Figure 34.16: The photon mass attenuation length (or mean free path) $\lambda = 1/(\mu/\rho)$ for various elemental absorbers as a function of photon energy. The mass attenuation coefficient is μ/ρ, where ρ is the density. The intensity I remaining after traversal of thickness t (in mass/unit area) is given by $I = I_0 \exp(-t/\lambda)$. The accuracy is a few percent. For a chemical compound or mixture, $1/\lambda_{\rm eff} \approx \sum_{\rm elements} w_Z/\lambda_Z$, where w_Z is the proportion by weight of the element with atomic number Z. The processes responsible for attenuation are given in Fig. 34.11. Since coherent processes are included, not all these processes result in energy deposition. The data for 30 eV $< E <$ 1 keV are from Ref. [52], those for 1 keV $< E <$ 100 GeV from Ref. [53].

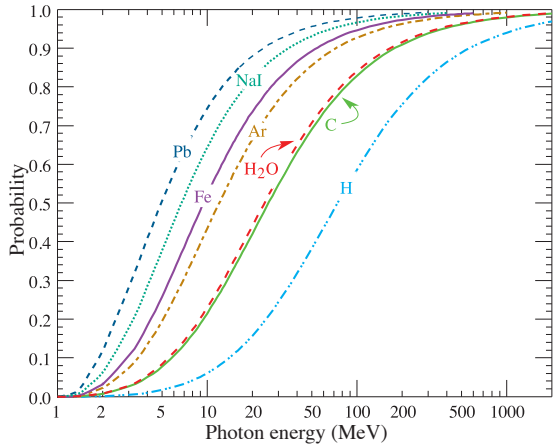

Figure 34.17: Probability P that a photon interaction will result in conversion to an e^+e^- pair. Except for a few-percent contribution from photonuclear absorption around 10 or 20 MeV, essentially all other interactions in this energy range result in Compton scattering off an atomic electron. For a photon attenuation length λ (Fig. 34.16), the probability that a given photon will produce an electron pair (without first Compton scattering) in thickness t of absorber is $P[1 - \exp(-t/\lambda)]$.

section is very closely related to that for bremsstrahlung, since the Feynman diagrams are variants of one another. The cross section is of necessity symmetric between x and $1 - x$, as can be seen by the solid curve in Fig. 34.18. See the review by Motz, Olsen, & Koch for a more detailed treatment [54]. Eq. (34.31) may be integrated to find the high-energy limit for the total e^+e^- pair-production cross section:

$$\sigma = \tfrac{7}{9}(A/X_0 N_A). \qquad (34.32)$$

Equation Eq. (34.32) is accurate to within a few percent down to energies as low as 1 GeV, particularly for high-Z materials.

34.4.6 *Bremsstrahlung and pair production at very high energies*

At ultrahigh energies, Eqns. 34.28–34.32 will fail because of quantum mechanical interference between amplitudes from different scattering centers. Since the longitudinal momentum transfer to a given center is small ($\propto k/E(E-k)$, in the case of bremsstrahlung), the interaction is spread over a comparatively long distance called the formation length ($\propto E(E-k)/k$) via the uncertainty principle. In alternate language, the formation length is the distance over which the highly relativistic electron and the photon "split apart." The interference is usually destructive. Calculations of the "Landau-Pomeranchuk-Migdal" (LPM) effect may be made semi-classically based on the average multiple scattering, or more rigorously using a quantum transport approach [44, 45].

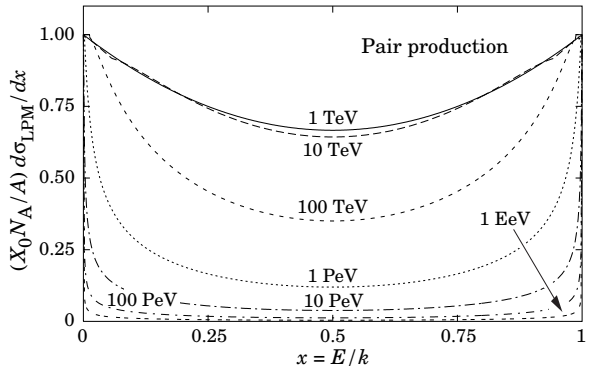

Figure 34.18: The normalized pair production cross section $d\sigma_{LPM}/dx$, versus fractional electron energy $x = E/k$.

In amorphous media, bremsstrahlung is suppressed if the pho-

ton energy k is less than $E^2/(E + E_{LPM})$ [45], where[8]

$$E_{LPM} = (m_e c^2)^2 \alpha \frac{X_0}{4\pi\hbar c\rho} = (7.7 \text{ TeV/cm}) \times \frac{X_0}{\rho} \ . \qquad (34.33)$$

Since physical distances are involved, X_0/ρ, in cm, appears. The energy-weighted bremsstrahlung spectrum for lead, $k\, d\sigma_{LPM}/dk$, is shown in Fig. 34.12. With appropriate scaling by X_0/ρ, other materials behave similarly.

For photons, pair production is reduced for $E(k - E) > k\, E_{LPM}$. The pair-production cross sections for different photon energies are shown in Fig. 34.18.

If $k \ll E$, several additional mechanisms can also produce suppression. When the formation length is long, even weak factors can perturb the interaction. For example, the emitted photon can coherently forward scatter off of the electrons in the media. Because of this, for $k < \omega_p E/m_e \sim 10^{-4}$, bremsstrahlung is suppressed by a factor $(km_e/\omega_p E)^2$ [47]. Magnetic fields can also suppress bremsstrahlung.

In crystalline media, the situation is more complicated, with coherent enhancement or suppression possible. The cross section depends on the electron and photon energies and the angles between the particle direction and the crystalline axes [56].

34.4.7 *Photonuclear and electronuclear interactions at still higher energies*

At still higher photon and electron energies, where the bremsstrahlung and pair production cross-sections are heavily suppressed by the LPM effect, photonuclear and electronuclear interactions predominate over electromagnetic interactions.

At photon energies above about 10^{20} eV, for example, photons usually interact hadronically. The exact cross-over energy depends on the model used for the photonuclear interactions. These processes are illustrated in Fig. 34.19. At still higher energies ($\gtrsim 10^{23}$ eV), photonuclear interactions can become coherent, with the photon interaction spread over multiple nuclei. Essentially, the photon coherently converts to a ρ^0, in a process that is somewhat similar to kaon regeneration [57].

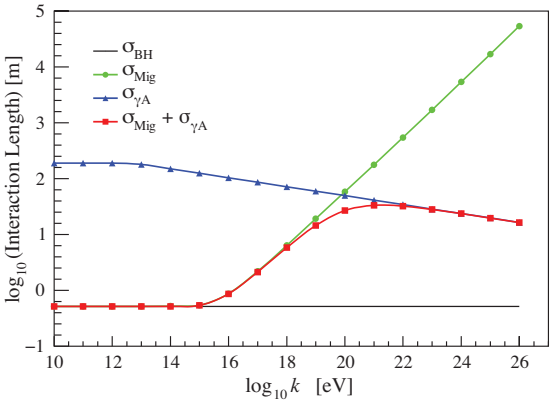

Figure 34.19: Interaction length for a photon in ice as a function of photon energy for the Bethe-Heitler (BH), LPM (Mig) and photonuclear (γA) cross sections [57]. The Bethe-Heitler interaction length is $9X_0/7$, and X_0 is 0.393 m in ice.

Similar processes occur for electrons. As electron energies increase and the LPM effect suppresses bremsstrahlung, electronuclear interactions become more important. At energies above 10^{21}eV, these electronuclear interactions dominate electron energy loss [57].

34.5 Electromagnetic cascades

When a high-energy electron or photon is incident on a thick absorber, it initiates an electromagnetic cascade as pair production and bremsstrahlung generate more electrons and photons with lower energy. The longitudinal development is governed by the high-energy part of the cascade, and therefore scales as the radiation length in the material. Electron energies eventually fall below the critical energy, and then dissipate their energy by ionization and excitation rather than by the generation of more shower particles. In describing shower behavior, it is therefore convenient to introduce the scale variables

$$t = x/X_0, \qquad y = E/E_c, \qquad (34.34)$$

so that distance is measured in units of radiation length and energy in units of critical energy.

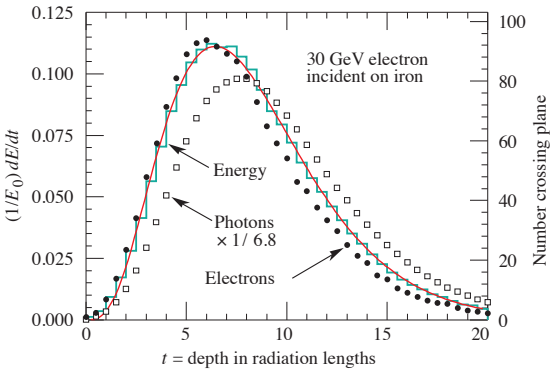

Figure 34.20: An EGS4 simulation of a 30 GeV electron-induced cascade in iron. The histogram shows fractional energy deposition per radiation length, and the curve is a gamma-function fit to the distribution. Circles indicate the number of electrons with total energy greater than 1.5 MeV crossing planes at $X_0/2$ intervals (scale on right) and the squares the number of photons with $E \geq$ 1.5 MeV crossing the planes (scaled down to have same area as the electron distribution).

Longitudinal profiles from an EGS4 [58] simulation of a 30 GeV electron-induced cascade in iron are shown in Fig. 34.20. The number of particles crossing a plane (very close to Rossi's Π function [2]) is sensitive to the cutoff energy, here chosen as a total energy of 1.5 MeV for both electrons and photons. The electron number falls off more quickly than energy deposition. This is because, with increasing depth, a larger fraction of the cascade energy is carried by photons. Exactly what a calorimeter measures depends on the device, but it is not likely to be exactly any of the profiles shown. In gas counters it may be very close to the electron number, but in glass Cherenkov detectors and other devices with "thick" sensitive regions it is closer to the energy deposition (total track length). In such detectors the signal is proportional to the "detectable" track length T_d, which is in general less than the total track length T. Practical devices are sensitive to electrons with energy above some detection threshold E_d, and $T_d = T\, F(E_d/E_c)$. An analytic form for $F(E_d/E_c)$ obtained by Rossi [2] is given by Fabjan in Ref. [59]; see also Amaldi [60].

The mean longitudinal profile of the energy deposition in an electromagnetic cascade is reasonably well described by a gamma distribution [61]:

$$\frac{dE}{dt} = E_0\, b\, \frac{(bt)^{a-1} e^{-bt}}{\Gamma(a)} \qquad (34.35)$$

The maximum $t_{\max}$ occurs at $(a - 1)/b$. We have made fits to shower profiles in elements ranging from carbon to uranium, at energies from 1 GeV to 100 GeV. The energy deposition profiles are well described by Eq. (34.35) with

$$t_{\max} = (a - 1)/b = 1.0 \times (\ln y + C_j), \qquad j = e, \gamma, \qquad (34.36)$$

where $C_e = -0.5$ for electron-induced cascades and $C_\gamma = +0.5$ for photon-induced cascades. To use Eq. (34.35), one finds $(a - 1)/b$ from Eq. (34.36) and Eq. (34.34), then finds a either by assuming $b \approx 0.5$ or by finding a more accurate value from Fig. 34.21. The results are very similar for the electron number profiles, but there

[8] This definition differs from that of Ref. [55] by a factor of two. E_{LPM} scales as the 4th power of the mass of the incident particle, so that $E_{LPM} = (1.4 \times 10^{10} \text{ TeV/cm}) \times X_0/\rho$ for a muon.

is some dependence on the atomic number of the medium. A similar form for the electron number maximum was obtained by Rossi in the context of his "Approximation B," [2] (see Fabjan's review in Ref. [59]), but with $C_e = -1.0$ and $C_\gamma = -0.5$; we regard this as superseded by the EGS4 result.

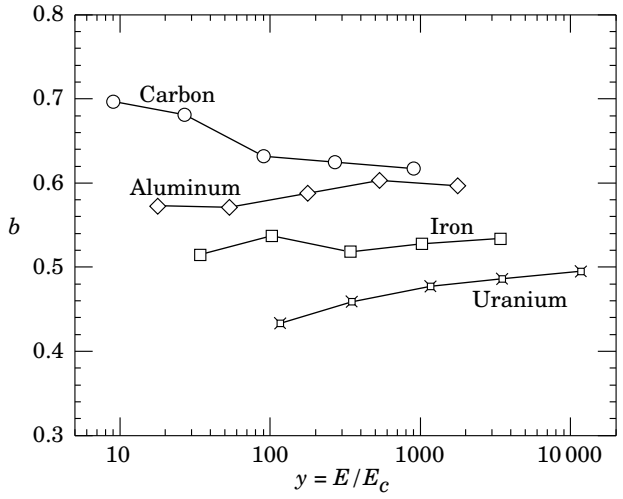

Figure 34.21: Fitted values of the scale factor b for energy deposition profiles obtained with EGS4 for a variety of elements for incident electrons with $1 \leq E_0 \leq 100$ GeV. Values obtained for incident photons are essentially the same.

The "shower length" $X_s = X_0/b$ is less conveniently parameterized, since b depends upon both Z and incident energy, as shown in Fig. 34.21. As a corollary of this Z dependence, the number of electrons crossing a plane near shower maximum is underestimated using Rossi's approximation for carbon and seriously overestimated for uranium. Essentially the same b values are obtained for incident electrons and photons. For many purposes it is sufficient to take $b \approx 0.5$.

The length of showers initiated by ultra-high energy photons and electrons is somewhat greater than at lower energies since the first or first few interaction lengths are increased via the mechanisms discussed above.

The gamma function distribution is very flat near the origin, while the EGS4 cascade (or a real cascade) increases more rapidly. As a result Eq. (34.35) fails badly for about the first two radiation lengths; it was necessary to exclude this region in making fits.

Because fluctuations are important, Eq. (34.35) should be used only in applications where average behavior is adequate. Grindhammer *et al.* have developed fast simulation algorithms in which the variance and correlation of a and b are obtained by fitting Eq. (34.35) to individually simulated cascades, then generating profiles for cascades using a and b chosen from the correlated distributions [62].

The transverse development of electromagnetic showers in different materials scales fairly accurately with the *Molière radius* R_M, given by [63, 64]

$$R_M = X_0\, E_s/E_c, \tag{34.37}$$

where $E_s \approx 21$ MeV (Table 34.1), and the Rossi definition of E_c is used.

In a material containing a weight fraction w_j of the element with critical energy E_{cj} and radiation length X_j, the Molière radius is given by

$$\frac{1}{R_M} = \frac{1}{E_s} \sum \frac{w_j\, E_{cj}}{X_j}\ . \tag{34.38}$$

Measurements of the lateral distribution in electromagnetic cascades are shown in Refs. [63, 64]. On the average, only 10% of the energy lies outside the cylinder with radius R_M. About 99% is contained inside of $3.5R_M$, but at this radius and beyond composition effects become important and the scaling with R_M fails. The distributions are characterized by a narrow core, and broaden as the shower develops. They are often represented as the sum of two Gaussians.

At high enough energies, the LPM effect (Sec. 34.4.6) reduces the cross sections for bremsstrahlung and pair production, and hence can cause significant elongation of electromagnetic cascades [45].

34.6 Muon energy loss at high energy

At sufficiently high energies, radiative processes become more important than ionization for all charged particles. For muons and pions in materials such as iron, this "critical energy" occurs at several hundred GeV. (There is no simple scaling with particle mass, but for protons the "critical energy" is much, much higher.) Radiative effects dominate the energy loss of energetic muons found in cosmic rays or produced at the newest accelerators. These processes are characterized by small cross sections, hard spectra, large energy fluctuations, and the associated generation of electromagnetic and (in the case of photonuclear interactions) hadronic showers [65–73] As a consequence, at these energies the treatment of energy loss as a uniform and continuous process is for many purposes inadequate.

It is convenient to write the average rate of muon energy loss as [74]

$$\langle -dE/dx \rangle = a(E) + b(E)\, E. \tag{34.39}$$

Here $a(E)$ is the ionization energy loss given by Eq. (34.5), and $b(E)$ is the sum of e^+e^- pair production, bremsstrahlung, and photonuclear contributions. To the approximation that these slowly-varying functions are constant, the mean range x_0 of a muon with initial energy E_0 is given by

$$x_0 \approx (1/b) \ln(1 + E_0/E_{\mu c}), \tag{34.40}$$

where $E_{\mu c} = a/b$.

Fig. 34.22 shows contributions to $b(E)$ for iron. Since $a(E) \approx 0.002$ GeV g^{-1} cm^2, $b(E)E$ dominates the energy loss above several hundred GeV, where $b(E)$ is nearly constant. The rates of energy loss for muons in hydrogen, uranium, and iron are shown in Fig. 34.23 [7].

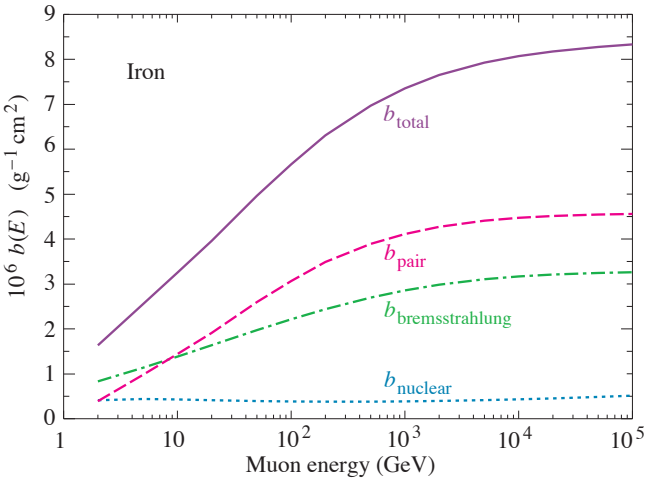

Figure 34.22: Contributions to the fractional energy loss by muons in iron due to e^+e^- pair production, bremsstrahlung, and photonuclear interactions, as obtained from Groom *et al.* [7] except for post-Born corrections to the cross section for direct pair production from atomic electrons.

The "muon critical energy" $E_{\mu c}$ can be defined more exactly as the energy at which radiative and ionization losses are equal, and can be found by solving $E_{\mu c} = a(E_{\mu c})/b(E_{\mu c})$. This definition corresponds to the solid-line intersection in Fig. 34.13, and is different from the Rossi definition we used for electrons. It serves the same function: below $E_{\mu c}$ ionization losses dominate, and above $E_{\mu c}$ radiative effects dominate. The dependence of $E_{\mu c}$ on atomic number Z is shown in Fig. 34.24.

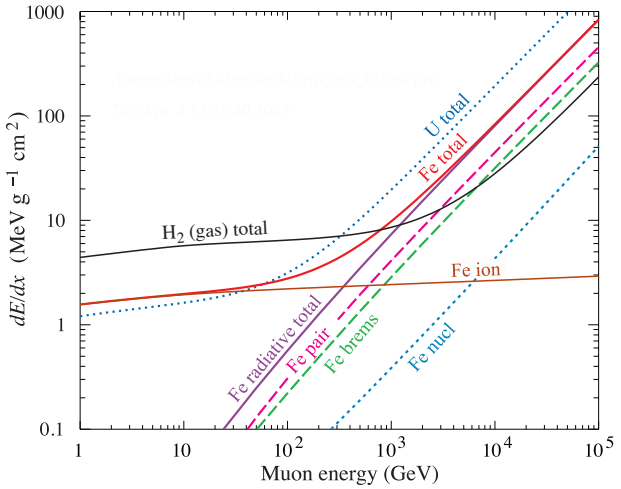

Figure 34.23: The average energy loss of a muon in hydrogen, iron, and uranium as a function of muon energy. Contributions to dE/dx in iron from ionization and pair production, bremsstrahlung and photonuclear interactions are also shown.

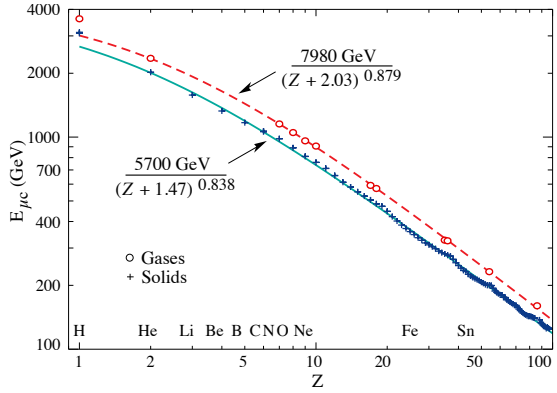

Figure 34.24: Muon critical energy for the chemical elements, defined as the energy at which radiative and ionization energy loss rates are equal [7]. The equality comes at a higher energy for gases than for solids or liquids with the same atomic number because of a smaller density effect reduction of the ionization losses. The fits shown in the figure exclude hydrogen. Alkali metals fall 3–4% above the fitted function, while most other solids are within 2% of the function. Among the gases the worst fit is for radon (2.7% high).

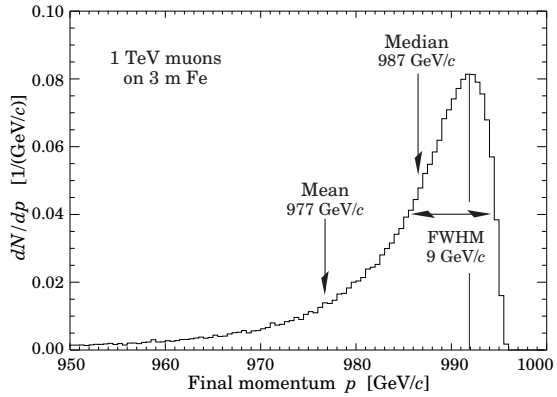

Figure 34.25: The momentum distribution of 1 TeV/c muons after traversing 3 m of iron as calculated by S.I. Striganov [7].

The radiative cross sections are expressed as functions of the fractional energy loss ν. The bremsstrahlung cross section goes roughly as $1/\nu$ over most of the range, while for the pair production case the distribution goes as ν^{-3} to ν^{-2} [75]. "Hard" losses are therefore more probable in bremsstrahlung, and in fact energy losses due to pair production may very nearly be treated as continuous. The simulated momentum distribution of an incident 1 TeV/c muon beam after it crosses 3 m of iron is shown in Fig. 34.25 [7]. The most probable loss is 8 GeV, or 3.4 MeV $g^{-1}cm^2$. The full width at half maximum is 9 GeV/c, or 0.9%. The radiative tail is almost entirely due to bremsstrahlung, although most of the events in which more than 10% of the incident energy lost experienced relatively hard photonuclear interactions. The latter can exceed detector resolution [76], necessitating the reconstruction of lost energy. Tables in Ref. [7] list the stopping power as 9.82 MeV $g^{-1}cm^2$ for a 1 TeV muon, so that the mean loss should be 23 GeV ($\approx$ 23 GeV/c), for a final momentum of 977 GeV/c, far below the peak. This agrees with the indicated mean calculated from the simulation. Electromagnetic and hadronic cascades in detector materials can obscure muon tracks in detector planes and reduce tracking efficiency [77].

34.7 Cherenkov and transition radiation [3, 78, 79]

A charged particle radiates if its speed is greater than the local phase speed of light (Cherenkov radiation) or if it crosses suddenly from one medium to another with different optical properties (transition radiation). Neither process is important for energy loss, but both are used in high-energy and cosmic-ray physics detectors.

34.7.1 *Optical Cherenkov radiation*

The angle θ_c of Cherenkov radiation, relative to the particle's direction, for a particle with speed βc in a medium with index of refraction n is

$$\begin{aligned} \cos\theta_c &= (1/n\beta) \\ \text{or} \quad \tan\theta_c &= \sqrt{\beta^2 n^2 - 1} \\ &\approx \sqrt{2(1-1/n\beta)} \quad \text{for small } \theta_c, \textit{e.g.} \text{ in gases.} \end{aligned} \tag{34.41}$$

The threshold speed β_t is $1/n$, and $\gamma_t = 1/(1-\beta_t^2)^{1/2}$. Therefore, $\beta_t\gamma_t = 1/(2\delta+\delta^2)^{1/2}$, where $\delta = n-1$. Values of δ for various commonly used gases are given as a function of pressure and wavelength in Ref. [80]. See its Table 6.1 for values at atmospheric pressure. Data for other commonly used materials are given in Ref. [81].

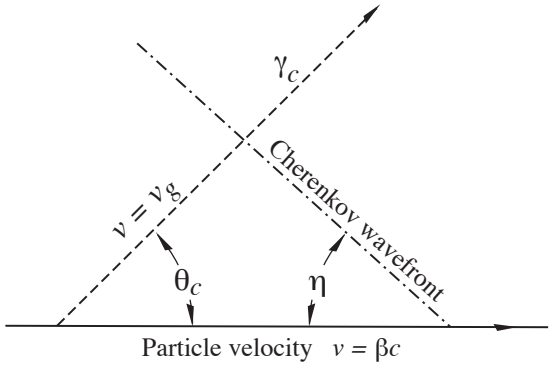

Figure 34.26: Cherenkov light emission and wavefront angles. In a dispersive medium, $\theta_c + \eta \neq 90^0$.

Practical Cherenkov radiator materials are dispersive. Let ω be the photon's frequency, and let $k = 2\pi/\lambda$ be its wavenumber. The photons propage at the group speed $v_g = d\omega/dk = c/[n(\omega) + \omega(dn/d\omega)]$. In a non-dispersive medium, this simplies to $v_g = c/n$.

In his classical paper, Tamm [82] showed that for dispersive media the radiation is concentrated in a thin conical shell whose

vertex is at the moving charge, and whose opening half-angle η is

$$\cot\eta = \left[\frac{d}{d\omega}(\omega\tan\theta_c)\right]_{\omega_0} = \left[\tan\theta_c + \beta^2\omega\, n(\omega)\,\frac{dn}{d\omega}\cot\theta_c\right]_{\omega_0}, \qquad (34.42)$$

where ω_0 is the central value of the small frequency range under consideration. (See Fig. 34.26.) This cone has a opening half-angle η, and, unless the medium is non-dispersive ($dn/d\omega = 0$), $\theta_c + \eta \neq 90^0$. The Cherenkov wavefront 'sideslips' along with the particle [83]. This effect has timing implications for ring imaging Cherenkov counters [84], but it is probably unimportant for most applications.

The number of photons produced per unit path length of a particle with charge ze and per unit energy interval of the photons is

$$\frac{d^2N}{dEdx} = \frac{\alpha z^2}{\hbar c}\sin^2\theta_c = \frac{\alpha^2 z^2}{r_e\, m_e c^2}\left(1 - \frac{1}{\beta^2 n^2(E)}\right) \approx 370\,\sin^2\theta_c(E)\ \mathrm{eV}^{-1}\mathrm{cm}^{-1} \qquad (z=1)\,, \qquad (34.43)$$

or, equivalently,

$$\frac{d^2N}{dxd\lambda} = \frac{2\pi\alpha z^2}{\lambda^2}\left(1 - \frac{1}{\beta^2 n^2(\lambda)}\right)\,. \qquad (34.44)$$

The index of refraction n is a function of photon energy $E = \hbar\omega$, as is the sensitivity of the transducer used to detect the light. For practical use, Eq. (34.43) must be multiplied by the the transducer response function and integrated over the region for which $\beta\, n(\omega) > 1$. Further details are given in the discussion of Cherenkov detectors in the Particle Detectors section (Sec. 35.5 of this *Review*).

When two particles are close together (lateral separation $\lesssim 1$ wavelength), the electromagnetic fields from the particles may add coherently, affecting the Cherenkov radiation. Because of their opposite charges, the radiation from an e^+e^- pair at close separation is suppressed compared to two independent leptons [85].

34.7.2 *Coherent radio Cherenkov radiation*

Coherent Cherenkov radiation is produced by many charged particles with a non-zero net charge moving through matter on an approximately common "wavefront"—for example, the electrons and positrons in a high-energy electromagnetic cascade. The signals can be visible for energies above 10^{16} eV; see Sec. 36.3.3 for more details. The phenomenon is called the Askaryan effect [86]. Near the end of a shower, when typical particle energies are below E_c (but still relativistic), a charge imbalance develops. Photons can Compton-scatter atomic electrons, and positrons can annihilate with atomic electrons to contribute even more photons which can in turn Compton scatter. These processes result in a roughly 20% excess of electrons over positrons in a shower. The net negative charge leads to coherent radio Cherenkov emission. The radiation includes a component from the decelerating charges (as in bremsstrahlung). Because the emission is coherent, the electric field strength is proportional to the shower energy, and the signal power increases as its square. The electric field strength also increases linearly with frequency, up to a maximum frequency determined by the lateral spread of the shower. This cutoff occurs at about 1 GHz in ice, and scales inversely with the Moliere radius. At low frequencies, the radiation is roughly isotropic, but, as the frequency rises toward the cutoff frequency, the radiation becomes increasingly peaked around the Cherenkov angle. The radiation is linearly polarized in the plane containing the shower axis and the photon direction. A measurement of the signal polarization can be used to help determine the shower direction. The characteristics of this radiation have been nicely demonstrated in a series of experiments at SLAC [87]. A detailed discussion of the radiation can be found in Ref. [88].

34.7.3 *Transition radiation*

The energy radiated when a particle with charge ze crosses the boundary between vacuum and a medium with plasma frequency ω_p is

$$I = \alpha z^2\gamma\hbar\omega_p/3, \qquad (34.45)$$

where

$$\hbar\omega_p = \sqrt{4\pi N_e r_e^3}\; m_e c^2/\alpha = \sqrt{\rho\ (\text{in g/cm}^3)\ \langle Z/A\rangle} \times 28.81\ \text{eV}. \qquad (34.46)$$

For styrene and similar materials, $\hbar\omega_p \approx 20$ eV; for air it is 0.7 eV.

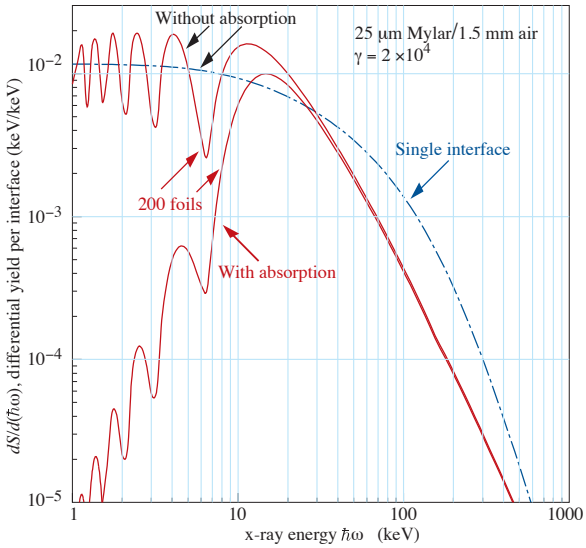

Figure 34.27: X-ray photon energy spectra for a radiator consisting of 200 25 μm thick foils of Mylar with 1.5 mm spacing in air (solid lines) and for a single surface (dashed line). Curves are shown with and without absorption. Adapted from Ref. [89].

The number spectrum $dN_\gamma/d(\hbar\omega$ diverges logarithmically at low energies and decreases rapidly for $\hbar\omega/\gamma\hbar\omega_p > 1$. About half the energy is emitted in the range $0.1 \leq \hbar\omega/\gamma\hbar\omega_p \leq 1$. Inevitable absorption in a practical detector removes the divergence. For a particle with $\gamma = 10^3$, the radiated photons are in the soft x-ray range 2 to 40 keV. The γ dependence of the emitted energy thus comes from the hardening of the spectrum rather than from an increased quantum yield.

The number of photons with energy $\hbar\omega > \hbar\omega_0$ is given by the answer to problem 13.15 in Ref. [3],

$$N_\gamma(\hbar\omega > \hbar\omega_0) = \frac{\alpha z^2}{\pi}\left[\left(\ln\frac{\gamma\hbar\omega_p}{\hbar\omega_0} - 1\right)^2 + \frac{\pi^2}{12}\right], \qquad (34.47)$$

within corrections of order $(\hbar\omega_0/\gamma\hbar\omega_p)^2$. The number of photons above a fixed energy $\hbar\omega_0 \ll \gamma\hbar\omega_p$ thus grows as $(\ln\gamma)^2$, but the number above a fixed fraction of $\gamma\hbar\omega_p$ (as in the example above) is constant. For example, for $\hbar\omega > \gamma\hbar\omega_p/10$, $N_\gamma = 2.519\,\alpha z^2/\pi = 0.59\% \times z^2$.

The particle stays "in phase" with the x ray over a distance called the formation length, $d(\omega) = (2c/\omega)(1/\gamma^2 + \theta^2 + \omega_p^2/\omega^2)^{-1}$. Most of the radiation is produced in this distance. Here θ is the x-ray emission angle, characteristically $1/\gamma$. For $\theta = 1/\gamma$ the formation length has a maximum at $d(\gamma\omega_p/\sqrt{2}) = \gamma c/\sqrt{2}\,\omega_p$. In practical situations it is tens of μm.

Since the useful x-ray yield from a single interface is low, in practical detectors it is enhanced by using a stack of N foil radiators—foils L thick, where L is typically several formation lengths—separated by gas-filled gaps. The amplitudes at successive interfaces interfere to cause oscillations about the single-interface spectrum. At increasing frequencies above the position of the last interference maximum ($L/d(w) = \pi/2$), the formation zones, which have opposite phase, overlap more and more and the

spectrum saturates, $dI/d\omega$ approaching zero as $L/d(\omega) \to 0$. This is illustrated in Fig. 34.27 for a realistic detector configuration.

For regular spacing of the layers fairly complicated analytic solutions for the intensity have been obtained [89, 90]. Although one might expect the intensity of coherent radiation from the stack of foils to be proportional to N^2, the angular dependence of the formation length conspires to make the intensity $\propto N$.

35.1 Introduction

This review summarizes the detector technologies employed at accelerator particle physics experiments. Several of these detectors are also used in a non-accelerator context and examples of such applications will be provided. The detector techniques which are specific to non-accelerator particle physics experiments are the subject of Chap. 36. More detailed discussions of detectors and their underlying physics can be found in books by Kolanoski & Wermes [1], Ferbel [2], Kleinknecht [3], Knoll [4], Green [5], Leroy & Rancoita [6], and Grupen [7].

In Table 35.1 are given typical resolutions and deadtimes of common charged particle detectors. The quoted numbers are usually based on typical devices, and should be regarded only as rough approximations for new designs. The spatial resolution refers to the intrinsic detector resolution, i.e. without multiple scattering. We note that analog detector readout can provide better spatial resolution than digital readout by measuring and averaging the deposited charge in neighboring channels. Quoted ranges attempt to be representative of both possibilities. The time resolution is defined by how accurately the time at which a particle crossed the detector can be determined. The deadtime is the minimum separation in time between two resolved hits on the same channel. Typical performance of calorimetry and particle identification are provided in the relevant sections below.

Table 35.1: Typical resolutions and deadtimes of common charged particle detectors in tracking applications. See respective sections for details on R&D efforts and their achieved performances. Revised September 2025.

Detector Type	Intrinsinc Spatial Resolution (rms)	Time Resolution	Dead Time
Resistive plate chamber	50 μm	50–1000 ps*	10 ns†
Liquid argon TPC	0.5–1 mm‡	0.01-1 μs§	—¶
Scintillation tracker	$\sim$100 μm	100 ps/n‖	10 ns
Bubble chamber	10–150 μm	1 ms	50 ms**
Wire chambers (proportional and drift chambers)	50–100 μm	5–10 ns††	20–200 ns‡‡
Micro-pattern gas detector	30–40 μm	5–10 ns††	20–200 ns‡‡
Silicon strips/pixels	$\lesssim$ 10 μm§§	few ns¶¶ ‡‡	$\lesssim$ 50 ns‡‡

*LHC: $\sim$2 mm gap, $\sim$1 ns. HL-LHC: $\sim$1 mm gap, $\sim$350 ps. Timing RPC: $\sim$50 ps
†Limited by amplifier and discriminator bandwidth, usually around 100 MHz
‡Detector geometry dependent
§Using the scintillation signal
¶No deadtime for medium
‖n = index of refraction.
**Multiple pulsing time.
††For MIPs
‡‡Depending/limited by the analog and digital front-end electronics (see [8] and 35.9)
§§Depending on electrode pitch, best values around a few μm have been achieved
¶¶Resolutions < 30 ps are reached in dedicated developments

35.2 Photon detectors

Revised August 2023 by P. Križan (Ljubljana U; Jozef Stefan Inst.).

Most detectors in high-energy, nuclear, and astrophysics rely on the detection of photons in or near the visible range, 100 nm $\lesssim \lambda \lesssim$ 1000 nm, or 1 eV $\lesssim E \lesssim$ 10 eV. This range covers scintillation and Cherenkov radiation as well as the light detected in many astronomical observations.

Generally, photodetection involves generating a detectable electrical signal proportional to the (usually very small) number of incident photons. The process involves three distinct steps:

1. generation of a primary photoelectron or electron-hole (e-h) pair by an incident photon by the photoelectric or photoconductive effect,
2. multiplication of the photoelectron or electron-hole pair signal to detectable levels, usually by one or more multiplicative bombardment steps and/or an avalanche process, and,
3. detection of charges induced by secondary electrons.

The important characteristics of a photodetector include the following:

1. quantum efficiency (QE or ϵ_Q): the average number of primary photoelectrons generated per incident photon ($0 \leq \epsilon_Q \leq 1$; in silicon more than one e-h pair per incident photon can be generated for $\lambda \lesssim$ 165 nm),
2. collection efficiency (CE or ϵ_C): the overall acceptance factor other than the generation of photoelectrons ($0 \leq \epsilon_C \leq 1$),
3. gain (G): the number of electrons collected for each photoelectron generated,
4. dark current or dark noise: the electrical signal when there is no incident photon,
5. precision of measuring the intensity I of the incoming light: electronic noise (ENC or N_e) and statistical fluctuations in the amplification process compound the Poisson distribution

of n_γ photons from a given source:

$$\frac{\sigma(I)}{\langle I\rangle} = \sqrt{\frac{f_N}{n_\gamma \epsilon_Q \epsilon_C} + \left(\frac{N_e}{G n_\gamma \epsilon_Q \epsilon_C}\right)^2}, \qquad (35.1)$$

where f_N, or the excess noise factor (ENF), is the contribution to the intensity distribution variance due to multiplication statistics [9],

6. dynamic range, linearity and saturation: relation between the number of incident photons and the sensor output in the pulsed mode,
7. time dependence of the response: this includes the transit time, which is the time between the arrival of the photon and the electrical pulse, and the transit time spread, and
8. rate capability: maximal rate of light pulses at which detection is still possible.

The QE is a strong function of the photon wavelength (λ), and is usually quoted at maximum, together with a range of λ where the QE is comparable to its maximum. Spatial uniformity and linearity with respect to the number of photons are highly desirable in a photodetector response.

Optimization of these factors involves many trade-offs and varies widely between applications. For example, while a large gain is desirable, attempts to increase the gain for a given device also increases the ENF and after-pulsing ("echos" of the main pulse). In solid-state devices, a higher QE often requires a compromise in the timing properties. In other types, coverage of large areas by focusing photoelectrons increases the transit time spread.

Other important considerations also are highly application-specific. These include the photon flux and wavelength range, the total area to be covered, and the efficiency required, the volume available to accommodate the detectors, characteristics of the environment such as chemical composition, temperature, magnetic field, ambient background, as well as ambient radiation of different types, mode of operation (continuous or triggered), bias (high-voltage) requirements, power consumption, calibration needs, aging, cost, and so on. Several technologies employing different phenomena for the three steps described above, and many variants within each, offer a wide range of solutions to choose from. The salient features of the main technologies and the common variants are described below. Some key characteristics are summarized in Table 35.2.

35.2.1 *Vacuum photodetectors*

Vacuum photodetectors can be broadly subdivided into three types: photomultiplier tubes, microchannel plate photomultiplier tubes, and hybrid photodetectors.

35.2.1.1 *Photomultiplier tubes*

A versatile class of photon detectors, vacuum photomultiplier tube (PMT) has been employed by a vast majority of all particle physics experiments to date [9]. Both "transmission-" and "reflection-type" PMTs are widely used. In the former, the photocathode material is deposited on the inside of a transparent window through which the photons enter, while in the latter, the photocathode material rests on a separate surface that the incident photons strike. The cathode material has a low work function, chosen for the wavelength band of interest. When a photon hits the cathode and liberates an electron (the photoelectric effect), the latter is accelerated and guided by electric fields to impinge on a secondary-emission electrode, or dynode, which then emits several($\sim$ 5) secondary electrons. The multiplication process is repeated typically about 10 times in series to generate a sufficient number of electrons, which are collected at the anode for delivery to the external circuit. The total gain of a PMT depends on the applied high voltage V as $G = AV^{kn}$, where $k \approx 0.7$–0.8 (depending on the dynode material), n is the number of dynodes in the chain, and A a constant (which also depends on n). Typically, G is in the range of 10^5–10^7; time resolution is $O(1ns)$ but can be as good as $\approx$ 100 ps for certain PMT types.

A large variety of PMTs covers a wide span of wavelength ranges from infrared (IR) to extreme ultraviolet (XUV) [10]. They are categorized by the window materials, photocathode materials, dynode structures, and anode configurations. Common window materials are borosilicate glass for IR to near-UV, fused quartz and sapphire (Al_2O_3) for UV, and MgF_2 or LiF for XUV. The choice of photocathode materials include a variety of mostly Cs- and/or Sb-based compounds such as CsI, CsTe, bi-alkali (SbRbCs, SbKCs), multi-alkali (SbNaKCs), GaAs(Cs), GaAsP(Cs), *etc.* Sensitive wavelengths and peak quantum efficiencies for these materials are summarized in Table-35.3. Typical dynode structures used in PMTs are circular cage, line focusing, box-and-grid, venetian blind, and fine mesh.

Multianode PMTs (MaPMTs) of up to 5×5 cm^2 in size are based on the parallel (side-by-side) arrangement of several dynode channels and anodes in the same tube, requiring advanced micro-machining and processing techniques. Fast PMTs with very large windows—measuring up to 508 mm across—have been developed for detection of Cherenkov radiation in neutrino experiments such as Super-Kamiokande and KamLAND among many others. Specially prepared low-radioactivity glass is used to make these PMTs, and they are also able to withstand the high pressure of the surrounding liquid.

PMTs are vulnerable to magnetic fields—sometimes even the geomagnetic field causes large orientation-dependent gain changes. A high-permeability metal shield is often necessary. However, proximity-focused PMTs, *e.g.* the fine-mesh types, can be used even in a high magnetic field ($\geq$ 1 T) if the direction of electric field of the tube is close to the direction of the external magnetic field. CMS uses custom-made vacuum phototriodes (VPT) mounted on the back face of projective lead tungstate crystals to detect scintillation light in the endcap sections of its electromagnetic calorimeters, which are inside a 3.8 T superconducting solenoid. A VPT employs a single dynode (thus, $G \approx 10$) placed close to the photocathode, and a mesh anode plane between the two, to help it cope with the strong magnetic field, which is not too unfavorably oriented with respect to the photodetector axis in the endcaps (within 25°), but where the radiation level is too high for Avalanche Photodiodes (APDs) like those used in the barrel section.

35.2.1.2 *Microchannel plate photomultiplier tubes*

A typical microchannel plate photomultiplier tube (MCP-PMT) consists of two or more $\sim$1 mm thick glass plates with densely packed $O(10\ \mu$m)-diameter cylindrical holes, or "microchannels", sitting between the transmission-type photocathode and anode planes, separated by $O(1$ mm) gaps. Instead of discrete dynodes, the inner surface of each cylindrical hole with a length-to-diameter ratio of 40-100 serves as a continuous dynode for the entire cascade of multiplicative bombardments initiated by a photoelectron. Gain fluctuations are reduced by operating each of the MCPs in the saturation mode. MCPs are stacked in a "chevron" configuration that alternates their bias angle; this reduces ion and photon feed-back effects and optimizes the overall amplification gain.

MCP-PMTs are thin, offer good spatial resolution, have excellent time resolution ($\sim$20 ps), and can tolerate magnetic fields up to 0.1 T and axial fields up to $1-2$ T. The technology has significantly evolved over the past 10 years [11]. A main breakthrough was the introduction of the atomic layer deposition (ALD) coatings on the MCP surfaces to increase the lifetime (>20 C/cm^2 of charge accumulated on the anode) and gain. The Large Area Picosecond Photo-Detector (LAPPD) project [12] is an important attempt to produce at a reasonable cost large (20 by 20 cm^2) sensors with a transit time spread of 50-70 ps.

35.2.1.3 *Hybrid photon detectors*

Hybrid photon detectors (HPD) combine the sensitivity of a vacuum PMT with the excellent spatial and energy resolutions of a silicon sensor [13]. A single photoelectron ejected from the photocathode is accelerated through a large potential difference of $\sim$20 kV before it impinges on the silicon sensor/anode. The gain nearly equals the maximum number of e-h pairs that could be created from the entire kinetic energy of the accelerated electron: $G \approx$ eV/w, where e is the electronic charge, V is the applied potential difference, and $w \approx 3.7$ eV is the mean energy required

Table 35.2: Representative characteristics of some photodetectors commonly used in particle physics.

Type	λ (nm)	$\epsilon_Q\,\epsilon_C$	Gain	Risetime (ns)	Single photon time resol. (ps)	Area (mm^2)	1-p.e noise * (Hz/mm^2)	HV (V)

*Normalized to photocathode/sensor area; room temperature operation assumed.
†These devices often come in multi-anode configurations. In such cases, the area is to be considered on a "per readout-channel" basis.
‡No single photon detection possible.
§Since in an APD no single photon detection is possible, dark current is usually quoted instead of the dark count rate; here we assumed a gain of 50 to convert from the dark current to the dark count rate.

to create an *e-h* pair in Si at room temperature. Since the gain is achieved in a single step, one can expect to have the excellent resolution of a simple Poisson statistic with large mean, but in fact it is even better, thanks to the Fano effect discussed in Sec. 35.8.

Low-noise electronics must be used to read out HPDs if one intends to take advantage of the low fluctuations in gain, *e.g.* when counting small numbers of photons. HPDs can have the same $\epsilon_Q\,\epsilon_C$ and window geometries as PMTs and can be segmented down to ∼50 μm. However, they require rather high biases and will not function in a magnetic field. The exception is proximity-focused devices (⇒ no (de)magnification) in an axial field. With time resolutions of ∼10 ps and superior rate capability, proximity-focused HPDs can be an alternative to MCP-PMTs. Applications of HPDs include the CMS hadronic calorimeter and the RICH detector in LHCb. Large-size HPDs with sophisticated focusing may be suitable for future water Cherenkov experiments.

Hybrid APDs (HAPDs) add an avalanche multiplication step following the electron bombardment to boost the gain by a factor of ∼50. This affords a higher gain and/or a lower bias voltage, but also increases the detector capacitance and fluctuations in multiplication. The forward RICH detector of Belle II uses a 144-channel device of this type [14].

Table 35.3: Properties of photocathode and window materials commonly used in vacuum photodetectors. [10]

Photocathode material	λ (nm)	Window material	Peak ϵ_Q (λ/nm)
CsI	115–200	MgF_2	0.13 (130)
CsTe	115–320	MgF_2	0.17 (200)
Bi-alkali	300–650	Borosilicate	0.27 (390)
	160-650	Synthetic Silica	0.27 (390)
"Ultra Bi-alkali"	300–650	Borosilicate	0.43 (350)
	160-650	Synthetic Silica	0.43 (350)
Multi-alkali	300–850	Borosilicate	0.20 (375)
	160-850	Synthetic Silica	0.25 (380)
GaAsP(Cs)	280-720	Borosilicate	0.40 (480-530)

35.2.2 *Gaseous photon detectors*

In a gaseous photon detector (GPD) a photoelectron in a suitable gas mixture initiates an avalanche in a high-field region, producing a large number of secondary impact-ionization electrons. In principle the charge multiplication and collection processes are identical to those employed in gaseous tracking detectors such as multiwire proportional chambers (MWPC), micromesh gaseous detectors (Micromegas), or gas electron multipliers (GEM). These are discussed in Sec. 35.6.3.

The devices can be divided into two types depending on the photosensitive material. One type uses solid photocathode materials much in the same way as PMTs. Since it is resistant to gas mixtures typically used in tracking chambers, CsI is a common choice. In the other type, photoionization occurs on suitable molecules vaporized and mixed in the drift volume. Most gases have photoionization work functions in excess of 10 eV, which would limit their sensitivity to wavelengths far too short. However, vapors of tetrakis dimethyl-amine ethylene (TMAE) or triethyl-amine (TEA), which have smaller work functions (5.3 eV for TMAE and 7.5 eV for TEA), are suited for XUV photon detection [15]. Since devices like GEMs offer sub-mm spatial resolution, GPDs are often used as position-sensitive photon detectors. They can be made into flat panels to cover large areas ($O(1\ \mathrm{m}^2)$), can operate in high magnetic fields, and are relatively inexpensive. Many of the ring imaging Cherenkov (RICH) detectors have used GPDs for the detection of Cherenkov light [16–19]. Special care must be taken to suppress the ion-feedback and photon-feedback processes in GPDs. It is also important to maintain high purity of the gas as minute traces of O_2 or H_2O can significantly degrade the detection efficiency.

35.2.3 *Solid-state photon detectors*

In a phase of rapid development, solid-state photodetectors are competing with vacuum- or gas-based devices for many existing applications and making way for a multitude of new ones. Compared to traditional vacuum- and gaseous photodetectors, solid-state devices are more compact, lightweight, rugged, tolerant to magnetic fields, and often cheaper. They also allow fine pixelization, are easy to integrate into large systems, and can operate at low electric potentials, while matching or exceeding most performance criteria.

Silicon photodiodes (PD) are widely used in high-energy physics as particle detectors and in a large number of applications as photon detectors. The structure is discussed in some detail in Sec. 35.8. In its simplest form, the PD is a reverse-biased *p-n* junction. Photons with energies above the indirect bandgap energy (wavelengths shorter than about 1050 nm, depending on the temperature) can create *e-h* pairs (the photoconductive effect), which are collected on the *p* and *n* sides, respectively. Often, as in the PDs used for crystal scintillator readout in CLEO, L3, Belle, BaBar, and GLAST, intrinsic silicon is doped to create a *p-i-n* structure. The reverse bias increases the thickness of the depleted region; in the case of these particular detectors, to full depletion at a depth of about 100 μm. Increasing the depletion depth decreases the capacitance (and hence electronic noise) and extends the red response. Quantum efficiency can exceed 90%, but falls toward the red because of the decrease of the light absorption probability in silicon; the absorption length reaches 100 μm at 985 nm. However, since $G = 1$, electronic signal amplification is necessary. Optimal low-noise amplifiers are slow, but, even so, noise limits the minimum detectable signal in room-temperature devices to several hundred photons.

In APDs, an exponential cascade of impact ionizations initiated by the original photogenerated *e-h* pair under a large reverse-bias voltage leads to an avalanche multiplication [20–23], and even-

tually to breakdown in Geiger-mode APDs. As a result, detectable electrical response can be obtained from low-intensity optical signals down to single photons. Excellent junction uniformity is critical, and a guard ring is generally used as a protection against edge breakdown. Well-designed APDs, such as those used in CMS crystal-based electromagnetic calorimeter, have achieved $\epsilon_Q\,\epsilon_C \approx 0.7$ with sub-ns response time. The sensitive wavelength window and gain depend on the semiconductor used. The gain is typically 10–200 in linear and up to 10^8 in Geiger mode of operation. Stability and close monitoring of the operating temperature are important for linear-mode operation, and substantial cooling is often necessary.

One of the most promising recent developments in the field is SiPMs ("Silicon Photomultiplier"), a device consisting of large arrays ($O(10^3)$) of tiny APDs packed over a small area ($O(1\ \mathrm{mm}^2)$) and operated in a limited Geiger mode [24–26]. Although each cell only offers a binary output, linearity with respect to the number of photons is achieved by summing the cell outputs. The sum of all cells is proportional to the number of photons received so long as the probability of an individual cell receiving multiple photons during a single time gate is negligible. SiPMs are being adopted as the preferred solution for various purposes including medical imaging, *e.g.* positron emission tomography (PET). These compact, rugged, and economical devices allow auto-calibration through decent separation of photoelectron peaks and offer gains of $O(10^6)$ at a moderate bias voltage (∼30 V). However, the single-photoelectron noise of a SiPM, being the logical "or" of $O(10^3)$ Geiger APDs, is rather large: O(10-100 kHz/mm^2) at room temperature. Intensive R&D in recent years [27] led to a substantial reduction in dark count rates and in correlated noise levels, resulting in coverage of larger areas and in a wider range of applications. One way to further improve the signal-to-noise ratio in SiPMs is by using dedicated light collectors, either as quartz Winston cone like arrays [28] or suitably designed meta-materials [29]. In this way, photons propagate from a larger entry window to a considerably smaller semiconductor sensor, resulting in an improved signal photon to dark-count ratio. Intense R&D is expected to improve radiation hardness of these sensors. The fabrication of the sensors and the front-end electronics combined in the same process with the goal of making SiPMs extremely easy to use has already been successful (digital SiPMs) [30], and remains a topic of intense R&D.

More solid-state light sensors have either been developed or are potentially interesting for use in HEP experiments. The Run 2 DØ detector used 86000 Visible-light photon counters (VLPC) to read the optical signal from its scintillating-fiber tracker and scintillator-strip preshower detectors. These light sensors utilize the formation of an impurity band only 50 meV below the conduction band in As-doped Si to generate strong ($G \approx 5 \times 10^4$) yet sharp response to single photons with $\epsilon_Q \approx 0.9$ [31–33]. Only a very small bias (∼7 V) is needed, but high sensitivity to infrared photons requires cooling below 10 K. Another interesting light sensor that has not yet found its use in HEP instrumentation are quantum dots, realized by nanometer-sized semiconductor 'particles' embedded in a semiconductor bulk.

35.2.4 *Superconducting photon detectors*

In this rapidly developing technology field, three most established technologies are the superconducting nano-wire single photon detector (SNSPD), the transition edge sensor (TES), and the microwave kinetic inductance detector (MKID). An SNSPD consists of a thin (4 nm) and narrow (100-250 nm) superconducting nanostrip that is current-biased just below its critical current. Absorption of a photon generates a resistive domain in the superconducting nanostrip, which leads to a transient voltage signal that can be detected. SNSPDs offer a unique combination of speed, both in terms of count rate (∼GHz) and low timing jitter (< 3 ps [34]), large range of wavelength sensitivity from VUV (120 nm) to mid-IR (10 μm), high detection efficiencies (approaching 100% for UV to near-IR), and low dark count rates (∼5-10 Hz), making them appealing for a wide variety of demanding applications.

Examples of present use in particle physics are small nanowire detectors for dark matter and dark photons. Work is in progress that could make these sensors relevant to HEP applications by increasing the area (using 300 mm wafers and larger) and pixel size, coupling via windows to cryogenic stages, and readout of arrays (superconducting electronics for data processing). While the performance of these sensors is impressive, an application in large accelerator-based detectors would require an extensive R&D program because of the severe cryogenic requirements.

35.3 Organic scintillators

Revised August 2025 by S.C. Eno (U. Maryland) and M. Hamel (Paris-Saclay U. CEA, LIST).

Organic scintillators produce light when transversed by a charged particle. They can be broadly categorized into four types: single crystal, liquid, plastic, and a recently emerged organic glass [35]. The most useful scintillators produce photons with wavelengths between 370-750 nm (ultraviolet to red), typically peaking at 425 nm [36] via a series of processes that are initialized when charged particles interact with the material via both excitation and ionization/recombination (see Sec. 34.2 of this *Review*). Typical light yields are about 1 photon per 100 eV of energy deposit [37], although the collected and transduced signal can be much lower. Methods to guide the light towards the photon-electron converter, such as diffusive paint, reflectors, photonic crystals, or light guides, may be required to optimize light yield.

Organic scintillators have found use in a wide variety of detectors [38]. Plastics are mostly used in collider detectors, and liquids in neutrino experiments. Ease of fabrication into desired shapes and low cost has made plastic scintillator ideal for large detectors. In the form of scintillating fiber, it has found widespread use in tracking and calorimetry. Demand for large volume detectors (e.g. neutrino detectors: MiniBooNE, NOvA) has led to increased use of liquid scintillator, which can be very low cost.

35.3.1 *Scintillation mechanism*

Plastic and liquid scintillators are based on an aromatic "matrix" such as benzene. The p electrons form both "pi" and "sigma" bonds between the atoms; the pi bonds are responsible for scintillation. Scintillation is produced via standard photophysical interactions, shown schematically in Fig. 35.1. Via radiation-matter interactions, the matrix is excited to various singlet states. By internal conversion (which is non radiative), the system relaxes to the S_1 state. Vibrational relaxation can also lead to non-radiative decays from excited singlet states. Intersystem crossing occurs primarily for particles with large energy deposition per unit path length dE/dx, and can be be used for their identification. While there have been claims of delayed light production on long time scales (labeled "phosphorescence" in the figure), this is still a subject of active debate in the community. As aromatic molecules scintillate in the ultraviolet (UV), useful scintillators have one or several fluorophores dissolved into the matrix as dopants. Common fluorophores include 2,5-diphenyloxazole, *p*-terphenyl, 9,10-diphenylanthracene (9,10-DPA), 1,4-bis(2-methylstyryl)benzene (bis-MSB) and 1,4-bis(5-phenyl-2-oxazolyl)benzene (POPOP). The key aspects of their molecular structure include pi-conjugated systems and steric effects; in particular functional groups located on the aromatic rings strongly influence their scintillation performance. Each molecule has its own role: the matrix (whether liquid or plastic) is where most of the radiation/matter interaction occurs. Numerous publications have demonstrated the strong dependence of the scintillator's response to the fluorophores concentration. At high concentrations, the probability of quenching increases, and the light output generally plateaus. After radiation interaction, ions may recombine giving birth to excited molecules (excitons). Excitons in the matrix are transferred to a "primary fluorophore", whose concentration is typically 1-3 weight % in commercial plastic and liquid scintillators. This concentration is large enough to ensure exciton transfer – primarily via the Förster mechanism, a resonant dipole-dipole interaction which decreases at sixth the power of the distance between molecules. The concentration, however, can be up to the solubility limit. Transfer via the Förster mechanism increases both speed and light output of the organic scintillator. To

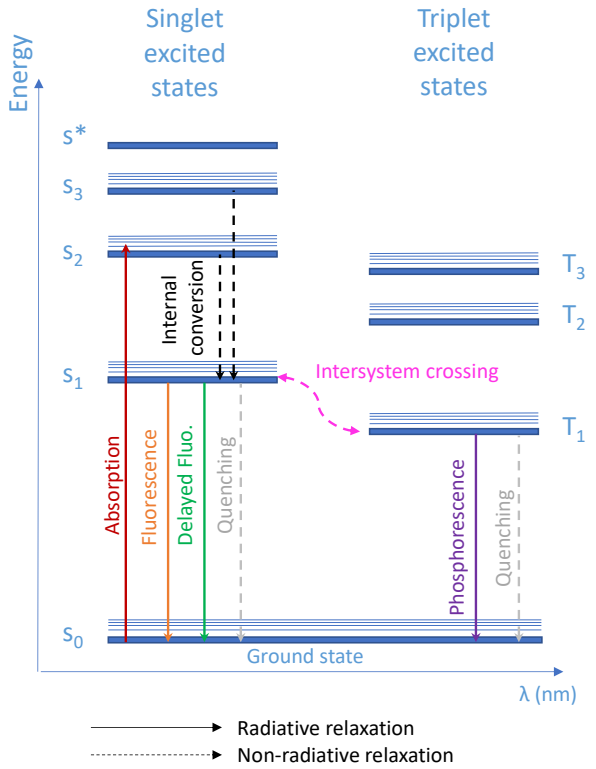

Figure 35.1: Schematic of scintillation mechanism. Schematic of typical excitation and de-excitation of matrix modules.

reduce reabsorption of the emitted light by the matrix or the primary fluorophore, and the resulting shortened attenuation length, a "secondary fluorophore" is also used to shift the light to longer wavelengths. Transfer from the primary to the secondary is generally radiative. Typical secondary concentrations in plastic and liquids are 0.01-0.2 weight %. The chain of emission and absorption from the matrix to the subsequent fluorophores is shown in Fig. 35.2.

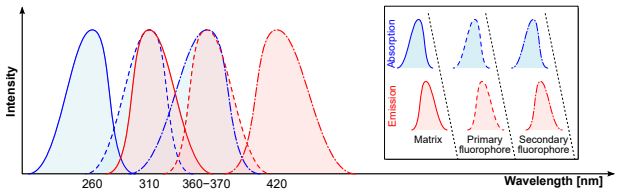

Figure 35.2: Schematic of scintillation mechanism. Typical emission and absorption spectra for the matrix, the primary, and the secondary fluorophore.

Scintillators with two fluorophores typically have absorption lengths of several meters. The longest attenuation lengths require a third fluorophore: when the matrix is transparent up to 1 cm, adding a primary fluorophore increases the light transmission up to ≈ 10 cm, whereas the ternary cocktail is transparent up to 2 m and longer [39].

For most scintillators, decay times are in the ns range; rise times are much faster. Sub-ns timing resolutions have been achieved [40].

Organic scintillators do not respond linearly to the ionization density. Very dense ionization tracks, with large dE/dx, emit less light than expected compared to minimum-ionizing particles. A widely used semi-empirical model by Birks posits that recombination and quenching effects between the excited molecules reduce the light yield [41]. These effects are more pronounced when the density of excited molecules is larger. Birks' formula is

$$\frac{d\mathcal{L}}{dx} = \mathcal{L}_0 \frac{dE/dx}{1 + kB\, dE/dx}, \tag{35.2}$$

where $\mathcal{L}$ is the luminescence, $\mathcal{L}_0$ is the luminescence at low specific ionization density, and the product kB is known as Birks' constant, which must be determined for each scintillator by measurement. The value of kB for polystyrene is 0.126 mm/MeV, which is large enough to play an important role in compensation in scintillator-based calorimetry. The high hydrogen content of plastic, which enhances the neutron interaction cross section, as well as its large mass stopping power, also contributes to calorimetry compensation. In the case of large or small [42] dE/dx values (e.g. with alpha particles or tritium, respectively), ion recombination may lead to the creation of triplet excited states instead of singlet excited states. If two triplet states are close enough (typically in the order of 10Å), then triplet-triplet annihilation may occur following the Dexter process [43], leading to delayed fluorescence. This phenomenon is useful for α/β or neutron/γ discrimination and is more efficient in liquid scintillators than in plastics due to the molecular motion.

Extensive research for new efficient molecules that can act as matrix, primary, or secondary fluorophores, is ongoing [44]. Other chemical modifications can affect the scintillator emission wavelength and decay time, or be used *e.g.* as stabilizers or to enhance thermal neutron sensitivity. Other parameters that can be modified are the density and the effective atomic number. Recently a new chemical formulation was developed for the search for double beta plus decays at the NuDoubt^{++} experiment. The new scintillator is a combination of hybrid ("slow" plastic scintillator for Cherenkov rejection) and opaque scintillator (to confine scintillation light through Mie scattering of optical photons) [45]. Also of note is a development related to the Mobile Antineutrino Demonstrator Project: embedding ^{6}Li-doped pulse shape discriminating plastic scintillators into 1 m long segments at 6 cm ×6,cm cross section assembled as a 2D array [46].

A major issue is efficiently choosing the most promising molecules, and so usually new organic scintillators are found via a lengthy trial-and-error procedure. A neural architecture built for organic molecule selection for sub-GeV dark matter detection [47] obtained promising results, notably by confirming the backbone of well-known fluorophores.

35.3.2 *Plastic scintillator practicalities*

Plastic scintillators are cheap, can be prepared at large volumes and purity, are reliable, robust, and convenient. Their high chemical versatility allows innovations in material science to open new research fields in high-energy physics. Most commercial plastic scintillators use either polystyrene (PS) or poly(vinyltoluene) (PVT) as matrix. A variety of manufacturing techniques [44] are used in the production of plastic scintillator. Cast plastic has the highest light yield, while extruded scintillator is less expensive and allows creation of the scintillator and coating with a diffusive reflector in a single process. 3D printing of plastic scintillator has also emerged as a reliable production method. The technique has been applied to plastics for pulse-shape discrimination [48] and 3D tracking [49]. However, large-scale production (10+ liters) has not yet been achieved. Plastic scintillator is also used to produce scintillating, wavelength-shifting, and clear fibers. These fibers can be useful to guide light to photodetectors, and as the active element in the type of calorimeter pioneered by the RD52/DREAM collaboration [50]. They have even been used in the construction of trackers [51,52]. A 3D-segmented detector for particle tracking and calorimetry has been achieved. SuperCube is a $5 \times 5 \times 5$ configuration of 1 cm^3 PS-based plastic scintillators prepared by additive manufacturing (fused deposition modeling) with embedded Kuraray Y11 wavelength-shifting fibers connected to Multi-Pixel Photon Counters [53].

Plastic scintillators are reliable, robust, and convenient. However, exposure to solvent vapors, high temperatures, mechanical flexing, irradiation, or rough handling will cause degradation. The surface is a particularly fragile region and can "craze" – develop microcracks which degrade transmission of light by total internal

reflection. Crazing is particularly likely where oils, solvents, or fingerprints have contacted the surface or when mechanical stresses are present. The light yield is influenced by several environmental factors: it decreases with the partial pressure of oxygen [54] and increases with increasing magnetic field [55]. In particular, the combination of elevated temperature with relative humidity accelerates aging. This apparent fogging is typically observed in radiation portal monitors, which are exposed to harsh environmental conditions. The aging can become irreversible after multiple cycles. Recently the T2K collaboration reported a 10-year light-yield measurement showing damage due to aging [56].

Plastics are susceptible to radiation damage [57, 58]. At high enough dose, the visible color of the plastic can change to yellow or even brown. The amount of damage for a fixed dose is higher at lower dose rates [59–61]. During irradiation, the transparency of the plastic decreases. When the irradiation ends, this can reverse and the transparency can increase ("anneal"). This process is faster in the presence of oxygen, which can diffuse into the plastic. Oxygen can also suppress temporary damage during irradiation, although this mechanism can be strongly suppressed at low enough temperatures [62]. The ratio of the light output to the unirradiated light output can roughly be parameterized as an exponential. For dose rates typical of current collider detectors at the Large Hadron Collider (from a few 10^{-3} to 10 Gy/hr), an exponential dose constant of tens of kGy is observed.

35.3.3 *Organic glass scintillators*

Starting in 2016, extensive research by Sandia National Laboratories lead to a new organic scintillator family: organic glasses (OGSs) [63]. Whereas polymers are long-chain molecules built from a standard unit called a monomer, OGSs consist of small organic molecules. In addition, polymers such as PS or PVT require dopants, when OGSs are intrinsically good scintillators. This new material has the useful properties present in inorganic single crystals (light yield, pulse-shape discrimination properties, along with fast-timing properties), without the poor mechanical characteristics seen in single crystals. The maintenance of the amorphous state of these bulk optical materials was achieved mainly either by using molecules with high configurational disorder or by introducing compositional disorder. OGSs can be prepared in medium to large scales when they are blended with polymers, or pixelated for neutron detection systems, and they can eventually be loaded with heavy elements. In 2021 Blueshift Optics secured a license from Sandia National Laboratories for the industrial production of OGSs.

35.3.4 *Liquid scintillator practicalities*

Liquid scintillators have been used in large scale neutrino experiments 36.3.1.1 due to their low cost. They can hermetically fill any vessel shape. Liquid scintillators are also, due to the mobility of the molecules, much less susceptible to radiation damage.

Care must be taken to avoid dissolved water, solvents such as isopropyl alcohol, and oxygen, which reduce light yield. As they can dissolve many materials (e.g. plastics, adhesives, paints..) care must be taken in their handling. Flammability concerns limit their use in practical experiments in intense radiation fields.

35.3.5 *Summary*

Table 35.4 summarizes some of the characteristics of and differences between plastic, liquid and organic glass scintillators.

35.4 Inorganic scintillators

Revised August 2025 by C.L. Woody (BNL) and R.-Y. Zhu (HEP California Inst. of Technology).

Inorganic crystals form a class of scintillating materials with much higher densities than organic plastic scintillators (typically $\sim$ 4–8 g/cm^3) with a variety of different properties for use as scintillation detectors. Due to their high density and high effective atomic number, they can be used in applications where high stopping power or a high conversion efficiency for electrons or photons is required. These include total absorption electromagnetic calorimeters (see Sec. 35.10.2), which consist of a totally active absorber (as opposed to a sampling calorimeter), and time of flight detectors as well as serving as gamma-ray detectors over a wide range of energies. Many of these crystals also have very high light output, and can therefore provide excellent energy resolution down to very low energies ($\sim$ few hundred keV).

Some crystals are intrinsic scintillators in which the luminescence is produced by a part of the crystal lattice itself. However, other crystals require the addition of a dopant, typically fluorescent ions such as thallium (Tl) or cerium (Ce), which is responsible for producing the scintillation light. However, in both cases, the scintillation mechanism is the same. For charged particles, energy is deposited in the crystal by ionization. For photons, energy is deposited by Compton electrons, photoelectrons, and electron-positron pairs, and the corresponding cross sections depend on the photon energy and the scintillator material. This energy is transferred to the luminescent centers which then radiate scintillation photons. The light yield LY in terms of the number of scintillation photons produced per MeV of energy deposited in the crystal can be expressed as [64]

$$LY = 10^6 \; S \cdot Q/(\beta \cdot E_g), \tag{35.3}$$

where $\beta \cdot E_g$ is the energy required to create an e-h pair expressed as a multiple of the band gap energy Eg (eV), S is the efficiency of energy transfer to the luminescent center and Q is the quantum efficiency of the luminescent center. The values of β, S and Q are crystal dependent and are the main factors in determining the intrinsic light yield of the scintillator. The decay time of the scintillator is mainly dominated by the decay time of the luminescent center.

Table-35.5 lists the basic properties of inorganic crystals commonly used in high energy or nuclear physics experiments. A

more extensive list of organic and inorganic scintillators and their properties can be found in [65], which describes the open access library https://scintillator.lbl.gov/.

NaI(Tl) is one of the most common and widely used scintillators, with an emission that is well matched to a bialkali photomultiplier tube, but it is highly hygroscopic and difficult to work with, and has a rather low density. CsI(Tl) and CsI(Na) have high light yield, low cost, and are mechanically robust (high plasticity and resistance to cracking). However, they need careful surface treatment and are slightly and highly hygroscopic respectively. Pure CsI has identical mechanical properties as CsI(Tl), but has a faster emission at shorter wavelength and a much lower light yield.

Undoped BaF_2 has a fast component with a less than 0.6 ns decay time, and is the fastest known scintillator. However, it also has a slow component with a much longer decay time ($\sim$ 630 ns). Bismuth gemanate ($Bi_4Ge_3O_{12}$ or BGO) has a high density, and consequently a short radiation length X_0 and Molière radius R_M. Similar to CsI(Tl), BGO's emission is well-matched to the spectral sensitivity of silicon photodiodes, and it is easy to handle and not hygroscopic. Lead tungstate ($PbWO_4$ or PWO) has a very high density, with a very short X_0 and R_M, but its intrinsic light yield is rather low.

Cerium doped lutetium oxyorthosilicate (Lu_2SiO_5:Ce, or LSO:Ce) [66] and cerium doped lutetium-yttrium oxyorthosilicate ($Lu_{2(1-x)}Y_{2x}SiO_5$, LYSO:Ce) [67] are dense crystal scintillators which have a high light yield and a fast decay time. Only the properties of LSO:Ce are listed in Table-35.5 since the properties of LYSO:Ce are similar to that of LSO:Ce except a slightly lower density than LSO:Ce depending on the yttrium fraction (typically 5 to 10%) in LYSO:Ce. This material also exhibits excellent radiation hardness [68, 69], and can be used where extraordinary radiation hardness is required, such as the HL-LHC and FCC-hh.

Also listed in Table-35.5 are other fluoride crystals such as PbF_2 , which is a Cherenkov material, and CeF_3, which has been shown to provide excellent energy resolution in calorimeter applications [70, 71]. Table-35.5 also includes lanthanum tri-halides, such as $LaBr_3$(Ce) [72] and $CeBr_3$ [73], which are brighter and faster than LSO:Ce, but are highly hygroscopic and have a lower density. The FWHM energy resolution measured for these materials coupled to a PMT with bi-alkali photocathode for 0.662 MeV γ-rays from a ^{137}Cs source is about 3%, and has been improved to 2% by co-doping with calcium and strontium [74], which is the best among all inorganic crystal scintillators. For this reason, $LaBr_3$(Ce) and $CeBr_3$ are used in applications where good energy resolution for low energy photons are required, such as homeland security.

Beside the crystals listed in Table-35.5, a number of newer crystals are being investigated that may have potential applications in high energy or nuclear physics. Of particular interest is the family of yttrium and lutetium perovskites and garnets, which include YAP ($YAlO_3$:Ce), LuAP ($LuAlO_3$:Ce), YAG ($Y_3Al_5O_{12}$:Ce), LuAG ($Lu_3Al_5O_{12}$:Ce), GAGG ($Gd_3Al_2Ga_3O_{12}$:Ce) and their mixed compositions. These have been shown to be linear over a large energy range [75], and have the potential for providing good intrinsic energy resolution. Cerium doped garnets (YAG, LuAG and GAGG) are also radiation hard [76–80], and have been proposed for future applications in a severe radiation environment.

Aiming at the best jet-mass resolution, inorganic scintillators are being investigated for HEP calorimeters with dual readout for both Cherenkov and scintillation light to be used at future lepton colliders. These materials may be used for an electromagnetic calorimeter [81] or a homogeneous hadronic calorimetry (HHCAL) detector concept, including both electromagnetic and hadronic parts [82, 83]. Because of the unprecedented volume (70 to 100 m^3) foreseen for the HHCAL detector concept, the materials must be dense to minimize the leakage and also cost-effective. It should also be UV transparent (for effective collection of the Cherenkov light) and allow for a clear discrimination between the Cherenkov and scintillation light. The preferred scintillation light is thus at a longer wavelength, and not necessarily bright or fast.

Scintillating glasses [84] offer a very attractive option where large volumes of scintillating material are required, such as for the HHCAL detector concept, and are currently under development for future collider applications. Recent investigations of cerium doped ABS (Aluminoborosilicate) [85,86] and DSB ($BaO \bullet 2SiO2$) [87, 88] show high density (6 and 4.3 g/cc respectively) for large samples heavily loaded with Gd. Their main limitation is a poorer optical quality, with light attenuation lengths at a level $\sim$ ten cm, as compared to longer than a meter for scintillating crystals used in total absorption calorimeters.

Fast scintillation light also provides timing information about electromagnetic interactions and showers, which may be used to mitigate pile-up effects and/or for particle identification, since the time development of electromagnetic and hadronic showers, as well as minimum ionizing particles, are different. The timing information is primarily determined by the scintillator rise time and decay time, and the number of photons produced. For fast timing, it is important to have a large number of photons emitted in the initial part of the scintillation pulse, e.g. in the first ns, since one is often measuring the arrival time of the particle

in the crystal using the leading edge of the light pulse. A good example of this is BaF_2, which has $\sim 10\%$ of its light in its fast component with a decay time of less than 0.6 ns. Investigations also show that doping BaF_2 with yttrium reduces its slow component significantly, while keeping its ultrafast scintillation component unchanged [89, 90]. Ultrafast crystals of this type provide the best timing resolution [91, 92]. However, light propagation can spread out the arrival time of the scintillation photons at the photodetector due to time dispersion [93]. The time response of the photodetector also plays a major role in achieving good time resolution with fast scintillating crystals.

In summary, the timing precision of a scintillation detector generally depends on five parameters: the rise and decay times of the scintillator, the time dispersion of optical photons in the scintillator, the time response and jitter of the photodetector signal for single photons, and the number of photons that produce the photodetector signal. The numerical formulas that estimate the timing precision as a function of these parameters can be found in [64].

Table-35.5 gives the light yield of other crystals relative to NaI(Tl) and their dependence to temperature variations. The light output was measured for 1.5 X_0 cube crystal samples with a Tyvek paper wrapping and a full end face coupled to a photodetector [94]. The quantum efficiency of the photodetector is taken out to facilitate a direct comparison of crystal's light yield. However, the measured light output produced by a scintillator is usually quoted in terms of the number of photoelectrons per MeV produced by a given photodetector. The relationship between the light yield (LY) in number of photons/MeV produced (N_{photons}/MeV) and the light output (LO) in number of photoelectrons/MeV detected involves the factors for the light collection efficiency (LCE) and the quantum efficiency (QE) of the photodetector:

$$LO = LY \cdot LCE \cdot QE. \tag{35.4}$$

LCE depends on the size and shape of the crystal sample, and includes effects such as the transmission of scintillation light within the crystal (i.e., the bulk attenuation length of the material), scattering from within the crystal, reflections and scattering from the crystal surfaces, and reflections back into the crystal by wrapping materials. These factors can vary considerably depending on the sample, but can be in the range of ∼10–60%. The internal light transmission depends on the intrinsic properties of the material, e.g. the density and type of scattering centers and defects that can produce internal absorption within the crystal, and can be highly affected by factors such as radiation damage, as discussed below.

The quantum efficiency depends on the type of photodetector used to detect the scintillation light, which is typically ∼15–30% for photomultiplier tubes and higher for silicon photodetectors for visible wavelengths. The response of the detector is usually highly wavelength dependent and should be matched to the particular crystal of interest to give the highest quantum yield at the wavelength corresponding to the peak of the scintillation emission. Fig. 35.3 shows the quantum efficiency for a Hamamatsu R2059 PMT with bi-alkali cathode and quartz window, and the photon detection efficiency (PDE) for a Hamamatsu S14160-3015ps multi-pixel photon counter (MPPC), which is also called a silicon photomultiplier (SiPM), as a function of wavelength. Also shown in the figure are emission spectra of three crystal scintillators, BGO, LSO:Ce/LYSO:Ce and CsI(Tl), and the numerical values of the emission weighted quantum efficiency. The area under each emission spectrum is proportional to crystal's light yield, as shown in Table-35.5, where the quantum efficiencies of the photodetector has been taken out. Results with different photodetectors can be significantly different. For example, the response of CsI(Tl) relative to NaI(Tl) with a standard photomultiplier tube with a bi-alkali photo-cathode (e.g. Hamamatsu R2059) would be 45% rather than 165% because of the photomultiplier's low quantum efficiency at longer wavelengths. For scintillators which emit in the UV, a detector with a quartz window should be used.

For very low energy applications (typically below 1 MeV), the non-proportionality of the scintillation light yield may be important. It has been known for a long time that the number of photons produced is not proportional to the absorbed energy. It is also known that the energy resolution measured by all crystal scintillators for low energy γ-rays is significantly worse than the contribution from photo-electron statistics alone, indicating an intrinsic contribution from the scintillator itself. Precision measurements using a low energy electron beam show that this non-proportionality is crystal dependent [95, 96]. Followup investigations have greatly improved our understanding on this issue [97–102].

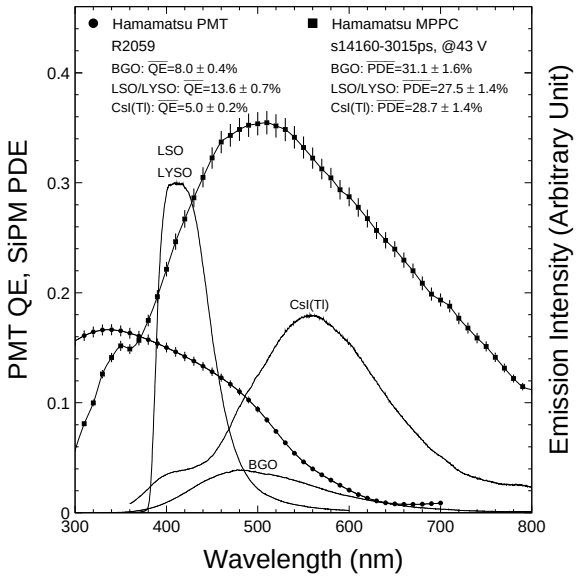

Figure 35.3: The quantum efficiency for a Hamamatsu R2059 PMT with bi-alkali cathode and quartz window and the particle detection efficiency (PDE) for a Hamamatsu S14160-3015ps multi-pixel photon counter (MPPC), which is also called a silicon photomultiplier (SiPM), are shown as a function of wavelength. Also shown in the figure are emission spectra of three crystal scintillators, BGO, LSO and CsI(Tl), and the numerical values of the emission weighted quantum efficiencies. The area under each emission spectrum is proportional to crystal's light yield.

One important issue related to the application of a crystal scintillator is its radiation hardness. Stability of its light output, or the ability to track and monitor the variation of its light output in a radiation environment, is required for high resolution and precision calibration [103]. All known crystal scintillators suffer from ionization dose induced radiation damage [104], where a common damage phenomenon is the appearance of radiation induced absorption caused by the formation of color centers originating from the impurities or point defects in the crystal. This radiation induced absorption reduces the light attenuation length in the crystal, and hence its light output. For crystals with high defect density, a severe reduction of light attenuation length may cause a distortion of the light response uniformity, leading to a degradation of the energy resolution. Additional radiation damage effects may include a reduced intrinsic scintillation light yield (damage to the luminescent centers) and an increased phosphorescence (afterglow). For crystals to be used in a high precision calorimeter in a radiation environment, its scintillation mechanism must not be damaged and its light attenuation length in the expected radiation environment must be long enough so that its light response uniformity, and thus its energy resolution, does not change.

While radiation damage induced by ionization dose is well understood [105], further investigations have been carried out to understand radiation damage caused by hadrons, including both charged hadrons [106] and neutrons [107]. Hadrons may cause damage by two additional fundamental processes: displacement damage and nuclear breakup. Charged hadrons can produce all three types of damage (and it's often difficult to separate them), but neutrons can only produce damage from the last two, and

Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 04/15/26. For personal use and distribution is strictly not permitted, except for Open Access articles.

electrons and photons only produce ionization damage. Studies on hadron induced radiation damage in lead tungstate [108] show a proton-specific damage component caused by fragments from fission induced in lead and tungsten by particles in the hadronic shower. The fragments cause severe, local damage to the crystalline lattice due to their extremely high energy loss over a short distance [108]. An investigation also shows evidence of neutron-specfic damage in various crystals [107]. A more extensive list of investigations on this topic can be found in https://www.its.caltech.edu/~rzhu/.

Most of the crystals listed in Table-35.5 have been used in high energy or nuclear physics experiments when the ultimate energy resolution for electrons and photons is desired, as discussed in Sec. 35.10.2. Examples are the Crystal Ball NaI(Tl) calorimeter at SPEAR, the L3 BGO calorimeter at LEP, the CLEO CsI(Tl) calorimeter at CESR, the KTeV CsI calorimeter at the Tevatron, and the BaBar, BELLE and BES III CsI(Tl) calorimeters at PEP-II, KEK and BEPC II, respectively. Because of their high density and relatively low cost, PWO calorimeters have been used by CMS and ALICE at LHC, by CLAS and PrimEx at CEBAF, and by PANDA at GSI, and is planned to be used for the Backward Endcap Calorimeter for the ePIC experiment at the EIC. Similarly, PbF_2 calorimeters are used by the A4 experiment at MAINZ and by the g-2 experiment at Fermilab. CsI calorimeters are used by KTeV at Fermilab and by the Mu2e experiment at Fermilab. LYSO:Ce crystals are used by the COMET experiment at J-PARC, and by the CMS experiment to build a precision timing layer for the HL-LHC. GAGG:Ce crystals are considered as a candidate scintillator for the LHCb ECAL upgrade for the HL-LHC. Heavy scintillating glass, BaF_2:Y crystal and LuAG:Ce ceramics are considered for CEPC/FCC-ee, Mu2e-II and FCC-hh, respectively.

35.5 Cherenkov detectors

Revised March 2026 by J. Schwiening (GSI Darmstadt).

Although devices using Cherenkov radiation are often thought of as only particle identification (PID) detectors, in practice they are used over a much broader range of applications including; (1) fast particle counters; (2) hadronic PID; (3) electromagnetic calorimeters (EMC); and (4) tracking detectors performing complete event reconstruction. Examples of applications from each category include; (1) the BaBar luminosity detector [109] and the Quartic fast timing counter for the ATLAS Forward Proton Detector, designed to measure small angle scatters at the LHC [110]; (2) the hadronic PID detectors at the B factory detectors—DIRC in BaBar [111], and the modern Imaging Aerogel and TOP counters at Belle II [112]; (3) the CMS Hadron Forward calorimeter based on Cherenkov light emitted in quartz fibers embedded in a steel absorber [113]; and (4) large water Cherenkov counters such as Super-Kamiokande [114].

Cherenkov counters contain two main elements; (1) a radiator through which the charged particle passes, and (2) a photodetector. As Cherenkov radiation is a weak source of photons, light collection and detection must be as efficient as possible. The refractive index n and the particle's path length through the radiator L appear in the Cherenkov relations allowing the tuning of these quantities for particular applications. One or more of the properties of Cherenkov radiation discussed in the Passages of Particles through Matter section (Sec. 34 of this *Review*) are utilized in Cherenkov detectors: the prompt emission of a light pulse; the existence of a velocity threshold for radiation; and the dependence of the Cherenkov cone half-angle θ_c and the number of emitted photons on the velocity of the particle v_p and the refractive index n of the medium. The Cherenkov angle can be calculated as

$$\cos\theta_c = \frac{1}{n(E)\beta}, \tag{35.5}$$

where $\beta = v_p/c$ with c being the speed of light, and E the photon energy. The number of photoelectrons ($N_{\rm p.e.}$) detected in a given device with radiator of length L is

$$N_{\rm p.e.} = L\frac{\alpha^2 z^2}{r_e\, m_e c^2}\int \epsilon(E)\, \sin^2\theta_c(E) dE, \tag{35.6}$$

where $\epsilon(E)$ is the efficiency for collecting the Cherenkov light and transducing it into photoelectrons, and $\alpha^2/(r_e\, m_e c^2) = 370\ \mathrm{cm^{-1}eV^{-1}}$. The quantities ϵ and θ_c are functions of the photon energy. As the typical energy dependent variation of the index of refraction is modest, a quantity called the *Cherenkov detector quality factor* N_0 can be defined as

$$N_0 = \frac{\alpha^2 z^2}{r_e\, m_e c^2}\int \epsilon\, dE, \tag{35.7}$$

so that, taking the charge number $z = 1$ (the usual case in high-energy physics),

$$N_{\rm p.e.} \approx L N_0 \langle \sin^2\theta_c\rangle. \tag{35.8}$$

This definition of the quality factor N_0 is not universal, nor, indeed, very useful for those common situations where ϵ factorizes as $\epsilon = \epsilon_{\rm coll}\epsilon_{\rm det}$ with the geometrical photon collection efficiency ($\epsilon_{\rm coll}$) varying substantially for different tracks while the photon detector efficiency ($\epsilon_{\rm det}$) remains nearly track independent. In this case, it can be useful to explicitly remove ($\epsilon_{\rm coll}$) from the definition of N_0. A typical value of N_0 for a photomultiplier (PMT) detection system working in the visible and near UV, and collecting most of the Cherenkov light, is about 100 $\mathrm{cm^{-1}}$. Practical counters, utilizing a variety of different photodetectors, have values ranging between about 30 and 180 $\mathrm{cm^{-1}}$. Radiators can be chosen from a variety of transparent materials (Sec. 34 of this *Review* and Table 6). In addition to refractive index, the choice requires consideration of factors such as material density, radiation length and radiation hardness, transmission bandwidth, absorption length, chromatic dispersion, optical workability (for solids), availability, environmental impact, and cost. When the momenta of particles to be identified is high, the refractive index must be set close to one, so that the photon yield per unit length is low and a long particle path in the radiator is required. In recent years, the gap in refractive index that has traditionally existed between gases and liquid or solid materials has been partially closed with transparent *silica aerogels* with indices that range between about 1.003 and 1.26. Due to the potential ability to tune the refractive index to the exact requirements of an experiment, metamaterials, including photonic crystals, are being investigated as radiators for future Cherenkov counters [115–117].

Cherenkov counters may be classified as either *imaging* or *threshold* types, depending on whether they do or do not make use of Cherenkov angle (θ_c) information. Imaging counters may be used to track particles as well as identify them. The recent development of very fast photodetectors such as micro-channel plate PMTs (MCP-PMT) (see 35.2 of this *Review*) also potentially allows very fast Cherenkov based time of flight (TOF) detectors of either class [115–117]. The track timing resolution of imaging detectors can be extremely good as it scales approximately as $\frac{1}{\sqrt{N_{\rm p.e.}}}$.

Threshold Cherenkov detectors [118], in their simplest form, make a yes/no decision based on whether the particle is above or below the Cherenkov threshold velocity $\beta_t = 1/n$. A straightforward enhancement of such detectors uses the number of observed photoelectrons (or a calibrated pulse height) to discriminate between species or to set probabilities for each particle species [119]. This strategy can increase the momentum range of particle separation by a modest amount (to a momentum some 20% above the threshold momentum of the heavier particle in a typical case).

Careful designs give $\langle\epsilon_{\rm coll}\rangle \gtrsim 90\%$. For a photomultiplier with a typical bialkali cathode, $\int \epsilon_{\rm det} dE \approx 0.27$ eV, so that

$$N_{\rm p.e.}/L \approx 90\ \mathrm{cm^{-1}}\ \langle\sin^2\theta_c\rangle \qquad (i.e.,\ N_0 = 90\ \mathrm{cm^{-1}}). \tag{35.9}$$

Suppose, for example, that n is chosen so that the threshold for species a is p_t; that is, at this momentum species a has velocity

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

$\beta_a = 1/n$. A second, lighter, species b with the same momentum has velocity β_b, so $\cos\theta_c = \beta_a/\beta_b$, and

$$N_{\rm p.e.}/L \approx 90\ {\rm cm}^{-1}\ \frac{m_a^2 - m_b^2}{p_t^2 + m_a^2}. \tag{35.10}$$

For K/π separation at $p = p_t = 1(5)$ GeV/c, $N_{\rm p.e.}/L \approx 16(0.8)$ cm^{-1} for π's and (by design) 0 for K's.

For limited path lengths $N_{\rm p.e.}$ will usually be small. The overall efficiency of the device is controlled by Poisson fluctuations, which can be especially critical for separation of species where one particle type is dominant. Moreover, the effective number of photoelectrons is often less than the average number calculated above due to additional equivalent noise from the photodetector (see the discussion of the excess noise factor in 35.2 of this *Review*). It is common to design for at least 10 photoelectrons for the high velocity particle in order to obtain a robust counter. As rejection of the particle that is below threshold depends on *not* seeing a signal, electronic and other background noise, especially overlapping tracks, can be important. Physics sources of light production for the below threshold particle, such as decay to an above threshold particle, scintillation light, or the production of delta rays in the radiator, often limit the separation attainable, and need to be carefully considered. Well designed, modern multi-channel counters, such as the ACC at Belle [120], can attain adequate particle separation performance over a substantial momentum range.

Imaging counters make the most powerful use of the information available by measuring the ring-correlated angles of emission of the individual Cherenkov photons. They typically provide positive ID information both for the "wanted" and the "unwanted" particles, thus reducing mis-identification substantially. Since low-energy photon detectors can measure only the position (and, perhaps, a precise detection time) of the individual Cherenkov photons (not the angles directly), the photons must be "imaged" onto a detector so that their angles can be derived [121]. Typically the optics map the Cherenkov cone onto (a portion of) a distorted "circle" at the photodetector. Though the imaging process is directly analogous to familiar imaging techniques used in telescopes and other optical instruments, there is a somewhat bewildering variety of methods used in a wide variety of counter types with different names. Some of the imaging methods used include (1) focusing by a lens or mirror; (2) proximity focusing (i.e., focusing by limiting the emission region of the radiation); and (3) focusing through an aperture (a pinhole). In addition, the prompt Cherenkov emission coupled with the speed of some modern photon detectors allows the use of (4) time imaging, a method which is little used in conventional imaging technology, and may allow some separation with particle TOF. Finally, (5) correlated tracking (and event reconstruction) can be performed in large water counters by combining the individual space position and time of each photon together with the constraint that Cherenkov photons are emitted from each track at the same polar angle (Sec. 36.3.1of this *Review*).

In a simple model of an imaging PID counter, the fractional error on the particle velocity (δ_β) is given by

$$\delta_\beta = \frac{\sigma_\beta}{\beta} = \tan\theta_c \sigma(\theta_c)\ , \tag{35.11}$$

where

$$\sigma(\theta_c) = \frac{\langle\sigma(\theta_i)\rangle}{\sqrt{N_{\rm p.e.}}} \oplus C, \tag{35.12}$$

and $\langle\sigma(\theta_i)\rangle$ is the average single photoelectron resolution, as defined by the optics, detector resolution and the intrinsic chromaticity spread of the radiator index of refraction averaged over the photon detection bandwidth. C combines a number of other contributions to resolution including, (1) correlated terms such as tracking, alignment, and multiple scattering, (2) hit ambiguities, (3) background hits from random sources, and (4) hits coming from other tracks. The actual separation performance is also limited by physics effects such as decays in flight and particle interactions in the material of the detector. In many practical cases, the performance is limited by these effects.

For a $\beta \approx 1$ particle of momentum (p) well above threshold entering a radiator with index of refraction (n), the number of σ separation (N_σ) between particles of mass m_1 and m_2 is approximately

$$N_\sigma \approx \frac{|m_1^2 - m_2^2|}{2p^2\sigma(\theta_c)\sqrt{n^2-1}}. \tag{35.13}$$

In practical counters, the angular resolution term $\sigma(\theta_c)$ varies between about 0.1 and 5 mrad depending on the size, radiator, and photodetector type of the particular counter. The range of momenta over which a particular counter can separate particle species extends from the point at which the number of photons emitted becomes sufficient for the counter to operate efficiently as a threshold device (∼20% above the threshold for the lighter species) to the value in the imaging region given by the equation above. For example, for $\sigma(\theta_c)$ =2 mrad, a fused silica radiator ($n = 1.474$), or a fluorocarbon gas radiator (C_5F_{12}, $n = 1.0017$), would separate π/K's from the threshold region starting around 0.15(3) GeV/c through the imaging region up to about 4.2(18) GeV/c at better than 3σ.

Many different imaging counters have been built during the last several decades [115–117]. Among the earliest examples of this class of counters are the very limited acceptance *Differential Cherenkov detectors*, designed for particle selection in high momentum beam lines. These devices use optical focusing and/or geometrical masking to select particles having velocities in a specified region. With careful design, a velocity resolution of $\sigma_\beta/\beta \approx 10^{-4}$–$10^{-5}$ can be obtained [118].

Practical multi-track *Ring-Imaging Cherenkov detectors* (generically called RICH counters) are a more recent development. RICH counters are sometimes further classified by 'generations' that differ based on historical timing, performance, design, and photodetection techniques. Prototypical examples of first generation RICH counters are those used in the DELPHI and SLD detectors at the LEP and SLC Z factory e^+e^- colliders [115–117]. They have both liquid (C_6F_{14}, $n = 1.276$) and gas (C_5F_{12}, $n = 1.0017$) radiators, the former being proximity imaged with the latter using mirrors. The phototransducers are a TPC/wire-chamber combination. They are made sensitive to photons by doping the TPC gas (usually, ethane/methane) with ∼ 0.05% TMAE (tetrakis(dimethylamino)ethylene). Great attention to detail is required, (1) to avoid absorbing the UV photons to which TMAE is sensitive, (2) to avoid absorbing the single photoelectrons as they drift in the long TPC, and (3) to keep the chemically active TMAE vapor from interacting with materials in the system. In spite of their unforgiving operational characteristics, these counters attained good $e/\pi/K/p$ separation over wide momentum ranges (from about 0.25 to 20 GeV/c) during several years of operation at LEP and SLC. Related but smaller acceptance devices include the OMEGA RICH at the CERN SPS, and the RICH in the balloon-borne CAPRICE detector [115–117]. Despite their excellent match to the radiator requirement for gaseous RICHes, saturated fluorocarbons may soon need to be replaced due to their high global warming impact. Possible alternatives for a similar refractive index include hydrofluoroolefins or Argon, pressurized at a few bar [115–117].

Later generation counters [115–117] generally operate at much higher rates, with more detection channels, than the first generation detectors just described. They also utilize faster, more forgiving photon detectors, covering different photon detection bandwidths. Radiator choices have broadened to include materials such as lithium fluoride, fused silica, and aerogel.

Vacuum-based photodetection systems (*e.g.*, single or multi anode PMTs, MCP-PMTs, or hybrid photodiodes (HPD)) have become increasingly common (see 35.2 of this *Review*). They handle high rates, and can be used with a wide choice of radiators. Examples include (1) the SELEX RICH at Fermilab, which mirror focuses the Cherenkov photons from a neon radiator onto a camera array made of ∼ 2000 PMTs to separate hadrons over a wide momentum range (to well above 200 GeV/c for heavy hadrons);(2) the NA62 RICH at CERN, which uses a 17 m long tank filled with neon gas as radiator and spherical mirrors to focus the photons on two arrays of 2 000 PMTs to separate pions from muons for momenta between 15 and 35 GeV/c; (3) the CBM RICH under

Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 12/12/25. For personal use and distribution is strictly not permitted, except for Open Access articles.

construction at FAIR where the Cherenkov photons, produced in about 30 m^3 of CO_2 radiator gas, are mirror-focused on arrays of multi-anode PMTs (MaPMTs) with a total of about 55,000 pixels, to identify electrons with momenta up to 8 GeV/c; and (4) the LHCb detector now running at the LHC. It uses two separate counters. One volume contains C_4F_{10} (originally in combination with aerogel, which was removed in 2015) while the second volume contains CF_4. Photons are mirror-focused onto arrays of photon detectors to cover a π/K separation momentum range between 1 and 150 GeV/c. Additional upgrades, including the replacement of the HPDs by MaPMTs and improved readout electronics, were performed to deal with increases in luminosity.

Other fast detection systems that use solid cesium iodide (CsI) photocathodes or triethylamine (TEA) doping in proportional chambers are useful with certain radiator types and geometries. Examples include (1) the CLEO-III RICH at CESR that uses a LiF radiator with TEA doped proportional chambers; (2) the ALICE detector at the LHC that uses proximity focused liquid (C_6F_{14} radiators and solid CsI photocathodes (similar photodectors have been used for several years by the HADES and COMPASS detectors), and the hadron blind detector (HBD) in the PHENIX detector at RHIC that couples a low index CF_4 radiator to a photodetector based on electron multiplier (GEM) chambers with reflective CsI photocathodes [115–117].

Recent technological advances in the production of aerogel with improved transparency in the UV range and finely tuned refractive indices enable several new RICH designs. The innovative hybrid geometry of the CLAS12 RICH, with complex photon paths that feature multiple passes through the aerogel tiles, is only possible due to the improved scattering length of the aerogel. It minimizes the material inside of the detector acceptance as well as the size and cost of the photon sensor array. Beam tests have demonstrated that the counter will be able to provide clean π/K separation up to 8 GeV/c. The forward endcap Aerogel RICH (ARICH) for the Belle II upgrade at KEKB, designed to provide clean π/K separation for momenta up to 3.5 GeV/c, is an example of the so-called focusing aerogel approach [122]. The radiator is a dual-layer aerogel, with a thickness of 20 mm for each layer and increasing refractive indices of $n = 1.045$ and $n = 1.055$ along the particle path. The Cherenkov ring images from the two layers overlap on the array of Hybrid Avalanche Photo Detectors (HAPDs), which provide efficient single photon detection in the 1.5 T magnetic field.

A DIRC (Detection [of] Internally Reflected Cherenkov [light]) is a distinctive, compact RICH subtype first used in the BaBar detector [111]. A DIRC "inverts" the usual RICH principle for use of light from the radiator by collecting and imaging the total internally reflected light rather than the transmitted light. It utilizes the optical material of the radiator in two ways, simultaneously: as a Cherenkov radiator and as a light pipe. The magnitudes of the photon angles are preserved during transport by the flat, rectangular cross section radiators, allowing the photons to be efficiently transported to a detector outside the path of the particle where they may be imaged in up to three independent dimensions (the usual two in space and, due to the long photon paths lengths, one in time). Because the index of refraction in the radiator is large ($n \sim 1.47$ for fused silica), the momentum range with good π/K separation goes up to 4–5 GeV/c. It is plausible, but difficult, to extend it up to about 10 GeV/c with an improved design.

The BaBar experiment at the asymmetric PEP-II e^+e^- collider studied CP violation in $\Upsilon(4S)$ decays. Excellent pion/kaon separation for particle momenta up to 4 GeV/c was required. The BaBar DIRC used 4.9 m long, rectangular bars made from synthetic fused silica as radiator and light guide. The photons were imaged via a "pin-hole" through an expansion region filled with 6 000 liters of purified water onto an array of 10 752 densely packed photomultiplier tubes placed at a distance of about 1.2 m from the bar end. During more than 8 years of operation, the BaBar DIRC achieved π/K separation of 2.5 standard deviations or more up to 4 GeV/c momentum. For a pion identification rate around 85% the DIRC provided a kaon misidentification rate well below 1% up to 3 GeV/c.

The next generation of DIRC detectors [123] takes advantage of the new, very fast, pixelated photodetectors becoming available, such as MaPMTs and MCP-PMTs. They typically utilize either time imaging or lens/mirror-focused optics, or both, leading not only to a precision measurement of the Cherenkov angle, but in some cases, to a precise measurement of the particle time of flight, and/or to correction of the chromatic dispersion in the radiator. Examples [115–117] include (1) the Belle II Time of Propagation (TOP) counter that emphasizes precision timing for both Cherenkov imaging and TOF to perform π/K separation of at least 3 standard deviations up to 4 GeV/c; (2) the DIRC upgrade of the GlueX experiment at Jefferson Lab that places four decommissioned BaBar DIRC modules, coupled to upgraded optics and readout, perpendicular to the beamline, the first application of a DIRC in a detector endcap; (3) the high-performance DIRC for the ePIC detector at the EIC, to be installed in 2032, that will combine lens focusing with fast photon time imaging and is expected to provide more than 3 standard deviations π/K separation up to 6 GeV/c; and (4) the TORCH counter being developed for an LHCb upgrade in 2034 which uses DIRC imaging for individual photons with fast photon detectors to provide π/K separation up to 10 GeV/c via particle TOF with a precision of 10-15 ps per particle over a flight path length of 9.5 m.

35.6 Gaseous detectors

35.6.1 *Energy loss and charge transport in gases*

Revised August 2025 by P. Gasik (GSI Darmstadt; FAIR Darmstadt; Technische U., Darmstadt).

Gas-filled detectors rely on localized ionization produced by ionizing particles—charged particles or photons (via photoelectrons)—typically followed by charge multiplication. The statistics of ionization processes, which exhibit asymmetries in the ionization trails, impact the coordinate determination derived from measurements of drift time or the center of gravity of the collected charge. For thin gas layers, the width of the energy loss distribution can be larger than its average, requiring multi-sampling devices or truncated mean analysis for reliable particle identification. In the truncated mean method for calculating $\langle \mathrm{d}E/\mathrm{d}x \rangle$, the ionization measurements along the particle track are divided into many samples, and a fixed fraction of high-side (and sometimes low-side) values are discarded [124].

Table 35.6: Properties of noble and molecular gases at normal temperature and pressure (NTP: 20° C, 1 atm). E_X, E_I: first excitation, ionization energy; W_I: average energy for creation of electron-ion pair; $\mathrm{d}E/\mathrm{d}x|_{\min}$, N_P, N_T: differential energy loss, primary and total number of electron-ion pairs per cm, for unit-charge minimum ionizing particles. Values often vary, depending on the source, and those in the table should be considered approximate.

Gas	Density, mg cm^{-3}	E_X eV	E_I eV	W_I eV	$\mathrm{d}E/\mathrm{d}x\|_{\min}$ keV cm^{-1}	N_P cm^{-1}	N_T cm^{-1}

The energy loss of charged particles and photons in matter is discussed in Sec. 34. Every ionization process is a quantum mechanical transition initiated by the Coulomb field of the particle and the field created by neighbouring polarizable atoms. The average energy losses are described by the Bethe-Bloch formula with Sternheimer's density effect corrections. The fluctuations caused by Rutherford scattering on quasi-free electrons follow a Landau distribution and the influence of atomic shells is described by the

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

photoabsorption ionization (PAI) model, which allows simulation of each energy transfer [125], with relaxation cascades and simulation of delta-electrons [126]. Table 35.6 provides values of relevant parameters in some commonly used gases at NTP for unit-charge minimum ionizing particles (MIPs) [127] [128]. When an ionizing particle passes through a gas, it produces electron-ion pairs. In many cases, the ejected (primary) electrons possess enough energy to further ionize the medium, giving rise to secondary ionizations. These secondary electrons are generated in the immediate vicinity of the primary ionization site, and together with the primary electrons, they form clusters consisting of one, several, or sometimes many electron-ion pairs. The probability distribution describing the number of electron-ion pairs – both primary and secondary – produced in a single ionization encounter is referred to as the cluster-size distribution. As shown in Table 35.6, the total number of pairs ($N_{\rm T}$) is a few times larger than the number of primaries ($N_{\rm P}$). For different conditions and for mixtures, and neglecting energy transfer processes (*e.g.* Penning effect), one can scale the density, $N_{\rm P}$, and $N_{\rm T}$ with temperature and pressure assuming a perfect gas law.

The probability for a released electron to have an energy E or larger follows an approximate $1/E^2$ dependence (Rutherford law), shown in Fig. 35.4 for Ar at NTP (dotted line, left scale). More detailed estimates taking into account the electronic structure of the medium are shown in the figure, for three values of the particle velocity factor $\beta\gamma$ [129]. The dot-dashed line provides, on the right scale, the practical range of electrons (including scattering) of energy E. As an example, about 0.6% of released electrons have 1 keV or more energy, substantially increasing the total ionization loss. The practical range of 1 keV electrons in argon is approximately 70 μm, which can contribute to the uncertainty in the coordinate determination.

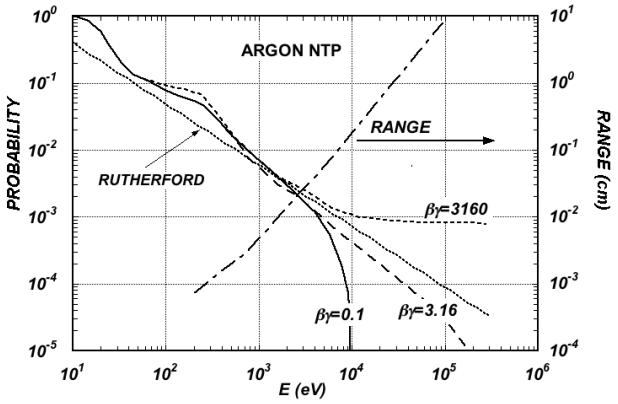

Figure 35.4: Probability of single collisions in which released electrons have an energy E or larger (left scale) and practical range of electrons in Ar at NTP (dot-dashed curve, right scale) [129].

Garfield^{++} [130], together with HEED [126], Degrad [131], Magboltz [132,133], SRIM, ANSYS, COMSOL, and neBEM [134] software packages represent the core simulation tools for microscopic modeling of gaseous detector response. The number of electron-ion pairs per primary ionization, or cluster size, depends little on the medium; it can be computed with the programs mentioned above or experimentally measured. For example, there is about 3% probability for primary clusters to contain ten or more electron-ion pairs in argon [135].

Once released into the gas, electrons and ions drift in opposite directions under the influence of an applied electric field, while simultaneously undergoing diffusion. The electron-molecule collision cross sections are determined by the details of atomic and molecular structure and depend strongly on the electron energy and therefore on the electric field $\boldsymbol{E}$ for most gases. High values of the total electron scattering cross section reduce the electron diffusion and increase the drift velocity; a large inelasticity implies that high fields are required to raise the electron energy. For noble gases, the inelastic cross section is zero until the electrons reach the first excitation and ionization energies, which are on the order of 10 eV; on the contrary, for molecular gases, like CH_4, inelastic channels, involving rotational and vibrational levels, open up at energies above ∼0.1 eV. Large drift velocities are achieved by adding polyatomic gases (usually hydrocarbons $C_x H_y$, CO_2, CF_4) which have significant inelastic scattering components at moderate electron energies of a few electronvolts; this results in the electron "cooling" into the energy range of the Ramsauer-Townsend minimum (∼0.3 eV in argon) of the elastic ("momentum-transfer") cross-section [128]. Similar to argon, krypton, and xenon also show the Ramsauer-Townsend minimum, while helium and neon do not. Under these circumstances, it is clear that the addition of very small quantities of one gas to another can dramatically modify the average electron energy and alter the dependence of the drift velocity ($v_{\rm d}$) on $\boldsymbol{E}/p$, where p is the gas pressure, and temperature T; this has a particularly strong effect for noble gases, as illustrated in Fig. 35.5 for argon. Carbon tetrafluoride (CF_4) has the largest drift velocity and the lowest electron diffusion among known gases due to the sizeable Ramsauer-Townsend dip in the elastic cross-section, which coincides with very large vibrational modes. Another principal role of the polyatomic gas is to absorb the ultraviolet photons emitted by the excited noble gas atoms. Addition of molecular gases (hydrocarbons or CO_2 is widely used in the proportional counters as a quencher) to noble gas allows to dissipate a good fraction of energy through rotational and vibrational radiationless transitions without the creation of photons or ions. On the contrary, CF_4 has a small quenching cross-section of excited Ar states and light emission in CF_4 (from the far UV to the visible light) is a complex process, involving the creation of CF_3^+ excited states [136].

Extensive collections of experimental data [137] and theoretical calculations based on transport theory permit evaluation of drift and diffusion properties in pure gases and their mixtures. Modern compilations of the electron-molecule cross sections are available at the open-access website LXCAT [138]. Fig. 35.5 and Fig. 35.6 show the drift velocity as well as transverse and longitudinal diffusion for some commonly used gases at NTP, computed with the Magboltz program [132, 133]. For different conditions, the horizontal axis must be scaled inversely with the gas density. The standard deviations for longitudinal ($\sigma_{\rm L}$) and transverse diffusion ($\sigma_{\rm T}$) are specified per centimeter of drift and scale with the square root of the drift distance.

In a simple approximation, gas kinetic theory provides the drift velocity $v_{\rm d}$ as a function of the mean collision time τ and the electric field E: $v_{\rm d} = eE\tau/m_e$ (Townsend's expression). In the presence of an external magnetic field, the Lorentz force acting on electrons between collisions deflects the drifting electrons and modifies the drift properties. The electron trajectories, velocities and diffusion parameters can be computed with Magboltz. The friction force model provides an approximate expression for the vector drift velocity $\boldsymbol{v_{\rm d}}$ as a function of electric and magnetic field vectors $\boldsymbol{E}$ and $\boldsymbol{B}$, of the Larmor frequency $\omega = eB/m_e$, and of the mean collision time τ (a more precise calculation is available in Magboltz, which computes the drift velocity by tracing electrons at the microscopic level through numerous collisions with gas molecules):

$$\boldsymbol{v_{\rm d}} = \frac{e}{m_e}\,\frac{\tau}{1+\omega^2\tau^2}\left(\boldsymbol{E} + \frac{\omega\tau}{B}(\boldsymbol{E}\times\boldsymbol{B}) + \frac{\omega^2\tau^2}{B^2}(\boldsymbol{E}\cdot\boldsymbol{B})\boldsymbol{B}\right) \quad (35.14)$$

To a good approximation, and for moderate fields, one can assume that the energy of the electrons is not affected by the magnetic field, and use for τ the values deduced from the drift velocity at $B = 0$ (Townsend's expression). For $\boldsymbol{E}$ perpendicular to $\boldsymbol{B}$, the drift angle relative to the electric field vector is $\tan\theta_{\rm B} = \omega\tau$ and $v_{\rm d} = (E/B)(\omega\tau/\sqrt{1+\omega^2\tau^2})$. For parallel electric and magnetic fields, the drift velocity and longitudinal diffusion are not affected, whereas the transverse diffusion can be strongly reduced: $\sigma_{\rm T}(B) = \sigma_{\rm T}(B=0)/\sqrt{1+\omega^2\tau^2}$. As an example, the dotted line in Fig. 35.6 represents $\sigma_{\rm T}$ for the classic Ar-CH_4 (90-10) mixture at 4 T. Large values of $\omega\tau \approx 20$ at 5 T are consistent with the measurement of the diffusion coefficient in Ar-CF_4-iC_4H_{10} (95-3-2). This reduction is exploited to substantially improve spatial resolution in the Drift (Sec. 35.6.2) and Time Projection Chambers (Sec. 35.6.4).

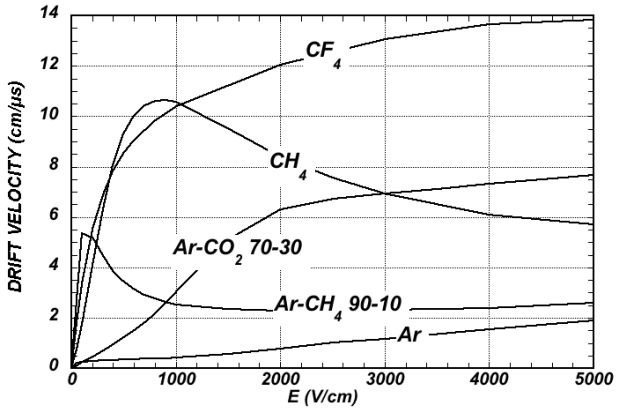

Figure 35.5: Computed electron drift velocity as a function of electric field in several gases at NTP and $B = 0$ [132, 133].

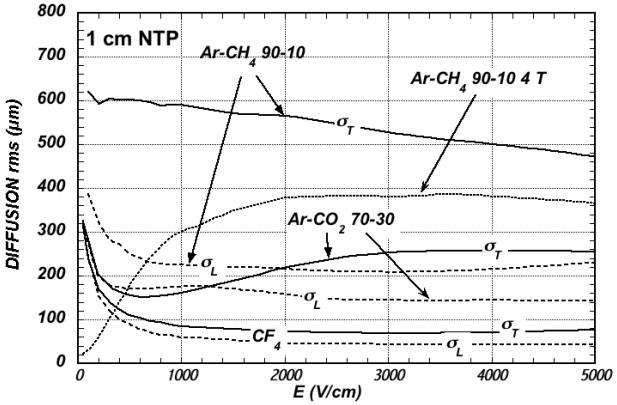

Figure 35.6: Electron longitudinal diffusion ($\sigma_{\rm L}$) (dashed lines) and transverse diffusion ($\sigma_{\rm T}$) (full lines) for 1 cm of drift at NTP and $B = 0$. The dotted line shows $\sigma_{\rm T}$ for the P10 mixture at 4 T [132, 133].

In some mixtures containing molecules with electronic affinity, electrons can be captured to form negative ions. Capture cross sections vary considerably with energy and, hence, the electric field. As a consequence, the three-body electron attachment coefficients may differ significantly for the same additive in different mixtures. As an example, at moderate fields (up to 1 kV/cm), the addition of 0.1% of oxygen to an Ar-CO_2 mixture results in an electron capture probability about twenty times larger than in Ar-CH_4. Among common molecules, the largest electron affinities are found for the halogenides, O_2 and H_2O. The attachment probability in O_2 or H_2O is large at low fields and electron energies close to thermal, but decreases at increasing fields. On the contrary, CF_4 is not electronegative at low and moderate fields, but has a large electron capture cross section at fields above ∼8 kV/cm, before reaching the avalanche field strengths. Depending on the exact mixture and detector geometry, some signal reduction and energy resolution loss is expected in this gas.

If the electric field is increased sufficiently, electrons gain enough energy between collisions to excite and ionize molecules. Above a gas-dependent threshold, the mean free path for ionization, λ_i, decreases exponentially with the field; its inverse, $\alpha = 1/\lambda_i$, is named the first Townsend coefficient. Free charges originally deposited in the chamber volume are multiplied in the electron avalanche process. Gains of the order of 10^5–10^6 can be achieved, and the detected charge is proportional, via the multiplication factor, to the primary charge liberated by the incoming particle. The detector is operated in the proportional counter mode. In uniform fields, N_0 initial electrons multiply over a length x forming an electron avalanche of size $N = N_0\, e^{\alpha x}$; N/N_0 is the gain of the detector. Fig. 35.7 shows examples of Townsend coefficients for several gas mixtures, computed with Magboltz [132, 133].

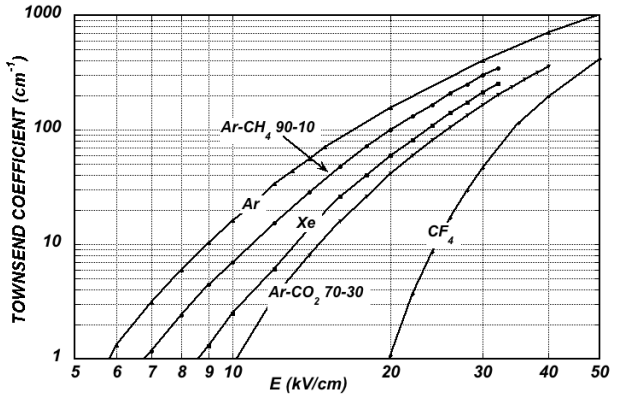

Figure 35.7: Computed first Townsend coefficient α as a function of the electric field in several gases at NTP [132, 133].

Additional ionizing energy transfer mechanisms due to the excited noble gas atoms, called collisional Penning energy transfers, occur when the excitation energy of a noble gas is higher than the ionization potential of an admixture gas. The energy transfer rate, the probability that an excited atom ionizes a quenching agent, is a priori not known for a mixture, but can be extracted from the fits of the experimental gas gain data [139] using the Magboltz simulations [132, 133]. In the gain calculations, the Penning adjusted Townsend coefficient is defined in terms of the total production frequencies of the noble gas excitations and direct ionizations of the mixture. Systematic gas gain measurements for varying mixing ratios and pressures are critical for determining the efficiency of the different mechanisms involved in the transfers. Collisional energy transfer mostly scales linearly with the gas pressure and the fraction of quenching gas in the mixture, while ionization by photons emitted from excitations is independent of the medium [140]. In addition, collisional Penning transfers of some higher excited states can occur before they decay at atmospheric pressure and are not restricted to metastable states of the excited noble gas. For example, the impact of the Penning effect on gas gain is roughly a factor of 10 in Ar-CO_2 mixtures and exceeding a factor of 100 in Ar-C_2H_2 mixtures [140].

The proportionality of the amplification process is gradually lost at continuously increasing voltages, due to the electric field distortions (screening) resulting from the large charge densities around the wire. At the end of the region of limited proportionality, the gain is saturated and does not depend on the initial value of the deposited charge anymore. This is a region of the Geiger-Müller counter where the photon-mediated avalanche over the full length of the anode wire takes place. Finally, after reaching the so-called breakdown voltage $V_{\rm b}$, a discharge region is reached, corresponding to the self-sustaining discharges in which a steady discharge current flows between the electrodes. The voltage beyond $V_{\rm b}$ is so high that, once ionization takes place in the gas, a continuous discharge develops, and the detector can not be used for radiation detection anymore.

Positive ions originating from primary ionization or generated in avalanches undergo drift and diffusion under the influence of the electric field. Negatively charged ions may also be produced by electron attachment to gas molecules. The drift velocity of ions in the fields encountered in gaseous detectors (up to a few kV/cm) is typically about three orders of magnitude smaller than for electrons. The ion mobility μ, the ratio of drift velocity to electric field, is constant for a given ion type up to very high fields. Values of ion mobility at NTP are given in Table 35.7 [141]. For different temperatures and pressures, the mobility can be scaled inversely with the density, assuming an ideal gas law. Both the longitudinal and transverse diffusion of ions are proportional to the square root of the drift time, with a coefficient that depends on temperature but not on the ion mass. Historically, it was assumed that, due to efficient charge-transfer processes, only the ions with the lowest ionization potential would survive after a short drift

path in a gas mixture. Recent experimental data, however, indicate that in CO_2-quenched Ar or Ne mixtures the actual signal carriers are $CO_2^+ \cdot (CO_2)_n$ cluster ions rather than bare CO_2^+ or noble-gas ions [142]. Since such cluster ions drift more slowly than the primary ions, the time structure of the induced signals is correspondingly modified. The effect can be present in constant-field detectors and TPCs (see Sec. 35.6.4), and might affect devices such as Micromegas (see Sec. 35.6.3) and drift tubes.

Negative ions, formed through the capture of primary ionization electrons by highly electronegative gas components (e.g., CS_2), can be utilized in negative-ion time projection chambers (TPCs). In such detectors, the negative ions drift toward the anode under the influence of an electric field, with their diffusion reduced to the thermal limit. This technique enables high spatial resolution and can extend the sensitivity of directional dark matter searches [143].

Table 35.7: Mobility of ions in gases and mixtures at NTP [141].

Gas	Mobility μ ($cm^2\ V^{-1}\ s^{-1}$)
He	10.4
Ne	4.7
Ar	1.54
Ar-CH_4	1.87
Ar-CO_2	1.72
CH_4	2.26
CO_2	1.09

35.6.2 *Multi-Wire Proportional and Drift Chambers*

Revised August 2025 by P. Gasik (GSI Darmstadt; FAIR Darmstadt; Technische U., Darmstadt).

Single-wire counters that detect the ionization produced in a gas by a charged particle, followed by charge multiplication and collection around a thin (typically 20 – 50 µm diameter) wire, have been used for decades. Good energy resolution is obtained in the proportional amplification mode, while very large saturated pulses can be detected in the streamer and Geiger modes [144].

35.6.2.1 *Multi-wire proportional chamber, MWPC*

Modern fully electronic devices, multiwire proportional chambers (MWPCs) [145, 146] introduced in the late 1960s, detect, localize, and measure energy deposit by charged particles over large areas. A plane of parallel anode wires at a suitable potential, inserted between two cathodes, can be regarded as a set of independent proportional counters (see Fig. 35.8a). Electrons released in the gas volume drift towards the anodes and produce avalanches in the increasing field. Analytic expressions for the electric field can be found in many textbooks. The fields close to the wires $E(r)$, in the drift region E_D, and the capacitance C per unit length of anode wire is approximately given by

$$E(r) = \frac{CV_0}{2\pi\epsilon_0}\,\frac{1}{r} \qquad E_D = \frac{CV_0}{2\epsilon_0 s} \qquad C = \frac{2\pi\epsilon_0}{\pi(\ell/s) - \ln(2\pi a/s)}\ , \tag{35.15}$$

where r is the distance from the center of the anode, s is the wire spacing, ℓ and V_0 are the distance and potential difference between anode and cathode, and a is the anode wire radius.

In wire chambers, most of the increase of avalanche particle density occurs very close to the anode wires, and a simple electrostatic consideration shows that the largest fraction of the detected signal is due to the motion of positive ions receding from the wires. The electron component, although very fast, contributes very little to the signal. This determines the characteristic shape of the detected signals in the proportional mode: an extremely sharp onset followed by a long "ion tail". The latter limits the time resolution of the detector, and is usually removed by differentiation of the signal.

Because of electrostatic forces, anode wires are in equilibrium only for a perfect geometry. Small deviations result in forces displacing the wires alternatively below and above the symmetry plane, sometimes with catastrophic results [147]. These displacement forces are countered by the mechanical tension of the wire, up to a maximum unsupported stable length, L_M [148], above which the wire displaces:

$$L_M = \frac{s}{CV_0}\sqrt{4\pi\epsilon_0 T_M} \tag{35.16}$$

The maximum tension T_M depends on the wire diameter and modulus of elasticity. Internal supports and spacers can be used in the construction of longer detectors to overcome limits on the wire length imposed by Eq. (35.16).

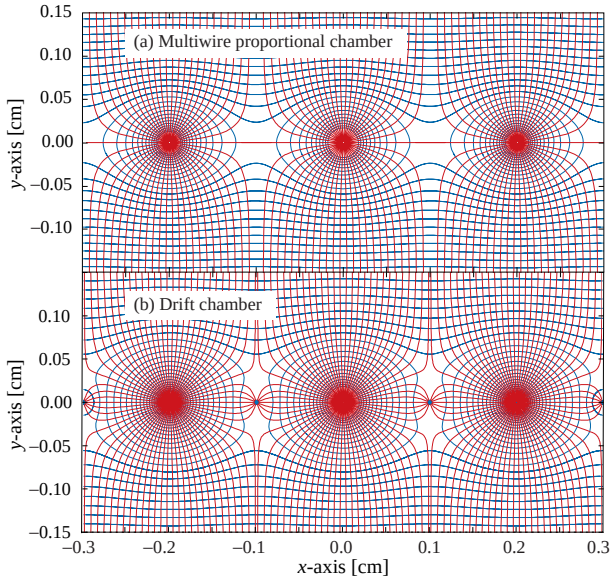

Figure 35.8: Electric field lines and equipotentials in (a) a multiwire proportional chamber and (b) a drift chamber.

Detection of charge on the wires over a predefined threshold provides the transverse coordinate to the wire with an accuracy comparable to that of the wire spacing. The coordinate along each wire can be obtained by measuring the ratio of the collected charge at the two ends of the resistive wires. The cathode planes can be fabricated in the form of a group of wires or isolated strips, which are often patterned in orthogonal directions. By exploiting the charge profile induced by avalanches on segmented cathodes, the so-called electronic center-of-gravity (COG) method enables track localization with sub-millimeter accuracy. Due to the statistics of energy loss and asymmetric ionization clusters, the position accuracy is ∼50 µm rms for fast particles perpendicular to the wire plane, but degrades to ∼250 µm at 30° to the normal [149].

35.6.2.2 *Drift chambers*

Drift chambers, developed in the early '70s, can be used to estimate the space coordinate perpendicular to the wires by exploiting the arrival time of electrons at the anodes if the time of interaction is known [150]. The distance between anode wires is typically several centimeters, enabling the coverage of large areas at reduced cost. In the original design, a thicker wire (the field wire, often from Cu-Be or Al) at the proper voltage, placed between the anode wires (e.g., gold-plated tungsten), removes the low-field region at the mid-point between anodes and improves charge collection (Fig. 35.8b). In some drift chamber designs, and with the help of suitable voltages applied to field-shaping electrodes, the electric field structure is adjusted to improve the linearity of the space-to-drift-time relation, resulting in better spatial resolution [151].

Drift chambers can achieve a longitudinal spatial resolution from timing measurements on the order of 100 µm (rms) or better for minimum ionizing particles, depending on the geometry and operating conditions. However, a degradation of resolution is observed due to primary ionization statistics for tracks close to the anode wires, caused by the spread in arrival time of the nearest

Int. J. Mod. Phys. A 2025.40:2530001-616. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 12/01/25. For personal use and distribution is strictly not permitted, except for Open Access articles.

ionization clusters [152]. The effect can be reduced by operating the detector at higher pressures. Sampling the drift time on rows of anodes led to the concept of multiple arrays, such as the multi-drift module [153] and the JET chamber [154]. A measurement of drift time, together with the recording of charge sharing from the two ends of the anode wires, provides the coordinates of segments of tracks. An ultimate drift chamber design is the Time Projection Chamber (TPC) concept [155], which provides 3D precision tracking with low material budget and enables particle identification through differential energy loss $\mathrm{d}E/\mathrm{d}x$ measurement or cluster counting $\mathrm{d}N_{\mathrm{cl}}/\mathrm{d}x$ techniques (see Sec. 35.6.4). In all cases, a good knowledge of electron drift velocity and diffusion properties is required. This has to be combined with the knowledge of the electric fields in the structures [133]. For an overview of detectors exploiting the drift time for coordinate measurement, see Refs. [148, 156].

Multiwire and drift chambers have been operated with a variety of gas fillings and operating modes, depending on experimental requirements. For example, a mixture of argon, isobutane and freon in the volume proportions 70-29.6-0.4 [146], permits very high and saturated gains ($\sim 10^6$), i.e., a pulse-height distribution independent of the number of primary ionization charges. While this mixture was successfully used in early wire chambers, it was later found to suffer from severe aging effects. Similarly, light mixtures based on helium and hydrocarbons, although commonly employed, do not provide the reliability needed for long-term, high-rate operation [157]. To meet the demands of future colliders, dedicated R&D is required to identify suitable hydrocarbon-free gas mixtures that can ensure both stable operation and the desired detector performance.

The next generation of ultralight central trackers for future colliders aims at minimizing material budget, where the dominant contribution to the radiation length originates from tungsten wires. Significant progress has been achieved through the development of alternative wire materials (e.g., carbon monofilaments) and novel wiring and assembly procedures, building on experience from detectors such as the DAFNE KLOE Drift Chamber and its recent evolution for the MEG2 experiment [158].

35.6.2.3 *Straw and drift tubes*

Although very powerful in terms of performance, multi-wire structures can have reliability issues, as a single broken wire can disable a larger part or even the entire detector. Introduced in the 1980s, straw and drift tube systems make use of large arrays of proportional counters where each wire is encased and protected in a tube and acts as an independent wire counter [159]. Techniques for low-cost mass production of these detectors have been developed for large experiments, such as the Transition Radiation Tracker and the Drift Tubes arrays for CERN's LHC experiments [160]. The state-of-the-art straw trackers utilize new construction techniques of ultrasonic welding of the straw film tube, keeping it straight and withstanding the surrounding vacuum pressure without breaking (see [161], for example). Future efforts for straw detectors, e.g., COMET Phase-II at JPARC, Mu2e-II at Fermilab, or SHiP at CERN, will focus on ultra-thin wall developments, smaller tube diameters, long and thin wire handling, precise mechanics, and innovative designs.

35.6.2.4 *High-rate effects*

The production of positive ions in the avalanches and their slow drift before neutralization result in a rate-dependent accumulation of positive charge in the detector. This may result in significant field distortion, gain reduction, and degradation of spatial resolution. As shown in Fig. 35.9 [162], the proportional gain drops above a charge production rate around 10^9 electrons per second per millimeter of wire, independently of the avalanche size. For a proportional gain of 10^4 and 100 electrons per track, this corresponds to a particle flux of $10^3\,\mathrm{s}^{-1}\mathrm{mm}^{-1}$ (1 kHz/mm^2 for 1 mm wire spacing). Improvement of rate capability can be achieved by reducing the anode-to-cathode distance.

During the operation of gaseous detectors in particle accelerator experiments, performance degradation due to the formation of polymer deposits (so-called ageing) on electrode surfaces is often observed. Ageing phenomena can lead to operational instabilities and even total malfunctioning of the detectors operated under increasing charge density doses [163]. This process has been extensively investigated both in operating experiments and in dedicated laboratory studies. In general, gas polymerisation originates from the use of hydrocarbons as quenchers as well as from the outgassing of organic pollutants from certain insulators, glues, and silicon oils. Since the deposited layers are usually insulating, the addition of water vapour can sometimes mitigate performance degradation, although it does not necessarily stop the polymerisation process. Modern detectors, therefore, rely on a strict selection of construction materials and carefully controlled gas mixtures and purities, allowing the collection of several C/cm^2 on the relevant electrodes without observable ageing effects.

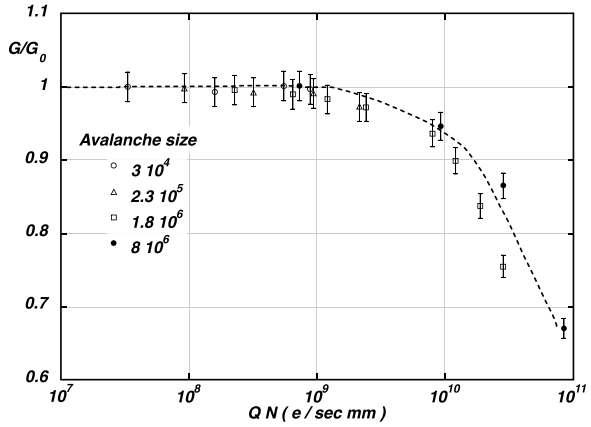

Figure 35.9: Charge rate dependence of normalized gas gain G/G_0 (relative to zero counting rate) in proportional thin-wire detectors [162]. Q is the total charge in a single avalanche; N is the particle rate per wire length.

35.6.3 *Micro-Pattern Gas Detectors*

Revised August 2025 by P. Gasik (GSI Darmstadt; FAIR Darmstadt; Technische U., Darmstadt).

Despite continuous improvements, position-sensitive detectors based on wire structures remain fundamentally limited by diffusion processes and space-charge effects, which restrict localization accuracies to about 50–100 µm [164]. Advances in microelectronics and photolithographic technology on flexible and standard PCB substrates enabled, toward the end of the 20th century, the development of novel Micro-Pattern Gaseous Detectors (MPGD) [165–167]. From the outset, the objective was to design devices combining high-rate capability (up to 10^6 Hz/mm^2), excellent spatial resolution (down to 30 µm), single-photoelectron timing in the nanosecond range, large sensitive area and dynamic range, superior radiation hardness, and cost-effectiveness for large-area coverage. Today, a broad family of MPGD technologies is being developed and optimized for a wide spectrum of applications, including [168, 169]: the Micro-Strip Gas Chamber (MSGC), Gas Electron Multiplier (GEM), Micro-Mesh Gaseous Structure (Micromegas), THick GEMs (THGEM, also referred to as Large Electron Multipliers, LEM), Resistive Plate WELL (RPWELL), GEM-derived architectures such as the µ-RWELL, the Micro-Pixel Gas Chamber (µ-PIC), and integrated gaseous detector readout concepts (GridPix, InGrid) that couple amplification stages with solid-state pixel detector ASICs (e.g., Medipix or Timepix).

The **MSGC** concept, invented in 1988, was the first of the micro-structure gas chambers [165]. It consists of a set of tiny parallel metal strips laid on a thin resistive support, alternatively connected as anodes and cathodes, and resembles a multi-anode proportional counter. Through an accurate and simple photolithography process, the anode strips can be made very narrow ($\sim$10 µm) with a typical pitch (distance between strips) of $\sim$100 µm. When appropriate potentials are applied to the electrodes, electrons released in the drift volume move toward the strips and multiply in the high-field region. Owing to the small

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

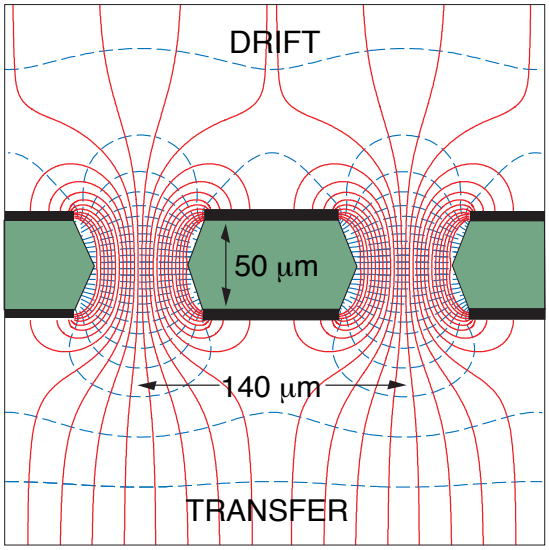

Figure 35.10: Schematic view and typical dimensions of the hole structure in the GEM amplification cell. Electric field lines (solid) and equipotentials (dashed) are shown. Electron trajectories do not strictly follow the electric field lines, since drifting electrons undergo isotropic scattering with gas molecules and, consequently, diffuse transversely.

anode-to-cathode distance, the fast removal of positive ions by nearby cathode strips reduces space charge build-up and significantly improves the rate capability, compared to the wire counter. Despite their promising performance, experience with MSGCs has raised serious concerns about their long-term behavior. There are several major processes, particularly at high rates, leading to the MSGC operational instabilities: substrate charging-up and time-dependent distortions of the electric field, surface deposition of polymers ("ageing") during sustained irradiation, and destructive discharges under exposure to heavily ionizing particles [170]. The physical parameters used to manufacture and operate these detectors (substrate material, metal of strips, type and purity of the gas mixture) appeared to play dominant roles in determining the medium- and long-term stability. The problems encountered inspired the development of novel structures, using modern photolithographic processes: GEM, Micromegas, and others, having increased reliability and radiation hardness.

A **GEM** detector consists of a thin-foil copper-insulator-copper sandwich chemically perforated to obtain a high density of holes in which avalanches occur [166, 171]. The hole diameter is typically of $\mathcal{O}(50\ \mu\text{m})$, with a hole pitch of 140 µm, which can be further optimized depending on the application. The central insulator is usually (in the original design) a polyimid foil, with a thickness of 50 µm. Application of a potential difference between the two metal sides of the GEM generates the electric fields indicated in Fig. 35.10. Each hole acts as an independent proportional counter. Electrons created by primary ionization in the drift gap above the GEM foil drift into its holes, where they undergo avalanche multiplication in the strong electric field (50–70 kV/cm). A significant fraction of the avalanche electrons exits the multiplication region and is extracted into the transfer gap below the foil, from where it can either be collected by an electrode or injected into a subsequent amplification stage. Systematic measurements with cascaded multi-GEM structures confirm that the gains and charge transfer processes are predictable from electrostatic considerations and avalanche development models; an overall gas gain well above 10^4 can be reached in the presence of highly ionizing particles, while strongly reducing the risk of discharges [172]. Other important parameters, such as attachment or diffusion, depend on the gas mixture composition and the reduced electric field E/p, where E is the electric field and p is the gas pressure. The majority of charges created in the avalanche process follow the electric field lines and are collected by the metallic electrodes. Owing to diffusion, however, a fraction may instead deposit on dielectric surfaces, thereby modifying the field configuration and affecting both the gain and the transparency of the structures [173]. This phenomenon is known as the "charging-up" effect; its time constant and amplitude depend strongly on the hole geometry.

The negative signal on the readout anode (below the last GEM in a multi-GEM structure) is primarily induced by the motion of electrons, with only a minor contribution from the ions produced in the amplification process. As a result, the signal is very fast, with a width determined by the drift of the high-mobility electrons over a distance of a few millimetres. Depending on the gas mixture, this enables time resolutions better than 10 ns. The achievable energy resolution is comparable to that of conventional proportional counters, around 17% FWHM for 5.9 keV X-rays [169].

For position measurements, the readout anode can be segmented into strips or pads. Because of the diffusion of the electron cloud in the transfer gaps between GEM foils and in the induction gap above the anode, the charge is shared among several neighbouring readout elements. A centre-of-gravity reconstruction of this charge distribution yields a spatial resolution that surpasses the segmentation pitch. In practice, resolutions well below 100 µm can be obtained, reaching 30 µm with finely segmented electrodes.

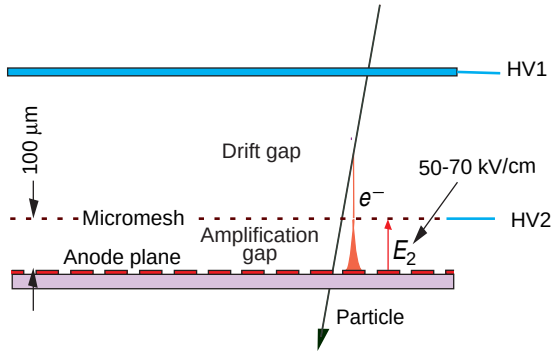

Figure 35.11: Schematic drawing of the Micromegas detector.

A **Micromegas** is a thin parallel-plate avalanche counter, as illustrated in Fig. 35.11 [167]. It employs a stretched metallic mesh, suspended on insulating pillars at a distance of $\mathcal{O}(100\,\mu\text{m})$ above a readout electrode, consisting of strips or pads of conductor printed on an insulating board. The pillars are attached to the mesh and patterned regularly using photolithography techniques. Electrons from the primary ionization drift through the mesh into the narrow multiplication gap, where they are amplified. The electric field is largely homogeneous in both the drift region (∼1 kV/cm) and the amplification region (50–70 kV/cm), but assumes a funnel-like shape near the micromesh openings: the field lines are compressed into a diameter of only a few micrometers, depending on the field ratio between the two gaps. The electron transparency, i.e. the fraction of ionization electrons transmitted into the amplification gap, is determined by the mesh geometry and the ratio of drift to amplification fields. High collection efficiency is obtained when the drift field exceeds the amplification field by a factor of 30–40 [169]. In the narrow multiplication region, small variations of the amplification gap are approximately compensated by the inverse dependence of the Townsend coefficient on the electric field, resulting in a more uniform gain. The transverse size of the electron avalanche due to diffusion is on the order of 10–15 µm, depending on the gas mixture, the electric field, and the gap width. This results in excellent spatial resolution, reaching about 12 µm for MIPs [174]. Most positive ions created in the avalanche process are quickly removed by the micromesh. This prevents space-charge accumulation and leads to very fast signals (∼100 ns), dominated by the electrons, with a small tail contribution from the ions.

Employment of photolithography and etching techniques allows for an improved spatial resolution and improved rate capabilities

(up to a few MHz/cm^2). For the same reason, the $E \times B$ effects can be neglected. The absence of space-charge effects in GEMs at the highest rates reached so far, thanks to its fine-pitch structure of a few hundred microns, improves the maximum rate capability by more than two orders of magnitude compared to MWPC (see Fig.35.12) [175] [176]. Even larger rate capability has been reported for Micromegas [177]. In addition, the peculiar shape of the electric field lines obtained in MPGD structures provides intrinsic ion feedback reduction capabilities (see also Sec. 35.6.4).

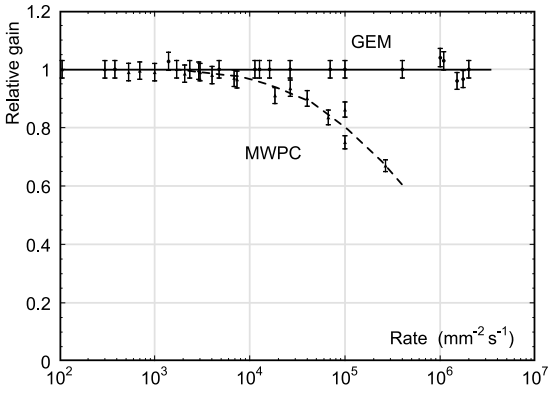

Figure 35.12: Normalized gas gain as a function of particle rate for MWPC [175] and GEM [176].

The fine granularity and high-rate capability of GEM and Micromegas can be fully exploited by using high-density pixel readout with a size corresponding to the intrinsic width of the detected avalanche charge. An elegant solution is the use of a CMOS pixel ASIC, assembled directly below the GEM or Micromegas amplification structure. Modern wafer post-processing technology allows an integration of a small-scale micromesh grid directly on top of a Timepix chip, thus forming an integrated MPGD readout, called GridPix concept (see Fig.35.13) [178]. With this arrangement, avalanche electrons are collected on the metalized input pads, exposed to the gas, and signals are induced at the input gate of a charge-sensitive preamplifier. Every pixel is then directly connected to the amplification and digitization circuits, integrated in the underlying CMOS layers. A thin insulating layer, e.g., a few µm of silicon nitride, is usually deposited on top of CMOS ASIC to protect against destructive discharges across the $\mathcal{O}(50$ µm) amplification gap. The GridPix concept provides the high granularity needed to resolve individual electron clusters (separated by an average distance of a few hundred µm) and to determine energy loss by the cluster counting technique ($\mathrm{d}N/\mathrm{d}x$), rather than by the charge measurement, with a precision better than 3 %. New structures, where a GEM foil is facing the Medipix chip, forming the GEMpix detector, are in use for medical applications [179] as well as for monitoring the radioactive waste [180].

Gaseous detectors represent the most cost-effective solution to cover very large areas with photosensitive elements. MPGD-based gaseous photomultipliers, conceived to overcome the limitations of MWPCs, with semi-transparent or reflective photocathodes (PC), allow for minimizing PC aging due to the ion and photon feedback and to avoid secondary effects causing electrical instability. For RICH applications requiring large-area coverage and moderate spatial resolution, coarser macro-patterned structures such as THGEM offer an interesting, cheaper solution [181].

Following the same principles, a **THGEM** shares a structural similarity with a GEM foil but features dimensions larger by roughly an order of magnitude in all directions. Instead of a thin polyimide sheet, it employs a thick PCB substrate as the dielectric, with holes produced through mechanical drilling and subsequent chemical rim etching of the metal cladding. While the spatial resolution of a THGEM is reduced compared to that of GEMs, it offers a robust alternative for large-area cryogenic detectors or photodetectors. Notably, MPGDs are already applied in single-photon detection—for instance, in the COMPASS RICH detector, which uses a hybrid architecture composed of two THGEM layers (one coated with a CsI photocathode) followed by a Micromegas as the final amplification stage.

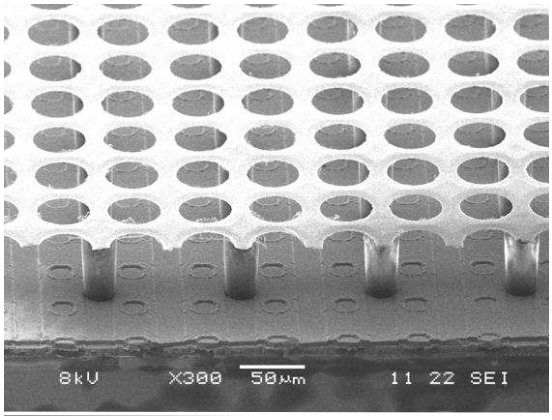

Figure 35.13: Photo of the Micromegas ('GridPix") detector. The grid holes can be accurately aligned with the readout pixels of the Timepix CMOS chip. The insulating pillars are centered between the grid holes, thus avoiding dead regions.

Resistive electrodes are increasingly employed in MPGD-based detectors to enhance spatial resolution and reduce the number of readout channels via charge sharing. Moreover, they provide effective spark protection for front-end electronics and reduce the discharge probability. When used as a high-voltage electrode or as a resistive layer capacitively coupled to the readout elements (e.g., strips or pads), they introduce a self-quenching mechanism that suppresses discharge development.

As an example, closed-geometry THGEM-based structures, known as **RPWELL** [182], have been developed, incorporating resistive anodes and combining features of THGEMs with those of Resistive Plate Chambers (RPCs, see Sec. 35.6.6). The concept consists of a single-faced THGEM, copper-clad only on its top side, placed directly on a resistive film deposited on a thin insulating sheet. Compared to a standard THGEM with an induction gap, the RPWELL configuration allows higher gains to be reached at lower applied voltages across the THGEM electrode, owing to the stronger electric field inside the closed holes.

With the gas discharge quenching capabilities, on the other hand, gain reduction comes into play at higher rates. In one of the pioneering studies with resistive Micromegas it was shown that the signal amplitude slowly decreases with increasing rate, reaching a drop of ∼20% at the rate of 10 kHz/cm^2 [183, 184].

Further improvements in resistive-electrode technology continue. A diamond-like carbon (DLC), a class of meta-stable amorphous carbon material that contains both diamond-structure and graphite-structure, has recently attracted much attention in the MPGD community and is exploited to make resistive electrodes to suppress discharges occurring in MPGDs [185, 186]). The DLC coating can also reduce gain variations over time and minimize charging-up effects.

One such implementation is the **µ-PIC** structure, an industrially manufactured PCB featuring anode strips on one side and orthogonal cathode strips on the opposite side. Along the cathode strips, a regular pattern of uncoated regions is formed; at the center of each, a conductive "dot" connected via a buried electrode in the thin substrate transmits the anode potential. Electron avalanches develop in the high-electric-field region surrounding these point-like anodes. Compared to MSGCs, the electric field near the cathode edges is significantly reduced, leading to a lower discharge probability. Furthermore, a DLC coating on the cathode strips ensures tolerance to occasional discharges [187].

A very promising GEM-derived architecture is the **µ-RWELL** [188], featuring a pitch approximately seven times smaller than that of the RPWELL. Various configurations of the

resistive stage (DLC) have been explored during the detector's development, culminating in a high-rate-optimized design that incorporates 3D charge evacuation through conductive vias [189]. This layout enables the detector to achieve gains up to 10^4 in a single amplification stage, and a rate capability exceeding $10\,\mathrm{MHz/cm^2}$.

A major step toward large-scale applications has been achieved through both conceptual consolidation and the development of industrial, cost-effective MPGD manufacturing techniques, such as resistive Micromegas [183] and single-mask or self-stretching GEM methods [190]. The successful scaling of MPGDs to very large single-unit detectors of $\mathcal{O}(\mathrm{m}^2)$ has enabled their deployment in the High-Luminosity LHC upgrades: Micromegas now cover an area of about $1000\,\mathrm{m}^2$ in the New Small Wheel of the ATLAS muon endcaps, GEMs are employed in the CMS muon system and the ALICE TPC readout, and a GEM+μRWELL hybrid is foreseen for the upgrade of the innermost regions of the LHCb muon system.

Exploiting the Micromegas, GEM, and μ-RWELL ability to measure both position and arrival time of the charge released in the drift gap, a novel μ-TPC concept has been developed. It permits achieving nearly constant spatial resolution over a wide range of particle incident angles and allows 3D track reconstruction with a single MPGD layer [191]

The consolidation of well-established technologies has been accompanied by the emergence of novel ones, often tailored to specific applications. Building on the Micromegas and GEM concepts, modern developments increasingly adopt hybrid approaches that integrate different elements within a single device – for instance, combining gaseous with non-gaseous detectors, as in optically read out detectors. Hybrid structures, combining various MPGD technologies, aimed at enhancing detector performance, remains a valuable strategy to address future experimental challenges such as high granularity and picosecond-level timing (e.g., the PICOSEC-Micromegas concept [192]). Moreover, GEMs, Micromegas, and μ-RWELLs can be bent to form cylindrically curved, ultra-light inner tracking systems that operate without support or cooling structures [193].

A clear direction for future MPGD developments is the use of resistive materials and related detector architectures. Their introduction enhances detector stability and allows higher gain to be reached within a single multiplication stage. Beyond resistive electrodes, further progress requires novel materials and advanced fabrication techniques. Contributions to detector concepts are needed in several areas, including resistive layers, solid-state photon and neutron converters, and innovative nanotechnology components. Material studies are particularly relevant for meeting stringent requirements such as low outgassing, radiation hardness, radio-purity, converter robustness, and compatibility with eco-friendly gases. The next generation of MPGDs can also profit from emerging technologies, such as Micro-Electro-Mechanical Systems (MEMS), advanced sputtering methods, novel photoconverters, and 3D-printed amplification structures or cooling circuits. These developments are being actively pursued in the framework of the world-wide CERN-DRD1 collaboration and its broad program of R&D on gaseous detector technologies [194].

35.6.4 *Time-projection chambers*

Revised August 2023 by C. Lippmann (GSI Darmstadt).

The Time Projection Chamber (TPC) concept was invented by David Nygren in the 1970's [195]. It consists of a cylindrical or square field cage that is filled with a gaseous (or liquid) detection medium. Charged particles produce tracks of ionization electrons that drift in a uniform electric field towards a position-sensitive amplification stage which provides a 2D projection of the particle trajectories. The third coordinate can be calculated from the arrival times of the drifted electrons. The start for this drift time measurement is usually derived from an external detector, e.g. a fast interaction trigger detector.

This section focuses on the gas-filled TPCs that are often used in particle or nuclear physics experiments at accelerators on account of their low material budget. For neutrino physics (Sec. 36) or for detecting rare events (Sec. 36.4), on the contrary, usually high density and large active mass are required, and a liquid detection medium is favored.

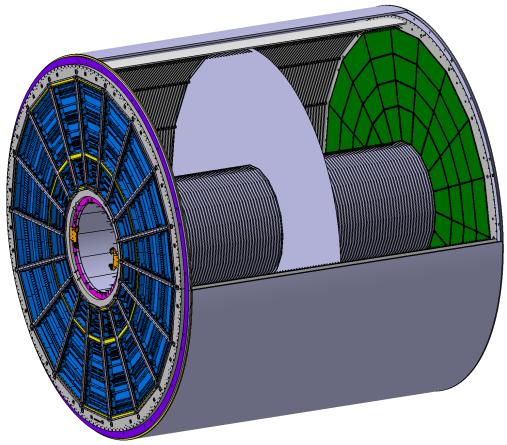

Figure 35.14: Schematic view of the ALICE TPC [196, 197]. The drift volume with 5 m diameter is divided into two halves, each providing 2.5 m drift length. The amplification stage has recently been upgraded from wire planes to GEMs.

The TPC enables full 3D measurements of charged particle tracks, which gives it a distinct advantage over other tracking detector designs which record information only in two-dimensional detector planes and have less overall segmentation. The track points recorded in a TPC are basically adjacent, which facilitates the track finding enormously. This advantage is often exploited for pattern recognition in events with large numbers of particles, e.g. heavy-ion collisions. Two examples of modern large-volume gaseous TPCs are shown in (Figure 35.14) and (Figure 35.15).

Identification of the charged particles crossing the TPC is possible by simultaneously measuring their momentum and specific energy deposit through ionisation ($\mathrm{d}E/\mathrm{d}x$). The momentum, as well as the charge sign, are calculated from a helix fit to the particle trajectory in the presence of a magnetic field (typically parallel to the drift field). For this application, precise spatial measurements in the plane transverse to the magnetic field are most important. The specific energy deposit is estimated from many charge measurements along the particle trajectory (e.g. one measurement per anode wire or per row of readout pads). As the charge collected per readout segment depends on the track angle and on the ambient conditions, the measured values are corrected for the effective length of the track segments and for variations of the gas temperature and pressure. The most probable value of the corrected signal amplitudes for a given track provides the best estimator for the specific energy deposit (see Sec. 34.2.3); it is usually approximated by the truncated mean, i.e. the average of the 50%–70% smallest values. The resulting particle identification performance is illustrated in (Figure 35.16), for the ALICE TPC.

The dependence of the achievable energy resolution on the number of measurements N, on the thickness of the sampling layers t, and on the gas pressure P can be estimated using an empirical formula [199]:

$$\sigma_{dE/dx} = 0.41\ N^{-0.43}(t\,P)^{-0.32}. \qquad (35.17)$$

Typical values at nominal pressure are $\sigma_{dE/dx} = 4.5$ to 7.5%, with $t = 0.4$ to 1.5 cm and $N = 40$ up to more than 300. The record, with an unprecedented energy resolution of 3%, is held by the PEP-4/9 TPC [200], due to the high gas pressure of 8.5 bar.

The greatest challenges for a large TPC are due to the length of the drift of up to a few meters. In particular, it can make the device sensitive to small distortions in the electric field. Such distortions can arise from a number of sources, e.g. imperfections in the field cage construction or the presence of ions in the drift volume. The electron drift in a TPC in the presence of a magnetic

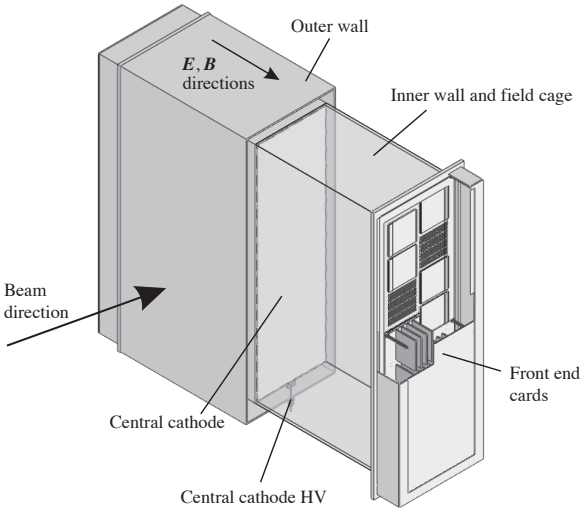

Figure 35.15: One of the 3 TPC modules for the near detector of the T2K experiment [198]. The size is $2 \times 2 \times 0.8\,\mathrm{m}^3$. Micromegas devices are used for gas amplification and readout.

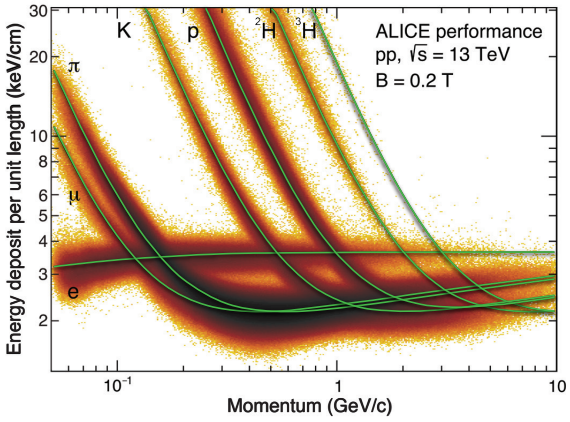

Figure 35.16: Energy deposit versus momentum measured in the ALICE TPC.

field is defined by Eq. (35.14). The $E \times B$ term of Eq. (35.14) vanishes for perfectly aligned electric and magnetic fields, which can however be difficult to achieve in practice. Furthermore, the electron drift depends on the $\omega\tau$ factor, which is defined by the gas mixture and the magnetic field strength. The electrons will tend to follow the magnetic field lines for $\omega\tau > 1$, or the electric field lines for $\omega\tau < 1$. The former mode of operation makes the TPC less sensitive to non-uniformities of the electric field, which is usually desirable.

The drift of the ionization electrons is superposed with a random diffusion motion which degrades their position information. The ultimate resolution of a single position measurement is limited to around

$$\sigma_x = \frac{\sigma_D \sqrt{L}}{\sqrt{n}}\,, \tag{35.18}$$

where σ_D is the transverse diffusion coefficient for 1 cm drift, L is the drift length in cm and n is the effective number of electrons collected. Without a magnetic field, $\sigma_{D,B=0}\sqrt{L}$ is typically a few mm after a drift of $L = 100\,\mathrm{cm}$. However, in a strong magnetic field parallel to the drift field, a large value of $\omega\tau$ can significantly reduce diffusion:

$$\frac{\sigma_{D,B>0}}{\sigma_{D,B=0}} = \frac{1}{\sqrt{1+\omega^2\tau^2}}\,. \tag{35.19}$$

This factor can reach values of up to 10. In practice, the final resolution limit due to diffusion typically lies around $\sigma_x = 100\,\mu\mathrm{m}$.

The drift and diffusion of electrons depend strongly on the gas mixture. The optimal gas mixture varies according to the environment in which the TPC operates. In all cases, the oxygen concentration must be kept very low (few ten parts per million in a large TPC) in order to avoid electron loss through attachment.

Ideally, the drift velocity should depend only weakly on the electric field at the nominal operating condition. The classic Ar/CH_4 (90:10) mixture, known as P10, has a drift velocity maximum of $5\,\mathrm{cm}/\mu\mathrm{s}$ at an electric field of only $125\,\mathrm{V/cm}$ (Figure 35.5). In this regime, the electron arrival time is not affected by small variations in the ambient conditions. Moreover, low electric fields simplify the design and operation of the field cage. The mixture has a large transverse diffusion at $B = 0$, but this can be reduced significantly in a strong magnetic field due to the relatively large value of $\omega\tau$.

For some applications organic gases like CH_4 are not desirable since they may cause aging. An alternative is to replace CH_4 with CO_2. An Ar/CO_2 (90:10) mixture has a low transverse diffusion at all magnetic field strengths, but does not provide a saturated drift velocity for the typical electric fields used in TPCs (up to a few $100\,\mathrm{V/cm}$). As a consequence, it is quite sensitive to the ambient conditions. Freon admixtures like CF_4 can be an attractive option for a TPC as well, since the resulting gas mixtures provide high drift velocities at low electric fields. However, the use of CF_4 always needs to be thoroughly validated for compatibility with all materials of the detector and the gas system.

Historically, the amplification stages used in gaseous TPCs have been planes of anode wires operated in proportional mode. The performance is limited by effects related to the feature size (wire spacing) of a few mm. Since near the wires the electric and magnetic fields are not parallel, the incoming ionisation electrons are displaced in the direction of the wires ("wire $E \times B$ effect"), which degrades the resolution. The smaller feature sizes of Micro-Pattern Gas Detectors (MPGDs) like GEMs and Micromegas lead to many advantages as compared to wire planes (see Sec. 35.6.3). In particular, $E \times B$ effects in the amplification stage are much smaller. Moreover, the signal induction process in MPGDs leads to a very narrow pad response, allowing for a much finer segmentation, which improves the separation for two very close tracks. Combinations of MPGDs with silicon sensors have resulted in the highest granularity readout systems so far (see Sec. 35.6.3). These devices make it possible to count the number of ionization clusters along the length of a track, which can, in principle, improve the particle identification capability. However, the big challenge for such a system is the huge number of readout channels for a TPC of a typical size.

The accumulation of the positive ions created by the ionization from the particle tracks can lead to time-dependent distortions of the drift field. Due to their low drift velocity, ions from many events may coexist in the drift volume. To reduce the effect of such a build-up of space charge, Argon can be replaced by Neon as the main component of the gas mixture. Neon features a lower number of ionisation electrons per unit of track length (see 35.6) and a higher ion mobility (see 35.7).

Of greater concern are the ions produced in the gas amplification stage. In order to prevent them from entering the drift volume, large TPCs built until now have a gating grid. The gating grid can be switched to transparent mode (usually in the presence of an interaction trigger) to allow the ionization electrons to pass into the amplification region. After all electrons have reached the amplification region, it is usually closed such that it is rendered opaque to electrons and ions. For triggered operation, a combination of a MPGD and a gating structure may be an attractive solution. However, a gating grid implies a principal rate limitation to a few kHz.

A next generation of TPCs (e.g. ALICE [197], sPHENIX [201]) has been developed for applications where a triggered operation would lead to inacceptable data loss. The employed readout

schemes are based on MPGDs, as these can be optimised in order to drastically reduce the ion back-flow. Extensive work has been carried out during the 2010's to design such readout structures. In ALICE and sPHENIX ion back-flow values below 1 % are achieved with a thorough adjustment of the various fields in a quadruple GEM system. Similar levels of ion back-flow can be reached with Micromegas detectors [202].

35.6.5 *Transition radiation detectors (TRD's)*

Revised August 2025 by P. Nevski (BNL) and A. Romaniouk (Innsbruck U.; Istinye U.).

Transition radiation (TR) x-rays are produced when a highly relativistic particle with Lorentz factor $\gamma \gtrsim 10^3$ crosses a refractive index interface, as discussed in Sec. 34.7. Since the TR yield is about a few % per boundary crossing, radiation from multiple surface crossings (e.g., a stack of foils) is used in practical detectors. The x-rays, ranging from a few keV to a few dozen keV or more, are emitted in a forward direction at small angles (within few mrad) to the particle trajectory. The TR intensity for a single boundary crossing always increases with γ, but, for multiple boundary crossings, interference leads to saturation above $\gamma_{\,\mathrm{sat}} = 0.6\ \omega_1\sqrt{\ell_1\ell_2}/c$ [203], where ω_1 is the radiator material plasma frequency, ℓ_1 is its thickness, and ℓ_2 the spacing between material elements. The probability density function of TR is a fairly complex function of γ, radiator parameters, photon energy (ω) and its emission angle (θ). For well defined radiator parameters a measured two-dimensional distribution of photon energy vs its reconstructed emission angle is in very good agreement with the theory predictions [204].

Integration over the angle yields the TR spectrum, which typically features many maxima (see Sec. 34.7). Most of the TR energy is emitted near the last maximum of the spectra determined by radiator material parameters at $\omega_{max} = \ell_1\omega_1^2/2\pi c$. The effective TR photon emission starts at about $\gamma_{thr} = \ell_1\omega_1/c$. By varying radiator parameters one may optimize the particle separation for a given range of the γ-factor. The angular distribution of TR photons has a few maxima and extends up to $\theta_{max} = (1/\gamma^2 + \omega_1^2/\omega^2)^{1/2}$ [205]. For a single foil the largest part of the TR energy is emitted around the most probable angle $\theta = (1/\gamma^2 + \omega_2^2/\omega^2)^{1/2}$, where ω_2 is the plasma frequency of the gas surrounding the radiator material elements. However, in case of multiple interfaces, interference effects may significantly change this angle and more realistic expression for the angle which corresponds to the last interference maximum of the energy spectra is $\theta \approx \sqrt{1.4\pi^2/\gamma_{\,\mathrm{sat}}^{\,2} - 1/\gamma^2}$ [204]. The higher is the gamma-factor, the larger is the angle of the first interference maximum. It reaches almost its asymptotic limit at $\gamma = \gamma_{sat}$. This effect is illustrated in Fig. 35.17 [204] which shows two-dimensional distribution of the TR photon energy versus the reconstructed production angle obtained in 20 GeV electron beam with the radiator containing a stack of foils of 15.5 μm thickness spaced by 210 μm (the left plot) using a Si-pixel detector. TR produced by 20 GeV electrons is emitted mostly around $\theta \sim 0.9$ mrad. All features of this distribution are well reproduced with MC simulations (the right plot).

The simplified numerical expressions can be used for practical estimation of the main TR production parameters [204]: $\theta \sim 1.2/\omega_1\sqrt{l_1 l_2}$, $\gamma_{thr} \sim 3\times10^3\ \omega_1\ell_1$, $\gamma_{\,\mathrm{sat}} \sim 3\times10^3\ \omega_1\sqrt{\ell_1\ell_2}$ and $\omega_{max} = 0.65\ \ell_1\omega_1^2$, where θ in mrad, ω_1 in eV, ω_{max} in keV and l_1 and l_2 in mm.

In the simplest concept, a detector module might consist of a low-Z TR radiator followed by a high-Z active layer made of proportional counters filled with a Xe-rich gas mixture. The atomic number considerations follow from the dominant photoelectric absorption cross section per atom going roughly as $Z^{\,n}/\omega^3$, where n varies between 4 and 5 over the region of interest.[1] To minimize self-absorption, materials such as polypropylene, Mylar, carbon, and (rarely) lithium in the form of foils, fibers or foams are used as radiators. The TR signal in the active regions is in most cases superimposed upon the particle ionization losses, which are proportional to Z. In most of the detectors used in particle physics the radiator parameters are chosen to provide $\gamma_{\,\mathrm{sat}} \approx 3000$. Those detectors normally work as threshold devices, ensuring the best electron/pion separation in the momentum range 1 GeV/$c \lesssim p \lesssim$ 150 GeV/c.

One can distinguish two design concepts—"thick" and "thin" detectors. In "thick" detectors the radiator, optimized for a fixed total radiation length at maximum TR yield and maximum TR absorption in the detector, consists of few hundred foils (for instance 300 20 μm thick polypropylene foils). Most of the TR photons are absorbed in the radiator itself. To maximise the number of TR photons reaching the detector, part of the radiator far from the active layers is often made of thicker foils, which shifts the x-ray spectrum to higher energies. The detector thickness, about 2-4 cm for Xe-filled gas chambers, is optimized to absorb most of the incoming x-ray spectrum. A classical detector is composed of several similar modules which respond nearly independently. Such detectors were used in the UA2, NA34 and other experiments [206], are being used in the ALICE experiment [207, 208] and are built for the CBM experiment [209]. In another TRD concept a fine granular radiator/detector structure exploits the soft part of the TR spectrum more efficiently. This can be achieved, for instance, by distributing small-diameter straw-tube detectors uniformly or in thin layers throughout the radiator material. This approach allows to realise a TRD as an integral part of a tracking detector providing many points of measurements on the particle track. Even with a relatively thin radiator stack, radiation below 4 keV is mostly lost in the radiators themselves. However, for photon energies above this value, the absorption is reduced and the radiation can be registered by several consecutive detector layers, thus creating a strong TR build-up effect. Descriptions of detectors using this approach in both accelerator and space experiments can be found in [207, 210–213]. For example, in the ATLAS TR tracker (TRT), charged particles on average cross about 35 straw tube layers embedded in the radiator material [210]. The effective thickness of the Xe gas per straw is about 2.5 mm and the average number of foils per straw is about 40 with an effective foil thickness of about 18 μm. In this approach straw walls also act as radiator and make some contribution to the TR spectrum.

Although the radiator parameters mentioned above are typical, they can vary significantly depending on the specific requirements of the detector. Careful simulations are usually needed to build a detector optimized for a particular application. For TRD simulations the codes are based on well understood TR emission formulas (see for instance [205] for regular radiators and [214] for irregular radiators). They are realised as the stand-alone simulation programs [204, 215, 216] or GEANT4 based ones [217] and give both a good agreement of the TR energy spectra and of the angular distributions with data [204, 218, 219].

Discrimination between electrons and pions can be based on the total energy deposition measured in each detection module, the number of clusters – defined as energy depositions exceeding an optimal threshold (typically 5—7 keV) – or on more sophisticated methods, such as pulse-shape analysis as a function of time. The total energy measurement technique is more suitable for thick gas volumes, which absorb most of the TR radiation and where the ionization loss fluctuations are relatively small. The cluster-counting method works better for detectors with thin gas layers, where the fluctuations of the ionization losses are bigger. Cluster-counting replaces the Landau-Vavilov distribution of background ionization energy losses with the Poisson statistics of δ-electrons, responsible for the distribution tails. The latter distribution is narrower than the Landau-Vavilov distribution. In practice, most of the experiments use a likelihood method, which exploits detailed knowledge of the detector response for different particles and gives the best separation. The neural network method is the most powerful tool. When used by the ALICE TRD (ALICE point in Fig. 35.18), it led to an increase in rejection power by a factor of 2–3 compared to the likelihood method [207]. However, the more parameters are included in the likelihood method, the better the achievable separation power, approaching the performance level of the neural network method [208].

Once the detector structure is optimized, the particle separa-

[1] Photon absorption coefficients for the elements (via a NIST link), and $dE/dx|_{\mathrm{min}}$ and plasma energies for many materials are given in https://pdg.lbl.gov/current/AtomicNuclearProperties.

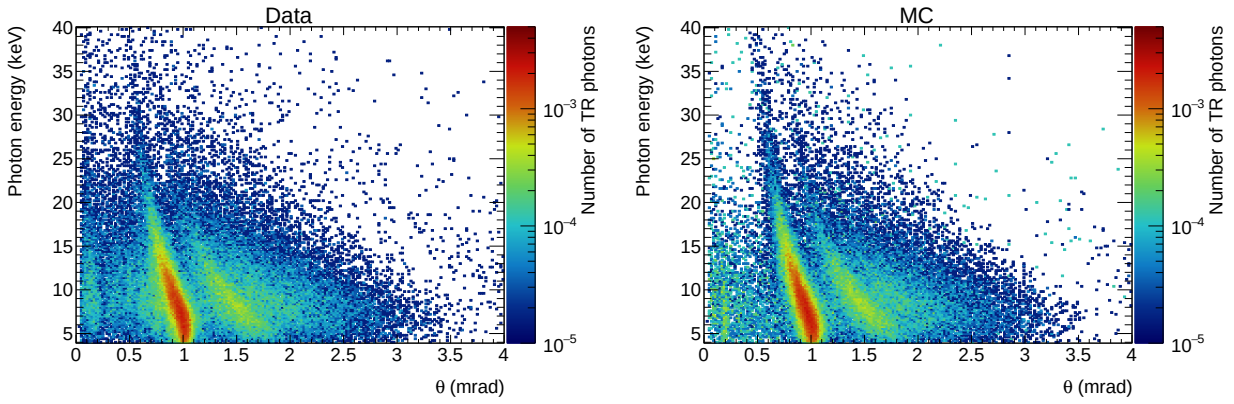

Figure 35.17: Two dimensional distributions of photon energy versus reconstructed production angle obtained with the polypropylene radiator with 20 GeV/c electron beam. Data - the left plot, MC - the right plot. Z-axis is a number of photons per particle [204]

tion power critically depends on the overall detector length. This is illustrated in Fig. 35.18, which shows, for a variety of detectors, the pion efficiency at a fixed electron efficiency of 90% as a function of the overall detector length. As TRD performance depends on particle energy, the experimental data in this figure covering a range of particle energies from 1 GeV to 40 GeV, are rescaled to an energy of 10 GeV when possible. Phenomenologically, the rejection power against pions increases as $5 \cdot 10^{L/38}$, where the range of validity is $L \approx$ 20–100 cm. Apart from the beam energy variations, the observed scattering of the points in the plot reflects how effectively the detector space is used and how well the exact response to different particles is taken into account in the analysis. For instance, the ATLAS TRT was built as a compromise between TR and tracking requirements; that is why the test-beam prototype result (lower point) is better than the real End-Cap TRT performance at the LHC shown in Fig. 35.18 for different regions in the detector (in agreement with MC).

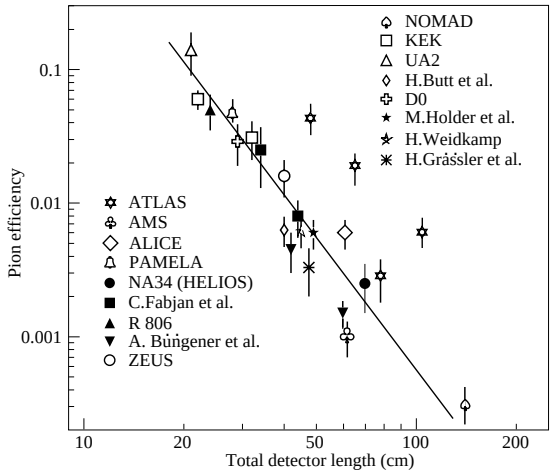

Figure 35.18: Pion efficiency measured (or predicted) for different TRDs as a function of the detector length for a fixed electron efficiency of 90%. The plot is based on the table given in [206]. Results from more recent detectors are added from [207, 211–213, 220].

In most cases, recent TRDs combine particle identification with charged-track measurement in the same detector [207, 209, 212]. This is particularly important for collider experiments, where the available space for the inner detector is very limited and the primary function of all detectors is particle tracking. For a modest increase of the radiation length due to the radiator (∼4% X0), a significant enhancement of the electron identification was obtained in the case of the ATLAS TRT. Here, the combination of the two detector functions provides a powerful tool for electron identification even at very high particle densities.

In addition to the enhancement of the electron identification during offline data analysis, TRD signatures are often used in the trigger algorithms at collider experiments. The ALICE experiment [208] is a good example for the use of the TRD in a First Level Trigger. In the ATLAS experiment, the TRT information is used in the High Level Trigger (HLT) algorithms. At increasing luminosities, the electron trigger output rate becomes so high that special measures must be taken to keep it at an acceptable level. Even a very soft TR cut at the HLT level, which preserves high electron efficiency (98%), allows to suppress a significant part of fake triggers and enhance the purity for physics events with electrons in a final state. The TRT also plays a crucial role in the studies where an electron suppression is required (e.g. hadronic mode of τ–decays). TR information is a completely independent tool for electron identification and allows to study systematic uncertainties of other electron reconstruction methods.

Electron identification is not the only application of TRDs. They are also sometimes used for hadron separation, which is a more challenging task, as the mass ratio of the particles involved is smaller. In the past, the TRD technique was successfully used to separate pions from protons and kaons at momenta up to 200 GeV/c (see, for example, [221]). In the TeV energy range, TRD remains the only viable technique for hadron separation [222]. For particle astrophysics some TRDs are designed to directly measure the Lorentz factor of high-energy nuclei by using the quadratic dependence of the TR yield on nuclear charge; see, for instance, in [223]. The radiator configuration (ℓ_1, ℓ_2) is tuned to extend the TR yield rise up to $\gamma \approx 10^5$ using the more energetic part of the TR spectrum (up to 100 keV). High density radiator materials (such as Al) are the best for this purpose. Direct absorption of the TR-photons of these energies with thin detectors becomes problematic and TR detection methods based on Compton scattering have been proposed, see in [224].

New detector techniques for TRDs are also under consideration. GasPixel detectors allow to reconstruct a track segment with a space point accuracy of $< 30\ \mu m$ and exploit all details of the particle tracks to highlight individual TR clusters in the gas, see in [225]. However, their ability to separate TR clusters from the energy losses of particles in space is limited by electron cloud diffusion in the gas. Semiconductor pixel or microstrip detectors with high granularity are promising candidates for the spatial separation of TR photons and dE/dx signals at relatively short distances between the radiator and the detector. This capability allows for the reconstruction of the TR production angle, which – together with the TR energy measurements – can help improve the particle identification (PID) performance of the TRD. Such detectors may be the basis for novel devices which combine precise tracking and PID properties [204, 216, 226]. The presence of a magnetic field could enhance the separation between TR photons and dE/dx losses [227]. Thin films of heavy scintillators might be a very attractive option for non-gas based TRD [228].

35.6.6 *Resistive-plate chambers*

Revised August 2025 by G. Aielli (Rome U. Tor Vergata).

The resistive-plate chamber (RPC) is a gaseous detector working at atmospheric pressure developed by R. Santonico and R. Cardarelli in the early 1980's [229]. A precursor of the RPC was the Pestov spark chamber [230] [231], which had a metallic plate cathode and a thick glass plate anode, designed to work at 12 bar to obtain an outstanding 0.1 ns time resolution. Although the original purpose of RPCs was to provide a competitive alternative to large scintillator counters, the RPC's potential for timing tracker systems was quickly recognized given its high detection efficiency (>95%), excellent temporal and spatial resolutions and ease of constructing large-format single frame detectors. The RPC, as sketched in Fig. 35.19, is a large planar capacitor with two parallel high bulk resistivity electrode plates (10^9–10^{13} Ω·cm) separated by a set of insulating spacers. The spacers define a gap in the range from a few millimeters down to 0.1 mm with a precision of a few μm. The gap is filled with a suitable atmospheric-pressure gas mixture which serves as a target for ionizing radiation. A thinner gas gap corresponds practically to an higher time resolution, on the other hand, the minimum gaseous target for reaching full detection efficiency at atmospheric pressure is typically 1 mm (also influenced by the gas molecular weight). Since the primary ionization released in sub-millimeter gas gaps is limited, multiple gaps can be combined to effectively obtain a high detection efficiency [232]. The electrodes are most commonly made of high pressure phenolic-melaminic laminate (HPL), commonly referred to as "bakelite", or glass. In the last case, typically soda-lime or alumino-silicate glass types are used, having a lower resistivity than borosilicate glass. An uniform electric field of several kV/mm is established on the gas gap, sufficient to promptly start an avalanche multiplication of the primary electrons. The electric field is typically applied through a moderately conductive ($\sim 10^5 to 10^8$ $\Omega/\square$) graphite varnish, forming an ohmic contact with the external faces of the electrodes. Its conductivity is sufficiently low to be transparent to the fast avalanche signal transients, and high enough to suppress surface voltage gradients arising from the working current flowing in it. Due to the high electrode resistivity in RPCs, the time constant of the equivalent RC circuit ($\tau = \rho\epsilon_r$ being ρ the electrode resistivity and ϵ_r its dielectric constant) is much longer than the discharge processes duration. Therefore only the locally-stored electrostatic energy contributes to the discharge, preventing the formation of sparks and leaving the rest of the detector field unaffected. The gas-facing surface of HPL electrodes are commonly coated with $\sim$ μm-thick layer of polymerized linseed oil [233] with the function of smoothing the electrode surface, improving the electric field uniformity. It also has the function of protecting the electrode from the being eventually etched by free radicals generated in the discharge e.g. in presence of fluorocarbons. Glass-based RPCs don't require such treatment. In RPCs the gaseous target and the multiplication region coincide. In the early stage of the avalanche multiplication the uniform electric field exponentially amplifies each primary ionization cluster, as the avalanche progresses away from the location of the primary ionization. Since the ionization clusters generated by the incident MIP are randomly distributed along the ionizing particle track, for low gains the observed RPC charge spectrum is broad and approximately exponentially distributed[2] with the mode close to zero. Because of this, it is difficult to separate noise from signals using a discrimination threshold. This is not the case in gaseous detectors where ionization and amplification occur in separate regions.

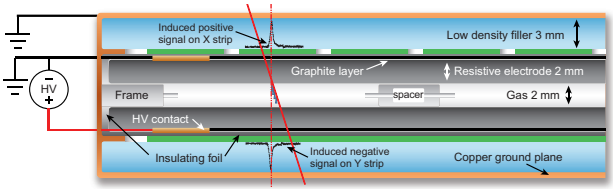

Figure 35.19: Schematic cross section of a generic single gap RPC. The thickness values shown are given just as an example.

For increasingly larger avalanches, the space-charge progressively saturates the avalanche growth from exponential to almost linear, producing a peaked charge spectrum, essential to efficiently separate the signal from the noise [235]. For large gains[3] the avalanche, with increasing probability, onsets a transition to "streamer" [236], a plasma filament connecting the electrodes, depleting all the locally-available energy [237], and generating an almost fixed amplitude signal. This prevents any further evolution of the discharge. This streamer mode was the first ever used by RPCs, until the introduction of very electronegative gases and more sensitive front end electronics made it possible to detect the precursor avalanche independently on the streamer [238,239] Any of this operating regimes can be used in RPC detectors, depending on the application.

As with other gaseous detectors, the gas mixture is optimized for each specific application. In general it needs to contain a UV photons quencher suppressing the photon-mediated feedback that can lead to self generated after-pulse discharges, and one or more electronegative components, to extend the avalanche growth limit before increasing significantly the probability of generating a streamer. Even though there is not yet an accepted and robust avalanche-to-streamer-transition model, this effect is commonly explained as a delay in the growth of the electron density of the avalanche front, which perturbates the electric field driving the transition to streamer. The addition of small fractions of electronegative molecules with a very high capture cross section for slow electrons, such as SF_6, was proven [240] to inhibit the transition to streamer over a wide electric field range above the working point. Having such a wide interval is crucial in real applications, to cope with all the unavoidable gas gaps size fluctuations and surface quality, stabilizing and making uniform the detector response. In the last decades ATLAS and CMS adopted as a standard the mixture $C_2H_2F_4$/i-C_4H_10/SF_6=94.5%/5%/0.3% for stable avalanche operation (ATLAS changed it since 2023 as explained in Section 35.6.6.4).

The avalanche induces a fast electron signal on a set of metallic readout electrodes (e.g. pads or strips) commonly placed externally and electrically insulated from the resistive electrodes. The induced charge is isotropically distributed on the electrode plans with equal but opposite amplitude on both sides of the RPC. This symmetry makes both sides of the RPC functionally equivalent for the signal readout. The induced charge density distribution can be calculated for a simplified RPC model [241] [242] as: $\sigma(x) = A/\cosh[(r)/\delta]$ where A is a normalization constant, r is the distance from the center of the avalanche axis and $\delta = (g + 2d)/\pi$ depends on the gap and electrode width (g and d, respectively). Depending on the specific RPC layout and geometry, the interplay between conductive coating and pick-up electrodes typically broadens, by means of a diffusion-like process (see [242] [243]). This effect mostly preserves the information on the avalanche position, which can be obtained using the charge centroid method, with the drawback of increasing the signal space occupancy. A fast detector response, requires to preserve sensitivity to the high-end of electron avalanche signal frequency spectrum, and guaranteeing this across large RPC areas, requires a correspondingly adequate Faraday cage and readout design. At the same time, to preserve the excellent timing features of the RPC signal, the front end electronics should have a short rise time (ideally $\ll$ than the signal rise time) and low noise, although these are competing requirements [244].

35.6.6.1 *RPC types and applications*

RPCs are generally classified in two categories depending on the gas gap structure: single gap RPCs (described above) and multiple gap RPCs [232] (typically referred as MRPCs). While they are

[2] An analytic treatment of the low gain avalanche process shows that the charge distribution is well described by the Γ function [234]

[3] A multiplicity of the order of 10^8 electrons is classically referred as Raether/Meek limit for on-setting a streamer

Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 06/15/22. For personal use and distribution is strictly not permitted, except for Open Access articles.

both based on the same principle they have different construction techniques, performance and limitations, making them suitable for different applications. Due to its simplicity and robustness, the single gap RPC is ideal for covering very large surfaces. Typical detector systems can have sensitive surface areas up to $\sim 10^4$ m^2, with single module areas of a few m^2, a space resolution up to 100 μm [245] and a time resolution up to $\sim$0.4 ns [246]. Representative examples are the muon systems of ATLAS [247] and CMS [248] or ground and underground based cosmic rays [249] and neutrino arrays [250]. It is interesting to note that CMS implemented a bi-gap structure, i.e. the pickup signal is sandwiched by 2 single gas gaps, both contributing to the signal induction, improving efficiency and time resolution with respect to the single gas gap. Relevant new trends for single gap RPC applications are represented by new Dark Matter search experiments such as CODEX-B [251] and ANUBIS [252], in both cases exploiting RPCs to enclose and instrument large detection volumes with a good space-time tracker. Single gap RPCs have also recently demonstrated good candidates for application in tracking calorimetry [253].

The MRPC [254], as sketched in Fig. 35.20, segments the gaseous target by means of a stack of floating glass electrodes separated by a monofilament (i.e. fishing line) sandwiched between two external electrodes providing the high-voltage bias. Since the current flowing in between the gas gaps must be in average equal, the difference of potential between each couple of adjacent floating electrodes will tend to be the same. An extensive description can be found in [255]. It has been observed that higher time resolution is inversely correlated to the gas gap size, so this configuration allows for smaller gas thicknesses while maintaining a sufficient total gas thickness. This tends to separate primary clusters avalanches in different gas gaps, treating them independently, and determines a shorter avalanche growth time, increasing time resolution by one order of magnitude with respect to the classic RPCs [256]. The mechanical fragility of sub-mm-gap structures makes this technique less suitable for very large detector areas. Moreover the only material nowadays practically suitable for building such structures is glass with resistivity above 10^{12} Ω·cm, limiting the rate capability to about 500 Hz/cm^2 [257].

MRPCs have been largely used in Time of Flight systems such as ALICE [258], HADES [259], FOPI [260] and BESSIII [261], and in applications such as timing PET [262]. In perspective MRPC will be used for upgraded and new nuclear physics experiments such as CBM@FAIR [263] and SoLID [264].

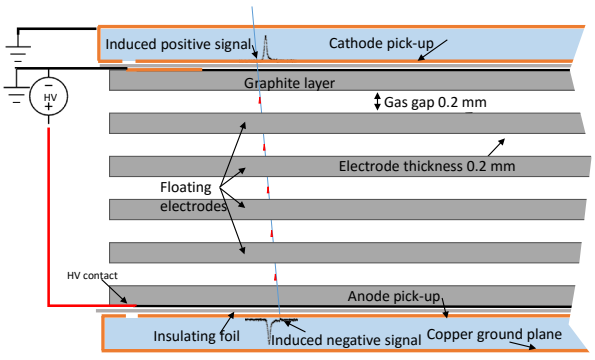

Figure 35.20: Schematic cross section of a generic multi gap RPC.

35.6.6.2 *Time and space resolution*

Space-time uncertainties in RPCs are intrinsically determined by the statistical fluctuations of the primary and secondary ionization, the avalanche multiplication rate and drift velocity, which are both a function of the electric field and gas composition. The Signal/Noise ratio of the front end electronics is crucial to preserve this information. The intrinsic signal latency (time lapsed between the ionizing event and the growth of the signal above detection threshold) is commonly in a few ns range, making the RPC suitable for applications where a low latency is essential.

The gas gap size is a crucial feature for the RPC timing performance: producing the same total charge (for a detectable signal) in a smaller gas gap implies the necessity of increasing the first Townsend coefficient by increasing the electric field, reducing at the same time the total signal duration and the related time fluctuations. Moreover, a thinner gas gap reduces the number on effective clusters participating to the signal formation, for an unknown amount of time, corresponding to their distance from the anode, thus decreasing the charge collection fluctuations [265]. Another important factor is the gas mixture, affecting both the drift velocity and multiplication rate. Depending on the gas mixture and on applied voltage, typical intrinsic resolution, ranges between $\sim$ 1 ns and $\sim$1.5 ns, for a 2 mm gas, and between $\sim$0.3 ns and $\sim$0.4 ns for a 1 mm gas gap [266].

The intrinsic position sensitivity of an RPC is in the range of tens of μm depending on the lateral spread of the avalanche induced charge distribution, influenced also by the gap size. In typical RPC applications the pick up electrodes pitch L ($\sim$1 cm) is much broader than the intrinsic resolution, and being readout via a discriminator, the spatial resolution is geometrically limited in the range of L/$\sqrt{12}$. A much better result is obtained by using a finer electrodes granularity and measuring the charge in each strip collecting the avalanche charge, so to reconstruct the charge centroid. It has been demonstrated, through charge centroid techniques, that the RPC avalanche space-time localization can be as good as $\sim$50 ps $\times$ 40 μm [267] [268]. Nevertheless, the high space resolution for large size RPCs, as well for any other planar detector structure, is often practically limited by the extensive mechanical precision of the readout electrode (which bulk is typically made of plastic), challenging to be kept negligible with respect to the intrinsic local resolution of the detector.

35.6.6.3 *Rate capability and ageing*

RPC rate capability is limited by the voltage drop on resistive electrodes, $\Delta V = V_{\rm a} - V_{\rm gas} = I \cdot R$ [269]. Here $V_{\rm a}$ is the applied voltage, $V_{\rm gas}$ is the effective voltage on the gas, $R = \rho \cdot d/S$ is the total electrode resistance, ρ being the resistivity and d,S the sample thickness and surface respectively, and I is the working current. Assuming uniform irradiation we can express $I = \phi \cdot S \cdot \langle Q \rangle$ where ϕ is the particle fluence and $\langle Q \rangle$ is average charge per avalanche. So we obtain a state equation for the RPC rate capability:

$$\Delta V/\phi = \rho \cdot d \cdot \langle Q \rangle$$

A large I not only limits the rate capability but also affects the long term performance of the detector, for three leading effects. Firstly, the working current, depletes the ionic electrode's carriers [270]. Secondly, the current builds up an electric field RI/d in the electrode bulk, accelerating the drif of internal ionic components to opposite surfaces. Thirdly, in presence of fluorocarbons and water, discharges generate hydrofluoric acid (HF) and other fluorinated compounds, which may damage internal detector surfaces. In case of electrodes made of glass, known to be not resistant to HF [271], it is necessary to suppress HF formation preventing water vapor contamination. Conversely, HPL electrodes, coated with linseed oil, notwithstanding the necessary presence of water which drives the conduction mechanism, demonstrated to be tolerant to HF in moderate concentrations, obtained by removing it with a forced flow of clean gas through the gas gap. Several ageing test have been carried out [272–275], confirming that measurable ageing effects were limited to a controlled increase of the ohmic current, of the electrode resistance and of the spontaneous counts. However, in extreme conditions, etching and surface damage have also been observed.

Operating in streamer regime places low requirements on the front end electronics sensitivity, but generally limits the counting rate capability to $\sim$100 Hz/cm^2. Higher-rate operation can be achieved by reducing gas gain in favor of electronic amplification, operating the detector in avalanche mode. Increasing concentrations of electronegative gases, such as $C_2H_2F_4$ and SF_6 [240], extends the avalanche signal distribution, requiring the front-end electronics a high sensitivity to the low end signal distribution and stability in presence of large signals. By further lowering the avalanche mode gas gain, efficient and stable performance at high

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

rates (e.g. 10 kHz/cm^2) has been achieved for large area single gap RPCs [244].

Further increasing the rate capability, can be achieved with complementary strategies: increasing the front end sensitivity to smaller signals and operating with a smaller amplification, relying on redundancy and higher signal yield of multiple micro gap structures [276] or lowering the electrodes resistivity [277]. The last strategy is increasingly difficult to be pursued, in presence of high electric field, since high resistivity limits the appearance of larger discharge events and increase of spurious counts, induced by the effect of local electrode defects on the field gradient. It seems in this case, that lowering the electrodes resistivity would require at the same time to reduce the operating electric field, achieving at the same time a lower average charge per count.

35.6.6.4 *Alternative gas mixtures*

The standard gas mixture mentioned above is based on Hydrofluorocarbon (HFC), specifically the R134a, and SF6, both extensively used in the industry. R134a features matches very well the RPCs performance requirements: high primary ionization yield; electronegative, limiting secondary discharge phenomena; not flammable; the absence of saturated bonds makes it robust to UV degradation, which is responsible for the production of fluoride radicals. SF6, as mentioned above is crucial to extend the streamer-free avalanche regime. The drawback is the high Global Warming Potential (GWP) of these gases (1430 and 24300 respectively), for which reason, their industrial application will be progressively limited in future according to the European Regulation [278]. In the last years the search for a possible replacement of R134a, relied on the Hydro-Fluoro-Olefins [279, 280], a category of gases recently proposed for industrial applications. However, HFOs exhibit important limitations with respect to HFCs, if used as main component of the mixture: for its electronegativity (higher than for R134a [281]) increasing the HV working point, and the charge per count, due to a large fraction of negative ions produced by electron capture [282, 283]. Moreover it is expected to produce a larger amount of fluoride radicals by UV decomposition of the gas, increasing the operative current and worsening the detector longevity [284, 285]. To contrast the ageing acceleration, driven by the effects stated above, the proposed strategy was to largely dilute HFO with a neutral gas, such as CO_2, compatibly with keeping an enough dense gaseous target, and, for future systems, operate at a lower gain by using very performing front end electronics. It has to be said that increasing of CO_2 finds its limits in the correspondingly increasing probability of inducing streamers [282, 283], which is further worsened by operating the RPC with an high discrimination threshold. A representative example of the several variants tested [286] is $CO_2/C_3H_2F_4$/i-C_4H_{10}/SF_6=59%/35%/5%/1%. This mixture with a large fraction of CO_2 is suitable for thicker (2mm) gas gap. The presence of CO_2 in 1 mm gas gaps reduces the amount of primary electrons, practically limiting its fraction to no more than 30% to keep the efficiency above 95%. Thus for a safe operation a reduction of the charge per count by an order of magnitude is necessary to compensate the expected stronger ageing phenomena. Detector performance and physics summaries can be found in [287, 288], not yet conclusive results about the detector longevity [284] confirm that the HFO based mixtures are more impacting than the standard one. On the base of the known results, LHC experiments conservatively opted either to hold on the standard gas mixture (CMS) or replace part of the R134a with an equivalent amount of CO2 (ATLAS). Several variants of this type of mixture have been tested, observing an improved longevity, with respect to the standard gas mixture, for lower fractions both of R134a and SF_6 [289, 290]. After this test,ATLAS decided to modify the standard gas mixture in two steps: first using $CO_2/C_2H_2F_4$/i-C_4H_{10}/SF_6=30%/64%/5%/1% in 2024 run. Then experimental confirmation of the expectations about ageing, lead to halve in 2025 run the fraction of SF_6, observing a further improvement (ATLAS internal). This allowed to safely lower the ATLAS CO_2 equivalent emissions by 25%. Given the very high GWP of SF_6 a dedicated investigation pointed out various alternatives [287, 291], in particular $C_3H_2ClF_3$ has been tested both for performance and longevity with very encouraging preliminary results [291].

35.6.6.5 *A new detector: the **R**esistive **C**ylindrical **C**ounter*

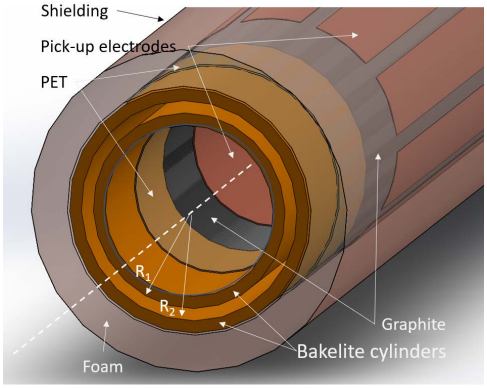

Figure 35.21: Schematic drawing of an RCC.

The RCC, illustrated in fig. 35.20, has been recently proposed as an evolution of the RPC [292] and is essentially an RPC warped to a cylindrical shape. The idea is to combine the advantages of parallel plate geometry and high pressure drift tubes in a single detector. The electric field $E(r)$, which is uniform in RPCs, here depends instead on the distance from the axis r, according to $E(r) = -\frac{V}{r\ln(R_1/R_2)}$. By choosing appropriate values for R_1, R_2, V and its polarization (the innermost cylinder is the cathode), it is possible to virtually segment the cylindrical gap in a innermost sensitive layer, where the field is sufficiently high to start the avalanche multiplication, and an outermost layer where the drift happens, increasing the induced signal with lower or no multiplication at all. This effect is called geometrical quenching and limits the avalanche growth without the necessity of electronegative gases. Moreover a geometrically quenched avalanche would have a much better prompt to total charge ratio, lowering the total operative current, hence increasing the rate capability. The cylindrical structure has a further major advantage with respect to the planar one, it can be easily pressurized overcoming the RPC limitation of working at atmospheric pressure only. Pressurization on one side increases the gaseous target density, thus increasing the efficiency of narrow gaps, on the other, it could largely improve RPC time resolution since the Townsend coefficient $\alpha = A\,p{\cdot}\exp(-Bp/E)$ (where p is the pressure, E the electric field and A,B are constants), as we learn from the RPC precursor, the Pestov spark chamber [231]. The preliminary performance of the first RCC prototypes in terms of efficiency, time resolution and counting rates are reported in [293] using the standard gas mixture. Further test will be needed to show the full potential of this device, such as its ability to work without fluorinated gases, and at high internal and external pressure, potentially extending its applicability range to space and under water applications.

35.7 LAr Time Projection Chamber

Written in October 2021 by F. Pietropaolo (CERN; INFN, Padova) and S. Pordes (FNAL). Revised in August 2025 by A. Fava (FNAL) and F. Pietropaolo (CERN; INFN, Padova).

35.7.1 *Introduction*

Liquid argon (LAr) is an attractive medium for particle detection. The most relevant physical properties of LAr are listed in Table 35.8; additional details can be found in [294]. In LAr, the energy deposited by charged particles is converted into ionization electrons and scintillation light; several tens of thousands scintillation photons and a similar number of ionization electrons are generated per MeV of deposited energy.

The LAr's high density (relative density ∼1.4), the electron drift over long distances with minimal diffusion, and the commercial availability as a by-product of air distillation make LAr especially suitable for large time projection chambers (TPCs) aimed at rare event detection, as first proposed in [296, 297]. Since then, LAr TPC technology has matured into a high-resolution (∼mm^3), fully

Table 35.8: Some physical properties of liquid argon from [295].

Property	Unit	Value

Latent Heat of Evaporation	kJ kg^{-1}	161
Freezing Point (1013 hPa)	K	83.8

active detector offering excellent particle identification, calorimetric capabilities, and nearly 100% live-time. Operating a liquid argon TPC requires the following core components:

1. A cryostat and cryogenics system to maintain ultra-pure liquid argon,
2. An electric field to drift ionization electrons toward the readout,
3. Charge readout sensors and electronics to amplify and digitize the signals,
4. Photodetectors and associated electronics to capture scintillation light,
5. A data acquisition (DAQ) system for readout and storage,
6. Reconstruction and analysis software.

This article discusses the challenges and practical solutions related to items 1–4. Topics 5 and 6 —DAQ and data processing— are also briefly introduced due to their critical role in realizing the full potential of LAr TPCs [298–300]. A number of auxiliary systems have been developed to enhance LAr TPC performance, including: in-argon cameras [301], purity monitors for fast assessment of argon quality [302, 303], and UV lasers for mapping drift field distortions due to space charge or electric field irregularities [304].

Detectors of up to 800 tons of LAr have been constructed and operated, and designs for tens-of-kiloton-scale detectors are underway. Extensive reviews of existing and planned LAr TPC detectors can be found in [305,306], as well as in detailed experiment reports [301, 307–316]. A summary of current and proposed LAr TPC experiments and their respective detector masses is provided in Table 35.9.

35.7.2 *Ultra-pure Liquid Argon*

A core requirement of the LAr TPC is the ability to maintain a large volume of ultra-pure liquid argon at stable temperature and pressure. This is achieved through a combination of cryostat design and cryogenic purification systems. For detectors with masses on the order of 100 tons, double-walled, vacuum-insulated, evacuable cryostats are practical. However, for larger detectors, this approach becomes impractical. The development of techniques to achieve ultra-high purity without prior evacuation [303] has enabled the use of non-evacuable, foam-insulated cryostats—adapted from liquefied natural gas (LNG) transport technology [301]. These cryostats are modular and designed for underground assembly. Furthermore, their passive insulation offers improved safety over vacuum insulation, as the insulation performance cannot abruptly change, as it would happen in case of vacuum loss.

Maintaining an extremely low level of electronegative impurities —primarily oxygen and water— is critical to preserving ionization electrons as they drift to the charge sensors. These contaminants capture free electrons, forming negative ions that drift too slowly to be detected. The argon purity is quantified by the electron lifetime τ, which describes the average time an electron can drift before being captured. For example, at an oxygen concentration of 0.1 ppb (by volume), the electron lifetime is approximately 3 ms [317, 318]. Since electron drift times in large detectors are often in the millisecond range, achieving oxygen concentrations well below 0.1 ppb is essential.

To reach these purity levels, the cryostat is first purged with argon gas to displace air, typically reducing oxygen and nitrogen concentrations to ppm levels [319]. During filling, commercial liquid argon —often containing oxygen and water at ppm levels— is passed through purification filters. Molecular sieves and activated copper on alumina [320] are widely used to remove water and oxygen, respectively. The realization that these purification materials remain effective at cryogenic temperatures [321] allowed for high-throughput liquid-phase purification, a major advancement over earlier gas-phase methods. Once the detector is operational, continuous recirculation of both liquid and boil-off gas through the purification system ensures the removal of contaminants introduced through outgassing or micro-leaks. Cryogenic system schematics are available in [301, 309, 311]. While the ultimate measure of argon purity comes from track reconstruction, dedicated "purity monitors" —double-gridded ionization chambers— are commonly employed for rapid, real-time feedback [301].

Nitrogen is another possible contaminant. While it does not significantly impact electron lifetime at concentrations up to several ppm, it degrades scintillation light yield and transmission with the few ppm N2 concentration [322, 323]. Oxygen at ppm concentrations also affects scintillation light [324], but in TPCs, this effect is typically negligible due to the stricter requirements imposed by charge readout.

35.7.3 *Charge and Light Signals*

Charged particles traversing liquid argon (LAr) deposit energy, producing both ionization electrons and scintillation light. Figure 35.22 (left) illustrates how these yields vary with applied electric field for a minimum ionizing particle (m.i.p.). The number of free electrons produced per unit energy is determined by the average energy required to form an electron-ion pair, $W_{el} = 23.6$ eV [325], the particle's energy loss rate (dE/dx), and the recombination factor R, which quantifies the fraction of electrons that escape recombination. Although several models have been proposed to describe recombination dynamics [326,327], the "box model" [328], which assumes mobile electrons and stationary ions, is widely used for its realistic assumptions [329], and has very recently been further improved to include an angular dependent effect [330]. Measurements of electron yield across various fields and ionization densities show good agreement [330–335]. One commonly used parameterization, based on ICARUS data [334], is $R = \frac{0.8}{(1+0.049(dE/dx)/\mathcal{E})}$ with dE/dx in MeV/cm and $\mathcal{E}$ in kV/cm. At a field of 500 V/cm, this yields $R \approx 0.70$ for m.i.p.s. corresponding to about 30,000 electrons/MeV escaping recombination. A detailed review of charge yield and recombination models is given in [336]. Under a uniform electric field, free electrons drift toward the charge readout system. This process is characterized by:

1. **Drift velocity**, which depends on electric field and slightly on temperature (see Table 35.10). A widely used parametrization [337,338] gives a drift velocity of 1.55 mm/μs at 500 V/cm and 89 K, shown in Figure 35.22 (right).
2. **Charge attenuation**, caused by capture on residual impurities. The surviving fraction after a drift time t is $\exp(-t/\tau)$, where τ is the electron lifetime. Lifetimes exceeding tens of milliseconds have been demonstrated [339–341].
3. **Diffusion**, which broadens the charge cloud. The spatial spread after time t is $\sigma_D^2 = 2Dt$, where D is the diffusion coefficient. Longitudinal diffusion measurements typically yield $D_L \approx 0.4$ mm^2/ms [333, 342–344], corresponding to a spread of $\sim$1.5 mm over a 3 ms drift.

Scintillation light in LAr arises from the decay of excited argon dimers (excimers), Ar_2^*, produced via both direct excitation and electron-ion recombination [356]. The recombination contribution decreases with increasing electric field, as shown in Figure 35.22 (left). At a field of 500 V/cm, about 30,000 photons/MeV are emitted after recombination.

Excimers form in either singlet or triplet states, with lifetimes of approximately 6 ns and 1.5 μs, respectively. These nearly degenerate states decay radiatively, emitting vacuum ultraviolet (VUV) photons centered at 128 nm with a $\sim$16 nm FWHM [349]. The singlet-to-triplet ratio depends on ionization density: 1:3 for m.i.p.s and up to 3:1 for highly ionizing tracks [353]. The long-lived triplet component is particularly sensitive to quenching by

Dielectric strength	kV cm^{-1}	>40 [314, 355]

impurities such as nitrogen and oxygen, which can non-radiatively absorb the excimer energy [322, 324].

Scintillation light propagation is influenced by **absorption** and **Rayleigh scattering**. Pure LAr is transparent to its own light due to a large Stokes shift [357], but trace levels of methane (ppb) [358] and nitrogen (ppm) [323] can significantly attenuate light. Rayleigh scattering, with a short mean free path in LAr, increases the photon path length and degrades spatial resolution in large detectors. To mitigate these effects, **wavelength-shifting dopants** have been proposed and tested. Xenon is a leading candidate: at tens of ppm concentrations, it efficiently absorbs excitation energy from argon dimers and re-emits photons at longer wavelengths, improving transparency and reducing scattering losses [359, 360].

35.7.4 *LAr TPC topologies*

Single-phase detectors, ranging from small-scale prototypes to large multi-kiloton systems, share a common layout: a cathode and surrounding field cage establish a uniform electric field across the active volume, directing electrons toward anode planes at ground potential. To maximize mass for a given readout complexity, long drift distances are favored. As a result, TPCs are often built with single drift regions, dual-drift volumes sharing a central cathode, or multiple drift modules. A notable exception is the DUNE Near Detector, where high event rates necessitate segmentation into many small TPCs [313].

The electric field is typically established by a planar cathode held at high negative voltage (up to -300 kV), a field cage that linearly degrades the potential, and sense planes at a voltage around 0 V. Uniformity of the field is essential, though it can be distorted in surface detectors by the accumulation of slow-moving positive ions produced by cosmic ray interactions [336, 341, 361–363]. Key challenges in high-voltage delivery include designing robust feedthroughs that transport the HV into the cryostat without breakdown [309, 364], preventing damage from possible discharges [301], and ensuring the integrity of the field cage resistor chains [365]. Maintaining HV stability in a medium designed for long-distance electron transport is one of the most demanding aspects of TPC design.

Figure 35.23 illustrates the typical single-phase geometry using wire planes with a horizontal drift field. Charge readout is performed by wire planes arranged perpendicularly to the drift direction, typically with two or three planes at different wire angles to enable 3D reconstruction. Although only two planes are strictly necessary to reconstruct the three-dimensional event topology, a third plane improves pattern recognition and mitigates inefficiencies due to noisy or dead channels. Wire pitch and inter-plane spacing are typically a few millimeters. The biasing scheme ensures that the drifting electrons pass through the intermediate planes and are collected on the final (collection) plane. Bipolar signals are induced on the induction planes, and a unipolar signal is recorded on the collection plane [366]. The condition for transparency is discussed in [367].

Signals are digitized at 2–2.5 MHz sampling rates over the full drift window. The 3D position of the charge deposit is reconstructed from the wire intersections and the drift time, converted to spatial coordinate via the known drift velocity.

Large-scale TPCs face intrinsic electrical design constraints: long cables between the sensing elements and amplifiers introduce capacitance and thus noise, while attempts to shorten cables can restrict sensor layout [366]. This challenge has been addressed by the development of cryogenic CMOS-based ASIC amplifiers that can operate directly in liquid argon [368, 369]. These cold electronics minimize noise and enable close proximity to the sensing elements, whether wires, strips, or pixels. The issue of routing hundreds of thousands of signals through the cryostat is further mitigated by implementing digitization and multiplexing within the cryostat itself [370], reducing the number and complexity of feedthroughs.

These developments have enabled equivalent noise levels of a few hundred electrons [341, 371], compared to expected charge yields of ∼30,000 electrons/MeV, or 60,000 electrons/cm for min-

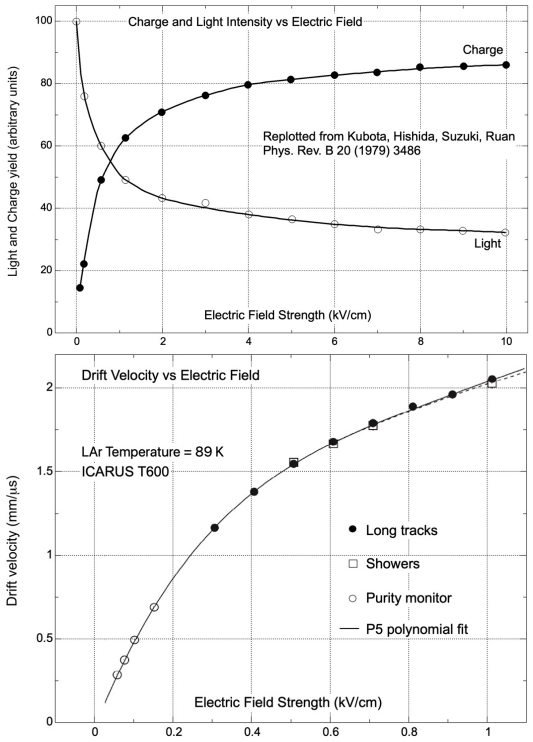

Figure 35.22: (*top*) the form of the light yield and the charge yield vs electric field redrawn from [356]; (*bottom*) electron drift velocity vs electric field redrawn from [337].

imum ionizing particles. This signal-to-noise ratio allows reliable detection of sub-MeV depositions and enables sub-centimeter spatial resolution with wire or pixel pitches below 5 mm.

Most large LAr TPCs also incorporate systems to detect primary scintillation light, which provides crucial timing information for 3D reconstruction [372], triggers [373, 374], complementary calorimetric information [341], and additional localization capability [298]. Given the VUV nature of LAr scintillation (128 nm), wavelength shifters are commonly employed to convert light into the visible range [375]. Photomultiplier tubes capable of cryogenic operation were originally developed for ICARUS [376], and recent systems increasingly use silicon photomultipliers (SiPMs). This allows for decoupling of the light collection and light detection components, and various strategies are being explored for each [301, 377, 378].

35.7.5 *Data Acquisition*

Operating large-mass LAr TPCs requires managing and processing immense volumes of data from digitized charge waveforms and scintillation light channels. For example, in the DUNE experiment, the data throughput is expected to reach up to 1.7 TB/s per detector module (with a 10 kt fiducial mass). To cope with this, several data reduction strategies are typically employed [379,380]:

1. **Zero suppression**: Applied channel-by-channel to digitized waveforms to discard time samples below a given threshold (generally related to the electronic noise level).
2. **Triggered readout**: Fast signals from photon detectors or external sources (e.g., a neutrino beam) trigger the readout of the TPC over a predefined time window. The trigger rate is tuned to match the DAQ throughput capabilities.

Historically, DAQ systems could not afford to buffer or process the full complement of TPC data. However, recent advances in computing and high-speed networking have reshaped this paradigm. It is now possible to read out and buffer the complete digitized TPC data in commercial off-the-shelf (COTS) computers, enabling online processing [381,382] to identify regions with significant charge or light activity. These "trigger primitives" can be used by higher-level software triggers to selectively store data from all or parts of the TPC, similarly to how external triggers are used. Additionally, trigger primitives can be saved as a separate, low-volume data stream, enabling continuous activity monitoring with minimal bias.

This approach permits significant data reduction—up to a factor of 300 for DUNE's four 10 kt modules—while maintaining sensitivity to low-energy signals. It also allows for complementary integration of charge and photon detector information in real-time. This combined readout enhances detection capabilities, particularly for low-energy depositions at the MeV scale, such as supernova neutrino bursts or rare decay signatures.

35.7.6 *Event reconstruction*

The goal of LAr TPC event reconstruction is to extract the physics content of interactions: event topology, particle identification, and energy measurement. Reconstruction generally proceeds in the following stages:

1. **Signal Processing**: Raw waveforms, which reflect the charge collected over time on each readout channel, are processed to correct for pedestal shifts, suppress noise, and deconvolve the detector and electronics response. The result is a set of "hit" objects representing localized energy depositions in space and time [383–385].
2. **Pattern Recognition (PR)**: In wire-readout TPCs, the signal from each wire plane forms a 2D image (drift time vs. position). Typically, three planes at different orientations allow stereo reconstruction of 3D structures. PR can be performed either by matching objects across 2D planes (as in Pandora [386]) or directly in 3D using tomographic reconstruction (as in WireCell [387]). The goal is to identify tracks, showers, common vertices, and the global event topology.
3. **Calorimetry and Particle Identification (PID)**: Reconstructed tracks and showers are calibrated and used to compute energy deposition per unit length (dQ/dx), which is further converted into dE/dx. This enables estimation of total energy and particle type [388].

Recent developments have made **machine learning (ML)** integral to LArTPC reconstruction. Early ML efforts included simple multivariate classifiers and boosted decision trees. More advanced techniques now dominate many tasks, particularly **convolutional neural networks (CNNs)**, which are applied for signal processing assistance [389,390], semantic segmentation [391–393], and vertex reconstruction [394]. CNNs are also used for high-level reconstruction tasks such as PID [300, 395] and energy estimation [396].

Beyond CNNs, newer architectures include **Recurrent Neural Networks (RNNs)** for time-series energy reconstruction [397], **Graph Neural Networks (GNNs)** for hit clustering and labeling [398], and hybrid CNN-GNN models for full event reconstruction pipelines [399]. These developments are accelerated by the availability of public datasets [400] and integration of ML tools within GPU-accelerated software frameworks [299, 401].

35.7.7 *Developments*

The successful operation of the ICARUS T600 detector [402] provided a milestone in demonstrating the feasibility of large-scale liquid argon TPCs. Since then, the technology has rapidly evolved, with the community expanding significantly. Notable advancements include:

- **Cold electronics**: CMOS-based amplifiers now operate reliably within liquid argon.
- **Modern photon detectors**: Silicon Photomultipliers (SiPMs) and novel light collection designs and readout are increasingly replacing traditional photomultiplier tubes.
- **Improved light performance**: Dopants (e.g., xenon, TMG) and advanced wavelength shifters improve light yield and timing.
- **Scalable cryostat technology**: Membrane cryostats, as adopted in DUNE, enable safe and cost-effective scaling to tens of kilotons.

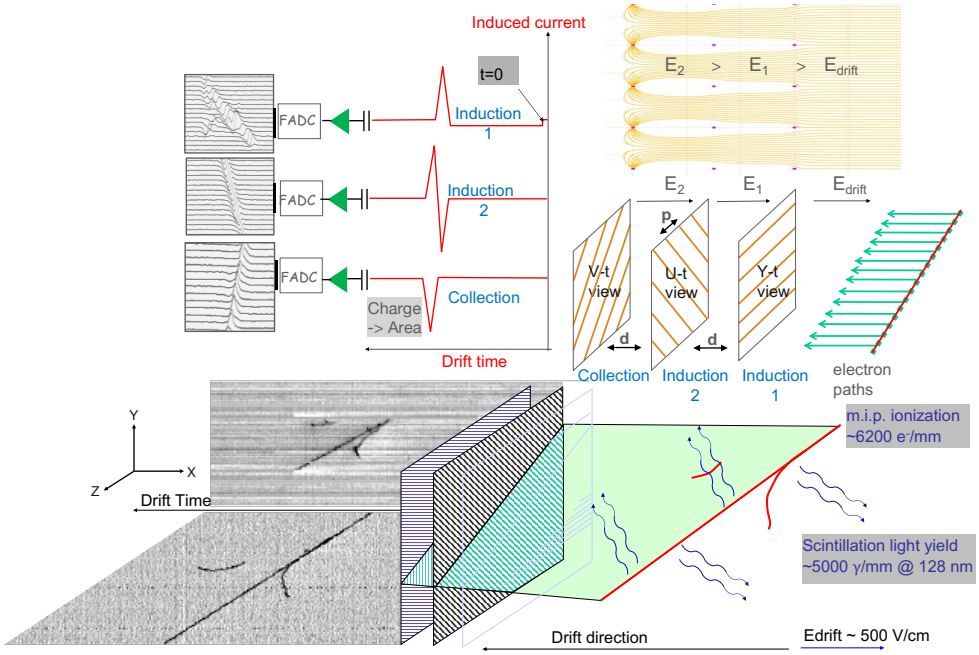

Figure 35.23: Schematic of an event in the ICARUS 3 t LAr TPC; *Top (from right to left)*: field lines from drift region to collection wires, electron flow & arrangement of wire-planes, signal shapes on the wires, and wave-forms from the continuous readout and digitization; *Bottom*: the passage of a muon. The gray scale on the track indicates the ionization density.

- **Pixelated readout**: Replaces traditional wire planes in high-rate or high-occupancy environments, allowing unambiguous 3D charge localization [403].
- **LAr Purification**: novel techniques to capture not only electronegative impurities but also Nitrogen dissolved in LAr through specific molecular sieves [404].

Several new directions are under exploration. These include the **vertical drift** single-phase TPC, proposed for the second DUNE far detector module, which uses perforated PCB strips for charge readout [405]; **optical-only dual-phase readout**, where the electroluminescence light is imaged by fast cameras [406]; and **photon sensors powered and readout by optical systems** (Power over Fiber, Signal over Fiber) [407] which enable light detection at arbitrary electric potentials and positions. In parallel, efforts are underway to **build high voltages in-situ** using Greinacher-style multipliers, eliminating the need for ultra-high-voltage feedthroughs [408]. Operation of a small **LAr-TPC in a magnetic field** of up to 0.7T is also being pursued [307] to investigate benefits of distinguishing particle's charge sign (enabling electron/positron discrimination and increasing electron/photon separation) and measuring momentum of particles via curvature (especially important for muons and pions exiting the detector).

Simultaneously, extensive datasets from current experiments are enabling deeper insights into the argon medium [336, 409] and revealing novel phenomena. These range from the detailed understanding of light propagation, scattering, and absorption, to the behavior of impurities and their impact on charge and light transport. Emerging topics—including the measurement of Rayleigh scattering, precise determination of water capture time, and the role of dopants—highlight the continuing richness of this research area.

The field is active, rapidly advancing, and full of opportunity.

35.8 Semiconductor detectors

Revised November 2025 by G. Kramberger (Jozef Stefan Inst.) and N. Wermes (Bonn U.).

Semiconductor detectors offer outstanding detection opportunities in terms of position, energy and also time resolution, often in combination. In accelerator experiments, they are most widely used as position-sensing devices, *e.g.* in tracking detectors, or as photodetectors (Sec. 35.2), for example in calorimeters (Sec. 35.10) or in imaging Cherenkov detectors (Sec. 35.5). In recent years, also precise time measurement ($\mathcal{O}$(10–30 ps)) with silicon detectors has come into the focus of developments. When comparing semiconductor detectors, particularly with gaseous detectors, the main features are high density and low ionisation threshold, providing in depleted substrates comparatively large signals even without intrinsic amplification. Silicon detectors with active layers only 50–300 µm thick provide adequately large and fast signals on a typical time scale[4] of 10–50 ns. Challenges are the purity of the semiconductor material, characterised by its mobility-lifetime ($\mu\tau$) product, and its radiation resistance. The development of modern semiconductor detectors is closely tied to integrated circuit (IC) technology. Micro-processing and microelectronics technologies enable fabrication of high-density micron-scale electrodes on large wafers (6–8 in $\approx$ 15–20 cm diameter of sensor wafers) and allow for high-density amplification and readout circuits connected to them (chip-wafer sizes are up to 12 in $\approx$ 30 cm with typical reticles of 26×33 mm^2). For larger than reticle-size area stitching over the reticle boundary is mandatory. In recent years stitching has been demonstrated even for wafer-scale area-sizes.

Some important material properties of common semiconductors used as detectors are summarised in Tab. 35.11. While for particle tracking the excellent position resolution is the main (but not the only) interest, high stopping power and high energy resolution are key parameters in X-ray, γ-ray, and β spectroscopy, for example, in neutrino-less double-beta decay searches. Due to its small bandgap, germanium excels in energy resolution but needs to be operated at very low temperatures (liq. N_2) to reduce thermally generated reverse bias current. Besides Ge, also GaAs, CdTe and CdZnTe (CZT) feature high atomic numbers and hence much higher stopping power and shorter absorption length than Si, which is important, especially for X-ray detection. Diamond, fabricated by chemical vapour deposition (CVD) and strictly speaking classified as an insulator with a large bandgap (Tab. 35.11), features low Z and large radiation length X_0. Thanks to its radiation hardness (Sec. 35.8.5), it is used for particle detection in

[4] Characterised here by the peaking time of the signal pulse.

dedicated applications, especially in zones with high particle flux (see *e.g.* [410] and references therein).

Materials R&D for radiation sensors extends to other bulk semiconductors as well, for example, ZnS, SiC, GaN or InP. SiC, in particular, shares most of the beneficial properties of diamond for particle detection and is available in high-quality, large-diameter wafers (see Tab. 35.11). Also, new material structures and metamaterials have come into focus. Examples are semiconductor Quantum Dots, realised by nanometer-sized semiconductor "particles" embedded in a semiconductor bulk, or graphene, which—as a zero-bandgap 2D material—features extraordinarily high conductivity (electrical and thermal) and outstanding photonic properties. A bandgap can be introduced by employing doped bi- or multi-layer graphene structures, thus rendering transistor and sensor realisations possible. The interested reader is referred to references [411] or [412], for example.

Operating usually without intrinsic amplification, semiconductor detectors crucially depend on low-noise electronics (see Sec. 35.9), so the detection sensitivity is determined largely by signal charge and input capacitance. Reviews of semiconductor detectors and electronics can be found, for example, in refs. [1, 8, 413–415].

35.8.1 *Signal generation in semiconductors*

35.8.1.1 *Creation of charges*

Semiconductor detectors are solid-state ionisation chambers. Absorbed energy forms electron-hole (*e-h*) pairs, *i.e.* negative and positive charge carriers which—when moving e.g. in an applied electric field—generate a signal current on the electrodes by electrostatic induction (see Sec. 35.8.1.2). For the signal charge carriers to (freely) drift in the electric field and become detectable, a semiconductor must feature a small intrinsic charge-carrier density (as exists, for example, in diamond and SiC, and to some extent also in GaAs and CZT) or they must be depleted by reverse-bias junction configurations (as for Si, Ge or CdTe). In addition, they should feature a low intrinsic density of defects which can act as trapping or generation/recombination centers (see Sec. 35.8.5).

The minimum energy required to form an *e-h* pair is the bandgap energy (1.12 eV in Si, 0.66 eV in Ge, 5.5 eV in diamond). However, impinging radiation or particles also release energy to lattice vibrations (phonons) such that the average energy for *e-h* pair creation is higher. In an "indirect" semiconductor like Si, the valence-band maximum is not at the same position in k-space (crystal-momentum space) as the conduction-band minimum and additional momentum transfer is required for a band transition to occur. Since the "direct" bandgap energy without k-transfer in Si is 3.4 eV, photons with energies less than 3.4 eV must receive momentum from lattice phonons. Because phonons are Bose-Einstein distributed, the needed momentum kick causes a steep rise in photon absorption probability between 1.12 eV and about 3.4 eV (see e.g. [1]). For larger energy deposits, the average energy $w_{\rm i}$ needed to produce an *e-h* pair assumes a constant value of 3.65 eV at room temperature. For other semiconductors consult Tab. 35.11.

For minimum-ionising particles, the most probable charge deposition in a 300 µm thick silicon detector is about 3.7 fC (∼23 000 electrons). In tracking detectors, a particle's energy loss and scattering in the detector material should be minimal (large X_0), whereas, for energy spectroscopy, *e.g.* of X-ray photons, the stopping power should be maximised by choosing high-Z semiconductors[5]. A smaller bandgap (in fact a smaller w_i) leads to a larger signal per deposited energy and improves the energy resolution, but also (exponentially) increases thermally excited carrier generation. To cope with excessive leakage currents at room temperature, Ge diodes are typically operated at liquid nitrogen temperature (77 K). In pure Si at 300 K, the intrinsic carrier concentration is $n_i \simeq 10^{10}\,\mathrm{cm}^{-3}$ (Tab. 35.11), corresponding to a resistivity in the order of $\rho \simeq (e\mu n)^{-1} \approx 400\,\mathrm{k\Omega\,cm}$. In reality, crystal imperfections and minute impurity concentrations limit Si carrier concentrations to about $10^{11}\,\mathrm{cm}^{-3}$ at 300 K ($\rho \approx 40\,\mathrm{k\Omega\,cm}$). In practice, wafer resistivities up to 20 kΩ cm are available, with mass production ranging from 1 to 10 kΩ cm.

[5] The cross section for photo effect scales as Z^5 (see Sec. 34)

The energy released in a semiconductor is absorbed by electronic excitations (e/h) and lattice excitations (phonons) in an anti-correlated way. Therefore, for a fixed released energy E (for example, of an X-ray photon), the variance in the number of charge carriers $N = E/w_i$ follows binomial statistics. Due to the energy constraint, this variance is reduced by the Fano factor F relative to Poisson statistics (F ≈ 0.1 in Si and Ge). Thus, $\sigma_N = \sqrt{FN}$ and the energy resolution is $\sigma_E/E = \sqrt{Fw_i/E}$. However, for semiconductors, the measured fluctuations of a detected energy signal are usually dominated by electronic noise rather than by signal fluctuations. The electronic noise contribution depends much on the detector leakage current and the electrode capacitance as well as on pulse shaping (*i.e.* the shaping time) in the signal processing electronics (see Sec. 35.9).

For X-ray detection, a major effort is made to find high-Z materials with a bandgap that is sufficiently large to allow for room-temperature operation while still providing good energy resolution. Compound semiconductors, *e.g.* CZT, can allow this, but typically suffer from charge collection problems, which are characterised by the product $\mu\tau$ of mobility and carrier lifetime; this is the depth per field strength that generated carriers can drift before being trapped.

In Si and Ge, $\mu\tau$ is orders of magnitude larger than in compound semiconductors for both electrons and holes (see Tab. 35.11). Since for holes $\mu\tau$ is typically much smaller than for electrons, detector configurations where the electron contribution to the charge signal near the readout electrode dominates (as *e.g.* in strip or pixel structures with electron collection) usually provide better performance (see also next section).

35.8.1.2 *Signal formation*

The signal and its pulse shape depend on the instantaneous carrier velocity $\vec{v}(\vec{x}) = \mu\vec{E}(\vec{x})$, μ = mobility, and on the electrode configuration and its geometry, which determine the form of the induced current according to the Shockley-Ramo theorem

$$i_S(t) = N_{e/h}\, e\, \vec{E}_w(\vec{x})\, \vec{v}(\vec{x}(t))\,, \qquad (35.20)$$

where $N_{e/h}\, e$ represents a drifting charge cloud of $N_{e/h}$ elementary charges, $\vec{E}_w(\vec{x})$ is the "weighting field", which accounts for the coupling of the charge to a specific electrode and depends on the electrode configuration, and $\vec{v}$ is the drift velocity. Note the difference between the electric field $\vec{E}$ and the weighting field $\vec{E}_w$ and take account of the fact that the mobility is, in general, field-dependent, $\mu = \mu(E)$, with $v \approx const$ at high fields (velocity saturation, for electrons in Si approaching 10^7cm/s at $E > 10^4$ V/cm). Both electron and hole movements contribute to an electrode's signal. Hence, if the carrier mobility is very different for electrons and holes, like *e.g.* in CdTe where $\mu_h \ll \mu_e$ (Tab. 35.11), a photon signal, for example, can become absorption-point dependent.

Integration of the induced current signal on an electrode yields the "collected charge". The average time to collect the created charge decreases with increasing bias voltage (*i.e.* field strength) until velocity saturation occurs.

For a simple parallel-plate geometry with two electrodes, the weighting field is constant, whereas for structured electrode geometries, like for example strips or pixels, $\vec{E}_w$ is position dependent, which for small electrodes (compared to the sensor thickness) strongly enhances the contribution of the movement close to the electrode ("small-pixel effect"). More details and practical accounts of the Shockley-Ramo theorem and its usage can be found in [1, 8] and references therein.

Position resolution is ultimately limited by transverse diffusion of the moving charge cloud (typically 3–5 µm for 200–300 µm thickness) and by the emission of δ electrons. The performance then depends on optimal usage of charge sharing between neighbouring electrodes and on the noise. In magnetic fields, Lorentz drift deflects the electron and hole trajectories by an angle $\tan\alpha_L = \mu\, r_H B$, thus increasing the spatial spreading. The factor r_H accounts for the mobility difference with and without a magnetic field. For silicon at room temperature and small B-fields, $r_H \approx 1.15$ for electrons and $r_H \approx 0.8$ for holes; for large magnetic fields $r_H \approx 1$. The total spreading and hence charge sharing between electrodes can be tuned (increased or decreased) by tilting

‡Approximate averages. Mobility values for diamond quoted in the literature vary strongly.

the detector relative to the incoming (average) particle direction. Overall spatial resolutions of 2–4 µm (rms) have been obtained.

35.8.2 *Junction detectors*

Si and Ge detector substrates must be—others like CdTe, GaAs should be, and CZT can be—depleted of free charge carriers by operating them as reverse-bias junctions (p-n or Schottky) to be sensitive to the charge created by impinging particles. SiC, although intrinsically almost free of charge carriers, usually comes as wafers with doped epitaxial layers of thickness $\lesssim 100$ µm and SiC detectors are hence built as junction detectors.

A typical cross-section of a junction detector is shown in Fig. 35.24, here with structured electrodes at the top. A p-n junction—even without external voltage—forms a sensitive space-charge region across itself, depleted of mobile charges, hence also called "depletion region". The space charge establishes an electric field corresponding to a "built-in" voltage V_{bi}. An additional reverse-bias voltage V, applied externally, increases the space-charge region, allowing radiation-generated charge to be swept to the electrodes by the existing field. Detectors typically use an asymmetric structure, for example, a thin and highly doped p^+ electrode[6] region and a lightly doped n^- substrate region – or vice versa, so that the depletion region extends predominantly into the more lightly doped bulk volume.

In such planar Si (or Ge) devices, the thickness of the depleted region is

$$d = \sqrt{2\epsilon\,(V + V_{bi})/Ne} = \sqrt{2\rho\mu\epsilon\,(V + V_{bi})} \qquad (35.21)$$

$$\approx \frac{0.5}{\mu\text{m}} \times \sqrt{\frac{\rho\,V}{\Omega\,\text{cm}\cdot\text{V}}} \qquad \text{for } n\text{-type Si bulk}$$

$$\approx \frac{0.3}{\mu\text{m}} \times \sqrt{\frac{\rho\,V}{\Omega\,\text{cm}\cdot\text{V}}} \qquad \text{for } p\text{-type Si bulk}$$

with (values for Si)

V = external bias voltage
V_{bi} = "built-in" voltage (≈ 0.5 V for typ. used resistivities)
N = doping concentration
e = elementary charge
ϵ = dielectric constant = $11.9\,\epsilon_0 \approx 1$ pF/cm
ρ = resistivity (typically 1–10 kΩ cm)
μ = charge carrier mobility (∼ 1450 cm^2/Vs (electrons), ∼ 500 cm^2/Vs (holes) [417])

The conductive p and n regions together with the depleted volume form a capacitor with capacitance per unit area

$$C' = \frac{\epsilon}{d} \approx \frac{1\,\text{pF/cm}}{d} \qquad \text{in Si.} \qquad (35.22)$$

The depletion depth d becomes as large as the sensor's thickness at the "full depletion voltage" $V = V_{fd}$ for which the sensor capacitance reaches a minimum (about 35 pF/cm^2 for $d = 300$ µm). In strip and pixel detectors (see next section), the capacitance is dominated by the fringing capacitance to neighbouring electrodes as the electrode pitch is typically much smaller than the sensor thickness. For example, the strip-to-strip Si fringing capacitance is about 1–1.5 pF per cm of strip length at a strip pitch of 25–50 µm, depending also on the electrode width.

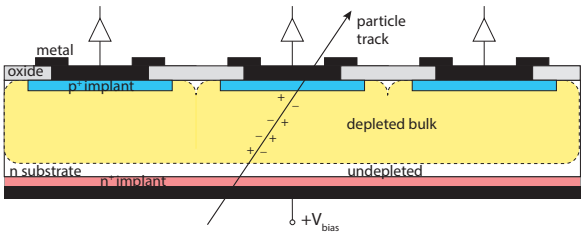

Figure 35.24: Reverse-bias junction detector with planar readout electrodes at the top in a standard sensor configuration (p^+-in-n): lightly doped n-type substrate with p^+ implants forming the diode junction at the top side. Electrons move to the bottom electrode and holes to the top. Both movements contribute to the (induced) signal at the top electrodes with amounts as specified by the weighting field (see Sec. 35.8.1.2). The n^+ implant at the bottom side forms an ohmic contact between bulk and metal.

The electric field strength and shape inside the semiconductor bulk are important for efficient signal-charge collection. Governed not only by the applied external voltage, but also by the space charge inside the semiconductor bulk, the field strength decreases linearly (for constant space charge) from its maximum at the junction's boundary into the depleted semiconductor bulk. Apart from

[6] $n^{+/++}$, $p^{+/++}$ as well as n^-, p^- qualitatively denote relative doping-concentration levels.

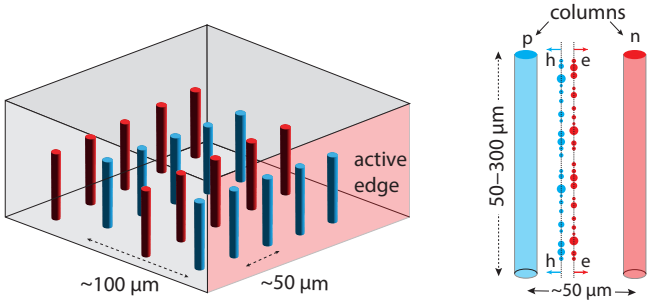

Figure 35.25: Junction detector with vertical electrodes, n (red) and p (blue), and "active" edges called 3D-Si. Dimensions given are typical. This electrode configuration provides short drift paths for moving charges while keeping a large sensing thickness. An active edge minimises dead areas at the sensor boundaries. This geometry has also been employed in CVD diamond substrates.

the doping atoms, space charge can also occur from ionised lattice defects which either naturally exist for example in GaAs or can be created by irradiation in any semiconductor material (see Sec. 35.8.5). This can lead to low-field regions as well as to changes in the field's shape (deviating from linear), both of which usually deteriorate the charge collection properties of a detector.

In partial depletion (*i.e.* $V < V_{fd}$), the field decreases to zero at the end of the depletion zone. Overbias ($V > V_{fd}$) adds a constant electric field component, which avoids a vanishing field region and also provides faster charge collection as long as the carrier drift velocity has not yet saturated. At an average field of $E = 10^4$ V/cm, the onset of velocity saturation, where $\mu_e \approx 7{\times}10^2\,\mathrm{cm}^2/\mathrm{Vs}$, $\mu_h \approx 3.5{\times}10^2\,\mathrm{cm}^2/\mathrm{Vs}$, the collection times for Si are about 15 ps/µm for electrons and 30 ps/µm for holes. In typical fully-depleted detectors, 100–300 µm thick, electrons are collected within less than about 5 ns, and holes within less than about 10 ns.

Large volume ($\sim 10^2 - 10^3\,\mathrm{cm}^3$) germanium detectors, especially for gamma-ray detection, are commonly configured in cylindrical or hexagonal rod shapes, for example, a 10 cm long cylindrical n-type crystal with 5–10 cm diameter with an inner 5–10 mm diameter n^+ electrode and an outer p^+ layer forming the diode junction. Germanium can be grown with fairly low impurity levels, 10^9–$10^{10}\,\mathrm{cm}^{-3}$ (HPGe, high-purity germanium), so these large volumes can be depleted with several kilovolts.

Diamond, featuring free charge carrier densities close to zero, needs no further depletion and is operated as a parallel plate capacitor with an insulator dielectric inside. Still, a substantial bias voltage is required to overcome charge trapping.

35.8.3 *Detectors with structured electrodes*

35.8.3.1 *Microstrip-, Si-drift- and hybrid-pixel detectors*

In HEP experiments semiconductor detectors usually aim at good position resolution achieved with electrodes patterned in "strips" or "pixels" with typical dimension scales (electrode pitch) of 50–100 µm, or in "pads" (mm^2–cm^2) if coarser granularity is affordable for the benefit of fewer channels.

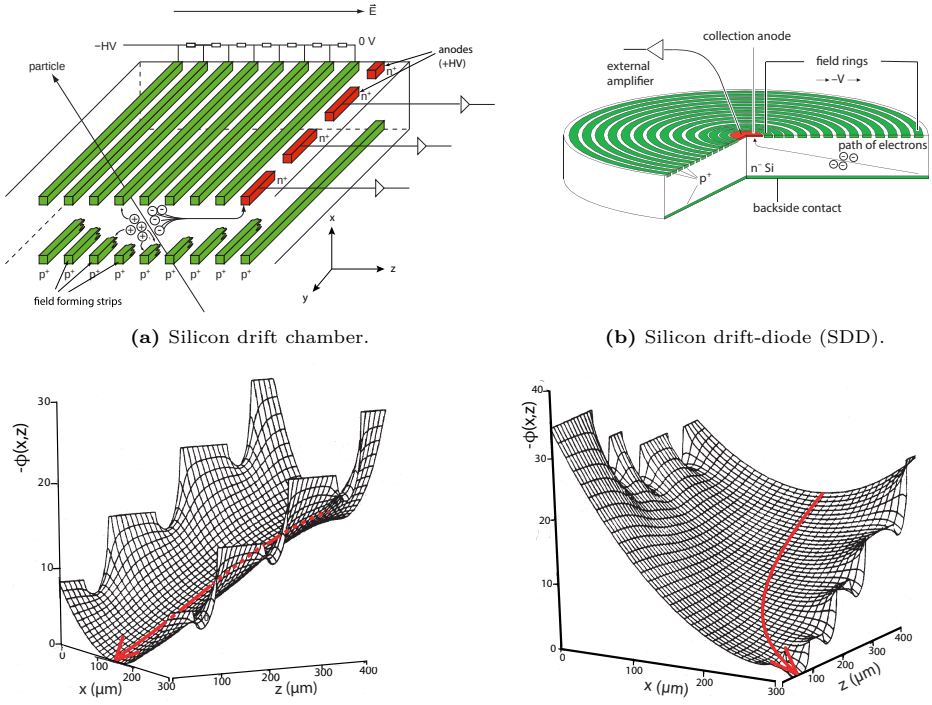
Electrodes are usually placed "planar", *i.e.* at the surface of the sensing Si bulk (Fig. 35.24). In an alternative, but more elaborate way, electrodes can be shaped as columns or trenches running orthogonally to the surface and hence parallel to the average direction of impinging particles (Fig. 35.25) [418]. This geometry which is termed "3D-Si", but is also exercised with diamond, enhances the radiation tolerance due to shorter drift distances of charges at the same thickness, hence decreasing the probability for carrier trapping (see also Sec. 35.8.5).

The 3D technology offers a large variety of cell geometries usually optimized for a given task, realized with column electrodes, trench electrodes (plane parallel-trench cells) or a combination of both. In recent years, manufacturing the vertical electrodes has advanced to simpler single-sided processing, reaching aspect ratios (diameter to depth) of up to 70, thus enabling smaller cells and thicker detectors. The processing techniques employed for 3D devices also enable the creation of continuous trenches with conductive sensor side-walls ("active edge" in Fig. 35.25), which are useful for laterally extending the depleted volume up to the physical edges.

In strip detectors, the strip ends are connected to dedicated readout ICs where the signals are amplified and processed. Two-dimensional readout is realised either by angled double-layers of strip detectors or by "double-sided" strip sensors, structured by readout strips on either side (see *e.g.* [1, 414] and references therein). For the latter, one electrode surface features n^+n or p^+p strip junctions (rather than pn), respectively, which require dedicated measures, *e.g.* intermediate strips or special doping profiles to break the electron accumulation layer that occurs at an n^+n interface. For p^+p, intermediate n strips or similar are not necessary, owing to positive oxide charges residing at the Si/SiO_2 interface, thus preventing the formation of a hole accumulation layer.

Following the concept of gaseous drift chambers, silicon drift chambers provide the position of a hit orthogonal to a strip's coordinate from a measurement of the charge cloud's drift time, drifting over centimeter-long paths inside the silicon bulk (Fig. 35.26a). For this to work, the bulk is "sidewards depleted" by using junction strip-implants of the same polarity on both sides of the sensor (p in n or n in p, respectively), *i.e.* different to standard double-sided strip detectors (see *e.g.* [1]). This way, a quadratic potential minimum for electrons is created, confining them amidst the sensor bulk; holes, instead, drift to the sides. A constant potential (linear field) is superimposed in drift direction (Fig. 35.26c); near the anodes, electrons are pushed towards n-strip collection electrodes by appropriate biasing (Fig. 35.26d). Unlike strip detectors, far fewer electrodes are necessary for the same active area coverage. A drawback is the low rate capability of Si-drift detectors caused by the long drift path of the created charges. Arranged with only one small electrode with low capacitance in the center of a cylindrical disk, so-called silicon drift-diodes (SDD, Fig. 35.26b) are low-noise single-channel devices with large area coverage (typically cm^2), used for example in X-ray fluorescence analysis, electron microscopy and space applications.

Very small pixel structures for particle detection were first realised with CCDs (Charge Coupled Device) [419]. Most current applications, particularly those for high-rate applications such as at the LHC, employ the "hybrid-pixel" concept in which both the sensing diode structure as well as the readout IC have equal electrode structures and patterns (pixels). The connection is made by two-dimensional arrays of solder or indium bumps that mate the two parts by employing the flip-chip technology (Fig. 35.27, usually chip-to-(sensor)chip or several-chips-to-sensor; more details in [414,420,421]). Further advancements in bonding-technique development especially address chip-to-wafer or even wafer-to-wafer placements [420]. Attractive in this context of particle detectors are Cu–Cu, Cu–Sn, or oxide–oxide (SiO_2) diffusion bonding without solder. Also, SLID (Solid Liquid Interface Diffusion), which employs a very thin liquid metal layer (Sn) in between metals with higher melting points (*e.g.* Cu) is an option.



The hybrid approach excels in optimally utilising chip and sensor materials and technologies for radiation hardness and rate capability (see *e.g.* [420]). It is, therefore, the technology of choice for pixel trackers in high-rate, high-radiation environments optimised for that purpose by employing very thin modules ($\mathcal{O}(300\,\mu\mathrm{m})$ total). A disadvantage is the complex and cost-intensive module assembly.

35.8.3.2 *Monolithic pixels*

Partially or fully monolithic pixel detectors directly connect the generated signal charge with an embedded active electronics device (*i.e.* one or several transistors). An example of a partially monolithic device is the DEPFET (depleted p-channel FET) pixel sensor (see *e.g.* [422]), employed in the Belle-II pixel-vertex detector and—with circular cells—also developed for satellite experiments as shown in Fig. 35.28a. A single transistor (pMOSFET) is implemented in every pixel. The sensor substrate is "sidewards depleted"—as done similarly in Si driftchambers (Sec. 35.8.3.1)—employing the backside p-contact and several p regions near the transistor. Depletion is provided by the n^+ *clear* contact (see

(d) Electric potential near the anode region. (b) Si drift diode featuring circular field rings and only one small collection anode in the center of the diode, constituting very low capacitance for the readout electronics.

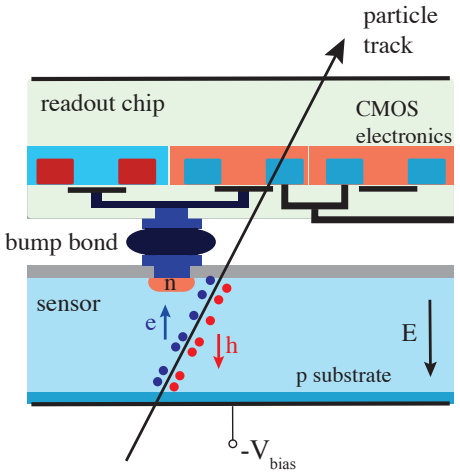

Figure 35.27: Cross-sectional view of a hybrid-pixel detector cell (one pixel) consisting of sensor (bottom) and readout chip (top) with CMOS circuitry illustrated by three transistors (red and blue implant areas plus metal lines). The sensor is a depleted diode structure (here p substrate with n electrode). Both parts are mated by a microbond (bump bond), typically solder or indium.

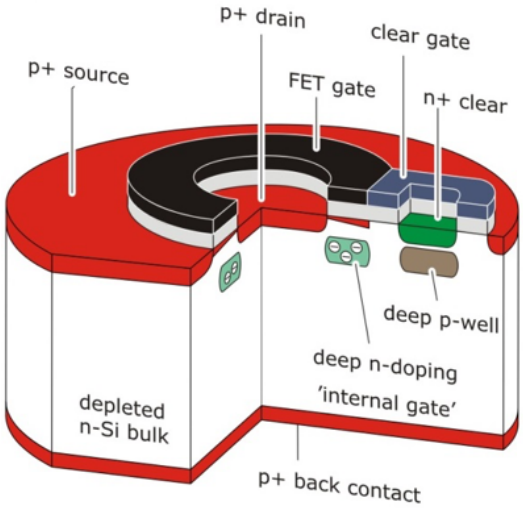
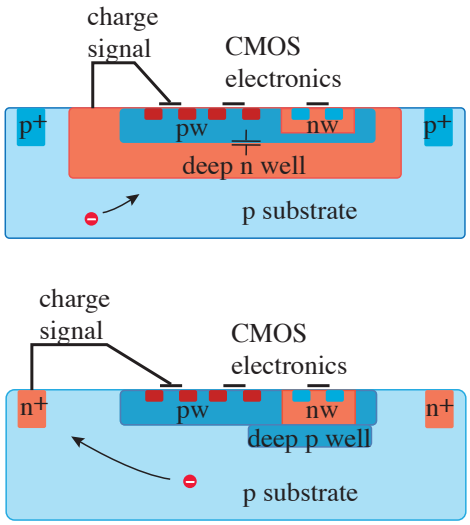


below) plus a bulk n-implant outside the matrix. In addition, the structure features a deep n-implant located a few micrometers underneath the transistor channel on floating potential. This implant becomes the most positive point of the structure, hence being an electron accumulation point which acts as an "internal gate" of the transistor. The gate voltage changes by an amount $\alpha q_S/C$, with signal charge q_S, gate-oxide capacitance $C = C_{ox}\,WL$ where $W{\times}L$ = gate area, and with $\alpha \lesssim 1$ accounting for stray capacitance. The gate voltage changes due to an accumulated signal charge q_S in the internal gate, leading to a detectable change in drain current (in saturation):

$$I_D = \frac{W}{2L}\,\mu C_{ox}\left(V_G + \frac{\alpha\, q_S}{C} - V_{th}\right)^2 . \qquad (35.23)$$



Other elements in Fig. 35.28a like the external FET gate and the *clear* implant provide control and reset of the structure. The device gain $g_q = dI_D/dq_S \approx \alpha g_m/C$, with transconductance $g_m = \mu C_{ox}\frac{W}{L}(V_G - V_{th})$, is of order 500 pA/e$^-$. The small capacitance of the internal gate (few fF) enables very low-noise operation ($\lesssim 2\mathrm{e}^-$) when operating with long shaping times (cf. Sec. 35.9).

Fully monolithic pixels combine the sensing task and the complete readout circuitry, *i.e.* the two separated parts of hybrid pixels, in one chip. Both functions must be properly shielded from each other, which is achieved by exploiting multi-well IC technology. Realised as MAPS (monolithic active pixel sensors, see Fig. 35.28b), standard CMOS wafers can be used for pixel detector fabrication. CMOS wafers often feature a Si epitaxial layer where the transistors are implanted. It is possible to use this epi-layer as a sensitive detection volume for particle detection. However, in such detectors, usually only the immediate regions near the collection nodes are depleted. Outside these confined regions, there is no or little electric field and charge collection is dominantly governed by slow and non-directional charge diffusion, a problem for high-rate applications. Depleted MAPS (DMAPS) exploit non-standard high resistivity wafers or high-ohmic epi-layers, typically with resistivities $>1\,\mathrm{k\Omega\,cm}$, as well as high bias voltage (up to $\gtrsim 300\,\mathrm{V}$), resulting in charge collection by directed drift motion. Charge collecting electrodes are deep wells (n-wells in Fig. 35.28b), either formed as large (typ. $50{\times}100\,\mu\mathrm{m}^2$) structures to fully contain the CMOS circuitry (Fig. 35.28b, top) or as small nodes, set aside the electronics (Fig. 35.28b, bottom), with obvious pros and cons resulting from shorter average drift distance (large electrode) versus much smaller capacitance (small

electrode). The former features a more uniform shape of the electric and the weighting field as well as short drift paths, benefiting radiation tolerance and timing performance in charge collection, whereas the latter allows for smaller pixels and benefits in noise and rise time from the small sensor capacitance. Yet, in both approaches radiation tolerance levels of $\gtrsim 10^{15}\,\mathrm{n_{eq}/cm^2}$ (fluence) and 1 MGy (ion. dose) have been demonstrated.

A variant of the monolithic approach are SOI (silicon-on-insulator) pixel devices, providing high spatial resolution, but less radiation tolerance: A high-resistivity supporting wafer, employed for particle sensing, connects through an embedded insulator (a buried oxide layer, BOX) to the CMOS readout circuitry. The BOX separates the sensing volume from the electronics layer and provides shielding. Because the area between the BOX and the transistor layer acts as a "back-gate", transistor operation can be affected, requiring careful considerations of radiation tolerance (see *e.g.* [423]).

35.8.4 *Precise timing with silicon detectors*

Typical time scales for silicon detector output signals are several tens of nanoseconds (*e.g.* rise times, shaping times, etc.) accompanied by a typical time mark precision in the order of nanoseconds. Essential for achieving precision time resolution ($\sigma_t < 100\,\mathrm{ps}$) are a large and steep signal as well as low noise, because time jitter (σ_{jitter}) relates to signal-amplitude fluctuations as:

$$\sigma_{\mathrm{jitter}} = \frac{\sigma_n}{(dS/dt)_{\mathrm{trig}}} \approx \frac{t_r}{SNR}, \tag{35.24}$$

where σ_n is the rms noise, t_r the rise time, SNR the signal-to-noise ratio, and dS/dt the "slew rate" evaluated at trigger threshold (see also Sec. 35.9), in which S is the "signal", *e.g.* an induced current or a voltage. This, in turn, requires fast charge collection, *e.g.* in thin planar or 3D-Si detectors with high E-fields, as well as fast and high amplification, both together yielding large slew rates. Important parameters that influence timing precision are the detector capacitance (including stray contributions), leakage current and—if present—the size of the amplification gain.

Among the detectors that have achieved precise time measurement are so-called LGADs (low gain avalanche detectors, Fig. 35.29). Their planar electrode geometry includes an implanted low-gain ($g = 10$–50) amplification structure on either the top or bottom electrode side to maximise the slew rate. Electrons created from impinging ionising particles drift towards a very high field created by an amplification layer near the (here) top electrode, where impact ionisation creates a multitude of e-h pairs. They induce a fast and large signal rise, mainly governed by the holes' movement away from the amplification layer. Sufficiently low amplification gain minimises excess noise contributions and avoids the creation of hole-induced avalanches moving in the opposite direction to electron avalanches.

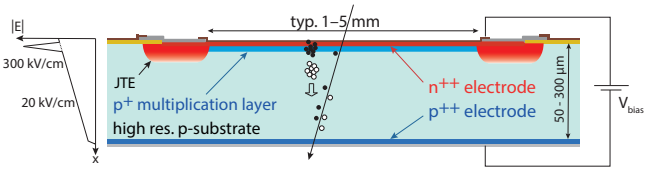

Figure 35.29: LGAD amplification structure for precision timing. Amplification (typ. $\times$ 10–50) occurs at the structure boundary in a highly doped p-n junction near the (here: top) surface (JTE = Junction Termination Extension, deep n-well).

The achievable time resolution has several contributions:

$$\sigma_t^2 \approx \left(\frac{\sigma_S^{thr}}{dS/dt}\right)^2 + \left(\frac{\sigma_n}{dS/dt}\right)^2 + \sigma^2_{\mathrm{arrival}}(V_{thr}) + \sigma^2_{\mathrm{dist}} + \sigma^2_{\mathrm{TDC}}\,. \tag{35.25}$$

The first term represents "time walk" coming from Landau fluctuations, defined as originating from number and energy-transfer fluctuations in the energy-loss process with σ_S^{thr} being the signal-height variations at discriminator threshold (V_{thr}). This term can be kept minimal, *e.g.* by employing constant-fraction discrimination or by applying corrections using amplitude information. The second term is the contribution of noise to the time jitter. Both first terms are kept small by large signal slew rates. An irreducible contribution comes from fluctuations in non-uniform depositions of charge along the particle path (including fluctuations in the amplification process), which causes an intrinsic jitter in the arrival time (third term)[7]. The smaller the threshold and the thinner

[7] In LGAD literature, these fluctuations are sometimes also referred to as "Landau fluctuations".

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

the detector, the less disturbing the effect is. If the amplification gain is mandatory for crossing V_{thr}, this term can become dominant as it explicitly depends on the gain. The fourth contribution is signal distortion due to non-uniform weighting-field regions and variations in (non-saturated) drift velocities. "Junction Termination Extensions" (JTE, see Fig. 35.29) serve to lower this term; it is usually marginal for LGADs with pitch/thickness $\gg 1$. The final term denotes time fluctuations due to uncertainties in digitisation, which can, however, be made negligible with GHz digital time conversion. Timing precision down to 15-20 ps for minimum-ionising particles has been reached for thin LGADs with relatively high gain (>40). Improving the time resolution for tracks beyond this value is possible by employing LGADs in multiple-layer structures.

Structural and operational variants to improve charge collection (uniform and efficient over the entire surface), position and also time resolution, are "resistive AC-coupled LGADs" (capacitively coupled electrodes on top of the gain layer), "inverse LGADs" (backside is segmented), "trench-isolated LGADs" (an oxide trench separates the electrodes) and other less mature ones like "deep junction LGADs". The LGAD technology is not limited to silicon detectors, but is also applicable, for example, in SiC: due to the doping profiles used in SiC, which are swapped compared to those in Fig. 35.29, dominantly holes are multiplied instead of electrons, albeit at higher electric fields. More details on LGADs can be found in [424] and [425].

Columnar electrode geometries such as shown in Fig. 35.25 with small diameter and small pitch are by design a very suitable choice for precision timing due to short collection paths and strong fields. Employing a trench-like shape of the columns, field- and weighting-field distortions are minimised and time resolutions in the order of 10 ps have been measured in prototypes [426].

High precision timing can also be approached by exploiting the benefits of SiGe BiCMOS technology: The strain mismatch of Si-Ge alloy layers results in a smaller bandgap as well as higher mobility, and hence larger transconductance. This benefits the speed in hetero-junction bipolar transistors (HBTs), which also feature less 1/f noise than MOS transistors. Resolutions of order 20 ps have been reached in a monolithic pixel matrix using this technology [427]. More elaborate discussions on timing with silicon detectors can be found *e.g.* in [428].

35.8.5 *Radiation damage in silicon detectors*

High channel density and response times in the nanosecond range render micro-patterned semiconductor detectors particularly suited for high particle rates. This is usually accompanied by high radiation, which causes damage to sensors and front-end electronics. We restrict ourselves here to the description of damage mechanisms typical in Si detectors and their electronics. Radiation damage occurs in semiconductor detectors through two basic mechanisms:

1. *Bulk damage* due to the displacement of atoms from their lattice sites, resulting in defect energy levels inside the bandgap. This leads to increased leakage current, carrier trapping, and build-up of space charge that changes the required operating voltage. Displacement damage results from non-ionising energy loss (NIEL). The energy imparted to the recoil atoms can initiate a chain of subsequent displacements, including "damage clusters". For NIEL scaling (see below), it is critical to consider both particle type and energy: conventionally, for silicon, the received NIEL is normalised to the damage level caused by 1 MeV neutrons and specified in units of neutron-equivalent fluence Φ_{eq} with units n_{eq}/cm^2.
2. *Surface damage* due to charge build-up in surface layers and formation of interface traps at *e.g.* Si–SiO_2 boundaries. These influence transistor currents and thresholds or cause thin charge carrier layers at a silicon surface. This leads to increased surface leakage currents in sensors as well as circuits, affects the insulation of electrode implants and changes the characteristics of transistors. The effects of charge build-up are strongly dependent on the device structure and on fabrication details. The damage is mainly due to the ionising energy loss (IEL) and is hence proportional to the absorbed total ionisation dose (TID) measured in Gy (or rad), independent of the irradiating particle type.

We note that the increase in reverse bias generation current (leakage current) due to bulk damage is $\Delta I_L = \alpha_I \Phi_{eq} V$, where V is the depleted volume under an electrode and $\alpha_I \simeq 4 \times 10^{-17}$ A/cm, a universal constant when normalised to temperature (conventionally 20°C), and measured after annealing for 80 min at 60 °C. Note that for devices with intrinsic amplification, the generation current is amplified accordingly. Reverse bias leakage current depends strongly on temperature

$$I_L(T) \propto T^2 \exp\left(-\frac{E_a}{2kT}\right) , \qquad (35.26)$$

where $E_a \approx 1.2$ eV (activation energy), so rather modest cooling can reduce the current substantially (∼7-fold reduction in cooling from room temperature to 0 °C).

For bulk damage in silicon, the *NIEL hypothesis* is a good first-order description of the observed damage (especially regarding I_L). It states that all lattice radiation damage in silicon linearly scales with NIEL and can be traced back to the abundance of primary defects (point defects and clusters), irrespective of their initial distribution over energy and space, that is, regardless of the damage's topology and origin. Under the NIEL hypothesis, the observed differences in damage caused by neutrons, protons, pions and electrons are therefore usually scaled to each other. For other damage manifestations besides I_L, the NIEL hypothesis is moderately violated.

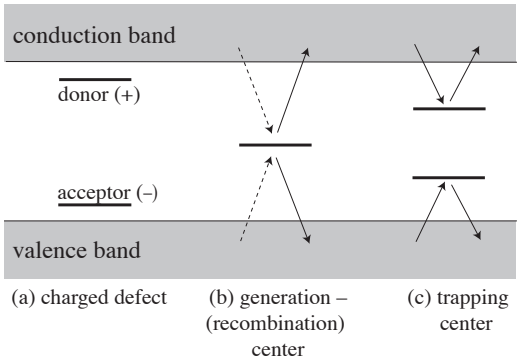

Figure 35.30: Characteristic locations of energy levels caused by bulk radiation damage and their main action effects.

Three main bulk displacement damage effects are sketched in Fig. 35.30: (a) defects acting as charged donors/acceptors, (b) deep defects (near the middle of the bandgap) causing increased leakage current, and (c) carrier trapping centers. Another consequence of deep defects is that any non-depleted bulk becomes more resistive, hence impacting the electric and the weighting field distributions. At very high fluences ($\Phi_{\mathrm{eq}} > 10^{16}$ cm^{-2}) also carrier mobilities decrease, leading to resistivities even lower than intrinsic.

Damage effects are not constant with time; for example, in n-type bulk, radiation-induced negative space charge anneals at first reaching a stable space charge minimum (beneficial annealing), but later electrically active defects (negative space charge from acceptor-type damage) build up over the time scale of months (reverse annealing) at room temperature and much longer at lower temperatures.

Acceptor- (usually dominant) or donor-like (deep) defects, when ionised, build up space charge (dominantly negative), which in turn normally requires an increase in the applied voltage to deplete the active volume of the detector and sweep the signal charge through the detector thickness. For n-type bulk starting material, however, shallow donor (*e.g.* phosphorus) removal is initiated by incipient radiation (production of lattice vacancies V) through formation of electrically inactive vacancy-phosphorus (V-P) complexes. This leads to a faster decrease in depletion voltage (faster

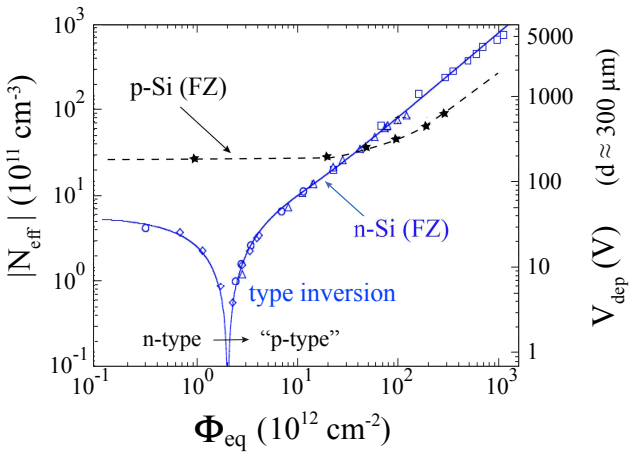

Figure 35.31: Effective space charge concentration $N_{\rm eff}$ (left axis) and required voltage for full depletion $V_{\rm dep}$ (right axis) of approximately 300 µm thick Si sensors as a function of neutron-equivalent radiation fluence for typical n-type (blue) and p-type (black) silicon float zone (FZ) material before annealing. While initial n-type Si inverts to effectively p-type Si, this is not observed for initial p-type silicon. Bias voltage supply for large systems is usually limited to less than 600–1000 V. Figure adapted using [429, 430] and [431].

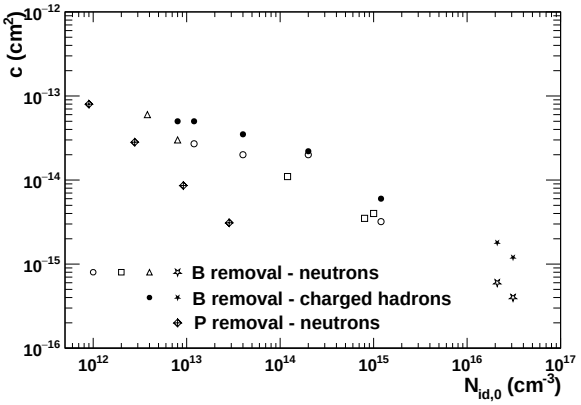

Figure 35.32: Initial dopant-removal (B boron, P phosphorous) constant c (immediately after irradiation) measured at different initial concentrations $N_{\rm id,0}$ for silicon irradiated with charged hadrons and with neutrons. Different markers indicate different types of devices. Data from CERN RD48/RD50 studies.

than only by the compensation of donors through generated deep acceptors) until positive and negative space charges effectively balance; only small bias voltage is then required for efficient operation (point of effective space charge inversion, also called "type inversion" (Fig. 35.31)). At larger fluences, the negative space charge dominates, and the required operating voltage increases proportionally to the increasing effective space charge density $N_{\rm eff}$, also called effective doping concentration.

The drift of thermally generated electrons and holes (generation current) in opposite directions and their (partial) trapping leads to a surplus of these carriers at the electrodes on either side. This affects the charge state of the deep energy levels (more carriers are trapped) and hence the space charge distribution, which can no longer be regarded as constant and homogeneous over the detector volume. Hence, the linear slope of the electric field from the junction to the backside, as was introduced in Sec. 35.8.2, is distorted; instead "double-junction"-like field distributions typically occur. The magnitude of the effect depends on the material and the type of radiation.

Today, p-type bulk silicon with n^+ electrode-implants is the preferred choice for sensors operating in high-radiation environments for reasons of cost-effectiveness in production as well as high radiation hardness due to fast (high mobility) electron collection in high electric- and high weighting-field regions at small segmented n^+ electrodes. Space charge inversion is usually not observed since the initial space charge is negative already (Fig. 35.31).

Removal of initial shallow dopants (donor or acceptor) through irradiation plays a major role in the property changes of various detector technologies. The decrease of initial doping concentration ($N_{id,0}$) is exponential $N_{id} = N_{id,0}\,\exp(-c\,\Phi_{\rm eq})$, with the removal constant c depending on $N_{id,0}$, particle type and on impurities in the semiconductor (see Fig. 35.32). Removal of acceptors (*i.e.* substitution of electrically active boron at its lattice site) in p material is found to be dominantly caused by interstitial silicon replacing boron on its lattice position. The highly active interstitial boron then can cause the formation of other defects such as interstitial oxygen-boron complexes (B_iO_i, subscript i for "interstitial") which absorb boron atoms into electrically active defects, dominantly as donors, that means that space charge can be changed twice.

Different techniques have been explored to neutralise radiation damage effects by defect engineering. For n-type material, oxygen enrichment, introduced during the Si growth, to a larger abundance than phosphorus, successfully reduces the formation of multi-vacancy, acceptor-like complexes, which are dominantly produced by charged-hadron irradiation. Instead, the oxygen enhances the formation of electrically neutral V-O complexes. For p-type Si, carbon enrichment reduces acceptor-dopant removal by building stable C_i-S_i complexes, thus trapping the Si interstitials, which could otherwise remove boron as described above.

Dopant removal plays a particularly important role in more complex sensor structures, such as DMAPS or LGADs. In particular, the high p-doping concentration in the LGAD's gain layer is vulnerable to acceptor removal, causing a drastic gain decrease with increasing fluence.

Deep level defects (Fig. 35.30b) typically are the origin of leakage current increase, whereas trapping centers (Fig. 35.30c) affect carrier trapping times and cause signal loss. The cumulative effect of different trapping centers can be expressed by effective trapping times of electrons and holes $\tau_{{\rm eff},e/h}$. The induced current equation Eq. (35.20) is multiplied by $\exp(-\frac{t}{\tau_{{\rm eff},e/h}})$, describing the reduction of the number of charge carriers $N_{e/h}$ due to trapping. The effective trapping probability of electrons and holes in silicon, proportional to $1/\tau_{{\rm eff},e/h}$, increases linearly with fluence up to around 10^{15} n$_{\rm eq}$/cm^2, where $\tau_{{\rm eff},e/h}$ is of order 1 ns, and then exhibits saturation [432]. Performance implications of trapping mainly reduce the charge collection efficiency and affect charge sharing among electrodes. Due to their larger drift velocity and smaller trapping probability, electron collection is favoured in irradiated silicon devices.

The safe limit on the operating voltage ultimately limits the detector lifetime. Strip and pixel detectors, specifically designed for high voltages, have been extensively operated at bias voltages of 500–600 V. The limit of operation voltage in highly energetic particle environment is set by single event effects (SEE), which occur when highly ionising nuclear fragments originating from the impinging particle cause permanent detector breakdown, happening at average electric fields approaching ∼12 V/µm. Sensors with columnar electrodes normal to the surface (3D-Si, Fig. 35.25) need significantly lower voltages for full depletion and are prime contenders for radiation-hard sensors.

Synthetic CVD diamond has proven strong against radiation damage due to its large bandgap (see Tab. 35.11) and strong lattice binding with a roughly twice higher threshold (∼ 40 eV) for the displacement of lattice atoms than silicon (see *e.g.* [410]). Even for polycrystalline material, charge collection distances (sum of the mean free paths $\mu\tau E$ of e and h over which charges reach the electrodes) of 300–400 µm have been achieved. The cost of diamond wafers, however, is very high in comparison. Smaller-scale diamond trackers acting *e.g.* as beam monitors have been built.

GaAs has received interest as a potentially radiation-hard material in the 1990s. For particle detection, it must still be depleted

from charge carriers despite comparatively small intrinsic carrier densities (see Tab. 35.11). It suffers from a strong loss in charge collection efficiency when irradiated, dominantly because of electron trapping. Other semiconductor materials such as SiC or GaN feature wider bandgaps (3.26 eV and 3.39 eV, respectively) than Si (but smaller than diamond) and possess other suitable properties relevant to high-fluence operation, such as density, e-h ionisation energy, and displacement energies. They have regained attention after the material quality has improved much due to an industrial push coming from power devices and LEDs. So far, charge collection degrades faster with radiation fluence than for Si and diamond, however.

Strip and pixel detectors have remained functional in large detectors even at particle fluences well beyond $10^{15}\,\mathrm{n_{eq}/cm^2}$ where charge loss due to recombination and trapping becomes significant. Thin planar ($\sim$100 µm) and 3D silicon detectors have been successfully operated at fluences of 2 and $3\times10^{16}\,\mathrm{n_{eq}/cm^2}$, respectively, and measurements indicate that operation above $10^{17}\,\mathrm{n_{eq}/cm^2}$ does not seem impossible. The large SNR obtainable with low capacitance pixel structures extends the detector lifetime. The higher mobility of electrons makes them less sensitive to carrier lifetime than holes, so detector configurations that emphasize the electron contribution to the charge signal are advantageous, *i.e.* n^+ strips or pixels on p- or n-substrates. The occupancy of the defect charge states is strongly temperature dependent; competing processes can increase or decrease space charge and the required operating voltage. It is critical to choose the operating temperature judiciously (−30 °C to 0 °C in typical collider detectors) and to limit warm-up periods during maintenance. Detailed discussions of radiation damage and its effects on semiconductor detectors can be found *e.g.* in [430, 433]; an introduction to the subject is given in [1].

Tolerance against surface damage, especially in SiO_2 layers as in gates and in oxide trenches of CMOS transistor structures, largely depends on the feature size of a technology and on appropriately designed circuitry. Deep submicron technology nodes of 130 nm and 65 nm sustain total ionisation doses of up to 5 MGy (500 Mrad), corresponding to fluences of up to $5\times10^{15}\,\mathrm{cm^{-2}}$ of minimum ionising pions or protons.

35.9 Low-noise detector readout

Revised November 2025 by J. Kaplon (CERN), revised November 2021 by N. Wermes (Bonn U.)

Many detectors rely critically on low-noise readout electronics for the best energy resolution or to allow low thresholds. A typical detector front-end is shown in Fig. 35.33.

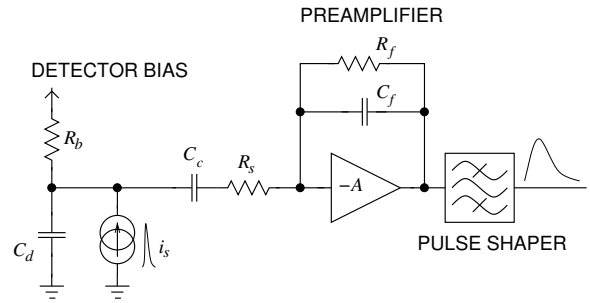

Figure 35.33: A typical front-end amplifier for a detector, with the shaper represented as an idealized band-pass filter. The operation of a charge-sensitive amplifier (CSA) relies on the feedback capacitor C_f, which determines the gain of the preamplifier.

In a model relevant to most readout applications, the detector, represented by a capacitance C_d, delivers a delta-function-shaped current signal, represented by a current source in parallel. Bias voltage is applied through resistor R_b, and the signal is (often) coupled to the amplifier through a blocking capacitor C_c. The series resistance R_s represents the sum of all resistances present in the input signal path, *e.g.* the electrode resistance, connection lines, any input protection network, and parasitic series resistances in the input transistor.

The amplification stage contains the preamplifier providing gain and a pulse shaper, which tailors the overall frequency response to optimise the signal-to-noise ratio (SNR), while limiting the duration of the signal pulse to accommodate the signal-pulse rate.

Detectors are often segmented with a granularity that matches the spatial resolution requirements of the experiment. In this case, the input stage must ensure efficient readout of the charge despite the presence of parasitic capacitances between adjacent detector electrodes. In order to minimise the cross-talk to adjacent channels, a low input impedance of the preamplifier is required. The basic solution for the input stage, which effectively addresses cross-talk and ensures efficient signal collection, is the charge-sensitive amplifier (CSA). This amplifier features high open-loop gain and employs shunt-shunt feedback through an integrating capacitor C_f, along with either an active or a passive discharging circuitry (for example, resistor R_f in Fig. 35.33) to prevent saturation of this stage within the signal processing chain. The CSA gain is primarily determined by the value of the feedback capacitor and does not depend on the detector capacitance.

In addition to the widely used charge-sensitive amplifiers in traditional tracking detectors, other low-noise architectures are employed for different applications. Transimpedance amplifiers (TIA) and wide-band voltage amplifiers are used when very high timing precision is required and the power budget is less constrained. Low-power voltage amplifiers are also employed in circuits with extremely low input capacitance—in the femtofarad range—where they can achieve adequate gain, avoiding significant power consumption. A typical example is monolithic active pixel sensors with small charge collection nodes. Although the following analysis focuses on the noise performance of CSA amplifiers, the applied methodology as well as conclusions *i.e.*, formulas for the equivalent input noise, are equally applicable to TIA and voltage preamplifiers working with capacitive sensors.

The classical theory of noise filtering, outlined in [434, 435] for nuclear spectroscopy systems, aims to maximise the signal-to-noise ratio, introducing the concept of the optimal noise filter. In modern high-energy physics experiments, front-end electronics must provide both amplitude measurement and precise timing requirements. Additionally, for multi-channel systems, minimizing power consumption and maintaining design simplicity are critical goals, which translates to enhanced robustness, particularly given the radiation-prone environments in which these chips typically operate. To balance performance with power consumption and design complexity, conventional band-pass filters, such as CR-$(\mathrm{RC})^m$, are often preferred for multi-channel front-end chips. These filters consist of a differentiating stage to filter low-frequency noise, followed by m integrator stages that attenuate high-frequency components.

In high data-rate applications, avoiding CSA saturation requires a low feedback impedance, typically achieved by employing a low-value feedback resistor. In these configurations, the feedback resistor R_f and capacitor C_f usually constitute the first CR (differentiation) stage of the pulse shaper, placing the charge-sensitive amplifier in what is referred to as transimpedance mode. This mode is commonly employed in the front-end input stages of modern detector readout electronics, as it accommodates high signal rates and reduces input impedance, thereby minimising cross-talk and offering advantages over a basic CSA configuration. It is essential to note that placing the high-pass CR filter—either in the preamplifier feedback loop or within the shaper stage—has no impact on the input noise analysis and is equivalent in terms of signal processing.

Assuming an ideal amplifier with infinite open-loop gain A and unlimited bandwidth to facilitate analysis, the Laplace-domain transfer function $H(s)$ of a charge-sensitive amplifier followed by an m-order CR-RC filter with equal differentiation and integration time constants τ is given by

$$H(s) = \frac{1}{s\,C_f}\,\frac{s\,\tau}{(1+s\,\tau)^{m+1}}\,, \qquad (35.27)$$

Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 06/12/25. For personal use and distribution is strictly not permitted, except for Open Access articles.

where s denotes the complex frequency variable in the Laplace domain, and τ represents the time constant of the filter. The response in the time domain to the Dirac delta function of the preamplifier connected to a CR-(RC)^m filter is given by the formula

$$V_{out}(t) = \mathcal{L}^{-1}\Big\{ H(s) \Big\} = \frac{\left(\frac{t}{\tau}\right)^m \; e^{-\frac{t}{\tau}}}{C_f \; \Gamma(1+m)} \,, \tag{35.28}$$

where $\mathcal{L}^{-1}$ is the inverse Laplace transform and Γ is the Euler Gamma-function. The signal reaches its peak at the time $t_p = m\,\tau$, commonly referred to as the shaping time. The response amplitude, G_{FE}, representing the overall gain of the processing chain, is given by

$$G_{FE} = \frac{m^m \; e^{-m}}{C_f \; \Gamma(1+m)} \tag{35.29}$$

35.9.1 *Principal noise origins*

It is useful to distinguish between noise inherent to a detector's signal amplification and processing circuitry (per channel) on the one hand, and — on the other hand — external noise sources propagated as a radiated or conducted electromagnetic interference (EMI) introduced *e.g.* by systems external to a specific readout circuit often resulting in "common-mode" noise, *i.e.* common to all channels. External noise can be introduced by power supplies, digital signal switching, RF pick-up, or effects due to "common grounding" allowing noise to couple to the current loop connecting the detector to the preamplifier. These noise sources differ from setup to setup and must be addressed individually, ideally to be eliminated. In the following, therefore, only the noise inherent to typical detector signal processing is discussed.

As principal noise origins in circuit elements, we distinguish *thermal noise*, *shot noise*, and *low-frequency* $1/f$ *noise*. Generally, noise is a fluctuation of current or voltage around a base level. Since the average value of noise is zero, noise is quantified by the variance of this fluctuation, $\langle v^2 \rangle$ or $\langle i^2 \rangle$. Noise sources are characterised by their power spectral densities, *i.e.*, $d\langle v^2 \rangle / df$ and $d\langle i^2 \rangle / df$, where f is the frequency.

Thermal noise results from the thermal random motion of charge carriers in a conductor (Brownian motion). In any conductor or resistor at a temperature $T > 0$, the random motion of electrons leads to current fluctuations giving rise to a voltage appearing across its terminals. For a resistor R, the (power) spectral density is proportional to the Boltzmann constant k and the temperature T. In electronic circuits, it can be represented either by a current or a voltage source with spectral densities given as:

$$d\langle i^2 \rangle = 4\,k\,T\,\frac{1}{R}\;df \qquad\qquad d\langle v^2 \rangle = 4\,k\,T\,R\;df \tag{35.30}$$

The spectral density distribution of thermal noise is 'white', *i.e.*, all frequencies contribute equally to the total noise intensity.

Shot noise arises from the discrete nature of charge carriers, creating discrete current fluctuations when crossing a potential barrier in electronic devices. Examples include fluctuations in the current flowing through a semiconductor junction or a metal-semiconductor junction. In contrast, a simple conductor or resistor lacks such a barrier and therefore does not exhibit shot noise.

The current spectral density is described as

$$d\langle i^2 \rangle = 2\,q\,I\;df \;, \tag{35.31}$$

where q is the elementary charge and I is the DC current. Shot noise also exhibits a 'white' frequency spectrum.

Low frequency $1/f$ *noise*, also known as flicker noise, or pink noise, is a widespread phenomenon that appears not only in electronic devices but also in a variety of natural systems other than electronics. Common to all is a similar spectral density behaviour which is proportional to $1/f^{\alpha_f}$ with α_f between 0.5 and 2. In metal-oxide-semiconductor (MOS) devices, $1/f$ noise primarily arises from two mechanisms. The first involves the surface properties of the material, specifically, charge trapping and detrapping at the interface between the transistor channel and the gate insulating layer. The second mechanism, which becomes more significant in deep-submicron technologies, is due to mobility fluctuations caused by the scattering of charge carriers within the MOS channel. Enhanced surface treatment during manufacturing and the overall size of the transistor gate are key factors influencing the level of flicker noise.

35.9.2 *Noise in MOS devices*

In the following, we focus on the noise sources in MOSFETs, as the majority of front-end circuits used in today's HEP experiments are based on MOS transistor technology.

The primary noise source observed in MOSFETs is *thermal noise* in the transistor channel, which acts as a conductor. To calculate its spectral density, we employ the model proposed by Van der Ziel [436], adapted for devices implemented in integrated circuits that share a common substrate—thereby accounting for the noise contribution from the bulk transconductance g_{mb}—and operating in any inversion [8] region [437]. The current noise generator i_{nd} is placed between the drain and source of the input transistor, with its noise spectral density given by[9]

$$d\langle i_{nd}^2 \rangle = 4\,k\,T\;n\;\gamma\;g_m\;df \;. \tag{35.32}$$

The noise contribution from the bulk transconductance, g_{mb}, is represented by a technology-dependent parameter n, known as the slope factor, which typically ranges from 1.25 to 1.45. It is defined as the ratio $n = (g_m + g_{mb})/g_m$, where g_m is the gate transconductance, hereafter referred to simply as transconductance.

The bias-dependent parameter γ ranges from 1/2 in weak inversion to 2/3 in strong inversion for an ideal long-channel transistor. While this assumption holds well for long-channel devices, it does not account for short-channel effects, which introduce excess noise. A practical approach to this issue is to use an excess noise factor α_w, which is usually characterised for a given technology and transistor length. In submicron technologies used today for HEP applications, transistors with channel lengths approximately twice the minimum feature size—thus avoiding short-channel effects—typically exhibit an excess noise factor α_w below 1.1 when operating in the weak to moderate inversion region.

The next source of noise taken into account in this analysis is *1/f noise*. In the commonly used model of 1/f noise, the current noise generator is placed between the drain and source of the MOS transistor. The power spectral density is given by:

$$d\langle i_{nf}^2 \rangle = \frac{K_f}{f}\;\frac{g_m^2}{C_{ox}}\;df \;. \tag{35.33}$$

The technology-dependent parameter K_f is highly sensitive to the fabrication process, typically ranging from 1×10^{-24} to 1×10^{-25} Joule. Its value also depends on the device type and is typically lower for PMOS transistors. The values of K_f are also affected by transistor bias conditions and short-channel effects. C_{ox} represents the so-called gate-oxide capacitance of the transistor, defined as

$$C_{ox} = W\,L\,\frac{\varepsilon_{ox}}{t_{ox}} \;, \tag{35.34}$$

where W and L denote the gate's width and length; ε_{ox} is the permittivity of the silicon oxide, and t_{ox} represents the gate oxide

[8] Inversion in a MOS device occurs when the gate voltage attracts minority carriers to the semiconductor surface, forming a conductive channel under the gate that enables current flow between the source and drain—a fundamental principle of MOSFET operation. In strong inversion, where the gate voltage exceeds the threshold and a well-defined channel is formed, conduction is drift-dominated, and transconductance is given by $g_m = \sqrt{2\,K_p\,I_d\,W/(n\,L)}$, where K_p is the technology-dependent transconductance parameter, n is the slope factor, I_d is the drain current, and W and L are the transistor's width and length respectively. Here, g_m scales with the square root of current and depends on device dimensions. In weak inversion (sub-threshold operation), the device conducts a small diffusion-driven current even below the threshold voltage. The transconductance is given as $g_m = I_d/(n\,V_T)$, where V_T is the thermal voltage (∼26 mV at room temperature), so it scales linearly with current and is independent of transistor geometry. In the moderate inversion region (between weak and strong inversion), transconductance is typically modeled using semi-empirical interpolation functions, such as those found in the EKV model.

[9] Here and in the following, the subscript part n always denotes *noise*, whereas further subscript letters denote specifics of this noise density.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

thickness. Thus, the 1/f noise is inversely proportional to the transistor gate area.

Further noise nomenclature, such as *RTS (random telegraph signal) noise*, also known as burst noise or popcorn noise, is also related to its origin to trapping/detrapping processes in small MOS devices, where a single trap can cause a considerable variation in the channel current. For larger devices with many trapping centers, the popping-up nature of individual RTS bursts eventually leads to the $1/f$ noise spectral density when the noise from multiple traps with a wide range of trapping time constants is superimposed. Noise optimisation in front-end circuits typically involves using relatively large-area MOS transistors, where RTS noise is usually not observed. Consequently, the RTS noise is omitted in the following for simplicity reasons.

Another noise phenomenon observed in MOS devices at higher frequencies is known as *gate-induced current noise (GIC)*. Thermal fluctuations of current within the device channel couple to the transistor gate via the gate-oxide capacitance, resulting in an induced frequency-dependent current that acts as an additional noise source correlated with the channel thermal noise. Noise expressions for GIC have been derived in [436] for an ideal MOS transistor operating in strong inversion. Adapted to apply across all inversion regions and including also the noise contribution from the bulk transconductance, the GIC power spectral density is expressed as:

$$d\langle i_{ng}^2\rangle = 8\,\gamma\,k\,T\,g_g\,df \qquad \text{with} \qquad g_g = \frac{4}{45}\,\frac{\omega^2\,C_{ox}^2}{n\,g_m}\,, \quad (35.35)$$

where γ and n parametrise transistor operation modes and technology features, respectively and $\omega = 2\pi f$. The correlation between channel thermal noise and gate-induced noise is given by:

$$d\langle i_{ng}\;i_{nd}^*\rangle = \frac{\gamma}{6}\;j\;\omega\;C_{ox}\;4\,k\,T\;df\;, \quad (35.36)$$

where j denotes the imaginary unit and i_{nd}^* is the complex conjugate of i_{nd}.

35.9.3 *Equivalent noise analysis*

The equivalent circuit used for noise analysis (Fig. 35.34) illustrates the contributions of all previously discussed noise sources at various points in the circuit.

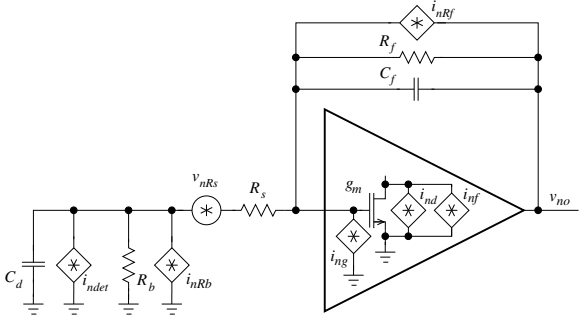

Figure 35.34: Equivalent front-end circuit diagram of the CSA showing the basic noise sources.

Shot noise, arising from fluctuations in detector leakage current, is modelled as a current noise source placed at the amplifier input in parallel with the detector. Its spectral density depends entirely on the magnitude of the leakage current I_{det} and can be expressed as

$$d\langle i_{ndet}^2\rangle = 2\;q\;I_{det}\;df\;. \quad (35.37)$$

Although any voltage source in series with a resistor can be transformed into an equivalent current source in parallel with a resistor (according to Norton's theorem), it is a common practice to represent (parallel) input-shunting resistors as noise current sources and series resistors at the amplifier input as noise voltage sources. These are typically referred to as equivalent input *parallel* and *series* noise sources, respectively. The noise spectral densities for the detector bias resistor R_b (parallel noise) and the series resistor R_s (series noise) are respectively given by:

$$d\langle i_{nRb}^2\rangle = \frac{4\,k\,T}{R_b}\,df \qquad \text{and} \qquad d\langle v_{nRs}^2\rangle = 4\,k\,T R_s\,df\,. \quad (35.38)$$

The value of the detector bias resistor is typically chosen such that its noise contribution to the overall noise can be neglected. The feedback resistor R_f also acts as a parallel noise source. It is particularly relevant for preamplifiers operating in transimpedance mode, contributing with a noise spectral density as in Eq. (35.38) (left) with R_b being replaced by R_f.

An important noise source is the preamplifier input stage, specifically the active devices operating within the circuit. In a well-designed input stage—characterised by high gain and degenerated active loads—the dominant noise source is the input transistor. Both flicker and channel thermal current noise generators are internal to the preamplifier structure (see Fig. 35.34). To evaluate their contribution to the output noise—without requiring knowledge of the amplifier's internal details—they are represented as equivalent noise sources at the preamplifier input, exploiting the definition of the input transistor's transconductance, $g_m = \partial I_d\,/\partial V_{gs}$, where I_d and V_{gs} are drain current and gate-to-source voltage, respectively. This leads to:

$$d\langle v_{nd}^2\rangle = d\langle i_{nd}^2\rangle\frac{1}{g_m^2} = \frac{4\,k\,T\;n\;\gamma}{g_m}\,df \qquad \text{and}$$
$$d\langle v_{nf}^2\rangle = d\langle i_{nf}^2\rangle\frac{1}{g_m^2} = \frac{K_f}{f\,C_{ox}}\,df\;. \quad (35.39)$$

Noise spectrum calculation is simplified by assuming that filtering takes place in the shaper stage treating the feedback resistor solely as a noise source. The CSA output noise spectral density is obtained by accounting for all parallel and series noise sources. Series noise at the input is first converted to equivalent parallel noise via the input conductance $s\,C_{in}$, then all contributions are transferred to the output through the feedback impedance $1/s\,C_f$, yielding:

$$\frac{d\langle v_{no}^2\rangle}{df} = \frac{d\langle v_{ns}^2\rangle}{df}\;\frac{C_{in}^2}{C_f^2}\;+\;\frac{d\langle i_{np}^2\rangle}{df}\;\frac{1}{\omega^2\,C_f^2}\;, \quad (35.40)$$

where C_{in} represents the total input capacitance (including detector capacitance C_d, input transistor gate capacitance C_g, and any additional parasitic capacitance at the preamplifier input), the term $d\langle v_{ns}^2\rangle/df$ represents the noise spectral density of any series-noise source as shown in Eq. (35.39) and Eq. (35.38) (right equation), whereas $d\langle i_{np}^2\rangle/df$ is the noise spectral density of any parallel-noise source as in Eq. (35.35), Eq. (35.37) and Eq. (35.38) (left equation). The transfer function of the CR-(RC)^{m} filter in the Laplace domain is given by Eq. (35.41).

$$T(s) = \frac{s\,\tau}{(1+s\,\tau)^{m+1}}\;. \quad (35.41)$$

Consequently, the RMS value of noise at the shaper output can be obtained by integrating the preamplifier output noise spectra density, coming from all partial contributions, over the entire frequency range, taking into account the frequency characteristic of the applied filter:

$$\sigma_n^2 = \int_0^\infty \frac{d\langle v_{no}^2\rangle}{df}\,\frac{\omega^2\,\tau^2}{(1+\omega^2\,\tau^2)^{m+1}}\,df\;. \quad (35.42)$$

Dividing the result by the signal gain given by Eq. (35.29) we obtain the equivalent input noise charge:

$$ENC = \frac{\sigma_n}{G_{FE}} = \sigma_n\;\frac{C_f\;\Gamma(1+m)}{m^m\;e^{-m}}\;. \quad (35.43)$$

It is convenient to perform the above integral and ENC calculation for the individual noise sources separately. Table 35.12 summarises the individual contributions to the total ENC, where the

coefficients F_V, F_I, F_F, F_G, and F_C depend on the filter characteristic. The table also includes the GIC–thermal noise correlation term; however, its calculation is omitted here for brevity. In particle physics, ENC is often quoted in units of electrons (e^-) by dividing (35.43) by the elementary charge q.

Table 35.12: Partial contributions to the total ENC.

k		ENC_k
1	channel thermal	$F_V \frac{C_{in}}{\sqrt{t_p}} \sqrt{\frac{4\,k\,T\,\gamma\,n}{g_m}}$
2	series resistor	$F_V \frac{C_{in}}{\sqrt{t_p}} \sqrt{4\,k\,T\,R_s}$
3	flicker	$F_F\, C_{in} \sqrt{\frac{K_f}{C_{ox}}}$
4	feedback resistor	$F_I \sqrt{t_p} \sqrt{\frac{4\,k\,T}{R_f}}$
5	detector leakage	$F_I \sqrt{t_p} \sqrt{2\,q\,I_{det}}$
6	GIC	$F_G \frac{C_{ox}}{\sqrt{t_p}} \sqrt{\frac{4\,k\,T\,\gamma}{n\,g_m}}$
7	GIC-thermal corr.	$F_C \frac{\sqrt{C_{ox}\,C_{in}}}{\sqrt{t_p}} \sqrt{\frac{4\,k\,T\,\gamma}{g_m}}$

For the example of a first-order CR-RC filter, the filter coefficients F_V, F_I, F_F, F_G, and F_C are evaluated to be 0.96, 0.96, 1.92, 0.41, and 0.56, respectively. Finally, the total ENC squared is obtained by the quadrature sum of the individual contributions:

$$ENC^2 = \sum_{k=1}^{7} ENC_k^2 \ . \qquad (35.44)$$

The formulas in Table 35.12 show that the first three contributions from series noise sources are directly proportional to the input capacitance and, except for 1/f noise, inversely proportional to the square root of the signal shaping time. Often, the dominant contribution comes from channel thermal noise (first entry in Table 35.12). Large thermal noise contribution must be compensated by a large transconductance g_m, or longer shaping time. Since g_m is determined by both the bias current and the transistor's dimensions, the first step in optimisation of the preamplifier involves sizing the input transistor appropriately to the detector capacitance and the target bias current. Furthermore, flicker noise as well as GIC and the GIC-thermal correlation term are also affected by the transistor's dimensions through its gate capacitance. A compact model like EKV [437] is essential, providing accurate, temperature-aware expressions for transconductance and gate capacitances across all inversion regions. Finally, noise optimisation can be achieved by selecting a shaping time that balances series and parallel noise contributions (series noise decreases with longer shaping time, while parallel noise increases; see Table 35.12). This optimisation is limited by the time resolution requirements of the front-end electronics, which impose an upper bound on the shaping time. In systems with high parallel noise and low series noise, the theoretically optimal very short shaping time may be unattainable due to technological constraints, such as the transistor transit frequency that limits the maximum operational speed of the electronics. If balancing parallel and series noise sources fails to meet noise specifications, the front-end design requirements may need to be revised. Increasing the bias current of the input transistor can improve transconductance and help suppress thermal noise. If excessive parallel noise is caused by radiation-induced leakage current, it may be necessary to adjust the detector segmentation—which will also impact the contribution from series noise—or improve cooling efficiency to operate at lower temperatures.

Figure 35.35 shows an example of the noise analysis for a preamplifier designed in 130 nm CMOS technology and developed for the ATLAS ITK strip tracker (ABCStar chip). The design is intended for short silicon strips with lengths ranging from 1.8 cm to 5.5 cm, corresponding to input capacitances between 2 pF and 7 pF. The ENC is shown as a function of shaping time, with individual contributions explicitly illustrated for two detector capacitance values representing different strip lengths. The optimal shaping time

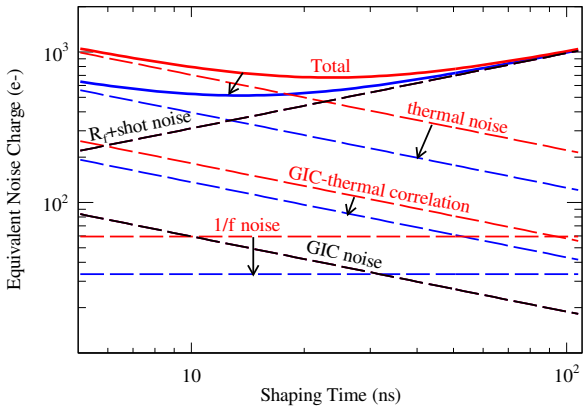

Figure 35.35: Equivalent noise charge as a function of the shaping time for the ABCstar front-end. Individual contributions include series channel thermal and 1/f noise, parallel shot and thermal R_f noise, as well as GIC noise and the GIC-thermal correlation. The contributions are shown for two detector capacitance values: 6 pF (RED traces), for which the input transistor was optimized, and 3 pF (BLUE traces), corresponding to the 2.4 cm strips. Noise contributions independent of the input capacitance, namely from the feedback resistor (105 kΩ), shot noise from detector leakage current (1 μA), and GIC noise, are shown in BLACK.

depends strongly on the detector capacitance. In particular, the contributions from series noise, flicker noise, and the GIC–thermal noise correlation term scale with input capacitance, whereas parallel noise and GIC contributions are independent of it. In the presented example, a shaping time of 22 ns is chosen, as it meets timing requirements, optimizes noise for the longer strips, and satisfies the stricter ENC limits for shorter strips, imposed by higher expected radiation damage. Analysing the individual contributions to the ENC from various noise sources reveals that, in the example under consideration—front-end designed for high signal rates and operation in radiation environments with significant sensor leakage—the dominant noise contributors are the input transistor channel thermal noise and the parallel noise resulting from the shot noise of the sensor leakage current and the preamplifier feedback resistor. However, in low-rate, low-radiation applications where the contribution from the feedback resistor can be minimised and sensor leakage current is negligible, longer shaping times can be employed. Then, flicker noise becomes the primary factor limiting the minimum achievable noise level.

The impact of GIC noise on the front-end amplifier's overall noise performance can be assessed by analysing the expressions for GIC noise and the correlation term, each normalized to the originating thermal noise. These normalised contributions are roughly $\approx 0.42\,C_{ox}/(n\,C_{in})$ and $\approx 0.58\,\sqrt{C_{ox}/(n\,C_{in})}$, respectively. It can be observed that when the front-end is connected to the sensor and $C_{in} \gg C_{ox}$, both contributions become negligible, since they combine with the thermal noise and finally with the total ENC in quadrature. In contrast, these contributions may become visible when evaluating the amplifier without a connected sensor, particularly in scenarios where the parallel noise from the feedback circuit is negligible.

35.9.4 *Timing measurements*

In timing measurements, the slope-to-noise ratio must be optimized, rather than the signal-to-noise ratio alone, so the rise time t_r of the pulse is important. The "jitter" σ_t of the timing distribution is

$$\sigma_t = \frac{\sigma_n}{(dS/dt)_{\text{trig}}} \approx \frac{t_r}{SNR}, \tag{35.45}$$

where σ_n is the rms noise, SNR the signal-to-noise ratio—defined for a CSA as the ratio of a MIP signal to the ENC—, and the slope dS/dt, *i.e.* the derivative of the signal, is evaluated at the discrimination level. The rise time of an amplifier, t_r, in the absence of a shaper, is limited by internal parasitic capacitances, which reduce its bandwidth and effectively act as a low-pass filter. Approximating the amplifier's behaviour with a CR-RC response, we find that linearly decreasing t_p leads to an ENC increase proportional to $\sqrt{t_p}$ from series noise sources, while the ENC contributions from parallel noise sources decrease (see Table 35.12). Therefore, from a jitter perspective, enhancing the amplifier's response time—even if it results in a noise increase—can be beneficial. However, preserving an adequate signal-to-noise ratio, which is critical for maintaining acceptable noise occupancy, imposes a fundamental constraint. Another undesired effect of increasing the front-end speed and input stage bandwidth will be higher susceptibility to the EMI interferences. From an EMI sensitivity standpoint, systems and detectors that employ higher-granularity sensors characterized by low parasitic capacitance offer an advantage.

For timing measurements with standard or 3D sensors, the preferred preamplifier is typically a CSA based on a buffered cascode [10] featuring high open-loop gain, operating in transimpedance mode. The rise time of the preamplifier response—more precisely, the integration time constant—is given by:

$$\tau_i = \frac{C_0}{g_m}\,\frac{C_{in}}{C_f}\,, \tag{35.46}$$

where the C_0 is the parasitic capacitance at the cascode output defining its bandwidth, g_m is the transconductance of the input transistor, C_{in} is the total capacitance at the preamplifier input and C_f is the feedback capacitance. As Eq. (35.46) shows, good timing performance can be achieved by minimizing the total input capacitance, which aligns well with the characteristics of pixel sensors. While increasing C_f can enhance timing performance, it is constrained by the requirement to maximise the stage gain, which is inversely proportional to C_f. Increasing g_m by raising the bias current improves the timing response. However, to maintain all transistors within their proper operating region, it eventually becomes necessary to increase the transistor dimensions, which in turn raises the parasitic capacitance C_0. The optimal g_m/C_0 ratio defines the maximum achievable Gain-Bandwidth-Product (GBP) of the cascode. For a given architecture, the GBP reaches a limit that can only be improved through technology scaling. The discharge time constant (τ_d), in turn, is defined by the product $R_f\,C_f$. The advantage of the CSA is that GBP optimisation can be achieved without necessarily increasing power consumption; the transistor dimensions and bias current can be scaled down according to the power budget and noise performance requirements.

For timing measurements with low-gain sensors of a few picofarad capacitance (LGAD, [424]), a common approach is a transimpedance amplifier based on a non-buffered cascode, featuring a resistive or active load (R_l) and resistive feedback through R_f. The input impedance R_{in} is determined by the g_m of the input transistor and the resistances R_f and R_l, and is approximately given by $R_f/[g_m\,(R_l \parallel R_f)]$. In contrast to the CSA, the rise time of the TIA amplifier is independent of the input capacitance, which is a significant advantage for timing detectors using sensors with higher capacitance. The integration time constant expressed by:

$$\tau_i = C_0\ (R_l \parallel R_f)\ , \tag{35.47}$$

is instead determined by the parasitic capacitance at the cascode output C_0 and the resistance formed by the parallel combination of the feedback and load resistances. The discharge time constant is set by the input capacitance C_{in} and input impedance R_{in}. The response amplitude scales inversely with C_{in} and is amplified by the cascode gain $g_m\,(R_l \parallel R_f)$. Although the front-end amplifier is a typical TIA in topology, it behaves more like a voltage amplifier sensing current integrated on the input capacitance. This results from the resistive feedback defining a constant input impedance, while the sensor's capacitance dominates at high frequencies, presenting a lower impedance path for fast and prompt signals.

Optimal noise filtering is achieved when the integration (τ_i) and discharge (τ_d) time constants are matched, yielding a CR-RC-like shaping response. In this case, the timing jitter can be estimated by applying the ENC formulas from Table 35.12 in conjunction with Eq. (35.45). It is important to note that, to optimise the signal-to-noise ratio, the intrinsic response time of the amplifier should not be significantly faster than the rise time of the signal from the sensor. This consideration is particularly important for the TIA architecture presented here, which is capable of providing a very fast intrinsic rise time. To align the amplifier's response with the sensor signal, the practical implementations usually incorporate a switchable capacitive matrix at the cascode output, slowing down the integration time constants.

The time resolution of binary electronics with a leading-edge discriminator is limited by signal jitter and time walk, *i.e.*, timing variations due to amplitude-dependent threshold crossing. These amplitude fluctuations arise from the Landau signal distribution and charge sharing in segmented sensors. Time walk can be corrected using the time-over-threshold (ToT) value, which is correlated with pulse height. In systems with a high signal-to-noise ratio, constant-fraction discriminators can be used to provide timing information independent of signal amplitude.

35.9.5 *Digital signal processing*

The filtering principles apply to both analog and digital signal processing. In digital signal processing, the pulse shaper shown in Fig. 35.33 is replaced by an analog to digital converter (ADC) followed by a digital processor that determines the pulse shape. Digital signal processing allows great flexibility in implementing filtering functions. The software can be changed readily to adapt to a wide variety of operating conditions and it is possible to implement filters that are impractical or even impossible using analog circuitry. However, this comes at the expense of increased circuit complexity and increased demands on the ADC compared to analog shaping.

If the sampling rate of the ADC is too low, high-frequency components will be transferred to lower frequencies ("aliasing"). The sampling rate of the ADC must be high enough to capture the maximum frequency component of the input signal. Apart from missing information on the fast components of the pulse, undersampling introduces spurious artefacts. If the frequency range of the input signal is much larger than the sampling rate, the noise at the higher frequencies will be transferred to lower frequencies and will increase the noise level in the frequency range of pulses formed in the subsequent digital shaper. The Nyquist criterion states that the sampling frequency must be at least twice the maximum relevant input frequency. This requires that the bandwidth of the circuitry preceding the ADC must be limited. The most reliable technique is to insert a low-pass filter.

The digitisation process also introduces inherent noise, since the voltage range ΔV corresponding to a minimum bit step introduces quasi-random fluctuations relative to the exact amplitude

$$\sigma_n = \frac{\Delta V}{\sqrt{12}}\,. \tag{35.48}$$

When the Nyquist condition is fulfilled, the noise bandwidth Δf_n is spread nearly uniformly and extends to 1/2 the sampling fre-

[10] The cascode amplifier is a two-stage topology—comprising a common-source stage followed by a common-gate stage—widely used in analog design for its high gain-bandwidth product. Behaving like a single-stage amplifier, it exhibits one dominant pole, which simplifies frequency compensation in feedback systems such as charge-sensitive amplifiers. In CSA applications, the cascode topology enables the use of large input transistors—optimized for low noise—while preserving high-speed performance by suppression of the Miller effect thanks to a low input impedance of the common-gate stage.

quency f_S, so the spectral noise density is

$$\frac{\sigma_n}{\sqrt{\Delta f_n}} = \frac{\Delta V}{\sqrt{12}} \cdot \frac{1}{\sqrt{f_S/2}} = \frac{\Delta V}{\sqrt{6 f_S}} \,. \qquad (35.49)$$

Sampling at a higher frequency spreads the total noise over a larger frequency range, so oversampling can be used to increase the effective resolution. In practice, this quantisation noise is increased by the ADC's differential non-linearity (DNL). Furthermore, the equivalent input noise of ADCs is often rather high, so the overall gain of the stages preceding the ADC must be sufficiently large for the preamplifier to override the ADC input noise.

35.9.6 *What to use when?*

When implemented properly, digital signal processing provides significant advantages in systems where the shape of detector signal pulses changes greatly, for example, in large semiconductor detectors for gamma rays or in gaseous detectors (*e.g.* TPCs) where the duration of the current pulse varies with drift time, which can range over orders of magnitude. Analog signal processing is best or most efficient in systems that require a fast time response, but the high power requirements of high-speed ADCs are prohibitive. Systems that are not sensitive to pulse shape can use fixed shaping time constants and rather simple filters (like CR–RC), which can be either continuous or sampled. In high-density systems that require small circuit area and low power (*e.g.*, in strip and pixel detectors), analog filtering often yields the required response and tends to be most efficient.

As stressed already in the introduction, it is important to consider that additional noise is often introduced externally. Recognising additional noise sources and minimising cross-coupling to the detector current loop is often essential to obtain the best overall noise performance. Understanding basic physics and its practical effects is important in forming a broad view of the detector system and recognising potential problems (*e.g.* modified data), rather than merely following standard recipes. More comprehensive treatments of low-noise detector readout and signal processing can be found, for example, in [1, 8, 421, 438–440].

35.10 Calorimeters

35.10.1 *Introduction*

Revised August 2023 by F. Sefkow (DESY, Hamburg) and F. Simon (KIT).

A calorimeter measures the energy and direction of particles by absorption in the detector material and registration of the energy deposited in an (ideally) contained electromagnetic (EM) or hadronic shower. Calorimeters are central components of modern high energy physics experiments, due to their ability to measure not only the energy of charged particles (with the exception of muons), but also of photons and neutral hadrons, thus enabling the reconstruction of π^0 and η decays and of exclusive final states involving long-lived neutral kaons, or neutrons. They are indispensable for the measurement of particle jets and for the reconstruction of total event properties, which, via the measurement of missing energy (or missing transverse energy in hadron colliders). enable the detection of the presence of "invisible" particles such as neutrinos and hypothetical particles such as dark-matter candidates. Calorimeters are also important for the identification of particle species, using information on the longitudinal and transverse shape of the energy deposition to separate electrons, photons, hadrons and muons. While the performance of calorimeters is typically assessed by the quality of their energy measurements, position resolution, both for EM and hadronic showers, is also highly relevant, for example for the reconstruction of effective jet masses. The capability to measure high-level observables that serve to classify events, such as particle and jet energies, missing energy and isolated leptons, makes calorimeters central components of the trigger systems in high-energy physics experiments.

In collider experiments, the importance of calorimeters tends to increase with increasing collision energies since the relative energy resolution improves with increasing particle energy while the depth required for full containment of the showers shows only logarithmic growth with energy. This is in contrast to the precision of track-based measurements, which is decreasing with increasing momentum. With recent advances in timing capabilities calorimeters are also contributing to the rejection of pile-up from multiple interactions within the same bunch crossings at colliders.

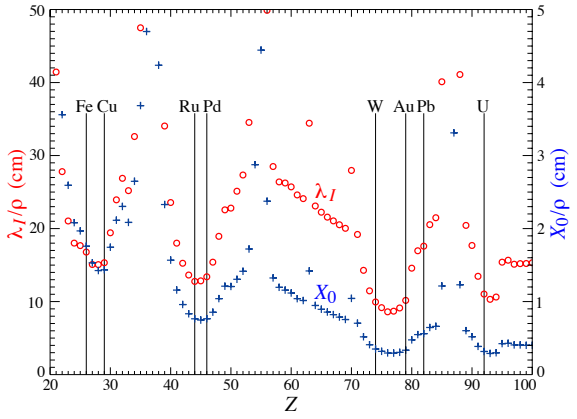

Figure 35.36: Nuclear interaction length λ_I/ρ (circles) and radiation length X_0/ρ (+'s) in cm for the chemical elements with $Z > 20$ and $\lambda_I < 50$ cm.

The characteristic length scale for EM showers is the radiation length X_0, which ranges from 1.8 cm (13.8 g cm^{-2}) in iron to 3.2 mm (6.0 g cm^{-2}) in uranium for materials used to generate showers in calorimeters.[11] Similarly, the characteristic nuclear interaction length λ_I varies from 16.8 cm (132.1 g cm^{-2}) (Fe) to 11.0 cm (209 g cm^{-2}) (U).[12] There is a premium on small λ_I/ρ and X_0/ρ (both with units of length). These quantities are shown for elements with $Z > 20$ in Fig. 35.36. The minima for both X_0 and λ_I correspond to elements between W and Au. Some of these elements are very difficult to work with (e.g. W) or expensive (e.g. Au), so, depending on the application (size of the required calorimeter) other materials, such as Fe, Cu, Pb, and different alloys like brass and CuW are often chosen. For EM calorimeters high Z is preferred; here Pb is a popular choice, while W provides even higher density and is generally affordable due to the limited volume of EM systems.

Most existing calorimeters are subdivided into a front EM section (ECAL) and a hadronic part (HCAL) behind; electrons and photons are measured in the ECAL, while hadrons and jets are measured in the combined ECAL and HCAL system. The detailed design depends on energy range and performance requirements as well as on size and cost constraints for the entire system. EM calorimeters tend to be 15–30 X_0 deep, while hadronic calorimeters are usually optimised for cost and performance at 5–8 λ_I. The depth of the ECAL typically corresponds to approximately 1 λ_I, with the exact value depending on the material. This means that approximately 70% of all hadronic showers will already begin in the electromagnetic calorimeter, making its response to a hadronic cascade highly relevant for the overall performance of the system. The choice of the calorimeter technology for the ECAL is thus a result of simultaneous optimisation for EM and hadronic performance of the overall system.

Sampling calorimeters consist of a high-density, normally metallic absorber sandwiched (or threaded) with an active material which generates a signal in response to shower particles. The active medium may be a scintillator, a noble liquid, a gas, silicon, or a Cherenkov radiator. These active media all have a relatively low Z, a significantly lower density, and larger X_0 and λ_I values than typical absorber materials. The average radiation and interaction lengths in the full detector are thus larger than those of the absorber alone.

There are also *homogeneous calorimeters*, in which the entire volume contributes to the signal. Homogeneous calorime-

[11] $X_0 = 120\ \mathrm{g\,cm^{-2}}\ Z^{-2/3}$ to better than 5% for $Z > 23$.
[12] $\lambda_I = 37.8\ \mathrm{g\,cm^{-2}}\ A^{0.312}$ to within 0.8% for $Z > 15$.

ters may be built with inorganic heavy scintillating crystals or non-scintillating Cherenkov radiators such as lead glass and lead fluoride. Nuclear interaction lengths in inorganic crystals range from 17.8 cm ($LuAlO_3$) to 42.2 cm (NaI). Materials with low X_0 used in large systems are for example BGO with $\lambda_I = 22.3\,\text{cm}$ and $X_0 = 1.12\,\text{cm}$, and $PbWO_4$ (20.3 cm and 0.89 cm). Properties of these and other commonly used inorganic crystal scintillators can be found in Table 35.5. Cryogenic noble liquids, where scintillation light and/or inonization can be detected, are also suitable materials for homogeneous detectors.

Homogeneous calorimeters at colliders are usually only used for the EM section. For the use of homogeneous calorimeters for hadron energy measurement, the large differences in the response to EM and hadronic parts of the shower are a significant challenge, as is the three-dimensional segmentation. This is still requiring substantial R&D, including the search for affordable materials. In non-accelerator physics experiments or at neutrino beams, homogeneous calorimeters, where the sensitive medium can be water or ice, scintillator, a noble liquid or the atmosphere itself, are used to detect both EM and hadronic showers.

Comprehensive tables of particle-physics calorimeters are given as Appendix C in Ref. [441].

35.10.1.1 *Energy Resolution and System Performance*

The energy resolution of calorimeters is a complex observable, due to the variety of contributing processes with different energy dependencies, and response functions often not perfectly Gaussian. Nevertheless, a simplified picture is useful in practice, and in particular for EM calorimeters also numerically accurate. For hadronic calorimeters additional complications must be taken into account. In such a simplified picture, due to the stochastic nature of shower evolution, the intrinsic calorimeter energy resolution, σ, is proportional to $\sqrt{E}$, as the number of charged particles, or the total ionising track length in a shower are on average proportional to the incident particle energy E. The relative resolution σ/E therefore improves with $A/\sqrt{E}$, where A denotes the so-called *stochastic term*. The readout system of the active medium will contribute noise to the resolution, $\sigma_N = B$, which in general is not energy-dependent. Effects that are proportional to the total deposited energy result in a *constant term*, $\sigma_C = C \cdot E$. Different sources contribute to this term, depending on the type of calorimeter. For both EM and hadronic calorimeters, imperfections of the detector, inhomogeneities such as density variations or those introduced by the detector mechanics, instabilities in time, imperfections of the readout or incorrect calibration of channels contribute. Shower leakage, which depends on particle energy, also contributes to the resolution with approximately linear dependence on energy. In non-compensating hadronic calorimeters, fluctuations of the EM fraction f_{em} from shower to shower, together with the energy dependence of the average f_{em} value, can lead to a significant constant term that often dominates over the instrumental effects. Adding up all contributions in quadrature yields the standard parameterisation of the relative energy resolution of a calorimeter:

$$\frac{\sigma}{E} = \frac{A}{\sqrt{E}} \oplus \frac{B}{E} \oplus C\,. \tag{35.50}$$

In particular the effects specific to hadronic showers give rise to non-Gaussian distributions of the energy response. Therefore care must be used in performance comparisons, as different parameterisations of the line shape and different definitions of the resolution are in use. In some cases, a linear rather than a quadratic addition of the stochastic and constant term may provide a better description of the energy resolution as a function of energy. It should be noted that the individual terms then lose the simplified interpretation discussed above, and care has to be taken when comparing performance based on fits to the energy dependence of the resolution.

Typically, primarily the stochastic term — which is determined by the calorimeter design in terms of material and geometry — is considered in order to describe the overall properties of a calorimeter. For the calorimeters of the multi-purpose experiments at the LHC, the stochastic terms are $3 - 10\%$ for electromagnetic and $50 - 80\%$ for hadronic calorimeters. In practice, the energy resolution of a calorimeter at high energies is limited by the constant term C, which in the EM case mainly reflects the precision and stability of the mechanical construction, electronic readout system and calibration. Typical constant terms are a few per-mil for EM and a few percent for hadronic calorimeters. For concrete examples and references see Tables 35.13 and 35.15.

For sampling calorimeters, the stochastic term depends on the *sampling fraction* f_{samp}, i.e. the ratio of energies deposited in the active and passive material. Also the *sampling frequency* enters, which is determined by the number N of different sampling elements present in the region in which the shower develops. The stochastic term A scales approximately with $1/\sqrt{f_{\text{samp}}}$, and for given f_{samp} and total depth, with $1/\sqrt{N}$.

While the energy resolution for single hadrons (most commonly pions) is often used as the key performance criterion for a hadronic calorimeter, it has to be noted that this value is only of limited relevance in high-energy physics experiments. In most experiments, the calorimetric measurement of hadrons is based on the combined system consisting of ECAL and HCAL. Moreover, for the physics capabilities of a detector at a high-energy particle collider, also the combined calorimetric resolution for single hadrons is not a sufficient criterion to fully characterise hadronic performance, but rather the jet energy resolution, the resolution for missing (transverse) energy, and the capability to cope with high background and pile-up levels. These quantities cannot be measured directly with prototypes in beam tests, and strongly depend on overall system aspects and reconstruction tools. However, the performance in these observables can be reliably inferred from system simulations once the simulated response to single particles and the simulated topology of showers has been validated in detail by beam tests.

Besides energy resolution, response linearity is an important factor in the design of calorimeters. While a non-linear response for single particles can be corrected for if appropriate calibration measurements exist, such corrections deteriorate the energy resolution, in particular in the case of superposition of several showers, as it often occurs in jets. Sources for non-linearities can be intrinsic to the design, for example due to saturation effects in the active medium with increasing energy density, due to leakage, or connected to shower physics as discussed in section 35.10.3.

The energy resolution for hadrons is intrinsically limited by large event-to-event fluctuations of the shower evolution and of "invisible" components not contributing to the detector signal. It remains the limiting factor for single particles and for the high-level performance for jets and total event properties. This has motivated intense research in the past decades. One direction aims at improving the hadronic resolution by extracting additional signals to disentangle the shower composition, e.g.with so-called dual read-out methods, and is explained in the hadron calorimeter section 35.10.3. Another, so-called "particle flow" approach described below optimises the combination of measurements of individual particles in different detector components. Ideally, both methods can be combined.

35.10.1.2 *Role of Simulations*

Simulations have become indispensable for the design of detectors and the development of reconstruction algorithms. Since event-to-event fluctuations drive calorimeter performance, Monte Carlo techniques that accurately model the evolution of particle cascades in material are required. By far the most common computer code in use today is the *GEANT4* toolkit [442, 443], which provides a step-based simulation of the passage of particles through matter. Thanks to the relative simplicity of EM cascades, simulations of EM showers are typically highly accurate. The modelling of hadronic showers is more complex, and suffers from larger uncertainties. Significant improvement has been achieved in this area, moving from simpler parameterised models to physics-driven interaction models. From early on, detailed codes and data describing nuclear break-up and neutron transport like *CALOR* [444] or *FLUKA* [445, 446] contributed crucially to the understanding of hadron calorimetry. The simulations reproduce the general features of the substructure of hadronic showers,

characterised by dense shower activity and sparser ionising track segments, and their accuracy is adequate for most purposes of quantitative design optimisations. Details of the implementation of physics models in *GEANT4* are discussed in [447].

35.10.1.3 *Particle flow approach*

In a typical collider experiment, the EM and hadronic calorimeter system surrounds a charged-particle tracking volume devised for momentum measurement in a magnetic field. Matching tracks to calorimetric energy deposits provides corrections for the magnetic deflection of the charged particles, necessary for the reconstruction of invariant masses in multi-jet final states, or of the total momentum imbalance. Furthermore, for charged particles the track-based measurements are far more precise for particles in jets with energies of up to several hundred GeV, so using these instead of calorimeter energies may optimise the jet energy resolution. This so-called "particle flow" approach aims at reconstructing each particle individually, using a combination of the best measurements from the detector.

About 60% of the energy in a typical jet is carried by charged particles, predominantly hadrons, 30% by photons and only 10% by long-lived neutral hadrons (K_L^0 and n), for which hadronic calorimetry is unavoidable. Assuming, as motivated by detector designs proposed for a future Higgs factory, $15\%/\sqrt{E(\mathrm{GeV})}$ for photons and $55\%/\sqrt{E(\mathrm{GeV})}$ for hadrons, then, in the ideal case, where each particle is resolved, a jet energy resolution of $19\%/\sqrt{E(\mathrm{GeV})}$ could be obtained. Here the dominant part ($18\%/\sqrt{E(\mathrm{GeV})}$) is still due to the calorimeter resolution for neutral hadrons.

The particle flow method places high demands on the imaging capabilities of the calorimeters, and on the pattern recognition performance of the reconstruction algorithms. Only energy deposits not associated with charged particles and not identified as photons, will be interpreted as neutral hadrons. In practice, this cannot always be done unambiguously, and mis-assignments give rise to an additional measurement uncertainty, which is called *confusion*. For simulated detectors at proposed future Higgs factories jet energy resolutions of 3-4% have been demonstrated, significantly larger than in the ideal case, but sufficient for the required efficient separation of W and Z hadronic final states.

Particle flow-like techniques were first applied in the ALEPH detector [448], which achieved a jet energy resolution of $60\%/\sqrt{E}$, or 6.2 GeV for hadronic Z decays. More recently, particle flow techniques are successfully used in the CMS experiment [449], for example improving the missing energy resolution by one third over a wide range.

The Pandora particle flow algorithm (PFA) [450] is the most developed and best performing today in the context of future lepton colliders. The algorithms make use of topological information, including the sub-structure of showers, as well as the compatibility of calorimetric and track-based measurements. In this way the purely calorimetric performance for the jet is either retained or improved. In the framework of studies for CLIC [451], it was shown that the required jet energy resolution of 3.5% can be achieved with the PF technique for jet energies up to 1500 GeV.

For the use of energy-momentum matching in the assignment of energy depositions, and for energy flow treatment of dense jets, particle flow calorimeters with their emphasis on imaging must still feature a good energy resolution. Furthermore, the neutral hadron energy uncertainty is the dominant contribution to the jet resolution for low energy jets, where particles are well separated, while at higher energies the confusion effects take over.

High granularity in all three space dimensions comparable to or smaller than the length scales of particle showers given by X_0 and ρ_M for both ECAL and HCAL brings additional advantages; for example it offers ideal conditions for the application of software compensation methods, which improves the intrinsic resolution and also reduces "confusion" [452]. A particular strength is the possibility to use topological information such as the reconstructed starting point of the shower for the estimation of leakage. Moreover, the combination of fine-grained topological reconstruction and cuts on cluster-wise timing with a precision of few tens of pico-seconds allows for powerful pile-up rejection. This extends the application range of particle flow methods towards collider environments with less benign background conditions, like multi-TeV e^+e^- collisions, and it is an asset on its own for high-intensity hadron colliders, even if particle flow methods are difficult to apply.

The performance of highly granular calorimeters depends, among others, on the particle separation and pattern recognition capabilities and on the single particle energy and timing resolution. They are thus not only optimised for energy measurement, but also for multi-dimensional shower reconstruction and particle separation in space and time. The potential of such calorimeters can be further enhanced by combining a fine spatial segmentation with maximised information on energy, time, and possibly the nature of the energy deposition, for example by using dual-readout methods. This may be achieved, for example, by combining multiple optical materials sensitive to different components in the shower in finely segmented sandwich calorimeters, or by using timing information to extract the position of the energy deposition along a fibre. For future collider experiments, different approaches based on silicon, scintillator, noble liquid, fibre and crystal readout are being pursued [453]. They all foresee, with different level of emphasis, high granularity to enable the application of particle flow methods, and in some cases to further enhance their performance by additional information not exploited in current algorithms. One such example is the proposal [454] to benefit from the superior electromagnetic energy performance of crystals to pair photons from π^0 decays and thereby resolve jet finding ambiguities to improve the jet energy resolution.

35.10.2 *Electromagnetic calorimeters*

Revised August 2025 by C.L. Woody (BNL) and R.-Y. Zhu (HEP California Inst. of Technology).

The development of electromagnetic showers is discussed in the section on "Passage of Particles Through Matter" (Sec. 34 of this *Review*). Formulae are given which approximately describe average showers, but since the physics of electromagnetic showers is well understood, a detailed and reliable Monte Carlo simulation is possible. EGS4 [455] and GEANT [442] have emerged as the standards.

Electromagnetic calorimeters are devices that are designed to measure the total energy of electrons and photons by total absorption. They come in two general categories: homogeneous and sampling. In a homogeneous calorimeter, all of the particle's energy is deposited in the active detector volume and is used to produce a measurable signal (either scintillation light, Cherenkov light or charge). Homogeneous electromagnetic calorimeters are typically constructed using high density, high Z inorganic scintillating crystals such as BaF_2, BGO, CsI, CsI(Tl), LYSO, NaI(Tl) and PWO, non-scintillating Cherenkov radiators such as lead glass and lead fluoride (PbF_2), or ionizing noble liquids such as liquid argon, liquid krypton or liquid xenon. The properties of some commonly used inorganic crystal scintillators can be found in Table 35.5. Total absorption homogeneous calorimeters, such as those built with heavy crystal scintillators, provide the best energy resolution for measuring electromagnetic showers and are generally used when the best possible performance is required, particularly at lower energies. Attention, however, needs to be paid to radiation damage in inorganic scintillators when exposed to the typical environment of high luminosity proton colliders, as discussed below and in Section 35.4. In addition, it is often challenging to achieve high segmentation with homogeneous radiator materials, both longitudinal and transverse, which is necessary for techniques such as particle flow analysis.

A sampling calorimeter consists of an active medium which generates a signal and a passive medium which functions as an absorber. In this case, most of the particle's energy is deposited in the absorber and only a fraction of the energy is detected in the active medium. The ratio of energy in the sampling medium to the total enegy in calorimeter is called the sampling fraction. The active medium may be a scintillator, an ionizing noble liquid, a semiconductor, or a gas ionization detector. The absorber is typically a heavy metal with a high Z such as lead, tungsten, iron,

Table 35.13: Resolution of typical electromagnetic calorimeters. E is in GeV.

Technology (Experiment)	Depth	Energy resolution	Date
NaI(Tl) (Crystal Ball)	$20X_0$	$2.7\%/\mathrm{E}^{1/4}$	1983
$Bi_4Ge_3O_{12}$ (BGO) (L3)	$22X_0$	$2\%/\sqrt{E} \oplus 0.7\%$	1993
CsI (KTeV)	$27X_0$	$2\%/\sqrt{E} \oplus 0.45\%$	1996
CsI(Tl) (BaBar)	16–$18X_0$	$2.3\%/E^{1/4} \oplus 1.4\%$	1999
CsI(Tl) (BELLE)	$16X_0$	1.7% for $E_\gamma > 3.5$ GeV	1998
CsI(Tl) (BES III)	$15X_0$	2.5% for $E_\gamma = 1$ GeV	2010
$PbWO_4$ (PWO) (CMS)	$25X_0$	$3\%/\sqrt{E} \oplus 0.5\% \oplus 0.2/E$	1997
$PbWO_4$ (PWO) (ALICE)	$19X_0$	$3.6\%/\sqrt{E} \oplus 1.2\%$	2008
Lead glass (OPAL)	$20.5X_0$	$5\%/\sqrt{E}$	1990
PbF_2 (g-2)	$15X_0$	$3.6\%/\sqrt{E} \oplus 1.9\%$	2019
Liquid Kr (NA48)	$27X_0$	$3.2\%/\sqrt{E} \oplus 0.42\% \oplus 0.09/E$	1998
Scintillator/depleted U (ZEUS)	20–$30X_0$	$18\%/\sqrt{E}$	1988
Scintillator/Pb (CDF)	$18X_0$	$13.5\%/\sqrt{E}$	1988
SciFi/Pb spaghetti (KLOE)	$15X_0$	$5.7\%/\sqrt{E} \oplus 0.6\%$	1995
SciFi/W (sPHENIX)	$20X_0$	$13\%/\sqrt{E}$	2022
Liquid Ar/Pb (NA31)	$27X_0$	$7.5\%/\sqrt{E} \oplus 0.5\% \oplus 0.1/E$	1988
Liquid Ar/Pb (SLD)	$21X_0$	$8\%/\sqrt{E}$	1993
Liquid Ar/Pb (H1)	20–$30X_0$	$12\%/\sqrt{E} \oplus 1\%$	1998
Liquid Ar/depl. U (DØ)	$20.5X_0$	$16\%/\sqrt{E} \oplus 0.3\% \oplus 0.3/E$	1993
Liquid Ar/Pb accordion (ATLAS)	$25X_0$	$10\%/\sqrt{E} \oplus 0.4\% \oplus 0.3/E$	1996

copper, or depleted uranium. The active material is interspersed with the passive absorber in a variety of ways, e.g. by using alternating plates of active material and absorber, or embedding the active material, such as scintillating fibers, into the absorber.

The main difficulty in this approach is extracting the signal from the active material. One possibility is a simple stack of alternating absorber and active material. However, this usually leads to gaps for the readout and services and hence non-uniformities. This can be improved by using a so-called "spaghetti" design, where scintillating fibers are brought to the front or back of the detector and read out. This can also be done with either wavelength shifting plates or fibers, such as in a so-called "shashlik" design where wavelength shifting fibers run through the stack of alternating scintillator and absorber plates and are read out at one or both ends, or embedding wavelength shifting fibers in the scintillating plates which are then brought out to the edges or back of the detector and read out. Another similar design is the Tungsten SciFi (W/SciFi) configuration, which consists of a matrix of tungsten powder and epoxy with embedded scintillating fibers that are brought out to the back and form a bundle that is read out with silicon photomultipliers (SiPMs). This design was utilized for the sPHENIX EMCAL at RHIC and will be used for the Forward EMCAL for the ePIC Experiment at the EIC.

For sampling calorimeters that use ionizing liquids as the sampling medium, there is also an "accordion" design which avoids all gaps for services, where the absorber plates are folded into an accordion shape along with interspersed electrodes to collect the ionization charge [456]. While these readout schemes are generally more complicated than those for homogeneous calorimeters, the sampling calorimeter design allows more flexibility in terms of segmentation and the construction of very large calorimeters at much lower cost than homogeneous calorimeters.

The energy resolution σ_E/E of a calorimeter can be parameterized as $a/\sqrt{E} \oplus b \oplus c/E$, where $\oplus$ represents the square root of the sum in quadrature of the three terms, and E and σ_E are in GeV. The stochastic term a represents statistics-related fluctuations such as intrinsic shower fluctuations, photoelectron statistics, dead material at the front of the calorimeter, and sampling fluctuations for minimum ionizing particles. For a fixed number of radiation lengths, the stochastic term a for a sampling calorimeter is expected to be proportional to $\sqrt{t/f}$, where t is plate thickness and f is sampling fraction [457–459]. The stochastic term a is typically of the order of a few percent for a homogeneous calorimeter, and is generally in the range of 8 to 20% for sampling calorimeters, depending on the sampling fraction.

The main contributions to the systematic, or constant, term b are detector non-uniformity and calibration uncertainties. In the case of hadronic cascades discussed below, non-compensation also contributes deviations from $\sqrt{E}$ scaling. Another important contribution to the energy resolution of calorimeters that are used in high radiation environments such as high lumnosity colliders is radiation damage of the active medium. Radiation damage can induce optical absorption in scintillating materials which reduces the measured light output and produces non-uniformities in light collection. This can be mitigated by developing radiation-hard active media [460], by reducing the signal path length [461] and by frequent *in situ* calibration and monitoring [103,459]. With effort, the constant term b can be reduced to below one percent. The term c is due mainly to electronic noise summed over the readout channels required to measure the shower energy (typically a few Molière radii).

The position resolution depends on the effective Molière radius and the transverse granularity of the calorimeter. Like the energy resolution, it can be factored as $a/\sqrt{E} \oplus b$, where a is the stochastic term, typically of the order of a few mm to 20 mm, and b can be as small as a fraction of mm for a dense calorimeter with fine granularity. Fine granularity also helps particle flow analysis discussed in the hadron calorimeters section below.

Electromagnetic calorimeters may also provide angular and pointing measurements for electrons and photons. This is particularly important for photon-related physics to identify the correct primary vertex, since photons are not detected by the tracking system of the overall experiment. The typical photon angular resolution is about 45 mrad$/\sqrt{E}$, which can be achieved by implementing longitudinal segmentation [456] for a sampling calorimeter or by adding a preshower detector [462] for a homogeneous calorimeter without longitudinal segmentation.

There have been many electromagnetic calorimeters built and used in particle physics experiments for a variety of applications. Table 35.13 provides a short list of the major ones used in some of the larger experiments. Also listed are calorimeter depths in radiation lengths (X_0) and the achieved energy resolution. Whenever possible, the performance of the calorimeters *in situ* is quoted, which is usually in good agreement with prototype test beam results as well as EGS or GEANT simulations, provided that all systematic effects are properly included. Details about detector design and performance can be found in Appendix C of refer-

ence [459] and Proceedings of the International Conference series on Calorimetry in High Energy Physics.

35.10.3 *Hadronic calorimeters*

Revised August 2025 by F. Sefkow (DESY, Hamburg) and F. Simon (KIT).

Hadronic calorimetry [441, 463, 464] is considerably more complex than electromagnetic (EM) calorimetry due to the wider range and different nature of physical processes contributing to shower development and energy deposition, which in turn are characterised by different length and time scales. Hadronic showers are initiated by inelastic strong interactions of highly-energetic charged and neutral hadrons with atomic nuclei. These interactions result in the production of secondary particles, which drive the development of the shower. Among these are energetic hadrons, as well as lower-energy nucleons, photons and nuclear fragments. Energy transferred to nuclear break-up, excitation or recoil does not, in general, produce a signal, but remains *invisible*, and event-to-event fluctuations of this invisible energy deposit ultimately limit the resolution of hadronic calorimeters (HCALs).

The length scale of the interaction of relativistic hadrons is given by the nuclear interaction length λ_I. As discussed in Section 35.10.1, λ_I is a factor 10 to 30 larger than X_0 for common materials used in the construction of calorimeters. HCALs thus require a significantly larger geometrical depth for full containment than electromagnetic calorimeters (ECALs), albeit not by the factor suggested by the ratio of λ_I/X_0 due to the different nature of the showers. A key role is played by the production of π^0s and their subsequent decay into two photons. These result in the formation of electromagnetic sub-showers which evolve on the scale given by the radiation length X_0, and thus require sufficiently fine sampling of the shower activity to capture also this electromagnetic component. The two different length scales occurring in hadronic showers, and the large fluctuations of hadronic, electromagnetic and invisible activity, result in significant event-to-event variations of the energy response and of the shower topology. This topology is characterized by a lumpy structure, with compact regions of high local energy density originating from electromagnetic sub-showers, and sparser hadronic activity with minimum-ionizing hadrons.

Figure 35.37 (top) shows the distribution of the longitudinal position of the first inelastic interaction measured for pion-induced hadronic showers with the highly-granular scintillator-steel HCAL of the CALICE collaboration [465]. The figure illustrates the exponential distribution, with a slope consistent with the pion interaction length expected from the geometry and material composition of the calorimeter. This distribution is well reproduced by simulations using GEANT4 [442, 447]. Figure 35.37 (bottom) shows the mean longitudinal shower profile, given by the mean energy deposition in each calorimeter layer, both relative to the front face of the calorimeter (dots, without corrections for dead cells) and relative to the measured shower starting point given by the first inelastic interaction (filled histogram). The latter is much more compact than the former, which is a convolution of the latter with the distribution of shower starting point shown in the left panel of the figure. This shows that the detector depth required for adequate shower containment is significantly influenced by the fluctuations of the position of the first hadronic interaction. Detection of this position allows for an estimate of leakage from a finite calorimeter volume, and it enables stringent tests of shower evolution models. In the past years, motivated by precision needs at the next generation of e^+e^- colliders, the CALICE collaboration has constructed a number of prototypes with high 3-dimensional spatial granularity and recorded large sets of data at test beams, allowing for studies of shower evolution processes in unprecedented detail. The refined simulations support the trend to proceed from research focused on understanding the global intrinsic properties of showers, e.g. for the purpose of compensation, towards the study of detailed information, in space, time, and energy deposition type, through many and multiple readout channels.

In an inelastic hadronic collision a significant fraction f_{em} of the energy is removed from further hadronic interaction by the production of secondary π^0/η's, whose decay photons generate high-energy electromagnetic showers. Charged secondaries ($\pi^\pm$, p, ...) deposit energy via ionization and excitation, but also interact with nuclei, producing evaporation neutrons, spallation protons and neutrons, and heavier spallation fragments. The charged collision products produce detectable ionization, as do the showering γ-rays from the prompt de-excitation of highly excited nuclei. The recoiling nuclei generate little or no detectable signal, as mentioned previously. The neutrons lose kinetic energy in elastic collisions which generate ionization signals via recoiling protons, thermalize on a time scale of several μs, and are finally captured, with the production of more γ-rays—usually outside the acceptance gate of the electronics. Between endothermic spallation losses, nuclear recoils, and late neutron capture, a significant fraction of the hadronic energy (20%–40%, depending on the absorber

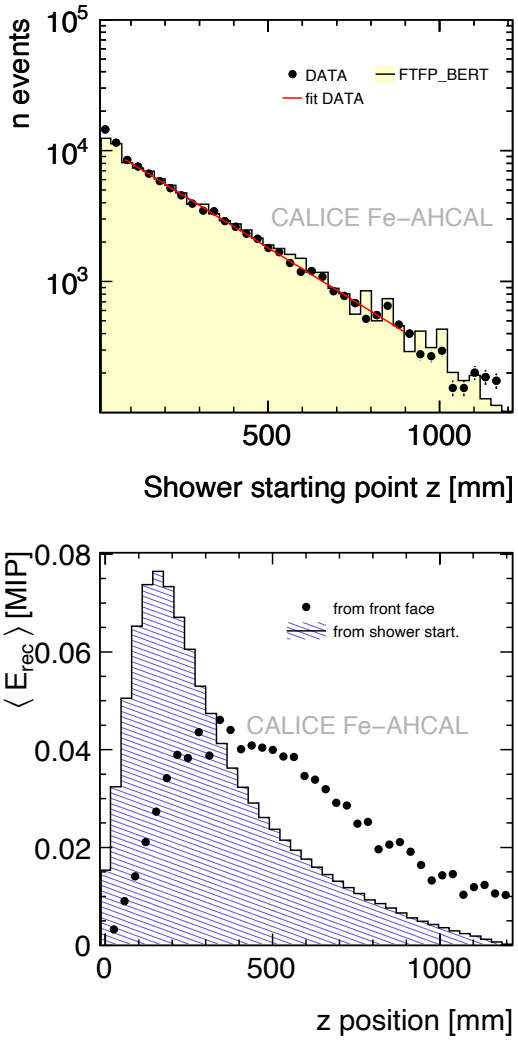

Figure 35.37: Longitudinal profile of hadronic showers induced by 45 GeV negative pions measured in he CALICE highly-granular steel-scintillator sampling calorimeter [465]. Top: Reconstructed position of the first inelastic interaction, compared to simulations (GEANT4 9.4p03, FTFP_BERT), and an exponential fit yielding a slope consistent with the expected pion interaction length. Bottom: Longitudinal shower profile measured from the front face of the calorimeter (dots, without corrections for dead cells) and relative to the position of the shower start given by the first inelastic interaction (filled histogram). The visible energy is given in units of the most probable energy loss of a minimum-ionizing particle (MIP). The integrals of the distributions are normalized to unity.

and energy of the incident particle) is used to overcome nuclear binding energies and is therefore lost or "invisible."

In a hadron-nucleus collision a large fraction of the incident energy is carried by a "leading particle" with the same quark content as the incident hadron. If the projectile is a charged pion, the leading particle is usually a pion, which can be neutral and hence contributes to the EM sector. This is not true for incident protons. The result is an increased mean hadronic fraction for incident protons.

The complexity of hadronic showers also has a significant impact on the energy measurement. In contrast to EM showers, hadronic cascade processes are characterised by the production of relatively few high-energy particles. The number multiplicity of these particles produced in hadronic interactions increases only logarithmically with energy. The lost energy and f_{em} are highly variable from event to event, and on average increase with increasing energy [466]. Electromagnetic sub-showers typically result in a higher response than the hadronic parts of the cascade, where undetectable energy loss due to nuclear dissociation, the long time scales and the material dependence of neutron signals, as well as other effects reduce the measured signal. This difference in response is often expressed by the $\langle h/e \rangle$ ratio, a calorimeter-dependent quantity which is smaller than unity for many, but not all, HCALs. The increase of the electromagnetic fraction with energy thus introduces a non-linear contribution to the response. Combined with the significant event-by-event fluctuations between electromagnetic and hadronic fractions of the showers and between different hadronic processes the non-equality of h and e deteriorates the energy resolution of HCALs. Different strategies to address this exist, as discussed further below.

Most large HCALs are parts of complex 4π detectors at colliding beam facilities. To date, all these HCALs are sampling calorimeters. This choice is imposed by the physics of hadronic showers, both by the required depth for containment which favours high-density materials with short λ_I, and by the differences in response to electromagnetic and hadronic parts of the cascade, which are particularly severe for homogeneous calorimeters. Common absorber materials are Fe, Cu, Pb, and U, with W also used occasionally. A large variety of different active materials are used, depending on application and optimisation, from plastic scintillators (plates, tiles, bars, fibers), crystals and Cherenkov media, silicon, liquid argon (LAr), to gaseous detectors. The energy loss of particles in the active medium is either detected directly by collecting charge, or via scintillation or Cherenkov light observed with conventional photomultipliers (PMTs), photodiodes or silicon photomultipliers (SiPMs). The choice of both active and passive materials is driven by different, sometimes conflicting, constraints, including performance requirements, space and other mechanical boundary conditions, radiation tolerance, and cost considerations.

A wide range of different geometries of absorbers and sensors is used, with design choices depending on the chosen priorities of addressing these constraints, also considering the need to bring the signals to the outside of the detector while achieving a hermetic coverage and other constraints. In this context it is important to note that a classic sandwich structure with absorber plates and active elements approximately perpendicular to the particle incidence is not required, and arbitrary orientations are viable for good calorimetric measurements, as long as channelling, meaning the extended passage of primary particles through low-density active regions, is excluded. Figure 35.38 shows two examples of plastic scintillator-based calorimeters to illustrate differences in design between coarsely-segmented and highly-granular calorimeters. The ATLAS tile calorimeter [467] uses scintillator tiles coupled to wavelength-shifting fibers which collect the light from the tiles and guide them to PMTs outside of the active region of the calorimeter. The calorimeter is segmented in ϕ (azimuthal angle) and η (pseudorapidity, defined as $\eta = -\ln\tan(\theta/2)$, where θ is the angle relative to the beam axis), with coarse longitudinal segmentation. The technological prototype of the CALICE analog HCAL, a highly granular SiPM-on-tile calorimeter is based on scintillator tiles directly coupled to SiPMs, which, together with the front-end electronics, are embedded inside of the the active

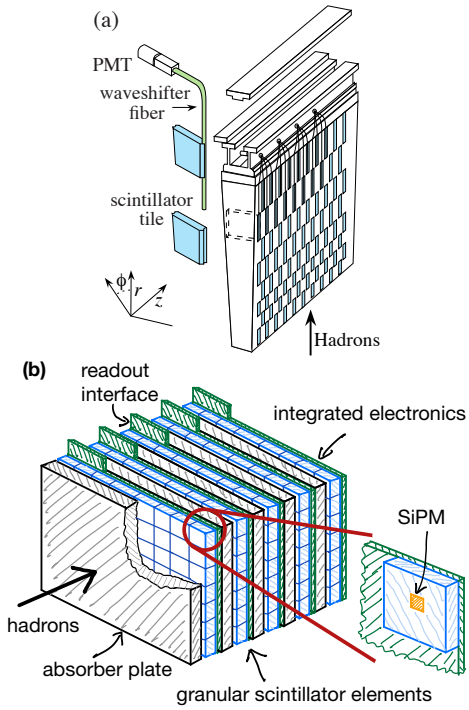

Figure 35.38: Two examples of geometrical structures of scintillator-based HCALs. (a) A wedge of the ATLAS central tile calorimeter consisting of scintillator tiles in iron, read out via wavelength-shifting fibers and PMTs [467]. The coordinate system is that of the ATLAS calorimeter within the experiment, with the z axis along the beam direction, r pointing radially outward, and ϕ being the azimuthal angle. (b) An illustration of the "SiPM-on-tile" structure used in the CALICE analogue HCAL prototype, and in the CMS High-Granularity Calorimeter (HGCAL), highly granular calorimeters with steel absorbers and small scintillator tiles directly read out via SiPMs with embedded electronics [464, 468–470].

volume of the calorimeter. The CMS HGCAL [470] uses the same concept in part of the detector, and in addition embeds elements for digital data concentration and power distribution in the active volume. Other detector solutions include scintillating fibres threading an absorber [471], liquid-argon-filled tubes [472] and the "accordion" LAr detector [473]. The latter has zig-zag absorber plates to minimize channeling effects; the calorimeter is hermetic (no cracks), and plates are oriented so that cascades cross the same plate repeatedly.

In particular, but not exclusively, the combination of heavy absorber materials (Pb, U) with plastic scintillators allows the construction of HCALs that have a near-equal response to electromagnetic and hadronic parts of the cascade, so-called compensating calorimeters [474]. In this first study, it was recognized that nuclear fission can amplify the hadronic signal when using uranium absorbers. However, the key drivers of compensation are the reduction of the electromagnetic response with high-Z absorbers and an increased sensitivity to neutrons, which are strongly correlated to otherwise invisible energy loss due to nuclear dissociation, with a hydrogeneous active medium [475–479]. Since the electromagnetic cross section increases, and the critical energy decreases with Z, and since most of the energy of an electromagnetic shower is deposited by low-energy, short-range electrons, a disproportionate fraction of the total electromagnetic energy is deposited in the absorber in the high-Z case. Hydrogenous active media, such as organic scintillators, have a high sensitivity to spallation neutrons via elastic $n-p$ scattering. The number of produced neutrons is highly correlated with the invisible energy of the hadronic cascade. Increasing the sensitivity to these particles can thus boost the visible hadronic signal. Achieving compensation requires carefully-chosen sampling fractions and frequencies, with the response to

Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 06/14/23. For personal use and distribution is strictly not permitted, except for Open Access articles.

the hadronic parts of the shower also sensitive to the integration time of the electronics due to the time structure of the neutron component of the signal.

Since Cherenkov light, for example in quartz plates or fibers, or in crystals, is produced only by relativistic particles in the cascade and thus predominantly by the electromagnetic component of the shower, such media are less common in hadronic than in ECALs. Notable exceptions are applications that require high radiation tolerance, and dual-readout calorimeters which specifically exploit this feature, as discussed below.

Silicon offers high compactness, high granularity, high radiation tolerance, long-term stability and fast charge collection, and is thus an interesting active material for sampling calorimeters. A thorough overview of the development and of the features of this technology can be found in a recent review paper [480]. The first silicon-based calorimeter in a collider experiment was a HCAL, the H1 PLUG calorimeter [481] covering the very forward region of the H1 experiment at HERA. The SICAPO collaboration has demonstrated the conceptual possibility of constructing compensating HCALs using silicon sensors [482]. Silicon is currently the technology of choice for several ECALs for future Higgs factories [483–485]. It is also being used extensively in the CMS HGCAL [470] in both electromagnetic and hadronic sections, complemented by scintillator tiles with on-tile SiPM readout where the radiation levels allow.

More generally, high-granularity calorimeters play an increasingly important role, in particular motivated by the use of particle-flow algorithms for global event reconstruction (see Section 35.10.1). The associated technologies for both electromagnetic and HCALs have been pioneered by the CALICE collaboration, which has built and tested an increasingly sophisticated series of "imaging" calorimeters with a highly granular readout [486]. In the area of HCALs, this includes the scintillator-based analog HCAL [487] with the latest SiPM-on-tile technological prototype with fully-integrated electronics having approximately 22,000 channels [468, 469], as well as digital [488] and semidigital [489] calorimeters using gas detectors, such as RPCs (Sec. 35.6.6) and micropattern gas detectors (Sec. 35.6.3), with channel counts of up to 500,000. The large numbers of channels of high-granularity calorimeters presents a significant integration challenge for full detector systems, and requires the full integration of the front-end electronics inside of the active volume of the detector, as well as very compact data concentration and interface units. The first such detector in construction for a collider experiment is the CMS HGCAL [470]. Beam tests with a combined prototype using both silicon and scintillator-SiPM instrumented active layers have confirmed simulation-based expectations [490]. The timing resolution is found to be 60ps for single-channel measurements and better than 20ps for full showers at the highest energies [491], setting excellent perspectives for the HGCAL calorimeter performance at the HL-LHC. The total silicon area of the full HGCAL amounts to about 600 m^2, and about 240,000 SiPMs are foreseen. The calibration of such calorimeters requires the monitoring of a large number of cells, which is achieved in-situ using reconstructed track segments within hadronic showers [470,492] or externally identified muons. For this method, the capability to detect the most probable energy loss of a minimum-ionizing particle in a single cell is essential. This is required over the full lifetime of the detector, also after the active elements have received significant radiation damage, resulting in increased noise and reduced charge or signal collection efficiency. Due to the large number of cells contributing to the measurement of one shower, the requirements on the precision of the calibration of individual cells is relaxed relative to the global energy calibration of the calorimeter.

The energy resolution of HCALs is severely affected by fluctuations between different components of the cascade, exacerbated by differences in response to purely hadronic and to electromagnetic sub-showers. In many detectors, fluctuations in the electromagnetic energy fraction, $f_{\rm em}$, and the related, consequential variations in nuclear energy dissociation losses, represent the biggest single contribution to the hadron energy resolution. One strategy to address this problem is the construction of intrinsically-compensating calorimeters, which imposes stringent constraints on materials and geometries as discussed above. Compensating calorimeters are not used in current large collider experiments, and are at the moment not considered for future collider detectors. Two different strategies are presently followed to improve the energy resolution in non-compensating calorimeters: Offline weighting or software compensation in longitudinally-segmented or in highly-granular calorimeters; and dual-readout calorimetry.

Software compensation and *Machine Learning* techniques exploit the fact that electromagnetic sub-showers typically have a higher spatial density than the purely hadronic parts of the cascade. Amplitude (or energy-density) dependent weights are applied in the reconstruction to reduce the effects of shower-to-shower fluctuations. These techniques were pioneered by the CDHS collaboration for a longitudinally segmented steel-plastic scintillator calorimeter [493], where an improvement of the energy resolution of 10% (at 10 GeV) to 30% (at 140 GeV) for charged pion showers was achieved. Similar techniques were successfully applied in the H1 [494] liquid argon calorimeter system resulting in a stochastic term of $51\%/\sqrt{E}$, and in the ATLAS [495] endcap calorimeters, also based on liquid argon, with an energy resolution of $84\%/\sqrt{E}$. Inspired by these approaches, a software compensation technique using the detailed spatial information provided by highly-granular calorimeters of the CALICE collaboration has been developed, achieving up to 25% improvement of the energy resolution compared to the resolution without software compensation, resulting in a stochastic term of $45\%/\sqrt{E}$ [496] in a scintillator tile calorimeter with steel absorbers. This technique has also been successfully transferred to particle-flow reconstruction [497], resulting in an improvement of the jet-energy resolution in simulated events by 8% - 15%, depending on jet energy. Highly-granular calorimeters with software compensation and particle-flow reconstruction are currently studied as the baseline configuration for several Higgs-factory detectors.

The wealth of detailed information provided by highly granular calorimeters with timing capabilities suggests the application of machine learning (ML) methods to optimise their performance. Using test beam data collected with CALICE and CMS HGCAL prototypes, significant improvements have been demonstrated for the hadron shower energy resolution [498, 499] as well as for the separation of showers [500] in multi-particle events for particle flow reconstruction.

The *dual-readout method*, originally proposed by Mockett in 1983 [501], measures $f_{\rm em}$ event by event in parallel to the total deposited energy. It uses the fact that most of the relativistic particles in the shower originate from the electromagnetic part, and that only those produce Cherenkov light, while the signal of the hadronic part is mostly due to non-relativistic protons. In practice either two different active media, e.g. scintillator and quartz, are used to register scintillation and Cherenkov light, respectively, or the optical signals from the two processes occurring in heavy crystals are disentangled, using their different spectral, directional or timing properties.

The Cherenkov and scintillation signals, normalised to the response for electrons, are given by

$$C = [f_{\rm em} + (h/e)_C(1 - f_{\rm em})]E\,, \tag{35.51}$$

$$S = [f_{\rm em} + (h/e)_S(1 - f_{\rm em})]E\,, \tag{35.52}$$

respectively, which can be solved for the fraction $f_{\rm em}$ and the energy

$$E = (\xi S - C)/(\xi - 1)\,, \tag{35.53}$$

where $\xi = [1 - (h/e)_C]/[1 - (h/e)_S]$ and $(h/e)_{C,S}$ denote the average ratios of hadronic to electromagnetic response in the Cherenkov and scintillator parts, respectively. This is illustrated in Figure 35.39, which shows their correlation for a set of simulated negative pion events [502] using FLUKA [446].

It was noted that the method demands a steep slope ξ, which implies that the scintillator read-out should be as compensating as possible, which however reduces the room for improvement by adding Cherenkov information.

The method was tested by the DREAM/RD52 collaboration [503,504], using a 1 ton copper matrix with embedded quartz and

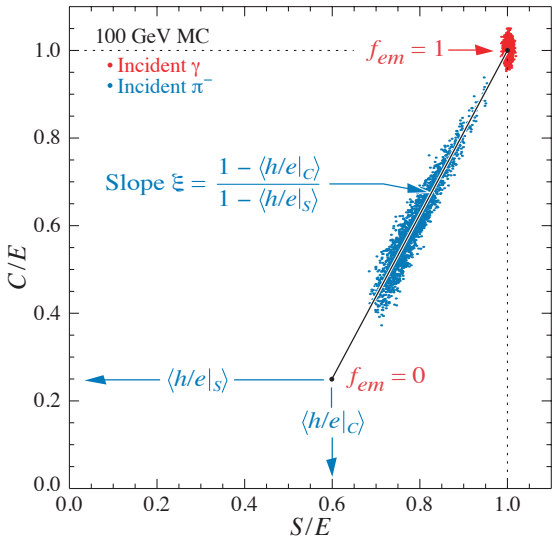

Figure 35.39: Scatter plot of Monte Carlo C/E (Cherenkov) vs S/E (scintillator) signals for individual events in a dual-readout calorimeter for 100 GeV negative pions and photons. Hadronic events are shown in blue, and scatter about the indicated event locus. Electromagnetic events cluster about $(C/E, S/E) = (1,1)$. In this case worse resolution (fewer p.e.'s) was assumed for the Cherenkov events, leading to the "elliptical" distribution.

scintillating fibers. The value of ξ was about 3 in this detector. With this detector, a resolution of $70\%/\sqrt{E(\mathrm{GeV})}$ was obtained for single hadrons [505]. Due to the small size of the module, this includes contributions from transverse leakage which prevent the full exploitation of key features of dual readout, and thus underestimates the potential of the method.

The separate Cherenkov read-out evidently provides excellent pion-electron separation for particle identification. In another RD52 prototype, each fiber is read out individually by SiPMs, giving also a superior transverse granularity. A fiber-based calorimeter with full solid-angle coverage requires a pointing geometry due to the limited or missing longitudinal segmentation. The resulting challenges for a mechanical design are studied in the framework of the IDEA detector concept [506].

Table 35.14 shows selected examples of the energy resolution of HCALs for single charged pions achieved in beam tests. The examples are selected to illustrate the performance achieved with different designs ranging from intrinsic compensation to software compensation and dual readout, with a focus on results by R&D projects. It should be noted that the exact values of the different resolution terms depend on the functional form used in the fit, here the addition in quadrature is used for the cases where more than just the stochastic term is quoted. The results shown in the table illustrate that (close to) compensating calorimeters with optimized sampling fraction and frequency, such as HELIOS (U-plastic scintillator) and SPACAL (Pb-plastic scintillator), achieve a very good energy resolution. The comparison with Bernardi *et al.*, which has the same Pb/scintillator ratio by volume as SPACAL, but coarser sampling in a sandwich structure, illustrates the importance of the geometrical details. Beyond the examples shown in the table, liquid argon has also been explored as an active medium, for example in the context of the SLD detector with different absorber options [511]. Due to the reduced sensitivity to neutrons in the shower, not the same resolution as for plastic-scintillator-based systems is achieved. This technology has also been used in the D0 experiment, as discussed below. The dual-readout method has the potential to reach or surpass this performance, but would require a prototype sufficiently large for full longitudinal and transverse shower containment for an experimental demonstration. The two CALICE calorimeters shown, which use the same active elements (5 mm thick scintillator tiles) but different absorbers (21.4 mm Fe vs 10 mm W + 4 mm Fe) per layer, illustrate the impact of the absorber choice on energy resolution and reconstruction possibilities. While the tungsten-based W-AHCAL setup is very close to compensating, the steel-based AHCAL achieves a better energy resolution when software compensation is applied, profiting from the finer sampling of the electromagnetic parts of the cascade and the correction for shower-to-shower fluctuations of the electromagnetic fraction in the reconstruction. In the case of tungsten, software compensation does not significantly improve the energy resolution, as expected. The comparison of the CALICE AHCAL performance with the one of CDHS illustrates the benefits of higher granularity for software compensation techniques, but it should be noted that the absorber thickness of the latter is 25 mm, with the same scintillator thickness as in the case of CALICE.

As explained in the introduction, in most high-energy physics experiments, the HCAL follows after an ECAL, making the response of the latter to hadronic cascades highly relevant for the overall performance of the combined ECAL HCAL system. For scenarios where the electromagnetic and the HCAL have very different $\langle h/e \rangle$, as is typically the case for crystal-based ECALs, the fluctuations of the fraction of the hadronic shower contained within the ECAL result in a significant deterioration of the energy resolution for hadrons. A deterioration of the hadronic performance also results from larger amounts of not-instrumented material, e.g. supports and services, between electromagnetic and hadronic sections. In particle-flow calorimeters, a large value of the λ_I/X_0 ratio of the absorber material, like in tungsten, maximises the longitudinal separation of electromagnetic and hadronic showers. This is reflected in the design of particle-flow-based detector concepts for future Higgs Factories.

Table 35.15 summarizes the single hadron energy resolution obtained from test beams of the combined ECAL and HCAL systems of the large multi-purpose experiments at HERA, the Tevatron and at the LHC. These systems are examples of different optimization strategies. D0 and ZEUS are near-compensating systems with the same technology in ECAL and HCAL emphasizing hadronic performance. ATLAS and H1 use sampling ECALs with good electromagnetic resolution and weighting techniques exploiting longitudinal and transverse shower information for hadronic energy reconstruction. CMS, with a crystal ECAL and a scintillator-brass HCAL, prioritizes electromagnetic performance, with very different $\langle h/e \rangle$ in the electromagnetic and hadronic system. Of the detectors shown in the table, CMS has the best electromagnetic resolution by a comfortable margin, but consequently the weakest hadronic resolution. The best hadronic performance is achieved with the compensating calorimeter of ZEUS, which however has a weaker electromagnetic performance than the other calorimeter systems shown here. It should be noted that an excellent single-hadron resolution in general does not fully propagate into the jet-energy performance. Inactive material in front of the calorimeter can significantly worsen the energy resolution for jets, with an impact in particular on lower-energy particles. For example, the core of the invariant mass distribution of hadronically-decaying Z^0 bosons measured in ZEUS, which had a superconducting coil in front of the calorimeter, is well described by a Gaussian with a σ of 6 GeV [518], approximately 40% wider than would be expected for a jet-energy resolution that is identical to the single-hadron performance.

35.10.4 *Free electron drift velocities in liquid ionization chambers*

Revised August 2009 by W. Walkowiak (Siegen U.).

Drift velocities of free electrons in LAr [338] are given as a function of electric field strength for different temperatures of the medium in Fig. 35.40. The drift velocites in LAr have been measured using a double-gridded drift chamber with electrons produced by a laser pulse on a gold-plated cathode. The average temperature gradient of the drift velocity of the free electrons in LAr is described [338] by

$$\frac{\Delta v_d}{\Delta T\, v_d} = (-1.72 \pm 0.08)\ \%/\mathrm{K}. \qquad (35.54)$$

Previous measurements [519, 520, 522, 523] range from 13%

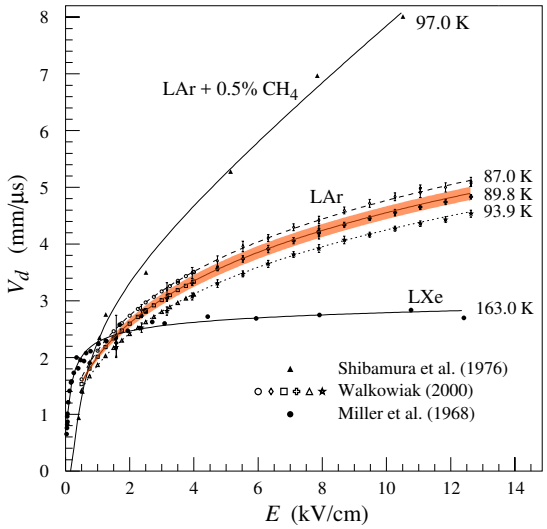

Figure 35.40: Drift velocity of free electrons as a function of electric field strength for LAr [338], LAr + 0.5% CH_4 [519] and LXe [520]. The average temperatures of the liquids are indicated. Results of a fit to an empirical function [521] are superimposed. In case of LAr at 91 K the error band for the global fit [338] including statistical and systematic errors as well as correlations of the data points is given. Only statistical errors are shown for the individual LAr data points.

higher [520] to 18% lower [522] than these measurements. They used different techniques and show drift velocities for free electrons which cannot be explained by the temperature dependence mentioned above.

Drift velocities of free electrons in LXe [519] as a function of electric field strength are also displayed in Fig. 35.40. The drift velocity saturates for $|E| > 3$ kV/cm, and decreases with increasing temperature for LXe as well as measured e.g. by [524].

The addition of small concentrations of other molecules like N_2, H_2 and CH_4 in solution to the liquid typically increases the drift velocities of free electrons above the saturation value [519, 522], see example for CH_4 admixture to LAr in Fig. 35.40. Therefore, actual drift velocities are critically dependent on even small additions or contaminations.

35.11 Superconducting magnets for collider detectors

Revised August 2025 by Y. Makida (KEK).

35.11.1 *Solenoid Magnets*

In all cases SI unit are assumed, so that the magnetic field, B, is in Tesla, the stored energy, E, is in joules, the dimensions are in meters, and vacuum permeability of $\mu_0 = 4\pi \times 10^{-7}$.

The magnetic field (B) in an simple solenoid with a flux return iron yoke, in which the magnetic field is lower than magnetic saturation of < 2 T, is given by

$$B = \frac{\mu_0\, n\, I}{L} \tag{35.55}$$

where n is the number of turns, I is the current and L is the coil length.

In an air-core solenoid case, the central field is given by

$$B(0,0) = \mu_0\, n\, I \frac{1}{\sqrt{L^2 + 4R^2}}\ , \tag{35.56}$$

where R is the coil radius.

In most cases, momentum analysis is made by measuring the circular trajectory of the passing particles according to $p = mv = qrB$, where p is the momentum, m the mass, q the charge, r the bending radius. By using the sagitta, s, of the trajectory, p is given by

$$s = q\, B\, \ell^2/8p\ , \tag{35.57}$$

where ℓ is the path length in the magnetic field as shown in Fig. 35.41 .

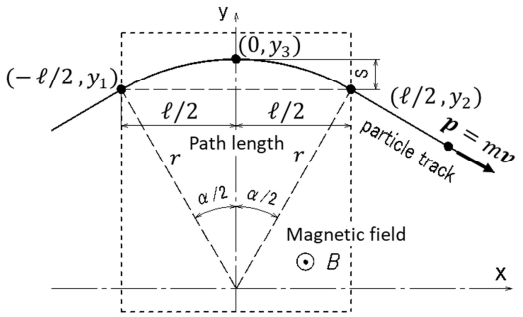

Figure 35.41: Geometric relation of sagitta between path length.

In a practical momentum measurement in colliding beam detectors, it is more effective to increase the magnetic volume than the field strength, since

$$dp/p \propto p/B\,\ell^2 \ , \tag{35.58}$$

where ℓ corresponds to the solenoid coil radius R. The energy stored in the magnetic field of any magnet is calculated by integrating B^2 over all space:

$$E = \frac{1}{2\mu_0}\int B^2 dV \tag{35.59}$$

If the coil thin and inside an iron return yoke , (which is the case if it is to superconducting coil), then

$$E \approx (B^2/2\mu_0)\pi R^2 L \ . \tag{35.60}$$

For a detector in which the calorimetry is outside the aperture of the solenoid, the coil must be transparent in terms of radiation and absorption lengths. This usually means that the superconducting solenoid and its cryostat is of minimum real thickness and is made of a material with long radiation length. There are two major contributors to the thickness of a thin solenoid:

1. The conductor consisting of the current-carrying superconducting material (usually Nb-Ti/Cu) and the quench protecting stabilizer (usually aluminum) are wound on the inside of a structural support cylinder (usually aluminum alloy). The coil thickness scales as B^2R, so the thickness in radiation lengths (X_0) is

$$t_{\rm coil}/X_0 = (R/\sigma_h X_0)(B^2/2\mu_0) \ , \tag{35.61}$$

   where $t_{\rm coil}$ is the physical thickness of the coil, X_0 the average radiation length of the coil/stabilizer material, and σ_h is the hoop stress in the coil [525]. $B^2/2\mu_0$ is the magnetic pressure. In large detector solenoids, the aluminum stabilizer and support cylinders dominate the thickness; the superconductor (Nb-TI/Cu) contributes a smaller fraction. The main coil and support cylinder components typically contribute about 2/3 of the total thickness in radiation lengths.
2. Another contribution to the material comes from the outer cylindrical shell of the vacuum vessel. Since this shell is susceptible to buckling collapse, its thickness is determined by the diameter, length and the modulus of the material of which it is fabricated. The outer vacuum shell represents about 1/3 of the total thickness in radiation length.

35.11.2 *Properties of collider detector magnets*

The physical dimensions, central field stored energy and thickness in radiation lengths normal to the beam line of the superconducting solenoids associated with the major collider are given in Table 35.16 [526]. Fig. 35.42 shows thickness in radiation lengths as a function of B^2R in various collider detector solenoids.

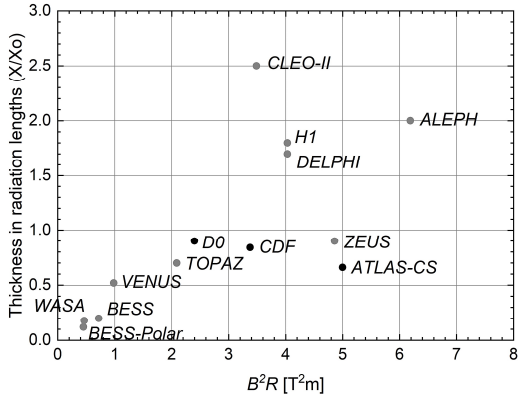

Figure 35.42: Magnet wall thickness in radiation length as a function of B^2R for various detector solenoids. Gray entries are for magnets no longer in use.

The ratio of stored energy to cold mass (E/M) is a useful performance measure. It can also be expressed as the ratio of the stress, σ_h, to twice the equivalent density, ρ, in the coil [525]:

$$\frac{E}{M} = \frac{(B^2/2\mu_0)\pi R^2 L}{\rho\, 2\pi t_{\rm coil} RL} \approx \frac{\sigma_h}{2\rho} \tag{35.62}$$

The E/M ratio in the coil is approximately equivalent to H,[†††] the enthalpy of the coil, and it determines the average coil temperature rise after energy absorption in a quench:

$$E/M = H(T_2) - H(T_1) \approx H(T_2) \tag{35.63}$$

where T_2 is the average coil temperature after the full energy absorption in a quench, and T_1 is the initial temperature. E/M ratios of 5, 10, and 20 kJ/kg correspond to ∼65, ∼80, and ∼100 K, respectively. The E/M ratios of various detector magnets are shown in Fig. 35.43 as a function of total stored energy. One would like the cold mass to be as small as possible to minimize the thickness, but temperature rise during a quench must also be minimized. An E/M ratio as large as 12 kJ/kg is designed into the CMS solenoid, with the possibility that about half of the stored energy can go to an external dump resistor. Thus the coil temperature can be kept below 80 K if the energy extraction system works well. The limit is set by the maximum temperature that the coil design can tolerate during a quench. This maximum local temperature should be <130 K (50 K + 80 K), so that thermal expansion effects, which are remarkable beyond 80 K, in the coil are manageable less than 50 K.

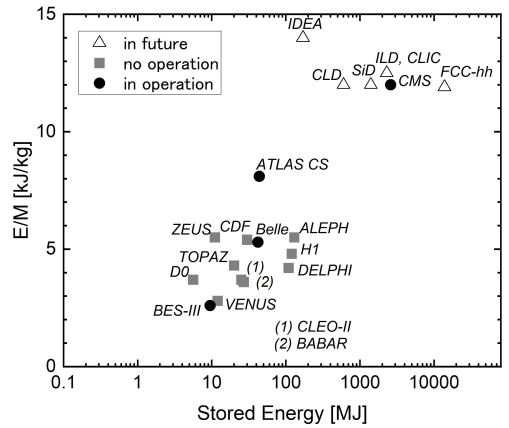

Figure 35.43: Ratio of stored energy to cold mass for major detector solenoids. Gray indicates magnets no longer in operation.

[†††]The enthalpy, or heat content, is called H in the thermodynamics literature. It is not to be confused with the magnetic field intensity B/μ.

35.11.3 *Toroidal magnets*

Toroidal coils uniquely provide a closed magnetic field without the necessity of an iron flux-return yoke. Because no field exists at the collision point and along the beam line, there is, in principle, no effect on the beam. On the other hand, the field profile generally has $1/R$ dependence. R is the distance from the center of the toroid. The particle momentum may be determined by measurements of the deflection angle combined with the sagitta. The deflection (bending) power BL is

$$BL \approx \int_{R_i}^{R_0} \frac{B_i R_i \, dR}{R \sin\theta} = \frac{B_i \, R_i}{\sin\theta} \ln(R_0/R_i) \ , \tag{35.64}$$

where R_i is the inner coil radius, R_0 is the outer coil radius, and θ is the angle between the particle trajectory and the beam line axis . The momentum resolution given by the deflection may be expressed as

$$\frac{\Delta p}{p} \propto \frac{p}{BL} \approx \frac{p \sin\theta}{B_i R_i \ln(R_0/R_i)} \ . \tag{35.65}$$

The momentum resolution is better in the forward/backward (smaller θ) direction. The geometry has been found to be optimal when $R_0/R_i \approx 3$–4. In practical designs, the coil is divided into 6–12 lumped coils in order to have reasonable acceptance and accessibility. This causes the coil design to be much more complex. The mechanical structure needs to sustain the decentering force between adjacent coils, and the peak field in the coil is 3–5 times higher than the useful magnetic field for the momentum analysis [527].

35.12 Measurement of particle momenta in a uniform magnetic field

The trajectory of a particle with momentum p (in GeV/c) and charge ze in a constant magnetic field $\vec{B}$ is a helix, with radius of curvature R and pitch angle λ. The radius of curvature and momentum component perpendicular to $\vec{B}$ are related by

$$p \cos\lambda = 0.3 \, z \, B \, R \ , \tag{35.66}$$

where B is in tesla and R is in meters.

The distribution of measurements of the curvature $k \equiv 1/R$ is approximately Gaussian. The curvature error for a large number of uniformly spaced measurements on the trajectory of a charged particle in a uniform magnetic field can be approximated by

$$(\delta k)^2 = (\delta k_{\rm res})^2 + (\delta k_{\rm ms})^2, \tag{35.67}$$

where δk = curvature error
$\delta k_{\rm res}$ = curvature error due to finite measurement resolution
$\delta k_{\rm ms}$ = curvature error due to multiple scattering.

If many (≥ 10) uniformly spaced position measurements are made along a trajectory in a uniform medium,

$$\delta k_{\rm res} = \frac{\epsilon}{L'^2} \sqrt{\frac{720}{N+4}}, \tag{35.68}$$

where N = number of points measured along track
L' = the projected length of the track onto the bending plane
ϵ = measurement error for each point, perpendicular to the trajectory.

If a vertex constraint is applied at the origin of the track, the coefficient under the radical becomes 320.

For arbitrary spacing of coordinates s_i measured along the projected trajectory and with variable measurement errors ϵ_i the curvature error $\delta k_{\rm res}$ is calculated from:

$$(\delta k_{\rm res})^2 = \frac{4}{w} \ \frac{V_{ss}}{V_{ss} V_{s^2 s^2} - (V_{ss^2})^2}, \tag{35.69}$$

where V are covariances defined as $V_{s^m s^n} = \langle s^m s^n - \rangle s^m \langle s^n$ with $\rangle s^m = w^{-1} \sum (s_i{}^m / \epsilon_i{}^2)$ and $w = \sum \epsilon_i{}^{-2}$.

The contribution due to multiple Coulomb scattering is approximately

$$\delta k_{\rm ms} \approx \frac{(0.016)(\text{GeV}/c) z}{L p \beta \cos^2\lambda} \sqrt{\frac{L}{X_0}}, \tag{35.70}$$

where p = momentum (GeV/c)
z = charge of incident particle in units of e
L = the total track length
X_0 = radiation length of the scattering medium (in units of length; the X_0 defined elsewhere must be multiplied by density)
β = the kinematic variable v/c.

More accurate approximations for multiple scattering may be found in the section on Passage of Particles Through Matter

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

(Sec. 34 of this *Review*). The contribution to the curvature error is given approximately by $\delta k_{\rm ms} \approx 8 s^{\rm rms}_{\rm plane}/L^2$, where $s^{\rm rms}_{\rm plane}$ is defined there.

36.1 Introduction

Non-accelerator experiments have become increasingly important in particle physics and astrophysics. From them comes the evidence of physics beyond the SM, with the discovery of neutrino oscillations and adiabatic flavor conversion. Explored energies range from the meV scale to above the EeV, some 24 orders of magnitude. The physics and the design of the detectors vary as a consequence. Some experiments look at astrophysical high-energy phenomena using the atmosphere as a detector in the fluorescence and Cherenkov observatories or the polar ice and the ocean water in neutrino telescopes. Experiments on extremely rare events, such as neutrino-less double beta decay, solar neutrinos and dark matter induced scattering, need dedicated fully equipped deep underground laboratories, existing in different countries. Critical is the research to push back the ultra-low radioactive background frontier, with dedicated facilities in these laboratories. Detectors range from hyper-pure liquid scintillators, both organic and not, to thermalized and ballistic phonon detectors at the sub-Kelvin temperature, to dual phase noble fluid TPCs, etc. Space-based detectors also use some unique instrumentation, but these are beyond the present scope of this review. Gravitational wave detectors are not included as well.

36.2 High-energy cosmic-ray hadron and gamma-ray detectors

36.2.1 *Atmospheric fluorescence detectors*

Revised October 2025 by F. Salamida (L'Aquila U.; INFN, LNGS).

Cosmic-ray fluorescence detectors (FDs) use the atmosphere as a giant calorimeter to measure isotropic scintillation light that traces the development profiles of extensive air showers. An extensive air shower (EAS) is produced by the interactions of ultra high-energy ($E > 10^{17}$ eV) subatomic particles in the stratosphere and upper troposphere. The amount of scintillation light generated by an EAS is proportional to the energy deposited in the atmosphere and nearly independent of the primary species. With energies extending beyond 10^{20} eV, ultra high energy cosmic rays (UHECRs) are the highest energy subatomic particles known to exist. In addition to particle arrival directions, energy spectra and primary composition, the astroparticle science investigated with FDs also includes multi-messenger studies, searches for high energy photons, neutrinos, monopoles and deeply penetrating forms of dark matter. The Pierre Auger Observatory FD also measures UV scintillation that traces the development of ring-shaped atmospheric transient luminous events, called Elves, in the ionosphere that are initiated by strong lightning [1]. Similar phenomena have also been observed from space by Mini-EUSO [2].

Previous experiments with FDs included the pioneering Fly's Eye [3, 4], and the High Resolution Fly's Eye (HiRes and HiRes prototype) [5]. The use of atmospheric nitrogen fluorescence to detect extensive air showers was proposed in the 1950's by Greisen and Chudakov, and further developed in the 1960's through the systematic studies of Bunner [6, 7]. The current generation of experiments include the Telescope Array (TA) [8] in the northern hemisphere, and the larger Pierre Auger Observatory (Auger) [9] in the southern hemisphere. (Discussion, with extensive references, of current and possible future UHECR experiments can be found[in [10].) Auger and TA are hybrid observatories. Their FD telescopes overlook sparse arrays of particle detectors on the ground. Select parameters are listed in Table 36.1. TA and Auger have each one FD site populated with additional telescopes that view up to 60° in elevation to measure lower EASs using a combination of scintillation and direct Cherenkov light. As part of a fourfold coverage upgrade of TA (TAx4), 12 HiRes refurbished telescopes have been installed at the north and south-east sites of TA. A set of prototype fluorescence telescopes, known as FAST [11], has been developed as a cost-effective design for next-generation ultra-high energy cosmic ray observatories. These small-aperture telescopes, equipped with a single wide field-of-view photomultiplier and simple optics, have been successfully deployed and operated at both the Telescope Array site and the Pierre Auger Observatory, where they have detected air showers and validated the concept. A similar approach is being pursued by the CRAFFT [12] project in Japan, which uses Fresnel lenses and single-PMT readout to achieve comparable goals of simplicity and scalability.

The fluorescence light is emitted primarily between 290 and 430 nm (Figure 36.1) with major lines at 337, 357, and 391 nm, when relativistic charged particles, primarily electrons and positrons, excite nitrogen molecules in air, resulting in transitions of the 1P and 2P systems. Reviews and references for the pioneering and recent laboratory measurements of fluorescence yield, $Y(\lambda, P, T, u)$, including dependence on wavelength (λ), temperature (T), pressure (p), and humidity (u) may be found in Refs. [13–15]. The results of various laboratory experiments have been combined (Figure 36.2) to obtain an absolute average and uncertainty for Y(337 nm, 800 hPa, 293 K, dry air) of 7.04 ± 0.24 ph/ MeV after corrections for different electron beam energies and other factors. The units of ph/ MeV correspond to the number of fluorescence photons produced per MeV of energy deposited in the atmosphere by the electromagnetic component of an EAS.

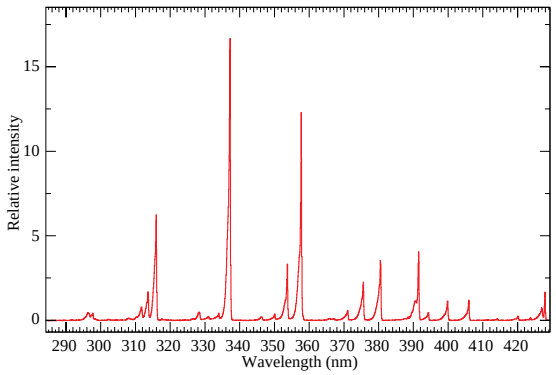

Figure 36.1: Measured fluorescence spectrum excited by 3 MeV electrons in dry air at 800 hPa and 293 K. Airfly experiment. Figure from Ref [16].

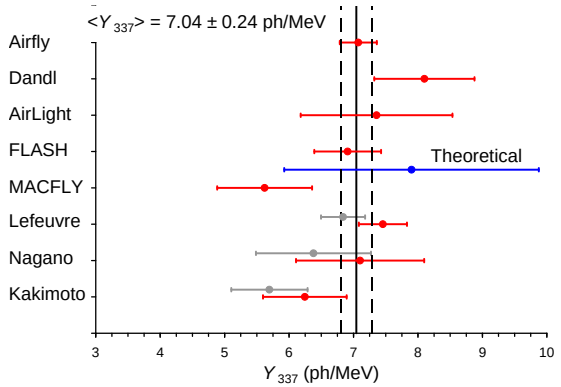

Figure 36.2: Fluorescence yield values and associated uncertainties at 337 nm (Y_{337}) in dry air at 800 hPa and 293 K The methodology and corrections that were applied to obtain the average and the uncertainty are discussed extensively in this reference. The vertical axis denotes different laboratory experiments that measured FY. The gray bars show three of the original measurements to illustrate the scale of the corrections applied. Figure from Ref [17].

An FD element (telescope) consists of a non-tracking spherical mirror of less than astronomical quality, a"camera" of photomultiplier tubes (PMTs) near the focal plane, and a flash ADC readout system with a pulse and track-finding trigger scheme [9, 18]. The major experiments listed in Table 36.1 all use conventional PMTs (for example, Hamamatsu R9508 or Photonis XP3062) with grounded cathodes and AC coupled readout. Segmented mirrors have been fabricated from slumped or slumped/polished glass with an anodized aluminum coating or fabricated using shaped aluminum that was then chemically anodized with $AlMgSiO_5$. A broadband UV filter (custom fabricated, BG-3, or Schott MUG-6) reduces background light such as starlight, airglow, man-made light pollution, and airplane strobe-lights.

At 10^{20} eV, where the flux drops below 1 EAS/km^2 century, the aperture for an eye of adjacent FD telescopes that span the horizon can reach 10^4 km^2 sr. FD operation requires (nearly) moonless nights and clear atmospheric conditions, which typically imposes a duty cycle of about 10%. Arrangements of LEDs, calibrated diffuse sources [19], pulsed UV lasers [20], LIDARs [1] and IR detectors that are sensitive to clouds are used for photometric calibration, atmospheric calibration [21], and determination of exposure [22]. For purposes of optical transmission, the atmosphere is treated as having a dominant molecular component and a secondary aerosol component. The latter is well described [23] by molecular scattering theory and models derived from radiosonde measurements. The aerosol component can include dust, haze and pollution and the aerosol optical depth profile must be measured on site in the UV during FD data taking.

The EAS generates a track consistent with a light source moving at $v = c$ across the FOV. The number of photons (N_γ) as a function of atmospheric depth (X) can be expressed as [14]

$$\frac{\mathrm{d}N_\gamma}{\mathrm{d}X} = \frac{dE_{\mathrm{dep}}^{\mathrm{tot}}}{dX} \int Y(\lambda, P, T, u) \cdot \tau_{\mathrm{atm}}(\lambda, X) \cdot \varepsilon_{\mathrm{FD}}(\lambda)\mathrm{d}\lambda, \quad (36.1)$$

where $\tau_{atm}(\lambda, X)$ is the atmospheric transmission, including wavelength (λ) dependence, and $\varepsilon_{\mathrm{FD}}(\lambda)$ is the FD efficiency. $\varepsilon_{\mathrm{FD}}(\lambda)$ includes geometric factors and collection efficiency of the optics, quantum efficiency of the PMTs, and other throughput factors. The typical systematic uncertainties, τ_{atm} (10%) and $\varepsilon_{\mathrm{FD}}$ (photometric calibration 10%), currently dominate the systematic uncertainty the absolute EAS energy scale. FD energy resolution, defined as event-to-event statistical uncertainty, is typically less than 10% for final data samples used for science analysis.

Analysis methods to reconstruct the EAS profile and deconvolve the contributions of re-scattered scintillation light, and direct and scattered Cherenkov light are described in [3] and more recently in [25]. The EAS energy is typically obtained by integrating over the Gaisser-Hillas function [26]

$$E_{\mathrm{cal}} = \int_0^\infty [w_{\max} \left(\frac{X - X_0}{X_{\max} - X_0}\right)^{(X_{\max}-X_0)/\lambda} e^{(X_{\max}-X)/\lambda}]\mathrm{d}X, \quad (36.2)$$

where E_{cal} is the energy of electromagnetic energy component of the EAS and $X_{\max}$ is the atmospheric slant depth at which the shower reaches its maximum energy deposit rate. This maximum dE/dX is denoted as $w_{\max}$. X_0 and λ are two shape parameters. Recent analyses adopt a modified Gaisser–Hillas parameterization that decouples the width L and asymmetry R, improving the robustness of the fit [27].

The energy of the primary cosmic ray is obtained by correcting E_{cal} upward by about 10% to account for the invisible energy carried by particles that do not interact in the atmosphere. Auger reported a data-driven method to estimate the invisible energy from the muon number at ground level and Xmax to reduce systematic uncertainties [28]. Energy resolution, $\Delta E/E$, of 15-20% is achievable, provided the geometric fit of the EAS axis is constrained, typically by multi-eye stereo projection or hybrid observations, and the profile fit of EAS development along the track is constrained by the observed rise and fall about $X_{\max}$. An example of a recorded EAS light profile and its corresponding dE/dX development profile are shown in Fig. 36.3. In 2023, the Pierre Auger Collaboration released a public dataset [29] of the

[1] LIDAR stands for "Light Detection and Ranging" and refers here to systems that measure atmospheric properties from the light scattered backwards from laser pulses directed into the sky.

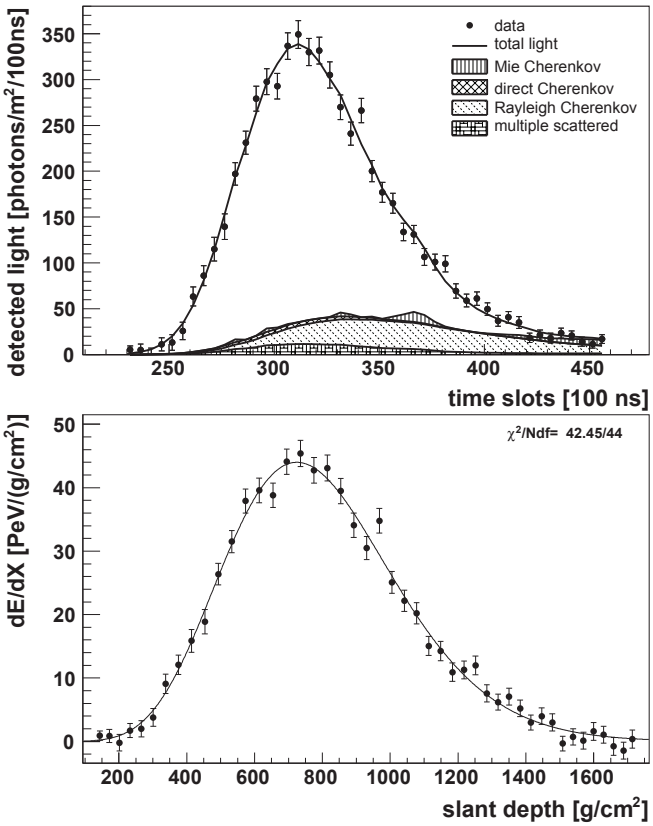

Figure 36.3: Example light profile (left) of one EAS recorded by the Pierre Auger FD and the corresponding profile (right) of energy deposited in the atmosphere vs atmospheric slant depth. The light profiles include the estimated components of Cherenkov light that have been scattered out of the forward beam by the molecular and aerosol (Mie) components of the atmosphere. The reconstructed energy of this EAS was $3.0 \pm 0.2 \times 10^{19}$ eV. Figure from Ref [24].

100 highest energy cosmic ray events collected over a 17-year span through 2020 with an additional 9 energetic hybrid events used in the calibration procedure. In 2024 the Pierre Auger Collaboration published the first systematic comparison of $X_{\max}$ measured with radio and fluorescence techniques for the same set of 53 air showers, finding no significant bias (-3.9 ± 11.2 g/cm^2) and a resolution better than 15 g/cm^2 [30]. These results also benefit from the ongoing *AugerPrime* upgrade [31]. Besides enhancing the surface-detector array with the installation of Surface Scintillator Detectors (SSD) and dedicated radio antennas, AugerPrime also deploys new front-end electronics that provide higher sampling speed and dynamic range, thereby enabling a more accurate time synchronisation of FD–SD coincident events. Recent results also show excellent agreement between the radio and FD-based energy scales, providing a strong and independent validation of the energy scale determined by the FD [32].

An FD that would look down on the Earth's atmosphere from orbit, and thus monitor a far larger area than any ground-based instrument, is an active area of R&D. Prototypes already flown include the pioneering TUS instrument [33,34] (2016–2018 on the Lomonosov satellite). The JEM-EUSO collaboration has tested balloon pathfinders in 2014 (EUSO-Balloon) [35], 2017 (EUSO-SPB1) [36], and 2023 (EUSO-SPB2) [37]. During its 2023 flight the EUSO-SPB2 mission recorded UV signals compatible with extensive air showers using both a fluorescence and a Cherenkov telescope, providing a critical validation of the optical and trigger systems planned for future orbital detectors [37, 38]. The Mini-EUSO [39] FD continues recording terrestrial UV emission by looking down through a 25 cm diameter UV-transmitting window inside the International Space Station since 2019.

Looking ahead, the Probe of Extreme Multi-Messenger Astrophysics (POEMMA) is in the NASA Probe-class pre-proposal phase. Its baseline design foresees two wide-field Schmidt satellites flying in formation to observe UHECRs and cosmogenic tau neutrinos from space [40, 41].As a precursor to the satellite mission, the POEMMA collaboration is developing a super-pressure balloon pathfinder (PBR), combining fluorescence, Cherenkov, and radio detectors, with a launch planned in 2027 [42].

36.2.2 *Atmospheric Cherenkov telescopes for high-energy gamma ray astronomy*

Revised October 2025 by W. Hofmann (MPIK).

A wide variety of astrophysical objects produce high-energy γ-ray photons. Leptonic or hadronic particles, accelerated to relativistic energies, produce γ-rays typically through inverse Compton boosting of ambient photons or through the decay of neutral pions produced in hadronic interactions. Below some 10s of GeV, γ-ray emission can be efficiently detected using satellite or balloon-borne instrumentation, with an effective area approximately equal to the size of the detector (typically $< 1\,\mathrm{m}^2$). At higher energies, a technique with much larger effective collection area is required to measure astrophysical γ-ray fluxes, which decrease rapidly with increasing energy. Atmospheric Cherenkov detectors achieve effective collection areas of $> 10^5\,\mathrm{m}^2$ by using the Earth's atmosphere as an intrinsic part of the detection technique. A hadronic cosmic ray or high energy γ-ray incident on the Earth's atmosphere induces a particle cascade, or air shower. Relativistic charged particles in the air shower generate Cherenkov radiation, which is emitted along the shower direction. For vertically incident γ-rays in the TeV range, the maximum emission occurs at an altitude of $\sim$10 km [43]. Following absorption and scattering in the atmosphere [43], the Cherenkov light at ground level peaks at a wavelength $\lambda \approx 300$–350 nm. At typical observatory altitudes of 1-2 km a.s.l., Cherenkov light illuminates a light pool with a radius of $\sim$120-130 m, with roughly uniform light intensity across the light pool [43, 44]. Beyond the light pool radius, the intensity of Cherenkov light decreases rapidly. More deeply penetrating higher-energy γ-ray showers generate a peaked intensity distribution, distant showers at large zenith angles a larger light pool [43, 44]. The intensity is approximately proportional to the energy of the primary γ-ray, and is typically $\sim$100 photons/m^2 for a vertical 1 TeV primary, arriving in a brief flash of a few nanoseconds. The light yield varies with the seasonal atmospheric density profile, by 10% or more [43]. The Cherenkov pulse can be detected by using large reflecting surfaces to focus the Cherenkov light onto fast photo sensors. See [45, 46] for accounts of the historical development of the technique, [47] for a recent overview, and [48] for an exhaustive compilation of materials.

Imaging atmospheric Cherenkov telescopes (IACTs), such as H.E.S.S., MAGIC and VERITAS, use large ($> 100\,\mathrm{m}^2$) segmented mirrors on steerable mounts to focus the Cherenkov light onto arrays of photosensors (referred to as the "cameras") that record a Cherenkov image of each air shower. The intensity, shape and orientation of the Cherenkov images are used to reconstruct the γ-ray energy and arrival direction, and to discriminate γ-ray primaries from cosmic rays that provide a uniform background. Images resulting from purely electromagnetic γ-ray induced cascades appear as narrow, elongated ellipses in the camera. The long axis of the ellipse corresponds to the vertical extension of the air shower, and points back towards the source position in the field-of-view. If multiple telescopes are used to view the same shower ("stereoscopy"), the source position is simply the intersection point of the various image axes. Cosmic-ray primaries produce secondaries with large transverse momenta, which initiate sub-showers. Their images are consequently wider and less regular than those with γ-ray primaries. Reflecting the distance to the air shower maximum ($\sim$10 km for vertical incidence) and the scale of transverse structures in γ-ray showers (some 10 meters), IACT cameras mostly use relatively coarse pixel sizes in the range of $0.08^\circ - 0.19^\circ$ (Table 36.2). The image of a $\sim$10 km long air shower viewed at $\sim$100 m impact distance extends over roughly one degree, hence cameras need to provide fields of view of few degrees. Most modern instruments have larger fields of view, up to 10°, to cover extended γ-ray

Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 06/14/23. For personal use and distribution is strictly not permitted, except for Open Access articles.

sources and enable sky surveys. Table 36.2 lists major IACT systems operating or under construction; all are stereoscopic systems, that provide improved resolution of the γ-ray direction and higher background rejection compared to single telescopes. Whereas in the operating few-telescope stereoscopic systems the telescopes are distributed over an area of the scale of the light pool radius – to ensure that multiple telescopes are illuminated by a given shower – the systems under construction use larger numbers of IACTs, covering areas larger than the light pool, and providing effective detection areas on the scale of 10^6 m^2.

IACTs are deployed at sites with dark skies and a large number of clear nights. Most IACT sites are well above sea level, at 1-2 km elevation (VERITAS, H.E.S.S., MAGIC, CTAO). Altitudes in the 4-5 km range provide lower energy thresholds [58]; for example, the MACE telescope [59] is located at 4.3 km a.s.l. IACTs benefit from sites with low geomagnetic field; large transverse fields spread the shower and reduce performance by $\sim 1\%$ per μG field [44]. At typical sites, IACTs log about 1000 - 1500 h per year, also depending on the level of moon light up to which telescopes are operated.

Traditionally, IACTs use single-mirror optics for imaging; for cost reasons, segmented mirrors are used. Mirror facet size ranges from $\sim 0.3\,\mathrm{m}^2$ to ~ 2 m^2, increasingly moving from aluminized ground-glass mirrors to lightweight composite sandwich structures. For mirror diameters d up to 10 - 15 m (VERITAS, H.E.S.S. CT1-4, CTAO MST), mostly Davies-Cotton optics is used, with facets of focal length f arranged on a shell of radius f, whereas larger mirrors use a parabolic shape (MAGIC, H.E.S.S. CT5, CTAO LST). Davies-Cotton optics provides better imaging over an extended field of view, but is not isochronous; for large telescopes the time dispersion is significant compared to the (ns) Cherenkov signal time scales. The off-axis point spread function (PSF) of single-mirror telescopes deteriorates rapidly with decreasing f/d [60, 61]; large f on the other hand results in large cameras and heavy support structures. As a compromise, $f/d \approx 1.0 - 1.3$ is typically chosen. Dual-mirror Schwarzschild-Coulder optics was proposed [62] to provide a near-uniform PSF across fields of view up to 10°, and a small plate scale suitable for silicon photo multipliers (SiPM). The first IACTs to implement Schwarzschild-Couder optics are the pSCT prototype telescope [63], and the ASTRI and CTAO SST telescopes. IACTs are usually focused on the height of shower maximum (about 10 km for vertical TeV γ-rays). For very large telescopes (d beyond 25 - 30 m), the finite depth of field limits telescope performance; Plenoscope optics [64] has been proposed as a way out. Alt-az mounts are generally employed to point IACTs, either using a central positioner (e.g. VERITAS, CTAO MSTs) or – in particular for larger telescopes - a cradle on a circular rail (e.g. H.E.S.S., MAGIC). Positioning speeds range from 20 s (CTAO LST) to 1-2 minutes. Cameras use mostly photomultipliers (PMTs), with a peak quantum efficiency (QE) approaching 40%, but silicon sensors (SiPM) as pioneered in the FACT telescope [65] are increasingly used (pSCT, ASTRI, CTAO SST, LACT) since they can operate under high illumination (moonlight) and provide higher QE, but not necessarily a better performance (signal to noise) for detecting the Cherenkov photons; see [66] for a comparison. A disadvantage of SiPMs is their red-sensitivity resulting in high night-sky background (NSB) rates unless filtered. Even with the blue-sensitive PMT response, night-sky background rates are in the range of few 100 MHz per pixel, for large mirrors. To avoid pile-up of NSB, exposure time for Cherenkov images should not exceed a few ns. For signal recording, either fast Flash-ADC systems used, or 1-2 GHz analog capacitor pipelines that store signals until a trigger decision is obtained. In most modern cameras, the full readout electronics is housed in the camera body. Triggering is usually multi-level, with a first-level decision based on the camera image using a coincidence or signal sum of neighboring pixels, followed by a second-level decision requesting a coincidence of multiple telescopes and initiating data transfer to storage. Camera-level triggers typically require about 50-100 detected photons in an air shower image; readout rates are in the kHz range.

For an overview of data analysis techniques, see e.g. [67]. The simplest form of image reconstruction parametrizes images by an ellipse (Hillas parameters) and reconstructs the shower direction from the intersection of image ellipses [68]. A wide range of improved reconstruction algorithms is used, in particular fits of the image distribution using semi-analytical [69] or MC-generated [70] image templates. Cosmic-ray rejection in its simplest form uses the size of the minor axis of the image ellipse to remove cosmic-ray showers; advanced techniques use the quality-of-fit of gamma-ray image templates, and/or machine learning using a wide range of image parameters. For optimizing the analysis, and determining effective detection areas, extensive Monte Carlo simulations are used, frequently based on the CORSIKA [71] air shower simulator. Lacking a "test beam" and relying on the atmosphere as detection medium, the absolute calibration of IACTs is challenging. Intensity of muon rings is one means for calibrating the telescope response [72], and atmospheric monitoring by independent devices (e.g. LIDARs [73]) or via the telescope trigger rates serves to monitor atmospheric transmission. Low-level image and air shower reconstruction is usually performed using custom software, but high-level analysis is increasingly relying on open-source packages such as Gammapy [74]. While cosmic rays are effectively rejected, still background remains that must be subtracted in the study of γ-ray sources. Techniques for background determination [75] include pointing the telescope offset from the source, and using off-regions distributed symmetrically to the telescope axis; using event rates in a ring around the source; globally fitting a background level from the full field of view; or using dedicated off-runs pointing towards an empty region of sky.

At low energies, where the light intensity in the Cherenkov light pool is below the trigger threshold of a telescope, IACTs only trigger because of fluctuations in shower development or light yield, and the trigger probability and hence the effective detection areas increase steeply with energy. Once the intensity in the light pool matches the trigger threshold, the effective area starts to saturate at $\sim 10^5$ m^2 (for vertical incidence on a single telescope or telescope array with size not larger than the light pool). Typical angular resolutions of telescope systems are $\sim$5 arc-min, but arc-min scale resolution can be achieved for well-reconstructed high-energy events. Typical γ-ray energy resolution is $\sim$10%. In the image analysis, 99% or more of the cosmic rays can be rejected based on image shapes; an additional factor of $\gg 100$ suppression can be gained from an angular cut around the (point) source position. Sensitivity is usually quoted as the minimally detectable point-source γ-ray energy flux $E^2F_{min}(E)$ in a 0.2 decade energy band. Fig. 36.4 illustrates the flux sensitivity of IACT systems. At low energy, sensitivity is governed by the strong energy dependence of the effective area, but often starts to be limited by background systematics. At mid-energy, with roughly constant effective area, background statistics limits the sensitivity, resulting in a roughly constant $E^2F_{min}(E)$. At high energy, telescopes are γ-ray rate limited, with $E^2F_{min}(E) \sim E$. Currently operating systems reach peak sensitivities around 10^{-12} erg cm^{-2}s^{-1} for 50 h of observations, the larger next-generation systems approach 10^{-13} erg cm^{-2}s^{-1}. A special mode are observations at large zenith angles, of 60° and beyond. At these angles, the distance to the shower maximum is increased by factors of a few, and the size of the light pool is increased correspondingly. Effective detection areas can be increased by up to an order of magnitude compared to observations near zenith, at the expense of an increase in energy threshold (e.g. [76, 77]) and potentially increased systematic errors.

The first astrophysical source to be convincingly detected using the imaging atmospheric Cherenkov technique was the Crab Nebula, in 1989 [80]. Modern imaging atmospheric Cherenkov telescopes have sensitivity sufficient to detect sources at 1% of the Crab Nebula flux in about 10 hours, can measure the spectrum of the Crab pulsar and the nebula from $\sim$20 GeV to $\sim$100 TeV [76, 81], and can resolve the $\sim$1 arc-min size of the Crab Nebula [82]. Well over 200 TeV γ-ray sources – both galactic and extragalactic – were discovered using IACTs [83]. A significant fraction of the galactic sources were detected by scanning the Galactic plane from the southern hemisphere with the H.E.S.S. telescope array [84]. The CTAO IACT arrays – the first IACT system to be operated as an open observatory – are expected to

Table 36.2: Parameters of major IACT systems, operating or under construction. In the optics line, DC stands for Davies-Cotton, DC' for modified DC, P for parabolic, SC' for modified Schwarzschild-Couder. "Max. tel. dist." is the maximum distance between pairs of telescopes, as a measure for the extent of the array. The CTAO telescope numbers refer to the "alpha" configuration.

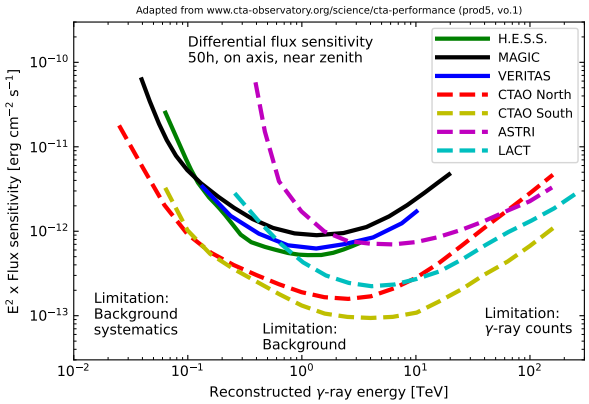

Figure 36.4: Differential flux sensitivity for IACT systems, in operation (solid lines) or under construction (dashed). Adapted from CTAO; sensitivity curves from [78](H.E.S.S.), [51](MAGIC), [79](VERITAS), [54](ASTRI), [57](LACT). Differences at the level of 20-30% may arise from slight differences in definition of sensitivity.

boost the number of detected sources to 500 or more; see [85] for a discussion of science with CTAO. The first 23 m diameter CTAO-LST is already operational on La Palma (e.g. [86]); the "alpha" configuration of CTAO (Table 36.2) should become operational around 2030. On the same time scale, the LACT telescopes at the LHAASO site will provide a significant step in sensitivity.

A recent development is the use of IACT arrays for intensity interferometry, using either dedicated photon detectors or special pixels in the camera. The multiple baselines provided by IACT arrays allow imaging of stars on milli-arc-sec scales, and first results are highly promising (e.g. [87–89]).

36.3 Large neutrino detectors

36.3.1 *Deep liquid detectors for rare processes*

Revised October 2025 by J. Cao (IHEP Beijing).

Deep, large detectors for rare processes tend to be multi-purpose with physics reach that includes not only solar, reactor, supernova and atmospheric neutrinos, but also searches for baryon number violation and lepton number violation, searches for exotic particles and beyond-the-standard-model physics, and neutrino and cosmic-ray astrophysics in different energy regimes. The detectors may also serve as targets for long-baseline neutrino beams for neutrino oscillation studies. In general, detector design considerations can be divided into high- and low-energy regimes, for which background and event reconstruction issues differ. The high-energy regime, from about 100 MeV to a few hundred GeV, is relevant for proton decay searches, atmospheric neutrinos and high-energy astrophysical neutrinos. The low-energy regime (a few tens of MeV or less) is relevant for supernova, solar, reactor and geological neutrinos.

Large water Cherenkov and scintillator detectors (see Table 36.3) usually consist of a volume of transparent liquid viewed by photosensors (see Section 35.2); the liquid serves as active target. While some early detectors are segmented into subvolumes individually viewed by photosensors, monolithic detectors usually have better performance and are cost-effective for large volume. A typical detector configuration is shown in Figure 36.5.

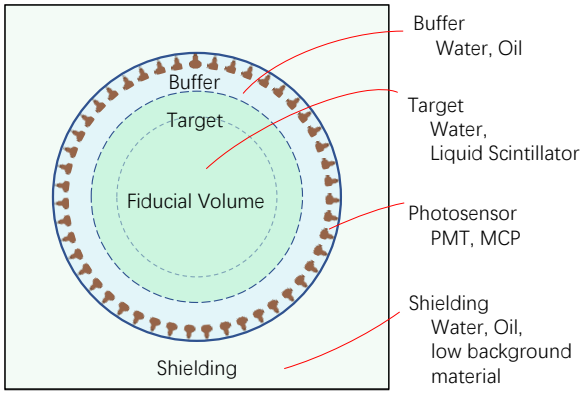

Figure 36.5: Schematic illustration of a typical water Cherenkov or liquid scintillator detector. An array of photosensors view the active target volume to detect the Cherenkov and/or scintillation light. For a liquid scintillator detector, usually there is a non-scintillating buffer between the target and the photosensors. The whole detector is usually surrounded by shielding materials and equipped with muon veto detectors.

A "fiducial volume" is usually defined within the target volume, some distance away from the photosensors, to have relatively uniform detector response and to suppress ambient backgrounds. A nonscintillating buffer is necessary only for liquid scintillator (LS) detectors to shield the active target from natural radioactivities from the photosensors and detector structures. The liquid volume usually requires purification and there may be continuous recirculation of liquid.

Photomultiplier tubes (PMTs) commonly used as photosensors for such large detectors have typical sizes ranging from 20 cm to 51 cm in diameter, quantum efficiencies in the 20–31% range, and time responses at nano-second level. PMTs are usually potted to be water-proof or oil-proof to protect the bases containing high voltage dividers. Protection covers may be needed to avoid chain reaction of implosion. Earth magnetic field can be shielded either for individual PMTs by wrapping high magnetic permeabil-

ity material or for the whole detector with compensating coils, to diminish the impact to the PMT collection efficiency. Devices to increase light collection, *e.g.*, reflectors or waveshifter plates, may be employed. Silicon Photomultipliers (SiPMs) and Microchannel Plates (MCPs) are new optional photosensors. Comparing with PMTs, SiPMs have higher quantum efficiency but much higher dark noise, and MCPs have faster time response.

Charges and times, sometimes the full waveforms, of photosensors are recorded and digitized. Triggering is usually based on coincidence of hits within a time window comparable to the detector's light-crossing time. For large homogeneous detectors, the event interaction vertex and energy deposition are determined using relative timing and/or charge distribution of photosensors in the detector. Usually, arbitrary light reflection is minimized to understand the light propagation and improve vertex and energy reconstruction. This can be achieved by placing black sheets between photosensors or blackening the inner surface of the detector. Meanwhile, light reflection is usually maximized to increase muon detection efficiency for outer veto detectors.

Because in most cases one is searching for rare events, large detectors are usually sited underground to reduce cosmic-ray-related background (see Chapter 30). The minimum depth required varies according to the physics goals [90]. To shield the cosmogenic backgrounds (for both water and LS detectors) and ambient natural radioactivities (for LS detectors), detectors are usually surrounded by water, oil, or other shielding material and equipped with muon veto detectors.

36.3.1.1 *Liquid scintillator detectors*

Past and current large underground detectors based on hydrocarbon scintillator include BUST, MACRO, LVD, KamLAND, Borexino, SNO+ and JUNO. Experiments at nuclear reactors include CHOOZ, Double CHOOZ, Daya Bay, and RENO. As shown in Figure 36.5, a nonscintillating buffer hosting the photosensors is necessary. A large LS detector usually consists of two or even three concentric liquid layers, separating by concentric thin acrylic vessels or balloons made of nylon transparent to scintillation light.

Organic liquid scintillators (see Section 35.3) for large detectors are chosen for high light yield and attenuation length, good stability, compatibility with other detector materials, high flash point, low toxicity, and low cost. They are made by dissolving a few gram per litre fluor into solvent. The most popular solvents are 1,2,4-trimethylbenzene (pseudocumene) and linear alkylbenzene (LAB). LAB is an ideal choice especially with very good transparency for a gigantic detector. Pseudocumene has a low flash point and is relatively aggressive to detector materials; thus is often diluted with alkane. Xylene is more volatile but has very good pulse shape discrimination power. The most popular fluor is 2,5-diphenyloxazole (PPO). Besides the primary fluor, a secondary fluor, aka waveshifter, is usually added to shift the scintillation light to longer wavelength where the LS is more transparent; thus the light yield increases. The most popular waveshifters include p-bis-(o-methylstyryl)-benzene (bis-MSB) and 1,4-bis(5-phenyl-2-oxazolyl)benzene (POPOP). Antioxidant may be added into LS for long-term stability.

Liquid scintillators have a typical light yield of $\sim 10^4$ photons/MeV. The attenuation length ranges from 5 to 20 meters when measured at $\sim$ 430 nm wavelength. Some solvents such as LAB have strong Rayleigh scattering, which contributes significantly to the attenuation length. The absorption length of LS can be as long as 70 meters. With current highest photocathode coverage 78% and 30% PMT photon detection efficiency (PDE, defined as the peak quantum efficiency times collection efficiency), about 1,780 pe/MeV of energy deposition can be obtained. The energy resolution reaches 3% at 1 MeV [91] and is still dominated by photon statistics. With a typical 20–40% coverage and $\sim$ 20% PDE, the energy resolution is about $5 - 7\%/\sqrt{E(\mathrm{MeV})}$. The energy response of LS is not linear and depends on particle types due to ionization quenching. Careful calibration with multiple sources at

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

multiples energy points is needed. Other quenching effects, such as oxygen and temperature, may reduce the light yield at 10% level. Light is emitted with a time response consisting of several exponential components, depending on the solvents and fluors. Usually most light is emitted in tens of nanoseconds. Typical resolution of position reconstruction, using charges and times of PMT hits, is a few tens of cm at $\sim$ 1 MeV.

Radioactive backgrounds from photosensors, detector materials, LS itself, and immediate environment are serious issues for LS detectors. Dedicated detector design, careful selection of materials, purification of the scintillator, and well controlled assembly environment and procedure are essential (see Section 36.6). Radon and Krypton in air as well as Radon decay daughters may impose serious challenges to the experiment. The lower detection threshold of a LS detector is often determined by the ^{14}C content in LS with the 156 keV β-decay endpoint energy. Fiducialization helps to reduce the backgrounds originating from the outer part of the detector. The intrinsic backgrounds from the LS itself have been purified to $< 9.4 \times 10^{-20}$ g/g for ^{238}U and $< 5.7 \times 10^{-19}$ g/g for ^{232}Th [92].

For $\bar{\nu}_e$ detection via inverse beta decay on free protons, $\bar{\nu}_e + p \rightarrow n + e^+$, the time coincidence of the prompt positron signal and the delayed neutron capture signal suppresses significantly the radioactive backgrounds. Doping a small fraction of Gadolinium (or other elements with high neutron capture cross section, such as Cadmium and Lithium) in the LS, *e.g.* $\sim$ 0.1% by mass, the neutron capture time could be reduced from $\sim$ 200 μs to $\sim$ 30 μs. Futhermore, the total gamma energy released from the neutron capture increases from 2.2 MeV to 8 MeV, well above the radioactive background energy thus providing a clean tag for antineutrino. Doping inorganic Gadolinium (as well as other elements) into organic scintillator requires specialized formulation to ensure adequate transparency and stability.

One can also dissolve neutrinoless double beta decay ($0\nu\beta\beta$) isotopes in scintillator. This has been realized by KamLAND-Zen, which deployed a 1.9 m-radius balloon containing enriched Xe dissolved in scintillator inside KamLAND, and ^{130}Te is planned for SNO+.

Liquid scintillator is especially suitable for detection of low-energy events. However, scintillation light emission is nearly isotropic, and therefore directional capabilities are relatively weak. Developing technology such as water-based liquid scintillator with reduced scintillation light yield [93] or liquid scintillator with slow fluors [94] provides the directional capability by separating the Cherenkov light from the scintillation.

36.3.1.2 *Water Cherenkov detectors*

Very large imaging water detectors reconstruct ten-meter-scale Cherenkov rings produced by charged particles (see Section 35.5). The first such large detectors were IMB and Kamiokande. Currently, the only operational detector of this kind is Super-Kamiokande (Super-K, SK), which has a fiducial mass of 22.5 kton and a total mass of 50 kton. Hyper-Kamiokande (Hyper-K) is under construction and will have a fiducial mass of 188 kton and a total mass of 258 kton.

Super-K is instrumented with 11,129 20-inch PMTs of a peak quantum efficiency $\sim$ 20%, corresponding to a photocathode coverage of $\sim$ 40%. Hyper-K will be equipped with at least 20,000 20-inch PMTs and 800 mPMTs, a module about 20-inch in size and assembled with multiple 3-inch PMTs, corresponding to $\sim$ 20% photocathode coverage. Hyper-K PMTs have a quantum efficiency $\sim$ 31% and a higher collection efficiency than Super-K, resulting in similar pe yields for the two detectors.

For volumes of this scale, absorption and scattering of Cherenkov light are non-negligible. Attenuation length of the high purity water have been achieved at the order of 100 meters with continuous recirculation and purification. Radon need be carefully stripped from water to reduce the detector noise during both the water production and recirculation. Maintaining a temperature gradient in the detector to avoid water convection helps to further reduce such noise. Given the giant detector size, PMT readout electronics works usually underwater to avoid signal attenuation; thus requires high reliability. Degassing may be a serious issue that causes high voltage breakdown when air in the underwater electronics boxes or cracks in connectors is gradually removed by the degassed pure water. A solution is to regas the pure water with nitrogen [95].

Cherenkov detectors are excellent electromagnetic calorimeters. The number of Cherenkov photons produced by an e/γ is nearly proportional to its kinetic energy, $\sim$ 6 pe/MeV for Super-K. For massive particles, the number of photons produced is also related to the energy, but not linearly. The directionality of Cherenkov light allows individual particle tracks to be reconstructed. Vertex and direction fits are performed using PMT hit charges and times, requiring that the hit pattern be consistent with a Cherenkov ring.

High-energy ($\sim$100 MeV or more) neutrinos from the atmosphere or beams interact with nucleons; for the nucleons bound inside the ^{16}O nucleus, nuclear effects must be considered. Various event topologies, with final-state particles contained, exiting, or entering the detector, can be distinguished by their timing and fit patterns, and by presence or absence of light in a veto. At high energies, the energy resolution is approximately $3\%/\sqrt{E_{\rm vis}({\rm GeV})}$ for Super-K. The absolute energy scale in this regime can be known to $\sim$ 2–3% using cosmic-ray muon energy deposition, Michel electrons and π^0 from atmospheric neutrino interactions. Typical vertex resolutions for GeV energies are a few tens of cm. Angular resolution for determination of the direction of a charged particle track is a few degrees. For a neutrino interaction, because some final-state particles are usually below Cherenkov threshold, knowledge of direction of the incoming neutrino direction itself is generally worse, depending on neutrino energy.

Multiple particles in an interaction (so long as they are above Cherenkov threshold) may be reconstructed, allowing for the exclusive reconstruction of final states. In searches for proton decay, multiple particles can be kinematically reconstructed to form a decaying nucleon. Particle identification can be done with high reliability with pattern recognition: γ rays and electrons shower, and electrons scatter, which results in fuzzy rings, whereas muons, pions and protons make sharp rings.

In spite of the fairly low light yield, large water Cherenkov detectors may be employed for reconstructing low-energy events, down to *e.g.* $\sim$ 4-5 MeV for Super-K. Using an electron LINAC and/or nuclear sources, approximately 0.5% determination of the absolute energy scale has been achieved at solar neutrino energies. Angular resolution is limited by multiple scattering in this energy regime (25–30°). At these energies, radioactive backgrounds become a dominant issue. In the few to few tens of MeV range, radioactive products of cosmic-ray-muon-induced spallation are troublesome, and are removed by proximity in time and space to preceding muons. Gadolinium doping using $Gd_2(SO_4)_3$ has now been initiated for Super-K to improve selection of low-energy $\bar{\nu}_e$ and other events with accompanying neutrons.

The Sudbury Neutrino Observatory (SNO) detector was the only instance of a large heavy water detector. In addition to an outer 1.7 kton of light water, SNO contained 1 kton of D_2O, giving it unique sensitivity to neutrino neutral current ($\nu_x + d \rightarrow \nu_x + p + n$), and charged current ($\nu_e + d \rightarrow p + p + e^-$) deuteron breakup reactions. The neutrons were detected in three ways: via capture on deuterons, via capture on dissolved ^{35}Cl, and via specialized ^{3}He counters.

36.3.1.3 *Noble liquid detectors*

Noble liquids scintillate and can be used as the active medium for particle detection. Detectors employing argon and xenon are also used as time-projection chambers (TPCs), either as dual-phase low-energy recoil detectors, or as track-imaging detectors. Noble-liquid detectors with low energy (few to few tens of keV) capability for detecting electronic and nuclear recoils are employed for dark matter and other rare event searches and are described in Sec. 36.4. These detectors can also be employed for some of the same physics (solar neutrino, baryon number violation, astrophysical neutrino transient searches, etc.) as for the other large detectors described here, especially as they approach tens of ton scale and higher (e.g., XLZD, DarkSide-20k, ARGO). Track-imaging time-projection chambers, which are described in detail Section 36.4, have a dynamic range reaching down to the few to

few tens of MeV scale, enabling sensitivity to e.g., solar and supernova burst neutrinos. Surface LArTPCs have significant cosmic backgrounds, but may still have sensitivity to astrophysical transients such as supernova burst neutrinos. DUNE will be sufficiently deep to have sensitivity to steady-state low-energy neutrino sources such as solar neutrinos.

36.3.2 *Neutrino telescopes*

Revised March 2026 by U.F. Katz (Erlangen U.) and C. Spiering (DESY, Zeuthen).

The primary goal of neutrino telescopes (NTs) is the detection of astrophysical neutrinos, in particular those which are expected to accompany the production of high-energy cosmic rays in astrophysical accelerators. NTs in addition address a variety of other fundamental physics issues like the indirect search for dark matter, studies of neutrino oscillations, searches for exotic particles like magnetic monopoles or study of cosmic rays and their interactions [96–98]. Electromagnetic radio frequency detectors for high energy neutrinos are discussed in "Radio emission from (ultra-) high energy particle showers" section 36.3.3.

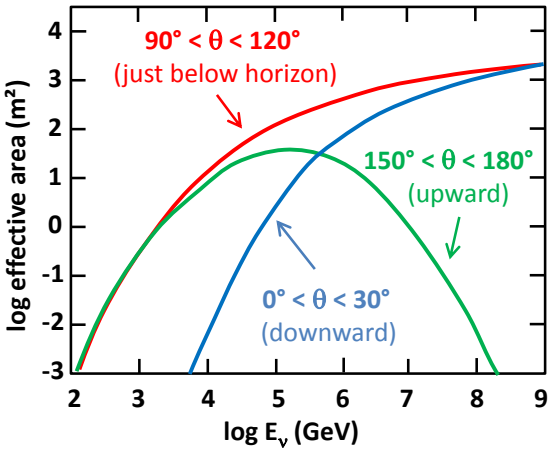

Figure 36.6: Average over the effective ν_μ and $\overline{\nu}_\mu$ areas for IceCube as an example of a cubic-kilometre NT, as a function of neutrino energy for three intervals of the zenith angle θ. The values shown here correspond to a specific event selection for point source searches.

NTs are large-volume arrays of "optical modules" (OMs) installed in open transparent media like water or ice, at depths that completely block the daylight. The OMs are sensitive to individual photons of the Cherenkov light induced by charged secondary particles produced in reactions of high-energy neutrinos in or around the instrumented volume. The time of photon-induced signals ("hits") is registered with a precision of a few nanoseconds. The neutrino energy, E_ν, and direction can be reconstructed from the hit pattern recorded. NTs typically target an energy range $E_\nu \gtrsim 100\,\text{GeV}$; sensitivity to lower energies is achieved in dedicated setups with denser instrumentation.

In detecting cosmic neutrinos, three sources of backgrounds have to be considered: (i) *atmospheric neutrinos* from cosmic-ray interactions in the atmosphere, which can be separated from cosmic neutrinos on a statistical basis, or, for down-going neutrinos, by vetoing accompanying muons; (ii) down-going punch-through *atmospheric muons* from cosmic-ray interactions, which are suppressed by several orders of magnitude with respect to the ground level due to the large detector depths and can be further reduced by selecting upward-going or high-energy neutrinos or by self-veto methods; (iii) random backgrounds due to photomultiplier (PMT) dark counts, ^{40}K decays (mainly in sea water) or bioluminescence (only water). Atmospheric neutrinos and muons allow for investigating neutrino oscillations and cosmic ray anisotropies, respectively. Since 2012, it has become obvious that a precise measurement of the energy-zenith-distribution of atmospheric neutrinos in the energy range from a few to about 100 GeV may allow for determining the neutrino mass hierarchy by exploiting matter-induced oscillation effects in the Earth [99, 100].

Neutrinos can interact with target nucleons N through charged current ($\overset{(-)}{\nu}_\ell N \to \ell^\mp X$, CC) or neutral current ($\overset{(-)}{\nu}_\ell N \to \overset{(-)}{\nu}_\ell X$, NC) processes. A CC reaction of a $\overset{(-)}{\nu}_\mu$ produces a muon track and a hadronic particle cascade, whereas all NC reactions and CC reactions of $\overset{(-)}{\nu}_e$ produce particle cascades only. CC interactions of $\overset{(-)}{\nu}_\tau$ can have either signature, depending on the τ decay mode. Of particular interest is the so-called double-bang signature, where the τ decays sufficiently far away from the primary interaction to create a second, distinguishable cascade (typically at PeV energies and above). In most astrophysical models, neutrinos are expected to be produced through the $\pi/K \to \mu \to e$ decay chain, *i.e.*, with a flavour ratio $\nu_e : \nu_\mu : \nu_\tau \approx 1 : 2 : 0$. For sources outside the solar system, neutrino oscillations turn this ratio to $\nu_e : \nu_\mu : \nu_\tau \approx 1 : 1 : 1$ upon arrival on Earth.

The total neutrino-nucleon cross section is about $10^{-34}\,\text{cm}^2$ at $E_\nu = 20\,\text{TeV}$ and rises roughly linearly with E_ν below this energy and as $E_\nu^{0.3-0.5}$ above, flattening out towards high energies. The CC:NC cross-section ratio is about 2:1. At energies above several TeV, neutrino absorption in the Earth becomes noticeable; for vertically upward-moving neutrinos (zenith angle $\theta = 180°$), the survival probability is $74\,(27, < 2)\%$ for $10\,(100, 1000)\,\text{TeV}$. The energy transferred to the final-state lepton varies between 0 and 100% of E_ν, with a mean of 50% (65%) for neutrinos (antineutrinos) at 100 GeV and 75% for both neutrinos and antineutrinos at 10 PeV.

The final-state lepton follows the initial (anti)neutrino direction with an average mismatch angle of about $\langle \phi_{\nu\ell} \rangle \approx 1°/(E_\nu/\text{TeV})^{0.55}$, with a steeper decrease beyond 10 TeV, reaching 0.005° at 1 PeV [101]. These values indicate the intrinsic kinematic limit to the angular resolution of NTs. For CC $\overset{(-)}{\nu}_\mu$ reactions at energies above about 10 TeV, the angular resolution is dominated by the muon reconstruction accuracy of a few times 0.1° at most. For muon energies $E_\mu \gtrsim 1\,\text{TeV}$, the increasing light emission due to radiative processes allows for reconstructing E_μ from the measured Cherenkov light intensity with an accuracy of $\sigma(\log E_\mu) \approx 0.3$; at lower energies, E_μ can be estimated from the length of the muon track if it is contained in the detector. These properties make CC $\overset{(-)}{\nu}_\mu$ reactions the prime channel for the identification of individual astrophysical neutrino sources.

Hadronic and electromagnetic particle cascades at the relevant energies are 5–20 m long, *i.e.*, short compared to typical OM spacings. The total amount of Cherenkov light provides a direct measurement of the cascade energy with an accuracy of about 20% at energies above 10 TeV and 10% beyond 100 TeV for events contained in the instrumented volume. Except for double-bang events, the neutrino flavour and reaction mechanism can, however, be determined on a statistical basis at best, and neutrinos from NC reactions or τ decays may carry away significant "invisible" energy. Above 100 TeV, the average directional reconstruction accuracy of cascades is better than 10 (2) degrees in polar ice (sea water), the difference being due to the inhomogeneity of the ice and stronger light scattering in ice. These features, together with the small background of atmospheric $\overset{(-)}{\nu}_e$ and $\overset{(-)}{\nu}_\tau$ events, makes the cascade channel particularly interesting for searches for a diffuse, high-energy excess of extraterrestrial over atmospheric neutrinos. Cascade events can also be used to complement the muon channel in searches for point sources or transient signals, albeit with inferior angular accuracy compared to muon tracks.

The detection efficiency of a NT is quantified by its effective area, *e.g.*, the fictitious area for which the full incoming neutrino flux would be recorded (see Figure 36.6). The increase with E_ν is due to the rise of neutrino cross section and muon range, while neutrino absorption in the Earth causes the decrease at large θ for large E_ν. Identification of downward-going neutrinos requires stringent event selection to suppress atmospheric muons, hence the cut-off towards low E_ν at low θ. Due to the small cross section, the effective area is many orders of magnitude smaller than the geometrical dimension of the detector; a $\overset{(-)}{\nu}_\mu$ with 1 TeV can, *e.g.*, be detected with a probability of the order 10^{-6} if the NT is on its path.

Due to the long muon range, CC interactions of up-going $\overset{(-)}{\nu}_\mu$ can be detected from far outside the instrumented volume. This

method also works for horizontal neutrinos up to about 10° above the horizon (depth dependent), where the background from atmospheric muons become prohibitive. Alternatively, one can select events that start inside the instrumented volume and thus remove incoming muons that generate early hits in the outer layers of the detector. Such a veto-based event selection is sensitive to neutrinos of all flavours from all directions, albeit with a reduced efficiency since a part of the instrumented volume is sacrificed for the veto. Such a muon veto, or vetoing events with a coincident signal in the surface array, also rejects down-going atmospheric neutrinos that are accompanied by muons from the same air shower and thus reduces the atmospheric-neutrino background. Actually, the breakthrough in detecting high-energy cosmic neutrinos was first achieved with this technique.

Note that the fields of view of NTs at the South Pole and in the Northern hemisphere are complementary for each reaction channel and neutrino energy.

36.3.2.1 *The Projects*

Table 36.4 lists past, present and future neutrino telescope projects and their main parameters.

Table 36.4: Past, present and future NT projects and their main parameters. The milestone years give the times of project start, of first data taking with partial configurations, of detector completion, and of project termination. Projects with first data expected past 2026 are indicated in italics. The size refers to the largest instrumented volume reached during the project development. The status of projects under construction is reported at the time of writing. See [98] for references to the different projects where unspecified.

36.3.2.2 *Properties of media*

The efficiency and quality of event reconstruction depend strongly on the optical properties (absorption and scattering length, intrinsic optical activity) of the medium in the spectral range of bialkali photocathodes (300–550 nm). Large absorption lengths result in a better light collection, large scattering lengths in superior angular resolution. Deep-sea sites typically have effective scattering lengths of > 100 m and, at their peak transparency around 450 nm, absorption lengths of 50–65 m. The absorption length for Lake Baikal is 22–24 m. The properties of South Polar ice vary strongly with depth; at the peak transparency wave length (400 nm), the scattering length is between 5 and 75 m and the absorption length between 15 and 250 m, with the best values in the depth region 2200–2450 m and the worst ones in the layer 1950–2100 m.

Noise rates measured by PMTs with a diameter of 25 cm in deep polar ice are about 0.5 kHz per PMT and almost entirely due to radioactivity in the OM components. The corresponding rates in sea water are typically 60 kHz, mostly due to ^{40}K decays. Bioluminescence activity can locally cause rates on the MHz scale for seconds; the frequency and intensity of such "bursts" depends strongly on the sea current, the season, the geographic location, and the geometry of the detector elements. Experience from ANTARES shows that these backgrounds are manageable without a major loss of efficiency or experimental resolution.

36.3.2.3 *Technical realisation*

Optical modules (OMs) and PMTs: An OM is a pressure-tight glass sphere housing one or several PMTs with a time resolution in the nanosecond range, and in most cases also electronics for control, high-voltage generation, operation of calibration LEDs, time synchronisation and signal digitisation.

Hybrid PMTs with 37 cm diameter have been used for NT-200, conventional hemispheric PMTs with 20 cm diameter for AMANDA and with 25 cm diameter for ANTARES, IceCube and Baikal-GVD. A novel concept has been chosen for KM3NeT. Each OM (43 cm) is equipped with 31 PMTs (7.5 cm), plus control, calibration and digitisation electronics. Advantages are that (i) the overall photocathode area exceeds that of a 25 cm PMT by more

Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 04/15/26. For personal use and distribution is strictly not permitted, except for Open Access articles.

Int. J. Mod.

than a factor of 3; (ii) the individual readout of the PMTs results in a very good separation between one- and two-photoelectron signals which is essential for online data filtering and random background suppression; (iii) the hit pattern on an OM provides directional information; (iv) no mu-metal shielding against the Earth magnetic field is required. A multi-PMT optical module is also one of the two selected options for the IceCube Upgrade (see below). It contains 24 3-inch PMTs in a smaller-diameter glass vessel matching the maximal size of the ice holes. The second OM type for the Upgrade features two 8-inch PMTs (one upward- and one downward-pointing). See [104] for details. Figure 36.7 shows the OM designs currently used in IceCube and KM3NeT.

Readout and data filtering: In current NTs the PMT data are digitised in situ: for ANTARES and Baikal-GVD in special electronics containers close to the OMs, for IceCube and KM3NeT inside the OMs. For IceCube, data are transmitted via electrical cables of up to 3.3 km length, depending on the location of the strings and the depth of the OMs; for ANTARES, KM3NeT and Baikal-GVD optical fibre connections have been chosen (several 10 km for the first two and 4 km for GVD).

The full digitised waveforms of the IceCube OMs are transmitted to the surface for pulses appearing in local coincidences on a string; for other pulses, only time and charge information is provided. For ANTARES (time and charge) and KM3NeT (time and time over threshold), all PMT signals above an adjustable threshold are sent to shore.

The data are subsequently processed on online computer farms, where multiplicity- and topology-driven filter algorithms are applied to select event candidates. The filter output data rate is about 10 GByte/day for ANTARES and of the order 1 TByte/day for IceCube (100 GByte/day transferred via satellite) and KM3NeT.

Calibration: For efficient event recognition and reconstruction, the OM timing must be synchronised at the few-nanosecond level and the OM positions and orientations must be known to a few 10 cm and a few degrees, respectively. Time calibration is achieved by sending synchronisation signals to the OM electronics and also by light calibration signals emitted in situ at known times by LED or laser flashers (ANTARES, KM3NeT). Precise position calibration is achieved by measuring the travel time of light calibration signals sent from OM to OM (IceCube) or acoustic signals sent from transducers at the sea floor to receivers on the detector strings (ANTARES, KM3NeT, Baikal-GVD). Absolute pointing and angular resolution can be determined by measuring the "shadow of the moon" (*i.e.*, the directional depletion of muons generated in cosmic-ray interactions). IceCube and ANTARES have both shown that they have angular resolution below 1°, confirming MC calculations which indicate a precision of $\approx 0.5°$ for energies above 10 TeV. For KM3NeT, simulations indicate that sub-degree precision in the absolute pointing can be reached; for ORCA, 0.5° accuracy has been demonstrated..

Detector configurations: IceCube [103] (see Figure 36.8) consists of 5160 Digital OMs (DOMs) installed on 86 strings at depths of 1450 to 2450 m in the Antarctic ice; except for the DeepCore region, string distances are 125 m and vertical distances between OMs 17 m. 324 further DOMs are installed in IceTop, an array of detector stations on the ice surface above the strings. DeepCore is a high-density sub-array at large depths (*i.e.*, in the best ice layer) at the centre of IceCube.

The NT200 detector in Lake Baikal at a depth of 1100 m consisted of 8 strings attached to an umbrella-like frame, with 12 pairs of OMs per string. The diameter of the instrumented volume was 42 m, its height 70 m. Meanwhile, at the time of writing, the Baikal collaboration has installed and is operating the first 14 clusters of a future cubic-kilometre array, GVD [102]. It will consist of 20 clusters, each with 288 OMs at 8 strings, plus several single strings between the clusters; its completion is scheduled for 2028.

The operation of ANTARES (see [98, 109] and references therein) was terminated in 2022. It comprised 12 strings with lateral distances of 60–70 m, each carrying 25 triplets of OMs at vertical distances of 14.5 m, located at depths of 2.1–2.4 km, starting 100 m above the sea floor. An additional string held devices for calibration and environmental monitoring. A system to investigate the feasibility of acoustic neutrino detection was also implemented.

KM3NeT will consist of building blocks of 115 strings each, with 18 OMs per string. Operation of the first strings deployed has successfully verified the KM3NeT technology and sensitivity. In the upcoming phase of its staged implementation, KM3NeT aims at two building blocks for neutrino astronomy, with vertical distances between OMs of 36 m and a lateral distance between adjacent strings of 90 m (ARCA, for *Astroparticle Research with Cosmics in the Abyss*) and at one block for the measurement of the neutrino mass hierarchy, with vertical distances between OMs of 9 m and a lateral distance between adjacent strings of about 20 m (ORCA, for *Oscillation Research with Cosmics in the Abyss*) [100]. The installation of ARCA near Capo Passero, East of Sicily (depth 3440 m) and of ORCA near Toulon (depth 2450 m) is ongoing and as of now (March 2026) 45/33 strings have been deployed for ARCA/ORCA and are continuously taking data. Completion of the full ARCA and ORCA arrays is planned for 2030.

P-ONE (*Pacific Ocean Neutrino Experiment*) [105] is a new initiative in its R&D phase, envisaging a large NT in the Pacific Ocean off the Canadian coast. It is intended to use an existing deep-sea cable infrastructure and to optimise the sensitivity for horizontal neutrinos with energies beyond about 100 TeV.

Three Chinese collaborations are currently working towards projects on the 10 km^3 scale. TRIDENT (*Tropical Deep-Sea Neutrino Telescop*) is a proposed neutrino telescope in the South China Sea with an instrumented volume of 7.5 km^3. R&D and site exploration efforts are ongoing and a pathfinder (TRIDENT Phase-1) is planned to be commissioned around 2026 [110]. HUNT (*High-energy Underwater Neutrino Telescope*) aims at an instrumented volume of 30 km^3, either in the South China Sea or in Lake Baikal [107]. NEON (*NEutrino Observatory in the Nahnhai*) envisages another detector of 10 km^3 in the South China Sea [108]. Whether there will be a process convergence among these three projects appears open at present.

36.3.2.4 *Results*

See Sect. 30.4 for a summary of the results from neutrino telescopes.

36.3.2.5 *Plans beyond 2025*

The IceCube Upgrade project serves to create a very densely instrumented region by deploying additional strings in the DeepCore volume. Main objectives are to inclease the low-energy sensitivity, to improve the calibration of ice properties and thus also the archival data, and to test new technologies. In the Antarctic summer season 2025/26, six strings for the Upgrade have been deployed and are currently in their commissioning phase.

Within the future IceCube-Gen2 project, it is planned to extend the sensitivity of IceCube towards higher energies by installing a large-volume extension, combined with a radio array for highest-energy neutrinos and a surface array providing also a powerful veto against atmospheric events [104].

More information on the future extensions of GVD and KM3NeT and on P-ONE and the Chinese projects TRIDENT, HUNT and NEON are given above and in Table 36.4.

36.3.3 *Radio emission from (ultra-)high energy particle showers*

Revised March 2026 by S.R. Klein (NSD LBNL; UC Berkeley) and A. Nelles (DESY, Zeuthen; Erlangen U.).

Coherent radio-frequency (RF) electromagnetic radiation is an attractive signature to search for particle cascades produced by interactions of high-energy particles. RF signatures have been used to study both cosmic-ray air showers and to search for neutrino-induced showers. This article will discuss the radio signal generation in neutrino-induced showers. Radio signals from cosmic rays are discussed elsewhere [111,112]. The density of the medium (i.e. ice, air, lunar regolith, salt) determines how rapidly a shower develops. This, in turn, affects the radio emission mechanisms. In dense media, radio Cherenkov radiation dominates, while in air, geomagnetic radiation is dominant.

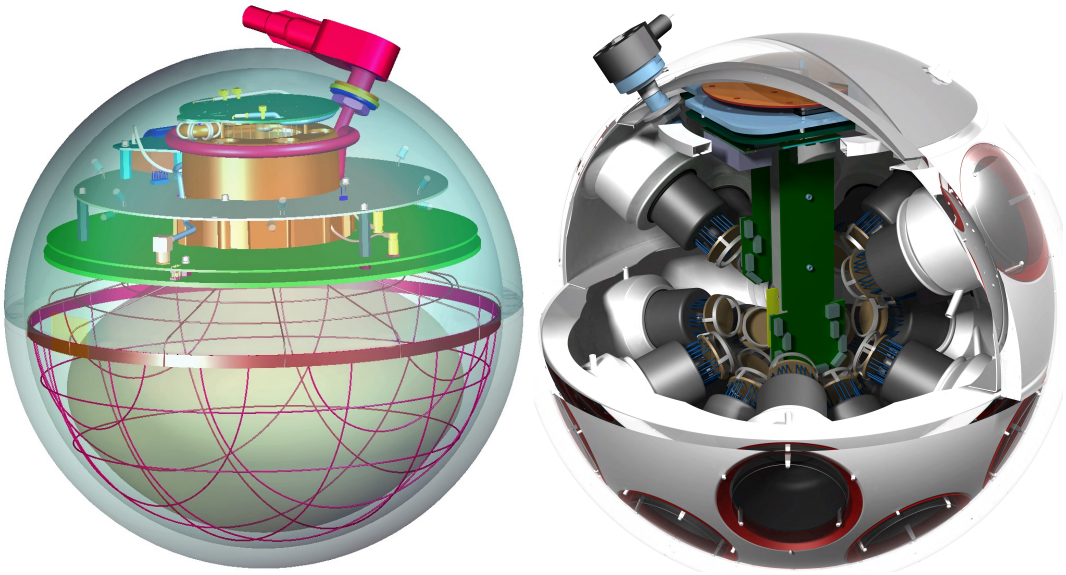

Figure 36.7: Schematic views of the digital OMs of IceCube (left) and KM3NeT (right).

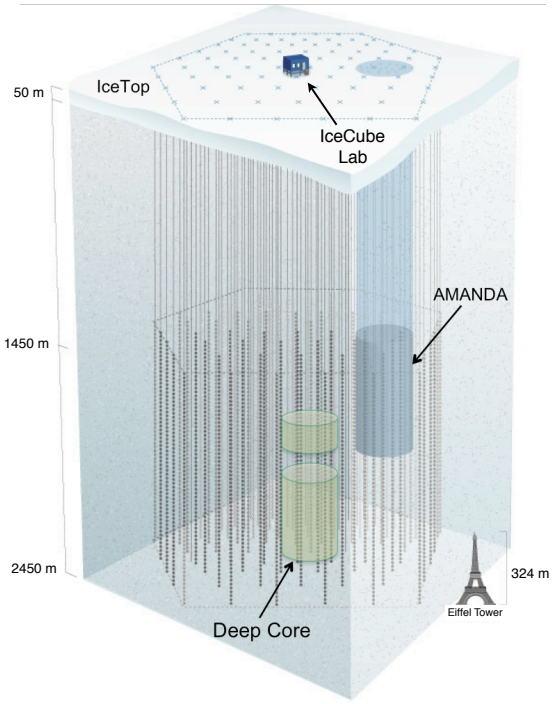

Figure 36.8: Schematic view of the IceCube neutrino observatory comprising the deep-ice detector including its nested dense part DeepCore, and the surface air shower array IceTop. Six strings of the IceCube Upgrade are installed in the DeepCore volume. The IceCube Lab houses data acquisition electronics and the computer farm for online processing. Operation of AMANDA was terminated in 2009.

At lower energies, incoherent optical Cherenkov radiation is frequently used, as discussed in "Neutrino telescopes" section 36.3.2. This article uses the general definitions and properties of neutrino telescopes as described in 36.3.2.

36.3.3.1 *Signal generation and its characteristics*

As discussed in the "Passage of Particles Through Matter" review Sec. 34 the electromagnetic component of a high energy shower gives rise to radio emission. The signal generation depends on the particle energy and the medium; the type of primary particle is unimportant. The medium must be non-conducting and transparent at RF frequencies. The shower develops over a length scale given by the radiation length X_0, which is much larger for air than for solids.

Coherent radio Cherenkov-like emission occurs because the shower contains more electrons than positrons. The coherent radio Cherenov emission, also known as Askaryan effect comes from the net current due to this excess [113–115].

In air, during propagation through the geomagnetic field, the relative motion of electrons and positrons is affected, which leads to a varying transverse current, usually referred to as the geomagnetic effect [111]. All effects may be described more generally as being due to radiation from a time-varying net charge [116]. Their relative importance is governed by the density of the medium, as the electric field of the Askaryan component scales as the net charge excess, and a lower density allows the geomagnetic effect to gain importance. Thus, in solid materials the emission from the Askaryan effect dominates, but it is a $< 20\%$ correction in air showers.

The net charge excess comes at the tail end of the shower, when the particles are mostly low-energy (< 100 MeV). There, positrons in the bean can annihilate on atomic electrons and inverse Compton scattering can accelerate atomic electrons into the shower. Even initially hadronic showers will have a low-energy tail that largely consists of $e^{\pm}$ and photons.

Coherent radiation is possible at wavelengths longer than the instantaneous thickness of the shower along an observer's line of sight. Since air showers have a larger extent than showers in solid media, their coherent radiation appears at lower frequencies [117]. If the density get too low, e.g. in very horizontal air showers, coherence is lost [118].

High-frequency radiation is concentrated around the Cherenkov angle θ_C. Viewed directly on the Cherenkov cone, the electric field strength, $\epsilon_{\rm Ch}$ at a frequency f from an electromagnetic shower from a ν_e with energy E_ν in ice may be roughly parameterized as [119, 120]

$$\epsilon_{\rm Ch}(V/{\rm mMHz}) = 2.53 \times 10^{-7} \frac{E_\nu}{1{\rm TeV}} \frac{f}{f_c} \left[\frac{1}{1 + (f/f_c)^{1.44}} \right] . \quad (36.3)$$

The electric field strength increases linearly with frequency, up to a cut-off frequency f_c, which is set by the transverse size of the shower [121, 122]. The maximum wavelength c/f_c is roughly the Molière radius divided by $\cos(\theta_C)$ where θ_C is the Cherenkov angle. The cutoff frequencies depend on the density (which affects the Molière radius). They are about 1 GHz in ice, about 3 GHz in the lunar regolith, and below 100 MHz in air, except exactly

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 06/14/16. For personal use and distribution is strictly not permitted, except for Open Access articles.
Int. J. Mod.

on the Cherenkov angle, where all frequencies are coherent by definition.

Near f_c, radiation is narrowly concentrated around θ_C [121, 122]. At lower frequencies, the limited length of the emitting region leads to a broadening in emission angle around the Cherenkov cone. Away from θ_C, the electric field from Eq. (36.3) is reduced by [119],

$$\frac{\epsilon}{\epsilon_{\rm Ch}} = \exp\left(-\frac{1}{2}\frac{(\theta-\theta_C)^2}{(2.2^\circ \times [1{\rm GHz}/f])^2}\right). \qquad (36.4)$$

The angular distribution of the signal around θ_C can be parameterized by a Gaussian peak modulated by a $\sin\theta$. In both ice and the lunar regolith, θ_C is about 56°, in air only 1°. Close to θ_C, the 1 GHz maximum frequency in ice/regolith leads to a generated pulse width of ≈ 1 ns.

These equations are appropriate for ice. More general parameterizations can be found in [120, 123].

More accurate calculations of the predicted radio signal, in particular air showers are not easily parameterized, but require detailed Monte Carlo simulations. For air showers, these are built on microscopic air shower simulations, calculate the emission from all individual particles in the shower development and add them for different observer positions [111]. For neutrinos, most approaches calculate (directly or from a parameterization) the Askaryan signal from a shower profile. The signal is then propagated through the medium and into an antenna model [120].

At energies above 10^{16} eV in ice, the Landau-Pomeranchuk-Migdal effect lengthens electromagnetic showers, by reducing the cross-sections for bremsstrahlung and pair production [124]. The lengthening of the shower leads to a narrowing of the radio emission around the Cherenkov cone, and a reduction in high-frequency emission away from the cone [120]. At higher energies, this leads to two separate components of the Askaryan radiation from a neutrino interaction: an un-altered component from the hadronic portion of the shower and an angularly narrowed component from the LPM-lengthened electromagnetic shower. The width of the narrowed component scales as $E_\nu^{1/3}$. If these two components can be observed separately, they could, in principle, be combined to determine the inelasticity of the neutrino interaction [125], allowing for improved measurements of low$-x$ parton distributions and searches for beyond-standard-model interactions.

Similarly, energetic outgoing $\mu^\pm$ and $\tau^\pm$ from neutrino interactions dominantly lose energy via stochastic pair production and photonuclear interactions. These secondary particles will produce electromagnetic showers that can be detected by radio detectors, if they are above threshold energy. This will enable multiple detections of the same particle track and thus present interesting reconstruction opportunities and flavor sensitivity [126].

At still higher energies, above 10^{20} eV, the LPM effect strengthens, and the electromagnetic shower splits into multiple subshowers with significant separation. When these separations become large enough, the subshowers will effectively become independent radiators, with the total emission showing substantial event-by-event variation, depending on the division into subshowers [124]. Because of this, many experiments that study higher energy (well above 10^{20} eV) neutrinos focus on the hadronic shower from the struck nucleus. This contains an average of only about 20% of the energy, but with fewer large fluctuations [127].

36.3.3.2 *Energy regime of radio detectors*

In the coherent regime, the electric field amplitude is linearly proportional to the shower energy. Since the signal is a radio wave, the field amplitude decreases as $1/R$, plus potential absorption in the intervening medium, while the energy fluence decreases as $1/R^2$, again, plus potential absorption. The detection threshold depends on the distance to the antenna and the bandwidth and noise characteristics of the antenna and detector. For an antenna located in the detection medium, at a distance of 1 km the typical threshold is around 10^{17} eV. For stand-off (remote sensing) detectors, the threshold rises roughly linearly with the distance. These thresholds can be reduced by using directional antennas and/or combining the signals from multiple antennas using beam-forming techniques.

RF detectors are used to search for energetic neutrinos from three types of sources: astrophysical objects (*i.e.* extending measurements of the neutrino energy spectrum observed at TeV to PeV energies upward in energy), cosmogenic neutrinos associated with cosmic-ray-cosmic microwave background radiation (CMBR) interactions, and neutrinos from beyond-standard-model physics. These three types are very roughly associated with energies below 10^{18} eV, the energy range 10^{18} to 10^{20} eV, and above 10^{20} eV, albeit with considerable overlap.

Cosmogenic neutrinos are produced when ultra-high energy (UHE) protons with energy $E \gtrsim 5\times10^{19}$ eV interact with photons from the CMBR, infrared light from old stars, and other extra-galactic background light. These protons are excited to a Δ^+ resonance which may decay via $\Delta^+ \to n\pi^+$, leading to neutrinos with energies above 10^{18} eV [128, 129]. The cosmogenic neutrino signal depends heavily on the fraction of UHE cosmic-rays that are protons. For a 100% proton composition (strongly disfavored by most data [130]), observing a cosmogenic neutrino signal of at least a few events per year requires a solid or liquid detector with an active volume of about 100 km^3 [131].

To reach the effective volumes necessary to observe the expected low fluxes of UHE neutrinos, common, naturally occurring, non-conducting solid (or potentially liquid) media, with a long absorption length for radio waves are needed. Optical Cherenkov detectors are limited by short (< 100 m) attenuation lengths [132] so would require a prohibitively expensive number of sensors. The radio detection technique has been used to detect air showers, targeting neutrinos as well as cosmic rays, and to search for neutrino showers in ice, salt domes and the lunar regolith.

36.3.3.3 *Reconstruction of particle energy and direction and background suppression*

Since radio detectors view the interaction from afar, the reconstruction techniques differ from optical neutrino telescopes.

Radio detection is a calorimetric measurement, thus provides good energy estimates of the shower energy. The energy fluence (time-integrated pulse power) of the signal scales quadratically with shower energy. It also depends on the distance to the shower, through potential attenuation losses and the usual $1/R$ loss in electric field amplitude. The arrival times in antennas and a spherical wave approximation can be used to determine the interaction vertex, although some uncertainty due to the viewing angle with respect to the Cherenkov angle may remain, if not corrected for by using the frequency information. If the radio signal travels through media where the index of refraction varies (like the firn of glacial ice), then ray-tracing techniques may be required to follow the signal back to the interaction point. For buried antennas, the bending of the signal trajectories due to the depth-dependent index of refraction creates an opportunity. For some geometries, there are two paths to the detector: a 'direct' path, with minor bending, and a second where the signal is bent beyond horizontal, bouncing off the surface before reaching the antenna. By measuring the time difference between the two paths, the distance to the interaction vertex may be determined; this greatly simplifies the energy determination [133, 134]. For most neutrino interactions (except for ν_e charged-current interactions), the shower energy is less than the neutrino energy. The uncertainty on the interaction inelasticity is a major contributor to the uncertainty in the neutrino energy, along with uncertainties on the distance between the antenna(s) and the interaction vertex [135].

Reconstruction of the neutrino arrival direction depends on several aspects of the signal and on a good understanding of the properties of the medium. First, the direction from the antenna to the interaction site must be determined. This can be done by using the relative timing from separated antennas, or using beam-forming techniques with multi-element arrays. For air showers, the signal arrival direction is (almost) equal to the particle arrival direction, with corrections being obtainable by fitting a hyperbolic wavefront [111, 112].

For showers in solid/liquid media, the arrival direction with respect to the interaction point - antenna vector is determined from two additional angles. The frequency spectrum can be used to de-

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

termine the angle between signal arrival direction and Cherenkov cone according to Eq. (36.4). The second angle can be determined from the polarization of the signal. The radio signal is produced with a linear polarization in the plane containing both the particle direction and the radio wave direction. These two angles can be combined to determine the direction, subject to a (usually) four-fold ambiguity, due to uncertainty as to whether the antenna is inside or outside the Cherenkov cone, and because the particle direction can be flipped 180° without affecting the observed signal [136]. Often, some of these solutions can be rejected because they correspond to long path lengths through the Moon or the Earth, where the neutrino would be absorbed. Spectral information is crucial for the reconstruction and background rejection. However, large bandwidth antennas typically disperse (i.e. broaden) the pulses. As long as the dispersion can be compensated for in the trigger and backgrounds controlled, a large bandwidth detector is the most sensitive.

All radio experiments must contend with background. Common sources are anthropogenic noise, antenna/preamp noise, charge generated by blowing snow, lightning, and, at low frequencies, radiation from the Milky Way. While narrowband noise impacts triggering and contaminates signal quality, impulsive backgrounds could mimic a signal. One of the major issues for radio-detection experiments is anthropogenic noise. Most anthropogenic noise has distinctive characteristics (such as being narrow-band, and coming from near the horizon) which makes it possible to reject during data analysis, via narrow-band filters and other techniques. However, these factors pose a challenge for triggering on the radio signal and reduce data purity. This is even an issue in Antarctica, where communication radios and passing satellites can mimic showers, at least at the trigger level. The need to limit anthropogenic noise has led most experimental groups to select remote locations for their detectors. Still, experiments need to reduce trigger-level noise, and/or to reject background at the analysis level. At this point, no robust and generally applicable strategy has been reported. For example, for multi-element arrays, the threshold drops as the square root of number of antennas, since the signal adds in-phase while the backgrounds add with random phases [137]. It seems, however, that e.g. triboelectric signals recorded in periods with winds exceeding 10 m/s are a problematic trigger-level background, for experiments in polar regions [138] and will require removal during analysis.

Most dedicated air shower experiments have used radio antennas in combination with at least one other detector technology, such as scintillation counters, if the site suffers from significant RF backgrounds and/or computing power on autonomous stations is limited. Exceptions are neutrino experiments with sensitivity to air showers, which are located in uninhabited polar regions, enabling them to relatively efficiently self-trigger on air showers [139, 140].

Lunar experiments (discussed below) use different techniques to reduce the anthropogenic background. Some experiments use multiple antennas, separated by at least hundreds of meters; by requiring a coincidence within a small time window, anthropogenic noise can be rejected. With good enough timing, beam-forming techniques can be used to further reduce the background. An alternative approach is to use beam forming with multiple feed antennas viewing a single reflector, to ensure that the signal points back to the moon.

Due to the similarity in the radio emission of air showers and neutrino showers, the more abundant cosmic rays can act as background to neutrino searches. In-ice detectors need to suppress in-air emission that is refracted into the ice, emission that is created from developing air showers continuing in the ice, as well as from stochastic energy-losses of atmospheric muons. Lunar experiments may faces challenges in separating neutrino interactions from cosmic ray interactions.

36.3.3.4 *Recent experiments*

Figure 36.9 shows some current limits from neutrino searches, including those from prototype arrays. Except for LOFAR, which is fully operational, projected limits from future experiments are not shown in the figure. Notably, the KM3NeT collaboration has observed an event with an energy above 100 PeV (with a central energy of 220 PeV) [141]. This observation is in tension (2.9σ) with the IceCube flux limit [142]. Various origin scenarios are being discussed.

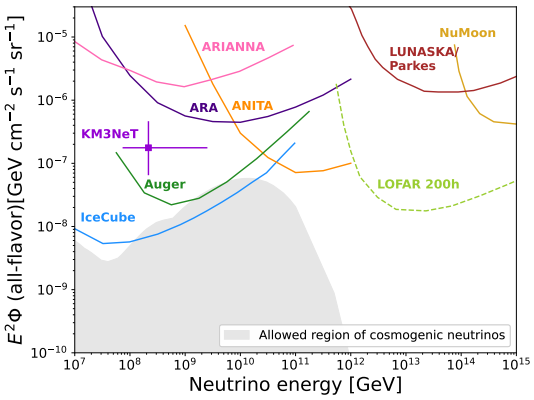

Figure 36.9: Representative 3-flavor (summed, assuming equal fluxes of each flavor) differential (over one decade in energy) limits from different experiments and prototype experiments. Shown are limits from the IceCube ultra-high energy ν search [142], the Auger search for earth-skimming ν_τ [143], the LUNASKA/-Parkes [144] and NuMoon lunar searches [145], the ANITA balloon experiment [146], ARA [147] and ARIANNA prototypes [148], along with projections for the LOFAR array [149]. Also shown is the flux implied by the event seen by KM3NeT [141]. The ARA and ARIANNA limits are from prototype arrays, and indicate the energy range that might be covered, with far higher sensitivity by larger arrays (see 36.3.3.5). The shaded area is the allowed region for cosmogenic neutrinos from a recent global analysis as published in [104] following the methods from [150].

i. *Ice*

The most common dense medium transparent to radio waves is ice. Natural ice is an attractive medium for neutrino detection with radio attenuation lengths from over 300 m to 1 km [151]. The attenuation length varies with frequency and ice temperature, with higher attenuation in warmer ice. Although glacial ice is mostly uniform, the top $\approx$ 100 m of ice, the 'firn,' exhibits a gradual transition from packed snow at the surface (typically $\rho = 0.35$ g/cm^3) to solid ice ($\rho = 0.92$ g/cm^3) below [152]. The thickness of the firn varies with location; it is thicker in central Antarctica than in the coastal ice sheets or in Greenland. The density variation has several implications.

The index of refraction depends linearly on the density, so radio waves curve downward in the firn. This bending reduces the effective volume of shallow or aerial antennas. A shallow antenna cannot see near-surface interactions at large horizontal distances. There are also indications that the increase in firn density is slightly non-monotonic [153, 154]. This leads to non-monotonic changes in index of refraction which may create waveguides that trap a small fraction of the radio energy and propagate it horizontally.

In one type of experiment, antennas mounted on high-altitude balloons observe the ice from above. Radio signals from in-ice neutrino interactions propagate to the surface, traverse the ice-air interface, and then travel to the balloon. The surface roughness of the ice can affect signals as they transition from the ice to the atmosphere. The best known example, ANITA, has made four flights around Antarctica, floating at an altitude around 35 km [155]. Its 32/40/48 (depending on the flight) dual-polarization horn antennas scanned the surrounding ice, out to the horizon (650 km away). Because of the small angle of incidence, ANITA could use polarization information to separate signals from background; ν signals should be vertically polarized, while most background from cosmic-ray air showers should be horizontally polarized.

Int. J. Mod.

As with all radio-detection experiments, ANITA had to contend with anthropogenic backgrounds. The ANITA collaboration uses their multiple antennas as a phased array to achieve good pointing accuracy, with a resolution of 0.2-0.4° in elevation, and 0.5-1.1° in azimuth. They rejected all events that pointed toward known or suspected areas of human activity. ANITA has set the most stringent flux limits yet on neutrinos with energies above 10^{20} eV [146]. The ANITA experiment has also reported several anomalous events, matching cosmic ray signals, but with unexpected polarization signature, which the collaboration has indicated might be from Earth-skimming ν_τ [156, 157]. However, this interpretation is controversial and firmly excluded by both Auger [158] and IceCube [142].

Because of the significant source-detector separation, ANITA is most sensitive at energies above 10^{19} eV. A lower energy threshold requires a smaller antenna-target separation.

Other ice based experiments use antennas located within the active volume, allowing them to reach thresholds around 10^{17} eV, or lower with phased array antennas. This approach was pioneered by the RICE experiment [159] which buried 18 half-wave dipole antennas in holes drilled for AMANDA at the South Pole, at depths from 100 to 300 m. The hardware was sensitive from 200 MHz to 1 GHz. Each antenna fed an in-situ preamplifier which transmitted the signals to surface digitizing electronics.

Following RICE, two groups have deployed prototype arrays which have explored different detector concepts. The Askaryan Radio Array (ARA) deployed surface and buried antennas at the South Pole [160], while the Antarctic Ross Iceshelf Antenna Neutrino Array (ARIANNA) installed shallow antennas on the Ross Ice Shelf [148], about 110 km north of McMurdo station. ARIANNA offered the possibility of detecting downward-going ν, from the radio waves reflected off the ice-sea water interface on the bottom of the Ross Ice Shelf, while ARA took advantage of the colder, deeper ice at the South Pole, with its longer radio attenuation length. ARA buried antennas up to 200 m deep to be able to observe a larger portion of ice, due to the refraction of the signal in the firn. In contrast, ARIANNA deployed antennas just below the surface, allowing them to use high-gain, but large log periodic dipole antennas. At ARA, phased-array trigger techniques have been demonstrated that can reduce the energy threshold by a factor of several [137, 161].

Both experiments use stations which operate independently, spaced far enough to maximize sensitivity, but where only a small fraction of neutrino events will be visible in multiple stations. Each station includes multiple antennas, which will be sensitive to both horizontal and vertical polarization. The expected angular resolution is a few degrees [136].

The Radio Neutrino Observatory Greenland (RNO-G) is under construction at Summit Station, Greenland, where the ice is about 3,000 m thick. RNO-G is planned to consist of 35 stations, which employ ARIANNA-style shallow antennas, an ARA-style phased array and deep antennas, and draws on ANITA's electronics heritage [162]. Installation speed is limited by the drill speed. In July, 2025, 8 stations were operational with holes for 4 additional stations prepared for installation.

ii. *The Moon*

Because of its large size and non-conducting regolith, and the availability of large radio-telescopes, the Moon is an attractive target [163]. Conventional radio-telescopes are quite well suited to lunar neutrino searches, with natural beam widths not too dissimilar from the size of the Moon. Still, there are experimental challenges. The attenuation length is typically estimated to be 9 m/f(GHz) [164], so only near-surface interactions can be studied. The composition of the lunar regolith is not well known, and there are significant uncertainties due to this uncertainty. One big limitation of lunar experiments is that the 385,000 km target-antenna separation leads to energy thresholds above 10^{20} eV.

The effective volume probed by experiments depends on the geometry, which itself depends on the frequency range used. At high frequencies f, the electric field strength is high, leading to a lower energy threshold, but the sensitive volume is limited because the Cherenkov cone only points toward the Earth for a narrow range of geometries. Lower frequency radiation is more isotropic, so the effective volume is larger, but, because the electric field is weaker, the energy threshold is higher. The $1/f$ dependence of the attenuation length in the lunar regolith further increases the effective volume at low frequencies. The frequency range affects the energy dependence of the sensitivity. As can be seen in Fig. 36.9, a low-frequency experiment like NuMoon (which covered 115-180 MHz) has good sensitivity, but only above about 10^{14} GeV, while Lunaska/Parkes, which observed in the range 1200-1500 MHz, has a higher flux limit, but is sensitive above about $10^{12.5}$ GeV.

Current limits and projected sensitivities are sensitive to many details. A recent review [165] compared different radio-detection experiments using a common framework, and found some significant shifts in sensitivities due to, e.g. different assumptions about lunar composition and inelasticities.

With modern technology, it is increasingly viable to search over very broad frequency ranges [166]. One technical challenge is due to dispersion (frequency dependent time delays) in the ionosphere. Dispersion can be largely removed with a de-dispersion filter, using either analog circuitry or post-collection digital processing.

iii. *Air*

Radio detection in air is sensitive to all particles inducing air showers. Radio-detection can be used to determine the energy of cosmic rays, as done by e.g. the Auger and Tunka-Rex experiments [167, 168]. Radio signals can also be used to infer the atmospheric depth for shower-maximum, where the shower contains the most particles, as done by e.g. the LOFAR and Tunka-Rex collaborations [168, 169]. This depth is sensitive to the cosmic-ray composition. Reconstructing the particle arrival direction is much easier in air since the Cherenkov angle, and thus the radio wavefront, aligns with the axis to 1°. Radio-detection is also useful for energy cross-calibrations between different experiments. The Pierre Auger collaboration has recently shown that radio can provide an independent energy scale calibration, in good agreement with the other detectors of the observatory [170].

One variation on the radio-detection approach is to look for radio emission from Earth-skimming ν_τ [171, 172]. Although ν_τ are much less commonly produced than ν_μ and ν_e, over astrophysical distances, oscillations lead to a $\nu_e : \nu_\mu : \nu_\tau$ ratio near $1 : 1 : 1$, for almost all non-exotic acceleration and propagation mechanisms.

If the ν_τ traverse the Earth and interact while traveling upward, the resulting $\tau^\pm$ may exit the Earth before decaying. 83% of the time, the decay produces a hadronic or electromagnetic shower in the atmosphere [173]. Experiments have searched for these upgoing showers, and for the resulting optical Cherenkov and coherent RF radiation. The threshold energy dependence for these searches depends on several factors, notably including the average $\tau^\pm$ decay length, which increases linearly with energy. For somewhat lower energy ν_τ, with shorter decay lengths, a mountain may serve as a target, with $\tau^\pm$ expected to emerge from the other side. The Pierre Auger observatory sets stringent limits on this neutrino flux at energies above 10^{17} eV [143]. The Pierre Auger Collaboration has recently upgraded their surface array to include radio antennas at all water Cherenkov detectors. This array will improve the sensitivity of the instrument to horizontal showers, both for composition sensitivity for cosmic rays and for the detection of Earth skimming neutrinos [174].

36.3.3.5 *Future experiments*

Looking ahead, RNO-G [162] will continue deployment in the next years and has reached the largest yearly sensitivity of any radio array thus far. Further out, the proposed IceCube-Gen2 expansion includes a substantial radio array component [104], which will be sensitive to both neutrinos from the ice and air showers from cosmic rays. PUEO, a successor of ANITA, with significantly improved sensitivity, completed its first flight early 2026 [175].

For lunar neutrino detection, several large radio detector arrays should reach significantly lower energies in the near future. The LOFAR array is taking data with 36 detector clusters spread over Northern Europe [149]. Also, the Square Kilometer Array (SKA) with its roughly 60,000 antennas will push thresholds down to near 10^{20} eV [166]. The SKA will also study air showers [176].

A number of dedicated prototype ν_τ radio-detection experiments exist. The GRAND Collaboration, e.g., is proposing to deploy a large array of simple autonomous radio stations optimized for near-horizontal signals [177]. As of 2025 a first proto-array is operational.

36.4 Large time-projection chambers for rare event detection

Written October 2025 by L. Baudis (Zurich U.).

Initially developed for particle physics experiments at accelerators (see *Section 35.6.5*), the concept of a Time Projection Chamber (TPC) [178] evolved and is now tailored to a large range of applications, most notably to experiments in astroparticle physics searching for rare interactions deep underground. Present and proposed experiments designed to observe interactions of dark matter and other exotic particles, second order weak nuclear decays, as well as neutrinos from a variety of sources are based on TPCs operated with pure noble elements, either in gaseous or liquid form. The detectors aim for large target masses, low energy thresholds (keV-scale) and ultra-low levels of backgrounds from radioactivity and cosmic rays. Historical introductions, reviews of the operation principles, instrumentation and technological aspects, as well as applications, are found in Refs. [179–184].

The two most common noble fluids employed as detector media in present TPCs for rare event searches are argon and xenon, either as a high-pressure gas, or in liquid phase, or in liquid and gas phase (dual-phase). An interaction within the active volume of a TPC will create ionisation electrons and scintillation photons. The prompt scintillation signal is detected with one or two arrays of photosensors, while the ionisation electrons, which drift in the pure medium under the influence of an external, uniform electric field, are observed either directly with charge sensors, or via proportional scintillation, or electroluminescence. Since transverse electron diffusion is small, albeit non-negligible, the ionisation signal provides the $x-y$ information of the interaction site, with the $z-$information coming from the drift time measurement. The TPC thus yields a three-dimensional event localisation, enabling fiducial volume selections and differentiation between single- and multiple-scatters in the active volume. These features are crucial for filtering out rare events from the much higher backgrounds due to residual radioactivity of detector components. The specific energy loss (dE/dx) depends on the primary interacting particle, and leads to a distinct ratio of scintillation to ionisation for gammas/electrons, alphas and fast neutrons, allowing for further background discrimination. Two examples for the operation principle of TPCs for rare event detection are shown in Fig. 36.10.

The properties of liquid argon as detection medium in a TPC are reviewed in *Section 35.7*. Here some properties for xenon are given in Tab. 36.5. In the liquid phase, the high xenon density allows for compact, large and homogeneous detector geometries with efficient self-shielding against external radiation, given that the cross sections for the photoelectric effect, Compton scattering and pair production scale as $Z^5/E_\gamma^{7/2}$, Z/E_γ and $Z^2 \ln(2E_\gamma)$, respectively, for incoming X-rays and gammas with energy E_γ. The radioactive isotopes ^{124}Xe, ^{126}Xe, ^{134}Xe and ^{136}Xe have very long half-lives, and their second-order weak decay modes are subject to investigation (see *Section 36.4.2*).

In an argon or xenon detector, the energy loss of an incident particle is shared between ionisation, excitation and sub-excitation electrons liberated in the ionisation process. The average energy loss in ionisation is slightly larger than the ionisation potential, as it includes multiple ionisation processes. In their condensed phases, argon and xenon exhibit a band structure of electronic states, with the band gap energy being around 14.3 eV and 9.3 eV for liquid argon and xenon, respectively. In gaseous xenon, the ionisation potential is about 12.1 eV. Scintillation arises from excited atoms (excitons) and from ions, via recombination, with the emitted vacuum-ultraviolet (VUV) photons in single bands centred at $\lambda = 128$ nm for argon and $\lambda = 175$ nm for xenon. The excited dimers (or excimers), at their lowest excited level, de-excite to the dissociative ground state by the emission of a single VUV photon. This comes from the large energy gap between the lowest excitation and the ground levels, forbidding other de-

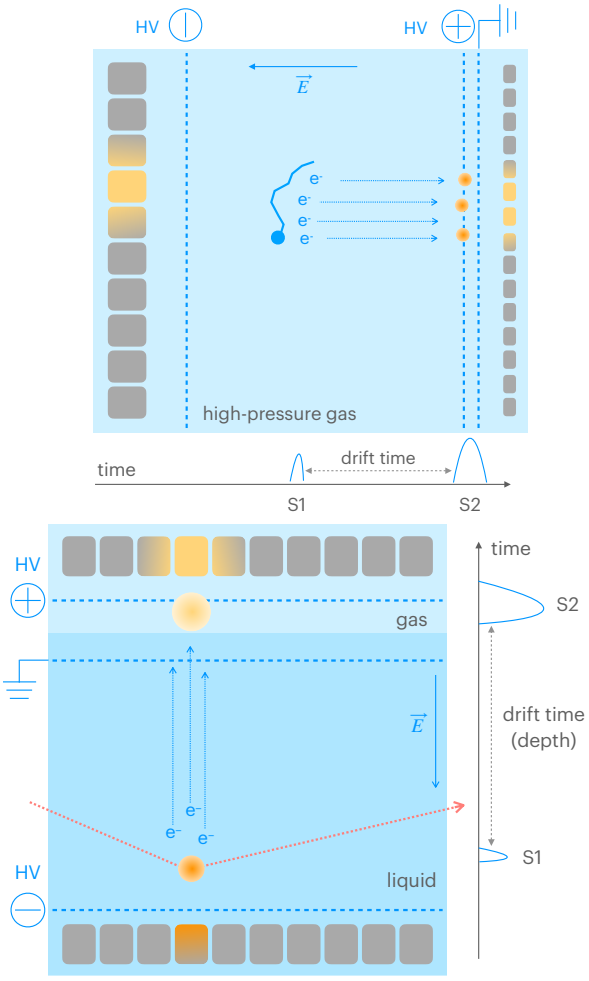

Figure 36.10: Operation principle of TPCs for rare event detection: a high-pressure gas (top) and a dual (liquid/gas) phase (bottom) TPC. A particle interaction yields a prompt scintillation signal (S1) and a delayed, amplified proportional scintillation signal (S2). The latter is caused by ionisation electrons drifted in a homogeneous electric field (and, for dual phase TPCs, extracted into the gas phase above the liquid). In these examples, both S1 and S2 signals are observed with photosensor arrays placed behind the anode and cathode (left), or at the top and bottom (bottom) of the TPC. The position information along the drift field is inferred from the time difference between the two light signals, while the position in the transverse plane to the field is derived from the S2 light pattern in the photosensor plane close to the electroluminiscent light production site.

cay channels such as non-radiative transitions. The scintillation light has two decay components due to de-excitation of spin singlet and spin triplet states of the excited dimers to the ground state. The singlet and triplet states refer to the total spin quantum number (s=0 or s=1) of the excited Rydberg electron and the angular momentum due to the molecular orbit, with the shorter and longer decay shapes being produced by the de-excitation of s=0 states (spin-allowed) and s=1 states (spin-forbidden), respectively. The different pulse decay time for different type of particle interactions, and thus ionisation densities, is employed to discriminate electronic from nuclear recoils. While this is very effective in liquid argon, due to the large time separation of (6 ± 1) ns versus (1500 ± 100) ns, it is more difficult to put in practice for xenon [185], considering the much smaller separation, (2.2 ± 0.3) ns versus (27 ± 1) ns, of the two components.

The recombination-independent, mean energy required to produce a single detectable quantum (photon or electrons), called

Table 36.5: Physical properties, volume fraction in the atmosphere, radioactive isotopes of the noble element xenon.

Property [unit]	Xe

*Measured values in two benchmark regimes, so-called "cold" and "hot" electrons [187]. In the first case, the electron energies are due to thermal bath of the xenon fluid and they rapidly gain energy with increasing field; in the second case, the electrons have gained most of their energy through acceleration in the field and experience increased energy loss on their path due to collisions with Xe atoms.

the W-value, assumes that each recombining electron-ion pair produces an exciton, which leads to a photon. In liquid argon, the W-value is (19.5 ± 1.0) eV [196]. In liquid xenon, the widely-adopted W-value is (13.7 ± 0.2) eV, measured with 122 keV γ-rays from an external ^{57}Co source [197]. Recently, a lower value of $11.5^{+0.2}_{-0.3}$ (syst.) eV was obtained in a small TPC with internal sources at energies between 2.8 keV and 42 keV [198], consistent with the value measured at the MeV-scale, 11.5 ± 0.5(syst.) $\pm$ 0.1(stat.) eV with the EXO-200 detector [199]. The ionisation and scintillation W-values in gaseous xenon are 24.8 eV and (76 ± 6) eV, respectively [200].

The partition between excitation and ionisation depends on the density of the electron-ion pairs produced along the track of a particle, and the recombination fraction depends on the applied electric field, as well as on the ionisation density in the track. While several phenomenological models exist to describe electron-ion recombination as a function of stopping power and electric drift field (see [179] and discussions therein), a solid theory of energy loss of low-energy ions in noble fluids is still missing. For nuclear recoils as generated by interactions of neutrons, neutrinos or hypothetical WIMPs, an energy-dependent quenching is introduced via the Lindhard factor $\mathcal{L}$ [201], with $\mathcal{L}$ being around $0.2 - 0.25$ and $0.15 - 0.2$ in liquid argon [202] and xenon [203], respectively, at nuclear recoil energies in the range 3-100 keV. A comprehensive framework to simulate scintillation and ionisation yields in argon and xenon as a function of interaction type, energy and electric field in a TPC is the Noble Element Simulation Technique (NEST) [204].

To calibrate the energy scale and determine the energy resolution of low-background TPCs, mono-energetic lines from external (e.g., ^{57}Co, ^{60}Co, ^{137}Cs, ^{228}Th, etc) and internal (^{83m}Kr, ^{37}Ar) calibration sources, as well as from neutron activation lines (e.g., ^{129m}Xe, ^{131m}Xe in xenon) are used. Relative energy resolutions (σ/μ) at the level of 4-6% at energies of a few tens of keV and 2-3% at energies of a few 100 keV were reached in argon and xenon TPCs, respectively. At higher energies, relevant for the neutrinoless double beta decay of ^{136}Xe, relative resolutions of 0.67%, 0.8% and 1.2% around 2.5 MeV were obtained by LZ [205], XENON1T [206] and EXO-200 [207], respectively. Superior energy resolutions are attained in high-pressure gas TPCs with electroluminiscent amplification [208], with a relative resolution of 0.4% obtained in the NEXT-White detector [209]. This is due to the fact that the Fano factor in pure gaseous xenon, F_{GXe} = 0.15$\pm$0.02, is about two orders of magnitude smaller than in the liquid phase.

To achieve a high collection efficiency for both ionisation and scintillation signals, the concentration of impurities is reduced and maintained at a level below one part per 10^9 (ppb) oxygen equivalent. While the light can be strongly reduced by the presence of water vapour, the ionisation signal also requires high purity in terms of molecules with high electronegative affinity. The purity is commonly expressed via the electron drift lifetime, τ_e, which is the time over which the number of drifting electrons, n_e, is reduced by a factor e: $n_e(t) = n_e(t_0) \exp(-t/\tau_e)$. Ideally, τ_e should be a few times larger than the total drift time in a TPC, to prevent charge losses. Lifetimes > 10 ms were achieved both in argon and xenon (corresponding to impurity concentrations $\ll$1 ppb O_2 equivalent) via continuous recirculation and purification in the liquid or gas phase.

The drift velocity of electrons, which depends on the drift field E_d and the electron mobility μ as $v_d = \mu \cdot E_d$, has been measured for drift fields between $\sim (10 - 10^4)$ V/cm. It also depends on the temperature in the medium and the impurity concentration, often making the comparison between different measurements difficult. In general, the drift velocity raises from about 0.25 mm/μs at low fields to 2 mm/μs at high fields in both argon and xenon. As electrons drift in the electric field, the initial electron cloud spreads both in longitudinal and transversal direction to the field, expressed in terms of longitudinal D_L and transversal D_T diffusion coefficients, with $D_L < D_T$ and $D_L/D_T \approx 1$ for fields approaching zero. In argon, D_L was measured as $\sim$4.2 cm^2/s at 200 V/cm [210], $\sim$3.7 cm^2/s at 274 V/cm [211], $\sim$7.2 cm^2/s at 500 V/cm and D_T as $\sim$12 cm^2/s [212]. In xenon, D_L is around 100 cm^2/s at low fields, reaching $\sim$25 cm^2/s at higher drift fields [188], while D_T has been measured to be $\sim$55 cm^2/s at fields between (20-600) V/cm [213]. As an example, the spatial distribution of an initially point-like electron cloud, after a drift time t, is $\sigma_D = \sqrt{2Dt}$, resulting in a value of $\sim$20 mm for 1 ms drift and a 25 cm^2/s diffusion coefficient.

The scintillation light can be attenuated by absorption on impurities or due to Rayleigh scattering, the latter depending strongly on the wavelengths of the photons and the optical properties of the materials. Since only the combined effect is observed, it is non-trivial to disentangle the two contributions. A combination of measurements and theoretical calculations yield total attenuation and Rayleigh scattering lengths between 55-110 cm and 60-99 cm for argon and 30-50 cm and 30-50 cm for xenon detectors, with refractive indexes between 1.34 and 1.57-1.72, respectively, and absorption lengths >100 cm [179, 214].

Background sources for rare-event searches, their mitigation

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com

techniques and radio-purity assays are discussed in *Section 36.6* of this *Review*. The main backgrounds in large TPCs are due to decays of other noble isotopes mixed with the argon and xenon (^{39}Ar, ^{85}Kr, ^{222}Rn), from natural, anthropogenic or cosmogenic radioactivity of detector materials in close proximity to the target (^{238}U, ^{232}Th, ^{40}K, ^{60}Co), and from muons and their secondary particles, including *in situ* production of isotopes which are sufficiently long-lived to render their vetoing difficult (e.g., ^{137}Xe in xenon TPCs). Astrophysical neutrinos cause largely irreducible backgrounds in dark matter detectors, but deliver exciting physics signatures in their own right. To mitigate the ^{39}Ar background, argon is extracted from underground sources (CO_2 wells), ^{85}Kr and ^{222}Rn are reduced by cryogenic distillation, exploiting the different vapour pressures of the different noble gases, or with gas chromatography using synthetic charcoal. In xenon detectors, $^{\rm nat}$Kr concentrations of < 50 ppq [215] and ^{222}Rn concentrations of $0.8\,\mu$Bq/kg were achieved by cryogenic distillation In argon TPCs, ^{39}Ar concentrations of (0.73 ± 0.11) mBq/kg were demonstrated [216].

An overview of large TPCs for rare event searches is given in Table 36.6.

36.4.1 *Dark matter and other low energy signals*

TPCs built to search for particle dark matter are based on the two-phase principle. Starting with total masses of a few kilogram the detectors evolved and reached active target masses at the tonne- and more recently multi-tonne scale. Concomitantly, the background levels in the most inner regions constantly decreased, with current electronic recoil rates of 15 events/(t y keV) in the energy region below 100 keV for xenon detectors [217]. Typically, the TPCs contain two arrays of photosensors, one immersed in the liquid, and one in the gas phase above the liquid at similar low temperature. The xenon scintillation light can be observed directly by PMTs with synthetic silica (quartz) windows or with VUV-sensitive SiPMs, while for argon detectors, tetraphenyl butadiene (TPB) is used to shift the 128 nm light to 420 nm, given that it is absorbed by quartz windows.

The DarkSide-50 experiment [216] operated a 50 kg TPC with liquid argon depleted in ^{39}Ar until 2019. DarkSide-20k [218], to operate 51.1 t of underground LAr in an octogonal TPC, the walls made of gadolinium-loaded acrylic panels, with two arrays of SiPMs, is under construction in Hall C of the Laboratori Nazionali del Gran Sasso (LNGS) in Italy. The first filling with liquid argon is planned for the end of 2026, with data taking starting in 2027. A larger, 400 t LAr detector, Argo, has been proposed for SNOLAB in Canada. After the successful operation of TPCs for LUX, PandaX-II and XENON1T, the current generation of xenon detectors, LUX-ZEPLIN (LZ) [219] at the Sanford Underground Facility (SURF) in USA, PandaX-4T [220] at the China Jinping Laboratory (CJPL) and XENONnT [221] at LNGS, employ several tons of LXe as active target mass. Their overall TPC design is rather similar, with cylindrical, polytetrafluoroethylene (PTFE) enclosed target regions viewed by two arrays of low-radioactivity, 3-inch diameter Hamamatsu R11410 PMTs. The PTFE has a high reflectivity for the Xe scintillation light [222]. Next-generation detectors, at the 50 t LXe scale or beyond, have been proposed with XLZD [223] and PandaX-xT [224], while DARWIN [225,226] continues the R&D towards XLZD. Recent constraints on various dark matter candidates are presented in *Section 27.6*. The search for WIMP dark matter is ongoing, with the sensitivity goal of current experiments to the spin-independent WIMP-nucleon cross section around $1.5\times10^{-48}\,$cm^2 at 40-50 GeV/c^2 mass [219, 221].

Owing to low electronic recoil backgrounds and low energy thresholds in noble liquid TPCs, high-sensitivity searches for dark matter electron scattering with particle candidates from a hidden sector, for keV-scale axion-like-particles (ALPs) and dark photons via absorption in LXe, as well as searches for solar axions, became feasible (see *Section 27.6*). Looking at ionisation-only signals allows for a further reduction of the energy threshold, given the much higher efficiency to detect an ionisation electron compared to a primary scintillation photon (typically 90% versus 10%). While this gain comes at the expense of higher backgrounds, it allows nonetheless to set stringent limits on light dark matter electron interactions at masses from a few tens of MeV to a few GeV, as shown by DarkSide-50 [227], PandaX-4T [228], XENONnT [229] and LZ [230]. Further, current-generation dual-phase TPCs have reached target masses which will allow for the first time the detection of solar *pp* neutrinos via elastic neutrino-electron scattering at energies down to 1 keV. Recently, the first detection of ^{8}B neutrinos via coherent elastic neutrino-nucleus scattering (CEνNS) was reported by PandaX-4T [231] and XENONnT [232].

Dual-phase TPCs were successful in gradually scaling up their target mass and in reducing the background levels for each iteration, while maintaining a low-energy threshold of $\sim$1 keV for electronic recoils. Notwithstanding, the construction of next-generation detectors at the multi-ten-tons scale poses multiple technological challenges. The background goals are such that electronic and nuclear recoils rates are below the ones from irreducible astrophysical neutrino interactions. This requirement sets the goals for the intrinsic ^{222}Rn and ^{85}Kr concentrations: the background from the decay of these isotopes should be significantly lower than the solar pp-neutrino elastic scattering rate. This translates into $0.1\,\mu$Bq/kg for ^{222}Rn[2] and 0.1 ppt (parts per billion, or 10^{-9}) for $^{\rm nat}$Kr, assuming a ^{85}Kr/$^{\rm nat}$Kr ratio of 2×10^{-11}mol/mol. While $^{\rm nat}$Kr concentrations of < 50 ppq (parts per quadrillion, or 10^{-15}) were already achieved, for ^{222}Rn a factor of about 10 reduction compared to the current values [233] is needed. This calls for a high liquid throughput (close to 1 t/hour) with efficient cooling power based on cryogenic heat pumps and radon-free heat exchangers. Cryogenic distillation or charcoal chromatography must go hand in hand with selection of low radon emanation materials and new coating techniques to prevent radon emanation from surfaces.

Other challenges related to the liquid target are the continuous purification for electronegative impurities and water, to maintain high charge and light yields, while not introducing radon into the TPCs, as well as new solutions for reliable storage and recuperation at large scales. A dedicated single-closed-loop cryogenic system capable of handling 100 t of underground argon was designed and constructed for DarkSide-20k [234]. Liquid phase purification powered by a liquid xenon pump, as demonstrated in [235], was employed to achieve an electron drift lifetime above 15 ms in about 8.6 t of xenon in XENONnT. A system capable of handling 30 t of xenon in liquid phase, including long-term storage and and transfer of the cryogenic liquid between storage module and detectors was constructed for PandaX-xT [224, 236].

Regarding the detector design, electrodes with large (>2.5 m) diameters, with high transparency, minimal sagging and low spurious electron emission, as well as high-voltage feed-throughs that can safely deliver 50 kV or more to the cathode must be employed. DarkSide-20k will use for the first time anode and cathode plates made out of acrylic coated with a commercial conductive polymer and with TPB. LZ successfully built custom-woven wire-mesh grids with 1.5 m diameter, produced with an in-house built loom to weave the wire meshes [237]. Finally the cryostat design must ensure stability, while reducing as much as possible the amount of material, and thus gamma and neutron emitters in proximity to the TPCs.

Besides Ar and Xe TPCs, detectors using superfluid ^{4}He, targeted at low-mass dark matter, are under development within the HeRALD [238] and DELight [239] programs, based on the basic principles demonstrated by the HERON solar neutrino project [240]. The detectors will be instrumented with transition edge sensors or magnetic micro-calorimeters to observe both atomic signals, such as scintillation light, and quasiparticle (phonon and roton) excitations. As in other noble elements, the He_2^* dimers appear in a short-lived (<10 ns) singlet and long-lived (13 s) triplet state. The former decay promptly, emitting photons with energies peaked around 16 eV, while the triplet states can propagate through the fluid and de-excite at surfaces. Liquid helium is transparent to its VUV photons, since the first excited state of atomic helium is at 20 eV. Quasiparticles will propagate

[2] A ^{222}Rn concentration of $0.1\,\mu$Bq/kg corresponds to less than one radon atom per 100 mol of xenon. The main background is due to ^{214}Bi β-decays which are not accompanied by an α-decay and thus cannot be tagged in the TPC.

Table 36.6: Experiments using large TPCs for rare event searches. Shown are current, soon-to-be-operating and proposed experiments. UAr stands for underground argon; HP-GXe stands for high-pressure gaseous xenon. For some of the proposed experiments, the location or the readout scheme is not yet decided (marked as "TBD").

Experiment	Location	TPC type	Total (active) mass	Readout
Dark matter				
DarkSide-20k	LNGS	Dual-phase, UAr	50 t (50 t)	SiPMs, TPB
Argo	SNOLAB	Dual-phase*, UAr	∼400 t (∼400 t)	SiPMs, TPB
LUX-ZEPLIN	SURF	Dual-phase, Xe	10 t (7 t)	3″ PMTs
PandaX-4T	CJPL	Dual-phase, Xe	5.6 t (3.7 t)	3″ PMTs
PandaX-xT	CJPL	Dual-phase, Xe	47 t (43 t)	2″ PMTs
XENONnT	LNGS	Dual-phase, Xe	8.6 (5.9 t)	3″ PMTs
XLZD	TBD	Dual-phase, Xe	50-100 t (40-80 t)	3″ PMTs
$0\nu\beta\beta$ decay				
nEXO	SNOLAB	LXe, ^{136}Xe 90%	4.8 t (3.65 t)	SiPMs, charge pads
NEXT-100	LSC	HP-GXe, ^{136}Xe 90%	100 kg (80 kg)	3″ PMTs, SiPMs, TPB
NEXT-HD	TBD	HP-GXe, ^{136}Xe 90%	1.2 t (1 t)	Fibres + SiPMs, TPB
PandaX-III†	CJPL	HP-GXe, ^{136}Xe 90%	140 kg (100 kg)	Micromegas

*The option to build Argo as a single-phase detector is also under consideration.
†This is an R&D program for a future larger, enriched PandaX-xT detector.

ballistically through the liquid without decaying, and can also be detected via the evaporation of ^{4}He atoms from the surface of the liquid, with the helium binding energy being ∼0.7 meV.

Large volume, low-background TPCs are also developed for directional dark matter searches. An example is CYGNO [241] which aims to built a TPC with 50 cm drift, filled with a He:CF_4 gas mixture at room temperature and atmospheric pressure at LNGS. The liberated charge in a particle interaction is drifted towards an amplification stage consisting of a triple GEM structure, where the charge is multiplied and also light is produced. The readout will consist of light detectors, PMTs and scientific CMOS cameras, yielding the energy and z-position of events and the 2D track projections, respectively. The combined information thus allows for a 3D track reconstruction, with the goal being to achieve energy thresholds for electronic recoils around 1 keV.

36.4.2 $0\nu\beta\beta$ *Decay*

Experiments built to search for the $0\nu\beta\beta$-decay of ^{136}Xe, at a Q-values of 2457.8 keV, are based on single-phase TPCs, filled either with liquid or gas xenon at high pressure. The drift region is horizontal (EXO-200, NEXT-100) or vertical (nEXO, NEXT-HD, PandaX-xT-enriched).The TPCs are enclosed by radio-pure, thin-walled Cu vessels in a cryofluid, hydro-fluoro ether, or in a cold liquid scintillator, acting as a thermal bath, radiation shield and active veto in the latter case. In EXO-200, which took data at the Waste Isolation Pilot Plant (WIPP) until 2018, the charge drifted to crossed-wire planes at each anode, while the light was collected by arrays of large area avalanche photodiodes placed behind the wire planes at both ends. In nEXO, the TPC vessel is planned as a vertical Cu cylinder with 130 cm height and diameter (for 118.3 cm drift), with the charge collected at the anode by 0.6 cm pitch and 9.6 m long electrode strips, and the scintillation light observed by SiPMs arranged in a barrel configuration. Unlike for dark matter TPCs, there are no reflector panels and the field rings and cathode are coated with reflective aluminium deposition. The design drift field is 400 V/cm and the goal for the relative energy resolution is 0.8%. EXO-200 set a lower limit on the half-life of $0\nu\beta\beta$-decay of 3.5×10^{25} y with a total exposure of 231.4 kg y [242]. The proposed nEXO aims for a sensitivity of 1.35×10^{28} y with 5 t of enriched xenon and ten years of data taking [243].

TPCs using high-pressure xenon gas aim to reconstruct the tracks from the two electrons emitted in double beta decays, and the decay vertex, thus providing also a topological signature. In the NEXT project at the Laboratorio Subterráneo de Canfranc (LSC), the horizontal TPC, to be operated at 10-15 bar, features a single drift region. The primary (S1) and secondary (S2) scintillation light, the latter due to electroluminescence when the ionisation electrons cross a high-field region close to the anode, are collected by arrays of PMTs and SiPMs placed behind the cathode and anode, respectively, for energy measurements and tracking. The surfaces facing the active volume are coated with TPB to shift the VUV light to the visible spectrum. An inner Cu shield absorbs radiation from the high-pressure vessel of the cryostat.

The NEXT-White experiment, a prototype for NEXT-100 and for the proposed tonne-scale NEXT-HD, has operated a TPC with 20.8 cm radius and 53 cm drift, with 4.3 kg of xenon at 10 bar until 2023. It demonstrated excellent energy resolution (< 1% FWHM [209]) and background rejection using the capability to reconstruct the trajectories of ionising charges in the gas, thus separating the two-electron signature of $\beta\beta$-decay from single electrons due to background sources [244, 245]. Using data collected with xenon enriched and depleted in ^{136}Xe, it measured the half-life of the $2\nu\beta\beta$-decay and demonstrated clear Bragg peaks for the two electrons emitted in the decay [246]. NEXT-100 is currently acquiring data at LSC 5 bar [247], and will operate with >10 bar in 2026-2027. NEXT-HD will operate a vertical-drift TPC, 2.6 m in diameter and height, to accommodate ∼1.1 t of enriched xenon at 15 bar [248]. An intense R&D programe for the *in situ* identification of the barium ions ($^{136}Ba^{2+}$, $^{136}Ba^{+}$) produced in the $0\nu\beta\beta$-decay (called Ba-tagging) is ongoing [249–251]. PandaX-III, an R&D program for a future, enriched PandaX-xT detector, operates a high-pressure Xe gas TPC, where the xenon is mixed with 1% trimethylamine (TMA) to ensure stable operation of the Micromegas employed in the readout planes, and to minimise electron diffusion [252, 253]. Experimental searches for $0\nu\beta\beta$-decay are discussed in more detail in *Section 14.9*.

Apart from enriched xenon detectors, large TPCs using xenon in its natural isotopic abundance are also sensitive to second-order weak decays, such as the double beta decay of ^{134}Xe and ^{136}Xe, and the double electron capture process in ^{124}Xe and ^{126}Xe. In its electronic recoil channel, XENON1T observed for the first time the 2νECEC process in ^{124}Xe by detecting the simultaneously emitted K-shell X-rays/Auger electrons of the daughter atom ^{124}Te with a combined energy of 64.33 keV, which is twice the K-shell binding energy [191,254]. The decay has also been observed by LZ [192] and PandaX-4T [193]. With a half-life around 1×10^{22} y, this is the slowest process ever measured directly. The double electron capture in ^{124}Xe can also be studied with high-pressure xenon gas TPCs, as demonstrated by NEXT [255]. LZ, PandaX-4T and XENONnT will improve upon existing results and will also search for the $2\nu\beta^+$EC decay. This channel has a distinct signature due to the two 511 keV gammas emitted after the positron annihilates with an electron in the medium. With a predicted half-life around 1.6×10^{23} y [256] its first observa-

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

tion is within reach of these running experiments, which will also measure the half-life and in particular also the shape of the $2\nu\beta\beta$-decay of ^{136}Xe with high statistics and at low energies not previously accessed. The current generation of dark matter detectors can also set constraints on the $0\nu\beta\beta$-decays of ^{136}Xe and ^{134}Xe, as predicted or shown in [191, 257–261], delivering proof-of-principle methods towards higher sensitivity searches in XLZD and PandaX-xT. As an example, with 80 t of natural xenon in a TPC, a ^{136}Xe half-life exclusion sensitivity of 1.3×10^{28} y (90% C.L.) can be reached after ten years of operation [262, 263], fully probing the inverted neutrino mass ordering scenario.

36.5 Sub-kelvin detectors

Revised October 2025 by O. Cremonesi (INFN, Milano-Bicocca), L. Hsu (FNAL) and G. Signorelli (Pisa U.; INFN, Pisa).

36.5.1 *Motivation for Sub-kelvin Detectors*

Detectors operating below 1 K are referred to as low-temperature detectors (LTDs). The advantage of using LTDs over conventional detectors resides in their better energy resolutions, lower noise, and improved energy thresholds, which can all be achieved with a versatile choice in materials. In certain applications, these advantages outweigh the potential drawbacks of cooling and reading out a detector payload at sub-kelvin temperatures, and thus enable exploration of new frontiers in fundamental physics, astrophysics and cosmology. Among the endeavors enabled by LTDs are direct searches for dark matter over a wide mass range, precision experiments to measure the electron neutrino mass, searches for neutrinoless double-beta decay, and X-ray observation of the Universe. Large arrays of LTDs are also employed to measure the properties of the cosmic microwave background (CMB) spectrum whose parameters are determined by fundamental physics. These include dark matter and dark energy densities, the sum of neutrino masses and the number of light relativistic species, as well as probing the physics of inflation at energy scales of $\sim 10^{16}$ GeV. This article presents a brief overview of LTDs, their features, and several applications. More detailed treatment of this subject is available in the literature [264–267].

The advantages of LTDs are enabled by the detection of very low energy excitations (e.g. phonons and quasiparticles). In a typical interaction, energy from an incident particle is dissipated through excitation of secondary particles such as electrons, ions, holes, photons, phonons etc. These particles will in turn produce their own secondaries. Thus there is a cascade down in energy until the original energy deposit is converted entirely into heat and the detector reaches thermal equilibrium. Prior to the equilibrium phase, the energy at any given moment is partitioned among multiple excitation modes. Conventional particle detectors work by sensing the higher energy excitation modes, such as ionization and scintillation, which require an average minimum energy of few eV to 10's of eV to produce. For such detectors, a large fraction of the deposited energy remains undetected in the form of heat. Furthermore, the measurements are subject to the fluctuations inherent in the partition of energy across different excitation modes. Secondaries that don't eventually escape the detector, will de-excite or recombine to dissipate their energy in the form of phonons and quasiparticles, which are characterized by energies in the range of meV down to μeV. These can be detected by LTDs at various stages of their final degradation towards thermal equilibrium. Thus LTDs allow for energy resolutions and operational thresholds much lower than detectors that only sense scintillation and ionization. Furthermore, LTDs provide a precise energy measurement owing to the relatively large number of excitation quanta that can be detected. In fact, LTDs designed to measure thermal phonons achieve the highest possible energy resolutions with optimal noise performance.

At thermal equilibrium, energy E deposited in an LTD causes a temperature rise $\Delta T = E/C$ where C is the heat capacity. Thermal equilibrium is characterized by the condition where the average heat flowing to an LTD equals the average heat flowing from the LTD (into a proper heat sink or bath). In this state, the ideal intrinsic energy resolution is determined by the statistical fluctuations in the phonon system. Fluctuations in the total number of phonons in the LTD absorber have variance C/k_B, which yields a minimum resolution of $\Delta E^2 = k_B T^2 C$ to the device energy resolution, where k_B is Boltzmann's constant. Thus, the smaller the heat capacity, the more sensitive the response of the calorimeter and the better the energy resolution. The most relevant feature of this result is that the latter is independent of the energy deposition. The heat capacity itself is the product of the detector volume (V) and the specific heat (c_p). Optimization of LTD response can be achieved by using small detector volumes and materials with low specific heat. Noise contributions from additional sources will increase the variance and are generally parameterized as a multiplicative factor ($\xi \gtrsim 1$) to the variance expression above.

Similarly, the power P from incident particles or radiation can be measured through a temperature rise given by $\Delta T = P/G$, where G is the thermal conductance to a weakly linked bath held at constant temperature. Power fluctuations are limited by G and have a spectral density of $S_P = NEP^2 = 4k_B T^2 G$, where NEP is the noise equivalent power, defined as the power in a 1 Hz bandwidth that gives a response signal with an amplitude equal to the noise. Hence lower conductance yields better sensitivities. To minimize thermal conductance in precise power measurements, weak thermal links can be realized by using thin membranes or by decoupling the electron and phonon systems. However, a compromise must be made. While lower G yields better noise metrics, conversely, larger G is needed to dissipate all incident power (which can be large in the case of CMB detectors) or to have a faster detector response (the characteristic response time being $\tau = C/G$).

LTDs that measure power are sometimes referred to as *bolometers* in literature, as opposed to *calorimeters* that measure energy, generating some confusion. In principle, there is no clear distinction between a calorimeter and a bolometer. The operation mode is generally determined by the ratio of the characteristic time constant and the average time between the arrival of incident particles or quanta [268].Yet another convention is to refer to *non-equilibrium* LTDs as those detectors that measure incident energy or power by counting excitations that have energy $\gg k_B T$. In such detectors, energy resolution is determined by the statistical fluctuations of the energy partition, similar to conventional ionization detectors but with a much lower average excitation energy and hence a larger number of excitation quanta.

Table 36.7: Low temperature dependence on temperature (T) for specific heat, based on different material classes. In the table below Θ_D is the Debye temperature and T_C is the transition temperature of the superconductor.

Heat Capacity	Material
$\propto \left(\frac{T}{\Theta_D}\right)^3$	Dielectric and diamagnetic
$\propto T$	Conductor
$\propto \exp\left(-\frac{2T_C}{T}\right)$	Superconductor
$\propto \left(\frac{\mu_B B}{k_B T}\right)^2 \operatorname{sech}^2\left(\frac{\mu_B B}{k_B T}\right)$	Paramagnet (in magnetic field **B**)

A variety of possible detector materials and sensor technologies makes LTDs very versatile and highly customizable. Dielectric, superconducting and paramagnetic materials are often used owing to the fact that at very low temperatures, the specific heat decreases strongly as a function of T (see table 36.7). Superconductors offer additional advantages: the abrupt change in resistance when a material transitions from its normal to superconducting state enables highly sensitive measures of temperature changes. Additionally, the existence of a small (less than a meV) but distinct energy gap that is required to break a Cooper pair, provides a means to measure energy deposits by counting the resulting quasiparticles (QP). QP relaxation processes are typically faster than thermal processes making these detectors suitable for high-rate photo-counting. In summary, both the sensitivity and

energy resolution of an LTD benefit greatly from low temperature operation.

36.5.2 *Detector Types*

A generalized LTD calorimeter consists of an absorber in thermal contact with a phonon or quasiparticle sensor, and a thermal link to a heat bath at a constant temperature (see figure 36.11). The absorber provides the mass necessary for the interaction of the particle and a fast and complete thermalization of the deposited energy. The sensor accomplishes the task of translating the particle interaction into measurable parameters. It is generally sensitive to equilibrium phonons (e.g. thermistors and MMCs) and thus provides a precise measurement of the temperature. However, non-equilibrium (e.g. STJ's or KIDs) and mixed (e.g. TES) phonon sensors have been devised and implemented in many applications as well. The goal of the thermal link is to cool the absorber down to its equilibrium temperature after the absorption of a particle. In monolithic detectors the thermometer and absorber are identical, while in composite detectors the thermometer is attached to a separate absorber. This basic design applies to single-event particle detection as well as for continuous radiation measurement devices. In the case of the latter, a suitable absorber whose mass is irrelevant, *e.g.* an antenna at the end of a waveguide, collects the incident power and dissipates it onto a resistive (*e.g.* Au) film, which is put in contact with a sensor capable of detecting tiny temperature changes (e.g. semiconductor thermistors, transition-edge sensors, and kinetic inductance detectors, to name a few).

Superconducting Tunnel Junctions (STJs) and Kinetic Inductance Detectors (KIDs) are examples of non-equilibrium detectors. STJs exploit tunnelling of particles and QPs between two superconductors. The superconductors act as radiation absorbers, and are separated by a thin insulating layer. When such a junction is DC biased at a voltage just below the gap voltage, the excess quasiparticles generated by the incoming radiation are detected as a tunneling-current proportional to the incoming energy. Statistical fluctuations in the tunnelling process limit the energy resolution which is given by:

$$\sigma_E = \sqrt{\varepsilon(F+G)E_0}, \tag{36.5}$$

where $\varepsilon \sim \Delta$, the band-gap, while $F \sim 0.2$ and $G > 1$ are the Fano factor and tunnelling fluctuation respectively. STJs have been proven to be excellent single photon and UV-VIS spectroscopic detectors with near theoretical energy resolutions, high detection efficiencies and excellent time resolution. In astrophysics they are used as mixers to detect radiation in the 100 GHz to 1 THz range by exploiting the non-linear behaviour of their current versus voltage characteristic curve. Despite their extremely good energy resolutions, STJs cannot be scaled-up to produce sensors with large observing volumes due to readout complexity and the difficulty in uniformly suppressing the superconducting Josephson current, which is superimposed on the QP current.

Qubits share similar design elements as STJs. Using a Josephson Junction (JJ, a thin normal layer separating two superconductors) as a non-linear inductor in a superconducting LC circuit, it is possible to realize a two-level system whose status can be read out by a suitable superconducting circuit [269]. When qubits are coupled to a resonant cavity, they can be used as ultra-sensitive detectors of electromagnetic radiation, especially in the microwave regime. Incident radiation can interact with the cavity field, inducing a measurable shift in the qubit's energy levels through dispersive coupling. This interaction alters the qubit's transition frequency or induces excitation, depending on the setup, which can be read out via high-fidelity quantum measurement techniques. Similarly, qubits can be patterned onto large absorbers such as silicon or sapphire in order to detect energy depositions of less than an eV, which may arise from scatters of dark matter or neutrinos [270–272]. A particle interaction in the absorber will down-convert to sub-ballistic phonons. Those that diffuse into the JJ may tunnel across it, thus altering the qubit's state. Such qubit systems are particularly useful for detecting weak signals, such as single microwave photons or very low energy particle interactions, making them powerful tools in quantum sensing for astrophysical or dark matter detection experiments [273].

KIDs exploit the variation of the kinetic energy T stored in a superconductor by Cooper pairs whose inertia acts as an effective inductance, given by:

$$T = \frac{1}{2}nm^*v^2 = \frac{1}{2}LI^2 \tag{36.6}$$

where n is the number density of Cooper pairs, $m^* = 2m_e$ is the Cooper pair mass and $I = 2nev$ is the Cooper pair current. $L = m_e/2ne$ is defined as Kinetic Inductance and is inversely proportional to the number of Cooper pairs [274]. When a KID is placed in series with a superconducting capacitor, the resonance frequency of the circuit will be temporarily shifted by incident radiation, which converts Cooper pairs to QPs, thus changing the effective inductance. The presence and amount of radiation is observed as a change in amplitude or phase of a tuned sinusoidal signal that is sent through the circuit. In practice the change in L is small, and very high Q microwave resonance circuits are needed to sense this variation (hence the name MKIDs, for Microwave-KIDs). Furthermore, only areas of the film where large currents are flowing will be sensitive to pair breaking, thus making the response of a distributed KID position dependent. To overcome this issue, QP trapping (by coupling two superconductors with different band-gaps) is used for absorbing optical photons and X-rays. To detect lower frequencies (*e.g.* in the 100-1000 GHz range for CMB) a lumped element resonator (LEKID), with little current variation across the device, is used. The device itself, based on a series LC circuit inductively coupled to a microstrip feed line, can act as the absorber as well as the sensing element in a detector system. Macroscopic devices (few mm^2) can be fabricated by shaping the inductor in the form of a meander coupled to an inter-digitated capacitor [275]. The theoretical noise limit of these devices is governed by generation-recombination noise and takes the form:

$$NEP_{QP} = 2\Delta\sqrt{\frac{n_{QP}}{\tau_{QP}}}, \tag{36.7}$$

where n_{QP} and τ_{QP} are the QP number and lifetime respectively. KIDs are easy to fabricate, very sensitive, broad band and easily multiplexable: they can be coupled with a single microstrip that simultaneously reads 1000s of detectors resonating at different frequencies. They provide therefore a promising solution for deploying large arrays of detectors with applications to high-energy physics, astronomy or CMB measurements, although there are still some challenges, especially at frequencies below 100 GHz, related to their worse noise performance when compared to other LTDs, and to the choice of materials with a sufficiently small energy-gap.

Semiconductor thermistors are resistive elements characterised by a strong dependence of the resistance on the temperature. Usually, they consist of small crystals of germanium or silicon with a dopant concentration slightly below the metal-to-insulator transition. However, they can also be realized in the form of amorphous films such as NbSi. At low temperatures, their resistivity (ρ) is governed by variable range hopping (VRH) conduction and is described by the expression $\rho(T) = \rho_0 \ \exp\left((T_0/T)^\gamma\right)$, where T_0 and ρ_0 are parameters controlled by the doping level, while γ depends on the compensation level K (ratio of acceptor to donor concentrations). For low values of K, γ is well approximated by 1/4 while it converges to 1/2 as K increases.

Semiconductor thermistors are high impedance devices (1–100 MΩ) whose performance is usually parameterized in terms of the logarithmic sensitivity $\alpha = \mathrm{d}\log R/\mathrm{d}\log T$, typically in the range of 1–10. Silicon thermistors are fabricated using a multiple ion implantation process in high purity silicon wafers to produce a thin and uniformly doped box-like volume. The best germanium thermistors are fabricated starting from bulk, high-purity germanium crystals doped by means of neutron irradiation in the core of a nuclear reactor, referred to as nuclear transmutation doping (NTD). Individual sensors are then produced by dicing the irradiated samples and finishing them by hand. The great advantage of NTDs is the highly uniform doping level over large volumes which results in a better signal to noise ratio with respect to other doping

Int. J. Mod.

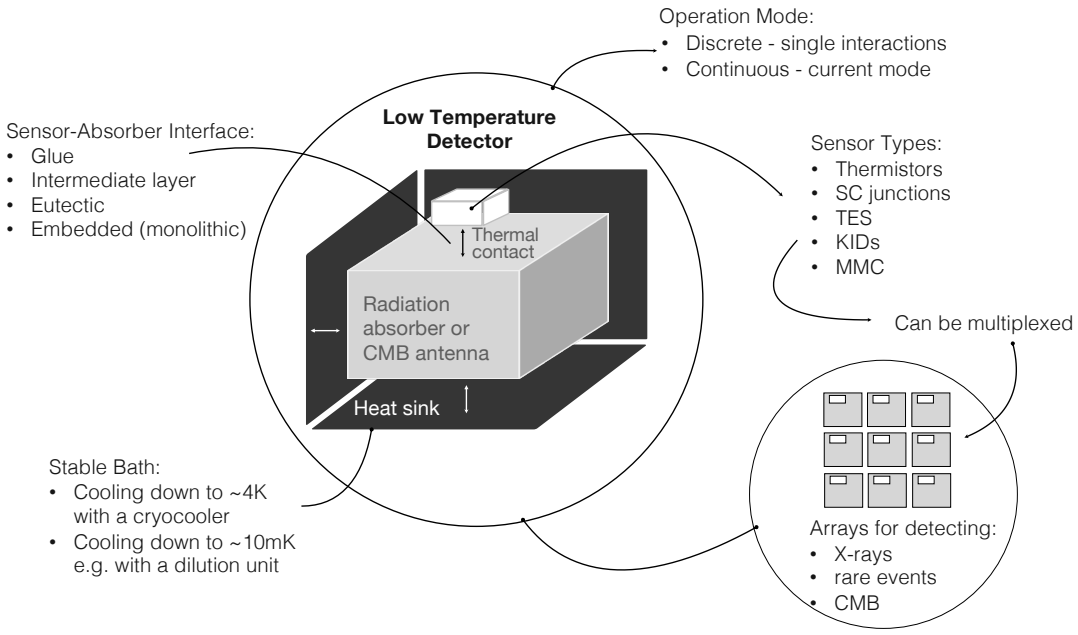

Figure 36.11: A generalized LTD consists of an absorber, a sensor and a thermal link to a stable-temperature bath. Biasing schemes and readout is described in detail in the text for individual sensor types.

techniques. The doping level depends on the isotopic composition of the starting material and the irradiation time.

The weak coupling to the heat sink can be provided by the electrical leads used for the read-out. However, nowadays microelectronic planar technologies and silicon micromachining are more commonly preferred, and sensors are suspended on thin silicon nitride membranes or thin silicon beams. Thermistors are read-out in an approximately constant current biasing configuration obtained by inserting large load resistors in the bias circuit, which allows for direct conversion of the thermal signal (ΔT) into a voltage signal (ΔV).

Semiconductor thermistors are very practical to use with some drawbacks. One of these is related to their high impedance which requires a JFET front-end placed as close as possible to the device in order to minimize the signal integration on parasitic electrical capacitances. This can represent a technical challenge, because JFETs must be maintained at significantly higher temperatures ($\gtrapprox$100 K). Furthermore, deviations from the exponential behaviour of the conductivity have been observed at low temperatures. They are usually described in terms of a finite thermal coupling between electrons and phonons which results in an intrinsic limit to the signal rise times, which is of the order of hundreds of milliseconds at temperatures below 100 mK. Nevertheless, semiconductor thermistors are an established and robust technology, and arrays of detectors based on these devices have been widely used for neutrinoless double beta decay searches, neutrino mass measurements and X-ray spectroscopy. Energy resolutions lower than 5 eV have been achieved with Sn or HgTe absorbers.

Superconducting Transition Edge Sensors (TESs) exploit the sharp transition between superconducting and normal conducting phases, yielding a high sensitivity to temperature variations. Temperature perturbations, and hence resistance changes, are sensed as modulations in the current through the TES. TESs are operated in a constant voltage biasing configuration where Joule heating, arising from the current flowing in the TES, decreases with a rise in resistance, which then brings the TES back to its nominal operating temperature. This electrothermal feedback (ETF) is achieved by providing a TES with a voltage bias whose power, $P_J = V_{\rm bias}^2/R(T)$, heats the TES to its nominal operation point, the superconducting transition temperature. Operation in ETF mode improves linearity, speeds up response (to faster than $\tau = C/G$), and in some cases it provides tolerance for $T_{\rm C}$ (critical temperature) variation between multiple TESs in a large array. The low impedance in this configuration makes them well-suited for readout by SQUID (Superconducting QUantum Interference Device) based amplifiers. Logarithmic sensitivities $\alpha = {\rm d}\log R/{\rm d}\log T$ of the order of several hundreds can be achieved. By using different superconductors, or superconductor-metal pairs patterned in suitable shapes, a wide range of resistances, transition temperatures and time constants are obtainable to meet the requirements of the desired application [276].

Nano-TESs are fabricated by lithographic techniques in the form of long (few μm) and narrow (nm) wires that exhibit extremely small NEPs due to their reduced C and G, enabling single-photon sensing. Superconducting Nanowire Single-Photon Detectors (SNSPDs) are similarly patterned superconductors or superconducting bilayers maintained at a temperature well below their $T_{\rm C}$. When a DC current just below the critical current is driven through the nanowire, the absorption of a single photon causes the formation of a hot spot that drives the superconductor to a normal conducting state, resulting in a very fast (tens of picoseconds) current pulse through a shunt resistor. For this reason, nano-TESs and SNSPDs are used as single photon detectors for light dark matter and axion searches in applications where large detecting mass is not critical [277].

Magnetic Metallic Calorimeters (MMC) exploit paramagnetic sensors exposed to a weak magnetic field with a weak thermal link to a heat bath. A temperature rise causes a change in the sensor magnetization, which is sensed by a SQUID magnetometer. A common material is an Au:Er mixture, with the addition of a few hundred ppm of enriched ^{166}Er, which is needed to reduce the unwanted contribution of nuclear magnetic moments of other Er isotopes. The read-out is non-dissipative and avoids the noise sources common to the dissipative devices. The use of a metallic host ensures relatively fast time response, since the typical spin-electron relaxation times are of the order of 0.1 microseconds at $\sim$50 mK [278]. For an optimized MMC, the energy resolution is given by $\Delta_E = \sqrt{2k_B T^2 C}\,(\tau_0/\tau_1)^{1/4}$, where τ_0 (order of micro second) and τ_1 (order of milli second) denote the signal rising and decay times respectively [264]. In order to obtain a fast and efficient energy thermalization, MMC are typically fabricated from gold. The intrinsically large heat capacity of the paramagnet does

not spoil the temperature sensitivity and allows the use of relatively large gold absorbers without degrading the device performance. Furthermore, thermal isolation from the heat sink is not generally an issue. Owing to the simple concept of these devices, MMC can be precisely customized and fabricated by employing standard microtechnology. Planar MMC arrays characterized by an excellent energy resolution, large dynamic range and good linearity have been successfully used for the detection of soft X-rays.

Performance and technological constraints limit the maximum size of LTDs. To improve overall experimental sensitivities, a large number of sensors must be deployed, typically at temperatures of a few tens of mK, where cooling power is limited to a few μW. To reduce the readout complexity and the heat load at the colder stages, multiplexing (MUX) techniques are often employed. Multiplexing consists of reading multiple detectors out through a limited number of lines that traverse room temperature to cryogenic temperatures [279]. In frequency-domain multiplexing (FDM), a tuned superconducting LC circuit is placed in series with each sensor, and a frequency comb of AC biases (usually in the MHz range) is sent to a group of sensors in parallel. A synchronous demodulation of the amplified current signal allows the recovery of the resistance variation of each detector. Microwave-multiplexing (μMUX) represents a variation of this concept, based on the usage of rf-SQUIDs, where the frequency comb is in the GHz range. Alternatively, the signal from a single detector can be recovered by readout of one detector at a time (time-domain multiplexing, TDM). KIDs have been gaining popularity owing to the fact that they naturally form resonant circuits, hence multiplexing in the frequency domain is readily achieved by adjusting their capacitance.

36.5.3 *Experimental Applications*

LTDs are sensitive over a wide range of energy, from centimetre wavelength ($\sim$ meV) through the visible spectrum ($\sim$ eV) up to the X-ray domain ($\sim$ keV) and beyond. Several broad categories of LTD applications towards measurements of fundamental physics are described in more detail in the text below and summarized in tables 36.8 and 36.9.

Bolometric detectors are favored as microwave detectors owing to their nearly constant response over frequency, playing an important role in far-infrared astronomy and in the survey of the cosmic background radiation. The high-frequency instrument of the Planck satellite (HFI) used spiderweb bolometers read by NTD-Ge thermistors, but current experiments use mainly TESs or, more recently, KIDs. Depending on the objective of the experiment, antenna coupling or absorber coupling is used. In the former case, the bolometer detects one polarization and one (or a few) modes of the radiation, while absorber-coupled bolometers do not distinguish between polarizations. In order to avoid the absorption or emission from Earth's atmosphere, many (CMB) instruments are operated by observatories located at high altitude, dry places (such as the Atacama desert or Antarctica), balloon-borne platforms, or from space. In Table 36.8, we list a subset of the ongoing or planned CMB experiments (see Section 29 of this Review for the details on present challenges).

In the Atacama Desert, CLASS continues to collect data and has recently reported large scale E-mode polarization measurements and constraints on reionization [280], while Advanced ACT-Pol observations (2017–2022) continue to yield new maps and cosmology results [281]. POLARBEAR-2 (PB2-A), part of the Simons Array [282]. The Simons Observatory has achieved first light and is operating [283]. At the South Pole, SPT-3G, BICEP3, and the BICEP Array remain active with new results and ongoing receiver deployments. The CMB-S4 project, initially envisioned as the next-generation ground-based CMB survey with unprecedented sensitivity and scale, has been cancelled, and the project is proceeding with an orderly shutdown. In the Canary Islands, QUIJOTE and GroundBIRD are operating, while LSPE-STRIP is nearing construction [284, 285]. In Argentina, QUBIC resumed operations in 2025 and began sky calibration [286]. In Tibet, AliCPT-1 completed its first phase and captured initial 150 GHz images of the Moon and Jupiter. Among stratospheric balloon experiments, SPIDER has flown twice (2015 and 2022/23), EBEX flew in 2012–13, and LSPE/SWIPE remains in advanced development. Finally, in space, LiteBIRD remains in development with a launch targeted for the 2030s [287], and PICO (Probe of Inflation and Cosmic Origins) has been proposed as a NASA flagship mission concept to provide complementary full-sky, high-sensitivity CMB polarization measurements.

The incoming radiation couples directly to the antenna probes (as in BICEP/Keck) or through micro-machined horn waveguides (AdvancedACT-Pol, CLASS) or lenslets (Simons Array, SPT-3G), depending on the frequency range. All of these experiments have focal planes with hundreds to hundreds of thousands of sensors. To optimize focal plane occupancy, multi-mode or multi-chroic, dual polarization sensitive detectors are used. In the former case, the sensitivity is enhanced by collecting power from a larger number of modes at the expense of angular resolution. In the latter, one single mode of the radiation is focused on a broad band antenna, and on-chip polarization separation and band-pass filters split the signal in different frequency bands directing the power to different absorbers and sensors.

Experimental design is driven by a trade-off between the sensitivity and the complexity of the production processes and readout. On the one front, single-sensor NEP at the level of 10^{-21} W/$\sqrt{\text{Hz}}$ has been achieved in laboratories and research centers. Meanwhile, efforts are in place for the industrialization of the fabrication processes, which is essential for scaling up production for the large number of detectors needed for future experiments.

Massive cryogenic calorimeters have been proposed since the 1980's as particle detectors for the search of rare processes (e.g. dark matter, neutrinoless double beta decay) [288]. Almost simultaneously, the use of arrays of small mass calorimeters was suggested for X-ray astrophysics [289] and precision measurements of the neutrino mass [290, 291]. Although essential to understanding the nature of neutrinos, neutrinoless double beta decay (NDBD) has eluded discovery (or definitive exclusion) for over 50 years. Calorimeteric techniques provide the best sensitivities to NDBD. However, before the advent of low temperature calorimeters (LTC), only a few isotopes (^{48}Ca, ^{136}Xe and ^{76}Ge) could be utilized for NDBD studies with the calorimetric approach. This limitation was removed by the advancement of LTC's, and in particular by CUORE, which takes advantage of the naturally high abundance of ^{130}Te in TeO_2 crystals. Additionally, the operation of CUORE at LNGS [292] has demonstrated that the technical challenges of operating ton-sized LTD detectors in a deep, underground location are surmountable. Currently, the most promising future approach is based on the hybrid approach of scintillating LTCs, which unfortunately cannot be used for ^{130}Te. Now, new projects are being proposed based on different scintillating compounds. In particular ^{100}Mo is the choice of CUPID [293, 294] (NTD thermistors glued to $Li_2{}^{100}MoO_4$ crystals), which will use the same infrastracture of CUORE and follows from the successful operation of several demonstrators (CUPID-0 [295] and CUPID-Mo [296]), and AMORE (MMC sensors on $Ca^{100}MoO_4$ or $Li_2{}^{100}MoO_4$ crystals) [297]. With an energy resolution comparable to germanium diodes and a mass of the order of a ton, these experiments aim to probe the inverted hierarchy of neutrino masses. Extremely pure materials, careful assembly procedures, and deep underground laboratories are therefore necessary. These detectors are characterised by relatively slow responses, which still represent a major limitation for some of the proposed applications.

In the 1980's, the calorimetric technique was recognized as a feasible approach to make a direct measurement of the neutrino mass from the end-point of a beta spectrum. Thus, LTCs were proposed as a possible alternative to the standard spectrometric measurements [298]. Calorimetric measurements offer a number of advantages [299]: i) a weak dependence on the final excited states, ii) no source effects (e.g. self-absorption), and iii) lack of back-scattering from the detector. Therefore LTCs provide a faithful reconstruction of the beta spectral shape over a broad energy range below the end-point. However, the difficulty in resolving a small fraction of the spectrum near the end-point is a serious limitation that strongly constrains the source strength and the statistics that need to be accumulated. Such an inconvenience can be mitigated by selecting beta emitters with a small Q value, owing to the fact that the fraction of counts in an interval,

Table 36.8: Some selected experiments using LTDs to measure the CMB. These experiments constrain the physics of inflation and the absolute mass, hierarchy, and number of neutrino species. The experiment location determines the part of the sky that is observed. The size of the aperture determines the angular resolution. The table also indicates the type of sensor used, the number of sensors, the frequency range, and the number of frequency bands. Data for planned upgrades or future experiments are provided in parentheses.

δ close to Q, scales as $(\delta/\mathrm{Q})^3$. However, this is generally at the cost of choosing decays with more complex nuclear transitions. In addition, LTCs may be affected by specific systematics (e.g. solid state effects). Ultimately it is recognized that spectrometers and calorimeters have complicated but different systematic effects. It is therefore critical to develop complementary experiments exploiting both techniques.

LTCs were initially proposed as perfect calorimeters to measure the energy spectrum of a low Q beta emitter embedded in an absorber. However, the requirements of excellent energy resolution and a low rate (to avoid pileup) requires a very large number, $\mathrm{O}(10^4 - 10^6)$, of small mass devices (micro-calorimeters). Early experiments used ^{187}Re, which is a long-lived beta emitter that is naturally abundant in rhenium samples and is characterised by a very low Q value (2.4709 keV [300]). A large number of ^{187}Re based experiments have been developed over the years (MANU [301], MIBETA [302], MARE [303]). Nowadays a different approach is preferred and is based on the measurement of the atomic radiation following electron capture, typically in ^{163}Ho which is also characterized by a very low Q (2.837 keV [304]). Different experiments have been proposed to face the challenge: ECHo in Germany [305] (using MMC sensors), HOLMES in Italy [306] and NUMECS [307] in the US (using TESs). LTCs are also included in PTOLEMY's proposal, whose main purpose is to detect relic neutrinos, but which also includes an initial stage dedicated to measuring the mass of neutrinos [308]. The very large number of microcalorimeters needed to obtain sensitivities comparable to spectrometric measurements is a serious challenge, both for the readout and the thermal heat load. An alternative readout based on the use of KIDs, for their multiplexing capability, has been proposed and is presently under development.

Traditional searches for WIMP-like dark matter aim to measure the scatter of a massive (>10 GeV/c^2) dark matter particle off of a target nucleus. Similar to detectors employed for neutrinoless double beta decay, these searches benefit from large-mass absorbers for the target because the dark matter interaction rate scales directly with the number of nuclei in the target and hence its mass. Among the most successful experiments to date, are those that combine the detection of phonons with another channel such as ionization energy (EDELWEISS [309] and SuperCDMS [310]) or scintilation light (CRESST [311]). This simultaneous, dual measurement takes advantage of the fact that the energy deposited in the absorber is partitioned into these channels differently depending on whether the initial particle interaction produces electron or nuclear recoils (or both). This particle identification allows for the rejection of background from natural sources of radiation, which most commonly manifest themselves as electron recoils in the detector.

In recent years, multi-ton liquid noble detectors have outclassed LTD-based technologies in searches for heavy dark matter owing to their ability to more easily and cheaply scale to large target masses. However, the lower thresholds achieved by LTDs continue to make them the technology of choice for low-mass dark matter searches. New advances have enabled these detectors to reach much lower energy thresholds than previously obtained, albeit sometimes at the cost of being able to detect energy in more than one channel as described above. For example, the use of an electric field to generate Neganov-Trofimov-Luke [317, 318] phonons in proportion to the applied voltage, has enabled the detection of single electron hole pairs in detectors with thresholds as low as a few eV (SuperCDMS HVeV [319], EDELWEISS_SubGeV [320]) and is proposed for the CUPID light detectors [321]. These advances have enabled sensitive searches for dark photons and dark matter that scatters off electrons. Next generation experiments such as TESSERACT aim to further optimize the intrinsic energy resolution of TES detectors, coupled with a strategic choice of target materials (He, GaAs) to enable sensitivites to dark matter with masses below an MeV/c^2 [322]. KIDs can be also applied to readout silicon dice to be sensitive to GeV DM, as in the BULLKID [323] proposal. Current state-of-the-art axion searches use SQUID based quantum amplifiers such as Josephson Parametric Amplifiers along with resonant cavities operating below 100 mK to look for a signal above fluctuations in the thermal noise [324,325]. Future axion experiments are also working to close the sensitivity gap between particle and wave-like dark matter with the help of LTDs. Broad-band axion searches in the THz range are being

Int. J. Mod.

proposed, which will make use of TES, SNSPDs or KIDs for single photon detection [326]. Finally, LTD-based dark matter detectors are also actively employed to study coherent neutrino scattering, owing to the fact that the hypothesized signal from dark matter-nucleus scattering is nearly identical to that from neutrino-nucleus scattering, with both inducing nuclear recoils in a similar energy range [327–330].

36.6 Low-radioactivity background techniques

Revised October 2025 by Al. Ianni (INFN, LNGS) and S. Schönert (TU Munich).

36.6.1 *Introduction*

The study of rare phenomena in fundamental physics, such as proton decay, neutrinoless double beta decay, dark matter, and MeV-scale neutrino interactions, requires extremely low levels of background radiation. Experiments searching for these rare events record electron recoils or nuclear recoils in the energy scale from a few eV to several MeV. The detector technologies used are multiple from organic and cryogenic liquid scintillators, to bolometers, solide state calorimeters, gaseous detectors, and crystal scintillators. As far as the background contamination is concerned at some extent the application defines the requirements, although the common denominator is that an extreme reduction of all background sources is essential. Leading experiments in rare events search have obtained in the region-of-interest (ROI) a background as low as $\sim 10^{-4}$ cts/kg/y/keV. As a first and crucial step, a dedicated radio-purity assay of the detector set-up components has to be carried out. Over the last fifty years, special screening and cleaning techniques have been developed to measure and mitigate ultra-low levels of background. In order to characterize the background sources we refer to Heusser [331] and identify the following five main categories:

- environmental radioactivity in the location where the detector is installed;
- radioimpurities in the detector and shielding;
- radon and its progenies;
- cosmic rays and induced radioactivity;
- neutrons from natural fission, (α,n) reactions, and from cosmic-ray muons interactions.

The energy range affected by these background sources is mainly <10 MeV. All materials contain traces of long-lived primordial radioimpurities, such as ^{238}U, ^{232}Th, ^{235}U (^{238}U/^{235}U $\sim$ 138), and ^{40}K (^{40}K/K^{nat} $\sim 1.17 \times 10^{-4}$). We recall that 1 *ppt* of ^{238}U and ^{232}Th corresponds to 12.36 and 4.06 μBq/kg, respectively; 1 *ppb* of K^{nat} corresponds to 30.25 μBq/kg. In the Earth's crust the abundance of uranium and thorium is of the order of $1-10$ ppm which corresponds to about $10-100$ Bq/kg. Taking into account these contamination levels and the low background requirements, a fundamental background reduction and mitigation is essential to carry out rare phenomena research.

Besides primordial radionuclides other radioactive elements are produced through interactions with matter of secondary cosmic ray particles. Among these so-called cosmogenic radionuclides we recall, in particular, ^{3}H, ^{14}C, ^{7}Be, ^{39}Ar, ^{42}Ar , and, in copper, steel and iron often used as shielding materials, ^{57,60}Co.

A third category of background source in our environment consists of anthropogenic radionuclides. These are artificially produced mainly through nuclear reactions in nuclear power plants, nuclear fuel reprocessing plants, and nuclear weapons testing. Anthropogenic background elements of concern for rare phenomena are ^{85}Kr, ^{137}Cs, ^{241}Am, ^{60}Co, and ^{90}Sr. The concentration of ^{85}Kr ($T_{1/2}$=10.76 y, Q_β=687 keV) in air has been slowly increasing since World War Two with a present activity of order 1 Bq/m^3. As a consequence ^{85}Kr is a crucial background in experiments making use of nitrogen, xenon, and argon from air.

Once detector components radioactive backgrounds have been assayed and reduced by a careful selection campaign, which can last several years, a further step to push the background level beyond the screening possibilities is needed to reach the required sensitivity. For this purpose special active vetos, purification methods, and offline analyses have been developed. A meticulous background understanding and mitigation is crucial to explain any possible signal excess which may be detected. Background mitigation techniques are based on:

- use of radio-pure materials that absorb ionizing radiation;
- identify radio-pure material for detector construction;
- perform advanced surface and sub-surface cleaning treatment;
- reduce muon flux with underground detector deployment and

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

using active vetos;

- exploit advanced detection and tagging techniques to discriminate signal from background.

In the following we describe radio-assay and background mitigation techniques developed and exploited in the framework of rare phenomena searches in deep underground laboratories.

36.6.2 *Radio-purity assay*

The radio-purity assay of detector components is a basic prerequisite to be carried out in low counting experiments. Several techniques are exploited for radio-purity assay. They are complementary to characterise the radio-purity of materials for shielding or core detector components. Next generation experiments radioassay campaign requires a considerable effort and organization for several years [332–335].

Gamma spectroscopy (GS) via high purity germanium (HPGe) detectors is a powerful and crucial technique [331]. It is nondestructive and thanks to the energy resolution allows to distinguish various radionuclides elements. Radiation from ^{238}U and ^{232}Th comes with all decay products in the radioactive chains. However, if secular equilibrium is broken, this crucial information can be addressed by separating different gamma-ray lines characterizing elements in the decay chains. In the ^{238}U chain one can have three sub-chains out of equilibrium. The first sub-chain can be assessed through ^{234}Th direct progeny of ^{238}U. The second sub-chain, which originates from ^{226}Ra, can be probed by ^{214}Pb and ^{214}Bi. A third sub-chain, which starts from ^{210}Pb, cannot be efficiently probed by GS, yet is of crucial importance and alternative methods must be used. In the ^{232}Th chain again one can probe two sub-chains which can be out of secular equilibrium: the first one through ^{228}Ac from ^{228}Ra; the second from ^{228}Th can be measured through ^{212}Pb, ^{212}Bi and ^{208}Tl. The technology for HPGe operated in deep underground counting facilities [336,337] or in shallow laboratories with an efficient active veto shielding [338] has been boosted to sensitivities of the order of 10-100 μBq/kg by carefully selecting detector components, electronics and sample handling systems. The HPGe screening method requires order of $\sim$ 0.1-a few kg of material, and weeks of acquisition to produce a reliable measurement.

A second crucial technique is based on inductively coupled plasma mass spectrometry (ICP-MS) [339]. This technique can probe primordial parent activities at the level of 1 μBq/kg. It is a destructive method and often needs special sample preparation on a small quantity of material. The ICP-MS does not measure the radioactive decay of isotopes but determines their concentration. At present, it is the most sensitive and rapid screening technique which allows to select materials at sub-ppt level of impurities. The drawback is that ICP-MS cannot assess whether the uranium and thorium chains are out of equilibrium and to reach ultra-high sensitivities one needs to carefully prepare and handle the samples in a cleanroom environment. ICP-MS screening must be coupled with other methods to properly assess the radio-purity of materials in the context of rare events searches. The Glow Discharge Mass Spectroscopy (GDMS) is a trace element analysis technique somehow alternative to ICP-MS. An advantage of GDMS is the possibility to determine the bulk composition of the sample, assuming homogeneity. Sensitivities of the order of 10 ppt can be achieved.

A third screening technique is based on neutron activation analysis (NAA) [340]. A sample exposed to a neutrons flux can be activated to form radioactive isotopes which can be detected using HPGe detectors or ICP-MS. Considering the difficulties to irradiate samples, this method is less often used. NAA can probe sensitivities at the level of 0.01 μBq/kg.

In case out of secular equilibrium conditions are measured for uranium and thorium from GS screening, a rigorous assessment cannot avoid radon emanation measurements. This matter is discussed in Section 36.6.3.

Complementarity between radio-purity assay techniques is a crucial parameter to design detectors for rare phenomena searches. As it has been pointed out above, requirements can be more stringent than the best sensitivity which can be obtained with the current radioassay techniques. In these cases, a number of prototype detectors have been built and operated to prove the feasibility to reach ultra-low backgrounds.

36.6.3 *Radon and its progeny*

Radon is considered to be rare in nature because most of its isotopes are short-lived. However, ^{222}Rn ($T_{1/2}$=3.82 d) is of particular concern in our context. ^{222}Rn is produced by ^{226}Ra and is a radioactive noble gas which can move within active detector components. ^{222}Rn daughters are heavy metals which can deposit on surfaces. Diffusive ^{222}Rn, supported by ^{226}Ra, can deposit on surfaces the long-lived ^{210}Pb, which is a major concern for low counting experiments. In addition, due to $\sim$100 keV nuclear recoil energies from alpha decays in the ^{226}Ra sub-chain, eventually ^{210}Pb can be implanted into a sub-surface layer of a material exposed to radon. This sub-surface contamination can remain even after surface cleaning. Surface contamination of ^{210}Pb is a serious background for direct dark matter experiments through alpha decay of ^{210}Po, which can generate neutrons by (α,n) reactions. Low energy beta/gamma emissions from ^{210}Pb are also a concern. Therefore, radon-free cleanrooms are essential for the assembly of the detector components. Effective radon abatement systems are available for this purpose. Air at the level of 1 mBq/m^3 of ^{222}Rn can be produced with such systems.

In assembling and commissioning rare events experiments, special care must be dedicated to the estimate of radon emanation of the materials and continuous radon monitoring. For this purpose different methods for radon assay have been developed and exploited since the beginning of solar neutrino observations. ^{222}Rn atoms are collected inside an exhalation chamber for several half-lives before adsorption and counting. Detection limits of the order of 100 μBq (about 50 ^{222}Rn atoms) can be obtained with $\sim$50 l stainless steel electro-polished chambers [341]. This limit can be pushed down to 30 μBq for 1-liter scale chamber. Emanation of large vessels (cryostats, storage tanks, purification columns) can be determined by collecting exhaled radon into transportable charcoal traps [342]. The same method can be used for liquid samples. In this case instead of evacuating the exhalation chamber into a charcoal trap, He is flushed through a sparger tube for about 10 times the volume of the liquid used. Sensitivities of the order of 10 μBq/kg have been reached. A novel technique of Rn emanation measurement developed in the framework of nEXO allows continuous gas transport and detection in a recirculation gas loop with an electrostatic chamber [343]. Another innovative method has been developed by using cryogenic physisorption traps [344]. Surface treatments can be exploited to enhance significantly the emanation measurement sensitivity and surface treatment with epoxy coating or covering it with alluminized Mylar is also shown to reduce emanation [345].

Nitrogen or synthetic air is often used in rare events experiments for purging, stripping, and assembling the experimental apparatus. These gases might contain radon. In gases ^{222}Rn can also be detected using electrostatic collection of ^{218}Po and ^{214}Po [346,347]. Sensitivities of the order of mBq/m^3 can be obtained. In Borexino three grades of nitrogen purity were used: regular purity, high purity, and low argon and krypton purity. The regular purity is obtained from boil-off gas and has radon, measured with the method reported above, at the level of $< 100\mu$Bq/m^3. For nitrogen stripping the purified liquid scintillator a higher purity is needed. To remove radon from regular purity nitrogen a dedicated absorber plant has been built. This system can reduce radon by a factor of 100. Finally, we mention that not only radon is found in nitrogen. For specific applications the long-lived ^{39}Ar and ^{85}Kr in nitrogen are an important source of background.

36.6.4 *Surface backgrounds*

Surface contamination of long-lived ^{222}Rn daughters can be challenging in low-counting experiments. Considering required sensitivities of the next generation experiments, this source of background has to be properly quantified and mitigated. Therefore, exposure to ^{222}Rn should be monitored and limited to reduce build-up of ^{210}Pb on surfaces. In addition, ^{222}Rn exposure could also produce sub-surface contamination as discussed in Section 36.6.3. For one cannot avoid radon contamination in many circumstances during production of detectors components, it is

Int. J. Mod.

crucial to quantify the effectiveness of cleaning aiming at removing surface contamination of ^{210}Pb, ^{210}Bi, and ^{210}Po. Depending on material, progeny are deposited deeper into the subsurface. A simple cleaning procedure, which implies degreasing, wiping, and rinsing the material surfaces is not effective in removing these surface contaminants. Studies of cleaning procedures have been carried out exposing stainless steel, copper and other materials (PTFE a common used material) to a strong radon source. Etching, leaching, and electropolishing with subsequential passivation and rinsing have been investigated in great details. Several recipes have been proposed [348,349]. Electropolishing has been shown to be very effective in reducing ^{210}Pb, ^{210}Bi, and ^{210}Po from both copper and stainless steel by a factor greater than 100. Etching, which is easier to perform than electropolishing, followed by passivation and rinsing with deionized water is effective in reducing ^{210}Pb and ^{210}Bi by a factor between 50 and 100. However, it is less effective for ^{210}Po, which in copper is very poorly reduced. Removing ^{210}Po from surfaces is crucial, therefore, naturally ^{210}Po contaminated copper and stainless steel surfaces have been deeply investigated with a high sensitivity ($1\,\mathrm{mBq/m^2}$) alpha spectrometer [350]. After multi-etching steps (≥ 3), followed by a passivation, a reduction of order 100 has been obtained. On the contrary, static etching (single step) is poorly effective. Electropolishing, or multi-etching are recommended in case copper is in direct contact with the active core of the detector and ultra-high radio-purity is essential or when copper electroforming cannot be used. Electroplating of a thin layer of high radio-pure copper onto the surface of less radio-pure copper has also been investigate to mitigate surface background [350]. This technique is shown to be efficient in reducing surface activity of ^{210}Po when electroformed copper is used [350].

Besides copper and steel other materials often used, such as polyethylene and teflon, have been investigated to understand how to reduce radon plate-out contaminations [351].

As far as surface contamination is concerned particulate fallout in cleanroom environments could be of concern. In general, chemical composition of dust reflects local composition of soil and dust. This is not necessarily true in cleanroom spaces, where the composition of dust depends on ongoing activities and handled materials [352]. The rate of fallout is an important information in the framework of rare events experiments, where assembling is performed in cleanrooms. The ^{210}Pb contamination, inferred from stable lead measured by ICP-MS, due to dust fallout has been investigated [352]. This contamination has a different origin with respect to ^{210}Pb from radon progeny implantation. Ultimately, one can conclude that radon exposure is more crucial than dust fallout. Therefore, the best practice for rare events experiments to face surface background contamination is to perform cleaning and assembling in a radon-free cleanroom environment.

36.6.5 *Mitigation of backgrounds and active background discrimination*

In this Section we discuss a selection of different background mitigation techniques used in experiments to search for rare events in deep underground laboratories. This includes both the avoidance or reduction of specific radioactive contamination, as well as active background suppression techniques based on specific event features and topologies.

- *Mitigation of ^{222}Rn daughters deposition.* In dark matter direct search radiogenic (α,n) reactions due to radioactive decays are of great concern. The emitted neutron can mimic a nuclear recoil induced by a dark matter particle interaction. In the DarkSide-50 and LUX-ZEPLIN (LZ) experiments to mitigate this background, cleaning of parts and assembling of the dual-phase Time Projection Chamber have been carried out in a radon-free cleanroom with ^{222}Rn activity of the order of $\lesssim 50\,\mathrm{mBq/m^3}$.
- *Underground argon.* Liquid argon is an excellent scintillator to search for dark matter interactions due to the high electron-recoils rejection power through pulse shape discrimination. Events from $\beta-\gamma$ background can be rejected at the level of 10^7 or better with respect to nuclear-recoils. Liquid argon is very effective as active shield and has been used in experiments for neutrinoless double beta decay. However, a major drawback for dark matter search using argon as a target is due to the fact that atmospheric argon contains about 1 Bq/kg of cosmogenic ^{39}Ar ($T_{1/2}$=269 y, Q_β=565 keV) [353]. For neutrinoless double beta decay search using argon as an active veto, ^{42}Ar ($T_{1/2}$=32.9 y, Q_β=599 keV) with its short lived progeny ^{42}K ($T_{1/2}$=12 h, Q_β=3525 keV) is a major source of background. ^{39}Ar limits significantly the dark matter and ^{42}Ar the neutrinoless double beta decay sensitivity search. Therefore, a source of argon with reduced ^{39}Ar and ^{42}Ar is crucial. Centrifugation or differential thermal diffusion are established methods to separate $^{39/42}$Ar and ^{40}Ar. However, this is an expensive method for a large fiducial mass. Argon from underground natural gas reservoirs is shown to contain low ^{39}Ar [354], and it is expected that ^{42}Ar is similar or even strongly reduced. Therefore, the use of underground argon mitigates the $^{39/42}$Ar backgrounds. DarkSide-50, with a mass of 150 kg of underground argon, has shown that this source of argon contains ^{39}Ar at a level reduced by a factor of $(1.4 \pm 0.3) \times 10^3$ with respect to atmospheric argon [355]. DarkSide-20k and LEGEND-1000 are planning to exploit underground argon from the Urania facility with a production capacity of order 300 kg/day [356]. The former to reduce ^{39}Ar and the latter ^{42}Ar.
- *Electro-formed copper.* High radio-purity copper is often used as shielding and as core detectors components. The radioimpurities in the copper can be a dominant source of external background. Copper electro-forming is a technique used to reduce this background component in rare events experiments. Copper electro-forming is a well known process to obtain ultra-high radio-purity copper. This technique has been used in the framework of the Majorana and LEGEND-200 experiments to search for neutrinoless double beta decay and in ANAIS to search for dark matter annual modulation. Sub-ppt levels in uranium and thorium have been achieved with electro-formed copper [334, 357].
- *Background suppression using topological event information.* In addition to rigorous selection of high-purity target and shielding materials from external radiation, additional active suppression techniques must usually be employed in low background experiments to achieve the appropriate experimental sensitivities. While signal and background events may be indistinguishable if only their energy deposition is measured, their event features may differ significantly in time and space. Liquid scintillators use the characteristic photon emission time distributions to distinguish between electron- and alpha-like signals [358] and nuclear recoils [359], respectively. High-purity germanium detectors use the time evolution of the induced charges to separate point-like signal candidates for neutrinoless double-beta decay events from background signals induced, for example, by gamma interactions with multiple interactions within a crystal, or from β or α events on the n+ or p+ electrodes [360]. The operation of bare high-purity germanium detectors in an instrumented liquid argon shield enabled the GERDA and LEGEND experiments to identify backgrounds with signal-like event topology within the HPGe detectors, but with characteristic energy deposition in the surrounding liquid argon. These synergistic background suppression techniques enabled for a first time ever a quasi background-free search for neutrinoless double beta decays with GERDA [361] and LEGEND-200 [362].
  EXO-200 [242] exploited topological event information distinghuishing single-site against multi-site events with a liquid xenon TPC for neutrinoless double beta decay in ^{136}Xe to reject background and threby enhancing signal discovery sensitivity. With a gas xenon TPC the NEXT experiment will fully exploit the differences in the spatial ionization patterns of double beta decay and single electron events [363]. The former is characterized by two Bragg peaks at opposite ends of the tracks, the latter on the contrary displays only one peak. The combination of topology information and good

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

energy resolution offer a powerful tool for background rejection. In general, the 3D reconstruction of detected events in a multivariate fit, which accounts for spacial surface and bulk distributions of signal and background together with other properties, such as pulse shape and topological features, is a powerful tool for background mitigation [364].

- *Signal selection in direct Dark Matter experiments.* In direct dark matter experiments electron recoil events have to be mitigated with respect to nuclear recoil events. In semiconductor bolometers, operating at a few tens of mK under a bias electric field and used as calorimeters, drifting charges produce a large phonon signal proportional to the ionization, which allows to discriminate electron recoils by the combination of charge and phonon signals [365]. In scintillating bolometers the phonon and light signals are used for the same purpose [366]. Cryogenic scintillators, such as xenon and argon, in time projection chambers offer a strong electron recoils background mitigation through the detection of a primary scintillation signal in liquid and a secondary signal in gas from the drift and extraction of ionization electrons. This background mitigation technique is also being used for neutrinoless double beta decay with ^{136}Xe. The accurate fiducialization and good rejection of multiple-scattering events allow dark matter optimized experiments to attempt a search for this very rare phenomenon.
- *Neutron tagging.* Present and next generation experiments need large neutron tagging detectors. In DarkSide-50 a dedicated active veto has been developed to both suppress and measure *in situ* the rate of neutron-induced background events [367]. The detector consisted of a boron-loaded liquid scintillator, which served both as shielding against γ-rays and as a tag for neutrons. Neutrons are thermalised and captured on ^{10}B. Experimental data has shown a neutron rejection power greater than 99.1% with 5% concentration of TMB in 30 tonnes pseudocumene-based liquid scintillator. The LZ direct dark matter detector with a central TPC of 7 tonnes of liquid xenon makes use of an outer Gd-loaded liquid scintillator neutron tagging veto, which works similarly to the DarkSide-50 veto, replacing boron with gadolinium. The 22 tonnes liquid scintillator is based on linear alkyl benzene (LAB) as solvent. This detector has been designed to operate with a neutron tagging efficiency greater than 95%. The nuclear-recoil background is reduced by a factor of 10. The XENONnT detector is making use of a cylindrical stainless steel tank filled with Gd-loaded water, which surrounds the cryostat with a TPC of 5.9 tonnes of active liquid xenon. The Gd concentration in water is 0.2% in mass. Neutrons leaving the TPC volume will be moderated and captured by the Gd with a probability of 91%. The gamma-rays emitted after the capture are detected from Cherenkov photons, providing a neutron tagging [368]. When operated with only demineralized water the efficiency for detecting neutrons is (82±1)% [369].

  Neutron tagging techniques are also crucial for coherent neutrino-nucleus elastic scattering detection from pion-decay-at-rest neutrino source at spallation sources [370, 371]. Neutrons can be produced in the Pb shielding from CC and NC interactions and propagate into the nuclear recoil sensitive volume, generating a beam-related background. Careful shielding design and implementation of neutron tagging is crucial.
- *Mitigation of cosmogenic background.* In recent years the required sensitivity to search for dark matter and neutrinoless double beta decay asks for a strong reduction of cosmogenic background. Muons can produce neutrons that can enter the active volume of the detector from the surrounding rock or from external detector components. The yield of these so-called *cosmogenic neutrons* depend on the muon energies and the material properties of the medium the muon passes through. In addition, muons can produce by spallation radioisotopes inside the detector active volume. Cosmogenic backgrounds are a function of depth and experimental design, and can limit the sensitivity to search for rare events. Most of these radioisotopes are short-lived and their effect can be easily removed by an active veto based on the time correlation with a crossing muon. However, a number of cosmogenic radioisotopes are long-lived and they require an important consideration. Mitigation of these cosmogenic backgrounds produced in-situ deep underground are a major challenge for upcoming and future experiments. Optimizing the detector design and analysis strategies at a given depth equals an effective muon flux reduction. In particular, we mention two discrimination techniques for muon-induced isotopes: 1) ^{11}C tagging by a three-fold coincidence between the crossing muon, the capture of the ejected neutron from ^{12}C, and the ^{11}C decay [372]; 2) similar delayed coincidence tagging can be exploited to mitigate the background due to ^{77}Ge and its metastable state ^{77m}Ge, which have been identified as dominant cosmogenic background in the search for neutrinoless double beta decay of ^{76}Ge [373].
- *Purification.* A number of high efficiency specific purification methods have been developed for different detectors in order to remove long-lived radio-isotopes, ^{39}K, ^{85}Kr, and ^{210}Pb progeny. For organic liquid scintillators, distillation and water extraction have been shown to be very effective to reach radiopurity levels of the order of $10^{-5}\mu$Bq/kg or better in uranium and thorium, and $10^{-3}\mu$Bq/kg in ^{210}Pb [374]. Distillation has been used to reduce ^{85}Kr in xenon by a factor of 10^3 [375]. Cryogenic distillation can be used to reduce the isotopic abundance of ^{39}Ar in argon extracted from underground with a 350 m column in the ARIA project [376]. Cryogenic distillation has been used in XENONnT to reduce online radon reaching a level of order 1 μBq/kg in the inner 5.9 tonne of liquid xenon [233]. For semiconductors [377] and scintillating crystals [378] zone-refining followed by single-crystal growth has been exploited to remove impurities at the cost of a small fraction of material kept after the purification.
- *Direct isotope tagging.* In neutrinoless double beta decay in order to explore half-lives greater than 10^{28} y one needs an almost background-free detector. The most robust signature is the identification of the daughter atom in the decay: for example, for ^{136}Xe, the $^{136}Ba^{2+}$. Important step forwards to establish a valid and promising method for this tagging have been recently made [379, 380].

37. Radioactivity and Radiation Protection

Revised August 2025 by S. Roesler (CERN) and M. Silari (CERN).

37.1 Definitions [1–3]

It would be desirable if legal protection limits could be expressed in directly measurable *physical quantities*. However, this does not allow quantifying biological effects of the exposure of the human body and its detriment to ionizing radiation.

For this reason, dose limits are expressed in terms of so-called *protection quantities* which, although calculable, are not measurable. Protection quantities are used to quantify the extent of exposure of the human body to ionizing radiation from both whole and partial body external irradiation and from intakes of radionuclides.

In order to demonstrate compliance with dose limits, so-called *operational quantities* are typically used, which aim at providing conservative estimates of protection quantities. Often radiation protection detectors used for individual and area monitoring are calibrated in terms of operational quantities and, thus, these quantities become "measurable".

37.1.1 *Physical quantities*

• **Fluence,** Φ (unit: $1/m^2$): The fluence is the quotient of the sum of the particle track lengths dl in the volume dV

$$\Phi = dl/dV \ .$$

It can also be expressed in terms of number of particles dN incident upon a small sphere of cross-sectional area da

$$\Phi = dN/da \ .$$

• **Absorbed dose,** D (unit: gray, 1 Gy=1 J/kg=100 rad): The absorbed dose is the energy imparted by ionizing radiation in a volume element of a specified material divided by the mass of this volume element.

• **Kerma,** K (unit: gray): Kerma is the sum of the initial kinetic energies of all charged particles set in motion by indirectly ionizing radiation in a volume element of the specified material divided by the mass of this volume element.

• **Linear energy transfer,** L **or** LET (unit: J/m, often given in keV/μm, 1 keV/μm $\approx 1.602 \times 10^{-10}$ J/m): The linear energy transfer is the mean energy, dE, lost by a charged particle owing to collisions with electrons in traversing a distance dl in matter. *Low-LET radiation:* X rays and gamma rays (accompanied by charged particles due to interactions with the surrounding medium) or light charged particles such as electrons that produce sparse ionizing events far apart at a molecular scale ($L < 10$ keV/μm). *High-LET radiation:* neutrons and heavy charged particles that produce ionizing events densely spaced at a molecular scale ($L > 10$ keV/μm). While the above LET definition refers to electronic stopping power only, at low energy nuclear stopping power could be a significant fraction of the total stopping power.

• **Activity,** A (unit: Becquerel, 1 Bq=1/s=27 pCi): Activity is the expectation value of the number of nuclear decays occurring in a given quantity of material per unit time.

37.1.2 *Protection quantities*

• **Organ absorbed dose,** D_T (unit: gray): The mean absorbed dose in an organ or tissue T of mass m_T is defined as

$$D_T = \frac{1}{m_T} \int_{m_T} D dm \ .$$

• **Equivalent dose,** H_T (unit: sievert, 1 Sv=1 J/kg=100 rem):

The equivalent dose H_T in an organ or tissue T is equal to the sum of the absorbed doses $D_{T,R}$ in the organ or tissue caused by different radiation types R weighted with so-called radiation weighting factors w_R:

$$H_T = \sum_R w_R \times D_{T,R} \ .$$

It expresses long-term risks (primarily cancer and leukemia) from low-level chronic exposure. The values for w_R recommended by ICRP [2] are given in Table 37.1.

Table 37.1: Radiation weighting factors, w_R.

Radiation type	w_R
Photons, electrons and muons	1
Neutrons, $E_n < 1$ MeV	$2.5 + 18.2 \times \exp[-(\ln E_n)^2/6]$
1 MeV $\leq E_n \leq$ 50 MeV	$5.0 + 17.0 \times \exp[-(\ln(2E_n))^2/6]$
$E_n >$ 50 MeV	$2.5 + 3.25 \times \exp[-(\ln(0.04E_n))^2/6]$
Protons and charged pions	2
Alpha particles, fission fragments, heavy ions	20

• **Effective dose,** E (unit: sievert): The sum of the equivalent doses, weighted by the tissue weighting factors w_T ($\sum_T w_T = 1$) of several organs and tissues T of the body that are considered to be most sensitive [2], is called "effective dose":

$$E = \sum_T w_T \times H_T \ . \tag{37.1}$$

37.1.3 *Operational quantities*

• **Dose equivalent,** H (unit: sievert): The dose equivalent at a point in tissue is given by:

$$H = D \times Q \tag{37.2}$$

where D is the absorbed dose and Q is the quality factor at that point. The quality factor at a point in tissue, is given by:

$$Q = \frac{1}{D} \int_{L=0}^{\infty} Q(L) D_L dL$$

where D_L is the distribution of D in unrestricted linear energy transfer L at the point of interest, and $Q(L)$ is the quality factor as a function of L. The integration is to be performed over D_L, due to all charged particles, excluding their secondary electrons.

• **Ambient dose equivalent,** $H^*(10)$ (unit: sievert): The dose equivalent at a point in a radiation field that would be produced by the corresponding expanded and aligned field in a 30 cm diameter sphere of unit density tissue (so-called ICRU sphere/tissue with a mass composition of 76.2% oxygen, 11.1% carbon, 10.1% hydrogen and 2.6% nitrogen) at a depth of 10 mm on the radius vector opposing the direction of the aligned field. Ambient dose equivalent is the operational quantity for *area monitoring*.

• **Personal dose equivalent,** $H_p(d)$ (unit: sievert): The dose equivalent in ICRU tissue at an appropriate depth, d, below a specified point on the human body. The specified point is normally taken to be where the individual dosimeter is worn. For the assessment of effective dose, $H_p(10)$ with a depth $d = 10$ mm is chosen, and for the assessment of the dose to the skin and to the hands and feet the personal dose equivalent, $H_p(0.07)$, with a depth $d = 0.07$ mm, is used. Personal dose equivalent is the operational quantity for *individual monitoring*.

37.1.4 *Dose conversion coefficients*

Dose conversion coefficients allow direct calculation of protection or operational quantities from particle fluence and are functions of particle type, energy and irradiation configuration. The most common coefficients are those for effective dose and ambient dose equivalent. The former are based on simulations in which the dose to organs of anthropomorphic phantoms is calculated for approximate actual conditions of exposure, such as irradiation of the front of the body (antero-posterior irradiation) or isotropic irradiation.

Conversion coefficients from fluence to effective dose are given for anterior-posterior irradiation and various particle types in Fig. 37.1 [4]. For example, the effective dose from an anterior-posterior irradiation in a field of 1-MeV neutrons with a fluence of 1 neutron per cm^2 is about 290 pSv. In Monte Carlo simulations such coefficients allow multiplication with fluence at scoring

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

time such that effective dose to a human body at the considered location is directly obtained.

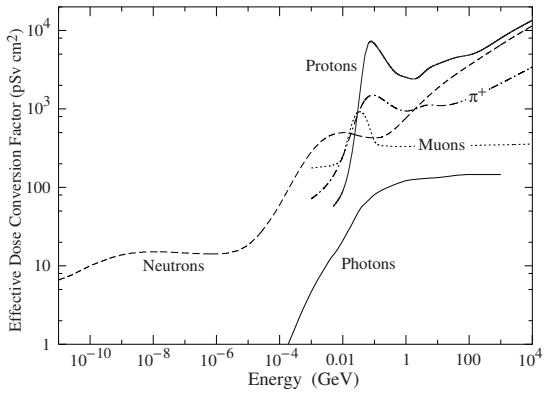

Figure 37.1: Fluence to effective dose conversion coefficients for anterior-posterior irradiation and various particle types [4].

37.2 Radiation levels [5]

• **Natural background radiation**:

On a worldwide average, the annual whole-body dose equivalent due to all sources of natural background radiation ranges from 1.0 to 13 mSv (0.1–1.3 rem) with an annual average of 2.4 mSv [6]. In certain areas values up to 50 mSv (5 rem) have been measured. A large fraction (typically more than 50%) originates from inhaled natural radioactivity, mostly radon and radon daughters [7]. The latter can vary by more than one order of magnitude: it is 0.1–0.2 mSv in open areas, 2 mSv on average in a house and more than 20 mSv in poorly ventilated mines.

• **Cosmic ray background radiation**: At sea level, the whole-body dose equivalent due to cosmic ray background radiation is dominated by muons; at higher altitudes also nucleons contribute. Dose equivalent rates range from less than 0.1 μSv/h at sea level to a few μSv/h at aircraft altitudes. Details on cosmic ray fluence levels are given in the Cosmic Rays section (Sec. 30 of this *Review*).

37.3 Health effects of ionizing radiation

Radiation can cause two types of health effects, deterministic and stochastic:

• **Deterministic effects** are tissue reactions which cause injury to a population of cells if a given threshold of absorbed dose is exceeded. The severity of the reaction increases with dose. The quantity in use for tissue reactions is the absorbed dose, D. When particles other than photons and electrons (low-LET radiation) are involved, a Relative Biological Effectiveness (RBE)-weighted dose may be used. The RBE of a given radiation is the reciprocal of the ratio of the absorbed dose of that radiation to the absorbed dose of a reference radiation (usually X rays) required to produce the same degree of biological effect. It is a complex quantity that depends on many factors such as cell type, dose rate, fractionation, etc.

• **Stochastic effects** are malignant diseases and heritable effects for which the probability of an effect occurring, but not its severity, is a function of dose without threshold.

• **Lethal dose**: The whole-body dose from penetrating ionizing radiation resulting in 50% mortality in 30 days (assuming no medical treatment) is 2.5–4.5 Gy (250–450 rad)[1], as measured internally on the body longitudinal center line. The surface dose varies due to variable body attenuation and may be a strong function of energy.

• **Cancer induction**:

The cancer induction probability is about 5% per Sv on average for the entire population [3].

• **Recommended effective dose limits**: The International Commission on Radiological Protection (ICRP) recommends a limit for radiation workers of 20 mSv effective dose per year averaged over 5 years, with the provision that the dose should not exceed 50 mSv in any single year [3]. The limit in the EU-countries and Switzerland is 20 mSv per year, in the U.S. it is 50 mSv per year (5 rem per year). Many physics laboratories in the U.S. and elsewhere set lower limits. The effective dose limit for the general public is typically 1 mSv per year.

[1] RBE-weighted when necessary

37.4 Prompt neutrons at accelerators

Neutrons dominate the radiation environment outside thick shielding (*e.g.*, > 1 m of concrete) for high energy (> a few hundred MeV) electron and hadron accelerators. In addition, for accelerators with energies above about 10 GeV, muons contribute significantly at small angles with regard to the beam, even behind several meters of shielding. Another special case are synchrotron light sources where particular care has to be taken to shield the very intense low-energy photons extracted from the electron synchrotron into the experimental areas. Due to its importance at high energy accelerators this section focuses on prompt neutrons.

37.4.1 *Electron accelerators*

At electron accelerators, neutrons are generated via photonuclear reactions from bremsstrahlung photons. Neutron production takes place above a threshold value which varies from 10 to 19 MeV for light nuclei (with important exceptions, such as 2.23 MeV for deuterium and 1.67 MeV for beryllium) and from 4 to 6 MeV for heavy nuclei. It is commonly described by different mechanisms depending on the photon energy: the giant dipole resonance interactions (from threshold up to about 30 MeV, often the dominant process), the quasi-deuteron effect (between 30 MeV and a few hundred MeV), the delta resonance mechanism (between 200 MeV and a few GeV) and the vector meson dominance model at higher energies.

The giant dipole resonance reaction consists in a collective excitation of the nucleus, in which neutrons and protons oscillate in the direction of the photon electric field. The oscillation is damped by friction in a few cycles, with the photon energy being transferred to the nucleus in a process similar to evaporation. Nucleons emitted in the dipolar interaction have an anisotropic angular distribution, with a maximum at 90°, while those leaving the nucleus as a result of evaporation are emitted isotropically with a Maxwellian energy distribution described as [8]:

$$\frac{dN}{dE_n} = \frac{E_n}{T^2} e^{-E_n/T} \ , \qquad (37.3)$$

where T is a nuclear 'temperature' (in units of MeV) characteristic of the particular target nucleus and its excitation energy. For heavy nuclei the 'temperature' generally lies in the range of $T =$ 0.5–1.0 MeV. Neutron yields from semi-infinite targets per kW of electron beam power are plotted in Fig. 37.2 as a function of the electron beam energy [8].

While for thick targets neutron production is mainly due to photonuclear interactions, for thin targets (thickness of fractions of the radiation length) electronuclear interactions are the dominating process.

Typical neutron energy spectra outside of concrete (80 cm thick, 2.35 g/cm^3) and iron (40 cm thick) shields are shown in Fig. 37.3. In order to compare these spectra to those caused by proton beams (see below) the spectra are scaled by a factor of 100, which roughly corresponds to the difference in the high energy hadronic cross sections for photons and hadrons (*e.g.*, the fine structure constant). The shape of these spectra are generally characterized by a low-energy peak at around 1 MeV (evaporation neutrons) and a high-energy shoulder at around 70–80 MeV. In case of concrete shielding, the spectrum also shows a pronounced peak at thermal neutron energies.

37.4.2 *Proton accelerators*

At proton accelerators, neutron yields emitted per incident proton by different target materials are roughly independent of proton energy between 20 MeV and 1 GeV, and are given by the ratio C : Al : Cu-Fe : Sn : Ta-Pb = 0.3 : 0.6 : 1.0 : 1.5 : 1.7 [11]. Above about 1 GeV, the neutron yield is proportional to E^m, where $0.80 \leq m \leq 0.85$ [12].

Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 04/11/15. For personal use and distribution is strictly not permitted, except for Open Access articles.

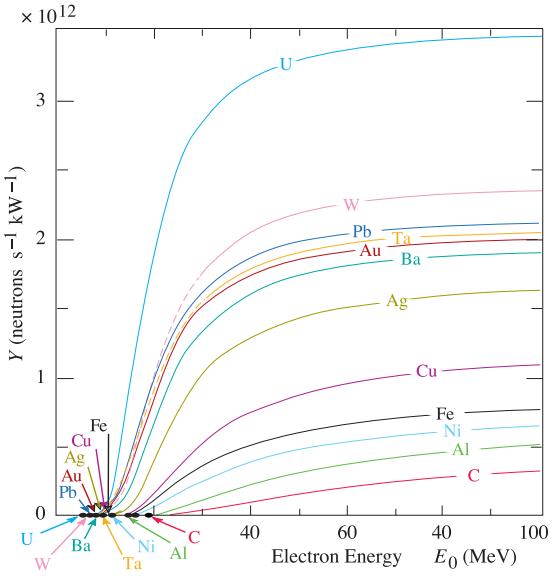

Figure 37.2: Neutron yields from semi-infinite targets per kW of electron beam power, as a function of the electron beam energy, disregarding target self-shielding [8].

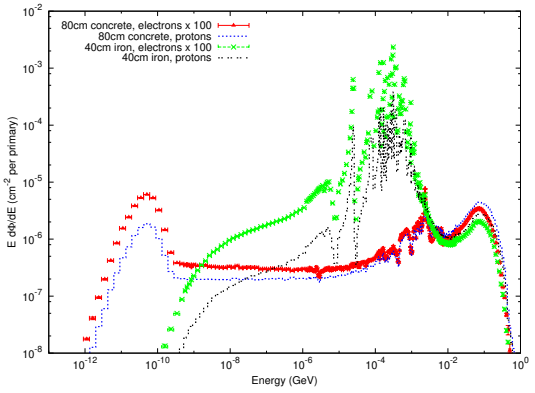

Figure 37.3: Neutron energy spectra calculated with the FLUKA code [9,10] from 25 GeV proton and electron beams on a thick copper target. Spectra are evaluated at 90° to the beam direction behind 80 cm of concrete or 40 cm of iron. All spectra are normalized per beam particle. For better visualization, spectra for electron beam are multiplied by a factor of 100.

Typical neutron energy spectra outside of concrete and iron shielding are shown in Fig. 37.3. Here, the radiation fields are caused by a 25 GeV proton beam interacting with a thick copper target. The comparison of these spectra with those for an electron beam of the same energy reflects the difference in the hadronic cross sections between photons and hadrons above a few 100 MeV. Differences are increasing towards lower energies because of different interaction mechanisms. Furthermore, the slight shift in energy above about 100 MeV follows from the fact that the energies of the interacting photons are lower than 25 GeV. Apart from this the shapes of the two spectra are similar.

The neutron-attenuation length is shown in Fig. 37.4 for concrete and mono-energetic broad-beam conditions. It reaches an asymptotic value of about 117 g/cm^2 above 200 MeV. As the cascade through thick shielding is carried by particles with energies between about 100 MeV and 300 MeV (in this energy range non-elastic cross sections are at minimum and are dominated by quasi-elastic processes leading to low attenuation) this value is equal to the equilibrium attenuation length for particles emitted at 90° in concrete.

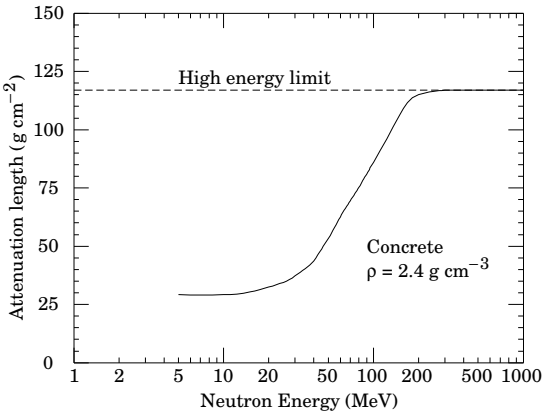

Figure 37.4: The variation of the attenuation length for mono-energetic neutrons in concrete as a function of neutron energy [11].

37.5 Photon sources

The dose equivalent rate in tissue (in mSv/h) from a gamma point source emitting one photon of energy E (in MeV) per second at a distance of 1 m is $4.6\times10^{-9}\ \mu_{en}/\rho\, E$, where μ_{en}/ρ is the mass energy absorption coefficient. The latter has a value of 0.029 ± 0.004 cm^2/g for photons in tissue over an energy range between 60 keV and 2 MeV (see Ref. [13] for tabulated values).

Similarly, the dose equivalent rate in tissue (in mSv/h) at the surface of a semi-infinite slab of uniformly activated material containing 1 Bq/g of a gamma emitter of energy E (in MeV) is $2.9 \times 10^{-4}\, R_\mu\, E$, where R_μ is the ratio of the mass energy absorption coefficients of the photons in tissue and in the material.

37.6 Accelerator-induced radioactivity

Typical medium- and long-lived activation products in metallic components of accelerators are ^{22}Na, ^{46}Sc, ^{48}V, ^{51}Cr, ^{54}Mn, ^{55}Fe, ^{59}Fe, ^{56}Co, ^{57}Co, ^{58}Co, ^{60}Co, ^{63}Ni and ^{65}Zn. Gamma-emitting nuclides dominate doses from external irradiation at longer decay times (more than one day) while at short decay times β^+ emitters are also important (through photons produced by β^+ annihilation). Due to their short range, β^- emitters are relevant, for example, only for dose to the skin and eyes or for doses due to inhalation or ingestion. Fig. 37.5 and Fig. 37.6 illustrate the contributions of gamma and β^+ emitters to the total dose rate at 12.4 cm distance to a copper sample [14]. The sample was activated by the stray radiation field created by a 120 GeV mixed hadron beam dumped in a copper target during about 8 hours at intensities between $10^7 - 10^8$ hadrons per second. Here, the contributions by individual nuclides were calculated analytically assuming exponential decay of the nuclide inventory present at 20 minute cooling time. The total dose rate, however, also includes decay chains and as such also contributions from daughter nuclides.

Typically, dose rates at a certain decay time are mainly determined by radionuclides having a half-life of the order of the decay time. Extended irradiation periods might be an exception to this general rule as in this case the activity of long-lived nuclides can build up sufficiently so that it dominates that one of short-lived even at short cooling times.

Activation in concrete is dominated by ^{24}Na (short decay time) and ^{22}Na (long decay time). Both nuclides can be produced either by low-energy neutron reactions on the sodium-component in the concrete or by spallation reactions on silicon, calcium and other constituents such as aluminum. At long decay times nuclides of radiological interest in activated concrete can also be ^{60}Co, ^{152}Eu, ^{154}Eu and ^{134}Cs, all of which produced by (n,γ)-reactions with traces of natural cobalt, europium and cesium, Thus, such trace elements might be important even if their content in concrete is only a few parts per million or less by weight.

The explicit simulation of radionuclide production with general-purpose Monte Carlo codes has become the most commonly applied method to calculate induced radioactivity and its radiologi-

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

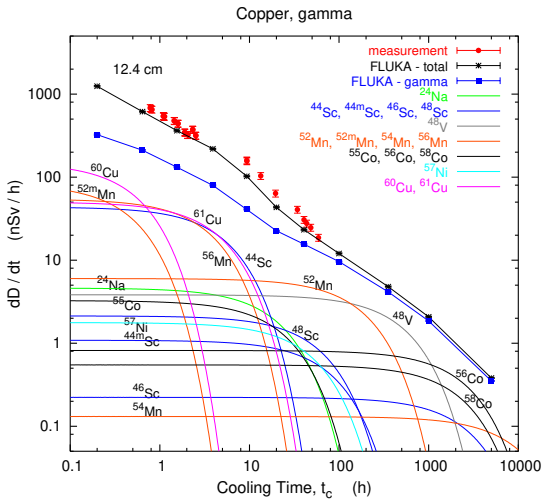

Figure 37.5: Contribution of individual gamma-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [14].

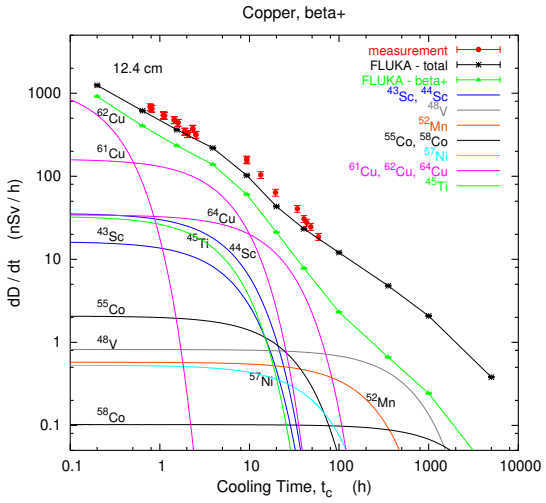

Figure 37.6: Contribution of individual positron-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [14].

cal consequences [14] (see also Sec. 37.8). They are complemented by analytical codes based on folding particle fluence spectra with nuclide production cross sections. ActiWiz [15, 16] is an example of such a code targeting the domain of radiological characterization and material optimization. It allows for calculating nuclide inventories by convolution of fluence spectra with nuclide production data for 85 chemical elements and arbitrary compounds from threshold to an energy of 100 TeV.

37.7 Radiation protection instrumentation

The capacity to distinguish and measure the high-LET (mostly neutrons) and the low-LET components (photons, electrons, muons) of the radiation field at workplaces is of primary importance to evaluate the exposure of personnel. At proton accelerators the prompt dose equivalent outside a shield is mainly due to neutrons, with some contribution from photons and, to a minor extent, charged particles. At high-energy electron accelerators the dominant stray radiation during operation consists also of neutrons, because the shielding is normally thick enough to absorb most of the bremsstrahlung photons. Most of the personnel exposure at accelerator facilities is often received during maintenance interventions, and is due to gamma/beta radiation coming from residual radioactivity in accelerator components.

Radiation detectors used both for radiation surveys and area monitoring are normally calibrated in ambient dose equivalent $H^*(10)$.

37.7.1 *Neutron detectors*

• **Rem counters:** A rem counter [17] is a portable detector consisting of a thermal neutron counter embedded in a polyethylene moderator, with a response function that approximately follows the curve of the conversion coefficients from neutron fluence to $H^*(10)$ over a wide energy range. Conventional rem counters provide a response to neutrons up to approximately 10-15 MeV, extended-range units are heavier as they include a converter consisting of a material with high mass number to correctly measure $H^*(10)$ up to several hundred MeV [18].

• **Bonner Sphere Spectrometer (BSS):** A BSS [19] consists of a thermal neutron detector at the centre of moderating spheres of different diameters made of polyethylene (PE) or a combination of PE and a high-A material to enhance its response to high energy neutrons (similar to rem counters). Each sphere has a different response function versus neutron energy, and the neutron energy, at which the sensitivity peaks, increases with sphere diameter. The energy resolution of the system is rather low but satisfactory for radiation protection purposes. The neutron spectrum is obtained by unfolding the experimental counts of the BSS with its response matrix by a computer code that is often based on an iterative algorithm such as GRAVEL [20] and MAXED [21]. BSS exist in active (using ^{3}He or BF_3 proportional counters or ^{6}LiI scintillators) and passive versions (using CR-39 track detectors or LiF), for use *e.g.* in strongly pulsed fields. With ^{3}He counters the discrimination with respect to gamma rays and noise is excellent.

• **Bubble detectors:** A bubble detector [22] is a dosimeter based on a super-heated emulsion (super-heated droplets suspended in a gel) contained in a vial and acting as a continuously sensitive, miniature bubble chamber. The total number of bubbles evolved from the radiation-induced nucleation of drops gives an integrated measure of the total neutron exposure. Various techniques exist to record and count the bubbles, *e.g.*, visual inspection, automated reading with video cameras or acoustic counting. Bubble detectors are insensitive to low-LET radiation. Super-heated emulsions are used as personal, area and environmental dosimeters, as well as neutron spectrometers.

• **Track etched detectors:** Track etched detectors (TEDs) [23] are based on the preferential dissolution of suitable, mostly insulator, materials along the damage trails of charged particles of sufficiently high-energy deposition density. The detectors are effectively not sensitive to radiation which deposits the energy through the interactions of particles with low LET. These dosimeters are generally able to determine neutron ambient dose equivalent down to around 100 μSv. They are used both as personal dosimeters and for area monitoring, *e.g.*, in BSS.

37.7.2 *Photon detectors* [24]

• **Geiger Müller (GM) counters:** GM counters are low cost devices simple to operate. They work in pulse mode and since they only count radiation-induced events, any spectrometric information is lost. In general they are calibrated in terms of air kerma, for instance in a ^{60}Co field. The response of GM counters to photons is constant within 15% for energies up to 2 MeV and shows considerable energy dependence above.

• **Ionization chambers:** Ionization chambers are gas-filled detectors used both as hand-held instruments (*e.g.*, for radiation surveys) and environmental monitors. They are normally operated in current mode although pulse-mode operation is also possible. They possess a relatively flat response to a wide range of X- and gamma ray energies (typically from 10 keV to several MeV), can measure radiation over a wide intensity range and are capable of discriminating between the beta and gamma components of a radiation field (by use of, *e.g.*, a beta window). Pressurized ion chambers (filled, *e.g.*, with Ar or H gas to several tens of bars) are used for environmental and stray radiation monitoring applications. They have good sensitivity to neutrons and charged hadrons in addition to low LET radiation (gammas and muons),

Int. J. Mod. ... by KARLSRUHE INSTITUTE OF TECHNOL... nloaded from www.worldscientific.com ...se and distribution is strictly not permitted, except for Open Access articles.

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

with the response function to the former being strongly non-linear with energy.

• **Proportional counters:** Proportional counters are another type of gas-filled detector, operated in pulse mode. They are normally of cylindrical geometry, with a thin central wire (the anode) on the axis of a hollow tube (the cathode). The initial electron charge created by the interaction of the radiation with the gas is amplified by the multiplication process (Townsend avalanche) produced by the strong electric field in a narrow volume around the anode. The generated pulses are still proportional to the original number of ion pairs but are much larger than in an ionization chamber, yielding a much improved signal-to-noise ratio. Proportional counters are also used for neutron detection: the rem counter and BSS discussed in the previous sections typically employ ^{3}He or BF_3 filled tubes with a large sensitivity to thermal neutrons.

• **Scintillators:** Scintillation-based detectors are used in radiation protection as hand-held probes and in fixed installations, *e.g.*, portal monitors. A scintillation detector or counter is obtained coupling a scintillator to an electronic light sensor such as a photomultiplier tube (PMT), a photodiode or a silicon photomultiplier (SiPM). There is a wide range of scintillating materials, inorganic (such as CsI and BGO), organic or plastic; they find application in both photon dosimetry and spectrometry.

37.7.3 *Operation in pulsed radiation fields*

There are many practical situations with particle accelerators used for scientific, industrial and medical applications where the time structure of the stray radiation limits the use of active monitors or requires specifically designed electronics. Pulsed neutron and gamma fields may be present because of beam losses at, *e.g.*, targets, collimators and beam dumps. The time duration of a single burst can range from a few ns to about 1 ms with a typical repetition rate in the range 0.1–100 Hz. Conventional detectors generally suffer from dead time effects and have strong limitations in the measurements of pulsed fields. Severe under response has been observed, *e.g.*, in commercial rem counters, with tremendous underestimation of the ambient dose equivalent, $H^*(10)$, up to three orders of magnitude [25]. The common techniques used to correct the response of radiation detectors which include dead-time corrections operate properly in a steady-state radiation field, whereas it is much more difficult to cope with dead time losses in a pulsed radiation field of unknown time structure and burst dose. Generally speaking the monitoring instrumentation must be chosen on the basis of the knowledge of the radiation field. Detectors with specifically designed electronics must be employed in pulsed field conditions in place of conventional rem counters for neutrons, such as the LUPIN detector [26]. If real-time monitoring is not required, passive detectors or dosimeters such as TEDs mentioned in Sec. 37.7.1 or LiF mentioned in Sec. 37.7.5 can be employed, as they are insensitive to the time structure of the radiation.

37.7.4 *Operation in presence of magnetic fields*

There may be circumstances in which a radiation survey needs to be performed in the presence of a magnetic field. This may be the case for example for measurements on activated detector components in the underground experimental areas of CERN LHC experiments without switching off the intense magnetic field ofthe detectors; or measurements of the residual radioactivity of permanent magnets sometimes used in particle accelerators. In hospitals, one of most advanced diagnostic modalities is PET-MRI, in which PET imaging uses radioactive substances (radiopharmaceuticals) in proximity of the strong magnetic field of the MRI scanner. Another emerging technology is MR-Linac for image-guided adaptive radiation therapy. Most of the commercial survey meters do not operate correctly or do not function at all in the presence of even comparatively weak magnetic fields below 0.3 T, and often already at 0.1 T. This is either because of the presence of components in their electronics sensitive to magnetic field (e.g. inductive elements), ferromagnetic materials in general (such as shells, screws and frames), battery drain/heating or LCD screen failure. An instrument called B-RAD has recently been developed [27] that overcomes the above limitations and is now commercially available. It is a hand-held instrument for gamma dose rate and gamma spectrometry measurements, consisting of a central unit (housing a microcontroller, magnetic field insensitive electronic circuitry, the battery and two displays) and a probe connected through a cable, certified to operate up to 3 T fields. The probe uses a $LaBr_3$(Ce) crystal coupled to an array of silicon photomultipliers. The excellent scintillation properties and the high photon resolution of the scintillator (3.3% FWHM at 662 keV) make the device capable of operating in the energy range from 30 keV to 2 MeV photons with a very fast response.

37.7.5 *Personal dosimeters*

Personal dosimeters, calibrated in $H_p(10)$, are worn by persons exposed to ionizing radiation for professional reasons to record the dose received. They are typically passive detectors, either film, track etched detectors, ^{6}Li/^{7}Li-based dosimeters (*e.g.* LiF), optically stimulated luminescence (OSL) or radiophotoluminescence detectors (RPL) but semi-active dosimeters using miniaturized ion-chambers also exist, like the Direct Ion Storage (DIS) dosimeters in use at CERN.

Electronic personal dosimeters are small active units for on-line monitoring of individual exposure, designed to be worn on the body. They can give an alarm on both the integral dose received or dose rate once a pre-set threshold is exceeded.

37.8 Monte Carlo codes for radiation protection studies

The use of general-purpose particle interaction and transport Monte Carlo codes is often the most accurate and efficient choice for assessing radiation protection quantities at accelerators. Due to the vast spread of such codes to all areas of particle physics and the associated extensive benchmarking with experimental data, the modeling has reached an unprecedented accuracy. Furthermore, most codes allow the user to simulate all aspects of a high energy particle cascade in one and the same run: from the first interaction of a TeV nucleus over the transport and re-interactions (hadronic and electromagnetic) of the produced secondaries, to detailed nuclear fragmentation, the calculation of radioactive decays and even of the electromagnetic shower caused by the radiation from such decays. A brief account of the codes most widely used for radiation protection studies at high energy accelerators is given in the following.

• **FLUKA [9, 10, 28, 29]:** FLUKA is a general-purpose particle interaction and transport code. It comprises all features needed for radiation protection, such as detailed hadronic and nuclear interaction models up to 10 PeV, full coupling between hadronic and electromagnetic processes and numerous variance reduction options. The latter include weight windows, region importance biasing, and leading particle, interaction, and decay length biasing (among others). The capabilities of FLUKA are unique for studies of induced radioactivity, especially with regard to nuclide production, decay, and transport of residual radiation. In particular, particle cascades by prompt and residual radiation are simulated in parallel based on the microscopic models for nuclide production and a solution of the Bateman equations for activity build-up and decay.

• **GEANT4 [30–32]:** GEANT4 is an object-oriented toolkit consisting of a kernel that provides the framework for particle transport, including tracking, geometry description, material specifications, management of events and interfaces to external graphics systems. The kernel also provides interfaces to physics processes. It allows the user to freely select the physics models that best serve the particular application needs. Implementations of interaction models exist over an extended range of energies, from optical photons and thermal neutrons to high-energy interactions required for the simulation of accelerator and cosmic ray experiments. To facilitate the use of variance reduction techniques, general-purpose biasing methods such as importance biasing, weight windows, and a weight cut-off method have been introduced directly into the toolkit. Other variance reduction methods, such as leading particle biasing for hadronic processes, come with the respective physics packages.

• **MARS15 [33,34]:** The MARS15 code system is a set of Monte Carlo programs for the simulation of hadronic and electromagnetic cascades. It covers a wide energy range: 1 keV to 100 TeV for

muons, charged hadrons, heavy ions and electromagnetic showers; and 0.00215 eV to 100 TeV for neutrons. Hadron-nucleus interactions as well as practically all other strong, weak and electromagnetic interactions in the entire energy range can be simulated either inclusively or exclusively. MARS15 uses ENDFB-VII nuclear data to handle interactions of neutrons with energies below 14 MeV. Several variance reduction techniques, such as weight windows, particle splitting, and Russian roulette, are available. A tagging module allows tagging the origin of a given signal for source term or sensitivity analyses. The geometry module allows either a basic solid body representation option or a ROOT-based powerful engine. Further features of MARS15 include a MAD-MARS merge for a convenient creation of accelerator models and multi-turn tracking and cascade simulation in accelerator and beamline lattices.

• **MCNP6 [35, 36]:** MCNP6 is the latest version of the Monte Carlo N-Particle transport (MCNP) family of neutron interaction and transport codes and, therefore, features one of the most comprehensive and detailed descriptions of the related physical processes. It transports 37 different particle types, including ions and electromagnetic particles. The neutron interaction and transport modules use standard evaluated data libraries mixed with physics models where such libraries are not available. The transport is continuous in energy. MCNP6 contains one of the most powerful implementations of variance reduction techniques. Spherical mesh weight windows can be created by a generator in order to focus the simulation time on certain spatial regions of interest. In addition, a more generalized phase space biasing is also possible through energy- and time-dependent weight windows. Other biasing options include pulse-height tallies with variance reduction and criticality source convergence acceleration.

• **PHITS [37, 38]:** The Particle and Heavy-Ion Transport code System PHITS was among the first general-purpose codes to simulate the transport and interactions of heavy ions in a wide energy range, from 10 MeV/nucleon to 100 GeV/nucleon. It is based on the high-energy hadron transport code NMTC/JAM that was extended to heavy ions. The transport of low-energy neutrons employs cross sections from evaluated nuclear data libraries such as ENDF and JENDL below 20 MeV. Electromagnetic interactions are simulated based on the ITS code in the energy range between 1 keV and 100 MeV for electrons and positrons and between 1 keV and 100 GeV for photons. Several variance reduction techniques, including weight windows and region importance biasing, are available.

$^{244}_{96}$Cm	18.11 y	α	5.763	24%	Pu L x rays	$\sim 9\%$
			5.805	76%		
$^{252}_{98}$Cf	2.645 y	α	6.076	15%		
		(97%)	6.118	82%		
Fission (3.1%): Average 7.8 γ's/fission; $\langle E_\gamma\rangle = 0.88$ MeV ≈ 4 neutrons/fission; $\langle E_n\rangle = 2.14$ MeV						

"Emission probability" is the probability per decay of a given emission; because of cascades these may total more than 100%. Only principal emissions are listed. EC means electron capture, and e^- means monoenergetic internal conversion (Auger) electron. The intensity of 0.511 MeV e^+e^- annihilation photons depends upon the number of stopped positrons. Endpoint $\beta^\pm$ energies are listed. In some cases when energies are closely spaced, the γ-ray values are approximate weighted averages. Radiation from short-lived daughter isotopes is included where relevant.

Isotopic data may be found at `https://physics.nist.gov/cgi-bin/Compositions/stand_alone.pl`.

Neutron sources: See *e.g.* J. Liu *et al.*, "Neutron Calibration Sources in the Daya Bay Experiment" [1]. $^{51}_{24}$Cr calibration of neutrino detectors is discussed in *e.g.* J.N. Abdurashitov *et al.*, "Measurement of the response of a gallium metal solar neutrino experiment to neutrinos from a ^{51}Cr source" [2]. The use of $^{75}_{34}$Se and other isotopes has also been proposed.

39. Probability

Revised August 2025 by G. Cowan (RHUL).

39.1 General

Further discussion of probability can be found, *e.g.*, in Refs. [1–8].

An abstract definition of probability can be given by considering a set S, called the sample space, and possible subsets $A, B, \ldots$, the interpretation of which is left open. The probability P is a real-valued function defined by the following axioms due to Kolmogorov [9]:

1. For every subset A in S, $P(A) \geq 0$;
2. For disjoint subsets (*i.e.*, $A \cap B = \emptyset$), $P(A \cup B) = P(A) + P(B)$;
3. $P(S) = 1$.

In addition, one defines the conditional probability $P(A|B)$ (read as P of A given B) as

$$P(A|B) = \frac{P(A \cap B)}{P(B)} \ . \tag{39.1}$$

From this definition and using the fact that $A \cap B$ and $B \cap A$ are the same, one obtains *Bayes' theorem*,

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)} \ . \tag{39.2}$$

From the three axioms of probability and the definition of conditional probability, one obtains the *law of total probability*,

$$P(B) = \sum_i P(B|A_i)P(A_i) \ , \tag{39.3}$$

for any subset B and for disjoint A_i with $\cup_i A_i = S$. This can be combined with Bayes' theorem (Eq. (39.2)) to give

$$P(A|B) = \frac{P(B|A)P(A)}{\sum_i P(B|A_i)P(A_i)} \ , \tag{39.4}$$

where the subset A could, for example, be one of the A_i.

The most commonly used interpretation of the elements of the sample space are outcomes of a repeatable experiment. The probability $P(A)$ is assigned a value equal to the limiting frequency of occurrence of A. This interpretation forms the basis of *frequentist statistics*.

The elements of the sample space might also be interpreted as *hypotheses*, *i.e.*, statements that are either true or false, such as 'The mass of the W boson lies between 80.3 and 80.5 GeV.' Upon repetition of a measurement, however, such statements are either always true or always false, *i.e.*, the corresponding probabilities in the frequentist interpretation are either 0 or 1. Using *subjective probability*, however, $P(A)$ is interpreted as the degree of belief that the hypothesis A is true. Subjective probability is used in *Bayesian* (as opposed to frequentist) statistics. Bayes' theorem can be written

$$P(\text{theory}|\text{data}) \propto P(\text{data}|\text{theory})P(\text{theory}) \ , \tag{39.5}$$

where 'theory' represents some hypothesis and 'data' is the outcome of the experiment. Here $P(\text{theory})$ is the *prior* probability for the theory, which reflects the experimenter's degree of belief before carrying out the measurement, and $P(\text{data}|\text{theory})$ is the probability to have gotten the data actually obtained, given the theory, which is also called the *likelihood*.

Bayesian statistics provides no fundamental rule for obtaining the prior probability, which may depend on previous measurements, theoretical prejudices, *etc.* Once this has been specified, however, Eq. (39.5) tells how the probability for the theory must be modified in the light of the new data to give the *posterior* probability, $P(\text{theory}|\text{data})$. As Eq. (39.5) is stated as a proportionality, the probability must be normalized by summing (or integrating) over all possible hypotheses.

39.2 Random variables

A *random variable* is a numerical characteristic assigned to an element of the sample space. In the frequency interpretation of probability, it corresponds to an outcome of a repeatable experiment. Let x be a possible outcome of an observation. If x can take on any value from a continuous range, we write $f(x;\theta)dx$ as the probability that the measurement's outcome lies between x and $x + dx$. The function $f(x;\theta)$ is called the *probability density function* (p.d.f.), which may depend on one or more parameters θ. If x can take on only discrete values (*e.g.*, the non-negative integers), then we use $f(x;\theta)$ to denote the probability to find the value x. In the following the term p.d.f. is often taken to cover both the continuous and discrete cases, although technically the term density should only be used in the continuous case.

The p.d.f. is always normalized to unity. Both x and θ may have multiple components and are then often written as vectors. If θ is unknown, we may wish to estimate its value from a given set of measurements of x; this is a central topic of *statistics* (see Sec. 40).

The *cumulative distribution function* $F(a)$ is the probability that $x \leq a$:

$$F(a) = \int_{-\infty}^{a} f(x)\,dx \ . \tag{39.6}$$

Here and below, if x is discrete-valued, the integral is replaced by a sum. The endpoint a is expressly included in the integral or sum. Then $0 \leq F(x) \leq 1$, $F(x)$ is nondecreasing, and $P(a < x \leq b) = F(b) - F(a)$. If x is discrete, $F(x)$ is flat except at allowed values of x, where it has discontinuous jumps equal to $f(x)$.

Any function of random variables is itself a random variable, with (in general) a different p.d.f. The *expectation value* of any function $u(x)$ is

$$E[u(x)] = \int_{-\infty}^{\infty} u(x)\,f(x)\,dx \ , \tag{39.7}$$

assuming the integral is finite. The expectation value is linear, *i.e.*, for any two functions u and v of x and constants c_1 and c_2, $E[c_1u + c_2v] = c_1E[u] + c_2E[v]$.

The nth moment of a random variable x is

$$\alpha_n \equiv E[x^n] = \int_{-\infty}^{\infty} x^n f(x)\,dx \ , \tag{39.8a}$$

and the nth central moment of x (or moment about the mean, α_1) is

$$m_n \equiv E[(x - \alpha_1)^n] = \int_{-\infty}^{\infty} (x - \alpha_1)^n f(x)\,dx \ . \tag{39.8b}$$

The most commonly used moments are the mean μ and variance σ^2:

$$\mu \equiv \alpha_1 \ , \tag{39.9a}$$

$$\sigma^2 \equiv V[x] \equiv m_2 = \alpha_2 - \mu^2 \ . \tag{39.9b}$$

The mean is the location of the "center of mass" of the p.d.f., and the variance is a measure of the square of its width. Note that $V[cx + k] = c^2V[x]$. It is often convenient to use the *standard deviation* of x, σ, defined as the square root of the variance.

Any odd moment about the mean is a measure of the skewness of the p.d.f. The simplest of these is the dimensionless coefficient of skewness $\gamma_1 = m_3/\sigma^3$.

The fourth central moment m_4 provides a convenient measure of the tails of a distribution. For the Gaussian distribution (see Sec. 39.4), one has $m_4 = 3\sigma^4$. The *kurtosis* is defined as $\gamma_2 = m_4/\sigma^4 - 3$, *i.e.*, it is zero for a Gaussian, positive for a *leptokurtic* distribution with longer tails, and negative for a *platykurtic* distribution with tails that die off more quickly than those of a Gaussian.

The *quantile* x_α is the value of the random variable x at which the cumulative distribution is equal to α. That is, the quantile

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

is the inverse of the cumulative distribution function, *i.e.*, $x_\alpha = F^{-1}(\alpha)$. An important special case is the *median*, $x_{\rm med}$, defined by $F(x_{\rm med}) = 1/2$, *i.e.*, half the probability lies above and half lies below $x_{\rm med}$. (More rigorously, $x_{\rm med}$ is a median if $P(x \geq x_{\rm med}) \geq 1/2$ and $P(x \leq x_{\rm med}) \geq 1/2$. If only one value exists, it is called '*the* median.')

Under a monotonic change of variable $x \to y(x)$, the quantiles of a distribution (and hence also the median) obey $y_\alpha = y(x_\alpha)$. In general the expectation value and *mode* (most probable value) of a distribution do not, however, transform in this way.

Let x and y be two random variables with a *joint* p.d.f. $f(x,y)$. The *marginal* p.d.f. of x (the distribution of x with y unobserved) is

$$f_1(x) = \int_{-\infty}^{\infty} f(x,y)\, dy \;, \tag{39.10}$$

and similarly for the marginal p.d.f. $f_2(y)$. The *conditional* p.d.f. of y given fixed x (with $f_1(x) \neq 0$) is defined by $f_3(y|x) = f(x,y)/f_1(x)$, and similarly $f_4(x|y) = f(x,y)/f_2(y)$. From these, we immediately obtain Bayes' theorem (see Eqs. (39.2) and (39.4)),

$$f_4(x|y) = \frac{f_3(y|x) f_1(x)}{f_2(y)} = \frac{f_3(y|x) f_1(x)}{\int f_3(y|x') f_1(x')\, dx'} \;. \tag{39.11}$$

The mean of x is

$$\mu_x = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} x\, f(x,y)\, dx\, dy = \int_{-\infty}^{\infty} x\, f_1(x)\, dx \;, \tag{39.12}$$

and similarly for y. The *covariance* of x and y is

$$\mathrm{cov}[x,y] = E[(x-\mu_x)(y-\mu_y)] = E[xy] - \mu_x\mu_y \;. \tag{39.13}$$

A dimensionless measure of the covariance of x and y is given by the *correlation coefficient*,

$$\rho_{xy} = \mathrm{cov}[x,y]/\sigma_x\sigma_y \;, \tag{39.14}$$

where σ_x and σ_y are the standard deviations of x and y. It can be shown that $-1 \leq \rho_{xy} \leq 1$.

Two random variables x and y are *independent* if and only if

$$f(x,y) = f_1(x) f_2(y) \;. \tag{39.15}$$

If x and y are independent, then $\rho_{xy} = 0$; the converse is not necessarily true. If x and y are independent, $E[u(x)v(y)] = E[u(x)]E[v(y)]$, and $V[x+y] = V[x]+V[y]$; otherwise, $V[x+y] = V[x]+V[y]+2\mathrm{cov}[x,y]$, and $E[uv]$ does not necessarily factorize.

Consider a set of n continuous random variables $\boldsymbol{x} = (x_1,\ldots,x_n)$ with joint p.d.f. $f(\boldsymbol{x})$, and a set of n new variables $\boldsymbol{y} = (y_1,\ldots,y_n)$, related to $\boldsymbol{x}$ by means of a function $\boldsymbol{y}(\boldsymbol{x})$ that is one-to-one, *i.e.*, the inverse $\boldsymbol{x}(\boldsymbol{y})$ exists. The joint p.d.f. for $\boldsymbol{y}$ is given by

$$g(\boldsymbol{y}) = f(\boldsymbol{x}(\boldsymbol{y}))|J| \;\;, \tag{39.16}$$

where $|J|$ is the absolute value of the determinant of the square matrix $J_{ij} = \partial x_i/\partial y_j$ (the Jacobian determinant). If the transformation from $\boldsymbol{x}$ to $\boldsymbol{y}$ is not one-to-one, the $\boldsymbol{x}$-space must be broken into regions where the function $\boldsymbol{y}(\boldsymbol{x})$ can be inverted, and the contributions to $g(\boldsymbol{y})$ from each region summed.

Given a set of functions $\boldsymbol{y} = (y_1,\ldots,y_m)$ with $m < n$, one can construct $n-m$ additional independent functions, apply the procedure above, then integrate the resulting $g(\boldsymbol{y})$ over the unwanted y_i to find the marginal distribution of those of interest.

Transformation of p.d.f.s of continuous random variables of any dimension can also be formulated using the Dirac delta function. Starting from an n-dimensional vector random variable $\boldsymbol{x} = (x_1,\ldots,x_n)$ that follows $f(\boldsymbol{x})$ and given m functions $\boldsymbol{a}(\boldsymbol{x}) = (a_1(\boldsymbol{x}),\ldots,a_m(\boldsymbol{x}))$, the p.d.f. of $\boldsymbol{y} \equiv \boldsymbol{a}(\boldsymbol{x})$ can be expressed as

$$g(\boldsymbol{y}) = \int d^n\boldsymbol{x}\, f(\boldsymbol{x})\, \delta^{(m)}(\boldsymbol{y} - \boldsymbol{a}(\boldsymbol{x})) \;, \tag{39.17}$$

where $\delta^{(m)}(\boldsymbol{y}-\boldsymbol{a}(\boldsymbol{x})) = \prod_{i=1}^{m} \delta(y_i - a_i(\boldsymbol{x}))$. A proof and examples can be found in Ref. [10].

For a one-to-one transformation of discrete random variables, the probability is obtained by simple substitution; no Jacobian is necessary because in this case f is a probability rather than a probability density. If the transformation is not one-to-one, then one must sum the probabilities for all values of the original variable that contribute to a given value of the transformed variable. If f depends on a set of parameters $\boldsymbol{\theta}$, a change to a different parameter set $\boldsymbol{\eta}(\boldsymbol{\theta})$ is made by simple substitution; no Jacobian is used.

39.2.1 *Propagation of errors*

Consider n random variables $\boldsymbol{x} = (x_1,\ldots,x_n)$ and m functions $\boldsymbol{y}(\boldsymbol{x}) = (y_1(\boldsymbol{x}),\ldots,y_m(\boldsymbol{x}))$. Suppose here that the mean values $\boldsymbol{\mu} = (\mu_1,\ldots,\mu_n) = E[\boldsymbol{x}]$ are known, although in practice they will only be estimated, and suppose we also know or have estimated the covariance matrix $V_{ij} = \mathrm{cov}[x_i,x_j]$. The goal of *error propagation* is to determine the covariance matrix for the functions, $U_{ij} = \mathrm{cov}[y_i,y_j]$. In particular, the diagonal elements $U_{ii} = V[y_i]$ give the variances. The new covariance matrix can be found by expanding the functions $\boldsymbol{y}(\boldsymbol{x})$ about the means $\boldsymbol{\mu}$ to first order in a Taylor series. Using this one finds

$$U_{ij} \approx \sum_{k,l} \frac{\partial y_i}{\partial x_k}\frac{\partial y_j}{\partial x_l}\bigg|_{\boldsymbol{\mu}} V_{kl} \;. \tag{39.18}$$

This can be written in matrix notation as $U \approx AVA^T$ where the matrix of derivatives A is

$$A_{ij} = \left.\frac{\partial y_i}{\partial x_j}\right|_{\boldsymbol{\mu}} \;, \tag{39.19}$$

and A^T is its transpose. The approximation is exact if $\boldsymbol{y}(\boldsymbol{x})$ is linear. If this is not the case, the approximation can break down if, for example, $\boldsymbol{y}(\boldsymbol{x})$ is significantly nonlinear close to $\boldsymbol{\mu}$ in a region of a size comparable to the standard deviations of $\boldsymbol{x}$.

39.3 Characteristic functions

The characteristic function $\phi(u)$ associated with the p.d.f. $f(x)$ is essentially its Fourier transform, or the expectation value of e^{iux}:

$$\phi(u) = E\left[e^{iux}\right] = \int_{-\infty}^{\infty} e^{iux} f(x)\, dx \;. \tag{39.20}$$

Once $\phi(u)$ is specified, the p.d.f. $f(x)$ is uniquely determined and vice versa; knowing one is equivalent to the other. Characteristic functions are useful in deriving a number of important results about moments and sums of random variables.

It follows from Eqs. (39.8) and (39.20) that the nth moment of a random variable x that follows $f(x)$ is given by

$$i^{-n}\left.\frac{d^n\phi}{du^n}\right|_{u=0} = \int_{-\infty}^{\infty} x^n f(x)\, dx = \alpha_n \;. \tag{39.21}$$

Thus it is often easy to calculate all the moments of a distribution defined by $\phi(u)$, even when $f(x)$ cannot be written down explicitly.

If the p.d.f.s $f_1(x)$ and $f_2(y)$ for independent random variables x and y have characteristic functions $\phi_1(u)$ and $\phi_2(u)$, then the characteristic function of the weighted sum $ax + by$ is $\phi_1(au)\phi_2(bu)$. The rules of addition for several important distributions (*e.g.*, that the sum of two Gaussian distributed variables also follows a Gaussian distribution) easily follow from this observation.

Let the (partial) characteristic function corresponding to the conditional p.d.f. $f_2(x|z)$ be $\phi_2(u|z)$, and the p.d.f. of z be $f_1(z)$. The characteristic function after integration over the conditional value is

$$\phi(u) = \int \phi_2(u|z) f_1(z)\, dz \;. \tag{39.22}$$

Suppose we can write ϕ_2 in the form

$$\phi_2(u|z) = A(u) e^{ig(u)z} \;. \tag{39.23}$$

Then

$$\phi(u) = A(u)\phi_1(g(u)) \; . \tag{39.24}$$

The cumulants (semi-invariants) κ_n of a distribution with characteristic function $\phi(u)$ are defined by the relation

$$\phi(u) = \exp\left[\sum_{n=1}^{\infty} \frac{\kappa_n}{n!}(iu)^n\right] = \exp\left(i\kappa_1 u - \frac{1}{2}\kappa_2 u^2 + \ldots\right) \; . \tag{39.25}$$

The values κ_n are related to the moments α_n and m_n. The first few relations are

$$\begin{aligned} \kappa_1 &= \alpha_1 \;\; (= \mu, \text{ the mean}) \\ \kappa_2 &= m_2 \;\; = \alpha_2 - \alpha_1^2 \;\; (= \sigma^2, \text{ the variance}) \\ \kappa_3 &= m_3 = \alpha_3 - 3\alpha_1\alpha_2 + 2\alpha_1^3. \end{aligned} \tag{39.26}$$

39.4 Commonly used probability distributions

Table 39.1 gives a number of common probability density functions and corresponding characteristic functions, means, and variances. Further information may be found in Refs. [1–8], [11] and [12], which has particularly detailed tables. Monte Carlo techniques for generating each of them may be found in our Sec. 42.4 and in Ref. [11]. We comment below on all except the trivial uniform distribution.

39.4.1 *Binomial and multinomial distributions*

A random process with exactly two possible outcomes which occur with fixed probabilities is called a *Bernoulli* process. If the probability of obtaining a certain outcome (a "success") in an individual trial is p, then the probability of obtaining exactly r successes ($r = 0, 1, 2, \ldots, N$) in N independent trials, without regard to the order of the successes and failures, is given by the binomial distribution $f(r; N, p)$ in Table 39.1. If r and s are binomially distributed with parameters (N_r, p) and (N_s, p), then $t = r + s$ follows a binomial distribution with parameters $(N_r + N_s, p)$. If there are are m possible outcomes for each trial having probabilities $p_1, p_2, \ldots, p_m$, then the joint probability to find $r_1, r_2, \ldots, r_m$ of each outcome after a total of N independent trials is given by the multinomial distribution as shown in Table 39.1. We can regard outcome i as "success" and all the rest as "failure", so individually, any of the r_i follow a binomial distribution for N trials and a success probability p_i.

39.4.2 *Poisson distribution*

The Poisson distribution $f(n; \nu)$ gives the probability of finding exactly n events in a given interval of x (*e.g.*, space or time) when the events occur independently of one another and of x at an average rate of ν per the given interval. The variance σ^2 equals ν. It is the limiting case $p \to 0$, $N \to \infty$, $Np = \nu$ of the binomial distribution. The Poisson distribution approaches the Gaussian distribution for large ν.

For example, a large number of radioactive nuclei of a given type will result in a certain number of decays in a fixed time interval. If this interval is small compared to the mean lifetime, then the probability for a given nucleus to decay is small, and thus the number of decays in the time interval is well modeled as a Poisson variable.

39.4.3 *Normal or Gaussian distribution*

The normal (or Gaussian) probability density function $f(x; \mu, \sigma^2)$ given in Table 39.1 has mean $E[x] = \mu$ and variance $V[x] = \sigma^2$. Comparison of the characteristic function $\phi(u)$ given in Table 39.1 with Eq. (39.25) shows that all cumulants κ_n beyond κ_2 vanish; this is a unique property of the Gaussian distribution. Some other properties are:

$$\begin{aligned} &P(x \text{ in range } \mu \pm \sigma) = 0.6827, \\ &P(x \text{ in range } \mu \pm 0.6745\sigma) = 0.5, \\ &E[|x - \mu|] = \sqrt{2/\pi}\sigma = 0.7979\sigma, \\ &\text{half-width at half maximum} = \sqrt{2\ln 2}\,\sigma = 1.177\sigma. \end{aligned}$$

For a Gaussian with $\mu = 0$ and $\sigma^2 = 1$ (the *standard normal*) the cumulative distribution, often written $\Phi(x)$, is related to the error function erf by

$$F(x; 0, 1) \equiv \Phi(x) = \frac{1}{2}\left[1 + \mathrm{erf}(x/\sqrt{2})\right] \; . \tag{39.27}$$

For a mean μ and variance σ^2, replace x by $(x - \mu)/\sigma$. The probability of x in a given range can be calculated with Eq. (40.78).

For x and y independent and normally distributed, $z = ax + by$ follows a normal p.d.f. $f(z; a\mu_x + b\mu_y, a^2\sigma_x^2 + b^2\sigma_y^2)$; that is, the weighted means and variances add.

The Gaussian derives its importance in large part from the *central limit theorem*:

If independent random variables $x_1, \ldots, x_n$ are distributed according to *any* p.d.f. with finite mean and variance, then the sum $y = \sum_{i=1}^{n} x_i$ will have a p.d.f. that approaches a Gaussian for large n. If the p.d.f.s of the x_i are not identical, the theorem still holds under somewhat more restrictive conditions. The mean and variance are given by the sums of corresponding terms from the individual x_i. Therefore, the sum of a large number of fluctuations x_i will be distributed as a Gaussian, even if the x_i themselves are not.

For a set of n Gaussian random variables $\boldsymbol{x}$ with means $\boldsymbol{\mu}$ and covariances $V_{ij} = \mathrm{cov}[x_i, x_j]$, the p.d.f. for the one-dimensional Gaussian is generalized to

$$f(\boldsymbol{x}; \boldsymbol{\mu}, V) = \frac{1}{(2\pi)^{n/2}\sqrt{|V|}} \exp\left[-\frac{1}{2}(\boldsymbol{x} - \boldsymbol{\mu})^T V^{-1} (\boldsymbol{x} - \boldsymbol{\mu})\right] \; , \tag{39.28}$$

where the determinant $|V|$ must be greater than 0. For diagonal V (independent variables), $f(\boldsymbol{x}; \boldsymbol{\mu}, V)$ is the product of the p.d.f.s of n Gaussian distributions.

For $n = 2$, $f(\boldsymbol{x}; \boldsymbol{\mu}, V)$ is

$$\begin{aligned} f(x_1, x_2;\; \mu_1, \mu_2, \sigma_1, \sigma_2, \rho) = {} & \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \\ \times \;\; & \exp\left\{\frac{-1}{2(1-\rho^2)}\left[\frac{(x_1-\mu_1)^2}{\sigma_1^2} - \frac{2\rho(x_1-\mu_1)(x_2-\mu_2)}{\sigma_1\sigma_2} \right.\right. \\ & \left.\left. + \frac{(x_2-\mu_2)^2}{\sigma_2^2}\right]\right\}. \end{aligned} \tag{39.29}$$

The characteristic function for the multivariate Gaussian is

$$\phi(\boldsymbol{u}; \boldsymbol{\mu}, V) = \exp\left[i\boldsymbol{\mu}\cdot\boldsymbol{u} - \frac{1}{2}\boldsymbol{u}^T V \boldsymbol{u}\right] \; . \tag{39.30}$$

If the components of $\boldsymbol{x}$ are independent, then Eq. (39.30) is the product of the characteristic functions of n Gaussians.

For an n-dimensional Gaussian distribution for $\boldsymbol{x}$ with mean $\boldsymbol{\mu}$ and covariance matrix V, the marginal distribution for any single x_i is is a one-dimensional Gaussian with mean μ_i and variance V_{ii}. The equation $(\boldsymbol{x} - \boldsymbol{a})^T V^{-1} (\boldsymbol{x} - \boldsymbol{a}) = C$, where C is any positive number, defines an n-dimensional ellipse centered about $\boldsymbol{a}$. If $\boldsymbol{a}$ is equal to the mean $\boldsymbol{\mu}$, then C is a random variable obeying the χ^2 distribution for n degrees of freedom, which is discussed in the following section. The probability that $\boldsymbol{x}$ lies outside the ellipsoid for a given value of C is given by $1 - F_{\chi^2}(C; n)$, where F_{χ^2} is the cumulative χ^2 distribution. This may be read from Fig. 40.2. For example, the "s-standard-deviation ellipsoid" occurs at $C = s^2$. For the two-variable case ($n = 2$), the point $\boldsymbol{x}$ lies outside the one-standard-deviation ellipsoid with 61% probability. The use of these ellipsoids as indicators of probable error is described in Sec. 40.4.2.3; the validity of those indicators assumes that $\boldsymbol{\mu}$ and V are correct.

39.4.4 *Log-normal distribution*

If a random variable y follows a Gaussian distribution with mean μ and variance σ^2, then $x = e^y$ follows a log-normal distribution, as given in Table 39.1. As a consequence of the central limit theorem described in Sec. 39.4.3, the distribution of the product of a large number of positive random variables approaches a log-normal. It is bounded below by zero and is thus well suited

Table 39.1: Some common probability density functions, with corresponding characteristic functions and means and variances. In the Table, $\Gamma(k)$ is the gamma function, equal to $(k-1)!$ when k is an integer; ${}_1F_1$ is the confluent hypergeometric function of the 1st kind [12].

Distribution	Probability density function f (variable; parameters)	Characteristic function $\phi(u)$	Mean	Variance
Uniform	$f(x;a,b) = \begin{cases} 1/(b-a) & a \le x \le b \\ 0 & \text{otherwise} \end{cases}$	$\frac{e^{ibu}-e^{iau}}{(b-a)iu}$	$\frac{a+b}{2}$	$\frac{(b-a)^2}{12}$
Binomial	$f(r;N,p) = \frac{N!}{r!(N-r)!}\, p^r q^{N-r}$ $r = 0,1,2,\ldots,N;\quad 0 \le p \le 1;\quad q = 1-p$	$(q + pe^{iu})^N$	Np	Npq
Multinomial	$f(r_1,\ldots,r_m;N,p_1,\ldots,p_m) = \frac{N!}{r_1!\cdots r_m!} p_1^{r_1}\cdots p_m^{r_m}$	$\left(\sum_{k=1}^m p_k e^{iu_k}\right)^N$	$E[r_i] = Np_i$	$\mathrm{cov}[r_i,r_j] = Np_i(\delta_{ij}-p_j)$
Poisson	$f(n;\nu) = \frac{\nu^n e^{-\nu}}{n!};\ n = 0,1,2,\ldots;\ \nu > 0$	$\exp[\nu(e^{iu}-1)]$	ν	ν
Normal (Gaussian)	$f(x;\mu,\sigma^2) = \frac{1}{\sigma\sqrt{2\pi}}\ \exp(-(x-\mu)^2/2\sigma^2)$	$\exp(i\mu u - \frac{1}{2}\sigma^2 u^2)$	μ	σ^2
Multivariate Gaussian	$f(\boldsymbol{x};\boldsymbol{\mu},V) = \frac{1}{(2\pi)^{n/2}\sqrt{\lvert V\rvert}} \times \exp\left[-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu})^T V^{-1}(\boldsymbol{x}-\boldsymbol{\mu})\right]$ $-\infty < x_j < \infty;\quad -\infty < \mu_j < \infty;\quad \lvert V\rvert > 0$	$\exp\left[i\boldsymbol{\mu}\cdot\boldsymbol{u} - \frac{1}{2}\boldsymbol{u}^T V \boldsymbol{u}\right]$	$\boldsymbol{u}$	V_{jk}
Log-normal	$f(x;\mu,\sigma^2) = \frac{1}{\sigma\sqrt{2\pi}}\frac{1}{x}\ \exp(-(\ln x-\mu)^2/2\sigma^2)$ $0 < x < \infty;\quad -\infty < \mu < \infty;\quad \sigma > 0$	—	$\exp(\mu+\sigma^2/2)$	$\exp(2\mu+\sigma^2)$ $\times[\exp(\sigma^2)-1]$
χ^2	$f(z;n) = \frac{z^{n/2-1}e^{-z/2}}{2^{n/2}\Gamma(n/2)};\quad z \ge 0$	$(1-2iu)^{-n/2}$	n	$2n$
Student's t	$f(t;n) = \frac{1}{\sqrt{n\pi}}\ \frac{\Gamma[(n+1)/2]}{\Gamma(n/2)}\left(1+\frac{t^2}{n}\right)^{-(n+1)/2}$ $-\infty < t < \infty;\qquad$ n not required to be integer	—	0 for $n > 1$	$n/(n-2)$ for $n > 2$
Gamma	$f(x;\lambda,k) = \frac{x^{k-1}\lambda^k e^{-\lambda x}}{\Gamma(k)};\quad 0 \le x < \infty\ ;$ k not required to be integer	$(1-iu/\lambda)^{-k}$	k/λ	k/λ^2
Beta	$f(x;\alpha,\beta) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)}x^{\alpha-1}(1-x)^{\beta-1}$ $0 \le x \le 1$	${}_1F_1(\alpha;\alpha+\beta;iu)$	$\frac{\alpha}{\alpha+\beta}$	$\frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$

for modeling quantities that are intrinsically non-negative such as an efficiency. One can implement a log-normal model for a random variable x by defining $y = \ln x$ so that y follows a Gaussian distribution.

39.4.5 χ^2 *distribution*

If $x_1,\ldots,x_n$ are independent Gaussian random variables, the sum $z = \sum_{i=1}^n (x_i-\mu_i)^2/\sigma_i^2$ follows the χ^2 p.d.f. with n *degrees of freedom*, which we denote by $\chi^2(n)$. More generally, for n correlated Gaussian variables as components of a vector $\boldsymbol{X}$ with covariance matrix V, $z = \boldsymbol{X}^T V^{-1}\boldsymbol{X}$ follows $\chi^2(n)$ as in the previous section. For a set of z_i, each of which follows $\chi^2(n_i)$, $\sum z_i$ follows $\chi^2(\sum n_i)$. For large n, the χ^2 p.d.f. approaches a Gaussian with a mean and variance given by $\mu = n$ and $\sigma^2 = 2n$, respectively (here the formulae for μ and σ^2 are valid for all n).

The χ^2 p.d.f. is often used in evaluating the level of compatibility between observed data and a hypothesis for the p.d.f. that the data might follow. This is discussed further in Sec. 40.3.2 on significance tests.

39.4.6 *Student's t distribution*

Suppose that y and $x_1,\ldots,x_n$ are independent and Gaussian distributed with mean 0 and variance 1. We then define

$$z = \sum_{i=1}^n x_i^2 \quad \text{and} \quad t = \frac{y}{\sqrt{z/n}}\ . \tag{39.31}$$

The variable z thus follows a $\chi^2(n)$ distribution. Then t is distributed according to Student's t distribution with n degrees of freedom, $f(t;n)$, given in Table 39.1.

If defined through gamma functions as in Table 39.1, the parameter n is not required to be an integer. As $n \to \infty$, the distribution approaches a Gaussian, and for $n = 1$ it is a *Cauchy* or *Breit–Wigner* distribution.

As an example, consider the *sample mean* $\overline{x} = \sum x_i/n$ and the *sample variance* $s^2 = \sum(x_i-\overline{x})^2/(n-1)$ for normally distributed x_i with unknown mean μ and variance σ^2. The sample mean has a Gaussian distribution with a variance σ^2/n, so the variable $(\overline{x}-\mu)/\sqrt{\sigma^2/n}$ is normal with mean 0 and variance 1. The quantity $(n-1)s^2/\sigma^2$ is independent of this and follows $\chi^2(n-1)$. The ratio

$$t = \frac{(\overline{x}-\mu)/\sqrt{\sigma^2/n}}{\sqrt{(n-1)s^2/\sigma^2(n-1)}} = \frac{\overline{x}-\mu}{\sqrt{s^2/n}} \tag{39.32}$$

is distributed as $f(t;n-1)$. The unknown variance σ^2 cancels, and t can be used to test the hypothesis that the true mean is some particular value μ.

39.4.7 *Gamma distribution*

For a process that generates events as a function of x (*e.g.*, space or time) according to a Poisson distribution, the distance in x from an arbitrary starting point (which may be some particular event) to the kth event follows a *gamma* distribution, $f(x;\lambda,k)$. The Poisson parameter μ is λ per unit x. The special case $k = 1$ (*i.e.*, $f(x;\lambda,1) = \lambda e^{-\lambda x}$) is called the *exponential* distribution. A sum of k' exponential random variables x_i is distributed as $f(\sum x_i;\lambda,k')$.

The parameter k is not required to be an integer. For $\lambda = 1/2$ and $k = n/2$, the gamma distribution reduces to the $\chi^2(n)$ distribution.

39.4.8 *Beta distribution*

The beta distribution describes a continuous random variable x in the interval $[0,1]$. By scaling and translation one can easily generalize it to have arbitrary endpoints. In Bayesian inference about the parameter p of a binomial process, if the prior p.d.f. is a beta distribution $f(p;\alpha,\beta)$ then the observation of r successes out of N trials gives a posterior beta distribution $f(p;r+\alpha,N-r+\beta)$ (Bayesian methods are discussed further in Sec. 40). The uniform distribution is a beta distribution with $\alpha = \beta = 1$.

This chapter gives an overview of statistical methods used in high-energy physics. In statistics, we are interested in using a given sample of data to make inferences about a probabilistic model, *e.g.*, to assess the model's validity or to determine the values of its parameters. There are two main approaches to statistical inference, which we may call frequentist and Bayesian.

In frequentist statistics, probability is interpreted as the limiting frequency of the outcome of a repeatable experiment. The most important tools in this framework are parameter estimation, covered in Section 40.2, statistical tests, discussed in Section 40.3, and confidence intervals, which are constructed so as to cover the true value of a parameter with a specified probability, as described in Section 40.4.2. Note that in frequentist statistics one does not define a probability for a hypothesis or for the value of a parameter.

In Bayesian statistics, the subjective interpretation of probability is used to quantify one's *degree of belief* in a hypothesis. This allows one to define a probability density function (p.d.f.) for a parameter, which reflects one's knowledge about where its true value lies.

Bayesian methods provide a natural means to include additional information, which in general may be subjective; in fact they *require* prior probabilities for the hypotheses (or parameters) in question, *i.e.*, the degree of belief about the parameters' values, before carrying out the measurement. Using Bayes' theorem (Eq. (39.4)), the prior degree of belief is updated by the data from the experiment. Bayesian methods for interval estimation are discussed in Sections 40.4.1 and 40.4.2.5.

For many inference problems, the frequentist and Bayesian approaches give similar numerical values, even though they answer different questions and are based on fundamentally different interpretations of probability. In some important cases, however, the two approaches may yield very different results. For a discussion of Bayesian vs. non-Bayesian methods, see references written by a statistician [1], by a physicist [2], or the detailed comparison in Ref. [3].

40.1 Fundamental concepts

Consider an experiment whose outcome is characterized by one or more data values, which we can write as a vector $\boldsymbol{x}$. A *hypothesis* H is a statement about the probability for the data, often written $P(\boldsymbol{x}|H)$. (We will usually use a capital letter for a probability and lower case for a probability density. Often the term p.d.f. is used loosely to refer to either a probability or a probability density). This could, for example, define completely the p.d.f. for the data (a *simple* hypothesis), or it could specify only the functional form of the p.d.f., with the values of one or more parameters not determined (a *composite* hypothesis).

If the probability $P(\boldsymbol{x}|H)$ for data $\boldsymbol{x}$ is regarded as a function of the hypothesis H, then it is called the *likelihood* of H, usually written $L(H)$. Often the hypothesis is characterized by one or more parameters $\boldsymbol{\theta}$, in which case $L(\boldsymbol{\theta}) = P(\boldsymbol{x}|\boldsymbol{\theta})$ is called the likelihood function.

In some cases one can obtain at least approximate frequentist results using the likelihood evaluated only with the data obtained, for example, when determining confidence regions with Eq. (40.78). In general, however, the frequentist approach requires a full specification of the probability model $P(\boldsymbol{x}|H)$ both as a function of the data $\boldsymbol{x}$ and hypothesis H.

In the Bayesian approach, inference is based on the posterior probability for H given the data $\boldsymbol{x}$, which represents one's degree of belief that H is true given the data. This is obtained from Bayes' theorem (39.4), which can be written

$$P(H|\boldsymbol{x}) = \frac{P(\boldsymbol{x}|H)\pi(H)}{\int P(\boldsymbol{x}|H')\pi(H')\,dH'}\,. \tag{40.1}$$

Here $P(\boldsymbol{x}|H)$ is the likelihood for H, which depends only on the data actually obtained. The quantity $\pi(H)$ is the prior probability for H, which represents one's degree of belief for H before carrying out the measurement. The integral in the denominator (or sum, for discrete hypotheses) serves as a normalization factor. If H is characterized by a continuous parameter θ then the posterior probability is a p.d.f. $p(\theta|\boldsymbol{x})$. Note that the likelihood function itself is not a p.d.f. for θ.

40.2 Parameter estimation

Here we review *point estimation* of parameters, first with an overview of the frequentist approach and its two most important methods, maximum likelihood and least squares, treated in Sections 40.2.2 and 40.2.3. The Bayesian approach is outlined in Sec. 40.2.5. In both approaches it is useful to define the *Fisher Information* for a set of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$ as the matrix

$$I_{ij}(\boldsymbol{\theta}) = E\left[\left(\frac{\partial \ln L}{\partial \theta_i}\right)\left(\frac{\partial \ln L}{\partial \theta_j}\right)\right] = -E\left[\frac{\partial^2 \ln L}{\partial \theta_i \partial \theta_j}\right]\,, \tag{40.2}$$

where the operator $E[\,]$ is the expectation value with respect to the data. For the final equality to hold, the range of allowed data values must not depend on $\boldsymbol{\theta}$.

An *estimator* $\widehat{\theta}$ (written with a hat) is a function of the data used to estimate the value of the parameter θ. Sometimes the

word "estimate" is used to denote the value of the estimator when evaluated with given data. There is no fundamental rule dictating how an estimator must be constructed. One tries, therefore, to choose that estimator which has the best properties. The most important of these are (a) *consistency*, (b) *bias*, (c) *efficiency*, and (d) *robustness*.

(a) An estimator is said to be *consistent* if the estimate $\widehat{\theta}$ converges in probability (see Ref. [3]) to the true value θ as the amount of data increases. This property is so important that it is possessed by all commonly used estimators.

(b) The *bias*, $b = E[\widehat{\theta}] - \theta$, is the difference between the expectation value of the estimator and the true value of the parameter. The expectation value is taken over a hypothetical set of similar experiments in which $\widehat{\theta}$ is constructed in the same way. When $b = 0$, the estimator is said to be unbiased. The bias depends on the chosen metric, *i.e.*, if $\widehat{\theta}$ is an unbiased estimator of θ, then $\widehat{\theta}^2$ is not in general an unbiased estimator for θ^2.

(c) *Efficiency* is the ratio of the minimum possible variance for any estimator of θ to the variance $V[\widehat{\theta}]$ of the estimator $\widehat{\theta}$. For the case of a single parameter, under rather general conditions, the variance of any estimator satisfies the *information* (or *Rao-Cramér-Fréchet*) *inequality*,

$$V[\hat{\theta}] \geq \left(1 + \frac{\partial b}{\partial \theta}\right)^2 / I(\theta) \,, \tag{40.3}$$

where $I(\theta) = I_{11}(\theta)$ is the only element of the Fisher information from Eq. (40.2).

The *mean-squared error*,

$$\mathrm{MSE} = E[\,(\widehat{\theta} - \theta)^2\,] = V[\widehat{\theta}] + b^2 \,, \tag{40.4}$$

is a measure of an estimator's quality which combines bias and variance.

(d) *Robustness* is the property of being insensitive to departures from assumptions about the p.d.f., *e.g.*, owing to uncertainties in the distribution's tails.

It is not in general possible to optimize simultaneously for all the measures of estimator quality described above. For some common estimators, the properties above are known exactly. More generally, it is possible to evaluate them by Monte Carlo simulation. Note that they will in general depend on the unknown θ.

40.2.1 *Estimators for mean, variance, and median*

Suppose we have a set of n independent measurements, $x_1, \ldots, x_n$, each assumed to follow a p.d.f. with unknown mean μ and unknown variance σ^2 (the measurements do not necessarily have to follow a Gaussian distribution). Then

$$\widehat{\mu} = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{40.5}$$

$$\widehat{\sigma^2} = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \widehat{\mu})^2 \tag{40.6}$$

are unbiased estimators of μ and σ^2. The variance of $\widehat{\mu}$ is σ^2/n and the variance of $\widehat{\sigma^2}$ is

$$V\left[\widehat{\sigma^2}\right] = \frac{1}{n}\left(m_4 - \frac{n-3}{n-1}\sigma^4\right) \,, \tag{40.7}$$

where m_4 is the 4th central moment of x (see Eq. (39.8)). For Gaussian distributed x_i, this becomes $2\sigma^4/(n-1)$ for any $n \geq 2$, and for large n the standard deviation of $\widehat{\sigma}$ is $\sigma/\sqrt{2n}$. For any n and Gaussian x_i, $\widehat{\mu}$ is an efficient estimator for μ, and the estimators $\widehat{\mu}$ and $\widehat{\sigma^2}$ are uncorrelated. Otherwise the arithmetic mean (40.5) is not necessarily the most efficient estimator; this is discussed further in Sec. 8.7 of Ref. [4].

If σ^2 is known, it does not improve the estimate $\widehat{\mu}$, as can be seen from Eq. (40.5); however, if μ is known, one can substitute it for $\widehat{\mu}$ in Eq. (40.6) and replace $n-1$ by n to obtain an estimator of σ^2 still with zero bias but smaller variance. If the x_i have different, known variances σ_i^2, then the weighted average

$$\widehat{\mu} = \frac{1}{w}\sum_{i=1}^{n} w_i x_i \,, \tag{40.8}$$

where $w_i = 1/\sigma_i^2$ and $w = \sum_i w_i$, is an unbiased estimator for μ with a smaller variance than an unweighted average. The standard deviation of $\widehat{\mu}$ is $1/\sqrt{w}$.

As an estimator for the median x_{med}, one can use the sample median defined as the value $\widehat{x}_{\mathrm{med}}$ such that half of the x_i are below and half above, if n is odd, or the arithmetic mean of the two consecutive values such that half of the remaining half of the x_i are below and half above those two values.

If the p.d.f. of x has the form $f(x-\mu)$ and μ is both mean and median, then for large n the variance of the sample median approaches $1/[4nf^2(0)]$, provided $f(0) > 0$ [5]. Although estimating the median can often be more difficult computationally than the mean, the resulting estimator is generally more robust, as it is insensitive to the exact shape of the tails of a distribution.

40.2.2 *The method of maximum likelihood*

Suppose we have a set of measured quantities $\boldsymbol{x}$ and the likelihood $L(\boldsymbol{\theta}) = P(\boldsymbol{x}|\boldsymbol{\theta})$ for a set of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$. The *maximum likelihood estimators* (MLEs) for $\boldsymbol{\theta}$ are defined as the values that give the maximum of L. Because of the properties of the logarithm, it is usually easier to work with $\ln L$, and since both are maximized for the same parameter values $\boldsymbol{\theta}$, the MLEs can be found by solving the *likelihood equations*,

$$\frac{\partial \ln L}{\partial \theta_i} = 0 \,, \qquad i = 1, \ldots, M \,. \tag{40.9}$$

Often the solution must be found numerically.

In general the likelihood function is obtained from the probability of the data under assumption of the parameters $\boldsymbol{\theta}$. In evaluating the likelihood function, it is important that any normalization factors in the p.d.f. that involve $\boldsymbol{\theta}$ be included. However, we will only be interested in the maximum of L and in ratios of L at different values of the parameters; hence any multiplicative factors that do not involve the parameters that we want to estimate may be dropped, including factors that depend on the data but not on $\boldsymbol{\theta}$.

Under a one-to-one change of parameters from $\boldsymbol{\theta}$ to $\boldsymbol{\eta}$, the MLEs $\widehat{\boldsymbol{\theta}}$ transform to $\boldsymbol{\eta}(\widehat{\boldsymbol{\theta}})$. That is, the maximum-likelihood solution is invariant under change of parameter. However, other properties of MLEs, in particular the bias, are not invariant under change of parameter.

40.2.2.1 *Large-sample properties and variance of the MLE*

The method of maximum likelihood has particularly attractive properties when the size of the data sample (number of events) is very large. This situation is called the large-sample or asymptotic limit. The asymptotic properties emerge only if certain regularity conditions are satisfied. A complete statement of these conditions can be found, e.g., in [3]; they include the requirements that the range of possible data values not depend on the model parameters, and the true value of a parameter cannot lie on the boundary of its allowed values. For small samples the properties hold only in special cases, e.g., where the means of Gaussian distributed data are linear functions of the parameters.

Provided the regularity conditions are satisfied, in the large-sample limit the bias of the MLEs goes to zero and the information inequality becomes an equality. For a multi-parameter model, the inverse of the covariance matrix $V_{ij} = \mathrm{cov}[\widehat{\theta}_i, \widehat{\theta}_j\,]$ for a set of MLEs becomes approximately equal to the Fisher Information (40.2), i.e.,

$$V_{ij}^{-1} \approx I_{ij} = -E\left[\frac{\partial^2 \ln L}{\partial\theta_i \partial\theta_j}\right] \,. \tag{40.10}$$

To obtain a numerical estimate for V^{-1} one can use the matrix

of second derivatives of $\ln L$ evaluated at its maximum:

$$(\widehat{V}^{-1})_{ij} = -\left.\frac{\partial^2 \ln L}{\partial\theta_i \partial\theta_j}\right|_{\widehat{\boldsymbol{\theta}}} . \quad (40.11)$$

In addition, in the large-sample limit the likelihood function itself takes on a Gaussian shape, so that the log-likelihood becomes a quadratic function of the form

$$\ln L(\boldsymbol{\theta}) = \ln L_{\max} - \frac{1}{2}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})^T V^{-1} (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) . \quad (40.12)$$

One therefore finds s times the standard deviations σ_i of the MLEs from their distances to the tangents of the hypersurface defined by

$$\ln L(\boldsymbol{\theta}) = \ln L_{\max} - \frac{s^2}{2} , \quad (40.13)$$

where $\ln L_{\max}$ is the value of $\ln L$ at the MLE. This formula relates the standard deviations to a log-likelihood contour and holds for any number of parameters. This is in contrast to a similar formula for a confidence region given in Eq. (40.78), which does depend on the number of parameters.

Equation (40.13) represents an ellipsoid in the M-dimensional parameter space. For $M = 2$ and $s = 1$, it gives the ellipse in the parameters space (θ_1, θ_2) centered about the estimated values $(\widehat{\theta}_1, \widehat{\theta}_2)$ shown in Fig. 40.1. The tangents to the ellipse give the standard deviations of the estimators, σ_1 and σ_2, and the angle of the major axis of the ellipse is given by

$$\tan 2\phi = \frac{2\rho_{12}\,\sigma_1\sigma_2}{\sigma_1^2 - \sigma_2^2} , \quad (40.14)$$

where $\rho_{12} = \mathrm{cov}[\,\widehat{\theta}_1, \widehat{\theta}_2\,]/\sigma_1\sigma_2$ is the correlation coefficient.

The correlation coefficient can be visualized as the fraction of the distance σ_2 from the ellipse's horizontal center-line at which the ellipse becomes tangent to vertical, *i.e.*, at the distance $\rho_{12}\sigma_2$ below the center-line as shown. As ρ_{12} goes to $+1$ or -1, the ellipse thins to a diagonal line.

If one considers one of the parameters, say θ_1, as known and its value is $\hat{\theta}_1$, then the quantity $\sigma_{\mathrm{inner}} = \sqrt{1-\rho_{12}^2}\,\sigma_2$ represents the statistical error of the estimate $\hat{\theta}_2$. It corresponds to the intercept of the vertical center-line with the ellipse, as shown in the figure. This illustrates that constraining θ_1 decreases the statistical uncertainty of the estimate of θ_2, as long as $\hat{\theta}_1$ and $\hat{\theta}_2$ are correlated, i.e., the ellipse is tilted. The corresponding principle applies also to problems with more parameters.

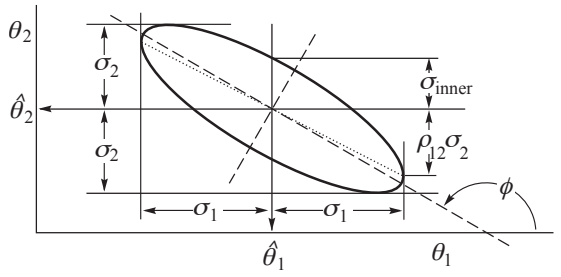

Figure 40.1: Standard error ellipse for the estimators $\widehat{\theta}_1$ and $\widehat{\theta}_2$. In the case shown the correlation is negative.

40.2.2.2 *MLE with different likelihood functions: binned and unbinned data samples*

An important special case is when the data consist of *i.i.d.* (independent and identically distributed) values. Here one has a set of n statistically independent quantities $\boldsymbol{x} = (x_1, \ldots, x_n)$, where each component follows the same p.d.f. $f(x;\boldsymbol{\theta})$. In this case the joint p.d.f. of the data sample factorizes and the likelihood function is

$$L(\boldsymbol{\theta}) = P(\boldsymbol{x}|\boldsymbol{\theta}) = \prod_{i=1}^{n} f(x_i;\boldsymbol{\theta}) . \quad (40.15)$$

Here the number n of observations is regarded as fixed.

If, however, the probability to observe n events itself depends on the parameters $\boldsymbol{\theta}$, then this dependence should be included in the likelihood. For example, if n follows a Poisson distribution with mean μ and the independent x values all follow $f(x;\boldsymbol{\theta})$, then the likelihood becomes

$$L(\boldsymbol{\theta}) = P(\boldsymbol{x}, n|\boldsymbol{\theta}) = P(n)P(\boldsymbol{x}|n) = \frac{\mu^n}{n!} e^{-\mu} \prod_{i=1}^{n} f(x_i;\boldsymbol{\theta}) . \quad (40.16)$$

Equation (40.16) is often called the *extended likelihood* (see, *e.g.*, Refs. [6, 7]).

If μ is given as a function of $\boldsymbol{\theta}$, then including the probability for n given $\boldsymbol{\theta}$ in the likelihood provides additional information about the parameters. This therefore leads to a reduction in their statistical uncertainties and in general changes their estimated values.

If the total number of data values is small, the unbinned maximum-likelihood method, *i.e.*, use of Equation (40.15) (or (40.16) for extended maximum likelihood), is preferred since binning can only result in a loss of information, and hence larger statistical errors for the parameter estimates. If the sample is large, it can be convenient to bin the values in a histogram with N bins, so that one obtains a vector of data $\boldsymbol{n} = (n_1, \ldots, n_N)$ with expectation values $\boldsymbol{\mu} = E[\,\boldsymbol{n}\,]$ and probabilities $f(\boldsymbol{n};\boldsymbol{\mu})$. Suppose the mean values $\boldsymbol{\mu}$ can be determined as a function of a set of parameters $\boldsymbol{\theta}$. Then one may maximize the likelihood function based on the contents of the bins.

As mentioned in Sec. 40.2.2, the total number of entries $n_{\mathrm{tot}} = \sum_i n_i$ can be regarded either as fixed or as a random variable. If it is fixed, the histogram's values $\boldsymbol{n}$ follow a multinomial distribution,

$$f_{\mathrm{M}}(\boldsymbol{n};\boldsymbol{\theta}) = \frac{n_{\mathrm{tot}}!}{n_1! \cdots n_N!}\, p_1^{n_1} \cdots p_N^{n_N} , \quad (40.17)$$

where we assume the probabilities p_i are given functions of the parameters $\boldsymbol{\theta}$. The distribution can be written equivalently in terms of the expected number of entries in each bin, $\mu_i = n_{\mathrm{tot}} p_i$. If the n_i are regarded as independent and Poisson distributed, then the data are instead described by a product of Poisson probabilities,

$$f_{\mathrm{P}}(\boldsymbol{n};\boldsymbol{\theta}) = \prod_{i=1}^{N} \frac{\mu_i^{n_i}}{n_i!} e^{-\mu_i} , \quad (40.18)$$

where the mean values μ_i are given functions of $\boldsymbol{\theta}$. The total number of entries n_{tot} thus follows a Poisson distribution with mean $\mu_{\mathrm{tot}} = \sum_i \mu_i$.

When using maximum likelihood with binned data, one can find the estimators and at the same time obtain a statistic usable for a test of goodness of fit (see Sec. 40.3.3.1). For independent Poisson distributed data, maximizing the likelihood $L(\boldsymbol{\theta}) = f_{\mathrm{P}}(\boldsymbol{n};\boldsymbol{\theta})$ is equivalent to maximizing the likelihood ratio $\lambda(\boldsymbol{\theta}) = f_{\mathrm{P}}(\boldsymbol{n};\boldsymbol{\theta})/f_{\mathrm{sat}}(\boldsymbol{n};\hat{\boldsymbol{\mu}})$, where in the denominator $f_{\mathrm{sat}}(\boldsymbol{n};\boldsymbol{\mu})$ is the corresponding model with an adjustable parameter for each bin, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_N)$, with estimators $\hat{\boldsymbol{\mu}} = (n_1, \ldots, n_N)$ (called the "saturated model"). Equivalently one often minimizes the quantity $-2\ln\lambda(\boldsymbol{\theta})$. For independent Poisson distributed n_i this is [8]

$$-2\ln\lambda(\boldsymbol{\theta}) = 2\sum_{i=1}^{N}\left[\mu_i(\boldsymbol{\theta}) - n_i + n_i \ln\frac{n_i}{\mu_i(\boldsymbol{\theta})}\right] , \quad (40.19)$$

where for bins with $n_i = 0$, the last term in (40.19) is zero. The expression (40.19) without the terms $\mu_i - n_i$ also gives $-2\ln\lambda(\boldsymbol{\theta})$ for multinomially distributed n_i, *i.e.*, when the total number of entries is regarded as fixed. In the limit of zero bin width, minimizing (40.19) is equivalent to maximizing the unbinned extended likelihood function (40.16); in the corresponding multinomial case without the $\mu_i - n_i$ terms one obtains Eq. (40.15).

A smaller value of $-2\ln\lambda(\widehat{\boldsymbol{\theta}})$ corresponds to better agreement between the data and the hypothesized form of $\boldsymbol{\mu}(\boldsymbol{\theta})$. The value of $-2\ln\lambda(\widehat{\boldsymbol{\theta}})$ can thus be translated into a p-value as a measure of

goodness-of-fit, as described in Sec. 40.3.3.1. Provided the model is correct and the same regularity conditions as needed for the asymptotic properties of the MLE are satisified (see Sec. 40.2.2.1), Wilks' theorem [9] states that the minimum of $-2\ln\lambda$, as defined by Eq. (40.19), follows a chi-square distribution (see, *e.g.*, Ref. [8]). If there are N bins and M fitted parameters, then the number of degrees of freedom for the chi-square distribution is $N-M$ if the data are treated as Poisson-distributed, and $N-M-1$ if the n_i are multinomially distributed.

Suppose the n_i are Poisson-distributed and the overall normalization $\mu_{\rm tot}=\sum_i \mu_i$ is taken as an adjustable parameter, so that $\mu_i = \mu_{\rm tot}\, p_i(\boldsymbol{\theta})$, where the probability to be in the ith bin, $p_i(\boldsymbol{\theta})$, does not depend on $\mu_{\rm tot}$. Then by minimizing Eq. (40.19), one obtains that the area under the fitted function is equal to the sum of the histogram contents, *i.e.*, $\sum_i \hat{\mu}_i = \sum_i n_i$. This is a property not possessed by the estimators from the method of least squares (see, *e.g.*, Sec. 40.2.3 and Ref. [10]).

40.2.3 *The method of least squares*

In the special case of a set of N independent measurements y_i at known points x_i where the measurements y_i are assumed to be Gaussian distributed with mean $\mu(x_i;\boldsymbol{\theta})$ and known variance σ_i^2, the method of maximum likelihood assumes a simplified form called *method of least squares* (LS). The log-likelihood function contains the sum of squares

$$\chi^2(\boldsymbol{\theta}) = -2\ln L(\boldsymbol{\theta}) + \text{ constant } = \sum_{i=1}^{N} \frac{(y_i-\mu(x_i;\boldsymbol{\theta}))^2}{\sigma_i^2}\ . \quad (40.20)$$

The parameter values that maximize L are the same as those which minimize χ^2. This method can also be used to build estimators of the unknown parameters $\boldsymbol{\theta}$ in the more general case where measurements are not necessarily Gaussian distributed.

The minimum of the chi-square function in Eq. (40.20) defines the least-squares estimators $\widehat{\boldsymbol{\theta}}$ for the more general case where the y_i are not Gaussian distributed as long as they are independent. If they are not independent but rather have a covariance matrix $V_{ij} = \mathrm{cov}[\,y_i, y_j\,]$, then the LS estimators are determined by the minimum of

$$\chi^2(\boldsymbol{\theta}) = (\boldsymbol{y}-\boldsymbol{\mu}(\boldsymbol{\theta}))^T V^{-1} (\boldsymbol{y}-\boldsymbol{\mu}(\boldsymbol{\theta}))\ , \quad (40.21)$$

where $\boldsymbol{y}=(y_1,\ldots,y_N)$ is the (column) vector of measurements, $\boldsymbol{\mu}(\boldsymbol{\theta})$ is the corresponding vector of predicted values, and the superscript T denotes the transpose. If the y_i are not Gaussian distributed, then the least-squares and maximum-likelihood estimators will not in general coincide.

Often one further restricts the problem to the case where $\mu(x_i;\boldsymbol{\theta})$ is a linear function of the parameters, *i.e.*,

$$\mu(x_i;\boldsymbol{\theta}) = \sum_{j=1}^{M} \theta_j h_j(x_i)\ . \quad (40.22)$$

Here the $h_j(x)$ are M linearly independent functions, *e.g.*, $1, x, x^2, \ldots, x^{M-1}$ or Legendre polynomials. We require $M<N$ and at least m of the x_i must be distinct.

Minimizing χ^2 in this case with m parameters reduces to solving a system of M linear equations. Defining $H_{ij}=h_j(x_i)$ and minimizing χ^2 by setting its derivatives with respect to the θ_i equal to zero gives the LS estimators,

$$\widehat{\boldsymbol{\theta}} = (H^T V^{-1} H)^{-1} H^T V^{-1} \boldsymbol{y} \equiv D\boldsymbol{y}\ . \quad (40.23)$$

The covariance matrix for the estimators $U_{ij} = \mathrm{cov}[\,\widehat{\theta}_i, \widehat{\theta}_j\,]$ is given by

$$U = DVD^T = (H^T V^{-1} H)^{-1}\ , \quad (40.24)$$

or equivalently, its inverse U^{-1} can be found from

$$(U^{-1})_{ij} = \frac{1}{2}\frac{\partial^2\chi^2}{\partial\theta_i\partial\theta_j}\bigg|_{\boldsymbol{\theta}=\widehat{\boldsymbol{\theta}}} = \sum_{k,\,l=1}^{N} h_i(x_k)(V^{-1})_{kl}\, h_j(x_l)\ . \quad (40.25)$$

The LS estimators can also be found from the expression

$$\widehat{\boldsymbol{\theta}} = U\boldsymbol{g}\ , \quad (40.26)$$

where the vector $\boldsymbol{g}$ is defined by

$$g_i = \sum_{j,\,k=1}^{N} y_j\, h_i(x_k)(V^{-1})_{jk}\ . \quad (40.27)$$

For the case of uncorrelated y_i, for example, one can use (40.26) with

$$(U^{-1})_{ij} = \sum_{k=1}^{N} \frac{h_i(x_k)h_j(x_k)}{\sigma_k^2}\ , \quad (40.28)$$

$$g_i = \sum_{k=1}^{N} \frac{y_k\, h_i(x_k)}{\sigma_k^2}\ . \quad (40.29)$$

Expanding $\chi^2(\boldsymbol{\theta})$ about $\widehat{\boldsymbol{\theta}}$, one finds that the contour in parameter space defined by

$$\chi^2(\boldsymbol{\theta}) = \chi^2(\widehat{\boldsymbol{\theta}}) + 1 = \chi^2_{\rm min} + 1 \quad (40.30)$$

has tangent planes located at plus-or-minus-one standard deviation $\sigma_{\widehat{\theta}_i}$ from the LS estimates $\widehat{\theta}_i$ (the relation is approximate if the fit function $\mu(x;\boldsymbol{\theta})$ is nonlinear in the parameters).

In constructing the quantity $\chi^2(\boldsymbol{\theta})$ one requires the variances or, in the case of correlated measurements, the covariance matrix. Often these quantities are not known *a priori* and must be estimated from the data. In this case the least-squares and maximum-likelihood methods are no longer exactly equivalent even for Gaussian distributed measurements. An important example is where the measured value y_i represents the number of entries in a histogram bin. If, for example, y_i represents a Poisson variable, for which the variance is equal to the mean, then one can either estimate the variance from the predicted value, $\mu(x_i;\boldsymbol{\theta})$, or from the observed number itself, y_i. In the first option, the variances become functions of the parameters, and as a result the estimators may need to be found numerically. The second option can be undefined if y_i is zero, and for small y_i, the variance will be poorly estimated. In either case, one should constrain the normalization of the fitted curve to the correct value, *i.e.*, one should determine the area under the fitted curve directly from the number of entries in the histogram (see Ref. [10], Section 7.4). As noted in Sec. 40.2.2.2, this issue is avoided when using the method of extended maximum likelihood with binned data by minimizing Eq. (40.19). In that case if the expected number of entries $\mu_{\rm tot}$ does not depend on the other fitted parameters $\boldsymbol{\theta}$, then its extended MLE is equal to the observed total number of entries.

As the minimum value of the χ^2 represents the level of agreement between the measurements and the fitted function, it can be used for assessing the goodness-of-fit; this is discussed further in Section 40.3.3.1.

40.2.4 *Parameter estimation with constraints*

In some applications one is interested in using a set of measured quantities $\boldsymbol{y}=(y_1,\ldots,y_N)$ to estimate parameters $\boldsymbol{\theta}=(\theta_1,\ldots,\theta_M)$ subject to a number of constraints. For example, one may have measured coordinates from two tracks, and the goal is to estimate their momentum vectors subject to the constraint that the tracks have a common vertex. The parameters can also include momenta of undetected particles such as neutrinos, as long as the constraints from conservation of energy and momentum and from known masses of particles involved in the reaction chain provide enough information for these quantities to be inferred.

A set of K constraints can be given in the form of equations

$$c_k(\boldsymbol{\theta}) = 0\ , \quad k=1,\ldots,K\ . \quad (40.31)$$

In some problems it may be possible to define a new set of parameters $\boldsymbol{\eta}=(\eta_1,\ldots,\eta_L)$ with $L=M-K$ such that every point

by KARLSRUHE INSTI DGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles. Phys. A 2026.41. Downloaded from www.worldscientific.com

in $\boldsymbol{\eta}$-space automatically satisfies the constraints. If this is possible then the problem reduces to one of estimating $\boldsymbol{\eta}$ with, *e.g.*, maximum likelihood or least squares and then transforming the estimators back into $\boldsymbol{\theta}$-space.

In many cases it may be difficult or impossible to find an appropriate transformation $\boldsymbol{\eta}(\boldsymbol{\theta})$. Suppose that the parameters are determined by minimizing an objective function such as $\chi^2(\boldsymbol{\theta})$ in the method of least squares. Here one may enforce the constraints by finding the stationary points of the *Lagrange function*

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\lambda}, \boldsymbol{y}) = \chi^2(\boldsymbol{\theta}, \boldsymbol{y}) + \sum_{k=1}^{K} \lambda_k c_k(\boldsymbol{\theta}) \tag{40.32}$$

with respect to both the parameters $\boldsymbol{\theta}$ and a set of *Lagrange multipliers* $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_K)$. Combining the parameters and Lagrange multipliers into an $(M + K)$-component vector $\boldsymbol{\gamma} = (\theta_1, \ldots, \theta_M, \lambda_1, \ldots, \lambda_K)$, the solutions for $\boldsymbol{\gamma}$, *i.e.*, the estimators $\hat{\boldsymbol{\gamma}}$, are found (*e.g.*, numerically) from the system of equations

$$F_i(\boldsymbol{\gamma}, \boldsymbol{y}) \equiv \frac{\partial \mathcal{L}}{\partial \gamma_i} = 0 \ , \quad i = 1, \ldots, M + K \ . \tag{40.33}$$

To obtain the covariance matrix of the estimated parameters one can find solutions $\tilde{\boldsymbol{\gamma}}$ corresponding to the expectation values of the data $\langle \boldsymbol{y} \rangle$ and expand $F_i(\hat{\boldsymbol{\gamma}}, \boldsymbol{y})$ to first order about these values. This gives (see, e.g., Sec. 11.6 of Ref. [10]) linearized approximations for the estimators, $\hat{\boldsymbol{\gamma}}(\boldsymbol{y}) \approx \tilde{\boldsymbol{\gamma}} + C(\boldsymbol{y} - \langle \boldsymbol{y} \rangle)$, where the matrix $C = -A^{-1}B$, and A and B are given by

$$A_{ij} = \left[\frac{\partial F_i}{\partial \gamma_j} \right]_{\tilde{\boldsymbol{\gamma}}, \langle \boldsymbol{y} \rangle} \quad \text{and} \quad B_{ij} = \left[\frac{\partial F_i}{\partial y_j} \right]_{\tilde{\boldsymbol{\gamma}}, \langle \boldsymbol{y} \rangle} \ . \tag{40.34}$$

In practice the values $\langle \boldsymbol{y} \rangle$ and corresponding solutions $\tilde{\boldsymbol{\gamma}}$ are estimated using the data from the actual measurement. Using this approximation for $\hat{\boldsymbol{\gamma}}(\boldsymbol{y})$, one can find the covariance matrix $U_{ij} = \mathrm{cov}[\,\hat{\gamma}_i, \hat{\gamma}_j\,]$ of the estimators for the γ_i in terms of that of the data $V_{ij} = \mathrm{cov}[\,y_i, y_j\,]$ using error propagation (cf. Eqs. (39.18) and (39.19)),

$$U = CVC^T \ . \tag{40.35}$$

The upper-left $M \times M$ block of the matrix U gives the covariance matrix for the estimated parameters $\mathrm{cov}[\,\hat{\theta}_i, \hat{\theta}_j\,]$. One can show for linear constraints that $\mathrm{cov}[\,\hat{\theta}_i, \hat{\theta}_j\,]$ is also given by the upper-left $M \times M$ block of $2A^{-1}$. If the parameters are estimated using the method of least squares, then the number of degrees of freedom for the distribution of the minimized χ^2 is increased by the number of constraints, *i.e.*, it becomes $N - M + K$. Further details can be found in, *e.g.*, Ch. 8 of Ref. [4] and Ch. 7 of Ref. [11].

40.2.5 *The Bayesian approach*

In the frequentist methods discussed above, probability is associated only with data, not with the value of a parameter. This is not the case in Bayesian statistics, however, which we introduce in this section. For general introductions to Bayesian statistics see, *e.g.*, Refs [12–15].

Suppose the outcome of an experiment is characterized by a vector of data $\boldsymbol{x}$, whose probability distribution depends on an unknown parameter (or parameters) $\boldsymbol{\theta}$ that we wish to determine. In Bayesian statistics, all knowledge about $\boldsymbol{\theta}$ is summarized by the posterior p.d.f. $p(\boldsymbol{\theta}|\boldsymbol{x})$, whose integral over any given region gives the degree of belief for $\boldsymbol{\theta}$ to take on values in that region, given the data $\boldsymbol{x}$. It is obtained by using Bayes' theorem,

$$p(\boldsymbol{\theta}|\boldsymbol{x}) = \frac{P(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})}{\int P(\boldsymbol{x}|\boldsymbol{\theta}')\pi(\boldsymbol{\theta}')\, d\boldsymbol{\theta}'} \ , \tag{40.36}$$

where $P(\boldsymbol{x}|\boldsymbol{\theta})$ is the likelihood function, *i.e.*, the joint p.d.f. for the data viewed as a function of $\boldsymbol{\theta}$, evaluated with the data actually obtained in the experiment, and $\pi(\boldsymbol{\theta})$ is the prior p.d.f. for $\boldsymbol{\theta}$. Note that the denominator in Eq. (40.36) serves to normalize the posterior p.d.f. to unity.

As it can be difficult to report the full posterior p.d.f. $p(\boldsymbol{\theta}|\boldsymbol{x})$, one would usually summarize it with statistics such as the mean, mode or median value and covariance matrix. In addition one may construct intervals with a given probability content, as is discussed in Sec. 40.4.1 on Bayesian interval estimation.

40.2.5.1 *Priors*

Bayesian statistics supplies no unique rule for determining the prior $\pi(\boldsymbol{\theta})$; this reflects the analyst's subjective degree of belief (or state of knowledge) about $\boldsymbol{\theta}$ before the measurement was carried out. For the result to be of value to the broader community, whose members may not share these beliefs, it is important to carry out a *sensitivity analysis*, that is, to show how the result changes under a reasonable variation of the prior probabilities.

One might like to construct $\pi(\boldsymbol{\theta})$ to represent complete ignorance about the parameters by setting it equal to a constant. A problem here is that if the prior p.d.f. is flat in $\boldsymbol{\theta}$, then it is not flat for a nonlinear function of $\boldsymbol{\theta}$, and so a different parametrization of the problem would lead in general to a non-equivalent posterior p.d.f.

For the special case of a constant prior, one can see from Bayes' theorem (40.36) that the posterior is proportional to the likelihood, and therefore the mode (peak position) of the posterior is equal to the maximum-likelihood estimator. The posterior mode, however, will change in general upon a transformation of parameter. One may use as the Bayesian estimator a summary statistic other than the mode, such as the median, which is invariant under parameter transformation. But this will not in general coincide with the MLE.

The difficult and subjective nature of encoding personal knowledge into priors has led to what is called *objective Bayesian statistics*, where prior probabilities are based not on an actual degree of belief but rather derived from formal rules. These give, for example, priors which are invariant under a transformation of parameters, or ones which result in a maximum gain in information for a given set of measurements. For an extensive review see, *e.g.*, Ref. [16].

Objective priors do not in general reflect degree of belief, but they could in some cases be taken as possible subjective priors. The posterior probabilities as well therefore do not necessarily reflect a degree of belief. However one may regard investigating a variety of objective priors to be an important part of the sensitivity analysis. Furthermore, use of objective priors with Bayes' theorem can be viewed as a recipe for producing estimators or intervals which have desirable frequentist properties.

An important procedure for deriving objective priors is due to Jeffreys. According to *Jeffreys' rule* one takes the prior as

$$\pi(\boldsymbol{\theta}) \propto \sqrt{\det(I(\boldsymbol{\theta}))} \ , \tag{40.37}$$

where $I(\boldsymbol{\theta})$ is the Fisher information matrix from Eq. (40.2). One can show that the Jeffreys prior leads to inference that is invariant under a transformation of parameters. One should note that the Jeffreys prior does not in general correspond to one's degree of belief about the value of a parameter. As examples, the Jeffreys prior for the mean μ of a Gaussian distribution is a constant, and for the mean of a Poisson distribution one finds $\pi(\mu) \propto 1/\sqrt{\mu}$.

Neither the constant nor $1/\sqrt{\mu}$ priors can be normalized to unit area and are therefore said to be *improper*. This can be allowed because the prior always appears multiplied by the likelihood function, and if the likelihood falls to zero sufficiently quickly then one may have a normalizable posterior density.

An important type of objective prior is the reference prior due to Bernardo and Berger [17–19]. To find the reference prior for a given problem one considers the Kullback-Leibler divergence $D_n[\,\pi, p\,]$ of the posterior $p(\boldsymbol{\theta}|\boldsymbol{x})$ relative to a prior $\pi(\boldsymbol{\theta})$, obtained from a set of i.i.d. data $\boldsymbol{x} = (x_1, \ldots, x_n)$:

$$D_n[\,\pi, p\,] = \int p(\boldsymbol{\theta}|\boldsymbol{x}) \ln \frac{p(\boldsymbol{\theta}|\boldsymbol{x})}{\pi(\boldsymbol{\theta})}\, d\boldsymbol{\theta} \ . \tag{40.38}$$

This is effectively a measure of the gain in information provided by the data. The reference prior is chosen so that the expectation value of this information gain is maximized for the limiting case of $n \to \infty$, where the expectation is computed with respect to the marginal distribution of the data,

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

$$p(\boldsymbol{x}) = \int p(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})\, d\boldsymbol{\theta} \ . \tag{40.39}$$

For a single, continuous parameter the reference prior is usually identical to the Jeffreys prior. In the multiparameter case an iterative algorithm exists, which requires sorting the parameters by order of inferential importance. Often the result does not depend on this order, but when it does, this can be part of a sensitivity analysis. Further discussion and applications to particle physics problems can be found in Ref. [20].

40.2.6 *Nuisance parameters*

Suppose we want to determine the values of parameters $\boldsymbol{\theta}$ using a set of measurements $\boldsymbol{x}$ described by a probability model $P(\boldsymbol{x}|\boldsymbol{\theta})$. In general the model is not perfect, which is to say it cannot provide an accurate description of the data even at the most optimal point of its parameter space. As a result, the estimated parameters can have a systematic bias.

One can improve the model by including in it additional parameters. That is, $P(\boldsymbol{x}|\boldsymbol{\theta})$ is replaced by a more general model $P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})$, which depends on parameters of interest $\boldsymbol{\theta}$ and *nuisance parameters* $\boldsymbol{\nu}$. The additional parameters are not of intrinsic interest but must be included for the model to be sufficiently accurate for some point in the enlarged parameter space.

40.2.6.1 *Frequentist treatment of nuisance parameters*

Although including additional parameters may eliminate or at least reduce the effect of systematic uncertainties, their presence will result in increased statistical uncertainties for the parameters of interest. This occurs because the estimators for the nuisance parameters and those of interest will in general be correlated, which results in an enlargement of the contour defined by Eq. (40.13).

To reduce the impact of the nuisance parameters one often tries to constrain their values by means of control or calibration measurements, say, having data $\boldsymbol{y}$. For example, some components of $\boldsymbol{y}$ could represent estimates of the nuisance parameters, often from separate experiments. Suppose the measurements $\boldsymbol{y}$ are statistically independent from $\boldsymbol{x}$ and are described by a model $P(\boldsymbol{y}|\boldsymbol{\nu})$. The joint model for both $\boldsymbol{x}$ and $\boldsymbol{y}$ is in this case therefore the product of the probabilities for $\boldsymbol{x}$ and $\boldsymbol{y}$, and thus the likelihood function for the full set of parameters is

$$L(\boldsymbol{\theta},\boldsymbol{\nu}) = P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})P(\boldsymbol{y}|\boldsymbol{\nu}) \ . \tag{40.40}$$

Note that in this case if one wants to simulate the experiment by means of Monte Carlo, both the primary and control measurements, $\boldsymbol{x}$ and $\boldsymbol{y}$, must be generated for each repetition under assumption of fixed values for the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\nu}$.

Using all of the parameters $(\boldsymbol{\theta},\boldsymbol{\nu})$ in Eq. (40.13) to find the statistical errors in the parameters of interest $\boldsymbol{\theta}$ is equivalent to using the *profile likelihood*, which depends only on $\boldsymbol{\theta}$. It is defined as

$$L_{\rm p}(\boldsymbol{\theta}) = L(\boldsymbol{\theta},\widehat{\widehat{\boldsymbol{\nu}}}(\boldsymbol{\theta})), \tag{40.41}$$

where the double-hat notation indicates the profiled values of the parameters $\boldsymbol{\nu}$, defined as the values that maximize L for the specified $\boldsymbol{\theta}$. The profile likelihood is discussed further in Section 40.3.2.1 in connection with hypothesis tests.

40.2.6.2 *Bayesian treatment of nuisance parameters*

As discussed in Sec. 40.2.2, a model may depend on parameters of interest $\boldsymbol{\theta}$ as well as on nuisance parameters $\boldsymbol{\nu}$, which must be included for an accurate description of the data. Knowledge about the values of $\boldsymbol{\nu}$ may be supplied by control measurements, theoretical insights, physical constraints, etc. Suppose, for example, one has data $\boldsymbol{y}$ from a control measurement which is characterized by a probability $p(\boldsymbol{y}|\boldsymbol{\nu})$. Suppose further that before carrying out the control measurement one's state of knowledge about $\boldsymbol{\nu}$ is described by an initial prior $\pi_0(\boldsymbol{\nu})$, which in practice is often taken to be a constant or in any case very broad. By using Bayes' theorem (40.1) one obtains the updated prior $\pi(\boldsymbol{\nu})$ (*i.e.*, now $\pi(\boldsymbol{\nu}) = \pi(\boldsymbol{\nu}|\boldsymbol{y})$, the probability for $\boldsymbol{\nu}$ given $\boldsymbol{y}$),

$$\pi(\boldsymbol{\nu}|\boldsymbol{y}) \propto p(\boldsymbol{y}|\boldsymbol{\nu})\pi_0(\boldsymbol{\nu}) \ . \tag{40.42}$$

In the absence of a model for $P(\boldsymbol{y}|\boldsymbol{\nu})$ one may make some reasonable but *ad hoc* choices in order to approximate $\pi(\boldsymbol{\nu})$. For a single nuisance parameter ν, for example, one might characterize the uncertainty by a p.d.f. $\pi(\nu)$ centered about its nominal value with a certain standard deviation σ_ν. Often a Gaussian p.d.f. provides a reasonable model for one's degree of belief about a nuisance parameter; in other cases, more complicated shapes may be appropriate. If, for example, the parameter represents a non-negative quantity then a log-normal or gamma p.d.f. can be a more natural choice than a Gaussian truncated at zero. Note also that truncation of the prior of a nuisance parameter ν at zero will in general make $\pi(\nu)$ nonzero at $\nu = 0$, which can lead to an unnormalizable posterior for a parameter of interest that appears multiplied by ν.

The likelihood function, prior, and posterior p.d.f.s all depend on both $\boldsymbol{\theta}$ and $\boldsymbol{\nu}$, and are related by Bayes' theorem, as usual. Note that the likelihood here only refers to the primary measurement $\boldsymbol{x}$. Once any control measurements $\boldsymbol{y}$ are used to find the updated prior $\pi(\boldsymbol{\nu})$ for the nuisance parameters, this information is fully encapsulated in $\pi(\boldsymbol{\nu})$ and the control measurements do not appear further.

One can obtain the posterior p.d.f. for $\boldsymbol{\theta}$ alone by integrating over the nuisance parameters, *i.e.*,

$$p(\boldsymbol{\theta}|\boldsymbol{x}) = \int p(\boldsymbol{\theta},\boldsymbol{\nu}|\boldsymbol{x})\, d\boldsymbol{\nu} \ . \tag{40.43}$$

Such integrals can often not be carried out in closed form, and if the number of nuisance parameters is large, then they can be difficult to compute with standard Monte Carlo methods. *Markov Chain Monte Carlo* (MCMC) techniques are often used for computing integrals of this type (see Sec. 42.6).

40.2.7 *Unfolding*

An important class of parameter estimation problem involves measurement of the differential distribution of a kinematic variable in the form of a histogram with N bins. The data thus consist of the vector of measured data values $\boldsymbol{n} = (n_1, \ldots n_N)$, with expectation values $\nu_i = E[\, n_i \,]$. The n_i are usually independent and often modeled as Poisson distributed, from which it follows that the maximum-likelihood estimators are $\hat{\nu}_i = n_i$ for all i.

Because of the limited acceptance and resolution of the experiment, however, the measured values of the kinematic variable in question differ in general from their true values, and as a consequence the form of the data histogram is distorted relative to what would be obtained with perfect resolution. The desired parameters are not, therefore, the ν_i but rather one wants to estimate the expected number of entries in a given bin that would be found with a perfect detector. We call this the "true histogram" and denote it with $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_M)$, where the number of bins M is not required to equal that of the observed histogram. The μ_i are related to the expected numbers of entries in the observed histogram by

$$\nu_i = \sum_{j=1}^{M} R_{ij}\mu_j + \beta_i \ , \tag{40.44}$$

where β_i here represents the expected number of entries in bin i due to background processes and the $N \times M$ *response matrix* R_{ij} gives the probability for an event to be observed in bin i of $\boldsymbol{\nu}$ given that the true value of the variable was in bin j of $\boldsymbol{\mu}$. For purposes of this discussion let us suppose that the response matrix and expected background values are known. There are two main approaches to this type of problem, which we can call *unfolding* and *folding*.

In unfolding, one treats the true histogram $\boldsymbol{\mu}$ as the parameters of interest. The result is thus given by estimators $\hat{\boldsymbol{\mu}}$ and the corresponding covariance matrix $U_{ij} = \mathrm{cov}[\, \hat{\mu}_i, \hat{\mu}_j \,]$. Provided the response matrix can be inverted, the maximum-likelihood solution is easily found as $\hat{\boldsymbol{\mu}} = R^{-1}(\boldsymbol{n} - \boldsymbol{\beta})$. If the response matrix allows for significant migration of entries between bins, then the variances of these estimators can be very large, sometimes to the point where the $\hat{\boldsymbol{\mu}}$ bear essentially no resemblance to the true

$\boldsymbol{\mu}$. In such cases the estimators can be found by maximizing a linear combination of the log-likelihood and a regularization function that imposes some degree of smoothness on the unfolded distribution. In achieving a reduction in variance one inevitably introduces some bias into the estimators.

In the approach of folding, by contrast, to test a given model prediction for the true histogram $\boldsymbol{\mu}$ it is first "folded" with the response matrix and corrected for expected background to give the corresponding $\boldsymbol{\nu}$ according to Eq. (40.44), and these are compared to the corresponding $\boldsymbol{n}$ using, e.g., a likelihood ratio as shown in Sec. 40.2.2.2. In this way, one avoids any bias due to regularization.

To account for systematic uncertainties, the response matrix and background values may not be expressed as constants but rather as functions of nuisance parameters $\boldsymbol{\theta}$. These may be constrained by auxiliary measurements $\boldsymbol{u}$ with p.d.f. $p(\boldsymbol{u}|\boldsymbol{\theta})$ so that the full likelihood becomes (as in Eq. (40.40) but with different notation)

$$L(\boldsymbol{\mu}, \boldsymbol{\theta}) = P(\boldsymbol{n}|\boldsymbol{\nu}(\boldsymbol{\mu}, \boldsymbol{\theta}))\, p(\boldsymbol{u}|\boldsymbol{\theta}) \; . \tag{40.45}$$

Here the mean values $\boldsymbol{\nu} = R(\boldsymbol{\theta})\boldsymbol{\mu} + \boldsymbol{\beta}(\boldsymbol{\theta})$ now depend on both the true histogram parameters $\boldsymbol{\mu}$ as well as the nuisance parameters $\boldsymbol{\theta}$. Thus to record enough information for a future analysis using folding one must provide all of the ingredients used above: the primary data $\boldsymbol{n}$, the auxiliary measurements $\boldsymbol{u}$, and also the response matrix $R(\boldsymbol{\theta})$ and expected backgrounds $\boldsymbol{\beta}(\boldsymbol{\theta})$ as functions of the nuisance parameters. If unfolding is used, then future model tests or comparisons with other experiments can be carried out directly using the estimators $\hat{\boldsymbol{\mu}}$ and their covariance matrix.

If several distributions are unfolded, then to combine these in a test of a given model one should know how estimators for bins of different distributions are correlated, as can arise, e.g., through common systematic effects. If only the unfolded distributions and their separate covariance matrices are reported, however, then information on such correlations is not retained. In folding, one can include information on correlated systematic effects if the ingredients (R and $\boldsymbol{\beta}$) are known in terms of nuisance parameters that are common to different distributions.

In unfolding, the estimators for $\boldsymbol{\mu}$ can be constructed either by maximizing the log-likelihood using Eq. (40.45) or in the case where regularization is required one can maximize $\varphi(\boldsymbol{\mu}, \boldsymbol{\theta}) = \ln L(\boldsymbol{\mu}, \boldsymbol{\theta}) + \tau S(\boldsymbol{\mu})$, where the *regularization function* $S(\boldsymbol{\mu})$ reflects the smoothness of the true histogram and serves to reduce the variances of the estimators. Possible functions are based on the mean squared second derivative (a commonly used type of Tikhonov regularization) or the entropy of the true histogram. The parameter τ fixes the relative weighting of the log-likelihood and the regularization function and thus determines the balance between the bias and variance of the resulting estimators. Further discussion of the unfolding problem including methods for choosing the regularization function and parameter, as well as techniques that employ other types of regularization such as the iterative Bayes (Richardson-Lucy) method, can be found in Refs. [10, 11, 21, 22] and references therein.

40.3 Statistical tests

In addition to estimating parameters, one often wants to assess the validity of certain statements concerning the data's underlying distribution. Frequentist *hypothesis tests*, described in Sec. 40.3.1, provide a rule for accepting or rejecting hypotheses depending on the outcome of a measurement. In *significance tests*, covered in Sec. 40.3.2, one gives the probability to obtain a level of incompatibility with a certain hypothesis that is greater than or equal to the level observed with the actual data. Goodness-of-fit tests that quantify the general level of compatibility between data and a hypothesis are described in Sec. 40.3.3. In the Bayesian approach, the corresponding procedure is based fundamentally on the posterior probabilities of the competing hypotheses. In Sec. 40.3.4 we describe a related construct called the Bayes factor, which can be used to quantify the degree to which the data prefer one or another hypothesis.

40.3.1 *Hypothesis tests*

A frequentist *test* of a hypothesis (often called the null hypothesis, H_0) is a rule that states for which data values $\boldsymbol{x}$ the hypothesis is rejected. A region of $\boldsymbol{x}$-space called the critical region, w, is specified such that there is no more than a given probability under H_0, α, called the *size* or *significance level* of the test, to find $\boldsymbol{x} \in w$. If the data are discrete, it may not be possible to find a critical region with exact probability content α, and thus we require $P(\boldsymbol{x} \in w|H_0) \leq \alpha$. If the data are observed in the critical region, H_0 is rejected.

The data $\boldsymbol{x}$ used to construct a test could be, for example, a set of values that characterizes an individual event. In this case the test corresponds to classification as, *e.g.*, signal or background. Alternatively the data could represent a set of values from a collection of events. Often one is interested in knowing whether all of the events are of a certain type (background), or whether the sample contains at least some events of a new type (signal). Here the background-only hypothesis plays the role of H_0, and in the alternative H_1 both signal and background are present. Rejecting H_0 is, from the standpoint of frequentist statistics, the required step to establish discovery of the signal process.

The choice of the critical region is not unique. Its choice should take into account the probabilities for the data predicted by some alternative hypothesis (or set of alternatives) H_1. Rejecting H_0 if it is true is called a *type-I error*, and occurs by construction with probability no greater than α. Not rejecting H_0 if an alternative H_1 is true is called a *type-II error*, and for a given test this will have a certain probability $\beta = P(\boldsymbol{x} \notin w|H_1)$. The quantity $1 - \beta$ is called the *power* of the test of H_0 with respect to the alternative H_1. A strategy for defining the critical region can therefore be to maximize the power with respect to some alternative (or alternatives) given a fixed size α.

To maximize the power of a test of fixed size α of H_0 with respect to the alternative H_1, the *Neyman–Pearson lemma* states that the critical region w should be chosen such that for all data values $\boldsymbol{x}$ inside w, the likelihood ratio

$$\lambda(\boldsymbol{x}) = \frac{f(\boldsymbol{x}|H_1)}{f(\boldsymbol{x}|H_0)} \tag{40.46}$$

is greater than or equal to a given constant c_α, and everywhere outside the critical region one has $\lambda(\boldsymbol{x}) < c_\alpha$, where the value of c_α is determined by the size of the test α. The hypotheses H_0 and H_1 must be simple, *i.e.*, they should not contain undetermined parameters.

It is convenient to define the test using a scalar function of the data $\boldsymbol{x}$ called a *test statistic*, $t(\boldsymbol{x})$, such that the boundary of the critical region is given by a surface of constant $t(\boldsymbol{x})$. The Neyman–Pearson lemma is equivalent to the statement that the likelihood ratio (40.46) represents the optimal test statistic. It can be difficult in practice, however, to determine $\lambda(\boldsymbol{x})$, since this requires knowledge of the joint p.d.f.s $f(\boldsymbol{x}|H_0)$ and $f(\boldsymbol{x}|H_1)$. Often one does not have explicit formulae for these, but rather Monte Carlo models that allow one to generate instances of $\boldsymbol{x}$ that follow the p.d.f.s.

In the case where the likelihood ratio (40.46) cannot be used explicitly, there exist a variety of other multivariate methods for constructing a test statistic that may approach its performance. These are based on machine-learning algorithms that use samples of *training data* corresponding to the hypotheses in question, often generated from Monte Carlo models. Further information on Machine Learning can be found in Sec. 41 of this Review.

The multivariate algorithms designed to classify events into signal and background types also form the basis of tests of the hypothesis that a sample of events consists of background only. Such a test can be constructed using the distributions of the test statistic $t(\boldsymbol{x})$ for event classification obtained from a multivariate algorithm such as a Neural Network output. The distributions $p(t|s)$ and $p(t|b)$ for signal and background events, respectively, are used to construct the likelihood ratio of the signal-plus-background hypothesis relative to that of background only. To the extent that the test statistic $t(\boldsymbol{x})$ approximates the likelihood ratio (or a monotonic function thereof) for individual events given by (40.46), the resulting test of the background-only hypothesis for the event

sample will have maximum power with respect to the signal-plus-background alternative (see Ref. [23]).

40.3.2 *Tests of significance, p-values*

A frequentist *significance test* allows one to assign a numerical value, called the p-value, that reflects the level of agreement between a hypothesis H_0 and the observed data $\boldsymbol{x}$. To carry out a significance test one must specify a subset of the data space, whose boundary includes the observed data point $\boldsymbol{x}_{\rm obs}$, that is deemed to have equal or lesser compatibility with H_0 relative to $\boldsymbol{x}_{\rm obs}$. The p-value of H_0 is the probability, assuming data distributed according to H_0, to find $\boldsymbol{x}$ in the region of equal or lesser compatibility.

For continuous data, one can show that the p-value of H_0, here called p_0, follows a uniform distribution for data generated under H_0. Therefore, one has $P(p_0 \leq \alpha|H_0) = \alpha$ for any constant α in $[0,1]$. In this way the region of data space where $p_0 \leq \alpha$ gives a critical region w of a test of size α, as it satisfies $P(\boldsymbol{x} \in w|H_0) \leq \alpha$. Thus rejecting H_0 if $p_0 \leq \alpha$ is equivalent to the hypothesis test of Sec. 40.3.1 above. For the critical region w defined by $p_0 \leq \alpha$ one can find the power $P(\boldsymbol{x} \in w|H_1)$ with respect to an alternative hypothesis H_1, as defined in Sec. 40.3.1. In general the region of low compatibility with H_0 is defined so as to have a high probability for data generated under H_1, so that the distribution of p_0, assuming data $\boldsymbol{x}$ that follows H_1, will be concentrated at low values, and the critical region w derived from $p_0 \leq \alpha$ will have a high power with respect to H_1.

Similar to construction of a test's critical region in Sec. 40.3.1, finding the p-value is generally done by defining a statistic $t(\boldsymbol{x})$ whose value corresponds to better or worse levels of agreement with the hypothesis. The hypothesis being tested, H_0, will determine the p.d.f. $f(t|H_0)$ for the statistic. If, for example, t is defined such that large values correspond to poor agreement with the hypothesis, then the p-value is

$$p = \int_{t_{\rm obs}}^{\infty} f(t|H_0)\, dt \ , \tag{40.47}$$

where $t_{\rm obs} = t(\boldsymbol{x}_{\rm obs})$ is the value of the statistic obtained in the actual experiment.

Note that the p-value is not the probability of the hypothesis, which in frequentist statistics is not defined. The p-value should also not be confused with the size of a test, or the confidence level of a confidence interval (Section 40.4), both of which are pre-specified constants.

When searching for a new phenomenon, one tries to reject the hypothesis H_0 that the data are consistent with known (*e.g.*, Standard Model) processes. If the p-value of H_0 is sufficiently low, then one is willing to accept that some alternative hypothesis is true. Often one converts the p-value into an effective significance Z, defined as an equivalent number of standard deviations of a Gaussian distributed random variable. In a search for an intrinsically positive signal, *i.e.*, where only upward fluctuations of the estimated rate appear signal like, this is defined as

$$Z = \Phi^{-1}(1-p) \ . \tag{40.48}$$

Here Φ is the cumulative distribution of the standard Gaussian, and Φ^{-1} is its inverse (quantile) function. In this way, a p-value of $1/2$ gives $Z = 0$, *i.e.*, having an estimated signal rate of zero corresponds to zero significance. Under assumption of H_0, the p-value is uniformly distributed in $[0,1]$ and Z follows $\varphi(Z)$, the standard (zero mean and unit variance) Gaussian. If either positive or negative data fluctuations would indicate evidence of the signal, then one defines

$$Z = \Phi^{-1}(1-p/2) \ . \tag{40.49}$$

In this case an estimated signal rate of zero gives $p = 1$ and $Z = 0$. The p.d.f. of Z is $2\varphi(Z)$ for $Z \geq 0$.

Often in particle physics the level of significance where an effect is said to qualify as a discovery is $Z = 5$, *i.e.*, a 5σ effect, corresponding to a p-value of 2.87×10^{-7}. One's actual degree of belief that a new process is present, however, will depend in general on other factors as well, such as the plausibility of the new signal hypothesis and the degree to which it can describe the data, one's confidence in the model that led to the observed p-value, and possible corrections for multiple observations out of which one focuses on the smallest p-value obtained (the "look-elsewhere effect", discussed in Section 40.3.2.2).

40.3.2.1 *Frequentist treatment of nuisance parameters and asymptotic methods for tests*

Suppose one wants to test hypothetical values of parameters $\boldsymbol{\theta}$, but the model also contains nuisance parameters $\boldsymbol{\nu}$. To find a p-value for $\boldsymbol{\theta}$ we can construct a test statistic $q_{\boldsymbol{\theta}}$ such that larger values constitute increasing incompatibility between the data and the hypothesis. Then for an observed value of the statistic $q_{\boldsymbol{\theta},\rm obs}$, the p-value of $\boldsymbol{\theta}$ is

$$p_{\boldsymbol{\theta}}(\boldsymbol{\nu}) = \int_{q_{\boldsymbol{\theta},\rm obs}}^{\infty} f(q_{\boldsymbol{\theta}}|\boldsymbol{\theta},\boldsymbol{\nu})\, dq_{\boldsymbol{\theta}} \ , \tag{40.50}$$

which depends in general on the nuisance parameters $\boldsymbol{\nu}$. In the strict frequentist approach, $\boldsymbol{\theta}$ is rejected only if the p-value is less than α for all possible values of the nuisance parameters.

The test of $\boldsymbol{\theta}$ becomes easy to carry out if we can define the test statistic $q_{\boldsymbol{\theta}}$ such that its distribution $f(q_{\boldsymbol{\theta}}|\boldsymbol{\theta})$ is known and is independent of the nuisance parameters. Although exact independence is only found in special cases, it can be achieved approximately by using the *profile likelihood ratio*. This is given by the profile likelihood from Eq.(40.41) divided by the value of the likelihood at its maximum, *i.e.*, when evaluated with the maximum-likelihood estimators $\widehat{\boldsymbol{\theta}}$ and $\widehat{\boldsymbol{\nu}}$:

$$\lambda_p(\boldsymbol{\theta}) = \frac{L(\boldsymbol{\theta},\widehat{\widehat{\boldsymbol{\nu}}}(\boldsymbol{\theta}))}{L(\widehat{\boldsymbol{\theta}},\widehat{\boldsymbol{\nu}})} \ . \tag{40.51}$$

In the large-sample limit and assuming the same regularity conditions needed for the asymptotic properties of the MLE (cf. Sec. 40.2.2.1), Wilks' theorem [9] states that the distribution of $q_{\boldsymbol{\theta}} = -2\ln\lambda_{\rm p}(\boldsymbol{\theta})$, under assumption of $\boldsymbol{\theta}$, approaches a chi-square distribution where the number of degrees of freedom is equal to M, the number of components of $\boldsymbol{\theta}$. More details on use of the profile likelihood are given in Refs. [24–26] and in contributions to the PHYSTAT conferences [27]; explicit formulae for special cases can be found in Ref. [28,29]. Further discussion on how to incorporate systematic uncertainties into p-values can be found in Ref. [30].

Even with use of the profile likelihood ratio, for a finite data sample, the p-value of hypothesized parameters $\boldsymbol{\theta}$ will retain in general some dependence on the nuisance parameters $\boldsymbol{\nu}$. Ideally one would find the the maximum of $p_\theta(\boldsymbol{\nu})$ from Eq. (40.50) explicitly, but that is often impractical. An approximate and computationally feasible technique is to use $p_\theta(\widehat{\widehat{\boldsymbol{\nu}}}(\theta))$, where $\widehat{\widehat{\boldsymbol{\nu}}}(\theta)$ are the profiled values of the nuisance parameters as defined in Section 40.2.6.1. The resulting p-value is correct if the true values of the nuisance parameters are equal to the profiled values used; otherwise it could be either too high or too low. This is discussed further in Section 40.4.2 on confidence intervals.

The methods above based on the profile likelihood ratio are useful in practice because, provided one has a sufficiently large data sample, the distributions of the test statistics are related through Wilks' theorem to the chi-square distribution. If the data sample is not large enough to justify use of the asymptotic formulae, then some adjustments can be made to the test statistics so that their distributions are better approximated by the asymptotic ones; these improvements go under the general name of "higher-order asymptotics", which are discussed briefly below. Using these methods one may obtain p-values using the asymptotic formulae even for smaller data samples, avoiding costly Monte Carlo simulation to find distributions of test statistics.

The chi-square distribution for the profile likelihood ratio relies on having a Gaussian distribution for estimators of the model's parameters. An important type of corrected statistic relies on an improved distribution for the maximum-likelihood estimator due to Barndorff–Nielsen [31] (the p^* approximation). Another class

of improved statistic due to Bartlett [32,33] starts with a statistic t which, asymptotically, should be chi-square distributed with $n_{\rm d}$ degrees of freedom. A new statistic is defined as $t' = t\, n_{\rm d}/E[t]$, which by construction has mean $E[t'] = n_{\rm d}$, as for the chi-square distribution. Further details and applications of these methods are described in Refs. [34, 35].

One may also treat model uncertainties in a Bayesian manner but then use the resulting model in a frequentist test. Suppose the uncertainty in a set of nuisance parameters $\boldsymbol{\nu}$ is characterized by a Bayesian prior p.d.f. $\pi(\boldsymbol{\nu})$. This can be used to construct the marginal (also called the prior predictive) model for the data $\boldsymbol{x}$ and parameters of interest $\boldsymbol{\theta}$,

$$P_{\rm m}(\boldsymbol{x}|\boldsymbol{\theta}) = \int P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})\pi(\boldsymbol{\nu})\, d\boldsymbol{\nu}\ . \tag{40.52}$$

The marginal model does not represent the probability of data that would be generated if one were really to repeat the experiment, as in that case one would assume that the nuisance parameters do not vary. Rather, the marginal model represents a situation in which every repetition of the experiment is carried out with new values of $\boldsymbol{\nu}$, randomly sampled from $\pi(\boldsymbol{\nu})$. It is in effect an average of models each with a given $\boldsymbol{\nu}$, where the average is carried out with respect to the prior p.d.f. $\pi(\boldsymbol{\nu})$.

The marginal model for the data $\boldsymbol{x}$ can be used to determine the distribution of a test statistic Q, which can be written

$$P_{\rm m}(Q|\boldsymbol{\theta}) = \int P(Q|\boldsymbol{\theta},\boldsymbol{\nu})\pi(\boldsymbol{\nu})\, d\boldsymbol{\nu}\ . \tag{40.53}$$

In a search for a new signal process, the test statistic can be based on the ratio of likelihoods corresponding to the experiments where signal and background events are both present, L_{s+b}, to that of background only, L_b. Often the likelihoods are evaluated with the profiled values of the nuisance parameters, which may give improved performance. It is important to note, however, that it is through use of the marginal model for the distribution of Q that the uncertainties related to the nuisance parameters are incorporated into the result of the test. Different choices for the test statistic itself only result in variations of the power of the test with respect to different alternatives. Studies of marginalization versus profiling of nuisance parameters and the effects on coverage for specific problems, e.g., related to a Poisson counting experiment, can be found in Refs. [36, 37].

40.3.2.2 *The look-elsewhere effect*

The "look-elsewhere effect" relates to multiple measurements used to test a single hypothesis. The classic example is when one searches in a distribution for a peak whose position is not predicted in advance. Here the no-peak hypothesis is tested using data in a given range of the distribution. In the frequentist approach the correct p-value of the no-peak hypothesis is the probability, assuming background only, to find a signal as significant as the one found or more so anywhere in the search region. This can be substantially higher than the probability to find a peak of equal or greater significance in the particular place where it appeared. There is in general some ambiguity as to what constitutes the relevant search region or even the broader set of relevant measurements. Although the desired p-value is well defined once the search region has been fixed, an exact treatment can require extensive computation.

The "brute-force" solution to this problem by Monte Carlo involves generating data under the background-only hypothesis and for each data set, fitting a peak of unknown position and recording a measure of its significance. To establish a discovery one often requires a p-value smaller than 2.87×10^{-7}, corresponding to a 5σ or larger effect. Determining this with Monte Carlo thus requires generating and fitting a very large number of experiments, perhaps several times 10^7. In contrast, if the position of the peak is fixed, then the fit to the distribution is much easier, and furthermore one can in many cases use formulae valid for sufficiently large samples that bypass completely the need for Monte Carlo (see, *e.g.*, Ref. [28, 29]). However, this fixed-position or "local" p-value would not be correct in general, as it assumes the position of the peak was known in advance.

A method that allows one to modify the local p-value computed under assumption of a fixed position to obtain an approximation to the correct "global" value using a relatively simple calculation is described in Ref. [38]. Suppose a model contains a nuisance parameter such as the peak position that is only defined under the signal model (there is no peak in the background-only model). Furthermore, suppose a test statistic q_0 is defined using the profile likelihood ratio, so that by Wilks' theorem it would be asymptotically chi-square distributed if the peak position were to be fixed. The asymptotic distribution no longer holds if the peak position is adjustable, however, as this violates the regularity conditions of Wilks' theorem. If the statistic has an observed value u, then an approximation for the global p-value is found to be

$$p_{\rm global} \approx p_{\rm local} + \langle N_u \rangle\ , \tag{40.54}$$

where $\langle N_u \rangle$, which is much smaller than one in cases of interest, is the mean number of "upcrossings" (as defined in Ref. [38]) of the statistic q_0 above the level u in the range of the nuisance parameter considered (*e.g.*, the mass range). The value of $\langle N_u \rangle$ can be estimated from the number of upcrossings $\langle N_{u_0} \rangle$ above some much lower value, u_0, by using a relation due to Davis [39],

$$\langle N_u \rangle \approx \langle N_{u_0} \rangle\, e^{-(u-u_0)/2}\ . \tag{40.55}$$

By choosing u_0 sufficiently low, the value of $\langle N_u \rangle$ can be estimated by simulating only a very small number of experiments, or even from the observed data, rather than of the order 10^7 needed if one is dealing with a 5σ effect.

In some cases, more than one parameter is determined from data. For instance, when both the mass and the width of a particle are fitted from a spectrum. In those cases, the number of upcrossing can be generalized by the Euler characteristic $\varphi(u)$, equal to the number of disconnected components minus the number of "holes" in the multidimensional set of the parameter space defined by $q_0(\boldsymbol{\theta}) > u$ [40], which reduces to N_u for one fitted parameter. For instance, when two parameters are determined from a one-dimensional spectrum, the scaling law in Eq. (40.55) can be extended as

$$\langle \varphi(u) \rangle = 1 - F_{\chi^2_1}(u) + (N_1 + N_2\sqrt{u})e^{-u/2}\ , \tag{40.56}$$

where N_1 and N_2 can be evaluated using two convenient values for u. In the above equation, $F_{\chi^2_M}$ denotes the cumulative chi-square distribution for M degrees of freedom, M is equal to one in this case.

40.3.3 *Goodness of fit*

At times one wants to quantify the level of agreement between the data $\boldsymbol{x}$ and a hypothesis H_0 without explicit reference to alternative hypotheses. In the frequentist approach this is done using a *goodness-of-fit test*. The result is quantified with a p-value, in general obtained from a statistic $t(\boldsymbol{x})$ as done in Sec. 40.3.2 with a significance test. Here, however, the *goodness-of-fit statistic* is defined using general considerations of what constitutes greater or lesser compatibility between data and hypothesis and not with reference to alternative hypotheses or power. Nevertheless, for a given statistic $t(\boldsymbol{x})$, the power of the resulting test with respect to an alternative can be found, so that types of alternatives to which one is sensitive (*i.e.*, to which the test has high power) can be investigated.

The Neyman–Pearson lemma (see Sec. 40.3.1) states that a test of H_0 that has maximum power with respect to an alternative H_1 should be based on a statistic that is monotonic in the likelihood ratio $P(\boldsymbol{x}|H_1)/P(\boldsymbol{x}|H_0)$. Therefore, a goodness-of-fit statistic derived without reference to a specific H_1 will not in general attain this maximum power. And even if a given $t(\boldsymbol{x})$ happens to be optimal or nearly so for some alternative H_1, there may be other relevant alternatives for which its power is lower. In practice, goodness-of-fit statistics are defined so as to provide sensitivity to a broad class of alternatives, e.g., those that differ in the location of the bulk of the distribution's probability or the distribution's

width or the nature of the tails. It may therefore be useful to use several goodness-of-fit tests that are sensitive to different aspects of the data distribution in question.

The most important application of goodness-of-fit tests is no doubt in conjunction with the method of least squares, which we describe in Sec. 40.3.3.1 below. Other types of tests, particularly those based on the *empirical distribution function* are described in Sec. 40.3.3.2. Further discussion of goodness of fit can be found in Refs. [4, 41] and references therein.

40.3.3.1 *Goodness-of-fit with chi-square or likelihood ratio*

An important type of goodness-of-fit test arises when a set of measurements $\boldsymbol{y} = (y_1, \ldots, y_N)$ are used to test the hypothesis that the values are Gaussian distributed with given mean values $E[\,y_i\,] = \mu_i$ and variances $V[\,y_i\,] = \sigma_i^2$ (or covariance $V_{ij} = \mathrm{cov}[\,y_i, y_j\,]$ if the values are correlated). The general procedures also hold when the data are Poisson or multinomially distributed with sufficiently large mean values so that the Gaussian represents an adequate approximation. The Gaussian hypothesis may be simple (all parameters fully specified), or the mean values μ_i may be given as functions of some other parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$, with $M < N$. The (co)variances are treated as fixed.

The test statistic derived from the likelihood ratio has already been introduced in Sec. 40.2.3 in connection with the method of least squares, and is given by the minimum of the function $\chi^2(\boldsymbol{\theta})$ with respect to $\boldsymbol{\theta}$, i.e., $t = \chi^2_{\mathrm{min}} = \chi^2(\hat{\boldsymbol{\theta}})$, *e.g.*, in the case of uncorrelated measurements

$$t = \sum_{i=1}^{N} \frac{(y_i - \mu_i(\hat{\boldsymbol{\theta}}))^2}{\sigma_i^2} \; . \tag{40.57}$$

For Gaussian distributed $\boldsymbol{y}$, the statistic t follows a chi-square distribution for $N - M$ degrees of freedom. From Eq. (40.57) one sees that greater t corresponds to increasing incompatibility between the measured y_i and predicted μ_i. The p-value of the Gaussian hypothesis is therefore taken to be

$$p = \int_{\chi^2_{\mathrm{min}}}^{\infty} f(t; n_{\mathrm{d}})\, dt \; , \tag{40.58}$$

where $f(t; n_{\mathrm{d}})$ is the chi-square distribution and $n_{\mathrm{d}} = N - M$ is the appropriate number of degrees of freedom. Values are shown in Fig. 40.2 or obtained from standard computer libraries. If the asymptotic conditions for using the chi-square distribution do not hold, the statistic can still be defined as before, but its p.d.f. must be determined by other means in order to obtain the p-value, *e.g.*, using a Monte Carlo calculation.

Often the data represent numbers of events in N bins of a histogram, *i.e.*, $\boldsymbol{n} = (n_1, \ldots, n_N)$. An important case is when $\boldsymbol{n}$ follows a multinomial distribution with $n_{\mathrm{tot}} = \sum_{i=1}^{N} n_i$ total entries and mean values μ_i, or equivalently bin probabilities $p_i = \mu_i / n_{\mathrm{tot}}$. Alternatively one may model the n_i as independent and Poisson distributed with means μ_i. If there are no adjustable parameters in the hypotheses, then the goodness-of-fit can be quantified with *Pearson's* χ^2 *statistic*, defined for multinomial data as

$$t_{\mathrm{M}} = \sum_{i=1}^{N} \frac{(n_i - n_{\mathrm{tot}} p_i)^2}{n_{\mathrm{tot}} p_i} \; , \tag{40.59}$$

or for the independent Poisson data as

$$t_{\mathrm{P}} = \sum_{i=1}^{N} \frac{(n_i - \mu_i)^2}{\mu_i} \; . \tag{40.60}$$

In the limit where the means μ_i are large, the statistics t_{M} and t_{P} are found to follow chi-square distributions for $N - 1$ and N degrees of freedom, respectively. Having one fewer degrees of freedom in the multinomial case is related to the fact that n_{tot} is fixed and thus the n_i are correlated.

Alternatively one can use the test statistic based on the likelihood ratio $t = -2 \ln \lambda(\hat{\boldsymbol{\theta}})$ given previously in Eq. (40.19). Here the likelihood ratio λ is chosen to correspond to the multinomial or Poisson model as appropriate, as described in Sec. 40.2.2.2. One finds that the distribution of the likelihood-ratio statistic approaches the asymptotic limit faster than does Pearson's χ^2 and thus when using the chi-square p.d.f. to compute a p-value one obtains in general a more accurate result from $-2 \ln \lambda$ (see [8]).

Since the mean of the chi-square distribution is equal to n_{d}, one expects in a "reasonable" experiment to obtain $\chi^2 \approx n_{\mathrm{d}}$ (here χ^2 refers to the minimized value). Hence the quantity χ^2/n_{d} is sometimes reported. Since the p.d.f. of χ^2/n_{d} depends on n_{d}, however, one must report n_{d} as well if one wishes to determine the p-value. The p-values obtained for different values of χ^2/n_{d} are shown in Fig. 40.3.

If the minimized χ^2 value indicates a low level of agreement between data and hypothesis, one may be tempted to expect a high degree of uncertainty for any fitted parameters. Poor goodness-of-fit, however, does not mean that one will have large statistical errors for parameter estimates. If, for example, the error bars (or covariance matrix) used in constructing the χ^2 are underestimated, then this will lead to underestimated statistical errors for the fitted parameters and an increased value of the minimized χ^2. The standard deviations of estimators that one finds from, say, Eq. (40.13) reflect how widely the estimates would be distributed if one were to repeat the measurement many times, assuming that the hypothesis and measurement errors used in the χ^2 are also correct. They do not include the systematic error which may result from an incorrect hypothesis or incorrectly estimated measurement errors in the χ^2.

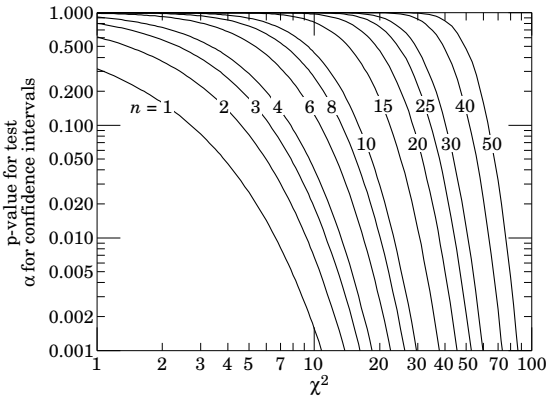

Figure 40.2: One minus the chi-square cumulative distribution, $1 - F_{\chi^2_n}(\chi^2)$, for n degrees of freedom, for n from one to fifty. This gives the p-value for the chi-square goodness-of-fit test as well as one minus the coverage probability for confidence regions (see Sec. 40.4.2.3).

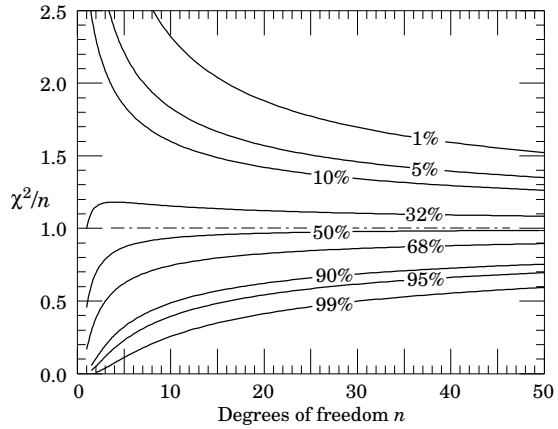

Figure 40.3: The "reduced" χ^2, equal to χ^2/n, for n degrees of freedom, corresponding to different values of the p-value.

40.3.3.2 *Goodness-of-fit with the empirical distribution function*

Suppose a measurement yields a sample of independent and identically distributed (i.i.d.) values $\boldsymbol{x} = (x_1, \ldots, x_n)$. Often the values may be summarized by creating a histogram, but this inevitably results in a loss of information, since the position of the x values within each bin is not retained. Particularly with small numbers of observations n one therefore may prefer to keep the values of each of the x_i (*i.e.*, "unbinned"). The sample may be displayed graphically using the *empirical distribution function* (e.d.f.)

$$F_n(x) = \frac{\text{number of elements in sample with value } \leq x}{n} \,. \tag{40.61}$$

The e.d.f. $F_n(x)$ begins at zero for x less than the lowest observed value, increases by $1/n$ at each observed x_i, and saturates at unity for x equal to the highest value in the sample.

Given an i.i.d. data sample $\boldsymbol{x} = (x_1, \ldots, x_n)$, suppose one wants to test the hypothesis H_0 that x follows the p.d.f. $f(x)$ using a goodness-of-fit test, *i.e.*, without reference to a specific alternative. The hypothesis of the p.d.f. $f(x)$ is equivalent to saying the cumulative distribution function (c.d.f.) is $F(x) = \int_{-\infty}^{x} f(x')\,dx'$. As the e.d.f. $F_n(x)$ can be viewed as an estimator for the c.d.f. $F(x)$, we can derive a goodness-of-fit statistic by some appropriately defined measure of the "distance" between the two.

A widely used example is the Kolmogorov–Smirnov (K–S) test, based on

$$D_n = \sup_x |F_n(x) - F(x)| \,, \tag{40.62}$$

where sup denotes the supremum. That is, D_n is the greatest vertical distance between $F_n(x)$ and $F(x)$ for any x. In the limit of large sample size n, one can show that the distribution of D_n, assuming the data follows the c.d.f. $F(x)$, approaches the Kolmogorov distribution, which is independent of the specific form of $F(x)$ and is provided in many software packages. A larger value of D_n corresponds to greater incompatibility between data and hypothesis, so the p-value is the probability $P(D_n \geq D_{n,\text{obs}}|H_0)$. The K–S test is sensitive in particular to differences in location (*i.e.*, in the mean of x), as this corresponds to a horizontal shift between $F_n(x)$ and $F(x)$, giving a large maximum vertical distance D_n.

The Cramér-von Mises family of tests is based on the squared difference between $F_n(x)$ and $F(x)$ through an integral of the form

$$W^2 = \int_{-\infty}^{\infty} (F(x) - F_n(x))^2 w(x) f(x)\,dx \,, \tag{40.63}$$

where $f(x) = dF/dx$ is the p.d.f. of x and $w(x)$ is a weight function that must be specified. Two important choices are the classic Cramér-von Mises test with $w(x) = 1$, and the Anderson-Darling test with $w(x) = [F(x)(1 - F(x))]^{-1}$, which gives increased sensitivity to departures in the tails of the distribution. For cases such as these, where the weight function depends on x only through the cumulative distribution $F(x)$, one can show (see, *e.g.*, Refs. [4,41]) that the distribution of W^2, assuming data that follows $F(x)$, is independent of the form of $F(x)$. The distributions of the Smirnov-Cramér-von Mises and Anderson-Darling statistics are available in standard computer libraries.

40.3.4 *Bayes factors*

In Bayesian statistics, all of one's knowledge about a model is contained in its posterior probability, which one obtains using Bayes' theorem (Eq. (40.36)). Thus one could reject a hypothesis H if its posterior probability $P(H|\boldsymbol{x})$ is sufficiently small. The difficulty here is that $P(H|\boldsymbol{x})$ is proportional to the prior probability $P(H)$, and there will not be a consensus about the prior probabilities for the existence of new phenomena. Nevertheless one can construct a quantity called the Bayes factor (described below), which can be used to quantify the degree to which the data prefer one hypothesis over another, and is independent of their prior probabilities.

Consider two models (hypotheses), H_i and H_j, described by vectors of parameters $\boldsymbol{\theta}_i$ and $\boldsymbol{\theta}_j$, respectively. Some of the components will be common to both models and others may be distinct. The full prior probability for each model can be written in the form

$$\pi(H_i, \boldsymbol{\theta}_i) = P(H_i)\pi(\boldsymbol{\theta}_i|H_i) \,. \tag{40.64}$$

Here $P(H_i)$ is the overall prior probability for H_i, and $\pi(\boldsymbol{\theta}_i|H_i)$ is the normalized p.d.f. of its parameters. For each model, the posterior probability is found using Bayes' theorem,

$$P(H_i|\boldsymbol{x}) = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i) P(H_i) \pi(\boldsymbol{\theta}_i|H_i)\,d\boldsymbol{\theta}_i}{P(\boldsymbol{x})} \,, \tag{40.65}$$

where the integration is carried out over the internal parameters $\boldsymbol{\theta}_i$ of the model. The ratio of posterior probabilities for the models is therefore

$$\frac{P(H_i|\boldsymbol{x})}{P(H_j|\boldsymbol{x})} = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i)\,d\boldsymbol{\theta}_i}{\int P(\boldsymbol{x}|\boldsymbol{\theta}_j, H_j)\pi(\boldsymbol{\theta}_j|H_j)\,d\boldsymbol{\theta}_j} \frac{P(H_i)}{P(H_j)} \,. \tag{40.66}$$

The *Bayes factor* is defined as

$$B_{ij} = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i)\,d\boldsymbol{\theta}_i}{\int P(\boldsymbol{x}|\boldsymbol{\theta}_j, H_j)\pi(\boldsymbol{\theta}_j|H_j)\,d\boldsymbol{\theta}_j} \,. \tag{40.67}$$

This gives what the ratio of posterior probabilities for models i and j would be if the overall prior probabilities for the two models were equal. If the models have no nuisance parameters, *i.e.*, no internal parameters described by priors, then the Bayes factor is simply the likelihood ratio. The Bayes factor therefore shows by how much the probability ratio of model i to model j changes in the light of the data, and thus can be viewed as a numerical measure of evidence supplied by the data in favor of one hypothesis over the other.

Although the Bayes factor is by construction independent of the overall prior probabilities $P(H_i)$ and $P(H_j)$, it does require priors for all internal parameters of a model, *i.e.*, one needs the functions $\pi(\boldsymbol{\theta}_i|H_i)$ and $\pi(\boldsymbol{\theta}_j|H_j)$. In a Bayesian analysis where one is only interested in the posterior p.d.f. of a parameter, it may be acceptable to take an unnormalizable function for the prior (an improper prior) as long as the product of likelihood and prior can be normalized. Improper priors are, however, only defined up to an arbitrary multiplicative constant, and so the Bayes factor would depend on this constant. Furthermore, although the range of a constant normalized prior is unimportant for parameter determination (provided it is wider than the likelihood), this is not so for the Bayes factor when such a prior is used for only one of the hypotheses. So to compute a Bayes factor, all internal parameters must be described by normalized priors that represent meaningful probabilities over the entire range where they are defined.

Both integrals in Equation (40.67) are of the form

$$m = \int P(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})\,d\boldsymbol{\theta} \,, \tag{40.68}$$

which is similar to the marginal likelihood seen previously in Eq. (40.52) (in some fields this quantity is called the *evidence*). Computing marginal likelihoods can be difficult; in many cases it can be done with the nested sampling algorithm [42]. A review of Bayes factors can be found in Ref. [43].

40.4 Intervals and limits

When the goal of an experiment is to determine a parameter θ, the result is usually expressed by quoting, in addition to the point estimate, some sort of interval which reflects the statistical precision of the measurement. In the simplest case, this can be given by the parameter's estimated value $\widehat{\theta}$ plus or minus an estimate of the standard deviation of $\widehat{\theta}$, $\widehat{\sigma_{\widehat{\theta}}}$. If, however, the p.d.f. of the estimator is not Gaussian or if there are physical boundaries on the possible values of the parameter, then one usually quotes instead an interval according to one of the procedures described below.

In reporting an interval or limit, the experimenter may wish to

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

- communicate as objectively as possible the result of the experiment;
- provide an interval that is constructed to cover on average the true value of the parameter with a specified probability;
- provide the information needed by the consumer of the result to draw conclusions about the parameter or to make a particular decision;
- draw conclusions about the parameter that incorporate stated prior beliefs.

With a sufficiently large data sample, the point estimate and standard deviation (or for the multiparameter case, the parameter estimates and covariance matrix) satisfy essentially all of these goals. For small data samples, no single method for quoting an interval will achieve all of them.

In addition to the goals listed above, the choice of method may be influenced by practical considerations such as ease of producing an interval from the results of several measurements. Of course the experimenter is not restricted to quoting a single interval or limit; one may choose, for example, first to communicate the result with a confidence interval having certain frequentist properties, and then in addition to draw conclusions about a parameter using a judiciously chosen subjective Bayesian prior. It is recommended, however, that there be a clear separation between these two aspects of reporting a result. In the remainder of this section, we assess the extent to which various types of intervals achieve the goals stated here.

40.4.1 *Bayesian credible intervals*

As described in Sec. 40.2.5, a Bayesian posterior probability may be used to determine regions that will have a given probability of containing the true value of a parameter. In the single parameter case, for example, an interval (called a Bayesian or credible interval) $[\theta_{\rm lo}, \theta_{\rm up}]$ can be determined which contains a given fraction $1-\alpha$ of the posterior probability, *i.e.*,

$$1-\alpha = \int_{\theta_{\rm lo}}^{\theta_{\rm up}} p(\theta|\boldsymbol{x})\, d\theta \ . \tag{40.69}$$

Sometimes an upper or lower limit is desired, *i.e.*, $\theta_{\rm lo}$ or $\theta_{\rm up}$ can be set to a physical boundary or to plus or minus infinity. In other cases, one might be interested in the set of θ values for which $p(\theta|\boldsymbol{x})$ is higher than for any θ not belonging to the set, which may constitute a single interval or a set of disjoint regions; these are called highest posterior density (HPD) intervals. Note that HPD intervals are not invariant under a nonlinear transformation of the parameter.

An important case is when we have a Poisson variable n which counts signal events with unknown mean s as well as background with mean b, assumed known. To obtain an upper limit on s, one may proceed as follows. The likelihood for s is given by the Poisson distribution for n with mean $s+b$,

$$P(n|s) = \frac{(s+b)^n}{n!} e^{-(s+b)} \ . \tag{40.70}$$

Assuming a uniform prior in the allowed range $s \geq 0$, Eq. (40.36) gives the posterior density for s. An upper limit $s_{\rm up}$ at confidence level (or here, rather, *credibility* level) $1-\alpha$ can be obtained by requiring

$$1-\alpha = \int_0^{s_{\rm up}} p(s|n) ds = \frac{\int_0^{s_{\rm up}} P(n|s)\, \pi(s)\, ds}{\int_0^{\infty} P(n|s)\, \pi(s)\, ds} \ . \tag{40.71}$$

By relating the integrals in Eq. (40.71) to incomplete gamma functions, the solution for the upper limit is found to be

$$s_{\rm up} = \frac{1}{2} F_{\chi^2}^{-1}(p; 2(n+1)) - b \ , \tag{40.72}$$

where F_{χ^2} is the cumulative chi-square distribution here for $2(n+1)$ degrees of freedom and $F_{\chi^2}^{-1}$ its inverse, i.e.: the quantile of the chi-square distribution. The p-value is

$$p = 1-\alpha \left(1 - F_{\chi^2}(2b; 2(n+1))\right) \ , \tag{40.73}$$

For the special case of $b=0$, the limit reduces to

$$s_{\rm up} = \frac{1}{2} F_{\chi^2}^{-1}(1-\alpha; 2(n+1)) \ . \tag{40.74}$$

It happens that for the case of $b=0$, the upper limit from Eq. (40.74) coincides numerically with the frequentist upper limit discussed in Section 40.4.2.4. Values of $\mu_{\rm up}$ for $1-\alpha = 0.9$ and 0.95 are given in Table 40.2. The frequentist properties of confidence intervals for the Poisson mean found in this way are discussed in Refs. [2] and [44].

As in any Bayesian analysis, it is important to show how the result changes under assumption of different prior probabilities. For example, one could consider the Jeffreys prior as described in Sec. 40.2.5. For this problem one finds the Jeffreys prior $\pi(s) \propto 1/\sqrt{s+b}$ with $s \geq 0$. As with the constant prior, one would not regard this as representing one's prior beliefs about s, both because it is improper and also as it depends on b. Rather it is used with Bayes' theorem to produce an interval whose frequentist properties can be studied.

If the model contains nuisance parameters then these are eliminated by marginalizing, as in Eq. (40.43), to obtain the p.d.f. for the parameters of interest. For example, if the parameter b in the Poisson counting problem above were to be characterized by a prior p.d.f. $\pi(b)$, then one would first use Bayes' theorem to find $p(s,b|n)$. This is then marginalized to find $p(s|n) = \int p(s,b|n)\pi(b)\, db$, from which one may determine an interval for s. One may not be certain whether to extend a model by including more nuisance parameters. In this case, a Bayes factor may be used to determine to what extent the data prefer a model with additional parameters, as described in Section 40.3.4.

40.4.2 *Frequentist confidence intervals*

The unqualified phrase "confidence intervals" refers to frequentist intervals obtained with a procedure due to Neyman [45], described below. The boundary of the interval (or in the multiparameter case, region) is given by a specific function of the data, which would fluctuate if one were to repeat the experiment many times. The *coverage probability* refers to the fraction of intervals in such an ensemble that contain the true parameter value. Confidence intervals are constructed so as to have a coverage probability greater than or equal to a given *confidence level*, regardless of the true parameter's value. It is important to note that in the frequentist approach, such a probability is not meaningful for a fixed interval. In this section we discuss several techniques for producing intervals that have, at least approximately, this property of coverage.

40.4.2.1 *The Neyman construction for confidence intervals*

Consider a p.d.f. $f(x;\theta)$ where x represents the outcome of the experiment and θ is the unknown parameter for which we want to construct a confidence interval. The variable x could (and often is) used to build an estimator for θ if it monothonically depends on θ. Using $f(x;\theta)$ we can find, using a pre-defined rule and probability $1-\alpha$ for every value of θ, a set of values $x_1(\theta,\alpha)$ and $x_2(\theta,\alpha)$ such that

$$P(x_1 < x < x_2; \theta) = \int_{x_1}^{x_2} f(x;\theta)\, dx \geq 1-\alpha \ . \tag{40.75}$$

If x is discrete, the integral is replaced by the corresponding sum where the extreme values x_1 and x_2 are excluded. In that case there may not exist a range of x values whose summed probability is exactly equal to a given value of $1-\alpha$, and one requires by convention $P(x_1 < x < x_2; \theta) \geq 1-\alpha$.

This is illustrated for continuous x in Fig. 40.4: a horizontal line segment $[x_1(\theta,\alpha), x_2(\theta,\alpha)]$ is drawn for representative values of θ. The union of such intervals for all values of θ, designated in the figure as $D(\alpha)$, is known as a *confidence belt*. Typically, the curves $x_1(\theta,\alpha)$ and $x_2(\theta,\alpha)$ are monotonic functions of θ, which we assume for this discussion.

Upon performing an experiment to measure x and obtaining a value x_0, one draws a vertical line through x_0. The confidence interval for θ is the set of all values of θ for which the corresponding line segment $[x_1(\theta,\alpha), x_2(\theta,\alpha)]$ is intercepted by this vertical line.

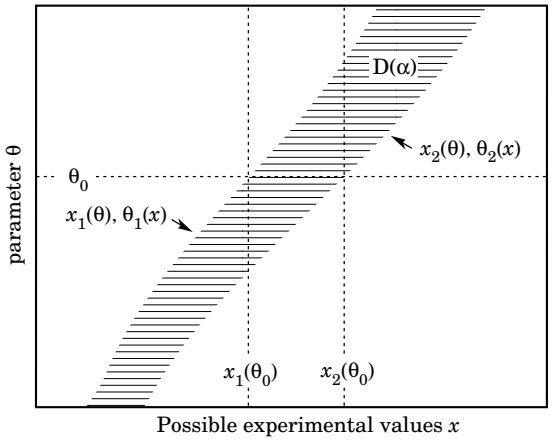

Figure 40.4: Construction of the confidence belt (see text).

Such confidence intervals are said to have a *confidence level* (CL) equal to $1-\alpha$.

Now suppose that the true value of θ is θ_0, indicated in the figure. We see from the figure that θ_0 lies between $\theta_1(x)$ and $\theta_2(x)$, where x is an outcome of our measurement, if and only if x lies between $x_1(\theta_0)$ and $x_2(\theta_0)$. The two events thus have the same probability, and since this is true for any value θ_0, we can drop the subscript 0 and obtain

$$1-\alpha = P(x_1(\theta) < x < x_2(\theta)) = P(\theta_2(x) < \theta < \theta_1(x)) \ . \quad (40.76)$$

In this probability statement, $\theta_1(x)$ and $\theta_2(x)$, *i.e.*, the endpoints of the interval, are the random variables and θ is an unknown constant. If the experiment were to be repeated a large number of times, the interval $[\theta_1, \theta_2]$ would vary, covering the fixed value θ in a fraction $1-\alpha$ of the experiments.

The condition of coverage in Eq. (40.75) does not determine x_1 and x_2 uniquely, and additional criteria are needed. One possibility is to choose *central intervals* such that the probabilities to find x below x_1 and above x_2 are each $\alpha/2$. In other cases, one may want to report only an upper or lower limit, in which case one of $P(x \le x_1)$ or $P(x \ge x_2)$ can be set to α and the other to zero. Another principle based on *likelihood ratio ordering* for determining which values of x should be included in the confidence belt is discussed below.

When the observed random variable x is continuous, the coverage probability obtained with the Neyman construction is $1-\alpha$, regardless of the true value of the parameter. Because of the requirement $P(x_1 < x < x_2) \ge 1-\alpha$ when x is discrete, one obtains in that case confidence intervals that include the true parameter with a probability greater than or equal to $1-\alpha$.

40.4.2.2 *Confidence interval from a hypothesis test*

An equivalent view of the Neyman construction from the previous section is to consider a test (see Sec. 40.3) of the hypothesis that the parameter's true value is θ (assume one constructs a test for all physical values of θ). One then excludes all values of θ where the hypothesis would be rejected in a test of size α or less. The remaining values constitute the confidence interval at confidence level $1-\alpha$. If the critical region of the test is characterized by having a p-value $p_\theta \le \alpha$, then the endpoints of the confidence interval are found in practice by solving $p_\theta = \alpha$ for θ. The confidence belt seen in Sec. 40.4.2.1 is a graphical representation of the complement of the critical region of the test of each θ.

In this view it is straightforward to generalize from scalar data x and single parameter θ to a vector of data values $\boldsymbol{x}$ that follow a probability $P(\boldsymbol{x}|\boldsymbol{\theta})$, which depends on a set of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$. We will refer to the result generically as a confidence interval or for multiple components a confidence *region*.

One is still free to choose the test to be used; this corresponds to the freedom in the Neyman construction as to which values of the data are included in the confidence belt. One possibility is to use a test statistic based on the *likelihood ratio*,

$$\lambda(\boldsymbol{\theta}) = \frac{P(\boldsymbol{x}|\boldsymbol{\theta})}{P(\boldsymbol{x}|\widehat{\boldsymbol{\theta}})} \ , \quad (40.77)$$

where $\widehat{\boldsymbol{\theta}}$ is the maximum-likelihood estimator. This results in the intervals described in Ref. [46] by Feldman and Cousins.

If the model contains nuisance parameters $\boldsymbol{\nu}$, then these can be incorporated into the test (or the p-values) used to determine the limit by profiling as discussed in Section 40.3.2.1. That is, the likelihood ratio (40.77) is replaced by the profile likelihood ratio of Eq. (40.51). As mentioned there, one excludes the parameter of interest $\boldsymbol{\theta}$ only if it is rejected for all possible values of $\boldsymbol{\nu}$. The resulting region for $\boldsymbol{\theta}$ will then cover the true value with a probability greater than or equal to the nominal confidence level for all points in $\boldsymbol{\nu}$-space.

If the p-value is based on the profiled values of the nuisance parameters, *i.e.*, with $\boldsymbol{\nu} = \widehat{\widehat{\boldsymbol{\nu}}}(\theta)$ used in Eq. (40.50), then the coverage probability of the resulting interval for the parameter of interest is approximate and may be too high or too low. This procedure has been called *profile construction* in particle physics [36] (see also Ref. [30]).

40.4.2.3 *Confidence regions from the likelihood function*

The procedure for determining confidence intervals or regions is greatly simplified in the large-sample limit with use of the profile likelihood ratio $\lambda_{\rm p}(\boldsymbol{\theta})$ from Eq. (40.51) to test each value of the parameters of interest $\boldsymbol{\theta}$, also in the case where the model contains nuisance parameters $\boldsymbol{\nu}$. In the large-sample limit and assuming the regularity conditions (see Sec. 40.2.2.1), the estimators for all of the parameters become Gaussian distributed. Wilks' theorem follows from this property and states that the asymptotic distribution of $-2\ln\lambda_{\rm p}(\boldsymbol{\theta})$ is chi-square for M degrees of freedom, where M is the number of parameters interest only. A test of $\boldsymbol{\theta}$ thus becomes independent of the nuisance parameters and the confidence region at confidence level $1-\alpha$ is therefore given by the set of $\boldsymbol{\theta}$ values satisfying

$$\ln L(\boldsymbol{\theta}) = \ln L(\hat{\boldsymbol{\theta}}) - \frac{1}{2} F^{-1}_{\chi^2_M}(1-\alpha) \ . \quad (40.78)$$

where F_M^{-1} is the quantile (inverse of the cumulative distribution) for a chi-square distribution with M degrees of freedom. This holds as long as the estimators for the parameters are Gaussian-distributed, which could hold even in a small-sample problem. One should be aware, however, of potential violations of the regularity conditions if, e.g., the true value of a parameter is at the boundary of the parameter space.

A common application of Eq. (40.78) is in the method of least squares, where the sum of squares to be minimized is related to the likelihood by $\chi^2(\boldsymbol{\theta}) = -2\ln L(\boldsymbol{\theta}) + C$, where the constant C does not depend on the parameters $\boldsymbol{\theta}$. In this case, Eq. (40.78) becomes

$$\chi^2(\boldsymbol{\theta}) = \chi^2(\hat{\boldsymbol{\theta}}) + F^{-1}_{\chi^2_M}(1-\alpha) \ . \quad (40.79)$$

The allowed departure of χ^2 or $\ln L$ from its optimized value is therefore found from $\Delta\chi^2 = 2\Delta\ln L = F^{-1}_{\chi^2_M}(1-\alpha)$. Values of $\Delta\chi^2$ or $2\Delta\ln L$ are given in Table 40.1 for several values of the coverage probability $1-\alpha$ and number of fitted parameters M.

For the special case of $M = 1$ and $1-\alpha = 0.683$ one has $F^{-1}_{\chi^2_1}(0.683) = 1$, so the formula for the 68.3% CL confidence interval coincides with Eq. (40.13) for the standard deviation of an estimator. The numerical factor $F^{-1}_{\chi^2_M}(1-\alpha)$ grows with M for fixed α, i.e., with more parameters, one needs a larger decrease in $\ln L$ from its maximum to obtain a region with a given confidence level. Comparison of Eqs. (40.13) and (40.78) gives the number of standard deviations from the MLE to the tangent of a $1-\alpha$ CL confidence region with N parameters as $s = [F^{-1}_{\chi^2_M}(1-\alpha)]^{1/2}$, e.g., for $M = 2$ and $1-\alpha = 0.95$, $s = 2.45$.

For small-sample problems, the likelihood ratio is no longer chi-square distributed and these are not exact confidence regions

Table 40.1: Values of $\Delta\chi^2$ or $2\Delta \ln L$ corresponding to a coverage probability $1-\alpha$ in the large data sample limit, for joint estimation of M parameters.

$(1-\alpha)$ (%)	$M=1$	$M=2$	$M=3$
68.27	1.00	2.30	3.53
90.	2.71	4.61	6.25
95.	3.84	5.99	7.82
95.45	4.00	6.18	8.03
99.	6.63	9.21	11.34
99.73	9.00	11.83	14.16

according to our previous definition, the coverage probability is no longer guaranteed to be equal to the nominal confidence level, and it will in general depend on $\boldsymbol{\theta}$. Nevertheless, they can still have a coverage probability only weakly dependent on the true parameter, and approximately as given in Table 40.1. In any case, the coverage probability of the intervals or regions obtained according to this procedure can in principle be determined as a function of the true parameter(s), for example, using a Monte Carlo calculation.

One of the practical advantages of intervals that can be constructed from the log-likelihood function or χ^2 is that it is relatively simple to produce the interval for the combination of several experiments. If N independent measurements result in log-likelihood functions $\ln L_i(\boldsymbol{\theta})$, then the combined log-likelihood function is simply the sum,

$$\ln L(\boldsymbol{\theta}) = \sum_{i=1}^{N} \ln L_i(\boldsymbol{\theta}) \; . \tag{40.80}$$

This can then be used to determine an approximate confidence interval or region with Eq. (40.78).

40.4.2.4 *Limits for Poisson or binomial data*

Another important class of measurements consists of counting a certain number of events, n. In this section, we will assume these are all events of the desired type, *i.e.*, there is no background. If n represents the number of events produced in a reaction with cross section σ and selection efficiency ε in a fixed integrated luminosity $\mathcal{L}$, then it follows a Poisson distribution with mean $\mu = \sigma\varepsilon\mathcal{L}$. If, on the other hand, one has selected a larger sample of N events and found n of them to have a particular property, then n follows a binomial distribution where the parameter p gives the probability for the event to possess the property in question. This is appropriate, *e.g.*, for estimates of branching ratios or selection efficiencies based on a given total number of events.

For the case of Poisson distributed n, limits on the mean value μ can be found from the Neyman procedure as discussed in Section 40.4.2.1 with n used directly as the statistic x . The upper and lower limits are found to be

$$\mu_{\rm lo} = \frac{1}{2} F^{-1}_{\chi^2}(\alpha_{\rm lo}; 2n) \; , \tag{40.81a}$$

$$\mu_{\rm up} = \frac{1}{2} F^{-1}_{\chi^2}(1-\alpha_{\rm up}; 2(n+1)) \; , \tag{40.81b}$$

where confidence levels of $1-\alpha_{\rm lo}$ and $1-\alpha_{\rm up}$ refer separately to the corresponding intervals $\mu \geq \mu_{\rm lo}$ and $\mu \leq \mu_{\rm up}$. For central confidence intervals at confidence level $1-\alpha$, set $\alpha_{\rm lo} = \alpha_{\rm up} = \alpha/2$.

It happens that the upper limit from Eq. (40.81b) coincides numerically with the Bayesian upper limit for a Poisson parameter, using a uniform prior p.d.f. for μ. Values for confidence levels of 90% and 95% are shown in Table 40.2.

For the case of binomially distributed n successes out of N trials with probability of success p, the upper and lower limits on p can be determined with a similar procedure due to Clopper and Pearson [47], which is available in computer libraries.

40.4.2.5 *Parameter exclusion in cases of low sensitivity*

An important example of a statistical test arises in the search for a new signal process. Suppose the parameter μ is defined such that it is proportional to the signal cross section. A statistical test may be carried out for hypothesized values of μ, which may be done by computing a p-value, p_μ, for all μ. Those values not rejected in a test of size α, *i.e.*, for which one does not find $p_\mu \leq \alpha$, constitute a confidence interval with confidence level $1-\alpha$.

Table 40.2: Lower and upper (one-sided) limits for the mean μ of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

	$1-\alpha$ =90%		$1-\alpha$ =95%	
n	$\mu_{\rm lo}$	$\mu_{\rm up}$	$\mu_{\rm lo}$	$\mu_{\rm up}$
0	–	2.30	–	3.00
1	0.105	3.89	0.051	4.74
2	0.532	5.32	0.355	6.30
3	1.10	6.68	0.818	7.75
4	1.74	7.99	1.37	9.15
5	2.43	9.27	1.97	10.51
6	3.15	10.53	2.61	11.84
7	3.89	11.77	3.29	13.15
8	4.66	12.99	3.98	14.43
9	5.43	14.21	4.70	15.71
10	6.22	15.41	5.43	16.96

In general one will find that for some regions in the parameter space of the signal model, the predictions for data are almost indistinguishable from those of the background-only model. This corresponds to the case where μ is very small, as would occur, *e.g.*, in a search for a new particle with a mass so high that its production rate in a given experiment is negligible. That is, one has essentially no experimental sensitivity to such a model.

One would prefer that if the sensitivity to a model (or a point in a model's parameter space) is very low, then it should not be excluded. Even if the outcomes predicted with or without signal are identical, however, the probability to reject the signal model will equal α, the type-I error rate. As one often takes α to be 5%, this would mean that in a large number of searches covering a broad range of a signal model's parameter space, there would inevitably be excluded regions in which the experimental sensitivity is very small, and thus one may question whether it is justified to regard such parameter values as disfavored.

Exclusion of models to which one has little or no sensitivity occurs, for example, if the data fluctuate very low relative to the expectation of the background-only hypothesis. In this case the resulting upper limit on μ may be anomalously low. As a means of controlling this effect one often determines the mean or median limit under assumption of the background-only hypothesis, as discussed in Sec. 40.5.

One way to mitigate the problem of excluding models to which one is not sensitive is the $\mathrm{CL_s}$ method, where the measure used to test a parameter is increased for decreasing sensitivity [48, 49].

The procedure is based on a statistic called $\mathrm{CL_s}$, which is defined as

$$\mathrm{CL_s} = \frac{p_\mu}{1-p_{\rm b}} \; , \tag{40.82}$$

where $p_{\rm b}$ is the p-value of the background-only hypothesis. In the usual formulation of the method, both p_μ and $p_{\rm b}$ are defined using a single test statistic, and the definition of $\mathrm{CL_s}$ above assumes this statistic is continuous; more details can be found in Refs. [48, 49].

A point in a model's parameter space is regarded as excluded if one finds $\mathrm{CL_s} \leq \alpha$. As the denominator in Eq. (40.82) is always less than or equal to unity, the exclusion criterion based on $\mathrm{CL_s}$ is more stringent than the usual requirement $p_\mu \leq \alpha$. In this sense the $\mathrm{CL_s}$ procedure is conservative, and the coverage probability of the corresponding intervals will exceed the nominal confidence level $1-\alpha$. If the experimental sensitivity to a given value of μ is very low, then one finds that as p_μ decreases, so does the denominator $1-p_{\rm b}$, and thus the condition $\mathrm{CL_s} \leq \alpha$ is effectively prevented from being satisfied. In this way the exclusion of parameters in the case of low sensitivity is suppressed.

The $\mathrm{CL_s}$ procedure has the attractive feature that the resulting intervals coincide with those obtained from the Bayesian method

Phys. A 2026.41. Downloaded from www.worldscientific.com

by KARLSRUHE INSTI

in two important cases: the mean value of a Poisson or Gaussian distributed measurement with a constant prior. The CL_s intervals overcover for all values of the parameter μ, however, by an amount that depends on μ.

The problem of excluding parameter values to which one has little sensitivity is particularly acute when one wants to set a one-sided limit, *e.g.*, an upper limit on a cross section. Here one tests a value of a rate parameter μ against the alternative of a lower rate, and therefore the critical region of the test is taken to correspond to data outcomes with a low event yield. If the number of events found in the search region fluctuates low enough, however, it can happen that all physically meaningful signal parameter values, including those to which one has very little sensitivity, are rejected by the test.

Another solution to this problem, therefore, is to replace the one-sided test by one based on the likelihood ratio, where the critical region is not restricted to low rates. This is the approach followed in the Feldman-Cousins procedure described in Section 40.4.2.1. The critical region for the test of a given value of μ contains data values characteristic of both higher and lower rates. As a result, for a given observed rate one can in general obtain a two-sided interval. If, however, the parameter estimate $\hat{\mu}$ is sufficiently close to the lower limit of zero, then only high values of μ are rejected, and the lower edge of the confidence interval is at zero. Note, however, that the coverage property of $1-\alpha$ pertains to the entire interval, not to the probability for the upper edge $\mu_{\rm up}$ to be greater than the true value μ. For parameter estimates increasingly far away from the boundary, *i.e.*, for increasing signal significance, the point $\mu = 0$ is excluded and the interval has nonzero upper and lower edges.

An additional difficulty arises when a parameter estimate is not significantly far away from the boundary, in which case it is natural to report a one-sided confidence interval (often an upper limit). It is straightforward to force the Neyman prescription to produce only an upper limit by setting $x_2 = \infty$ in Eq. (40.75). Then x_1 is uniquely determined and the upper limit can be obtained. If, however, the data come out such that the parameter estimate is not so close to the boundary, one might wish to report a central confidence interval (*i.e.*, an interval based on a two-sided test with equal upper and lower tail areas). As pointed out by Feldman and Cousins [46], if the decision to report an upper limit or two-sided interval is made by looking at the data ("flip-flopping"), then in general there will be parameter values for which the resulting intervals have a coverage probability less than $1-\alpha$. With the confidence intervals suggested in Ref. [46], the prescription determines whether the interval is one- or two-sided in a way which preserves the coverage probability (and are thus said to be *unified*).

The intervals according to this method for the mean of Poisson variable in the absence of background are given in Table 40.3[1]. The values of $1-\alpha$ given here refer to the coverage of the true parameter by the whole interval $[\mu_1, \mu_2]$. In Table 40.2 for the one-sided upper limit, however, $1-\alpha$ refers to the probability to have $\mu_{\rm up} \geq \mu$ (or $\mu_{\rm lo} \leq \mu$ for lower limits).

A potential difficulty with unified intervals arises if, for example, one constructs such an interval for a Poisson parameter s of some yet to be discovered signal process with, say, $1-\alpha = 0.9$. If the true signal parameter is zero, or in any case much less than the expected background, one will usually obtain a one-sided upper limit on s. In a certain fraction of the experiments, however, a two-sided interval for s will result. Since, however, one typically chooses $1-\alpha$ to be only 0.9 or 0.95 when setting limits, the value $s = 0$ may be found below the lower edge of the interval before the existence of the effect is well established. It must then be communicated carefully that in excluding $s = 0$ at, say, 90% or 95% confidence level from the interval, one is not necessarily claiming to have discovered the effect, for which one would usually require a higher level of significance (*e.g.*, 5 σ).

Another possibility is to construct a Bayesian interval as described in Section 40.4.1. The presence of the boundary can be incorporated simply by setting the prior density to zero in the unphysical region. More specifically, the prior may be chosen using formal rules such as the reference prior or Jeffreys prior mentioned in Sec. 40.2.5.

In particle physics a widely used prior for the mean μ of a Poisson distributed measurement has been the uniform distribution for $\mu \geq 0$. This prior does not follow from any fundamental rule nor can it be regarded as reflecting a reasonable degree of belief, since the prior probability for μ to lie between any two finite values is zero. The procedure above can be more appropriately regarded as a way for obtaining intervals with frequentist properties that can be investigated. The resulting upper limits have a coverage probability that depends on the true value of the Poisson parameter, and is nowhere smaller than the stated probability content. Lower limits and two-sided intervals for the Poisson mean based on uniform priors undercover, however, for some values of the parameter, although to an extent that in practical cases may not be too severe [2, 44].

In any case, it is important to always report sufficient information so that the result can be combined with other measurements. Often this means giving an unbiased estimator and its standard deviation, even if the estimated value is in the unphysical region.

It can also be useful with a frequentist interval to calculate its subjective probability content using the posterior p.d.f. based on one or several reasonable guesses for the prior p.d.f. If it turns out to be significantly less than the stated confidence level, this warns that it would be particularly misleading to draw conclusions about the parameter's value from the interval alone.

Table 40.3: Unified confidence intervals $[\mu_1, \mu_2]$ for a the mean of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

	$1-\alpha$ =90%		$1-\alpha$ =95%

40.5 Experimental sensitivity

In this section we describe methods for characterizing the sensitivity of a search for a new physics signal. As discussed in Sec. 40.3, an experimental analysis can often be formulated as a test of hypothetical model parameters. Therefore, we may quantify the sensitivity by giving the results that we expect from such a test under specific assumptions about the signal process.

Here to be concrete we will consider a parameter μ proportional to the rate of a signal process, although the concepts described in this section may be easily generalized to other parameters. One may wish to establish discovery of the signal process by testing and rejecting the hypothesis that $\mu = 0$, and in addition one often wants to test nonzero values of μ to construct a confidence interval (*e.g.*, limits) as described in Sec. 40.4. In the frequentist framework, the result of each tested value of μ is the p-value p_μ or equivalently the significance $Z_\mu = \Phi^{-1}(1-p_\mu)$, where as usual Φ is the standard Gaussian cumulative distribution and its inverse Φ^{-1} is the standard Gaussian quantile.

Prior to carrying out the experiment, one generally wants to quantify what significance Z_μ is expected under given assumptions for the presence or absence of the signal process. Specifically, for the significance of a test of $\mu = 0$ (the discovery significance) one usually quotes the Z_0 one would expect if the signal is present at a given nominal rate, which we can define in general to cor-

[1] Note that α in Ref. [46] is defined following Neyman [45] as the coverage probability; this is opposite the modern convention used here in which the coverage probability is $1-\alpha$.

respond to $\mu = 1$. For limits, one often gives the expected limit under assumption of the background-only ($\mu = 0$) model. These quantities are used to optimize the analysis and to quantify the experimental sensitivity, that is, to characterize how likely it is to make a discovery if the signal is present, and to say what values of μ one may be able to exclude if the signal is in fact absent.

First we clarify the notion of *expected significance*. Because the significance Z_μ is a function of the data, it is itself a random quantity characterized by a certain sampling distribution. This distribution depends on the assumed value of μ, which is not necessarily the same as the hypothesized value of μ being tested. We may therefore consider the distribution $f(Z_\mu|\mu')$, *i.e.*, the distribution of Z_μ that would be obtained by considering data samples generated under assumption of μ'. In a similar way one can talk about the sampling distribution of an upper limit for μ, $f(\mu_{\rm up}|\mu')$.

One can identify the expected significance or limit with either the mean or median of these distributions, but the median may be preferred since it is invariant under monotonic transformations. For example, the monotonic relation between p-value and significance, $p = 1-\Phi(Z)$, then gives $\mathrm{med}[\,p_\mu|\mu'\,] = 1-\Phi(\mathrm{med}[\,Z_\mu|\mu'\,])$, whereas the corresponding relation does not hold in general for the mean.

In some cases one may be able to write down approximate formulae for the distributions of Z_μ and for limits, but more generally they must be determined from Monte Carlo calculations. In many cases of interest, the significance Z_μ and the limits on μ will have approximate Gaussian distributions.

As an example, consider a Poisson counting experiment, where the result consists of an observed number n of events, modeled as a Poisson distributed variable with a mean of $\mu s+b$. Here s and b, the expected numbers of events from signal and background processes, are taken to be known. If we are interested in discovering the signal process we test and try to reject the hypothesis $\mu = 0$. To characterize the experimental sensitivity, we want to give the discovery significance expected under the assumption of $\mu = 1$.

In the limit where its mean value is large, the Poisson variable n can be approximated as an almost continuous Gaussian variable with mean $\mu s + b$ and standard deviation $\sigma = \sqrt{\mu s + b}$. In the usual case where a physical signal model corresponds to $\mu > 0$, the p-value of $\mu = 0$ is the probability to find n greater than or equal to the value observed,

$$p_0 = \Phi\left(\frac{n-b}{\sqrt{b}}\right) , \tag{40.83}$$

and the corresponding significance is $Z_0 = \Phi^{-1}(1-p_0) = (n-b)/\sqrt{b}$. The median (here equal to the mean) of n assuming $\mu = 1$ is $s + b$, and therefore the median discovery significance is

$$\mathrm{med}[\,Z_0|\mu = 1\,] = \frac{s}{\sqrt{b}} . \tag{40.84}$$

The figure of merit "$s/\sqrt{b}$" has been widely used in particle physics as a measure of expected discovery significance. A better approximation for the Poisson counting experiment, however, may be obtained by testing $\mu = 0$ using the likelihood ratio (40.51) $\lambda(0) = L(0)/L(\hat{\mu})$, where

$$L(\mu) = \frac{(\mu s + b)^n}{n!} e^{-(\mu s+b)} \tag{40.85}$$

is the likelihood function, and $\hat{\mu} = (n-b)/s$ is the estimator of μ. In this example there are no nuisance parameters, as s and b are taken to be known. For the case where the relevant signal models correspond to positive μ, one may test the $\mu = 0$ hypothesis with the statistic $q_0 = -2\ln\lambda(0)$ when $\hat{\mu} > 0$, *i.e.*, an excess is observed, and $q_0 = 0$ otherwise. One can show (see, *e.g.*, Ref. [28, 29]) that in the large-sample limit, the discovery significance is then $Z_0 = \sqrt{q_0}$, for which one finds

$$Z_0 = \sqrt{2\left(n\ln\frac{n}{b} + b - n\right)} \tag{40.86}$$

for $n > b$ and $Z_0 = 0$ otherwise. To approximate the expected discovery significance assuming $\mu = 1$, one may simply replace n with the expected value $E[\,n|\mu = 1\,] = s+b$, the so-called "Asimov data set" [28], giving

$$\mathrm{med}[Z_0|\mu = 1] = \sqrt{2\left((s+b)\ln\left(1+\frac{s}{b}\right) - s\right)} . \tag{40.87}$$

This has been shown in Ref. [28,29] to provide a good approximation to the median discovery significance for values of s of several and for b well below unity. The right-hand side of Eq. (40.87) reduces to $s/\sqrt{b}$ in the limit $s \ll b$.

Beyond the simple Poisson counting experiment, in general one may test values of a parameter μ with more complicated functions of the measured data to obtain a p-value p_μ, and from this one can quote the equivalent significance Z_μ or find, *e.g.*, an upper limit $\mu_{\rm up}$. In this case as well one may quantify the experimental sensitivity by giving the significance Z_μ expected if the data are generated with a different value of the parameter μ'. In some problems, finding the sampling distribution of the significance or limits may be possible using large-sample formulae as described, *e.g.*, in Ref. [28, 29]. In other cases a Monte Carlo study may be needed. Using whatever method of calculation is most appropriate, one usually quotes the expected (mean or, preferably, median) discovery significance or exclusion limit as the primary measure of experimental sensitivity.

Even if the true signal is present at its nominal rate, the actual discovery significance Z_0 obtained from the real data is subject to statistical fluctuations and will not in general be equal to its expected value. In an analogous way, the observed limit will differ from the expected limit even if the signal is absent. Upon observing such a difference one would like to know how large this is compared to expected statistical fluctuations. Therefore, in addition to the observed significance and limits it is useful to communicate not only their expected values but also a measure of the width of their distributions.

As the distributions of significance and limits are often well approximated by a Gaussian, one may indicate the intervals corresponding to plus-or-minus one and/or two standard deviations. If the distributions are significantly non-Gaussian, one may use instead the quantiles that give the same probability content, *i.e.*, $[0.159, 0.841]$ for $\pm1\sigma$, $[0.0228, 0.9772]$ for $\pm2\sigma$. An upper limit found significantly below the background-only expectation may indicate a strong downward fluctuation of the data, or perhaps as well an incorrect estimate of the background rate.

The procedures described above pertain to frequentist hypothesis tests and limits. Bayesian limits, just like those found from a frequentist procedure, are functions of the data and one may therefore find, usually with approximations or Monte Carlo studies, their sampling distribution and corresponding mean (or, preferably, median) and standard deviation.

When trying to establish discovery of a signal process, the Bayesian approach may employ a Bayes factor as described in Sec. 40.3.4. In the case of the Poisson counting experiment with the likelihood from Eq. (40.85), the log of the Bayes factor that compares $\mu = 1$ to $\mu = 0$ is $\ln B_{10} = \ln(L(1)/L(0)) = n\ln(1+s/b) - s$. That is, the expectation value, assuming $\mu = 1$, of $\ln B_{10}$ for this problem is

$$E[\,\ln B_{10}|\mu = 1\,] = (s+b)\ln\left(1+\frac{s}{b}\right) - s . \tag{40.88}$$

Comparing this to Eq. (40.87), one finds $\mathrm{med}[\,Z_0|1\,] = \sqrt{2E[\,\ln B_{10}|1\,]}$. Thus for this particular problem the frequentist median discovery significance can be related to the corresponding Bayes factor in a simple way.

In some analyses, the goal may not be to establish discovery of a signal process but rather to measure, as accurately as possible, the signal rate. If we consider again the Poisson counting experiment described by the likelihood function of Eq. (40.85), the maximum-likelihood estimator $\hat{\mu} = (n-b)/s$ has a variance, assuming $\mu = 1$, of

$$V[\,\hat{\mu}\,] = V\left[\frac{n-b}{s}\right] = \frac{1}{s^2}V[\,n\,] = \frac{s+b}{s^2} , \tag{40.89}$$

so that the standard deviation of $\hat{\mu}$ is $\sigma_{\hat{\mu}} = \sqrt{s+b}/s$. One may therefore use $s/\sqrt{s+b}$ as a figure of merit to be maximized in order to obtain the best measurement accuracy of a rate parameter. The quantity $s/\sqrt{s+b}$ is also the expected significance with which one rejects s assuming the signal is absent, and thus can be used to optimize the expected upper limit on s.

41.1 Introduction

This chapter gives an overview of the core concepts of machine learning (ML)—the use of algorithms that learn from data, identify patterns, and make predictions or decisions without being explicitly programmed—that are relevant to particle physics with some examples of applications to the energy, intensity, cosmic, and accelerator frontiers. ML is an enormous field that has grown substantially in the last decade, largely driven by the emergence of so-called deep learning (DL) [1, 2]. ML has a long history in particle physics going back to the late 1980s and early 1990s; see Refs. [3–5] for recent reviews. ML is a subset of artificial intelligence (AI), which generally refers to computational systems that can perform tasks typically associated with human intelligence, such as learning, reasoning, problem-solving, perception, and decision-making.

Physicists are exploring and contributing to machine learning at an unprecedented rate, which poses a challenge for those who wish to have an up-to-date view of the field. This motivated an effort to create *A Living Review of Machine Learning for Particle and Nuclear Physics* [6], which can be accessed here: `https://iml-wg.github.io/HEPML-LivingReview/`. At the time of writing, the Living Review included more than 1,800 references organized hierarchically by topic. Although we make references to some of these papers, this chapter focuses on the methodology and does not attempt to give a comprehensive review of the applications.

Machine learning and artificial intelligence have a mathematical foundation that is closely tied to statistics (see Ch. 40), the calculus of variations, approximation theory, and optimal control theory. Nevertheless, there have been tremendous advances in recent years, driven by increased computational power, enormous datasets, and new insights, that are impacting physics and society.

The topic can be organized along a few axes, which we use to structure this section. First, there are different learning paradigms, for example, supervised learning, unsupervised learning, and reinforcement learning. Within these paradigms, there are various tasks; for example, classification and regression—which have been the primary use of ML in particle physics—are examples of supervised learning. In addition to the learning paradigm and tasks, there are various types of machine learning models that generically process some input and produce some output. The types of models vary based on what they are modeling (*e.g.*, so-called discriminative vs. generative models), as well as how they are implemented (*e.g.*, neural networks, decision trees, or kernel machines). Next, there are the issues around training or learning within the context of a given task and model class, which connects to optimization and regularization. We will briefly discuss the various considerations that emerge in the application of machine learning methods to physics, such as the treatment of systematic uncertainty, the interpretability of the models, and the incorporation of symmetry.

41.1.1 *A gentle introduction with a representative example*

We will use a specific, familiar example to introduce the various ingredients in context before factorizing and abstracting them. Consider the task of *classifying* energy deposits in a particle detector as coming from electrons or protons. For this example, let the detector data consist of energy deposits in d sensors so that the data can be represented as a *feature vector* $x \in \mathbb{R}^d$. Different components of x may correspond to physical quantities with different units (*e.g.*, units of energy, momentum, or position).

Due to the complex interactions of particles in the detector, we do not have an explicit probability model for the high-dimensional data for the electron and proton scenarios, but we do have a simulator that allows us to generate Monte Carlo samples for each. This allows us to assemble a *training dataset* $\{x_i, y_i\}_{i=1,\ldots,n}$, where y is a *label* that identifies how the example was generated (*e.g.*, $y = 0$ for electrons and $y = 1$ for protons). We would like to find a function that accurately *predicts* the label on new data. Because we have feature-label pairs, this is a *supervised learning* problem. We can use a *neural network* to provide a flexible family of functions $f_\phi : \mathbb{R}^d \to \mathbb{R}$, where ϕ denotes the internal parameters of the neural network (*i.e.*, the weights and biases that we will discuss in Sec. 41.8.4). The goal of *training* is to find

the value of the parameters ϕ that provide the 'best' predictions. This is made concrete through a *loss function* $\mathcal{L}(y, f_\phi(x))$. Instead of the obvious zero-one loss, which is 0 if $f_\phi(x) = y$ and 1 if not, we use the squared-loss $\mathcal{L}_{\text{sq}}(y, f_\phi(x)) = (y - f_\phi(x))^2$, which will be motivated in Sec. 41.2.3. We can evaluate the average of the loss on the training set of size n, known as the *empirical risk* or *training loss* $\mathcal{R}_{\text{emp}}(f_\phi) = \sum_{i=1}^{n} \mathcal{L}(y_i, f_\phi(x_i))/n$. *Training* refers to numerically minimizing the empirical risk. We can numerically optimize the model through *gradient descent*, which iteratively adjusts the parameters of the network according to $\phi^{t+1} = \phi^t - \lambda \nabla_\phi \mathcal{R}_{\text{emp}}(f_\phi)$, where λ is the *learning rate*.

Once the optimization is complete and we obtain the solution $\hat{\phi}$, it is natural to assess the quality of the trained model $f_{\hat{\phi}}$ on an independent *testing dataset*[1]. The empirical risk evaluated on the testing set is often larger than on the training set, and large differences indicate *overfitting*, meaning that the model does not generalize well to the unseen data. The ability to accurately predict on unseen data is referred to as *generalization* and the empirical risk on the test data provides a measure of the *generalization error*. In order to reduce the generalization error one might explore different model choices (*e.g.*, neural network architectures), additional regularization terms in the loss function, different learning rates, optimization algorithms, or early stopping criterion in the optimization.

In order to produce a binary electron vs. proton decision from the continuous output of the neural network, one typically chooses a threshold (*i.e.*, classify as proton if $f_{\hat{\phi}}(x) > c$). The choice of the threshold c is often referred to as a working point and it sets the tradeoff between electron and proton efficiencies, fake rates, and purities. A *receiver operating characteristic curve*, or ROC curve, is used to summarize the tradeoff between true positive rate (TPR) and false positive rate (FPR). Importantly, the characterization of the efficiency and rejection power (or equivalently the ROC curve) requires labeled data. In a particle physics context, it is recognized that the simulation is not perfect and the mismodeling is associated to the presence of systematic uncertainty. The discrepancy between the distribution of the training dataset and the distribution of the data where the model will be applied is referred to as *domain shift* or *distribution shift*. While mismodeling in the training dataset might lead to a suboptimal classifier, the real source of systematic uncertainty comes from the mismatch between the data used to characterize the performance of the classifier and the unlabeled data that the classifier is applied to. This motivates the use of data-driven methods to calibrate the resulting model.

This example provides a vertical slice through the various aspects of supervised machine learning in particle physics. Now we factorize and abstract the various ingredients in order to provide a more general treatment with a broader scope.

41.2 Supervised learning

Supervised learning generally refers to the class of problems where the training dataset are presented as input-output pairs $\{(x_i, y_i)\}_{i=1,\ldots,n}$, where $x_i \in \mathcal{X}$ are the input features and $y_i \in \mathcal{Y}$ are the corresponding target labels. Furthermore, it is typically the case that x_i and y_i are independent and identically distributed (i.i.d.) according to the data distribution $p(x, y)$, $(x_i, y_i) \overset{\text{i.i.d.}}{\sim} p(x, y)$, though $p(x, y)$ is usually not known explicitly.

The goal of supervised learning is find a function $f : \mathcal{X} \to Y$ that 'best' captures the relationship between the input features and the corresponding target labels, similar to parameter estimation described in Sec. 40.2 of the Statistics chapter. Section 41.2.1 discusses how we quantify which function is best.

41.2.1 *Loss, risk, empirical risk*

The term *learning* in machine learning generally refers to optimization of some objective, which can be thought of as minimizing *risk*. The risk brings together three main ingredients. The first is the *model family* $\mathcal{F}$ (where $f \in \mathcal{F}$ is the quantity that we vary during optimization), the second is the *loss function* $\mathcal{L}$, and the third is a data distribution $p(x, y)$. The *risk* for a model $f \in \mathcal{F}$ is defined as its expected loss

$$\mathcal{R}[f] \coloneqq \mathbb{E}_{p(x,y)}[\mathcal{L}(y, f(x))] \equiv \int \mathcal{L}(y, f(x))\, p(x, y)\, \mathrm{d}x\, \mathrm{d}y \ , \quad (41.1)$$

where $\mathbb{E}_p[\cdot]$ refers to the expectation with respect to the distribution p. Written this way, the risk is a functional, and the idealized goal for machine learning is to solve the optimization problem

$$f^* = \arg\min_{f \in \mathcal{F}} \mathcal{R}[f] \ , \quad (41.2)$$

where $\mathcal{F}$ would include all possible functions.

One of the defining characteristics of machine learning in practice is that one does not know the data distribution $p(x, y)$, but does have access to samples from that distribution, *i.e.* $\{x_i, y_i\}_{i=1,\ldots,n}$ with $(x_i, y_i) \overset{\text{i.i.d.}}{\sim} p(x, y)$. This leads to the corresponding *empirical risk*

$$\mathcal{R}_{\text{emp}}[f] \coloneqq \mathbb{E}_{\hat{p}(x,y)}[\mathcal{L}(y, f(x))] \equiv \frac{1}{n} \sum_{i=1}^{n} \mathcal{L}(y_i, f(x_i)) \ , \quad (41.3)$$

where $\hat{p}(x, y) = \frac{1}{n} \sum_{i=1}^{n} \delta(x - x_i)\delta(y - y_i)$ is referred to as the empirical distribution of the dataset $\{(x_i, y_i)\}_{i=1,\ldots,n}$. The *empirical risk minimization* principle is a core idea in statistical learning theory [7], which approximates f^* with its empirical analogue

$$\hat{f} = \arg\min_{f \in \hat{\mathcal{F}}} \mathcal{R}_{\text{emp}}[f] \ , \quad (41.4)$$

where $\hat{\mathcal{F}}$ is the set of all possible functions parametrized by the model parameters ϕ. In an idealized infinite parameter limit machine learning functions, such as neural networks, are often universal approximators, meaning they cover all functions and $\hat{\mathcal{F}} = \mathcal{F}$. For finite size models, this may not be a valid approximation. Expressivity of the network characterizes this universality property and is a function of the network architecture and its parameters such as width and depth of neural network layers. If the expressivity is too small it leads to underfitting. However, an equally important consideration is the risk of overfitting if we optimize Eq. 41.4 for too long or use an unrestricted model class (see Sec. 41.2.5).

While the loss function may quantify some well-motivated notion of risk, it is also common to design loss functions so that f^* has some desired property. In Secs. 41.2.2–41.2.5, we will consider several such loss functions where one can show that the corresponding f^* has the desired property even if the form of the loss is not obvious. Furthermore, there are often multiple loss functions that can lead to the same f^*. Thus, one can think of machine learning as solving Eq. 41.4 with a sufficiently flexible model, powerful optimization algorithms, and practical considerations to break the degeneracy between different loss functions that lead to the same f^*. As we shall see, commonly used loss functions can also be mathematically derived from a probabilistic approach.

41.2.2 *Regression*

The goal of regression is to predict a label $y \in \mathcal{Y}$ given an input feature vector $x \in \mathcal{X}$. Typically, the label is a real-valued scalar, but $\mathcal{X}$ can be $\mathbb{R}^d$ or some more structured target (*e.g.*, an image, sequence, graph, quantile, or distribution). When $\mathcal{Y}$ is discrete, the task is usually referred to as classification (see Sec. 41.2.3); however, the two are closely related and *logistic regression* is an example where the model predicts a continuous probability associated to the possible label values. In elementary statistical language, the target label y is often called a dependent variable, while the feature x is called the independent variable. In classical statistics, one often assumes a model for the data such as

$$y_i = f_\phi(x_i) + e_i \ , \quad (41.5)$$

where e_i is an additive error term that is often assumed to be independent of x and normally distributed. This leads to classic approaches like least-squares (see Sec. 40.2.3), and when the

[1] It is important to never use the testing dataset to make decisions about the model. For this purpose, another independent dataset, usually called the *validation dataset*, should be used (see Sec. 41.2.4).

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

model f_ϕ is linear in ϕ (not in x!) linear regression, which has a closed-form solution. However, we can relax these assumptions and consider the general case of an arbitrary joint distribution $p(x, y)$, which can be written as $p(y|x)p(x)$ without loss of generality (see Sec. 39.1). Consider the *squared error* as a loss function, which corresponds to the mean-squared error (MSE) empirical risk:

$$\mathcal{L}_{\text{MSE}}(y, f(x)) = (y - f(x))^2 \,. \tag{41.6}$$

One might expect that the squared error would only be appropriate in the case that the conditional distribution $p(y|x)$ is normally distributed, but one can use the calculus of variations to show that in general

$$f^*_{\text{MSE}}(x) = \mathbb{E}_{p(y|x)}[y] \,, \tag{41.7}$$

that is the optimal regressor for the MSE is the conditional expectation of y given x.

One issue with the squared-error as a loss function is that it is very sensitive to outliers. Alternatively, one can use the absolute error $|y - f(x)|$ as a loss function[2]. However, the discontinuous derivative of the absolute (L1) error leads to challenges in optimization. As a result there are various other loss functions, such as the Huber loss, that aim to be both robust and more amenable to optimization.

Note that this framing of regression yields a function $f(x)$ that only provides a point estimate for y. An alternative approach to regression is to model the full conditional distribution $p(y|x)$. One such example is Gaussian process regression, which is discussed in Sec. 41.8.2. In that probabilistic approach, one can still obtain a point estimator, such as the conditional expectation or the maximum a posteriori (MAP) estimator

$$f^*(x) = \arg\max_y p(y|x) \,, \tag{41.8}$$

and one can also derive uncertainty estimates on the predicted value y (see Sec. 41.10 for more details). In this setting, the prior distribution on the model family is closely related to the concept of regularization, which we touch on in Secs. 41.2.5 and 41.8.2.

When one directly models $p(y|x)$, or goes further to model the joint distribution $p(x, y) = p(y|x)p(x)$, then one can use maximum likelihood for the loss function. In that approach, the problem is really one of density estimation, which is a type of unsupervised learning that we discuss in Sec. 41.3.3. These two approaches are a classic examples of two different approaches to modeling. Regression with $f^*_{\text{MSE}}(x)$ is the prototypical example of *discriminative* modeling, while modeling the joint distribution is a prototypical example of *generative* modeling. Generally, discriminative approaches with supervised learning outperform generative approaches when there is sufficient data, but generative approaches can be beneficial in data-starved settings [8].

41.2.3 *Classification*

The goal of classification is to predict one of a finite number of class labels $y \in \mathcal{Y}$ given an input feature vector $x \in \mathbb{X}$. It is similar to regression in this way, but the focus is on discrete target space $\mathcal{Y}$. An important special case is when the label can only take on one of two values (*e.g.*, "signal" or "background"), which is referred to as binary classification and is equivalent to simple hypothesis testing in statistics. It is common for a classifier to be the composition of two functions: $f(g(x))$. The first function $g : \mathcal{X} \to \mathbb{R}^{|\mathcal{Y}|}$ predicts continuous probabilities for each class (*i.e.*, $g_c(x) \approx p(y = c|x)$). The second function $f : \mathbb{R}^{|\mathcal{Y}|} \to \mathcal{Y}$ then chooses the discrete label $y \in \mathcal{Y}$, such as $f(g(x)) = \arg\max_c g_c(x) \approx \arg\max_y p(y|x)$. This is the case for both classical methods like logistic regression and modern, deep learning approaches to classification; therefore, we will use the term probabilistic classifier for $g(x)$ or just classifier when it is clear in context.

An intuitive loss function for classification is the zero-one loss, which simply counts the number of mis-classifications:

$$\mathcal{L}_{0/1}(y, f(x)) = \begin{cases} 0, & \text{if } f(x) = y \\ 1, & \text{otherwise} \,. \end{cases} \tag{41.9}$$

[2] The absolute error and squared error are often denoted as L1 and L2 errors, respectively, in reference to the corresponding norms.

The zero-one loss can also be written as $\mathcal{L}_{0/1}(y, f(x)) = \mathbf{1}(y \neq f(x))$, where $\mathbf{1}(\cdot)$ is the indicator function. The zero-one loss is non-differentiable, so it does not pair well with gradient-based optimization.

For binary classification, one can use $y = \{0, 1\}$ as numerical values for the class labels and the *binary cross-entropy* loss function

$$\mathcal{L}_{\text{bxe}}(y, g(x)) = -\left[y \log(g(x)) + (1 - y) \log(1 - g(x))\right] \,. \tag{41.10}$$

The resulting model will approximate $f^*_{\text{bxe}}(x)$, which takes on the form

$$\begin{aligned} f^*_{\text{bxe}}(x) &= \mathbb{E}_{p(y|x)}[y] = p(y = 1|x) \\ &= \frac{p(x|y = 1)p(y = 1)}{p(x|y = 0)p(y = 0) + p(x|y = 1)p(y = 1)} \,. \end{aligned} \tag{41.11}$$

That is the binary cross-entropy loss for binary classification leads to the Bayesian posterior probability that the label $y = 1$ given the feature vector x (see Bayes theorem in Sec. 39.1).

Equation 41.11 highlights an important feature of supervised learning relevant for particle physics: the joint distribution $p(x, y)$ of the training dataset implies a prior distribution $p(y)$ on the labels or classes. This prior distribution reflects the frequency in the training dataset, not necessarily in the real data. When applying the resulting model to a different dataset with the same conditional distribution (data likelihood) $p(x|y)$ for the features and a different prior $p'(y)$ for the labels, the probabilistic interpretation of the result will not be properly calibrated, meaning $g(x) \not\approx p(y|x)$. A common choice for binary classification is to use a balanced training dataset with $p(y = 0) = p(y = 1) = \frac{1}{2}$, while in many cases the true $p'(y = 1)$ in the experimental data might be very small (*i.e.*, low signal-to-background), unknown, or zero (*i.e.*, a hypothetical particle that does not exist).

If $p'(y)$ and $p(y)$ are known then Bayes theorem can be used to re-calibrate the posterior $p(y|x)$ from one prior to another. One example of such re-calibration is the correspondence of binary classification to simple hypothesis tests in frequentist statistics discussed in Sec. 40.3.1 of the Statistics chapter. In that setting, the Neyman-Pearson lemma states that the optimal classifier is given by the likelihood ratio

$$f^*_{\text{NP}}(x) = \frac{p(x|y = 1)}{p(x|y = 0)} \,, \tag{41.12}$$

which does not depend on the prior probabilities $p'(y = 0)$ or $p'(y = 1)$ as in Eq. 41.11, or, equivalently, assumes equal priors $p'(y = 0) = p'(y = 1)$. Bayes theorem can be used to show that the two functions, $f^*_{\text{NP}}(x)$ and $f^*_{\text{bxe}}(x)$, are related by a one-to-one, monotonic transformation

$$f^*_{\text{NP}}(x) = \frac{p(y = 0)}{p(y = 1)} \frac{f^*_{\text{bxe}}(x)}{1 - f^*_{\text{bxe}}(x)} \,, \tag{41.13}$$

which is referred to as the *likelihood-ratio trick* and plays an important role in simulation-based inference (see Sec. 41.6).

A standard way to evaluate the performance of a classifier is to evaluate the true positive rate (TPR)—the proportion of $y = 1$ samples that are correctly identified based on a fixed threshold $g(x) > c$—as a function of the false positive rate (FPR)—the proportion of $y = 0$ samples that are misidentified based on the same fixed threshold. Plotting these values generates a graph known as the receiver operating characteristic (ROC) curve. Importantly, the monotonic transformation of Eq. 41.13 does not impact the tradeoff between FPR and TPR, therefore the ROC curves for $f^*_{\text{NP}}(x)$ and $f^*_{\text{bxe}}(x)$ are identical and do not depend on the prior probabilities $p(y)$. This property has been leveraged in *weakly supervised* approaches [9] to train a classifier in data without access to labels as long as one has two datasets with different $p(y = 1)/p(y = 0)$ ratios and the same conditional distribution $p(x|y)$ of the features given the labels.

A generalization of Eq. 41.10 that applies to multiple classes, is the *categorical cross-entropy* loss

$$\mathcal{L}_{\text{xe}}(y, f(x)) = -\sum_{c \in |\mathcal{Y}|} \mathbf{1}(y = c) \log(f_c(x)) \,, \tag{41.14}$$

where $f : \mathcal{X} \to \mathbb{R}^{|\mathcal{Y}|}$ and the indicator function picks out the term in the sum for the corresponding class label y. This loss can be derived by maximizing the posterior of Eq. 41.25 using a discrete set of class labels y, which identifies $f_c(x) = \tilde{f}(y = c|x) = p(y = c|x)$ and thus assumes the constraint $\sum_c f_c(x) = 1$ and $f_c(x) \geq 0$ (see Sec. 41.8.4.2 for an activation function that enforces this). The function $\tilde{f}(y|x)$ can be interpreted as a conditional distribution, *i.e.*, an approximation to the true posterior $p(y|x)$. The risk associated to the cross entropy loss function is

$$\begin{aligned}\mathcal{R}_{\text{xe}}[f] &= \mathbb{E}_{p(x,y)}\left[-\sum_{c\in|\mathcal{Y}|} \mathbf{1}(y = c)\log f_c(x)\right] \\ &= -\sum_{c\in|\mathcal{Y}|} p(y = c)\mathbb{E}_{p(x|y)}[\log \tilde{f}(y = c|x)] \,.\end{aligned} \tag{41.15}$$

This is equivalent to $\mathcal{R}_{\text{xe}}[f] = \mathbb{E}_{p(x)}[H[p(y|x), \tilde{f}(y|x)]]$, where

$$H[p, f] \equiv \mathbb{E}_p[-\log f] = -\int p(x)\log(f(x))\,\mathrm{d}x \tag{41.16}$$

is the cross entropy between the two distributions. One can use a Lagrange multiplier to enforce the normalization constraint and the calculus of variations to show that

$$f^*_{\text{xe},c}(x) = p(y = c|x) \,, \tag{41.17}$$

which is equivalent to the solution in Eq. 41.11 in the binary case.

This approach is closely related to the loss functions that are used for density estimation, the forward Kullback-Leibler (KL) divergence, and the maximum likelihood estimation. Minimizing cross entropy $H[p, f_\phi]$ to ϕ is equivalent to minimizing the forward KL divergence

$$\text{KL}(p\|f_\phi) \coloneqq \mathbb{E}_p[\log p(x)) - \log f_\phi] = H[p, f_\phi] - H[p] \,, \tag{41.18}$$

where $H[p] \coloneqq \int p(x)\log p(x)dx$ is the entropy and independent of f_ϕ. The KL divergence $\text{KL}[p\|f] \geq 0$, and equal if and only if $p = f$.

Unlike in the binary classification case, the multi-class classifier is sensitive to the priors $p(y)$ used in training. This leads to complications as often the class proportions are unknown. For example, one might be interested in classifying a signal when multiple backgrounds are present and the relative proportion of those different background components is uncertain. Ideally one would like the class proportions for the background components used in training to match those in the data, which presents an additional training challenge if those proportions are heavily unbalanced.

41.2.4 *Generalization and model complexity*

With a sufficiently flexible model, it is possible to fit the training dataset very well, though the model might not *generalize* well to unseen data, a phenomenon known as *overfitting*. More concretely, for a nonnegative loss function one might have $\mathcal{R}_{\text{emp}}[\hat{f}] \to 0$, while the true risk $\mathcal{R}[\hat{f}]$ might be large. Conversely, *underfitting* occurs when a model is unable to capture the relationship between the inputs and labels accurately, resulting in large empirical and true risks. While it is generally not possible to evaluate $\mathcal{R}[\hat{f}]$ exactly because we do not know $p(u)$, we can use an independent dataset (also called validation dataset) to obtain an unbiased estimate of it. This *cross-validation* method motivates the test-train-validation split of the data.

Intuitively, a model with many parameters has more flexibility and is more prone to overfitting. However, some highly over-parameterized models (that have large subspaces of their parameters where $\mathcal{R}_{\text{emp}}[\hat{f}_\phi] \to 0$) generalize well [10, 11]. Often this is achieved through *regularization*, both explicit and implicit (Sec. 41.2.5).

Two main sources of error prevent models from generalizing beyond their training dataset. One is *bias* arising from erroneous assumptions in the model and the other is *variance* arising from sensitivity to statistical fluctuations in the training dataset. The *bias-variance decomposition* is a way of analyzing a model's expected risk as a sum of bias and variance terms. Concretely, if $\mathcal{L}$ is the squared loss, one can decompose the expected risk $\mathbb{E}_{\mathcal{D}}[\mathcal{R}_{\text{emp}}[\hat{f}_\phi]]$ over all possible training datasets $\mathcal{D}$ into three terms [12, 13],

$$\begin{aligned}\mathbb{E}_{\mathcal{D}}\left[\mathcal{R}[\hat{f}^{\mathcal{D}}_\phi]\right] &= \mathbb{E}_{\mathcal{D}}\mathbb{E}_{p(x,y)}\left[(y - \hat{f}^{\mathcal{D}}_\phi(x))^2\right] \\ &= \mathbb{E}_{p(x)}\Big[\underbrace{\mathbb{E}_{p(y|x)}\left[(y - \bar{y})^2\right]}_{\text{noise}} + \underbrace{\mathbb{E}_{\mathcal{D}}\left[(\hat{f}_\phi(x) - \bar{f}(x))^2\right]}_{\text{variance}} \\ &\qquad + \underbrace{(\bar{y} - \bar{f}(x))^2}_{\text{bias}}\Big] \,,\end{aligned} \tag{41.19}$$

where $\bar{f}(x) \equiv \mathbb{E}_{\mathcal{D}}\left[\hat{f}^{\mathcal{D}}_\phi(x)\right]$ is the "average" prediction of the model over different possible training datasets. In this expression, the first term is the inherent "noise" in the dataset, *i.e.*, the variance of y around its mean, which is zero if y is deterministically related to x. The second term is the variance of the model around its average when considering different training datasets, and the third term is the squared bias, *i.e.*, the difference between the average prediction and the true conditional mean.

Classically, there is a correspondence between overfitting and underfitting and the concepts of bias and variance discussed in Sec. 40.2 on parameter estimation. Overfitting implies high variance: the model class is too complex and retraining yields vastly different models. Variance tends to increase with model complexity and decrease with more training data. Underfitting implies high bias: the model class is too simple and has a large error rate. Thus, there exists a tradeoff between bias and variance, shown schematically in Fig. 41.1 (left).

However, in modern machine learning, very high-capacity models such as neural networks can be trained to exactly fit the data, and yet obtain high accuracy on test data [14], as shown in Fig. 41.1 (right). This phenomenon is known as "double descent." The apparent contradiction may be addressed by considering the regularizing (Sec. 41.2.5) effects of neural network training, specifically stochastic gradient descent (Sec. 41.9.2).

41.2.5 *Regularization*

The trained model $\hat{f}$, or equivalently, the parameters of the trained model $\hat{\phi}$ can be thought of as point estimates of f^*. The bias-variance tradeoff means that introducing a small bias can often lead to a significant reduction in variance. This motivates the explicit addition of a *regularization* term to the loss function, which will introduce some bias $f^*_{\text{reg}} \neq f^*$. A common form of regularization is to penalize by the L2 norm of the parameters (*i.e.* $\|\phi\|^2$), which is referred to as *L2 or Tikhonov regularization*. This appears in the form of penalized maximum likelihood, and it is also commonly used in unfolding [15]. Alternatively, one can penalize by the L1 norm $\|\phi\|$, which is known as *L1 regularization*. One can also interpret the regularization term as an explicit prior on the parameters, and the resulting model as the Bayesian maximum a posteriori (MAP) estimator. When L1 or L2 regularization is paired with linear regression, it is known as *LASSO regression* or *ridge regression*, respectively. In addition, L2 regularization paired with kernel machines gives rise to Gaussian process regression.

These two types of explicit regularization generally have solutions with different properties. For example, L1 regularization naturally induces sparsity, *i.e.*, a fraction of the parameters are nearly zero, whereas L2 regularization tends to keep all parameters nonzero but with lower magnitudes, as illustrated in Fig. 41.2. Because L1 regularization sets certain parameters to zero, it is often used as part of feature selection and model compression techniques, as discussed in Sec. 41.11.

Another form of regularization is to restrict the model class $\hat{\mathcal{F}}$. For example, a neural network and a sequence of narrow step functions (delta functions) can both be shown to be universal approximators in infinite parameter size limit, but on real world examples the former generalizes much better than the latter. Within the class of neural network models, convolutional neural networks are a subset of generic feedforward neural networks that approximately preserve translational symmetry (see Sec. 41.8.4.4 for more discussion). These types of choices are often encoded in

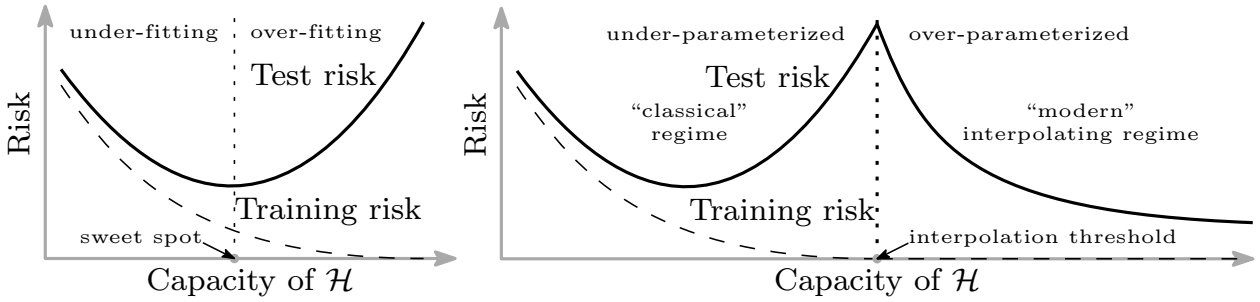

Figure 41.1: Curves for training risk (dashed line) and test risk (solid line) from Belkin et al. in Proceedings of the National Academy of Sciences, 2019. The classical U-shaped risk curve arising from the bias-variance trade-off (left) and the double descent risk curve (right), which incorporates the U-shaped risk curve (*i.e.*, the "classical" regime) together with the observed behavior from using high capacity function classes (*i.e.* the "modern" regime).

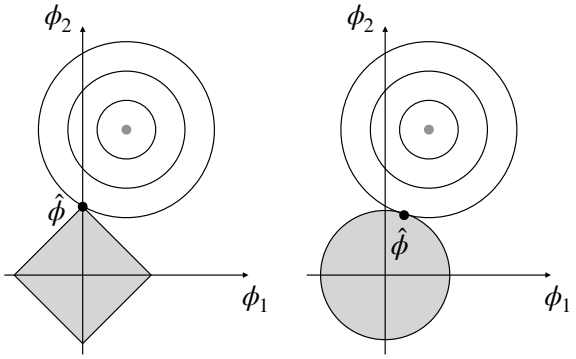

Figure 41.2: Depiction of L1 (left) and L2 (right) regularization constraint regions and the contours of an unregularized loss function. The intersection with the L1 constraint region gives an optimal value $\hat{\phi}$ that is sparse, *i.e.*, $\phi_1 = 0$, while the L2 contraint region yields an optimal value $\hat{\phi}$ where both ϕ_1 and ϕ_2 are small, but nonzero.

the architecture of a neural network and are broadly referred to as *inductive bias* in the model.

In addition to explicit regularization terms in the loss function or through restrictions to the model class, it is also possible to regularize implicitly. One implicit regularization is through early stopping [15,16], where we monitor the loss on the training dataset and the loss on held-out validation dataset. While the training loss continues to decrease with more gradient descent cycles, the validation loss may not, and early stopping stops the training when validation loss flattens out or begins to increase. Another powerful form of regularization used in deep learning models is known as *dropout* [17], which randomly removes some some parts of the model during training and can be thought of as implementing a type of model averaging [18].

The chosen numerical optimization procedure can also act as an implicit regularization. In the case of highly over-parameterized models where there is a large degenerate parameter space that achieves zero loss, $\Phi_0 = \{\phi | \mathcal{R}_{\text{emp}}[f_\phi]\} = 0$, the dynamics of the optimization algorithm will break the degeneracy and favor some particular $\hat{\phi} \in \Phi_0$ as if an additional regularization term was included. Despite zero loss and over-parametrization, the corresponding generalization error may be small, a phenomenon called *benign overfitting* [19]. Different optimization algorithms will have different implicit regularization effects, and thus favor different parameter points in Φ_0 that will have different generalization error [20]. Understanding this interaction is a topic of contemporary research in machine learning [21].

Some methods such as Gaussian process (GP) do not require optimization, and instead use linear algebra to obtain the solution. Benign overfitting is explicit for GP in that in the absence of noise the solution goes through all the training data, yet it generalizes well if the kernel is well chosen. Infinitely wide neural networks have an explicit correspondence to Gaussian process [22]. When applied to deep networks this leads to the concept of neural tangent kernel [23].

41.3 Unsupervised learning

Unsupervised learning generally refers to the class of problems that use unlabeled training dataset $\{x_i\}_{i=1,\ldots,n}$, where $x_i \in \mathcal{X}$ are the input features. Furthermore, it is typically assumed that $(x_i) \overset{\text{i.i.d.}}{\sim} p(x)$, though $p(x)$ is usually not known explicitly. Finally, the loss function in unsupervised learning takes on the special form $\mathcal{L}(x, f(x))$. This class of learning has many different applications, such as density estimation, anomaly detection, generative learning, representation learning and clustering, each with the corresponding set of methods. Some of these tasks can be achieved with the same methods, *e.g.* normalizing flows (see Sec. 41.3.4.3) can perform density estimation, generative sampling and anomaly detection.

41.3.1 *Representation learning, compression, and autoencoders*

A recurring topic in machine learning and statistics is how to represent the data. Much of classical statistics involves constructing a low-dimensional summary statistic that extracts the relevant information from the data for a particular task (a sufficient statistic in the language of classical statistics). There is a spectrum of representations with tradeoffs. At one end of this spectrum is lossless compression that allows one to encode the data into a smaller, intermediate representation that carries all the information since it can be decoded back into the original data. At the other end of the spectrum is something like the likelihood ratio, which is a single scalar that carries the relevant information needed for hypothesis testing for a single hypothesis, but it discards all the other information that might be needed for other tasks, such as testing other hypotheses. An intermediate point in this spectrum is the process of feature engineering, which refers to the creation of new features $\mathcal{X}'$ from the original features $\mathcal{X}$ in hopes that the downstream task will be easier with the new features. For example, instead of working directly with the energy and momentum of particles, one might compute invariant masses or angles between particles. This type of feature engineering generally improves performance for shallow neural networks and decision trees; however, with the rise of deep learning this is often no longer necessary and may limit performance compared to working with the original features [4]. One can think of the intermediate layers of a neural network between the input and the output a representation of the data that is good for the task at hand, and by training all the layers of the network simultaneously (or "end-to-end") one can see the intermediate layers as a learned representations. For a review, see Ref. [24].

An example of a linear dimensionality reduction representation and data compression is principal component analysis (PCA) of data $x \in \mathbb{R}^d$ at fixed latent space dimensionality k ($k < d$), which

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

finds the orthogonal linear transformation, O,

$$O : \mathbb{R}^k \to \mathbb{R}^d, z \mapsto Oz,\ OO^\intercal = I_d \tag{41.20}$$

that maximizes the data variance in the latent space. Maximizing the variance of the transformed data is equivalent to minimizing the average reconstruction error (the residual variance in data space),

$$\mathcal{L}_{\text{reco}}(x, f(x)) = \|x - f(x)\|^2 \,. \tag{41.21}$$

A PCA can thus be interpreted as a linear, orthogonal model that is trained to minimize the L_2-distance between the input data and the reconstructed data given the fixed dimensionality k. In practice, the PCA problem can be solved analytically without the use of optimization algorithms or the loss function: the principal components are given by the eigenvectors of the data covariance matrix.

A suitable latent space dimensionality, k, is chosen by ordering the eigenvalues, λ_i, of the data covariance in descending order, and keeping only the first few eigenvectors that correspond to the largest eigenvalues. The cut is often made at dimensionalities that capture around 90% of the data variance. For many data sets this results in $k \ll d$. The average reconstruction error that originates from the discarded eigenvalues is $\sigma^2_{\text{reco}} = \sum_{i=k+1}^{d} \lambda_i$.

Another common type of representation learning and nonlinear dimensionality reduction is based on the *autoencoder* $f = g \circ e : \mathcal{X} \to \mathcal{X}$, where $e : \mathcal{X} \to \mathcal{Z}$ is referred to as the *encoder* and $g : \mathcal{Z} \to \mathcal{X}$ is referred to as the *generator* or *decoder*. Typically the dimensionality of $\mathcal{Z}$ is much less than $\mathcal{X}$, and $z = e(x)$ can be thought of as a compressed representation of the input. The intermediate space $\mathcal{Z}$ is sometimes referred to as the bottleneck or the latent space of the autoencoder. If the bottleneck is sufficiently large and the encoder and decoder are sufficiently flexible, then the function f could just be the identity (*i.e.*, lossless compression). However, if the encoder and decoder are not sufficiently flexible or the dimensionality of the latent space is not large enough there will be some reconstruction error. Therefore, the reconstruction error of Eq. 41.21 serves as a natural loss function of an autoencoder.

Once trained, the encoder $e(x)$ can be used independently of the decoder to provide a generic low-dimensional representation of the data. The flexibility of this approach is attractive; however, there are no guarantees that this representation will be optimal for the other task. Indeed, the transition from pre-trained autoencoders to end-to-end learning is one of the important trends that characterized the onset of the deep learning era.

While achieving zero reconstruction error may seem good as it would imply lossless compression, it often performs poorly in practice. First, the encoder may be overfit to the training dataset and not generalize well to held out data. This can be addressed by adding a prior to the training, discussed in Sec. 41.3.4.1. Second, it may not be robust to domain shift (see Sec. 41.10.2).

41.3.2 *Clustering*

The goal of clustering is to group the data $\{x_i\}_{i=1,\dots,n}$ into k groups, or *clusters*, usually with $k \ll n$. Intuitively, if two data points belong to the same cluster, then they should be similar in some sense. Conversely, if two data points are very different, then they should be assigned to different clusters. The notion of similarity usually is based on some heuristic, and there are a variety of algorithmic and probabilistic clustering algorithms. In some cases k is specified, while in others it is determined by the clustering algorithm. There is also a distinction between flat clustering that directly partitions the data into k clusters and hierarchical clustering where clusters are nested hierarchically as the name suggests. In many cases, clustering uses some notion of distance $d(x_i, x_j)$, which may be the L_p norm $\|x_i - x_j\|_p$.

One of the most common clustering algorithms is known as k-means, where k is specified by the user and results in sets $S = \{S_1, \dots, S_k\}$ that minimize the variance of each cluster. Thus, the objective is

$$\begin{aligned} \arg\min_{\mathbf{S}} \sum_{i=1}^{k} \sum_{\mathbf{x} \in S_i} \|\mathbf{x} - \boldsymbol{\mu}_i\|^2 &= \arg\min_{\mathbf{S}} \sum_{i=1}^{k} |S_i| \operatorname{Var} S_i \\ &= \arg\min_{\mathbf{S}} \sum_{i=1}^{k} \frac{1}{2|S_i|} \sum_{\mathbf{x},\mathbf{y} \in S_i} \|\mathbf{x} - \mathbf{y}\|^2 \end{aligned} \tag{41.22}$$

where μ_i is the mean of points in S_i. k-means can be interpreted as a Gaussian mixture density estimation of $p(x)$, where all the Gaussians are isotropic. It can be generalized to a Gaussian mixture model, where both the means and the covariance matrix are estimated.

Among the other class of algorithms that determine k, density-based spatial clustering of applications with noise (DBSCAN) is one of the most frequently used. DBSCAN clusters points based on a distance metric (*e.g.*, Euclidean) defined for each application. Two hyperparameters are ϵ, the maximum distance threshold to determine whether a neighboring point belongs to the same cluster, and the minimum sample size for a group of close points to be identified as a valid cluster or noise. While DBSCAN is robust against irregularly shaped clusters with a simple distance-based metric, single threshold parameter ϵ shared to distinguish all clusters can be challenging. Hierarchical DBSCAN (HDBSCAN) generalizes to varying densities by building a hierarchy of density-based clusters across all ϵ via mutual-reachability distances, then extracts the most stable clusters from a condensed tree.

Finally, neural networks are often used for clustering in particle physics. One use case is to transform the data points into a latent space where clustering is performed using an unsupervised, traditional algorithm. For example, an input dataset may not follow an isotropic gaussian distribution which is assumed by k-means, but one can design a neural network to learn a transformation into the latent space where this assumption holds. Another use case is to use neural network directly for clustering operation. Examples include object detection [25] and segmentation [26, 27] in computer vision (see Sec. 41.8.4.4) as well as clustering of graph nodes via edge classification [28–32] (see Sec. 41.8.4.7).

41.3.3 *Density estimation*

The goal of density estimation is to estimate a distribution $p(x)$ based on samples $\{x_i\}_{i=1,\dots,n}$ with $x_i \overset{\text{i.i.d.}}{\sim} p(x)$. Conceptually, this is the same goal as when fitting a parameterized distribution $f(x;\theta)$ to data using the method of maximum likelihood as described in Sec. 40.2.2 of the chapter on statistics. In practice, the difference in the machine learning context has to do with the flexibility of the model and the dimensionality of the data. A highly-flexible model, which can effectively approximate any distribution, is referred to as a non-parametric model (though, ironically, usually this means the model has many parameters). In contrast, typical maximum likelihood fits in particle physics are based on restricted families of distributions with relatively few parameters and the data is typically one- or two-dimensional, though occasionally five- or six-dimensional.

Maximizing the likelihood function in Eq. 40.10, $\mathcal{L}(\theta) = \prod_{i=1}^{n} f(x_i;\theta)$ is equivalent to minimizing the empirical risk:

$$\mathcal{R}_{\text{emp,xe}}[f_\phi] = -\frac{1}{n} \sum_{i=1}^{n} \log f_\phi(x) \,, \tag{41.23}$$

where we adopt the notation used in this chapter. The loss is simply $\mathcal{L}(x, f_\phi(x)) = -\log f_\phi(x)$, and the corresponding risk is

$$\mathcal{R}_{\text{xe}}[f_\phi] = \mathbb{E}_{p(x)}[-\log f_\phi(x)] \,, \tag{41.24}$$

which is the cross entropy $H[p, f_\phi]$. For density estimation, the model is usually constructed to enforce $\int f_\phi(x) dx = 1$ and $f_\phi(x) \geq 0$ so that it can be interpreted as a distribution. With this constraint, one can show that $f^*_{\text{xe}}(x) = p(x)$. This is not the only form of training: flow matching and diffusion methods train on a different objective, discussed further below.

The concepts of generalization and overfitting are particularly acute in *unsupervised* learning, where the likelihood maximization of equation 41.23, combined with universal approximator assumption, must converge onto $\hat{p}(x) = \frac{1}{n}\sum_{i=1}^{n}\delta(x - x_i)$, the empirical distribution of the dataset $\{x_i\}_{i=1,\ldots,n}$. This distribution has the highest likelihood on the training dataset and the lowest likelihood on the test data where it gives $\hat{p}(x) = 0$ as long as the test dataset are not identical to the training dataset. So the empirical distribution of the training dataset has the worst possible generalization property, yet it is the solution we converge to for sufficiently expressive architectures in the absence of any regularization. In contrast, in supervised learning we often observe the phenomenon of benign overfitting, where even zero loss can generalize well.

In addition to approaches to density estimation that involve learning in the sense of minimizing a loss or risk function, we note that there are also classical density estimation techniques such as histogramming and kernel density estimation [33–35]. These techniques often fail in very high dimensions.

41.3.4 *Generative models*

Deep generative models are powerful machine learning models that can learn complex, high-dimensional distributions and generate samples from them. Because of their inherently probabilistic formulation, generative models are rapidly becoming an indispensable tool for scientific data analysis in a range of domains. The goal of generative models is to draw samples from $p(x)$. For some formulations of learned $p(x)$, such as normalizing flows, the samples can be drawn directly. For other explicit formulations of $p(x)$, such as Boltzmann machines, one can use sampling techniques such as Monte Carlo Markov chain sampling. There are however many other approaches to drawing samples from $p(x)$ that do not rely on its explicit form.

Generative models can be contrasted against discriminative models that are primarily used for supervised learning tasks. Roughly, discriminative models are used for prediction and $f(x)$ provides a point estimate of the target y, and they are more closely connected to function approximation. In contrast, generative models describe the data distribution $p(x)$ (or the joint data distribution $p(x, y)$ in a supervised setting). An enlightening discussion of these two approaches can be found in Ref. [8].

There are a number of different types of deep generative models that have various pros and cons as they do not all have the same capabilities. We will focus on variational autoencoders (VAEs) [36,37] , generative adversarial networks (GANs) [38,39], normalizing flows (NFs) [40–44], and flow-matching and diffusion models [45–48], though other approaches have been explored in this quickly developing area of research. Consider these three distinct types of functionality:

- **generation:** ability to sample or "generate" a data point $x_i \sim p(x)$.
- **likelihood for generated data:** ability to evaluate the probability density (likelihood) $p(x_i)$ for a data point x_i sampled from the model $x_i \sim p(x)$.
- **likelihood for arbitrary data:** ability to evaluate the probability density $p(x_i)$ for an arbitrary data point $x_i \in \mathcal{X}$.

Each of the models above can be used for generation; however, only normalizing flows provide all three capabilities. For reasons that we will describe below, GANs and VAEs do not provide a tractable likelihood function, and they are sometimes referred to as *implicit models*. This establishes a connection to simulation-based inference where most scientific simulators are also implicit models with an intractable likelihood. Because normalizing flows have a tractable likelihood, they can be trained via maximum likelihood (Eq. 41.23) as described in Sec. 41.3.3. GANs and VAEs, on the other hand, need to employ some other loss function to be trained. In the case of VAEs, training is based on the ELBO used in variational inference (see Sec. 41.2.3 and the discussion around the reverse KL divergence below Eq. 41.18). While GANs are also implicit models they data they can generate is typically restricted to a lower-dimensional manifold $\mathcal{M} \subset \mathcal{X}$, meaning that almost all real training dataset doesn't "live on" the subspace of possibilities that the model can produce. In this case, the likelihood is for almost all data is zero, and so even ELBO-based training will not work. The breakthrough idea introduced in Ref. [38] was to use adversarial training where a classifier would be used to quantify how different the data generated from the model is from the data from the target distribution.

VAEs, GANs, and normalizing flows introduce a mapping $g(z, \theta)$ from a base random variable z to the space of the data $\mathcal{X}$. The map $g(z, \theta)$ is typically implemented with a neural network. The random variable z is sampled from some known base distribution $p(z)$ that is both easy to sample and has a density that is easy to evaluate. Typically, the base distribution is a multivariate normal.

In the literature on GANs and normalizing flows, this base random variable is often referred to as a latent variable and $p(z)$ is often referred to as a prior distribution. In the case of VAEs, one additionally adds some normally-distributed (Gaussian) random noise ϵ to the output so that $x = g(z, \theta) + \epsilon$. In this case, x and z are not deterministically related and z is a legitimate latent variable in the model and $p(z)$ can be interpreted as the prior on that latent variable. In this case, the model can populate the full space of the data. Unfortunately, the marginal likelihood $p(x) = \int p(x, z)dz$ involves an intractable integral, thus maximum likelihood training is infeasible. However, the likelihood term $p(x|z)$ is tractable (*i.e.* the Gaussian noise), so training with the ELBO is possible.

Note that the dimensionality of z need not be the same as that of x. If $z \in \mathbb{R}^q$ and $\mathcal{X} = \mathbb{R}^d$ with $q < d$, then all points $g(z, \theta)$ will lie on a d-dimensional surface in $\mathbb{R}^d$. In the case of a VAE, the Gaussian noise ϵ means that the generated data x will be distributed in a thin region around the surface defined by $g(z, \theta)$. The presence of a bottleneck (*i.e.* $q < d$) leads to advantages and disadvantages. The disadvantages for GANs is that the likelihood assigned to almost all real world data (*i.e.* data not generated by the model) will be zero, so training is more difficult and many tasks in probabilistic inference won't be applicable. However, often real world data is also effectively described by a low-dimensional subspace in the full space of the data – random images look like noise, while natural images are in some sense special. For this reason, images produced by GANs for instance often have better visual quality than those produced by other techniques. This points to the ambiguity encountered in quantifying how close two distributions are, and also motivates the use of distance measures such as the Earth movers distance or Wasserstein distance [49,50]. Conversely, the lack of a bottleneck (*i.e.* $q = d$) leads to very large models and scalability issues when the data is high dimensional.

Recent work has also focused on combining ideas from VAEs, GANs, and normalizing flows so that the generative model does involve a bottleneck but can still provide tractable likelihoods for density estimation restricted to that manifold [40,51–54]. Some of these models can also be used in the context of anomaly detection and out of distribution detection by identifying data that is off the manifold.

The parametrization of the mapping (the architecture of the neural network) should match the structure of the data and be expressive enough. For problems with explicit symmetries it is beneficial to include them into the architecture of the network explicitly, which restricts the allowed space of the models and matches their inductive bias (implicit regularization inherently built into the choice of architecture of the network) to the data. Different architectures have been proposed [43,55–57], and to achieve the best performance on a new dataset one needs extensive hyperparameter explorations [58].

41.3.4.1 *Variational autoencoders*

The autoencoder was described in Sec. 41.3.1 as model for compression and representation learning. The model is $f = g \circ e : \mathcal{X} \to \mathcal{X}$, where $e : \mathcal{X} \to \mathcal{Z}$ is referred to as the *encoder* and $g : \mathcal{Z} \to \mathcal{X}$ is referred to as the *generator* or *decoder*. The standard autoencoder is not a probabilistic model, but additional probabilitic structure can be added.

One approach is VAE mentioned above [36,37]. By equipping the latent space with a prior distribution $p(z)$, the decoder of the autoencoder $g(z, \theta)$ implies a distribution on a manifold in the out-

by KARLSRUHE INSTI Phys. A 2026.41. Downloaded from www.worldscientific.com DGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

put space $\mathcal{X}$. VAEs additionally add some normally-distributed (Gaussian) random noise ϵ to the output so that $x = g(z, \theta) + \epsilon$. This implies that $p_\theta(x|z)$ is a tractable quantity, and it is interpreted as the likelihood in this context.

In a VAE one also elevates the encoder to have a probabilistic form. Instead of encoding $z = e(x)$ in a deterministic way, one seeks a distribution over z given x. A natural target for the probabilistic encoder would be to probabilistically invert the decoder. This inverse problem is solved by the posterior distribution $p(z|x)$ via Bayes theorem

$$p(z|x) = \frac{p(x|z)p(z)}{p(x)} \,. \tag{41.25}$$

While the likelihood and the prior may both be tractable, the normalizing constant $p(x) = \int p(x, z)dz$ involves an intractable integral (the same intractable integral that makes maximum likelihood training of the VAE infeasible).

One approach to Bayesian inference in these settings is variational inference (VI). In VI one approximates the posterior with some parametric family $q_\phi(z|x)$ in a parametric form, and then optimizes the ELBO with respect to its parameters ϕ.

$$\begin{aligned} \text{ELBO} &= \mathbb{E}_{q(z)} \log p(x|z) - D_{\text{KL}}[q(z)||p(z)] \\ &\leq \log \mathbb{E}_{q(z)} \left[\frac{p(x, z)}{q(z)} \right] = \log p(x) \,, \end{aligned} \tag{41.26}$$

where we used Jensen's inequality for concave functions (log) and the reverse Kullback-Leibler (KL) divergence term is

$$D_{\text{KL}}[q(z)||p(z)] = \mathbb{E}_{q(z)}[\log q(z) - \log p(z)] \geq 0 \,. \tag{41.27}$$

In a VAE, the variational model for the posterior $q_\phi(z|x)$ is often assumed to be an uncorrelated Gaussian (this is often called mean field approximation) defined by the mean μ and variance Σ. Instead of optimizing the mean and variance independently for each x, VAEs use neural networks to predict the mean $\mu_\phi(x)$ and the variance $\Sigma_\phi(x)$. This is called *amortized inference*, since after an up-front training cost the approximate posterior $q_\phi(z|x)$ can be evaluated efficiently with a single forward pass of the neural network. Note the standard auto-encoder is recovered if one only used the mean $\mu_\phi(x)$ for the encoder and did not add noise ϵ to the decoder.

Both the probabilistic encoder $q_\phi(z|x)$ and the probabilistic decoder $p_\theta(x|z)$ are trained jointly by optimizing the ELBO. Unlike the standard autoencoder, which only minimizes the reconstruction error, ELBO optimization of Eq. 41.26 has a tradeoff between minimizing the reconstruction error in the first term (averaged over the approximate posterior $q(z)$), which encourages high quality reconstructions, and minimizing the KL divergence term, which forces the posterior $q(z)$ to be as close to the chosen prior $p(z)$, and thus controls the sample quality by matching the aggregate posterior with a chosen prior distribution [59]. This term regularizes the VAE latent space, such that every sample drawn from the prior $p(z)$ correspond to a valid sample. Successful VAE training requires to find a delicate balance between the two contributing terms to the ELBO. Whether the VAE training process succeeds in striking this balance depends on a number of factors, including the network architectures, the chosen prior and the class of allowed posterior distributions. Once trained, the VAE can be used as a generative model by sampling from the prior $z_i \sim p(z)$ and then decoding according to $p_\theta(x|z) = g(z, \theta) + \epsilon$.

VAEs allow for expressive architectures, enjoy the benefits of regularization through data compression and have a firm theoretical foundation. Compared to GANs [38] 41.3.4.2, VAEs are of particular interest to the scientific community as they provide a lower bound to the marginal likelihood (albeit potentially with a large gap) and a posterior distribution for the latent variables.

It is also interesting to consider a special case of the autoencoder and VAE where the encoder and decoder are restricted to be linear transformations, which is effectively PCA. In PCA the (linear) decoder can be written $g(z) = Oz$, where O is a matrix. As in the case of the autoencoder, PCA is not a probabilistic model, but probabilistic structure can be added. Probabilistic PCA [60] assumes that the latent variables follow a Gaussian distribution with mean zero and covariance Λ, where Λ is a diagonal matrix with the rank-ordered eigenvalues λ_i along its diagonal. The true distribution of the PCA components may be non-Gaussian, but a Gaussian is the maximum entropy approximation given their first two moments. Note that in probabilistic PCA these moments are measured on training dataset (when finding the principal components).

One can generalize probabilistic PCA to use nonlinear encoder and decoder as in an autoencoder. A Gaussian prior is a poor ansatz for the latent space distribution of data proceed by an autoencoder. Instead one can learn the density of the training samples in latent space using a normalizing flow. This model was introduced in $\mathcal{M}$-flows [53] and in probabilistic autoencoder (PAE) [54], which achieves similar performance to a VAE in terms of sample quality without explicit ELBO optimization. In all these cases the dimensionality of the latent space is a hyperparameter to be chosen or optimized by the user. Unlike a standard VAE, these models do not add noise to the decoded output, thus the data is strictly restricted to the manifold defined by the decoder $g(z, \theta)$. However, unlike a GAN there is a well defined way to take an arbitrary data point x, project it onto the manifold, and calculate the density of the data point projected onto the manifold. Thus these models can also be used in the context of anomaly detection and out of distribution detection by identifying data that is off the manifold.

41.3.4.2 *Generative adversarial networks*

GANs [38] also typically choose a low dimensional latent space z with a known prior distribution $p(z)$, typically a normal (Gaussian) distribution with zero mean and unit variance. GANs do not add noise to the output $g(z, \theta)$, so the likelihood $p(x|z)$ (and marginal likelihood $p(x)$) for almost all of the data space is 0, which precludes training by maximum likelihood and the ELBO. Instead of training on ELBO, GANs train on a dissimilarity measure defined implicitly by a discriminator $D(x)$ (also referred to as the critic). Calculating the dissimilarity often involves it's own learning problem (*i.e.*, adversarial training of the discriminator).

The training is usually framed as a mini-max game

$$\begin{aligned} &\min_g \max_D \mathcal{L}_{\text{GAN}} = \\ &\min_g \max_D \{\mathbb{E}_{x\sim p(x)} \log D(x) + \mathbb{E}_{z\sim p(z)} \log[1 - D(g(z))]\}. \end{aligned} \tag{41.28}$$

The goal of the discriminator is to distinguish between true and generated data, hence we want to maximize this loss with respect to D, assigning 1 to true data and 0 to generated data. The goal of generator is to fool the discriminator such that it cannot distinguish between true and generated data, hence we want to minimize this loss with respect to g at fixed D. This can be viewed as a game theoretical setup in a zero sum game between generator and discriminator.

Instead of this game theory interpretation we can view the internal objective $\max_D \mathcal{L}_{\text{GAN}}$ as an implicit loss function that measures the dissimilarity between the target and generated distributions. The loss of Eq. 41.28 corresponds to the Jensen-Shannon (JS) divergence, which is a symmetrized form of KL divergence. However, JS divergence is hard to directly work with, and the adversarial training could bring many problems such as vanishing gradient, mode collapse (tendency of generator to cluster the samples around the training samples, with holes between them) and non-convergence [49, 50]. One of the core issues is that the distribution generated by the GAN is not guaranteed to cover the entire space. To address these issues Wasserstein GANs train on

$$\min_g \max_D \mathcal{L}_{\text{WGAN}} = \min_g \max_D \{\mathbb{E}_{x\sim p(x)} D(x) - \mathbb{E}_{z\sim p(z)} D(g(z))\}. \tag{41.29}$$

Here again the goal of discriminator is to make the loss as large as possible between the true data and the generated data, while the goal of generator is to make it as small as possible, so that the discriminator cannot distinguish between the two. There is no requirement for $D(x)$ to be between 0 and 1, which helps with the above mentioned problems of JS divergence. Instead, this

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

is replaced with a requirement that $D(x)$ is 1-Lipshitz, i.e. the absolute value of the norm of the gradient of the discriminator output with respect to the input has to be less or equal to 1.

Eq. 41.29 can be interpreted as the dual form of the 1-Wasserstein distance between the true and generated distribution [61]. Wasserstein distances are a measure of dissimilarity between two distributions used in the context of optimal transport, a mathematical theory of how to define a notion of distance between probability distributions. Since the transport distance increases with the separation between the two distributions when they are non-overlapping, there is no gradient collapse that plagues other measures. In its primal form p-Wasserstein distance, $p \in [1, \infty)$, between two probability distributions p_1 and p_2, is defined as $W_p(p_1, p_2) = \inf_{\gamma \in \Pi(p_1,p_2)} \left(\mathbb{E}_{(x,y)\sim\gamma} \left[|x-y|^p\right]\right)^{\frac{1}{p}}$, where $\Pi(p_1, p_2)$ is the set of all possible joint distributions $\gamma(x, y)$ with marginalized distributions p_1 and p_2. In 1D the Wasserstein distance has a closed form solution via cumulative distribution functions (CDFs), but this evaluation is intractable in high dimensions.

In the dual form of 1-Wasserstein distance, one instead maximizes Eq. 41.29 over all possible functions $D(x)$ that are 1-Lipschitz. One way to implement this is through weight clipping of the parameters of discriminator network, but a simpler solution is to add a gradient norm penalty term explicitly to the loss function [62].

Because of the discriminative nature of the dissimilarity measure defined in data space, GANs and Wasserstein GANs often generate more realistic samples than VAE or normalizing flows in high dimensions such as natural images (although flow matching and diffusion models can outperform GANs). However, GANs do not provide an encoder from data to latent space nor a tractable likelihood $p(x)$.

41.3.4.3 *Normalizing flows and autoregressive models*

Normalizing flows (NFs) provide a powerful framework for density estimation and sampling [40–44, 63]. These models map the data x to latent variables z through a sequence of invertible transformations $f = f_1 \circ f_2 \circ \cdots \circ f_n$, such that $z = f(x)$ or $x = g(z) = f^{-1}(x)$. As in the VAE and GAN, z is modeled as a random number with a simple base distribution $p_Z(z)$, which is typically chosen to be a standard normal (Gaussian) distribution. Since NFs are invertible the dimensionality of the latent space equals the dimensionality of the data space, in contrast to VAE and GANs where the latent space dimensionality is often lower. The probability density of the model be evaluated using the change of variables formula:

$$p_X(x) = p_Z(f(x)) \left|\det\left(\frac{\partial f(x)}{\partial x}\right)\right| = p_Z(f(x)) \prod_{l=1}^{n} \left|\det\left(\frac{\partial f_l(x)}{\partial x}\right)\right|, \tag{41.30}$$

where we have added subscripts to $p_X(x)$ and $p_Z(z)$ for clarity. The Jacobian determinant $\det(\frac{\partial f_l(x)}{\partial x})$ must be efficient to compute for density estimation to be practical, and the transformation f_l should be easy to invert for sampling. In contrast to VAE and GANs, standard normalizing flows preserve the dimensionality of the data space as they are invertible (though there are normalizing flows that are defined on lower dimensional manifolds embedded in the data space [40, 51–54]). As such, unlike GANs and VAEs, they can be trained via maximum likelihood (Eq. 41.23) as described in Sec. 41.3.3.

There are several popular architectures of NFs. A method used by NICE, RealNVP and Glow [41–43] is to split the space into two disjoint sets z_1 and z_2, and then use an identity forward map $z \to x$ for x_1, $x_1 = z_1$, and an affine transformation for x_2 of the form

$$x_2 = \exp(s(z_1)) \odot z_2 + m(z_1), \tag{41.31}$$

where $\odot$ is elementwise product and $m(z_1)$, $s(z_1)$ are neural networks. The Jacobian of this map is lower triangular, and its determinant is simply the product of elements along the diagonal, which is tractable, as is the inverse of the transformation. At the next layer one then performs a different split of dimensions into z_1 and z_2. The affine transformation can be further generalized to a nonlinear form using rational splines [64].

One can interpret the sequence of invertible transformations $f_1 \circ f_2 \circ \cdots \circ f_n$ as n discrete time steps in a continuous flow. In particular, one can think of a continuous-time flow described by an ordinary differential equation (ODE) and then interpret the discrete time steps as the result of a numerical integration of that ODE. This is the approach taken by the Ffjord algorithm [65] and other variants. A residual flow has an update $f_i(x) = x_i + \delta u_i(x)$, which for $\delta_i = n^{-1}$ and taking $n \to \infty$ limit gives rise to an ordinary differential equation (ODE)

$$dx_t = u_t(x_t)dt. \tag{41.32}$$

Here u_t is the velocity field that defines the flow and is a vector field. One can build the density estimator for all intermediate times t $p_t(x)$ using its divergence,

$$\ln p_t(x_t) = \ln p_0(x_0) - \int_0^t \nabla \cdot u_s(x_s)ds, \tag{41.33}$$

where p_0 at t_0 is the initial base distribution and p_1 at $t = 1$ is the target distribution. Continuous normalizing flows parametrize u_t as a neural network. They are very expressive, but expensive to train using maximum likelihood.

A different approach creating a deep generative model with a tractable likelihood is to model $p(x)$ autoregressively as

$$p(x) = \prod_{i=1}^{n} p(x_i|x_1, x_2, \ldots, x_{i-1}) \ . \tag{41.34}$$

This form describes each new dimension conditionally on all previous dimensions. It can model a general likelihood $p(x)$ as a sequence of conditional 1d distributions, whose conditional dependence on the parameters $x_1, x_2, \ldots, x_{i-1}$ can be modeled with neural networks. If x is a time series this form imposes a causal structure where x_i depends on all previous times x_j, $j < i$. WaveNet [66] and PixelCNN [67]) are two well known examples. Sampling from an autoregressive model is sequential, and can be slow in high dimensions. Inverse autoregressive flow reverses this process and makes sampling fast, but the likelihood evaluation is slow. Some normalizing flows have autoregressive coupling layers, such as masked autoregressive flow (MAF) [63].

All of the methods above use maximum likelihood training of likelihood $p(x)$ against network parameters, so the training is to minimize KL divergence between the data distribution and a Gaussian in latent space. This can be overly sensitive to small variance directions that dominate the likelihood, without being sensitive to the global structure of the data. An alternative is to use Optimal Transport Wasserstein distance between the density of the generated samples and the data, which can be evaluated either in data space or in latent space. As Wasserstein distance is difficult to evaluate in high dimensions, one can instead use slices, 1d projections of the data along different directions in high dimensional space, to build the flow [68]. Because this training is less sensitive to small variance directions than maximum likelihood training it achieves better results on anomaly detection tasks [68].

We end by noting that normalizing flows, autoregressive models, and other deep generative models that provide a tractable likelihood are powerful tools for simulation-based inference. They can provide surrogate models trained from large simulated datasets when the simulators have intractable likelihood functions, which is usually the case. As described in Sec. 41.6, one would like to work with models that can provide conditional density estimation in order to model either the likelihood $p(x|\theta)$ or the posterior $p(\theta|x)$ [69, 70]. These techniques are being actively explored and applied to a number of scientific problems.

41.3.4.4 *Flow-matching and diffusion models*

In flow-matching models, we start from a base distribution such as a Gaussian $p_0 = \mathcal{N}(0, I)$, and use ODEs to generate samples with a flow vector field $u_t^\theta(x)$ as in Eq. 41.32. As discussed above, continuous normalizing flows are expensive to train via maximum likelihood. Instead, one can learn directly the velocity

field parametrized as a neural network $u_t^\theta(x_t)$ with parameters θ via the flow-matching loss

$$\mathcal{L} = \mathbb{E}_{t\sim U(0,1),\ x\sim p_t}\left[u_t(x_t) - u_t^\theta(x_t)\right]^2, \tag{41.35}$$

where the expectation is uniform over time t and over all intermediate distributions p_t. This equation is however not practical since we do not know the target $u_t(x)$. Instead, one can take advantage of the target conditional velocity field $u_t(x_t|z)$, where $z \sim \hat{p}$ is a training data sample

$$\mathcal{L} = \mathbb{E}_{t\sim U(0,1),\ x\sim p_t,\ z\sim\hat{p}}\left[u_t(x|z) - u_t^\theta(x_t)\right]^2. \tag{41.36}$$

It has been shown that this conditional target velocity field training also leads to the correct distribution in the flow models [45,48]. Figure 41.3, taken from Ref. [71], illustrates the main idea, which is that training a conditional flow, and averaging over all the training data, is the same as training on unconditional flow.

The advantage of this formulation is that conditional velocity fields are a lot simpler to construct. A typical case is a flow from the initial Gaussian $p_0(x|z) = \mathcal{N}(0, I)$ to a delta function at z $p_1(x|z) = \delta_z(x)$. A very simple linear flow that achieves this is $p_t(x|z) = \mathcal{N}(tz, (1-t)^2 I)$. The flow itself moves from a random Gaussian variable $\epsilon \sim \mathcal{N}(0, I)$ to the data point z, so $x_t = \epsilon(1-t) + tz$. Finally, the conditional velocity field is given by $u(x_t|z) = z - \epsilon$, so the training loss is

$$\mathcal{L} = \mathbb{E}_{t\sim U(0,1),\ \epsilon\sim\mathcal{N}(0,I),\ z\sim\hat{p}}\left[z - \epsilon - u_t^\theta(\epsilon(1-t) + tz)\right]^2. \tag{41.37}$$

This leads to a simple training algorithm where one randomly chooses a minibatch of data z, random Gaussian variables ϵ, and a time t to update the parameters θ based on stochastic gradient descent using the loss of Eq. 41.37. The simplicity and efficiency of this training procedure has led flow matching to become one of the leading generative models for large image based data. Sampling from flow-matching models requires randomly choosing an initial condition $x_0 \sim N(0, I)$ and discretizing Eq. 41.32. Note that this is a deterministic ODE and all the randomness is in the initial conditions.

Diffusion models also start from a Gaussian base distribution, but also continuously add noise during the evolution in time, *i.e.*, they are based on a stochastic differential equation (SDE)

$$x_0 \sim p_0,\ \ dx_t = u_t^\theta(x_t)dt + \frac{\sigma_t^2}{2}s_t(x_t) + \sigma_t dW_t, \tag{41.38}$$

where we define score $s_t(x_t) = \nabla \ln p_t(x_t)$. Here, dW_t is the stochastic term, which adds Brownian motion (also called a Wiener process) in the form of uncorrelated Gaussian random noise. Note that with $\sigma_t = 0$, a diffusion model becomes a flow model. The noise variance σ_t is a free parameter that can be tuned for optimal performance. If our target is a static distribution so that $p_t = p$ then $u_t = 0$ and we obtain the Langevin equation.

In diffusion, we also need to learn the gradient field via the score function, and as before we can replace the marginal score with conditional score during the training to obtain score matching training procedure

$$\mathcal{L} = \mathbb{E}_{t\sim U(0,1),\ x\sim p_t,\ z\sim\hat{p}}\left[\nabla \ln p_t(x|z) - s_t^\theta(x_t)\right]^2. \tag{41.39}$$

In the simple Gaussian example with $p_t(x_t) = \mathcal{N}(\alpha_t z, \beta_t^2 I)$, where $\alpha_0 = \beta_1 = 0$ and $\alpha_1 = \beta_0 = 1$, we have a trajectory $x_t = \alpha_t z + \beta_t \epsilon$, and the score loss

$$\mathcal{L} = \mathbb{E}_{t\sim U(0,1),\ \epsilon\sim\mathcal{N}(0,I),\ z\sim\hat{p}}\left[\frac{\epsilon}{\beta_t} + s_t^\theta(\alpha_t z + \beta_t\epsilon)\right]^2. \tag{41.40}$$

It would appear that in diffusion, one must train both the flow and the score, but for simple linear models the two can be related to one another, and one can choose the flow-matching or score-matching training procedure. For the example in Eq. 41.38, the corresponding score-matching training is

$$x_0 \sim p_0,\ \ dx_t = \left[\left(\beta_t^2\frac{\dot{\alpha}}{\alpha} - \beta_t\dot{\beta}_t + \frac{\sigma_t^2}{2}\right)s_t(x_t) + \frac{\dot{\alpha}}{\alpha}x_t\right]dt + \sigma_t dW_t. \tag{41.41}$$

One of the advantages of score- and flow-based methods is that one can reduce the architectural restrictions imposed by normalizing flows or autoregressive models. Score- and flow-based training avoid the normalization requirement. Score-based models learn gradients of log probability density functions on a large number of noise-perturbed data distributions, and then generate samples by Langevin-type sampling.

The generative models described in this subsection are called flow-based models [45], score-based generative models [46], diffusion probabilistic models [47], or stochastic interpolants [48]. They have several advantages over other model families. They often outperform GAN-level sample quality without adversarial training, and enable exact log-likelihood computation through their connection to continuous-time flows, which can be represented as a probability flow ordinary differential equation [47]. The main advantage is that the distribution $p(x)$ can be specified solely by its score or flow. This in turn enables more flexible model architectures than what can be used in normalizing flows or autoregressive models.

41.3.5 *Anomaly detection and out-of-distribution detection*

Unsupervised anomaly detection techniques detect anomalies in an unlabeled test data set under the assumption that the majority of the in-distribution data are normal under some measure, while out-of-distribution (OOD) data are not. In the context of autoencoders a popular technique is to use the reconstruction error of Eq. 41.21 to identify an outlier as one with a large reconstruction error [72–74]. One issue with this method is that for higher dimensional latent space and flexible neural network architectures the encoder-decoder map become identity for any input data, $f(x) = x$, regardless of whether input x is from the in-distribution training dataset or from the out-of-distribution data. The choice of autoencoder latent space dimensionality is thus an important hyperparameter that must be tuned.

Another set of anomaly detection techniques construct a model representing normal behavior from a given in-distribution training dataset, and then evaluate the likelihood of a test instance to be generated by the utilized model. For instance, one can use density estimation methods such as normalizing flows (section 41.3.4.3) to learn the density (likelihood) of the in-distribution training dataset $p(x)$, and apply it to the test data. The expectation is that out-of-distribution data will have a lower density (likelihood) under the in-distribution density model. This expectation is however not always met in high dimensions and the method suffers because likelihood-based training is sensitive to the smallest variance directions [75]. Low-variance directions may contain little or no information on the global structure of the image, so there is a mismatch between the training objective and outlier detection objective. Lower dimensional autoencoders with NF in the latent space deal better with this issue [54].

A related issue is that of typicality: an in-distribution data sample likelihood will typically be lower than the maximum value, so an out-of-distribution data sample that is closer to the peak would have a higher likelihood. If this happens in low-variance directions that dominate the likelihood, normalizing flows can assign higher likelihoods to out-of-distribution data than to in-distribution training data [76]. A number of techniques have been proposed to circumvent these limitations, such as likelihood regret [77], likelihood-ratio [75], likelihood in autoencoder latent space [54], and Wasserstein distance training of the likelihood $p(x)$ [68,78]. These methods can achieve better anomaly detection performance than the autoencoder reconstruction error [53,54,78]. However, even perfect density estimation cannot guarantee good anomaly detection performance [79,80].

Supervised anomaly detection techniques require a data set that has been labeled as in-distribution and out-of-distribution and involves training a classifier (the key difference to many other statistical classification problems is the inherent unbalanced nature of outlier detection). These methods assume some form for what out-of-distribution data may look like, and their success relies on whether the assumed form is a realistic representation of actual out-of-distribution data. When this assumption is valid these methods can be more powerful than unsupervised methods, but the reverse is also true. A hybrid between the two approaches

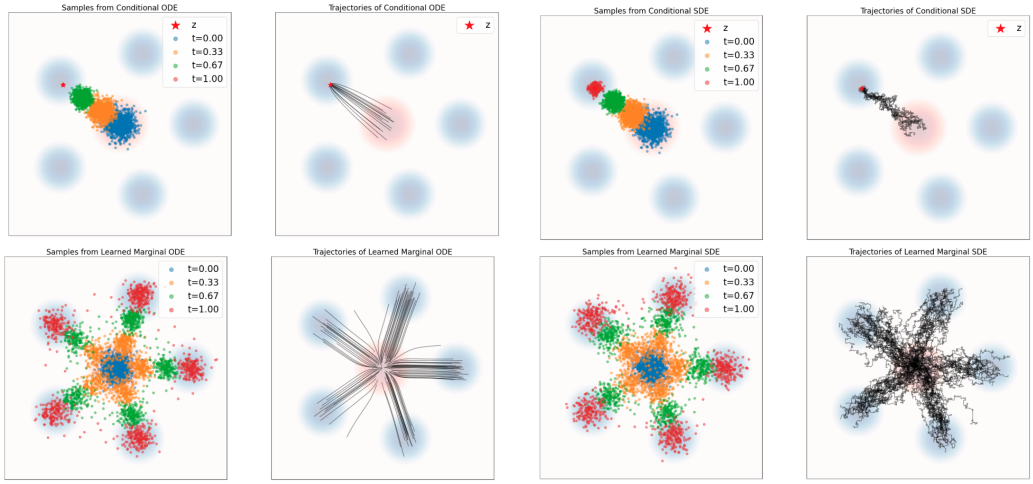

Figure 41.3: Illustration of the marginalization trick for flow-based models (left) and diffusion models (right), which simulate a probability path with ODEs or SDEs, respectively (Holderrieth and Erives, 2025). The data distribution $\hat{p}$ is the blue background, while the initial Gaussian distribution is the red background. The top graphs represent conditional probability paths, while the bottom graphs represent marginal probability paths. Both samples and trajectories are shown.

is to train a classifier without labels [81]. All these approaches are largely complementary to each other [82]. Examples of different anomaly detection methods applied to HEP are the LHC Olympics 2020 and Dark Machines challenges [83, 84].

41.4 Self-supervised learning

Self-supervised learning (SSL) also aims to distill useful features in the data without requiring supervision labels for every sample in the input data. Self-supervised methods make use of large unlabeled datasets to build meaningful representations. They can generally be categorized as *autoassociative*, where the model is trained to reproduce or reconstruct its own (masked) input or *contrastive*, where the model is trained to learn a mapping that is insensitive to different "views" of the data. These methods are often used to build "foundation models" (FMs) discussed in Sec. 41.9.11, which are pre-trained using self-supervised learning and fine-tuned using supervised learning for different downstream tasks. However, FMs are not the only possible use case.

A classic autoassociative task is masked language modeling popularized by the bidirectional encoder representations from transformers (BERT) model [85]. In this task, BERT ingests a sequence of words, a fraction of which are randomly masked, and tries to predict the original words that have been masked. For example, in the sentence "The Milky Way is a [MASK] galaxy," BERT would need to predict "spiral." This helps BERT learn bidirectional context. A variant of this approach is next token prediction, popularized by the generative pretrained transformer (GPT) [86]. A common theme in these methods is *tokenization*, in which elements of the input data are mapped to discrete vectors, known as tokens. These approaches have been applied in the context of particle jets [87–89], enabling the construction of backbone models that can be fine-tuned for different tasks and provide improvements for small training samples.

Sensory data (*e.g.*, 1D waveforms, 2D images, or 3D scenes) pose a significant challenge for autoassociative tasks compared to symbolic data such as language, math, and high-level physical concepts like jets and particles. For symbolic data, the masking unit is naturally defined (*e.g.*, a word for language) and associated with a strong semantic meaning, which yields a well-defined learning objective for mask-based self-supervision. On the contrary, sensory data captures raw information and a unit of data (*e.g.* a single pixel in an image) does not carry meaningful information alone. This challenge has resulted in in-depth R&D for self-supervision techniques in computer vision. The masked autoencoder (MAE) laid the initial ground work [90]: the authors discovered that a large fraction of masking (*i.e.*, 75%) is crucial for successful training using an asymmetric encoder-decoder architecture. Distillation with no labels (DINO) made another breakthrough by introducing a self-distillation technique where a student and teacher model pair—the teacher model typically being an exponential moving average of the student model—are forced to agree across different augmentations (*e.g.*, cropping, adding jitter, and rotating) of the same data instance [91, 92]. For effective representation learning of 3D geometrical shapes, multi-view projection matching techniques [93–95] are promising and a strong promise and relevant to time projection chamber (TPC) image data in high energy physics. Exploration of these specialized techniques in computer vision has impacted HEP applications [96, 97].

In contrastive learning, portions of the input data are paired together and the model is tasked to find matching pairs. Pairs can be constructed based on different data modalities, such as text and images, or based on data augmentations, that may be generic, such as adding noise, or domain-specific, like symmetry transformations. For example, the contrastive language-image pre-training (CLIP) [98] allows joint pretraining of a text encoder and an image encoder, such that a matching image-text pair have image encoding vector $\mathbf{z}_i$ and text encoding vector $\mathbf{z}_j$ that span a small angle, *i.e.*, have a large cosine similarity

$$c(\mathbf{z}_i, \mathbf{z}_j) = \frac{\mathbf{z}_i \cdot \mathbf{z}_j}{|\mathbf{z}_i||\mathbf{z}_j|} = \cos\theta_{ij} \ , \tag{41.42}$$

with θ_{ij} being the angle between the encoding vectors. This approach has been applied in astrophysics [99].

Positive pairs may also be constructed by applying data augmentations. For example, in the case of galaxy images, one may augment the data by performing image rotations, adding noise, size scaling, or adding point spread function smoothing, all of which are realistic transformations expected in a real galaxy image survey [100, 101]. For particle jets, tailored augmentations may include rotations about the jet axis, translations in the (η, ϕ) plane, smearing the positions of the soft jet constituents, and collinear splitting of the jet constituents [102–105]. Another augmentation strategy is based on re-simulating the stochastic shower and detector interactions, thus generating multiple physical realizations of a primary particle's evolution [106, 107].

A well-known approach for contrastive learning with augmentations is SimCLR [108]. In this approach, the contrastive loss for a positive pair of an input and its augmentation $(\mathbf{z}_i, \mathbf{z}_i')$ is defined

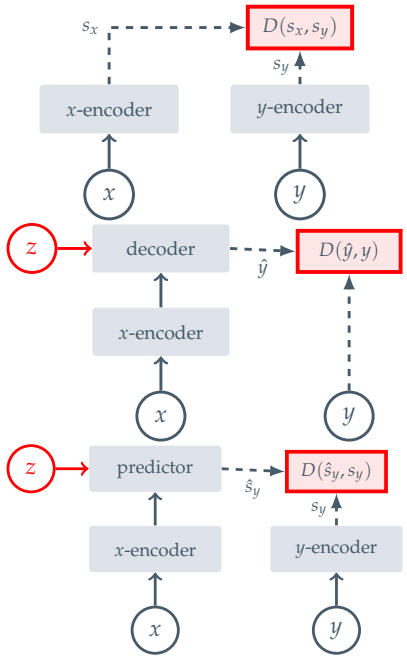

Figure 41.4: Common architectures for self-supervised learning, in which the system learns to assign a large scalar value to incompatible inputs, and a low scalar value to compatible inputs (M. Assran, et al. in ICCV, 2023). Joint-embedding architectures (left) learn to output similar embeddings for compatible inputs x, y and dissimilar embeddings for incompatible inputs. Generative architectures (center) learn to directly reconstruct a signal y from a compatible signal x, using a decoder network that is conditioned on additional (possibly latent) variables z to facilitate reconstruction. Joint-embedding predictive architectures (right) learn to predict the embeddings of a signal y from a compatible signal x, using a predictor network that is conditioned on additional (possibly latent) variables z to facilitate prediction.

in terms of the cosine similarity of Eq. 41.42 as

$$\mathcal{L}(\mathbf{z}, \mathbf{z}'_i) = -\ln \frac{\exp[c(\mathbf{z}_i, \mathbf{z}'_i)/\tau]}{\sum_{j \neq i \in \text{batch}} \left[\exp[c(\mathbf{z}_i, \mathbf{z}_j)/\tau] + \exp[c(\mathbf{z}_i, \mathbf{z}'_j)/\tau]\right]}, \tag{41.43}$$

and the total loss is given by the sum over all positive pairs in the batch, $\sum_{i \in \text{batch}} \mathcal{L}(\mathbf{z}_i, \mathbf{z}'_i)$. The loss decreases when the distance between positive pairs decreases or when the distance between negative pairs increases. The hyperparameter τ is known as temperature and controls the relative influence of positive and negative pairs. SimCLR has been applied in radio astronomy [109], neutrino physics [110], and collider physics [102]. Another application of contrastive regularization is self-distillation introduced in DINO discussed above. Self-distillation is a powerful technique that can be applied regardless of the target task, and improves the quality of self-supervision for many computer vision models for both image and point cloud data.

Finally, an alternative paradigm is the joint-embedding predictive architecture (JEPA) [111], which learns meaningful representations by modeling missing or unseen embeddings directly in the latent space without a decoder or full input reconstruction. The advantages of this approach are no data augmentations are required and unnecessary details of the input can be ignored. This approach has been applied to particle jets [112, 113] and Square Kilometer Array (SKA) light cones [114]. A comparison between the different self-supervised learning approaches can be found in Fig. 41.4, reproduced from Ref. [111].

41.5 Optimal control, reinforcement learning, and active learning

Many problems in science and engineering can be cast as a control problem, which comprises a cost functional that is a function of state and some control variables that specify some underlying dynamical system. This is relevant for the control of accelerators where the dynamical system is physical. This formalism can also be used to describe the design of experiments, planning of an observational survey, and other decision making processes relevant to the scientific method. It is closely connected to planning, dynamic programming, and reinforcement learning. Optimal control generalizes the framing of learning presented in Sec. 41.2.1.

41.5.1 *Optimal control*

Optimal control theory deals with finding a control for a dynamical system over a period of time such that the objective function is optimized. The underlying system can be discrete or continuous and may be deterministic or stochastic. The commonalities and differences between optimal control and reinforcement learning can be best understood through the formalism of a Markov decision process (MDP), which is a discrete-time stochastic control process.

A Markov decision process comprises four components often organized as a 4-tuple (S, A, P_a, R_a), where: S is a set of states called the state space, A is a set of actions called the action space, $P_a(s, s') = \Pr(s_{t+1} = s' \mid s_t = s, a_t = a)$ is the probability that action a in state s at time t will lead to state s' at time $t + 1$, $R_a(s, s')$ is the immediate reward (or expected immediate reward) received after transitioning from state s to state s', due to action a.

The policy function π is a mapping from state space to action space that can be either deterministic or probabilistic. For examples, the policy that drives a computer chess playing system, decides which move to make given the current state of the board. Similarly, policies dictate which experiment should be built next, which field of the sky should be observed, or how to adjust the operational parameters of an accelerator. The dynamics of the resulting system are then fixed by combining the policy with the underlying MDP. The evolution of the resulting dynamical system behaves like a Markov chain since the action chosen in state s is completely determined by $\pi(s)$ and $\Pr(s_{t+1} = s' \mid s_t = s, a_t = a)$ implies the Markov transition matrix $\Pr(s_{t+1} = s' \mid s_t = s)$.

The objective optimal control is to choose a policy π that will maximize a cumulative function of the instantaneous rewards R_a. A common choice is the expected discounted sum:

$$\mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t R_{a_t}(s_t, s_{t+1})\right], \tag{41.44}$$

where $a_t \sim \pi(s_t)$ are the actions given by the policy, the expectation computed with respect to the distribution $s_{t+1} \sim P_{a_t}(s_t, s_{t+1})$, and γ is the discount factor satisfying $0 \leq \gamma \leq 1$. The discount factor is usually close to 1 and sometimes reparameterized as $\gamma = 1/(1 + r)$, where r is called the discount rate. A lower discount factor motivates the decision maker to favor taking actions early, rather than postpone them indefinitely.

A policy that maximizes the objective function is called an optimal policy and denoted π^*, though the optimal policy need not be unique. Importantly, the Markov property implies that the optimal policy is only a function of the current state. Dynamic programming can be used to find the optimal policy for MDPs with finite state and action spaces. For instance, in value iteration (a.k.a. backward induction) can be used to solve the "Bellman equation" [115]. For continuous-time systems, the optimal policy is defined by the Hamilton–Jacobi–Bellman equation [116].

In many settings, it is assumed that the state s is fully known when action is to be taken and there are no latent variables. When this assumption is not true, the problem is called a partially observable MDP. These problems are generally more difficult and the dynamic programming algorithms do not directly apply [117].

41.5.2 *Reinforcement learning*

The main difference between the classical dynamic programming methods and reinforcement learning (RL) algorithms is that the latter do not assume knowledge of an exact mathematical model of the MDP and they target large MDPs where exact methods become infeasible. For example, RL was used in the context of jet physics to search for the most likely jet clustering when the number of constituents was too large for the exact dynamic programming algorithm to be used [118]. In addition, RL can be used when the probabilities or rewards are unknown. Instead, the transition probabilities are often accessed indirectly through interaction with a real or simulated environment.

Numerous variations to RL exist, which include so-called model-based and model-free approaches (referring to models of the instantaneous rewards and the state transitions) and on-policy and off-policy (which describes how the actions taken during learning are related to the current policy). See Ref. [119] for an introduction and Ref. [120] for a recent review. Some examples of RL use in particle physics are in Refs. [121–123].

41.5.3 *Multi-arm bandits*

Multi-arm bandit problems are a classic reinforcement learning problem where one tries to maximize the expected gain by allocating a limited set of resources to various alternatives. The name is a reference to a gambler with a fixed amount of money that must choose between multiple slot machines (or "one-armed" bandits) when the payoff for the individual machines is unknown. A hallmark of multi-arm bandit problems is that they involve a tradeoff between exploration (playing machines to estimate their payoff) and exploitation (playing machines with the highest estimated payoff). Multi-armed bandits are used to manage large projects, organizations, and scheduling problems. The theory has a long history going back to Robbins in 1952 that used it to study the sequential design of experiments [124] and Gittins who derived an optimal policy under some conditions [125].

41.5.4 *Bayesian optimization*

A closely related set of techniques involve optimizing some expensive black box function $f(x)$. For instance, the function may be computationally expensive to evaluate or low-latency, *e.g.* it may involve manually re-configuring a system. This is particularly relevant for analysis optimization in particle physics where evaluating $f(x)$ involves processing large numbers of simulated collisions. Another common use case involves optimizing the hyperparameters of a learning algorithm.

Without any assumptions about the function $f(x)$ this is hopeless; however, if one assumes something about the functions (*e.g.* some notion of smoothness) then one can leverage function evaluations evaluations $\{f(x_t)\}_{t=1,\ldots,T}$ to say something about what value the function might take on at other values of x. This is usually cast in Bayesian terms, and Gaussian processes (Section 41.8.2) are often used to model the distribution over $f(x)$. The optimization techniques that use this framing are generically referred to as Bayesian optimization [126].

Optimization in this context is usually characterized by an *exploration-exploitation* tradeoff, similar to what is found in multi-arm bandits. Here, exploration refers to function evaluations that characterize the function in regions that haven't been evaluated, while exploitation refers to evaluations near what is predicted to be its maximum. This setting is similar to reinforcement learning in that it involves sequential decisions (*i.e.*, where to evaluate the function next), but usually the target function $f(x)$ is assumed to be static. In that sense, the state referred to in the language of an MDP is the state of knowledge about the function after sequential evaluations $\{f(x_t)\}_{t=1,\ldots,T}$. The reward at time t is not the value of the function $f(x_t)$, but some quantity that characterizes what was learned about the function's maximum. In this literature, one often refers to the *acquisition function*, which plays a similar role as the expected value of the reward in RL. Common acquisition functions include the probability of improvement, the expected improvement, and an upper-confidence bound [127].

41.5.5 *Active learning*

Active learning is closely related to Bayesian optimization, described above. In Bayesian optimization one estimates the function $f(x)$ from some set of evaluations $\{y_t = f(x_t)\}_{t=1,\ldots,T}$; however, the goal is to find the maximum $x^* = \arg\max_x f(x)$. In active learning, the goal is not to find the maximum of $f(x)$, but to approximate the function as one does in supervised learning. The main difference compared to vanilla supervised learning is that the labeled training dataset isn't provided a priori in a passive way, but the learning algorithm actively decides where to generate $(x_t, y_t = f(x_t))$ pairs. The function $f(x)$ is sometimes referred to as an *oracle*. Active learning is particularly attractive when obtaining labeled data is a costly process.

More broadly, a challenge of many machine learning applications is obtaining labeled data, which can be a costly process. If a system could learn from small amounts of data, and choose by itself what data it would like the user to label via an external process called oracle, it would make machine learning more powerful. Such frameworks are also called experiment design or active learning. In active learning, a model is trained on a small amount of data (the initial training dataset), and an acquisition function (often based on the model's uncertainty) decides on which data points to ask for a label. The acquisition function selects one or more points from a pool of unlabeled data points, with the pool points lying outside of the training dataset. Once we label the selected data points, these are added to the training dataset, and a new model is trained on the updated training dataset. This process is then repeated, with the training dataset increasing in size over time. The advantage of such systems is that they often result in dramatic reductions in the amount of labeling required to train an ML system (and therefore cost and time).

41.6 Simulation-based inference

The goal of simulation-based inference (related to, but distinct from, likelihood-free inference) is to extend the statistical procedures described in the Chapter on Statistics (*e.g.* parameter estimation, hypothesis tests, confidence intervals, and Bayesian posterior distributions) to the situation where one does not know the explicit likelihood $p(x|\theta)$, the probability of the data given the parameters θ, but has access to a simulator that defines the likelihood $p(x|\theta)$ implicitly [128,129]. In a typical setup we would like to solve the so called inverse problem of getting the posterior of the parameters given the data, $p(\theta|x)$, but we cannot use Bayes theorem directly because we do not have explicit $p(x|\theta)$.

In particle physics and cosmology, the simulators usually use Monte Carlo event generators (see Sec. 43) to sample unobserved latent variables z, such as the z_p phase space of the hard scattering (see Sec. 49.4), z_s associated to showering and hadronization, z_d associated to the interaction of particles with the detector (see Sec. 34), or initial Gaussian modes of the universe realization. As such, the full simulation chain can be expressed approximately as

$$\begin{aligned} p(x|\theta) &= \int dz p(x,z|\theta) \\ &= \int \mathrm{d}z_d \int \mathrm{d}z_s \int \mathrm{d}z_p \, p(x|z_d) p(z_d|z_s) p(z_s|z_p) p(z_p|\theta) \,, \end{aligned} \tag{41.45}$$

where θ are the Lagrangian parameters that dictate the hard scattering. Evaluating the marginal likelihood $p(x|\theta)$ is intractable as it would require evaluating the integral above for each event.

While the marginal likelihood is intractable, simulators provide the ability to generate synthetic data $x_i \overset{\text{i.i.d.}}{\sim} p(x|\theta)$ for any value of the parameters θ. One can use a suitable proposal distribution $\tilde{p}(\theta)$, sample $\theta_i \overset{\text{i.i.d.}}{\sim} \tilde{p}(\theta)$, generate synthetic data $x_i \sim p(x|\theta_i)$, and then assemble a training dataset $\{x_i, \theta_i\}_{i=1,\ldots,n}$ that can be used to train various machine learning models.

There is thus a close analogy between simulation-based inference and data driven machine learning tasks discussed so far, replacing θ with y. One difference is that in simulation-based inference we can always generate new samples by running additional simulations, while we typically view training dataset in machine learning as fixed. This property of simulation-based inference enables active learning, where the additional simulations are chosen such as to minimize the error on the desired statistical inference

by KARLSRUHE INSTI

task. Another difference is that we often have access to the joint likelihood $p(x, z|\theta)$, where z are unobserved latent variables[3].

Typically in particle physics, one uses histograms or kernel density estimation to model the distribution of observables (low-dimensional summary statistics such as the invariant mass) of simulated data [130]. Alternatively, one can use an explicit parametric family (such as a falling exponential or a Gaussian distribution) to model $\hat{f}(x|\theta) \approx p(x|\theta)$. That model is then used as as a surrogate for the unknown density implicitly defined by the simulator. A related approach is known as approximate Bayesian computation (ABC), which approximates the likelihood through an acceptance probability that synthetic data is sufficiently close to the observed data [131, 132]. In practice, these techniques are limited to low-dimensional representations of the data. Thus the potential of recent machine learning approaches to simulation-based inference is to extend this approach to higher-dimensional data, while maintaining the already well-established statistical procedures.

For instance, one can use normalizing flows (see Sec. 41.3.4.3) and the loss functions for density estimation (see Sec. 41.3.3) to learn a surrogate model for the likelihood $\hat{f}(x|\theta) \approx p(x|\theta)$ [69]. Similarly, one can use conditional density estimation to learn a surrogate model for the posterior $\hat{f}(\theta|x) \approx p(\theta|x)$, which may involve including the prior-to-proposal ratio $\tilde{p}(\theta)/p(\theta)$ [70]. In addition to the unsupervised learning techniques, one can also use supervised learning to learn the likelihood-ratio $r(x|\theta_0, \theta_1) = p(x|\theta_0)/p(x|\theta_1)$ by leveraging the *likelihood-ratio trick* of Eq. 41.13 [133, 134].

In some cases one can also augment the training dataset to include the joint likelihood-ratio

$$r(x_i, z_i|\theta_0, \theta_1) \coloneqq p(x_i, z_i|\theta_0)/p(x_i, z_i|\theta_1) \,, \tag{41.46}$$

which can be used to reduce the variance for the squared-error or cross-entropy losses [134, 135]. While the marginal likelihood $p(x|\theta)$ is intractable due to the high-dimensional integral over the latent space, the joint likelihood is often tractable since no integration is necessary.

In some cases performing the marginal integral of Eq. 41.45 is tractable even for high dimensional latent space z. One of the approaches to make it feasible in high dimensional latent space is to make simulations differentiable with respect to all of its parameters, global variables θ and latent variables z. While differentiable simulations have not traditionally been developed for scientific applications, the success of machine learning based on backpropagation combined with gradient descent (see Sec. 41.9.1), has inspired a renewed interest. One example is FlowPM cosmological N-body simulation, which takes advantage of Mesh-Tensorflow to achieve a GPU-accelerated, distributed, and differentiable simulation [136]. Availability of simulation gradients in turn enables gradient based Monte Carlo Markov chain methods to perform high dimensional marginal integral over the latent space z and over parameter space θ [137].

Often SBI uses predetermined summary statistics, such as binned histograms in particle physics, or power spectrum in cosmology, to avoid the curse of dimensionality. It is however possible to train on uncompressed high dimensional data in cosmology by exploiting the symmetries [138]. Yet another alternative is to train the network to search for the best possible summary statistic. The summary statistic can then simply be $\hat{\theta}$, which is the estimate of the parameters θ that emerge from a supervised training on simulations. In SBI these can often be biased even after training, and one possible solution is to form a pseudo-likelihood to model the bias as a function of the true value of θ [139].

41.6.1 *Latent space reconstruction and unfolding*

While much of the work on simulation-based inference described above is aimed at inferring the parameters θ of the simulator, there is work that aims to infer the latent variables z. A common approach in particle physics is to think of the parameters θ as parameters of a theory, such as masses, coupling constants, or Lagrangian parameters, while z might describe the kinematics of a collision before the detector response. Inferring the distribution $p(z|\{x_1, \ldots, x_n\})$ from a dataset of multiple observations is commonly referred to as unfolding in particle physics, and deconvolution in other contexts. Unfolding is a classic inverse problem, and the collection of ideas being used for machine-learning based simulation-based inference are also being applied in this setting [140]. For example, the OmniFold method [141] iteratively reweights a dataset in an unbinned way using machine learning to produce a simultaneous measurement of many observables. In this method, samples $\vec{x}_r$ from detector-level MC simulation are first corrected by a learned weighting function $\omega(\vec{x}_r)$ to match data. Then, samples $\vec{x}_p$ from particle-level MC simulation are corrected by another learned weighting function $\nu(\vec{x}_p)$ to match the $\omega(\vec{x}_r)$-weighted MC simulation. The method is iterated multiple times, to achieve $\nu(\vec{x}_p)$-weighted MC events whose event yields and kinematics match those observed in data. The H1 [142] and ATLAS [143] Collaborations have used the OmniFold method in experimental measurements. It has also been applied to T2K [144] and CMS [145] open data.

In cosmology, a common task is to reconstruct initial density distribution of the dark matter, or its final distribution, from data such as galaxy positions. This can then be used for various downstream tasks such as cosmological parameter inference or making maps of dark matter in our universe. High dimensional SBI can be used for this task [146]. An alternative is Bayesian inverse problem inference using the forward model $g(z, \theta)$, which can be an N-body simulation with some simple galaxy formation model added to it [137, 147, 148]. Standard Bayesian methodology using for example MCMC can be used to solve this task and find the posterior $p(z, \theta|x)$, which specifies initial distribution of dark matter. To draw samples of final dark matter distribution, and of the reconstructed data, we can first draw samples from the posterior $p(z, \theta|x)$, and then evaluate forward model $g(z, \theta)$ for each sample.

41.7 Data representations, inductive bias, and example applications

In Sec. 41.2 we describe the input data as living in an abstract space $x_i \in \mathcal{X}$. In this section, we briefly discuss some of the common types of structured data that are encountered in physics and refer to the corresponding models classes that have been developed to work with them. We elaborate on the model classes in more detail in the following section.

The most basic and common type of data structure is when $\mathcal{X} = \mathbb{R}^d$. This is often referred to as *tabular data* since the entire data set $\{x_i\}_{i=1,\ldots,n}$ can be thought of as a table with n rows and d columns. It is common to think of an individual entry x_i as a vector in d-dimensional Euclidean space, where the coordinates correspond to the columns of this table. In some cases individual components of x_i might be integers or take on only discrete values, in which case describing the space of the data as real-valued is a slight abuse of notation and representation. For many years this was the dominant type of data in high energy physics as it is a natural input type for shallow neural networks, multilayer perceptrons, support vector machines, and tree-based methods found in popular tools such as `TMVA` [149].

For categorical data, one typically uses a numerical representation such as *integer encoding* where different categories are mapped to integers with a corresponding dictionary. Another common representation of categorical data is based on the so-called *one-hot encoding* (aka 'one-of-K' or 'dummy'), in which case the category is mapped to a k-dimensional binary vector where k is the number of categories and each component of this vector corresponds to a particular category. In the one-hot encoding, only one of the components is non-zero. Finally, there are approaches in one learns an *embedding* that maps discrete categories into $\mathbb{R}^d$; an example of this is `Word2Vec` [150]. Interestingly, such embeddings can preserve various types of semantics; for instance, the vector `walking - walk` is similar to the vector `swimming - swam` as are the vectors connecting countries and their capital cities. This allows for a loose sense of algebra on the word

[3] For this reason we prefer to use simulation-based inference instead of likelihood-free inference: joint likelihood $p(x, z|\theta)$ is often available, it is the marginal integral over latent space z that is assumed to be intractable.

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

embeddings such as `walking - swimming + swam = walk`. Similar types of embeddings have also been used in a number of scientific use-cases including biological sequences (*e.g.*, DNA, RNA, and proteins) for bioinformatics applications [151].

Particle physics data often is represented with an extension of the simple tabular data structure where the number of columns is not fixed. For instance, if the rows correspond to data for individual collisions, the number of electrons (and positrons) reconstructed in the event is variable. Thus the number of columns needed to represent the energy, momentum, and charge of these particles is also variable. A common solution to this problem is to fix a maximum number of particles and then *truncate* and *zero-pad* to fit the data into a fixed tabular representation, though this is not the natural representation of the data and it leads to a loss of information.

Sequential data is also commonly encountered in physics (*e.g.* in time series). Here an individual entry $x_i = (x_i^1, \ldots, x_i^t, \ldots x_i^{T_i})$ where t is index for the ordered sequence, T_i is the length of the sequence (which might be variable), and the data associated to each "time" $x_i^t \in \mathbb{R}^d$. This is similar to the previous example where the energy, momentum, and charge of the tth electron in the ith event would be x_i^t and the electrons might be sorted according to their energy or transverse momentum. Sequential data is also encountered in natural language processing, where x_i^t correspond to individual words in a sentence. Recurrent neural networks (see Sec. 41.8.4.5) are particularly well suited to sequential data. Examples applications from the Living Review include Refs. [152–157].

Image-like data is one of the most dominant forms of data in industrial applications of deep learning, is very relevant for astronomy and cosmology, and also appears in particle physics in various forms. Image-like data typically involves d-dimensional features associated to a regular grid or lattice that does not vary across the individual instances x_i. The canonical example is a standard image from a camera with $W \times H$ pixels where the pth pixel has data $x_i^p \in \mathbb{R}^3$ corresponding to the three *channels* in the RGB color model. It is important to recognize that the data corresponding to the 2-dimensional image is not 2-dimensional; instead, it is $(W \times H \times c)$-dimensional, where c is the number of channels. In astronomy, an image may be grey scale ($c = 1$) or there may be more *channels* ($c > 3$) corresponding to different color filters. In other applications, the grid or lattice might be 3- or 4-dimensional. For example, the data associated to a regularly segmented calorimeter can be thought of as a 3-dimensional image and the data associated to a lattice simulation of a classical or quantum system can be thought of as a 4-dimensional image. Convolutional neural networks, described in Sec. 41.8.4.4, are particularly well suited to image-like data. Example applications from the Living Review include Refs. [153, 158–180].

It is also possible that the data (or features) associated to one "pixel" or lattice site may itself be structured. For example, the single read-out plane of a liquid argon time projection chamber (LArTPC) may involve a 1-dimensional or 2-dimensional grid, but the data associated to each "pixel" is itself a sequence or waveform. Example applications in neutrino physics from the Living Review include Refs. [26, 27, 30, 181–208]. Similarly, in lattice quantum chromodynamics, the data associate to a particular site (or link) would be group valued (*e.g.* $x_i^p \in SU(3)$ as in Refs. [209, 210]).

Both sequential and image-like data have a notion of temporal or spatial structure. While it is possible to unroll an image into a $(W \times H \times c)$-dimensional vector, that would erase the spatial structure and obfuscate the fact that nearby pixels are highly correlated. Similarly, one could permute the time index for sequential data, but that would destroy the temporal structure of the data. The complementary point of view is that the model class should also be aware of the structure of the data. Recurrent and convolutional neural networks are good examples of *inductive bias* as the models incorporate the structure of the data. In some cases this can be formalized in terms of symmetry. For example, if we train model to classify images of cats and dogs, we would like it's prediction to be invariant to where in the image the cat is. This type of translational invariance can be enforced in the design of the model class.

While permuting the elements of a sequence destroys the temporal structure of a time series, attaching a temporal index t to a set of objects with features x_i^t can also be problematic. If the data corresponding to x_i are really a set $\{x_i^1, \ldots, x_i^{T_i}\}$ (*e.g.*, a point cloud), then we would like the output of the model to be *permutation invariant* or *permutation equivariant* depending on if the output is per-set or per-element, respectively. A standard sequential or convolutional model will not generally be permutation invariant, but models such as deep sets, various types of graph neural networks, and transformers can be made to enforce permutation symmetry. Example applications from the Living Review include Refs. [172, 211–222].

The temporal and spatial structure of sequences and image like data can also be generalized. For instance, a 1-dimensional sequence can be generalized to a tree structured data like one finds in the hierarchical clustering of jets or as in a directed-acyclic graph (DAG). Generalizations of recurrent neural networks have been constructed that can operate over these more complex data structures [223, 224]. More generally, one can considered graph-structured data composed of nodes and edges or multi-graphs that group together three nodes into faces or k nodes into k-edges. Graph neural networks are a class of models that work with this type of data. The emerging subfield of geometric deep learning aims to unify the notation, terminology, and theory that connect these considerations of the structure of the data and the corresponding model architecture. Example applications in the Living Review include Refs. [32, 190, 197, 200, 201, 203, 225–250].

If the data are expected to have a symmetry associated to them but one is working with a model class that does not enforce this symmetry, then *data augmentation* is a common procedure used to improve generalization performance. Here one starts with an initial dataset $\{x_i\}_{i=1,\ldots,n}$ and produces an augmented dataset $\{x'_i\}_{i'=1,\ldots,n'}$ through some data augmentation strategy. For example, one might apply a random rotation $R_{i'}$ to an image to produce $x'_i = R_{i'}(x_i)$ if one assumes rotational invariance in the underlying problem.

In some cases some of the individual features (components) of x are functions of other features. For instance, one may include components of a four-vector (E, p_x, p_y, p_z) as well as redundant information such as transverse momentum, azimuthal angles, rapidity, etc. In this case, the data is restricted to a lower-dimensional surface embedded in $\mathcal{X}$. Even if the features aren't redundant, statistically the data are often effectively restricted to a small subspace of statistically likely samples and those that are exceedingly unlikely. For instance, the space of natural images is a small and highly structured subspace of all possible images, which are dominated by what we would perceive visually as noise. The term *data manifold* is used to describe this restricted subspace where the data are to be found, even though it does not necessarily satisfy the formal requirements of a manifold in the mathematical sense.

These considerations on the structure of the data not only apply not to the input data $x_i \in \mathcal{X}$, but also to the output data $y_i \in \mathcal{Y}$. For instance, one might want a sequence-to-sequence model as in machine translation of written text [251] or to learn a function that takes sets as input and produces graphs as output as in the Set2Graph mode [252]. One might also want the input and output of the model to be different in representations of an underlying symmetry group and for the model to enforce group-equivariance [209, 210]. The development of the necessary modeling components to enable practitioners to compose and train these types of models is a significant development for the field of physics.

41.8 Flavors of ML models

41.8.1 *Support vector machines*

Support vector machines (SVMs) are a class of supervised learning models used for classification and regression. The learning algorithm involves a convex optimization problem that has a unique solution and can be solved with quadratic programming techniques. In this sense, they are robust and easier to characterize than neural networks that involve non-convex optimization.

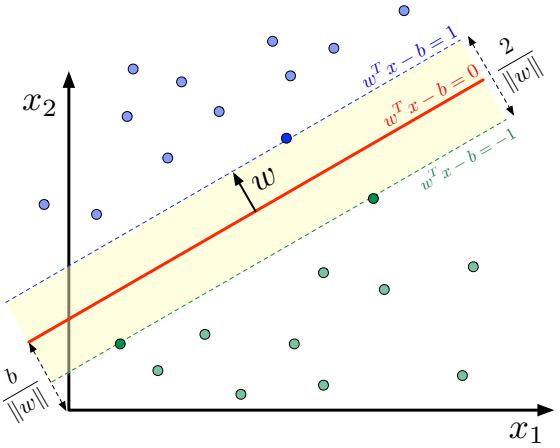

Figure 41.5: Illustration of a maximum margin classifier for a linear support vector machine in the separable case.

Linear support vector machines are used for binary classification, where $\mathcal{X} = \mathbb{R}^d$ and the target labels are conventionally defined as $\mathcal{Y} = \{-1, 1\}$. The classification is simply based on which side of a hyperplane the data lie. Any hyperplane can be written as the set of points x satisfying $w^T x - b = 0$, where $w, b \in \mathbb{R}^d$ are the parameters of the model. The vector w is normal to the hyperplane, but not necessarily normalized. The quantity $\frac{b}{\|w\|}$ quantifies the offset of the hyperplane from the origin along the normal vector w.

If the training dataset is linearly separable, then there is a region bounded by two parallel hyperplanes, called the *margin*, that separate the two classes of data. The maximum margin classifier is uniquely defined by making the distance between these two hyperplanes as large as possible. The boundaries of the margin can be defined by $w^T x_i - b = \pm 1$, and the width of the margin is given by $\frac{2}{\|w\|}$. Figure 41.5 illustrates this for $x \in \mathbb{R}^2$.

Since the width of the margin is maximized when $\|w\|$ is minimized, we can state the goal of the (hard) maximum-margin classifier in the linear separable case as the following constrained optimization problem: Minimize $\|w\|^2$ subject to the constraint $y_i(w^T x_i - b) \geq 1$ for $i = 1, \ldots, n$. The w and b that solve this problem uniquely determine the resulting classifier, $\hat{y}(x) = \text{sgn}(w^T x - b)$. This geometric description makes it clear that the maximum-margin hyperplane is completely determined by those x_i that lie nearest to it: the eponymous *support vectors*.

41.8.2 *From Bayesian linear regression to kernel regression and Gaussian processes*

As discussed in Sec. 41.2.2, linear regression is a specific case of regression where the solution is parameterized as a linear combination of basis functions $\phi(x)$,

$$f_\phi(x) = \sum_k w_k \phi_k(x) = w^\intercal \phi, \tag{41.47}$$

using a short-hand vector notation. If we aggregate all the basis functions of the training data into $\Phi(x)$ and all x into X, and assuming a Gaussian noise model $\epsilon \sim \mathcal{N}(0, \sigma_n^2)$, we can write the noise probability distribution as

$$p(y|X, w) = \mathcal{N}(w^\intercal \Phi, \sigma_n^2 I). \tag{41.48}$$

In overparametrized models, this needs to be regularized, with explicit L2 norm of the weights, as discussed in Sec. 41.2.5. If we view the process in the Bayesian context, we add a weight prior $p(w) = \mathcal{N}(0, \Sigma_p)$ to the data likelihood. With this one can define the posterior of the weights as

$$p(w|X, y) \propto p(y|X, w)p(w) = \mathcal{N}(\sigma_n^{-2} A^{-1} \Phi y, A^{-1}), \tag{41.49}$$

where $A = \sigma_n^{-2} \Phi\Phi^\intercal + \Sigma_p^{-1}$.

Our main task is not to predict the weights themselves, but to predict f^* given some x^*. In the Bayesian view, one must model average over the weights,

$$\begin{aligned} p(f^*|x^*, X, y) &= \int \mathrm{d}w p(f^*|x^*, w)p(w|X, y) \\ &= \mathcal{N}(\sigma_n^{-2} \phi(x^*)^\intercal A^{-1} \Phi y, \phi(x^*)^T A^{-1} \phi(x^*)), \end{aligned} \tag{41.50}$$

where we used $p(f^*|x^*, w) = N(0, \sigma_n^2)$. This can be rewritten as

$$\begin{aligned} &p(f^*|x^*, X, y) \\ &= \mathcal{N}(\phi(x^*)^T \Sigma_p \Phi (K + \sigma_n^2 I)^{-1} y, \\ &\quad \phi(x^*)^\intercal \Sigma_p \phi(x^*)) - \phi(x^*) \Sigma_p \Phi (K + \sigma_n^2 I)^{-1} \Phi^T \Sigma_p \phi(x^*)), \end{aligned} \tag{41.51}$$

where $K = \Phi^T \Sigma_p \Phi$. In general we call $k(x, x') = \phi^T(x) \Sigma_p \phi(x')$ a kernel or covariance function between x and x'. The final expression for the regression mean and covariance has a form

$$f^* = K(x^*, X)[K(X, X) + \sigma_n I]^{-1} y, \tag{41.52}$$

with covariance

$$\text{cov}(f^*) = K(x^*, x^*) - K(x^*, X)[K(X, X) + \sigma_n^2 I]^{-1} K(x^*, X). \tag{41.53}$$

One can see that the prediction takes the observed values y at the training data X, and predicts the value at x^* by incorporating the strength of their correlations via $K(x^*, X)$. In addition, the prediction also suppresses the training points with a small inverse covariance, a generalization of inverse noise weighting.

This expression simply rewrites the standard Bayesian regression, and the kernel is still defined as an inner product of the regression basis functions $\phi(x)$ with respect to Σ_p. However, the kernel can be replaced by any kernel form that describes the level of correlations between x and x', a process known as the *kernel trick*. A general condition for the kernel to be valid is that the covariance matrix is always invertible. In a Gaussian process the kernel is often stationary, defined as $k(x, x') = f(|x - x'|)$. This and many other kernels cannot be related to a finite set of basis functions $\phi(x)$, which is why it is often stated that Gaussian process corresponds to an infinite basis function expansion. Yet another form of the kernels are neural tangent kernels of neural networks in the infinitely wide network limit [23].

Another path to Gaussian processes is via kernel regression, where one makes kernel regression Bayesian [253]. Standard kernel regression, also called Nadaraya-Watson regression, is of the form $f^* = \sum_x k(x, x^*) y(x) / \sum_x k(x, x^*)$, which can be interpreted as a soft version of the k-nearest neighbors algorithm. Bayesian kernel regression in the form of a Gaussian process replaces kernel sums with matrix operations, and is closer to linear regression than to the nearest neighbor methods.

One advantage of Gaussian process is that one can work with a family of kernel functions parameterized by some hyperparameters η. One can then optimize the hyperparameters via gradient-ascent on the marginal likelihood function. In contrast, hyperparameter tuning in other models typically requires a grid search or some other black-box optimization procedure evaluated on held out data or some form of cross-validation.

While we only describe Gaussian process regression, there is a corresponding Gaussian process classification. Rasmussen and Williams provides an excellent review of Gaussian processes [254]. Numerically, Gaussian process libraries are confronted with computing the inverse of the covariance kernel, which scales like $\mathcal{O}(n^3)$ in computational complexity. Gaussian processes are often used as emulators or surrogate models, specially in the context of low dimensional input x and low number of training data n to avoid the steep $\mathcal{O}(n^3)$ scaling. They are used widely in cosmology, and there are a growing number of applications in (astro-)particle physics [255]. Recent works explore the design of physics-inspired kernels and use Gaussian processes to model the intensity for a Poisson point process like those found in experimental particle

physics and γ-ray and X-ray astronomy [256–258]. Gaussian processes are also extensively used in Bayesian optimization (Section 41.5), because the uncertainty quantification that is automatically provided by the Gaussian process enables exploration-exploitation strategies where to evaluate the function next.

41.8.3 *Decision trees*

Tree-based models Classification and regression trees (CART) typically partition the input space into J disjoint regions $\mathcal{X} = \mathcal{X}^1 \cup \cdots \cup \mathcal{X}^J$ through a sequence of $J-1$ binary splits based on an individual components of $x \in \mathcal{X}$ (*e.g.* $x_4 < 0.7$) [259]. The model is piecewise constant and assigns the value $b_j \in \mathcal{Y}$ to the jth terminal region $\mathcal{X}^j$. The model can be written

$$\hat{y}(x) = f_\phi(x) = \sum_j b_j \mathbf{1}(x \in \mathcal{X}^j) \; . \tag{41.54}$$

The parameters ϕ of the model comprise the components index and thresholds for the successive splittings and the coefficients b_j.

Tree learning refers to the algorithm used to choosing the tree structure and determining the predictions at leaf nodes. Optimization of the tree structure involves a difficult discrete optimization since the change in the loss with respect to the tree structure is non-differentiable and it is intractable to explore the combinatorially large space of possible trees with brute force. Therefore, the discrete optimization component of tree learning typically involves some approximate algorithm based on heuristics. In contrast, optimization of the b_j for a given tree structure can exploit gradient-based optimization algorithms.

Common approaches to building the decision tree start with a root node and grow with splits based on individual attributes (components of x). These are referred to as top-down induction strategies. There are various impurity heuristics used for choosing the best attribute to split on such as the Gini index, cross-entropy and mis-classification error. Generally they aim to find a split that will refine the the terminal nodes such that they have higher purity than the parent node.

Because most tree learning algorithms consider splits aligned with individual feature components, there are some failure modes for tree-based models. However, tree-based models work well with tabular data composed of a mix of continuous and discrete features. Tools such as `XGBoost` [260] and LightGBM [261] are competitive on tabular data benchmarks like TabArena [262] and are widely used in industry; the boosted decision trees (BDTs) implemented in
`StatPatternRecognition` [263] and `TMVA` [149] have been one of the most used techniques in particle physics [3].

Individual trees are often referred to as weak learners and they can be combined in various ways described below. Regularization is also an important consideration with tree-based models as one can always learn a tree that assigns exactly one training dataset point per terminal node and memorize the training dataset exactly. One approach to this is called *pre-pruning*, which simply terminates the growing of the trees if the number of training samples reaching the terminal node drops below some threshold, the purity of a terminal nodes is below some threshold, or if the improvement in purity due to a proposed split is not above a threshold. Another regularization approach is called *post-pruning*, which uses a validation data set that is disjoint from the training dataset to probe generalization performance. In this approach, after initially growing a tree with the training dataset, a sequence of pruned trees is considered where splits are removed based on some heuristic. The tree in this sequence of pruned trees that minimizes the generalization error on the validation set is chosen. Alternatively, in tools such as `XGBoost` there is an explicit regularization term included in the loss function (see Eq. 41.61).

Ensemble methods The idea of ensemble methods is to combine multiple models into a more performant one by exploiting the bias-variance tradeoff [264]. This is most commonly achieved through averaging (*e.g.* bagging and random forests), which primarily reduces variance, or boosting (*e.g.*, AdaBoost and gradient boosting), which primarily reduces bias. Here, bias refers to the difference between the Bayes optimal model and the average model produced by the learning procedure with different training sets and variance quantifies how much the learned model varies from one training set to another.

The motivation of boosting is to combine the outputs of many "weak" models to produce a more expressive model. Compared to averaging techniques like bagging and random forests, the model is built sequentially on modified versions of the data and the final predictions are combined through a weighted sum

$$\hat{y}(x) = \sum_{t=1}^{T} \beta_t \hat{y}_t(x) \; , \tag{41.55}$$

where β_t expand the parameters of the model ϕ.

Bagging The idea behind bagging (bootstrap aggregation) is to create T bootstrap training datasets $B_1, \ldots, B_T$ drawn from the training dataset $\{x_i, y_i\}_{i=1,\ldots,n}$, then learn a model $\hat{y}_t$ for each, and finally construct an average model $\hat{y}(x) = (1/T)\sum_t \hat{y}_t(x)$. If one had T independent training datasets each of size n, then the bias of the average model would be the same as the original model, but the variance would be reduced by a factor of T. By using bootstrap resampling, the bias may increase but the reduction in variance often dominates, which leads to improved performance.

Random forests Random forests refers to a type of "perturb and combine algorithm" that combines bagging and random attribute subset selection. Again one builds trees $\hat{y}_t(x)$ from bootstrap training datasets B_t, but instead of choosing the best split among all attributes, one select the best split among a random subset of k attributes. If k includes all attributes, then it is equivalent to bagging.

AdaBoost In AdaBoost (adaptive boost) the sequence of trees $\hat{y}_1, \ldots, \hat{y}_T$ are trained with reweighted versions of the original training dataset such that the weight of individual training sample is based on the prediction error in the previous iteration [265]. This requires working with a loss function that and learning procedure for the individual iterations that is amenable to weighted training dataset $\{x_i, y_i, w_i\}_{i=1,\ldots,n}$. Incorporating the weights w_i is straight forward when the risk is expressed as an expectation, since the emperical risk of Eq. 41.3 is just replaced with the weighted average. Similarly, the heuristic for many of the tree-based learning algorithms (*e.g.* the Gini index) also have natural generalizations with weighted events.

In the context of classification, the weighted error of the model $\hat{y}_t(x)$ is

$$\mathrm{err}_t = \frac{\sum_i w_i^{(t)} \mathbf{1}[y_i \neq \hat{y}_t(x_i)]}{\sum_i w_i^{(t)}} \; . \tag{41.56}$$

Based on this weighted error, the coefficient β_t of the component $\hat{y}_t(x)$ in Eq. 41.55 is given by

$$\beta_t = \log\left(\frac{1-\mathrm{err}_t}{\mathrm{err}_t}\right) \; . \tag{41.57}$$

Then for the next iteration the weights of the misclassified events are updated as $w^{(t+1)} = w^{(t)} \exp(\beta_t)$ and then renormalized so that the sum of all weights is 1. This reweighted dataset is then used to train the next model $\hat{y}_{t+1}(x)$ and the entire procedure is initialized with uniform weights $w_i^{t=0} = 1/n$.

There is an analogous procedure for regression with the squared loss function based on the residuals $r_i = y_i - \hat{y}_t(x_i)$ (see for example Ref. [149] for details).

Gradient boosting One of the most powerful forms of tree based models, which is implemented in the tool `XGBoost` is referred to as *gradient boosting* [266]. In this setup, the model is purely additive as in the case of random forests, so the model is Eq. 41.55 with all $\beta_t = 1$. Note this is without loss of generality since the β_t can be absorbed into the b_j of Eq. 41.54. As with AdaBoost, the model is built sequentially through the sequence $\hat{y}_1, \ldots, \hat{y}_T$.

by KARLSRUHE INSTI Phys. A 2026.41. Downloaded from www.worldscientific.com DGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

At each iteration, a new term f_t will be added to the sum in Eq. 41.55. For a given decision tree defined by splits on attributes, one can approximate the objective function (the loss function $\mathcal{L}$ plus a regularization term Ω) as a function of b_j in a second order Taylor series:

$$\text{obj}^{(t)} = \sum_{i=1}^{n} [\mathcal{L}(y_i, \hat{y}_i^{(t-1)}) + g_i f_t(x_i) + \frac{1}{2} h_i f_t^2(x_i)] + \Omega(f_t) + \text{constant} , \tag{41.58}$$

where

$$g_i = \partial_{\hat{y}_i^{(t-1)}} \mathcal{L}(y_i, \hat{y}_i^{(t-1)}) \tag{41.59}$$

and

$$h_i = \partial^2_{\hat{y}_i^{(t-1)}} \mathcal{L}(y_i, \hat{y}_i^{(t-1)}) \tag{41.60}$$

In `XGBoost`, the regularization term is taken to be

$$\Omega(f) = \gamma J + \frac{1}{2} \lambda \sum_{j=1}^{J} b_j^2 , \tag{41.61}$$

where J is the number of terminal nodes in the tree. With the second-order approximation of the objective, one can directly solve for the optimal b_j for the next tree and the corresponding value of the optimized objective function. The improvement in the objective function can then be used as a heuristic for choosing the best split. Specifically, define $G_j = \sum_{i \in I_j} g_i$ and $H_j = \sum_{i \in I_j} h_i$, where I_j is the set of indices of data points assigned to the jth leaf. The heuristic used in `XGBoost` for splitting a node is

$$\text{Gain} = \frac{1}{2} \left[\frac{G_L^2}{H_L + \lambda} + \frac{G_R^2}{H_R + \lambda} - \frac{(G_L + G_R)^2}{H_L + H_R + \lambda} \right] - \gamma . \tag{41.62}$$

This formula can be interpreted as the score on the new left leaf plus the score on the new right leaf minus the score on the original leaf minus a regularization penalty on the additional leaf. If the gain from splitting a leaf is smaller than γ, then the total Gain is negative and the split will not be added, which can be seen as implementing a form of pruning.

41.8.4 *Neural networks*

In this section we focus on the different types of components used in modern neural network architectures. Gradient-based optimization techniques are most commonly used for training neural networks, and they are described in Sec. 41.9.1. Similarly, other important aspects to effectively training neural network models such as parameter initialization and early stopping are discussed in Sec. 41.9.

The vanishing and exploding gradient problem is a common challenge for gradient-based optimization of neural networks and is described in Sec. 41.9.5. That problem is referred to repeatedly in this section because it has motivated the development of numerous architectural components described below.

41.8.4.1 *Feed-forward multilayer perceptron*

One of the core components in neural networks is the fully-connected, feedforward network or *multilayer perceptron* (MLP), which is composed of L *layers*: $f = f^{(L)} \circ \cdots \circ f^{(1)}$. The lth layer defines a function that maps a d_{l-1}-dimensional input vector, called *features*, to an d_l-dimensional output $f^{(l)} : \mathbb{R}^{d_{l-1}} \to \mathbb{R}^{d_l}$. A unit producing an individual component of the d_l-dimensional output is called a *neuron* or a *filter* interchangeably. For $l < L$, the functions f_l are called hidden layers, and the number of neurons (d_l) is referred to as the width of the hidden layers. The layers in an MLP take on the form:

$$f^{(l)}(u) = \sigma^{(l)}(W^{(l)} u + b^{(l)}) , \tag{41.63}$$

where $W^{(l)} \in \mathbb{R}^{d_l \times d_{l-1}}$ is called the *weight matrix*, the components of the vector $b^{(l)} \in \mathbb{R}^{d_l}$ are referred to as the *biases*, $u \in \mathbb{R}^{d_{l-1}}$ is the input from the previous layer, $W^{(l)}u$ denotes a matrix-vector product, and $\sigma^{(l)}$ is a non-linear *activation function* that is usually applied element-wise. The parameters of the network comprise the full collection of weights and biases, $\phi = (W^{(1)}, \ldots, W^{(L)}, b^{(1)}, \ldots, b^{(L)})$.

41.8.4.2 *Activation functions*

The activation functions σ in neural networks are nonlinear functions and key to the expressiveness of the resulting family of functions. Two traditionally used functions are the *logistic or sigmoid* function $\sigma(x) = 1/(1 + e^{-x})$ and *hyperbolic tangent* function $\tanh(x) = (e^x - e^{-x})/(e^x + e^{-x})$. These functions are bounded to be $(0, 1)$ and $(-1, 1)$ respectively, and are symmetric about the input value of zero. On the other hand, away from the zero input value, a gradient of both functions quickly vanishes and this poses a challenge in using gradient-based optimization method (see Sec. 41.9.1). This can be avoided, to some extent, by normalizing the input values and carefully initializing the values of $W^{(l)}$ and $b^{(l)}$. These are discussed in Sec. 41.9.7, 41.9.8 and 41.9.9. Yet, it becomes difficult to maintain a null input value for a *deep* neural network, a model with many layers. Instead, a popular choice for a deep neural network is the *rectified linear unit* (ReLU):

$$\text{ReLU}(x) = \begin{cases} x & \text{if } x > 0 \\ 0 & \text{otherwise} \end{cases} \tag{41.64}$$

whose computational cost is small and ensures that the gradient does not vanish for $x \in (0, +\infty)$ [267,268]. An alternative to preserve a non-zero gradient in negative input values are called *leaky ReLU* and modifies the output to $0.01x$ for $x \in (-\infty, 0)$ [269]. Another variant, called *parametric ReLU* (PReLU), turns the coefficient 0.01 into a variable that is optimized as a part of the model during optimization [270].

The choice of activation functions depends on the model architecture and applications. As described, while the use of ReLU types are a typical choice for a deep neural network, a logistic function is a popular choice at the final layer for classification tasks. In the area of neural scene representation, sinusoidal activation functions have been found to be surprisingly effective [271].

Recently, additional smooth loss functions have been found to work well with larger models, such as the Gaussian-error linear unit (GELU) [272],

$$\text{GELU}(x) = \frac{1}{2} \left(1 + \text{erf} \left(\frac{x}{\sqrt{2}} \right) \right) \tag{41.65}$$

and swish function [273]

$$\text{swish}_\beta(x) = \frac{x}{1 + e^{-\beta x}}, \tag{41.66}$$

which smoothly interpolates between a linear function ($\beta = 0$) and ReLU ($\beta = \infty$). In addition, the value of $\beta = 1$ corresponds to the sigmoid-weighted linear unit (SiLU) [274].

Softmax A softmax function is often used to normalize elements of a discrete vector u, or to interpret the output as a probability over a set of n discrete categories. Given a real-valued input vector $u \in \mathbb{R}^n$, the softmax function computes the output vector $v \in \mathbb{R}^n$ the ith component is given by:

$$v_i = \frac{\exp(u_i)}{\sum_{j=1}^{n} \exp(u_j)} . \tag{41.67}$$

The result has the property that $v_i \in (0, 1)$ and $\sum v_i = 1$. The components of the input vector u are often referred to as *logits* in reference to their connection to the logistic function used in logistic regression. The softmax function is commonly used as the last layer in multi-class classifier. The softmax is also used in the context of attention (see Sec. 41.8.4.6).

41.8.4.3 *Universal approximation and deep learning*

There are a number of universal approximation theorems in the theory of neural networks. One of the first was that even with one hidden layer ($L = 2$), an MLP can approximate any continuous function if the nonlinear activation function σ is not a polynomial and the width d_1 is large enough [275]. However, it is often more efficient (in terms of the number of parameters) to increase the *depth* of the network L [276].

Training a deep network (*i.e.* $L > 2$) that generalizes well can be difficult, requiring large training datasets, many gradient updates, and suitable regularization. The introduction of large labeled training sets, advances in computing (*e.g.* graphic processing units or GPUs which enabled orders of magnitude acceleration in parallel computation including matrix multiplies [277]), development of ReLU, research progress in initialization and optimization algorithms for model parameters, and regularization techniques like *dropout* [17] all played an important role in the rise of *deep learning* [2,278]. Though the name deep learning was originally a reference to the depth L of such networks, modern deep learning is characterized more by the composition of various types of modules that are trained through gradient-based optimization. Below we introduce some other common network architectures.

41.8.4.4 *Convolutional neural networks*

Convolutional neural networks (CNNs) are widely used for image-like data. They implement the convolution of the input image u and a *filter* W (also referred to as a kernel). The parameters of the filter are learnable and the convolution involves traversing over input and calculating the inner product of the filter W with the part of the input in the *receptive field*, which has the same spatial shape as the filter and is centered at the target pixel. At each location—indexed by i and j below—there is a pixel that may have a vector of features associated with it. In the context of CNNs, these components of these features—indexed by c and c' below—are often referred to as *channels* in reference to the red, green, and blue color channels in a traditional image. The convolution operation is often denoted with a $*$, and the result can be expressed as

$$v_c(j) = (W * u_c)(j) = \sum_{c'} \sum_{i} W_{c,c'}(i) u_{c'}(\text{“}j - i\text{”}) \,, \quad (41.68)$$

where “$j - i$” is shorthand for the pixel index corresponding to the translation from pixel j to i. By repeating the operation over all pixels, the result of a kernel convolution is also an image as illustrated in Fig. 41.6. Note that the the number of channels in the output v does not need to be the same as in the input, and the collection of filters $W_{c,c'}$ is often referred to as a filter bank. The entire image for a fixed channel index is often referred to as a *feature map*.

A key feature of the CNN architecture is that it is *equivariant* to translations, meaning that if the input image is shifted (*e.g.*, $u(i) \to u'(i) = u(i - k)$), then the output is also shifted by the same amount (*e.g.*, $v(j) \to v'(j) = v(j - k)$). This equivariance property is a natural consequence of using convolutions. A fully connected MLP would not generally have this symmetry; however, it is enlightening to imagine transferring the computation performed by a CNN to the weights and biases of a fully connected MLP, which would result in duplicating the weights of the filters multiple times. In this view, the CNN can be interpreted as a fully connected MLP with *shared weights*, which would maintain the equivariance property. This view is helpful for gaining intuition about the inductive bias of models and makes clear that a CNN is a subset of the fully connected MLPs that satisfy the translation equivariance property.

One may wonder how CNNs identify features with a spatial size larger than a typical kernel size. One mechanism for this is by stacking multiple convolutional layers, *e.g.*, the composition of two 3×3 kernels will lead to an effective 5×5 kernel in terms of the receptive field. In addition, a typical CNN architecture uses pooling (described below), which effectively downsamples the image so that it can be processed at different resolutions. The effective receptive field in the input image may be much larger than the kernel size in this case. An alternative approach is to use an *inception module*, which is designed to extract features simultaneously using kernels of different size [279].

Pooling *Pooling* plays an important role in convolutional neural networks both practically and in terms of their mathematical properties. A pooling operation is a type of aggregation or downsampling that takes many pixels as input and produce one pixel for output. Typically, the pooling operation is applied independently for each channel or feature component. The most popular pooling operations are *max* and *average* pooling. Max pooling picks the highest activation pixel value within the specified receptive field, while the average pooling computes the average pixel value in the receptive field. The idea of pooling generalizes to other architectures, including graph neural networks where the receptive field includes the neighbors of a particular node in the graph (see Sec. 41.8.4.7). Pooling can make the model robust to small, local deformations in the input, a property called *geometric stability* [280–282]. This type of local deformation is important and distinct from the equivariance to rigid translations provided by the convolutional structure. Repeated pooling operations that eventually lead to a single feature vector with no spatial index is what gives rise to the invariance of common CNN architectures to translations (*i.e.*, an image with a dog will be labeled ‘dog’ regardless of where the dog is in the image).

CNN architectures for image analysis A typical CNN for extracting a 1-dimensional array of features is designed with repeating blocks of convolution layers and pooling operations [283]. Figure 41.7 shows an example evolution of a data tensor through the succession of convolution and pooling operations to extract a 1-dimensional array of features, which then can be fed into a block of MLP for an image classification (or a regression) task. This type of architecture is referred to as an *encoder* or *feature extractor*.

The reduction in the spatial size of an image is performed slowly, typically by a factor of 2, which is the minimum possible reduction factor. After the reduction of the spatial extent, the number of channels is typically increased (also by a factor of 2 in most cases), converging one set of feature maps into a larger number of downsampled feature maps. There may be more than one convolution layer within each spatial resolution (*i.e.*, between the grouping operations). Following these design principles, CNN encoders typically become *deep*, consisting of dozens or sometimes hundreds of convolution layers, and face challenges of vanishing gradient problem (see Sec. 41.9.5). A standard practice to mitigate this issue is to explicitly *normalize* the input tensor input in each convolution layer using algorithms such as *batch normalization*. This will be discussed in Sec. 41.9.9.

There are three main categories of computer vision tasks where CNNs are often used:

- *image classification or regression* requires a prediction of single value for the whole image (*i.e.*, a category or target value),
- *object detection* produces a list location information, typically as a rectangular shaped bounding box, for detecting arbitrary number of objects in the input image, and
- *semantic segmentation* brings a classification task down at the pixel-level (or regression although less common) to identify the class or a feature of every pixel in an image.

As discussed previously, a CNN feature extractor followed by MLP is often used for image classification and regression tasks in wide range of applications including particle physics. Many successful CNN architectures for object detection and semantic segmentation applications share key designs which we briefly discuss below.

Region convolutional neural network (R-CNN) is one of the most successful design for object detection [284]. R-CNN has been explored in HEP experiments where the number and location of signal (*e.g.*, neutrino interactions) are not known apriori in large image data such as neutrino detectors [3,25,187]. R-CNN consists of multiple CNNs. The first is a feature extractor which

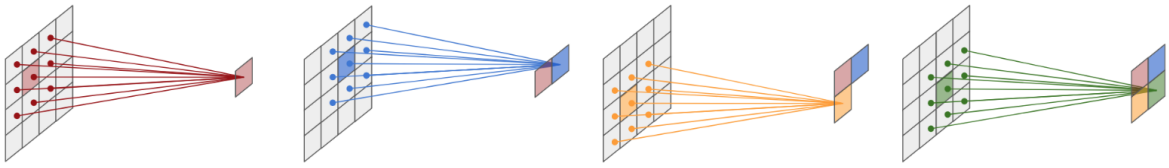

Figure 41.6: A pictorial description of a kernel convolution over four input pixels. It takes a product of the weight matrix (kernel) and the local input matrix centered at a target pixel. The operation is repeated over the input image using the same kernel. The size of the output image depends on the size of the kernel, stride, and padding. In this figure, the kernel size of 3, stride of 1, and padding of 0 is used.

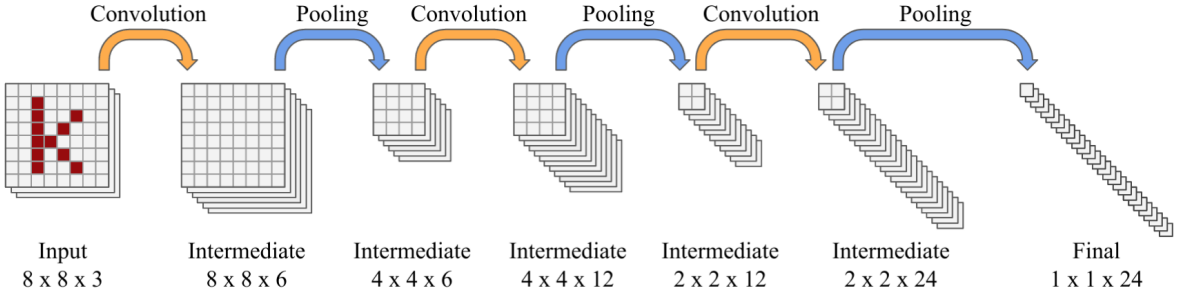

Figure 41.7: An example CNN architecture to extract a 1-dimensional array of features from an image via succession of convolution layers and pooling operations. The (square) kernel, stride, and padding size of a convolution operation are 3, 1, and 1 in respective order. The pooling operation uses a square kernel size of 2. The number of filters at the first convolution layer is 6, and is increased by a factor of 2 at subsequent convolution layers.

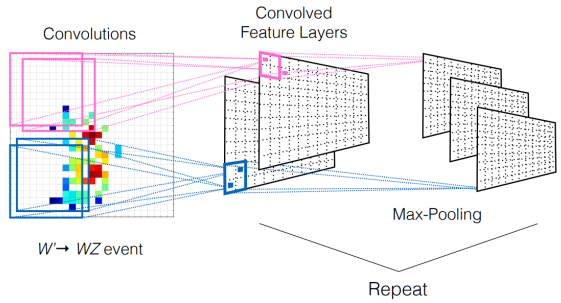

Figure 41.8: CNN classifier for identifying highly boosted W bosons at ATLAS.

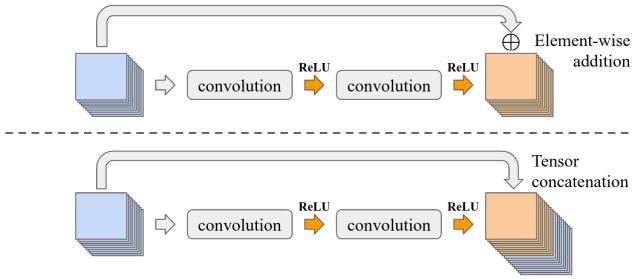

Figure 41.9: Two types of skip connections: the top is from ResNet where the input is element-wise added to the output tensor of a block of convolution layers while the bottom shows a concatenation of the input to the output tensor as employed in other models including U-Net and DenseNet.

produces a spatially compressed feature tensor. For every pixel in the compressed tensor, the second CNN applies 1×1 convolution to predict two information: an *object score* to inspect whether or not there is a target object in the (spatially compressed) pixel, and prediction of the location and size of a rectangular, axis-aligned bounding box that contains the object (if exists). This second CNN is called the *region proposal network* (RPN), and the bounding box is called the *region of interest* (ROI). For each ROI with an object score above threshold (hyperparameter), the third CNN operates in the corresponding sub-field of an already-compressed tensor (*i.e.* by the first CNN) to perform a classification for an object inside the ROI. This approach can produce multiple ROIs for the same object with a high overlap. Those predictions are reduced using non-maximum suppression (NMS) algorithm which computes the intersection-over-union (IoU) to combine overlapping ROIs that are likely detecting the same object.

Residual networks and skip connections

The expressivity of a neural network increases as more hidden layers are added, but gradient-based optimization of deep models can be notoriously difficult due to vanishing gradients (see Sec. 41.9.5). One powerful technique to address this challenge is a *residual network* (ResNet), which is a modular architecture design that can be applied to neural network models [285]. Suppose a $f(x)$ as the target transformation to be learned by a few stacked layers where x is the input to the first layer. The authors of ResNet hypothesized that it may be easier for a model to learn a residual transformation $\tilde{f}(x) \coloneqq f(x) - x$, thus the objective to learn is $\tilde{f}(x) + x$ where $\tilde{f}(x)$ denotes the output of stacked layers. This form assumes $\tilde{f}(x)$ and x share the same tensor dimension and size. If they differ in the feature dimension, equivalently the count of channels in an image tensor, one could use 1×1 convolutions to transform and match the dimension. Adding the input tensor x to the output of a convolution operation $\tilde{f}(x)$ in ResNet is a form of *skip connection*. For a residual block that outputs $y = \tilde{f}(x) + x$, the backpropagated gradient to the input x becomes

$$\frac{\partial \mathcal{L}}{\partial x} = \frac{\partial \mathcal{L}}{\partial y} \cdot \left(I + \frac{\partial \tilde{f}}{\partial x} \right), \tag{41.69}$$

meaning it sums an identity path with the gradient through the residual branch, helping prevent vanishing gradients. ResNet authors demonstrated performance improvement at depths exceeding 1000 layers where the non-residual counterpart could not improve beyond a few dozen layers. The ResNet design is widely used in many CNN architectures as it is modular, *i.e.*, a *residual block*, and can be applied per a stack of convolution layers (*e.g.*, U-ResNet introduced for LArTPC detectors uses ResNet modules within a U-Net architecture [26, 184]).

U-Net is one of the of most successful models used for semantic segmentation [286]. Since the output of U-Net is also an image, it is more interpretable compared to models for image-level classification or regression. The model is used widely in HEP experiments in both 2D and 3D image data [26, 27, 184, 194, 196]. The architecture of U-Net consists of a CNN encoder and *decoder*. A decoder consists of convolution and *transposed convolution* layers (also called deconvolution). The operation of a transposed convolution can be seen as the opposite of a convolution: for every input pixel, its value is multiplied by the kernel and copied to the output. In contrast to a regular convolution layer that reduces input pixels via the kernel, a transposed convolution layer broadcasts input pixels via the kernel, producing an output that is larger than the input. In the decoder of U-Net, transposed convolution layers are used to upsample spatially compressed feature tensors back to the original image resolution. Standard convolution layers are placed between upsampling operations. Features for every output pixel can be used for either a classification or a regression task. The idea behind encoder-decoder architecture is to extract features in the encoder, and the decoder interpolates those features back to the original spatial resolution. The downsampling operation (*e.g.*, max pooling) in the encoder is, however, a lossy process where spatial information is permanently lost. This is a major obstacle to achieve a high precision semantic segmentation task. The U-Net architecture overcomes this challenge by concatenating intermediate tensors in the encoder block with the tensors of the corresponding spatial size in the decoder block. This is a type of a *skip connection* discussed previously, which dramatically improves the performance of semantic segmentation.

41.8.4.5 *Recurrent neural networks*

Recurrent neural networks (RNNs) [287] are a family of neural networks designed for sequential data (*e.g.*, time series). Consider sequential data where x_t represents each step in a sequence with $t \in [1, n]$. A typical RNN takes the following form:

$$h_t = g_h(h_{t-1}, x_t, \theta) \tag{41.70}$$

where h_t and θ denote the *hidden state* of the system and parameters of g_h, the RNN model. The term *recurrent* refers the nature of the model operating on the previous state of the system (and hence the whole history). RNNs operate on three types of tasks:

- *One-to-many* takes a single input and generates a sequence (e.g. generates a sequence data, such as a sentence or waveform, given a category).
- *Many-to-one* takes a sequence and generates an output (e.g. sequence-labeling).
- *Many-to-many* takes a sequence and generates a sequence where the length of input and output sequence may be same (e.g. classification of individual element in a sequence) or different (e.g. sequence to sequence mapping).

Figure 41.10 shows an example for a many-to-many task, where $\{x_t\}_{t=1:n}$, $\{y_t\}_{t=1:n}$, and $\{h_t\}_{t=0:n}$ denote the inputs, outputs, and hidden states respectively. A set of operations at each time step is called a *cell*. A simple RNN cell may look like:

$$\begin{aligned} h_t &= g_h(Wx_t + Vh_{t-1} + b) \\ y_t &= g_o(Uh_t) \end{aligned} \tag{41.71}$$

where $W \in \mathbb{R}^{d_h \times d_i}$, $V \in \mathbb{R}^{d_h \times d_h}$, $U \in \mathbb{R}^{d_o \times d_h}$ are matrices g_h and g_o represent functions. d_i, d_h, and d_o are the dimension of input, hidden state, and output. $b \in \mathbb{R}^{d_h}$ is a bias term. An example application is sequence-labeling where the goal is for y_t to classify each input x_t in the sequence. In that case, one might use $g_h = \tanh$ and $g_o = \text{softmax}$ and use a loss function that averages classification accuracy over the sequence.

Variations in RNN architectures result from the design of cells (described below) and flow of information across the cells. For instance, a bidirectional RNN (Figure 41.11 left) employs two set of RNNs, one processing the sequence in the forward direction and the other in the backward direction, and the hidden states from both directions are then combined to capture the context from both parts of the sequence. An RNN encoder-decoder (Figure 41.11 right) use one RNN to generate a context vector that encodes the whole input sequence, and use a separate RNN to generate another sequence from the encoded context. This can be used for machine translation.

LSTM and GRU An RNN applies the same functions g_h and g_o in Eq. 41.71 repeatedly for each element of the sequence. This repeated component is similar to the shared weights for a convolutional filter in a CNN.

A hyperbolic tangent (tanh) is traditionally a popular choice for g_h as it regulates the magnitude of the hidden states and prevents it from diverging. Yet, this simple model is challenging to train for a long sequence of data [288, 289]. This is partially due to the fact that tanh contributes to the vanishing gradient problem and because repeated multiplication of the same weight matrices (i.e. V and W in Eq. 41.71) can lead to gradients that can either explode or vanish (see Sec. 41.9.5). Additionally, the way the signal accumulates means that changes early in the sequence have different impact from changes late in the sequence.

Long short-term memory (LSTM) [290] is a model designed to address the issue of vanishing gradient for RNNs. In this model, a *context* is introduced as a way to enable the model to hold long-term memory while the hidden states remain to hold short-term memory. The context c_t and hidden state h_t at step t are computed as follows:

$$\begin{aligned} c_t &= f_t \bigodot c_{t-1} + i_t \bigodot \tilde{c}_t \\ h_t &= o_t \bigodot c_t \\ &\text{where} \\ f_t &= \sigma\left(W^f x_t + V^f h_{t-1} + b^f\right) \\ i_t &= \sigma\left(W^i x_t + V^i h_{t-1} + b^i\right) \\ o_t &= \sigma\left(W^o x_t + V^o h_{t-1} + b^o\right) \\ \tilde{c}_t &= \tanh\left(W^c x_t + V^c h_{t-1} + b^c\right) \end{aligned} \tag{41.72}$$

where σ and $\bigodot$ denote logistic function and an element-wise (*i.e.*, Hadamard) product and f_t, i_t, and o_t are referred to as *gates*. Each gate outputs a value between 0 and 1, and is associated with unique weights, W and V, and a bias b. One can see c_t is a combination of the previous context vector c_{t-1} and a new context vector $\tilde{c}_t$. The *forget* gate f_t controls which and how much of the past context should be kept or forgotten. The *input* gate i_t controls how much of the present context $\tilde{c}_t$ should propagate to the current state c_t. The output gate o_t controls which and how much of the context vector should represent the present hidden state h_t. From Figure 41.12, one can see that the context vector c_t evolves with a gated addition operation. As such, it can be seen as an uninterrupted path for gradients to flow. This is similar to a residual connection (see ResNet in Sec. 41.8.4.4), which enabled training of CNNs with thousands of layers.

Another gated model to solve a vanishing gradient problem is the *gated recurrent unit* (GRU) [251]. The GRU is similar to the LSTM with a few simplifications: the GRU merges the context vector and the hidden states and combines three gates into two. As a result, it requires less computational resources while retaining a similar level of performance for long sequences. The GRU

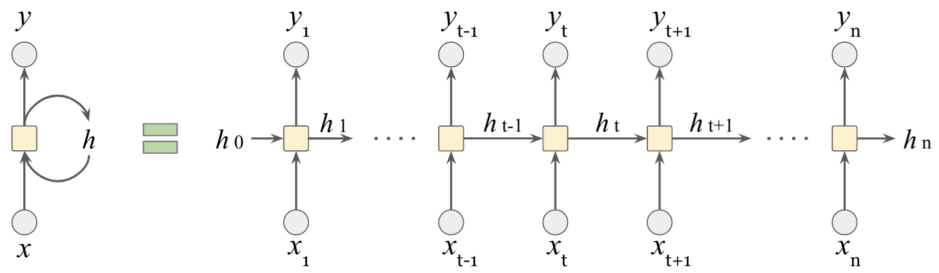

Figure 41.10: Pictorial description of a RNN (on the left) which takes an input and produces an output at every step with a hidden-to-hidden connection. The right diagram is unrolled over discrete steps. The yellow box represents a cell: a set of operations unique to each architecture.

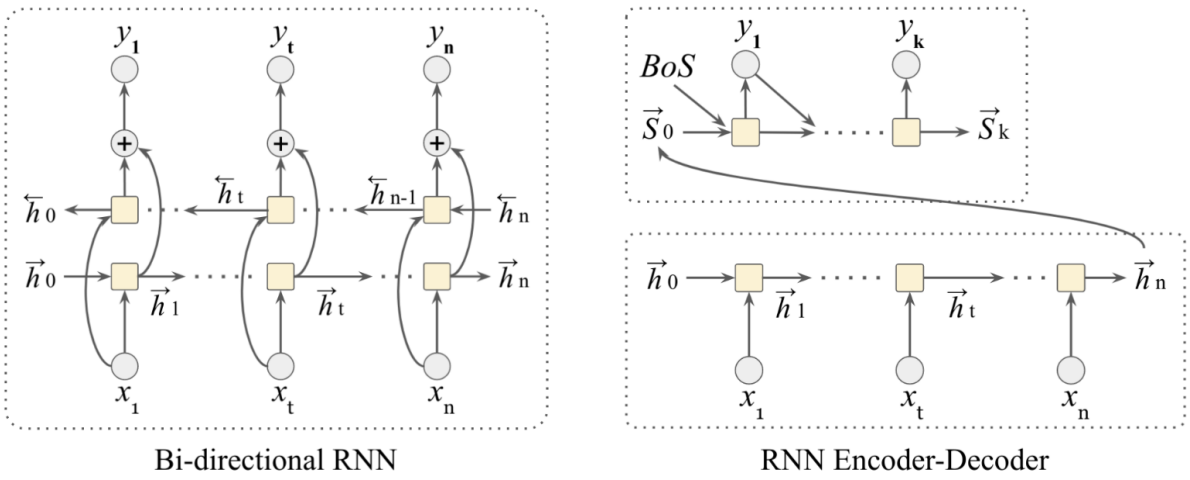

Figure 41.11: Bidirectional RNN (left) provides contexts in the preceding and subsequent parts of the input sequence. RNN encoder-decoder (right) can generate an output with a different sequence length from an input. Each cell in the decoder may take a previously generated element, starting from a special marker that signals the beginning of the sequence (BoS) and ending when the end of sequence is generated.

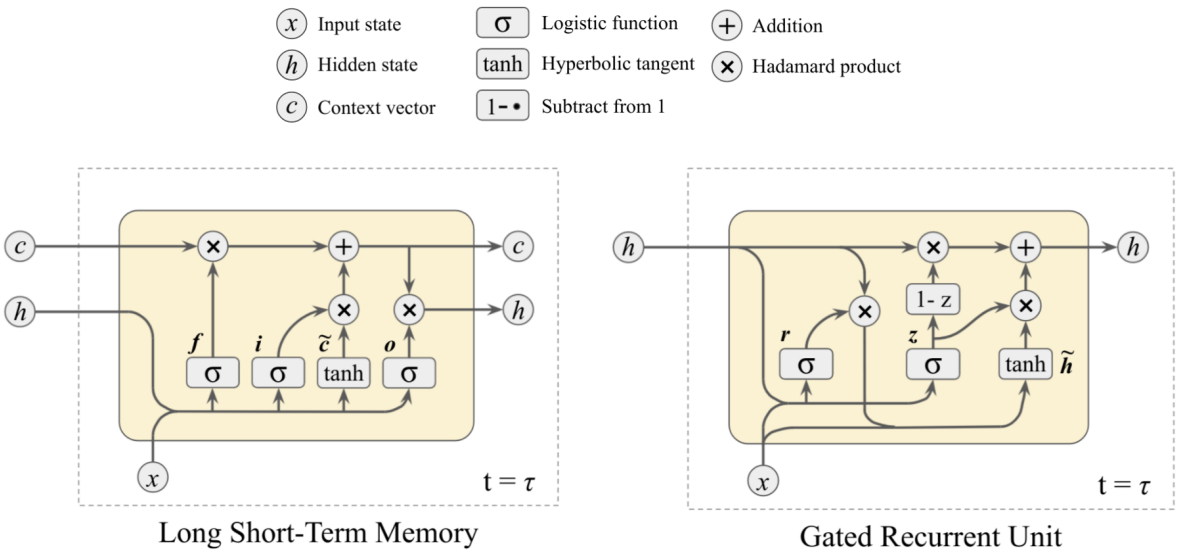

Figure 41.12: LSTM (left) and GRU (right) are both gated neural network designed to address a vanishing gradient problem for RNNs.

operations are defined as follows:

$$
\begin{aligned}
h_t &= z_t \bigodot h_{t-1} + (1 - z_t)\tilde{h}_t \\
&\text{where} \\
r_t &= \sigma\left(W^r x_t + V^r h_{t-1} + b^r\right) \\
z_t &= \sigma\left(W^z x_t + V^z h_{t-1} + b^z\right) \\
\tilde{h}_t &= \tanh\left(W^h x_t + V^h \left(r_t \bigodot h_{t-1}\right) + b^h\right)
\end{aligned}
\tag{41.73}
$$

where r_t and z_t are referred to as *reset* and *update* gate. As one can see in Figure 41.10, the reset gate in GRU performs the same task as the forget gate in LSTM by removing or reducing the elements of its memory (*i.e.* the hidden state). The update gate z_t determines the relative proportion of the previous hidden state h_{t-1} and the new context $\tilde{h}_t$ to be mixed in producing the new hidden state.

In addition to sequential data, the LSTM and GRU units can be used for data that has a tree-like structure. In this setting, the networks are often referred to as recursive neural networks or TreeRNN and they have found applications in natural language processing and jet physics [223, 224, 291–293].

41.8.4.6 *Attention and transformers*

The idea behind *attention* is to form a representation for the input, but different parts of the input are weighted differently according to the task at hand. By making the weights learnable, the network can learn to attend to the relevant parts of the input. For the ith task, one can form a task-specific context c_i by computing the weighted average of the hidden state representations h_j for each component of the input. A softmax function is used to produce attention scores α_{ij} for the jth input and ith task because it assigns a positive value to each component of the input and sums to one, $\sum_j \alpha_{ij} = 1$. Putting these ingredients together, we have the *additive attention mechanism*

$$
c_i = \sum_{j=1}^{n} \alpha_{ij} h_j \qquad \text{where} \qquad \alpha_{ij} = \underset{j}{\text{softmax}}(\beta_{ij}) \ , \tag{41.74}
$$

where softmax_j indicates that normalizing sum runs over the index j and the logits β_{ij} can be computed from a neural network. In the case of a cell of an RNN encoder-decoder network (see Fig. 41.11) that is decoding element i with an incoming input state s_{i-1}, the logits for the attention mechanism can be computed as

$$
\beta_{ij} = U \tanh\left(W s_{i-1} + \widetilde{W} h_j + b_i\right) \ , \tag{41.75}
$$

where U, W, and $\widetilde{W}$ are the weights and b is the bias term of the model. Figure 41.13 from Ref. [294] illustrates the full attention mechanism. This idea was first implemented by a model called *RNNSearch* that made a breakthrough in machine translation by combining a bidirectional RNN with an additive attention mechanism [295].

The values α_{ij} can be used to visualize the influence of the jth input element on the ith output element, which improves interpretability of the model [294] as shown in Fig. 41.14.

In additive attention (Eq. 41.74), the hidden representations h_j, also called *values*, are combined through a weighted average based on the coefficients α_{ij}, resulting in a task-specific context vector c_i. These values are often arranged in a matrix labeled $V \in \mathbb{R}^{m \times d_v}$, where the m rows of the matrix correspond to individual hidden state vectors of length d_v. The α_{ij} can also be represented as a $n \times m$ matrix α resulting from applying the softmax function to the $n \times m$ matrix β, normalized independently for each row. With this notation, Eq. 41.74 could be rewritten as $c = \text{softmax}(\beta)V$, where the softmax is normalized per row.

One powerful and widely used variant of the attention mechanism is *scaled dot-product attention*. In scaled dot-product attention, instead of using an neural network to compute the logits β as in Eq. 41.75, the logits are computed by forming a dot product between an incoming *query* and *key*. The set of n query vectors can be arranged into the matrix $Q \in \mathbb{R}^{n \times d}$ and the set of d key

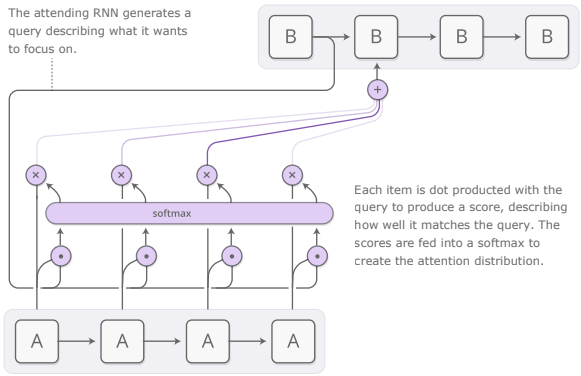

Figure 41.13: An illustration of the attention mechanism from Olah and Carter, "Attention and Augmented Recurrent Neural Networks." Lower boxes labeled `A` represent input elements in the sequence and upper boxes labeled `B` indicate output elements. The left-most line originating from the first `B` corresponds to the state s_{i-1} in the text.

vectors can be arranged into the matrix (transpose) $K^\intercal \in \mathbb{R}^{d \times m}$. One can interpret the keys as trying to detect certain types of queries and routing the attention to the relevant value. Typically, the dot-product is scaled by a factor of $1/\sqrt{d}$. The resulting task-dependent context is $c_i = \text{softmax}_j(q_i \cdot k_j/\sqrt{d})v_j$. A common, though confusing, notation is simply

$$
c = \text{Attention}\left(Q, K, V\right) = \text{softmax}\left(\frac{QK^\intercal}{\sqrt{d}}\right) V \ , \tag{41.76}
$$

where c is a $n \times d_v$ matrix organizing the n context vectors of length d_v that are tailored summaries of the input vector for each of the n tasks.

The *transformer* architecture is a powerful encoder-decoder model based on the scaled-dot product attention mechanism. It was originally designed for sequential data and subsequently used in other areas of research including computer vision. One advantage of scaled-dot product attention is that computing the attention weights does not involve any sequential processing. This allows the models to better leverage the parallelism of the hardware to train more expressive models faster than before. In place of the gated units of an RNN that are key to avoiding the vanishing gradient problem, the transformer architecture employs a residual connections at every attention module (*i.e.*, the input tensor is added to the output as in Fig. 41.9).

The second major ingredient in the transformer architecture is *multi-head attention*. A multi-head attention module executes multiple scaled dot-product attention modules in parallel. The query Q, key K, and value V matrices in each scaled dot-product attention module are obtained by applying linear transformations (with learnable weights) to the common Q, K, and V input matrices. Each of them can be considered a different (albeit related) *perspective* from which to derive attention.

For a sequence-to-sequence mapping task, the output of encoder is used to derive key K and value V matrices for the multi-head attention module in the decoder. The decoder is then responsible for mapping between the key-value features derived from the input (the encoder) and the queries from the decoder (which is still executed sequentially) in order to produce the final decoded output.

Finally, we note that the transformer architecture does not just employ an attention mechanism in the decoder. By employing attention in the encoder as well the model has more capacity to "interpret" the input—a concept referred to as *self-attention*. Transformer models have contributed to breakthroughs in many areas of scientific and industrial research [296]. While transformers are very powerful, they also require a larger number of training samples due to the weaker inductive bias than other models.

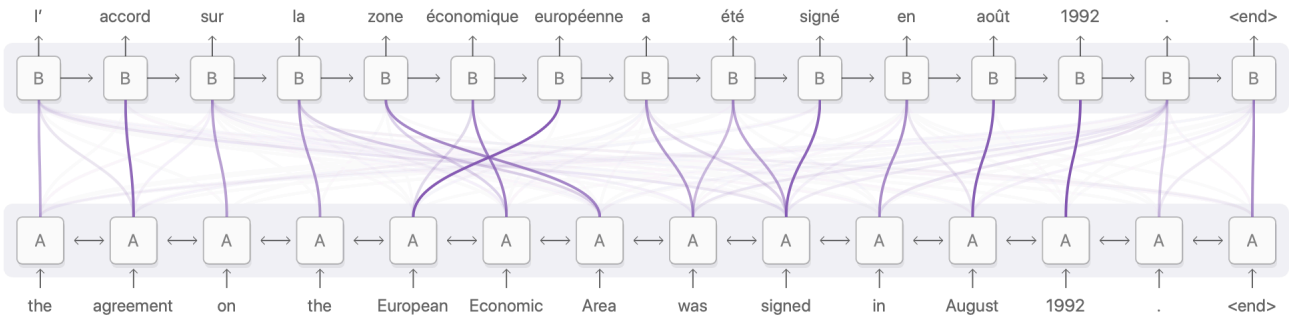

Figure 41.14: Visualization of the attention weights in a sequence-to-sequence problem from Olah and Carter, "Attention and Augmented Recurrent Neural Networks." The thickness of the lines is proportional to the attention weights α_{ij}.

41.8.4.7 *Graph networks and geometric deep learning*

Graphs are a powerful archetype for representing structure data. A graph consists of *nodes* as elements and *edges* between between them. Graphs are sufficiently flexible to describe many types of structured data including images and sequences. Graph-based neural networks can also be seen as a generalization of many common types of machine learning models such as recurrent and convolutional neural networks [282]. The term *geometric deep learning* refers to this recent formulation that focuses largely on the symmetries of the data.

An earlier attempt to organize the variations on different flavors of graph-based neural networks can be found in Ref. [297]. In their formalism, a graph network may be represented as $G(\mathbf{u}, V, E)$ where $\mathbf{u}$ represents an array of global features, $V = \{\mathbf{v}_i\}_{i=1:N^v}$ represents a set of N^v nodes with $\mathbf{v}_i$ as features for the ith node (e.g. such as RGB channels if a node represents a pixel in image data), and $E = \{(\mathbf{e}_k, r_k, s_k)\}_{k=1:N^e}$ represents a set of N^e edges with $\mathbf{e}_k$ as features for the kth edge. An edge may be (bi)directional where r_k and s_k denotes the destination and origin nodes respectively. The features of a graph may evolve with three *update* functions ϕ and three *aggregate* functions ρ:

$$\begin{aligned}
&\mathbf{e}'_k = \phi^e(\mathbf{e}_k, \mathbf{v}_{r_k}, \mathbf{v}_{s_k}, \mathbf{u}) \quad \mathbf{e}'_i = \rho^{e\to v}(E'_i) \\
&\quad \text{where} \quad E'_i = \{(\mathbf{e}'_k, r_k, s_k)\}_{r_k=i, k=1:N^e} \\
&\mathbf{v}'_i = \phi^v(\bar{\mathbf{e}}_i, \mathbf{v}_i, \mathbf{u}) \qquad \bar{\mathbf{e}}' = \rho^{e\to u}(E') \\
&\quad \text{where} \quad E' = \cup_i E'_i = \{(\mathbf{e}'_k, r_k, s_k)\}_{k=1:N^e} \\
&\mathbf{u}' = \phi^u(\bar{\mathbf{e}}', \bar{\mathbf{v}}', \mathbf{u}) \qquad \bar{\mathbf{v}}' = \rho^{v\to u}(V') \\
&\quad \text{where} \quad V' = \{\mathbf{v}'_i\}_{i=1:N^v}
\end{aligned} \tag{41.77}$$

where $\mathbf{e}'$, $\mathbf{v}'$, and $\mathbf{u}'$ denote the updated node, edge, and graph features. In Graph Networks, three types of information are updated in the following order. The first step is ϕ^e to update every edge. The second step updates every node: for ith node, compute $\rho^{e\to v}$ to aggregate updated attributes from the edges with $r_k = i$ then compute ϕ^v to update the node attributes. The third step updates the graph attributes through ϕ^u which takes the original state $\mathbf{u}$, aggregated node and edge attributes by $\rho^{v\to u}$ and $\rho^{e\to u}$ respectively.

Graph neural networks [298] (GNNs) are the class of neural networks that work on graph-structured data. A related data format in computer vision and physics is the *point cloud*, which is an unordered set of points (*i.e.*, a graph with no edges). Operations on point cloud need to be permutation invariant (*e.g.* min, max, $+$, $\cdot$), and analysis of 3-dimensional physical object represented by point cloud need to be rotation and translation invariant as in the case for an image. PointNet [299,300], a GNN that performs an object classification on point cloud of 3-dimensional positions, treats each point as a node, applies MLPs as ϕ^v to update node features, and global max-pooling operation as $\rho^{v\to u}$. There is no explicit edge definition in PointNet (though the model applies affine transformation to all points using spatial transformer network [301], which could be considered as a separate graph operation, to introduce rotation and translation invariance and to capture topological features). Deep sets [302] follow the same manner except ϕ^v takes the global entities $\mathbf{u}$. This is same for PointNet when performing point cloud segmentation: ϕ^v takes a step of simply concatenating $\mathbf{u}$ to node entities to combine a local and global features. Dynamic graph CNN [303] is a variant that (re)define edges dynamically using attention mechanism: $\rho^{e\to v}$ aggregates k neighbor nodes where the inter-node distance is defined as a Cartesian distance in the feature space. ϕ^v remains a MLP and, while edges are defined, there is no associated entity. A similar technique is used in nonlocal neural network [304] to efficiently propagate local feature information to points that may be far in the 3D cartesian coordinate. Message-passing neural network [305] (MPNN) explicitly defines a feature vector as edge entities. In MPNN, $\rho^{e\to v}$ performs element-wise sum of features and feed into ϕ^e, explicitly passing features across nodes as the name suggests. While these are representative models that are frequently used in particle physics applications [30,190,201,211,212,226,252,306–308,308], it is only a tiny fraction of GNN models developed over the past decade.

Graph-based models are particularly interesting for science applications because they offer a natural way to organize the entities in the data and encode how those components interact each other. This particular type of inductive bias is referred to as *relational inductive bias* in Ref. [298]. Graph edges may be intrinsically defined in the data (*e.g.*, when representing a social network) or not (*e.g.*, a point cloud). In the latter case, the graph structure must be chosen. A naive approach may be defining a fully-connected graph. However, for applications on hundreds of thousands of nodes (*e.g.*, high resolution 3D point cloud), this may require a prohibitive amount of memory and computation. On the other hand, if the graph is too sparse, it may negatively impact the performance. One may need to compare the model performance among differently constructed graphs and balance against computational burden. Ideally, the graph would be based on some knowledge of the interactions, but in the absence of such knowledge, popular graph construction methods include fully-connected, k-nearest neighbors, a Delaunay graph, minimum spanning tree, and locality-sensitive hashing [309].

Classification and regression tasks for graphs can be formulated such that the prediction is made for the entire graph or its individual nodes or edges. Graph-level prediction is like classifying an entire image, while node-level prediction is like semantic segmentation where individual pixels are classified. For clustering of points, GNNs can approximate a transformation function for nodes into the latent space where an optimal clustering of points can be performed. For instance, Ref. [310] proposes the *object condensation* approach to extract particle information from a graph of detector measurements as well as grouping of the measurements. The model predicts the properties of a smaller number of particles than there are measurements, in essence reducing the graph without explicit assumptions on the number of targeted particles. Certain nodes are chosen to be the "condensation" point of a particle, to which the target properties are attached. A special loss function mimics attractive and repulsive electromagnetic po-

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

tentials to ensure nodes belonging to the same particle are close in the latent space. Alternatively, one can formulate clustering as an edge classification task [29–32]. See Ref. [311] for a comprehensive review on particle physics applications.

41.8.5 *Model design with physics inductive bias*

Designing neural networks that respect the structure of particle physics can materially improve sample efficiency, robustness to systematics, and physical interpretability. Rather than relying on generic inductive biases (*e.g.*, translation equivariance in image CNNs), particle-physics–informed models hard-wire symmetries, conservation laws, and kinematics into the architecture or loss. This reduces the hypothesis space to functions that are a priori plausible, which is particularly valuable when training data is scarce, for extrapolation outside the training distribution, and for tasks where trust and uncertainty quantification matter as much as raw accuracy.

Exploitation of symmetry groups and hence *equivariance* is arguably one of the most important forms of physics-informed approaches. At the constituent level, events and jets are sets of particles, so permutation symmetry is fundamental. Deep sets and graph neural networks implement this by aggregating over particles with symmetric operations [211]. Beyond permutation symmetry, Lorentz symmetry is the natural arena for high energy physics experiments. Networks can be built from Lorentz scalars and tensors or by representing features as four-vectors and ensuring intermediate outputs transform equivariantly under boosts and rotations [312–318]. Gauge symmetry offers another avenue where symmetry-aware design pays off. In lattice gauge theory, gauge-equivariant networks ensures locality and exact invariance under gauge transformations [209, 319–322].

While these models explicitly integrate laws of physics into mathematical operations and model architecture designs, it is also possible to implicitly enforce physics constraints through a loss definition and model optimization method. For instance, physics-informed neural networks (PINNs) introduce regularization terms that force predicted physics quantities to follow laws of physics in the form of partial differentiable equations (*e.g.*, acceleration as the time derivative of velocity) [323, 324]. Variants of PINNs incorporate differentiable physics models as a part of a model architectures [325]. Finally, it is also possible to introduce physics constraints in an optimization process. For example, for a machine learning model for data reconstruction, an output of the model may go through a forward physics simulator that infers the original input to the reconstruction model. By minimizing the difference between the original input and the inferred one, the reconstruction model is forced to learn a solution that is consistent with the forward physics model [326].

41.9 Learning algorithms

41.9.1 *Gradient-based optimization*

Given a parameterized model $f(x, \theta)$ and a loss function $\mathcal{L}(x, \theta)$, where x and θ denotes data and model parameters, one way to optimize θ is to first apply an appropriate initialization, $\theta_{t=0}$ (e.g. Sec. 41.9.7 for neural networks), and perform an iterative update:

$$\theta_t = \theta_{t-1} - \lambda \nabla_\theta \mathcal{L}(x, \theta), \tag{41.78}$$

where λ is a small, real valued hyperparameter called *learning rate*. To see how this works, define $\delta\theta \equiv \theta_t - \theta_{t-1}$ and consider $\delta(\nabla_\theta \mathcal{L}(x, \theta))$:

$$\delta\left(\nabla_\theta \mathcal{L}(x, \theta)\right) \approx \delta\theta \cdot \nabla_\theta \mathcal{L}(x, \theta) = -\lambda |\nabla_\theta \mathcal{L}(x, \theta)|^2 \tag{41.79}$$

which would monotonically decrease the loss function, and locally move the parameter values in the desired direction of loss function minimization. This algorithm is called *gradient descent* (GD). We note that λ needs to be sufficiently small for the approximation to hold. When λ is too large, this can be a cause of a gradient explosion discussed in Sec. 41.9.7.

41.9.2 *Stochastic gradient descent*

Stochastic gradient descent (SGD) follows GD but replaces the exact gradient term $\nabla_\theta \mathcal{L}(x, \theta)$ with a stochastic approximation, where we subsample the data in the loss function using N samples, where $N < n$,

$$\nabla_\theta \mathbb{E}_{\hat{p}(x)} \mathcal{L} \approx \frac{1}{N} \sum_i^N \nabla_\theta \mathcal{L}_i, \tag{41.80}$$

where $\mathcal{L}_i$ is the loss function for data sample i. It should be noted that N needs to be randomly and independently sampled for the approximation to hold. Implementation of SGD follows three steps: take new samples of size N, approximate the gradient, then update the parameters θ.

In the case of optimizing the loss using a static database (*i.e.* one cannot take new N samples for every update), *mini-batch learning* is often employed. This replaces the first step with a randomly sampled *batch* of data, which is a subset of all the samples in the database. In this case, however, since a batch of data used for each parameter update is not entirely independent, a model may overfit. In practice, a part of the whole dataset is reserved as a *validation* sample, and the model performance is carefully monitored during the optimization process to avoid overfitting via an early stopping criterion (see Sec. 41.9.6 and Fig. 41.15).

SGD with slowly decreasing learning rate can be shown to converge to a local minimum almost surely under mild conditions, and to a global minimum for unimodal loss functions. SGD may also prevent getting stuck in shallow local minima of the loss function, thereby reaching a better local minimum for multi-modal loss functions. The noise in SGD with a constant learning rate can be viewed as a form of Langevin dynamics, which under proper conditions on the learning rate and mini-batch size converges to the stationary posterior distribution of the weights [327]. Thus SGD at a constant learning rate can be viewed as a sampler bouncing around and exploring the posterior surface for better solutions, descending onto the best found solution as the learning rate is decreased, a process related to temperature annealing in global optimization.

Another advantage of SGD is simply the computational cost: rather than evaluating the loss over all the data samples at each update, we use a small subset of data instead at each update. Furthermore, mini-batching can take advantage of vectorization libraries and GPU architectures. Large batch training requires specialized methods of training, such as layer-wise adaptive rate scaling (LARS) [328].

41.9.3 *Optimization algorithms*

GD and SGD are the basic building blocks for more advanced optimization algorithms. One can improve the convergence rate of gradient based optimization by considering the learning rate λ to depend on individual θ_i. Second order algorithms such as Newton's method take into account second order derivatives (Hessian) to find the minimum, and give an exact solution in a single update when the loss is quadratic around the peak. However, this requires a matrix inversion of the Hessian, which is exceedingly expensive in ML applications, where the number of network parameters is very large. As a consequence, second order optimization is rarely used in ML.

There are several improvements to the basic SGD even in the absence of Hessian information. Momentum based optimization takes a physics perspective of a viscous fluid in an external potential, where one updates current velocity with the potential gradient (force), followed by an update in position based on velocity. This approach therefore uses previous gradients in addition to the current one to compute a running average of the gradient, with a forgetting factor that controls how far back the averaging goes. This helps move faster towards the minimum in ravines, where gradient descent is usually inefficient due to the high condition number of the Hessian.

Beyond SGD with momentum, modern optimizers adapt step sizes across parameters or layers using recent gradient statistics and decouple regularization from the update. RMSprop tracks a running RMS of gradients and scales steps inversely to damp oscillations. Adam adds momentum (first moment) and variance (second moment) estimates to provide per-parameter adaptive updates. AdamW [329] improves Adam [330] by decoupling weight decay from the adaptive step, applying true L2 regularization directly to weights, which typically yields better generalization and

Phys. A 2026.41. Downloaded from www.worldscientific.com
DGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.
by KARLSRUHE INSTI

has become a common default in vision and language models. For very large-batch regimes, layer-wise trust-ratio methods such as LARS (Layer-wise Adaptive Rate Scaling) [328] and LAMB (Layer-wise Adaptive Moments optimizer for Batch training) [331] scale each layer's effective learning rate by the ratio of parameter norm to gradient norm, enabling stable training with batch sizes of tens of thousands. More recently, Lion [332] uses the sign of the momentum update instead of a second-moment estimate, reducing memory and often improving speed and generalization; it can also be combined with decoupled weight decay. In practice, these optimizers are paired with warmup, cosine or exponential decay schedules, and sometimes gradient clipping; the best choice depends on model size, data regime, and whether you prioritize fast convergence, large-batch scalability, or final generalization.

41.9.4 *Automatic differentiation and backpropagation*

In practice, $f(x, \theta)$ might take a complex form and may include a large set of parameters. The term $\nabla_\theta \mathcal{L} = \nabla_\theta \mathcal{L}(f(x, \theta))$ requires computing partial derivatives with respect to individual parameter θ_i. If f is a composite model (i.e. $f = f_n(f_{n-1}(\cdots, \theta_{n-1}), \theta_n)$), and if all of $f_{i:1,n}$ are differentiable, a chain rule can be applied:

$$\nabla_{\theta_i} \mathcal{L} = \frac{\partial \mathcal{L}(f(x, \theta))}{\partial \theta_i} = \frac{\partial \mathcal{L}}{\partial x_n} \cdot \frac{\partial x_n}{\partial x_{n-1}} \cdots \frac{\partial x_i}{\partial \theta_i} \tag{41.81}$$

where x_n denotes the output of nth composite function f_n. In order to compute $\nabla_{\theta_i} \mathcal{L}$ for f_i, it needs computation of a gradient at all preceding (or subsequent if seen in the forward context) functions. As the gradients accumulate across differentiable functions in the reverse order of the model composition, this technique is called *backpropagation* [287]. An example of f that satisfies conditions to apply backpropagation is a neural network, which consists of repeating blocks of a (differentiable) activation function and an affine transformation.

When the model $f(x, \theta)$ is implemented as a computer program in practice, *automatic differentiation* (AD), also called *algorithmic differentiation*, is used to compute the derivatives. AD exploits the fact that any computer program consists of a sequence of elementary arithmetic operations (*i.e.*, addition, subtraction, multiplication, and division) and functions (*e.g.*, log, exp, sin, and cos) and apply chain rules to compute the target derivative. AD has advantages over traditional approaches including symbolic and numerical differentiation. The symbolic differentiation faces a serious difficulty of converting a program into a single expression, and the numerical differentiation suffers from round-off errors. Finally, both methods scale poorly in speed of computation for calculating partial derivatives with a large number of inputs. AD delivers much faster speed and does not suffer from increasing errors for calculating higher derivatives.

There are two modes of AD: the *forward* and *backward* mode. Consider a composite function $f(x, \theta) = f_n(f_{n-1}(\cdots f_1(x, \theta_1) \cdots), \theta_{n-1}), \theta_n)$. The forward mode applies the chain rule in the same order of the forward evaluation of f by computing $\partial f_1 / \partial x$ first, then $\partial f_2 / \partial f_1$, and continue to $\partial f_n / \partial f_{n-1}$. The backward mode traverses the reverse direction: starting from the last (outer-most) function $\partial f_n / \partial f_{n-1}$, next $\partial f_{n-1} / \partial f_{n-2}$, and continue to $\partial f_1 / \partial x$. Therefore, the backpropagation of gradients can be implemented using the backward AD, in which the target variable to be differentiated is fixed and the derivative is computed with respect to each sub-expression recursively as shown in Eq. 41.81. The forward mode is simpler to implement as the order of gradient calculation follows the order of composite functions to be executed. The reverse mode typically requires less amount of computation than the forward mode, but more memory is required to store intermediate function output values to calculate derivatives efficiently. Another consideration is the mapping of dimensionality $f : \mathbb{R}^k \to \mathbb{R}^\ell$ as it concerns the number of variables to sweep from each end. The forward mode is efficient when $k \ll \ell$ while the reverse mode takes an advantage if $\ell \ll k$. For instance, in the case of an image classification where $(k, \ell) = (\text{pixel count}, 1)$, the reverse AD is more efficient.

Development of a differentiable physics simulator is an active area of research and AD-enabled programming frameworks are at the core of those research work. AD-enabled simulator can be used to solve an inverse problem of inferring the physics model parameters (e.g. calibration) or the input (i.e. reconstruction) [333, 334]. A fully differentiable physics simulator often requires, however, a custom algorithm to approximate gradients to handle cases where gradient calculation is not straightforward (e.g. due to stochastic processes) [335]. Beyond AD, a specifically designed neural network that ensures accurate gradient calculation is also frequently used, sometimes in combination with AD-enabled framework [326, 336].

41.9.5 *The vanishing and exploding gradient problems*

Gradient based optimization crucially depends on the size of gradient with respect to each model parameter. If the magnitude of gradient is too large with respect to the distance to an optimal parameter value, it may repeatedly overshoot the target and cause an oscillation preventing convergence. If the gradient is too small, it may take an impractically long time to converge. As shown in Eq. 41.81, the gradient of ith function f_i is a product of gradients from the subsequent functions. If those gradients are too large or too small, the magnitude can can either increase or decrease exponentially in the number of layers. These are called *exploding* and *vanishing* gradient problem respectively.

Modern deep neural networks consist with many composite functions (*i.e.*, layers) and are particularly prone to this effect. Let us consider a simple RNN. From Eq. 41.71, we can write the backpropagating gradient:

$$\frac{\partial h_t}{\partial h_{t-1}} = \text{diagonal}\left(f'\left(Wx_t + Vh_{t-1} + b1\right)\right) W \tag{41.82}$$

where f' denotes the derivative of an activation function. The gradient of the contribution to the loss $\mathcal{L}_i$ from the ith element in the sequence with respect to the jth hidden state h_j is therefore:

$$\frac{\partial \mathcal{L}_i}{\partial h_j} = \frac{\partial \mathcal{L}_i}{\partial h_i} V^{i-j} \prod_{j < t \leq i} \text{diagonal}\left(f'\left(Wx_t + Vh_{t-1} + b1\right)\right) \tag{41.83}$$

where we can see that V contributes multiplicatively with $i - j$ powers when $i - j > 1$. This example is explored in depth for recurrent models [288, 289] but is common for all types of deep neural networks.

In practice, one may explicitly inspect the magnitude of gradients propagating across layers to ensure an effective optimization. One way to mitigate an exploding gradient is to set the maximum gradient value $\delta_{\max}$ as a model hyperparameter and *clip* any larger gradients δ where it appears in the backpropagation:

$$\delta = \frac{\delta_{\max}}{\|\delta\|} \delta \text{if} \|\delta\| > \delta_{\max}. \tag{41.84}$$

This is called *gradient clipping* [289].

Alternatively, there are many architecture designs that are motivated by the vanishing and exploding gradient problem or which aim to help propagate gradients across many layers. These considerations drove the design of gated models like the LSTM and GRU for sequential data and also motivated the ReLU non-linearity. Other example architectural designs or components motivated by these considerations include identity mapping and skip connections used in ResNet, U-Net, and DenseNet, which allow gradients to flow across many layers.

Other factors contributing to vanishing and exploding gradient include initialization of model parameters and normalization of input data. These factors contribute in keeping the magnitude of activation, which also concerns the magnitude of gradient, within a reasonable range. A recommended practice for a gradient-based optimization of a neural network is to maintain the input values centered around zero and a similar level of covariance across the inputs (and the outputs that are the inputs to the next layer) [337]. These factors are discussed in the following.

41.9.6 *Early stopping*

Early stopping is a form of regularization used to avoid overfitting when an iterative method, such as gradient descent, is used as a learning algorithm. Imagine a plot of the training loss and test

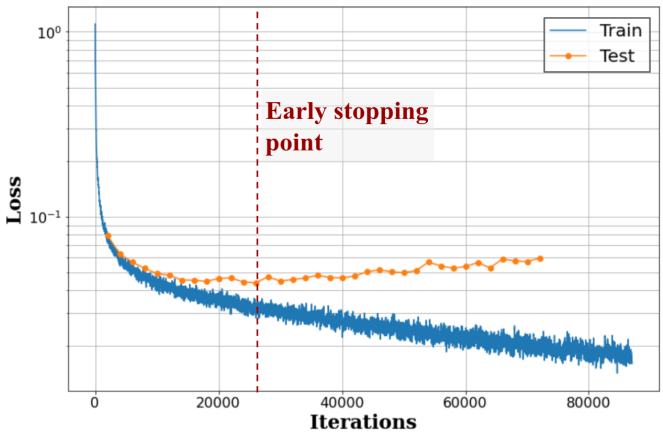

Figure 41.15: An example instance of overfitting. The training loss (vertical axis) shown in blue decreasing over iterations (horizontal axis) while the loss values evaluated on test samples shown in orange start to increase at around 26,000 iterations as indicated by the vertical line.

loss as a function of iterations (*i.e.* parameter updates). As learning proceeds, the training loss will generally decrease. However, the test loss will often decrease initially and then start to increase, which is the classic sign of overfitting as shown in Fig. 41.15. The basic idea of early stopping is simply to stop training before overfitting takes place. In some approaches to early stopping theoretical analysis of the learning problem provides a prescription for when to stop the training [338]; however, the most straight forward approaches use a held-out validation dataset to monitor the generalization performance [339].

41.9.7 *Initialization of model parameters*

An improper initialization can slow down the optimization process or even result in a loss of convergence. While $b^{(l)}$ is typically initialized to zero, $W^{(l)}$ values need to be stochastic to avoid identical updates during optimization. One way is to sample $W^{(l)}$ from a zero-centered Gaussian distribution with a small variance (e.g. 0.01) [340]. However, this method does not guarantee the same variance in the input to each layer, which depends on the size of the input layer, and makes it difficult to train a deep neural network [283]. The *Glorot* or *Xavier* initialization takes this into account and sets the variance of a Gaussian distribution to be $\sigma^2 = 1/d^{(l-1)}$ assuming a symmetric activation function around zero, such as a logistic function or hyperbolic tangent [341]. The *He* initialization uses the variance $\sigma^2 = 0.5/d^{(l-1)}$, and is a simple extension of Xavier initialization for leaky, parametric, and standard ReLU activation [270].

41.9.8 *Input normalization*

Input data to a neural network is often pre-processed for the same goals discussed previously: values are shifted to have the mean of zero and scaled to keep a similar covariance across features. Furthermore, a data may be transformed using techniques including PCA and whitening (sphering) to keep input features independent and uncorrelated from each other [337].

41.9.9 *Batch normalization*

Even with careful normalization of the input data and initialization of model parameters, the mean and covariance of the data representations in hidden layers will evolve during training and may pose challenges for learning for downstream layers. This is called an *internal covariate shift* [342] and may cause negative effects to an optimization process. Accordingly, techniques to explicitly normalize features in between hidden layers are often employed for a deep neural network. One of them is *batch normalization (BN)*, which shifts and scales the input to a hidden layer:

$$\tilde{u}^{(l)} = \gamma \frac{u^{(l)} - \mu_B}{\sqrt{\sigma_B^2 + \epsilon}} + \beta \tag{41.85}$$

where $u^{(l)}$ and $\tilde{u}^{(l)}$ refer to the raw and normalized input to the lth layer, μ_B and σ_B represent the mean and mean-squared-error of $u^{(l)}$ calculated using a *batch* of input data used to update the network parameters. γ and β are part of model parameters that are updated during the optimization. After optimization is complete, these parameters are fixed for model evaluation during production. ϵ is a small, fixed constant value to ensure numerical stability. While it is popular (especially in computer vision), a downside of BN is its dependency on the batch size. In situations where the batch size is limited to be a small number (*e.g.*, memory limitation for a large data or a model), the performance using BN could degrade since β and γ values may not be generalized for the dataset during training.

There are several variants to batch normalization with considerations on how to group a subset of values in u^l. For instance, an image naturally has three groupings: a set of pixels across spatial axis, features within one pixel (*i.e.*, image *channels*), alongside with a grouping across multiple images (*i.e.*, batch). Different groupings have been studied and found and some are found effective to particular type of applications: layer normalization groups values along the channel and spatial dimensions [343], instance normalization groups along the spatial dimension but not along the batch nor channel [344], and group normalization is similar to layer normalization but forms multiple sub-groups of channels [345]. These variants do not apply normalization across samples within a batch, and thus are agnostic to the batch size.

41.9.10 *Transfer learning: pre-training and fine-tuning*

Transfer learning is a technique to improve performance and accelerate optimization process by reusing a pre-trained machine learning model for a new task. The two tasks and corresponding datasets may differ, but fundamental features, such as implicitly learned symmetries in the underlying data, may be reusable across tasks and datasets. Transfer learning typically takes two steps: the first is to alter the model or data if necessary, then continue updating some or all of the model parameters on the new data or task, *fine-tuning* the model. The first step is required, for example, when solving a different task that requires a different architecture (*e.g.*, regression vs. classification), or when input data format requires a change (*e.g.*, original model trained on three channel image, such as RGB images, while new data has a single channel). Transfer learning has been widely practiced in the field of computer vision where large, labeled data sets are available [346–349]: a CNN trained for classifying images of an animal can be largely reused for object detection, or even for analyzing image data in science (*e.g.*, particle trajectories recorded by an imaging detector). It is a critical aspect for the development of general AI as well as interdisciplinary sharing of models across research fields.

While transformers were initially introduced for machine translation, later models such as GPT [86, 350] and BERT [85] showed that these models can be generalized to multiple NLP tasks through transfer learning by *pre-training* for several seemingly different tasks, including sentence classification, semantic similarity, question answering, and commonsense reasoning [350]. These models are collectively referred to as large language models (LLMs) and some have been fine-tuned for physics domains [351, 352].

41.9.11 *Foundation models*

A key to successful transfer learning is an effective pre-training process through which general (and thus re-usable) representations are learned by a model. When a large, comprehensive dataset within a certain domain is combined with an effective representation learning method, typically using self-supervision or multi-task supervision, which forces a model to learn foundational concepts, the resulting model may potentially be generalized for any task defined in the data domain. Such AI models are referred to as *foundation models* (FMs), which are a central theme of general AI research today [353]. The LLMs such as GPTs are the first and the most successful FMs to date. The core of LLM pre-training is based on self-supervised learning (see Sec. 41.4), where, *e.g.*, a model is tasked to predict the next or missing word in a sentence. To solve this task, a model must learn not only gram-

mar or parts of speech but also a concept of visual colors and the probability distribution over possible colors an apple can take. Using the vast online corpus as a training data, LLMs are trained to learn foundational representations of the world interpreted and generated by humans in the form of texts.

The critical properties of FMs include the *emergence*, *homogenization*, and *scalability* [353]. Emergence means the system behavior is implicitly induced rather than explicitly constructed (*e.g.*, a model's capability to generalize through self-supervised pre-training). Homogenization implies a single model or a system that can perform multiple tasks. Scalability is improvement in model performance when increasing the computing resources, number of model parameters, and size of training dataset. These properties are also used to evaluate the quality of FMs. Following the initial success of LLMs, R&D of FMs has expanded to computer vision and audio data domains.

Many modern FMs combine multiple data modalities (*e.g.*, image generation from text input, audio generation from text and image input) [98, 354, 355]. Multi-modal FMs are trained to correlate features from different data modalities either during a pre-training or fine-tuning stage. For example, the CLIP model achieves this by minimizing the distance between extracted features from an image and its corresponding caption (text) data [98]. It should be noted, however, pre-training FMs on sensory data (*e.g.*, 1D waveforms, 2D images, or 3D scenes) is more difficult compared to symbolic data (*e.g.*, language, math, or high-level physics data) as discussed in Sec. 41.4.

HEP datasets present unique R&D opportunities to advance understanding of FMs. Particles in high energy collisions follow well-established physics models and can be learned by FMs similar to words in natural language [87, 88]. Large public datasets of galaxies recorded in multiple modalities (*e.g.*, images and spectroscopy data) enable a contrastive learning approach based on CLIP [99]. Similarly, a high-fidelity simulator in HEP can be used to formulate contrastive learning objectives across different scenarios in a stochastic process [106]. Finally, HEP detectors offer big, high-precision data sets with challenging tasks to extract complicated physics information [96]. A schematic of a foundation model based on HEP data is shown in Fig. 41.16.

41.10 Incorporating uncertainty

A fundamental aspect of data analysis is the quantification of uncertainty. This broad topic includes the traditional distinction between statistical and systematic uncertainty, procedures for propagation of errors, and the incorporation of uncertainty in to the statistical models (*e.g.* with nuisance parameters) that are used in Bayesian or frequentist statistical procedures (see Sec. 40). Accounting for systematic uncertainty can be seen as a requirement, but ideally systematic uncertainties are also taken into account in the design of the analysis so as to mitigate their effect. The introduction of machine learning into the analysis pipeline requires revisiting the techniques used for uncertainty quantification and exposes many fundamental issues that have nothing to do with the use of machine learning per se. See Ref. [356] for a recent review on this topic.

In machine learning research and industrial settings, the mismatch between the data distribution $p_{\text{train}}(x, y)$ used for training and the data distribution $p_{\text{prod}}(x, y)$ that the model will be applied to in production is referred to as *covariate shift* or *domain shift*. For example, one might train a classifier to identify cats and dogs with images from a well lit studio and then apply the classifier on images taken in doors with poor lighting conditions and a scratched lens. Not surprisingly, the mis-classification rate of the classifier will be different between the two settings.

Physicists are keenly aware that the simulations that we use to describe the data are not perfect, and this mismodeling corresponds to a large fraction of the of systematic uncertainties accounted for in published works. Since simulated data is often used to train machine learning models (*i.e.* $p_{\text{train}}(x, y)$), it is important to understand and account for how this mismodeling will influence results when applied to real data (*i.e.* $p_{\text{prod}}(x, y)$).

One of the primary approaches to incorporating this type of uncertainty is to introduce nuisance parameters ν corresponding to the uncertain inputs to the simulation. One then parametrizes various types of perturbations (*e.g.*, corrections to efficiencies or energy scales) in the hopes that the resulting family of distributions $p(x|y, \nu)$ is flexible enough to encompass the true data distribution for class y. In this approach one does not have just two "domains" for the data (*i.e.*, p_{train} and p_{prod}), but a continuous family of domains parameterized by the nuisance parameters ν.

With this framing in mind, there are several approaches to incorporating uncertainty into an analysis that includes ML-based components:

- **propagation of errors:** one works with a model $f(x)$ and simply characterizes how uncertainty in the data distribution propagate through the function to the down-stream task irrespective of how it was trained.
- **domain adaptation:** one incorporates knowledge of the distribution for domains (or the parameterized family of distributions $p(x|y, \nu)$) into the training procedure so that the

performance of $f(x)$ for the down-stream task is robust or insensitive to the uncertainty in ν.

- **parameterized models:** instead of learning a single function of the data $f(x)$, one learns a family of functions $f(x;\nu)$ that is explicitly parameterized in terms of nuisance parameters and then accounts for the dependence on the nuisance parameters in the down-stream task.
- **data augmentation:** one trains a model $f(x)$ in the usual way using training dataset from multiple domains by sampling from some distribution over ν.

In this setting it is best to consider the trained model $f(x)$ or $f(x;\nu)$ to be a fixed function and decouple the variability associated to training or the choice of architecture. The fact that one could have chosen a different architecture or learning algorithm should be treated in the same way as other choices that are made in the data analysis pipeline. While it is reasonable to want down-stream inference and decisions to be robust to these choices, they are of a different nature than the uncertainty in the modeling of the data distribution. We return to this point in Sections 41.10.5 and 41.10.6.

41.10.1 *Propagation of errors*

In this Section, we consider the common scenario in which one has used some machine learning technique to train a model $f(x)$ for classification or regression and wants to assess the sensitivity of the output of $f(x)$ to uncertainty in the input x. We regard the function $f(x)$ as fixed and we are not concerned with how the model was trained.

Propagating uncertainty through a ML-based model $f(x)$ is not fundamentally different than for any other function, and one can use the standard propagation of errors formula of Sec. 39.2.1. As always, it is important to recognize the limitations of the propagation of errors formula, which is accurate when the uncertainty on x is Gaussian and the function $f(x)$ is approximately linear within the region set by the uncertainty on x.

Similarly, classifiers are often used for particle identification or event selection. In that case, one is primarily interested in the efficiency ϵ to satisfy a cut on the classifier output. The efficiency depends on the distribution $p(x|y)$ through the equation $\epsilon_y = P(f(x) > f_{\rm cut}|y) = \int H(f(x) - f_{\rm cut})p(x|y)dx$, where H is the Heaviside step function and y is an index or label for the category of data that is being considered (*e.g.*, signal vs. background or electron vs. jet). Thus, the question in this context is what is the uncertainty on the efficiency ϵ_y due to uncertainty in the distribution $p(x|y)$. In practice, the quantification of the uncertainty in the efficiency ϵ_y is usually based on either a calibration measurement on real data or estimated with simulated data. These procedures typically treat the classifier as a black-box, and thus nothing precludes using those procedures on a ML-based classifier. An early example of this approach for b-tagging can be found in Ref. [357].

In the case where simulation is used to estimate the efficiency ϵ_y and its uncertainty, one usually varies nuisance parameters ν associated to the simulation. One then uses simulated samples to approximate $\epsilon_y(\nu) = P(f(x) > f_{\rm cut}|y,\nu) = \int H(f(x) - f_{\rm cut})p(x|y,\nu)dx$. Again, the procedure for incorporating uncertainty isn't fundamentally different if the classifier $f(x)$ is based on machine learning or a hand-crafted observable.

41.10.2 *Domain adaptation*

While estimating the uncertainty for a ML-based model is not fundamentally different than any other hand-crafted observable used for regression or classification, the worry of many physicists is that by working with a high-dimensional set of features x that one is more susceptible to mismodeling of subtle correlations. This is a valid concern, and it should be appreciated that a great deal of prior knowledge and physical insight goes into the construction of hand-crafted observables so that they will be robust to the most uncertain aspects of data. However, much of this craft is based on heuristics that are difficult to systematize. Furthermore, one can only validate that such an observable is robust if one can explicitly evaluate the performance for a perturbed distribution. Thus in the settings where one can validate the robustness to a perturbed scenario ν_0, one must have access to $p(x|y,\nu_0)$.

One approach to formalize this type of robustness is to consider the dependence on the distribution of the output of the model $f(x)$ to the nuisance parameters. In statistics, if the distribution of f is independent of the nuisance parameters, then f is referred to as a *pivotal quantity*. This is a property that we can incorporate directly into the training procedure to target a particular notion of robustness. The authors of Ref. [358] introduced an adversarial approach (similar to what is used in the generative adversarial network of Sec. 41.3.4.2) to penalize a model during training if the distribution of the output varies with the nuisance parameters. To construct the training dataset $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$, one must sample y and ν according to some proposal distribution (similar to a prior, but only used for the creation of training dataset, not necessarily for statistical inference), corresponding to a joint distribution $p(x,y,\nu)$. Instead of minimizing the target loss $\mathcal{L}_f$ (*e.g.* cross-entropy or squared-error) with respect to the parameters ϕ_f that parameterize the model f, one trains with a minimax strategy that also includes an adversary q with parameters ϕ_r. The trained model is characterized by the saddle point

$$\hat{\phi}_f, \hat{\phi}_r = \arg\min_{\phi_f} \arg\max_{\phi_r} E_\lambda(\phi_f, \phi_r) \,, \tag{41.86}$$

where the value function E_λ includes the target loss as well as a regularization term associated to the adversary

$$E_\lambda(\phi_f, \phi_r) = \mathcal{L}_f(\phi_f) - \lambda \mathcal{L}_r(\phi_f, \phi_r) \,. \tag{41.87}$$

The constant λ is a hyperparameter, since generally there is a tradeoff between the two terms and only in special cases can the model that minimizes $\mathcal{L}_f$ also be a pivotal quantity. The regularization term

$$\mathcal{L}_r(\phi_f, \phi_r) = \mathbb{E}_{p(x,y,\nu)}[-\log q_{\phi_r}(\nu|f_{\phi_f}(x))] \tag{41.88}$$

is an example of conditional density estimation (see Sec. 41.3.3), where the model $q_{\phi_r}(\nu|f)$ is trying to predict the distribution of the nuisance parameter ν given the output of the model $f(x)$. This term is maximized when f is independent of ν. Earlier work had also used an adversarial technique for domain adaptation, but was limited to just two domains [359–361], while here ν parametrizes a continuous family of distributions and can have multiple components corresponding to different sources of uncertainty. Furthermore, the previous work aimed to make the distribution for a high-dimensional, intermediate representation of the data be invariant to the domain shift as opposed to just the final output $f(x)$.

One way of interpreting Eq. 41.86 is that the goal is to minimize a regularized loss function $\tilde{\mathcal{L}}(\phi_f) = \arg\max_{\phi_r} E_\lambda(\phi_f, \phi_r)$, where the optimization with respect to ϕ_r is not exposed. This motivates another approach in which the regularization is not achieved through a learned adversary, but by a measure of discrepancy between distributions that can be computed directly from samples. In particular, the authors of Ref. [362] proposed the use of *distance correlation* to avoid what can be a challenging min-max optimization problem.

In either case, the optimization of the hyperparameter λ is based on the downstream task. For example, in Ref. [358] considered the case where f was a signal vs. background binary classifier where the nuisance parameter ν was associated to uncertainty in the background model. The hyperparameter λ was then optimized to maximize the approximate median significance (AMS). Similarly, the authors of Refs. [363] and [362] considered new physics searches in the context of boosted jet tagging, where the hyperparameter controls the sculpting of the side-bands used for background estimation.

While these strategies modify the training procedure so that the sensitivity to the nuisance parameters is reduced, it does not typically eliminate it. As a result, one still needs to propagate the uncertainty in the data distribution through the learned model as described in the preceding section. Furthermore, care must be taken in interpreting the loss of sensitivity to the nuisance parameter. For example, for theoretical uncertainties estimated as the difference between two different calculations (*i.e.*, two-point

uncertainties), decorrelation methods may reduce the apparent uncertainty while the true uncertainty remains much larger [364].

Note, this adversarial technique has also been employed in other settings where one would like to decorrelate the output of the classifier with an observed quantity so that it can be used for background estimation [363], although other techniques like moment decomposition [365] may suffice without full decorrelation. Widely used alternative approaches to decorrelation include uboost [366], DDT [367], and using dedicated training samples that vary the chosen quantity to be decorrelated [368]. Other examples of the domain adaptation and decorrelation use cases from the Living Review include Refs. [358, 362–367, 369–378].

41.10.3 *Parameterized models*

An alternative to learning a model $f(x)$ that is pivotal—*i.e.*, whose distribution is independent of the nuisance parameter ν—is to learn a family of models $f(x;\nu)$ that is parameterized in terms of the nuisance parameters. In general, there is a tradeoff between the two terms of Eq. 41.87 for a single model $f(x)$. In a parameterized model, $f(x;\nu)$ optimizes the performance of the model for every value of ν. Parameterized classifiers were first advocated in Ref. [133] in the context of simulation-based inference (see Sec. 41.10.7) and in Ref. [379] for new physics searches. It has also been applied to simulation-based inference for effective field theory parameters in Ref. [380] and Ref. [381] provides additional pedagogical examples.

The training of a parameterized model is similar to the standard procedure. For example, if one originally wanted to minimize the squared loss function $\mathcal{L}(y, f(x)) = (y - f(x))^2$ with training dataset $\{x_i, y_i\}_{i=1,\ldots,n}$, then the corresponding training procedure for the parameterized model would be as follows. One would need to construct a training set $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$ as described in the preceding section, construct a parameterized model $f(x;\nu)$ that takes as input the original feature vector x as well as the nuisance parameters ν, and then train using the same loss $\mathcal{L}(y, f(x;\nu)) = (y - f(x;\nu))^2$.

One complication of the parameterized approach is that it is no longer possible to evaluate the model on a dataset $\{x_i\}$ and pass on only $\{f_i\}$ for downstream analysis tasks since $f(x_i;\nu)$ still depends on ν. Instead, one delay evaluating the model to some down-stream stage when the dependence on ν would accounted for. For example, in the context of a likelihood based analysis where one is testing a hypothesis where the nuisance parameters take on a particular value ν_{test}, then one will consider the data distribution $p(x|\nu_{\text{test}})$, and at that point one would evaluate the model at the corresponding nuisance parameter value, *i.e.* $f(x;\nu_{\text{test}})$. Explicit examples are given in Refs. [133,356,380,381]. While this may seem complicated, it actually corresponds to what is done in a typical likelihood-based fit when the statistical model has nuisance parameters; *i.e.* the likelihood-ratio corresponds to the model $f(x;\nu)$ as in Eq. 41.13.

41.10.4 *Data augmentation*

An intuitive approach to building in robustness to systematic effects that can lead to domain shift, is simply to augment the training dataset so that it includes examples corresponding to several values of the nuisance parameter or systematic variations. As before one can construct a dataset $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$, but instead of leveraging the information about ν_i, one simply discards this information. This corresponds to sampling from the marginal distribution $x_i, y_i \sim p(x,y) = \int d\nu p(x,y|\nu)p(\nu)$, and is often referred to as *smearing*. One can then use this smeared dataset for supervised learning in the traditional way. While it is possible that this approach will lead to improved robustness to systematic variations (*i.e.* generalization for ν other than the nominal value) than if systematic uncertainty weren't considered at all), this intuitive approach has several shortcomings. The approach does not yield a pivotal quantity as in the adversarial approach, so propagation of uncertainty through the network is still required. Moreover, there is no direct way to control the tradeoff between independence from the nuisance parameter and the original target loss as in the adversarial approach. Finally, it can lead to significant performance loss compared to what is possible with the parameterized approach. These tradeoffs were studied in Refs. [379, 381] with both pedagogical and physically-motivated examples.

41.10.5 *Aleatoric and epistemic uncertainty*

In the machine learning and risk assessment literature, uncertainty is often characterized in terms of *aleatoric* and *epistemic* uncertainty [382–385]. Familiarity with these terms is useful, but the distinction between the two can be ambiguous, the terms are not always consistently used, and they do not clearly map onto the concepts used physics.

For example, Ref. [384], states that "roughly speaking, aleatoric (*a.k.a.*, statistical) uncertainty refers to the notion of randomness, that is, the variability in the outcome of an experiment which is due to inherently random effects", while "epistemic (*a.k.a.*, systematic) uncertainty refers to uncertainty caused by a lack of knowledge (about the best model)." This seems clear enough, but in that same reference (and in Ref. [386]) the aleatoric uncertainty is considered irreducible, while the epistemic uncertainty could be reduced with additional information. This may seem backwards for many physicists since often in particle physics, we think of how uncertainties scale as we collect more data but keep the experimental design fixed. In that case, the statistical uncertainty will be reduced with time while the systematic uncertainty will remain constant[4]. There is no paradox here, it is simply a different point of view. The emphasis of the risk assessment community is not on collecting more data with the same experimental design, but collecting different types of data that will inform the models themselves. Clearly even for physicists, data from new experiments or calibration measurements could also reduce our systematic uncertainties. While there are exceptions in the literature, the bulk of it associates aleatoric uncertainty with the randomness of classical probability (*i.e.*, the statistical uncertainty associated to repeating the same experiment many times) and epistemic uncertainty with our state of knowledge.

Perhaps a more important distinction between the perspective of physicists and machine learning researchers has to do with the use of the term "model" and what exactly is uncertain. In physics, the systematic and epistemic uncertainty is typically associated to our understanding of the underlying physics and "the model" usually refers to the physics model, detector model encapsulated in a simulation. In contrast, for machine learning research, "the model" usually refers to the trained model $\hat{f} \in \mathcal{F}$ used as described in Section 41.2.1 (or the class of functions $\mathcal{F}$ itself). This makes sense if we recall that in the bulk of machine learning research, one has little insight into the process that generated the data (*e.g.*, images of cats and dogs, or natural language). In that sense, the epistemic uncertainty in machine learning is usually associated to uncertainty in the model parameters ϕ after training, which would be reduced if one could collect more training dataset (see Ref. [385] for this point of view).

In the literature on uncertainty quantification (UQ), which is more closely connected to physics given the role of computer simulations, the terminology is more fine grained and less ambiguous. That community uses the terms parameter uncertainty (*i.e.* nuisance parameters), structural uncertainty (*i.e.*, mismodelling), algorithmic uncertainty (*i.e.* numerical uncertainty), experimental uncertainty (*i.e.*, uncertainty from experimental resolution and statistical fluctuations), and interpolation uncertainty (*i.e.*, uncertainty due to interpolating between different parameter values due to lack of computational resources).

41.10.6 *Model averaging and Bayesian machine learning*

The core of Bayesian machine learning is the model averaging view. Here one often takes a more ambitious view of learning than described in Sec. 41.2.1, which is framed mainly as function approximation. While in Sec. 41.2.1, the goal is to find a function that minimizes the risk, in Bayesian machine learning one explicitly builds a probability model $q_\phi(x,y)$ for the training dataset $\mathcal{D} = \{x_i, y_i\}_{i=1,\ldots,n}$. It is the same change in perspective that one has when one views the squared error loss function $\mathcal{L}_{\text{MSE}} = (y - f_\phi(x))^2$ as the log-likelihood for a probability model

[4] Further complicating the relationship between the terms is that many experimental uncertainties that are characterized as systematic are actually statistical in nature as auxiliary measurements and control regions are used to constrain the corresponding nuisance parameters.

$y \sim N(f(x), \sigma)$. In addition, one assumes some prior on the model parameters $p(\phi)$, which is often a Gaussian distribution, and is analogous to Tikhonov regularization (see Sec. 41.2.5). In this way, a single trained model $\hat{f} = f_{\hat{\phi}}$ is the MAP point estimate and the more complete Bayesian solution is the entire posterior distribution over the model parameters $p(\phi|\mathcal{D})$. With this view, it is clear how increasing the number of training examples n will lead to a reduction in uncertainty on ϕ. However, this notion of epistemic uncertainty has little to do with the notion of systematic uncertainty as the term is used by particle physicists.

Bayesian methods can be applied to non-probabilistic regression problems, in which case they can provide uncertainty quantification. Consider the case of regression in traditional (non-Bayesian) machine learning. The trained model $f_{\hat{\phi}}(x)$ is used to predict the target label y. For a fixed x, the model does not provide any notion of uncertainty on the prediction. One could propagate uncertainty on x through $f(x)$, but that is also not the desired quantity to characterize the intrinsic spread $p(y|x)$ in the data, which may exist even if x has negligible uncertainty. In contrast, Gaussian process regression (a Bayesian method) does provide a natural way to communicate the uncertainty on the prediction, which is possible because one first had to specify a prior on the mean and covariance of the Gaussian process.

In the context of Bayesian deep learning and Bayesian neural networks, one would place a prior on the weights and biases of the neural network $p(\phi)$ and then use one of the many emerging techniques to calculate the approximate posterior $p(\phi|\mathcal{D})$. However, we should recognize that we have little-to-no insight into the parameters of a deep neural network, so the prior on ϕ is hardly well-justified. Furthermore, just as in all Bayesian approaches, the prior is not invariant to reparametrizing the model: $\phi \to \eta(\phi)$. While it is difficult to justify the choice of the prior on the parameters (and, thus, the resulting posterior), the resulting model may perform well empirically. In such high-dimensional parameter spaces, the bias-variance tradeoff can be dramatic.

Bayesian model averaging (BMA) performs Bayesian average over the posterior $p(\phi|\mathcal{D})$. This can be applied to any quantity f_ϕ, such as a regression or classification prediction y. Suppose we can draw from the posterior $\phi \sim p(\phi|\mathcal{D})$. For each draw we can evaluate the predicted regression variable $y = f_\phi(x) + \epsilon$, where ϵ is some noise to account for uncertainty in the predictions. We can denote this process as a draw from $p(y|x,\phi)$, $y \sim p(y|x,\phi) = N(f_\phi(x), \sigma_\epsilon^2)$, where σ_ϵ^2 is the noise variance. The BMA then performs

$$p(y|x,\mathcal{D}) = \int d\phi p(\phi|\mathcal{D}) p(y|x,\phi). \tag{41.89}$$

In practice $p(y|x,\phi)$ is evaluated by drawing samples of y and ϕ, so the posterior is defined implicitly by the samples. For example, the mean prediction is obtained by averaging $f_\phi(x)$ over the samples of ϕ, and the covariance matrix is similarly evaluated by averaging the second moments over the samples of ϕ.

Ref. [387] provides a different perspective on BMA analyzed in what are referred to as the $\mathcal{M}$-open and $\mathcal{M}$-closed settings [387]. The $\mathcal{M}$-closed setting refers to the situation where the true data generating process is in the space of models, even if it is unknown to us. In contrast, the $\mathcal{M}$-open setting refers to when the true data generating process is not in model space (*i.e.* the model is mis-specified). Interestingly, in the $\mathcal{M}$-open case one can potentially do better than any one model in the model class by considering an average over the models, since averaging can create a new model that is not in the model class. BMA provides one such averaging, but other averages, which are not weighted by $p(\phi|\mathcal{D})$, can be a better choice. When the weights of each model are optimized against appropriate loss the resulting procedure is called stacking, which has been shown to be superior to BMA in the $\mathcal{M}$-open setting [387]. Ref. [388] performed experiments indicating that in some cases model averaging can also improve predictive uncertainty estimates under domain shifts.

Neural network model averaging beyond BMA comes in several different flavors. Two successful model averaging procedures are Monte Carlo dropout [389], which uses dropout ensembling, and deep ensembles [390], which use random initialization ensembling. These methods may not only be superior to BMA, they are also often significantly faster than BMA. Whether these model averages are an approximation to BMA, or an alternative to it, remains a debated topic, and both views have been advocated. BMA itself can be accelerated using approximate methods, such as stochastic Variational Inference with reparametrization trick [391].

Finally, in the context of Bayesian model uncertainty estimation, there are two practical ways to capture: repulsive ensembles and evidential regression. Repulsive ensembles are standard deep ensembles trained with an extra diversity penalty so the ensemble members make deliberately different but plausible predictions, improving coverage with fewer models. Evidential regression uses one network to predict the parameters of a simple probabilistic family plus an "evidence" term; when data are ambiguous it learns low evidence and returns wider intervals, and when data are plentiful it narrows them. The latter has been studied for uncertainty quantification for neutrino applications [392]. In practice, both approaches can yield similarly well-calibrated uncertainties. An open direction is to bring such calibrated epistemic uncertainty into the density estimators of generative models (*e.g.*, flows, VAEs, or diffusion), for example via ensemble/Bayesian variants with diversity or evidential parameterizations, so we can represent and propagate uncertainty over whole distributions, not just point predictions.

41.10.7 *Connection to probabilistic machine learning*

We end this Section by reinforcing the connection between uncertainty quantification in traditional machine learning and the more probabilistic approaches to machine learning exemplified by simulation-based inference (see Sec 41.6) and deep generative models (see Sec. 41.3.4). In the standard approach to supervised learning (*e.g.* classification and regression) the model $f(x)$ provides a point estimate for y. Estimating an uncertainty on y goes a step further, but the complete picture would be to model the posterior distribution $p(y|x)$. Gaussian processes (see Sec. 41.8.2) are an example, but the form of the models is limited to Gaussian posteriors. In Sec 41.6 we discussed approaches to model $p(y|x)$ using conditional density estimation [69,70,128]. If we extend this task to include a family of distributions parameterized by some nuisance parameters ν, then the task is to model $p(y|x,\nu)$, which is structurally similar.

In the context of classification, the output is already probabilistic, and the interpretation of the resulting classifier is $\hat{f}_{\rm MSE}(x) \approx p(y=1|x)$ (see Eq. 41.11). Incorporating the dependence on the nuisance parameter, then connects to the likelihood-ratio trick (see Eq. 41.13), approaches to simulation-based inference that involve learning the likelihood-ratio, and the parameterized approaches described in Sec. 41.10.3.

If one pairs the training procedure for classification, regression, or density estimation used in the approaches above with model averaging techniques such as BMA, then it would be possible to incorporate both uncertainty associated to finite training dataset and the uncertainty associated to systematic uncertainties. However, as described in Sec. 41.10.5 and Sec. 41.10.1, it is not clear that in physics applications it is desirable to account for the variability associated to training when the more common practice is to regard the trained model $\hat{f}(x)$ as fixed.

While these probabilistic approaches to machine learning are attractive conceptually, it is known in the machine learning community that classifiers often are poorly calibrated and often overly confident in their predictions. This is a problem even if one regards the trained model $\hat{f}(x)$ as fixed. Various approaches, including model averaging, are being pursued to improve the calibration of trained models, but the problem is unlikely to be eliminated entirely. Miscalibration can be verified by evaluating the true positive and false positive rates on held out data. This is common practice in experimental particle physics, where the output of a binary classifier is rarely taken at face value. Instead, the true and false positive rates are estimated with simulated data or control samples as described in Sec. 41.10.1. Furthermore, the true and false positives can be characterized as a function of the nuisance parameters. These procedures can be used to help calibrate parameterized models based on the likelihood-ratio trick (see Refs. [133, 381]). Unfortunately, calibration in the con-

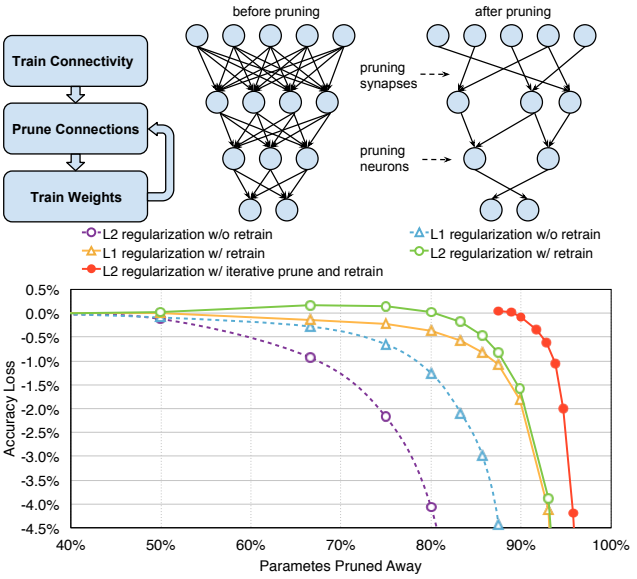

Figure 41.17: Illustration of the iterative magnitude-based parameter pruning and retraining with regularization procedure from Han et al. in NeurIPS, 2015. The top-5 accuracy loss is shown as a function of parameter reduction (sparsity) for VGG-16 on ImageNet following different pruning procedures. Without retraining, L1 regularization performs better than L2, but L2 performs better than L1 with retraining. Iterative pruning gives the best result.

text of density estimation is more challenging. This connects to topics and challenges in anomaly detection (see Sec. 41.3.5).

41.11 Model compression and deployment in experiments

The software and computing needs of training a machine learning model are different than those encountered when it is deployed for use. The two stages are referred to as *training* and *inference*, *i.e.* making a prediction $\hat{f}(x)$ given an input x and a trained model $\hat{f}$. Sometimes this transition also involves using different programming languages for implementing the trained model from the ones used for training them. Modern machine learning frameworks support various serialization formats to exchange trained models. For instance, `ONNX` [393] provides an open source format for many types of models, is widely supported, and can be found in many frameworks, tools, and hardware. This is important when integrating a trained model into the software frameworks used by the large experiments.

While hardware acceleration with GPUs is important for efficiently training modern machine learning techniques, there are also advantages of hardware acceleration at inference time. This may include GPUs or field programmable gate arrays (FPGAs), and the Living Review includes many example works focusing on efficient inference for a given hardware architecture [153, 180, 394–403]. Programming FPGAs requires the use of dedicated hardware description languages (HDLs) such as VHDL or Verilog as well as a design methodology that is aware of the limitations and nature of the relevant device. Recently, high-level synthesis (HLS) tools [404–406], which ingest algorithms written in C/C++ code, have lowered the barrier to entry for using FPGAs. Several tools, including hls4ml [407], FINN [408, 409], Conifer [410], and fwXmachina [411], have been developed to automatically create firmware from ML algorithms. These tools have been used for applications ranging from jet tagging [412–414] to muon transverse momentum regression [415], on-detector data compression [416], charged particle tracking [417, 418], calorimeter reconstruction [237], and anomaly detection [419–421].

For applications where latency is a key concern (*e.g.*, triggering at collider experiments), various accelerators have been investigated [237, 241, 407, 410, 411, 416, 419, 422–431]. To enable the use of an ML model in resource-constrained or latency-sensitive experimental settings, reducing the size and computational complexity of the model through *compression* is often essential. Compression techniques aim to improve the computational efficiency of models, while keeping the performance as close as possible to the original. The two most ubiquitous methods are *quantization* [432–448], which modifies the number of bits used to calculate and store results in the model, and *pruning* [433, 449–453], which removes model parameters. However, symbolic regression [454] and knowledge distillation [455] have also been explored to learn compact algorithms.

While it is common to use 32-bit floating-point precision, for many applications, this may not be required to ensure adequate performance. Reduced-precision formats, such as integer or fixed-point precision, may be used instead. We can distinguish *post-training quantization* (PTQ), in which model parameters are quantized after a traditional training is performed with 32-bit floating-point precision, and *quantization-aware training* (QAT), in which the training procedure is modified to emulate reduced precision formats. QAT results in better performance for a smaller bit width, but requires (re)training with a dedicated framework [447, 448, 456–458]. Serializing and exchanging quantized models is a challenge addressed by the `QONNX` format, which extends `ONNX` to represent arbitrary-precision quantized neural networks [459].

Pruning is the removal of unimportant weights, quantified in some way, from a neural network. The two main categories are *unstructured pruning*, where weights are removed without considering their location within a network, and *structured pruning*, where weights connected to a particular node, channel, or layer are removed. Pruning reduces the number of computations that must be performed to produce an inference result, thus reducing the hardware resources or algorithm latency. The development of pruning algorithms and understanding their behavior is an active area of research [453]. One relatively simple method is iterative, magnitude-based pruning [407, 460], as shown in Fig. 41.17. In this process, the model is trained with L1 or L2 regularization (discussed in Sec. 41.2.5), resulting in a set of optimal parameters, where some are close to zero. Those parameters with values below a certain threshold can be set to exactly zero (thereby removing them from the model), and training can be repeated. Successive iterations of this procedure can remove more parameters until the desired reduction in parameters, or *sparsity*, is achieved. This process usually results in models that have slightly reduced performance, although the performance loss is typically negligible for sparsities $\lesssim$90% [460]. Pruning and quantization can also be applied together [429].

Finally, some solutions for deployment of ML models involve using cloud resources [461, 462] or using hardware coprocessors, like GPUs and FPGAs, *as a service* [463–466]. In this approach, coprocessor resources are decoupled from CPUs, and CPU-based clients can send inference requests to coprocessor-based servers via network calls. The advantages of this approach are coprocessors can accept inference requests from local or remote CPUs, certain types of coprocessors can be allocated for specific tasks, the coprocessor-to-CPU ratio can be optimized, the separation of software support for coprocessor and CPU workflows reduces the maintenance burden, and developments from industry can be more easily leveraged [465].

42. Monte Carlo Techniques

Revised September 2025 by G. Cowan (RHUL).

Monte Carlo techniques are often the only practical way to evaluate difficult integrals or to sample random variables governed by complicated probability density functions. Here we describe an assortment of methods for sampling some commonly occurring probability density functions.

42.1 Sampling the uniform distribution

Most Monte Carlo sampling or integration techniques assume a "random number generator," which generates uniform statistically independent values on the half open interval $[0, 1)$; for reviews see, *e.g.*, Refs. [1, 2].

Uniform random number generators are available in software libraries such as CLHEP [3], and ROOT [4], as well as from the standard C++ library [5]. The ROOT generators are available in Python using the PyROOT interface [6]. All of the algorithms produce a periodic sequence of numbers, and to obtain effectively random values, one must not use more than a small subset of a single period. The performance of the generators can be investigated with tests such as DIEHARD [7] or TestU01 [8]. Many commonly available congruential generators fail these tests and often have sequences (typically with periods less than 2^{32}), which can be easily exhausted on modern computers.

The generators in ROOT can be accessed through the interface class `TRandom`. These include the widely used `TRandom3` generator, which implements the Mersenne twister algorithm of Matsumoto and Nishimura [9]. This is very fast and has an extremely long period of $2^{19937} - 1$, although it fails some of the more stringent TestU01 tests. Two somewhat slower generators available in ROOT that do not fail any TestU01 tests are the `Ranlux++` generator [10] based on the method of Lüscher [11], and the `MIXMAX` generator of Savvidy [12]. A recent review of high-quality random number generators can be found in Ref. [13].

42.2 Inverse transform method

If the desired probability density function is $f(x)$ on the range $-\infty < x < \infty$, its cumulative distribution function (expressing the probability that $x \leq a$) is given by Eq. (39.6). If a is chosen with probability density $f(a)$, then the integrated probability up to point a, $F(a)$, is itself a random variable which will occur with uniform probability density on $[0, 1]$. Suppose u is generated according to a uniformly distributed in $(0, 1)$. If x can take on any value, and ignoring the endpoints, we can then find a unique x chosen from the p.d.f. $f(x)$ for a given u if we set

$$u = F(x) \ , \tag{42.1}$$

provided we can find an inverse of F, defined by

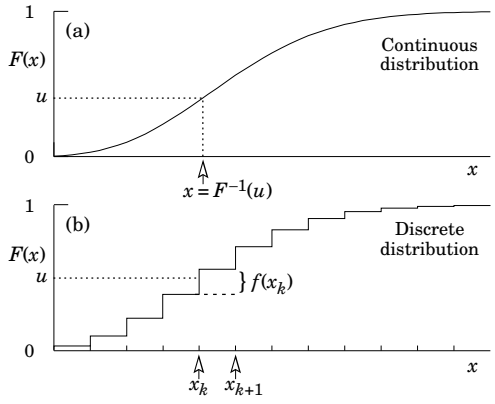

Figure 42.1: Use of a random number u chosen from a uniform distribution (0,1) to find a random number x from a distribution with cumulative distribution function $F(x)$.

$$x = F^{-1}(u) \ . \tag{42.2}$$

This method is shown in Fig. 42.1a. It is most convenient when one can calculate by hand the inverse function of the indefinite integral of f. This is the case for some common functions $f(x)$ such as $\exp(x)$, $(1 - x)^n$, and $1/(1 + x^2)$ (Cauchy or Breit-Wigner), although it does not necessarily produce the fastest generator. Standard libraries contain software to implement this method numerically, working from functions or histograms in one or more dimensions, *e.g.*, the UNU.RAN package [14], available in ROOT.

For a discrete distribution, $F(x)$ will have a discontinuous jump of size $f(x_k)$ at each allowed $x_k, k = 1, 2, \cdots$. Choose u from a uniform distribution on (0,1) as before. Find x_k such that

$$F(x_{k-1}) < u \leq F(x_k) \equiv \text{Prob}\ (x \leq x_k) = \sum_{i=1}^{k} f(x_i) \ ; \tag{42.3}$$

then x_k is the value we seek (note: $F(x_0) \equiv 0$). This algorithm is illustrated in Fig. 42.1b.

42.3 Acceptance-rejection method (Von Neumann)

Very commonly an analytic form for $F(x)$ is unknown or too complex to work with, so that obtaining an inverse as in Eq. (42.2) is impractical. We suppose that for any given value of x, the probability density function $f(x)$ can be computed, and further that enough is known about $f(x)$ that we can enclose it entirely inside a shape which is C times an easily generated distribution $h(x)$, as illustrated in Fig. 42.2. That is, $Ch(x) \geq f(x)$ must hold for all x.

Frequently $h(x)$ is uniform or is a normalized sum of uniform distributions. Note that both $f(x)$ and $h(x)$ must be normalized to unit area, and therefore, the proportionality constant $C > 1$. To generate $f(x)$, first generate a candidate x according to $h(x)$. Calculate $f(x)$ and the height of the envelope $C\,h(x)$; generate u and test if $uC\,h(x) \leq f(x)$. If so, accept x; if not reject x and try again. If we regard x and $uC\,h(x)$ as the abscissa and ordinate of a point in a two-dimensional plot, these points will populate the entire area $C\,h(x)$ in a smooth manner; then we accept those which fall under $f(x)$. The efficiency is the ratio of areas, which must equal $1/C$; therefore we must keep C as close as possible to 1.0. Therefore, we try to choose $C\,h(x)$ to be as close to $f(x)$ as convenience dictates, as in the lower part of Fig. 42.2.

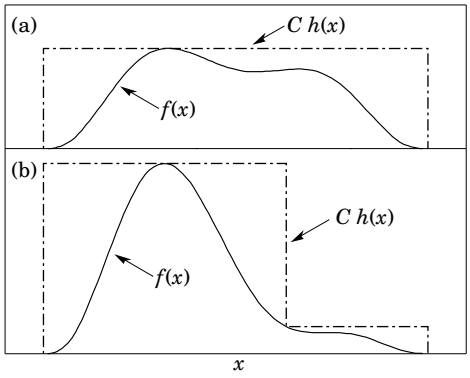

Figure 42.2: Illustration of the acceptance-rejection method. Random points are chosen inside the upper bounding figure, and rejected if the ordinate exceeds $f(x)$. The lower figure illustrates a method to increase the efficiency (see text).

42.4 Algorithms

Algorithms for generating random numbers belonging to many different distributions are given for example by Press [15], Ahrens and Dieter [16], Rubinstein [17], Devroye [18], Walck [19] and Gentle [20]. For many distributions, alternative algorithms exist, varying in complexity, speed, and accuracy. For time-critical applications, these algorithms may be coded in-line to remove the significant overhead often encountered in making function calls.

by KARLSRUHE INSTI

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

In the examples given below, we use the notation for the variables and parameters given in Table 39.1. Variables named "u" are assumed to be independent and uniform on [0,1). Denominators must be verified to be non-zero where relevant.

42.4.1 *Exponential decay*

This is a common application of the inverse transform method, and uses the fact that if u is uniformly distributed in $[0,1]$, then $(1-u)$ is as well. Consider an exponential p.d.f. $f(t) = (1/\tau)\exp(-t/\tau)$ that is truncated so as to lie between two values, a and b, and renormalized to unit area. To generate decay times t according to this p.d.f., first let $\alpha = \exp(-a/\tau)$ and $\beta = \exp(-b/\tau)$; then generate u and let

$$t = -\tau \ln(\beta + u(\alpha - \beta)). \tag{42.4}$$

For $(a,b) = (0,\infty)$, we have simply $t = -\tau \ln u$. (See also Sec. 42.4.6.)

42.4.2 *Isotropic direction in 3D*

Isotropy means the density is proportional to solid angle, the differential element of which is $d\Omega = d(\cos\theta)d\phi$. Hence $\cos\theta$ is uniform $(2u_1 - 1)$ and ϕ is uniform $(2\pi u_2)$. For alternative generation of $\sin\phi$ and $\cos\phi$, see the next subsection.

42.4.3 *Sine and cosine of random angle in 2D*

Generate u_1 and u_2. Then $v_1 = 2u_1 - 1$ is uniform on (−1,1), and $v_2 = u_2$ is uniform on (0,1). Calculate $r^2 = v_1^2 + v_2^2$. If $r^2 > 1$, start over. Otherwise, the sine (S) and cosine (C) of a random angle (*i.e.*, uniformly distributed between zero and 2π) are given by

$$S = 2v_1v_2/r^2 \quad \text{and} \quad C = (v_1^2 - v_2^2)/r^2\ . \tag{42.5}$$

42.4.4 *Gaussian distribution*

If u_1 and u_2 are uniform on (0,1), then

$$z_1 = \sin(2\pi u_1)\sqrt{-2\ln u_2} \quad \text{and} \quad z_2 = \cos(2\pi u_1)\sqrt{-2\ln u_2} \tag{42.6}$$

are independent and Gaussian distributed with mean 0 and $\sigma = 1$.

There are many variants of this basic algorithm, which may be faster. For example, construct $v_1 = 2u_1 - 1$ and $v_2 = 2u_2 - 1$, which are uniform on (−1,1). Calculate $r^2 = v_1^2 + v_2^2$, and if $r^2 > 1$ start over. If $r^2 < 1$, it is uniform on (0,1). Then

$$z_1 = v_1\sqrt{\frac{-2\ln r^2}{r^2}} \quad \text{and} \quad z_2 = v_2\sqrt{\frac{-2\ln r^2}{r^2}} \tag{42.7}$$

are independent numbers chosen from a normal distribution with mean 0 and variance 1. $z_i' = \mu + \sigma z_i$ distributes with mean μ and variance σ^2.

For a multivariate Gaussian with an $n \times n$ covariance matrix V, one can start by generating n independent Gaussian variables, $\{\eta_j\}$, with mean 0 and variance 1 as above. Then the new set $\{x_i\}$ is obtained as $x_i = \mu_i + \sum_j L_{ij}\eta_j$, where μ_i is the mean of x_i, and L_{ij} are the components of L, the unique lower triangular matrix that fulfils $V = LL^T$. The matrix L can be easily computed by the following recursive relation (Cholesky's method):

$$L_{jj} = \left(V_{jj} - \sum_{k=1}^{j-1} L_{jk}^2\right)^{1/2}\ , \tag{42.8a}$$

$$L_{ij} = \frac{V_{ij} - \sum_{k=1}^{j-1} L_{ik}L_{jk}}{L_{jj}}\ ,\ j = 1,...,n\,;\ i = j+1,...,n, \tag{42.8b}$$

where $V_{ij} = \rho_{ij}\sigma_i\sigma_j$ are the components of V. For $n = 2$ one has

$$L = \begin{pmatrix} \sigma_1 & 0 \\ \rho\sigma_2 & \sqrt{1-\rho^2}\,\sigma_2 \end{pmatrix}\ , \tag{42.9}$$

and therefore the correlated Gaussian variables are generated as $x_1 = \mu_1 + \sigma_1\eta_1$, $x_2 = \mu_2 + \rho\sigma_2\eta_1 + \sqrt{1-\rho^2}\,\sigma_2\eta_2$.

42.4.5 $\chi^2(n)$ distribution

To generate a variable following the χ^2 distribution for n degrees of freedom, use the Gamma distribution with $k = n/2$ and $\lambda = 1/2$ using the method of Sec. 42.4.6.

42.4.6 *Gamma distribution*

All of the following algorithms are given for $\lambda = 1$. For $\lambda \neq 1$, divide the resulting random number x by λ.

- If $k = 1$ (the *exponential* distribution), accept $x = -\ln u$. (See also Sec. 42.4.1.)

- If $0 < k < 1$, initialize with $v_1 = (e+k)/e$ (with $e = 2.71828...$ being the natural log base). Generate u_1, u_2. Define $v_2 = v_1u_1$.

  Case 1: $v_2 \leq 1$. Define $x = v_2^{1/k}$. If $u_2 \leq e^{-x}$, accept x and stop, else restart by generating new u_1, u_2.

  Case 2: $v_2 > 1$. Define $x = -\ln([v_1 - v_2]/k)$. If $u_2 \leq x^{k-1}$, accept x and stop, else restart by generating new u_1, u_2. Note that, for $k < 1$, the probability density has a pole at $x = 0$, so that return values of zero due to underflow must be accepted or otherwise dealt with.

- Otherwise, if $k > 1$, initialize with $c = 3k - 0.75$. Generate u_1 and compute $v_1 = u_1(1-u_1)$ and $v_2 = (u_1 - 0.5)\sqrt{c/v_1}$. If $x = k + v_2 - 1 \leq 0$, go back and generate new u_1; otherwise generate u_2 and compute $v_3 = 64v_1^3u_2^2$. If $v_3 \leq 1 - 2v_2^2/x$ **or** if $\ln v_3 \leq 2\{[k-1]\ln[x/(k-1)] - v_2\}$, accept x and stop; otherwise go back and generate new u_1.

42.4.7 *Binomial distribution*

Begin with $k = 0$ and generate u uniform in $[0,1)$. Compute $P_k = (1-p)^n$ and store P_k into B. If $u \leq B$ accept $r_k = k$ and stop. Otherwise, increment k by one; compute the next P_k as $P_k \cdot (p/(1-p)) \cdot (n-k)/(k+1)$; add this to B. Again, if $u \leq B$, accept $r_k = k$ and stop, otherwise iterate until a value is accepted. If $p > 1/2$, it will be more efficient to generate r from $f(r; n, q)$, *i.e.*, with p and q interchanged, and then set $r_k = n - r$.

42.4.8 *Poisson distribution*

Iterate until a successful choice is made: Begin with $k = 1$ and set $A = 1$ to start. Generate u. Replace A with uA; if now $A < \exp(-\mu)$, where μ is the Poisson parameter, accept $n_k = k - 1$ and stop. Otherwise increment k by 1, generate a new u and repeat, always starting with the value of A left from the previous try.

Note that the Poisson generator used in ROOT's `TRandom` classes before version 5.12 (including the derived classes `TRandom1, TRandom2, TRandom3`) uses a Gaussian approximation when μ exceeds a given threshold. This may be satisfactory (and much faster) for some applications. To do this, generate z from a Gaussian with zero mean and unit standard deviation; then use $x = \max(0, [\mu + z\sqrt{\mu} + 0.5])$ where [ ] signifies the greatest integer $\leq$ the expression. The routines from Numerical Recipes [15] and CLHEP's routine `RandPoisson` do not make this approximation.

42.4.9 *Student's t distribution*

Generate u_1 and u_2 uniform in $(0,1)$; then $t = \sin(2\pi u_1)[n(u_2^{-2/n} - 1)]^{1/2}$ follows the Student's t distribution for $n > 0$ degrees of freedom (n not necessarily an integer).

Alternatively, generate x from a Gaussian with mean 0 and $\sigma^2 = 1$ according to the method of 42.4.4. Next generate y, an independent gamma random variate, according to 42.4.6 with $\lambda = 1/2$ and $k = n/2$. Then $z = x/\sqrt{y/n}$ is distributed as a t with n degrees of freedom.

For the special case $n = 1$, the Breit-Wigner distribution, generate u_1 and u_2; set $v_1 = 2u_1 - 1$ and $v_2 = 2u_2 - 1$. If $v_1^2 + v_2^2 \leq 1$ accept $z = v_1/v_2$ as a Breit-Wigner distribution with unit area, center at 0.0, and FWHM 2.0. Otherwise start over. For center M_0 and FWHM Γ, use $W = z\Gamma/2 + M_0$.

by KARLSRUHE INSTIT Phys. A 2026.41. Downloaded from www.worldscientific.com DGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

42.4.10 *Beta distribution*

The choice of an appropriate algorithm for generation of beta distributed random numbers depends on the values of the parameters α and β. For, *e.g.*, $\alpha = 1$, one can use the transformation method to find $x = 1 - u^{1/\beta}$, and similarly if $\beta = 1$ one has $x = u^{1/\alpha}$. For more general cases see, *e.g.*, Refs. [19, 20] and references therein.

42.5 Importance sampling and weighted Monte Carlo

Often the goal of a Monte Carlo calculation is to determine an expectation value of a function $h(x)$, where x is a (single or vector) random variable that follows a pdf $f(x)$,

$$E_f[h(x)] = \int h(x) f(x)\, dx \equiv \mu \,. \tag{42.10}$$

A Monte-Carlo estimator $\hat{\mu}_{\rm MC}$ for μ is the average of N values of $h(x)$ where x is sampled (generated) from $f(x)$, i.e., $\hat{\mu}_{\rm MC} = \frac{1}{N}\sum_{i=1}^{N} h(x_i)$. This has a variance

$$V[\hat{\mu}_{\rm MC}] = \frac{1}{N} V_f[h(x)] = \frac{1}{N}\left(E_f[h^2(x)] - \mu^2\right) \,. \tag{42.11}$$

By using the method of *importance sampling*, one can achieve a reduction in this variance and thus a more accurate determination of the expectation value for a given number of random values generated. The key idea is to rewrite the expectation value in Eq. (42.10) as

$$\mu = \int h(x) f(x)\, dx = \int \frac{h(x) f(x)}{g(x)}\, g(x)\, dx = E_g\left[\frac{h(x) f(x)}{g(x)}\right] \,, \tag{42.12}$$

where $g(x)$ is any other pdf of x with the same support as $f(x)$ (i.e., nonzero for the same region of x). Thus the desired quantity μ is the expectation value with respect to g of $h(x)f(x)/g(x)$. It can be estimated by generating N values of x sampled from g and computing

$$\hat{\mu}_{\rm IS} = \frac{1}{N}\sum_{i=1}^{N} \frac{h(x_i) f(x_i)}{g(x_i)} \,. \tag{42.13}$$

The variance of $\hat{\mu}_{\rm IS}$ is given by

$$V[\hat{\mu}_{\rm IS}] = \frac{1}{N} V_g\left[\frac{h(x) f(x)}{g(x)}\right] = \frac{1}{N}\left(E_g\left[\frac{h^2(x) f^2(x)}{g^2(x)}\right] - \mu^2\right) \,, \tag{42.14}$$

By choosing $g(x)$ such that $h(x)f(x)/g(x)$ is as constant as possible, the variance of $\hat{\mu}_{\rm IS}$ can be substantially reduced. One can show (see, e.g., Refs. [21,22]) that the variance is minimized when $g(x) \propto |h(x)|f(x)$.

An alternative importance sampling estimator can be constructed by replacing the number of generated values N in Eq. (42.13) by the sum $\sum_{i=1}^{N} f(x_i)/g(x_i)$. This can given an even smaller variance at the price of a small bias. It can be of further advantage in problems where the pdf $f(x)$ is known only up to a normalization constant, which then cancels (see Refs. [21, 22]).

A closely related application of importance sampling is the use of weighted Monte Carlo to compute the probability $P_f(x \in A)$ for x to be in a specified region A:

$$P_f(x \in A) = \int_A f(x)\, dx \,. \tag{42.15}$$

It may be, however, that one does not have an MC model capable of generating $x \sim f(x)$, but rather one can generate x according to a different density $g(x)$. The probability $P_f(x \in A)$ can be written

$$\begin{aligned} P_f(x \in A) &= \frac{\int_A \frac{f(x)}{g(x)}\, g(x)\, dx}{\int_A g(x)\, dx} \int_A g(x)\, dx \\ &= E_g[w(x)|x \in A]\, P_g(x \in A) \,, \end{aligned} \tag{42.16}$$

where $w(x) = f(x)/g(x)$ is the *weight function* and $P_g(x \in A) = \int_A g(x)\, dx$ is the probability to find $x \in A$ assuming $x \sim g(x)$. That is, $P_f(x \in A)$ is the conditional expectation value of $w(x)$ with respect to $g(x)$ given $x \in A$ multiplied by the probability to find $x \in A$ under assumption of $g(x)$.

Suppose N values of x are generated according to $g(x)$ and m of them are found in the region A. Then the probability to be in A for $x \sim g(x)$ can be estimated by m/N, and the expectation value above can be obtained from the average of the weights in A. Therefore the desired probability $P_f(x \in A)$ can be estimated using

$$\hat{P}_f(x \in A) = \frac{1}{m}\sum_{i=1}^{m} w_i \;\times\; \frac{m}{N} = \frac{1}{N}\sum_{i=1}^{m} w_i \,, \tag{42.17}$$

where $w_i = w(x_i)$ and the sum includes only the m values of x found in A. That is, when generating the x values according to $g(x)$ instead of $f(x)$, the number of events m found in A is replaced by the corresponding sum of weights. The variance of $\hat{P}_f(x \in A)$ can be found from

$$\widehat{V}[\hat{P}_f(x \in A)] = \frac{1}{N^2}\sum_{i=1}^{m} w_i^2 \,. \tag{42.18}$$

By choosing $g(x)$ so that a larger fraction of x values are sampled in the "important" region A, one can reduce the variance of the estimated probability for a given total number of generated values.

42.6 Markov Chain Monte Carlo

In applications involving generation of random numbers following a multivariate distribution with a high number of dimensions, the transformation method may not be possible and the acceptance-rejection technique may have too low of an efficiency to be practical. If it is not required to have independent random values, but only that they follow a certain distribution, then Markov Chain Monte Carlo (MCMC) methods can be used. In depth treatments of MCMC can be found, *e.g.*, in the texts by Robert and Casella [21], Liu [22], and the review by Neal [23]. HEP-oriented software for MCMC is available from the Bayesian Analysis Toolkit (BAT) [24, 25].

MCMC is particularly useful in connection with Bayesian statistics, where a p.d.f. $p(\boldsymbol{\theta})$ for an n-dimensional vector of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_n)$ is obtained, and one needs the marginal distribution of a subset of the components. Here one samples $\boldsymbol{\theta}$ from $p(\boldsymbol{\theta})$ and simply records the marginal distribution for the components of interest.

A simple and broadly applicable MCMC method is the Metropolis-Hastings algorithm, which allows one to generate multidimensional points $\boldsymbol{\theta}$ distributed according to a target p.d.f. that is proportional to a given function $p(\boldsymbol{\theta})$. It is not necessary to have $p(\boldsymbol{\theta})$ normalized to unit area, which is useful in Bayesian statistics, as posterior probability densities are often determined only up to an unknown normalization constant.

To generate points that follow $p(\boldsymbol{\theta})$, one first needs a proposal p.d.f. $q(\boldsymbol{\theta}; \boldsymbol{\theta}_0)$, which can be (almost) any p.d.f. from which independent random values $\boldsymbol{\theta}$ can be generated, and which contains as a parameter another point in the same space $\boldsymbol{\theta}_0$. For example, a multivariate Gaussian centered about $\boldsymbol{\theta}_0$ can be used. Beginning at an arbitrary starting point $\boldsymbol{\theta}_0$, the Hastings algorithm iterates the following steps:

1. Generate a value $\boldsymbol{\theta}$ using the proposal density $q(\boldsymbol{\theta}; \boldsymbol{\theta}_0)$;

2. Form the Hastings test ratio, $\alpha = \min\left[1, \frac{p(\boldsymbol{\theta})q(\boldsymbol{\theta}_0;\boldsymbol{\theta})}{p(\boldsymbol{\theta}_0)q(\boldsymbol{\theta};\boldsymbol{\theta}_0)}\right]$;
3. Generate a value u uniformly distributed in $[0, 1]$;
4. If $u \leq \alpha$, take $\boldsymbol{\theta}_1 = \boldsymbol{\theta}$. Otherwise, repeat the old point, *i.e.*, $\boldsymbol{\theta}_1 = \boldsymbol{\theta}_0$.
5. Set $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_1$ and return to step 1.

If one takes the proposal density to be symmetric in $\boldsymbol{\theta}$ and $\boldsymbol{\theta}_0$, then this is the *Metropolis*-Hastings algorithm, and the test ratio becomes $\alpha = \min[1, p(\boldsymbol{\theta})/p(\boldsymbol{\theta}_0)]$. That is, if the proposed $\boldsymbol{\theta}$ is at a value of probability higher than $\boldsymbol{\theta}_0$, the step is taken. If the proposed step is rejected, the old point is repeated.

Methods for assessing and optimizing the performance of the algorithm are discussed in, *e.g.*, Refs. [21–23]. One can, for example, examine the autocorrelation as a function of the lag k, *i.e.*, the correlation of a sampled point with that k steps removed. This should decrease as quickly as possible for increasing k.

Generally one chooses the proposal density so as to optimize some quality measure such as the autocorrelation. For certain problems it has been shown that one achieves optimal performance when the acceptance fraction, that is, the fraction of points with $u \leq \alpha$, is around 40%. This can be adjusted by varying the width of the proposal density. For example, one can use for the proposal p.d.f. a multivariate Gaussian with the same covariance matrix as that of the target p.d.f., but scaled by a constant.

43. Monte Carlo Event Generators

Revised Oct 2025 by P. Nason (INFN, Milano-Bicocca; Milano-Bicocca U.) and P. Skands (Monash U.).

General-purpose Monte Carlo (GPMC) generators like HERWIG [1,2], PYTHIA [3,4], and SHERPA [5], provide detailed simulations of high-energy collisions. They play an essential role in QCD modeling (in particular for aspects beyond fixed-order perturbative QCD) and in data analysis and the planning of new experiments, where they are used together with detector simulation to estimate signals and backgrounds in high-energy processes. They are built from several components, that describe the physics starting from very short distance scales, up to the typical scale of hadron formation and decay. Since QCD is weakly interacting at short distances (below a femtometer), the components of the GPMC dealing with short-distance physics are based upon perturbation theory. At larger distances, all soft hadronic phenomena, like hadronization and the formation of the underlying event in hadron collisions, cannot be computed from first principles at present, and one must rely upon QCD-inspired models.

The purpose of this review is to illustrate the main components of these generators. It is divided into four sections. The first one deals with short-distance, perturbative phenomena. The basic concepts leading to the simulations of the dominant QCD processes are illustrated here. In the second section, the nonperturbative transition from partons to hadrons ("hadronization") is treated. The two most popular hadronization models, the string and cluster models, are illustrated. The basics of the implementation of decay chains of unstable "primary" hadrons into stable "secondaries" is also illustrated here. In the third section, models for soft hadron physics are discussed. These include models for the underlying event and for low-$p_\perp$ ("minimum-bias") interactions. Aspects of collective effects, such as Bose-Einstein and color-reconnection effects, are also discussed here. The fourth section briefly introduces the challenges of MC uncertainty estimates and tuning.

We use natural units throughout, such that $c = 1$ and $\hbar = 1$, with energies, momenta and masses measured in GeV, and times and distances measured in GeV^{-1}.

43.1 Short-distance physics in GPMC generators

The short-distance components of a GPMC generator deal with the computation of the primary process at hand, with decays of short-lived particles, and with the generation of QCD and QED radiation. QCD radiation is computable in perturbation theory as long as the time scales involved are well below $1/\Lambda$, where Λ is a typical hadronic scale of few hundred MeV. Because of the presence of logarithmic enhancements due to both collinear and soft emissions, this description involves an indefinite number of final-state particles that are emitted at time scales below $1/\Lambda$. In e^+e^- annihilation into hadrons, for example, the time scale of the primary process is of the order of the inverse of the annihilation energy Q. Collinear and soft emissions take place at all time scales between $1/Q$ and $1/\Lambda$, Technically, the computation of the dominant collinear and soft radiation is carried out by the so called shower algorithms. Historically, "Parton Shower" algorithms were first developed for resummation of collinear singularities. We will briefly describe this approach in this section. We stress, however, that many modern generators adopt approaches that focus initially upon soft singularities, leading to "Dipole Showers", discussed in Sec. 43.1.3.

Collinear singularities arise when the angle between two emitted light partons becomes small. For example, in a process in which a quark and a gluon are emitted, if the angle θ among them is very small (and is smaller than the angles among all other pairs of light partons in the process) the squared amplitude factorizes as follows

$$|M_{qg}|^2 \mathrm{d}\Phi_{qg} \approx |M_q|^2 \,\mathrm{d}\Phi_q \frac{\alpha_s}{2\pi} P_{q,qg}(z)\mathrm{d}z \frac{\mathrm{d}\phi}{2\pi}\frac{\mathrm{d}\theta^2}{\theta^2} \qquad (43.1)$$

where M_{qg}, $\mathrm{d}\Phi_{qg}$ are the amplitude and phase space describing the emission of both the gluon and the quark; M_q, $\mathrm{d}\Phi_q$ are the amplitude and phase space when only the quark is emitted; $z = E_q/(E_q + E_g)$ is the fraction of energy carried by the quark; ϕ is the azimuth of the splitting plane, and $P_{q,qg}(z) = C_F(1+z^2)/(1-z)$ is the Altarelli-Parisi splitting kernel for gluon emission from a quark line, with color factor $C_F = 4/3$. The factorized form of Eq. (43.1) is due to the fact that for small angle the process is dominated by a single amplitude in which the splitting quark is almost on shell and hence propagates for long distances. We define the energy scale corresponding to the inverse of this distance as the *hardness* of the splitting process, so that larger hardness corresponds to shorter distance. We can define the hardness t as the product $E^2\theta^2$, or as the virtuality of the splitting parton p^2, or as a measure of the relative transverse momentum in the splitting such as the k_t of an emitted parton relative to its parent, defined by

$$\begin{aligned} p^2 &= 2E^2 z(1-z)(1-\cos\theta) \approx z(1-z)E^2\theta^2\,, \\ k_t^2 &= z^2(1-z)^2E^2\theta^2\,. \end{aligned} \qquad (43.2)$$

If the region of small values of z and $1-z$ was not important, these definitions would be equivalent. In QCD we also have soft divergences, arising when soft gluons are emitted. In Eq. (43.1) they appear as $z \to 1$, because of the $1/(1-z)$ singularity of $P_{q,qg}(z)$. Thus, we expect that the choice of the appropriate ordering variable will be relevant when dealing with soft divergences (see Sec. 43.3). The $\mathrm{d}\theta^2/\theta^2$ factor in Eq. (43.1) can be equivalently written in terms of the hardness $\mathrm{d}t/t$. After integration, it gives rise to a logarithmic factor $\log(Q^2/\Lambda^2)$. We can have many subsequent splittings, that we can describe by applying Eq. (43.1) recursively, as long as the splittings are strongly ordered in decreasing hardness. This means that, from a typical final-state configuration, by clustering together final-state parton pairs with the smallest hardness recursively, we can reconstruct a branching tree, that may be viewed as the splitting history of the event. We stress that all hardness values between the hardness of the primary process and the cutoff scale Λ are equally involved here. The collinear approximation is applied recursively to splitting processes that have much smaller hardness with respect to all previous ones.

By integrating over the phase space (and neglecting for the moment soft divergences), a process with n collinear splittings will be of order $(\alpha_S(Q^2)\log(Q^2/\Lambda^2))^n$ with respect to the primary process. Since $\alpha_S(Q^2) \propto 1/\log(Q^2/\Lambda^2)$ [6], these corrections are not small. The so-called KLN theorem [7,8] guarantees that large logarithmic enhancements arising from final-state collinear splitting cancel against the virtual corrections in inclusive cross sections, order by order in perturbation theory. Furthermore, the factorization theorem guarantees that initial-state collinear singularities can be factorized into the parton density functions (PDFs) [6]. Therefore, the cross section for the basic process remains accurate up to corrections of higher orders in $\alpha_S(Q)$, provided it is interpreted as an inclusive cross section, rather than as a bare partonic cross section. For example, the leading order (LO) cross section for $e^+e^- \to q\bar{q}$ is a good estimate of the e^+e^- cross section for the production of a pair of quarks accompanied by an arbitrary number of collinear and soft gluons, but is not a good estimate of the cross section for the production of a $q\bar{q}$ pair with a veto on extra radiation. In summary, perturbation theory at fixed order can yield increasingly accurate predictions for inclusive observables, but cannot be used to describe the indefinite sequence of collinear and soft radiations that accompany the hard partons.

Parton-Shower algorithms are used to compute the cross section for generic hard processes including all dominant collinear radiation. These algorithms begin with the generation of the kinematics of the basic process, performed with a probability proportional to its LO partonic cross section. This is interpreted physically as the inclusive cross section for the basic process, followed by an arbitrary sequence of shower splittings. The algorithm then assigns a probability to each splitting sequence, so that the initial LO cross section is partitioned into the cross sections for a multitude of final states of arbitrary multiplicity, with their sum being equal to the cross section of the primary process. This property of the GPMCs reflects the KLN cancellation mentioned earlier, and it is often called "unitarity of the shower process", a name

that reminds us that the KLN cancellation itself is a consequence of unitarity. The fact that a quantum mechanical process can be described in terms of composition of probabilities, rather than amplitudes, follows from the collinear approximation. In fact, because of strong ordering, a radiated parton cannot be collinear to more than one parton in the amplitude, and this suppresses interference effects.

We now illustrate the basic parton-shower algorithm, as first introduced in Ref. [9]. (For more pedagogical introductions see Ref. [10] and references therein.) For simplicity, we consider the example of e^+e^- annihilation into $q\bar{q}$ pairs, where we only have to deal with final state radiation (FSR). We consider all final states that can be built by dressing the q and $\bar{q}$ partons with an indefinite number of splitting processes. By recursively clustering together final state parton pairs with the smallest relative hardness, from each final state configuration we can construct two trees rooted at the q and $\bar{q}$ partons. The momenta of all intermediate lines of the tree diagrams are then uniquely determined from the final-state momenta. Hardnesses in the trees are ordered. One assigns to each splitting vertex the hardness t, the energy fractions z and $1-z$ of the two generated partons, and the azimuth ϕ of the splitting process with respect to the momentum of the incoming parton. For definiteness, we assume that z and ϕ are defined in the center-of-mass (CM) frame of the e^+e^- collision. The differential cross section for a given final state is given by the product of the differential cross section for the initial $e^+e^- \to q\bar{q}$ process, multiplied by a factor

$$\Delta_i(t_m,t_n)\frac{\alpha_S(t)}{2\pi}P_{i,jk}(z)\frac{dt_m}{t_m}dz\frac{d\phi}{2\pi} \tag{43.3}$$

for each intermediate line arising from the nth and ending in the mth splitting vertex. $\Delta(t_m,t_n)$ is the so-called Sudakov form factor

$$\Delta_i(t_m,t_n)=\exp\left[-\int_{t_m}^{t_n}\frac{dq^2}{q^2}\,\frac{\alpha_S(q^2)}{2\pi}\int dz\frac{d\phi}{2\pi}\sum_{jk}P_{i,jk}(z)\right]. \tag{43.4}$$

The suffixes i and jk represent the parton species of the incoming and final partons, respectively, and $P_{i,jk}(z)$ are the Altarelli-Parisi [11] splitting kernels. Notice that the endpoints on the z integration depend upon the definition of hardness. For example, in case of virtuality or transverse momentum ordering, the z integration is automatically cut-off near the extremes, see eq. (1.2). When this is not the case (as, for example, for angular ordering) an explicit cut-off on z must be introduced, corresponding to the requirement that an emission must have some minimum energy to be distinguishable from no emission. For lines originating at the primary vertex, the scale t_n is replaced by the typical scale of the primary process and for lines ending without any further splitting the scale t_m is replaced by t_0, an infrared cutoff defined by the shower hadronization scale (at which the charges are screened by hadronization) or, for an unstable particle, its width (a source cannot emit radiation with a period exceeding its lifetime).

Eq. (43.3) can be obtained by iterating formula Eq. (43.1) recursively, with two important corrections: a) the strong coupling is evaluated at a scale corresponding to the hardness of the splitting process; b) the presence of the Sudakov form factor. Both these modifications arise from the inclusion of all collinear-dominant virtual corrections.

Notice that the Sudakov form factor for a small hardness interval $\Delta_i(t,t+\delta t)$ is equal to one minus the integrated emission probability of Eq. (43.3), i.e. it can be interpreted as the probability of no emission in the interval $t,t+\delta t$. From this, it immediately follows that $\Delta_i(t_m,t_n)$ can be interpreted as the no-emission probability in the full t_m,t_n interval. This interpretation allows one to formulate the shower process as a probabilistic algorithm. We first notice that $0<\Delta_i(t_m,t_n)\leq 1$, where the upper extreme is reached for $t_m=t_n$, and the lower extreme is approached for $t_m=t_0$. Starting from each of the partons in the primary process (e.g., $e^+e^-\to q\bar{q}$), event generation then proceeds recursively as follows. Given a parton exiting a vertex with hardness t_n, (taken to be of order the annihilation scale Q^2 for the first branching) one seeks a solution of the equation $r=\Delta_i(t_m,t_n)$, with $r\in[0,1]$ a uniform random number, and solves it for the hardness of the next branching t_m. If $t_m\leq t_0$, no splitting is generated and the line is interpreted as a final parton. If $t_m>t_0$, a branching is generated at the scale t_m. Its z value and the final parton species jk are generated with a probability proportional to $P_{i,jk}(z)$. If angular correlations are neglected (see Sec. 43.1.1) the azimuth can be generated uniformly. This procedure is started with each of the primary process partons, and is applied recursively to all generated partons. It may generate an arbitrary number of partons, and it stops when no final-state partons undergo further splitting.

The four-momenta of the final-state partons are reconstructed from the momenta of the initial ones, and from the whole sequence of splitting variables, subject to overall momentum conservation. Different algorithms employ different strategies to treat recoil effects due to momentum conservation, which may be applied either locally for each splitting, or globally for the entire set of partons (a procedure called *momentum reshuffling*).

We emphasize that the shower cross sections described above can be derived from perturbative QCD by keeping only the collinear-dominant real and virtual contributions to the cross section. As such it is unpredictive for large-angle radiation. It is thus unsafe to rely upon Parton Shower Monte Carlo alone to compute backgrounds to new physics signals that are characterized by several widely separated jets.

A Shower Monte Carlo builds its final state as if it developed from an iterative process, often with each intermediate stage made available to the user. It should be remarked that the meaning of these intermediate stages is only relevant within the approximation adopted by the generator, and could also differ in different implementations.

43.1.1 *Angular correlations*

In gluon-splitting processes ($g\to q\bar{q},\ g\to gg$) in the collinear approximation, the distribution of the split pair is not uniform in azimuth, and the Altarelli-Parisi splitting functions are recovered only after azimuthal averaging. This dependence is due to the interference of positive and negative helicity states for the gluon that undergoes splitting. Spin correlations propagate through the splitting process, and determine acausal correlations of the EPR kind [12]. A method to partially account for these effects was introduced in Ref. [13], in which the azimuthal correlation between two successive splittings is computed by averaging over polarizations. This can then be applied at each branching step. Acausal correlations are argued to be small, and are discarded with this method, that is still used in `PYTHIA` [3]. A method that fully includes spin correlation effects was later proposed [14], and has been implemented in `HERWIG` [2, 15]. For more recent developements, see Ref. [16] and references therein.

43.1.2 *Initial-state radiation*

Initial-state radiation (ISR) arises because incoming particles may undergo collinear radiation before entering the hard-scattering process. In doing so, they acquire a non-vanishing transverse momentum, and their virtuality becomes negative (spacelike). In order to efficiently sample the hard collision, it turns out to be convenient to develop the ISR shower starting with the highest hardness (i.e. with the hard process) and ending with the smallest (i.e. with the incoming parton in the hadron). Unlike the case of FSR, however, hardness ordering is opposite to time ordering in the ISR case. A corresponding backwards-evolution algorithm was formulated by Sjöstrand [17], and was basically adopted in all shower models. It can be illustrated by considering a primary interaction initiated by a quark where no collinear emissions of hardness $\geq t$ have taken place, and the same process where the quark also emits a collinear gluon of hardness t. The respective cross sections are proportional to

$$\begin{aligned}&|M_q(x)|^2\mathrm{d}x f_q(x,t),\quad \text{and}\\ &|M_q(x)|^2\,\mathrm{d}x\frac{\alpha_s(t)}{2\pi}f_q(x/z,t)P_{q,qg}(z)\mathrm{d}z\frac{\mathrm{d}\phi}{2\pi}\frac{\mathrm{d}t}{t}\,.\end{aligned} \tag{43.5}$$

Here f_q is the quark PDF in the incoming hadron, x is the fraction of momentum of the incoming quark that enters the basic

process, while x/z is the fraction of momentum of the incoming quark *before* it emits the collinear gluon. The elementary *emission probability* is the ratio of the second over the first expression in Eq. (43.5). In analogy with the final state radiation case, this ratio will appear in the exponent of the Sudakov form factor, that (after the inclusion of all splitting subprocesses) is given by

$$\Delta_i^{\rm ISR}(t,t') = \exp\left[-\int_{t'}^{t}\frac{dt''}{t''}\frac{\alpha_{\rm S}(t'')}{2\pi}\int_x^1\frac{dz}{z}\sum_{jk}P_{j,ik}(z)\frac{f_j(t'',x/z)}{f_i(t'',x)}\right]. \tag{43.6}$$

Notice that there are two uses of the PDFs: they are used to compute the cross section for the basic hard process, and they control ISR via backward evolution. Since the evolution is generated with leading-logarithmic accuracy, it is acceptable to use two different PDF sets for these two tasks, provided they agree at the LO level.

In the context of GPMC evolution, each ISR emission generates a finite amount of transverse momentum. Details on how the recoils generated by these transverse "kicks" are distributed among other partons in the event, in particular the ones involved in the hard process, constitute one of the main areas of difference between existing algorithms, see Ref. [10]. An additional $\mathcal{O}(1\,\text{GeV})$ of "primordial k_T" is typically added, to represent the sum of unresolved and/or non-perturbative motion below the shower cutoff scale.

43.1.3 *Soft emissions and QCD coherence*

Soft singularities arise in QCD due to the real or virtual emission of soft gluons. For example, the cross section for the emission of a soft gluon in e^+e^- annihilation into hadrons is given by

$$\begin{aligned}\mathrm{d}\sigma_{q\bar{q}g} &\approx \mathrm{d}\sigma_{q\bar{q}}C_F(4\pi\alpha_s)\left[\frac{2\,p_q\cdot p_{\bar{q}}}{p_q\cdot l\;p_{\bar{q}}\cdot l}\right]\frac{\mathrm{d}^3 l}{2l^0(2\pi)^3}\\ &= \mathrm{d}\sigma_{q\bar{q}}\frac{\alpha_s}{2\pi}C_F\frac{\mathrm{d}l^0}{l^0}\frac{\mathrm{d}\phi}{2\pi}\frac{\mathrm{d}\cos\theta}{1-\cos^2\theta},\end{aligned} \tag{43.7}$$

where p_q, $p_{\bar{q}}$ and l are the quark, antiquark and gluon momentum, and θ and ϕ are the polar and azimuthal angle of the gluon momentum with respect to the quark direction. Since the gluon is soft, we may assume that p_q and $p_{\bar{q}}$ are unaffected by the gluon emission. The soft singularity is manifest in the $\mathrm{d}l^0/l^0$ factor. Notice that also collinear singularities are present at the same time when $\theta\to 0$ and $\theta\to\pi$, corresponding to the gluon becoming collinear to either the quark or the antiquark. It is easy to check that in the collinear limits Eq. (43.7) becomes equivalent to Eq. (43.1) with $P_{q,qg}(z) = C_F 2/(1-z)$, i.e. the limiting form of $P_{q,qg}(z)$ when z approaches 1. Thus, soft singularities coexist with collinear ones, so that two potentially large logarithms can arise simultaneously due to gluon emission.

Unlike the case of collinear emission, soft emission is not tied to a single emitting particle. The amplitude for the emission of a soft gluon from an external (incoming or outgoing) line with momentum p is proportional to $p\cdot\epsilon/p\cdot l$. When squaring the amplitude, products like the one appearing in the square bracket of Eq. (43.1) arise for all pairs of external particles, with the product of a single emission amplitude with itself appearing only if $p^2>0$, i.e. for massive colored particles. Thus, interference plays here a crucial role. This is unlike the case of collinear singularities, where because of strong ordering a radiated parton cannot be collinear to more than one other parton.

It was shown in a set of publications (see Ref. [18]) that, within the conventional parton-shower formalism based on collinear factorization, the region of collinear and soft emissions can be correctly described by using the angle of the emissions as the ordering variable, rather than the virtuality, and by setting the argument of $\alpha_{\rm S}$ at the splitting vertex equal to the relative parton transverse momentum after the splitting. Physically, the ordering in angle approximates the coherent interference arising from large-angle soft emission from a bunch of collinear partons. Without this effect, the particle multiplicity would grow too rapidly with energy, in conflict with e^+e^- data. For this reason, angular ordering is used as the default evolution variable in all versions of `HERWIG` (see Ref. [19]). To partially account for soft interference effects, an angular veto is imposed on the virtuality-ordered evolution in `PYTHIA` 6 [20]. In modern designs this type of fix is avoided, the soft problem being addressed from the start.

A radical alternative formulation of QCD cascades first proposed in Ref. [21] focuses upon soft emission, rather than collinear emission, as the basic splitting mechanism. It then becomes natural to consider a branching process where it is a parton pair (i.e. a dipole) rather than a single parton, that emits a soft parton. Adding a suitable correction for non-soft, collinear partons, one can simultaneously achieve the correct logarithmic structure for both the collinear and soft emissions in the so called leading color approximation, i.e. when terms suppressed by a power of the number of colors are neglected. The `ARIADNE` [22] and `VINCIA` [23] programs are based on this approach. Dipole-type showers [24] are also used by default in `SHERPA` [25] and exist as an option in `HERWIG` [26]. The $p_\perp$-ordered showers in `PYTHIA` 6 and 8 represent a hybrid, combining collinear splitting kernels with dipole kinematics [27].

43.1.4 *Resummation*

Shower Monte Carlo generators perform resummation of all-order collinear- and/or soft-enhanced perturbative contributions, and it is thus natural to compare them to QCD resummation calculations [6]. The latter start from the definition of specific infrared-safe observables, that develop towers of large logarithms in certain regions of phase space, typically organized as

$$A(\alpha_{\rm S})\exp[Lg_0(\alpha_{\rm S}L)+g_1(\alpha_{\rm S}L)+\alpha_{\rm S}g_2(\alpha_{\rm S}L)+\ldots] \tag{43.8}$$

where L is the large logarithm, $\alpha_{\rm S}$ is the strong coupling constant evaluated at some hard scale. The functions A has a power expansion in $\alpha_{\rm S}$ starting with a constant, and the functions g_i have a power series expansion in their argument starting with the linear term. We talk about $\mathrm{N}^n\mathrm{LL}$ accuracy if all g_i functions for $i\le n$ are fully included in the resummation formula, and the A function is given up to the order $n-1$ in $\alpha_{\rm S}$. In particular we talk about LL accuracy if the function g_0 is included, NLL accuracy if also g_1 is included. In both cases only the constant term in A is needed, while for $\mathrm{N}^2\mathrm{LL}$ (or NNLL) g_0, g_1 and g_2 are included and A is given up to order $\alpha_{\rm S}$.

In general, a dedicated resummation calculation must be performed for each new observable. The predictions of shower MCs, on the other hand, are cast in terms of complete sets of final-state momenta, on which one can evaluate any observable; i.e., the shower algorithm itself is normally independent of the specific observable(s) under study. Because of this, it is not easy to qualifying the accuracy of a shower MC using the same criteria adopted in resummation calculation. In spite of this fact, shower MCs perform generally quite well in the description of observables that require resummation. This is related to their inclusion of several universal but formally subleading aspects. There is no guarantee, however, that the shower MC should perform to a certain level of accuracy for all distributions that require resummation. Thus, a more systematic treatment of subleading effects is quite desirable.

Several studies have appeared in the literature, aiming at either improving the current shower algorithms or formulate totally new ones, in such a way that the theoretical accuracy can be discussed in more precise terms [28–31]. Indeed, criteria for defining the accuracy of Shower Generators can be given on a quite general grounds. Two such criteria are [28]:

1. The approximations to multi-parton real matrix elements generated by the shower algorithm must be accurate in the region of phase space that are relevant for $\mathrm{N}^n\mathrm{LL}$ accuracy.
2. The implementation of the virtual corrections must be such that the shower MC agrees with resummed calculations at the $\mathrm{N}^n\mathrm{LL}$ level for a large class of shape variables.

The PanScales collaboration has constructed shower algorithms that are (with some restrictions) NLL accurate according to these criteria (see Ref. [32] and references therein). Other NLL accu-

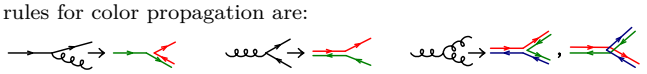
rate (according to the same criteria) shower algorithms have been proposed in refs. [29] and [31].



43.1.5 *Massive quarks*

Quark masses act as a cut-off on collinear singularities. If the mass of a quark is below, or of the order of Λ, its effect in the shower is small. For larger quark masses, like in c, b, or t production, it is the mass, rather than the typical hadronic scale, that cuts off collinear radiation. For a quark with energy E and mass m_Q, the divergent behavior $d\theta/\theta$ of the collinear splitting process is regulated for $\theta \leq \theta_0 = m_Q/E$. We thus expect less collinear activity for heavy quarks than for light ones, which in turn is the reason why heavy quarks carry a larger fraction of the momentum acquired in the hard production process.

This feature can be implemented with different levels of sophistication. Using the fact that soft radiation is strongly suppressed at zero emission angle, older parton shower algorithms simply limited the shower emission to be not smaller than the angle θ_0. More modern approaches are used in both `PYTHIA`, where mass effects are included using a kind of matrix-element correction method [33], and in `HERWIG` and `SHERPA`, where a generalization of the Altarelli-Parisi splitting kernel is used for massive quarks [34]. For newer approaches for QCD evolution in processes with massive partons see ref. [35] and references therein.

43.1.6 *Color information*

In event generators, quarks and antiquarks are represented by color lines, with arrows indicating the direction of color flow. In the limit of infinitely many colors (called the leading color approximation), each such line can be associated with a unique label; the probability for two quarks (or antiquarks) to have the same color (anticolor) vanishes. Moreover, in the same limit gluons can be represented by a pair of color lines with opposite arrows, as can be realized e.g. from the SU(3) group relation $8 = 3 \otimes \bar{3} \ominus 1$. The rules for color propagation are:

During the shower development, partons are connected by color lines. We can have a quark directly connected by a color line to an antiquark, or via an arbitrary number of intermediate gluons, as shown in Fig. 43.1. It is also possible for a set of gluons to be connected cyclically in color, as e.g. in the decay $\Upsilon \to ggg$. The color information is used in angular-ordered showers, where

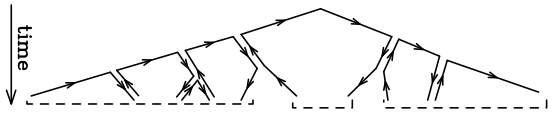


Figure 43.1: Color development of a shower in e^+e^- annihilation. Color-neutral clusters of partons are indicated by the dashed under-brackets.

the angle of color-connected partons (i.e. partons connected by the same color line) determines the initial angle for the shower development, and in dipole showers, where dipoles are formed by color-connected partons. It is also used in hadronization models, where the initial strings or clusters used for hadronization are formed by color-neutral clusters of partons.

43.1.7 *Electromagnetic (and weak) corrections*

The physics of photon emission from charged particles, and of photon splittings to pairs of charged fermions, can also be treated with a shower MC algorithm. High-energy electrons and quarks, for example, are accompanied by bremsstrahlung photons. Also here, similarly to the QCD case, electromagnetic corrections are of order $\alpha_{\rm em} \ln(Q/m)$, where m is the mass of the radiating particle, or even of order $\alpha_{\rm em} \ln(Q/m) \ln(E_\gamma/E)$ for soft γ emissions, so that, especially for the case of electrons, their inclusion in the simulation process is mandatory. This is done in most GPMCs (for a comparative study see [36]), which typically agree in collinear (DGLAP) limits but differ in whether and how soft (multipole) QED interference effects are handled. The specialized generator `PHOTOS` [37] is sometimes used as an afterburner for an improved treatment of QED radiation in non-hadronic resonance decays.

For photon emissions off leptons, the shower can be continued down to virtualities arbitrarily close to the lepton mass shell (unlike the case in QCD). In practice, an infrared cutoff is still required for the shower algorithm to terminate. Therefore, there is always an energy cut-off for emitted photons that depends upon the implementations [36]. In the case of electrons, this energy is typically of the order of its mass. Electromagnetic radiation below this scale is not enhanced by collinear singularities, and is thus bound to be soft, so that the electron momentum is not affected by it.

For photons emitted from quarks, there is instead the obvious limitation that the photon wavelength cannot exceed the typical hadronic size. Longer-wavelength photons are in fact emitted by hadrons, rather than quarks. This last effect is in practice never modeled by existing shower MC implementations. Thus, electromagnetic radiation from quarks is cut off at a typical hadronic scale. Finally, hadron (and τ) decays involving charged particles can produce additional soft bremsstrahlung. In `PYTHIA`, this is done via interfacing with `PHOTOS`, while `HERWIG` and `SHERPA` contain their own dedicated implementations [38,39] based upon the YFS formalism [40], which is also adopted in the KKMC-hh Monte Carlo [41].

At energies significantly above the electroweak (EW) scale, showers involving emissions (and splittings) of weak gauge and Higgs bosons can also be relevant, with recent implementations based on collinear limits ranging from weak-boson emissions from fermions in `PYTHIA` 8 [42], to triple-boson couplings in `HERWIG` 7 [43], to the full set of EW branching processes in `VINCIA` [44].

43.1.8 *Beyond-the-Standard-Model Physics*

The inclusion of processes for physics beyond the Standard Model (BSM) in event generators is to some extent only a matter of implementing the relevant hard processes and (chains of) decays, with the level of difficulty depending on the complexity of the model and the degree of automation [45,46]. Notable exceptions are long-lived colored particles [47], particles in exotic color representations, and particles showering under new gauge symmetries, with a growing set of implementations documented in the individual GPMC manuals. Further complications that may be relevant are finite-width effects (discussed in Sec. 43.1.9) and the assumed threshold behavior.

In addition to code-specific implementations [10], there are a few commonly adopted standards that are useful for transferring information and events between codes. Currently, the most important of these is the Les Houches Event File (LHEF) standard [48], normally used to transfer parton-level events from a hard-process generator to a shower generator. Another important standard is the Supersymmetry Les Houches Accord (SLHA) format [49], originally used to transfer information on supersymmetric particle spectra and couplings, but by now extended to apply also to more general BSM frameworks and incorporated within the LHEF standard [50]. Unfortunatly, at present no standard method for handling multiple shower starting scales has been define in the LHEF, so that further code, specific to the given GPMC, needs to be added to the interface in this case.

43.1.9 *Decay Chains and Particle Widths*

In most BSM processes and some SM ones, an important aspect of the event simulation is how decays of short-lived particles, such as top quarks, EW and Higgs bosons, and new BSM resonances, are handled. We here briefly summarize the spectrum of possibilities, but emphasize that there is no universal standard. Users are advised to check whether the treatment of a given code is adequate for the physics study at hand.

The appearance of an unstable resonance as a physical particle at an intermediate stage of the event generation implies that its production and decay processes are treated as being factorized. This is valid up to corrections of order Γ/m_0, with Γ the width and m_0 the pole mass. States whose widths are a substantial fraction of their mass should instead be treated as intrinsically off-shell internal propagator lines.

For states treated as physical particles, two aspects are relevant: the mass distribution of the decaying particle itself and the distributions of its decay products. For the former, matrix-

element generators often use a simple δ function at m_0. The next level up, typically used in GPMCs, is to use a Breit-Wigner distribution, which formally resums higher-order virtual corrections to the mass distribution. Note, however, that this still only generates an improved picture for *moderate* fluctuations away from m_0. Similarly to above, particles that are significantly off-shell (in units of Γ) should not be treated as resonant, but rather as internal off-shell propagator lines. In most GPMCs, further refinements are included, for instance by letting Γ be a function of m ("running widths") and by limiting the magnitude of the allowed fluctuations away from m_0. We finally point out that NLO+PS generators have appeared that can deal with resonances including off-shell effects, non-resonance contributions and interference of radiation generated in resonance decay and production, see [51] and references therein. A new "interleaved" shower treatment also allows for interference between production and decay in the `VINCIA` model [44].

For the distributions of the decay products, the simplest treatment is again to assign them their respective m_0 values, with a uniform phase-space distribution. A more sophisticated treatment distributes the decay products according to the differential decay matrix elements, capturing at least the internal dynamics and helicity structure of the decay process, including EPR-like correlations. Further refinements include polarizations of the external states [52] and assigning the decay products their own Breit-Wigner distributions, the latter of which opens the possibility to include also intrinsically off-shell decay channels, like $H \to WW^*$.

GPMC manuals often give instructions on how to include new decay modes, at varying levels of sophistications ranging from simple uniform phase-space sampling (which the user can reweight a posteriori) and step-function thresholds, to fully matrix-element weighted decay implementations including potential off-shell / threshold effects.

During subsequent showering of the decay products, most parton-shower models will preserve the total invariant mass of the decayed resonance, so as not to skew the original resonance shape. In the context of passing externally generated LHEF files [48] to a GPMC for showering, note that this is only possible if the intermediate resonances are present (with status code 2) in the LHEF event record [53].

43.1.10 *Matching and Merging with Fixed-Order Matrix Elements*

Shower algorithms are based upon a combination of the collinear (small-angle) and soft (small-energy) approximations and are thus normally inaccurate for hard, wide-angle emissions (i.e., additional well-resolved jets). They also contain only the leading singular pieces of next-to-leading order (NLO) and higher corrections to the basic process.

Traditional GPMCs, like `HERWIG` and `PYTHIA`, have included for a long time the so called Matrix-Element Corrections (MEC), first formulated in Ref. [54] with later developments summarized in Ref. [10]. They are typically available for $2 \to 1$ or $1 \to 2$ processes, like DIS, vector boson and Higgs production and decays, and top decays. The MEC corrects the emission of the hardest jet at large angles, so that it becomes exact at LO. A generalization of the method to multiple emissions was formulated in Ref. [55].

Aside from MECs implemented directly in the GPMCs, the improvements on the parton-shower description of hard collisions have been made in two main directions: the so called Matrix Elements and Parton Shower matching (ME+PS from now on), and the matching of NLO calculations and Parton Showers (NLO+PS). We now discuss each of these, and then briefly summarize techniques becoming available for combining them.

The ME+PS method allows one to use tree-level matrix elements for hard, large-angle emissions. It was first formulated in the so-called CKKW paper [56], and several variants have appeared, including the CKKW-L, MLM, pseudoshower and MESS methods, see refs. [10, 57, 58] and references therein. So called "Truncated Showers" are required [59] to maintain color coherence when interfacing to angular-ordered parton showers, and care must be taken to use consistent α_S choices for the real (ME-driven) and virtual (PS-driven) corrections [60].

In the ME+PS method one typically starts by generating LO matrix elements for the production of the basic process plus a certain number $\leq n$ of other partons. A minimum separation is imposed on the produced partons, requiring, for example, that the relative transverse momentum in any pair of partons is above a given cut $Q_{\rm cut}$. One then reweights these amplitudes in such a way that, in the strongly ordered region, the virtual effects that are included in the shower algorithm (i.e. running couplings and Sudakov form factors) are also accounted for. At this stage, before parton showers are added, the generated configurations are tree-level accurate at large angle, and at small angle they match the results of the shower algorithm, except that there are no emissions below the scale $Q_{\rm cut}$, and no final states with more than n partons. These kinematic configurations are thus fed into a GPMC, that must generate all splittings with relative transverse momentum below the scale $Q_{\rm cut}$, for initial events with less than n partons, or below the scale of the smallest pair transverse momentum, for events with n partons. The matching parameter $Q_{\rm cut}$ must be chosen to be large enough for fixed-order perturbation theory to hold, but small enough so that the shower is accurate for emissions below it. Notice that the accuracy achieved with MEC is equivalent to that of ME+PS with $n = 1$, where MEC has the advantage of not having a matching parameter $Q_{\rm cut}$.

The popularity of the ME+PS method is due to the fact that processes with many jets often appear as backgrounds to new-physics searches. These jets are typically required to be well separated, and to have large transverse momenta. These kinematic configurations are exactly those for which pure shower algorithms are unreliable, hence it is mandatory to describe them using at least LO matrix elements.

Several ME+PS implementations use existing LO generators, like `ALPGEN` [61], `MADGRAPH` [62], and others summarized in Ref. [57], for the calculation of the matrix elements, and feed the partonic events to a GPMC like `PYTHIA` or `HERWIG` using the Les Houches Interface for User Processes (LHI/LHEF) [48, 53]. `SHERPA` and `HERWIG` also include their own matrix-element generators.

The NLO+PS methods promote the accuracy of the generation of the basic process from LO to NLO in QCD. They must thus include the radiation of one extra parton with tree-level accuracy, since this radiation constitutes a NLO correction to the basic process. They must also include NLO virtual corrections. They can be viewed as an extension of the MEC methods with the inclusion of NLO virtual corrections. They are however more general, since they are applicable to processes of arbitrary complexity. Two of these methods are now widely used: MC@NLO [63] and POWHEG [59, 64], with several alternative methods now also being pursued [65]. For more recent proposals see refs. [66, 67] and references therein.

NLO+PS generators produce NLO accurate distributions for inclusive quantities, and generate the hardest jet with tree-level accuracy. Note also that the optimal tuning of an NLO+PS generator may well be different from that of the pure PS.

Several NLO+PS processes are implemented in the MC@NLO program [63], together with the `AMC@NLO` development [68], and in the POWHEG-BOX framework [64]. `HERWIG` supports its own variants of POWHEG and MC@NLO for several processes. `SHERPA` instead implements a variant of the MC@NLO method.

For applications that require an accurate description of more than one hard, large-angle jet associated with the primary process, ME+PS schemes are still superior to NLO+PS ones. Ideally, one would like to improve NLO generators in such a way that also the production of associated jets achieves NLO accuracy. The FXFX [69], UNLOPS [70], MiNLO [71] and `MEPS@NLO` [72] methods address this problem. The solution of this problem is also a prerequisite for the construction of NNLO+PS generators, i.e. generators that, besides being NLO accurate for the production of an associated jet, are also NNLO accurate for fully inclusive observables. Three different approaches have appeared in the literature for dealing with this problem: the UN^{2}LOPS, based upon UNLOPS method [73]; methods extending the MiNLO approach by reweigthting [74] and by the so called MiNNLO$_{\rm PS}$ technique [75]; and the GENEVA method [76]. Several processes have been implemented with the MiNLO related and GENEVA meth-

ods, mostly for the production of color singlet systems, with the exception of the recent MiNNLO$_{\rm PS}$ implementation of $t\bar{t}$ production (see refs. [65, 77, 78] for an extensive list of references).

43.2 Hadronization Models

In the context of GPMCs, *hadronization* denotes the process by which a set of colored partons (*after* showering) is transformed into a set of "primary hadrons", which may then subsequently decay further (to "secondary hadrons"). This non-perturbative transition takes place at the *hadronization scale* $Q_{\rm had}$, which by construction is equal to the infrared cutoff of the parton shower. In the absence of a first-principles solution to the relevant dynamics, GPMCs use QCD-inspired phenomenological models to describe this transition.

An important result in "quenched" lattice QCD (see Chap. 17 of PDG book) is that the potential energy between two partons with opposite color charges grows linearly with their separation, at distances greater than about a femtometer. This is known as "linear confinement", and it forms the starting point for the *string model of hadronization*, discussed below in Sec. 43.2.1. Alternatively, a property of perturbative QCD called "preconfinement" is the basis of the *cluster model of hadronization*, discussed in Sec. 43.2.2.

A key difference between MC hadronization models and the fragmentation-function (FF) formalism used to describe inclusive hadron spectra in perturbative QCD (see Chap. 9 and Chap. 19 of PDG book) is that FFs can be defined at an arbitrary perturbative scale Q while MC hadronization models are intrinsically defined at the scale $Q_{\rm had}$. Direct comparisons are therefore only meaningful if the perturbative evolution between Q and $Q_{\rm had}$ is taken into account. FFs are calculable in pQCD, given a non-perturbative initial condition obtained by fits to hadron spectra. In the MC context, one can prove that the correct QCD evolution of the FFs arises from the shower formalism, with the hadronization model providing an explicit parameterization of the non-perturbative component. However, the MC modeling of shower and hadronization includes much more information on the final state since it is fully exclusive (i.e., it addresses all particles in the final state explicitly), while FFs only describe inclusive spectra. This exclusivity also enables MC models to make use of the color-flow information coming from the perturbative shower evolution (see Sec. 43.1.6) to determine between which partons confining potentials should arise. E.g., in the string picture, the nonperturbative limit of a QCD dipole is a string piece [79].

Given an ideal, exact hadronization model, its dependence on the scale $Q_{\rm had}$ should in principle be compensated by the corresponding scale dependence of the shower algorithm, which stops generating branchings at the scale $Q_{\rm had}$. However, due to their complicated and fully exclusive nature, it is generally not possible to enforce this compensation automatically in MC models. One must therefore be aware that the nonperturbative model parameters must be "retuned" by hand if the infrared cutoff is modified. Any other changes to the perturbative part of the calculation, such as matching to further (fixed-order or resummed) coefficients, may also necessitate a retuning. Tuning is discussed briefly in Sec. 43.4.

The impact of hadronization corrections in a GPMC can be estimated by switching off hadronization. It should be emphasized, however, that the so-called "parton level" obtained this way is not a fully universal concept. This is because $Q_{\rm had}$ is typically defined in a model-dependent way, via a cutoff in the respective shower model's evolution variable, sometimes with supplementary cutoffs, e.g., in invariant mass, $p_{\rm T}$, or the like and different tunes possibly using different numerical values for the cutoff(s). Variations of the main shower cutoff scale (e.g., by a factor of 2) may give an indication of the level of model dependence, which may be mild for sufficiently inclusive observables. Nevertheless our recommendation is to avoid correcting experimental measurements to "parton level" as the intrinsic model dependence will always imply a loss of accuracy.

43.2.1 *The String Model*

Starting from early concepts [80], several hadronization models based on strings have been proposed [10]. Of these, the most widely used today is the so-called Lund model [81, 82], implemented in PYTHIA [3, 4]. We concentrate on that particular model here, though many of the overall concepts would be shared by any string-inspired method.

Consider a quark and an antiquark that have a large relative momentum and which are in an overall color-singlet state, such as the $\bar{q}q$ pair produced at the end of the shower in the center of Fig. 43.1. As the charges move apart, linear confinement implies that a potential $V(r) = \kappa\, r$ is reached for large distances r. (At short distances, there is a Coulomb term $\propto 1/r$ as well, but this is neglected in the Lund string.) This potential describes a string with tension $\kappa \sim 1\,\text{GeV/fm} \sim 0.2\,\text{GeV}^2$. The physical picture is that of a color flux tube being stretched between the q and the $\bar{q}$. As the string grows, the nonperturbative creation

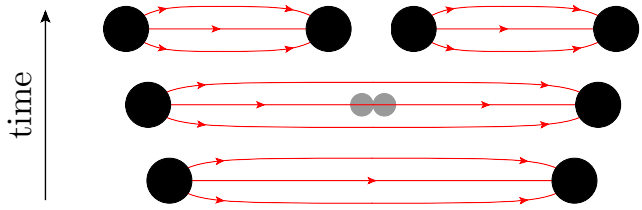

Figure 43.2: Illustration of string breaking by quark pair-creation in the string field.

of quark-antiquark pairs can break the string, via the process illustrated in Fig. 43.2. If either of the resulting string pieces after the break still has a large invariant mass, new breaks will then continue to occur until every piece has a mass of the order of that of a typical hadron. In nature, quantum mechanics ensures that these masses are (Breit-Wigner-distributed around) those of the physical hadron states in QCD, while in an algorithmic implementation, this is less trivial to impose. Within the Lund model, the constraint that each final string piece must have a mass consistent with that of physical hadron is addressed by first noting that each breakup vertex is spacelike separated from all others (the string cannot break again in the forward lightcone of a point where it has already broken); since the breakups are therefore causally disconnected, they do not have to be considered in any particular order. The Lund model exploits this to perform the fragmentation in an outwards-in manner [82], splitting off one physical hadron at a time from either the left or right endpoint (chosen randomly in each step).

The first hadron to be generated (starting either from the left or right) is thus the "outermost" one (sometimes called the "first-rank" hadron), formed by combining the original hadronizing endpoint quark (or antiquark) q_0 with an antiquark (or quark) $\bar{q}_1$ produced by the first breakup. The new leftover quark (or antiquark) q_1 becomes the string endpoint for the next iteration, in a Markov chain which continues, alternating randomly between the left and right ends of the string, until finally a small last bit of string is decayed directly to two hadrons, with no energy left over.

Not only does this allow for the hadron that is split off in each step to be assigned a physical mass, the fact that the fragmentation spectrum should be independent of whether one performs the fragmentation from left to right or vice versa places a strong constraint on the form of the nonperturbative *string fragmentation function*[1], $f(z)$, which governs the probability for the hadron produced in a given step to take a fraction $z \in [0, 1]$ of the remaining energy. Thus, in the Lund model, causality dictates that the fragmentation function should be of the form,

$$f(z) \propto \frac{1}{z}(1-z)^a \exp\left(-\frac{b\,(m_h^2 + p_{{\rm T},h}^2)}{z}\right) . \qquad (43.9)$$

This is known as the Lund symmetric fragmentation function (normalized to unit integral). The dimensionless parameter a

[1] Note that the string fragmentation function differs from the parton-to-hadron fragmentation functions discussed earlier. In principle, the two kinds should be related (with the latter evolved to a low scale of the order of the hadronization scale), but the relationship is not trivial and goes beyond the scope of this review.

by KARLSRUHE INSTI

dampens the hard tail of the fragmentation function, towards $z \to 1$, and may in principle be flavor-dependent, while b, with dimension GeV^{-2}, is a universal constant related to the string tension [82] which determines the behavior in the soft limit, $z \to 0$. Note that the dependence on the hadron mass, m_h, in $f(z)$ implies that heavier hadrons have higher $\langle z \rangle$. We return to the transverse momentum $p_{\mathrm{T},h}$ below.

The model is Lorentz invariant, so considerations involving boosted string systems are straightforward, involving the usual Lorentz effects.

As a by-product, the probability distribution in invariant time τ of $q'\bar{q}$ breakup vertices, or equivalently $\Gamma = (\kappa\tau)^2$, is also obtained, with $dP/d\Gamma \propto \Gamma^a \exp(-b\Gamma)$ implying an area law for the color flux, and the average breakup time lying along a hyperbola of constant invariant time $\tau_0 \sim 10^{-23}$s [82].

For massive endpoints (e.g. c and b quarks), which do not move along straight lightcone sections, the exponential suppression with string area leads to modifications of the form $f(z) \to f(z)/z^{b\,m_Q^2}$, with m_Q the mass of the heavy quark [83]. Although different forms, such as the Peterson formula [84], can also be used to describe inclusive heavy-meson spectra (see Sec 19.8 of PDG book), such choices are not strictly consistent with causality in the string framework. For a recent summary of heavy-quark hadronization, see Ref. [85].

43.2.1.1 *Strings with Gluons*

In the string model, energetic gluons lead to transverse "kinks" on strings, illustrated in Fig. 43.3. The order of these kinks follows from the color ordering produced by the parton shower, cf. the $\bar{q}gggq$ and $\bar{q}gq$ systems on the left and right part of Fig. 43.1. (Modifications to this order, by possible color reconnection/rearrangement effects, are discussed in Sec. 43.3.2.) Thus gluons

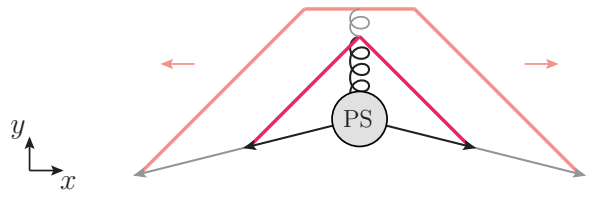

Figure 43.3: Schematic illustration of an $e^+e^- \to qg\bar{q}$ configuration emerging from the parton shower (PS). Snapshots of string positions are shown at two different times (full and shaded lines respectively). The gluon forms a transverse kink which grows in the y direction until all the gluon's kinetic energy has been used up.

effectively build up a transverse structure in the originally one-dimensional object, with infinitely soft ones smoothly absorbed into the string. Note: cyclic topologies made entirely of gluons (closed strings) are also possible, e.g. in decays such as $H \to gg$ or $\Upsilon \to ggg$. The space-time evolution is more involved when kinks are taken into account [82], but no additional free parameters need to be introduced. The main difference between quark and gluon hadronization stems from the fact that gluons are connected to two string pieces (one on either side), while quarks are only connected to a single string piece. Hence, the relative rate of energy loss per unit invariant time — and consequently also the rate of hadron production — is larger by a factor of 2 for gluons (analogously to the ratio of gluon to quark color charges $C_A/C_F = 2.25$).

43.2.1.2 *Transverse Momentum and Flavors*

For each breakup vertex, quantum mechanical tunneling is assumed to control the masses and p_{T} kicks (transverse to the string axis, in a frame in which the string itself has no transverse motion) that can be produced, leading to a Gaussian suppression

$$\mathrm{Prob}(m_q^2, p_{\mathrm{T},q}^2) \;\propto\; \exp\left(\frac{-\pi m_q^2}{\kappa}\right) \exp\left(\frac{-\pi p_{\mathrm{T},q}^2}{\kappa}\right) , \quad (43.10)$$

where m_q is the mass of the produced quark flavor and p_{T} is the nonperturbative transverse momentum imparted to it by the breakup process, with a universal average value of $\left\langle p_{\mathrm{T},q}^2 \right\rangle = \kappa/\pi \sim (250\,\mathrm{MeV})^2$. The antiquark has the same mass and opposite p_{T}.

In an MC model with a fixed shower cutoff t_0, the effective amount of p_{T} in string breaks may be larger than the purely nonperturbative κ/π above, to account for effects of additional (unresolved) radiation below t_0.

From the mass term in Eq. (43.10), one concludes that charm and bottom quarks are too heavy to be produced in string breaks, while strange quarks will be suppressed relative to up and down ones. Lacking unambiguous and precise mass definitions for light quarks, however, the effective amount of strangeness suppression is normally extracted from experimental data, using observables such as K/π, K^*/ρ, and ϕ/K^* ratios.

Baryon production can also be incorporated, at various levels of sophistication. The simplest option is to allow string breaks to produce a diquark-antidiquark pair, where a diquark is a loosely bound states of two quarks in an overall $\bar{3}$ representation. Again, the relative rate of such pairs is extracted from data, e.g. using p/π or Λ/K ratios. Since the perturbative shower splittings do not produce diquarks, the optimal value for this parameter is mildly correlated with the amount of $g \to q\bar{q}$ splittings in the shower. More sophisticated options, including the so-called "popcorn" mechanism, are discussed in Ref. [82]. Finally, the PYTHIA framework also allows for baryon string junctions [86], in which three string pieces (which can be thought of as red, green, and blue, respectively) join together. These are used, e.g., to model the fragmentation of baryon beam remnants, and can also be created (in pairs of junctions and antijunctions) in some color-reconnection scenarios [87], making the effective baryon-to-meson ratios in such models dependent on the amount and type of color reconnections that occur in each event

The next step of the algorithm is the assignment of the produced quarks within hadron multiplets. Using a nonrelativistic classification of spin states, the hadronizing q may combine with the $\bar{q}'$ from a newly created breakup to produce a hadron of a given spin S and angular momentum L. The lowest-lying pseudoscalar and vector meson multiplets, and spin-1/2 and -3/2 baryons, are assumed to dominate in a string framework[2], but individual rates are not predicted by the model, and hence the ratios of spin-1 to spin-0 mesons and diquarks are free parameters (modulo a factor 3 from spin counting) which must be constrained by data.

43.2.2 *The Cluster Model*

The cluster hadronization model is based on *preconfinement*, i.e., on the observation [88, 89] that the color structure of a perturbative QCD shower evolution at any scale Q_0 is such that color-singlet subsystems of partons (labeled "clusters") occur with a universal invariant mass distribution which is power suppressed at large masses. For any starting scale $Q \gg Q_0 \gg \Lambda_{\mathrm{QCD}}$, only the number of such clusters depends on Q, while the shape of their mass distribution only depends on Q_0 and on Λ_{QCD}.

Following early models based on this universality [9, 90], the cluster model developed by Webber [91] has for many years been a hallmark of the HERWIG generators, with an alternative implementation [92] now available in the SHERPA generator. The key idea, in addition to preconfinement, is to force "by hand" all gluons to split into quark-antiquark pairs at the end of the parton shower. Compared with the string description, this effectively amounts to viewing gluons as "seeds" for string breaks, rather than as kinks in a continuous object. After the splittings, a new set of low-mass color-singlet clusters is obtained, formed only by quark-antiquark pairs. These can be decayed to on-shell hadrons in a simple manner, with the relative yields of different hadron species mainly governed by their masses and the size of the phase space.

The algorithm starts by generating the forced $g \to q\bar{q}$ breakups, and by assigning flavors and momenta to the produced quark

[2] In PYTHIA, the four $L = 1$ meson multiplets (scalar, tensor, and 2 pseudovectors) are also available but are disabled by default, since many states (and their decays) are poorly known.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

pairs. For a typical shower cutoff corresponding to a gluon virtuality of $Q_{\rm had} \sim 1\,\text{GeV}$, the $p_{\rm T}$ generated by the splittings can be neglected. The constituent light-quark masses, $m_{u,d} \sim 300\,\text{MeV}$ and $m_s \sim 450\,\text{MeV}$, imply a suppression (typically even an absence) of strangeness production. In principle, the model also allows for diquarks to be produced at this stage, but due to the larger constituent masses this would only become relevant for shower cutoffs larger than 1 GeV.

If a cluster formed in this way has an invariant mass above some cutoff value, typically 3–4 GeV, it is forced to undergo sequential $1 \to 2$ cluster breakups, along an axis defined by the constituent partons of the original cluster, until all sub-cluster masses fall below the cutoff value. Due to the preservation of the original axis in these breakups, this treatment has some resemblance to the string-like picture, though the nonperturbative $p_\perp$ kicks generated in this way are generally larger, up to half the allowed cluster mass.

Next, on the low-mass side of the spectrum, some clusters are allowed to decay directly to a single hadron, with nearby clusters absorbing any excess momentum. This improves the description of the high-z part of the spectrum — where the hadron carries almost all the momentum of its parent jet — at the cost of introducing one additional parameter, controlling the probability for single-hadron cluster decay.

Having obtained a final distribution of small-mass clusters, now with a strict cutoff at 3–4 GeV and with the component destined to decay to single hadrons already removed, the remaining clusters are interpreted as a smoothed-out spectrum of excited mesons, each of which decays isotropically to two hadrons, with relative probabilities proportional to the available phase space for each possible two-hadron combination that is consistent with the cluster's internal flavors, including spin degeneracy. It is important that all the light members (containing only uds) of each hadron multiplet be included, as the absence of members can lead to unphysical isospin or SU(3) flavor violation. Typically, the lightest pseudoscalar, vector, scalar, even and odd charge conjugation pseudovector, and tensor multiplets of light mesons are included. In addition, some excited vector multiplets of light mesons may be available. For baryons, usually only the lightest flavor-octet, -decuplet and -singlet baryons are present, although both the `HERWIG` and `SHERPA` implementations now include some heavier baryon multiplets as well.

Differently from the string model, the mechanism of phase-space suppression employed here leads to a natural enhancement of the lighter pseudoscalars, and no parameters beyond the spectrum of hadron masses need to be introduced at this point. The phase space also limits the transverse momenta of the produced hadrons relative to the jet axis.

Note that, since the masses and decays of excited heavy-flavor hadrons in particular are not well known, there is some freedom in the model to adjust these, which in turn will affect their relative phase-space populations.

43.2.3 *Hadron and τ Decays*

Of the so-called primary hadrons, originating directly from string breaks and/or cluster decays (see above), many are unstable and so decay further, until a set of particles is obtained that can be considered stable on time scales relevant to the given measurement. (A typical hadron-collider definition of a "stable particle" $c\tau \geq 10\,\text{mm}$ includes weakly-decaying strange hadrons K, Λ, $\Sigma^\pm$, $\bar{\Sigma}^\pm$, Ξ, Ω.) The decay modeling can therefore have a significant impact on final particle yields and spectra, especially for the lowest-lying hadronic states, which receive the largest relative contributions from decays (feed-down). This interplay also implies that hadronization parameters may need to be retuned if significant changes to the decay treatment are made.

Particle summary tables, such as those given elsewhere in this *Review*, represent a condensed summary of the available experimental measurements and hence may be incomplete and/or exhibit inconsistencies within the experimental precision. In an MC decay package, on the other hand, all information must be quantified and consistent, with all branching ratios summing to unity. When adapting particle summary information for use in a decay package, a number of choices must therefore be made. The amount of ambiguity increases as more excited hadron multiplets are added to the simulation, about which less and less is known from experiment, with each GPMC making its own choices.

A related choice is how to distribute the decay products differentially in phase space, in particular which matrix elements to use. Historically, MC generators contained matrix elements only for selected (generator-specific) classes of hadron and τ decays, coupled with a Breit-Wigner smearing of the masses, truncated at the edges of the physical decay phase space (the treatment of decay thresholds can be important for certain modes [10]). A more sophisticated treatment can then be obtained by reweighting the generated events using the obtained particle four-momenta and/or by using specialized external packages such as `EVTGEN` [93] for hadron decays and `TAUOLA` [94] for τ decays.

More recently, `HERWIG` and `SHERPA` include helicity-dependence in τ decays [95, 96], with a more limited treatment available in `PYTHIA` 8 [4]. The `HERWIG` and `SHERPA` generators have also included significantly improved internal simulations of hadronic decays, which include spin correlations between those decays for which matrix elements are used. Photon-bremsstrahlung effects are discussed in Sec. 43.1.7.

`HERWIG` and `PYTHIA` include the probability for B mesons to oscillate into $\bar{B}$ ones before decay. `SHERPA` and `EVTGEN` also include CP-violating effects and, for common decay modes of the neutral meson and its antiparticle, the interference between the direct decay and oscillation followed by decay.

We end on a note of warning on double counting. This may occur if a particle can decay via an intermediate on-shell resonance. An example is $a_1 \to \pi\pi\pi$ which may proceed via $a_1 \to \rho\pi$, $\rho \to \pi\pi$. If these decay channels of the a_1 are both included, each with their full partial width, a double counting of the on-shell $a_1 \to \rho\pi$ contribution would result. Such cases are normally dealt with consistently in the default MC generator packages, so this warning is mostly for users that wish to edit decay tables on their own.

43.3 Models for Soft Hadron-Hadron Physics

43.3.1 *Underlying Event*

In the GPMC context, "underlying event" (UE) denotes any additional activity *beyond* the basic process and its associated ISR and FSR activity. The UE is thus only defined in the context of events selected with a "hard" (i.e., high-$\text{p}_\perp$) trigger which defines the basic process at hand. The dominant contribution to the UE is believed to come from additional color exchanges between the colliding hadronic states. These multiple exchanges can be modeled either as additional perturbative (mainly t-channel gluon) exchanges, called multiple parton-parton interactions (MPI), or nonperturbatively using so-called cut pomerons (roughly equivalent to exchange of gluons with $p_\perp \to 0$). The experimental observation that events with a hard trigger are accompanied by a higher-than-average level of associated activity is called the "jet pedestal" effect.

The most clearly identifiable consequence of MPI is arguably the possibility of observing several hard parton-parton interactions in one and the same hadron-hadron event. Typically, these are QCD $2 \to 2$ interactions, which produce additional back-to-back jet pairs, with each pair having a small value of $\text{sum}(\vec{p}_\perp)$. The fraction of MPI that give rise to additional reconstructible jets is, however, small. Soft interactions, that exchange color and a small amount of momentum without giving rise to observable jets, are much more plentiful, and can give significant corrections to the color flow and total scattered energy of the event. This affects the final-state activity in a more global way, increasing hadron-multiplicity and summed E_T distributions, and contributing to the break-up of the beam remnants in the forward direction.

The first detailed Monte Carlo model for perturbative MPI was proposed in Ref. [97], and with some variation this still forms the basis for most modern implementations. Some useful additional references can be found in Ref. [10]. The first crucial observation is that the t-channel propagators appearing in perturbative QCD $2 \to 2$ scattering almost go on shell at low $p_{\rm T}$, causing the

differential cross sections to behave roughly as

$$d\sigma_{2\to 2} \propto \frac{dt}{t^2} \sim \frac{dp_{\mathrm{T}}{}^2}{p_{\mathrm{T}}{}^4} . \quad (43.11)$$

This cross section represents the inclusive scattering of partons against partons in perturbative QCD, summed over all partons. Thus, if a single hadron-hadron scattering contains *two* parton-parton interactions, that event will contribute twice to the parton-parton cross section $\sigma_{2\to 2}$ but only once to the hadron-hadron one σ_{tot}, and so on. In the limit that all the parton-parton interactions are independent and equivalent, one has

$$\sigma_{2\to 2} = \langle n \rangle \, \sigma_{\mathrm{tot}} , \quad (43.12)$$

with $\langle n \rangle$ the average number of parton-parton interactions, typically defined with some minimal $p_{\mathrm{T}} > p_{\perp \mathrm{min}}$ to render the parton-parton cross section finite. The probability for n parton-parton scatterings then follows a Poisson distribution,

$$\mathcal{P}_n = \langle n \rangle^n \frac{\exp\left(-\langle n \rangle\right)}{n!} . \quad (43.13)$$

This simple argument expresses unitarity; instead of the total hadron-hadron interaction cross section diverging as the parton-parton $p_{\mathrm{T}} \to 0$ (which would violate unitarity), we have restated the problem so that it is now the *number of parton-parton interactions per hadron-hadron collision* that diverges, with the total hadron-hadron cross section remaining finite. At LHC energies, the parton-parton scattering cross sections computed using the LO QCD cross section folded with modern PDFs become larger than the total pp one for $p_{\perp \mathrm{min}}$ values of order 4–5 GeV (see e.g. [98, 99]). One therefore expects the average number of perturbative MPI to exceed unity at around that scale.

Two ingredients remain to fully regulate the remaining divergence. Firstly, the interactions cannot use up more momentum than is available in the parent hadron. This suppresses the large-n tail of the estimate above. In `PYTHIA`-based models, the MPI are ordered in p_{T}, and the parton densities for each successive interaction are explicitly constructed so that the sum of x fractions can never be greater than unity. In the `HERWIG` models, the Poisson estimate of $\langle n \rangle$ above is used as an initial guess, but the generation of actual MPI is stopped once the energy-momentum conservation limit is reached. Both of these approaches generate momentum (conservation) correlations among the MPI.

The second ingredient invoked to suppress the number of interactions, at low p_{T} and x, is color screening; if the wavelength $\sim 1/p_{\mathrm{T}}$ of an exchanged colored parton becomes larger than a typical color-anticolor separation distance, it will only see an *average* color charge that vanishes in the limit $p_{\mathrm{T}} \to 0$. This provides an infrared cutoff for MPI similar to that provided by the hadronization scale for parton showers. A first estimate of the color-screening cutoff would be the proton size, $p_{\perp \mathrm{min}} \approx \hbar / r_p \approx 0.3\,\mathrm{GeV} \approx \Lambda_{\mathrm{QCD}}$, but empirically this appears to be far too low. In current models, one replaces the proton radius r_p in the above formula by a "typical color screening distance," i.e., an average size of a region within which the net compensation of a given color charge occurs. This number is not known from first principles [100] and is perceived of simply as an effective cutoff parameter. The simplest choice is to introduce a step function $\Theta(p_{\mathrm{T}} - p_{\perp \mathrm{min}})$. Alternatively, one may note that the jet cross section is divergent like $\alpha_{\mathrm{S}}^2(p_{\mathrm{T}}{}^2)/p_{\mathrm{T}}{}^4$, cf. Eq. (43.11), and that therefore a factor

$$\frac{\alpha_{\mathrm{S}}^2(p_{\mathrm{T},0}^2 + p_{\mathrm{T}}{}^2)}{\alpha_{\mathrm{S}}^2(p_{\mathrm{T}}{}^2)} \frac{p_{\mathrm{T}}{}^4}{(p_{\mathrm{T},0}^2 + p_{\mathrm{T}}{}^2)^2} \quad (43.14)$$

would smoothly regulate the divergences, now with $p_{\mathrm{T},0}$ as the free parameter. Regardless of whether it is imposed as a smooth (`PYTHIA` and `SHERPA`) or step (`HERWIG`) function, this is effectively the main "tuning" parameter in such models.

Note that the numerical value obtained for the cross section depends upon the PDF set used, and therefore the optimal value to use for the cutoff will also depend on this choice. Note also that the cutoff does not have to be energy-independent. Higher energies imply that parton densities can be probed at smaller x values, where the number of partons rapidly increases. Partons then become closer packed and the color screening distance d decreases. The uncertainty on the energy and/or x scaling of the cutoff is a major concern when extrapolating between different collider energies [101].

We now turn to the origin of the observational fact that hard jets appear to sit on top of a higher "pedestal" of underlying activity than events with no hard jets. This is interpreted as a consequence of impact-parameter-dependence: in peripheral collisions, only a small fraction of events contain any high-p_{T} activity, whereas central collisions are more likely to contain at least one hard scattering; a high-p_{T} triggered sample will therefore be biased towards small impact parameters, b. The ability of a model to describe both the UE in events with a hard trigger as well as the activity in inclusive "minimum-bias" (MB) samples (see below) therefore depends upon its modeling of the b-dependence, and correspondingly the impact-parameter shape constitutes another main tuning parameter.

For each impact parameter b, the number of interactions $\tilde{n}(b)$ can still be assumed to be distributed according to Eq. (43.13), again modulo momentum conservation, but now with the mean value of the Poisson distribution depending on impact parameter, $\langle \tilde{n}(b) \rangle$. This causes the final n-distribution (integrated over b) to be wider than a Poissonian.

Finally, there are two perturbative modeling aspects which go beyond the introduction of MPI themselves: 1) parton showers off the MPI, and 2) perturbative parton-rescattering effects. Without showers, MPI models would generate very sharp peaks for back-to-back MPI jets, caused by unshowered partons passed directly to the hadronization model. However, with the exception of the oldest `PYTHIA6` model, all GPMC models do include such showers [10], and hence should exhibit more realistic (i.e., broader and more decorrelated) MPI jets. On the initial-state side, the main questions are whether and how correlated multi-parton densities are taken into account and, as discussed previously, how the showers are regulated at low p_{T} and/or low x. Although none of the general purpose MC models currently impose a rigorous correlated multi-parton evolution, all of them include some elementary aspects. The most significant for parton-level results is arguably momentum conservation, which is enforced explicitly in all the models. The so-called "interleaved" models [27] attempt to go a step further, generating an explicitly correlated multi-parton evolution in which flavor sum rules are imposed to conserve, e.g. the total numbers of valence and sea quarks [86]. Fully correlated double-parton evolution is so far only available in the more specialised code dShower [102]; see [103] for comparisons between this and Pythia's interleaved model.

Perturbative rescattering in the final state can occur if partons are allowed to undergo several distinct interactions, with showering activity possibly taking place in-between. This has so far not been studied extensively, but a first exploratory model is available [104]. In the initial state, parton rescattering/recombination effects have so far not been included in any of the GPMC models.

43.3.2 *Bose-Einstein and Color-Reconnection Effects*

In the context of e^+e^- collisions, Bose-Einstein (BE) correlations have mostly been discussed as a source of uncertainty on high-precision W mass determinations at LEP [105]. In hadron-hadron (and nucleus-nucleus) collisions, however, BE correlations are used extensively to study the space-time structure of hadronizing matter ("femtoscopy").

In MC models of hadronization, each string break or particle/-cluster decay is normally factorized from all other ones. This reduces the number of variables that must be considered in each step, but also makes it intrinsically difficult to introduce correlations among particles from different breaks/decays. In GPMCs, a few semi-classical models are available within the `PYTHIA` 6 and 8 generators [106], in which the BE effect is mimicked by an attractive interaction between pairs of identical particles in the final state, with no higher correlations included. Variants of this model differ mainly by the assumed shape of the correlation function and how overall momentum conservation is handled.

As discussed in Sec. 43.2, leading-color ("planar") color flows

are used to set up the hadronizing systems (clusters or strings) at the hadronization stage. If the systems do not overlap significantly in space and time, subleading-color ambiguities and/or nonperturbative reconnections are expected to be small. However, if the density of displaced color charges is sufficiently high that several systems can overlap significantly, full-color and/or reconnection effects should become progressively larger.

In the specific context of MPI, a crucial question is how color is neutralized *between* different MPI systems, including the remnants. The large rapidity differences involved imply large invariant masses (though normally low p_{T}), and hence large amounts of (soft) particle production. Indeed, in the context of soft-inclusive physics, it is these "inter-system" strings/clusters that furnish the dominant particle-production mechanism, and hence their modeling is an essential part of the soft-physics description, affecting topics such as MB/UE multiplicity and p_{T} distributions, rapidity gaps, and precision mass measurements. Reviews of color-reconnection effects can be found in [10, 87].

43.3.3 *Minimum-Bias Events and Diffraction*

The term "minimum bias" (MB) originates from the experimental requirement of a minimal number of tracks (or hits) in a given instrumented region. In order to make MC predictions for such observables, all possible contributions to the relevant phase-space region must be accounted for. There are essentially four types of physics processes, which together make up the total hadron-hadron (hh) cross section: 1) elastic scattering[3]: $hh \to hh$, 2) single diffractive dissociation: $hh \to h + \mathrm{gap} + X$, with X denoting anything that is not the original beam particle, and "gap" denoting a rapidity region devoid of observed activity; 3) double diffractive dissociation: $hh \to X + \mathrm{gap} + X$, and 4) inelastic non-diffractive scattering: everything else. A fifth class may also be defined, called central diffraction ($hh \to h + \mathrm{gap} + X + \mathrm{gap} + h$). Note that different terminologies exist [107]: in experimental settings, diffraction is typically defined by an observable gap, of some minimal size in rapidity, while in the MC context, each diffractive physics process produces a whole spectrum of gaps, with small ones suppressed but not excluded.

The inelastic non-diffractive part of the cross section is typically modeled either by smoothly regulating and extending the perturbative QCD scattering cross sections all the way to zero $p_{\perp}$ [97] (`PYTHIA` and `SHERPA`), or by regulating the QCD cross sections with a sharp cutoff [108] and adding a separate class of nonperturbative scatterings below that scale [109] (`HERWIG`). See also Sec. 43.3.1. In all cases, the most important ingredients are: 1) the IR regularization of the perturbative scattering cross sections, including their PDF dependence, 2) the assumed matter distribution of the colliding hadrons, possibly including multi-parton correlations [86] and/or x dependence [110], and 3) additional soft-QCD effects such as color reconnections, discussed in Sec. 43.3.2.

Currently, there are essentially three methods for simulating diffraction in the main MC models: 1) in `PYTHIA` 6, one picks a diffractive mass according to parameterized cross sections $\propto \mathrm{d}M^2/M^2$ [111]. This mass is represented as a string, which is hadronized as described in Sec. 43.2.1, though differences in the effective scale of the hadronization may necessitate a (re)tuning of the hadronization parameters for diffraction; 2) in `PYTHIA` 8, the high-mass tail beyond $M \sim 10\,\mathrm{GeV}$ is augmented by a partonic description in terms of pomeron PDFs [112], allowing diffractive jet production including showers and underlying event [4]; 3) the `PHOJET` and `DPMJET` programs also include central diffraction and rely directly on a formulation in terms of pomerons (color-singlet multi-gluon states) [113–115]. Cut pomerons correspond to exchanges of soft gluons while uncut ones give elastic and diffractive topologies as well as virtual corrections that help preserve unitarity. So-called "hard pomerons" provide a transition to the perturbative regime. Hadronization is still handled using the Lund string model, so there is some overlap with the above models at the hadronization stage. In addition, a pomeron-based package exists for `HERWIG` [116], and an effort is underway to construct an MC implementation of the "KMR" model [100] within the `SHERPA` generator. Color reconnections (Sec. 43.3.2) may also play a role in creating rapidity gaps and the underlying event (Sec. 43.3.1) in filling them.

[3]The QED elastic cross section diverges and is normally a non-default option.

43.4 Uncertainties and Tuning

The accuracy that can be achieved by a GPMC model depends on the sophistication of the theory models it incorporates, on the available constraints on its free parameters, and on the nature of the observable(s) under study. Using existing data to constrain the model parameters is referred to as generator tuning. Although tuned models do tend to yield improved results also for observables that they have not been tuned to, the question of evaluating the remaining uncertainties reliably is still far from solved. It is worth noting, however, that all of the GPMCs now provide options for automatic evaluation of perturbative shower uncertainties (e.g., via renormalization-scale variations), in the form of vectors of alternative event weights [117–119]. One must be aware that these variations are not necessarily exhaustive and significant weight fluctuations can be a problem for processes with large shower phase spaces. Nonperturbative uncertainties are normally still evaluated by varying salient model parameters by hand, though this looks set to change with a new method based on reweighting [120]. A general method called eigentunes [121] is also available, based on global fits to data.

Typically, the overall event properties are determined by only a few, very important parameters, such as the effective value of α_{S}, for perturbative corrections, and the shape of the fragmentation functions, for nonperturbative ones. More parameters may then be introduced to describe successively more detailed aspects (e.g., the rates and decays of individual hadron species), but these should have progressively less impact on the overall modeling. One may therefore take a factorized approach, first constraining the perturbative parameters and thereafter the nonperturbative ones, in order of decreasing significance to the overall modeling. Furthermore, by identifying which measurements are most sensitive to each parameter, this ordering can be reflected in the way that data is selected and applied to constrain the models. Thus, measurements sensitive to global event properties would typically be applied first, to constrain the most inclusive parameters, and so on for progressively more exclusive aspects. For high-p_{T} processes, one should be aware that if the perturbative modelling is not adequate, there is a risk that one may end up effectively mistuning nonperturbative parameters to compensate for perturbative deficiencies. This is obviously wrong and care must be taken to avoid it. E.g., it would not make sense to tune to get the right total number of hadrons unless one also gets the right total number of jets. In this context, it may be more desirable to use ratios like the number of hadrons *per jet*.

Note also that the unitarity of shower and hadronization models implies that the Born-level cross-section normalization is not tunable, hence in tuning contexts one tends to focus on the shapes of distributions rather than their normalizations.

At LO×(N)LL, perturbation theory is doing well if it agrees with an IR safe shape measurement within $\sim 10\%$. It would therefore not make much sense to tune a GPMC to agree with individual data points beyond this level. To reflect this, and to protect against overfitting, a 5% sanity limit has sometimes been enforced in tuning studies [98, 122]. The advent of NLO Monte Carlos may reduce this number slightly, but only for quantities for which one expects NLO precision. For quantities governed by nonperturbative physics, uncertainties are larger. For some quantities, e.g. ones for which the underlying modeling is known to be poor, an order-of-magnitude agreement or worse may have to be accepted.

In the context of LO×LL GPMC tuning, subleading aspects of coupling-constant and PDF choices are relevant. In particular, one should be aware that the choice of QCD Λ parameter $\Lambda_{\mathrm{MC}} = 1.569\Lambda_{\overline{\mathrm{MS}}}$ (for 5 active flavors) improves the predictions of coherent shower algorithms at the NLL level for a class of relevant observables [123]. The question of LO vs. NLO PDFs is more involved [10], but it should be emphasized that the gluon PDF at (very) low x is important for determining the level of the underlying event in MPI models (Sec. 43.3.1), and hence the MB/UE tuning (and energy scaling [101]) is linked to the choice

of PDF in such models. Further issues and an example of a specific recipe that could be followed in a realistic set-up can be found in Ref. [98]. A useful online resource can be found at the mcplots.cern.ch website [124], based on the RIVET tool [125].

Recent years have seen the emergence of automated tools to reduce the amount of both computer and manpower required for tuning [121,126,127]. Automating the human expert input is more difficult. In the tools currently on the market, this is addressed by a combination of input solicited from the GPMC authors (e.g., which parameters and ranges to consider, which observables constitute a complete set, etc) and a set of weights determining the relative priority given to each bin in each distribution. The final result is therefore still subjective but at least reproducible. Backed by careful demonstrations of sensitivities, correlations, and uncertainties, competitive tunes can be produced. The field is still burgeoning, with future sophistications to be expected.

44. Monte Carlo Neutrino Generators

Revised September 2025 by H. Gallagher (Tufts U.) and Y. Hayato (Kamioka Observatory, ICRR, UTokyo; Kavli IPMU (WPI), UTokyo).

Monte Carlo neutrino generators are programs or libraries which simulate neutrino interactions with electrons, nucleons and nuclei. In this capacity their usual task is to take an input neutrino and nucleus and produce a set of 4-vectors for particles emerging from the interaction, which are then input to full detector simulations. Since these generators have to simulate not only the initial interaction of neutrinos with target particles, but reinteractions of the generated particles in the nucleus, they contain a wide range of elementary particle and nuclear physics. Viewed more broadly, they are the access point for neutrino experimentalists to the theory inputs needed for analysis. Examples include cross section libraries for event rate calculations and parameter uncertainties and reweighting tools for systematic error evaluation.

Neutrino experiments typically operate in neutrino beams that are neither completely pure nor mono-energetic. Generators are a crucial component in the convolution of beam flux, neutrino interaction physics, and detector response that is necessary to make predictions about observable quantities. Generated events are used to define experimental analyses, like event selection criteria, for efficiency determination and background subtraction. Similarly they are used to relate reconstructed quantities back to true quantities. In these various capacities they are used from the detector design stage through the extraction of physics measurements from reconstructed observable. Monte Carlo neutrino generators play unique and important roles in the experimental study of neutrino interactions and oscillations.

There are several neutrino event generators available, such as ANIS [1], GENIE [2, 3], GiBUU [4, 5], MARLEY [6], NEGN [7], NEUT [8], NUANCE [9], the FLUKA routines NUNDIS/NUNRES [10, 11], NuWro [12], and ACHILLES [13] as well as tools to facilitate cross-generator comparisons, such as NUISANCE [14]. Historically, experiments would develop their own generators. This was often because they were focused on a particular measurement, energy range, or target, and wanted to ensure that the best physics was included for them. These 'homegrown' generators were often tuned primarily or exclusively to the neutrino data most similar to the data that the experiment would be collecting. A major advance in the field was the introduction of conference series devoted to the topic of neutrino interaction physics, NuINT (https://indico.cern.ch/event/703880/) and NuFACT (https://indico.cern.ch/event/855372/) in particular. Event generator comparisons have been a regular staple of the NuINT conference series from its inception, and a great deal of information on this topic can be found in the Proceedings of these meetings. These meetings have facilitated experiment-theory discussions leading to the first generator developed by a theory group (NuWro) [12], the extension of established nuclear interaction codes (FLUKA and GiBUU) to include neutrino-nuclear processes [4,5,10,11], and inclusion of theorists in existing generator development teams.

These activities have led to more careful scrutiny of the crucial hadron and nuclear theory inputs to these generators, which is evaluated in particular through comparisons to electron-scattering data. At this point in time all simulation codes face challenges in describing the full extent of the lepton scattering data, and the tension between incorporating the best available theory versus obtaining the best agreement with the data plays out in a variety of ways within the field. For the field to make progress, inclusion of state of the art theory needs to be coupled to global analyses that correctly incorporate correlations between measurements. Given the rapid pace of new data and the complexity of analyses, this is a significant challenge for the field in the coming years.

There are many neutrino experiments which use various sources of neutrinos, from reactors, accelerators33, the atmosphere, and astrophysical sources30,thereby covering a range of energies from MeV to TeV. Much of the emphasis has been on the few-GeV region in the generators, as this is the relevant energy range for short- and long-baseline neutrino oscillation experiments. Also, modern neutrino experiments utilize nuclei as interaction targets, such as scintillator (hydro-carbon), water, argon, and iron. Therefore, the generators must be capable of simulating neutrino interactions with various nuclear targets. Neutrino-nucleus interactions are separated in two stages: the initial neutrino interactions (ISI), and the final-state interactions (FSI) of the particles produced in the initial neutrino interaction. Traditionally, generators use the impulse approximation, which treats the nucleus as a collection of independent nucleons and the primary interaction, ISI, occurs between the probe and a single nucleon[1], for most of the initial interaction, and subsequently simulates the interactions of secondary particles in the nucleus (FSI) in semi-classical ways. However, the impulse approximation with simple nucleus modeling has limitations, and some interaction models in recent generators consider both the initial state and the final state of the nucleus when simulating ISI. Some of the generators go further and consider the correlation of ISI and FSI. Semi-classical hadron transport approaches are commonly used as they are able simulate a variety of nuclei in a single model, fully describe complex multi-particle final states, and for practical considerations as these approaches are fast. However, there are several challenges facing these simulations coming mainly from the complexity of the nuclear physics, and the need to avoid double counting in combining perturbative and non-perturbative models for the neutrino-nucleon scattering processes. One example of addressing this is in GiBUU, which treats the final state propagation using quantum-kinetic transport theory. The overall validity of impulse approximation-based scheme, and in particular the importance of scattering channels that involve more than one nucleon, is a crucial question that is the topic of much current work. While generators share many common ingredients, differences in implementation, parameter values, and approaches to avoid double counting can yield dramatically different predictions [15]. In the following sections, interaction models and their implementations, including final-state interactions of hadrons produced in the nuclei, are described.

In order to assure their validity, neutrino event generators are tuned and validated against a wide variety of data. This means that the quality of the outputs from generators is limited by the quality of experimental data. The existing neutrino-nucleon and neutrino-nucleus scattering data sets are not restrictive enough to eliminate many approaches. On the other hand, there are various precise data sets, which use photon, charged lepton, and hadron probes. These data sets are extensively used to validate the generators. The results from these external data tuning exercises are important for experiments as they quantify the uncertainty on model parameters, needed by experiments in the evaluation of generator-related systematic errors. Electron scattering data plays an important role in determining the vector contribution to the form-factors and structure functions, as well as in evaluating specific aspects of the nuclear model [16, 17]. Hadron scattering data is used in validating the nuclear model, in particular of interactions between hadrons produced in the primary interaction and the residual target nucleus (final state interactions). As mentioned, tuning of neutrino-nucleon scattering and hadronization models relies heavily on the previous generation of high energy neutrino scattering and hydrogen and deuterium bubble chamber experiments. More recent data from the K2K, MiniBooNE, NOMAD, SciBooNE, MINOS, T2K, ArgoNEUT, MINERvA, NOvA, MicroBooNE, ICARUS, SBND, Ninja and JSNS2 experiments has been, or will be, used for this purpose, although caution is advisable due to possible biases that mismodeled nuclear effects might introduce. In practice, there are often choices to be made about which models to include in an overall simulation, and which data sets to use for tuning. The process of developing a comprehensive tune in GENIE is discussed in Ref. [3].

However, all the recent experiments use nuclear targets and it is challenging to disentangle the neutrino-nucleon interaction from the effects of the nuclear environment. For example, it is diffi-

[1] Recently, importance of two nucleon processes are widely recognized and implemented in several generators. In such a case, two nucleons are involved in the ISI.

cult to separate charged current quasi-elastic scattering from the multi-nucleon quasi-elastic like scattering or single pion production, in which a pion is absorbed in the nucleus. Sometimes, there are tensions between the data sets from different experiments. Data on multi-pion and meson production are limited, but are anticipated to be measured in the near future experiments. Next generation experiments are expected to provide better detection capabilities with higher statistics and these data will help in evaluating and validating the models implemented in the generators.

44.1 Neutrino-Nucleon Scattering

Event generators typically begin with free-nucleon cross sections which are then embedded into a nuclear physics model. The most important processes are quasi-elastic (elastic for neutral current (NC)) scattering, resonance production, and non-resonant inelastic scattering, which make comparable contributions for few-GeV interactions. The neutrino cross sections in this energy range can be seen in Figure 52.1 of this *Review*.

44.1.1 *Quasi-Elastic Scattering*

The cross section for the neutrino nucleon charged current quasi-elastic scattering is described in terms of the leptonic and hadronic weak currents, where dominant contributions to the hadronic current come from the vector (V) and axial-vector (A) form factors. Contributions from the pseudo-scalar form factor (P) are typically small for muon and electron neutrinos and are related to the axial form factor (A) assuming partially conserved axial currents (PCAC). Owing to isospin symmetry, the vector form factors are related to those measured by precise electron scattering experiments [18]. Therefore, most of the generators use parametrizations of these form factors taken directly from the data. For the axial form factor there is no such precise experiment, and most of the generators use a dipole form [19]. Generally, the value of axial form factor at $q^2 = 0$ (q is the four-momentum transfer) is extracted from the polarized nucleon beta decay experiment. The axial vector mass (M_A) has been determined to be ~ 1.0 GeV/c^2 by the results of bubble chamber neutrino scattering experiments and electro-pion production experiments. However, the selection of the axial vector mass parameter depends on the generator as the simulated results show significant differences from observations in several experiments. Nuclear modeling in the generators and missing interactions are thought to be the main causes. Recent LQCD axial form factor calculations indicate that the dipole axial-vector form factor with M_A =1.0 GeV/c^2 may not be appropriate [20]. The LQCD results provide better agreement with recent experiments. The MINERvA experiment measured the $\bar{\nu}_\mu$ differential cross-section on hydrogen, which also shows discrepancies in the large 4-momentum transfer region [21]. Recently, there are several attempts to use the new function forms of the axial form factors [20,22,23] and some generators have already implemented these form factors [8,24].

44.1.2 *Inelastic Production*

Most generators use the prescriptions of Rein-Sehgal [25], which is based on the relativistic harmonic oscillator model [26], to simulate neutrino-induced single pion production, or updated versions that incorporate lepton mass terms and pion pole contributions [27,28]. To obtain the cross section for a particular channel, they calculate the amplitude for the production of each resonance multiplied by the probability for the decay of that resonance into that particular channel. Implementation differences include the number of resonances included, whether the amplitudes are added coherently or incoherently, the invariant mass range over which the model is used, how non-resonant backgrounds are included, inclusion of lepton mass terms, and the model parameter values (in particular the axial mass). In this model it is also possible to calculate the cross-sections of single photon, and η production by changing the decay probability of the resonances, which are included in some of the programs. However, it is known that discrepancies exist between the recent pion electro/photo-production data and the results from the simulation data with the same framework, i.e. vector part of this model. There are several attempts to overcome this issue [29] and some of the generators started using more appropriate form factors. Recently, there are approaches that improve the theoretical description of non-resonant contributions in the resonance region, [30–32], and which account for interference between resonant and non-resonant amplitudes. GiBUU and NuWro generators do not use the Rein-Sehgal model, and instead rely directly on electro-production data for the vector contribution and fit bubble chamber data to determine the remaining parameters for the axial contribution [33–36]. These implementations do not include higher resonances explicitly. The dynamical coupled-channel model, which has been developed to simulate various electro- and photo-meson productions, was extended to simulate the neutrino single pion production [37]. In this approach pion-nucleon scattering is used to fix the form of the axial current at $q^2 = 0$. This model is also being implemented and is available in NEUT. Even with the new models, the axial-vector contributions must be determined experimentally; therefore, further experimental studies are essential to improve the prediction accuracy.

44.1.3 *Deep and Shallow Inelastic Scattering*

For this process the fundamental target shifts from the nucleon to its quark constituents. Therefore, the generators construct the nucleon structure functions F_2 and xF_3 from parton distributions for high Q^2 (the DIS regime: W$\gtrsim$ 2 GeV/c^2 and Q$^2 \gtrsim$ 1 GeV^2) to calculate the direction and momentum of the lepton. The first challenge is in extending this picture to the lower values of Q^2 and W that dominate the available phase space for few-GeV interactions (the so-called 'shallow inelastic scattering', or SIS regime). GRV98LO parton distribution functions [38] with the corrections proposed in [39,40] are widely used, while others [10] implement their own modifications to the parton distributions at low Q^2. Both DIS and SIS generate hadrons but their production depends on each generator's implementation of a hadronization model as described in the next section. There are various difficulties not only in the actual hadronization but the relation with the single meson production. It is necessary to avoid double counting between the resonance and SIS/DIS models, and all generators are different in this regard. The scheme chosen can have a significant impact on the results of simulations at a few-GeV neutrino energies. For simulating ultra-high energy interactions currently being studied with neutrino telescopes, fully partonic descriptions, which utilize beyond-leading-order pQCD calculations [41,42] are the norm [43].

44.2 Hadronization Models

For hadrons produced via baryonic resonances, the underlying model amplitudes and resonance branching fractions can be used to fully characterize the hadronic system. For shallow- and deep-inelastic scattering, a hadronization model is required. Most generators use PYTHIA [44] for this purpose, although some with modified parameters. In addition some implement their own models to handle invariant masses that are too low for PYTHIA, typically somewhere around 2.0 GeV/c^2. Such models rely heavily on measurements of neutrino hadro-production in high-resolution devices, such as bubble chambers and the CHORUS [45] and NOMAD experiments [46], to construct empirical parametrizations that reproduce the key features of the data [47,48]. The basic ingredients are the empirical observations that average charged particle multiplicities increase logarithmically with the invariant mass of the hadronic system, and that the distribution of charged particle multiplicities about this average are described by a single function (an observation known as KNO scaling [49]). The multiplicity of the neutral particles are usually obtained by scaling the charged particle multiplicity. Simple parametrizations to more accurately reproduce differences observed in the forward/backward hemispheres of hadronic systems are included in GENIE, NEUT, and NuWro.

44.3 Nuclear Physics

The nuclear physics relevant to neutrino-nucleus scattering at few-GeV energies is complicated, involving Fermi motion, nuclear binding, Pauli blocking, in-medium modifications of form factors and hadronization, intranuclear rescattering of hadrons, and many-body scattering mechanisms including long- and short-range nucleon-nucleon correlations.

44.3.1 *Treatment of nuclear effects*

In order to obtain the cross-section off nucleons in the nucleus, it is necessary to take into account various in-medium effects. Most of the models used for neutrino-nuclear scattering kinematics were developed in the context of few-GeV inclusive electron scattering, by experiments going back nearly 50 years. The basic models employed in event generators rely on impulse approximation schemes, the most simple of which is the Relativistic Fermi Gas Model, such as the Smith-Moniz [50] and Bodek-Ritchie [51] models. However, the results from neutrino-nucleus scattering experiments in 2000 and afterwards, beginning with K2K, MiniBooNE have shown large discrepancies from the naive expectation from the models. Most striking differences are a suppression of forward going muons (low Q^2), a high Q^2 enhancement in the event rate, and an overall larger than expected number of observed events. In order to reproduce the data, the quasi-elastic axial mass was used as the effective parameter and increased by roughly 20% from the nominal values obtained by an earlier generation of bubble chamber experiments using hydrogen or deuterium [19]. Because the resolution and detection efficiencies of the detectors are limited, it is not possible to disentangle the contributions from the form factors of the neutrino (weak) interaction or nuclear in-medium effects. Recently, several LQCD groups have calculated the axial-vector nucleon form factor, and their results show different tendencies compared to the bubble-chamber data and are closer to the results of recent experiments. Therefore, the axial-vector form factor may be one reason for the discrepancies. However, it is known that the problem cannot be completely resolved by simply changing the axial-vector factor. Consequently, simple nuclear models are insufficient for recent and future neutrino experiments. Additionally, the discrepancies may indicate contributions from other interactions that are either not taken into account or are poorly modeled. Moreover, these simple Fermi-Gas models are not expected to describe the kinematical distributions of final state nucleons. Therefore, several generators have to implement better models, such as local Fermi-Gas model or more sophisticated models. Within the electron scattering community, the analogous calculations have for decades relied on spectral functions, which incorporate information about nucleon momenta and binding energies in the impulse approximation scheme [16]. Therefore, most of the generators have implemented the realistic spectral functions in their latest releases. Actually, the discrepancies in small q^2 could not be solved alone by just introducing the local Fermi-gas model nor spectral function models. This implies that appropriate medium correction effects are needed to be taken into account. One of the implemented solutions is the local Fermi-Gas model with medium correction calculated using the random phase approximation, which is known to give large suppression in small q^2 [52, 53]. Although, the fundamental parts of the models are same, actual implementations are quite different between the generators. Especially, the constructions of the final state hadron kinematics are quite different. Especially for the quasi-elastic scattering case, treatment of the nucleon masses in the nucleus, the binding and the separation energies are sometimes quite different [54]. Recently, Super-Scaling model with relativistic mean field theory effects (SuSAv2) [55, 56] is implemented in some of the generators. Different from the other generators, GiBUU treats various in-medium effects consistently, and ACHILLES is also designed to treat the nuclear modeling as consistent as possible.

Indications of the suppression in small q^2 in the single pion productions were also observed in K2K and MiniBooNE and it is clearly observed at the MINERνA and NOνA experiments. However, the models to explain the suppression have not been implemented, other than the phenomenological ones. Also, q^2 dependence of the cross-section is largely model and parameter dependent. Further studies of newly implemented single pion models and new data sets may give new insights. Also, there may be some interaction channels which are missing and not considered in the generators.

These led to a revisitation of the role played by excitation of multiple particle-hole states in the nucleus, and the experimental study of these scattering channels is an area of intense experimental interest [57]. The contribution of these scattering processes is an extremely active area of theoretical research as well, with significant implications for generators and analyses [58]. Several approaches, ranging from strictly phenomenological descriptions to full theoretical calculations, have recently been incorporated into generators [59–61]. One example of a phenomenological approach utilizes an Effective Spectral Function [62] and a Transverse Enhancement Model [63], which together encapsulate information derived from electron scattering experiments at relevant kinematics. The microscopic model of Nieves and collaborators is now available in GENIE and NEUT [64, 65]. SuSAv2 model [56] also has capability to simulate this multi-nucleon quasi-elastic like interaction and is also implemented in GENIE.

One of the challenges in incorporating full theoretical models of these processes is that they are typically slow, so generators have developed new approaches whereby much of the computation is done offline, and the generators simply read in the hadronic tensor components. This allows for a full prediction of the lepton kinematics, however the ability to simulate the hadronic component of these multinucleon states then relies on separate models. The other challenge is that the theoretical models are not designed to describe exclusive final states. These approaches, while making simulations computationally tractable, neglect correlations between the lepton and hadron kinematics. Also, there are limitations of the model itself to describe some of the kinematic regions. However, the generators need to simulate final all the state particles and thus, several assumptions are made by authors of the generators from time to time.

Also, it is known from photo and electro-nuclear scattering that the Delta width is affected by Pauli blocking and collisional broadening. These effects are included in some, but not all generators.

The remnant nucleus after the scattering is usually in an excited state. Therefore, the remnant may emit gamma-rays, additional nucleons or an alpha particle during the de-excitation process. This de-excitation gamma-ray is used in searching for proton decay in water Cherenkov detectors. Some generators have implemented this process. GENIE has deexcitation processes for various nuclei. Recently, a dedicated library, called NUCDEEX [66], which simulates de-excitation based on TALYS [67] was released. This library is designed to be used with any generators to simulate nuclear de-excitation processes. When scattering from a nucleus, coherent scattering of various kinds is possible. Most simulations incorporate, at least, coherent neutral and charged single pion production. While the interaction rate for these interactions is typically around a percent of the total yield, the unique kinematic features of these events can make them potential backgrounds for oscillation searches. Implemented in Monte Carlo are several PCAC-based methods [68, 69]. Microscopic models, valid at lower neutrino energies [70–73], have also been implemented in several generators. One commonly used model by Rein and Sehgal [68] predicts a cross section for charged-current coherent pion production that is much larger than what is observed by K2K, MINERvA and T2K. However, the cross-section is sensitive to the pion cross-section used in the model as parameters and improved models with lepton mass correction [69] give better agreement with the recent data. This improved model is implemented in most of the generators. In addition to coherent pion production, some generators can simulate coherent single photon production [74] and coherent elastic neutrino-nucleus scattering.

44.3.2 *Hadron Production in Nuclei*

Neutrino pion production is one of the dominant neutrino scattering mechanisms in the few-GeV region and the pions produced in the nucleus have quite large interaction cross sections. Therefore, pion intranuclear scattering can have sizable effects on the results of simulations at these energies. Also, recent neutrino oscillation experiments use the observed information of protons and pions more extensively, in addition to the charged leptons. Therefore, most generators implement this physics through an intranuclear cascade simulation. In generators which utilize cascade models, a hadron, which has been formed in the nucleus, is moved step by step until it interacts with a nucleon or escapes from the nucleus. The probabilities of each interaction in nucleus are usually given as the mean free paths and used to determine whether

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

the hadron has interacted or not. If the hadron is found to have interacted, appropriate final states are selected. Usually, absorption, elastic, charge exchange, and inelastic scatterings including particle productions are simulated as intranuclear interactions. The determination method of the kinematics for the final state particles heavily depends on the generators but most of them use experimentally validated models to simulate hadron interactions in nucleus. No two intranuclear cascade simulations implemented in neutrino event generators are the same [75]. In all cases hadrons propagate from an interaction vertex chosen based on the density distribution of the target nucleus. In determining the generated position of the hadrons in nucleus, the concept of the formation length is sometimes employed. Based on this idea, the hadronization process is not instantaneous and it takes some time before generating the hadrons [12]. The basis for formation times are measurements at relatively high energy and Q^2, and most generators that employ the concept do not apply them to resonance interactions.

GiBUU does not employ an intranuclear cascade simulation, instead, it utilizes a semi-classical transport model in coupled channels that describes the space-time evolution of a many body system in the presence of potentials and a collision term [4]. This approach assures consistency between nuclear effects in the initial state, such as Fermi motion, Pauli blocking, hadron self-energies [76], and modified cross sections, and the final state, such as particle re-interactions, since the two are derived from the same model. This model has been previously used to describe a wide variety of nuclear interaction data. Similarly, the hadronic simulation of the NUNDIS/NUNRES programs are handled by the well-established FLUKA hadronic simulation package [10]. Recently, GENIE included the interface to the external hadronic simulation package INCL++ [77].

45. Monte Carlo Particle Numbering Scheme

Revised August 2025 by A. Buckley (Glasgow U.), F. Krauss (Durham U.), S. Navas (Granada U.) and P. Richardson (Durham U.).

The Monte Carlo particle numbering scheme presented here is intended to facilitate interfacing between matrix-element generators, event generators, detector simulators, and analysis packages used in particle physics, and is widely accepted as the "industry standard".

The numbering scheme was introduced in 1988 [1], and has since been revised and expanded in the light of new information on hadronic resonances, and to encompass as yet undiscovered and hypothetical particles. The scheme was substantially updated and extended in 2012. Encodings have since been added for generic dark matter and for tetra- and penta-quark states; the 2026 update further refines the tetra/penta-quark schemes, and reserves ranges for user-specified states and PDG-node indexing. Further revisions and/or extensions of the numbering scheme are anticipated.

The general form for most particles is a 7-digit number:

$$\pm n\, n_r\, n_L\, n_{q1}\, n_{q2}\, n_{q3}\, n_J\ .$$

This encodes information about the particle's spin, flavor content, and internal quantum numbers. A 9–digit extension is used specifically for tetra- and penta-quark states, and a distinct 10-digit scheme is used for encoding (hyper)nuclear states. The details are as follows:

1. Particles are given positive numbers, antiparticles negative numbers. The PDG convention for mesons is used, so that K^+ and B^+ are particles.
2. Quarks and leptons are numbered consecutively starting from 1 and 11 respectively; to do this they are first ordered by family and within families by weak isospin.
3. In composite quark systems (diquarks, mesons, and baryons) $n_{q_{1-3}}$ are quark numbers used to specify the quark content, while the rightmost digit $n_J = 2J+1$ gives the system's spin (except for the K^0_S and K^0_L). The scheme does not cover particles of spin $J > 4$.
4. Diquarks have 4-digit numbers with $n_{q1} \geq n_{q2}$ and $n_{q3} = 0$.
5. The numbering of mesons is guided by the non-relativistic (L–S decoupled) quark model, as listed in Tables 15.2, 15.3, and 15.4.
   (a) The numbers specifying the meson's quark content conform to the convention $n_{q_1} = 0$ and $n_{q_2} \geq n_{q_3}$. The special case K^0_L is the sole exception to this rule.
   (b) The quark numbers of flavorless, light (u, d, s) mesons are: 11 for the member of the isotriplet $(\pi^0, \rho^0, \ldots)$, 22 for the lighter isosinglet $(\eta, \omega, \ldots)$, and 33 for the heavier isosinglet $(\eta', \phi, \ldots)$. Since isosinglet mesons are often large mixtures of $u\bar{u} + d\bar{d}$ and $s\bar{s}$ states, 22 and 33 are assigned by mass and do not necessarily specify the dominant quark composition.
   (c) The special numbers 310 and 130 are given to the K^0_S and K^0_L respectively.
   (d) The fifth digit n_L is reserved to distinguish mesons of the same total (J) but different spin (S) and orbital (L) angular momentum quantum numbers. For $J > 0$ the numbers are: $(L, S) = (J-1, 1)$ $n_L = 0$, $(J, 0)$ $n_L = 1$, $(J, 1)$ $n_L = 2$ and $(J+1, 1)$ $n_L = 3$. For the exceptional case $J = 0$ the numbers are $(0, 0)$ $n_L = 0$ and $(1, 1)$ $n_L = 1$ (*i.e.* $n_L = L$). See Table 45.1.
   (e) If a set of physical mesons correspond to a (non-negligible) mixture of basis states, differing in their internal quantum numbers, then the lightest physical state gets the smallest basis state number. For example the $K_1(1270)$ is numbered 10313 (1^1P_1 K_{1B}) and the $K_1(1400)$ is numbered 20313 (1^3P_1 K_{1A}), using $n^{(2s+1)}L_J$ spectroscopic notation.
   (f) The sixth digit n_r is used to label mesons radially excited above the ground state.

Table 45.1: Meson numbering logic. Here qq stands for $n_{q2}\, n_{q3}$.

	$L = J-1,\ S = 1$			$L = J,\ S = 0$			$L = J,\ S = 1$			$L = J+1,\ S = 1$		
J	code	J^{PC}	L	code	J^{PC}	L	code	J^{PC}	L	code	J^{PC}	L
0	—	—	—	00qq1	0^{-+}	0	—	—	—	10qq1	0^{++}	1
1	00qq3	1^{--}	0	10qq3	1^{+-}	1	20qq3	1^{++}	1	30qq3	1^{--}	2
2	00qq5	2^{++}	1	10qq5	2^{-+}	2	20qq5	2^{--}	2	30qq5	2^{++}	3
3	00qq7	3^{--}	2	10qq7	3^{+-}	3	20qq7	3^{++}	3	30qq7	3^{--}	4
4	00qq9	4^{++}	3	10qq9	4^{-+}	4	20qq9	4^{--}	4	30qq9	4^{++}	5

   (g) Numbers have been assigned for complete $n_r = 0$ S- and P-wave multiplets, even where states remain to be identified.
   (h) In some instances assignments within the $q\bar{q}$ meson model are only tentative; here best guess assignments are made.
   (i) Many states appearing in the Meson Listings are not yet assigned within the $q\bar{q}$ model. Here $n_{q_{2-3}}$ and n_J are assigned according to the state's likely flavors and spin; all such unassigned light isoscalar states are given the flavor code 22. Within these groups $n_L = 0, 1, 2, \ldots$ is used to distinguish states of increasing mass. These states are flagged using $n = 9$. It is to be expected that these numbers will evolve as the nature of the states are elucidated. Codes are assigned to most mesons that are listed in the one-page table at the end of the Meson Summary Table as long as they have a preferred or established spin. Additional heavy meson states expected from heavy quark spectroscopy are also assigned codes.
6. The numbering of baryons is again guided by the non-relativistic quark model, see Table 15.6. This numbering scheme is illustrated through a few examples in Table 45.2.
   (a) The numbers specifying a baryon's quark content are generally ordered $n_{q_1} \geq n_{q_2} \geq n_{q_3}$.
   (b) Two states exist for $J = 1/2$ baryons containing 3 distinct quark flavours. In the lighter state the light quarks are in an antisymmetric ($J = 0$) configuration, while for the heavier state they are in a symmetric ($J = 1$) configuration. In this situation n_{q_2} and n_{q_3} are reversed for the lighter state, so that the smaller number corresponds to the lighter baryon. For example, $uds \to \{\Lambda = 3122, \Sigma^0 = 3212\}$, the $udc = \{\Xi_c^+, \Xi_c^{'+}\}$ and $scb = \{\Omega_{bc}^0, \Omega_{bc}^{'0}\}$ baryon pairs, and equivalents in those families.
   (c) For excited baryons a scheme is adopted, where the n_r label is used to denote the excitation bands in the harmonic oscillator model, see Sec. 15.5. Using the notation employed there, n_r is given by the N-index of the D_N band identifier.
   (d) Further degeneracies of excited hadron multiplets with the same excitation number n_r and spin J are lifted by labelling such multiplets with the n_L index according to their mass, as given by its N or Δ-equivalent.
   (e) In such excited multiplets extra singlets may occur, the $\Lambda(1520)$ being a prominent example. In such cases the ordering is reversed such that the heaviest quark label is pushed to the last position: $n_{q_3} > n_{q_1} > n_{q_2}$.
7. The gluon, when considered as a gauge boson, has code number 21. In codes for glueballs, however, 9 is used to allow a notation in close analogy with that of hadrons.
8. The pomeron and odderon trajectories and a generic reggeon trajectory of states in QCD are assigned codes 990, 9990, and 110 respectively, where the final 0 indicates the indeterminate nature of the spin, and the other digits reflect the expected "valence" flavor content. We do not attempt a complete classification of all reggeon trajectories, since there is currently no

Table 45.2: Some examples of octet (top) and decuplet (bottom) members for the numbering scheme for excited baryons. Here qqq stands for $n_{q_1}n_{q_2}n_{q_3}$. See the text for the definition of the notation. The numbers in parenthesis correspond to the mass of the baryons. The states marked as (?) are not experimentally confirmed.

need to distinguish a specific such trajectory from its lowest-lying member.

9. Two-digit numbers in the range 21–30 are provided for the Standard Model gauge and Higgs bosons.
10. Codes 81–100 are reserved for generator-specific pseudoparticles and concepts not corresponding to physical states. Codes 901–930, 1901–1930, 2901–2930, and 3901–3930 are for additional components of Standard Model parton distribution functions: the latter three ranges are intended to distinguish left/right/longitudinal components. Codes 998 and 999 are reserved for GEANT tracking purposes.
11. The search for physics beyond the Standard Model is an active area, so these codes are also standardized as far as possible.

(a) A standard fourth generation of fermions is included by analogy with the first three.

(b) The graviton and the boson content of a two-Higgs-doublet scenario and of additional SU(2)×U(1) groups are found in the range 31–40.

(c) "One-of-a-kind" exotic particles are assigned numbers in the range 41–80. The subrange 61-80 is reserved for new heavier fermions in generic models, where partners to the SM fermions would have codes offset by 60. If required, however, other assignments could be made.

(d) Fundamental supersymmetric particles are identified by adding a non-zero n to the particle number. The superpartner of a boson or a left-handed fermion has $n = 1$ while the superpartner of a right-handed fermion has $n = 2$. When mixing occurs, such as between the winos and charged Higgsinos to give charginos, or between left and right sfermions, the lighter physical state is given the smaller basis-state number.

(e) Technicolor states have $n = 3$, with technifermions treated like ordinary fermions. States which are ordinary color singlets have $n_r = 0$. Color octets have $n_r = 1$. If a state has non-trivial quantum numbers under the top-color groups numbers are specified by tech,ij, where i and j are 1 or 2. n_L is then $2i + j$. The coloron, V_8, is a heavy gluon color octet and thus is 3100021.

(f) Excited (composite) quarks and leptons are identified by setting $n = 4$ and $n_r = 0$.

(g) Within several scenarios of new physics, it is possible to have colored particles sufficiently long-lived for color-singlet hadronic states to form around them. In the context of supersymmetric scenarios, these states are called R-hadrons, since they carry odd R-parity. R-hadron codes, defined here, should be viewed as templates for corresponding codes also in other scenarios, for any long-lived particle that is either an unflavored color octet or a flavored color triplet. The R-hadron code is obtained by combining the SUSY particle code with a code for the light degrees of freedom, with as many intermediate zeros removed from the former as required to make place for the latter at the end. (To exemplify, a sparticle $n00000n_{\tilde{q}}$ combined with quarks q_1 and q_2 obtains code $n00n_{\tilde{q}}n_{q_1}n_{q_2}n_J$.) Specifically, the new-particle spin decouples in the limit of large masses, so that the final n_J digit is defined by the spin state of the light-quark system alone. An appropriate number of n_q digits is used to define the ordinary-quark content. As usual, 9 rather than 21 is used to denote a gluon/gluino in composite states. The sign of the hadron agrees with that of the constituent new particle (a color triplet) where there is a distinct new antiparticle, and else is defined as for normal hadrons. Particle names are R with the flavor content as lower index.

(h) A black hole in models with extra dimensions has code 5000040. Kaluza-Klein excitations in models with extra dimensions have $n = 5$ or $n = 6$, to distinquish excitations of left- or right-handed fermions or, in case of mixing, the lighter or heavier state (cf. 11d). The nonzero n_r digit gives the radial excitation number, in scenarios where the level spacings allow these to be distinguished. Should the model also contain supersymmetry, excited SUSY states would be denoted by an $n_r > 0$, with $n = 1$ or 2 as usual. Should some colored states be long-lived enough that hadrons would form around them, the coding strategy of Ref. 11g applies, with the initial two nn_r digits preserved in the combined code.

(i) Magnetic monopoles and dyons are assumed to have one unit of Dirac monopole charge and a variable integer number $n_{q1}n_{q_2}n_{q_3}$ units of electric charge. Codes $411n_{q1}n_{q_2}n_{q_3}0$ are then used when the magnetic and electrical charge sign agree and $412n_{q1}n_{q_2}n_{q_3}0$ when they disagree, with the overall sign of the particle set by the magnetic charge. For now no spin information is provided.

(j) The nature of dark matter (DM) is not known, and therefore a definitive classification would be premature. Candidates from specific BSM scenarios are classified within those ranges, such as 1000022 for the lightest neutralino. Generic fundamental states can be given temporary codes in the range 51–60, with 51, 52 and 53 reserved for spin 0, 1/2 and 1 DM states (this could also include axions). Generic mediators of s-channel DM pair creation of annihilation can be given codes 54 and 55 for spin-0 or 1 respectively. Separate antiparticles, with negative codes, may or may not exist. More elaborate new scenarios should be constructed with $n = 5$ and $n_r = 9$.

(k) Hidden Valley particles have $n = 4$ and $n_r = 9$, and

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

trailing numbers in agreement with their nearest-analog standard particles, as far as possible. Thus 4900021 is the gauge boson g_v of a confining gauge field, $490000n_{q_v}$ and $490001n_{\ell_v}$ are fundamental constituents charged or not under this, 4900022 is the γ_v of a non-confining field, and $4900n_{q_{v1}}n_{q_{v2}}n_J$ a Hidden-Valley meson.

12. Occasionally users and program authors add their own states. These should be flagged by setting $nn_r = 99$, and $n_L = 0$ or 9 for user and program customisations respectively.

    In addition, the $nn_r = 99$ range may be used to provide an alternative classification of states by their PDG "node" identifier[1]. This non-decodeable approach is specifically intended for states with sufficiently tentative quantum numbers that they cannot yet be given unambiguous MC ID codes; where states are listed in the MC ID table at the end of this review, those explicit codes should be strongly preferred. For tentative states, the mapping of PDG nodes to MC custom IDs is as follows:

    991xxxx: S-nodes encoding, includes SM leptons, bosons, some hadrons, and BSM groups

    992xxxx: Q-node encoding, for quarks

    993xxxx: G-node encoding, currently only the gluon

    994xxxx: M-node encoding, for mesons and tetraquarks

    995xxxx: B-node encoding, for baryons and pentaquarks.

    where the xxxx placeholders are zero-padded, i.e. node Q005 maps to ID number 9920005. $n_L = 6$–8 codes are reserved for future expansion of the custom-state scheme.

13. Concerning the non-99 numbers, it may be noted that only quarks, excited quarks, squarks, and diquarks have $n_{q_3} = 0$; only diquarks, baryons, and the odderon have $n_{q_1} \neq 0$; and only mesons, the reggeon, and the pomeron have $n_{q_1} = 0$ and $n_{q_2} \neq 0$. Concerning mesons (not antimesons), if n_{q_1} is odd then it labels a quark and an antiquark if even.

14. Tetra-quark states are specified with 9-digit codes $\pm 1 n_r n_L n_{q_1} n_{q_2} 0 n_{q_3} n_{q_4} n_J$. For the particle $q_1 q_2$ is a diquark and $\bar{q}_3 \bar{q}_4$ an antidiquark, sorted such that $n_{q_1} \geq n_{q_2}$, $n_{q_3} \geq n_{q_4}$, $n_{q_1} \geq n_{q_3}$, and $n_{q_2} \geq n_{q_4}$ if $n_{q_1} = n_{q_3}$. For the antiparticle, given with a negative sign, $\bar{q}_1 \bar{q}_2$ is an antidiquark and $q_3 q_4$ a diquark, with the same sorting except that either $n_{q_1} > n_{q_3}$ or $n_{q_2} > n_{q_4}$ (so that flavour-diagonal states are particles). The n_J number has the same meaning as for ordinary hadrons. The n_r and n_L numbers do not have physical meaning as the non-relativistic quark model and masses (as for baryon disambiguation) are less clear with these novel states; instead, they are to be used as a two-digit indexing, from 00 to 99 and incrementing with new additions to the tables at the end of this section.

15. Penta-quark states are specified with 9-digit codes $\pm 1 n_r n_L n_{q_1} n_{q_2} n_{q_3} n_{q_4} n_{q_5} n_J$, sorted such that $n_{q_1} \geq n_{q_2} \geq n_{q_3} \geq n_{q_4}$. In the particle the first four are quarks and the fifth an antiquark while the opposite holds in the antiparticle, which is given with a negative sign. The n_J number has the same meaning as for ordinary hadrons. The n_r and n_L numbers do not have physical meaning as the non-relativistic quark model and masses (as for baryon disambiguation) are less clear with these novel states; instead, they are to be used as a two-digit indexing, from 00 to 99 and incrementing with new additions to the tables at the end of this section.

16. Nuclear codes are given as 10-digit numbers $\pm 10LZZZAAAI$. For a (hyper)nucleus consisting of n_p protons, n_n neutrons and n_Λ Λ's, $A = n_p + n_n + n_\Lambda$ gives the total baryon number, $Z = n_p$ the total charge and $L = n_\Lambda$ the total number of strange quarks. I gives the isomer level, with $I = 0$ corresponding to the ground state and $I > 0$ to excitations, see [2], where states denoted m, n, p, q translate to $I = 1$–4. As examples, the deuteron is 1000010020 and ^{235}U is 1000922350. To avoid ambiguities,

    nuclear codes should not be applied to a single hadron, like p, n or Λ^0, where quark-contents-based codes already exist.

The following tables give explicit codings for established states listed in the Summary Tables and unestablished states required for MC modelling, following the preceding rules. This list is not exhaustive, and further codes may be used following the rules.

Notes to the tables:

1) Numbers or names in **bold face** are new or have changed since the 2024 *Review*. Entries in square brackets are necessary multiplet states for consistent MC hadronisation models, which do not currently have experimentally evidenced entries in the RPP listings. Entries in parentheses do not currently have experimentally evidenced entries in the RPP listings.
2) All previously listed pentaquark states have been removed from the MC ID tables in the 2026 update due to not being considered experimentally established in the Summary Tables (Θ^+ [100221132] and Φ^{--} [100331122]).

a) Particularly in the third generation, the left and right sfermion states may mix, as shown. The lighter mixed state is given the smaller number.
b) The physical $\widetilde{\chi}$ states are admixtures of the pure $\widetilde{\gamma}$, $\widetilde{Z}^0$, $\widetilde{W}^+$, $\widetilde{H}_1^0$, $\widetilde{H}_2^0$, and $\widetilde{H}^+$ states.
c) Σ^* and Ξ^* are alternate names for $\Sigma(1385)$ and $\Xi(1530)$.

47. SU(3) Isoscalar Factors and Representation Matrices

Revised August 2019 by R. Kelly (LBNL).

The most commonly used SU(3) isoscalar factors, corresponding to the singlet, octet, and decuplet content of $8 \otimes 8$ and $10 \otimes 8$, are shown at the right. The notation uses particle names to identify the coefficients, so that the pattern of relative couplings may be seen at a glance. We illustrate the use of the coefficients below. See J.J de Swart, Rev. Mod. Phys. **35**, 916 (1963) for detailed explanations and phase conventions.

A $\sqrt{\ }$ is to be understood over every integer in the matrices; the exponent 1/2 on each matrix is a reminder of this. For example, the $\Xi \to \Omega K$ element of the $10 \to 10 \otimes 8$ matrix is $-\sqrt{6}/\sqrt{24} = -1/2$.

Intramultiplet relative decay strengths may be read directly from the matrices. For example, in decuplet → octet + octet decays, the ratio of $\Omega^* \to \Xi\overline{K}$ and $\Delta \to N\pi$ partial widths is, from the $10 \to 8 \times 8$ matrix,

$$\frac{\Gamma\,(\Omega^* \to \Xi\overline{K})}{\Gamma\,(\Delta \to N\pi)} = \frac{12}{6} \times \text{ (phase space factors)} \,. \tag{47.1}$$

Including isospin Clebsch-Gordan coefficients, we obtain, *e.g.*,

$$\frac{\Gamma(\Omega^{*-} \to \Xi^0 K^-)}{\Gamma(\Delta^+ \to p\,\pi^0)} = \frac{1/2}{2/3} \times \frac{12}{6} \times p.s.f. = \frac{3}{2} \times p.s.f. \tag{47.2}$$

Partial widths for $8 \to 8 \otimes 8$ involve a linear superposition of 8_1 (symmetric) and 8_2 (antisymmetric) couplings. For example,

$$\Gamma(\Xi^* \to \Xi\pi) \sim \left(-\sqrt{\frac{9}{20}}\, g_1 + \sqrt{\frac{3}{12}}\, g_2 \right)^2 \,. \tag{47.3}$$

The relations between g_1 and g_2 (with de Swart's normalization) and the standard D and F couplings that appear in the interaction Lagrangian,

$$\mathscr{L} = -\sqrt{2}\; D\; Tr\,(\{\overline{B}, B\}M) + \sqrt{2}\; F\; Tr\,([\overline{B}, B]\,M) \;\;, \tag{47.4}$$

where $[\overline{B}, B] \equiv \overline{B}B - B\overline{B}$ and $\{\overline{B}, B\} \equiv \overline{B}B + B\overline{B}$, are

$$D = \frac{\sqrt{30}}{40}\; g_1 \;, \qquad F = \frac{\sqrt{6}}{24}\; g_2 \;. \tag{47.5}$$

Thus, for example,

$$\Gamma(\Xi^* \to \Xi\pi) \sim (F - D)^2 \sim (1 - 2\alpha)^2 \;, \tag{47.6}$$

where $\alpha \equiv F/(D + F)$. (This definition of α is de Swart's. The alternative $D/(D + F)$, due to Gell-Mann, is also used.)

The generators of SU(3) transformations, λ_a ($a = 1, 8$), are 3×3 matrices that obey the following commutation and anticommutation relationships:

$$[\lambda_a,\ \lambda_b] \equiv \lambda_a\lambda_b - \lambda_b\lambda_a = 2if_{abc}\lambda_c \tag{47.7}$$

$$\{\lambda_a,\ \lambda_b\} \equiv \lambda_a\lambda_b + \lambda_b\lambda_a = \frac{4}{3}\delta_{ab}I + 2d_{abc}\lambda_c \;, \tag{47.8}$$

where I is the 3×3 identity matrix, and δ_{ab} is the Kronecker delta symbol. The f_{abc} are odd under the permutation of any pair of indices, while the d_{abc} are even. The nonzero values are:

$\mathbf{1} \to \mathbf{8} \otimes \mathbf{8}$

$$(\Lambda) \to \begin{pmatrix} N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \end{pmatrix} = \frac{1}{\sqrt{8}} \begin{pmatrix} 2 & 3 & -1 & -2 \end{pmatrix}^{1/2}$$

$\mathbf{8_1} \to \mathbf{8} \otimes \mathbf{8}$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \to \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ & N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ & & \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{20}} \begin{pmatrix} 9 & -1 & -9 & -1 \\ -6 & 0 & 4 & 4 & -6 \\ 2 & -12 & -4 & -2 \\ 9 & -1 & -9 & -1 \end{pmatrix}^{1/2}$$

$\mathbf{8_2} \to \mathbf{8} \otimes \mathbf{8}$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \to \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ & N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ & & \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} 3 & 3 & 3 & -3 \\ 2 & 8 & 0 & 0 & -2 \\ 6 & 0 & 0 & 6 \\ 3 & 3 & 3 & -3 \end{pmatrix}^{1/2}$$

$\mathbf{10} \to \mathbf{8} \otimes \mathbf{8}$

$$\begin{pmatrix} \Delta \\ \Sigma \\ \Xi \\ \Omega \end{pmatrix} \to \begin{pmatrix} N\pi & \Sigma K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ & \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \\ & & \Xi\overline{K} \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} -6 & 6 \\ -2 & 2 & -3 & 3 & 2 \\ 3 & -3 & 3 & 3 \\ 12 \end{pmatrix}^{1/2}$$

$\mathbf{8} \to \mathbf{10} \otimes \mathbf{8}$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \to \begin{pmatrix} \Delta\pi & \Sigma K \\ \Delta\overline{K} & \Sigma\pi & \Sigma\eta & \Xi K \\ & \Sigma\pi & \Xi K \\ \Sigma\overline{K} & \Xi\pi & \Xi\eta & \Omega K \end{pmatrix} = \frac{1}{\sqrt{15}} \begin{pmatrix} -12 & 3 \\ 8 & -2 & -3 & 2 \\ & -9 & 6 \\ 3 & -3 & -3 & 6 \end{pmatrix}^{1/2}$$

$\mathbf{10} \to \mathbf{10} \otimes \mathbf{8}$

$$\begin{pmatrix} \Delta \\ \Sigma \\ \Xi \\ \Omega \end{pmatrix} \to \begin{pmatrix} \Delta\pi & \Delta\eta & \Sigma K \\ \Delta\overline{K} & \Sigma\pi & \Sigma\eta & \Xi K \\ \Sigma\overline{K} & \Xi\pi & \Xi\eta & \Omega K \\ & \Xi\overline{K} & \Omega\eta \end{pmatrix} = \frac{1}{\sqrt{24}} \begin{pmatrix} 15 & 3 & -6 \\ 8 & 8 & 0 & -8 \\ 12 & 3 & -3 & -6 \\ & 12 & -12 \end{pmatrix}^{1/2}$$

abc	f_{abc}	abc	d_{abc}	abc	d_{abc}
123	1	118	$1/\sqrt{3}$	355	1/2
147	1/2	146	1/2	366	−1/2
156	−1/2	157	1/2	377	−1/2

257	1/2	247	−1/2	558	$-1/(2\sqrt{3})$
345	1/2	256	1/2	668	$-1/(2\sqrt{3})$
367	−1/2	338	$1/\sqrt{3}$	778	$-1/(2\sqrt{3})$
458	$\sqrt{3}/2$	344	1/2	888	$-1/\sqrt{3}$
678	$\sqrt{3}/2$				

The λ_a's are

$$\lambda_1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_2 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

$$\lambda_4 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad \lambda_5 = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix} \quad \lambda_6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$

$$\lambda_7 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix} \quad \lambda_8 = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}$$

Equation (47.7) defines the Lie algebra of SU(3). A general d-dimensional representation is given by a set of $d \times d$ matrices satisfying Eq. (47.7) with the f_{abc} given above. Equation (47.8) is specific to the defining 3-dimensional representation.

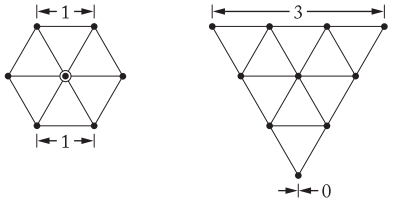
48. SU(n) Multiplets and Young Diagrams



Revised August 2019 by C.G. Wohl (LBNL).

This note tells (1) how SU(n) particle multiplets are identified or labeled, (2) how to find the number of particles in a multiplet from its label, (3) how to draw the Young diagram for a multiplet, and (4) how to use Young diagrams to determine the overall multiplet structure of a composite system, such as a 3-quark or a meson-baryon system.

In much of the literature, the word "representation" is used where we use "multiplet," and "tableau" is used where we use "diagram."

48.1 Multiplet labels

An SU(n) multiplet is uniquely identified by a string of ($n-1$) nonnegative integers: $(\alpha, \beta, \gamma, \ldots)$. Any such set of integers specifies a multiplet. For an SU(2) multiplet such as an isospin multiplet, the single integer α is the number of *steps* from one end of the multiplet to the other (*i.e.*, it is one fewer than the number of particles in the multiplet). In SU(3), the two integers α and β are the numbers of steps across the top and bottom levels of the multiplet diagram. Thus the labels for the SU(3) octet and decuplet

are (1,1) and (3,0). For larger n, the interpretation of the integers in terms of the geometry of the multiplets, which exist in an ($n-1$)-dimensional space, is not so readily apparent.

The label for the SU(n) singlet is $(0, 0, \ldots, 0)$. In a flavor SU(n), the n quarks together form a $(1, 0, \ldots, 0)$ multiplet, and the n antiquarks belong to a $(0, \ldots, 0, 1)$ multiplet. These two multiplets are *conjugate* to one another, which means their labels are related by $(\alpha, \beta, \ldots) \leftrightarrow (\ldots, \beta, \alpha)$.

48.2 Number of particles

The number of particles in a multiplet, $N = N(\alpha, \beta, \ldots)$, is given as follows (note the pattern of the equations). In SU(2), $N = N(\alpha)$ is

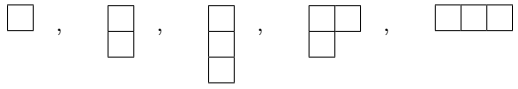
$$N = \frac{(\alpha + 1)}{1} \ . \tag{48.1}$$

In SU(3), $N = N(\alpha, \beta)$ is

$$N = \frac{(\alpha + 1)}{1} \cdot \frac{(\beta + 1)}{1} \cdot \frac{(\alpha + \beta + 2)}{2} \ . \tag{48.2}$$

In SU(4), $N = N(\alpha, \beta, \gamma)$ is

$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\gamma+1)}{1} \cdot \frac{(\alpha+\beta+2)}{2} \cdot \frac{(\beta+\gamma+2)}{2} \cdot \frac{(\alpha+\beta+\gamma+3)}{3} \ . \tag{48.3}$$



Note that in Eq. (48.3) there is no factor with $(\alpha + \gamma + 2)$: only a *consecutive* sequence of the label integers appears in any factor. One more example should make the pattern clear for any SU(n). In SU(5), $N = N(\alpha, \beta, \gamma, \delta)$ is

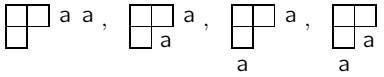
$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\gamma+1)}{1} \cdot \frac{(\delta+1)}{1} \cdot \frac{(\alpha+\beta+2)}{2} \cdot \frac{(\beta+\gamma+2)}{2} \times \frac{(\gamma+\delta+2)}{2} \cdot \frac{(\alpha+\beta+\gamma+3)}{3} \cdot \frac{(\beta+\gamma+\delta+3)}{3} \cdot \frac{(\alpha+\beta+\gamma+\delta+4)}{4} \ . \tag{48.4}$$

From the symmetry of these equations, it is clear that multiplets that are conjugate to one another have the same number of particles, but so can other multiplets. For example, the SU(4) multiplets (3,0,0) and (1,1,0) each have 20 particles. Try the equations and see.

48.3 Young diagrams

A Young diagram consists of an array of boxes (or some other symbol) arranged in one or more *left-justified* rows, with each row being *at least as long* as the row beneath. The correspondence between a diagram and a multiplet label is: The top row juts out α boxes to the right past the end of the second row, the second row juts out β boxes to the right past the end of the third row, *etc.* A diagram in SU(n) has at most n rows. There can be any number of "completed" columns of n boxes buttressing the left of a diagram; these don't affect the label. Thus in SU(3) the diagrams

represent the multiplets (1,0), (0,1), (0,0), (1,1), and (3,0). In any SU(n), the quark multiplet is represented by a single box, the antiquark multiplet by a column of ($n-1$) boxes, and a singlet by a completed column of n boxes.

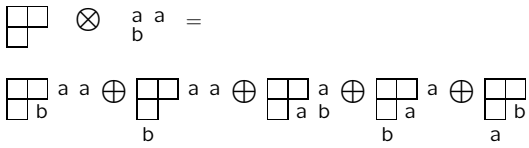


48.4 Coupling multiplets together

The following recipe tells how to find the multiplets that occur in coupling two multiplets together. To couple together more than two multiplets, first couple two, then couple a third with each of the multiplets obtained from the first two, *etc.*

First a definition: A sequence of the letters $a, b, c, \ldots$ is *admissible* if at any point in the sequence at least as many a's have occurred as b's, at least as many b's have occurred as c's, *etc.* Thus *abcd* and *aabcb* are admissible sequences and *abb* and *acb* are not. Now the recipe:

(a) Draw the Young diagrams for the two multiplets, but in one of the diagrams replace the boxes in the first row with a's, the boxes in the second row with b's, *etc.* Thus, to couple two SU(3) octets (such as the π-meson octet and the baryon octet), we start with  and  . The *unlettered* diagram forms the *upper left-hand corner* of all the enlarged diagrams constructed below.



(b) Add the a's from the lettered diagram to the right-hand ends of the rows of the unlettered diagram to form all possible legitimate Young diagrams that have no more than one a per column. In general, there will be several distinct diagrams, and all the a's appear in each diagram. At this stage, for the coupling of the two SU(3) octets, we have:

(c) Use the b's to further enlarge the diagrams already obtained, subject to the same rules. Then throw away any diagram in which the full sequence of letters formed by reading *right to left* in the first row, then the second row, *etc.*, is not admissible.

(d) Proceed as in (c) with the c's (if any), *etc.*

The final result of the coupling of the two SU(3) octets is:

Here only the diagrams with admissible sequences of a's and b's and with fewer than four rows (since $n = 3$) have been kept. In terms of multiplet labels, the above may be written

$$(1, 1) \otimes (1, 1) = (2, 2) \oplus (3, 0) \oplus (0, 3) \oplus (1, 1) \oplus (1, 1) \oplus (0, 0) \ .$$

In terms of numbers of particles, it may be written

$$\mathbf{8} \otimes \mathbf{8} = \mathbf{27} \oplus \mathbf{10} \oplus \overline{\mathbf{10}} \oplus \mathbf{8} \oplus \mathbf{8} \oplus \mathbf{1} \ .$$

The product of the numbers on the left here is equal to the sum on the right, a useful check. (See also Sec. 15 on the Quark Model.)

49. Kinematics

Reviewed August 2021 by D. Miller (Glasgow), D.R. Tovey (Sheffield), written January 2000 by J.D. Jackson (LBNL).

Throughout this section units are used in which $\hbar = c = 1$. The following conversions are useful: $\hbar c = 197.3$ MeV fm, $(\hbar c)^2 = 0.3894$ (GeV)^2 mb.

49.1 Lorentz transformations

The energy E and 3-momentum $\boldsymbol{p}$ of a particle of mass m form a 4-vector $p = (E, \boldsymbol{p})$ whose square $p^2 \equiv E^2 - |\boldsymbol{p}|^2 = m^2$. The velocity of the particle is $\boldsymbol{\beta} = \boldsymbol{p}/E$. The energy and momentum $(E^*, \boldsymbol{p}^*)$ viewed from a frame moving with velocity $\boldsymbol{\beta}_f$ are given by

$$\begin{pmatrix} E^* \\ p_\parallel^* \end{pmatrix} = \begin{pmatrix} \gamma_f & -\gamma_f \beta_f \\ -\gamma_f \beta_f & \gamma_f \end{pmatrix} \begin{pmatrix} E \\ p_\parallel \end{pmatrix} , \quad p_T^* = p_T , \tag{49.1}$$

where $\gamma_f = (1 - \beta_f^2)^{-1/2}$ and p_T ($p_\parallel$) are the components of $\boldsymbol{p}$ perpendicular (parallel) to $\boldsymbol{\beta}_f$. Other 4-vectors, such as the space-time coordinates of events, of course transform in the same way. The scalar product of two 4-momenta $p_1 \cdot p_2 = E_1 E_2 - \boldsymbol{p}_1 \cdot \boldsymbol{p}_2$ is invariant (frame independent).

49.2 Center-of-mass energy and momentum

In the collision of two particles of masses m_1 and m_2 the total center-of-mass energy can be expressed in the Lorentz-invariant form

$$\begin{aligned} E_{\rm cm} &= \left[(E_1 + E_2)^2 - (\boldsymbol{p}_1 + \boldsymbol{p}_2)^2\right]^{1/2} , \\ &= \left[m_1^2 + m_2^2 + 2E_1 E_2 (1 - \beta_1 \beta_2 \cos\theta)\right]^{1/2} , \end{aligned} \tag{49.2}$$

where θ is the angle between the particles. In the frame where one particle (of mass m_2) is at rest (lab frame),

$$E_{\rm cm} = (m_1^2 + m_2^2 + 2E_{1\,\rm lab}\, m_2)^{1/2} . \tag{49.3}$$

The velocity of the center-of-mass in the lab frame is

$$\boldsymbol{\beta}_{\rm cm} = \boldsymbol{p}_{\rm lab}/(E_{1\,\rm lab} + m_2) , \tag{49.4}$$

where $\boldsymbol{p}_{\rm lab} \equiv \boldsymbol{p}_{1\,\rm lab}$ and

$$\gamma_{\rm cm} = (E_{1\,\rm lab} + m_2)/E_{\rm cm} . \tag{49.5}$$

The c.m. momenta of particles 1 and 2 are of magnitude

$$p_{\rm cm} = p_{\rm lab} \frac{m_2}{E_{\rm cm}} . \tag{49.6}$$

For example, if a 0.80 GeV/c kaon beam is incident on a proton target, the center of mass energy is 1.699 GeV and the center of mass momentum of either particle is 0.442 GeV/c. It is also useful to note that

$$E_{\rm cm}\, dE_{\rm cm} = m_2\, dE_{1\,\rm lab} = m_2\, \beta_{1\,\rm lab}\, dp_{\rm lab} . \tag{49.7}$$

49.3 Lorentz-invariant amplitudes

The matrix elements for a scattering or decay process are written in terms of an invariant amplitude $-i\mathscr{M}$. As an example, the S-matrix for $2 \to 2$ scattering is related to $\mathscr{M}$ by

$$\langle p_1' p_2' \,|S-1|\, p_1 p_2\rangle = i(2\pi)^4\, \delta^4(p_1 + p_2 - p_1' - p_2')\mathscr{M}(p_1, p_2;\, p_1', p_2') . \tag{49.8}$$

The state normalization is such that

$$\langle p'|p\rangle = (2\pi)^3\, 2E_p\, \delta^3(\boldsymbol{p}' - \boldsymbol{p}) , \tag{49.9}$$

with $E_p = \sqrt{\boldsymbol{p}^2 + m^2}$.

For a $2 \to 2$ scattering process producing unstable particles $1'$ and $2'$ decaying via $1' \to 3'4'$ and $2' \to 5'6'$ the matrix element for the complete process can be written in the narrow width approximation as:

$$\begin{aligned} &\mathscr{M}(12 \to 3'4'5'6') = \\ &\sum_{h_{1'}, h_{2'}} \frac{\mathscr{M}(12 \to 1'2')\mathscr{M}(1' \to 3'4')\mathscr{M}(2' \to 5'6')}{(m_{3'4'}^2 - m_{1'}^2 + i m_{1'}\Gamma_{1'})(m_{5'6'}^2 - m_{2'}^2 + i m_{2'}\Gamma_{2'})} . \end{aligned} \tag{49.10}$$

Here, m_{ij} is the invariant mass of particles i and j, m_k and Γ_k are the mass and total width of particle k, and the sum runs over the helicities of the intermediate particles. This enables the cross section for such a process to be written as the product of the cross section for the initial $2 \to 2$ scattering process with the branching ratios (relative partial decay rates) of the subsequent decays. A more sophisticated treatment, beyond the narrow width approximation, can be found in the review on "Resonances".

49.4 Particle decays

The partial decay rate of a particle of mass M into n bodies in its rest frame is given in terms of the Lorentz-invariant matrix element $\mathscr{M}$ by

$$d\Gamma = \frac{(2\pi)^4}{2M} |\mathscr{M}|^2\, d\Phi_n\, (P;\, p_1, \ldots, p_n), \tag{49.11}$$

where $d\Phi_n$ is an element of n-body phase space given by

$$d\Phi_n(P;\, p_1, \ldots, p_n) = \delta^4\, (P - \sum_{i=1}^n p_i)\, \prod_{i=1}^n \frac{d^3 p_i}{(2\pi)^3 2E_i} . \tag{49.12}$$

This phase space is reduced by combinatoric factors whenever there are identical particles in the final state. The phase space can be generated recursively, viz.

$$\begin{aligned} d\Phi_n(P;\, p_1, \ldots, p_n) &= d\Phi_j(q;\, p_1, \ldots, p_j) \\ &\times\ d\Phi_{n-j+1}\, (P;\, q, p_{j+1}, \ldots, p_n)(2\pi)^3 dq^2 , \end{aligned} \tag{49.13}$$

where $q^2 = (\sum_{i=1}^j E_i)^2 - \left|\sum_{i=1}^j \boldsymbol{p}_i\right|^2$. This form is particularly useful in the case where a particle decays into another particle that subsequently decays.

49.4.1 *Survival probability*

If a particle of mass M has mean proper lifetime τ ($= 1/\Gamma$) and has momentum $(E, \boldsymbol{p})$, then the probability that it lives for a time t_0 or greater before decaying is given by

$$P(t_0) = e^{-t_0\, \Gamma/\gamma} = e^{-M t_0\, \Gamma/E} , \tag{49.14}$$

and the probability that it travels a distance x_0 or greater is

$$P(x_0) = e^{-M x_0\, \Gamma/|\boldsymbol{p}|} . \tag{49.15}$$

49.4.2 *Two-body decays*

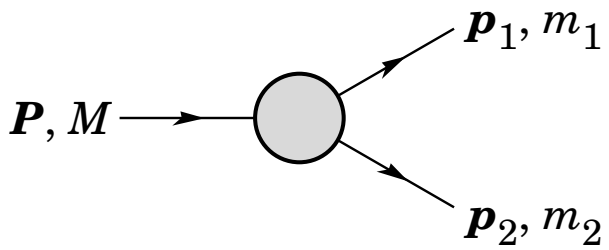

Figure 49.1: Definitions of variables for two-body decays.

In the rest frame of a particle of mass M, decaying into 2 particles labeled 1 and 2,

$$E_1 = \frac{M^2 - m_2^2 + m_1^2}{2M} , \tag{49.16}$$

$$|\boldsymbol{p}_1| = |\boldsymbol{p}_2| = \frac{1}{2M} \sqrt{\lambda(M^2, m_1^2, m_2^2)} , \tag{49.17}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

and

$$d\Gamma = \frac{1}{32\pi^2}\,|\mathscr{M}|^2\,\frac{|\boldsymbol{p}_1|}{M^2}\,d\Omega\,, \tag{49.18}$$

where $\lambda(\alpha,\beta,\gamma) = \alpha^2+\beta^2+\gamma^2-2\alpha\beta-2\alpha\gamma-2\beta\gamma$ is the Källén function and $d\Omega = d\phi_1 d(\cos\theta_1)$ is the solid angle of particle 1. The invariant mass M can be determined from the energies and momenta using Eq. (49.2) with $M = E_{\rm cm}$.

49.4.3 *Three-body decays*

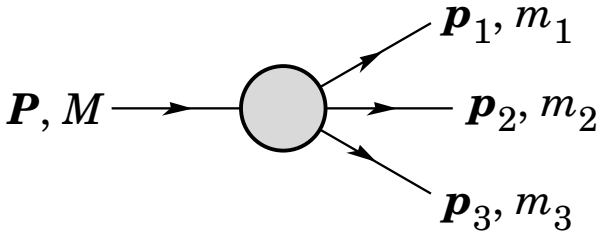

Figure 49.2: Definitions of variables for three-body decays.

Defining $p_{ij} = p_i + p_j$ and $m_{ij}^2 = p_{ij}^2$, then $m_{12}^2+m_{23}^2+m_{13}^2 = M^2+m_1^2+m_2^2+m_3^2$ and $m_{12}^2 = (P-p_3)^2 = M^2+m_3^2-2ME_3$, where E_3 is the energy of particle 3 in the rest frame of M. In that frame, the momenta of the three decay particles lie in a plane. The relative orientation of these three momenta is fixed if their energies are known. The momenta can therefore be specified in space by giving three Euler angles (α,β,γ) that specify the orientation of the final system relative to the initial particle. The direction of any one of the particles relative to the frame in which the initial particle is described can be specified in space by two angles (α,β) while a third angle, γ, can be set as the azimuthal angle of a second particle around the first [1]. Then

$$d\Gamma = \frac{1}{(2\pi)^5}\frac{1}{16M}\,|\mathscr{M}|^2\,dE_1\,dE_3\,d\alpha\,d(\cos\beta)\,d\gamma\,. \tag{49.19}$$

Alternatively

$$d\Gamma = \frac{1}{(2\pi)^5}\frac{1}{16M^2}\,|\mathscr{M}|^2\,|\boldsymbol{p}_1^*|\,|\boldsymbol{p}_3|\,dm_{12}\,d\Omega_1^*\,d\Omega_3\,, \tag{49.20}$$

where $(|\boldsymbol{p}_1^*|,\,\Omega_1^*)$ is the momentum of particle 1 in the rest frame of 1 and 2, and Ω_3 is the angle of particle 3 in the rest frame of the decaying particle. $|\boldsymbol{p}_1^*|$ and $|\boldsymbol{p}_3|$ are given by

$$|\boldsymbol{p}_1^*| = \frac{1}{2m_{12}}\sqrt{\lambda(m_{12}^2,m_1^2,m_2^2)}\,, \tag{49.21a}$$

and

$$|\boldsymbol{p}_3| = \frac{1}{2M}\sqrt{\lambda(M^2,m_{12}^2,m_3^2)}\,. \tag{49.21b}$$

[Compare with Eq. (49.17).]

If the decaying particle is a scalar, or we average over its spin states, then integration over the angles in Eq. (49.19) gives

$$\begin{aligned} d\Gamma &= \frac{1}{(2\pi)^3}\frac{1}{8M}\,\overline{|\mathscr{M}|^2}\,dE_1\,dE_3 \\ &= \frac{1}{(2\pi)^3}\frac{1}{32M^3}\,\overline{|\mathscr{M}|^2}\,dm_{12}^2\,dm_{23}^2\,. \end{aligned} \tag{49.22}$$

This is the standard form for the Dalitz plot.

49.4.3.1 *Dalitz plot*

For a given value of m_{12}^2, the range of m_{23}^2 is determined by its values when $\boldsymbol{p}_2$ is parallel or antiparallel to $\boldsymbol{p}_3$:

$$(m_{23}^2)_{\rm max} = (E_2^*+E_3^*)^2 - \left(\sqrt{E_2^{*2}-m_2^2}-\sqrt{E_3^{*2}-m_3^2}\right)^2\,, \tag{49.23a}$$

$$(m_{23}^2)_{\rm min} = (E_2^*+E_3^*)^2 - \left(\sqrt{E_2^{*2}-m_2^2}+\sqrt{E_3^{*2}-m_3^2}\right)^2\,. \tag{49.23b}$$

Here $E_2^* = (m_{12}^2-m_1^2+m_2^2)/2m_{12}$ and $E_3^* = (M^2-m_{12}^2-m_3^2)/2m_{12}$ are the energies of particles 2 and 3 in the m_{12} rest frame. The scatter plot in m_{12}^2 and m_{23}^2 is called a Dalitz plot. If $\overline{|\mathscr{M}|^2}$ is constant, the allowed region of the plot will be uniformly populated with events [see Eq. (49.22)]. A nonuniformity in the plot gives immediate information on $|\mathscr{M}|^2$. For example, in the case of $D\to K\pi\pi$, bands appear when $m_{(K\pi)} = m_{K^*(892)}$, reflecting the appearance of the decay chain $D\to K^*(892)\pi\to K\pi\pi$.

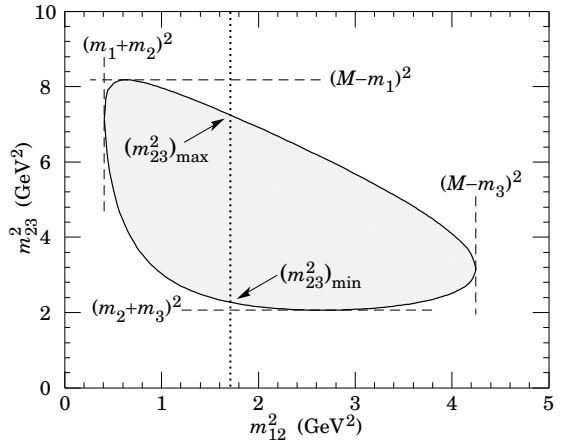

Figure 49.3: Dalitz plot for a three-body final state. In this example, the state is $\pi^+\overline{K}^0 p$ at 3 GeV. Four-momentum conservation restricts events to the shaded region.

49.4.4 *Kinematic limits*

49.4.4.1 *Three-body decays*

In a three-body decay (Fig. 49.2) the maximum of $|\boldsymbol{p}_3|$, [given by Eq. (49.21)], is achieved when $m_{12} = m_1+m_2$, *i.e.*, particles 1 and 2 have the same vector velocity in the rest frame of the decaying particle. If, in addition, $m_3 > m_1, m_2$, then $|\boldsymbol{p}_3|_{\rm max} > |\boldsymbol{p}_1|_{\rm max}$, $|\boldsymbol{p}_2|_{\rm max}$. The distribution of m_{12} values possesses an end-point or maximum value at $m_{12} = M-m_3$. This can be used to constrain the mass difference of a parent particle and one invisible decay product.

49.4.4.2 *Sequential two-body decays*

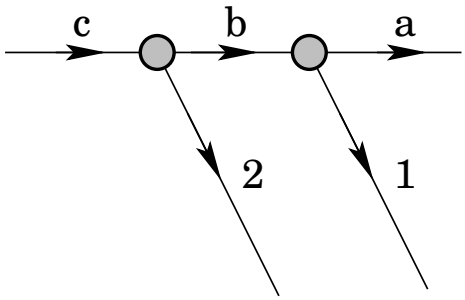

Figure 49.4: Particles participating in sequential two-body decay chain. Particles labeled 1 and 2 are visible while the particle terminating the chain (a) is invisible.

When a heavy particle initiates a sequential chain of two-body decays terminating in an invisible particle, constraints on the masses of the states participating in the chain can be obtained from end-points and thresholds in invariant mass distributions of the aggregated decay products. For the two-step decay chain depicted in Fig. 49.4 the invariant mass distribution of the two visible particles possesses an end-point given by:

$$(m_{12}^{\rm max})^2 = \frac{(m_{\rm c}^2-m_{\rm b}^2)(m_{\rm b}^2-m_{\rm a}^2)}{m_{\rm b}^2}\,, \tag{49.24}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by TUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

provided particles 1 and 2 are massless. If visible particle 1 has non-zero mass m_1 then Eq. (49.24) is replaced by

$$(m_{12}^{\max})^2 = m_1^2 + \frac{(m_{\rm c}^2 - m_{\rm b}^2)}{2m_{\rm b}^2} \times \left(m_1^2 + m_{\rm b}^2 - m_{\rm a}^2 + \sqrt{(-m_1^2 + m_{\rm b}^2 - m_{\rm a}^2)^2 - 4m_1^2 m_{\rm a}^2}\right) \quad (49.25)$$

See Refs. [2] and [3] for other cases.

49.4.5 *Multibody decays*

The above results may be generalized to final states containing any number of particles by combining some of the particles into "effective particles" and treating the final states as 2 or 3 "effective particle" states. Thus, if $p_{ijk\ldots} = p_i + p_j + p_k + \ldots$, then

$$m_{ijk\ldots} = \sqrt{p^2{}_{ijk\ldots}} \ , \quad (49.26)$$

and $m_{ijk\ldots}$ may be used in place of *e.g.*, m_{12} in the relations in Sec. 49.4.3 or Sec. 49.4.4 above.

49.5 Cross sections

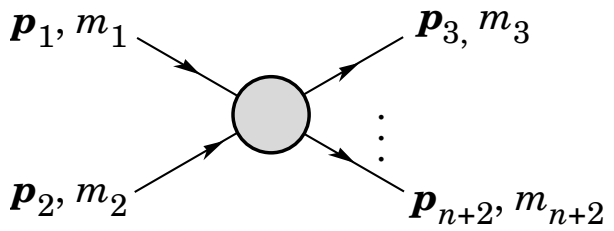

Figure 49.5: Definitions of variables for production of an n-body final state.

The differential cross section is given by

$$d\sigma = \frac{(2\pi)^4 |\mathscr{M}|^2}{4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}} \times \ d\Phi_n(p_1 + p_2;\ p_3,\ \ldots,\ p_{n+2}) \ . \quad (49.27)$$

[See Eq. (49.12).] In the rest frame of m_2(lab),

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = m_2 p_{1\,\rm lab}; \quad (49.28a)$$

while in the center-of-mass frame

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = p_{1\rm cm}\sqrt{s} \ . \quad (49.28b)$$

49.4.1 *Two-body reactions*

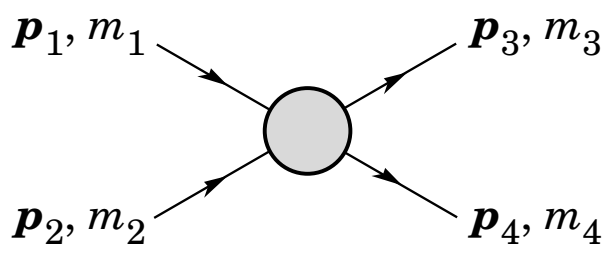

Figure 49.6: Definitions of variables for a two-body final state.

Two particles of momenta p_1 and p_2 and masses m_1 and m_2 scatter to particles of momenta p_3 and p_4 and masses m_3 and m_4; the Lorentz-invariant Mandelstam variables are defined by

$$\begin{aligned} s &= (p_1 + p_2)^2 = (p_3 + p_4)^2 \\ &= m_1^2 + 2E_1E_2 - 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_2 + m_2^2 \ , \quad (49.29) \\ t &= (p_1 - p_3)^2 = (p_2 - p_4)^2 \\ &= m_1^2 - 2E_1E_3 + 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_3 + m_3^2 \ , \quad (49.30) \\ u &= (p_1 - p_4)^2 = (p_2 - p_3)^2 \\ &= m_1^2 - 2E_1E_4 + 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_4 + m_4^2 \ , \quad (49.31) \end{aligned}$$

and they satisfy

$$s + t + u = m_1^2 + m_2^2 + m_3^2 + m_4^2 \ . \quad (49.32)$$

The two-body cross section may be written as

$$\frac{d\sigma}{dt} = \frac{1}{64\pi s} \ \frac{1}{|\boldsymbol{p}_{1\rm cm}|^2} \ |\mathscr{M}|^2 \ . \quad (49.33)$$

In the center-of-mass frame

$$\begin{aligned} t &= (E_{1\rm cm} - E_{3\rm cm})^2 - (p_{1\rm cm} - p_{3\rm cm})^2 - 4p_{1\rm cm}\, p_{3\rm cm}\, \sin^2(\theta_{\rm cm}/2) \\ &= t_0 - 4p_{1\rm cm}\, p_{3\rm cm}\, \sin^2(\theta_{\rm cm}/2) \ , \end{aligned} \quad (49.34)$$

where $\theta_{\rm cm}$ is the angle between particle 1 and 3. The limiting values t_0 ($\theta_{\rm cm} = 0$) and t_1 ($\theta_{\rm cm} = \pi$) for $2 \to 2$ scattering are

$$t_0(t_1) = \left[\frac{m_1^2 - m_3^2 - m_2^2 + m_4^2}{2\sqrt{s}}\right]^2 - (p_{1\,\rm cm} \mp p_{3\,\rm cm})^2 \ . \quad (49.35)$$

In the literature the notation $t_{\min}$ ($t_{\max}$) for t_0 (t_1) is sometimes used, which should be discouraged since $t_0 > t_1$. The center-of-mass energies and momenta of the incoming particles are

$$E_{1\rm cm} = \frac{s + m_1^2 - m_2^2}{2\sqrt{s}} \ , \quad E_{2\rm cm} = \frac{s + m_2^2 - m_1^2}{2\sqrt{s}} \ , \quad (49.36)$$

For $E_{3\rm cm}$ and $E_{4\rm cm}$, change m_1 to m_3 and m_2 to m_4. Then

$$p_{i\,\rm cm} = \sqrt{E_{i\,\rm cm}^2 - m_i^2} \text{ and } p_{1\rm cm} = \frac{p_{1\,\rm lab}\, m_2}{\sqrt{s}} \ . \quad (49.37)$$

Here the subscript lab refers to the frame where particle 2 is at rest. [For other relations see Eqs. (49.2)–(49.4).]

49.5.2 *Inclusive reactions*

Choose some direction (usually the beam direction) for the z-axis; then the energy and momentum of a particle can be written as

$$E = m_{_T} \cosh y \ , \ p_x \ , \ p_y \ , \ p_z = m_{_T} \sinh y \ , \quad (49.38)$$

where $m_{_T}$, conventionally called the 'transverse mass', is given by

$$m_{_T}^2 = m^2 + p_x^2 + p_y^2 \ . \quad (49.39)$$

and the rapidity y is defined by

$$\begin{aligned} y &= \frac{1}{2} \ln\left(\frac{E + p_z}{E - p_z}\right) \\ &= \ln\left(\frac{E + p_z}{m_{_T}}\right) = \tanh^{-1}\left(\frac{p_z}{E}\right) \ . \end{aligned} \quad (49.40)$$

Note that the definition of the transverse mass in Eq. (49.39) differs from that used by experimentalists at hadron colliders (see Sec. 49.6.1 below). Under a boost in the z-direction to a frame with velocity β, $y \to y - \tanh^{-1}\beta$. Hence, the shape of the rapidity distribution dN/dy is invariant, as are differences in rapidity. The invariant cross section may also be rewritten

$$E\frac{d^3\sigma}{d^3p} = \frac{d^3\sigma}{d\phi\, dy\, p_{_T} dp_{_T}} \Longrightarrow \frac{d^2\sigma}{\pi\, dy\, d(p_{_T}^2)} \ . \quad (49.41)$$

The second form is obtained using the identity $dy/dp_z = 1/E$, and the third form represents the average over ϕ.

Feynman's x variable is given by

$$x = \frac{p_z}{p_{z\,\max}} \approx \frac{E + p_z}{(E + p_z)_{\max}} \quad (p_T \ll |p_z|) \ . \tag{49.42}$$

In the c.m. frame,

$$x \approx \frac{2p_{z\,\mathrm{cm}}}{\sqrt{s}} = \frac{2m_T \sinh y_{\mathrm{cm}}}{\sqrt{s}} \tag{49.43}$$

and

$$= (y_{\mathrm{cm}})_{\max} = \ln(\sqrt{s}/m) \ . \tag{49.44}$$

The invariant mass M of the two-particle system described in Sec. 49.4.2 can be written in terms of these variables as

$$M^2 = m_1^2 + m_2^2 + 2[E_T(1)E_T(2)\cosh \Delta y - \boldsymbol{p}_T(1)\cdot\boldsymbol{p}_T(2)] \ , \tag{49.45}$$

where

$$E_T(i) = \sqrt{|\boldsymbol{p}_T(i)|^2 + m_i^2} \ , \tag{49.46}$$

and $\boldsymbol{p}_T(i)$ denotes the transverse momentum vector of particle i.

For $p \gg m$, the rapidity [Eq. (49.40)] may be expanded to obtain

$$\begin{aligned} y &= \frac{1}{2} \ln \frac{\cos^2(\theta/2) + m^2/4p^2 + \ldots}{\sin^2(\theta/2) + m^2/4p^2 + \ldots} \\ &\approx -\ln \tan(\theta/2) \equiv \eta \end{aligned} \tag{49.47}$$

where $\cos\theta = p_z/p$. The pseudorapidity η defined by the second line is approximately equal to the rapidity y for $p \gg m$ and $\theta \gg 1/\gamma$, and in any case can be measured when the mass and momentum of the particle are unknown. From the definition one can obtain the identities

$$\sinh\eta = \cot\theta \ , \quad \cosh\eta = 1/\sin\theta \ , \quad \tanh\eta = \cos\theta \ . \tag{49.48}$$

49.6 Transverse variables

At hadron colliders, a significant and unknown proportion of the energy of the incoming hadrons in each event escapes down the beam-pipe. Consequently, if invisible particles are created in the final state, their net momentum can only be constrained in the plane transverse to the beam direction. Defining the z-axis as the beam direction, this net momentum is equal to the missing transverse energy vector

$$\boldsymbol{E}_T^{\mathrm{miss}} = -\sum_i \boldsymbol{p}_T(i) \ , \tag{49.49}$$

where the sum runs over the transverse momenta of all visible final state particles.

49.6.1 *Single production with semi-invisible final state*

Consider a single heavy particle of mass M produced in association with visible particles which decays as in Fig. 49.1 to two particles, of which one (labeled particle 1) is invisible. The mass of the parent particle can be constrained with the quantity M_T defined by

$$\begin{aligned} M_T^2 &\equiv [E_T(1) + E_T(2)]^2 - [\boldsymbol{p}_T(1) + \boldsymbol{p}_T(2)]^2 \\ &= m_1^2 + m_2^2 + 2[E_T(1)E_T(2) - \boldsymbol{p}_T(1)\cdot\boldsymbol{p}_T(2)] \ , \end{aligned} \tag{49.50}$$

where

$$\boldsymbol{p}_T(1) = \boldsymbol{E}_T^{\mathrm{miss}} \ . \tag{49.51}$$

This quantity is called the 'transverse mass' by hadron collider experimentalists but it should be noted that it is quite different from that used in the description of inclusive reactions [Eq. (49.39)]. The distribution of event M_T values possesses an end-point at $M_T^{\max} = M$. If $m_1 = m_2 = 0$ then

$$M_T^2 = 2|\boldsymbol{p}_T(1)||\boldsymbol{p}_T(2)|(1 - \cos\phi_{12}) \ , \tag{49.52}$$

where ϕ_{ij} is defined as the angle between particles i and j in the transverse plane.

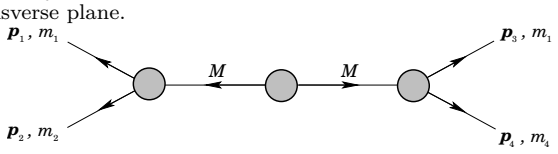

Figure 49.7: Definitions of variables for pair production of semi-invisible final states. Particles 1 and 3 are invisible while particles 2 and 4 are visible.

49.6.2 *Pair production with semi-invisible final states*

Consider two identical heavy particles of mass M produced such that their combined center-of-mass is at rest in the transverse plane (Fig. 49.7). Each particle decays to a final state consisting of an invisible particle of fixed mass m_1 together with an additional visible particle. M and m_1 can be constrained with the variables M_{T2} and M_{CT} which are defined in Refs. [4] and [5].

50. Resonances

Revised August 2025 by D.M. Asner (SNOLAB, Lively), C. Hanhart (FZ Jülich) and M. Mikhasenko (Ruhr U. Bochum).

50.1 General Considerations

Perturbative methods can be applied to systems of quarks and gluons only for large momentum transfers (see review on 'Quantum Chromodynamics') and, under certain conditions, to some properties of systems that contain heavy quarks or very large momentum scales (see review on "Heavy-quark and soft-collinear effective theory"). Dealing with Quantum Chromodynamics (QCD) in the low momentum transfer region is a very complicated, nonperturbative problem. Most hadrons are resonances, which means that they appear as poles of the $\mathcal{S}$-matrix in the complex energy plane, a notion further detailed in Sec. 50.2. These resonances can show up either in so-called formation experiments,

$$A + B \to \mathbf{R} \to C_1 + ... + C_n \ ,$$

where they become visible in an energy scan (for example, the R-function measured in e^+e^- annihilation, *cf.* the corresponding plots in the review on "Plots of Cross Sections and Related Quantities"), or together with a spectator particle S in production experiments of the kind

$$\begin{aligned} A + B \to \mathbf{R} + S \to [C_1 + ... + C_n] + S \ , \\ Z \to \mathbf{R} + S \to [C_1 + ... + C_n] + S \ , \end{aligned}$$

where the first reaction corresponds to an associated production, the second is a decay (see "Review of Multibody Charm Analyses"). In the latter case, the resonance properties are commonly extracted from a Dalitz-plot analysis (see review on "Kinematics") or projections thereof.

Resonance phenomena are very rich: while typical hadronic widths are of the order of 100 MeV (*e.g.*, for the meson resonances $\rho(770)$ or $\psi(4040)$ or the baryon resonance $\Delta(1232)$) corresponding to a lifetime of 10^{-23} s, the widths can also be as small as a few MeV (*e.g.* of $\phi(1020)$) or even a lot smaller (*e.g.* of J/ψ) or as large as several hundred MeV (*e.g.* of the meson resonances $f_0(500)$ or $D_1(2430)$ or the baryon resonance $N(2190)$).

Typically, a resonance appears as a peak in the total cross section, however, under certain conditions they can induce dips or become visible only after a partial wave decomposition. If the structure is narrow and if there are no relevant thresholds or other resonances nearby, the resonance properties may be extracted employing a Breit–Wigner parameterization, if necessary improved by using an energy-dependent width (*cf.* Sec. 50.3.1 of this review). However, in general, unitarity and analyticity call for the use of more refined tools as described in this manuscript, as well as in recent review articles [1,2]. When there are overlapping resonances with the same quantum numbers, the resonance terms should not simply be added but combined in a non-trivial way either in a $\mathcal{K}$-matrix approach (*cf.* Sec. 50.3.2 of this review) or using other advanced methods (*cf.* Sec. 50.3.5 of this review). Additional constraints from the $\mathcal{S}$-matrix allow one to build more reliable amplitudes and, in turn, to reduce the systematic uncertainties of the resonance parameters: pole locations and residues. In addition, for broad resonances there is no direct relation between pole location and the total width/lifetime — then, the pole residues need to be used in order to quantify the decay properties.

For simplicity, throughout this review we will primarily focus on the two-body kinematics. The formulas are given for resonances in a system of distinguishable, scalar particles. The additional complications that appear in the presence of spins can be controlled in the helicity framework developed by Jacob and Wick [3], or in a non-covariant [4] or covariant [5] tensor-operator formalisms. Within these approaches, sequential (cascade) decays are commonly treated as a coherent sum of two-body interactions.

50.1.1 *Properties of the $\mathcal{S}$-matrix*

The unitary operator that connects asymptotic *in* and *out* states is called the $\mathcal{S}$-matrix. The scattering amplitude is defined as the interacting part of the $\mathcal{S}$-matrix. For a two-particle scattering process, it is commonly defined via:

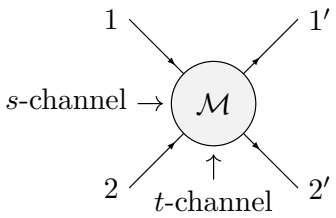

Figure 50.1: Illustration of the relation between s- and t-channel.

$$\begin{aligned} i(2\pi)^4\delta^4(p_1 + p_2 - p_{1'} - p_{2'})\,\mathcal{M}(p_1, p_2; p_{1'}, p_{2'})_{ba} \\ == {}_{\text{out}}\langle p_{1'}p_{2'}, b|\,\mathcal{S} - 1\,|p_1p_2, a\rangle_{\text{in}} \end{aligned} \tag{50.1}$$

where $|p_1p_2, a\rangle$ and $|p_{1'}p_{2'}, b\rangle$ are asymptotic states with on-shell four-momenta p_1, p_2 and $p_{1'}$, $p_{2'}$, respectively, that can be treated as non-interacting particles in the spirit of the Lehmann-Symanzik-Zimmermann (LSZ) reduction (for details see [6]).

The labels a and b are used to specify the *reaction channels*. In general terms, a reaction channel describes the possible outcome of a scattering event, characterized by the quantum numbers of the particles involved. Note that in general $\mathcal{M}_{ab}$ operates as a matrix in channel space and encodes both elastic transitions ($a = b$) and inelastic ones ($a \neq b$).

In many situations, however, the initial state is not itself part of the strongly interacting channel space. Typical examples are an electromagnetic current, e.g. e^+e^-, a weak decay, or a hadronic configuration with only a very small coupling to the system. Formally, such a source defines an additional row and column of the full scattering matrix, but its feedback on the hadronic submatrix is negligible. It is therefore advantageous to restrict attention to the strongly coupled channels, while collecting the source transitions into a *production amplitude* vector $\mathcal{A}_a$, with one component per hadronic channel. In Section 50.1.2, we make a great use of this distinction. The strong dynamics and rescattering are governed entirely by the coupled-channel matrix $\mathcal{M}_{ab}$, but the external source enters only as a driving term feeding into the hadronic system.

For a single-particle state, we employ the relativistic normalization,

$$\left\langle p'|p\right\rangle = (2\pi)^3 2E_p\,\delta^3(\vec{p}\,' - \vec{p}), \tag{50.2}$$

with $E_p = \sqrt{\vec{p}^{\,2} + m^2}$.

Mandelstam variables are defined as $s = (p_1 + p_2)^2$, $t = (p_1 - p_{1'})^2$, and $u = (p_1 - p_{2'})^2$. They are not independent, since

$$s + t + u = m_1^2 + m_2^2 + m_{1'}^2 + m_{2'}^2$$

holds, where the m_i with $i \in \{1, 1', 2, 2'\}$ represent the masses of the particles involved. As a result, the reaction amplitude can be expressed as a function of two variables, $\mathcal{M}(s, t)$.

The Mandelstam variables represent a common choice of variables for characterizing particle scattering. Specifically, the process described in Eq. (50.1) is known as *s-channel*, referring to a reaction, $1, 2 \to 1', 2'$. Here, $\sqrt{s}$ represents the total energy of the interacting system in the center-of-momentum frame. The variable t corresponds to the *momentum transfer squared*, which is related to the scattering angle, the angle between the momenta of particles 1 and $1'$ in the center-of-momentum frame (see also the review on "Kinematics" in this Review of Particle Physics). The scattering process with particles 1 and the antiparticle of $1'$, denoted by $\overline{1'}$, incoming and the antiparticle of 2, denoted by $\overline{2}$, and $2'$ outgoing represents a different reaction, it is referred to as the *t-channel* reaction. The scattering amplitudes of s- and t-channel are related via the so-called *crossing symmetry*. The *u-channel* is introduced analogously as a reaction with the initial state of particles 1 and $\overline{2'}$ and the final state of particles $1'$ and $\overline{2}$. The t-channel and the u-channel are referred to as the *crossed*

channels relative to the reaction in Eq. (50.1). This relationship is illustrated in Fig. 50.1.

The analysis of resonance phenomena requires going deeper into the complex analysis of the amplitude: $\mathcal{M}(s,t)$ is a multivalued function due to the complex *branch points* associated with the Mandelstam variables. These branch points emerge whenever a new channel becomes accessible, that is, whenever s exceeds $s_{\mathrm{thr},a} = (m_{1,a}+m_{2,a})^2$, where $m_{i,a}$ denotes the masses of the two particles in channel a. Every two-particle threshold introduces a square-root singularity. The square-root function is inherently double-valued; for instance, the equation $x = y^2$ has two solutions: $\sqrt{x}$ and $-\sqrt{x}$. In the complex plane, these two solutions are represented as separate layers or surfaces, known as *Riemann sheets* or Riemann surfaces. Consequently, each square-root singularity causes the number of Riemann sheets of the scattering amplitude to double. If a channel opens that has an odd number of particles, the branch point at the threshold exhibits a logarithmic singularity [7]. Such a branch point gives rise to an infinite number of sheets. The branch points come with their associated branch cuts — by convention these are taken from the threshold to infinity along the real axis and accordingly called *right-hand cuts*. To explore a reaction amplitude in the complex energy plane, one can introduce a complex component to the Mandelstam variable s. The section of the complex plane that corresponds to a positive imaginary component of the relative momentum can be directly accessed from the physical region and is called the first Riemann sheet or the *physical sheet*. The other sheets are called *unphysical sheets*. The *physical axis* of an s-channel scattering amplitude represents a line for real values of the variable s larger than the lowest threshold to be evaluated on the physical sheet.

While the physical Riemann sheet is free of singularities off the real axis (which hosts the mentioned branch points and, in some cases, poles below the lowest threshold), the unphysical sheets may contain resonance poles and branch points. Branch points within the complex plane of an unphysical sheet appear, *e.g.*, when there is a resonance in a subsystem of involved particles [7,8] (for some in-depth discussion of the discontinuities, see Ref. [9]). The branch points related to thresholds in the crossed channels are located on the real axis to the left of the physical region, and, therefore, are referred to as the *left-hand cuts*. An illustrative example for a left-hand cut is the one-pion exchange in nucleon-nucleon scattering that is located in the unphysical domain at $s = 4m_N^2 - m_\pi^2$. Triangle topologies, which are Feynman diagrams characterized by a triangular loop of three propagators, can lead to logarithmic singularities in the scattering amplitude. These singularities, appearing on the unphysical sheets, are often termed *triangle singularities* (TS) [7,10,11].

The reaction amplitude has poles that can be categorized as bound states, virtual states, or resonances. Poles corresponding to bound and virtual states manifest at real values of s. Specifically, *bound state* poles are found on the physical sheet below the lowest threshold, while *virtual state* poles are situated on an unphysical sheet, below the threshold. *Resonance poles*, on the other hand, are located inside the complex plane of the unphysical sheets. Notably, those resonance poles that are on the unphysical sheet nearest to the physical region exert the most significant influence on experimental observables. Analyticity dictates that for every pole at a specific complex value of s_p, there must be a corresponding pole at its complex conjugate value s_p^*. This relationship is a direct consequence of the *Schwarz reflection principle*, a mathematical technique utilized for analytic continuation within scattering theory. For a single-channel case, the complex structure of an amplitude with a single resonance is illustrated in Fig. 50.2(a)-(c). Among the two poles, symmetrically positioned relative to the real axis on the second sheet, the one exhibiting a negative imaginary part seamlessly connects to the physical axis, which becomes especially clear in panel (c) of the figure where the physical axis is shown as the blue line. It therefore has a more pronounced effect on observables in the vicinity of the resonance region compared to its conjugate counterpart. The shortest continuous path from the physical region to the second sheet pole with the positive imaginary part is via a line that goes around the threshold. However, the effective distance to both poles becomes comparable for near threshold kinematics, thereby rendering the influence of both poles on observables similarly significant—in fact it is the interplay of the various resonance poles that renders scattering amplitudes real below the lowest threshold.

An alternative way to depict the complex sheet structure is through the momentum or k-plane, where k denotes the relative momentum of the two scattering particles in their center-of-momentum frame. For particles of equal mass, denoted as m (expression for unequal masses is given in Eq. (50.7)), one finds

$$k = \frac{1}{2}\sqrt{s - s_\mathrm{thr}}\,, \tag{50.3}$$

where $s_\mathrm{thr} = 4m^2$ is the threshold for two particles of mass m. Unlike the complex s-plane, in the single channel case the k-plane does not have a two-body threshold cut. Consequently, both the physical and unphysical Riemann sheets, which are linked along the branch cut in s, are mapped onto the upper and lower half of the complex k-plane, respectively. The k-plane is sketched in Fig. 50.2(d), including possible locations of resonance poles. In this representation it becomes especially clear that only one resonance pole drives the dynamics on the physical axis in the resonance region, while at the threshold, where $k = 0$, both poles are of equal significance.

In situations involving two relevant channels, we encounter four Riemann sheets. These are illustrated in the left panel of Fig. 50.3. For a system with two channels, the four-sheeted Riemann surface can also be transformed into a single plane free of cuts. For non-relativistic kinematics, it is represented by the new variable, ω, which is defined in relation to the channel-momenta, as detailed in references [12,13] (for a recent application, see Ref. [14]).

$$k_a = \sqrt{\frac{\mu_a \Delta}{2}}\left(\omega + \frac{1}{\omega}\right)\,, \quad k_b = \sqrt{\frac{\mu_b \Delta}{2}}\left(\omega - \frac{1}{\omega}\right)\,, \tag{50.4}$$

where Δ denotes the energy difference between the two thresholds and μ_a is the reduced mass of the particles in channel a, $\mu_a = m_{1,a}m_{2,a}/(m_{1,a}+m_{2,a})$. The lower threshold is located at $\omega = 0+i$, the higher at $\omega = 1+0i$. The mapping of the Riemann sheets and the different areas in the ω-plane is shown in the right panel of Fig. 50.3. The ω-plane nicely shows how the different sheets connect to each other.[1] The solid green line shows the physical axis in the physical regime. The thick black line shows its analytic continuation below the lowest threshold. The pronounced kinks in this line for the ω plane show the thresholds. Please observe that for $\omega \approx 0 + i$ the sheet structure agrees with panel (d) of Fig. 50.2, since in this kinematic regime the second channel does not matter.

In the context of a two-channel scenario, the proximity of a sheet to the physical axis varies with increasing energy. Specifically, for energies that exceed the first threshold, but remain below the second, sheet (21) is the one that smoothly connects to the upper half-plane of the physical sheet (11). Once the energy surpasses the second threshold, sheet (22) assumes this role. As a result, any pole on sheet (21) that lies above the second threshold will manifest in the data solely as a cusp right at the second threshold. Sheet (12), on the other hand, is remote for all energies, except those very close to the second threshold (for illustration see Ref. [15]).

Singularities, poles and branch points induce visible structures in observables. However, it is crucial to note that not every observable bump is indicative of a resonance as discussed in [16]. Under certain kinematic conditions, Triangle Singularities, in particular, can either mimic resonance signals, as suggested in Refs. [17–22], or significantly alter resonance signals [23] (see Ref. [24] for a review). Conversely, not all resonances produce a noticeable bump across all observables. For example, in the baryon sector, there is no clear trace of the $N(1440)1/2^+$, the so-called Roper resonance, in the πN observables or phase shifts, although careful analyses reveal a pole [25]. In the meson sector, the $f_0(500)$, also known as σ meson, was firmly established

[1] An alternative illustration for this two-channel case as well as an extension to three channels can be found in Ref. [2].

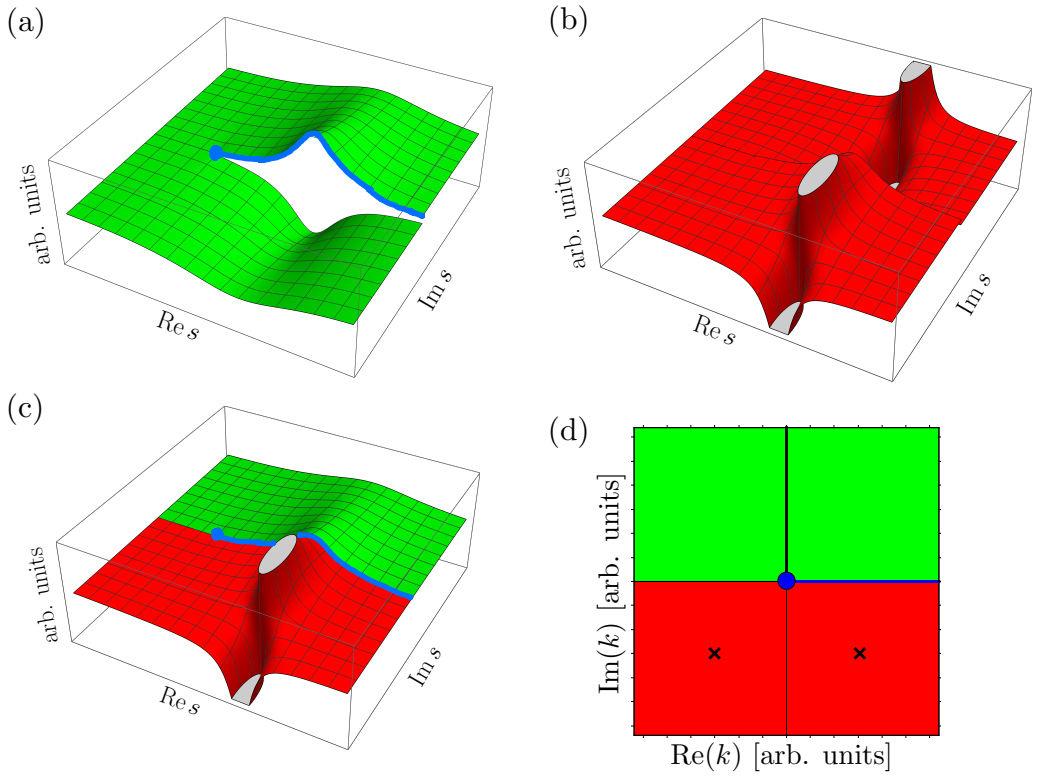

Figure 50.2: (a)-(c): Imaginary part of a typical scattering amplitude with an isolated resonance. The blue line shows the physical range of the Mandelstam variable s: it is real and starts from the threshold shown by the blue dot. Plot (a) shows the imaginary part of the amplitude in the complex s-plane that corresponds to the first or physical sheet (green surface), plot (b) shows the related unphysical or the second sheet (red surface) which contains the resonance poles, and plot (c) shows the analytic continuation of the same amplitude from the upper half plane of the physical sheet to the lower half plane of the unphysical sheet. The two sheets are connected smoothly along the real axis above the threshold. Panel (d) shows the k-plane, which is free of cuts. The upper (lower) half plane maps onto the physical (unphysical) sheet. Also here the blue line corresponds to the physically accessible values of the momentum k, which starts at threshold, where $k = 0$. The thick black line shows the analytic continuation of the on-shell momentum in the below threshold regime. The locations of the resonance poles are indicated by the black crosses.

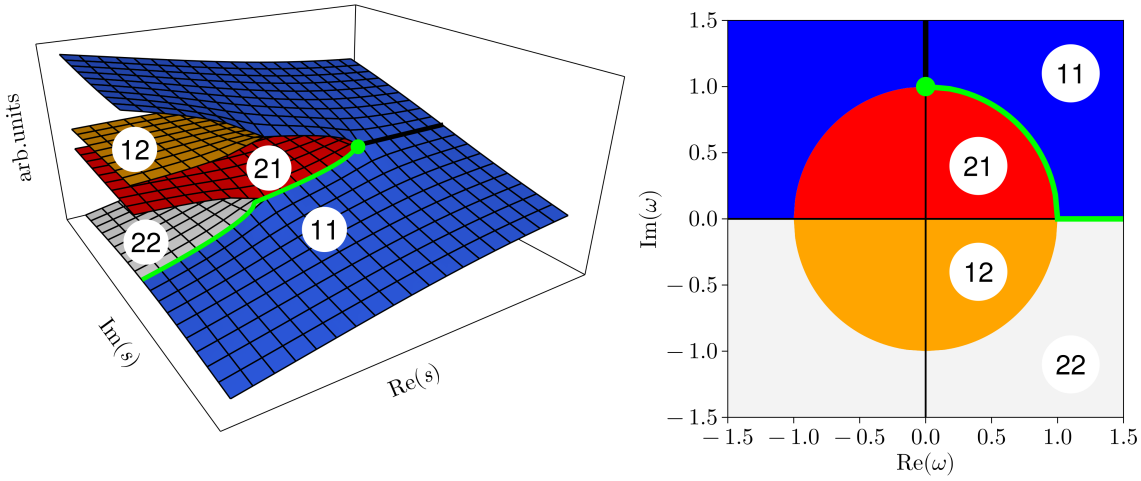

Figure 50.3: Cut structure of the $\mathcal{S}$-matrix with two channels present. The diagrams feature four sheets, labeled (ij), where both i and j can be 1 or 2. These labels indicate the doubling of the sheets at the first and second thresholds. The left panel displays the complex s plane, while the right panel represents the ω plane. The physical axis, along with its analytic continuation below the threshold, is highlighted with a thick solid line, green in the physical regime, black for the analytic continuation below the lowest threshold.

only after the application of very sophisticated theoretical analysis tools (see, *e.g.*, Ref. [26] for a review). This complexity arises since the approximate chiral symmetry of QCD calls for a zero in the scalar-isoscalar scattering amplitude right below threshold. Because of this, the scalar-isoscalar $\pi\pi$ phase shifts reach 90 degrees only near 800 MeV, which is approximately 400 MeV above the resonance mass. At this energy, the onset of the next resonance, the $f_0(980)$, is already visible.

The analyticity principle of the $\mathcal{S}$-matrix, germane to quantum scattering theories, dictates that only poles and branch points can exist on the real axis of the first Riemann sheet, excluding any singularities in the complex plane. This principle is closely linked to causality, ensuring that effects follow their causes in a chronological order. In non-relativistic scattering, the analyticity finds a solid mathematical base [27]. Similarly, perturbative relativistic theory maintains this analyticity through a series expansion of the $\mathcal{S}$-matrix, each term depicted by a Feynman diagram, representing processes with distinct analytical expressions. A deeper level of analyticity is proposed by the Mandelstam hypothesis, suggesting not only the analytic properties of the scattering amplitude within the complex plane of the first Riemann sheet but also a nuanced interconnection between crossed scattering processes through analytic continuation [28].

Unitarity further constrains the imaginary part of the amplitude on this real axis, a topic we will explore in the subsequent section. Additional constraints are introduced by principles such as crossing symmetry, duality [29] and positivity [30]. Approaches based on analyticity and crossing symmetry have been implemented through *dispersion theory*. Among the most notable are the Roy equations and their variants [31]. These have been applied to a range of processes, including $\pi\pi \to \pi\pi$ [32–34], πK scattering [35], $\gamma\gamma \to \pi\pi$ interactions [36], and pion-nucleon scattering [37–39].

50.1.2 *Consequences from unitarity*

Scattering amplitudes, denoted as $\mathcal{M}$, and production amplitudes, represented by $\mathcal{A}$, have distinct characteristics due to the different constraints imposed by unitarity. When considering the scattering amplitude, all coupled channels are treated equally within the formalism. In contrast, for production amplitudes, it is assumed that for the dynamics of the particles in the final state, the channel of the initial state does not play a role. Accordingly, the interactions in the final state among the produced particles are described by relevant scattering amplitudes of those particles only. Scattering processes are, for example, $\pi^+\pi^- \to K\bar{K}$ and $D^0\bar{D}^0 \to D^0\bar{D}^0$. Examples of production processes are $e^+e^- \to \gamma^* \to \pi^+\pi^-$, which provides access to the pion vector form factor, $\tau^- \to K^-\pi^0\nu_\tau$, and $B^0 \to J/\psi\pi^+\pi^-$.

The unitarity of the $\mathcal{S}$-matrix, represented by the equation $S^\dagger S = \mathbb{I}$, ensures the conservation of probability. This principle imposes a specific constraint on the imaginary part of the reaction amplitude. Below the lowest threshold (and above the first left-hand cut), the amplitude remains real. However, once the energy is higher than this threshold, there is a discontinuity associated with the threshold branch point. The $\mathcal{S}$-matrix unitarity relates the value of the discontinuity to the amplitude itself [6]:

$$\begin{aligned}\operatorname{Disc}\mathcal{M}_{ba} &= \mathcal{M}_{ba} - \mathcal{M}^*_{ab}\,,\\ &= i\,(2\pi)^4 \sum_c \int \mathrm{d}\Phi_c \mathcal{M}^*_{cb}\,\mathcal{M}_{ca}\,,\end{aligned} \tag{50.5}$$

where $\mathrm{d}\Phi_c$ denotes the Lorentz invariant phase space for a given channel, labeled as c. The factor $(2\pi)^4$ aligns with the convention for the phase space expression provided in the review on "Kinematics". It is essential to note that the summation only considers open channels, meaning those with a production threshold below the scattered system's energy. In the evaluation of an actual Feynman diagram, the discontinuity can be extracted by employing the Cutkosky rule, which comprises replacing the propagators in the pertinent intermediate state by delta-distributions. Eq. (50.5) is illustrated graphically in Fig. 50.4. The left part of the expression yields $2i\,\mathrm{Im}\,\mathcal{M}_{ba}$ in accordance to analytic properties of reaction amplitude [40]. For forward scattering, $t = 0$, the right part of Eq. (50.5) resembles the total cross section up to a kinematic factor, a relationship known as the optical theorem:

$$\mathrm{Im}\,\mathcal{M}_{aa}(s,0) = 2q_a\sqrt{s}\,\sigma_{\mathrm{tot}}(a \to \text{anything})\,. \tag{50.6}$$

In this equation, q_a represents the break-up momentum of the particles in the center-of-momentum frame,

$$q_a = \frac{\lambda^{1/2}(s, m^2_{1,a}, m^2_{2,a})}{2\sqrt{s}}\,, \tag{50.7}$$

where $\lambda(x,y,z) = x^2 + y^2 + z^2 - 2xy - 2yz - 2xz$ is the Källén function, and the masses of the two particles in the channel a, $m_{1,a}$ and $m_{2,a}$, *cf.* Eq. (17) of the review on "Kinematics".

The unitarity relation for a production amplitude in channel a is represented by:

$$\begin{aligned}\operatorname{Disc}\mathcal{A}_a &= \mathcal{A}_a - \mathcal{A}^*_a\,,\\ &= i\,(2\pi)^4 \sum_c \int \mathrm{d}\Phi_c \mathcal{M}^*_{ca}\mathcal{A}_c\,.\end{aligned} \tag{50.8}$$

Equation (50.8) is illustrated graphically in Fig. 50.4. A direct consequence of this equation is that the production amplitude shares its poles with the scattering amplitude. The relation between the production and scattering amplitudes is primarily explored for partial-wave amplitudes introduced in the next section. A common method to model the production amplitude that adheres to this unitary relation is to express it as a linear combination of scattering amplitudes. This approach, known as the $\mathcal{Q}$-vector method (see Sec 50.3.4), has its limitations. Specifically, in this way the production amplitude inherits the left-hand singularities of the scattering amplitude, while, in general, it has a different cut structure. To address this drawback, a more sophisticated method, known as *unitarization* is employed. This method, rooted in dispersion theory, offers a more refined approach to the problem and is detailed in [41]. A notable application of this method is the Khuri-Treiman framework [42, 43], which is frequently used to study three-body decays. This framework has been successfully applied to a range of decays, from light mesons [44–56] to heavy-flavour decays [57–61].

50.1.3 *Partial-wave decomposition*

It is often convenient to expand an amplitude in partial waves in using particle subsystems. Since resonances have a well-defined spin, they appear only in a specific partial wave of the reaction amplitude. For scalar particles, the expansion reads:

$$\mathcal{M}_{ba}(s,t) = \sum_{j=0}^{\infty}(2j+1)\mathcal{M}^j_{ba}(s)P_j(\cos(\theta))\,, \tag{50.9}$$

where j denotes the total angular momentum and the $P_j(\cos(\theta))$ denotes the Legendre polynomials. In the presence of spins an expansion more complicated than Eq. (50.9) is necessary — for a general discussion on how to handle spins see *e.g.* Ref. [62]. In the absence of spins, the parameter j coincides with the orbital angular momentum of the particle pairs in the initial and the final state. To simplify notation and since all amplitudes from here on are understood to be partial wave projected, we drop the label j for the single-argument function $\mathcal{M}_{ba}(s)$. Plugging Eq. (50.9) into Eq. (50.5), one finds the unitarity relation for the partial-wave amplitude $\mathcal{M}_{ba}(s)$, namely

$$\mathrm{Im}\,\mathcal{M}_{ba}(s) = \sum_c \mathcal{M}_{cb}(s)^*\,\rho_c(s)\,\mathcal{M}_{ca}(s)\,, \tag{50.10}$$

with $\rho_c(s)$ being a factor that is related to the two-body phase space in Eq. (12) of the review on "Kinematics",

$$\rho_c(s) = \frac{(2\pi)^4}{2}\int \mathrm{d}\Phi_2 = \frac{1}{16\pi}\frac{2|\vec{q}_c|}{\sqrt{s}}\,, \tag{50.11}$$

with the momentum q_c being defined in Eq. (50.7). Note that in the case of the two particles being identical, the inclusion of

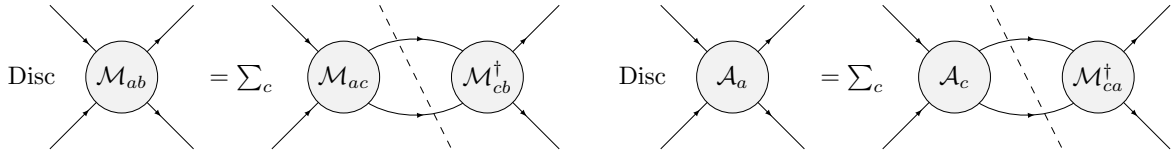

Figure 50.4: Graphical illustration of the discontinuity equations for the scattering and the production amplitude, respectively. The dashed line indicates that the intermediate state is to be put on-shell to find the discontinuity.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

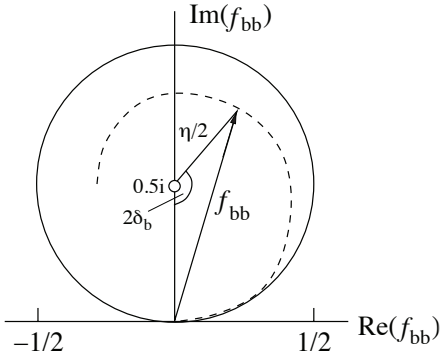

Figure 50.5: Argand plot showing a trajectory of the diagonal element of a partial-wave amplitude, f_{bb}, as a function of energy in the complex plane. As the energy increases the amplitude follows the line counter clockwise. The amplitude leaves the unitary circle (solid line) as soon as inelasticity sets in, $\eta < 1$ (dashed line).

symmetry factors becomes necessary. The partial-wave amplitude $f_{ba}(s)$ is introduced by normalizing the scattering amplitude with the phase space factors,

$$f_{ba}(s) = \sqrt{\rho_b}\,\mathcal{M}_{ba}(s)\,\sqrt{\rho_a}\,. \tag{50.12}$$

The unitarity condition for f_{ba} follows from Eq. (50.10):

$$\mathrm{Im}\, f_{ba}(s) = \sum_c f^*_{cb}(s) f_{ca}(s)\,. \tag{50.13}$$

It leads us to deduce that the imaginary part of $1/f_{ba}$ is equal to $-\delta_{ba}$. Moreover, $\mathcal{S} = \mathbb{I} + 2if$ is a unitary matrix. Hence, the diagonal elements of f can be parameterized as

$$f_{bb} = \frac{\eta_b \exp(2i\delta_b) - 1}{2i}\ , \tag{50.14}$$

where δ_b denotes the phase shift for the scattering from channel b to channel b and η_b is the elasticity parameter, also known as inelasticity. Building upon Eq. (50.13), we can further deduce that

$$\mathrm{Im}\, f_{bb}(s) = \frac{1 - \eta_b \cos(2\delta_b)}{2} = \sum_c |f_{cb}(s)|^2\ . \tag{50.15}$$

Using Eq. (50.14) for the last term in the sum, we obtain a relation highlighting the meaning of the inelasticity,

$$\frac{1}{4}(1 - \eta_b^2) = \sum_{c \neq b} |f_{cb}(s)|^2\ . \tag{50.16}$$

We note that the parameter η_b is confined within the range $[0, 1]$, where the case $\eta_b = 1$ is referred to as a purely elastic scattering. Thus, the function $\eta_b(s)$ is a direct measure of the contribution of the inelastic channels on the scattering amplitude in a given channel.

The evolution of the partial-wave amplitude f_{bb} with energy can be displayed as a trajectory in the Argand plot, as shown in Fig. 50.5. In the case of a two-channel problem, distinct channels a and b, $\eta_a = \eta_b = \eta$, and the off-diagonal element is $f_{ab} = \sqrt{1-\eta^2}/2\,\exp(i(\delta_1 + \delta_2))$. The unitarity condition Eq. (50.14) sets the limit to the squared amplitude f_{bb}:

$$|f_{bb}|^2 = \frac{1}{4}(\eta_b^2 - 2\eta_b \cos(2\delta_b) + 1) \leq \frac{1}{4}(\eta_b + 1)^2\ , \tag{50.17}$$

where the maximum value is reached for $\delta_b = \pi/2$. For the absolute square of the partial-wave-projected scattering amplitude the *unitarity bound* thus reads:

$$|\mathcal{M}_{bb}|\ \leq\ \frac{1}{2\rho_b}(\eta_b + 1)\ \leq\ \frac{8\pi}{q_b}\sqrt{s}\,, \tag{50.18}$$

where the second inequality comes from $\eta_b \leq 1$. For energies much larger than the masses of the scattering particles the upper bound for $|\mathcal{M}_{bb}|$ tends to 16π for large s.

The partial-wave projected production amplitude $\mathcal{A}(s)$ (note that the label j has been omitted for consistency) is also constrained by unitarity. As derived from Eq. (50.8):

$$\mathrm{Im}\,\mathcal{A}_a = \sum_b \mathcal{M}^*_{ba}\,\rho_b\,\mathcal{A}_b\ , \tag{50.19}$$

where the summation encompasses all open channels. For elastic scattering, only one channel, denoted by a, contributes to the sum. Consequently, the phase of $\mathcal{A}_a$ must align with the phase of $\mathcal{M}_{aa}$, given that the left-hand side of Eq. (50.19) represents a real value. This principle is recognized as the *Watson theorem* [63]. Accordingly, the phase of the pion vector form factor agrees with that of $\pi\pi$ scattering in the vector isovector channel (aside from effects of the isospin-violating $\rho - \omega$ mixing) up to about 1 GeV, where inelastic contributions start gaining significance.

50.2 Properties of resonances

A resonance is defined by its *pole position* in the complex s-plane, denoted as $s_{\rm R}$, and by the strength parameters of its couplings to various decay channels evaluated at this pole, known as the *pole residues*. The pole mass $M_{\rm R}$ and pole width $\Gamma_{\rm R}$ are defined via the pole parameters

$$\sqrt{s_{\rm R}} = M_{\rm R} - i\Gamma_{\rm R}/2\ . \tag{50.20}$$

For states where the relevant thresholds are situated significantly below the resonance location, the lifetime $\tau_{\rm R}$ of the resonance is given by $\tau_{\rm R} = 1/\Gamma_{\rm R}$ (refer to the review on "Kinematics" and for a recent discussion, see Ref. [64]). It is important to note that the conventional Breit–Wigner parameters $m_{\rm BW}$ and $\Gamma_{\rm BW}$, to be introduced in Eq. (50.31), differ from the pole parameters due to finite width effects and the influence of thresholds and background terms. It should be stressed that pole location $s_{\rm R}$ and pole residues are the only resonance properties that are model and parameterization independent.

When a resonance interacts with multiple channels, each channel contributes to the imaginary part of the pole position. However, these individual contributions do not simply sum up, calling for a careful definition of partial widths. This behavior is discussed using the example of the $f_0(980)$ in Refs. [65–68].

The pole residues are defined via

$$\mathcal{R}_{ba} = -\lim_{s \to s_{\rm R}} (s - s_{\rm R})\mathcal{M}_{ba}\ . \tag{50.21}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

These can be conveniently calculated via an integration along a closed contour around the pole using

$$\mathcal{R}_{ba} = -\frac{1}{2\pi i}\oint \mathrm{d}s\mathcal{M}_{ba} \ . \tag{50.22}$$

Equivalently, the residue can also be computed using a derivative of inverted matrix element as (note element inversion, not the matrix inversion)

$$\mathcal{R}_{ba} = -\left(\frac{\mathrm{d}\mathcal{M}^{-1}_{ba}}{\mathrm{d}s}\Big|_{s=s_\mathrm{R}}\right)^{-1} . \tag{50.23}$$

The residue adheres to the factorization relation, $(\mathcal{R}_{ba})^2 = \mathcal{R}_{aa} \times \mathcal{R}_{bb}$. This factorization emerges as a universal property stemming from the unitarity of scattering processes [7]. Building on this relation, one can define *pole couplings* as follows:

$$\tilde{g}_a^2 = \mathcal{R}_{aa} = \mathcal{R}^2_{ba}/\mathcal{R}_{bb} \, . \tag{50.24}$$

The pole couplings characterize the transition strength of a given resonance to some channel a independently of how the particular resonance was produced. They are in general complex valued.

In the baryon sector, it is customary to define the residue of the pole for the f_{ba} amplitude (as described in Eq. (50.13)) in terms of the variable $\sqrt{s}$ rather than s. This residue can be related to the residues mentioned earlier by:

$$r_{ba} = \frac{1}{2}\sqrt{\frac{\rho_a(s_\mathrm{R})\rho_b(s_\mathrm{R})}{s_\mathrm{R}}}\,\mathcal{R}_{ba} \ , \tag{50.25}$$

where the phase-space factors are to be continued analytically to the pole location. The residues quoted in the baryon listings are those for πN scattering (both a and b are πN channel).

Note that in general each resonance has various poles on different Riemann sheets with their own residues. For example, in a single channel reaction the Schwarz reflection principle calls for a pole at s_R to be accompanied by a pole at s^*_R. In this most simple case the residue of the one pole is the complex conjugate of that of the other. In multi-channel settings no simple relation can be given anymore. Thus, the equations discussed above are to be understood to refer to the physically most relevant pole—to ease notation we did not put a label specifying this.

The branching ratio of a resonance decay to a specific channel represents the fraction of the decay probability directed to that channel.

$$\mathrm{Br}_a = N_a/N_\mathrm{tot} \ . \tag{50.26}$$

Here, N_a is the experimental count of events for the decay channel $R \to a$, while N_tot represents the total number of events produced in the decay of the resonance. Since the amplitudes of decays to different final states add incoherently, we have $N_\mathrm{tot} = \sum_b N_b$. We note, however, that both N_a and N_tot may exhibit a dependence on the reaction through which the resonance is produced, due to the resonance's finite width. For a narrow resonance, the experimental count is determined by integrating the squared production amplitude over the decay channel's phase space:

$$N_a = N_0 \int |\mathcal{A}_a|^2 \, \mathrm{d}\Phi_a \ , \tag{50.27}$$

where N_0 is a normalization constant associated with the integrated luminosity, and $\mathcal{A}_a$ represents the amplitude of the resonance decay to channel a. When the decay rate's variation across the resonance width becomes significant, the resonance's lineshape must be considered:

$$N_a = N_0 \int_{s_{\mathrm{thr},a}}^{\infty} \mathrm{d}s\,\sigma_\mathrm{R}(s) \int |\mathcal{A}_a(s)|^2 \, \mathrm{d}\Phi_a(s) \ . \tag{50.28}$$

Here, $\sigma_\mathrm{R}(s)$ denotes a proper weight function of the resonance and $s_{\mathrm{thr},a}$ is the threshold value for the channel a. Additionally, the phase-space integral, $\mathrm{d}\Phi_a(s)$, puts the integrand to zero below the energy threshold of the decay channel a. This aspect is particularly crucial for the decays of broad resonances into channels with energy thresholds exceeding the resonance's nominal mass. This methodology is frequently employed in light-meson studies, as demonstrated in Ref. [69], and is also prevalent in light baryon research, as referenced in Ref. [67].

In the case of the decay of a state into multi-body final states, the transition amplitude can include resonances within subsystems of particles. When the total amplitude is decomposed as $\mathcal{A}_a = \sum_\mathrm{R} \mathcal{A}_{a(\mathrm{R})}$, the relative branching fraction for the decay of the given heavy state into final state a via resonance R in some subsystem, denoted as $\mathrm{Br}_{a(\mathrm{R})} \,/\, \mathrm{Br}_a$, is given by:

$$\mathrm{Br}_{a(\mathrm{R})} \,/\, \mathrm{Br}_a = \int \left|\mathcal{A}_{a(\mathrm{R})}\right|^2 \mathrm{d}\Phi_a \Big/ \int |\mathcal{A}_a|^2 \, \mathrm{d}\Phi_a \, . \tag{50.29}$$

The decomposition of the total amplitude, $\mathcal{A}_a$, into resonance amplitudes, $\mathcal{A}_{a(\mathrm{R})}$, is not a straightforward process. Beyond the differentiation of components based on distinct quantum numbers, this separation is inherently model-dependent. Furthermore, it is essential to be aware that the amplitudes $\mathcal{A}_{a(\mathrm{R})}$ can interfere with one another. As a result, their individual probabilities might not sum up to the total branching fraction of channel a. Nonetheless, in many scenarios, the interference contributions are small, making the fractions $\mathrm{Br}_{a(\mathrm{R})} \,/\, \mathrm{Br}_a$ indicative. For recent applications of these formulas in the context of B-decays see Refs. [70–73].

Lastly, an expression analogous to the branching fraction can be formulated using the pole parameters. For two-particle decays in the S-wave, one writes:

$$\mathrm{Br}_a = \frac{|\tilde{g}_a|^2}{M_\mathrm{R}\Gamma_\mathrm{R}}\rho_a(M^2_\mathrm{R}) \ , \tag{50.30}$$

where M_R and Γ_R are defined in Eq. (50.20) and the pole coupling $\tilde{g}_a$ in Eq. (50.24). This approach was utilized to define a two-photon width for the broad $f_0(500)$ resonance [74, 75]. Similarly, one should use residues to quantify the coupling of resonances to certain production channels [76]. For an application of this approach to the coupling of the $K_0^*(1430)$ resonance to a leptonic current, see Ref. [77]. Equation (50.30) provides a definition of branching fraction that remains independent of the reaction used to derive the quantity. For narrow resonances, this definition aligns well with Eq. (50.26) and Eq. (50.27). However, for broad, overlapping resonances, Eq. (50.30) is primarily used to convert residues into metrics that facilitate a more straightforward comparison of resonance transitions across different channels. For resonances with a coupling to a channel that remains closed at the resonance mass, Eq. (50.30) is not applicable due to the phase-space factor. In such scenarios, modification of the expression is required as elaborated upon in Refs. [67, 68], and in Sec. 50.3.5.

50.3 Common parameterizations

In general, there is no universal, model-independent recipe to build scattering amplitudes. However, a few approaches presented in this section are practical for extracting resonance properties in experimental analyses. The systematic theory uncertainties need to be assessed from a range of model variations that provide a sufficient quality of description of the available data and are permitted by general $\mathcal{S}$-matrix principles and the symmetries controlling the system at hand.

50.3.1 *The Breit–Wigner parameterization*

The relativistic Breit–Wigner parameterization represents a dressed propagator for an isolated resonance. An amplitude for a resonance observed in a channel a is given by

$$\mathrm{BW}(s) = \frac{1}{m^2_\mathrm{BW} - s - im_\mathrm{BW}\Gamma(s)} \tag{50.31}$$

where m_BW represents the Breit–Wigner mass, and $\Gamma_\mathrm{BW} = \Gamma(m^2_\mathrm{BW})$ denotes the Breit–Wigner width. The function $\Gamma(s)$ is defined by the channels to which the resonance can decay. When

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

considering only two-body channels, it is given by

$$\Gamma(s) = \sum_b \Gamma_b(s) \text{ with } \Gamma_b(s) = \frac{1}{m_{\text{BW}}} g_b^2 \rho_b(s) n_b^2(s) \,. \quad (50.32)$$

Here the index b runs over all channels coupled to the resonance. The bare coupling constants are represented by g_b, and ρ_b is the phase-space factor as defined in Eq. (50.11). The expression for $n_a(s)$ is:

$$n_a = (q_a/q_0)^{l_a} F_{l_a}(q_a/q_0) \,, \quad (50.33)$$

where l_a indicates the orbital angular momentum in channel a, $q_a(s)$ is the break-up momentum as defined in Eq. (50.7), and q_0 is a suitably selected momentum scale. The term $(q_a)^{l_a}$ ensures the amplitude's appropriate threshold behavior. The rapid growth of this factor for angular momenta $l_a > 0$ is offset at specific s values by a phenomenological form factor, represented here by $F_{l_a}(q_a/q_0)$. We note that the presence of these suppression factors is also a requirement from positivity which demands that the dressed propagator, the denominator of Eq. (50.31) and similar equations below, is not allowed to drop faster than $1/s$ [30]. The Blatt-Weisskopf form factors are frequently employed in the literature [78–80] to model F_j:

$$\begin{aligned} F_0^2(z) &= 1 \,, \quad (50.34) \\ F_1^2(z) &= 1/(1+z^2) \,, \\ F_2^2(z) &= 1/(9+3z^2+z^4) \,, \end{aligned}$$

where $z = q/q_0$, the scale parameter $1/q_0$ typically falls within the range of $1\,\text{GeV}^{-1}$ to $5\,\text{GeV}^{-1}$.

Bare coupling constants g_b do not have strict physical meaning, but rather serve as parameters reflecting the importance of a particular channel to the resonance lifetime. For narrow resonances with all coupled channel thresholds below the nominal mass, the coupling constant can be traded for the partial width $\Gamma_{\text{BW},b}$.

$$g_b = \sqrt{\frac{m_{\text{BW}}\,\Gamma_{\text{BW},b}}{\rho_b(m_{\text{BW}}^2) F_{l_b}^2(q_{b\,\text{r}}/q_0)}} \left(\frac{q_0}{q_{b\,\text{r}}}\right)^{l_b} . \quad (50.35)$$

Here the $q_{b\,\text{r}}$ are the values of the break-up momenta evaluated at $s = m_{\text{BW}}^2$. It is essential to note that this substitution is valid only for channels where the decay channel's threshold is positioned below the nominal resonance mass. In other scenarios, Eq. (50.32) should be applied.

Equation (50.32) incorporates thresholds for each of the coupled channels. As an analytic function, it must remain valid in regions below any of these thresholds. Its evaluation in such regions, however, requires careful analytic continuation of the break-up momentum q_a that has a square root ambiguity. As outlined in Refs. [81, 82], it's done as

$$q_a = i\sqrt{-q_a^2} \quad \text{for} \quad q_a^2 < 0 \,. \quad (50.36)$$

The *Flatté parameterization* [81] describes the amplitude for two S-wave channels near the threshold of a heavier channel, evaluated in the physical region of the lighter channel using Eq. (50.36). When a resonance's coupling to the channel with a higher threshold is notably strong, the parameterization exhibits scaling invariance. This implies that individual partial decay widths cannot be extracted; only their ratios can be determined [83].

Commonly, one uses the Breit–Wigner amplitude to describe the production amplitude, then,

$$\mathcal{A}_a(s) = \mathcal{N}_a(s) \text{BW}(s) \,. \quad (50.37)$$

The *numerator function* $\mathcal{N}_a(s) = \alpha\, g_a\, n_a(s)$ is tailored to the production process, encompassing kinematic factors and couplings pertinent to both the production and decay processes. The Breit–Wigner amplitude is an example of a unitary parameterization; it satisfies Eq. (50.10) with the scattering amplitude $\mathcal{M}_{ab}(s)$ given by

$$\mathcal{M}_{ab}(s) = g_a\, n_a(s)\, \text{BW}(s)\, g_b\, n_b(s) \,. \quad (50.38)$$

The Breit–Wigner parameterization is an accurate representation of resonance phenomena strictly in the $\Gamma/\Delta \to 0$ limit, where Γ is the resonance width and Δ is the distance to the closest unaccounted singularity, be it a pole of a higher resonance or a kinematic threshold related to a channel that couples to the resonance. However, the situation is often more complex due to multiple singularities in the complex plane around the resonance with different importance. For instance, in P-wave $\pi\pi$ scattering, the Breit–Wigner parameterization aptly describes the ρ-meson resonance relatively well over an extensive range. Although the closest singularity to the ρ-meson pole is the ω-pole ($\Gamma_\rho/\Delta_\omega \gg 1$), this isospin breaking effect is insignificant for $\pi\pi$ scattering. However, in production reactions it can show a sizable effect—examples are $\chi_{c1}(3872) \to J/\psi\pi\pi$ [84], $e^+e^- \to \pi\pi$ [85], $B \to J/\psi\pi\pi$ [86] and $\eta' \to \pi\pi\gamma$ [87]. Subsequent singularities, namely the 3π, 4π, and 6π thresholds, can also be disregarded in the pertinent mass range. The two-pion threshold is incorporated in the Breit–Wigner parameterization through an energy-dependent width and can be improved further by using the Gounaris-Sakurai parameterization [88], which also includes dispersive corrections that will be discussed below in some detail. Finally, the parameterization's efficacy diminishes around 1.2 GeV due to the ρ' resonance, situated approximately at 1.4 GeV.

The extraction of the pole position from the Breit–Wigner amplitude is a straightforward technical task, achieved through analytic continuation. However, even if the applicability of the Breit–Wigner parameterization is established for a given resonance, it is crucial to recognize that its parameters will only align with the pole parameters if the width is small. Moreover, there can be sizable effects from non-resonant contributions, inducing some reaction dependence. Thus, neither the Breit–Wigner parameters nor the pole parameters deduced from those should be deemed reliable in general. If there is more than one resonance in one partial wave that significantly couples to the same channel, it is generally inappropriate to employ a sum of Breit–Wigner functions. Such an approach often results in a breach of unitarity constraints, potentially introducing an indeterminate bias to the inferred resonance properties from the reaction amplitude. For overlapping resonances in the same partial wave, more sophisticated methods, such as the $\mathcal{K}$-matrix approach detailed in the subsequent section, are recommended.

50.3.2 *$\mathcal{K}$-matrix approach*

The *$\mathcal{K}$-matrix* method offers a comprehensive framework for modeling coupled-channel amplitudes [89]. This method ensures two-particle unitarity. However, it traditionally omits the physical left-hand cuts, and introduces spurious branch points when using the phase space factor for particle loops (see *cf.* Sect. 50.3.3). The scattering amplitude $\mathcal{M}_{ba}(s)$ can be derived from the equation:

$$n_b\, \mathcal{M}_{ba}^{-1}\, n_a = \mathcal{K}_{ba}^{-1} - i\delta_{ba}\rho_a n_a^2 \,. \quad (50.39)$$

Here, $\mathcal{K}_{ba}$ represents a real function and is subject to modeling. The factor n_a is elaborated upon in Eq. (50.33). Since there is no unique recipe to build $\mathcal{K}$, it is essential to explore various parameterizations to gauge the theoretical systematic uncertainty—this idea is often used for the extraction of resonance poles of lattice studies; see e.g. Ref. [90]. A commonly adopted choice for the $\mathcal{K}$-matrix is given by:

$$\mathcal{K}_{ba}(s) = \sum_{\text{r}} \frac{g_b^{\text{r}} g_a^{\text{r}}}{m_{\text{r}}^2 - s} + \sum_n b_{ba}^{(n)} s^n \,, \quad (50.40)$$

where m_{r} is referred to as the bare mass of the bare K-matrix pole r (not to be confused with the physical mass), and the g_a^{r} represents the bare couplings of the bare pole r to the channel a (not to be confused with the residues). The $b_{ba}^{(n)}$ are matrices that parameterize the non-pole components of the $\mathcal{K}$-matrix. Provided all parameters in Eq. (50.40) are real, the amplitude $\mathcal{M}_{ba}(s)$ remains unitary. We note that $\mathcal{K}$-matrix poles labeled by r produce the physical resonance poles labeled by R in the scattering amplitude, $\mathcal{M}$, but the converse is not true. Non-pole components of the $\mathcal{K}$-matrix can also produce poles in $\mathcal{M}$. From Eq. (50.39), the scattering amplitude $\mathcal{M}$ can be directly computed using its

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by TUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

matrix form:

$$\mathcal{M} = n[1 - \mathcal{K}\, i\rho\, n^2]^{-1}\mathcal{K}\, n\ , \tag{50.41}$$

where n and ρ are diagonal matrices, $n = \mathrm{diag}(n_a, n_b, \dots)$, and $\rho = \mathrm{diag}(\rho_a, \rho_b, \dots)$. As an alternative to Eq. (50.40), the same functional structure on the right side of Eq. (50.40) can be employed to parameterize the inverse $\mathcal{K}$-matrix, termed the M-matrix, by the authors of Ref. [91]. Numerous alternative formulations within the $\mathcal{K}$-matrix framework are utilized for amplitude studies related to lattice QCD calculations [90, 92–94].

A prevalent method to construct the production amplitude within the $\mathcal{K}$-matrix framework is the *$\mathcal{P}$-vector* parameterization [80, 89, 95]. The method utilizes the $\mathcal{K}$-matrix poles and bare couplings from Eq. (50.40):

$$\mathcal{A}_a(s) = n_a \sum_c \left[1 - \mathcal{K}\, i\rho n^2\right]^{-1}_{ac} \mathcal{P}_c\,, \tag{50.42}$$

$$\mathcal{P}_c = \sum_{\mathrm{r}} \frac{\alpha^{\mathrm{r}} g^{\mathrm{r}}_c}{m^2_{\mathrm{r}} - s} + \mathcal{B}_c. \tag{50.43}$$

The production vector, denoted as $\mathcal{P}_c$, comprises two main components. The first component represents a transition driven by the coupling of the bare resonance, r, to the channel c as well as the source. The coupling of the latter is characterized by a strength parameter, α^{r}. The second component, $\mathcal{B}_c$, signifies the direct transition from the source to the channel c. The formalism ensures that the complete production vector gets dressed via the final state interaction.

The *$\mathcal{Q}$-vector*, as discussed in Ref. [80, 91, 96], offers an alternative methodology for constructing a production amplitude:

$$\mathcal{A}_a(s) = \sum_c \mathcal{M}_{ac}(s)\mathcal{Q}_c(s)/n_c\ . \tag{50.44}$$

Here, $\mathcal{Q}_c(s)$ represents a smooth function of s and can be parameterized using a polynomial series. The unitarity condition of Eq. (50.19) is satisfied when $\mathcal{Q}_c(s)$ is a real function and in particular does not have singularities above the lowest threshold for all channels c. Besides these conditions, $\mathcal{Q}_c(s)$ is arbitrary. In a study of $\gamma\gamma \to \pi\pi$, *cf.* Ref. [74, 75] a low-order polynomial is claimed to be sufficient to parameterize the energy dependence of the function $\mathcal{Q}_c(s)$. The $\mathcal{Q}$-vector method is convenient if the full matrix $\mathcal{M}$ is known, *cf.* Ref. [91]. An important distinction between the $\mathcal{P}$-vector and the $\mathcal{Q}$-vector methods is highlighted in [95]. When the two-particle scattering amplitude approaches zero, the production amplitude in the $\mathcal{Q}$-vector construction unavoidably vanishes for finite values of $\mathcal{Q}_c$, whereas it can remain non-zero in the $\mathcal{P}$-vector approach.

Traditionally, amplitudes constructed using the $\mathcal{K}$-matrix technique exclude the left-hand cuts. Nevertheless, these can be customarily incorporated into the non-pole part of Eq. (50.40) for the scattering amplitude [97, 98], or via properly chosen background amplitudes [68]. Similarly, for the production amplitude, the functions $\mathcal{B}_c$ and $\mathcal{Q}_c$ from Eq. (50.43) and Eq. (50.44), respectively, might also encompass the left-hand cuts. These can often be parameterized by low order polynomials [74, 75, 99].

The position of the resonance poles can be determined by examining the zeros of the analytic function $\det[1 - \mathcal{K}\, i\rho\, n^2]$. Owing to the ρ factor, this determinant exhibits a complex multisheet structure. Nonetheless, the nearest unphysical sheet usually has the highest influence on the physical region. It is always the one which is determined by the heaviest threshold below the studied point in s (*cf.* Fig. 50.3). If for a given resonance the pole closest to the physical region is not located on a sheet that connects directly to the physical region, it is possible that $\mathcal{K}$-matrix fits do not allow one to fix the pole parameters, since a larger distance of the pole to the physical region can be balanced by increased residues—for a detailed discussion and a recent application see Ref. [83] and [100], respectively.

50.3.3 *Further improvements: Chew-Mandelstam function*

The $\mathcal{K}$-matrix framework often enables an accurate fit of physical amplitudes and is straightforward to handle. However, it does present a significant drawback: it breaches constraints imposed by analyticity. For instance, ρ_a, as defined in Eq. (50.11), is not well-defined at $s = 0$. Moreover, in cases of unequal masses, it manifests an unphysical cut, as depicted in the left panel of Fig. 50.6.

A method to improve the analytic properties has been suggested in Refs. [88, 101–104]. This approach replaces the term $i\rho_a(s)n_a^2$ from Eq. (50.39) with the analytic function $\Sigma_a(s)$, known as the Chew-Mandelstam function. This function produces the imaginary part $i\rho_a(s)n_a^2$ on the right-hand cut, while maintaining analyticity on the left-hand side, as represented by the once subtracted dispersion integral:

$$\Sigma_a(s + i0) = \frac{s - s_{\mathrm{thr},a}}{\pi} \int_{s_{\mathrm{thr},a}}^{\infty} \frac{\rho_a(s')n_a^2(s')}{(s' - s_{\mathrm{thr},a})(s' - s - i0)}\, \mathrm{d}s'. \tag{50.45}$$

Here, we chose the channel threshold, $s_{\mathrm{thr},a}$, as the subtraction point, and assumed that the subtraction constant is absorbed into the other parameters used for the amplitude. For an S-wave where $n_a = 1$, the integral has a closed form [41, 102]:

$$\Sigma_a(s) = \frac{1}{16\pi^2}\left[\frac{2q_a}{\sqrt{s}} \log \frac{m_{1,a}^2 + m_{2,a}^2 - s + 2\sqrt{s}q_a}{2m_{1,a}m_{1,a}}\right. , \\ \left. - (m_{1,a}^2 - m_{2,a}^2)\left(\frac{1}{s} - \frac{1}{s_{\mathrm{thr},a}^2}\right)\log\frac{m_{1,a}}{m_{2,a}}\right], \tag{50.46}$$

where $m_{1,a}$ and $m_{2,a}$ are masses of the final-state particles in channel a, with $s_{\mathrm{thr},a} = (m_{1,a} + m_{2,a})^2$. A closed form expression for the P-wave is provided in Ref. [105]. The behavior of $\Sigma_a(s)$ as given in Eq. (50.46) along the real axis is illustrated in the right panel of Fig. 50.6. A further discussion of the calculation of the Chew-Mandelstam function can be found in Refs. [106, 107].

If there is only a single resonance in a given channel, it is possible to feed the imaginary part of the Breit–Wigner function, Eq. (50.31) with an energy-dependent width, directly into a dispersion integral to get a resonance propagator with the correct analytic structure [108, 109].

50.3.4 *Effective-range expansion and scattering-length approximation*

For elastic scattering, $\eta_b = 1$, Eq. (50.14) simplifies to

$$f_{bb} = e^{i\delta}\sin(\delta) = \frac{q}{q\cot(\delta) - iq}\ , \tag{50.47}$$

where q is the relative momentum of the scattering particles. For S-waves one may then employ the *effective-range expansion* [110, 111] (ERE)

$$q\cot\delta = \frac{1}{a} + \frac{1}{2}rq^2 + O\left(R_f^3 q^4\right)\ , \tag{50.48}$$

whose radius of convergence is set by the closest non-analyticity, which may be the next threshold, a left-hand cut or a zero in the amplitude, which is equivalent to a pole in $q\cot\delta$. The ERE is understood to be an expansion in $R_f q$, where R_f denotes the range of forces provided by the inverse of the mass of the lightest exchange particle allowed. The *scattering length*, a, provides the strength of the scattering amplitude at threshold and is thus defined as the first term in an expansion of the real part of the inverse scattering amplitude. The sign convention used in Eq. (50.48) is the one commonly employed in particle physics. In this convention a positive scattering length indicates attraction; if, however, the attraction is strong enough to generate a bound state, the scattering length changes sign and turns negative. A negative scattering length also occurs for repulsive interactions. Note that in nuclear physics the leading term in the expansion of Eq. (50.48) is usually defined as $-1/a$ such that *e.g.* a bound state would be related to a positive scattering length. The parameter r is called the *effective range*. Especially, in cases where the scattering length is large, the ERE not only describes the low-energy scattering well, but also allows for an analytic continuation to find bound states below threshold by proper analytic continuation. This method was, *e.g.*, employed recently to analyze near threshold scattering

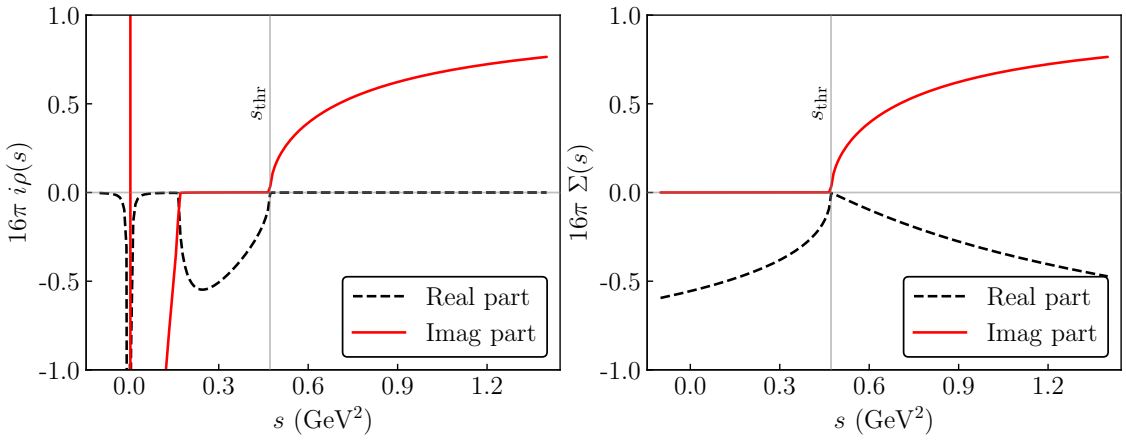

Figure 50.6: Comparison of the $i\rho$ function (left plot) to the *Chew-Mandelstam function* from Eq. (50.46) (right plot), evaluated for the case of S-wave $\eta\pi$ scattering. The values of s are taken slightly above the real axis, $s + i0$. The solid red line shows the imaginary part that is the same for both functions above threshold, $s_{\rm thr} = (m_\eta + m_\pi)^2$. The dashed black line presents the real part. One finds indications of the unphysical singularities, a branch point at the pseudothreshold $s_{\rm pth} = (m_\eta - m_\pi)^2$ and a pole at $s = 0$, of the function $i\rho$ on the left plot, while the Chew-Mandelstam function is analytic below the two-particle threshold.

phase shifts for $D^{*+}D^0$ scattering found in lattice analyses to extract properties of the $T_{cc}(3875)^+$ [112–114] at unphysical pion masses. It should be stressed that the analyses of the lattice data might call for a modification to account for the nearby left-hand cut which sets the radius of convergence of the ERE [115, 116].

When considering only the scattering length within the ERE, the scattering amplitude is represented as:

$$\mathcal{M}(s) = \frac{8\pi\sqrt{s}}{1/a - iq(s)}\,. \tag{50.49}$$

It is worth noting that the scattering length approximation is applicable only in a very limited energy range, however, it might well be appropriate to analyze the recently discovered narrow very near-threshold states [117, 118]. Examples of such analyses can be found in Refs. [119–121]. Moreover, it is possible to introduce the effect of a weakly coupled lower channel [122, 123]. Such coupling results in a positive imaginary part of the scattering length. It is also crucial to highlight that for large values of a, the amplitude of Eq. (50.49) develops a near-threshold pole located on the physical or unphysical sheet for negative or positive values of a, respectively. For readers interested in an exploration of how close-to-threshold poles interact with remote thresholds, we refer to Ref. [124].

While easy to use, it is important to stress, however, that the approximation in Eq. (50.49) is a specific choice of the dynamic function. This choice results in a single pole close to the physical region, suggesting that the state under study has the characteristics of a hadronic molecule, as discussed in references such as [121, 125–127]. Virtual states are discussed in this context in Ref. [128].

50.3.5 *Two-potential decomposition*

Another advanced technique to construct the scattering amplitude, which is widely used in the literature [61, 77, 129–133], is based on the two-potential formalism [134, 135]. While it is possible to formulate this method for the full unprojected amplitude $\mathcal{M}_{ba}(s,t)$, for clarity, we focus on presenting the equations in their partial-wave-projected form.

The scattering amplitude, $\mathcal{M}(s)$, can be broken down into two components: a background part and a pole part. This can be represented as:

$$\mathcal{M}(s) = \mathcal{M}^{\rm b.g.}(s) + \mathcal{M}^{\rm pole}(s)\,. \tag{50.50}$$

It is important to note that the division presented in Eq. (50.50) is not unique and model-dependent. This is further discussed in references such as [136, 137]. The background scattering matrix is assumed to satisfy the unitarity relations by itself. One approach to parameterize it, especially at lower energies, is by using phase shifts and inelasticities, as seen in [61, 77, 133]. Alternatively, it can be computed based on some potential, $V^{\rm b.g.}$, fed into a proper scattering equation [131, 132] or parameterized [68].

The complete amplitude, $\mathcal{M}$, from Eq. (50.50) satisfies the unitarity relations, if the pole part follows a specific construction. Namely,

$$\mathcal{M}^{\rm pole}_{ab}(s) = \sum_{c,d,e} n_a(s)\Omega_{ac}(s)\ [1 - V^{\rm pole}\Sigma^u(s)]^{-1}_{cd} V^{\rm pole}_{de}\ \Omega^T_{eb}(s) n_b(s)\,, \tag{50.51}$$

with the tamed centrifugal barrier factors introduced in Eq. (50.33). In this context, we introduce the vertex functions, denoted as $\Omega_{ab}(s)$, and the resonance potential, represented as $V^{\rm pole}(s)$. This potential operates as a matrix in the channel space and can be expressed as:

$$V^{\rm pole}_{ab}(s) = \sum_{\rm r} \frac{g^{\rm r}_a\ g^{\rm r}_b}{m^2_{\rm r} - s}\,. \tag{50.52}$$

The term Σ^u_{ab} represents the self-energy matrix. Additionally, $g^{\rm r}_a$ denotes the bare coupling of the resonance, labeled as r, to the channel a, and $m_{\rm r}$ is its bare mass. The vertex functions obey a unitarity relation similar to the production amplitude in Eq. (50.8). However, in this case, the final state interaction is determined by $\mathcal{M}^{\rm b.g.}$. This can be represented as:

$$\text{Disc}\ \Omega_{ab}(s) = 2i \sum_c \mathcal{M}^{\rm b.g.\,*}_{ca}(n_c(s)/n_a(s))\ \rho_c(s)\ \Omega_{cb}(s)\,. \tag{50.53}$$

When using low-energy phase shifts for the background term, it is practical to express the vertex functions in terms of an Omnès matrix, as discussed in [61]. The matrix reduces to the well-known Omnès function

$$\Omega(s) = \exp\left(\frac{s}{\pi}\int_{s_{\rm thr}}^{\infty} {\rm d}s' \frac{\delta^{\rm b.g.}(s')}{s'(s' - s - i\epsilon)}\right), \tag{50.54}$$

in the single-channel case [138], where $\delta^{\rm b.g.}(s)$ denotes the phase of the background scattering matrix $\mathcal{M}^{\rm b.g.}(s)$. The discontinuity associated with the self-energy matrix, $\Sigma^u(s)$, is given by:

$$\text{Disc}\ \Sigma^u_{ab}(s) = 2i \sum_c \Omega^*_{ca}(s)\ \rho_c(s) n_c(s)^2\ \Omega_{cb}(s)\,. \tag{50.55}$$

To determine the real part of Σ^u, one can use Eq. (50.55) with a properly subtracted dispersion integral — *cf.* Eq. (50.45).

When $\mathcal{M}^{\text{b.g.}}$ satisfies the unitarity relations, the full amplitude also does given Eq. (50.51). However, it is essential to note that the pole term alone does not satisfy the unitarity relation unless the background amplitude vanishes. Under such conditions, the described amplitude simplifies to the $\mathcal{K}$-matrix construction with improved analytic behavior as detailed in Sec. 50.3.3. Neglecting non-pole terms is not a good approximation for certain interactions, such as the scalar-isoscalar $\pi\pi$ at low energies, as discussed in Refs. [68, 139]. However, for higher partial waves, this approximation is generally effective.

A production amplitude consistent with Eq. (50.51) reads [61, 133]:

$$\mathcal{A}_a^{\text{pole}}(s) = n_a(s) \sum_{c,d} \Omega_{ac}(s)\, [1 - V^{(\text{r})}(s)\Sigma^u(s)]^{-1}_{cd} \mathcal{P}_d \ , \quad (50.56)$$

with function $\mathcal{P}_d$ given in Eq. (50.43). This form was employed in Refs. [61, 133] to treat the pion vector and scalar form factor, respectively, and in Ref. [77] for the scalar πK form factor.

The ideas presented above can be used to define branching fractions for broad resonances with minimal bias [68]. The starting point is the dressed resonance propagator for a single resonance that may be read off Eq. (50.56):

$$G_{\text{R}}(s) = \frac{1}{s - m_{\text{r}}^2 + \sum_a g_a^{\text{r}\,2} \Sigma^u_{aa}(s)} \ , \quad (50.57)$$

where the parameters m_{r}, g_a^{r} as well as those of the background interactions are to be adjusted such that pole locations and residues get reproduced. For this construction the background interactions contained in $\Sigma^u_{aa}(s)$ are taken diagonal, which implies diagonal vertex functions and therefore diagonal self energies, i.e. $\Sigma^u_{ab}(s)$=$\delta_{ab}\Sigma^u_{aa}(s)$. With this one can define branching ratios in line with Eq. (50.26) via

$$\text{Br}_a = \frac{g_a^{\text{r}\,2}}{2\pi i} \int_{s_{\text{thr},a}}^{\infty} \text{d}s\, |G_{\text{R}}(s)|^2\, \text{Disc}\, \Sigma^u_{aa}(s) = \frac{g_a^{\text{r}\,2}}{\pi} \int_{s_{\text{thr},a}}^{\infty} \text{d}s\, |G_{\text{R}}(s)\Omega_{aa}(s) n_a(s)|^2\, \rho_c(s) \ . \quad (50.58)$$

Thus, in this approach the weight function of Eq. (50.28) can be identified with

$$\sigma_{\text{R}}(s) = \frac{M_{\text{R}}\Gamma_{\text{R}}}{\pi} |G_{\text{R}}(s)|^2 \ . \quad (50.59)$$

The individual branching ratios automatically sum to one, since by construction

$$\sum_a \frac{g_a^{\text{r}\,2}}{2\pi i} \int_{s_{\text{thr},a}}^{\infty} \text{d}s\, |G_{\text{R}}(s)|^2\, \text{Disc}\Sigma^u_{aa}(s) = -\frac{1}{2\pi i} \int_{s_{\text{thr}}}^{\infty} \text{d}s\, \text{Disc}\, G_{\text{R}}(s) = 1 \ , \quad (50.60)$$

where s_{thr} denotes the lowest of the different thresholds. To see the last identity we follow Ref. [140] and use Cauchy's theorem as well as the fact that the resonance propagator has no non-analyticities on the physical sheet besides the threshold branch points, with the branch cuts extending to infinity along the positive real axis, to find

$$0 = \oint \text{d}s\, G_{\text{R}}(s) = \lim_{s_{\max}\to\infty} \left[\int_{s_{\text{thr}}}^{s_{\max}} \text{d}s\, \text{Disc}\, G_{\text{R}}(s) + i \int_0^{2\pi} \text{d}\phi\, s_{\max} e^{i\phi} G_{\text{R}}(s_{\max} e^{i\phi}) \right] \quad (50.61)$$

where the integration contour is chosen such that it encloses the branch cut from the lowest threshold and is closed by an arc of radius $s_{\max}$. Using that $\lim_{s\to\infty} \Sigma_{aa}(s)/s = 0$ such that $\lim_{s\to\infty} G_{\text{R}}(s) = 1/s$ the second integral above evaluates to $2\pi i$ which proves the identity from above. An alternative formal proof of Eq. (50.60) is provided in Ref. [30].

There has been considerable interest in the $3 \to 3$ scattering recently, particularly in light of new data on three-hadron interactions [141] and advancements in lattice calculations [142]. One finds that the methodologies devised for accounting for one-pion exchange bear a resemblance to the two-potential decomposition. For details see Ref. [143], also Eq. (93) in Ref. [144].

51. Cross-Section Formulae for Specific Processes

Revised August 2019 by H. Baer (Oklahoma U.) and R.N. Cahn (LBNL).

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

PART I: STANDARD MODEL PROCESSES

Setting aside leptoproduction (for which, see Sec. 16 of this *Review*), the cross sections of primary interest are those with light incident particles, e^+e^-, $\gamma\gamma$, $q\overline{q}$, gq , gg, *etc.*, where g and q represent gluons and light quarks. The produced particles include both light particles and heavy ones - t, W, Z, and the Higgs boson H. We provide the production cross sections calculated within the Standard Model for several such processes.

51.1 Resonance Formation

Resonant cross sections are generally described by the Breit-Wigner formula (Sec. 50.3 of this *Review*).

$$\sigma(E) = \frac{2J+1}{(2S_1+1)(2S_2+1)}\frac{4\pi}{k^2}\left[\frac{\Gamma^2/4}{(E-E_0)^2+\Gamma^2/4}\right]B_{in}B_{out}, \tag{51.1}$$

where E is the c.m. energy, J is the spin of the resonance, and the number of polarization states of the two incident particles are $2S_1+1$ and $2S_2+1$. The c.m. momentum in the initial state is k, E_0 is the c.m. energy at the resonance, and Γ is the full width at half maximum height of the resonance. The branching fraction for the resonance into the initial-state channel is B_{in} and into the final-state channel is B_{out}. For a narrow resonance, the factor in square brackets may be replaced by $\pi\Gamma\delta(E-E_0)/2$.

51.2 Production of light particles

The production of point-like, spin-1/2 fermions in e^+e^- annihilation through a virtual photon, $e^+e^- \to \gamma^* \to f\overline{f}$, at c.m. energy squared s is given by

$$\frac{d\sigma}{d\Omega} = N_c\frac{\alpha^2}{4s}\beta\left[1+\cos^2\theta+(1-\beta^2)\sin^2\theta\right]Q_f^2 \ , \tag{51.2}$$

where β is v/c for the produced fermions in the c.m., θ is the c.m. scattering angle, and Q_f is the charge of the fermion. The factor N_c is 1 for charged leptons and 3 for quarks. In the ultrarelativistic limit, $\beta \to 1$,

$$\sigma = N_cQ_f^2\frac{4\pi\alpha^2}{3s} = N_cQ_f^2\frac{86.8\text{ nb}}{s\,(\text{GeV}^2)} \ . \tag{51.3}$$

The cross section for the annihilation of a $q\overline{q}$ pair into a distinct pair $q'\overline{q}'$ through a gluon is completely analogous up to color factors, with the replacement $\alpha \to \alpha_s$. Treating all quarks as massless, averaging over the colors of the initial quarks and defining $t=-s\sin^2(\theta/2)$, $u=-s\cos^2(\theta/2)$, one finds [1]

$$\frac{d\sigma}{d\Omega}(q\overline{q}\to q'\overline{q}') = \frac{\alpha_s^2}{9s}\frac{t^2+u^2}{s^2} \ . \tag{51.4}$$

Crossing symmetry gives

$$\frac{d\sigma}{d\Omega}(qq'\to qq') = \frac{\alpha_s^2}{9s}\frac{s^2+u^2}{t^2} \ . \tag{51.5}$$

If the quarks q and q' are identical, we have

$$\frac{d\sigma}{d\Omega}(q\overline{q}\to q\overline{q}) = \frac{\alpha_s^2}{9s}\left[\frac{t^2+u^2}{s^2}+\frac{s^2+u^2}{t^2}-\frac{2u^2}{3st}\right] \ , \tag{51.6}$$

and by crossing

$$\frac{d\sigma}{d\Omega}(qq\to qq) = \frac{\alpha_s^2}{9s}\left[\frac{t^2+s^2}{u^2}+\frac{s^2+u^2}{t^2}-\frac{2s^2}{3ut}\right] . \tag{51.7}$$

Annihilation of e^+e^- into $\gamma\gamma$ has the cross section

$$\frac{d\sigma}{d\Omega}(e^+e^-\to\gamma\gamma) = \frac{\alpha^2}{2s}\frac{u^2+t^2}{tu} \ . \tag{51.8}$$

The related QCD process also has a triple-gluon coupling. The cross section is

$$\frac{d\sigma}{d\Omega}(q\overline{q}\to gg) = \frac{8\alpha_s^2}{27s}(t^2+u^2)\left(\frac{1}{tu}-\frac{9}{4s^2}\right) . \tag{51.9}$$

The crossed reactions are

$$\frac{d\sigma}{d\Omega}(qg\to qg) = \frac{\alpha_s^2}{9s}(s^2+u^2)(-\frac{1}{su}+\frac{9}{4t^2}) \tag{51.10}$$

and

$$\frac{d\sigma}{d\Omega}(gg\to q\overline{q}) = \frac{\alpha_s^2}{24s}(t^2+u^2)(\frac{1}{tu}-\frac{9}{4s^2}) \ . \tag{51.11}$$

Finally,

$$\frac{d\sigma}{d\Omega}(gg\to gg) = \frac{9\alpha_s^2}{8s}(3-\frac{ut}{s^2}-\frac{su}{t^2}-\frac{st}{u^2}) \ . \tag{51.12}$$

Lepton-quark scattering is analogous (neglecting Z exchange)

$$\frac{d\sigma}{d\Omega}(eq\to eq) = \frac{\alpha^2}{2s}e_q^2\frac{s^2+u^2}{t^2} \ . \tag{51.13}$$

where e_q is the charge of the quark. For neutrino scattering with the four-Fermi interaction

$$\frac{d\sigma}{d\Omega}(\nu d\to\ell^- u) = \frac{G_F^2 s}{4\pi^2} \ , \tag{51.14}$$

where the Cabibbo angle suppression is ignored. Similarly

$$\frac{d\sigma}{d\Omega}(\nu\overline{u}\to\ell^-\overline{d}) = \frac{G_F^2 s}{4\pi^2}\frac{(1+\cos\theta)^2}{4} \ . \tag{51.15}$$

To obtain the formulae for deep inelastic scattering (presented in more detail in Section 18) we consider quarks of type i carrying a fraction $x = Q^2/(2M\nu)$ of the nucleon's energy, where $\nu = E-E'$ is the energy lost by the lepton in the nucleon rest frame. With $y=\nu/E$ we have the correspondences

$$1+\cos\theta \to 2(1-y) \ ,$$

$$d\Omega_{cm} \to 4\pi f_i(x)dx\,dy \ , \tag{51.16}$$

where the latter incorporates the quark distribution, $f_i(x)$. In this way we find

$$\frac{d\sigma}{dx\,dy}(eN\to eX) = \frac{4\pi\alpha^2 xs}{Q^4}\frac{1}{2}\left[1+(1-y)^2\right] \times \left[\frac{4}{9}(u(x)+\overline{u}(x)+\ldots)+\frac{1}{9}(d(x)+\overline{d}(x)+\ldots)\right] \tag{51.17}$$

where now $s=2ME$ is the cm energy squared for the electron-nucleon collision, and we have suppressed contributions from higher mass quarks.

Similarly,

$$\frac{d\sigma}{dx\,dy}(\nu N\to\ell^- X) = \frac{G_F^2 xs}{\pi}[(d(x)+\ldots)+(1-y)^2(\overline{u}(x)+\ldots)] \tag{51.18}$$

and

$$\frac{d\sigma}{dx\,dy}(\overline{\nu}N\to\ell^+ X) = \frac{G_F^2 xs}{\pi}[(\overline{d}(x)+\ldots)+(1-y)^2(u(x)+\ldots)] \ . \tag{51.19}$$

Quasi-elastic neutrino scattering ($\nu_\mu n\to\mu^- p$, $\overline{\nu}_\mu p\to\mu^+ n$) is directly related to the crossed reaction, neutron decay. The formula for the differential cross section is presented, for example, in N.J. Baker *et al.*, Phys. Rev. **D23**, 2499 (1981).

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

51.3 Hadroproduction of heavy quarks

For hadroproduction of heavy quarks $Q = c,\ b,\ t$, it is important to include mass effects in the formulae. For $q\bar{q} \to Q\bar{Q}$, one has

$$\frac{d\sigma}{d\Omega}(q\bar{q} \to Q\bar{Q}) = \frac{\alpha_s^2}{9s^3}\sqrt{1-\frac{4m_Q^2}{s}} \left[(m_Q^2-t)^2 + (m_Q^2-u)^2 + 2m_Q^2 s\right], \quad (51.20)$$

while for $gg \to Q\bar{Q}$ one has

$$\begin{aligned}\frac{d\sigma}{d\Omega}(gg \to Q\bar{Q}) = \frac{\alpha_s^2}{32s}\sqrt{1-\frac{4m_Q^2}{s}} \Bigg[&\frac{6}{s^2}(m_Q^2-t)(m_Q^2-u) - \\ &-\frac{m_Q^2(s-4m_Q^2)}{3(m_Q^2-t)(m_Q^2-u)} + \\ &\frac{4}{3}\frac{(m_Q^2-t)(m_Q^2-u) - 2m_Q^2(m_Q^2+t)}{(m_Q^2-t)^2} \\ &+\frac{4}{3}\frac{(m_Q^2-t)(m_Q^2-u) - 2m_Q^2(m_Q^2+u)}{(m_Q^2-u)^2} \\ &-3\frac{(m_Q^2-t)(m_Q^2-u) + m_Q^2(u-t)}{s(m_Q^2-t)} \\ &-3\frac{(m_Q^2-t)(m_Q^2-u) + m_Q^2(t-u)}{s(m_Q^2-u)}\Bigg]. \end{aligned} \quad (51.21)$$

51.4 Production of Weak Gauge Bosons

51.4.1 *W and Z resonant production*

Resonant production of a single W or Z is governed by the partial widths

$$\Gamma(W \to \ell_i \overline{\nu}_i) = \frac{\sqrt{2}G_F m_W^3}{12\pi} \quad (51.22)$$

$$\Gamma(W \to q_i \bar{q}_j) = 3\frac{\sqrt{2}G_F |V_{ij}|^2 m_W^3}{12\pi} \quad (51.23)$$

$$\Gamma(Z \to f\overline{f}) = N_c \frac{\sqrt{2}G_F m_Z^3}{6\pi} \times \left[(T_3 - Q_f \sin^2\theta_W)^2 + (Q_f \sin^2\theta_W)^2\right] \quad (51.24)$$

The weak mixing angle is θ_W. The CKM matrix elements are indicated by V_{ij} and N_c is 3 for $q\bar{q}$ final states and 1 for leptonic final states.

The full differential cross section for $f_i\bar{f}_j \to (W,Z) \to f_{i'}\bar{f}_{j'}$ is given by

$$\begin{aligned}\frac{d\sigma}{d\Omega} = &\frac{N_c^f}{N_c^i}\cdot\frac{1}{256\pi^2 s}\cdot\frac{s^2}{(s-M^2)^2+s\Gamma^2} \\ &\times\Big[(L^2+R^2)(L'^2+R'^2)(1+\cos^2\theta) \\ &+(L^2-R^2)(L'^2-R'^2)2\,cos\theta\Big] \end{aligned} \quad (51.25)$$

where M is the mass of the W or Z. The couplings for the W are $L = (8G_F m_W^2/\sqrt{2})^{1/2} V_{ij}/\sqrt{2}; R = 0$ where V_{ij} is the corresponding CKM matrix element, with an analogous expression for L' and R'. For Z, the couplings are $L = (8G_F m_Z^2/\sqrt{2})^{1/2}(T_3 - \sin^2\theta_W Q); R = -(8G_F m_Z^2/\sqrt{2})^{1/2}\sin^2\theta_W Q$, where T_3 is the weak isospin of the initial left-handed fermion and Q is the initial fermion's electric charge. The expressions for L' and R' are analogous. The color factors $N_c^{i,f}$ are 3 for initial or final quarks and 1 for initial or final leptons.

51.4.2 *Production of pairs of weak gauge bosons*

The cross section for $f\bar{f} \to W^+W^-$ is given in term of the couplings of the left-handed and right-handed fermion f, $\ell = 2(T_3 - Qx_W)$, $r = -2Qx_W$, where T_3 is the third component of weak isospin for the left-handed f, Q is its electric charge (in units of the proton charge), and $x_W = \sin^2\theta_W$:

$$\begin{aligned}\frac{d\sigma}{dt} = &\frac{2\pi\alpha^2}{N_c s^2}\Bigg\{\Bigg[\left(Q + \frac{\ell+r}{4x_W}\frac{s}{s-m_Z^2}\right)^2 \\ &+\left(\frac{\ell-r}{4x_W}\frac{s}{s-m_Z^2}\right)^2\Bigg]A(s,t,u) \\ &+\frac{1}{2x_W}\left(Q + \frac{\ell}{2x_W}\frac{s}{s-m_Z^2}\right) \\ &\qquad(\Theta(-Q)I(s,t,u) - \Theta(Q)I(s,u,t)) \\ &+\frac{1}{8x_W^2}\left(\Theta(-Q)E(s,t,u) + \Theta(Q)E(s,u,t)\right)\Bigg\}, \end{aligned} \quad (51.26)$$

where $\Theta(x)$ is 1 for $x > 0$ and 0 for $x < 0$, and where

$$\begin{aligned} A(s,t,u) &= \left(\frac{tu}{m_W^4} - 1\right)\left(\frac{1}{4} - \frac{m_W^2}{s} + 3\frac{m_W^4}{s^2}\right) + \frac{s}{m_W^2} - 4, \\ I(s,t,u) &= \left(\frac{tu}{m_W^4} - 1\right)\left(\frac{1}{4} - \frac{m_W^2}{2s} - \frac{m_W^4}{st}\right) + \frac{s}{m_W^2} - 2 + 2\frac{m_W^2}{t}, \\ E(s,t,u) &= \left(\frac{tu}{m_W^4} - 1\right)\left(\frac{1}{4} + \frac{m_W^4}{t^2}\right) + \frac{s}{m_W^2}, \end{aligned} \quad (51.27)$$

and s,t,u are the usual Mandelstam variables with $s = (p_f + p_{\bar{f}})^2, t = (p_f - p_{W^-})^2, u = (p_f - p_{W^+})^2$. The factor N_c is 3 for quarks and 1 for leptons.

The analogous cross-section for $q_i\bar{q}_j \to W^\pm Z^0$ is

$$\begin{aligned}\frac{d\sigma}{dt} = &\frac{\pi\alpha^2|V_{ij}|^2}{6s^2x_W^2}\Bigg\{\left(\frac{1}{s-m_W^2}\right)^2\Bigg[\left(\frac{9-8x_W}{4}\right)\left(ut - m_W^2 m_Z^2\right) \\ &+(8x_W-6)\,s\left(m_W^2+m_Z^2\right)\Bigg] \\ &+\left[\frac{ut - m_W^2m_Z^2 - s(m_W^2+m_Z^2)}{s-m_W^2}\right]\left[\frac{\ell_j}{t} - \frac{\ell_i}{u}\right] \\ &+\frac{ut - m_W^2m_Z^2}{4(1-x_W)}\left[\frac{\ell_j^2}{t^2} + \frac{\ell_i^2}{u^2}\right] + \frac{s(m_W^2+m_Z^2)}{2(1-x_W)}\frac{\ell_i\ell_j}{tu}\Bigg\}, \end{aligned} \quad (51.28)$$

where ℓ_i and ℓ_j are the couplings of the left-handed q_i and q_j as defined above. The CKM matrix element between q_i and q_j is V_{ij}.

The cross section for $q_i\bar{q}_i \to Z^0Z^0$ is

$$\frac{d\sigma}{dt} = \frac{\pi\alpha^2}{96}\frac{\ell_i^4 + r_i^4}{x_W^2(1-x_W^2)^2 s^2}\left[\frac{t}{u} + \frac{u}{t} + \frac{4m_Z^2 s}{tu} - m_Z^4\left(\frac{1}{t^2} + \frac{1}{u^2}\right)\right]. \quad (51.29)$$

51.5 Production of Higgs Bosons

51.5.1 *Resonant Production*

The Higgs boson of the Standard Model can be produced resonantly in the collisions of quarks, leptons, W or Z bosons, gluons, or photons. The production cross section is thus controlled by the partial width of the Higgs boson into the entrance channel and its total width. The branching fractions for the Standard Model Higgs boson are shown in Fig. 1 of the "Searches for Higgs bosons"

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

review in the Particle Listings section, as a function of the Higgs boson mass. The partial widths are given by the relations

$$\Gamma(H \to f\bar{f}) = \frac{G_F m_f^2 m_H N_c}{4\pi\sqrt{2}} \left(1 - 4m_f^2/m_H^2\right)^{3/2}, \quad (51.30)$$

$$\Gamma(H \to W^+W^-) = \frac{G_F m_H^3 \beta_W}{32\pi\sqrt{2}} \left(4 - 4a_W + 3a_W^2\right), \quad (51.31)$$

$$\Gamma(H \to ZZ) = \frac{G_F m_H^3 \beta_Z}{64\pi\sqrt{2}} \left(4 - 4a_Z + 3a_Z^2\right), \quad (51.32)$$

where N_c is 3 for quarks and 1 for leptons and where $a_W = 1 - \beta_W^2 = 4m_W^2/m_H^2$ and $a_Z = 1 - \beta_Z^2 = 4m_Z^2/m_H^2$. The decay to two gluons proceeds through quark loops, with the t quark dominating [2]. Explicitly,

$$\Gamma(H \to gg) = \frac{\alpha_s^2 G_F m_H^3}{36\pi^3\sqrt{2}} \left| \sum_q I(m_q^2/m_H^2) \right|^2, \quad (51.33)$$

where $I(z)$ is complex for $z < 1/4$. For $z < 2 \times 10^{-3}$, $|I(z)|$ is small so the light quarks contribute negligibly. For $m_H < 2m_t$, $z > 1/4$ and

$$I(z) = 3\left[2z + 2z(1-4z)\left(\sin^{-1}\frac{1}{2\sqrt{z}}\right)^2\right], \quad (51.34)$$

which has the limit $I(z) \to 1$ as $z \to \infty$.

51.5.2 *Higgs Boson Production in W^* and Z^* decay*

The Standard Model Higgs boson can be produced in the decay of a virtual W or Z ("Higgstrahlung") [3,4]: In particular, if k is the c.m. momentum of the Higgs boson,

$$\sigma(q_i\bar{q}_j \to WH) = \frac{\pi\alpha^2|V_{ij}|^2}{36\sin^4\theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_W^2}{(s - m_W^2)^2} \quad (51.35)$$

$$\sigma(f\bar{f} \to ZH) = \frac{2\pi\alpha^2(\ell_f^2 + r_f^2)}{48N_c \sin^4\theta_W \cos^4\theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_Z^2}{(s - m_Z^2)^2}, \quad (51.36)$$

where ℓ and r are defined as above.

51.5.3 *W and Z Fusion*

Just as high-energy electrons can be regarded as sources of virtual photon beams, at very high energies they are sources of virtual W and Z beams. For Higgs boson production, it is the longitudinal components of the Ws and Zs that are important [5]. The distribution of longitudinal Ws carrying a fraction y of the electron's energy is [6]

$$f(y) = \frac{g^2}{16\pi^2} \frac{1-y}{y}, \quad (51.37)$$

where $g = e/\sin\theta_W$. In the limit $s \gg m_H \gg m_W$, the partial decay rate is $\Gamma(H \to W_L W_L) = (g^2/64\pi)(m_H^3/m_W^2)$ and in the equivalent W approximation [7]

$$\sigma(e^+e^- \to \overline{\nu}_e\nu_e H) = \frac{1}{16m_W^2}\left(\frac{\alpha}{\sin^2\theta_W}\right)^3 \times \left[\left(1 + \frac{m_H^2}{s}\right)\log\frac{s}{m_H^2} - 2 + 2\frac{m_H^2}{s}\right]. \quad (51.38)$$

There are significant corrections to this relation when m_H is not large compared to m_W [8]. For $m_H = 150$ GeV, the estimate is too high by 51% for $\sqrt{s} = 1000$ GeV, 32% too high at $\sqrt{s} = 2000$ GeV, and 22% too high at $\sqrt{s} = 4000$ GeV. Fusion of ZZ to make a Higgs boson can be treated similarly. Identical formulae apply for Higgs production in the collisions of quarks whose charges permit the emission of a W^+ and a W^-, except that QCD corrections and CKM matrix elements are required. Even in the absence of QCD corrections, the fine-structure constant ought to be evaluated at the scale of the collision, say m_W. All quarks contribute to the ZZ fusion process.

51.6 Inclusive hadronic reactions

One-particle inclusive cross sections $Ed^3\sigma/d^3p$ for the production of a particle of momentum p are conveniently expressed in terms of rapidity y (see above) and the momentum p_T transverse to the beam direction (in the c.m.):

$$E\frac{d^3\sigma}{d^3p} = \frac{d^3\sigma}{d\phi\, dy\, p_T\, dp_T}. \quad (51.39)$$

In appropriate circumstances, the cross section may be decomposed as a partonic cross section multiplied by the probabilities of finding partons of the prescribed momenta:

$$\sigma_{\rm hadronic} = \sum_{ij} \int dx_1\, dx_2\, f_i(x_1)\, f_j(x_2)\, d\widehat{\sigma}_{\rm partonic}, \quad (51.40)$$

The probability that a parton of type i carries a fraction of the incident particle's that lies between x_1 and $x_1 + dx_1$ is $f_i(x_1)dx_1$ and similarly for partons in the other incident particle. The partonic collision is specified by its c.m. energy squared $\hat{s} = x_1x_2s$ and the momentum transfer squared $\hat{t}$. The final hadronic state is more conveniently specified by the rapidities y_1, y_2 of the two jets resulting from the collision and the transverse momentum p_T. The connection between the differentials is

$$dx_1dx_2d\hat{t} = dy_1dy_2\frac{\hat{s}}{s}dp_T^2, \quad (51.41)$$

so that

$$\frac{d^3\sigma}{dy_1dy_2dp_T^2} = \frac{\hat{s}}{s}\left[f_i(x_1)f_j(x_2)\frac{d\hat{\sigma}}{d\hat{t}}(\hat{s},\hat{t},\hat{u}) + f_i(x_2)f_j(x_1)\frac{d\hat{\sigma}}{d\hat{t}}(\hat{s},\hat{u},\hat{t})\right], \quad (51.42)$$

where we have taken into account the possibility that the incident parton types might arise from either incident particle. The second term should be dropped if the types are identical: $i = j$.

51.7 Two-photon processes

In the Weizsäcker-Williams picture, a high-energy electron beam is accompanied by a spectrum of virtual photons of energies ω and invariant-mass squared $q^2 = -Q^2$, for which the photon number density is

$$dn = \frac{\alpha}{\pi}\left[1 - \frac{\omega}{E} + \frac{\omega^2}{E^2} - \frac{m_e^2\,\omega^2}{Q^2E^2}\right]\frac{d\omega}{\omega}\frac{dQ^2}{Q^2}, \quad (51.43)$$

where E is the energy of the electron beam. The cross section for $e^+e^- \to e^+e^-X$ is then [9]

$$d\sigma_{e^+e^-\to e^+e^-X}(s) = dn_1dn_2d\sigma_{\gamma\gamma\to X}(W^2), \quad (51.44)$$

where $W^2 = m_X^2$. Integrating from the lower limit $Q^2 = m_e^2\frac{\omega_i^2}{E_i(E_i-\omega_i)}$ to a maximum Q^2 gives

$$\sigma_{e^+e^-\to e^+e^-X}(s) = \frac{\alpha^2}{\pi^2}\int_{z_{th}}^1 \frac{dz}{z} \times \left[\left(\ln\frac{Q^2_{max}}{zm_e^2} - 1\right)^2 f(z) + \frac{1}{3}(\ln z)^3\right]\sigma_{\gamma\gamma\to X}(zs), \quad (51.45)$$

where

$$f(z) = \left(1 + \tfrac{1}{2}z\right)^2\ln(1/z) - \tfrac{1}{2}(1-z)(3+z). \quad (51.46)$$

The appropriate value of Q^2_{max} depends on the properties of the produced system X. For production of hadronic systems, $Q^2_{max} \approx m^2_\rho$, while for lepton-pair production, $Q^2 \approx W^2$. For production of a resonance with spin $J \neq 1$, we have

$$\sigma_{e^+e^-\to e^+e^- R}(s) = (2J+1)\frac{8\alpha^2\Gamma_{R\to\gamma\gamma}}{m_R^3} \times \left[f(m_R^2/s)\left(\ln\frac{m_V^2 s}{m_e^2 m_R^2} - 1\right)^2 - \frac{1}{3}\left(\ln\frac{s}{M_R^2}\right)^3\right], \quad (51.47)$$

where m_V is the mass that enters into the form factor for the $\gamma\gamma \to R$ transition, typically m_ρ.

PART II: PROCESSES BEYOND THE STANDARD MODEL

51.8 Production of supersymmetric particles

In supersymmetric (SUSY) theories (see Supersymmetric Particle Searches in this *Review*), every boson has a fermionic superpartner, and every fermion has a bosonic superpartner. The minimal supersymmetric Standard Model (MSSM) is a direct supersymmetrization of the Standard Model (SM), although a second Higgs doublet is needed to avoid triangle anomalies [10]. Under *soft* SUSY breaking, superpartner masses are lifted above the SM particle masses. In weak scale SUSY, the superpartners are invoked to stabilize the weak scale under radiative corrections, so the superpartners are expected to have masses of order the TeV scale.

51.8.1 *Gluino and squark production*

The superpartners of gluons are the color octet, spin$-\frac{1}{2}$ gluinos ($\tilde{g}$), while each helicity component of quark flavor has a spin-0 *squark* partner, *e.g.* $\tilde{q}_L$ and $\tilde{q}_R$. Third generation left- and right- squarks are expected to have large mixing, resulting in mass eigenstates $\tilde{q}_1$ and $\tilde{q}_2$, with $m_{\tilde{q}_1} < m_{\tilde{q}_2}$ (here, q denotes any of the SM flavors of quarks and $\tilde{q}_i$ the corresponding flavor and type ($i = L, R$ or $1, 2$) of squark). Gluino pair production ($\tilde{g}\tilde{g}$) takes place via either glue-glue or quark-antiquark annihilation [11].

The subprocess cross sections are usually presented as differential distributions in the Mandelstam variables s, t and u. Note that for a $2 \to 2$ scattering subprocess $ab \to cd$, the Mandelstam variable $s = (p_a + p_b)^2 = (p_c + p_d)^2$, where p_a is the 4-momentum of particle a, and so forth. The variable $t = (p_c - p_a)^2$, where c and a are taken conventionally to be the most similar particles in the subprocess. The variable u would then be equal to $(p_d - p_a)^2$. Note that since s, t and u are squares of 4-vectors, they are invariants in any inertial reference frame.

Gluino pair production at hadron colliders is described by:

$$\frac{d\sigma}{dt}(gg \to \tilde{g}\tilde{g}) = \frac{9\pi\alpha_s^2}{4s^2}\left\{\frac{2(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)}{s^2} + \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) - 2m_{\tilde{g}}^2(m_{\tilde{g}}^2 + t)}{(m_{\tilde{g}}^2 - t)^2} + \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) - 2m_{\tilde{g}}^2(m_{\tilde{g}}^2 + u)}{(m_{\tilde{g}}^2 - u)^2} + \frac{m_{\tilde{g}}^2(s - 4m_{\tilde{g}}^2)}{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)} - \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) + m_{\tilde{g}}^2(u - t)}{s(m_{\tilde{g}}^2 - t)} - \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) + m_{\tilde{g}}^2(t - u)}{s(m_{\tilde{g}}^2 - u)}\right\}, \quad (51.48)$$

where α_s is the strong fine structure constant. Also,

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{g}\tilde{g}) = \frac{8\pi\alpha_s^2}{9s^2}\left\{\frac{4}{3}\left(\frac{m_{\tilde{g}}^2 - t}{m_{\tilde{q}}^2 - t}\right)^2 + \frac{4}{3}\left(\frac{m_{\tilde{g}}^2 - u}{m_{\tilde{q}}^2 - u}\right)^2 + \frac{3}{s^2}\left[(m_{\tilde{g}}^2 - t)^2 + (m_{\tilde{g}}^2 - u)^2 + 2m_{\tilde{g}}^2 s\right] - 3\frac{\left[(m_{\tilde{g}}^2 - t)^2 + m_{\tilde{g}}^2 s\right]}{s(m_{\tilde{q}}^2 - t)} - 3\frac{\left[(m_{\tilde{g}}^2 - u)^2 + m_{\tilde{g}}^2 s\right]}{s(m_{\tilde{q}}^2 - u)} + \frac{1}{3}\frac{m_{\tilde{g}}^2 s}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)}\right\}. \quad (51.49)$$

Gluinos can also be produced in association with squarks: $\tilde{g}\tilde{q}_i$ production, where $\tilde{q}_i$ represents any of the various types (left, right- or mixed) and flavors of squarks. The subprocess cross section is independent of whether the squark is the right-, left- or mixed type:

$$\frac{d\sigma}{dt}(gq \to \tilde{g}\tilde{q}_i) = \frac{\pi\alpha_s^2}{24s^2}\frac{\left[\frac{16}{3}(s^2 + (m_{\tilde{q}_i}^2 - u)^2) + \frac{4}{3}s(m_{\tilde{q}_i}^2 - u)\right]}{s(m_{\tilde{g}}^2 - t)(m_{\tilde{q}_i}^2 - u)^2} \times \left((m_{\tilde{g}}^2 - u)^2 + (m_{\tilde{q}_i}^2 - m_{\tilde{g}}^2)^2 + \frac{2sm_{\tilde{g}}^2(m_{\tilde{q}_i}^2 - m_{\tilde{g}}^2)}{(m_{\tilde{g}}^2 - t)}\right). \quad (51.50)$$

There are many different subprocesses for production of squark pairs. Since left- and right- squarks generally have different masses and different decay patterns, we present the differential cross section for each subprocess of $\tilde{q}_i$ ($i = L,\ R$ or $1,\ 2$) separately. (In early literature, the following formulae were often combined into a single equation which didn't differentiate the various squark types.) The result for $gg \to \tilde{q}_i\bar{\tilde{q}}_i$ is:

$$\frac{d\sigma}{dt}(gg \to \tilde{q}_i\bar{\tilde{q}}_i) = \frac{\pi\alpha_s^2}{4s^2}\left\{\frac{1}{3}\left(\frac{m_{\tilde{q}}^2 + t}{m_{\tilde{q}}^2 - t}\right)^2 + \frac{1}{3}\left(\frac{m_{\tilde{q}}^2 + u}{m_{\tilde{q}}^2 - u}\right)^2 + \frac{3}{32s^2}\left(8s(4m_{\tilde{q}}^2 - s) + 4(u - t)^2\right) + \frac{7}{12} - \frac{1}{48}\frac{(4m_{\tilde{q}}^2 - s)^2}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)} + \frac{3}{32}\frac{\left[(t - u)(4m_{\tilde{q}}^2 + 4t - s) - 2(m_{\tilde{q}}^2 - u)(6m_{\tilde{q}}^2 + 2t - s)\right]}{s(m_{\tilde{q}}^2 - t)} + \frac{3}{32}\frac{\left[(u - t)(4m_{\tilde{q}}^2 + 4u - s) - 2(m_{\tilde{q}}^2 - t)(6m_{\tilde{q}}^2 + 2u - s)\right]}{s(m_{\tilde{q}}^2 - u)} + \frac{7}{96}\frac{\left[4m_{\tilde{q}}^2 + 4t - s\right]}{m_{\tilde{q}}^2 - t} + \frac{7}{96}\frac{\left[4m_{\tilde{q}}^2 + 4u - s\right]}{m_{\tilde{q}}^2 - u}\right\}, \quad (51.51)$$

which has an obvious $u \leftrightarrow t$ symmetry.

For $q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_i$ with the same initial and final state flavors, we have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_i) = \frac{2\pi\alpha_s^2}{9s^2}\left\{\frac{1}{(t - m_{\tilde{g}}^2)^2} + \frac{2}{s^2} - \frac{2/3}{s(t - m_{\tilde{g}}^2)}\right\} \times \left[-st - (t - m_{\tilde{q}_i}^2)^2\right], \quad (51.52)$$

while if initial and final state flavors are different ($q\bar{q} \to \tilde{q}_i'\bar{\tilde{q}}_i'$) we instead have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i'\bar{\tilde{q}}_i') = \frac{4\pi\alpha_s^2}{9s^4}\left[-st - (t - m_{\tilde{q}_i'}^2)^2\right]. \quad (51.53)$$

If the two initial state quarks are of different flavors, then we have

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by TUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

$$\frac{d\sigma}{dt}(q\bar{q}' \to \tilde{q}_i\bar{\tilde{q}}'_i) = \frac{2\pi\alpha_s^2}{9s^2}\frac{-st-(t-m_{\tilde{q}_i}^2)^2}{(t-m_{\tilde{g}}^2)^2}. \quad (51.54)$$

If the initial quarks are of different flavor and final state squarks are of different type ($i \neq j$) then

$$\frac{d\sigma}{dt}(q\bar{q}' \to \tilde{q}_i\bar{\tilde{q}}'_j) = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.55)$$

For same-flavor initial state quarks, but final state unlike-type squarks, we also have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_j) = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.56)$$

There also exist cross sections for quark-quark annihilation to squark pairs. For same flavor quark-quark annihilation to same flavor/same type final state squarks,

$$\frac{d\sigma}{dt}(qq \to \tilde{q}_i\tilde{q}_i) =$$
$$= \frac{\pi\alpha_s^2}{9s^2}m_{\tilde{g}}^2 s\left\{\frac{1}{(t-m_{\tilde{g}}^2)^2}+\frac{1}{(u-m_{\tilde{g}}^2)^2}-\frac{2/3}{(t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2)}\right\}, \quad (51.57)$$

while if the final type squarks are different ($i \neq j$), we have

$$\frac{d\sigma}{dt}(qq \to \tilde{q}_i\tilde{q}_j) =$$
$$\frac{2\pi\alpha_s^2}{9s^2}\times$$
$$\left\{\frac{[-st-(t-m_{\tilde{q}_i}^2)(t-m_{\tilde{q}_j}^2)]}{(t-m_{\tilde{g}}^2)}+\frac{[-su-(u-m_{\tilde{q}_i}^2)(u-m_{\tilde{q}_i}^2)]}{(u-m_{\tilde{g}}^2)}\right\} \quad (51.58)$$

If initial/final state flavors are different, but final state squark types are the same, then

$$\frac{d\sigma}{dt}(qq' \to \tilde{q}_i\tilde{q}'_i) = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.59)$$

If initial quark flavors are different and final squark types are different, then

$$\frac{d\sigma}{dt}(qq' \to \tilde{q}_i\tilde{q}'_j) = \frac{2\pi\alpha_s^2}{9s^2}\frac{-st-(t-m_{\tilde{q}_i}^2)(t-m_{\tilde{q}_j}^2)}{(t-m_{\tilde{g}}^2)^2}. \quad (51.60)$$

51.8.2 *Gluino and squark associated production*

In the MSSM, the charged spin-$\frac{1}{2}$ winos and higgsinos mix to make chargino states $\chi_1^\pm$ and $\chi_2^\pm$, with $m_{\chi_1^\pm} < m_{\chi_2^\pm}$. The spin$-\frac{1}{2}$ neutral bino, wino and higgsino fields mix to give four neutralino mass eigenstates $\chi^0_{1,2,3,4}$ ordered according to mass. We sometimes denote the charginos and neutralinos collectively as -inos for notational simplicity

For gluino and squark production in association with charginos and neutralinos [12], the quark-squark-neutralino couplings[1] are defined by the interaction Lagrangian terms

$$\mathcal{L}_{\tilde{f}f\tilde{\chi}_i^0} = \left[iA^f_{\tilde{\chi}_i^0}\tilde{f}_L^\dagger\bar{\tilde{\chi}}_i^0 P_L f + iB^f_{\tilde{\chi}_i^0}\tilde{f}_R^\dagger\bar{\tilde{\chi}}_i^0 P_R f + \text{h.c.}\right],$$

,where $A^f_{\tilde{\chi}_i^0}$ and $B^f_{\tilde{\chi}_i^0}$ are coupling constants involving gauge couplings, neutralino mixing elements and in the case of third generation fermions, Yukawa couplings. Their form depends on the conventions used for setting up the MSSM Lagrangian, and can be found in various reviews [14] and textbooks [13, 15]. P_L and P_R are the usual left- and right- spinor projection operators and f denotes any of the SM fermions u, d, e, $\nu_e, \cdots$. The fermion-sfermion- chargino couplings have the form $\mathcal{L} = \left[iA^d_{\tilde{\chi}_i^-}\tilde{u}_L^\dagger\overline{\tilde{\chi}_i^-}P_L d + iA^u_{\tilde{\chi}_i^-}\tilde{d}_L^\dagger\overline{\tilde{\chi}_i^c}P_L u + \text{h.c.}\right]$ for u and d quarks, where the $A^d_{\tilde{\chi}_i^-}$ and $A^u_{\tilde{\chi}_i^-}$ couplings are again convention-dependent, and can be found in textbooks. The superscript c denotes "charge conjugate spinor", defined by $\psi^c \equiv C\bar{\psi}^T$.

The subprocess cross sections for chargino-squark associated production occur via squark exchange and are given by

$$\frac{d\sigma}{dt}(\bar{u}g \to \tilde{\chi}_i^-\bar{\tilde{d}}_L) = \frac{\alpha_s}{24s^2}|A^u_{\tilde{\chi}_i^-}|^2\psi(m_{\tilde{d}_L}, m_{\tilde{\chi}_i^-}, t), \quad (51.61)$$

$$\frac{d\sigma}{dt}(dg \to \tilde{\chi}_i^-\tilde{u}_L) = \frac{\alpha_s}{24s^2}|A^d_{\tilde{\chi}_i^-}|^2\psi(m_{\tilde{u}_L}, m_{\tilde{\chi}_i^-}, t), \quad (51.62)$$

while neutralino-squark production is given by

$$\frac{d\sigma}{dt}(qg \to \tilde{\chi}_i^0\tilde{q}) = \frac{\alpha_s}{24s^2}\left(|A^q_{\tilde{\chi}_i^0}|^2+|B^q_{\tilde{\chi}_i^0}|^2\right)\psi(m_{\tilde{q}}, m_{\tilde{\chi}_i^0}, t), \quad (51.63)$$

where

$$\psi(m_1,m_2,t) = \frac{s+t-m_1^2}{2s} - \frac{m_1^2(m_2^2-t)}{(m_1^2-t)^2} + \frac{t(m_2^2-m_1^2)+m_2^2(s-m_2^2+m_1^2)}{s(m_1^2-t)}. \quad (51.64)$$

Here, the variable t is given by the square of "squark-minus-quark" four-momentum. The neutralino-gluino associated production cross section also occurs via squark exchange and is given by

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{\chi}_i^0\tilde{g}) = \frac{\alpha_s}{18s^2}\left(|A^q_{\tilde{\chi}_i^0}|^2+|B^q_{\tilde{\chi}_i^0}|^2\right)\left[\frac{(m^2_{\tilde{\chi}_i^0}-t)(m_{\tilde{g}}^2-t)}{(m_{\tilde{q}}^2-t)^2} + \frac{(m^2_{\tilde{\chi}_i^0}-u)(m_{\tilde{g}}^2-u)}{(m_{\tilde{q}}^2-u)^2} - \frac{2\eta_i\eta_{\tilde{g}}m_{\tilde{g}}m_{\tilde{\chi}_i^0}s}{(m_{\tilde{q}}^2-t)(m_{\tilde{q}}^2-u)}\right], \quad (51.65)$$

where η_i is the sign of the neutralino mass eigenvalue and $\eta_{\tilde{g}}$ is the sign of the gluino mass eigenvalue. We also have chargino-gluino associated production:

$$\frac{d\sigma}{dt}(\bar{u}d \to \tilde{\chi}_i^-\tilde{g}) = \frac{\alpha_s}{18s^2}\left[|A^u_{\tilde{\chi}_i^-}|^2\frac{(m^2_{\tilde{\chi}_i^-}-t)(m_{\tilde{g}}^2-t)}{(m^2_{\tilde{d}_L}-t)^2} + |A^d_{\tilde{\chi}_i^-}|^2\frac{(m^2_{\tilde{\chi}_i^-}-u)(m_{\tilde{g}}^2-u)}{(m^2_{\tilde{u}_L}-u)^2} + \frac{2\eta_{\tilde{g}}Re(A^u_{\tilde{\chi}_i^-}A^d_{\tilde{\chi}_i^-})m_{\tilde{g}}m_{\tilde{\chi}_i}s}{(m^2_{\tilde{d}_L}-t)(m^2_{\tilde{u}_L}-u)}\right], \quad (51.66)$$

where $\hat{t} = (\tilde{g}-d)^2$ and in the third term one must take the real part of the in general complex coupling constant product.

51.8.3 *Slepton and sneutrino production*

The subprocess cross section for $\tilde{\ell}_L\bar{\tilde{\nu}}_{\ell_L}$ production ($\ell = e$ or μ) occurs via s-channel W exchange and is given by

$$\frac{d\sigma}{dt}(d\bar{u} \to \tilde{\ell}_L\bar{\tilde{\nu}}_{\ell_L}) = \frac{g^4|D_W(s)|^2}{192\pi s^2}\left(tu - m^2_{\tilde{\ell}_L}m^2_{\tilde{\nu}_{\ell_L}}\right), \quad (51.67)$$

where $D_W(s) = 1/(s-M_W^2+iM_W\Gamma_W)$ is the W-boson propagator denominator. The production of $\tilde{\tau}_1\bar{\tilde{\nu}}_\tau$ is given as above, but replacing $m_{\tilde{\ell}_L} \to m_{\tilde{\tau}_1}$, $m_{\tilde{\nu}_{\ell_L}} \to m_{\tilde{\nu}_\tau}$ and multiplying by an overall factor of $\cos^2\theta_\tau$ (where θ_τ is the tau-slepton mixing angle). Similar substitutions hold for $\tilde{\tau}_2\bar{\tilde{\nu}}_\tau$ production, except the overall factor is $\sin^2\theta_\tau$.

[1] The couplings $A^f_{\tilde{\chi}_i^0}$ and $B^f_{\tilde{\chi}_i^0}$ are given explicitly in Ref. [13] in Eq. (8.87). Also, the couplings $A^d_{\tilde{\chi}_i^-}$ and $A^u_{\tilde{\chi}_i^-}$ are given in Eq. (8.93). The couplings X_i^j and Y_i^j are given by Eq. (8.103), while the x_i and y_i couplings are given in Eq. (8.100). Finally, the couplings W_{ij} are given in Eq. (8.101).

Table 51.1: The constants α_f and β_f that appear in in the SM neutral current Lagrangian. Here $t \equiv \tan\theta_W$ and $c \equiv \cot\theta_W$.

f	q_f	α_f	β_f
ℓ	-1	$\frac{1}{4}(3t-c)$	$\frac{1}{4}(t+c)$
ν_ℓ	0	$\frac{1}{4}$(t+c)	$-\frac{1}{4}(t+c)$
u	$\frac{2}{3}$	$-\frac{5}{12}t+\frac{1}{4}c$	$-\frac{1}{4}(t+c)$
d	$-\frac{1}{3}$	$\frac{1}{12}t-\frac{1}{4}c$	$\frac{1}{4}(t+c)$

The subprocess cross section for $\tilde{\ell}_L\bar{\tilde{\ell}}_L$ production occurs via s-channel γ and Z exchange, and depends on the neutral current interaction, with fermion couplings to γ and Z^0 given by $\mathcal{L}_{\rm neutral} = -eq_f\bar{f}\gamma^\mu f A_\mu + e\bar{f}\gamma^\mu(\alpha_f+\beta_f\gamma_5)fZ_\mu$ (with values of q_f, α_f, and β_f given in Table-51.1.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\ell}_L\bar{\tilde{\ell}}_L) = \frac{e^4}{24\pi s^2}\left(tu-m^4_{\tilde{\ell}_L}\right)\times$$
$$\left\{\frac{q_\ell^2 q_q^2}{s^2} + (\alpha_\ell-\beta_\ell)^2(\alpha_q^2+\beta_q^2)|D_Z(s)|^2\right.$$
$$\left. + \frac{2q_\ell q_q\alpha_q(\alpha_\ell-\beta_\ell)(s-M_Z^2)}{s}|D_Z(s)|^2\right\}, \qquad (51.68)$$

where $D_Z(s) = 1/(s-M_Z^2+iM_Z\Gamma_Z)$. The cross section for sneutrino production is given by the same formula, but with α_ℓ, β_ℓ, q_ℓ and $m_{\tilde{\ell}_L}$ replaced by α_ν, β_ν, 0 and $m_{\tilde{\nu}_L}$, respectively. The cross section for $\tilde{\tau}_1\bar{\tilde{\tau}}_1$ production is obtained by replacing $m_{\tilde{\ell}_L}\to m_{\tilde{\tau}_1}$ and $\beta_\ell\to\beta_\ell\cos 2\theta_\tau$. The cross section for $\tilde{\ell}_R\bar{\tilde{\ell}}_R$ production is given by substituting $\alpha_\ell-\beta_\ell\to\alpha_\ell+\beta_\ell$ and $m_{\tilde{\ell}_L}\to m_{\tilde{\ell}_R}$ in the equation above. The cross section for $\tilde{\tau}_2\bar{\tilde{\tau}}_2$ production is obtained from the formula for $\tilde{\ell}_R\bar{\tilde{\ell}}_R$ production by replacing $m_{\tilde{\ell}_R}\to m_{\tilde{\tau}_2}$ and $\beta_\ell\to\beta_\ell\cos 2\theta_\tau$.

Finally, the cross section for $\tilde{\tau}_1\bar{\tilde{\tau}}_2$ production occurs only via Z exchange, and is given by

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\tau}_1\bar{\tilde{\tau}}_2) = \frac{d\sigma}{dt}(q\bar{q}\to\bar{\tilde{\tau}}_1\tilde{\tau}_2) =$$
$$\frac{e^4}{24\pi s^2}(\alpha_q^2+\beta_q^2)\beta_\ell^2\sin^2 2\theta_\tau|D_Z(s)|^2(ut-m^2_{\tilde{\tau}_1}m^2_{\tilde{\tau}_2}). \qquad (51.69)$$

51.8.4 *Chargino and neutralino pair production*

51.8.4.1 $\tilde{\chi}_i^-\tilde{\chi}_j^0$ *production*

The subprocess cross section for $d\bar{u}\to\tilde{\chi}_i^-\tilde{\chi}_j^0$ depends on Lagrangian couplings

$$\mathcal{L}_{W\bar{u}d} = -\frac{g}{\sqrt{2}}\bar{u}\gamma_\mu P_L d W^{+\mu} + \text{h.c.},$$
$$\mathcal{L}_{W\tilde{\chi}_i^-\tilde{\chi}_j^0} = -g(-i)^{\theta_j}\overline{\tilde{\chi}^-}_i[X_i^j+Y_i^j\gamma_5]\gamma_\mu\tilde{\chi}_j^0 W^{-\mu} + \text{h.c.},$$
$$\mathcal{L}_{q\bar{q}\tilde{\chi}_i^-} = iA^d_{\tilde{\chi}_i^-}\bar{u}_L^\dagger\overline{\tilde{\chi}_i^-}P_L d + iA^u_{\tilde{\chi}_i^-}\bar{d}_L^\dagger\overline{\tilde{\chi}_i^c}P_L u + \text{h.c.}$$

and

$$\mathcal{L}_{q\bar{q}\tilde{\chi}_j^0} = iA^q_{\tilde{\chi}_j^0}\bar{q}_L^\dagger\overline{\tilde{\chi}^0}_j P_L q + \text{h.c.}.$$

Contributing diagrams include W exchange and also $\tilde{d}_L$ and $\tilde{u}_L$ squark exchange. The X_i^j and Y_i^j couplings are new, and again convention-dependent: the cross section formulae works if the interaction Lagrangian is written in the above form, so that the couplings can be suitably extracted. The term $\theta_j = 0$ (1) if $m_{\tilde{\chi}_j^0} > 0$ (< 0); it comes about because the neutralino field must be re-defined by a $-i\gamma_5$ transformation if its mass eigenvalue is negative [13]. The subprocess cross section is given in terms of dot products of four momenta, where particle labels are used to denote their four-momenta; note that all mass terms in the cross section formulae are positive definite, so that the signs of mass eigenstates have been absorbed into the Lagrangian couplings, as for instance in Ref. [13]. We then have

$$\frac{d\sigma}{dt}(d\bar{u}\to\tilde{\chi}_i^-\tilde{\chi}_j^0) = \frac{1}{192\pi s^2}$$
$$\left[T_W + T_{\tilde{d}_L} + T_{\tilde{u}_L} + T_{W\tilde{d}_L} + T_{W\tilde{u}_L} + T_{\tilde{d}_L\tilde{u}_L}\right] \qquad (51.70)$$

where

$$T_W = 8g^4|D_W(s)|^2\left\{[X_i^{j2}+Y_i^{j2}](\tilde{\chi}_j^0\cdot d\tilde{\chi}_i^-\cdot\bar{u} + \tilde{\chi}_j^0\cdot\bar{u}\tilde{\chi}_i^-\cdot d)\right.$$
$$+ 2(X_i^jY_i^j)(\tilde{\chi}_j^0\cdot d\tilde{\chi}_i^-\cdot\bar{u} - \tilde{\chi}_j^0\cdot\bar{u}\tilde{\chi}_i^-\cdot d)$$
$$\left. + [X_i^{j2}-Y_i^{j2}]m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\}, \qquad (51.71)$$

$$T_{\tilde{d}_L} = \frac{4|A^u_{\tilde{\chi}_i^-}|^2|A^d_{\tilde{\chi}_j^0}|^2}{[(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}]^2}\; d\cdot\tilde{\chi}_j^0\tilde{\chi}_i^-\cdot\bar{u}, \qquad (51.72)$$

$$T_{\tilde{u}_L} = \frac{4|A^d_{\tilde{\chi}_i^-}|^2|A^u_{\tilde{\chi}_j^0}|^2}{[(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}]^2}\; \bar{u}\cdot\tilde{\chi}_j^0\tilde{\chi}_i^-\cdot d \qquad (51.73)$$

$$T_{W\tilde{d}_L} = \frac{-\sqrt{2}g^2 Re[A^{d*}_{\tilde{\chi}_j^0}A^u_{\tilde{\chi}_i^-}(-i)^{\theta_j}](s-M_W^2)|D_W(s)|^2}{(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}}$$
$$\times\left\{8(X_i^j+Y_i^j)\tilde{\chi}_j^0\cdot d\bar{u}\cdot\tilde{\chi}_i^- + 4(X_i^j-Y_i^j)m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\} \qquad (51.74)$$

$$T_{W\tilde{u}_L} = \frac{\sqrt{2}g^2 Re[A^{d*}_{\tilde{\chi}_i^-}A^u_{\tilde{\chi}_j^0}(-i)^{\theta_j}](s-M_W^2)|D_W(s)|^2}{(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}}$$
$$\times\left\{8(X_i^j-Y_i^j)\tilde{\chi}_j^0\cdot\bar{u}d\cdot\tilde{\chi}_i^- + 4(X_i^j+Y_i^j)m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\} \qquad (51.75)$$

and

$$T_{\tilde{d}_L\tilde{u}_L} = -\frac{4Re[A^d_{\tilde{\chi}_j^0}A^{u*}_{\tilde{\chi}_i^-}A^{d*}_{\tilde{\chi}_i^-}A^u_{\tilde{\chi}_j^0}]m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}}{[(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}][(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}]}. \qquad (51.76)$$

51.8.4.2 *Chargino pair production*

The subprocess cross section for $d\bar{d}\to\tilde{\chi}_i^-\tilde{\chi}_i^+$ ($i=1,2$) depends on Lagrangian couplings $\mathcal{L} = e\overline{\tilde{\chi}_i^-}\gamma_\mu\tilde{\chi}_i^- A^\mu - e\cot\theta_W\overline{\tilde{\chi}_i^-}\gamma_\mu(x_i - y_i\gamma_5)\tilde{\chi}_i^- Z^\mu$ and also $\mathcal{L}\ni iA^d_{\tilde{\chi}_i^-}\bar{u}_L^\dagger\overline{\tilde{\chi}_i^-}P_L d + iA^u_{\tilde{\chi}_i^-}\tilde{d}_L^\dagger\overline{\tilde{\chi}_i^{-c}}P_L u + \text{h.c.}$. Contributing diagrams include s-channel γ, Z^0 exchange and t-channel $\tilde{u}_L$ exchange [16, 17]. The couplings x_i and y_i are again new and as usual convention-dependent.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(d\bar{d}\to\tilde{\chi}_i^-\tilde{\chi}_i^+) =$$
$$\frac{1}{192\pi s^2}\left[T_\gamma + T_Z + T_{\tilde{u}_L} + T_{\gamma Z} + T_{\gamma\tilde{u}_L} + T_{Z\tilde{u}_L}\right] \qquad (51.77)$$

where

$$T_\gamma = \frac{32e^4q_d^2}{s^2}\left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}d\cdot\bar{d}\right] \qquad (51.78)$$

$$T_Z = 32e^4\cot^2\theta_W|D_Z(s)|^2$$
$$\left\{(\alpha_d^2+\beta_d^2)(x_i^2+y_i^2)\left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}d\cdot\bar{d}\right]\right.$$

$$\mp 4\alpha_d\beta_d x_i y_i \left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- - d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+\right] - 2y_i^2(\alpha_d^2+\beta_d^2)m^2_{\tilde{\chi}_i^-} d\cdot\bar{d}\Bigg\}, \tag{51.79}$$

$$T_{\tilde{u}_L} = \frac{4|A^d_{\tilde{\chi}_i^-}|^4}{[(d-\tilde{\chi}_i^-)^2 - m^2_{\tilde{u}_L}]^2}\; d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ \tag{51.80}$$

$$T_{\gamma Z} = \frac{64e^4\cot\theta_W q_d(s-M_Z^2)|D_Z(s)|^2}{s}\times$$
$$\Bigg\{\alpha_d x_i\left(d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-} d\cdot\bar{d}\right)$$
$$\pm\beta_d y_i\left(d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ - d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^-\right)\Bigg\} \tag{51.81}$$

$$T_{\gamma\tilde{u}_L} = \mp\frac{8e^2 q_d}{s}\frac{|A^d_{\tilde{\chi}_i^-}|^2}{[(d-\tilde{\chi}_i^-)^2 - m^2_{\tilde{u}_L}]}\left\{2\bar{d}\cdot\tilde{\chi}_i^+ d\cdot\tilde{\chi}_i^- + m^2_{\tilde{\chi}_i^-} d\cdot\bar{d}\right\} \tag{51.82}$$

and

$$T_{Z\tilde{u}_L} = \mp 8e^2\cot\theta_W|D_Z(s)|^2\frac{|A^d_{\tilde{\chi}_i^-}|^2(s-M_Z^2)}{[(d-\tilde{\chi}_i^-)^2 - m^2_{\tilde{u}_L}]}(\alpha_d-\beta_d)$$
$$\times\left\{2(x_i\mp y_i)d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}(x_i\pm y_i)d\cdot\bar{d}\right\} \tag{51.83}$$

using the upper of the sign choices.

The cross section for $u\bar{u}\to\tilde{\chi}_i^+\tilde{\chi}_i^-$ can be obtained from the above by replacing $\alpha_d\to\alpha_u$, $\beta_d\to\beta_u$, $q_d\to q_u$, $\tilde{u}_L\to\tilde{d}_L$, $A^d_{\tilde{\chi}_i^-}\to A^u_{\tilde{\chi}_i^-}$, $d\to\bar{u}$, $\bar{d}\to u$ and adopting the lower of the sign choices everywhere.

The cross section for $q\bar{q}\to\tilde{\chi}_1^-\tilde{\chi}_2^+$, $\tilde{\chi}_1^+\tilde{\chi}_2^-$ can occur via Z and $\tilde{q}_L$ exchange. It is usually much smaller than $\tilde{\chi}^-_{1,2}\tilde{\chi}^+_{1,2}$ production, so the cross section will not be presented here. It can be found in Appendix A of Ref. [13].

51.8.4.3 *Neutralino pair production*

Neutralino pair production via $q\bar{q}$ fusion takes place via s-channel Z exchange plus t- and u-channel left- and right- squark exchange (5 diagrams) [17, 18]. The Lagrangian couplings (see previous footnote*) needed include terms given above plus terms of the form $\mathcal{L} = W_{ij}\overline{\tilde{\chi}^0}_i\gamma_\mu(\gamma_5)^{\theta_i+\theta_j+1}\tilde{\chi}^0_j Z^\mu$. The couplings W_{ij} depend only on the *higgsino* components of the neutralinos i and j. The subprocess cross section is given by:

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\chi}_i^0\tilde{\chi}_j^0) = \frac{1}{192\pi s^2}\left[T_Z + T_{\tilde{q}_L} + T_{\tilde{q}_R} + T_{Z\tilde{q}_L} + T_{Z\tilde{q}_R}\right] \tag{51.84}$$

where

$$T_Z = 128e^2|W_{ij}|^2(\alpha_q^2+\beta_q^2)|D_Z(s)|^2$$
$$\left[q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 + q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right], \tag{51.85}$$

$$T_{\tilde{q}_L} = 4|A^q_{\tilde{\chi}_i^0}|^2|A^q_{\tilde{\chi}_j^0}|^2\left\{\frac{q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}]^2} + \frac{q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]^2}\right.$$
$$\left. - \eta_i\eta_j\frac{m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}][(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]}\right\} \tag{51.86}$$

$$T_{\tilde{q}_R} = 4|B^q_{\tilde{\chi}_i^0}|^2|B^q_{\tilde{\chi}_j^0}|^2\left\{\frac{q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}]^2} + \frac{q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]^2}\right.$$
$$\left. - \eta_i\eta_j\frac{m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}][(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]}\right\} \tag{51.87}$$

$$T_{Z\tilde{q}_L} = 16e(\alpha_q-\beta_q)(s-M_Z^2)|D_Z(s)|^2$$
$$\left\{\frac{Re(W_{ij}A^{q*}_{\tilde{\chi}_i^0}A^q_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}]}\left[2q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right]\right.$$
$$\left. + \eta_i\eta_j\frac{Re(W_{ij}A^q_{\tilde{\chi}_i^0}A^{q*}_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]}\left[2q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right]\right\} \tag{51.88}$$

$$T_{Z\tilde{q}_R} = 16e(\alpha_q+\beta_q)(s-M_Z^2)|D_Z(s)|^2$$
$$\left\{\frac{Re(W_{ij}B^{q*}_{\tilde{\chi}_i^0}B^q_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}]}\left[2q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right]\right.$$
$$\left. - \frac{Re(W_{ij}B^q_{\tilde{\chi}_i^0}B^{q*}_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]}\left[2q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0} q\cdot\bar{q}\right]\right\}. \tag{51.89}$$

As before, $\eta_i = \pm 1$ corresponding to whether the neutralino mass eigenvalue is positive or negative. When $i = j$ in the above formula, one must remember to integrate over just 2π steradians of solid angle to avoid double counting in the total cross section.

51.9 Universal extra dimensions

In the Universal Extra Dimension (UED) model of Ref. [19] (see Ref. [20] for a review of models with extra spacetime dimensions), the Standard Model is embedded in a five dimensional theory, where the fifth dimension is compactified on an S_1/Z_2 orbifold. Each SM chirality state is then the zero mode of an infinite tower of Kaluza-Klein excitations labeled by $n = 0-\infty$. A KK parity is usually assumed to hold, where each state is assigned KK-parity $P = (-1)^n$. If the compactification scale is around a TeV, then the $n = 1$ (or even higher) KK modes may be accessible to collider searches.

Of interest for hadron colliders are the production of massive $n \geq 1$ quark or gluon pairs. These production cross sections have been calculated in Ref. [21, 22]. We list here results for the $n = 1$ case only with $M_1 = 1/R$ (R is the compactification radius) and s, t and u are the usual Mandelstam variables; more general formulae can be found in Ref. [22]. The superscript $*$ stands for any KK excited state, while $\bullet$ stands for left chirality states and $\circ$ stands for right chirality states.

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}T \tag{51.90}$$

where

$$T(q\bar{q}\to g^*g^*) = \frac{2g_s^4}{27}\left[M_1^2\left(-\frac{4s^3}{t'^2u'^2} + \frac{57s}{t'u'} - \frac{108}{s}\right)\right.$$
$$\left. + \frac{20s^2}{t'u'} - 93 + \frac{108t'u'}{s^2}\right] \tag{51.91}$$

and

$$T(gg\to g^*g^*) =$$
$$\frac{9g_s^4}{27}\left[3M_1^4\frac{s^2+t'^2+u'^2}{t'^2u'^2} - 3M_1^2\frac{s^2+t'^2+u'^2}{st'u'} + 1\right.$$
$$\left. + \frac{(s^2+t'^2+u'^2)^3}{4s^2t'^2u'^2} - \frac{t'u'}{s^2}\right] \tag{51.92}$$

where $t' = t - M_1^2$ and $u' = u - M_1^2$.

Also,

$$T(q\bar{q}\to q_1^{*\prime}\bar{q}_1^{*\prime}) = \frac{4g_s^4}{9}\left[\frac{2M_1^2}{s} + \frac{t'^2+u'^2}{s^2}\right],$$

$$T(q\bar{q}\to q_1^*\bar{q}_1^*) = \frac{g_2^4}{9}\left[2M_1^2\left(\frac{4}{s} + \frac{s}{t'^2} - \frac{1}{t'}\right)\right.$$
$$\left. + \frac{23}{6} + \frac{2s^2}{t'^2} + \frac{8s}{3t'} + \frac{6t'}{s} + \frac{8t'^2}{s^2}\right],$$

$$T(qq\to q_1^*q_1^*)=\frac{g_s^4}{27}\left[M_1^2\left(6\frac{t'}{u'^2}+6\frac{u'}{t'^2}-\frac{s}{t'u'}\right)\right.$$
$$\left.+2\left(3\frac{t'^2}{u'^2}+3\frac{u'^2}{t'^2}+4\frac{s^2}{t'u'}-5\right)\right],$$
$$T(gg\to q_1^*\bar{q}_1^*)=g_s^4\left[M_1^4\frac{-4}{t'u'}\left(\frac{s^2}{6t'u'}-\frac{3}{8}\right)\right.$$
$$\left.+M_1^2\frac{4}{s}\left(\frac{s^2}{6t'u'}-\frac{3}{8}\right)+\frac{s^2}{6t'u'}-\frac{17}{24}+\frac{3t'u'}{4s^2}\right],$$
$$T(gq\to g^*q_1^*)=\frac{-g_s^4}{3}\left[\frac{5s^2}{12t'^2}+\frac{s^3}{t'^2u'}+\frac{11su'}{6t'^2}+\frac{5u'^2}{12t'^2}+\frac{u'^3}{st'^2}\right],$$
$$T(q\bar{q}'\to q_1^*\bar{q}_1^{*'})=\frac{g_s^4}{18}\left[4M_1^4\frac{s}{t'^2}+5+4\frac{s^2}{t'^2}+8\frac{s}{t'}\right],$$
$$T(qq'\to q_1^*q_1^{*'})=\frac{2g_s^4}{9}\left[-M_1^2\frac{s}{t'^2}+\frac{1}{4}+\frac{s^2}{t'^2}\right],$$
$$T(qq\to q_1^\bullet q_1^\circ)=$$
$$\frac{g_s^4}{9}\left[M_1^2\left(\frac{2s^3}{t'^2u'^2}-\frac{4s}{t'u'}\right)+2\frac{s^4}{t'^2u'^2}-8\frac{s^2}{t'u'}+5\right],$$
$$T(q\bar{q}'\to q_1^\bullet\bar{q}_1^{'\circ})=\frac{g_s^4}{9}\left[2M_1^2\left(\frac{1}{t'}+\frac{u'}{t'^2}\right)+\frac{5}{2}+\frac{4u'}{t'}+\frac{2u'^2}{t'^2}\right],$$

and

$$T(qq'\to q_1^\bullet q_1^{'\circ})=\frac{g_s^4}{9}\left[-2M_1^2\left(\frac{1}{t'}+\frac{u'}{t'^2}\right)+\frac{1}{2}+\frac{2u'^2}{t'^2}\right].$$

51.10 Large extra dimensions

In the ADD theory [23] with large extra dimensions (LED), the SM particles are confined to a 3-brane, while gravity propagates in the bulk. It is assumed that the n extra dimensions are compactified on an n-dimensional torus of volume $(2\pi r)^n$, so that the fundamental $4+n$ dimensional Planck scale M_* is related to the usual 4-dimensional Planck scale M_{Pl} by $M_{Pl}^2=M_*^{n+2}(2\pi r)^n$. If $M_*\sim 1$ TeV, then the M_W-M_{Pl} hierarchy problem is just due to gravity propagating in the large extra dimensions.

In these theories, the KK-excited graviton states $G_{\mu\nu}^n$ for $n=1-\infty$ can be produced at collider experiments. The graviton couplings to matter are suppressed by $1/M_{Pl}$, so that graviton emission cross sections $d\sigma/dt\sim 1/M_{Pl}^2$. However, the mass splittings between the excited graviton states can be tiny, so the graviton eigenstates are usually approximated by a continuum distribution. A summation (integration) over all allowed graviton emissions ends up cancelling the $1/M_{Pl}^2$ factor, so that observable cross section rates can be attained. Some fundamental production formulae for a KK graviton (denoted G) of mass m at hadron colliders include the subprocesses

$$\frac{d\sigma_m}{dt}(f\bar{f}\to\gamma G)=\frac{\alpha Q_f^2}{16N_f}\frac{1}{sM_{Pl}^2}F_1(\frac{t}{s},\frac{m^2}{s}),\qquad(51.93)$$

where Q_f is the charge of fermion f and N_f is the number of QCD colors of f. Also,

$$\frac{d\sigma_m}{dt}(q\bar{q}\to gG)=\frac{\alpha_s}{36}\frac{1}{sM_{Pl}^2}F_1(\frac{t}{s},\frac{m^2}{s}),\qquad(51.94)$$

$$\frac{d\sigma_m}{dt}(qg\to qG)=\frac{\alpha_s}{96}\frac{1}{sM_{Pl}^2}F_2(\frac{t}{s},\frac{m^2}{s}),\qquad(51.95)$$

$$\frac{d\sigma_m}{dt}(gg\to gG)=\frac{3\alpha_s}{16}\frac{1}{sM_{Pl}^2}F_3(\frac{t}{s},\frac{m^2}{s}),\qquad(51.96)$$

where

$$F_1(x,y)=\frac{1}{x(y-1-x)}\left[-4x(1+x)(1+2x+2x^2)+\right.$$
$$\left.y(1+6x+18x^2+16x^3)-6y^2x(1+2x)+y^3(1+4x)\right]\qquad(51.97)$$

$$F_2(x,y)=-(y-1-x)F_1\left(\frac{x}{y-1-x},\frac{y}{y-1-x}\right)\qquad(51.98)$$

and

$$F_3(x,y)=\frac{1}{x(y-1-x)}\left[1+2x+3x^2+2x^3+x^4\right.$$
$$\left.-2y(1+x^3)+3y^2(1+x^2)-2y^3(1+x)+y^4\right]\qquad(51.99)$$

These formulae must then be multiplied by the graviton density of states formula $dN=S_{n-1}\frac{M_{Pl}^2}{M_*^{n+2}}m^{n-1}dm$ to gain the cross section

$$\frac{d^2\sigma}{dtdm}=S_{n-1}\frac{M_{Pl}^2}{M_*^{n+2}}m^{n-1}\frac{d\sigma_m}{dt}\qquad(51.100)$$

where $S_n=\frac{(2\pi)^{n/2}}{\Gamma(n/2)}$ is the surface area of an n-dimensional sphere of unit radius.

Virtual graviton processes can also be searched for at colliders. For instance, in Ref. [24] the cross section for Drell-Yan production of lepton pairs via gluon fusion was calculated, where it is found that, in the center-of-mass system

$$\frac{d\sigma}{dz}(gg\to\ell^+\ell^-)=\frac{\lambda^2s^3}{64\pi M_*^8}(1-z^2)(1+z^2)\qquad(51.101)$$

where $z=\cos\theta$ and λ is a model-dependent coupling constant ~ 1. Formulae for Drell-Yan production via $q\bar{q}$ fusion can also be found in Refs. [24, 25].

51.11 Warped extra dimensions

In the Randall-Sundrum model [26] of warped extra dimensions, the arena for physics is a 5-d anti-deSitter (AdS_5) spacetime, for which a non-factorizable metric exists with a metric warp factor $e^{-2\sigma(\phi)}$. It is assumed that two opposite tension 3-branes exist within AdS_5 at the two ends of an S_1/Z_2 orbifold parameterized by co-ordinate ϕ which runs from $0-\pi$. The 4-D solution of the Einstein equations yields $\sigma(\phi)=kr_c|\phi|$, where r_c is the compactification radius of the extra dimension and $k\sim M_{Pl}$. The 4-D effective action allows one to identify $\overline{M}_{Pl}^2=\frac{M^3}{k}(1-e^{-2kr_c\pi})$, where M is the 5-D Planck scale. Physical particles on the TeV scale (SM) brane have mass $m=e^{-kr_c\pi}m_0$, where m_0 is a fundamental mass of order the Planck scale. Thus, the weak scale-Planck scale hierarchy occurs due to the existence of the exponential warp factor if $kr_c\sim 12$.

In the simplest versions of the RS model, the TeV-scale brane contains only SM particles plus a tower of KK gravitons. The RS gravitons have mass $m_n=kx_ne^{-kr_c\pi}$, where the x_i are roots of Bessel functions $J_1(x_n)=0$, with $x_1\simeq 3.83$, $x_2\simeq 7.02$ etc. While the RS zero-mode graviton couplings suppressed by $1/\overline{M}_{Pl}$ and are thus inconsequential for collider searches, the $n=1$ and higher modes have couplings suppressed instead by $\Lambda_\pi=e^{-kr_c\pi}\overline{M}_{Pl}\sim TeV$. The $n=1$ RS graviton should have width $\Gamma_1=\rho m_1x_1^2(k/\overline{M}_{Pl})^2$, where ρ is a constant depending on how many decay modes are open. The formulae for dilepton production via virtual RS graviton exchange can be gained from the above formulae for the ADD scenario via the replacement [27]

$$\frac{\lambda}{M_*^4}\to\frac{i^2}{8\Lambda_\pi^2}\sum_{n=1}^{\infty}\frac{1}{s-m_n^2+im_n\Gamma_n}.\qquad(51.102)$$

52. Neutrino Cross Section Measurements

Revised August 2025 by G.P. Zeller (FNAL).

Neutrino cross sections are an essential ingredient in all neutrino experiments. Interest in neutrino scattering has increased due to the need for such information in the interpretation of neutrino data and given that uncertainties in neutrino-nucleus scattering remain a dominate source of systematic uncertainty in neutrino oscillation measurements. Historically, neutrino scattering results on both charged current (CC) and neutral current (NC) channels have been collected over many decades using a variety of targets, analysis techniques, and detector technologies. With the advent of intense neutrino sources constructed for neutrino oscillation investigations, experiments are now remeasuring such interaction cross sections with a renewed appreciation for nuclear effects[1] and the need for more precise neutrino flux estimations [1, 2]. This work summarizes neutrino cross section measurements performed in the $\sim 0.1-1000$ GeV range with an emphasis on inclusive, deep inelastic, quasi-elastic, and resonance production processes, areas where we have the most experimental input at present (Table 52.1). For a more comprehensive discussion of neutrino cross sections, including neutrino-electron scattering and lower energy measurements, the reader is directed to a review of this subject [3]. Here, we survey existing experimental data on neutrino interactions and do not attempt to provide a census of the associated theoretical calculations [4], which are both critical and plentiful. Companion electron-nucleus scattering data [5] are additionally playing an increased role in neutrino interaction predictions through such efforts as the e4ν Collaboration [6].

Table 52.1: List of properties of modern experiments measuring neutrino cross sections in the $\sim 0.1 - 1000$ GeV energy range.

Experiment	beam	$\langle E_\nu \rangle$, $\langle E_{\overline{\nu}} \rangle$ (GeV)	neutrino target(s)	run period
ArgoNeuT	$\nu, \overline{\nu}$	4.3, 3.6	Ar	2009 – 2010

52.1 Inclusive Scattering

Over the years, many experiments have measured the total inclusive charged current cross section for neutrino ($\nu_\mu N \to \mu^- X$) and antineutrino ($\overline{\nu}_\mu N \to \mu^+ X$) scattering covering a very broad range of energies. As can be seen in Fig. 52.1, which shows this data over decades of time and energy, the inclusive cross section approaches a linear dependence on neutrino energy. This behavior is expected for point-like scattering of neutrinos from quarks, an assumption which breaks down at lower energies.

To provide a more complete picture, differential cross sections for such inclusive scattering processes have also been reported. These include historical measurements on iron from NuTeV [7] and modern measurements on a variety of nuclear targets (Table 52.2). More recently, MINERvA has provided measurements in terms of longitudinal and transverse muon momenta [8, 9], MicroBooNE has measured the first triple differential cross sections in argon [10], and T2K has provided the first measurement of the antineutrino inclusive cross section at low energy [11] (Fig. 52.1).

At high energy, the inclusive cross section is dominated by deep inelastic scattering (DIS). Several neutrino experiments have measured DIS cross sections for specific targets and final states, for example, MINERvA has measured ratios of neutrino DIS cross sections on a variety of nuclear targets including lead, iron, and carbon [12, 13]. Other experiments have measured opposite-sign dimuon production, the most recent being from CHORUS [14], NOMAD [15], and NuTeV [16]. Multiple efforts are also now underway to measure inclusive neutrino scattering cross sections at significantly higher neutrino energies (in the TeV-PeV range), including at the LHC in FASERν [17] and SND@LHC [18], as well as using atmospheric neutrinos in IceCube [19–21].

Table 52.2: Published measurements of muon neutrino and antineutrino CC inclusive cross sections from modern neutrino experiments.

experiment	measurement	target
ArgoNeuT	ν_μ [22, 23], $\overline{\nu}_\mu$ [23]	Ar
FASERν	ν_μ [17], $\overline{\nu}_\mu$ [17]	W, emulsion
IceCube	$\nu + \overline{\nu}$ [20]	H_2O
MicroBooNE	ν_μ [10, 24–27]	Ar
MINERνA	ν_μ [8, 9, 12, 13, 28–31], $\overline{\nu}_\mu$ [28, 31], $\overline{\nu}_\mu/\nu_\mu$ [32]	C, CH, Fe, Pb
MINOS	ν_μ [33], $\overline{\nu}_\mu$ [33]	Fe
NINJA	ν_μ [34, 35], $\overline{\nu}_\mu$ [34]	H_2O, Fe
NOMAD	ν_μ [36]	C
NOvA	ν_μ [37–39]	CH_2
SciBooNE	ν_μ [40]	CH
T2K	ν_μ [41–45], $\overline{\nu}_\mu/\nu_\mu$ [11]	CH, H_2O, Fe

The reader is also referred to a recent review of the status of measurements and calculations in the shallow and deep inelastic scattering regions [46]. MINERvA has recently reported new measurements in the transition region between resonance production and DIS [31]. At lower neutrino energies, the inclusive cross section is an additionally complex combination of quasi-elastic scattering and resonance production processes, two areas we discuss next.

52.2 Quasi-elastic scattering

Quasi-elastic (QE) scattering is the dominant neutrino interaction for neutrino energies less than $\sim$ 1 GeV and represents a large fraction of the signal samples in many neutrino oscillation experiments, which is why this process has received considerable attention in recent years. Historically, neutrino (antineutrino) quasi-elastic scattering refers to the process, $\nu_\mu n \to \mu^- p$ ($\overline{\nu}_\mu p \to \mu^+ n$), where a charged lepton and single nucleon are ejected in the elastic interaction of a neutrino (or antineutrino) with a nucleon in the target material. This is the final state one would strictly observe, for example, in scattering off of a *free* nucleon target. There were many early measurements of neutrino QE scattering that span back to the 1970's [3]. In many of these initial measurements, bubble chamber experiments employed light targets (hydrogen or deuterium) and required both the detection of the final state muon and single nucleon[2]; thus the final state was clear and elastic kinematic conditions could be verified. The situation is more complicated, of course, for heavier nuclear targets used in modern neutrino experiments. In this case, nuclear effects can impact the size and shape of the cross section as well as the final state composition, kinematics, and topology. Due to intranuclear hadron rescattering and the effects of correlations between target nucleons, additional particles may be ejected in the final state; hence, a QE interaction on a nuclear target does not necessarily imply the ejection of a lepton and a *single* nucleon. One therefore needs to take care in

[1] Nuclear effects refer to kinematic, final state, and rate effects which impact neutrino scattering off nuclei. Such effects can be significant and are particularly relevant given that modern neutrino experiments use of nuclear targets to increase their event yields.

[2] In the case of deuterium, many experiments additionally observed the spectator proton.

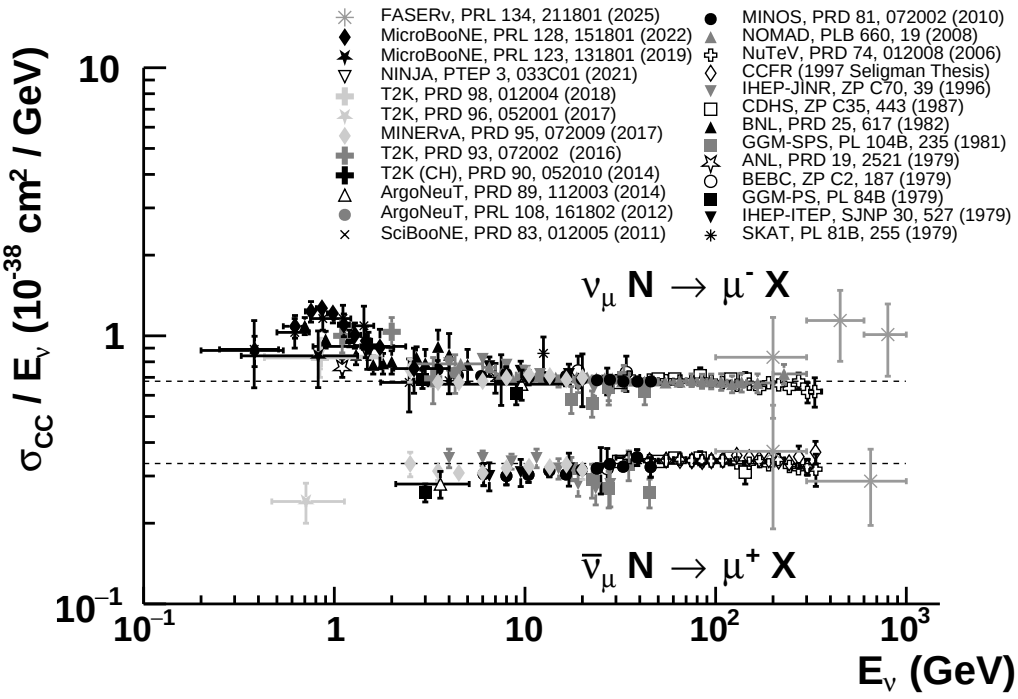

Figure 52.1: Measurements of per nucleon ν_μ and $\overline{\nu}_\mu$ CC inclusive scattering cross sections divided by neutrino energy as a function of neutrino energy. The data are on a variety of nuclear targets. The world-average values of $\sigma_{CC}/E_\nu = 0.677$ (neutrino) and 0.334 (antineutrino) $\times 10^{-38}$ cm^2/GeV are plotted as dashed lines. Neutrino cross sections are typically twice as large as their corresponding antineutrino counterparts, although this difference can be larger at lower energies. NC cross sections (not shown) are generally smaller compared to their CC counterparts.

defining what one means by neutrino QE scattering when scattering off targets heavier than hydrogen or deuterium. Because of this, modern experiments tend to instead report cross sections for processes involving pionless (e.g., nucleon-only) final states, often referred to as CC 0π or QE-like reactions in recent literature. Such measurements are summarized in Table 52.3. Many modern experiments have also recently opted to report QE-like cross sections as a function of observed final state particle (lepton, nucleon) kinematics. Such measurements can be more difficult to directly compare between experiments but have the advantage of being much less model-dependent and provide more stringent tests of the theory than historical cross sections as a function of derived quantities such as neutrino energy (E_ν) or 4-momentum transfer (Q^2). More recently, new thought has been given to the means for directly comparing experimental measurements produced in these less model-dependent forms [47].

The topic of neutrino QE scattering began drawing considerable attention following the first high statistics measurements of this process that revealed a significantly larger cross section than originally anticipated, predominantly in the backwards muon scattering region [75, 76]. Such an enhancement was observed many years prior in transverse electron-nucleus scattering [94] and was attributed to the presence of correlations between nucleons in the target nucleus. As a result, the impact of such nuclear effects on neutrino QE scattering has recently become the subject of intense experimental and theoretical scrutiny with implications on event rates, nucleon emission, neutrino energy reconstruction, and neutrino versus antineutrino cross sections. The reader is referred to reviews of the situation in [4, 95, 96]. To help drive further progress in understanding the underlying nuclear contributions, pionless (e.g., nucleon-only) cross sections have been reported for the first time in the form of double-differential distributions by MicroBooNE [56–58], MiniBooNE [75, 76], MINERvA [60–64, 70], and T2K [84–89]. Such double-differential cross sections in terms of final state particle kinematics reduce the model-dependence of the reported data, provide the most robust measurements available, and allow a more rigorous two-dimensional test of the underlying nuclear theory. MicroBooNE, MINERvA, and T2K have been especially prolific in recent years in probing this interaction process (Table 52.3). Neutrino experiments have also launched dedicated studies of the hadronic side of these interactions, including ArgoNeuT [48, 97], MicroBooNE [50, 51, 57], MINERvA [69, 98], and T2K [93]. MINERvA has been the first modern experiment to measure neutron emission in antineutrino interactions [99] and has simultaneously measured the A-dependence of neutrino QE cross sections on a variety of nuclear targets ranging from carbon to lead [64, 73]. ArgoNeuT [48], MicroBooNE [54], and NINJA [81] have explored two-proton final states. T2K has probed ratios of oxygen to carbon [87, 100], asymmetries between neutrino and antineutrino scattering [88], and simultaneous measurements both on and off axis to the neutrino beam [89]. In addition, the exploration of transverse kinematic variables and momentum imbalances in pionless neutrino scattering is allowing better constraints on the various nuclear contributions to the cross section. Such scrutiny includes important evaluations from MicroBooNE [52, 53, 59], MINERvA [60, 61, 65, 66] and T2K [93]. With the MiniBooNE results having first revealed these additional complexities in neutrino-nucleus QE scattering, measurements from multiple neutrino experiments, on multiple targets, and using a variety of kinematic information have been crucial in gaining a better handle on the underlying nuclear physics (2p2h, MEC, FSI) impacting neutrino-nucleus interactions. What we once thought was "simple" QE scattering is in fact not so simple.

Equally important, neutrino experiments such as MINERvA have revisited the extraction of the axial form factor from light target data using modern higher statistics data sets [72]. In addition to such charged current investigations, measurements of the neutral current counterpart of this channel have also been performed. The most recent NC elastic scattering cross section measurements include those from BNL E734 [101], MiniBooNE [78, 79], Super-K [83], and T2K [92]. A number of measurements of the Cabibbo-suppressed antineutrino QE hyperon (Λ) production cross section have additionally been reported [102,103], most recently by MicroBooNE [55]. As an exciting new addition, there have also been the

first observations of the very challenging-to-detect coherent elastic neutrino-nucleus scattering (CEνNS) process now in multiple nuclei by COHERENT [104].

52.3 Pion Production

In addition to such elastic scattering processes, neutrinos can also inelastically scatter producing a nucleon excited state (Δ, N^*). Such baryonic resonances quickly decay, most often to a nucleon and single-pion final state. Historically, experiments have measured various exclusive final states associated with these reactions, the majority of which have been on hydrogen and deuterium targets [3]. There have been several recent re-analyses of this data to better understand the consistency between data sets [105], nucleon form factors [106], and non-resonant contributions [107]. Also, modern measurements of neutrino-induced pion production have since been performed on a variety of nuclear targets (Table 52.4).

Table 52.4: Summary of modern measurements of NC and CC scattering cross sections involving a single pion or multiple pions in the final state.

experiment	$\pi^\pm$	π^0	target
ArgoNeuT	CC [108, 109]	NC [110]	Ar
K2K	CC[111, 112]	CC [113], NC [114]	CH, H_2O
MicroBooNE	–	CC [115, 116], NC [117, 118]	Ar
MINERνA	CC [119–126]	CC [120, 127–129], NC [130]	C, CH, Fe H_2O, Pb
MiniBooNE	CC [131, 132]	CC [133], NC [134, 135]	CH_2
MINOS	–	NC [136]	Fe
NOMAD	–	NC [137]	C
NOvA	–	NC [138, 139]	C
SciBooNE	CC [140]	NC [141, 142]	CH
T2K	CC [143–146], NC [147]	–	CH, H_2O

In addition to resonance production processes, neutrinos can also coherently scatter off of the entire nucleus and produce a distinctly forward-scattered single pion final state. Both CC ($\nu_\mu\, A \to \mu^-\, A\, \pi^+$, $\overline{\nu}_\mu\, A \to \mu^+\, A\, \pi^-$) and NC ($\nu_\mu\, A \to \nu_\mu\, A\pi^0, \overline{\nu}_\mu\, A \to \overline{\nu}_\mu\, A\pi^0$) processes are possible in this case. Even though the level of coherent pion production is small compared to their resonant counterpart, observations exist across a broad energy range and on multiple nuclear targets [148]. More recently, several modern neutrino experiments have either measured or set limits on coherent pion production cross sections including ArgoNeuT [108], K2K [112], MINERvA [121, 123, 125], MiniBooNE [135], MINOS [136], NOMAD [137], NOvA [138], SciBooNE [140,142], and T2K [112, 149].

As with inclusive and quasi-elastic scattering, a new appreciation for the significance of nuclear effects has also surfaced in pion production physics, again due to the use of heavy nuclear targets in modern neutrino experiments. Many experiments have been careful to report cross sections for various detected final states, thereby not correcting for large and uncertain nuclear effects (e.g., pion rescattering, charge exchange, and absorption) which can introduce significant sources of uncertainty and model dependence. Providing the most comprehensive survey of neutrino single-pion production to date, MiniBooNE has published a total of 16 single- and double-differential cross sections for both the final state muon (in the case of CC scattering) and pions in these interactions; thus, providing the first measurements of such final state kinematic distributions [131–134]. At similar neutrino energies, T2K has provided new data including the first measurement of the Adler angles in neutrino-nucleus scattering [145], the first exploration of transverse kinematic imbalances in pion production processes [146], and the first modern measurements of NC π^+ production [147]. MINERvA has produced a similar accompaniment of measurements at higher neutrino energies and uniquely on multiple nuclear targets [126]. Importantly, MINERvA has been working towards an improved nuclear model [129] that can potentially describe all of the pion reaction channels simultaneously, an issue that many experiments have struggled with up until now [120]. ArgoNeuT and MicroBooNE have since been adding new information on single pion production in argon. Regardless of the interaction channel or

target material, differential cross section measurements in terms of observed final state particle (lepton, pion, nucleon) kinematics are preferred for their reduced model dependence and for the additional kinematic information they provide. Such a new direction has been the focus of modern measurements as opposed to the reporting of more model-dependent, historical cross sections as a function of E_ν or Q^2. Together with similar results for other interaction channels, a better understanding and modeling of nuclear effects will be possible moving forward. MINERvA [150] has already taken a large step in this direction by explicitly tuning the physics in existing neutrino event generators to best fit the experimental data on pion production.

It should be noted that baryonic resonances can also decay to multi-pion, other mesonic (K, η, ρ, etc.), and even photon final states. Experimental results for these channels are typically sparse or non-existent. More recently, MicroBooNE has produced the first measurement of neutrino-induced η [151] production on argon. Photon production processes can comprise an important background for $\nu_\mu \to \nu_e$ appearance searches in some detectors and thus have become the focus of recent experimental investigations, most notably in NOMAD [152] and T2K [153, 154]. There have also been several recent measurements of kaon final states by MicroBooNE [155] and MINERvA [156–158] that are providing needed background constraints for nucleon decay searches ($p \to K^+\overline{\nu}$).

52.4 Electron Neutrino Scattering

The aforementioned cross section measurements are all for either muon neutrino or muon antineutrino scattering. With the production of predominantly muon neutrino beams for neutrino oscillation studies, the availability of electron neutrino scattering data is by construction limited. However, for the first time, measurements of electron neutrino scattering cross sections are being produced by a variety of modern neutrino experiments (Table 52.5). Such measurements are important as they verify our assumptions about lepton universality and validate the use of muon neutrino data to constrain electron neutrino interaction predictions. For lower energy and historical electron neutrino cross section measurements, the reader is directed to reference [3].

Table 52.5: Published measurements of electron neutrino and antineutrino cross sections from modern neutrino experiments.

experiment	CC inclusive	QE-like	π production	target
ArgoNeuT	[159]	-	-	Ar
COHERENT	[160]	-	-	I
FASERν	[161]	-	-	W, emulsion
MicroBooNE	[162, 163]	[164]	[165]	Ar
MINERνA	[166]	[166, 167]	-	CH
NOvA	[168]	-	-	CH_2
T2K	[169–171]	-	[172]	CH, H_2O

52.5 Outlook

Neutrino experiments continue to produce critical neutrino scattering measurements on nuclei as they accumulate increased statistics and pursue new ways of reporting their measurements to reduce model dependencies. Analysis of a broad energy range of data from MINERvA is providing some of the most detailed analysis of nuclear effects in neutrino interactions by examining multiple nuclei in a single experiment. Data from ArgoNeuT, MicroBooNE, ICARUS and soon also SBND are probing deeper into complex neutrino final states using the superior capabilities of liquid argon time projection chambers, while the T2K and NOvA near detectors continue to collect high statistics samples in intense neutrino beams. Excitingly, new results from IceCube, FASERν, and SND@LHC are starting to probe up into the TeV region. Together with dedicated discussions between experiments on how best to report neutrino cross section measurements [173] and with accompanying work being advanced by theorists to further increase the sophistication of nuclear model calculations [4], we continue to advance our understanding of neutrino-nucleus scattering [174].

52.6 Acknowledgments

The author thanks Anne Schukraft (Fermilab) for help in preparing the plots and content of this review.

53. Plots of Cross Sections and Related Quantities

Updated in 2023. See various sections for details. For additional cross section results, please see earlier editions of the *Review of Particle Physics (https://pdg.lbl.gov/rpp-archive/).*

53.1 Pseudorapidity Distributions in pp and $\bar{p}p$ Interactions 831
53.2 Average Hadron Multiplicities in Hadronic e^+e^- Annihilation Events 832
53.3 Annihilation Cross Section Near M_Z 834

53.1 Pseudorapidity Distributions in pp and $\bar{p}p$ Interactions

Revised August 2013 by D.R. Ward (Cavendish Lab.).

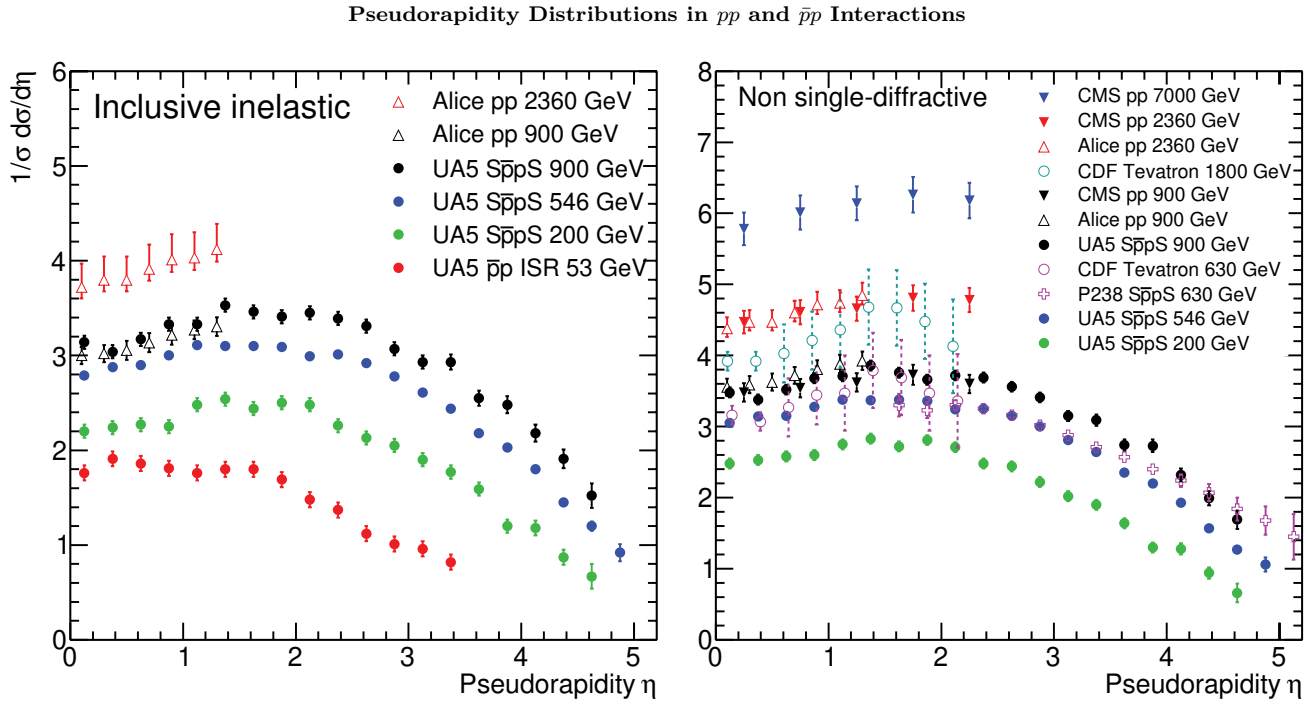

Figure 53.1: Charged particle pseudorapidity distributions in $p\bar{p}$ collisions for 53 GeV $\leq \sqrt{s} \leq$ 1800 GeV. UA5 data from the S$p\bar{p}$S are taken from [1], and from the ISR from [2]. The UA5 data are shown for both the full inelastic cross-section and with singly diffractive events excluded. Additional non single-diffractive measurements are available from CDF at the Tevatron [3] and from P238 at the S$p\bar{p}$S [4]. These may be compared with both inclusive and non single-diffractive measurements in pp collisions at the LHC from ALICE [5] and for non single-diffractive interactions from CMS [6, 7]. (Courtesy of D.R. Ward, Cambridge Univ., 2013)

53.2 Average Hadron Multiplicities in Hadronic e^+e^- Annihilation Events

Revised August 2023 by O. Biebel (Ludwig-Maximilians U.).

Table 53.1: Average hadron multiplicities per hadronic e^+e^- annihilation event at $\sqrt{s} \approx 10$, 29–35, 91, and 130–200 GeV. The rates given include decay products from resonances with $c\tau < 10$ cm, and include the corresponding anti-particle state. Correlations of the systematic uncertainties were considered for the calculation of the averages. Quoted errors are not increased by scale factor S.

(*a*) $\sigma_{\rm had} = 3.33 \pm 0.05 \pm 0.21$ nb (**CLEO**: [99]) has been used in converting the measured cross sections to average hadron multiplicities.
(*b*) B($D_s \to \eta\pi,\ \eta'\pi$) was used (RPP 1994).

(c) Comprises both charged and neutral B meson states.
(d) The Standard Model B($Z \to b\bar{b}$) = 0.217 was used.
(e) $x_p = p/p_{\rm beam} > 0.1$ only.
(f) Both charge states.
(g) B($D^*(2010)^+ \to D^0\pi^+$) × B($D^0 \to K^-\pi^+$) has been used (RPP 2000).
(h) B($D_s^* \to D_S^+\gamma$), B($D_s^+ \to \phi\pi^+$), B($\phi \to K^+K^-$) have been used (RPP 1998).
(i) Any charge state (*i.e.*, B_d^*, B_u^*, or B_s^*).
(j) B($Z \to$ hadrons) = 0.699 was used (RPP 1994).
(k) Any charge state (*i.e.*, B_d^{**}, B_u^{**}, or B_s^{**}).
(ℓ) Assumes B($D_{s1}^+ \to D^{*+}K^0 + D^{*0}K^+$) = 100% and B($D_{s2}^+ \to D^0K^+$) = 45%.
(m) Derived from the production cross section of $\Lambda_c^+ \to p\pi K$ using (a) and using B($\Lambda_c^+ \to p\pi K$) = (6.26 ± 0.29)% (RPP 2022).
(n) Derived from [96], updated with B($\Lambda_c^+ \to p\pi K$) = (6.26 ± 0.29)% (RPP 2022), and complemented by the Λ_c^+ contribution from $g \to c\bar{c}$ of [47].

53.3 Annihilation Cross Section Near M_Z

Courtesy of M. Grünewald and the LEP Electroweak Working Group, 2007.

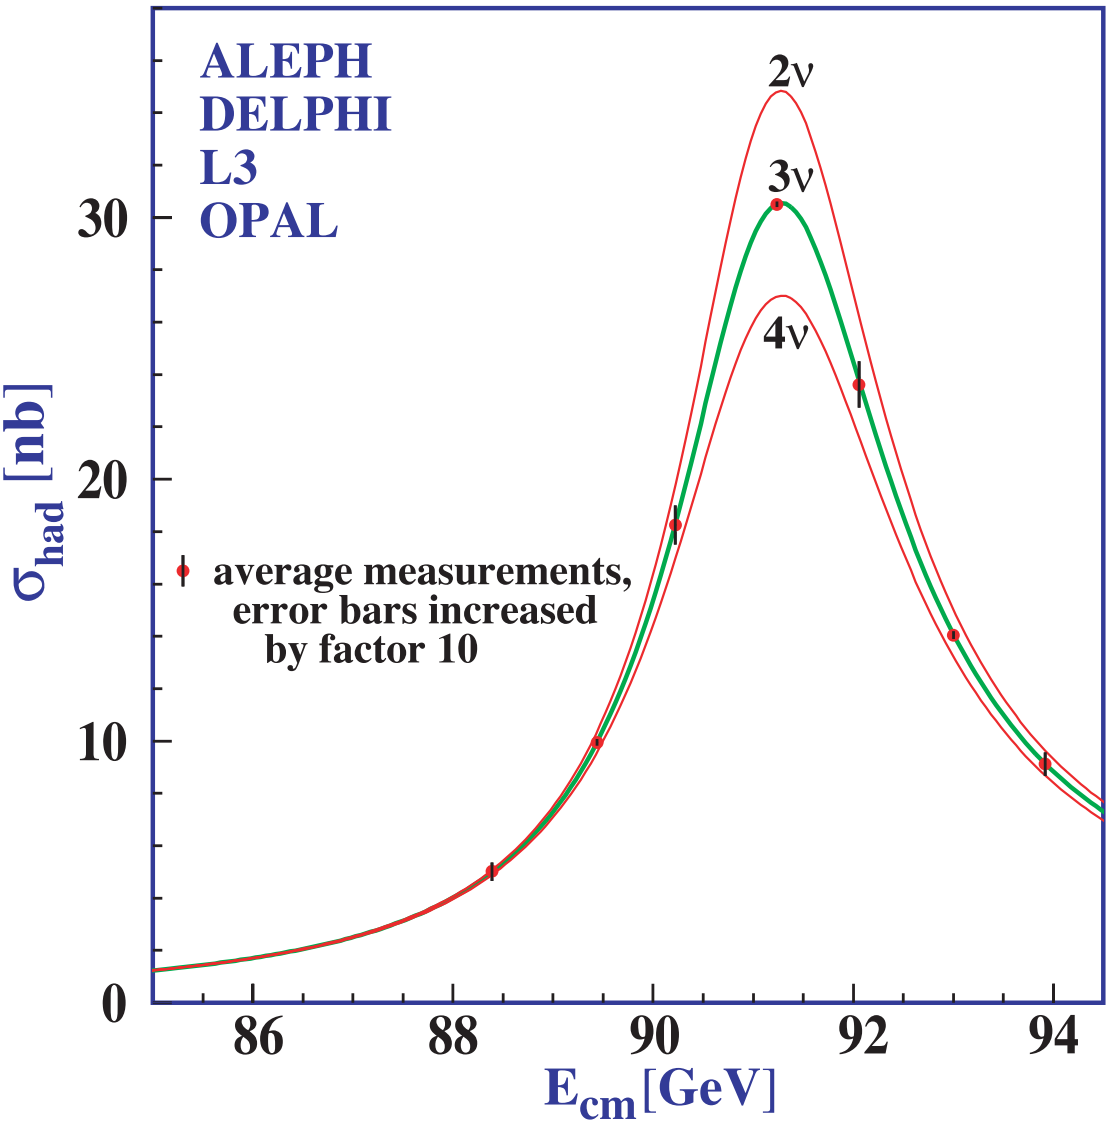

Figure 53.2: Combined data from the ALEPH, DELPHI, L3, and OPAL Collaborations for the cross section in e^+e^- annihilation into hadronic final states as a function of the center-of-mass energy near the Z pole. The curves show the predictions of the Standard Model with two, three, and four species of light neutrinos. The asymmetry of the curve is produced by initial-state radiation. Note that the error bars have been increased by a factor ten for display purposes. References: ALEPH [100], DELPHI [101], L3 [102], OPAL [103], Combination [104],

54. Mass and Width of the W Boson

Revised May 2026 by M. Grünewald (University Coll. Dublin), A. Gurtu (CERN; TIFR Mumbai) and J. Kretzschmar (Liverpool U.).

Precision determination of the W mass is of great importance in testing the internal consistency of the Standard Model. From the time of its discovery in 1983, the W boson has been studied and its mass determined in $p\bar{p}$, e^+e^- and pp interactions. The mass m_W and width Γ_W definition used in measurements corresponds to a Breit-Wigner with mass-dependent width with a propagator $\propto 1/(s - m_W^2 + is\Gamma_W/m_W)$.

At the e^+e^- collider LEP, the dependence of the W-pair production cross section on m_W is large close to the production threshold ($\sqrt{s} \approx 2m_W \approx 161\,\text{GeV}$). Hence this was used for the mass measurement, together with the precise knowledge of the beam energy. At higher center-of-mass energies ($\sqrt{s} = 172$ to 209 GeV) this dependence is much weaker, thus W bosons were directly reconstructed and the mass determined as the invariant mass of the decay products, improving the resolution with a kinematic fit. The LEP average W mass was then determined in a combination of the measurements from each experiment for all channels ($q\bar{q}q\bar{q}$ and $q\bar{q}\ell\nu$, $\ell = e, \mu, \tau$) and centre-of-mass energies along with a detailed decomposition of uncertainty contributions [1]. This yielded a combined LEP average W mass of $m_W = 80.376 \pm 0.033\,\text{GeV}$. Errors on m_W due to uncertainties in the LEP beam energy (9 MeV), and possible effect of color reconnection (CR) and Bose-Einstein correlations (BEC) between quarks from different W bosons (8 MeV) are included.

Currently the most precise measurements of the W mass are performed in hadron collisions at the Tevatron ($p\bar{p}$) and the LHC (pp). These analyses use the electron or muon decay modes of the W boson ($\ell\nu$, $\ell = e, \mu$) and tag the production of W bosons with the high p_T charged lepton and missing energy transverse to the beam direction arising from the neutrino. Owing to the unknown parton-parton effective energy and the unmeasured missing energy in the longitudinal direction, the hadron collider experiments reconstruct the transverse mass of the W boson, and derive the W mass from comparing the distribution with Monte Carlo predictions obtained for different values of m_W. The transverse momentum of the charged lepton itself and the transverse missing energy are also sensitive to the W mass and used in its determination. Specifically, measurements by the LHC experiments so far rely primarily on the charged lepton p_T distribution.

In the past, the two Tevatron experiments CDF [2] and D0 [3] provided a combined value for the W mass by identifying common systematic uncertainties due to the parton distribution functions (PDF), radiative corrections, and choice of the width [4]. With the first mass results from the two LHC experiments, ATLAS [5] and LHCb [6], a simplified W-mass average for the LHC was obtained, assuming a correlated uncertainty of 9 MeV (PDF) [7]. Similarly, assuming a correlated uncertainty of 7 MeV, a hadron collider average of the Tevatron and LHC measurements was obtained [7].

All measurements were in good agreement with each other, until the CDF collaboration published a result $m_W = 80.4335 \pm 0.0094\,\text{GeV}$ [8] in April 2022, based upon their full Run-II dataset of $8.8\,\text{fb}^{-1}$. This result is of higher precision than the 2022 world average, but the two values disagree significantly.[1] The LHC-TeV W-mass Working Group with W-mass experts from all hadron collider experiments, CDF, D0, ATLAS, CMS, LHCb, has been working to understand better the nature of this disagreement and suggest a new world average value of the W mass. Theoretical corrections, uncertainties and their correlations between different hadron collider experiments have been evaluated in detail and used in the combination: the central values are corrected to a common theory description and PDF set, and the uncertainties and correlations due to PDFs have been re-evaluated. The group reported in 2023 [9] that a combination of all W-mass measurements has a probability of compatibility of only 0.5%. A 91% probability of compatibility is obtained when the CDF Run-II measurement is removed.

Two new results have appeared since this combination. The ATLAS Collaboration published a refined analysis of their data used in [5] and obtained a more precise mass value of $80.3665 \pm 0.0159\,\text{GeV}$ [10]. The CMS Collaboration published their first measurement of $m_W = 80.3602 \pm 0.0099\,\text{GeV}$ [11], reaching a precision close to the CDF Run-II result.

In May 2026, LHC-TeV W-mass Working Group updated their combination with these new results [12], using the same combination strategy as previously in [9]. The ATLAS and CMS measurement uncertainties, resulting from profile-likelihood ratio fits, are decomposed using the prescription detailed in [13]. A combination of all W-mass measurements has a probability of compatibility of only 0.06%, and is therefore disfavoured. A 96.9% probability of compatibility is obtained when the CDF Run-II measurement is removed. The corresponding value of the W boson mass is $m_W = 80362.5 \pm 7.7\,\text{MeV}$ [12] which we quote as the World Average. More details can be found in [9, 12, 13].

The results on the W mass published by the experiments are shown in Figure 54.1.

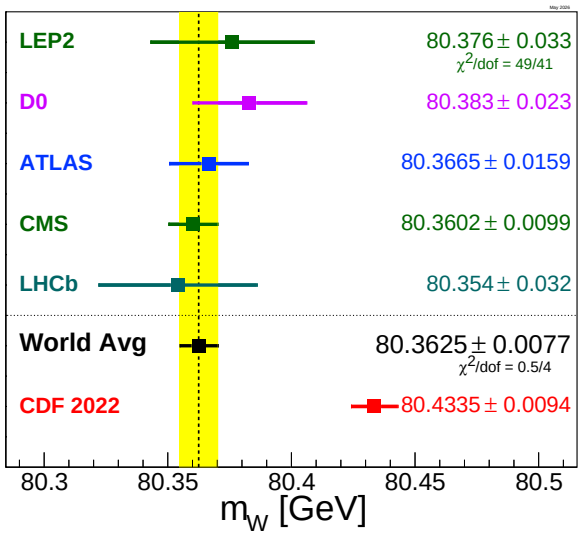

Figure 54.1: Measurements of the W-boson mass by the LEP, Tevatron and LHC experiments as well as their combination. Below the combination, the CDF 2022 result is shown which is currently not used in the world average.

Similarly, the W boson total width has been measured in e^+e^-, $p\bar{p}$ and pp collision data. The combined LEP average of the W boson total width was determined to be $\Gamma_W = 2.195 \pm 0.083\,\text{GeV}$ [1], with a good internal consistency of 27% χ^2 probability. The most recent width measurements from the Tevatron experiments CDF and D0 were combined to $\Gamma_W = 2.046 \pm 0.049\,\text{GeV}$ [14], also with very good internal compatibility of 84%. The latest and most precise measurement to date was performed by ATLAS yielding $\Gamma_W = 2.202 \pm 0.047\,\text{GeV}$ [10]. All results are shown in Figure 54.2 together with our weighted average of the three results of $\Gamma_W = 2.14 \pm 0.05\,\text{GeV}$, where the error is scaled by a factor of 1.7 to account for a tension between the three width results (5.3% χ^2 probability) as shown in Figure 54.2.

The Standard Model prediction from an electroweak fit, including Z-pole data and the measured masses of the top quark and of the Higgs boson but excluding results on m_W and Γ_W, implies a W-boson mass of $m_W = 80.357 \pm 0.006\,\text{GeV}$ and a W-boson width of $\Gamma_W = 2.090 \pm 0.001\,\text{GeV}$; see Section 10, Electroweak Model and Constraints on New Physics, J. de Blas, S. Dittmaier and R. Kogler, 2026, this review.

[1] The 2022 CDF result includes the $2.2\,\text{fb}^{-1}$ of data used for the previous CDF Run-II result of $80.387 \pm 0.019\,\text{GeV}$ [2]. Incorporating the improved understanding of PDFs and track reconstruction , the central value of the $2.2\,\text{fb}^{-1}$ result is increased by 0.0135 GeV to 80.4005 GeV [8].

55. Z Boson

Revised August 2025 by M. Grünewald (University Coll. Dublin), A. Gurtu (CERN; TIFR Mumbai) and J. Kretzschmar (Liverpool U.).

Precision measurements at the Z-boson resonance using electron–positron colliding beams began in 1989 at the SLC and at LEP. During 1989–95, the four LEP experiments (ALEPH, DELPHI, L3, OPAL) made high-statistics studies of the production and decay properties of the Z. Although the SLD experiment at the SLC collected much lower statistics, it was able to match the precision of LEP experiments in determining the effective electroweak mixing angle $\sin^2\overline{\theta}_W$ and the rates of Z decay to b- and c-quarks, owing to availability of polarized electron beams, small beam size, and stable beam spot. Measurements in $p\bar{p}$ and pp collisions at the Tevatron and the LHC have reached a precision competitive with the e^+e^- colliders in a limited set of observables.

The Z-boson properties reported in this section may broadly be categorized as:

- The standard 'lineshape' parameters of the Z consisting of its mass, M_Z, its total width, Γ_Z, and its partial decay widths, Γ(hadrons), and $\Gamma(\ell\bar{\ell})$ where $\ell = e, \mu, \tau, \nu$;
- Z asymmetries in leptonic decays and extraction of Z couplings to charged and neutral leptons;
- The b- and c-quark-related partial widths and charge asymmetries which require special techniques.

The effective vector and axial-vector coupling constants describing the Z-to-fermion coupling are also measured in $p\bar{p}$ and ep collisions at the Tevatron and at HERA. The corresponding cross-section formulae are given in Section 39 (Cross-section formulae for specific processes) and Section 16 (Structure Functions) in this *Review*. In this review, we concentrate on the measurements in e^+e^- collisions at LEP and SLC, mentioning hadron-collider measurements where relevant.

The standard 'lineshape' parameters of the Z are primarily determined from an analysis of the production cross sections of these final states in e^+e^- collisions. The $Z \to \nu\overline{\nu}$ state is identified directly by detecting single photon production (e^+e^-) or single jet production (pp) or indirectly by subtracting the visible partial widths from the total width. Inclusion of the forward-backward asymmetry of charged leptons, $A_{FB}^{(0,\ell)}$, of the τ polarization, $P(\tau)$, and its forward-backward asymmetry, $P(\tau)^{FB}$, enables the separate determination of the effective vector ($\overline{g}_V$) and axial vector ($\overline{g}_A$) couplings of the Z to these leptons and the ratio ($\overline{g}_V/\overline{g}_A$), which is related to the effective electroweak mixing angle $\sin^2\theta_{\rm eff}^{\rm lept}$ (see the "Electroweak Model and Constraints on New Physics" review).

Determination of the b- and c-quark-related partial widths and charge asymmetries involves tagging the b and c quarks for which various methods are employed: requiring the presence of a high momentum prompt lepton in the event with high transverse momentum with respect to the accompanying jet; impact parameter and lifetime tagging using precision vertex measurement with high-resolution detectors; application of neural-network techniques to classify events as b or non-b on a statistical basis using event–shape variables; and using the presence of a charmed meson (D/D^*) or a kaon as a tag.

55.1 Z-parameter determination

LEP was run at energy points on and around the Z mass (88–94 GeV) constituting an energy 'scan'. The shape of the cross-section variation around the Z peak can be described by a Breit-Wigner *ansatz* with an energy-dependent total width [1–3]. The **three** main properties of this distribution, viz., the **position** of the peak, the **width** of the distribution, and the **height** of the peak, determine respectively the values of M_Z, Γ_Z, and $\Gamma(e^+e^-) \times \Gamma(f\bar{f})$, where $\Gamma(e^+e^-)$ and $\Gamma(f\bar{f})$ are the electron and fermion partial widths of the Z. The quantitative determination of these parameters is done by writing analytic expressions for these cross sections in terms of the parameters, and fitting the calculated cross sections to the measured ones by varying these parameters, taking properly into account all the errors. Single-photon exchange (σ^0_γ) and γ-Z interference ($\sigma^0_{\gamma Z}$) are included, and the large (∼25 %) initial-state radiation (ISR) effects are taken into account by convoluting the analytic expressions over a 'Radiator Function' [1–5] $H(s,s')$. Thus for the process $e^+e^- \to f\bar{f}$:

$$\sigma_f(s) = \int H(s,s')\ \sigma_f^0(s')\ ds' \tag{55.1}$$

$$\sigma_f^0(s) = \sigma_Z^0 + \sigma_\gamma^0 + \sigma_{\gamma Z}^0 \tag{55.2}$$

$$\sigma_Z^0 = \frac{12\pi}{M_Z^2}\ \frac{\Gamma(e^+e^-)\Gamma(f\bar{f})}{\Gamma_Z^2}\ \frac{s\ \Gamma_Z^2}{(s-M_Z^2)^2\ +\ s^2\Gamma_Z^2/M_Z^2} \tag{55.3}$$

$$\sigma_\gamma^0 = \frac{4\pi\alpha^2(s)}{3s}\ Q_f^2 N_c^f \tag{55.4}$$

$$\sigma_{\gamma Z}^0 = -\frac{2\sqrt{2}\alpha(s)}{3}\ (Q_f G_F N_c^f \mathcal{G}_V^e \mathcal{G}_V^f) \times \frac{(s-M_Z^2)M_Z^2}{(s-M_Z^2)^2 + s^2\Gamma_Z^2/M_Z^2} \tag{55.5}$$

where Q_f is the charge of the fermion, $N_c^f = 3$ for quarks and 1 for leptons, and $\mathcal{G}_V^f$ is the vector coupling of the Z to the fermion-antifermion pair $f\bar{f}$.

Since $\sigma^0_{\gamma Z}$ is expected to be much less than σ^0_Z, the LEP Collaborations have generally calculated the interference term in the framework of the Standard Model. This fixing of $\sigma^0_{\gamma Z}$ leads to a tighter constraint on M_Z, and consequently a smaller error on its fitted value. It is possible to relax this constraint and carry out the fit within the S-matrix framework, which is briefly described in the next section.

Hadron-collider experiments have shown the ability to measure M_Z by analysing the line shape of $pp/p\bar{p} \to Z/\gamma^* \to \mu^+\mu^-$ and comparing to simulation with an equivalent Breit-Wigner ansatz [6, 7]. While the LEP measurement depends most critically on the beam energy measurement (see Sec. 55.4 and 55.7), the hadron collider results rely on a precise calibration of the final-state muons using the masses of J/ψ and Υ resonances that are known to a precision significantly better than the current overall analysis uncertainties.

In the above framework, the QED radiative corrections have been explicitly taken into account by convoluting over the ISR and allowing the electromagnetic coupling constant to run [8]: $\alpha(s) = \alpha/(1-\Delta\alpha)$. On the other hand, weak radiative corrections that depend upon the assumptions of the electroweak theory and on the values of $M_{\rm top}$ and $M_{\rm Higgs}$ are accounted for by **absorbing them into the couplings**, which are then called the *effective* couplings $\mathcal{G}_V$ and $\mathcal{G}_A$ (or alternatively the effective parameters of the $\star$ scheme of Kennedy and Lynn [9].)

$\mathcal{G}_V^f$ and $\mathcal{G}_A^f$ are complex numbers with small imaginary parts. As experimental data does not allow simultaneous extraction of both real and imaginary parts of the effective couplings, the convention $g_A^f = {\rm Re}(\mathcal{G}_A^f)$ and $g_V^f = {\rm Re}(\mathcal{G}_V^f)$ is used and the imaginary parts are added in the fitting code [4].

Defining

$$A_f = 2\frac{g_V^f \cdot g_A^f}{(g_V^f)^2 + (g_A^f)^2} \tag{55.6}$$

the lowest-order expressions for the various lepton-related asymmetries on the Z pole are [10–12] $A_{FB}^{(0,\ell)} = (3/4)A_e A_f$, $P(\tau) = -A_\tau$, $P(\tau)^{fb} = -(3/4)A_e$, $A_{LR} = A_e$. The full analysis takes into account the energy-dependence of the asymmetries. Experimentally A_{LR} is defined as $(\sigma_L - \sigma_R)/(\sigma_L + \sigma_R)$, where $\sigma_{L(R)}$ are the $e^+e^- \to Z$ production cross sections with left- (right)-handed electrons.

The measurement of the effective leptonic electroweak mixing angle, $\sin^2\theta_{\rm eff}^{\rm lept}$, can be extracted from asymmetries measured in e^+e^- collisions, but also the from the forward-backward asymmetry in the $q\bar{q} \to Z/\gamma^* \to e^+e^-/\mu^+\mu^-$ process in hadronic collisions. It is related to the ratio of leptonic vector and axial-vector coupling constants, $\sin^2\theta_{\rm eff}^{\rm lept} = (1 - g_V^\ell/g_A^\ell)/4$. The ambi-

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

guity regarding the direction of the initial quark and anti-quark can only be resolved on a statistical basis using the parton distribution functions. It results in significant uncertainties that are typically constrained using large event samples and ancillary measurements. The most recent measurements [13–17] approach a precision similar to the most sensitive e^+e^- collider results.

The definition of the partial decay width of the Z to $f\overline{f}$ includes the effects of QED and QCD final-state corrections, as well as the contribution due to the imaginary parts of the couplings:

$$\Gamma(f\overline{f}) = \frac{G_F M_Z^3}{6\sqrt{2}\pi}\, N_c^f (\left|\mathcal{G}_A^f\right|^2 R_A^f + \left|\mathcal{G}_V^f\right|^2 R_V^f) + \Delta_{ew/\mathrm{QCD}} \quad (55.7)$$

where R_V^f and R_A^f are radiator factors to account for final state QED and QCD corrections, as well as effects due to nonzero fermion masses, and $\Delta_{ew/\mathrm{QCD}}$ represents the non-factorizable electroweak/QCD corrections.

55.2 S-matrix approach to the Z

While most experimental analyses of LEP/SLC data have followed the 'Breit-Wigner' approach, an alternative S-matrix-based analysis is also possible. The Z, like all unstable particles, is associated with a complex pole in the S matrix. The pole position is process-independent and gauge-invariant. The mass, $\overline{M}_Z$, and width, $\overline{\Gamma}_Z$, can be defined in terms of the pole in the energy plane via [18–21]

$$\overline{s} = \overline{M}_Z^2 - i\overline{M}_Z\overline{\Gamma}_Z \quad (55.8)$$

leading to the relations

$$\begin{aligned}\overline{M}_Z &= M_Z/\sqrt{1+\Gamma_Z^2/M_Z^2} \\ &\approx M_Z \ - 34.1 \text{ MeV} \quad (55.9)\\ \overline{\Gamma}_Z &= \Gamma_Z/\sqrt{1+\Gamma_Z^2/M_Z^2} \\ &\approx \Gamma_Z \ - 0.9 \text{ MeV} \ . \quad (55.10)\end{aligned}$$

The LEP collaborations [22] have analyzed their data using the S–matrix approach as defined in Eq. (55.8), in addition to the conventional one. They observe a downward shift in the Z mass as expected.

55.3 Handling the large-angle e^+e^- final state

Unlike other $f\overline{f}$ decay final states of the Z, the e^+e^- final state has a contribution not only from the s-channel but also from the t-channel and s-t interference. The full amplitude is not amenable to fast calculation, which is essential if one has to carry out minimization fits within reasonable computer time. The usual procedure is to calculate the non-s channel part of the cross section separately using the Standard Model programs ALIBABA [23] or TOPAZ0 [24], with the measured value of M_{top}, and $M_{\mathrm{Higgs}} = 150$ GeV, and add it to the s-channel cross section calculated as for other channels. This leads to two additional sources of error in the analysis: firstly, the theoretical calculation in ALIBABA itself is known to be accurate to $\sim 0.5\%$, and secondly, there is uncertainty due to the error on M_{top} and the unknown value of M_{Higgs} (100–1000 GeV). These errors are propagated into the analysis by including them in the systematic error on the e^+e^- final state. As these errors are common to the four LEP experiments, this is taken into account when performing the LEP average.

55.4 Errors due to uncertainty in LEP energy determination

The systematic errors related to the LEP energy measurement, see [25–30], can be classified as:

- The absolute energy scale error;
- Energy-point-to-energy-point errors due to the nonlinear response of the magnets to the exciting currents;
- Energy-point-to-energy-point errors due to possible higher-order effects in the relationship between the dipole field and beam energy;
- Energy reproducibility errors due to various unknown uncertainties in temperatures, tidal effects, corrector settings, RF status, *etc.*

Precise energy calibration was done outside normal data-taking using the resonant depolarization technique. Run-time energies were determined every 10 minutes by measuring the relevant machine parameters and using a model which takes into account all the known effects, including leakage currents produced by trains in the Geneva area and the tidal effects due to gravitational forces of the Sun and the Moon. The LEP Energy Working Group has provided a covariance matrix from the determination of LEP energies for the different running periods during 1993–1995 [25].

55.5 Choice of fit parameters

The LEP Collaborations have chosen the following primary set of parameters for fitting:

$$M_Z, \Gamma_Z, \sigma^0_{\mathrm{hadron}}, R(\mathrm{lepton}), A_{FB}^{(0,\ell)},$$

where

$$\begin{aligned}R(\mathrm{lepton}) &= \Gamma(\mathrm{hadrons})/\Gamma(\mathrm{lepton}), \sigma^0_{\mathrm{hadron}} \\ &= 12\pi\Gamma(e^+e^-)\Gamma(\mathrm{hadrons})/M_Z^2\Gamma_Z^2.\end{aligned}$$

With a knowledge of these fitted parameters and their covariance matrix, any other parameter can be derived. The main advantage of these parameters is that they form a physics motivated set of parameters with much reduced correlations.

Thus, the most general fit carried out to cross section and asymmetry data determines the **nine parameters**: M_Z, Γ_Z, $\sigma^0_{\mathrm{hadron}}$, $R(e)$, $R(\mu)$, $R(\tau)$, $A_{FB}^{(0,e)}$, $A_{FB}^{(0,\mu)}$, $A_{FB}^{(0,\tau)}$. Assumption of lepton universality leads to a **five-parameter fit** determining M_Z, Γ_Z, $\sigma^0_{\mathrm{hadron}}$, $R(\mathrm{lepton})$, $A_{FB}^{(0,\ell)}$.

55.6 Combining results from LEP and SLC experiments

With a steady increase in statistics over the years and improved understanding of the common systematic errors between LEP experiments, the procedures for combining results have evolved continuously [31]. The Line Shape Sub-group of the LEP Electroweak Working Group investigated the effects of these common errors, and devised a combination procedure for the precise determination of the Z parameters from LEP experiments. Using these procedures, this note also gives the results after combining the final parameter sets from the four experiments, and these are the results quoted as the fit results in the Z listings below. Transformation of variables leads to values of derived parameters like partial decay widths and branching ratios to hadrons and leptons. Finally, transforming the LEP combined nine parameter set to (M_Z, Γ_Z, $\sigma^0_{\mathrm{hadron}}$, g_A^f, g_V^f, $f = e, \mu, \tau$) using the average values of lepton asymmetry parameters (A_e, A_μ, A_τ) as constraints, leads to the best fitted values of the vector and axial-vector couplings (g_V, g_A) of the charged leptons to the Z.

Brief remarks on the handling of common errors and their magnitudes are given below. The identified common errors are those coming from

(a) LEP energy-calibration uncertainties, and

(b) the theoretical uncertainties in (i) the luminosity determination using small angle Bhabha scattering, (ii) estimating the non-s channel contribution to large angle Bhabha scattering, (iii) the calculation of QED radiative effects, and (iv) the parametrization of the cross section in terms of the parameter set used.

55.7 Common LEP energy errors

All the collaborations incorporate in their fit the full LEP energy error matrix as provided by the LEP energy group for their intersection region [25]. The effect of these errors is separated out from that of other errors by carrying out fits with energy errors scaled up and down by $\sim 10\%$ and redoing the fits. From the observed changes in the overall error matrix, the covariance matrix of the common energy errors is determined. Common LEP energy errors lead to uncertainties on M_Z, Γ_Z, and $\sigma^0_{\mathrm{hadron}}$ of 1.7, 1.2 MeV, and 0.011 nb, respectively.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

55.8 Common luminosity errors

BHLUMI 4.04 [32] is used by all LEP collaborations for small-angle Bhabha scattering leading to a common uncertainty in their measured cross sections of 0.061% [33]. BHLUMI does not include a correction for production of light fermion pairs. OPAL explicitly corrects for this effect and reduces their luminosity uncertainty to 0.054%, which is taken fully correlated with the other experiments. The other three experiments among themselves have a common uncertainty of 0.061%.

55.9 Common non-s channel uncertainties

The same standard model programs ALIBABA [23] and TOPAZ0 [24] are used to calculate the non-s channel contribution to the large angle Bhabha scattering [34]. As this contribution is a function of the Z mass, which itself is a variable in the fit, it is parameterized as a function of M_Z by each collaboration to properly track this contribution as M_Z varies in the fit. The common errors on R_e and $A_{FB}^{(0,e)}$ are 0.024 and 0.0014 respectively, and are correlated between them.

55.10 Common theoretical uncertainties: QED

There are large initial-state photon and fermion pair radiation effects near the Z resonance, for which the best currently available evaluations include contributions up to $\mathcal{O}(\alpha^3)$. To estimate the remaining uncertainties, different schemes are incorporated in the standard model programs ZFITTER [5], TOPAZ0 [24], and MIZA [35]. Comparing the different options leads to error estimates of 0.3 and 0.2 MeV on M_Z and Γ_Z respectively, and of 0.02% on $\sigma^0_{\rm hadron}$.

55.11 Common theoretical uncertainties: parametrization of lineshape and asymmetries

To estimate uncertainties arising from ambiguities in the model-independent parametrization of the differential cross-section near the Z resonance, results from TOPAZ0 and ZFITTER were compared by using ZFITTER to fit the cross sections and asymmetries calculated using TOPAZ0. The resulting uncertainties on M_Z, Γ_Z, $\sigma^0_{\rm hadron}$, R(lepton), and $A_{FB}^{(0,\ell)}$ are 0.1 MeV, 0.1 MeV, 0.001 nb, 0.004, and 0.0001 respectively.

Thus, the overall theoretical errors on M_Z, Γ_Z, $\sigma^0_{\rm hadron}$ are 0.3 MeV, 0.2 MeV, and 0.008 nb respectively; on each R(lepton) is 0.004 and on each $A_{FB}^{(0,\ell)}$ is 0.0001. Within the set of three R(lepton)'s and the set of three $A_{FB}^{(0,\ell)}$'s, the respective errors are fully correlated.

All the theory-related errors mentioned above utilize Standard Model programs which need the Higgs mass and running electromagnetic coupling constant as inputs; uncertainties on these inputs will also lead to common errors. All LEP collaborations used the same set of inputs for Standard Model calculations: $M_Z = 91.187$ GeV, the Fermi constant $G_F = (1.16637 \pm 0.00001) \times 10^{-5}$ GeV^{-2} [36], $\alpha^{(5)}(M_Z) = 1/128.877 \pm 0.090$ [37], $\alpha_s(M_Z) = 0.119$ [38], $M_{\rm top} = 174.3 \pm 5.1$ GeV [38] and $M_{\rm Higgs} = 150$ GeV. The only observable effect, on M_Z, is due to the variation of $M_{\rm Higgs}$ between 100–1000 GeV (due to the variation of the γ/Z interference term which is taken from the Standard Model): M_Z changes by +0.23 MeV per unit change in $\log_{10} M_{\rm Higgs}/{\rm GeV}$, which is not an error but a correction to be applied once $M_{\rm Higgs}$ is determined. The effect is much smaller than the error on M_Z ($\pm$2.1 MeV).

55.12 Methodology of combining the LEP experimental results

The LEP experimental results actually used for combination are slightly modified from those published by the experiments (which are given in the Listings below). This has been done in order to facilitate the procedure by making the inputs more consistent. These modified results are given explicitly in [31]. The main differences compared to the published results are (a) consistent use of ZFITTER 6.23 and TOPAZ0 (the published ALEPH results used ZFITTER 6.10); (b) use of the combined energy-error matrix, which makes a difference of 0.1 MeV on the M_Z and Γ_Z for L3 only as at that intersection the RF modeling uncertainties are the largest.

Thus, nine-parameter sets from all four experiments with their covariance matrices are used together with all the common errors correlations. A grand covariance matrix, V, is constructed and a combined nine-parameter set is obtained by minimizing $\chi^2 = \Delta^T V^{-1} \Delta$, where Δ is the vector of residuals of the combined parameter set to the results of individual experiments. Imposing lepton universality in the combination results in the combined five-parameter set.

55.13 Study of $Z \to b\bar{b}$ and $Z \to c\bar{c}$

In the sector of c- and b-physics, the LEP experiments have measured the ratios of partial widths $R_b = \Gamma(Z \to b\bar{b})/\Gamma(Z \to$ hadrons), and $R_c = \Gamma(Z \to c\bar{c})/\Gamma(Z \to$ hadrons), and the forward-backward (charge) asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. The SLD experiment at SLC has measured the ratios R_c and R_b and, utilizing the polarization of the electron beam, was able to obtain the final state coupling parameters A_b and A_c from a measurement of the left-right forward-backward asymmetry of $b-$ and $c-$quarks. The high precision measurement of R_c at SLD was made possible owing to the small beam size and very stable beam spot at SLC, coupled with a highly precise CCD pixel detector. Several of the analyses have also determined other quantities, in particular the semileptonic branching ratios, B($b \to \ell^-$), B($b \to c \to \ell^+$), and B($c \to \ell^+$), the average time-integrated $B^0\overline{B}^0$ mixing parameter $\overline{\chi}$ and the probabilities for a c–quark to fragment into a D^+, a D_s, a D^{*+} , or a charmed baryon. These quantities are correlated with the electroweak parameters, and since the mixture of b hadrons is different from the one at the $\Upsilon(4S)$, their values might differ from those measured at the $\Upsilon(4S)$. As these measurements do not concern properties of the Z boson, they do not appear in the listing. Numerical values may be found in Ref. [31] and earlier versions of this review.

All the above quantities are correlated to each other since:

- Several analyses (for example the lepton fits) determine more than one parameter simultaneously;
- Some of the electroweak parameters depend explicitly on the values of other parameters (for example R_b depends on R_c);
- Common tagging and analysis techniques produce common systematic uncertainties.

The LEP Electroweak Heavy Flavour Working Group has developed [39] a procedure for combining the measurements taking into account known sources of correlation. The combining procedure determines fourteen parameters: the six parameters of interest in the electroweak sector, R_b, R_c, $A_{FB}^{b\bar{b}}$, $A_{FB}^{c\bar{c}}$, A_b and A_c and, in addition, B($b \to \ell^-$), B($b \to c \to \ell^+$), B($c \to \ell^+$), $\overline{\chi}$, $f(D^+)$, $f(D_s)$, $f(c_{\rm baryon})$ and $P(c \to D^{*+}) \times$ B($D^{*+} \to \pi^+ D^0$) Before the fit both the peak and off-peak asymmetries are translated to the common energy $\sqrt{s} = 91.26$ GeV using the predicted energy-dependence from ZFITTER [5].

55.13.1 *Summary of the measurements and of the various kinds of analysis*

The measurements of R_b and R_c fall into two classes. In the first, named single-tag measurement, a method for selecting b and c events is applied and the number of tagged events is counted. A second technique, named double-tag measurement, has the advantage that the tagging efficiency is directly derived from the data thereby reducing the systematic error on the measurement.

The measurements in the b- and c-sector can be essentially grouped in the following categories:

- Lifetime (and lepton) double-tagging measurements of R_b. These are the most precise measurements of R_b and obviously dominate the combined result. The main sources of systematics come from the charm contamination and from estimating the hemisphere b-tagging efficiency correlation;
- Analyses with $D/D^{*\pm}$ to measure R_c. These measurements make use of several different tagging techniques (inclusive/exclusive double tag, exclusive double tag, reconstruction of all weakly decaying charmed states) and no assumptions are made on the energy-dependence of charm fragmentation;

- A measurement of R_c using single leptons and assuming $B(b \to c \to \ell^+)$;
- Lepton fits which use hadronic events with one or more leptons in the final state to measure the asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. Each analysis usually gives several other electroweak parameters. The dominant sources of systematics are due to lepton identification, to other semileptonic branching ratios and to the modeling of the semileptonic decay;
- Measurements of $A_{FB}^{b\bar{b}}$ using lifetime tagged events with a hemisphere charge measurement. These measurements dominate the combined result;
- Analyses with $D/D^{*\pm}$ to measure $A_{FB}^{c\bar{c}}$ or simultaneously $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$;
- Measurements of A_b and A_c from SLD, using several tagging methods (lepton, kaon, D/D^*, and vertex mass). These quantities are directly extracted from a measurement of the left–right forward–backward asymmetry in $c\bar{c}$ and $b\bar{b}$ production using a polarized electron beam.

55.13.2 *Averaging procedure*

All the measurements are provided by the LEP and SLD Collaborations in the form of tables with a detailed breakdown of the systematic errors of each measurement and its dependence on other electroweak parameters.

The averaging proceeds via the following steps:

- Define and propagate a consistent set of external inputs such as branching ratios, hadron lifetimes, fragmentation models *etc.* All the measurements are checked to ensure that all use a common set of assumptions (for instance, since the QCD corrections for the forward–backward asymmetries are strongly dependent on the experimental conditions, the data are corrected before combining);
- Form the full (statistical and systematic) covariance matrix of the measurements. The systematic correlations between different analyses are calculated from the detailed error breakdown in the measurement tables. The correlations relating several measurements made by the same analysis are also used;
- Take into account any explicit dependence of a measurement on the other electroweak parameters. As an example of this dependence, we illustrate the case of the double-tag measurement of R_b, where c-quarks constitute the main background. The normalization of the charm contribution is not usually fixed by the data and the measurement of R_b depends on the assumed value of R_c, which can be written as:

$$R_b = R_b^{\rm meas} + a(R_c)\frac{(R_c - R_c^{\rm used})}{R_c} \ , \qquad (55.11)$$

  where $R_b^{\rm meas}$ is the result of the analysis which assumed a value of $R_c = R_c^{\rm used}$ and $a(R_c)$ is the constant which gives the dependence on R_c;
- Perform a χ^2 minimization with respect to the combined electroweak parameters.

After the fit the average peak asymmetries $A_{FB}^{c\bar{c}}$ and $A_{FB}^{b\bar{b}}$ are corrected for the energy shift from 91.26 GeV to M_Z and for QED (initial state radiation), γ exchange, and γZ interference effects, to obtain the corresponding pole asymmetries $A_{FB}^{0,c}$ and $A_{FB}^{0,b}$. The results of the averaging procedure are presented in the Z particle listing. Further information can be found in Ref. [31].

56. Muon Anomalous Magnetic Moment

Revised August 2025 by D.W. Hertzog (U. Washington) and M. Hoferichter (U. Bern).

56.1 Introduction and summary

The Dirac equation predicts a muon magnetic moment, $\boldsymbol{\mu} = g_\mu \frac{q}{2m_\mu}\mathbf{S}$, with gyromagnetic ratio $g_\mu = 2$, charge q, and mass m_μ. Quantum loop effects lead to a small calculable deviation from $g_\mu = 2$, parameterized by the anomalous magnetic moment of the muon $a_\mu \equiv (g_\mu - 2)/2$. This observable can be measured in storage-ring experiments and predicted within the Standard Model (SM) to high precision, testing the SM at its quantum loop level. In short, the current world average of the experimental determination after the final results of the FNAL E989 experiment reads [1–8]

$$a_\mu^{\rm exp} = 116\,592\,071.5(14.5) \times 10^{-11}\,, \tag{56.1}$$

to be compared with the SM prediction as compiled by the Muon $g-2$ Theory Initiative [9–69]

$$a_\mu^{\rm SM} = 116\,592\,033(62) \times 10^{-11}\,. \tag{56.2}$$

Accordingly, the difference

$$\Delta a_\mu \equiv a_\mu^{\rm exp} - a_\mu^{\rm SM} = 38(63) \times 10^{-11} \tag{56.3}$$

is compatible with zero, but the uncertainty is completely dominated by the SM prediction, allowing for a SM test at threefold improved precision once the experimental uncertainty can be matched. In Sec. 56.2 we briefly review the status of experiment, Eq. (56.1), in Sec. 56.3 the status of the SM prediction, Eq. (56.2), and conclude with some remarks on future improvements in Sec. 56.4.

56.2 Precision measurement of a_μ

The two most precise muon $g-2$ experiments—BNL E821 and FNAL E989—were developed based on the experiences of earlier storage ring experiments at CERN [70, 71]. The most significant improvements are related to the intensity and purity of muon delivery to the ring, which has led to the world average precision of 124 ppb in the determination of a_μ. Figure 56.1 displays the consistency of the individual BNL and FNAL run-period publications,[1] the final precision achieved, and the average. With the exception of BNL-01, all measurements used positive muons. Details of the combination procedure, including updated corrections since the original publication, can be found in Ref. [1].

Figure 56.1: Experimental values of a_μ from BNL E821 (blue triangles) [72–74],[1] FNAL E989 (red squares) [1, 2, 4], and the world average (black diamond). The uncertainties combine statistics and systematics. BNL values are rounded to the nearest 10 ppb. All measurements employed positive muons except BNL-01, which ran with negative muons (inverted triangle).

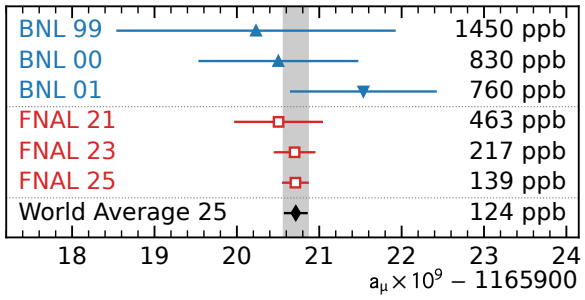

Table 56.1: $\mathcal{R}'_\mu$ values and uncertainties from BNL E821,[1] with uncertainties rounded to the nearest 10 ppb, and those from FNAL E989.

	$\mathcal{R}'_\mu$	Total (ppb)	Statistical (ppb)	Systematics (ppb)
BNL E821	0.00370730154	540	460	280
FNAL E989	0.00370730088	125	98	78
Combined	0.00370730091	122	96	75

In this compact description, we emphasize aspects of the common storage ring technique to determine a_μ to high precision, while also pointing out the relatively balanced final systematics table from FNAL that would have to be overcome for further improvements.

Polarized muon bunches are injected into a 7.1 m radius superconducting storage ring (SR) [76] having a highly uniform vertical magnetic field, $|\mathbf{B}| \approx 1.45$ T. A fast kicker magnet [77] deflects the muons during the first turn into a fiducial toroidal volume that is concentric with the SR center. Four regions containing electrostatic quadrupole (ESQ) plates provide weak vertical focusing. Approximately 5000 muons are stored in each "fill" of the ring.

The muons circulate in the ring at the cyclotron angular frequency $\boldsymbol{\omega}_c = -\frac{q}{m_\mu\gamma}\mathbf{B}$, $\gamma = 1/\sqrt{1-\beta^2}$ being the Lorentz factor, and their spins rotate at $\boldsymbol{\omega}_s = -g_\mu \frac{q}{2m_\mu}\mathbf{B} - (1-\gamma)\frac{q}{m_\mu\gamma}\mathbf{B}$. If g_μ were exactly equal to 2, the cyclotron and spin frequencies would be the same. For $g_\mu \neq 2$, and for the ideal case that $\boldsymbol{\beta}\cdot\mathbf{B} = 0$, the anomalous precession frequency $\boldsymbol{\omega}_a$ is simply given by

$$\boldsymbol{\omega}_a = \boldsymbol{\omega}_s - \boldsymbol{\omega}_c = -\frac{q}{m_\mu} a_\mu \mathbf{B}. \tag{56.4}$$

In practice, the betatron oscillations of the muon beam and the presence of the quadrupole electric field lead to a more complete expression [78]

$$\boldsymbol{\omega}_a = -\frac{q}{m_\mu}\left[a_\mu \mathbf{B} - a_\mu\left(\frac{\gamma}{\gamma+1}\right)(\boldsymbol{\beta}\cdot\mathbf{B})\boldsymbol{\beta} - \left(a_\mu - \frac{1}{\gamma^2-1}\right)\boldsymbol{\beta}\times\mathbf{E}\right]. \tag{56.5}$$

The second term accounts for the vertical betatron oscillations owing to the average value of $(\boldsymbol{\beta}\cdot\mathbf{B})^2$. A measurement of the vertical amplitude distribution leads to a "pitch" correction. The third term accounts for the motional magnetic field felt by the relativistic muons in the presence of the ESQ electric field $\mathbf{E}$. The CERN-III experiment [71] recognized that this term vanishes for $\gamma = \sqrt{1+1/a_\mu} \approx 29.3$, corresponding to a muon "magic momentum" of $P_0 \approx 3.094$ GeV.[2] The CERN-III, BNL, and FNAL experiments each operated at this momentum. The momentum spread with respect to P_0 ($\sim \Delta P/P_0 < 0.2\%$) requires an electric-field correction of order several hundred ppb, by far the largest correction in the experiment.

The magnetic field $\mathbf{B}$ in Eq. (56.5) is measured using pulsed proton NMR techniques and is expressed as $\tilde{\omega}'_p(T_r)$, which is the proton spin precession frequency inside a room-temperature spherical water sample and averaged over the stored muon distribution. Equation (56.5) demonstrates that $a_\mu \propto \omega_a/\tilde{\omega}'_p(T_r) \equiv \mathcal{R}'_\mu$, which is the quantity reported by all $g-2$ experiments. The muon anomaly is then determined from

$$a_\mu = \mathcal{R}'_\mu \frac{\mu'_p(T_r)}{\mu_B}\frac{m_\mu}{m_e}, \tag{56.6}$$

where $\mu'_p(T_r)/\mu_B$ is the ratio of the shielded proton magnetic moment to the Bohr magneton and m_μ/m_e is the muon-to-electron mass ratio [75]. Reporting this ratio allows a_μ to be recalculated if the fundamental constants are updated; see Table 56.1.

[1] The quoted BNL $\mathcal{R}'_\mu$ and a_μ values were computed by the FNAL Muon $g-2$ collaboration [1], converting the reported values for free protons in vacuum in the BNL references and using the converted $\mathcal{R}'_\mu$ values to recompute the a_μ values relying on CODATA 2022 [75] for the external inputs.

[2] The E34 experiment at J-PARC [79] plans to inject lower momentum muons with negligible transverse momentum components into a ring that does not include an electric quadrupole field. This will greatly reduce any needed electric field or pitch correction.

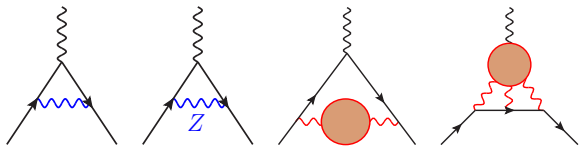
Table 56.2: Corrections and uncertainties from combined FNAL running periods, and current uncertainties due to the external parameters. Here ω_a^m is the fit precession frequency. Corrections to ω_a^m yield ω_a, needed in the numerator of $\mathcal{R}_\mu^{'}$. Numerical summary courtesy of Alberto Lusiani, on behalf of the FNAL Muon $g-2$ Collaboration.

Quantity	Correction (ppb)	Uncertainty (ppb)
ω_a^m (statistical)	–	98
Beam dynamic (BD) corrections to ω_a^m to yield ω_a	+538	43
Net ω_a (statistical + BD + fitting uncertainties)	–	111
$\omega_p^{'}$ (all systematics)	–	48
Magnetic field transient corrections to $\omega_p^{'}$	−58	31
Net $\omega_p^{'}$ uncertainty	–	57
Total uncertainties for $\mathcal{R}_\mu^{'}$	–	125
$\mu_p^{'}/\mu_B$ and m_μ/m_e external parameters	–	23
Total for a_μ		127

The absolute magnetic field [6] is established using custom high-purity water [80] and He-3 [81] probes measured in a special-purpose highly uniform MRI magnet. These probes cross-calibrate an in-ring movable "plunging" probe system, which in turn cross-calibrates one-by-one the 17 probes in an NMR trolley [82]. This device periodically maps the entire storage ring field *in situ*. The temporal variation of the field is continuously monitored using an additional set of 378 probes [83] placed above and below the fiducial volume.

Two arrays of in-vacuum straw Tracker detectors [84] located at two azimuthal positions in the SR record the inward bending trajectories of e^+ from muon decay. The fit tracks are then traced back to the approximate upstream decay location within the storage ring vs. time-in-fill. The measured stored muon distribution is folded with the azimuthally averaged field maps to give the muon-weighted field. Details are found in Refs. [3, 6].

Parity violation in weak $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$ decay provides the polarimetry needed to deduce the average muon spin direction vs. time-in-fill. The decay positron energy in the boosted laboratory frame is related to the energy and angular distribution in the center-of-mass (CM) as in $E_{e,\mathrm{lab}} \approx \gamma E_{e,\mathrm{CM}}(1+\cos\theta_{\mathrm{CM}})$, and thus the highest-energy positrons are preferentially emitted in the direction of the muon spin. All decay positrons curl to the inside of the SR, where their time-of-arrival and energy are measured in calorimeters [85], forming a measured spectrum $N(t, E_e)$. In first order, this spectrum can be described by $N(t) = N_0 e^{-t/(\gamma\tau_\mu)}[1 + A\cos(\omega_a t - \phi)]$, where the asymmetry A depends on the energy threshold and the average polarization of the muons. The statistical precision of the experiment is optimized by fitting a histogram whose entries are weighted by the energy-dependent asymmetry $A(E)$; that is,



$$\frac{\delta\omega_a}{\omega_a} = \frac{1}{\omega_a\gamma\tau_\mu}\sqrt{\frac{2}{N\langle A(E)^2\rangle}}\,, \tag{56.7}$$

which emphasizes the importance of the higher-energy positrons.

The fit of $N(t, E_e)$ results in the measured precession frequency ω_a^m. To achieve a good χ^2, additional terms that account for the rate variations from the coupling of calorimeter acceptance to beam motions are required. The largest of these are associated with coherent betatron oscillations (CBO), which, if ignored, would pull ω_a^m from the true precession frequency ω_a by several hundred ppb. An RF modulation system [86], tuned to the CBO frequency and applied to the ESQ plates, creates a dipole field that significantly damps the intrinsic CBO effect. Details on the extraction of ω_a^m and the many independent checks and methods used can be found in Refs. [3, 5].

Table 56.2 lists the corrections and uncertainties reported for the entire FNAL E989 measurement [1, 2, 4]. For simplicity, this table combines the individual effects that impact ω_a^m or $\omega_p^{'}$. Corrections to the measured precession frequency, ω_a^m, are dominated by the effect of the electric field and pitch as expressed in Eq. (56.5). Several additional and much smaller corrections are needed because the stored muon phase space slightly evolves during the fill. Transient-magnetic-field corrections to $\omega_p^{'}$ correspond to a residual eddy current from the fast kicker and a vibration-induced field perturbation from the charging of the ESQ plates. The systematic uncertainties are relatively balanced. The final precision on $\mathcal{R}_\mu^{'}$, and thus also on a_μ, is dominated by the statistical uncertainty.

Figure 56.2: Sample diagrams for a_μ in the SM: solid lines refer to the muon, wiggly lines to photons, and the red blobs to hadronic matrix elements. The first diagram gives the leading QED contribution by Schwinger, the second one represents a one-loop EW diagram with Z exchange, and the last two diagrams correspond to HVP and HLbL topologies, respectively.

56.3 Standard Model prediction of a_μ

The SM prediction of a_μ decomposes into pure QED contributions, electroweak (EW) effects, and hadronic corrections

$$a_\mu^{\mathrm{SM}} = a_\mu^{\mathrm{QED}} + a_\mu^{\mathrm{EW}} + a_\mu^{\mathrm{had}}\,, \qquad a_\mu^{\mathrm{had}} = a_\mu^{\mathrm{HVP}} + a_\mu^{\mathrm{HLbL}}\,, \tag{56.8}$$

where the latter are further separated into topologies featuring hadronic vacuum polarization (HVP) and hadronic light-by-light scattering (HLbL), see Fig. 56.2 for representative diagrams in each category. In the subsequent sections we briefly discuss the status for each class of corrections, referring to Refs. [9, 87] for a thorough review, labeled as WP20 [87] and WP25 [9] below.[3] The resulting bottom line is summarized in Table 56.3.

56.3.1 *QED and electroweak contributions*

By far the dominant contribution to a_μ^{SM} arises from QED, including all diagrams with purely photonic and leptonic ($\ell = e, \mu, \tau$) loops. Starting from Schwinger's seminal result [89], the expansion can be expressed as

$$\begin{aligned} a_\mu^{\mathrm{QED}} = {} & \frac{\alpha}{2\pi} + 0.765\,857\,420(8)_e(11)_\tau[13]\left(\frac{\alpha}{\pi}\right)^2 \\ & + 24.050\,509\,77(17)_e(16)_\tau[23]\left(\frac{\alpha}{\pi}\right)^3 \\ & + 130.8782(60)_{\mathrm{MC}}\left(\frac{\alpha}{\pi}\right)^4 + 750.2(9)_{\mathrm{MC}}\left(\frac{\alpha}{\pi}\right)^5 + \mathcal{O}\left(\alpha^6\right), \end{aligned} \tag{56.9}$$

where the uncertainties derive from $m_\mu/m_e = 206.7682827(46)$, $m_\tau/m_\mu = 16.8170(11)$ [75], and Monte-Carlo (MC) integration,

[3] These white papers (WP) were compiled by the Muon $g-2$ Theory Initiative [88], reflecting a community consensus of the status of the SM prediction in 2020 and 2025, respectively.

respectively. Up to $\mathcal{O}(\alpha^3)$, analytical results are available, both for the mass-independent terms [90–92] and mass-dependent corrections [93–95], so that the uncertainties in the coefficients in Eq. (56.9) only depend on the input for the lepton mass ratios. At $\mathcal{O}(\alpha^4)$, the mass-independent term is known essentially analytically [96], and the uncertainty in the mass-dependent corrections is dominated by MC errors [10, 97]. Finally, at $\mathcal{O}(\alpha^5)$ both mass-independent and mass-dependent contributions are evaluated numerically, and the size of the mass-independent term recently decreased by $\simeq 0.8$ upon improved MC sampling [10–13], about the same size as the MC uncertainty in the mass-dependent correction. Numerically, the largest contributions to the coefficients arise from terms enhanced by powers of $\log \frac{m_\mu}{m_e}$ (and factors of π^2), explaining their rapid increase. For the evaluation of $a_\mu^{\rm QED}$, input for the fine-structure constant α is required, the current most precise determinations being [9]

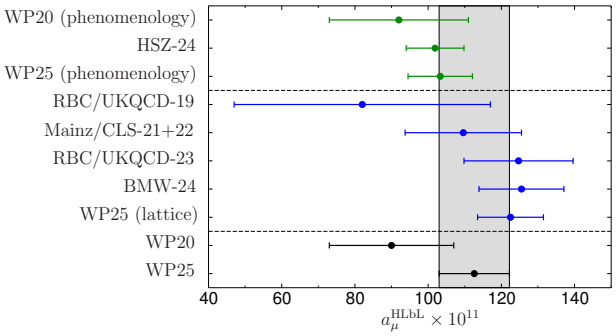
$$\alpha^{-1}[\mathrm{Cs}] = 137.035\,999\,045(27)\,, \tag{56.10}$$

$$\alpha^{-1}[\mathrm{Rb}] = 137.035\,999\,2052(97)\,, \tag{56.11}$$

$$\alpha^{-1}[a_e] = 137.035\,999\,163(15)\,, \tag{56.12}$$

derived from atom-interferometry measurements in Cs [14], Rb [15], and the anomalous magnetic moment of the electron a_e [16], respectively. α^{-1}[Cs] and α^{-1}[Rb] disagree by 5.5σ, which translates to an uncertainty of about 0.14×10^{-11} in $a_\mu^{\rm QED}$. This is the same level at which $\mathcal{O}(\alpha^6)$ contributions are expected to enter, estimated based on the maximally possible enhancement with $\log \frac{m_\mu}{m_e}$ at six-loop order [10]. The combination of these two effects leads to the final uncertainty quoted for $a_\mu^{\rm QED}$ in Table 56.3.

Loop contributions that involve W, Z, or Higgs bosons are summarized in the EW contribution $a_\mu^{\rm EW}$. At one-loop order, the result can be expressed as [98–102]



$$\begin{aligned} a_\mu^{\rm EW}[\text{1-loop}] =& \frac{G_F}{\sqrt{2}}\frac{m_\mu^2}{8\pi^2}\left[\frac{5}{3}+\frac{1}{3}(1-4s_{\rm W}^2)^2+\mathcal{O}\left(\frac{m_\mu^2}{M_W^2},\frac{m_\mu^2}{M_H^2}\right)\right] \\ =& 194.79(1)\times10^{-11}\,, \end{aligned} \tag{56.13}$$

with on-shell weak mixing angle $s_W^2 = \sin^2\theta_W = 1 - M_W^2/M_Z^2$ and the SM prediction expressed in terms of the Fermi constant G_F as measured in muon decay [103], M_Z, and α, while M_W is a derived quantity [18]. Two-loop contributions are sizable, $a_\mu^{\rm EW}$[2-loop] $= -40.4(4)\times10^{-11}$, and are typically further separated into bosonic [104–106], Higgs-dependent [18, 107], and other fermionic contributions [17, 108, 109]. In particular, the latter include quark triangle loops, for which non-perturbative effects become important. Improvements in their evaluation [19, 20] together with the consideration of α_s corrections for the heavy quarks [110] and lattice-QCD input for γ–Z mixing [111] lead to the updated result [20]

$$a_\mu^{\rm EW} = 154.4(4)\times10^{-11}\,, \tag{56.14}$$

where three-loop effects are estimated to be $\lesssim 0.2\times10^{-11}$ [17,112].

Figure 56.3: Summary of HLbL evaluations, from data-driven methods (green), lattice QCD (blue), and combinations (black). The averages are from WP20 and WP25, respectively, the other points refer to HSZ-24 [61, 113], RBC/UKQCD-19 [65], Mainz/CLS-21+22 [66, 67], RBC/UKQCD-23 [68], and BMW-24 [69]. Adapted from Ref. [9].

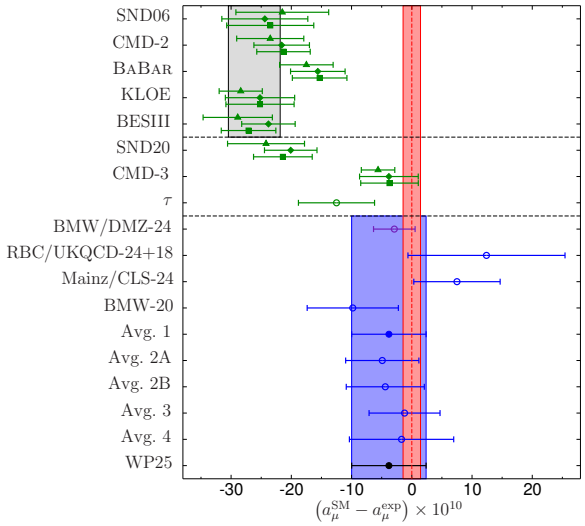
56.3.2 *Hadronic light-by-light scattering*

HLbL contributions enter at $\mathcal{O}(\alpha^3)$, involving the hadronic four-point function as indicated in Fig. 56.2, which can be determined with data-driven techniques or using lattice QCD. For a detailed review we refer to Ref. [9], while a summary of the present situation is shown in Fig. 56.3. Phenomenological [19, 41–63] and lattice-QCD [65–69] evaluations agree at a level of 1.5σ, leading to the overall average

$$a_\mu^{\rm HLbL}[\text{phenomenology + lattice}] = 112.6(9.6)\times10^{-11}\,, \tag{56.15}$$

whose error includes a scale factor $S = 1.5$. Including an estimate for NLO HLbL topologies [64] then produces the final HLbL number quoted in Table 56.3.

56.3.3 *Hadronic vacuum polarization*



The leading, and most critical, hadronic effect already arises at $\mathcal{O}(\alpha^2)$ in the form of the HVP diagram shown in Fig. 56.2. Traditionally, this contribution has been evaluated using the master formula [114, 115]

$$a_\mu^{\rm HVP,\ LO} = \left(\frac{\alpha m_\mu}{3\pi}\right)^2 \int_{s_{\rm thr}}^{\infty} ds \frac{\hat{K}(s)}{s^2} R_{\rm had}(s)\,, \tag{56.16}$$

Figure 56.4: Summary of various determinations of $a_\mu^{\mathrm{HVP,\,LO}}$, propagated to a_μ^{SM}. The first two panels refer to data-driven determinations, where the three points for each e^+e^- experiment reflect the CHKLS [123,126–128] (triangle), DHMZ [121,125,129] (diamond), and KNTW [38,122,130] (square) methods, see WP25 for details. The gray band indicates the WP20 result, based on the e^+e^- experiments above the first dashed line. The second panel represents e^+e^- experiments that became available afterwards as well as the τ-based estimate from WP25. The last panel summarizes lattice-QCD determinations, including the hybrid evaluation by BMW/DMZ-24 [31], three individual lattice-QCD calculations by RBC/UKQCD-24+18 [33], Mainz/CLS-24 [34], BMW-20 [23], and five lattice HVP averages from WP25. The blue band refers to the final WP25 result, which coincides with "Avg. 1." In all cases, except for the gray WP20 band, the remaining contributions to a_μ^{SM} beyond $a_\mu^{\mathrm{HVP,\,LO}}$ are taken from WP25. The red band denotes the experimental world average. Adapted from Ref. [9].

which allows one to express its effect via a dispersion integral in terms of the hadronic R-ratio,

$$R_{\mathrm{had}}(s) = \frac{3s}{4\pi\alpha^2}\sigma\left[e^+e^- \to \mathrm{hadrons}(+\gamma)\right], \qquad (56.17)$$

and a kernel function $\hat{K}(s)$. In particular, the LO contribution is defined photon-inclusively, but removing vacuum-polarization effects in the photon propagator. Accordingly, the integration starts at the threshold of the $e^+e^- \to \pi^0\gamma$ channel, $s_{\mathrm{thr}} = M_{\pi^0}^2$. In WP20, the final result for the HVP contribution was based on e^+e^- data, including data for the by far numerically dominant $e^+e^- \to \pi^+\pi^-$ channel from the SND06 [116], CMD-2 [117], BaBar [118], KLOE [119], and BESIII [120] experiments. Moreover, different methodologies for the compilation of e^+e^- data were taken into account [38, 121–125], and an additional uncertainty beyond a simple scale factor was introduced to account for the tension between the BaBar and KLOE measurements, leading to the gray band in Fig. 56.4.

Subsequently, new $\pi^+\pi^-$ measurements from SND20 [131] and CMD-3 [132, 133] have become available, and while the former falls within the previous range, the latter increases tensions to a level that cannot be taken into account anymore by a meaningful inflation of uncertainties. For that reason, e^+e^- data are not used in WP25 for the LO HVP evaluation at this point, until the origin of the discrepancies among data sets is understood.[4]

An alternative data-driven evaluation relies on $\tau \to \nu_\tau +$ hadrons decays [136], in which case isospin symmetry provides access to the isovector part of the hadronic cross section as long as isospin-breaking corrections [137–142] can be controlled. A critical review of these corrections is provided in WP25, identifying several effects that currently preclude the use of τ data for the HVP evaluation due to a remaining model dependence that is difficult to quantify in a reliable manner. However, the current best estimate from WP25 (based on Refs. [126,129,140,142,143]) is included in the second panel of Fig. 56.4.

While the HVP evaluation from data-driven methods is thus inconclusive at this point, material progress has been achieved since WP20 in lattice QCD, based on the time-momentum representation of the hadronic two-point function [144]. In particular, detailed cross checks have been performed using windows in Euclidean time [21] as a tool to scrutinize the different systematic errors of the calculation. In total, the final average quoted in WP25,

$$a_\mu^{\mathrm{HVP,\,LO}}[\mathrm{lattice}] = 7132(61) \times 10^{-11}\,, \qquad (56.18)$$

is based on 17 different papers from 8 independent lattice-QCD collaborations [21–37], from which three almost complete lattice calculations of the entire LO HVP contribution are derived [23, 33, 34], see Fig. 56.4. Moreover, different strategies to combine the individual results (corresponding to the five averages shown in Fig. 56.4) prove very stable, and additional systematic errors have been assigned to cover the most challenging aspects of the calculation related to the evaluation of isospin-breaking effects and the noisy contributions at long distances. Given this consolidation of lattice-QCD results, the final SM prediction in WP25, as reproduced in Table 56.3, is based on Eq. (56.18),[5] until the tensions among the data-driven evaluations are resolved.

56.4 Outlook

In the current situation, it is obvious that the SM prediction (56.2) needs to be improved by a factor of four to fully leverage the precision achieved in experiment (56.1), which would result in a three-fold improved precision of the SM test (56.3). Ongoing efforts include [145]:

- Data-driven and lattice-QCD evaluations of the HLbL contribution will be further scrutinized to better understand their slight tension and hopefully further improve the precision.
- Lattice-QCD calculations will be performed at increased precision, with focus on more precise evaluations of isospin-breaking effects and the noisy contributions at long distances.
- New e^+e^- results are expected from BaBar, KLOE (existing data that were never analyzed before) and Belle II, BESIII, SND (new data). In addition, the role of radiative corrections and MC generators will be carefully scrutinized [146–152].
- New data for τ decays are expected from Belle II, and improved determinations of the required isospin-breaking corrections will be developed using lattice QCD, dispersion relations, and data-driven techniques.
- An independent direct measurement of a_μ is the goal of the E34 experiment at J-PARC [79].
- The MUonE experiment [153–155] aims at a measurement of the HVP contribution in a spacelike process, yielding another independent determination with completely different systematics.

[4] The exception concerns higher-order HVP iterations [40,134], for which the increased uncertainty can be tolerated [38, 39]. Mixed leptonic and hadronic corrections at $\mathcal{O}(\alpha^4)$ are $\lesssim 1 \times 10^{-11}$ [135].

[5] This result agrees with the hybrid evaluation by BMW/DMZ-24 [31], using data input for the long-distance tail.

57. Muon Decay Parameters

Revised August 2023 by W. Fetscher (ETH Zurich) and H.-J. Gerber (ETH Zurich).

57.1 Introduction:

All measurements in direct muon decay, $\mu^- \to e^- + 2$ neutrals, and its inverse, $\nu_\mu + e^- \to \mu^-$ + neutral, are successfully described by the "V-A interaction," which is a particular case of a local, derivative-free, lepton-number-conserving, four-fermion interaction [1]. As shown below, within this framework, the Standard Model assumptions, such as the V-A form and the nature of the neutrals (ν_μ and $\bar{\nu}_e$), and hence the doublet assignments $(\nu_e\, e^-)_L$ and $(\nu_\mu\, \mu^-)_L$, have been determined from experiments [2,3]. All considerations on muon decay are valid for the leptonic tau decays $\tau^- \to \ell^- + \nu_\tau + \bar{\nu}_\ell$ with the replacements $m_\mu \to m_\tau$, $m_e \to m_{ell}$, $\ell^- = e^-, \mu^-$.

57.2 Parameters:

The differential decay probability to obtain an $e^\pm$ with (reduced) energy between x and $x + \mathrm{d}x$, emitted in the direction $\widehat{\boldsymbol{x}}_3$ at an angle between ϑ and $\vartheta + \mathrm{d}\vartheta$ with respect to the muon polarization vector $\boldsymbol{P}_\mu$, and with its spin parallel to the arbitrary direction $\widehat{\boldsymbol{\zeta}}$, neglecting radiative corrections, is given by

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} = \frac{m_\mu}{4\pi^3}\, W_{e\mu}^4\, G_\mathrm{F}^2\, \sqrt{x^2 - x^{2}_{0}} \times \left(F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta F_\mathrm{AS}(x)\right) \times \left[1 + \widehat{\boldsymbol{\zeta}} \cdot \boldsymbol{P}_e(x,\vartheta)\right] \,. \tag{57.1}$$

Here, $W_{e\mu} = \max(E_e) = (m_\mu^2 + m_e^2)/2m_\mu$ is the maximum $e^\pm$ energy, $x = E_e/W_{e\mu}$ is the reduced energy, $x_0 = m_e/W_{e\mu} = 9.67 \times 10^{-3}$, and $P_\mu = |\boldsymbol{P}_\mu|$ is the degree of muon polarization. $\widehat{\boldsymbol{\zeta}}$ is the direction in which a perfect polarization-sensitive electron detector is most sensitive. The isotropic part of the spectrum, $F_\mathrm{IS}(x)$, the anisotropic part $F_\mathrm{AS}(x)$, and the electron polarization, $\boldsymbol{P}_e(x,\vartheta)$, may be parametrized by the Michel parameter ρ [1], by η [4], by ξ and δ [5,6], *etc.* These are bilinear combinations of the coupling constants $g^\gamma_{\varepsilon\mu}$, which occur in the matrix element (given below).

If the masses of the neutrinos as well as x_0^2 are neglected, the energy and angular distribution of the electron in the rest frame of a muon ($\mu^\pm$) measured by a polarization insensitive detector, is given by

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} \sim x^2 \cdot \left\{3(1-x) + \frac{2\rho}{3}(4x-3) + 3\eta\; x_0(1-x)/x \pm P_\mu \cdot \xi \cdot \cos\vartheta \left[1 - x + \frac{2\delta}{3}(4x-3)\right]\right\} \,. \tag{57.2}$$

Here, ϑ is the angle between the electron momentum and the muon spin, and $x \equiv 2E_e/m_\mu$. For the Standard Model coupling, we obtain $\rho = \xi\delta = 3/4$, $\xi = 1$, $\eta = 0$ and the differential decay rate is

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} = \frac{G_\mathrm{F}^2 m_\mu^5}{192\pi^3}\, [3 - 2x \pm P_\mu \cos\vartheta(2x-1)] \cdot x^2 \,. \tag{57.3}$$

The coefficient in front of the square bracket is the total decay rate.

If only the neutrino masses are neglected, and if the $e^\pm$ polarization is detected, then the functions in Eq. (57.1) become

$$F_\mathrm{IS}(x) = x\,(1-x) + \tfrac{2}{9}\,\rho\,(4x^2 - 3x - x_0^2) + \eta \cdot x_0\,(1-x) \tag{57.4a}$$

$$F_\mathrm{AS}(x) = \tfrac{1}{3}\,\xi\,\sqrt{x^2 - x_0^2} \times \left[(1-x) + \tfrac{2}{3}\delta\left\{(4x-3) + \left(\sqrt{1-x_0^2} - 1\right)\right\}\right] \tag{57.4b}$$

$$\boldsymbol{P}_e(x,\vartheta) = P_{\mathrm{T}_1} \cdot \widehat{\boldsymbol{x}}_1 + P_{\mathrm{T}_2} \cdot \widehat{\boldsymbol{x}}_2 + P_\mathrm{L} \cdot \widehat{\boldsymbol{x}}_3 \tag{57.4c}$$

Here $\widehat{\boldsymbol{x}}_1$, $\widehat{\boldsymbol{x}}_2$, and $\widehat{\boldsymbol{x}}_3$ are orthogonal unit vectors defined as follows:

$\widehat{\boldsymbol{x}}_3$	is along the e momentum $\boldsymbol{p}_e$
$\dfrac{\widehat{\boldsymbol{x}}_3 \times \boldsymbol{P}_\mu}{\lvert\widehat{\boldsymbol{x}}_3 \times \boldsymbol{P}_\mu\rvert} = \widehat{\boldsymbol{x}}_2$	is transverse to $\boldsymbol{p}_e$ and perpendicular to "the decay plane"
$\widehat{\boldsymbol{x}}_2 \times \widehat{\boldsymbol{x}}_3 = \widehat{\boldsymbol{x}}_1$	is transverse to $\boldsymbol{p}_e$ and in the decay plane

The components of $\boldsymbol{P}_e$ then are given by

$$P_{\mathrm{T}_1}(x,\vartheta) = P_\mu \sin\vartheta \cdot F_{\mathrm{T}_1}(x) / \left\{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)\right\} \tag{57.5a}$$

$$P_{\mathrm{T}_2}(x,\vartheta) = P_\mu \sin\vartheta \cdot F_{\mathrm{T}_2}(x) / \left\{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)\right\} \tag{57.5b}$$

$$P_\mathrm{L}(x,\vartheta) = \frac{\pm F_\mathrm{IP}(x) + P_\mu \cos\vartheta \cdot F_\mathrm{AP}(x)}{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)} \quad , \tag{57.5c}$$

where

$$F_{\mathrm{T}_1}(x) = \tfrac{1}{12}\left\{-2\left[\xi'' + 12\left(\rho - \tfrac{3}{4}\right)\right](1-x)x_0 - 3\,\eta\left(x^2 - x_0^2\right) + \eta''\left(-3x^2 + 4x - x_0^2\right)\right\} \tag{57.6a}$$

$$F_{\mathrm{T}_2}(x) = \tfrac{1}{3}\,\sqrt{x^2 - x_0^2} \cdot \left\{3\,\frac{\alpha'}{A}(1-x) + 2\,\frac{\beta'}{A}\sqrt{1 - x_0^2}\right\} \tag{57.6b}$$

$$F_\mathrm{IP}(x) = \tfrac{1}{54}\sqrt{x^2 - x_0^2} \cdot \left\{9\,\xi'\left(-2x + 2 + \sqrt{1 - x_0^2}\right) + 4\,\xi\left(\delta - \tfrac{3}{4}\right)\left(4x - 4 + \sqrt{1 - x_0^2}\right)\right\} \tag{57.6c}$$

$$F_\mathrm{AP}(x) = \tfrac{1}{6}\left\{\xi''\left(2x^2 - x - x_0^2\right) + 4\left(\rho - \tfrac{3}{4}\right)\left(4x^2 - 3x - x_0^2\right) + 2\,\eta''(1-x)\,x_0\right\}. \tag{57.6d}$$

For the experimental values of the parameters ρ, ξ, ξ', ξ'', δ, η, η'', α/A, β/A, α'/A, β'/A, which are not all independent, see the Data Listings below. Experiments in the past have also been analyzed using the parameters a, b, c, a', b', c', α/A, β/A, α'/A, β'/A (and $\eta = (\alpha - 2\beta)/2A$), as defined by Kinoshita and Sirlin [5,6]. They serve as a model-independent summary of all possible measurements on the decay electron (see Listings below). The relations between the two sets of parameters are

$$\rho - \tfrac{3}{4} = \tfrac{3}{4}\,(-a + 2\,c)/A \tag{57.7a}$$

$$\eta = (\alpha - 2\beta)/A \tag{57.7b}$$

$$\eta'' = (3\,\alpha + 2\,\beta)/A \tag{57.7c}$$

$$\delta - \tfrac{3}{4} = \tfrac{9}{4} \cdot \frac{(a' - 2\,c')\,/A}{1 - [a + 3\,a' + 4\,(b + b') + 6\,c - 14\,c']\,/A} \tag{57.7d}$$

$$1 - \xi\,\frac{\delta}{\rho} = 4\,\frac{[(b + b') + 2\,(c - c')]\,/A}{1 - (a - 2\,c)/A} \tag{57.7e}$$

$$1 - \xi = \left[\left(a + a'\right) + 4\left(b + b'\right) + 6\left(c + c'\right)\right]/A \tag{57.7f}$$

$$1 - \xi'' = (-2\,a + 20\,c)/A \tag{57.7g}$$

$$\text{with} \qquad A = a + 4\,b + 6\,c \tag{57.7h}$$

The differential decay probability to obtain a *left-handed* ν_e with (reduced) energy between y and $y + dy$, neglecting radiative corrections as well as the masses of the electron and of the neutrinos, is given by [7]

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}y} = \frac{m_\mu^5 G_\mathrm{F}^2}{16\,\pi^3} \cdot Q_L^{\nu_e} \cdot y^2 \left\{(1-y) - \omega_L \cdot \left(y - \tfrac{3}{4}\right)\right\} \,. \tag{57.8}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Here, $y = 2\ E_{\nu_e}/m_\mu$. $Q_L^{\nu_e}$ and ω_L are parameters. ω_L is the neutrino analog of the spectral shape parameter ρ of Michel. Since in the Standard Model, $Q_L^{\nu_e} = 1$, $\omega_L = 0$, the measurement of $\mathrm{d}\Gamma/\mathrm{d}y$ has allowed a null-test of the Standard Model (see Listings below).

Table 57.1: Coupling constants $g^\gamma_{\varepsilon\mu}$ and some combinations of them. Ninety-percent confidence level experimental limits. The limits on $|g^S_{LL}|$ and $|g^V_{LL}|$ are from [8–10], and the others from a general analysis of muon decay measurements. Top three rows: [11], fourth row: [12], next three rows: [13], last row: [14]. The experimental uncertainty on the muon polarization in pion decay is included. Note that, by definition, $|g^S_{\varepsilon\mu}| \le 2$, $|g^V_{\varepsilon\mu}| \le 1$ and $|g^T_{\varepsilon\mu}| \le 1/\sqrt{3}$.

$\lvert g^S_{RR}\rvert < 0.035$	$\lvert g^V_{RR}\rvert < 0.017$	$\lvert g^T_{RR}\rvert \equiv 0$
$\lvert g^S_{LR}\rvert < 0.050$	$\lvert g^V_{LR}\rvert < 0.023$	$\lvert g^T_{LR}\rvert < 0.015$
$\lvert g^S_{RL}\rvert < 0.420$	$\lvert g^V_{RL}\rvert < 0.105$	$\lvert g^T_{RL}\rvert < 0.105$
$\lvert g^S_{LL}\rvert < 0.550$	$\lvert g^V_{LL}\rvert > 0.960$	$\lvert g^T_{LL}\rvert \equiv 0$
$\lvert g^S_{LR} + 6\,g^T_{LR}\rvert < 0.143$	$\lvert g^S_{RL} + 6\,g^T_{RL}\rvert < 0.418$	
$\lvert g^S_{LR} + 2\,g^T_{LR}\rvert < 0.108$	$\lvert g^S_{RL} + 2\,g^T_{RL}\rvert < 0.417$	
$\lvert g^S_{LR} - 2\,g^T_{LR}\rvert < 0.070$	$\lvert g^S_{RL} - 2\,g^T_{RL}\rvert < 0.418$	
$Q_{RR} + Q_{LR} < 8.2{\times}10^{-4}$		

57.3 Matrix element:

All results in direct muon decay (energy spectra of the electron and of the neutrinos, polarizations, and angular distributions), and in inverse muon decay (the reaction cross section) at energies well below $m_W c^2$, may be parametrized in terms of amplitudes $g^\gamma_{\varepsilon\mu}$ and the Fermi coupling constant G_F, using the matrix element

$$\frac{4G_\mathrm{F}}{\sqrt{2}} \sum_{\substack{\gamma=S,V,T\\ \varepsilon,\mu=R,L}} g^\gamma_{\varepsilon\mu}\, \langle \bar{e}_\varepsilon | \Gamma^\gamma | (\nu_e)_n \rangle\, \langle (\bar{\nu}_\mu)_m | \Gamma_\gamma | \mu_\mu \rangle \tag{57.9}$$

We use the notation of Fetscher *et al.* [2], who in turn use the sign conventions and definitions of Scheck [15]. Here, $\gamma = S, V, T$ indicates a scalar, vector, or tensor interaction; and $\varepsilon, \mu = R, L$ indicate a right- or left-handed chirality of the electron or muon. The chiralities n and m of the ν_e and $\bar{\nu}_\mu$ are then determined by the values of γ, ε, and μ. The particles are represented by fields of definite chirality [16].

As shown by Langacker and London [17], explicit lepton-number nonconservation still leads to a matrix element equivalent to Eq. (57.9). They conclude that it is not possible, even in principle, to test lepton-number conservation in (leptonic) muon decay if the final neutrinos are massless and are not observed.

The ten complex amplitudes $g^\gamma_{\varepsilon\mu}$ (g^T_{RR} and g^T_{LL} are identically zero) and G_F constitute 19 independent (real) parameters to be determined by experiment. The Standard Model interaction corresponds to one single amplitude g^V_{LL} being unity and all the others being zero.

The (direct) muon decay experiments are compatible with an arbitrary mix of the scalar and vector amplitudes g^S_{LL} and g^V_{LL} – in the extreme even with purely scalar $g^S_{LL} = 2$, $g^V_{LL} = 0$. The decision in favour of the Standard Model comes from the quantitative observation of inverse muon decay, which would be forbidden for pure g^S_{LL} [2].

57.4 Experimental determination of $V{-}A$:

In order to determine the amplitudes $g^\gamma_{\varepsilon\mu}$ uniquely from experiment, the following set of equations, where the left-hand sides represent experimental results, has to be solved.

$$a = 16\left(|g^V_{RL}|^2 + |g^V_{LR}|^2\right) + \left|g^S_{RL} + 6\,g^T_{RL}\right|^2 + \left|g^S_{LR} + 6\,g^T_{LR}\right|^2 \tag{57.10a}$$

$$a' = 16\left(|g^V_{RL}|^2 - |g^V_{LR}|^2\right) + \left|g^S_{RL} + 6\,g^T_{RL}\right|^2 - \left|g^S_{LR} + 6\,g^T_{LR}\right|^2 \tag{57.10b}$$

$$\alpha = 8\,\mathrm{Re}\left\{g^V_{RL}\left(g^{S*}_{LR} + 6\,g^{T*}_{LR}\right) + g^V_{LR}\left(g^{S*}_{RL} + 6\,g^{T*}_{RL}\right)\right\} \tag{57.10c}$$

$$\alpha' = 8\,\mathrm{Im}\left\{-g^V_{RL}\left(g^{S*}_{LR} + 6\,g^{T*}_{LR}\right) + g^V_{LR}\left(g^{S*}_{RL} + 6\,g^{T*}_{RL}\right)\right\} \tag{57.10d}$$

$$b = 4\left(|g^V_{RR}|^2 + |g^V_{LL}|^2\right) + |g^S_{RR}|^2 + |g^S_{LL}|^2 \tag{57.10e}$$

$$b' = 4\left(|g^V_{RR}|^2 - |g^V_{LL}|^2\right) + |g^S_{RR}|^2 - |g^S_{LL}|^2 \tag{57.10f}$$

$$c = \tfrac{1}{2}\left\{|g^S_{RL} - 2\,g^T_{RL}|^2 + |g^S_{LR} - 2\,g^T_{LR}|^2\right\} \tag{57.10g}$$

$$c' = \tfrac{1}{2}\left\{|g^S_{RL} - 2\,g^T_{RL}|^2 - |g^S_{LR} - 2\,g^T_{LR}|^2\right\} \tag{57.10h}$$

and

$$Q_L^{\nu_e} = 1 - \left\{\tfrac{1}{4}|g^S_{LR}|^2 + \tfrac{1}{4}|g^S_{LL}|^2 + |g^V_{RR}|^2 + |g^V_{RL}|^2 + 3\,|g^T_{LR}|^2\right\}$$

$$\omega_L = \tfrac{3}{4}\,\frac{|g^S_{RR}|^2 + 4\,|g^V_{LR}|^2 + |g^S_{RL} + 2\,g^T_{LR}|^2}{|g^S_{RL}|^2 + |g^S_{RR}|^2 + 4\,|g^V_{LL}|^2 + 4\,|g^V_{LR}|^2 + 12\,|g^T_{RL}|^2}\,. \tag{57.10i}$$

It has been noted earlier by C. Jarlskog [18], that certain experiments observing the decay electron are especially informative if they yield the V-A values. The complete solution is now found as follows. Fetscher *et al.* [2] introduced four probabilities $Q_{\varepsilon\mu}(\varepsilon, \mu = R, L)$ for the decay of a μ-handed muon into an ε-handed electron, and showed that there exist upper bounds on Q_{RR}, Q_{LR}, and Q_{RL}, and a lower bound on Q_{LL}. These probabilities are given in terms of the $g^\gamma_{\varepsilon\mu}$'s by

$$Q_{\varepsilon\mu} = \tfrac{1}{4}|g^S_{\varepsilon\mu}|^2 + |g^V_{\varepsilon\mu}|^2 + 3\,(1 - \delta_{\varepsilon\mu})|g^T_{\varepsilon\mu}|^2 \tag{57.11}$$

where $\delta_{\varepsilon\mu} = 1$ for $\varepsilon = \mu$, and $\delta_{\varepsilon\mu} = 0$ for $\varepsilon \ne \mu$. They are related to the parameters $a,\ b,\ c,\ a', b'$, and c' by

$$Q_{RR} = 2\,(b + b')/A \tag{57.12a}$$

$$Q_{LR} = \left[(a - a') + 6\,(c - c')\right]/2A \tag{57.12b}$$

$$Q_{RL} = \left[(a + a') + 6\,(c + c')\right]/2A \tag{57.12c}$$

$$Q_{LL} = 2\,(b - b')/A \tag{57.12d}$$

with $A = 16$. In the Standard Model, $Q_{LL} = 1$ and the others are zero.

Since the upper bounds on Q_{RR}, Q_{LR}, and Q_{RL} are found to be small, and since the helicity of the ν_μ in pion decay is known from experiment [19, 20] to very high precision to be -1 [21], the cross section S of *inverse* muon decay, normalized to the V-A value, yields [2]

$$|g^S_{LL}|^2 \le 4(1 - S) \tag{57.13a}$$

and

$$|g^V_{LL}|^2 = S\,. \tag{57.13b}$$

Thus the Standard Model assumption of a pure V-A leptonic charged weak interaction of e and μ is derived (within errors) from experiments at energies far below the mass of the $W^\pm$: Eq. (57.13 b) gives a lower limit for V-A, and Eqs. (57.12 a, b, c)

and (57.13 a) give upper limits for the other four-fermion interactions. The existence of such upper limits may also be seen from $Q_{RR}+Q_{RL}=(1-\xi')/2$ (e^+ longitudinal polarization) and $Q_{RR}+Q_{LR}=\frac{1}{2}(1+\xi/3-16\,\xi\delta/9)$ (decay asymmetry). Table 57.1 gives the current experimental limits on the magnitudes of the $g^{\gamma}_{\varepsilon\mu}$'s. More stringent limits on the six coupling constants g^S_{LR}, g^V_{LR}, g^T_{LR}, g^S_{RL}, g^V_{RL}, and g^T_{RL} have been derived from upper limits on the neutrino mass [22]. Limits on the "charge retention" coordinates, as used in the older literature (*e.g.*, Ref. [23]), are given by Burkard *et al.* [24].

58. τ Branching Fractions

Revised August 2025 by Sw. Banerjee (Louisville U.) and A. Lusiani (INFN, Pisa; SNS, Pisa).

58.1 τ Branching Fractions

The τ Listings contains 252 entries that correspond to either a τ partial decay fraction into a specific decay mode (branching fraction) or a ratio of two τ partial decay fractions (branching ratio). Experimental measurements provide values for 148 of these quantities, upper limits for 67 branching fractions to Lepton Family number, Lepton number, or Baryon number violating modes, and 37 additional upper limits for other modes. A total of 129 τ branching fractions and branching ratios are determined with a fit of 171 measurements. 85 quantities have at least one measurement in the fit.

58.2 The constrained fit to τ branching fractions

The τ branching fractions fit uses the reported values, uncertanties and statistical correlations of the τ branching fractions and branching ratios measurements. Asymmetric uncertainties are symmetrized as $\sigma^2_{\rm symm} = (\sigma^2_+ + \sigma^2_-)/2$. If only a few measurements are correlated, the correlation coefficients are listed in the footnote for each measurement (see for example $\Gamma(\text{particle}^- \geq 0\,\text{neutrals} \geq 0\,K^0\nu_\tau$ ("1-prong"))$/\Gamma_{\rm total}$). If a large number of measurements are correlated, then the full correlation matrix is listed in the footnote to the measurement that first appears in the τ Listings. Footnotes to the other measurements refer to the first one. For example, the large correlation matrices for the branching fraction or ratio measurements contained in Refs. [1] [2] are listed in Footnotes to the $\Gamma(e^-\overline{\nu}_e\nu_\tau)/\Gamma_{\rm total}$ and $\Gamma(h^-\nu_\tau)/\Gamma_{\rm total}$ measurements respectively. Additionally, the most precise experimental inputs are treated according to how they depend on external parameters on the basis of their documentation [3]. The τ measurements may depend on parameters such as the τ pair production cross-section in e^+e^- annihilations at the $\Upsilon(4S)$ peak. In some cases, measurements reported in different papers by the same collaboration may depend on common parameters like the estimate of the integrated luminosity or of particle identification efficiencies. For all the significant detected dependencies, the τ measurements and their uncertainties are updated to account for the updated values of the external parameters. The dependencies on common systematic effects are also determined in size and sign, and all the common systematic dependencies of different measurements are used together with the published statistical and systematic uncertainties and correlations in order to compute an updated all-inclusive variance and covariance matrix of the experimental inputs of the fit.

The fit parameters correspond to all measured τ branching fractions and ratios, to some non-measured branching fractions and ratios like for instance $\mathcal{B}(\tau^- \to \pi^- K^0_L K^0_L \nu_\tau)$ and to one nuisance variable. When discussing the fit results in the following, the fit χ^2, the number of degrees of freedom, the residuals and pulls all refer to the subset of fit parameters that correspond to τ branching fractions and ratios, excluding nuisance variables. Due to the small number of nuisance fit parameters with respect to the tau decay fit parameters, we assume that the "restricted" fit χ^2, residuals and pulls approximately share the statistical properties expected for a minimum χ^2 fit. The fit parameters are optimized while respecting relations described by a series of constraint equations. All the experimental inputs and all the constraint equations are reported in the τ Listings section that follows this review. In some cases, constraints describe approximate relations that nevertheless hold within the present experimental precision. For instance, the constraint $\mathcal{B}(\tau^- \to K^-K^-K^+\nu_\tau) = \mathcal{B}(\tau^- \to K^-\phi\nu_\tau) \times \mathcal{B}(\phi \to K^+K^-)$ is only empirically justified within the current experimental evidence. The constraint equations between the τ branching fractions and ratios include quantities other than τ branching fractions and branching ratios, like for instance the branching fractions of the η and ω mesons. We neglect the uncertainties on these values for all quantities except $\mathcal{B}(a_1^- \to \pi^-\gamma)$, whose value and uncertainty were estimated by ALEPH [1] to be $(0.21 \pm 0.08)\cdot 10^{-2}$, relying on a measurement of $\Gamma(a_1^- \to \pi^-\gamma)$ [4]. This quantity is included in the fit parameters as nuisance variable, with a χ^2 term corresponding to its estimate,

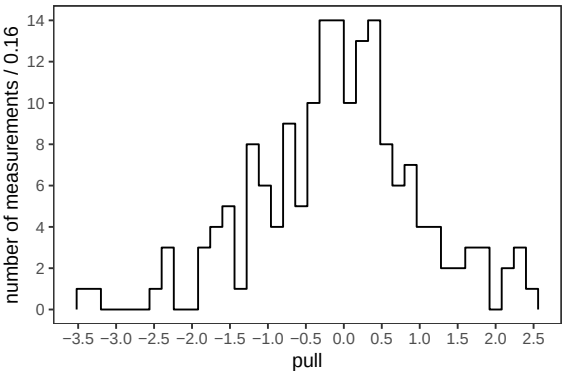

Figure 58.1: Pulls of individual measurements against the respective fitted quantity.

which is accomodated without a dedicated treatment in the general framework of the fit procedure described in Section 58.5. We assume that

$$\begin{aligned}\mathcal{B}(\tau^- \to a_1^-\nu_\tau) = \mathcal{B}(\tau^- \to \pi^-\pi^+\pi^-\nu_\tau\ (\text{ex.}K^0,\omega))+ \\ \mathcal{B}(\tau^- \to \pi^- 2\pi^0\nu_\tau\ (\text{ex.}K^0))+ \\ \mathcal{B}(\tau^- \to a_1^-(\pi^-\gamma)\nu_\tau)\ ,\end{aligned} \tag{58.1}$$

neglecting the observed but negligible branching fractions to other modes, and that

$$\mathcal{B}(\tau^- \to a_1^-(\pi^-\gamma)\nu_\tau) = \mathcal{B}(\tau^- \to a_1^-\nu_\tau)\cdot\mathcal{B}(a_1^- \to \pi^-\gamma)\ . \tag{58.2}$$

The values of all other quantities in the constraint equations are taken from the 2024 edition of the Review of Particle Physics.

In the fit, uncertainty scale factors are applied to the published uncertainties of measurements only if significant inconsistency between different measurements remain after accounting for all relevant uncertainties and correlations. When performing the fit with no scale factors, the two measurements of $\mathcal{B}(\tau^- \to K^-K^-K^+\nu_\tau)$ have pulls exceeding $5\,\sigma$ from the fit values. There are 171 pulls, one per measurement. They are partially correlated, and the effective number of independent pulls is equal to the number of degrees of freedom of the fit, 126. The probability of getting pulls equal or larger than either one of the two very large pulls in a sample of 126 is smaller than the probability of a $3\,\sigma$ deviation for a Normal variable. Therefore, it has been decided to apply an uncertainty scale factor of 5.4 on all measurements of $\mathcal{B}(\tau^- \to K^-K^-K^+\nu_\tau)$ (one by BaBar and one by Belle). The scale factor has been computed according to the standard PDG procedure. After applying the scale factor, the pull distribution of the measurements in figure 58.1 is reasonably Normal and the pull probability distribution in figure 58.2 is reasonably flat.

Considering only the residuals with respect to τ branching fractions and ratios measurements, the constrained fit has a χ^2 of 138 for 126 degrees of freedom, corresponding to a χ^2 probability of 21.3%. We use 171 measurements and 84 constraints on the branching fractions and ratios to determine 129 quantities, consisting of 112 branching fractions and 17 branching ratios. The constraints include the unitarity constraint on the sum of all the exclusive τ decay modes, $\mathcal{B}_{\rm all} = 1$. If the unitarity constraint is released, the fit result for $\mathcal{B}_{\rm all}$ is consistent with unitarity with $1 - \mathcal{B}_{\rm all} = (0.07 \pm 0.11)\%$.

For the convenience of summarizing the fit results, we list in Table 58.1 the values and uncertainties for a set of 46 "basis" decay modes, from which all remaining branching fractions and ratios can be obtained using the constraints. The sum of all known τ branching fractions, which adds up to one according to the unitarity constraint, can be obtained by summing the fit values of all "basis" modes with a few adjustements:

- the modes $\mathcal{B}(\tau^- \to \pi^- K^0_S K^0_S \nu_\tau)$ and $\mathcal{B}(\tau^- \to \pi^- K^0_S K^0_S \pi^0 \nu_\tau)$ are both summed with a weight of 2, in or-

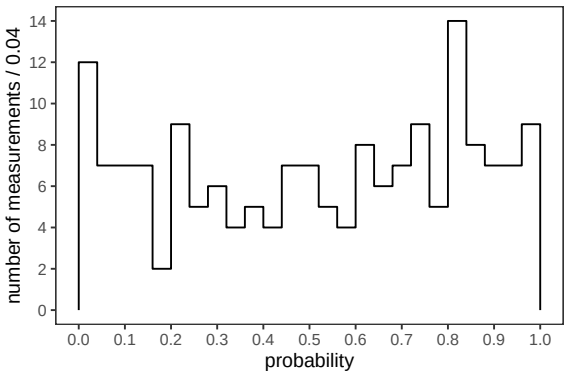

Figure 58.2: Probability of individual measurement pulls against the respective fitted quantity.

der to include the corresponding modes with K_L's, which are predicted to have the same respective branching fractions by the constraint equations;

- the mode $\mathcal{B}(\tau^- \to K^-\phi\nu_\tau)$ has a weight smaller than 1 because some of its final states are described by other "basis" modes;
- the modes $\mathcal{B}(\tau^- \to \pi^-2\pi^0\nu_\tau$ (ex.K^0)) and $\mathcal{B}(\tau^- \to \pi^-\pi^+\pi^-\nu_\tau$ (ex.K^0,ω)) have weights slighly larger than 1 to account for the $\mathcal{B}(\tau^- \to a_1^-(\pi^-\gamma)\nu_\tau)$ mode, which is predicted by them according to the constraint Eqs. 58.1 and 58.2.

Table 58.1 reports the weights with which the "basis" modes are summed to get the total τ branching fraction. The correlation matrix between the basis modes is reported in the τ Listings.

In defining the fit constraints and in selecting the modes that sum up to one we made some assumptions and choices. We assume that some channels, like $\tau^- \to \pi^-K^+\pi^- \geq 0\pi^0\nu_\tau$ and $\tau^- \to \pi^+K^-K^- \geq 0\pi^0\nu_\tau$, have negligible branching fractions as expected from the Standard Model, even if the experimental limits for these branching fractions are not very stringent. The 95% confidence level upper limits are $\mathcal{B}(\tau^- \to \pi^-K^+\pi^- \geq 0\pi^0\nu_\tau) < 0.25\%$ and $\mathcal{B}(\tau^- \to \pi^+K^-K^- \geq 0\pi^0\nu_\tau) < 0.09\%$, values not so different from measured branching fractions for allowed 3-prong modes containing charged kaons. For decays to final states containing one neutral kaon we assume that the branching fractions with the K_L^0 are the same as the corresponding one with a K_S^0. On decays with two neutral kaons we assume that the branching fractions with $K_L^0K_L^0$ are the same as the ones with $K_S^0K_S^0$.

58.3 New measurements in this edition

With respect to the 2024 editions of the τ Listings and of this Review, a new precise measurement of the branching ratio $\mathcal{B}_\mu/\mathcal{B}_e = \mathcal{B}(\tau^- \to \mu^-\bar\nu_\mu\nu_\tau)/\mathcal{B}(\tau^- \to e^-\bar\nu_e\nu_\tau)$ by the Belle II collaboration [5] has been added. The updated fit has a slightly smaller value of $\mathcal{B}_\mu = \mathcal{B}(\tau^- \to \mu^-\bar\nu_\mu\nu_\tau)$ and a slightly larger value of $\mathcal{B}_e = \mathcal{B}(\tau^- \to e^-\bar\nu_e\nu_\tau)$, while $\mathcal{B}_\mu/\mathcal{B}_e$ has decreased and is closer to the Standard Model prediction. The other fit branching fractions and ratios have negligible changes.

58.4 Overconsistency of leptonic branching fraction and ratio measurements

As observed in the previous editions of this review, measurements of the leptonic branching fractions are more consistent with each other than expected from the quoted uncertainties on the individual measurements. When fitting all measurements of $\mathcal{B}_\mu$, $\mathcal{B}_e$ and $\mathcal{B}_\mu/\mathcal{B}_e$, the χ^2/n.d.o.f. is 2.6/11 and the probability of getting a smaller χ^2 is 0.53%.

58.5 Technical implementation of the fit

The fit computes a set of quantities denoted with q_i by minimizing a χ^2 while respecting a series of equality constraints on the q_i. The quantities q_i represent τ branching fractions and branching ratios, and nuisance variables. The fit minimization procedure is equivalent to choosing a set of basis fit variables, using functions of these basis variables to predict measurements, and determining these basis variables by minimizing the measurements' χ^2. The χ^2 is computed using the measurements m_i and their covariance matrix M_{ij} as $\chi^2 = (m_i - A_{ik}q_k)^t M_{ij}^{-1}(m_j - A_{jl}q_l)$, where the model matrix A_{ij} is used to get the vector of the predicted measurements m'_i from the vector of the fit parameters q_j as $m'_i = A_{ij}q_j$. There is one fit variable for each of the modes that have measurements, therefore $A_{ij} = 1$ when q_j corresponds to the τ branching fraction or branching ratio of the measurement m_i, and $A_{ij} = 0$ otherwise. The constraints are equations involving the fit parameters. The fit does not impose limitations on the functional form of the constraints. In summary, the fit requires:

$$\min\left[\chi^2(q_k)\right] = \min\left[(m_i - A_{ik}q_k)^t M_{ij}^{-1}(m_j - A_{jl}q_l)\right] \ , \quad (58.3)$$

$$\text{subjected to} \quad f_r(q_s) - c_r = 0 \ , \quad (58.4)$$

where the left term of Eq. 58.4 defines the constraint expressions. Using the method of Lagrange multipliers, a set of equations is obtained by taking the derivatives with respect to the fitted quantities q_k and the Lagrange multipliers λ_r of the sum of the χ^2 and the constraint expressions multiplied by the Lagrange multipliers

Table 58.1: Values, uncertainties and unitarity-constraint coefficients of the 46 "basis" modes of the τ branching fractions and ratios fit.

λ_r, one for each constraint:

$$\min\left[(m_i - A_{ik}q_k)^t M_{ij}^{-1}(m_j - A_{jl}q_l) + 2\lambda_r(f_r(q_s) - c_r)\right] = \\ = \min\left[\tilde{\chi}^2(q_k, \lambda_r)\right] \ , \\ (\partial/\partial q_k, \partial/\partial\lambda_r)\left[\tilde{\chi}^2(q_k, \lambda_r)\right] = 0 \ . \quad (58.5)$$

Eq. 58.5 defines a set of equations for the vector of the unknowns (q_k, λ_r), some of which may be non-linear, in case of non-linear constraints. An iterative minimization procedure approximates at each step the non-linear constraint expressions by their first order Taylor expansion around the current values of the fitted quantities, $\bar{q}_s$:

$$f_r(q_s) - c_r = f_r(\bar{q}_s) + \left.\frac{\partial f_r(q_s)}{\partial q_s}\right|_{\bar{q}_s}(q_s - \bar{q}_s) - c_r \ ,$$

which can be written as

$$B_{rs}q_s - c'_r \ ,$$

where c'_r are the resulting known terms, independent of q_s at first order. After the linearization of the constraint expressions in $\tilde{\chi}^2(q_k, \lambda_r)$, the differentiation by q_k and λ_r is trivial and leads to a set of linear equations

$$A_{ki}^t M_{ij}^{-1} A_{jl} q_l + B_{kr}^t \lambda_r = A_{ki}^t M_{ij}^{-1} m_j \ , \quad (58.6)$$

$$B_{rs}q_s = c'_r \ , \quad (58.7)$$

which can be expressed as

$$F_{ij}u_j = v_i \ , \quad (58.8)$$

where $u_j = (q_k, \lambda_r)$ and v_i is the vector of the known constant terms running over the index k and then r in the right terms of Eq. 58.6 and Eq. 58.7, respectively. Solving the equation set in Eq. 58.8 by matrix inversion gives the the fitted quantities and their variance and covariance matrix, using the measurements and their variance and covariance matrix. The fit procedure starts by computing the linear approximation of the non-linear constraint expressions around the quantities seed values. With an iterative procedure, the unknowns are updated at each step by solving the equations and the equations are then linearized around the updated values, until the variation of the fitted unknowns is reduced below a numerically small threshold.

59. τ-Lepton Decay Parameters

Revised February 2024 by A. Stahl (RWTH Aachen U.).

The purpose of the measurements of the decay parameters (also known as Michel parameters) of the τ is to determine the structure (spin and chirality) of the current mediating its decays.

59.1 Leptonic Decays:

The Michel parameters are extracted from the energy spectrum of the charged daughter lepton $\ell = e, \mu$ in the decays $\tau \to \ell\nu_\ell\nu_\tau$. Ignoring radiative corrections, neglecting terms of order $(m_\ell/m_\tau)^2$ and $\left(m_\tau/\sqrt{s}\right)^2$, and setting the neutrino masses to zero, the spectrum in the laboratory frame reads

$$\frac{d\Gamma}{dx} = \frac{G_{\tau\ell}^2\, m_\tau^5}{192\,\pi^3} \times \left\{ f_0(x) + \rho f_1(x) + \eta \frac{m_\ell}{m_\tau} f_2(x) - P_\tau \left[\xi g_1(x) + \xi\delta g_2(x)\right] \right\} \tag{59.1}$$

with

$$\begin{aligned} f_0(x) &= 2 - 6\,x^2 + 4\,x^3 \\ f_1(x) &= -\tfrac{4}{9} + 4x^2 - \tfrac{32}{9}x^3 \qquad g_1(x) = -\tfrac{2}{3} + 4x - 6x^2 + \tfrac{8}{3}x^3 \\ f_2(x) &= 12\,(1-x)^2 \qquad\qquad g_2(x) = \tfrac{4}{9} - \tfrac{16}{3}x + 12x^2 - \tfrac{64}{9}\,x^3\,. \end{aligned} \tag{59.2}$$

The quantity x is the fractional energy of the daughter lepton ℓ, *i.e.*, $x = E_\ell/E_{\ell,max} \approx E_\ell/(\sqrt{s}/2)$ and P_τ is the polarization of the tau leptons. The integrated decay width is given by

$$\Gamma = \frac{G_{\tau\ell}^2\, m_\tau^5}{192\,\pi^3}\left(1 + 4\,\eta\,\frac{m_\ell}{m_\tau}\right)\,. \tag{59.3}$$

The situation is similar to muon decays $\mu \to e\nu_e\nu_\mu$. The generalized matrix element with the couplings $g_{\varepsilon\mu}^\gamma$ and their relations to the Michel parameters ρ, η, ξ, and δ have been described in the "Note on Muon Decay Parameters". The Standard Model expectations are 3/4, 0, 1, and 3/4, respectively. For more details, see [1].

More information can be extracted from the decays, if the polarization of the daughter lepton is measured. Belle presented a first result (see [2]). A new parameter ξ' is introduced. Its relation to the couplings is given by (see [3]):

$$\xi' = 1 - 2\sum_{\omega=L,R}\left(\frac{1}{4}\left|g_{R\omega}^S\right|^2 + \left|g_{R\omega}^V\right|^2\right) + 3\left|g_{RL}^T\right|^2\,. \tag{59.4}$$

The new measurement improves the limit on g_{RL}^T by about a factor of two.

Additional Michel parameters can be defined in radiative decays $\tau \to \ell\nu_\ell\nu_\tau\gamma$, see [4]. A first measurement is presented in [5]. The experimental precision does not provide a significant impact on the knowledge about the couplings, yet.

59.2 Hadronic Decays:

In the case of hadronic decays $\tau \to h\nu_\tau$, with $h = \pi$, ρ, or a_1, the ansatz is restricted to purely vectorial currents. The matrix element is

$$\frac{G_{\tau h}}{\sqrt{2}}\sum_{\lambda=R,L} g_\lambda\ \langle\ \overline{\Psi}_\omega(\nu_\tau)\ |\ \gamma^\mu\ |\ \Psi_\lambda(\tau)\ \rangle\ \ J_\mu^h \tag{59.5}$$

with the hadronic current J_μ^h. The neutrino chirality ω is uniquely determined from λ. The spectrum depends only on a single parameter ξ_h

$$\frac{d^n\Gamma}{dx_1 dx_2 \ldots dx_n} = f(\vec{x}) + \xi_h P_\tau\, g(\vec{x})\ , \tag{59.6}$$

with f and g being channel-dependent functions of the n observables $\vec{x} = (x_1, x_2, \ldots, x_n)$ (see [6]). The parameter ξ_h is related to the couplings through

$$\xi_h = |g_L|^2 - |g_R|^2\,. \tag{59.7}$$

ξ_h is the negative of the chirality of the τ neutrino in these decays. In the Standard Model, $\xi_h = 1$. Also included in the Data Listings for ξ_h are measurements of the neutrino helicity which coincide with ξ_h, if the neutrino is massless (ASNER 00 [7], ACKERSTAFF 97R [8], AKERS 95P [9], ALBRECHT 93C [10], and ALBRECHT 90I [11]).

59.3 Combination of Measurements:

The individual measurements are combined, taking into account the correlations between the parameters. In a first fit, universality between the two leptonic decays, and between all hadronic decays, is assumed. A second fit is made without these assumptions. The results of the two fits are provided as OUR FIT in the Data Listings below in the tables whose title includes "(e or mu)" or "(all hadronic modes)", and "(e)", "(mu)" *etc.*, respectively. The measurements show good agreement with the Standard Model. The χ^2 values with respect to the Standard model predictions are 24.1 for 41 degrees of freedom and 26.8 for 56 degrees of freedom, respectively. The correlations are reduced through this combination to less than 20%, with the exception of ρ and η which are correlated by +23%, for the fit with universality and by +70% for $\tau \to \mu\nu_\mu\nu_\tau$.

59.4 Model-independent Analysis:

From the Michel parameters, limits can be derived on the couplings $g_{\varepsilon\lambda}^\kappa$ without further model assumptions. In the Standard model $g_{LL}^V = 1$ (leptonic decays), and $g_L = 1$ (hadronic decays) and all other couplings vanish. First, the partial decay widths have to be compared to the Standard Model predictions to derive limits on the normalization of the couplings $A_x = G_{\tau x}^2/G_F^2$ with Fermi's constant G_F:

$$\begin{aligned} A_e &= 1.0022 \pm 0.0041\ , \\ A_\mu &= 0.983 \pm 0.017\ , \\ A_\pi &= 0.9957 \pm 0.0049\ . \end{aligned} \tag{59.8}$$

Then limits on the couplings (95% CL) can be extracted (see [12] and [13]). Without the assumption of universality, the limits given in Table 59.1 are derived.

Table 59.1: Coupling constants $g_{\varepsilon\mu}^\gamma$. 95% confidence level experimental limits. The limits include the quoted values of A_e, A_μ, and A_π and assume $A_\rho = A_{a_1} = 1$.

$\tau \to e\nu_e\nu_\tau$		
$\lvert g_{RR}^S\rvert < 0.70$	$\lvert g_{RR}^V\rvert < 0.17$	$\lvert g_{RR}^T\rvert \equiv 0$
$\lvert g_{LR}^S\rvert < 0.99$	$\lvert g_{LR}^V\rvert < 0.13$	$\lvert g_{LR}^T\rvert < 0.082$
$\lvert g_{RL}^S\rvert < 2.01$	$\lvert g_{RL}^V\rvert < 0.52$	$\lvert g_{RL}^T\rvert < 0.51$
$\lvert g_{LL}^S\rvert < 2.01$	$\lvert g_{LL}^V\rvert < 1.004$	$\lvert g_{LL}^T\rvert \equiv 0$
$\tau \to \mu\nu_\mu\nu_\tau$		
$\lvert g_{RR}^S\rvert < 0.72$	$\lvert g_{RR}^V\rvert < 0.18$	$\lvert g_{RR}^T\rvert \equiv 0$
$\lvert g_{LR}^S\rvert < 0.95$	$\lvert g_{LR}^V\rvert < 0.12$	$\lvert g_{LR}^T\rvert < 0.079$
$\lvert g_{RL}^S\rvert < 2.01$	$\lvert g_{RL}^V\rvert < 0.52$	$\lvert g_{RL}^T\rvert < 0.27$
$\lvert g_{LL}^S\rvert < 2.01$	$\lvert g_{LL}^V\rvert < 1.006$	$\lvert g_{LL}^T\rvert \equiv 0$
$\tau \to \pi\nu_\tau$		
$\lvert g_R^V\rvert < 0.15$	$\lvert g_L^V\rvert > 0.984$	
$\tau \to \rho\nu_\tau$		
$\lvert g_R^V\rvert < 0.10$	$\lvert g_L^V\rvert > 0.995$	
$\tau \to a_1\nu_\tau$		
$\lvert g_R^V\rvert < 0.16$	$\lvert g_L^V\rvert > 0.987$	

59.5 Model-dependent Interpretation:

More stringent limits can be derived assuming specific models. For example, in the framework of a two Higgs doublet model, the measurements correspond to a limit of $m_{H^\pm} > 2.0$ GeV $\times \tan\beta$ on the mass of the charged Higgs boson, or a limit of 500 GeV on the mass of the second W boson in left-right symmetric models for arbitrary mixing (both 95% CL). See [13] and [14].

60. Quark Masses

Revised August 2023 by R.M. Barnett (LBNL), L.P. Lellouch (CNRS & Aix-Marseille U.) and A.V. Manohar (UC San Diego).

60.1 Introduction

This note discusses some of the theoretical issues relevant for the determination of quark masses, which are fundamental parameters of the Standard Model of particle physics. Unlike the leptons, quarks are confined inside hadrons and are not observed as physical particles. Quark masses therefore cannot be measured directly, but must be determined indirectly through their influence on hadronic properties. Although one often speaks loosely of quark masses as one would of the mass of the electron or muon, any quantitative statement about the value of a quark mass must make careful reference to the particular theoretical framework that is used to define it. It is important to keep this *scheme dependence* in mind when using the quark mass values tabulated in the data listings.

Historically, the first determinations of quark masses were performed using quark models. These are usually called constituent quark masses and are of order 350 MeV for the u and d quarks. Constituent quark masses model the effects of dynamical chiral symmetry breaking discussed below, and are not directly related to the quark mass parameters m_q of the QCD Lagrangian of Eq. (60.1). The resulting masses only make sense in the limited context of a particular quark model, and cannot be related to the quark mass parameters, m_q, of the Standard Model. In order to discuss quark masses at a fundamental level, definitions based on quantum field theory must be used, and the purpose of this note is to discuss these definitions and the corresponding determinations of the values of the masses.

60.2 Mass parameters and the QCD Lagrangian

The QCD [1] Lagrangian is

$$\mathcal{L} = \sum_{q=u,d,s,\ldots,t} \overline{q}\,(i\not{D} - m_q)\,q - \tfrac{1}{2}\mathrm{tr}\,G_{\mu\nu}G^{\mu\nu}, \tag{60.1}$$

where the sum runs over the quark flavors u, d, s, c, b and t. $\not{D} = (\partial_\mu - igA_\mu)\,\gamma^\mu$ is the gauge covariant derivative, A_μ is the SU(3)-valued gluon field, $G_{\mu\nu} = \frac{i}{g}[D_\mu, D_\nu]$ is the gluon field strength, m_q is the mass parameter of quark flavor q, and q is the quark Dirac field. After renormalization, the QCD Lagrangian Eq. (60.1) gives finite values for physical quantities, such as scattering amplitudes. Renormalization is a procedure that invokes a subtraction scheme to render the amplitudes finite, and requires the introduction of a dimensionful scale parameter μ. The mass parameters in the QCD Lagrangian Eq. (60.1) depend on the renormalization scheme used to define the theory, and also on the scale parameter μ. The most commonly used renormalization scheme for QCD perturbation theory is the $\overline{\mathrm{MS}}$ scheme.

The QCD Lagrangian has a chiral symmetry in the limit that the quark masses vanish. This symmetry is spontaneously broken by dynamical chiral symmetry breaking, and explicitly broken by the quark masses. The nonperturbative scale of dynamical chiral symmetry breaking, Λ_χ, is around 1 GeV [2]. It is conventional to call quarks heavy if $m_q > \Lambda_\chi$, so that explicit chiral symmetry breaking dominates (c, b, and t quarks are heavy), and light if $m_q < \Lambda_\chi$, so that spontaneous chiral symmetry breaking dominates (the u and d are light and the s is considered to be light when using $\mathrm{SU}(3)_L \times \mathrm{SU}(3)_R$ chiral perturbation theory). The determination of light- and heavy-quark masses is considered separately in Sec. 60.5 and Sec. 60.6 below.

At high energies or short distances, nonperturbative effects, such as chiral symmetry breaking, become small and one can, in principle, determine quark masses by analyzing mass-dependent effects using QCD perturbation theory. Such computations are conventionally performed using the $\overline{\mathrm{MS}}$ scheme at a scale $\mu \gg \Lambda_\chi$, and give the $\overline{\mathrm{MS}}$ "running" mass $\overline{m}(\mu)$. We use the $\overline{\mathrm{MS}}$ scheme when reporting quark masses; one can readily convert these values into other schemes using perturbation theory.

The μ dependence of $\overline{m}(\mu)$ at short distances can be calculated using the renormalization group (RG) equation,

$$\mu^2 \frac{\mathrm{d}\overline{m}\,(\mu)}{\mathrm{d}\mu^2} = -\gamma(\overline{\alpha}_s\,(\mu))\;\overline{m}\,(\mu)\,, \tag{60.2}$$

where γ is the anomalous dimension which is now known to four-loop order in perturbation theory [3] [4]. $\overline{\alpha}_s$ is the coupling constant [1] in the $\overline{\mathrm{MS}}$ scheme. Defining the expansion coefficients γ_r by

$$\gamma\,(\overline{\alpha}_s) \equiv \sum_{r=1}^{\infty} \gamma_r \left(\frac{\overline{\alpha}_s}{4\pi}\right)^r, \tag{60.3}$$

the first four coefficients are given by

$$\begin{aligned}
\gamma_1 &= 4,\\
\gamma_2 &= \frac{202}{3} - \frac{20N_L}{9},\\
\gamma_3 &= 1249 + \left(-\frac{2216}{27} - \frac{160}{3}\zeta\,(3)\right) N_L - \frac{140}{81}N_L^2,\\
\gamma_4 &= \frac{4603055}{162} + \frac{135680}{27}\zeta\,(3) - 8800\zeta\,(5)\\
&\quad + \left(-\frac{91723}{27} - \frac{34192}{9}\zeta\,(3) + 880\zeta\,(4) + \frac{18400}{9}\zeta\,(5)\right) N_L\\
&\quad + \left(\frac{5242}{243} + \frac{800}{9}\zeta\,(3) - \frac{160}{3}\zeta\,(4)\right) N_L^2\\
&\quad + \left(-\frac{332}{243} + \frac{64}{27}\zeta\,(3)\right) N_L^3,
\end{aligned}$$

where N_L is the number of active light quark flavors at the scale μ, i.e. flavors with masses $\leq \mu$, and ζ is the Riemann zeta function ($\zeta(3) \simeq 1.2020569$, $\zeta(4) \simeq 1.0823232$, and $\zeta(5) \simeq 1.0369278$). Eq. (60.2) must be solved in conjunction with the RG equation for $\overline{\alpha}_s\,(\mu)$ given in [1]. In addition, as the renormalization scale crosses quark mass thresholds one needs to match the scale dependence of $\overline{m}$ below and above the threshold. There are finite threshold corrections; the necessary formulae can be found in Ref. [5].

60.3 Lattice QCD

Ab initio lattice QCD calculations of the fundamental parameters of QCD, i.e. the coupling constant and quark masses (except for the top-quark mass), has become a precision science (see also the sections on Lattice Quantum Chromodynamics and on Quantum Chromodynamics in this *Review*). Here we only briefly recall those features which are required for the determination of quark masses. For more details on lattice QCD, please see the section on Lattice Quantum Chromodynamics.

The inputs into lattice calculations are bare, dimensionless versions of the fundamental parameters of QCD: the bare strong coupling and the bare quark masses in lattice units, i.e. multiplied by the lattice spacing a, the distance between neighboring points of the lattice. The physical values of the quark masses are determined by computing as many physical quantities as there are parameters, including one for the gauge coupling. In practice, the computations are performed for multiple lattice spacings, determined by the bare coupling via dimensional transmutation, and a number of bare quark masses. After renormalizing these masses and converting them to physical units, the resulting renormalized masses are interpolated to their physical values. This is achieved by requiring that the computed physical quantities reproduce their measured values as the $a \to 0$ limit to our continuum world is taken. Such a tuning of fundamental parameters is required in any regularization of QCD: lattice QCD is simply a tool to perform QCD calculations in the low-energy, nonperturbative domain.

As discussed in the previous paragraph, one must renormalize the bare quark masses of lattice QCD simulations. The values of these bare masses refer to a particular discretization of QCD with the lattice spacing as the ultraviolet cut-off. In order for the resulting physical masses to be useful in phenomenological applications, it is necessary to give their values in some standard

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

renormalization scheme such as $\overline{\rm MS}$. Provided that both the ultraviolet cut-off a^{-1} and the renormalization scale μ are much greater than $\Lambda_{\rm QCD}$, the bare masses can be renormalized in perturbation theory. However, in order to avoid uncertainties due to the unknown higher-order coefficients in lattice perturbation theory, most results obtained recently use *nonperturbative renormalization*. This procedure relates the bare masses to those defined in renormalization schemes which can be realized directly in lattice and continuum QCD, e.g. those obtained from quark and gluon Green functions at specified momenta in the Landau gauge [6] or those defined using finite-volume techniques and the Schrödinger functional [7], but not $\overline{\rm MS}$ that is only defined for dimensional regularization. These methods require $\mu \gg \Lambda_{\rm QCD}$ so that unwanted (nonperturbative) corrections proportional to inverse powers of μ, which appear in some approaches, remain small corrections that can be identified and removed. This condition is also necessary so that matching to other schemes can be performed reliably in perturbation theory. Moreover these methods require $a^{-1} \gg \mu$ so that cutoff effects are small enough to be extrapolated away when the continuum limit is taken. The conversion to the $\overline{\rm MS}$ scheme is then performed using continuum perturbation theory, which is more readily obtained to higher orders and is usually better behaved than its lattice counterpart.

It is important to note that the final renormalized values for the quark masses must be the same in the continuum limit for any valid discretization of QCD and for any sensible choice of the physical quantities used for calibration, as long as the calculation is performed with a sufficient number of sea-quark flavors and with the relevant electromagnetic and strong-isospin breaking corrections for the claimed precision. It is also worth noting that issues surrounding the renormalization of quark masses disappear when considering pairwise ratios of these masses in QCD alone. Indeed, if the same renormalization scheme and scale are implemented, also for the definition of QCD in the absence or electromagnetism,[1] QCD renormalization factors are identical for all quark flavors, and these factors therefore cancel exactly in quark-mass ratio [2]. In particular, this means that these ratios are scheme and scale independent up to possible QED corrections. Moreover these ratios may suffer less from the uncertainties in the determination of the lattice scale, in particular in cases where the quantities used to fix the two quarks masses depend on these masses in a similar way, because these ratios are dimensionless. Thus, quark-mass ratios are often determined with significantly higher precision using lattice QCD than are the individual masses.

The determination of quark masses using lattice simulations is well established and the current emphasis is on the reduction and control of uncertainties. With better methods, improved algorithms and access to more powerful computing resources, the precision of the results has improved significantly in recent years. Vacuum polarization effects are included with $N_f = 2,\ 2+1$ or $N_f = 2+1+1$ flavors of sea quarks. The number 2 here indicates that the up and down quarks are degenerate. The first $+1$ corresponds to the inclusion of strange sea-quark effects and the second $+1$ to those of the charm. Simulations with $2+1$ and $2+1+1$ flavors represent controlled approximations to physical QCD at the low energies considered for quark mass determinations, up to corrections of $O((\Lambda_{\rm QCD}/m_c)^2/N_c)$ and $O((\Lambda_{\rm QCD}/m_b)^2/N_c)$, respectively. This is not the case for simulations with $N_f = 2$ or in which vacuum polarization effects are treated as a mean field (this is the so-called *quenched* approximation) and results obtained in those frameworks will not enter the discussion here.

Particularly pleasing is the observation that different formulations of lattice QCD and different approaches, with different systematic uncertainties, yield results which are largely consistent with each other. This gives us broad confidence in the estimates of the systematic errors. As the precision of the results approaches (or even exceeds in some cases) 1%, isospin breaking effects, including electromagnetic corrections need to be considered and this is beginning to be done as will be discussed below. In particular, a reliable estimate of these effects is required for determining the individual u and d quark masses.

Members of the lattice QCD community have organized a Flavour Lattice Averaging Group (FLAG) which, against stated quality criteria, critically reviews quantities computed in lattice QCD that are relevant to flavor physics and presents its view of the current status of the results. This includes the determination of quark masses. The latest edition reviews lattice results that appeared in print before April 30th 2021 [8]. Since that deadline and the writing of the previous edition of the present review, the only new results on quark masses that have been published are those of Ref. [9].

60.4 Averaging procedure for lattice QCD results

In this review we present summary numbers for each quark mass which are solely based on averages of lattice results. Those summary numbers differ from those presented in the particle listings, for three reasons. The first is that they do not include non-lattice estimates of the quark masses. The second is that they may differ slightly in the lattice results retained, as made explicit here and in the listings. The third difference comes from the averaging procedures, which are described in the listings and below. In the listings, summary numbers are obtained from averages of the individual quark-mass estimates, weighted by their total errors. Moreover, the resulting one-standard-deviation errors are rescaled by the usual $\sqrt{\chi^2/{\rm dof}}$ factor, which is further multiplied by 1.645 to obtain the uncertainty corresponding to a 90% confidence interval. Nevertheless, the averages presented here and in the listings are fully consistent, with comparable uncertainties, signalling the robustness of the two combination procedure.

The results on which the lattice summary numbers presented here are those used in the FLAG reviews, supplemented by any new calculations that satisfy their selection criteria. The methodology that we use is also close to that of FLAG, but here we make an attempt to separate uncertainties into their statistical and systematic components, to provide some idea of what the relative weight of each is for different quark masses. In some cases, also, slightly different choices are also made. Thus, agreement between the results obtained is a further sign of the robustness of the combination procedures used here, as well as in FLAG.

We now lay out our averaging procedure. For each of m_{ud}, m_s or m_s/m_{ud}, and for each of $N_f = 2+1$ or $N_f = 2+1+1$, we perform averages of the relevant, individual lattice results with weights that include the sum in quadrature of the statistical and systematic uncertainties. The weights also account for correlations by assuming that they are 100% on any uncertainty components that may be correlated. This procedure yields a central value and a total error for each of the quantities of interest. The total uncertainty is rescaled by the usual factor of $\sqrt{\chi^2/{\rm dof}}$ if that factor is larger than 1, where χ^2 is the one corresponding to the weighted average procedure. To isolate the statistical component of the uncertainty on any given average, like for the total uncertainty we use the standard error formula for correlated data, this time only taking into account the statistical uncertainties on the different collaborations' results. If the total error has been rescaled, this statistical uncertainty is multiplied by the same factor. The candidate systematic error on an average is then obtained by subtracting in quadrature the statistical uncertainty from the total one. For each quantity, the final systematic error on the average is the largest of two uncertainties: the candidate systematic error and the minimum of the systematic uncertainties on the individual lattice determinations. This guarantees that the final systematic error is no smaller than the one of any given calculation. We then repeat this whole procedure to average the $N_f = 2+1$ and $N_f = 2+1+1$ averages, for reasons discussed below. In cases where the error separation is not explicit in a particular collaboration's result, we assume that the quoted error is statistical and take, as the minimum of systematic error, the smallest non-vanishing one among those of the other individual results. While this procedure may change the balance between statistical and systematic errors, it does change the average (which

[1] Since QCD without QED is not the real world, it makes a difference, for example, which hadron mass is used to tune a quark mass and the QED correction will differ for different choices.

[2] The same remains true in the presence of QED if the two quarks in the ratio have the same charge.

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

is weighted by the total errors of the individual entries and the correlations between them) and does not decrease the total error. When quantities involving m_c or m_b are averaged, we consider only the averages of $N_f = 2+1+1$ calculations, for reasons also explained below.

The values of the individual results used in the averages obtained below can be found in the quark properties listings of this *Review*.

60.5 Light quarks

In this section we review the determination of the masses of the light quarks u, d and s from lattice simulations and then discuss the consequences of the approximate chiral symmetry.

60.5.1 *Lattice QCD results*

The most reliable determinations of the strange quark mass, m_s, and of the up and down quark masses, m_u and m_d, are obtained from lattice simulations. This is reflected in part by the uncertainties of individual determinations of these masses given in this *Review's* listings of quark properties: lattice results typically have smaller error bars than phenomenological extractions. As explained in the previous section, the simulations are generally performed in the isospin-symmetric limit of QCD, i.e. with degenerate up and down quarks ($m_u = m_d$) and the electromagnetic coupling α set to zero. Thus, it is initially $m_{ud} = (m_u + m_d)/2$ which is obtained from the computations. The numerical values of these masses depend on the choice of renormalization scale and scheme. [3]

Below we discuss the derivation of m_u and m_d separately, but we start by briefly presenting our estimates for m_{ud}, m_s and their ratio, using the latest lattice results. FLAG [8] bases its summary numbers on references that the authors consider to have the most reliable estimates of systematic uncertainties, i.e. [12–18] for $N_f = 2+1$ and [19–24] for $N_f = 2+1+1$ flavors of sea quarks. Note that the $N_f = 2+1+1$ results of Ref. [9] did not make the FLAG deadline. In the estimates given below, we use the fact that Ref. [9] supersedes Ref. [22].

Applying the averaging procedure described in the previous section and the results of Refs. [12–18], for $N_f = 2+1$ we obtain $\overline{m}_{ud} = (3.382 \pm 0.026 \pm 0.040[\pm 0.050])$ MeV, $\overline{m}_s = (92.24 \pm 0.24 \pm 1.00[\pm 1.03])$ MeV and $(\overline{m}_s/\overline{m}_{ud}) = 27.42 \pm 0.05 \pm 0.12[\pm 0.12]$. These numbers are $\overline{m}_{ud} = (3.421 \pm 0.035 \pm 0.049[\pm 0.060])$ MeV, $\overline{m}_s = (92.93 \pm 0.51 \pm 0.37[\pm 0.063])$ MeV and $(\overline{m}_s/\overline{m}_{ud}) = 27.25 \pm 0.03 \pm 0.07[\pm 0.08]$ using the latest $N_f = 2+1+1$ calculations [9, 19–21, 23, 24]. The masses are given in the $\overline{\rm MS}$ scheme at a renormalization scale of 2 GeV. In these averages, the first error is statistical, the second systematic and the third one in brackets is the sum in quadrature of the first two. Also, QED corrections have been accounted for only to the extent that they have been removed from the hadron mass inputs phenomenologically.

A few comments are in order concerning the compatibility of the results which enter these averages. We begin with the case of $N_f = 2+1$. For m_{ud} the results show a good degree of compatibility with a $\chi^2/\text{dof} = 5.7/4$ and the final systematic uncertainty is given by the one of Ref. [17]. The level of compatibility is similar in the case of m_s and the final systematic uncertainty is also given by the one of Ref. [17]. For m_s/m_{ud} the results are even more compatible and here the final systematic error is derived from the averaging procedure. In the case of $N_f = 2+1+1$, there are only two results for m_{ud} [9, 20] and their level of compatibility is poor, with $\chi^2/\text{dof} = 6.4/1$. This is due to the value of Ref. [9], $m_{ud} = (3.636 \pm 0.066 \pm 0.059)$ MeV, which is significantly larger than all other determinations, including those obtained in $N_f = 2+1$ determinations. The scenario repeats for m_s, but is diluted by the fact that there are four results [9, 19–21] which enter the average. However, compatibility is recovered for m_s/m_{ud}, suggesting a problem in the determination of the renormalization constants or the lattice spacing in at least one of the calculations. Since the different collaborations use different formulations of lattice QCD, the (relatively) small variations of the results between the groups provides important information about the reliability of the estimates. Furthermore, the conservative nature of our method for estimating uncertainties is confirmed by the excellent agreement of the averages obtained for $N_f = 2+1$ and $N_f = 2+1+1$ calculations.

Despite being reported in the $\overline{\rm MS}$ scheme at a renormalization scale of 2 GeV, the schemes in simulations with $2+1$ and $2+1+1$ sea-quark flavors actually differ. This is because the former are renormalized with $N_L = 3$ and the latter with $N_L = 4$. Thus for a comparison one should convert the results to the same scheme. That is not the case for (m_s/m_{ud}), where renormalization factors cancel in the absence of electromagnetic corrections. The conversion of the $N_f = 2+1$ results to the $N_L = 4$ scheme can be performed, for instance, by running them down to the charm threshold in the $N_L = 3$ theory, matching the results to the $N_L = 4$ theory at that scale, and running them back up to 2 GeV with four active flavors. Such a conversion leads to an upward shift in the values of the quark masses of only around 0.3%, well within the quoted uncertainties on the quark masses themselves. Quark-mass ratios are not concerned by this upward shift, because it is identical for the numerator and denominator. There are also nonperturbative contributions to this procedure, of $O((\Lambda_{\rm QCD}/m_c)^2/N_c) \sim 2\%$. However lattice QCD studies of these effects have shown that they are typically an order of magnitude smaller on hadronic quantities or on $\Lambda_{\rm QCD}$ [25, 26]. Given that the total errors on the $N_f = 2+1$ results for $\overline{m}_{ud}$ and $\overline{m}_s$ are larger than 1%, we consider these matching effects negligible. In addition, for m_{ud} in particular there are six $N_f = 2+1$ calculations in which all sources of uncertainty have been accounted for, while there are only two for $N_f = 2+1+1$. Thus, we average the averages from the two frameworks in the same way as above (see Sec. 60.4), yielding as a final lattice QCD estimate in the $\overline{\rm MS}$ scheme at $\mu = 2\,\text{GeV}$ in the $N_L = 4$ theory:

$$\overline{m}_{ud} = (3.397 \pm 0.021 \pm 0.040[\pm 0.045])\,\text{MeV}, \tag{60.4}$$

$$\overline{m}_s = (92.74 \pm 0.22 \pm 0.49[\pm 0.54])\,\text{MeV}, \tag{60.5}$$

and

$$r_s \equiv \frac{\overline{m}_s}{\overline{m}_{ud}} = 27.30 \pm 0.03 \pm 0.07[\pm 0.08]. \tag{60.6}$$

In these averages, the first error is statistical, the second systematic and the third one in brackets is the sum in quadrature of the first two. QED corrections have been accounted for only to the extent that they have been removed from the hadron mass inputs phenomenologically. It is worth noting that the result for r_s in Eq. (60.6) is identical to the ratio of m_s and m_{ud} from Eqs. (60.4) and (60.5), within the four digits for r_s given in Eq. (60.6), albeit with a significantly smaller total uncertainty.

To obtain the individual values of $\overline{m}_u$ and $\overline{m}_d$ requires the introduction of isospin breaking effects, including electromagnetism. This is now being done completely using lattice field theory, albeit neglecting electromagnetic effects in the sea in most cases (for an exception, see Ref. [27] which includes a calculation of the valence and sea QED contributions to $\Delta M_K^2 = M_{K^0}^2 - M_{K^+}^2$ that is critical for determining $\overline{m}_d - \overline{m}_u$). The effect of neglecting QED contributions from the sea on the u and d quark masses has been estimated in Ref. [28] to induce a contribution to the uncertainty that ranges from about 3% in $\overline{m}_u/\overline{m}_d$ to less than 1% in $\overline{m}_d$. FLAG has also reviewed results for these masses [8]. Again, they separate results obtained from $N_f = 2+1$ and $N_f = 2+1+1$ simulations. For the former, they use the results of Ref. [28] and for the latter, those of Refs. [20, 29, 30].

To obtain our estimates, we proceed as for the light quark masses above. For $N_f = 2+1$, our estimates are the results

[3] If QED is not included, then quark masses also depend on the conditions used to match isospin-symmetric QCD to the low energy effective theory of the Standard Model, which includes QCD and QED with $m_u \neq m_d$. Those matching conditions, which define a matching scheme, are quite similar in the calculations reported on below. Moreover, they have been designed to minimize the impact of isospin-breaking effects on isospin-symmetric combinations of quark masses, such m_{ud} and m_s here, and m_c and m_b below. Thus, as does FLAG [8], we generally assume that any remaining differences between schemes are within the quoted errors. Such an assumption is certainly true for $\overline{m}_c(\overline{m}_c)$ [10], where QED effects have been studied explicitly. On the other hand, in the case of m_b/m_c, where the effects of QED have also been studied explicitly [11] and where uncertainties are less than 0.3%, these effects are no longer negligible.

of the only calculation in which all sources of uncertainty are accounted for [28]. These are $\overline{m}_u = (2.27 \pm 0.06 \pm 0.06[\pm 0.09])$ MeV, $\overline{m}_d = (4.67 \pm 0.06 \pm 0.06[\pm 0.09])$ MeV and $\overline{m}_u/\overline{m}_d = (0.485 \pm 0.011 \pm 0.016[\pm 0.020])$. For $N_f = 2+1+1$, they rely on Refs. [20, 29, 30]. Our estimates are $\overline{m}_u = (2.14 \pm 0.04 \pm 0.07[\pm 0.08])$ MeV, $\overline{m}_d = (4.70 \pm 0.03 \pm 0.04[\pm 0.05])$ MeV and $\overline{m}_u/\overline{m}d = (0.460 \pm 0.008 \pm 0.018[\pm 0.020])$. These masses are given the the $\overline{\rm MS}$ scheme at 2 GeV in the $N_L = 3$ and 4 theories, respectively. Given the size of the uncertainties on these averages, tiny corrections due to QED effects in the renormalization constants have been neglected.

In obtaining the $N_f = 2+1+1$ averages, there is a significant $\chi^2/1 = 4.7$ tension between the two results for m_u [20, 29] and a $\chi^2/1 = 3.4$ one between those for m_u/m_d [29,30]. These tensions are accounted for by the usual rescaling of uncertainties. However, agreement is found between the two results for m_d [20, 29]. Moreover, at the level of our conservative uncertainties, agreement is found with the $N_f = 2+1$ results.

Again, given the small number of results and the few percent uncertainties, we average the $N_f = 2+1$ and $N_f = 2+1+1$ results, as explained in Sec. 60.4, to obtain our final estimates:

$$\overline{m}_u = (2.20 \pm 0.04 \pm 0.06[\pm 0.07])\,\text{MeV}, \tag{60.7}$$

$$\overline{m}_d = (4.69 \pm 0.03 \pm 0.04[\pm 0.05])\,\text{MeV}, \tag{60.8}$$

$$r \equiv \frac{\overline{m}_u}{\overline{m}_d} = (0.473 \pm 0.007 \pm 0.016[\pm 0.017]), \tag{60.9}$$

where the three uncertainties have the same meaning as described after Eq. 60.6. r in Eq. (60.9) is the combination of direct lattice computations of that ratio in which some systematics cancel. The averages are given in the $\overline{\rm MS}$ scheme at 2 GeV in the $N_L = 4$ theory and, as above, tiny corrections due to QED effects in the renormalization constants have been neglected. Within one standard deviation it agrees with the ratio of $\overline{m}_u$ over $\overline{m}_d$ from Eqs. (60.7) and (60.8).

It is also worth noting that m_u differs from zero by more than 30 times the quoted error, making a scenario in which $m_u = 0$ very unlikely. This is important because there would be no strong CP problem if m_u were to vanish.

60.5.2 *Chiral Perturbation Theory*

For light quarks, one can use the techniques of chiral perturbation theory [31–33] to extract quark mass ratios. The mass term for light quarks in the QCD Lagrangian is

$$\overline{\Psi} M \Psi = \overline{\Psi}_L M \Psi_R + \overline{\Psi}_R M^\dagger \Psi_L, \tag{60.10}$$

where M is the light quark mass matrix,

$$M = \begin{pmatrix} m_u & 0 & 0 \\ 0 & m_d & 0 \\ 0 & 0 & m_s \end{pmatrix}, \tag{60.11}$$

$\Psi = (u, d, s)$, and L and R are the left- and right-chiral components of Ψ given by $\Psi_{L,R} = P_{L,R}\Psi$, $P_L = (1-\gamma_5)/2$, $P_R = (1+\gamma_5)/2$. The mass term is the only term in the QCD Lagrangian that mixes left- and right-handed quarks. In the limit $M \to 0$, there is an independent SU(3)×U(1) flavor symmetry for the left- and right-handed quarks. The vector U(1) symmetry is baryon number; the axial U(1) symmetry of the classical theory is broken in the quantum theory due to the anomaly. The remaining $G_\chi = {\rm SU}(3)_L \times {\rm SU}(3)_R$ chiral symmetry of the QCD Lagrangian is spontaneously broken to ${\rm SU}(3)_V$, which, in the limit $M \to 0$, leads to eight massless Goldstone bosons, the π's, K's, and η.

The symmetry G_χ is only an approximate symmetry, since it is explicitly broken by the quark mass matrix M. The Goldstone bosons acquire masses which can be computed in a systematic expansion in M, in terms of low-energy constants, which are unknown nonperturbative parameters of the effective theory, and are not fixed by the symmetries. One treats the quark mass matrix M as a uniform, external field that transforms under G_χ as $M \to LMR^\dagger$, where $\Psi_L \to L\Psi_L$ and $\Psi_R \to R\Psi_R$ are the ${\rm SU}(3)_L$ and ${\rm SU}(3)_R$ transformations, and writes down the most general Lagrangian invariant under G_χ. Then one sets M to its given constant value Eq. (60.11), which implements the symmetry breaking. To first order in M one finds that [34]

$$\begin{aligned} m^2_{\pi^0} &= B\,(m_u + m_d)\,, \\ m^2_{\pi^\pm} &= B\,(m_u + m_d) + \Delta_{\rm em}, \\ m^2_{K^0} &= m^2_{\overline{K}{}^0} = B\,(m_d + m_s)\,, \\ m^2_{K^\pm} &= B\,(m_u + m_s) + \Delta_{\rm em}, \\ m^2_\eta &= \frac{1}{3} B\,(m_u + m_d + 4m_s)\,, \end{aligned} \tag{60.12}$$

with two unknown constants B, related to the light quark condensate, and $\Delta_{\rm em}$, the electromagnetic mass difference. From Eq. (60.12), one can determine the quark mass ratios [34]

$$\begin{aligned} \frac{m_u}{m_d} &= \frac{2m^2_{\pi^0} - m^2_{\pi^+} + m^2_{K^+} - m^2_{K^0}}{m^2_{K^0} - m^2_{K^+} + m^2_{\pi^+}} = 0.56, \\ \frac{m_s}{m_d} &= \frac{m^2_{K^0} + m^2_{K^+} - m^2_{\pi^+}}{m^2_{K^0} + m^2_{\pi^+} - m^2_{K^+}} = 20.2, \end{aligned} \tag{60.13}$$

to lowest order in chiral perturbation theory, with an error which will be estimated below. Since the mass ratios extracted using chiral perturbation theory use the symmetry transformation property of M under the chiral symmetry G_χ, it is important to use a renormalization scheme for QCD that does not change this transformation law. Any mass-independent subtraction scheme such as $\overline{\rm MS}$ is suitable. The ratios of quark masses are scale independent in such a scheme (up to electromagnetic corrections), and Eq. (60.13) can be taken to be the ratio of $\overline{\rm MS}$ masses. Chiral perturbation theory cannot determine the overall scale of the quark masses, since it uses only the symmetry properties of M, and any multiple of M has the same G_χ transformation law as M.

Chiral perturbation theory is a systematic expansion in powers of the light quark masses. The typical expansion parameter is $m^2_K/\Lambda^2_\chi \sim 0.25$ if one uses SU(3) chiral symmetry, and $m^2_\pi/\Lambda^2_\chi \sim 0.02$ if instead one uses SU(2) chiral symmetry. Electromagnetic effects at the few percent level also break SU(2) and SU(3) symmetry. The mass formulæ Eq. (60.12) were derived using SU(3) chiral symmetry, and are expected to have approximately a 25% uncertainty due to second order corrections. This estimate of the uncertainty yields results consistent with the lattice results summarized in Eq. (60.5)–(60.6).

There is a subtlety which arises when one tries to determine quark mass ratios at second order in chiral perturbation theory. The second order quark mass term [35]

$$\left(M^\dagger\right)^{-1} \det M^\dagger \tag{60.14}$$

(which can be generated by instantons) transforms in the same way under G_χ as M. Chiral perturbation theory cannot distinguish between M and $(M^\dagger)^{-1} \det M^\dagger$; one can make the replacement $M \to M(\lambda) = M + \lambda M (M^\dagger M)^{-1} \det M^\dagger$ in the chiral Lagrangian,

$$\begin{aligned} M(\lambda) &= \text{diag}\,(m_u(\lambda),\ m_d(\lambda),\ m_s(\lambda)) \\ &= \text{diag}\,(m_u + \lambda m_d m_s,\ m_d + \lambda m_u m_s,\ m_s + \lambda m_u m_d)\,, \end{aligned} \tag{60.15}$$

and leave all observables unchanged.

The combination

$$\left(\frac{m_u}{m_d}\right)^2 + \frac{1}{Q^2}\left(\frac{m_s}{m_d}\right)^2 = 1 \tag{60.16}$$

where

$$Q^2 = \frac{m_s^2 - m_{ud}^2}{m_d^2 - m_u^2}, \qquad m_{ud} = \frac{1}{2}\,(m_u + m_d)\,,$$

is insensitive to the transformation in Eq. (60.15). Eq. (60.16) gives an ellipse in the m_u/m_d-m_s/m_d plane. The ellipse is well-determined by chiral perturbation theory, but the location on the

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

ellipse, and the absolute normalization of the quark masses, have larger uncertainties.

A leading-order result for Q in SU(3) chiral perturbation theory can be derived using Eq. (60.12) and the values for the relevant meson masses. This result actually holds to next-to-leading order, yielding $Q \overset{\text{NLO}}{=} 24.3$. Phenomenologically, the preferred way to determine Q is from $\eta \to 3\pi$ decay, giving the smaller value $Q = 22.1(7)$ [36]. Lattice QCD collaborations have also reported determinations of Q. Using $N_f = 2+1$ simulations, Ref. [28] obtains $Q = 23.4 \pm 0.6$ and Ref. [29] determines $Q = 23.8 \pm 1.1$ with $N_f = 2+1+1$ simulations, results which are fully compatible. These results are also compatible with $Q = 23.4 \pm 0.5$, obtained from $Q^2 = (r_s^2 - 1)(1+r)/[4(1-r)]$ and from our lattice averages for r_s and r from Eqs. (60.6) and (60.9), respectively. Given the size of the uncertainties on the lattice results for Q, it is safe to neglect effects due to the definition of isosymmetric QCD (see footnote 3). On the whole, the lattice results are larger than the one from phenomenology [36]. This difference could be due to surprisingly large corrections to the NLO substitution of meson masses by Q in the phenomenological determination, as suggested by the authors of [36].

The absolute normalization of the quark masses cannot be determined using chiral perturbation theory. Other methods, such as lattice simulations discussed above, or spectral function sum rules [37,38] for hadronic correlation functions reviewed next, are necessary.

60.5.3 *Sum rules*

Sum rule methods have been used extensively to determine quark masses and for illustration we briefly discuss here their application to hadronic τ decays [39]. Other applications involve very similar techniques.

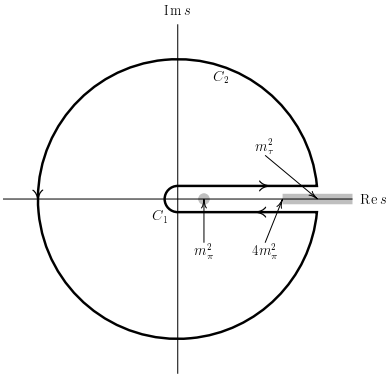

Figure 60.1: The analytic structure of $\Pi(s)$ in the complex s-plane. The contours C_1 and C_2 are the integration contours discussed in the text, and the integral over the closed contour C_1+C_2 vanishes. m_τ^2 has not been drawn to scale; $m_\tau^2 \sim 40(4m_\pi^2)$.

The experimentally measured quantity is R_τ,

$$\frac{\mathrm{d}R_\tau}{\mathrm{d}s} = \frac{\mathrm{d}\Gamma/\mathrm{d}s\left(\tau^- \to \text{hadrons} + \nu_\tau(\gamma)\right)}{\Gamma\left(\tau^- \to e^-\overline{\nu}_e\nu_\tau(\gamma)\right)} \tag{60.17}$$

the hadronic invariant mass spectrum in semihadronic τ decay, normalized to the leptonic τ decay rate. It is useful to define q as the total momentum of the hadronic final state, so $s = q^2$ is the hadronic invariant mass. The total hadronic τ decay rate R_τ is then given by integrating $\mathrm{d}R_\tau/\mathrm{d}s$ over the kinematically allowed range $0 \le s \le M_\tau^2$.

R_τ can be written as

$$R_\tau = 12\pi \int_0^{M_\tau^2} \frac{\mathrm{d}s}{M_\tau^2}\left(1 - \frac{s}{M_\tau^2}\right)^2 \times \left[\left(1 + 2\frac{s}{M_\tau^2}\right)\mathrm{Im}\,\Pi^T(s) + \mathrm{Im}\,\Pi^L(s)\right] \tag{60.18}$$

where the hadronic spectral functions $\Pi^{L,T}$ are defined from the time-ordered correlation function of two weak currents ($j^\mu(x)$ and $j^\nu(0)$) by

$$\Pi^{\mu\nu}(q) = i\int \mathrm{d}^4x\; e^{iq\cdot x}\,\langle 0|\,T\left(j^\mu(x)j^\nu(0)^\dagger\right)|0\rangle\,, \tag{60.19}$$

$$\Pi^{\mu\nu}(q) = (-g^{\mu\nu} + q^\mu q^\nu)\,\Pi^T(s) + q^\mu q^\nu \Pi^L(s), \tag{60.20}$$

and the decomposition Eq. (60.19) is the most general possible structure consistent with Lorentz invariance.

By the optical theorem, the imaginary part of $\Pi^{\mu\nu}$ is proportional to the total cross-section for the current to produce all possible states. A detailed analysis including the phase space factors leads to Eq. (60.18). The spectral functions $\Pi^{L,T}(s)$ are analytic in the complex s plane, with singularities along the real axis. There is an isolated pole at $s = m_\pi^2$, and single- and multi-particle singularities for $s \ge 4m_\pi^2$, the two-particle threshold. The discontinuity along the real axis is $\Pi^{L,T}(s+i0^+) - \Pi^{L,T}(s-i0^+) = 2i\mathrm{Im}\,\Pi^{L,T}(s)$. As a result, Eq. (60.18) can be rewritten with the replacement $\mathrm{Im}\,\Pi^{L,T}(s) \to -i\Pi^{L,T}(s)/2$, and the integration being over the contour C_1. Finally, the contour C_1 can be deformed to $-C_2$ without crossing any singularities, and so leaving the integral unchanged, i.e. the integral over the closed contour $C_1 + C_2$ vanishes. One can derive a series of sum rules analogous to Eq. (60.18) by weighting the differential τ hadronic decay rate by different powers of the hadronic invariant mass [40],

$$R_\tau^{kl} = \int_0^{M_\tau^2} \mathrm{d}s\,\left(1 - \frac{s}{M_\tau^2}\right)^k \left(\frac{s}{M_\tau^2}\right)^l \frac{\mathrm{d}R_\tau}{\mathrm{d}s}\,. \tag{60.21}$$

This leads to the final form of the sum rule(s),

$$R_\tau^{kl} = -6\pi i \int_{C_2} \frac{\mathrm{d}s}{M_\tau^2}\left(1 - \frac{s}{M_\tau^2}\right)^{2+k}\left(\frac{s}{M_\tau^2}\right)^l \times \left[\left(1 + 2\frac{s}{M_\tau^2}\right)\Pi^T(s) + \Pi^L(s)\right]. \tag{60.22}$$

The manipulations so far are completely rigorous and exact, relying only on the general analytic structure of quantum field theory. The left-hand side of the sum rule Eq. (60.22) is obtained from experiment. The right hand-side can be computed for s far away from any physical cuts using the operator product expansion (OPE) for the time-ordered product of currents in Eq. (60.18), and QCD perturbation theory. The OPE is an expansion in a series of local operators, and is an expansion about the $q \to \infty$ limit. It gives $\Pi^{L,T}(s)$ as an expansion in powers of $\alpha_s(s)$ and Λ_{QCD}^2/s, and is valid when s is far (in units of Λ_{QCD}^2) from any singularities in the complex s-plane.

The OPE gives $\Pi^{L,T}(s)$ as a series in α_s, quark masses, and various nonperturbative vacuum matrix elements. By computing $\Pi^{L,T}(s)$ theoretically, and comparing with the experimental values of R_τ^{kl}, one determines various parameters such as α_s and the quark masses. The theoretical uncertainties in using Eq. (60.22) arise from neglected higher order corrections (both perturbative and nonperturbative), and because the OPE is no longer valid near the real axis, where $\Pi^{L,T}$ have singularities. The contribution of neglected higher order corrections can be estimated as for any other perturbative computation. The error due to the failure of the OPE is more difficult to estimate. In Eq. (60.22), the OPE fails on the endpoints of C_2 that touch the real axis at $s = M_\tau^2$. The weight factor $(1 - s/M_\tau^2)$ in Eq. (60.22) vanishes at this point, so the importance of the endpoint can be reduced by choosing larger values of k.

Light quark masses are often determined using QCD sum rules [38], which are similar to the τ sum rules. One takes the correlator of two light-quark-bilinear operators (e.g. an axial vector current), as in Eq. (60.18), and computes their Laplace transforms or moments

$$\mathcal{L}_n(\tau) = \int_0^\infty \mathrm{d}s\, s^n\, e^{-\tau s}\,\mathrm{Im}\,\Pi(s),$$

$$\mathcal{M}_n(Q^2) = \int_0^\infty \frac{\mathrm{d}s}{(s+Q^2)^n}\,\mathrm{Im}\,\Pi(s)$$

to get Laplace or moment sum rules, respectively. The quark masses are extracted by comparing the theoretical and experimental values of $\mathcal{L}_n(\tau)$ and $\mathcal{M}_n(Q^2)$. Considerable theoretical effort has gone into optimizing n and Q^2 to improve the precision of the resulting light quark masses.

60.6 Heavy quarks

60.6.1 *Continuum approaches and results*

For heavy quark physics one can exploit the fact that $m_Q \gg \Lambda_{\rm QCD}$ to construct effective theories (m_Q is the mass of the heavy quark Q). The masses and decay rates of hadrons containing a single heavy quark, such as the B and D mesons can be determined using the heavy quark effective theory (HQET) [41]. The theoretical calculations involve radiative corrections computed in perturbation theory with an expansion in $\alpha_s(m_Q)$ and nonperturbative corrections with an expansion in powers of $\Lambda_{\rm QCD}/m_Q$. Due to the asymptotic nature of the QCD perturbation series, the two kinds of corrections are intimately related; an example of this are renormalon effects in the perturbative expansion which are associated with nonperturbative corrections.

Systems containing two heavy quarks such as the Υ or J/Ψ are treated using non-relativistic QCD (NRQCD) [42]. The typical momentum and energy transfers in these systems are $\alpha_s m_Q$, and $\alpha_s^2 m_Q$, respectively, so these bound states are sensitive to scales much smaller than m_Q. However, smeared observables, such as the cross-section for $e^+e^- \to \bar{b}b$ averaged over some range of s that includes several bound state energy levels, are better behaved and only sensitive to scales near m_Q. For this reason, most determinations of the c, b quark masses using perturbative calculations compare smeared observables with experiment [43–45]. The method is similar to that outlined for τ decays. The current correlator in Eq. (60.18) is the electromagnetic current, and the experimental data is the value of $R(s)$ in the threshold region for $e^+e^- \to Q\overline{Q}$. The theoretical values for the moments are computed using renormalization group improved calculations in non-relativistic QCD.

There are many continuum extractions of the c and b quark masses, some with quoted errors of 10 MeV or smaller. There are systematic effects of comparable size, which are typically not included in these error estimates. Reference [46], for example, shows that even though the error estimate of m_c using the rapid convergence of the α_s perturbation series is only a few MeV, the central value of m_c can differ by a much larger amount depending on which algorithm (all of which are formally equally good) is used to determine m_c from the data. This leads to a systematic error from perturbation theory of around 20 MeV for the c quark and 25 MeV for the b quark. Electromagnetic effects, which also are important at this precision, are often not included. For this reason, we inflate the errors on the continuum extractions of m_c and m_b. The average values of m_c and m_b from continuum determinations are (see Sec. 60.7 for the 1S scheme)

$$\overline{m}_c(\overline{m}_c) = (1.280 \pm 0.025)\text{GeV},$$

$$\overline{m}_b(\overline{m}_b) = (4.18 \pm 0.03)\,\text{GeV}, \quad m_b^{\rm 1S} = (4.65 \pm 0.03)\,\text{GeV}.$$

60.6.2 *Lattice approaches and results*

Lattice QCD simulations of a heavy quark Q, described in a relativistic fermion formulation, lead to potentially large discretization errors which are powers of am_Q (modulated by logarithms); the leading power depends on the formulation of lattice QCD being used and in most cases is quadratic. Clearly those errors can be reduced by performing simulations at smaller lattice spacings a, but also by using *improved* discretizations of the theory, in which the leading discretization errors are systematically eliminated. Recently, with more powerful computing resources, better algorithms and improved discretizations of QCD, it has become possible to perform simulations with quarks more massive than the charm and even up to the b [11], decreasing or eliminating the extrapolation which has to be performed to reach the m_b. It is worth noting that computations using a relativistic fermion formulation for the valence charm with $N_f = 2+1$ sea-quark flavors, or with $N_f = 2+1+1$ flavors and a relativistic b, suffer from partial-quenching effects. This is because the heavy valence quarks are absent from the sea. While these effects are not expected to be large in $N_f = 2+1+1$ computations, they should be investigated when quoting results below the percent level in the case of $N_f = 2+1$ sea-quark flavors. For that reason we will omit heavy-quark results obtained with $N_f = 2+1$ sea-quark flavors from our averages and, more generally focus on $N_f = 2+1+1$ results. Note that these partial-quenching effects are accounted for systematically in lattice calculations in which the heavy valence quarks are described by HQET or NRQCD.

Traditionally the charm quark mass is obtained by tuning its bare, simulation input value to reproduce the physical mass of charmonium mesons or of the D, D_s mesons (requiring a more precise tuning of the light quark masses and the computation of larger QED effects in some cases). This mass can then be renormalized and matched to the $\overline{\rm MS}$ scheme using the methods discussed for the light quarks.

An alternative approach for obtaining the $\overline{\rm MS}$ mass was proposed in [47]. Euclidean-time moments of pseudoscalar, two-point functions of $c\bar{c}$ quark-bilinear operators can readily be computed on the lattice and extrapolated to the continuum limit where they can be compared to perturbative calculations of the same quantities at 4-loop order. In this way, both the strong coupling constant and the charm quark mass can be determined with remarkably small errors. As this approach uses the same perturbative expressions for two-point correlators as the continuum determinations discussed in Sec. 60.6.1, it suffers from similar perturbation-theory, systematic errors. FLAG [8] has reviewed lattice determinations of the charm-quark mass obtained using both approaches. For their $N_f = 2+1$ average they retain the results [13, 48–50], with [51] being published after their deadline. As stated above, we focus here on $N_f = 2+1+1$ results. For these, FLAG uses the results of Refs. [10, 19, 20, 22, 52].

Since the FLAG review, Refs. [22, 52] have been superseded by Ref. [9]. In that reference, only $\overline{m}_c(3\,\text{GeV})$ is given and we multiply it by the running factor 0.7739 ± 0.0060 from $\mu = 3\,\text{GeV}$ to $\overline{m}_c$ [8]. With this substitution and using the combination method described in Sec. 60.4, we obtain:

$$\overline{m}_c(\overline{m}_c) = (1.275 \pm 0.004 \pm 0.008[\pm 0.009])\,\text{GeV} \qquad (60.23)$$

where the three uncertainties have the same meaning as described after Eq. (60.6). This result is in good agreement with the continuum result given above, but with a smaller error.

It is worth noting that three [10, 19, 20] of the four results entering this average agree, while the other [9] is over 2 standard deviations larger than the average. This is taken into account by stretching errors in the usual way, but the total uncertainty on the lattice average of $\overline{m}_c$ will not significantly be reduced until this discrepancy is resolved. It should also be noted that [10] includes QED directly in the lattice calculation, albeit only for valence quarks, while some of the other computations account for these effects using phenomenology. For $\overline{m}_c(\overline{m}_c)$ considered above, these effects are below the permil [10] and are therefore neglected here.

Historically, the main approach to controlling the discretization errors in lattice studies of b-quark physics was to perform simulations of effective theories such as HQET and NRQCD. This remains an important technique, both in its own right and in providing additional information for extrapolations from lower masses to the bottom region. Using effective theories, m_b is obtained from what is essentially a computation of the difference of $M_{H_b} - m_b$, where M_{H_b} is the mass of a hadron H_b containing a b quark. The relative error on m_b is therefore much smaller than that for $M_{H_b} - m_b$. The principal systematic errors are the matching of the effective theories to QCD and the presence of power divergences in a^{-1} in the $1/m_b$ corrections which have to be subtracted numerically. A procedure for performing these subtractions fully nonperturbatively was proposed and implemented for the first time in [53].

The most recent $N_f = 2+1+1$ lattice QCD determinations of the b quark mass rely on a variety of approaches, including Euclidean-time moments of correlation functions with [54] or without NRQCD [19] and interpolations [55, 56] (using results from HQET simulations) or extrapolations [11, 20] from above the

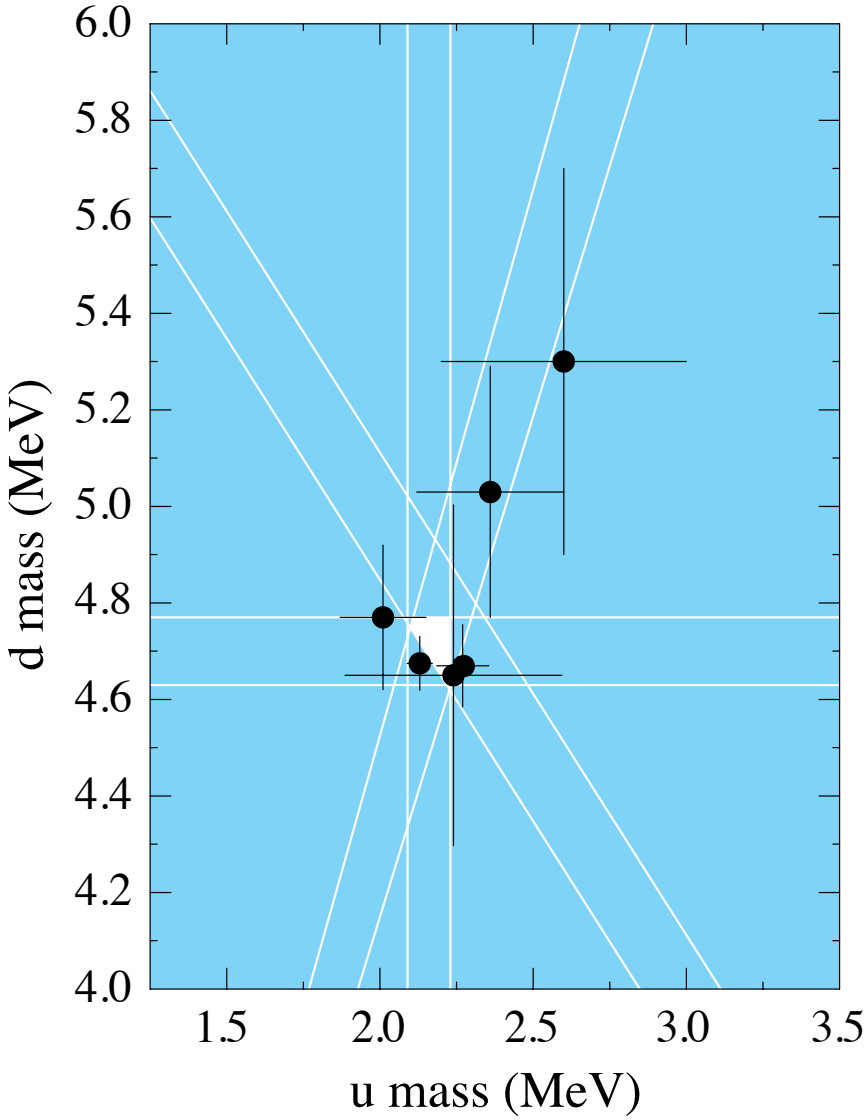

Figure 60.2: The allowed region (shown in white) for up quark and down quark masses renormalized in the $\overline{\rm MS}$ scheme at 2 GeV, determined from the allowed ranges of mass parameters (see Fig. 60.3). The parameter $(m_u + m_d)/2$ yields the two downward-sloping white lines, while m_u/m_d yields the two rising white lines originating at $(0, 0)$. The white region is the remaining allowed parameter space after applying the limits on m_u, m_d, $(m_u + m_d)/2$ and m_u/m_d, where those limits are 90% confidence levels including the scale factors shown in the ideograms in the Data Listings.

charm mass to that of the b. One calculation [11] even includes simulations performed with a heavy quark whose mass is very near that of the b quark. The overall agreement of the results obtained using these very different approaches, which have different systematic errors, is a confirmation that the various groups control these uncertainties. As the range of heavy-quark masses which can be used in numerical simulations increases, the extrapolation or interpolation of results to the physical b mass, possibly including some obtained directly at that mass, are becoming ever more reliable (see e.g. Refs. [11, 20]).

Using the results from Refs. [11, 19, 20, 55, 56], converting those given in the $N_L = 4$ theory to the $N_L = 5$ one and applying the averaging method described in Sec. 60.4, we obtained the estimate:

$$\overline{m}_b(\overline{m}_b) = (4.196 \pm 0.009 \pm 0.009[\pm 0.012])\,\text{GeV}\ , \qquad (60.24)$$

where the three uncertainties have the same meaning as in the estimates given above for light-quark masses.

Among the results entering this average, only one [11] accounts for electromagnetic effects. Using Refs. [10, 11], it is straightforward to show that QED effects on the value of $\overline{m}_b$ at $\mu = 3\,\text{GeV}$, and thus at $\mu = \overline{m}_b$, are smaller than one permil in the separation scheme of those two references. Assuming that the same is true for the other results, we neglect these corrections here.

The lattice result of Eq. (60.24) is compatible with the average value of continuum results, but with a significantly smaller uncertainty. Note that FLAG [8] also provides an average of $N_f = 2+1$ results, taken from [13, 50]. It is about one combined, standard deviations lower that the result quoted above.

As explained in Sec. 60.3, ratios of quark masses can have significantly smaller errors than the individual masses if they are determined within the same lattice QCD framework. This led HPQCD to leverage their precise determination of m_c [47] to determine m_s and m_{ud} [57], through a precise computation of m_c/m_s [57] and of m_s/m_{ud} [58]. The $N_f = 2 + 1$ calculation [57] was updated using $N_f = 2 + 1 + 1$ simulations in [19]. The ratio m_c/m_s was also computed in Refs [48, 59] with $N_f = 2 + 1$ simulations and in Refs. [20, 22] with $N_f = 2 + 1 + 1$ ones. On the basis of those references, FLAG [8] gives average results from $N_f = 2 + 1$ and $N_f = 2+1+1$ simulations. Here we focus on $N_f = 2+1+1$ results and we replace the results of Ref. [22] by the collaboration's update [9]. Applying to the modern $N_f = 2+1+1$ computations of

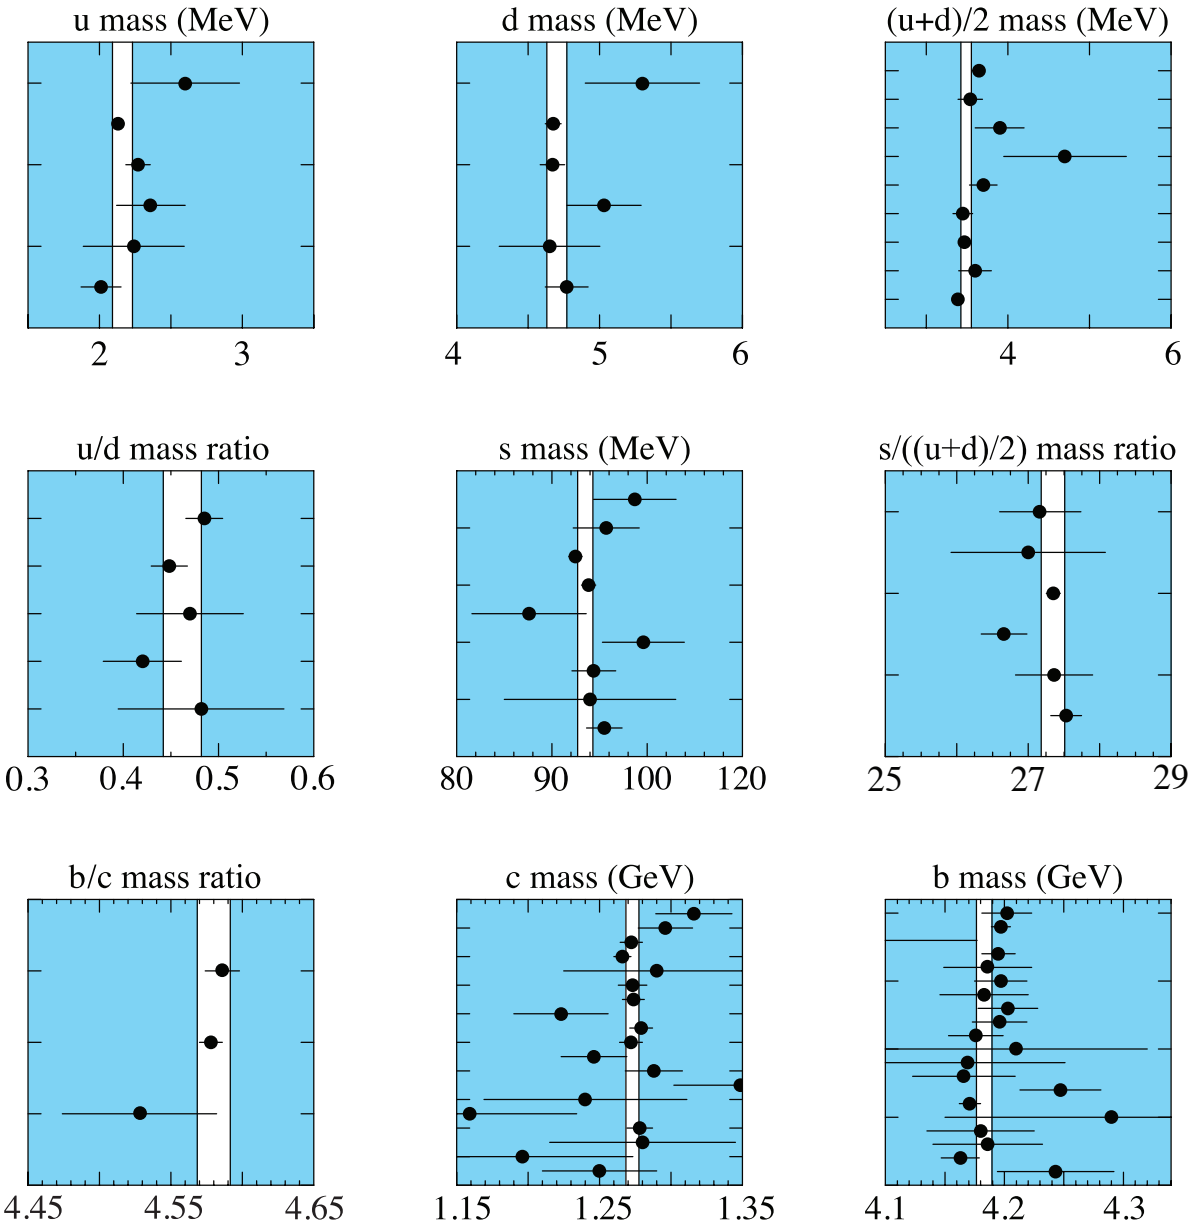

Figure 60.3: The allowed regions (shown in white) for quark masses renormalized in the $\overline{\rm MS}$ scheme at 2 GeV. The points (taken from the Data Listings) are in chronological order with the more recent measurements shown at the top. The white regions indicate values allowed at the 90% confidence level including the scale factors shown in the ideograms in the Data Listings.

Refs. [9, 19, 20] the combination procedure described in Sec. 60.4, we obtain the following lattice average:

$$\overline{m}_c/\overline{m}_s = 11.769 \pm 0.021 \pm 0.028[\pm 0.035],$$

where the three uncertainties have the some meaning as described after Eq. 60.6. The average is dominated by Ref. [20] that has a substantially smaller error than the other results. The result of Ref. [9] is a little more that 1 standard deviation below that average and the one of Ref. [19] close to 2σ above, for a total $\chi^2/\text{dof} = 5.0/2$ and a rescaling factor of ~ 1.6 in the statistical and systematic errors.

The above ratio is renormalization scheme and scale independent, in the absence of electromagnetic corrections. None of the calculations above estimates the size of those corrections. Nevertheless, they are expected to still be smaller than the total uncertainty quoted above in a standard scheme for defining QCD in the isospin limit.

The ratio m_b/m_c has also been computed on the lattice. The two $N_f = 2+1$ results which satisfy FLAG's criteria are [13, 50]. As explained above, we focus on $N_f = 2+1+1$ calculations [11, 20, 55]. Ref. [11] is the only calculation which accounts for QED directly in the lattice simulations, albeit only for valence quarks, and thus must specify the renormalization scheme and scale of its result, which it chooses to be $\overline{\rm MS}$ at 3 GeV. Here we correct the results of Refs. [20, 55] by the QED factor 1.0017 obtained in Ref. [11], and ascribe to it a 100% systematic uncertainty with 100% correlation. This means that we assume that the differences due to the separation schemes used in each calculation lies within that error. Averaging the resulting numbers, as prescribed in Sec. 60.4, yields

$$\overline{m}_b/\overline{m}_c = 4.584 \pm 0.006 \pm 0.010[\pm 0.012],$$

where exceptionally the bar indicates that the masses are renormalized in the $\overline{\rm MS}$ at 3 GeV in the four-flavor theory. Here a scale factor of $\sqrt{\chi^2/\text{dof}} = 1.30$ has been applied to the error bar. Indeed, [55] contributes 3.3 to the total χ^2.

60.6.3 *Warnings concerning the use of the pole mass*

For an observable particle such as the electron, the position of the pole in the propagator is the definition of its mass. In QCD this definition of the quark mass is known as the pole mass. It is known that the on-shell quark propagator has no infrared divergences in perturbation theory [60,61], so this provides a perturbative definition of the quark mass. However, the pole mass cannot be used to arbitrarily high accuracy because of nonperturbative infrared effects in QCD. In fact the full quark propagator has no pole because the quarks are confined, so that the pole mass cannot be defined outside of perturbation theory. The relation between the pole mass m_Q and the $\overline{\rm MS}$ mass $\overline{m}_Q$, used throughout this review, is known to three loops [62–65]

$$m_Q = \overline{m}_Q(\overline{m}_Q)\Bigg\{1 + \frac{4\overline{\alpha}_s(\overline{m}_Q)}{3\pi} + \left[-1.0414\sum_q\left(1 - \frac{4}{3}\frac{\overline{m}_q}{\overline{m}_Q}\right) + 13.4434\right]\left[\frac{\overline{\alpha}_s(\overline{m}_Q)}{\pi}\right]^2 + \left[0.6527N_L^2 - 26.655N_L + 190.595\right]\left[\frac{\overline{\alpha}_s(\overline{m}_Q)}{\pi}\right]^3\Bigg\}, \tag{60.25}$$

where $\overline{\alpha}_s(\mu)$ is the strong interaction coupling constants in the $\overline{\rm MS}$ scheme, and the sum over q extends over the N_L flavors lighter than Q. The complete mass dependence of the α_s^2 term can be found in [62]; the mass dependence of the α_s^3 term is not known. For the b-quark, Eq. (60.25) reads

$$m_b = \overline{m}_b\,(\overline{m}_b)\,[1 + 0.10 + 0.05 + 0.03]\,, \tag{60.26}$$

where the contributions from the different orders in α_s are shown explicitly. The two and three loop corrections are comparable in size and have the same sign as the one loop term. This is a signal of the asymptotic nature of the perturbation series (there is a renormalon in the pole mass [66]). Such a badly behaved perturbation expansion can be avoided by directly extracting, from data, the mass defined in the $\overline{\rm MS}$ (used in this review) or other short-distance schemes (see below), without invoking the pole mass as an intermediate step.

60.7 Numerical values and caveats

The quark masses in the particle data listings have been obtained by using a wide variety of methods. Each method involves its own set of approximations and uncertainties. In most cases, the errors are an estimate of the size of neglected higher-order corrections or other uncertainties. The expansion parameters for some of the approximations are not very small (for example, they are $m_K^2/\Lambda_\chi^2 \sim 0.25$ for the SU(3) chiral expansion and $\Lambda_{\rm QCD}/m_b \sim 0.1$ for the heavy-quark expansion), so an unexpectedly large coefficient in a neglected higher-order term could significantly alter the results. Thus, before using a particular result, it is important to understand the possible limitations of the approach used to obtain it. It is also important to note that the quark mass values can be significantly different in the different schemes.

We have specified all masses in the $\overline{\rm MS}$ scheme. For light quarks, the renormalization scale has been chosen to be $\mu = 2$ GeV. Quoting these masses at smaller values of μ, where perturbative corrections become significantly larger, would introduce unnecessary uncertainties in the results. In fact, as lattice calculations, performed on finer and finer lattices, allow to determine quark masses, fully nonperturbatively, at larger and larger values of μ, it may become advantageous to quote quark mass results at renormalization scales above 2 GeV, where perturbative uncertainties are smaller.

The heavy quark masses obtained using HQET, QCD sum rules, or lattice gauge theory are consistent with each other if they are all converted into the same scheme and scale. For these quarks it is conventional to choose the renormalization scale equal to the quark mass, so we have quoted $\overline{m}_Q(\mu)$ at $\mu = \overline{m}_Q$ for the c and b quarks. Given the small size of the charm quark mass, in the future it may become advantageous to quote its value at larger values of μ so as not to introduce unnecessary perturbative uncertainties (see discussion above). Analyses of inclusive B meson decays have shown that other mass definitions lead to a better behaved perturbation series than for the $\overline{\rm MS}$ mass, and hence to more accurate mass values [67–70]. Thus, we have chosen to also give values for one of these, the b quark mass in the 1S scheme [67, 68]. Other schemes that have been proposed are the PS-scheme [69], the kinetic scheme [71] and, most recently, the minimal renormalon-subtracted mass (MRS) [70] used in the lattice calculation [20].

If necessary, we have converted values in the original papers to our chosen scheme using two-loop formulæ. It is important to realize that our conversions introduce significant additional errors. In converting to the $\overline{\rm MS}$ b-quark mass, for example, the three-loop conversions from the 1S and pole masses give values about 35 MeV and 135 MeV lower than the two-loop conversions. The uncertainty in $\alpha_s(M_Z) = 0.1179 \pm 0.0010$ [1] gives an uncertainty of ± 9 MeV and ± 21 MeV respectively in the same conversions. We have not added these additional errors when we do our conversions. The α_s value in the conversion is correlated with the α_s value used in determining the quark mass, so the conversion error is not a simple additional error on the quark mass.

61. Top Quark

Revised September 2025 by F. Canelli (Zurich U.), A. Knue (TU Dortmund) and F. Maltoni (CP3 U. catholique de Louvain; Bologna U.).

61.1 Introduction and SM theory overview

In the Standard Model (SM), the left-handed top quark is the $Q = 2/3$, $T_3 = +1/2$ member of the weak-isospin doublet containing the bottom quark, while the right-handed top quark is an $SU(2)_L$ singlet. The phenomenology of the top quark is driven by its large mass, $m_t \simeq v/\sqrt{2}$, where $v = 246$ GeV is the Higgs vacuum expectation value, implying a Yukawa coupling of order unity. Being heavier than the W boson, it is the only quark that can decay weakly into a real W boson and a b quark. Its lifetime is shorter than the timescale of non-perturbative strong interactions, which prevents hadronization and preserves properties such as its spin, allowing the top to behave almost as a free quark. Through loop effects, it gives important contributions to SM precision observables, and its unique role makes it central to many extensions of the SM, often linked to new particles or interactions. These features strongly motivate increasingly precise studies of top-quark physics, providing a unique laboratory for testing the SM at the electroweak symmetry-breaking scale (EWSB) and beyond. At the same time, the abundant production of top quarks at the LHC enables precision measurements of their mass, couplings, production cross sections, and decay branching ratios. This review summarizes the experimental and theoretical issues in determining these properties and reports on recent progress.

61.1.1 *Mass*

The top-quark mass largely determines its unique phenomenology. In the SM, quark masses are derived parameters that are determined by the Yukawa coupling and the vacuum expectation value. At the loop level, with the Higgs boson discovery and better than per mil measurement of its mass, the values of the W-boson and top-quark mass are correlated, so that their precise determinations provide a strong test of the SM (see Section 10 "Electroweak Model and constraints on new physics" of this *Review*). At present, there is some tension at the $1.7\,\sigma$ level, between the indirect top-quark (pole) mass determination from electroweak (EW) precision data of 175.2 ± 1.8 GeV (see Section 10 in this *Review*) and the combination of direct measurements at the LHC that yields 172.52 ± 0.33 GeV [1].

The top-quark mass value is also crucial in the issue of vacuum stability in the SM [2–4]. At high scales, the Higgs quartic coupling λ evolves to increasingly small values as m_t grows. Above $m_t = 171$ GeV, i.e., very close to the most precise measurements, λ becomes negative at the Planck scale, leading to a meta-stable EW vacuum, while for slightly larger values, $m_t > 176$ GeV, the EW vacuum would become unstable. Current top-quark measurements therefore point to a Higgs quartic coupling that is nearly vanishing at the Planck scale. While being quite suggestive, in the absence of a clear UV picture, this argument allows only to conclude that comparison between our best SM predictions and the data does not imply new physics below the Planck scale (see Section 11.2.3 of "Status of Higgs Boson Physics" in this *Review*).

Due to its fundamental importance, precisely determining the top-quark mass has been a central objective of precision measurement programs carried out by the ATLAS and CMS collaborations at the LHC, and previously by the CDF and DØ collaborations at the Tevatron. The basic methodology rests on the idea of fitting m_t-dependent kinematic distributions to fully-exclusive (Monte Carlo) predictions, via the full or partial reconstruction of the system of the t and $\bar{t}$ decay products. These are called "direct measurements" and aim for a target accuracy in the permil range. With an absolute uncertainty of order or better than $\Lambda_{\rm QCD}$, however, a clear relation between the extracted mass and a well-defined quantum field theory parameter of the underlying theory has become necessary.

Several mass parameter definitions exist with a precise field-theoretical meaning, which can be organized into two broad classes: the long-distance ones, such as the "pole mass", and short-distance masses, such as the $\overline{\rm MS}$ mass. An additional mass definition [5] interpolates between the two.

Direct determinations rely on mass-sensitive observables constructed from the kinematics of the top-quark decay products. Monte Carlo generators enforce the invariant mass of this system to follow, as closely as possible, the virtuality of the top quark, which is modeled by a Breit–Wigner distribution centered on the Monte Carlo mass parameter. In this framework, the latter acts as an effective proxy for the pole mass. At e^+e^- colliders, one can define a short-distance mass, e.g., the "potential mass" that can be determined by measurements at the $t\bar{t}$ threshold, and it does not suffer from non-perturbative ambiguities. At hadron colliders, all observables that can be connected to the top-quark mass involve a top-quark reconstruction from the final state, and at the end are connected to the pole mass.

A top-quark mass measurement cannot be defined solely in terms of the mass of the system of its decay products: the top quark is a colored object; therefore, it cannot be an asymptotic state of the theory, and no final-state hadronic system can be unambiguously associated with it. On the other hand, final state observables, such as those arising from its decay, can be related to the top-quark mass through computations that have both perturbative and non-perturbative components, as seen in Monte Carlo generators.

From a purely theoretical (calculational) point of view, the top-quark mass parameter is defined within a given renormalization scheme, since divergent perturbative corrections arise order by order in perturbation theory and need to be subtracted. The pole mass scheme prescribes to subtract the divergent mass corrections so that the pole in the quark propagator remains fixed order by order in perturbation theory. The $\overline{\rm MS}$ scheme prescribes to employ dimensional regularization and subtract the pure $1/\epsilon$ pole in the divergent mass correction. In doing so, the corresponding mass becomes scale-dependent. In this scheme, the pole in the top quark propagator receives corrections at all orders in perturbation theory. This scheme has the advantage of making the relation between the mass and the Yukawa coupling straightforward in the SM and independent of non-perturbative corrections.

The relation between the top quark pole mass $m_t^{\rm pole}$ and $m_t^{\overline{\rm MS}}$ up to four loops reads [6]

$$m_t^{\rm pole} = m_t^{\overline{\rm MS}}(m_t)[1 + 0.4244\,\alpha_s + 0.8345\,\alpha_s^2 + 2.375\,\alpha_s^3 + (8.49 \pm 0.25)\,\alpha_s^4]\,, \tag{61.1}$$

which for strong coupling constant $\alpha_s = \alpha_s^{(6)}(m_t) = 0.1088$ and $m_t^{\rm pole} = 172.5$ GeV gives $m_t^{\overline{\rm MS}}(m_t) = 162.69 \pm 0.006$ GeV. The two definitions lead to perturbatively equivalent theories: the perturbative expression of the pole mass in terms of the $\overline{\rm MS}$ can be used to turn a result expressed in the pole mass scheme into the corresponding one in the $\overline{\rm MS}$ scheme. However, the relation above has only a perturbative meaning, as the two masses differ by non-perturbative, long-distance effects. The difference between the top-quark pole mass and the mass extracted in direct measurements arises due to non-perturbative effects, which are currently modeled by shower Monte Carlo programs. It is expected to be of order $Q_0 \cdot \alpha_s(Q_0)$ with $Q_0 \sim 1$ GeV, i.e., of order 0.5 GeV. Recent efforts to precisely define and estimate the uncertainties of the top-quark mass can be found in Refs. [7, 8].

61.1.2 *Width*

Like other unstable elementary particles in the SM, the top-quark lifetime, and thus its decay width, can be perturbatively calculated within the SM. With a mass exceeding the Wb production threshold and given that $|V_{tb}| \gg |V_{td}|, |V_{ts}|$, the top-quark decay width is dominated by the two-body decay channel $t \to Wb$. At next-to-leading order (NLO) prediction for the width within the SM is given by [9]:

$$\Gamma_t = \frac{G_F m_t^3}{8\pi\sqrt{2}} \left(1 - \frac{M_W^2}{m_t^2}\right)^2 \left(1 + 2\frac{M_W^2}{m_t^2}\right) \left[1 - \frac{2\alpha_s}{3\pi}\left(\frac{2\pi^2}{3} - \frac{5}{2}\right)\right], \tag{61.2}$$

where m_t refers to the top-quark pole mass (to keep the formula simple, known m_b^2/m_t^2, α_s^2, and $(\alpha_s/\pi)(M_W^2/m_t^2)$ are not

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

included). The known quantum chromodynamics (QCD) corrections of order α_s^2 to Γ_t, and the EW NLO corrections [10, 11] improve the overall theoretical accuracy to better than 1%. As a result, between $m_t = 170$ GeV and 175 GeV, the width changes from 1.258 GeV to 1.394 GeV, with a linear dependence on m_t assuming $\alpha_s(M_Z) = 0.1179$ and $M_W = 80.377$ GeV. At the reference value of $m_t = 172.5$ GeV, one finds $\Gamma_t = 1.326$ GeV.

With its correspondingly short lifetime of about 0.5×10^{-24} s, the top quark is expected to decay before top-flavored hadrons or $t\bar{t}$ quarkonium-like bound states can form [12]. However, in the latter case, since the decay time is very close to the would-be-resonance binding time, a peak is predicted in e^+e^- scattering at the $t\bar{t}$ threshold [13] (whose position and width are linked to the "potential mass" of the top quark and its width, respectively), and it is also present in hadron collisions [14–16]. The short lifetime of the top quark also prevents strong interactions from efficiently scrambling its spin, as such processes would require a much longer timescale. Moreover, the purely left-handed structure of the weak interaction dictates that the top-quark decays predominantly via $t \to Wb$, followed by $W \to f\bar{f}'$, with the direction of the fermion f (the charged lepton or down-type quark component) being almost 100% correlated with the top-quark spin. Taken together, these features render the top quark unique among quarks, as they allow for direct experimental access to its spin properties through the angular distributions of its decay products.

Other decay modes of the top quark provide negligible contributions to the total width. For example, flavor-changing neutral current (FCNC) interactions, which are allowed starting at the one-loop level, give [17, 18]:

$$\begin{aligned}
&\mathrm{Br}^{\mathrm{SM}}(t \to gc) = 5 \cdot 10^{-12},\ \mathrm{Br}^{\mathrm{SM}}(t \to gu) = 4 \cdot 10^{-14},\\
&\mathrm{Br}^{\mathrm{SM}}(t \to \gamma c) = 5 \cdot 10^{-14},\ \mathrm{Br}^{\mathrm{SM}}(t \to \gamma u) = 4 \cdot 10^{-16},\\
&\mathrm{Br}^{\mathrm{SM}}(t \to Zc) = 1 \cdot 10^{-14},\ \mathrm{Br}^{\mathrm{SM}}(t \to Zu) = 7 \cdot 10^{-17},\\
&\mathrm{Br}^{\mathrm{SM}}(t \to Hc) = 3 \cdot 10^{-15},\ \mathrm{Br}^{\mathrm{SM}}(t \to Hu) = 2 \cdot 10^{-17}\,.
\end{aligned}$$

61.1.3 *Couplings*

The SM couplings involving top quarks are of two types: gauge couplings, which are universal, and Yukawa couplings, which instead depend on the generation. Following the notation of Sections 9 and 10 of this *Review*, after EWSB the top-quark interactions read

$$\begin{aligned}
\mathcal{L}_t^{\mathrm{SM}} = {} & \bar{\psi}_t \left[i\partial\!\!\!/ - m_t \right] \psi_t - g_s \bar{\psi}_t \gamma^\mu t^C \psi_t \mathcal{A}_\mu^C - eQ_t \bar{\psi}_t \gamma^\mu \psi_t A_\mu \\
& - \frac{g}{2\sqrt{2}} \bar{\Psi} \gamma^\mu (1-\gamma^5)(T^+ W_\mu^+ + T^- W_\mu^-) \Psi \\
& - \frac{g}{2\cos\theta_W} \bar{\psi}_t \gamma^\mu \left(g_V^t - g_A^t \gamma^5 \right) \psi_t Z_\mu \\
& - \frac{m_t}{v} H \bar{\psi}_t \psi_t \,, \qquad (61.3)
\end{aligned}$$

where in the first line we include the kinetic term, the coupling to the $SU(3)$ field $\mathcal{A}_\mu^C$, to the EM field A_μ, to the weak bosons, $W_\mu^\pm, Z_\mu$ and to the Higgs boson ($\Psi = (t, b')$ with $b' = V_{tb}\, b + V_{ts}\, s + V_{td}\, d$). As mentioned above, there are no neutral flavor-changing interactions in the SM at tree level.

In the absence of evidence for physics beyond the SM at the weak scale or below, the SM Effective Field Theory (SMEFT) [19–21] provides a simple and consistent framework to systematically parameterize possible deviations from the SM predictions in the interactions among the known particles, using minimal theoretical assumptions. It amounts to extending the Lagrangian of the SM by all higher-dimensional operators that respect the gauge symmetry

$$\mathcal{L}^{\mathrm{SMEFT}} = \mathcal{L}^{\mathrm{SM}} + \sum_{D>4} \sum_i^{N_D} \frac{C_i^{(D)} O_i^{(D)}}{\Lambda^{D-4}} \,, \qquad (61.4)$$

where D is the dimension of the operator $O_i^{(D)}$ and Λ provides an upper bound for the scale of new physics. An EFT model is generally characterized by power counting rules that identify a hierarchy among operators. In the case of the SMEFT, a minimal approach is considered, where the large-scale Λ provides a universal suppression factor for the higher-dimensional operators.

The currently adopted parametrization for SMEFT interpretations of top-quark measurements relies on the Warsaw basis of gauge-invariant dimension-six operators [21] and it is detailed in Ref. [22] (see [23, 24] for early discussions of top-quark related operators). For convenience, often specific degrees of freedom are identified from combinations of Warsaw-basis operator coefficients aligned with the directions of the EFT parameter space, which appear in given processes, in interferences with SM amplitudes, and top-quark interactions with some of the gauge boson mass eigenstates. Model implementations are available for tree-level and even one-loop Monte Carlo simulations [25, 26].

The definitions of the SMEFT operators can be organized in four categories: Four-quark, two-quark-two-bosons, two-quark-two-lepton, and baryon-lepton-number-violating operators. The overwhelming number of four-fermion operators is tamed by adopting simplifying assumptions about beyond-the-standard-model flavor structures. A baseline flavor scenario in the quark sector and motivated by the minimal flavor violation ansatz [27–29] corresponds to imposing a $U(2)_q \times U(2)_u \times U(2)_d$ symmetry among the first two generations (q refers to the SU(2) left-handed doublet, while u, d are right-handed singlets). In this case, the following numbers of degrees of freedom are produced for the operators of each category of field content:

four heavy quarks	$11 + 2$ CPV
two light and two heavy quarks	14
two heavy quarks and bosons	$9 + 6$ CPV
two heavy quarks and two leptons	$(8 + 3$ CPV$)\times$ 3 lepton flavors

where we counted separately CP-conserving and CP-violating (CPV) parameters. These operators are collected in Tab. 61.1. Other less restricted scenarios, such as that obtained by imposing $U(2)_{q+u+d}$ symmetry featuring additional $10 + 10$ CPV degrees of freedom, or more restricted ones, such as *top-philic* scenario where it is assumed that new physics couples dominantly to the left-handed doublet and right-handed up-type quark singlet of the third generation as well as to bosons, featuring only 19+6 (CPV) degrees of freedom, are often considered. It is also customary to analyze top-quark FCNCs separately, as at the tree level, they enter only quadratically.

61.1.4 *Production*

Top-quark production provides a powerful probe of QCD and the EW theory. Precise measurements of production rates and kinematic distributions constrain PDFs, α_s, and m_{t}. Since its discovery in 1995 at the Tevatron, direct measurements of top-quark production have been extensively performed. At the LHC, the broad range of center-of-mass energies, large production cross sections, and the ability to study forward production and heavy-ion collisions make top-quark measurements a uniquely sensitive tool for testing the SM and probing the partonic structure of matter.

Top-quark production processes are classified according to the underlying interaction mechanism. The primary categories include: *top-antitop quark pair production* through QCD interactions ($t\bar{t}$), *single top-quark production* via EW interactions (t or $\bar{t}$), and *associated production* involving the creation of a single top quark or a top-quark pair alongside gauge bosons or other particles via EW or QCD interactions ($t\bar{t} + X$, $t/\bar{t} + X$). Associated production also encompasses the rare scenarios where multiple top quarks are produced, specifically three-top ($tt\bar{t}/\bar{t}\bar{t}t$) and four-top ($t\bar{t}t\bar{t}$) production. Among these, pair production is the most abundant mode of top-quark production.

A key aspect of top-quark phenomenology is the study of its spin through the angular distributions of decay products, which directly reflect the production mechanism. In single-top-quark production via the weak interaction, the top quark is predicted to be fully polarized. In contrast, in $t\bar{t}$ production dominated by QCD interactions, individual top quarks are nearly unpolarized, but their spins exhibit nontrivial correlations. These spin effects are known up to NNLO in QCD and NLO in EW theory [30, 31]. In specific kinematic regimes, such as near threshold or at high transverse momentum (p_{T}), the correlations are strong enough that the $t\bar{t}$ spin system becomes entangled [32]. Recent

Table 61.1: List of SMEFT operators at dimension six, assuming $U(2)_q \times U(2)_u \times U(2)_d$ flavor symmetry. For more details on notation and conventions, see the reference in the text.

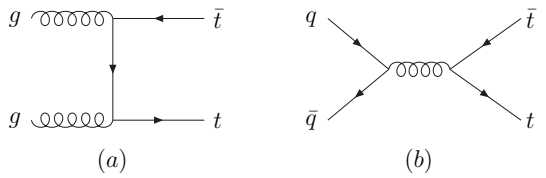

Figure 61.1: Representative Feynman diagrams for $t\bar{t}$ production (a) via gluon-gluon fusion and (b) via quark-antiquark annihilation.

LHC measurements at threshold by ATLAS and CMS have provided experimental confirmation of this phenomenon [33–35], see Sec. 61.2.5.3. Fully exclusive predictions via Monte Carlo generators for the $t\bar{t}$ and single top production processes at NLO accuracy in QCD are available, including top-quark decays and possibly off-shell effects [36–39] through the MC@NLO [40] and POWHEG [41] methods. The first Monte Carlo implementation of the NNLO QCD computation is also available [42, 43].

61.1.4.1 *Pair production*

The dominant production mode for top quarks in hadron collisions is top-antitop pair production via QCD interactions. Due to its significantly higher event rates compared to other production modes, this process is primarily used to extract top-quark properties. Additionally, it constitutes a significant background for many other collider physics measurements, making its thorough understanding and accurate modeling a key priority.

At leading order in QCD, the two principal partonic subprocesses that contribute to $t\bar{t}$ production are: gluon-gluon fusion ($gg \to t\bar{t}$) and quark-antiquark annihilation ($q\bar{q} \to t\bar{t}$), as shown in Fig. 61.1.

The relative contributions of these subprocesses depend on the collision energy and the PDFs of the incoming hadrons. At the Tevatron, where the initial state is proton-antiproton, and the energy is lower, the production of $t\bar{t}$ is dominated by quark-antiquark annihilation (approximately 85%), with gluon-gluon fusion contributing the remaining 15%. At the LHC, where protons collide at higher energies, the parton composition at low momentum fraction x is dominated by gluons, resulting in gluon-gluon fusion being the dominant production mechanism. At $\sqrt{s} = 13$ TeV, around 90% of $t\bar{t}$ pairs originate from gluon–gluon fusion, decreasing to approximately 80% at $\sqrt{s} = 7$ TeV.

Theoretical predictions for the inclusive $t\bar{t}$ production cross sections are available at NNLO in QCD, supplemented by next-to-next-to-leading logarithmic (NNLL) resummation of soft-gluon emissions [44, 45]. A combination of NNLO in QCD and NLO EW corrections is also available [46].

Assuming a top-quark mass of 173.3 GeV, the NNLO+NNLL prediction for the $t\bar{t}$ cross section at the Tevatron at $\sqrt{s} = 1.96$ TeV is:

$$\sigma_{t\bar{t}} = 7.16^{+0.11}_{-0.20}\,(\text{scale})^{+0.17}_{-0.12}\,(\text{PDF})\ \text{pb},$$

where the first uncertainty reflects variations in the renormalization and factorization scales, and the second arises from PDF uncertainties [44].

The $t\bar{t}$ cross sections for pp collisions at various center-of-mass energies for a top quark mass of 172.5 GeV and $\alpha_s = 0.118$ are presented in Tab. 61.2. They are calculated with the Top++2.0 program to NNLO in perturbative QCD (pQCD), including soft-gluon resummation to NNLL order (see [47] and references therein). The first uncertainty comes from the independent variation of the factorization and renormalization scales. In contrast, the second one is associated with variations in the PDF and α_s, following the PDF4LHC prescription with the MSTW2008 68% C.L. NNLO, CT10 NNLO and NNPDF2.3 5f FFN PDF sets (see [48] and references therein, and [49–51]).

The $t\bar{t}$ production is typically accompanied by additional QCD radiation, primarily driven by the initial states. Events with high jet multiplicities offer sensitivity to higher-order QCD radiation and to the accuracy of parton shower modeling. The exclusive $t\bar{t} + n-$jet cross sections are known at NLO in QCD. Inclusive samples matched with parton shower (PS) can be obtained by merging samples that are accurate at NLO in QCD at fixed jet multiplicities [52, 53].

Table 61.2: Theoretical predictions for top quark pair production at LHC calculated at NNLO+NNLL in QCD. Results collected by the LHCTopWG, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/TtbarNNLO`.

$\sqrt{s}$ (TeV)	$\sigma_{t\bar{t}}$ (pb)
5.02	$69.5^{+2.0}_{-2.3}\,(\text{scale})^{+2.9}_{-2.9}(\text{PDF})$
7	$179.6^{+4.8}_{-6.2}\,(\text{scale})^{+6.1}_{-6.1}(\text{PDF})$
8	$256.0^{+6.7}_{-8.9}\,(\text{scale})^{+8.0}_{-8.0}(\text{PDF})$
13	$833.9^{+20.5}_{-30.0}\,(\text{scale})^{+21.0}_{-21.0}(\text{PDF})$
13.6	$923.6^{+22.6}_{-33.4}\,(\text{scale})^{+22.8}_{-22.8}(\text{PDF})$

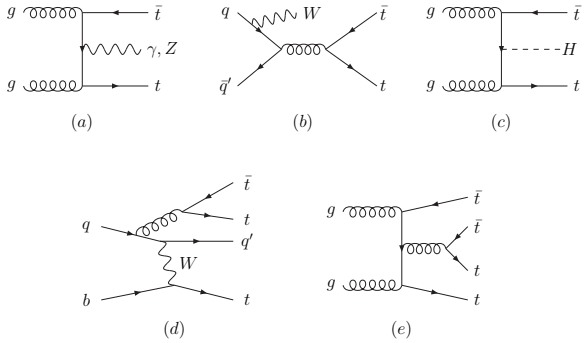

Figure 61.2: Representative Feynman diagrams for $t\bar{t}$ associated production with (a) γ, Z, (b) W, (c) Higgs, (d) a single-top, (e) an extra $t\bar{t}$ pair.

Additional jets may originate from heavy quarks, such as b and c quarks. Predictions for these processes can be obtained in different flavor schemes. For example, in the 4-flavor (3-flavor) scheme, b (c) quarks are treated as massive and not included as initial-state partons [54], while in the 5-flavor (4-flavor) scheme they are treated as massless and included on the same footing as the light quarks [55]. Matching or merging with parton showers can also be applied [39]. Despite these advances, theoretical predictions still carry sizable uncertainties. In particular, measurements of $t\bar{t}$+heavy-flavor production reveal moderate mismodeling, often requiring data-driven corrections in the background estimation for precise measurements.

61.1.4.2 *Pair production in heavy-ion collisions*

The top quark constitutes a novel and theoretically precise probe of the nuclear parton distribution functions (nuclear PDFs, or nPDFs), in the poorly explored region where partons have a significant fraction of the nucleon momentum, as well as of the properties of the produced quark-gluon plasma (QGP).

First, precise knowledge of nPDFs is a key prerequisite for extracting detailed information on QGP properties from experimental data. Second, on average, top quarks decay on a timescale similar to the formation of the QGP, offering a unique opportunity to study its time evolution [56].

For lead-lead ($PbPb$) collisions at center-of-mass energy of 5.02 TeV, the prediction for $t\bar{t}$ cross section is given by

$$\sigma^{t\bar{t}}_{\text{theory}} = \sigma^{\text{NNLO+NNLL}}_{\text{PbPb}\to t\bar{t}+X} = 3.22^{+0.38}_{-0.35}\,(\text{nPDF4 PDF})\,^{+0.09}_{-0.10}\,(\text{scale})\,\mu\text{b},$$

calculated with the Top++2.0 program at NNLO in QCD, including soft-gluon resummation at NNLL accuracy, with the nuclear EPPS16 and free-nucleon CT14 PDFs [47]. Results with a central value lower than about 7% are obtained from free-nucleon CT14 and NNPDF30 NNLO PDFs (scaled by the square of the number of nucleons in the Pb nucleus, $A^2 = 208^2$). A small difference between the cross sections obtained with nuclear and free-nucleon PDFs arises from the nPDF "antishadowing" effect, which is only mildly dependent on the center of mass energy.

61.1.4.3 *Associated pair production*

The $t\bar{t}$ production in association with other particles has substantially smaller cross sections compared to standard top-quark production modes. Nevertheless, these associated production processes offer valuable possibilities for precise tests of the SM, specifically enabling detailed studies of the top-quark couplings and EW interactions. Representative diagrams for each production channel are given in Fig. 61.2.

$t\bar{t}V$ ($V = W, Z, \gamma$): Associated $t\bar{t}$ production with vector bosons. Processes with γ and Z bosons in the final state test the neutral EW couplings of the top quark, see Fig. 61.2 (a). In $t\bar{t}W$, , on the other hand, the W-boson couples to the initial $q\bar{q}'$ state, see Fig. 61.2 (b). Predictions for $t\bar{t}W$ and $t\bar{t}Z$ are computed at complete NLO accuracy, including both QCD and EW effects, with resummation of soft emissions to NNLL accuracy in QCD [57]. Additionally, motivated by the large NLO QCD corrections, approximate NNLO QCD predictions have been obtained for $t\bar{t}W$ [58, 59]. Approximate NNLO and N^{3}LO predictions for $t\bar{t}Z$ production include, respectively, second- and third-order soft-gluon corrections added to the exact NLO QCD calculation, together with NLO EW contributions [60]. Predictions for $t\bar{t}\gamma$ are available at NLO in QCD [61].

$t\bar{t}H$: This process directly explores the top-quark Yukawa coupling. Predictions have been computed similarly to the $t\bar{t}W$ and $t\bar{t}Z$ processes, incorporating NLO corrections with soft-gluon emission resummation [57]. Recently, approximate NNLO QCD predictions have also been derived for $t\bar{t}H$ production [62].

$tt\bar{t}/\bar{t}\bar{t}t$: EW production of single t or $\bar{t}$ can be accompanied by the QCD emission of a $t\bar{t}$ pair. This leads to a final state with three top quarks. Depending on the EW single-top-quark production channel, predictions can be calculated either at LO (for tW) or at NLO (for $s-$ and t-channels) through automated codes. The LO expectation for the cross section at 14 TeV LHC is around 2 fb [63].

$t\bar{t}t\bar{t}$: The production of four top quarks at hadron colliders probes very high scales and is sensitive to higher-order EW and QCD effects [64]. Predictions have been computed to next-to-leading logarithmic (NLL') accuracy, matched to full NLO QCD and EW corrections. The NLL' corrections enhance the total production rate by approximately 26%, significantly reducing theoretical uncertainties from scale variations, which are now smaller than current experimental uncertainties [65].

Theoretical predictions for these processes are implemented in Monte Carlo event generators to at least NLO accuracy, and discussed in detail in the corresponding section in this *Review*. Many of these processes have already been observed at the LHC, and their computed cross sections are summarized in Tab. 61.3 at $\sqrt{s} = 13\,\text{TeV}$.

Table 61.3: Predictions for inclusive cross sections at LHC at $\sqrt{s} = 13\,\text{TeV}$ for $t\bar{t}$ production in association with additional particles. The first uncertainty comes from scale variation, while the second (when present) comes from the PDF. The perturbative order refers to the highest order in QCD and EW available (aNNLO=approximated NNLO).

Process	Cross section [fb]	Perturbative order	Ref.
$t\bar{t}W$	745.3^{+37+14}_{-48-14}	aNNLO QCD +EW NLO	[59]
$t\bar{t}Z$	811^{+89+19}_{-78-19}	NLO+NNLL QCD	[57]
$t\bar{t}\gamma$ (w/cuts)	$1720^{+207+16}_{-208-16}$	NLO QCD + EW NLO	[66]
$t\bar{t}H$	529^{+8}_{-12}	aNNLO+NNLL QCD +EW NLO	[67]
$t\bar{t}t\bar{t}$	$14.7^{+1.2}_{-2.5}$	NLO+NLL' QCD + EW NLO	[65]

61.1.4.4 *Single production*

There are three main mechanisms to produce top quarks singly in pp and $p\bar{p}$ collisions, see Fig. 61.3: t-channel ($qb \to q't$), mediated by a space-like (virtual) W boson [68], s-channel production

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com

($q\bar{q}' \to t\bar{b}$) [69] mediated by a time-like W boson, and tW production ($bg \to tW^-$) [70], where the W boson is on-shell. These processes have smaller cross sections than QCD-driven $t\bar{t}$ production but offer unique sensitivity to the EW sector and top-quark couplings. Separate measurements of the s- and t-channel processes provide sensitivity to physics beyond the SM [71]. Additionally, the production of single top-quarks associated with a Z or Higgs boson is classified as *associated single top-quark production*.

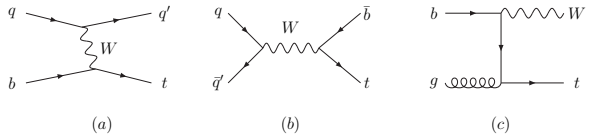

Figure 61.3: Representative Feynman diagrams for single top production (a) via t-channel, (b) via s-channel, and (c) via tW-channel.

Assuming $|V_{tb}| \gg |V_{td}|, |V_{ts}|$ (see the Section "The CKM Quark-Mixing Matrix" in this *Review*), the cross sections for single-top-quark production are proportional to $|V_{tb}|^2$. This brings the unique possibility that no additional assumptions about the number of quark families or CKM unitarity are required to extract $|V_{tb}|$.

While suppressed by the weak coupling relative to QCD $t\bar{t}$ production, t-channel single-top-quark production is kinematically enhanced, leading to sizeable cross sections at both Tevatron and LHC energies. At the Tevatron, the s-channel production is symmetric, while t-channel exhibits a forward–backward asymmetry; at the LHC, the symmetric pp initial state yields different top and antitop production rates in the t-channel.

For $m_t = 173.2\,\text{GeV}$, the NNLO prediction for t-channel single top ($t + \bar{t}$) in $p\bar{p}$ collisions at $\sqrt{s} = 1.96\,\text{TeV}$ is [72]:

$$\sigma^{t+\bar{t}}_{t\text{-ch}} = 2.08^{+0.04}_{-0.03}\,(\text{scale})^{+0.08}_{-0.10}\,(\text{PDF})\,\text{pb}.$$

Updated NNLO predictions for $m_t = 172.5$ GeV at the LHC are given in Tab. 61.4, where the first uncertainty reflects scale variation and the second PDF and α_s uncertainties [72–74].

Finite-order expansions of resummed cross sections, including soft and collinear gluon corrections, have been computed through NNLO for single-top-quark production in the s-channel. At the Tevatron, the results for single top and antitop quarks are identical. For $\sqrt{s} = 1.96\,\text{TeV}$ and $m_t = 173\,\text{GeV}$, the NNLO prediction is [75]:

$$\sigma^{t+\bar{t}}_{s\text{-ch}} = 1.05^{+0.001}_{-0.005}\,(\text{scale})^{+0.030}_{-0.028}\,(\text{PDF})\,\text{pb}.$$

At the LHC, the NNLO cross sections are summarized in Tab. 61.4, with uncertainties quoted from scale variation only.

Although negligible at Tevatron energies, tW production becomes sizeable at the LHC. Accurate predictions for this process are difficult to obtain as, starting at NLO in QCD, it interferes with $t\bar{t}$ production. Several schemes to proper account for this effect have been proposed [76] and implemented in MC generators [37, 77]. Approximate NNLO predictions, obtained from NNLL-resummed calculations, are available for the combined ($t + \bar{t}$) production rates, which are expected to be equal for top and antitop quarks. These predictions, summarized in Tab. 61.4, include uncertainties from scale variation and PDFs [70]. The approximate NNLO corrections enhance the cross section by about 8% relative to the NLO result.

61.1.4.5 *Associated single production*

These rare processes can probe the EW interactions of the top quark and are sensitive to potential contributions from new physics, such as anomalous couplings or effective operators. (Note that in this section, with t we mean both top and antitop quarks). Representative diagrams for each production channel are given in Fig. 61.4.

tZ: In this process, a Z boson is radiated from the top quark, the initial-state quark, or an internal W-boson line, and it can occur in all three single-top-quark production channels, with the t-channel contribution dominating. It provides direct sensitivity to anomalous tqZ and FCNC couplings [79]. At the LHC, the cross section for t-channel+Z production at $\sqrt{s} = 13$ TeV has been computed at NLO in QCD and EW [80] and is listed in Tab. 61.5.

Table 61.4: Predictions for inclusive cross sections of single top-quark production at the LHC. The first uncertainty corresponds to renormalization and factorization scale dependence, while the second is due to PDF+α_s variations.

$\sqrt{s}$ (TeV)	$\sigma^{t+\bar{t}}_{t-ch}$ (pb)	$\sigma^{t+\bar{t}}_{s-ch}$ (pb)	$\sigma^{t+\bar{t}}_{Wt-ch}$ (pb)
pp	(NNLO) [72–74]	(NNLO) [78]	(approx. NNLO) [70]
5.02	$30.3^{+0.4\,+0.6}_{-0.3\,-0.4}$	NA	$6.54^{+0.16\,+0.33}_{-0.14\,-0.33}$
7	$63.7^{+0.9\,+1.1}_{-0.5\,-0.7}$	$3.00^{+0.03}_{-0.03}$	$17.1^{+0.4\,+0.7}_{-0.3\,-0.7}$
8	$84.3^{+1.1\,+1.4}_{-0.7\,-0.9}$	$5.63^{+0.03}_{-0.03}$	$24.4^{+0.6\,+0.9}_{-0.5\,-0.9}$
13	$214.2^{+2.4\,+3.3}_{-1.7\,-2.0}$	$11.07^{+0.06}_{-0.03}$	$79.3^{+1.9\,+2.2}_{-1.8\,-2.2}$
13.6	$232.2^{+2.6\,+3.4}_{-1.7\,-2.2}$	$11.78^{+0.06}_{-0.04}$	$87.9^{+2.0\,+2.3}_{-1.9\,-2.4}$

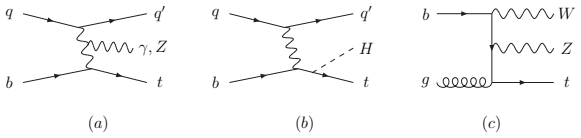

Figure 61.4: Representative Feynman diagrams for single top-quark associated production with (a) γ, Z (b) Higgs, and (c) WZ.

$t\gamma$: Photon emission in association with single-top-quark production or decay gives rise to this process, which probes the electromagnetic structure of the top-quark coupling. It is sensitive to anomalous $tq\gamma$ and dipole interactions. At the LHC, the cross section for t-channel+γ production at $\sqrt{s} = 13$ TeV has been calculated at NLO in QCD and EW [66] (see Tab. 61.5), with predictions depending on photon identification ($p_{\text{T}} > 25$ GeV, $|\eta| < 1.44$) and isolation requirements (see [66] for details).

tH: The associated production of a Higgs boson can occur through radiation from either the top quark or the intermediate W bosons. Non-trivial unitarity cancellations among diagrams make this final state highly sensitive to anomalous interactions [79], thereby playing a crucial role in global fits of top-quark EW couplings. At the LHC, the cross section for t-channel+H production at $\sqrt{s} = 13$ TeV has been calculated at NLO in QCD and EW [80] and is reported in Tab. 61.5.

tWZ: A rare mode, this process produces a single top quark together with a W and a Z boson, radiated from either initial-state quarks or intermediate propagators. The tWZ final state is sensitive to a broad range of anomalous interactions [81] and contributes to global analyses of top-quark EW couplings. At the LHC, the cross section for tWZ production at $\sqrt{s} = 13$ TeV has been computed at NLO in QCD [81] (see Tab. 61.5).

Table 61.5: Cross sections at $\sqrt{s} = 13\,\text{TeV}$ for $t(+\bar{t})$ in association with additional particles.

Process	Cross section [fb]	Perturbative order	Ref.
tZ (t-channel only)	$805^{+45}_{-89}\,(\text{scale})\,^{+3}_{-3}\,(\text{PDF})$	NLO QCD+EW	[80]
$t\gamma$ (t-channel only	$806^{+57}_{-66}\,(\text{scale})\,^{+4}_{-4}\,(\text{PDF})$	NLO QCD+EW	[66]
w/cuts)	$806^{+57}_{-66}\,(\text{scale})\,^{+4}_{-4}\,(\text{PDF})$	NLO QCD+EW	[66]
tH (t-channel only)	$71.3^{+5.2}_{-7.7}\,(\text{scale})\,^{+0.3}_{-0.3}\,(\text{PDF})$	NLO QCD+EW	[80]
tWZ	$106.8^{+5.3}_{-6}(\text{scale})$	NLO QCD	[81]

61.2 Top-quark and precision SM tests

The first direct observation of the top quark was made in 1995 at the Tevatron in $p\bar{p}$ collisions at $\sqrt{s} = 1.8$ TeV by the CDF and DØ experiments [82, 83], followed by more precise measurements at $\sqrt{s} = 1.96$ TeV. Since 2010, the ATLAS and CMS experiments at the LHC have extended top-quark studies to higher energies, performing measurements in pp collisions at $\sqrt{s} = 5.02, 5.36, 7, 8, 13$, and 13.6 TeV. The LHCb experiment has further contributed by observing top-quark production in the forward region [84], a phase-space domain inaccessible to other detectors. Dedicated low-energy runs at $\sqrt{s} = 5.02$ TeV and $\sqrt{s} = 5.36$ TeV in $PbPb$ collisions [85–87] and at $\sqrt{s} = 8.16$ TeV in proton–lead (pPb) collisions [88, 89] have provided a novel and theoretically precise probe of nuclear parton distribution functions.

The experiments have collected approximately 10 fb^{-1} of data at the Tevatron and substantial datasets at the LHC: 255 pb^{-1} at 5 TeV, nearly 5 fb^{-1} at 7 TeV, 20 fb^{-1} at 8 TeV, 139 fb^{-1} at 13 TeV, and about 250 fb^{-1} at 13.6 TeV to date. These diverse datasets enable unprecedented precision in a wide range of top-quark measurements, including production mechanisms mediated by EW and QCD interactions, precise determinations of the top-quark mass, detailed studies of production dynamics such as $t\bar{t}$ spin correlations and charge asymmetries, extensive measurements of differential cross sections, investigations of the tWb vertex, and constraints on Wilson coefficients describing physics beyond the SM.

The top-quark mass has now been measured with a precision better than 0.2%, making it the most accurately determined quark mass to date [1]. Combined with precision measurements of the W-boson mass and Higgs-boson properties, these results provide stringent and comprehensive tests of the SM.

Significant progress has also been achieved in associated production processes involving the top quark, such as $t\bar{t}b\bar{b}$, $t\bar{t}t\bar{t}$, $t\bar{t}\gamma$, $t\bar{t}Z$, $t\bar{t}H$, tH, tZq, $t\gamma q$, and tWZ. Most of these processes have now been observed, including the recent observation of tWZ production, while tH associated production remains beyond current experimental reach. These channels probe novel aspects of top-quark physics, including its EW couplings to neutral gauge bosons and possible four-top production mediated by new contact interactions. The measurements of tH and $t\bar{t}H$ production are discussed in the *Review* "Status of Higgs Boson Physics" in Sec. 11.3.5.

Recent pioneering analyses have begun to explore quantum entanglement phenomena in top-quark pair production, and an excess has been reported compatible with a pseudoscalar quasi-bound state [90, 91], discussed further in chapters 61.2.5.3 and 61.2.5.5. In parallel, numerous searches for BSM physics exploit the top quark as a sensitive probe, either through its production dynamics or through decays involving hypothetical new particles.

The following sections review the current status of top-quark measurements and discuss their implications for our broader understanding of fundamental particle physics.

61.2.1 *Cross-section measurements of pair production*

Top quarks decay before they hadronize, and their presence is inferred from detecting their decay products. Each top quark decays almost exclusively to a W boson and a b quark. The $t\bar{t}$ final states are categorized based on the decays of the W bosons:

- **All-hadronic (AH) channel (45.7%):** $t\bar{t} \to W^+ b\, W^- \bar{b} \to q\bar{q}' b\, q''\bar{q}''' \bar{b}$
- **Lepton+jets (LJ) channel (43.8%):** $t\bar{t} \to W^+ b\, W^- \bar{b} \to q\bar{q}' b\, \ell^- \bar{\nu}_\ell\, \bar{b}$ or $\ell^+ \nu_\ell b\, q\bar{q}' \bar{b}$
- **Dilepton (DL) channel (10.5%):** $t\bar{t} \to W^+ b\, W^- \bar{b} \to \ell^+ \nu_\ell b\, \ell'^- \bar{\nu}_{\ell'} \bar{b}$

The branching fractions in parentheses are computed assuming lepton universality for the decay of the W-boson. The symbol ℓ refers to any charged lepton (e, μ, or τ). However, most analyses focus on electrons and muons due to the challenges associated with reconstructing τ leptons. The symbol q refers to any quark flavor other than a b quark. Final-state quarks hadronize into jets, whose reconstruction depends on the decay kinematics and the analysis algorithm. Neutrinos are not detected directly but are inferred as an imbalance in the event transverse momentum.

In general, the top-quark measurements extracted from $t\bar{t}$ are categorized depending on the number of leptons in the final state as dilepton (DL), lepton+jets (LJ), and all-hadronic (AH) decay channels. The DL channel offers the highest signal purity but is affected by larger statistical uncertainties due to its small branching ratio. The DL($e\mu$) channel specifically refers to events containing one electron and one muon in the final state. In contrast, the LJ channel benefits from a larger branching ratio and better statistical precision, although it is more susceptible to background contamination and larger systematic uncertainties. As data samples increased from the Tevatron to the LHC, the relative precision of these channels improved, with the DL channel often becoming the most precise. Measurements in the AH channel are less common due to the overwhelming QCD multijet background, which is challenging to model and suppress.

In some events, the top quarks are produced with high transverse momentum ($p_{\mathrm{T}} > 400$–500 GeV), resulting in a **boosted** topology where the decay products become collimated. In this case, traditional **resolved** analyses, which reconstruct separate jets, may not resolve individual decay products. Instead, jet substructure techniques are employed to identify large-radius jets consistent with hadronic top decays. Consequently, $t\bar{t}$ final states are further classified into *resolved* and *boosted* categories depending on the top-quark p_{T}.

Experimentally, the measurement of the $t\bar{t}$ production cross section begins with the selection of collision events consistent with the expected $t\bar{t}$ signatures described above. After event selection, background contributions from processes that mimic the signal, such as W/Z+jets, single-top production, QCD multijet and nonprompt-lepton events, and diboson production, are carefully estimated. These estimates are typically obtained using data-driven techniques or Monte Carlo simulations, which are validated against control regions in the data.

To distinguish genuine $t\bar{t}$ events from background processes, analyses employ a variety of discriminating methods, ranging from simple event-counting or kinematic selections to advanced multivariate classifiers such as boosted decision trees, neural networks, or matrix-element techniques. Once suitable discriminants are defined, the signal yield and corresponding cross section are extracted using statistical inference methods, including template fits, profile likelihood fits, or simultaneous maximum-likelihood fits across analysis categories. These inference techniques optimize the use of information in the data and improve the overall precision of the measurement.

Subsequently, detector effects such as trigger efficiency, acceptance, and event-selection efficiency must be corrected to obtain the true $t\bar{t}$ production rate. In simple event-counting analyses, these corrections are typically applied multiplicatively to the observed signal yield, using factors derived from detailed detector simulations calibrated with data. In more sophisticated analyses, such effects are incorporated directly into the signal modeling used for the statistical inference, through templates or parameterized response functions, which allows the fit to constrain the corresponding uncertainties from data and improves the overall measurement precision.

Cross-section measurements rely on a specific Monte Carlo model of $t\bar{t}$ production and decay, which defines the kinematic properties, acceptance, and efficiency of the signal. These simulations assume a value for the top-quark mass, typically 172.5GeV, and a particular modeling of QCD radiation, hadronization, and parton showering. The assumed mass and modeling both affect the acceptance corrections and, in some cases, the shapes of key kinematic and topological distributions used in the analysis. The precision of the measurements, therefore, benefits greatly from Monte Carlo generators that accurately reproduce the observables studied in data.

Comprehensive evaluations of systematic uncertainties, including detector performance and object reconstruction, background and signal modeling uncertainties, and luminosity measurement accuracy, are integral to ensuring the reliability and robustness of the measurement.

Systematic uncertainties related to object reconstruction include the jet energy scale (JES), b-tagging, and lepton identifi-

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

cation. The JES uncertainty accounts for possible mismatches between the true jet energy and its reconstructed value in the detector, affecting all measurements that rely on jet kinematics. The b-tagging systematic reflects differences between data and simulation in the efficiency of correctly identifying b-jets or misidentifying other jet flavors. Since nearly all top-quark measurements rely on b-tagging, this uncertainty appears prominently in most analyses. The lepton identification uncertainty accounts for potential discrepancies between data and simulation in the efficiency of reconstructing and identifying electrons or muons, and tends to dominate in analyses with multiple leptons.

A dominant source of systematic uncertainty in these measurements is the integrated luminosity, which is typically quoted separately from other systematic uncertainties. To mitigate this, some analyses have measured the $t\bar{t}$ production cross section relative to the Z boson production cross section, thus reducing the dependence on the absolute luminosity estimate. This is typically done in the early stages of data-taking, when the luminosity uncertainty is still large.

Finally, the measured $t\bar{t}$ cross section is interpreted by comparing it with theoretical predictions. Agreement or deviation from these predictions provides essential tests of the SM and opens opportunities to explore potential new physics phenomena.

Figure 61.5 summarizes the measured $t\bar{t}$ production cross sections from Tevatron and LHC collisions at various center-of-mass energies, compared to theoretical predictions at NNLO+NNLL accuracy.

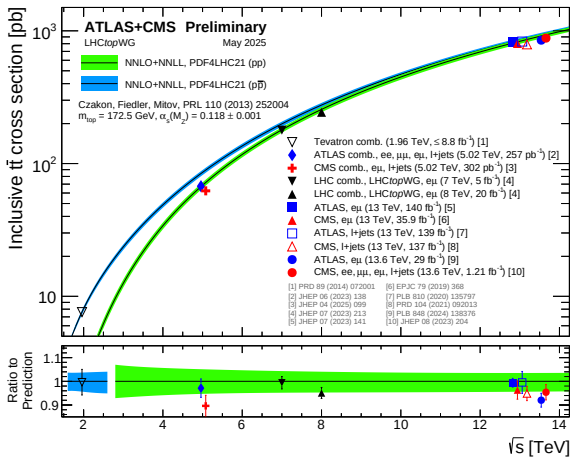

Figure 61.5: Measured and predicted $t\bar{t}$ production cross sections from Tevatron energies in $p\overline{p}$ collisions to LHC energies in pp collisions. The LHCtopWG working group kindly provides the plot, status as of May 2025, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

Studies of $t\bar{t}$ production in single-, double-, or, more recently, even triple-differential measurements are essential. Such measurements allow increasingly stringent tests of perturbative QCD as a description of the production mechanism and, in combination with other data, facilitate the extraction of PDFs. Measurements of the differential $t\bar{t}$ cross section also allow for the extraction of m_t, α_s, and the top Yukawa coupling to the Higgs boson. Moreover, such measurements enhance sensitivity to possible new physics contributions, particularly now that NNLO predictions for the main differential observables in $t\bar{t}$ production are available [92] and have been independently confirmed [45]. Finally, precise differential results also reduce uncertainties in modeling $t\bar{t}$ production as a background in other SM measurements and in searches for rare processes or physics beyond the SM.

Differential cross sections are typically determined by selecting candidate events, reconstructing their kinematics, and unfolding the measured event to the parton level, binned in kinematic variables to correct for detector resolution, acceptance, and migration effects. While bin-by-bin unfolding is used in some analyses, others apply more sophisticated approaches. The most commonly employed methods include iterative Bayesian unfolding (IBU) [93], often implemented through the `RooUnfold` package [94], and profile-likelihood unfolding [95,96]. Alternative techniques, such as singular value decomposition [97] and maximum likelihood fits [98], are also utilized. A general observation of $t\bar{t}$ differential measurements is that the measured top-quark p_{T} spectrum tends to be significantly softer than the corresponding NLO+PS theoretical predictions presented in the existing literature, while the agreement improves significantly when compared to NNLO+PS predictions [43].

At the Tevatron, both the CDF and DØ collaborations evolved from an initial search program aimed at discovering the top quark to performing precise measurements of the inclusive $t\bar{t}$ production cross section. Table 61.6 summarizes the earliest $t\bar{t}$ measurements, the most precise individual results, and the final combination.

The latest measurements of the $t\bar{t}$ production cross section from the DØ collaboration [101] and the CDF collaboration [102] assume a top-quark mass of 172.5 GeV, while earlier measurements assumed 175 GeV. Combining these measurements using the Best Linear Unbiased Estimator (BLUE) method, the Tevatron collaborations report a combined cross section: $\sigma_{t\bar{t}} = 7.60 \pm 0.20\,(\mathrm{stat.}) \pm 0.29\,(\mathrm{syst.}) \pm 0.21\,(\mathrm{lumi.})$ pb, which is in agreement with the SM prediction calculated at the same top-quark mass [44]. The correlation coefficient between the measurements from the two experiments is determined to be 17%.

Additionally, CDF has measured the $t\bar{t}$ production cross section in the DL channel, including one hadronically decaying τ lepton, obtaining $\sigma_{t\bar{t}} = 8.1 \pm 2.1$ pb. By separately identifying the single-τ and di-τ leptons, CDF extracted the branching fraction of the top quark into a τ lepton, τ neutrino, and b-quark as $(9.6 \pm 2.8)\%$ [104]. CDF has also measured the $t\bar{t}$ production cross section normalized to the Z boson production cross section, thus reducing the impact of luminosity uncertainties [105].

The ATLAS and CMS experiments at the LHC employ similar techniques to measure the $t\bar{t}$ production cross section in pp collisions. The most precise determinations are typically obtained in the DL channel, particularly in the $e\mu$ final state, owing to the large statistical yield and high purity of this channel. Numerous measurements have been performed across a wide range of center-of-mass energies, including pPb and $PbPb$ collisions, in different channels, and using a variety of techniques. The uncertainties are divided into statistical, systematic, luminosity, and beam components. In CMS measurements, the uncertainty associated with the beam energy is typically included within the quoted systematic uncertainty. As the beam energy determination improved, this convention was also adopted in later ATLAS measurements. The systematic uncertainties strongly depend on the final state and include experimental contributions, related to the identification of objects and background estimates, as well as theoretical contributions that rely on the modeling assumptions used to extract the measurement.

Most results are summarized in Tab. 61.7 and found to be consistent with theoretical predictions. A description of the measurements at different collision energies follows.

61.2.1.1 *Measurements at* $\sqrt{s} = 5.02$ *TeV*

In a dedicated LHC run at this energy, both ATLAS and CMS measured the $t\bar{t}$ production cross section in the DL and LJ channels. Each experiment subsequently combined the results from its individual channels. The ATLAS combination yields $\sigma_{t\bar{t}} = 67.5 \pm 0.9\,(\mathrm{stat.}) \pm 2.3\,(\mathrm{syst.}) \pm 1.1\,(\mathrm{lumi.}) \pm 0.2\,(\mathrm{beam})$ pb, with the dominant uncertainty arising from background modeling [106]. The corresponding CMS combination gives $\sigma_{t\bar{t}} = 62.3 \pm 1.5\,(\mathrm{stat.}) \pm 2.4\,(\mathrm{syst.}) \pm 1.2\,(\mathrm{lumi.})$ pb, where the main contributions to the uncertainty come from the integrated luminosity and from the b-tagging scale factors for b-jets [107]. The two measurements are consistent with each other and with the SM prediction within two standard deviations. These measurements provide important constraints on the proton PDFs at large Bjorken-x.

61.2.1.2 *Measurements at* $\sqrt{s} = 7$ *TeV*

At this energy, a wide variety of final states and methods were explored. The ATLAS measurement in the DL($e\mu$) chan-

Table 61.6: Summary of $t\bar{t}$ cross-section measurements at the Tevatron.

Experiment [Ref.]	Lumi. (fb^{-1})	$\sqrt{s}$ (TeV)	Topology	Measurement (pb)
CDF (first observation) [82]	0.0067	1.8	LJ	$6.8^{+3.6}_{-2.4}$
DØ (first observation) [83]	0.0050	1.8	LJ	5.9 ± 1.7
CDF [99]	0.00109	1.8	DL+LJ	$6.5^{+1.7}_{-1.4}$
DØ [100]	0.00125	1.8	DL+LJ	5.9 ± 1.4
DØ [101]	9.7	1.96	DL+LJ	$7.26^{+0.58}_{-0.51}$
CDF [102]	8.8	1.96	DL	7.09 ± 0.84
CDF [103]	4.3–8.8	1.96	DL+LJ+AH	7.63 ± 0.50
DØ [103]	5.3–9.7	1.96	DL+LJ+AH	7.56 ± 0.59
Tevatron [103]	4.3–9.7	1.96	DL+LJ+AH	7.60 ± 0.41

nel yields $\sigma_{t\bar{t}} = 182.9 \pm 3.1(\text{stat.}) \pm 4.2(\text{syst.}) \pm 3.6(\text{lumi.}) \pm 3.3(\text{beam})$ pb [108], with the dominant uncertainty arising from the modeling of $t\bar{t}$ production, evaluated by comparing different Monte Carlo generators and hadronization models. CMS obtained its most precise measurement also in the DL($e\mu$) final state, using a binned likelihood fit to multi-dimensional distributions related to b-quark jets and other jets identified in the event. The measured cross-section is $\sigma_{t\bar{t}} = 173.6 \pm 2.1(\text{stat.})^{+4.5}_{-4.0}(\text{syst.}) \pm 3.8(\text{lumi.})$pb [109].

In the LJ channel, ATLAS utilized a three-class, multidimensional event classifier based on support vector machines to distinguish $t\bar{t}$ from $W/Z+b\bar{b}$ and other background processes, obtaining $\sigma_{t\bar{t}} = 168.5 \pm 0.7(\text{stat.})^{+6.2}_{-5.9}(\text{syst.})^{+3.4}_{-3.2}(\text{lumi.})$ pb [110].

Additional measurements using partial datasets by ATLAS and CMS played a crucial role in refining techniques and enhancing data understanding. These studies were carried out in several channels, including e/μ+jets [111], DL [112] [113], AH [114], lepton+τ [115], hadronic τ+lepton [116], and τ+jets [117] [118]. These results are consistent with theoretical predictions, although they are characterized by larger uncertainties due to limited data statistics and systematic effects.

Furthermore, both collaborations have jointly published a combined "legacy" cross-section measurement at $\sqrt{s} = 7$ TeV, which is also included in Tab. 61.7.

The first observation of $t\bar{t}$ production in the forward region of pp collisions was performed by LHCb using the e+jets and μ+jets channels. The inclusive $t\bar{t}$ production cross section measured in the fiducial region is $\sigma_{t\bar{t}} = 239 \pm 53(\text{stat.}) \pm 33(\text{syst.}) \pm 24(\text{theo.})$fb [84]. This result is in agreement with the SM predictions of 180^{+51}_{-41} fb at 7 TeV obtained at NLO using MCFM program [119].

ATLAS and CMS measured single-differential $t\bar{t}$ cross sections for the jet multiplicity, the top-quark p_{T}, and m_t, and the rapidity of the top quark as well as of the $t\bar{t}$ system or kinematic properties of the final-state charged leptons and jets associated with b-quarks. While CMS finds in general good agreement with the pQCD calculations [120–122], ATLAS finds the data to be softer, in particular in the $t\bar{t}$ mass and the top-quark p_{T} than the ALPGEN+HERWIG generator. Also, some disagreement in the rapidity spectrum is observed, indicating a preference for the HERAPDF1.5 PDF set over CT10 [123–125].

61.2.1.3 *Measurements at $\sqrt{s} = 8$ TeV*

The DIL($e\mu$) channel provided the most precise measurements of the $t\bar{t}$ production cross section at this energy, which is included in Tab. 61.7. ATLAS determined $\sigma_{t\bar{t}} = 242.9 \pm 1.7(\text{stat.}) \pm 5.5(\text{syst.}) \pm 5.1(\text{lumi.}) \pm 4.2(\text{beam})$ pb through a simultaneous extraction of the b-tagging efficiency [126]. CMS conducted a measurement by fitting multidimensional final-state distributions involving identified b-quark jets and other jets, obtaining $\sigma_{t\bar{t}} = 244.9 \pm 1.4(\text{stat.})^{+6.3}_{-5.5}(\text{syst.}) \pm 6.4(\text{lumi.})$ pb [109,127]. This measurement was also used to determine the m_t^{pole} and set constraints on potential new physics models.

In the LJ channel, ATLAS modeled the W+jets background using Z+jets data and employed neural networks to classify events across three regions defined by jet and b-jet multiplicities. This analysis resulted in $\sigma_{t\bar{t}} = 248.3 \pm 0.7(\text{stat.}) \pm 13.4(\text{syst.}) \pm 4.7(\text{lumi.})$ pb [128]. CMS performed a template fit to the invariant mass distribution M_{lb}, extracting from it $\sigma_{t\bar{t}} = 228.5 \pm 3.8(\text{stat.}) \pm 13.7(\text{syst.}) \pm 6.0(\text{lumi.})$ pb [129].

Additionally, both ATLAS and CMS measured the cross section in the hadronic τ+jets channel, producing consistent but less precise results [130, 131]. CMS also obtained a measurement in the AH final state [132].

ATLAS and CMS combined their DL($e\mu$) channel results [133], performing cross-section ratio studies to verify the internal consistency of the measurements and to reduce sensitivity to specific systematic uncertainties. Ratios of measurements taken at $\sqrt{s} = 7$ TeV and 8 TeV provided precise tests of perturbative QCD and constraints on PDFs. Additionally, ratios between $t\bar{t}$ and Z-boson production cross sections were analyzed to minimize luminosity uncertainties while maintaining sensitivity to the gluon-to-quark PDF ratio. These combined analyses also enabled the extraction of m_t^{pole} and the determination of α_s.

LHCb measured $t\bar{t}$ production in the forward region of pp collisions at 8 TeV in the e+jets and μ+jets channels. The measured cross section is $\sigma_{t\bar{t}} = 289 \pm 43(\text{stat.}) \pm 40(\text{syst.}) \pm 29(\text{theo.})$ fb [84], which agrees with the NLO SM prediction of 312^{+83}_{-68} fb calculated using MCFM. Additionally, the measured differential yield distributions and charge asymmetry are consistent with SM predictions.

ATLAS measured single-differential cross sections in the DL and LJ channels, analyzing observables such as m_t, top-quark p_{T}., rapidity of the $t\bar{t}$ system, and other event-level kinematic variables [134,135]. These measurements demonstrate good or fair agreement with theoretical predictions across a wide kinematic range, with predictions beyond NLO accuracy notably improving the consistency at high p_{T}.

CMS performed extensive measurements of normalized differential cross sections for $t\bar{t}$ production in the LJ channel, examining kinematic variables such as missing transverse energy, scalar sums of jet p_{T}, scalar sums of the p_{T} of all event objects, and the p_{T} of the leptonically decaying W bosons originating from top-quark decays [121]. Furthermore, CMS has measured differential cross sections in both the LJ and DL decay channels, focusing on kinematic properties of charged leptons, jets associated with b quarks, top quarks, and the entire $t\bar{t}$ system, comparing the results to predictions at approximate NNLO precision [136]. Notably, in the DL($e\mu$) channel, CMS's normalized double-differential cross-section measurements as a function of paired kinematic observables significantly impacted the determination of gluon distributions in PDF fits [137].

Additionally, ATLAS and CMS carried out targeted differential $t\bar{t}$ measurements in the boosted topology using the LJ channel. In these analyses, the hadronically decaying top quark was reconstructed as a single large-radius jet and identified as a top candidate through jet substructure techniques. ATLAS focused on events with hadronic top quarks of $p_{\mathrm{T}} > 300$ GeV [138], while CMS used a threshold of $p_{\mathrm{T}} > 400$ GeV [139]. Predictions from NLO and LO matrix-element calculations interfaced with parton-shower Monte Carlo generators generally overestimate the measured cross sections. This can be explained by the softer p_{T} spectra in the data compared to the simulation.

61.2.1.4 *Measurements at* $\sqrt{s} = 13$ *TeV*

The most precise measurement of the $t\bar{t}$ cross section is obtained in the DL($e\mu$) final state with b-tagged jets by ATLAS, yielding $\sigma_{t\bar{t}} = 829 \pm 1(\text{stat.}) \pm 13(\text{syst.}) \pm 8(\text{lumi.}) \pm 2(\text{beam})$ pb [140]. This analysis includes differential and double-differential measurements of kinematic variables of leptons from top-quark decays, comparing results against predictions from several Monte Carlo generators. Although no single prediction matches all distributions, reweighting the simulated $t\bar{t}$ events to align with the top-quark p_{T} distribution calculated at NNLO significantly improves agreement, especially for lepton p_{T} distributions.

CMS measured the $t\bar{t}$ cross section in the DL channel using a likelihood fit, reporting $\sigma_{t\bar{t}} = 803 \pm 2(\text{stat.}) \pm 25(\text{syst.}) \pm 20(\text{lumi.})$ pb [141]. This result facilitated the extraction of the m_t^{pole} and $\overline{\text{MS}}$ schemes at NNLO and allowed the determination of α_s.

In the LJ channel, ATLAS measured the inclusive $t\bar{t}$ cross section using a profile-likelihood fit, obtaining $\sigma_{t\bar{t}} = 830 \pm 0.4(\text{stat.}) \pm 36(\text{syst.}) \pm 14(\text{lumi.})$ pb [142]. CMS measured this channel, dividing events into regions based on top-quark p_{T} and b-tag scores, and employed a combined χ^2 fit with migration matrices, measuring $\sigma_{t\bar{t}} = 791 \pm 1(\text{stat.}) \pm 21(\text{syst.}) \pm 14(\text{lumi.})$ pb, noting generally good agreement with SM predictions except for certain double-differential distributions [143].

ATLAS utilized partial datasets in the DL $e\mu$ channel with one or two b-tags to determine the m_t^{pole}, compute ratios and double ratios of $t\bar{t}$ to Z cross sections across different energies, and measure absolute and normalized differential cross sections as functions of LJ and DL kinematic variables [144]. A pioneering measurement of inclusive and normalized differential cross sections in the LJ channel was also conducted by CMS [145]. Other significant results using partial datasets include CMS measurements in the DL channel featuring a hadronically decaying τ [146].

CMS-TOTEM performed the first search for the central exclusive production of $t\bar{t}$ pairs using proton-tagged events with an integrated luminosity of 29.4 fb^{-1}. The top-quark pair decay products were reconstructed by the central CMS detector, while forward protons were measured using the TOTEM precision proton spectrometer. An observed (expected) upper limit on the production cross section of 0.59 (1.14) pb was established at a 95% C.L. for proton collisions with fractional momentum losses ranging from 2% to 20% [147].

LHCb measured the forward production of $t\bar{t}$ in the μeb final state, consisting of a muon, an electron, and a b-jet. The cross section is measured in a fiducial region defined by both leptons p_{T} and pseudorapidities as well as their angular separation, the b-jet p_{T} and its angular separation from the leptons, yielding $\sigma_{t\bar{t}} = 126 \pm 19(\text{stat.}) \pm 16(\text{syst.}) \pm 5(\text{lumi.})$fb [148].

Single- and double-differential cross-section measurements for $t\bar{t}$ production have been extensively performed in various channels. Both ATLAS and CMS have performed high-precision measurements of these cross sections in the DL and LJ channels, probing the kinematic properties of leptons, b-quark jets, top quarks, top-quark pairs, and jet multiplicities [149–153]. All results are compared with SM predictions from Monte Carlo simulations with NLO accuracy in QCD at matrix-element level interfaced to parton-shower simulations. While these measurements generally agree well with theoretical predictions, notable discrepancies have been observed in specific DL analyses. CMS has used these results to constrain the top-quark chromomagnetic dipole moment [154] within an EFT framework at NLO QCD, and to extract $t\bar{t}$ and leptonic charge asymmetries [155].

CMS performed the first triple-differential measurement of the $t\bar{t}$ production cross section in the dilepton (DL) channel, as a function of the invariant mass and rapidity of the $t\bar{t}$ system and the multiplicity of additional jets, using a partial Run 2 dataset. From this measurement, α_s, m_t^{pole}, and PDFs were extracted [156]. With the full Run 2 dataset, CMS measured differential $t\bar{t}$ and $t\bar{t}$+jets cross sections as functions of up to three kinematic variables, unfolded to both parton and particle levels. Comparisons with QCD predictions show that theoretical calculations do not consistently reproduce the data, with the most considerable deviations appearing in multi-differential observables. Predictions beyond NLO provide similar or improved agreement for top-quark and $t\bar{t}$ observables, while improvements for lepton and b-jet variables remain limited. The observed dependence on PDF choice indicates that these measurements can provide valuable input to future global PDF fits [157].

ATLAS measured absolute and normalized differential cross sections for the $t\bar{t}$ process in the $e\mu$ DL channel as functions of different observables. Also, it provided complementary measurements of $e\mu b\bar{b}$ production, treating both $t\bar{t}$ and Wt as signal. Comparisons with event generator predictions show that state-of-the-art generators such as Powheg MiNNLO or Powheg bb4l better model the lepton kinematics than the Powheg hvq process traditionally used for LHC physics analyses. These precise measurements provide input that can be used to further refine the modeling of the top quark production at hadron colliders [158].

ATLAS has performed measurements in the AH channel, examining the resolved regime with individually reconstructed jets [159], and measuring differential cross sections as a function of various kinematic properties of the top quarks and the overall $t\bar{t}$ system, both at the stable-particle level within a fiducial phase space and at the parton level in the full phase space.

In boosted topologies, CMS and ATLAS have performed dedicated analyses of $t\bar{t}$ cross sections as a function of top-quark and $t\bar{t}$ system kinematics. CMS measured these cross sections in the AH and LJ channels using large-radius jets with b-tags, finding absolute cross sections notably lower than theoretical predictions [160]. ATLAS carried out similar measurements in these channels, focusing on high-p_{T} hadronic decays, characterizing additional radiation, and setting limits on Wilson coefficients describing potential physics beyond the SM [161]. Mild discrepancies with the data were observed in the modeling of additional radiation. ATLAS has also measured differential $t\bar{t}$ cross sections in AH events in boosted topologies [162]. CMS has further performed single- and double-differential measurements in the LJ channel, categorized by top-quark p_{T}, boosted versus resolved topologies, and b-tagging scores, extending momentum measurements well into the TeV range [143].

Several differential $t\bar{t}$ cross-section measurements have been performed to aid in the tuning of Monte Carlo generators. ATLAS measured one- and two-dimensional differential cross sections for eight jet substructure variables, defined using charged jet components and corrected for detector effects [140, 163]. QCD predictions agree well with measured energy-flow variables, whereas discrepancies arise for variables sensitive to the three-body structure of top-quark jets. Additionally, observables sensitive to color reconnection effects in top-quark pair-production events, such as charged-particle multiplicity and scalar sums of charged-particle p_{T}, were measured and unfolded to the stable-particle level. These data disfavor certain color reconnection models, informing future Monte Carlo parameter optimizations [164].

Furthermore, ATLAS measured observables related to b-quark fragmentation into b-hadrons. Observables characterizing longitudinal and transverse momentum distributions of b-hadrons within jets were corrected for detector effects. The unfolded results were compared to various Monte Carlo generators, showing varying levels of agreement. These measurements complement similar results from e^+e^- collider experiments, where b-quarks originate from color-singlet Z/γ^* states [165].

61.2.1.5 *Measurements at* $\sqrt{s} = 13.6$ *TeV*

The LHC began colliding protons at $\sqrt{s} = 13.6$ TeV in 2022 and is expected to continue until mid-2026. ATLAS and CMS have already performed inclusive $t\bar{t}$ cross-section measurements using partial Run 3 datasets at this energy.

The first result was reported by the CMS collaboration using 1.21 fb^{-1} of data in events in the LJ channel [166]. Events were categorized according to lepton flavor and multiplicity, the number of jets, and the number of b-tagged jets, and the cross section was extracted from a profile-likelihood fit. CMS measured $\sigma_{t\bar{t}} = 881 \pm 23$ (stat+syst) ± 20 (lumi) pb.

ATLAS performed a complementary measurement in the DIL($e\mu$) final state with b-tagged jets using 29 fb^{-1} of data [167]. The result, $\sigma_{t\bar{t}} = 850 \pm 3$ (stat.) ± 18 (syst.) ± 20 (lumi.) pb, corresponds to a relative uncertainty of 3.2%, dominated by the

luminosity calibration. To reduce its impact, ATLAS also extracted the ratio of $t\bar{t}$ to Z+jets production, obtaining $R_{t\bar{t}/Z} = 1.145 \pm 0.003$ (stat.) ± 0.021 (syst.) ± 0.002 (lumi.) with a relative uncertainty of 1.9%, benefitting from cancellations of common systematic effects.

Both ATLAS and CMS results are consistent with SM expectations and the NNLO+NNLL prediction, and already achieve percent-level precision despite being based on early Run 3 datasets.

61.2.2 *Cross-section measurements of associated pair production*

The associated production of a $t\bar{t}$ pair with an additional particle ($t\bar{t}X$, with $X = \gamma$, W, Z, H, top quarks or jets) provides direct probes of the top-quark couplings. The $t\bar{t}H$ process offers the most direct access to the top–Higgs Yukawa coupling, while $t\bar{t}Z$ and $t\bar{t}W$ test the EW couplings of the top quark and are sensitive to anomalous interactions in the EFT framework.

Measurements typically require the reconstruction of a $t\bar{t}$ final state in the DL or LJ channels, together with the specific signature of the associated particle (isolated photon, additional leptons, $b\bar{b}$ pair from $H \to b\bar{b}$, or extra jets), and employ multivariate techniques to separate signal from background. CDF reported the first measurement of the associated $t\bar{t}\gamma$ production, while studies of $t\bar{t}W$, $t\bar{t}Z$, $t\bar{t}H$, and $t\bar{t}t\bar{t}$ processes were initiated at the LHC. Evidence and subsequent observations of several of these processes began to emerge during Run 1.

This has become a very active area of research, with many new associated production processes observed in recent years. As larger datasets are collected, these measurements are becoming increasingly precise, and analyses are moving toward differential cross sections, which provide enhanced sensitivity to EFT coefficients.

The next section is organized by associated production processes, beginning with the most common production channel and progressing to increasingly rare ones.

61.2.2.1 *Associated pair production with jets*

The production of $t\bar{t}$ in association with jets, denoted as $t\bar{t}$+jets, where the additional jets originate from the fragmentation of quarks of any flavor or gluons, offers a valuable probe of QCD radiation in a multi-scale environment. Within this context, the subset of events involving additional b-quarks, $t\bar{t}+b$-jets, is of particular interest due to the added complexity introduced by heavy-flavor production. Although NLO QCD calculations are available for both $t\bar{t}$+jets and $t\bar{t}+b\bar{b}$ final states [170], these predictions are subject to sizable theoretical uncertainties. A major source of uncertainty lies in the choice of factorization and renormalization scales, which is complicated by the presence of at least two relevant physical scales: the m_t and the p_{T} of the additional jets. The measurements of $t\bar{t}$+jets offer useful constraints for tuning theoretical models of QCD radiation in $t\bar{t}$ events.

Measurements are usually performed in fiducial regions and unfolded to the particle level to enable direct comparisons with NLO calculations and Monte Carlo simulations.

At $\sqrt{s} = 7$ TeV, ATLAS performed a study of $t\bar{t}$ production with a veto on central jet activity, measuring the fraction of events that pass the jet veto as a function of the p_{T} threshold across multiple rapidity intervals [171]. Following, ATLAS measured the fiducial $t\bar{t}$ production cross section as a function of jet multiplicity, including up to eight jets, in both the LJ and DL decay channels [172]. The precision of these measurements ranged from approximately 10% to 30%, with the dominant uncertainties arising from background modeling at low jet multiplicities and uncertainties in the jet energy scale at higher multiplicities.

CMS conducted similar measurements of normalized differential $t\bar{t}$ cross sections as a function of jet multiplicity in the LJ and DL channels [122]. In the LJ channel, the cross section was studied as a function of the number of additional jets, while in the DL channel, the fraction of events with no additional jets above a specified threshold was measured. Comparisons with perturbative QCD predictions revealed no significant deviations.

At $\sqrt{s} = 8$ TeV, CMS extended these studies with measurements of absolute and normalized differential $t\bar{t}$+jets cross sections in the DL channel, exploring various jet p_{T} thresholds and the kinematics of the leading additional jets [173]. The fraction of events without additional jets was also determined as a function of the p_{T} of the leading additional jet and the scalar sum of the transverse momenta of all additional jets. These results were compared with predictions from a range of perturbative QCD event generators and NLO calculations, and were found to agree within uncertainties.

ATLAS performed studies in the DL($e\mu$) channel with two identified b-jets and measured the multiplicity and kinematic properties of additional jets for several p_{T} thresholds [174]. Normalized differential cross sections were reported for the five highest-p_{T} additional jets, as well as gap fraction observables, defined as the fraction of events lacking additional jets in a central rapidity region, as functions of jet p_{T} thresholds or the scalar p_{T} sum. These observables were also explored in different regions of the $e\mu b\bar{b}$ system invariant mass. After correcting for detector effects, the results were found to be largely consistent with LO and NLO event generator predictions, provided suitable parameter settings were used.

At $\sqrt{s} = 13$ TeV, both ATLAS and CMS significantly extended the study of $t\bar{t}$+jets, offering more precise tests of QCD radiation patterns and generator modeling. These analyses focused on inclusive and differential cross sections in both the LJ and DL decay channels, probing jet multiplicities and detailed jet kinematics.

ATLAS measured normalized differential $t\bar{t}$+jets cross sections in the LJ channel as functions of jet multiplicity and the properties of the leading additional jets [175]. These measurements, unfolded to particle level, were compared to predictions from several Monte Carlo event generators. While the Monte Carlo simulations described the general features of the data, notable discrepancies appeared in high jet multiplicity regions and in specific jet kinematic distributions.

In the DL channel, ATLAS performed a complementary study of $t\bar{t}$+jets production [176], which included differential measurements of jet multiplicities, transverse momenta, and gap fractions, defined as the fraction of events without additional jet activity above a given threshold. The results provided sensitivity to soft and collinear QCD radiation and were used to test both leading-order and NLO predictions matched to parton showers. Although broad agreement was observed, no single generator configuration consistently described all observables.

CMS measured differential and double-differential $t\bar{t}$+jets cross sections in the DL channel across a wide range of observables, including additional-jet momenta, angular separations, and global event variables [177]. This extended set of observables provides tighter constraints on parton-shower modeling and on the treatment of initial- and final-state radiation. Normalized $t\bar{t}$+jets cross sections were also measured as a function of jet multiplicity and the kinematics of additional jets in both the DL and LJ channels [178]. The measurements are performed in a fiducial phase space and extrapolated to the full phase space. The values of $\sigma_{t\bar{t}b\bar{b}}$ are extracted from the product of $\sigma_{t\bar{t}jj}$ and the measured cross-section ratio. Results unfolded to the particle level are broadly consistent with NLO+PS predictions, although some tension is observed in observables sensitive to hard radiation and color-reconnection effects.

Together, the ATLAS and CMS results at 13 TeV form a comprehensive dataset for validating QCD predictions in top-quark production with jets. They highlight the strengths and limitations of current theoretical tools and serve as benchmarks for improving Monte Carlo simulations used throughout top-quark physics and beyond.

61.2.2.2 *Associated pair production with b-jets*

The production of $t\bar{t}$ in association with additional b-jets arising from gluon radiation provides a stringent test of perturbative QCD. This process is particularly challenging to predict due to the interplay of multiple mass scales: the large mass of the top quark, the smaller but non-negligible b-quark mass, and the energy scale associated with gluon splitting into $b\bar{b}$ pairs. The hierarchy among these scales introduces significant theoretical uncertainties, especially in modeling the emission of heavy-flavor jets in the presence of top quarks.

Table 61.7: Summary of $t\bar{t}$ cross-section measurements at LHC.

Experiment [Ref.]	**Lumi.** (fb^{-1})	$\sqrt{s}$ **(TeV)**	**Topology**	**Measurement** (pb)
ATLAS [106]	0.257	5.02	DL+LJ	67.5 ± 2.7
CMS [168], [169]	0.302, 0.0274	5.02	DL($e\mu$)+LJ	63.0 ± 5.1
ATLAS [108]	4.6	7	DL($e\mu$)	182.9 ± 7.1
ATLAS [110]	4.6	7	LJ	$168.5^{+7.1}_{-6.7}$
CMS [109]	5	7	DL($e\mu$)	$173.6^{+6.3}_{-5.9}$
ATLAS+CMS [133]	5	7	DL,LJ	178.5 ± 4.7
LHCb [84]	1	7	LJ (fwd)	0.239 ± 0.067
ATLAS [126]	20.3	8	DL($e\mu$)	242.9 ± 8.8
ATLAS [128]	20.2	8	LJ	248.3 ± 14.2
CMS [109]	19.7	8	DL($e\mu$)	$244.9^{+9.1}_{-8.6}$
CMS [129]	19.6	8	LJ	228.5 ± 15.4
ATLAS+CMS [133]	20	8	DL	$243.3^{+6.0}_{-5.9}$
LHCb [84]	2	8	LJ (fwd)	0.289 ± 0.065
ATLAS [126]	140	13	DL($e\mu$)	829 ± 15.4
ATLAS [142]	139	13	LJ	830 ± 38.6
CMS [141]	35.9	13	DL	803 ± 32.1
CMS [143]	137	13	LJ	791 ± 25.3
LHCb [148]	1.93	13	DL($e\mu$) (fwd)	126 ± 25.3
ATLAS [167]	29	13.6	DL	850 ± 27
CMS [166]	1.21	13.6	DL+LJ	881 ± 30

Beyond its theoretical significance, $t\bar{t}$ production with additional b-jets is also an important background in several key analyses, such as those targeting $t\bar{t}H$ and $t\bar{t}t\bar{t}$ production, where its modeling uncertainty can significantly impact the overall sensitivity. The most precise theoretical predictions for these final states rely on fixed-order calculations at NLO accuracy in pQCD, typically matched to parton showers. These calculations are still limited by significant uncertainties from missing higher-order corrections, making direct experimental measurements of these processes especially valuable for improving the theoretical modeling.

To reduce the model dependence, experimental measurements are often performed in fiducial phase-space regions that are closely aligned with the detector acceptance. This strategy enables a more robust comparison with theoretical predictions, which are evaluated within the same fiducial region, thereby minimizing extrapolation uncertainties into unmeasured regions.

The first measurements of $t\bar{t}$ production with b-jets were performed by ATLAS at $\sqrt{s} = 7$ TeV [179]. Events with at least three b-tagged jets were selected, where two b-jets are attributed to top-quark decays and the third to additional heavy-flavor jets, defined to include both b- and c-jets. The result was expressed as the ratio of events with heavy-flavor jets to the total number of $t\bar{t}$ events with additional jets.

At $\sqrt{s} = 8$ TeV, CMS measured fiducial cross sections in the DL channel, requiring at least four jets, of which two were identified as b-jets [180]. ATLAS performed similar measurements in both the LJ and DL channels, targeting $t\bar{t}$ production in association with one or two additional b-jets [181].

CMS extended these studies with the first differential measurements of $t\bar{t}$ cross sections as functions of the jet multiplicity, exploring various jet transverse momentum thresholds and the kinematics of the leading additional jets. Furthermore, it provided differential cross-section measurements for $t\bar{t} + b$ and $t\bar{t} + b\bar{b}$ final states as a function of the kinematic properties of the leading additional b-jets [173].

At $\sqrt{s} = 13$ TeV, ATLAS measured inclusive and differential cross sections for $t\bar{t} + b\bar{b}$ production in both DL and LJ channels using a partial dataset [182]. The measured inclusive fiducial cross sections were generally found to exceed theoretical predictions from various NLO matrix element generators matched to parton showers.

CMS has performed complementary measurements of $t\bar{t} + b\bar{b}$ production across diverse event topologies: first in the DL channel [183], later in both the DL and LJ channels [184], and in the AH channel [185] using partial datasets. In the AH final state, events with at least eight jets, including at least two b-jets, were analyzed. A combination of multivariate techniques was used to suppress the substantial multijet background and to discriminate jets from top-quark decays from those originating from additional radiation. A two-dimensional likelihood fit yielded a $\sim 25\%$ precision on the $t\bar{t} + b\bar{b}$ cross section in this channel.

CMS reported comprehensive measurements of inclusive and normalized differential $t\bar{t} + b\bar{b}$ cross sections using the full dataset in the LJ channel [186], providing results in four distinct fiducial phase-space regions optimized to probe different aspects of the process. Distributions were unfolded to the particle level using maximum likelihood fits, enabling direct comparisons with theoretical predictions from a range of event generators. The measured inclusive cross sections tend to exceed the predictions obtained with the default settings of these generators. At the differential level, the data exhibit varying degrees of agreement, with discrepancies observed particularly in regions sensitive to additional b-jet radiation.

ATLAS performed differential measurements in the DL final state, analyzing events with exactly one electron and one muon and requiring at least three or four identified b-jets [187]. Results were unfolded to the particle level and reported for both inclusive and normalized differential cross sections. The differential measurements encompass global event properties, individual jet kinematics, and observables sensitive to correlations among b-jets, including those stemming from top-quark decays as well as those originating from additional heavy-flavor radiation. After correcting for detector effects, the measured integrated fiducial cross sections are generally consistent with predictions from various NLO matrix-element calculations matched to parton showers, within the quoted theoretical and experimental uncertainties.

In both ATLAS and CMS results, the unfolded differential measurements are compared with state-of-the-art theoretical predictions. While some event generators describe certain kinematic distributions well, none achieves a fully consistent agreement across all observables. The differences among the various theoretical predictions are generally smaller than the experimental uncertainties for most measured quantities, underscoring the need for further theoretical improvements and more precise data to better discriminate between modeling approaches.

61.2.2.3 *Associated pair production with c-jets*

Predicting and detecting production of $t\bar{t}$ in association with additional c-jets arising from gluon radiation is even more challenging than with additional b-jets. Both ATLAS and CMS have published such measurements using the 13 TeV dataset. The first measurement was performed by the CMS collaboration using a

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

partial 13 TeV dataset [188]. The measurement is based on events with dileptonic $t\bar{t}$ final states and differentiates the three processes $t\bar{t}$+light, $t\bar{t}+b\bar{b}$ and $t\bar{t}+c\bar{c}$. The events are categorised using a neural-network approach that utilises charm-jet tagging information. The output probabilities of the different classes are then used to construct a two-dimensional discriminator that is used in a binned profile-likelihood fit to extract the cross-sections for the three processes. The measurement is performed in a fiducial and in the inclusive phase space. Also the ratios of cross-sections are extracted, which benefit from the cancellation of several uncertainties. The measured cross-sections agree with the MC generator predictions within the uncertainties. The cross-section of the $t\bar{t}+c\bar{c}$ process has an uncertainty of 18%, which is dominated by statistical uncertainties as well as uncertainties in the c-tagging calibration and the ME-PS matching uncertainties.

The ATLAS measurement based on the full 13 TeV datasets uses top-quark pairs with either one or two charged leptons in the final state [189]. The cross-sections are extracted for two $t\bar{t}$+charm categories, namely $t\bar{t}+\geq 2c$ and $t\bar{t}+1c$. A new flavour-tagging algorithm is employed that allows to tag b and c jets simultaneously. The discriminating variables in this approach are either the invariant masses of the two closest c-jets or b-jets, or the number of events in the specific region. Seven signal-enriched regions are included in the fit alongside 12 control regions. The cross-sections of the two signal processes as well as for the $t\bar{t}$ and $t\bar{t}+\bar{b}$ processes are extracted simultaneously, both for the fiducial and the inclusive cross-sections. Also ratios of cross-sections are measured. The signal cross-sections have uncertainties of 20% and 14% for $\sigma(t\bar{t}+\geq 2c)$ and $\sigma(t\bar{t}+1c)$, respectively. They are consistent with the predictions within the uncertainties, but are all slightly below the predictions. The precision is limited by data statistics as well as the tagger calibration and the modelling of the signal process.

61.2.2.4 *Associated pair production with massive vector bosons*

The associated production of $t\bar{t}$ with a vector boson V ($V = W, Z$) is a rare but powerful probe of the SM, accessible only at high energies and luminosities. These heavy final states allow precision studies of EW couplings in the top sector and offer unique sensitivity to new physics. In particular, $t\bar{t}W$ production features complex QCD and EW corrections, charge asymmetry from the initial state, and same-sign dilepton signatures, key ingredients in many beyond-the-SM searches. It also forms a major background in rare processes such as $t\bar{t}H$ and $t\bar{t}t\bar{t}$ production. Meanwhile, $t\bar{t}Z$ production provides the most direct probe of the t–Z coupling. In the SM, the W boson is expected to arise primarily from initial-state radiation. In contrast, the Z boson can also be emitted from a final-state top quark, offering direct sensitivity to the top-quark neutral-current interactions and, in particular, to the third component of its weak isospin, a property not yet directly measured. Together, $t\bar{t}V$ processes are central to both precision tests of the SM and the ongoing search for new phenomena at the LHC.

Experimental measurements of $t\bar{t}Z$ and $t\bar{t}W$ typically rely on leptonic decays of the Z and W bosons to suppress the large backgrounds from $t\bar{t}$+jets and $t\bar{t}+b$-jets. The most sensitive channels are final states with three or more charged leptons and events with two same-sign leptons (electrons or muons), which provide substantial background reduction. These analyses require lepton identification with high efficiency and purity to maximize the signal and minimize systematic uncertainties from misidentified leptons.

A summary of the LHC measurements of the inclusive $t\bar{t}V$ cross sections is given in Tab. 61.8.

The first measurement of $t\bar{t}V$ in pp collisions was performed by CMS at $\sqrt{s} = 7$ TeV using two independent analysis channels: a trilepton analysis targeting $t\bar{t}Z$ events and a same-sign dilepton analysis sensitive to $t\bar{t}V$ production. The trilepton channel enabled a direct measurement of the $t\bar{t}Z$ production rate, observed with a significance of 3.3 standard deviations above the background-only hypothesis. The same-sign dilepton analysis yielded evidence for $t\bar{t}V$ production with a significance of 3.0 standard deviations. In both cases, the measured rates were found to be consistent with NLO SM predictions within uncertainties [190].
