^2)$ from our non-lattice result and the lattice result presented in the FLAG 2024 report [800].

9.4.1 *Hadronic τ decays and low Q^2 continuum:*

Based on complete N^{3}LO predictions [34], analyses of the τ hadronic decay width and spectral functions have been performed, *e.g.* in Refs. [34, 801–806], and lead to precise determinations of α_s at the energy scale of m_τ^2. They are based on different approaches to treat perturbative and non-perturbative contributions, the impacts of which have been a matter of intense discussions for a long time, see *e.g.* Refs. [805–808]. In particular, in τ decays there is

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

a significant difference between results obtained using fixed-order (FOPT) or contour-improved perturbation theory (CIPT), such that analyses based on CIPT generally arrive at larger values of $\alpha_s(m_\tau^2)$ than those based on FOPT.

As detailed in the last edition of this *Review* we do not consider anymore determinations of the strong coupling constant based on CIPT, as long as a dedicated treatment of non-perturbative contributions in such derivations is missing. More details on recent developments can be found in Refs. [809–813].

We determine the pre-average value of $\alpha_s(m_Z^2)$ for this subfield only from studies that employ FOPT expansions and remove any eventual averaging with CIPT central values or increased uncertainties due to the differences in CIPT vs. FOPT. As the results from Refs. [34] and [808] are not totally independent, we pre-average these two results, $\alpha_s(m_Z^2) = 0.1183 \pm 0.0026$ and $\alpha_s(m_Z^2) = 0.1181 \pm 0.0015$, to give the first entry to this category of $\alpha_s(m_Z^2) = 0.1182 \pm 0.0021$ (summarized as BP 2008-16 FO in Fig. 9.2).

Subsequently, this is combined with $\alpha_s(m_Z^2) = 0.1158 \pm 0.0022$ [814] and $\alpha_s(m_Z^2) = 0.1159 \pm 0.0014$ [815], which replaces the previous result from Ref. [816]. We note that the uncertainty increased, even though more and more precise data, *e.g.* from the Belle experiment, are included in the updated analysis. The authors of Ref. [815] trace this back to updated particle properties as reported by the Heavy Flavor Averaging Group in Ref. [817].

We also include the result from τ decay and lifetime measurements, obtained in Sec. *Electroweak Model and constraints on New Physics* of the 2024 edition of this *Review* [794], $\alpha_s(m_Z^2) = 0.1171 \pm 0.0018$, which is unchanged as compared to the previous edition. The latter result, being a global fit of τ data, involves some correlations with the other extractions of this category. However, since we perform an unweighted average of the central value and uncertainty, the effects of the potential correlations are reduced. As before, the determination reported in Ref. [818] is added to this category: $\alpha_s(m_Z^2) = 0.1183^{+0.0009}_{-0.0012}$.

All these results are summarized in Fig. 9.2. Determining the unweighted average of the central values and their overall uncertainties, we arrive at $\alpha_s(m_Z^2) = 0.1171 \pm 0.0017$, which we will use as the first input for determining the world average value of $\alpha_s(m_Z^2)$.

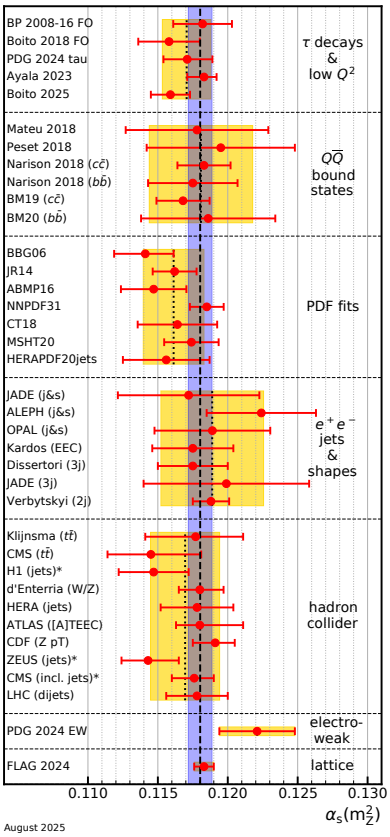

Figure 9.2: Summary of determinations of $\alpha_s(m_Z^2)$ with uncertainty in the seven subfields as discussed in the text. The yellow (light shaded) bands and dotted lines indicate the pre-average values of each subfield. The dashed line and blue (dark shaded) band represent the final world average value of $\alpha_s(m_Z^2)$. The "*" symbol within the "hadron colliders" subfield indicates a determination including a simultaneous fit of PDFs.

9.4.2 *Heavy quarkonia decays:*

Since the previous edition, a determination of $\alpha_s(m_Z^2)$ from inclusive semileptonic decay of charmed meson appeared resulting in $\alpha_s(Q = 1.37GeV) = 0.445 \pm 0.114$ [819], and has clearly an uncertainty which is not competitive to other determinations in this category. Lacking any new inputs the result of this subfield is unchanged from the previous edition.

Two determinations of $\alpha_s(m_Z^2)$ have been performed [820, 821] that are based on N^{3}LO accurate predictions. Reference [820] performs a simultaneous fit of the strong coupling and the bottom mass $\overline{m_b}$, including states with principal quantum number up to $n \leq 2$ in order to break the degeneracy between α_s and $\overline{m_b}$, finding $\alpha_s(m_Z^2) = 0.1178 \pm 0.0051$. Reference [821] instead uses as input of the fit the renormalon-free combination of masses of the meson B_c, the bottomonium η_b and the charmonium η_c, $M_{B_c} - M_{\eta_b}/2 - M_{\eta_c}/2$, which is weakly dependent on the heavy-quark masses, but shows a good dependence on α_s. Using this observable, they obtain $\alpha_s(m_Z^2) = 0.1195 \pm 0.0053$. Two further values are derived at NNLO in Ref. [822, 823] from mass splittings and sum rules giving $\alpha_s(m_Z^2) = 0.1183 \pm 0.0019$ and $\alpha_s(m_Z^2) = 0.1175 \pm 0.0032$ when evolved from the relevant charmonium respectively bottomonium mass scales to m_Z^2. Finally, by means of quarkonium sum rules, Refs. [824, 825] quote $\alpha_s(m_Z^2) = 0.1168 \pm 0.0019$ and $\alpha_s(m_Z^2) = 0.1186 \pm 0.0048$ for charmonium and bottomonium respectively. These six determinations satisfy our criteria to be included in the heavy-quarkonia category of the world average. Their unweighted combination leads to the pre-average for this category of $\alpha_s(m_Z^2) = 0.1181 \pm 0.0037$.

9.4.3 *PDF fits:*

Also in this subfield the $\alpha_s(m_Z^2)$ averaging remains for now unchanged from the previous edition. A few recent results, discussed in the following, did not yet qualify for inclusion.

Studies analyzing structure functions at NNLO QCD (and partly beyond), provide results that serve as relevant inputs for the world average of α_s. Some of these studies do *not*, however, explicitly include estimates of theoretical uncertainties when quoting fit results of α_s. In such cases we add, in quadrature, half of the difference between the results obtained in NNLO and NLO to the quoted errors.

A combined analysis of non-singlet structure functions from DIS [826], based on QCD predictions up to N^{3}LO in some of its parts, results in $\alpha_s(m_Z^2) = 0.1141 \pm 0.0022$ (BBG). Studies of singlet and non-singlet structure functions, based on NNLO predictions, result in $\alpha_s(m_Z^2) = 0.1162 \pm 0.0017$ [827] (JR14). The AMBP group [828, 829] determined a set of parton distribution functions using data from HERA, NOMAD, CHORUS, from the Tevatron and the LHC using the Drell-Yan process and the hadro-production of single-top and top-quark pairs, and determined $\alpha_s(m_Z^2) = 0.1147 \pm 0.0024$ [828]. A new analysis with the same methodology [830] compares significantly more and double-differential data on top-quark production to calculations at NNLO and quotes a value of $\alpha_s(m_Z^2) = 0.1150 \pm 0.0009$, but without estimation of a MHO uncertainty.

The MSHT group [831], also including hadron collider data, determined a set of parton distribution functions (MSHT20) together with $\alpha_s(m_Z^2) = 0.1174 \pm 0.0013$. Moreover, in Ref. [832] they present a first simultaneous fit of PDFs and $\alpha_s(m_Z^2)$ at approximate N^{3}LO (aN^{3}LO) giving $\alpha_s(m_Z^2) = 0.1170 \pm 0.0016$, where the uncertainty also comprises an estimate of the MHO uncertainty by means of theory nuisance parameters as mentioned in Section 9.2.2. This first attempt is much appreciated, however, we

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s xcept for Open Access articles.

feel that, considering the number of approximations to be made, it would be somewhat premature to include this number already in the averaging or the uncertainty derivation for the value derived at NNLO in the same publication. Therefore, lacking an NLO result to estimate a MHO uncertainty, we stick with the previous MSHT result for this edition of the review.

The CT group [86] determined the CT18 PDF set together with $\alpha_s(m_Z^2) = 0.1164 \pm 0.0026$. The NNPDF group [833] presented NNPDF3.1 parton distribution functions together with $\alpha_s(m_Z^2) = 0.1185 \pm 0.0012$. They also advanced to an $\alpha_s(m_Z^2)$ extraction at aN^{3}LO employing their fit methodology to include MHO effects through scale variations as described in Ref. [834], which, at the time of writing, is not yet published in a peer-reviewed journal. The last result in this category, $\alpha_s(m_Z^2) = 0.1156 \pm 0.0031$, is reported as HERAPDF2.0Jets in Ref. [835]. In addition to DIS data from HERA, jet cross sections are considered in this fit to theory at NNLO. For criticism expressed on some of the above extractions please confer references in the previous edition of this *Review* and the recent more extensive discussions in Ref. [87].

Summarizing the results from world data on structure functions, taking the *unweighted average* of the central values and errors of all selected results, leads to a pre-average value of $\alpha_s(m_Z^2) = 0.1161 \pm 0.0022$, see also Fig. 9.2.

9.4.4 ***Hadronic final states of e^+e^- annihilations:***
An analysis of JADE data [836] from e^+e^- annihilation (j&s) at center-of-mass energies between 14 and 46 GeV gives $\alpha_s(m_Z^2) = 0.1172 \pm 0.0051$, with contributions from the hadronization model and from perturbative QCD uncertainties of 0.0035 and 0.0030, respectively. Similarly, re-analyses of jets and event shapes measured around the Z peak and at LEP2 center-of-mass energies up to 209 GeV, using NNLO predictions matched to NLL resummation and Monte Carlo models to correct for hadronization effects, resulted in $\alpha_s(m_Z^2) = 0.1224 \pm 0.0039$ (ALEPH) [837], and in $\alpha_s(m_Z^2) = 0.1189 \pm 0.0043$ (OPAL) [838]. A fit of energy-energy-correlation (EEC), also based on an NNLO+NNLL calculation, together with a Monte Carlo based modeling of hadronization corrections gives $\alpha_s(m_Z^2) = 0.1175 \pm 0.0029$ [839]. Precise determinations of α_s from three-jet production alone (3j), at NNLO, resulted in $\alpha_s(m_Z^2) = 0.1175 \pm 0.0025$ [840] from ALEPH data and in $\alpha_s(m_Z^2) = 0.1199 \pm 0.0059$ [841] from JADE. A determination based on an NNLO+NNLL accurate calculation allows to fit the region of lower three-jet rate (2j) using data collected at LEP and PETRA at different energies. This fit gives $\alpha_s(m_Z^2) = 0.1188 \pm 0.0013$ [842], where the dominant uncertainty is the hadronization uncertainty, which is estimated from Monte Carlo simulations. These results are summarized in the e^+e^- sector of Fig. 9.2.

Another class of α_s determinations is based on analytic modeling of non-perturbative and hadronization effects, rather than on Monte Carlo models, using methods like power corrections, factorization of soft-collinear effective field theory, dispersive models and low scale QCD effective couplings. In these studies, data on thrust distributions, or the C-parameter distributions, are analyzed and fitted to perturbative QCD predictions at NNLO matched with resummation of leading logs up to N^{3}LL accuracy, see Sec. 9.2.3.3. Earlier determinations include $\alpha_s(m_Z^2) = 0.1135 \pm 0.0011$ [843] and $\alpha_s(m_Z^2) = 0.1134^{+0.0031}_{-0.0025}$ [844] from thrust, and $\alpha_s(m_Z^2) = 0.1123 \pm 0.0015$ [845] from C-parameter.

A long-standing question was why this latter class of determinations led systematically to rather small values of $\alpha_s(m_Z^2)$ as compared to the former one based on Monte Carlo models to correct for hadronization effects. New insights have now been gained in this regard, but the subject is still under active development. First, the leading non-perturbative contribution to the C-parameter in the three-jet symmetric limit based on an effective coupling approach was calculated and it was found to differ by a factor of two from the one in the two-jet limit [846]. Subsequently, using the same effective coupling approach, the leading $1/Q$ power correction was computed for thrust and the C-parameter in the full three-jet region under the assumption of a large (negative) n_f limit [847]. Expanding on this approach, Ref. [848] extended the calculation of non-perturbative corrections to include the heavy-jet mass, the difference of jet masses, wide broadening, and, with some caveat, the three-jet resolution variable in the Durham algorithm. The key finding in Refs. [848,849] is that non-perturbative corrections computed in the three-jet region significantly deviate from those computed in the two-jet limit, which can impact determinations of $\alpha_s(m_Z^2)$. Another important observation is that the inclusion of resummation effects introduces a relatively substantial ambiguity outside the two-jet limit. Currently there is no general agreement concerning the range of the dijet and three-jet regions. Moreover, other factors such as ambiguities related to the procedure used to evaluate the inverse Laplace transform [850, 851], or the choice of mass-scheme used to extend the definition of event shapes to massive hadrons can have significant effects. Since the seminal renormalon-based analyses [26, 852] it has been understood that hadron masses can break the universality of leading power corrections. In particular, Ref. [853] showed that they can induce logarithmically enhanced power corrections of the form $\sim \ln^{1.6} Q/Q$. More recently, Ref. [854], building on the operator-based framework of Ref. [855] and expressing the leading power correction in terms of matrix elements of a *transverse velocity* operator, demonstrated that event shapes in the dijet limit fall into different, scheme-specific universality classes that nevertheless share universal power corrections. This provides a field-theoretic confirmation of the results of Ref. [853]. Reference [856], whose main result is a remarkably simple expression for the all-order anomalous scaling of non-perturbative linear power corrections — reproducing both the Q-dependence and the event-shape dependence observed in Pythia — provides arguments in favor of the so-called decay scheme over alternative mass schemes. These findings merit further investigation.

The novel determinations of α_s presented in Refs. [857–859] extend and refine earlier analyses [843, 845]. Key improvements include optimized choices of renormalization scales, modifications to the renormalon subtraction scheme, an assessment of the impact of the fit range, and the incorporation of three-jet power-correction models. Despite these refinements, the extracted values of the strong coupling remain, consistent with previous results, rather small yielding for instance $\alpha_s(m_Z^2) = 0.1136 \pm 0.0012$ from thrust [858] and $\alpha_s(m_Z^2) = 0.1123 \pm 0.0015$ from the C-parameter [845]. Although the newly quoted uncertainties are more conservative than in previous determinations, they still fail to account for important sources of uncertainty associated with the choice of mass scheme, as highlighted *e.g.* in Refs. [848, 849].

Given the rapid progress currently being made in this field, we consider it premature to include any of the recent determinations based on analytic models for estimating power corrections. Determinations based on corrections for non-perturbative hadronization effects using QCD-inspired Monte Carlo generators have also faced criticism due to the differing nature of parton-level simulations compared to fixed-order calculations. However, these determinations typically exhibit a more conservative theoretical uncertainty.

Other determinations, not included in the computation of the world average but worth mentioning are a computation of the NLO corrections to 5-jet production and comparison to the measured 5-jet rates at LEP [860], giving $\alpha_s(m_Z^2) = 0.1156^{+0.0041}_{-0.0034}$, and a computation of non-perturbative and perturbative QCD contributions to the scale evolution of quark and gluon jet multiplicities, including resummation, resulting in $\alpha_s(m_Z^2) = 0.1199 \pm 0.0026$ [861].

The unweighted average of the considered determinations as shown in the e^+e^- sector of Fig. 9.2 remains unchanged from the previous edition of this *Review* and yields $\alpha_s(m_Z^2) = 0.1189 \pm 0.0037$.

9.4.5 ***Observables from hadron-induced collisions:***
In the last decade, several determinations of α_s using hadron collider data in comparison to NNLO calculations have become available. Complementing $t\bar{t}$ [147, 251, 349] and Z+jet production [342, 387], inclusive jet, dijet, and three-jet production [336, 337, 355, 360, 862] have joined this subfield. In addition to NNLO, also logarithms to NNLL or N^{3}LL have been resummed for the $t\bar{t}$ and Z+jet processes, *cf.* also Section 9.2.3.3. For high-p_{T} collisions at the LHC, these predictions must be supplemented

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

by electroweak corrections [863–866].

Moreover, determinations of α_s from production cross sections at hadron colliders also require a knowledge of the relevant PDFs for those α_s values. Three strategies of increasing sophistication are pursued: The first two make use of input PDFs that are pre-determined for a central value of $\alpha_s(m_Z^2) = 0.118$, close or equal to the world average, together with complementary PDF sets that are produced by each global PDF group for a wide range above and below 0.118 in increments of 0.001. In the simplest method, the pre-determined central PDF set is taken as it is, ignoring a potential impact of the new data on the central PDFs when they would have been combined beforehand with all the datasets entering the original PDF fit. The alternative PDF sets for the range of pre-set $\alpha_s(m_Z^2)$ values are used only to estimate an additional uncertainty. This technique has been critisized to potentially result in a bias of unknown magnitude [867]. In the second method, the impact of new data on the PDFs is examined by means of a technique known as Hessian profiling. As long as their impact is found to be limited and the new data are not in conflict with the original datasets, correlations among a determination of $\alpha_s(m_Z^2)$ and the PDFs can be accounted for, albeit at a level less accurate than obtained from method three, *i.e.* a simultaneous global $\alpha_s(m_Z^2)$ and PDF fit. In particular, the new data used in the determination of $\alpha_s(m_Z^2)$ may require PDF adaptations in a manner not taken into account by the $\alpha_s(m_Z^2)$-variation PDFs provided by the fitting collaborations. Another caveat in the use of Hessian profiling is the determination of the appropriate value of $\Delta\chi^2$ that should be assumed for a 1-sigma uncertainty on the resultant value of $\alpha_s(m_Z^2)$. Assuming a $\Delta\chi^2$ of unity does not necessarily reflect the correct level of uncertainty inherent in the PDF fit [868]. As the LHC experiments have the ability to combine a PDF fit with the $\alpha_s(m_Z^2)$ determination, for example with tools like described in Refs. [869, 870], we expect more experimental joint determinations of PDFs and of $\alpha_s(m_Z^2)$ for future iterations of this *Review*.

The first determination of α_s at NNLO accuracy in QCD has been reported by CMS from the $t\bar{t}$ production cross section at $\sqrt{s} = 7\,\text{TeV}$ [781]. In former *Reviews* this opened up a new subfield on its own. In the meantime, multiple datasets on $t\bar{t}$ production from Tevatron at $\sqrt{s} = 1.96\,\text{TeV}$ and from LHC at $\sqrt{s} = 7$, 8, and 13 TeV have been analyzed simultaneously to determine α_s [782] to $\alpha_s(m_Z^2) = 0.1177^{+0.0034}_{-0.0036}$, where the largest uncertainties are associated with missing higher orders and with PDFs, and where an additional complication arises from the top-mass dependence. Since this combined analysis contains among other things an updated measurement as compared to the dataset used by CMS, the latter is replaced in the averaging by this combined result. A second entry into this subfield is given by an analysis of $t\bar{t}$ production data at $\sqrt{s} = 13\,\text{TeV}$ from the CMS Collaboration [775]. From the four values derived for different PDF sets, the unweighted average is taken: $\alpha_s(m_Z^2) = 0.1145^{+0.0036}_{-0.0031}$. A second analysis by CMS using differential distributions of $t\bar{t}$ production [776] has been performed at NLO only and is not further considered.

From collisions at HERA the α_s determination at NNLO using inclusive jet and dijet measurements in addition to DIS data of the H1 Collaboration [662] has been corrected for an issue with the theory prediction reported in Ref. [334]. We choose the result $\alpha_s(m_Z^2) = 0.1147 \pm 0.0025$ that is derived from a simultaneous fit of the strong coupling constant together with proton PDFs. We note that results of this section derived from such a simultaneous fit will be marked with a "*" in the corresponding figures. A second determination [419] combines multiple datasets on inclusive jet production of the H1 and ZEUS collaborations into one fit also using interpolation grids at NNLO. The result of $\alpha_s(m_Z^2) = 0.1178 \pm 0.0026$ has been updated for the same issue reported above [334] and is included in the unweighted average, although some of the inclusive jet data have already been used in the previous analysis. This is also the case for a new result by the ZEUS Collaboration [871], where previously published jet cross sections have been combined with a new inclusive jet measurement to give $\alpha_s(m_Z^2) = 0.1143^{+0.0022}_{-0.0019}$, where the scale-variation uncertainty has been treated as fully correlated.

A first determination of $\alpha_s(m_Z^2)$ at NNLO from inclusive jet production at the LHC by the CMS Collaboration [684] giving $\alpha_s(m_Z^2) = 0.1166 \pm 0.0016$ has been superseded by $\alpha_s(m_Z^2) = 0.1176^{+0.0014}_{-0.0016}$, also from a simultaneous fit of $\alpha_s(m_Z^2)$ and the proton PDFs to the HERA DIS and CMS jet data at four center-of-mass energies [872]. Using dijet production at $\sqrt{s} = 13\,\text{TeV}$ instead of the inclusive jet datasets the CMS Collaboration derived a value of $\alpha_s(m_Z^2) = 0.1179 \pm 0.0019$ at NNLO in the leading-color approximation. Since in the meantime a more complete analysis at full NNLO evaluating all dijet cross sections from the ATLAS and CMS collaborations has been published in Ref. [873], we include the corresponding result of $\alpha_s(m_Z^2) = 0.1178 \pm 0.0022$ in this subfield. The ATLAS Collaboration has extracted of $\alpha_s(m_Z^2)$ at NNLO from the transverse energy-energy correlation (TEEC) and its asymmetry (ATEEC) [617]. The results of this first derivation from an event shape observable requiring three-jet predictions at NNLO are $\alpha_s(m_Z^2) = 0.1175^{+0.0035}_{-0.0018}$ for the TEEC and $\alpha_s(m_Z^2) = 0.1185^{+0.0027}_{-0.0015}$ for the ATEEC, respectively. We include the unweighted average of the two numbers $\alpha_s(m_Z^2) = 0.1180^{+0.0031}_{-0.0017}$ as a new result in this category. Also, two determinations of the strong coupling constant, albeit at NLO, have been reported by CMS based on novel observables from energy correlators inside jets and from azimuthal correlations among jets [874, 875].

Reference [876] extracts the strong coupling constant from a fit at NNLO to measurements of inclusive Z and W boson production by experiments at the LHC and Tevatron colliders. From the four values quoted for different PDF sets we include the unweighted average for the CT14 and MMHT14 PDFs $\alpha_s(m_Z^2) = 0.1180^{+0.0017}_{-0.0015}$. The other results suffer from either a bad fit quality or $\alpha_s(m_Z^2)$ values outside the range of validity for the PDF set. Furthermore, a determination using the Z boson's recoil at low p_T as measured by the CDF experiment is reported in Ref. [877] and gives $\alpha_s(m_Z^2) = 0.1191^{+0.0014}_{-0.0016}$. A similar result by the ATLAS experiment [878] has not been considered as it is yet unpublished. Furthermore, it has been critisized for example in Ref. [574] concerning the estimated uncertainties.

As unweighted pre-average for this subfield we now obtain $\alpha_s(m_Z^2) = 0.1170 \pm 0.0025$. If the stricter requirement of simultaneous fits with PDFs is imposed, then only the H1, ZEUS, and CMS results as well as a result from the appendix of Ref. [877] $\alpha_s(m_Z^2) = 0.1188^{+0.0014}_{-0.0017}$ are left giving $\alpha_s(m_Z^2) = 0.1155 \pm 0.0021$. In sect. 9.4.8 below, we will also report the outcome for this choice.

9.4.6 *Electroweak precision fit:*

From this category, we removed the outdated global electroweak fit of Ref. [879], which does not consider important updates on the LEP luminosity at the Z pole from beam-beam effects [880] and from the Bhabha cross section reported in Ref. [881]. In view of a new, precise measurement of the W boson mass by the CMS experiment [882] that agrees with the standard model prediction as well as with other measurements but contradicts the outlying CDF result [883], we also excluded the $\alpha_s(m_Z^2)$ value reported in Ref. [884], even though we were using the result with increased uncertainty ("conservative scenario"). The only result left in this category therefore is the electroweak fit at the Z mass pole from LEP and SLC data presented in Sec. *Electroweak Model and constraints on New Physics* of the 2024 edition of this *Review* giving $\alpha_s(m_Z^2) = 0.1221 \pm 0.0027$ [794], which is unchanged as compared to the previous one from 2022. This is higher by more than one standard deviation as compared to our world average for $\alpha_s(m_Z^2)$ reported here.

We note, however, that results from electroweak precision data strongly depend on the strict validity of Standard Model predictions and the existence of the minimal Higgs mechanism to implement electroweak symmetry breaking. Any - even small - deviation of nature from this model could strongly influence this extraction of α_s.

9.4.7 *Lattice QCD:*

Several methods exist to extract the strong coupling constant from lattice QCD, as reviewed also in Sec. *Lattice QCD* of this *Review* and in Ref. [885]. The Flavour Lattice Averaging Group maintains

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is subject to Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com except for Open Access articles.

a list of the most up-to-date determinations that are considered as input for their $\alpha_s(m_Z^2)$ estimate [800, 886, 887]. From a multitude of possible input calculations only those are retained that fulfill predefined quality criteria, *cf. e.g.* Sec. 9.2.1 of Ref. [800], which so far are unchanged since the FLAG 2019 Review [886]. In summary, a determination of α_s needs to satisfy the following requirements:

- The determination of α_s should be based on a comparison of a short-distance quantity $\mathcal{Q}$ at scale μ with a well-defined continuum limit, which does not involve UV or infrared divergences, when the quantity is expressed by using an expansion in terms of a short distance definition of the strong coupling (*e.g.* in the $\overline{\text{MS}}$ scheme);
- The scale μ, at which the determination is carried out, has to be sufficiently large such that the error associated with the perturbative truncation remains small enough;
- If $\mathcal{Q}$ is defined by physical quantities in infinite volume, one needs to satisfy the constraints $L/a \gg \mu/\Lambda_{\text{QCD}}$, where L is the lattice size and a the lattice spacing;
- Only results for $n_f \geq 3$ are considered.
- As is the case for the PDG average, a calculation must be published in a peer-reviewed journal to be eligible for inclusion into the FLAG estimate.

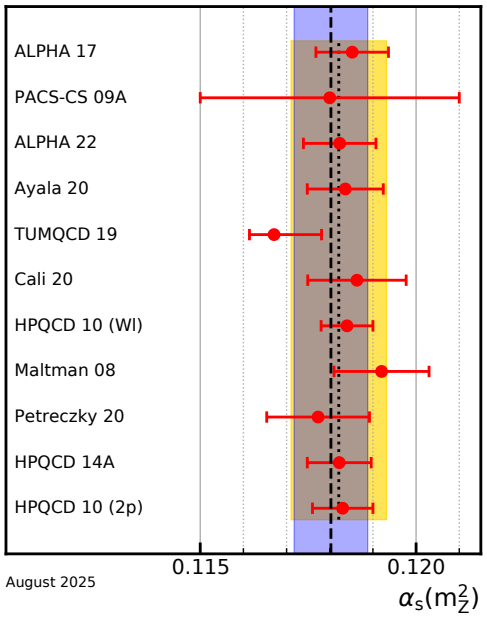

Figure 9.3: Lattice determinations that enter the FLAG 2024 estimate. The yellow (light shaded) band and dotted line indicate the *unweighted average* value for this subfield. The dashed line and blue (dark shaded) band represent our final world average value of $\alpha_s(m_Z^2)$.

Altogether, from a large number of previous results, six from the 2019 [888–892][12] and three from the 2021 edition of the FLAG review [893–895] are kept for the 2024 FLAG estimate. Moreover, two new determinations qualified for inclusion: one from heavy-quark current two-point functions [896] giving $\alpha_s(m_Z^2) = 0.1177 \pm 0.0012$, and a first one from the decoupling method [897] resulting in $\alpha_s(m_Z^2) = 0.1182 \pm 0.0008$.

These determinations, together with their uncertainties, are displayed in Fig. 9.3. The yellow (light shaded) band and dotted line indicate the *unweighted average* value for this subfield, while the dashed line and blue (dark shaded) band represent the world average (see later). The level of agreement of individual results to the world average, or to the non-lattice world average is very similar.

[12] Reference [890] contains two results.

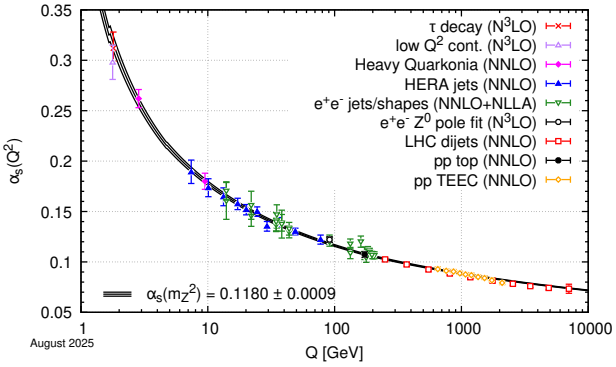

Figure 9.4: Summary of determinations of α_s as a function of the energy scale Q compared to the running of the coupling computed at five loops taking as an input the current PDG average, $\alpha_s(m_Z^2) = 0.1180 \pm 0.0009$. Compared to the previous edition, numerous points have been updated or added.

Similarly to what is done in this *Review*, the FLAG Collaboration built dedicated pre-averages of results within the various classes. The six categories that contribute to their final estimate are: step-scaling methods ($\alpha_s(m_Z^2) = 0.11848 \pm 0.00081$), for the first time the decoupling method ($\alpha_s(m_Z^2) = 0.11823 \pm 0.00084$), the potential at short distances ($\alpha_s(m_Z^2) = 0.11782 \pm 0.00165$), light quark vacuum polarization ($\alpha_s(m_Z^2) = 0.11863 \pm 0.00360$), Wilson loops ($\alpha_s(m_Z^2) = 0.11871 \pm 0.00128$), and heavy-quark current two-point functions ($\alpha_s(m_Z^2) = 0.11818 \pm 0.00119$). Other categories such as the calculation of QCD vertices, or of the eigenvalue spectrum of the Dirac operator have not yet published results that fulfill all requirements.

We note that the novel approach to non-perturbative renormalization called decoupling introduced by the ALPHA Collaboration [898] now has lead to a first result included in the 2024 FLAG estimate. This strategy shifts the perspective on results involving unphysical flavor numbers, particularly $n_f = 0$. By performing a non-perturbative matching calculation, these results can be non-perturbatively related to results with $n_f > 0$. Consequently, obtaining precise and controlled $n_f = 0$ results becomes of great importance as further discussed in the 2024 edition of the FLAG report.

The final value is obtained in two steps. First, accounting for their known correlation, a combination of the two results ALPHA 17 and ALPHA 22 is performed, which subsequently is combined with PACS-CS 09A to give a number of $\alpha_s(m_Z^2) = 0.1184 \pm 0.0007$ for the two categories of step scaling and decoupling, where the dominating uncertainty is of statistical origin. This uncertainty is also chosen to be the one of the final FLAG estimate, while the central value is derived from the weighted average together with the remaining pre-averages. The final FLAG 2024 estimate (rounded to four digits) is

$$\alpha_s(m_Z^2) = 0.1183 \pm 0.0007 \qquad \text{(FLAG 2024 estimate)}\,, \quad (9.23)$$

which is very close to the previous FLAG result of $\alpha_s(m_Z^2) = 0.1184 \pm 0.0008$.

We believe that this result expresses to a large extent the consensus of the lattice community and that the imposed criteria and the rigorous assessment of systematic uncertainties qualify for a direct inclusion of this FLAG estimate here. As in the previous review, we therefore adopt the FLAG estimate with its uncertainty as our value of α_s for the lattice category. Moreover, this lattice result will not be directly combined with any other subfield average, but with our non-lattice average to give our final world average value for α_s.

9.4.8 *Determination of the world average value of $\alpha_s(m_Z^2)$:*

Obtaining a world average value for $\alpha_s(m_Z^2)$ is a non-trivial exercise. A certain arbitrariness and subjective component is inevitable because of the choice of measurements to be included in

Table 9.1: Unweighted and weighted pre-averages of $\alpha_s(m_Z^2)$ for each subfield in columns two and three. The bottom line corresponds to the combined result (without lattice gauge theory) using the χ^2 averaging method. The same χ^2 averaging is used for column four combining all unweighted averages except for the subfield of column one. See text for more details.

averages per subfield	unweighted	weighted	unweighted without subfield
τ decays & low Q^2	0.1171 ± 0.0017	0.1172 ± 0.0011	0.1181 ± 0.0012
$Q\bar{Q}$ bound states	0.1181 ± 0.0037	0.1177 ± 0.0011	0.1177 ± 0.0010
PDF fits	0.1161 ± 0.0022	0.1168 ± 0.0014	0.1182 ± 0.0011
e^+e^- jets & shapes	0.1189 ± 0.0037	0.1187 ± 0.0017	0.1177 ± 0.0011
hadron colliders	0.1170 ± 0.0025	0.1173 ± 0.0017	0.1179 ± 0.0011
electroweak	0.1221 ± 0.0027	0.1221 ± 0.0027	0.1171 ± 0.0011
PDG 2025 (without lattice)	0.1178 ± 0.0010	0.1177 ± 0.0006	n/a

the average, the treatment of (non-Gaussian) systematic uncertainties of mostly theoretical nature, as well as the treatment of correlations among the various inputs, of theoretical as well as experimental origin.

We have chosen to determine pre-averages for subfields of measurements that are considered to exhibit a maximum degree of independence among each other, considering experimental as well as theoretical issues. The six pre-averages, illustrated also in Fig. 9.2, are listed in column two of Table 9.1. We recall that these are exclusively obtained from extractions that are based on (at least) NNLO QCD predictions, and are published in peer-reviewed journals at the time of completing this *Review*. To obtain our final world average, we first combine these six pre-averages, excluding the lattice result, using a χ^2 *averaging method*. This gives

$$\alpha_s(m_Z^2) = 0.1178 \pm 0.0010 \qquad \text{(PDG 2025 without lattice)}\,. \tag{9.24}$$

This result is fully compatible with the lattice estimate Eq. (9.23) and has a slightly larger uncertainty. To avoid overestimating the precision, we combine these two numbers using an unweighted average and take as an uncertainty the average between these two uncertainties rounded to give the same number of digits as for α_s itself. This gives our final world average value

$$\alpha_s(m_Z^2) = 0.1180 \pm 0.0009 \qquad \text{(PDG 2025 average)}\,. \tag{9.25}$$

If for the subfield of hadron colliders we are more restrictive and instead only accept results from a simultaneous fit of PDFs, we arrive at $\alpha_s(m_Z^2) = 0.1164 \pm 0.0020$ for this subfield leading to 0.1176 ± 0.0010 (without lattice) and $\alpha_s(m_Z^2) = 0.1179 \pm 0.0008$ for the final average. Both the new world average value and the restricted result are compatible with each other and changed only marginally as compared to the values reported in the last edition of this *Review*.

It also stands to question whether the subfields of PDF fits and hadron colliders still are as independent as originally assumed. To test the potential impact, the fit has been repeated while grouping all $\alpha_s(m_Z^2)$ determinations of both subfields into a common one. We obtain 0.1166 ± 0.0024 for the new larger subfield and 0.1177 ± 0.0010 for the combination with all other subfields except lattice, which is well within the estimated uncertainties. Moreover, we present in column four of Table 9.1 the combined result for $\alpha_s(m_Z^2)$ when the respective subfield is omitted from the combination. The variation in values obtained for $\alpha_s(m_Z^2)$ is ± 0.0006, which is roughly half our estimated uncertainty.

Since two long-standing issues causing offsets among determinations of $\alpha_s(m_Z^2)$ in the subfields of τ decays and low Q^2 and e^+e^- jets & shapes have been better understood, it may be argued that a weighted fit among the non-lattice subfields may be warranted. We compare the outcome of weighted fits with our standard procedure in columns two and three of Table 9.1. We observe that the weighted averages are rather close to the unweighted ones. However, the uncertainties become significantly smaller. This approach may be too aggressive as it ignores the correlations among the data, methods, and theory ingredients of the various determinations. We feel that the uncertainty of ± 0.0006 is an underestimation of the true error. We also note that in the unweighted combination the estimated uncertainty for each subfield is larger than the spread of the results as given by the standard deviation. In the weighted fit this crosscheck fails in four out of five cases (not counting the electroweak subfield with only one entry).

The last several years have seen clarification of some persistent concerns and a wealth of new results at NNLO, providing not only a rather precise and reasonably stable world average value of $\alpha_s(m_Z^2)$, but also a clear signature and proof of the energy dependence of α_s in full agreement with the QCD prediction of asymptotic freedom.This is demonstrated in Fig. 9.4, where results of $\alpha_s(Q^2)$ obtained at discrete energy scales Q are summarized, which now include only those based on at least NNLO QCD. the results from the LHC, the energy scales, at which α_s is determined, now extend up to 7 TeV. [13] The points in this plot are extracted from Refs. [419,617,782,794,814,823,836–838,841,873].

In this combination, as in the past, we have considered lattice QCD calculations of α_s independently of other determinations. In the future, when the lattice continuum extrapolations are under better control, it may be useful to group lattice QCD determinations of α_s with experimental determinations of α_s that have systematics of similar origin, in a similar manner as we currently group, for example, hadron collider results together [885].

[13] We note, however, that the relevant energy scale of a measurement is not uniquely defined. In addition to being multiplied by factors of *e.g.* 1/2 or 2, for instance in studies of the ratio of three- to two-jet cross sections at the LHC, the relevant scale can be taken to be the average of the transverse momenta of the two leading jets [899], or alternatively might be chosen to be the transverse momentum of the 3rd jet.

10.1 Introduction

The *Standard Model* of the electroweak interactions (SM) [1–4] is a renormalizable gauge quantum field theory based on the group $\mathrm{SU}(2) \times \mathrm{U}(1)$, with gauge bosons W^i_μ, $i = 1, 2, 3$, and B_μ for the SU(2) and U(1) factors, respectively, and the corresponding gauge coupling constants g and g'. The quantum numbers of the two subgroups are known as *weak isospin* and *weak hypercharge,* respectively. The left-handed lepton and quark fields of the ith fermion family transform as doublets $\Psi_i = \begin{pmatrix} \nu_i \\ \ell_i^- \end{pmatrix}$ and $\begin{pmatrix} u_i \\ d_i' \end{pmatrix}$ under SU(2), respectively. Here we assume a flavor basis where the lepton and up-quark fields are aligned with the physical basis, whereas for the down-type quarks the interaction and mass bases are related by the Cabibbo–Kobayashi–Maskawa mixing [5,6] matrix V^{CKM}: $d_i' \equiv \sum_j V_{ij}^{\text{CKM}}\, d_j$. The right-handed fermion fields transform as SU(2) singlets. From Higgs and electroweak (EW) precision data it is known that there are precisely three sequential fermion families. Constraints on V^{CKM} and tests of universality are discussed in Ref. [7] and in Section 12 on the "CKM Quark-Mixing Matrix" in this *Review.* The extension of the formalism to allow for an analogous leptonic mixing matrix is discussed in Section 14 on "Neutrino Masses, Mixing, and Oscillations" in this *Review.*

A complex scalar Higgs doublet, ϕ, is added to the model for mass generation through spontaneous symmetry breaking with the Higgs potential given by

$$V(\phi) = \mu^2 \phi^\dagger \phi + \frac{\lambda^2}{2} (\phi^\dagger \phi)^2 \,, \qquad \phi \equiv \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} \,. \tag{10.1}$$

For μ^2 negative, ϕ develops a vacuum expectation value, $\langle \phi \rangle = (0, v/\sqrt{2})^{\mathrm{T}}$, where $v = \sqrt{2}|\mu|/\lambda \approx 246$ GeV, breaking the EW symmetry down to the remaining $U(1)_{\text{em}}$ symmetry of *Quantum Electrodynamics* (QED). After this, only one neutral Higgs scalar, H, remains in the physical particle spectrum. The three remaining degrees of freedom in the doublet ϕ correspond to *would-be Goldstone fields,* which open up longitudinal polarizations of the W/Z bosons, but do not correspond to additional particles. In the following we assume the use of the *unitary gauge*, in which the would-be Goldstone fields formally vanish and the vector fields for the W/Z bosons directly describe three physical polarizations. In non-minimal models there are additional charged and neutral scalar Higgs particles. Higgs-boson physics is reviewed in Section 11 on the "Status of Higgs Boson Physics" in this *Review.*

After symmetry breaking the Lagrangian for the fermion fields, ψ_i, is

$$\begin{aligned} \mathscr{L}_F = & \sum_i \bar\psi_i \left(i \not\partial - m_i - \frac{m_i H}{v} \right) \psi_i \\ & - \frac{g}{2\sqrt{2}} \sum_i \overline{\Psi}_i \, \gamma^\mu \, (1 - \gamma^5) (T^+ \, W_\mu^+ + T^- \, W_\mu^-) \, \Psi_i \\ & - e \sum_i Q_i \, \bar\psi_i \, \gamma^\mu \, \psi_i \, A_\mu \\ & - \frac{g}{2 \cos\theta_W} \sum_i \bar\psi_i \, \gamma^\mu (g_V^i - g_A^i \gamma^5) \, \psi_i \, Z_\mu \,. \end{aligned} \tag{10.2}$$

Here $\theta_W \equiv \tan^{-1}(g'/g)$ is the weak mixing angle and $e = g \sin\theta_W$ is the positron electric charge. Furthermore,

$$A_\mu \equiv B_\mu \cos\theta_W + W_\mu^3 \sin\theta_W \,, \tag{10.3a}$$

$$Z_\mu \equiv -B_\mu \sin\theta_W + W_\mu^3 \cos\theta_W \,, \tag{10.3b}$$

$$W_\mu^\pm \equiv \frac{W_\mu^1 \mp i W_\mu^2}{\sqrt{2}} \tag{10.3c}$$

are the photon field (A) and the neutral (Z) and charged ($W^\pm$) weak boson fields, respectively.

The Yukawa coupling of H to ψ_i in the first term in $\mathscr{L}_F$, which is flavor diagonal in the minimal model, is $g m_i / 2 M_W$. From the bosonic interaction Lagrangian,

$$\begin{aligned} \mathscr{L}_{HV} = & \frac{1}{2}(v + H)^2 \left[\frac{g^2}{2} W_\mu^+ W^{\mu -} + \frac{g^2 + g'^2}{4} Z_\mu Z^\mu \right] \\ & - V\left(\frac{v + H}{\sqrt{2}} \right) \,, \end{aligned} \tag{10.4}$$

one obtains the EW boson masses (at tree level, *i.e.*, to lowest order in perturbation theory)

$$M_H = \sqrt{2}|\mu| = \lambda \, v \,, \tag{10.5a}$$

$$M_W = \frac{g v}{2} = \frac{e v}{2 \sin\theta_W} \,, \tag{10.5b}$$

$$M_Z = \sqrt{g^2 + g'^2} \, \frac{v}{2} = \frac{e v}{2 \sin\theta_W \cos\theta_W} \,, \tag{10.5c}$$

$$M_\gamma = 0 \,. \tag{10.5d}$$

The second term in $\mathscr{L}_F$ represents the charged-current weak interaction [8–10], where $T^\pm = (\sigma_1 \pm i\sigma_2)/2$ are the weak isospin raising and lowering operators, with σ_a denoting the Pauli matrices.

For example, the coupling of a W to an electron and a neutrino is

$$- \frac{e}{2\sqrt{2} \sin\theta_W} \left[W_\mu^- \, \bar e \, \gamma^\mu (1 - \gamma^5) \nu + W_\mu^+ \, \bar\nu \, \gamma^\mu \, (1 - \gamma^5) e \right] \,. \tag{10.6}$$

For momenta small compared to M_W, this term gives rise to the effective four-fermion interaction with the Fermi constant given by $G_F/\sqrt{2} = 1/(2v^2) = g^2/(8 M_W^2)$. CP violation is incorporated into the EW model by a single observable phase in V^{CKM}.

The third term in $\mathscr{L}_F$ describes electromagnetic interactions [11, 12], and the last is the weak neutral-current interaction [9,10,13]. The vector and axial-vector couplings of the Z boson are

$$g_V^i \equiv T_i^3 - 2 Q_i \sin^2\theta_W \,, \tag{10.7a}$$

$$g_A^i \equiv T_i^3 \,, \tag{10.7b}$$

where $T_i^3 = \sigma_3/2$ is the third component of the weak isospin of fermion i ($+1/2$ for left-handed u_i and ν_i; $-1/2$ for left-handed d_i and e_i; zero for right-handed fields), and Q_i is the charge of ψ_i

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

in units of e. The weak hypercharge Y_i is related to weak isospin and electric charge according to the *Gellman-Nishijima relation*, $Q_i = T_i^3 + Y_i/2$.

The first term in Eq. (10.2) also gives rise to Dirac fermion masses. In the SM, for the case of the neutrinos, the absence of the corresponding right-handed fields prevents the existence of such terms. Furthermore, the requirements of gauge invariance and renormalizability prevents writing Lagrangian terms with the SM fields that can give rise to Majorana neutrino masses after EW symmetry breaking. We refer to Section 14 on "Neutrino Mass, Mixing, and Oscillations" in this *Review* for a discussion on the possible origin of neutrino masses.

We recall that the full Lagrangian for EW interactions also contains gauge-boson self-interactions, encoded in its Yang–Mills part not spelled out here, which influence the predictions for the observables discussed below via EW radiative corrections.

This review is organized as follows: In Section 10.2 we cover several theoretical aspects that are fundamental for the understanding of the SM at the quantum level and the calculation of the phenomenology of the EW sector. Section 10.3 describes several low-energy observables that are key inputs for the SM description of EW interactions, such as the electromagnetic and Fermi constants. We also comment on the latest updates in the experimental status of the determination of the muon anomalous magnetic moment; however, this section has been substantially simplified with respect to previous editions of this *Review*. Section 10.4 focuses mostly on the description of the so-called EW precision observables that are used in the global EW fit, whose results are presented and discussed in Section 10.5. Finally, in Section 10.6 we move our focus to scenarios of physics beyond the SM and discuss the implications of the global EW fit from the point of view of constraining new physics.

10.2 Renormalization and radiative corrections

Before going into detail in the confrontation of the EW theory with experimental results, we clarify some notions and concepts that are essential in the perturbative evaluation of quantum field theories.

10.2.1 *Ultraviolet and infrared divergences and regularization*

Perturbative calculations in quantum field theories are typically plagued with different types of divergences. *Ultraviolet (UV)* divergences originate from the high-momentum regions in loop diagrams, while singularities resulting from finite momentum transfer are known as *infrared (IR)* divergences. Before eliminating the various divergences from predictions, it is necessary to map them to finite quantities in a mathematically consistent way, a step called *regularization*. This step embeds the whole theory into a wider class of theories parametrized by some new parameter δ, and the original theory corresponds to a specific value δ_0. Quantities that diverge in the original theory are finite for $\delta \neq \delta_0$, but diverge for $\delta \to \delta_0$, typically like $\ln(\delta - \delta_0)$ or some power of $1/(\delta - \delta_0)$. The most common regularization scheme is *dimensional regularization*, where the whole theory is formulated in D-dimensional flat space–time and both UV and IR divergences take the form of poles in the parameter $\epsilon = (4 - D)/2$, which is consistently treated as a complex parameter. Other regularization schemes are possible as well, such as the use of small mass parameters for regularizing IR singularities, but dimensional regularization has the advantage of maximal simplicity and preserving gauge and Lorentz invariance.

While the IR divergences are eliminated from physical predictions upon properly designing observables in such a way that IR singularities cancel by virtue of the Kinoshita–Lee–Nauenberg (KLN) theorem [14,15],[1] UV singularities are dealt in the context of the *renormalization* of the quantum field theory, as described in the next section.

[1] The KLN theorem states that singularities cancel in predictions for observables that are "sufficiently inclusive" with respect to the selected initial and final states, a property called *IR safety*. If IR safety cannot be achieved, IR singularities often exhibit *universal factorization properties* allowing for their absorption into non-perturbative quantities, such as *parton distribution* or *fragmentation functions* in the theory of strong interactions (see Section 9 on "Quantum Chromodynamics" in this *Review*).

Since symmetries are central in the construction of successful quantum field theories, regularization schemes should respect symmetries as much as possible. However, it might happen that a specific symmetry is necessarily broken by any regularization scheme. In this case the symmetry is *anomalous*, and the underlying theory is in danger of developing an *anomaly* in the sense that the quantized theory is less symmetric than the corresponding classical theory. Anomalies seriously jeopardize the cancellation of UV divergences, even if the cancellation existed in the presence of the considered symmetry. In this context, one of the most important symmetries is the *chiral symmetry*, which rules the relation between right- and left-handed fermions, because there is no regularization scheme that fully respects all algebraic properties of the Dirac matrix γ_5 as well as Lorentz and gauge symmetry simultaneously—a fact known as the γ_5 *problem* (see, *e.g.*, Ref. [16] for general facts and Refs. [17–20] for more recent developments and further literature). In spite of the existence of chiral couplings in the standard EW theory, the model does not develop a corresponding anomaly owing to special relations among the quantum numbers within the fermion spectrum. In practice, this means that chiral symmetry might be broken in intermediate steps of calculations, a fact that can seriously complicate higher-order calculations, but complete predictions do respect the symmetry.

10.2.2 *Renormalization procedure and renormalization schemes*

In the SM briefly outlined above, the mass parameters m_i have been identified such that the squared masses correspond to the locations of the poles of the lowest-order propagators of the corresponding fields. In the full theory, however, m_i does not have this property owing to higher-order corrections. Similarly, coupling parameters c_i appearing in the Lagrangian determine certain processes, such as decay rates, in lowest-order, but the relation between c_i and observables are modified by perturbative corrections as well. Finally, the fields encoding particle creation and annihilation are typically canonically normalized (to produce normalized states) in lowest order, but lose this property owing to corrections. The intended physical meaning of model parameters (*e.g.* masses and couplings) and the normalization of quantum fields of an underlying theory, generically denoted p and F in the following, can be restored by proper redefinitions, a step known as *renormalization*.

Marking the initial *bare* parameters and fields with subscript "0", p_0 and F_0, the *renormalized parameters and fields* p and F can be introduced by the *renormalization transformation*

$$p_0 \equiv Z_p\, p \equiv p + \delta p, \quad F_0 \equiv Z_F\, F, \tag{10.8}$$

where Z_p, δp and Z_F are parameter and field *renormalization constants,* which have to be determined by imposing appropriate *renormalization conditions* on field-theoretical quantities or physical observables. Assuming that the leading-order quantities p_0 and F_0 already fulfill the conditions, the deviations $\delta Z_i \equiv Z_i - 1$ are due to higher-order corrections. Substituting the bare quantities in favor of the renormalized quantities in the original Lagrangian $\mathcal{L}(p_0, F_0)$ according to (10.8), the leading-order parts of Z_i reproduce the original Lagrangian, $\mathcal{L}(p, F)$, but now parametrized in terms of renormalized quantities p and F, and the parts containing all δZ_i dependence form the *counterterm Lagrangian*

$$\delta\mathcal{L}(p, F, \delta Z_p, \delta Z_F) = \mathcal{L}(p_0, F_0) - \mathcal{L}(p, F) = \mathcal{L}(Z_p p, Z_F F) - \mathcal{L}(p, F), \tag{10.9}$$

which implies Feynman rules for *counterterm* contributions to Green functions. In other words, the step of renormalization just represents a reparametrization of the original theory.

The choice of renormalization conditions defines the *renormalization scheme,* which, thus, gives the model parameters their physical meaning. The details of the field renormalization, on the other hand, are merely a matter of convenience without any influence on predictions for observables. In order to avoid mixing between asymptotic states used in the calculation of scattering amplitudes, matrix-valued field renormalization constants Z_F are necessary in general. The form of the renormalization transformation (10.8) corresponds to the *multiplicative renormalization*

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s xcept for Open Access articles.

of a theory, which might not be general enough in the presence of *anomalies*, which appear if symmetries observed for a classical Lagrangian do not survive the step of quantization. On the other hand, the use of multiplicative (Z_p) or additive (δp) renormalization constants for parameters is a mere question of taste.

Theories that allow for the complete elimination of UV divergences from predictions are called *renormalizable*, otherwise they are *non-renormalizable*. Note that even UV-finite theories require the step of renormalization to define the precise meaning of input parameters, *i.e.* renormalization is more than eliminating UV divergences. In spite of the fact that predictions of non-renormalizable theories are not free of UV divergences, such theories can often still be exploited in the framework of *effective field theories* which involve a cutoff scale Λ that sets the order of the maximal energy up to which predictions can be made; for energies above Λ, effects of a more comprehensive *UV-complete theory* are expected to restore renormalizability.

Giving the model parameters their physical meaning, the renormalization scheme determines the parametrization of predictions for physical observables in terms of the renormalized input parameters p. The actual scheme choice might depend on various factors, such as the accessibility or precision to which a parameter can be determined by experiment, the perturbative stability of predictions, *i.e.* whether the size of higher-order corrections show the necessary decrease with increasing orders, or the transportability of the input parameters to predictions of observables that are connected to very different energy scales. In practice, a confrontation of a very comprehensive theory, such as the EW SM, with experimental results requires the use of different schemes adapted to different observables, so that a *conversion* of parameters and fields between different renormalization schemes is necessary. To this end, the renormalized parameters and fields in one scheme have to be expressed in terms of the ones in another scheme. For EW physics two different types of schemes are in use: (i) *on-shell (OS) renormalization* and (ii) renormalization based on *modified minimal subtraction* ($\overline{MS}$). Some schemes also mix these types of conditions, *i.e.* different parameters might employ different types of schemes. However, it is crucial that independent renormalization conditions are posed only for truly independent parameters, and that one and the same condition is consistently used for each independent input parameter within a given scheme.

In OS schemes, the renormalization conditions are imposed on S-matrix elements, *i.e.* on (at least in principle) measurable quantities. Typical examples are OS conditions for masses that tie mass parameters to the locations of the poles in full propagators, which might be experimentally reconstructed from event kinematics. On-shell conditions for coupling parameters can, *e.g.*, be tied to specific decay widths of particles or specific scattering cross sections in certain kinematic regimes. The advantage of OS schemes often lies in the accessibility of input parameters by experiment and the fact that predictions are rather safe against the introduction of artificial gauge dependences in predictions. On the other hand, $\overline{\text{MS}}$ renormalization has the advantage of maximal simplicity, because $\overline{\text{MS}}$ conditions reduce all renormalization constants to the UV-divergent contributions that are necessary to render all Green functions of the underlying theory UV finite in the framework of dimensional regularization. Moreover, the necessity of keeping all input parameters and fields at their canonical mass dimension introduces an arbitrary *renormalization scale* μ_{ren} in the $\overline{\text{MS}}$ scheme, so that Green functions obey *renormalization group equations (RGEs)* which rule the behaviour of input parameters, fields, and Green functions under the change of μ_{ren} while keeping (all-order) predictions for physical observables fixed. The RGEs can, thus, be used to transport the input quantities from one scale to another, and the residual μ_{ren}-dependence of predictions, which occurs because the perturbative series is necessarily truncated somewhere, offers a convenient device for estimating (at least part of) the theoretical uncertainty due to missing higher-order corrections.

The concept for renormalization and explicit schemes have been worked out in the 1970s to 1990s for the EW SM in different variants. The idea of EW OS renormalization dates back to Ref. [21] and has, *e.g.*, been worked out in Refs. [22–25]. Electroweak renormalization in the $\overline{\text{MS}}$ scheme is, for instance, described in Ref. [26]. A detailed review and more original references can be found in Ref. [27]. Most formulations are restricted to the one-loop level, a complete renormalization framework for the EW SM at the two-loop level is laid out in Refs. [28–30]. The renormalization of the EW SM is considerably more involved than for QED and Quantum Chromodynamics (QCD); major issues are:

- Any solution to the γ_5 problem actually goes beyond pure multiplicative renormalization. For instance, in dimensional regularization one of the defining algebraic properties of γ_5 valid in four dimensions has to be abandoned, and counterterms involving *evanescent operators* have to be fixed to restore symmetries. For more details and possible solutions, see, Ref. [16].
- Most particles of the EW SM are unstable, and experimental analyses of W/Z bosons, the Higgs boson, and the top-quark have to be based on event signatures of their decay products. Predictions for resonance processes necessarily go beyond any fixed perturbative order, since lowest-order propagators involve a pole, which diverges, instead of a proper resonance structure, which remains finite. Perturbation theory solves this problem by an infinite power series, known as *Dyson series*, of propagator corrections that shifts the pole into the complex k^2 plane for four-momentum transfer k, leading to a Breit–Wigner-like resonance structure with the total decay width of the unstable particle delivering the finite width of the resonance. Identifying the mass square of an unstable particle with the location of the propagator pole, renders the mass of an unstable particle a complex quantity, posing a challenge for the renormalization of the input mass parameter, which is a real quantity. Moreover, the Dyson summation of propagator corrections has to be done with great care, since it necessarily leads to perturbative orders that are only partially included. This jeopardizes the mathematical consistency in predictions, as further discussed at the end of Sec. 10.2.4.
- Non-vanishing vacuum expectation values (vevs) in quantum field theories lead to the appearance of *tadpole graphs,* which are subdiagrams with exactly one external field leg. It is very convenient to eliminate such diagrams by generating a corresponding tadpole counterterm in the renormalization transformation. It is a matter of choice, defining the *tadpole scheme*, to generate the tadpole counterterm in the context of parameter renormalization [24, 25, 31] or field renormalization [28, 32], or both [33]. While predictions within pure OS renormalization schemes do not depend on this choice, predictions employing $\overline{\text{MS}}$-renormalized mass parameters in general do depend on the tadpole scheme. Since some tadpole schemes are prone to lead to very large higher-order corrections and others introduce gauge dependences in predictions, care is needed in applications, especially in the context of $\overline{\text{MS}}$-renormalized masses, see, *e.g.*, Ref. [33].

10.2.3 *Electroweak input parameter schemes*

Starting from its original form, the Lagrangian of the EW SM contains the following free parameters: the couplings g and g' from the gauge interactions, the parameters μ^2, λ from the Higgs potential, and three complex 3×3 matrices y^ℓ, y^u, y^d from the Yukawa interactions of charged leptons and quarks to the Higgs field—there is no such interactions for neutrinos, which are massless in the SM. Owing to possible reparametrizations of the fermion fields that have no effect on observables, not all coefficients of the matrices y^f ($f = \ell, u, d$) are "physical": Only the nine fermion masses $m_{f,i}$, with $i = 1, 2, 3$ labelling the fermion generations, and four independent variables (three angles and one phase) parametrizing the unitary CKM matrix V^{CKM} describing quark mixing are "physical" and have to be taken from experiment. In total, this makes a set of 17 free parameters of the EW model, which are completed to the full SM input by the strong coupling constant α_s and possibly a non-zero parameter θ quantifying strong CP-violation.

The choice of the input parameters for the fermionic sector is widely independent from the input in the bosonic sector. The use

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

of OS-renormalized lepton masses is uncontroversial and common practice. If perturbative predictions sensitively depend on the masses of light quarks, this is a sign of significant non-perturbative effects and mostly connected to strong interactions. In such cases, an input scheme for the perturbative part of a prediction should be chosen to avoid mass-singular contributions from light quarks; if non-perturbative contributions are unavoidable (such as in the running of the electromagnetic coupling at low energies, in parton distribution, or fragmentation functions) these require dedicated additional input from experiment or non-perturbative calculations. Concerning input and renormalization schemes for heavy quarks (top, bottom, etc., in detail depending on the considered observables), the aspects relevant for EW physics are discussed in Sec. 10.4.3; more details can be found in the "Quantum chromodynamics" and "Heavy-quark and soft-collinear effective theory" sections of this *Review*. The determination and use of the CKM parameters is discussed in the section "CKM Quark-Mixing Matrix".

The original set g, g', μ^2, λ of free parameters of the bosonic sector, in practice, is replaced by an equivalent set of four parameters that are more directly accessible by experiment. Candidates for such parameters are the electromagnetic coupling $\alpha = e^2/(4\pi)$, the weak mixing angle θ_W, the weak-boson masses M_W, M_Z, M_H, and the Fermi constant G_F. The ideal choice of four input parameters, which aims at minimal uncertainty in predictions, depends on actual applications. However, it is crucial to consistently stick to one choice for the set of four parameters within a prediction for an observable, in order to guarantee the self-consistency of the result (finiteness, gauge invariance). Apart from the selection of the set of input parameters, the choice of renormalization scheme for each input parameter matters as well. Below we describe the most important choices of input sets and renormalization schemes, also known as *EW input schemes* that are used in calculations of EW precision observables and EW corrections to particle processes. All of these schemes take the (OS-renormalized) Higgs-boson mass M_H as direct input, but differ in the choice or scheme of the other three EW parameters (see, *e.g.*, Refs. [27,34,35] for more details):

- *LEP scheme* with input parameters $\alpha(0), G_F, M_Z$. The W-boson mass M_W can be calculated to high precision in this scheme, exploiting the prediction for muon lifetime τ_μ including radiative corrections, which are encoded in the quantity Δr [22]. In most applications the masses M_Z and M_W are renormalized on-shell, but $\overline{\text{MS}}$ masses can be used as well, proper scheme conversion assumed. The evaluation of Δr requires non-perturbative input in terms of the running effect of $\alpha(Q^2)$ from $Q^2 = 0$ to the EW scale, which is quantified in terms of the quantity $\Delta\alpha(Q^2)$, which in turn is obtained from the *R-ratio* in e^+e^- annihilation via dispersion relations or from lattice calculations. Since M_W, $c_W \equiv \cos\theta_W^{\text{OS}} = M_W/M_Z$, and $s_W \equiv \sin\theta_W^{\text{OS}}$ enter the prediction for τ_μ in a rather complicated way, technically M_W is obtained by solving the experimental τ_μ constraint numerically. Calculations for observables other than the W-boson mass, then best proceed in one of the following schemes employing the calculated value for M_W and dropping $\alpha(0)$ or G_F from the input set.
- $\alpha(0)$*-scheme* with input parameters $\alpha(0), M_W, M_Z$. The electromagnetic coupling is directly fixed by the fine-structure constant $\alpha(0)$, and the weak mixing angle by the OS relation $c_W \equiv \cos\theta_W^{\text{OS}} = M_W/M_Z$. Radiative corrections to most processes at and above the GeV energy range involve the running effect $\Delta\alpha(M_Z^2)$, which then has to be taken as additional non-perturbative input.
- $\alpha(M_Z^2)$*-scheme* with input parameters $\alpha(M_Z^2), M_W, M_Z$. This scheme takes the running coupling constant $\alpha(M_Z^2) \equiv \alpha(0)/[1 - \Delta\alpha(M_Z^2)]$ as input instead of $\alpha(0)$ as in the $\alpha(0)$-scheme. For many processes at and above the EW energy scale, this absorbs the non-perturbative running effects of α into the coupling constant and, thus, into lowest-order predictions, so that no additional non-perturbative input beyond the value of $\alpha(M_Z^2)$ is required in the radiative corrections.
- G_F*-scheme* with input parameters G_F, M_W, M_Z. In this scheme the electromagnetic coupling α, called α_{G_F} in the following, is derived from the lowest-order prediction for τ_μ (*i.e.* G_F) in the $\alpha(0)$ scheme. This procedure effectively absorbs the correction Δr [22] to muon decay into the electromagnetic coupling, which can be expressed by

$$\alpha_{G_F} \equiv \frac{\sqrt{2} G_F M_W^2 (1 - M_W^2/M_Z^2)}{\pi} = \alpha(0)[1 + \Delta r]. \quad (10.10)$$

  Since muon decay is a charged-current process, the G_F-scheme effectively absorbs the universal corrections related to the transition from the electromagnetic to the weak charged-current interaction into the lowest-order coupling. These universal corrections are intrinsically connected to the ρ-parameter [36, 37], which relates the ratio of neutral- to charged current-current interactions to the corresponding gauge-boson mass ratio and is discussed in more detail in Sec. 10.2.5 below. Similarly, and although not completely, the G_F-scheme also absorbs into the lowest-order weak neutral-current couplings a large part of corrections to the ρ-parameter.
- EW input parameter schemes with the *leptonic effective weak mixing angle* $\sin^2\theta_{\text{eff}}^\ell$ as free parameter [38] (for the precise definition of $\sin^2\theta_{\text{eff}}^\ell$, see Sec. 10.4.5). Such schemes are motivated by an analysis of neutral-current processes, such as Drell–Yan production, to fit $\sin^2\theta_{\text{eff}}^\ell$ to experimental data and can be obtained from the $\alpha(0)$-, $\alpha(M_Z^2)$-, or G_F-schemes upon replacing M_W by $\sin^2\theta_{\text{eff}}^\ell$ in the list of input parameters. Using $\sin^2\theta_{\text{eff}}^\ell$ as input, the renormalized mass M_W is derived from $\sin^2\theta_{\text{eff}}^\ell$ and M_Z via their LO relation, and the renormalization constant δM_W^2 contains the EW corrections contained in the difference $\sin^2\theta_{\text{eff}}^\ell - (1 - M_W^2/M_Z^2)$ from the renormalization scheme change. The schemes should not be used to predict processes where M_W enters already at LO apart from its indirect appearance via gauge couplings, since the derived LO value for M_W is not in line with precision data. Although this mismatch is cured in higher orders, the scheme would be prone to large corrections, e.g., in predictions for charged-current processes.

From the above, it is clear that a judicious choice of the EW input scheme can be used to absorb the universal effects from the running of α and the ρ-parameter into lowest-order predictions, which systematically helps to minimize EW corrections and, thus, to stabilize predictions. Processes dominated by charged- or neutral-current weak interactions at the EW scale or somewhat above are best described in the G_F-scheme, while processes dominated by the electromagnetic interaction are best described by the $\alpha(0)$ or $\alpha(M_Z^2)$ schemes. Which of the two is more appropriate depends on the number of external photons involved that are truly identified as photons, *i.e.* that are distinguishable from low-virtuality photons splitting in $f\bar{f}$ pairs. True on-shell photons effectively couple with strength $\alpha(0)$, while photons that include splittings $\gamma^* \to f\bar{f}$ up to some scale Q effectively couple with strength $\alpha(Q^2)$.

Note that there are many particle processes for which none of the EW input schemes directly absorbs all universal corrections from $\Delta\alpha$ and $\Delta\rho$ (where $\rho = 1/(1 - \Delta\rho)$) because neither weak nor electromagnetic interactions are dominating all involved couplings. In many cases, however, uniformly[2] rescaling cross-section contributions that are proportinal to some power α^N according to $\alpha(0)^k \alpha(M_Z^2)^l \alpha_{G_F}^m$ with $N = k + l + m$ can help to absorb these universal corrections into lowest-order predictions. Finally, note that any change in the input value of α comes along with some additive contribution from $\Delta\alpha$ and/or Δr to the EW corrections. More details on optimal scheme choices and the necessary modifications in the renormalization procedure can be found in Ref. [27].

[2] Uniformly, in this context means that contributions of a given perturbative order are not taken apart, in order to avoid any disturbance in the cancellation of divergences or gauge dependences.

10.2.4 *Particle masses*

The masses of the SM particles are a cornerstone in the phenomenological input of the EW SM and its extensions. The masses of the leptons are most uncontroversial in this context: The masses of the charged leptons are measured to very high precision, and the instability of the μ and the τ leptons does not entail any problems owing to their long lifetimes (with ratios of width over mass $\sim 10^{-18}$ and $\sim 10^{-12}$, respectively). We note that, despite the knowledge from neutrino oscillations, which imply that said particles possess non-vanishing masses, neutrinos are treated to be massless in the SM. However, because of the smallness of neutrino masses compared to the energy scales in collider experiments, this approximation is valid to high precision in collider physics.

The situation with quarks is rather different and more complicated: Because of quark confinement, the masses of the quarks u, d, s, c, and b are not directly experimentally accessible; their role in EW physics is described in Sec. 10.4.3 below and more generally in Section 60 on "Quark Masses" in this *Review*. The top-quark is special, since it decays before hadronization. Its mass is directly accessible via kinematical reconstruction in collider experiments or through cross-section measurements of processes involving top-quarks; see the above-mentioned sections as well.

The masses of the EW gauge bosons Z and W play a key role in EW precision physics. Due to the large ratio of total decay width over mass, $\Gamma_V/M_V \sim 3\%$ with $V = Z, W$, and the experimental accessibility of their decay signatures, the masses M_Z and M_W can be extracted from the analysis of differential cross sections featuring resonance structures, i.e. via kinematical reconstruction. On the other hand, the significant ratio Γ_V/M_V implies theoretical subtleties in the calculation of predictions for EW observables, as discussed in the subsequent section.

Since the total decay width Γ_H is rather small ($\sim 4\,\text{MeV}$ in the SM), the resonance lineshape of the Higgs boson cannot be resolved at the LHC, and Γ_H is accessible only indirectly with the caveat of model-dependent assumptions. On the other hand, the smallness of $\Gamma_H/M_H \sim 3 \times 10^{-5}$ implies that there are no subtleties in theory predictions for a SM-like Higgs boson originating from its instability.

Up to higher-order corrections, resonances of an unstable particle P are of Breit–Wigner type, *i.e.* the scattering matrix elements involve contributions enhanced by propagator factors of the form

$$P_P(p^2) = \frac{1}{p^2 - M_P^2 + iM_P\Gamma_P(p^2)}, \tag{10.11}$$

where p is the momentum transferred by the propagator. If the experimental resolution is of the order of the decay width Γ_P, cross-section predictions featuring this resonance, such as invariant-mass distributions of decay products of P, can be fitted to experimental data with fit values for the mass M_P and $\Gamma_P(M_P^2)$. In detail, the fit result depends on the assumed or predicted momentum dependence of $\Gamma_P(p^2)$. Fitting the resonance structure for a constant width, $\Gamma_P(M_P^2) \equiv \overline{\Gamma}_P$, produces the location

$$\mu_P^2 = \overline{M}_P^2 - i\overline{M}_P\overline{\Gamma}_P \tag{10.12}$$

of the propagator pole in the complex p^2-plane, and the resulting masses μ_P and $\overline{M}_P$ are called *complex* and *real pole masses* of P, respectively. Note, however, that most of the existing results on the Z- and W-boson masses M_V ($V = Z, W$) have been based on the parametrization $\Gamma_V(p^2) = p^2/M_P^2 \times \Gamma_V$ with constant Γ_V, which parametrizes the momentum dependence of propagator corrections near the resonance ($p^2 \sim M_V^2$) for the decay of $V = Z, W$ into massless particles. The corresponding mass and width values, M_V and Γ_V, are known as *LEP masses* and *LEP widths*, owing to their first use in the analysis of LEP precision data. The two sets of mass and width are related by [39]

$$\overline{M}_V = \frac{M_V}{\sqrt{1+\Gamma_V^2/M_V^2}}, \qquad \overline{\Gamma}_V = \frac{\Gamma_V}{\sqrt{1+\Gamma_V^2/M_V^2}}, \tag{10.13}$$

in particular implying

$$M_W - \overline{M}_W \approx 27\,\text{MeV}, \qquad M_Z - \overline{M}_Z \approx 34\,\text{MeV}, \tag{10.14}$$

i.e. the scheme differences are much larger than the corresponding experimental uncertainties on the W and Z masses (see next section).

To make use of the masses obtained via fitting resonances, it is necessary to identify renormalization schemes that lead to the parametrizations of the resonances employed in the fit:

- In OS renormalization schemes that identify the renormalized (squared) mass with the real part of the location μ_P^2 of the complex pole of the propagator $G^{PP^\dagger}$, the renormalized mass directly corresponds to $\overline{M}_P$. The location of the propagator pole is identical to the complex position of the zero in the (physical part) of the corresponding inverse propagator, also known as *two-point vertex function* $\Gamma^{P^\dagger P} = -i(G^{PP^\dagger})^{-1}$. Since the location of the propagator pole is an intrisinc (and measurable) property of the S-matrix, adopting $\overline{M}_P$ as independent input quantity of the theory does not induce any gauge dependences in predictions [40, 41]. The OS renormalization for $\overline{M}_Z$ and $\overline{M}_W$ is worked out in Ref. [30, 42] at the two-loop level. The complex-mass scheme [43] (see also [27, 44]), which is employed in most EW NLO calculations for resonance processes at the LHC, is an OS renormalization scheme with the complex renormalized mass μ_P based on $\overline{M}_P$ and the (measured or calculated) value of $\overline{\Gamma}_P$.
- Tying the OS renormalized mass to the real zero in $\text{Re}\{\Gamma^{P^\dagger P}\}$ (which is the prescription in the real OS scheme, see *e.g.* Refs. [22, 24, 25]), instead of taking the real part of the complex zero of $\Gamma^{P^\dagger P}$, is equivalent at NLO, but not beyond. For the Z and W masses, these differences have, *e.g.*, been worked out in Refs. [27, 30, 42, 45, 46], revealing that the Z and W masses in the real OS scheme (based on the zeroes of $\text{Re}\{\Gamma^{V^\dagger V}\}$, $V = Z, W$) correspond to the LEP masses M_Z and M_W introduced above that result from the fit to Breit–Wigner distributions with running widths (at least in the 't Hooft–Feynman gauge). As already pointed out in Ref. [45], using renormalized masses of this real OS scheme to parametrize predictions leads to gauge dependences starting at the two-loop level.[3] For predictions beyond NLO precision, the use of $\overline{M}_P$ is, thus, preferable over the use of M_P.
- $\overline{\text{MS}}$-renormalized masses are not directly related to parameters appearing in any form of Breit–Wigner-like resonances. To extract them from data, one either has to make use of precision calculations for measured observables (such as cross sections or decay widths) with complicated mass dependences, or to convert measured OS masses into the $\overline{\text{MS}}$ scheme. For the Z and W bosons this scheme conversion is carried out in Refs. [47–50].
- Extracting the top-quark mass from kinematical distributions is impeded by strong-interaction effects, limiting the concept of *long-distance top-quark masses* such as OS-renormalized masses. Perturbative predictions are more stable if a *short-distance top-quark mass* is employed, such as provided by the $\overline{\text{MS}}$ scheme. More details on this subject can be found section "Top Quark" of this *Review*.

We finally emphasize that the issue of calculating higher-order corrections to processes with unstable particles goes far beyond a proper definition of mass and width of the unstable particle, and beyond parametrizing resonance patterns and identifying resonance parameters with renormalized parameters of the underlying field theory. Issues with gauge invariance, unitarity, UV and IR divergences, and the embedding of resonances into full off-shell processes concern the complete underlying matrix elements. These issues are due to the fact that the identities ruling gauge invariance *(Ward and Slavnov-Taylor identities)* and finiteness are typically working order by order in perturbation theory, but the inclusion of finite-width effects in resonance propagators originates from a Dyson summation of propagator corrections, necessarily resulting

[3] This means that all higher-order calculations beyond NLO (including the ones used to extract M_Z and M_W from data) would have to be carried out in the same gauge, or proper parameter conversions would have to be made when changing the gauge.

in perturbative orders that are taken into account only partially in predictions. Different solutions to these problems have been described in the literature, targeting at different kinematical situations and different levels of sophistication: If resonances need not be resolved, variants of *narrow-width approximations* based on production and decay subprocesses might be sufficient (depending on the experimental precision). The neighborhood of resonances can be described via dedicated *pole expansions* [51, 52] of matrix elements leading to *pole approximations*, as described for single resonances in Refs. [35, 53–58]. The concept of leading pole approximations has also been successfully applied to processes with multiple resonances, see, *e.g.*, Refs. [59–63]. Many modern analyses of many-particle processes even require precision in resonant and non-resonant regions of phase space, as, *e.g.*, provided by the complex-mass scheme [43, 44] at NLO. Descriptions of these concepts as well as further references can be found in Ref. [27].

10.2.5 *Radiative corrections to electroweak processes*

Radiative corrections, in particular the ones induced by the EW interactions, play an integral role in the simulation of EW processes and predictions for corresponding observables analyzed at particle colliders. For instance, for a proper analysis of data collected at the LHC [64–67], most precision calculations have reached the standard that QCD and EW corrections are known at NLO for virtually all EW key processes and even at next-to-next-to-leading order (NNLO) QCD for the $2 \to 2$ processes [68–70]. The underlying modern methods for calculating radiative corrections are very well advanced and implemented in public tools that make (semi-)automatic calculations possible, depending on their complexity (see, *e.g.*, Refs. [27,71] and references therein). Predictions for specific kinematic configurations, such as low-p_{T} production of W/Z production, might call for improvements beyond fixed perturbative orders; details and references on the corresponding QCD resummation and parton-shower techniques can be found in Section 9 on "Quantum Chromodynamics" in this *Review*. Event simulations typically require additional improvements on particle emission effects in QCD and QED via matching fixed-order predictions, as provided by dedicated precision Monte Carlo programs or MadGraph/MadEvent [72, 73], with *parton showers* and merging them with corrections for higher jet multiplicities based on matrix elements. This matching and merging is provided in different variants within the multi-purpose Monte Carlo event generators Herwig [74,75], Pythia [76], and Sherpa [77–79]. For the analysis of high-precision EW observables (see, *e.g.*, Ref. [80]) even NNLO EW corrections and the dominant effects beyond the two-loop level are relevant.

Different types of radiative corrections to particle processes have to be combined with care in order to avoid double-counting of effects, to respect gauge invariance, and to guarantee a proper cancellations of IR singularities.

- Complicated processes, such as vector-boson scattering, often receive LO contributions from different perturbative orders $\propto \alpha_s^m \alpha^n$, so that already NLO corrections lead to a tower of mixed orders formed by contributions $\propto \alpha_s^{m+1}\alpha^n$ or $\propto \alpha_s^m \alpha^{n+1}$. In such cases, a strict classification of corrections into QCD and EW contributions is not generally possible, but separating the various orders is possible and often instructive.
- Single perturbative orders $\propto \alpha_s^m \alpha^n$ can be further split into gauge-invariant subcontributions by considering contributions featuring closed fermion loops or the emission of fermion–antifermion pairs.[4] These *fermionic corrections* can be further classified according to their multiplicity factor N_f^k, where N_f is the number of light fermion flavors. Isolating such subcontributions often helps to locate dominant corrections that warrant the inclusion of higher-order corrections with similar enhancements.
- Since photonic corrections can be potentially large, their separation from the remaining EW corrections is desirable, but this is not always possible in a gauge-invariant way. For processes that feature only neutral-current interactions at LO, this separation can be achieved, however. Arguments for this gauge-invariant separation of QED effects, which can be further decomposed into photonic and fermionic parts as described in the previous item, can be based on the observation that the charged-current sector can be removed from the SM in such a way that a fully consistent "neutral-current theory" with gauge group $\mathrm{U}(1)_Z \times \mathrm{U}(1)_{\mathrm{em}}$ results [27]. The separation of photonic corrections was extremely useful in precision calculations for Z production via e^+e^- annihilation at LEP and SLC, $e^+e^- \to Z/\gamma^* \to f\bar{f}$, so that the inclusion of higher-order photonic corrections to the Z lineshape was possible without knowing the full EW corrections beyond NLO [34, 35, 54].

The analysis of the Z resonance in $e^+e^- \to Z/\gamma^* \to f\bar{f}$ is a cornerstone of EW precision physics. The separation of the large photonic corrections from the remaining weak corrections to the Z lineshape, in combination with the smallness of the irreducible (box) weak corrections near the Z resonance, is the basis of the parametrization of the cross section and its asymmetries in terms of *pseudo-observables*, such as the Z peak cross section, the total and partial Z decay widths, forward–backward (FB) as well as polarization asymmetry variables, effective Z couplings, and the *effective weak mixing angle for each fermion* f quantified by $\bar{s}_f^2 \equiv \sin^2\theta^f_{\mathrm{eff}}$, etc. (see Section 10.4 for a precise definition of these quantities). The Z-pole pseudo-observables can be predicted to high precision, independent of the full prediction of the Z-boson lineshape, and play a key role in the global SM fit to data:

- EW corrections to the Z-pole pseudo-observables comprise (flavor-dependent) $Zf\bar{f}$ vertex corrections (see, *e.g.*, Refs. [24, 81]) as well as (flavor-independent) contributions to the $\gamma\gamma$, γZ, ZZ, and WW gauge-boson self-energies (*i.e.vacuum polarization* diagrams), the latter entering via EW renormalization constants (see, *e.g.*, Refs. [24, 25]).
  While being gauge dependent in general, there are several distinct and important contributions from gauge-boson self-energies that lead to gauge-invariant corrections to EW precision observables, in particular contributions from closed fermion loops and the corresponding QCD corrections. For instance, the mixed QCD–EW contributions to gauge-boson self-energies of orders $\alpha\alpha_s m_t^2$ [82, 83], $\alpha\alpha_s^2 m_t^2$ [84, 85], and $\alpha\alpha_s^3 m_t^2$ [86–88] increase the predicted value of m_t by 6%.[5] The sub-leading $\alpha\alpha_s$ corrections [89–93] are also included in the predictions for the Z-pole pseudo-observables. Further three-loop corrections of order $\alpha\alpha_s^2$ [94, 95], $\alpha^3 m_t^6$, $\alpha^2\alpha_s m_t^4$ [96,97], α_f^3 and $\alpha_f^2\alpha_s$ [98,99] are rather small (here α_f denotes EW corrections with a closed fermion loop).
- Z-pole pseudo-observables are among the still very few examples for which complete NNLO EW corrections are known. The EW two-loop corrections for the relation between $\bar{s}_\ell^2$ and s_W^2 are given in Refs. [100–105], the ones to $\bar{s}_f^2$ ($f \neq$ top), the effective couplings of fermions f to the Z boson, and the partial and total Z decay widths in Refs. [58, 106–110].
- All EW observables that depend on the weak mixing angle θ_W in LO receive contributions from its renormalization, in particular significant corrections from the ρ parameter [36, 37], $\rho = 1/(1-\Delta\rho)$, as defined from the neutral-to-charged-current cross-section ratio at low energies, *i.e.*

$$\Delta\rho = \frac{\Sigma_{\mathrm{T}}^{ZZ}(0)}{M_Z^2} - \frac{\Sigma_{\mathrm{T}}^{WW}(0)}{M_W^2}, \tag{10.15}$$

  where $\Sigma_{\mathrm{T}}^{VV}(0)$ is the (transverse part of the) Z/W boson self-energy at zero momentum transfer, following the notation of

[4] This is due to the fact that adding or removing fermion generations to or from the SM respects gauge invariance. (Working in a field basis corresponding to mass eigenstates, the added/removed generations should not mix with the other generations.)

[5] This is, however, almost entirely an artifact of using the pole mass definition for m_t. The equivalent corrections when using the $\overline{\mathrm{MS}}$ definition $\widehat{m}_t(\widehat{m}_t)$ increase m_t by less than 0.5%.

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is subject to CC BY except for Open Access articles.

Refs. [24, 25, 27]. The largest contribution $\Delta\rho_t$ to $\Delta\rho$,

$$\Delta\rho_t = \frac{3G_F m_t^2}{8\sqrt{2}\pi^2} = 0.00934 \times \frac{m_t^2}{(172.61\ \text{GeV})^2} \ , \qquad (10.16)$$

results from one-loop diagrams with closed fermion loops involving the top-quark. Two-loop corrections involving the top-quark modify $\Delta\rho_t$ by

$$\Delta\rho_t \to \Delta\rho_t \left[1 + R(M_H, m_t)\, \frac{\Delta\rho_t}{3}\right] \ . \qquad (10.17)$$

The function $R(M_H, m_t)$ can be described as an expansion in M_Z^2/m_t^2, for which the leading m_t^4/M_Z^4 [111, 112] and next-to-leading m_t^2/M_Z^2 [113, 114] terms are known. Beyond the two-loop level, leading top-mass-enhanced contributions to $\Delta\rho$ have been calculated to the orders $\alpha_s^2\alpha m_t^2$ [84, 85, 95], $\alpha_s\alpha^2 m_t^4$ and $\alpha^3 m_t^6$ [96, 97], and $\alpha_s^3\alpha m_t^2$ [86–88].

The extraction of the W-boson mass M_W from the measured muon decay lifetime (or Fermi constant) is another cornerstone in the fit of the SM to precision observables. In detail, M_W is obtained by solving the implicit equation (10.10) for M_W, where the Fermi constant G_F is extracted from the measured muon lifetime (see Section 10.3.2) and the quantity Δr [22] represents the radiative corrections to muon decay. At NLO, the correction Δr receives sizeable contributions from $\Delta\alpha$ and $\Delta\rho$ of $\sim +6\%$ and $\sim -3\%$, respectively, leaving only a small remainder Δr_{rem} of $\sim 1\%$,

$$\Delta r^{(1)} = \Delta\alpha - \frac{c_W^2}{s_W^2}\,\Delta\rho + \Delta r_{\text{rem}} \ . \qquad (10.18)$$

The complete two-loop calculation of Δr in the OS renormalization scheme has been performed in Refs. [42, 115–118]. The two-loop QCD correction of order $\alpha\alpha_s$ and the fermionic[6] electroweak two-loop correction of order α^2 amount to about 10% of the one-loop correction to Δr, both with the same sign, $\sim +0.4\%$ and $\sim 0.3\%$, respectively. The three-loop QCD correction, $\alpha\alpha_s^2$, amounts to $\sim 0.07\%$ while the bosonic two-loop electroweak correction is very small ($\sim 0.006\%$). Taking into account leading higher-order effects from $\Delta\rho$, the theoretical uncertainty from unknown higher-order corrections is estimated to 4 MeV for the prediction of M_W [119]. The recent calculation [120] of $\alpha^2\alpha_s$ corrections to Δr, which is not yet employed in the SM fits described below, revealed a further shift of ~ 3 MeV in M_W, confirming that the 4 MeV theory uncertainty in M_W is quite realistic and not too conservative. In an alternative approach, Ref. [121] obtained the $\overline{\text{MS}}$ quantities $\Delta\widehat{r}$ and $\widehat{\rho}$ to two-loop accuracy, confirming the prediction of M_W in the OS scheme from Refs. [42, 119] within about 4 MeV. More recently, Δr has been calculated within an alternative ("tadpole-free") version of EW $\overline{\text{MS}}$ renormalization at the two- and three-loop levels in Refs. [122, 123], respectively, the latter in the approximation of the "gauge-less limit"; the calculations within this scheme, however, have not yet been applied to predictions for the OS-renormalized W-boson mass.

Throughout this *Review* we utilize predictions for EW precision observables including the relevant EW radiative corrections from the programs `Gfitter` [124–127] and `HEPfit` [128–132]. Both `Gfitter` and `HEPfit` follow the OS renormalization scheme in their implementations of the radiative corrections for EW precision observables, in contrast to the `GAPP` package [133], used in the fits presented in previous editions of this *Review*, which works entirely in the $\overline{\text{MS}}$ scheme. Observables including corrections beyond NLO, such as the W-boson mass, the effective weak mixing angle(s), and the pseudo-observables at the Z resonance are implemented via the semi-analytical approximations provided in Refs. [105, 106, 110, 119]. The uncertainties from missing higher-order corrections on the different (pseudo-)observables are also taken into account, using the estimates given in those references, in the computation of the SM predictions. The W-boson decay width is computed at the one-loop level, using the expressions given in Refs. [55, 134, 135] (in agreement with the independent results of Ref. [136]). This observable is currently known with comparatively lower precision than those at the Z pole, but the corresponding theory uncertainty is still smaller than the experimental precision.

Several other tools are available in the literature for the calculation of EW corrections to the considered (pseudo-)observables and to perform the EW fit. The package `GRIFFIN` [58] provides a framework for the calculation of $2 \to 2$ fermion processes which, in its current version provides the full NNLO and the leading higher-order corrections for processes at the Z pole. Among the different codes for calculating EW precision observables available in the literature, `ZFITTER` has a prominent place [137, 138], due to its key role in the original studies of the LEP Electroweak Working Group [139, 140].

After this overview of the practical aspects relevant to SM calculations in the EW sector, we next discuss some of the most important observables that validate the SM description of EW interactions.

10.3 Low-energy observables

10.3.1 *The electromagnetic coupling*

As in pure QED, the coupling constant e is identified with the electromagnetic coupling strength of physical (on-shell) electrons in the limit of low-energy transfer *(Thomson limit), i.e.*, e is the electric unit charge of classical electrodynamics.[7] This OS renormalization of e in the Thomson limit ensures the property of *charge universality*, *i.e.* it guarantees that, in this limit, one can renormalize e via the electromagnetic interaction of any fermion (actually any charged particle), obtaining the same result as for electrons.

The *fine structure constant* $\alpha(0) \equiv e^2/(4\pi)$ can be extracted from the anomalous magnetic moment of the electron, $a_e = (1\,159\,652\,180.59 \pm 0.13) \times 10^{-12}$ [143]. Application of QED corrections up to five-loop order [144–146] produces the value $\alpha(0)^{-1} = 137.035\,999\,166(15)$. Here, the number in parentheses denotes the uncertainty in the last digits shown. This determination of $\alpha(0)^{-1}$ from a_e has recently been re-evaluated [147], updating the tenth-order QED term of a_e and the evaluation of the hadronic vacuum polarization (HVP) contribution, finding the compatible value $\alpha(0)^{-1} = 137.035\,999\,163(15)$. Another approach combines measurements of the Rydberg constant and atomic masses with interferometry of atomic recoil kinematics. Applied to ^{87}Rb [148] and ^{133}Cs [149], this method implies the results $\alpha(0)^{-1} = 137.035\,999\,206(11)$ and $\alpha(0)^{-1} = 137.035\,999\,046(27)$, respectively. These two measurements differ by 5.5 σ, where the origin of this discrepancy is currently not understood. While it is not advisable to combine measurements with such a tension, it is worth pointing out that the absolute magnitude of this discrepancy is at a level where it has no significant impact on the EW fit. We use the value quoted in Section 1 ("Physical Constants") in this *Review*,

$$\alpha(0)^{-1} = 137.035\,999\,177(21), \qquad (10.19)$$

which is a combination of the results from a_e and atomic interferometry.

As explained in Section 10.2.3, in EW higher-order calculations it can be convenient to define a running α dependent on the energy scale of the process, with $\alpha(0)^{-1} \approx 137.036$ appropriate at very low energy, *i.e.* close to the Thomson limit. The L3 [150] and OPAL [151] collaborations at LEP could also observe the running directly in small and large angle Bhabha scattering, respectively. For scales above a few GeV the low-energy hadronic contribution to the electromagnetic vacuum polarization introduces a theoretical uncertainty in α, so that it is often convenient to use the value

$$\alpha(M_Z^2) = \frac{\alpha(0)}{1 - \Delta\alpha(M_Z^2)} \qquad (10.20)$$

[6] Fermionic contributions at NNLO denote contributions from diagrams with closed fermion loops, whereas bosonic contributions are all remaining two-loop diagrams.

[7] *Thirring's QED theorem [141],* which is valid in the EW theory as well [142], makes this link between quantum field theory and classical electrodynamics very explicit, as it states that the Compton scattering cross section turns into the classical Thomson cross section in the low-energy limit, *i.e.*, the radiative corrections to Compton scattering vanish in the Thomson limit to all perturbative orders.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

as phenomenological input, where $\Delta\alpha(M_Z^2)$ contains the running effects of $\alpha(Q^2)$ from $Q^2 = 0$ to $Q^2 = M_Z^2$. In particular, the hadronic contribution $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$, corresponding to five active quark flavors (*i.e.* without top-quark contribution) driving the running, is a non-perturbative input obtained from measurements of the R ratio in e^+e^- annihilation at low energies, and perturbative QCD predictions of R at medium and large energies. Various evaluations of $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$ are summarized in Table 10.1.

The quantity $\alpha(Q^2)$ is closely related to the running electromagnetic coupling $\widehat{\alpha}(Q^2)$ in the $\overline{\rm MS}$ scheme[8] [26] used in previous editions of this *Review*. The precise relation between $\alpha(M_Z^2)$ and $\widehat{\alpha}(M_Z^2)$ is determined by the difference in $\Delta\alpha(M_Z^2)$ (obtained using Refs. [152, 153]),[9]

$$\begin{aligned}
&\Delta\widehat{\alpha}(M_Z^2) - \Delta\alpha(M_Z^2) \\
&= \frac{\alpha}{\pi}\left[\frac{100}{27} - \frac{1}{6} - \frac{7}{4}\ln\frac{M_Z^2}{M_W^2} + \frac{\alpha_s(M_Z^2)}{\pi}\left(\frac{605}{108} - \frac{44}{9}\zeta(3)\right)\right. \\
&+ \frac{\alpha_s^2}{\pi^2}\left(\frac{976481}{23328} - \frac{253}{36}\zeta(2) - \frac{781}{18}\zeta(3) + \frac{275}{27}\zeta(5)\right) \\
&+ \frac{\alpha_s^3}{\pi^3}\left(\frac{1483517111}{3359232} - \frac{22781}{144}\zeta(2) - \frac{3972649}{7776}\zeta(3) - \frac{31}{81}\zeta(2)^2\right. \\
&\left.\left.+ \frac{521255}{7776}\zeta(5) - \frac{7315}{324}\zeta(7) + \frac{5819}{54}\zeta(2)\zeta(3) + \frac{14675}{162}\zeta(3)^2\right)\right] \\
&= 0.007123(1)(5)\ , \qquad (10.21)
\end{aligned}$$

where the first part of the lowest-order term is from fermions and the other two are from $W^\pm$ loops, which are usually excluded from the OS definition. Fermion mass effects and corrections of $\mathcal{O}(\alpha^2)$ contributing to Eq. (10.21) are small, partly cancel each other and are not included here. The first error in Eq. (10.21) is parametric from α_s and the second is from the truncation of the perturbative expansion.

The most recent results of $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$ [163–166] typically assume the validity of perturbative QCD (pQCD) at scales of about 2 GeV and above for the continuum contribution and are in good agreement with each other. In regions where pQCD cannot be trusted, one can use $e^+e^- \to$ hadrons cross-section data (for a list of references see, *e.g.*, Ref. [165]) and isospin rotated information derived from τ decay spectral functions [167], where the latter derive from ALEPH [168], Belle [169], CLEO [170], and OPAL [171]. More recently, new results at low energy $(\pi^+\pi^-)$ have been published from the CMD-3 experiment [172] at the e^+e^- collider VEPP-2000. There is noticeable spread in the existing results, with lattice QCD [156] and CMD-3 suggesting a stronger running than KLOE data. While VEPP-2000 and VEPP-4M scanned center-of-mass (CM) energies up to 2 GeV and between about 3 and 4 GeV, respectively, the BABAR collaboration studied multi-hadron events radiatively returned from the $\Upsilon(4S)$, reconstructing the radiated photon and normalizing to $\mu^+\mu^-\gamma$ final states. A discrepancy in the $e^+e^- \to \pi^+\pi^-$ data from BABAR and KLOE has been taken into account in Ref. [165] as an additional uncertainty. The new results from CMD-3 cannot be included in determinations of $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$ without introducing additional uncertainties to accommodate for the discrepancy with KLOE data or taking into account small p-values. We use the value $\Delta\alpha^{(5)}_{\rm had}(M_Z^2) = 0.02760 \pm 0.00010$ from Ref. [165] in our fit, which has been obtained for $\alpha_s(M_Z^2) = 0.1193 \pm 0.0028$. The dependence on $\alpha_s(M_Z^2)$ is taken into account in the fit. The uncertainty on $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$ is dominated by systematic effects in the cross-section data and the uncertainty in the pQCD prediction.

10.3.2 *The Fermi constant*

Owing to its extraordinarily high experimental precision, the Fermi constant G_F is often taken as input in the EW model, *e.g.*, replacing the electromagnetic coupling α or the W-boson mass M_W in the list of input parameters. The parameter G_F is derived from the muon lifetime $\tau_\mu = 2196981.1 \pm 2.2$ ps, obtained in the Particle Listings in this *Review*. The average is dominated by the result of the MuLan Collaboration [173, 174] at the PSI that reduced the uncertainty by an order of magnitude compared to previous results. The Fermi constant is derived from τ_μ according to[10]

$$\begin{aligned}
\frac{\hbar}{\tau_\mu} = \frac{G_F^2 m_\mu^5}{192\pi^3}\,F(\rho)\Big[1 + H_1(\rho)\frac{\widehat{\alpha}(m_\mu^2)}{\pi} + H_2(\rho)\frac{\widehat{\alpha}^2(m_\mu^2)}{\pi^2} \\
+ H_3\frac{\widehat{\alpha}^3(m_\mu^2)}{\pi^3}\Big]\ , \qquad (10.22)
\end{aligned}$$

where $\rho = m_e^2/m_\mu^2$, $\widehat{\alpha}(Q^2)$ is the electromagnetic coupling in the $\overline{\rm MS}$ scheme, and

$$F(\rho) = 1 - 8\rho + 8\rho^3 - \rho^4 - 12\rho^2\ln\rho = 0.99981295\ , \qquad (10.23a)$$

$$\begin{aligned}
H_1(\rho) &= \frac{25}{8} - \frac{\pi^2}{2} - \left(9 + 4\pi^2 + 12\ln\rho\right)\rho \\
&+ 16\pi^2\rho^{3/2} + \mathcal{O}(\rho^2) = -1.80793\ , \qquad (10.23b)
\end{aligned}$$

$$\begin{aligned}
H_2(\rho) &= \frac{156815}{5184} - \frac{518}{81}\pi^2 - \frac{895}{36}\zeta(3) + \frac{67}{720}\pi^4 + \frac{53}{6}\pi^2\ln 2 \\
&- (0.042 \pm 0.002)_{\rm had} - \frac{5}{4}\pi^2\sqrt{\rho} + \mathcal{O}(\rho) = 6.64\ , \qquad (10.23c)
\end{aligned}$$

$$\widehat{\alpha}(m_\mu^2)^{-1} = \alpha^{-1} + \frac{1}{3\pi}\ln\rho + \mathcal{O}(\alpha) = 135.901\ . \qquad (10.23d)$$

H_1, H_2, and H_3 capture the QED corrections within the Fermi model. The results for $\rho = 0$ have been obtained in Refs. [175] and [176, 177] for H_1 and H_2, respectively, where the term in parentheses is from the hadronic vacuum polarization [176]. The mass corrections to H_1 and H_2 have been calculated in [178] and [179], respectively. Notice the term linear in m_e in H_2 whose appearance was unforeseen and can be traced to the use of the muon pole mass in the prefactor [179]. The coefficient $H_3 = -15.3 \pm 2.3$ has been estimated in Refs. [180–182].

The estimation of H_3 reduces the uncertainty from missing higher orders significantly, resulting in

$$G_F = 1.1663785(6) \times 10^{-5}\ {\rm GeV}^{-2}, \qquad (10.24)$$

where the remaining uncertainty in G_F is mostly from experimental sources in the measurement of τ_μ.

10.3.3 *The muon anomalous magnetic moment*

In 2025 the Muon $g-2$ Collaboration at Fermilab has released a new measurement [183] of the muon anomalous magnetic moment $a_\mu \equiv (g_\mu - 2)/2$, based on theirs Runs 4–6, which combines with their previous result from Runs 1–3 [184, 185] to

$$a_\mu^{\rm FNAL} = (116592070.5 \pm 14.8) \times 10^{-11}\ . \qquad (10.25)$$

Combining the FNAL result with the result from the BNL E821 collaboration [186], which is compatible with all FNAL results on a_μ, leads to the world average

$$a_\mu^{\rm exp} = (116592071.5 \pm 14.5) \times 10^{-11}\ . \qquad (10.26)$$

[8] In this Section we denote quantities defined in the $\overline{\rm MS}$ scheme by a caret; the exception is the strong coupling constant, α_s, which will always correspond to the $\overline{\rm MS}$ definition and where the caret will be dropped. Furthermore, $\alpha^{(n)}$ and $\alpha_s^{(n)}$ denote the running couplings with n active quark flavors.

[9] $\widehat{\alpha}(M_Z^2)$ can be directly evaluated in the $\overline{\rm MS}$ scheme using the FORTRAN package GAPP [133], including the QED contributions of both leptons and quarks. The leptonic three-loop [154] and four-loop [155] contributions in the OS scheme are known as well.

[10] In the spirit of the Fermi theory, the small propagator correction, $3/5\ m_\mu^2/M_W^2$, is included into the correction Δr (see below). This is also the convention adopted by the MuLan collaboration [173]. While this breaks with historical consistency, the numerical difference was negligible in the past.

Table 10.1: Evaluations of the on-shell $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$ by different groups. For better comparison we adjusted central values and errors to correspond to a common and fixed value of $\alpha_s(M_Z^2) = 0.120$, except for Ref. [156], for which α_s is not an explicit input. References quoting results without the top-quark decoupled are converted to the five flavor definition. Ref. [157] uses $\Lambda_{\rm QCD} = 380 \pm 60$ MeV; for the conversion we assumed $\alpha_s(M_Z^2) = 0.118 \pm 0.003$.

This experimental result is in good agreement with the SM prediction released in the 2025 White Paper (WP25) [147],

$$a_\mu^{\rm SM} = (116592033 \pm 62) \times 10^{-11} \ , \qquad (10.27)$$

which contains a significant upward shift with respect to the previous SM prediction reported in the 2020 White Paper (WP20) [187], resolving a long-standing tension of ~ 2–$4\,\sigma$ between experiment and theory.

The by far dominating contribution to $a_\mu^{\rm SM}$ is due to QED corrections, which have been calculated to five loops [144, 146, 188–190] (fully analytic to three loops [191–195]). The SM EW contribution [196–201], reported in [147] to $a_\mu^{\rm EW} = (154.4 \pm 4.0) \times 10^{-11}$, includes two-loop [202–206] and leading three-loop [207, 208] corrections and is roughly an order of magnitude larger than the current experimental uncertainty. The major part of the theory uncertainties result from HVP effects, which were entirely taken from lattice-QCD calculations in WP25 (see references therein). The small, but non-negligible NLO and NNLO HVP contributions are taken from mixing data from $e^+e^- \to$ hadrons with perturbative QCD predictions, with the corresponding uncertainties. The switch from the previously used experimental HVP results from $e^+e^- \to$ hadrons cross sections to lattice results accounts for the significant change in $a_\mu^{\rm SM}$ from WP20 to WP25. This paradigm shift was justified in WP25 in part by the great consolidation of lattice HVP results in recent years and in part by the increasing tension among the relevant experimental $e^+e^- \to \pi^+\pi^-$ cross-section data after including recent measurements by CMD-3 [172,209]. The second largest uncertainty in $a_\mu^{\rm SM}$ is due to effects from hadronic light-by-light (HLbL) scattering. In the step from WP20 to WP25, the predictions for HLbL effects, both on the lattice and data-driven side (see WP25 for references) have increased in precision and show good mutual agreement. Further reducing the theory uncertainty in $a_\mu^{\rm SM}$ and resolving the tension between lattice and data-driven HVP determinations will be an important goal for future work. For more details and references, see Section 56 on the "Muon Anomalous Magnetic Moment" in this *Review*.

The results on a_μ have not been taken into account in the SM fit to data below, because they do not influence the fit significantly. The sensitivity of $a_\mu^{\rm SM}$ to the EW parameters is way below the remaining theory uncertainty. On the other hand, predictions for a_μ are sensitive to new physics effects, such as in supersymmetric models with large $\tan\beta$ and moderately light superparticle masses [210], or a dark Z boson [211].

10.4 Electroweak precision physics

10.4.1 *Z- and W-boson masses and widths*

The most precise measurement of the mass of the Z boson has been obtained by a combination of the ALEPH, DELPHI, L3, and OPAL data from LEP 1 [139],

$$M_Z = 91.1876 \pm 0.0021\,{\rm GeV} \ . \qquad (10.28)$$

The uncertainty in this result is dominated by the knowledge of the LEP beam energy. Recently, new results from hadron colliders have been obtained. The CDF Collaboration determined M_Z from fits to the dimuon and dielectron mass distributions [212], resulting in $M_Z = 91.1920 \pm 0.0075$ GeV and 91.1943 ± 0.0158 GeV, respectively. The LHCb Collaboration used $Z \to \mu^+\mu^-$ decays only and obtained a value of 91.1857 ± 0.0092 GeV [213]. Combined, these measurements result in the current world average

$$M_Z = 91.1879 \pm 0.0020\,{\rm GeV}, \qquad (10.29)$$

which we use in the global fit presented below. In the context of a measurement of the W-boson mass, the CMS Collaboration reports $M_Z = 91.1858 \pm 0.0048$ GeV [214], obtained from $Z \to \mu^+\mu^-$ decays. While the uncertainty in this measurement is only about two times larger than the LEP 1 combination, this measurement is only used to define the systematic uncertainty in the muon momentum scale calibration for the M_W measurement and detailed studies of systematic uncertainties are missing. Hence, we do not include this measurement in the M_Z combination.

The values above correspond to a definition based on a Breit–Wigner shape with an energy-dependent width, which differs from $\overline{M}_Z$ derived from the complex location of the propagator pole as given in Eq. (10.14).

The LEP 1 results also include a determination of the total Z-boson decay width with a precision of one per-mil [139, 215],

$$\Gamma_Z = 2.4955 \pm 0.0023\,{\rm GeV}. \qquad (10.30)$$

Among the most important LEP 2 results were the measurements of the W-boson mass, M_W [216][11]. These were dominated by measurements using the direct kinematic reconstruction of the W-boson decay products, but included a complementary determination from a WW threshold cross-section measurement. The latter determination resulted in a less precise value of M_W because of a large statistical uncertainty, but this technique offers

[11] LEP 2 [216] ran at several energies above the Z pole up to ~ 209 GeV. Measurements were made of a number of observables, including the total production cross sections of $f\bar{f}$ pairs for $f = \mu, \tau$, and q (hadrons), of four-fermion final states, of $\gamma\gamma$, ZZ, WW and $WW\gamma$. The differential cross sections for all three lepton flavors, and the leptonic and hadronic W branching ratios were also extracted, as discussed in Section 10.4.7. The measurements of single- and di-boson production were also used to set constraints on anomalous triple and quartic gauge couplings. These anomalous interactions have also been studied in hadron collisions at the Tevatron and the LHC. We refer the reader to the "Extraction of Triple Gauge Couplings (TGCs)", "Anomalous W/Z Quartic Couplings (QGCs)" notes in the W particle listing and the "Anomalous $ZZ\gamma$, $Z\gamma\gamma$, and ZZV Couplings" note in the Z particle listing for details.

the possibility for precise determinations at future e^+e^- colliders. The kinematic method was also employed at the Tevatron [217] and by ATLAS [218] and LHCb [219] at the LHC. A combination [220] of all M_W measurements available until 2023, using a careful calibration of simulation tools and parton distribution functions (PDFs), resulted in

$$M_W = 80.395 \pm 0.012 \text{ GeV}. \tag{10.31}$$

However, the χ^2 probability of this combination is 0.5% or less, depending on the chosen PDF set, which is mostly due to the W-mass measurement by CDF from Run II at the Tevatron [212], $M_W = 80.432 \pm 0.016$ GeV (adjusted to the common PDF set CT18 [221] in Ref. [220]). It differs by almost 4σ from the combination of the other measurements of M_W, while the latter agree well among each other, with the average [220]

$$M_W = 80.369 \pm 0.013 \text{ GeV}, \tag{10.32}$$

without CDF II. In 2024, the ATLAS result was updated by incorporating nuisance parameters encoding the effect of systematic uncertainties in the fit to data, including those from the PDFs [222]. This resulted in a downward shift of M_W by 3.5 MeV with a reduced uncertainty, $M_W = 80.3665 \pm 0.0159$ GeV. Most recently, the CMS Collaboration has presented their first determination of M_W [214]. The measurement reported in the nominal analysis, which used the CT18Z PDF set [221], is $M_W = 80.3602 \pm 0.0099$ GeV. When performing the measurement with the CT18 PDF set, the same used in the ATLAS 2024 measurement and in the 2023 M_W combination in (10.32), CMS reports $M_W = 80.3618 \pm 0.0100$ GeV. This value is in agreement with both the SM prediction and previous M_W determinations, and it further increases the tension with the latest CDF value [212].

For the global fits presented in the next section, we use an update of the M_W combination by the LHC-TeVatron M_W Working Group, released in May 2026 [223]. The combination is based on the methods developed for the previous combination [220]. It includes the M_W measurements from LEP 2 [216], DØ [224, 225], LHCb [219], ATLAS [222], and CMS [214]. All measurements are performed using the CT18 PDF set, where the DØ value has been adjusted to this PDF set and to the latest signal modelling [220]. The total fit uncertainties of profile-likelihood measurements are decomposed into elementary uncertainty components following Ref. [226], and the PDF-induced correlations are propagated coherently across all measurements. The resulting average has a very high p-value of 0.97 and is

$$M_W = 80.3625 \pm 0.0077 \text{ GeV}, \tag{10.33}$$

which we use in the global fits. Note that this average does not include the CDF M_W measurement [212], which would reduce the p-value of the combination to 0.0006.

Again, these values on M_W correspond to an energy-dependent W width in the resonance propagator and differ from $\overline{M}_W$ from the complex location of the propagator pole as given in Eq. (10.14).

The ATLAS update in Ref. [222] also included the first LHC measurement of the W-boson width, $\Gamma_W = 2.202 \pm 0.047$ GeV, the most precise single measurement of this quantity. When derived simultaneously with M_W, the two measurements show a 30% anticorrelation. Although consistent with the LEP 2 determination [216], the new and more precise ATLAS Γ_W value differs by about 2σ from the Tevatron result [227] and the SM prediction. We refer again to Section 54 on the "Mass and Width of the W Boson" in this *Review* for more details and references.

10.4.2 *Higgs-boson mass and width*

After their discovery of the Higgs boson [228, 229], the LHC experiments ATLAS and CMS have performed high precision measurements of its mass, M_H. The PDG average

$$M_H = 125.13 \pm 0.11 \text{ GeV (LHC)} \tag{10.34}$$

is a result from a combination of the LHC Run 1 average from ATLAS and CMS [230], a CMS measurement in the $H \to \gamma\gamma$ channel at 13 TeV [231], a CMS measurement in the $H \to ZZ^* \to 4\ell$ channel at 13 TeV [232], and an ATLAS combination at 13 TeV [233]. The uncertainty includes a scale factor of 1.5 because of the incompatibility of the CMS $H \to \gamma\gamma$ result [231] with the other measurements. This increased uncertainty has a negligible impact in the global fits.

Measurements of the Higgs-boson width Γ_H at the LHC are based on the comparison between off-shell and on-shell Higgs boson production rates assuming the validity of the SM. The most precise results are $\Gamma_H = 3.0^{+2.0}_{-1.5}$ MeV from CMS [232] and $\Gamma_H = 4.3^{+2.7}_{-1.9}$ MeV from ATLAS [234]. Both measurements are compatible with the SM prediction $\Gamma_H = 4.10 \pm 0.06$ MeV [235]. Owing to the smallness of $\Gamma_H/M_H \sim 3 \times 10^{-5}$, there is no significant difference between the two variants of OS masses and widths (M_H, Γ_H versus $\overline{M}_H$, $\overline{\Gamma}_H$) at the current (and most likely also future) level of precision.

For further references and more details on Higgs-boson properties, see Section 11 on the "Status of Higgs Boson Physics" in this *Review*.

10.4.3 *Quark masses*

The top-quark mass m_t, being the largest mass in the SM, plays a prominent role in the description of the EW sector, inducing some of the largest fermionic radiative corrections to EW precision observables. As in the case of the other SM parameters that can be obtained indirectly from the EW precision fit, it is important to have direct determinations of m_t to perform consistency tests of the SM. The top-quark mass has been measured in top-quark decays by directly reconstructing the decay products, also known as "direct measurements", by the Tevatron collaborations, CDF and DØ, in leptonic, hadronic, and mixed channels with the result [236],

$$m_t = 174.30 \pm 0.35_{\text{stat.}} \pm 0.54_{\text{syst.}} \text{ GeV (Tevatron)}\ . \tag{10.35}$$

Likewise, using data from CM energies $\sqrt{s} = 7$ and 8 TeV (Run 1), ATLAS and CMS (including alternative technique measurements) at the LHC obtained [237],

$$m_t = 172.52 \pm 0.14_{\text{stat.}} \pm 0.30_{\text{syst.}} \text{ GeV (LHC Run 1)}\ . \tag{10.36}$$

In addition, there are results derived from $\sqrt{s} = 13$ TeV data (Run 2). The CMS collaboration obtained $m_t = 171.77 \pm 0.37_{\text{tot.}}$ GeV [238] in the lepton+jets channel with a kinematic fit of the decay products combined with a profile likelihood method. Using the same channel, CMS measured $m_t = 173.06 \pm 0.24_{\text{stat.}} \pm 0.80_{\text{syst.}}$ GeV [239] using a template fit to the jet mass in hadronic decays of highly boosted top quarks. In addition, CMS reports $m_t = 172.33 \pm 0.14_{\text{stat.}} \pm 0.69_{\text{syst.}}$ GeV [240] in the dilepton channel, $m_t = 172.34 \pm 0.20_{\text{stat+JSE}} \pm 0.70_{\text{syst.}}$ GeV [241] in the all-jets channel, and $m_t = 172.13 \pm 0.32_{\text{stat.}} \pm 0.70_{\text{syst.}}$ GeV [242] in t-channel single top events (leptonic decays), where the uncertainty named stat+JSE denotes the combination of the statistical uncertainty and the uncertainty in the jet energy scale. A comprehensive summary of the CMS measurements of the top-quark mass is given in Ref. [243]. ATLAS measured $m_t = 174.41 \pm 0.39_{\text{stat.}} \pm 0.71_{\text{syst.}}$ GeV [244] in the lepton+jets channel by identifying soft leptons from the semileptonic decays of b-hadrons assigned to the leptonically decaying top quark, $m_t = 172.95 \pm 0.53$ GeV [245] in the lepton+jets channel with boosted hadronically decaying top quarks, and $m_t = 172.21 \pm 0.20_{\text{stat.}} \pm 0.78_{\text{syst.}}$ GeV [246] in the dilepton channel.

There is some ambiguity in relating these measurements to the top-quark pole mass [247], which we discuss below. Alternatively, the experimental collaborations have determined the top-quark mass from inclusive cross-section measurements [248–254]. While these determinations represent unambiguous measurements of the top-quark pole mass, they have larger uncertainties than the direct measurements presently. For the fits discussed later we will use the average value of direct measurements reported in the Top Quark Listings in this *Review*, which is based exclusively on fully published results. It must be noted that this combination assumes vanishing correlations between the different measurements and across experiments. We note that there exists some tension at

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is subject to Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com except for Open Access articles.

the 2σ level between the Tevatron combination and some LHC measurements, which results in a scaling of the uncertainty by a factor of 1.5. We take

$$m_t = 172.60 \pm 0.27\,\text{GeV} + \Delta m_{\text{MC}}, \tag{10.37}$$

where the term Δm_{MC} has been added to account for any difference between the top-quark pole mass, m_t, and the mass parameter implemented in the Monte Carlo event generators employed by the experimental groups. The parameter Δm_{MC} is expected to be of order $\alpha_s(Q_0)Q_0$ with a low scale $Q_0 \sim \mathcal{O}(1\text{ GeV})$ [255], but its value is unknown in hadron collider environments so that we will treat it as an uncertainty instead,[12] and choose for definiteness $Q_0 = \Gamma_t = 1.42$ GeV to arrive at $\Delta m_{\text{MC}} = 0 \pm 0.52$ GeV. We further assume that an uncertainty [258] of ± 0.32 GeV in the relation [259] between m_t and the $\overline{\text{MS}}$ definition, $\widehat{m}_t(\widehat{m}_t^2)$, entering EW radiative correction libraries, including the renormalon ambiguity [260], is already included in Δm_{MC}, as m_t merely serves as an intermediate bookkeeping device in Ref. [255]. A complementary direction to arrive at a competitive independent constraint on m_t is to analyze differential top-quark pair production cross sections at NNLO QCD [261, 262]. Extractions of m_t using fixed-order perturbative calculations can remove the Δm_{MC} uncertainty and benefit from the recently increased experimental precision of differential measurements [263–266]. We note that m_t determinations from cross sections assume the validity of the SM within the energy range accessible to the LHC. For more details and references, see Section 61 on the "Top Quark" and the Quarks Listings in this *Review*.

The charm and bottom quark masses play a minor but non-negligible role in the EW fit. We consider the running $\overline{\text{MS}}$ masses for these quarks, evaluated at a scale equal to the quark mass itself, $\widehat{m}_q(\widehat{m}_q^2)$:

$$\widehat{m}_c(\widehat{m}_c^2) = 1273.0 \pm 2.8\text{ MeV}, \quad \widehat{m}_b(\widehat{m}_b^2) = 4183 \pm 4\text{ MeV}. \tag{10.38}$$

To improve the precisions in $\widehat{m}_c(\widehat{m}_c^2)$ and $\widehat{m}_b(\widehat{m}_b^2)$ in the future it would help to remeasure the threshold regions of the heavy quarks, as well as the electronic decay widths of the narrow $c\bar{c}$ and $b\bar{b}$ resonances. It would also be important to obtain data on the R-ratio in e^+e^- annihilation for center-of-mass energies $\gtrsim 11.2$ GeV, as in this region QCD perturbation theory cannot be sufficiently relied upon for b quarks [267].

The masses of the light quarks play a subordinate role in the calculation of EW observables. Indeed, in order to minimize non-perturbative effects in the predictions of high-energy observables, these observables are typically defined to be *infrared safe*, *i.e.* insensitive to energy scales near the QCD parameter Λ_{QCD}, allowing for the neglect of the light-quark masses. In cases where these masses are relevant, they are typically defined in the $\overline{\text{MS}}$ scheme. As further explained in Section 60 on "Quark Masses" in this *Review*, a fit for the u, d, and s masses gives

$$\widehat{m}_u = 2.16 \pm 0.04\text{ MeV}, \quad \widehat{m}_d = 4.70 \pm 0.04\text{ MeV}, \quad \widehat{m}_s = 93.5 \pm 0.5\text{ MeV}, \tag{10.39}$$

where these running $\overline{\text{MS}}$ masses are evaluated at the scale $\mu = 2$ GeV.

10.4.4 *The strong coupling constant*

The strong coupling constant is one of the key parameters of the SM, setting the strength of QCD interactions. While not contributing to the EW precision observables at leading order, it enters in the EW precision fit via radiative corrections, most notably to hadronic observables at the one-loop order or to the W mass and the weak mixing angle starting at two loops. From the point of view of EW precision observables, in particular measurements of the Z-lineshape, the relevant scale is $Q^2 \sim M_Z^2$, and the SM EW precision fit provides a determination of $\alpha_s(M_Z^2)$. It is important to complement the information from the EW fit on this input with additional measurements at lower and higher energy scales. Alternative determinations, both from low- and high-energy observables are available, and reduce the dependence of the extraction of $\alpha_s(M_Z^2)$ on potential new physics effects. These determinations differ in statistical precision, experimental systematic uncertainties, and uncertainties from theoretical considerations. Considering the total uncertainty, some of these determinations are more precise than the one from the EW fit, *e.g.*, from lattice QCD, PDF fits, LHC data, or from τ decays. However, the EW fit provides a determination of $\alpha_s(M_Z^2)$ with the smallest uncertainty from missing higher orders or non-perturbative effects compared to other measurements, making it an important element in the combination with other determinations. We refer to Section 9 on Quantum Chromodynamics in this *Review* for more details on the different methods to obtain α_s and probe its energy dependence.

While measurements of the Z-lineshape have the power to determine $\alpha_s(M_Z^2)$ without further experimental input, the most precise test of the EW sector of the SM is obtained by including external information on $\alpha_s(M_Z^2)$. Following the methods reported in the *Review on Quantum Chromodynamics*, we consider the average of $\alpha_s(M_Z^2)$ excluding information from the EW fit, and before combining it with the lattice QCD results,

$$\alpha_s(M_Z^2) = 0.1171 \pm 0.0011 \quad \text{(PDG 2025 average without EW fit)}, \tag{10.40}$$

and perform an unweighted average of this value with the FLAG 2024 estimate, combining the best results from lattice QCD, $\alpha_s(M_Z^2) = 0.1183 \pm 0.0007$ [268]. This results in

$$\alpha_s(M_Z^2) = 0.1177 \pm 0.0009\ , \tag{10.41}$$

which we use as a constraint in our fits.

10.4.5 *The weak mixing angle*

The quantities $\sin^2\theta_W$ and M_W can be calculated from M_Z, $\alpha(M_Z^2)$, and G_F, when values for m_t and M_H are given, or conversely, M_H can be constrained by $\sin^2\theta_W$ and M_W. The value of $\sin^2\theta_W$ depends on the renormalization prescription. There are a number of popular schemes [9] leading to values which differ by small factors depending on m_t and M_H. The notation for these schemes is shown in Table 10.2.

(i) As proposed in Ref. [22], the OS scheme promotes the tree-level formula $\sin^2\theta_W = 1 - M_W^2/M_Z^2$ to a definition of the renormalized $\sin^2\theta_W$ to all orders in perturbation theory, *i.e.*,

$$\sin^2\theta_W \to s_W^2 \equiv 1 - \frac{M_W^2}{M_Z^2}\ , \tag{10.42a}$$

$$M_W = \frac{A_0}{s_W(1-\Delta r)^{1/2}}\ , \qquad M_Z = \frac{M_W}{c_W}\ , \tag{10.42b}$$

where $c_W \equiv \cos\theta_W$, $A_0 = (\pi\alpha(0)/\sqrt{2}G_F)^{1/2} = 37.28038(1)$ GeV, and Δr includes the radiative corrections relating $\alpha(0)$, $\alpha(M_Z^2)$, G_F, M_W, and M_Z (see Sect. 10.2.5). Other definitions are motivated by the tree-level coupling constant definition $\theta_W = \tan^{-1}(g'/g)$:

(ii) The $\overline{\text{MS}}$ scheme introduces the quantity,

$$\sin^2\widehat{\theta}_W(\mu^2) \equiv \frac{\widehat{g}'(\mu^2)^2}{\widehat{g}(\mu^2)^2 + \widehat{g}'(\mu^2)^2}\ , \tag{10.43}$$

where the couplings $\widehat{g}$ and $\widehat{g}'$ are defined by modified minimal subtraction and the scale μ is conveniently chosen to be M_Z for many EW processes. The value of $\widehat{s}_Z^2 \equiv \sin^2\widehat{\theta}_W(M_Z^2)$ is less sensitive than s_W^2 to m_t (by a factor of $\tan^2\theta_W$), and is less sensitive to most types of new physics. It is also useful for comparisons with the predictions of grand unification. There are several definitions of $\sin^2\widehat{\theta}_W(M_Z^2)$, which differ in whether and how finite $\alpha\ln(m_t/M_Z)$ terms are decoupled (i.e. subtracted from the couplings). One cannot entirely decouple these terms from all EW quantities

[12] However, see Refs. [256, 257] for proposed procedures to calibrate the Monte Carlo mass parameter at hadron colliders.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Table 10.2: Notations and numerical values of the weak mixing angle $\sin^2\theta_W$ discussed in the text. The effective weak mixing angle $\bar{s}^2_\ell$ is obtained using the two-loop results of Ref. [106] with the direct experimental measurements of $\alpha_s(M_Z^2)$, $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$, M_Z, m_t, and M_H as input parameters, given in Table 10.5 below. The on-shell and $\overline{\rm MS}$ quantities are derived from $\bar{s}^2_\ell$. The uncertainties induced by the imperfectly known input parameters and unknown higher orders [106] are also given.

Scheme	Notation	Value	Uncertainty
On-shell	s^2_W	0.22342	$\pm$0.00009
Effective angle	$\bar{s}^2_\ell$	0.23154	$\pm$0.00006
$\overline{\rm MS}$	$\widehat{s}^2_Z$	0.23122	$\pm$0.00006
$\overline{\rm MS}$ (ND)	$\widehat{s}^2_{\rm ND}$	0.23140	$\pm$0.00006

because $m_t \gg m_b$ breaks SU(2) symmetry. The scheme adopted in the EW fits presented in the previous editions of this *Review* decouples the $\alpha\ln(m_t/M_Z)$ terms from the γ–Z mixing [26,269], essentially eliminating any $\ln(m_t/M_Z)$ dependence in the formulae for asymmetries at the Z pole when written in terms of $\widehat{s}^2_Z$. (A similar definition was used for $\widehat{\alpha}$.) The OS and $\overline{\rm MS}$ definitions are related by

$$\widehat{s}^2_Z = c\,(m_t, M_H) s^2_W = (1.0349 \pm 0.0003) s^2_W \ . \qquad (10.44)$$

The quadratic m_t dependence is given by $c \sim 1 + \Delta\rho_t/\tan^2\theta_W$. The expressions for M_W and M_Z in the $\overline{\rm MS}$ scheme are

$$M_W = \frac{A_0}{\widehat{s}_Z(1-\Delta\widehat{r}_W)^{1/2}} \ , \quad M_Z = \frac{M_W}{\widehat{\rho}^{\,1/2}\widehat{c}_Z} \ , \qquad (10.45)$$

and one predicts $\Delta\widehat{r}_W = 0.06937 \pm 0.00006$. $\Delta\widehat{r}_W$ has no quadratic m_t dependence, because shifts in M_W are absorbed into the observed G_F, so that the error in $\Delta\widehat{r}_W$ is almost entirely due to $\Delta r_0 = 1 - \alpha(0)/\widehat{\alpha}(M_Z^2)$. The quadratic m_t dependence has been shifted into $\widehat{\rho} \sim 1 + \Delta\rho_t$, where including bosonic loops, $\widehat{\rho} = 1.01016 \pm 0.00009$.

(iii) A variant $\overline{\rm MS}$ quantity $\widehat{s}^2_{\rm ND}$ (used in the 1992 edition of this *Review*) does not decouple the $\alpha\ln(m_t/M_Z)$ terms [270]. It is related to $\widehat{s}^2_Z$ by

$$\widehat{s}^2_Z = \frac{\widehat{s}^2_{\rm ND}}{1+\frac{\widehat{\alpha}}{\pi}d} \ ,$$
$$d = \frac{1}{3}\left(\frac{1}{\widehat{s}^2} - \frac{8}{3}\right)\left[\left(1+\frac{\alpha_s}{\pi}\right)\ln\frac{m_t}{M_Z} - \frac{15\alpha_s}{8\pi}\right] \ . \qquad (10.46)$$

Thus, $\widehat{s}^2_Z - \widehat{s}^2_{\rm ND} = -0.00018$.

(iv) Another very useful definition of the mixing angle, known as the *effective weak mixing angle* [271, 272] $\bar{s}^2_f \equiv \sin^2\theta^f_{\rm eff}$, is based on effective couplings of a fermion f to the Z boson on the Z pole, as discussed in detail in Sec. 10.4.6 below.

In previous versions of this *Review,* special attention was dedicated to EW precision observables obtained at low momentum transfers [273], *i.e.*, $|Q^2| \ll M_Z^2$, in particular those measured in neutrino and electron scattering experiments, namely ν–hadron, ν–e, as well as parity violating e–hadron and e–e neutral-current processes. Within the SM, these are sensitive to the weak mixing angle at almost vanishing momentum transfer $\widehat{s}^2_0 \equiv \sin^2\widehat{\theta}_W(0)$ [163, 274–276]. Similarly, new physics effects contributing to the EW neutral-currents interactions or new particle exchanges in the form of additional four-fermion interactions could be tested in these types of processes.

A precise determination of the OS quantity s^2_W, which depends only very weakly on m_t and M_H, is obtained from deep inelastic scattering (DIS) of neutrinos [277, 278] from (approximately) isoscalar targets. The ratio $R_\nu \equiv \sigma^{NC}_{\nu N}/\sigma^{CC}_{\nu N}$ of neutral-to-charged-current cross sections has been measured to 1% accuracy by CDHS [279] and CHARM [280] at CERN. CCFR [281] at Fermilab has obtained an even more precise result. The NuTeV collaboration found $s^2_W = 0.2277 \pm 0.0016$, which was $\sim 3\sigma$ higher than the SM prediction [282]. However, since then several groups have raised concerns about the interpretation of the NuTeV result, which could affect the extracted value of s^2_W. A detailed discussion and a list of references can be found in the 2016 edition of this *Review*. Similarly, experiments of parity violation electron scattering can probe the weak mixing angle by measuring the parity violating left–right (LR) asymmetry $A_{\rm LR} \equiv \frac{\sigma_{\rm L}-\sigma_{\rm R}}{\sigma_{\rm L}+\sigma_{\rm R}}$. This was determined by the SLAC polarized electron-deuteron DIS (eDIS) experiment [283] and improved by the Jefferson Lab Hall A collaboration [284, 285], measuring the weak mixing angle to 2% precision, $\widehat{s}^2_Z = 0.2299 \pm 0.0043$. $A_{\rm LR}$ can also be measured in fixed target polarized Møller scattering, and has been determined at low $Q^2 = 0.026$ GeV^2 in the SLAC E158 experiment [286], yielding $\widehat{s}^2(161\ {\rm MeV}) = 0.2403 \pm 0.0013$, and, as shown in Fig. 10.1, established the scale dependence of the weak mixing angle at the level of 6σ. Finally, measurement of the nuclear weak charge, $Q_W(Z,N)$, in experiments of atomic parity violation, in particular for Cesium, when interpreted in terms of the SM lead to value of the weak mixing angle $\widehat{s}^2(2.4\ {\rm MeV}) = 0.2349 \pm 0.0018$ [287–294]. We refer to the review article by M. A. and C. Bouchiat [295] and to previous editions of this *Review* for a much more in-depth description of these types of low-energy probes of the weak mixing angle.

The scale dependence of the weak mixing angle defined in the $\overline{\rm MS}$ scheme [163, 275] is shown in Fig. 10.1.

10.4.6 *Z-pole physics*

If the CM energy $\sqrt{s}$ is large compared to the fermion mass m_f, the unpolarized Born cross section for $e^+e^- \to f\bar{f}$, including γ exchange, Z-boson exchange, and γ–Z interference can be written as [297]

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2(s)}{2s}\left[F_1(1+\cos^2\theta) + 2F_2\cos\theta\right] + B \ , \qquad (10.47a)$$

$$F_1 = Q_e^2 Q_f^2 - 2\chi Q_e Q_f \bar{g}^e_V \bar{g}^f_V \cos\delta_R + \chi^2(\bar{g}^{e2}_V + \bar{g}^{e2}_A)(\bar{g}^{f2}_V + \bar{g}^{f2}_A) \ , \qquad (10.47b)$$

$$F_2 = -2\chi Q_e Q_f \bar{g}^e_A \bar{g}^f_A \cos\delta_R + 4\chi^2 \bar{g}^e_V \bar{g}^e_A \bar{g}^f_V \bar{g}^f_A \ , \qquad (10.47c)$$

where

$$\tan\delta_R = \frac{\overline{M}_Z\overline{\Gamma}_Z}{\overline{M}_Z^2 - s} \ , \quad \chi = \frac{G_F}{2\sqrt{2}\pi\alpha(s)} \frac{s\overline{M}_Z^2}{\left[(\overline{M}_Z^2 - s)^2 + \overline{M}_Z^2\overline{\Gamma}_Z^2\right]^{1/2}} \ . \qquad (10.48)$$

Here, B accounts for box graphs involving virtual Z and W bosons, and the $\bar{g}^f_{V,A}$ are defined in Eq. (10.49) below. $\overline{M}_Z$ and $\overline{\Gamma}_Z$ correspond to mass and width definitions based on a Breit–Wigner shape with an energy-independent width (see Sec. 10.2.4 and Section 55 on the "Z Boson" in this *Review*). The differential cross section receives important corrections from QED effects in the initial and final states, and interference between the two [298]. For $q\bar{q}$ production, there are additional final-state QCD corrections, which are relatively large. Note also that the equations above are written in the CM frame of the incident e^+e^- system, which may be boosted due to the initial-state QED radiation.

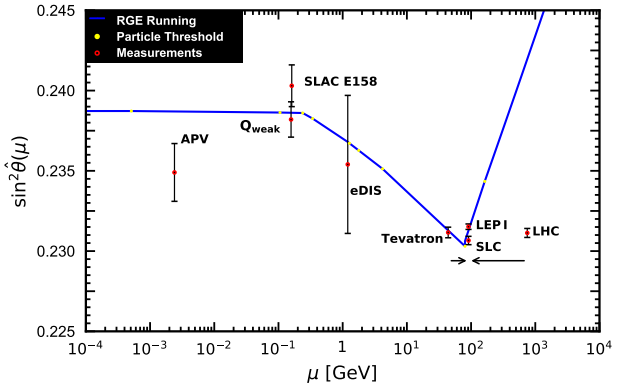

Figure 10.1: Scale dependence of the weak mixing angle defined in the $\overline{\rm MS}$ scheme [163, 275] (for the scale dependence in a mass-dependent renormalization scheme, see Ref. [274]). The minimum of the curve corresponds to $\mu = M_W$, below which an effective theory is used with the $W^\pm$ bosons integrated out, and where the β-function for $\widehat{s}^2(\mu^2)$ changes sign. At M_W and each fermion mass there are also discontinuities arising from scheme dependent matching terms, which are necessary to ensure that the various effective field theories within a given loop order describe the same physics. However, in the $\overline{\rm MS}$ scheme these are very small numerically and barely visible in the figure provided one decouples quarks at $\mu = \widehat{m}_q(\widehat{m}_q^2)$. The width of the curve exceeds the theory uncertainty from strong interaction effects which at low energies is at the level of $\pm 2\times 10^{-5}$ [163]. The Tevatron and LHC measurements are strongly dominated by invariant masses of the final-state di-lepton pair of $\mathcal{O}(M_Z)$ and can thus be considered as additional Z pole data points. For clarity, the Tevatron and LHC points are slightly shifted horizontally to the left and right, respectively. Figure taken from the previous edition of this *Review*, which we refer to for more details [296].

Some of the leading virtual EW corrections are captured by the running QED coupling $\alpha(s)$ and the Fermi constant G_F. The remaining corrections to the $Zf\bar{f}$ interactions are absorbed by replacing the tree-level couplings in Eq. (10.7) with the s-dependent *effective couplings* [139],

$$\bar{g}_V^f = \sqrt{\rho_f}\left(t_{3L}^f - 2Q_f\kappa_f \sin^2\theta_W\right) , \tag{10.49a}$$

$$\bar{g}_A^f = \sqrt{\rho_f}\, t_{3L}^f . \tag{10.49b}$$

In these equations, the effective couplings are to be taken at the scale $\sqrt{s}$, but for notational simplicity we do not show this explicitly. At tree level, $\rho_f = \kappa_f = 1$, but inclusion of EW radiative corrections leads to $\rho_f \neq 1$ and $\kappa_f \neq 1$, which depend on the fermion f and on the renormalization scheme. In the OS scheme, the quadratic m_t dependence is given by,

$$\rho_f \sim 1 + \Delta\rho_t , \qquad \kappa_f \sim 1 + \frac{\Delta\rho_t}{\tan^2\theta_W} , \tag{10.50}$$

while in $\overline{\rm MS}$, $\widehat{\rho}_f \sim \widehat{\kappa}_f \sim 1$, for $f \neq b$, and

$$\widehat{\rho}_b \sim 1 - \frac{4}{3}\Delta\rho_t , \qquad \widehat{\kappa}_b \sim 1 + \frac{2}{3}\Delta\rho_t , \tag{10.51}$$

which account for the non-flavor-universal effects arising from diagrams where a virtual top quark couples to a W boson inducing a correction to the $Zb\bar{b}$ vertex. In the $\overline{\rm MS}$ scheme the normalization is changed according to $G_F M_Z^2/2\sqrt{2}\pi \to \widehat{\alpha}/4\widehat{s}_Z^2\widehat{c}_Z^2$ in the second Eq. (10.48).

As reviewed in Sec. 10.2.5, for the high precision Z pole observables discussed below, many additional bosonic and fermionic loop effects, vertex corrections, and higher order contributions, *etc.*, must be included.

To connect to measured quantities, it is convenient to define the effective angle

$$\bar{s}_f^2 \equiv \sin^2\bar{\theta}_{Wf} \equiv \widehat{\kappa}_f\widehat{s}_Z^2 = \kappa_f s_W^2 , \tag{10.52}$$

in terms of which $\bar{g}_V^f$ and $\bar{g}_A^f$ are given by $\sqrt{\rho_f}$ times their tree-level formulae. One finds that the $\widehat{\kappa}_f$ ($f \neq b$) are almost independent of m_t and M_H, and thus one can write,

$$\bar{s}_\ell^2 = \widehat{s}_Z^2 + 0.00032 , \tag{10.53}$$

while the κ_f for the OS scheme are m_t dependent.

High-precision measurements of various Z pole ($\sqrt{s} \approx M_Z$) observables [9, 308, 309] have been performed at LEP 1 and SLC [139, 305, 306, 310, 311], as summarized in Table 10.3. These include the Z mass and total width, Γ_Z, and partial widths $\Gamma_{f\bar{f}}$ for $Z \to f\bar{f}$, where $f = e$, μ, τ, light hadrons, b, and c. It is convenient to use the variables, also called "pseudo-observables", because these need to be determined from cross-section measurements,

$$M_Z, \quad \Gamma_Z, \quad \sigma_{\rm had} \equiv \frac{12\pi\Gamma_{e^+e^-}\Gamma_{\rm had}}{M_Z^2\,\Gamma_Z^2}, \quad R_\ell \equiv \frac{\Gamma_{\rm had}}{\Gamma_{\ell^+\ell^-}}, \quad R_q \equiv \frac{\Gamma_{q\bar{q}}}{\Gamma_{\rm had}}, \tag{10.54}$$

for $\ell = e, \mu$, or τ, and $q = b$ or c, where $\Gamma_{\rm had}$ is the partial decay width into hadrons. [13] Most of these are weakly correlated experimentally. These quantities have been obtained by the LEP collaborations from fits to the measured cross sections around the Z pole in e^+e^- collisions. Initial-state radiation reduces the peak cross section by more than 25%, where $\mathcal{O}(\alpha^3)$ QED effects and the dependence on Γ_Z induce an anti-correlation of about -30% between Γ_Z and $\sigma_{\rm had}$, and correlations of about 10% between $\sigma_{\rm had}$ and R_e, R_μ, and R_τ. Newer calculations of beam-beam effects on the luminosity measurement at LEP [312] and an improved Bhabha cross section [215], which was underestimated by 0.048% when the measurements were done, result in updated values

$$\Gamma_Z = 2.4955 \pm 0.0023 \text{ GeV} \quad \text{and} \quad \sigma_{\rm had} = 41.480 \pm 0.033 \text{ nb}. \tag{10.55}$$

The anti-correlation between R_b and R_c amounts to -18% [139]. The observable R_ℓ exhibits only a mild dependence on m_t, which enters through the $Z \to b\bar{b}$ vertex in the total Z boson width, final-state corrections, and the implicit dependence through $\sin^2\theta_W$. Thus, R_ℓ is especially useful for constraining $\alpha_s(M_Z^2)$.

Very important constraints follow from measurements of various Z-pole asymmetries. These include the FB asymmetry $A_{\rm FB}$, and the polarization or LR asymmetry $A_{\rm LR}$, defined by

$$A_{\rm FB}^f = \frac{\sigma_{\rm F}^f - \sigma_{\rm B}^f}{\sigma_{\rm F}^f + \sigma_{\rm B}^f} , \qquad A_{\rm LR} = \frac{\sigma_{\rm L}^f - \sigma_{\rm R}^f}{\sigma_{\rm L}^f + \sigma_{\rm R}^f} . \tag{10.56}$$

Here, $\sigma_{\rm F(B)}^f$ are the cross sections to produce a fermion in the forward (backward) hemisphere, defined with respect to the direction of the electron beam, and $\sigma_{\rm L(R)}^f$ are the total cross sections for left-handed (right-handed) incoming electrons. The LR asymmetry was measured precisely by the SLD collaboration at the SLC [305] using a polarized electron beam, and has the advantages of being very sensitive to $\bar{s}_\ell^2$ and that systematic uncertainties largely cancel. After removing initial-state QED corrections and contributions from photon exchange, γ–Z interference, as well as the EW boxes in Eq. (10.47a), one can use the effective tree-level expressions,

$$A_{\rm LR} = A_e P_e , \qquad A_{\rm FB}^f = \frac{3}{4}A_f\,\frac{A_e + P_e}{1 + P_e A_e} , \tag{10.57}$$

where,

$$A_f \equiv \frac{2\bar{g}_V^f\bar{g}_A^f}{\bar{g}_V^{f2} + \bar{g}_A^{f2}} = \frac{1 - 4|Q_f|\bar{s}_f^2}{1 - 4|Q_f|\bar{s}_f^2 + 8Q_f^2\bar{s}_f^4} . \tag{10.58}$$

P_e is the initial e^- polarization. The Z-pole FB asymmetries at LEP 1 ($P_e = 0$) are given by $A_{\rm FB}^f = \frac{3}{4}A_e A_f$ for $f = e$, μ,

[13] In this review, we only consider Z-pole observables corrected for radiative effects, photon exchange, γ–Z interference, and EW boxes. These are denoted with a superscript '0' in the original LEP literature, *e.g.* $\sigma_{\rm had}^0$, but here we drop the '0' from the superscript.

Table 10.3: Principal Z-pole observables and their SM predictions. The first M_Z is from LEP 1 [139] and the second from CDF [212]. The first $\bar{s}^2_\ell$ is the effective weak mixing angle extracted from the hadronic charge asymmetry at LEP 1 [139], the second is the combined value from the Tevatron [299], and the third is from the LHC [300–304]. The values of A_e are (i) from $A_{\rm LR}$ for hadronic final states [305]; (ii) from $A_{\rm LR}$ for leptonic final states and from polarized Bhabha scattering [306]; and (iii) from the angular distribution of the τ polarization at LEP 1 [139]. The A_τ values are from SLD [306], the total τ polarization from LEP [139] and from CMS [307], respectively. The SM predictions are obtained using the values of the first five parameters listed in the second column of Table 10.5. Note that the SM errors in Γ_Z, the R_ℓ, and $\sigma_{\rm had}$ are largely dominated by the uncertainty in α_s.

A_s		0.895 ± 0.091	0.9357 ± 0.00004

τ, b, c, s [139], and q, and where $A^q_{\rm FB}$ refers to the hadronic charge asymmetry. Corrections for t-channel exchange and s/t-channel interference cause $A^e_{\rm FB}$ to be strongly anti-correlated with R_e with a coefficient of -37%. The m_b-dependence [313] of the $\mathcal{O}(\alpha_s^2)$ QCD correction [314], affecting the reference axis of the b-quark asymmetry [315], increased the extracted $A^b_{\rm FB}$ by about 0.2σ. The correlation between $A^b_{\rm FB}$ and $A^c_{\rm FB}$ amounts to 15%.

The six measured values of R_ℓ and $A^\ell_{\rm FB}$ are consistent with lepton universality[14] within their 68% confidence level contours, as shown in Fig. 10.2. The value of R_τ has been corrected for mass effects [110] to be comparable to R_e and R_μ. In our global SM fit, we use the combined values

$$R_\ell = 20.767 \pm 0.025 \ , \qquad A^\ell_{\rm FB} = 0.0171 \pm 0.0010 \ , \qquad (10.59)$$

obtained for massless leptons with an anti-correlation of -5.6% [139].

The SLD collaboration extracted the final-state couplings A_b, A_c [139], A_s [310], A_τ, and A_μ [306], from left–right forward–backward asymmetries, using

$$A^{\rm FB}_{\rm LR}(f) = \frac{\sigma^f_{LF} - \sigma^f_{LB} - \sigma^f_{RF} + \sigma^f_{RB}}{\sigma^f_{LF} + \sigma^f_{LB} + \sigma^f_{RF} + \sigma^f_{RB}} = \frac{3}{4} A_f \ , \qquad (10.60)$$

where, for example, σ^f_{LF} is the cross section for a left-handed incident electron to produce a fermion f traveling in the forward hemisphere. We note that $A^{\rm FB}_{\rm LR}$ is equal to $A^f_{\rm FB}$ in Eq. (10.57) for $P_e = 1$. Similarly, A_τ and A_e were measured at LEP 1 [139] (A_τ also recently by CMS [307]) through the τ polarization, $\mathcal{P}_\tau$, as a function of the scattering angle θ, which can be written as,

$$\mathcal{P}_\tau = -\frac{A_\tau(1+\cos^2\theta) + 2A_e\cos\theta}{(1+\cos^2\theta) + 2A_\tau A_e \cos\theta} \ . \qquad (10.61)$$

The average polarization, $\langle \mathcal{P}_\tau \rangle$, obtained by integrating over $\cos\theta$ in the numerator and denominator of Eq. (10.61), yields $\langle \mathcal{P}_\tau \rangle = -A_\tau$, and A_e can be extracted from the $\mathcal{P}_\tau$ angular distribution. The initial-state coupling, A_e, was also determined through the LR charge asymmetry [311] and in polarized Bhabha scattering [306] at the SLC. Because $\bar{g}^\ell_V$ is very small, not only $A_{\rm LR} = A_e$, $A^\ell_{\rm FB}$, and $\mathcal{P}_\tau$, but also $A^q_{\rm FB}$ for $q = b$, c, and s, as well as the hadronic asymmetries are mainly sensitive to $\bar{s}^2_\ell$. The leptonic results are compatible with lepton universality and can be combined into [139]

$$A_\ell({\rm SLD}) = 0.1513 \pm 0.0021 \ , \quad A_\ell({\rm LEP}) = 0.1465 \pm 0.0033 \ , \qquad (10.62)$$

[14] Tests of lepton universality of the neutral current are also available from hadron collider data. The ratio of branching fractions for Z bosons decaying into e^+e^- relative to $\mu^+\mu^-$ final states has also been measured by ATLAS [316], obtaining $R_{e/\mu} = 1.0026 \pm 0.0050$, in perfect agreement with lepton universality. Similar tests have also been performed with $Z \to \tau^+\tau^-$ decays by the LHCb collaboration, finding also good agreement with lepton universality at the few-percent level: $R_{\tau/e} = 1.02 \pm 0.06$, $R_{\tau/\mu} = 1.01 \pm 0.05$ [317].

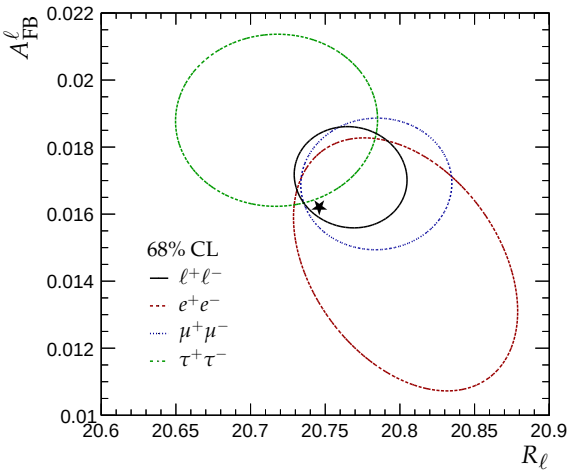

Figure 10.2: Contour lines at 68% confidence level for the LEP 1 measurements of R_ℓ and $A_{\rm FB}^{\ell}$ for e^+e^-, $\mu^+\mu^-$, $\tau^+\tau^-$ final states, and all leptons combined. The value of R_τ has been corrected for mass effects, shifting the measurement by -0.047. The SM prediction for massless leptons is shown as a black star.

where the first value is obtained from SLD data and the second one from LEP. The two values are statistically compatible within 1.2 standard deviations and are compatible with the CMS determination [307]

$$A_\tau(\text{CMS}) = 0.144 \pm 0.015 \ . \tag{10.63}$$

The LEP and SLD Collaborations reported a value of $\bar{s}^2_\ell = 0.23153 \pm 0.00016$ [139] from the combination of $A_{\rm FB}^{\ell}$, A_ℓ(SLD), A_ℓ(LEP), $A_{\rm FB}^{b}$, $A_{\rm FB}^{c}$, and the direct measurement 0.2324 ± 0.0012 from the hadronic charge asymmetry at LEP 1 [139]. The correction of the reference axis in the b-quark asymmetry [313] leads to a reduced value of $\bar{s}^2_\ell$ when extracted from $A_{\rm FB}^{b}$ alone, 0.23214 ± 0.00029, which is smaller by 0.00007 than without this correction. Including this correction in the combination of all LEP and SLD asymmetries yields

$$\bar{s}^2_\ell = 0.23150 \pm 0.00016 \ \text{(LEP + SLD)} \tag{10.64}$$

with a χ^2/d.o.f. of 10.7/5, corresponding to a p-value of 0.06.

As for hadron colliders, the FB asymmetry, $A_{\rm FB}$, for e^+e^- and $\mu^+\mu^-$ final states (with invariant masses restricted to or dominated by values around M_Z) in $p\bar{p}$ collisions has been measured by the CDF [318] and DØ [319] collaborations, and the values $\bar{s}^2_\ell = 0.23221 \pm 0.00046$ and $\bar{s}^2_\ell = 0.23095 \pm 0.00040$ were extracted, respectively. The combination of these measurements (which differ by more than 2 σ) yields [299],

$$\bar{s}^2_\ell = 0.23148 \pm 0.00033 \ \text{(Tevatron)} \ . \tag{10.65}$$

By varying the invariant mass and the scattering angle (and assuming the electron couplings), information on the effective Z couplings to light quarks, $\bar{g}^{u,d}_{V,A}$, could also be obtained [320,321], but with large uncertainties, mutual correlations, and not independently of $\bar{s}^2_\ell$ above. Similar analyses have also been reported by the H1 [322] and ZEUS [323] collaborations at HERA and by the LEP collaborations [139]. This kind of measurement is harder in the pp environment due to the difficulty to assign the initial quark and antiquark in the underlying Drell–Yan process to the protons, thus requiring excellent control of uncertainties from parton distribution functions. ATLAS obtained $\bar{s}^2_\ell = 0.2308 \pm 0.0012$ using 7 TeV data [300] and a preliminary result $\bar{s}^2_\ell = 0.23140 \pm 0.00036$ at 8 TeV [301], while CMS measured $\bar{s}^2_\ell = 0.23101 \pm 0.00053$ at 8 TeV [302] and $\bar{s}^2_\ell = 0.23152 \pm 0.00031$ at 13 TeV [324]. [15] The LHCb collaboration measured $\bar{s}^2_\ell = 0.23142 \pm 0.00106$ using 7 and 8 TeV data [304], and $\bar{s}^2_\ell = 0.23147 \pm 0.00050$ using 13 TeV data [325], both in $\mu^+\mu^-$ final states. In all hadron-collider measurements of $\bar{s}^2_\ell$, the largest systematic uncertainty stems from uncertainties in the PDFs. The correlated part of these uncertainties is difficult to estimate without a dedicated analysis, exacerbated by a different choice of PDF set in each measurement. We assume that the PDF uncertainties are correlated between 25% and 75%, depending on the CM energy, the choice of PDF, and the fiducial region of the measurement. We take the other systematic uncertainties to be 50% correlated for measurements by the same experiment at different CM energies, and else assume no correlation. This choice leads to an uncertainty of $20 \cdot 10^{-5}$ in the hadron collider (HC) average of $\bar{s}^2_\ell$. Varying these assumptions by $\pm 25\%$ for the PDF correlations and between 0 and 100% for the correlations in the other systematic uncertainties, the central value changes by $10 \cdot 10^{-5}$, which we take as an additional systematic uncertainty. The resulting average is

$$\bar{s}^2_\ell = 0.23149 \pm 0.00022 \ \text{(HC)}. \tag{10.66}$$

Removing the Tevatron combination from this average results in the LHC value $\bar{s}^2_\ell = 0.23148 \pm 0.00027$, where an uncertainty of $13 \cdot 10^{-5}$ from varying the correlations is included in the total uncertainty.

The combination of LEP, Tevatron, and LHC results is still mostly dominated by the lepton collider measurement and gives [16]

$$\bar{s}^2_\ell = 0.23150 \pm 0.00013 \ \text{(collider average)}. \tag{10.67}$$

Since this average includes $\bar{s}^2_\ell$ determinations from asymmetry measurements at LEP and SLD, it cannot be used in a global EW fit that already includes these measurements. Instead, we use the HC combination (10.66) as additional input in the fit.

10.4.7 *W and Z decays*

The partial widths of weak gauge boson decays into massless fermion pairs $f_1\bar{f}_2$ (the numerical values include small final-state mass effects) are given by,

$$\begin{aligned}\Gamma(W^+ \to e^+\nu_e) &= \frac{M_W^3 G_F}{6\sqrt{2}\pi} + \text{EW corrections} \\ &= 226.29 \pm 0.04\,\text{MeV} \ ,\end{aligned} \tag{10.68a}$$

$$\begin{aligned}\Gamma(W^+ \to u_i\bar{d}_j) &= \frac{M_W^3 G_F}{6\sqrt{2}\pi}\,|V_{ij}|^2\mathcal{R}_V^q \\ &\quad + \text{EW corrections} = (705.3 \pm 0.4\,\text{MeV})|V_{ij}|^2 \ ,\end{aligned} \tag{10.68b}$$

$$\Gamma(Z \to f\bar{f}) = \frac{M_W^3 G_F}{6\sqrt{2}\pi}\left[\mathcal{R}_V^f \bar{g}_V^{f2} + \mathcal{R}_A^f \bar{g}_A^{f2}\right] \ , \tag{10.68c}$$

where the result for the latter are shown in Table 10.4. Final-state QED and QCD corrections [326] to the vector and axial-vector form factors are given by,

$$\mathcal{R}^f_{V,A} = N_C\left[1 + \frac{3}{4}\left(Q_f^2\frac{\alpha(s)}{\pi} + \frac{N_C^2-1}{2N_C}\frac{\alpha_s(s)}{\pi}\right) + \cdots\right] \ , \tag{10.69}$$

where $N_C = 3$ (1) is the color factor for quarks (leptons) and the dots indicate finite fermion mass effects proportional to m_f^2/s which are different for $\mathcal{R}_V^f$ and $\mathcal{R}_A^f$, as well as higher-order QCD corrections [327], which are known to $\mathcal{O}(\alpha_s^4)$ [328]. For the Z boson, these include singlet contributions starting from two-loop order in QCD that are large, strongly top-quark mass dependent, family universal, and flavor non-universal [329–333]. The $\mathcal{O}(\alpha^2)$

[15] The measurement of the τ polarization in Eq. (10.63) provides another determination of the weak mixing angle, $\bar{s}^2_\ell = 0.2319 \pm 0.0019$. Due to its large uncertainty, this measurement has a negligible impact in the collider average of $\bar{s}^2_\ell$ presented below.

[16] This differs from the value presented in the Particle Listings in this *Review* due to the inclusion of the ATLAS 8 TeV measurement [301] in this combination, and the correction of the b-quark forward-backward asymmetry determination from LEP 1.

Table 10.4: Partial and total Z decay widths [in MeV]. The results are derived from Table 10.3 and the corresponding covariance matrices [139,215]. The results in the second column are derived without the assumption of lepton universality, while lepton universality is assumed in the third column. The SM predictions are given in the fourth column.

Quantity	Value	Value (universal)	Standard Model
$\Gamma_{e^+e^-}$	83.87 ± 0.12	83.942 ± 0.085	83.983 ± 0.018
$\Gamma_{\mu^+\mu^-}$	83.95 ± 0.18	83.941 ± 0.085	83.982 ± 0.018
$\Gamma_{\tau^+\tau^-}$	84.03 ± 0.21	83.759 ± 0.085	83.793 ± 0.018
$\Gamma_{\rm inv}$	498.9 ± 2.5	500.5 ± 1.5	501.605 ± 0.048
$\Gamma_{u\bar{u}}$	—	—	299.88 ± 0.16
$\Gamma_{c\bar{c}}$	300.3 ± 5.3	300.0 ± 5.2	299.80 ± 0.16
$\Gamma_{d\bar{d}}, \Gamma_{s\bar{s}}$	—	—	382.82 ± 0.12
$\Gamma_{b\bar{b}}$	377.4 ± 1.3	377.0 ± 1.2	375.90 ± 0.20
$\Gamma_{\rm had}$	1744.8 ± 2.6	1743.2 ± 1.9	1741.21 ± 0.65
Γ_Z	2495.5 ± 2.3	2495.5 ± 2.3	2494.56 ± 0.73

QED self-energy corrections from Ref. [334] are also taken into account.

For the W decay into quarks, Eq. (10.68b), only the universal massless part (non-singlet and $m_q = 0$) of the final-state QCD radiator function in $\mathcal{R}_V$ from Eq. (10.69) is used, and some remaining QED corrections are part of the EW corrections. Expressing the widths in terms of $G_F M_{W,Z}^3$ incorporates the largest radiative corrections from the running QED coupling. EW corrections to the Z widths are then taken into account through the effective couplings $\bar{g}^{\,i\,2}_{V,A}$. Hence, in the OS scheme the Z widths are proportional to $\rho_i \sim 1 + \Delta\rho_t$. There is additional (negative) quadratic m_t dependence in the $Z \to b\bar{b}$ vertex corrections [335,336] which causes $\Gamma_{b\bar{b}}$ to decrease with m_t. The dominant effect is to multiply $\Gamma_{b\bar{b}}$ by the vertex correction $1 + \delta\rho_{b\bar{b}}$, where $\delta\rho_{b\bar{b}} \sim 10^{-2}(-\frac{1}{2}m_t^2/M_Z^2 + \frac{1}{5})$.

Starting at $\mathcal{O}(\alpha\alpha_s)$, the factorized form indicated in Eq. (10.68) is violated and corrections need to be included [337–339]. They add coherently, resulting in a sizable effect, and shift $\alpha_s(M_Z^2)$ when extracted from Z lineshape observables by about $+0.0007$. Similar non-factorizable corrections are also known for mixed QED-EW corrections [106,108,109].

For three fermion families, the total widths of the Z [53,340–343] and W [25,136] bosons are predicted to be

$$\Gamma_Z = 2.4944 \pm 0.0006\,\text{GeV}\ , \qquad \Gamma_W = 2.090 \pm 0.001\,\text{GeV}\ . \tag{10.70}$$

The uncertainties in these predictions are almost entirely induced by the parametric error from the strong coupling constant, $\alpha_s(M_Z^2) = 0.1177 \pm 0.0009$, from the average in Eq. (10.41). These predictions can be compared with the experimental results, $\Gamma_Z = 2.4955 \pm 0.0023$ GeV [139,215] and the average from LEP, Tevatron and ATLAS, $\Gamma_W = 2.14 \pm 0.05$ GeV presented in the Gauge & Higgs Bosons Particle Listings in this *Review*. The different leptonic branching fractions of the W boson, $\mathcal{B}(W \to \ell\nu_\ell)$ have been measured at high precision by the LEP 2 experiments [216]. The measurements of the total and partial widths are generally in good agreement with the SM. The exceptions are Γ_W, which is 1.3σ larger than the SM prediction, and the branching fraction $W \to \tau + \nu_\tau$ from LEP 2, which is 2.6σ larger than the electron–muon average [216]. However, a measurement from ATLAS more precise than LEP 2 on the ratio of branching fractions $W \to \tau + \nu_\tau$ to $W \to \mu + \nu_\mu$, using top quark decays, shows good agreement with the SM prediction and lepton universality [344]. Additional measurements from ATLAS, CMS, and LHCb, on ratios of branching fractions for W decays into different lepton flavors are also in agreement with lepton universality [316,344–347].

The invisible decay width, $\Gamma_{\rm inv} = \Gamma_Z - \Gamma_{e^+e^-} - \Gamma_{\mu^+\mu^-} - \Gamma_{\tau^+\tau^-} - \Gamma_{\rm had}$, can be used to determine the number of neutrino flavors, N_ν, much lighter than $M_Z/2$. The hadronic peak cross section, and therefore the extracted $\Gamma_{\rm had}$, relies on the precise knowledge of the LEP luminosity measured by each experiment using small-angle Bhabha scattering. However, the earlier prediction for the Bhabha cross section was found to be overestimated, and consequently the luminosity underestimated [215]. An updated analysis led to a significant reduction in $\sigma_{\rm had}$ and a small increase in Γ_Z, as given in Eq. (10.55). The resulting value, $N_\nu = 2.9963 \pm 0.0074$ [215], is in agreement with the observed number of three fermion generations $N_\nu = 3$.

10.5 Global fit results

In this section, we present the results of global fits, subject to the experimental data and theoretical predictions discussed in Sections 10.2−10.4. For earlier analyses and other recent global fits, see Refs. [80,127,131,132,139,348–351] and previous editions of this *Review*. We recall that the latter have been obtained with the `GAPP` package [133], which consistently employs $\overline{\rm MS}$-renormalized quantities. For the results given here, we use the observables summarized in Table 10.5. This includes non-Z-pole observables such as the values of m_t (see Sec. 10.4.3), M_H [231,352], M_W [220,222], Γ_W [216,222,227], and $\mathcal{BR}(W \to \ell\nu)$ [216,345]. We also use the values of $\alpha_s(M_Z^2)$, $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$, and the heavy-quark masses as inputs, as explained in the previous sections. The heavy-quark masses, other than m_t, have a negligible impact on the fit and are omitted in Table 10.5. The principal Z-pole observables from the LEP 1 averages of the ALEPH, DELPHI, L3, and OPAL results include the corresponding correlations [139,215]. We assume lepton universality throughout this section, as confirmed by the measurements discussed above. In the SM fit, we use as inputs the combinations of leptonic observables obtained under this assumption. The recent τ-polarization measurement from CMS [307] (10.63) is not included in the fit, because of its negligible impact due to its large uncertainty compared to the LEP and SLD measurements. The heavy-flavor results [139,313] of LEP 1 and SLD are based on common inputs, and are thus correlated as well. For the effective weak mixing angle, we use the value extracted from the hadronic charge asymmetry at LEP 1 ($Q_{\rm FB}$) [139] and the hadron-collider (HC) average from Eq. (10.66).

Next to the experimental values in Table 10.5, we report the SM predictions from the EW fit. In the column labelled "SM fit", the result is shown from a fit with all experimental inputs included. The next column, labelled "indirect determination", shows the result of the fit where the observable in the given line is excluded from the fit. This column can be understood as the unbiased prediction for a given observable, obtained from the current best theoretical knowledge for the given observable, combined with the best experimental and theoretical knowledge of all observables relevant for the corresponding prediction. The fits presented in this *Review* have been performed using the `HEPfit` [128] and `Gfitter` [124] codes. The `HEPfit` results are derived following a Bayesian statistical analysis of the data and hypotheses, whereas `Gfitter` follows a frequentist approach with a global least-squares (χ^2) fit. Experimental uncertainties of all input observables are treated as one standard deviation of a Gaussian function. For simplicity, theoretical uncertainties estimating the size of missing higher-order contributions are also treated as Gaussian. However, we note that this assumption is not strictly fulfilled. This choice is justified by the fact that current theory uncertainties are smaller

Table 10.5: Electroweak precision observables included in the SM fit. The second column gives the experimental input, the third the result of the full fit, the fourth shows the value of the parameter in this line if the respective parameter is not included in the fit, and the last column gives the pull of the parameter. The pull is defined as the difference between the experimental value and the value of the indirect determination, divided by the total uncertainty, given by the quadratic sum of experimental uncertainty and uncertainty in the prediction. The first set of five parameters consists of the SM input parameters in the LEP input scheme, where G_F and $\alpha(0)$ are fixed. These five input parameters are constrained by the observables included in the fit, also encompassing their direct experimental measurements. The other three sets of parameters are measurements related to the W boson, leptonic Z-pole observables together with Γ_Z, $\sigma_{\rm had}$ and the hadron collider average of $\bar{s}^2_\ell$ from Eq. (10.66), and asymmetries of heavy quarks.

Parameter	Experimental value	SM fit	Indirect determination	Pull

by more than a factor of two than the experimental uncertainties, so that the fit result is driven by the experimental uncertainties. The main uncertainties associated with missing higher-order corrections are given by [110]

$$\delta_{\rm th} M_W = 4\,{\rm MeV}\,, \quad \delta_{\rm th}\sin^2\theta^f_{\rm eff} = 4.7\cdot 10^{-5}\,, \quad (10.71)$$
$$\delta_{\rm th}\Gamma_Z = 0.4\,{\rm MeV}\,, \quad \delta_{\rm th}\sigma_{\rm had} = 6\,{\rm pb}\,,$$
$$\delta_{\rm th} R_\ell = 0.006\,, \quad \delta_{\rm th} R_c = 0.00005\,, \quad \delta_{\rm th} R_b = 0.0001\,.$$

The reported uncertainty for each parameter is defined from the 68.3% probability range, upon profiling or marginalizing (depending on the approach) over the other parameters. These uncerainties are, in general, well approximated by the 1σ errors obtained from the values satisfying $\Delta\chi^2 = \chi^2 - \chi^2_{\rm min} = 1$. For the two-dimensional figures presented here, we show contours corresponding to the 68.3% and 95.5% confidence levels.

All results presented here have been obtained with both fit programs, `HEPfit` and `Gfitter`. We cross-checked these against each other and found excellent agreement between the numerical results from the two programs, with differences typically smaller than 10% of the quoted uncertainties in the predictions. In the Bayesian approach of `HEPfit`, the shapes of most of the posterior distributions follow Gaussian functions to a good approximation, such that the uncertainties from the two fit programs agree very well.

The agreement between the measurements and the predictions is generally very good. Despite the few discrepancies addressed in the following, the global EW fit describes the data very well, with a χ^2/d.o.f. = 14.4/17, corresponding to a p-value of 64%. The largest tensions are only at the 2σ level, which correspond to A_ℓ(SLD), $A^b_{\rm FB}$ from LEP 1, and Γ_W(ATLAS). Also, there is currently no understanding as to why the M_W value reported by the CDF collaboration [212] (not included in the fit) is significantly larger than the measurements by other experiments. We also emphasize that there are a number of discrepancies among individual measurements of certain quantities, as discussed in previous sections, but these are not reflected in the overall χ^2 of the fit as only the corresponding combinations are used as constraints.

There is still a long-standing tension in the EW fit with the combined measurement of the bottom-quark asymmetry $A^b_{\rm FB}$ that is below the SM prediction by 2.2σ, despite a slight improvement in recent years thanks to developments in related theory calculations [313]. The value of A_b can be extracted from $A^b_{\rm FB}$ when $A_e = 0.1501 \pm 0.0016$ is taken from a fit to leptonic asymmetries. The result, $A_b = 0.885 \pm 0.017$, is 2.9σ below the SM prediction[17] and also 1.4σ below $A_b = 0.923 \pm 0.020$ obtained from $A^{\rm FB}_{\rm LR}(b)$ at SLD. Thus, it seems that at least some of the tension in A_b is due to a statistical fluctuation. We note that the uncertainties in $A^b_{\rm FB}$ from LEP 1 and $A_{\rm LR}$ from SLD are dominated by the statistical component. The combined value, $A_b = 0.901 \pm 0.013$ deviates by 2.6σ from the SM prediction.

The left-right asymmetry $A_{\rm LR} = 0.15138 \pm 0.00216$ [305], obtained by counting hadronically decaying Z bosons for each electron-beam polarization at SLD, differs by 2σ from the SM fit value of 0.1470 ± 0.0004. The combined value of $A_\ell = 0.1513 \pm 0.0021$ from SLD is also 2.1σ above the SM prediction; but there is experimental agreement between this SLD value and the LEP 1 value, $A_\ell = 0.1481 \pm 0.0027$, obtained from a fit to $A^\ell_{\rm FB}$, $A_e(\mathcal{P}_\tau)$, and $A_\tau(\mathcal{P}_\tau)$.

The third and fourth columns in Table 10.5 reveal that the results from the full fit, including the Higgs-boson mass [231, 352], do not deviate from the indirect determinations by more than 1σ. Except for the input parameters, each parameter can be predicted with a precision better than the experimental precision. The indirect determinations of the input parameters M_H and m_t have uncertainties of about $^{+19}_{-17}$ GeV and ± 1.5 GeV, compared to experimental precisions of 0.1 GeV and 0.27 GeV, respectively. The logarithmic dependence of the SM predictions on M_H results

[17] Alternatively, one can use $A_\ell = 0.1481 \pm 0.0027$, which is from LEP 1 alone and in excellent agreement with the SM, and obtain $A_b = 0.897 \pm 0.022$, which is 1.7σ low.

in an uncertainty much larger than the experimental precision from the kinematic reconstruction of the Higgs boson. The precision of the indirect determination of m_t is strongly influenced by the uncertainty in the M_W measurement. In the full fit in column three, no input parameter is pulled from its measured value by more than 1σ, with small correlations among the input parameters. Moreover, because the SM parameters entering the predictions of the EW observables are measured with high precision, the parametric uncertainties in the predictions are currently smaller than the corresponding experimental uncertainties. This is shown in Table 10.6, indicating the contribution from the experimental measurements in each of the input parameters to the total uncertainty in a given observable.

Despite the high precision of the direct measurements of the chosen set of SM input parameters, M_Z, M_H, m_t, $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$, and $\alpha_s(M_Z^2)$, it is interesting to note that the data allow for a simultaneous determination of these parameters from the global EW fit without constraints from direct measurements. Excluding the direct measurement of the SM input parameters from the fit, the resulting values for each of these inputs and their correlations are shown in Table 10.7. Whereas M_Z and $\alpha_{\rm em}(M_Z^2)$ enter the predictions of most observables at the tree level, the dependence on M_H, m_t, and $\alpha_s(M_Z^2)$ is solely through radiative corrections. We note the consistency between the values in Table 10.7 and the actual measurements in Table 10.5.

From the EW precision observables, the strong coupling constant $\alpha_s(M_Z^2)$ is determined mainly through R_ℓ, Γ_Z, $\sigma_{\rm had}$, but Γ_W and the W branching fractions also have an impact. When including only the most sensitive observables in the fit, together with the experimental constraints on the input parameters but leaving $\alpha_s(M_Z^2)$ unconstrained, we obtain the following values:

$$R_\ell : \alpha_s(M_Z^2) = 0.1210 \pm 0.0042\,, \tag{10.72}$$

$$\Gamma_Z : \alpha_s(M_Z^2) = 0.1203 \pm 0.0049\,, \tag{10.73}$$

$$\sigma_{\rm had} : \alpha_s(M_Z^2) = 0.1202 \pm 0.0068\,, \tag{10.74}$$

$$\text{all three} : \alpha_s(M_Z^2) = 0.1206 \pm 0.0029\,. \tag{10.75}$$

The values of $\alpha_s(M_Z^2)$ are compatible with each other within the uncertainties. The corrections from beam–beam effects on the luminosity measurement at LEP [312] and the improved Bhabha cross section [215] result in an upwards shift in $\alpha_s(M_Z^2)$ from $\sigma_{\rm had}$ and as a consequence the fit with all three observables gives a very small $\chi^2/\text{d.o.f.} = 0.02/2$. The full EW fit gives

$$\alpha_s(M_Z^2) = 0.1200 \pm 0.0028\,, \tag{10.76}$$

with a central value very close to the one from the reduced fit to R_ℓ, Γ_Z, and $\sigma_{\rm had}$, and only a slightly smaller uncertainty. This value is compatible at about 1σ with the averages obtained from τ decays ($\alpha_s(M_Z^2) = 0.1171^{+0.0018}_{-0.0017}$), heavy quarkonia spectroscopy (0.1181 ± 0.0037), DIS and global PDF fits (0.1161 ± 0.0022), hadronic final states of e^+e^- annihilations (0.1189 ± 0.0037), hadron colliders (0.1168 ± 0.0027), as well as lattice QCD simulations (0.1184 ± 0.0008). For more details, other determinations, and references, see Section 9 on "Quantum Chromodynamics" in this *Review*.

The loop-level sensitivity of the EW fit to M_H and m_t comes mainly from M_W and $\bar{s}^2_\ell$. The dependence of M_W on m_t is illustrated in Fig. 10.3. The EW fit contour, including all observables except M_W and m_t, is still somewhat larger than the precision of the direct measurements. Without M_W included in the fit, the uncertainty in the predicted value of m_t is ± 4.1 GeV. Without an experimental constraint on M_H, the allowed range for m_t is significantly larger, increasing to $^{+9.8}_{-8.1}$ GeV. The measurements of A_ℓ, $\bar{s}^2_\ell$, and $A^b_{\rm FB}$ result in a determination of m_t with an uncertainty of about ± 7, ± 7.5, and ± 8 GeV, respectively. The strongest constraint on m_t comes from the measurement of M_W, resulting in $m_t = 173.6 \pm 1.5$ GeV. The slight preference for a larger value of m_t compared to the experimental measurement is correlated with the equally slightly larger observed value of M_W compared to the prediction, see Table 10.5 and Fig. 10.3. The result is, in any case, compatible with the direct constraint at less than 1σ, illustrating again the good agreement of the SM with data.

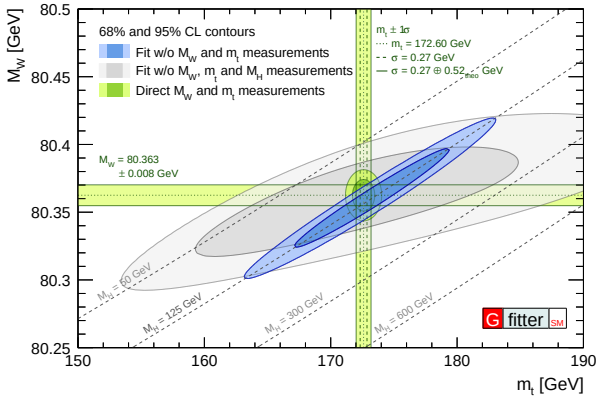

Figure 10.3: Determination of the W-boson and top-quark masses from the EW fit, compared to the experimental values. Shown are the 68% and 95% confidence level contours, together with the SM prediction of M_W as a function of m_t, where the other input parameters are given in Table 10.5. The grey contours show the EW fit without using the measured M_H as input.

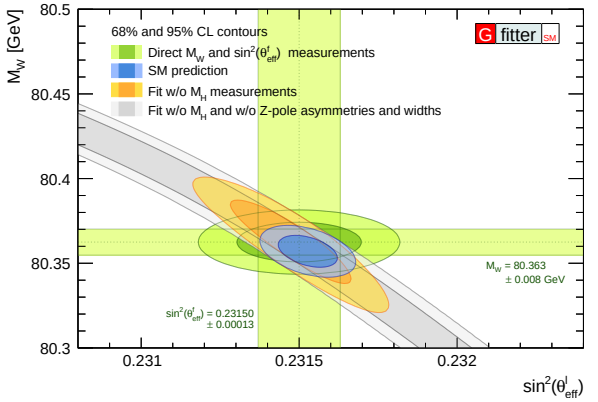

Figure 10.4: Prediction of the W-boson mass and $\bar{s}^2_\ell$ in the EW fit obtained with the input values from Table 10.5 (blue contours), compared to the world average of M_W and the collider average of $\bar{s}^2_\ell$ (10.67) (green contours). Shown are the 68% and 95% confidence level contours. The orange contours show the result of a fit that includes Z-pole data (asymmetries and partial widths), but without M_H. The grey contours show the fit result without M_H and without the Z-pole data.

In Fig. 10.4, we compare the predictions of M_W and $\bar{s}^2_\ell$ with the experimental measurements. The largest uncertainties in the prediction of M_W are the parametric uncertainties in m_t and $\alpha_s(M_Z^2)$ and the theoretical uncertainties of ± 4 MeV from missing higher orders and $\Delta m_{\rm MC}$ from Eq. (10.37). In the prediction of $\bar{s}^2_\ell$, the largest uncertainties are the parametric uncertainties in $\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$, m_t, and M_Z, which are of similar size as the uncertainty from missing higher orders, $4.7 \cdot 10^{-5}$. The experimental uncertainty in M_W comes from a combination of results from the LEP, Tevatron, and LHC experiments. The experimental uncertainty in $\bar{s}^2_\ell$ is still dominated by the precise asymmetry measurements from LEP 1, but hadron-collider measurements start to become relevant. In hadron-collider measurements, the uncertainty in $\bar{s}^2_\ell$ is currently dominated by PDF uncertainties, but with a prospect of reduced future uncertainties because PDFs can be simultaneously constrained with $\bar{s}^2_\ell$ using large data sets. The result of a fit including Z-pole observables, most notably the asymmetry measurements, but without the experimental value of M_H (shown in orange), has an uncertainty larger by a factor of

Table 10.6: Contributions to the parametric uncertainties in the SM predictions of different EW precision observables. The contribution from the uncertainty in M_H is negligible and is omitted here. The last column shows the present experimental precision in the respective observable for comparison.

	Contribution to parametric uncertainty				Total param. unc.	Total exp. unc.

$\Delta\alpha^{(5)}_{\rm had}(M_Z^2)$	0.02786 ± 0.00089	−0.43	−0.22	−0.83	0.44	1.00

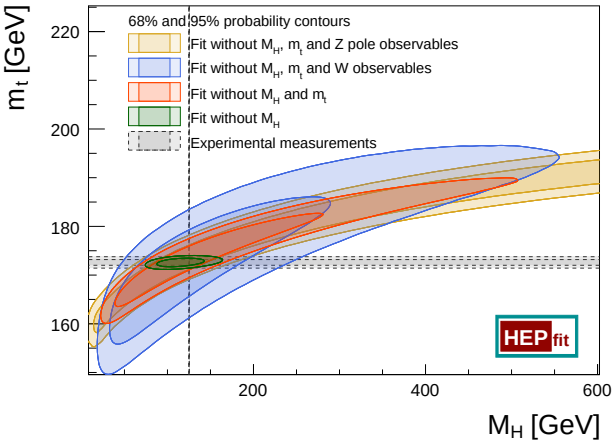

Figure 10.5: Bayesian probability contours at 68% and 95% for the Higgs-boson and top-quark masses from EW fits excluding different sets of input measurements. The grey bands indicate the experimental precision of the direct measurements of the two parameters. The width of the vertical band, corresponding to the precision in M_H, is not visible on the scale of the plot.

about 2.5 compared to the SM prediction. This fit matches the experimental precision in $\bar{s}^2_\ell$, but has an uncertainty about twice as large in M_W when compared to the world average Eq. (10.33). Without M_H and without Z-pole observables, the prediction becomes undetermined in the $\bar{s}^2_\ell$–M_W plane, as shown by the grey contours in Fig. 10.4.

The sensitivity of the EW fit to M_H is substantially increased when including the measurements of the other SM input parameters, as illustrated in Fig. 10.5. Despite the very precise determinations of these observables, the sensitivity to the actual value of M_H is diminished by the fact that the leading contributions to the predictions of EW observables is logarithmic. Removing the direct LHC measurements of M_H from the EW fit results in a loop-level determination of M_H from precision data, given in the fourth column in Table 10.5. At 95% confidence level, we obtain

$$80 \text{ GeV} < M_H < 150 \text{ GeV}\,, \tag{10.77}$$

which encloses the observed value in Eq. (10.34). The measurements of $\bar{s}^2_\ell$, M_W, A_ℓ, and $A^b_{\rm FB}$ show the highest sensitivity to M_H. Including only one of these observables at a time, the value of M_H is determined to be

$$\bar{s}^2_\ell(\text{HC}) : M_H = 114^{+69}_{-44} \text{ GeV}\,, \tag{10.78}$$

$$M_W : M_H = 112^{+21}_{-19} \text{ GeV}\,, \tag{10.79}$$

$$A_\ell(\text{SLD}) : M_H = 36.7^{+31.4}_{-18.9} \text{ GeV}\,, \tag{10.80}$$

$$A_\ell(\text{LEP}) : M_H = 140^{+190}_{-84} \text{ GeV}\,, \tag{10.81}$$

$$A^b_{\rm FB} : M_H = 487^{+398}_{-212} \text{ GeV}\,. \tag{10.82}$$

The obtained values agree well within the uncertainties, except for the values from $A^b_{\rm FB}$ and A_ℓ(SLD), which are apart by about 2.2σ. The predicted value from the full EW fit,

$$M_H = 111^{+19}_{-17} \text{ GeV}\,, \tag{10.83}$$

agrees with the individual values and the direct measurement, evidencing the excellent internal consistency of the SM and its capability of predicting observables to very high precision.

In summary, the remarkable agreement between SM predictions and experimental EW precision data, which is reached only after including radiative (meaning *quantum*) corrections, impressively confirms the model as a *quantum field theory*, while tree-level predictions (without quantum corrections) are away from data by many standard deviations.

10.6 Constraints on new physics

The precise measurements of EW observables available at different energies and their overall agreement with the SM predictions can be used to set strong limits on new physics modifying, in particular, the properties of the EW gauge bosons. Since the LEP era, the limits from EW precision measurements have

typically been interpreted in terms of the so-called oblique new physics, which assumes only modifications in the gauge-boson self-energies coming from new particles (*e.g.*, heavy particles with masses $\Lambda \gg M_W$), and have been traditionally parametrized in terms of the Peskin-Takeuchi S, T, and U parameters [353].[18] Denoting the contributions of new physics to the various self-energies by $\Pi_{ij}^{\rm new}$, we have

$$\alpha(M_Z^2)T \equiv \frac{\Pi_{WW}^{\rm new}(0)}{M_W^2} - \frac{\Pi_{ZZ}^{\rm new}(0)}{M_Z^2} \ , \tag{10.84a}$$

$$\frac{\alpha(M_Z^2)}{4\,s_W^2 c_W^2} S \equiv \frac{\Pi_{ZZ}^{\rm new}(M_Z^2) - \Pi_{ZZ}^{\rm new}(0)}{M_Z^2} - \frac{c_W^2 - s_W^2}{c_W s_W} \frac{\Pi_{Z\gamma}^{\rm new}(M_Z^2)}{M_Z^2} - \frac{\Pi_{\gamma\gamma}^{\rm new}(M_Z^2)}{M_Z^2} \ , \tag{10.84b}$$

$$\frac{\alpha(M_Z^2)}{4\,s_W^2}(S+U) \equiv \frac{\Pi_{WW}^{\rm new}(M_W^2) - \Pi_{WW}^{\rm new}(0)}{M_W^2} - \frac{c_W}{s_W} \frac{\Pi_{Z\gamma}^{\rm new}(M_Z^2)}{M_Z^2} - \frac{\Pi_{\gamma\gamma}^{\rm new}(M_Z^2)}{M_Z^2} \ . \tag{10.84c}$$

The S, T, and U parameters are defined with a coupling factor proportional to α, so that they are expected to be of order unity in the presence of new physics. The S parameter measures the momentum dependence of custodial-symmetric new-physics effects modifying the neutral-current interactions. On the other hand, the parameter T only receives contributions from custodial SU(2) breaking new physics, measuring the difference between contributions to neutral and charged-current processes at low energies. Finally, the momentum dependence of such contributions is probed by the U parameter. Note that the full SM contributions to S, T, and U are gauge dependent, which is the reason that the gauge-boson self-energies are restricted to their non-standard contributions $\Pi_{VV'}^{\rm new}(q^2)$, with SM parts subtracted for a given input scenario.

The *STU* formalism was also the approach taken in previous versions of this *Review*, and its results can be translated into bounds of a large class of new-physics models, as long as the leading-order effects are oblique in the previous sense, and therefore also flavor universal. The available EW precision data does, however, allow to test a larger type of new-physics effects beyond the one of oblique nature. For instance, new physics that couples directly to ordinary fermions cannot be fully parametrized in the *STU* framework. Such examples include heavy Z' bosons [358], mixing with exotic fermions [9, 359, 360], leptoquark exchange [216, 361, 362], supersymmetric models, strong EW dynamics [363], Little Higgs models [364, 365], and TeV-scale extra spatial dimensions [366–369] (for more details and references, see Section 84 on "Extra Dimensions" in this *Review*). These types of new-physics scenarios, and more, can be described within the more general framework of *Effective Field Theories* (EFTs).

Under the assumptions that new physics is heavy compared to the scale of energies explored so far, and that at those energies the symmetries and field content are those of the SM, with the Higgs field being part of an SU(2) doublet ϕ like in the SM,[19] the so-called *Standard Model Effective Field Theory (SMEFT)* [373, 374] provides a rather general description of new-physics effects, parametrized in terms of an expansion in higher-dimensional operators, suppressed by the cut-off of the EFT, $\Lambda \gg v$, where new physics is expected to complete the SM:

$$\mathcal{L} = \mathcal{L}_{\rm SM} + \sum_{d>4} \sum_i \frac{C_i}{\Lambda^{d-4}} \mathcal{O}_i \ . \tag{10.85}$$

In this $1/\Lambda$ expansion, the observable effects of each higher-dimensional operator are suppressed by increasing powers of E/Λ, with $E \ll \Lambda$ the typical energy of a physical process. For a given level of experimental precision δ, one can then truncate the EFT expansion as long as $(E/\Lambda)^{d-4} \ll \delta$ and work with a finite number of operators. In this regard, although the EFT is technically non-renormalizable in the strict sense, at each order in the EFT expansion only a finite number of counterterms is needed, and the theory remains predictive at the desired level of experimental precision. In Eq. (10.85) the specific information about the new physics is encoded in the values of the *Wilson coefficients* C_i. These can be computed in terms of the masses and couplings of the new particles in a given model by, *e.g.*, matching the EFT and model results for a representative set of amplitudes.

Assuming lepton and baryon number conservation and a SMEFT-type new physics scenario, the leading-order new-physics effects in the $1/\Lambda$ expansion are given by dimension-six operators, and we restrict the discussion to this level of approximation in the following.[20] The full set of all possible new-physics effects can be parametrized in a widely model-independent way specifying a basis for the SMEFT at each order in the $1/\Lambda$ expansion and, to dimension six, several bases have been proposed [372–375]. In particular, the so-called *Warsaw basis* [374] presented the first complete set of physically independent dimension-six interactions which, assuming individual conservation of baryon and lepton number, contains a total of 59 operator structures, and 2499 interactions for three generations of fermions. Despite this large number of operators, at the (leading) order of $1/\Lambda$ only a relatively small number of operators modify the SM predictions for the EW precision observables measuring the properties of the W and Z bosons. For instance, assuming fermion-universal new-physics effects, in the Warsaw basis only 10 operators modify the SM predictions at order $1/\Lambda^2$ and tree level. These are:[21]

$$\mathcal{O}_{\phi D} = (\phi^\dagger D_\mu \phi)^* \, (\phi^\dagger D^\mu \phi), \ \ \mathcal{O}_{\phi WB} = (\phi^\dagger \sigma_a \phi)\, (B^{\mu\nu} W^a_{\mu\nu}), \tag{10.86}$$

$$\begin{aligned} (\mathcal{O}^{(1)}_{\phi F})_{ij} &= i(\phi^\dagger \overleftrightarrow{D}_\mu \phi)\, (\overline{F^i_L} \gamma^\mu F^j_L), \\ (\mathcal{O}^{(3)}_{\phi F})_{ij} &= i(\phi^\dagger \overleftrightarrow{D}^a_\mu \phi)\, (\overline{F^i_L} \gamma^\mu F^j_L), \\ (\mathcal{O}_{\phi f})_{ij} &= i(\phi^\dagger \overleftrightarrow{D}_\mu \phi)\, (\overline{f^i_R} \gamma^\mu f^j_R), \qquad F = l, q, \quad f = e, u, d, \end{aligned} \tag{10.87}$$

$$(\mathcal{O}_{ll})_{1221} = (\overline{l^1_L} \gamma_\mu l^2_L)\, (\overline{l^2_L} \gamma^\mu l^1_L). \tag{10.88}$$

The effects of the operators $\mathcal{O}_{\phi WB}$ and $\mathcal{O}_{\phi D}$ can be described in terms of the oblique S and T parameters introduced above, respectively. To be more precise, the S and T parameters can be directly associated to linear combinations of these two dimension-six bosonic operators and fermion-universal contributions from the interactions $\mathcal{O}^{(1),(3)}_{\phi F}$ and $\mathcal{O}_{\phi f}$ in Eq. (10.87) [376]. These operators also describe cases where new physics couples to the different SM fermion generations in a non-universal manner. These induce modifications to the EW couplings to the Z and W bosons parameterized by:

$$(\Delta g^f_L)_{ij} = -\frac{1}{2}\left(C^{(1)}_{\phi F} \pm C^{(3)}_{\phi F}\right)_{ij} \frac{v^2}{\Lambda^2}, \ (\Delta g^f_R)_{ij} = -\frac{1}{2}(C_{\phi f})_{ij} \frac{v^2}{\Lambda^2}, \tag{10.89}$$

$$(\Delta U^f_L)_{ij} = (C^{(3)}_{\phi F})_{ij} \frac{v^2}{\Lambda^2}. \tag{10.90}$$

In Eq. (10.89), Δg^f_L and Δg^f_R give the corrections to the left-handed and right-handed neutral currents, respectively, and

[18] We note that other parametrizations exist, see for example Refs. [354–357].

[19] A more general type of EFT, known as *Higgs Effective Field Theory (HEFT)* [370–372], relaxes this assumption by allowing the physical Higgs field to be a gauge singlet and including the Goldstone fields as SU(2) triplet in some non-linear field representation.

[20] From the point of view of observables measuring the W and Z boson properties, with experimental precision in some cases at the per-mil level, this truncation is justified if new physics is not present well below the TeV scale, in which case effects of dimension-eight operators are suppressed by $M_W^4/(1\,\text{TeV})^4 \sim \mathcal{O}(10^{-4})$.

[21] The hermitian covariant derivatives $\overleftrightarrow{D}$ and $\overleftrightarrow{D}^a$ appearing below are defined as $\overleftrightarrow{D}_\mu = D_\mu - \overleftarrow{D}_\mu$, $\overleftrightarrow{D}^a_\mu = \sigma_a D_\mu - \overleftarrow{D}_\mu \sigma_a$, with σ_a the Pauli matrices.

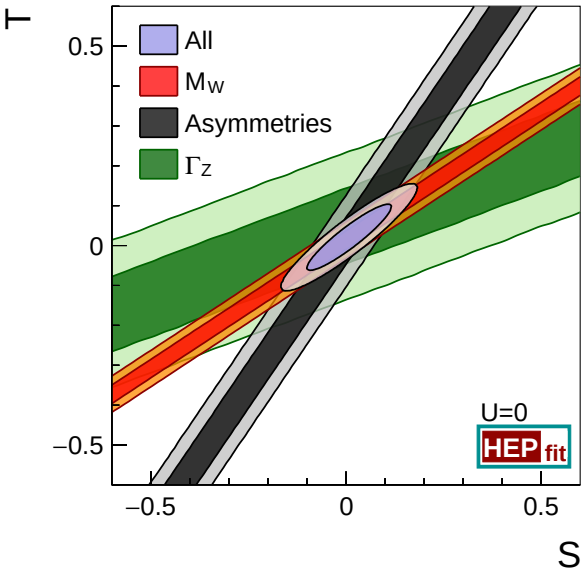

Figure 10.6: EW precision constraints on the S and T plane (assuming $U = 0$). The boundaries of the dark and light regions correspond to the 68% and 95% probability contours, respectively. We also show the constraints imposed by different sets of EW precision measurements. See text for details.

the plus (minus) sign corresponds to fermions of weak isospin $-1/2\,(+1/2)$. On the other hand, Eq. (10.90) denote the modifications of the (left-handed) charged currents. For simplicity, for the quark interactions we have ignored the CKM effects that would be introduced when rotating to the physical basis. Finally, the operator $(\mathcal{O}_{ll})_{1221}$ in Eq. (10.88) contributes to the muon decay and, therefore, the determination of the Fermi constant. In recent years, NLO calculations including the complete dimension-six effects in EW precision observables have become available [377,378], including also calculations in different input schemes [379]. More details can be found in the original references.

The EFT formalism also gives additional context to the description of EW precision observables via oblique parameters and the connection to new physics generating these effects. For instance, while the S and T parameters arise from contributions of dimension-six operators, the U parameter is a dimension-eight effect, and it is therefore expected to be parametrically suppressed with respect to S and T by a factor M_Z^2/Λ^2. Furthermore, additional oblique effects coming from the q^4 terms of the expansions of the gauge-boson self-energies also contribute to EW observables at the level of dimension-six EFT operators. Their inclusion leads to the so-called W and Y parameters [357], which, however, also generate universal four-fermion interactions whose effects are expected to be better constrained at high-energy $2 \to 2$ fermion processes.

As in previous editions of this *Review,* in this section we update the results coming from the interpretation of the EW precision measurements in terms of the STU formalism, and the implications for several types of new-physics models. These results are then extended beyond the case of fermion-universal theories with the interpretation within the SMEFT formalism, where we discuss the bounds from EW precision observables on the leading interactions in the dimension-six effective Lagrangian, keeping the discussion at a more model-independent level.

The results of the EW fit extending the SM with the S, T, and U parameters are presented in Table 10.8. We present the cases where $U = 0$, as a proxy for the case of heavy decoupling new physics where $|U| \ll |S|, |T|$, and a scenario where all three parameters are freely floating. Regardless of whether U is assumed to be zero or not, the results from the EW fit to the oblique parameters is fully consistent with the SM hypothesis.[22] The impact of the different EW observables in the S–T plane, assuming $U = 0$, is shown in Figure 10.6. The shape of these regions can be understood from the fact that, in the LEP scheme used in this figure, Γ_Z only depends on the combination

$$-10(3 - 8s_W^2)S + (63 - 126s_W^2 - 40s_W^4)T,$$

the U parameter only contributes to the W mass and width via

$$S - 2c_W^2 T - \frac{c_W^2 - s_W^2}{2s_W^2} U,$$

and the corrections to all other EW precision observables can be written in terms of

$$S - 4c_W^2 s_W^2 T.$$

From the results in Table 10.8 one can also derive individual limits on each parameter (*i.e.* assuming all the other oblique parameters are zero). We obtain the following 95% probability individual bounds,

$$T, U = 0: \quad -0.072 \le S \le 0.039; \quad S \ge -0.068 \quad (S \le 0); \quad S \le 0.045 \quad (S \ge 0); \tag{10.91a}$$

$$S, U = 0: \quad -0.027 \le T \le 0.058; \quad T \ge -0.034 \quad (T \le 0); \quad T \le 0.054 \quad (T \ge 0); \tag{10.91b}$$

$$S, T = 0: \quad -0.039 \le U \le 0.074; \quad U \ge -0.046 \quad (U \le 0); \quad U \le 0.069 \quad (U \ge 0); \tag{10.91c}$$

where the numbers in each row are obtained assuming the corresponding parameter can have any sign, or is restricted to be negative or positive, respectively.

As mentioned above, the STU results can be used to set constraints on a relatively large class of new-physics models inducing universal corrections to the SM predictions. For instance, the T parameter modifies the ρ parameter according to

$$\Delta\rho = \alpha(M_Z^2)T\ . \tag{10.92}$$

In this way, T can be connected to new-physics violations of custodial symmetry. These can be generated by additional sources of SU(2) breaking not induced by Higgs doublets, via

$$\rho = \frac{\sum_i [T_i(T_i+1) - T_{3i}^2]|v_i|^2}{2\sum_i T_{3i}^2 |v_i|^2}\ , \tag{10.93}$$

where v_i is the expectation value of the neutral component of a Higgs multiplet with weak isospin T_i and third component T_{3i}. Thus, the limits on T can be translated into constraints on higher-dimensional Higgs representations, such that their vacuum expectation values can only be less than a few percent of those of the doublets.

Similarly, the bounds on T can be used to set constraints on non-degenerate multiplets of heavy fermions or scalars, since these break the vector part of weak SU(2) and lead to a decrease in the value of M_Z/M_W. Each non-degenerate SU(2) doublet $\binom{f_1}{f_2}$ yields a positive contribution to ρ (and therefore T) [37,384,385] of

$$\frac{N_C\, G_F}{8\sqrt{2}\pi^2}\Delta m^2\ , \tag{10.94}$$

where

$$\Delta m^2 \equiv m_1^2 + m_2^2 - \frac{4m_1^2 m_2^2}{m_1^2 - m_2^2}\ln\frac{m_1}{m_2} \ge (m_1 - m_2)^2\ , \tag{10.95}$$

and $N_C = 1$ (3) for color singlets (triplets). The limit on the T parameter (assuming $T \ge 0$) taken together with Eq. (10.92) and

[22] For a discussion of the impact of the M_W CDF measurement [212] on the EW fit, we refer the reader to, e.g., Refs. [132, 380–383] and to the previous edition of this *Review*.

Eq. (10.94) implies the following constraint on the mass splitting at the 95% probability,

$$\sum_i \frac{N_C^i}{3}\, \Delta m_i^2 \leq (37\ \text{GeV})^2 \ , \tag{10.96}$$

where the sum runs over all new-physics doublets, for example fourth-family quarks or leptons, $\binom{t'}{b'}$ or $\binom{\nu'}{\ell'-}$, vector-like fermion doublets (which contribute to the sum in Eq. (10.96) with an extra factor of 2), and scalar doublets such as $\binom{\tilde{t}}{\tilde{b}}$ in supersymmetry (in the absence of L–R mixing).

Non-degenerate multiplets usually imply $\Delta\rho > 0$ ($T > 0$). Similarly, heavy Z' bosons decrease the prediction for M_Z due to mixing and generally lead to $\Delta\rho > 0$ ($T > 0$) [358]. On the other hand, extra Higgs doublets participating in spontaneous symmetry breaking [386–388] or heavy lepton doublets involving Majorana neutrinos [389], both of which have more complicated expressions, and the v_i of higher-dimensional Higgs representations can contribute to ρ with either sign.

The effects of non-standard Higgs representations cannot be separated from heavy non-degenerate multiplets unless the new physics has other consequences, such as vertex corrections. Most of the original papers defined T to include the effects of loops only. However, the way T has been defined here includes all new sources of SU(2) breaking, including non-standard Higgs bosons.

A multiplet of heavy degenerate chiral fermions yields

$$S = \frac{N_C}{3\pi} \sum_i \left(T_{3i}^L - T_{3i}^R\right)^2 \ , \tag{10.97}$$

where $T_{3i}^{L,R}$ is the third component of weak isospin of the left-(right-)handed component of fermion i. For example, a heavy degenerate ordinary or mirror family would contribute $2/(3\pi)$ to S. Therefore, the S parameter can also be used to constrain the number of fermion families, *under the assumption* that there are no other contributions to T or U, and therefore that any new families are degenerate. Then an extra generation of SM fermions is excluded with more than 8σ confidence, corresponding to $N_F = 2.92 \pm 0.13$. Allowing T to vary as well, the constraint on a fourth family is weaker [390]. However, a heavy fourth family would increase the Higgs production cross section through gluon fusion by a factor of about nine [391, 392], which has been excluded by ATLAS and CMS at the LHC [393]. Combining the limits from EW precision data with the measured Higgs production rate and limits from direct searches for heavy quarks [394], a fourth family of chiral fermions is now excluded by more than five standard deviations [395, 396]. Similar remarks apply to a heavy mirror family [397] involving right-handed SU(2) doublets and left-handed singlets. In contrast, new doublets that receive most of their mass from a different source than the Higgs vacuum expectation value, such as vector-like fermion doublets or scalar doublets in supersymmetry, give small or no contribution to S, T, U, and the Higgs production cross section and are therefore still not excluded. Partial or complete vector-like fermion families are predicted in many Grand Unified Theories [398] (see Section 92 on "Grand Unified Theories" in this *Review*), and many other models including supersymmetric and superstring inspired ones [399–402].

In models with warped extra dimensions [403], sizeable corrections to the S parameter are generated through mixing between the SM gauge bosons and their Kaluza-Klein (KK) excitations, and one finds $S \approx 30\, v^2 M_{KK}^{-2}$ [404], where M_{KK} is the mass scale of the KK gauge bosons. Large positive values of S can also be generated in models with dynamical EW symmetry breaking, where the Higgs boson is composite. In simple composite Higgs models, the dominant contribution stems from heavy spin-1 resonances of the strong dynamics leading to $S \approx 4\pi v^2 (M_V^{-2} + M_A^{-2})$, where $M_{V,A}$ are the masses of the lightest vector and axial-vector resonances, respectively [405]. From the results in Table 10.8 one obtains $S \leq 0.15$ at 95% probability, which puts the constraint $M_{KK} \gtrsim 3.5$ TeV on the masses of KK gauge bosons in warped extra dimensions. In minimal composite Higgs models, the bound on S requires $M_V \gtrsim 4.1$ TeV, which is obtained from the one-sided 95% probability bound on $S > 0$ for $T = 0$ and using Weinberg sum rules [406]. However, this constraint can be relaxed, *e.g.*, if the fermionic sector is also allowed to be partially composite [363, 407] and in soft-wall models [408].

Negative values of S are possible, for example, in composite Higgs models with larger gauge group representations [409,410], or from loops involving scalars or Majorana particles [411–413]. The simplest origin of $S < 0$ would probably be an additional heavy Z' boson [358]. Supersymmetric extensions of the SM [414, 415] generally give very small effects. For more details and references, see Refs. [416–425] and Sections 87 and 88 on "Supersymmetry" in this *Review*. Most simple types of new physics yield $U = 0$, although there are counter-examples, such as the effects of anomalous triple gauge vertices [426].

We conclude this section by moving beyond fermion-universal extensions of the SM and presenting the results of a SMEFT fit to electroweak precision observables. In this case, we adopt the G_F-scheme (with G_F, M_Z, M_W as input), which has become the standard in SMEFT combinations of different observables with LHC measurements [427].[23] We assume all the operators in Eqs. (10.86)–(10.88) can be generated by new physics. On the lepton side we allow new-physics corrections to be non-universal. Because of this, and contrary to what was done for the SM fits, for the fits in the SMEFT formalism we use as experimental inputs for leptonic observables, such as the ratios $R_{e,\mu,\tau}$ and asymmetries $A_{e,\mu,\tau}$, the values reported in Refs. [139, 215, 216, 345] *without* assuming lepton flavor universality. For quarks, we impose a U(2) flavor symmetry on the first two families to avoid large contributions to flavor-changing neutral currents. The third family is defined in flavor space along the direction of the top-quark. The operators in Eqs. (10.86)-(10.88) are the interactions that enter in EW precision observables at leading EFT order and tree level. Although many other operators contribute at NLO, we restrict the fit to this setup, as a full global analysis taking into account the constraints on all interactions would require combining with numerous additional data sets, which is beyond the scope of this *Review*. Finally, in the calculation of new-physics effects, we work consistently with the truncation of the SMEFT Lagrangian to dimension six, *i.e.* up to $O(1/\Lambda^2)$, and keep only corrections of this order in the observables.

It is well known that in the Warsaw basis the EW fit has two blind directions [428, 429]. In Table 10.9 we present the central values and 1σ uncertainties from this EW SMEFT fit, in terms of the following combinations of Wilson coefficients at the EW

[23] One of the main reasons is practical, since including the EW gauge-boson masses reduces the SMEFT dependences in propagators, but any choice for the EW input scheme will lead to equivalent fit results within theoretical uncertainties.

Table 10.9: Results from the global SMEFT fit discussed in the text, in terms of the combinations of Wilson coefficients in Eq. (10.98). All the operators in those combinations as well as the SM input parameters are taken as free parameters in the fit. The coefficients $(\hat{C}^{(1),(3)}_{\phi l,\phi e})_{11,22,33}$ denote interactions with each of the three lepton generations. For quarks, interactions with the light two families are assumed to be flavour universal, denoted by $(\hat{C}^{(1),(3)}_{\phi q,\phi u,\phi d})_{aa}$, but independent of the ones with the third family. Results in units of TeV^{-2}.

scale [428]:

$$\hat{C}^{(1)}_{\phi f} = \frac{C^{(1)}_{\phi f}}{\Lambda^2} - \frac{Y_f}{4}\frac{C_{\phi D}}{\Lambda^2}, \quad f = l, q, e, u, d,$$
$$\hat{C}^{(3)}_{\phi f} = \frac{C^{(3)}_{\phi f}}{\Lambda^2} + \frac{c_W^2}{4s_W^2}\frac{C_{\phi D}}{\Lambda^2} + \frac{c_W}{s_W}\frac{C_{\phi WB}}{\Lambda^2}, \quad f = l, q, \qquad (10.98)$$
$$\hat{C}_{ll} = \frac{1}{2}\frac{(C_{ll})_{1221} + (C_{ll})_{2112}}{\Lambda^2} = \frac{(C_{ll})_{1221}}{\Lambda^2}.$$

For the case of left-handed quarks, we further consider the combination $(\hat{C}^{(+)}_{\phi q})_{33} = ((\hat{C}^{(1)}_{\phi q})_{33} + (\hat{C}^{(3)}_{\phi q})_{33})/2$, which modifies the $Z \to b_L\bar{b}_L$ vertex, whereas the orthogonal combination modified the corresponding top-quark coupling and does not enter in the fit at the tree level. (In the previous expressions, s_W, c_W are the tree-level values of the sine and cosine of the weak mixing angle and Y_f denotes the fermion hypercharge.) In order to resolve the blind directions of this SMEFT EW fit, one would need to add additional observables, *e.g.* Higgs observables or measurements from diboson processes [428]. These, however, introduce further dependences on operators not entering in the EW fit and, in general, extra flat directions that need to be resolved including additional data. Eventually, this leads to the study of global SMEFT analyses that are becoming more popular in the literature, both from the theory and experimental sides, and that combine many types of observables from the EW, Higgs, top, and flavor sectors, to constrain as many directions in the SMEFT parameter space as possible. Some examples of these studies, with different levels of completeness in terms of both the scope of experimental observables included and the number of new-physics interactions considered, are presented in Refs. [430–440].

The presence of flat directions in the SMEFT fit is, however, not an impediment to derive interesting conclusions about the physics in the EW sector. For instance, the results in Table 10.9 can be translated into the space allowed for the modifications of the *effective* EW couplings of the fermions to the neutral currents in the SMEFT formalism, Δg_{eff}, defined such that the tree-level relations between the EW pseudo-observables and couplings are preserved in the presence of new-physics effects. The corresponding values are shown in Table 10.10.

In general, the results of the fit show again good agreement with the SM, with the data suggesting that new-physics modifications of the leptonic couplings must be below a few per-mil, whereas the bounds are significantly weaker for quarks. There is one notable exception to this good agreement with the SM predictions. As discussed in Sec. 10.5, there is a $(3.6 \pm 1.4)\%$ deviation in the asymmetry parameter A_b. This becomes manifest in the results in Table 10.10 in terms of a preference for a non-SM value of the $Z \to b_R\bar{b}_R$ vertex with right-handed b quarks (equivalently, in a non-zero value for the coefficient $(\hat{C}_{\phi d})_{33}$ in Table 10.9). Similarly, the $Z \to b_L\bar{b}_L$ vertex with left-handed b quarks also shows a tension with the SM prediction, and both corrections are highly correlated. This is due to the fact that R_b is in good agreement with the SM, and is also much better determined than A_b. Given the size of the correction to the $Zb\bar{b}$ interactions required to account for the deviation in A_b, it is difficult to attribute this solely to new physics entering through radiative corrections. Thus, if new physics is responsible, it is most likely of tree-level origin and affects preferentially the third generation. Examples include the decay of a scalar neutrino resonance [441], mixing of the b quark with heavy exotic particles [442], and a heavy Z' with family non-universal couplings [443, 444]. It is difficult, however, to simultaneously account for R_b without tuning, which has been measured on the Z peak and off-peak [445] at LEP 1. Measurements at future e^+e^- colliders will help to test different scenarios modifying the $Zb\bar{b}$ interaction [446].

11.1 Introduction

Understanding how the masses of the known elementary particles are generated has been one of the fundamental endeavors in particle physics for several decades. Due to the nature of the $SU(2)_L \times U(1)_Y$ electroweak (EW) gauge symmetry that defines the Standard Model (SM) [1], mass terms for the W and Z weak gauge bosons as well as for all fermions (quarks and leptons) can only appear as emergent quantities after the spontaneous breaking of the EW symmetry. The mechanism of electroweak symmetry breaking (EWSB) [2] provides a general framework to keep untouched the structure of the SM gauge interactions at high energies and still generate all observed particle masses at the scale of EW interactions. The EWSB mechanism posits a self-interacting complex EW doublet scalar field, whose CP-even neutral component acquires a vacuum expectation value (VEV) $v \approx 246\,\text{GeV}$[1], which sets the scale of the symmetry breaking. Three massless Goldstone bosons are generated and are absorbed to give masses to the W and Z gauge bosons. The remaining component of the complex doublet becomes the Higgs boson – a new, and so far unique, fundamental scalar particle. The masses of all fermions are also a consequence of EWSB since the Higgs doublet is postulated to couple to the fermions through Yukawa interactions in a way consistent with all the gauge symmetries of the SM.

The existence of a Higgs boson as predicted by the mechanism of EWSB is crucial to the consistency of the SM at the quantum level such that its mass has been indirectly constrained by SM precision measurements well before its discovery. In fact, without the Higgs boson, SM predictions would show clear indications of new phenomena at the TeV scale. Perturbative unitarity [3] would be lost at high energies since the longitudinal W/Z boson scattering amplitudes would grow with the center-of-mass energy. In addition, the radiative corrections to the gauge boson self-energies would exhibit dangerous logarithmic divergences that would be difficult to reconcile with EW precision data.

The observation of a Higgs boson as predicted by the mechanism of EWSB of the SM has therefore been the holy grail of particle physics for the decades that led up to its discovery in 2012.

11.1.1 *Searches for the SM Higgs boson*

Prior to the observation of the Higgs boson in July of 2012, searches for the SM Higgs boson were carried out by the LEP and Tevatron experiments. The combined results of the LEP experiments [4] yielded a lower bound of $m_H > 114.4$ GeV at the 95% confidence level (CL). The Tevatron experiments [5] subsequently excluded the mass range between 156 and 177 GeV at the 95% CL. These exclusions are shown in Fig. 11.1 (left) together with those obtained by the CERN Large Hadron Collider (LHC) [6] experiments in the Summer of 2011.

Right before its discovery, the latest direct searches from the LHC experiments had excluded Higgs-boson mass hypotheses below 600 GeV at the 95% CL, except for a narrow window around $115.5 < m_H < 127$ GeV. This was also the mass range independently favored by indirect constraints from precision measurements of EW-boson masses and couplings in e^+e^- collisions, on and off the Z-boson mass peak, at SLD, LEP, and LEP2, supplemented by results at the $p\bar{p}$ Tevatron collider that also measured the top-quark mass [7–9]. The right-hand-side plot of Fig. 11.1 illustrates the indirect constraint on m_H from precision fits of the SM as of March 2012 [10], i.e. right before the Higgs-boson discovery. In the SM, m_W and m_t are correlated by their dependence on m_H through radiative corrections. The diagonal green band in Fig. 11.1 represents the region of the (m_t, m_W) plane corresponding to values of m_H between 114 GeV and 1 TeV, a large portion of which (the diagonal yellow band) was already excluded in 2012 by the aforementioned direct LHC limits. On the other hand, the blue ellipse in Fig. 11.1 defines the experimentally allowed region of (m_t, m_W) as of March 2012, greatly improved by LEP2 and Tevatron direct measurements with respect to the case in which LEP1 and SLD data only could be used (red-dashed contour). Consistency with SM measurements, corresponding to the tiny region at the intersection between the blue ellipse and the green diagonal band in Fig. 11.1, yielded a best fit Higgs-boson mass value of $m_H = 94^{+29}_{-24}$ GeV, and a 95% CL upper bound of $m_H < 154$ GeV, in agreement with the LHC exclusion limits and quite on top of where the SM Higgs boson was soon to be found. More details on pre-discovery Higgs-boson direct and indirect bounds can be found in previous PDG reviews [11].

11.1.2 *Discovery of the SM Higgs boson*

In July 2012, the ATLAS [12] and CMS [13] experiments at CERN's LHC announced the discovery of a new particle with properties consistent with the SM Higgs boson [14, 15]. Subsequent analyses of the complete 2011–2012 Run 1 proton–proton dataset provided additional evidence of its compatibility with SM predictions: measurements of its spin, CP properties and width [16–21], and combined fits [22] all agreed well with theoretical expectations.

The characterization of the Higgs boson has continued during the Run 2 (2015-2018) and Run 3 (2022-2026) data-taking periods. The results presented in this Review provide a summary of these measurements.

11.1.3 *The SM Higgs boson as a portal to new physics*

With the discovery of the Higgs boson, the SM is confirmed to be a spontaneously broken gauge theory and, as such, it could a priori be consistently extrapolated well above the masses of the W and Z bosons. Hence, formally there is no need for new physics at the EW scale. However, as the SM Higgs boson is a scalar particle, it has sensitivity to possible new physics scales. Quite generally, the Higgs-boson mass is affected by the presence of heavy particles and it receives large quantum corrections which destabilize the weak scale barring a large fine-tuning of unrelated parameters. This is known as the Higgs naturalness or hierarchy

[1] As measured in muon decay with high precision, see Sec. 11.2.1.

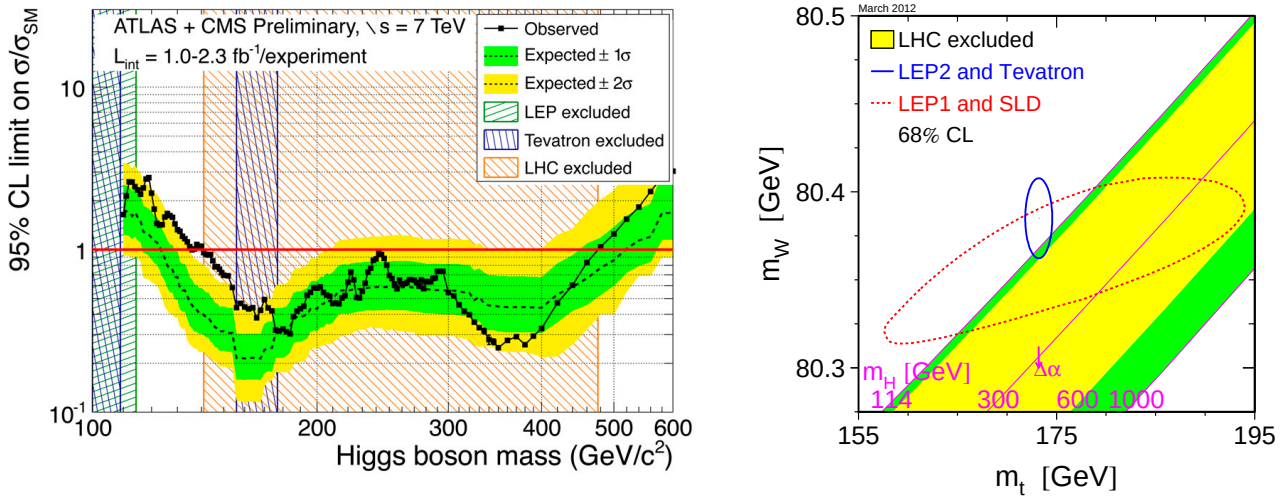

Figure 11.1: Left: Combined 95 % CL upper limits on SM Higgs-boson production prior to the discovery at the LHC in the Summer of 2011. The limits are normalized to the SM expectation, as a function of the Higgs-boson mass. Regions where the observed limit falls below unity are excluded. Right: indirect bounds on m_H from EW precision fits (March 2012).

problem [23], and it has been the prime argument for expecting new physics around and not far above the TeV scale.

To remedy this unsatisfactory feature, theoretically motivated paradigms have been explored for several decades, such as a new fermion-boson symmetry called supersymmetry (SUSY) [24] (for recent reviews, see Refs. [25, 26]), or the existence of strong interactions at a scale of the order of a TeV from which the Higgs boson would emerge as a composite state [27] (see Refs. [28, 29] for recent reviews). Alternatively, new agents stabilizing the weak scale could also be light but elusive, like in models of neutral naturalness [30, 31]. It was also recently appreciated [32, 33] that the cosmological evolution of the Universe could drive the Higgs-boson mass to a value much smaller than the cutoff of the theory, alleviating the hierarchy problem without the need for TeV scale new physics, even though there might still be interesting and spectacular signatures [32, 34]. This approach spurs a change in perspective invoking our Universe as part of a multiverse that should be treated as a quantum statistical system [35].

Another puzzling aspect of the SM Higgs boson concerns the arbitrariness of its couplings to fermions. This is encoded in the SM through a series of Yukawa couplings, one per massive fermion, proportional to the corresponding fermion mass and therefore displaying a huge and unexplained scale hierarchy. Furthermore, fermion masses and fermion mass eigenstates are intrinsically related to the origin of flavor mixing and CP-violation in the SM charged gauge currents, where four more arbitrary parameters are embedded in the Cabibbo-Kobayashi-Maskawa (CKM) matrix. Hence, the scalar sector of the SM is responsible for introducing 15 of the 19 input parameters of the theory, 13 of which are related to the Yukawa interaction between the Higgs-boson and massive-fermion (9 masses, excluding neutrinos which are strictly speaking massless in the SM, and 4 CKM parameters) while the remaining two define the scalar potential). These interactions are not of gauge nature and could be messengers of new physics (NP) that will eventually explain the hierarchy of fermion masses and the flavor dynamics of the SM at a deeper level [36].

The Higgs boson offers a special portal to new physics and, in the years since its discovery, it has become a powerful tool to stress test the quantum structure of the SM and to probe the physics landscape beyond it. This has greatly influenced the discussion about future facilities which has emphasized the need for both high-luminosity lower-energy e^+e^- colliders to obtain percent-level measurements of Higgs-boson couplings and higher-energy pp or $\mu^+\mu^-$ colliders to explore NP up to about 10 TeV.

11.1.4 *Synopsis of this review*

This review is organized as follows. Section 11.2 is a theoretical introduction to the SM Higgs boson, its properties, production mechanisms and decay rates, and a concise updated review of the corresponding theoretical predictions. The state-of-the-art of experimental measurements are described in Section 11.3, including measurements of SM Higgs-boson inclusive cross sections and branching ratios, differential cross sections and simplified template cross sections, couplings to gauge bosons and fermions, self-coupling, mass, width, and spin and CP properties. Section 11.4 reviews how the discovery of the SM Higgs boson has provided a portal to NP exploration and has greatly influenced the direct search for NP at the LHC. Finally, Section 11.5 provides a short summary and a brief outlook.

11.2 The Standard Model and the mechanism of electroweak symmetry breaking

11.2.1 *The scalar Lagrangian of the Standard Model*

In the SM [1] EWSB [2] is responsible for generating a mass for the W and Z gauge bosons rendering the weak interactions short ranged. The SM $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ gauge symmetry is spontaneously broken to $\mathrm{SU}(3)_C \times \mathrm{U}(1)_Q$ by introducing a complex scalar field (Φ), doublet of $\mathrm{SU}(2)_L$ and with hypercharge $Y = 1$, through the gauge-invariant *Higgs Lagrangian* [2],

$$\mathcal{L}_{\mathrm{Higgs}} = (D_\mu \Phi)^\dagger (D^\mu \Phi) - V(\Phi)\,, \tag{11.1}$$

where $D_\mu \Phi = (\partial_\mu + ig\sigma^a W_\mu^a/2 + ig' Y B_\mu/2)\Phi$, g and g' are the $\mathrm{SU}(2)_L$ and $\mathrm{U}(1)_Y$ gauge couplings, respectively, σ^a $(a = 1, 2, 3)$ are the Pauli matrices, Y is the hypercharge quantum number, and the potential $V(\Phi)$ reads:

$$V(\Phi) = \mu^2 \Phi^\dagger \Phi + \lambda (\Phi^\dagger \Phi)^2\,. \tag{11.2}$$

$Q = T_{3L} + Y/2$ is the conserved electric charge quantum number, with T_{3L} the eigenvalue of the diagonal generator of $\mathrm{SU}(2)_L$ (e.g. $T_{3L} = 1/2$ for up-type quarks, etc.).

The scalar field Φ can be written as

$$\Phi = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}\phi^+ \\ \phi^0 + ia^0 \end{pmatrix}, \tag{11.3}$$

where ϕ^0 and a^0 denote the doublet's CP-even and CP-odd neutral components, and ϕ^+ its complex charged component, respectively. The covariant-derivative *kinetic* term in Eq. (11.1) contains both truly kinetic terms and the interaction terms between the

except for Open Access articles.

gauge fields and the scalar field Φ. Upon spontaneous symmetry breaking it is also responsible for the W and Z gauge-boson mass terms. $V(\Phi)$ is the most general renormalizable scalar potential invariant under $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. If the quadratic term is negative ($\mu^2 < 0$), the global minimum of the $V(\Phi)$ potential occurs for a non-zero vacuum expectation value (VEV) of the field Φ such that $\langle \Phi^\dagger \Phi \rangle = v^2/2 = -\mu^2/2\lambda$. Choosing a particular field configuration that satisfies this condition breaks the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ gauge symmetry on the vacuum and induces the spontaneous breaking of the electroweak SM gauge symmetry $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ to the residual $\mathrm{U}(1)_Q$ gauge symmetry of quantum electrodynamics (QED). In particular, if one chooses the neutral component of the scalar doublet to acquire a non-zero (real) vacuum expectation value $\langle \phi^0 \rangle \equiv v = \sqrt{-\mu^2/\lambda}$, the global minimum of the theory is realized by

$$\langle \Phi \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v \end{pmatrix} . \tag{11.4}$$

The global minimum of the theory defines the ground state, and spontaneous symmetry breaking occurs since the (global and/or local) symmetry of the Lagrangian is not respected by the ground state. From the four generators of the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ SM gauge group, three are spontaneously broken on the vacuum, i.e. they do not leave the ground state invariant. This implies the existence of three massless (would-be) Goldstone bosons identified with three of the four degrees of freedom of the scalar field Φ. Using a gauge choice (*unitary gauge*) where three components of the scalar field Φ are reabsorbed by an $\mathrm{SU}(2)_L$ gauge transformation into the longitudinal components of the W and Z gauge fields, one can then parametrize the field Φ in terms of a single scalar (CP-even, spin $s = 0$) real component (H), the physical *Higgs field*, as

$$\Phi = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ H + v \end{pmatrix} . \tag{11.5}$$

This parametrization makes the physical content of the scalar Lagrangian in Eq. (11.1) completely manifest. The scalar field Φ couples to the W_μ and B_μ gauge fields associated with the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ local symmetry through the covariant derivative appearing in the kinetic term of the Higgs Lagrangian in Eq. (11.1). The neutral and the two charged massless Goldstone degrees of freedom mix with the gauge fields corresponding to the broken generators of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ and become, in the unitarity gauge, the longitudinal components of the Z and W physical gauge bosons, respectively. As a result, the Z and W gauge bosons acquire masses,

$$m_W^2 = \frac{g^2 v^2}{4} , \quad m_Z^2 = \frac{(g'^2 + g^2) v^2}{4} . \tag{11.6}$$

The fourth generator remains unbroken since it is the one associated with the conserved $\mathrm{U}(1)_Q$ gauge symmetry, and its corresponding gauge field, the photon, remains massless. Similarly, the eight color gauge bosons, the gluons, corresponding to the conserved $\mathrm{SU}(3)_C$ gauge symmetry with eight unbroken generators, also remain massless (though confined inside hadrons and mesons as the result of the asymptotic freedom behavior of Quantum ChromoDynamics (QCD)). Hence, from the initial four degrees of freedom of the Higgs field, two are absorbed by the $W^\pm$ gauge bosons, one by the Z gauge boson, and there is one remaining degree of freedom, H, that is the physical Higgs boson [2].

The Higgs boson couples to the $W^\pm$ and Z gauge-boson with strength proportional to their mass square as dictated by the minimal coupling induced by the covariant-derivative terms, namely:

$$\mathcal{L}^V_{\mathrm{Higgs}} = \delta_V \frac{2 m_V^2}{v} V_\mu V^\mu H + \delta_V \frac{m_V^2}{v^2} V_\mu V^\mu H^2 , \tag{11.7}$$

where $V = W^\pm$ or Z and $\delta_W = 1, \delta_Z = 1/2$. On the other hand, the Higgs boson is neutral under the electromagnetic interactions and transforms as a singlet under $\mathrm{SU}(3)_C$. Hence it does not couple at tree level to photons and gluons. The Higgs boson coupling to gluons [37, 38] is induced at the lowest perturbative order by a one-loop process in which H couples to a virtual $t\bar{t}$ pair (with minor contributions from the other lighter quarks). Likewise, the Higgs boson coupling to photons is also generated via loops, although in this case the one-loop graph with a virtual W^+W^- pair provides the dominant contribution [39] and it is interfering destructively with the smaller contribution involving a virtual $t\bar{t}$ pair (as such, the Higgs coupling to photons is sensitive to the relative phase of the interactions between bosons and fermions).

Finally the $V(\Phi)$ potential once expressed in terms of the Higgs-field H through Eq. (11.5) contributes the following terms to the Higgs Lagrangian:

$$\mathcal{L}^H_{\mathrm{Higgs}} = -\frac{1}{2} m_H^2 H^2 - \frac{3 m_H^2}{v} \frac{H^3}{3!} - \frac{3 m_H^2}{v^2} \frac{H^4}{4!} , \tag{11.8}$$

where one can identify the first term as the Higgs-field mass term ($m_H^2 = 2\lambda v^2$) and the remaining two terms as the H-field cubic and quartic self-interaction terms. We notice that the Higgs Lagrangian depends on two parameters, μ^2 and λ, that can be traded for any other two precisely measured quantities, such as m_H and v, which are normally chosen as input parameters in precision fits of the SM. Indeed, the Higgs-boson mass is not predicted by the SM and its precise measurement (see Sec. 11.3.7) is therefore essential to test the consistency of the SM theory. We remind that $v = (\sqrt{2} G_F)^{-1/2} \simeq 246$ GeV can be determined very precisely in terms of the so-called Fermi constant (G_F) which is measured in muon decay with a precision of 0.6 ppm [40].

11.2.2 *The Yukawa Lagrangian of the Standard Model*

A separate term in the SM Lagrangian, the so-called Yukawa Lagrangian,

$$\mathcal{L}_{\mathrm{Yukawa}} = -\hat{Y}_{d_{ij}} \bar{q}_{L_i} \Phi \, d_{R_j} - \hat{Y}_{u_{ij}} \bar{q}_{L_i} \tilde{\Phi} u_{R_j} - \hat{Y}_{l_{ij}} \bar{l}_{L_i} \Phi \, e_{R_j} + h.c., \tag{11.9}$$

introduces a renormalizable gauge invariant interaction between the scalar field Φ and all the massive fermions (quarks and leptons) of the SM and, upon spontaneous symmetry breaking, generates their mass terms. In fact, Dirac-type mass terms violates the chiral gauge symmetry of the SM that assigns left-handed and right-handed fermion fields to different $\mathrm{SU}(2)_L$ representations. In the Lagrangian above, $\tilde{\Phi} = i\sigma_2 \Phi^*$ and q_L (l_L) and u_R, d_R (e_R) are the quark (lepton) $\mathrm{SU}(2)_L$ doublets and singlets, respectively, while in each term $\hat{Y}_{f_{ij}}$ is a 3×3 matrix of couplings in family space with indices ($i, j = 1, 2, 3$) referring to the three families in the up-quark, down-quark or charged lepton sectors ($f = u, d, l$). The mass term for neutrinos is omitted, but could be added in an analogous manner to the up-type quarks when right-handed neutrinos are supplementing the SM particle content. Neutrinos (having $Q = 0$) can also acquire Majorana masses via non-renormalizable dimension-5 effective interactions with the Higgs field [41]. Because of the special nature of neutrino masses and their potential origin from the interactions with new physics well above the electroweak scale, the extension of adding right-handed neutrino fields to the SM is considered in the context of models beyond the SM. Once the Higgs field acquires a VEV, and after rotation to the fermion mass-eigenstate basis that also diagonalizes the Higgs-fermion interactions, $\hat{Y}_{f_{ij}} \to y_{f_i} \delta_{ij}$, all fermions acquire a mass given by $m_{f_i} = y_{f_i} v/\sqrt{2}$ ($i = 1, 2, 3$). Rotating to the fermion mass-eigenstate basis has two major consequences: 1) it simultaneously diagonalizes the fermion mass matrices and their couplings to the Higgs boson therefore forbidding Higgs-mediated flavor changing neutral currents, and 2) since the rotations of the up-type (U_L^u) and down-type (U_L^d) left-handed quarks are independent ($U_L^u \neq U_L^d$) rotating to the mass eigenstates gives rise to the Cabibbo-Kobayashi-Maskawa (CKM) mixing matrix in the charged gauge currents, where $V_{\mathrm{CKM}} = (U_L^u)^\dagger U_L^d$, and can therefore be considered as the origin of flavor dynamics and CP-violation in the EW sector of the SM. The Yukawa Lagrangian therefore connects some of the aspects of the SM that are most likely to offer a natural portal to new physics.

11.2.3 *The Standard Model custodial symmetry*

The SM Higgs and Yukawa Lagrangians, $\mathcal{L}_{\mathrm{Higgs}} + \mathcal{L}_{\mathrm{Yukawa}}$ of Eq. (11.1) and Eq. (11.9), are, by construction, $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ gauge invariant, but they also have an approximate global symmetry. In the limit $g' \to 0$ and $y_f \to 0$, a global $\mathrm{SU}(2)_R$ symmetry

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

emerges. This symmetry is preserved for non-vanishing Yukawa couplings provided $\hat{Y}_u = \hat{Y}_d$. Once the Higgs field acquires a VEV, both the $SU(2)_L$ and $SU(2)_R$ symmetry groups are broken but the diagonal subgroup $SU(2)_{L+R}$ remains unbroken and it is this subgroup that defines the so-called custodial symmetry of the SM [42].

In the limit $g' \to 0$, the $W^\pm$ and Z gauge bosons have equal mass and form a triplet of the $SU(2)_{L+R}$ unbroken global symmetry. Using the expressions for the W and Z gauge boson masses in term of the gauge couplings, one obtains at tree level

$$\frac{m_W^2}{m_Z^2} = \frac{g^2}{g'^2 + g^2} \equiv \cos^2\theta_W \quad \text{i.e.} \quad \rho \equiv \frac{m_W^2}{m_Z^2 \cos^2\theta_W} = 1. \tag{11.10}$$

The custodial symmetry protects the above relation from large radiative corrections. All corrections to the ρ parameter are therefore proportional to terms that break the custodial symmetry. For instance, radiative corrections involving the Higgs boson are proportional to $\sin^2\theta_W$, $\delta\rho = -11 G_F m_Z^2 \sin^2\theta_W \log(m_H^2/m_Z^2)/(24\sqrt{2}\pi^2)$, and vanish in the limit $g' \to 0$. Since $m_t \neq m_b$, there are also relevant radiative corrections generated by massive fermions. They are proportional to $m_t^2 + m_b^2 - 2(m_t^2 m_b^2)\log(m_t^2/m_b^2)/(m_t^2 - m_b^2)$ and would indeed vanish for $m_t = m_b$ [43]. Precision measurements of electroweak observables are powerful in constraining such large radiative corrections.

Given the extreme precision with which the ρ parameter has been measured experimentally, the custodial isospin symmetry is a very powerful probe of physics beyond the SM since it imposes the same strong constraints on any large radiative corrections coming from new-physics degrees of freedom.

11.2.4 *Stability of the scalar potential of the Standard Model*

Quantum effects determine the evolution of the parameters of the SM and can therefore affect the shape of the scalar potential and the stability of the SM vacuum (for a recent review on the topic see [44]). Proving absolute stability versus metastability depends in a very sensitive way on the values of the Higgs-boson mass, the top-quark mass, and the strong coupling constant, their uncertainties, and correlations [45]. In this respect, the discovery of the Higgs boson with $m_H \approx 125$ GeV has far reaching consequences within the SM framework.

For the value of Higgs-boson mass experimentally measured, the EW vacuum of the Higgs potential is most likely metastable [45], although this is influenced by new physics that may exists below the Planck scale. The high-energy evolution of λ shows that it becomes negative at energies $\Lambda = \mathcal{O}(10^{11})$ GeV (even though λ could remain positive till higher energy, maybe all the way to the Planck scale, if the top quark mass exceeds its current measured value by 3σ). When this occurs, the SM Higgs potential develops an instability and the long term existence of the EW vacuum is challenged. This behavior may call for new physics at an intermediate scale before the instability develops, i.e., below M_{Planck}, even though new physics at M_{Planck} could influence the stability of the EW vacuum and possibly modify this conclusion [46]. The consequences of the instability of the EW vacuum on high-scale inflation have been discussed in Ref. [47]. It was also noticed that Higgs field fluctuations during inflation could seed the formation of primordial black holes, possibly making up the Dark Matter relic abundance [48] or they could produce a stochastic background of gravitational waves with characteristic structures [49], offering a probe of the EW vacuum near criticality.

The lifetime of the EW metastable vacuum is determined by the rate of quantum tunneling from this vacuum into the true vacuum of the theory (for the most recent computation of the EW vacuum lifetime within the SM, see Ref. [44, 50, 51]).

Within the SM, the running of the Higgs self coupling slows down at high energies with a cancellation of its β-function at energies just one to two orders of magnitude below the Planck scale [52]. This slow evolution of the quartic coupling is responsible for saving the EW vacuum from premature collapse. It might also help the Higgs boson to play the role of an inflaton [53] (see, however, Ref. [54] for potential issues with this Higgs-boson-as-an-inflaton idea).

11.2.5 *Production and decay modes of the Standard-Model Higgs boson*

Production and decay modes of the SM Higgs boson (H) can be calculated within the Standard Model including quantum corrections. This section briefly reviews the state-of-the-art of SM predictions for Higgs-boson production cross sections at hadron colliders and discusses the main characteristics of Higgs-boson production at lepton colliders. The most updated predictions for the SM Higgs-boson decay branching ratios and total decay width are also presented. In-depth studies of the corresponding theoretical uncertainties are available in the literature and will be referred to in the following as needed. A summary of all most recent measurements of SM Higgs-boson production and decay rates by the LHC experiments is the subject of Sec. 11.3.

11.2.5.1 *Standard-Model Higgs-boson production at hadron colliders*

The main production mechanisms of the SM Higgs boson at the Tevatron collider and the LHC are gluon fusion ($gg \to H$), vector-boson fusion ($qq \to qqH$, for both quarks and antiquarks), associated production with a gauge boson ($q\bar{q}^{(\prime)} \to ZH/WH$ and $gg \to ZH$), associated production with a $t\bar{t}$ pair ($q\bar{q}, gg \to t\bar{t}H$) or $b\bar{b}$ pair ($q\bar{q}, gg \to b\bar{b}H$), and associated production with a single top quark ($bq \to tH + q'$). [2] Examples of Feynman diagrams for each production mode are illustrated in Figures 11.2(a)–(f).

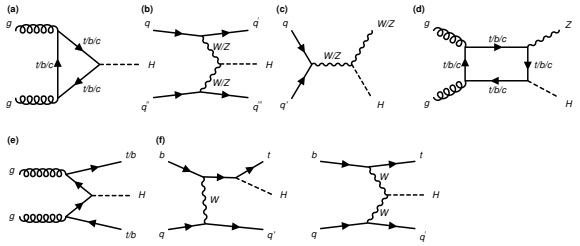

Figure 11.2: Examples of Feynman diagrams for Higgs-boson production via (a) gluon fusion, (b) vector-boson fusion, and associated production with (c)-(d) vector bosons, (e) top- or bottom-quark pairs, or (f) a single top quark.

The total cross sections for the main production processes of a SM Higgs boson with $m_H = 125$ GeV in pp collisions (LHC) as a function of $\sqrt{s}$, the center-of-mass energy, are summarized in Fig. 11.3 (left) [55].

The bands indicate the residual theoretical uncertainties based on the studies presented in Refs. [56–60] and correspond to the perturbative order of QCD and EW corrections indicated on each band. The corresponding results for $\sqrt{s} = 7$, 8, 13, 13.6, and 14 TeV are summarized in Table 11.1 which has been updated with results that will be published in Report 5 of the LHC Higgs Working Group. A detailed discussion, including uncertainties in the theoretical calculations due to missing higher-order effects and experimental uncertainties on the determination of SM parameters involved in the calculations, can be found in Refs. [56–60]. These references also contain state-of-the-art discussions on the impact of PDF uncertainties, QCD scale uncertainties, and uncertainties due to different procedures for including higher-order corrections matched to parton shower simulations, as well as uncertainties due to hadronization and parton-shower effects.

More recent improved calculations and the corresponding accuracy will be highlighted in the following discussion of individual production modes, where the status of the corresponding differential distributions is also illustrated.

[2] The order in which the SM Higgs-boson production modes have been listed here reflects their cross-section hierarchy at the LHC for $\sqrt{s} = 13$ TeV. The relative importance of various production modes is different between pp and $p\bar{p}$ colliders and depends on the center-of-mass energy.

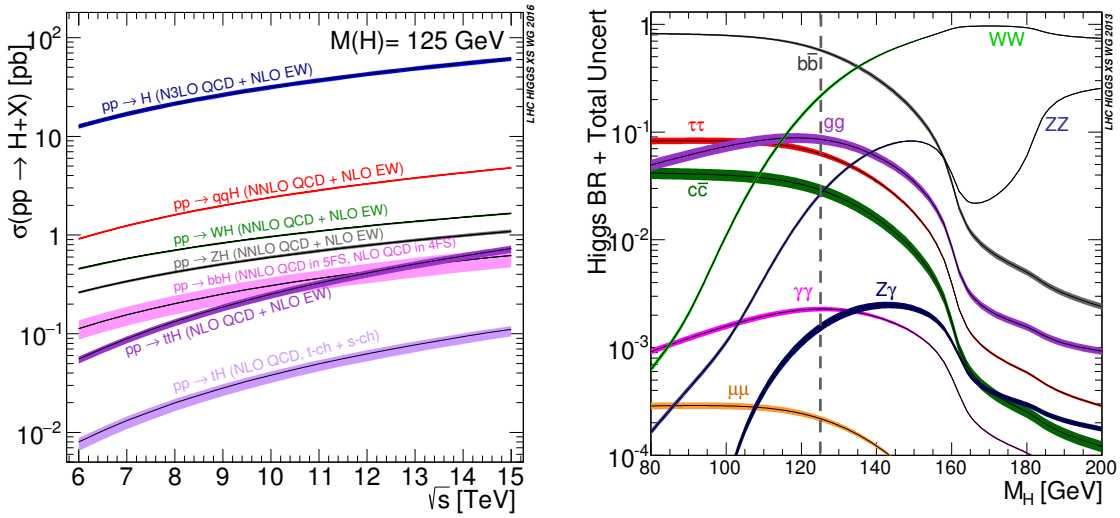

Figure 11.3: (Left) The SM Higgs boson production cross sections as a function of the center-of-mass energy, $\sqrt{s}$, for pp collisions [55]. The VBF process is indicated here as qqH. (Right) Branching ratios for the main decays of a SM-like Higgs boson in the low mass region, including near $m_H = 125\,\text{GeV}$ [56,57]. The theoretical uncertainties are indicated as bands.

i. *Gluon fusion production mechanism*

At high-energy hadron colliders, the Higgs boson production mechanism with the largest cross section is the gluon-fusion process (ggF), $gg \to H + X$, mediated by the exchange of a virtual heavy quark (see Fig. 11.2-a), where the top quark is dominant due to its large Yukawa coupling [61]. Perturbative corrections to the gluon-fusion process are extremely important and have been studied in detail with the goal of reducing the theoretical uncertainty to a few percent, as needed to realize the HL-LHC Higgs-physics program. Including the full dependence on the quark and Higgs boson masses, the cross section has been calculated at the next-to-leading order (NLO) α_s in Refs. [62,63]. To a very good approximation, the leading top-quark contribution can be evaluated in the limit $m_t \to \infty$ by matching the SM to an effective theory [64]. The gluon-fusion amplitude is then evaluated from an effective Lagrangian containing a local $HG^a_{\mu\nu}G^{a\,\mu\nu}$ operator [37,38]. In this approximation, the cross section has been first calculated at next-to-next-to-leading order (NNLO) [65] and is now known at next-to-next-to-next-to-leading order in the α_s expansion (N3LO QCD) [66,67]. Recently, first building blocks towards the next-to-N3LO calculation (N4LO) have appeared in the literature [68–71]. Public tools such as `iHixs` [72] and `SusHi` [73] allow to derive state-of-the-art predictions for ggF inclusive production in the $m_t \to \infty$ approximation[3].

The validity of the effective theory with infinite m_t is greatly enhanced by rescaling the result by the exact LO result: $\sigma = (\sigma^{\text{LO}}_{m_t}/\sigma^{\text{LO}}_{m_t=\infty}) \times \sigma_{m_t=\infty}$ [57]. The large top-quark mass approximation, after this rescaling of the cross section, yields a NNLO QCD result that has been found to approximate the full NNLO total cross section to percent level accuracy [65], as confirmed by the the exact NNLO QCD calculation including full top-quark mass dependence [75]. Contributions from lighter quarks propagating in the loop are suppressed proportionally to m_q^2/m_H^2. Their leading contribution arise from the interference with top-quark induced gluon fusion, and can be enhanced by logarithms of m_q^2/m_H^2 [76–78]. Finite-mass effects from bottom-top quark interference at NNLO in QCD have been recently calculated [79] including their dependence on the light-quark renormalization and flavor scheme [80]. These studies have reduced the residual 6% theoretical uncertainty of the N3LO results by more than a third.

The LO contribution and NLO QCD corrections [64] amount to about 80% of the total N3LO QCD cross section. The NNLO QCD corrections [81] further enhance the cross section by approximately 30% of the LO plus NLO result (at $\mu_f = \mu_r = m_H/2$). At N3LO QCD, the perturbation series is rather stable with a mere enhancement of 3% with respect to the NNLO QCD total cross section, and a central value quite insensitive to threshold resummation effects with the scale choice $\mu_f = \mu_r = m_H/2$ [57,66,67,82,83]. EW radiative corrections have been computed at NLO and increase the LO cross section by about 5% for $m_H \simeq 125\,\text{GeV}$ [84]. Mixed QCD-EW corrections have been intensively investigated beyond initial studies obtained in either limit of heavy [85] or massless [86] gauge bosons, and first estimates including most relevant building blocks have been calculated, reducing the residual uncertainties from mixed QCD-EW corrections to less than 1% [87]. The residual PDF uncertainty, estimated to contribute 1-2% to the total theoretical uncertainty, relies on NNLO or approximate N3LO (aN3LO) PDF sets [88–90], and, given the shift observed when using aN3LO versus NNLO PDF, may have been underestimated. Up-to-date values of the N3LO QCD+NLO EW predictions for ggF production of a SM Higgs boson with $m_H = 125$ GeV for different LHC center-of-mass energies are collected in Table 11.1, from an update of the results reported in Ref. [57] to which we refer for a comprehensive discussion of input parameters and residual uncertainties.

Besides considering the inclusive Higgs boson production cross section at the LHC, it is crucial to study differential distributions in order to probe the properties of the Higgs boson in regions that could be particularly sensitive to new physics effects. The Higgs boson rapidity distribution has been computed in the $m_t \to \infty$ limit at the N3LO QCD order in Ref. [91] and fully differential N3LO QCD predictions for Higgs production in gluon fusion have been obtained by combining N3LO QCD predictions for the Higgs rapidity distribution with NNLO QCD predictions for H+jet [92, 93]. First results for the prediction of H+jet at N3LO have been presented in Ref. [94]. Finite quark-mass effects in the Higgs-boson p_T distribution significantly alter its shape. At NLO QCD both top-quark mass effects [95–97] and bottom-quark mass [76, 77, 98] as well as top-bottom interference effects [99] are known in an approximation based on expansions in the quark mass. Beyond NLO, the first differential calculation of NNLO QCD corrections with full top-quark mass dependence, consistently matched to parton shower has been presented in Ref. [100]. Experimental analyses often impose cuts on the kinematics of final-state products in order to improve the signal-to-background ratio. To provide a more exclusive account of Higgs-boson production, NNLO fully differential calculations have been interfaced with parton-shower event generators in various frameworks [101–103]. Using soft-collinear effective theory, large

[3] In `iHixs`, the top-quark mass dependence is exact at NLO, and only the NNLO is calculated in the $m_t \to \infty$ approximation

Table 11.1: The SM Higgs boson production cross sections for $m_H = 125\,\text{GeV}$: 1) at the Tevatron ($*$), corresponding to $p\bar{p}$ collisions at center-of-mass energy $\sqrt{s} = 1.96$ TeV, and 2) at the LHC, corresponding to pp collisions at center-of-mass energies $\sqrt{s} = 7, 8$ TeV (Run 1), 13 TeV (Run 2), 13.6 TeV (Run 3), and 14 TeV (Run 4). The predictions for the Tevatron energy are the ones used in Ref. [74], while the ones for the LHC energies are taken from Refs. [55–60] with updates that will be published in the Report 5 of the LHC Higgs Working Group. The uncertainties are estimated assuming no correlation between α_S and PDF uncertainties. Parametric uncertainties are combined linearly with the rest of theoretical uncertainties. A detailed discussion of the estimated uncertainties is given for each case in the references above.

fiducial power corrections induced by fiducial cuts have been resummed at N3LO+N3LL′ QCD accuracy, i.e. at next-to-next-to-next-leading-log (N3LL), incorporating the complete $\mathcal{O}(\alpha_s^3)$ singular structure for $q_T \to 0$ allowing one to consistently match to N3LO QCD [83]. This allows for the direct comparison with fiducial measurements and explore different fiducial cuts to suppress fiducial effects. At the same time, resummed calculation are often less flexible and less transparent than fixed-order ones. Given the level of precision currently reached in fixed-order calculations, recent studies for $H \to \gamma\gamma$ in gluon fusion [104] motivate revisiting the choice of standard fiducial cuts and design new ones that could at the same time maximize signal significances and minimize experimental and perturbative systematics, to fully retain the power and conceptual simplicity of fixed-order calculations.

In addition progress has been made to improve the calculation of the Higgs-boson production cross section with a jet veto (the "0-jet bin" or in the presence of a veto bounding the transverse momentum of the hardest accompanying jet) [105], reaching NNLL accuracy matched to N3LO QCD. These accurate predictions for the jet-veto cross section are required, e.g., to suppress the $t\bar{t}$ background in the $H \to WW$ channel [106, 107], and to accurately quantify Higgs-boson production in specific regions of phase space.

ii. *Vector-boson fusion production mechanism*

The SM Higgs boson production mode with the second-largest cross section at the LHC is vector-boson fusion (VBF). At the Tevatron collider, VBF also occurred, but for $m_H = 125\,\text{GeV}$ had a smaller cross section than Higgs boson production in association with a W or Z boson. Higgs boson production via VBF, $qq \to qqH$, proceeds by the scattering of two (anti-)quarks, mediated by t- or u-channel exchange of a W or Z boson, with the Higgs boson radiated off the weak-boson propagator (see Fig. 11.2-b). The scattered quarks give rise to two hard jets in the forward and backward regions of the detector with a large rapidity gap [108]. Because of the color-singlet nature of the weak-gauge boson exchange, gluon radiation from the central-rapidity regions is strongly suppressed. These characteristic features of VBF processes can be exploited to distinguish them from overwhelming QCD backgrounds, including gluon-fusion induced Higgs boson + 2 jet production, and from s-channel WH or ZH production with a hadronically decaying weak gauge boson. After the application of specific selection cuts, the VBF channel provides a clean environment, not only for the Higgs boson searches originally performed, but also for the subsequent determination of Higgs boson couplings at the LHC.

The cross-section is known at N3LO QCD at the inclusive level [109] and at NNLO enforcing the VBF cuts [110–112]. Uncertainties have been estimated to be quite small (permille) at the inclusive level but can be larger (percent) at differential and fiducial level. However, this result is obtained in the DIS/factorized approximation [113] where the fusing gauge bosons are emitted from the two quark legs independently. The leading non-factorizable contributions with two forward jets have been estimated [114, 115] and the impact of non-factorizable effects have been studied in Ref. [116]. They give some corrections, also of the order of few permille, to inclusive quantities, but they are an order of magnitude larger for differential observables. Overall, the residual uncertainty is of the order of a few percent but is quite sensitive to the tagging jet cuts and jet radius modeling [117]. VBF production followed by $H \to b\bar{b}$ or $H \to W^+W^-$ with the W bosons decaying leptonically have been studied at NLO QCD in Ref. [118]. Extensive studies on VBF at fixed order and with parton shower matched computations can be found in Ref. [119], and more recently in Ref. [120]. In addition, EW corrections have been calculated and the VBF process is known at NLO QCD+EW order for some time [121, 122]. When EW corrections are considered, a separation of the $H + 2$ jets production process into VBF and HV ($V = W, Z$) contributions is no longer straightforward and recent studies [123] have implemented the NLO QCD+EW calculation of $H + 2$ jets with parton-shower including both VBF and HV topologies. A state-of-the-art review of VBF can be found in Ref. [124].

iii. *WH and ZH associated production mechanism*

The next most relevant Higgs boson production mechanisms are associated production with W and Z gauge bosons (see Fig. 11.2-c). The cross sections for the associated production processes, $pp \to VH + X$, with $V = W^\pm, Z$ receive contributions at NLO from NLO QCD corrections to the Drell–Yan cross section [125, 126] and from NLO EW corrections. The latter, unlike the QCD corrections, do not respect the factorization into Drell–

Yan production since there are irreducible box contributions already at one loop [121,127]. At NNLO QCD, while Drell–Yan-like contributions give the bulk of the corrections to WH production, corrections to ZH production consist of both Drell–Yan-like [128] and gluon-gluon induced contributions that do not involve a virtual Z gauge boson but are such that the Z gauge boson and H boson couple to gluons via top-quark loops (see Fig. 11.2-d) [129]. NLO QCD virtual corrections to the partonic cross section for $gg \to ZH$, in the high-energy and large top mass limits were calculated in Ref. [130], while NLO QCD corrections with full top-quark mass dependence have obtained in Ref. [131, 132], and an updated review can be found in Ref. [133]. In addition, WH and ZH production receive non Drell–Yan-like corrections in the $q\bar{q}'$ and $q\bar{q}$ initiated channels, respectively, at the NNLO level in QCD, where the Higgs boson is radiated off top-quark loops [134]. The full QCD corrections up to NNLO order, the NLO EW corrections and the NLO corrections to the gluon-gluon channel are available in `VH@NNLO` [135]. NNLO QCD corrections to $pp \to WH$+jet are important for signal modeling. NLO corrections to the cross section inclusive in the number of jets show excellent convergence while NNLO QCD corrections to exclusive single jet cross section are much more significant [136]. More recently, the inclusive cross section for associated Higgs boson production with a massive gauge boson has been determined up to N3LO QCD too [137].Recently, the inclusive cross section for associated Higgs-boson production with a massive gauge boson has been determined up to N3LO QCD [137].

As neither the Higgs boson nor the weak gauge bosons are stable particles, their decays also have to be taken into account. Providing full kinematical information for the decay products can furthermore help in the suppression of large QCD backgrounds. Differential distributions for the processes $pp \to WH \to \bar{\nu}_\ell \ell H$ and $pp \to ZH \to \ell^+\ell^- H/\nu_\ell \bar{\nu}_\ell H$, including NLO QCD and EW corrections, have been presented in Ref. [138]. The NNLO QCD corrections to differential observables for WH production at the LHC, including the leptonic decays of the W boson and the decay of the Higgs boson into a $b\bar{b}$ pair, are presented in Ref. [139]. Full NNLO QCD results for both the production and decay are available [140] and show a large impact of radiation from the final-state bottom quarks. Calculations at the same level, including also the ZH process have been performed [141]. The WH production mode has also been matched to a parton shower at NNLO QCD accuracy [142]. The WH and ZH production modes, especially in the boosted regime, provide a relatively clean environment for studying the decay of the Higgs boson into bottom quarks [143]. Bottom mass effects have been computed at NNLO [144, 145] and tend to increase the rates by 6-7%.

iv. *Higgs boson production in association with $t\bar{t}$*

Higgs boson radiation off top quarks, $pp \to t\bar{t}H$ (see Fig. 11.2-e), provides a direct probe of the top-Higgs Yukawa coupling. The LO cross section for this production process was computed in Ref. [146]. Later, the NLO QCD [147] and NLO EW corrections [148] were evaluated yielding a moderate increase in the total cross section of at most 20%, but significantly reducing the scale dependence of the inclusive cross section. The EW corrections can be enhanced by large electroweak Sudakov logarithms in particular in the boosted regime often used in the phenomenological analyses [149]. The resummation of soft and Coulomb gluon corrections is presented in Ref. [150] while the resummation of soft gluon contributions close to the partonic kinematical threshold are considered in Refs. [151] to reach a result at NLO+NNLL QCD order. Full off-shell calculations with decaying top quarks are computed at NLO QCD [152] and NLO QCD + EW [153] order, respectively. The fixed-order NLO QCD calculation has been interfaced with the standard parton shower Monte-Carlo generators in Refs. [154], allowing an accurate description of the $t\bar{t}H$ signal, from the energy scale of the hard scattering to the hadronization energy scale. These programs provide the most flexible tools to date for the computation of differential distributions, including experimental selection cuts and vetoes on the final-state particles and their decay products.

The total theoretical uncertainty has been further reduced from 10-15% to about 4% at 13 TeV center-of-mass energy by the first approximate NNLO QCD calculation [155, 156] combined with NLO EW corrections in a fully differential comprehensive study of this production mode [157]. These results do not yet include the two-loop virtual corrections, but they evaluate them using two different methods that yield consistent results within their respective uncertainties. The first method relies on a soft Higgs-boson factorization formula, while the second is based on a high-energy expansion in the small top-quark mass limit. The missing two-loop virtual contributions, which are essential to have a consistent NNLO calculation of $pp \to t\bar{t}H$, are quite challenging and at the cutting edge of current technologies due to the presence of several mass scales (m_H, m_t, plus five kinematic invariants of the $2 \to 3$ process). Partial results for well-defined gauge-invariant classes of leading-color two-loop QCD virtual amplitudes have been calculated [158–160] and progress is ongoing to complete the remaining building blocks. For a recent review of the state-of-the-art of theoretical predictions for $pp \to t\bar{t}H$ production see Ref. [161].

Also recently, the fragmentation and splitting functions for the production of a Higgs boson have been computed at order $y_t^2\alpha_s$ and they can be used in the fragmentation region to compute differential cross sections with arbitrary top-quark and Higgs-boson masses directly from the results in the massless limit [162].

Apart from the case in which $H \to \gamma\gamma$, the exploitation of the $t\bar{t}H$ channel requires a proper description of the background, in particular $t\bar{t}b\bar{b}$, which exhibits an enhancement from shower effects, see Ref. [57] for a detailed discussion. Off-shell effects in $t\bar{t}b\bar{b}$ have been studied in Ref. [163]. Besides the $H \to b\bar{b}$ decay mode, the focus has been broadened and other modes have been studied, in particular the multilepton channel (which combines $H \to \tau^+\tau^-$, $H \to WW^*$, and $H \to ZZ^*$ with subsequent decay to leptons). Other backgrounds such as $t\bar{t}W$ and $t\bar{t}Z$ have also become relevant and intensively analyzed.

v. *Other single Higgs-boson production mechanisms at the LHC*

The Higgs boson production in association with a single top quark, though subdominant, can bring valuable information on the sign of the top Yukawa coupling. This is due to an almost totally destructive interference between two large contributions, one where the Higgs boson couples to a space-like W boson and the other where it couples to the top quark (see Fig, 11.2-f). This process has been computed at NLO QCD in a five-flavor scheme [164] and amounts to about 90 fb at $\sqrt{s} = 14$ TeV (with the opposite sign of the top Yukawa coupling, the cross section increases by one order of magnitude while the cross section for associated production with a pair of top quarks is unaffected). Recently, the tHj (and tZj) process has been computed at NLO QCD+EW accuracy [165]. The NLO EW correction is found to be within the NLO QCD theory uncertainties if the 4 vs 5 flavor scheme uncertainty is taken into account. The EW corrections reduce the total cross section by 3-4%.

The inclusive Higgs boson production in association with a pair of bottom quarks ($b\bar{b}H$) has been computed at the N3LO QCD order in the 5-flavor scheme [166][4], while the production with one/two b-jets, defined by specific kinematic cuts, is known respectively at NLO QCD in the 4-flavor scheme and at NNLO QCD in the 5-flavor scheme [167, 168]. Recently, full-color two-loop amplitudes for the $pp \to b\bar{b}H$ have been computed [169], extending previous leading-color results [170]. They contribute at NNLO QCD to the production of a Higgs boson with 2 tagged b jets, and at N3LO QCD to the production with 1 tagged b jet. The first NNLO calculation of $b\bar{b}H$ production in the 4FS interfaced with parton-shower has been recently presented in Ref. [171].

The coupling of the Higgs boson to a bottom quark is suppressed in the SM by the bottom-quark mass over the Higgs VEV, m_b/v, implying that associated production of a SM Higgs boson with bottom quarks is small at the LHC. Yet, at high energy, large logarithms are present and need to be resummed, leading to

[4] The Higgs boson production in association with charm quarks at N3LO QCD can also be obtained from the same calculation modulus a change of parton densities. NNLO QCD results for the cross section as a function of m_H can be found in [57].

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

an enhancement of the inclusive cross section. At $\sqrt{s} = 14\,\text{TeV}$, the $b\bar{b}H$ cross section can be as large as 550 fb, still two orders of magnitude below the ggF production cross section. Furthermore, the overwhelming ZH and VBF backgrounds (at the inclusive but also differential levels) make it challenging to extract a genuine bottom-quark Yukawa signal in a traditional cut-based analysis [172]. Innovative machine-learning techniques are a promising avenue to obtain information complementary to the ones extracted from $gg \to h \to b\bar{b}$, in particular for what concerns the phase of the bottom-quark Yukawa coupling [173]. In a two Higgs doublet model or a SUSY model, which will be discussed in Section 11.4, this coupling is proportional to the ratio of neutral Higgs boson vacuum expectation values, $\tan\beta$, and can be significantly enhanced for large values of this ratio. Consequently, the $b\bar{b}H$ mode can even become the dominant production process for the Higgs boson, unlike in the SM.

The Higgs boson production in association with charm quarks is also known at NNLO QCD and its cross section is approximately 85 fb at $\sqrt{s} = 13\,\text{TeV}$ [57].

vi. *Double Higgs boson production at the LHC*

The main interest in the double Higgs-boson production is that it can provide invaluable information on the Higgs potential. In particular, it gives access to the Higgs-boson trilinear self coupling. The dominant production is via ggF $gg \to HH$ (slightly more than 33 fb at 13 TeV) which accounts for more than 90% of the total inclusive cross-section. The sub-leading production mechanisms are VBF $HHjj$ (around 1.7 fb at 13 TeV), HHW^+ (0.33 fb), HHW^- (0.17 fb), HHZ (0.36 fb), and $t\bar{t}HH$ (0.8 fb).[5] Examples of ggF and VBF double-Higgs production are illustrated in Fig. 11.4, where the possibility of anomalous couplings parametrized by κ_X rescaling factors have also been indicated for future reference (see Sec. 11.3.5.1).

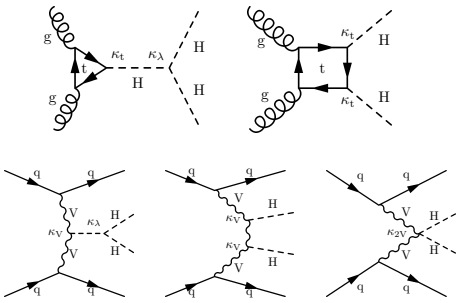

Figure 11.4: Feynman Diagrams for double-Higgs production in proton-proton collisions for ggF (top) and VBF (bottom) production. κ_X factors denote ratios of measured to SM couplings that will be introduced in the discussion of Higgs-boson couplings in Sec. 11.3.5.1.

The fixed order QCD corrections to ggF double-Higgs production, computed in the infinite top mass limit, are large, typically doubling the cross section from LO to NLO QCD [174], further enhancing it by 20% and reducing the scale uncertainty by a factor 2-3 from NLO to NNLO QCD [175], with a milder increase of order 3% at N3LO [176]. The complete NLO corrections with all top-quark mass effects has also become available numerically [177], revealing a differential K-factor much less flat than predicted in the large top-quark mass approximation. The non-trivial dependence of the results on the renormalization scheme and scale for the top-quark mass has been recognized as one of the main sources of uncertainty and progress has been made in identifying the logarithmic terms responsible for such dependence [178]. In terms of accounting for the top-quark mass dependence, the most complete results so far have been obtained in Ref. [179]. These results include the full top-quark mass dependence at NLO and in the NNLO QCD real radiation matrix elements, and and form the basis of the current recommendation of the LHC Higgs Working Group. A definite assessment of the scale uncertainty would warrant a proper NNLO computation that remains out of reach for the moment, although considerable progress towards it has been recently made [180–182]. The current state-of-the-art for Higgs-pair production via ggF is N3LO+N3LL QCD including full top-quark mass dependence at NLO QCD, with a predicted cross section at 13 TeV of

$$\sigma(gg \to HH)^{\text{N3LO}+N3LL}_{\text{ggF}} = 33.47\,^{+0.88\%}_{-0.85\%}\,\text{fb}. \tag{11.11}$$

Among the subleading production modes, double-Higgs production in VBF can be used to derive bounds on both the triple Higgs-boson coupling and the quartic HHVV coupling. Although the rate is quite small, the experiments have been performing searches including the VBF channel [183, 184]. The process is known at N3LO QCD [185] and NLO EW [186]. While the NNLO QCD [111, 187, 188] and NLO-EW corrections are quite sizable in some kinematic regions, the N3LO QCD are small. NNLO-QCD non-factorizable corrections have been calculated and shown to be small [116]. VBF di-Higgs production has also been interfaced with parton-shower at NLO QCD in multiple frameworks [189, 190].

With a small inclusive cross section and a difficult signal vs background discrimination, the double-Higgs boson production remains a challenging channel to probe and will greatly benefit from the high-luminosity run of the LHC. Nevertheless, as discussed in Section 11.3.6, by combining various decay modes, and using full Run 2 and partial Run 3 data, both ATLAS and CMS have already been able to constrain the trilinear Higgs-boson coupling via double-Higgs production beyond expectations. Continuous theoretical progress will therefore be necessary and timely.

11.2.5.2 *Standard-Model Higgs-boson production at lepton colliders*

Recently Higgs-boson production at lepton colliders has been a major component of the discussion for future colliders [191, 192]. For a more detailed discussion of Higgs boson production properties at lepton colliders see for example Refs. [193–198].

Lepton colliders, both e^+e^- and $\mu^+\mu^-$, provide alternative mechanisms of Higgs-boson production compared to hadron colliders. The leading production modes depend on the center-of-mass energy and the type of collider.

The dominant Higgs-boson production cross sections at an e^+e^- collider are from the Higgs-strahlung process [37, 199], $e^+e^- \to ZH$, and the WWfusion process [200], $e^+e^- \to \bar{\nu}_e\nu_e W^*W^* \to \bar{\nu}_e\nu_e H$. The cross-section for the Higgs-strahlung process scales as the inverse of the collision center-of-mass squared energy, s, and is predominant at lower energies, while the cross-section for the WW-fusion process scales as $\ln(s/m_H^2)$ and dominates at higher energies [201]. The ZZ-fusion mechanism, $e^+e^- \to e^+e^-Z^*Z^* \to e^+e^-H$, also contributes to the Higgs boson production, with a cross-section suppressed by an order of magnitude with respect to that of WW-fusion. The process $e^+e^- \to t\bar{t}H$ [202] becomes important for $\sqrt{s} \geq 500\,\text{GeV}$. e^+e^- lepton colliders with energies between 350 and 500 GeV can provide an absolute measurement of the $e^+e^- \to ZH$ cross section independent of the Higgs-boson detailed properties by counting events with an identified Z boson and a recoiling mass against the Z that clusters around the Higgs-boson mass. This allows for a model-independent measurement of the HZZ coupling. Combined with the measurement of the $H \to ZZ$ branching ratio, this allows for an indirect measurement of the Higgs-boson width.

All e^+e^- Higgs-production modes are known at NLO of SM interactions (QCD+EW). First results for two-loop EW corrections to $e^+e^- \to ZH$ have been calculated in Refs. [203, 204]. In order to match the experimental precision expected at potential future e^+e^- colliders all processes will have to be known at NNLO, SM input parameters will have to be known with higher precision, and matching schemes between EW corrections and QED parton shower event generators will have to be fully developed [205, 206]. In this respect, interesting progress has been made recently [207]

[5] Results for the subleading modes are from the wiki-page of WG4 of the LHC Higgs Working Group (`https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCHWGHH`.

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is subject to Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com except for Open Access articles.

to accurately account for beamstrahlung and initial state radiation using the factorization approach primarily developed for hadron colliders and this method is being implemented in Monte Carlo event generators.

Muon colliders running at low-energy can scan the Higgs-boson threshold around $m_H = 125$ GeV and measure the Higgs-boson line shape through $\mu^+\mu^- \to H$ s-channel Higgs-boson production. This could give direct access to a precision absolute measurement of the Higgs-boson width and of the muon Yukawa coupling, as well as other couplings entering in the decay of the resonant Higgs boson. Most recently, the focus has shifted to multi-TeV muon collider scenarios with center-of-mass energies between 3 and 10 TeV. In this regime, the virtual electroweak gauge boson content of the muon beam becomes relevant and vector-boson, as W-boson fusion $\mu^+\mu^- \to H\nu_\mu\bar{\nu}_\mu$ and Z-boson fusion $\mu^+\mu^- \to H\mu^+\mu^-$, dominates by several orders of magnitude over off-shell production and associated production ($\mu^+\mu^- \to ZH$ or $\mu^+\mu^- \to t\bar{t}H$).

11.2.5.3 *Standard-Model Higgs-boson decays: branching ratios and total width*

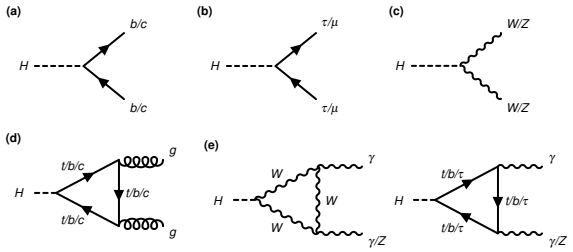

Figure 11.5: Feynman diagrams for the Higgs-boson decays into (a) a pair of quarks, (b) a pair of charged leptons, (c) a pair of vector bosons, (d) a pair of gluons, (e) a pair of photons or a Z boson and a photon.

For the understanding and interpretation of the experimental results, the computation of all relevant Higgs boson decay widths is essential, including an estimate of their uncertainties and, when appropriate, the effects of Higgs boson decays into off-shell particles with successive decays into lighter SM ones.

The most relevant decay modes of a SM Higgs boson are illustrated in Fig. 11.5(a)-(e) and the corresponding branching ratios as a function of m_H, for m_H up to 200 GeV, are shown in Fig. 11.3 (right), including the most recent theoretical uncertainties. It is interesting to notice how a Higgs boson in the low-mass region allows for the exploration of its couplings to many SM particles through a variety of available decay channels. For the SM Higgs boson with a mass of about 125 GeV the dominant decay modes are $H \to b\bar{b}$ and $H \to WW^*$, followed by $H \to gg$, $H \to \tau^+\tau^-$, $H \to c\bar{c}$ and $H \to ZZ^*$. With much smaller rates follow the Higgs boson decays into $H \to \gamma\gamma$, $H \to Z\gamma$ and $H \to \mu^+\mu^-$. Since the decays into pairs of gluons or photons, and $Z\gamma$ are loop induced, they provide indirect information on the Higgs-boson couplings to WW, ZZ and $t\bar{t}$ in different combinations. They are also sensitive to possible NP contributions running in the loop.

Theoretical results for the branching ratios of the most relevant decay modes of the SM Higgs boson with $m_H = 125$ GeV are listed in Table 11.2. The uncertainties in the branching ratios include the missing higher-order corrections in the theoretical calculations as well as the errors in the SM input parameters, in particular fermion masses and the QCD gauge coupling, involved in the decay. In the following the state-of-the-art of the theoretical calculations compiled by the LHC Higgs Working Group [55] will be discussed and the reader is referred to Refs. [56–59, 208] for more details.

The evaluation of the radiative corrections to the fermionic decays of the SM Higgs boson are implemented in HDECAY [209] at different levels of accuracy. The computations of the $H \to b\bar{b}$ and $H \to c\bar{c}$ decays include the NLO QCD corrections with full mass effects and up to N4LO QCD corrections with leading mass corrections, resulting in a corresponding scale dependence of about 0.1% [210, 211]. The top-induced QCD corrections, which are related to interference effects between $H \to gg$ and $H \to q\bar{q}$, are known at NNLO in the limit of heavy top quarks and light bottom quarks [211–213] and more recently including the full mass dependence [214–217] with first results at N3LO [218]. Both the electroweak corrections to $H \to b\bar{b}$, $c\bar{c}$ as well as $H \to \tau^+\tau^-$ are known at NLO [219] providing predictions with an overall accuracy of about 1–2% for $m_H \simeq 125$ GeV.

The loop induced decays of the SM Higgs boson are known fully at NLO and partially beyond that approximation. For $H \to gg$, the N4LO QCD corrections calculated in the limit of heavy top quarks [220] have reduced the uncertainty from scale dependence to about 0.6% from the 3% uncertainty of the N3LO prediction [63, 221]. For $H \to \gamma\gamma$, the full NLO QCD corrections are available [63, 222] and the three-loop QCD corrections have also been evaluated [223]. The NLO electroweak corrections to $H \to gg$ and $H \to \gamma\gamma$ have been computed in Ref. [224]. All these corrections are implemented in `HDECAY` [209]. For $m_H \simeq 125$ GeV, the overall impact of known QCD and EW radiative effects turns out to be well below 1%. In addition, the contribution of the $H \to \gamma e^+ e^-$ decay via virtual photon conversion has been computed in Ref. [225]. The partial decay width $H \to Z\gamma$ is only implemented at LO in `HDECAY`, including the virtual W, top-, bottom-, and τ-loop contributions. The NLO QCD corrections have been calculated in Refs. [226–228] leaving a residual estimated uncertainty of about 1.7%. The theoretical uncertainty due to unknown electroweak corrections is estimated to be less than 5%, an accuracy that will be hard to achieve in the measurement of this process at the LHC.

Table 11.2: The branching ratios and the relative uncertainty for a SM Higgs boson with $m_H = 125$ GeV. The uncertainties in the branching ratios include the missing higher-order corrections in the theoretical calculations as well as the errors in the SM input parameters, in particular fermion masses and the QCD gauge coupling, involved in the decay [55–57].

Decay channel	Branching ratio	Rel. uncertainty
$H \to b\bar{b}$	5.82×10^{-1}	$\pm 1.7\%$
$H \to W^+W^-$	2.14×10^{-1}	$\pm 2.2\%$
$H \to gg$	8.18×10^{-2}	$\pm 7.2\%$
$H \to \tau^+\tau^-$	6.27×10^{-2}	$\pm 2.3\%$
$H \to c\bar{c}$	2.89×10^{-2}	$^{+6.6\%}_{-2.8\%}$
$H \to ZZ$	2.62×10^{-2}	$\pm 2.2\%$
$H \to \gamma\gamma$	2.27×10^{-3}	$\pm 2.8\%$
$H \to Z\gamma$	1.53×10^{-3}	$\pm 6.9\%$
$H \to \mu^+\mu^-$	2.18×10^{-4}	$\pm 2.4\%$

The decays $H \to WW/ZZ \to 4f$ can be simulated with the `Prophecy4f` Monte-Carlo generator [229] that includes complete NLO QCD and EW corrections for Higgs decays into any possible four-fermion final state. All calculations are consistently performed with off-shell gauge bosons, without any on-shell approximation. For the SM Higgs boson, the missing higher-order corrections are estimated to be roughly 0.5%. Such uncertainties will have to be combined with the parametric uncertainties, in particular those associated to the bottom-quark mass and the

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

strong gauge coupling, to arrive at the full theory uncertainty. A detailed treatment of the differential distributions for a Higgs boson decay into four charged leptons in the final state is discussed in Refs. [56, 230].

The total width of a 125 GeV SM Higgs boson is $\Gamma_H = 4.1$ MeV, with a relative uncertainty of $\pm 1.37\%$. As discussed in Section 11.3.8, the width of the SM Higgs-boson is too narrow to allow for a direct mass line-shape measurement at the LHC. Even the channels with the best mass resolution, namely $H \to \gamma\gamma$ and $H \to ZZ^{(*)} \to 4\ell$ (ℓ = leptons), can only place an upper bound on Γ_H around 50 MeV at 68% CL (330 MeV at 95% CL) [231]. On the other hand, much stricter indirect constraints on the Higgs-boson widths can be obtained using simultaneously on-shell and off-shell measurements in the $pp \to VV \to 4\ell$ ($V = Z, W$) channels [232, 233]. For a given Higgs-boson production channel i (i = ggF,VBF, etc.) followed by the decay of the Higgs boson to four leptons ($pp \to H \to VV \to 4\ell$), the on-shell and off-shell cross sections are proportional to

$$\sigma_i^{\text{on-shell}} \propto \frac{g_p^2 g_d^2}{\Gamma_H} \propto \mu_i^{\text{on-shell}} \quad \text{and} \quad \sigma_i^{\text{off-shell}} \propto g_p^2 g_d^2 \propto \mu_i^{\text{off-shell}} \tag{11.12}$$

where g_p and g_d are the couplings associated with the Higgs boson production and decay, respectively, and $\mu_i^{\text{on/off-shell}} = \sigma_i^{\text{on/off-shell}}/\sigma_{i,\text{SM}}^{\text{on/off-shell}}$ are the on/off-shell signal strengths. Measuring only on-shell production cannot constrain the Higgs-boson width since, in the presence of new physics, the rescaling of the couplings and of the total width can conspire to compensate each other. On the other hand, a bound on the Higgs boson width can then be obtained at hadron colliders from the simultaneous measurements of the on-shell and off-shell signal strengths. This assumes that no new physics alters the Higgs boson couplings in the on-shell and off-shell regime differently [234, 235].

While $pp \to 4\ell$ production on the Higgs-boson peak is dominated by the Higgs-boson exchange (*signal*), off-peak other $pp \to VV \to 4\ell$ *background* processes dominate ($gg \to VV \to 4\ell$ for ggF and $qq/q\bar{q} \to VV \to 4\ell$ for EW Higgs-boson production). Nevertheless, the Higgs-mediated *signal* is still sizable due to the enhanced couplings of the Higgs boson to the longitudinal polarization of the massive vector bosons at high energy. Furthermore, the interference between signal and background processes is quite large and negative, leaving as a characteristic feature a deficit of expected events from background only. Based on the most recent theoretical prediction for both on-shell and off-shell $pp \to VV \to 4\ell$ production [232, 233, 236–238] the LHC experiments have obtained the quite constraining bounds on Γ_H presented in Section 11.3.8.

11.3 Phenomenology of the 125 GeV Higgs boson

The properties of the SM Higgs boson, discovered at CERN in 2012 with a mass near 125 GeV, have been measured with increasing precision by both the ATLAS and CMS experiments. At the LHC, Higgs-boson measurements typically focus on a specific production mechanism and decay mode, taking advantage of the fact that each production–decay combination exhibits distinctive kinematic and topological features. Analysis selections are designed to exploit these features to enhance the separation of the Higgs-boson signal from background processes, and to distinguish among different production and decay modes. To improve the analysis sensitivity, events are typically categorized into exclusive regions based on kinematic properties, such as jet multiplicity, transverse momentum, or invariant mass, as well as lepton flavor. In addition, multivariate algorithms, including boosted decision trees (BDTs) and deep neural networks (DNNs), are used to exploit correlations among observables and to improve the separation between signal and background. The combined use of categorization and multivariate techniques has led to significant improvements in the overall sensitivity of Higgs boson production and decay measurements.

The discussion in this section begins with the experimental features and challenges associated with each decay channel, followed by a treatment of the main production channels. It then reviews the latest measurements of inclusive cross sections, branching ratios, differential cross sections, and simplified template cross sections, and concludes with measurements of the Higgs-boson couplings, mass, width, spin, and CP properties.

11.3.1 *Higgs-Boson Decay Channels*

As discussed in Section 11.2.5.3, a Higgs boson with a mass of 125 GeV is predicted to decay within 10^{-21} seconds to a wide variety of final states. The identification of each decay mode relies on the distinctive experimental signatures summarized below.

- $H \to b\bar{b}$: This decay mode has by far the largest branching ratio but its measurement is particularly challenging due to a very large multi-jet background, which can be suppressed by identifying the presence of two b hadrons and also requiring the presence of additional particles associated with the WH or ZH, VBF and $t\bar{t}H$ production processes. Despite these challenges, this channel is particularly useful for Higgs boson transverse momentum measurements in the high-p_{T} regime, where the signal-to-background ratio is enhanced.
- $H \to W^+W^-$: the fully leptonic final state is targeted for this decay mode as it presents two important advantages. The first is the reduction of the multi-jet background that would dominate if one or both W bosons decayed hadronically. The second is related to the particular kinematics resulting from the decay of a scalar and the subsequent decay of the W bosons via the (V-A) interaction. This leads to the charged leptons having a smaller opening angle and a smaller invariant mass compared to the inclusive WW background. The disadvantage of this final state is the presence of neutrinos, which, because they are not detected, leads to a loss of information and prevents a full reconstruction of the final state.
- $H \to gg$: This final state has not been searched for directly since the multi-jet background would overwhelm the signal. It can be inferred indirectly as an "unobserved" decay in combinations of measurements.
- $H \to \tau\bar{\tau}$: The final states targeted for this decay process involve all the decay modes of the tau leptons. Typically, the most sensitive final state involves a combination of one tau lepton that decayed hadronically, and one that decayed leptonically. This decay mode provides sensitive measurements particularly when paired with the VBF production process and in the Higgs boson high-p_t regime when using the ggF production process.
- $H \to c\bar{c}$: Like the $b\bar{b}$ decay mode above, $c\bar{c}$ suffers from a large multi-jet background, from a smaller branching ratio than $b\bar{b}$, and from the $H \to b\bar{b}$ background. In addition, the efficiency for identifying c quarks is less than for b quarks. All of these factors make this final state very challenging to observe at a hadron collider.
- $H \to ZZ$: the decay of the Z bosons to charged leptons is targeted for most measurements, except for off-shell measurements where the decay of one Z boson to neutrinos is also considered. The four charged lepton final state has the advantage of having small backgrounds and allows for a full and precise reconstruction of the Higgs boson's kinematics, including its mass. Its main drawback is the limited event yield, which results in large statistical uncertainties.
- $H \to \gamma\gamma$: Although this final state suffers from a small branching ratio and a very large continuum $\gamma\gamma$ background, a clear resonance in the $\gamma\gamma$ spectrum can be observed thanks to the excellent electromagnetic calorimeter resolution of both experiments. Like the ZZ decay mode, this channel allows for a full reconstruction of the Higgs boson kinematics and provides a high-resolution mass peak used in mass measurements.
- $H \to Z\gamma$: The final state targeted for this decay mode involves the decay of the Z boson to charged leptons. As was the case for $\gamma\gamma$, this decay mode suffers from a very large continuum background and an even smaller branching ratio.
- $H \to \mu\bar{\mu}$: This decay mode is particularly challenging because of of the very small branching ratio predicted in the SM

and the comparatively much larger Drell-Yan background. However, this Higgs boson final state can be fully reconstructed and features a narrow dimuon mass peak.

There are other SM Higgs boson decays often referred to as 'rare'. Examples of these are the decays to lighter quarks, to meson plus photon final states, or to an electron–positron pair. While many of these modes are searched for at the LHC, either directly or indirectly, the current experimental sensitivity is far from the SM expectation.

11.3.2 *Higgs-Boson Production Channels*

The main production processes of a SM Higgs boson were discussed in Section 11.2.5. The experimental signatures used to identify these various production modes in measurements at the LHC are summarized below:

- ggH: ggH is the process that contributes the most to Higgs production at the LHC. Unlike other production processes, it does not result in extra particles in the final states (at leading order), which turns out to be its distinguishing feature.
- VBF: This process is characterized by the presence of two forward jets that result from the emission of the two fusing W or Z bosons from the quarks that originate from the incoming protons. The final state consists of two jets that tend to be emitted in the forward and backward directions, respectively, resulting in a large rapidity difference between the jets and a large invariant mass. These kinematic features are also used to reduce the multi-jet background.
- ZH: This production process takes advantage of the leptonic decay of the Z boson, either to two charged leptons or to two neutrinos, to reduce the background.
- WH: The final state targeted by this process also involves the leptonic decay of the W boson. The final state signature of a charged lepton and missing momentum from the undetected neutrino allows for a clear identification of the production process and a reduction of the backgrounds.
- ttH: This production process results in the most complex of the final states considered in this list. The two top quarks decay to a b quark and a W boson, which in turn can decay leptonically or hadronically. The presence of two b hadrons that can be identified and the possible presence of leptons from the W decays allow for what is generally a clear identification of the production process.
- bbH: this production process corresponds to about 1% of the Higgs production cross section and no attempt has yet been made to distinguish it from ggH. It has therefore been added to the ggH process in the categorization of production modes.
- tH: The experimental considerations for this process are similar to ttH, but the production rate is smaller, and the final state has only one top quark which reduces the identification efficiency compared to ttH. Finally, ttH itself can contribute as a background.

11.3.3 *Inclusive Cross Section and Branching Ratio Measurements*

The most basic experimental results in Higgs boson physics are measurements of the product of the production cross section and the decay branching fraction, $\sigma \times \mathrm{BR}$, for a given combination of production and decay modes. These quantities correspond to the number of Higgs bosons produced through a particular process and observed in a specific decay channel, normalized to the integrated luminosity and corrected for acceptance and efficiency.

As mentioned previously, analyses are typically divided into event categories defined by final-state or kinematic properties in order to maximize the precision of these $\sigma \times \mathrm{BR}$ measurements. For example, in measurements targeting $H \to \tau^+\tau^-$ decays, separate categories may be defined according to the τ-lepton decay mode (leptonic or hadronic) and the presence of additional jets, which can indicate a specific production process such as vector boson fusion. The sensitivity in each category depends on factors such as the production cross section for the chosen mode, its decay branching fraction, the reconstructed mass resolution, the selection efficiency, and the background level in the final state. These categories form the input granularity for more advanced combinations that will be discussed later, including those aimed at measuring production cross sections, extracting branching fractions, or determining Higgs boson couplings.

The extraction of the coupling strengths of the Higgs boson with various SM particles proceeds through the simultaneous fit of many such measurements. The contributions of those input measurements in the combination depend on the relative sensitivity of each analysis, which is determined by their associated statistical or systematic uncertainties. Both ATLAS and CMS have performed comprehensive combinations of measurements that use the full Run 2 dataset collected at a center-of-mass energy of 13 TeV. The input measurements presented below were mostly performed with this dataset.

The agreement between the measurement of the signal yields and the SM predictions can be expressed in terms of the signal-strength modifiers μ: the ratio of the observed yield to that of the SM prediction. The specific definition of μ will depend on the analysis. For given initial (i) and final (f) state, the signal-strength modifiers for individual production channels, μ_i, and decay modes, μ^f, are defined as the ratio of the measured event rate to its SM prediction:

$$\mu_i = \sigma_i/(\sigma_i)_{\mathrm{SM}}, \quad \mu^f = B^f/(B^f)_{\mathrm{SM}}, \quad \text{and}$$
$$\mu_{if} = \frac{\sigma_i \times B_f}{\left(\sigma_i^{\mathrm{SM}} \times B_f^{\mathrm{SM}}\right)}\,. \tag{11.13}$$

This way of presenting the experimental results gives a global indication of their compatibility with the Standard Model. A more generic treatment of potential BSM effects will be given in Section 11.4.

The input measurements of the CMS [239] and ATLAS [240] experiments that enter some of the combinations presented below are shown in Figure 11.6. It is important to note that the theoretical uncertainty on the SM prediction is included in μ measurements through the denominator in the formula above. The p-value for the compatibility of the measurements and the SM predictions is 3% for CMS and 84% for ATLAS. Taking into account the results of both experiments, the overall agreement between the data and the SM prediction is good.

The combination of Higgs boson analysis channels, both within each experiment and across the two experiments, is performed by fitting a combined signal–plus–background model to the data. The principle underlying this combination is captured by the combination formula 11.14. As mentioned previously, the input granularity for the fits is the "category", where the category can represent, for example, particular kinematic selections or lepton flavours. Then, for each category "c" within a given channel, the measured number of signal events, n_s^c, is expressed in terms of a small set of parameters as follows:

$$n_s^c = \left(\sum_{i,f} \mu_i\, \sigma_i^{\mathrm{SM}} \times A_{if}^c \times \varepsilon_{if}^c \times \mu_f\, \mathrm{BR}_f^{\mathrm{SM}}\right) \times \mathcal{L}^{\mathrm{c}}. \tag{11.14}$$

The production index is defined as $i \in \{\mathrm{ggF}, \mathrm{VBF}, ZH, WH, t\bar{t}H, tH, \ldots\}$ (including specific modes and regions of phase space) and the decay index is defined as $f \in \{\gamma\gamma, WW, ZZ, bb, \tau\tau, \mu\mu, Z\gamma\}$, while σ_i^{SM} and $\mathrm{BR}_f^{\mathrm{SM}}$ are the corresponding production cross sections and decay branching fractions, estimated as described in Section 11.2.5, assuming that the observed Higgs boson is described by the SM. A_{if}^c and ε_{if}^c are the signal acceptance and the reconstruction efficiency for the given production and decay modes in the category c. Bins are defined such that the acceptance A_i and efficiency ε_i are approximately uniform within each bin and stable under plausible BSM-induced shape variations. As a result, A_i and ε_i can be computed from SM simulation. $\mathcal{L}^c$ is the integrated luminosity used for that specific category.

In the combination formula, the parameters of interest are the signal strengths for production (μ_i) and decay (μ_f). The expression assumes factorization of the production cross section and

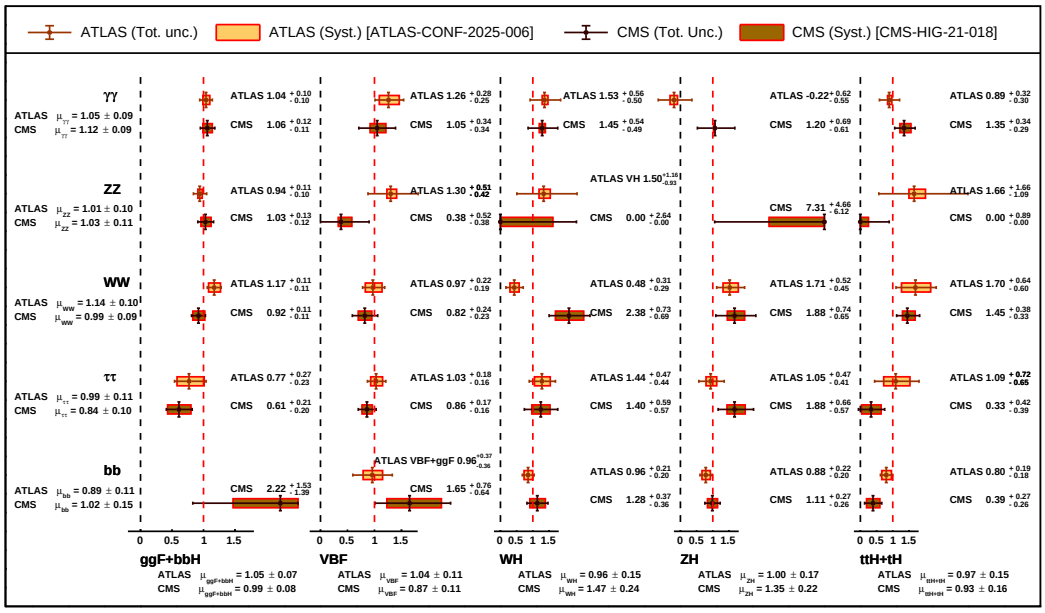

Figure 11.6: Ratio of observed rate to predicted SM event rate (μ_{if}) for different combinations of Higgs boson production and decay processes. The theoretical predictions are based on a Higgs boson mass of 125.09 GeV in the ATLAS fit [240] and 125.38 in the CMS one [239]. The original references consider similar but not identical set of measurements in the combined fit. As a result, in some cases a particular measurement is only available for one of the experiments. This is clarified in the labels with the numerical value. Both experiments also include the $\mu\mu$ and $Z\gamma$ decay modes in their fits, and, in the case of ATLAS, the VH $c\bar{c}$ process as well.

decay branching fraction, which are valid under the narrow-width approximation. The observation of a narrow resonance in high-mass-resolution channels is sufficient for the precision required here. The equation also makes it clear that μ_i and μ_f cannot be extracted independently, which implies that the total cross sections or branching fractions cannot be determined without additional assumptions.

The combination formula also highlights an important limitation in the interpretation of the signal strength parameters. If these are treated as scale factors for the production cross sections or branching fractions, then all other inputs, such as the acceptances and efficiencies, A^c_{if} and ε^c_{if}, must be assumed independent of the couplings and fixed to their Standard Model estimates. Another caveat is that, in the combined fits, only the overall normalization is varied, and the shapes of the discriminating variables for the signal are kept fixed. These assumptions are particularly relevant when using the combination to extract the Higgs boson coupling properties, as discussed in Section 11.3.5. For small deviations of the couplings from their Standard Model values, these approximations remain valid.

In an individual measurement, the quantity directly determined is the product of the production cross section and the decay branching fraction, $\sigma \cdot \mathrm{BR}$, which corresponds to $\mu_i \times \mu_f$ in the signal strength framework. These products can be treated as free parameters and, provided there is sufficient sensitivity from the chosen categories, can be measured without additional assumptions. The separate values of μ_i and μ_f can then be inferred only through a global combination of multiple measurements.

The most constrained fit in the combination allows for only one single parameter to vary, i.e., $\forall(i,f), \mu_i = \mu_f = \mu$. This global signal strength model provides the simplest probe of the compatibility of the signal with the SM Higgs boson. Indeed, it is sensitive to any deviation from the SM Higgs boson couplings provided that these deviations do not cancel overall. The ATLAS measurement of this inclusive μ yields [240]:

$$\mu = 1.023^{+0.056}_{-0.053}$$

$$= 1.023 \pm 0.028(\mathrm{stat})^{+0.026}_{-0.025}(\mathrm{exp})^{+0.039}_{-0.036}(\mathrm{sig\ theo}) \pm 0.012(\mathrm{bkg\ theo})$$

where (stat.) refers to the statistical uncertainties, (exp.) to the experimental systematic uncertainties, (sig. theo.) to theory uncertainties on the Higgs boson signal, and (bkg. theo.) to theory uncertainties on the background processes.

The equivalent result for CMS yields [239]:

$$\mu = 1.014^{+0.055}_{-0.053} = 1.014 \pm 0.028\,(\mathrm{stat})^{+0.025}_{-0.024}\,(\mathrm{exp})^{+0.040}_{-0.039}\,(\mathrm{theory})$$

The results from the two experiments are in excellent agreement with each other and with the Standard Model prediction. It is worth emphasizing that the overall theoretical uncertainty is larger than both the experimental systematic component and the statistical component, making it the dominant contribution to the total uncertainty. Reducing this theoretical component is therefore essential for fully exploiting the increasing precision of current and future measurements.

In one variant of the Higgs boson combination, the focus is placed on determining the branching fractions for various decay modes. For each mode included in the combinations performed by ATLAS and CMS, a specific production process is identified via event classification, based on the properties of particles produced in association with the Higgs boson, as described above. The branching fractions are then extracted by fixing the cross sections for all Higgs boson production processes to their Standard Model values. The resulting measurements [240] for the ATLAS experiment are shown in Figure 11.7 (left), and equivalent results from CMS can be found in [239].

In another variant of the Higgs boson combination, the emphasis is placed on the determination of the production process.

Where several production processes are combined, the combination assumes the relative fractions to be those from the SM within their corresponding theory uncertainties. Here, Higgs boson branching fractions are then set to their SM values, within the uncertainties specified in Ref. [57]. The results [240] are shown for the ATLAS experiment in Figure 11.7 (right). The corresponding production cross section results expressed in picobarns are provided in Table 11.3, and the equivalent results for CMS, adapted from [239] are presented in Table 11.4. It is important to note that the SM theory predictions from ATLAS and CMS differ from those presented in 11.1 because of the addition of a fiducial cut on rapidity, different mass assumptions, and different decay mode selections for associated particles (e.g. for the W and Z bosons in WH and ZH production).

Table 11.3: Measured values of Higgs boson production cross-sections by ATLAS [240] at a center-of-mass energy of 13 TeV, assuming branching ratios to match their expectations in the SM. The second column provides SM predictions with theory uncertainties based on a Higgs boson mass of 125.09 GeV, and the third column gives the ratio of the measured values to the SM predictions.

Cross-section Measurement (pb)	SM prediction (pb)	Ratio to SM
$ggF + bbH$	$47.0^{+3.1}_{-2.7}$	44.8 ± 2.6	$1.05^{+0.07}_{-0.06}$

ZH	$0.33^{+0.06}_{-0.05}$	$0.24^{+0.02}_{-0.02}$	$1.38^{+0.26}_{-0.22}$
ttH	$0.38^{+0.07}_{-0.07}$	$0.50^{+0.03}_{-0.05}$	$0.76^{+0.15}_{-0.15}$
tH	$0.55^{+0.21}_{-0.20}$	$0.088^{+0.013}_{-0.007}$	$6.25^{+2.36}_{-2.22}$

The branching fractions of the $\gamma\gamma$, ZZ, $W^{\pm}W^{\mp}$, bb, and $\tau^+\tau^-$ decays, are measured with a precision of 10%. The observed signal significance for the rare $H \to \mu^+\mu^-$ decay was found to be above 3σ by CMS [241] using the Run 2 dataset, and above 3σ by ATLAS [242] using a combination of Run 2 and Run 3 datasets. The significance for the rare $H \to Z\gamma$ decay mode was found to be above 3σ when ATLAS and CMS combined their Run 2 search results [243]. All production modes are in agreement with the SM prediction. The gluon fusion process yields the most precise cross-section measurement, with a 6% uncertainty, which is of comparable size to the theoretical uncertainty on the SM prediction. In general, for both the production and decay processes, the statistical uncertainties are comparable to the systematic uncertainties.

Measuring the Higgs boson production cross section as a function of the center-of-mass energy also provides an important test of Standard Model predictions. This is illustrated in Figure 11.8, which shows the combined results from the diphoton and four-lepton decay channels at four different collision energies collected from Run 1 to Run 3 [244].

The predicted cross sections increase steadily with center-of-mass energy, more than doubling from Run 1 to Run 3. The measurements follow this trend and are, overall, consistent with Standard Model predictions.

In summary, Higgs boson measurements from both ATLAS and CMS exhibit good overall agreement with SM expectations, reinforcing the interpretation of the observed particle as a very "SM-like" Higgs boson. In some cases, the experimental uncertainties have reached a level comparable to that of theoretical uncertainties on cross sections. This highlights the critical importance of reducing theoretical uncertainties to fully exploit the precision of current and future Higgs measurements, especially in the high-luminosity LHC era.

11.3.4 *Differential and Template Cross Sections*

The characterization of Higgs boson production at the LHC goes beyond inclusive cross section measurements. The large datasets collected enable the experiments to perform detailed studies of kinematic observables that can be essential for probing the structure of the Higgs sector and identifying potential deviations from SM expectations. Differential cross section measurements as a function of key variables offer a sensitive test of higher-order corrections in perturbative theory and allow for indirect constraints on new physics. These measurements are also key for improving the modeling accuracy of Higgs boson production in Monte Carlo simulations, providing essential input for both theoretical predictions and experimental analyses. Two primary approaches are employed by the LHC experiments to characterize this information: traditional differential cross-section measurements and simplified template cross sections (STXS).

Differential distributions have been measured in the decay modes of the Higgs boson ($H \to ZZ$, $H \to \gamma\gamma$, $H \to WW$, $H \to \tau^+\tau^-$, and $H \to b\bar{b}$), mapping the kinematics of Higgs production. The size of the Run 2 dataset allows for the measurement of single- and in some cases double-differential cross sections for key observables such as the transverse momentum of the Higgs boson (p_T^H). These measurements are unfolded to particle or parton level to enable direct comparison with theoretical predictions (see the PDG review on Statistics [245] for a general discussion of unfolding techniques).

The decay channels $H \to ZZ^* \to 4\ell$ and $H \to \gamma\gamma$ provide the cleanest experimental signatures due to their fully reconstructed final states and excellent invariant mass resolution. Despite their relatively small branching ratios, these modes allow for the most precise measurements of differential cross sections, including a broad array of observables related to the Higgs boson and its decay products, the accompanying jets, and global event topology. Double-differential cross sections have also been extracted for key observables, offering a deeper view into the event structure.

Complementing these channels are the higher-branching-ratio decay modes $H \to b\bar{b}$, $H \to WW$, and $H \to \tau^+\tau^-$, which enable differential studies in regions of phase space with lower production cross sections such as events with high jet multiplicities or large Lorentz boosts of the Higgs boson. These channels are especially valuable for probing the high-p_T regime, where the sensitivity to BSM physics is enhanced. Advances in the identification of large-radius jets originating from highly boosted decays to $b\bar{b}$ or $\tau^+\tau^-$ pairs have been fundamental to enabling these measurements in the highest p_T ranges. See for instance Refs. [246–248].

While most of these measurements currently focus on the gluon-gluon fusion (ggF) production mode, subleading modes such as VBF and ttH are also now being mapped differentially with increasing precision. Individual final state measurements of the cross section have been combined in ATLAS [249] and CMS [250, 251]. Figure 11.9 shows an example of two observables.

These measurements of Higgs kinematics can be exploited to constrain Higgs boson couplings and other parameters of the theory. For instance, the shape of the Higgs p_T distribution is sensitive to loop-level effects and can be used to place bounds on the charm Yukawa coupling modifier κ_c. See 11.3.5 for further discussion on coupling constraints.

An alternative approach to characterizing Higgs boson production is the Simplified Template Cross Sections (STXS) framework [252]. In this method, fiducial cross sections are measured for each production mode in a set of predefined kinematic regions (*bins*) of phase space. These regions are defined using observ-

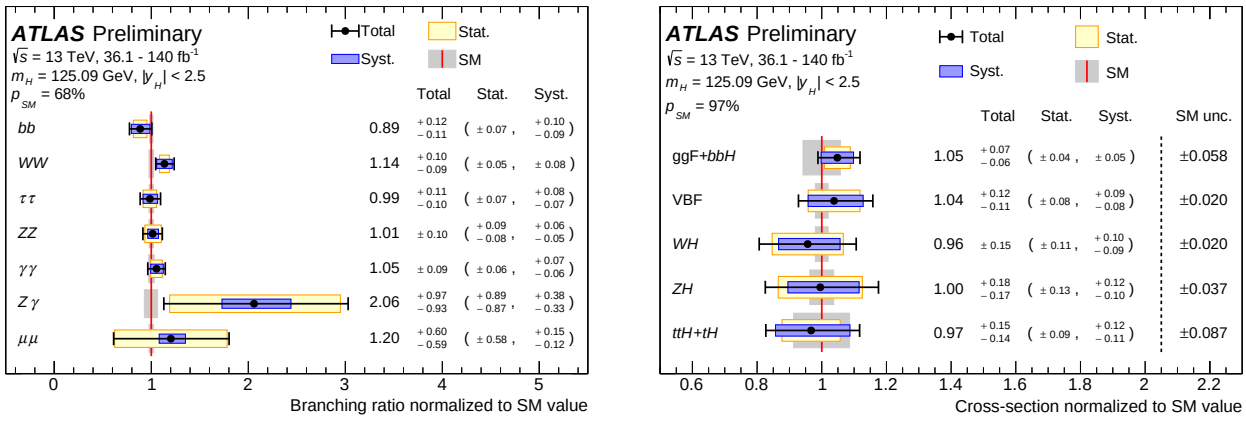

Figure 11.7: (Left) Observed and predicted branching fractions for different Higgs boson decay modes assuming SM values for the production cross sections. (Right) Observed and predicted cross sections for different Higgs boson production processes, assuming SM values for the decay branching fractions. Equivalent results from CMS can be found in Ref. [239]

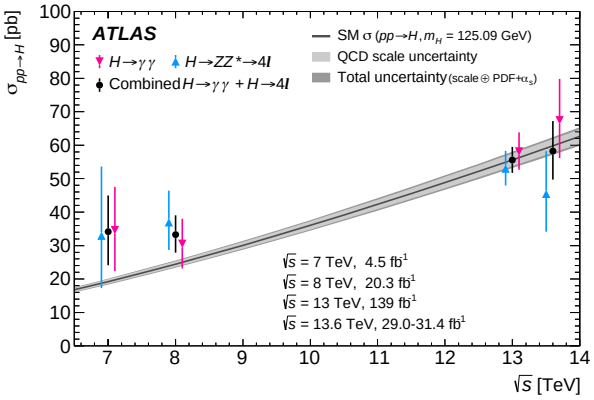

Figure 11.8: ATLAS measurements of the Higgs boson production cross section in the four-lepton and diphoton channels as a function of the proton-proton center-of-mass energy.

ables such as the transverse momentum of the Higgs boson (p_T^H), the dijet invariant mass (m_{jj}), the transverse momentum of the Higgs plus leading jets (p_T^{Hjj}), and the transverse momentum of the associated vector boson (p_T^V). The STXS bins are carefully chosen through consensus between the theoretical and experimental community to optimize sensitivity to new physics while minimizing minimal theoretical uncertainties. These regions isolate contributions from different production mechanisms and improve the stability of theoretical predictions. They are designed with the combination of measurements across decay channels and experiments in mind. The goal is to reduce the dependence on extrapolations beyond the experimentally accessible phase space, improving the fidelity of comparisons between data and theory. STXS measurements serve as well-defined benchmarks that test both Standard Model (SM) predictions and potential BSM deviations in differential distributions.

The LHC Higgs Working Group proposed this framework [57, 252] to address the challenges of combining measurements across a large number of decay channels, each affected by its own set of systematic uncertainties. To facilitate this, fiducial phase space definitions are standardized across analyses, focusing on Higgs boson production characteristics rather than specific decay signatures. The observables used correspond to the production modes $gg \to H$ (gluon fusion and $gg \to Z(\to qq)H$), EW qqH (vector boson fusion and $qq \to V(\to qq)H$), VH (associated production with vector bosons in leptonic channels, $qq + gg \to V(\to \text{leptons})H$), and top-associated production ($t\bar{t}H$), constrained to well-defined and mutually exclusive kinematic regions.

ATLAS and CMS experiment has produced STXS measurements in all the main production modes and decay channels with the Run-2 dataset. A combination of STXS across decay channels has also been carried out by ATLAS [253–255] and CMS [239], also with the full Run-2 dataset. Figure 11.10 illustrates the results obtained by ATLAS in each of the kinematic regions. These combined STXS measurements provide a powerful probe of Higgs production mechanisms and constitute an important input for interpretations in the κ formalism, in global EFT fits, or in dedicated BSM analyses.

11.3.5 *Probing the Couplings of the Higgs Boson: κ framework and EFT approach*

As discussed in Section 11.2.1 and Section 11.2.2, all the SM Higgs-boson couplings are proportional to the mass of the particle it couples to. More precisely, the SM Higgs-boson couplings to fundamental fermions are linearly proportional to the fermion masses, whereas the couplings to bosons are proportional to the square of the boson masses. The Higgs terms in the SM Lagrangian were presented in Eqns. 11.8 and 11.9. Reformulating these expressions to highlight the SM Higgs-boson couplings to gauge bosons and fermions, as well as the Higgs-boson self coupling, we find the following Lagrangian:

$$\mathcal{L} = -g_{Hf\bar{f}}\bar{f}fH - \frac{g_{3H}}{6}H^3 - \frac{g_{4H}}{24}H^4 + \delta_V V_\mu V^\mu \left(g_{HVV}H + \frac{g_{HHVV}}{2}H^2\right), \tag{11.15}$$

with

$$g_{Hf\bar{f}} = \frac{m_f}{v},\ g_{HVV} = \frac{2m_V^2}{v},\ g_{HHVV} = \frac{2m_V^2}{v^2}, \quad g_{3H} = \frac{3m_H^2}{v},\ g_{4H} = \frac{3m_H^2}{v^2}, \tag{11.16}$$

where $V = W^\pm$ or Z and $\delta_W = 1, \delta_Z = 1/2$. The Higgs-boson couplings are therefore unambiguously determined once the particle masses are known. Any deviation from such pattern in the measurement of the couplings of the Higgs boson would therefore provide a clear indication of the existence of BSM physics. Later in this section (see Figure 11.11), we will present the recent results of the ATLAS and CMS constraints of these potential deviations.

Measuring the Higgs-boson couplings without relying on the SM assumption requires a general framework treating deviations from the SM coherently at the quantum level in order to provide theoretical predictions for relevant observables to be con-

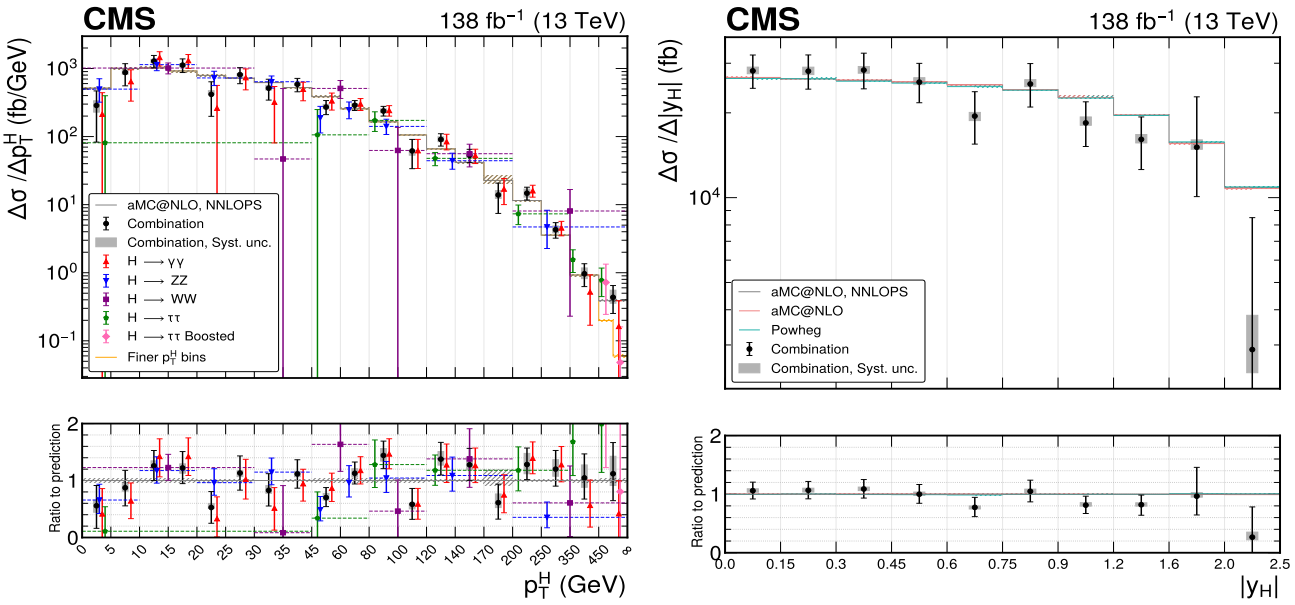

Figure 11.9: (Left) Combination of the fiducial differential cross sections in Higgs boson transverse momentum in the $H \to \gamma\gamma$, $H \to ZZ$, $H \to WW$, $H \to \tau\tau$ decay modes. (Right) Differential cross section as a function of the Higgs boson rapidity, combining the $H \to \gamma\gamma$ and $H \to ZZ$ modes, comparing to different Monte Carlo generators [251].

fronted with experimental data. Out of the different approaches to this problem, two approaches have been mainly followed by the LHC experimental collaborations in interpreting their measurements. The first is the so-called kappa (κ) formalism [256], in which Higgs-boson couplings are rescaled by arbitrary multiplicative factors (κ parameters), while preserving the Lorentz structure of the SM interactions. This approach has been extensively used by the LHC experimental collaborations due to its close connection to the measurement of the signal strengths described in Section 11.3.3. It allows for well-defined scenarios with various degrees of flexibility for incorporating BSM effects, and provides a global picture of the behavior in the Higgs sector. However, this κ formalism is limited in scope, as it does not fully account for modifications to the tensor structure of the interactions that influence both the kinematic distributions and the total rates. Also, arbitrary rescalings can destroy gauge invariance.

An alternative approach is the use of Effective Field Theories (EFTs) to parameterize BSM effects through higher-dimensional effective operators originating from the EW-scale projection of generic extensions of the SM living at a much higher ultraviolet (UV) scale. Indeed, while light new physics cannot be fully excluded, stringent direct limits on many well-motivated models makes the assumption of heavy new physics a very well-justified starting point. The EFT approach reaches beyond a purely phenomenological approach, and, as a coherent quantum-field-theory, also allows for the correlation of different effects and a systematic estimate of the residual uncertainties of its predictions. Depending on the assumptions made on the scalar field introduced in the SM to generate EWSB, two main EFT options have been considered in exploring potential deviations from SM-like Higgs-boson couplings: the so-called Standard Model Effective Field Theory (SMEFT), where the scalar field is assumed to be a doublet of $SU(2)_L$ as in the SM, and the Higgs Effective Field theory (HEFT) where such assumption is not made. The SMEFT approach has received particular attention in recent phenomenological explorations of BSM physics. This approach includes both targeted analyses in specific final states (e.g., $H \to ZZ$, $H \to \tau^+\tau^-$), which directly probe operators through the use of dedicated discriminators that are sensitive to specific BSM-induced deformations of the Higgs-boson kinematics, and also global analyses that typically exploit cross section measurements including differential distributions, and target a full spectra of observables. The latter normally require combination with other precision measurements, such as electroweak precision observables (EWPO), top-quark, Drell-Yan, as well as flavor-physics and low-energy observables, for a complete coverage. On the other hand, the HEFT approach has been recently considered in analyses aimed at constraining the Higgs-boson self-coupling since, at the lowest order, the EFT couplings involved in this case have a straightforward relation to the κ formalism.

In the following, the κ and SMEFT approaches are discussed in more detail given their broad applications to the interpretation of experimental data.

11.3.5.1 *Kappa Framework*

The κ-formalism [256] was developed within the LHC Higgs Working Group [55]. It introduces arbitrary factors called κ parameters that rescale the SM Higgs boson couplings (e.g. $\kappa_j = g_{Hjj}/g_{Hjj}^{SM}$ for $j = f, V$ and similarly for other couplings), keeping the same Lorentz structure of the SM interactions. It followed earlier attempts [257] and initial phenomenological studies of the first hints of the existence of the Higgs boson [258]. It has been utilized to test various physics scenarios, like the existence of additional new particles contributing to the radiative Higgs-boson production and decays, or to probe various symmetries of the SM itself, as for example the custodial symmetry (see Sec. 11.2.3). It only compares the experimental measurements to their best SM predictions and does not require any new BSM computations per se. From a more theoretical perspective, its relevance arises from the fact that it fully captures the leading effects in Higgs processes of well-motivated scenarios.

The κ framework, described in detail in Refs. [56, 256], facilitates the characterization of Higgs coupling properties in terms of a series of Higgs coupling strength modifier parameters κ_i, which are defined as the ratios of the couplings of the Higgs boson to particles i and their corresponding SM values. It is the simplest parametrization directly related to experimental measurements of the Higgs boson production and decay modes, and, in some cases, it coincides with the lowest-order of the consistent EFT framework of the HEFT. The κ framework has been widely used by the community, exploiting the framework described in Section 11.3.3 to combine the very large number of exclusive categories aimed at reconstructing the main production and decay modes of the Higgs boson. The μ_i and μ_f signal strength parameters defined there can be further interpreted in terms of modifiers of the SM couplings κ_j. The list of couplings g_j included in the experimental fits has been expanded progressively since the first results. In the latest experimental combinations,

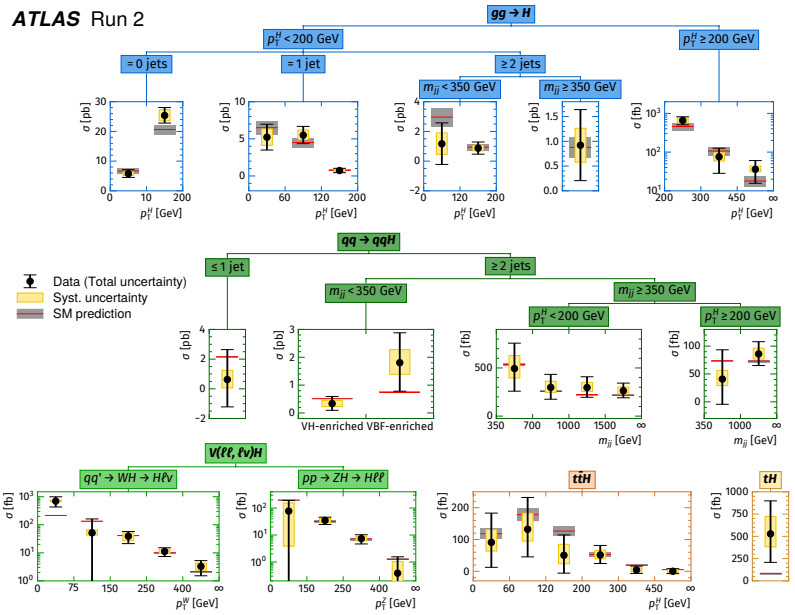

Figure 11.10: Simultaneous combined measurement of simplified template cross sections assuming SM branching fractions of the Higgs boson [255]

$j \in \{HZZ, HWW, H\tau\tau, Hbb, Htt, H\mu\mu, Hcc, Hgg, H\gamma\gamma, HZ\gamma\}$.

The κ framework assumes a single narrow resonance so that the narrow-width approximation can be used to decompose the cross section as a product of two factors characterizing the production and the decay of the Higgs boson. The κ parameters are introduced by expressing each of the these factors as their SM expectation multiplied by the square of a coupling strength modifier for the corresponding process at leading order:

$$(\sigma \cdot \mathrm{BR})(i \to \mathrm{H} \to f) = \frac{\sigma_i^{SM}\kappa_i^2 \cdot \Gamma_f^{SM}\kappa_f^2}{\Gamma_H^{SM}\kappa_H^2} \quad \to$$
$$\to \quad \mu_i^f \equiv \frac{\sigma \cdot \mathrm{BR}}{\sigma_{\mathrm{SM}} \cdot \mathrm{BR}_{\mathrm{SM}}} = \frac{\kappa_i^2 \cdot \kappa_f^2}{\kappa_H^2}, \tag{11.17}$$

where μ_i^f is the rate relative to the SM expectation, Γ_H is the total Higgs width, and κ_H^2 is an expression that adjusts the SM Higgs width to take into account the modifications induced by the deformed Higgs boson couplings. κ_H is a priori an independent parameter. However, when it is assumed that the Higgs boson cannot decay to new particles beyond those of the SM, κ_H can also be treated as an effective parameter and expressed in terms of the coupling modifiers to the SM field content. The κ_j modifiers scale either production cross sections or decay partial widths:

$$\kappa_i^2 = \frac{\sigma_i}{\sigma_i^{\mathrm{SM}}} \quad \text{or} \quad \kappa_j^2 = \frac{\Gamma_j}{\Gamma_j^{\mathrm{SM}}}, \tag{11.18}$$

depending on the process. Here, σ_i is the measured cross section in production mode i and Γ_j the partial Higgs width in decay mode j. σ_i^{SM} and Γ_j^{SM} are their respective theoretical predictions in the SM. When all κ_j are set to 1, the SM is reproduced.

In the simplest configuration of the kappa framework, all loops in Higgs boson production and decay diagrams are resolved, coupling modifiers are introduced for each tree-level Higgs boson coupling to another SM particle, and no BSM decay of the Higgs is considered. The parameters include therefore κ_W, κ_Z, κ_t, κ_b, κ_τ, and κ_μ. This configuration can be extended to account for loop induced processes and to better incorporate possible new physics effects. For loop-induced processes, $gg \to H$, $H \to \gamma\gamma$ and $H \to Z\gamma$, there is a choice of either resolving the coupling strength modification in its SM expectation, e.g. $\kappa_\gamma(\kappa_t, \kappa_W)$, or keeping them as an effective coupling strength parameter, determined in the fit [259].

In the absence of a measurement of the Higgs-boson width the LHC requires some hypotheses in order to extract the Higgs couplings from the measured Higgs signal strengths. In particular, one can assume either (i) that there are no BSM particles in the decay, (ii) that any BSM particles in the decay would only give rise to invisible signatures and therefore be detectable through invisible Higgs boson channels (or in other terms that there is no BSM undetected contribution), or (iii) that BSM physics would modify the κ_j according to specific patterns favored by several new physics models. An external constraint is needed when BSM decays are allowed. For instance, the requirement that $|\kappa_V| \leq 1$ ($V = W, Z$) (see for instance the ATLAS+CMS Run 1 combination [260] for a discussion of this constraint) or constraints on Γ_H from indirect measurements (eg offshell/onshell cross sections (see Section 11.3.8). The general expression of the total width of the Higgs boson can be written as follows:

$$\Gamma_H = \frac{\kappa_H^2 \Gamma_H^{\mathrm{SM}}}{1 - \mathrm{BR}_{\mathrm{BSM}}} = \frac{\kappa_H^2 \Gamma_H^{\mathrm{SM}}}{1 - (\mathrm{BR}_{\mathrm{inv}} + BR_{\mathrm{undet}})} \tag{11.19}$$

where Γ_H^{SM} is the total width of the SM Higgs boson and $\mathrm{BR}_{\mathrm{BSM}}$ is the branching fraction of the Higgs boson to new particles beyond the SM. This BSM fraction can be broken down into two contributions. The first one, $\mathrm{BR}_{\mathrm{inv}}$, corresponds to an "invisible" branching ratio of the Higgs boson that can be directly constrained through H → (invisible) searches (see Section 11.4.3) and included as an input in the coupling fits. The second, $\mathrm{BR}_{\mathrm{undet}}$, corresponds to the *undetected* or *unprobed* Higgs-boson branching ratio. This contribution is not directly measured by any search, and therefore not included as an input to the fits.

Negative values of Higgs couplings, i.e. negative κ_j, are not excluded a priori although they are not favored by the most recent measurements (see Table 11.5). With increased sensitivity to interference effects between vector (κ_V, $V = W, Z$) and fermion couplings (κ_F, $F = t, \ldots$), their relative sign could be established. The relative sign of κ_W and κ_Z has also been explored through associated production of Higgs and W bosons via vector-boson fusion (VBF) in Refs. [261, 262], which exclude opposite-sign scenarios for κ_W and κ_Z with a significance of more than 5 standard deviations. Among the five main Higgs-boson decay channels, only the $\gamma\gamma$ channel is sensitive to the sign of κ_F (or κ_V) through the interference of the W and t loops (see Ref. [259] for the parametrization). Access to the sign of the κ_F coupling can be obtained through the inclusion of analyses targeting single

top-quark production, proposed in Ref. [263, 264], and currently part of the standard LHC combinations.

Taking into account the above discussion of the different possible scenarios that can be implemented, the ATLAS and CMS collaborations followed a common interpretation approach that yielded the first LHC combination of Higgs-boson couplings results already at the end of the first Run of the LHC [260]. A very similar configuration is used in the subsequent Run-2 results [239, 240, 255, 265].

Figure 11.11 and Table 11.5 summarize the measurements of the kappa parameters by ATLAS [240] and CMS [239], using the full LHC Run-2 dataset, with an integrated luminosity of up to 140 fb^{-1} of pp collisions at $\sqrt{s} = 13$ TeV. For the statistically dominated modes, $H \to Z\gamma$ and $H \to \mu\mu$, ATLAS has also included partial Run-3 statistics, 165 fb^{-1} of 13.6 TeV collisions. These correspond to the cross section measurements presented in Section 11.3.3. Figure 11.11 (left) shows one of the interpretations discussed above: the measured coupling modifiers in the approach where the Higgs-boson loop couplings are resolved, as a function of the mass of the probed particles. Remarkable agreement with the SM is observed over several orders of magnitude. See the original references [239, 240] for further details.

Table 11.5 presents the coupling measurements for the scenario that includes effective couplings. The Run-2 results (13 TeV, $\approx$ 140 fb^{-1}) are compared to the Run-1 ATLAS+CMS combination (7 and 8 TeV, 5+20 fb^{-1}) and the latest HL-LHC projection for the measurements, based on a combination of ATLAS and CMS for an integrated luminosity of 3000 fb^{-1} per experiment. The interpretation included in the table assumes no BSM physics in the decay of the Higgs boson.

The combinations and projections can incorporate in the fit the searches for invisible decays of the Higgs boson. These searches directly constrain $BR_{\rm inv}$ and enable the distinction between *invisible* (directly constrained) versus *undetermined* or *unprobed* (not accesses experimentally in any measurement or search) decays mentioned earlier through a modification of the combination fit. Starting from the no BSM scenario, one may relax the assumptions on the Higgs boson decay by introducing $BR_{\rm inv}$ and $BR_{\rm undet}$ as parameters, allowing for a modification of the decays but introducing an external constraint to alleviate a complete degeneracy in the Higgs boson total decay width, where each coupling modifier can be scaled up equally to account for a non-zero $BR_{\rm undet}$. An example of constraint is $\kappa_V \leq 1$, commonly used since Run-1, as shown for example in Ref. [260]. An alternative constraint uses the Higgs boson width derived from the off-shell Higgs boson production measurements. In this interpretation, the off-shell Higgs measurement constrains the visible, invisible and undetected branching fractions. The *visible* branching fractions corresponds to the measured Higgs decays to SM particles. The invisible branching fraction is constrained from the direct, *invisible* Higgs searches. The *undetected* branching fraction will be then constrained by the off-shell Higgs boson measurements. Figure 11.11 (right) shows a comparison of the kappa measurements in the three models: no BSM allowed, BSM constrained by $\kappa_V \leq 1$, and BSM constrained by the inclusion of off-shell production ($H \to 4\ell$). More details on this comparison can be found in the CMS paper [239], and a discussion of off-shell production and the measurement of the total width in Section 11.3.8.

The limits obtained at the 95%CL on the invisible and undetected branching fractions with the Higgs combination and the corresponding HL-LHC constraints are:

$$\begin{aligned} &\mathrm{BR_{inv}} < 13\% \ , \ \mathrm{BR_{undet}} < 12\% \ \text{(ATLAS [255], Run2)} \, , \\ &\mathrm{BR_{inv}} < 12\% \ , \ \mathrm{BR_{undet}} < 11\% \ \text{(CMS [239], Run2)} \, , \\ &\mathrm{BR_{inv}} < 1.9\% \ , \ \mathrm{BR_{undet}} < 4\% \ \text{(HL-LHC [194])} \, . \end{aligned} \tag{11.20}$$

A longer discussion of the different Higgs invisible searches can be found in Section 11.4.3, including updated BR_{inv} constraints not yet included in some of these combinations.

Interpretations which are less sensitive to modeling systematic uncertainties and require no constraints on the natural width of the Higgs bosons have been considered, either through the ratio of cross section and branching ratios (see Ref. [263]) or through a more generic approach to avoid the degeneracy in the measurement of the coupling modifiers, probing the coupling properties of the Higgs boson through ratios of couplings ($\lambda_{ij} = \kappa_i/\kappa_j$). In the latter model, all combination signals can be parametrized with the ratios of coupling modifiers. For example, (i) the $\lambda_{Zg} = \kappa_Z/\kappa_g$ ratio which is mainly probed by the measurements of the VBF and ZH production; (ii) the $\lambda_{tg} = \kappa_t/\kappa_g$ ratio constrained by the $t\bar{t}H$ production process; (iii) the $\lambda_{WZ} = \kappa_W/\kappa_Z$ ratio mainly probed by the WW and ZZ decay modes; (iv) the $\lambda_{\tau Z} = \kappa_\tau/\kappa_Z$ ratio constrained by the $\tau^+\tau^-$ channel; (v) the $\lambda_{bZ} = \kappa_b/\kappa_Z$ ratio probed mainly by the $VH(b\bar{b})$ channels; and (vi) the $\lambda_{\gamma Z} = \kappa_\gamma/\kappa_Z$ ratio constrained by the diphoton channel. In this parametrization, the ZZ channel plays an important normalization role, and a reference combined coupling modifier, κ_{gZ}, is introduced to represent the high-precision measurement of the $gg \to H \to ZZ$ production rate $\kappa_{gZ} = \kappa_g \times \frac{\kappa_Z}{\kappa_H}$. Current uncertainties on the ratios vary from 5 to 20% [239]. They are expected to be reduced to a few percent level at the HL-LHC [266].

It is important to note that the global fit described above does not include all possible Higgs couplings, but only those related to measurements included as inputs in the fit. A particularly important example is the coupling to charm quarks, κ_c. The significant experimental challenges in isolating Higgs decays to charm at the LHC limit the LHC sensitivity. Generally speaking, this coupling is considered a target for future Higgs factories, that will be able to measure it precisely [194]. Nevertheless, the progress in recent years has been impressive and it deserves a special mention. Dedicated analyses have been developed in ATLAS and CMS to probe this coupling both directly and indirectly. Direct searches target the decay mode $H \to c\bar{c}$, relying heavily on associated production and advanced charm-tagging algorithms. The most stringent current constraint comes from CMS using the full Run-2 dataset, which combines VH and ttH production and yields a constraint at 95% CL of $|\kappa_c| < 3.5$ (expected 2.7) [267]. ATLAS set a limit of $|\kappa_c| < 4.2$ at 95% CL [268] using the VH channel alone. These limits are significantly looser than those for third-generation fermions, illustrating the difficulty of separating charm from background in hadronic environments. Indirect constraints on κ_c have also been derived from differential distributions sensitive to loop contributions involving charm quarks [249, 251]. Searches for rare Higgs boson decays to a meson and a photon [269] as well as searches for Higgs boson production in association with a charm quark (cH) [270, 271] or a photon (γH) [272] have also been used to set constraints on $|\kappa_c|$. At present, these searches allow values of κ_c several times larger than the SM expectation. Looking ahead, the HL-LHC is expected to improve sensitivity significantly, potentially reaching observation of the decay and its first measurement. The available projections [266] propose a sensitivity to the charm Yukawa coupling of $\kappa_c < 1.5$ by the end of HL-LHC at 95%. This projection is likely conservative considering the newest results and the rate of improvement in recent years. Measuring κ_c remains one of the key challenges in precision Higgs-boson physics and a critical test of the Yukawa-type interaction assumed in the SM.

Beyond the charm quark, probing the Yukawa couplings of the first- and second-generation fermions remains an even greater challenge. Current LHC studies can only set very loose indirect constraints on the light quark Yukawa couplings. As an example, in Ref. [272] CMS excludes scenarios where first- or second-generation quarks have Yukawa couplings comparable to those of the third generation, probing $H\gamma$ production. The Yukawa coupling to the electron has also been constrained via direct searches for $H \to ee$ by ATLAS [273] and CMS [274], with limits several orders of magnitude above the SM prediction. Future lepton colliders and dedicated Higgs factories are expected to significantly improve these constraints.

A more in-depth discussion of the kappa framework formalism can be found in the LHC Higgs Working Group Reports [56, 256].

11.3.5.2 *SMEFT Formalism and Results*

The SMEFT Lagrangian has the same field content and it respects the same linearly-realized $\mathrm{SU(3)}_C \times \mathrm{SU(2)}_L \times \mathrm{U(1)}_Y$ local symmetry as the SM. The difference is the presence of operators

$\kappa_{Z\gamma}$	–	$1.36\,^{+0.30}_{-0.36}$	$1.61^{+0.32}_{-0.35}$	6.8%

with canonical mass-dimension d larger than 4, built of SM fields, and representing the projection at the EW scale of generic extensions of the SM living at a UV mass scale Λ well above the EW scale. At the EW scale the heavy particles of the UV-complete theory cannot be produced as physical states and only leave their imprint as quantum effects induced by $d > 4$ effective operators that can affect SM couplings and masses but also introduce new interactions not present in the SM Lagrangian. While a modification of the SM Higgs-boson couplings as introduced by the κ-formalism discussed in Sec. 11.3.5.1 can only describe BSM effects that amount to a rescaling of production rates and branching ratios, the SMEFT formalism (similarly to the HEFT formalism) can be used to also explain anomalies arising in differential distributions since it introduces Lorentz structures not existing in the SM Lagrangian. Furthermore, the same SMEFT operators contribute not only to Higgs-boson processes but to a much larger number of observables and can therefore be constrained by a broad spectrum of measurements that could reveal underneath correlations among EFT couplings and point to classes of preferred BSM models.[6] Last but not least, the SMEFT is a full fledged quantum field theory and as such can systematically include effects induced by SM quantum corrections below the scale Λ and can also seamlessly be matched to low-energy EFT below the EW scale, e.g. the 4-fermion operator Lagrangian commonly used to describe the dynamics of flavor physics[7].

The SMEFT Lagrangian consists of the SM Lagrangian ($\mathcal{L}_{\rm SM}$) and a series of operators organized in a systematic expansion in d, where each consecutive term is suppressed by an increasingly larger power of a the high mass scale Λ such that the SMEFT Lagrangian can be written as:

$$\mathcal{L}_{\rm SMEFT} = \mathcal{L}_{\rm SM} + \sum_d \sum_i \frac{C_i^{(d)}}{\Lambda^{(d-4)}} \mathcal{O}_i^{(d)} \,. \qquad (11.21)$$

The contribution of the SMEFT operators of dimension $d > 4$ to physical amplitudes is therefore suppressed by $(E/\Lambda)^{d-4}$, where E is the relevant energy scale of the process. The applicability of the SMEFT approach requires that $\Lambda \gg E$, under which assumption the expansion in d can be truncated and only a finite number of new interactions is considered. The Wilson coefficients $C_i^{(d)}$ encode the virtual effects of the heavy new physics in low-energy observables. For a given UV completion of the SM, their dependence on masses and couplings of the new particles can be obtained via matching with the UV theory at the scale Λ. More generally, and in the absence of a specific assumption on the UV theory, they can be inferred using specific power-counting rules [278, 279], or constrained by fitting to specific sets of observables. All parameters of the SMEFT Lagrangian, namely SM parameters and Wilson coefficients, are scale dependent and their scale dependence is determined by the renormalization group equations of the full SMEFT.

The SMEFT approach is clearly very general, and can be made more specific and predictive by further assumptions on the UV physics of which it is a low-energy projection. For instance, assuming baryon and lepton number conservation, the most general SMEFT Lagrangian only contains even-dimension operators. This is commonly assumed in studies of Higgs-boson and more generally collider observables which therefore start by including $d = 6$ operators, while the inclusion of $d = 8$ or higher-dimension operators is considered in assessing the validity of truncating the SMEFT expansion at $d = 6$ or for those observables that are more sensitive to $d = 8$ operators, such as e.g. certain Drell-Yan angular distributions [280–282].

The list of $d = 6$ operators was first classified in a systematic way in Ref. [283] after the works of Ref. [284]. Subsequent analyses pointed out the presence of redundant operators, and a minimal and complete list of operators was finally provided in Ref. [285][8]. For a single family of fermions, i.e. not considering flavor indices, the SMEFT Lagrangian can be expressed in terms of 59 independent operators. Considering the 3 families of fermions of the SM, flavor indices can be added to these 59 operators, and furthermore, new operator structures, that have been dismissed by means of Fierz transformations in the single family case, have to be considered, for a total of 2499 independent operators that do not violate baryon and lepton number [288].

The numbers of operators can be reduced by requiring additional symmetry properties of the UV-complete theory. For instance, requiring no additional CP-violation besides the one already introduced in the SM via the CKM matrix restricts the number of $d = 6$ operators for a single family to 53 (out of 59) and requires the Wilson coefficients to be real. At the same time, assumptions on the level of flavor-violation introduced by NP at the UV scale can drastically limit the number of flavor-structures allowed in the SMEFT operators. Requiring the UV theory to have maximal flavor symmetry, namely $U(3)^5$, and therefore assuming that the SM Yukawa couplings are the only sources of

[6] It should be pointed out that some of the processes considered in global fits of the SMEFT are backgrounds to Higgs-boson analyses and their SMEFT interpretation should be consistently considered along with the signal one in such analyses. This is true in general for all background processes, and, together with other improvements, is part of the ongoing effort to improve SMEFT global fits.

[7] For comprehensive reviews of the SMEFT see Ref. [275–277].

[8] Complete enumerations of $d = 8$ operators have been obtained [286] and some preliminary constraints on particular subsets of these operators have been derived from experimental measurements [287]. Still, in this review, the SMEFT Lagrangian will be truncated at the level of dimension-6 operators.

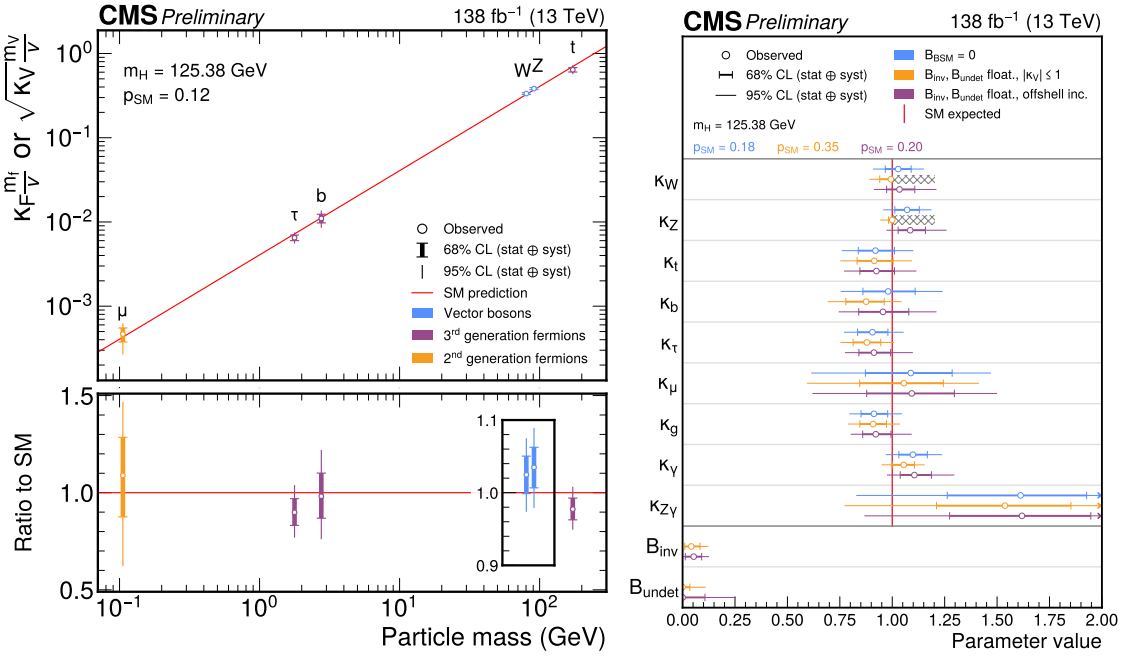

Figure 11.11: Reduced Higgs boson coupling strength modifiers and their uncertainties, CMS [239] (left). Combined measurements of coupling modifiers with various assumptions, CMS [239] (right). Equivalent plots for ATLAS can be found in Ref. [240].

$U(3)^5$ breaking (a.k.a. Minimal Flavor Violation), reduces the number of allowed SMEFT operators to 41. If NP breaks flavor by distinguishing the first two generations from the third one, the SMEFT operators only respect a $U(2)^5$ flavor symmetry, and a total of 124 SMEFT operators needs to be considered [289]. Further generalization are possible although most of the existing studies have so far considered the $U(3)^5$ and $U(2)^5$ benchmarks, or a hybrid $U(2)^3$ for quarks and $U(3)^2$ for leptons.

Given a set of $d = 6$ SMEFT operators generated at the UV scale Λ, their mixing under renormalization and the scale evolution of the corresponding Wilson coefficients is completely known at leading-order of SM interactions (QCD and EW). The tree-level matching conditions at the UV scale have been systematically calculated [290–293] and their evolution from Λ to the EW scale can be obtained via the LO anomalous dimensions of SMEFT operators [288,294,295]. A variety of tools exist that allow to automatically perform both the matching at the UV scale [292,293,296] and the LO scale evolution [297–299]. Observables at the EW scale are either computed with independent codes or obtained with automated tools such as `MadGraph5_aMC@NLO` [300] interfaced with SMEFT Feynman-rules generators such as `SMEFTsim` [301, 302] or `SMEFT@NLO` [303]. They can be calculated including $d = 6$ effects at linear or quadratic order, although these last ones are technically of $O(1/\Lambda^4)$ and therefore of the same order in Λ as the effects generated by the $d = 8$ operators. Several studies have included them to quantitatively estimate their impact and test the validity of the EFT expansion.

Once the EFT formalism is in place, it can be used either *top-down* with a specific UV-completion in mind and a specific decoupling scale Λ or *bottom-up* when no or little assumptions are made on the BSM physics above a generic scale Λ. In the first case the matching to the SMEFT at the given scale Λ can be calculated at the desired perturbative order, singling out only a limited number of operators that are generated by such theory and testing how they can successfully reproduce the EW and low-energy phenomenology. Vice versa, if the UV theory is not known, the Wilson coefficients at the scale Λ are fitted, together with the SM parameters, to existing data and information on the UV theory is obtained. In this last case, the fit will identify preferred $c_i(\Lambda)/\Lambda^2$ ratios, such that from perturbativity arguments a lower bound on the scale of new physics Λ can be placed.

The Higgs-boson mass, width, branching ratios, as well as total and differential cross sections can be calculated in the SMEFT in terms of Wilson coefficients at the EW scale and the role of different SMEFT operators can be constrained by comparing to LHC experimental measurements. Individual Higgs-boson couplings can be expressed in terms of SMEFT Wilson coefficients such that their deformation can be related to effects in non-Higgs related observables. In fact, through the EFT formalism individual operators both mix by the effect of SM radiative corrections and at the same time contribute to multiple processes, not only Higgs-boson related, such that considering their broad impact can stress-test the SMEFT framework and isolate the regions of SMEFT parameters that are phenomenologically allowed. An exhaustive review of the SMEFT and its phenomenological studies, including studies limited to specific Higgs-boson observables and assuming different orders of SM effects, can be found in [277] (and references therein). Among them, several recent studies have presented individual and global fits of SMEFT Wilson coefficients that consider a broad spectrum of observables including Higgs-boson production and decay rates as well as STXS, top-quark rates and asymmetries, electroweak precision observables and diboson production, Drell-Yan observables, jet production cross sections, and flavor observables [304–312].

As an illustration, Fig. 11.12 shows the result of a global fit of SMEFT operators containing the SM scalar field ϕ, and hence directly affecting Higgs-boson observables, but also being constrained by electroweak, top-quark, Drell-Yan, and flavor observables through renormalization group evolution (RGE). The lower plot gives the 95% probability bounds obtained on the $C_i(\Lambda)/\Lambda^2$ coefficients, while the upper plot translates those bounds into a lower bound on the scale of new physics (normalized by the square root of the maximum of the 95% Highest Posterior Density Interval, or HPDI, for $|C_i|$). Both panels show results for the three cases 1)$\Lambda = 10$ TeV with RGE, 2) $\Lambda = 3$ TeV with RGE, and 3) $\Lambda = 1$ TeV with no RGE. Furthermore, the horizontal lines indicate the maximum value allowed for each Wilson coefficient in the fit, corresponding to the perturbativity limit (4π), for the different values chosen for the scale Λ. The cases in which the 95% HPDI interval touches the prior's edges are hatched with red diagonal lines, indicating that the fit is just returning what assumed in the prior and further precision in the determination of the most con-

xcept for Open Access articles.

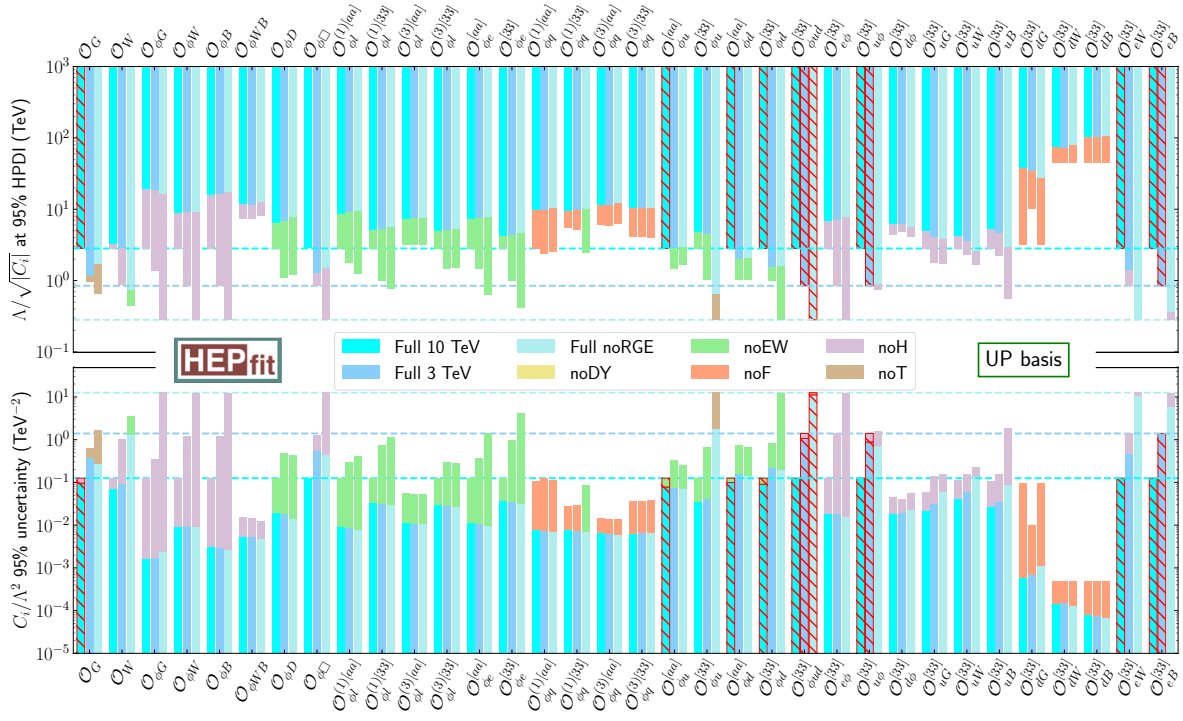

Figure 11.12: Results from a global fit in the $U(2)^5$ flavor-symmetric SMEFT (from Ref. [304]). For each coefficient C_i, the bottom panel shows the width of the 95% probability range divided by two, while the top panel shows the (normalized) scale of new physics allowed by the data at 95% probability. Each case includes results obtained for different values of Λ and removing the most constraining data set for that particular coefficient. The color code is as explained in the legend (see text for more details).

straining observables is needed. When the posterior distribution of a coefficient is completely flat, indicating that more observables need to be included in the fit, the 95% HPDI interval is hatched with diagonal white lines. The role of Higgs-boson measurements of signal strengths and STXS on several new physics interaction is manifest (see difference between blue and purple bounds). More details can be found in Ref. [304].

Overall, several operators that directly affect leading Higgs-boson production or decay modes are strongly constrained by LHC measurements, while operators whose main role is to affect e.g. high-p_T^H distributions are still marginally constrained, due to limited statistics in the experimental measurements, but their effects will be within the reach of the HL-LHC sensitivity. At the same time, several correlations have emerged with operators that are mainly constrained by non-Higgs observables, such that precision measurements of SM parameters, top-quark couplings, and Drell-Yan cross sections will provide very constraining complementary information.

In addition to the global fits prepared by theoretical groups, ATLAS and CMS have published interpretations of the Higgs boson measurements discussed in this document in terms of EFT constraints. The studies range from interpretations of differential cross sections or of STXS measurements (see for instance Refs. [239, 251, 311]) to analyses based on the construction of dedicated observables sensitive to specific operators. Several examples of the latter, related to CP properties, will be discussed in Section 11.3.9. Finally, first attempts by the collaborations to perform global fits including data from LHC Higgs boson, EW vector boson, top quark, and multi-jet measurements, and also EWPO measurements from LEP and SLC, have been reported in Refs. [312, 313].

11.3.6 *Higgs-boson Self-Couplings*

One of the most important open questions in the field is the precise mapping of the Higgs potential and the exploration of the inner workings of the EWSB mechanism. Probing the structure of the Higgs potential has deep implications in several areas of fundamental physics, including electroweak phase transitions, baryogenesis, and early universe cosmology (see Section 11.2.4).

As discussed in the introduction (see Eq. 11.8), in the SM the Higgs potential can be decomposed in a Higgs-field mass term and two self-interaction terms, one trilinear and one quadrilinear in the Higgs-boson field. In the SM they can both be expressed through the unique self-coupling $\lambda_{SM} = \frac{m_H^2}{2v^2}$, but in the presence of new physics they could be interpreted as independent effective interactions expressed through different self-coupling parameters λ_3 and λ_4. In the spirit of the κ framework described in Section 11.3.5.1, these self-couplings can be parameterized by modifiers κ_3 and κ_4, both equal to 1 in the SM:

$$\kappa_3 = \frac{\lambda_3}{\lambda_3^{\rm SM}}, \quad \kappa_4 = \frac{\lambda_4}{\lambda_4^{\rm SM}}. \tag{11.22}$$

Probing these couplings is one of the central goals of the HL-LHC program. Current datasets do not yet provide sufficient sensitivity to directly measure κ_3 or κ_4. However, κ_3 can already be constrained through studies of Higgs pair production ($pp \to HH$). See Figure 11.4 for the main Feynman diagrams for HH production at the LHC. Single Higgs production processes also provide indirect sensitivity to κ_3 through global fits. In contrast, probing κ_4 directly requires access to triple Higgs production ($pp \to HHH$), which has an extremely low cross section in the SM and is out of reach even for the HL-LHC. Nevertheless, recent analyses have begun placing first experimental constraints on κ_4.

i. *Higgs Pair Production at the LHC*

The theory of double-Higgs (HH) production is discussed in Section 11.2.5.1. This process has not been observed yet at the LHC due to its very small production cross section in the SM. We recall that the N3LO+N3LL prediction for $\sigma_{\rm ggF}^{HH}$ is $33.46^{+0.88\%}_{-0.85\%}$ fb

at the 13 TeV LHC (see Sec. 11.2).

Experimentally, the most sensitive final states are HH $\to \gamma\gamma b\bar{b}$, HH $\to \tau\tau b\bar{b}$, HH $\to b\bar{b}b\bar{b}$, which benefit from the larger branching fraction of $b\bar{b}$ decays and the identification of the diphoton or ditau pair. Other decay modes, such as $VVb\bar{b}$, multilepton final states, and other final states involving tau leptons, are more limited in sensitivity, though they can provide complementary information and can help to constrain specific regions of phase space in a combined HH global fit.

The study of HH production provided the best avenue to access the trilinear self-coupling κ_3 at the LHC. Variations in the value of the κ_3 affect not only the total yield of HH events produced, but also the shape of key kinematical distributions such as the mass of the HH system. These changes need to be taken into account in the analysis for an optimal sensitivity to the self-coupling. Furthermore, a precise knowledge of the top-Yukawa coupling is needed. The best measurements of the HH production and of κ_3 require different optimizations that probe different regimes in p_T^H: lower for the measurement of κ_3 and higher for the observation of HH production.

ATLAS Ref. [183] and CMS Ref. [184] have placed limits at 95% CL on HH production cross section through the combination of all available Run-2 analyses, for an integrated luminosity of up to 140 fb^{-1} at 13 TeV. The results target the dominant ggF production and the subleading qqHH production, which provides access to the VVHH vertex and enables constraints on the κ_{2V} parameter. The experiments are starting to explore also rarer production modes, like VHH [314, 315] or ttHH production modes [316].

The latest observed and expected upper limits on the HH production signal strength at 95% CL for ATLAS Ref. [183] and CMS Ref. [184] are:

$$\begin{aligned} \text{ATLAS:} \quad & \mu_{\text{HH}} < 2.9 \quad (\text{expected} : 2.4)\,, \\ \text{CMS:} \quad & \mu_{\text{HH}} < 3.5 \quad (\text{expected} : 2.5)\,. \end{aligned} \tag{11.23}$$

For the VBF production mode the upper limits are $\mu_{\text{VBFHH}} <$ 44 (47) (ATLAS) and $\mu_{\text{VBFHH}} < 79$ (91) (CMS) also at 95% CL. These HH combinations yield the following constraints on the coupling modifiers κ_3 and κ_{2V}:

$$\begin{aligned} \text{ATLAS:} \quad & -1.2 < \kappa_3 < 7.2 \quad (-1.6 < \kappa_3 < 7.2 \quad \text{expected})\,, \\ & 0.6 < \kappa_{2V} < 1.5 \quad (0.4 < \kappa_{2V} < 1.6 \text{ expected})\,. \\ \text{CMS:} \quad & -1.39 < \kappa_3 < 7.02 \quad (-1.02 < \kappa_3 < 7.19 \quad \text{expected})\,, \\ & 0.62 < \kappa_{2V} < 1.42 \quad (0.69 < \kappa_{2V} < 1.35 \quad \text{expected})\,. \end{aligned} \tag{11.24}$$

These results have been combined in a joint ATLAS and CMS study of HH production using Run-2 data [317], including the most sensitive channels from each experiment, with integrated luminosities ranging between 126 and 140 fb^{-1}. An observed 95% CL upper limit on $\mu_{HH} < 2.5$ is set, with an expected value of 1.7 (2.8) assuming the absence (presence) of the SM HH signal. The HH signal strength is measured to be $0.8^{+0.9}_{-0.7}$, for an observed significance of 1.1 standard deviations (1.3 expected for the SM HH signal). Corresponding constraints are set on the couplings, also at 95% CL: $-0.71 < \kappa_3 < 6.1$ and $0.73 < \kappa_{2V} < 1.3$.

ATLAS and CMS have extended the study of HH production to new physics scenarios using the HEFT frameworks [184,318]. The results are interpreted in terms of constraints on HEFT operators and the correlation between them. They are also presented in terms of upper limits on specific benchmarks proposed by the LHC Higgs Working Group. In Ref. [318], constraints on individual SMEFT operators are also proposed, while in Refs. [184,318] the possibility of constraining HEFT operators whose coefficients, at the lowest order, are in direct correspondence with κ modifiers, is also explored. Overall, the results are consistent with the SM predictions. For more details, see the original references.

The Higgs pair searches can be combined with single-Higgs coupling measurements. We can exploit the complementarity between single-Higgs and di-Higgs processes to simultaneously probe multiple Higgs boson couplings, including the self-coupling and the top-quark Yukawa coupling. A joint fit enables the simultaneous constraint of key Higgs boson couplings such as κ_t, κ_V, κ_3, and κ_{2V}, and the study of their correlation. For the latest experimental $H + HH$ constraints see Refs. [319, 320].

Given the statistically limited nature of the Higgs boson pair production analyses and the ongoing advancements in experimental techniques, incorporating data from the LHC Run 3 is of particular importance. The first analysis utilizing the Run 3 dataset is presented in Ref. [321], where ATLAS presents a search for HH production in the $b\bar{b}\gamma\gamma$ final state using a combined dataset of 140 fb^{-1} at 13 TeV and 168 fb^{-1} at 13.6 TeV. This search sets a 95% CL upper limit on the signal strength of $\mu_{HH} < 3.8$, and constrains the Higgs boson self-coupling to $-1.7 < \kappa_3 < 6.6$. CMS has recently made public their first Run 3 search for this final state, for an integrated luminosity of 61.9 fb^{-1} at 13.6 TeV (2022-2023) [322]. They report a limit on the signal strength of $\mu_{HH} < 11.0$ (7.3) and a constraint on the self-coupling of $-5 < \kappa_3 < 12$ using a two-dimensional fit to the diphoton and dijet mass observables. CMS has also released a study of the $HH \to 4b$ final state using the same dataset [323]. The analysis sets observed (expected) upper limits of $\mu_{HH} < 4.4$ (4.4), as well as couplings constraints of $-3.3 < \kappa_3 < 9.7$, and $0.63 < \kappa_{2V} < 1.43$. Compared to previous LHC results in this final state, the sensitivity for an equivalent integrated luminosity shows a very significant improvement. Although these results do not yet exceed the sensitivity of the full Run 2 combinations, they clearly demonstrate the power of the Run 3 dataset and its potential to significantly improve κ_3 constraints already in the near term.

Projections for the HL-LHC, shown in Figure 11.13, indicate that each experiment can achieve a sensitivity better than 4σ by the end of the HL-LHC [266]. The combined ATLAS+CMS significance will result in an expected $> 5\sigma$ observation of the process already with 2 ab^{-1}. The uncertainty on the κ_3 parameter is projected to be better than 30% at 3ab^{-1}, with the statistical uncertainty expected to remain dominant. Ongoing improvements in analysis techniques are likely to outperform this expectation. Projections for κ_{2V} based on the performance of the ATLAS boosted VBF 4b analysis [324] search yield a precision of about 13% with 3 ab^{-1}.

ii. *The Hunt for Triple Higgs Boson Production*

Recent studies have focused on the extremely rare HHH production. Although the SM cross section for this process is far below the LHC sensitivity, its direct access to the Higgs quartic self-coupling λ_4 has motivated the first experimental attempts to constrain potential deviations from the SM prediction.

ATLAS placed a first 95% upper limit of 59 fb on the cross section for SM HHH production through the 6b final state, using the full Run-2 dataset [325] . This limit is equivalent to 760 times the SM cross section (750 expected). Assuming $\kappa_3 = 1$ then κ_4 is constrained to $-230 < \kappa_4 < 240$ at 95% CL (both for expected and observed limits). CMS has searched for HHH in the final states with four b jets and two photons [326] and six b jets [327] with the full Run-2 dataset. The observed (expected) 95% CL upper limits on the inclusive HHH production cross section are found to be 244 (152) fb and 44 (43) fb, respectively. They can be translated to constraints of $-533 < \kappa_4 < 541$ ([-397,406] expected) and $-190 < \kappa_4 < 190$ ([-190,190] expected), also at 95% CL. In these analyses simultaneous constraints of κ_3 and κ_4 are also explored. The ATLAS 4b results have been projected to the end of the HL-LHC, yielding a limit on HHH production that amounts to 86 times the SM expectation. This is a conservative estimation, since more final states will be explored in the future.

11.3.7 *Higgs-Boson Mass Measurements*

The mass of the Higgs boson is not predicted by the SM and must be determined experimentally. A precise determination of its value is therefore an essential input to all theoretical predictions of Higgs boson production cross sections and decay branching ratios. And, as discussed in Section 11.2, the Higgs boson mass not only plays a key role in Higgs phenomenology but also has fundamental consequences for the structure and long-term stability of the electroweak vacuum.

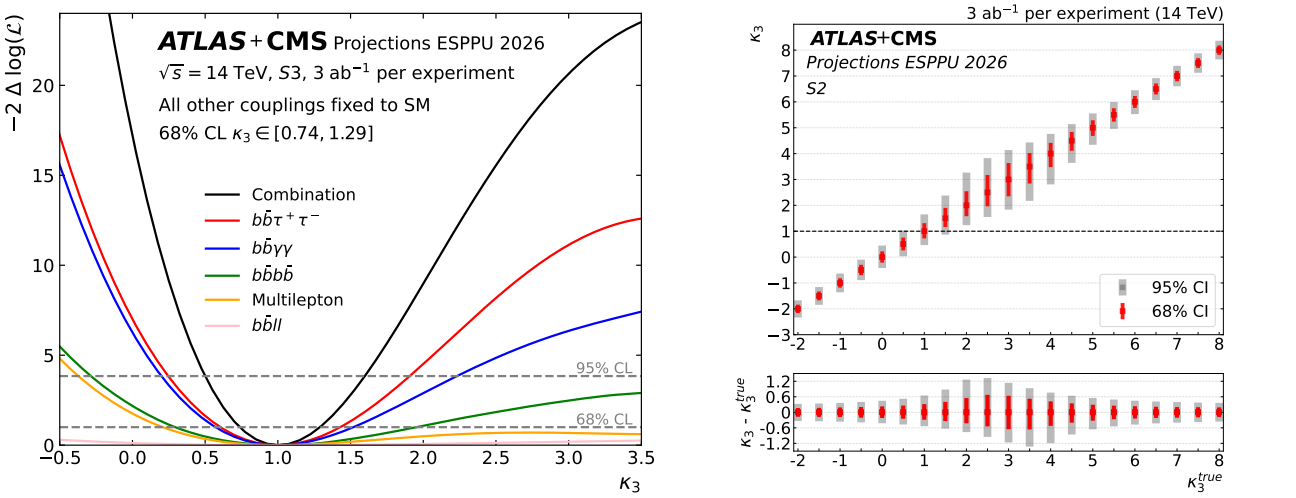

Figure 11.13: (Left) Expected ATLAS+CMS κ_3 likelihood scans for single decay channels and the combination for 3ab^{-1}, fixing $\kappa_3 = 1$ (Right) Precision on κ_3 as a function of its value [266].

The precision measurements of the Higgs boson mass at the LHC are based on two decay channels: $\gamma\gamma$ and $ZZ^*/4\ell$. These channels allow for a complete reconstruction of the decay products and provide mass resolutions that range from 1.4 GeV to 2 GeV for ATLAS and from 1.0 GeV to 2.8 GeV for CMS (see Ref. [328] and the reconstruction-performance references therein). The diphoton channel provides a larger sample of Higgs bosons but with a much larger background. The four-lepton channel has less signal events, but a much smaller background and better mass resolution. The measurements require a precise calibration of the energy and momentum scales for electrons, muons, and photons. The electron and muon calibrations are based primarily on the large $Z \to ee$ and $Z \to \mu\mu$ data samples, taking advantage of the precisely known mass of the Z boson. Since photons interact differently from electrons, an extrapolation from the electron calibration is necessary, which introduces additional systematic uncertainties.

ATLAS and CMS have published many Higgs boson mass measurements using both the Run 1 and Run 2 datasets. The most precise results from both experiments are summarized below:

- The most precise measurement of the Higgs boson mass was obtained by ATLAS using the Run 1 and Run 2 datasets by combining the diphoton and ZZ channels [329]. This yielded a mass of:

$$m_H = 125.11 \pm 0.09\,(\text{stat.}) \pm 0.06(\text{syst.})\ \text{GeV}.$$

- The most precise diphoton channel measurement was obtained by ATLAS [330], combining their Run 1 and Run 2 measurements. The mass was measured to be:

$$m_H = 125.22 \pm 0.11\,(\text{stat.}) \pm 0.09(\text{syst.})\ \text{GeV}.$$

  The systematic uncertainty of 90 MeV is worth noting, as it results from a highly challenging calibration procedure and the estimation of the material upstream of the calorimeter, which is required to extrapolate the calorimeter energy response from electrons in Z boson decays to photons. This result is promising for future precision measurements in this channel. In addition, ATLAS estimated the expected effect of the interference between the signal and the gluon fusion continuum di-photon background to be about 24 MeV (Ref. [330]).
- The most precise four-lepton channel result was obtained by CMS [231], combining the Run 1 and Run 2 measurements. This yielded a mass of :

$$m_H = 125.08 \pm 0.10\,(\text{stat.}) \pm 0.05(\text{syst.})\ \text{GeV}.$$

  It is the most precise single-channel measurement at the LHC. Since the result is dominated by the statistical uncertainty of 100 MeV, this channel will very likely continue to yield the most precise measurements in the future as the sizes of the data sets increase.

The ATLAS and CMS collaborations combined their mass measurements using the Run-1 dataset [328] yielding

$$m_H = 125.09 \pm 0.21\,(\text{stat.}) \pm 0.11(\text{syst.})\ \text{GeV}.$$

The mass combination using the full Run-2 datasets of the two collaborations will significantly improve our knowledge of the Higgs boson mass, given the doubling of the signal sample and the fact that most uncertainties are uncorrelated. It will be a useful input to future SM predictions and for the LHC combination of current and future Higgs boson measurements.

11.3.8 *Higgs-boson Width Measurements*

In the SM, the Higgs boson width is very precisely predicted once the Higgs boson mass is known. For a mass of 125 GeV, the Higgs boson has a very narrow width of 4.1 MeV [57]. It is dominated by the fermionic decays partial width at approximately 75%, while the vector boson modes are suppressed and contribute 25% only.

In proton-proton collisions such as the ones at the LHC only the cross sections times branching fractions can be measured in all production modes. As a consequence, the total width of the Higgs boson cannot be directly derived form the measurements of Higgs boson rates without additional assumptions. Direct constraints on the Higgs boson width are much larger than the expected width of the SM Higgs boson. Indirect constraints, subject to assumptions, with all the statistics of the HL-LHC will constrain the measurement only to the $\approx 20\%$ level. In contrast, a future Higgs factory would be able to constrain the width to the level of 1% through the recoil against a Z boson in $e^+e^- \to ZH$ events [194]. The different approaches at LHC and the latest experimental measurements are discussed in the following.

11.3.8.1 *Direct constraints*

Analyses of the reconstructed mass line-shape in the two channels with a good mass resolution, the $H \to \gamma\gamma$ and $H \to ZZ^{(*)} \to 4\ell$ channels, allow for a direct measurement of the width of the SM Higgs boson. The intrinsic mass resolution in these channels is much larger than the expected width of the SM Higgs boson. As a result, only upper limits on the Higgs boson width have been set by ATLAS [331] and CMS [231]. The two main challenges of direct constraints on the width through the

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
except for Open Access articles.

measurement of the line-shape are: (i) the modeling of resolution uncertainties and (ii) the modeling of the interference between the signal and the continuum background which can be sizeable for large widths, in particular in the range where direct constraints are set. These challenges affect mostly the diphoton channel. Given that these interference effects are small with respect to the individual channels sensitivity, they are usually neglected in deriving constraints on the total width. The combined constraints, however, being more precise, could be affected by the interference. Direct lineshape measurements provide the most unambiguous access to the Higgs boson width, however constraints are still much larger than the expected SM width. The current results are fully compatible with the SM hypothesis.

CMS reported an upper limit on the total width of $\Gamma_H < 50$ MeV at 68% CL (330 MeV at 95% CL) [231] for the $H \to ZZ^{(*)} \to 4\ell$ channel, using the 138 fb^{-1} collision dataset at 13 TeV. This is the most stringent constraint to date in this final state. Recently CMS followed this result with a new constraint in the diphoton channel [332] which considers the effect of the interference with the continuum, for the first time at the LHC. See more details in the following section.

11.3.8.2 *Constraints in the diphoton channel*

In the diphoton channel, it was noticed in Refs. [236, 333–335] that the effect of the interference between the main signal $gg \to H \to \gamma\gamma$ and the continuum irreducible background $gg \to \gamma\gamma$, taking into account detector resolution effects, is responsible for a non negligible mass shift. A similar interference effect is found between $q\gamma \to \gamma\gamma$ and $q\gamma \to H \to \gamma\gamma$. The size of the mass shift depends on the total width of the Higgs boson and it was suggested that measuring this mass shift could provide a constraint on the width [333]. It was further noticed that the mass shift has a dependence also on the diphoton transverse momentum. The total width of the Higgs boson could therefore be constrained using the diphoton channel alone.

Furthermore, Ref. [336], reported that the interference between the main signal $gg \to H \to \gamma\gamma$ amplitude and the continuum irreducible background $gg \to \gamma\gamma$ amplitude generates non-negligible change in the on-shell cross sections, as a result of the existence of a relative phase between these amplitudes. The size of this on-shell interference effect depends on the total width of the Higgs boson and it was suggested that measuring this on-shell cross section precisely could provide a constraint on the Higgs total width. This interference effect yields a reduction of around 2% for the $gg \to H \to \gamma\gamma$ cross section measurement in the SM. The current evaluation of this interference effect is performed at NLO and has a $^{+50\%}_{-30\%}$ uncertainty, due to the fact that the large relative phase is driven by the two-loop $gg \to \gamma\gamma$ background amplitude [236, 333, 336]. This on-shell interference effect has a dependence on the p_T of the diphoton system and the photon polar angle in the diphoton rest frame, which can be further exploited to improve the measurement to constrain the Higgs total width. Taking the ratios of the on-shell cross section of the Higgs boson to diphoton channel and the cross section of the Higgs boson to four-leptons channel where the interference effect is negligible could put a bound on the Higgs boson total width. This ratio is free from many dominant sources of systematic uncertainties for cross section measurements, i.e., PDF uncertainty and luminosity uncertainty, and can be further improved by the accumulation of the LHC data.

Experimental studies were performed to estimate the size of these effects [330, 337]. As discussed in Section 11.3.7, the estimation of the expected mass shift in the diphoton channel in ATLAS is 24 MeV. Very preliminary studies of the sensitivity of the mass shift method to estimate the width of the Higgs boson in the HL-LHC were made by ATLAS [338] and yielded an expected 95% CL upper limit on the total width of approximately 200 MeV from 3 ab^{-1} of 14 TeV data. Similarly, a preliminary estimation of the current limit from the cross section ratio measurement and the the interference effect set constraints of 60 MeV for 3 ab^{-1} of 14 TeV data [339].

These projections are superseded by a new Run-2 result by CMS that reports the first Higgs width constraint in the diphoton channel exploiting the effect of interference [332]. It uses the $H \to \gamma\gamma$ lineshape and studies the distortions in the mass spectrum caused by the interference between $gg \to H \to \gamma\gamma$ and the continuum $gg \to \gamma\gamma$ background. The measurement yields an upper limit of $\Gamma_H < 92$ (138) MeV at 95% CL and is the most stringent Γ_H constraint to date using measurements of on-shell Higgs boson final states.

11.3.8.3 *Indirect constraints from off-shell couplings*

The total width of the Higgs boson can also be constrained through the simultaneous analysis of on-shell and off-shell production measurements in the VV channel [232, 233]. In the off-shell regime, introduced in Section 11.2.5.3, production in the VV final state is enhanced when the invariant mass exceeds $2m_V$ and both vector bosons become on-shell. This enhancement partially offsets the decline in Higgs boson production away from its mass peak and enables the measurement described here.

The signal strength measurements for on-shell $\mu_{\text{on-shell}}$ and off-shell $\mu_{\text{off-shell}}$ for a given production mechanism j can be expressed in terms of coupling modifiers g_p and g_d for production and decay respectively. The corresponding cross-sections are given by Eq. 11.12, repeated here for completeness:

$$\begin{aligned} \sigma_j^{\text{on-shell}} &\propto \frac{g_p^2 g_d^2}{\Gamma_H} \propto \mu_j^{\text{on-shell}} \quad \text{and} \\ \sigma_j^{\text{off-shell}} &\propto g_p^2 g_d^2 \propto \mu_j^{\text{on-shell}} \Gamma_H \end{aligned} \tag{11.25}$$

Assuming that the coupling modifiers are identical in both regimes, the total Higgs boson width Γ_H can be extracted from the ratio of the measured on-shell and off-shell signal strengths. This measurement relies on the assumption that the ratio of couplings in the off-shell and on-shell regimes follows the SM prediction, that ggF is the dominant production mechanism, and that there are no significant contributions from BSM particles to the ggH loop within the mass range considered in the analysis. Another important aspect to consider is the sizable destructive interference between the Higgs boson signal and the non-resonant VV production in the off-shell region. This interference scales with $\sqrt{\mu_j^{on-shell}}$.

ATLAS and CMS have studied off-shell production in the $H \to ZZ \to 4\ell$ channel, and are able to exclude the background-only hypothesis $\mu_{\text{off-shell}} = 0$ with a significance of 3.7σ (2.4σ) observed (expected) for ATLAS [340] and 3.8σ (2.4σ expected) for CMS [231]. This corresponds to evidence for the off-shell production of a Higgs boson, through the measurement of a significant deficit in the overall $gg \to VV$ production. The measured total off-shell signal strengths $\mu_{\text{off-shell}}$, combining the 4ℓ and $2\ell 2\nu$ final states and the ggF, VBF and VH production modes, are the following:

$$\begin{aligned} &\text{(ATLAS)}\ \ \mu_{\text{off-shell}} = 1.06^{+0.62}_{-0.45}\ \text{(obs)}\ \ [1.00^{+0.83}_{-0.83}\ \text{(exp)}], \\ &\text{(CMS)}\ \ \mu_{\text{off-shell}} = 0.67^{+0.42}_{-0.32}\text{(obs)}\ \ [1.00^{0.83}_{-0.84}\ \text{(exp)}]. \end{aligned} \tag{11.26}$$

These off-shell production analyses exploit kinematic event characteristics to further gain in sensitivity to discriminate between the signal and background. From these measurements of the cross-section a constraint on the total width can be derived as mentioned above, following 11.25. The sensitivity to the Higgs width already reached at Run 2 is remarkable:

$$\text{(ATLAS)}\ \ \Gamma_H = 4.3^{+2.7}_{-1.9}\ \ [4.1^{+3.5}_{-3.4}\ \text{(exp)}]\ \text{MeV}, \tag{11.27}$$

$$\text{(CMS)}\ \ \Gamma_H = 3.0^{+2.0}_{-1.5}\ \ [4.1 \pm 3.5\ \text{(exp)}]\ \text{MeV}. \tag{11.28}$$

CMS has also derived results allowing for anomalous couplings of the Higgs boson [341], reducing the discriminating power of the kinematic variables used in the analysis but also mitigating the model dependence. Neither the results nor the sensitivities are significantly affected by allowing specific anomalous coupling parameters to float in the fits. The best fit of Γ_H in the anomalous couplings scenario ranges from $\Gamma_H = 2.7^{+2.1}_{-1.4}$ MeV to $\Gamma_H = 3.4^{+2.3}_{-1.8}$

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

MeV, depending on the coupling addressed. CMS has also investigated the impact of heavy particles in the ggH loop, through the introduction of a new heavy quark with an unconstrained coupling strength κ_Q [231]. This scenario results in less stringent limits on Γ_H, though largely consistent with the previous quoted values. The resulting Γ_H measurement in this case is $\Gamma_H = 2.7^{+2.7}_{-1.8}$ MeV (expected $4.1^{+5.5}_{-4.1}$). More details can be found in Refs. [341] and [231], respectively.

ATLAS has recently applied the "on-shell to off-shell" technique to constrain the total width of the Higgs boson in the $H \to WW \to 2\ell 2\nu$ decay mode the 140 fb^{-1} Run-2 dataset [342]. The analysis sets an observed (expected) 95% CL upper limit on the rate of off-shell Higgs boson production at 3.4 (4.4) times the SM prediction. This translates into an observed (expected) upper limit on the Higgs boson total width of 13.1 (17.3) MeV. ATLAS has applied a similar on-sell to off-shell logic to $t\bar{t}H$ production, assuming the tree-level Higgs-top Yukawa coupling is the same in the on-sell and off-sell regimes. The measurements of on-shell $t\bar{t}H$ production and four-top-quark production, which includes contributions from off-shell processes, are combined to yield an observed (expected) 95% CL upper limit of 450 MeV (75 MeV). Considering as well the constraint on the Higgs-top Yukawa coupling from loop-induced Higgs boson production and decay processes improves this result down to 160 MeV (55 MeV) [343].

Finally, ATLAS and CMS performed a study of the prospects for HL-LHC for measuring the Higgs boson width in the four lepton channel using the on-shell to off-shell method. Within assumptions similar to the ones mentioned above for the Run-2 measurements and assuming the SM central value, the width of the Higgs boson could be constrained with a $\approx 20\%$ precision with a luminosity of 3 ab^{-1} [344]:

$$\Gamma_H = 4.1^{+0.7}_{-0.8}\,\text{MeV}. \tag{11.29}$$

11.3.9 *Higgs-boson Spin and CP Properties*

In the SM, the Higgs boson has quantum numbers $J^{PC} = 0^{++}$, meaning that it is a spin-0 particle, with even charge-parity (CP). The determination of the spin and CP quantum numbers of the observed Higgs boson is therefore an essential test of the theory. Alternative spin and parity hypotheses can be tested through measurements of the kinematic distributions of the particles produced in association with the Higgs boson or resulting from the Higgs boson's decay. The charge conjugation quantum number can be inferred by the fact that the observed particle decays to two photons: since charge conjugation is multiplicative and since photons are C-odd eigenstates, the observation of the decay to two photons implies that the observed neutral particle is C-even, if we assume C conservation.

The spin of a particle directly impacts the angular distributions and relative momenta of its decay products. For example, in the decay of a spin-0 particle, the matrix element does not depend on the production and decay angles in its rest frame, which results in isotropic distributions. In contrast, a spin-2 boson would generate characteristic angular modulations and correlations among final-state momenta.

Channels in which the Higgs boson decays can be fully or partially reconstructed provide sensitivity to spin-parity assignments, anomalous couplings, and possible CP-violating contributions. The most powerful channel in this respect is $H \to ZZ^* \to 4\ell$, where all final-state momenta are measured with high precision. The fully differential decay rate depends on seven observables: the invariant masses of the two lepton pairs, and five angles defined in the Higgs boson rest frame [345, 346]. These include the decay angles θ_1 and θ_2 (the angles between the negatively charged leptons and the directions of the Z_1 and Z_2 bosons in their respective rest frames), Φ (the angle between the decay planes of the two Z bosons), Φ_1 (the angle between the Z_1 decay plane and the production plane defined by the beam axis), and θ^* (the polar angle of the Z_1 boson relative to the beam axis). These observables, illustrated in Fig. 11.14, provide detailed information on the spin and CP structure of the Higgs boson and are used in both model-specific and effective field theory interpretations.

In this channel, both ATLAS and CMS have used matrix element-based kinematic discriminants and multivariate techniques to test alternative J^P hypotheses. The results show excellent agreement with the scalar (0^+) hypothesis and exclude a pure pseudoscalar (0^-) interpretation, as well as a wide range of spin-1 and spin-2 models, at high confidence levels [40].

Complementary information is provided by the $H \to WW^* \to \ell\nu\ell\nu$ decay channel. Although a full kinematic reconstruction is not possible due to the presence of neutrinos, spin correlations induced by the V–A structure of the W boson decay lead to distinctive patterns in the final-state leptons. In particular, for a scalar Higgs boson, the charged leptons tend to be emitted close together in the transverse plane, have a small invariant mass $m_{\ell\ell}$, and the transverse mass of the reconstructed Higgs boson candidate has a distinctive distribution. These kinematic features provide discrimination power between scalar, pseudoscalar, and higher-spin hypotheses. Both experiments have excluded spin-1 alternatives in this channel at the 95% confidence level or higher.

The $H \to \gamma\gamma$ channel contributes useful constraints on alternative spin-CP scenarios. For example, the production angle of the photons in the Collins–Soper frame is sensitive to the spin of the decaying boson. Spin-2 hypotheses predict markedly different distributions from spin-0 and have been excluded with high significance. Moreover, spin-1 hypotheses are strongly disfavored on theoretical grounds: the Landau–Yang theorem forbids the decay of a spin-1 particle into two identical massless vector bosons. While exotic models involving intermediate decays to collimated photons can evade this constraint, they are not consistent with global fits to the data and are tightly constrained by existing measurements.

In addition to information from the decay kinematics, production observables sensitive to the structure of the Higgs–vector boson and Higgs-fermion couplings have been exploited in channels such as vector boson fusion (VBF), and associated production channels (VH and ttH).

In summary, the combined data from ATLAS and CMS have excluded a pure pseudoscalar (CP-odd) Higgs boson and a range of spin-1 and spin-2 models at confidence levels that exceed 99%. These results are covered in more detail in previous reviews [40].

11.3.9.1 *CP-odd interactions and CP-mixing*

While a pure CP-odd hypothesis for the observed Higgs boson has been excluded at high confidence level, the presence of a small CP-odd admixture, which would signal CP violation in the Higgs sector, remains experimentally allowed. CP-odd interactions can be expressed in the framework of the SMEFT, formulated in various operator bases (as discussed in Section 11.3.5.2). This formalism aligns naturally with global analyses of a broader set of observables probing the Standard Model and its possible extensions. The CP properties inferred for the Higgs boson depend on the coupling being probed, since different inter-

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
except for Open Access articles.

actions can exhibit different CP-mixing structures. In the context of Higgs boson interactions with electroweak bosons, the effective Lagrangian includes higher-dimensional operators constructed from the gauge-invariant combination $\Phi^\dagger\Phi$ and the electroweak field-strength tensors $W^I_{\mu\nu}$ and $B_{\mu\nu}$, defined prior to electroweak symmetry breaking. The CP-odd interactions are then encoded in three dimension-six operators: $\Phi^\dagger\Phi\,\tilde{W}^I_{\mu\nu}W^{I\mu\nu}$, $\Phi^\dagger\Phi\,\tilde{W}^I_{\mu\nu}B^{\mu\nu}$, and $\Phi^\dagger\Phi\,\tilde{B}_{\mu\nu}B^{\mu\nu}$, with corresponding Wilson coefficients $c_{H\tilde{W}}$, $c_{H\tilde{W}B}$, and $c_{H\tilde{B}}$, respectively.

It is important to note that CP-odd couplings of the Higgs boson to vector bosons are not allowed at tree level [347] and are therefore suppressed by Λ, the scale of new physics. However, CP-odd couplings of the Higgs boson to fermions are allowed at tree level, and these can be parametrised in a somewhat simpler way with the following Lagrangian, which accounts only for an additional pseudo-scalar term:

$$\mathcal{L}_0^{\psi_f} \supset \frac{\lambda_f}{\sqrt{2}}\left(\kappa_f H\overline{\psi}_f\psi_f + i\tilde{\kappa}_f H\overline{\psi}_f\gamma_5\psi_f\right). \tag{11.30}$$

This formulation is equivalent to the definition of the CP-mixing angle $\varphi_f = \tan\frac{\tilde{\kappa}_f}{\kappa_f}$.

It is interesting to note that CP-odd Higgs couplings to fermions can have sizable effects on low-energy observables, such as the electron electric dipole moment (EDM), which is both precisely measured and theoretically well understood [348, 349]. In particular, due to the large value of the top Yukawa coupling, CP-violating interactions involving the top quark are subject to stringent indirect limits. Current bounds on the electron EDM constrain the CP-odd top Yukawa coupling to values below $\tilde{\kappa}_t < 0.001$ [348], a level of precision that is extremely challenging to surpass with direct measurements at the LHC. It should be emphasized, however, that EDM experiments constrain the product of Yukawa couplings, in this case $\kappa_e \times \tilde{\kappa}_t$. As a result, assumptions must be made about the value of κ_e, which is itself not experimentally accessible at present.

By contrast, the constraints on the CP-odd Yukawa coupling of the tau lepton are considerably weaker. The current electron EDM bounds allow values as large as $\tilde{\kappa}_\tau < 0.3$ [348], leaving significant room for potential CP violation in the Higgs–tau sector. This makes direct searches for CP-odd or mixed CP Higgs couplings to taus particularly compelling. Such effects can be probed using kinematic observables sensitive to tau polarization in Higgs decays, as will be discussed in Sec. 11.3.9.3 of this review. For a discussion of searches for CP-odd couplings to vector bosons, we refer the reader to previous editions of this review [40].

With the full Run 2 dataset, analyses began to simultaneously exploit both the production and decay kinematics of the Higgs boson for CP measurements. This strategy is exemplified by the analysis of the $H \to ZZ^* \to 4\ell$, $H \to \gamma\gamma$, and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channels, in both ATLAS and CMS, which combine information from the production and decay angles of the process with observables sensitive to VBF production [350, 351]. In addition, studies of off-shell Higgs boson production have provided complementary information on the CP structure of the Higgs–electroweak boson interaction [341].

Some of these studies make use of "optimal observables" constructed from matrix elements within the SMEFT framework. Specifically, they are defined as the ratio of the interference term between the SM and SMEFT amplitudes to the squared SM matrix element, evaluated for given values of the Wilson coefficients $c_{H\tilde{W}}$, $c_{H\tilde{W}B}$, and $c_{H\tilde{B}}$.

Tests of CP in the HVV coupling can also be probed with the VBF production process in the $H \to \tau^+\tau^-$ channel or in the WH($b\bar{b}$) channels. Some examples of such measurements performed by ATLAS [352] are shown in Fig. 11.15. All results are found to be in agreement with the SM expectations. CMS has performed an analysis using the VBF and VH production channels and has combined its results with the aforementioned ZZ^* channel using the same dataset [353].

These results emphasize the complementarity between production and decay observables and the power of a global strategy that combines all accessible experimental information to test the Higgs boson's properties.

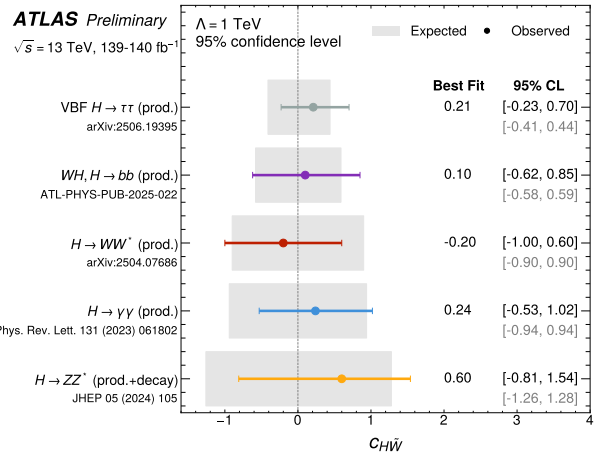

Figure 11.15: Comparison of results for the expected and observed measurements of the CP-odd Wilson coefficient $c_{H\tilde{W}}$ by ATLAS using the Run 2 dataset. The data and 95% confidence level (CL) bars show the observed values with statistical and systematic uncertainties, and the grey bands centered at zero show the expected 95% CL intervals. The test fit values and 95% CL observed (expected) limits are also explicitly listed on the rightmost side of the plot in black (gray). All couplings scale as $1/\Lambda^2$ with the assumed value of $\Lambda = 1$ TeV.

11.3.9.2 *Probing the $Hf\bar{f}$ coupling CP properties in $pp \to t\bar{t}H$ production*

As mentioned above, although EDM experiments provide stringent constraints on CP-violating effects in the top Yukawa sector, these limits are subject to model-dependent uncertainties. It is therefore important to probe such CP-violating effects through direct measurements. The associated production of a Higgs boson with a top-quark pair ($pp \to t\bar{t}H$) offers a powerful channel for this purpose. In particular, Run 2 data have provided enhanced sensitivity to the CP structure of the top Yukawa coupling, especially in final states where the Higgs boson decays to two photons. In this channel, angular and kinematic correlations between the Higgs boson and the top quarks offer sensitivity to possible CP-odd contributions.

Using the full Run 2 dataset, several Higgs boson decay channels have been studied in this context. In the $H \to \gamma\gamma$ channel, ATLAS excludes CP-mixing angles $\varphi_t > 43°$ and $\varphi_t < -43°$ at 95% confidence level [354]. More recently, constraints from the $H \to b\bar{b}$ channel have been reported, with a measured value of $\varphi_t = 11° \,^{+52°}_{-73°}$ [355].

Using the full Run 2 dataset, CMS [356] measured the CP-odd fraction of the top Yukawa coupling in the diphoton channel, defined as:

$$f_{CP} = \frac{|\tilde{\kappa}_t|^2}{|\kappa_t|^2 + |\tilde{\kappa}_t|^2} \times \text{sign}\left(\frac{\tilde{\kappa}_t}{\kappa_t}\right), \tag{11.31}$$

and obtained a value of $|f_{CP}| = 0.00 \pm 0.33$. A complementary constraint on the CP-odd fraction was also derived using the $H \to 4\ell$ channel [357]. More recently, CMS has analyzed the $t\bar{t}H$ multi-lepton channel, which is sensitive to both $H \to WW$ and $H \to \tau^+\tau^-$ decays, to further probe the CP properties of the top Yukawa interaction [358]. Combining this analysis with those from the diphoton and four-lepton channels, CMS obtained an updated constraint on the CP-odd fraction:

$$|f_{CP}| = 0.28^{+0.27}_{-0.28}. \tag{11.32}$$

In these analyses, events with both leptonic and hadronic top-quark decays were included to maximize acceptance and statistical power.

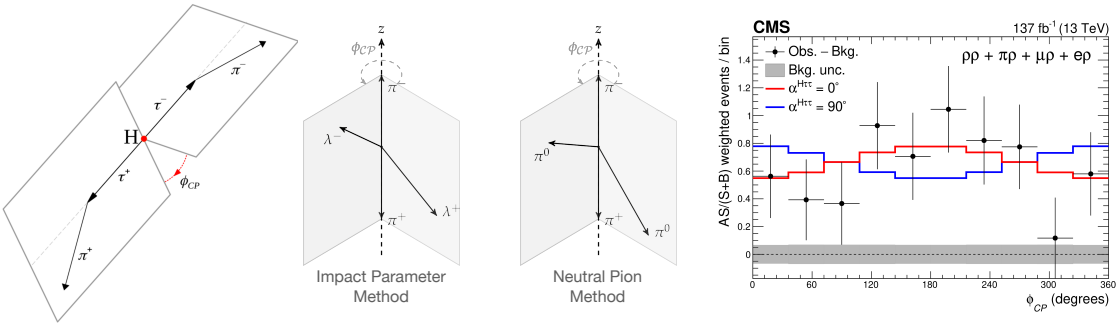

Figure 11.16: Sketch of the definition of the φ_{CP} angle for for the decays $\tau^{\pm} \to \pi^{\pm}\nu_{\tau}$ (left) and the definition at reconstruction level of φ_{CP} observables (center). The rightmost plot shows the distribution weighted per tau decay categories of the φ_{CP} observables, including the expected distributions for the expected pure scalar or pure pseudo scalar cases.

11.3.9.3 *Probing $Hf\bar{f}$ coupling CP properties in $H \to \tau^+\tau^-$ decays*

As discussed in Section 11.3.9.1, the decay of the Higgs boson to tau leptons provides opportunities to probe the CP properties of the $Hf\bar{f}$ coupling, thanks to the sensitivity of certain observables to tau polarization.

Using the full Run 2 dataset, CMS performed the first analysis of transverse spin correlations between the tau leptons in this final state [359]. These correlations are sensitive to the CP-mixing angle, which characterizes the relative contributions of scalar and pseudoscalar components in the Higgs–tau coupling. The transverse spin correlations manifest themselves through the angular distributions of the visible tau decay products, which are experimentally accessible.

In the case of the two-body decay of a tau lepton into a charged pion and a neutrino, the transverse momenta of the two charged pions tend to be anti-aligned for a scalar Higgs boson and aligned for a pseudoscalar. Consequently, the angle between the decay planes of the two tau leptons, as illustrated in Fig. 11.16 (left), is sensitive to the CP-mixing of the Higgs–tau coupling.

Since the tau direction cannot be reconstructed directly, the direction of the impact parameter is used as a proxy. The impact parameter is defined as the vector pointing from the interaction point to the point of closest approach of the charged pion track. In the Higgs boson rest frame, these directions are denoted by $\lambda^{\pm}$, as shown in Fig. 11.16 (center).

For multi-body tau decays—such as those proceeding via intermediate vector mesons like the ρ or $a_1(1260)$, the decay planes are constructed from the visible final-state particles. In the case of $\rho \to \pi^+\pi^0$, the decay plane is defined by the charged and neutral pion momenta. For $a_1 \to \pi^+\pi^0\pi^0$, the plane is typically defined using the charged pion and the combined momentum of the two neutral pions. These angular correlations provide sensitivity to the CP structure of the Higgs–tau interaction. The separation between pure scalar and pure pseudoscalar scenarios is illustrated in Fig. 11.16 (right). A similar analysis was performed by ATLAS [360]. The observed (expected) results are summarized below:

$$\begin{array}{lll} \text{ATLAS} & \varphi_\tau = 9^o \pm 16^o & (0^o \pm 28^o) \quad [359]\,, \\ \text{CMS} & \varphi_\tau = -1^o \pm 19^o & (0^o \pm 21^o) \quad [360]\,. \end{array}$$

The current experimental precision achieved by ATLAS and CMS is already comparable to the targets originally foreseen for the HL-LHC, as outlined in Ref. [361], which projected an angular resolution between $\pm 18°$ and $\pm 30°$.

11.3.9.4 *Implications of Higgs boson measurements on its CP properties*

Beyond the hypothesis testing performed in specific final states, the global consistency of measured Higgs production and decay kinematics, which assumes a spin-0, CP-even boson, provides compelling evidence for this assignment. Kinematic features, including transverse momentum spectra, jet correlations, and angular observables, have been measured with high precision across various production and decay channels. The excellent agreement with SM expectations implies that large deviations from the spin-0, CP-even scenario are highly disfavored. While small admixtures of non-SM CP-odd components in the coupling structure remain experimentally allowed, the data strongly support the conclusion that the observed particle is dominantly a spin-0 scalar with positive parity.

11.4 Beyond the Standard Model (BSM) Higgs boson

The discovery of a light scalar with couplings to gauge bosons and fermions that are consistent with SM predictions, together with the slow running of the Higgs boson self-coupling at high energies allow one to consider the SM as a valid perturbative description of nature all the way to the Planck scale. This picture is admittedly very attractive, but it posits that the Higgs boson is an elementary scalar field, whose mass has quantum sensitivity to possible new physics scales. As discussed in Section 11.1.3 this EW/Higgs naturalness problem [23] has become much more definite after the Higgs boson discovery at $m_H = 125$ GeV. Finding a more fundamental explanation of the origin of EWSB and of the EW scale is by itself a strong motivation to explore BSM theories that could induce the existence of the scalar sector of the SM as it has now been experimentally confirmed.

There are two broad classes of models addressing the naturalness problem[9], that we can in full generality classify as based on a weakly coupled or strongly coupled approach to EWSB. The first one is based on SUSY [24] (for comprehensive reviews, see Refs. [25,26]). This is a weakly coupled approach to EWSB, maintaining the perturbativity of the SM. The Higgs boson remains elementary and the corrections to its mass are screened at the scale at which SUSY is broken, generically identified with the soft SUSY breaking parameter, M_{SUSY}. Provided M_{SUSY} is of order of a few TeV, the fine-tuning problem is solved, in the sense that the low energy mass parameters of the Higgs sector become insensitive to physics at the GUT or Planck scale. Another interesting feature of SUSY theories is related to the dynamical generation of EWSB [363]. While in the SM a negative Higgs-boson mass parameter μ^2 (see Eq. 11.2) needs to be inserted by hand to induce EWSB, in SUSY, even if the relevant Higgs mass parameter is positive in the ultraviolet, it may become negative and induce EWSB radiatively through the strong effect of the top quark-Higgs boson coupling in its renormalization group evolution [363]. The scalar sector of SUSY-based theories is a particular realization of a Two Higgs-Doublet Model (2HDM) that only extend the scalar sector of the SM by one extra complex $SU(2)$ doublet, under certain additional symmetry conditions. It predicts three neutral and a pair of charged Higgs particles [39]. One of the neutral Higgs bosons, most often the lightest CP-even one, has properties that can resemble those of the SM Higgs boson (at least in some regions of

[9] Another solution to the naturalness problem is to lower the fundamental scale of quantum gravity, like for instance in models with large extra-dimensions, see Ref. [362].

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s xcept for Open Access articles.

the parameter space referred to as the alignment limit [364,365], which in the case of sufficiently heavy additional Higgs bosons is dubbed the decoupling limit [366,367]). Such scalar is referred to as a SM-like Higgs boson, meaning that its couplings are close to the ones predicted in the SM.

The other approach invokes the existence of strong interactions at a scale of the order of one TeV or above and these new interactions induce the breaking of the electroweak symmetry [368]. In the original incarnation, dubbed technicolor, the strong interactions themselves trigger EWSB without the need of a Higgs boson. Another possibility, compatible with the ATLAS and CMS discovery, is that the strong interactions produce four light resonances identified with the Higgs-field doublet and EWSB proceeds through vacuum misalignment [27] (see also Refs. [28, 29] for recent reviews). In that case, the Higgs boson itself has a finite size and thus never feels the UV degrees of freedom that would otherwise have dragged its mass to much higher scales. The Higgs boson could also correspond to the Goldstone boson associated with the spontaneous breaking of scale invariance, see Ref. [369] and references therein. However, this dilaton/radion scenario now requires a jumbled model-building to be consistent with the constraints from the coupling measurements. The idea that the Higgs boson itself could be a composite bound state emerging from a new strongly-coupled sector has been also reconsidered thanks to the insights gained from the AdS/CFT duality. The composite Higgs boson idea is a realization of EWSB via strong dynamics that smoothly interpolates between the standard technicolor approach and the true SM limit. To avoid the usual conflict with EW data, it is sufficient, if not necessary, that a mass gap separates the Higgs resonance from the other resonances of the strong sector. Such a mass gap can naturally follow from dynamics if the strongly-interacting sector exhibits a global symmetry, G, broken dynamically to a subgroup H at the scale f, such that, in addition to the three Nambu–Goldstone bosons of SO(4)/SO(3) that describe the longitudinal components of the massive W and Z, the coset G/H contains a fourth Nambu–Goldstone boson that can be identified with the physical Higgs boson. Modern incarnations of composite Higgs models have been recently investigated in the framework of 5D warped models where, according to the principles of the AdS/CFT correspondence, the holographic composite Higgs boson then originates from a component of a gauge field along the 5th dimension with appropriate boundary conditions. A last proposed ingredient in the construction of viable composite Higgs-boson models is the concept of partial compositeness [370], i.e., the idea that there are only linear mass mixings between elementary fields and composite states. After diagonalization of the mass matrices, the SM particles, fermions and gauge bosons, are admixtures of elementary and composite states and thus they interact with the strong sector, and in particular with the Higgs boson through their composite component. This setup has important consequences on the flavor properties, chiefly the suppression of large flavor-changing neutral currents involving light fermions. It also plays an important role in dynamically generating a potential for the would-be Goldstone bosons. Partial compositeness also links the properties of the Higgs boson to the spectrum of the fermionic resonances, i.e., the partners of the top quark. The bounds from the direct searches for the top partners, in addition to the usual constraints from EW precision data, force the minimal composite Higgs models into some unnatural corners of their parameter spaces [371].

Beyond models that directly address the problem of naturalness and the origin of the EWSB, NP explorations through the Higgs portal can be more agnostic and test the existence of exotic particles from unknown extensions of the SM. Among weakly-interactive theories derived from extended gauge symmetry groups (e.g. grand-unified theories [372]), many include extended scalar sectors, that involve scalar singlets, extra doublets, triplets, or even more complicated scalar multiplet structures. In these models, as for SUSY-inspired models, EWSB is realized in such a way to generate a physical scalar mass eigenstate with the property of the SM Higgs boson. However, the spectrum of physical scalars also includes a variety of extra heavier CP-even scalars, both neutral and charged, as well as CP-odd pseudoscalars, that can be searched for at the LHC. At the same time, many NP scenarios involve light scalar degrees of freedom, such as axion-like-particles [373].

All these BSM scenarios can have important effects on the phenomenology of the discovered Higgs boson and reveal themselves through precision measurements of its branching ratios, width, mass, and couplings. For instance, deviations from the SM Higgs-boson pattern of couplings, explored through the κ or EFT frameworks described in Section 11.3.5, could point to specific classes of BSM theories. At the same time, direct search for heavy scalar resonances decaying into SM particles or for exotic decays of the SM Higgs boson become essential to identify evidence of NP. Furthermore, in all cases, the role of the Higgs boson in the unitarization of scattering amplitudes is shared by other particles, not just scalar particles, which remain targets of experimental searches, both in the heavy and light mass regime [29, 373–375].

In the following, we will briefly recall the most relevant phenomenological implications of NP models that motivates existing BSM Higgs searches at the LHC. Because of their distinct phenomenology, they will be grouped into weakly- and strongly-coupled models, discussed in Sections 11.4.1 and 11.4.2 respectively. Constraints on exotic decays of the discovered Higgs boson will be presented in Section 11.4.3 and a comprehensive summary of existing searches for BSM scalars will be the subject of Section 11.4.4.

11.4.1 *Weakly coupled approach to EWSB*

11.4.1.1 *Higgs bosons in the Minimal Supersymmetric Standard Model (MSSM)*

The simplest realistic model of low-energy SUSY is the minimal SUSY extension of the SM (MSSM) [26, 376], that associates a SUSY partner to each gauge boson and chiral fermion of the SM, and provides a realistic model of physics at the weak scale. Of the more than 100 new parameters that are introduced in the general MSSM [26] only a subset of them impact the Higgs-boson phenomenology either directly at tree-level or through quantum effects.

The MSSM contains the particle spectrum of a 2HDM extension of the SM and the corresponding SUSY partners (see Section 11.4.1.2 for a brief overview of 2HDM). Two Higgs doublets, Φ_1 and Φ_2, with hypercharge $Y = -1$ and $Y = 1$, respectively, are required to ensure an anomaly-free SUSY extension of the SM and to generate mass for down-type quarks/charged leptons (Φ_1) and up-type quarks (Φ_2) [39]. The Higgs potential reads

$$\begin{aligned} V =& m_1^2 \Phi_1^\dagger \Phi_1 + m_2^2 \Phi_2^\dagger \Phi_2 - m_3^2 (\Phi_1^T i\sigma_2 \Phi_2 + \text{h.c.}) \\ &+ \frac{1}{2}\lambda_1 (\Phi_1^\dagger \Phi_1)^2 + \frac{1}{2}\lambda_2 (\Phi_2^\dagger \Phi_2)^2 + \lambda_3 (\Phi_1^\dagger \Phi_1)(\Phi_2^\dagger \Phi_2) \\ &+ \lambda_4 |\Phi_1^T i\sigma_2 \Phi_2|^2 + \frac{1}{2}\lambda_5 \left[(\Phi_1^T i\sigma_2 \Phi_2)^2 + \text{h.c.} \right] \\ &+ \left[[\lambda_6 (\Phi_1^\dagger \Phi_1) + \lambda_7 (\Phi_2^\dagger \Phi_2)] \Phi_1^T i\sigma_2 \Phi_2 + \text{h.c.} \right], \end{aligned} \tag{11.33}$$

where $m_i^2 = \mu^2 + m_{H_i}^2$ $(i = 1, 2)$, with μ being the supersymmetric Higgsino mass parameter and m_{H_i} the soft supersymmetric breaking mass parameters of the two Higgs doublets; $m_3^2 \equiv B\mu$ is associated to the B-term soft SUSY breaking parameter; and λ_i, for $i = 1$ to 7, are all the Higgs quartic couplings.

After the spontaneous breaking of the electroweak symmetry, five physical Higgs particles are left in the MSSM spectrum: one charged Higgs pair, $H^\pm$, one CP-odd neutral scalar, A, and two CP-even neutral states, H and h, with h being the lightest.[10] The Higgs sector at tree level depends on the electroweak gauge coupling constants and the vacuum expectation value v – or equivalently the Z gauge boson mass – and is determined by only two

[10] Observe that in the SM sections of this review, H denotes the SM Higgs boson, whereas in the sections about SUSY, or extensions of the SM with two Higgs doublets, H is used for the heaviest CP-even Higgs boson, since this is the standard notation in the literature, and the 125 GeV SM-like light Higgs boson will be denoted by h. Generically, in the MSSM, the lightest CP-even Higgs boson is indeed SM-like and thus it is naturally identified with the 125 GeV Higgs boson discovered by ATLAS and CMS, while in general 2HDM extensions, with or without SUSY, there could still be lighter scalar states below 125 GeV. To avoid confusion we will keep denoting the SM-like Higgs boson by h in the entire BSM Higgs section.

free parameters: $\tan\beta$ - the ratio of the two Higgs doublets' vacuum expectation values v_2/v_1 - and one Higgs boson mass, conventionally chosen to be the CP-odd Higgs boson mass, m_A. The other tree-level Higgs boson masses are then given in terms of these parameters. The tree level value of m_h is maximized not only for $m_A \gg m_Z$ but also for $\tan\beta \gg 1$. For $m_A \gg m_Z$ it acquires a maximum value $m_h = m_Z \cos 2\beta$. Radiative corrections have a significant impact on the values of Higgs boson masses and couplings in the MSSM. They have been computed using a number of techniques, with a variety of approximations, see Ref. [377] for a recent review. The discovered SM-like Higgs boson, if interpreted as the lightest MSSM Higgs boson with a mass of about 125 GeV, provides information on the possible MSSM parameter space [26].

The phenomenology of the Higgs sector depends on the couplings of the Higgs bosons to gauge bosons and fermions [11]. At tree-level, the couplings of the two CP-even Higgs bosons to W and Z bosons are given in terms of the angles α, that diagonalizes the CP-even Higgs boson squared-mass matrix, and β

$$g_{hVV} = g_V m_V \sin(\beta-\alpha), \quad g_{HVV} = g_V m_V \cos(\beta-\alpha), \tag{11.34}$$

where $g_V \equiv 2m_V/v$, for $V = W$ or Z ($g_V m_V$ is the SM hVV coupling). Observe that in the limit $\cos(\beta-\alpha) \to 0$, the lightest CP-even Higgs boson h behaves as the SM Higgs boson. This situation is called alignment and is achieved in specific regions of parameter space for $m_A \geq m_Z$ [366] or in the large $m_A \gg m_Z$ limit, in which alignment is achieved through decoupling [366, 367]. There are no tree-level couplings of A or $H^\pm$ to VV. The couplings of the Z boson to two neutral Higgs bosons are given by $g_{\phi AZ}(p_\phi - p_A)$, where $\phi = H$ or h, the momenta p_ϕ and p_A point into the vertex, and

$$g_{hAZ} = g_Z \cos(\beta-\alpha)/2, \quad g_{HAZ} = -g_Z \sin(\beta-\alpha)/2\,. \tag{11.35}$$

The expressions of the couplings between a charged Higgs boson, a neutral Higgs boson and the W boson as well as the expressions of the four-point couplings of vector bosons and Higgs bosons can be found in Ref. [39].

The tree-level Higgs boson couplings to fermions obey the following property: the neutral components of one Higgs doublet, Φ_1, couple exclusively to down-type fermion pairs while the neutral components of the other doublet, Φ_2, couple exclusively to up-type fermion pairs [39]. This Higgs-fermion coupling structure corresponds to a Type-II 2HDM (see Section 11.4.1.2). In the MSSM, fermion masses are generated when both neutral Higgs components acquire a vacuum expectation value, and the relations between Yukawa couplings and fermion masses are (in third-generation notation)

$$y_{b,\tau} = \sqrt{2}\, m_{b,\tau}/(v\cos\beta), \quad y_t = \sqrt{2}\, m_t/(v\sin\beta)\,. \tag{11.36}$$

The couplings of the neutral Higgs bosons to $f\bar{f}$, relative to their SM values, $g\, m_f/(2m_W)$, are therefore given by

$$\begin{array}{ll} h b\bar{b}: & -\sin\alpha/\cos\beta, \\ H b\bar{b}: & \cos\alpha/\cos\beta, \\ A b\bar{b}: & \gamma_5 \tan\beta, \end{array} \qquad \begin{array}{ll} h t\bar{t}: & \cos\alpha/\sin\beta\,, \\ H t\bar{t}: & \sin\alpha/\sin\beta\,, \\ A t\bar{t}: & \gamma_5 \cot\beta\,. \end{array} \tag{11.37}$$

In each relation above, the factor listed for $b\bar{b}$ also pertains to $\tau^+\tau^-$. The charged Higgs boson couplings to fermion pairs, normalized to $g/(\sqrt{2}m_W)$, are given by

$$\begin{aligned} &g_{H^- t\bar{b}}: m_t \cot\beta \frac{1+\gamma_5}{2} + m_b \tan\beta \frac{1-\gamma_5}{2}, \\ &g_{H^-\tau^+\nu}: m_\tau \tan\beta \frac{1-\gamma_5}{2}\,. \end{aligned} \tag{11.38}$$

The non-standard neutral Higgs bosons have significantly enhanced couplings to down-type fermions at sizable $\tan\beta$. Radiative corrections can modify significantly the values of the Higgs boson couplings to fermion pairs and to vector boson pairs, through a radiatively-corrected value for $\cos(\beta-\alpha)$ as well as from the one-loop vertex corrections to tree-level Higgs-fermion Yukawa couplings, see Ref. [26] and references therein, for a detailed discussion.

Given the outlined structure of the MSSM Higgs bosons couplings to SM fermions and gauge bosons the MSSM parameters have to be arranged such that the mass, the CP properties, as well as the decay and production properties of one of the neutral Higgs bosons agree with the LHC Higgs data. Given that present data allows only for moderate departures from the SM predictions, it implies that some degree of alignment is necessary.

The SM-like branching ratios of h can be modified if decays into SUSY particles are kinematically allowed, and, in particular, decays into a pair of the lightest SUSY particles – i.e., the lightest neutralinos, $\tilde{\chi}_1^0$, can become dominant and would be invisible if R-parity is conserved [380]. Moreover, if light superpartners exist and couple to photons and/or gluons, the h loop-induced coupling to gg and $\gamma\gamma$ could deviate sizeably from the corresponding SM predictions (see for instance the review [379]), and would be in conflict with present data (see Section 11.3.5). For the heavier Higgs states, there are two possibilities to be considered[12]:

i) Alignment triggered by decoupling, hence $m_A \geq$ several hundred GeV: the HWW and HZZ couplings are very small. The dominant H, A decay branching ratios strongly depend on $\tan\beta$. The decay modes $H, A \to b\bar{b}, \tau^+\tau^-$ dominate when $\tan\beta$ is large (this holds even away from decoupling). For small $\tan\beta$, the $t\bar{t}$ decay mode dominates above its kinematic threshold. For the charged Higgs boson, $H^+ \to t\bar{b}$ dominates.

ii) Some degree of alignment without decoupling, hence $m_A \leq$ a few hundred GeV: the main difference with the previous case is that, in the low $\tan\beta$ regime ($\tan\beta \leq 5$), additional decay channels may be allowed which involve decays into the lightest SM-like Higgs boson; $A \to Zh$, $H \to hh$ as well as $H \to WW/ZZ$ decay modes are available (they are suppressed in the strict alignment limit). When kinematically open, the decays $A/H \to t\bar{t}$ become relevant or even dominant for sufficiently small $\tan\beta$. For the charged Higgs boson, $H^+ \to \tau^+\nu_\tau$ dominates below the $t\bar{b}$ threshold, and also $H^\pm \to W^\pm h$ may be searched for.

In both cases i) and ii), the heavier Higgs states, H, A and $H^\pm$, are roughly mass degenerate (with masses $\pm$ 20 GeV or less apart). If kinematically allowed, the heavy Higgs boson decays into charginos, neutralinos and third-generation squarks and sleptons can be important [383].

At hadron colliders, the dominant neutral Higgs boson production mechanism at moderate values of $\tan\beta$ is gluon fusion, mediated by loops containing heavy top and bottom quarks and the corresponding SUSY partners. The effect of light stops that may contribute to the gluon fusion production can be partially cancelled by mixing effects. Higgs boson radiation off bottom quarks becomes important for large $\tan\beta$, where at least two of the three neutral Higgs bosons have enhanced couplings to bottom-type fermions [384, 385]. Detailed discussions of the impact of radiative corrections in these search modes are presented for instance in Ref. [386]. The vector boson fusion and Higgs-strahlung production of the CP-even Higgs bosons as well as the associated production of neutral Higgs bosons with top quark pairs have lower production cross sections by at least an order of magnitude with respect to the dominant ones, depending on the precise region of MSSM parameter space [56–59]. Higgs boson pair production of non-standard MSSM Higgs bosons has been studied in Ref. [387, 388]. For a discussion of charged Higgs boson production at LHC, see Refs. [56, 59, 389]. Strong production of a heavy neutral Higgs boson followed by its decay into top-quark pairs is a challenging channel, only most recently being searched for by ATLAS and CMS. Interference effects between the signal and the SM $t\bar{t}$ background need to be carefully taken into account [390, 391].

[11] Reviews of the properties and phenomenology of the Higgs bosons of the MSSM can be found for example in Refs. [26, 378, 379].

[12] In very special regions of the parameter space, there is still the possibility that the heavier CP-even Higgs state is identified with the 125 GeV Higgs boson discovered by ATLAS and CMS, see for instance the discussion in Ref. [381] and the benchmark M_H^{125} defined in Ref. [382].

In summary, the additional Higgs bosons are sought for mainly via the following channels:

$$
\begin{aligned}
&pp \to A/H \to \tau^+\tau^- \text{ (inclusive)},\\
&b\bar{b}A/H, A/H \to \tau^+\tau^- \text{ (with } b\text{-tag)},\\
&b\bar{b}A/H, A/H \to b\bar{b} \text{ (with } b\text{-tag)},\\
&pp \to t\bar{t} \to H^\pm W^\mp b\bar{b},\ H^\pm \to \tau^+\nu_\tau(\tau^-\bar{\nu}_\tau) \text{ or } t\bar{b}\,(b\bar{t})\,,\\
&gb \to H^-t \text{ or } g\bar{b} \to H^+\bar{t},\ H^\pm \to \tau^+\nu_\tau(\tau^-\bar{\nu}_\tau) \text{ or } t\bar{b}\,(b\bar{t}).
\end{aligned}
\tag{11.39}
$$

After the Higgs boson discovery, updated MSSM benchmarks scenarios have been defined to highlight interesting conditions for the MSSM Higgs boson searches [56, 382] and are scrutinised by the LHC Higgs Working Group [392].

The compatibility between the predicted and measured Higgs boson mass sets stringent constraints on the parameter space of BSM models. As an example, Fig. 11.17 illustrates the constraints imposed on a specific scenario labeled as M_h^{125} [393] by Higgs-boson searches at the LHC. The M_h^{125} benchmark assumes that super partners are heavy, so that the phenomenology of the observed Higgs boson is not altered except in its couplings due to the existence of another doublet. Note that to use the predicted Higgs boson mass as a constraint (exclusion at nearly constant $\tan\beta$ at high M_A in the (M_A,$\tan\beta$) plane), it is important to account for the theoretical uncertainty on the prediction which is in excess of an order of magnitude larger than the experimental uncertainty on the measured mass of the Higgs boson. The theoretical uncertainty depends itself on the specific SUSY spectrum for a given MSSM parameter set. It is therefore highly model-dependent and influenced by parameters that do not affect much the phenomenology of the heavy Higgs bosons. A more generic estimate of ± 3 GeV is made and found to be a conservative choice [377]. It should also be noticed that the red region of parameter space is highly model-dependent and it depends on parameters that do not affect much the phenomenology of the heavy Higgs bosons.

The scalar sector of the MSSM can be also extended to include extra singlets. The addition of a singlet superfield to the MSSM may come along with additional symmetries imposed to the theory. Depending on such symmetries, different models with singlet extensions of the MSSM (xMSSM) have been proposed, see Ref. [395] for a general review. A singlet extended SUSY Higgs sector opens new avenues for discovery. Since the singlet pseudoscalar particle may be identified as the pseudo-Goldstone boson of a spontaneously broken Peccei–Quinn symmetry, it may become naturally light [396]. Generally, there is mixing of the singlet sector with the MSSM Higgs sector, and for a sufficiently light, singlet-dominated scalar or pseudoscalar, h_S or A_S, respectively, the SM-like Higgs boson h may decay to pairs of h_S or A_S. The light scalar and/or pseudoscalar may subsequently decay to $\tau\tau$ or $b\bar{b}$ pairs. Such cascade decays are more difficult to detect than in standard searches due to the potentially soft decay products. There is also a rich phenomenology for the decays of the heavy CP-even and CP-odd doublets, H and A into two lighter Higgs bosons such as $H \to hh_S$, hh, h_Sh_S or $A \to A_Sh_S$, A_Sh as well as into a light Higgs boson and a gauge boson: $H \to A_SZ$; $A \to h_SZ$, hZ. If kinematically allowed, the heavy Higgs bosons decay into $t\bar{t}$. If the singlet-dominated scalar or pseudoscalar are somewhat heavier, the decays $h_S \to WW$ or $A_S \to h_SZ$ will be allowed.

Additional extensions of the MSSM have been considered to either avoid phenomenological constraints or address phenomena not explained in the SM. For instance, SUSY scenarios with CP-violation (CPV) phases are theoretically appealing, since additional CPV beyond that observed in the $K-$, $D-$, and B-meson systems is required to explain the observed cosmic matter-antimatter asymmetry. In the MSSM, CPV effects in the Higgs sector appear at the quantum level, while in singlet extensions of the MSSM CPV effects can already be present at tree level. In general, CPV effects in the Higgs sector have significant constraints from electric dipole moments data [397]. Major variations to the Higgs-boson phenomenology occur in the presence of explicit CPV phases. In the CPV case, vector-boson pairs couple to all three neutral Higgs-boson mass eigenstates. The discovery of a 125 GeV Higgs boson has put strong constraints on the realization of the CPV scenario within the MSSM. This is partly due to the fact that the observed Higgs-boson rates are close to the SM values, and a large CPV component would necessarily induce a large variation in the rate of the SM-like Higgs-boson decays into the weak gauge bosons $W^\pm$ and Z. The measured Higgs-boson mass imposes additional constraints on the realization of this scenario.

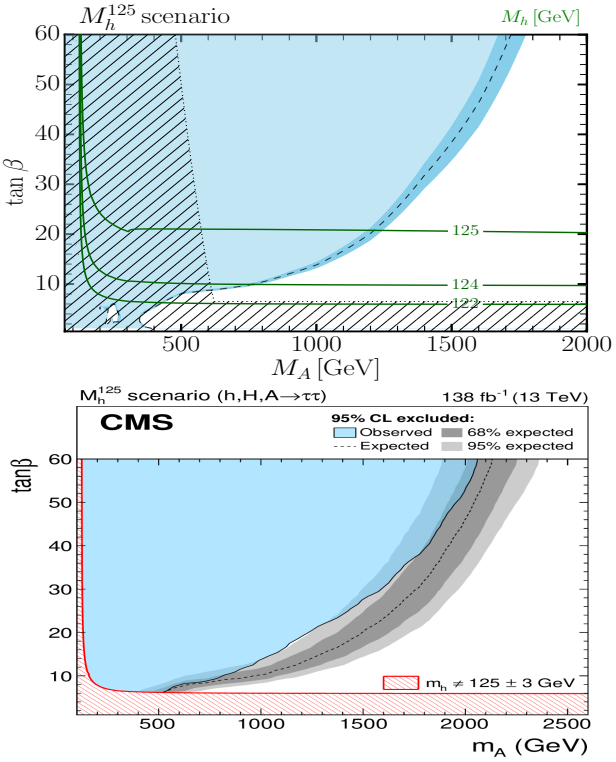

Figure 11.17: (Left) The predicted 95% CL exclusion contours in the (M_A, $\tan\beta$) parameter space for the M_h^{125} benchmark scenarios [393]. The blue area represents the bounds from searches for heavy Higgs bosons (H and A), with the darker blue band indicating the theoretical uncertainty. The green solid lines are predictions for the mass of the lighter CP-even scalar h, the hatched area is excluded by a mismatch between the properties of h and those of the observed Higgs boson. The nearly vertical dotted line illustrates the lower limit on the mass of the A boson from precision measurements of the Higgs-boson couplings and the close-to horizontal dotted line represents the limit on $\tan\beta$ from the compatibility of the measured mass of the observed Higgs boson and the prediction using radiative corrections. (Right) Expected and observed 95% CL exclusion contours. The expected median in the absence of a signal is shown as a dashed black line. The dark and bright grey bands indicate the central 68% and 95% intervals of the expected exclusion. The observed exclusion contour is indicated by the colored blue area. Those parts of the parameter space where M_h deviates by more then ± 3 GeV from the mass of $h(125)$ are indicated by a red hatched area [394].

Future precision measurements of the Higgs-boson couplings to fermions and gauge bosons together with information on heavy Higgs-boson searches will provide powerful information on the SUSY parameter space [398]. Improvements in our understanding of B-physics observables put indirect constraints on additional Higgs bosons in mass ranges that would not be accessible in direct LHC searches. In particular, BR($B_s \to \mu^+\mu^-$), BR($b \to s\gamma$), and BR($B_u \to \tau\nu$) play an important role within minimal flavour-violating (MFV) models [399], in which flavour effects proportional to the CKM matrix elements are induced as in the SM [400].

11.4.1.2 *Non-supersymmetric extensions of the Higgs sector*

There are many ways to extend the minimal scalar sector of the SM. In the case of SUSY models illustrated in Section 11.4.1.1, the scalar sector consists of a constrained *type-II* 2HDM (see point i. below), with restrictions on the Higgs-boson masses and couplings induced by SUSY. In the following discussion, more generic 2HDM's are presented (for some comprehensive reviews, see [401]). These models are theoretically less compelling since they do not provide an explanation for the SM Higgs naturalness problem, but on the other hand they are agnostic about the overall theoretical framework they may derive from, and can lead to different patterns of Higgs-fermion couplings, hence, to different phenomenology. It is also possible to consider models with a SM Higgs boson and one or more additional scalar SU(2) doublets that acquire no VEV and hence play no role in the EWSB mechanism. Such models are dubbed Inert Higgs Doublet Models (IHD) [402]. Without a VEV associated to it, a Higgs boson from an inert doublet has no tree-level coupling to gauge bosons and hence cannot decay into a pair of them. Moreover, imposing a Z_2 symmetry that prevents them from coupling to the fermions, it follows that, if the lightest inert Higgs boson is neutral, it becomes a good DM candidate with interesting associated collider signals. Various studies of IHD models in the light of a 125 GeV Higgs boson have been performed, see for instance Ref. [403], showing an interesting interplay between collider and direct DM detection signals.

An interesting type of 2HDMs are those in which an Abelian flavour symmetry broken at the electroweak scale creates the fermion mass hierarchies and mixing angles [404]. This idea is based on the Froggatt–Nielsen model [405], where a flavon field couples differently to the SM fermions of different flavour charges. Such flavon acquires a vacuum expectation value, breaking the flavour symmetry but leaving both the flavour breaking and the new physics scales undetermined. In Refs. [406], it was proposed to relate the flavour breaking scale to the electroweak scale by identifying the flavon with the modulus square of the Higgs field. A 2HDM, however, provides a more compelling realisation of the electroweak scale flavour breaking idea. In the most ambitious constructions of two Higgs doublet flavour models (2HDFM), the textures of the Yukawa couplings are a result of an Abelian flavour symmetry that only allows renormalisable Yukawa couplings of the top quark to the Higgs bosons. All other Yukawa couplings are generated by higher dimensional operators that produce hierarchical entries of the Yukawa matrices, explaining the observed quark masses and mixing angles. Flavour observables, LHC Higgs signal strength measurements, electroweak precision measurements, unitarity and perturbativity bounds, as well as collider searches for new scalar resonances result in precise predictions for the parameters of these 2HDFMs. In particular, correlated departures from SM Higgs boson couplings, as well as additional Higgs bosons with masses < 700 GeV must be observed at the LHC. Other incarnations of 2HDFMs can aim at only partially explaining the fermion mass hierarchies but are therefore less restrictive.

Other extensions of the Higgs sector can include multiple copies of $\mathrm{SU}(2)_L$ doublets [407], additional scalar singlets [408], triplets or more complicated combinations of scalar multiplets in the Higgs Lagrangian . It is also possible to enlarge the gauge symmetry beyond $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ along with the necessary Higgs-field structure to generate gauge boson and fermion masses. There are two main experimental constraints on these extensions: (i) precision measurements which constrain $\rho = m_W^2/(m_Z^2 \cos^2\theta_W)$ to be very close to 1 and (ii) flavour changing neutral current (FCNC) effects. In electroweak models based on the SM gauge group, the tree-level value of ρ is determined by the Higgs multiplet structure. By suitable choices for the hypercharges, and in some cases the mass splitting between the charged and neutral Higgs sector or the vacuum expectation values of the Higgs fields, it is possible to obtain a richer combination of singlets, doublets, triplets and higher multiplets compatible with precision measurements.

In the following the case of 2HDMs and models with an additional Higgs triplet will be briefly discussed as the most common examples constrained by experiments. There is a lot of activity on the study of non-supersymmetric models with an extended Higgs sector, with an intense collaboration between theorists and experimentalists in particular inside the LHC Higgs Working Group [392].

i. *Two-Higgs-doublet models*

General two-Higgs-doublet models [401] can have a more diverse Higgs-fermion coupling structure than in SUSY, and can be viewed as a simple extension of the SM to realize the spontaneous breakdown of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ to $\mathrm{U}(1)_{\mathrm{em}}$. Quite generally, if the two Higgs doublets contain opposite hypercharges, the scalar potential will contain mixing mass parameters of the kind $m_{12}^2 \Phi_1^T i\sigma_2 \Phi_2 + h.c.$. In the presence of such terms, both Higgs doublets will acquire vacuum expectation values, $v_1/\sqrt{2}$ and $v_2/\sqrt{2}$, respectively, and the gauge boson masses will keep their SM expressions with the Higgs VEV v replaced by $\sqrt{v_1^2 + v_2^2}$. Apart from the mass terms, the most generic renormalisable and gauge invariant scalar potential for two Higgs doublets with opposite hypercharges contains seven quartic couplings, as presented in Eq. (11.33).

Just as in the MSSM case, after electroweak symmetry breaking and in the absence of CP-violation in the scalar sector, the physical spectrum contains a pair of charged Higgs bosons $H^\pm$, a CP-odd Higgs boson A and two neutral CP-even Higgs bosons, h and H. The angles α and β diagonalize the CP-even, and the CP-odd and charged Higgs sectors, respectively. The complete 2HDM is defined only after considering the interactions of the Higgs fields to fermions. Yukawa couplings of the generic form

$$- y_{ij}^a \bar{\Psi}_L^i H_a \Psi_R^j + h.c. \tag{11.40}$$

may be added to the renormalisable Lagrangian of the theory. Contrary to the SM, the two Higgs doublet structure does not ensure the alignment of the fermion mass terms $m_{ij} = y_{ij}^a v_a/\sqrt{2}$ with the Yukawa couplings y_{ij}^a. This implies that quite generally the neutral Higgs bosons will mediate flavour changing interactions between the different mass eigenstates of the fermion fields. Such flavour changing interactions should be suppressed in order to describe properly the Kaon, D and B meson phenomenology. Based on the Glashow–Weinberg criterion [409], according to which the tree-level FCNC's mediated by neutral Higgs bosons will be absent if all fermions of a given electric charge couple to no more than one Higgs doublet, the simplest way of avoiding such transitions is to assume the existence of a symmetry that ensures the couplings of the fermions of each given quantum number (up-type and down-type quarks, charged and neutral leptons) to only one of the two Higgs doublets. Different models may be defined depending on which of these fermion fields couple to a given Higgs boson. Conventionally, models of *type-I* are those in which all SM fermions couple to a single Higgs field, while in *type-II* models, down-type quarks and charged leptons couple to a common Higgs field, while the up-type quarks and neutral leptons couple to the other. Two other realizations of type-II models are commonly referred to as "*lepton-specific*", when quarks couple to one of the Higgs bosons while leptons couple to the other, or "*flipped*" when up-type quarks and charged leptons couple to one of the Higgs fields while down-quarks and neutral leptons couple to the other. Finally, alternative ways of suppressing tree-level scalar FCNC in a 2HDM through specific assumptions on the structure of the Yukawa mixing matrices have been proposed, the so-called *type-III* models [410, 411], and shown to be phenomenologically viable [412].

The two Higgs doublet model phenomenology depends strongly on the size of the mixing angle α and therefore on the quartic couplings. For large values of m_A, $\sin\alpha \to -\cos\beta$, $\cos\alpha \to \sin\beta$, $\cos(\beta - \alpha) \to 0$, and the lightest CP-even Higgs boson h behaves as the SM Higgs boson. The same behaviour is obtained if the quartic couplings are such that $\mathcal{M}_{12}^2 \sin\beta = -(\mathcal{M}_{11}^2 - m_h^2)\cos\beta$. The latter condition represents a situation in which the couplings of h to fermions and weak gauge bosons become the same as in the SM, without decoupling the rest of the non-standard scalars and it is of particular interest due to the fact that the discovered Higgs boson has SM-like properties. This situation will be referred to as alignment, as in the MSSM case.

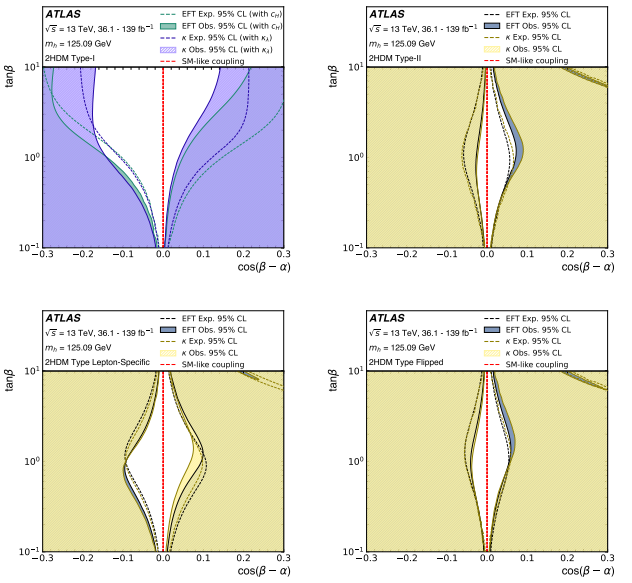

Figure 11.18: Constraints on the parameters space of 2HDM of Type I and II, based on either the κ or SMEFT approach to the parametrization of NP effects in the SM Higgs boson couplings. See Ref. [311] for more details.

In type-II 2HDM, at large values of $\tan\beta$ and moderate values of m_A, the non-standard Higgs bosons H, A and $H^\pm$ couple strongly to bottom quarks and τ leptons. Hence, the decay modes of the non-standard Higgs bosons tend to be dominated by the b-quark and τ-lepton modes, including top quarks or neutrinos in the case of the charged Higgs boson. However, for large and negative values of λ_4 (see Eq. 11.33), the charged Higgs boson mass may be sufficiently heavy to allow on-shell decays $H^\pm \to W^\pm + (H, A)$, via a trilinear coupling

$$g_{H^\pm W^\mp H,A} \simeq \frac{M_W}{v} \sin(\beta-\alpha)(p_{H^+} - p_{H,A}), \quad (11.41)$$

where p_{H^+} and $p_{H,A}$ are the charged and neutral scalar Higgs-boson momenta pointing into the vertex. On the other hand, for large and positive values of λ_5 (see Eq. 11.33), the above charged Higgs-boson decay into a $W^\pm$ and the CP-odd Higgs boson may be allowed, but the heavy Higgs boson H may be sufficiently heavy to decay into a CP-odd Higgs boson and an on-shell Z, $H \to Z + A$, via

$$g_{HZA} \simeq \frac{M_Z}{v} \sin(\beta-\alpha)(p_H - p_A). \quad (11.42)$$

The decay $H^\pm \to W^\pm + H$, on the other hand may be allowed only if $\lambda_4 < -\lambda_5$. The couplings controlling all the above decay modes are proportional to $\sin(\beta-\alpha)$ and therefore they are unsuppressed in the alignment limit. Moreover, these could still be the dominant decay modes at moderate values of $\tan\beta$, offering a way to evade the current bounds obtained assuming a dominant decay into b-quarks or τ-leptons. The quartic couplings are restricted by the condition of stability of the effective potential as well as by the restriction of obtaining the proper value of the lightest CP-even Higgs boson mass. LHC measurements of Higgs-boson couplings are already constraining the 2HDM parameter space, as illustrated in Fig. 11.18 for the case of models of Type I and II.

As discussed in the case of the SUSY 2HDM, additional effects of explicit CPV can be introduced by allowing some of the parameters of the Higgs potential to be complex. As for the SUSY case, the three neutral mass eigenstates mix with each other and give origin to a different phenomenology. For a comprehensive detailed discussions of 2HDM phenomenology, see for example Refs. [57, 401].

ii. *Higgs-boson triplets*

Electroweak triplet scalars are the simplest non-doublet extension of the SM that can participate in the spontaneous breakdown of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ to $\mathrm{U}(1)_{\mathrm{em}}$. Two types of model have been developed in enough detail to make a meaningful comparison to LHC data: the Higgs triplet model (HTM) [413] and the Georgi–Machacek model (GM) [414].

The Higgs triplet model extends the SM by the addition of a complex $\mathrm{SU}(2)_L$ triplet scalar field Δ with hypercharge $Y = 2$, and a general gauge-invariant renormalisable potential $V(\Phi, \Delta)$ for Δ and the SM Higgs doublet Φ. The components of the triplet field can be parameterised as

$$\Delta = \frac{1}{\sqrt{2}} \begin{pmatrix} \Delta^+ & \sqrt{2}\Delta^{++} \\ v_\Delta + \delta + i\xi & -\Delta^+ \end{pmatrix}, \quad (11.43)$$

where Δ^+ is a singly-charged field, Δ^{++} is a doubly-charged field, δ is a neutral CP-even scalar, ξ is a neutral CP-odd scalar, and v_Δ is the triplet VEV. The general scalar potential mixes the doublet and triplet components. After electroweak symmetry breaking there are seven physical mass eigenstates, denoted $H^{\pm\pm}$, $H^\pm$, A, H, and h.

A distinguishing feature of the HTM is that it violates the custodial symmetry of the SM (see Sec. 11.2.3); thus the ρ parameter deviates from 1 even at tree level. Letting x denote the ratio of triplet and doublet VEVs, the tree level expression is

$$\rho = \frac{1+2x^2}{1+4x^2}. \quad (11.44)$$

The measured value of the ρ parameter then limits the triplet VEV to be quite small, $x \lesssim 0.03$, or $v_\Delta < 8\,\mathrm{GeV}$. This constraint severely limits the role of the triplet scalar in the EWSB mechanism.

The small VEV of the Higgs triplet in the HTM is a virtue from the point of view of generating neutrino masses without the necessity for introducing right-handed neutrino fields. The gauge invariant dimension four interaction

$$h_{\nu_{ij}}\, \ell_i^T C^{-1} i\sigma_2\, \Delta\, \ell_j, \quad (11.45)$$

where ℓ_i are the lepton doublets, C is the charge conjugation matrix, and $h_{\nu_{ij}}$ is a complex symmetric coupling matrix, generates a Majorana mass matrix for the neutrinos:

$$m_{\nu_{ij}} = \sqrt{2} h_{\nu_{ij}} v_\Delta. \quad (11.46)$$

This can be combined with the usual neutrino seesaw to produce what is known as the type-II seesaw [415].

The HTM suggests the exciting possibility of measuring parameters of the neutrino mass matrix at the LHC. If the doubly-charged Higgs boson is light enough and/or its couplings to W^+W^+ are sufficiently suppressed, then its primary decay is into same-sign lepton pairs: $H^{++} \to \ell_i^+ \ell_j^+$; from Eq. (11.45) and Eq. (11.46), it is apparent that these decays are in general lepton-flavour violating with branchings proportional to elements of the neutrino mass matrix [416].

Precision electroweak data constrain the mass spectrum as well as the triplet VEV of the HTM [417]. These constraints favor a spectrum where H^{++} is the lightest of the exotic bosons, and where the mass difference between H^+ and H^{++} is a few hundred GeV. The favored triplet VEV is a few GeV, which also favors H^{++} decays into W^+W^+ over same-sign dileptons.

The GM model addresses the ρ parameter constraint directly by building in a custodial symmetry (it was however argued that large corrections to $\rho = 1$ are generated at one-loop [418], requiring some fine-tuning to preserves agreement with EW precision data). Writing the complex scalar doublet of the SM as a $(2, 2)$ under $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$, it is obvious that the next simplest construction respecting custodial symmetry is a scalar transforming like a $(3, 3)$ [419]. These nine real degrees of freedom correspond to a complex electroweak triplet combined with a real triplet, with the scalar potential required to be invariant under $\mathrm{SU}(2)_R$. Under the custodial $\mathrm{SU}(2)_{L+R}$, they transform as $1 \oplus 3 \oplus 5$, with a

CP-even neutral scalar as the custodial singlet (thus matching the SM Higgs boson), a CP-odd neutral scalar in the custodial triplet, and another CP-even neutral scalar in the custodial 5-plet. The scalar components can be decomposed as

$$\Xi = \begin{pmatrix} \chi_3^* & \xi_1 & \chi_1 \\ -\chi_2^* & \xi_2 & \chi_2 \\ \chi_1^* & -\xi_1^* & \chi_3 \end{pmatrix}, \tag{11.47}$$

where ξ_2 is a real scalar and the others are complex scalars. Linear combinations of these scalars account for the neutral custodial singlet, a neutral and singly-charged field making up the custodial triplet, and neutral, singly-charged, and doubly-charged fields making up the custodial 5-plet.

When combined with the usual SM doublet field Φ, the electroweak scale v is now related to the doublet and triplet VEVs by

$$v^2 = v_\Phi^2 + 8v_\Xi^2 \,. \tag{11.48}$$

Note that the GM triplets by themselves are sufficient to explain electroweak symmetry breaking and the existence of a 125 GeV neutral boson along with a custodial triplet of Goldstone bosons; the complex doublet field in the GM model is required to generate fermion masses via the usual dimension four Yukawa couplings. This raises the question of whether one can rule out the possibility that the 125 GeV boson is the neutral member of a custodial 5-plet rather than a custodial singlet, without invoking decays to fermions. A conclusive answer is given by observing that the ratio of the branching fractions to W versus Z bosons is completely determined by the custodial symmetry properties of the boson. For a custodial 5-plet, the ratio of the signal strength to WW over that to ZZ is predicted to be 1/4 that of a SM Higgs boson [419], and thus already ruled out by the experimental results presented in Section 11.3.5.

Another interesting general feature of Higgs triplet models is that, after mixing, the SM-like neutral boson can have stronger couplings to WW and ZZ than predicted by the SM [420]; this is in contrast to mixing with additional doublets and singlet, which can only reduce the WW and ZZ couplings versus the SM. This emphasises that LHC Higgs data cannot extract model independent coupling strengths for the Higgs boson [256].

Because of the built-in custodial symmetry, the triplet VEV in the GM model can be large compared to the doublet VEV. The custodial singlet neutral boson from the triplets mixes with the neutral boson from the doublet. Two interesting special cases are (i) the triplet VEV is small and the 125 GeV boson is SM-like except for small deviations, and (ii) the 125 GeV boson is mostly the custodial singlet neutral boson from the electroweak triplets. The phenomenology of the doubly-charged and singly-charged bosons is similar to that of the HTM. The constraints on the GM model from precision electroweak data, LEP data, and current LHC data are summarised in Ref. [57].

11.4.2 *EWSB induced by strong dynamics*

11.4.2.1 *Little Higgs models*

The idea behind the Little Higgs boson models [421] is to identify the Higgs doublet as a (pseudo) Nambu–Goldstone boson while keeping some sizeable non-derivative interactions, in particular a larger Higgs-boson quartic interaction. By analogy with QCD where the pions $\pi^{\pm,0}$ appear as Nambu–Goldstone bosons associated to the breaking of the chiral symmetry $\mathrm{SU(2)_L} \times \mathrm{SU(2)_R}/\mathrm{SU(2)}$, switching on some interactions that break explicitly the global symmetry will generate masses for the would-be massless Nambu–Goldstone bosons of the order of $g\Lambda_{G/H}/(4\pi)$, where g is the coupling of the symmetry breaking interaction and $\Lambda_{G/H} = 4\pi f_{G/H}$ is the dynamical scale of the global symmetry breaking G/H. In the case of the Higgs boson, the top Yukawa interaction or the gauge interactions themselves will certainly break explicitly (part of) the global symmetry since they act non-linearly on the Higgs boson. Therefore, obtaining a Higgs boson mass around 125 GeV would demand a dynamical scale $\Lambda_{G/H}$ of the order of 1 TeV, which is known to lead to too large oblique corrections. Raising the strong dynamical scale by at least one order of magnitude requires an additional selection rule to ensure that a Higgs boson mass is generated at the 2-loop level only

$$m_h^2 = \frac{g^2}{16\pi^2}\Lambda_{G/H}^2 \to m_h^2 = \frac{g_1^2 g_2^2}{(16\pi^2)^2}\Lambda_{G/H}^2. \tag{11.49}$$

The way to enforce this selection rule is through a "collective breaking" of the global symmetry:

$$\mathcal{L} = \mathcal{L}_{G/H} + g_1\mathcal{L}_1 + g_2\mathcal{L}_2. \tag{11.50}$$

Each interaction $\mathcal{L}_1$ or $\mathcal{L}_2$ individually preserves a subset of the global symmetry such that the Higgs boson remains an exact Nambu–Goldstone boson whenever either g_1 or g_2 is vanishing. A mass term for the Higgs boson can be generated only by diagrams involving simultaneously both interactions. At one-loop, such diagrams are not quadratically divergent, so the Higgs boson mass is not UV sensitive. Explicitly, the cancellation of the SM quadratic divergences is achieved by a set of new particles around the Fermi scale: gauge bosons, vector-like quarks, and extra massive scalars, which are related, by the original global symmetry, to the SM particles with the same spin. Contrary to SUSY, the cancellation of the quadratic divergences is achieved by same-spin particles. These new particles, with definite couplings to SM particles as dictated by the global symmetries of the theory, are perfect goals for the LHC.

The simplest incarnation of the collective breaking idea, the so-called littlest Higgs boson model, is based on a non-linear σ-model describing the spontaneous breaking SU(5) down to SO(5). A subgroup $\mathrm{SU(2)_1 \times U(1)_1 \times SU(2)_2 \times U(1)_2}$ is weakly gauged. This model contains a weak doublet, that is identified with the Higgs doublet, and a complex weak triplet whose mass is not protected by collective breaking. Other popular little Higgs models are based on different coset spaces: minimal moose ($\mathrm{SU(3)^2/SU(3)}$), the simplest little Higgs ($\mathrm{SU(3)^2/SU(2)^2}$), the bestest little Higgs ($\mathrm{SO(6)^2/SO(6)}$). For comprehensive reviews, see Ref. [422].

11.4.2.2 *Models of partial compositeness*

As in all composite-Higgs models the Higgs boson appears as a pseudo Nambu–Goldstone boson: the new strongly coupled sector is supposed to be invariant under a global symmetry G spontaneously broken to a subgroup H at the scale f (the typical mass scale of the resonances of the strong sector is $m_\rho \sim g_\rho f$ with g_ρ the characteristic coupling of the strong sector). To avoid conflict with EW precision measurements, the strong interactions themselves should better not break the EW symmetry. Hence the SM gauge symmetry itself should be contained in H. The SM (light) fermions and gauge bosons cannot be part of the strong sector itself since LEP data have already put stringent bounds on the compositeness scale of these particles far above the TeV scale. The gauge bosons couple to the strong sector by a weak gauging of a SU(2)×U(1) subgroup of the global symmetry G. The couplings of the SM fermions to the strong sector could a priori take two different forms:

- **(i)** a bilinear coupling of two SM fermions to a composite scalar operator, $\mathcal{O}$, of the form $\mathcal{L} = y\,\bar{q}_L u_R \mathcal{O} + h.c.$, in simple analogy with the SM Yukawa interactions. This is the way fermion masses were introduced in technicolor theories and it generically comes with severe flavour problems and calls for extended model-building gymnastics [29] to circumvent them;
- **(ii)** a linear mass mixing with fermionic vector-like operators: $\mathcal{L} = \lambda_L\,\bar{q}_L \mathcal{Q}_R + \lambda_R \bar{\mathcal{U}}_L u_R$. $\mathcal{Q}$ and $\mathcal{U}$ are two fermionic composite operators of mass M_Q and M_U.

Being part of the composite sector, the composite fermionic operators can have a direct coupling of generic order Y_* to the Higgs boson. In analogy with the photon-ρ mixing in QCD, once the linear mixings are diagonalised, the physical states are a linear combination of elementary and composite fields. Effective Yukawa couplings are generated and read for instance for the up-type quark

$$y = Y_* \sin\theta_L \sin\theta_R \tag{11.51}$$

where $\sin\theta_i = \lambda_i/\sqrt{M_{Q,U}^2 + \lambda_i^2}$, $i = L, R$, measure the amount of compositeness of the SM left- and right-handed up-type quark.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
except for Open Access articles.

If the strong sector is flavour-anarchic, i.e., if the couplings of the Higgs boson to the composite fermions does not exhibit any particular flavour structure, the relation Eq. (11.51) implies that the light fermions are mostly elementary states ($\sin\theta_i \ll 1$), while the third generation quarks need to have a sizable degree of compositeness. The partial compositeness paradigm offers an appealing dynamical explanation of the hierarchies in the fermion masses. In fact, if the UV scale at which the linear mixings are generated is large, then $\mathcal{O}(1)$ differences in the anomalous dimensions can generate naturally large hierarchies in the fermion masses via renormalisation group running [423].

Another nice aspect of the partial compositeness structure is the dynamical generation of the Higgs potential that is not arbitrary like in the SM. The Higgs boson being a pseudo-Nambu–Goldstone boson, its mass does not receive any contribution from the strong sector itself but it is generated at the one-loop level via the couplings of the SM particles to the strong sector since these interactions are breaking the global symmetries under which the Higgs doublet transforms non-linearly. Obtaining $v \ll f$, as required phenomenologically, requires some degree of tuning, which scales like $\xi \equiv v^2/f^2$. A mild tuning of the order of 10% ($\xi \approx 0.1$) is typically enough to comply with electroweak precision constraints.

As in SUSY scenarios, the top sector is playing a crucial role in the dynamics of EWSB and can provide the first direct signs of new physics. The direct searches for these top partners, in particular the ones with exotic electric charges 5/3, are already exploring the natural parameter spaces of these models [424].

The main physics properties of a pseudo Nambu–Goldstone Higgs boson can be captured in a model-independent way by a small number of higher-dimensional operators. Indeed, the strong dynamics at the origin of the composite Higgs boson singles out a few operators among the complete list discussed earlier in Section 11.3.5: these are the operators that involve extra powers of the Higgs doublets, and they are therefore generically suppressed by a factor $1/f^2$ as opposed to the operators that involve extra derivatives or gauge bosons that are suppressed by a factor $1/(g_\rho^2 f^2)$. Typically, these new interactions induce deviations in the Higgs boson couplings that scale like $\mathcal{O}(v^2/f^2)$. Hence, the measurements of the Higgs boson couplings can be translated into some constraints on the compositeness scale, $4\pi f$, of the Higgs boson. The peculiarity of these composite models is that, due to the Goldstone nature of the Higgs boson, the direct couplings to photons and gluons are further suppressed and generically the coupling modifiers defined in Section 11.3.5 scale like

$$\kappa_{W,Z,f} \sim 1 + \mathcal{O}\left(\frac{v^2}{f^2}\right), \quad \kappa_{Z\gamma} \sim \mathcal{O}\left(\frac{v^2}{f^2}\right), \\ \kappa_{\gamma,g} \sim \mathcal{O}\left(\frac{v^2}{f^2} \times \frac{y_t^2}{g_\rho^2}\right), \tag{11.52}$$

where g_ρ denotes the typical coupling strength among the states of the strongly coupled sector and y_t is the top Yukawa coupling, the largest interaction that breaks the Goldstone symmetry. The coupling modifiers also receive additional contributions from the other resonances of the strong sector, in particular the fermionic resonances of the top-quark sector that are required to be light to generate a 125 GeV Higgs-boson mass. Some indirect information on the resonance spectrum could thus be inferred by a precise measurement of the Higgs boson coupling deviations. Measurable effects of the top-quark partner have been predicted for differential distribution, like the Higgs boson p_T distribution [425]. The off-shell channel $gg \to h^* \to 4\ell$ [235] and the double Higgs boson production $gg \to hh$ [426] can also help to resolve the gluon loop and separate the top and top-partner contributions.

11.4.2.3 *Minimal composite Higgs models*

The minimal composite Higgs models (MCHM) are concrete examples of the partial compositeness paradigm. The Higgs doublet is described by the coset space SO(5)/SO(4) where a subgroup $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ is weakly gauged and under which the four Goldstone bosons transform as a doublet of hypercharge 1. There is some freedom on how the global symmetry is acting on the SM fermions, and the Higgs boson couplings to the fermions depend on the representation which the SM fermions are embedded into [427]. The non-linearly realised symmetry acting on the Goldstone bosons leads to general predictions of the coupling of the Higgs boson to the EW gauge bosons. For instance, it can be shown that the quadratic terms in the W and Z bosons read

$$m_W^2(h)\left(W_\mu W^\mu + \frac{1}{2\cos^2\theta_W} Z_\mu Z^\mu\right), \tag{11.53}$$

with $m_W(h) = \frac{gf}{2}\sin\frac{H}{f}$. Expanding around the EW vacuum, the expression of the weak scale is $v = f\sin(\langle H\rangle/f)$. And the values of the modified Higgs boson couplings to the W and Z become:

$$g_{hVV} = \frac{2m_V^2}{v}\sqrt{1 - v^2/f^2}, \quad g_{hhVV} = \frac{2m_V^2}{v^2}(1 - 2v^2/f^2). \tag{11.54}$$

Note that the Higgs boson couplings to gauge bosons is always suppressed compared to the SM prediction. This is a general result [428] that holds as long as the coset space is compact.

The (κ_V, κ_f) experimental fit of the Higgs boson couplings can be used to derive a lower bound on the Higgs boson compositeness scale $4\pi f \gtrsim 9\,\mathrm{TeV}$, which is less stringent than the indirect bound obtained from EW precision data, $4\pi f \gtrsim 15\,\mathrm{TeV}$ [429] but more robust and less subject on assumptions [430].

11.4.2.4 *Twin Higgs models*

In all composite models presented above, the particles responsible for canceling the quadratic divergences in the Higgs boson mass are charged under the SM gauge symmetries. In particular, the top partner carries color charge, implying a reasonably large minimal production cross section at the LHC. An alternative scenario, which is experimentally quite challenging and might explain the null result in various new physics searches, is the case nowadays referred to as "neutral naturalness" [30, 31], where the particles canceling the 1-loop quadratic divergences are neutral under the SM. The canonical example for such theories is the Twin Higgs model of Ref. [30]. This is an example of a pseudo-Goldstone boson model with an approximate global SU(4) symmetry broken to SU(3). The Twin Higgs model is obtained by gauging the $\mathrm{SU}(2)_A \times \mathrm{SU}(2)_B$ subgroup of SU(4), where $\mathrm{SU}(2)_A$ is identified with the SM $\mathrm{SU}(2)_L$, while $\mathrm{SU}(2)_B$ is the twin SU(2) group. Gauging this subgroup breaks the SU(4) symmetry explicitly, but quadratically divergent corrections do not involve the Higgs boson when the gauge couplings of the two SU(2) subgroups are equal, $g_A = g_B$. The SU(4)→ SU(3) breaking will also result in the breaking of the twin $\mathrm{SU}(2)_B$ group and, as a result, three of the seven Goldstone bosons will be eaten, leaving 4 Goldstone bosons corresponding to the SM Higgs doublet. In fact, imposing the Z_2 symmetry on the full model will ensure the cancellation of all 1-loop quadratic divergences to the Higgs boson mass. Logarithmically divergent terms can, however, arise for example from gauge loops, leading to a Higgs boson mass of order $g^2 f/4\pi$, which is of the order of the physical Higgs boson mass for $f \sim 1\,\mathrm{TeV}$. The quadratic divergences from the top sector can be eliminated if the Z_2 protecting the Higgs boson mass remains unbroken by the couplings that result in the top Yukawa coupling. This can be achieved by introducing top partners charged under a twin $\mathrm{SU}(3)_C$. In this case, the quadratic divergences are canceled by top partners that are neutral under the SM gauge symmetries. For more details about the composite twin Higgs models, see Refs. [432].

11.4.3 *Exotic Higgs-boson decays*

While the measured properties of the Higgs boson are roughly consistent with SM predictions, the Higgs-boson total width remains only loosely constrained as discussed in Section 11.3.8. This leaves ample room for BSM decays, often referred to as "exotic Higgs decays". These include invisible decays into dark matter candidates, non-standard signatures like lepton-flavor-violating (LFV) modes, and decays into new light scalars or pseudoscalars, which may decay promptly or be long-lived. They probe a broad spectrum of models, including for instance Higgs portal dark matter and dark photons, two-Higgs-doublet plus singlet (2HDM+S) frameworks, and axion-like particle scenarios. For a theoretical

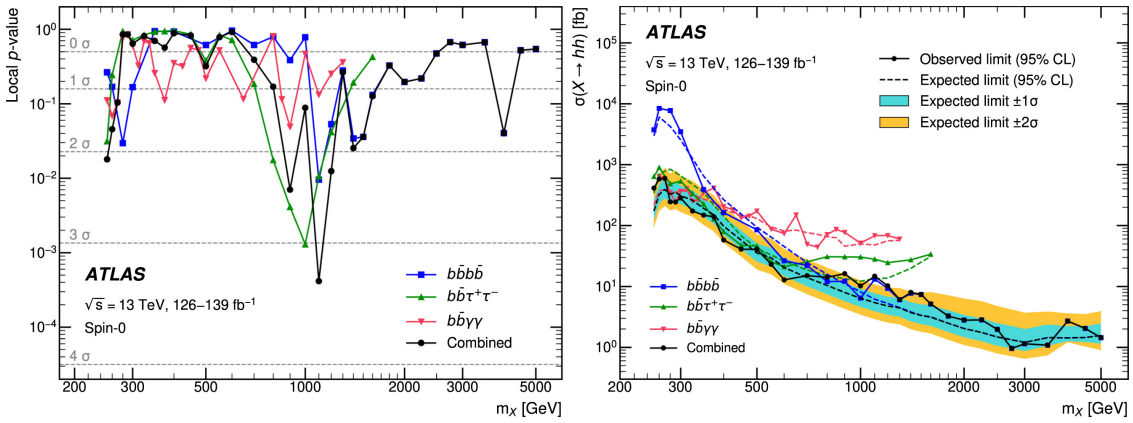

Figure 11.19: (left) Local p-value and (right) observed and expected upper limits at the 95% CL on the resonant Higgs boson pair production cross section as a function of the resonance mass m_X. The symbol h denotes a SM Higgs boson with a mass of 125 GeV. The results are taken from Ref. [431].

review of exotic signatures, see for instance Ref. [433, 434] and the documents of the LHC Higgs Working Group WG3 [392]. In the following we discuss some of these cases and their current experimental status.

11.4.3.1 *Invisible Higgs Decays*

A hypothetical coupling of the Higgs to dark matter candidates is motivated in many theoretical models [392, 436]. Higgs-boson decay modes in which the decay products escape detection are commonly named "invisible" Higgs decays, first proposed in Ref. [437]. Experimentally they are characterized by signatures dominated by a large imbalance of the transverse momentum in the detector (missing transverse energy, MET). These decays are possible in the SM through the very rare $h \to ZZ \to 4\nu$ final state (Br$\approx$ 0.1%), which is far below the reach of the LHC. An observation of a Higgs invisible decay rate would therefore signify new physics, such as a coupling of the Higgs boson to dark matter candidates.

Direct searches for invisible decays are performed in multiple Higgs production modes, including vector boson fusion (VBF), associated production with a Z or W boson (Zh, Wh), $t\bar{t}h$, and inclusive gluon fusion (jet+$E_{\mathrm{T}}^{\mathrm{miss}}$-based signatures). The VBF mode dominates the sensitivity due to its distinctive topology of forward jets which leads to reduced background contamination, and its larger production cross section when compared to VH production. Current Run 2 results yield 95% CL upper limits on the invisible branching fraction at $\mathcal{B}(h \to \mathrm{inv}) < 10.7\%$ (7.7% expected) in ATLAS [438] and $< 15\%$ (8% expected) in CMS [439]. These direct bounds are incorporated into the global Higgs coupling fits discussed in Section 11.3.5.1, Eq.(11.20).

Invisible Higgs-boson decays can also be interpreted in the context of "Higgs portal" models, where the Higgs boson mediates interactions between the SM and a dark sector. A more detailed discussion of such models and their connection to direct dark matter searches can be found in this volume's dark matter review [440].

11.4.3.2 *Flavor violating decays*

The measurement of the Yukawa couplings of the Higgs boson to quarks and leptons is an important piece in the puzzle of flavor and its connection to the mechanism of EWSB. The lepton-flavor-violating (LFV) decays $h \to e\mu$, $h \to e\tau$, and $h \to \mu\tau$ are forbidden in the SM but can arise in a variety of BSM scenarios, including 2HDM models or composite Higgs models. These LFV Higgs decays probe off-diagonal Yukawa couplings $Y_{e\mu}$, $Y_{e\tau}$, or $Y_{\mu\tau}$, which couple the Higgs boson to leptons of different flavors.

The analysis of the full 13 TeV Run 2 datasets collected by ATLAS and CMS has set stringent 95% confidence level (CL) upper limits on the branching ratios of LFV decays of the Higgs in the $h \to \mu\tau$, $h \to e\tau$, and $h \to e\mu$ channels. For $h \to \mu\tau$, the observed (expected) limits are $\mathcal{B}(h \to \mu\tau) < 0.18\%$ (0.09%) from ATLAS [441] and $< 0.15\%$ (0.15%) from CMS [442]. For $h \to e\tau$, the corresponding limits are $\mathcal{B}(h \to e\tau) < 0.20\%$ (0.12%) from ATLAS [441] and $< 0.22\%$ (0.16%) from CMS [442]. In the $h \to e\mu$ channel, the limits are $\mathcal{B}(h \to e\mu) < 6.2 \times 10^{-5}$ (5.9×10^{-5}) from ATLAS [273] and $< 4.4 \times 10^{-5}$ (4.7×10^{-5}) from CMS [443]. These numbers correspond to exotic decays of a 125 Higgs boson. The CMS search in the $e\mu$ channel was expanded to a wider mass range between 110 GeV and 160 GeV. A mild excess with a global significance of 2.8 standard deviations is observed for a mass hypothesis of approximately 146 GeV.

The presence of these off-diagonal LFV Yukawa couplings may enhance processes such as $\mu \to 3e$, $\mu \to e\gamma$, $\tau \to 3\mu$, $\tau \to \mu\gamma$ that can proceed via a virtual Higgs boson exchange. The direct limits derived by ATLAS and CMS on $Br(h \to \mu\tau)$ and $Br(h \to e\tau)$ are more than an order of magnitude stronger than limits derived from tau decays. On the other hand, the most stringent constraint on the $h \to e\mu$ branching ratio is derived indirectly from the results of searches for $\mu \to e\gamma$ [444], which yield a bound of $B(h \to e\mu) < O(10^{-8})$ [445].

Flavor-violating interactions of the Higgs boson may also involve quarks. These are studied in the context of top-quark flavor changing decays, such as $t \to hq$ ($q = u, c$), which provide complementary constraints on flavor-violating Yukawa couplings in the quark sector. ATLAS and CMS have searched for these processes with Run-1 and Run-2 data. Focusing on the Run-2 results, ATLAS has searched for FCNC top decays with subsequent decays of the Higgs boson to a pair of photons [446], yielding a 95% CL upper limit on BR($t \to hc$) $< 0.22\%$ with an expected sensitivity of 0.16%. CMS has searched for FCNC top decays with subsequent decays of the Higgs boson to a pair of b-quarks [447], yielding a 95% CL upper limit on BR($t \to hu$) $< 0.079\%$ with an expected sensitivity of 0.011% and on BR($t \to hc$) $< 0.094\%$ with an expected sensitivity of 0.086%.

11.4.3.3 *Other exotic decays: prompt and long-lived decays*

Higgs decays into pairs of light scalars or pseudoscalars ($h \to ss$ or $h \to aa$) are particularly well motivated in extended Higgs sectors such as the 2HDM+S and axion-like particle models. These provide a very rich phenomenology, with different final states favored depending on the intermediate particle and its mass (4μ, 4τ, $2\mu2\tau$, $2b2\mu$, $2b2\tau$, $4b$, 4γ, $2\gamma2\tau$...). They include both prompt decays of the mediator and long lived signatures. Experimental results on $h \to ss/aa$ signatures and their references can be found in the general summary of BSM Higgs searches presented in Table 11.6. An recent overview of the different decays from the point of view of ATLAS can also be found in Ref. [448]. For decays into axion-like particles, see the PDG review on the topic, Ref. [373].

Another class of models explores the connection between the Higgs boson and a "dark" sector of matter that does not interact directly with SM particles, and manifests itself only through mixing effects. A well known example is the hidden Abelian Higgs model (HAHM) [449], which introduces a dark photon, Z_D, that

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

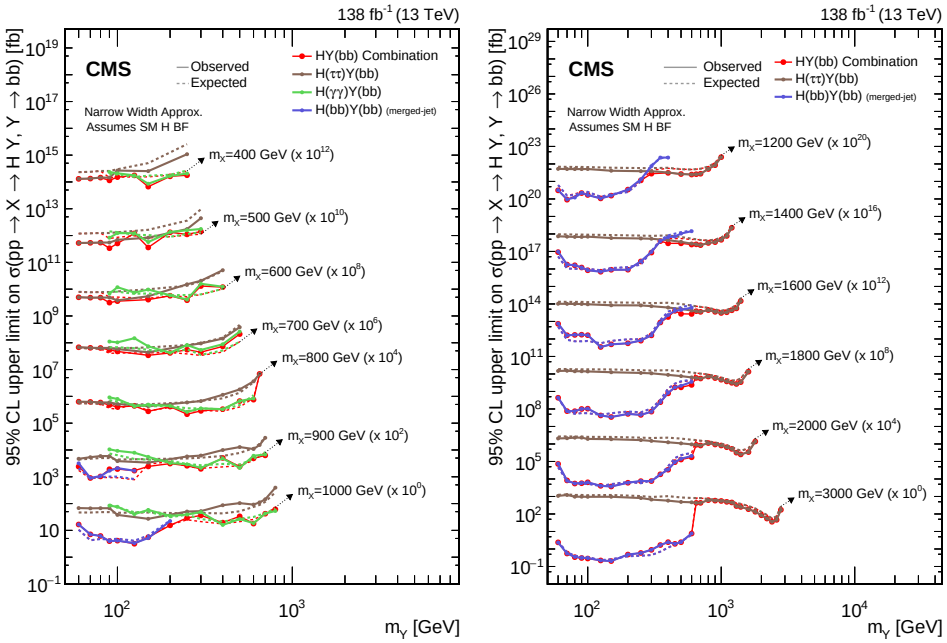

Figure 11.20: Search for $X \to YH$ where "H" is the 125 GeV Higgs boson: Observed and expected upper limits, at 95% CL, on the product of the cross section σ for the production of a resonance X via gluon–gluon fusion and the branching fraction $\mathcal{B}$ for the $X \to Y(b\bar{b})H$ decay. For the branching fractions of the $H \to \tau^+\tau^-$, $H \to \gamma\gamma$ and $H \to b\bar{b}$ decays, the SM values are assumed. The results derived from the individual analyses presented here and the result of their combined likelihood analysis are shown as functions of m_Y and m_X for $m_X \leq 1$ TeV (left), and $m_X \geq 1.2$ TeV (right). Observed limits are indicated by markers connected with solid lines, expected limits by dashed lines. For presentation purposes, the limits have been scaled in successive steps by two orders of magnitude, each. For each set of graphs, a black arrow points to the m_X-related legend. The results are taken from Ref. [435].

mediates a dark $U(1)_D$ gauge symmetry spontaneously broken by a dark Higgs mechanism. The Z_D can couple to SM particles via a hypercharge portal through kinetic mixing or via a Higgs portal through mixing with the SM Higgs. Higgs exotic decay searches in this framework have been performed by ATLAS and CMS, targeting both $h \to ZZ_D$ and $h \to Z_DZ_D$ decays [450–452], and probing both prompt and displaced signatures. Other examples of searches for dark photons in Higgs boson decays target final states with a visible photon and an undetected dark photon [453–455]. Further discussion on the dark sector comparing different search approaches can be found in Refs. [448,456], and from a more general perspective in the dark matter PDG review [440].

Long lived signatures are an area in particularly rapid development in the current LHC Run 3 and with great room for improvement in HL-LHC. These searches involve non-standard objects that require dedicated reconstructed algorithms for displaced objects, both at trigger and at reconstruction level as shown for example in Ref. [457] from the point of view of CMS. Although no deviations from SM expectations have yet been observed, the HL-LHC will clearly expand the discovery potential, with sensitivities to exotic branching fractions as low as 10^{-5}–10^{-6} in some channels [344].

11.4.4 *Summary of BSM Higgs boson search results*

The measurements presented in Sections 11.3.3–11.3.9 have established the existence of a single scalar particle in the electroweak symmetry-breaking sector, consistent with the SM Higgs boson. However, they do not exclude the possibility of additional scalar particles. As discussed above, many classes of models beyond the SM predict extended Higgs sectors. The corresponding searches are typically designed to be as model-independent as possible[13], and can be grouped into the following categories (in the following,"h" refers to the 125 GeV scalar):

(i) Searches for an additional CP-even state, primarily in the high-mass region, decaying to vector bosons. This could correspond either to the heavy CP-even state in a generic 2HDM, with the lighter state being the 125 GeV Higgs boson, or to an additional scalar singlet.

(ii) Searches for an additional CP-even state, decaying to a pair of 125 GeV Higgs bosons ($H \to hh$), or a pair of heavier scalars ($X \to YY$). Examples of results obtained by ATLAS in the search for $X \to hh$ given in Figure 11.19.

(iii) Searches for an additional scalar state X, with cascade decays to the 125 GeV Higgs boson and another scalar ($X \to Yh$). An example of results obtained by CMS in the search for $X \to Yh$ is given in Figure 11.20.

(iv) Searches for a heavy state decaying to fermion pairs, such as the CP-odd A or the heavy CP-even H in a generic 2HDM.

(v) Searches for charged Higgs bosons, also predicted in generic 2HDMs.

(vi) Searches for a light CP-odd state a in the low-mass region, as predicted in the NMSSM (an extension of the MSSM by one singlet chiral superfield containing a scalar), in a variety of final states. These include decays with one or two a bosons to photon, muon, tau, or b-quark pairs.

(vii) Searches for doubly charged Higgs bosons, expected in Higgs sector extensions with triplet representations.

A concise overview of the most recent searches at the LHC and elsewhere is given in Table 11.6. It summarizes these searches by final state, with the corresponding references provided for further

[13] Nevertheless, most non-SUSY models are expected to include additional states and dynamics above the weak scale to stabilize the scalar sector. Such new, unknown physics may influence the searches described in this section in ways that are difficult to quantify.

11.5 Summary and Outlook

Summary– The discovery of the Higgs boson is a major milestone in the history of particle physics as well as an extraordinary achievement of the LHC machine and the ATLAS and CMS experiments. Thirteen years after the discovery, substantial progress in the field of Higgs-boson physics has been accomplished and a significant number of measurements probing the nature of this unique particle have been made. They are revealing an increasingly precise profile of the Higgs boson.

The LHC has concluded its Run 2 in 2018, delivering a dataset of 13 TeV pp collisions corresponding to an integrated luminosity of more than 150 fb^{-1} of which more than 140 fb^{-1} have been collected by ATLAS and CMS. The Run 3 started in 2022 at 13.6 TeV and has already delivered more than the total Run 2 integrated luminosity. With the substantial increase in production rates at the higher center-of-mass energy (mostly from Run 1 to Run 2) and the larger datasets, the LHC collaborations have delivered detailed studies of not only inclusive but also differential cross sections that are essential to probe the structure of the scalar sector of the SM and identify potential deviations from SM predictions.

Results of fundamental importance have been achieved with Run-2 datasets by ATLAS and CMS independently [255, 265], such as the clear and unambiguous observation of the Higgs-boson decay to τ leptons and to b quarks, as well as the clear and unambiguous observation of the production of the Higgs boson through the $t\bar{t}H$ process. These results provide direct evidence for the Yukawa coupling of the Higgs boson to fermions of the third generation: taus, bottom quarks and top quarks, at rates compatible with those expected in the SM. The most recent combination of Run 2 results has established all Higgs-boson couplings to gauge bosons and third-generation fermions with a precision between 5 and 10%. In addition, data analyzed so far have already brought evidence for the $H \to \mu^+\mu^-$ rare decay above the 3σ level for each experiment, and at the 3σ level for the $H \to Z\gamma$ rare decay when ATLAS and CMS combine their Run 2 results. The challenging study of the Higgs–charm coupling is a good example of LHC performance exceeding original expectations, with constraints on κ_c already at about 3 at 95% CL, thanks to improvements in charm tagging. New ideas have been implemented to indirectly determine the Higgs-boson width from both on-shell and off-shell measurements reaching a remarkable sensitivity of about 4 MeV. The Higgs-boson mass has been measured with per-mille-level precision. Last but not least, great progress has been made in constraining the Higgs-boson self-coupling via di-Higgs production, which will probe the SM scalar potential and the origin of EWSB. These, and all other experimental measurements, are consistent at the moment with the EWSB mechanism of the SM.

New theoretical calculations and developments in Monte-Carlo simulations pertaining to Higgs physics are occurring at a rapid pace. For example, the theoretical prediction for the dominant gluon fusion production mode now includes the latest N3LO result at the inclusive and differential levels, which is twice as precise as previous NNLO calculations. All Higgs-boson production modes are known at (a)NNLO of QCD and NLO of EW corrections at both the inclusive and differential level, as well as in several fiducial volumes that have often been explored by interfacing fixed-order calculation with parton shower event generators at NNLO in QCD. At the inclusive level VBF and VH associate production are also known at N3LO. With these improvements in the state-of-the-art theory predictions and the increase in luminosity and center-of-mass energy, Higgs physics has definitively entered a precision era. Its impact can already be seen on the latest Run-2 combined measurements of the Higgs boson couplings (see Section 11.3.5). This situation allows for new challenges to ultimately increase further the reach in precision and it also widens the possibilities of unveiling the true nature and the dynamics of the EWSB mechanism.

Many extensions of the SM at higher energies call for an enlargement of the EWSB sector. Hence, direct searches for additional scalar states can provide valuable insights on the dynamics of the EWSB mechanism. The ATLAS and CMS experiments have searched for additional Higgs bosons in the Run-2 data, and have imposed constraints in broad ranges of mass and couplings for various scenarios with an extended Higgs sector.

Outlook– The unitarization of the vector boson scattering (VBS) amplitudes, dominated at high energies by their longitudinal polarization, has been the basis of the *no lose* theorem at the LHC, and was a determining consideration in the building of the accelerator and detectors. It motivated the existence of a Higgs boson or the observability of manifestations of strong dynamics at the TeV scale. Now that a Higgs boson has been found and its couplings to gauge bosons are - within current accuracy - consistent with the SM predictions, perturbative unitarity is preserved to a large extent with the sole exchange of the Higgs boson, and without the need for any additional states. VBS remains still an important channel to further investigate in order to better understand the nature of the Higgs sector and the possible completion of the SM at the TeV scale. In association with the double Higgs boson production channel by vector boson fusion, VBS could, for instance, confirm that the Higgs boson is part of a weak doublet and also establish whether it is an elementary object or a composite state that could emerge as a pseudo-Nambu–Goldstone boson from a new underlying broken symmetry.

The fermion-Higgs boson couplings are not governed by local gauge symmetry. Thus, in addition to a new particle, the LHC has also discovered a new force, different in nature from the other fundamental interactions since it is non-universal and distinguishes between the three families of quarks and leptons. The existence of the Higgs boson embodies the problem of an unnatural cancella-

except for Open Access articles.

tion among the quantum corrections to its mass if new physics is present at scales significantly higher than the EW scale. The non-observation of additional states which could stabilise the Higgs boson mass is a challenge for natural scenarios like SUSY or models with a new strong interaction in which the Higgs boson is not a fundamental particle. This increasingly pressing paradox starts questioning the principle of naturalness and it also inspires new solutions tied to the cosmological evolution of the Universe.

The search for the Higgs boson has occupied the particle physics community for the last 50 years. Its discovery has shaped and sharpened the physics programs of the LHC and the HL-LHC and has been central to the discussion of prospective future accelerators [191, 192, 194, 195, 592, 593]. Given the exceptional performance of the LHC so far, projections for the HL-LHC promise to establish a legacy Higgs-boson precision physics program that will test the SM at an unprecedented level and will serve to deepen our understanding of fundamental physics. In particular, with respect to current data, the HL-LHC with an integrated luminosity of 3 ab^{-1} per experiment is expected to (i) determine the $H \to \mu^+\mu^-$ and $H \to Z\gamma$ couplings with 3-7% precision; (ii) measure the other main Higgs-boson couplings to SM fermions and vector bosons, including loop-induced couplings to gluons and photons, with precision ranging from 1.6% to 3.6%; (iii) reach a sensitivity to the charm Yukawa coupling of 1.5 times the SM value at 95% C.L.; (iv) observe SM di-Higgs production with a significance exceeding 7σ; (v) measure the Higgs-boson trilinear coupling with a precision better than 30%; (vi) observe longitudinally polarized vector boson $W_L W_L$ scattering and measure its cross section with precision better than 20%; and (vi) continue placing strong bounds on high-scale new physics models both through direct searches and precision measurements of EW, top-quark, and flavor-physics observables [266]. The projected experimental systematic uncertainties are similar to the statistical uncertainties, but the dominant source of uncertainty arises from theory, and this remains the case even after assuming that, by the end of the HL-LHC run, the theory uncertainties can be reduced by a factor two compared to the current uncertainties [266]. Theoretical progress is hard to predict, but given the progress witnessed in theoretical calculations during the lifetime of the LHC, as well as the wealth of new ideas that have been employed and are currently being considered, a progress in theoretical predictions by a factor of two or more appears realistic but still requires dedicated and concerted effort.

Based on these outstanding achievements, future colliders currently being considered will improve our present knowledge of Higgs-boson physics by either increasing the precision or the energy reach of the HL-LHC [191, 192, 593, 593, 594]. Proposed e^+e^- colliders, both circular and linear, with center-of-mass energies between M_Z and about 350 GeV, the so called *Higgs factories*, will be able to measure all Higgs-boson couplings at percent and sub-percent level, including the couplings to charm and strange quarks, and put first bounds on the extremely small electron Yukawa coupling. Only the measurement of the top-quark Yukawa coupling will require energies of about $550 - 600$ GeV to reach a precision higher than the HL-LHC. Such energy upgrade is part of the proposed plan for an e^+e^- linear collider. e^+e^- colliders will also deliver a largely model-independent measurements of the Higgs-boson width and, for the case of circular e^+e^- colliders, even obtain a meaningful upper bound on the Yukawa couplings of the electron, getting us closer to establishing the origin of the electron mass which lies at the core of all atomic structures. A different class of colliders referred to as *Multi-TeV* colliders, colliding either pp or $\mu^+\mu^-$ beams, will explore LHC center-of-mass energy by roughly one order of magnitude and, besides measuring all Higgs-boson properties in a new energy regime, search for evidence of NP between the EW scale and about 10 TeV as suggested by the Higgs portal.

For both hadron and lepton colliders, substantial theoretical progress is crucial to fully exploit and capitalize on the experimental data. In particular, the expected HL-LHC data together with rapid ongoing progress in theoretical calculations are defining a new era of precision Higgs boson measurements.

12. CKM Quark-Mixing Matrix

Revised March 2026 by A. Ceccucci (CERN), Z. Ligeti (LBNL) and Y. Sakai (KEK).

12.1 Introduction

The masses and mixings of quarks have a common origin in the Standard Model (SM). They arise from the Yukawa interactions with the Higgs condensate,

$$\mathcal{L}_Y = -Y^d_{ij}\,\overline{Q^I_{Li}}\,\phi\,d^I_{Rj} - Y^u_{ij}\,\overline{Q^I_{Li}}\,\epsilon\,\phi^*\,u^I_{Rj} + \text{h.c.}, \tag{12.1}$$

where $Y^{u,d}$ are 3×3 complex matrices, ϕ is the Higgs field, i,j are generation labels, and ϵ is the 2×2 antisymmetric tensor. Q^I_L are left-handed quark doublets, and d^I_R and u^I_R are right-handed down- and up-type quark singlets, respectively, in the weak-eigenstate basis. When ϕ acquires a vacuum expectation value, $\langle\phi\rangle = (0, v/\sqrt{2})$, Eq. (12.1) yields mass terms for the quarks. The physical states are obtained by diagonalizing $Y^{u,d}$ by four unitary matrices, $V^{u,d}_{L,R}$, as $M^f_{\rm diag} = V^f_L\,Y^f\,V^{f\dagger}_R(v/\sqrt{2})$, $f = u, d$. As a result, the charged-current $W^\pm$ interactions couple to the physical u_{Lj} and d_{Lk} quarks with couplings given by

$$\frac{-g}{\sqrt{2}}(\overline{u_L},\,\overline{c_L},\,\overline{t_L})\gamma^\mu\,W^+_\mu\,V_{\rm CKM}\begin{pmatrix} d_L \\ s_L \\ b_L\end{pmatrix} + \text{h.c.},$$
$$V_{\rm CKM} \equiv V^u_L V^{d\dagger}_L = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb}\end{pmatrix}. \tag{12.2}$$

This Cabibbo-Kobayashi-Maskawa (CKM) matrix [1,2] is a 3×3 unitary matrix. It can be parameterized by three mixing angles and the CP-violating KM phase [2]. Of the many possible conventions, a standard choice has become [3]

$$V_{\rm CKM} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & c_{23} & s_{23} \\ 0 & -s_{23} & c_{23}\end{pmatrix}\begin{pmatrix} c_{13} & 0 & s_{13}e^{-i\delta} \\ 0 & 1 & 0 \\ -s_{13}e^{i\delta} & 0 & c_{13}\end{pmatrix}\begin{pmatrix} c_{12} & s_{12} & 0 \\ -s_{12} & c_{12} & 0 \\ 0 & 0 & 1\end{pmatrix}$$
$$= \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13}\end{pmatrix}, \tag{12.3}$$

where $s_{ij} = \sin\theta_{ij}$, $c_{ij} = \cos\theta_{ij}$, and δ is the phase responsible for all CP-violating phenomena in flavor-changing processes in the SM. The angles θ_{ij} can be chosen to lie in the first quadrant, so $s_{ij}, c_{ij} \geq 0$.

It is known experimentally that $s_{13} \ll s_{23} \ll s_{12} \ll 1$, and it is convenient to exhibit this hierarchy using the Wolfenstein parameterization. We define [4–6]

$$s_{12} = \lambda = \frac{|V_{us}|}{\sqrt{|V_{ud}|^2 + |V_{us}|^2}}\,, \qquad s_{23} = A\lambda^2 = \lambda\left|\frac{V_{cb}}{V_{us}}\right|,$$
$$s_{13}e^{i\delta} = V^*_{ub} = A\lambda^3(\rho + i\eta) = \frac{A\lambda^3(\bar\rho + i\bar\eta)\sqrt{1 - A^2\lambda^4}}{\sqrt{1-\lambda^2}\,[1 - A^2\lambda^4(\bar\rho + i\bar\eta)]}\,. \tag{12.4}$$

These relations ensure that $\bar\rho + i\bar\eta = -(V_{ud}V^*_{ub})/(V_{cd}V^*_{cb})$ is phase convention independent, and the CKM matrix written in terms of λ, A, $\bar\rho$, and $\bar\eta$ is unitary to all orders in λ. The definitions of $\bar\rho$, $\bar\eta$ reproduce all approximate results in the literature; *i.e.*, $\bar\rho = \rho(1-\lambda^2/2+\ldots)$ and $\bar\eta = \eta(1-\lambda^2/2+\ldots)$, and one can write $V_{\rm CKM}$ to $\mathcal{O}(\lambda^4)$ either in terms of $\bar\rho, \bar\eta$ or, traditionally,

$$V_{\rm CKM} = \begin{pmatrix} 1-\lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1-\lambda^2/2 & A\lambda^2 \\ A\lambda^3(1-\rho-i\eta) & -A\lambda^2 & 1\end{pmatrix} + \mathcal{O}(\lambda^4)\,. \tag{12.5}$$

The CKM matrix elements are fundamental parameters of the SM, so their precise determination is important. The unitarity of the CKM matrix imposes $\sum_i V_{ij}V^*_{ik} = \delta_{jk}$ and $\sum_j V_{ij}V^*_{kj} = \delta_{ik}$. The six vanishing combinations can be represented as triangles in a complex plane, of which those obtained by taking scalar products of neighboring rows or columns are nearly degenerate. The areas of all triangles are the same, half of the Jarlskog invariant, J [7], which is a phase-convention-independent measure of CP violation, defined by $\text{Im}\left[V_{ij}V_{kl}V^*_{il}V^*_{kj}\right] = J\sum_{m,n}\varepsilon_{ikm}\varepsilon_{jln}$.

The most commonly used unitarity triangle arises from

$$V_{ud}\,V^*_{ub} + V_{cd}\,V^*_{cb} + V_{td}\,V^*_{tb} = 0\,, \tag{12.6}$$

by dividing each side by $V_{cd}V^*_{cb}$ (see Fig. 12.1). Its vertices are exactly $(0,0)$, $(1,0)$, and, due to the definition in Eq. (12.4), $(\bar\rho, \bar\eta)$. An important goal of flavor physics is to overconstrain the CKM elements, and many measurements can be conveniently displayed and compared in the $\bar\rho, \bar\eta$ plane. While the Lagrangian in Eq. (12.1) is renormalized, and the CKM matrix has a well-known scale dependence above the weak scale [8], below $\mu = m_W$ the CKM elements can be treated as constants, with all μ-dependence contained in the running of quark masses and higher-dimension operators.

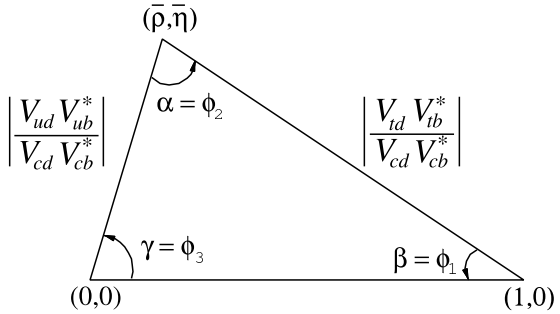

Figure 12.1: Sketch of the unitarity triangle.

Unless explicitly stated otherwise, we describe all measurements assuming the SM, to extract magnitudes and phases of CKM elements in Sec. 12.2 and 12.3. Processes dominated by loop-level contributions in the SM are particularly sensitive to new physics beyond the SM (BSM). We give the global fit results for the CKM elements in Sec. 12.4, and discuss some implications for beyond standard model physics in Sec. 12.5.

12.2 Magnitudes of CKM elements

12.2.1 $|V_{ud}|$

The most precise determination of $|V_{ud}|$ comes from the study of superallowed $0^+ \to 0^+$ nuclear beta decays, which are pure vector transitions. Taking the average of the fifteen most precise determinations [9] yields [10]

$$|V_{ud}| = 0.97367 \pm 0.00032\,. \tag{12.7}$$

This uncertainty is slightly more than twice as large as that in the 2020 edition, due to a more conservative estimate of the nuclear structure uncertainties. A less precise determination of $|V_{ud}|$ can be obtained from the measurement of the neutron lifetime. The theoretical uncertainties are very small, but the determination is limited by the knowledge of the ratio of the axial-vector and vector couplings, $g_A = G_A/G_V$ [10]. The PIBETA experiment [11] has improved the measurement of the $\pi^+ \to \pi^0 e^+\nu$ branching ratio to 0.6%, and Ref. [12] quotes $|V_{ud}| = 0.9739 \pm 0.0027$, in

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
except for Open Access articles.

agreement with the more precise result listed above. The interest in this measurement is that the determination of $|V_{ud}|$ is very clean theoretically, because it is a pure vector transition and is free from nuclear-structure uncertainties.

12.2.2 $|V_{us}|$

The product of $|V_{us}|$ and the form factor at $q^2 = 0$, $|V_{us}|\, f_+(0)$, has been extracted traditionally from $K^0_L \to \pi e\nu$ decays in order to avoid isospin-breaking corrections ($\pi^0 - \eta$ mixing) that affect $K^\pm$ semileptonic decay, and the complications induced by a second (scalar) form factor present in the muonic decays. The last round of measurements has led to enough experimental constraints to justify the comparison between different decay modes. Systematic errors related to the experimental quantities, *e.g.*, the lifetime of neutral or charged kaons, and the form factor determinations for electron and muonic decays, differ among decay modes, and the consistency between different determinations enhances the confidence in the final result. For this reason, we follow the prescription [13] to average $K^0_L \to \pi e\nu$, $K^0_L \to \pi\mu\nu$, $K^\pm \to \pi^0 e^\pm\nu$, $K^\pm \to \pi^0\mu^\pm\nu$ and $K^0_S \to \pi e\nu$. The average of these five decay modes yields $|V_{us}|\, f_+(0) = 0.21656 \pm 0.00035$. Results obtained from each decay mode, and exhaustive references to the experimental data, are listed for instance in Ref. [10]. The form factor average $f_+(0) = 0.9698 \pm 0.0017$ [14] from $N_f = 2+1+1$ lattice QCD calculations gives $|V_{us}| = 0.2233 \pm 0.0005$ [10].[1] The broadly used classic calculation of $f_+(0)$ [16] is in good agreement with this value, while other calculations [18] differ by as much as 2%.

The calculation of the ratio of the kaon and pion decay constants enables one to extract $|V_{us}/V_{ud}|$ from $K \to \mu\nu(\gamma)$ and $\pi \to \mu\nu(\gamma)$, where (γ) indicates that radiative decays are included [19]. The value of $\Gamma(K \to \mu\nu(\gamma))$ [10] derived from the KLOE measurement of the corresponding branching ratio [20], combined with the lattice QCD result, $f_K/f_\pi = 1.1978 \pm 0.0022$ [10], leads to $|V_{us}| = 0.2250 \pm 0.0004$, where the accuracy is limited by the knowledge of the ratio of the decay constants. The average of these two determinations, with the error scaled according to the PDG prescription [21] by $\sqrt{\chi^2} = 2.5$, is quoted as [10]

$$|V_{us}| = 0.22431 \pm 0.00085\,. \tag{12.8}$$

It is important to include both QED and QCD sources of isospin violations in the lattice QCD calculations.

The latest determination from hyperon decays can be found in Ref. [22]. The authors focus on the analysis of the vector form factor, protected from first order flavor $SU(3)$ breaking effects by the Ademollo-Gatto theorem [23], and treat the ratio between the axial and vector form factors g_1/f_1 as experimental input, thus avoiding first order $SU(3)$ breaking effects in the axial-vector contribution. They find $|V_{us}| = 0.2250 \pm 0.0027$, although this does not include an estimate of the theoretical uncertainty due to second-order $SU(3)$ breaking, contrary to Eq. (12.8). Concerning hadronic τ decays to strange particles, averaging the inclusive decay and the exclusive $\tau \to h\nu$ ($h = \pi$, K) measurements yields $|V_{us}| = 0.2208 \pm 0.0014$ [24].

12.2.3 $|V_{cd}|$

The magnitude of V_{cd} can be extracted from semileptonic charm decays, using theoretical knowledge of the form factors. In semileptonic D decays, lattice QCD calculations have predicted the normalization of the $D \to \pi\ell\nu$ and $D \to K\ell\nu$ form factors [14]. The dependence on the invariant mass of the lepton pair, q^2, is determined from lattice QCD and theoretical constraints from analyticity [15]. Using $N_f = 2+1+1$ lattice QCD calculations for $D \to \pi\ell\nu$, $f_+^{D\pi}(0) = 0.6296 \pm 0.0050$ [14], and the average [24] of the measurements of $D \to \pi\ell\nu$ decays by *BABAR* [25], BESIII [26], CLEO-c [27], and Belle [28], one obtains $|V_{cd}| = 0.2265 \pm 0.0029 \pm 0.0018$, where the first uncertainty is experimental, and the second is from the theoretical uncertainty of the form factor.

The determination of $|V_{cd}|$ is also possible from the leptonic decay $D^+ \to \mu^+\nu$ and $\tau^+\nu$. The experimental uncertainties decreased significantly recently [29]. We take the average [30] (which includes the Sirlin factor, the universal short-distance electromagnetic correction), the BESIII [29] and earlier CLEO [31] measurements for $\mu^+\nu$ and BESIII [32] for $\tau^+\nu$, and use the $N_f = 2+1+1$ lattice QCD result, $f_D = 212.0 \pm 0.7$ MeV [14], to obtain $|V_{cd}| = 0.2330 \pm 0.0028 \pm 0.0007$.[2]

Earlier determinations of $|V_{cd}|$ came from neutrino scattering data. The difference of the ratio of double-muon to single-muon production by neutrino and antineutrino beams is proportional to the charm cross section off valence d quarks, and therefore to $|V_{cd}|^2$ times the average semileptonic branching ratio of charm mesons, $\mathcal{B}_\mu$. The method was used first by CDHS [33] and then by CCFR [34] and CHARM II [35]. Averaging these results is complicated, because it requires assumptions about the scale of the QCD corrections, and because $\mathcal{B}_\mu$ is an effective quantity, which depends on the specific neutrino beam characteristics. With no recent experimental input available, we quote the average from a past review, $\mathcal{B}_\mu |V_{cd}|^2 = (0.463 \pm 0.034) \times 10^{-2}$ [36]. Analysis cuts make these experiments insensitive to neutrino energies smaller than 30 GeV. Thus, $\mathcal{B}_\mu$ should be computed using only neutrino interactions with visible energy larger than 30 GeV. An appraisal [37] based on charm-production fractions measured in neutrino interactions [38] gives $\mathcal{B}_\mu = 0.088 \pm 0.006$. Data from the CHORUS experiment [39] are sufficiently precise to extract $\mathcal{B}_\mu$ directly, by comparing the number of charm decays with a muon to the total number of charmed hadrons found in the nuclear emulsions. Requiring the visible energy to be larger than 30 GeV, CHORUS found $\mathcal{B}_\mu = 0.085 \pm 0.009 \pm 0.006$. We use the average of these two determinations, $\mathcal{B}_\mu = 0.087 \pm 0.005$, and obtain $|V_{cd}| = 0.230 \pm 0.011$. Averaging the three determinations above, we find

$$|V_{cd}| = 0.2247 \pm 0.0022\,. \tag{12.9}$$

12.2.4 $|V_{cs}|$

The direct determination of $|V_{cs}|$ is possible from semileptonic D or leptonic D_s decays, using lattice QCD calculations of the semileptonic D form factor or the D_s decay constant. For muonic decays, the average of Belle [40], CLEO-c [41], *BABAR* [42], and BESIII [43,44] is $\mathcal{B}(D_s^+ \to \mu^+\nu) = (5.34 \pm 0.12) \times 10^{-3}$ [30]. For decays to τ leptons, the average of CLEO-c [41,45], *BABAR* [42], Belle [40], and BESIII [44,46] gives $\mathcal{B}(D_s^+ \to \tau^+\nu) = (5.388 \pm 0.093) \times 10^{-2}$ [30]. From each of these values, determinations of $|V_{cs}|$ can be obtained using the PDG values for the mass and lifetime of the D_s, the masses of the leptons, and $f_{D_s} = (249.9 \pm 0.5)$ MeV [14]. The average of these determinations gives $|V_{cs}| = 0.976 \pm 0.010$, where the error is dominated by the experimental uncertainty.

In semileptonic D decays, lattice QCD calculations of the $D \to K\ell\nu$ form factor are available [14]. Using $f_+^{DK}(0) = 0.7430 \pm 0.0027$ and the average [24] of CLEO-c [27], Belle [28], *BABAR* [47], and recent BESIII [26,48] measurements of $D \to K\ell\nu$ decays, one obtains $|V_{cs}| = 0.966 \pm 0.006$, where the dominant uncertainty is from the theoretical calculation of the form factor. Averaging the determinations from leptonic and semileptonic decays, we find

$$|V_{cs}| = 0.969 \pm 0.005\,. \tag{12.10}$$

Measurements of on-shell $W^\pm$ decays sensitive to $|V_{cs}|$ were made at LEP-2 and the LHC. The W branching ratios depend on the six CKM elements involving only the quarks lighter than m_W. The W branching ratio to each lepton flavor is $1/\mathcal{B}(W \to \ell\bar{\nu}_\ell) = 3\Big[1 + \sum_{u,c,d,s,b} |V_{ij}|^2\,(1 + \alpha_s(m_W)/\pi) + \dots\Big]$. Assuming lepton universality, and averaging the LEP [49] and CMS [50] measurements, we find $\mathcal{B}(W \to \ell\bar{\nu}_\ell) = (10.88 \pm 0.06)\%$, which implies $\sum_{u,c,d,s,b} |V_{ij}|^2 = 1.988 \pm 0.017$. This is a precise test of unitarity of the 1st and 2nd raw of the CKM matrix. However, only flavor-tagged W-decays determine $|V_{cs}|$ directly, such as DELPHI's tagged $W^+ \to c\bar{s}$ analysis, yielding $|V_{cs}| = 0.94^{+0.32}_{-0.26} \pm 0.13$ [51].

[1] For lattice QCD inputs, we use the averages from Ref. [14], unless the minireviews [10,15] choose different values. We only use unquenched results, and if both $N_f = 2+1+1$ and $2+1$ calculations are available, we use the former.

[2] Hereafter the first error is statistical and the second is systematic, unless mentioned otherwise.

12.2.5 $|V_{cb}|$

This matrix element can be determined from exclusive and inclusive semileptonic decays of B mesons to charm. The inclusive determinations use the semileptonic decay rate measurement, together with (certain moments of) the lepton energy and the hadronic invariant-mass spectra. The theoretical basis is the operator product expansion [52, 53], which allows calculation of the decay rate and various spectra as expansions in α_s and inverse powers of the heavy-quark mass. The dependence on m_b, m_c, and the parameters that occur at subleading order is different for different moments. The measurements of many moments overconstrain these parameters, and also test the consistency of their determination. The precise extraction of $|V_{cb}|$ requires using a "threshold" quark mass definition [54, 55]. Inclusive measurements have been performed using B mesons from Z^0 decays at LEP, and at e^+e^- colliders operated at the $\Upsilon(4S)$. At LEP, the large boost of B mesons from the Z^0 decay allows the determination of the moments throughout phase space, which is not possible otherwise, but the large statistics available at the B factories lead to more precise determinations. An average of the measurements and a compilation of the references are provided in Ref. [15]: $|V_{cb}| = (42.0 \pm 0.5) \times 10^{-3}$.

Complementary determinations are based on exclusive semileptonic B decays to D and D^*. In the $m_{b,c} \gg \Lambda_{\rm QCD}$ limit, all form factors are given by a single Isgur-Wise function [56], which depends on the product of the four-velocities of the B and $D^{(*)}$ mesons, $w = v \cdot v'$. Heavy-quark symmetry determines the rate (in the symmetry limit) at $w = 1$, the point in phase space at which the invariant mass of the $\ell\bar{\nu}$ pair is maximal; $|V_{cb}|$ is obtained from extrapolating a fit to the spectrum to $w = 1$. The current update of the V_{cb} and V_{ub} minireview quotes from exclusive decays $|V_{cb}| = (39.5 \pm 0.5) \times 10^{-3}$ [15], based on the only unfolded measurement of $B \to D^*$ semileptonic decay distributions [57], and using a more general fit [58] than in earlier B factory measurements. With the uncertainty scaled by $\sqrt{\chi^2} = 3.7$, this yields the combination [15],

$$|V_{cb}| = (40.7 \pm 1.3) \times 10^{-3} \,. \tag{12.11}$$

Determinations of $|V_{cb}|$ that are currently less precise and not included in this average, can be obtained from the measurement of $B_s \to D_s^{(*)} \mu\bar{\nu}$ decays [59]. In addition, semileptonic decays to τ leptons measured in $B \to D^{(*)}\tau\bar{\nu}$ and related modes are also sensitive to $|V_{cb}|$. The most precise data involving τ leptons are the $|V_{cb}|$-independent ratios, $\mathcal{B}(B \to D^{(*)}\tau\bar{\nu})/\mathcal{B}(B \to D^{(*)}\ell\bar{\nu})$ measured by BaBar, Belle, and LHCb. If the current, approximately $3.8\,\sigma$ [24] hint of lepton non-universality prevails, the determination of $|V_{cb}|$ becomes more complicated.

12.2.6 $|V_{ub}|$

The determination of $|V_{ub}|$ from inclusive $B \to X_u \ell\bar{\nu}$ decay is complicated due to large $B \to X_c \ell\bar{\nu}$ backgrounds. In most regions of phase space where the charm background is kinematically forbidden, the hadronic physics enters via unknown nonperturbative functions, so-called shape functions. (By contrast, the nonperturbative physics for $|V_{cb}|$ is encoded in a few parameters.) At leading order in $\Lambda_{\rm QCD}/m_b$, there is only one shape function, which can be extracted from the photon energy spectrum in $B \to X_s\gamma$ [60, 61], and applied to several spectra in $B \to X_u \ell\bar{\nu}$. The subleading shape functions are modeled in the current determinations. Phase space cuts for which the rate has only subleading dependence on the shape function are also possible [62]. The measurements of both the hadronic and the leptonic systems are important for an optimal choice of phase space. A different approach is to make the measurements more inclusive by extending them deeper into the $B \to X_c \ell\bar{\nu}$ region, and thus reduce the theoretical uncertainties. Analyses of the electron-energy endpoint from CLEO [63], *BABAR* [64], and Belle [65] quote $B \to X_u e\bar{\nu}$ partial rates for $|\vec{p}_e| \geq 2.0\,\text{GeV}$ and 1.9 GeV, which are well below the charm endpoint. The large and pure $B\overline{B}$ samples at the B factories permit the selection of $B \to X_u \ell\bar{\nu}$ decays in events where the other B is fully reconstructed [66]. With this full-reconstruction tag method, the four-momenta of both the leptonic and the hadronic final states can be measured. It also gives access to a wider kinematic region, because of improved signal purity. Ref. [15] quotes the inclusive average, $|V_{ub}| = (4.06 \pm 0.11 \pm 0.13 \pm 0.18) \times 10^{-3}$, where the first error is experimental, the second arises from the model dependence quoted by the individual measurements, and the third is an additional one estimated in Ref. [15].

To extract $|V_{ub}|$ from exclusive decays, the form factors have to be known. Experimentally, better signal-to-background ratios are offset by smaller yields. The $B \to \pi\ell\bar{\nu}$ branching ratio is now known to 5%. Lattice QCD calculations of the $B \to \pi\ell\bar{\nu}$ form factor are available [67] for the high q^2 region ($q^2 > 16$ or $18\,\text{GeV}^2$). A fit to the experimental partial rates and lattice QCD results versus q^2 yields $|V_{ub}| = (3.75 \pm 0.06 \pm 0.19) \times 10^{-3}$ [24].

The uncertainties in extracting $|V_{ub}|$ from inclusive and exclusive decays are different to a large extent. An average of these determinations, with the uncertainty scaled by $\sqrt{\chi^2} = 1.1$, is [15]

$$|V_{ub}| = (3.89 \pm 0.16) \times 10^{-3} \,. \tag{12.12}$$

A determination of $|V_{ub}|$ not included in this average can be obtained from $\mathcal{B}(B \to \tau\bar{\nu}) = (1.12 \pm 0.19) \times 10^{-4}$ [24]. Using $f_B = (190.0 \pm 1.3)\,\text{MeV}$ [14] and $\tau_{B^\pm} = (1.638 \pm 0.004)\,\text{ps}$ [68], we find the remarkably consistent result, $|V_{ub}| = (4.16 \pm 0.35) \times 10^{-3}$. This decay is sensitive, for example, to tree-level charged Higgs contributions, and the measured rate is consistent with the SM expectation. The LHCb measurements of $|V_{ub}/V_{cb}|$ from the ratios of $\Lambda_b \to p^+\mu^-\bar{\nu}$ and $\Lambda_b \to \Lambda_c^+\mu^-\bar{\nu}$ [69] and $B_s^0 \to K^-\mu^+\nu$ and $B_s^0 \to D_s^-\mu^+\nu$ [70] in different regions of q^2, provides another complementary determination.

12.2.7 $|V_{td}|$ *and* $|V_{ts}|$

The CKM elements $|V_{td}|$ and $|V_{ts}|$ are not likely to be precisely measurable in tree-level processes involving top quarks, so one has to rely on determinations from $B^0 - \overline{B}^0$ mixing, dominated by box diagrams with top quarks, or loop-mediated rare K and B decays. Theoretical uncertainties in hadronic effects limit the accuracy of the current determinations. These can be reduced by taking ratios of processes that are equal in the flavor $SU(3)$ limit to determine $|V_{td}/V_{ts}|$.

The phenomenon of $B^0 - \overline{B}^0$ mixing was discovered by ARGUS [71], and the mass difference is now precisely measured as $\Delta m_d = (0.5068 \pm 0.0019)\,\text{ps}^{-1}$ [72]. In the B_s^0 system, Δm_s was first measured significantly by CDF [73] and the world average, dominated by an LHCb measurement [74], is $\Delta m_s = (17.765 \pm 0.006)\,\text{ps}^{-1}$ [72]. Neglecting corrections suppressed by $|V_{tb}| - 1$, and using the lattice QCD results $f_{B_d}\sqrt{\widehat{B}_{B_d}} = (210.6 \pm 5.5)\,\text{MeV}$ and $f_{B_s}\sqrt{\widehat{B}_{B_s}} = (256.1 \pm 5.7)\,\text{MeV}$ [14],

$$|V_{td}| = (8.6 \pm 0.2) \times 10^{-3} \,, \qquad |V_{ts}| = (41.5 \pm 0.9) \times 10^{-3} \,. \tag{12.13}$$

The uncertainties are dominated by lattice QCD. Several uncertainties are reduced in the calculation of the ratio $\xi = \left(f_{B_s}\sqrt{\widehat{B}_{B_s}}\right)/\left(f_{B_d}\sqrt{\widehat{B}_{B_d}}\right) = 1.216 \pm 0.016$ [14] and therefore the constraint on $|V_{td}/V_{ts}|$ from $\Delta m_d/\Delta m_s$ is more reliable theoretically. These provide a theoretically clean and significantly improved determination,

$$\left|V_{td}/V_{ts}\right| = 0.207 \pm 0.001 \pm 0.003 \,. \tag{12.14}$$

The inclusive branching ratio $\mathcal{B}(B \to X_s\gamma) = (3.49 \pm 0.19) \times 10^{-4}$ extrapolated to $E_\gamma > E_0 = 1.6\,\text{GeV}$ [24] is also sensitive to $|V_{tb}V_{ts}|$. In addition to t-quark penguins, a substantial part of the rate comes from charm contributions proportional to $V_{cb}V_{cs}^*$ via the application of 3×3 CKM unitarity (which is used here). With the NNLO calculation of $\mathcal{B}(B \to X_s\gamma)_{E_\gamma > E_0}/\mathcal{B}(B \to X_c e\bar{\nu})$ [75], we obtain $|V_{ts}/V_{cb}| = 1.00 \pm 0.04$. The $B_s \to \mu^+\mu^-$ rate is also proportional to $|V_{tb}V_{ts}|^2$ in the SM, and the world average, $\mathcal{B}(B_s \to \mu^+\mu^-) = (3.34 \pm 0.27) \times 10^{-9}$ [68], is consistent with the SM, with sizable uncertainties.

A complementary determination of $|V_{td}/V_{ts}|$ is possible from the ratio of $B \to \rho\gamma$ and $K^*\gamma$ rates. The ratio of the neutral modes is theoretically cleaner than that of the charged ones, because the poorly known spectator-interaction contribution is expected to be

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
except for Open Access articles.

smaller (W-exchange vs. weak annihilation). For now, because of low statistics, we average the charged and neutral rates assuming the isospin symmetry and heavy-quark limit motivated relation, $|V_{td}/V_{ts}|^2/\xi_\gamma^2 = [\Gamma(B^+ \to \rho^+\gamma) + 2\Gamma(B^0 \to \rho^0\gamma)]/[\Gamma(B^+ \to K^{*+}\gamma) + \Gamma(B^0 \to K^{*0}\gamma)] = (3.63 \pm 0.41)\%$ [24, 76]. Here ξ_γ contains the poorly known hadronic physics. Using $\xi_\gamma = 1.2 \pm 0.2$ [77] gives $|V_{td}/V_{ts}| = 0.228 \pm 0.013 \pm 0.038$, where the first uncertainty is experimental and the second is theoretical.

A theoretically clean determination of $|V_{td}V_{ts}^*|$ is possible from $K^+ \to \pi^+\nu\bar{\nu}$ decay [78]. Experimentally, the decay has been observed by NA62 [79] and the branching fraction is consistent with the SM within uncertainties. Much more data are needed for a precision measurement.

12.2.8 $|V_{tb}|$

The determination of $|V_{tb}|$ from top decays uses the ratio of branching fractions $R = \mathcal{B}(t \to Wb)/\mathcal{B}(t \to Wq) = |V_{tb}|^2/(\sum_q |V_{tq}|^2) = |V_{tb}|^2$, where $q = b, s, d$. The CDF and DØ measurements performed on data collected during Run II of the Tevatron give $|V_{tb}| > 0.85$ [80] and $0.99 > |V_{tb}| > 0.90$ [81], respectively, at 95% CL. CMS measured the same quantity at 8 TeV and obtained $|V_{tb}| > 0.975$ [82] at 95% CL.

The direct determination of $|V_{tb}|$, without assuming unitarity, is possible from the single top quark production cross section. The $(3.30^{+0.52}_{-0.40})$ pb combined cross section [83] of DØ and CDF measurements implies $|V_{tb}| = 1.02^{+0.06}_{-0.05}$. The LHC experiments, ATLAS and CMS, have measured single top quark production cross sections (and extracted $|V_{tb}|$) in t-channel, Wt-channel, and s-channel at 7 TeV, 8 TeV, and 13 TeV [84]. The average of these $|V_{tb}|$ values is calculated to be $|V_{tb}| = 0.998 \pm 0.026$, where all systematic errors and theoretical errors are treated to be fully correlated. The average of Tevatron and LHC values gives

$$|V_{tb}| = 1.002 \pm 0.024\,. \tag{12.15}$$

The experimental systematic uncertainties dominate, and a dedicated combination would be welcome.

A weak constraint on $|V_{tb}|$ can be obtained from precision electroweak data, where top quarks enter in loops. The sensitivity is best in $\Gamma(Z \to b\bar{b})$ and yields $|V_{tb}| = 0.77^{+0.18}_{-0.24}$ [85].

12.3 Phases of CKM elements

As can be seen from Fig. 12.1, the angles of the unitarity triangle are

$$\begin{aligned}
\beta &= \phi_1 = \arg\Big(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\Big),\\
\alpha &= \phi_2 = \arg\Big(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\Big),\\
\gamma &= \phi_3 = \arg\Big(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\Big).
\end{aligned} \tag{12.16}$$

Since CP violation involves phases of CKM elements, many measurements of CP-violating observables can be used to constrain these angles and the $\bar{\rho}, \bar{\eta}$ parameters.

12.3.1 ϵ and ϵ'

The measurement of CP violation in K^0–$\overline{K}^0$ mixing, $|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}$ [86], provides important information about the CKM matrix. The phase of ϵ is determined by long-distance physics, $\epsilon = \frac{1}{2}\, e^{i\phi_\epsilon} \sin\phi_\epsilon \arg(-M_{12}/\Gamma_{12})$, where $\phi_\epsilon = \arctan|2\Delta m_K/\Delta\Gamma_K| \simeq 43.5°$. The SM prediction can be written as

$$\begin{aligned}
\epsilon = \kappa_\epsilon\, e^{i\phi_\epsilon} \frac{G_F^2 m_W^2 m_K}{12\sqrt{2}\,\pi^2 \Delta m_K} f_K^2 \widehat{B}_K \Big\{ &\eta_{tt} S(x_t) \,\mathrm{Im}[(V_{ts}V_{td}^*)^2] \\
&+ 2\eta_{ct} S(x_c, x_t) \,\mathrm{Im}(V_{cs}V_{cd}^* V_{ts}V_{td}^*) + \eta_{cc}\, x_c \,\mathrm{Im}[(V_{cs}V_{cd}^*)^2] \Big\},
\end{aligned} \tag{12.17}$$

where $\kappa_\epsilon \simeq 0.94 \pm 0.02$ [87] includes the effects of strangeness changing $\Delta s = 1$ operators and additional dependence on $\phi_\epsilon \neq \pi/4$ (see also Ref. [88]). The displayed terms are the short-distance $\Delta s = 2$ contribution to $\mathrm{Im}M_{12}$ in the usual phase convention, S is an Inami-Lim function [89], $x_q = m_q^2/m_W^2$, and η_{ij} are perturbative QCD corrections. The constraint from ϵ in the $\bar{\rho}, \bar{\eta}$ plane is bounded by approximate hyperbolas. Lattice QCD determined the bag parameter $\widehat{B}_K = 0.717 \pm 0.024$ [14] and the main uncertainties are from $(V_{ts}V_{td}^*)^2$ (approximately given by that of $|V_{cb}|^4$ or A^4), the η_{ij} coefficients, and estimates of κ_ϵ.

The measurement of $6\,\mathrm{Re}(\epsilon'/\epsilon) = 1 - |\eta_{00}/\eta_{+-}|^2$, where each $\eta_{ij} = \langle\pi^i\pi^j|\mathcal{H}|K_L\rangle/\langle\pi^i\pi^j|\mathcal{H}|K_S\rangle$ violates CP, provides a qualitative test of the CKM mechanism, and strong constraints on many BSM scenarios. Its nonzero value, $\mathrm{Re}(\epsilon'/\epsilon) = (1.67 \pm 0.23) \times 10^{-3}$ [86], demonstrated the existence of direct CP violation, a prediction of the KM ansatz. While $\mathrm{Re}(\epsilon'/\epsilon) \propto \mathrm{Im}(V_{td}V_{ts}^*)$, this quantity cannot easily be used to extract CKM parameters, because cancellations between the electromagnetic and gluonic penguin contributions for large m_t [90] enhance the hadronic uncertainties. Most SM estimates [91] agree with the observed value, indicating that $\bar{\eta}$ is positive. Progress in lattice QCD [92] may yield a precise SM prediction in the future, and trigger new work on assessing the consistency of the SM with the measured value [93, 94].

12.3.2 β / ϕ_1

12.3.2.1 *Charmonium modes*

CP-violation measurements in B-meson decays provide direct information on the angles of the unitarity triangle, shown in Fig. 12.1. These overconstraining measurements serve to improve the determination of the CKM elements, and to reveal possible effects beyond the SM.

The time-dependent CP asymmetry of neutral B decays to a final state f common to B^0 and $\overline{B}^0$ is given by [95–97]

$$\begin{aligned}
\mathcal{A}_f &= \frac{\Gamma(\overline{B}^0(t) \to f) - \Gamma(B^0(t) \to f)}{\Gamma(\overline{B}^0(t) \to f) + \Gamma(B^0(t) \to f)}\,,\\
&= S_f \sin(\Delta m_d\, t) - C_f \cos(\Delta m_d\, t)\,,
\end{aligned} \tag{12.18}$$

where

$$S_f = \frac{2\,\mathrm{Im}\lambda_f}{1 + |\lambda_f|^2}\,, \qquad C_f = \frac{1 - |\lambda_f|^2}{1 + |\lambda_f|^2}\,, \qquad \lambda_f = \frac{q}{p}\frac{\bar{A}_f}{A_f}\,. \tag{12.19}$$

Here, q/p describes B^0–$\overline{B}^0$ mixing and, to a good approximation in the SM, $q/p = V_{tb}^* V_{td}/V_{tb}V_{td}^* = e^{-2i\beta + \mathcal{O}(\lambda^4)}$ in the usual phase convention. A_f ($\bar{A}_f$) is the amplitude of the $B^0 \to f$ ($\overline{B}^0 \to f$) decay. If f is a CP eigenstate, and amplitudes with one CKM phase dominate the decay, then $|A_f| = |\bar{A}_f|$, $C_f = 0$, and $S_f = \sin(\arg\lambda_f) = \eta_f \sin 2\phi$, where η_f is the CP eigenvalue of f and 2ϕ is the phase difference between the $B^0 \to f$ and $B^0 \to \overline{B}^0 \to f$ decay paths. A contribution of another amplitude to the decay with a different CKM phase makes the value of S_f sensitive to relative strong-interaction phases between the decay amplitudes (it also makes $C_f \neq 0$ possible).

The $b \to c\bar{c}s$ decays to CP eigenstates ($B^0 \to$ charmonium $K^0_{S,L}$) give currently the most precise measurements of $S_f = -\eta_f \sin 2\beta$. The $b \to s$ penguin amplitudes have dominantly the same weak phase as the $b \to c\bar{c}s$ tree amplitude. Since only λ^2-suppressed penguin amplitudes introduce a different CP-violating phase, amplitudes with a single weak phase dominate, and we expect $\Big||\bar{A}_{\psi K}/A_{\psi K}| - 1\Big| < 0.01$. The e^+e^- asymmetric-energy B-factory experiments, *BABAR* [98] and Belle [99], and LHCb [100] provided precise measurements. The world average, including some other measurements, is [24, 97, 101]

$$\sin 2\beta = 0.710 \pm 0.011\,. \tag{12.20}$$

This measurement has a four-fold ambiguity in β, which can be resolved by a global fit as mentioned in Sec. 12.4. Experimentally, the two-fold ambiguity $\beta \to \pi/2 - \beta$ (but not $\beta \to \pi + \beta$) can be resolved by a time-dependent angular analysis of $B^0 \to J/\psi K^{*0}$ [102, 103], or a time-dependent Dalitz plot analysis of $B^0 \to \overline{D}^0 h^0$. The time-dependent Dalitz plot analysis of $B^0 \to \overline{D}^0 h^0$ ($h^0 = \pi^0, \eta, \omega$) with $\overline{D}^0 \to K^0_S\pi^+\pi^-$, jointly performed by Belle and *BABAR*, excludes the $\pi/2 - \beta$ solution with

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

7.3σ confidence level [104]. These results exclude the negative $\cos 2\beta$ solutions, in agreement with the global CKM fit, which is no longer shown in Fig. 12.2.

The $b \to c\bar{c}d$ mediated transitions, such as $B^0 \to J/\psi\pi^0$ and $B^0 \to D^{(*)+}D^{(*)-}$, also measure approximately $\sin 2\beta$. However, the dominant component of the $b \to d$ penguin amplitude has a different CKM phase ($V_{tb}^* V_{td}$) than the tree amplitude ($V_{cb}^* V_{cd}$), and their magnitudes are of the same order in λ. Therefore, the effect of penguins could be large, resulting in $S_f \neq -\eta_f \sin 2\beta$ and $C_f \neq 0$. Such decay modes have been measured by *BABAR*, Belle, and LHCb. The world averages [24], $S_{J/\psi\pi^0} = -0.87 \pm 0.11$, $S_{J/\psi\rho^0} = -0.66^{+0.16}_{-0.12}$, $S_{D^+D^-} = -0.69 \pm 0.07$, and $S_{D^{*+}D^{*-}} = -0.71 \pm 0.09$ (where $\eta_f = +1$ for the $J/\psi\pi^0$ and D^+D^- modes, while $J/\psi\rho^0$ and $D^{*+}D^{*-}$ are mixtures of CP even and odd states), are consistent with $\sin 2\beta$ obtained from $B^0 \to$ charmonium K^0 decays, and the C_f's are consistent with zero, although the uncertainties are sizable.

The $b \to c\bar{u}d$ decays $B^0 \to \overline{D}^{0(*)}h^0$, with $\overline{D}^0 \to CP$ eigenstates and $\overline{D}^0 \to K^0_S\pi^+\pi^-$ with Dalitz plot analysis, have no penguin contributions, and provide theoretically clean $\sin 2\beta$ measurements. The average of joint analyses of *BABAR* and Belle data [104, 105] give $\sin 2\beta = 0.71 \pm 0.09$ [24].

12.3.2.2 *Penguin-dominated modes*

The $b \to s\bar{q}q$ penguin-dominated decays have the same CKM phase as the $b \to c\bar{c}s$ tree level decays, up to corrections suppressed by λ^2, since $V_{tb}^* V_{ts} = -V_{cb}^* V_{cs}[1 + \mathcal{O}(\lambda^2)]$. Therefore, decays such as $B^0 \to \phi K^0$ and $\eta' K^0$ provide $\sin 2\beta$ measurements in the SM. Any BSM contribution to the amplitude with a different weak phase would give rise to $S_f \neq -\eta_f \sin 2\beta$, and possibly $C_f \neq 0$. Therefore, the main interest in these modes is not simply to measure $\sin 2\beta$, but to search for new physics. Measurements of many other decay modes in this category, such as $B \to \pi^0 K^0_S$, $K^0_S K^0_S K^0_S$, *etc.*, have also been performed by *BABAR* and Belle. The results and their uncertainties are summarized in Fig. 13.3 and Table 13.1 of Ref. [96]. The comparison of CP violation measurements between tree-dominated and penguin-dominated modes in B^0_s decays provides similar sensitivity to new physics.

12.3.3 α / ϕ_2

Since α is the phase between $V_{tb}^* V_{td}$ and $V_{ub}^* V_{ud}$, only time-dependent CP asymmetries in decay modes dominated by $b \to u\bar{u}d$ transitions can directly measure $\sin 2\alpha$, in contrast to $\sin 2\beta$, where several different quark-level transitions can be used. Since $b \to d$ penguin amplitudes have a different CKM phase than $b \to u\bar{u}d$ tree amplitudes, and their magnitudes are of the same order in λ, the penguin contribution can be sizable, which makes the determination of α complicated. To date, α has been measured in $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ decay modes.

12.3.3.1 $B \to \pi\pi$

It is well-established from the data that there is a sizable contribution of $b \to d$ penguin amplitudes in $B \to \pi\pi$ decays. Thus, $S_{\pi^+\pi^-}$ in the time-dependent $B^0 \to \pi^+\pi^-$ analysis does not measure $\sin 2\alpha$, but

$$S_{\pi^+\pi^-} = \sqrt{1 - C^2_{\pi^+\pi^-}}\, \sin(2\alpha + 2\Delta\alpha)\,, \tag{12.21}$$

where $2\Delta\alpha$ is the phase difference between $e^{2i\gamma}\bar{A}_{\pi^+\pi^-}$ and $A_{\pi^+\pi^-}$. The value of $\Delta\alpha$, and hence α, can be extracted using the isospin relation among the amplitudes of $B^0 \to \pi^+\pi^-$, $B^0 \to \pi^0\pi^0$, and $B^+ \to \pi^+\pi^0$ decays [106],

$$\frac{1}{\sqrt{2}}\, A_{\pi^+\pi^-} + A_{\pi^0\pi^0} - A_{\pi^+\pi^0} = 0\,, \tag{12.22}$$

and a similar expression for the $\bar{A}_{\pi\pi}$'s. This method utilizes the fact that a pair of pions from $B \to \pi\pi$ decay must be in a zero angular momentum state, and, because of Bose statistics, they must have even isospin. Consequently, $\pi^\pm\pi^0$ is in a pure isospin-2 state, while the penguin amplitudes only contribute to the isospin-0 final state. The latter does not hold for the electroweak penguin amplitudes, but their effect is expected to be small. The isospin analysis uses the world averages of *BABAR*, Belle, and LHCb measurements, $S_{\pi^+\pi^-} = -0.666 \pm 0.029$, $C_{\pi^+\pi^-} = -0.311 \pm 0.030$, the decay widths of all three modes, and the direct CP asymmetry $C_{\pi^0\pi^0} = -0.23 \pm 0.18$ [24]. This analysis leads to 16 mirror solutions for $0 \leq \alpha < 2\pi$. Because of this, and due to the experimental uncertainties, some of these solutions are not well separated [97].

12.3.3.2 $B \to \rho\rho$

The decay $B^0 \to \rho^+\rho^-$ contains two vector mesons in the final state, and so in general is a mixture of CP-even and CP-odd components. At the current level of precision, it simplifies the analysis that the longitudinal polarization fractions in $B^+ \to \rho^+\rho^0$ and $B^0 \to \rho^+\rho^-$ decays were measured to be close to unity [107], which implies that the final states are almost purely CP-even. Furthermore, $\mathcal{B}(B^0 \to \rho^0\rho^0) = (0.95 \pm 0.15) \times 10^{-6}$ is much smaller than $\mathcal{B}(B^0 \to \rho^+\rho^-) = (28.0 \pm 1.7) \times 10^{-6}$ and $\mathcal{B}(B^+ \to \rho^+\rho^0) = (24,0 \pm 1.9) \times 10^{-6}$ [24], which implies that the effect of the penguin contributions is small. The isospin analysis using the world averages, $S_{\rho^+\rho^-} = -0.18 \pm 0.11$ and $C_{\rho^+\rho^-} = -0.01 \pm 0.08$ [24], together with the time-dependent CP asymmetry, $S_{\rho^0\rho^0} = 0.3 \pm 0.7$ and $C_{\rho^0\rho^0} = 0.2 \pm 0.9$ [108], and the above mentioned branching fractions and longitudinal polarization fractions, gives two solutions (with mirror solutions at $3\pi/2 - \alpha$) [97]. A possible small violation of Eq. (12.22) due to the finite width of the ρ [109] is so far neglected.

12.3.3.3 $B \to \rho\pi$

The final state in $B^0 \to \rho^+\pi^-$ decay is not a CP eigenstate, but this decay proceeds via the same quark-level diagrams as $B^0 \to \pi^+\pi^-$, and both B^0 and $\overline{B}^0$ can decay to $\rho^+\pi^-$, while the final state in $B^0 \to \rho^0\pi^0$ is a CP eigenstate. Consequently, mixing-induced CP violation can occur in B^0 and $\overline{B}^0$ decays to $\rho^\pm\pi^\mp$ and $\rho^0\pi^0$. The time-dependent Dalitz plot analysis of $B^0 \to \pi^+\pi^-\pi^0$ decays permits the extraction of α with a single discrete ambiguity, $\alpha \to \alpha + \pi$, since one knows the variation of the strong phases in the interference regions of the $\rho^+\pi^-$, $\rho^-\pi^+$, and $\rho^0\pi^0$ amplitudes in the Dalitz plot [110]. The combination of Belle [111] and *BABAR* [112] measurements gives only moderate constraints [97].

Combining the $B \to \pi\pi$, $\rho\pi$, and $\rho\rho$ decay modes [24, 97, 101], α is constrained as

$$\alpha = \left(84.1^{+3.7}_{-3.0}\right)^\circ\,. \tag{12.23}$$

Similar results can be found in Refs. [113, 114].

12.3.4 γ / ϕ_3

By virtue of Eq. (12.16), γ does not depend on CKM elements involving the top quark, so it can be measured in tree-level B decays. This is an important distinction from the measurements of α and β, and implies that measurements of γ are unlikely to be affected by physics beyond the SM.

12.3.4.1 $B_{(s)} \to D_{(s)}K^{(*)}$

The interference of $B^- \to D^0K^-$ ($b \to c\bar{u}s$) and $B^- \to \overline{D}^0K^-$ ($b \to u\bar{c}s$) transitions can be studied in final states accessible in both D^0 and $\overline{D}^0$ decays [95]. In principle, it is possible to extract the B and D decay amplitudes, the relative strong phases, and the weak phase γ from the data [97].

A practical complication is that the precision depends sensitively on the ratio of the interfering amplitudes

$$r_B = \left|A(B^- \to \overline{D}^0K^-)\big/A(B^- \to D^0K^-)\right|, \tag{12.24}$$

which is around 0.1. The original GLW method [115, 116] considers D decays to CP eigenstates, such as $B^\pm \to D^{(*)}_{CP}(\to \pi^+\pi^-)K^{(*)\pm}$. To alleviate the smallness of r_B and make the interfering amplitudes (which are products of the B and D decay amplitudes) comparable in magnitude, the ADS method [117] considers final states where Cabibbo-allowed $\overline{D}^0$ and doubly-Cabibbo-suppressed D^0 decays interfere. Measurements have been made by the B factories, CDF, and LHCb, using both methods [24]. The GLW method currently gives only a loose constraint on γ, while the ADS method provides a moderate constraint.

The BPGGSZ method [118, 119] utilizes the fact that both D^0 and $\overline{D}^0$ can have large branching fractions to CP self-conjugate

except for Open Access articles.

three- and four-body final states, such as $K^0_S\pi^+\pi^-$, and the analysis can be optimized by studying the Dalitz plot dependence of the interferences. The best present determination of γ comes from this method, dominated by 3-body D decay modes. Combining results in 3-body decay modes from Belle [120], *BABAR* [121], and the most precise LHCb [122] one, $\gamma = (68 \pm 4)^\circ$ is obtained [97]. The uncertainty is sensitive to the central value of the amplitude ratio r_B (and r^*_B for the D^*K mode), for which Belle found somewhat larger central values than *BABAR* and LHCb. The same values of $r_B^{(*)}$ enter the ADS analyses, and the data (including 4-body D decays [123]) can be combined to fit for $r_B^{(*)}$ and γ. The effect of $D^0 - \overline{D}^0$ mixing on γ is either below the present experimental accuracy or can be taken into account in the analysis [124] (even if $D^0 - \overline{D}^0$ mixing is due to CP-violating new physics [125]).

The amplitude ratio is much larger in the analogous $B^0_s \to D^\pm_s K^\mp$ decays, which allows a model-independent extraction of $\gamma - 2\beta_s$ [126] (here $\beta_s = \arg(-V_{ts}V^*_{tb}/V_{cs}V^*_{cb})$ is related to the phase of B_s mixing). Measurements by LHCb with $B^0_s \to D^\pm_s K^\mp$ [127] and $B^0_s \to D^\pm_s K^\mp\pi^+\pi^-$ [128] give $\gamma = (76 \pm 10)^\circ$ using a constraint on $2\beta_s$ (see Sec. 12.5).

Combining all the above measurements [24, 97, 101], γ is constrained as

$$\gamma = \left(66.4^{+2.7}_{-2.8}\right)^\circ . \tag{12.25}$$

Similar results can be found in Refs. [113, 114].

12.3.4.2 $B^0 \to D^{(*)\pm}\pi^\mp$

The interference of $b \to u$ and $b \to c$ transitions can be studied in $\overline{B}^0 \to D^{(*)+}\pi^-$ ($b \to c\bar{u}d$) and $\overline{B}^0 \to B^0 \to D^{(*)+}\pi^-$ ($\bar{b} \to \bar{u}cd$) decays and their CP conjugates, since both B^0 and $\overline{B}^0$ decay to $D^{(*)\pm}\pi^\mp$ (or $D^\pm\rho^\mp$, *etc.*). Since there are only tree and no penguin contributions to these decays, in principle, it is possible to extract from the four time-dependent rates the magnitudes of the two hadronic amplitudes, their relative strong phase, and the weak phase between the two decay paths, which is $2\beta + \gamma$.

A complication is that the ratio of the interfering amplitudes is very small, $r_{D\pi} = A(B^0 \to D^+\pi^-)/A(\overline{B}^0 \to D^+\pi^-) = \mathcal{O}(0.01)$ (and similarly for $r_{D^*\pi}$ and $r_{D\rho}$), and therefore it has not been possible to measure it. To obtain $2\beta + \gamma$, $SU(3)$ flavor symmetry and dynamical assumptions have been used to relate $A(\overline{B}^0 \to D^-\pi^+)$ to $A(\overline{B}^0 \to D^-_s\pi^+)$, so this measurement is not model independent at present. Combining the $D^\pm\pi^\mp$, $D^{*\pm}\pi^\mp$ and $D^\pm\rho^\mp$ measurements [129] gives $\sin(2\beta + \gamma) > 0.68$ at 68% CL [113], consistent with the previously discussed results for β and γ.

12.4 Global fit in the Standard Model

Using the independently measured CKM elements mentioned in the previous sections, the unitarity of the CKM matrix can be checked. We obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9984 \pm 0.0007$ (1st row), $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 0.991 \pm 0.010$ (2nd row), $|V_{ud}|^2 + |V_{cd}|^2 + |V_{td}|^2 = 0.9986 \pm 0.0011$ (1st column), and $|V_{us}|^2 + |V_{cs}|^2 + |V_{ts}|^2 = 0.991 \pm 0.010$ (2nd column), respectively. There is currently a $2.3\,\sigma$ tension with unitarity in the 1st row. The uncertainties in the second row and column are dominated by that of $|V_{cs}|$. (Less precise tests of 1st and 2nd row unitarity can be obtained from the measurement of $\sum_{u,c,d,s,b} |V_{ij}|^2$ in Sec. 12.2.4, combined with either the LEP–LHC average of $\mathcal{B}(W \to cq)/\mathcal{B}(W \to qq') = 0.490 \pm 0.018$ [130] or with the 1st row unitarity check above.) These provide strong tests of the unitarity of the CKM matrix. With the significantly improved direct determination of $|V_{tb}|$, the unitarity checks for the third row and column have also become fairly precise, leaving decreasing room for mixing with other states. The sum of the three angles of the unitarity triangle, $\alpha + \beta + \gamma = \left(173^{+5}_{-4}\right)^\circ$, is also consistent with the SM expectation.

The CKM matrix elements can be most precisely determined using a global fit to all available measurements and imposing the SM constraints (*i.e.*, three generation unitarity). The fit must also use theory predictions for hadronic matrix elements, which sometimes have significant uncertainties. There are several approaches to combining the experimental data. CKMfitter [6, 113] and Ref. [131] (which develops [132, 133] further) use frequentist statistics, while UTfit [114, 134] uses a Bayesian approach. These approaches provide similar results.

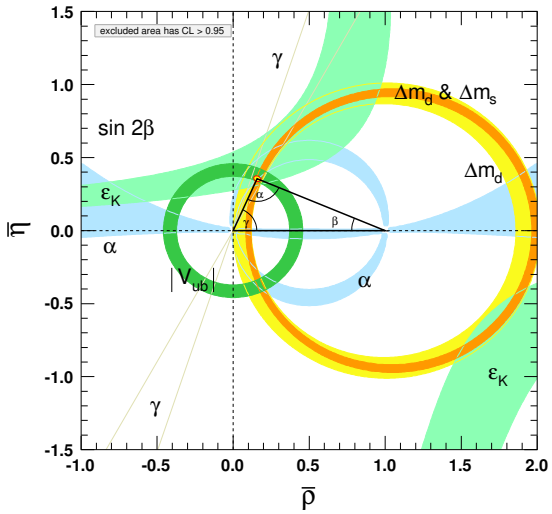

Figure 12.2: Constraints on the $\bar{\rho}, \bar{\eta}$ plane. The shaded areas have 95% CL.

The constraints implied by the unitarity of the three generation CKM matrix significantly reduce the allowed range of some of the CKM elements. The fit for the Wolfenstein parameters defined in Eq. (12.4) gives

$$\lambda = 0.22517 \pm 0.00068\,, \qquad A = 0.826^{+0.017}_{-0.015}\,,$$
$$\bar{\rho} = 0.1576^{+0.0092}_{-0.0091}\,, \qquad \bar{\eta} = 0.3556^{+0.0071}_{-0.0069}\,. \tag{12.26}$$

These values are obtained using the method of Refs. [6, 113]. The prescription of Refs. [114, 134] gives $\lambda = 0.22519 \pm 0.00068$, $A = 0.820 \pm 0.011$, $\bar{\rho} = 0.1561 \pm 0.0088$, and $\bar{\eta} = 0.3587 \pm 0.0069$ [135]; these results are very close to one another. The fit results for the magnitudes of all nine CKM elements are

$$\left|V_{\rm CKM}\right| = \begin{pmatrix} 0.97431 \pm 0.00016 & 0.22517 \pm 0.00068 & 0.003763^{+0.000088}_{-0.000083} \\ 0.22503 \pm 0.00068 & 0.97345 \pm 0.00016 & 0.04189^{+0.00081}_{-0.00069} \\ 0.00863^{+0.00019}_{-0.00017} & 0.04117^{+0.00079}_{-0.00068} & 0.999115^{+0.000029}_{-0.000034} \end{pmatrix}, \tag{12.27}$$

and the Jarlskog invariant is $J = \left(3.16^{+0.13}_{-0.11}\right) \times 10^{-5}$. The parameters in Eq. (12.3) are

$$\sin\theta_{12} = 0.22517 \pm 0.00068\,, \quad \sin\theta_{13} = 0.003763^{+0.000088}_{-0.000083}\,,$$
$$\sin\theta_{23} = 0.04189^{+0.00081}_{-0.00069}\,, \qquad \delta = 1.154 \pm 0.025\,. \tag{12.28}$$

Fig. 12.2 illustrates the constraints on the $\bar{\rho}, \bar{\eta}$ plane from various measurements, and the global fit result. The shaded 95% CL regions all overlap consistently around the global fit region.

If one uses only tree-level inputs (magnitudes of CKM elements not coupling to the top quark and the angle γ), the resulting fit is almost identical for λ in Eq. (12.26), while the other parameters' central values can change by about a sigma and their uncertainties double, yielding $\lambda = 0.22528 \pm 0.00069$, $A = 0.802 \pm 0.026$, $\bar{\rho} = 0.166^{+0.021}_{-0.020}$, and $\bar{\eta} = 0.379^{+0.022}_{-0.021}$. This illustrates how the constraints can be less tight in the presence of BSM physics.

12.5 Implications beyond the SM

The effects in B, B_s, K, and D decays and mixings due to high-scale physics (W, Z, t, H in the SM, and unknown heavier particles) can be parameterized by operators composed of SM fields, obeying the $SU(3) \times SU(2) \times U(1)$ gauge symmetry. Flavor-changing neutral currents, suppressed in the SM, are especially sensitive to beyond SM contributions. Processes studied in great

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

detail, both experimentally and theoretically, include neutral meson mixings, $B_{(s)} \to X\gamma$, $X\ell^+\ell^-$, $\ell^+\ell^-$, $K \to \pi\nu\bar{\nu}$, etc. The BSM contributions to these operators are suppressed by powers of the scale at which they are generated. Already at lowest order, there are many dimension-6 operators, and the observable effects of BSM interactions are encoded in their coefficients. In the SM, these coefficients are determined by just the four CKM parameters, and the W, Z, and quark masses. For example, Δm_d, $\Gamma(B \to \rho\gamma)$, $\Gamma(B \to \pi\ell^+\ell^-)$, and $\Gamma(B \to \ell^+\ell^-)$ are all proportional to $|V_{td}V_{tb}|^2$ in the SM, however, they may receive unrelated BSM contributions. These BSM contributions may or may not obey the SM relations. (For example, the flavor sector of the MSSM contains 69 CP-conserving parameters and 41 CP-violating phases, *i.e.*, 40 new ones [136]). Thus, similar to the measurements of $\sin 2\beta$ in tree- and loop-dominated decay modes, overconstraining measurements of the magnitudes and phases of flavor-changing neutral-current amplitudes gives good sensitivity to BSM.

To illustrate the level of suppression required for BSM contributions, consider a class of models in which the unitarity of the CKM matrix is maintained, and the dominant BSM effects modify the neutral meson mixing amplitudes [137] by $(z_{ij}/\Lambda^2)(\bar{q}_i\gamma^\mu P_L q_j)^2$, where z_{ij} is an unknown coefficient and Λ is the scale suppressing this BSM contribution (see, [138, 139]). It is only known since the first measurements of γ and α that the SM gives the leading contribution to $B^0 - \overline{B}^0$ mixing [6,140]. Nevertheless, new physics with a generic weak phase may still contribute to neutral meson mixings at a significant fraction of the SM [134, 141, 142]. The existing data imply that $\Lambda/|z_{ij}|^{1/2}$ has to exceed about 10^4 TeV for $K^0 - \overline{K}^0$ mixing, 10^3 TeV for $D^0 - \overline{D}^0$ mixing, 500 TeV for $B^0 - \overline{B}^0$ mixing, and 100 TeV for $B_s^0 - \overline{B}_s^0$ mixing [134, 139]. (Some other operators are even better constrained [134].) The constraints are the strongest in the kaon sector, because the CKM suppression is the most severe. Thus, if there is new physics at the TeV scale, $|z_{ij}| \ll 1$ is required. Even if $|z_{ij}|$ are suppressed by a loop factor and $|V_{ti}^* V_{tj}|^2$ (in the down quark sector), similar to the SM, one expects percent-level effects, which may be observable in forthcoming flavor physics experiments. To constrain such extensions of the SM, many measurements irrelevant for the SM-CKM fit, such as the CP asymmetry in semileptonic $B_{d,s}^0$ decays, $A_{\rm SL}^{d,s}$, are important [143]. The current world averages [24] are consistent with the SM, with experimental uncertainties far greater than those of the theory predictions.

There are many key measurements sensitive to BSM physics, which do not constrain the unitarity triangle in Fig. 12.1. For example, a key quantity in the B_s system is $\beta_s = \arg(-V_{ts}V_{tb}^*/V_{cs}V_{cb}^*)$, which is the small, λ^2-suppressed, angle of a "squashed" unitarity triangle, obtained by taking the scalar product of the second and third columns of the CKM matrix. This angle can be measured via time-dependent CP violation in $B_s^0 \to J/\psi\,\phi$, similar to β in $B^0 \to J/\psi K^0$. Since the $J/\psi\,\phi$ final state is not a CP eigenstate, an angular analysis of the decay products is needed to separate the CP-even and CP-odd components, which give opposite asymmetries. In the SM, the asymmetry for the CP-even part is $2\beta_s$, when one neglects subdominant amplitudes with a weak phase V_{ub}. (Sometimes the notation $\phi_s = -2\beta_s$ plus a possible BSM contribution to the B_s mixing phase is used.) Testing if the data agree with the SM prediction, $2\beta_s = 0.03768^{+0.00076}_{-0.00075}$ [113], is another sensitive probe of the SM. The current world average, dominated by LHC measurements including the $B_s \to J/\psi\,K^+K^-$ and $J/\psi\,\pi^+\pi^-$ decay modes, is $2\beta_s = 0.053 \pm 0.013$ [72]. Since the uncertainty is much larger than that in the SM, a lot will be learned from more precise future measurements. Searches for CP violation in the charm sector, in particular in $D^0 - \overline{D}^0$ mixing, provide complementary sensitivity to BSM.

In the kaon sector, the CP-violating observables, ϵ and ϵ', are tiny, so models in which all sources of CP violation are small were viable before the B-factory measurements. Since the measurement of $\sin 2\beta$, we know that CP violation can be an $\mathcal{O}(1)$ effect, and only flavor mixing is suppressed between the three quark generations. Thus, many models with spontaneous CP violation were excluded. In the kaon sector, clean tests of the SM can come from measurements of $K^+ \to \pi^+\nu\bar{\nu}$ [79] and $K_L^0 \to \pi^0\nu\bar{\nu}$ [144] These loop-induced rare decays are sensitive to BSM, and will allow precise tests [145] of the CKM paradigm, independent of B decays.

The CKM elements are fundamental parameters, so they should be measured as precisely as possible. The overconstraining measurements of CP asymmetries, mixing, semileptonic, and rare decays severely constrain the magnitudes and phases of possible BSM contributions to flavor-changing interactions. If new particles are observed at the LHC, it will be important to explore their flavor parameters as precisely as possible to understand the underlying physics.

13. *CP* Violation in the Quark Sector

Revised August 2025 by T. Gershon (Warwick U.) and Y. Nir (Weizmann Inst.).

The *CP* transformation combines charge conjugation C with parity P. Under C, particles and antiparticles are interchanged, by conjugating all internal quantum numbers, *e.g.*, $Q \to -Q$ for electromagnetic charge. Under P, the handedness of space is reversed, $\vec{x} \to -\vec{x}$. Thus, for example, a left-handed electron e_L^- is transformed under *CP* into a right-handed positron, e_R^+.

If *CP* were an exact symmetry, the laws of nature would be the same for matter and for antimatter. We observe that most phenomena are C- and P-symmetric, and therefore, also *CP*-symmetric. In particular, these symmetries are respected by the electromagnetic and strong interactions. The weak interactions, on the other hand, violate C and P in the strongest possible way. For example, the W bosons couple to left-handed electrons, e_L^-, and to their *CP*-conjugate right-handed positrons, e_R^+, but to neither their C-conjugate left-handed positrons, e_L^+, nor their P-conjugate right-handed electrons, e_R^-. While weak interactions violate C and P separately, *CP* is still preserved in most weak interaction processes. The *CP* symmetry is, however, violated in certain processes involving interference effects, as discovered in neutral K decays in 1964 [1], and established later in B (2001) and D (2019) decays. For example, as discovered in 1967, a K_L meson decays more often to $\pi^- e^+ \nu_e$ than to $\pi^+ e^- \overline{\nu}_e$, thus allowing electrons and positrons to be unambiguously distinguished, but the decay-rate asymmetry is only at the 0.003 level. The *CP*-violating effects observed in the B system are larger: the parameter describing the *CP* asymmetry in the decay time distribution of $B^0/\overline{B}^0$ meson transitions to *CP* eigenstates like $J/\psi K_S$ is about 0.7 [2,3]. These effects are related to K^0–$\overline{K}^0$ and B^0–$\overline{B}^0$ mixing, but *CP* violation arising solely from decay amplitudes has also been observed, first in $K \to \pi\pi$ decays [4–6], and subsequently in B^0 [7,8], B^+ [9–11], B_s^0 [12] and Λ_b^0 [13] decays. *CP* violation arising solely from decay amplitudes has also been observed in charm decays [14]. All of these observed *CP* asymmetries are within the range of Standard Model predictions. Given that neutrino masses and lepton mixing have been established, it is expected that *CP* is violated also in the lepton sector [15]. Discovering *CP* violation in the lepton sector is one of the main goals of current and near-future experiments. *CP* violation has not yet been observed in processes involving the top quark, nor in flavor-conserving processes such as electric dipole moments; for these, any significant observation would be a clear indication of physics beyond the Standard Model.

In addition to parity and to continuous Lorentz transformations, there is one other spacetime operation that could be a symmetry of the interactions: time reversal T, $t \to -t$. Violations of T symmetry have been observed in neutral K decays [16]. More recently, T violation has been observed between states that are not *CP*-conjugate [17], exploiting the fact that for neutral B mesons both flavor tagging and *CP* tagging can be used [18]. Moreover, T violation is expected as a corollary of *CP* violation if the combined *CPT* transformation is a fundamental symmetry of nature [19]. All observations indicate that *CPT* is indeed a symmetry of nature [16]. Furthermore, one cannot build a locally Lorentz-invariant quantum field theory with a Hermitian Hamiltonian that violates *CPT*. (At several points in our discussion, we avoid assumptions about *CPT*, in order to identify cases where evidence for *CP* violation relies on assumptions about *CPT*.)

Within the Standard Model, *CP* symmetry is broken by complex phases in the Yukawa couplings (that is, the couplings of the Higgs scalar to quarks). When all transformations to remove unphysical phases in this model are exhausted, a single *CP*-violating parameter remains [20]. In the basis of mass eigenstates, this single phase appears in the 3×3 unitary matrix that gives the W-boson couplings to an up-type antiquark and a down-type quark. (If the Standard Model is supplemented with Majorana mass terms for the neutrinos, the analogous mixing matrix for leptons has three *CP*-violating phases.) The beautifully consistent and economical Standard-Model description of *CP* violation in terms of Yukawa couplings, known as the Kobayashi-Maskawa (KM) mechanism [20], agrees with all measurements to date. Furthermore, one can fit the data allowing contributions from beyond the Standard Model (referred to subsequently as new physics) to loop processes to compete with, or even dominate over, the Standard Model amplitudes [21,22]. Such an analysis provides model-independent proof that the KM phase is different from zero, and that the matrix of three-generation quark mixing is the dominant source of *CP* violation in the quark sector.

The current level of experimental accuracy and the theoretical uncertainties involved in the interpretation of the various observations leave room, however, for additional subdominant sources of *CP* violation from new physics. Indeed, almost all extensions of the Standard Model imply that there are such additional sources. Moreover, *CP* violation is a necessary condition for baryogenesis, the process of dynamically generating the matter-antimatter asymmetry of the Universe [23]. Despite the phenomenological success of the KM mechanism, it fails (by several orders of magnitude) to accommodate the observed asymmetry [24]. This discrepancy strongly suggests that nature provides additional sources of *CP* violation beyond the KM mechanism. The evidence for neutrino masses implies that *CP* can be violated also in the lepton sector. This situation makes leptogenesis [25,26], a scenario where *CP*-violating phases in the Yukawa couplings of the neutrinos play a crucial role in the generation of the baryon asymmetry, a very attractive possibility. The expectation of new sources motivates the large ongoing experimental effort to find deviations from the predictions of the KM mechanism.

CP violation can be experimentally searched for in a variety of processes, such as hadron decays, electric dipole moments of neutrons, electrons and nuclei, and neutrino oscillations. Hadron decays via the weak interaction probe flavor-changing *CP* violation. The search for electric dipole moments may find (or constrain) sources of *CP* violation that, unlike the KM phase, are not related to flavor-changing couplings. Following the discovery of the Higgs boson [27,28], searches for *CP* violation in the Higgs sector are becoming feasible. Future searches for *CP* violation in neutrino oscillations might provide further input on leptogenesis.

The present measurements of *CP* asymmetries provide some of the strongest constraints on the weak couplings of quarks. Future measurements of *CP* violation in K, D, B, and B_s^0 meson decays will provide additional constraints on the flavor parameters of the Standard Model, and can probe new physics. In this review, we give the formalism and basic physics motivations that are relevant to present and near future measurements of *CP* violation in the quark sector.

13.1 Formalism

The phenomenology of *CP* violation for neutral flavored mesons is particularly interesting, since many of the observables can be cleanly interpreted. Although the phenomenology is superficially different for K^0, D^0, B^0, and B_s^0 decays, this is primarily because each of these systems is governed by a different balance between decay rates, oscillations, and lifetime splitting. However, the general considerations presented in this section are identical for all flavored neutral pseudoscalar mesons. The phenomenology of *CP* violation for neutral mesons that do not carry flavor quantum numbers (such as the $\eta^{(\prime)}$ state) is quite different: such states are their own antiparticles and have definite *CP* eigenvalues, so the signature of *CP* violation is simply the decay to a final state with the opposite *CP*. Such decays are mediated by the electromagnetic or (OZI-suppressed [29–31]) strong interaction, where *CP* violation is not expected and has not yet been observed. In the remainder of this review, we restrict ourselves to considerations of weakly decaying hadrons.

In this section, we present a general formalism for, and classification of, *CP* violation in the decay of a weakly decaying hadron, denoted M. We pay particular attention to the case that M is a K^0, D^0, B^0, or B_s^0 meson. Subsequent sections describe the *CP*-violating phenomenology, approximations, and alternative formalisms that are specific to each system.

13.1.1 *Charged- and neutral-hadron decays*

We define decay amplitudes of M (which could be charged or neutral) and its *CP* conjugate $\overline{M}$ to a multi-particle final state f

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

and its CP conjugate $\overline{f}$ as

$$A_f = \langle f\,|\mathcal{H}|\,M\rangle\ , \quad \overline{A}_f = \langle f\,|\mathcal{H}|\,\overline{M}\rangle\ , \tag{13.1a}$$

$$A_{\overline{f}} = \langle \overline{f}\,|\mathcal{H}|\,M\rangle\ , \quad \overline{A}_{\overline{f}} = \langle \overline{f}\,|\mathcal{H}|\,\overline{M}\rangle\ , \tag{13.1b}$$

where $\mathcal{H}$ is the Hamiltonian governing weak interactions. The action of CP on these states introduces phases ξ_M and ξ_f that depend on their flavor content, according to

$$CP|M\rangle = e^{+i\xi_M}\,|\overline{M}\rangle\ , \quad CP|f\rangle = e^{+i\xi_f}\,|\overline{f}\rangle\ , \tag{13.2a}$$

$$CP|\overline{M}\rangle = e^{-i\xi_M}\,|M\rangle\ , \quad CP|\overline{f}\rangle = e^{-i\xi_f}\,|f\rangle\ , \tag{13.2b}$$

so that $(CP)^2 = 1$. The phases ξ_M and ξ_f are arbitrary and unobservable because of the flavor symmetry of the strong interaction. If CP is conserved by the dynamics, $[CP, \mathcal{H}] = 0$, then A_f and $\overline{A}_{\overline{f}}$ have the same magnitude and an arbitrary unphysical relative phase

$$\overline{A}_{\overline{f}} = e^{i(\xi_f - \xi_M)}\,A_f\ . \tag{13.3}$$

13.1.2 *Neutral-meson mixing*

A state that is initially a superposition of M^0 and $\overline{M}^0$, say

$$|\psi(0)\rangle = a(0)|M^0\rangle + b(0)|\overline{M}^0\rangle\ , \tag{13.4}$$

will evolve in time acquiring components that describe all possible decay final states $\{f_1, f_2, \ldots\}$, that is,

$$|\psi(t)\rangle = a(t)|M^0\rangle + b(t)|\overline{M}^0\rangle + c_1(t)|f_1\rangle + c_2(t)|f_2\rangle + \cdots\ . \tag{13.5}$$

If we are interested in computing only the values of $a(t)$ and $b(t)$ (and not the values of all $c_i(t)$), and if the times t under study are much larger than the typical strong interaction scale, then we can use a much simplified formalism [32]. The simplified time evolution is determined by a 2×2 effective Hamiltonian $\mathbf{H}$ that is not Hermitian, since otherwise the mesons would only oscillate and not decay. Any complex matrix, such as $\mathbf{H}$, can be written in terms of Hermitian matrices $\mathbf{M}$ and $\mathbf{\Gamma}$ as

$$\mathbf{H} = \mathbf{M} - \frac{i}{2}\,\mathbf{\Gamma}\ . \tag{13.6}$$

$\mathbf{M}$ and $\mathbf{\Gamma}$ are associated with $(M^0, \overline{M}^0) \leftrightarrow (M^0, \overline{M}^0)$ transitions via off-shell (dispersive), and on-shell (absorptive) intermediate states, respectively. Diagonal elements of $\mathbf{M}$ and $\mathbf{\Gamma}$ are associated with the flavor-conserving transitions $M^0 \to M^0$ and $\overline{M}^0 \to \overline{M}^0$, while off-diagonal elements are associated with flavor-changing transitions $M^0 \leftrightarrow \overline{M}^0$.

The eigenvectors of $\mathbf{H}$ have well-defined masses and decay widths. To specify the components of the strong interaction eigenstates, M^0 and $\overline{M}^0$, in the light (M_L) and heavy (M_H) mass eigenstates, we introduce three complex parameters: p, q, and, for the case that both CP and CPT are violated in mixing, z. Then

$$|M_L\rangle \propto p\sqrt{1-z}\,|M^0\rangle + q\sqrt{1+z}\,|\overline{M}^0\rangle\ , \tag{13.7a}$$

$$|M_H\rangle \propto p\sqrt{1+z}\,|M^0\rangle - q\sqrt{1-z}\,|\overline{M}^0\rangle\ , \tag{13.7b}$$

with the normalization $|q|^2 + |p|^2 = 1$ when $z = 0$. (Another possible choice of labeling, which is in standard usage for K mesons, defines the mass eigenstates according to their lifetimes: K_S for the short-lived and K_L for the long-lived state. The K_L is experimentally found to be the heavier state. Yet another choice is often used for the D mesons [33]: the eigenstates are labeled according to their dominant CP content.)

The real and imaginary parts of the eigenvalues $\omega_{L,H}$ corresponding to $|M_{L,H}\rangle$ represent their masses and decay widths, respectively. The mass and width splittings are

$$\Delta m \equiv m_H - m_L = \mathcal{R}e(\omega_H - \omega_L)\ , \tag{13.8a}$$

$$\Delta\Gamma \equiv \Gamma_H - \Gamma_L = -2\,\mathcal{I}m(\omega_H - \omega_L)\ . \tag{13.8b}$$

Note that here Δm is positive by definition, while the sign of $\Delta\Gamma$ must be experimentally determined. The sign of $\Delta\Gamma$ has not yet been established for B^0 mesons, while $\Delta\Gamma < 0$ is established for K and B_s^0 mesons. The Standard Model predicts $\Gamma_L > \Gamma_H$ for $B^0_{(s)}$ mesons; for this reason, $\Delta\Gamma = \Gamma_L - \Gamma_H$, which is still a signed quantity, is often used in the $B^0_{(s)}$ literature and is the convention used in the PDG experimental summaries.

Solving the eigenvalue problem for $\mathbf{H}$ yields

$$\left(\frac{q}{p}\right)^2 = \frac{\mathbf{M}_{12}^* - (i/2)\mathbf{\Gamma}_{12}^*}{\mathbf{M}_{12} - (i/2)\mathbf{\Gamma}_{12}} \tag{13.9}$$

and

$$z \equiv \frac{\delta m - (i/2)\delta\Gamma}{\Delta m - (i/2)\Delta\Gamma}\ , \tag{13.10}$$

where

$$\delta m \equiv \mathbf{M}_{11} - \mathbf{M}_{22}\ , \quad \delta\Gamma \equiv \mathbf{\Gamma}_{11} - \mathbf{\Gamma}_{22} \tag{13.11}$$

are the differences in effective mass and decay-rate expectation values for the strong interaction states M^0 and $\overline{M}^0$.

If either CP or CPT is a symmetry of $\mathbf{H}$ (independently of whether T is conserved or violated), then the values of δm and $\delta\Gamma$ are both zero, and hence $z = 0$. We also find that

$$\omega_H - \omega_L = 2\sqrt{\left(\mathbf{M}_{12} - \frac{i}{2}\mathbf{\Gamma}_{12}\right)\left(\mathbf{M}_{12}^* - \frac{i}{2}\mathbf{\Gamma}_{12}^*\right)}\ . \tag{13.12}$$

If either CP or T is a symmetry of $\mathbf{H}$ (independently of whether CPT is conserved or violated), then $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is real, leading to

$$\left(\frac{q}{p}\right)^2 = e^{2i\xi_M} \quad \Rightarrow \quad \left|\frac{q}{p}\right| = 1\ , \tag{13.13}$$

where ξ_M is the arbitrary unphysical phase introduced in Eq. (13.2). If, and only if, CP is a symmetry of $\mathbf{H}$ (independently of CPT and T), then both of the above conditions hold, with the result that the mass eigenstates are orthogonal

$$\langle M_H|M_L\rangle = |p|^2 - |q|^2 = 0\ . \tag{13.14}$$

13.1.3 *CP-violating observables*

All CP-violating observables in M and $\overline{M}$ decays to final states f and $\overline{f}$ can be expressed in terms of phase-convention-independent combinations of A_f, $\overline{A}_f$, $A_{\overline{f}}$, and $\overline{A}_{\overline{f}}$, together with, for neutral meson decays only, q/p. CP violation in charged meson and all baryon decays depends only on the combination $|\overline{A}_{\overline{f}}/A_f|$, while CP violation in flavored neutral meson decays is enriched by $M^0 \leftrightarrow \overline{M}^0$ oscillations, and depends, additionally, on $|q/p|$ and on $\lambda_f \equiv (q/p)(\overline{A}_f/A_f)$.

The decay rates of the two neutral kaon mass eigenstates, K_S and K_L, are different enough ($\Gamma_S/\Gamma_L \sim 500$) that one can, in most cases, actually study their decays independently. For D^0, B^0, and B_s^0 mesons, however, values of $\Delta\Gamma/\Gamma$ (where $\Gamma \equiv (\Gamma_H + \Gamma_L)/2$) are relatively small, and so both mass eigenstates must be considered in their evolution. We denote the state of an initially pure $|M^0\rangle$ or $|\overline{M}^0\rangle$ after an elapsed proper time t as $|M^0_{\rm phys}(t)\rangle$ or $|\overline{M}^0_{\rm phys}(t)\rangle$, respectively. Using the effective Hamiltonian approximation, but not assuming CPT to be a good symmetry, we obtain

$$|M^0_{\rm phys}(t)\rangle = (g_+(t) + z\,g_-(t))\,|M^0\rangle - \sqrt{1-z^2}\,\frac{q}{p}\,g_-(t)|\overline{M}^0\rangle\ , \tag{13.15a}$$

$$|\overline{M}^0_{\rm phys}(t)\rangle = (g_+(t) - z\,g_-(t))\,|\overline{M}^0\rangle - \sqrt{1-z^2}\,\frac{p}{q}\,g_-(t)|M^0\rangle\ , \tag{13.15b}$$

where

$$g_\pm(t) \equiv \frac{1}{2}\left[\exp\left(-im_H t - \frac{1}{2}\Gamma_H t\right) \pm \exp\left(-im_L t - \frac{1}{2}\Gamma_L t\right)\right] \tag{13.16}$$

and $z = 0$ if either CPT or CP is conserved.

Defining $x \equiv \Delta m/\Gamma$ and $y \equiv \Delta\Gamma/(2\Gamma)$, and assuming $z = 0$, one obtains the following time-dependent decay rates:

$$\begin{aligned}\frac{d\Gamma\left[M^0_{\rm phys}(t) \to f\right]/dt}{e^{-\Gamma t}\mathcal{N}_f} &= \left(|A_f|^2 + |(q/p)\overline{A}_f|^2\right)\cosh(y\Gamma t) \\ &+ \left(|A_f|^2 - |(q/p)\overline{A}_f|^2\right)\cos(x\Gamma t) \\ &+ 2\,\mathcal{R}e((q/p)A_f^*\overline{A}_f)\sinh(y\Gamma t) \\ &- 2\,\mathcal{I}m((q/p)A_f^*\overline{A}_f)\sin(x\Gamma t)\ ,\end{aligned} \tag{13.17a}$$

$$\begin{aligned}\frac{d\Gamma\left[\overline{M}^0_{\rm phys}(t) \to f\right]/dt}{e^{-\Gamma t}\mathcal{N}_f} &= \left(|(p/q)A_f|^2 + |\overline{A}_f|^2\right)\cosh(y\Gamma t) \\ &- \left(|(p/q)A_f|^2 - |\overline{A}_f|^2\right)\cos(x\Gamma t) \\ &+ 2\,\mathcal{R}e((p/q)A_f\overline{A}_f^*)\sinh(y\Gamma t) \\ &- 2\,\mathcal{I}m((p/q)A_f\overline{A}_f^*)\sin(x\Gamma t)\ ,\end{aligned} \tag{13.17b}$$

where $\mathcal{N}_f$ is a common, time-independent, normalization factor that can be determined bearing in mind that the range of t is $0 < t < \infty$. Decay rates to the *CP*-conjugate final state $\overline{f}$ are obtained analogously, with $\mathcal{N}_f = \mathcal{N}_{\overline{f}}$ and the substitutions $A_f \to A_{\overline{f}}$ and $\overline{A}_f \to \overline{A}_{\overline{f}}$ in Eqs. (13.17a) and (13.17b). Terms proportional to $|A_f|^2$ or $|\overline{A}_f|^2$ are associated with decays that occur without any net $M^0 \leftrightarrow \overline{M}^0$ oscillation, while terms proportional to $|(q/p)\overline{A}_f|^2$ or $|(p/q)A_f|^2$ are associated with decays following a net oscillation. The $\sinh(y\Gamma t)$ and $\sin(x\Gamma t)$ terms of Eqs. (13.17a) and (13.17b) are associated with the interference between these two cases. Note that, in multi-body decays such as $D^0 \to K_S\pi^+\pi^-$ or $B^0 \to \pi^+\pi^-\pi^+\pi^-$, amplitudes are functions of variables that describe the phase-space of the final state. Interference may be present in some regions but not others, and is strongly influenced by resonant substructure.

When neutral pseudoscalar mesons are produced coherently in pairs from the decay of a vector resonance, $V \to M^0\overline{M}^0$ (for example, $\Upsilon(4S) \to B^0\overline{B}^0$, $\psi(3770) \to D^0\overline{D}^0$ or $\phi \to K^0\overline{K}^0$), the time-dependence of their subsequent decays to final states f_1 and f_2 has a similar form to Eqs. (13.17a) and (13.17b):

$$\begin{aligned}\frac{d\Gamma\left[V_{\rm phys}(t_1,t_2) \to f_1 f_2\right]/d(\Delta t)}{e^{-\Gamma|\Delta t|}\mathcal{N}_{f_1 f_2}} &= \left(|a_+|^2 + |a_-|^2\right)\cosh(y\Gamma\Delta t) \\ &+ \left(|a_+|^2 - |a_-|^2\right)\cos(x\Gamma\Delta t) \\ &- 2\,\mathcal{R}e(a_+^* a_-)\sinh(y\Gamma\Delta t) \\ &+ 2\,\mathcal{I}m(a_+^* a_-)\sin(x\Gamma\Delta t)\ ,\end{aligned} \tag{13.18}$$

where $\Delta t \equiv t_2 - t_1$ is the difference in the production times, t_1 and t_2, of f_1 and f_2, respectively, and the dependence on the average decay time and on decay angles has been integrated out. The normalization factor $\mathcal{N}_{f_1 f_2}$ can be evaluated, noting that the range of Δt is $-\infty < \Delta t < \infty$. The coefficients in Eq. (13.18) are determined by the amplitudes for no net oscillation from $t_1 \to t_2$, $\overline{A}_{f_1}A_{f_2}$, and $A_{f_1}\overline{A}_{f_2}$, and for a net oscillation, $(q/p)\overline{A}_{f_1}\overline{A}_{f_2}$ and $(p/q)A_{f_1}A_{f_2}$, via

$$a_+ \equiv \overline{A}_{f_1}A_{f_2} - A_{f_1}\overline{A}_{f_2}\ , \tag{13.19a}$$

$$\begin{aligned}a_- \equiv &-\sqrt{1-z^2}\left(\frac{q}{p}\overline{A}_{f_1}\overline{A}_{f_2} - \frac{p}{q}A_{f_1}A_{f_2}\right) \\ &+ z\left(\overline{A}_{f_1}A_{f_2} + A_{f_1}\overline{A}_{f_2}\right)\ .\end{aligned} \tag{13.19b}$$

Assuming *CPT* conservation, $z = 0$, and identifying $\Delta t \to t$ and $f_2 \to f$, we find that Eqs. (13.18) and (13.19) reduce to Eq. (13.17a) with $A_{f_1} = 0$, $\overline{A}_{f_1} = 1$, or to Eq. (13.17b) with $\overline{A}_{f_1} = 0$, $A_{f_1} = 1$. Indeed, this plays an important role in experiments that exploit the coherence of $V \to M^0\overline{M}^0$ production. Final states f_1 with $A_{f_1} = 0$ or $\overline{A}_{f_1} = 0$ are called tagging states, because they identify the decaying pseudoscalar meson as, respectively, $\overline{M}^0$ or M^0. Before one of M^0 or $\overline{M}^0$ decays, they evolve in phase, so that there is always one M^0 and one $\overline{M}^0$ present. A tagging decay of one meson sets the clock for the time evolution of the other: it starts at t_1 as purely M^0 or $\overline{M}^0$, with time evolution that depends only on $t_2 - t_1$.

When f_1 is a state that both M^0 and $\overline{M}^0$ can decay into, then Eq. (13.18) contains interference terms proportional to $A_{f_1}\overline{A}_{f_1} \neq 0$ that are not present in Eqs. (13.17a) and (13.17b). Even when f_1 is dominantly produced by M^0 decays rather than $\overline{M}^0$ decays, or vice versa, $A_{f_1}\overline{A}_{f_1}$ can be non-zero owing to doubly-CKM-suppressed decays (with amplitudes suppressed by at least two powers of λ relative to the dominant amplitude, in the language of Section 13.3), and these terms should be considered for precision studies of *CP* violation in coherent $V \to M^0\overline{M}^0$ decays [34]. The correlations in $V \to M^0\overline{M}^0$ decays can also be exploited to determine phase differences between favored and suppressed decay amplitudes [35, 36].

13.1.4 *Classification of CP-violating effects*

We distinguish three types of *CP*-violating effects that can occur in the quark sector:

I. *CP* violation in decay is defined by

$$|\overline{A}_{\overline{f}}/A_f| \neq 1\ . \tag{13.20}$$

In charged meson (and all baryon) decays, where mixing effects are absent, this is the only possible source of *CP* asymmetries:

$$\mathcal{A}_{f^\pm} \equiv \frac{\Gamma(M^- \to f^-) - \Gamma(M^+ \to f^+)}{\Gamma(M^- \to f^-) + \Gamma(M^+ \to f^+)} = \frac{|\overline{A}_{f^-}/A_{f^+}|^2 - 1}{|\overline{A}_{f^-}/A_{f^+}|^2 + 1}\ . \tag{13.21}$$

Note that the usual sign convention for *CP* asymmetries of hadrons is for the difference between the rate involving the particle that contains a heavy quark and that which contains an antiquark. Hence, Eq. (13.21) corresponds to the definition for $B^\pm$ mesons, but the opposite sign is used for $D^\pm_{(s)}$ decays.

II. *CP* (and *T*) violation in mixing is defined by

$$|q/p| \neq 1\ . \tag{13.22}$$

In charged-current semileptonic neutral meson decays $M, \overline{M} \to \ell^\pm X^\mp$ (taking $|A_{\ell^+X^-}| = |\overline{A}_{\ell^-X^+}|$ and $A_{\ell^-X^+} = \overline{A}_{\ell^+X^-} = 0$, as is the case in the Standard Model, to lowest order in G_F, and in most of its extensions), this is the only source of *CP* violation, and can be measured via the asymmetry of "wrong-sign" decays induced by oscillations:

$$\begin{aligned}&\mathcal{A}_{\rm SL}(t) \\ &\equiv \frac{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to \ell^+X^-\right] - d\Gamma/dt\left[M^0_{\rm phys}(t) \to \ell^-X^+\right]}{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to \ell^+X^-\right] + d\Gamma/dt\left[M^0_{\rm phys}(t) \to \ell^-X^+\right]}\ ,\end{aligned} \tag{13.23a}$$

$$= \frac{1 - |q/p|^4}{1 + |q/p|^4}\ . \tag{13.23b}$$

Note that this asymmetry of time-dependent decay rates is actually time-independent.

III. *CP* violation in interference between a decay without mixing, $M^0 \to f$, and a decay with mixing, $M^0 \to \overline{M}^0 \to f$ (such an effect occurs only in decays to final states that are common to M^0 and $\overline{M}^0$, including all *CP* eigenstates), is defined by

$$\arg(\lambda_f) + \arg(\lambda_{\bar{f}}) \neq 0\ , \qquad \text{with} \qquad \lambda_f \equiv \frac{q}{p}\frac{\overline{A}_f}{A_f}\ . \tag{13.24}$$

For final *CP* eigenstates, f_{CP}, the condition Eq. (13.24) simplifies to

$$\mathcal{I}m(\lambda_{f_{CP}}) \neq 0\ , \tag{13.25}$$

This form of *CP* violation can be observed, for example, using the asymmetry of neutral meson decay rates into *CP* eigenstates

$$\mathcal{A}_{f_{CP}}(t) \equiv \equiv \frac{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to f_{CP}\right] - d\Gamma/dt\left[M^0_{\rm phys}(t) \to f_{CP}\right]}{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to f_{CP}\right] + d\Gamma/dt\left[M^0_{\rm phys}(t) \to f_{CP}\right]} . \tag{13.26}$$

If $\Delta\Gamma = 0$, as expected to a good approximation for B^0 mesons but not for K^0 and B^0_s mesons, and $|q/p| = 1$, then $\mathcal{A}_{f_{CP}}$ has a particularly simple form (see Eq. (13.75), below). If, in addition, the decay amplitudes fulfill $|\overline{A}_{f_{CP}}| = |A_{f_{CP}}|$, the interference between decays with and without mixing is the only source of asymmetry and $\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_{f_{CP}})\sin(x\Gamma t)$.

Examples of these three types of *CP* violation will be given in Sections 13.4, 13.5, and 13.6.

13.2 Theoretical Interpretation: General Considerations

Consider the $M \to f$ decay amplitude A_f, and the *CP* conjugate process, $\overline{M} \to \overline{f}$, with decay amplitude $\overline{A}_{\overline{f}}$. There are two types of phases that may appear in these decay amplitudes. Complex parameters in any Lagrangian term that contributes to the amplitude will appear in complex conjugate form in the *CP*-conjugate amplitude. Thus, their phases appear in A_f and $\overline{A}_{\overline{f}}$ with opposite signs. In the Standard Model, these phases occur only in the couplings of the $W^\pm$ bosons, and hence, are often called "weak phases." The weak phase of any single term is convention-dependent. However, the difference between the weak phases in two different terms in A_f is convention-independent. A second type of phase can appear in scattering or decay amplitudes, even when the Lagrangian is real. This phase originates from the possible contribution from intermediate on-shell states in the decay process. Since such phases are generated by *CP*-invariant interactions, they are the same in A_f and $\overline{A}_{\overline{f}}$. Usually the dominant rescattering is due to strong interactions; hence the designation "strong phases" for the phase shifts so induced. Again, only the relative strong phases between different terms in the amplitude are physically meaningful.

The "weak" and "strong" phases discussed here appear in addition to the spurious *CP*-transformation phases of Eq. (13.3). Those spurious phases are due to an arbitrary choice of phase convention, and do not originate from any dynamics or induce any *CP* violation. For simplicity, we set them to zero from here on.

It is useful to write each contribution a_i to A_f in three parts: its magnitude $|a_i|$, its weak phase ϕ_i, and its strong phase δ_i. If, for example, there are two such contributions, $A_f = a_1 + a_2$, we have

$$A_f = |a_1|e^{i(\delta_1+\phi_1)} + |a_2|e^{i(\delta_2+\phi_2)} , \tag{13.27a}$$

$$\overline{A}_{\overline{f}} = |a_1|e^{i(\delta_1-\phi_1)} + |a_2|e^{i(\delta_2-\phi_2)} . \tag{13.27b}$$

Similarly, for neutral mesons, it is useful to write

$$\mathbf{M}_{12} = |\mathbf{M}_{12}|e^{i\phi_M} , \quad \mathbf{\Gamma}_{12} = |\mathbf{\Gamma}_{12}|e^{i\phi_\Gamma} . \tag{13.28}$$

Each of the phases appearing in Eqs. (13.27) and (13.28) is convention-dependent, but combinations such as $\delta_1 - \delta_2$, $\phi_1 - \phi_2$, $\phi_M - \phi_\Gamma$, and $\phi_M + \phi_1 - \overline{\phi}_1$ (where $\overline{\phi}_1$ is a weak phase contributing to $\overline{A}_f$) are physical.

It is now straightforward to evaluate the various asymmetries in terms of the theoretical parameters introduced here. We will do so with approximations that are often relevant to the most interesting measured asymmetries.

1. The *CP* asymmetry in charged meson and all baryon decays [Eq. (13.21)] is given by

$$\mathcal{A}_f = -\frac{2|a_1a_2|\sin(\delta_2-\delta_1)\sin(\phi_2-\phi_1)}{|a_1|^2+|a_2|^2+2|a_1a_2|\cos(\delta_2-\delta_1)\cos(\phi_2-\phi_1)} . \tag{13.29}$$

Ideally, this relation would be used to determine the weak phase difference $\phi_2 - \phi_1$, enabling comparison with theoretical predictions for this quantity. This is only possible, however, if the amplitude ratio $|a_2/a_1|$ and the strong phase difference $\delta_2 - \delta_1$ are known. Both quantities depend on non-perturbative hadronic parameters that are difficult to calculate, but in some cases can be obtained from experiment.

2. In the approximation that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| \ll 1$ (valid for B^0 and B^0_s mesons), the *CP* asymmetry in semileptonic neutral-meson decays [Eq. (13.23)] is given by

$$\mathcal{A}_{\rm SL} = -\left|\frac{\mathbf{\Gamma}_{12}}{\mathbf{M}_{12}}\right|\sin(\phi_M - \phi_\Gamma) . \tag{13.30}$$

The quantity of most interest to theory is the weak phase $\phi_M - \phi_\Gamma$. Its extraction from the asymmetry requires, however, that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}|$ is known. State of the art calculations of this quantity for the B^0 and B^0_s mesons have uncertainties of around 10% [37].

3. In the approximations that only a single weak phase contributes to decay, $A_f = |a_f|e^{i(\delta_f+\phi_f)}$, and that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| = 0$, we obtain $|\lambda_f| = 1$, and the *CP* asymmetries in decays to a final *CP* eigenstate f [Eq. (13.26)] with eigenvalue $\eta_f = \pm 1$ are given by

$$\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_f)\ \sin(\Delta m t)\ \text{ with }\ \mathcal{I}m(\lambda_f) = \eta_f \sin(\phi_M + 2\phi_f) . \tag{13.31}$$

Note that the phase measured is purely a weak phase, and no hadronic parameters are involved in the extraction of its value from $\mathcal{I}m(\lambda_f)$.

The discussion above allows us to introduce another classification of *CP*-violating effects:

1. *Indirect CP violation* is consistent with taking $\phi_M \neq 0$ and setting all other *CP* violating phases to zero. *CP* violation in mixing (type II) belongs to this class.
2. *Direct CP violation* cannot be accounted for by just $\phi_M \neq 0$. *CP* violation in decay (type I) belongs to this class.

The historical significance of this classification is related to theory. In superweak models [38], *CP* violation appears only in diagrams that contribute to $\mathbf{M}_{12}$, hence predicting no direct *CP* violation. In most models and, in particular, in the Standard Model, *CP* violation is both direct and indirect. As concerns type III *CP* violation, a single observation of such an effect would be consistent with indirect *CP* violation, but observing $\eta_{f_1}\mathcal{I}m(\lambda_{f_1}) \neq \eta_{f_2}\mathcal{I}m(\lambda_{f_2})$ (for the same decaying meson and two different final *CP* eigenstates f_1 and f_2) would establish direct *CP* violation. The experimental observation of $\epsilon' \neq 0$, which was achieved by establishing that $\mathcal{I}m(\lambda_{\pi^+\pi^-}) \neq \mathcal{I}m(\lambda_{\pi^0\pi^0})$ (see Section 13.4), excluded the superweak scenario.

13.3 Theoretical Interpretation: The KM Mechanism

Of all the Standard Model quark parameters, only the Kobayashi-Maskawa (KM) phase is *CP*-violating. Having a single source of *CP* violation, the Standard Model is very predictive for *CP* asymmetries: some vanish, and those that do not are correlated.

To be precise, *CP* could be violated also by strong interactions. The experimental upper bound on the electric-dipole moment of the neutron [39] implies, however, that $\theta_{\rm QCD}$, the non-perturbative parameter that determines the strength of this type of *CP* violation, is tiny, if not zero [40]. The smallness of $\theta_{\rm QCD}$ constitutes a theoretical puzzle, known as "the strong *CP* problem." This, however, is irrelevant to our discussion of hadron decays.

The charged current interactions (that is, the $W^\pm$ interactions) for quarks are given by

$$-\mathcal{L}_{W^\pm} = \frac{g}{\sqrt{2}}\ \overline{u_{Li}}\ \gamma^\mu\ (V_{\rm CKM})_{ij}\ d_{Lj}\ W^+_\mu + \text{h.c.} \tag{13.32}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Here $i, j = 1, 2, 3$ are generation numbers. The Cabibbo-Kobayashi-Maskawa (CKM) mixing matrix for quarks is a 3×3 unitary matrix [41]. Ordering the quarks by their masses, *i.e.*, $(u_1, u_2, u_3) \to (u, c, t)$ and $(d_1, d_2, d_3) \to (d, s, b)$, the elements of $V_{\rm CKM}$ are written as follows:

$$V_{\rm CKM} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} . \tag{13.33}$$

While a general 3×3 unitary matrix depends on three real angles and six phases, the freedom to redefine the phases of the quark mass eigenstates can be used to remove five of the phases, leaving a single physical phase, the Kobayashi-Maskawa phase, that is responsible for all *CP* violation in the Standard Model.

The fact that one can parameterize $V_{\rm CKM}$ by three real and only one imaginary physical parameters can be made manifest by choosing an explicit parametrization. The Wolfenstein parametrization [42, 43] is particularly useful:

$$V_{\rm CKM} = \begin{pmatrix} 1 - \frac{1}{2}\lambda^2 - \frac{1}{8}\lambda^4 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda + \frac{1}{2}A^2\lambda^5[1 - 2(\rho + i\eta)] & 1 - \frac{1}{2}\lambda^2 - \frac{1}{8}\lambda^4(1 + 4A^2) & A\lambda^2 \\ A\lambda^3[1 - (1 - \frac{1}{2}\lambda^2)(\rho + i\eta)] & -A\lambda^2 + \frac{1}{2}A\lambda^4[1 - 2(\rho + i\eta)] & 1 - \frac{1}{2}A^2\lambda^4 \end{pmatrix} . \tag{13.34}$$

Here $\lambda \approx 0.23$ (not to be confused with λ_f), the sine of the Cabibbo angle, plays the role of an expansion parameter, and η represents the *CP*-violating phase. Terms of $\mathcal{O}(\lambda^6)$ have been neglected.

The unitarity of the CKM matrix, $(VV^\dagger)_{ij} = (V^\dagger V)_{ij} = \delta_{ij}$, leads to twelve distinct complex relations among the matrix elements. The six relations with $i \neq j$ can be represented geometrically as triangles in the complex plane. Two of these,

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0 , \tag{13.35a}$$
$$V_{td}V_{ud}^* + V_{ts}V_{us}^* + V_{tb}V_{ub}^* = 0 , \tag{13.35b}$$

have terms of equal order, $\mathcal{O}(A\lambda^3)$, and so have corresponding triangles whose interior angles are all $\mathcal{O}(1)$ physical quantities that can be independently measured. The angles of the first triangle (see Fig. 13.1) are given by

$$\alpha \equiv \varphi_2 \equiv \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right) \simeq \arg\left(-\frac{1 - \rho - i\eta}{\rho + i\eta}\right) , \tag{13.36a}$$
$$\beta \equiv \varphi_1 \equiv \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right) \simeq \arg\left(\frac{1}{1 - \rho - i\eta}\right) , \tag{13.36b}$$
$$\gamma \equiv \varphi_3 \equiv \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right) \simeq \arg(\rho + i\eta) . \tag{13.36c}$$

The angles of the second triangle are equal to (α, β, γ) up to corrections of $\mathcal{O}(\lambda^2)$. The notations (α, β, γ) and $(\varphi_1, \varphi_2, \varphi_3)$ are both in common usage but, for convenience, we only use the first convention in the following.

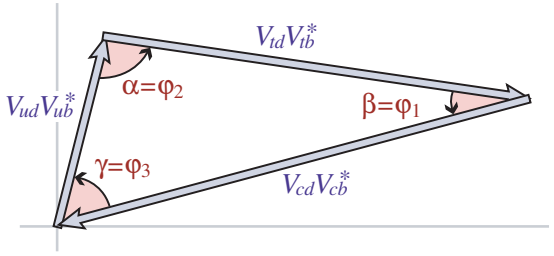

Figure 13.1: Graphical representation of the unitarity constraint $V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0$ as a triangle in the complex plane.

Another relation that can be represented as a triangle,

$$V_{us}V_{ub}^* + V_{cs}V_{cb}^* + V_{ts}V_{tb}^* = 0 , \tag{13.37}$$

and, in particular, its small angle, of $\mathcal{O}(\lambda^2)$,

$$\beta_s \equiv \arg\left(-\frac{V_{ts}V_{tb}^*}{V_{cs}V_{cb}^*}\right) , \tag{13.38}$$

is convenient for analyzing *CP* violation in the B_s^0 sector.

All unitarity triangles have the same area, commonly denoted by $J/2$ [44]. If *CP* is violated, J is different from zero and can be taken as the single *CP*-violating parameter. In the Wolfenstein parametrization of Eq. (13.34), $J \simeq \lambda^6 A^2 \eta$.

13.4 Kaons

CP violation was discovered in $K \to \pi\pi$ decays in 1964 [1]. The same mode provided the first observation of direct *CP* violation [4–6].

The decay amplitudes actually measured in neutral K decays refer to the mass eigenstates K_L and K_S, rather than to the K and $\overline{K}$ states referred to in Eq. (13.1). The final $\pi^+\pi^-$ and $\pi^0\pi^0$ states are *CP*-even. In the *CP* conservation limit, K_S (K_L) would be *CP*-even (odd), and therefore would (would not) decay to two pions. We define *CP*-violating amplitude ratios for two-pion final states,

$$\eta_{00} \equiv \frac{\langle \pi^0\pi^0|\mathcal{H}|K_L\rangle}{\langle \pi^0\pi^0|\mathcal{H}|K_S\rangle} , \quad \eta_{+-} \equiv \frac{\langle \pi^+\pi^-|\mathcal{H}|K_L\rangle}{\langle \pi^+\pi^-|\mathcal{H}|K_S\rangle} . \tag{13.39}$$

Another important observable is the asymmetry of time-integrated semileptonic decay rates:

$$A_L \equiv \frac{\Gamma(K_L \to \ell^+\nu_\ell\pi^-) - \Gamma(K_L \to \ell^-\overline{\nu}_\ell\pi^+)}{\Gamma(K_L \to \ell^+\nu_\ell\pi^-) + \Gamma(K_L \to \ell^-\overline{\nu}_\ell\pi^+)} . \tag{13.40}$$

CP violation has been observed as an appearance of K_L decays to two-pion final states [45],

$$|\eta_{00}| = (2.220 \pm 0.011) \times 10^{-3} , \tag{13.41a}$$
$$|\eta_{+-}| = (2.232 \pm 0.011) \times 10^{-3} , \tag{13.41b}$$
$$|\eta_{00}/\eta_{+-}| = 0.9950 \pm 0.0007 , \tag{13.41c}$$

where the *CP*-conserving phases ϕ_{ij} of the amplitude ratios η_{ij} have been determined both assuming *CPT* invariance:

$$\phi_{00} = (43.52 \pm 0.05)^\circ , \qquad \phi_{+-} = (43.51 \pm 0.05)^\circ , \tag{13.42}$$

and without assuming *CPT* invariance:

$$\phi_{00} = (43.7 \pm 0.6)^\circ , \qquad \phi_{+-} = (43.4 \pm 0.5)^\circ . \tag{13.43}$$

CP violation has also been observed in semileptonic K_L decays [45]

$$A_L = (3.32 \pm 0.06) \times 10^{-3} , \tag{13.44}$$

where A_L is a weighted average of muon and electron measurements, as well as in K_L decays to $\pi^+\pi^-\gamma$ and $\pi^+\pi^-e^+e^-$ [45]. *CP* violation in $K \to 3\pi$ decays has not yet been observed [45, 46].

Historically, *CP* violation in neutral K decays has been described in terms of the complex parameters ϵ and ϵ'. The observables η_{00}, η_{+-}, and A_L are related to these parameters, and to

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
except for Open Access articles.

those of Section 13.1, by

$$\eta_{00} = \frac{1-\lambda_{\pi^0\pi^0}}{1+\lambda_{\pi^0\pi^0}} = \epsilon - 2\epsilon' , \quad (13.45a)$$

$$\eta_{+-} = \frac{1-\lambda_{\pi^+\pi^-}}{1+\lambda_{\pi^+\pi^-}} = \epsilon + \epsilon' , \quad (13.45b)$$

$$A_L = \frac{1-|q/p|^2}{1+|q/p|^2} = \frac{2\mathcal{R}e(\epsilon)}{1+|\epsilon|^2} , \quad (13.45c)$$

where, in the last line, we have assumed that $\left|A_{\ell^+\nu_\ell\pi^-}\right| = \left|\overline{A}_{\ell^-\overline{\nu}_\ell\pi^+}\right|$ and $\left|A_{\ell^-\overline{\nu}_\ell\pi^+}\right| = \left|\overline{A}_{\ell^+\nu_\ell\pi^-}\right| = 0$. (The convention-dependent parameter $\tilde{\epsilon} \equiv (1-q/p)/(1+q/p)$, sometimes used in the literature, is, in general, different from ϵ but yields a similar expression, $A_L = 2\mathcal{R}e(\tilde{\epsilon})/(1+|\tilde{\epsilon}|^2)$. Further alternative definitions of ϵ and ϵ' can be found in the literature, as discussed in detail in Ref. [47].) A fit to the $K \to \pi\pi$ data yields [45]

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3} , \quad (13.46a)$$

$$\mathcal{R}e(\epsilon'/\epsilon) = (1.66 \pm 0.23) \times 10^{-3} . \quad (13.46b)$$

In discussing two-pion final states, it is useful to express the amplitudes $A_{\pi^0\pi^0}$ and $A_{\pi^+\pi^-}$ in terms of their isospin components via

$$A_{\pi^0\pi^0} = \sqrt{\frac{1}{3}}\,|A_0|\,e^{i(\delta_0+\phi_0)} - \sqrt{\frac{2}{3}}\,|A_2|\,e^{i(\delta_2+\phi_2)} , \quad (13.47a)$$

$$A_{\pi^+\pi^-} = \sqrt{\frac{2}{3}}\,|A_0|\,e^{i(\delta_0+\phi_0)} + \sqrt{\frac{1}{3}}\,|A_2|\,e^{i(\delta_2+\phi_2)} , \quad (13.47b)$$

where we parameterize the amplitude $A_I(\overline{A}_I)$ for $K^0(\overline{K}^0)$ decay into two pions with total isospin $I = 0$ or 2 as

$$A_I \equiv \langle(\pi\pi)_I\,|\mathcal{H}|\,K^0\rangle = |A_I|\,e^{i(\delta_I+\phi_I)} , \quad (13.48a)$$

$$\overline{A}_I \equiv \langle(\pi\pi)_I\,|\mathcal{H}|\,\overline{K}^0\rangle = |A_I|\,e^{i(\delta_I-\phi_I)} . \quad (13.48b)$$

The smallness of $|\eta_{00}|$ and $|\eta_{+-}|$ allows us to approximate

$$\epsilon \simeq \frac{1}{2}(1-\lambda_{(\pi\pi)_{I=0}}) , \qquad \epsilon' \simeq \frac{1}{6}\left(\lambda_{\pi^0\pi^0} - \lambda_{\pi^+\pi^-}\right) . \quad (13.49)$$

The parameter ϵ represents indirect *CP* violation, while ϵ' parameterizes direct *CP* violation: $\mathcal{R}e(\epsilon')$ measures *CP* violation in decay (type I), $\mathcal{R}e(\epsilon)$ measures *CP* violation in mixing (type II), and $\mathcal{I}m(\epsilon)$ and $\mathcal{I}m(\epsilon')$ measure the interference between decays with and without mixing (type III).

The following expressions for ϵ and ϵ' are useful for theoretical evaluations:

$$\epsilon \simeq \frac{e^{i\pi/4}}{\sqrt{2}}\frac{\mathcal{I}m(\mathbf{M}_{12})}{\Delta m} , \qquad \epsilon' = \frac{i}{\sqrt{2}}\left|\frac{A_2}{A_0}\right| e^{i(\delta_2-\delta_0)}\sin(\phi_2-\phi_0) . \quad (13.50)$$

The expression for ϵ is only valid in a phase convention where $\phi_2 = 0$, corresponding to a real $V_{ud}V_{us}^*$, and in the approximation that also $\phi_0 = 0$. The phase of ϵ, $\arg(\epsilon) \approx \arctan(-2\Delta m/\Delta\Gamma)$, is determined by non-perturbative QCD dynamics and is experimentally determined to be about $\pi/4$. The calculation of ϵ benefits from the fact that $\mathcal{I}m(\mathbf{M}_{12})$ is dominated by short distance physics. Consequently, the main sources of uncertainty in theoretical interpretations of ϵ are the values of matrix elements, such as $\langle K^0\,|(\overline{s}d)_{V-A}(\overline{s}d)_{V-A}|\,\overline{K}^0\rangle$. The expression for ϵ' is valid to first order in $|A_2/A_0| \sim 1/20$. The phase of ϵ' is experimentally determined, $\pi/2+\delta_2-\delta_0 \approx \pi/4$, and is independent of the model of electroweak interactions. Note that, accidentally, ϵ'/ϵ is real to a good approximation. Determination of weak phase information from the measurement of $\mathcal{R}e(\epsilon'/\epsilon)$ given in Eq. (13.46) has until now been precluded by uncertainties in the hadronic parameters, but recent advances in lattice QCD calculations and other theoretical approaches [48–50] suggest that it may become possible.

A future measurement of much interest is that of *CP* violation in the rare $K \to \pi\nu\overline{\nu}$ decays. The signal for *CP* violation is simply observing the $K_L \to \pi^0\nu\overline{\nu}$ decay. The effect here is that of interference between decays with and without mixing (type III) [51]:

$$\frac{\Gamma(K_L \to \pi^0\nu\overline{\nu})}{\Gamma(K^+ \to \pi^+\nu\overline{\nu})} = \frac{1}{2}\left[1 + |\lambda_{\pi\nu\overline{\nu}}|^2 - 2\,\mathcal{R}e(\lambda_{\pi\nu\overline{\nu}})\right] \simeq 1 - \mathcal{R}e(\lambda_{\pi\nu\overline{\nu}}) , \quad (13.51)$$

where in the last equation we neglect *CP* violation in decay and in mixing (expected, model-independently, to be of order 10^{-5} and 10^{-3}, respectively). Such a measurement is experimentally very challenging but would be theoretically very rewarding [52]. Similar to the *CP* asymmetry in $B^0 \to J/\psi K_S$, the *CP* violation in $K \to \pi\nu\overline{\nu}$ decay is predicted to be large (that is, the ratio in Eq. (13.51) is neither CKM- nor loop-suppressed) and can be very cleanly interpreted. In particular, the independent determinations of the CKM parameters via B-meson and K-meson decays and mixing will over-constrain the unitarity triangle and provide a stringent text of the KM mechanism.

Within the Standard Model, the $K_L \to \pi^0\nu\overline{\nu}$ decay is dominated by an intermediate top quark contribution and, consequently, can be interpreted in terms of CKM parameters [53]. (For the charged mode, $K^+ \to \pi^+\nu\overline{\nu}$, the contribution from an intermediate charm quark is not negligible, and constitutes a source of hadronic uncertainty.) In particular, $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu})$ provides a theoretically clean way to determine the Wolfenstein parameter η [54]:

$$\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) = \kappa_L[X(m_t^2/m_W^2)]^2 A^4\eta^2 , \quad (13.52)$$

where the hadronic parameter $\kappa_L \sim 2 \times 10^{-10}$ incorporates the value of the four-fermion matrix element which is deduced, using isospin relations, from $\mathcal{B}(K^+ \to \pi^0 e^+\nu_e)$, and $X(m_t^2/m_W^2)$ is a known function of the top mass. An explicit calculation gives $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) = (3.00 \pm 0.30) \times 10^{-11}$ [55].

Currently the most stringent experimental limit is $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) < 2.2 \times 10^{-9}$ [56] which does not yet reach the bound that can be derived from Eq. (13.51), $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) < 4.4 \times \mathcal{B}(K^+ \to \pi^+\nu\overline{\nu})$ [51], with the most precise result for the charged kaon decay being $\mathcal{B}(K^+ \to \pi^+\nu\overline{\nu}) = \left(13.0\,^{+3.3}_{-3.0}\right) \times 10^{-11}$ [57]. Significant further progress is anticipated from experiments searching for $K \to \pi\nu\overline{\nu}$ decays in the next few years.

13.5 Charm

The existence of D^0–$\overline{D}^0$ mixing is well established [58–62], with the latest experimental constraints giving [63, 64] $x \equiv \Delta m/\Gamma = (0.407 \pm 0.044) \times 10^{-2}$ and $y \equiv \Delta\Gamma/(2\Gamma) = (0.645\,^{+0.024}_{-0.023}) \times 10^{-2}$. Long-distance contributions make it difficult to calculate Standard Model predictions for the D^0–$\overline{D}^0$ mixing parameters. Therefore, the goal of the search for D^0–$\overline{D}^0$ mixing is not to constrain the CKM parameters, but rather to probe new physics. Here *CP* violation plays an important role. Within the Standard Model, the *CP*-violating effects are predicted to be small, since the mixing and the relevant decays are described, to an excellent approximation, by the physics of the first two generations only. The expectation is that the Standard Model size of *CP* violation in D decays is $\mathcal{O}(10^{-3})$ or less. At present, the most sensitive searches involve the $D^0 \to K^+K^-$, $D^0 \to \pi^+\pi^-$ and $D^0 \to K^\pm\pi^\mp$ modes.

The neutral D mesons decay via a singly-Cabibbo-suppressed transition to the *CP* eigenstates K^+K^- and $\pi^+\pi^-$. These decays are dominated by Standard-Model tree diagrams. Thus, we can write, for $f = K^+K^-$ or $\pi^+\pi^-$,

$$A_f = A_f^T e^{+i\phi_f^T}\left[1 + r_f e^{i(\delta_f+\phi_f)}\right] , \quad (13.53a)$$

$$\bar{A}_f = A_f^T e^{-i\phi_f^T}\left[1 + r_f e^{i(\delta_f-\phi_f)}\right] , \quad (13.53b)$$

where $A_f^T e^{\pm i\phi_f^T}$ is the Standard Model tree-level contribution, ϕ_f^T and ϕ_f are weak, *CP* violating phases, δ_f is a strong phase difference, and r_f is the ratio between a subleading ($r_f \ll 1$) contribution with a weak phase different from ϕ_f^T and the Standard

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Model tree-level contribution. Neglecting r_f, λ_f is universal, and we can define an observable phase ϕ_D via

$$\lambda_f \equiv -|q/p|e^{i\phi_D} \,. \tag{13.54}$$

(In the limit of *CP* conservation, choosing $\phi_D = 0$ is equivalent to defining the mass eigenstates by their *CP* eigenvalue: $|D_\mp\rangle = p|D^0\rangle \pm q|\overline{D}^0\rangle$, with D_- (D_+) being the *CP*-odd (*CP*-even) state; that is, the state that does not (does) decay into K^+K^-.)

We define the time integrated *CP* asymmetry for a final *CP* eigenstate f as follows:

$$a_f \equiv \frac{\int_0^\infty \Gamma(D^0_{\rm phys}(t) \to f)dt - \int_0^\infty \Gamma(\overline{D}^0_{\rm phys}(t) \to f)dt}{\int_0^\infty \Gamma(D^0_{\rm phys}(t) \to f)dt + \int_0^\infty \Gamma(\overline{D}^0_{\rm phys}(t) \to f)dt} \,. \tag{13.55}$$

(This expression corresponds to the D meson being tagged at production, hence the integration goes from 0 to $+\infty$; measurements are also possible with $\psi(3770) \to D^0\overline{D}^0$, in which case the integration goes from $-\infty$ to $+\infty$ giving slightly different results; see the discussion in Section 13.1.3.) We take $x, y, r_f \ll 1$ and expand to leading order in these parameters. We can then separate the contribution to a_f into three parts [65],

$$a_f = a_f^d + a_f^m + a_f^i \,, \tag{13.56}$$

with the following underlying mechanisms:

1. a_f^d signals *CP* violation in decay (similar to Eq. (13.21)):

$$a_f^d = 2r_f \sin\phi_f \sin\delta_f \,. \tag{13.57}$$

2. a_f^m signals *CP* violation in mixing (similar to Eq. (13.30)). With our approximations, it is universal:

$$a^m = -\frac{y}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right)\cos\phi_D \,. \tag{13.58}$$

3. a_f^i signals *CP* violation in the interference of mixing and decay (similar to Eq. (13.31)). With our approximations, it is universal:

$$a^i = \frac{x}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right)\sin\phi_D \,. \tag{13.59}$$

In the SM, both a^m and a^i are $\mathcal{O}(10^{-5})$ or less, while a^d could be up to two orders of magnitude larger.

One can isolate the effects of direct *CP* violation by taking the difference between the *CP* asymmetries in the K^+K^- and $\pi^+\pi^-$ modes:

$$\Delta a_{CP} \equiv a_{K^+K^-} - a_{\pi^+\pi^-} = a^d_{K^+K^-} - a^d_{\pi^+\pi^-} \,, \tag{13.60}$$

where we neglected a residual, experiment-dependent, contribution from indirect *CP* violation due to the fact that there may be a decay time-dependent acceptance function that can be different for the K^+K^- and $\pi^+\pi^-$ channels. The current average gives [14, 63]:

$$a^d_{K^+K^-} - a^d_{\pi^+\pi^-} = (-0.159 \pm 0.029) \times 10^{-2} \,, \tag{13.61}$$

demonstrating *CP* violation in charm decay. While the asymmetry is somewhat larger than the theoretical predictions that preceded the measurement, it can in principle be explained by non-perturbative QCD effects.

One can also isolate the effects of indirect *CP* violation in the following way. Consider the time-dependent decay rates in Eq. (13.17a) and Eq. (13.17b). The mixing processes modify the time dependence from a pure exponential. However, given the small values of x and y, the time dependences can be recast, to a good approximation, into purely exponential form, but with modified decay-rate parameters [66,67] (given here for the K^+K^- final state):

$$\Gamma_{D^0\to K^+K^-} = \Gamma \times [1 + |q/p|\,(y\cos\phi_D - x\sin\phi_D)] \,, \tag{13.62a}$$

$$\Gamma_{\overline{D}^0\to K^+K^-} = \Gamma \times [1 + |p/q|\,(y\cos\phi_D + x\sin\phi_D)] \,. \tag{13.62b}$$

One can define *CP*-conserving and *CP*-violating combinations of these two observables (normalized to the true width Γ):

$$\begin{aligned} y_{CP} &\equiv \frac{\Gamma_{\overline{D}^0\to K^+K^-} + \Gamma_{D^0\to K^+K^-}}{2\Gamma} - 1 \\ &= (y/2)\,(|q/p| + |p/q|)\cos\phi_D - (x/2)\,(|q/p| - |p/q|)\sin\phi_D \,, \end{aligned} \tag{13.63a}$$

$$\begin{aligned} A_\Gamma &\equiv \frac{\Gamma_{D^0\to K^+K^-} - \Gamma_{\overline{D}^0\to K^+K^-}}{2\Gamma} \\ &= -(a^m + a^i) \,. \end{aligned} \tag{13.63b}$$

In the limit of *CP* conservation (and, in particular, within the Standard Model), $y_{CP} = (\Gamma_+ - \Gamma_-)/2\Gamma = y$ (where $\Gamma_+(\Gamma_-)$ is the decay width of the *CP*-even (-odd) mass eigenstate) and $A_\Gamma = 0$. Indeed, present measurements imply that *CP* violation is small [63],

$$y_{CP} - y_{CP}(K\pi) = (+0.697 \pm 0.028) \times 10^{-2} \,, \tag{13.64a}$$

$$A_\Gamma = (0.009 \pm 0.011) \times 10^{-2} \,, \tag{13.64b}$$

where the correction $y_{CP}(K\pi)$ is necessary at high precision since experimentally the denominator of the relative widths in Eq. (13.63a) is measured with the $D^0 \to K^-\pi^+$ mode [68, 69].

The $K^\pm\pi^\mp$ states are not *CP* eigenstates, but they are still common final states for D^0 and $\overline{D}^0$ decays. Since $D^0(\overline{D}^0) \to K^-\pi^+$ is a Cabibbo-favored (doubly-Cabibbo-suppressed) process, these processes are particularly sensitive to x and/or $y = \mathcal{O}(\lambda^2)$. Taking into account that $|\lambda_{K^-\pi^+}|\,, \left|\lambda^{-1}_{K^+\pi^-}\right| \ll 1$ and $x, y \ll 1$, assuming that there is no direct *CP* violation (these are Standard Model tree-level decays dominated by a single weak phase, and there is no contribution from penguin-like and chromomagnetic operators), and expanding the time-dependent rates for $xt, yt \lesssim \Gamma^{-1}$, one obtains

$$\begin{aligned} &\Gamma[D^0_{\rm phys}(t) \to K^+\pi^-] = e^{-\Gamma t}|\overline{A}_{K^-\pi^+}|^2 \\ &\times \left[r_d^2 + r_d\left|\frac{q}{p}\right|(y'\cos\phi_D - x'\sin\phi_D)\Gamma t + \left|\frac{q}{p}\right|^2 \frac{y^2+x^2}{4}(\Gamma t)^2\right] \,, \end{aligned} \tag{13.65a}$$

$$\begin{aligned} &\Gamma[\overline{D}^0_{\rm phys}(t) \to K^-\pi^+] = e^{-\Gamma t}|\overline{A}_{K^-\pi^+}|^2 \\ &\times \left[r_d^2 + r_d\left|\frac{p}{q}\right|(y'\cos\phi_D + x'\sin\phi_D)\Gamma t + \left|\frac{p}{q}\right|^2 \frac{y^2+x^2}{4}(\Gamma t)^2\right] \,, \end{aligned} \tag{13.65b}$$

where

$$y' \equiv y\cos\delta - x\sin\delta \quad \text{and} \quad x' \equiv x\cos\delta + y\sin\delta \,. \tag{13.66}$$

The weak phase ϕ_D is the same as that of Eq. (13.54) (a consequence of neglecting direct *CP* violation) and $r_d = \mathcal{O}(\tan^2\theta_c)$ is the amplitude ratio, $r_d = \left|\overline{A}_{K^-\pi^+}/A_{K^-\pi^+}\right| = \left|A_{K^+\pi^-}/\overline{A}_{K^+\pi^-}\right|$, that is, $\lambda_{K^-\pi^+} = r_d|q/p|e^{-i(\delta-\phi_D)}$ and $\lambda^{-1}_{K^+\pi^-} = r_d|p/q|e^{-i(\delta+\phi_D)}$. The parameter δ is a strong-phase difference for these processes, that can be obtained from measurements of quantum correlated $\psi(3770) \to D^0\overline{D}^0$ decays [70,71]. By fitting to the six coefficients of the various time-dependences, one can determine r_d, $|q/p|$, (x^2+y^2), $y'\cos\phi_D$, and $x'\sin\phi_D$. In particular, finding *CP* violation ($|q/p| \neq 1$ and/or $\sin\phi_D \neq 0$) at a level much higher than 10^{-3} would constitute evidence for new physics. The most stringent constraints to date on *CP* violation in charm mixing have been obtained with this method [72] and from the A_Γ measurement [73].

A fit to all data [63], including also results from time-dependent analyses of $D^0 \to K_S\pi^+\pi^-$ decays, from which x, y, $|q/p|$ and ϕ_D can be determined directly, yields no evidence for indirect *CP* violation:

$$1 - |q/p| = +0.006\,^{+0.015}_{-0.016} \,, \tag{13.67a}$$

$$\phi_D = \left(-2.6\,^{+1.1}_{-1.2}\right)^\circ \,. \tag{13.67b}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.wo
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is s
except for Open Access articles.

With the additional assumption of no direct *CP* violation in doubly-Cabibbo-suppressed D decays [74–76], more stringent constraints are obtained:

$$1 - |q/p| = -0.005 \pm 0.007 \,, \tag{13.68a}$$

$$\phi_D = (-0.19 \pm 0.26)^\circ \,. \tag{13.68b}$$

More details on various theoretical and experimental aspects of D^0–$\overline{D}^0$ mixing can be found in Ref. [33].

Searches for *CP* violation in charged $D_{(s)}$ decays have been performed in many modes. Searches in decays mediated by Cabibbo-suppressed amplitudes are particularly interesting, since in other channels effects are likely to be too small to be observable in current experiments. Examples of relevant two-body modes are $D^+ \to \pi^+\pi^0$, $K_S K^+$, $\phi\pi^+$ and $D_s^+ \to K^+\pi^0$, $K_S\pi^+$, ϕK^+. The most precise results are $\mathcal{A}_{D^+\to K_S K^+} = +0.0011 \pm 0.0017$ and $\mathcal{A}_{D_s^+\to K_S\pi^+} = +0.0038 \pm 0.0048$ [63]. The precision of experiments is now sufficient that the effect from *CP* violation in the neutral kaon system can be seen in $D^+ \to K_S\pi^+$ decays [77,78].

Three- and four-body final states provide additional possibilities to search for *CP* violation, since effects may vary over the phase-space [79]. A number of methods have been proposed to exploit this feature and search for *CP* violation in ways that do not require modelling of the decay distribution [80–83]. Such methods are useful for analysis of charm decays since they are less sensitive to biases from production asymmetries, and are well suited to address the issue of whether or not *CP* violation effects are present. They can also be applied to tagged neutral D mesons as well as to charged $D_{(s)}$ decays (flavor tagging is typically achieved from the charge of the pion produced in $D^{*+} \to D^0\pi^+$ decays). The results of all searches to date are consistent with the absence of *CP* violation, with the most significant hint at the level of 2.7σ [84].

13.6 Beauty

13.6.1 *CP violation in mixing of B^0 and B_s^0 mesons*

The upper bound on the *CP* asymmetry in semileptonic B decays [85] implies that *CP* violation in B^0–$\overline{B}^0$ mixing is a small effect (we use $\mathcal{A}_{\rm SL}/2 \approx 1 - |q/p|$, see Eq. (13.23)):

$$\mathcal{A}^d_{\rm SL} = (-2.1 \pm 1.7) \times 10^{-3} \implies |q/p| = 1.0010 \pm 0.0008 \,. \tag{13.69}$$

The Standard Model prediction is

$$\mathcal{A}^d_{\rm SL} = \mathcal{O}\left[(m_c^2/m_t^2)\sin\beta\right] \lesssim 0.001 \,. \tag{13.70}$$

An explicit calculation gives $(-4.73 \pm 0.42) \times 10^{-4}$ [37].

The experimental constraint on *CP* violation in B_s^0–$\overline{B}_s^0$ mixing is somewhat weaker than that in the B^0–$\overline{B}^0$ system [85]

$$\mathcal{A}^s_{\rm SL} = (-0.6 \pm 2.8) \times 10^{-3} \implies |q/p| = 1.0003 \pm 0.0014 \,. \tag{13.71}$$

The Standard Model prediction is $\mathcal{A}^s_{\rm SL} = \mathcal{O}\left[(m_c^2/m_t^2)\sin\beta_s\right] \lesssim 10^{-4}$, with an explicit calculation giving $(2.06 \pm 0.18) \times 10^{-5}$ [37].

The fit to experimental data that results in the averages quoted above has a χ^2 probability of 4.5% indicating some tension between the different measurements [63]. This originates in part from a result from the D0 collaboration for the inclusive same-sign dimuon asymmetry that deviates from the Standard Model prediction by 3.6σ [86]. As yet, this has not been confirmed by independent studies.

In models where $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is approximately real, such as the Standard Model, an upper bound on $\Delta\Gamma/\Delta m \approx \mathcal{R}e(\mathbf{\Gamma}_{12}/\mathbf{M}_{12})$ provides yet another upper bound on the deviation of $|q/p|$ from one. This constraint does not hold if $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is approximately imaginary. (An alternative parameterization uses $q/p = (1 - \tilde{\epsilon}_B)/(1 + \tilde{\epsilon}_B)$, leading to $\mathcal{A}_{\rm SL} \simeq 4\mathcal{R}e(\tilde{\epsilon}_B)$.)

13.6.2 *CP violation in interference of B^0 decays with and without mixing*

The small deviation (less than one percent) of $|q/p|$ from 1 implies that, at the present level of experimental precision, *CP* violation in B^0 mixing is a negligible effect. Thus, for the purpose of analyzing *CP* asymmetries in hadronic B^0 decays, we can use

$$\lambda_f = e^{-i\phi_{M(B^0)}}(\overline{A}_f/A_f) \,, \tag{13.72}$$

where $\phi_{M(B^0)}$ refers to the phase of $\mathbf{M}_{12}$ appearing in Eq. (13.28) that is appropriate for B^0–$\overline{B}^0$ oscillations. Within the Standard Model, the corresponding phase factor is given by

$$e^{-i\phi_{M(B^0)}} = (V_{tb}^* V_{td})/(V_{tb} V_{td}^*) \,. \tag{13.73}$$

The class of *CP* violation effects in interference between mixing and decay is studied with final states that are common to B^0 and $\overline{B}^0$ decays [87–89]. It is convenient to rewrite Eq. (13.26) for B^0 decays as [90–92]

$$\mathcal{A}_f(t) = S_f \sin(\Delta m t) - C_f \cos(\Delta m t) \,, \tag{13.74}$$

$$S_f \equiv \frac{2\,\mathcal{I}m(\lambda_f)}{1 + \left|\lambda_f\right|^2} \,, \quad C_f \equiv \frac{1 - \left|\lambda_f\right|^2}{1 + \left|\lambda_f\right|^2} \,, \tag{13.75}$$

where we assume that $\Delta\Gamma = 0$ and $|q/p| = 1$. An alternative notation in use is $A_f \equiv -C_f$ – this A_f should not be confused with the A_f of Eq. (13.1), but is equivalent with the $\mathcal{A}_f$ of Eq. (13.21) in the limit that $|q/p| = 1$.

A large class of interesting processes proceed via quark transitions of the form $\overline{b} \to \overline{q}q\overline{q}'$ with $q' = s$ or d. For $q = c$ or u, there are contributions from both tree (t) and penguin (p^{q_u}, where $q_u = u, c, t$ is the quark in the loop) diagrams (see Fig. 13.2) which carry different weak phases:

$$A_f = \left(V_{qb}^* V_{qq'}\right) t_f + \sum_{q_u = u,c,t} \left(V_{q_u b}^* V_{q_u q'}\right) p_f^{q_u} \,. \tag{13.76}$$

(The distinction between tree and penguin contributions is a heuristic one; the separation by the operator that enters is more precise. A more detailed discussion of the operator product expansion approach, which also includes higher order QCD corrections, can be found in Ref. [93,94] for example.) Using CKM unitarity, the various decay amplitudes can always be written in terms of just two CKM combinations. For example, for $f = \pi\pi$, which proceeds via a $\overline{b} \to \overline{u}u\overline{d}$ transition, we can write

$$A_{\pi\pi} = \left(V_{ub}^* V_{ud}\right) T_{\pi\pi} + \left(V_{tb}^* V_{td}\right) P^t_{\pi\pi} \,, \tag{13.77}$$

where $T_{\pi\pi} = t_{\pi\pi} + p^u_{\pi\pi} - p^c_{\pi\pi}$ and $P^t_{\pi\pi} = p^t_{\pi\pi} - p^c_{\pi\pi}$. *CP*-violating phases in Eq. (13.77) appear only in the CKM elements, so that

$$\frac{\overline{A}_{\pi\pi}}{A_{\pi\pi}} = \frac{\left(V_{ub} V_{ud}^*\right) T_{\pi\pi} + \left(V_{tb} V_{td}^*\right) P^t_{\pi\pi}}{\left(V_{ub}^* V_{ud}\right) T_{\pi\pi} + \left(V_{tb}^* V_{td}\right) P^t_{\pi\pi}} \,. \tag{13.78}$$

For $f = J/\psi K$, which proceeds via a $\overline{b} \to \overline{c}c\overline{s}$ transition, we can write

$$A_{\psi K} = \left(V_{cb}^* V_{cs}\right) T_{\psi K} + \left(V_{ub}^* V_{us}\right) P^u_{\psi K} \,, \tag{13.79}$$

where $T_{\psi K} = t_{\psi K} + p^c_{\psi K} - p^t_{\psi K}$ and $P^u_{\psi K} = p^u_{\psi K} - p^t_{\psi K}$. A subtlety arises in this decay that is related to the fact that B^0 decays into a final $J/\psi K^0$ state while $\overline{B}^0$ decays into a final $J/\psi\overline{K}^0$ state. A common final state, *e.g.*, $J/\psi K_S$, is reached only via K^0–$\overline{K}^0$ mixing. Consequently, the phase factor (defined in Eq. (13.28)) corresponding to neutral K mixing, $e^{-i\phi_{M(K)}} = (V_{cd}^* V_{cs})/(V_{cd} V_{cs}^*)$, plays a role:

$$\frac{\overline{A}_{\psi K_S}}{A_{\psi K_S}} = -\frac{\left(V_{cb} V_{cs}^*\right) T_{\psi K} + \left(V_{ub} V_{us}^*\right) P^u_{\psi K}}{\left(V_{cb}^* V_{cs}\right) T_{\psi K} + \left(V_{ub}^* V_{us}\right) P^u_{\psi K}} \times \frac{V_{cd}^* V_{cs}}{V_{cd} V_{cs}^*} \,. \tag{13.80}$$

For $q = s$ or d, there are only penguin contributions to A_f, that is, $t_f = 0$ in Eq. (13.76). (The tree $\overline{b} \to \overline{u}u\overline{q}'$ transition followed by $\overline{u}u \to \overline{q}q$ rescattering is included below in the P^u terms.) Again, CKM unitarity allows us to write A_f in terms of two CKM combinations. For example, for $f = \phi K_S$, which proceeds via a $\overline{b} \to \overline{s}s\overline{s}$ transition, we can write

$$\frac{\overline{A}_{\phi K_S}}{A_{\phi K_S}} = -\frac{\left(V_{cb} V_{cs}^*\right) P^c_{\phi K} + \left(V_{ub} V_{us}^*\right) P^u_{\phi K}}{\left(V_{cb}^* V_{cs}\right) P^c_{\phi K} + \left(V_{ub}^* V_{us}\right) P^u_{\phi K}} \times \frac{V_{cd}^* V_{cs}}{V_{cd} V_{cs}^*} \,, \tag{13.81}$$

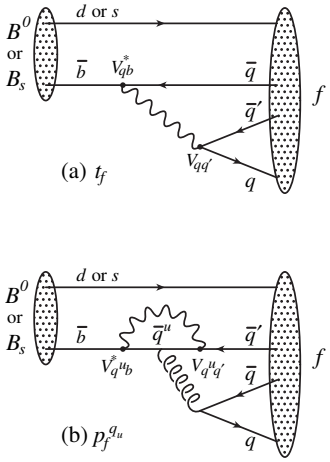

Figure 13.2: Feynman diagrams for (a) tree and (b) penguin amplitudes contributing to $B^0 \to f$ or $B_s^0 \to f$ via a $\bar{b} \to \bar{q}q\bar{q}'$ quark-level process.

where $P^c_{\phi K} = p^c_{\phi K} - p^t_{\phi K}$ and $P^u_{\phi K} = p^u_{\phi K} - p^t_{\phi K}$.

Since in general the amplitude A_f involves two different weak phases, the corresponding decays can exhibit both *CP* violation in the interference of decays with and without mixing, $S_f \neq 0$, and *CP* violation in decay, $C_f \neq 0$. (At the present level of experimental precision, the contribution to C_f from *CP* violation in mixing is negligible, see Eq. (13.69).) If the contribution from a second weak phase is suppressed, then the interpretation of S_f in terms of Lagrangian *CP*-violating parameters is clean, while C_f is small. If such a second contribution is not suppressed, S_f depends on hadronic parameters and, if the relevant strong phase difference is large, C_f is large.

A summary of $\bar{b} \to \bar{q}q\bar{q}'$ modes with $q' = s$ or d is given in Table 13.1. The $\bar{b} \to \bar{d}d\bar{q}$ transitions lead to final states that are similar to those from $\bar{b} \to \bar{u}u\bar{q}$ transitions and have similar phase dependence. Final states that consist of two vector mesons ($\psi\phi$ and $\phi\phi$) are not *CP* eigenstates, and angular analysis is needed to separate the *CP*-even from the *CP*-odd contributions.

The cleanliness of the theoretical interpretation of S_f can be assessed from the information in the last column of Table 13.1. In case of small uncertainties, the expression for S_f in terms of CKM phases can be deduced from the fourth column of Table 13.1 in combination with Eq. (13.73) (and, for $b \to q\bar{q}s$ decays, the example in Eq. (13.80)). Here we consider several interesting examples.

For $B^0 \to J/\psi K_S$ and other $\bar{b} \to \bar{c}c\bar{s}$ processes, we can neglect the P^u contribution to A_f, in the Standard Model, to an approximation that is better than one percent, giving

$$\lambda_{\psi K_S} = -e^{-2i\beta} \;\Rightarrow\; S_{\psi K_S} = \sin(2\beta)\,, \quad C_{\psi K_S} = 0\,. \qquad (13.82)$$

It is important to verify experimentally the level of suppression of the penguin contribution. Methods based on flavor symmetries [95–98] allow limits to be obtained. All are currently consistent with the P^u term being negligible. Explicit calculations [98–101] also support this conclusion.

In the presence of new physics, A_f is still likely to be dominated by the T term, but the mixing amplitude might be modified. Thus, model-independently, $C_f \approx 0$ while S_f cleanly determines the mixing phase ($\phi_M - 2\arg(V_{cb}V_{cd}^*)$). The experimental measurement gave the first precision test of the Kobayashi-Maskawa mechanism. The latest world average [63] is

$$S_{\psi K^0} = +0.710 \pm 0.011\,. \qquad (13.83)$$

(We use K^0 throughout to denote results that combine K_S and K_L modes, but use the sign appropriate to K_S.) The consistency of this measurement with the predictions for $\sin 2\beta$ makes it very likely that this mechanism is indeed the dominant source of *CP* violation in the quark sector.

For $B^0 \to \phi K_S$ and other $\bar{b} \to \bar{s}s\bar{s}$ processes (as well as some $\bar{b} \to \bar{u}u\bar{s}$ processes), we can neglect the subdominant contributions, in the Standard Model, to an approximation that is good to the order of a few percent:

$$\lambda_{\phi K_S} = -e^{-2i\beta} \;\Rightarrow\; S_{\phi K_S} = \sin 2\beta\,, \quad C_{\phi K_S} = 0\,. \qquad (13.84)$$

A review of explicit calculations of the effects of subleading amplitudes can be found in Ref. [102]. In the presence of new physics, both A_f and $\mathbf{M}_{12}$ can have contributions that are comparable in size to those of the Standard Model and carry new weak phases. Such a situation gives several interesting consequences for penguin-dominated $\bar{b} \to \bar{q}q\bar{s}$ decays ($q = u, d, s$) to a final state f:

1. The value of $-\eta_f S_f$ may be different from $S_{\psi K_S}$ by more than a few percent, where η_f is the *CP* eigenvalue of the final state.
2. The values of $\eta_f S_f$ for different final states f may be different from each other by more than a few percent (for example, $S_{\phi K_S} \neq S_{\eta' K_S}$).
3. The value of C_f may be different from zero by more than a few percent.

While a clear interpretation of such signals in terms of Lagrangian parameters will be difficult because, under these circumstances, hadronic parameters play a role, any of the above three options will clearly signal new physics. In addition, flavor symmetry relations, such as those that relate observables in $B \to K\pi$ decays [103,104] can be used to provide further tests of the Standard Model. Fig. 13.3 summarizes the present experimental results: none of the possible signatures listed above is unambiguously established, but there is definitely still room for new physics.

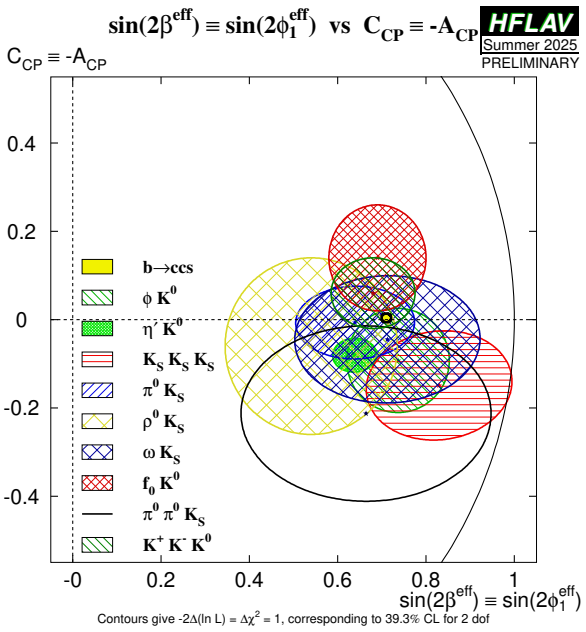

Figure 13.3: Summary of the results [63] of time-dependent analyses of $b \to q\bar{q}s$ decays, which are potentially sensitive to new physics.

For the $\bar{b} \to \bar{u}u\bar{d}$ process $B \to \pi\pi$ and other related channels, the penguin-to-tree ratio can be estimated using SU(3) relations and experimental data on related $B \to K\pi$ decays. The result (for $\pi\pi$) is that the suppression is at the level of $0.2 - 0.3$ and so cannot be neglected. The expressions for $S_{\pi\pi}$ and $C_{\pi\pi}$ to leading order in $R_{PT} \equiv (|V_{tb}V_{td}|\, P^t_{\pi\pi})/(|V_{ub}V_{ud}|\, T_{\pi\pi})$ are:

$$\lambda_{\pi\pi} = e^{2i\alpha}\left[(1 - R_{PT}e^{-i\alpha})/(1 - R_{PT}e^{+i\alpha})\right] \;\Rightarrow \qquad (13.85)$$

$$S_{\pi\pi} \approx \sin 2\alpha + 2\,\mathcal{R}e(R_{PT})\cos 2\alpha \sin\alpha\,, \quad C_{\pi\pi} \approx 2\,\mathcal{I}m(R_{PT})\sin\alpha\,. \qquad (13.86)$$

Table 13.1: Summary of $\bar{b} \to \bar{q}q\bar{q}'$ modes with $q' = s$ or d. The second and third columns give examples of hadronic final states (usually those which are experimentally most convenient to study). The fourth column gives the CKM dependence of the amplitude A_f, using the notation of Eqs. ((13.77), (13.79), (13.81)), with the dominant term first and the subdominant second. The suppression factor of the second term compared to the first is given in the last column. "Loop" refers to a penguin versus tree-suppression factor (it is mode-dependent and roughly $\mathcal{O}(0.2-0.3)$) and $\lambda \simeq 0.23$ is the expansion parameter of Eq. (13.34).

$\bar{b} \to \bar{q}q\bar{q}'$	$B^0 \to f$	$B_s^0 \to f$	CKM dependence of A_f	Suppression
$\bar{b} \to \bar{c}c\bar{s}$	ψK_S	$\psi\phi$	$(V_{cb}^* V_{cs})T + (V_{ub}^* V_{us})P^u$	loop $\times\, \lambda^2$
$\bar{b} \to \bar{s}s\bar{s}$	ϕK_S	$\phi\phi$	$(V_{cb}^* V_{cs})P^c + (V_{ub}^* V_{us})P^u$	λ^2
$\bar{b} \to \bar{u}u\bar{s}$	$\pi^0 K_S$	K^+K^-	$(V_{cb}^* V_{cs})P^c + (V_{ub}^* V_{us})T$	λ^2/loop
$\bar{b} \to \bar{c}c\bar{d}$	D^+D^-	ψK_S	$(V_{cb}^* V_{cd})T + (V_{tb}^* V_{td})P^t$	loop
$\bar{b} \to \bar{s}s\bar{d}$	$K_S K_S$	ϕK_S	$(V_{tb}^* V_{td})P^t + (V_{cb}^* V_{cd})P^c$	$\lesssim 1$
$\bar{b} \to \bar{u}u\bar{d}$	$\pi^+\pi^-$	$\rho^0 K_S$	$(V_{ub}^* V_{ud})T + (V_{tb}^* V_{td})P^t$	loop
$\bar{b} \to \bar{c}u\bar{d}$	$D_{CP}\pi^0$	$D_{CP}K_S$	$(V_{cb}^* V_{ud})T + (V_{ub}^* V_{cd})T'$	λ^2
$\bar{b} \to \bar{c}u\bar{s}$	$D_{CP}K_S$	$D_{CP}\phi$	$(V_{cb}^* V_{us})T + (V_{ub}^* V_{cs})T'$	$\lesssim 1$

Note that R_{PT} is mode-dependent and, in particular, could be different for $\pi^+\pi^-$ and $\pi^0\pi^0$. If strong phases can be neglected, then R_{PT} is real, resulting in $C_{\pi\pi} = 0$. The size of $C_{\pi\pi}$ is an indicator of how large the strong phase is. The present experimental average is $C_{\pi^+\pi^-} = -0.311 \pm 0.030$ [63]. As concerns $S_{\pi\pi}$, it is clear from Eq. (13.86) that the relative size or strong phase of the penguin contribution must be known to extract α. The theoretical uncertainty stemming from $|R_{PT}| \ll 1$ is referred to in the literature as penguin pollution.

The cleanest solution involves isospin relations among the $B \to \pi\pi$ amplitudes [105]:

$$\frac{1}{\sqrt{2}} A_{\pi^+\pi^-} + A_{\pi^0\pi^0} = A_{\pi^+\pi^0} \,. \tag{13.87}$$

The method exploits the fact that the penguin contribution to $P_{\pi\pi}^t$ is pure $\Delta I = 1/2$ (this is not true for the electroweak penguins which, however, are expected to be small), while the tree contribution to $T_{\pi\pi}$ contains amplitudes that are both $\Delta I = 1/2$ and $\Delta I = 3/2$. A simple geometric construction then allows one to find R_{PT} and extract α cleanly from $S_{\pi^+\pi^-}$. The key experimental difficulty is that one must measure accurately the separate rates for B^0 and $\overline{B}^0 \to \pi^0\pi^0$.

CP asymmetries in $B \to \rho\pi$ and $B \to \rho\rho$ can also be used to determine α. In particular, the $B \to \rho\rho$ measurements are presently very significant in constraining α. The extraction proceeds via isospin analysis similar to that of $B \to \pi\pi$. There are, however, several important differences. First, due to the finite width of the ρ mesons, a final $(\rho\rho)_{I=1}$ state is possible [106]. The effect is, however, of the order of $(\Gamma_\rho/m_\rho)^2 \sim 0.04$. Second, due to the presence of three helicity states for the two vector mesons, angular analysis is needed to separate the *CP*-even and *CP*-odd components. The theoretical expectation is that the *CP*-odd component is small. This is supported by experiments which find that the $\rho^+\rho^-$ and $\rho^\pm\rho^0$ modes are dominantly longitudinally polarized. Third, an important advantage of the $\rho\rho$ modes is that the penguin contribution is expected to be small due to different hadronic dynamics. This expectation is confirmed by the smallness of $\mathcal{B}(B^0 \to \rho^0\rho^0) = (0.96 \pm 0.15) \times 10^{-6}$ compared to $\mathcal{B}(B^0 \to \rho^+\rho^-) = (27.7 \pm 1.9) \times 10^{-6}$ [63]. Thus, $S_{\rho^+\rho^-}$ is not far from $\sin 2\alpha$. Finally, both $S_{\rho^0\rho^0}$ and $C_{\rho^0\rho^0}$ are experimentally accessible, which may allow a precise determination of α. However, a full isospin analysis should allow that the fractions of longitudinal polarization in B and $\overline{B}$ decays may differ, which has not yet been done by the experiments.

Detailed discussion of the determination of α with these methods can be found in Refs. [107, 108]. The latest world average is

$$\alpha = \left(84.1\,^{+3.7}_{-3.0}\right)^\circ \,. \tag{13.88}$$

The consistency between the range of α determined by the $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism.

All modes discussed in this Section so far have possible contributions from penguin amplitudes. As shown in Table 13.1, *CP* violation can also be studied with final states, typically containing charmed mesons, where no such contribution is possible. The neutral charmed meson must be reconstructed in a final state, such as a *CP* eigenstate, common to D^0 and $\overline{D}^0$ so that the amplitudes for the B and $\overline{B}$ meson decays interfere. Although there is a second tree amplitude with a different weak phase, the contributions of the different diagrams can in many cases be separated experimentally (for example by exploiting different decays of the neutral D mesons) making these channels very clean theoretically. A determination of $\sin(2\beta)$, with significance of *CP* violation over 5σ, with this method has been reported [109]. Moreover, the interference between the two tree diagrams gives sensitivity to γ, as will be discussed in Section 13.6.4.

13.6.3 *CP violation in interference of B_s^0 decays with and without mixing*

Similarly to the B^0 case, the value of $|q/p|$ in the B_s^0 system reported in Eq. (13.71) is consistent with unity with sufficient precision that *CP* violation in B_s^0 mixing can be considered negligible. We therefore use

$$\lambda_f = e^{-i\phi_M(B_s^0)}(\overline{A}_f/A_f) \,. \tag{13.89}$$

Within the Standard Model,

$$e^{-i\phi_{M(B_s^0)}} = (V_{tb}^* V_{ts})/(V_{tb} V_{ts}^*) \,. \tag{13.90}$$

Note that in the B_s^0 system, and with the sign convention of Eq. (13.8b), $\Delta\Gamma/\Gamma = -0.126 \pm 0.007$ [63] and therefore y should not be put to zero in Eqs. (13.17a) and (13.17b). However, $|q/p| = 1$ is expected to hold to an even better approximation than for B^0 mesons. One therefore obtains

$$\mathcal{A}_f(t) = \frac{S_f \sin(\Delta m t) - C_f \cos(\Delta m t)}{\cosh(\Delta\Gamma t/2) - A_f^{\Delta\Gamma} \sinh(\Delta\Gamma t/2)} \,, \tag{13.91}$$

$$\text{where} \quad A_f^{\Delta\Gamma} \equiv \frac{-2\,\mathcal{R}e(\lambda_f)}{1 + \left|\lambda_f\right|^2} \,. \tag{13.92}$$

The presence of the $A_f^{\Delta\Gamma}$ term implies that information on λ_f can be obtained from analyses that do not use tagging of the initial flavor, through so-called effective lifetime measurements [110].

The $B_s^0 \to J/\psi\phi$ decay proceeds via the $\bar{b} \to \bar{c}c\bar{s}$ transition. The *CP* asymmetry in this mode thus determines $\sin 2\beta_s$, where β_s is defined in Eq. (13.38) [111]. Angular analysis is needed to disentangle the *CP*-even and *CP*-odd components of the final state, and the interference between these components also allows $\cos 2\beta_s$ to be determined. The $B_s^0 \to J/\psi\pi^+\pi^-$ decay, which has a large contribution from $J/\psi f_0(980)$ and is assumed to also proceed dominantly via the $\bar{b} \to \bar{c}c\bar{s}$ transition, has also been used to determine $\sin 2\beta_s$. In this case no angular analysis is necessary, since the final state has been shown to be dominated by the *CP*-odd component [112]. The combination of measurements yields [63]

$$2\beta_s = 0.052 \pm 0.013 \,, \tag{13.93}$$

consistent with the Standard Model prediction, assuming negligible penguin contributions, $\beta_s = 0.01882\,^{+0.00026}_{-0.00028}$ [21].

A time-dependent *CP* asymmetry was established in $B^0_s \to K^+K^-$ decay, which proceeds via the $\overline{b} \to \overline{u}u\overline{s}$ transition [113]:

$$C_{KK} = +0.172 \pm 0.031\,, \quad S_{KK} = +0.139 \pm 0.032\,. \tag{13.94}$$

For both C_{KK} and S_{KK}, the hadronic ratio (T/P^c) plays an important role (see Table 13.1), making a clean theoretical interpretation challenging. Results on time-dependent *CP* violation in the $\overline{b} \to \overline{q}q\overline{s}$ decays $B^0_s \to \phi\phi$ and $K^{*0}\overline{K}^{*0}$ have also been reported. These are penguin-dominated $\overline{b} \to \overline{q}q\overline{s}$ decays, in which the *CP* violation effects are expected to be very small in the Standard Model; measurements to date are consistent with these predictions. Parameters of *CP* violation have also been determined from the decay-time distributions of $B^0_s \to D^\mp_s K^\pm$ and $D^\mp_s K^\pm\pi^+\pi^-$ decays, involving interference between $\overline{b} \to \overline{c}u\overline{s}$ and $\overline{b} \to \overline{u}c\overline{s}$ tree amplitudes. The latest results in $B^0_s \to D^\mp_s K^\pm$ decays [114] provide observation of *CP* violation in the interference between mixing and decay, through $\arg(\lambda_f) + \arg(\lambda_{\bar{f}}) \neq 0$ (see Eq. (13.24)).

13.6.4 *Direct CP violation in the B system*

An interesting class of decay modes is that of the tree-level decays $B^\pm \to D^{(*)}K^\pm$, which allow a theoretically pristine determination of the angle γ [115–120]. The method uses the decays $B^+ \to D^0K^+$, which proceeds via the quark transition $\overline{b} \to \overline{u}c\overline{s}$, and $B^+ \to \overline{D}^0K^+$, which proceeds via the quark transition $\overline{b} \to \overline{c}u\overline{s}$, with the D^0 and $\overline{D}^0$ decaying into a common final state. The decays into common final states, such $(\pi^0K_S)_DK^+$, involve interference effects between the two amplitudes, with sensitivity to the relative phase, $\delta + \gamma$ (δ is the relevant strong phase difference). The *CP*-conjugate processes are sensitive to $\delta - \gamma$. Measurements of branching ratios and *CP* asymmetries allow the determination of γ and δ from amplitude triangle relations. The method suffers from discrete ambiguities but, since all hadronic parameters can be determined from the data, has negligible theoretical uncertainty [121].

Unfortunately, the smallness of the CKM-suppressed $b \to u$ transitions makes it difficult to use the simplest methods alone [115–117] to determine γ. These difficulties are overcome (and the discrete ambiguities are removed) by performing a Dalitz plot analysis for multi-body D decays [118–120]. Detailed discussion of the determination of γ with these methods can be found in Ref. [108].

Constraints on γ from combinations of results on various $B \to D^{(*)}K^{(*)}$ processes have been obtained by experiments [122,123]. The latest world average is [63, 108]

$$\gamma = \left(66.3\,^{+2.7}_{-2.8}\right)^\circ\,. \tag{13.95}$$

The consistency between the range of γ determined by the $B \to DK$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism. As more data become available, determinations of γ from $B^0_s \to D^\mp_s K^\pm$ [124, 125] and $B^0 \to DK^{*0}$ [126–130] are expected to also give competitive measurements.

Decays to the final state $K^\mp\pi^\pm$ provided the first observations of direct *CP* violation in both B^0 and B^0_s systems. The asymmetry arises due to interference between tree and penguin diagrams [131], similar to the effect discussed in Section 13.6.2. In principle, measurements of $\mathcal{A}_{B^0\to K^+\pi^-}$ and $\mathcal{A}_{B^0_s\to K^-\pi^+}$ could be used to determine the weak phase difference γ, but lack of knowledge of the relative magnitude and strong phase of the contributing amplitudes limits the achievable precision. The uncertainties on these hadronic parameters can be reduced by exploiting flavor symmetries, which predict a number of relations between asymmetries in different modes. One such relation is that the partial rate differences for B^0 and B^0_s decays to $K^\mp\pi^\pm$ are expected to be approximately equal and opposite [132], which is consistent with current data. It is also expected that the partial rate asymmetries for $B^0 \to K^+\pi^-$ and $B^+ \to K^+\pi^0$ should be approximately equal; however, the experimental results currently show a significant discrepancy [63]:

$$\mathcal{A}_{B^0\to K^+\pi^-} = -0.0831\pm0.0031\,, \quad \mathcal{A}_{B^+\to K^+\pi^0} = +0.027\pm0.012\,. \tag{13.96}$$

It is therefore of great interest to understand whether this originates from Standard Model QCD corrections, or whether it is a signature of new dynamics. Improved tests of a more precise relation between the partial rate differences of all four $K\pi$ final states [133–136], currently limited by knowledge of the *CP* asymmetry in $\overline{B}^0 \to K_S\pi^0$ decays, may help to resolve the situation.

It is also of interest to investigate whether similar patterns appear among the *CP* violating asymmetries in B meson decays to final states containing one pseudoscalar and one vector meson. Since the vector resonance decays to two particles, such channels can be studied through Dalitz plot analysis of the three-body final state. Model-independent analyses of $B^+ \to K^+K^-K^+$, $\pi^+\pi^-K^+$, $\pi^+\pi^-\pi^+$ and $K^+K^-\pi^+$ decays have revealed large *CP* violation effects in certain regions of phase space [137]. For the $B^+ \to K^+K^-\pi^+$ decay, an amplitude analysis has established a large *CP* violation effect associated with $\pi\pi \leftrightarrow KK$ S-wave rescattering [138]. In $B^+ \to \pi^+\pi^-\pi^+$ decays, amplitude analysis has established *CP* violation effects in the decay amplitude involving the $f_2(1270)$ resonance, in the $\pi^+\pi^-$ S-wave at low invariant mass, and in the interference between the $\pi^+\pi^-$ S-wave and the P-wave $B^+ \to \rho(770)^0\pi^+$ amplitude [139, 140]. For the other channels it remains to be seen whether the *CP* violation effects are associated to particular resonances or to interference effects, which will be necessary to understand the underlying dynamics.

13.7 Summary and Outlook

CP violation has been experimentally established in K, D and B meson decays. In Section 13.1.4 we introduced three types of *CP*-violating effects. Examples of these three types include the following:

1. All three types of *CP* violation have been observed in $K \to \pi\pi$ decays:

$$\begin{aligned}
\mathcal{R}e(\epsilon') &= \frac{1}{6}\left(\left|\frac{\overline{A}_{\pi^0\pi^0}}{A_{\pi^0\pi^0}}\right| - \left|\frac{\overline{A}_{\pi^+\pi^-}}{A_{\pi^+\pi^-}}\right|\right) \\
&= (2.5 \pm 0.4) \times 10^{-6}\,, \qquad \text{(I)} \qquad (13.97a)\\
\mathcal{R}e(\epsilon) &= \frac{1}{2}\left(1 - \left|\frac{q}{p}\right|\right) \\
&= (1.66 \pm 0.02) \times 10^{-3}\,, \qquad \text{(II)} \qquad (13.97b)\\
\mathcal{I}m(\epsilon) &= -\frac{1}{2}\mathcal{I}m(\lambda_{(\pi\pi)_{I=0}}) \\
&= (1.57 \pm 0.02) \times 10^{-3}\,. \qquad \text{(III)} \qquad (13.97c)
\end{aligned}$$

2. For D mesons, *CP* violation in decay has been established in the difference of asymmetries for $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays.

$$\begin{aligned}
\Delta a_{CP} &= \frac{|\overline{A}_{K^+K^-}/A_{K^+K^-}|^2 - 1}{|\overline{A}_{K^+K^-}/A_{K^+K^-}|^2 + 1} - \frac{|\overline{A}_{\pi^+\pi^-}/A_{\pi^+\pi^-}|^2 - 1}{|\overline{A}_{\pi^+\pi^-}/A_{\pi^+\pi^-}|^2 + 1} \\
&= (-0.159 \pm 0.029) \times 10^{-2}\,. \quad \text{(I)}
\end{aligned} \tag{13.98}$$

3. In the B meson system, *CP* violation in decay has been observed in, for example, $B^0 \to K^+\pi^-$ transitions, while *CP* violation in interference of decays with and without mixing has been observed in, for example, the $B^0 \to J/\psi K_S$ channel:

$$\begin{aligned}
\mathcal{A}_{K^+\pi^-} &= \frac{|\overline{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 - 1}{|\overline{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 + 1} \\
&= -0.0831 \pm 0.0031\,, \qquad \text{(I)} \qquad (13.99a)\\
S_{\psi K^0} &= \mathcal{I}m(\lambda_{\psi K^0}) \\
&= +0.710 \pm 0.011\,. \qquad \text{(III)} \qquad (13.99b)
\end{aligned}$$

Based on Standard Model predictions, further observations of *CP* violation in b hadron decays seem likely in the near future, at both LHCb and its upgrades [141–143] as well as the Belle II experiment [144]. Further improvements in the sensitivity to *CP* violation effects in the charm sector can also be anticipated, though uncertainty in the Standard Model predictions makes it difficult to forecast whether or not additional discoveries will be forthcoming. Further progress on rare kaon decays is also anticipated. Observables that are subject to clean theoretical interpretation, such as β from $S_{\psi K_S}$, β_s from $B_s^0 \to J/\psi\phi$, $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu})$ and γ from *CP* violation in $B \to DK$ decays, are of particular value for constraining the values of the CKM parameters and probing the flavor sector of extensions to the Standard Model. Progress in lattice QCD calculations is also needed to complement the anticipated experimental results. Other probes of *CP* violation now being pursued experimentally include the electric dipole moments of the neutron and electron, and the decays of tau leptons. Additional processes that are likely to play an important role in future *CP* studies include top-quark production and decay, Higgs boson decays and neutrino oscillations.

All measurements of *CP* violation to date are consistent with the predictions of the Kobayashi-Maskawa mechanism of the Standard Model. In fact, it is now established that the KM mechanism plays a dominant role in the *CP* violation measured in the quark sector. However, a dynamically-generated matter-antimatter asymmetry of the universe requires additional sources of *CP* violation, and such sources are naturally generated by extensions to the Standard Model. New sources might eventually reveal themselves as small deviations from the predictions of the KM mechanism, or else might not be observable in quark flavor-changing processes at all, but rather with future probes such as neutrino oscillations or electric dipole moments. The fundamental nature of *CP* violation demands a vigorous search.

A number of excellent reviews of *CP* violation are available [145–152], where the interested reader may find a detailed discussion of the various topics that are briefly reviewed here.

We thank David Kirkby for significant contributions to earlier versions of this review.

14.1 Neutrinos in the Standard Model: Massless Neutrinos

The gauge symmetry principle is one of the pillars of the great success of modern particle physics as it establishes an unambiguous connection between local (gauge) symmetries and forces mediated by spin-1 particles. In the Standard Model (SM) of particle physics the strong, weak, and electromagnetic interactions are connected to gauge symmetry under $SU(3)_{\rm C} \times SU(2)_L \times U(1)_Y$ where C stands for colour, L for left-handedness, and Y for hypercharge. The SM gauge symmetry is spontaneously broken to $SU(3)_{\rm C} \times U(1)_{\rm EM}$ where $U(1)_{\rm EM}$ couples to the electromagnetic charge $Q_{\rm EM} = T_{L3} + Y$ (T_{L3} is the third generator of the weak isospin $SU(2)_L$). The model explains all the interactions of the known fermions once they are assigned to a well defined representation of the gauge group. The construction and tests of the Standard Model as a gauge theory are covered in Chapter 9 "Quantum chromodynamics" and Chapter 10 "Electroweak model and constraints on new physics" of this *Review*. Here we emphasize that the gauge invariance principle requires that all terms in the Lagrangian, including the mass terms, respect the local symmetry. This has important implications for the neutrino and in particular for the question of the neutrino mass [1].

In the SM, neutrinos are fermions that do not have strong nor electromagnetic interactions. Consequently, they are singlets of the subgroup $SU(3)_C \times U(1)_{\rm EM}$. They are part of the lepton doublets $L_{L\ell} = \begin{pmatrix} \nu_\ell \\ \ell \end{pmatrix}_L$ where f_L is the left-handed component of the fermion f, $f_L = P_L f \equiv \frac{1-\gamma_5}{2} f$. In what follows we will refer as *active* neutrinos to neutrinos that are part of these lepton doublets. In the SM there is one active neutrino for each charged leptons, $\ell = e, \mu, \tau$. $SU(2)_L$ gauge invariance dictates the form of weak charged current (CC) interactions between the neutrinos and their corresponding charged leptons and neutral current (NC) among themselves to be:

$$-\mathcal{L}_{\rm CC} = \frac{g}{\sqrt{2}} \sum_\ell \bar{\nu}_{L\ell} \gamma^\mu \ell_L^- W_\mu^\dagger + \text{h.c.}\,, \tag{14.1}$$

$$-\mathcal{L}_{\rm NC} = \frac{g}{2\cos\theta_W} \sum_\ell \bar{\nu}_{L\ell} \gamma^\mu \nu_{L\ell} Z_\mu^0\,. \tag{14.2}$$

In the above equations, g is the coupling constant associated with $SU(2)$ and θ_W is the Weinberg angle. Equations (14.1) and (14.2) describe all the neutrino interactions in the SM. In particular, Eq. (14.2) determines the decay width of the Z boson into light ($m_\nu \leq m_Z/2$) left-handed neutrinos states. Thus from the measurement of the total decay width of the Z one can infer the number of such states. At present the measurement implies $N_\nu = 2.984 \pm 0.008$ (see Particle Listing). As a result any extension of the SM should contain three, and only three, light active neutrinos.

Sterile neutrinos are defined as having no SM gauge interactions, that is, they are singlets of the complete SM gauge group. Thus the SM, as the gauge theory able to describe all known particle interactions, contains no sterile neutrinos.

The SM with its gauge symmetry and the particle content required for the gauge interactions, that is, in the absence of SM singlets, respects an accidental global symmetry that is not imposed but appears as a consequence of the gauge symmetry and the representation of the matter fields:

$$G_{\rm SM}^{\rm global} = U(1)_B \times U(1)_{L_e} \times U(1)_{L_\mu} \times U(1)_{L_\tau}, \tag{14.3}$$

where $U(1)_B$ is the baryon number symmetry, and $U(1)_{L_e, L_\mu, L_\tau}$ are the three lepton flavour symmetries. The total lepton number, $L_e + L_\mu + L_\tau$, is then also an accidental symmetry since it is a subgroup of $G_{\rm SM}^{\rm global}$. This fact has consequences that are relevant to the question of the neutrino mass as we argue next.

In the SM, the masses of the fermions are generated via a Yukawa coupling of the scalar Higgs doublet ϕ with a fermion right-handed and left-handed component. The former is an $SU(2)_L$ singlet, the latter is part of a doublet. For leptons, we can build such a term coupling the left-handed lepton doublets L_L with the right-handed charged lepton fields E_R:

$$-\mathcal{L}_{\rm Yukawa,lep} = Y_{ij}^\ell \bar{L}_{Li} \phi E_{Rj} + \text{h.c.}\,. \tag{14.4}$$

After spontaneous symmetry breaking these terms lead to charged lepton masses

$$m_{ij}^\ell = Y_{ij}^\ell \frac{v}{\sqrt{2}}\,, \tag{14.5}$$

where v is the vacuum expectation value of the Higgs field. However, since the model does not contain right-handed neutrinos, no such Yukawa interaction can be built for the neutrinos, which are consequently massless at the Lagrangian level.

In principle, a neutrino mass term could be generated at loop level. With the particle content of the SM the only possible neutrino mass term that could be constructed is the bilinear $\bar{L}_L L_L^c$, where L_L^c is the charge conjugated field, $L_L^c = C\bar{L_L}^T$ and C is the charge conjugation matrix. However this term is forbidden in the SM because it violates the total lepton symmetry by two units and therefore it cannot be induced by loop corrections because it breaks the accidental symmetry of the model. Also, because $U(1)_{B-L}$ is a non-anomalous subgroup of $G_{\rm SM}^{\rm global}$, the bilinear $\bar{L}_L L_L^c$, cannot be induced by nonperturbative corrections either since it breaks $B - L$.

We conclude that within the SM neutrinos are precisely massless. Consequently one must go beyond the SM in order to add a mass to the neutrino.

[1] The physics of massive neutrinos has been the subject of excellent books such as [1–5] and multiple review articles. The contents of the present review is built upon the structure and the contents of the review articles [6, 7].

14.2 Extending the Standard Model to Introduce Massive Neutrinos

From the above discussion, we conclude that it is not possible to construct a renormalizable mass term for the neutrinos with the fermionic content and gauge symmetry of the SM. The obvious consequence is that in order to introduce a neutrino mass in the theory one must extend the particle content of the model, depart from gauge invariance and/or renormalizability, or do both.

As a matter of fact, neutrino mass terms can be constructed in different ways. In the following we shall assume that the gauge symmetry is mantained and explore the different possibilities to introduce a neutrino mass term adding to the SM an arbitrary number of sterile neutrinos ν_{si} $(i = 1, \dots m)$.

In the SM extended with the addition of m number of sterile neutrinos one can construct two gauge invariant renormalizable operators leading to two types of mass terms

$$-\mathcal{L}_{M_\nu} = M_{D\,ij}\bar{\nu}_{si}\nu_{Lj} + \frac{1}{2}M_{N\,ij}\bar{\nu}_{si}\nu^c_{sj} + \text{h.c.}\,, \tag{14.6}$$

where ν^c is the neutrino charge conjugated field (defined in section 14.1). M_D is a complex matrix of dimension $m \times 3$ and M_N is a symmetric $m \times m$ matrix.

The first term is generated after spontaneous electroweak symmetry breaking from Yukawa interactions,

$$Y^\nu_{ij}\bar{\nu}_{si}\tilde{\phi}^\dagger L_{Lj} \Rightarrow M_{D\,ij} = Y^\nu_{ij}\frac{v}{\sqrt{2}}\,, \tag{14.7}$$

in a similar way to Eqs.(14.4) and (14.5) for the charged fermion masses. It is correspondingly called a Dirac mass term. It conserves total lepton number but it can break the lepton flavour number symmetries.

The second term in Eq. (14.6) is a Majorana mass term and it differs from the Dirac mass terms in several relevant aspects. First, it is a singlet of the SM gauge group and, as such, it can appear as a bare mass term in the Lagrangian. Second, since it involves two neutrino fields (right-handed in this case), it breaks lepton number by two units. In general, such a term is not allowed if the neutrinos carry any additive conserved charge.

It is possible to rewrite Eq. (14.6) as:

$$-\mathcal{L}_{M_\nu} = \frac{1}{2}(\overline{\vec{\nu}^c_L}, \overline{\vec{\nu}_s}) \begin{pmatrix} 0 & M_D^T \\ M_D & M_N \end{pmatrix} \begin{pmatrix} \vec{\nu}_L \\ \vec{\nu}^c_s \end{pmatrix} + \text{h.c.} \equiv \overline{\vec{\nu}^c} M_\nu \vec{\nu} + \text{h.c.}\,, \tag{14.8}$$

where $\vec{\nu} = (\vec{\nu}_L,\, \vec{\nu^c_s})^T$ is a $(3+m)$-dimensional vector. The matrix M_ν is complex and symmetric[2]. Thus it can be diagonalized by a unitary matrix V^ν of dimension$(3+m)$, so

$$(V^\nu)^T M_\nu V^\nu = \text{diag}(m_1, m_2, \dots, m_{3+m})\,. \tag{14.9}$$

One can express the original weak eigenstates in terms of the resulting $3+m$ mass eigenstates

$$\vec{\nu}_{\text{mass}} = (V^\nu)^\dagger \vec{\nu}\,, \tag{14.10}$$

and in terms of the mass eigenstates, Eq. (14.8) takes the form:

$$\begin{aligned} -\mathcal{L}_{M_\nu} &= \frac{1}{2}\sum_{k=1}^{3+m} m_k \left(\bar{\nu}^c_{\text{mass},k}\nu_{\text{mass},k} + \bar{\nu}_{\text{mass},k}\nu^c_{\text{mass},k}\right) \\ &= \frac{1}{2}\sum_{k=1}^{3+m} m_k \bar{\nu}_{Mk}\nu_{Mk}\,, \end{aligned} \tag{14.11}$$

where

$$\nu_{Mk} = \nu_{\text{mass},k} + \nu^c_{\text{mass},k} = (V^{\nu\,\dagger}\vec{\nu})_k + (V^{\nu\,\dagger}\vec{\nu})^c_k\,. \tag{14.12}$$

[2]Notice that Eq. (14.8) corresponds to the tree-level neutrino mass matrix. Corrections are induced at the loop level, which in particular lead to non-vanishing $\bar{\nu}^c_L\nu_L$ entry [8].

So these states obey the Majorana condition

$$\nu_M = \nu^c_M\,, \tag{14.13}$$

and are referred to as Majorana neutrinos. The Majorana condition implies that only one field describes both neutrino and antineutrino states, unlike the case of a charged fermion for which particles and antiparticles are described by two different fields. So a Majorana neutrino can be described by a two-component spinor unlike the charged fermions, which are Dirac particles, and are represented by four-component spinors.

Inverting Eq. (14.12) we can write the weak-doublet components of the neutrino fields as:

$$\nu_{Li} = P_L \sum_{j=1}^{3+m} V^\nu_{ij}\nu_{Mj} \quad i = 1, 2, 3\,, \tag{14.14}$$

where P_L is the left projector.

In the following, we will discuss some interesting particular cases of this general framework: light Dirac neutrinos in Sec. 14.2.1, and light Majorana neutrinos and the see-saw mechanism in Sec. 14.2.2. A special case of the second example is the possibility of light-sterile neutrinos discussed in Sec. 14.2.3. In Sec. 14.2.4 we shall discuss the effective generation of neutrino masses from non-renormalizable operators (of which the see-saw mechanism is a particular realization).

14.2.1 *Dirac Neutrinos*

Imposing $M_N = 0$ is equivalent to imposing lepton number symmetry on the model. In doing this only the first term in Eq. (14.6), the Dirac mass term, is allowed. If there are only three sterile neutrinos($m = 3$), we can identify them with the right-handed component of a four-spinor neutrino field. In this case the Dirac mass term can be diagonalized with two 3×3 unitary matrices, V^ν and V^ν_R as:

$$V^{\nu\,\dagger}_R M_D V^\nu = \text{diag}(m_1, m_2, m_3)\,. \tag{14.15}$$

The neutrino mass term can be written as:

$$-\mathcal{L}_{M_\nu} = \sum_{k=1}^{3} m_k \bar{\nu}_{Dk}\nu_{Dk}\,, \tag{14.16}$$

where

$$\nu_{Dk} = (V^{\nu\,\dagger}\vec{\nu}_L)_k + (V^{\nu\,\dagger}_R\vec{\nu}_s)_k\,, \tag{14.17}$$

so the weak-doublet components of the neutrino fields are

$$\nu_{Li} = P_L \sum_{j=1}^{3} V^\nu_{ij}\nu_{Dj}\,. \qquad i = 1, 2, 3\,. \tag{14.18}$$

Let us stress that in this case both the low-energy matter content and the assumed symmetries are different from those of the SM. Consequently, the SM is not even a good low-energy effective theory. Furthermore, this scenario does not explain the fact that neutrinos are much lighter than the corresponding charged fermions, because all of them acquire their mass via the same mechanism.

14.2.2 *The See-saw Mechanism*

If the mass eigenvalues of M_N are much higher than the scale of electroweak symmetry breaking v, the diagonalization of M_ν leads to three light neutrinos, ν_l, and m heavy neutrinos, N:

$$-\mathcal{L}_{M_\nu} = \frac{1}{2}\bar{\nu}_l M^l \nu_l + \frac{1}{2}\bar{N} M^h N\,, \tag{14.19}$$

with

$$M^l \simeq -V_l^T M_D^T M_N^{-1} M_D V_l, \qquad M^h \simeq V_h^T M_N V_h\,, \tag{14.20}$$

and

$$V^\nu \simeq \begin{bmatrix} \left(1 - \frac{1}{2}M_D^\dagger M_N^{*\,-1} M_N^{-1} M_D\right) V_l & M_D^\dagger M_N^{*\,-1} V_h \\ -M_N^{-1} M_D V_l & \left(1 - \frac{1}{2}M_N{}^{-1} M_D M_D^\dagger M_N^{*\,-1}\right) V_h \end{bmatrix}, \tag{14.21}$$
