At $\sqrt{s} = 8$ TeV, both ATLAS and CMS observed the production of $t\bar{t}$ with a W or Z boson. Both collaborations made simultaneous measurements of the $t\bar{t}W$ and $t\bar{t}Z$ cross sections using final states with two same-sign leptons, three leptons, and four leptons. ATLAS obtained significances of 5.0 and 4.2 standard deviations above the background-only hypothesis for $t\bar{t}W$ and $t\bar{t}Z$, respectively [191]. CMS also reported significances of 4.8 standard deviations for $t\bar{t}W$ and 6.4 for $t\bar{t}Z$ [192]. All results were found to be consistent with NLO SM predictions. In addition, the CMS analysis was used to set constraints on five dimension-six operators in the framework of EFT that could modify the $t\bar{t}W$ and $t\bar{t}Z$ production rates.

At $\sqrt{s} = 13$ TeV, the SM cross sections for $t\bar{t}Z$ and $t\bar{t}W$ production increase by factors of approximately 3.5 and 2.4, respectively, compared to 8 TeV. As Tab. 61.3 shows, these cross sections, calculated at different orders in EW and QCD, carry an uncertainty of about 10%, primarily from renormalization and factorization scale variations. At this center-of-mass energy, ATLAS and CMS performed various measurements in final states with two same-sign leptons or three and four leptons. Using partial datasets, ATLAS simultaneously measured the $t\bar{t}Z$ and $t\bar{t}W$ cross sections via a combined fit across multiple analysis regions [193]. The results are consistent with SM predictions and were used to set constraints on dimension-six SMEFT operators involving the top quark and the Z boson. CMS also reported measurements of the $t\bar{t}V$ cross section using similar final states. For $t\bar{t}W$ production in the same-sign dilepton channel, the observed (expected) significance reached 5.3 (4.5) standard deviations. In the three- and four-lepton channels targeting $t\bar{t}Z$, both observed and expected significances exceeded 5 standard deviations. These results agree with SM predictions and were further used to constrain Wilson coefficients of eight dimension-six EFT operators that would modify $t\bar{t}W$ and $t\bar{t}Z$ production [194].

The first differential $t\bar{t}Z$ measurement by CMS used events with three or four leptons, with the Z boson reconstructed from an oppositely charged lepton pair [195]. Results were presented as functions of the Z p_{T} and the angular distribution of the negatively charged decay lepton, providing a detailed characterization of the process and enabling stringent limits on anomalous tZ couplings.

ATLAS measured inclusive and differential $t\bar{t}Z$ cross sections [196] also using events with three or four isolated leptons. Differential results were unfolded at both the particle and parton levels in specific fiducial regions and are reported as absolute and normalized cross sections. A range of kinematic observables was studied to probe the dynamics of the $t\bar{t}Z$ system. The measurements were compared with predictions from several fixed-order calculations and Monte Carlo generators, showing good overall agreement.

An updated and extended $t\bar{t}Z$ measurement by ATLAS was later performed using the same dataset [197]. This analysis introduced an additional final state targeting the AH decay of the $t\bar{t}$, alongside the multilepton channels. The measurement benefits from improved calibrations, better background modeling, and reduced experimental and theoretical uncertainties. The inclusive and differential cross sections were extracted using a simultaneous profile-likelihood fit across all analysis regions. Unfolding was performed at both particle and parton levels using a consistent fiducial volume, yielding robust and precise results. These measurements were further interpreted in the EFT framework to constrain dimension-six operators relevant to the tZ interaction. Additionally, the spin density matrix coefficients of the $t\bar{t}Z$ system were extracted for the first time, offering a new perspective on the polarization structure of this process.

CMS measured inclusive and differential cross sections of $t\bar{t}Z$ simultaneously with tWZ and tZq in events with three or more leptons. A multiclass deep neural network was employed to separate $t\bar{t}Z$+tWZ, tZq, and background processes. The inclusive cross sections for $70 < m_{\ell\ell} < 110$ GeV are measured to be 1.14 ± 0.07 pb for $t\bar{t}Z$+tWZ and 0.81 ± 0.10 pb for tZq, both consistent with SM predictions [198].

A pioneering study of $t\bar{t}Z$ and $t\bar{t}H$ production in the LJ final state has been performed by CMS to probe potential effects of BSM in top-quark interactions with the Z and Higgs bosons [199]. The analysis selected events with a single charged lepton, multiple

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

jets, two of which are b-tagged, and an additional large-radius jet with high p_{T}, identified as a boosted Z or Higgs boson decaying into a $b\bar{b}$ pair. Signal strengths for boosted $t\bar{t}Z$ and $t\bar{t}H$ production were measured, and upper limits are set on their differential cross sections as functions of the boson p_{T}. These results are translated into constraints on eight dimension-six EFT operators. Limits are also placed on eight leading-order EFT parameters that significantly impact boosted $t\bar{t}Z$ and $t\bar{t}H$ production.

Using the full Run 2 datasets, both ATLAS and CMS have measured the $t\bar{t}W$ production cross section. CMS determined the inclusive cross section and the separate contributions from $t\bar{t}W^+$ and $t\bar{t}W^-$ production [200], obtaining values slightly higher than but consistent with SM predictions within two standard deviations. It also measured differential cross sections in final states with two same-sign or three leptons, using multivariate and selection-based methods. The normalized results agree with SM expectations, while the absolute cross sections are somewhat higher, in line with previous measurements [201].

ATLAS performed both inclusive and differential measurements of $t\bar{t}W$ production [202]. The inclusive result lies slightly above the NNLO QCD prediction. At the same time, the unfolded differential cross sections show good overall agreement with various theoretical models and provide detailed insight into the $t\bar{t}W$ process. In addition, ATLAS reported separate measurements of the $t\bar{t}W^+$ and $t\bar{t}W^-$ cross sections.

61.2.2.5 *Associated pair production with one or two photons*

The $t\bar{t}\gamma$ production provides a direct probe of the top-quark EM interactions. In particular, deviations in the p_T spectrum of the photon from the SM prediction could point to new physics through anomalous dipole moments of the top quark or the production of excited top quarks decaying radiatively via $t^* \to t\gamma$ [203–206].

The EM coupling of the top quark can be accessed experimentally by studying final states where a photon is radiated in $t\bar{t}$ events via measurements of the absolute cross sections, cross section ratios (e.g. $\sigma_{t\bar{t}\gamma}/\sigma_{t\bar{t}}$), or through fits within the framework of EFT using differential distributions.

In $t\bar{t}\gamma$ measurements, the cross section must be defined within a well-specified fiducial phase space because the photon can originate from different parts of the event, such as top-quark decay products or initial-state radiation. A clear fiducial selection area is required to unambiguously define which phase-space region and photon kinematics are included in the measurement.

A summary of the Tevatron and LHC measurements of the inclusive $t\bar{t}\gamma$ cross sections is given in Tab. 61.9.

The first evidence for $t\bar{t}\gamma$ production was reported by the CDF collaboration [207]. The analysis targeted events with a lepton, a photon, significant missing transverse momentum, at least one b-tagged jet, three or more additional jets, and large total transverse energy. The first observation of the $t\bar{t}\gamma$ process was reported by ATLAS in pp collisions at $\sqrt{s} = 7$ TeV, using events with an electron or muon and a high-p_{T} photon, with results consistent with LO theoretical predictions [208]. At $\sqrt{s} = 8$ TeV, ATLAS measured the $t\bar{t}\gamma$ cross section for photons with $p_{\mathrm{T}} > 15$ GeV and $|\eta| < 2.37$, selecting events with an isolated high-p_{T} lepton, large missing transverse momentum, and at least four jets, including at least one b-tagged jet [209]. The results are in good agreement with the NLO prediction [210]. CMS performed a similar measurement in the LJ channel, requiring photons with $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 1.44$ [211]. When the measured cross-section is extrapolated to the cross-section times branching fraction by dividing by the kinematic acceptance, it is also consistent with theoretical predictions.

At $\sqrt{s} = 13$ TeV, ATLAS measured the fiducial and differential cross sections for $t\bar{t}\gamma$ production in LJ and DL final states containing exactly one isolated photon [212]. Differential cross sections were extracted as functions of the photon p_{T}, $|\eta|$, and the angular distance between the photon and the nearest lepton ($\Delta R(\gamma, \ell)$) in both channels. In the DL channel, additional observables include the azimuthal opening angle and the absolute pseudorapidity difference between the two leptons. All results are found to be consistent with theoretical predictions.

ATLAS measured the inclusive and differential cross-sections of combined $t\bar{t}\gamma$ and $tW\gamma$ in $e\mu + \gamma$ events with at least two jets, including at least one b-tagged jet [213]. Differential cross sections were measured as functions of the photon p_{T}, $|\eta|$, and angular correlations between the photon and leptons, as well as between the two leptons. The results are in good agreement with NLO predictions and state-of-the-art Monte Carlo simulations.

A subsequent ATLAS analysis measured inclusive and differential $t\bar{t}\gamma$ cross sections in both the LJ and DL channels [214], focusing on events where the photon was radiated in the production stage. The combined measurement achieves a relative uncertainty of 5.2%. Differential distributions were further used to set limits on EFT parameters related to the EW dipole moments of the top quark, with a significant improvement obtained when combining $t\bar{t}\gamma$ and $t\bar{t}Z$ differential measurements in a joint interpretation.

CMS measured $t\bar{t}\gamma$ production in the LJ channel in a fiducial phase space defined at particle level [215], requiring an isolated high-p_{T} lepton, at least three jets (including one or more b-tagged jets), and a single isolated photon. For photons with $p_{\mathrm{T}}^{\gamma} > 20$ GeV and $|\eta^{\gamma}| < 1.4442$, the inclusive fiducial cross section agrees with NLO QCD predictions. Differential cross sections were measured as functions of the photon p_{T} and η, and the angular separation between the photon and the lepton, and were interpreted in the EFT framework to constrain the Wilson coefficients c_{tZ} and c_{tZ}^{I}.

CMS also measured the inclusive $t\bar{t}\gamma$ cross section in the DL channel [216], selecting events with exactly one isolated photon with $p_{\mathrm{T}}^{\gamma} > 20$ GeV and at least one b-tagged jet. Differential cross sections were extracted as functions of observables related to the photon, leptons, and jets, and combined with the LJ results in a joint EFT interpretation, further improving the constraints on c_{tZ} and c_{tZ}^{I}. In addition, CMS measured in the DL channel the ratios of the inclusive and differential $t\bar{t}\gamma$ to $t\bar{t}$ cross sections, performed differential studies including the kinematics of the top quarks, and extracted the top-quark charge asymmetry, A_C, in $t\bar{t}\gamma$ events [217].

The production of a $t\bar{t}$ pair in association with two photons has been observed by ATLAS [218]. This process constitutes an important background to $t\bar{t}H(\gamma\gamma)$ and provides sensitivity to the top-quark chromomagnetic and electric dipole moments [154], the latter also probed through the ratio of $t\bar{t}$ events with one or two photons. The measurement includes both the fiducial cross-section and the cross-section ratio, extracted using a boosted decision tree as the final discriminant in a profile-likelihood fit. In the fiducial phase space at stable-particle level, events with at least one high-p_{T} electron or muon are selected, requiring two photons with $p_{\mathrm{T}}^{\gamma} > 20$ GeV. ATLAS measured a fiducial cross section of $\sigma_{t\bar{t}\gamma\gamma} = 2.42^{+0.46}_{-0.38}\,(\mathrm{stat})^{+0.35}_{-0.38}\,(\mathrm{syst})$ fb, with an observed significance of $5.2\,\sigma$.

61.2.2.6 *Four top quarks*

BSM effects that modify top-quark couplings are particularly relevant in rare processes with small SM cross sections, such as $t\bar{t}t\bar{t}$ production, where they can notably enhance the rate or distort kinematic distributions. Because of its tiny SM cross section, this process is highly sensitive to such effects and is widely used in EFT fits to constrain four-fermion operators, especially the four-top-quark operator. While $t\bar{t}t\bar{t}$ production offers the cleanest and most sensitive probe due to its low SM background, other processes—such as high-energy tails of $t\bar{t}$ production and other rare top-quark final states—also exhibit sensitivity to the same operators. Owing to this, the study of $t\bar{t}t\bar{t}$ production has attracted substantial theoretical and experimental interest in recent years.

Given its heavy final state and extremely low production rate, the first searches for $t\bar{t}t\bar{t}$ production were conducted at a center-of-mass energy of 13 TeV. Similar to $t\bar{t}V$ analyses, these studies target multilepton channels to improve signal purity and rely extensively on multivariate techniques to separate signal from background. The large number of b-jets in the final state makes efficient and well-calibrated b-tagging crucial, together with high reconstruction efficiency and small systematic uncertainties for all final-state objects.

Table 61.10 summarizes recent measurements. Throughout this review, quoted signal significances are taken directly from the corresponding publications; however, it should be noted that these are sometimes evaluated relative to different theoretical hypothe-

Table 61.8: Summary of $t\bar{t}V$ cross-section measurements from LHC.

Experiment [Ref.]	$\sqrt{s}$ (TeV)	Measurement	Comment
CMS [190]	7	$\sigma_{t\bar{t}Z} = 280^{+152.3}_{-114.0}$ fb	3.3σ

CMS [217]	13	Fiducial cross section: $\sigma_{t\bar{t}\gamma} = 54 \pm 5$ fb DL channel $R(t\bar{t}\gamma/t\bar{t}) = 0.0125 \pm 0.0005$ $A_C = (-0.012 \pm 0.042)\%$

ses. While this caveat applies broadly, it is particularly relevant for $t\bar{t}t\bar{t}$ production, where variations in the assumed signal theoretical cross section can lead to notably different significance estimates.

CMS initiated the effort with a search in the one-lepton and two-lepton opposite-sign channels [219]. This was followed by the first measurement using events with two same-sign leptons or at least three leptons, which benefit from relatively low backgrounds but cover only a small fraction of the total branching ratio [220], achieving an observed (expected) significance of 2.6σ (2.7σ), approaching the threshold for evidence.

ATLAS measured $t\bar{t}t\bar{t}$ production in the same-sign dilepton and trilepton channels [221]. The analysis was extended to include the one-lepton and opposite-sign dilepton channels, which are dominated by $t\bar{t}+$heavy-flavor backgrounds [222]. The combination of these channels yielded an observed (expected) significance of 4.7σ (2.6σ), providing the first evidence for the $t\bar{t}t\bar{t}$ production.

CMS later reported evidence for $t\bar{t}t\bar{t}$ production using a complementary approach targeting the traditional $t\bar{t}$ channels: DL, LJ, and AH final states [223]. Combining this result with the previous multilepton measurements further increased the overall significance to 4.0σ (expected 3.2σ).

The first observations of $t\bar{t}t\bar{t}$ production were made following improvements in object reconstruction and analysis techniques. ATLAS reported the observation in events with two same-sign leptons or at least three leptons [224]. A graph neural network was employed to enhance signal-to-background discrimination, and dedicated control regions were used to constrain dominant backgrounds. The observed (expected) significance reached 6.1σ (4.3σ). In addition, the measurement was interpreted to constrain

the top-Higgs Yukawa coupling and EFT operator coefficients.

CMS reported the observation of the $t\bar{t}t\bar{t}$ production process using events with two same-sign, three, or four charged leptons and multiple jets [225]. The analysis featured improved lepton and b-jet identification, as well as a multivariate classification based on a multi-class boosted decision tree, and achieved an observed (expected) significance of 5.6σ (4.9σ).

The cross-sections measured by ATLAS and CMS are almost twice the SM prediction and compatible with it within 2 standard deviations.

61.2.3 *Cross-section measurements of single production*

The traditionally considered mechanisms for single-top-quark production are the t-channel exchange of a virtual W boson ($qb \to q't$) and the s-channel process ($q\bar{q}' \to t\bar{b}$). Additionally, the associated production with a W boson tW-channel ($b\bar{q} \to tW$) is also regarded as a main production mode. The primary motivation for precise measurements of single-top production is that they enable a direct determination of the CKM matrix element V_{tb}, without relying on assumptions about the number of quark generations or the unitarity of the CKM matrix.

At the Tevatron, the t-channel dominates, with a cross section approximately twice that of the s-channel. At the LHC, the t-channel is further enhanced by the large gluon and light-quark parton fluxes, while the s-channel rate is more than a factor of three smaller. Associated production of a single top quark with a vector boson (W, Z, γ) is negligible at the Tevatron but becomes non-negligible at the LHC.

In t-channel production, the final state contains a single top quark and a light spectator quark. A characteristic signature is a forward, high-$|\eta|$ spectator jet, typically well separated in rapidity from the b-jet originating from the top-quark decay. Events generally have little additional jet activity, and the absence of a second central b-jet provides further discrimination from $t\bar{t}$ production.

In s-channel production, the final state consists of a single top quark produced together with a second b-quark from the hard interaction. This process is of particular interest because deviations from the SM cross section could signal physics beyond the SM, as predicted in scenarios involving non-SM mediators such as a W' boson or a charged Higgs boson.

In tW channel, the signal is difficult to isolate because of its close resemblance to the $t\bar{t}$ signature. Its definition is also non-trivial, as at NLO a subset of diagrams leads to the same final state as $t\bar{t}$ production, resulting in interference between the two processes [77]. The tW channel is particularly interesting since it probes the Wtb vertex in a kinematic regime different from that of the s- and t-channels, and because of its similarity to the associated production of a charged Higgs boson with a top quark.

The top-quark decays almost exclusively via $t \to Wb$, producing a high-p_{T} central b-jet accompanied by an isolated lepton and missing transverse momentum in leptonic W decays, or by two additional jets in hadronic decays. Because the t-, s-, and tW-channel final states are relatively simple and contain only a few reconstructed objects, they are easily mimicked by background processes. Consequently, measurements of the t- and s-channels primarily use the single-lepton plus jets (LJ) final state, where the lepton is an electron or muon, which provides a favorable signal-to-background ratio. In contrast, the presence of two W bosons in the tW final state makes dileptonic topologies (DL), characterized by two leptons, missing transverse energy, and jets, the most sensitive channel for this mode.

61.2.3.1 *Measurements at the Tevatron*

The single-top production process was first observed in 2009 by the DØ collaboration [226–228] and by CDF [229–231] at the Tevatron. Although the single-top production cross section at the Tevatron is about half that of $t\bar{t}$ production, its final states are more difficult to isolate due to large backgrounds from W+jets and other processes. Comprehensive reviews of these early measurements and the analysis strategies employed to extract the signal from background-dominated datasets are provided in [232, 233].

At the Tevatron, searches targeted single-top production in both the t-channel and s-channel modes. These processes can in principle be separated kinematically, which is of particular interest since various new-physics scenarios—such as a fourth-generation quark, heavy W'/Z' bosons, flavor-changing neutral currents [71], or a charged Higgs boson—affect the two channels differently. In practice, however, this separation proved challenging, and the initial Tevatron results focused on the combined s and t contributions.

Due to the diverse backgrounds, the experiments developed multiple parallel analyses to optimize signal discrimination, employing advanced multivariate techniques, including likelihood fits, artificial neural networks, matrix-element methods, and BDTs. Each approach provided an independent cross-section measurement and statistical assessment of the excess over background expectations. To maximize sensitivity, the analyses were combined using a higher-level discriminant that took as input the outputs of the individual analysis discriminants for each event [231].

The CDF and DØ collaborations later combined their results, first for the $s+t$ channel using partial datasets [234], and subsequently with the full Run 2 dataset to measure the t-channel cross section [235]. In the latter publication, simultaneous extractions of the s-, t-, and combined $s+t$ cross sections were reported. The measurements were consistent with theoretical predictions at $\sqrt{s} = 1.96$ TeV and $m_t = 172.5$ GeV, yielding for both t and $\bar{t}$ production $\sigma_{s+t} = 2.08 \pm 0.13$ pb [75, 236].

These results were also used to extract the CKM matrix element $|V_{tb}|$, again in agreement with theoretical expectations. It is worth noting that theoretical cross sections are typically quoted separately for top and antitop quarks, whereas the Tevatron results refer to their sum. Since the two contributions are equal in $p\bar{p}$ collisions, the quoted theory predictions include a factor of two.

Finally, CDF and DØ combined their data to achieve the first observation of single-top production in the s-channel, with an observed significance of 6.3 standard deviations [237].

A summary of Tevatron single-top measurements is provided in Tab. 61.11.

61.2.3.2 *Measurements at the LHC*

At the LHC, single-top-quark production is enhanced by the higher energy and gluon-rich initial state with respect to the Tevatron. The t channel dominates, exceeding the combined rates of the s channel and tW production by a factor of more than three. While the t and tW channels have been observed, the s-channel process still has significance below 4σ.

Figure 61.6 summarizes the measured single-top-quark production cross sections in the t-channel, s-channel, and tW-channel from LHC collisions at various center-of-mass energies, compared to theoretical predictions at NNLO+NNLL accuracy. The following sections provide a detailed description of these measurements.

t-channel at the LHC

Studies of the t-channel process focus on precise measurements of the single top-quark (σ_t) and top-antiquark ($\sigma_{\bar{t}}$) production cross sections, which differ at the LHC, as well as their ratio (R_t) and the inclusive cross section ($\sigma_{t+\bar{t}}$). Comparing these measured cross sections with theoretical predictions allows the extraction of $|V_{tb}|^2$. The measurements are performed separately for each production mode and center-of-mass energy..

Measurements of t-channel single-top-quark production have been performed at several LHC energies and are summarized in Tab. 61.12. Figure 61.7 summarizes the ATLAS and CMS measurements of R_t compared to NLO QCD calculations using the PDF4LHC21 and CT18 PDF sets.

At $\sqrt{s} = 5.02$ TeV, ATLAS and CMS reported the observation of single-top production in the t-channel [238, 239]. Separate measurements of top and antitop quark production allowed the determination of their production ratio and an extraction of $|V_{tb}|$. This lower-energy result provides an independent test of the SM, with backgrounds and systematic uncertainties distinct from those at higher LHC energies.

At $\sqrt{s} = 7$ TeV, ATLAS measured the t-channel cross section in the LJ channel with one b-tagged jet, relying on a neural-network discriminant [240, 241]. Differential cross sections for top- and antitop-quark production were reported as functions of p_{T} and

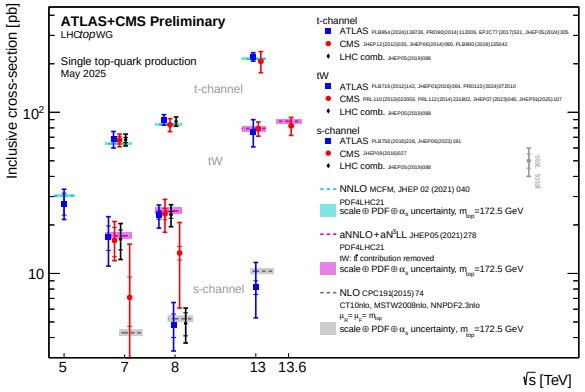

Figure 61.6: The LHC measured and predicted single-top-quark production cross sections as a function of the center-of-mass energy. The measurements are compared to theoretical calculations based on: NLO QCD, aNNLO QCD complemented with aN^{3}LL resummation and NNLO QCD. The LHCtopWG working group kindly provides the plot, status as of May 2025, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

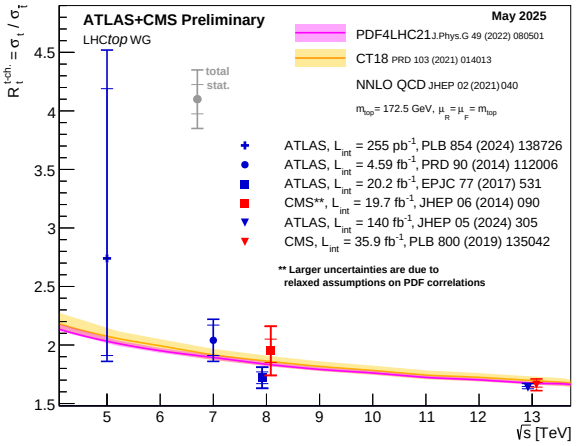

Figure 61.7: Summary of the ATLAS and CMS measurements of R_t, the ratio of the t-channel top-quark production cross section to the t-channel top-antiquark production cross section. The data measurements are compared to NLO QCD calculations using the PDF4LHC21 and CT18 PDF sets. The colored bands represent the uncertainties on the theoretical predictions (scale and PDF uncertainties). The plot is kindly provided by the LHCtopWG working group, status as of May 2025, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`

$|y|$. CMS carried out analogous measurements in the same channel [242]. One approach used the η distribution of the recoil jet and the reconstructed m_t with background estimates from data control samples, while another employed multivariate techniques. A combined ATLAS+CMS result at this energy shows good agreement with SM predictions [243].

At $\sqrt{s} = 8$ TeV, both experiments extended and refined their studies. ATLAS measured total, fiducial, and differential cross sections for top- and antitop-quark production evaluated at both the parton and particle levels, extracting $|V_{tb}|$ [244], and probed the structure of the Wtb vertex using polarization observables, with asymmetries in angular distributions consistent with the SM [245]. CMS performed measurements in the LJ channel, extracting the signal yield through maximum-likelihood fits to the $|\eta_j|$ distribution of the recoil jet [246], and reported separate fits for top and antitop quark cross sections. Combined ATLAS+CMS results again confirmed SM expectations [243]. CMS measured the top-quark spin asymmetry to be $A_\mu = 0.26 \pm 0.03$ (stat.) $\pm$ 0.10 (syst.), derived from the angular distribution of the charged lepton relative to the top-quark spin axis, defined by the spectator quark direction in t-channel production [247]. The measurement assumes the SM spin-analyzing power of 100% for the charged lepton and corresponds to a p-value of 4.6% (a 2.0σ deviation from the SM prediction, corresponding to $A_\mu^{\text{TH}} = 0.44$ with very small uncertainty). The asymmetry probes the correlation between the lepton direction and the top-quark spin, providing sensitivity to

the polarization and chiral structure of the top-quark interaction.

At $\sqrt{s} = 13$ TeV, the first analyses were performed with partial datasets. ATLAS extracted cross sections and their ratio using a binned maximum-likelihood fit to the output of a neural-network discriminant [248], while CMS employed simultaneous fits to the transverse W-mass and the output of a neural network to measure the cross section and determine $|V_{tb}|$ [249]. CMS later refined the measurement with a larger dataset, categorizing events by jet and b-jet multiplicity and applying multivariate discriminators [250]. From these data, cross sections and their ratio were measured, differential distributions obtained [251], and constraints placed on $|V_{tb}|$ and other CKM elements in a model-independent framework [252]. The spin asymmetry was measured as 0.440 ± 0.070, consistent with the SM but in tension with the 8 TeV result. Using the full dataset, ATLAS measured top and antitop quark cross sections with precisions of 6% and 8%, respectively [253], in agreement with NNLO QCD predictions. These results are also sensitive to PDFs, interpreted in terms of EFT operators, and used to measure $|V_{tb}|$ and set 95% C.L. limits on $|V_{td}|$ and $|V_{ts}|$. ATLAS further determined the three components of the polarization vectors for top and antitop quarks in t-channel events [254], reporting values consistent with SM expectations, and presented normalized differential cross sections as functions of charged-lepton angles, used to bound the complex Wilson coefficient of the dimension-six O_{tW} operator.

s-channel at the LHC

The growth of the s-channel cross section from $\sqrt{s} = 8$ to 13 TeV is slightly larger than that of W-boson production, the second most important background, but smaller than that of $t\bar{t}$ production, which remains dominant. Theory predicts that the ratio of the s-channel single-top cross section to the W-boson cross section is 1.4×10^{-4} (1.7×10^{-4}) at $\sqrt{s} = 8$ (13) TeV, and its ratio to the $t\bar{t}$ cross section is 2.1×10^{-2} (1.2×10^{-2}). Consequently, the analysis of this process becomes increasingly challenging as the center-of-mass energy rises.

A summary of results at different center-of-mass energies is given in Tab. 61.13.

At $\sqrt{s} = 7$ TeV, CMS analyzed events in the LJ channel using a maximum-likelihood fit to a BDT discriminant, presenting results that were later combined with those at 8 TeV [255].

At $\sqrt{s} = 8$ TeV, ATLAS reported the first evidence for s-channel single-top-quark production at the LHC [256], employing a discriminant based on the Matrix Element Method optimized against the dominant $t\bar{t}$ and W+jets backgrounds. CMS measured the s-channel cross section using a maximum-likelihood fit to a BDT discriminant [255] and combined the result with the 7 TeV measurement, obtaining a best-fit value of 2.0 ± 0.9 for the ratio of the measured to the expected cross section. A joint ATLAS+CMS combination confirmed consistency with the SM [243], but did not allow for observing the process.

At $\sqrt{s} = 13$ TeV, ATLAS studied the s-channel cross section using the full Run 2 dataset in events with an electron or muon, missing transverse momentum, and exactly two b-tagged jets. A discriminant based on Matrix-Element Method calculations was used to separate the s-channel signal from $t\bar{t}$ and W+jets backgrounds. The result was found to be consistent with the SM prediction [257], but the significance of the result is still below 4σ.

61.2.3.3 *tW-channel at LHC*

The tW signal is difficult to isolate because of its similarity to the $t\bar{t}$ final state. Its definition is further complicated at NLO, where part of the contributing diagrams lead to identical final states as $t\bar{t}$ production, giving rise to interference between the two processes [77]. The standard approach is to define the signal using the diagram-removal technique [76], in which the interfering diagrams are removed at the amplitude level. An alternative method, diagram subtraction, removes these contributions at the cross-section level, leading to similar results [76]. Both techniques are valid provided that the event selection cuts are chosen to keep interference effects small, which is typically the case.

Experimentally, the presence of two W bosons in the final state makes dileptonic topologies the most sensitive, requiring two leptons, missing transverse energy, and jets. A summary of results is given in Tab. 61.14.

At $\sqrt{s} = 7$ TeV, both ATLAS and CMS reported evidence for this process [259, 260]. ATLAS employed template fits to BDT classifiers, while CMS used a multivariate analysis. Both of them used events in the DL channel with exactly one b-tagged jet. The combination of ATLAS and CMS results is consistent with SM predictions [243].

At $\sqrt{s} = 8$ TeV, the two experiments strengthened their measurements. ATLAS observed tW production with a significance of 7.7σ using a BDT discriminant and extracted the cross section with a profile-likelihood fit; a fiducial cross section was also reported [261]. In a separate analysis, ATLAS studied the LJ channel with at least three jets, training a neural network to discriminate signal from $t\bar{t}$ and extracting the cross section with a two-dimensional fit involving the neural network output and the invariant mass of the hadronic W boson [262]. CMS analyzed the DL channel with a b-tagged jet, employing a multivariate discriminant to suppress the $t\bar{t}$ background and observing the signal with a significance of 6.1σ [263]. ATLAS and CMS combined their results to determine σ_{tW} and extract $|V_{tb}|f_{\mathrm{LV}}$, where f_{LV} is a real form factor parameterizing potential anomalous left-handed vector couplings. The extraction is based on the ratio of the measured to the predicted cross section, under the assumption that $|V_{td}|, |V_{ts}| \ll |V_{tb}|$. The combined result shows good agreement with the NLO+NNLL SM prediction [243].

At $\sqrt{s} = 13$ TeV, analyses progressed with increasingly larger datasets. ATLAS first studied the DL channel, defining signal and control regions by jet and b-tag multiplicities and employing BDTs to separate the tW signal from backgrounds, measuring a cross section consistent with the SM [264]. Differential cross sections were also obtained as functions of the b-jet energy, the energy of the $\ell\ell b$ system, and various invariant and transverse masses involving the leptons, b-jet, and neutrinos [265].

A subsequent ATLAS analysis using the full Run 2 dataset improved precision by employing a BDT discriminant in three jet and b-tag–defined signal regions, with the cross section extracted from a profile-likelihood fit [266]. The measurement is dominated by systematic uncertainties, and a value of V_{tb} was also extracted.

CMS performed measurements in the DL channel with a partial dataset, selecting events with one tight and one loose lepton and at least one b-tagged jet. A BDT was used to separate signal from background, and the cross section was extracted with a likelihood fit [267]. The same dataset enabled a preliminary differential measurement in a fiducial region requiring exactly one b-tagged jet [268]. CMS also analyzed the LJ channel, where a BDT was employed to discriminate tW from $t\bar{t}$, with other backgrounds constrained using data-driven methods. This led to the first observation of tW production in the LJ final state, with a significance exceeding 5σ [269].

Finally, using the full Run 2 dataset, CMS measured inclusive and normalized differential cross sections in $e\mu$ events [270]. A multivariate discriminant was used to isolate the signal for the inclusive measurement, yielding a cross section consistent with the SM. The differential distributions were unfolded to the particle level in a fiducial region requiring exactly one b jet and were found to agree with NLO QCD predictions.

At $\sqrt{s} = 13.6$ TeV, CMS measured tW production using a partial dataset of 34.7 fb^{-1} [271]. The analysis includes both inclusive and differential cross sections in the DL($e\mu$) channel. For the differential measurements at the stable-particle level in a fiducial phase space, good agreement was observed with the predictions. The inclusive cross section is consistent with the NNLO QCD prediction, with the overall precision limited by systematic uncertainties.

61.2.4 *Cross-section measurements of associated single production*

Beyond the primary single-top-quark production channels, rarer processes occur in association with EW bosons, such as tZ, $t\gamma$, tH, and tWZ. Although their cross sections are much smaller, these modes provide unique sensitivity to the couplings of the top quark to the Z boson, photon, and Higgs boson. They thus serve as precision tests of the SM and impose powerful constraints on

anomalous couplings and possible effects of new physics [272,273]. The Tevatron lacked the sensitivity to observe these processes, and only with the increased energy and luminosity of the 13 TeV LHC dataset has evidence for them been obtained. The following sections summarize these measurements in order of decreasing production rate, and Fig. 61.8 presents an overview of the ATLAS and CMS results for associated single-top-quark production at 13 TeV.

61.2.4.1 *Associated single production with a photon*

As in the case of $t\bar{t}+\gamma$, the measurement of single-top+γ production requires a well-defined fiducial phase-space definition that specifies the photon kinematic and isolation criteria, as well as its separation from other objects, to ensure that the measured cross section corresponds to a clearly defined and reproducible region of phase space.

The first evidence for the associated production of a single top quark with a photon was reported by CMS at $\sqrt{s} = 13$ TeV using a partial dataset [274]. A multivariate discriminant was applied to events containing a muon, a photon, and jets. For isolated photons with $p_{\mathrm{T}} > 25$ GeV in the central detector region ($|\eta_\gamma| < 1.44$), the measured cross section times branching fraction was found to be consistent with the SM expectation. At the same center-of-mass energy, ATLAS achieved the first observation of this process [275], exploiting the presence of a forward jet and using neural networks for signal discrimination. Requiring a photon with $p_{\mathrm{T}} > 20$ GeV within the detector acceptance ($|\eta_\gamma| < 2.37$), ATLAS measured a fiducial cross section consistent with the NLO QCD prediction of 515^{+36}_{-42} fb, with $t\bar{t}\gamma$ modeling among the leading sources of uncertainty. The results are summarized in Table 61.15.

61.2.4.2 *Associated single production with a Z boson*

The tZq process probes both the WWZ coupling, when the Z boson is emitted from the t-channel W in single-top production, and the tZ coupling, when the Z is radiated from the top quark.

At $\sqrt{s} = 8$ TeV, CMS searched for tZq production in trilepton

Table 61.14: Single top-quark tW-channel measurements from the LHC. Unless indicated, measurements are extracted in the DL channel.

Experiment [Ref.]	$\sqrt{s}$ (TeV)	Measurement

CMS [269]	13	$\sigma_{tW} = 89 \pm 13$ pb (LJ channel)
CMS [270]	13	$\sigma_{tW} = 79.2^{+7.8}_{-8.1}$ pb
CMS [271]	13.6	$\sigma_{tW} = 82.3^{+10.6}_{-10.5}$ pb

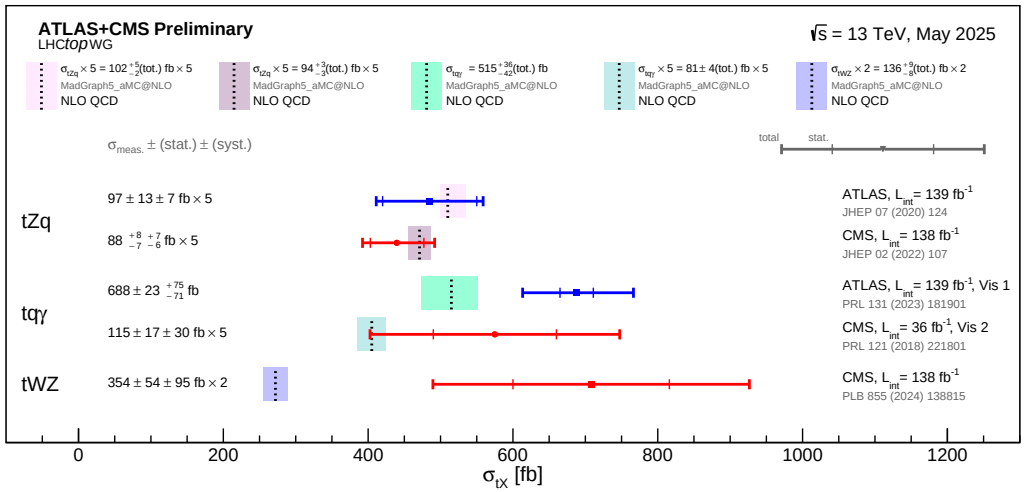

Figure 61.8: Summary of ATLAS and CMS measurements of $t + WZ$, $t + Z$ and $t + \gamma$ cross sections at 13 TeV. The cross-section measurements are compared to the NLO QCD theoretical calculation. "Vis 1" and "Vis 2" highlight that the relevant phase space used for the ATLAS and CMS $t\gamma$ measurements is different. The theory prediction and experimental results of tZ, and those of the CMS $t\gamma$ measurement, are multiplied by a factor of 5 to allow for easy visualization on the same scale; those of the CMS tWZ measurement are multiplied by a factor of 2. The theory bands represent uncertainties due to renormalization and factorization scales and parton density functions. The LHCtopWG working group kindly provides the plot, status as of May 2025, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

Table 61.15: Associated single top-quark production with a photon measurements from the LHC.

Experiment [Ref.]	$\sqrt{s}$ (TeV)	Measurement
CMS [274]	13	$\sigma_{t\gamma} = 115 \pm 34$fb ($p_{\mathrm{T}}^{\gamma} > 25$ GeV; $\lvert\eta_{\gamma}\rvert < 1.44$) 4.4σ obs. (3.0σ exp.)
ATLAS [275]	13	$\sigma_{t\gamma} = 688^{+78}_{-75}$fb ($p_{\mathrm{T}}^{\gamma} > 20$ GeV; $\lvert\eta_{\gamma}\rvert < 2.37$) 9.3σ obs. (6.8σ exp.)

events and reported a hint of signal with a significance of 2.4σ relative to the background-only hypothesis [276].

At $\sqrt{s} = 13$ TeV, both CMS and ATLAS measured tZq production in events with three leptons from $Z \to \ell^+\ell^-$ and top quark decay. CMS reported evidence using a partial dataset [274], followed by an observation with the full dataset [277], and later a comprehensive analysis of inclusive and differential cross sections [278]. The latter included the ratio of cross sections for top-and antitop-associated production, as well as the first differential measurements at both parton and particle levels. The spin asymmetry, sensitive to top-quark polarization, was also determined from the parton-level distribution of the polarization angle. All results were consistent with NLO SM predictions. ATLAS employed a simultaneous binned maximum-likelihood fit with neural-network discriminants to improve background rejection, extracting a signal also consistent with the SM expectation [279].

These results are summarized in Tab. 61.16.

61.2.4.3 *Associated single production with a W and Z boson*

At $\sqrt{s} = 13$ TeV, CMS reported the first evidence for single-top-quark production in association with a W and a Z boson in multilepton final states [280], with the Z reconstructed from e^+e^- or $\mu^+\mu^-$ pairs. The analysis made extensive use of multivariate techniques applied across multiple regions and event categories to suppress backgrounds and extract the signal. A key challenge was separating the tWZ signal from the dominant $t\bar{t}Z$ background, which was addressed using improved tWZ modeling.

This result was recently updated using both 13 and 13.6 TeV datasets, corresponding to an integrated luminosity of about 200 fb^{-1} [281]. Events with three or four leptons were divided into distinct signal regions based on the output of a machine-learning classifier with multiple output nodes, and the distributions in these categories were used in a profile-likelihood fit. For the 13 TeV dataset alone, the expected significance increased from 1.4σ in the first analysis to approximately 3σ. Combining the 13 and 13.6 TeV results, summarized in Tab. 61.17, led to the first observation of the tWZ process.

61.2.5 *Properties*

The following sections provide an overview of experimental results on **top-quark properties**, that is, the intrinsic or fundamental characteristics of the particle itself, rather than how it is produced or which process it participates in. In this context, "top-quark properties" serves as an umbrella term for all observables that characterize the nature of the top quark itself, independent of the particular process used to measure them. Measurements of these properties provide stringent tests of the SM and sensitivity to new physics.

Intrinsic properties are quantities that define the top quark as a fundamental particle in the SM, including its mass (m_t), electric charge ($+2/3\,e$), spin (1/2), and lifetime or decay width (Γ_t). Interaction properties describe how the top quark couples to other SM particles, its couplings to the W, Z, and Higgs bosons, as well as to gluons and photons. These reflect the particle's gauge and Yukawa interactions, which are part of its defining characteristics within the SM. Derived properties, such as polarization, spin correlations, and charge asymmetries, characterize the behavior of the top quark in production and decay and reveal how its intrinsic features manifest dynamically.

This section begins with measurements of m_t and Γ_t, followed by studies of its decay and spin structure, including polarization, spin correlations in $t\bar{t}$ pairs, and the observation of quantum entanglement in $t\bar{t}$ events. In this context, results on the production of a pseudo-bound state at the $t\bar{t}$ threshold are also reviewed. The V–A structure of the Wtb vertex is examined through measurements in both single-top-quark and $t\bar{t}$ events. Finally, results on asymmetries in $t\bar{t}$ and $t\bar{t}+X$ production are summarized and compared with theoretical expectations.

Most results are obtained from $t\bar{t}$ events, with analyses categorized according to the final state: lepton+jets (LJ), dilepton (DL), and all-hadronic (AH), as described in Sect. 61.2.1.

61.2.5.1 *Mass*

In the early 1990s, indirect constraints from precision measurements at CERN's LEP collider suggested that m_t lay between about 150 and 200 GeV, based on radiative corrections to EW observables involving the Z boson. In 1995, the top quark was directly discovered by the CDF and D0 collaborations at the Tevatron $p\bar{p}$ collider at Fermilab, with an initial mass estimate in the range of 151–197 GeV. Subsequent measurements at the Tevatron rapidly improved the precision, establishing the top-quark mass near 175 GeV. With the start of the LHC program, measurements by ATLAS and CMS further reduced the uncertainty to below 1 GeV, making m_t one of the most precisely determined parameters of the SM.

Final state topologies The top-quark mass has been determined in both top-quark pair and single-top-quark production, exploiting a variety of decay channels, each with distinct sensitivities to systematic uncertainties. This diversity enables internal consistency checks and improved precision when results are combined. The "standard" analyses use inclusive $t\bar{t}$ final states, classified into the DL, LJ, and AH channels, and further distinguished as **resolved**, when all decay products can be individually reconstructed, or **boosted**, when the large p_{T} of the top quarks causes two or more decay products to merge into a single reconstructed object in the detector, as described in Sec. 61.2.1. Since final states with many jets lead to larger overall systematic uncertainties, alternative channels have also been explored for measuring the m_t. Examples include events in which the b hadron decays semileptonically and produces a low-p_{T} ("soft") lepton, which can be combined with other objects to form an observable sensitive to m_t, or decays containing a J/ψ meson. These approaches benefit from a reduced impact of jet-related uncertainties but suffer from the low branching ratios of the relevant b-hadron decays, resulting in larger statistical uncertainties.

Reconstruction of observables

The first step in a top-quark mass measurement is to identify an observable sensitive to m_t and reconstruct it from the event. The calculation of such observables requires assigning the parton-level objects to the reconstructed objects in the detector. An assignment is considered correct ("matched") if $\Delta R(\text{parton}, \text{detector object}) < 0.3$ or 0.4. Three categories are defined: correctly matched events, incorrectly matched events, and unmatched events, the latter occurring when at least one parton cannot be matched to a reconstructed object, for example, because it fails the selection criteria or lies outside the detector acceptance. While leptons are matched with very high efficiency, the matching efficiency for jets is significantly lower.

Several methods exist for jet–parton assignment. Kinematic fits are widely used, as they both improve the resolution of reconstructed observables and provide a goodness-of-fit estimator, which helps identify correctly matched events [282]. Matching can be further enhanced using machine-learning techniques, such as deep neural networks trained with correct assignments as signal and incorrect assignments as background. Since combinatorial mismatches worsen mass resolution and increase overall uncertainty, removing unmatched or incorrectly matched events is crucial. One common strategy is to reject events in the tails of reconstructed mass distributions, which are rarely populated by correctly matched events. The goodness-of-fit from kinematic fits also enables event selection with high probability of correct assignment [283–286]. In another approach, a BDT was trained to distinguish correctly from incorrectly or unmatched events, and events were selected by applying a cut on the classifier output [282].

In the LJ and AH final states, the invariant mass of the objects assigned to their parton-level particles, m_t^{reco}, is often used for the measurement. In the DL channel, a full reconstruction of the events is more challenging due to the presence of two neutrinos in the final state. To address this, several methods have been developed, such as full kinematic reconstruction [287,288]. At the Tevatron, the neutrino-weighting and matrix-element-weighting techniques were introduced [289–291].

In the neutrino-weighting method, for each assumed value of m_t, energy and momentum conservation is applied to the decay, yielding up to four possible solutions for the neutrino and antineutrino momenta. The missing transverse energy calculated from these solutions is then compared with the observed missing E_T to assign a weight. In the matrix-element weighting method, the neutrino momenta are likewise solved up to a fourfold ambiguity, but each solution is assigned a weight proportional to the likelihood of the kinematics arising from $t\bar{t}$ production and decay at that mass hypothesis. By scanning over m_t values (typically in the range 80–280 GeV), one obtains a weight distribution that reflects the production kinematics, decay distributions, and available phase space, which is then used to extract m_t.

Alternatively, without requiring full event reconstruction, several observables directly sensitive to the top-quark mass can be used, albeit with larger systematic uncertainties. One example is the invariant mass of the b-jet–lepton pair, $m_{\ell b}^{\mathrm{reco}}$ [292], or event variables such as the scalar sum of jet transverse energies and the missing transverse energy [293], both of which reduce the depen-

dence on jet-related uncertainties. In final states with additional leptons from b-hadron decays, the invariant mass of all leptons can be used [294–296]. Another approach exploits the invariant mass of a charged lepton from the W decay and the tracks forming a secondary vertex from the b hadron [297].

In addition to observables directly sensitive to the top-quark mass, auxiliary observables are often employed to reduce specific groups of uncertainties. The invariant mass of the hadronically decaying W boson, m_W^{reco}, is widely used to constrain the jet-energy scale (JES). This can be achieved either by extracting a dedicated jet-energy scale factor (JSF) simultaneously with m_t [298,299], or by using the ratio of the jet energies assigned to the top quark and to the W boson [300, 301].

When the uncertainty in the b-JES is also relevant, an additional observable can be introduced to determine the b-to-light jet scale factor (bJSF) [282]. To ensure sensitivity primarily to the bJSF rather than the overall JSF, the ratio of jet momenta assigned to the W boson and to the b jets is used, denoted R_{bq}^{reco} in the following.

Measurement techniques

A wide range of techniques has been developed to extract m_t, many of which have subsequently found applications in other areas of particle physics. The most precise determinations proceed by reconstructing an observable in data and comparing it to the same observable obtained from Monte Carlo simulations generated with different input values of m_t. This so-called *template method* has been the most widely used approach, see for example Refs. [283, 284, 302, 303]. The template method has been used to extract m_t since the first direct measurement at the Tevatron. It remains in use today, now often fitting multiple observables simultaneously to constrain the main systematic uncertainties.

Owing to its good signal-to-background ratio and the ability to use the hadronic W decay to constrain the dominant JES uncertainty, the LJ channel is considered the golden channel for top-quark mass measurements.

At the Tevatron, considerable effort was devoted to improving the statistical precision of m_t measurements, leading to the development of new techniques. In the DL channel, methods were introduced that fit the dynamics of the decay products and evaluate per-event weights (matrix-element weighting) as mentioned above. In the LJ channel, the so-called *matrix-element method* was pioneered [304]. In this approach, a probability density is calculated for each event as a function of m_t, using a leading-order matrix element for $t\bar{t}$ production and decay. The probability densities are calculated using the four-momenta of the reconstructed objects, taking into account all possible jet–parton assignments. An *in situ* calibration of dijet pairs to the $W \to jj$ hypothesis is simultaneously performed to constrain the JES uncertainty [299]. The top-quark mass is then extracted from a likelihood fit to the ensemble of events, with each event contributing its own likelihood distribution, in contrast to the template method, where each event contributes a single number.

In the template method, templates are constructed from simulated samples generated with different input values of m_t for the observables used in the measurement. Typically, only one jet–parton permutation is considered per event. The top-quark mass is then extracted from a binned or unbinned maximum-likelihood fit. In the LJ channel, simultaneous fits of m_t together with the JSF and bJSF parameters have also been performed [282, 298].

The *ideogram* m_t method [305] is an unbinned likelihood fit that incorporates up to four jet–parton permutations, weighted to reduce the impact of incorrect assignments. The weights are derived from the goodness-of-fit probabilities obtained from the kinematic reconstruction. CMS employed this method to measure m_t simultaneously with an overall JSF, where the JSF was constrained by a Gaussian prior whose width was set to the total uncertainty of the JES corrections [306].

As the available statistics increased, methods aimed at reducing systematic uncertainties became more widely developed. In recent years, the use of *profile-likelihood fits* has grown. These are maximum-likelihood fits in which systematic uncertainties are incorporated as nuisance parameters. The nuisance parameters can be constrained in the fit, resulting in a reduction in overall uncertainty compared to traditional methods. However, greater care is required for uncertainties derived from comparisons of different Monte Carlo setups, which combine the effects of multiple variations. A notable example is the modeling uncertainty associated with hadronization, which is often evaluated by comparing simulations based on string and cluster models.

Results from the Tevatron

Both the DØ and CDF experiments performed numerous top-quark mass measurements, exploring various strategies to reduce the overall uncertainty in different final states. These included the use of matrix-element and template techniques, as well as alternative approaches such as exploiting soft-muon decays [294], the transverse momentum of the lepton [307], and global event variables like the scalar sum of jet transverse energies and the missing transverse energy [293].

The most precise results from both experiments are summarized in Tab. 61.18, which also shows their combination. This average incorporates published Run 1 (1992–1996) results together with the most precise published and preliminary Run 2 (2001–2011) measurements, based on up to 9.7 fb^{-1} of Tevatron data. Accounting for correlations among uncertainties, and combining statistical and systematic contributions in quadrature, the Tevatron average yields $m_t = 174.30 \pm 0.65$ GeV, corresponding to a relative precision of 0.37% [308].

Results from the LHC

In the following, the precision of top-quark mass measurements at the LHC is examined across different decay topologies and anal-

ysis methods. Due to the large number of measurements that were carried out at the LHC, the focus will be on the most precise ones. Further measurements and more detailed discussions can be found in the reviews of the ATLAS and CMS experiments, published in Refs. [288, 317].

For the direct measurements, the most precise individual result is presented in Tab. 61.19 for each topology. Except for the measurement using J/ψ mesons in b-hadron decays, performed with the 8 TeV dataset, all results are based on 13 TeV data. Owing to the very large $t\bar{t}$ dataset available at the LHC (the 13 TeV sample alone contains more than 115 million events per experiment), statistical uncertainties are negligible for most analyses and become relevant only in rare topologies that exploit additional leptons from b-hadron decays.

The use of auxiliary observables in combination with profile-likelihood fits has substantially reduced the overall uncertainty in the LJ channel. In the resolved analysis [286], several auxiliary variables are included, such as m_W^{reco} and R_{bq}^{reco}. The former helps constrain uncertainties from JES corrections and final-state radiation (FSR). These sources, however, still dominate the overall uncertainty, with jet-flavor–dependent jet-energy corrections being the largest component.

In the boosted analysis [318], the observable sensitive to m_t is the average mass of the large-R jets, $\bar{m}_J$. As in the resolved analysis, m_W^{reco} is used to reduce sensitivity to jet-related uncertainties. A significant uncertainty in this channel arises from modeling the recoil scheme in Pythia for secondary and subsequent gluon emissions. This effect is mitigated by introducing a third observable, m_{tj}, defined as the invariant mass of the leptonically decaying top quark and the nearest additional jet. After these improvements, the dominant remaining uncertainties stem from the JES and $t\bar{t}$ modeling, particularly FSR and color-reconnection effects.

The systematic models used by ATLAS and CMS are not identical, leading to different dominant uncertainties in the measurements discussed here.

Each experiment has produced a combined measurement of the top-quark mass using its individual results. The CMS combination gives $m_t = 172.44 \pm 0.13$ (stat.) ± 0.47 (syst.) GeV [319], while the ATLAS combination yields $m_t = 172.69 \pm 0.25$ (stat.) $\pm$ 0.41 (syst.) GeV [282].

Global combinations from the Tevatron and the LHC account for correlations both within individual experiments and between different experiments. A Tevatron–LHC combination released in 2014 reported $m_t = 173.34 \pm 0.76$ GeV (0.44%) [320], but this result, based only on the 7 TeV LHC data, has since been superseded by the most recent LHC combination [1]. In this latest combination, ATLAS and CMS included fifteen individual measurements in leptonic and hadronic top-quark decays, as well as a measurement in events enriched with single-top production via the EW t-channel. The datasets correspond to the full 7 and 8 TeV samples. The combination was performed using the BLUE method [321], incorporating estimator correlations both within and across experiments. The impact of correlation choices on the final result was investigated and found to be small. The combined result is $m_t = 172.52 \pm 0.33$ GeV, corresponding to a relative precision of 0.2%, and is limited primarily by the b-jet energy scale (b-JES) uncertainty.

The direct measurements of the top-quark mass correspond to the parameter used in Monte Carlo generators, which is closely related to the pole mass [8]. The relation between the pole mass and short-distance mass definitions, such as $\overline{\mathrm{MS}}$, is affected by non-perturbative effects. Recent calculations estimate the renormalon ambiguity to be below 250 MeV, which remains smaller than the current measurement uncertainty [322, 323]. Other ambiguities, for example, the one related to the parton-shower cut-off value, can be of the order of 500 MeV [8, 324]. A calibration of the top-quark mass parameter in Powheg+Pythia 8 with respect to the MSR mass scheme [325] was performed by ATLAS. Using simulated $t\bar{t}$ events in the LJ channel and the mass distribution of large-radius jets containing the three quarks from the hadronic top decay, a difference between the Monte Carlo mass and the MSR mass of about 80 MeV was obtained, with large associated uncertainties [326].

As a result of renormalization at higher orders in perturbation theory, m_t depends on the scale at which it is defined. The first measurement of the running of the top-quark mass in the $\overline{\mathrm{MS}}$ scheme was reported by CMS [327]. The running mass was extracted from the differential cross section as a function of the $t\bar{t}$ invariant mass, unfolded to parton level in DL($e\mu$) final states. The result shows a variation of about 15% between $M_{t\bar{t}} = 400$ GeV and $M_{t\bar{t}} \approx 1$ TeV, in good agreement with the one-loop renormalization-group prediction. Relative to the hypothesis of no running, the significance of the observed effect is 2.6σ, although the interpretation is subject to large theoretical uncertainties [328].

Measurements of m_{t} based on inclusive and differential cross sections of $t\bar{t}$ and $t\bar{t}$+jet final states are summarized in Fig. 61.9. These have been performed at center-of-mass energies between 7 and 13 TeV using observables related to the production cross section. The most recent result, not yet included in this comparison, obtained by ATLAS at 13 TeV in the DL channel with $t\bar{t}$+jet final states, yields $m_{\mathrm{t}} = 170.9 \pm 1.5$ GeV [329].

Vacuum stability

With the discovery of a Higgs boson at the LHC with a mass of about 125 GeV [330, 331], the precise determination of the top-quark mass has taken a central role in assessing the stability of the EW vacuum. Radiative corrections from the top quark tend to drive the Higgs quartic coupling λ negative, potentially leading to vacuum instability. An NNLO calculation [2] indicates vacuum stability for a Higgs mass satisfying $M_H \geq 129.4 \pm 5.6$ GeV [332]. Within this uncertainty, a Higgs boson mass of 125 GeV is compatible with stability, although the central values of the Higgs boson and top-quark masses still allow for a metastable scenario.

In the context of the European Strategy for Particle Physics 2025 update, ATLAS and CMS prepared projections of future Higgs boson and m_t determinations [333], shown in Fig. 61.10. These projections are based on two m_t measurements at 8 and

13 TeV, obtained from differential cross-section measurements in $t\bar{t}$+jets final states. For the projections, different scenarios for reducing systematic uncertainties and employing alternative analysis methods are explored. Further projections can be found in the same document.

CPT test based on m_t measurements

The CPT theorem requires that particles and their antiparticles have identical masses, lifetimes, and absolute charges. A test of this symmetry has been performed by measuring the mass difference between the top and antitop quarks, $\Delta m_t = m_t - m_{\bar{t}}$, which is expected to vanish if CPT is conserved. The top and antitop quarks are distinguished through the charge of the decay lepton, and such measurements have been performed at both the Tevatron and the LHC. The results, summarized in Tab. 61.20, are consistent with the SM expectation of no mass difference, with a current sensitivity at the level of a few hundred MeV.

61.2.5.2 *Width*

The top-quark width, inversely proportional to its lifetime, is expected to be of order 1 GeV (Eq. 1). Early measurements made at CDF [340] and CMS [341] established confidence-level intervals for the width but lacked the sensitivity to make a direct measurement.

The total width of the top quark can be inferred from the partial decay width $\Gamma(t \to Wb)$ and the branching fraction $B(t \to Wb)$. DØ extracted $\Gamma(t \to Wb)$ from the measured t-channel single-top-quark production cross section, and $B(t \to Wb)$ from the ratio $R = B(t \to Wb)/B(t \to Wq)$ in $t\bar{t}$ events in the LJ channel with 0, 1, and 2 b-tags. Assuming $B(t \to Wq) = 1$ for any kinematically allowed quark q, the result was $\Gamma_t = 2.00^{+0.47}_{-0.43}$ GeV, corresponding to a top-quark lifetime of $\tau_t = (3.29^{+0.90}_{-0.63}) \times 10^{-25}$ s. Under the assumption of a heavy fourth-generation b' quark and unitarity of the four-generation mixing matrix, an upper limit of $|V_{tb'}| < 0.59$ at 95% C.L. was obtained [342].

The first direct measurement of the top-quark width was performed by ATLAS at $\sqrt{s} = 8$ TeV, fitting reconstructed LJ events, and yielded $\Gamma_t = 1.76 \pm 0.33$ (stat.)$^{+0.79}_{-0.68}$ (syst.) GeV [343]. A more recent ATLAS analysis at $\sqrt{s} = 13$ TeV, based on a template fit to the lepton–b-quark invariant mass in DL final states, obtained $\Gamma_t = (1.9 \pm 0.5)$ GeV [344].

A similar analysis performed by CMS at $\sqrt{s} = 8$ TeV provided a more precise determination of the width, yielding $\Gamma_t = 1.36 \pm 0.02$ (stat.) $^{+0.14}_{-0.11}$ (syst.) GeV [345].

61.2.5.3 *Top Quark Spin Correlations, Polarization, and Entanglement*

One of the unique features of the top quark is that it decays before QCD interactions can flip its spin. Thus, the top quark polarization is directly observable via the angular distribution of its decay products, and it is possible to define and measure observables sensitive to the top quark spin and its production mechanism. Although the top and antitop-quarks produced by QCD interactions in hadron collisions are essentially unpolarized, the spins of t and $\bar{t}$ are correlated. For QCD production at threshold, the $t\bar{t}$ system is produced in a $^3S_1$ state with parallel spins for $q\bar{q}$ annihilation or in a $^1S_0$ state with antiparallel spins for gluon-gluon fusion, as shown in Fig. 61.11.

The production mechanisms at the Tevatron, where $t\bar{t}$ pairs

Table 61.20: Comparison of the measurements of $\Delta m_t = m_t - m_{\bar{t}}$ in $t\bar{t}$ and single-top events.

Exp. [Ref]	$\sqrt{s}$ (TeV)	Δm_t [GeV]	Topology
CDF [334]	1.96	$-1.95 \pm 1.11(stat.) \pm 0.59(syst.)$	$t\bar{t}$ LJ
DØ [335]	1.96	$0.84 \pm 1.81(stat.) \pm 0.48(syst.)$	$t\bar{t}$ LJ

CMS [338]	8	$-0.15 \pm 0.19(stat.) \pm 0.09(syst.)$	$t\bar{t}$ LJ
CMS [339]	13	$0.83^{+1.79}_{-1.35}(stat. + syst.)$	single-top LJ

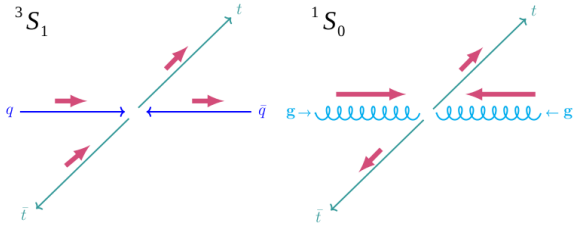

Figure 61.11: Spin state of the $t\bar{t}$ system at the production threshold for $q\bar{q}$ annihilation (left) and gluon-gluon fusion (right). The thin arrows describe the momentum direction of the particles, while the thicker arrows reflect the spin direction of the gluons (long arrows) and the quarks (short arrows).

are predominantly produced via $q\bar{q}$ annihilation, and at the LHC, where gluon–gluon fusion dominates, are therefore complementary. At the LHC, $t\bar{t}$ production at large invariant mass arises mainly from gluons with opposite helicities, resulting in $t\bar{t}$ pairs with parallel spins, similar to the configuration produced at the Tevatron through $q\bar{q}$ annihilation.

The top-quark spin is fully correlated with the angular distributions of the down-type fermion (charged lepton or d-type quark) in the decay. The corresponding joint angular distribution is given in Refs. [346–348]

$$\frac{1}{\sigma}\frac{d^2\sigma}{d(\cos\theta^i_+)d(\cos\theta^j_-)} = \frac{1}{4}(1 + B^i_+ \cos\theta^i_+ + B^j_- \cos\theta^j_- + C_{ij} \cdot \cos\theta^i_+ \cdot \cos\theta^j_-), \quad (61.5)$$

where θ^i_+ and θ^j_- are the angles of the daughters in the top-quark (antitop-quark) rest frame with respect to a particular spin quantization axis i (j). The maximum value for C, 0.782 at NLO at the Tevatron [349], is found in the off-diagonal basis [346], while at the LHC the value at NLO is 0.326 in the helicity basis [349]. The coefficients B_+ and B_- are near zero in the SM because the top quarks are unpolarized in $t\bar{t}$ production. In place of C, $A\alpha_+\alpha_-$ is often used, where α_i is the spin analyzing power, and A is the spin correlation coefficient, defined as

$$A = \frac{N(\uparrow\uparrow) + N(\downarrow\downarrow) - N(\uparrow\downarrow) - N(\downarrow\uparrow)}{N(\uparrow\uparrow) + N(\downarrow\downarrow) + N(\uparrow\downarrow) + N(\downarrow\uparrow)}, \quad (61.6)$$

where the first arrow represents the direction of the top quark spin along a chosen quantization axis, and the second arrow represents the same for the antitop-quark. The spin analyzing power α_i at parton level is +0.998 for positively charged leptons, -0.966 for down-type quarks from W decays, and -0.393 for bottom quarks [350]. The sign of α flips for the respective antiparticles. The spin correlation could be modified by a new $t\bar{t}$ production mechanism such as through a Z' boson, Kaluza-Klein gluons, a dark-matter mediator, or a Higgs boson.

Measurement of SM spin correlation fraction

The experiments typically use Monte Carlo simulation to provide templates for the measured distributions, or a matrix-element method, and fit a parameter $f_{\rm SM}$, representing the fraction of events with the expected SM correlation, with $(1 - f_{\rm SM})$ the fraction with no correlation. The correlation coefficient is extracted via $A_{\rm meas} = f \cdot A_{\rm SM}$. A 'fraction' $f_{\rm SM} > 1$ means that the measured correlation coefficient is larger than the SM expectation. DØ pioneered the study of spin correlations in $t\bar{t}$ production during Run 1 [351], setting the first limits of $\kappa > -0.25$ at the 68% confidence level using the DL channel. In Run 2, both CDF and DØ extended the studies to the DL and LJ channels. Although the sensitivity was limited, these analyses provided the first evidence for spin-correlation effects [352–355].

Spin correlations have been conclusively established at the LHC by both ATLAS and CMS. In the dominant gluon-gluon-fusion production mode for $t\bar{t}$ pairs, the angular separation between the two leptons in the DL channel is sensitive to the degree of spin correlation [356].

Measurements have been performed at $\sqrt{s} = 7$, 8, and 13 TeV, with the corresponding values of $f_{\rm SM}$ summarized in Tab. 61.21. While the $\sqrt{s}$ dependence of the correlations is of interest as a probe of the production mechanism ($q\bar{q}$ annihilation versus gluon-gluon fusion) and as a potential window to new physics, the 7 and 8 TeV results [357–363] were limited by relatively large uncertainties. These have since been superseded by the high-statistics measurements at 13 TeV, which are reviewed here in more detail.

At $\sqrt{s} = 13$ TeV, the most recent ATLAS measurement of $f_{\rm SM}$ is based on $\Delta\phi$, the azimuthal angle between the two charged leptons in $e\mu$ events, within an analysis that also measures the differential cross sections in $\Delta\phi$ and $\Delta\eta$ [364]. The comparison with NLO Monte Carlo generators yields $f = 1.249 \pm 0.024$ (stat.) $\pm$ 0.061 (syst.)$^{+0.067}_{-0.090}$ (theo.). While earlier measurements were statistically consistent with the SM expectation of $f = 1.0$, the current result lies above this value by about 2.2σ. The NLO predictions considered are based on QCD corrections only and correspond to the production level. When EW corrections are included, the SM prediction becomes compatible with the measurement within uncertainties, although it is affected by a relatively large uncertainty, $f = 1.03 \pm 0.13$.

The CMS measurement at $\sqrt{s} = 13$ TeV was obtained from DL events by measuring parton-level normalized differential cross sections, which are sensitive to each of the independent coefficients of the spin-dependent parts of the $t\bar{t}$ production density matrix. These measured distributions and extracted coefficients were compared with SM predictions from simulations at NLO accuracy in QCD, and from NLO QCD calculations including EW corrections. The comparison with the simulation yields $f = 0.98 \pm 0.03$ (stat.) $\pm$ 0.04 (syst.) $\pm$ 0.01 (theo.). The normalized differential cross sections are used in fits to constrain the anomalous chromomagnetic and chromoelectric dipole moments of the top quark [154]: $-0.24 < C_{tG}/\Lambda^2 < 0.07$ TeV^{-2} and $-0.33 < C^I_{tG}/\Lambda^2 < 0.20$ TeV^{-2}, respectively, at 95% C.L. [365].

These results are part of a comprehensive study of the top quark spin density matrix at $\sqrt{s} = 13$ TeV, as measured through the coefficients of Eq. 61.5, which will be discussed further below.

Measurement of the full spin density matrix

Instead of extracting a single overall correlation coefficient or the fraction of SM-like spin correlation, the full spin density matrix can be measured. This requires determining the top- and antitop-quark polarizations P in the three spatial directions and the nine components of the spin-correlation matrix C[1]. An introduction to the spin-density-matrix formalism is given in Ref. [30].

[1] Some publications denote the polarizations by P instead of B, and the correlations by C instead of A, as the notation has varied over time.

To extract all coefficients, spin-quantization axes must first be defined. A full reconstruction of the $t\bar{t}$ final state is required. In the notation of the first ATLAS measurement [366], the helicity axis is denoted k, the transverse axis n, and the r axis orthogonal to both. Spin analyzers are boosted into the rest frames of the respective top or antitop quark, and the angular distribution $\cos\theta$ of their momenta relative to the chosen axis is reconstructed. The 15 parameters are then obtained from data using one observable per parameter, as listed in Fig. 61.12 from Ref. [366].

The most precise individual measurement of these 15 coefficients has recently been performed by CMS in LJ events at $\sqrt{s} = 13$ TeV [35], using the down-type quark and the charged lepton as spin analyzers. In this analysis, the coefficients are extracted from a combined fit to data. Events are categorized according to $m_{t\bar{t}}$, $p_{\mathrm{T}}^{\mathrm{top}}$, and the absolute value of the top-quark scattering angle $|\cos\theta|$. The templates are parametrized as functions of the angular distributions of the top- and antitop-quark decay products. The setup achieving the best precision is based on event categories in bins of $p_{\mathrm{T}}^{\mathrm{top}}$ and $|\cos\theta|$.

Expectation values	NLO predictions	Observables
B_+^k	0.0030 ± 0.0010	$\cos\theta_+^k$
B_-^k	0.0034 ± 0.0010	$\cos\theta_-^k$

$C(k,k)$	0.318 ± 0.003	$\cos\theta_+^k \cos\theta_-^k$
$C(n,n)$	0.332 ± 0.002	$\cos\theta_+^n \cos\theta_-^n$
$C(r,r)$	0.055 ± 0.009	$\cos\theta_+^r \cos\theta_-^r$
$C(n,k) + C(k,n)$	0.0023	$\cos\theta_+^n \cos\theta_-^k + \cos\theta_+^k \cos\theta_-^n$
$C(n,k) - C(k,n)$	0	$\cos\theta_+^n \cos\theta_-^k - \cos\theta_+^k \cos\theta_-^n$
$C(n,r) + C(r,n)$	0.0010	$\cos\theta_+^n \cos\theta_-^r + \cos\theta_+^r \cos\theta_-^n$
$C(n,r) - C(r,n)$	0	$\cos\theta_+^n \cos\theta_-^r - \cos\theta_+^r \cos\theta_-^n$
$C(r,k) + C(k,r)$	-0.226 ± 0.004	$\cos\theta_+^r \cos\theta_-^k + \cos\theta_+^k \cos\theta_-^r$
$C(r,k) - C(k,r)$	0	$\cos\theta_+^r \cos\theta_-^k - \cos\theta_+^k \cos\theta_-^r$

Figure 61.12: Expected values and corresponding observables for the measurement of spin correlations and polarizations of the top and antitop quarks [366].

61.2.5.4 *Measurement of spin entanglement in pair production*

Entanglement, such as between the spin states of two particles, is a fundamental property of quantum mechanics [367–369]. Two particles are entangled if the state of one cannot be described independently of the state of the other. While entanglement has been observed in many physical systems, its study at high-energy colliders has been limited until recently. Notable examples include flavor entanglement in $\Upsilon(4S) \to B_0\bar{B}_0$ decays [370] and tests of Bell non-locality in $B_0 \to J/\psi K^*(892)^0$ decays [371]. The idea of probing entanglement in top-quark pairs through their spin correlations was first proposed in 2020 [32, 372–378].

At the LHC, $t\bar{t}$ pairs are predominantly produced via gluon–gluon fusion. Near production threshold ($m_{t\bar{t}} \approx 2m_t \approx 350$ GeV), they are expected to form dominantly a spin-singlet state ($^1S_0$), which is maximally entangled. The different spin states are illustrated in Fig. 61.11. Since the spin state of an individual top quark cannot be determined directly in a collision experiment, the presence of quantum entanglement must be inferred statistically from ensembles of $t\bar{t}$ events. The spin singlet is rotationally invariant, which motivates the use of the trace of the spin-correlation matrix C as an entanglement witness. A sufficient condition for entanglement is given by $\mathrm{tr}[C]+1 < 0$, measuring entanglement, a natural extension of spin-correlation studies. This can be rewritten as

$$D = tr[C]/3, \tag{61.7}$$

which can be experimentally measured as:

$$D = -3 \cdot \langle \cos\varphi \rangle. \tag{61.8}$$

Here $\langle\cos\varphi\rangle$ is the average of the opening angle between the two spin analyzers in their respective parent-top rest frames. If $D < -1/3$, the top quarks are entangled [32].

The first measurement of D at $\sqrt{s} = 13$ TeV was performed by CMS using a partial dataset [365]. In that analysis, the full $m_{t\bar{t}}$ spectrum was included, which reduced the sensitivity and prevented a significant deviation from zero.

The first observation of quantum entanglement in $t\bar{t}$ events was reported by ATLAS using the full Run 2 dataset at 13 TeV [33]. The analysis employed the mean value of the $\cos\phi$ distribution to construct a calibration curve relating detector-level to particle-level observables. This calibration was then applied to the detector-level measurement of D in data, and the resulting particle-level value was compared with theoretical predictions. Since entanglement effects are expected to be most pronounced near threshold, the analysis was restricted to events with

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

$340 < m_{t\bar{t}} < 380$ GeV. The precision of the measurement is limited by signal-modeling uncertainties, particularly those arising from differences between parton-shower algorithms.

Subsequently, CMS observed entanglement in $t\bar{t}$ events in both the DL channel [34] and the LJ channel [35]. In the DL analysis, a template fit to the full $\cos\phi$ spectrum was performed using a partial Run 2 dataset, with phase-space selections listed in Tab. 61.22. Non-relativistic bound-state effects were included in the prediction, improving agreement with the data. The LJ result forms part of the measurement of the full spin density matrix discussed above. Although the sensitivity to entanglement near threshold in this channel is insufficient for an observation, it provides access to a second phase space where entanglement is present: events at high $m_{t\bar{t}}$, where the top quarks are produced more widely separated in a $^3S_1$ state. Since in this region C_{rr} and C_{kk} become negative, the entanglement witness $\tilde{D}$ is defined as

$$\tilde{D} = \frac{1}{3}(C_{nn} - C_{rr} - C_{kk}) \tag{61.9}$$

and has to fulfill the criterion: $3\tilde{D} > 1$ [375]. This was achieved for events with $m_{t\bar{t}} > 800$ GeV and $|\cos\theta| < 0.4$. The ATLAS and CMS experiments have observed entanglement at the highest energy to date, both for $t\bar{t}$ events almost at rest and for more space-like separated top quarks. The measured values are summarized in Tab. 61.22.

61.2.5.5 *Pseudo-bound $t\bar{t}$ states at the production threshold*

During the development of quantum entanglement measurements, it became clear that modeling of the $t\bar{t}$ threshold region required improvements. As shown in the CMS analyses [34, 35], the inclusion of threshold effects leads to better agreement between the data and the prediction. Because the top quark decays before forming hadrons, bound states cannot occur in the usual sense. However, a $t\bar{t}$ pair produced nearly at rest can exchange gluons before one quark decays weakly [16, 379].

Threshold effects from non-relativistic QCD (NRQCD) have two main contributions: the potential has an attractive component from $t\bar{t}$ pairs in a color-singlet configuration (produced in gg fusion), corresponding to the $^1S_0^{[1]}$ spin–angular-momentum–color state. The second component of the potential is repulsive and originates from $t\bar{t}$ pairs produced in a color-octet configuration. The latter component is small and not included in the measurements discussed here. The resummation of Coulomb gluon exchange enhances $t\bar{t}$ production just below threshold. For $m_t = 172.5$ GeV and a binding energy of about 2 GeV, the expected mass of this state is $\simeq 343$ GeV, with a width of $2\Gamma_t$.

Standard Monte Carlo $t\bar{t}$ samples do not include these pseudo-bound-state effects, or other QCD effects occurring at the production threshold and discussed in Ref. [380]. Although these contributions amount to less than 1% of the total cross section and have negligible impact on most top-quark measurements, they become important for precision studies close to threshold, such as entanglement or top-quark Yukawa coupling measurements using the $m_{t\bar{t}}$ spectrum, and for new-physics searches in the low-$m_{t\bar{t}}$ region. To address this, CMS developed a dedicated cross-section measurement of this contribution using the full Run 2 dataset [90]. The analysis, performed in the DL channel, fitted the full $m_{t\bar{t}}$ spectrum, which was divided into nine signal regions defined by angular variables. This strategy significantly improved sensitivity compared with a single inclusive distribution. The signal was simulated with MG5_aMC@NLO using a simplified resonance model ($\eta_{t\bar{t}}$) decaying into $t\bar{t}$. The predicted cross section is 6.43 pb, and the measurement, limited by systematic uncertainties, yielded $\sigma(\eta_{t\bar{t}}) = 8.8^{+1.2}_{-1.4}$ pb with a significance greater than 5σ.

ATLAS carried out a similar analysis [91], also extracting the cross section from the $m_{t\bar{t}}$ distribution split into angular regions. The fit range was restricted to 300–500 GeV to avoid potential mis-modeling at high invariant masses. A more complete pseudo-bound state model was employed, in which LO $t\bar{t}$ matrix elements were reweighted using the NRQCD-resummed Green's function [16, 379]. The ATLAS result, also limited by systematic uncertainties, is $\sigma(t\bar{t}_{\mathrm{NRQCD}}) = 9.0 \pm 1.3$ pb with an observed significance of 7.7σ.

Both measurements are consistent with the production of a pseudo-bound color-singlet state. However, with the current invariant-mass resolution, a clear observation of the peak structure predicted by NRQCD cannot yet be claimed, and the enhancement can also be described within more inclusive approaches [380]. Further theoretical and experimental studies will be needed to clarify the nature of this enhancement.

61.2.5.6 *W-boson helicity in top-quark decay*

In the SM, the top quark couples to the W boson through the vector-minus-axial-vector ($V-A$) charged-current interaction, $-i\frac{g}{\sqrt{2}}V_{tb}\gamma^\mu\frac{1}{2}(1-\gamma_5)$. Because the fraction of decays to longitudinally polarized W bosons is proportional to the top-quark Yukawa coupling, it is enhanced relative to the weak coupling. The expected fraction is [381] $\mathcal{F}_0^{\mathrm{SM}} \approx x/(1+x)$, with $x = m_t^2/(2M_W^2)$, giving $\mathcal{F}_0^{\mathrm{SM}} \simeq 70\%$ for $m_t = 173$ GeV. The fractions of left-handed, right-handed, and longitudinal W bosons are denoted $\mathcal{F}_-$, $\mathcal{F}_+$, and $\mathcal{F}_0$, with SM expectations $\mathcal{F}_- \simeq 30\%$ and $\mathcal{F}_+ \simeq 0\%$. Predictions at NNLO in QCD are available [382].

Measurements of the W helicity in top-quark decays have been performed by both Tevatron and LHC experiments, in $t\bar{t}$ events reconstructed in the LJ and DL channels. As for the extraction of the top-quark mass, the template technique is widely used, although the matrix-element method and its variants have also been employed to determine the helicity fractions $\mathcal{F}$.

In Run 1 at the Tevatron, the charged-lepton p_{T} spectrum [383] and the invariant mass $M^2_{\ell b}$ of the lepton–b-quark system [384] in top-quark decays were used as template observables. In Run 2, both of these observables [385] the helicity angle $\cos\theta^*$, defined as the angle between the lepton and the b quark in the W-boson rest frame, became the primary observable [386–388]. In the DL channel, reconstruction is further improved by applying the neutrino-weighting technique (see Sec. 61.2.5.1), or both. The matrix element method has also been developed for this measurement, in which a likelihood is constructed from event probabilities expressed as functions of the W-helicity fractions $\mathcal{F}$ [389]. CDF and DØ combined their Run 2 results, based on 2.7–5.4 fb^{-1} of data [390], assuming a top-quark mass of 172.5 GeV. From the combination of measurements that simultaneously determined the fractions of W bosons, the results are $\mathcal{F}_0 = 0.722 \pm 0.081$ [± 0.062 (stat.) ± 0.052 (syst.)] and $\mathcal{F}_+ = -0.033 \pm 0.046$ [± 0.034 (stat.) ± 0.031 (syst.)]. In an alternative combination, where one of the helicity fractions was fixed to the SM expectation, the results are $\mathcal{F}_0 = 0.682 \pm 0.057$ [± 0.035 (stat.) ± 0.046 (syst.)] and $\mathcal{F}_+ = -0.015 \pm 0.035$ [± 0.018 (stat.) ± 0.030 (syst.)]. Both sets of results are consistent with SM predictions.

The large LHC datasets make it possible to perform simultaneous fits of $\mathcal{F}0$, $\mathcal{F}-$, and $\mathcal{F}_+$; the corresponding ATLAS and CMS results are summarized in Fig. 61.13.

At $\sqrt{s} = 7$ TeV, ATLAS used a template method for the $\cos\theta^*$ distribution and extracted angular asymmetries from the unfolded $\cos\theta^*$ distribution in both the LJ and DL channels [391]. CMS performed a similar measurement in the LJ channel, also based on template fits to the $\cos\theta^*$ distribution [392].

Since the polarization of W bosons in top-quark decays is directly sensitive to the Lorentz structure of the Wtb vertex and to possible anomalous couplings, both collaborations derived limits on non-SM contributions to the Wtb interaction. ATLAS and CMS also combined their 7 TeV results, also assuming a top-quark mass of 172.5 GeV, to obtain joint values of the W-boson helicity fractions and corresponding limits on anomalous couplings [393].

At $\sqrt{s} = 8$ TeV, ATLAS measured the W-boson helicity fractions in LJ events with at least one b tag [394]. CMS carried out complementary measurements: in LJ events with two b-tags [395] Using the same dataset, CMS also presented the first measurement of W-boson helicity in EW single-top production [396], obtaining results of similar precision and in agreement with the SM. The 8 TeV results from ATLAS and CMS in both $t\bar{t}$ and single-top events were subsequently combined [397]. The combined analysis, consistent with the SM predictions at NNLO in QCD, improved the precision by 25% (29%) for F_0 (F_L) compared to the most precise individual measurement, and set limits on anoma-

CMS [35]	$\tilde{D} = 0.652 \pm 0.052$	6.7σ (5.6σ)	SL	Fit to multi-differential distr. $m_{t\bar{t}} > 800$ GeV, $\lvert\cos\theta\rvert < 0.4$

lous right-handed vector (V_R) and left- and right-handed tensor (g_L, g_R) tWb couplings, as well as on the corresponding Wilson coefficients.

At $\sqrt{s} = 8$ TeV, ATLAS analyzed DL events with at least two b tags, measuring the normalized differential $t\bar{t}$ cross section with respect to $\cos\theta^*$ at parton level and, from template fits, extracting the W-boson helicity fractions [398]. The results are complementary to earlier measurements and consistent with SM expectations, with the precision limited by systematic uncertainties.

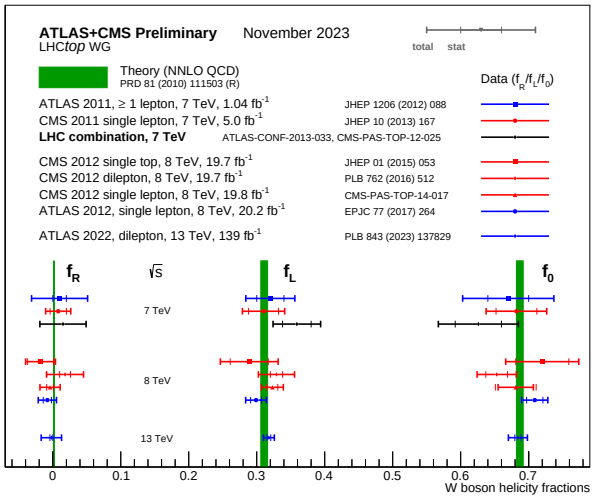

Figure 61.13: W-boson helicity fractions measured at the ATLAS and CMS experiments at different center-of-mass energies, compared to the theoretical NNLO predictions. The LHCtopWG working group kindly provides the plot, status as of November 2023, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

61.2.5.7 *Yukawa coupling*

The top-Higgs Yukawa coupling is expected to be the largest among all Yukawa couplings. It can be accessed directly by measurements of the $t\bar{t}$ cross section in association with a Higgs boson, $t\bar{t}H$, or indirectly via loop processes in $gg \to H$ production as well as $H \to \gamma\gamma$ or $H \to WW$ decays or in the rare process of $t\bar{t}t\bar{t}$ production. A discussion of the former can be found in Chapter 11 of this review. Searches for and recent observations of $t\bar{t}t\bar{t}$ production are discussed in Sec. 61.2.2. Measurements of y_t in kinematic distributions of $t\bar{t}$ production are providing additional information [399, 400].

61.2.5.8 *Top-quark asymmetries*

In $t\bar{t}$ production at hadron colliders, the SM predicts different predicts characteristic angular distributions that differ between the top and antitop quarks. Unlike most observables in the top-quark sector, measurements of asymmetries are still largely limited by statistical precision. This is particularly true for analyses probing the extreme regions of phase space, such as those targeting boosted top quarks, and for rare production modes like $t\bar{t}W$ and $t\bar{t}\gamma$. With the increasing luminosity delivered during Run 3 of the LHC and in future runs, significant improvements in these measurements are anticipated. Theoretical predictions for these asymmetries, however, have already reached a high level of precision.

Measurement of the forward-backward asymmetry A_{FB}

In $p\bar{p}$ collisions at the Tevatron collider, a forward-backward asymmetry arises in $t\bar{t}$ production starting at order α_S^3 in QCD. The asymmetry originates from the interference between the Born amplitude $q\bar{q} \to t\bar{t}$ with 1-loop box production diagrams and between diagrams with initial- and final-state gluon radiation. The asymmetry, A_{FB}, is defined by

$$A_{FB} = \frac{N(x > 0) - N(x < 0)}{N(x > 0) + N(x < 0)}. \tag{61.10}$$

Three types of asymmetries are discussed in the following:

- $A_{FB}^{t\bar{t}}$, where x is the rapidity difference between the top- and the antitop quark: $\Delta y = y_t - y_{\bar{t}}$. This asymmetry requires the full reconstruction of the $t\bar{t}$ final state.
- A_{FB}^{ℓ}, where x is the product of the charge and the rapidity of the lepton: $q_\ell \cdot \eta_\ell$.
  This asymmetry is only defined in the SL channel.
- $A_{FB}^{\ell\ell}$, where x is the rapidity difference between the two charged leptons: $\Delta\eta = \eta_{\ell^+} - \eta_{\ell^-}$. This asymmetry is only defined in the DL channel.

Calculations at α_S^3 predict a measurable A_{FB} at the Tevatron. Both CDF and DØ measured asymmetry values exceeding the SM prediction, which prompted considerable interest and speculation about possible contributions from new physics (see, for example, [401] and references therein). An overview of the early Tevatron measurements and the combined CDF and DØ results is given in Tab. 61.23. More recent calculations, extended to order α_S^4 and including EM and EW corrections, predict $A_{FB} \approx 0.095 \pm 0.007$ [402]. This value is about 10% larger than the previous NLO prediction [403, 404], leading to improved agreement with experimental results.

The first measured values at DØ and CDF were higher, though statistically consistent, with the SM expectation. With the addition of more data, the uncertainties were reduced, and the central values, if somewhat smaller, have remained consistent with the

Table 61.23: Forward-backward asymmetry measurements in $t\bar{t}$ events at the Tevatron, performed at $\sqrt{s} = 1.96$ TeV. If only one uncertainty is given, it reflects the total uncertainty on the measurement or prediction.

Experiment [Ref.]	Luminosity (fb^{-1})	Measurement Value ± (stat.) ± (syst.)	Note
DØ [405]	0.9	$A_{FB}^{t\bar{t}} = 0.12 \pm 0.08$	first DØ result
CDF [406]	1.9	$A_{FB}^{t\bar{t}} = 0.24 \pm 0.14$	first CDF result, parton level
Theory [402]		$A_{FB}^{t\bar{t}} = 0.095 \pm 0.007$	NNLO QCD + NLO EW
Comb. [407]	9-10	$A_{FB}^{t\bar{t}} = 0.128 \pm 0.021 \pm 0.014$	DØ+CDF combination
Theory [404]		$A_{FB}^{\ell} = 0.038 \pm 0.003$	NLO QCD + NLO EW
Comb. [407]	9-10	$A_{FB}^{\ell} = 0.073 \pm 0.016 \pm 0.012$	DØ+CDF combination
Theory [404]		$A_{FB}^{\ell\ell} = 0.048 \pm 0.004$	NLO QCD + NLO EW
Comb. [407]	9-10	$A_{FB}^{\ell\ell} = 0.108 \pm 0.043 \pm 0.016$	DØ+CDF combination

first measurements. At the same time, the improved calculations based on theory have increased the predicted asymmetry values, thereby improving the agreement between theory and experiment. Both experiments have also measured differential asymmetries, in bins of $m_{t\bar{t}}$, Δy, $q_\ell \cdot \eta_\ell$, and $\Delta\eta_{\ell\ell}$, with consistent results, though the growth of $A_{FB}^{t\bar{t}}$ with increasing $m_{t\bar{t}}$ and Δy appears somewhat more rapid than the SM prediction [407].

Charge asymmetry A_C

At the LHC, where $t\bar{t}$ production is dominated by charge-symmetric gluon–gluon fusion, the measurement is intrinsically different from that at the Tevatron. In the subdominant $q\bar{q}$ production mode, the symmetry of the pp initial state does not provide a natural definition of forward and backward directions. Instead, charge and energy asymmetries are defined based on Eq. 61.10 as follows:

- $A_C^{t\bar{t}}$, where x is the difference between the absolute rapidities of the top- and the antitop quark: $\Delta|y| = |y_t| - |y_{\bar{t}}|$. The asymmetry requires the full $t\bar{t}$ event reconstruction.
- $A_C^{\ell\ell}$, where x is the difference between absolute pseudorapidities of the two charged leptons: $\Delta|\eta| = |\eta_{\ell^+}| - |\eta_{\ell^-}|$. This asymmetry is only defined in the DL channel and is referred to as "leptonic charge asymmetry."
- A_E, which is defined as the difference between the top- and antitop-quark energies, and can be measured as a function of the associated high-p_{T} jet angle, θ_j. The energies and jet angle are measured in the $t\bar{t}j$ rest frame. This asymmetry is referred to as "energy asymmetry" [408].

Both CMS and ATLAS have measured the charge asymmetry in different channels and at various center-of-mass energies. Results from the individual experiments at 7 and 8 TeV, as well as their combination, are summarized in Tab. 61.24. Statistical uncertainties primarily limit the precision; however, in some measurements, the statistical and systematic components are of comparable size. In addition to inclusive values, differential measurements as functions of $m_{t\bar{t}}$, and of the p_{T} and rapidity y of the $t\bar{t}$ system, have also been performed.

To reduce model dependence, CMS performed a measurement in a reduced fiducial phase space [409], obtaining $A_C = (-0.35 \pm 0.72\ (\text{stat.}) \pm 0.31\ (\text{syst.}))\%$, consistent with the SM prediction. To probe the $m_{t\bar{t}}$ dependence, ATLAS carried out a measurement in boosted $t\bar{t}$ events with $m_{t\bar{t}} > 0.75$ TeV, and also reported results in three bins of $m_{t\bar{t}}$ [410].

Overall, the measurements from both experiments are in agreement with SM expectations.

At 13 TeV, the measurements are more diverse, targeting not only $t\bar{t}$ events but also $t\bar{t}$+jet and $t\bar{t}$+boson final states [217, 411–413]. The size and sign of the asymmetries differ for the various final states. While the $t\bar{t}$ asymmetry is diluted in inclusive measurements at the LHC owing to the large fraction of gluon–gluon-initiated $t\bar{t}$ events which increases as a function of the center-of-mass energy, it is enhanced in other topologies such as $t\bar{t}\gamma$ due to an increased fraction of the quark initiated production mode. Another interesting quantity is the leptonic charge asymmetry in $t\bar{t}W$ events using final states with exactly three charged light leptons (electrons or muons). Here, the events are also enhanced in quark-initiated production processes. Additionally, the W boson in the initial state causes polarization of the $t\bar{t}$ pair, which further leads to a sizeable asymmetry. The results for the $t\bar{t}$+boson and $t\bar{t}$+jet final states are still strongly limited by statistical uncertainties and will benefit from the increased dataset at 13.6 TeV and beyond.

The most precise measurement to date was performed by ATLAS at $\sqrt{s} = 13$ TeV, combining LJ and DL channels with reconstruction techniques for both resolved and boosted topologies [424]. Differential results are reported as functions of the invariant mass, p_{T}, and longitudinal boost of the $t\bar{t}$ system. Both inclusive and differential measurements are compatible with SM predictions at NLO QCD with NLO EW corrections. The results are also interpreted in SMEFT, setting bounds on several Wilson coefficients.

CMS measured the charge asymmetry in $t\bar{t}$ events with highly Lorentz-boosted top quarks for $m_{t\bar{t}} > 0.75$ TeV, a phase space particularly relevant for BSM searches [425]. The measurement, corrected for detector and acceptance effects using a binned maximum-likelihood fit, was performed in three $m_{t\bar{t}}$ ranges. The results are in good agreement with the SM.

A model-independent comparison of the Tevatron and LHC results is made difficult by the differing $t\bar{t}$ production mechanisms at work at the two accelerators and by the symmetric nature of the pp collisions at the LHC. An early analysis from the CMS collaboration [427] using LJ events at $\sqrt{s} = 13$ TeV, uses a likelihood analysis to separate the $q\bar{q}$ process from production via gluon-gluon and gluon-quark interactions. The values found for the asymmetry parameters are $A_{FB} = 0.048^{+0.095}_{-0.087}\,(\text{stat.})\,^{+0.020}_{-0.029}\,(\text{syst.})$, for the anomalous chromomagnetic dipole moment $\mu^t = -0.024^{+0.013}_{-0.009}\,(\text{stat.})\,^{+0.016}_{-0.011}\,(\text{syst.})$, and a limit is placed on the magnitude of a possible anomalous chromoelectric dipole moment $|d^t| < 0.03$ at 95% C.L. [427].

61.2.5.9 *Electric charge*

The top quark is the only quark whose electric charge has not been measured through threshold production in e^+e^- collisions, and its electromagnetic coupling has only recently been studied in detail. Early CDF and DØ analyses of top-quark production did not uniquely associate the b, $\bar{b}$, and $W^\pm$ to the top or antitop quark, so that exotic decays such as $t \to W^+\bar{b}$ and $\bar{t} \to W^-b$ could not be excluded. A quark with charge 4/3 is, in fact, compatible with EW precision data. In particular, the $Z \to \ell^+\ell^-$ and $Z \to b\bar{b}$ measurements, including the discrepancy between A_{LR} at SLC and $A_{FB}^{0,b}$ and $A_{FB}^{0,\ell}$ at LEP, can be fitted with a 270 GeV quark of charge 4/3, provided the right-handed b mixes with the isospin $+1/2$ component of an exotic doublet $(Q_1, Q_4)_R$ with charges $-1/3$ and $-4/3$ [428,429]. The third component of the top-quark weak isospin has likewise not been measured directly.

DØ studied the top-quark charge in double-tagged LJ events, while CDF analyzed single-tagged LJ and DL events. Assuming the top and antitop quarks carry equal and opposite charges, the b-quark charge was reconstructed using jet-charge discrimination to

test the $|Q_{top}| = 2/3$ SM scenario against the exotic $|Q_{top}| = 4/3$ hypothesis. Within the framework of the exotic model of Chang

et al. [429], CDF excluded $Q_{top} = 4/3$ at 99% C.L. [430], while DØ excluded it at more than 5σ and limited the fraction of such quarks in the data to below 0.46 [431]. These results firmly established that the observed particle is consistent with the SM quark of charge $+2/3$. At the LHC, ATLAS performed a similar measurement at $\sqrt{s} = 7$ TeV using jet-charge techniques and soft-lepton tagging in b decays combined with a kinematic likelihood fit. The measured top-quark charge was 0.64 ± 0.02 (stat.) ± 0.08 (syst.), excluding the exotic $Q = -4/3$ hypothesis at more than 8σ [432]. CMS also tested the exotic-charge scenario at $\sqrt{s} = 7$ TeV in the muon+jets channel, exploiting the correlation between high-p_{T} muons from W decays and soft muons from B-hadron decays inside b-jets. Using an asymmetry variable A, with $A = -1$ corresponding to $Q = -4/3$ and $A = +1$ to $Q = +2/3$, CMS preliminary measured $A = 0.97 \pm 0.12$ (stat.) ± 0.31 (syst.), in agreement with the SM and excluding the exotic scenario at 99.9% C.L. [433].

61.2.6 *Physics beyond the SM*

The top quark plays a special role in the SM. Being the only quark with a coupling to the Higgs boson of order one, it provides the most important contributions to the quadratic radiative corrections to the Higgs mass exposing the issue of the naturalness of the SM. It is therefore very common for models where the naturalness problem is addressed to have new physics associated with the top quark. In SUSY, for instance, naturalness predicts the scalar top-quark partners to be the lightest among the squarks and to be accessible at the LHC energies (see the review "Supersymmetry: Theory"). In models where the Higgs is a pseudo-Goldstone boson, such as Little Higgs models, naturalness predicts the existence of partners of the top quarks with the same spin and color, but with different EW couplings, the so-called vectorial t'. Stops and t''s are expected to have sizeable branching ratios to top quarks. Another intriguing prediction of SUSY models with universal couplings at the unification scale is that for a top-quark mass close to the measured value, the running of the Yukawa coupling down to 1 TeV naturally leads to the radiative breaking of the EW symmetry [434]. In fact, the top quark plays a role in the dynamics of EW symmetry breaking in many models [435]. One example is topcolor [436], where a large top-quark mass can be generated through the formation of a dynamic $t\bar{t}$ condensate, X, which is formed by a new strong gauge force coupling preferentially to the third generation. Another example is topcolor-assisted technicolor [437], predicting the existence of a heavy Z' boson that couples preferentially to the third generation of quarks. If light enough, such a state might be directly accessible at the present hadron collider energies, or if too heavy, lead to four-top interactions possibly visible in the $t\bar{t}t\bar{t}$ final state.

61.2.6.1 *Direct searches for physics beyond the SM*

In this section, the most recent direct searches for effects beyond the SM in top-quark production and decay are reviewed. These searches can be broadly divided into two categories: (i) searches for $t\bar{t}$ resonances, and (ii) searches for rare non-SM interactions involving top quarks, including flavor-changing neutral currents (FCNC). Resonance searches in the top sector include (a) $t\bar{t}$ resonances, in which a hypothetical heavy particle X decays into a $t\bar{t}$ pair, and (b) searches where a non-SM decay product of the top quark is identified through its resonant signature. The most recent results belong to the latter class. For comprehensive discussions of $X \to t\bar{t}$ searches, see Refs. [438–440]. Searches for rare non-SM interactions and FCNC processes are interpreted within the EFT framework described in Section 61.1.3. Here we focus on the limits on branching ratios obtained from these searches, while the corresponding EFT interpretations are discussed in Section 61.2.6.2.

FCNC searches. The most recent FCNC searches target the decay $t \to qH$ in $t\bar{t}$ production, or an FCNC vertex in single-top-quark production associated with a Higgs boson.

ATLAS probes both processes using $H \to VV$ decays. Neural-network outputs are used to define four signal regions, two each for production and decay, further divided into categories with two same-sign leptons or three leptons [441]. Despite the small branching ratio, this channel provides the best sensitivity. The results are combined with complementary searches using Higgs-boson decays to $b\bar{b}$ [442], $\tau\tau$ [443], and $\gamma\gamma$ [444], accounting for correlations among parameters. The combined upper limits on the branching ratios are $\mathcal{B}(t \to Hu) < 2.6 \times 10^{-4}$ and $\mathcal{B}(t \to Hc) < 3.4 \times 10^{-4}$.

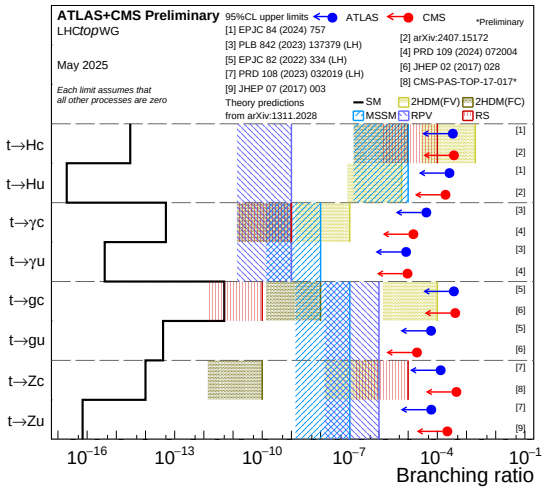

Figure 61.14: Overview of branching-ratio limits in searches for FCNCs in different production and decay channels, compared to different theory predictions. The LHCtopWG working group kindly provides the plot, status as of May 2025, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

CMS uses Higgs decays to vector bosons and $\tau\tau$ [445], and combines these results with analyses targeting $H \to b\bar{b}$ [446] and $H \to \gamma\gamma$ [447]. As in the ATLAS case, the $H \to VV$ decay mode yields the highest sensitivity. The combined limits are $\mathcal{B}(t \to Hu) < 1.9 \times 10^{-4}$ and $\mathcal{B}(t \to Hc) < 3.7 \times 10^{-4}$. A comparison of the ATLAS and CMS results with predictions from representative BSM models is shown in Fig. 61.14.

Searches targeting tZq couplings use leptonic decays of the Z-boson and a trilepton final state. In $t\bar{t}$ events, the signal occurs through the FCNC decay $t \to Zq$, in single-top quark the signal occurs through the associated production of a top quark and a Z-boson. The branching-ratio limits shown in Fig. 61.14 are for tZu and tZc left-handed couplings and assume, for tZu, that the tZc coupling is zero and vice versa. Reference [448] presents limits for right-handed couplings, which are close to the values quoted in Fig. 61.14 for left-handed couplings.

Searches targeting $t\gamma q$ couplings focus on a high-p_{T} photon in the final state. As with tZq couplings, signal events occur through top-quark decay in $t\bar{t}$ and through associated production of a top quark and a photon in single-top events. ATLAS has set limits on the corresponding EFT couplings, shown in Fig. 61.18 [449]. The limits are derived assuming left-handed couplings; those for right-handed couplings are also provided and are only slightly weaker.

FCNC couplings tgq between a top quark, a gluon, and an up or charm quark have been probed by ATLAS in single-top-quark production [450]. Such couplings enhance the single-top-quark production cross section and, in the case of the tgc interaction, modify the rapidity distribution of the top quark due to the different PDFs of valence and sea quarks.

Searches for charged-lepton flavor violation. CMS has searched for for charged-lepton-flavor-violating (CLFV) interactions in both production, $q \to e\mu t$, and decay, $t \to e\mu q$, with $q = u$ or c [451] in final states with two leptons. Additional searches have been performed in final states with three leptons [452] and, more recently, in single-lepton final states targeting $\mu\tau qt$ interactions [453]. Limits on scalar, vector, and tensor couplings are summarized in Tab. 61.26. These limits are also shown in Fig. 61.17 and compared with the corresponding ATLAS search for CLFV $\mu\tau qt$ interactions [454], which uses final states containing a same-sign dimuon pair.

Searches for baryon number violation. CMS recently reported a search for baryon-number violation (BNV) in top-quark production and decay [455], using events with two same-sign leptons and at least one b-tagged jet. Both single-top and top-quark-pair production modes are considered. Boosted decision trees are employed to discriminate signal from background processes. No significant excess is observed, and upper limits are set on the corresponding couplings. The obtained limits improve upon previous constraints by several orders of magnitude.

Resonance searches. While technically an FCNC search, a decay of the type $t \to qX$ where $q = u$ or c, could be missed when X is not the expected quark or boson. ATLAS has searched for $t \to qX$ where X is a light scalar with a mass below the top quark that decays to $b\bar{b}$ [442]. Such phenomena exist in composite Higgs models [456]. The ATLAS search used $t\bar{t}$ events and separated signal from background by categorizing events according to the number of jets and the number of jets tagged as originating from b-quarks. The observed limits correspond to the product of the BR $t \to qX$ and $X \to b\bar{b}$. The limit in the $t \to uX(t \to cX)$ channel is 0.019% (0.018%) for $M_X = 20$ GeV and 0.062% (0.078%) for $M_X = 160$ GeV.

There is a wide range of searches for new resonances decaying into $t\bar{t}$ events which are partially covered in the section "Hypothetical particles and concepts" of this review.

61.2.6.2 *Effective field theory*

As described in Sec. 61.1.3, EFTs have become an important tool to search for new physics processes. The EFT interpretations benefit from the increasing datasets, as this allows for very

precise inclusive and differential measurements of top processes. These precision measurements of diverse sets of observables allows to improve the EFT interpretations by combining these measurements in a global analysis, as can be done using tools such as SMEFit [457]. In Ref. [458], Zhang and Willenbrock elucidate the advantages of the EFT approach compared to the vertex-function approach for searching for BSM effects in top-quark interactions, including the fact that the EFT approach incorporates the SM gauge symmetry and contact interactions that are neglected in the vertex-function approach. As a result of these advantages, EFTs have become the dominant technique for evaluating search limits, and the most recent results are reviewed in this section.

The top-EFT operators are categorized as follows: operators involving the contact-interaction of four fermions together (four-fermion operators), operators involving the interaction between top quarks and a vector boson (vector-boson operators) and between top quarks and scalar bosons (scalar-boson operators). Operators can change the overall rate of top-quark production, modify the kinematics of production and/or decay, or produce new interactions, such as FCNCs. To date, all results are consistent with the SM expectation of zero for each Wilson coefficient C. The bounds are set on C/Λ^2 and have a dimension of TeV^{-}2. Once the value for the unknown coupling strength C of the interaction is set, the size of the interval is inversely proportional to the square of the new physics scale.

The individual limits from the ATLAS and CMS results provided by the LHCtopWG can be found in Figs. 61.15–61.18. Marginalised limits and different representations can be found on the LHCtopWG page linked from the individual figure captions. Additional limits and references can be found in the listings and for example in the references [199, 216, 451, 459, 460, 460–468].

61.3 Summary and outlook

In the three decades since its discovery, top-quark physics has evolved from the observation of a single particle into a precision field that probes the SM at the highest energy scales. With the large datasets collected at the LHC, a wide range of top-quark properties have been measured with unprecedented accuracy. Production cross sections and other $\sqrt{s}$-dependent quantities have been determined at multiple energies, enabling stringent tests of QCD and EW production mechanisms. All results to date are consistent with SM predictions, providing strong validation of the theory. The precision will continue to improve as larger datasets and refined theoretical and experimental techniques become available, enhancing sensitivity to potential deviations from the SM.

The large top-quark samples recorded in Run 2 have enabled detailed studies of both $t\bar{t}$ production and single-top processes, all now firmly established at the LHC. Many associated production modes have also become accessible: while Run 1 provided the first evidence and observations of processes such as $t\bar{t}\gamma$, $t\bar{t}Z$, $t\bar{t}W$, $t\bar{t}H$, and $t\bar{t}t\bar{t}$, Run 2 has opened the path to precision studies of these reactions. Rare single-top associated modes, including tZ, $t\gamma$, and tWZ, are now being measured as well, extending sensi-

tivity to the structure of top-quark couplings and to possible new physics. Many of these results are interpreted within the framework of EFT, providing global constraints on higher-dimensional operators that parameterize deviations from the SM.

The complexity of top-quark final states and the precision they demand have driven major advances in analysis techniques, notably multivariate methods and machine learning, which are now standard in collider physics. The large top-quark mass, its unique role in electroweak symmetry breaking, and its potential link to new dynamics continue to make it a central focus of particle physics.

For many measurements, uncertainties in event simulation remain the dominant limitation on precision. Differential measurements are essential to further reduce these uncertainties, particularly in complex final states such as $t\bar{t}$+heavy-flavor jets.

While most of the Run 2 dataset at $\sqrt{s} = 13$ TeV has been analyzed, Run 3 at $\sqrt{s} = 13.6$ TeV, with an expected integrated luminosity exceeding 300 fb^{-1}, will more than double the available statistics. The forthcoming High-Luminosity LHC (HL-LHC) phase, expected to deliver up to 3 ab^{-1} of data, will mark the next major step in this progression—from discovery to precision characterization. It will enable sub-percent precision in key measurements, stringent global EFT constraints, and unprecedented sensitivity to rare processes and possible new interactions. With many results already published and more to come, top-quark physics continues to provide one of the most powerful tools for testing the SM and exploring physics at the TeV scale.

62. Form Factors for Semileptonic Kaon ($K_{\ell 3}$), Radiative Pion ($\pi_{\ell 2\gamma}$) and Kaon ($K_{\ell 2\gamma}$) Decays

Revised August 2025 by M.A. Bychkov (Virginia U.) and G. D'Ambrosio (INFN, Napoli).

62.1 $\pi^{\pm}_{\ell 2\gamma}$ and $K^{\pm}_{\ell 2\gamma}$ Form Factors

The radiative decays, $\pi^{\pm} \to l^{\pm}\nu\gamma$ and $K^{\pm} \to l^{\pm}\nu\gamma$, with l standing for an e or a μ, and γ for a real or virtual photon (e^+e^- pair), provide a powerful tool to investigate the hadronic structure of pions and kaons. The structure-dependent part SD_i of the amplitude describes the emission of photons from virtual hadronic states, and is parametrized in terms of form factors V, A, (vector, axial vector), in the standard description [1–4]. Note that in the Listings and some literature, equivalent nomenclature F_V and F_A for the vector and axial form factors is often used. Exotic, non-standard contributions like $i = T, S$ (tensor, scalar) have also been considered. Apart from the SD terms, there is also the Inner Bremsstrahlung amplitude, IB, corresponding to photon radiation from external charged particles and described by Low theorem in terms of the physical decay $\pi^{\pm}(K^{\pm}) \to l^{\pm}\nu$. Experiments try to optimize their kinematics so as to minimize the IB part of the amplitude.

The SD amplitude in its standard form is given as

$$M(\mathrm{SD}_V) = \frac{-eG_F U_{qq'}}{\sqrt{2}m_P}\epsilon^\mu l^\nu V^P \epsilon_{\mu\nu\sigma\tau}k^\sigma q^\tau \tag{62.1}$$

$$M(\mathrm{SD}_A) = \frac{-ieG_F U_{qq'}}{\sqrt{2}m_P}\epsilon^\mu l^\nu \{A^P[(qk-k^2)g_{\mu\nu} - q_\mu k_\nu] + R^P k^2 g_{\mu\nu}\}\,, \tag{62.2}$$

which contains an additional axial form factor R^P which only can be accessed if the photon remains virtual. $U_{qq'}$ is the Cabibbo-Kobayashi-Maskawa mixing-matrix element; ϵ^μ is the polarization vector of the photon (or the effective vertex, $\epsilon^\mu = (e/k^2)\overline{u}(p_-)\gamma^\mu v(p_+)$, of the e^+e^- pair); $\ell^\nu = \overline{u}(p_\nu)\gamma^\nu(1-\gamma_5)v(p_\ell)$ is the lepton-neutrino current; q and k are the meson and photon four-momenta ($k = p_+ + p_-$ for virtual photons); and P stands for π or K.

For decay processes where the photon is real, the partial decay width can be written in analytical form as a sum of IB, SD, and IB/SD interference terms INT [1, 4]:

$$\begin{aligned}\frac{d^2\Gamma_{P\to\ell\nu\gamma}}{dxdy} &= \frac{d^2\left(\Gamma_{\mathrm{IB}} + \Gamma_{\mathrm{SD}} + \Gamma_{\mathrm{INT}}\right)}{dxdy} \\ &= \frac{\alpha}{2\pi}\Gamma_{P\to\ell\nu}\frac{1}{(1-r)^2}\Bigg\{\mathrm{IB}(x,y) \\ &+ \frac{1}{r}\left(\frac{m_P}{2f_P}\right)^2\Big[(V+A)^2\mathrm{SD}^+(x,y) + (V-A)^2\mathrm{SD}^-(x,y)\Big] \\ &+ \epsilon_P\frac{m_P}{f_P}\Big[(V+A)\mathrm{S}^+_{\mathrm{INT}}(x,y) + (V-A)\mathrm{S}^-_{\mathrm{INT}}(x,y)\Big]\Bigg\}.\end{aligned} \tag{62.3}$$

Here

$$\begin{aligned}\mathrm{IB}(x,y) &= \left[\frac{1-y+r}{x^2(x+y-1-r)}\right] \\ &\quad\left[x^2 + 2(1-x)(1-r) - \frac{2xr(1-r)}{x+y-1-r}\right] \\ \mathrm{SD}^+(x,y) &= (x+y-1-r)\Big[(x+y-1)(1-x) - r\Big] \\ \mathrm{SD}^-(x,y) &= (1-y+r)\Big[(1-x)(1-y) + r\Big] \\ \mathrm{S}^+_{\mathrm{INT}}(x,y) &= \left[\frac{1-y+r}{x(x+y-1-r)}\right]\Big[(1-x)(1-x-y) + r\Big] \\ \mathrm{S}^-_{\mathrm{INT}}(x,y) &= \left[\frac{1-y+r}{x(x+y-1-r)}\right]\Big[x^2 - (1-x)(1-x-y) - r\Big]\end{aligned} \tag{62.4}$$

where $x = 2E_\gamma/m_P$, $y = 2E_\ell/m_P$, $r = (m_\ell/m_P)^2$, f_P is the meson decay constant, and ϵ_P is +1 for pions and -1 for kaons. The structure dependent terms SD^+ and SD^- are shown in Fig. 1. The SD^- term is maximized in the same kinematic region where overwhelming IB term dominates (along $x + y = 1$ diagonal). Thus experimental yields with less background are dominated by SD^+ contribution and proportional to $A^P + V^P$ making simultaneous precise determination of the form factors difficult.

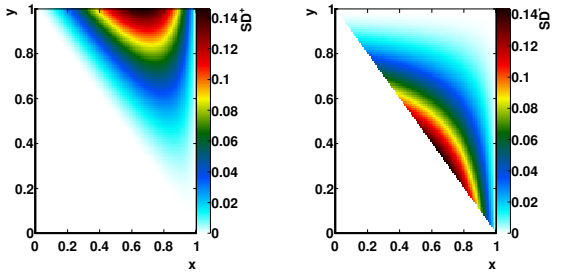

Figure 62.1: Components of the structure dependent terms of the decay width. Left: SD^+, right: SD^-

Recently, formulas 62.3 and 62.4 have been extended to describe polarized distributions in radiative meson and muon decays [5].

The "helicity" factor r is responsible for the enhancement of the SD over the IB amplitude in the decays $\pi^{\pm} \to e^{\pm}\nu\gamma$, while $\pi^{\pm} \to \mu^{\pm}\nu\gamma$ is dominated by IB. Interference terms are important for the decay $K^{\pm} \to \mu^{\pm}\nu\gamma$ [6], but contribute only a few percent correction to pion decays. However, they provide the basis for determining the signs of V and A. Radiative corrections to the decay $\pi^+ \to e^+\nu\gamma$ have to be taken into account in the analysis of the precision experiments. They make up to 4% corrections in the total decay rate [7]. In $\pi^{\pm} \to e^{\pm}\nu e^+e^-$ and $K^{\pm} \to \ell^{\pm}\nu e^+e^-$ decays, all three form factors, V^P, A^P, and R^P, can be determined [8, 9].

Theoretically, the first non-trivial χPT contributions to A^P and V^P appear at $\mathcal{O}(p^4)$ [4], respectively from Gasser-Leutwyler coefficients, L_i's, and the anomalous lagrangian:

$$A^P = \frac{4\sqrt{2}M_P}{F_\pi}(L^r_9 + L^r_{10}), \quad V^P = \frac{\sqrt{2}M_P}{8\pi^2 F_\pi}. \tag{62.5}$$

In case of the kaon $A^K = 0.042$ and $V^K = 0.096$. $\mathcal{O}(p^6)$ contributions to A^K can be predicted accurately: they are flat in the momentum dependence and shift the $\mathcal{O}(p^4)$ value to 0.034. $\mathcal{O}(p^6)$ contributions to V^K are model dependent and can be approximated by a form factor linearly dependent on momentum. For example, when looking at the spread of results obtained within two different models, the constant piece of this linear form factor is shifted to 0.078 ± 0.005 [1, 2, 4].

We give the experimental $\pi^{\pm}$ form factors V^π, A^π, and R^π in the Listings. In the $K^{\pm}$ Listings, we give the extracted sum $A^K + V^K$ and difference $A^K - V^K$, as well as V^K, A^K and R^K. In particular KLOE has measured for the constant piece of the form factor $A^K + V^K = 0.125 \pm 0.007 \pm 0.001$ [10] while ISTRA+, $V^K - A^K = 0.21 \pm 0.04 \pm 0.04$ [11].

The pion vector form factor, V^π, is related via CVC (Conserved Vector Current) to the $\pi^0 \to \gamma\gamma$ decay width. The constant term is given by $|V^\pi(0)| = (1/\alpha)\sqrt{2\Gamma_{\pi^0\to\gamma\gamma}/\pi m_{\pi^0}}$ [3]. The resulting value, $V^\pi(0) = 0.0259(9)$, has been confirmed by calculations based on chiral perturbation theory (χPT) [4], and by two experiments given in the Listings.

A recent experiment by the PIBETA collaboration [12] obtained a $V^\pi(0)$ that is in excellent agreement with the CVC hypothesis. It also measured the slope parameter a in $V^\pi(s) = V^\pi(0)(1 + a\cdot s)$, where $s = (1 - 2E_\gamma/m_\pi)$, and E_γ is the gamma energy in the pion rest frame: $a = 0.095 \pm 0.058$. A functional dependence on s is expected for all form factors. It becomes non-negligible in the case of $V^\pi(s)$ when a wide range of photon momenta is recorded; proper treatment in the analysis of K decays is mandatory.

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

The form factor, R^P, can be related to the electromagnetic radius, r_P, of the meson [2]: $R^P = \frac{1}{3} m_P f_P \langle r_P^2 \rangle$ using PCAC (Partial Conserved Axial vector Current).

In lowest order χPT, the ratio A^π/V^π is related to the pion electric polarizability $\alpha_E = [\alpha/(8\pi^2 m_\pi f_\pi^2)] \times A^\pi/V^\pi$ [13]. Direct experimental and theoretical status of pion polarizability studies currently is not settled. Most recent theoretical predictions from χPT at $\mathcal{O}(p^6)$ [14] and experimental results from COMPASS collaboration [15] favor a small value of pion polarizability $\alpha_\pi \sim (2 \div 3) \times 10^{-4}\,\mathrm{fm}^3$. Dispersive analysis of $\gamma\gamma \to \pi^+\pi^-$ crossection [16] and experimental results from MAMI collaboration [17] report a much larger value of $\alpha_\pi \sim 6 \times 10^{-4}\,\mathrm{fm}^3$. Precise measurement of the pion form factors by PIBETA collaboration favors smaller values of polarizability $\alpha_\pi = 2.7^{+0.6}_{-0.5} \times 10^{-4}\,\mathrm{fm}^3$.

Several searches for the exotic form factors F_T^π, F_T^K (tensor), and F_S^K (scalar) have been pursued in the past. In particular, F_T^π has been brought into focus by experimental as well as theoretical work [18]. New high-statistics data from the PIBETA collaboration have been re-analyzed together with an additional data set optimized for low backgrounds in the radiative pion decay. In particular, lower beam rates have been used in order to reduce the accidental background, thereby making the treatment of systematic uncertainties easier and more reliable. The PIBETA analysis now restricts F_T^π to the range $-5.2 \times 10^{-4} < F_T^\pi < 4.0 \times 10^{-4}$ at a 90% confidence limit [12]. This result is in excellent agreement with the most recent theoretical work [4].

Precision measurements of radiative pion and kaon decays are effective tools to study QCD in the non-perturbative region and are of interest beyond the scope of radiative decays. Meanwhile other processes such as $\pi^+ \to e^+\nu$ that seem to be better suited to search for new physics at the precision frontier are currently studied. The advantages of such process are the very accurate and reliable theoretical predictions and the more straightforward experimental analysis.

62.2 $K_{\ell 3}^\pm$ and $K_{\ell 3}^0$ Form Factors

Assuming that only the vector current contributes to $K \to \pi\ell\nu$ decays, we write the matrix element as

$$M \propto f_+(t)\left[(P_K + P_\pi)_\mu \bar{\ell}\gamma_\mu(1+\gamma_5)\nu\right] + f_-(t)\left[m_\ell \bar{\ell}(1+\gamma_5)\nu\right] , \quad (62.6)$$

where P_K and P_π are the four-momenta of the K and π mesons, m_ℓ is the lepton mass, and f_+ and f_- are dimensionless form factors which can depend only on $t = (P_K - P_\pi)^2$, the square of the four-momentum transfer to the leptons. If time-reversal invariance holds, f_+ and f_- are relatively real. $K_{\mu 3}$ experiments, discussed immediately below, measure f_+ and f_-, while K_{e3} experiments, discussed further below, are sensitive only to f_+ because the small electron mass makes the f_- term negligible.

62.2.1 $K_{\mu 3}$ *Decays*

Analyses of $K_{\mu 3}$ data frequently assume a linear dependence of f_+ and f_- on t, *i.e.*,

$$f_\pm(t) = f_\pm(0)\left[1 + \lambda_\pm(t/m_{\pi^+}^2)\right] . \quad (62.7)$$

Most $K_{\mu 3}$ data are adequately described by formula 62.7 for f_+ and a constant f_- (*i.e.*, $\lambda_- = 0$).

There are two equivalent parametrizations commonly used in these analyses: $\lambda_+, \xi(0)$ parametrization and λ_+, λ_0 parametrization.

Older analyses of $K_{\mu 3}$ data often introduce the ratio of the two form factors

$$\xi(t) = f_-(t)/f_+(t) . \quad (62.8)$$

The $K_{\mu 3}$ decay distribution is then described by the two parameters λ_+ and $\xi(0)$ (assuming time reversal invariance and $\lambda_- = 0$).

More recent $K_{\mu 3}$ analyses have parametrized in terms of the form factors f_+ and f_0, which are associated with vector and scalar exchange, respectively, to the lepton pair. f_0 is related to f_+ and f_- by

$$f_0(t) = f_+(t) + \left[t/(m_K^2 - m_\pi^2)\right] f_-(t) . \quad (62.9)$$

Here $f_0(0)$ must equal $f_+(0)$. The earlier assumption that f_+ is linear in t and f_- is constant leads to f_0 linear in t:

$$f_0(t) = f_0(0)\left[1 + \lambda_0(t/m_{\pi^+}^2)\right] . \quad (62.10)$$

With the assumption that $f_0(0) = f_+(0)$, the two parametrizations, $(\lambda_+, \xi(0))$ and (λ_+, λ_0) are equivalent as long as correlation information is retained. (λ_+, λ_0) correlations tend to be less strong than $(\lambda_+, \xi(0))$ correlations.

Since the 2006 edition of the *Review* [19], we no longer quote results in the $(\lambda_+, \xi(0))$ parametrization. We have removed many older low statistics results from the Listings. See the 2004 version of this note [20] for these older results, and the 1982 version [21] for additional discussion of the $K_{\mu 3}^0$ parameters, correlations, and conversion between parametrizations.

More recent high-statistics experiments have included a quadratic term in the expansion of $f_+(t)$,

$$f_+(t) = f_+(0)\left[1 + \lambda_+^{'}(t/m_{\pi^+}^2) + \frac{\lambda_+^{''}}{2}(t/m_{\pi^+}^2)^2\right] . \quad (62.11)$$

If there is a non-vanishing quadratic term, then λ_+ of formula 62.7 represents the average slope, which is then different from $\lambda_+^{'}$. Our convention is to include the factor $\frac{1}{2}$ in the quadratic term, and to use m_{π^+} even for K_{e3}^+ and $K_{\mu 3}^+$ decays. We have converted other's parametrizations to match our conventions, as noted in the beginning of the "$K_{\ell 3}^\pm$ and $K_{\ell 3}^0$ Form Factors" sections of the Listings.

There are two alternatives to the Taylor parametrization: The Pole Parametrization and Dispersive Parametrization.

The pole model describes the t-dependence of $f_+(t)$ and $f_0(t)$ in terms of the exchange of the lightest vector and scalar K^* mesons with masses M_V and M_S, respectively:

$$f_+(t) = f_+(0)\left[\frac{M_V^2}{M_V^2 - t}\right] , \quad f_0(t) = f_0(0)\left[\frac{M_S^2}{M_S^2 - t}\right] . \quad (62.12)$$

The Dispersive Parametrization approach, valid in a much wider kinematic range and able to describe at the same time τ-decay data, [22] uses dispersive techniques and the known low-energy K-π phases to parametrize the vector and scalar form factors:

$$f_+(t) = f_+(0)\exp\left[\frac{t}{m_\pi^2}(\Lambda_+ + H(t))\right]; \quad (62.13)$$

$$f_0(t) = f_+(0)\exp\left[\frac{t}{(m_K^2 - m_\pi^2)}\,(ln[C] - G(t))\right], \quad (62.14)$$

where Λ_+ is the slope of the vector form factor, and $\ln C = \ln[f_0(m_K^2 - m_\pi^2)]$ is the logarithm of the scalar form factor at the Callan-Treiman point. The functions $H(t)$ and $G(t)$ are dispersive integrals.

62.2.2 K_{e3} *Decays*

Analysis of K_{e3} data is simpler than that of $K_{\mu 3}$ because the second term of the matrix element assuming a pure vector current [formula 62.6 above] can be neglected. Here f_+ can be assumed to be linear in t, in which case the linear coefficient λ_+ of formula 62.7 is determined, or quadratic, in which case the linear coefficient $\lambda_+^{'}$ and quadratic coefficient $\lambda_+^{''}$ of formula 62.11 are determined.

If we remove the assumption of a pure vector current, then the matrix element for the decay, in addition to the terms in formula 62.6, would contain

$$+2m_K\, f_S\, \bar{\ell}(1+\gamma_5)\nu + (2f_T/m_K)(P_K)_\lambda (P_\pi)_\mu\, \bar{\ell}\,\sigma_{\lambda\mu}(1+\gamma_5)\nu , \quad (62.15)$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

where f_S is the scalar form factor, and f_T is the tensor form factor. In the case of the K_{e3} decays where the f_- term can be neglected, experiments have yielded limits on $|f_S/f_+|$ and $|f_T/f_+|$.

For K_{e3} data, we determine best values for the three parametrizations: linear (λ_+), quadratic (λ'_+, λ''_+) and pole (M_V). For $K_{\mu 3}$ data, we determine best values for the three parametrizations: linear (λ_+, λ_0), quadratic (λ'_+, λ''_+, λ_0) and pole (M_V, M_S). We then assume $\mu-e$ universality so that we can combine K_{e3} and $K_{\mu 3}$ data, and again determine best values for the three parametrizations: linear (λ_+, λ_0), quadratic (λ'_+, λ''_+, λ_0), and pole (M_V, M_S). When there is more than one parameter, fits are done including input correlations. Simple averages suffice in the two K_{e3} cases where there is only one parameter: linear (λ_+) and pole (M_V).

A comprehensive global analysis of the semileptonic kaon decay data and its effect on the CKM unitarity debate can be found in [23, 24]. An update on experimental data including NA48/2 newest results can be found in [25].

Both KTeV and KLOE see an improvement in the quality of their fits relative to linear fits when a quadratic term is introduced, as well as when the pole parametrization is used. The quadratic parametrization has the disadvantage that the quadratic parameter λ''_+ is highly correlated with the linear parameter λ'_+, in the neighborhood of 95%, and that neither parameter is very well determined. The pole fit has the same number of parameters as the linear fit, but yields slightly better fit probabilities, so that it would be advisable for all experiments to include the pole parametrization as one of their choices.

The "Kaon Particle Listings" show the results with and without assuming μ-e universality. The "Meson Summary Tables" show all of the results assuming μ-e universality, but most results not assuming μ-e universality are given only in the Listings.

63.1 Introduction

According to the constituent quark model, a light meson consists of a color singlet quark-antiquark pair made of the u, d, or s quarks and the $\overline{u}$, $\overline{d}$, or $\overline{s}$ antiquarks, grouped into a flavor multiplet of SU(3). However, additional mesons made of bound gluons (glueballs) could exist in the same mass range, suggested by the self coupling of gluons in QCD. Multiquark structures are also possible, such as quark-antiquark pairs with an excited gluon (hybrid mesons). Tetraquarks are compact color singlets of diquark-antidiquark pairs ($qq\overline{q}\overline{q}$) or 'molecular' bound states of two mesons ($q\overline{q}q\overline{q}$). More complex systems such as $qqq\overline{q}\overline{q}\overline{q}$ (baryonia) are also predicted.

Fundamentals on the constituent quark model on light and heavy mesons and baryons (including hadrons with charm and bottom quarks), and on predictions from lattice gauge theories, are described in 'Quark Model' in this issue of the *Review of Particle Physics*, henceforth called the *Review*. In the present text we describe the experimental spectrum of light mesons and their classifications within the constituent quark model, with emphasis on states exhibiting properties incompatible with $q\bar{q}$ structures. The discussion is driven by the publications quoted in the *Listings* of the *Review*. The spectrum of kaon excitations is less well-defined and therefore deferred to a future edition, when further data might become available. More detailed discussions on exotic mesons – including those involving the c and b quarks – can be found in Refs. [1–8] and in 'Heavy Non-$q\bar{q}$ Mesons' of the *Review*. For more information on the meson (and baryon) spectrum of light (and heavy) quarks we refer to one of the textbooks [9].

Figure 63.1 shows the mass spectrum of $q\bar{q}$ mesons. The mass (vertical axis) increases with orbital excitation ℓ and radial excitation n. In the quark model one uses the notation nS, nP, nD... for the radial excitations ($n = 1$ for the ground states), in contrast to the usual $1s$, $2p$, $3d$... notation in atomic physics. Each box represents an SU(3) nonet containing multiplets of the isospin I, (*e.g.* for the pseudoscalar ground state nonet, one isotriplet (π^+, π^0, π^-), two strange isodoublets (K^-, $\bar{K}^0$ and K^0, K^+) and two isosinglets (η, η'). The spin, parity [$P = -(-1)^\ell$] and C-parity [$C = (-1)^{\ell+s}$] take the possible values $J^{PC} = 0^{++}$ (scalar), 0^{-+} (pseudoscalar), 1^{--} (vector), $1^{+\pm}$ (axial- or pseudovector), 2^{++} (tensor), etc. Therefore mesons with the *exotic* quantum numbers 0^{--}, 0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, etc. cannot be $q\bar{q}$ states. Note that the C-parity is defined only for the electrically neutral nonstrange nonet members. The classification shown in fig. 63.1 is tentative for the radial excitations, in particular for those not fully established.

The two isosinglets in each nonet mix with an angle θ close to the *ideal* value of 35.3° for the 1^{--}, $1^{+\pm}$, 2^{++} and 3^{--} nonets, in which case the two isosinglets decouple to $u\overline{u} + d\overline{d}$ and $s\overline{s}$. The orbital excitations $\ell \geq 1$ consist of four nonets for each value of n, since $j = \ell$ for antiparallel quark spins and $j = \ell - 1, \ell$ or $\ell + 1$ for parallel spins. Since the C-parity is not defined for strange mesons, the K_{1A} and K_{1B} in the axial vector 1^{++} and 1^{+-} nonets of fig. 63.1 are mathematical constructs which mix to give the observed $K_1(1270)$ and $K_1(1400)$ mesons. A similar scenario occurs for the observed 2^{-+} $K_2(1770)$ and 2^{--} $K_2(1820)$ mesons, with a small mixing angle [10]. According to Ref. [11], the masses of radially excited mesons and baryons appear to grow logarithmically with quantum number n, a phenomenon that is not understood.

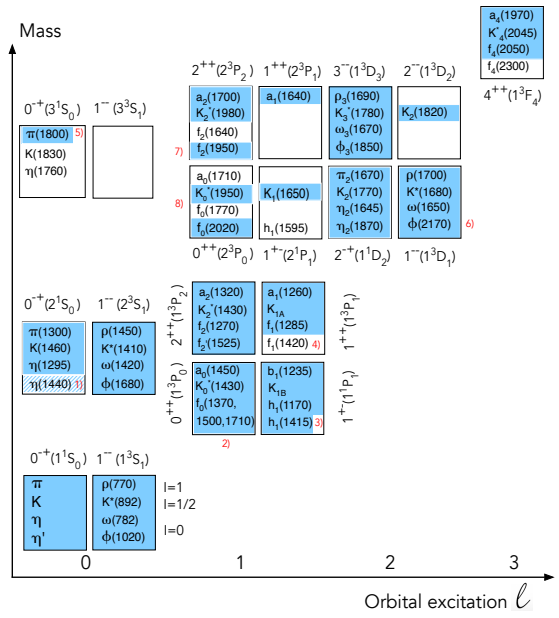

Figure 63.1: The mesons made of the u, d, and s light quarks are organised in $J^{PC}(n^{2s+1}\ell_j)$ nonets with isospin I. The established mesons (which appear in the *Summary Table* of the *Review*) are shown in the blue areas. The white areas contain those omitted in the *Summary Table* but reported in the *Listings*. States with the same J^{PC} mix, such as the 2^3S_1 and 1^3D_1 mesons. The states become broad and overlap with increasing masses, which complicates the determination of the masses, widths and spins. For a complete list of mesons see the *Listings*.

[1] The $\eta(1440)$ stands for the $\eta(1405)$ and the $\eta(1475)$ which may be manifestations of the same state, see section 63.4.

[2] The classification of the scalar nonet is controversial. In alternative schemes the 1^3P_0 nonet contains the light scalars below 1 GeV, section 63.2.

[3] Considered established, but more data would be desirable.

[4] An alternative to the $f_1(1420)$ is the $f_1(1510)$, section 63.6.

[5] The $\pi(1800)$ has also been proposed as a hybrid meson, section 63.7.

[6] The $\phi(2170)$ has also been proposed as a tetraquark state, section 63.8.

[7] The $f_2(1950)$ has also been proposed as a tensor glueball, section 63.3.2.

[8] Tentative assignment following Ref. [12].

As described in more detail below (section 63.2), it is hard to accommodate all the known scalar mesons in the lower $q\bar{q}$ nonets: The light scalar mesons $a_0(980)$, $K_0^*(700)$ (also known as κ), the $f_0(500)$ (also known as σ) and the $f_0(980)$, not shown in the figure, could build the lightest nonet, but could also be two-meson resonances or tetraquarks (section 63.8). Three isoscalars are known in the 1500 MeV region, the $f_0(1500)$ or $f_0(1710)$ being proposed as states with a large gluon content, mixing with the $f_0(1370)$ (section 63.3.1). The pseudoscalar labeled $\eta(1440)$ may consist of two states (section 63.4). The status of vector meson excitations is described in section 63.5. The axial-vector meson $f_1(1420)$ could be replaced in the 1^{++} nonet by the $f_1(1510)$ which, however, needs confirmation (see the *Listings* and section 63.6). Mesons with exotic quantum numbers are discussed in section 63.7.

63.2 Scalar mesons

Scalar mesons decay dominantly into pairs of pseudoscalar mesons ($\pi\pi$, $K\overline{K}$, $\pi\eta$, $\eta\eta$ or $\eta\eta'$). The widths tend to be large for those decaying into $\pi\pi$, due to the absence of angular momentum barrier and the large available phase space. Broad overlapping states decaying into the same final state interfere, which complicates the determination of their masses and widths. Furthermore, the ground state glueball, a 0^{++} expected below 2 GeV, will mix with the isoscalar 0^{++} $q\bar{q}$ states. The onset of the $K\overline{K}$, $\eta\eta$ or $\eta\eta'$ thresholds also distorts the line shapes and produces cusps. This requires high statistics data from various production and decay channels, and the use of coupled channel analyses taking into account unitarity and analyticity (see 'Resonances' in the *Review*).

There is long-time evidence for the existence of two scalar nonets, one below 1 GeV, one around 1.4 GeV and one glueball below 1.7 GeV [13]. The lighter nonet consists of the $a_0(980)$, $f_0(980)$, $f_0(500)$ and $K_0^*(700)$, and the heavier one contains the mesons shown in Fig. 63.1. Two isovector scalars are established, the $a_0(980)$ and the $a_0(1450)$, together with five isoscalars: the very broad $f_0(500)$, the $f_0(980)$, the broad $f_0(1370)$, and the comparatively narrow $f_0(1500)$ and $f_0(1710)$. The strange partners are the $K_0^*(700)$ and the $K_0^*(1430)$. The $f_0(500)$ and $K_0^*(700)$ deserve a separate treatment and are discussed in 'Scalar Mesons below 1 GeV', which also contains more details on the $a_0(980)$ and $f_0(980)$ briefly reviewed in section 63.8, see also Ref. [1].

The $a_0(1450)$ was first reported by the Crystal Barrel experiment (see [14] for a review) in $\bar{p}p$ annihilation with stopped antiprotons [15, 16]. An isovector scalar, possibly the $a_0(1450)$ (albeit at a lower mass of 1317 MeV), is observed by Belle in $\gamma\gamma$ collisions leading to $\eta\pi^0$ [17]. A contribution from $a_0(1450) \to K\bar{K}$ is also found in the CLEO-c analysis of $D^{\pm} \to K^+K^-\pi^{\pm}$ [18] and $D^0 \to K_S^0K^{\pm}\pi^{\mp}$ from LHCb [19]. The $a_0(1450)$ is reported at a lower mass in $\bar{p}p$ annihilation in flight, overlapping with the $a_2(1320)$ [20, 21].

The $f_0(1370)$ and $f_0(1500)$ were observed by Crystal Barrel [22–24] and by WA102 in central production with 450 GeV protons [25,26]. They decay mostly into 2π and 4π. The $f_0(1500)$ was also observed to decay into $\eta\eta$ [27–29] and $\eta\eta'$ [30]. All data agree that the 4π decay mode represents about half of the $f_0(1500)$ decay width, but is dominant for the $f_0(1370)$.

The determination of the $\pi\pi$ coupling of the very broad $f_0(1370)$ is complicated by its interference with the $f_0(500)$. The existence of the $f_0(1370)$ was questioned by COMPASS from $\pi^-p \to \pi^-\pi^-\pi^+p$ data [31] and by LHCb in $\overline{B}_s^0 \to J/\psi(1S)\pi^+\pi^-$ [32]. In $\overline{B}^0 \to J/\psi(1S)\pi^+\pi^-$ the $\pi\pi$ mass spectrum does not show any significant scalar component above ∼1.2 GeV [33] (an analysis that is challenged in [34]). The existence of the $f_0(1370)$ has also been disputed by a reassessment of various production modes [35] (with the $K_0^*(700)$ not needed in $K\pi$ scattering). This contrasts with its $\pi\pi$ decay analyzed in Ref. [36]. However, data from CLEO-c in $D^0 \to \pi^+\pi^-\pi^+\pi^-$ require a contribution from $f_0(500)f_0(1370) \to 4\pi$ [37]. A broad 2π signal is also observed by BaBar around 1400 MeV in the decay $B^{\pm} \to \pi^{\pm}\pi^{\pm}\pi^{\mp}$ [38] which is attributed to the $f_0(1370)$ (but could also be due to the $f_0(1500)$). The existence of the $f_0(1370)$ is confirmed by a recent dispersive analysis of $\pi\pi$ scattering data, which leads to a complex pole around 1245 MeV with a very large width of about 600 MeV [39].

While the $K\bar{K}$ decay branching ratio of the $f_0(1500)$ is small [25, 40], the $f_0(1710)$ decays dominantly into $K\overline{K}$. The $f_0(1710)$ is not observed in $p\bar{p}$ annihilation at rest [40] and only weakly produced in $p\bar{p}$ annihilation in flight [41], with a rate strongly suppressed compared to that of the $f_0(1500)$ (∼7%). (For comparison, the rate for the $(s\bar{s})$ $f_2'(1525)$ production is about 9% that of the $(u\bar{u}+d\bar{d})$ $f_2(1270)$, as expected from the OZI rule [41].) On the other hand the $f_0(1370)$ does not couple strongly to $K\bar{K}$ [25]. This suggests an $n\bar{n}$ structure $(u\bar{u}+d\bar{d})$ for the $f_0(1370)$ and $s\bar{s}$ for the $f_0(1710)$. The $f_0(1500)$ would also qualify as an $n\bar{n}$ state, although it is very narrow compared to the other states. Occam's razor principle therefore suggests that the $f_0(1370)$, $a_0(1450)$, and the $f_0(1710)$ form the 1^3P_0 $q\bar{q}$ flavor nonet, the $f_0(1370)$ and $a_0(1450)$ being the two (mostly) $n\bar{n}$ states, and the $f_0(1710)$ the (dominantly) $s\bar{s}$ one. The nature of the $f_0(1500)$ is discussed along this scheme in section 63.3.1.

Other schemes have been proposed, for example a tetraquark for the $f_0(1500)$ [42] or flavor octets for the $f_0(1500)$ and $f_0(1710)$ [3]. In Refs. [43, 44] the $f_0(1370)$ and $f_0(1710)$ are interpreted as bound systems of two vector mesons, a view is challenged in Ref. [45]. In Ref. [46] the $a_0(1450)$, $f_0(1370)$, $f_0(1500)$ and $K_0^*(1430)$ are radial excitations of the scalar nonet below 1 GeV. In Ref. [47] the light tetraquark scalar nonet mixes with the $q\bar{q}$ 1^3P_0 nonet, while in Ref. [48] both nonets are made of mixing tetraquarks. In the unitarized quark model with coupled $q\bar{q}$ and meson-meson channels, the scalars below 1 GeV are manifestations of bare $q\bar{q}$ confinement states, mass shifted from the 1.4 GeV region and distorted by the strong $^3P_0$ coupling to S-wave two-meson decay channels [49, 50]. Thus, in these models the light scalar nonet comprising the light and 1^3P_0 scalar nonets are manifestations of the same bare input states (see also [51]). Surprisingly for a state decaying strongly into 2π and 4π, the $f_0(1370)$ is assumed to be an $s\bar{s}$ state in Ref. [52]. The $f_0(1500)$ is then a radial excitation.

There is evidence for two further 0^{++} mesons in the 1700 – 1800 MeV range, the isovector $a_0(1710)$ and the $f_0(1770)$, possibly the isoscalar partner of the $f_0(1710)$. The $f_0(1770)$, claimed by BESII/III [53–55], and also observed in $\pi^-p \to n\omega\phi$ by VES [56], could be a radial excitation [57]. Two isoscalars at 1700 and 1765 MeV are also reported by a re-analysis of BESIII radiative $J/\psi(1S)$ decay data [58, 59].

The evidence for the $a_0(1710)$ was inferred from the interference of the K^+K^- and $K_S^0K_S^0$ decays of the $f_0(1710)$ in $D_s^+ \to f_0(1710)\pi^+$, leading to a relative branching ratio an order of magnitude larger than expected from isospin symmetry [60,61]. The $a_0(1710)$ is now confirmed by LHCb in B^+ decays to $K_SK^+K^{\pm}\pi^{\mp}$ from an analysis of the $\eta(1S, 2S) \to (K_SK^{\pm}\pi)^{\mp}$ Dalitz plots [62]. A signal for $a_0(1710)^{\pm} \to K_S^0K^{\pm}$ is also reported by BESIII [63], albeit at 1817 MeV, in contrast to the state observed by BaBar in $\eta\pi^{\pm}$ at 1704 MeV [64].

From a study of the vector-vector interaction the authors of Ref. [65], predict an isovector pole at 1780 MeV, while the $f_0(1710)$ is a $K^*\bar{K}^*$ molecule, a view also supported by Refs. [66–69]. Thus the $f_0(1710)$ and $a_0(1710)$ might be $K^*\bar{K}^*$ molecules, similar to the $f_0(980)$ and $a_0(980)$ which have been interpreted as $K\bar{K}$ molecules [70].

Scalar resonances near the D_0 mass such as the $f_0(1710)$ and the $f_0(1770)$ are also suggested to produce CP violation enhancements in the charm system [71].

63.3 Glueballs

Lattice calculations predict that the lightest glueball is a 0^{++} state with a mass in the 1600-1800 MeV range. The first and second excited states have 2^{++} and 0^{-+} with masses around 2300 and 2500 MeV, respectively, with large uncertainties. For more information and references on lattice calculations see 'Quark Model' in the *Review*, in particular fig. 15.3 for a mass spectrum. Predictions were made in the quenched approximation, neglecting $q\bar{q}$ loops. However quenched predictions and full QCD calculations lead to small mass shifts (see fig. 15.15 in the *Review*). The most recent prediction [72] quotes the more precise masses 1653 ± 26, 2376 ± 32 and 2561 ± 40 MeV for the 0^{++}, 2^{++} and 0^{-+} respectively. For an experimental review see Ref. [8].

The lightest glueballs lie in the same mass region as ordinary radial and orbital $q\bar{q}$ excitations, in the mass range of the 0^{++}, 2^{++} and 0^{-+} multiplets. Therefore, mixing of glueballs with nearby $q\bar{q}$ states of the same quantum numbers leads to supernumerary isoscalar state in the $q\bar{q}$ nonets.

Among the signatures naively expected for glueballs are (i) isoscalar states that do not fit in $q\bar{q}$ nonets, (ii) enhanced production in gluon-rich channels such as central production and radiative $J/\psi(1S)$ decay, (iii) decay branching fractions incompatible with SU(3) predictions for $q\bar{q}$ states, and (iv) small $\gamma\gamma$ couplings [73] (see however [74, 75]). Mixing effects with isoscalar $q\bar{q}$ mesons [35, 74, 76–83] and decay form factors [84] can obscure these simple signatures.

According to SU(3) the decay branching ratios for $q\bar{q}$ mesons and pure glueballs are different, and therefore useful to determine the internal structures of mesons. For pure glueballs with flavor

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

symmetric couplings the decay ratios are $\pi\pi : K\bar{K} : \eta\eta : \eta\eta' = 3 : 4 : 1 : 0$, apart from phase space factors. The partial widths for the decay of a scalar (or a tensor) meson into a pair of pseudoscalar mesons are given in fig. 63.2 (for a derivation see e.g. [9]). The decay of a $q\bar{q}$ meson into a pair of mesons involves the creation of a $q\bar{q}$ pair, and SU(3) symmetry assumes that the matrix elements for the creation of $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ pairs are equal. (The generalization to unequal $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ couplings is given in Ref. [76].) An excellent fit to the tensor meson decay widths is obtained with $\beta \simeq 0.5$ GeV/c, $\theta_V \simeq 26\,^\circ$ and $\theta_P \simeq -17\,^\circ$ [76].

Note that the assumption of flavor symmetric couplings may not apply in models describing the scalar glueball by a dilaton field, which lead to mass dependent couplings [85, 86] (Ref. [87] predicts that a scalar glueball above 1 GeV would be unobservably wide).

Another way to determine the flavor contents of neutral mesons is the decay $B^0 \to J/\psi(1S)X$ which filters out the $d\bar{d}$ content of X, while $B_s^0 \to J/\psi(1S)X$ selects its $s\bar{s}$ component [88]. More precise data on $B^0_{(s)} \to J/\psi(1S)[f_0(1370), f_0(1500), f_0(1710)]$ would help to pin down the nature of these scalar mesons [89].

63.3.1 *Scalar glueballs*

One of the three isoscalars, the $f_0(1370)$, $f_0(1500)$ or $f_0(1710)$, appears to be supernumerary. The branching ratios in fig. 63.2 can be used to deduce their structures, assuming that they are $q\bar{q}$. The comparison of decay branching ratios from Crystal Barrel annihilation and WA102 central collision data shows that the $f_0(1500)$ is compatible with an $n\bar{n}$ structure, while the $f_0(1710)$ is mostly $s\bar{s}$ [90]. However, the close vicinity of the very broad $n\bar{n}$ $f_0(1370)$, its narrow width and enhanced production at low transverse momentum transfer in central collisions [91–93] favor the $f_0(1500)$ to be the supernumerary non-$q\bar{q}$ state. According to [76, 82] the $f_0(1370)$ and $f_0(1710)$ would be dominantly $\bar{q}q$ states mixing with glue, while the $f_0(1500)$ would be dominantly a glueball mixing with $q\bar{q}$ states. Its suppressed $K\bar{K}$ decay would be due to interferences with the $f_0(1370)$ and $f_0(1710)$. In the analogous mixing scheme of Ref. [57], which uses central production data from WA102 and the hadronic $J/\psi(1S)$ decay data from BES [94, 95], glue is shared between the $f_0(1370)$ (mainly $n\bar{n}$), $f_0(1500)$(mainly glue) and $f_0(1710)$ (dominantly $s\bar{s}$). This agrees with the analyses [76, 82]. In the mixing scheme of Ref. [96] the QCD spectral sum rule also leads to a large gluonic component in the $f_0(1500)$ (satisfying the observed strong $\pi\pi$ and $f_0(500)f_0(500) \to 4\pi$ decays).

However, not everybody agrees that the strong $K\bar{K}$ signal is indicative of an $s\bar{s}$ structure for the $f_0(1710)$. The $f_0(1710)$ could still be the glueball, since the two-gluon coupling to $n\bar{n}$ appears to be suppressed by chiral symmetry [97], thus $K\bar{K}$ would be enhanced compared to $\pi\pi$. It was argued that chiral symmetry constraints in a multichannel analysis imply that the $f_0(1710)$ is an unmixed scalar glueball [98]. However, this view is challenged in [65].

The $K\bar{K}$ decay is also naturally enhanced in the extended linear sigma model with a dilaton as glueball [85] and in the holographic model of [86, 99] which both prefer the $f_0(1710)$ as the glueball. For a scalar glueball Ref. [86] finds a strong enhancement of the decays into $K\bar{K}$ and $\eta\eta$, in fairly close agreement with the measured branching ratios of the $f_0(1710)$, while Ref. [99] predicts the (so far not measured) rate into $\eta\eta'$ to be very small.

In $\gamma\gamma$ collisions leading to K_SK_S [100] and K^+K^- [101] a spin-0 signal is observed at the $f_0(1710)$ mass (together with a dominant spin-2 component), while the $f_0(1500)$ is not observed in $\gamma\gamma \to K\bar{K}$ nor $\pi^+\pi^-$ [102]. The $f_0(1500)$ is also not observed by Belle in $\gamma\gamma \to \pi^0\pi^0$, although a shoulder is seen which could also be due to the $f_0(1370)$ [103]. The absence of $f_0(1500)$ signal in the $\pi\pi$ channel in $\gamma\gamma$ collisions does not favor an $\overline{n}n$ interpretation for the $f_0(1500)$. The upper limit for $\Gamma_{2\gamma}$ (< 1.4 keV) in $\pi^+\pi^-$ [90]) excludes a large $n\overline{n}$ content, and hence points to a mainly $s\overline{s}$ content [90], which contradicts the small $K\overline{K}$ decay branching ratio of the $f_0(1500)$ [16, 25, 40]. Belle finds that in $\gamma\gamma \to K_SK_S$ collisions the 1500 MeV region is dominated by the $f_2'(1525)$. The $f_0(1710)$ is also observed with a production rate × branching ratio compatible with an $s\bar{s}$ state [104]. Ref. [74] predicts the glueball $\gamma\gamma$ partial width in the few keV range (comparable to that of $q\bar{q}$ mesons) due to couplings of vector mesons to γ via VDM, in agreement with holographic models [75], but this is disputed in Ref. [73] which predicts $\Gamma_{\gamma\gamma} \sim 1$ eV from lattice calculations of radiative glueball decay. Note, however, that the $\gamma\gamma$ couplings of glueballs are sensitive to glue mixing with $q\bar{q}$ [57].

Alternative assignments for the scalar glueball have been proposed:

- In Ref. [78] the gluonic signal is distributed over $f_0(1370)$, $f_0(1500)$ and another broad isoscalar around 1530 MeV, while the gluonic contribution to the $f_0(1710)$ is small.
- In Ref. [81, 85, 86] the $f_0(1710)$ is the glueball state, as in Ref. [83], where the $f_0(1500)$ is the $q\bar{q}$ octet state degenerate with the $a_0(1450)$.
- In the generalized linear sigma model [105] the $a_0(980)$ is dominantly a tetraquark and $a_0(1450)$ a $q\bar{q}$ state. The $f_0(980)$, $f_0(1370)$ and $f_0(1500)$ (or $f_0(1710)$) are dominantly tetraquark, $q\bar{q}$ and glue.
- In Ref. [80] the $f_0(500)$ and $f_0(1370)$ are signals from a single broad resonance proposed as the scalar glueball. The ground state scalar nonet then consists of the $f_0(980)$, $a_0(980)$, $K_0^*(1430)$ and $f_0(1500)$ [35]. The $f_0(980)$ and $f_0(1500)$ mix (similarly to the η and η' in the pseudoscalar nonet), while the $f_0(1500)$ mixes with a glueball in the 500 – 1000 MeV mass range, which is identified as the $f_0(500)$.
- In Ref. [106], a large K^+K^- scalar signal is reported by Belle in B decays into $KK\bar{K}$ [107], compatible with the $f_0(1500)$. It is due to constructive interference of a flavor octet with a broad glueball background. However, the Belle data are inconsistent with the BaBar measurements which show instead a broad scalar at this mass for B decays into both $K^\pm K^\pm K^\mp$ [108] and $K^+K^-\pi^0$ [109].

The $f_0(1500)$ is observed by BESII in $J/\psi(1S) \to \gamma\pi\pi$ [110] and by BESIII in $J/\psi(1S) \to \gamma\eta\eta$ [111] with a much smaller rate than for the $f_0(1710)$, which would speak against a glueball interpretation of the former, although the systematic uncertainties are large, and the $f_0(1500)$ appears at a lower mass and the $f_0(1710)$ at a higher mass than the accepted values.

The authors of Ref. [58] have analyzed the high statistics data from $J/\psi(1S)$ radiative decays into S-wave $\pi^0\pi^0$, $K_S^0K_S^0$, $\eta\eta$ and $\omega\phi$ from BESIII, including data on $\pi\pi$, $\eta\eta$ and $\eta\eta'$ from the CERN SPS, BNL data on $\pi\pi \to K_S^0K_S^0$ and $\bar{p}p$ annihilation data from LEAR into various final states. The coupled channel analysis requires ten scalar mesons, the established ones in the *Review* and the $f_0(2020)$, as well as the isoscalars $f_0(2100, 2200, 2330)$ so far omitted from the *Summary Table*. Comparable contributions from $f_0(1500)$ and $f_0(1710)$ are found, with a preference for $\pi\pi$ decay over $K\bar{K}$ for the former and $K\bar{K}$ over $\pi\pi$ for the latter. As a new feature, the $f_0(1710)$ splits into two states, one at about 1700 MeV, the former $f_0(1710)$, and the new $f_0(1770)$ discussed above, being mandatory to obtain a good fit. A broad (∼370 MeV) enhancement is observed in $J/\psi(1S)$ radiative decays around 1865 MeV, attributed to the contribution of glue distributed among the scalar mesons, with a very strong contribution from the 1770 MeV state [59]. In this model there are no supplementary states as the glue 'fragments' between the various isoscalars.

Ref. [112] presents a re-analysis of the BESIII $J/\psi(1S)$ radiative decay data into S- and P-wave $\pi^0\pi^0$ and $K_S^0K_S^0$ between 1.0 and 2.5 GeV. A good fit is obtained with only two scalar resonances below 2 GeV, the $f_0(1500)$ and $f_0(1710)$. The latter is more strongly produced, which points to a sizeable glueball component.

63.3.2 *Tensor glueballs*

Above the well known $f_2(1270)$ and $f_2'(1525)$ $q\bar{q}$ mesons, the $f_2(1640)$ and $f_2(1950)$ are tentatively assigned to the 2^3P_2 nonet (fig. 63.1). The broad $f_2(1950)$ has been observed by several experiments, *e.g.* in central production [26] and in $\overline{p}p$ annihilation in flight [21] and is often identified as a glueball [113], the ground state of the pomeron [114, 115].

Four further isoscalar tensors, the $f_2(2010)$, $f_2(2150)$, $f_2(2300)$ and $f_2(2340)$, which are in the range of the 1^3F_2 and 3^3P_2

Isospin	Decay channel	γ^2
0	$\pi\pi$	$3\cos^2\alpha$
	$K\overline{K}$	$(\cos\alpha - \sqrt{2}\sin\alpha)^2$
	$\eta\eta$	$(\cos\alpha\cos^2\phi - \sqrt{2}\sin\alpha\sin^2\phi)^2$
	$\eta\eta'$	$\frac{1}{2}\sin^2 2\phi\ (\cos\alpha + \sqrt{2}\sin\alpha)^2$
1	$\eta\pi$	$2\ \cos^2\phi$
	$\eta'\pi$	$2\ \sin^2\phi$
	$K\overline{K}$	1
$\frac{1}{2}$	$K\pi$	$\frac{3}{2}$
	$K\eta$	$(\sin\phi - \frac{\cos\phi}{\sqrt{2}})^2$
	$K\eta'$	$(\cos\phi + \frac{\sin\phi}{\sqrt{2}})^2$

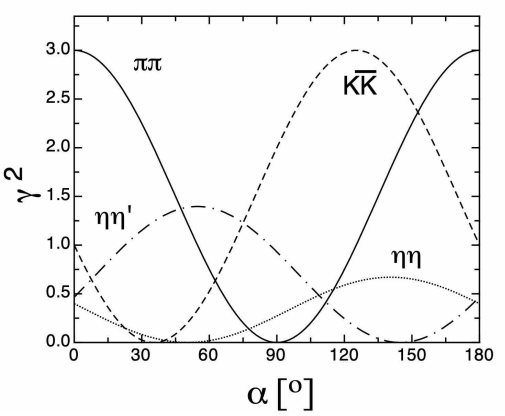

Figure 63.2: Left: SU(3) couplings γ^2 for scalar (or tensor) $q\bar{q}$ meson decays. The angles α and ϕ are defined as $\alpha = 54.7^\circ + \theta$ and $\phi = 54.7^\circ + \theta_P$, where θ is the mixing angle of the 0^{++} (2^{++}) isoscalars and θ_P the mixing angle in the 0^{-+} nonet. The partial decay width is given by $\Gamma = C \times \gamma^2 \times |F(q)|^2 \times q$, where C is a nonet constant, q the momentum of the decay products and $F(q)$ a form factor which may be taken as $|F(q)|^2 = q^{2\ell} \times \exp(-q^2/8\beta^2)$ with β= 0.5 GeV/c, and where ℓ is the relative angular momentum between the decay products ($\ell = 0$ for scalars and $\ell = 2$ for tensors). Right: SU(3) couplings γ^2 as a function of mixing angle α for isoscalar decays for $\theta_P = -17.3^\circ$ (from [76]).

nonets, exhibit a very large OZI breaking $\phi\phi$ production cross section in $\pi^- N \to \phi\phi n$ [116], in accord with earlier observations [117,118], which could be due to the production of the 2^{++} glueball. The enhanced $\phi\phi$ production is also observed in central collisions [119] and in $\overline{p}p \to \phi\phi$ just above threshold [120]. The $f_2(2010)$, $f_2(2300)$ and $f_2(2340)$ have been reported by BESIII in $J/\psi(1S) \to \gamma\phi\phi$ [121]. The production rate of a tensor glueball in $J/\psi(1S)$ radiative decay has been calculated in quenched lattice QCD to be large (around 1%) [122] and is claimed by BESIII to be compatible with their measured rates in $J/\psi(1S) \to \gamma f_2(2340)$, $f_2(2340) \to \eta\eta$ [111], and $f_2(2340) \to \phi\phi$ [121].

The authors of Ref. [123] have re-analyzed the $J/\psi(1S)$ radiative decay into $\pi^0\pi^0$ and $K_S K_S$ from BESIII and found as glueball candidate an enhancement described by a 360 MeV broad pole around 2210 MeV, possibly composed of the resonances observed earlier in $\phi\phi$. The relatively narrow $f_2(2300) \to \phi\phi$ (width of 150 MeV) is preferred by the holographic QCD model of Ref. [124]. However, the tensor glueball is predicted to be much broader (600-900 MeV) by the holographic model of Ref. [125].

There is no evidence for a narrow meson, $f_J(2220)$ (a tensor candidate) in $\overline{p}p$ annihilation (see the note under the $f_J(2220)$ in the 2004 issue of the *Review*). The measured partial width to $\overline{p}p$ in radiative $J/\psi(1S)$ decay [126] is too large and inconsistent with the upper limit from $\overline{p}p$ annihilation into $\pi\pi$ [127].

63.4 Pseudoscalar mesons

We now deal with the first radial excitations of the 0^{-+} nonet (fig. 63.1). The $\pi(1300)$ is a very broad resonance (200–600 MeV) decaying into 3π. The $K(1460)$ was confirmed with high statistics data from LHCb in $D^0 \to K3\pi$ decays [128] and has become an established kaon excitation.

The $\eta(1295)$ has been observed in various production mechanisms, in $\pi^- p$ experiments [129–132], and possibly in $\overline{p}p$ annihilation [133,134]. In $J/\psi(1S)$ radiative decay, a 0^{-+} signal is evident in the $\eta\pi\pi$ wave of the DM2 data, together with a 1^{++} of similar magnitude [135]. Also BaBar reports a signal around 1295 MeV in B decays into $\eta\pi\pi K$ [136]. The existence of the $\eta(1295)$ has been questioned [3, 137], being very close to the $f_1(1285)$. However, experimental evidences for a pseudoscalar in this mass region is reported by production mechanisms in which 1^{++} is suppressed, such as $\gamma\gamma$ production or $\overline{p}p$ annihilation at rest in liquid hydrogen. We therefore assume that the $\eta(1295)$ is one of the isoscalars in this nonet.

Two isoscalars were later observed in this mass region, the $\eta(1405)$ and $\eta(1475)$. The former decays mainly into $a_0(980)\pi$ (or direct $K\overline{K}\pi$) and the latter mainly into $K^*(892)\overline{K}$. The simultaneous observation of two pseudoscalars is reported in three production mechanisms: $\pi^- p$ [129, 138], radiative $J/\psi(1S)$ decay [135, 139], and $\overline{p}p$ annihilation at rest [140–143]. All of them give values for the masses, widths, and decay modes that are in reasonable agreement (except for Ref. [135] which favors a state decaying into $K^*(892)\overline{K}$ at a lower mass than the state decaying into $a_0(980)\pi$). In $J/\psi(1S)$ radiative decay, the $\eta(1405)$ decays into $K\overline{K}\pi$ through $a_0(980)\pi$, and hence a signal is also expected in the $\eta\pi\pi$ mass spectrum. This was indeed observed by MARK III in $\eta\pi^+\pi^-$ [144], which reported a mass of 1400 MeV, in line with the existence of the $\eta(1405)$ decaying into $a_0(980)\pi$. The $\eta(1405)$ decaying into $\eta\pi\pi$ was also observed by Crystal Barrel [134]. Two states were reported by BES: Around 1452 MeV BESII observed a $K\bar{K}\pi$ enhancement in $J/\psi(1S) \to \omega K\bar{K}\pi$ but not in $J/\psi(1S) \to \phi K\bar{K}\pi$ [145], while BESIII reported a 52 MeV broad state in $\psi(2S) \to \omega K^* K$ [146], both left without J^{PC} determination.

The $K\overline{K}\pi$ and $\eta\pi\pi$ channels were studied in $\gamma\gamma$ collisions by L3 [147]. (For the 2γ couplings of glueballs and $q\bar{q}$ mesons see [74, 75, 148, 149].) The analysis led to a clear $\eta(1475)$ signal in $K\overline{K}\pi$, decaying into $K^*\overline{K}$, well identified in the untagged data sample, where spin 1 resonances are not allowed. At the same time, L3 did not observe the $\eta(1405)$, neither in $K\overline{K}\pi$ nor in $\eta\pi\pi$ [147]. On the other hand, CLEO-II did not observe any pseudoscalar signal with tagged γ's in $\gamma\gamma \to \eta(1475) \to K^0_S K^\pm\pi^\mp$ [150], with an upper limit slightly smaller than the signal observed by L3. After the CLEO-II result, L3 performed a further analysis with full statistics [151], confirming their previous evidence for the $\eta(1475)$. The CLEO upper limit for $\Gamma_{\gamma\gamma}$ [150], and the L3 results [151], are consistent with the world average for the $\eta(1475)$ width. BaBar [136] also reported the $\eta(1475)$ in B decays into $K\bar{K}^*$ recoiling against a K, while upper limits only were given for the $\eta(1405)$.

Hence, in radiative $J/\psi(1S)$ decay, $\pi^- p$ and $\overline{p}p$ annihilation at rest two isoscalar signals are observed in the 1400 – 1500 MeV mass region, while the $\eta(1405)$ is not seen in $\gamma\gamma$ interactions nor in B decays. The $\eta(1475)$ could be the first radial excitation of the η', with the $\eta(1295)$ being the first radial excitation of the η. Ideal mixing, suggested by the $\eta(1295)$ and $\pi(1300)$ mass degeneracy, would then imply that the second isoscalar in the nonet is mainly $s\bar{s}$, and hence couples to $K^*\overline{K}$, in agreement with properties of the $\eta(1475)$. In addition, its width agrees with the expected one for the radially excited $s\bar{s}$ state [84, 91]. A study of radial excitations of pseudoscalar mesons [152] also favors the $s\bar{s}$ interpretation of the $\eta(1475)$. However, due to the strong kinematical suppression in $\eta(1405) \to K^*\overline{K}$ the data are not sufficient to exclude a sizeable $s\bar{s}$ admixture also in the $\eta(1405)$.

Here also, there are alternative explanations for the existence of two states:

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.
Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com

– The isoscalar $\eta(1405)$ would be a candidate for the 0^{-+} glueball (section 63.4.1).
– In Refs. [3,137], apart from questioning the mere existence of the $\eta(1295)$, the authors propose a single pseudoscalar meson at 1440 MeV, the first radial excitation of the η. According to Refs. [84,153] the splitting of the 1440 MeV state into $\eta(1405)$ and $\eta(1475)$ could be due to nodes in the decay amplitudes (which differ in $\eta\pi\pi$ and $K^*(892)\overline{K}$), nevertheless the following paper [154] underlines the relevance of $\gamma\gamma$ production and radiative decays to vector mesons to solve the $\eta(1440)$ riddle.
– The splitting could be due to a triangle singularity, hence the manifestation of one state only (fig. 63.3) [155–157]. The importance of the triangle singularity for the $\eta(1295)$ and $\eta(1405/1475)$ in the $\eta\pi\pi$ and $K\bar{K}\pi$ channels is stressed in Ref. [158]. In Ref. [159], using the triangle singularity approach of [155], the authors conclude that the BESIII results can be reproduced either with the $\eta(1405)$ or the $\eta(1475)$, or by a mixture of these two states.
– From a high statistics data sample in $J/\psi(1S) \to \gamma K_S K_S \pi^0$ BESIII reports the observation of both $\eta(1405)$ and $\eta(1475)$ using Breit-Wigner fits [160]. A one resonance parametrization is ruled out and triangle singularity models do not describe the data satisfactorily.
– The decay $J/\psi(1S) \to \gamma K_S K_S \pi^0$ has been studied in a three-body unitary coupled-channel analysis and compared to the BESIII data, including ratios of radiative branching ratios into $\eta\pi^+\pi^-$ and $K\bar{K}\pi$ through the $\eta(1405/1475)$ intermediate states [161]. Two poles emerge for $K^*\bar{K}$ in different Riemann sheets around 1400 MeV and only one pole around 1500 MeV.

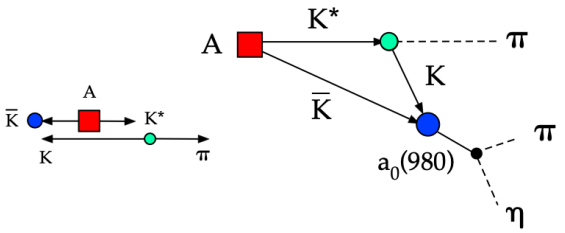

Figure 63.3: Triangle singularity: a state A decays into $K^*\overline{K}$. The K from K^* decay catches up with the $\overline{K}$ and excites the $a_0(980)$ resonance which in turn decays into $\eta\pi$. This mechanism can lead to two distinct peaks (depending on the width of A), one in $K^*\overline{K}$ and the other via rescattering in $\eta\pi\pi$. Similarly, the virtual $K^*\overline{K}$ loop can couple to $f_0(980)$ which, decaying into $\pi\pi$, leads to a peak in the 3π final state.

To summarise, the experimental data on the 1400 – 1500 MeV region span several decades, various production mechanisms and decay modes, with models for data analysis evolving with time. A coherent picture of all available data is therefore difficult. We believe that there is sufficient evidence to consider the 0^{-+} nonet with the $\eta(1440)$ in fig. 63.1 as established. Whether one or two different states – $\eta(1405)$ and $\eta(1475)$ – exist is an open question, in which case the $\eta(1405)$ would be supernumerary. The most recent high statistics data and their theoretical interpretation seem to favor the two-resonance scenario.

63.4.1 *Pseudoscalar glueballs*

The first observation of an isoscalar resonance around 1425 MeV – the E-meson – was made in $p\overline{p}$ annihilation at rest into $E\,\pi^+\pi^-$, $E \to K\overline{K}\pi$ [162]. This state was reported to decay into $a_0(980)\pi$ and $K^*(892)\overline{K}$ with roughly equal contributions. An isoscalar state, the ι meson, was observed in radiative $J/\psi(1S)$ decay into $K\overline{K}\pi$ [163–165] and $\gamma\rho$ [166], and was considered as a glueball candidate, owing to its strong signal in radiative $J/\psi(1S)$ decay. The E and ι were later assumed to be the same state, called $\eta(1440)$. For a historical survey see Ref. [167] and Ref. [168] for a review of the experimental status on the pseudoscalar glueball.

The $\eta(1405)$ would be a candidate for the 0^{-+} glueball in the fluxtube model [169], in which the 0^{++} glueball is also naturally related to a 0^{-+} glueball with mass degeneracy broken in QCD. The pseudoscalar glueball could lie at a lower mass than predicted from lattice calculation [170], see also Refs. [171–173]. The $\eta(1760)$, produced very strongly in radiative $J/\psi(1S)$ decay to $\omega\omega$ [174], has also been proposed for the 0^{-+} glueball mixed with the η and η' [175].

The holographic model of Ref. [75] predicts the pseudoscalar glueball below 2600 MeV, decaying dominantly into two vector mesons.

The $X(2370)$ has recently been studied by BESIII in radiative $J/\psi(1S)$ decay to $K_S K_S \eta'$ with $f_0(980) \to K_S K_S$ [176]. This channel is much less prone to γ background and more restrictive on the $X(2370)$ quantum numbers than $J/\psi(1S) \to \gamma K^+ K^- \eta'$ and $\gamma\pi^+\pi^-\eta'$ reported earlier by BESIII. This state is determined to be 0^{-+} isoscalar (and therefore renamed $\eta(2370)$) with a (Breit-Wigner) mass of 2317±9 MeV and a width of 140^{+80}_{-28} MeV (averaged over all three decay channels). According to Ref. [177] the $\eta(2370)$ would be a candidate for the ground state pseudoscalar glueball, but in a region where many 0^{-+} $q\bar{q}$ broad and overlapping radial excitations are also expected. Progress above 2000 MeV requires larger data sets and coupled channel K-matrix analyses.

63.5 Vector mesons

In this section we restrict ourselves to the isovector spectrum which contains broad and overlapping states.

63.5.1 $\rho(770)$

The determination of the parameters of the $\rho(770)$ is beset with many difficulties because of its large width. Its line shape depends on the production process and is not described by a relativistic Breit-Wigner function with a P-wave width, but requires some additional shape parameters [178]. Bose-Einstein correlations are another source of shifts in the $\rho(770)$ line shape, particularly in multiparticle final-state systems [179].

The same model dependence afflicts any other source of resonance parameters, such as the energy dependence of the phase shift δ_1^1, or the pole position. It is, therefore, not surprising that a study of $\rho(770)$ dominance in the decays of the η and η' reveals the need for specific dynamical effects, in addition to the $\rho(770)$ pole [180, 181].

The cleanest determination of the $\rho(770)$ mass and width comes from e^+e^- annihilation and τ-lepton decays. ALEPH data [182] showed that the charged $\rho(770)$ parameters measured from τ-lepton decays are consistent with those of the neutral one determined from e^+e^- data [183]. This conclusion is qualitatively supported by the later studies of CLEO [184] and Belle [185]. However, a comparison of the two-pion mass spectrum in τ decays from OPAL [186], CLEO [184], and ALEPH [187, 188], and the $e^+e^- \to \pi^+\pi^-$ cross section from CMD-2 [189, 190], showed significant discrepancies between the two shapes which can be as high as 10% above the ρ meson mass [191, 192]. This discrepancy remains after measurements of the two-pion cross section in e^+e^- annihilation at KLOE [193–196], SND [197, 198], BaBar [199] and BESIII [200]. The effect is not accounted for by isospin breaking [201–204], but the accuracy of its calculation may be overestimated [205, 206].

Two recent measurements of the $e^+e^- \to \pi^+\pi^-$ cross section by SND [207] and CMD-3 [208, 209] show discrepancies in the ρ region: while SND is consistent with previous e^+e^- experiments, CMD-3 finds differences as high as 5% around the ρ meson mass. In addition, in the fit of the $e^+e^- \to \pi^+\pi^-$ cross section CMD-3 reports values for the mass of the ω and the mass and width of the ϕ, which differ slightly from the PDG values, showing for the first time the effect of the $\phi \to \pi^+\pi^-$ interference.

The problem of the difference in the $\pi^+\pi^-$ shapes between e^+e^- and τ decays seems to be solved after the analysis of Ref. [210], which showed that, after correcting the τ data for the missing $\rho-\gamma$ mixing contribution, besides the other known isospin symmetry violating corrections, the $\pi\pi$ isospin 1 part of the hadronic vacuum polarization contribution to the muon $g-2$ is fully compatible between τ-based and e^+e^--based evaluations.

The global fit of the whole set of the ρ, ω, and ϕ decays, taking into account mixing effects in the hidden local symmetry model, also showed consistency of the two-pion data in τ decay and e^+e^- annihilation [211,212]. However, because of the progress in e^+e^- data, the τ input is now less precise and less reliable due to additional theoretical uncertainties [213] decreasing the importance of τ decay for the determination of the $\rho(770)$ parameters.

63.5.2 $\rho(770)$ *excitations*

In our 1988 edition, we replaced the $\rho(1600)$ entry with two new ones, the $\rho(1450)$ and the $\rho(1700)$, because there was emerging evidence that the 1600-MeV region actually contains two ρ-like resonances. This possibility was pointed out by a theoretical analysis [214] on the consistency of the 2π and 4π electromagnetic form factors and the $\pi\pi$ scattering length. A consistent picture of $e^+e^- \to 2\pi, 4\pi$ and diffractive photoproduction is obtained with two resonances [215]. The existence of the $\rho(1450)$ was supported by the analysis of $\eta\rho^0$ mass spectra obtained in photoproduction and e^+e^- annihilation [216], as well as that of $e^+e^- \to \omega\pi$ [217].

The analysis of [215] was further extended by [218, 219] to include new data on 4π-systems produced in e^+e^- annihilation, and in τ decays ($\tau \to 4\pi$ and $e^+e^- \to 4\pi$ are related by the Conserved Vector Current hypthesis). These systems were successfully analyzed using interfering contributions from two ρ-like states, and from the tail of the $\rho(770)$ two-body decay. While specific conclusions on $\rho(1450) \to 4\pi$ were obtained, little could be said about the $\rho(1700)$. Independent evidence for two 1^- states is provided by [220] in 4π electroproduction at $\langle Q^2\rangle = 1$ (GeV/c)^2, and by [221] in a high-statistics sample of the $\eta\pi\pi$ system in $\pi^- p$ charge exchange.

This scenario with two overlapping resonances is supported by other data. DM2 [222] measured the pion form factor in the interval 1.35–2.4 GeV, and observed a deep minimum around 1.6 GeV. The best fit was obtained with the hypothesis of ρ-like resonances at 1420 and 1770 MeV, with widths of about 250 MeV. DM2 [223] found that the $e^+e^- \to \eta\pi^+\pi^-$ cross section is better fitted with two fully interfering Breit-Wigners, with parameters in fair agreement with those of [215] and [222]. Recent LHCb data in $D^+ \to \pi^+\pi^+\pi^-$ also require both interfering $\rho(1450)$ and $\rho(1700)$ [224].

Decisive evidence for the $\pi\pi$ decay mode of both $\rho(1450)$ and $\rho(1700)$ comes from $\overline{p}p$ annihilation at rest [225]. It has been shown that these resonances possess a $K\overline{K}$ decay mode [16, 226, 227]. This decay mode has also been studied in three-body hadronic B decays [228]. High-statistics studies of the decays $\tau \to \pi\pi\nu_\tau$ [182, 184], and $\tau \to 4\pi\nu_\tau$ [229] also require the $\rho(1450)$, but are not sensitive to the $\rho(1700)$, being too close to the τ mass. A high-statistics study of the $\tau \to \pi\pi\nu_\tau$ from Belle [185] reports the first observation of both $\rho(1450)$ and $\rho(1700)$ in τ decays. A clear picture of the two $\pi^+\pi^-$ resonances interfering with the $\rho(770)$ in e^+e^- annihilation was also reported by BaBar using the ISR (Initial State Radiation) method [230], and more recently by CMD-3 [208].

The structure of these ρ states is not yet completely clear. From $e^+e^- \to \omega\pi^0$ data and using the $^3P_0$ model the authors of Ref. [231] find that $\rho(1450)$ and $\rho(1700)$ mix, the former being mainly $2S$ and the latter mainly $3D$. The authors of Refs. [84,232] also claim that $\rho(1450)$ has a mass consistent with radial $2S$, but its decays show characteristics of hybrids, and suggest that this state may be a $2S$-hybrid mixture. Hybrid states could have a 4π decay mode dominated by the $a_1\pi$ [233]. Such behavior has been observed by [234] in $e^+e^- \to 4\pi$ in the energy range 1.05–1.38 GeV, and by [229] in $\tau \to 4\pi\nu_\tau$ decays. CLEO [235] and Belle [236] observe the $\rho(1450) \to \omega\pi$ decay mode in B-meson decays, however, do not find $\rho(1700) \to \omega\pi^0$. The $e^+e^- \to \omega\pi^0$ Born cross section between 1 and 2 GeV from SND (including data from BaBar and BESIII) is described by the $\rho(770)$, $\rho(1570)$, $\rho(1700)$ and $\rho(2150)$ in a vector dominance fit [237], while earlier data [238, 239] did not observe a statistically significant signal of the $\rho(1700)$.

Various decay modes of the $\rho(1450)$ and $\rho(1700)$ are observed in $\overline{p}n$ and $\overline{p}p$ annihilation [240, 241], but no definite conclusions can be drawn. More data should be collected to clarify the nature of the ρ states, particularly in the energy range above 1.6 GeV.

Under the $\rho(1570)$ we list the $\phi\pi$ state with $J^{PC} = 1^{--}$ earlier observed in [242] – referred to as $C(1480)$ – also reported in [243] and possibly seen in [244] which cannot exclude that the observation of the $\rho(1570)$ is due to an OZI-suppressed decay mode of the $\rho(1700)$. The $C(1480)$ has not been seen in $\overline{p}p$ [245] nor in other e^+e^- [246, 247] experiments, which cannot exclude that the observation of the $\rho(1570)$ is due to an OZI-suppressed decay mode of the $\rho(1700)$.

Several observations on the $\omega\pi$ system in the 1200 MeV region [248–254] may be interpreted in terms of either $J^P = 1^-$ $\rho(770) \to \omega\pi$ production [255], or $J^P = 1^+$ $b_1(1235)$ production [253, 254]. Evidence for a $\rho(1250)$ from a reanalysis of elastic scattering data is claimed in Ref. [256] and was reported earlier by LASS [257].

Ref. [258] finds a very broad 1^{--} resonance-like K^+K^- state in $J/\psi \to K^+K^-\pi^0$ decays with pole mass 1576 MeV and width 818 MeV, with possibly molecular or multiquark structure [259–261], or due to the $\rho(1450)$ and $\rho(1700)$ interference [262–265]. We quote this state as $X(1575)$ in the section 'Further States'. Another state observed in $J/\psi \to K^+K^-\pi^0$ is the $\phi(2170)$ [266] which has been interpreted as exotic, e.g. as tetraquark, see section 63.8.

Evidence for ρ-like mesons decaying into 6π was first noted in [267] in the analysis of $e^+e^- \to 6\pi$ [268, 269] and diffractive photoproduction [270]. The authors of Ref. [267] argued that two states at about 2.1 and 1.8 GeV exist: while the former is a candidate for the $\rho(2150)$, the latter could be a manifestation of the $\rho(1700)$ distorted by threshold effects. BaBar reported observations of the new decay modes of the $\rho(2150)$ in the channels $\eta'(958)\pi^+\pi^-$, $f_1(1285)\pi^+\pi^-$ [271] and $\pi^+\pi^-$ [272]. The decay of the $\rho(2150)$ into K^+K^- has been observed by BESIII [273] and confirmed by BaBar [274]. The relativistic quark model [12] predicts the 2^3D_1 state with $J^{PC} = 1^{--}$ at 2.15 GeV which can be identified with the $\rho(2150)$.

Under $\rho(1900)$ we list various observations of irregular behavior of the cross sections near the $N\bar{N}$ threshold. Dips of various widths around 1.9 GeV were reported by the E687 Collaboration (a narrow one in the $3\pi^+3\pi^-$ diffractive photoproduction [275, 276]), by the FENICE experiment reporting a narrow dip [277], by BaBar in ISR (a narrow structure in $e^+e^- \to \phi\pi$ final state [244], but much broader in $e^+e^- \to 3\pi^+3\pi^-$ and $e^+e^- \to 2(\pi^+\pi^-\pi^0)$ [278]), by CMD-3 (also a rather broad dip in $e^+e^- \to 3\pi^+3\pi^-$ [279]). A dedicated scan of the $N\bar{N}$-threshold region by CMD-3 confirms this effect in the $e^+e^- \to 3\pi^+3\pi^-$ and $e^+e^- \to K^+K^-\pi^+\pi^-$ final states, but does not see it in the cross section of $e^+e^- \to 2\pi^+2\pi^-$ [280]. Most probably, these structures emerge as a threshold effect due to the opening of the $N\bar{N}$ channel [281–283]. A similar enhancement is observed by BESIII in $e^+e^- \to \Lambda\bar{\Lambda}$ near the $\Lambda\bar{\Lambda}$ threshold [284, 285] which can be described as $\Lambda\bar{\Lambda}$ final state interaction [286].

63.6 Axial-vector mesons

The 1^{++} nonet consists of the isovector $a_1(1260)$, the isoscalars $f_1(1285)$ and $f_1(1420)$, and the K_{1A}, which is a superposition of the physical states $K_1(1270)$ and $K_1(1400)$ with a mixing angle θ_{K_1} of about 35°, according to the phenomenological analysis of Ref. [287]. The nonet mixing angle $\theta_{1^{++}}$ is around 23°. The orthogonal combination – the K_{1B} – belongs to the 1^{+-} nonet with a mixing angle $\theta_{1^{+-}}$ of about 28° [287]. However, a two-pole structure for the $K_1(1270)$ emerges when using the unitary extension of chiral perturbation theory [288].

The mass region above 1400 MeV is rather complex [289–291]. The $f_1(1420)$ was first reported in $\pi^- p$ reactions at 4 GeV/c, decaying into $K^*\overline{K}$ [292]. The $K\overline{K}\pi$ decay was also observed in a reanalysis of the MARK III data [139], and a C=+1 state seen in tagged $\gamma\gamma$ collisions [293]. The $K^0_S K^0_S \pi^0$ decay mode of the $f_1(1420)$ establishes unambiguously C=+1. Axial-vector mesons are not observed in $\overline{p}p$ annihilation at rest in liquid hydrogen, which proceeds dominantly through S-wave annihilation. However, in gaseous hydrogen, P-wave annihilation is enhanced and the $f_1(1420)$ is observed, decaying into $K^*\overline{K}$ [141]. The $f_1(1420) \to K\overline{K}\pi$, is also seen in pp central production, together with the $f_1(1285)$. The latter decays via $a_0(980)\pi$, and the former only via $K^*\overline{K}$ which suggests an $s\bar{s}$ structure. Neither central

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

production [294] nor $\pi^- p$ interactions at 100 GeV [131] find any evidence for a $\eta\pi\pi$ decay mode of the $f_1(1420)$. However, the $f_1(1420)$ is not seen in the $K^- p$ data [295], which would argue against this state being the $s\bar{s}$ member of the 1^{++} nonet.

The $f_1(1285)$ has been suggested to be a $K^*\overline{K}$ molecule [296]. However, LHCb has determined the 1^{++} nonet mixing angle to be consistent with a mostly $n\bar{n}$ structure for the $f_1(1285)$ from $\overline{B}^0/\overline{B}^0 \to J/\psi(1S) f_1(1285)$, independent of the identity of its isoscalar partner [297]. The mixing angle $\theta_{1^{++}} = 24^\circ$ agrees with that of Ref. [287] quoted above. The $n\bar{n}$ structure is also suggested by ALICE [298] using a comparison of ϕ/π and $f_1(1285)/\pi$ yields in the canonical statistical hadronization model. The ratio of $\overline{B}^0/\overline{B}^0_s$ decay rates also excludes the tetraquark interpretation of the $f_1(1285)$ [297]. This is consistent with earlier determinations assuming that the $f_1(1420)$ is the other isoscalar in the nonet [299].

The $a_1(1420)$ decaying into 3π, reported earlier by COMPASS at 1420 MeV in $\pi^- p \to \pi^-\pi^-\pi^+ p$ [300,301], originates from a triangle singularity: the decay of the $a_1(1260)$ into $K^*(\to K\pi)\bar{K}$ is followed by rescattering into the $f_0(980)\pi$ channel, $f_0(980) \to \pi\pi$ [302] (see the caption of fig. 63.3). A similar triangle singularity is proposed for the $f_1(1420)$, resulting from the $K^*\overline{K}$ and $a_0(980)\pi$ decay modes of the $f_1(1285)$ [303,304].

The $f_1(1420)$ was also suggested to be a hybrid $q\bar{q}g$ meson [305] or a $K^*\overline{K}$ molecule, due to the proximity of the $K^*\overline{K}$ threshold [306]. Instead, the $s\bar{s}$ partner of the $f_1(1285)$ could be the $f_1(1510)$ [307] (omitted from the Summary Table). This state was seen to decay into $K\bar{K}\pi$ in $K^- p$ interactions at 4 and 11 GeV/c, recoiling against a Λ [295,308], which indeed points to an $s\bar{s}$ state. Evidence was reported in $\pi^- p$ interactions, based on the phase motion of the 1^{++} $K^*\overline{K}$ wave [291]. The $f_1(1510)$ is also needed by CMD-3 in $e^+e^- \to f_1(1285, 1420, 1510)\rho(770)$ to describe the shoulder in the $K_S K^\pm\pi^\mp$ mass around 1500 MeV [309]. A somewhat broader 1^{++} signal is observed in $J/\psi(1S) \to \gamma\eta\pi^+\pi^-$ [310] and a small signal in $J/\psi(1S) \to \gamma\eta'\pi^+\pi^-$ [311].

However, there is no evidence for the $f_1(1510)$ in other $K^- p$ experiments [312, 313]. The $f_1(1510)$ is not seen in central collisions [314], nor in $\gamma\gamma$ collisions [315], although surprisingly for an assumed $s\bar{s}$ meson, a signal is reported in 4π decays [316]. Data from LHCb in $B \to (K_S K\pi)K$ [317] require the $f_1(1420)$ and a much weaker $f_1(1510)$ signal. Given this confusing experimental situation, the isoscalar classification in the 1^{++} nonet is not yet settled.

63.7 Hybrid mesons

Hybrids may be viewed as $q\bar{q}$ mesons with a vibrating gluon flux tube. In contrast to glueballs, they have isospin 0 or 1 and can be electrically charged. The mass spectrum of hybrids with exotic (non-$q\bar{q}$) quantum numbers was predicted in Ref. [318], while Ref. [319] also deals with non-exotic quantum numbers. The ground-state hybrids with quantum numbers (0^{-+}, 1^{-+}, 1^{--}, and 2^{-+}) are expected around 1.7 to 1.9 GeV. Lattice calculations predict that the hybrid with exotic quantum numbers 1^{-+} lies at a mass of 1.9 ± 0.2 GeV [320,321]. Most hybrids are expected to be rather broad, but some can be as narrow as 100 MeV [322]. They prefer to decay into a pair of S- and P-wave mesons. The lattice study in [323, 324], based on full QCD with pion masses around 400 MeV, finds that several of the high-lying states observed in their spectrum show significant overlap with gluon rich source terms interpreted as hybrid states. A very broad 1^{-+} isovector structure is predicted by a recent lattice calculation [325]. The main decay mode is $b_1(1235)\pi$ (a pair of S- and P-wave mesons), while other modes, such as $\rho\pi$, $\eta\pi$ and $\eta'\pi$, are suppressed by at least an order of magnitude. For an experimental and theoretical review on hybrid mesons see Ref. [4, 326].

Two isovector 1^{-+} candidates have been reported, one around 1400 MeV (called earlier $\pi_1(1400)$) and the $\pi_1(1600)$. The ∼350–400 MeV broad $\pi_1(1400)$, was reported in $\pi^- p \to \eta\pi^- p$ [327,328] and in $\pi^- p \to \eta\pi^0 n$ [329]. It was observed as an interference between the angular momentum $L = 1$ and $L = 2$ $\eta\pi$ amplitudes, leading to a forward/backward asymmetry in the $\eta\pi$ angular distribution. This state had been reported earlier in $\pi^- p$ reactions [330], but ambiguous solutions in the partial wave analysis were pointed out [331,332]. A resonating 1^{-+} contribution to the $\eta\pi$ P-wave is also required in the Dalitz plot analysis of $\bar{p}n$ annihilation into $\pi^-\pi^0\eta$ [333], and in $\bar{p}p$ annihilation into $\pi^0\pi^0\eta$ [334]. Mass and width are consistent with the results of Ref. [327]. A coupled channel re-analysis of the $\pi^0\pi^0\eta$, $\pi^0\eta\eta$ and $K^+K^-\pi^0$ Crystal Barrel data at 900 MeV/c, supplemented with data from other collaboration in $\pi\pi \to \pi\pi, K\bar{K}, \eta\eta$ and $\eta\eta'$, leads to a single 1^{-+} ∼600 MeV broad state with a pole around 1400 MeV, decaying into $\eta\pi^0$ [20]. Ref. [335] suggested for the production in $\pi^- p$ that a Deck-generated $\eta\pi$ background from final state rescattering in $\pi_1(1600)$ decay could mimic $\pi_1(1400)$, a mechanism that is, however, absent in $\bar{p}p$ annihilation.

The $\pi_1(1600)$, decaying into $\rho\pi$, was reported by COMPASS with 190 GeV pions hitting a lead target [336,337]. It had already been observed in $\pi^- p$ interactions in the decay modes $\eta'\pi$ [338], $f_1(1285)\pi$ [339], and $\omega\pi\pi$ [340], $b_1(1235)\pi$, but not $\eta\pi$ [341]. A strong enhancement in the 1^{-+} $\eta'\pi$ wave, compared to $\eta\pi$, was reported at this mass in Ref. [342]. The enhancement is also observed by COMPASS in $\pi^- p \to \eta'\pi$ but in $\eta\pi$ a peak appears at 1400 MeV and in $\eta'\pi$ at 1600 MeV [343]. A coupled channel analysis of the $\eta\pi$ and $\eta'\pi$ COMPASS data leads to a single pole at 1564 ± 89 MeV, with a width of 492 ± 115 MeV [344]. The predicted width from the lattice calculation [325] is compatible with the COMPASS result. Furthermore, a combined analysis of the COMPASS and Crystal Barrel data at 900 MeV/c leads to similar results, a single pole around 1623 MeV, with a width of about 455 MeV, although a two-pole scenario cannot be completely excluded [345]. Accordingly, the $\pi_1(1400)$ data are listed in the $\pi_1(1600)$ section.

Very recently, BESIII reported a 188 MeV broad enhancement at 1855 MeV in $J/\psi(1S)$ radiative decay into the $\eta\eta'$ P-wave [346], hence with exotic quantum numbers 1^{-+}. This isoscalar resonance is needed with very high significance, albeit the contribution to $\gamma\eta\eta'$ is weak and several other isoscalars expected to contribute are absent [347]. Hence this state needs confirmation. We have listed claims for such a state decaying into $\eta\eta'$ in this mass range under the $f_2(1910)$ (see e.g. Ref. [30] from WA102 central production, suggesting 1^{-+} as an alternative to 2^{++}). If confirmed, the $\eta(1855)$ could be one of the isospin 0 partners of the $\pi_1(1600)$, a member of the 1^{-+} hybrid nonet [348–350] or a $K\bar{K}_1(1400)$ molecule [351]. In Ref. [348] this state is interpreted as the heavy isoscalar while its light partner is much narrower, with a mass of about 1660 MeV.

Hybrid candidates with the non-exotic quantum numbers 0^{-+}, 1^{--}, and 2^{-+} have also been reported: the $\pi(1800)$ is somewhat narrow if interpreted as the second radial excitation of the pion. It decays mostly into a pair of S- and P-wave mesons [352,353], in line with expectations for 0^{-+} hybrid mesons. The evidence for 1^{--} hybrids in e^+e^- annihilation and in τ decays has been discussed in [233]. The near degeneracy of the $\eta_2(1645)$ and $\pi_2(1670)$ suggests ideal mixing in the 2^{-+} $q\bar{q}$ nonet, and hence, the second isoscalar, presumably the $\eta_2(1870)$, should be mainly $s\bar{s}$ (fig. 63.1). However, the $\eta_2(1870)$ is also observed in $\bar{p}p$ annihilation and decays mainly into $a_2(1320)\pi$ and $f_2(1270)\pi$ [354], with a relative rate compatible with a hybrid state [319].

Evidence for another exotic $\pi_1(2015)$ has been claimed in $\pi^- p$ interactions [339, 340]. A flavor multiplet of vector hybrids between 2200 and 2300 MeV is predicted by the constituent gluon model [350]. Decays of light hybrids in the constituent model are discussed in Ref. [355].

Summarizing, there is evidence for a very broad 1^{-+} enhancement in the 1400–1600 MeV region, which consists of one (or possibly two) exotic states. As isovectors they cannot be glueballs. The coupling to $\eta\pi$ of the lighter one points to a four-quark state [356], while the $\eta'\pi$ coupling of the heavier one is favored for hybrid states [357, 358]. The mass of the latter, the $\pi_1(1600)$, is not far below the lattice and flux tube model predictions. The $\eta_1(1855)$ is an isoscalar candidate for the ground state 1^{-+} hybrid nonet.

63.8 Tetraquark states

The existence of multiquark states was suggested a long time ago, based on duality arguments [359, 360]. The most prominent light tetraquark candidates are the $a_0(980)$ and $f_0(980)$ [361–363].

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

A remarkable prediction for the existence of low-lying four quarks states is based on color hyperfine splitting. The lowest ground state ($L = 0$) tetraquark multiplet is predicted to be a scalar nonet. The scalar nonet lies just below 1 GeV when one assumes as mass scale the hyperfine color splitting between the ρ and the π (for a simple derivation see [9]). One then gets the nonet structure

$$\begin{aligned}
|a_0(980)\rangle &= |us\bar{d}\bar{s}\rangle, \frac{1}{\sqrt{2}}|(u\bar{u} - d\bar{d})s\bar{s}\rangle, |\bar{u}\bar{s}ds\rangle, \\
|f_0(980)\rangle &= \frac{1}{\sqrt{2}}|(u\bar{u} + d\bar{d})s\bar{s}\rangle, \\
|f_0(500)\rangle &= |\bar{u}\bar{d}ud\rangle, \\
|K_0^*(700)\rangle &= |\bar{s}\bar{d}ud\rangle, |\bar{s}\bar{u}ud\rangle \text{ and } |\bar{u}\bar{d}us\rangle, |\bar{u}\bar{d}ds\rangle. \qquad (63.1)
\end{aligned}$$

The two isoscalars are expected to mix with the angle φ:

$$\begin{aligned}
|f_0(980)\rangle &= \cos\varphi|s\bar{s}\rangle + \sin\varphi|n\bar{n}\rangle, \\
|f_0(500)\rangle &= -\sin\varphi|s\bar{s}\rangle + \cos\varphi|n\bar{n}\rangle. \qquad (63.2)
\end{aligned}$$

Table 63.1: Coupling amplitudes for $\bar{B}^0$ and $\bar{B}_s^0$ decays into $J/\psi(1S)f_0(500)/f_0(980)$, depending on the $q\bar{q}$ or tetraquark structures of the $f_0(500)$ and $f_0(980)$ (from [364] where illustrative decay diagrams can be found). The angle φ is defined in Eq. 63.2.

	$\bar{B}^0$		$\bar{B}_s^0$	
	$f_0(980)$	$f_0(500)$	$f_0(980)$	$f_0(500)$
$q\bar{q}$	$\sin\varphi/\sqrt{2}$	$\cos\varphi/\sqrt{2}$	$\cos\varphi$	$\sin\varphi$
$qq\bar{q}\bar{q}$	$1/\sqrt{2}$	1	$\sqrt{2}$	0

Whether these mesons are really tetraquark states or $q\bar{q}$ mesons, is still an open issue:

- The $f_0(980)$ is strongly produced in D_s^+ decay [365], which suggests a large $s\bar{s}$ component, due to the Cabibbo-favored $c \to s$ coupling. However, the mainly $n\bar{n}$ $f_0(1370)$ is also strongly produced in D_s^+ decay, hence additional graphs must contribute [366].
- The relative branching ratios for $\bar{B}^0$ and $\bar{B}_s^0 \to J/\psi(1S)f_0(500)$ and $J/\psi(1S)f_0(980)$ can be used to probe the $q\bar{q}$ or tetraquark natures of the $f_0(500)$ and $f_0(980)$ [364, 367]. LHCb observes the $f_0(980)$ in $\bar{B}_s^0$ decays, but not the $f_0(500)$ [32], as would be expected for tetraquarks (see Table 63.1). In contrast, LHCb also observes the $f_0(500)$ in $\bar{B}^0$ decays, but not the $f_0(980)$ with an upper limit eight standard deviations below the predicted value for a tetraquark state [33]. However, these contradicting findings have been challenged by a dispersive analysis [368], using a model independent inclusion of hadronic final state interactions, in which a substantial $f_0(980)$ contribution is nevertheless found in $\bar{B}^0$-decays, thus still leaving the tetraquark structure as an open possibility.
- The ALICE collaboration reports a much stronger K_SK_S femtoscopic correlation than for $K_SK^\pm$ in high energy pp collisions, indicative of the $a_0(980)$ being a tetraquark state [369].
- The $f_0(980)$ and $a_0(980)$ could also be $K\overline{K}$ molecular states [70, 370, 371], being close to the $K\overline{K}$ threshold and decaying strongly into $K\overline{K}$. For $q\bar{q}$ states, the expected $\gamma\gamma$ widths [372,373] are not significantly larger than for molecular states [372, 374] and both predictions are consistent with data.
- Radiative decays of the $\phi(1020)$ into $a_0(980)$ and $f_0(980)$ were proposed to disentangle compact tetraquark structures from hadronic molecules. In Ref. [13] these states are made of four-quark cores and virtual $K\overline{K}$ clouds at the periphery, a view that is challenged in Ref. [375] showing that radiative ϕ decay data are consistent with molecular structures of light scalars. However, following Refs. [376, 377], the data from KLOE [378] and SND [379] in $\phi \to \gamma\eta\pi^0$, from KLOE [380] in $\phi \to \gamma\pi^0\pi^0$ and in $\phi \to \gamma\pi^+\pi^-$ from CMD-2 [381] favor these mesons to be tetraquark states. This is also supported by a BESIII analysis of $J/\psi(1S) \to \gamma\pi^0\pi^0$ [382] and by a measurement of $a_0(980) - f_0(980)$ mixing at BESIII [383].

More information on the $a_0(980)$, $f_0(980)$, $f_0(500)$ and $K_0^*(700)$ is provided by 'Scalar Mesons below 1 GeV' in the *Review*. For the $f_0(500)$ see also Ref. [384].

As mentioned already, the $f_0(1500)$ [42] and the $f_1(1285)$ [364] have been proposed as tetraquarks, the latter also as $K^*\overline{K}$ molecule [296], together with the $f_1(1420)$ [306]. Another potential candidate for a tetraquark is the $\phi(2170)$. As an excited $q\bar{q}$ state of the $\phi(1020)$, this meson should decay strongly into K^+K^- and $K_S^0K_L^0$, and also $K^*\bar{K}^*$. However, these decays are not observed. Hence, based on its observed decay into $f_0(980)\phi(1020)$ this meson could be an $ss\bar{s}\bar{s}$ tetraquark [385]. However, Refs. [386, 387] claim that the $\phi(2170)$ may not be a good candidate for the $ss\bar{s}\bar{s}$ state, predicted to lie higher in mass, but could qualify as an $su\bar{s}\bar{u}$ tetraquark.

63.9 Baryonia

Nucleon-antinucleon ($N\bar{N}$) bound states and resonances (baryonium) were predicted a long time ago [388, 389], based on the strongly attractive $N\bar{N}$ meson exchange potential, which is obtained from the NN one by multiplying with the G-parity of the exchanged meson. Several candidates had been reported in the seventies by experiments at CERN, BNL and KEK, some of them being indisputably statistically significant (for details on the model and on experiments, see [390, 391] and references therein). Most potential models predict a sequence of deeply bound isoscalar baryonia with quantum numbers $J^{PC} = 2^{++}$, 1^{--} and 0^{++}, the latter being the mostly bound [392, 393]. The $f_2(1565)$ which is observed in $\bar{p}p$ annihilation only [394, 395], is a good candidate for the 2^{++} $\bar{p}p$ bound state.

Enhancements close to the $\bar{p}p$ threshold have also been reported in B decays [396–398]. The strong signal near the $p\bar{p}$ threshold in $J/\psi(1S) \to \gamma\bar{p}p$ [399–401] could be due to a 0^{-+} baryonium [402], but could also be generated by the $N\bar{N}$ final state interaction [403–406]. The strong energy dependence of the cross section in $e^+e^- \to \bar{p}p$ [407, 408] and $\bar{p}p \to e^+e^-$ [409] is attributed to the $N\bar{N}$ final state interaction [410] (see also our comments on the $\rho(1900)$ at the end of section 63.5.2). Alternative explanations to baryonia have been proposed for the signals in $B \to \bar{p}pK$, such as the dynamics of the fragmentation mechanism [397].

63.10 Conclusions

The ground state nonets 1^1S_0, 1^3S_1, 1^1P_1, 1^3P_2, 1^1D_2 and 1^3D_3 (see fig. 63.1) are established (although more data are desirable for the $h_1(1415)$ in the 1^1P_1 nonet). There are uncertainties and ambiguities in all other nonets. In the pseudoscalar sector the $\eta(1440)$ may consist of two states, one at 1405 MeV, the other at 1475 MeV, which could also be the manifestation of a single resonance decaying into two different final states. In this case the 1475 one could be the radial excitation of the η' and the 1405 the pseudoscalar ground state glueball predicted a long time ago by the bag model, although the lattice puts it above 2 GeV. In the 1^{++} nonet two isoscalars – the $f_1(1420)$ and $f_1(1510)$ – compete for the $s\bar{s}$ slot. The first radial excitation 2^3S_1 is complete, but questions have been raised as to the nature of the $\rho(1450)$ and its relation to the $\rho(1700)$. The classification of scalar mesons is not settled, with the ones below 1 GeV being tetraquark states or building the ground state $q\bar{q}$ nonet. The nature of the scalars in the 1.5 – 1.8 GeV region is unclear, obscured by the interference with the ground state scalar glueball predicted in this mass region. For example, the $f_0(1500)$ and the $f_0(1710)$ could be $q\bar{q}$ states ($n\bar{n}$ and $s\bar{s}$, respectively) or made of gluons mixed with $q\bar{q}$. The $f_0(1500)$, or alternatively the $f_0(1710)$, have been proposed as mostly gluonic. Scalar mesons above the $f_0(1710)$ need experimental confirmation. Another pair of scalars, $a_0(1710)$ and $f_0(1770)$, has been reported. An isovector meson with exotic (1^{-+}) quantum numbers, $\pi_1(1600)$, is observed around 1.6 GeV with mass not far below theoretical predictions, although a further 1^{-+} state, decaying into $\eta\pi$, cannot be entirely excluded

around 1.4 GeV. An isoscalar partner, the $\eta_1(1855)$, has been reported, needing confirmation. Above 1.8 GeV mesons are broad and overlap, which complicates the data analyses. This makes the classification difficult, in particular the identification of the 2^{++} and 0^{-+} glueballs, expected above 2000 MeV.

64. Scalar Mesons below 1 GeV

Revised October 2025 by T. Gutsche (Tübingen U.), C. Hanhart (FZ Jülich), R.E. Mitchell (Indiana U.) and S. Spanier (Tennessee U.).

64.1 Introduction

Scalar resonances are difficult to resolve experimentally, as they either have large decay widths, which cause a strong overlap between neighboring resonances, or several decay channels open up within a short mass range (*e.g.* at the $K\bar{K}$ and $\eta\eta$ thresholds), producing cusps in the line shapes of the nearby resonances. Furthermore, one expects non-$q\bar{q}$ scalar objects, such as hadronic molecules and multiquark states, in the mass range of interest (for reviews see, *e.g.*, Refs. [1–6]).

Light scalars are produced, for example, in πN scattering on polarized/unpolarized targets, $p\bar{p}$ annihilation, central hadronic production, $J/\psi(1S)$, ψ, B-, D- and K-meson decays, $\gamma\gamma$ formation, and ϕ radiative decays. Especially for the lightest scalar mesons, simple parameterizations like Breit-Wigner functions and variants thereof fail — this is demonstrated explicitly on the example of the $f_0(500)$ or σ, e.g., in Ref. [7]. Accordingly, more advanced theory tools are necessary to extract the resonance parameters from data.

The mass and width of a resonance are determined by the position of the corresponding pole of the process amplitude (S- or T-matrix) in the complex energy plane, specifically from the pole closest to the physical axis on an unphysical Riemann sheet. The pole's real part indicates the resonance mass M, and its imaginary part corresponds to half the width Γ:

$$\sqrt{s_{\rm Pole}} = M - i\,\Gamma/2\ . \tag{64.1}$$

It is important to note that, in general, the pole of a Breit-Wigner parameterization does not agree with the T-matrix pole. For a detailed discussion of this issue, we refer to the review on *Resonances* in this Review of Particle Physics (RPP).

In the analyses available in the literature, fundamental properties of the amplitudes, such as unitarity, analyticity, Lorentz invariance, and chiral and flavor symmetry are implemented at different levels of rigor. Especially, chiral symmetry implies the appearance of zeros, the so-called Adler zeros, close to the threshold in elastic S-wave scattering amplitudes involving Goldstone bosons [8, 9], which may be shifted or removed in associated production processes [10]. Moreover, especially for the lightest non-strange and strange scalar resonance, accurate extractions of pole parameters become complicated by the presence of both left-hand cuts as well as circular cuts (for a recent review on the subject see Ref. [5]). The methods employed are the K-matrix formalism, the N/D-method, the Dalitz-Tuan ansatz, the inverse amplitude method, unitarized quark models with coupled channels, effective chiral field theories, and the linear sigma model, *etc.* Dynamics near the lowest two-body thresholds in some analyses are described by crossed channel (t, u) meson exchange or with an effective range parameterization instead of, or in addition to, resonant features in the s-channel. Dispersion theory is applied to pin down the location of resonance poles for the low mass states [11–16] unambiguously — in particular, the existence of a nonet of light scalar mesons is not questioned anymore.

In parallel to the developments sketched above, lattice QCD also entered the field of precision spectroscopy, since it was acknowledged that a study of resonances calls for a proper treatment of the scattering process employing e.g. the Lüscher method [17], later extended to coupled channels in Refs. [18–23]. This allowed for determinations of the poles of the $I = 1/2$ [24], the $I = 1$ [25] as well as the $I = 0$ [26, 27] light scalar mesons—those findings were later confirmed and refined by sophisticated dispersive analyses of lattice data for the $I = 0$ and $I = 1/2$ sectors in Refs. [28, 29] and Refs. [30, 31], respectively. Besides an additional firm confirmation of the existence of a nonet of light scalar mesons, via the quark mass dependence of the pole locations, these studies allow for an alternative look on their nature [32–34].

In this review, we present proposed values for the mass parameters of the scalar resonances below 1 GeV. Note that those are labeled as 'our estimate' — it is not an average over the quoted analyses, but is chosen to include the bulk of the analyses. An averaging procedure is not justified, since the analyses use overlapping or sometimes even identical data sets so that they are not statistically independent.

In this note, we discuss the light scalars below 1 GeV organized in the *Listings* under the entries $K_0^*(700)$ (or κ) with isospin $I = 1/2$, $a_0(980)$ with $I = 1$, as well as $f_0(500)$ (or σ) and $f_0(980)$ both with $I = 0$. The $I = 2$ $\pi\pi$ and $I = 3/2$ $K\pi$ partial waves do not exhibit resonant behavior.

64.2 The $K_0^*(700)$, also known as κ ($I = 1/2$)

The $K_0^*(700)$ corresponds to a pole in the low-energy πK scattering. Its properties are challenging to establish, since it appears to have a large width ($\Gamma \approx 500$ MeV) and resides close to the $K\pi$ threshold. The widely used LASS parameterization [35] models the $K\pi$ S-wave amplitude with a Breit-Wigner function representing $K^\star(1430)$ together with an effective range non-resonant component. Hadronic D- and B-meson decays provide additional data points in the vicinity of the $K\pi$ threshold and are discussed in detail in the *Review on Multibody Charm Analyses* in this RPP. With a few exceptions discussed there, the multi-hadron final states are usually treated in the approximation of non-interacting two-body systems. Precise information from semileptonic D decays, where the strongly interacting two-particle final states could be treated without approximation, is not available. BES II [36] (re-analyzed in [37]) finds a $K_0^*(700)$-like structure in $J/\psi(1S)$ decays to $\bar{K}^{*0}(892)K^+\pi^-$ where $K_0^*(700)$ recoils against the $K^*(892)$. The decay $\tau^- \to K_S^0\pi^-\nu_\tau$ can be considered clean with respect to final-state interactions and is studied by Belle [38], with $K_0^*(700)$ parameters fixed to those of Ref. [36]. Some

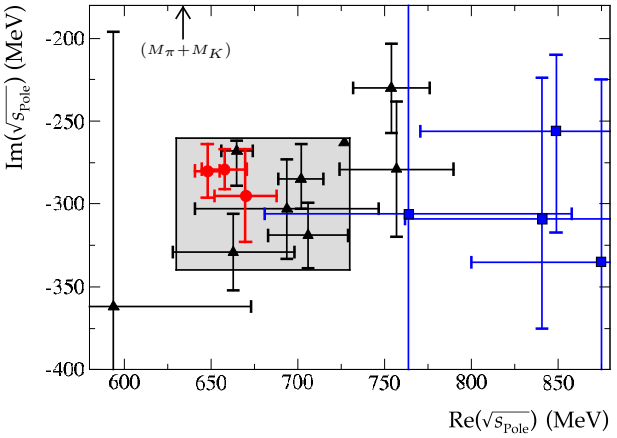

Figure 64.1: Location of the $K_0^*(700)$ (or κ) poles in the complex energy plane. Red circles denote the results of the analyses based on dispersion relations (see text for details), poles extracted from Breit-Wigner fits are shown as blue squares, while all other analyses quoted in the *Listings* are denoted by black triangles. The corresponding references are given in the listing. The arrow shows the location of the πK thresholds. The gray box indicates the range of pole locations classified as 'our estimate' .

authors find a $K_0^*(700)$ pole in their phenomenological analysis (see, *e.g.*, [39–48]), while others do not need to include it in their fits (see, *e.g.*, [49–52]; note that in Ref. [53] only a K_0^* meson above 825 MeV was discarded using scattering data fits and analyticity, which is not in conflict with the properties quoted below). All works including constraints from chiral symmetry at low energies naturally find a light $K_0^*(700)$ below 800 MeV, see, *e.g.*, [54–60]. The analyses of Ref. [15, 16] are based on the Roy-Steiner equations, which include analyticity and crossing symmetry constraints. Ref. [61] uses the Padé method to extract pole parameters after refitting scattering data constrained to satisfy forward dispersion relations. All three arrive at compatible pole positions for the $K_0^*(700)$ that are also consistent with the pole parameters deduced from other theoretical methods. Recently, the $K_0^*(700)$ was investigated using the femtoscopy technique at

ALICE [62]. The data is shown to be consistent with the dispersive analyses quoted above and, in particular, with the established properties of the $K_0^*(700)$ in Ref. [63], albeit calling for unusual source parameters.

Due to their large uncertainties, the pole locations deduced from the Breit-Wigner fits agree with the other determinations' widths, but their masses are found to be systematically higher. Moreover, phase shifts extracted from the Breit-Wigner functions for the $K_0^*(700)$ are very different from the known scalar πK phase shifts. The various poles are shown in Fig. 64.1. The compilation in this figure motivates the pole parameters of the $K_0^*(700)$, which we quote as 'our estimate', namely,

$$\sqrt{s^{\kappa}_{\rm Pole}} = (630-730) - i(260-340)\ \text{MeV}\ . \qquad (64.2)$$

For an extensive discussion about the πK system in general and the κ meson in particular, see Ref. [64]. Applying the same strategy to only those pole locations determined with the sophisticated dispersive methods (solid red circles in the figure) the region narrows down to

$$\sqrt{s^{\kappa}_{\rm Pole}} = (640-680) - i(265-305)\ \text{MeV}\ . \qquad (64.3)$$

64.3 The $a_0(980)$ ($I = 1$)

The $a_0(980)$ couples strongly to the channels $\pi\eta$ and $K\bar{K}$. The $K\bar{K}$ component must be large in the $a_0(980)$ wave function, since the mass of the $a_0(980)$ lies very close to the opening of the $K\bar{K}$ channel [65, 66]. This generates a pronounced cusp-like behavior in the resonant amplitude, and to reveal its properties, the presence of the $K\bar{K}$ channel cannot be ignored. All listed $a_0(980)$ measurements agree on a mass position value near 980 MeV, but the width deduced from the imaginary part of the pole location has values between 60 and 140 MeV. Note that the width of the $a_0(980)$ line shape is usually smaller than what is derived from the pole location because the aforementioned channel coupling heavily distorts the line shape. The relative coupling $K\bar{K}/\pi\eta$ is determined indirectly from $f_1(1285)$ [67–69] or $\eta(1410)$ decays [70–72], from the line shape observed in the $\pi\eta$ decay mode [73–76], or from the coupled-channel analysis of the $\pi\pi\eta$ and $K\bar{K}\pi$ final states of $p\bar{p}$ annihilation at rest [65]. The most recent data on the $a_0(980)$ come from measurements of different charge channels for $D \to a_0(980)\pi$ [77], from a measurement of $D^+ \to \pi^+\eta\eta$ [78], and from $\Lambda_c^+ \to \Lambda a_0^+(980)$ [79]. All three reactions are claimed to be driven by non-trivial production mechanisms [78, 80–82]. It remains to be checked if claims about the structure of the a_0 from, e.g., D-decay data [83] can be confirmed.

For the extraction of the $a_0(980)$ pole locations, Refs. [56, 57, 59, 84] use unitarized chiral perturbation theory. Ref. [85] uses a similar formalism, employing the amplitude fixed in Ref. [86]. A dispersion theoretical approach to the isovector scalar $\pi\eta - K\bar{K}$ system is presented in Ref. [87] that may be refined further from studies of heavy meson decays [88]. Those efforts lead to a rather precise determination of the $a_0(980)$ pole location [89]. A value consistent for the mass parameter, but with a larger width, is found in the analysis of $\bar{p}p$ annihilation in flight data employing a K-matrix [90]. The poles presented in Refs. [59, 65, 76, 89, 90] are shown in Fig. 64.2 together with the range of pole parameters estimated by us from this compilation, namely,

$$\sqrt{s^{a_0(980)}_{\rm Pole}} = (970-1020) - i(30-70)\ \text{MeV} \qquad (64.4)$$

indicated by the box. Two disclaimers are important here: First of all, both poles of $a_0(980)$ and of $f_0(980)$, to be discussed below, are located very close to the kaon thresholds, with the charged and neutral ones being only 8 MeV apart. To illustrate this point, the pertinent thresholds are shown explicitly in Figs. 64.2 and 64.4. Thus, pole extractions for the neutral $a_0(980)$ might be affected by the enhanced $a_0 - f_0$ mixing discussed in Refs. [91–94]. On the other hand, all analyses employed in the pole determinations quoted above are done assuming isospin symmetry. A second important remark is that the imaginary part of the pole location needs to be interpreted with care, in particular for those states that couple strongly to a near-by, yet closed threshold—for a detailed discussion see Refs. [95, 96] and the review "Resonances" in this *Review*.

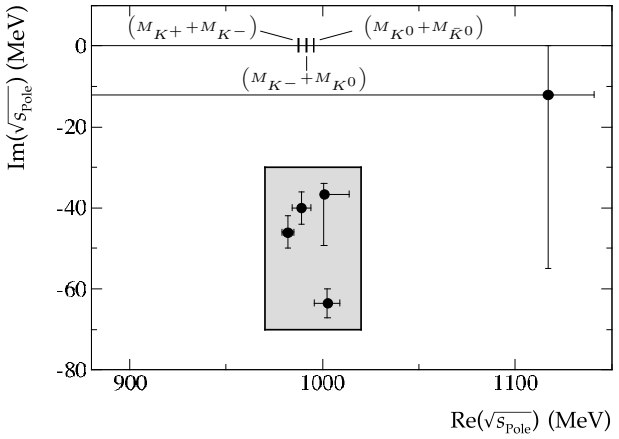

Figure 64.2: Location of the $a_0(980)$ poles from different extractions in the complex energy plane. The corresponding references are given in the *Listings*. Also shown are the thresholds for the K^+K^- and $K^0\bar{K}^0$ channels, relevant for $a_0(980)^0$, and for the K^-K^0 channel, relevant for the $a_0(980)^-$. The gray box indicates the range of pole locations classified as 'our estimate'. Note that by default, we take the pole located closest to the physical axis. Accordingly, not all poles shown are located on the same sheet. We refer to the original references for details.

64.4 The $f_0(500)$, also known as σ-meson ($I = 0$)

For discussions of the $\pi\pi$ S-wave below the $K\bar{K}$ threshold and on the long history of the $f_0(500)$, which was suggested in studies of nuclear interactions almost 70 years ago, see the review [5]. Information on the $\pi\pi$ S-wave phase shift $\delta_J^I = \delta_0^0$ was already extracted many years ago from πN scattering [97–99], and near the $\pi\pi$ threshold from K_{e4} decays [100]. The kaon decays were later revisited, leading to consistent data with very much improved statistics [101, 102]. The reported $\pi\pi \to K\bar{K}$ cross sections [103–106] have large uncertainties. The πN datasets have been analyzed in combination with high-statistics data (see entries labeled as RVUE for re-analyses of the data). The $2\pi^0$ invariant mass spectra, extracted from $p\bar{p}$ annihilation at rest into $3\pi^0$ [107,108] and into $5\pi^0$ [109] and from central pp collision [109] do not show a distinct resonance structure below 900 MeV, but these data sets are consistently described with the standard solution for the $\pi\pi$ scalar isoscalar S-wave extracted from high energy $\pi N \to \pi\pi N$ data [98, 110], which allows for the broad $f_0(500)$, but also fits without it existing. An enhancement is observed in the $\pi^+\pi^-$ invariant mass near threshold in the decays $D^+ \to \pi^+\pi^-\pi^+$ [111–113] and $J/\psi(1S) \to \omega\pi^+\pi^-$ [114, 115], and in $\psi(2S) \to J/\psi(1S)\pi^+\pi^-$ with very limited phase space [116, 117].

To establish the pole location of the $f_0(500)$, sophisticated theoretical tools are necessary, mainly because of its large width. The $\pi\pi$ scattering amplitude shows an unusual energy dependence due to the presence of the Adler zero in the unphysical regime close to the threshold [8, 9], required by chiral symmetry. Most of the modern analyses listed under $f_0(500)$ agree on a pole position near $(500 - i\,250$ MeV). In particular, analyses of $\pi\pi$ data that include unitarity are consistent with the near threshold $\pi\pi$ data from K_{e4} decays, and the chiral symmetry constraints from Adler zeroes and/or scattering lengths find a light $f_0(500)$, see, *e.g.*, [118, 119]. Interestingly, the Roy-equation analysis of Ref. [28] also shows the reverse, namely all amplitudes that meet the acceptability criteria display an Adler zero below threshold. Analogously, an Adler zero appears automatically, when a parameterization of the spectral function for the $f_0(500)$ with proper pole location and residue is constructed [120].

Precise pole positions with an uncertainty of less than 20 MeV

(see our table for the T-matrix pole in the *Listings*) are extracted using the Roy equations, which are twice-subtracted dispersion relations derived from crossing symmetry and analyticity. In Ref. [12], the subtraction constants are fixed to the S-wave scattering lengths a_0^0 and a_0^2 derived from matching the Roy equations and two-loop chiral perturbation theory [11]. The only additional relevant input to fix the $f_0(500)$ pole is the $\pi\pi$-wave phase shift at some higher energy point, chosen as 800 MeV. The analysis is improved further in Ref. [14]. Alternatively, in Ref. [13] Roy equations are used as constraints for a fit to data. In that reference, also once-subtracted Roy–like equations, called GKPY equations, are used, since the extrapolation into the complex plane based on the twice-subtracted equations leads to larger uncertainties, mainly due to the limited experimental information on the isospin-2 $\pi\pi$ scattering length. Ref. [121] uses Padé approximants for the analytic continuation. All these extractions find consistent results. Using only analyticity and unitarity to describe data from $K_{2\pi}$ and K_{e4} decays, Ref. [122] finds consistent values for the pole position and the scattering length a_0^0. The importance of the $\pi\pi$ scattering data for fixing the $f_0(500)$ pole is nicely illustrated by comparing analyses of $\bar{p}p \to 3\pi^0$ omitting [107, 123] or including [108, 124] information on $\pi\pi$ scattering: while the former analyses find an extremely broad structure above 1 GeV, the latter find $f_0(500)$ masses of the order of 400 MeV.

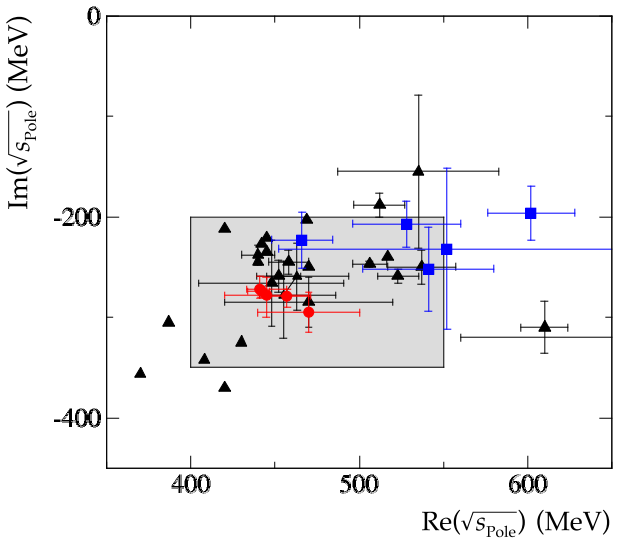

Figure 64.3: Location of the $f_0(500)$ (or σ) poles in the complex energy plane. Red circles denote the analyses based on Roy(-like) dispersion relations, poles extracted from Breit-Wigner fits are shown as blue squares, while all other analyses are denoted by triangles. The corresponding references are given in the *Listings*. The gray box indicates the range of pole locations classified as 'our estimate' .

From Fig. 64.3 we estimate the range of pole positions for the $f_0(500)$, namely,

$$\sqrt{s^{\sigma}_{\rm Pole}} = (400-550) - i(200-350)\ \text{MeV}\ . \qquad (64.5)$$

The plot contains the poles from Refs. [44, 55, 57, 59, 60, 75, 84, 97, 108, 113, 116–119, 122, 124–143] as well as the advanced dispersion analyses [11–14, 121]. The extracted $f_0(500)$ pole position is very sensitive to the high-accuracy low-energy $\pi\pi$ scattering data [101, 102]. In fact, all analyses consistent with this data find poles within the accepted range indicated in the figure. Similar to the case of the $K_0^*(700)$, we observe that poles identified through Breit-Wigner analyses usually appear at higher masses, although this effect is less noticeable here. One should not interpret this as justification for using Breit-Wigner functions in the case of the $f_0(500)$, since $\pi\pi$ phase shifts obtained from Breit-Wigners significantly differ from the measured scattering phase shifts.

If one uses just the most sophisticated dispersive analyses of Refs. [11–14], shown as red solid dots in Fig. 64.3 to determine the pole location of the $f_0(500)$, the range narrows down to

$$\sqrt{s^{\sigma}_{\rm Pole}} = (430-490) - i(260-310)\ \text{MeV}\ , \qquad (64.6)$$

which agrees in the central values to those provided in Ref. [5], however, with larger uncertainties.

Besides $\pi\pi$, the only other decay channel of the $f_0(500)$ is two photons. Due to the large width of $f_0(500)$ and the non-trivial phase motion connected to it, directly extracting its two-photon width from the data is not possible. Thus, the values for $\Gamma(\gamma\gamma)$ quoted in the literature as well as the in *Listings* are based on the expression in the narrow width approximation [144] $\Gamma(\gamma\gamma) \simeq \alpha^2|g_\gamma|^2/(4\mathrm{Re}(\sqrt{s^{\sigma}_{\rm Pole}}))$, where g_γ is derived from the residue at the $f_0(500)$ pole to two photons and α denotes the electromagnetic fine-structure constant (see also the review on *Resonances* in this issue of the RPP). The explicit form of the expression may vary between different authors due to different definitions of the coupling constant; however, the expression given for $\Gamma(\gamma\gamma)$ is free of ambiguities. This prescription leads to a two-photon branching ratio of 3×10^{-6}, which is about twice as large as the one derived from a formalism that accounts for the $f_0(500)$ line shape [120]. According to Refs. [145–148], $\pi\pi$ and $\gamma\gamma$ scattering data sets are consistently described including $f_0(500)$ via the two step process of $\gamma\gamma \to \pi^+\pi^-$ with pion exchange in the t- and u-channel, followed by a final-state interaction $\pi^+\pi^- \to \pi^0\pi^0$. The same conclusion is drawn in Ref. [149], where the $f_0(500) \to \gamma\gamma$ decay width is dominated by re-scattering. Therefore, it might be difficult to learn anything new about the nature of the $f_0(500)$ from its $\gamma\gamma$ coupling. For the recent work on $\gamma\gamma \to \pi\pi$, see Refs. [60, 84, 122–124, 131–144, 147–152]. There are strong indications (*e.g.*, [153–183]) that the $f_0(500)$ pole cannot be classified as a $q\bar{q}$ state.

64.5 The $f_0(980)$ ($I = 0$)

The $f_0(980)$ couples predominantly to the $\pi\pi$ and $K\bar{K}$ channels and its signal overlaps strongly with the background represented mainly by the $f_0(500)$ and the $f_0(1370)$. This can lead to a dip in the $\pi\pi$ spectrum at the $K\bar{K}$ threshold. It changes from a dip into a peak structure in the $\pi^0\pi^0$ invariant mass spectrum of the reaction $\pi^- p \to \pi^0\pi^0 n$ [157], with increasing four momentum transfer to the $\pi^0\pi^0$ system, which means increasing the a_1 exchange contribution in the amplitude, while the π exchange decreases. Also, when a $(u\bar{u} + d\bar{d})$ source is switched to a $s\bar{s}$ source, as it appears when moving from $B_d \to J/\psi(1S)\pi\pi$ to $B_s \to J/\psi(1S)\pi\pi$, the f_0 signal switches from a dip to a peak [171] (similarly in D versus D_s meson decays; see, *e.g.,* Refs. [184, 185]). For a general discussion of the underlying mechanism of near-threshold dips vs. peaks, see Ref. [186]. The $f_0(500)$ and the $f_0(980)$ are also observed in the data for radiative ϕ decays ($\phi \to f_0\gamma$) from SND [158, 159], CMD2 [160], and KLOE [161, 162].

Unitarized chiral perturbation theory is employed to extract the pole of the $f_0(980)$ in Refs. [56, 57, 59, 84, 85]. Two different dispersive analyses are used in Ref. [13] to simultaneously pin down the pole parameters of both the $f_0(500)$ and the $f_0(980)$. The poles extracted in Refs. [13, 14, 59, 60, 90, 127, 187–189] are shown in Fig. 64.4, together with the range of pole parameters estimated by us from this compilation, namely,

$$\sqrt{s^{f_0(980)}_{\rm Pole}} = (980-1010) - i(20-35)\ \text{MeV} \qquad (64.7)$$

indicated by the box. A disclaimer is important here: Both the poles of $a_0(980)$ and of $f_0(980)$ are located very close to the kaon thresholds, with the charged and neutral thresholds being 8 MeV apart — to illustrate this point the pertinent thresholds are shown explicitly in Figs. 64.2 and 64.4. This observation leads to the prediction of an enhanced $a_0 - f_0$ mixing [91–94]. On the other hand, all analyses employed in the pole determinations quoted above are done assuming isospin symmetry. Future studies need to show the impact of isospin violation on the extraction of the $a_0(980)/f_0(980)$ pole parameters.

It has also been recently shown [95, 96] that the proximity of the $f_0(980)$ pole to the $K\bar{K}$-threshold singularity does not always

allow for a direct identification of the total width with the imaginary part of the pole position as in Eq. (64.1). The correct relation is more subtle, when the pole lies in the unphysical sheet obtained from analytic continuation from below the $K\bar{K}$ threshold (second sheet) as it is the case of several poles in Fig. 64.4 [95]—see also the discussion in the section "Resonances" in this *Review*.

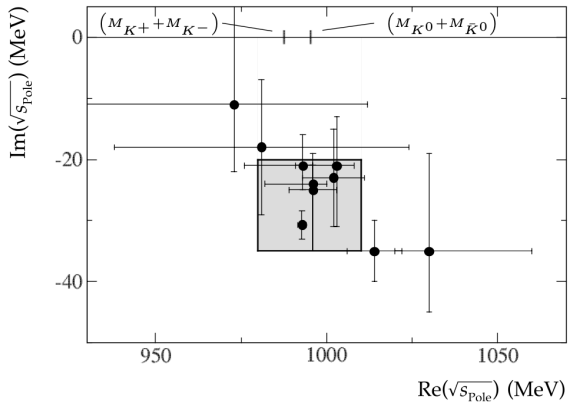

Figure 64.4: Location of the $f_0(980)$ poles from different extractions in the complex energy plane. The corresponding references are given in the *Listings*. Also shown are the thresholds for the K^+K^- and $K^0\bar{K}^0$ channels. The gray box indicates the range of pole locations classified as 'our estimate' .

Analyses of $\gamma\gamma \to \pi\pi$ data [163–165] underline the importance of the $K\bar{K}$ coupling of the $f_0(980)$, while the resulting two-photon width of the $f_0(980)$ cannot be determined precisely [166]. The prominent appearance of the $f_0(980)$ in the semileptonic D_s decays and decays of B and B_s mesons implies a dominant $(\bar{s}s)$ component: those decays occur via weak transitions that alternatively result in $\phi(1020)$ production. Ratios of decay rates of B and/or B_s mesons into $J/\psi(1S)$ plus $f_0(980)$ or $f_0(500)$ are proposed to extract the flavor mixing angle and to probe the tetraquark nature of those mesons within a certain model [167, 168]. The resulting phenomenological fits of the LHCb collaboration [169, 170] lead the authors to conclude that their data are incompatible with a model where $f_0(500)$ and $f_0(980)$ are formed from two quarks and two antiquarks (tetraquarks). However, a dispersive analysis of the same data that allows for a model-independent inclusion of the hadronic final-state interactions in Ref. [171] puts into question the conclusions of Ref. [169]. Moreover, the assumption underlying Ref. [169] that the production dynamics of $f_0(500)$ and $f_0(980)$ are equal such that they cancel in ratios appears not to be justified [5].

Ref. [190] investigates the p_T dependence of elliptic anisotropies for the production of $f_0(980)$ in proton-lead collisions. From the anticipated scaling of this observable with respect to the number of constitutents of the observed state, the authors conclude that the $f_0(980)$ is a $\bar{q}q$ state. However, this interpretation should also be re-examined critically, since the form factor $\langle\pi\pi|\bar{s}s|0\rangle$ probed here and discussed, e.g., in Ref. [171] is consistent also with other interpretations.

64.6 Interpretation of the scalars below 1 GeV

In the literature, various structures are discussed for light scalar mesons, such as conventional $q\bar{q}$ mesons, compact $(qq)(\bar{q}\bar{q})$ configurations (tetraquarks), or meson-meson bound states (hadronic molecules). In reality, these components can be superimposed, and identifying the dominant one is often model-dependent. Although progress has been made in recent years, this question remains unresolved. Here, we highlight some current conclusions.

The $f_0(980)$ and $a_0(980)$ are often interpreted as compact tetraquark states [180–183, 191] or $K\bar{K}$ bound states [192]. The insight into their internal structure using two-photon widths [159, 193–199] is not conclusive. The $f_0(980)$ appears as a peak structure in D_s decays without $f_0(500)$ background. Based on that observation, it is suggested that $f_0(980)$ has a large $s\bar{s}$ component, which according to Ref. [200] is surrounded by a virtual $K\bar{K}$ cloud (see also Ref. [201]). The relevance of a tetraquark flavor structure of the $a_0(980)$ in the decays $D \to a_0(980)P$ (P denotes a pseudoscalar meson) as opposed to a naive $q\bar{q}$ configuration is discussed in Ref. [83]. The inclusive production property of the $f_0(980)$ in Z^0 decays is consistent with mesons of other nonets [202]. However, as stated by the authors, the results should be taken as model-dependent measurements while presently no reliable predictions for production rates of non-$q\bar{q}$ states in Z^0 decay are available. Data sets on radiative decays ($\phi \to f_0\gamma$ and $\phi \to a_0\gamma$) from SND, CMD2, and KLOE (see above) are consistent with a prominent role of kaon loops. This observation is interpreted as evidence for a compact four-quark structure of the light scalars in Ref. [203], while it is claimed to point at a molecular nature in Ref. [204, 205]. Details of this controversy are given in the comments [206, 207]; see also Ref. [208]. There is now a rather broad consensus that the states $f_0(980)$ and $a_0(980)$, together with the $f_0(500)$ and the $K_0^*(700)$, form a nonet of predominantly four-quark states, where at larger distances the quarks recombine into a pair of pseudoscalar mesons creating a meson cloud (see, *e.g.,* Ref. [209]). Various QCD sum rule studies [210–215] do not agree on a tetraquark configuration for the same particle group.

Models that start directly from chiral Lagrangians, either in non-linear [56, 59, 118, 204] or in linear [216–222] realization, predict the existence of the $f_0(500)$ meson near 500 MeV. Here the $f_0(500)$, $a_0(980)$, $f_0(980)$, and $K_0^*(700)$ (in some models the $K_0^*(1430)$) would form a nonet (not necessarily $q\bar{q}$). In the linear sigma models, the lightest pseudoscalars appear as their chiral partners.

In the non-linear approaches of Refs. [56] and [118] the above resonances, together with the low mass vector states, are generated starting from chiral perturbation theory predictions near the first open channel, and then by shifting the states to the resonance locations, using unitarity and analyticity.

Ref. [216] uses a framework with explicit resonances that are unitarized and coupled to the light pseudoscalars in a chirally invariant way. Evidence for a dominant non-$\bar{q}q$ nature of the lightest scalar resonances is derived from their mixing scheme. In Ref. [217], the scheme is extended and applied to the decay $\eta' \to \eta\pi\pi$, which leads to the same conclusions. In Ref. [223], the large N_c behavior of the poles is studied to identify the nature of the resonances generated from scattering equations. This leads to the observation that, while the light vector states behave consistently with what is predicted for $\bar{q}q$ states, the light scalars behave very differently. This finding provides strong support for a dominant non-$\bar{q}q$ nature of the light scalar resonances. Note, the more refined study of Ref. [153] which finds, in the case of the $f_0(500)$, indications for a subdominant $\bar{q}q$ component located around 1 GeV in addition to a dominant non-$\bar{q}q$ nature. Additional support for the dominant non-$q\bar{q}$ nature of the $f_0(500)$ is given in Ref. [224], where the connection between the poles of resonances and their Regge trajectories is analyzed. All works including constraints from chiral symmetry at low energies naturally find a light $K_0^*(700)$ below 800 MeV and a $f_0(500)$ below 600 MeV, see, *e.g.*, [54–59]. In these works the $K_0^*(700)$, $f_0(500)$, $f_0(980)$, and $a_0(980)$ appear to form a nonet [55, 58]. Additional evidence for this assignment is presented in Ref. [14], where the couplings of the nine states to $\bar{q}q$ sources are compared. Similar conclusions are reached in Ref. [225] where in the analyzed data the $f_0(980)$ for example appears as a peak structure in $J/\psi(1S) \to \phi\pi^+\pi^-$ while in $J/\psi(1S) \to \omega\pi^+\pi^-$ the signal is suppressed. The same low mass scalar nonet is also found earlier in the unitarized quark model of Ref. [130]. A recent phenomenological study based on a $q\bar{q}$ flavor scheme for the light scalars concludes that their glueball content is ruled out because of low production rates in radiative $J/\psi(1S)$ decays [226]. This work was refined further in Ref. [188], where the $f_0(500)$ and the $f_0(980)$ are identified as mostly singlet and mostly octet, respectively.

There are, however, alternative interpretations of some of the light scalars. For example Ref. [227] (for a more recent, condensed discussion of the idea see Ref. [228]), also builds on chiral symmetry, but expands around an infrared fixed point such that the

$f_0(500)$ appears as a QCD dilaton with a mass driven by the QCD scale anomaly. The phenomenology studied in that work appears consistent with this proposal. An updated discussion on the properties of the $f_0(500)$ as a QCD dilaton candidate and their relation to flavor singlet-octet mixing can be found in Ref. [229]. In Ref. [127, 149, 230, 231] data sets on $\pi\pi - \bar{K}K$ scattering, as well as $\gamma\gamma \to \pi\pi$, are analyzed and the authors conclude that especially the $f_0(500)$ should have a significant gluon content. An extensive analysis on mass, width, and decay couplings of the light scalars in a QCD spectral sum rule study [232] leads to ambiguous results for their internal structure. The $f_0(500)$ can equally well have tetraquark, molecular, or gluonic content, while the states $f_0(980)$ and $a_0(980)$ can be of molecular or tetraquark nature. A scenario where the $f_0(500)$ and $f_0(980)$ result from quarkonia-glueball mixing is also possible. Note, however, that the large similarities of the features of the κ and the σ meson put into question both a dilaton and a glueball contribution to the latter, since neither of them can be present in the former.

A model-independent method to identify hadronic molecules goes back to a proposal by Weinberg [233] (an extension of the formalism to virtual states is provided in Ref. [34]), which is shown to be equivalent to the pole counting arguments of [91–94, 234–239] in Ref. [237]. The formalism allows one to extract the amount of the molecular component in the wave function from the effective coupling constant of a physical state to a nearby continuum channel. It can be applied to near-threshold states only and provides strong evidence that the $f_0(980)$ is predominantly a $\bar{K}K$ molecule, while the situation turns out to be less clear for the $a_0(980)$ (see also Refs. [197,199]). This is in line with the findings of Ref. [85], which reports an important role of the $\pi\eta$ channel to the formation of the $a_0(980)$ in addition to the $\bar{K}K$ channel, while the $f_0(980)$ also in this work appears to be predominantly a $\bar{K}K$ molecule. The relevance of both the $\bar{K}K$ and the $\pi\eta$ channels in a dynamically generated $a_0(980)$ is also pointed out in the description of the $\chi_{c1} \to \eta\pi^+\pi^-$ and $D_s^+ \to \pi^+\pi^0\eta$ reactions [240, 241]. Dynamically generated $f_0(500)$, $f_0(980)$ and $K_0^*(700)$ resonances also give sizable contributions to the measured mass distributions in $D_s^+ \to K^+\pi^+\pi^-$ decay as pointed out in Ref. [242]. A recent analysis on the compositeness of the $\pi\pi - K\bar{K}$ and $\pi\eta - K\bar{K}$ channels for the $f_0(980)$ and $a_0(980)$ resonances based on pole values and decay branchings is performed in Ref. [95]. While the $K\bar{K}$ configuration dominates in the $f_0(980)$, the meson-meson components are subdominant in $a_0(980)$. Further insights into $a_0(980)$ and $f_0(980)$ are expected from their mixing [91–94]. A corresponding signal predicted in Refs. [92,93] is reported by BES III [243]. The importance of the molecular structure of $a_0(980)$, $f_0(980)$ and of their mixing in the reactions $\bar{B}_s^0 \to J/\psi(1S)\pi^+\pi^-$ and $\bar{B}_s^0 \to J/\psi(1S)\pi^0\eta$ is pointed out in Ref. [244].

In the unitarized quark model with coupled $q\bar{q}$ and meson-meson channels, the light scalars are interpreted as additional manifestations of bare $q\bar{q}$ confinement states, strongly mass shifted from the 1.3 - 1.5 GeV region and very distorted due to the strong $^3P_0$ coupling to S-wave two-meson decay channels [239, 245]. Thus, in these models, the light scalar nonet comprising the $f_0(500)$, $f_0(980)$, $K_0^*(700)$, and $a_0(980)$, as well as the nonet consisting of the $f_0(1370)$, $f_0(1500)$ (or $f_0(1710)$), $K_0^*(1430)$, and $a_0(1450)$, respectively, are seen as two manifestations of the same bare input states (see also Ref. [246]). It should not remain unmentioned, however, that the heavier nonet lies rather close to the input nonet, and that the light scalar one emerges only once the coupling to the two-meson channels is switched on, again highlighting that the meson-meson interaction is indispensable for the light scalars. A similar phenomenology emerges in a coupled two-quark four-quark treatment employing Dyson-Schwinger equations [247, 248]: Also here, the $f_0(500)$ is by far dominated by its two-pion component.

Acknowledgment

The authors would like to thank Eberhard Klempt, Mikhail Mikhasenko and José R. Peláez for helpful input and discussions in the preparation of the review.

65. Rare Kaon Decays

Revised August 2025 by L. Littenberg (BNL) and G. Valencia (Monash U.).

65.1 Introduction

There are several useful reviews on rare kaon decays and related topics [1–13]. Activity in rare kaon decays can be divided roughly into four categories:

1. Searches for explicit violations of the Standard Model (SM)
2. The golden modes: $K \to \pi\nu\bar{\nu}$
3. Other constraints on SM parameters
4. Studies of strong interactions at low energy.

The paradigm of Category 1 is the lepton flavor violating decay $K_L \to \mu e$. Category 2 includes the two modes that can be calculated with negligible theoretical uncertainty, $K^+ \to \pi^+\nu\bar{\nu}$ and $K_L \to \pi^0\nu\bar{\nu}$. These modes can lead to precision determinations of CKM parameters or, in combination with other measurements of these parameters, they can constrain new interactions. They constitute the main focus of the current experimental kaon program. The search for new light particles through the reaction $K \to \pi X^0$ is a byproduct of these measurements. Category 3 is focused on decays with charged leptons, such as $K_L \to \pi^0\ell^+\ell^-$ or $K_L \to \ell^+\ell^-$ where $\ell \equiv e, \mu$. These modes are sensitive to CKM parameters, but they suffer from multiple hadronic uncertainties that can be addressed, at least in part, through a systematic study of the peripheral modes indicated in Fig. 65.1.

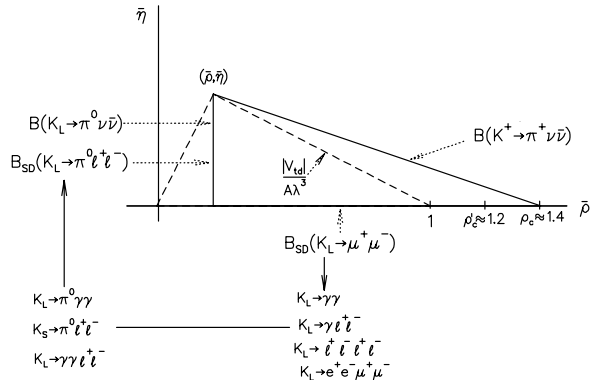

Figure 65.1: Role of rare kaon decays in determining the unitarity triangle. The solid arrows point to auxiliary modes needed to interpret the main results, or potential backgrounds to them.

The interplay between Categories 3-4 and their complementarity to Category 2 is illustrated in the figure. Category 4 includes reactions like $K^+ \to \pi^+\ell^+\ell^-$ those where long distance contributions are dominant and which constitute a testing ground for the ideas of chiral perturbation theory. Other decays in this category are $K_L \to \pi^0\gamma\gamma$ and $K_L \to \ell^+\ell^-\gamma$. The former is important in understanding a CP-conserving contribution to $K_L \to \pi^0\ell^+\ell^-$, whereas the latter could shed light on long distance contributions to $K_L \to \mu^+\mu^-$.

65.2 Explicit violations of the Standard Model

Much activity has focused on searches for lepton flavor violation (LFV). This is motivated by the fact that many extensions of the minimal Standard Model violate lepton flavor and by the potential to access very high energy scales. For example, the tree-level exchange of a LFV vector boson of mass M_X that couples to left-handed fermions with electroweak strength and without mixing angles yields $\mathrm{B}(K_L \to \mu e) = 4.7\times10^{-12}(148\ \mathrm{TeV}/M_X)^4$ [2]. This simple dimensional analysis may be used to read from Table 65.1 that the reaction $K_L \to \mu e$ is already probing scales of over 100 TeV. Table 65.1 summarizes the present experimental situation vis-à-vis LFV. The decays $K_L \to \mu^\pm e^\mp$ and $K^+ \to \pi^+ e^\mp \mu^\pm$ (or $K_L \to \pi^0 e^\mp \mu^\pm$) provide complementary information on potential family number violating interactions, since the former is sensitive to parity-odd couplings and the latter is sensitive to parity-even couplings.

Limits on certain lepton-number violating (LNV) kaon decays also have been obtained, with special interest arising from their role in constraining possible extensions of the neutrino sector [14, 15], and we list those in the table as well. Related searches in μ and τ processes are discussed in Section 5.

Table 65.1: Searches for lepton flavor and lepton number violation in K decay

LFV mode	90% CL upper limit	Experiment	Yr./Ref.	Type
$K^+ \to \pi^+ e^- \mu^+$	1.3×10^{-11}	BNL-865	2005/ [16]	LFV
$K^+ \to \pi^+ e^+ \mu^-$	6.6×10^{-11}	NA62	2021/ [17]	LFV
$K_L \to \mu e$	4.7×10^{-12}	BNL-871	1998/ [18]	LFV
$K_L \to \pi^0 e\mu$	7.6×10^{-11}	KTeV	2008/ [19]	LFV
$K_L \to \pi^0\pi^0 e\mu$	1.7×10^{-10}	KTeV	2008/ [19]	LFV
$K^+ \to \pi^- e^+ e^+$	5.3×10^{-11}	NA62	2022/ [20]	LNV
$K^+ \to \pi^-\pi^0 e^+ e^+$	8.5×10^{-10}	NA62	2022/ [20]	LNV
$K^+ \to \pi^- \mu^+ \mu^+$	4.2×10^{-11}	NA62	2019/ [21]	LNV
$K_L \to e^\pm e^\pm \mu^\mp \mu^\mp$	4.12×10^{-11}	KTeV	2003/ [22]	LNV
$K^+ \to \pi^- \mu^+ e^+$	4.2×10^{-11}	NA62	2021/ [17]	LNFV
$K^+ \to \mu^- \nu e^+ e^+$	8.1×10^{-11}	NA62	2023/ [23]	LNV/LFV

65.3 The golden modes: $K \to \pi\nu\bar{\nu}$

In the SM, the decay $K^+ \to \pi^+\nu\bar{\nu}$ is dominated by one-loop diagrams with top-quark intermediate states, while long-distance contributions are known to be quite small [25–27]. This permits a precise calculation of this rate in terms of SM parameters. Studies of this process are thus motivated by the possibility of detecting non-SM physics when comparing with the results of global fits [28, 29].

The branching ratio can be written in a compact form that exhibits the different ingredients that go into the calculation [30],

$$\mathrm{B}\left(K^+ \to \pi^+\nu\bar{\nu}(\gamma)\right) = \kappa_+(1+\Delta_{\mathrm{EM}})\left[\left(\frac{\mathrm{Im}(V_{ts}^\star V_{td})}{\lambda^5}X_t\right)^2 + \left(\frac{\mathrm{Re}(V_{cs}^\star V_{cd})}{\lambda}P_c + \frac{\mathrm{Re}(V_{ts}^\star V_{td})}{\lambda^5}X_t\right)^2\right]. \quad (65.1)$$

The parameters in Eq. 65.1 incorporate the *a priori* unknown hadronic matrix element in terms of the very well-measured K_{e3} rate [25] in κ_+; long distance QED corrections in Δ_{EM} [31]; the Inami-Lim function for the short distance top-quark contribution [32] , including NLO QCD corrections [33, 34] , and the two-loop electroweak correction [30], all in X_t; and the charm-quark contributions due to short distance effects, including NNLO QCD corrections [35, 36] and NLO electroweak corrections via P_c [37], which also includes certain long distance terms dubbed $\delta P_{c,u}$ [27, 38]. An interesting approximate way to cast this result in terms of the CKM parameters λ, V_{cb}, $\bar{\rho}$ and $\bar{\eta}$ (see Eq. 12.4) [9] is:

$$\mathrm{B}(K^+ \to \pi^+\nu\bar{\nu}) \approx 1.6\times10^{-5}|V_{cb}|^4[(\sigma\bar{\eta})^2 + (\rho_c - \bar{\rho})^2] \quad (65.2)$$

where $\rho_c \approx 1.45$ and $\sigma \equiv \frac{1}{(1-\frac{1}{2}\lambda^2)^2}$. Thus, $\mathrm{B}(K^+ \to \pi^+\nu\bar{\nu})$ determines an ellipse in the $\bar{\rho}$, $\bar{\eta}$ plane with center $(\rho_c, 0)$ and

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

semiaxes $\approx \frac{1}{|V_{cb}|^2}\sqrt{\frac{\mathrm{B}(K^+\to\pi^+\nu\bar{\nu})}{1.6\times10^{-5}}}$ and $\frac{1}{\sigma|V_{cb}|^2}\sqrt{\frac{\mathrm{B}(K^+\to\pi^+\nu\bar{\nu})}{1.6\times10^{-5}}}$.

BNL-787 observed two candidate events [39,40] in the clean high π^+ momentum and one event [41] in the low-momentum region. The successor experiment BNL-949 observed one more in the high-momentum region [42] , and three more in the low-momentum region [43], yielding a branching ratio of $(1.73^{+1.15}_{-1.05})\times10^{-10}$ [44].

NA62 was commissioned in 2015 and took data in 2016, 2017, and 2018, and published results from those runs [45]. Data taking recommenced in 2021, and a result based on all data taken through 2022 was published in 2025 [46]. They resumed data taking in 2023 after some upgrades to the detector and in 2026 reported a result taking into account all data taken through 2024. They observed 84 events, including an estimated background of 30^{+4}_{-3} events, yielding $\mathrm{B}(K^+\to\pi^+\nu\bar{\nu}) = (9.6^{+1.9}_{-1.8})\times10^{-11}$ [47]. The experiment continues to run in 2025 and 2026.

Using values for the Wolfenstein parameters from Eq. 12.26, we estimate $\mathrm{B}(K^+\to\pi^+\nu\bar{\nu})_{SM} = (8.2\pm0.6)\times10^{-11}$, near the lower end of the measurements of BNL-787/949 and NA62. Current parametric uncertainty in the CKM angles can result in numbers with central values differing from this one by up to 10% [48].

The second golden mode is the neutral counterpart to our preceding discussion: $K_L\to\pi^0\nu\bar{\nu}$. It is dominantly CP-violating and free of hadronic uncertainties [25, 49, 50]. In the Standard Model, this mode is dominated by an intermediate top-quark state and does not suffer from the small uncertainty associated with the charm-quark intermediate state that affects $K^+\to\pi^+\nu\bar{\nu}$. The branching ratio is given by [9]:

$$\mathrm{B}(K_L\to\pi^0\nu\bar{\nu}) = \kappa_L\left(\frac{\mathrm{Im}(V_{ts}^\star V_{td})}{\lambda^5}X_t\right)^2 \approx 7.6\times10^{-5}|V_{cb}|^4\bar{\eta}^2\ . \tag{65.3}$$

As with the charged mode, the hadronic matrix element can be related to that measured in $K_{\ell3}$ decay and is incorporated into κ_L.

Our estimate for the branching ratio within the SM, again with parameters from Eq. 12.26, is $(2.9\pm0.3)\times10^{-11}$. Similarly to the charged kaon case, parametric uncertainty in the CKM angles can result in a central value that differs from this one by up to almost 20% [48].

Grossman and Nir (GN) [51] pointed out that, in a nearly model-independent manner, the two golden modes satisfy the relation $\mathrm{B}(K_L\to\pi^0\nu\bar{\nu}) \lesssim 4.3\ \mathrm{B}(K^+\to\pi^+\nu\bar{\nu})$. Using the BNL 787/949 90% CL bound on $K^+\to\pi^+\nu\bar{\nu}$, GN then predict $B(K_L\to\pi^0\nu\bar{\nu}) < 1.46\times10^{-9}$. Using instead the latest NA62 result, the GN upper bound becomes $B(K_L\to\pi^0\nu\bar{\nu}) < 5.2\times10^{-10}$.

The KOTO experiment at J-PARC, whose goal is to make an initial observation of this decay, has been in operation since 2013. It has made a series of data collection runs and has reported on three data sets thus far. In 2018 it published a 90% CL upper limit of 3.0×10^{-9} [52], based on 2015 data. They have run almost every year since, making incremental improvements to the experimental configuration between runs. In 2021 they published a result on the data taken between 2016 and 2018 in which three events were observed in the signal region [53], whereas the expected background was 1.22 events, mainly from charged kaons produced by K_L interactions in the downstream collimator. Conservatively assuming the three events were due to background, they extracted a 90% CL upper limit of 4.9×10^{-9}. Subsequent hardware and analysis improvements reduced the expected background to 0.26 in a sample of similar sensitivity taken in 2021. No events were observed in the signal region, and a 90% CL upper limit of 2.2×10^{-9} was established [54]. An increase of 3-5 in sensitivity is anticipated from runs planned in the next three years.

The current theoretical and experimental situation for the golden modes is summarized in Fig. 65.2. The red area corresponds to the 1σ SM prediction we obtain with the CKM parameter values taken from Eq. 12.26. The yellow region shows the result established by the combined BNL-787 and BNL-949 results, whereas the green region marks the new NA62 result for $K^+\to\pi^+\nu\bar{\nu}$. The black shaded region marks the GN exclusion, which lies significantly above the SM expectation, leaving a large window for discovery of new physics contributions by experiments seeking to measure $\mathrm{B}(K_L\to\pi^0\nu\bar{\nu})$. The 90% CL upper bound on this mode from the KOTO result published in 2025 [54] is shown in orange, and is seen to still lie in the GN excluded zone.

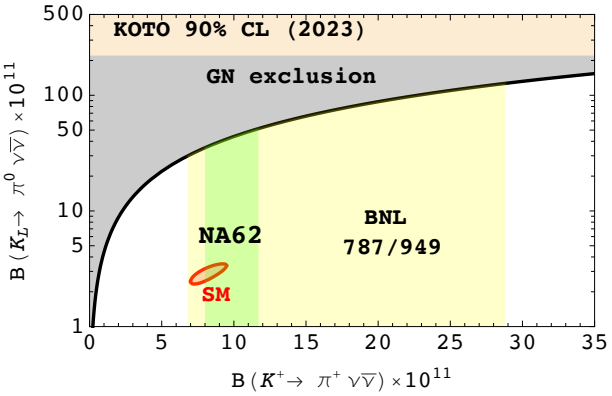

Figure 65.2: Summary of the current situation for the golden modes $K\to\pi\nu\bar{\nu}$. The red ellipse shows the 1σ SM prediction; the green (yellow) region corresponds to the NA62 (BNL787/949) 1σ measurement; and the orange region marks the 90% CL KOTO upper bound. The black shaded region shows the GN exclusion.

Much theoretical work has explored beyond the SM scenarios that can populate this window, as well as their correlations with other rare processes outside kaon physics. Although it would be relatively straightforward to establish the existence of new physics by observing deviations from their SM values in the $K\to\pi\nu\bar{\nu}$ rates, it would take much more extensive global fits to pinpoint the origin of any such deviation. Partial summaries with references focusing on quark flavor physics can be found in Refs. [9, 55–59]. Different possibilities emphasizing an interpretation of these modes as $K\to\pi+E_{\mathrm{miss}}$ can be found in Refs. [60–62].

There is a subtlety in converting the GN bound extracted from measurements of $K^+\to\pi^+\nu\bar{\nu}$ into an upper bound for $K_L\to\pi^0\nu\bar{\nu}$ as applied to KOTO [63]. This is due to a lack of sensitivity of the charged kaon experiments to a kinematic window near the pion mass. New physics appearing through a two body mode $K^+\to\pi^+X^0$, for an invisible X^0 particle with mass near the pion mass, has a much weaker constraint. The situation is illustrated in Fig. 65.3 which shows the BNL787/949 [44] (dashed black) and NA62 [64] (solid black) 90% c.l. limits on $K^+\to\pi^+X^0$ as a function of m_{X^0} assuming X^0 is stable. The implied GN bound for $K_L\to\pi^0X^0$, $B(K_L\to\pi^0X^0)\lesssim 4.3B(K^+\to\pi^+X^0)$ is shown as a blue line and can be compared with the actual KOTO [54] constraint on $K_L\to\pi^0X^0$ in red. Notice that the upper bound derived from NA62 is lower than that derived from BNL787/949 except for a small mass window. For $120\lesssim m_{X^0}\lesssim 150$ MeV, KOTO already has better sensitivity than that implied by the GN bound in this case. The possibility of new physics in this scenario has generated much theoretical speculation [65–75].

The search for a new light particle X^0 in $K^+\to\pi^+X^0$ has a long tradition covering both long-lived particles (*e.g.*, hyperphoton, axion, familon, *etc.*), and short-lived ones that decay to muon, electron, photon or neutrino pairs. The longstanding 90% CL upper limit on $K^+\to\pi^+X^0$ from BNL787/949 7.3×10^{-11} [42] for the case of massless X^0 has been slightly improved by NA62 to 5×10^{-11} as can be read from Fig. 65.3. These limits can also be reinterpreted in connection with a dark photon [76] or dark Z [77], and in this context, NA48/2 also constrained the mode $B(K^\pm\to\pi^\pm A'\to\pi^\pm e^+e^-)$ [78]. Complementary searches for new light particles in kaon experiments use modes with two pions and include the KTeV bound $B(K_L\to\pi^0\pi^0X^0\to\pi^0\pi^0\mu^+\mu^-) < 1\times10^{-10}$ [79] and the E391a bound $B(K_L\to\pi^0\pi^0X^0\to\pi^0\pi^0\gamma\gamma) < 2.4\times10^{-7}$ [80].

Neutrino pair modes with one extra pion, $K\to\pi\pi\nu\bar{\nu}$, are similarly dominated by short distance contributions in the SM [81–83]. Even though they are theoretically clean, they occur with very

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

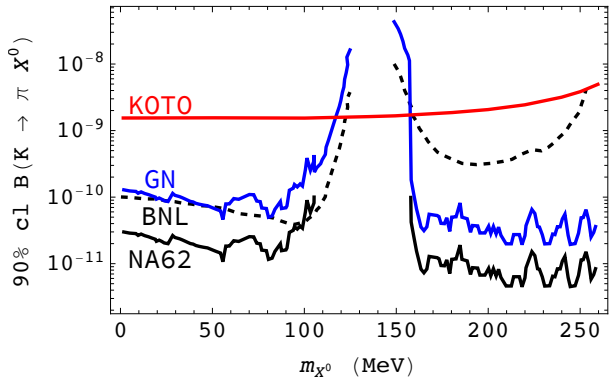

Figure 65.3: Summary of the current situation for $K \to \pi X^0$. The solid (dashed) black line shows the exclusion limit for $K^+ \to \pi^+ X^0$ from NA62 (BNL787/949) assuming X^0 is stable. The blue line marks the constraint implied for $K_L \to \pi^0 X^0$ by the Grossman-Nir relation and the red line marks the current KOTO limit on $K^+ \to \pi^+ X^0$.

low rates, with branching ratios of order 10^{-13}. The current best bound comes from KEK-391a, $B(K_L \to \pi^0\pi^0\nu\bar{\nu}) < 8.1 \times 10^{-7}$ at 90% CL [84]. There is also a bound for the charged kaon mode $B(K^+ \to \pi^+\pi^0\nu\bar{\nu}) < 4.3 \times 10^{-5}$ at 90% CL [85] from BNL-787. New physics contributions to these modes are discussed in [86].

65.4 Other constraints on Standard Model parameters

The decay $K_L \to \mu^+\mu^-$ has a short distance contribution sensitive to the CKM parameter $\bar{\rho}$, given by [5]:

$$\mathrm{B_{SD}}(K_L \to \mu^+\mu^-) \approx 2.7 \times 10^{-4} |V_{cb}|^4 (1.2 - \bar{\rho})^2. \quad (65.4)$$

This decay, however, is dominated by a long-distance contribution from a two-photon intermediate state. The absorptive (imaginary) part of the long-distance component is determined by the measured rate for $K_L \to \gamma\gamma$ to be $\mathrm{B_{abs}}(K_L \to \mu^+\mu^-) = (6.54 \pm 0.05) \times 10^{-9}$; and it almost completely saturates the observed rate $\mathrm{B}(K_L \to \mu^+\mu^-) = (6.84 \pm 0.11) \times 10^{-9}$ [87]. The difference between the observed rate and the absorptive component can be attributed to the (coherent) sum of the short-distance amplitude and the real part of the long-distance amplitude. A recent detailed evaluation that incorporates all known information from the ancillary modes in Fig. 65.1, finds $\mathrm{B}(K_L \to \mu^+\mu^-)_{SM} = (7.44^{+0.41}_{-0.34}) \times 10^{-9}$ [88].

By contrast, the decay $K_L \to e^+e^-$ is completely dominated by long distance physics and is easier to estimate. The result, $B(K_L \to e^+e^-) = (8.46 \pm 0.37) \times 10^{-12}$ [88], is in good agreement with the BNL-871 measurement, $(8.7^{+5.7}_{-4.1}) \times 10^{-12}$ [89].

The mode $K_S \to \mu^+\mu^-$ has a short distance contribution proportional to the square of the CKM parameter $\bar{\eta}$ entering at the 10^{-13} level [10]. It also has long distance contributions arising from the two photon intermediate state, which result in a rate $B(K_S \to \mu^+\mu^-)_{LD} = 5.1 \times 10^{-12}$ [10]. There is a 90% CL limit $B(K_S \to \mu^+\mu^-) < 2.1 \times 10^{-10}$ from LHCb [90, 91]. The interplay between $K_L \to \mu^+\mu^-$ and $K_S \to \mu^+\mu^-$ has been the subject of [92,93], and it has been pointed out that a measurement of time-dependent interference effects could be used to extract information on CKM angles from $K \to \mu^+\mu^-$ measurements [94, 95].

The decay $K_L \to \pi^0 e^+e^-$ is sensitive to the CKM parameter η through its CP-violating component. There are both direct and indirect CP-violating amplitudes that can interfere. The direct CP-violating amplitude is short distance dominated and has been calculated in detail within the SM [5]. The indirect CP-violating amplitude can be inferred from a measurement of $K_S \to \pi^0 e^+e^-$. The complete CP-violating contribution to the rate can be written as [96–98]:

$$\mathrm{B_{CPV}} \approx \left[15.7|a_S|^2 \pm 1.4 \left(\frac{|V_{cb}|^2\bar{\eta}}{10^{-4}} \right) |a_S| + 0.12 \left(\frac{|V_{cb}|^2\bar{\eta}}{10^{-4}} \right)^2 \right] \times 10^{-12} \quad (65.5)$$

where the three terms correspond to the indirect CP violation, the interference, and the direct CP violation, respectively. The parameter a_S has been extracted by NA48/1 from a measurement of $K_S \to \pi^0 e^+e^-$ with the result $|a_S| = 1.06^{+0.26}_{-0.21} \pm 0.07$ [99], as well as from a measurement of $K_S \to \pi^0\mu^+\mu^-$ with the result $|a_S| = 1.54^{+0.40}_{-0.32} \pm 0.06$ [100]. With current constraints on the CKM parameters, and assuming a positive sign for the interference term [98, 101], this implies that $\mathrm{B_{CPV}}(K_L \to \pi^0 e^+e^-) \approx (3.1 \pm 0.9) \times 10^{-11}$, where the three contributions to the central value from indirect, interference and direct CP violation are $(1.76, 0.9, 0.45) \times 10^{-11}$ respectively. It should be noted that more recent studies suggest a much larger uncertainty in the value of a_S [102].

$K_L \to \pi^0 e^+e^-$ also has a CP-conserving component dominated by a two-photon intermediate state. This component can be decomposed into an absorptive and a dispersive part. The absorptive part can be extracted from the measurement of the low $m_{\gamma\gamma}$ region of the $K_L \to \pi^0\gamma\gamma$ spectrum. The rate and the shape of the distribution $d\Gamma/dm_{\gamma\gamma}$ in $K_L \to \pi^0\gamma\gamma$ are well described in chiral perturbation theory in terms of three (*a priori*) unknown parameters [103–106].

Both KTeV and NA48 have studied the mode $K_L \to \pi^0\gamma\gamma$, reporting similar results. KTeV finds $B(K_L \to \pi^0\gamma\gamma) = (1.29 \pm 0.03_{\mathrm{stat}} \pm 0.05_{\mathrm{sys}}) \times 10^{-6}$ [107], while NA48 finds $B(K_L \to \pi^0\gamma\gamma) = (1.36 \pm 0.03_{\mathrm{stat}} \pm 0.03_{\mathrm{sys}} \pm 0.03_{\mathrm{norm}}) \times 10^{-6}$ [108]. Both experiments are consistent with a negligible rate in the low $m_{\gamma\gamma}$ region, suggesting a very small CP-conserving component $B_{\mathrm{CP}}(K_L \to \pi^0 e^+e^-) \sim \mathcal{O}(10^{-13})$ [98, 106, 108]. There remains some model dependence in the estimate of the dispersive part of the CP-conserving $K_L \to \pi^0 e^+e^-$ [98].

The related process, $K_L \to \pi^0\gamma e^+e^-$, is potentially an additional background to $K_L \to \pi^0 e^+e^-$ in some region of phase space [109]. This process has been observed with a branching ratio of $(1.62 \pm 0.14_{\mathrm{stat}} \pm 0.09_{\mathrm{sys}}) \times 10^{-8}$ [110].

The decay $K_L \to \gamma\gamma e^+e^-$ constitutes the dominant background to $K_L \to \pi^0 e^+e^-$. It was first observed by BNL-845 [111], and subsequently confirmed with a much larger sample by KTeV [112]. It has been estimated that this background will enter at about the 10^{-10} level [113, 114], comparable to or larger than the signal level. Because of this, the observation of $K_L \to \pi^0 e^+e^-$ at the SM level will depend on background subtraction with good statistics. Possible alternative strategies are discussed in [98] and references cited therein.

The 90% CL upper bound for the process $K_L \to \pi^0 e^+e^-$ is 2.8×10^{-10} [114]. For the closely related muonic process, the published upper bound is $\mathrm{B}(K_L \to \pi^0\mu^+\mu^-) \leq 3.8 \times 10^{-10}$ [115], compared with the SM prediction of $(1.9 \pm 0.5) \times 10^{-11}$. The latter assumes positive interference between the direct- and indirect-CP violating components and includes a CP-conserving component which contributes about 30% of the total [10, 116].

A study of $K_L \to \pi^0\mu^+\mu^-$ has indicated that it might be possible to extract the direct CP-violating contribution by a joint study of the Dalitz plot variables and the components of the μ^+ polarization [117]. The latter tends to be quite substantial so that large statistics may not be necessary.

Combined information from $K_L \to \pi^0\ell^+\ell^-$ as well as $K_L \to \mu^+\mu^-$ complements the $K \to \pi\nu\bar{\nu}$ measurements in constraining physics beyond the SM [118].

65.5 Other long distance dominated modes

The rates and spectra for the decays $K^+ \to \pi^+\ell^+\ell^-$ ($\ell = e$ or μ) have been measured [119–124] and are successfully described with a parameterization inspired by chiral perturbation theory but with large corrections beyond leading order [96, 97] (see [102, 125] for a review). The most recent NA62 result shows

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

good agreement between the electron and muon mode form factors [126]. NA62 has also obtained a first measurement of the forward-backward asymmetry in the muon mode [126].

The mode $K^+ \to \pi^+\pi^0 e^+ e^-$, analyzed by NA48/2 [127], is also dominated by long distance physics but it has been argued that measuring asymmetries can provide information on the short distance components [128]. The current status of these modes is discussed in [129]. Contributions to $K^+ \to \pi^+ e^+ e^- e^+ e^-$ beyond the double Dalitz decay in $K^+ \to \pi^+\pi^0$ are considered in [130], and have been measured by NA62 [131].

The decay $K^+ \to \pi^+\gamma\gamma$ can be predicted in terms of one unknown parameter to leading order in χPT, dubbed $\hat{c}$, resulting in a correlation between the rate and the diphoton mass spectrum [132]. Certain important corrections at the next order are also known [133]. The rate and spectrum were first measured by E787 [134], followed by NA48/2 [135] and NA62 [136]. The most recent measurement from NA62 [137], based on a sample of almost 4000 events, finds $B(K^+ \to \pi^+\gamma\gamma) = (9.61 \pm 0.17) \times 10^{-7}$ and a precise value for $\hat{c}$.

Much information was recorded by KTeV and NA48 on the rates and spectrum for the Dalitz pair conversion modes $K_L \to \ell^+\ell^-\gamma$ [138, 139], and $K_L \to \ell^+\ell^-\ell'^+\ell'^-$ for $\ell, \ell' = e$ or μ [22, 140], and LHCb has recently placed limits on $K_{L,S} \to \mu^+\mu^-\mu^+\mu^-$ [141]. All these results are used to test hadronic models and should eventually help unravel the underlying physics in $K_L \to \mu^+\mu^-$ [88, 92, 142, 143].

Despite the current theoretical uncertainties in $K^+ \to \pi^+\ell^+\ell^-$, $K_L \to \pi^0\ell^+\ell^-$ and $K_L \to \mu^+\mu^-$, these modes can serve to constrain new interactions, particularly when combined with $K \to \pi\nu\bar{\nu}$ and other observables. [86, 88, 93, 98, 118, 144–146].

66. *CPT* Invariance Tests in Neutral Kaon Decay

Revised August 2023 by M. Antonelli (INFN, Frascati), G. D'Ambrosio (INFN, Napoli) and M.S. Sozzi (Pisa U.; INFN, Pisa).

CPT theorem is based on three assumptions: quantum field theory, locality, and Lorentz invariance, and thus it is a fundamental probe of our basic understanding of particle physics. Strangeness oscillation in $K^0-\overline{K}^0$ system, described by the equation

$$i\frac{d}{dt}\begin{bmatrix}K^0\\ \overline{K}^0\end{bmatrix} = [M - i\Gamma/2]\begin{bmatrix}K^0\\ \overline{K}^0\end{bmatrix} ,$$

where M and Γ are hermitian matrices (see PDG review [1], references [2,3], and KLOE paper [4] for notations and previous literature), allows a very accurate test of CPT symmetry; indeed since CPT requires $M_{11} = M_{22}$ and $\Gamma_{11} = \Gamma_{22}$, the mass and width eigenstates, $K_{S,L}$, have a CPT-violating piece, δ, in addition to the usual CPT-conserving parameter ϵ:

$$K_{S,L} = \frac{1}{\sqrt{2\left(1+|\epsilon_{S,L}|^2\right)}}\left[\left(1+\epsilon_{S,L}\right)K^0 \pm \left(1-\epsilon_{S,L}\right)\overline{K}^0\right]$$

$$\epsilon_{S,L} = \frac{-i\Im\left(M_{12}\right) - \frac{1}{2}\Im\left(\Gamma_{12}\right) \mp \frac{1}{2}\left[M_{11} - M_{22} - \frac{i}{2}\left(\Gamma_{11} - \Gamma_{22}\right)\right]}{m_L - m_S + i(\Gamma_S - \Gamma_L)/2}$$

$$\equiv \epsilon \pm \delta. \tag{66.1}$$

Using the phase convention $\Im(\Gamma_{12}) = 0$, we determine the phase of ϵ to be $\varphi_{SW} \equiv \arctan\frac{2(m_L-m_S)}{\Gamma_S-\Gamma_L}$. Imposing unitarity to an arbitrary combination of K^0 and $\overline{K}^0$ wave functions, we obtain the Bell-Steinberger relation [5] connecting CP and CPT violation in the mass matrix to CP and CPT violation in the decay; in fact, neglecting $\mathcal{O}(\epsilon)$ corrections to the coefficient of the CPT-violating parameter, δ, we can write [4]

$$\Big[\frac{\Gamma_S+\Gamma_L}{\Gamma_S-\Gamma_L} + i\tan\phi_{\rm SW}\Big]\Big[\frac{\Re(\epsilon)}{1+|\epsilon|^2} - i\Im(\delta)\Big] = \frac{1}{\Gamma_S-\Gamma_L}\sum_f A_L(f)A_S^*(f), \tag{66.2}$$

where $A_{L,S}(f) \equiv A(K_{L,S} \to f)$. We stress that this relation is phase-convention-independent. The advantage of the neutral kaon system is that only a few decay modes give significant contributions to the r.h.s. in Eq. (66.2); in fact, defining for the hadronic modes

$$\alpha_i \equiv \frac{1}{\Gamma_S}\langle\mathcal{A}_L(i)\mathcal{A}_S^*(i)\rangle = \eta_i\ \mathcal{B}(K_S \to i),$$
$$i = \pi^0\pi^0, \pi^+\pi^-(\gamma), 3\pi^0, \pi^0\pi^+\pi^-(\gamma), \tag{66.3}$$

the recent data from CPLEAR, KLOE, KTeV, and NA48 have led to the following determinations (the analysis described in Ref. [4] has been updated by using the recent measurements of K_L branching ratios from KTeV [6, 7], NA48 [8, 9], the results described in the CP violation in K_L decays minireview, and the KLOE result [10])

$$\begin{aligned}\alpha_{\pi^+\pi^-} &= ((1.121\pm0.010) + i(1.061\pm0.010))\times10^{-3}\ ,\\ \alpha_{\pi^0\pi^0} &= ((0.493\pm0.005) + i(0.471\pm0.005))\times10^{-3}\ ,\\ \alpha_{\pi^+\pi^-\pi^0} &= ((0\pm2) + i(0\pm2))\times10^{-6},\\ |\alpha_{\pi^0\pi^0\pi^0}| &< 1.5\times10^{-6}\ \text{ at 95\% CL}\ .\end{aligned} \tag{66.4}$$

The semileptonic contribution to the right-handed side of Eq. (66.2) requires the determination of several observables: we define [2, 3]

$$\begin{aligned}\mathcal{A}(K^0 \to \pi^- l^+\nu) &= \mathcal{A}_0(1-y)\ ,\\ \mathcal{A}(K^0 \to \pi^+ l^-\nu) &= \mathcal{A}_0^*(1+y^*)(x_+ - x_-)^*\ ,\\ \mathcal{A}(\overline{K}^0 \to \pi^+ l^-\nu) &= \mathcal{A}_0^*(1+y^*)\ ,\\ \mathcal{A}(\overline{K}^0 \to \pi^- l^+\nu) &= \mathcal{A}_0(1-y)(x_+ + x_-)\ ,\end{aligned} \tag{66.5}$$

where x_+ (x_-) describes the violation of the $\Delta S = \Delta Q$ rule in CPT-conserving (violating) decay amplitudes, and y parameterizes CPT violation for $\Delta S = \Delta Q$ transitions. Taking advantage of their tagged $K^0(\overline{K}^0)$ beams, CPLEAR has measured $\Im(x_+)$, $\Re(x_-)$, $\Im(\delta)$, and $\Re(\delta)$ [11]. These determinations have been improved in Ref. [4] by including the information $A_S - A_L = 4[\Re(\delta) + \Re(x_-)]$ (valid at first order in the small parameters), where $A_{L,S}$ are the K_L and K_S semileptonic charge asymmetries, respectively, from the PDG [12] and the new KLOE semileptonic measurement [13]. Here we are also including the T-violating asymmetry measurement from CPLEAR [14] with a finer binning than appearing in the published article.

Table 66.1: Values, errors, and correlation coefficients for $\Re(\delta)$, $\Im(\delta)$, $\Re(x_-)$, $\Im(x_+)$, and $A_S + A_L$ obtained from a combined fit, including KLOE [4, 13] and CPLEAR [14].

	value	Correlations coefficients				
$\Re(\delta)$	$(4.3\pm2.7)\ \times10^{-4}$	1				
$\Im(\delta)$	$(-0.9\pm0.6)\times10^{-2}$	−0.40	1			
$\Re(x_-)$	$(-0.22\pm0.10)\times10^{-2}$	−0.14	−0.30	1		
$\Im(x_+)$	$(0.06\pm0.19)\times10^{-2}$	−0.12	−0.02	0.34	1	
A_S+A_L	$(-0.23\pm0.38)\times10^{-2}$	−0.12	−0.29	0.94	0.18	1

The value $A_S + A_L$ in Table 66.1 can be directly included in the semileptonic contributions to the Bell Steinberger relations in Eq. (66.2)

$$\begin{aligned}\sum_{\pi\ell\nu}&\langle\mathcal{A}_L(\pi\ell\nu)\mathcal{A}_S^*(\pi\ell\nu)\rangle\\ &= 2\Gamma(K_L\to\pi\ell\nu)(\Re(\epsilon) - \Re(y) - i(\Im(x_+) + \Im(\delta)))\\ &= 2\Gamma(K_L\to\pi\ell\nu)((A_S+A_L)/4 - i(\Im(x_+) + \Im(\delta)))\ .\end{aligned} \tag{66.6}$$

Defining

$$\alpha_{\pi\ell\nu} \equiv \frac{1}{\Gamma_S}\sum_{\pi\ell\nu}\langle\mathcal{A}_L(\pi\ell\nu)\mathcal{A}_S^*(\pi\ell\nu)\rangle + 2i\frac{\tau_{K_S}}{\tau_{K_L}}\mathcal{B}(K_L\to\pi\ell\nu)\Im(\delta)\ , \tag{66.7}$$

we find:

$$\alpha_{\pi\ell\nu} = ((-0.1\pm0.2) + i(-0.1\pm0.5))\times10^{-5}\ . \tag{66.8}$$

Table 66.2: Summary of results: values, errors, and correlation coefficients for $\Re(\epsilon)$, $\Im(\delta)$, $\Re(\delta)$, and $\Re(x_-)$.

	value	Correlations coefficients			
$\Re(\epsilon)$	$(161.2\pm0.5)\times10^{-5}$	+1			
$\Im(\delta)$	$(-0.3\pm1.4)\times10^{-5}$	+0.08	1		
$\Re(\delta)$	$(2.6\pm2.5)\times10^{-4}$	+0.00	−0.05	1	
$\Re(x_-)$	$(-2.7\pm1.0)\times10^{-3}$	+0.05	0.13	−0.30	1

The analysis of semileptonic decay asymmetries implicitly assumes Lepton Flavour Universality (LFU) of any effect violating CPT or $\Delta S = \Delta Q$, through the use of a single set of x, y parameters, consistently with the availability of experimental information on A_S for the electron mode only. The explicit LFU assumption in the input BR measurements has been lifted exploiting the measurement of $BR(K_S \to \pi\mu\nu)$ Ref. [15], with no effect on the numerical results.

Inserting the values of the α parameters into Eq. (66.2), we find

$$\Re(\epsilon) = (161.2 \pm 0.5) \times 10^{-5},$$
$$\Im(\delta) = (-0.3 \pm 1.4) \times 10^{-5}\,. \qquad (66.9)$$

The complete information on Eq. (66.9) is given in Table 66.2.

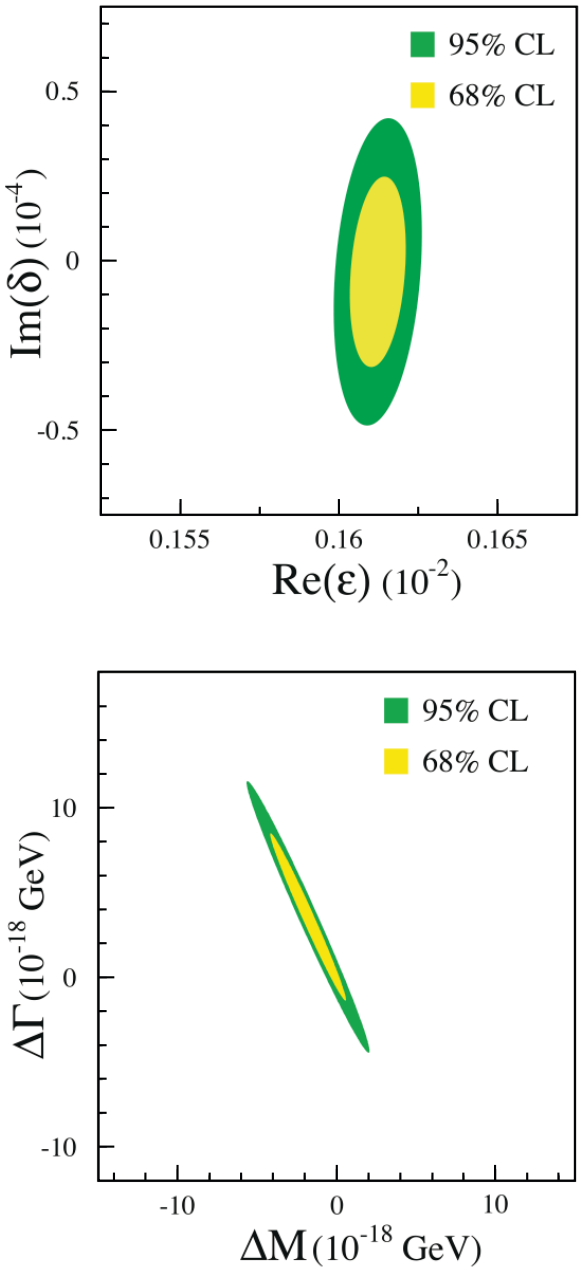

Figure 66.1: Top: allowed region at 68% and 95% C.L. in the $\Re(\epsilon)$, $\Im(\delta)$ plane. Bottom: allowed region at 68% and 95% C.L. in the $\Delta M, \Delta\Gamma$ plane.

Now the agreement with CPT conservation, $\Im(\delta) = \Re(\delta) = \Re(x_-) = 0$, is at 18% C.L.

The allowed region in the $\Re(\epsilon) - \Im(\delta)$ plane at 68% CL and 95% C.L. is shown in the top panel of Fig. 66.1.

The process giving the largest contribution to the size of the allowed region is $K_L \to \pi^+\pi^-$, through the uncertainty on ϕ_{+-}.

The limits on $\Im(\delta)$ and $\Re(\delta)$ can be used to constrain the $K^0 - \overline{K}^0$ mass and width difference

$$\delta = \frac{i(m_{K^0} - m_{\overline{K}^0}) + \frac{1}{2}(\Gamma_{K^0} - \Gamma_{\overline{K}^0})}{\Gamma_S - \Gamma_L} \cos\phi_{SW} e^{i\phi_{SW}} [1 + \mathcal{O}(\epsilon)]\,.$$

The allowed region in the $\Delta M = (m_{K^0} - m_{\overline{K}^0}), \Delta\Gamma = (\Gamma_{K^0} - \Gamma_{\overline{K}^0})$ plane is shown in the bottom panel of Fig. 66.1. As a result, we improve on the previous limits (see for instance, P. Bloch in Ref. [12]) and in the limit $\Gamma_{K^0} - \Gamma_{\overline{K}^0} = 0$ we obtain

$$-4.0\times10^{-19}\ \text{GeV} < m_{K^0} - m_{\overline{K}^0} < 4.0\times10^{-19}\ \text{GeV} \quad \text{at 95 \% C.L.}$$

67. V_{ud}, V_{us} the Cabibbo Angle, and CKM Unitarity

Revised August 2025 by E. Blucher (Chicago U.), G. D'Ambrosio (INFN, Napoli) and W.J. Marciano (BNL).

The Cabibbo-Kobayashi-Maskawa (CKM) [1, 2] three-generation quark mixing matrix written in terms of the Wolfenstein parameters (λ, A, ρ, η) [3] nicely illustrates the orthonormality constraint of unitarity, as well as the central role played by λ.

$$V_{\rm CKM} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} = \begin{pmatrix} 1-\lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1-\lambda^2/2 & A\lambda^2 \\ A\lambda^3(1-\rho-i\eta) & -A\lambda^2 & 1 \end{pmatrix} + \mathcal{O}(\lambda^4)\ . \tag{67.1}$$

That cornerstone parameter is a carryover from the two-generation Cabibbo angle, $\lambda = \sin(\theta_{\rm Cabibbo}) = V_{us}$. Its value is an important component in tests of CKM unitarity.

Up until 2003, the precise value of λ was controversial, with kaon decays (specifically $K \to \pi e \nu$) branching fractions suggesting [4] $\lambda \simeq 0.220$, while indirect determinations via V_{ud} obtained from nuclear β-decays combined with unitarity preferred a somewhat larger $\lambda \simeq 0.225 - 0.230$. This difference implied a 2 - 2.5 sigma deviation from the first row unitarity requirement

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 1, \tag{67.2}$$

a possible hint [5, 6] of new physics effects. Below, we describe the current status of V_{ud} and V_{us}, and their implication for the unitarity test in Eq. (67.2). (Since $|V_{ub}|^2 \simeq 1.7\times10^{-5}$ is negligibly small, it is ignored in this discussion.) Eq. (67.2) is currently the most stringent test of unitarity in the CKM matrix. As we shall see, it is again showing signs of a possible 2 to 3 sigma inconsistency.

67.1 V_{ud}

Precise values of V_{ud} have been obtained from superallowed nuclear, neutron, and pion beta decays. Currently, the best determination of V_{ud} comes from analysis of a set of 15 precisely measured superallowed nuclear beta-decays [5,6] ($0^+ \to 0^+$ transitions). Measuring their half-lives, t, and Q values gives the decay rate factors, f, which lead to a precise determination of V_{ud} via [7–12]. Based on several decades of dedicated studies, Hardy and Towner recently updated the average of the half-life, $\overline{\mathcal{F}t}$, [6]

$$|V_{ud}|^2 = \frac{K}{2G_F^2(1+\Delta_{\rm R}^{\rm V})\overline{\mathcal{F}t}} = \frac{2912.95 \pm 0.54}{\overline{\mathcal{F}t}} = 0.94815 \pm 0.00060 \quad \text{for } \Delta_R^V = 2.454(19)\%, \tag{67.3}$$

where $K/(\hbar c)^6 = 2\pi^3\hbar \ln 2/(m_e c^2)^5 = 8120.27648(26) \times 10^{-10} GeV^{-4}s$, Δ_R^V denotes the so-called inner or universal electroweak radiative corrections (RC) to superallowed nuclear beta decays. A dispersion relation (DR) calculational approach [13] to quantum loop corrections, specifically the gamma-W box diagram, gives $\Delta_R^V = 0.02467(22)$. Actually the authors of Ref. [13–19] have combined the different theoretical calculations leading to $\Delta_R^V = 0.02467(27)$ and

$$V_{ud} = 0.97367(11)_{\rm exp}(13)_{\Delta_R^V}(27)_{\rm NS}\ (32)_{\rm total}\ \text{(superallowed)}\ . \tag{67.4}$$

As a result of its small uncertainty and more rigorous theoretical footing, we use this value below. A somewhat different approach [16] found Δ_R^V= 0.02426(32). These recent values are roughly consistent. Both are larger than the 2018 PDG value of 0.02361(38). Implications and possible nuclear physics modifications of those studies are still under scrutiny [20–24]. Note that an additional uncertainty $(54)_{\rm NS}$ from nuclear structure (NS) [21] has been recently included [6] in that master formula. This recent determination of V_{ud} has shifted significantly down compared to the 2018 PDG value of 0.97420(21). In addition, NS uncertainties are now the dominant contribution to the overall uncertainty. Taken at face value, along with current V_{us} determinations (see subsection 67.2), the reduced V_{ud} would seem to violate the first row unitarity requirement, and thus suggest the presence of deviations from unitarity or unaccounted uncertainties.

Measurements of the neutron lifetime, τ_n, and the ratio of axial-vector/vector couplings, $g_A \equiv G_A/G_V$, via neutron decay asymmetries combined with the inner radiative corrections can also be used to determine V_{ud} via the precise formula [14, 25]

$$|V_{ud}|^2 = \frac{5099.33\ \text{s}}{\tau_n(1+3{g_A}^2)(1+\Delta_R)}, \tag{67.5}$$

where $\Delta_R = 0.03983(27)$ represents radiative corrections [14]. We present the V_{ud} results using either the the current published world averages [26] or the best measured values for λ [27] and for τ_n [28]. The average leads to

$$\tau_n^{\rm ave} = 879.4(6)\ \text{s}\ \ (1.6\ \text{PDG scale factor})$$
$$g_A^{\rm ave} = 1.2756(13),\ (2.6\ \text{PDG scale factor}), \tag{67.6}$$

$$|V_{ud}^{n,PDG}| = 0.97441(28)_{\tau_n}(82)_\lambda(13)_{\Delta_R}(88)_{\rm TOT}, \tag{67.7}$$

while the best values lead to

$$|V_{ud}^{n,best}| = 0.97413(20)_{\tau_n}(35)_\lambda(13)_{\Delta_R}(42)_{\rm TOT}. \tag{67.8}$$

Both central values are similar to the superallowed nuclear beta decay result reported above. Reconciliation with CKM unitarity suggests a shorter neutron lifetime near 878.5 s or a smaller g_A. We note that the most precise recent neutron lifetime update reported [28], $\tau_n = 877.75(34)$ s, has an uncertainty about half as big as the average given in Eq. 67.6. It corresponds to $|V_{ud}| = 0.9746(8)$, a value more in keeping with unitarity expectations; but too large an uncertainty from g_A to be meaningful. Future neutron studies [29, 30] are expected to resolve any current inconsistencies and further reduce the uncertainties in g_A and τ_n making them a potentially better way to determine V_{ud} without the nuclear physics uncertainties.

The PIBETA experiment at PSI measured the very small ($\mathcal{O}(10^{-8})$) branching ratio for $\pi^+ \to \pi^o e^+ \nu_e$ with about $\pm 0.6\%$ precision. Its result gives [31]

$$|V_{ud}| = 0.9739(27)\left[\frac{BR(\pi^+ \to e^+\nu_e(\gamma))}{1.2325\times10^{-4}}\right]^{\frac{1}{2}}, \tag{67.9}$$

which is normalized using the very precisely measured $BR(\pi^+ \to e^+\nu_e(\gamma)) = 1.2325(23) \times 10^{-4}$ [7], rather than the theoretical branching ratio of $1.2350(2)\times10^{-4}$, which if used, would increase $|V_{ud}|$ to 0.9749(27). Theoretical uncertainties in pion beta decay are very small [32], leaving open more than an order of magnitude improvement of its experimental branching ratio before theory uncertainties become a problem. Although challenging, improved measurements of pion beta decay currently under discussion would allow this decay mode to compete with superallowed beta decays and future neutron decay efforts for the most precise direct $|V_{ud}|$ determination.

67.2 V_{us}

$|V_{us}|$ may be directly obtained from kaon decays, hyperon decays, and tau decays. Early determinations most often used $K\ell3$ decays:

$$\Gamma_{K\ell3} = \frac{G_F^2 M_K^5}{192\pi^3} S_{EW}(1+\delta_K^\ell+\delta_{SU2})C^2\,|V_{us}|^2\,f_+^2(0)I_K^\ell. \tag{67.10}$$

Here, ℓ refers to either e or μ, G_F is the Fermi constant, M_K is the kaon mass, S_{EW} is the short-distance radiative correction, δ_K^ℓ is the mode-dependent long-distance radiative correction, $f_+(0)$ is the calculated form factor at zero momentum transfer for the $\ell\nu$ system, and I_K^ℓ is the phase-space integral, which depends on measured semileptonic form factors. For charged kaon decays, δ_{SU2} is the deviation from one of the ratio of $f_+(0)$ for the charged to neutral kaon decay; it is zero for the neutral kaon. C^2 is 1 (1/2) for neutral (charged) kaon decays. Most early determinations of

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

$|V_{us}|$ were based solely on $K \to \pi e\nu$ decays; $K \to \pi\mu\nu$ decays were not used because of large uncertainties in I_K^μ. The experimental measurements are the semileptonic decay widths (based on the semileptonic branching fractions and lifetime) and form factors (allowing calculation of the phase space integrals). Theory is needed for S_{EW}, δ_K^ℓ, δ_{SU2}, and $f_+(0)$.

Many measurements during the last 20 years have resulted in a shift in $|V_{us}|$. Most importantly, the $K \to \pi e\nu$ branching fractions are significantly different than much earlier PDG averages, probably as a result of inadequate treatment of radiation in older experiments. This effect was first observed by BNL E865 [33] in the charged kaon system and then by KTeV [34,35] in the neutral kaon system; subsequent measurements were made by KLOE [36–39], NA48 [40–42], and ISTRA+ [43]. Current averages (*e.g.*, by the PDG [44] or Flavianet [45]) of the semileptonic branching fractions are based only on recent, high-statistics experiments where the treatment of radiation is clear. In addition to measurements of branching fractions, new measurements of lifetimes [46] and form factors [47–51], have resulted in improved precision for all of the experimental inputs to $|V_{us}|$. Precise measurements of form factors for $K_{\mu 3}$ decay make it possible to use both semileptonic decay modes to extract V_{us}.

Following the analysis of Moulson [25, 52] and the Flavianet group [45, 53, 54], along with recent improvements in the QED radiative corrections [55], one finds [56], after including the isospin violating effect, δ_{SU2} , the values of $|V_{us}|f_+(0)$ in Table 67.1. The average of these measurements, including correlation effects [25, 56–58] gives [14]

$$f_+(0)|V_{us}| = 0.21656(35) \quad \text{FLAVIANET} \tag{67.11}$$

where the errors correspond to kaon experimental parameters and radiative corrections, respectively, leading, as we shall see, to $|V_{us}| = 0.22330(35)_{\rm exp}(39)_{\rm LAT}(8)_{\rm RC+IB}(53)_{TOT}$.

Lattice QCD calculations of $f_+(0)$ have been carried out for 2, 2+1, and 2+1+1 quark flavors and range from about 0.96 to 0.97. Here, we illustrate recent FLAG (2020) updated averages [59] for 2+1 and 2+1+1 flavors:

$$\begin{aligned} f_+(0) &= 0.9677(27) \quad N_f = 2+1 \\ f_+(0) &= 0.9698(17) \quad N_f = 2+1+1 \end{aligned} \tag{67.12}$$

Updating the result for $N_f = 2+1+1$ we obtain for V_{us} from Eq. (67.11) and Eq. (67.12),

$$\begin{aligned} |V_{us}| &= 0.2238(4)_{\rm exp+RC}(6)_{\rm lattice} \ (N_f = 2+1, \ K_{\ell 3} \text{ decays}) \\ &= 0.22330(4)_{\rm exp+RC}(4)_{\rm lattice} \ (N_f = 2+1+1, \ K_{\ell 3} \text{ decays}) \end{aligned} \tag{67.13}$$

based on ref. [25] and ref. [56]

Table 67.1: $|V_{us}|f_+(0)$ from $K\ell 3$, based on ref. [25, 56]

Decay Mode	$\lvert V_{us}\rvert f_+(0)$
$K^\pm e3$	0.2169(6)
$K^\pm \mu 3$	0.2168(10)
$K_L e3$	0.2162(5)
$K_L \mu 3$	0.2165(6)
$K_S e3$	0.2169(8)
$K_S \mu 3$	0.2125(47)
Average (including correlation effects [25, 56])	0.21656(35)

A value of V_{us} can also be obtained from a comparison of the radiative inclusive decay rates for $K \to \mu\nu(\gamma)$ and $\pi \to \mu\nu(\gamma)$ combined with a lattice gauge theory calculation of f_{K^+}/f_{π^+} via

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.23871(20) \left[\frac{\Gamma(K \to \mu\nu(\gamma))}{\Gamma(\pi \to \mu\nu(\gamma))}\right]^{\frac{1}{2}} \tag{67.14}$$

with the small error coming from electroweak radiative corrections [60–62]; these corrections were confirmed by direct lattice calculation of the kaon and pion leptonic decay rates [61, 62].

A recent fit [14, 25] gives

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27679(28)_{\rm BR}(20)_{\rm corr}. \tag{67.15}$$

Employing the FLAG [59] lattice QCD averages for the isospin broken decay constants

$$\frac{f_{K^+}}{f_{\pi^+}} = 1.1978(22) \quad N_f = 2+1+1 \tag{67.16}$$

leading to

$$\frac{|V_{us}|}{|V_{ud}|} = 0.23108(51) \ (N_f = 2+1+1, \ K_{\mu 2} \text{ decays}). \tag{67.17}$$

Actually we can average the Cabibbo angle determinations from kaons: from $K_{\ell 3}$ decays in eqs. 67.11, 67.12 and from $K_{\mu 2}$ in eqs. 67.15, 67.16 with $N_f = 2+1+1$. Assuming 20% correlation between $(|V_{us}/V_{ud}|f_K/f_\pi)$ and (f_K/f_π) we obtain

$$V_{us} = 0.22431(85) \quad \text{S} = 2.5. \tag{67.18}$$

The result shown in Eq. 67.18 is what we use when we consider the first row test of CKM unitarity. The quoted uncertainty includes a scale factor of 2.5 to account for the discrepancies between the values of V_{us} obtained from $K\ell 3$ and $K\mu 2$ decays.

This is the current status of the Cabibbo Angle determination from the kaon sector, and theoretical and experimental progress is expected to clarify the situation soon.

It should be mentioned that hyperon decay fits suggest [63]

$$|V_{us}| = 0.2250(27) \text{ (Hyperon Decays)} \tag{67.19}$$

modulo SU(3) breaking effects that could shift that value up or down. We note that a representative effort [64] that incorporates SU(3) breaking found $V_{us} = 0.226(5)$. Strangeness changing tau decays, averaging both inclusive and exclusive measurements, give [65, 66]

$$|V_{us}| = 0.2207(14) \text{ (Tau Decays)} \ , \tag{67.20}$$

which differs by about 2 sigma from the kaon determination discussed above, and would, if combined with V_{ud} from super-allowed beta decays, lead to a 4 sigma deviation from unitarity. This discrepancy results mainly from the inclusive tau decay results that rely on Finite Energy Sum Rule techniques and assumptions, as well as experimental uncertainties. Recent investigation of that approach suggests a larger value for V_{us}, which is more in accord with other determinations [67].

Employing the values of V_{ud} and V_{us} with an error scale factor of 2 from Eq. (67.4) and the average obtained after rescaling the errors from mEq. 67.18 leads to the unitarity consistency check

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9983(6)(4), \tag{67.21}$$

where the first error is the uncertainty from $|V_{ud}|^2$ and the second error is the uncertainty from the average $|V_{us}|^2$ in Eq. 67.18 . One finds about an overall 2 sigma deviation from unitarity. (The deviation increases to 3 sigma if nuclear structure uncertainties are ignored.) That deviation could be due a problem with $|V_{ud}|$ theory (RC or NS), the lattice determination of $f_+(0)$ or new physics.

67.3 CKM Unitarity Constraints

The current 2 sigma experimental disagreement with unitarity, $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9983(7)$, still provides strong confirmation of Standard Model radiative corrections (which range between 3-4% depending on the nucleus used) at a high significance level [68]. In addition, it implies constraints on "New Physics" effects at both the tree and quantum loop levels. Those effects could be in the form of contributions to nuclear beta decays, K decays and/or muon decays, with the last of these providing normalization via the muon lifetime [69], which is used to obtain the Fermi constant, $G_\mu = 1.1663787(6) \times 10^{-5}\text{GeV}^{-2}$.

In the following examples, we illustrate the implications of CKM unitarity for (1) exotic muon decays [70] (beyond ordinary

muon decay $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$) and (2) new heavy quark mixing V_{uD} [71]. Other examples in the literature [72, 73] include Z_χ boson quantum loop effects, supersymmetry, leptoquarks, compositeness etc.

68. CP Violation in K_L^0 Decays

Revised August 2023 by C.-J. Lin (LBNL).

The symmetries C (particle-antiparticle interchange) and P (space inversion) hold for strong and electromagnetic interactions. After the discovery of large C and P violation in the weak interactions, it appeared that the product CP was a good symmetry. In 1964 CP violation was observed in K^0 decays at a level given by the parameter $\epsilon \approx 2.3 \times 10^{-3}$.

A unified treatment of CP violation in K, D, B, and B_s mesons is given in "CP Violation in Meson Decays" by D. Kirkby and Y. Nir in this *Review*. A more detailed review including a thorough discussion of the experimental techniques used to determine CP violation parameters is given in a book by K. Kleinknecht [1]. Here we give a concise summary of the formalism needed to define the parameters of CP violation in K_L decays, and a description of our fits for the best values of these parameters.

68.1 Formalism for CP violation in Kaon decay

CP violation has been observed in the semi-leptonic decays $K_L^0 \to \pi^\mp \ell^\pm \nu$, and in the nonleptonic decay $K_L^0 \to 2\pi$. The experimental numbers that have been measured are

$$A_L = \frac{\Gamma(K_L^0 \to \pi^- \ell^+ \nu) - \Gamma(K_L^0 \to \pi^+ \ell^- \nu)}{\Gamma(K_L^0 \to \pi^- \ell^+ \nu) + \Gamma(K_L^0 \to \pi^+ \ell^- \nu)} \tag{68.1a}$$

$$\eta_{+-} = A(K_L^0 \to \pi^+\pi^-)/A(K_S^0 \to \pi^+\pi^-) = |\eta_{+-}|\, e^{i\phi_{+-}} \tag{68.1b}$$

$$\eta_{00} = A(K_L^0 \to \pi^0\pi^0)/A(K_S^0 \to \pi^0\pi^0) = |\eta_{00}|\, e^{i\phi_{00}} \ . \tag{68.1c}$$

CP violation can occur either in the $K^0 - \overline{K}^0$ mixing or in the decay amplitudes. Assuming CPT invariance, the mass eigenstates of the K^0–$\overline{K}^0$ system can be written

$$|K_S\rangle = p|K^0\rangle + q|\overline{K}^0\rangle \ , \quad |K_L\rangle = p|K^0\rangle - q|\overline{K}^0\rangle \ . \tag{68.2}$$

If CP invariance held, we would have $q = p$ so that K_S would be CP-even and K_L CP-odd. (We define $|\overline{K}^0\rangle$ as $CP\ |K^0\rangle$). CP violation in K^0–$\overline{K}^0$ mixing is then given by the parameter $\widetilde{\epsilon}$ where

$$\frac{p}{q} = \frac{(1+\widetilde{\epsilon})}{(1-\widetilde{\epsilon})} \ . \tag{68.3}$$

CP violation can also occur in the decay amplitudes

$$A\Big(K^0 \to \pi\pi(I)\Big) = A_I e^{i\delta_I} \ , \quad A\Big(\overline{K}^0 \to \pi\pi(I)\Big) = A_I^* e^{i\delta_I} \ , \tag{68.4}$$

where I is the isospin of $\pi\pi$, δ_I is the final-state phase shift, and A_I would be real if CP invariance held. The CP-violating observables are usually expressed in terms of ϵ and ϵ' defined by

$$\eta_{+-} = \epsilon + \epsilon' \ , \quad \eta_{00} = \epsilon - 2\epsilon' \ . \tag{68.5a}$$

One can then show [2]

$$\epsilon = \widetilde{\epsilon} + i\ \Big(\mathrm{Im}\ A_0/\mathrm{Re}\ A_0\Big) \ , \tag{68.5b}$$

$$\sqrt{2}\epsilon' = ie^{i(\delta_2-\delta_0)}(\mathrm{Re}\, A_2/\mathrm{Re}\, A_0)\ \Big(\mathrm{Im}\, A_2/\mathrm{Re}\, A_2 - \mathrm{Im}\, A_0/\mathrm{Re}\, A_0\Big) \ , \tag{68.5c}$$

$$A_L = 2\mathrm{Re}\ \epsilon/(1+|\epsilon|^2) \approx 2\mathrm{Re}\ \epsilon \ . \tag{68.5d}$$

In Eq. (68.5a), small corrections [3] of order $\epsilon' \times \mathrm{Re}\ (A_2/A_0)$ are neglected, and Eq. (68.5d) assumes the $\Delta S = \Delta Q$ rule.

The quantities Im A_0, Im A_2, and Im $\widetilde{\epsilon}$ depend on the choice of phase convention, since one can change the phases of K^0 and $\overline{K}^0$ by a transformation of the strange quark state $|s\rangle \to |s\rangle\ e^{i\alpha}$; of course, observables are unchanged. It is possible by a choice of phase convention to set Im A_0 or Im A_2 or Im $\widetilde{\epsilon}$ to zero, but none of these is zero with the usual phase conventions in the Standard Model. The choice Im $A_0 = 0$ is called the Wu-Yang phase convention [4], in which case $\epsilon = \widetilde{\epsilon}$. The value of ϵ' is independent of phase convention, and a nonzero value demonstrates CP violation in the decay amplitudes, referred to as direct CP violation. The possibility that direct CP violation is essentially zero, and that CP violation occurs only in the mixing matrix, was referred to as the superweak theory [5].

By applying CPT invariance and unitarity the phase of ϵ is given approximately by

$$\phi_\epsilon \ \approx\ \tan^{-1}\frac{2(m_{K_L} - m_{K_S})}{\Gamma_{K_S} - \Gamma_{K_L}} \approx 43.52 \pm 0.05^\circ \ , \tag{68.6a}$$

while Eq. (68.5c) gives the phase of ϵ' to be

$$\phi_{\epsilon'} = \delta_2 - \delta_0 + \frac{\pi}{2} \approx 42.3 \pm 1.5^\circ \ , \tag{68.6b}$$

where the numerical value is based on an analysis of π–π scattering using chiral perturbation theory [6]. The approximation in Eq. (68.6a) depends on the assumption that direct CP violation is very small in all K^0 decays. This is expected to be good to a few tenths of a degree, as indicated by the small value of ϵ' and of η_{+-0} and η_{000}, the CP-violation parameters in the decays $K_S \to \pi^+\pi^-\pi^0$ [7], and $K_S \to \pi^0\pi^0\pi^0$ [8]. The relation in Eq. (68.6a) is exact in the superweak theory, so this is sometimes called the superweak-phase $\phi_{\rm SW}$. An important point for the analysis is that $\cos(\phi_{\epsilon'} - \phi_\epsilon) \simeq 1$. The consequence is that only two real quantities need be measured, the magnitude of ϵ and the value of (ϵ'/ϵ), including its sign. The measured quantity $|\eta_{00}/\eta_{+-}|^2$ is very close to unity so that we can write

$$|\eta_{00}/\eta_{+-}|^2 \approx 1 - 6\mathrm{Re}\ (\epsilon'/\epsilon) \approx 1 - 6\epsilon'/\epsilon \ , \tag{68.7a}$$

$$\mathrm{Re}(\epsilon'/\epsilon) \approx \frac{1}{3}(1 - |\eta_{00}/\eta_{+-}|) \ . \tag{68.7b}$$

From the experimental measurements in this edition of the *Review*, and the fits discussed in the next section, one finds

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}, \tag{68.8a}$$

$$\phi_\epsilon = (43.5 \pm 0.5)^\circ, \tag{68.8b}$$

$$\mathrm{Re}(\epsilon'/\epsilon) \approx \epsilon'/\epsilon = (1.66 \pm 0.23) \times 10^{-3}, \tag{68.8c}$$

$$\phi_{+-} = (43.4 \pm 0.5)^\circ, \tag{68.8d}$$

$$\phi_{00} - \phi_{+-} = (0.34 \pm 0.32)^\circ, \tag{68.8e}$$

$$A_L = (3.32 \pm 0.06) \times 10^{-3}. \tag{68.8f}$$

Direct CP violation, as indicated by ϵ'/ϵ, is expected in the Standard Model. However, the numerical value cannot be reliably predicted because of theoretical uncertainties [9]. The value of A_L agrees with Eq. (68.5d). The values of ϕ_{+-} and $\phi_{00} - \phi_{+-}$ are used to set limits on CPT violation [see "Tests of Conservation Laws"].

68.2 Fits for K_L^0 CP-violation parameters

In recent years, K_L^0 CP-violation experiments have improved our knowledge of CP-violation parameters,

and their consistency with the expectations of CPT invariance and unitarity. To determine the best values of the CP-violation parameters in $K_L^0 \to \pi^+\pi^-$ and $\pi^0\pi^0$ decay, we make two types of fits, one for the phases ϕ_{+-} and ϕ_{00} jointly with Δm and τ_S, and the other for the amplitudes $|\eta_{+-}|$ and $|\eta_{00}|$ jointly with the $K_L^0 \to \pi\pi$ branching fractions.

68.2.1 *Fits to ϕ_{+-}, ϕ_{00}, $\Delta\phi$, Δm, and τ_S data*

These are joint fits to the data on ϕ_{+-}, ϕ_{00}, the phase difference $\Delta\phi = \phi_{00} - \phi_{+-}$, the $K_L^0 - K_S^0$ mass difference Δm, and the K_S^0 mean life τ_S, including the effects of correlations.

Measurements of ϕ_{+-} and ϕ_{00} are highly correlated with Δm and τ_S. Some measurements of τ_S are correlated with Δm. The correlations are given in the footnotes of the ϕ_{+-} and ϕ_{00} sections of the K_L^0 Listings, and the τ_S section of the K_S^0 Listings.

In most cases, the correlations are quoted as 100%, with the value and error of ϕ_{+-} or ϕ_{00} given at a fixed value of Δm and τ_S, with additional terms specifying the dependence of the value on Δm and τ_S. These cases lead to diagonal bands in Figs. 68.1

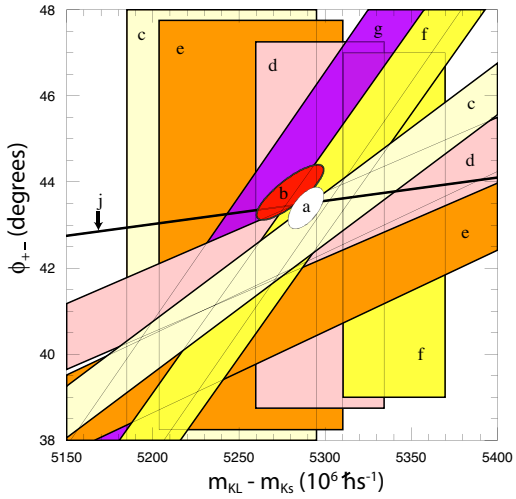

Figure 68.1: ϕ_{+-} vs Δm for experiments which do not assume CPT invariance. Δm measurements appear as vertical bands spanning $\Delta m \pm 1\sigma$, cut near the top and bottom to aid the eye. Most ϕ_{+-} measurements appear as diagonal bands spanning $\phi_{+-} \pm \sigma_\phi$. Data are labeled by letters: "b"–FNAL KTeV, "c"–CERN CPLEAR, "d"–FNAL E773, "e"–FNAL E731, "f"–CERN, "g"–CERN NA31, and are cited in Table 68.1. The narrow band "j" shows ϕ_{SW}. The ellipse "a" shows the $\chi^2 = 1$ contour of the fit result.

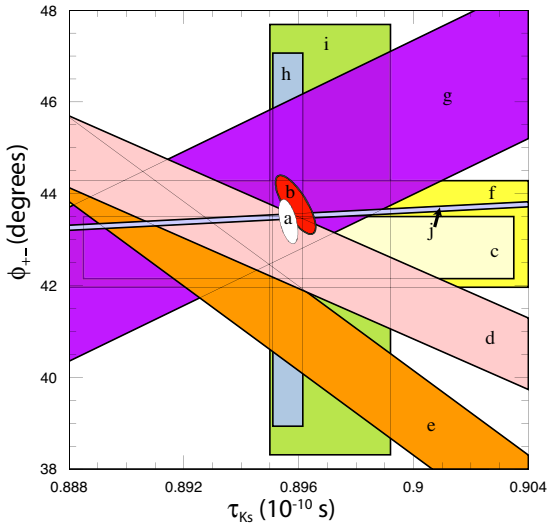

Figure 68.2: ϕ_{+-} vs τ_S. τ_S measurements appear as vertical bands spanning $\tau_S \pm 1\sigma$, some of which are cut near the top and bottom to aid the eye. Most ϕ_{+-} measurements appear as diagonal or horizontal bands spanning $\phi_{+-} \pm \sigma_\phi$. Data are labeled by letters: "b"–FNAL KTeV, "c"–CERN CPLEAR, "d"–FNAL E773, "e"–FNAL E731, "f"–CERN, "g"–CERN NA31, "h"–CERN NA48, "i"–CERN NA31, and are cited in Table 68.1. The narrow band "j" shows ϕ_{SW}. The ellipse "a" shows the fit result's $\chi^2 = 1$ contour.

and 68.2. The KTeV experiment [10] quotes its results as values of Δm, τ_S, ϕ_ϵ, Re(ϵ'/ϵ), and Im(ϵ'/ϵ) with correlations, leading to the ellipses labeled "b." The correlations for the KTeV measurements are given in the Im(ϵ'/ϵ) section of the K_L^0 Listings. For small $|\epsilon'/\epsilon|$, $\phi_{+-} \approx \phi_\epsilon + \text{Im}(\epsilon'/\epsilon)$.

Table 68.1: References, Document ID's, and sources corresponding to the letter labels in the figures. The data are given in the ϕ_{+-} and Δm sections of the K_L Listings, and the τ_S section of the K_S Listings.

j	This *Review*	SUPERWEAK 16	

The data on τ_S, Δm, and ϕ_{+-} shown in Figs. 68.1 and 68.2 are combined with data on ϕ_{00} and $\phi_{00} - \phi_{+-}$ in two fits, one without assuming CPT, and the other with this assumption. The results without assuming CPT are shown as ellipses labeled "a." These ellipses are seen to be in good agreement with the superweak phase

$$\phi_{SW} = \tan^{-1}\left(\frac{2\Delta m}{\Delta\Gamma}\right) = \tan^{-1}\left(\frac{2\Delta m \tau_S \tau_L}{\hbar(\tau_L - \tau_S)}\right) . \qquad (68.9)$$

In Figs. 68.1 and 68.2, ϕ_{SW} is shown as narrow bands labeled "j."

Table 68.2 column 2, "Fit w/o CPT," gives the resulting fitted parameters, while Table 68.3 gives the correlation matrix for this fit. The white ellipses labeled "a" in Figure 68.1 and 68.2 are the $\chi^2 = 1$ contours for this fit.

For experiments which have dependencies on unseen fit parameters, that is, parameters other than those shown on the x or y axis of the figure, their band positions are evaluated using the fit results and their band widths include the fitted uncertainty in the unseen parameters. This is also true for the ϕ_{SW} bands.

If CPT invariance and unitarity are assumed, then by Eq. (68.6a), the phase of ϵ is constrained to be approximately equal to

$$\phi_{SW} = (43.50258 \pm 0.00021)^\circ + 54.1(\Delta m - 0.5289)^\circ + 32.0(\tau_S - 0.89564) \qquad (68.10)$$

where we have linearized the Δm and τ_S dependence of Eq. (68.9). The error ± 0.00021 is due to the uncertainty in τ_L. Here Δm has units $10^{10}\,\hbar\,\text{s}^{-1}$ and τ_S has units 10^{-10} s.

If in addition we use the observation that $Re(\epsilon'/\epsilon) \ll 1$ and $cos(\phi_{\epsilon'} - \phi_\epsilon) \simeq 1$, as well as the numerical value of $\phi_{\epsilon'}$ given in Eq. (68.6b), then Eqs. 68.5a, which are sketched in Fig 68.3, lead to the constraint

$$\begin{aligned} \phi_{00} - \phi_{+-} &\approx -3\ \text{Im}\left(\frac{\epsilon'}{\epsilon}\right) \\ &\approx -3\ \text{Re}\left(\frac{\epsilon'}{\epsilon}\right) \tan(\phi_{\epsilon'} - \phi_\epsilon) \\ &\approx 0.006^\circ \pm 0.008^\circ , \end{aligned} \qquad (68.11)$$

so that $\phi_{+-} \approx \phi_{00} \approx \phi_\epsilon \approx \phi_{SW}$.

In the fit assuming CPT, we constrain $\phi_\epsilon = \phi_{SW}$ using the linear expression in Eq. (68.10), and constrain $\phi_{00} - \phi_{+-}$ using Eq. (68.11). These constraints are inserted into the Listings with the Document ID of SUPERWEAK 16. Some additional data for which the authors assumed CPT are added to this fit or substitute for other less precise data for which the authors did not make this assumption. See the Listings for details.

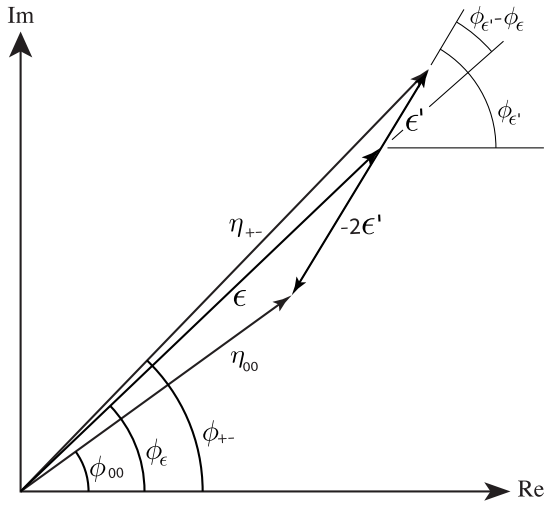

Figure 68.3: Sketch of Eqs. 68.5a. Not to scale

The results of this fit are shown in Table 68.2, column 3, "Fit w/CPT," and the correlation matrix is shown in Table 68.4. The Δm precision is improved by the CPT assumption.

Table 68.3: Correlation matrix for the results of the fit without the CPT assumption

	ϕ_{+-}	Δm	τ_S	ϕ_{00}	$\Delta\phi$	ϕ_ϵ

68.2.2 *Fits for ϵ'/ϵ, $|\eta_{+-}|$, $|\eta_{00}|$, and $B(K_L \to \pi\pi)$*

We list measurements of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ. Independent information on $|\eta_{+-}|$ and $|\eta_{00}|$ can be obtained from measurements of the K^0_L and K^0_S lifetimes (τ_L, τ_S), and branching ratios (B) to $\pi\pi$, using the relations

$$|\eta_{+-}| = \left[\frac{\mathrm{B}(K^0_L \to \pi^+\pi^-)}{\tau_L}\ \frac{\tau_S}{\mathrm{B}(K^0_S \to \pi^+\pi^-)}\right]^{1/2}, \quad (68.12a)$$

$$|\eta_{00}| = \left[\frac{\mathrm{B}(K^0_L \to \pi^0\pi^0)}{\tau_L}\ \frac{\tau_S}{\mathrm{B}(K^0_S \to \pi^0\pi^0)}\right]^{1/2}. \quad (68.12b)$$

For historical reasons, the branching ratio fits and the CP-violation fits are done separately, but we want to include the influence of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ measurements on $\mathrm{B}(K^0_L \to \pi^+\pi^-)$ and $\mathrm{B}(K^0_L \to \pi^0\pi^0)$ and vice versa. We approximate a global fit to all of these measurements by first performing two independent fits: 1) BRFIT, a fit to the K^0_L branching ratios, rates, and mean life, and 2) ETAFIT, a fit to the $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{+-}/\eta_{00}|$, and ϵ'/ϵ measurements. The results from fit 1, along with the K^0_S values from this edition, are used to compute values of $|\eta_{+-}|$ and $|\eta_{00}|$, which are included as measurements in the $|\eta_{00}|$ and $|\eta_{+-}|$ sections with a document ID of BRFIT 16. Thus, the fit values of $|\eta_{+-}|$ and $|\eta_{00}|$ given in this edition include both the direct measurements and the results from the branching ratio fit.

The process is reversed in order to include the direct $|\eta|$ measurements in the branching ratio fit. The results from fit 2 above (before including BRFIT 16 values) are used along with the K^0_L and K^0_S mean lives and the $K^0_S \to \pi\pi$ branching fractions to compute the K^0_L branching ratio $\Gamma(K^0_L \to \pi^0\pi^0)/\Gamma(K^0_L \to \pi^+\pi^-)$. This branching ratio value is included as a measurement in the branching ratio section with a document ID of ETAFIT 16. Thus, the K^0_L branching ratio fit values in this edition include the results of the direct measurement of $|\eta_{00}/\eta_{+-}|$ and ϵ'/ϵ. Most individual measurements of $|\eta_{+-}|$ and $|\eta_{00}|$ enter our fits directly via the corresponding measurements of $\Gamma(K^0_L \to \pi^+\pi^-)/\Gamma(\text{total})$ and $\Gamma(K^0_L \to \pi^0\pi^0)/\Gamma(\text{total})$, and those that do not have too large errors to have any influence on the fitted values of these branching ratios. A more detailed discussion of these fits is given in the 1990 edition of this *Review* [20].

69. Multibody Charm Analyses

Revised August 2025 by J. Rademacker (Bristol U.); written with D.M. Asner (BNL)

69.1 Overview

The study of multibody charm decays is a vibrant field, with vast and fast-increasing datasets, new developments in theory and experimental technique, and implications reaching beyond charm. This review is structured as follows: Sec. 69.2 summarizes key aspects of amplitude models that describe multibody charm decays, their application to data, and theory progress; Sec. 69.3 reviews the special role of charm threshold data in model-independent approaches; and Sec. 69.4 describes applications of multi-body charm analyses, focusing on Charge-Parity (CP) violation, charm mixing and the role of threshold data in this context. In Sec. 69.5, we conclude.

69.2 Kinematics & Models

The differential decay rate to a point $\mathbf{s} = (s_1, \ldots, s_n)$ in n dimensional phase space can be expressed as

$$d\Gamma = |\mathcal{M}(\mathbf{s})|^2 \left| \frac{\partial^n \phi}{\partial(s_1 \ldots s_n)} \right| d^n s \,, \tag{69.1}$$

where $|\partial^n \phi / \partial(s_1 \ldots s_n)|$ represents the density of states at $\mathbf{s}$, and $\mathcal{M}$ the matrix element for the decay at that point in phase space, which is $2, 5, 8, \ldots$ dimensional for D decays to $3, 4, 5, \ldots$ spinless particles. Additional parameters are required to fully describe decays involving particles with non-zero spin in the initial or final state.

For the important case of D decays to three pseudoscalars, the decay kinematics can be represented in a two-dimensional Dalitz plot [1]. This is usually parameterized in terms of $s_{12} \equiv (p_1+p_2)^2$ and $s_{23} \equiv (p_2+p_3)^2$, where p_1, p_2, and p_3 are the four-momenta of the final-state particles. In terms of these variables, phase-space density is constant across the kinematically allowed region, so that any structure seen in the Dalitz plot is a direct consequence of the dynamics encoded in $|\mathcal{M}|^2$. Note that decays to four or more particles cannot be unambiguously described in terms of analogously-defined variables s_{ij} and s_{ijk}, as these cannot describe parity-odd kinematics; these are absent in the three-body case because the decay products are confined to a plane. See Sec. 69.4.4 for a discussion on the use of parity-odd variables in four-body decays.

In the widely-used isobar approach, the matrix element $\mathcal{M}$ is modeled as a sum of interfering decay amplitudes, each proceeding through resonant two-body decays [2–6]. See [2, 7, 8] for a review of resonance phenomenology. In most analyses, each resonance is described by a relativistic Breit–Wigner [9] or Flatté [10] lineshape, and the model includes a non-resonant term with a constant phase and magnitude. This approach has well-known theoretical limitations, such as the violation of unitarity and analyticity, which can break the relationship between magnitude and phase across phase space. This motivates the use of more sophisticated descriptions, especially for broad, overlapping resonances (frequently found in S-wave components) where these limitations are particularly problematic. In charm analyses, these approaches have included the K-matrix [11] which respects two-body unitarity; the use of LASS scattering data [12]; dispersive methods [13–16]; multi-meson models using chiral Lagrangians [17–20]; and methods based on chiral unitarity [21–24]; QCD factorization [25–28]; and quasi model-independent parametrizations that use generic lineshapes, with minimal theory input and many free parameters, for a subset of resonances [29–37].

An important example of a multibody charm decay is $D^0 \to K^0_S \pi^+ \pi^-$, which is a key channel in CP violation and charm-mixing analyses. A joint analysis by BaBar and Belle [38] describes a Dalitz plot with 1.1M $D^0 \to K^0_S \pi^+ \pi^-$ events (the largest sample analyzed in this way) with 18 resonant components, including four doubly Cabibbo suppressed ones. The model uses a K-matrix description for the $\pi\pi$ S-wave based on [39] and input from LASS scattering data [12,40] for the $K\pi$ S-wave, with no need to add a non-resonant component to describe the data. These data were reanalyzed by [25] in a QCD factorization framework, using line-shape parametrizations for the S [41, 42] and P wave [14] contributions that preserve two-body unitarity and analyticity. The analyses give compatible results for the components they share. Recently, BESIII studied both the $D^0 \to K^0_S \pi^+ \pi^-$ and the $D^0 \to K^0_L \pi^+ \pi^-$ Dalitz plot, providing insights into U-spin breaking effects [43].

The field of charm amplitude analyses remains very active. Publications since the last update of this review two years ago include Dalitz plot analyses of $D^+ \to \pi^+ \eta\eta$, $D_s^+ \to K^0_S K^0_L \pi^+$, $D^+ \to K^0_S K^0_S \pi^+$, $D^+ \to K^0_S \pi^+ \eta$, $D^0 \to \pi^+ \pi^- \eta$, $D^+ \to \pi^+ \pi^0 \eta$, by BESIII [44–48] and $D_s^+ \to \pi^- \pi^+ \pi^+$ by LHCb [36]. LHCb performed an amplitude analyses of the decay of an excited charm state, $D_{s1}(2460)^+ \to D_s^+ \pi^+ \pi^-$ [49]. The amplitude structure of charm baryon decays was studied by BESIII in $\Lambda_c \to \Lambda \pi^+ \eta$ and by LHCb in $\Lambda_c \to p K^- \pi^+$ [50, 51] and $\Xi_c^+ \to p K^- \pi^+$ [52]. BESIII continued its series of four-body amplitude analyses, investigating the hadronic decays $D^+ \to K^- \pi^+ \pi^+ \pi^0$, $D_s^+ \to \pi^+ \pi^+ \pi^- \pi^0$, $D^0 \to \pi^+ \pi^- \pi^+ \pi^-$, and $D^0 \to \pi^+ \pi^- \pi^0 \pi^0$ [53–55] as well as the semileptonic decays $D^+ \to K^0_S \pi^0 \mu^+ \nu_\mu$, $D^+ \to K^0_S \pi^0 e^+ \nu_e$, $D^0 \to \overline{K}^0 \pi^- \mu^+ \nu_\mu$, $D^0 \to \overline{K}^0 \pi^- e^+ \nu_e$, $D^+ \to \pi^+ \pi^- e^+ \nu_e$, and $D_s^+ \to K^+ K^- \mu^+ \nu_\mu$ [56–61]. BESIII published five-body amplitude analyses of the decays $D_s^+ \to \pi^+ \pi^+ \pi^- \pi^0 \pi^0$, $D^+ \to K^- \pi^+ \pi^0 e^+ \nu_e$, and $D^0 \to K^- \pi^+ \pi^- e^+ \nu_e$. [62, 63].

Noteworthy is the increasing sophistication of recent amplitude analyses, most of which go substantially beyond the isobar model with Breit–Wigner and Flatté lineshapes. However, with the notable exceptions of [15, 16, 23, 24, 64, 65], they remain within the isobar framework, which describes the decay as a series of two-body processes. This approach ignores long-range hadronic effects such as re-scattering, and does not respect three (or four)-body unitarity and analyticity. Recent quasi model-independent measurements of the $\pi^+\pi^-$ lineshape emphasize the importance of such effects. Significant differences have been found between the $\pi^+\pi^-$ S-wave components observed in $D_s^+ \to \pi^+ \pi^- \pi^+$ [31,35,36] and $D^+ \to \pi^+ \pi^- \pi^+$ [37], and between either of them and phase shifts observed in scattering data [66–68].

Several groups work on improved models and their application to data. Dispersive techniques, which respect three-body unitarity and analyticity, have been applied to regions of the $D^+ \to K^- \pi^+ \pi^+$ and $D^+ \to K^0_S \pi^0 \pi^+$ Dalitz plots below the $\eta' K$ threshold [15, 16], where they provide a good description of the data with fewer fit parameters than the isobar approach. Reference [64] uses a unitary coupled channel approach to describe $D^+ \to K^- \pi^+ \pi^+$, which has no restrictions on the kinematic range, but requires additional parameters to describe the Dalitz plot above the $\eta' K$ threshold. Using an effective chiral Lagrangian, the authors of reference [19] provide a description of the annihilation contribution to the decay amplitude which respects three-body unitarity. The approach provides a good description of LHCb's $D^+ \to K^+ K^- K^+$ data, with fewer parameters than an equivalent isobar model [65]. The same channel has more recently been re-analyzed by the authors of [23], who argue that the internal emission diagram should dominate and use a chiral unitarity-based approach to achieve a reasonable description of the data with two free parameters.

Limitations in the theoretical description of interfering resonances are the leading source of systematic uncertainty in many analyses. In some cases, the model uncertainty can be removed through model-independent methods, often relying on input from the charm threshold, as discussed in Sec. 69.3. The authors of [69] expand the scope and applicability of the quasi model-independent approach in amplitude fits. At the same time, increasingly sophisticated models are being developed, and applied to data. The authors of [20] and [70] provide valuable practical frameworks for sophisticated amplitude analyses.

69.3 Model Independent Methods and the Charm Threshold

Precision measurements of the CP-violation phase γ/ϕ_3 using $B^- \to DK^-$, $D \to K^0_S \pi^+ \pi^-$ and related decay modes, as well as precision measurements of charm-mixing parameters in decay modes such as $D^0 \to K^0_S \pi^+ \pi^-$, require input on the relative de-

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

cay amplitudes of D^0 and $\overline{D}^0$. In the above examples, $K^0_S\pi^+\pi^-$ can be replaced with other final states accessible to both D^0 and $\overline{D}^0$ [71–79]. While the magnitudes of the decay amplitudes can be measured precisely using the vast charm samples at the B factories and LHCb, obtaining the relative phases requires either amplitude models with reliable phase motion, or model-independent approaches. More details on the measurements of γ/ϕ_3 and charm mixing can be found in sections 69.4.1 and 69.4.2.

Model-independent measurements of relative phases between D^0 and $\overline{D}^0$ decay amplitudes rely on interference effects in the decays of well-defined coherent superpositions of D^0 and $\overline{D}^0$. These are accessible at the charm threshold [74, 77, 79–84], where CLEO–c and BESIII operate. There, quantum-correlated D-meson pairs are produced, which have opposite CP and flavor content. For example, if one (the tag) is identified as a CP eigenstate through its decay (e.g. to K^+K^- or $K_S\pi^0$), the other D meson is an eigenstate state with the opposite CP eigenvalue. (For a discussion of other potential sources of correlated charm with different characteristics, see [85].) The decay rate of a CP eigenstate $\frac{1}{\sqrt{2}}\left(D^0 \pm \overline{D}^0\right)$ is proportional to $|A_D|^2 + |\overline{A}_D|^2 \pm 2|A_D||\overline{A}_D|\cos(\delta_D)$, where A_D and $\overline{A}_D$ are the D^0 and $\overline{D}^0$ decay amplitudes, and δ_D is their sought-after phase difference. Other quantum correlations give access to $\sin(\delta_D)$. For multibody decays, A_D, $\overline{A}_D$ and δ_D vary across phase space. Model-independent phase information is measured either integrated over the entire phase space of the decay, or in subregions/bins. The results can be expressed in terms of one complex parameter $\mathcal{Z} = Re^{-i\delta_D} = c + is$ per pair of CP-conjugate bins; c and s are the average of $\cos(\delta_D)$ and $\sin(\delta_D)$ over that region of phase space. Amplitude models can be used to optimize the binning for sensitivity to γ/ϕ_3, without introducing a model-dependent bias in the result [86]; novel unbinned approaches have the potential to further increase the precision on γ/ϕ_3 in future analyses [87–89].

BESIII data have been analyzed to provide binned $\mathcal{Z}$ for $K_{S,L}\pi^+\pi^-$, $K_{S,L}K^+K^-$, $K^+\pi^-\pi^0$, $\pi^+\pi^-\pi^+\pi^-$, $K^+K^-\pi^+\pi^-$, and $K^+\pi^-\pi^+\pi^-$ final states [90–96]. Many of these analyses were first carried out with CLEO–c data [97–102].

For self-conjugate decays such as $D^0 \to \pi^+\pi^-\pi^0$, one can define the CP-even fraction F_+ which is +1 for a CP-even eigenstate and 0 for a CP-odd one [82]. F_+ is related to $Re(\mathcal{Z}) = c$, defined for a single CP-conjugate bin pair. For the purpose of γ/ϕ_3 measurements, this information allows the decay to be treated equivalently to a two-body decay, where γ/ϕ_3 is constrained from decay rates without the need to resolve the phase-space distribution. In the mathematical expressions for the decay rates, a factor $(2F_+ - 1)$ multiplies the γ/ϕ_3-sensitive term, leading to the best sensitivity for $F_+ = 1$ or $F_+ = 0$. The decay $D^0 \to \pi^+\pi^-\pi^0$ is found to be, with $F_+ = (94.2 \pm 0.7)\%$, very close to being completely CP-even [83, 103]. The decays $D^0 \to \pi^+\pi^-\pi^+\pi^-$ [83, 94, 99, 104] and $D^0 \to K^+K^-\pi^+\pi^-$ [95, 105] are predominantly CP even with F_+ of 75%, as is $D^0 \to K^+K^-\pi^0$ with 73% [82, 83]; on the other hand, $D^0 \to K^0_S\pi^+\pi^-\pi^0$ is predominantly CP odd with $F_+ = 23\%$ [100, 106]; these measurements have percent-level uncertainties. Additional measurements for decays to four, five, and six pions can be found in [107].

Comparing measured parameters like F_+ and $\mathcal{Z}$ with those predicted from amplitude models provides a test of the models' phase motion. The measured value for F_+ in $D^0 \to \pi^+\pi^-\pi^+\pi^-$ for example, $F_+ = (74.6 \pm 0.8)\%$ [99, 104], compares well with $(72.9 \pm 2.0)\%$ calculated from [32]. The coherence factor $|\mathcal{Z}^{3\pi}| = R^{K3\pi} = 0.430^{+0.043}_{-0.039}$ measured in $D^0 \to K^\pm\pi^\mp\pi^\pm\pi^\mp$ quantum correlated events at BESIII and CLEO–c [96,102] and charm mixing at LHCb [108, 109], compares well with 0.459 ± 0.025 predicted by [33]. The bin-wise comparisons between model and data for $D^0 \to K^+K^-\pi^-\pi^+$, $\pi^+\pi^-\pi^+\pi^-$, $K_{L,S}\pi^+\pi^-$, $K^\pm\pi^\mp\pi^\pm\pi^\mp$, $K^\pm\pi^\mp\pi^0$, and $K^0_SK^+K^-$ can be found in [43, 91–96, 96, 99] and mostly show reasonable or good agreement. These results are a welcome surprise given the preceding discussion on the theoretical shortcomings of amplitude models.

69.4 Applications of multibody charm analyses for CP violation and mixing

Amplitude analyses provide sensitivity to both relative magnitudes and phases of the interfering decay amplitudes. It is especially the sensitivity to phases that makes amplitude analyses such a uniquely powerful tool for studying a wide range of phenomena. Here we concentrate on their critical role in CP violation and mixing measurements. Properties of light-meson resonances determined in D amplitude analyses are reported in the light-unflavored-meson section of this *Review*.

The closely related topics of multibody charm decays in measurements of CP violation in beauty decays to charm and charm mixing will be discussed in turn, followed by a review of searches for time-integrated CP violation in multibody charm decays.

69.4.1 *CP violation in decays of Beauty to Charm*

Neutral D mesons originating from $B^- \to DK^-$ (here denoted as D_{B^-}) are a superposition of D^0 and $\overline{D}^0$ with a relative phase that depends on the CKM unitarity triangle parameter γ/ϕ_3,

$$D_{B^-} \propto D^0 + r_B e^{i(\delta_B - \gamma)}\overline{D}^0,$$

where δ_B is a CP conserving strong phase, and $r_B \sim 0.1$ is the magnitude of the ratio of the $B^- \to \overline{D}^0K^-$ and $B^- \to D^0K^-$ decay amplitudes. In the corresponding CP-conjugate expression, γ/ϕ_3 changes sign. The amplitude analysis of the subsequent $D_{B^\pm}$ decay to a state accessible to both D^0 and $\overline{D}^0$ allows the measurement of γ/ϕ_3 [71–78]. The method generalizes to similar B hadron decays, such as $B^0 \to DK^{*0}$, and, albeit with reduced sensitivity, to decays where the kaon is replaced by a pion.

Measurements based on this technique have been reported by BaBar [110, 111], Belle [112–114], Belle II [115, 116], and LHCb [117–136]. Since it relies on $D^0 - \overline{D}^0$ interference, the phase differences between the relevant D^0 and $\overline{D}^0$ decay amplitudes are required in order to extract γ/ϕ_3. Because the theoretical shortcomings of amplitude models, discussed above, make their phases unreliable, most recent γ/ϕ_3 measurements use amplitude model-independent approaches to obtain this information [113, 114, 116–121, 123–129, 132, 135]. These depend critically on input from the charm threshold described in Sec. 69.3. Charm mixing also results in a (time-dependent) $D^0 - \overline{D}^0$ superposition, which can be used to measure the relevant phase information as input to γ/ϕ_3 measurements [137, 138]. This method is particularly powerful in doubly Cabibbo-suppressed decays such as $D^0 \to K^+\pi^-\pi^+\pi^-$, and when used in combination with threshold data.

Under some circumstances, with large data sets, the relevant strong phases and γ/ϕ_3 can be extracted without external input, for example in simultaneous analysis of the $B^0 \to DK^+\pi^-$ Dalitz plot and that of the subsequent $D \to K^0_S\pi^+\pi^-$ decay [139]. However, the global effort to measure γ/ϕ_3 to sub-degree precision will continue to rely critically on input from the charm threshold and the analysis of BESIII's full dataset [140].

The most precise individual γ/ϕ_3 measurement is $\gamma/\phi_3 = 68.5^{\circ\,+5.2^\circ}_{-5.1^\circ}$ resulting from LHCb's amplitude model-independent study of $D_{B^-} \to K^0_S\pi^+\pi^-$ and $D_{B^-} \to K^0_SK^+K^-$ [141], using input from the charm threshold [90, 92, 97]. LHCb's analysis of $D_{B^-} \to K^+\pi^-\pi^+\pi^-$ decays leads to the second most precise individual γ/ϕ_3 measurement with $\gamma/\phi_3 = 54.8^{\circ\,+6.0^\circ}_{-5.8^\circ} \pm 0.6^{\circ\,+6.7^\circ}_{-4.3^\circ}$ [128]. This analysis benefits from an optimized model-informed partition of the five-dimensional $D^0 \to K^+\pi^-\pi^+\pi^-$ phase space [33,102], and input from the charm threshold [96,102]; the third uncertainty on γ/ϕ_3 in the result quoted above quantifies the impact of the uncertainty on the charm parameters measured at the threshold. These have recently been constrained further from charm mixing measurements [108, 109], leading to a significant improvement in the precision of γ/ϕ_3 [135].

The current world average on γ/ϕ_3 [142, 143] is dominated by LHCb who finds, combining its results with input from CLEO–c and BESIII in an amplitude-model-independent approach, $\gamma = 62.8^\circ \pm 2.6^\circ$ [135]. Belle II is also expected to reach excellent precision in γ/ϕ_3, benefiting from its strength in reconstructing decays with neutral particles in the final state. Combining Belle

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

and Belle II data with charm threshold input, the collaborations find an average, dominated by model-independent results, of $\phi_3 = 75.2^\circ \pm 7.6^\circ$ [115].

The interference between mixing and decay in $B^0 \to D^0 h^0$ with $h^0 = \pi^0, \eta, \omega$ provides sensitivity to another CKM unitarity triangle parameter, β/ϕ_1, which can be extracted from the Dalitz plot of the subsequent $D^0 \to K^0_S \pi^+ \pi^-$ decay [38, 144–147]. The combined BaBar/Belle analysis based on this technique resolved the ambiguity in β/ϕ_1 present in other measurements [38].

Further details on *CP* violation in beauty and charm can be found in [148, 149].

69.4.2 *Charm Mixing and CP violation*

Time-dependent amplitude analyses in decays to final states that are accessible to both D^0 and $\overline{D}^0$ have unique sensitivity to mixing parameters. A Dalitz plot analysis of a self-conjugate final state, such as $K^0_S \pi^+ \pi^-$ and $K^0_S K^+ K^-$, allows a direct measurement of x and y, the normalized mass and width difference of the $D^0 - \overline{D}^0$ system's mass eigenstates [150]. This is in contrast to decays like $D^0 \to K^+ \pi^-$, which only provide access to decay-specific parameters x'^2, y'.

The phase differences between D^0 and $\overline{D}^0$ amplitudes across the Dalitz plot affect these measurements in the same way as those of γ/ϕ_3 in $B^+ \to DK^+$, and can be taken into account in an amplitude model-independent way using the same charm threshold results [74, 79–84, 148]. This approach resulted in the first observation of a non-zero mass difference between the neutral charm mass eigenstates by LHCb [151], using a model-independent analysis of $D^0 \to K^0_S \pi^+ \pi^-$. Applying the same technique to their combined dataset, Belle and Belle II find consistent results, albeit with lower precision [152]. The "bin flip" technique applied in these measurements exploits that *CP*-conjugate regions of the $D^0 \to K^0_S \pi^+ \pi^-$ Dalitz plot have near-identical experimental efficiencies [153]. This technique is also sensitive to *CP* violation in mixing and in the interference between mixing and decay, which is discussed further in [148, 149].

The simultaneous dependence on charm mixing parameters and the same relative phases that affect the measurement of γ/ϕ_3 can also be exploited to constrain those phases [137,138], using mixing parameters as external input. This led to an improvement in the measurement of the $D^0 \to K^+\pi^-\pi^+\pi^-$ coherence factor and relative strong phase from $R^{K3\pi} = 0.52^{+0.10}_{-0.09}$, $\delta^{K3\pi} = 167^{\circ\,+31^\circ}_{\quad -19^\circ}$ measured at the charm threshold [96,102] to $R^{K3\pi} = 0.430^{+0.043}_{-0.039}$, $\delta^{K3\pi} = 163^{\circ\,+13.8^\circ}_{\quad -14.8^\circ}$ when combined with LHCb charm mixing data [108, 109]. It is worth noting, though, that charm mixing alone is only sensitive to a linear combination of $R^{K3\pi}\cos(\delta^{K3\pi})$ and $R^{K3\pi}\sin(\delta^{K3\pi})$ - combining this with constraints from the threshold allows a measurement in terms of $R^{K3\pi}$ and $\delta^{K3\pi}$.

69.4.3 *Everything, Everywhere, All at Once*

The discussion above shows how closely related the measurements of γ/ϕ_3, charm mixing, and the analysis of charm threshold data are, due to the shared charm parameters. While above, the emphasis was on the importance of charm as input to γ/ϕ_3, and threshold data as input to charm mixing and γ/ϕ_3, these relationships are in fact omnidirectional. This is demonstrated by LHCb's combined analysis on beauty and charm data [135], as well as a global combination by UTfit members and collaborators [143]. Not only does charm input improve the precision on γ/ϕ_3, both analyses also show that input from beauty decays to charm (such as $B^- \to DK^-$) has a significant impact on charm parameters.

69.4.4 *Searches for time-integrated CPV in charm*

The recent observation of direct *CP* violation in LHCb's analysis of $D^0 \to \pi^+\pi^-$ and $D^0 \to K^+K^-$ decays [154,155], and the open question as to its Standard Model or beyond the Standard Model nature, add renewed interest in the search for *CP* violation in other decays.

Multibody decays, with their rich structure and varying strong phase across phase space, could potentially have particularly high sensitivity to *CP* violation. Comparing the results of amplitude fits for *CP*-conjugate decay modes provides a measure of *CP* violation, as for example done for $D^0 \to K^0_S K^\pm \pi^\mp$, $D^0 \to K^+K^-\pi^+\pi^-$, and $D^0 \to \pi^+\pi^-\pi^+\pi^-$ using LHCb and CLEO–c data [32, 156–158]. A widely-used amplitude model-independent technique to search for local *CP* violation in multibody phase space is based on performing a χ^2 comparison of *CP*-conjugate phase-space distributions. This method was pioneered by BaBar [159] and developed further in [160–162], with results reported by BaBar and LHCb in $D^\pm \to K^+K^-\pi^\pm$ [159, 163–166], CDF in $D^0 \to K^0_S\pi^+\pi^-$ [167], and LHCb in $D^0 \to K^0_S K^\pm\pi^\mp$, $D^+_{(s)} \to K^+K^-K^+$, $D^+ \to \pi^-\pi^+\pi^+$, $D^0 \to K^+K^-\pi^+\pi^-$, $D^0 \to \pi^+\pi^-\pi^+\pi^-$, and $\Xi_c^+ \to pK^-\pi^+$ [162, 168–171]. Unbinned methods can increase sensitivity [172, 173] and have been applied by LHCb to $D^+ \to \pi^-\pi^+\pi^+$, $D^0 \to \pi^+\pi^-\pi^0$, $D^0 \to \pi^+\pi^-\pi^+\pi^-$, $D^0 \to K^0_S K^\pm\pi^\mp$, and $\Xi_c^+ \to pK^-\pi^+$ [168, 170, 171, 174–176].

An alternative model-independent approach is based on observables in four body decays that are odd under motion reversal ("naïve T") [177–185], which is equivalent to P for scalar particles [185]. One such observable is $C_T = \vec{p}_2 \cdot (\vec{p}_3 \times \vec{p}_4)$, where $\vec{p}_i$ is the ith decay product's three momentum in the decay's center of mass frame. Comparing the P violating asymmetry $A_T \equiv \frac{\Gamma(C_T>0)-\Gamma(C_T<0)}{\Gamma(C_T>0)+\Gamma(C_T<0)}$ with its C-conjugate provides sensitivity to *CP* violation. Additional variables are proposed in [185], which also provides an excellent review of this topic. Searches for *CP* violation using P-odd variables have been carried out by BaBar, Belle, Belle II, FOCUS, and LHCb in $D^+ \to K^0_S K^-\pi^+\pi^+$,$D_s \to K^0_S K^-\pi^+\pi^+$ [186]; $D^0 \to K^+K^-\pi^+\pi^-$ [187–190]; $D^+ \to K^+K^0_S\pi^+\pi^-$, $D_s^+ \to K^+K^0_S\pi^+\pi^-$ [191]; $D^0 \to K^0_S\pi^+\pi^-\pi^0$ [192]; and $D^0 \to \pi^+\pi^-\pi^+\pi^-$ [175].

LHCb's angular analysis of the rare decays $D^0 \to \pi^+\pi^-\mu^+\mu^-$, $D^0 \to K^+K^-\mu^+\mu^-$, and $\Lambda_c^+ \to p\mu^+\mu^-$ yields several observables with sensitivity to physics beyond the Standard Model, including *CP*-violating ones. The results are in agreement with Standard-Model predictions [193–195].

All results of analyses mentioned in this section are compatible with *CP* conservation. The observation of *CP* violation in two body charm decays [154,155], and the vast data samples about to be collected, provide grounds for optimism that this may change in the foreseeable future.

69.5 Summary

Multibody charm decays offer a rich phenomenology, including unique sensitivity to *CP* violation and charm mixing. This is a highly dynamic field with many new results (some of which we presented here) and rapidly increasing, high quality datasets. These datasets constitute a huge opportunity, but also a challenge to improve the theoretical descriptions of soft hadronic effects in multibody decays. For some measurements, model-independent methods, many relying on input from the charm threshold, provide a way of removing model-induced uncertainties. At the same time, substantial progress in the theoretical description of multibody decays is being made.

70. D^0-$\overline{D}^0$ Mixing

Revised September 2025 by A.J. Schwartz (U. of Cincinnati); written with D.M. Asner (SNOLAB, Lively).

The formalism for D^0-$\overline{D}^0$ mixing is closely related to that for CP violation; for further details on the latter, see the note "CP Violation in the Quark Sector" in this *Review*. The time evolution of the D^0–$\overline{D}^0$ system is described by the Schrödinger equation

$$i\frac{\partial}{\partial t}\begin{pmatrix}D^0(t)\\ \overline{D}^0(t)\end{pmatrix} = \left(\mathbf{M}-\frac{i}{2}\mathbf{\Gamma}\right)\begin{pmatrix}D^0(t)\\ \overline{D}^0(t)\end{pmatrix}, \tag{70.1}$$

where the $\mathbf{M}$ and $\mathbf{\Gamma}$ matrices are Hermitian, and CPT invariance requires that $M_{11}=M_{22}\equiv M$ and $\Gamma_{11}=\Gamma_{22}\equiv\Gamma$. The off-diagonal elements of $\mathbf{M}$ and $\mathbf{\Gamma}$ are referred to as the dispersive and absorptive parts, respectively, of the mixing. The mass eigenstates D_1 and D_2 of the Hamiltonian $\mathbf{M}$ - $i\mathbf{\Gamma}/2$ are defined as

$$|D_{1,2}\rangle \equiv p|D^0\rangle \pm q|\overline{D}^0\rangle, \tag{70.2}$$

where normalization imposes $|p|^2+|q|^2=1$. Equation (70.1) implies that a charm meson created as a D^0 will time-evolve to a $\overline{D}^0$, and vice-versa. As shown in Eqs. (70.11) and (70.13) below, the probability for $D^0\to\overline{D}^0\propto|q/p|^2$, whereas the probability for $\overline{D}^0\to D^0\propto|p/q|^2$. Thus, if $|q/p|\neq1$, CP is violated in mixing. If $\mathrm{Arg}(q/p)\neq0$ or π, CP is violated in the interference between a mixed decay amplitude and a direct decay amplitude. These two types of CP violation are collectively referred to as *indirect CP* violation.

As the absolute phases of $|D^0\rangle$ and $|\overline{D}^0\rangle$ are arbitrary, the relative phase ξ between them is unphysical. This relative phase must appear in a CP transformation: $CP|D^0\rangle=e^{i\xi}|\overline{D}^0\rangle$ and $CP|\overline{D}^0\rangle=e^{-i\xi}|D^0\rangle$, resulting in $(CP)^2|D^0\rangle=|D^0\rangle$ and $(CP)^2|\overline{D}^0\rangle=|\overline{D}^0\rangle$. For definiteness we choose a phase convention $CP|D^0\rangle=-|\overline{D}^0\rangle$, which fixes $\xi=\pi$. In addition, for $\mathrm{Arg}(q/p)$ to have physical meaning it must be defined relative to a reference phase, i.e., only phase *differences* are physical. In Ref. [1], the reference phase is taken to be that of the $\Delta(U\text{-spin})=2$ component of $\langle\overline{D}^0|\Gamma|D^0\rangle$; this is equivalent to defining this component of Γ_{12} to be real and positive, and we retain this definition here. With these conventions, if $p=\pm q$ then D_1, D_2 are CP eigenstates, and there is no indirect CP violation ($|q/p|=1$ and $\mathrm{Arg}(q/p)=0$ or π).

The eigenvalues of the Hamiltonian $\mathbf{M}$ - $i\mathbf{\Gamma}/2$ are

$$\omega_{1,2} = \left(M-\frac{i}{2}\Gamma\right)\pm\frac{q}{p}\left(M_{12}-\frac{i}{2}\Gamma_{12}\right) \equiv m_{1,2}-\frac{i}{2}\Gamma_{1,2}, \tag{70.3}$$

where $m_{1,2}$ and $\Gamma_{1,2}$ are defined to be real and thus correspond to the masses and decay widths, respectively, of the eigenstates $D_{1,2}$. As the traces $M_{11}+M_{22}=2M$ and $\Gamma_{11}+\Gamma_{22}=2\Gamma$ are unchanged by diagonalizing $\mathbf{M}$ and $\mathbf{\Gamma}$, M must equal the mean value $(M_1+M_2)/2$ and Γ must equal the mean value $(\Gamma_1+\Gamma_2)/2$. Solving for the eigenstates of the Hamiltonian yields

$$\left(\frac{q}{p}\right)^2=\frac{M_{12}^*-\frac{i}{2}\Gamma_{12}^*}{M_{12}-\frac{i}{2}\Gamma_{12}}. \tag{70.4}$$

If $\mathrm{Arg}(M_{12})=\mathrm{Arg}(\Gamma_{12})$, then $|q/p|=1$ and CP is conserved in mixing. In the more restrictive case that M_{12} and Γ_{12} are real, Eq. (70.4) implies that $\mathrm{Arg}(q/p)=0$ or π and there is no indirect CP violation. In this case, Eq. (70.3) implies that the differences in eigenvalues $\Delta m\equiv m_2-m_1=2M_{12}$ and $\Delta\Gamma\equiv\Gamma_2-\Gamma_1=\Gamma_{12}$. The magnitudes and signs of Δm and $\Delta\Gamma$ are difficult to predict from theory and must be determined experimentally.

It is advantageous to define dimensionless mixing parameters x and y as

$$x\equiv\frac{\Delta m}{\Gamma}\qquad y\equiv\frac{\Delta\Gamma}{2\Gamma}. \tag{70.5}$$

These parameters are measured in several ways; the most precise values are obtained by measuring the time dependence of D^0 decays. As an alternative to parameters x, y, one can define mixing parameters [2]

$$x_{12}\equiv\frac{2|M_{12}|}{\Gamma}\qquad y_{12}\equiv\frac{|\Gamma_{12}|}{\Gamma}. \tag{70.6}$$

As shown above, CP violation in mixing arises from $\mathrm{Arg}(M_{12})\neq\mathrm{Arg}(\Gamma_{12})$, and CP violation due to interference arises from either $\mathrm{Arg}(M_{12})\equiv\phi^M\neq0,\pi$ or $\mathrm{Arg}(\Gamma_{12})\equiv\phi^\Gamma\neq0,\pi$. Defining $\phi\equiv\mathrm{Arg}(q/p)+n\pi$, the conversion between parameters $(x,y,|q/p|,\phi)$ and equivalent parameters $(x_{12},y_{12},\phi^M,\phi^\Gamma)$ is [1,3]

$$x^2=\frac{x_{12}^2-y_{12}^2+\sqrt{(x_{12}^2+y_{12}^2)^2-4x_{12}^2y_{12}^2\sin^2\phi_{12}}}{2} \tag{70.7}$$

$$y^2=\frac{y_{12}^2-x_{12}^2+\sqrt{(x_{12}^2+y_{12}^2)^2-4x_{12}^2y_{12}^2\sin^2\phi_{12}}}{2} \tag{70.8}$$

$$\left|\frac{q}{p}\right|^2=\sqrt{\frac{x_{12}^2+y_{12}^2+2x_{12}y_{12}\sin\phi_{12}}{x_{12}^2+y_{12}^2-2x_{12}y_{12}\sin\phi_{12}}} \tag{70.9}$$

$$\tan(2\phi)=-\frac{x_{12}^2\sin(2\phi^M)+y_{12}^2\sin(2\phi^\Gamma)}{x_{12}^2\cos(2\phi^M)+y_{12}^2\cos(2\phi^\Gamma)}, \tag{70.10}$$

where $\phi_{12}\equiv\phi^M-\phi^\Gamma$. If CP is conserved in mixing ($|q/p|=1$), then $\phi_{12}=0,\pi$ and $|x|=x_{12}$, $|y|=y_{12}$. In this case, Eq. (70.10) implies $\phi=-\phi^{M,\Gamma}$ modulo π. It can be shown that the product $xy=x_{12}\,y_{12}\cos\phi_{12}$, and thus the fact that x and y are measured to be positive implies ϕ_{12} is close to zero rather than π. It can also be shown that the parameter $y_{CP}(K^+K^-,\pi^+\pi^-)\approx y_{12}\cos\phi^\Gamma$, and thus the fact that y_{CP} is measured to be positive implies ϕ^Γ (and hence ϕ^M) is close to zero rather then π.

To measure mixing, the initial flavor of the D^0 or $\overline{D}^0$ when produced must be determined. The most common method used to identify the initial flavor is to reconstruct $D^{*+}\to D^0\pi^+$ or $D^{*-}\to\overline{D}^0\pi^-$ decays; the charge of the accompanying pion (which has low momentum in the lab frame and is often referred to as the "soft" pion) determines the flavor of the neutral D. BABAR and LHCb have also identified the flavor of the neutral D by reconstructing the semileptonic decays $B^+\to\overline{D}^0X\ell^+\nu$, $B^0\to D^{*-}X\ell^+\nu$, $B^-\to D^0X\ell^-\bar{\nu}$, and $\overline{B}^0\to D^{*+}X\ell^-\bar{\nu}$;[1] in this case the charge of the accompanying lepton determines (or "tags") the D flavor. Both experiments have used these tags together to select "double-tagged" $B^0\to D^{*-}X\ell^+\nu$, $D^{*-}\to\overline{D}^0\pi^-$ decays, which have especially high purity. At e^+e^- collider experiments such as Belle, Belle II, BABAR, and BESIII, the D flavor can also be determined by reconstructing a flavor-specific D decay on the "opposite side" of an event, i.e., recoiling against the signal-side D decay.

At BESIII, where $D\overline{D}$ pairs are produced near their threshold via $e^+e^-\to\psi(3770)\to D^0\overline{D}^0$, there is little background and the purity of opposite-side tagging is equivalent to that achieved using $D^{*\pm}$ decays. However, BESIII operates at a symmetric e^+e^- collider, and the $D\overline{D}$ pairs are produced almost at rest in the lab frame. As a consequence, the D's do not travel any appreciable distance before decaying, and time-dependent analyses are not possible. To overcome this, measurements of mixing at BESIII utilize the quantum coherence of the initial $\psi(3770)\to D^0\overline{D}^0$ state and time-integrated measurements [4–8].

70.1 Time-Dependent Analyses

Starting from a pure $|D^0\rangle$ state, after a time t there will exist a mixture of states:

$$|D^0(t)\rangle=g_+(t)|D^0\rangle+\left(\frac{q}{p}\right)g_-(t)|\overline{D}^0\rangle, \tag{70.11}$$

where

$$g_\pm(t)=\frac{1}{2}\left(e^{-i\omega_1 t}\pm e^{-i\omega_2 t}\right) \tag{70.12}$$

and $\omega_{1,2}$ are defined in Eq. (70.3). Similarly, a pure $|\overline{D}^0\rangle$ state will evolve to a mixture of states

$$|\overline{D}^0(t)\rangle=g_+(t)|\overline{D}^0\rangle+\left(\frac{p}{q}\right)g_-(t)|D^0\rangle. \tag{70.13}$$

[1] Charge-conjugate modes are implicitly included throughout this Review, unless noted otherwise.

The respective decay rates to a final state f are

$$r_f(t) \equiv \left|\langle f|H|D^0(t)\rangle\right|^2 = \left|g_+(t)\langle f|H|D^0\rangle + \frac{q}{p}\,g_-(t)\langle f|H|\overline{D}^0\rangle\right|^2 \tag{70.14}$$

$$\bar{r}_f(t) \equiv \left|\langle f|H|\overline{D}^0(t)\rangle\right|^2 = \left|g_+(t)\langle f|H|\overline{D}^0\rangle + \frac{p}{q}\,g_-(t)\langle f|H|D^0\rangle\right|^2. \tag{70.15}$$

In these expressions we have neglected phase-space factors, which divide out in ratios of D^0 and $\overline{D}^0$ decay rates to common final states. Denoting the decay amplitudes of pure D^0 and $\overline{D}^0$ states as $A_f \equiv \langle f|H|D^0\rangle$, $\overline{A}_f \equiv \langle f|H|\overline{D}^0\rangle$, $A_{\overline{f}} \equiv \langle \overline{f}|H|D^0\rangle$, and $\overline{A}_{\overline{f}} \equiv \langle \overline{f}|H|\overline{D}^0\rangle$, and defining the combinations of factors

$$\lambda_f \;\equiv\; \frac{q}{p}\frac{\overline{A}_f}{A_f} \qquad\qquad \lambda_{\overline{f}} \;\equiv\; \frac{q}{p}\frac{\overline{A}_{\overline{f}}}{A_{\overline{f}}}\,, \tag{70.16}$$

one obtains

$$r_f(t) = |A_f|^2\left[|g_+(t)|^2 + |\lambda_f|^2|g_-(t)|^2 + 2\mathrm{Re}\Big(\lambda_f\, g_+^*(t)\, g_-(t)\Big)\right] \tag{70.17}$$

$$= \frac{|A_f|^2}{2}\,e^{-\Gamma t}\Big[(1+|\lambda_f|^2)\cosh(y\Gamma t) + 2\mathrm{Re}(\lambda_f)\sinh(y\Gamma t) + (1-|\lambda_f|^2)\cos(x\Gamma t) - 2\mathrm{Im}(\lambda_f)\sin(x\Gamma t)\Big] \tag{70.18}$$

$$\bar{r}_f(t) = |\overline{A}_f|^2\left[|g_+(t)|^2 + |\lambda_f|^{-2}|g_-(t)|^2 + 2\mathrm{Re}\Big(\lambda_f^{-1}\, g_+^*(t)\, g_-(t)\Big)\right] \tag{70.19}$$

$$= \frac{|\overline{A}_f|^2}{2}\,e^{-\Gamma t}\Big[(1+|\lambda_f|^{-2})\cosh(y\Gamma t) + 2\mathrm{Re}(\lambda_f^{-1})\sinh(y\Gamma t) + (1-|\lambda_f|^{-2})\cos(x\Gamma t) - 2\mathrm{Im}(\lambda_f^{-1})\sin(x\Gamma t)\Big]. \tag{70.20}$$

The rates $r_{\overline{f}}$ and $\bar{r}_{\overline{f}}$ are identical to Eqs. (70.18) and (70.20), respectively, except that f is replaced by $\bar{f}$. We note that a change in convention for the relative phase between D^0 and $\overline{D}^0$ cancels between q/p and $\overline{A}_f/A_f$ or $\overline{A}_{\overline{f}}/A_{\overline{f}}$, leaving λ_f and $\lambda_{\overline{f}}$ unchanged.

As $x, y \ll 1$ and experiments typically measure t in the range $(1-8)/\Gamma$, the cosh, sinh, cosine, and sine functions can be expanded to second order in x and y. One obtains:

$$r_f(t) \;\approx\; |A_f|^2\,e^{-\Gamma t}\left\{1 + \Big[y\,\mathrm{Re}(\lambda_f) - x\,\mathrm{Im}(\lambda_f)\Big](\Gamma t) + |\lambda_f|^2\left(\frac{x^2+y^2}{4}\right)(\Gamma t)^2 + \left(\frac{y^2-x^2}{4}\right)(\Gamma t)^2\right\} \tag{70.21}$$

$$\bar{r}_f(t) \;\approx\; |\overline{A}_f|^2\,e^{-\Gamma t}\left\{1 + \left[y\,\mathrm{Re}\left(\frac{1}{\lambda_f}\right) - x\,\mathrm{Im}\left(\frac{1}{\lambda_f}\right)\right](\Gamma t) + \frac{1}{|\lambda_f|^2}\left(\frac{x^2+y^2}{4}\right)(\Gamma t)^2 + \left(\frac{y^2-x^2}{4}\right)(\Gamma t)^2\right\}. \tag{70.22}$$

For $r_{\overline{f}}$ and $\bar{r}_{\overline{f}}$, A_f, $\bar{A}_f$, and λ_f are replaced by $A_{\bar{f}}$, $\bar{A}_{\bar{f}}$, and $\lambda_{\overline{f}}$. In the sections below we discuss various final states f; our convention is that amplitudes A_f and $\overline{A}_{\overline{f}}$ are Cabibbo-favored (CF), whereas $\overline{A}_f$ and $A_{\overline{f}}$ are Cabibbo-suppressed. With this convention, $|\lambda_f| \ll 1$ and $|1/\lambda_{\overline{f}}| \ll 1$. For multibody final states, Eqs. (70.21) and (70.22) apply separately to each point in phase-space.

70.2 Semileptonic decays

Consider the semileptonic decay $D^0 \to K^-\ell^+\nu$. For this final state, $\overline{A}_f = A_{\overline{f}} = 0$ to excellent approximation.[2] Thus, the final state f is reached from a pure $\overline{D}^0$ state at $t = 0$ only via mixing. The parameters $\lambda_f = 1/\lambda_{\overline{f}} = 0$, and Eqs. (70.21) and (70.22) become

$$r_f(t) = \Big|A_f\Big|^2\,e^{-\Gamma t}\,,$$
$$\bar{r}_f(t) = \Big|A_f\Big|^2\,e^{-\Gamma t}\left|\frac{p}{q}\right|^2\left[\frac{x^2+y^2}{4}\right]\Gamma t)^2\,, \tag{70.23}$$

where the term proportional to $(y^2-x^2)(\Gamma t)^2$ in $r_f(t)$ is negligible and thus dropped. For $r_{\overline{f}}(t)$ and $\bar{r}_{\overline{f}}(t)$, the former equals the second expression in Eq. (70.23) with $|q/p|^2$ replacing $|p/q|^2$, and the latter equals the first expression. In the Standard Model, CP violation in charm mixing is tiny and $|q/p| \approx 1$. Assuming such CP violation is negligible, the time-integrated mixed decay rate relative to the time-integrated unmixed decay rate is

$$\frac{\displaystyle\int_0^\infty \bar{r}_f(t)\,dt}{\displaystyle\int_0^\infty r_f(t)\,dt} \;=\; \frac{\displaystyle\int_0^\infty r_{\overline{f}}(t)\,dt}{\displaystyle\int_0^\infty \bar{r}_{\overline{f}}(t)\,dt} \;=\; \frac{x^2+y^2}{2} \;\equiv\; R_M\,. \tag{70.24}$$

Measurements of R_M from semileptonic decays are listed in Table 70.1. The world average from the Heavy Flavor Averaging Group (HFLAV) [9] is $R_M = (1.30 \pm 2.69) \times 10^{-4}$.

70.3 Hadronic decays to non-CP eigenstates

Consider the hadronic decay $D^0 \to K^-\pi^+$, i.e., $\overline{A}_f$ and $A_{\overline{f}}$ are doubly Cabibbo-suppressed (DCS). Because these CF and DCS decays are dominated by tree-level amplitudes involving only the first two quark generations, direct CP violation is expected to be very small. The ratios of decay amplitudes can be written

$$\frac{\overline{A}_f}{A_f} \;=\; \sqrt{R_D^-}\,e^{-i\delta_f} \qquad\qquad \frac{A_{\overline{f}}}{\overline{A}_{\overline{f}}} \;=\; \sqrt{R_D^+}\,e^{-i\delta_f}\,, \tag{70.25}$$

where R_D^- and R_D^+ are the ratios of the DCS decay rate to the CF decay rate: $R_D^- \equiv |\overline{A}_f/A_f|^2$ and $R_D^+ \equiv |A_{\overline{f}}/\overline{A}_{\overline{f}}|^2$. A relative minus sign resulting from the weak phase difference between $V_{cd}^*V_{us}$ (for $\overline{A}_f$) and $V_{cs}^*V_{ud}$ (for A_f) is canceled by the phase difference π between D^0 and $\overline{D}^0$ resulting from our convention $CP|D^0\rangle = -|\overline{D}^0\rangle$. From the CKM matrix elements, one estimates R_D^-, $R_D^+ \approx \tan^4\theta_c$, where θ_c is the Cabibbo angle. The parameter δ_f is the strong phase difference between CF and DCS amplitudes: $\delta \equiv \mathrm{Arg}(A_f/\overline{A}_f) = \mathrm{Arg}(\overline{A}_{\overline{f}}/A_{\overline{f}})$. The amplitudes A_f and $\overline{A}_f$ can in principle involve higher-order (or sub-leading) diagrams with a different weak phase than the leading diagram. The phase differences φ_f would depend on the final state and contribute factors $e^{i\varphi_f}$ to Eq. (70.25). However, such amplitudes are highly suppressed and can be safely neglected here; this is referred to as "approximate universality." Eq. (70.25) implies

$$\lambda_f = \sqrt{R_D^-}\left|\frac{q}{p}\right|e^{-i(\delta_f-\phi)}\,, \quad \left(\lambda_{\overline{f}}\right)^{-1} = \sqrt{R_D^+}\left|\frac{p}{q}\right|e^{-i(\delta_f+\phi)}\,, \tag{70.26}$$

where $\phi = \mathrm{Arg}(q/p)$.

For convenience, we define the mean decay rate $R_D \equiv (R_D^+ + R_D^-)/2$ and the decay rate asymmetry $A_D \equiv (R_D^+ - R_D^-)/(R_D^+ + R_D^-)$. With these definitions, the rates for the mixed ("wrong-

[2] There exists a doubly Cabibbo-suppressed amplitude in which the c and $\bar{u}$ quarks exchange a W, and the resulting d quark from the c decays semileptonically. We neglect this higher-order process.

Table 70.1: Results for $R_M = (x^2 + y^2)/2$ in D^0 semileptonic decays. The HFLAV average assumes statistical and systematic uncertainties are uncorrelated. When a single uncertainty is listed, it corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded and are not included in the HFLAV average.

sign") decays $D^0 \to K^+\pi^-$ and $\overline{D}^0 \to K^-\pi^+$ are [17, 18]:

$$r_{\overline{f}}(t) = \left|\overline{A}_{\overline{f}}\right|^2 e^{-\Gamma t}\Big[R_D(1+A_D) + \sqrt{R_D(1+A_D)}\left|\frac{q}{p}\right| y'_+(\Gamma t) + \left|\frac{q}{p}\right|^2 \frac{(x'^2_+ + y'^2_+)}{4}(\Gamma t)^2\Big] \tag{70.27}$$

$$\bar{r}_f(t) = \left|A_f\right|^2 e^{-\Gamma t}\Big[R_D(1-A_D) + \sqrt{R_D(1-A_D)}\left|\frac{p}{q}\right| y'_-(\Gamma t) + \left|\frac{p}{q}\right|^2 \frac{(x'^2_- + y'^2_-)}{4}(\Gamma t)^2\Big], \tag{70.28}$$

where

$$x'_\pm = x'\cos\phi \ \pm\ y'\sin\phi \tag{70.29}$$

$$y'_\pm = y'\cos\phi \ \mp\ x'\sin\phi\,, \tag{70.30}$$

and

$$x' \equiv x\cos\delta_f \ +\ y\sin\delta_f \tag{70.31}$$

$$y' \equiv y\cos\delta_f \ -\ x\sin\delta_f\,. \tag{70.32}$$

The parameters x', y' are obtained from x, y via a rotation by the strong phase δ; these are often referred to as "strong-phase-rotated" mixing parameters. The parameters $x'_\pm, y'_\pm$ are obtained from x', y' via a subsequent rotation by the weak phase $+\phi$ for D^0 decays and $-\phi$ for $\overline{D}^0$ decays. Note that $x'^2_+ + y'^2_+ = x'^2_- + y'^2_- = x'^2 + y'^2 = x^2 + y^2$. In Eqs. (70.27) and (70.28), a fourth term proportional to $R_D(1 \pm A_D)(x^2_\pm - y^2_\pm)(\Gamma t)^2/4$ has been dropped, as it is negligible relative to the other terms for the range of decay times measured by experiments.

Comparing Eqs. (70.27) and (70.28), one sees that $r_{\overline{f}}(t) \neq \bar{r}_f(t)$ if either $A_D \neq 0$, $|q/p| \neq 1$, or $\phi \neq 0$. The first inequality corresponds to CP violation in the decay amplitudes ($R^+_D \neq R^-_D$), which is referred to as *direct* CP violation. The second inequality corresponds to CP violation in mixing, and the third inequality corresponds to CP violation due to interference between a mixed decay amplitude and an unmixed amplitude. Whereas CP violation in decay amplitudes is parameterized by A_D, CP violation in mixing is often parameterized by $A_M \equiv (|q/p| - |p/q|)/(|q/p| + |p/q|)$.

In the limit of CP conservation, $A_D = 0$, $|q/p| = 1$, and $\phi = 0$. In this case,

$$r_{\overline{f}}(t) = \bar{r}_f(t) \tag{70.33}$$
$$= \left|A_f\right|^2 e^{-\Gamma t}\left[R_D + \sqrt{R_D}\, y'(\Gamma t) + \frac{x'^2 + y'^2}{4}(\Gamma t)^2\right].$$

The time-integrated mixed decay rate relative to the time-integrated unmixed decay rate is

$$R \ =\ \frac{\displaystyle\int_0^\infty r_{\overline{f}}(t)\,dt}{\displaystyle\int_0^\infty \left|A_f\right|^2 e^{-\Gamma t}\,dt} \ =\ R_D \ +\ \sqrt{R_D}\,y' \ +\ \frac{x'^2 + y'^2}{2}\,. \tag{70.34}$$

The ratio R is straightforward to measure, as there is no decay-time dependence. Parameters R_D, x'^2, y' are measured by assuming CP conservation and fitting to the decay-time distribution of wrong-sign ($D^0 + \overline{D}^0$) decays. Experiments allow for CP violation and measure $x'^2, y', A_D, |q/p|, \phi$ by separately fitting the decay-time distributions of wrong-sign $D^0 \to K^+\pi^-$ and $\overline{D}^0 \to K^-\pi^+$ decays. Results for R, R_D, and A_D are listed in Table 70.2, and results for x'^2 and y' are listed in Table 70.3.

The LHCb experiment recently analyzed all Runs 1+2 data with a D^*-tag, fitting to the ratios $r_{\overline{f}}(t)/\bar{r}_{\overline{f}}(t) \equiv R^+_{K\pi}(t)$ and $\bar{r}_f(t)/r_f(t) \equiv R^-_{K\pi}(t)$ in bins of decay time [19]. The fitted functions are parameterized as

$$R^\pm_{K\pi}(t) = R_D(1 \pm A_D) + \sqrt{R_D(1 \pm A_D)}(c_{K\pi} \pm \Delta c_{K\pi})(\Gamma t) + (c'_{K\pi} \pm \Delta c'_{K\pi})(\Gamma t)^2\,. \tag{70.35}$$

Fit results for parameters $c_{K\pi}, \Delta c_{K\pi}, c'_{K\pi}$, and $\Delta c'_{K\pi}$ are listed also in Table 70.3.

Extraction of the mixing parameters x and y from measurements of x' and y' requires knowledge of the strong phase difference $\delta_{K\pi}$. This can be determined from the decay rates of $D_\pm \to K^+\pi^-$, where D_+ (D_-) denotes the CP-even (CP-odd) eigenstate. Since $|D_\pm\rangle = (|D^0\rangle \mp |\overline{D}^0\rangle)/\sqrt{2}$,

$$\sqrt{2}\,A(D_\pm \to K^+\pi^-) \ =\ A(D^0 \to K^+\pi^-) \mp A\left(\overline{D}^0 \to K^+\pi^-\right). \tag{70.36}$$

Squaring this amplitude and using Eq. (70.25) yields the relation

$$\cos\delta_{K\pi} \ =\ \frac{|A(D_- \to K^+\pi^-)|^2 - |A(D_+ \to K^+\pi^-)|^2}{2\,|A(D^0 \to K^+\pi^-)|\,|A(\overline{D}^0 \to K^+\pi^-)|}\,. \tag{70.37}$$

Measuring the right-hand side is possible if one can identify pure D_+, D_-, D^0, and $\overline{D}^0$ initial states. This is accomplished at CLEOc and BESIII utilizing the processes $e^+e^- \to \psi(3770) \to \overline{D}^0 D^0 \to (f_{CP})(K^+\pi^-)$, or $\psi(3770) \to \overline{D}^0 D^0 \to (f_{\overline{D}^0})(K^+\pi^-)$, where f_{CP} denotes a CP-specific final state, and $f_{\overline{D}^0}$ denotes a $\overline{D}^0$-flavor-specific final state. In the first case, quantum coherence and CP symmetry ensures that the $K^+\pi^-$ state originates from a neutral D with CP opposite that of f_{CP}. In the second case, when the $\overline{D}^0$ decays, the opposite side must be D^0. However, it can potentially mix to $\overline{D}^0$ before decaying to $K^+\pi^-$, and this introduces some dependence on the mixing parameters x and y. This dependence is seen explicitly in the observable

$$A^{CP}_{K\pi} \ \equiv\ \frac{|A(D_- \to K^-\pi^+)|^2 - |A(D_+ \to K^-\pi^+)|^2}{|A(D_- \to K^-\pi^+)|^2 + |A(D_+ \to K^-\pi^+)|^2}\,. \tag{70.38}$$

To lowest order in the mixing parameters [34],

$$A^{CP}_{K\pi} \ =\ \frac{2\sqrt{R_D}\cos\delta_{K\pi} + y}{1+R}\,, \tag{70.39}$$

where R is defined in Eq. (70.34). Such measurements are discussed in Section 70.5.

70.3.1 *Wrong-sign decays to multibody final states*

For multibody final states, Eqs. (70.25)-(70.34) apply to each point in phase-space. Although x and y do not vary across phase-space, knowledge of the resonant substructure is needed to determine the strong phase difference δ at each point in order to extract x and y. Alternatively, experimental knowledge of the strong phase difference between A_f and $\overline{A}_f$ or between $A_{\overline{f}}$ and $\overline{A}_{\overline{f}}$ in regions of phase space [35] allows one to determine x and y independent of the decay model of resonant substructure. This phase information can be measured in $e^+e^- \to \psi(3770) \to \overline{D}D$ reactions in a manner similar to that for measuring $\delta_{K\pi}$, i.e., applying Eq. (70.37) to regions of phase space.

A time-dependent analysis of DCS $D^0 \to K^+\pi^-\pi^0$ decays relative to CF $\overline{D}^0 \to K^+\pi^-\pi^0$ decays by BABAR [36, 37] fit for both mixing parameters and the strong phase variation across the Dalitz plot. They reported results $x'' = (2.61\,^{+0.57}_{-0.68} \pm 0.39)\%$ and $y'' = (-0.06\,^{+0.55}_{-0.64} \pm 0.34)\%$, where

$$x'' = x\cos\delta_{K\pi\pi^0} + y\sin\delta_{K\pi\pi^0} \tag{70.40}$$

$$y'' = y\cos\delta_{K\pi\pi^0} - x\sin\delta_{K\pi\pi^0}\,, \tag{70.41}$$

in analogy with x', y', and $\delta_{K\pi}$ for $D^0 \to K^+\pi^-$ decays. Here, $\delta_{K\pi\pi^0}$ is the "reference" strong phase difference between amplitudes $A(\overline{D}^0 \to K^+\rho^-)$ and $A(D^0 \to K^+\rho^-)$, which cannot be determined in this analysis. However, $\delta_{K\pi\pi^0}$ can be measured using Eq. (70.37) and quantum-correlated measurements in $e^+e^- \to \psi(3770) \to D\overline{D}$ events of the branching fractions

$B(D_+ \to K^+\rho^-)$, $B(D_- \to K^+\rho^-)$, $B(D^0 \to K^+\rho^-)$, and $B(\overline{D}^0 \to K^+\rho^-)$.

For decays $(D^0, \overline{D}^0) \to K^+\pi^-\pi^+\pi^-$, Belle measured $R = (0.324 \pm 0.008 \pm 0.007)\%$ [38]. A phase-space-integrated analysis from LHCb [39] measured the product of a "coherence factor" $R_D^{K3\pi}$ and the mixing parameter $y''_{K3\pi}$ with high statistics. This resulted in an observation of charm mixing with a significance of 8.2σ.

Both the sign and magnitude of x and y without strong phases entering can be determined by measuring the time-dependence of resonance structure for multibody D^0 decays to self-conjugate final states [40, 41]. This method has been used extensively for $D^0 \to K^0_S\pi^+\pi^-$ decays, in which the DCS and CF amplitudes populate the same Dalitz plot. Assuming a decay model of intermediate resonances, this allows for fitting for strong phase differences and direct measurement of x and y. Alternatively, several LHCb $D^0 \to K^0_S\pi^+\pi^-$ analyses [42–45] use values of strong phase differences measured in bins of phase space by CLEO-c [46] and BESIII [47,48]; these (x, y) measurements are independent of the decay model. The most recent LHCb analyses fit for CP-violating parameters Δx and Δy; the translation of these parameters to $|q/p|$ and ϕ is given in Ref. [49]. Belle II [50] also used values of strong phase differences measured by BESIII [47,48] to determine decay-model-independent values of x and y. Table 70.4 summarizes results from time-dependent analyses of self-conjugate multibody final states. World average values for x and y are given later, when discussing results from the HFLAV global fit.

BESIII recently updated their measurements of strong-phase differences for $D^0 \to K^0_S\pi^+\pi^-$ decays using 7.9 fb^{-1} of data [51]; these are now the world's most precise values. BESIII has also measured strong-phase differences in bins of phase space for $(D^0, \overline{D}^0) \to K^+K^-\pi^+\pi^-$ decays [52] and $(D^0, \overline{D}^0) \to \pi^+\pi^-\pi^+\pi^-$ decays [53]. Strong phase differences for the latter mode have also been measured using a small sample (0.82 fb^{-1}) of CLEO-c data [54]. These multibody self-conjugate final states can all be used to determine x and y.

70.4 Hadronic decays to *CP* eigenstates

When the final state f is a CP eigenstate, there is no distinction between f and $\overline{f}$. Thus, $A_f = A_{\overline{f}}$, $\overline{A}_{\overline{f}} = \overline{A}_f$, and $\lambda_f = \lambda_{\overline{f}}$. We denote final states with CP eigenvalues ± 1 by $f_\pm$. Decays to CP eigenstates are singly Cabibbo-suppressed and can proceed via both a tree amplitude and an internal-loop amplitude. These two amplitudes have different weak phases, and thus their interference leads to direct CP violation. As loop amplitudes are suppressed, direct CP violation is expected to be very small, and the presence of a weak phase is often neglected. For a negligible weak phase in the decay amplitude, $\lambda_{f_\pm} = \mp|q/p|\, e^{i\phi}$, where the choice of signs corresponds to $\phi = 0$ (rather than π) if CP is conserved.

The mixing parameter y can be measured by comparing the rate for D^0 decays to CP eigenstates such as K^+K^- with the rate to flavor eigenstates such as $K^-\pi^+$ [18]. If decays to K^+K^- have a shorter effective lifetime than those to $K^-\pi^+$, then $\Gamma_+ > \Gamma_-$. Since CP violation is very small, $\Gamma_2 > \Gamma_1$ and y is positive. Since mixing is very small, i.e., $x, y \ll 1$, the $(\Gamma t)^2$ terms in Eqs. (70.27) and (70.28) are often neglected. In this case the decay rates for $D^0 \to f_\pm$ and $\overline{D}^0 \to f_\pm$ are approximately exponential:

$$r_\pm(t) \propto \exp(-\Gamma_\pm\, t) \tag{70.42}$$

$$\overline{r}_\pm(t) \propto \exp(-\overline{\Gamma}_\pm\, t)\,, \tag{70.43}$$

with effective decay widths

$$\Gamma_\pm = \Gamma\left(1 \pm \left|\frac{q}{p}\right| (y\cos\phi - x\sin\phi)\right) \tag{70.44}$$

$$\overline{\Gamma}_\pm = \Gamma\left(1 \pm \left|\frac{p}{q}\right| (y\cos\phi + x\sin\phi)\right). \tag{70.45}$$

The effective decay rate to a CP eigenstate for a data sample containing equal numbers of D^0 and $\overline{D}^0$ decays (e.g., an untagged sample with no production asymmetry) is

$$r_\pm(t) \;+\; \overline{r}_\pm(t) \;\propto\; e^{-(1\pm y_{CP})\Gamma t}\,, \tag{70.46}$$

where

$$y_{CP} = \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) y\cos\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) x\sin\phi \tag{70.47}$$

$$\approx y\cos\phi - A_M\, x\sin\phi\,. \tag{70.48}$$

If CP is conserved ($\phi = 0$), $y_{CP} = y$. Equation (70.46) implies that y_{CP} can be determined from the decay-time dependence of either CP-even or CP-odd decays:

$$y_{CP} \;=\; \frac{\Gamma_+}{\Gamma} - 1 \;=\; 1 - \frac{\Gamma_-}{\Gamma}\,. \tag{70.49}$$

Most y_{CP} measurements have used $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays, which are CP-even, measured relative to $D^0 \to K^-\pi^+$. Belle measured y_{CP} also using $D^0 \to K^0_S\,\omega$ decays [58], which are CP-odd, and $D^0 \to K^0_S\,K^+K^-$ decays [59], which are dominated by the CP-odd final state $K^0_S\,\phi$. Table 70.5 summarizes the status of measurements. The most recent y_{CP} measurement from LHCb has sufficient precision that the tiny effect of mixing upon $D^0(t) \to K^-\pi^+$ decays, which are used in the measurement to determine Γ, must be accounted for. The measurement directly yields

$$\frac{\Gamma_+}{\Gamma_{K^-\pi^+}} - 1 \;=\; \frac{1 + y_{CP}}{1 + y^{K\pi}_{CP}} - 1 \;\approx\; y_{CP} - y^{K\pi}_{CP}\,, \tag{70.50}$$

where the correction $y^{K\pi}_{CP}$ is $\sim 10^{-4}$. This correction was first pointed out in Ref. [60]; it is calculated in terms of parameters $(x, y, |q/p|, \phi)$ in Ref. [61].

In addition to y_{CP}, the asymmetry in decay rates to CP-even final states (A_Γ) has been measured [62–66]:

$$A_\Gamma \equiv \frac{\Gamma_+ - \overline{\Gamma}_+}{\Gamma_+ + \overline{\Gamma}_+} \;=\; \frac{(1/\tau_+) - (1/\overline{\tau}_+)}{(1/\tau_+) + (1/\overline{\tau}_+)} \;=\; \frac{\overline{\tau}_+ - \tau_+}{\overline{\tau}_+ + \tau_+} \tag{70.51}$$

$$\approx \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) y\cos\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) x\sin\phi \tag{70.52}$$

$$\approx A_M\, y\cos\phi - x\sin\phi\,. \tag{70.53}$$

If CP is conserved ($A_M = 0$, $\phi = 0$), then $A_\Gamma = 0$.

There is a contribution to Eq. (70.53) from direct CP violation, i.e., $|\overline{A}_f/A_f| \neq 1$ [1, 67]. For $f = K^+K^-$ and $\pi^+\pi^-$, this contribution can be estimated from measurements of $A_{CP}(K^+K^-)$ and $A_{CP}(\pi^+\pi^-)$ (see below) and is much smaller than the current uncertainty on A_M; thus we neglect it here. We note that, when averaging A_Γ measurements over K^+K^- and $\pi^+\pi^-$ final states, the contribution from direct CP violation nominally cancels, as it is expected to have the same magnitude for K^+K^- and $\pi^+\pi^-$ but opposite signs due to U-spin symmetry [1].

The observable A_Γ is an asymmetry in the full decay widths. An asymmetry in *partial* widths is referred to as A_{CP} and depends on the final state:

$$A_{CP} \;\equiv\; \frac{\Gamma(D^0 \to f) - \Gamma(\overline{D}^0 \to \overline{f})}{\Gamma(D^0 \to f) + \Gamma(\overline{D}^0 \to \overline{f})}\,. \tag{70.54}$$

Unlike A_Γ, which is measured by fitting decay-time distributions, A_{CP} is measured by fitting for signal yields and, aside from acceptance effects, does not require measuring decay times. For neutral D decays, A_{CP} receives contributions from both direct and indirect CP violation: $A_{CP}(D^0 \to f) = A^f_{CP} + A^{\rm indirect}_{CP}$. The indirect contribution depends on x and y:

$$\begin{aligned} A^{\rm indirect}_{CP} \;&=\; \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) x\sin\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) y\cos\phi \\ &=\; -A_\Gamma\,. \end{aligned} \tag{70.55}$$

Numerous measurements of A_{CP} for decays to CP eigenstates are listed in this *Review* [68]. Table 70.6 summarizes the status of measurements of the *difference* in A_{CP} for $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays: $\Delta A_{CP} \equiv A_{CP}(K^+K^-) - A_{CP}(\pi^+\pi^-)$.

‡This result allows for all types of CP violation and is superseded by Ref. [57], which assumes no direct CP violation in CF or DCS decays.

U-spin symmetry predicts $A_{CP}(KK) = -A_{CP}(\pi\pi)$ [69]; consequently, even accounting for U-spin-breaking, ΔA_{CP} should increase any direct CP asymmetry present. The difference is also advantageous experimentally, as several systematic uncertainties cancel. As $A_{CP}^{\rm indirect}$ is independent of the final state, it subtracts out of ΔA_{CP}. However, at hadron experiments such as LHCb, there is a difference in efficiencies between K^+K^- and $\pi^+\pi^-$ such that $\langle t\rangle_{KK} \neq \langle t\rangle_{\pi\pi}$, i.e., the mean decay times differ slightly. This difference introduces a small contribution to ΔA_{CP} from $A_{CP}^{\rm indirect}$ [67]. A measurement of ΔA_{CP} from LHCb [70] based on 8.9 fb^{-1} of data differs from zero with a statistical significance of 5.3σ; this measurement constitutes the first (and only) observation of CP violation in charm decays. A subsequent measurement by LHCb of $A_{CP}(K^+K^-)$ [71] yielded $(0.068 \pm 0.056)\%$, which is consistent with zero. Taken together, these results suggest that the large value of ΔA_{CP} is due to $D^0 \to \pi^+\pi^-$ decays, and that the expectation $A_{CP}(KK) \approx -A_{CP}(\pi\pi)$ is violated. However, the uncertainty on $A_{CP}(K^+K^-)$ is sufficiently large that the central value can be explained as a statistical fluctuation at the level of $\sim 2.3\sigma$. These CP asymmetries are included in HFLAV's global fit for charm mixing parameters, as discussed below.

70.5 Quantum-correlated $D^0\overline{D}^0$ Analyses

Measurements of R_D, $\cos\delta_{K\pi}$, $\sin\delta_{K\pi}$, x, and y can be obtained from a combined fit to time-integrated yields of single-tagged (ST) and double-tagged (DT) $D^0\overline{D}^0$ events produced at the $\psi(3770)$ resonance. Single-tagged events are those in which either the D^0 or $\overline{D}^0$ decay is reconstructed (identified), and the other neutral D decays generically. Double-tagged events are those in which both the D^0 and $\overline{D}^0$ decays are identified. Due to quantum correlations, the decay of a D^0, $\overline{D}^0$, D_+, or D_- projects the other neutral D into a state $\overline{D}^0$, D^0, D_-, or D_+, respectively. Neglecting CP violation, states D_- and D_+ are 50% D^0 and 50% $\overline{D}^0$; thus the $D_\pm$ decay rates include an interference term proportional to $\sqrt{R_D}\cos\delta_{K\pi}$. The interference also includes contributions from D^0–$\overline{D}^0$ mixing and thus provides sensitivity to x and y. An example is the parameter $A_{K\pi}^{CP}$ in Eq. (70.39). For details of this method, see Refs. [4–8].

BESIII has reported results using 2.9 fb^{-1} of $e^+e^- \to \psi(3770)$ data, where the quantum-correlated $D^0\overline{D}^0$ pairs are produced in a $C=-1$ state. They measure $y_{CP} = (-2.0 \pm 1.3 \pm 0.7)\%$ [79] from DT yields using a CP-eigenstate tag for one D and a flavor-specific semileptonic tag for the other; and they measure $A_{K\pi}^{CP} = (13.2 \pm 1.1 \pm 0.7)\%$ [90] from DT yields using a CP tag for one D and a $K^\pm\pi^\mp$ tag for the other. For y_{CP}, the CP eigenstates used are K^-K^+ (f_+), $\pi^+\pi^-$ (f_+), $K^0_S\,\pi^0\pi^0$ (f_+), $K^0_S\,\pi^0$ (f_-), $K^0_S\,\eta$ (f_-), and $K^0_S\,\omega$ (f_-). For $A_{K\pi}^{CP}$, seven additional CP eigenstates are included: $\pi^0\pi^0$ (f_+), $K^0_S\,\eta'$ (f_-), $K^0_S\,\phi$ (f_-), $K^0_L\,\pi^0$ (f_+), $K^0_L\,\omega$ (f_+), $K^0_L\,\pi^0\pi^0$ (f_-), and $\pi^+\pi^-\pi^0$ (mixed CP). Using Eq. (70.39) and external inputs for the CP-even fraction of $D^0 \to \pi^+\pi^-\pi^0$ (from Ref. [72]) and values of R_D and y (from HFLAV [14]), BESIII obtains $\delta_{K\pi} = (7.6\,^{+10.4}_{-11.6})^\circ$ [90].

Recently, BESIII reported results (unpublished) using 7.13 fb^{-1} of data collected at center-of-mass energies in the range 4.13–4.12 GeV [91]. This range allows for the production of $D\overline{D}$, $D^*\overline{D}$, $\overline{D}^*D$, and $D^*\overline{D}^*$ pairs, and the resulting $D^0\overline{D}^0$ pair can be in either a CP-even or CP-odd state. The strong phase difference $\delta_{K\pi}$ is determined using $D^0\overline{D}^0$ pairs decaying to $K^-\pi^+$ versus K^+K^- (f_+), $\pi^+\pi^-$ (f_+), $K^0\pi^0$ (f_-), $\pi^+\pi^-\pi^0$ (nearly f_+), and $K^0_S\pi^+\pi^-$ (mixed CP) final states. Using external inputs for R_D and y, the analysis obtains similar precision for $\delta_{K\pi}$ as that of Ref. [90], with a higher central value of 12.8°.

CLEO-c has reported results using 0.82 fb^{-1} of $e^+e^- \to \psi(3770)$ data [92–94]. The values for y, R_M, $\cos\delta_{K\pi}$, and $\sin\delta_{K\pi}$ are obtained from a combined fit to the ST (hadronic only) and DT yields. The DT yields include events in which one D is reconstructed in a hadronic mode and the other D is partially reconstructed in flavor-specific $D \to K^\mp e^\pm\nu$ and $D \to K^\mp\mu^\pm\nu$ modes. The CLEO-c analysis obtains $\cos\delta_{K\pi} = 0.81\,^{+0.22\,+0.07}_{-0.18\,-0.05}$ and $\sin\delta_{K\pi} = -0.01 \pm 0.41 \pm 0.04$. These fits allow $\cos\delta_{K\pi}$ and

Table 70.5: Results for y_{CP} and A_Γ from D^0 decays to CP eigenstates. When a single uncertainty is listed, it corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded. The third row (8.4 fb^{-1} A_Γ) lists the LHCb combination of the LHCb measurements listed below it.

‡This measurement uses the $D^0\to\pi^+\pi^-\pi^0$ CP-even fraction measured in Ref. [72].

§This measurement has sufficient precision that y_{CP} for the normalization channel $D^0\to K^-\pi^+$ must be accounted for. HFLAV accounts for this small correction in their global fit.

¶This result for y_{CP} is not superseded, but it is not included in the HFLAV average due to having some correlations with the result of Ref. [76] but much worse precision.

$\sin\delta_{K\pi}$ (and also x^2) to be unphysical. Constraining $\cos\delta_{K\pi}$ and $\sin\delta_{K\pi}$ to the physical range $[-1,+1]$ (i.e., interpreting $\delta_{K\pi}$ as an angle) and also using external inputs for x, y, and y_{CP} from HFLAV 2012 [95], CLEO-c obtains $\delta_{K\pi}=(18^{+11}_{-17})^\circ$ [94].

70.6 Summary of Experimental Results

The first evidence for D^0-$\overline{D}^0$ mixing was obtained in 2007 by Belle [87] and BABAR [23]. These results were confirmed by CDF [96] and, much later, by LHCb [28]. There are now numerous measurements of D^0-$\overline{D}^0$ mixing with various levels of precision. Using $D^0\to K^+\pi^-$ decays, CDF [22], LHCb [27, 28], and Belle [21] each exclude the no-mixing hypothesis by more than five standard deviations. The most significant observation of mixing (8.2σ significance) was made by LHCb using $D^0\to K^+\pi^-\pi^+\pi^-$ decays [39]. However, strong phase differences for this multibody decay are not known, and thus x and y cannot be extracted. The most precise measurement of y is essentially LHCb's measurement of y_{CP} using $D^0\to(K^+K^-,\pi^+\pi^-)$ decays [74], and the most precise measurement of x is LHCb's measurement using $D^0\to K^0_S\,\pi^+\pi^-$ decays [44]. This measurement resulted in the first direct observation ($>5\sigma$ significance) of dispersive mixing ($x\neq0$).

These experimental measurements establish that D^0 and $\overline{D}^0$ mesons mix. In the Standard Model, this mixing is dominated by long-distance amplitudes, which are difficult to calculate. If one assumes the observed mixing is due to non-Standard Model processes, significant constraints on new physics models can be obtained [105]. A significant limitation to interpreting charm mixing in terms of new physics is the theoretical uncertainty on Standard Model predictions [106, 107]. We note that the HFLAV global fit results for x and y (see below) indicate that charm mixing is at the upper end of the range of predictions. The current situation would benefit from knowledge of strong phase differences between $\overline{D}^0\to K^+\pi^-\pi^0$ and $D^0\to K^+\pi^-\pi^0$ decays, and between $\overline{D}^0\to K^+\pi^-\pi^+\pi^-$ and $D^0\to K^+\pi^-\pi^+\pi^-$ decays. Such knowledge would allow one to extract x and y from measurements of $(x''^2_{K2\pi}, y''_{K2\pi})$ and $(x''^2_{K3\pi}, y''_{K3\pi})$ performed for these modes.

With regard to CP violation, by combining separate measurements from two data sets totalling 8.9 fb^{-1} of data, LHCb observed CP violation in D decays for the first time [70]. The observable measured, $\Delta A_{CP}=A_{CP}(K^+K^-)-A_{CP}(\pi^+\pi^-)$, is dominated by direct CP violation; contributions from indirect CP violation mostly cancel. The amount of direct CP violation measured is small: $\Delta A_{CP}=(-0.154\pm0.029)\%$. Several theory

calculations [108–110] indicate that this value is consistent with the Standard Model, although new physics contributions cannot be excluded (see e.g., [111, 112]). A subsequent LHCb measurement of $A_{CP}(K^+K^-)$ differs from zero by only 1.2σ [71]; thus, the ΔA_{CP} value is interpreted as indicating direct CP violation in $D^0 \to \pi^+\pi^-$ decays. Among all measurements, there is no evidence so far of indirect CP violation in the D^0-$\overline{D}^0$ system.

70.7 HFLAV Global Fit for Charm Mixing Parameters

The Heavy Flavor Averaging Group (HFLAV) performs global fits to all relevant mixing measurements to obtain world average values for the following: mixing parameters x and y or alternatively x_{12} and y_{12}; strong phase differences $\delta_{K\pi}$ and $\delta_{K\pi\pi^0}$; the ratio R_D of $\Gamma(D^0 \to K^+\pi^-)$ and $\Gamma(\overline{D}^0 \to K^+\pi^-)$ partial widths; direct CP-violating parameters $A_D(K^+\pi^-)$, $A_{CP}(D^0 \to K^+K^-) \equiv A_K$, and $A_{CP}(D^0 \to \pi^+\pi^-) \equiv A_\pi$; and indirect CP-violating parameters $|q/p|$ and ϕ or alternatively ϕ^M, ϕ^Γ, and their difference $\phi_{12} \equiv \phi^M - \phi^\Gamma$. Three separate fits are performed: *(a)* assuming no indirect CP violation; *(b)* assuming no subleading amplitudes in indirect CP violation (the "superweak" model); *(c)* allowing for all CP violation. Details of these fits are given in Ref. [14]. For fit *(b)* in which there are no subleading amplitudes, one can derive the relation $\tan\phi = (x/y) \cdot (1 - |q/p|^2)/(1 + |q/p|^2)$ [2, 3, 113]; this reduces four fitted parameters to three. Alternatively, one can fit for the three parameters x_{12}, y_{12}, and ϕ_{12}. However, the direct CP violation observed in ΔA_{CP} implies that subleading amplitudes play a role in Γ_{12}, the off-diagonal element of the decay matrix.

The fits use Belle, BABAR, CDF, and LHCb measurements of $D^0 \to K^{(*)+}\ell^-\overline{\nu}$, K^+K^-, $\pi^+\pi^-$, $K^+\pi^-$, $K^+\pi^-\pi^0$, $K^+\pi^-\pi^+\pi^-$, $K^0_S\pi^+\pi^-$, $K^0_S K^+K^-$, and $\pi^+\pi^-\pi^0$ decays, as well as CLEO-c and BESIII measurements of $\cos\delta$, $\sin\delta$, and $A_{CP}(K^+\pi-)$ obtained from quantum-correlated measurements of branching fractions in $e^+e^- \to \psi(3770) \to D^0\overline{D}^0$ reactions. Correlations among observables are taken into account by using the error matrices provided by the experiments. Three observables input to the fit are themselves world average values calculated by HFLAV: $R_M = (x^2 + y^2)/2$ from $D^0 \to K^{(*)+}\ell^-\overline{\nu}$ decays (Table 70.1), and y_{CP} and A_Γ from $D^0 \to f_{CP}$ decays (Table 70.5). A measurement of R_M by LHCb using $D^0 \to K^+\pi^-\pi^+\pi^-$ decays is input separately.

The results of the fit as of September, 2025 are listed in Table 70.7. Confidence contours in the two dimensions (x, y) and $(|q/p|, \phi)$ resulting from the fit are plotted in Fig. 70.1. These contours are obtained by allowing, for any point in the two-dimensional plane, all other floated parameters to take their preferred values. The 1σ–5σ boundaries drawn are the loci of points in which the χ^2 rises above the minimum by 2.30, 6.18, 11.83, 19.33, and 28.67 units. The fit excludes the no-mixing point $x = y = 0$ at more than 11.5σ. The fit is consistent with CP conservation ($|q/p| = 1$, $\phi = 0$) at the 2σ level. The χ^2 of the all-CP-violation-allowed fit is 70.7 for $59 - 10 = 49$ degrees of freedom, which is considered satisfactory. One-dimensional likelihood functions for parameters are obtained by allowing, for any value of the parameter, all other floated parameters to take their preferred values. The resulting likelihood functions give the 95% C.L. intervals listed in Table 70.7.

From the results of the HFLAV fit, one concludes the following: (1) since CP violation is small and y_{CP} is positive, the CP-even state is shorter-lived, as in the $K^0\overline{K}^0$ system; but since x is positive, the CP-even state is heavier, which is opposite to the $K^0\overline{K}^0$ system. (2) The strong phase difference $\delta_{K\pi}$ is nonzero: the 95% C.L. interval is $8.1^\circ < \delta_{K\pi} < 20.9^\circ$, with a preferred value of 14.8°. (3) While direct CP violation has been observed ($\Delta A_{CP} \neq 0$), there is still no evidence for indirect CP violation, i.e., $|q/p| \neq 1$ or $\phi \neq 0$ or $\phi^M \neq 0$ or $\phi^\Gamma \neq 0$. Observing such CP violation at the current level of experimental sensitivity would hint at new physics.

Finally, we note that the global fit to charm mixing measurements can be expanded to include $B \to (D^0, \overline{D}^0)K$ and $B \to (D^0, \overline{D}^0)\pi$ measurements; this larger fit is performed to determine the CKM angle ϕ_3 (or γ) [114, 115]. When $D^0 \to K^\pm\pi^\mp$, the B decay data is sensitive to the strong phase $\delta_{K\pi}$, and the fit gives improved precision for $\delta_{K\pi}$ [115]. This improvement leads to a small improvement in the precision for y (from measurements of y' via $D^0 \to K^+\pi^-$ decays and Eq. (70.32)).

70.8 Future Data

Current mixing and CP violation results are based mainly upon the following:

- CLEO-c (0.82 fb^{-1}) and BESIII (2.9 fb^{-1}) data recorded in $e^+e^- \to \psi(3770)$ reactions;
- BABAR (384 fb^{-1}), Belle (976 fb^{-1}), and Belle II (408 fb^{-1}) data recorded in $e^+e^- \to \Upsilon(4S)$ reactions;
- CDF (9.6 fb^{-1}) data of $\bar{p}p$ collisions at $\sqrt{s} = 2$ TeV; and
- LHCb Run 1 (3.0 fb^{-1}, $\sqrt{s} = 7$, 8 TeV) and Run 2 (6 fb^{-1}, $\sqrt{s} = 13$ TeV) data of pp collisions.

BESIII has recently completed its goal of accumulating 20 fb^{-1} of $e^+e^- \to \psi(3770)$ data. These data should provide numerous strong phase measurements that would enable additional model-independent determinations of mixing parameters from Belle II and LHCb. In 2019 Belle II began a long-range program to accumulate 50 ab^{-1} of $e^+e^- \to \Upsilon(4S)$ data [116]. To date, the experiment has recorded about 0.6 ab^{-1} of data and is expected to record several ab^{-1} over the next few years. At LHCb, Run 2 was completed in 2018, Run 3 is now in progress, and Run 4 is planned for 2030-33 [117]. The goal for Runs $3 + 4$ is to accumulate an additional 50 fb^{-1} of pp data at $\sqrt{s} \approx 14$ TeV [118]. These data, along with the substantial e^+e^- dataset from Belle II, should provide more precise measurements of D^0-$\overline{D}^0$ mixing and direct

Table 70.7: HFLAV global fit results (see text and Ref. [24]). The upper two sections list mixing and indirect CP violation (CPV) parameters; the third section lists strong phases and the ratio of decay rates R_D; and the bottom section lists direct CP violation parameters.

71. Leptonic Decays of Charged Pseudoscalar Mesons

Updated Aug. 2025 by R. A. Briere (Carnegie Mellon U.); written with J. L. Rosner (Chicago U.), S. L. Stone (Syracuse U.) and R. Van de Water (FNAL)

71.1 Introduction

This review updates one in Ref. [1]. Lattice QCD updates rely on the Flavor Lattice Averaging Group FLAG 24 update [2]; these updates were modest. The most significant updates involve D_s experimental results; some changes to the discussions of semileptonic decays in second-generation unitarity and inclusive-exclusive V_{ub} tension are also noted.

Charged mesons formed from a quark and antiquark can decay to a lepton-neutrino pair when these objects annihilate via a virtual W boson. Figure 71.1 illustrates this process for the purely leptonic decay of a D^+ meson.

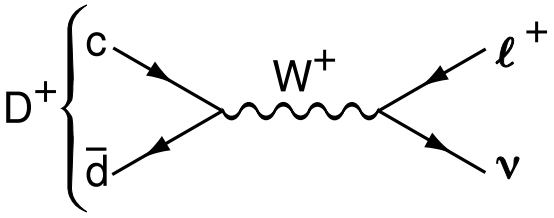

Figure 71.1: The annihilation process for pure D^+ leptonic decays in the standard model.

Similar quark-antiquark annihilations via a virtual W^+ to the $\ell^+\nu$ final states occur for the π^+, K^+, D_s^+, and B^+ mesons. (Whenever pseudoscalar-meson charges are specified in this article, use of the charge-conjugate particles and corresponding decays are also implied.) Let P be any of these pseudoscalar mesons. To lowest order, the decay width is

$$\Gamma^{(0)}(P \to \ell\nu) = \frac{G_F^2}{8\pi} f_P^2 \; m_\ell^2 M_P \left(1 - \frac{m_\ell^2}{M_P^2}\right)^2 |V_{q_1 q_2}|^2 \; . \quad (71.1)$$

Here M_P is the P mass, m_ℓ is the ℓ mass, $V_{q_1 q_2}$ is the Cabibbo-Kobayashi-Maskawa (CKM) matrix element between the quarks $q_1\bar{q}_2$ in P, and G_F is the Fermi coupling constant. The decay constant f_P is proportional to the matrix element of the axial current between the one-P-meson state and the vacuum:

$$\langle 0|\bar{q}_1\gamma_\mu\gamma_5 q_2|P(p)\rangle = ip_\mu f_P \, , \quad (71.2)$$

and can be thought of as proportional to the "wave function overlap" of the quark and antiquark. In this article, we use the convention in which $f_\pi \approx 130$ MeV. For brevity, we will often denote the purely leptonic decay width in Eq. (71.1) by $\Gamma^{(0)}$.

The decay of $P^\pm$ starts with a spin-0 meson, and ends up with a left-handed neutrino or right-handed antineutrino. By angular momentum conservation, the $\ell^\pm$ must then also be left-handed or right-handed, respectively. In the $m_\ell = 0$ limit, the decay is forbidden, and can only occur as a result of the finite ℓ mass. This helicity suppression is the origin of the m_ℓ^2 factor in the decay width.

Experimentally, it is difficult to isolate events in which there are *only* a lepton and neutrino in the final state from those with a lepton, neutrino, and soft photon. Thus, radiative contributions must be removed from the experimental measurements *a posteriori* to obtain $\Gamma^{(0)}$. The radiative contributions can be broken into three pieces: the short-distance contribution to leptonic and semileptonic decays mediated by a $W^\pm$ boson that accounts for electroweak corrections not included in the definition of G_F, the long-distance internal bremsstrahlung (IB) contribution, and the contribution from photon emission that depends upon the hadron's structure. The universal electroweak correction was calculated at $\mathcal{O}(\alpha)$ by Sirlin [3], and increases the purely leptonic decay rate by ~ 1.8–2.2% depending on the decaying meson. The $\mathcal{O}(\alpha)$ IB contribution was calculated by Kinoshita [4], and again is universal for all leptonic decays at this order. Numerically, this universal long-distance contribution lowers the purely leptonic decay rate by ~ 0.4–2.4%, where the correction is smallest for pions and largest for $D_{(s)}$ mesons. The structure-dependent contributions have been estimated within various effective theories and from lattice-QCD,QED calculations to increase the purely leptonic rate by one to a few percent [5–10].

In this review, we treat the radiative corrections differently for the light, charm, and bottom meson systems for several reasons. First, the experimental uncertainties on the decay widths vary substantially. Thus, while the inclusion of radiative corrections is essential for the pion, kaon, and $D_{(s)}$-meson decay widths, which have been measured to (sub)-percent precision, radiative corrections can be neglected (for now) for $B \to \tau\nu$ decay. Second, the photons are treated differently on the experimental side for the different decay processes. For pions and kaons, the experimental measurements of $\Gamma_{P\ell 2[\gamma]}$ are fully inclusive, while for $D_{(s)}$ mesons, the experiments impose cuts on the energy of any neutral cluster deposited in the calorimeter, which reduce the soft-photon background substantially. Some experiments also remove the QED bremsstrahlung in the leading-logarithmic approximation using the PHOTOS Monte-Carlo generator [11]. Third, the theoretical knowledge of the structure-dependent corrections varies for each meson system.

Once radiative corrections have been accounted for, measurements of purely leptonic decay branching fractions and lifetimes allow an experimental determination of the product $|V_{q_1 q_2}|\, f_P$. If the decay constant f_P is known to sufficient precision from theory, one can obtain the corresponding CKM element within the standard model. If, on the other hand, one takes the value of $|V_{q_1 q_2}|$ assuming CKM unitarity, one can infer an "experimental measurement" of the decay constant that can then be compared with theory.

The importance of measuring $\Gamma(P \to \ell\nu)$ depends on the particle being considered. Leptonic decays of charged pseudoscalar mesons occur at tree level within the standard model. Thus one does not expect large new-physics contributions to measurements of $\Gamma(P \to \ell\nu)$ for the lighter mesons $P = \pi^+, K^+$, and these processes, in principle, provide clean standard-model determinations of $|V_{ud}|$ and $|V_{us}|$. The situation is different for leptonic decays of charm and bottom mesons. The presence of new heavy particles such as charged Higgs bosons or leptoquarks could lead to observable effects in $\Gamma(P \to \ell\nu)$ for $P = D_{(s)}^+, B^+$ [12–16]. Thus, the determination of $|V_{ub}|$ from $B^+ \to \tau\nu$ decay, in particular, should be considered a probe of new physics. More generally, the ratio of leptonic decays to $\tau\nu$ over $\mu\nu$ final states probes lepton universality [12, 17].

The determinations of CKM elements from leptonic decays of charged pseudoscalar mesons provide complementary information to those from other decay processes. The decay $P \to \ell\nu$ proceeds in the standard model via the axial-vector current $\bar{q}_1\gamma_\mu\gamma_5 q_2$, whereas semileptonic pseudoscalar meson decays $P_1 \to P_2\ell\nu$ proceed via the vector current $\bar{q}_1\gamma_\mu q_2$. Thus the comparison of determinations of $|V_{q_1 q_2}|$ from leptonic and semileptonic decays tests the $V - A$ structure of the standard-model electroweak charged-current interaction. More generally, a small right-handed admixture to the standard-model weak current would lead to discrepancies between $|V_{q_1 q_2}|$ obtained from leptonic pseudoscalar-meson decays, exclusive semileptonic pseudoscalar-meson decays, exclusive semileptonic baryon decays, and inclusive semileptonic decays [18, 19].

Both measurements of the decay rates $\Gamma(P \to \ell\nu)$ and theoretical calculations of the decay constants f_P for $P = \pi^+, K^+, D_{(s)}^+$ from numerical lattice-QCD calculations are now quite precise. As a result, the elements of the first row of the CKM matrix $|V_{ud}|$ and $|V_{us}|$ can be obtained to sub-percent precision from $\pi^+ \to \ell\nu$ and $K^+ \to \ell\nu$, where the limiting error is from continuum theory radiative corrections. The elements of the second row of the CKM matrix $|V_{cd(s)}|$ can be obtained from leptonic decays of charmed pseudoscalar mesons to few-percent precision, where here the limiting error is from experiment. These enable stringent tests of the unitarity of the first and second rows of the CKM matrix.

This review is organized as follows. Because the experimental and theoretical issues associated with measurements of pions and kaons, charmed mesons, and bottom mesons differ, we discuss each one separately. We begin with the pion and kaon system in Sec. 71.2. First, in Sec. 71.2.1, we review current measurements of the experimental decay rates. We provide tables of branching-ratio measurements and determinations of the product $|V_{ud(s)}|f_{\pi^+(K^+)}$, as well as average values for these quantities including correlations and other effects needed to combine results. Then, in Sec. 71.2.2, we summarize the status of theoretical calculations of the decay constants. We provide tables of recent lattice-QCD results for f_{π^+}, f_{K^+}, and their ratio from calculations including dynamical u, d, s, and (in some cases c) quarks, along with averages including correlations and strong SU(2)-isospin breaking corrections as needed. We next discuss the charmed meson system in Sec. 71.3, again reviewing current experimental rate measurements in Sec. 71.3.1 and theoretical decay-constant calculations in Sec. 71.3.2. Last, we discuss the bottom meson system in Sec. 71.4, following the same organization as the two previous sections. For almost all of the decay constants presented in Secs. 71.2.2, 71.3.2, and 71.4.2, we take as our preferred values the four-flavor averages from the FLAG 24 review [2], with isospin-breaking corrections as noted.

After having established the status of both experimental measurements and theoretical calculations of leptonic charged pseudoscalar-meson decays, we discuss some implications for phenomenology in Sec. 71.5. For each process discussed in Secs. 71.2–71.4, we combine the average $\mathcal{B}(P \to \ell\nu)$ with the decay constant f_P to infer the associated CKM matrix element. We then compare these results with determinations of the same CKM elements from other processes. We also use the CKM elements obtained from leptonic decays to test the unitarity of the first and second rows of the CKM matrix. Further, as in previous reviews, we combine the experimental $\mathcal{B}(P \to \ell\nu)$s with the associated CKM elements obtained from CKM unitarity to infer "experimental" values for the decay constants. The comparison of these values with theory provides a test of lattice and other QCD approaches, assuming that new-physics contributions to these processes are not significant.

71.2 Pions and kaons

71.2.1 *Experimental rate measurements*

Experimental rate measurements of pion and kaon leptonic decays are fully radiation inclusive. Following Refs. [20, 21], and references therein, we combine the $\mathcal{O}(\alpha)$ radiative corrections to the purely leptonic rate as follows:

$$\Gamma(P \to \ell\nu[\gamma]) = \Gamma^{(0)}(P \to \ell\nu)\left[1 + \frac{\alpha}{\pi}C_P\right], \tag{71.3}$$

where $P = \pi, K$. The full expressions for C_π and C_K are given in Eq. (114) of Ref. [7]. In addition to the universal short- [3] and long-distance [4] corrections, C_π and C_K include hadronic-structure dependent contributions [5] through $\mathcal{O}(\alpha p^4)$ in chiral perturbation theory (χPT), where p is the pion or kaon momentum. The inclusion of radiative corrections to the purely leptonic rates is numerically important given the level of precision achieved on the experimental measurements of the $\pi^\pm \to \mu^\pm\nu$ and $K^\pm \to \mu^\pm\nu$ decay widths.

We evaluate $\delta_P \equiv (\alpha/\pi)C_P$ using experimentally-measured meson and lepton masses and coupling constants from the Particle Data Group [22], and taking the low-energy constants (LECs) that parametrize the hadronic contributions from Refs. [7, 23, 24]. Because the finite non-logarithmic parts of the LECs were estimated within the large-N_C approximation assuming that contributions from the lowest-lying resonances dominate, we conservatively assign a 100% uncertainty to the LECs, which leads to a ± 0.9 error in $C_{\pi,K}$.[1] We obtain the following correction factors to the individual charged pion and kaon decay widths:

$$\delta_\pi = 0.0176(21) \quad \text{and} \quad \delta_K = 0.0107(21)\,. \tag{71.4}$$

The error on the ratio of kaon-to-pion leptonic decay widths is under better theoretical control because the hadronic contributions from low-energy constants estimated within the large-N_c framework cancel at lowest order in the chiral expansion. For the ratio, we use the correction factor

$$\delta_{K/\pi} = -0.0069(17)\,, \tag{71.5}$$

where we take the estimated error due to higher-order corrections in the chiral expansion from Ref. [26].

There have been no new measurements of the pion leptonic decay rate since the review of Ref. [27]. The sum of branching fractions for $\pi^- \to \mu^-\bar\nu$ and $\pi^- \to \mu^-\bar\nu\gamma$ is 99.98770(4)% [1]. Together with the lifetime 26.033(5) ns [1] this implies $\Gamma(\pi^- \to \mu^-\bar\nu[\gamma]) = 3.8408(7) \times 10^7\ \text{s}^{-1}$. We then subtract the estimated radiative correction factor δ_π in Eq. (71.4) to obtain the purely leptonic rate $\Gamma^{(0)}(\pi^- \to \mu^-\bar\nu)$. Using this rate and the PDG masses [1] in Eq. (71.1) gives

$$f_{\pi^+}|V_{ud}| = (127.13 \pm 0.01 \pm 0.13)\ \text{MeV}\,, \tag{71.6}$$

where the errors are from the experimental rate measurement and the radiative correction factor, respectively.

The uncertainty on $f_{\pi^-}|V_{ud}|$ is dominated by that from theoretical estimate of the hadronic structure-dependent radiative corrections. The first direct lattice-QCD calculation of the radiative corrections to the pion and kaon leptonic decay rates was performed by the RM123-Soton Collaboration [10]. The results for both $\delta_\pi = 0.0153(19)$ and $\delta_K = 0.0088(9)$, which are given in the Gasser-Rusetsky-Scimemi scheme for separating strong and electromagnetic effects [28], are compatible with our chiral-perturbation-theory estimates above and have smaller quoted uncertainties, especially for δ_K. Less precise results have also been presented by RBC/UKQCD [29]. While further confirmation of these results is needed, they demonstrate a promising approach for reducing the theoretical uncertainties on the pion and kaon leptonic decay rates in the future.

The world average for the $K \to \mu\nu$ decay rate was previously obtained from a global fit of several kaon-decay branching ratios and lifetime measurements by the FlaviaNet Working Group on Kaon Decays in 2014 [42]; we have now updated to the PDG [1]. The radiation-inclusive branching ratio $\mathcal{B}(K^+ \to \mu^+\nu[\gamma]) = 63.56(11)\%$ and lifetime $\tau_{K^\pm} = 12.380(20)$ ns are now used; this is a very small change. These measurements imply $\Gamma(K^+ \to \mu^+\nu[\gamma]) = 5.134(12) \times 10^7\ \text{s}^{-1}$. As before, we subtract δ_K in Eq. (71.4) from the radiation-inclusive decay width to obtain $\Gamma^{(0)}(K^+ \to \mu^+\nu)$. We then use Eq. (71.1) to obtain

$$f_{K^+}|V_{us}| = (35.083 \pm 0.042 \pm 0.037)\ \text{MeV}\,, \tag{71.7}$$

where the errors are from the experimental rate measurement and the radiative correction factor, respectively.

Short-distance radiative corrections cancel in the ratio of pion-to-kaon decay rates [43]:

$$\frac{\Gamma_{K_{\ell 2[\gamma]}}}{\Gamma_{\pi_{\ell 2[\gamma]}}} = \frac{|V_{us}^2|f_{K^-}^2}{|V_{ud}|^2 f_{\pi^-}^2}\,\frac{m_K(1 - m_\ell^2/m_K^2)^2}{m_\pi(1 - m_\ell^2/m_\pi^2)^2}(1 + \delta_{K/\pi})\,, \tag{71.8}$$

where $\delta_{K/\pi}$ is given in Eq. (71.5). The left-hand side of Eq. (71.8) is 1.3367(32), which implies

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27599 \pm 0.00033 \pm 0.00024\,, \tag{71.9}$$

where the first uncertainty is from the branching fractions and the second is from $\delta_{K/\pi}$. Here, the estimated error on the hadronic structure-dependent radiative corrections is commensurate with the experimental error.

[1] This uncertainty on $C_{\pi,K}$ is smaller than the error estimated by Marciano and Sirlin in Ref. [25], which predates the calculations of the hadronic-structure contributions in Refs. [5, 7, 23, 24]. The hadronic LECs incorporate the large short-distance electroweak logarithm discussed in Ref. [25], and their dependence on the chiral renormalization scale cancels the scale-dependence induced by chiral loops, thereby removing the dominant scale uncertainty of the Marciano–Sirlin analysis [25].

Table 71.1: Recent published lattice-QCD results for f_{π^+}, f_{K^+}, and their ratio. The upper and lower panels show $(2+1+1)$-flavor and $(2+1)$-flavor determinations, respectively. When two errors are shown, they are statistical and systematic, respectively. Results for f_π and f_K in the isospin symmetric limit $m_u = m_d$ are noted with a ‡; they are corrected for isospin breaking via Eq. (71.13) before computing the averages. The 2+1+1 FLAG 24 averages are dominated by the Fermilab/MILC values.

In summary, the main experimental results pertaining to charged pion and kaon leptonic decays are

$$|V_{ud}|f_{\pi^+} = (127.13 \pm 0.01 \pm 0.13)\ \text{MeV}\,, \tag{71.10}$$

$$|V_{us}|f_{K^+} = (35.083 \pm 0.042 \pm 0.037)\ \text{MeV}\,, \tag{71.11}$$

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27599 \pm 0.00033 \pm 0.00024\,, \tag{71.12}$$

where the errors are from the experimental uncertainties in the branching fractions and the theoretical uncertainties in the radiative correction factors δ_P, respectively. These values are unchanged since the last reviews [1].

71.2.2 *Theoretical decay-constant calculations*

Table 71.1 presents recent published results for the charged pion and kaon decay constants and their ratio from numerical lattice-QCD calculations with three ($N_f = 2+1$) or four flavors ($N_f = 2+1+1$) of dynamical quarks. The uncertainties on both the individual decay constants and their ratio are at the sub-percent level. The SU(3)-breaking ratio f_{K^+}/f_{π^+} can be obtained with especially small errors because statistical errors associated with the Monte Carlo calculations are correlated between the numerator and denominator, as are some systematics. The results in Table 71.1 were obtained using several independent sets of gauge-field configurations, and a variety of lattice fermion actions that are sensitive to different systematic uncertainties.[2,3] Thus, the good agreement between them indicates that the lattice-QCD uncertainties are controlled and the associated error estimates are reliable.[4]

Table 71.1 also shows the three- and four-flavor averages for the pion and kaon decay constants and their ratio from the FLAG 24 review [2] in the lines labeled "FLAG 24 average." There is no four-flavor average for the pion decay constant in Table 71.1 because all of the four-flavor calculations use the quantity $f_{\pi^+} =$ 130.41(20) MeV [22] as an input to fix the absolute lattice scale needed to convert from lattice-spacing units to GeV [9,33,34].

All of the results in Table 71.1 were obtained using isospin-symmetric gauge-field configurations, *i.e.*, the dynamical up and down quarks have the same mass. Fortunately, however, the leading effect of strong-isospin breaking is easily included in lattice-QCD calculations as follows. Because the up-down mass difference $\Delta m_{ud} \equiv (m_u - m_d) \sim -2.5$ MeV [49,51] is much less than typical hadronic scales, the strong-isospin breaking corrections to physical observables can be systematically expanded in the small parameter $\delta m_{ud} \equiv \Delta m_{ud}/\Lambda_{\rm QCD}$. The leading strong-isospin-breaking corrections to pseudoscalar-meson decay constants arise from the light *valence* quarks in the initial- and final-state hadrons. (See, *e.g.,* the discussion in Ref. [52], for a detailed discussion of isospin-breaking effects in pion and kaon observables.) Thus, to include the effect of non-degenerate up- and down-quark masses, most recent lattice-QCD calculations of f_{π^+} and f_{K^+} evaluate the masses of the valence quarks in the pion at the physical m_u and m_d, and the mass of the valence light quark in the kaon at the physical m_u. This procedure yields a correction to the kaon decay constant below 0.5%. Consequently, strong-isospin breaking corrections from the light sea-quark masses — which are suppressed by an additional power of δm_{ud} — can be neglected given present uncertainties.

Some earlier lattice-QCD calculations, however, only provide the decay constants and their ratio in the $SU(2)$ isospin-symmetric limit [38,40,41]. The Flavour Lattice Averaging Group corrects these results for strong-isospin breaking using chiral perturbation theory before including them in the averages. The leading strong-isospin-breaking corrections to the pion and kaon decay constants in χPT can be parametrized as [26,56]

$$f_{\pi^+} = f_\pi\,, \qquad f_{K^+} = f_K\sqrt{1+\delta_{\rm SU(2)}}\,, \tag{71.13}$$

where f_π and f_K denote the values of the decay constants in the isospin-symmetric limit. The pion decay constant does not receive corrections linear in $m_u - m_d$ because of the G-parity symmetry[5] of the pion triplet, so at first order the δm_{ud} expansion, strong-isospin breaking corrections are characterized by a single parameter, $\delta_{\rm SU(2)}$. Next-to-leading order χPT yields numerical

[2]See the PDG mini-review on "Lattice Quantum Chromodynamics" [44–46] for a general review of numerical lattice-QCD calculations. Details on the different methods used in modern lattice-QCD calculations are provided in Appendix A of the FLAG "Review[s] of lattice results concerning low energy particle physics" [47–49].

[3]Note that one must be careful concerning issues of scheme dependence, particularly in the ambiguous separation of QED and QCD effects; see, e.g., Sec. 3 of Ref. [2].

[4]See the review by Kronfeld [50] for a summary of the large body of evidence validating the methods employed in modern lattice-QCD calculations.

[5]This is a combination of charge conjugation, C, and an $e^{i\pi I_2}$ rotation in isospin space that maps the triplet onto itself.

Table 71.2: Experimental results for $\mathcal{B}(D^+ \to \mu^+\nu[\gamma])$, $\mathcal{B}(D^+ \to \tau^+\nu[\gamma])$, and $|V_{cd}|f_{D^+}$. The first two uncertainties are experimental statistics and systematics, respectively. The third uncertainty on the extracted $|V_{cd}|f_{D^+}$ is from external inputs: masses, lifetimes, and radiative corrections. The uncertainty on the latter item dominates this third value. In the second CLEO line the τ^+ decays to $\mu^+\nu_\mu\bar{\nu}_\tau$.

Experiment	Mode	$\mathcal{B}$	$\lvert V_{cd}\rvert f_{D^+}$ (MeV)
CLEO-c [53]	$\mu^+\nu$	$(3.93 \pm 0.35 \pm 0.09) \times 10^{-4}$	$46.80 \pm 2.08 \pm 0.54 \pm 0.34$
CLEO-c [53]	$\mu^+\nu + \tau^+\nu$	$(3.82 \pm 0.32 \pm 0.09) \times 10^{-4}$	$46.14 \pm 1.93 \pm 0.54 \pm 0.34$
BESIII [54]	$\mu^+\nu$	$(4.034 \pm 0.080 \pm 0.040) \times 10^{-4}$	$47.42 \pm 0.47 \pm 0.24 \pm 0.35$
Our average	Lines 2+3	$(4.020 \pm 0.078 \pm 0.038) \times 10^{-4}$	$47.33 \pm 0.46 \pm 0.25 \pm 0.35$
CLEO-c [53]	$\tau^+\nu$ ($\pi^+\overline{\nu}$)	$< 1.2 \times 10^{-3}$	
BESIII [55]	$\tau^+\nu$ ($\pi^+\overline{\nu}$)	$(0.99 \pm 0.11 \pm 0.05) \times 10^{-3}$	$45.48 \pm 2.53 \pm 1.15 \pm 0.34$
Our average	$\mu^+\nu + \tau^+\nu$		$47.27 \pm 0.45 \pm 0.22 \pm 0.35$

values for $\delta_{\mathrm{SU}(2)}$ of approximately -0.004. Recent direct lattice-QCD calculations of $\delta_{\mathrm{SU}(2)}$ give larger values of around -0.005 to -0.008 [10, 32–34, 52, 57], but further studies are needed. Thus, to be conservative, FLAG includes an uncertainty of 100% on the χPT estimate for $\delta_{\mathrm{SU}(2)}$ when correcting those decay-constant values that are quoted in the isospin-symmetric limit.

The errors on the decay-constant results in Table 71.1 obtained from $(2+1)$-flavor lattice-QCD calculations do not include an estimate of the systematic uncertainty from the omission of charm sea quarks in the calculation. Consequently, when the uncertainty on the $(2+1+1)$-flavor FLAG average is comparable to or better than that on the $(2+1)$-flavor FLAG average, we simply use the four-flavor average as our preferred value. This is not possible, however, for the pion decay constant. To account for this, we first estimate the systematic uncertainty on pseudoscalar-meson decay constants associated with the omission of charm sea quarks. We then add this estimate in quadrature to the quoted error on the (2+1)-flavor FLAG average for f_{π^+} to obtain our preferred value.

The error introduced by omitting charm sea quarks can be roughly estimated by expanding the charm-quark determinant in powers of $1/m_c$ [58]; the resulting leading contribution is of order $\alpha_s \left(\Lambda_{\mathrm{QCD}}/2m_c\right)^2$ [59]. Taking the $\overline{\mathrm{MS}}$ values $\overline{m}_c(\overline{m}_c) = 1.275$ GeV, $\overline{\Lambda}_{\mathrm{QCD}} \sim 340$ MeV from FLAG [47], and $\overline{\alpha}_s(\overline{m}_c) \sim 0.4$, leads to an estimate of about 0.7% for the contribution to the decay constants from charm sea quarks. We can compare this power-counting estimate of charm sea-quark contributions with the observed differences between the (2+1)- and (2+1+1)-flavor lattice-QCD averages for kaon, $D_{(s)}$-meson, and $B_{(s)}$-decay constants in Tables 71.1, 71.4, and 71.6. Looking at Table 71.1, the three- and four-flavor averages for f_{K^+} agree to much better than our simple power-counting estimate. Inspection of Tables 71.4 and 71.6 shows, however, that charm sea-quark effects of this size are still allowed for both $D_{(s)}$-meson and $B_{(s)}$-meson decay constants.

Our final preferred theoretical values for the charged pion and kaon decay constants are

$$f_{\pi^+} = 130.2(1.2)\ \mathrm{MeV}\,, \quad f_{K^+} = 155.7(3)\ \mathrm{MeV}\,, \quad \frac{f_{K^+}}{f_{\pi^+}} = 1.193(2)\,, \tag{71.14}$$

where f_{K^+} and f_{K^+}/f_{π^+} are simply the four-flavor FLAG 2024 averages [2], and f_{π^+} is the three-flavor FLAG 2024 average with the error increased by the estimated 0.7% charm sea-quark contribution.

71.3 Charmed mesons

71.3.1 *Experimental rate measurements*

Measurements have been made of the branching fractions for D^+ and D_s^+ mesons decaying to both $\mu^+\nu$ and $\tau^+\nu$ final states. The CLEO-c and BESIII experiments have made measurements of D^+ decays using e^+e^- collisions at the $\psi(3770)$ resonant energy where D^-D^+ pairs are copiously produced. They fully reconstruct one of the D mesons; for concreteness, we will take this to be the D^-. Counting the number of these events provides the normalization for the branching fraction measurement. The experimental analyses then proceed by identifying a candidate μ^+ and forming the missing-mass squared, $MM^2 = (E_{\mathrm{cm}} - E_{D^-})^2 - \left(\vec{p}_{\mathrm{cm}} - \vec{p}_{D^-} - \vec{p}_{\mu^+}\right)^2$, where E_{cm} and p_{cm} are the center-of-mass energy (which is known) and momentum (which equals zero in e^+e^- collisions). A peak at zero MM^2 implies the existence of a missing neutrino, and hence the $\mu^+\nu$ decay of the D^+. CLEO-c does not explicitly identify the muon, so their data consists of a combination of $\mu^+\nu$ and $\tau^+\nu$, $\tau^+ \to \pi^+\nu$ events. This permits them to do two fits: in one they fit for the individual components, and in the other they fix the ratio of $\tau^+\nu/\mu^+\nu$ events to be that given by the standard-model expectation. Thus, the former measurement should be used for new-physics searches, and the latter for standard-model predictions. Our average uses the fixed-ratio value; this ratio is implied by Eq. 71.1 which is necessary to extract $|V_{cd}|f_{D^+}$.

Table 71.2 shows the available measurements of $D^+ \to \mu^+\nu$, an upper limit on $D^+ \to \tau^+\nu$ from CLEO-c, and the first measurement of this decay from BESIII. To extract the values of $|V_{cd}|f_{D^+}$ via Eq. (71.1), we use [1] the mass $m_{D^+} = 1.86966(5)$ GeV and the lifetime $\tau_{D^+} = 1.033(5)$ ps, and apply radiative corrections as described below. For calculating the average $\mu^+\nu$ number, we use the CLEO-c result from $\mu^+\nu + \tau^+\nu$.

To obtain the purely leptonic rates $\Gamma^{(0)}(D^+ \to \mu^+(\tau^+)\nu)$, we subtract the radiative contributions as in Sec. 71.2.1, but use numerical values for the corrections appropriate for D mesons. First, we reduce both the $\mu^+\nu$ and $\tau^+\nu$ branching fractions in Table 71.2 by 1.8%, which is the universal short-distance electroweak contribution of Sirlin [3] evaluated using the D-meson mass for the factorization scale. We do not adjust the experimental rates by the universal long-distance correction [4]. This is because QED bremsstrahlung contributions have already been subtracted at leading-log order from the measurements in Table 71.2 using Monte-Carlo estimates computed with PHOTOS [11]. The $\mu^+\nu$ rates should also be reduced by the 1% estimate of the structure-dependent contributions from Dobrescu and Kronfeld [16]. This correction accounts for tree-level radiative processes in which the D meson decays into a real photon and an off-shell vector meson, which subsequently decays weakly to a charged lepton and neutrino. It is estimated using Eq. (12) of Burdman *et al.* [6] with the CLEO-c cut on the photon energy from Ref. [72], which is typical of all the measurements. We do not need to apply the structure-dependent correction to the $\mu^+\nu$ branching fractions in Table 71.2, however, because the experiments have already included it in their quoted results. CLEO-c directly subtracts 1%, while BESIII simulates these structure- dependent radiative decays and adds a fit component describing them. Therefore, in summary, we reduce both the $D^+ \to \mu^+\nu$ and the $D^+ \to \tau^+\nu$ rates by 1.8% to account for radiative corrections. It is worth noting, however, that the universal long-distance electromagnetic contribution estimated for point-like charged mesons by Kinoshita [4], which we are not including because IB contributions are already subtracted from the measurements via PHOTOS, would *increase* both rates by about 2.5%.

We now discuss the D_s^+ decay process; there are significant updates since our previous review [1] due to new results from BESIII as well as our averaging strategy. Measurements of D_s^+

Table 71.3: Experimental results for $\mathcal{B}(D_s^+ \to \mu^+\nu[\gamma])$, $\mathcal{B}(D_s^+ \to \tau^+\nu[\gamma])$, and $|V_{cs}|f_{D_s^+}$. The uncertainties have the same meaning as in Table 71.2. The single-experiment average BFs are taken from the cited papers, for proper treatment of correlated systematic uncertainties.

Experiment	Mode	$\mathcal{B}(\%)$	$\lvert V_{cs}\rvert f_{D_s^+}$ (MeV)
CLEO-c [60]	$\mu^+\nu$	$0.565 \pm 0.045 \pm 0.017$	$248.2 \pm 9.9 \pm 3.7 \pm 1.8$

*An error in Ref. [65] has been corrected here; BESIII Collab., private communication.

leptonic decay branching fractions by several groups are listed in Table 71.3. We exclude older values obtained by normalizing to D_s^+ decay modes that are not well-defined. Many measurements, for example, used the $\phi\pi^+$ mode. This decay is a subset of the $D_s^+ \to K^+K^-\pi^+$ channel which has interferences from other modes populating the K^+K^- mass region near the ϕ, the most prominent of which is the $f_0(980)$. Thus, the extraction of the effective $\phi\pi^+$ rate is sensitive to the mass resolution of the experiment and the cuts used to define the ϕ mass region [73].[6]

To find D_s decays in the $\mu^+\nu$ signal channels, the experiments rely on fully reconstructing all of the final state particles except for the neutrino and use a missing-mass technique to infer the existence of the neutrino. CLEO and BESIII use $e^+e^- \to D_sD_s^*$ collisions at 4170 MeV, while BaBar and Belle use $e^+e^- \to DKn\pi D_s^*$ collisions at energies near the $\Upsilon(4S)$. CLEO and BESIII do a similar analysis as was done for the D^+ above. BaBar and Belle do a similar MM^2 calculation by using the reconstructed hadrons, the photon from the D_s^{*+} decay and a detected μ^+. To get the normalization they do a MM^2 fit without the μ^+ and use the signal at the D_s^+ mass squared to determine the total D_s^+ yield.

When selecting the $\tau^+ \to \pi^+\bar{\nu}$ and $\tau^+ \to \rho^+\bar{\nu}$ decay modes, CLEO uses both the calculation of the missing-mass and the fact that there should be no extra energy in the event beyond that deposited by the measured tagged D_s^- and the τ^+ decay products. The $\tau^+ \to e^+\nu\bar{\nu}$ mode, however, uses only extra energy. BaBar and Belle also use the extra energy to discriminate signal from background in their $\tau^+\nu$ measurements. BESIII uses $\tau^+ \to \pi^+\overline{\nu}$ decays, where they calculate the MM^2 and discriminate against μ^+ from $D_s^+ \to \mu^+\nu$ decays, and more recently $\tau^+ \to e^+\nu\overline{\nu}$ and $\tau^+ \to \pi^+\pi^0\overline{\nu}$ decays.

When extracting $|V_{cs}|f_{D_s^+}$ via Eq. (71.1), we first apply the -1.8% universal electroweak correction [3] to all of the $\mu^+\nu$ and $\tau^+\nu$ branching fractions in Table 71.3; this is the same as for D^+ mesons. We also decrease the BaBar, Belle, and third BESIII $\mu^+\nu$ branching fractions by the 1% structure-dependent correction [16]. This correction was already included in CLEO and other BESIII results for the $\mu^+\nu$ branching fractions in Table 71.3. We use the masses and lifetimes $m_{D_s^+} = 1.96835(7)$ GeV, $m_{\tau^+} = 1.77686(12)$ GeV, and $\tau_{D_s^+} = 0.5012(22)$ ps [1]. The inferred values for $f_{D_s^+}|V_{cs}|$ are in good agreement for the $\mu^+\nu$ and$\tau^+\nu$ decay modes.

It is clear from the discussion of radiative corrections in this section that they are less well understood theoretically for D^+ and D_s^+ meson decays than for pions and kaons. We therefore assign a 1.4% systematic uncertainty to the purely leptonic decay rates, which is half the size of the applied radiative corrections. This translates to a 0.7% error on the products of the decay constant times CKM matrix element. Putting everything together, the main experimental results pertaining to charmed meson leptonic decays are (see the bottom lines of Tables 71.2 and 71.3):

$$|V_{cd}|f_{D^+} = 47.27(45)(22)(35) = 47.27(0.61)\ \text{MeV}\,, \quad (71.15)$$

$$|V_{cs}|f_{D_s^+} = 244.0(1.2)(1.2)(1.8) = 244.0(2.4)\ \text{MeV}\,, \quad (71.16)$$

where the errors are the statistical and systematic uncertainties from the measured branching fractions, and the external inputs (including the applied radiative corrections), respectively.

71.3.2 *Theoretical decay-constant calculations*

Table 71.4 presents recent theoretical calculations of charmed heavy-light meson decay constants and their ratio in the isospin-symmetric limit $m_u = m_d$. (As in Sec. 71.2.2, we denote the physical D^+-meson decay constant by f_{D^+}, and use f_D for the isospin-symmetric value.) The upper two panels show results from lattice-QCD calculations with three ($N_f = 2+1$) or four flavors ($N_f = 2+1+1$) of dynamical quarks. Although there are fewer available results than for the pion and kaon sector, both f_D and f_{D_s} have been obtained using multiple sets of gauge-field configurations with different lattice fermion actions, providing independent confirmation. For comparison, the bottom panel of Table 71.4 shows QCD-model calculations of the D- and D_s-meson decay constants for which uncertainty estimates are provided. The lattice and non-lattice results agree, but numerical lattice-QCD calculations have now reached significantly greater precision than other approaches.

[6] We do not include two BaBar results [74, 75] for $\mathcal{B}(D_s^+ \to \mu^+\nu)$ and $\mathcal{B}(D_s^+ \to \tau^+\nu)$ that normalize to other D_S^+ decay modes.

*Ref. [32] provides values for f_D and f_{D_s} in the isopsin-symmetric limit, but not for their ratio. Here we infer the central value from those of the individual decay constants, and take the statistical and systematic errors to be the same as for the physical ratio f_{D_s}/f_{D^+}.

†Slight difference from preliminary value quoted in 2019 FLAG review.

‡Obtained using $m_c^{\overline{\rm MS}}$; results using $m_c^{\rm pole}$ are also given in the paper.

The lattice-QCD decay-constant results in Table 71.4 were all obtained using isospin-symmetric gauge-field configurations. As discussed in Sec. 71.2.2, however, the leading strong-isospin breaking corrections to heavy-light pseudoscalar-meson decay constants can be accounted for by using the physical down (or up) quark in the D (or B) meson. Strong-isospin breaking corrections to heavy-strange meson decay constants are roughly an order-of-magnitude smaller because there are no light valence quarks involved. Recently, the Fermilab Lattice and MILC Collaborations used this approach to calculate directly the leading strong-isospin breaking corrections to both f_D and f_B, finding [32]

$$\begin{aligned} f_{D^+} - f_D &= +0.58(1)(7)(1)\ \text{MeV}\,, \\ f_{B^+} - f_B &= -0.53(5)(7)(0)\ \text{MeV}\,, \end{aligned} \tag{71.17}$$

where the uncertainties are from statistics, systematics, and the EM scheme, respectively. These results agree with independent estimates of the strong-isospin-breaking corrections to heavy-light meson decay constants from QCD sum rules [90]. Combined with the determinations of f_D and f_B from the same work, Eq. (71.17) implies that the corrections to the SU(3)-flavor breaking ratios are

$$\frac{f_{D_s}}{f_{D^+}} = \frac{f_{D_s}}{f_D}\Big(1 - 0.0027(3)\Big)\,, \qquad \frac{f_{B_s}}{f_{B^+}} = \frac{f_{B_s}}{f_B}\Big(1 + 0.0028(5)\Big)\,. \tag{71.18}$$

These estimated strong-isospin-breaking corrections to f_D and f_{D_s}/f_D above are commensurate with the uncertainties on the (2+1+1)-flavor FLAG averages in Table 71.4. Consequently, it is important to account for isospin-breaking effects before combining the theoretical decay constants with the corresponding experimental decay rates.

To obtain the charged D^+-meson decay constant, we apply the correction in Eq. (71.17) to the (2+1+1)-flavor FLAG 2024 average for the D-meson decay constant in the isospin-symmetric limit. Similarly we use Eq. (71.18) to correct the (2+1+1)-flavor FLAG 2024 average for f_{D_s}/f_D. We take the four-flavor FLAG 2024 average for f_{D_s} directly. Our final preferred theoretical values for the charmed pseudoscalar-meson decay constants are

$$\begin{aligned} f_{D^+} &= 212.6(7)\ \text{MeV}\,, \\ f_{D_s} &= 249.9(5)\ \text{MeV}\,, \\ \frac{f_{D_s}}{f_{D^+}} &= 1.175(2)\,. \end{aligned} \tag{71.19}$$

71.4 Bottom mesons

71.4.1 *Experimental rate measurements*

The Belle and BaBar collaborations have found evidence for $B^- \to \tau^-\overline{\nu}$ decay in $e^+e^- \to B^-B^+$ collisions at the $\Upsilon(4S)$ energy. The analysis relies on reconstructing a hadronic or semileptonic B decay tag, finding a τ candidate in the remaining track and photon candidates, and examining the extra energy in the event which should be close to zero for a real τ^- decay to $e^-\nu\bar{\nu}$ or $\mu^-\nu\bar{\nu}$ opposite a B^+ tag. The results are listed in Table 71.5. These are unchanged since the previous review [1]. But we note a very recent result from Belle II using hadronic tagging [91] which gives $\mathcal{B}(B^+ \to \tau^+\nu_\tau) = (1.24 \pm 0.41 \pm 0.19) \times 10^{-4}$; this is not yet included in our averages pending an evaluation of correlated systematic uncertainties.

Table 71.5: Experimental results for $\mathcal{B}(B^- \to \tau^-\overline{\nu})$ and $|V_{ub}|f_{B^+}$. External systematic uncertainties from masses and lifetimes are negligible compared to current experimental uncertainties.

Experiment	Tag	$\mathcal{B}$ (units of 10^{-4})	$\lvert V_{ub}\rvert f_{B^+}$ (MeV)
Belle [92]	Hadronic	$0.72^{+0.27}_{-0.25} \pm 0.11$	
Belle [93]	Semileptonic	$1.25 \pm 0.28 \pm 0.27$	
Belle [93]	Average	0.91 ± 0.22	0.72 ± 0.09
BaBar [94]	Hadronic	$1.83^{+0.53}_{-0.49} \pm 0.24$	
BaBar [95]	Semileptonic	$1.7 \pm 0.8 \pm 0.2$	
BaBar [94]	Average	1.79 ± 0.48	1.01 ± 0.14
Our average		1.06 ± 0.20	0.77 ± 0.07

Because there are large backgrounds under the signals for these measurements, as well as substantial systematic errors, the significances of the individual results are still below the 5σ discovery threshold. Belle quotes 4.6σ for their combined hadronic and semileptonic tags, while BaBar quotes 3.3σ and 2.3σ, for hadronic and semileptonic tags. Greater precision is necessary to determine if any effects beyond the standard model are present.

We do not correct the measured branching ratios in Table 71.5 for radiative corrections because the experimental uncertainties are so large. The relative radiative corrections are expected to be larger, however, for $B \to \mu\nu$ leptonic decays because the corrections are no longer helicity suppressed [8], and may be a significant fraction of the purely leptonic rate. More theoretical work is

*Average of new HPQCD 17 and previous HPQCD 13 results allowing for correlations between the two sets of results.
†Obtained with static b quarks (*i.e.*, $m_b \to \infty$).
‡Ref. [101] does not provide results in the isospin-symmetric limit, so we show f_{B^+} and f_{B_s}/f_{B^+} for this work.
§Obtained using $m_b^{\overline{\rm MS}}$; results using $m_b^{\rm pole}$ are also given in the paper.

needed to understand radiative corrections to leptonic B decays in anticipation of future measurements with greater precision, and of new decay channels.

71.4.2 *Theoretical decay-constant calculations*

Table 71.6 presents recent theoretical calculations of bottom heavy-light meson decay constants and their ratio in the isospin-symmetric limit $m_u = m_d$. The upper two panels show results from lattice-QCD calculations with three ($N_f = 2+1$) or four flavors ($N_f = 2+1+1$) of dynamical quarks. For all decay constants, calculations using different gauge-field configurations, light-quark actions, and b-quark actions provide independent confirmation. For comparison, the bottom panel of Table 71.6 shows QCD-model calculations of the B- and B_s-meson decay constants for which uncertainty estimates are provided. These are consistent with the lattice values, but with much larger uncertainties.

The lattice-QCD decay-constant results in Table 71.6 were all obtained using isospin-symmetric gauge-field configurations. Some calculations, however, account for the leading effect of strong-isospin-breaking by using the correct value for the valence light-quark mass in the B meson (m_u for f_{B^+} and m_d for f_{B^0}). Early estimates of the strong-isospin-breaking correction obtained $f_{B^+} - f_B \sim -2$ MeV [99, 101], which would be significant given the present lattice-QCD uncertainties. It turns out, however, that these calculations inadvertently introduced a spurious sea-quark contribution, and therefore overestimated the size of the effect. A more recent calculation by the Fermilab/MILC Collaboration finds very little evidence for isospin violation ($f_{B^+} - f_B \sim -0.5$ MeV) [32], which is more than two times smaller than the total uncertainties on present lattice-QCD calculations. For this reason, we quote isospin averages in the current review. Our preferred theoretical values for the bottom pseudoscalar-meson decay constants are simply the $N_f = 2+1+1$ FLAG 2024 averages [2], after inclusion of the isospin-breaking corrections from Eq. (71.17) and Eq. (71.18):

$$\begin{aligned} f_{B^+} &= 189.5(1.3)\ \text{MeV}\,, \\ f_{B_s} &= 230.3(1.3)\ \text{MeV}\,, \\ \frac{f_{B_s}}{f_{B^+}} &= 1.212(5)\,. \end{aligned} \tag{71.20}$$

Because the uncertainties on the three-flavor results in Table 71.6 are substantially larger than those on the four-flavor results, including them in the average leaves the central values almost unchanged, and decreases the errors only slightly. Note that Ref. [96] is not included in the f_{B_s} average since it was published after the FLAG 24 deadline; including it would decrease f_{B_s} by about 0.3 MeV with little effect on the uncertainty.

71.5 Phenomenological implications

71.5.1 $|V_{ud}|$, $|V_{us}|$, *and status of first-row unitarity*

Using the average values for $f_{\pi^+}|V_{ud}|$, $f_{K^+}|V_{us}|$, and their ratio from Eqs. (71.10)–(71.12) and for f_{π^+}, f_{K^+}, and their ratio from Eq. (71.14), we obtain the following determinations of the CKM matrix elements $|V_{ud}|$, $|V_{us}|$, and their ratio from leptonic decays within the standard model:

$$\begin{aligned} &|V_{ud}| = 0.9763(1)(90)(10)\,, \quad |V_{us}| = 0.2253(3)(4)(2), \\ &\frac{|V_{us}|}{|V_{ud}|} = 0.2313(3)(4)(2)\,, \end{aligned} \tag{71.21}$$

where the errors are from the experimental branching fraction(s), the pseudoscalar decay constant(s), and radiative corrections, respectively. These results enable a test of the unitarity of the first row of the CKM matrix from leptonic decays alone (the contribution from $|V_{ub}|$ is negligible). Using the values of $|V_{ud}|$ and $|V_{us}|$ from Eq. (71.21), we find

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 - 1 = 0.004(18)\,, \tag{71.22}$$

which is consistent with three-generation unitarity at the few-percent level.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

The determinations of $|V_{ud}|$ and $|V_{us}|$ from leptonic decays in Eq. (71.21) can be compared to those obtained from other processes. The result above for $|V_{ud}|$ agrees with the determination from super-allowed β-decay (a previous value of $|V_{ud}| = 0.97420(21)$ [107] has been updated to $|V_{ud}| = 0.97373(31)$ [108]) but has a considerably larger error, primarily due to the uncertainty in the theoretical determination of f_{π^+}.

The CKM element $|V_{us}|$ can be determined from semileptonic $K^+ \to \pi^0 \ell^+ \nu$ decay. Here experimental measurements provide a value for the product $f_+^{K\pi}(0)|V_{us}|$, where $f_+^{K\pi}(0)$ is the form factor at zero four-momentum transfer between the initial state kaon and the final state pion. We quote a recent analysis by Seng *et al.* [109] which finds $|V_{us}| f_+^{K\pi}(0) = 0.21635(39)(3)$, with the first uncertainty from experiment and the second reflecting uncertainty in higher order corrections. This average involves detailed considerations of radiative corrections; these are taken from chiral perturbation theory with lattice-QCD inputs for some needed low-energy constants. Choosing the FLAG 2024 2+1+1-flavor average for $f_+(0)^{K\pi} = 0.9698(17)$ [2] based on the calculations of ETM [110] and Fermilab/MILC [111] gives $|V_{us}| = 0.22309(39)_{\rm exp}(39)_{\rm LQCD}(3)_{\rm HO}$ from semileptonic decay. The determinations of $|V_{us}|$ from leptonic and semileptonic kaon decays are both quite precise, with comparable errors, but the central values differ by 2.8σ.

Finally, the combination of the ratio $|V_{us}|/|V_{ud}|$ from leptonic decays [Eq. (71.21)] with $|V_{ud}|$ from β decay implies an alternative determination of $|V_{us}| = 0.2252(5)$ which agrees with the value from leptonic kaon decay, but again disagrees with the semileptonic-decay result at the 2.8σ level.

Given the roughly 3σ tension between $|V_{us}|$ from leptonic and semileptonic kaon decays, it is important to scrutinize the uncertainties on the theoretical and experimental inputs to $|V_{us}|$ and other elements of the first row of the CKM matrix. Seng *et al.* have introduced a new approach for calculating radiative corrections to neutron and nuclear beta decays using dispersion relations [112–115]. These calculations imply a value of $|V_{ud}| = 0.97395(23)$ [113], consistent with the updated analysis of Ref. [108]. An independent calculation of the radiative corrections by Czarnecki and Marciano using QCD sum rules yields similar results [116]. Using this value of $|V_{ud}|$ with the determination of $|V_{us}|$ from leptonic kaon decays in Eq. (71.21), we obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 - 1 = -0.0007(5)$, again consistent with first-row unitarity.

Last, we combine the experimental measurement of $f_{\pi^+}|V_{ud}|$ in Eq. (71.10) with $|V_{ud}|$ from super-allowed β-decay [108] to infer an "experimental" value for the pion decay constant:

$$f_{\pi^-}^{\text{"exp"}} = 130.56(2)(4)(13)\ \text{MeV}\,, \tag{71.23}$$

where the uncertainties are from the errors on Γ, $|V_{ud}|$, and higher-order corrections, respectively. Many recent (2+1+1)-flavor lattice-QCD calculations use this quantity to set the overall physical scale in their simulations, *e.g.*, Refs. [9, 32–34]. Conversely, comparing $f_{\pi^-}^{\text{"exp"}}$ with the FLAG 2024 (2+1)-flavor average [2] $f_{\pi^+} = 130.2(8)$ MeV, which only includes lattice-QCD results that employ other observables to set the scale [36–41], provides a test of lattice-QCD methods. The values are in good agreement within present uncertainties. We do not quote an "experimental" value for the kaon decay constant because the value of $|V_{us}|$ is less clear given the approximately 3σ tension between the values of $|V_{us}|$ obtained from leptonic and semileptonic kaon decays.

71.5.2 $|V_{cd}|$, $|V_{cs}|$, *and status of second-row unitarity*

Using the average values for $|V_{cd}|f_{D^+}$ and $|V_{cs}|f_{D_s^+}$ from Eqs. (71.15) and (71.16), and for f_{D^+} and $f_{D_s^+}$ from Eq. (71.19), we obtain the following determinations of the CKM matrix elements $|V_{cd}|$ and $|V_{cs}|$ from leptonic decays within the standard model:

$$|V_{cd}| = 0.2223(24)(7)(17) \quad \text{and} \quad |V_{cs}| = 0.9764(66)(20)(72)\,, \tag{71.24}$$

where the errors are from the measured branching fractions, decay constants, and external inputs (radiative corrections and masses and lifetimes), respectively. These results enable a test of the unitarity of the second row of the CKM matrix. Taking $|V_{cb}| = 41.8(0.8)) \times 10^{-3}$ [1], we obtain

$$|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 - 1 = +0.005(20)\,, \tag{71.25}$$

in agreement with three-generation unitarity. Note that correlations among the external uncertainties in the $f|V|$ values have a negligible effect.

The uncertainty on $|V_{cd}|$ in Eq. (71.24) is limited by the measurement error on the $D^+ \to \mu^+\nu$ decay rate. For $|V_{cs}|$, however, the experimental and radiative-correction errors are commensurate. The value of $|V_{cs}|$ from leptonic D_s decays decreased substantially from the value of 1.007(17) in an earlier version of this review [27, 117], and is now below unity as expected in the three-generation CKM framework. This change is due to our more consistent treatment of the radiative corrections, which lower the purely leptonic decay rates for $D_s^+ \to \mu^+\nu$ and $D_s^+ \to \tau^+\nu$. We emphasize, however, that we have taken a generous uncertainty on these estimates, and that more theoretical work is needed to really pin down the sizes of the radiative corrections to $D_{(s)}$-meson leptonic decays.

The CKM matrix elements $|V_{cd}|$ and $|V_{cs}|$ can also be obtained from semileptonic $D^+ \to \pi^0 \ell^+ \nu$ and $D_s^+ \to K^0 \ell^+ \nu$ decays, respectively. Here experimental measurements determine the product of the form factor times the CKM element, and theory provides the value for the form factor at zero four-momentum transfer between the initial $D_{(s)}$ meson and the final pion or kaon.

The latest experimental averages (2023, with data as of 2021) from the Heavy Flavor Averaging Group (HFLAV) are $f_+^{D\pi}(0)|V_{cd}| = 0.1426(18)$ and $f_+^{DK}(0)|V_{cs}| = 0.7180(33)$ [118]. The FLAG 2024 $2+1+1$ lattice-QCD averages for the form-factors at $q^2 = 0$ are $f_+^{D\pi}(0) = 0.6295(50)$ and $f_+^{DK}(0) = 0.7430(27)$. The $D\pi$ number is an average of FNAL/MILC Collaborations [119] and ETM Collaboration [120] results, while the DK number includes these two plus the HPQCD Collaboration [121]. The older ETM results have lower precision than the others. Combining of the HFLAV $f(0)|V|$ products and the FLAG average for $f(0)$ gives results for $|V_{cd}|$ and $|V_{cs}|$ consistent with the leptonic decays in Eq. (71.24):

$$|V_{cd}| = 0.2265(29)(18) \quad \text{and} \quad |V_{cs}| = 0.9664(44)(35)\,, \tag{71.26}$$

However, as with the leptonic case, one must exercise some care with corrections; this is beyond the scope of the present review. We do note that Ref. [119] presents a detailed discussion of CKM element extractions using their lattice-QCD results, including consideration of QED, electroweak and isospin corrections; a comparison of leptonic and semileptonic results and unitarity tests is also included.

We can combine the experimental measurements of $f_{D^+}|V_{cd}|$ and $f_{D_s^+}|V_{cs}|$ from Tables 71.2 and 71.3 with $|V_{cd}| = 0.22487(68)$ and $|V_{cs}| = 0.97349(16)$ from the PDG 2024 global unitarity-triangle analysis [1] to infer "experimental" values for the decay constants within the standard model. We take the CKM elements from the global fit because they are based on many input quantities, thereby reducing the sensitivity to any one outlying measurement or calculation. We obtain for the decay constants

$$\begin{aligned} f_{D^+}^{\text{"exp"}} &= 210.2(2.2)(0.6)(1.6)\ \text{MeV}\,, \\ f_{D_s^+}^{\text{"exp"}} &= 250.6(1.7)(0.04)(1.8)\ \text{MeV}\,, \\ (f_{D_s^+}/f_{D^+})^{\text{"exp"}} &= 1.191(16)(4)(9)\,. \end{aligned} \tag{71.27}$$

where the uncertainties are from the errors on $f|V|$, CKM matrix elements, and external inputs (radiative corrections and masses and lifetimes), respectively. Here, the 0.7% radiative correction uncertainty is taken as the the same size on the ratio as on the first two results (as opposed to a quadrature sum), due to presumed partial cancellation. Recent improvements in experimental precision make an improved understanding of the degree of cancellation desirable. The "experimental" values f_{D^+} $(f_{D_s^+}/f_{D^+})$ are consistent within 1σ with the (2+1+1)-flavor lattice-QCD averages in Eq. (71.19). The CKM matrix element $|V_{cd}|$ is approximately

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

equal to $|V_{us}|$, as first shown by Wolfenstein [122, 123]. Thus, resolving the inconsistencies between determinations of $|V_{us}|$ from leptonic and semileptonic decays discussed in Sec. 71.5.1 may benefit from the constraints observed here.

Last, we can test lepton-flavor universality in charm meson decays by checking the following relationship derived from Eq. (71.1):

$$\frac{\Gamma(D_s^+ \to \tau^+\nu)}{\Gamma(D_s^+ \to \mu^+\nu)} = \frac{m_\tau^2 \left(1 - m_\tau^2/M_{D_s}^2\right)^2}{m_\mu^2 \left(1 - m_\mu^2/M_{D_s}^2\right)^2} = 9.75\,, \qquad (71.28)$$

where the uncertainties from the masses are negligible to the number of digits quoted. The measured ratio of $\tau^+\nu$ to $\mu^+\nu$ rates is 10.06 ± 0.28 which, while 1.1σ high, is consistent with the standard-model expectation.

71.5.3 $|V_{ub}|$ *and other applications*

Using the average value for $|V_{ub}|f_{B^+}$ from Table 71.5, and for f_{B^+} from Eq. (71.20), we obtain the following determination of the CKM matrix element $|V_{ub}|$ from leptonic decays within the standard model:

$$|V_{ub}| = (4.06 \pm 0.37 \pm 0.003) \times 10^{-3}\,, \qquad (71.29)$$

where the errors are from experiment and theory, respectively. One should bear in mind when interpreting Eq. (71.29) that none of the experimental measurements of the branching fractions that enter the average for $|V_{ub}|f_{B^+}$ have individually reached the 5σ discovery level (see Sec. 71.4.1). Further, decays involving the third generation of quarks and leptons may be particularly sensitive to new physics associated with electroweak symmetry breaking due to their larger masses [12,14], so Eq. (71.29) is more likely to be influenced by new physics than the determinations of the elements of the first and second rows of the CKM matrix in the previous sections.

The CKM element $|V_{ub}|$ can also be obtained from semileptonic B-meson decays. A long-standing 2-3σ tension between the determinations of $|V_{ub}|$ from exclusive $B \to \pi\ell\nu$ decay and from inclusive $B \to X_u\ell\nu$ decay has diminished somewhat; here, X_u denotes all hadronic states populated by the $b \to u$ weak transition [22, 124–128]. The semileptonic review in the last PDG compilation [129] gives $|V_{ub}| = (3.70 \pm 0.10 \pm 0.12) \times 10^{-3}$ (exclusive) and $|V_{ub}| = (4.13 \pm 0.12\,^{+0.13}_{-0.14} \pm 0.18) \times 10^{-3}$ (inclusive). These agree now at the 1.4σ level; the difference is still only 1.8σ when dropping the third model uncertainty added to the inclusive value by the authors of Ref. [129]. The value of $|V_{ub}|$ from leptonic $B \to \tau\nu$ decay in Eq. (71.29) lies between these inclusive and exclusive determinations, and is compatible (within large uncertainties) with both.

Given the large uncertainties on the experimental measurements of $\mathcal{B}(B^- \to \tau^-\overline{\nu})$, and the evolving values of $|V_{ub}|$ obtained from inclusive and exclusive semileptonic B decays, we do not present an "experimental" value of the decay constant f_{B^+}.

71.6 Concluding remarks

The increasing precision of measurements of leptonic decays of charged pseudoscalar mesons has begun to require control over radiative corrections at a level superior to that presented here. Improvements will be called for both in theory and in experiment (for example, by BESIII and Belle II).

Unitarity of the CKM matrix is in reasonable shape. However, there is a lingering almost 3σ tension between the values of V_{us} determined by semileptonic and leptonic kaon decays. It will be interesting to follow experimental and theoretical developments on this quantity.

The b quark belongs to the third generation of quarks and is the weak–doublet partner of the t quark. The existence of the third–generation quark doublet was proposed in 1973 by Kobayashi and Maskawa [1] in their model of the quark mixing matrix ("CKM" matrix), and confirmed four years later by the first observation of a $b\bar{b}$ meson [2]. In the KM model, CP violation is explained within the Standard Model (SM) by an irreducible phase of the 3×3 unitary matrix. The regular pattern of the three lepton and quark families is one of the most intriguing puzzles in particle physics. The existence of families gives rise to many of the free parameters in the SM, including the fermion masses, and the elements of the CKM matrix.

Since the b quark is the lighter element of the third–generation quark doublet, the decays of b-flavored hadrons occur via generation-changing processes through CKM matrix. Because of this, and the fact that the CKM matrix is close to a 3×3 unit matrix, many interesting features such as loop and box diagrams, flavor oscillations, as well as large CP asymmetries, can be observed in the weak decays of b-flavored hadrons.

The CKM matrix is parameterized by three real parameters and one complex phase. This complex phase is the source of CP violation in B meson decays in the Standard Model. A crucial milestone was the first observation of CP violation in the B meson system in 2001, by the BaBar [3] and Belle [4] collaborations. They measured a large value for the parameter $\sin 2\beta$ $(= \sin 2\phi_1)$ [5], almost four decades after the discovery of a small CP asymmetry in neutral kaons. A more detailed discussion of the CKM matrix and CP violation can be found elsewhere in this *Review* [6, 7].

The structure of this mini-review is organized as follows. After a discussion of b-quark production and current results on spectroscopy, we discuss lifetimes of b-flavored hadrons. We then discuss some basic properties of B-meson decays, followed by summaries of dominant hadronic, rare hadronic, and electroweak penguin decays of B-mesons. There are separate mini-reviews for B^0–$\overline{B}^0$ mixing [8] and the extraction of the CKM matrix elements V_{cb} and V_{ub} from B-meson decays [9] in this *Review*.

72.1 Production and spectroscopy

The bound states of a $\bar{b}$ antiquark and a u, d, s, or c quark are referred to as the B_u (B^+), B_d (B^0), B_s (B_s^0), and B_c (B_c^+) mesons, respectively. The B_c^+ is the heaviest of the ground–state b-flavored mesons, and the most difficult to produce: it was observed for the first time in the semileptonic mode by CDF in 1998 [10], but its mass was accurately determined only in 2006, from the fully reconstructed mode $B_c^+ \to J/\psi\pi^+$ [11]. Many exclusive decay channels can now be used for the accurate mass measurements, given the large statistics available at the LHC. Currently the most precise measurement is made by LHCb and yields $m(B_c^+) = 6274.47 \pm 0.27 \pm 0.17$ MeV/c^2 [12], combining $B_c^+ \to J/\psi\pi^+$, $B_c^+ \to J/\psi\pi^+\pi^-\pi^+$, $B_c^+ \to J/\psi p\bar{p}\pi^+$, $B_c^+ \to J/\psi D_s^+$, $B_c^+ \to J/\psi D^0 K^+$ and $B_c^+ \to B_s^0\pi^+$ decay modes.

The first excited meson is called the B^* meson, while B^{**} is the generic name for the four orbitally excited $(L = 1)$ B-meson states that correspond to the P-wave mesons in the charm system, D^{**}. Excited states of the B_s^0 meson are similarly named B_s^* and B_s^{**}.

Of the possible bound $\bar{b}b$ states, the $\Upsilon(nS)$ and $\chi_{bJ}(nP)$ states are well studied. The pseudoscalar ground state η_b has been observed for the first time by BaBar [13] indirectly through the decay $\Upsilon(3S) \to \gamma\eta_b$, and then confirmed by Babar in $\Upsilon(2S)$ decays [14] and CLEO in $\Upsilon(3S)$ decays [15]. The most accurate mass and width measurements come now from Belle, using decays $\Upsilon(5S) \to h_b(1P)\pi^+\pi^-$, $h_b(1P) \to \gamma\eta_b(1S)$ [16], $\Upsilon(4S) \to \eta h_b(1P)$, $h_b(1P) \to \gamma\eta_b(1S)$ [17], and $\Upsilon(2S) \to \gamma\eta_b(1S)$ [18]. Belle has also reported first evidence for the $\eta_b(2S)$ in the $h_b(2P) \to \eta_b(2S)\gamma$ transition [16]. In addition, Belle has observed $T_{b\bar{b}1}(10610)$ (was $Z_b(10610)$) and $T_{b\bar{b}1}(10650)$ (was $Z_b(10650)$) states in the processes $\Upsilon(5S) \to \Upsilon(nS)\pi^+\pi^-$ $(n = 1, 2, 3)$ and $\Upsilon(5S) \to h_b(mP)\pi^+\pi^-$ $(m = 1, 2)$ [19]. These $T_{b\bar{b}1}$ states are observed to decay to $\Upsilon(nS)\pi^\pm$ and $h_b(mP)\pi^\pm$, hence electrically charged and do not belong to ordinary $q\bar{q}$ mesons. For classification and naming of these and other states, see Ref. [20].

Experimental studies of b decays have been performed in e^+e^- collisions at the $\Upsilon(4S)$ (ARGUS, CLEO, Belle, BaBar) and $\Upsilon(5S)$ (CLEO, Belle) resonances. The $e^+e^- \to b\bar{b}$ production cross-section at the $\Upsilon(4S)$ $(\Upsilon(5S))$ resonance is about 1.1 nb (0.3 nb). The full data samples of BaBar and Belle are 560 fb^{-1} and 1020 fb^{-1}, respectively, of which 433 fb^{-1} and 710 fb^{-1} are at the $\Upsilon(4S)$ resonance. Since the $\Upsilon(4S)$ decays dominantly to a pair of B mesons (either B^+B^- or $B^0\overline{B}^0$), a precise knowledge of the energy-momentum of one B meson (the 'tagging B') enables deducing the properties of the other B (the 'signal B'). This property has been exploited by both BaBar and Belle, in particular, to measure inclusive decay modes as well as final states with missing neutrinos. The Belle II experiment at SuperKEKB has started recording data in 2019, and the experiment has so far collected about 700 fb^{-1} of data by the March 2026. At the Z resonance (SLC, LEP) all species of b-flavored hadrons could be studied for the first time. The $e^+e^- \to b\bar{b}$ production cross-section at the Z resonance is about 6.6 nb.

High-energy $p\bar{p}$ (Tevatron) and pp collisions (LHC) produce b-flavored hadrons of all species with large cross-sections. At the Tevatron ($\sqrt{s} = 1.96$ TeV) the visible cross section $\sigma(p\bar{p} \to bX, |\eta| < 1)$ is about 30 μb. CDF and D0 experiments at the Tevatron have accumulated by the end of their running about 10 fb^{-1} each.

At the LHC pp collider at $\sqrt{s} = 7 - 13$ TeV, the visible b-hadron cross section at the LHCb experiment with pseudorapidity acceptance $2 < \eta < 5$ has been measured to be ~ 72 μb at 7 TeV and ~ 144 μb at 13 TeV [21] (cross section at 13 TeV corrected in Erratum). LHCb has collected about 1 fb^{-1} at 7 TeV, 2 fb^{-1} at 8 TeV, and close to 5.9 fb^{-1} at 13 TeV during LHC Runs 1 and 2. CMS and ATLAS have collected each about 5 fb^{-1} of data at $\sqrt{s} = 7$, 20 fb^{-1} at 8 TeV and about 150 fb^{-1} at 13 TeV during LHC Runs 1 and 2. The latest LHC Run 3 at 13.6 TeV started in summer 2022, with upgraded detectors. By the end of 2025, LHC has delivered about 330 fb^{-1} to ATLAS and CMS experiments, and about 24 fb^{-1} to the LHCb experiment.

In hadron collisions, production happens as $b\bar{b}$ pairs via leading order flavor creation or higher order processes such as gluon–splitting. Single b-quarks can be produced by flavor excitation. The total b-production cross section is an interesting test of our understanding of leading and higher order QCD processes. With a wealth of measurements at LHC and at Tevatron (see Ref. [21] and references therein), and improved calculations [22], there is a reasonable agreement between measurements and predictions.

Each quark of a $b\bar{b}$ pair produced in hadron collisions hadronizes separately and incoherently from the other, but it is still possible to obtain a statistical indication of the charge of a produced $b/\bar{b}$ quark ("flavor tag" or "charge tag") from the accompanying particles produced in the hadronization process, or from the decay products of the other quark. The momentum spectrum of produced b-quarks typically peaks near the b-quark mass, and extends to much higher momenta, dropping by about a decade for every ten GeV. Typical decay lengths are of the order of a centimeter at 13 TeV pp collisions; the resolution for the decay vertex must be more precise than this to resolve the fast oscillations of B_s^0 mesons.

In e^+e^- colliders, since the B mesons are very slow in the $\Upsilon(4S)$ rest frame, asymmetric beam energies are used to boost the decay products to allow time-dependent measurements that are crucial for the study of CP violation. At KEKB, the boost was $\beta\gamma = 0.43$, while PEP-II used a slightly larger boost, $\beta\gamma = 0.55$. The typical B-meson decay length is dilated from ≈ 20 μm to ≈ 200 μm. At SuperKEKB the boost is lower, $\beta\gamma = 0.28$, which puts more demanding requirements on the track reconstruction precision at Belle II to reach a resolution in decay time measurements similar to Belle. The two B mesons produced in $\Upsilon(4S)$ decay are in a coherent quantum state, which makes it easier than in hadron collisions to infer the charge state of one B meson from observation of the other; however, the coherence also requires determination

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

of the decay time of both mesons, rather than just one, in order to perform time–dependent CP–violation measurements. For B_s^0, which can be produced at $\Upsilon(5S)$ the situation is less favourable, as boost is not high enough to provide sufficient time resolution to resolve the fast B_s^0 oscillations.

For the measurement of branching fractions, the initial composition of the data sample must be known. The $\Upsilon(4S)$ resonance decays predominantly to $B^0\overline{B}^0$ and B^+B^-; the current experimental upper limit for non-$B\overline{B}$ decays of the $\Upsilon(4S)$ is less than 4% at the 95% confidence level (CL) [23]. The observed hadronic modes of this category are decays to lower Υ states and a pion pair, η, or η', measured branching fractions being of order $10^{-4} - 10^{-5}$ [24], and decays to $h_b(1P)\eta$ with branching fraction of order 10^{-3} [17].

The ratio f_+/f_0 of the fractions of charged to neutral B productions from $\Upsilon(4S)$ decays has been measured by CLEO, BaBar, and Belle in various ways. They typically use pairs of isospin-related decays of B^+ and B^0, such that it can be assumed that $\Gamma(B^+ \to x^+) = \Gamma(B^0 \to x^0)$. In this way, the ratio of the number of events observed in these modes is proportional to $(f_+\tau_+)/(f_0\tau_0)$ [25]. BaBar has also performed an independent measurement of f_0 with a different method that does not require isospin symmetry or the value of the lifetime ratio, based on the number of events with one or two reconstructed $B^0 \to D^{*-}\ell^+\nu$ decays [26]. The combined result, from the current average of τ_+/τ_0, is $f_+/f_0 = 1.058 \pm 0.024$ [27]. The result is consistent within 2.4σ with equal production of B^+B^- and $B^0\overline{B}^0$ pairs, and we assume $f_+/f_0 = 1$ in this mini-review except where explicitly stated otherwise. This assumption is also supported by the near equality of the B^+ and B^0 masses: our fit yields $m(B^0) = 5279.72 \pm 0.08$ MeV/c^2, $m(B^+) = 5279.41 \pm 0.07$ MeV/c^2, and $m(B^0) - m(B^+) = 0.31 \pm 0.05$ MeV/c^2.

Data collected at the $\Upsilon(5S)$ resonance gave CLEO, Belle and BaBar access to B_s^0 decays. In $\Upsilon(5S)$ decays there are seven possible final states including a pair of non-strange B mesons and 0, 1 or 2 pions, and three final states with a pair of strange B mesons ($B_s^{*0}\overline{B}_s^{*0}$, $B_s^{*0}\overline{B}_s^0$, and $B_s^0\overline{B}_s^0$). The fraction of events with a pair of B_s^0 mesons over the total number of events with a pair of b-flavored hadrons has been measured to be $f_s[\Upsilon(5S)] = 0.199^{+0.030}_{-0.029}$ [28], of which 88% is $B_s^{*0}\bar{B}_s^{*0}$ events. However, the small boost of B_s^0 mesons produced in this way prevents resolution of their fast oscillations for time-dependent measurements; these are only accessible in hadron collisions (or at the Z peak).

In high-energy collisions, the produced b or $\bar{b}$ quarks can hadronize with different probabilities into the full spectrum of b-hadrons, either in their ground or excited states. The hadronization does not have to be identical in $p\overline{p}$ or pp collisions and in Z decay, because of the different momentum distributions of the b-quark in these processes; the sample used in the $p\overline{p}$ measurements has momenta close to the b mass, rather than $m_Z/2$ in Z decay. The available data from Tevatron and LHC show that the production fractions f_d, f_u, f_s, and $f_{\rm baryon}$ of B^0, B^+, B_s^0, and b baryons, respectively, of weakly decaying b hadrons depend on the kinematics of the produced b hadron. Recently LHCb experiment found evidence for dependence of b-quark hadronization on multiplicity in pp collisions [29]. The production fractions of b hadrons are discussed in more detail in the $B^0 - \overline{B}^0$ mixing section in this *Review* [8].

Excited B-meson states have been thoroughly studied by CLEO, LEP, CUSB, D0 and CDF (an admixture of B mesons) and LHCb (B^{*+}-meson). The current PDG fit of the B^*–B mass difference is 45.18 ± 0.20 MeV/c^2. Excited B_s^*-meson states have observed in $\Upsilon(5S)$ decays by CUSB, CLEO and Belle.

For orbitally excited $B_{(s)}$ meson states, with relative angular momentum L=1 of the two quarks, there exist four states $(J, j_q) = (0, 1/2), (1, 1/2), (1, 3/2), (2, 3/2)$, where j_q is the total angular momentum of the light u, d or s quark and J is the total angular momentum of the B meson. These states are collectively called as $B_{(s)}^{**}$ mesons. The $j_q = 1/2$ states are named $B_{(s)0}^*$ ($J = 0$) and $B_{(s)1}$ ($J = 1$) mesons, while the states with $j_q = 3/2$ are named $B_{(s)1}$ ($J = 1$) and $B_{(s)2}^*$ ($J = 2$) mesons. The states with $j_q = 1/2$ can decay through an S-wave transition and are expected to have a large width, but the $j_q = 3/2$ states are narrow D-wave decays. Evidence for B^{**} production has been initially obtained at LEP as a broad $B\pi$ resonance [30] or a B^+K^- enhancement [31]. Detailed results have been obtained for the narrow states $B_1(5721)^{0,+}$ and $B_2(5747)^{0,+}$ at the Tevatron and by LHCb, and clear enhancements compatible with the higher mass states $B_J(5840)^{0,+}$ and $B_J(5970)^{0,+}$ have been observed [32]. Also the narrow B_s^{**} states $B_{s1}(5830)^0$ and $B_{s2}(5840)^0$ have been measured at the CDF [32], LHCb [33], and CMS [34].

Excited states of B_c^+ mesons will provide important information about the strong potential. A $B_c^+\pi^+\pi^-$ resonance has been observed for the first time by ATLAS [35]. The mass of the resonance has been measured precisely by CMS and LHCb as 6871.2 ± 1.0 MeV/c^2 [36]. The resonance may be interpreted as the second S-wave state of the B_c^+ meson, $B_c^+(2S)$, but the quantum numbers are to be confirmed.

Baryon states containing a b quark are labeled according to the same scheme used for non-b baryons, with the addition of a b subscript [20]. The first observed b baryon was the Λ_b^0 (quark composition udb). Thanks to the large samples accumulated at the Tevatron and specially at the LHC many new b baryons have been found. The masses of all these new baryons have been measured to a precision of a few MeV/c^2, and found to be in agreement with predictions from Heavy Quark Effective Theory (HQET).

Clear signals of four strongly–decaying baryon states, Σ_b^+, Σ_b^{*+} (uub), Σ_b^-, Σ_b^{*-} (ddb) have been obtained by CDF [37] and LHCb [38]. LHCb has also observed two new mass peaks in the $\Lambda_b^0\pi^\pm$ systems, consistent with single resonances and named as $\Sigma_b^\pm(6097)$ [38]. The nature of these resonances is, however, not yet clear. The isodublet of strange b baryons Ξ_b^0 (usb) and $\Xi_b^\pm$ (dsb) has been observed by CDF and D0 [39]. Masses, lifetimes, and branching ratios have been accurately measured by LHCb [40–43], CDF [44], and CMS [45]. LHCb has also measured several parameters sensitive to P and CP violation [42,46]. Other observed Ξ_b baryons are spin-3/2 states $\Xi_b(5945)^0$ (Ξ_b^{*0}) [45, 47, 48], $\Xi_b^*(5955)^-$ [48, 49] and $\Xi_b(6100)^-$ [48, 50], a spin-1/2 state $\Xi_b'(5935)^-$ [48,49], and resonance states $\Xi_b^0(6087)$ [48], $\Xi_b^0(6095)$ [48], $\Xi_b^-(6227)$ [41, 51], $\Xi_b^0(6227)$ [41], $\Xi_b^0(6327)$ [52] and $\Xi_b^0(6333)$ [52]. The doubly–strange bottom baryon Ω_b^- has been observed first by D0 and CDF [53]. Mass and mean life have been measured precisely by LHCb [43, 54] and CDF [44]. LHCb has also observed four excited Ω_b^- states $\Omega_b^-(6316)$, $\Omega_b^-(6330)$, $\Omega_b^-(6340)$ and $\Omega_b^-(6350)$ [55].

The so-called exotic states have raised a lot of interest recently. While many exotic states were seen in the charm sector, in bottom sector there are fewer seen. The D0 Collaboration claimed a narrow state $X(5568)$ decaying into a $B_s^0\pi^\pm$ final state [56]. While this would be an interesting addition to the observed states as the first exotic state with constituent quarks with four different flavours (b, s, u, d), analyses by LHCb, CMS, CDF and ATLAS yield negative results [57–60].

72.2 Lifetimes

Precise lifetimes are key in extracting the weak parameters that are important for understanding the role of the CKM matrix in CP violation, such as the determination of V_{cb} and B_s^0–$\overline{B}_s^0$ mixing parameters. In the naive spectator model, the heavy-flavored hadrons can decay only via the external spectator mechanism, and thus, the lifetimes of all mesons and baryons containing b quarks would be equal. Non–spectator effects, such as the interference between contributing amplitudes, modify this simple picture and give rise to a lifetime hierarchy for b-flavored hadrons similar to the one in the charm sector. However, since the lifetime differences are expected to scale as $1/m_Q^2$, where m_Q is the mass of the heavy quark, the variations in the b system are expected to be only 10% or less [61, 62]. We expect:

$$\tau(B^+) \geq \tau(B^0) \approx \tau(B_s^0) > \tau(\Lambda_b^0) \gg \tau(B_c^+)\,. \qquad (72.1)$$

For the B_c^+, both quarks decay weakly, so the lifetime is much shorter.

Measurements of the lifetimes of the different b-flavored hadrons thus provide a means to determine the importance of non-spectator mechanisms in the b sector. Availability of large samples of fully–reconstructed decays of different b-hadron species has resulted in precise measurements with small statistical and systematic uncertainties (∼1%). The world averages given in Table 72.1 have been determined by the Heavy Flavor Averaging Group (HFLAV) [63].

Table 72.1: Summary of the world-average b-hadron lifetime measurements. For the B_s^0 lifetimes, see text below.

Particle	Lifetime [ps]
B^+	1.637 ± 0.004
B^0	1.5113 ± 0.0027
B_s^0	1.515 ± 0.006
B_{sL}^0	1.430 ± 0.006
B_{sH}^0	1.611 ± 0.008
B_c^+	0.510 ± 0.009
Λ_b^0	1.465 ± 0.009
Ξ_b^-	1.575 ± 0.021
Ξ_b^0	1.472 ± 0.016
Ω_b^-	1.64 ± 0.16

The B_s^0 lifetime in Table 72.1 is defined as $1/\Gamma_s$, where Γ_s is the average width of the light (L) and heavy (H) mass eigenstates, $(\Gamma_L+\Gamma_H)/2$. In the absence of CP violation, the light (heavy) B_s^0 mass eigenstate is the CP-even (CP-odd) eigenstate. Thus, the lifetime of the light (heavy) mass eigenstate can be measured from CP-even (odd) final states. The lifetimes can also be obtained from time-dependent angular analysis of $B_s^0 \to J/\psi\phi$ decays.

The short B_c^+ lifetime is in good agreement with predictions [64]. With large samples of B_c^+ mesons at the LHC precision on the lifetimes can still improve. The measurement using semileptonic decays gives $\tau_{B_c^+} = 0.509 \pm 0.008 \pm 0.012$ ps [65] while using decays $B_c^+ \to J/\psi\pi^+$ yields $\tau_{B_c^+} = 0.5134 \pm 0.0110 \pm 0.0057$ ps [66]. Each of these is more precise than the combination of all previous experiments.

The recent Λ_b^0 lifetime measurements from LHC experiments and CDF are precise and favour lifetime close to the lifetime of B^0 meson, in agreement with theory.

For precision comparisons with theory, lifetime ratios are more sensitive. Experimentally it is found [67]:

$$\frac{\tau_{B^+}}{\tau_{B^0}} = 1.0832 \pm 0.0034\,, \quad \frac{\tau_{B_s^0}}{\tau_{B^0}} = 1.003 \pm 0.004\,, \quad \frac{\tau_{\Lambda_b^0}}{\tau_{B^0}} = 0.970 \pm 0.006\,,$$

$$\frac{\tau_{\Omega_b^-}}{\tau_{B^0}} = 1.09 \pm 0.11\,, \quad \frac{\tau_{\Xi_b^0}}{\tau_{\Xi_b^-}} = 0.934 \pm 0.014\,,$$

while recent Heavy Quark Expansion (HQE) predictions give [68–70]:

$$\frac{\tau_{B^+}}{\tau_{B^0}} = 1.086 \pm 0.022\,, \quad \frac{\tau_{B_s^0}}{\tau_{B^0}} = 1.003 \pm 0.006\,, \quad \frac{\tau_{\Lambda_b^0}}{\tau_{B^0}} = 0.955 \pm 0.014\,,$$

$$\frac{\tau_{\Omega_b^-}}{\tau_{B^0}} = 1.081 \pm 0.042\,, \quad \frac{\tau_{\Xi_b^0}}{\tau_{\Xi_b^-}} = 0.929 \pm 0.028.$$

The ratio of B^+ to B^0 lifetimes has a precision of better than 1%, and is significantly different from 1.0, in agreement with predictions [61, 68, 69]. The ratio of B_s^0 to B^0 lifetimes is predicted to be very close to 1.0 in scenario with small $SU(3)_F$ breaking from Ref. [71]. If on the other hand $SU(3)_F$ breaking is large as suggested by Ref. [72] the prediction is $\tau_{B_s^0}/\tau_{B^0} = 1.028 \pm 0.011$.

For a detailed discussion on neutral B^0 and B_s^0 oscillation and relevant CP violation measurements see Ref. [8].

72.3 Features of decays

The ground states of b-flavored hadrons decay via weak interactions. In most decays of the b-flavored hadrons, where the b-quark is accompanied by lighter partner quarks (d, u, s, or c), the decay modes are well described by the decay of the b quark (spectator model) [73]. The dominant decay mode of a b quark is $b \to cW^{*-}$ (referred to as a "tree" or "spectator" decay), where the virtual W materializes either into a pair of leptons $\ell\bar{\nu}$ ("semileptonic decay"), or into a pair of quarks which then hadronizes. The transition $b \to u$ is suppressed by $|V_{ub}/V_{cb}|^2 \sim (0.1)^2$ relative to $b \to c$ transitions. The decays in which the spectator quark combines with one of the quarks from W^* to form one of the final state hadrons are suppressed by a factor $\sim (1/3)^2$, because the colors of the two quarks from different sources must match ("color–suppression").

Semileptonic B decays $B \to X_c\ell\nu$ and $B \to X_u\ell\nu$ provide an excellent way to measure the magnitude of the CKM elements $|V_{cb}|$ and $|V_{ub}|$ respectively, because the strong interaction effects are much simplified due to the two leptons in the final state. Both exclusive and inclusive decays can be used with dominant uncertainties being complementary. For exclusive decay analysis, knowledge of the form factors for the exclusive hadronic system $X_{c(u)}$ is required. For inclusive analysis, it is usually necessary to restrict the available phase-space of the decay products to suppress backgrounds; subsequently uncertainties are introduced in the extrapolation to the full phase-space. Moreover, restriction to a small corner of the phase-space may result in breakdown of the operator-product expansion scheme, thus making theoretical calculations unreliable. A more detailed discussion of B semileptonic decays and the extraction of $|V_{cb}|$ and $|V_{ub}|$ is given elsewhere in this *Review* [9]. While traditionally B^0 and B^+ decays were used, over time also other B hadron studies became available. Most notably, determination of of $|V_{ub}|$ using $\Lambda_b^0 \to p\mu^-\bar{\nu}_\mu$ decays by LHCb [74] was more precise than expected. Besides, there have been measurements of inclusive semileptonic decay rates of B_s^0 [75] and B_c^+ [76] mesons. One of the latest additions in this area is the observation of the $B_s^0 \to K^-\mu^+\nu_\mu$ decays by LHCb using only a fraction of their available data [77].

On the other hand, hadronic B decays are complicated because of strong interaction effects caused by the surrounding cloud of light quarks and gluons. While this complicates the extraction of CKM matrix elements, it also provides a great opportunity to study perturbative and non-perturbative QCD, hadronization, and Final State Interaction (FSI) effects.

Many aspects of B decays can be understood through the Heavy Quark Effective Theory (HQET) [78]. This has been particularly successful for semileptonic decays. For further discussion of HQET, see for instance Ref. [79]. For hadronic decays, one typically uses effective Hamiltonian calculations that rely on a perturbative expansion with Wilson coefficients. In addition, some form of the factorization hypothesis is commonly used, where, in analogy with semileptonic decays, two-body hadronic decays of B mesons are expressed as the product of two independent hadronic currents, one describing the formation of a charm meson (in case of the dominant $b \to cW^{*-}$ decays), and the other describing the hadronization of the remaining $\overline{u}d$ (or $\overline{c}s$) system from the virtual W^-. Qualitatively, for B decays with a large energy release, e.g. $b \to uW^{*-}$ transitions, the $\overline{u}d$ pair (produced as a color singlet) travels fast enough to leave the interaction region without influencing the meson containing the spectator quark. This is known to work well for the dominant spectator decays [80]. There are several common implementations of these ideas for hadronic B decays, the most common of which are QCD factorization (QCDF) [81], perturbative QCD (pQCD) [82], and soft collinear effective theory (SCET) [83].

The transitions $b \to s$ and $b \to d$ are flavor-changing neutral-current (FCNC) processes. Although they are not allowed in the SM as a tree-process, they can occur via loop diagrams (denoted "penguin" decays). The rates for $b \to s$ penguin decays are comparable to the CKM-suppressed $b \to u$ tree processes. Pure-penguin decays were first established by the observation of $B \to K^*(892)\gamma$ [84]. Penguin processes involving $b \to d$ transitions are further suppressed by CKM, and have been observed for $B \to (\rho/\omega)\gamma$ decays [85, 86]. LHCb has observed a $b \to d$

penguin transition in the $B^+ \to \pi^+\mu^+\mu^-$ mode and measured its branching fraction to be $(1.83 \pm 0.24 \pm 0.05) \times 10^{-8}$ [87].

Other decay processes discussed in this *Review* include W–exchange (a W is exchanged between initial–state quarks), penguin annihilation (the gluon from a penguin loop attaches to the spectator quark, similar to an exchange diagram), and pure–annihilation (the initial quarks annihilate to a virtual W, which then decays). Some observed decay modes such as $B^0 \to D_s^- K^+$, may be interpreted as evidence of a W-exchange process [88]. The evidence for the purely leptonic decay $B^+ \to \tau^+\nu$ from Belle [89] and BaBar [90] is the first sign of a pure annihilation decay. The average branching fraction is $(1.09 \pm 0.24) \times 10^{-4}$, which is somewhat larger than, though consistent with, the value expected in the SM. A substantial region of parameter space of charged Higgs mass vs. $\tan\beta$ is excluded by the measurements of this mode. A dedicated discussion of purely leptonic decays of charged pseudoscalar mesons is given elsewhere in this *Review* [91].

72.4 Dominant hadronic decays

Most of the hadronic B decays involve $b \to c$ transition at the quark level, resulting in a charmed hadron or charmonium in the final state. Other types of hadronic decays are very rare and will be discussed separately in the next section. The experimental results on hadronic B decays have steadily improved over the years, and the measurements have reached sufficient precision to challenge our understanding of the dynamics of these decays. With good particle detection and hadron identification capabilities of B-factory detectors, a substantial fraction (roughly on the order of a few per mill) of hadronic B decay events can be fully reconstructed. In particular, good performances for detecting π^0 and other neutral particles helped Belle and BaBar to make comprehensive measurements of the decays $\overline{B}^0 \to D^{(*)0}h^0$ [92], where h^0 stands for light neutral mesons such as $\pi^0, \eta^{(\prime)}, \rho^0, \omega$. The measurements are being complemented by LHCb, in decays like $\overline{B^0} \to D^0\pi^+\pi^-$ [93], where no neutral particles reconstruction is needed. These decays proceed through color-suppressed diagrams, hence they provide useful tests on the factorization models.

Because of the kinematic constraint of $\Upsilon(4S) \to B\bar{B}$, the energy sum of the final-state particles of a B meson decay is always equal to one half of the total energy in the center of mass frame. As a result, the two variables, ΔE (energy difference) and M_B (B candidate mass with a beam-energy constraint) are very effective for reducing combinatorial background both from $\Upsilon(4S)$ and $e^+e^- \to q\bar{q}$ continuum events. In particular, the energy-constraint in M_B improves the signal resolution by almost an order of magnitude.

The kinematically clean environment of B meson decays provides an excellent opportunity to search for new states. For instance, quark-level $b \to c\bar{c}s$ decays have been used to search for new charmonium and charm-strange mesons and study their properties in detail. While narrow charm-strange states $D^*_{s0}(2317)$ [94] and $D_{s1}(2460)$ [95] were discovered by BaBar and CLEO, respectively, the properties of these new states were revealed by studying the B meson decays, $B \to DD^*_{s0}(2317)$ and $B \to DD_{s1}(2460)$ by Belle [96] and BaBar [97]. Another example is Dalitz plot analysis of decay $B_s^0 \to \bar{D}^0K^-\pi^+$ in which the decay to spin-3 resonance was observed for the first time [98]. One of the most significant improvements in the past decade is establishment of decays $B^+ \to D^0K^+$ and $B^+ \to D^0K^*(892)^+$ with D^0 decaying to final state common to D^0 and $\overline{D}^0$ [99]. This allows direct determination of CKM angle $\gamma(= \phi_3)$ to be $65.9^{+3.3}_{-3.5}$.

Information on B_s^0, B_c^+ and Λ_b^0 decays have been remarkably improved with recent studies of large samples from LHCb. Noticeable additions in B_s include decay modes to $D_s^{(*)+}D_s^{(*)-}$, $\bar{D}^0\bar{K}^0$, and $J/\psi\bar{K}^*(892)^0$. The $B_s^0 \to D_s^{(*)+}D_s^{(*)-}$ decays were first observed by CDF [100], followed by Belle [101]. LHCb has improved the precision with $\mathcal{B}(B_s^0 \to D_s^{(*)+}D_s^{(*)-}) = (3.07 \pm 0.22 \pm 0.33)\%$ [102], which suggests that $B_s^0 \to D_s^{(*)+}D_s^{(*)-}$ decays do not saturate the CP-even modes of the B_s decays. The $B_s^0 \to \bar{D}^0\bar{K}^0$ decay occurs mostly via a color-suppressed tree diagram, and has a small theoretical uncertainty in the SM, thus this mode can significantly improve the determination of the CP-violation angle ϕ_s. LHCb has observed this decay and the branching fraction is $(4.3 \pm 0.5 \pm 0.7) \times 10^{-4}$ [103]. The $B_s^0 \to J/\psi\bar{K}^*(892)^0$ decay can be used to constrain the penguin pollution in determining ϕ_s. LHCb has updated the branching fraction and measured the CP asymmetries of this decay, thereby constraining the penguin pollution in ϕ_s [104], although a much more stringent constraint on penguin pollution can come from $B^0 \to J/\psi\rho^0$ which has been observed by BaBar [105] and LHCb [106]. The $B_c^+ \to B_s^0\pi^+$ decay is unique as the only observed mode of b-flavored hadron decays where the partner quark decays (c in this case) while the b quark remains a spectator. LHCb has observed this mode [107] and measured $\mathcal{B}(B_c^+ \to B_s^0\pi^+)/\mathcal{B}(B_c^+ \to J/\psi\pi^+) = (91 \pm 10 \pm 8 \pm 3)$ [108]. In addition, LHCb [109] and ATLAS [110] have measured $B_c^+ \to J/\psi D_s^{(*)+}$, which, by comparing with $B_c^+ \to B_s^0\pi^+$, provides a ratio of exclusive $b \to c$ and $c \to s$ decays of B_c^+. For $\Lambda_b^0 \to \Lambda_c^+\pi^+\pi^-\pi^-$ [111], not only the total rate is measured, but also structure involving decays through excited Λ_c and Σ_c baryons.

In addition, a variety of exotic particles that do not fit the conventional meson spectroscopy have been discovered in B decays. Belle found the $X(3872)$ state by studying $B^+ \to J/\psi\pi^+\pi^-K^+$ [112], which was confirmed by CDF [113], D0 [114] and BaBar [115]. Production of $X(3872)$ has been studied by the LHC experiments, LHCb [116], CMS [117] and ATLAS [118].

A charged charmonium-like state $X(4430)^\pm$ that decays to $\psi(2S)\pi^\pm$ was observed by Belle in $B \to \psi(2S)K\pi^\pm$ [119]. Since it is charged, it could not be an ordinary charmonium state. A high-statistics study by LHCb confirmed the existence of the $X(4430)^\pm$ in decays $B \to \psi(2S)K\pi^\pm$ [120], demonstrated its resonance character by studying the phase motion, unambiguously determined its spin-parity, and saw evidence for another state. In a Dalitz plot analysis of $\bar{B}^0 \to J/\psi K^-\pi^+$ [121], Belle has found another state, labeled as $X(4200)^+$ in this *Review*, adding to the list of exotic charged charmonium-like states. In an amplitude analysis of the decay $\Lambda_b^0 \to J/\psi pK^-$, LHCb observed exotic structures, labeled as $P_c(4380)^+$ and $P_c(4450)^+$ in this *Review*, in the $J/\psi p$ channel [122]. The subsequent analysis with significantly increased statistics observed additional state and resolved the peak at 4450 MeV/c^2 as being due to the two states close in the mass [123]. The structure in the $J/\psi p$ channel was also seen in the $B_s^0 \to J/\psi p\bar{p}$ decays [124] and in the $J/\psi\Lambda$ channel in $B^+ \to J/\psi\Lambda p$ and $\Xi_b^- \to J/\psi\Lambda K^-$ decays [125]. They are referred to as charmonium-pentaquark states. More detailed discussions of exotic meson-like states and pentaquarks are given elsewhere in this *Review* [126].

72.5 Rare hadronic decays

All B-meson decays that do not occur through the $b \to c$ transition are usually called rare B decays. These include both semileptonic and hadronic $b \to u$ decays that are suppressed at leading order by the small CKM matrix element V_{ub}, as well as higher-order $b \to s(d)$ processes such as electroweak and gluonic penguin decays. In this section, we review hadronic rare B decays, while electroweak penguin decays and others are discussed in the next.

Charmless B meson decays into two-body hadronic final states such as $B \to \pi\pi$ and $K\pi$ are experimentally clean, and provide good opportunities to probe new physics and search for indirect and direct CP violations. Since the final state particles in these decays tend to have larger momenta than average B decay products, the event environment is cleaner than for $b \to c$ decays. Branching fractions are typically around 10^{-5}. Over the past decade, many such modes have been observed not only by e^+e^- collider experiments such as BaBar and Belle, but also by hadron collider experiments such as CDF ($p\bar{p}$) and LHCb (pp). In the latter cases, huge data samples of the modes with all charged final-state particles have been reconstructed by triggering on the impact parameter of the charged tracks. This has also allowed observation of charmless decays of the B_s, in final states such as $\phi\phi$ [127], K^+K^- [128,129], and $K^-\pi^+$ [129,130], and of charmless decays of the Λ_b^0 baryon [130]. The large samples available at LHCb experiment allow to perform also time-dependent CP violation measurements [131]. Charmless B_s modes are related to corresponding B^0 modes by U-spin symmetry, and are determined

by similar amplitudes. Combining the observables from B_s^0 and B^0 modes is a further way of eliminating hadronic uncertainties and extracting relevant CKM information [132].

Because of relatively high-momenta for final state particles, the dominant source of background in e^+e^- collisions is $q\bar{q}$ continuum events; sophisticated background suppression techniques exploiting event shape variables are essential for these analyses. In hadron collisions, the dominant background comes from QCD or partially reconstructed heavy flavors, and is similarly suppressed by a combination of kinematic and isolation requirements. The results are in general consistent among the experiments.

Most rare decay modes including $B^0 \to K^+\pi^-$ have contributions from both $b \to u$ tree and $b \to sg$ penguin processes. If the size of the two contributions are comparable, the interference between them may result in direct CP violation, seen experimentally as a charge asymmetry in the decay rate measurement. BaBar [133], Belle [134], CDF [128], and LHCb [131, 135] have measured the direct CP violating asymmetry in $B^0 \to K^+\pi^-$ decays. Direct CP violation has been observed in this decay with a significance of more than 5σ. The world average value of the asymmetry is now rather precise, $A_{CP}(K^+\pi^-) = -0.0831 \pm 0.0031$. The CP asymmetry in $B^+ \to K^+\pi^0$ mode has been measured by BaBar [136], Belle [134], Belle II [137] and [138] with the average value $A_{CP}(K^+\pi^0) = 0.027 \pm 0.012$. These two asymmetries differ significantly, in contrast to a naive expectation based on simplified picture in the SM. For more detailed tests, there are sum rules [139] that relate the decay rates and decay-rate asymmetries between the four $K\pi$ charge states. A crucial ingredient of the sum rule test is $A_{CP}(K^0\pi^0)$. Currently, measured values are reported by both BaBar [140] and Belle [141]. Using the $A_{CP}(K^0\pi^0)$ value of Ref. [141], Belle reports the sum rule test result that is consistent with zero within 1.9σ [134]. With the future improvements via Belle II and upgraded LHCb, the measurements are expected to become precise enough to shape a definite conclusion. The CP asymmetry in the π^+K^- mode has also been measured in B_s^0 decays, by CDF [128] and LHCb [131, 135]. The combined value is $A_{CP}(B_s^0 \to \pi^+K^-) = 0.224 \pm 0.012$.

In addition to $B_{(s)} \to K\pi$ modes, significant ($> 3\sigma$) non-zero CP asymmetries have been measured in several other rare decay modes: $A_{CP}(B^+ \to \rho^0K^+) = 0.37 \pm 0.10$ [142], $A_{CP}(B^+ \to \eta K^+) = -0.37 \pm 0.08$ [143], $A_{CP}(B^0 \to \eta K^{*0}) = 0.19 \pm 0.05$ [144], and $A_{CP}(B^+ \to f_2(1270)K^+) = -0.68^{+0.19}_{-0.17}$ [142]. In at least the first two cases, a large direct CP violation might be expected since the penguin amplitude is suppressed so the tree and penguin amplitudes may have comparable magnitudes. There are also measurements by LHCb of CP asymmetries in several 3-body modes: $A_{CP}(B^+ \to \pi^+\pi^-\pi^+) = 0.057 \pm 0.013$, $A_{CP}(B^+ \to K^+\pi^-\pi^+) = 0.027 \pm 0.008$, $A_{CP}(B^+ \to K^+K^-\pi^+) = -0.122 \pm 0.0021$, and $A_{CP}(B^+ \to K^+K^-K^+) = -0.033 \pm 0.008$ [145]. Many of these analyses now include Dalitz plot treatments with many intermediate resonances.

BaBar [146] and Belle [134, 147] have observed the decays $B^+ \to \overline{K}^0K^+$ and $B^0 \to K^0\overline{K}^0$. The world-average branching fractions are $\mathcal{B}(B^0 \to K^0\overline{K}^0) = (1.21 \pm 0.16) \times 10^{-6}$ and $\mathcal{B}(B^+ \to \overline{K}^0K^+) = (1.31 \pm 0.17) \times 10^{-6}$. These are the first observations of hadronic $b \to d$ transitions, with significance bigger than 5σ for all four measurements. CP asymmetries have been measured for these modes, but with large errors. LHCb has observed $B^0 \to K^+K^-$ mode which occurs via a weak-annihilation process and is the rarest hadronic B-meson decay thus far observed, with $\mathcal{B}(B^0 \to K^+K^-) = (7.80 \pm 1.52) \times 10^{-8}$ [148]. $B_s^0 \to K^+K^-$ decay mode, which occurs mostly via $b \to s$ penguin process, has been observed by Belle [149], CDF [150] and LHCb [129]. The average branching fraction is $\mathcal{B}(B_s^0 \to K^+K^-) = (27.2 \pm 2.3) \times 10^{-6}$. Belle has also observed $B_s^0 \to K^0\overline{K}^0$ [151] which also occurs via $b \to s$ penguin transition in the SM. This was recently confirmed by LHCb [152]. The average branching fraction is $(1.76 \pm 0.31) \times 10^{-5}$.

The decay $B^0 \to \pi^+\pi^-$ can be used to extract the CKM angle α (for details see elsewhere in this *Review* [153]). This is complicated by the presence of significant contributions from penguin diagrams. An isospin analysis [154] can be used to untangle the penguin complications. The decay $B^0 \to \pi^0\pi^0$ is crucial in this analysis. Both BaBar and Belle have observed $B^0 \to \pi^0\pi^0$, with a mild tension in the measured branching fractions: $(1.83 \pm 0.25) \times 10^{-6}$ for BaBar [133] and $(1.31 \pm 0.26) \times 10^{-6}$ for Belle [155]. It turns out that the amount of penguin pollution in the $B \to \pi\pi$ system is rather large. In the past few years, measurements in the $B^0 \to \rho\rho$ system have produced more precise values of α, since penguin amplitudes are generally smaller for decays with vector mesons. An important ingredient in the analysis is the $B^0 \to \rho^0\rho^0$ branching fraction. The average of measurements from BaBar [156] and Belle [157] yields a branching fraction of $(0.96 \pm 0.15) \times 10^{-6}$. This is only 3% of the $\rho^+\rho^-$ branching fraction, much smaller than the corresponding ratio ($\gtrsim 20\%$) in the $\pi\pi$ system.

Since $B \to \rho\rho$ has two vector mesons in the final state, the CP eigenvalue of the final state depends on the longitudinal polarization fraction f_L for the decay. Therefore, a measurement of f_L is needed to extract the CKM angle α. Both BaBar and Belle have measured f_L for the decays $\rho^+\rho^-$ [158] and $\rho^+\rho^0$ [159] and in both cases the measurements show $f_L > 0.9$, making a complete angular analysis unnecessary. In $B^0 \to \rho^0\rho^0$, f_L is measured by BaBar [156], Belle [157] and LHCb [160], with the average value being $0.71^{+0.08}_{-0.09}$.

By analyzing the angular distributions of the B decays to two vector mesons, we can learn a lot about both weak- and strong-interaction dynamics in B decays. Decays that are penguin-dominated surprisingly have values of f_L near 0.5. The list of such decays has now grown to include $B \to \phi K^*(892)$, $B \to \rho K^*(892)$, and $B \to \omega K^*(892)$. The reasons for this "polarization puzzle" are not fully understood. A detailed description of the angular analysis of B decays to two vector mesons can be found in a separate mini-review [161] in this *Review* .

72.6 Electroweak penguin decays

Electroweak penguin decays are one-loop FCNC decays proceeding through penguin or box Feynman diagrams with final state including real photon or pair of leptons. Such decays were first observed by CLEO experiment when it observed decay $B \to K^*(892)\gamma$ [84]. Since then significant amount of experimental information was obtained. Branching fractions for these decays are 10^{-5} or less, which makes them excellent candidates for searches for new physics beyond SM. Often several observables are available, which allows for stringent tests of the SM.

Starting with radiative decays, experimentally easiest to study are exclusive decays with a fully reconstructed final state. The best studied decay in this class is $B \to K^*(892)\gamma$ seen by CLEO, Belle, BaBar experiments [162, 163] with world average branching fraction $\mathcal{B}(B^0 \to K^*(892)^0\gamma) = (41.8 \pm 2.5) \times 10^{-6}$. Decays through several other kaon resonances such as $B \to K_1(1270)\gamma$, $K_2^*(1430)\gamma$, *etc.* were studied at B-factories [164,165]. It is worth to mention decay $B^+ \to K^+\pi^+\pi^-\gamma$ for which besides measurements of the branching fraction [165, 166] one can also use the angular distribution to access photon polarization. Such a measurement was done by the LHCb experiment, which was able to clearly demonstrate that the photon in $B^+ \to K^+\pi^+\pi^-\gamma$ decay is polarized [167]. Unfortunately given non-trivial hadronic structure, more work is needed before turning this into test of the SM. The exclusive radiative decays $B_s^0 \to \phi\gamma$ was seen by the Belle and LHCb experiments [168] with an average branching fraction of $(3.4 \pm 0.4) \times 10^{-5}$ and more recently also decay $\Lambda_b \to \Lambda\gamma$ was observed by LHCb [169].

Compared to $b \to s\gamma$, the $b \to d\gamma$ transitions such as $B \to \rho\gamma$, are suppressed by the CKM elements ratio $|V_{td}/V_{ts}|^2$. Both Belle and BaBar have observed these decays [85,86]. The world average $\mathcal{B}(B \to (\rho,\omega)\gamma) = (1.30 \pm 0.23) \times 10^{-6}$. This can be used to calculate $|V_{td}/V_{ts}|$ [170]; the measured values are $0.195^{+0.025}_{-0.024}$ from Belle [85] and $0.233^{+0.033}_{-0.032}$ from BaBar [86].

The observed radiative penguin branching fractions can constrain a large class of SM extensions [171]. However, due to the uncertainties in the hadronization, only the inclusive $b \to s\gamma$ rate can be reliably compared with theoretical calculations. This rate can be measured from the endpoint of the inclusive photon spectrum in B decay. By combining the measurements of $B \to X_s\gamma$ from the CLEO, BaBar, and Belle experiments [172,173], HFLAV

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

obtains the average: $\mathcal{B}(B \to X_s\gamma) = (3.49 \pm 0.19) \times 10^{-4}$ [67] for $E_\gamma \geq 1.6$ GeV, averaging over B^+ and B^0. Consistent but less precise results have been reported by ALEPH for inclusive b–hadrons produced at the Z, which includes also contribution from B_s^0 and Λ_b^0 hadrons. Using the sum of seven exclusive final states, the BaBar experiment measured the branching fraction of inclusive $b \to d\gamma$ decays to be $(9.2 \pm 2.0 \pm 2.3) \times 10^{-6}$ [174]. The measured branching fraction can be compared to theoretical calculations. Recent calculations of $\mathcal{B}(b \to s\gamma)$ at NNLO level predict for the $E_\gamma \geq 1.6$ GeV values of $(3.36 \pm 0.23) \times 10^{-4}$ for $b \to s\gamma$ and $(1.68 \pm 0.17) \times 10^{-5}$ for $b \to d\gamma$ decays [175].

The CP asymmetry in $b \to s\gamma$ is extensively studied theoretically both in the SM and beyond [176]. According to the SM, the CP asymmetry in $b \to s\gamma$ is smaller than 1%, but some non-SM models allow significantly larger CP asymmetry ($\sim$ 10%) without altering the branching fraction. The current world average is $A_{CP} = 0.015 \pm 0.011$, again dominated by BaBar and Belle [177, 178]. In addition to the CP asymmetry, BaBar and Belle also measured the isospin asymmetry $\Delta_{0-} = -0.005 \pm 0.020$ in $b \to s\gamma$ measured using sum of exclusive decays [177, 179]. An alternative measurement using full reconstruction of the companion B in the hadronic decay modes yields a consistent, but less precise result [180]. Both Belle and BaBar experiments measured the isospin asymmetry in exclusive $B \to K^*(892)\gamma$ decay with average of $6.3 \pm 1.7\%$ [163] and therefore providing evidence for the non-zero isospin asymmetry.

In addition, experiments have measured the inclusive photon energy spectrum for $b \to s\gamma$, and by analyzing the shape of the spectrum they obtain the first and second moments for photon energies. Belle has measured these moments covering the widest range in the photon energy ($1.7 < E_\gamma < 2.8$ GeV) [173]. The measurement by BaBar has slightly smaller range with lower limit at 1.8 GeV [181]. These results can be used to extract non-perturbative HQET parameters that are needed for precise determination of the CKM matrix element V_{ub} (see further discussion elsewhere in this *Review* [182]).

Additional information on FCNC processes can be obtained from $b \to s\ell^+\ell^-$ decays. These processes are studied as a function of dilepton invariant mass squared, q^2. Different q^2 regions are sensitive to different physics. Starting at the very low q^2 decays exhibit sensitivity to the same physics as the radiative decays. Then for the q^2 in region 1.1 to 6.0 GeV$^2/c^4$ the SM and new physics have best chance to compete. At the high q^2 above the $\psi(2S)$ mass, the interference of SM and new physics is to some extend complementary to that in lower q^2. Regions around J/ψ and $\psi(2S)$ is normally excluded from measurements as these are dominated by the $b \to c$ transitions to charmonia. For exclusive decays, theory predictions require calculations of hadronic form factors. With current theory predictions, the most useful are measurements within the q^2 regions 1.1 to 6.0 GeV$^2/c^4$ and from 16.0 GeV$^2/c^4$ up to the kinematic limit. From this reason in the listing we provide results mainly in those two regions.

Similar as for radiative decays, also for the $b \to s\ell^+\ell^-$ decays the inclusive measurements provide some benefits. Both Belle and BaBar performed such measurement without reconstructing hadronic part exclusively and measure a branching fraction of $(5.8 \pm 1.3) \times 10^{-6}$ [183]. Unfortunately this measurement is not trivially possible at hadron colliders and also does not easily allow the angular distributions of the decay products to be exploited. One alternative is to extract information on the inclusive decay as sum of exclusive decays. Such a measurement was performed by Belle [184], but in this case the difficulty lies in extrapolation for the missing hadronic states.

Turning to the exclusive decays, the initial measurements performed by B-factories typically averaged between charged and neutral B mesons as well as between e^+e^- and $\mu^+\mu^-$ finals states. The experiments CDF, LHCb, ATLAS and CMS are much better suited for the $\mu^+\mu^-$ finals states compared to the e^+e^- final states. As such most measurements at hadron colliders are done only with $\mu^+\mu^-$ pairs and by separating charged and neutral B mesons. Recently, however, with much increased statistics, LHCb measured several final states with e^+e^-, to make a series of tests of e/μ universality in $B \to K^{(*)}\ell^+\ell^-$ decays. At hadron colliders other b hadrons are produced and as such CDF and LHCb experiments did observe also $B_s^0 \to \phi\mu^+\mu^-$ [185, 186], $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ [185, 187] and $\Lambda_b^0 \to pK^-\mu^+\mu^-$ decays [188]. The averages of the total branching fractions integrated over whole q^2 regions are $(5.6 \pm 0.6) \times 10^{-7}$ for $B^+ \to K^+e^+e^-$, $(4.53 \pm 0.35) \times 10^{-7}$ for $B^+ \to K^+\mu^+\mu^-$, $(1.03^{+0.19}_{-0.17}) \times 10^{-6}$ for $B^0 \to K^*(892)^0e^+e^-$ and $(0.94 \pm 0.05) \times 10^{-6}$ for $B^0 \to K^*(892)^0\mu^+\mu^-$ decays [189–193]. The total branching fractions for $B_s^0 \to \phi\mu^+\mu^-$ and $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ decays are $(8.4 \pm 0.4) \times 10^{-7}$ [185, 186, 194] and $(1.08 \pm 0.28) \times 10^{-6}$ [185, 187] respectively. With increased precision of $B^0 \to K^*(892)^0\ell^+\ell^-$ decay, there is a question on what fraction of the seen branching fraction is due to the $K^*(892)^0$ resonance and what fraction is due to the $K\pi$ in s-wave. This has been studied by LHCb which found that the $K\pi$ in s-wave fraction varies between 1% and about 10% depending on the q^2 region [193]. It should be noted, that for all relevant B meson decays the branching fractions so far studied are consistently below the SM expectation.

In the $b \to s\ell^+\ell^-$ decays angular distributions offer rich source of information. The full angular analysis was performed for decays $B^+ \to K^+\ell^+\ell^-$, $B^0 \to K^0\ell^+\ell^-$, $B^+ \to K^*(892)^+\ell^+\ell^-$, $B^0 \to K^*(892)^0\ell^+\ell^-$, $B_s^0 \to \phi\mu^+\mu^-$ and $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ decays [195–203]. An attempt to increase sensitivity to the NP was made by constructing observables, which have reduced theory uncertainties and measurements of these are done. Most notably the observable called P_5' [204] shows a discrepancy with the SM in the q^2 region which is highly sensitive to new physics [197–199]. Measurements of the CP asymmetries [188, 189, 192, 205, 206] and the isospin asymmetry [190–192, 205] were also performed. All these measurements are well consistent with the small A_{CP} and small isospin asymmetry expected in the SM [207]. With statistics available at the LHC, the measurement of phase difference between long- and short-distance contribution in $B^+ \to K^+\mu^+\mu^-$ decays became possible [208].

With the data samples available at LHC, the lepton universality in $b \to s\ell^+\ell^-$ can be tested. While in the SM decays to electron-positron and muon pairs are expected to be same up to small corrections due to the different masses of leptons, in extensions of the SM this does not have to hold. The angular analysis of $B^0 \to K^*(892)^0e^+e^-$ decays was performed by LHCb at low dilepton invariant masses [209] and Belle in several regions over whole q^2 range [199]. The LHCb measurement yields the most stringent constraint on the photon polarization. The result on lepton universality test which over past few years attracted most attention is the ratio of branching fractions between $B^+ \to K^+\mu^+\mu^-$ and $B^+ \to K^+e^+e^-$ and between $B^0 \to K^*(892)^0\mu^+\mu^-$ and $B^0 \to K^*(892)^0e^+e^-$ decays [190, 210]. The measurements by LHCb showed mild discrepancy from the SM, with significance of $3.1\,\sigma$ for $B^+ \to K^+\ell^+\ell^-$ and about $2.4\,\sigma$ for $B^0 \to K^*(892)^0\ell^+\ell^-$. The latest analysis in Ref. [211] identified previously missed hadronic misidentification background. With better handling of such background the results are now consistent with the SM. LHCb experiment performed similar test with $\Lambda_b^0 \to pK^-\ell^+\ell^-$ decays [212], $B^0 \to K_S^0\ell^+\ell^-$ and $B^+ \to K^*(892)^+\ell^+\ell^-$ [213].

While $b \to d\ell^+\ell^-$ decays are further suppressed, they recently became accessible. Signals were observed for $B^+ \to \pi^+\mu^+\mu^-$ [87], $B^0 \to \pi^+\pi^-\mu^+\mu^-$ [214] and $\Lambda_b^0 \to p\pi^-\mu^+\mu^-$ [215] decays. Search for the $B_s^0 \to \overline{K}^*(892)^0\mu^+\mu^-$ at LHCb is complicated by large background from $B^0 \to K^*(892)^0\mu^+\mu^-$ and current significance for the decay is 3.4σ [216]. The total branching fractions are only quantities measured and these are about 2×10^{-8} for the meson decays and about 7×10^{-8} for the Λ_b^0 decay.

A closely related process is $B \to X_s\nu\overline{\nu}$. Since the neutrinos are not detected, the final state is a strange hadron system X_s plus missing energy-momentum. Depending on X_s, the SM branching fraction is $\mathcal{O}(10^{-6})$. New physics effects beyond SM, e.g. those from dark sector models can greatly enhance the yield of X_s plus missing energy. BaBar [217], Belle [218], and Belle II [219] have searched for these decays and determined the upper limits in the range $\mathcal{O}(10^{-5})$.

Finally the decays $B_{(s)}^0 \to e^+e^-$ and $\mu^+\mu^-$ are interesting

since they only proceed at second order in weak interactions in the SM, but may have large contributions from supersymmetric loops, proportional to $(\tan\beta)^6$. First limits were published more than 30 years ago and since then experiments at Tevatron, B-factories and LHC gradually improved those and effectively excluded whole models of new physics and significantly constrained allowed parameter space of others. For the decays to $\mu^+\mu^-$, Tevatron experiments pushed the limits down to roughly factor of 5-10 above the SM expectation [220]. The long journey in the search for these decays culminated in 2012, when first evidence for $B_s^0 \to \mu^+\mu^-$ decay was seen [221]. Subsequently, LHC experiments ATLAS [222], CMS [223] and LHCb [224] observed statistically significant signal for $B_s^0 \to \mu^+\mu^-$ decay. The current average branching fraction is $(3.34 \pm 0.27) \times 10^{-9}$. In experiments at hadron colliders searches for $B^0 \to \mu^+\mu^-$ decays are performed at the same time. The $B(B^0 \to \mu^+\mu^-)$ is extracted in simultaneously with $B(B_s^0 \to \mu^+\mu^-)$ and is found to be $(0.07^{+0.13}_{-0.11}) \times 10^{-9}$. The limits for the e^+e^- modes are: $< 9.4 \times 10^{-9}$ and $< 2.5 \times 10^{-9}$, respectively, for B_s^0 and B^0 [225]. The searches for decays to $\tau^+\tau^-$ are more challenging with current best limits of $B(B^0 \to \tau^+\tau^-) < 2.1 \times 10^{-3}$ and $B(B_s^0 \to \tau^+\tau^-) < 6.8 \times 10^{-3}$ at 95% C.L. [226]. All existing measurements of B^0 and B_s^0 decays to same flavour dilepton pair is consistent with SM expectation [227]. With $B_s^0 \to \mu^+\mu^-$ decay observed, it was suggested that the effective lifetime is useful further test of the decay [228]. Attempt was made by LHCb and CMS experiments, but its precision is not yet sufficient to provide test of the SM [223, 224]. It will take couple of years until interesting precision is reached. The searches were also performed for lepton flavour violating decays to two leptons with best limits in $e^\pm\mu^\mp$ channel, where limits are $< 1.3 \times 10^{-9}$ for B^0 and $< 6.3 \times 10^{-9}$ for B_s^0, at 95% confidence level [229].

Several theory groups performed global analysis of electroweak decays concluding that significant tension between data and SM is present [230]. The tension can be relieved by new physics beyond SM. For more detailed reviews see e.g. Ref. [231].

72.7 Summary and Outlook

The study of B mesons continues to be one of the most productive fields in particle physics. With the two asymmetric B-factory experiments Belle and BaBar, we now have a combined data sample of well over 1 ab^{-1}. CP violation has been firmly established in many decays of B mesons. Evidence for direct CP violation has been observed. Many rare decays resulting from hadronic $b \to u$ transitions and $b \to s(d)$ penguin decays have been observed, and the emerging pattern is still full of surprises. Despite the remarkable successes of the B-factory experiments, many fundamental questions in the flavor sector remain unanswered.

At Fermilab, CDF and D0 each has accumulated about 10 fb^{-1}, which is the equivalent of about 10^{12} b-hadrons produced. In spite of the low trigger efficiency of hadronic experiments, a selection of modes have been reconstructed in large quantities, giving a start to a program of studies on B_s and b-flavored baryons, in which a first major step has been the determination of the B_s oscillation frequency.

As Tevatron and B-factories finished their data taking few year ago, the experiments at the LHC have become very active. LHCb has collected about 1 fb^{-1} at 7 TeV, 2 fb^{-1} at 8 TeV, and close to 5.9 fb^{-1} at 13 TeV during LHC Runs 1 and 2. CMS and ATLAS have collected each about 5 fb^{-1} of data at $\sqrt{s} = 7$ TeV, 20 fb^{-1} at 8 TeV and about 150 fb^{-1} at 13 TeV during LHC Runs 1 and 2. The latest LHC Run 3 at 13.6 TeV started in summer 2022, with upgraded detectors. By the time of the writing (March 2026), LHC has delivered about 330 fb^{-1} to ATLAS and CMS experiments. LHCb, which is dedicated to the studies of b- and c-hadrons, has a data sample that is larger than the sum of all previous experiments. With it, we are entering to regime of precision physics even for many rare decays, which allows much more detailed measurements.

The Belle II experiment at the SuperKEKB has started recording data in 2019 and has by March 2026 collected about 700 fb^{-1} of data with successful restart of data taking after their long shutdown. The aim to increase sample to $\sim$ 50 ab^{-1} will make it possible to explore the indirect evidence of new physics beyond the SM in the heavy-flavor particles (b, c, and τ), in a way that is complementary to the LHC. The LHCb Collaboration successfuly commissioned upgrade of its detector and since 2024 is accummulating data as planned rate/ The aim of the upgrade was to increase flexibility of the trigger, which will allow about a factor of five increase in instantaneous luminosity and of about a factor of two in efficiencies on triggering on purely hadronic decays, which is being delivered. The plan is to integrate about 50 fb^{-1} of data during LHC runs 3 and 4.

These experiments promise a rich spectrum of rare and precise measurements that have the potential to fundamentally affecting our understanding of the SM and CP-violating phenomena.

[5] Currently two different notations (ϕ_1, ϕ_2, ϕ_3) and (α, β, γ) are used in the literature for CKM unitarity angles. In this mini-review, we use the latter notation following the other mini-reviews in this *Review*. The two notations are related by $\phi_1 = \beta$, $\phi_2 = \alpha$ and $\phi_3 = \gamma$.

73. Polarization in B Decays

Revised August 2025 by A.V. Gritsan (Johns Hopkins U.).

We review the notation used in polarization measurements in particle production and decay, with a particular emphasis on the B decays and the *CP*-violating observables in polarization measurements. We look at several examples of vector-vector and vector-tensor B meson decays, while more details about the theory and experimental results in B decays can be found in a separate mini-review [1] in this *Review*.

Figure 73.1 illustrates angular observables in an example of the sequential process $ab \to X \to P_1P_2 \to (p_{11}p_{12})(p_{21}p_{22})$ [2]. The angular distributions are of particular interest because they are sensitive to spin correlations and reveal properties of particles and their interactions, such as quantum numbers and couplings. In the case of a spin-zero particle X, such as B meson or a Higgs boson, there are no spin correlations in the production mechanism and the decay chain is to be analyzed. The angular distribution of decay products can be expressed as a function of three helicity angles which describe the alignment of the particles in the decay chain. The analyzer of the B-daughter polarization is normally chosen for two-body decays, as the direction of the daughters in the center-of-mass of the parent (*e.g.*, $\rho \to 2\pi$) [3], and for three-body decays as the normal to the decay plane (*e.g.*, $\omega \to 3\pi$) [4]. An equivalent set of transversity angles is sometimes used in polarization analyses [5]. The differential decay width depends on complex amplitudes $A_{\lambda_1\lambda_2}$, corresponding to the X-daughter helicity states λ_i.

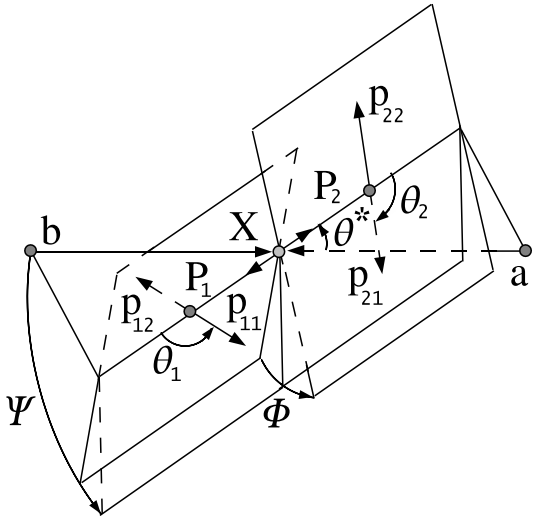

Figure 73.1: Definition of the production and helicity angles in the sequential process $ab \to X \to P_1P_2 \to (p_{11}p_{12})(p_{21}p_{22})$. The three helicity angles include θ_1 and θ_2, defined in the rest frame of the two daughters P_1 and P_2, and Φ, defined in the X frame as the angle between the two decay planes. The two production angles θ^* and Ψ are defined in the X frame, where Ψ is the angle between the production plane and the average of the two decay planes.

In the case of a spin-zero B-meson decay, its daughter helicities are constrained to $\lambda_1 = \lambda_2 = \lambda$. Therefore we simplify amplitude notation as A_λ. Moreover, most B-decay polarization analyses are limited to the case when the spin of one of the B-meson daughters is 1. In that case, there are only three independent amplitudes corresponding to $\lambda = 0$ or ±1 [6], where the last two can be expressed in terms of parity-even and parity-odd amplitudes $A_{\parallel,\perp} = (A_{+1} \pm A_{-1})/\sqrt{2}$. The overall decay amplitude involves three complex terms proportional to the above amplitudes and the Wigner d functions of helicity angles. The exact angular dependence would depend on the quantum numbers of the B-meson daughters and of their decay products, and can be found in the literature [6,7]. When both B-meson daughters are tensor mesons and the smaller of the two daughter spins is $J_1 > 1$, this formalism can be easily extended by introducing the parity-even and parity-odd amplitudes of higher order $A_{\parallel n,\perp n} = (A_{+n} \pm A_{-n})/\sqrt{2}$, with $1 < n \le J_1$, while the general angular parameterization may be found in Ref. [7]. However, we limit the following discussion to $J_1 = 1$. The differential decay rate would involve six real quantities α_i, including interference terms,

$$\frac{d\Gamma}{\Gamma\, d\cos\theta_1\, d\cos\theta_2\, d\Phi} = \sum_i \alpha_i\ f_i\,(\cos\theta_1,\, \cos\theta_2,\, \Phi)\,, \qquad (73.1)$$

where each $f_i\,(\cos\theta_1, \cos\theta_2, \Phi)$ has unique angular dependence specific to particle quantum numbers, and the α_i parameters are defined as:

$$\alpha_1 = \frac{|A_0|^2}{\Sigma|A_\lambda|^2} = f_L\,, \qquad (73.2)$$

$$\alpha_2 = \frac{|A_\parallel|^2 + |A_\perp|^2}{\Sigma|A_\lambda|^2} = (1 - f_L)\,, \qquad (73.3)$$

$$\alpha_3 = \frac{|A_\parallel|^2 - |A_\perp|^2}{\Sigma|A_\lambda|^2} = (1 - f_L - 2\,f_\perp)\,, \qquad (73.4)$$

$$\alpha_4 = \frac{\Im m(A_\perp A_\parallel^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_\perp(1-f_L-f_\perp)}\,\sin(\phi_\perp - \phi_\parallel)\,, \qquad (73.5)$$

$$\alpha_5 = \frac{\Re e(A_\parallel A_0^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_L\,(1 - f_L - f_\perp)}\,\cos(\phi_\parallel)\,, \qquad (73.6)$$

$$\alpha_6 = \frac{\Im m(A_\perp A_0^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_\perp\, f_L}\,\sin(\phi_\perp)\,, \qquad (73.7)$$

where the amplitudes have been expressed with the help of polarization parameters f_L, $f_\perp$, $\phi_\parallel$, and $\phi_\perp$ defined in Table 73.1. Note that the terms proportional to $\Re e(A_\perp A_\parallel^*)$, $\Im m(A_\parallel A_0^*)$, and $\Re e(A_\perp A_0^*)$ are absent in Eqs. (2-7). However, these terms may appear for some three-body decays of a B-meson daughter, see Ref. [7].

Table 73.1: Rate, polarization, and *CP*-asymmetry parameters defined for the B-meson decays to mesons with non-zero spin. Numerical examples are shown for the average of the $B^0 \to \varphi K^*(892)^0$ decay measurements obtained from BABAR [8], Belle [9], and LHCb [10]. The first six parameters are defined under the assumption of no *CP* violation in decay, while they are averaged between the $\overline{B}$ and B parameters in general. The last six parameters involve differences between the $\overline{B}$ and B meson decay parameters. The phase convention δ_0 is chosen with respect to a single A_{00} amplitude from a reference B decay mode, which is $B^0 \to \varphi K_0^*(1430)^0$ for numerical results.

parameter	definition	average
$\mathcal{B}$	$\Gamma/\Gamma_{\rm total}$	$(10.1^{+0.6}_{-0.5}) \times 10^{-6}$
f_L	$\lvert A_0\rvert^2/\Sigma\lvert A_\lambda\rvert^2$	0.497 ± 0.017
$f_\perp$	$\lvert A_\perp\rvert^2/\Sigma\lvert A_\lambda\rvert^2$	0.225 ± 0.015
$\phi_\parallel - \pi$	$\arg(A_\parallel/A_0) - \pi$	-0.712 ± 0.058
$\phi_\perp - \pi$	$\arg(A_\perp/A_0) - \pi$	-0.615 ± 0.056
$\delta_0 - \pi$	$\arg(A_{00}/A_0) - \pi$	-0.26 ± 0.10
A_{CP}	$(\bar\Gamma - \Gamma)/(\bar\Gamma + \Gamma)$	-0.003 ± 0.038
A_{CP}^0	$(\bar f_L - f_L)/(\bar f_L + f_L)$	-0.007 ± 0.030
$A_{CP}^\perp$	$(\bar f_\perp - f_\perp)/(\bar f_\perp + f_\perp)$	-0.014 ± 0.057
$\Delta\phi_\parallel$	$(\bar\phi_\parallel - \phi_\parallel)/2$	$+0.051 \pm 0.053$
$\Delta\phi_\perp$	$(\bar\phi_\perp - \phi_\perp - \pi)/2$	$+0.075 \pm 0.050$
$\Delta\delta_0$	$(\bar\delta_0 - \delta_0)/2$	$+0.13 \pm 0.08$

Overall, six real parameters describe three complex amplitudes A_0, $A_\parallel$, and $A_\perp$. These could be chosen to be the four polarization

parameters f_L, $f_\perp$, $\phi_\parallel$, and $\phi_\perp$, one overall size normalization, such as decay rate Γ, or branching fraction $\mathcal{B}$, and one overall phase δ_0. The phase convention is arbitrary for an isolated B decay mode. However, for several B decays, the relative phase could produce meaningful and observable effects through interference with other B decays with the same final states, such as for $B \to VK_J^*$ with $J = 0, 1, 2, 3, 4, ...$ The phase could be referenced to the single $B \to VK_0^*$ amplitude A_{00} in such a case, as shown in Table 73.1. Here V stands for any spin-one vector meson.

Moreover, *CP* violation can be tested in the angular distribution of the decay as the difference between the B and $\overline{B}$. Each of the six real parameters describing the three complex amplitudes would have a counterpart *CP*-asymmetry term, corresponding to three direct-*CP* asymmetries in three amplitudes, and three *CP*-violating phase differences, equivalent to the phase measurements from the mixing-induced *CP* asymmetries in the time evolution of B-decays [1]. In Table 73.1 and Ref. [11], these are chosen to be the direct-*CP* asymmetries in the overall decay rate $\mathcal{A}_{CP}$, in the f_L fraction $\mathcal{A}_{CP}^0$, and in the $f_\perp$ fraction $\mathcal{A}_{CP}^\perp$, and three weak phase differences:

$$\Delta\phi_\parallel = \frac{1}{2}\arg(\bar{A}_\parallel A_0 / A_\parallel \bar{A}_0)\,, \tag{73.8}$$

$$\Delta\phi_\perp = \frac{1}{2}\arg(\bar{A}_\perp A_0 / A_\perp \bar{A}_0) - \frac{\pi}{2}\,, \tag{73.9}$$

$$\Delta\delta_0 = \frac{1}{2}\arg(\bar{A}_{00} A_0 / A_{00} \bar{A}_0)\,. \tag{73.10}$$

The $\frac{\pi}{2}$ term in Eq. (73.9) reflects the fact that $A_\perp$ and $\bar{A}_\perp$ differ in phase by π if *CP* is conserved. The two parameters $\Delta\phi_\parallel$ and $\Delta\phi_\perp$ are equivalent to triple-product asymmetries constructed from the vectors describing the decay angular distribution [12]. The *CP*-violating phase difference in the reference decay mode [11] is, in the Wolfenstein CKM quark-mixing phase convention,

$$\Delta\phi_{00} = \frac{1}{2}\arg(A_{00}/\bar{A}_{00})\,. \tag{73.11}$$

This can be measured only together with the mixing-induced phase difference for some of the neutral B-meson decays similar to other mixing-induced *CP* asymmetry measurements [1].

It may not always be possible to have a phase-reference decay mode which would define δ_0 and $\Delta\delta_0$ parameters. In that case, it may be possible to define the phase difference directly similarly to Eq. (73.11):

$$\Delta\phi_0 = \frac{1}{2}\arg(A_0/\bar{A}_0)\,. \tag{73.12}$$

One can measure the angles of the CKM unitarity triangle, assuming Standard Model contributions to the $\Delta\phi_0$ and B-mixing phases. Examples include measurements of $\beta = \phi_1$ with $B \to J/\psi K^*$ and $\alpha = \phi_2$ with $B \to \rho\rho$.

Most of the B decays that arise from tree-level $b \to c$ transitions have the amplitude hierarchy $|A_0| > |A_+| > |A_-|$ which is expected from analyses based on quark-helicity conservation [13]. The larger the mass of the vector-meson daughters, the weaker the inequality. The B meson decays to heavy vector particles with charm, such as $B \to J/\psi K^*$, $\psi(2S)K^*$, $\chi_{c1}K^*$, $D^*\rho$, D^*K^*, D^*D^*, and $D^*D_s^*$, show a substantial fraction of the amplitudes corresponding to transverse polarization of the vector mesons ($A_{\pm 1}$), in agreement with the factorization prediction. The detailed amplitude analysis of the $B \to J/\psi K^*$ decays has been performed by the BABAR [14], Belle [15], CDF [16], CLEO [17], D0 [18], and LHCb [19] collaborations. Most analyses are performed under the assumption of the absence of direct *CP* violation. The parameter values are given in the particle listing of this *Review*. The difference between the strong phases $\phi_\parallel$ and $\phi_\perp$ deviates significantly from zero. The measurements [14, 15] of *CP*-violating terms similar to those in $B \to \varphi K^*$ [8] shown in Table 73.1 are consistent with zero.

In addition, the mixing-induced *CP*-violating asymmetry is measured in the $B^0 \to J/\psi K^{*0}$ decay [1, 14, 15] where angular analysis allows one to separate *CP*-eigenstate amplitudes. This allows one to resolve the sign ambiguity of the $\cos 2\beta$ ($\cos 2\phi_1$) term that appears in the time-dependent angular distribution due to interference of parity-even and parity-odd terms. This analysis relies on the knowledge of discrete ambiguities in the strong phases $\phi_\parallel$ and $\phi_\perp$, as discussed below. The BABAR experiment used a method based on the dependence on the $K\pi$ invariant mass of the interference between the S- and P-waves to resolve the discrete ambiguity in the determination of the strong phases $(\phi_\parallel, \phi_\perp)$ in $B \to J/\psi K^*$ decays [14]. The result is in agreement with the amplitude hierarchy expectation [13]. The CDF [20], D0 [21], LHCb [22], ATLAS [23], and CMS [24] experiments have studied the $B_s^0 \to J/\psi(K^+K^-)$, $J/\psi(\pi^+\pi^-)$, $\psi(K^+\pi^-)$ decays and provided the lifetime, polarization, and phase measurements.

The amplitude hierarchy $|A_0| \gg |A_+| \gg |A_-|$ was expected in B decays to light vector particles in both penguin transitions [25, 26] and tree-level transitions [13]. There is confirmation by the BABAR and Belle experiments of predominantly longitudinal polarization in the tree-level $b \to u$ transition, such as $B^0 \to \rho^+\rho^-$ [27], $B^+ \to \rho^0\rho^+$ [28], and $B^+ \to \omega\rho^+$ [29]; this is consistent with the analysis of the quark helicity conservation [13]. Because the longitudinal amplitude dominates the decay, a detailed amplitude analysis is not possible with current B samples, and limits on the transverse amplitude fraction are obtained. The small branching fractions of $B^0 \to \rho^0\rho^0, \omega\rho^0, \omega\omega$ [29–32] indicate that $b \to d$ penguin pollution is small in the charmless, strangeless vector-vector B decays. There is a measurement of large longitudinal polarization in $B^0 \to \rho^0\rho^0$ [30–32] and $B^0 \to \omega\omega$ [33] decays. The fraction of transverse polarization is large in decays to heavier mesons such as $B^0 \to a_1(1260)^+ a_1(1260)^-$ [34].

The interest in the polarization and *CP*-asymmetry measurements in penguin transition, such as $b \to s$ decays $B \to \varphi K^*$, ρK^*, ωK^*, or $B_s^0 \to \varphi\varphi$, K^*K^*, and $b \to d$ decay $B \to K^*\bar{K}^*$, is motivated by their potential sensitivity to physics beyond the Standard Model. The decay amplitudes for $B \to \varphi K^*$ have been measured by the BABAR, Belle, and LHCb experiments [9–11, 35, 36]. The fractions of longitudinal polarization are $f_L = 0.50 \pm 0.05$ for the $B^+ \to \varphi K^{*+}$ decay and $f_L = 0.497 \pm 0.017$ for the $B^0 \to \varphi K^{*0}$ decay. These indicate significant departure from the naive expectation of predominant longitudinal polarization, suggesting other contributions to the decay amplitude, previously neglected, either within the Standard Model, such as penguin annihilation [37] or QCD rescattering [38], or from physics beyond the Standard Model [39]. The complete set of twelve amplitude parameters measured in the $B^0 \to \varphi K^{*0}$ decay is given in Table 73.1. Several other parameters could be constructed from the above twelve parameters, as suggested in Ref. [40].

The discrete ambiguity in the phase $(\phi_\parallel, \phi_\perp, \Delta\phi_\parallel, \Delta\phi_\perp)$ measurements has been resolved by BABAR in favor of $|A_+| \gg |A_-|$ through interference between the S- and P-waves of $K\pi$. The search for vector-tensor and vector-axialvector $B \to \varphi K_J^{(*)}$ decays with $J = 1, 2, 3, 4$ revealed a large fraction of longitudinal polarization in the decay $B \to \varphi K_2^*(1430)$ with $f_L = 0.90^{+0.06}_{-0.07}$ [11, 41], but large contribution of transverse amplitude in $B \to \varphi K_1(1270)$ with $f_L = 0.46^{+0.13}_{-0.15}$ [42].

Like $B \to \varphi K^*$, the decays $B \to \rho K^*$ and $B \to \omega K^*$ may be sensitive to New Physics. Measurements of the longitudinal polarization fraction in $B \to \rho K^*$ [43] and in both vector-vector and vector-tensor final states of $B \to \omega K_J^*$ [29] by BABAR and Belle reveal a large fraction of transverse polarization, indicating an anomaly similar to $B \to \varphi K^*$ except for a different pattern in vector-tensor final states. An angular analysis of the $B^0 \to \rho^0 K^{*0}$ decay mode by LHCb [44] provides much higher precision and indicates remarkably small longitudinal polarization fraction and a significant direct CP asymmetry observed in angular distributions of $B \to VV$ decays for the first time. A large transverse polarization is also observed in the $B_s^0 \to \varphi\varphi$ decay by CDF [45] and LHCb [46], $B_s^0 \to K^{*0}\bar{K}^{*0}$ decays by LHCb [47], and $B_s^0 \to \varphi K^{*0}$ decays by LHCb [48]. At the same time, measurement of the polarization in the $b \to d$ penguin decays $B \to K^*\bar{K}^*$ indicates a large fraction of longitudinal polarization [47, 49]. The LHCb experiment has also provided the very first polarization results on the tensor-tensor, as well as vector-tensor, decays of the B_s^0 meson in the $(K\pi)(K\pi)$ final state [47]. The polarization pattern in penguin-dominated B-meson decays is not fully understood [37–39].

The three-body semileptonic B-meson decays, such as $B \to V\ell_1\ell_2$, share many features with the two-body $B \to VV$ decays. Their differential decay width can be parameterized with the two helicity angles defined in the V and $(\ell_1\ell_2)$ frames and with the azimuthal angle, as defined in Fig. 73.1. However, since the $(\ell_1\ell_2)$ pair does not come from an on-shell particle, the angular distribution is unique to each point in the dilepton mass $m_{\ell\ell}$ spectrum. The polarization measurements as a function of $m_{\ell\ell}$ provide complementary information on physics beyond the Standard Model, as discussed for $B \to K^*\ell^+\ell^-$ and $B_s \to \phi\ell^+\ell^-$ decays in Ref. [50]. The data in these modes have been analyzed by the BABAR, Belle, CDF, CMS, ATLAS, and LHCb experiments [51–56].

The examples of the angular distributions and observables in $B \to K^*\ell^+\ell^-$ are discussed in Ref. [50]. Two angular observables have been measured in this decay in certain ranges of the dilepton mass $m_{\ell\ell}$. One parameter is the fraction of longitudinal polarization F_L, which is determined by the K^* angular distribution and is similar to f_L defined for exclusive two-body decays. The other parameter is the forward-backward asymmetry of the lepton pair A_{FB}, which is the asymmetry of the decay rate with positive and negative values of $\cos\theta_1$. A complete set of observables and angular terms has been adopted by the LHCb collaboration [56] following Ref. [50] with the F_L, A_{FB}, and $S_3 - S_9$ coefficients in the angular distributions. Additional set of optimized observables $P_i^{(\prime)}$ is derived from those, for example $P_2 = 2A_{FB}/(3-3F_L)$ and $P_5' = S_5/\sqrt{F_L(1-F_L)}$. These observables have the advantage that the leading form-factor uncertainties cancel. There have been hints of deviations from SM in the measurement of P_5' and lepton flavor universality [51–56].

In summary, there has been considerable interest in the polarization measurements of B-meson decays because they reveal both weak- and strong-interaction dynamics [37–39,57]. New measurements will further elucidate the pattern of spin alignment measurements in rare B decays, and further test the Standard Model and strong interaction dynamics, including the non-factorizable contributions to the B-decay amplitudes.

74. B^0–$\overline{B}^0$ Mixing

Revised March 2026 by O. Schneider (EPFL).

There are two neutral B^0–$\overline{B}^0$ meson systems, B_d^0–$\overline{B}_d^0$ and B_s^0–$\overline{B}_s^0$ (generically denoted B_q^0–$\overline{B}_q^0$, $q = s, d$), which exhibit particle-antiparticle mixing [1]. This mixing phenomenon is described in Ref. [2]. In the following, we adopt the notation introduced in Ref. [2], and assume CPT conservation throughout. In each system, the light (L) and heavy (H) mass eigenstates,

$$|B_{q\mathrm{L},q\mathrm{H}}\rangle = p|B_q^0\rangle \pm q|\overline{B}_q^0\rangle, \tag{74.1}$$

have a mass difference $\Delta m_q = m_{q\mathrm{H}} - m_{q\mathrm{L}} > 0$, a total decay-width difference $\Delta\Gamma_q = \Gamma_{q\mathrm{L}} - \Gamma_{q\mathrm{H}}$ and an average decay width $\Gamma_q = (\Gamma_{q\mathrm{L}}+\Gamma_{q\mathrm{H}})/2$. In the absence of CP violation in the mixing, $|q/p| = 1$, the differences are given by $\Delta m_q = 2|M_{12}|$ and $|\Delta\Gamma_q| = 2|\Gamma_{12}|$, where M_{12} and Γ_{12} are the off-diagonal elements of the mass and decay matrices [2]. The evolution of a pure $|B_q^0\rangle$ or $|\overline{B}_q^0\rangle$ state at $t = 0$ is given by

$$|B_q^0(t)\rangle = g_+(t)\,|B_q^0\rangle + \frac{q}{p}\,g_-(t)\,|\overline{B}_q^0\rangle, \tag{74.2}$$

$$|\overline{B}_q^0(t)\rangle = g_+(t)\,|\overline{B}_q^0\rangle + \frac{p}{q}g_-(t)\,|B_q^0\rangle, \tag{74.3}$$

which means that the flavor states remain unchanged (+) or oscillate into each other (−) with time-dependent probabilities proportional to

$$|g_\pm(t)|^2 = \frac{e^{-\Gamma_q t}}{2}\left[\cosh\left(\frac{\Delta\Gamma_q}{2}\,t\right) \pm \cos(\Delta m_q\, t)\right]. \tag{74.4}$$

In the absence of CP violation, the time-integrated mixing probability $\int |g_-(t)|^2\,dt/(\int |g_-(t)|^2\,dt + \int |g_+(t)|^2\,dt)$ is given by

$$\chi_q = \frac{x_q^2 + y_q^2}{2(x_q^2+1)}, \quad \text{where} \quad x_q = \frac{\Delta m_q}{\Gamma_q}, \quad y_q = \frac{\Delta\Gamma_q}{2\Gamma_q}. \tag{74.5}$$

74.1 Standard Model predictions and phenomenology

In the Standard Model, the transitions $B_q^0 \to \overline{B}_q^0$ and $\overline{B}_q^0 \to B_q^0$ are due to the weak interaction. They are described, at the lowest order, by box diagrams involving two W bosons and two up-type quarks (see Fig. 74.1), as is the case for $K^0 - \overline{K}^0$ mixing. However, the long range interactions arising from intermediate virtual states are negligible for the neutral B meson systems, because the large B mass is off the region of hadronic resonances. The calculation of the dispersive and absorptive parts of the box diagrams yields the following predictions for the off-diagonal element of the mass and decay matrices [3],

$$M_{12} = -\frac{G_F^2 m_W^2 \eta_B m_{B_q} B_{B_q} f_{B_q}^2}{12\pi^2}\, S_0(m_t^2/m_W^2)\,(V_{tq}^* V_{tb})^2\,, \tag{74.6}$$

$$\Gamma_{12} = \frac{G_F^2 m_b^2 \eta'_B m_{B_q} B_{B_q} f_{B_q}^2}{8\pi} \times \left[(V_{tq}^* V_{tb})^2 + V_{tq}^* V_{tb} V_{cq}^* V_{cb}\,\mathcal{O}\left(\frac{m_c^2}{m_b^2}\right) + (V_{cq}^* V_{cb})^2\,\mathcal{O}\left(\frac{m_c^4}{m_b^4}\right)\right], \tag{74.7}$$

where G_F is the Fermi constant, m_W the W boson mass, and m_i the mass of quark i; m_{B_q}, f_{B_q} and B_{B_q} are the B_q^0 mass, weak decay constant and bag parameter, respectively. The known function $S_0(x_t)$ can be approximated very well by $0.784\,x_t^{0.76}$ [4], and V_{ij} are the elements of the CKM matrix [5]. The QCD corrections η_B and η'_B are of order unity. The only non-negligible contributions to M_{12} are from box diagrams involving two top quarks. The phases of M_{12} and Γ_{12} satisfy

$$\phi_M - \phi_\Gamma = \pi + \mathcal{O}\left(\frac{m_c^2}{m_b^2}\right), \tag{74.8}$$

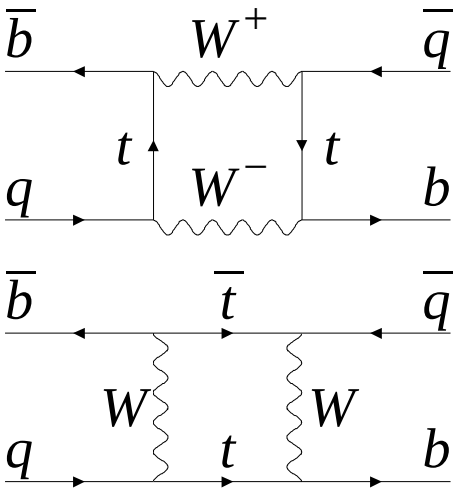

Figure 74.1: Dominant box diagrams for the $B_q^0 \to \overline{B_q}^0$ transitions ($q = d$ or s). Similar diagrams exist where one or both t quarks are replaced with c or u quarks.

implying that the mass eigenstates have mass and width differences of opposite signs. This means that, like in the K^0–$\overline{K}^0$ system, the heavy state is expected to have a smaller decay width than that of the light state: $\Gamma_\mathrm{H} < \Gamma_\mathrm{L}$. Hence, $\Delta\Gamma_q = \Gamma_\mathrm{L} - \Gamma_\mathrm{H}$ is expected to be positive in the Standard Model.

Furthermore, the quantity

$$\left|\frac{\Gamma_{12}}{M_{12}}\right| \simeq \frac{3\pi}{2}\,\frac{m_b^2}{m_W^2}\,\frac{1}{S_0(m_t^2/m_W^2)} \sim \mathcal{O}\left(\frac{m_b^2}{m_t^2}\right) \tag{74.9}$$

is small, and a power expansion of $|q/p|^2$ yields

$$\left|\frac{q}{p}\right|^2 = 1 + \left|\frac{\Gamma_{12}}{M_{12}}\right| \sin(\phi_M - \phi_\Gamma) + \mathcal{O}\left(\left|\frac{\Gamma_{12}}{M_{12}}\right|^2\right). \tag{74.10}$$

Therefore, considering both Eqs. (74.8) and (74.9), the CP-violating parameter

$$1 - \left|\frac{q}{p}\right|^2 \simeq \mathrm{Im}\left(\frac{\Gamma_{12}}{M_{12}}\right) \tag{74.11}$$

is expected to be very small: $\sim \mathcal{O}(10^{-3})$ for the B_d^0–$\overline{B}_d^0$ system and $\lesssim \mathcal{O}(10^{-4})$ for the B_s^0–$\overline{B}_s^0$ system [6].

In the approximation of negligible CP violation in mixing, the ratio $\Delta\Gamma_q/\Delta m_q$ is equal to the small quantity $|\Gamma_{12}/M_{12}|$ of Eq. (74.9); it is hence independent of CKM matrix elements, *i.e.*, the same for the B_d^0–$\overline{B}_d^0$ and B_s^0–$\overline{B}_s^0$ systems. Calculations [7] yield $\sim 5 \times 10^{-3}$ with a $\sim 15\%$ uncertainty. Given the published experimental knowledge [8] on the mixing parameter x_q

$$\begin{cases} x_d = 0.7659 \pm 0.0032 & (B_d^0\text{–}\overline{B}_d^0 \text{ system}) \\ x_s = 26.91 \pm 0.11 & (B_s^0\text{–}\overline{B}_s^0 \text{ system}) \end{cases}, \tag{74.12}$$

the Standard Model thus predicts that $\Delta\Gamma_d/\Gamma_d$ is very small (below 1%), but $\Delta\Gamma_s/\Gamma_s$ considerably larger ($\sim 10\%$). These width differences are caused by the existence of final states to which both the B_q^0 and $\overline{B}_q^0$ mesons can decay. Such decays involve $b \to c\bar{c}q$ quark-level transitions, which are Cabibbo-suppressed if $q = d$ and Cabibbo-allowed if $q = s$.

Complete sets of Standard Model predictions for all mixing parameters in both the B_d^0–$\overline{B}_d^0$ and B_s^0–$\overline{B}_s^0$ systems can be found in Refs. [7, 9].

74.2 Experimental issues and methods for oscillation analyses

Time-integrated measurements of B^0–$\overline{B}^0$ mixing were published for the first time in 1987 by UA1 [10] and ARGUS [11], and since then by other experiments. These measurements are typically based on counting same-sign and opposite-sign lepton pairs from the semileptonic decay of the produced $b\bar{b}$ pairs. Such analyses cannot easily separate the contributions from the different b-hadron species, therefore, the clean environment of $\Upsilon(4S)$ machines (where only B^0_d and charged B_u mesons are produced) is in principle best suited to measure χ_d.

However, better sensitivity is obtained from time-dependent analyses aiming at the direct measurement of the oscillation frequencies Δm_d and Δm_s, from the proper time distributions of B^0_d or B^0_s candidates identified through their decay in (mostly) flavor-specific modes, and suitably tagged as mixed or unmixed. This is particularly true for the B^0_s–$\overline{B}^0_s$ system, where the large value of x_s implies maximal mixing, *i.e.*, $\chi_s \simeq 1/2$. In such analyses, the B^0_d or B^0_s mesons are either fully reconstructed, partially reconstructed from a charm meson, selected from a lepton with the characteristics of a $b \to \ell^-$ decay, or selected from a reconstructed displaced vertex. At high-energy colliders (LEP, SLC, Tevatron, LHC), the proper time $t = \frac{m_B}{p} L$ is measured from the distance L between the production vertex and the B decay vertex, and from an estimate of the B momentum p. At asymmetric B factories (PEP-II, KEKB, SuperKEKB), producing $e^+e^- \to \Upsilon(4S) \to B^0_d\,\overline{B_d}{}^0$ events with a boost $\beta\gamma$ (= 0.55, 0.425, 0.28), the proper time difference between the two B candidates is estimated as $\Delta t \simeq \frac{\Delta z}{\beta\gamma c}$, where Δz is the spatial separation between the two B decay vertices along the boost direction. In all cases, the good resolution needed on the vertex positions is obtained with silicon detectors.

The average statistical significance $\mathcal{S}$ of a B^0_q oscillation signal can be approximated as [12]

$$\mathcal{S} \approx \sqrt{N/2}\, f_{\rm sig}\,(1-2\eta)\, e^{-(\Delta m_q\, \sigma_t)^2/2}\,, \qquad (74.13)$$

where N is the number of selected and tagged candidates, $f_{\rm sig}$ is the fraction of signal in that sample, η is the total mistag probability, and σ_t is the resolution on proper time (or proper time difference). The quantity $\mathcal{S}$ decreases very quickly as Δm_q increases; this dependence is controlled by σ_t, which is therefore a critical parameter for Δm_s analyses. At high-energy colliders, the proper time resolution $\sigma_t \sim \frac{m_B}{\langle p\rangle}\sigma_L \oplus t\frac{\sigma_p}{p}$ includes a constant contribution due to the decay length resolution σ_L (typically 0.04–0.3 ps), and a term due to the relative momentum resolution σ_p/p (typically 10–20% for partially reconstructed decays), which increases with proper time. At B factories, the boost of the B mesons is estimated from the known beam energies, and the term due to the spatial resolution dominates (typically 0.7–1.5 ps because of the much smaller B boost).

In order to tag a B^0_q candidate as mixed or unmixed, it is necessary to determine its flavor both in the initial state and in the final state. The initial and final state mistag probabilities, η_i and η_f, degrade $\mathcal{S}$ by a total factor $(1-2\eta) = (1-2\eta_i)(1-2\eta_f)$. In lepton-based analyses, the final state is tagged by the charge of the lepton from $b \to \ell^-$ decays; the largest contribution to η_f is then due to $\overline{b} \to \overline{c} \to \ell^-$ decays. Alternatively, the charge of a reconstructed charm meson (D^{*-} from B^0_d or D^-_s from B^0_s), or that of a kaon hypothesized to come from a $b \to c \to s$ decay [13], can be used. For fully-inclusive analyses based on topological vertexing, final-state tagging techniques include jet-charge [14] and charge-dipole [15, 16] methods. At high-energy colliders, the methods to tag the initial state (*i.e.*, the state at production), can be divided into two groups: the ones that tag the initial charge of the $\overline{b}$ quark contained in the B^0_q candidate itself (same-side tag), and the ones that tag the initial charge of the other b quark produced in the event (opposite-side tag). On the same side, the sign of a charged pion, kaon or proton from the primary vertex is correlated with the production state of the B^0_q meson if that particle is a decay product of a B^{**} state or the first in the fragmentation chain [17, 18]. Jet- and vertex-charge techniques work on both sides and on the opposite side, respectively. Finally, the charge of a lepton from $b \to \ell^-$, of a kaon from $b \to c \to s$ or of a charm hadron from $b \to c$ [19] can be used as an opposite-side tag, keeping in mind that its performance is degraded due to integrated mixing. At SLC, the beam polarization produced a sizeable forward-backward asymmetry in the $Z \to b\bar{b}$ decays, and provided another very interesting and effective initial state tag based on the polar angle of the B^0_q candidate [15]. Initial state tags have also been combined to reach $\eta_i \sim 26\%$ at LEP [18, 20] or 22% at SLD [15] with full efficiency. In the case $\eta_f = 0$, this corresponds to an effective tagging efficiency $Q = \epsilon D^2 = \epsilon(1-2\eta)^2$, where ϵ is the tagging efficiency, in the range $23 - 31\%$. The equivalent figure achieved by CDF during Tevatron Run I was $\sim 3.5\%$ (see tagging summary on page 160 of Ref. [21]), reflecting the fact that tagging is more difficult at hadron colliders. The CDF and DØ analyses of Tevatron Run II data reached $\epsilon D^2 = (1.8 \pm 0.1)\%$ [22] and $(2.5 \pm 0.2)\%$ [23] for opposite-side tagging, while same-side kaon tagging (for B^0_s analyses) contributed an additional $3.7-4.8\%$ at CDF [22], and pushed the combined performance to $(4.7 \pm 0.5)\%$ at DØ [24]. LHCb, operating in the forward region at the LHC where the environment is different in terms of track multiplicity and b-hadron production kinematics, has reported $\epsilon D^2 = (2.10 \pm 0.25)\%$ [25] for opposite-side tagging, $(1.80 \pm 0.26)\%$ [26] for same-side kaon tagging, and $(2.11 \pm 0.11)\%$ [27] for same-side pion and proton tagging: the combined figure ranges typically between $(3.73 \pm 0.15)\%$ [28] and $(6.3 \pm 0.5)\%$ [29] depending on the mode in which the tagged B^0_s meson is reconstructed, and reaches up to $(8.1 \pm 0.6)\%$ [30] for hadronic B^0_d modes. ATLAS [31] and CMS [32] have reported $\epsilon D^2 \sim 1.75\%$ and $\epsilon D^2 \sim 5.6\%$, respectively, using opposite-side tagging of $B^0_s \to J/\psi\phi$ decays.

At B factories, the flavor of a B^0_d meson at production cannot be determined, since the two neutral B mesons produced in a $\Upsilon(4S)$ decay evolve in a coherent P-wave state where they keep opposite flavors at any time. However, as soon as one of them decays, the other follows a time-evolution given by Eqs. (74.2) or (74.3), where t is replaced with Δt (which will take negative values half of the time). Hence, the "initial state" tag of a B can be taken as the final-state tag of the other B. Effective tagging efficiencies of 30% are achieved by BaBar and Belle [33], using different techniques including $b \to \ell^-$ and $b \to c \to s$ tags. It is worth noting that, in this case, mixing of the other B (*i.e.*, the coherent mixing occurring before the first B decay) does not contribute to the mistag probability.

Before the experimental observation of a decay-width difference, oscillation analyses typically neglected $\Delta\Gamma_q$ in Eq. (74.4), and described the time dependence with the functions $\Gamma_q e^{-\Gamma_q t}(1 \pm \cos(\Delta m_q t))/2$ (high-energy colliders) or $\Gamma_d e^{-\Gamma_d|\Delta t|}(1 \pm \cos(\Delta m_d \Delta t))/4$ (asymmetric $\Upsilon(4S)$ machines). As can be seen from Eq. (74.4), a non-zero value of $\Delta\Gamma_q$ would effectively reduce the oscillation amplitude with a small time-dependent factor that would be very difficult to distinguish from time resolution effects. Measurements of Δm_q are usually extracted from the data using a maximum likelihood fit.

74.3 Δm_d and $\Delta\Gamma_d$ measurements

Many B^0_d–$\overline{B}^0_d$ oscillation analyses have been published [34] by the ALEPH [35], DELPHI [16, 36], L3 [37], OPAL [38, 39], CDF [17], DØ [23], BaBar [40], Belle [41], Belle II [42], and LHCb [43–46] collaborations. Although a variety of different techniques have been used, the individual Δm_d results obtained at LEP and Tevatron have remarkably similar precision. Their average is compatible with the more precise measurements at the asymmetric B factories and the LHC. The systematic uncertainties are not negligible; they are often dominated by sample composition, mistag probability, or b-hadron lifetime contributions. Before being combined, the measurements are adjusted on the basis of a common set of input values, including the b-hadron lifetimes and fractions published in this *Review*. Some measurements are statistically correlated. Systematic correlations arise both from common physics sources (fragmentation fractions, lifetimes, branching ratios of b hadrons), and from purely experimental or algorithmic effects (efficiency, resolu-

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com

tion, tagging, background description). Combining all measurements [16, 17, 23, 35–46] and accounting for all identified correlations yields $\Delta m_d = 0.5068 \pm 0.0016(\text{stat}) \pm 0.0011(\text{syst})$ ps^{-1} [8], a result dominated by the latest LHCb measurement with $B^0 \to D^{(*)-}\mu^+\nu_\mu X$ decays [46].

The decay-width difference can be determined from the B^0 effective lifetimes [47, 48]

$$\tau_d^{\text{eff}} = \frac{1 + 2\mathcal{A}_{\Delta\Gamma}\, y_d + y_d^2}{\Gamma_d(1 - y_d^2)(1 + \mathcal{A}_{\Delta\Gamma}\, y_d)}\,, \tag{74.14}$$

where $\mathcal{A}_{\Delta\Gamma} = 0$ for a flavor-specific final state and $\mathcal{A}_{\Delta\Gamma} \simeq \eta_{CP}\cos(2\beta)$ for a CP eigenstate with eigenvalue η_{CP}. A fit to all available effective B^0 lifetime measurements using flavor-specific final states or the CP-odd $J/\psi K^0_S$ final state, as well as the dedicated measurements of $\Delta\Gamma_d/\Gamma_d$ by BaBar [49], Belle [50], LHCb [51], ATLAS [52] and CMS [53], using the external constraint $\beta \equiv \arg(-V_{cd}V_{cb}^*/(V_{td}V_{tb}^*)) = 22.63 \pm 0.45$ degrees [8], allows the simultaneous determination [8] of

$$\Delta\Gamma_d/\Gamma_d = +0.005 \pm 0.010 \quad \text{and} \quad 1/\Gamma_d = 1.5113 \pm 0.0027 \text{ ps}\,. \tag{74.15}$$

These results are compatible both with $\Delta\Gamma_d = 0$ and with the Standard Model prediction for $\Delta\Gamma_d$ of 0.00215 ± 0.00013 ps^{-1} [9].

The time-integrated mixing measurements published by ARGUS and CLEO [54–56] average to $\chi_d = 0.182 \pm 0.015$. Assuming no CP violation in mixing, the Δm_d, $1/\Gamma_d$, $\Delta\Gamma_d/\Gamma_d$ and χ_d results can be combined to yield the world average

$$\Delta m_d = 0.5068 \pm 0.0019 \text{ ps}^{-1} \tag{74.16}$$

or, equivalently,

$$\chi_d = 0.1849 \pm 0.0010\,. \tag{74.17}$$

This Δm_d value provides an estimate of $2|M_{12}|$, and can be used with Eq. (74.6) to extract $|V_{td}|$ within the Standard Model [57]. The main experimental uncertainties on the result come from m_t and Δm_d, but are still completely negligible with respect to the uncertainty due to the hadronic matrix element $f_{B_d}\sqrt{B_{B_d}} = 225 \pm 9$ MeV [58] obtained from three-flavor lattice QCD calculations.

74.4 Δm_s and $\Delta\Gamma_s$ measurements

After many years of intense search at LEP and SLC, B^0_s–$\overline{B}^0_s$ oscillations were first observed in 2006 by CDF using 1 fb^{-1} of Tevatron Run II data [22]. LHCb then observed B^0_s–$\overline{B}^0_s$ oscillations independently with $B^0_s \to D^-_s\pi^+$ [43, 59], $B^0_s \to D^-_s\mu^+\nu X$ [45] and $B^0_s \to J/\psi K^+K^-$ [28] decays using up to 3 fb^{-1} of LHC Run 1 data. More recent measurements based on LHC Run 2 data have been published by CMS with $B^0_s \to J/\psi\phi$ decays [32], and by LHCb with $B^0_s \to D^-_s\pi^+\pi^-\pi^+$ [60], $B^0_s \to D^-_s\pi^+$ [61] and $B^0_s \to J/\psi K^+K^-$ [62] decays. Taking systematic correlations into account, the average [8] of all published measurements of Δm_s [22, 28, 32, 43, 45, 59–62] is

$$\Delta m_s = 17.766 \pm 0.004(\text{stat}) \pm 0.004(\text{syst}) \text{ ps}^{-1}\,, \tag{74.18}$$

with an impressive precision dominated by the recent $B^0_s \to D^-_s\pi^+$ result [61] of Fig. 74.2.

The information on $|V_{ts}|$ obtained in the framework of the Standard Model is hampered by the hadronic uncertainty, as in the B^0_d case. However, several uncertainties cancel in the frequency ratio

$$\frac{\Delta m_s}{\Delta m_d} = \frac{m_{B_s}}{m_{B_d}}\,\xi^2\left|\frac{V_{ts}}{V_{td}}\right|^2\,, \tag{74.19}$$

where the SU(3) flavor-symmetry breaking factor $\xi = (f_{B_s}\sqrt{B_{B_s}})/(f_{B_d}\sqrt{B_{B_d}})$ is obtained as 1.206 ± 0.017 from a combination of three-flavor lattice QCD calculations [58] dominated by the results of Ref. [63], or as $1.2014^{+0.0065}_{-0.0072}$ from QCD sum rules [64]. Using the measurements of Eqs. (74.16) and (74.18), one can extract

$$\left|\frac{V_{td}}{V_{ts}}\right| = \begin{cases} 0.2054 \pm 0.0004 \pm 0.0029\,(\text{lattice QCD}) \\ 0.2045 \pm 0.0004^{+0.0011}_{-0.0012}\,(\text{QCD sum rules}) \end{cases}\,, \tag{74.20}$$

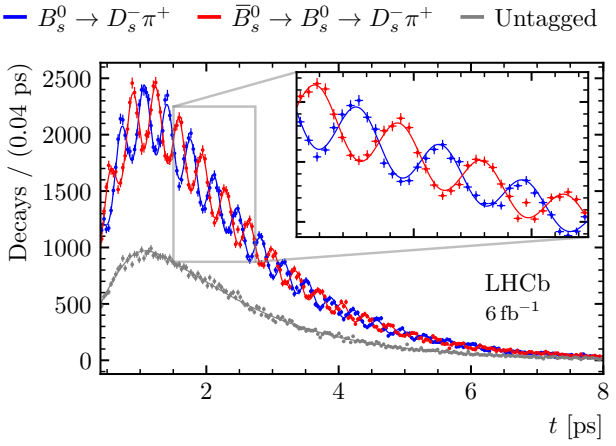

Figure 74.2: Proper decay-time distributions of background-subtracted $B^0_s \to D^-_s\pi^+$ decays tagged as unmixed (blue), tagged as mixed (red) or untagged (grey) in the Run 2 data of the LHCb experiment, displaying B^0_s–$\overline{B}^0_s$ oscillations [61].

in good agreement with (but much more precise than) the value obtained from the ratio of the $b \to d\gamma$ and $b \to s\gamma$ transition rates observed at the B factories [57].

The CKM matrix can be constrained using experimental results on observables such as Δm_d, Δm_s, $|V_{ub}/V_{cb}|$, ϵ_K, and $\sin(2\beta)$ together with theoretical inputs and unitarity conditions [57, 65, 66]. The constraint from our knowledge on the ratio $\Delta m_s/\Delta m_d$ is more effective in limiting the position of the apex of the CKM unitarity triangle than the one obtained from the Δm_d measurements alone, due to the reduced hadronic uncertainty in Eq. (74.19). We also note that the experimental value of Δm_s from Eq. (74.18) is consistent with the Standard Model predictions obtained from CKM fits where no experimental information on Δm_s is used, *e.g.*, 17.26 ± 0.58 ps^{-1} [65] or $17.05^{+0.75}_{-0.44}$ ps^{-1} [66]. It is also consistent with the prediction 18.23 ± 0.62 ps^{-1} from Ref. [7].

Information on $\Delta\Gamma_s$ can be obtained from the study of the proper time distribution of untagged B^0_s samples [47]. In the case of an inclusive B^0_s selection [67], or a flavor-specific (semileptonic or hadronic) B^0_s decay selection [20, 68–70], both the short- and long-lived components are present, and the proper decay-time distribution is a superposition of two exponentials with decay constants $\Gamma_{\text{L,H}} = \Gamma_s \pm \Delta\Gamma_s/2$. In principle, this provides sensitivity to both Γ_s and $(\Delta\Gamma_s/\Gamma_s)^2$. Ignoring $\Delta\Gamma_s$ and fitting for a single exponential leads to an estimate of $1/\Gamma_s$ (called effective lifetime) with a relative bias proportional to $(\Delta\Gamma_s/\Gamma_s)^2$. An alternative approach, sensitive to first order in $\Delta\Gamma_s/\Gamma_s$, is to determine the effective lifetime of untagged B^0_s decays to pure CP eigenstates; measurements exist for $B^0_s \to D^+_s D^-_s$ [69], $B^0_s \to K^+K^-$ [70, 71], $B^0_s \to J/\psi\eta$ [72, 73], $B^0_s \to J/\psi f_0(980)$ [74], $B^0_s \to J/\psi\pi^+\pi^-$ [53, 75, 76], $B^0_s \to J/\psi K^0_S$ [77], and $B^0_s \to \mu^+\mu^-$ [78]. The extraction of $1/\Gamma_s$ and $\Delta\Gamma_s$ from such measurements, discussed in detail in Ref. [48], requires additional information in the form of theoretical assumptions or external inputs on weak phases and hadronic parameters. In what follows, we only use the effective lifetimes of decays to CP-even ($D^+_s D^-_s$, $J/\psi\eta$) and CP-odd ($J/\psi f_0(980)$, $J/\psi\pi^+\pi^-$) final states where CP conservation can be assumed. In addition $\Delta\Gamma_s$ can be extracted from the decay-time distributions of B^0_s decays to CP-even and CP-odd final states, as has been done by LHCb with $B^0_s \to J/\psi\eta'$ and $B^0_s \to J/\psi\pi^+\pi^-$, respectively [79].

The best sensitivity to $1/\Gamma_s$ and $\Delta\Gamma_s$ is achieved by the time-dependent measurements of the $B^0_s \to J/\psi K^+K^-$ (including $B^0_s \to J/\psi\phi$) and $B^0_s \to \psi(2S)\phi$ decay rates performed at CDF [80], DØ [81], ATLAS [31, 82], CMS [32, 83] and LHCb [28, 62, 84–86], where the CP-even and CP-odd amplitudes are separated statistically through a full angular analysis (see Fig. 74.3). The LHCb collaboration analyzed the $B^0_s \to J/\psi K^+K^-$ decay considering that the K^+K^- system can be in a P-wave or S-wave state, and measured the dependence of

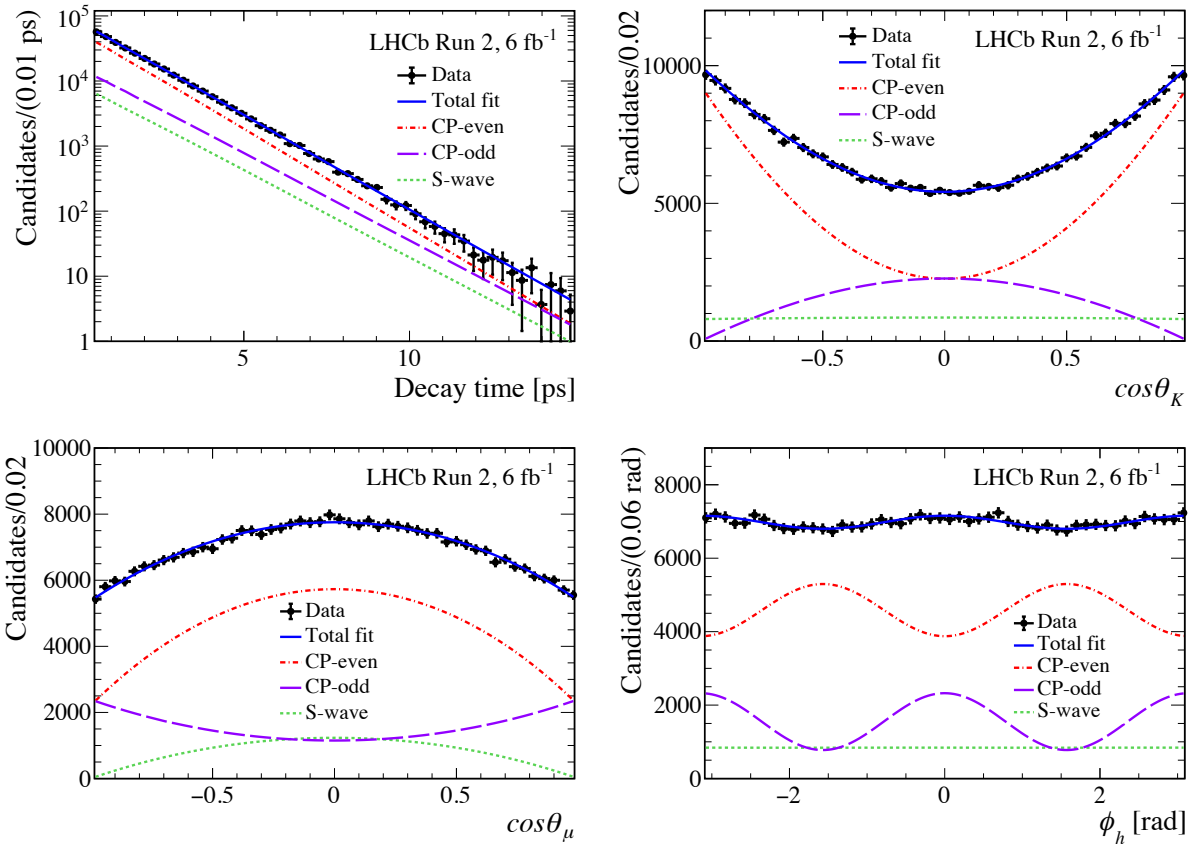

Figure 74.3: Distributions of the proper decay-time and of the three decay angles of background-subtracted $B_s^0 \to J/\psi K^+K^-$ decays reconstructed by LHCb in the vicinity of the ϕ resonance [62]. The kaon pair is predominantly in a P-wave state (from the ϕ decay) which can be CP-even or CP-odd, while a small S-wave state is CP-odd. The curves show the projections of a four-dimensional fit allowing the various components to be disentangled. The different lifetimes of the CP-even and CP-odd components are evident from the decay-time distribution.

the strong phase difference between the P-wave and S-wave amplitudes as a function of the K^+K^- invariant mass [28, 62, 87]; this allows the unambiguous determination of the sign of $\Delta\Gamma_s$, which is found to be positive. All these studies use both untagged and tagged B_s^0 candidates and are optimized for the measurement of the phase $\phi_s^{c\bar{c}s}$ that describes CP violation in the interference between B_s^0–$\overline{B}_s^0$ mixing and decay in $b \to c\bar{c}s$ transitions. The published $B_s^0 \to J/\psi K^+K^-$, $J/\psi\phi$ and $\psi(2S)\phi$ analyses [28, 31, 32, 62, 80–86] are combined in a multi-dimensional fit including all measured parameters and their correlations. To account for a tension in the time and angular parameters, scale factors are applied on the combined uncertainty of each parameter where a discrepancy arise. For example, the scale factors on the uncertainties of $\Delta\Gamma_s$, Γ_s and $\phi_s^{c\bar{c}s}$ are 1.65, 2.41 and 1.00, respectively. The averages are then further refined by applying constraints from the published lifetime measurements with flavor-specific [20, 68–70] and pure CP [53, 69, 72–76, 79] final states, to yield [8]

$$\Delta\Gamma_s = +0.0783 \pm 0.0035 \text{ ps}^{-1} \quad \text{and} \quad 1/\Gamma_s = 1.515 \pm 0.006 \text{ ps}\,, \tag{74.21}$$

or, equivalently,

$$1/\Gamma_{\rm sL} = 1.430 \pm 0.006 \text{ ps} \quad \text{and} \quad 1/\Gamma_{\rm sH} = 1.611 \pm 0.008 \text{ ps}\,, \tag{74.22}$$

in good agreement with the Standard Model predictions $\Delta\Gamma_s^{\rm SM} = +0.091 \pm 0.015$ ps^{-1} [7] and $\Delta\Gamma_s^{\rm SM} = +0.078 \pm 0.015$ ps^{-1} [9]. Estimates of $\Delta\Gamma_s/\Gamma_s$ obtained from measurements of the $B_s^0 \to D_s^{(*)+}D_s^{(*)-}$ branching fractions are not included in the average, since they are based on the questionable [88] assumption that these decays account for all CP-even final states.

From Eqs. (74.5), (74.18) and (74.21), one gets

$$\chi_s = 0.499313 \pm 0.000006\,. \tag{74.23}$$

74.5 *CP*-violation studies

Evidence for CP violation in B_q^0–$\overline{B}_q^0$ mixing has been searched for, both with flavor-specific and inclusive B_q^0 decays, in samples where the initial flavor state is tagged, usually with a lepton from the other b-hadron in the event. In the case of semileptonic (or other flavor-specific) decays, where the final-state tag is also available, the following asymmetry [2]

$$\mathcal{A}_{\rm SL}^q = \frac{N(\overline{B}_q^0(t) \to \ell^+\nu_\ell X) - N(B_q^0(t) \to \ell^-\overline{\nu}_\ell X)}{N(\overline{B}_q^0(t) \to \ell^+\nu_\ell X) + N(B_q^0(t) \to \ell^-\overline{\nu}_\ell X)} \simeq 1 - |q/p|_q^2 \tag{74.24}$$

has been measured either in time-integrated analyses at CLEO [56, 89], BaBar [90], CDF [91], DØ [92–94] and LHCb [95], or in time-dependent analyses at LEP [39, 96], BaBar [49, 97] and Belle [98]. In the inclusive case, also investigated at LEP [96, 99], no final-state tag is used, and the asymmetry [100]

$$\frac{N(\overline{B}_q^0(t) \to \text{all}) - N(B_q^0(t) \to \text{all})}{N(\overline{B}_q^0(t) \to \text{all}) + N(B_q^0(t) \to \text{all})} \simeq \mathcal{A}_{\rm SL}^q \left[\sin^2\left(\frac{\Delta m_q\, t}{2}\right) - \frac{x_q}{2}\sin(\Delta m_q\, t)\right] \tag{74.25}$$

must be measured as a function of the proper time to extract information on CP violation. In addition LHCb has studied the time dependence of the charge asymmetry of $B^0 \to D^{(*)-}\mu^+\nu_\mu X$ decays without tagging the initial state [101], which would be

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

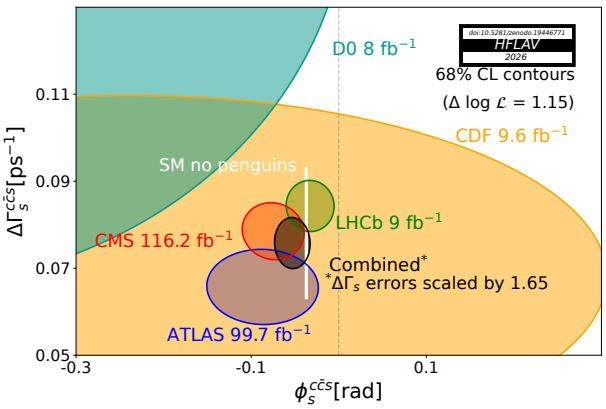

Figure 74.4: 68% CL contours in the $(\phi_s^{c\bar{c}s}, \Delta\Gamma_s)$ plane, showing all measurements from CDF [80], DØ [81], ATLAS [31, 82], CMS [32, 83] and LHCb [28, 62, 76, 84–86, 102–104] using B_s^0 decays governed by the $b \to c\bar{c}s$ transition. Their average [8] is represented as the black ellipse, where the combined uncertainty on $\Delta\Gamma_s$ has been multiplied by 1.65. The very thin white rectangle represents the Standard Model predictions of $-2\beta_s$ [65, 66] and $\Delta\Gamma_s$ [9].

equal to

$$\frac{N(D^{(*)-}\mu^+\nu_\mu X) - N(D^{(*)+}\mu^-\bar{\nu}_\mu X)}{N(D^{(*)-}\mu^+\nu_\mu X) + N(D^{(*)+}\mu^-\bar{\nu}_\mu X)} = \mathcal{A}_{\rm SL}^d \frac{1-\cos(\Delta m_d\, t)}{2} \tag{74.26}$$

in absence of detection and production asymmetries.

The DØ collaboration measured a like-sign dimuon charge asymmetry in semileptonic b decays that deviates by $2.8\,\sigma$ from the tiny Standard Model prediction and concluded, from a more refined analysis in bins of muon impact parameters, that the overall discrepancy is at the level of $3.6\,\sigma$ [92]. In all other cases, asymmetries compatible with zero have been found, with a precision limited by the available statistics. Several of the analyses at high energy don't disentangle the B_d^0 and B_s^0 contributions, and either quote a mean asymmetry or a measurement of $\mathcal{A}_{\rm SL}^d$ assuming $\mathcal{A}_{\rm SL}^s = 0$: we do not include these in the average. An exception is the dimuon DØ analysis [92], which separates the two contributions by exploiting their dependence on the muon impact parameter cut. The resulting measurements of $\mathcal{A}_{\rm SL}^d$ and $\mathcal{A}_{\rm SL}^s$ are then both compatible with the Standard Model. They are also correlated. We therefore perform a two-dimensional average of the measurements of Refs. [49, 56, 89, 90, 92–95, 97, 98, 101] and obtain [8]

$$\mathcal{A}_{\rm SL}^d = -0.0021 \pm 0.0017 \Leftrightarrow |q/p|_d = 1.0010 \pm 0.0008\,, \tag{74.27}$$
$$\mathcal{A}_{\rm SL}^s = -0.0006 \pm 0.0028 \Leftrightarrow |q/p|_s = 1.0003 \pm 0.0014\,, \tag{74.28}$$

with a correlation coefficient of -0.054 between $\mathcal{A}_{\rm SL}^d$ and $\mathcal{A}_{\rm SL}^s$. These results show no evidence of CP violation and are compatible with the very small Standard Model predictions, $\mathcal{A}_{\rm SL}^{d,\rm SM} = -(5.19 \pm 0.30) \times 10^{-4}$ and $\mathcal{A}_{\rm SL}^{s,\rm SM} = +(2.27 \pm 0.13) \times 10^{-5}$ [9], but have insufficient precision yet to constrain the Standard Model.

CP violation induced by B_s^0–$\overline{B}_s^0$ mixing in $b \to c\bar{c}s$ decays is controlled by the small weak phase $\phi_s^{c\bar{c}s}$. Measuring $\phi_s^{c\bar{c}s}$ requires tagging the initial flavor of the decaying B_s^0 meson. In addition to the previously mentioned $B_s^0 \to J/\psi K^+K^-$ (including $B_s^0 \to J/\psi\phi$) and $B_s^0 \to \psi(2S)\phi$ studies, the decay modes $B_s^0 \to J/\psi\pi^+\pi^-$ (including $B_s^0 \to J/\psi f_0(980)$) [76, 104] and $B_s^0 \to D_s^+ D_s^-$ [102, 103] have also been analyzed by LHCb to measure $\phi_s^{c\bar{c}s}$, without the need for an angular analysis. The $J/\psi\pi^+\pi^-$ final state has been shown indeed to be (very close to) a pure CP-odd state [105]. In the $B_s^0 \to J/\psi\phi$ and $B_s^0 \to J/\psi K^+K^-$ analyses, $\phi_s^{c\bar{c}s}$ is obtained together with several other observables, including $\Delta\Gamma_s$, Γ_s, the longitudinal and perpendicular ϕ polarisation amplitudes, the S-wave amplitude, and strong phases. In order to account for all correlations, the full sets of measurements provided by the different analyses are combined in a multi-dimensional fit [8] of which $\phi_s^{c\bar{c}s}$ is just one of the free parameters. As already mentioned the $B_s^0 \to J/\psi\phi$ analyses of ATLAS, CMS and LHCb show a poor overall compatibility, mostly in the lifetime and angular parameters. Therefore, scale factors are applied on the combined uncertainty of each parameter where a discrepancy arises. For the parameters already in agreement, such as $\phi_s^{c\bar{c}s}$, no scale factor is applied. The combined result based on all published analyses [28, 31, 32, 62, 76, 80–86, 102–104] is

$$\phi_s^{c\bar{c}s} = -0.053 \pm 0.013\,. \tag{74.29}$$

A two-dimensional projection of the overall situation in the $(\phi_s^{c\bar{c}s}, \Delta\Gamma_s)$ plane is shown in Fig. 74.4. The experimental determination of $\phi_s^{c\bar{c}s}$ is still statistically limited. It is consistent with the Standard Model prediction, which is equal to $-2\beta_s = -2\arg(-(V_{ts}V_{tb}^*)/(V_{cs}V_{cb}^*)) = -0.0367 \pm 0.0010$ [65] or -0.0377 ± 0.0006 [66] assuming negligible Penguin pollution.

CP violation induced by B_s^0–$\overline{B}_s^0$ mixing in $b \to s\bar{s}s$ decays is controlled by the weak phase $\phi_s^{s\bar{s}s}$, which is an observable different from $\phi_s^{c\bar{c}s}$. In the Standard Model, such pure gluonic Penguin decays have an amplitude with a CKM phase that cancels that of the mixing amplitude, and hence $\phi_s^{s\bar{s}s}$ is expected to be essentially zero. LHCb has performed a flavor-tagged time-dependent angular analysis of $B_s^0 \to \phi\phi$ decays [29, 106], similar to that of $B_s^0 \to J/\psi\phi$ decays, and measured

$$\phi_s^{s\bar{s}s} = -0.074 \pm 0.069\,, \tag{74.30}$$

in agreement with the Standard Model prediction.

74.6 Summary

B^0–$\overline{B}^0$ mixing has been and still is a field of intense study. The mass differences in the B_d^0–$\overline{B}_d^0$ and B_s^0–$\overline{B}_s^0$ systems are known to relative precisions of 0.37% and 0.03%, respectively. The non-zero decay-width difference in the B_s^0–$\overline{B}_s^0$ system is well established, with a relative difference of $\Delta\Gamma_s/\Gamma_s = (11.8 \pm 0.6)\%$, meaning that the heavy state of the B_s^0–$\overline{B}_s^0$ system lives $\sim 13\%$ longer than the light state. In contrast, the relative decay-width difference in the B_d^0–$\overline{B}_d^0$ system, $\Delta\Gamma_d/\Gamma_d = (0.5 \pm 1.0)\%$, is still consistent with zero. CP violation in B_d^0–$\overline{B}_d^0$ or B_s^0–$\overline{B}_s^0$ mixing has not been observed yet, with precisions on the semileptonic asymmetries below 0.3%. CP violation induced by B_s^0–$\overline{B}_s^0$ mixing in B_s^0 decays has not yet been observed either, with uncertainties on the $\phi_s^{c\bar{c}s}$ and $\phi_s^{s\bar{s}s}$ phases of 13 mrad and 69 mrad, respectively. All observations so far remain consistent with the Standard Model expectations.

However, the measurements where New Physics might show up are still statistically limited. More results are awaited from the LHC experiments and Belle II, with promising prospects for the investigation of the CP-violating phase $\arg(-M_{12}/\Gamma_{12})$ and improved determination of the $\phi_s^{c\bar{c}s}$ and $\phi_s^{s\bar{s}s}$ phases.

Mixing studies have clearly reached the stage of precision measurements, where much effort is needed, both on the experimental and theoretical sides, in particular to further reduce the hadronic uncertainties of lattice QCD calculations. In the long term, a stringent check of the consistency of the B_d^0 and B_s^0 mixing amplitudes (magnitudes and phases) with all other measured flavor-physics observables will be possible within the Standard Model, leading to very tight limits on (or otherwise a long-awaited surprise about) New Physics.

75. Semileptonic b-Hadron Decays, Determination of V_{cb}, V_{ub}

Revised March 2026 by A.X. El-Khadra (Physics, Illinois U.) and P. Urquijo (School of Phys. U. of Melbourne).

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

75.1 Introduction

Precision determinations of $|V_{ub}|$ and $|V_{cb}|$ are central to testing the CKM sector of the Standard Model, and complement the measurements of CP asymmetries in B decays. The length of the side of the unitarity triangle opposite the well-measured angle β is proportional to the ratio $|V_{ub}|/|V_{cb}|$; its precise determination is a high priority of the heavy-flavor physics program.

The transitions $b \to c\ell\bar{\nu}_\ell$ and $b \to u\ell\bar{\nu}_\ell$ ($\ell = e, \mu$) each provide two avenues for determining these CKM matrix elements, namely through measurements of inclusive decay rates, $\bar{B} \to X\ell\bar{\nu}_\ell$ with a sum over all possible hadronic states X or of exclusive rates, where the final state hadron is a specific meson ($X = D$, D^*, π, ρ etc.).

Purely leptonic decays, such as $B_c^- \to \tau\bar{\nu}$, $B^- \to \tau\bar{\nu}$, and $B^- \to \mu\bar{\nu}$, provide a third avenue that is theoretically very simple (see the RPP mini-review [1]). However, we do not use this information at present since none of the measurements have reached a competitive level of precision. Hence the results presented here are solely obtained from exclusive and inclusive semileptonic b-hadron decays. This article and the values quoted here update the previous review [2].

The theoretical methods underlying the different determinations of $|V_{qb}|$ are quite mature. The theoretical approach for inclusive determinations uses the fact that the mass m_b of the b quark is large compared to the scale $\Lambda_{\rm QCD}$ that determines low-energy hadronic physics. Thus the basis for precise calculations is a systematic expansion in powers of Λ/m_b, where $\Lambda \sim 500 - 700$ MeV is a hadronic scale of the order of $\Lambda_{\rm QCD}$. Such an expansion can be formulated in the framework of an effective field theory which is described in a separate RPP mini-review [3]. Exclusive determinations rely on non-perturbatively calculated form factors that encode the low-energy dynamics of the hadronic transition. Here, lattice QCD provides an, in principle, ab-initio method to calculate the non-perturbative QCD contributions to the exclusive decay amplitudes. Thanks to a combination of improved theoretical methods, better algorithms, and large increases in computational power, precise lattice QCD results are now available for the processes that are used in exclusive $|V_{ub}|$ and $|V_{cb}|$ determinations. State-of-the-art lattice QCD calculations are based on gauge-field ensembles that include realistic sea quark effects for degenerate up/down and strange quarks (aka $2+1$-flavor ensembles), and increasingly, also for charm (aka $2+1+1$-flavor ensembles). They employ ensembles generated at three (or more) lattice spacings, different spatial volumes, among other parameter variations to allow for quantification of the underlying systematic errors, and include detailed systematic error analyses. This is described in a separate RPP mini-review [4]. The lattice-QCD results discussed in this review are all state-of-the art with fully quantified uncertainties, and therefore play a central role in exclusive $|V_{qb}|$ determinations. In the case of exclusive $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decays, heavy quark symmetry (HQS) and heavy quark effective theory (HQET) yield constraints on the form factors that can be used to test lattice results and refined constraints on the form factors. Light-cone sum rules (LCSR) provide another nonperturbative approach to compute form factors. However, while the lattice-QCD results employed in this review have well-quantified uncertainties, LCSR results suffer, in general, from hard-to-quantify systematic errors. The two methods typically provide results in opposite regions of phase space. Lattice-QCD calculations work best at low hadronic recoil or high momentum transfer (q^2) to the leptons, while LCSR calculations provide estimates at high recoil, near $q^2 = 0$. However, the kinematic range for which lattice-QCD calculations provide information is increasing and further enhanced with the aid of model-independent parameterizations and HQE constraints. In general, we do not use form factor inputs obtained from LCSR in this review.

The measurements discussed in this review are of branching fractions, ratios of branching fractions, and decay kinematic distributions. The determinations of $|V_{cb}|$ and $|V_{ub}|$ also require a measurement of the total decay widths of the corresponding b hadrons, determined from lifetimes, which is the subject of a separate RPP mini-review [5]. The measurements of inclusive semileptonic decays relevant to this review come primarily from e^+e^- B factories operating at the $\Upsilon(4S)$ resonance, while the measurements of exclusive semileptonic decays come from both the e^+e^- B factories and from the LHCb experiment at CERN.

Semileptonic B-meson decay amplitudes to electrons and muons are well measured and consistent with Standard Model W-boson exchange. As they are expected to be insensitive to the effects of non-Standard-Model physics, they are used to extract $|V_{qb}|$. However, semileptonic decays to tau-lepton final states, such as $\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau$, may be sensitive to effects from beyond the Standard Model particles due to the large mass of the τ lepton. The currently observed tensions between Standard Model theory and experiment for these decays indicate that semitauonic decays must be studied further. For rare decays, tests of lepton-flavor universality violations (LFUV) in ratios involving μ/e final states provide CKM-free tests of the SM. These and other flavor dependent angular analyses are also included in this review.

Many of the numerical results quoted in this review have been provided by the Heavy Flavor Averaging Group (HFLAV) [6].

75.2 Determination of $|V_{cb}|$

Summary: The determination of $|V_{cb}|$ from inclusive decays has a relative uncertainty of about 1.2%; the limitations arise mainly from our ignorance of higher-order perturbative and non-perturbative corrections. Exclusive $\bar{B} \to D^*\ell\bar{\nu}_\ell$ decays provide a determination of $|V_{cb}|$ with a relative precision of about 1.6%, with comparable contributions from theory and experiment to the total uncertainty; the value determined from $\bar{B} \to D\ell\bar{\nu}_\ell$ decays is consistent and has an uncertainty of 1.8%. The values obtained from the inclusive and exclusive B decay determinations discussed below are:

$$|V_{cb}| = (42.0 \pm 0.5) \times 10^{-3} \quad \text{(inclusive)} \tag{75.1}$$

$$|V_{cb}| = (39.5 \pm 0.5) \times 10^{-3} \quad \text{(exclusive)}. \tag{75.2}$$

An average of these determinations has $p(\chi^2) < 1\%$, so we scale the error by $\sqrt{\chi^2/1} = 3.7$ to find

$$|V_{cb}| = (40.7 \pm 1.3) \times 10^{-3} \quad \text{(average)}. \tag{75.3}$$

Given the inconsistency this average should be treated with caution.

75.2.1 $|V_{cb}|$ *from exclusive decays*

Exclusive determinations of $|V_{cb}|$ make use of semileptonic B (or B_s) decays into the ground state charmed mesons D (D_s) and D^* (D_s^*). The corresponding hadronic matrix elements can be parameterized in terms of six independent form factors, which depend on the variable $w \equiv v \cdot v'$, where v and v' are the four velocities of the initial and final-state hadrons. In the rest frame of the decay this variable corresponds to the Lorentz factor of the final state $D^{(*)}$ meson. Determinations of $|V_{cb}|$ from experimental measurements of $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decay rates require precise knowledge of these form factors. Fortunately, lattice QCD results for all relevant form factors, including their recoil dependence, are now available [7–13]. Additional, new lattice-QCD results are expected to become available in the coming years [14–17].

Heavy Quark Symmetry (HQS) [18, 19] predicts that in the infinite mass limit the six form factors collapse into a single one, which is normalized at the "zero recoil point" $w = 1$, the point of maximum momentum transfer to the leptons. Heavy Quark Effective Theory (HQET) provides a framework for obtaining the corrections to the HQS prediction in a systematic expansion in powers of $\Lambda_{\rm QCD}/m_c$ which is discussed in a separate RPP mini-review [3].

75.2.2 $\bar{B} \to D^* \ell \bar{\nu}_\ell$

The decay rate for $\bar{B} \to D^* \ell \bar{\nu}_\ell$, assuming massless leptons, is given by

$$\frac{d\Gamma}{dw}(\bar{B} \to D^* \ell \bar{\nu}_\ell) = \frac{G_F^2 m_B^5}{48\pi^3} |V_{cb}|^2 |\eta_{\rm EW}|^2 (w^2-1)^{1/2} P(w) |\mathcal{F}(w)|^2, \tag{75.4}$$

where $P(w)$ is a phase space factor,

$$P(w) = r^3 (1-r)^2 (w+1)^2 \left(1 + \frac{4w}{w+1}\frac{1-2rw+r^2}{(1-r)^2}\right), \tag{75.5}$$

with $r = m_{D^*}/m_B$. The decay amplitude $\mathcal{F}(w)$ can be expressed in terms of the form factors which parametrize the vector and axial vector current matrix elements

$$\frac{\langle D^*(v',\epsilon)|\bar{c}\gamma^\mu b|B(v)\rangle}{\sqrt{m_B m_{D^*}}} = h_V(w)\, \varepsilon^{\mu\nu\rho\sigma} v_{B,\nu} v_{D^*,\rho} \epsilon^*_\sigma, \tag{75.6}$$

$$\begin{aligned}\frac{\langle D^*(v',\epsilon)|\bar{c}\gamma^\mu\gamma^5 b|B(v)\rangle}{\sqrt{m_B m_{D^*}}} &= i h_{A_1}(w)\,(1+w)\epsilon^{*\mu} \\ &\quad - i\left[h_{A_2}(w) v_B^\mu + h_{A_3}(w) v_{D^*}^\mu\right] \epsilon^* \cdot v_B\,,\end{aligned} \tag{75.7}$$

and the ratios

$$R_1(w) = \frac{h_V(w)}{h_{A_1}(w)}, \quad R_2(w) = \frac{h_{A_3}(w) + r\, h_{A_2}(w)}{h_{A_1}(w)}, \tag{75.8}$$

as

$$\begin{aligned} P(w)|\mathcal{F}(w)|^2 &= |h_{A_1}(w)|^2 \\ &\times \left\{ 2\frac{r^2-2rw+1}{(1-r)^2}\left[1 + \frac{w-1}{w+1} R_1^2(w)\right] \right. \\ &\left. + \left[1 + \frac{w-1}{1-r}(1-R_2(w))\right]^2 \right\}. \end{aligned} \tag{75.9}$$

Note that $\mathcal{F}$ at $w = 1$ is unity by HQS in the infinite-mass limit [20–23]. The effect of assuming massless leptons is typically very small, but for the muon case can be non-negligible in fits to data at high hadronic recoil.

The factor $\eta_{\rm EW} = 1.0066 \pm 0.0050$ accounts for the leading electroweak corrections to the four-fermion operator mediating the semileptonic decay [24], and includes an estimated uncertainty for missing long-distance and structure-dependent QED corrections [25]. While some QED radiative corrections are included in the experimental analysis, the Coulomb correction, which arises when the final-state hadron is charged, is not taken into account.

The determination of $|V_{cb}|$ requires knowledge of the normalization, where one commonly uses a theoretical calculation of the zero recoil input, $\mathcal{F}(1)$. Theoretical knowledge of the shapes of the form factors provides crucial compatibility checks between theory and experiment, and improves the precision of the determinations.

Model-independent shape parametrizations of the form factors make use of analyticity and unitarity constraints and are expressed in terms of the variable

$$z = \frac{\sqrt{w+1} - \sqrt{2N}}{\sqrt{w+1} + \sqrt{2N}}, \tag{75.10}$$

originating from a conformal transformation, where $N = (t_+ - t_0)/(t_+ - t_-)$, $t_\pm = (m_B \pm m_{D^*})^2$, and the choice of t_0 determines the kinematic point at which $z = 0$. The form factors (generically denoted as F) may then be written as [26–30]

$$F(z) = \frac{1}{P_F(z)\phi_F(z)} \sum_{n=0}^{\infty} a_n z^n \tag{75.11}$$

where the sum is bounded, $\sum |a_n|^2 < 1$. Furthermore, the function $P_F(z)$ takes into account the resonances in the $(\bar{c}b)$ system below the $\bar{D}B$ threshold, and the weighting functions $\phi_F(z)$ are derived from the unitarity constraint on the corresponding form factor. With the conventional choice $N = 1$, $z = 0$ when $w = 1$ and kinematic range of the decay corresponds to $0 \le z \le 0.06$. As a result, only very few terms are needed in the series in z. We refer to Eq. (75.11) as the "BGL" expansion. The Caprini-Lellouch-Neubert (CLN) parametrization [31] yields a simple form with only two fit parameters (the slope ρ and normalization $h_{A_1}(1)$), albeit at the cost of introducing model dependence and neglecting higher-order corrections in the $1/m_{c/b}$ expansion, which are relevant at the current level of precision [30,32–38]. Thus, this report focuses on analyses that employ lattice form factors at non-zero recoil, the model-independent BGL expansion. and HQET expansions through $\mathcal{O}(\alpha_s/m_{b,c}, 1/m_{b,c}^2)$. Typical fits include up to three parameters a_n in Eq. (75.11) for the different form factors.

While lattice QCD results for the form factor at the zero-recoil point, $\mathcal{F}(1)$ have been available for over a decade [25, 39], there now exist three independent lattice QCD calculations by [10], [11], and [12] of the $\bar{B} \to D^* \ell \bar{\nu}_\ell$ form factors at non-zero recoil. The three groups each employ statistically independent gauge-field ensembles and use different lattice actions for the heavy and light quarks. To obtain results in the continuum and at the physical point, all three analyses first perform chiral-continuum fits and systematic error studies on the corresponding lattice form factor data. The resulting continuum form factors are smooth functions (bands) obtained over recoil ranges which depend on the respective simulation details. For the next step, the lattice-QCD form factors are presented as synthetic data points (including the statistical and systematic correlations), to be used as inputs in BGL-expansion fits to obtain the form factors over the entire recoil range. A comparison of the resulting $|\mathcal{F}(w)|^2$ amplitudes is shown in Fig. 75.1. While the lattice results are reasonably consistent in the low-recoil region, small variations in the slopes yield the observed spread between the bands at large recoil. Indeed, the

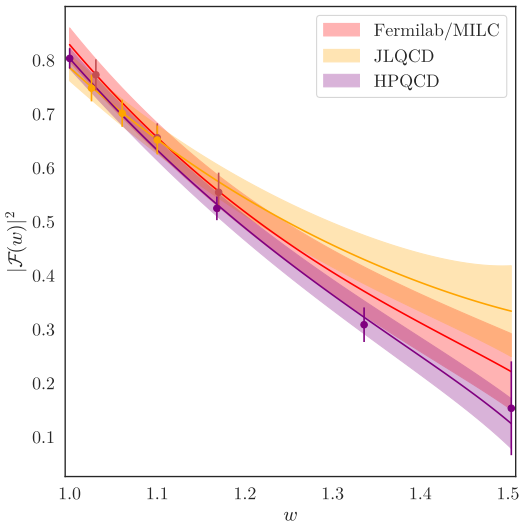

Figure 75.1: Comparison of lattice QCD results for $|\mathcal{F}(w)|^2$ obtained by the Fermilab Lattice and MILC collaborations (red), HPQCD (purple), and JLQCD (yellow). Plot courtesy of A. Vaquero.

FLAG collaboration [40] performs combined BGL fits using the form-factor results of Refs. [10,12], which both employ gauge field ensembles with three active flavors in the sea (representing light and strange quarks), with $\chi^2/\text{dof} < 1$. FLAG further finds that their BGL fits of the form factor results of Ref. [11], which employ gauge-field ensembles with four active flavors in the sea, are compatible with Refs. [10, 12].[1] Their BGL fits also yield results for the form factor at zero recoil, where they obtain $\mathcal{F}(1) = 0.894(10)$ for their three-flavor combination and $\mathcal{F}(1) = 0.899(14)$ for four-

[1] We note that as a matter of principle, the FLAG collaboration doesn't combine lattice-QCD results obtained from simulations with different numbers of sea-quark flavors.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

flavors. A weighted average yields

$$\mathcal{F}(1) = 0.896 \pm 0.008\,. \tag{75.12}$$

Non-lattice estimates based on zero-recoil sum rules for the form factor tend to yield lower central values for $\mathcal{F}(1)$ [41–43]. The sum rules indicate that $\mathcal{F}(1) < 0.92$ [41, 42, 44, 45], while an explicit estimate that includes excited state contributions yields $\mathcal{F}(1) \approx 0.86$ [43, 46]. While Light Cone Sum Rules (LCSR) can provide constraints on the form factors near maximum recoil, the underlying systematic errors are not fully quantified. A modern LCSR calculation [47] quotes uncertainties in the $\lesssim 20\%$ range for the $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ form factors at $q^2 = 0$.

Dispersive methods [48] can also be used to provide additional constraints on form factors calculated in lattice QCD. Refs. [49,50] introduce the dispersive matrix method and a lattice-QCD calculation of the susceptibilities, which are required inputs to the dispersive matrix method and also needed in z-expansion fits. The susceptibilities of Ref. [50] differ from the perturbative-QCD results of Ref. [51], in some cases outside of the quoted error bars, with a significance of up to 2.5σ, while more recent results [52,53] are more compatible with pQCD. A test of the dispersive matrix approach for the $D \to K\ell\nu$ form factors, which can be computed in lattice-QCD over the entire kinematic range, is presented in Ref. [49]. The implementation of the dispersive matrix in Ref. [54] imposes unitarity constraints on the input data via a so-called unitarity filter. The filter has the effect of altering the shapes of the form factor bands while reducing the uncertainties from extrapolating the form factors over the entire kinematic range. Subsequently, the authors of Ref. [54] determine $|V_{cb}|$ from a bin-by-bin analysis of the experimental data, which avoids the common shape constraints in joint z-expansion fits. In follow-up work, this method has also been applied to other semileptonic decay channels [55–60]. Another approach [61] employs Bayesian inference to implement unitarity constraints, which allows for a straightforward combination of inputs from multiple lattice calculations while including experimental data in joint z-expansion fits. However, the correlations between lattice form factor results at different recoil momenta (or q^2 or z values) may not be preserved in these implementations of the dispersive constraints, for which further studies would be welcome.

Many experiments [62–75] have measured the differential decay rate as a function of w, employing a variety of methods: using either B^+ or B^0 decays, with or without B-tagging, and with or without explicit reconstruction of the transition pion from $D^* \to D$ decays. The leading experimental uncertainties are due to detection efficiencies and $D^{(*)}$ decay branching fractions.

The most commonly accepted approach for the determination of $|V_{cb}|$ is to fit the available data with the BGL form-factor parameterization [27–30, 34]. The BABAR and Belle experiments have published analyses with BGL based parametrizations at a given order in the expansion [71–74]. The main results from these measurements are summarised in Table 75.1 after multiplying through the value of $\mathcal{F}(1)$ quoted in the nominal result of each respective study. These results have not yet been combined by the Heavy Flavor Averaging Group.

The Belle analysis [71] and the Belle II analysis [74] are both based on untagged approaches in the mode $\bar{B}^0 \to D^{*+}\ell\bar{\nu}_\ell$ and measure 1-d projections in bins of the hadronic recoil w, and angular variables $\cos\theta_\ell$, $\cos\theta_V$, and χ. The BABAR analysis [72] and the recent Belle analyses [73,75] are based on hadronic tagged samples using both charged and neutral B decays. BABAR performs a full 4-d unbinned analysis of neutral and charged B decay modes, while Belle [73] uses unfolded 1-d projections of w, $\cos\theta_\ell$, $\cos\theta_V$, and χ, and Belle [75] fits to normalised angular coefficients as a function of w. The latter Belle measurements are performed on the same dataset. Only the BGL form factors are directly determined in these tagged analysis, not the normalization, which is taken from the world average $\bar{B} \to D^*\ell\bar{\nu}_\ell$ branching fractions.

The studies in Refs. [71,73–75] publish the fully-differential decay rate data and associated covariance matrices. Some studies report fit results at low order in the three BGL expansion terms when non-zero lattice data is not used as an additional constraint, ranging from zero-order to second-order. Studies of the impact of higher order expansions based on the Belle untagged published decay rate data have been reported in Refs. [35,36], as well as in the recent Belle and Belle II studies [73,74], where it is shown that the fit uncertainty on $|V_{cb}|$ increases substantially with respect to the results reported at lower order, while the parameter correlations approach 1. This is due to larger number of degrees of freedom allowed in the higher order expansions, which are not sufficiently constrained without lattice-QCD inputs at nonzero recoil.

In Ref. [10], BGL expansion fits to the FNAL/MILC lattice QCD form factors show that they are insensitive to truncation effects beyond quadratic order, and similar results were obtained in Refs. [11,12] as well as for the combined lattice-QCD form factor fits performed by the FLAG collaboration [40]. While each lattice group separately performs combined lattice+experiment BGL fits to extract $|V_{cb}|$, here we quote the results of Ref. [40], which uses the same experimental inputs as HFLAV [6]. In particular, Ref. [40] quotes values for $|V_{cb}|$ from $\bar{B} \to D^*\ell\bar{\nu}_\ell$ data of $|V_{cb}| = 39.23(65) \times 10^{-3}$ for their their three-flavor combination and $|V_{cb}| = 39.44(89) \times 10^{-3}$ for the four-flavor result.

There is some spread between predictions from the three lattice-QCD form factor sets for derived quantities, such as the $R_2(w)$ ratio [77]. Similarly, while the experimental results for $R_2(w)$ in Refs. [73,74] are in tension with Refs. [10,11], the recent measurement of angular coefficients in Ref. [75] yields results for $R_2(w)$ that are compatible with Refs. [10, 12] and in mild tension with Ref. [11]. Furthermore, an analysis of the lattice form factors within the framework of the HQE [78] finds them to be well compatible with it and with each other and (with some spread) with HQE expectations for $R_2(w)$.

For this review, we take results of a combination performed by HFLAV. Firstly, the average value of the $\overline{B}^0 \to D^{*+}\ell^-\bar{\nu}_\ell$ branching fraction is determined by assuming isospin symmetry from measurements of the decays $\overline{B}^0 \to D^{*+}\ell^-\bar{\nu}_\ell$ [62–66, 68, 71, 74, 79, 80] and $\overline{B}^- \to D^{*0}\ell^-\bar{\nu}_\ell$ [66, 68, 79]. A fit is then performed on an average of the normalised unfolded $\overline{B}^0 \to D^{*+}\ell^-\bar{\nu}_\ell$ differential measurements by the Belle [73] and Belle II [74] collaborations. The untagged Belle [71] measurement was not included as unfolded spectra were not provided. Using the BGL parametrization for the form factors, the branching fraction measurement is combined with normalised differential distributions in w, $\cos\theta_\ell$, $\cos\theta_V$ and χ as well as non-zero lattice QCD input from FNAL/MILC [10], HPQCD [11], JLQCD [12] a fit for $|V_{cb}|$. The nominal result for $|V_{cb}|$ is therefore

$$|V_{cb}| = (40.0 \pm 0.7) \times 10^{-3}\ (\bar{B} \to D^*\ell\bar{\nu}_\ell,\ \mathrm{LQCD, BGL}), \tag{75.13}$$

where the uncertainty contains contributions from experimental, lattice QCD, and η_{EW} sources. We note that despite the improvements in the experimental data, theoretical inputs, and $|V_{cb}|$ extraction methods, this new exclusive determination of $|V_{cb}|$, while higher in central value compared to earlier ones, is still in tension with the inclusive determinations discussed in Section 75.2.5 and summarized in Eq. (75.27). However, we note that the new measurement of angular coefficients by the Belle collaboration [75], which is not yet included in the HFLAV average, yields a slightly higher value of $|V_{cb}| = (40.7 \pm 0.7) \times 10^{-3}$ when combined with the same lattice-QCD inputs.

75.2.3 $\bar{B} \to D\ell\bar{\nu}_\ell$

The differential rate for $\bar{B} \to D\ell\bar{\nu}_\ell$ is given by

$$\frac{d\Gamma}{dw}(\bar{B} \to D\ell\bar{\nu}_\ell) = \frac{G_F^2}{48\pi^3}|V_{cb}|^2(m_B + m_D)^2 m_D^3 (w^2-1)^{3/2}(\eta_{\mathrm{EW}}\mathcal{G}(w))^2. \tag{75.14}$$

The form factor is defined in terms of

$$\frac{\langle D(v')|\bar{c}\gamma^\mu b|B(v)\rangle}{\sqrt{m_B m_D}} = h_+(w)\,(v_B + v_D)^\mu + h_-(w)\,(v_B - v_D)^\mu \tag{75.15}$$

and reads

$$\mathcal{G}(w) = h_+(w) - \frac{m_B - m_D}{m_B + m_D} h_-(w), \tag{75.16}$$

Table 75.1: $\mathcal{F}(1)\eta_{EW}|V_{cb}|$ results from $B \to D^*\ell\nu$ with BGL expansion fits. Note that the tagged analyses combine results from B^- and $\bar{B}^0$ decays, while the untagged analyses study only $\bar{B}^0$ decays. The final column listed the non-zero recoil lattice QCD data used in each result.

Measurement	Tag	$\mathcal{F}(1)\eta_{EW}\lvert V_{cb}\rvert \times 10^3$	Fit inputs
Belle [76]	Untagged	35.22 ± 0.95	FNAL/MILC [25]
Babar [72]	Tagged	34.98 ± 0.65	
Belle [73]	Tagged	37.12 ± 0.57	FNAL/MILC [10], HPQCD [11], JLQCD [12]
Belle [75]	Tagged	36.94 ± 0.56	FNAL/MILC [10], HPQCD [11], JLQCD [12]
Belle II [74]	Untagged	37.00 ± 0.91	FNAL/MILC [10]

where $h_+(1)$ is normalized to unity due to HQS and $h_-(1)$ vanishes in the infinite-mass limit. Thus

$$\mathcal{G}(1) = 1 + \mathcal{O}\left(\left(\frac{m_B - m_D}{m_B + m_D}\right)^2 \frac{\Lambda_{\rm QCD}}{m_c}\right) \tag{75.17}$$

and the corrections to the HQS prediction are of order $\Lambda_{\rm QCD}/m_c$ in contrast to the case of $\mathcal{F}(1)$. The lattice-QCD result for the normalization $\mathcal{G}(1)$, obtained in Ref. [7] is

$$\mathcal{G}(1) = 1.054 \pm 0.004 \pm 0.008\,. \tag{75.18}$$

For the $\bar{B} \to D\ell\bar{\nu}_\ell$ modes, theoretical input on the shape of the form factor, especially near $w \sim 1$, is especially beneficial to $|V_{cb}|$ determinations, since experimental measurements of the differential decays rate near zero recoil are affected by the more severe phase space suppression, compared to the D^* case. Hence the best $|V_{cb}|$ determinations from exclusive $\bar{B} \to D\ell\bar{\nu}_\ell$ decays employ lattice-QCD form factors obtained over a range of $w \geq 1$ [7, 8]. We take the result from Ref. [6] for $|V_{cb}|$. Firstly, the average value of the $\overline{B}^0 \to D^+\ell^-\bar{\nu}_\ell$ branching fraction is determined by assuming isospin asymmetry from measurements of the decays $\overline{B}^0 \to D^+\ell^-\bar{\nu}_\ell$ [62, 81–84] and $\overline{B}^- \to D^0\ell^-\bar{\nu}_\ell$ [81–84]. Using the BGL parametrization for the form factors, the branching fraction measurement is combined with normalised w spectrum from Belle [83] in a fit for $|V_{cb}|$. Only Ref. [83] published the full measurement covariance matrix, while Ref. [82] provides the statistical uncertainty covariance. Non-zero recoil lattice QCD inputs are included in the fit following the procedure outlined in Ref. [40] to give

$$|V_{cb}| = (38.9 \pm 0.7) \times 10^{-3} \quad (\bar{B} \to D\ell\bar{\nu}_\ell,\ \text{LQCD, BGL}). \tag{75.19}$$

We note that a similar analysis by FLAG [40], obtains $|V_{cb}| = 40.0(1.0) \times 10^{-3}$ using the same lattice and similar experimental inputs.

The $|V_{cb}|$ averages from $\bar{B} \to D^*\ell\bar{\nu}_\ell$ and $\bar{B} \to D\ell\bar{\nu}_\ell$ decays (Eq. (75.13)) and (Eq. (75.19)), respectively, are consistent. The correlations between the lattice uncertainties for $\bar{B} \to D^*\ell\bar{\nu}_\ell$ and $\bar{B} \to D\ell\bar{\nu}_\ell$ form factors are discussed in Ref. [40, 85]. The statistical uncertainties for the form factors obtained by Fermilab/MILC are conservatively taken to be 100% correlated. We assume an experimental uncertainty correlation of order 20% and combine the results of Eq. (75.13) and Eq. (75.19), giving

$$|V_{cb}| = (39.5 \pm 0.5) \times 10^{-3} \quad \text{(exclusive)}. \tag{75.20}$$

75.2.4 $B_s \to D_s^{(*)-}\mu^+\nu_\mu$

Semileptonic decays of B_s mesons are being studied extensively by the LHCb experiment. On the theory side, lattice QCD calculations of the corresponding form factors can proceed using the same methods and gauge-field ensembles as for B-meson decays. In fact, the presence of a strange spectator quark in the B_s-meson decay amplitudes tends to yield smaller statistical and systematic errors in the lattice computation. Nevertheless, to-date there are still fewer lattice-QCD results for B_s-meson form factors available than for the B-meson case, but this situation is expected to change [14, 16]. For the case of the $B_s \to D_s$ transition, two lattice QCD calculations of the form factors over a range of recoil momenta have been performed by the HPQCD collaboration, the first on $2+1$-flavor gauge field ensembles (generated by the MILC collaboration) using NRQCD b-quarks [86]. The second calculation uses the $2+1+1$-flavor gauge-field ensembles (also generated by MILC), employing the HISQ action for all valence quarks [9]. The all-HISQ approach avoids the need to compute renormalization factors separately, at the cost of requiring an extrapolation to the physical b-quark mass at the lattice spacings used in Ref. [9]. For the $B_s \to D_s^{*-}$ transition, Refs. [11, 13] provide lattice QCD results for the form factors at nonzero recoils, building on previous zero-recoil results [39, 87] and Ref. [40] quotes

$$\mathcal{F}^{B_s \to D_s^*}(1) = 0.8972(92)\,. \tag{75.21}$$

LHCb has extracted $|V_{cb}|$ from semileptonic B_s^0 decays [88]. The measurement uses both $B_s^0 \to D_s^-\mu^+\nu_\mu$ and $B_s^0 \to D_s^{*-}\mu^+\nu_\mu$ decays. The value of $|V_{cb}|$ is determined from the observed yields of B_s^0 decays normalized to those of B^0 decays after correcting for the relative reconstruction and selection efficiencies. The normalization channels are $B^0 \to D^-\mu^+\nu_\mu$ and $B^0 \to D^{*-}\mu^+\nu_\mu$ decays, where the D^- is reconstructed with the same decay mode of the D_s ($D_{(s)}^- \to [K^+K^-]_\phi\pi^-$). The shape of the form factors are extracted using $p_\perp(D_s)$, which is the component of the D_s^- momentum perpendicular to the B_s^0 flight direction. This variable is correlated with q^2 and the helicity angles in the $B_s^0 \to D_s^{*-}\mu^+\nu_\mu$ decay. For the $B_s \to D_s^-\mu^+\nu_\mu$ decay, for example, $|V_{cb}|$ is related to the measured ratio of signal yields, N_{sig}, and the normalization channel yields, N_{ref}, through the relation

$$\frac{N_{\rm sig}}{N_{\rm ref}} = \xi\,\frac{f_s}{f_d}\frac{\mathcal{B}(D_s^- \to K^+K^-\pi^-)}{\mathcal{B}(D^- \to K^+K^-\pi^-)}\frac{1}{\mathcal{B}(B^0 \to D^-\mu\nu_\mu)}\,\tau_s \times \int \frac{d\Gamma(B_s \to D_s\mu\nu_\mu)}{dw}dw\,,$$

where τ_s is the B_s lifetime, and ξ is the efficiency ratio between the signal and the normalization. The analysis uses the lattice-QCD form factors obtained for $B_s \to D_s^-$ over the full kinematic range in Ref. [9] and the zero-recoil result for the $B_s \to D_s^{*-}$ form factor from Ref. [87]. Fits to both the CLN parameterization and a 5-parameter version of BGL were performed (although we will only quote the BGL results). The result for $|V_{cb}|$, updated with the most recent determination of f_s/f_d and $\mathcal{B}(D_s^- \to K^-K^+\pi^-)$ from Ref. [89], is $|V_{cb}|_{\rm BGL} = (41.7 \pm 0.8 \pm 0.9 \pm 1.1) \times 10^{-3}$, where the first uncertainty is statistical, the second systematic and the third due to the limited knowledge of the external inputs, in particular the constant $f_s/f_d \times \mathcal{B}(D_s^- \to K^+K^-\pi^-)$. The determination of $|V_{cb}|$ in Ref. [13], using the lattice form factors obtained therein combined with LHCb data yields a consistent result, $|V_{cb}| = 42.7(1.5)_{\rm latt}(1.7)_{\rm exp}(0.4)_{\rm EM} \times 10^{-3}$. The results obtained are consistent with the exclusive determinations of $|V_{cb}|$ using the B^0 and B^+ decays but are not used in the overall average in this review at this stage. These channels are important in the measurement of the ratio $|V_{ub}|/|V_{cb}|$, which cancels out the B_s normalisation uncertainties, discussed in Section 75.5. LHCb also perform measurements of the $B_s^0 \to D_s^{*-}\mu^+\nu_\mu$ differential decay rate [90]. Fits are performed to extract the form factors in CLN and BGL parametrizations.

75.2.5 $|V_{cb}|$ from inclusive decays

Measurements of the total semileptonic branching decay rate, along with moments of the lepton energy, lepton invariant mass squared, and hadronic invariant mass spectra in inclusive semileptonic $b \to c$ transitions, can be used for a precision determination

of $|V_{cb}|$. The total semileptonic decay rate can be calculated quite reliably in terms of non-perturbative parameters that can be extracted from the information contained in the moments.

75.2.6 *Inclusive semileptonic rate*

The theoretical foundation for the calculation of the total semileptonic rate is the Operator Product Expansion (OPE) which yields the Heavy Quark Expansion (HQE) [91, 92]. Details can be found in the RPP mini-review on Effective Theories [3].

The OPE result for the total rate can be written schematically (details can be found, *e.g.*, in Ref. [93]) as

$$\begin{aligned}\Gamma =&|V_{cb}|^2\frac{G_F^2 m_b^5(\mu)}{192\pi^3}|\eta_{\rm EW}|^2\times\\ &\left[z_0^{(0)}(r)+\frac{\alpha_s(\mu)}{\pi}z_0^{(1)}(r)+\left(\frac{\alpha_s(\mu)}{\pi}\right)^2 z_0^{(2)}(r)+\cdots\right.\\ &+\frac{\mu_\pi^2}{m_b^2}\left(z_2^{(0)}(r)+\frac{\alpha_s(\mu)}{\pi}z_2^{(1)}(r)+\cdots\right)\\ &+\frac{\mu_G^2}{m_b^2}\left(y_2^{(0)}(r)+\frac{\alpha_s(\mu)}{\pi}y_2^{(1)}(r)+\cdots\right)\\ &+\frac{\rho_{\rm D}^3}{m_b^3}\left(z_3^{(0)}(r)+\frac{\alpha_s(\mu)}{\pi}z_3^{(1)}(r)+\cdots\right)\\ &\left.+\frac{\rho_{\rm LS}^3}{m_b^3}\left(y_3^{(0)}(r)+\frac{\alpha_s(\mu)}{\pi}y_3^{(1)}(r)+\cdots\right)+...\right] \quad (75.22)\end{aligned}$$

where r is the ratio m_c/m_b and the y_i and z_i are perturbatively calculable Wilson coefficients functions that appear at different orders of the heavy mass expansion.

The parameters μ_π^2, μ_G^2, ρ_D^3 and ρ_{LS}^3 constitute the non-perturbative input into the heavy quark expansion; they correspond to certain matrix elements to be discussed below. In the same way the HQE can be set up for the moments of distributions of charged-lepton energy, hadronic invariant mass and hadronic energy, e.g.

$$\langle E_e^n\rangle_{E_e>E_{\rm cut}}=\int_{E_{\rm cut}}^{E_{\rm max}}\frac{d\Gamma}{dE_e}E_e^n dE_e\Big/\int_{E_{\rm cut}}^{E_{\rm max}}\frac{d\Gamma}{dE_e}dE_e\ . \quad (75.23)$$

The coefficients of the HQE are known up to order $1/m_b^5$ at tree level [94–97]. The leading term $z_0^{(i)}$ is the parton model, and is known completely through order α_s^2 [98–100] and now also at α_s^3 [101]. The terms of order $\alpha_s^{n+1}\beta_0^n$ (where β_0 is the first coefficient of the QCD β function, $\beta_0=(33-2n_f)/3$) have been included following the BLM procedure [93, 102–105]. Corrections of order $\alpha_s\mu_\pi^2/m_b^2$ have been computed in Ref. [106] and Ref. [107], while the $\alpha_s\mu_G^2/m_b^2$ terms have been calculated in Ref. [108] and Ref. [109], and the $\alpha_s\rho_D^3/m_b^3$ corrections in Refs. [110, 111].

Starting at order $1/m_b^3$ contributions with an infrared sensitivity to the charm mass, m_c, appear [94, 96, 112, 113]. At order $1/m_b^3$ this "intrinsic charm" contribution manifests as a $\log(m_c)$ in the coefficient of the Darwin term ρ_D^3. At higher orders, terms such as $1/m_b^3\times 1/m_c^2$ and $\alpha_s(m_c)1/m_b^3\times 1/m_c$ appear; numerically these terms may be comparable in size to the contributions of order $1/m_b^4$.

The HQE parameters are given in terms of forward matrix elements of local operators; the parameters entering the expansion for orders up to $1/m_b^3$ are ($D_\perp^\mu=(g_{\mu\nu}-v_\mu v_\nu)D^\nu$, where $v=p_B/M_B$ is the four-velocity of the B meson)

$$\begin{aligned}\overline{\Lambda}&=M_B-m_b\,,\\ \mu_\pi^2&=-\langle B|\bar b(iD_\perp)^2 b|B\rangle\,,\\ \mu_G^2&=\langle B|\bar b(iD_\perp^\mu)(iD_\perp^\nu)\sigma_{\mu\nu}b|B\rangle\,,\\ \rho_{\rm D}^3&=\langle B|\bar b(iD_{\perp\mu})(ivD)(iD_\perp^\mu)b|B\rangle\,,\\ \rho_{\rm LS}^3&=\langle B|\bar b(iD_\perp^\mu)(ivD)(iD_\perp^\nu)\sigma_{\mu\nu}b|B\rangle. \quad (75.24)\end{aligned}$$

These parameters still depend on the heavy quark mass. Sometimes the infinite mass limits of these parameters $\overline{\Lambda}\to\overline{\Lambda}_{\rm HQET}$, $\mu_\pi^2\to-\lambda_1$, $\mu_G^2\to 3\lambda_2$, $\rho_D^3\to\rho_1$ and $\rho_{LS}^3\to 3\rho_2$, are used instead. Beyond $1/m^3$ the number of independent HQE parameters starts to proliferate [97, 114]. In general, there are 13 parameters (at tree level) up to order $1/m^4$ and 31 (at tree level) up to order $1/m^5$, not including $\overline{\Lambda}$. A framework to compute observables at higher order in $1/m$ [97, 115] has been used to estimate the HQE parameters of the orders $1/m_b^4$ and $1/m_b^5$. Their their impact on the $|V_{cb}|$ determination has been studied in Ref. [116]. However, as pointed out in Ref. [117] one may reduce the number of independent parameters in the HQE by exploiting reparametrization invariance, which is a symmetry of the HQE stemming from Lorentz invariance of QCD. For a subset of observables this allows us to reduce the number of parameters to three up to order $1/m^3$ (ρ_{LS}^3 can be absorbed into μ_G^2 by a re-definition) and to 8 up to order $1/m^4$ [118].

The perturbative QCD expansion for the decay rate does not converge, in general. In addition, the expansion coefficients in the rates and spectra depend strongly on the scheme used for m_b (or equivalently on $\overline{\Lambda}$). It is well known (see eg. [119]) that using the pole mass definition for heavy quark masses leads to particularly badly behaved expansions. This motivates the use of "short-distance" mass definitions, such as the kinetic scheme [41] or the $1S$ scheme [120–122]. Both schemes are well suited for the HQE, since they allow the choice of the renormalization scale $\mu\le m_b$. Furthermore, in both schemes, the masses can be extracted from other observables with sufficient precision, enabling a precise determination of $|V_{cb}|$, despite of the strong quark-mass dependence of the total rate. Recent work has primarily been done in the kinetic scheme, so we will not discuss the 1S scheme results and further. In the kinetic scheme the "kinetic mass" $m_b^{\rm kin}(\mu)$ is introduced, which enters the non-relativistic expression for the kinetic energy of a heavy quark, and is defined using heavy-quark sum rules [41]. The relation between $m_b^{\rm kin}$ and $m_b^{\overline{MS}}$ is known through three-loop order [123]. .

Finally, we note that the theoretical description of inclusive decays employed here, is based on the assumption of quark-hadron duality. While there is no evidence of violations of quark-hadron duality, the theoretical uncertainties due to such violations are not well quantified [3]. Here, we note that a program to compute inclusive B-meson decay rates in lattice-QCD is being developed [124–126], and recent progress [127–131] shows promise for quantitative results with controlled systematic errors in the not-too-distant future.

75.2.7 *Determination of HQE Parameters and $|V_{cb}|$*

Several experiments have measured moments in $\bar B\to X_c\ell\bar\nu_\ell$ decays [132–140] as a function of the minimum lepton momentum. More recently, moments measurements have been performed as a function of lepton invariant mass squared, q^2 [141, 142]. The measurements of the moments of the electron energy spectrum ($0^{\rm th}$-$3^{\rm rd}$) and of the squared hadronic mass spectrum ($0^{\rm th}$-$2^{\rm nd}$) have statistical uncertainties that are roughly equal to their systematic uncertainties. The $3^{\rm rd}$ order hadronic mass spectrum moments have also been measured by some experiments, with relatively large statistical uncertainty. The sets of moments measured within each experiment have strong correlations; their use in a global fit requires fully specified statistical and systematic covariance matrices. Measurements of photon energy moments ($0^{\rm th}$-$2^{\rm nd}$) in $B\to X_s\gamma$ decays [143–147] as a function of the minimum accepted photon energy are also used in some fits; the dominant uncertainties on these measurements are statistical.

Global fits [140, 144, 148–155] to the moments of the electron energy spectrum and the squared hadronic mass spectrum have been performed in the $1S$ and kinetic schemes. The semileptonic moments alone determine a linear combination of m_b and m_c very accurately but leave the orthogonal combination poorly determined (See e.g. [156]); additional input is required to allow a precise determination of m_b. This additional information can come from the radiative $B\to X_s\gamma$ moments (with the caveat that the OPE for $b\to s\gamma$ breaks down beyond leading order in $\Lambda_{\rm QCD}/m_b$), which provide complementary information on m_b and μ_π^2, or from precise determinations of the charm and beauty quark masses [85, 157, 158]. The values obtained in the kinetic

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.
Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com

scheme fits [6, 152, 153] with these two constraints are consistent. Based on the charm and beauty quark mass constraints [85, 154] $\overline{m}_c(2\,\mathrm{GeV}) = 1.093 \pm 0.008\,\mathrm{GeV}$, and $m_{\mathrm{kin}}^{1\,\mathrm{GeV}} = 4.565 \pm 0.019)\mathrm{GeV}$ a fit in the kinetic scheme [154] obtains

$$|V_{cb}| = (42.16 \pm 0.51) \times 10^{-3} \tag{75.25}$$

where the error includes experimental and theoretical uncertainties. This analysis [154] includes calculations of the third-order corrections to the semi-leptonic $b \to c\ell\nu$ decay width [101] and mass relations [123, 159]. Theoretical uncertainties from higher orders in $1/m$ as well as in α_s are estimated and included in performing the fits. Similar values for the parameters are obtained with a variety of assumptions about the theoretical uncertainties and their correlations. The χ^2/dof is well below unity, which could suggest that the theoretical uncertainties may be overestimated. However, while one could obtain a satisfactory fit with smaller uncertainties, this would result in unrealistically small uncertainties on the extracted HQE parameters, which are used as input to other calculations (e.g. the determination of $|V_{ub}|$).

Measurements of higher order moments and moments of additional variables, such as q^2, can further improve the sensitivity of the fits to higher-order terms in the HQE [118]. The q^2 moments depend on a reduced set of operators, thereby possibly making it easier to extract higher-order terms from data. A fit to the q^2 moments measured by the Belle [141] and Belle II [142] experiments combined with the world average inclusive branching fractions, finds [160]:

$$|V_{cb}| = (41.69 \pm 0.63) \times 10^{-3}\ , \tag{75.26}$$

which is compatible with the fit to the other moments. Note there is a strong correlation with the other determinations due to the use of common inputs for the branching fractions.

Most recently, an updated calculation of the $\langle q^{2n} \rangle$ moments including $\mathcal{O}(\alpha_s^2\beta)$ corrections was published [155]. This work was used in a fit to the moments of the electron energy spectrum, the moments of the lepton invariant mass spectrum up to $\langle q^{2n} \rangle$, and the moments of the squared hadronic mass spectrum. These results are taken as the inclusive determination of $|V_{cb}|$

$$|V_{cb}| = (42.0 \pm 0.5) \times 10^{-3}\ \text{(inclusive)}. \tag{75.27}$$

75.3 Determination of $|V_{ub}|$

Summary: Currently the best determinations of $|V_{ub}|$ are from $\bar{B} \to \pi\ell\bar{\nu}_\ell$ decays, where combined fits to theory and experimental data as a function of q^2 provide a precision of about 4%; the uncertainties from experiment and theory are comparable in size. Determinations based on inclusive semileptonic B decays are based on different observables and use different strategies to suppress the $b \to c$ background. Most of the determinations are consistent and provide a precision of about 7%, with comparable contributions to the uncertainty from experiment and theory.

The values obtained from inclusive and exclusive B decay determinations are

$$|V_{ub}| = (4.06 \pm 0.11 \pm 0.13 \pm 0.18) \times 10^{-3} \quad \text{(inclusive)}, \tag{75.28}$$

$$|V_{ub}| = (3.75 \pm 0.06 \pm 0.19) \times 10^{-3} \quad \text{(exclusive)}, \tag{75.29}$$

where the last uncertainty on the inclusive result was added by the authors of this review and is discussed below. The exclusive and inclusive determinations are independent, and the dominant uncertainties are on multiplicative factors. The results from the two determinations are compatible to within one standard deviation.

This can be compared to the values derived from $|V_{ub}|/|V_{cb}|$ ratio measurements, described in the next section. Taking the value for this ratio from Eq. (75.49), and $|V_{cb}|$ from Eq. (75.3) we obtain.

$$|V_{ub}| = (3.43 \pm 0.32) \times 10^{-3} \qquad (\mathrm{B_s},\ \Lambda_\mathrm{b}), \tag{75.30}$$

We choose to combine only the direct determinations of $|V_{ub}|$, based on the inclusive and exclusive B measurements. In the combination they are weighted by their relative errors, where the uncertainties are treated as normally distributed. The resulting average has $p(\chi^2) = 29\%$, so we scale the error by $\sqrt{\chi^2/1} = 1.1$ to find

$$|V_{ub}| = (3.89 \pm 0.16) \times 10^{-3} \quad \text{(average)}. \tag{75.31}$$

In a future update we may consider the constraints in the $|V_{ub}|$-$|V_{cb}|$ plane from the direct determinations together with the LHCb $|V_{ub}|/|V_{cb}|$ results, although the agreement among all inputs is somewhat marginal.

75.3.1 $|V_{ub}|$ *from inclusive decays*

The theoretical description of inclusive $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays is based on the Heavy Quark Expansion and leads to a predicted total decay rate with uncertainties below 5% [121, 161]. However, the total decay rate is hard to measure due to the large background from CKM-favored $\bar{B} \to X_c\ell\bar{\nu}_\ell$ transitions, and hence the theoretical methods differ from the $\bar{B} \to X_c\ell\bar{\nu}_\ell$ case. For a calculation of the partial decay rate in regions of phase space where $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays are suppressed one cannot use the HQE as for $b \to c$, rather one needs to introduce non-perturbative distribution functions, the "shape functions" (SF) [162, 163]. Their exact form is not known, but its moments can be related to the HQE parameters known e.g from the $b \to c$ case.

The shape functions become important when the light-cone momentum component $P_+ \equiv E_X - |P_X|$ is not large compared to Λ_{QCD}, as is the case near the endpoint of the $\bar{B} \to X_u\ell\bar{\nu}_\ell$ lepton spectrum. Partial rates for $\bar{B} \to X_u\ell\bar{\nu}_\ell$ are predicted and measured in a variety of kinematic regions that differ in their sensitivity to shape-function effects.

At leading order in $1/m_b$ only a single shape function (SF) appears, which is universal for all heavy-to-light transitions [162, 163] and can be extracted in $\bar{B} \to X_s\gamma$ decays. At subleading order in $1/m_b$, several shape functions appear [164], along with small "resolved photon contributions" specific for $\bar{B} \to X_s\gamma$ [165–167], and thus the prescriptions that relate directly the partial rates for $\bar{B} \to X_s\gamma$ and $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays [168–176] are limited to leading order in $1/m_b$.

Existing approaches use parametrizations of the leading SF that respect constraints on the normalization and on the first and second moments, which are given in terms of the HQE parameters $\overline{\Lambda} = M_B - m_b$ and μ_π^2, respectively. The relations between SF moments and the HQE parameters are known to second order in α_s [177]; as a result, measurements of HQE parameters from global fits to $\bar{B} \to X_c\ell\bar{\nu}_\ell$ and $\bar{B} \to X_s\gamma$ moments can be used to constrain the SF moments, as well as to provide accurate values of m_b and other parameters for use in determining $|V_{ub}|$. Flexible parametrizations of the SF using orthogonal basis functions [178] or artificial neural networks [179] allow global fits to inclusive B meson decay data [167] that incorporate the known short-distance contributions and renormalization properties of the SF.

HFLAV performs fits on the basis of several approaches, with varying degrees of model dependence. We will consider here the approaches documented in Ref. [180] (BLNP), Ref. [181] (GGOU) and Ref. [182] (DGE).

The triple differential rate in the variables

$$P_\ell = M_B - 2E_\ell, \quad P_- = E_X + |\vec{P}_X|, \quad P_+ = E_X - |\vec{P}_X| \tag{75.32}$$

is

$$\frac{d^3\Gamma}{dP_+\,dP_-\,dP_\ell} = \frac{G_F^2|V_{ub}|^2}{16\pi^2}(M_B - P_+) \tag{75.33}$$
$$\Big\{(P_- - P_\ell)(M_B - P_- + P_\ell - P_+)\mathcal{F}_1 + (M_B - P_-)(P_- - P_+)\mathcal{F}_2 + (P_- - P_\ell)(P_\ell - P_+)\mathcal{F}_3\Big\}.$$

The "structure functions", $\mathcal{F}_i$, can be calculated using factorization theorems that have been proven to subleading order in the $1/m_b$ expansion [183].

The BLNP [180] calculation uses these factorization theorems to write the $\mathcal{F}_i$ terms as functions of perturbatively calculable hard coefficients and jet functions, which are convolved with the (soft) light-cone distribution functions. The calculation of $\mathcal{O}(\alpha_s^2)$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

contributions [184,185] is not yet complete and is not included in the $|V_{ub}|$ determination given below.

The leading order term in the $1/m_b$ expansion of the $\mathcal{F}_i$ terms contains a single non-perturbative function and is calculated to subleading order in α_s, while at subleading order in the $1/m_b$ expansion there are several independent non-perturbative functions that have been calculated only at tree level in the α_s expansion.

A distinct approach (GGOU) [181] uses a hard, Wilsonian cutoff that matches the definition of the kinetic mass. The non-perturbative input is similar to what is used in BLNP, but the shape functions are defined differently. In particular, they are defined at finite m_b and depend on the light-cone component k_+ of the b quark momentum and on the momentum transfer q^2 to the leptons. These functions include subleading effects to all orders; as a result they are non-universal, with one shape function corresponding to each structure function in Eq. (75.33). Their k_+ moments can be computed in the OPE.

Going to subleading order in α_s requires the definition of a renormalization scheme for the HQE parameters and for the SF. The relation between the moments of the SF and the forward matrix elements of local operators appearing the HQE is plagued by ultraviolet problems and requires additional renormalization. A scheme for improving this behavior was suggested in Refs. [180,186], which introduce a definition of the quark mass (the so-called shape-function scheme) based on the first moment of the measured $\bar{B} \to X_s\gamma$ photon energy spectrum. Likewise, the HQE parameters can be defined from measured moments of spectra, corresponding to moments of the SF.

There are various ideas to model the SF, but this requires additional assumptions. One approach (DGE) is the so-called "dressed gluon exponentiation" [182], where the perturbative result is continued into the infrared regime using the renormalon structure obtained in the large β_0 limit, where β_0 has been defined following Eq. (75.22). Other approaches make even stronger assumptions, such as in Ref. [187], which assumes an analytic behavior for the strong coupling in the infrared to perform an extrapolation of perturbation theory.

In order to reduce sensitivity to SF uncertainties, measurements that use a combination of cuts on the leptonic momentum transfer q^2 and the hadronic invariant mass m_X, as suggested in Ref. [188, 189], have been made. In general, experimental measurements of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ into charm-dominated regions (in order to reduce SF uncertainties) are sensitive to the modeling of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ and $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays. The measurements quoted below have used a variety of functional forms to parametrize the leading SF; a specific error budget for one determination is quoted in the next section. In no case is the parametrization uncertainty estimated to be more than a 2% on $|V_{ub}|$.

Weak Annihilation [181, 190, 191] (WA) can in principle contribute significantly in the high-q^2 region of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays. Estimates based on semileptonic D_s decays [113, 188, 189, 191] lead to a $\sim 2\%$ uncertainty on the total $\bar{B} \to X_u\ell\bar{\nu}_\ell$ rate from the $\Upsilon(4S)$. The q^2 spectrum of the WA contribution is not well known, but from the OPE it is expected to contribute predominantly at high q^2. Other theoretical investigations [113, 192, 193], a direct search [194], and $\mathcal{B}(B^0 \to X_u\ell\bar{\nu})/\mathcal{B}(B^+ \to X_u\ell\bar{\nu})$ ratio measurements [195–198] indicate that WA is a small effect, but may become a significant source of uncertainty for $|V_{ub}|$ measurements that accept only a small fraction of the full $\bar{B} \to X_u\ell\bar{\nu}_\ell$ phase space.

75.3.2 *Measurements*

We summarize the measurements used in the determination of $|V_{ub}|$ below. Given the improved precision and more rigorous theoretical interpretation of more recent measurements, determinations [199–202] done with LEP data are not considered in this review.

Inclusive electron momentum measurements [203, 204] reconstruct a single charged electron to determine a partial decay rate for $\bar{B} \to X_u\ell\bar{\nu}_\ell$ near the kinematic endpoint. This results in a selection efficiency of order 50% and only modest sensitivity to the modeling of detector response. The inclusive electron momentum spectrum from $B\bar{B}$ events, after subtraction of the $e^+e^- \to q\bar{q}$ continuum background, is fitted to a model $\bar{B} \to X_u\ell\bar{\nu}_\ell$ spectrum and several components ($D\ell\bar{\nu}_\ell$, $D^*\ell\bar{\nu}_\ell$, ...) of the $\bar{B} \to X_c\ell\bar{\nu}_\ell$ background; the dominant uncertainties are related to this subtraction and modeling. The decay rate can be cleanly extracted for $E_e > 2.3\,\text{GeV}$, but this is deep in the SF region, where theoretical uncertainties are large. More recent measurements have increased the accessed phase phase. The resulting $|V_{ub}|$ values for various E_e cuts are given in Table 75.2.

The final BABAR measurement [205] is based on the inclusive electron spectrum and determines the partial branching fraction and $|V_{ub}|$ for $E_e > 0.8\,\text{GeV}$. The analysis shows that the partial branching fraction measurements can have signal model dependence when the kinematic acceptance includes regions dominated by $\bar{B} \to X_c\ell\bar{\nu}_\ell$ background. The model dependence enters primarily through the partial branching fractions, and arises because the signal yield fit has sensitivity to $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays only in regions with good signal to noise.

An untagged "neutrino reconstruction" measurement [206] from BABAR uses a combination [207] of a high-energy electron with a measurement of the missing momentum vector. This allows $\text{S/B} \sim 0.7$ for $E_e > 2.0\,\text{GeV}$ and a $\approx 5\%$ selection efficiency, but at the cost of a smaller accepted phase space for $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays and uncertainties associated with the determination of the missing momentum.

The large samples accumulated at the B factories allow studies in which one B meson is fully reconstructed and the recoiling B decays semileptonically [208–211]. The experiments can fully reconstruct a "tag" B candidate in about 0.5% (0.3%) of B^+B^- ($B^0\bar{B}^0$) events. An electron or muon with center-of-mass momentum above 1.0 GeV is required amongst the charged tracks not assigned to the tag B and the remaining particles are assigned to the X_u system. The full set of kinematic properties (E_ℓ, m_X, q^2, *etc.*) are available for studying the semileptonically decaying B, making possible selections that accept up to 90% of the full $\bar{B} \to X_u\ell\bar{\nu}_\ell$ rate; however, the sensitivity to $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays is still driven by the regions where $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays are suppressed. Despite requirements (e.g. on the square of the missing mass) aimed at rejecting events with additional missing particles, undetected or mis-measured particles from $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decay (e.g., K_L^0 and additional neutrinos) remain an important source of uncertainty.

A recoil method measurement of partial branching fractions in three phase-space regions, covering about 31% to 86% of the accessible phase space, was performed by Belle [195], where machine learning techniques were used to reduce background levels. The measurement contains substantial decay model updates and supersedes previous measurements from Belle [209, 210]. The measurement of the partial branching fraction obtained in the $E_\ell^B > 1\text{GeV}$ region, the most precise one, is used to obtain $|V_{ub}|$ [195]. Belle also reports measurements of the background subtracted, and unfolded differential decay spectra in bins of m_X, m_X and q^2, P_+ and E_ℓ [212] for use in global fit analyses.

Earlier measurements by BABAR [208] were also performed with cuts on m_X, m_X and q^2, P_+ and E_ℓ using the recoil method. In each case the experimental systematic uncertainties have significant contributions from the modeling of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ and $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays and from the detector response to charged particles, photons and neutral hadrons.

To reduce modeling uncertainties associated to $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays a recent Belle tagged measurement [198] uses a novel data driven approach to correct the kinematics and normalization of this background component, while using less restrictive event selection with higher efficiency than the other recent Belle result. In the analysis the ratio $|V_{ub}|/|V_{cb}|$ is directly extracted from inclusive decays for the first time. While a value for $|V_{ub}|$ is provided here, it is not yet included in the combination.

The corresponding $|V_{ub}|$ values are given in Table 75.2.

75.3.3 $|V_{ub}|$ *from inclusive partial rates*

The measured partial rates and theoretical calculations from BLNP, GGOU and DGE described previously are used to determine $|V_{ub}|$ from all measured partial $\bar{B} \to X_u\ell\bar{\nu}_\ell$ rates [213]; selected values are given in Table 75.2. The correlations amongst the multiple BABAR recoil-based measurements [208] are fully accounted for in the average. The statistical corre-

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.
Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com

lations amongst the other measurements used in the average are small (due to small overlaps among signal events and large differences in S/B ratios) and have been ignored. Correlated systematic and theoretical errors are taken into account, both within an experiment and between experiments. As an illustration of the relative sizes of the uncertainties entering $|V_{ub}|$ we give the error breakdown for the GGOU average: statistical—1.4%; experimental—1.6%; $\bar{B} \to X_c \ell \bar{\nu}_\ell$ modeling—0.9%; $\bar{B} \to X_u \ell \bar{\nu}_\ell$ modeling—1.7%; HQE parameters (m_b) —1.6%; higher-order corrections—1.5%; q^2 modeling—1.3%; Weak Annihilation—$^{+0.0}_{-1.0}$%; SF parametrization—0.2%.

The averages quoted here are based on the following m_b values: $m_b^{SF} = 4.600 \pm 0.022$ GeV for BLNP, $m_b^{\rm kin} = 4.573 \pm 0.012$ GeV for GGOU, and $m_b^{\overline{MS}} = 4.206 \pm 0.040$ GeV for DGE. The $m_b^{\rm kin}$ value is determined in a global fit to moments in the kinetic scheme [155]; this value is translated into m_b^{SF} and $m_b^{\overline{MS}}$ at fixed order in α_s.

Hadronization uncertainties also impact the $|V_{ub}|$ determination. The theoretical expressions are valid at the parton level and do not incorporate any resonant structure (*e.g.* $\bar{B} \to \pi \ell \bar{\nu}_\ell$); this must be added to the simulated $\bar{B} \to X_u \ell \bar{\nu}_\ell$ event samples, since the detailed final state multiplicity and structure impacts the estimates of experimental acceptance and efficiency. The experiments have adopted procedures to input resonant structure while preserving the appropriate behavior in the kinematic variables (q^2, E_ℓ, m_X) averaged over the sample, but these prescriptions are *ad hoc* and ultimately require *in situ* calibration. The resulting uncertainties have been estimated to be $\sim$ 1-2% on $|V_{ub}|$. A recent inclusive $|V_{ub}|$ Belle measurement is the first to perform a fit to final state pion multiplicity for *in situ* calibration of the hadronization models used. The measurement simultaneously extracts inclusive and exclusive $|V_{ub}|$, with compatible results [214].

All calculations yield compatible $|V_{ub}|$ values and similar error estimates. The arithmetic mean of the values and errors of the HFLAV combinations listed in Table 75.2 is $|V_{ub}| = (4.06 \pm 0.12_{\rm exp} \pm 0.13_{\rm theo}) \times 10^{-3}$, although there is a spread of approximately 10% in the evaluations with the three theoretical models. For reasons discussed below, we assign an additional uncertainty due to model dependence that is not reflected in the HFLAV averages. As highlighted in the BABAR analysis [195,205], model dependence entering measurement procedures can be sizeable, and is not consistently treated across analyses. Many of the analyses shown in Table 75.2 were based on partial branching fraction measurements determined in a single model (i.e. the one used by that analysis when simulating $\bar{B} \to X_u \ell \bar{\nu}_\ell$ decays), although in some cases simulated events were weighted to match the expected spectra in other models and the differences introduced as systematic uncertainties, e.g. Ref. [195]. The $|V_{ub}|$ value quoted by HFLAV for each model are, typically, derived from this unique partial branching fraction combined with another model-specific partial rate calculation. The model dependence in the partial branching fraction is sensitive to how the model predictions compare in the restricted region with good signal-to-noise, not by how they compare when integrated over the full kinematic range used in the fit. Ideally this effect needs to be accounted for by the experiments; the published information is insufficient to determine it. To account for the range in results using the different theoretical models, we take half of the spread of the averages as an additional systematic uncertainty, denoted Δmodel. With this addition, the inclusive $|V_{ub}|$ average is

$$|V_{ub}| = (4.06 \pm 0.12_{\rm exp} \pm 0.13_{\rm theo} \pm 0.19_{\Delta \rm model}) \times 10^{-3} \quad \text{(inclusive)}. \tag{75.34}$$

75.3.4 $|V_{ub}|$ *from exclusive decays*

Exclusive charmless semileptonic decays offer a complementary means of determining $|V_{ub}|$. For the experiments, the specification of the final state provides better background rejection, but the branching fraction to a specific final state is typically only a few percent of that for inclusive decays. For theory, the calculation of the form factors for decays of B-mesons into exclusive final states is challenging, but brings in a different set of uncertainties from those encountered in inclusive decays. In this review we focus on $\bar{B} \to \pi \ell \bar{\nu}_\ell$, as it is the most promising decay mode for both experiment and theory. However, we also discuss $\bar{B}_s \to K \ell \bar{\nu}_\ell$ decays, for which there are recent interesting results. Measurements of other exclusive $\bar{B} \to X_u \ell \bar{\nu}_\ell$ decays can be found in Refs. [215–228].

75.3.5 $\bar{B} \to \pi \ell \bar{\nu}_\ell$ *form factor calculations*

The relevant form factors for the decay $\bar{B} \to \pi \ell \bar{\nu}_\ell$ are usually defined as

$$\langle \pi(p_\pi) | V^\mu | B(p_B) \rangle = f_+(q^2) \left[p_B^\mu + p_\pi^\mu - \frac{m_B^2 - m_\pi^2}{q^2} q^\mu \right] + f_0(q^2) \frac{m_B^2 - m_\pi^2}{q^2} q^\mu \tag{75.35}$$

in terms of which the rate becomes (in the limit $m_\ell \to 0$)

$$\frac{d\Gamma}{dq^2} = \frac{G_F^2 |V_{ub}|^2}{24\pi^3} |p_\pi|^3 |f_+(q^2)|^2, \tag{75.36}$$

where p_π is the pion momentum in the B meson rest frame.

Lattice-QCD calculations of the form factors for the $B \to \pi \ell \bar{\nu}$ and $B_s \to K \ell \bar{\nu}$ transitions are available from the FNAL/MILC [229, 230], HPQCD [231], [232, 233], and JLQCD [234] collaborations. The lattice form factors are obtained in the large q^2 region, $q^2_{\rm max} > q^2 \gtrsim 15\,{\rm GeV}^2$ and the calculations differ in actions employed for the b quark. While HPQCD [231] is using lattice-nonrelativistic QCD, the results from FNAL/MILC [229, 230] and RBC/UKQCD [232] are obtained with relativistic b quark actions based on the Fermilab approach [235], albeit using independently generated gauge-field configurations. The JLQCD collaboration is using all-domain-wall-fermion set-up, The results agree within the quoted errors. For the $B \to \pi$ form factor $f_+(q^2 = 20\,{\rm GeV}^2)$, Ref. [229] quotes uncertainty of 3.4%, where the leading contribution is due to the chiral-continuum extrapolation fit, which includes statistical and heavy-quark discretization errors.

Similar to the case of $\bar{B} \to D^{(*)} \ell \bar{\nu}_\ell$ form factors, the extrapolation to small values of q^2 (large recoil) can be performed using guidance from analyticity and unitarity together with a conformal mapping of the kinematical variables onto the complex unit disc,

$$z = \frac{\sqrt{t_+ - q^2} - \sqrt{t_+ - t_0}}{\sqrt{t_+ - q^2} + \sqrt{t_+ - t_0}}, \tag{75.37}$$

where $t_\pm = (M_B \pm m_\pi)^2$ and the choice of t_0 determines the range of z that corresponds to the kinematic range of the decay. Setting $t_0 = t_-$ results in $z = 0$ when $q^2 = q^2_{\rm max}$. The choice $t_0 = (m_B + m_\pi)/(\sqrt{m_B} - \sqrt{m_\pi})^2$ centers the kinematic range around $z = 0$, so that $|z| < 0.3$.

We note that the $\bar{B}_s \to K \ell \bar{\nu}_\ell$ decay is an example were the implementation of unitarity bounds is complicated by the fact that the location of the cut in the q^2 plane is different from the $B_s K$ threshold, because the cut starts at $B\pi$ production threshold. Modifications of the unitarity constraints in this and similar examples are discussed in Refs. [233, 236–239].

The "BCL" parameterization of Ref. [240] is commonly used for these decays, as it is consistent with the asymptotic scaling ($q^2 \to \infty$) as well as near threshold, $q^2 = t_+$. As pointed out in Ref. [241] the unitarity sum of the z-expansion coefficients for f_+ is expected to be of order $(\Lambda/m)^3$, hence yielding a rapidly converging series. We note that relatively small differences in different lattice QCD form factor results can be amplified by a long extrapolation to the low-q^2 region. However, such extrapolations are not needed, when lattice form factors are combined with experimental measurements of the differential decay rate. The joint fits provide constraints on the shape of the form factor over the entire kinematic range, in addition to enabling precise determinations of $|V_{ub}|$ [242].

LCSR calculations provide estimates for the product $f_B f_+(q^2)$, valid in the region $0 < q^2 \lesssim 12$ GeV [47, 243–247] and unitarity constraints can be used to extrapolate the form factors away from the low-q^2 region [248, 249] where reasonable agreement with lattice QCD form factor predictions is found. However, in this review we do not pursue LCSR-based determinations of $|V_{ub}|$.

Table 75.2: $|V_{ub}|$ (in units of 10^{-5}) from inclusive $\bar{B} \to X_u \ell \bar{\nu}_\ell$ measurements. The first uncertainty on $|V_{ub}|$ is experimental, while the second includes both theoretical and HQE parameter uncertainties. The values are generally listed in order of increasing kinematic acceptance, f_u (0.19 to 0.90), except for the BABAR E_e >0.8 GeV measurement; those below the horizontal bar are based on recoil methods.

75.3.6 $\bar{B} \to \pi \ell \bar{\nu}_\ell$ measurements

The $\bar{B} \to \pi \ell \bar{\nu}_\ell$ measurements fall into two broad classes: untagged, in which case the reconstruction of the missing momentum of the event serves as an estimator for the unseen neutrino, and tagged, in which the second B meson in the event is fully reconstructed in either a hadronic or semileptonic decay mode. The tagged measurements have better q^2 resolution, high and uniform acceptance, and S/B as high as 10, but lower statistical power. The untagged measurements have higher background (S/B< 1) and make slightly more restrictive kinematic cuts, but still provide statistical power precision on the q^2 dependence of the form factor.

CLEO has analyzed $\bar{B} \to \pi \ell \bar{\nu}_\ell$ and $\bar{B} \to \rho \ell \bar{\nu}_\ell$ using an untagged analysis [222–224]. Similar analyses have been done at BABAR [225–228] and Belle [250]. The leading systematic uncertainties in the untagged $\bar{B} \to \pi \ell \bar{\nu}_\ell$ analyses are associated with modeling the missing momentum reconstruction, with background from $\bar{B} \to X_u \ell \bar{\nu}_\ell$ decays and $e^+e^- \to q\bar{q}$ continuum events, and with varying the form factor used to model $\bar{B} \to \rho \ell \bar{\nu}_\ell$ decays.

Analyses [217,251] based on reconstructing a B in the $\bar{D}^{(*)} \ell^+ \nu_\ell$ decay mode and looking for a $\bar{B} \to \pi \ell \bar{\nu}_\ell$ or $\bar{B} \to \rho \ell \bar{\nu}_\ell$ decay amongst the remaining particles in the event make use of the fact that the B and $\bar{B}$ are back-to-back in the $\Upsilon(4S)$ frame to construct a discriminant variable that provides a signal-to-noise ratio above unity for all q^2 bins. A related technique was discussed in Ref. [252]. BABAR [251] and Belle [215] have used their samples of B mesons reconstructed in hadronic decay modes to measure exclusive charmless semileptonic decays, resulting in very clean but smaller samples. The dominant systematic uncertainties in the tagged analyses arise from tag calibration.

$|V_{ub}|$ can be obtained from the average $\bar{B} \to \pi \ell \bar{\nu}_\ell$ branching fraction and the measured q^2 spectrum. Fits to the q^2 spectrum using a theoretically motivated parametrization (e.g. "BCL" from Ref. [240]) remove most of the model dependence from theoretical uncertainties in the shape of the spectrum. The most sensitive method for determining $|V_{ub}|$ from $\bar{B} \to \pi \ell \bar{\nu}_\ell$ decays employs a simultaneous fit [6, 229, 232, 234, 241, 242, 253–255] to measured experimental partial rates and lattice points versus q^2 (or z) to determine $|V_{ub}|$ and the first few coefficients of the expansion of the form factor in z. We quote the result from Ref. [6], which uses as experimental input an average of the measurements in Refs. [215, 225, 228, 250] and an average [40] of the LQCD input from Refs. [229, 232, 234]. The p-value of the q^2 measurement average is 40%. The average for the total $B^0 \to \pi^- \ell^+ \nu_\ell$ branching fraction is obtained by summing up the partial branching fractions:

$$\mathcal{B}(B^0 \to \pi^- \ell^+ \nu_\ell) = (1.50 \pm 0.02_{\rm stat} \pm 0.05_{\rm syst}) \times 10^{-4} \quad (75.38)$$

The corresponding value of $|V_{ub}|$ with this approach is found to be

$$|V_{ub}| = (3.75 \pm 0.06 \pm 0.19\,) \times 10^{-3} \quad \text{(exclusive)}, \quad (75.39)$$

where the first uncertainty is experimental and the second is from theory. The theory uncertainty is scaled in Ref. [40] to account for disagreements between inputs from Refs. [229, 232, 234]. We note that Ref. [40] obtains $|V_{ub}| = 3.61(16) \times 10^{-3}$ from the same lattice inputs and similar experimental inputs.

75.3.7 $\bar{B}_s \to K \ell \bar{\nu}_\ell$

The LHCb experiment have conducted the first observation of the decay $B_s^0 \to K^- \mu^+ \nu_\mu$ and the measurements of its branching fraction normalised to the $B_s^0 \to D_s^- \mu^+ \nu_\mu$ decays [256]. The measurement has been performed in two bins of q^2, derived using the B_s^0 flight direction and the known B_s^0 mass. The analysis uses a BDT classifier to suppress semileptonic b-hadron background. The results of the partial branching fractions have been translated into measurements of $|V_{ub}|/|V_{cb}|$ using form factor calculations from LCSR for $q^2 < 7$ GeV^2 [257], and a LQCD calculation for $q^2 > 7$ GeV^2 [230]. The results are

$$|V_{ub}|/|V_{cb}| = 0.0946 \pm 0.0041 \pm 0.0068, \; q^2 > 7 \text{ GeV}^2, \quad (75.40)$$

$$|V_{ub}|/|V_{cb}| = 0.0607 \pm 0.0021 \pm 0.0030, \; q^2 < 7 \text{ GeV}^2, \quad (75.41)$$

where the first uncertainties also include experimental and external input sources, and the latter are due to the form factor calculations. The discrepancy between the values of $|V_{ub}|/|V_{cb}|$ for the low and high q^2, requires further theoretical and experimental investigation. On the theory side, FLAG [40] perform a joint z-fit to the lattice QCD results in Refs. [230, 231, 233], with error inflation to account for the tensions between lattice results for f_0. They then combine the form factors for $\bar{B}_s \to K \ell \bar{\nu}_\ell$ with the $\bar{B}_s \to D_s^* \ell \bar{\nu}_\ell$ form factors from Ref. [9] to determine the ratio $|V_{ub}|/|V_{cb}|$ in combination with the LHCb measurements in the high- and low-q^2 regions, finding good agreement between the two:

$$|V_{ub}|/|V_{cb}| = \quad 0.0861 \pm 0.0038_{\rm exp} \pm 0.0057_{\rm lat}, \; q^2 > 7 \text{ GeV}^2 \quad (75.42)$$

$$|V_{ub}|/|V_{cb}| = \quad 0.0779 \pm 0.0028_{\rm exp} \pm 0.0098_{\rm lat}, \; q^2 < 7 \text{ GeV}^2. \quad (75.43)$$

While the experimental measurement has higher purity in the low q^2 region, the lattice QCD form factors are constrained more reliably in high-q^2 region. RBC/UKQCD presented in Ref. [233] a study the effect of different strategies for obtaining the form factors $f_{+,0}$ in the continuum limit, finding sizeable differences for f_0, but not f_+. This issue needs to be studied further. In particular, such differences were not seen in a similar study, albeit for D-meson decay form factors [258]. However, the resulting effect on $|V_{ub}|/|V_{cb}|$ is relatively small, as the f_0 form factor enters the determination only via the kinematic constraint at $q^2 = 0$.

An analysis in Ref. [259] combines the lattice QCD form factors from Refs. [231,233] with the LHCb data in $|V_{ub}|/|V_{cb}|$ determinations that are compatible with Eq. (75.42). When they combine their updated LCSR results with the low-q^2 LHCb data, they find $|V_{ub}|/|V_{cb}| = 0.057 \pm 0.005$, compatible with Eq. (75.41), and hence also in tension with Eq. (75.42). Experimental measurements of the differential rates in smaller bins would provide valuable shape constraints and additional compatibility tests, improving the reliability of the $|V_{ub}|/|V_{cb}|$ determinations by reducing the need for extrapolations of form factors.

75.4 Semileptonic *b*-baryon decays

Summary: A significant sample of Λ_b^0 baryons is available at the LHCb experiment, and methods have been developed to study their semileptonic decays. Both $\Lambda_b^0 \to p\mu\bar{\nu}$ and $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ decays have been measured at LHCb, and the ratio of branching fractions to these two decay modes is used to determine the ratio $|V_{ub}/V_{cb}|$.

75.4.1 $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ and $\Lambda_b^0 \to p\mu\bar{\nu}$

The $\Lambda_b^0 \to \Lambda_c^+$ and $\Lambda_b^0 \to p$ semileptonic transitions are described in terms of six form factors each. The three form factors corresponding to the vector current can be defined as [260]

$$\begin{aligned}\langle F(p',s')|\bar{q}\,\gamma_\mu\,b|\Lambda_b^0(p,s)\rangle = \bar{u}_F(p',s')\Bigg\{ & f_0(q^2)\,(M_{\Lambda_b^0}-m_F)\,\frac{q_\mu}{q^2} \\ & + f_+(q^2)\,\frac{M_{\Lambda_b^0}+m_F}{s_+}\left(p_\mu + p'_\mu - \frac{q_\mu}{q^2}\,(M^2_{\Lambda_b^0}-m_F^2)\right) \\ & + f_\perp(q^2)\left(\gamma_\mu - \frac{2m_F}{s_+}\,p_\mu - \frac{2M_{\Lambda_b^0}}{s_+}\,p'_\mu\right)\Bigg\}\,u_{\Lambda_b^0}(p,s)\,,\end{aligned} \tag{75.44}$$

where $F = p$ or Λ_c^+ and where we define $s_\pm = (M_{\Lambda_b^0} \pm m_F)^2 - q^2$. At vanishing momentum transfer, $q^2 \to 0$, the kinematic constraint $f_0(0) = f_+(0)$ holds. The form factors are defined in such a way that they correspond to time-like (scalar), longitudinal and transverse polarization with respect to the momentum-transfer q^μ for f_0, f_+ and $f_\perp$, respectively. Likewise, the expression for the axial-vector current is

$$\begin{aligned}\langle F(p',s')|\bar{q}\,\gamma_\mu\gamma_5\,b|\Lambda_b^0(p,s)\rangle = & \\ & -\bar{u}_F(p',s')\gamma_5\Bigg\{ g_0(q^2)\,(M_{\Lambda_b^0}+m_F)\,\frac{q_\mu}{q^2} \\ & + g_+(q^2)\,\frac{M_{\Lambda_b^0}-m_F}{s_-}\left(p_\mu + p'_\mu - \frac{q_\mu}{q^2}\,(M^2_{\Lambda_b^0}-m_F^2)\right) \\ & + g_\perp(q^2)\left(\gamma_\mu + \frac{2m_F}{s_-}\,p_\mu - \frac{2M_{\Lambda_b^0}}{s_-}\,p'_\mu\right)\Bigg\}\,u_{\Lambda_b^0}(p,s)\,,\end{aligned} \tag{75.45}$$

with the kinematic constraint $g_0(0) = g_+(0)$ at $q^2 \to 0$.

In the heavy-quark limit, where both the b and c quarks are treated as heavy, all the form factors reduce to the Isgur Wise function ξ_B for baryons [260]:

$$f_0 = f_+ = f_\perp = g_0 = g_+ = g_\perp = \xi_B \tag{75.46}$$

With a light baryon in the final state, the form factors are related through the heavy quark symmetries of the Λ_b^0, reducing the number of independent form factors to two. It should be noted that the differential $\Lambda_b^0 \to (p/\Lambda_c^+)\mu\bar{\nu}$ decay rates peak at high q^2, so that the kinematic regions where both lattice QCD calculations and experimental measurements are precise are well matched.

The form factors for Λ_b^0 decays have been studied with lattice QCD [261]. Based on these results the differential rates for both $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ as well as for $\Lambda_b^0 \to p\mu\bar{\nu}$ can be predicted in the full phase space. In particular, for the experimentally interesting region, they find the ratio of decay rates to be [261]

$$\frac{\mathcal{B}(\Lambda_b^0 \to p\mu\bar{\nu})_{q^2>15\,\mathrm{GeV}^2}}{\mathcal{B}(\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu})_{q^2>7\,\mathrm{GeV}^2}} = (1.471 \pm 0.095 \pm 0.109)\left|\frac{V_{ub}}{V_{cb}}\right|^2 \tag{75.47}$$

where the first uncertainty is statistical and the second systematic. We note that the FLAG review [40] of this calculation points out that the finite volume effects may not be under complete control due to the small valence-quark masses used in the calculation. Furthermore, the analysis of Ref. [261] is based on only three ensembles at two lattice spacing and with heavy sea-pion masses. An ongoing project [262] to calculate the Λ_b form factors includes a larger range of lattice spacings, volumes and ensembles with physical sea-pion masses.

75.4.2 *Measurements at LHCb*

The LHCb experiment has measured the branching fractions of the semileptonic decays $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ and $\Lambda_b^0 \to p\mu\bar{\nu}$, from which they determine $|V_{ub}|/|V_{cb}|$. This is the first such determination at a hadron collider, the first to use a b baryon decay, and the first observation of $\Lambda_b^0 \to p\mu\bar{\nu}$. Excellent vertex resolution allows the $p\mu$ and production vertices to be separated, which permits the calculation of the transverse momentum $p_\perp$ of the $p\mu$ pair relative to the Λ_b^0 flight direction. The corrected mass, $m_{\mathrm{corr}} = \sqrt{p_\perp^2 + m_{p\mu}^2} + p_\perp$, peaks at the Λ_b^0 mass for signal decays and provides good discrimination against background combinations. The topologically similar decay $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ is also measured, which eliminates the need to know the production cross-section or absolute efficiencies. Using vertex and Λ_b^0 mass constraints, q^2 can be determined up to a two-fold ambiguity. The LHCb analysis requires both solutions to be in the high q^2 region to minimise contamination from the low q^2 region. Their result [263], rescaled [6] to take into account the branching fraction measurement [264] $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+) = (6.28 \pm 0.32)\%$, is

$$\frac{\mathcal{B}(\Lambda_b^0 \to p\mu\bar{\nu})_{q^2>15\mathrm{GeV}^2}}{\mathcal{B}(\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu})_{q^2>7\mathrm{GeV}^2}} = (0.92 \pm 0.04 \pm 0.07) \times 10^{-2} \quad . \tag{75.48}$$

The largest systematic uncertainty is from the measured $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+)$; uncertainties due to trigger, tracking and the Λ_c^+ selection efficiency are each about 3%.

A LHCb analysis [265] measures the normalized q^2 spectrum and finds good agreement with the shape calculated with lattice QCD [261].

The decay rate for $\Lambda_b^0 \to p\mu\bar{\nu}$ peaks at high q^2 where the calculation of the associated form factors using lattice QCD is under good control. Using the measured ratio from Eq. (75.48) along with the calculated ratio from Ref. [261] (see Eq. (75.47)) results in [6]

$$|V_{ub}|/|V_{cb}| = 0.079 \pm 0.004 \pm 0.004(\Lambda_b). \tag{75.49}$$

where the first uncertainty is experimental and the second is from the LQCD calculation.

75.5 The ratio $|V_{ub}|/|V_{cb}|$

The ratio of matrix elements, $|V_{ub}|/|V_{cb}|$, is often required when testing the compatibility of a set of measurements with theoretical predictions. It can be determined from the ratio of branching fractions and has been directly measured by the LHCb (quoted in the previous sections) and Belle experiments. It can also be calculated based on the $|V_{ub}|$ and $|V_{cb}|$ values quoted earlier in this review.

The first direct extraction of this ratio from inclusive B decays was recently performed by Belle [198]. Belle measures the ratio of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ and $\bar{B} \to X_c\ell\bar{\nu}_\ell$ branching fractions with a lepton energy threshold of 1.0 GeV. The partial decay widths, omitting the CKM factors, are taken from BLNP and GGOU for $|V_{ub}|$ and the kinetic scheme for $|V_{cb}|$ to extract the ratio of CKM factors. The results are found to be

$$|V_{ub}|/|V_{cb}| = 0.098 \pm 0.008 \quad \text{(BLNP)}, \tag{75.50}$$

$$|V_{ub}|/|V_{cb}| = 0.101 \pm 0.007 \quad \text{(GGOU)}. \tag{75.51}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

These values are in excellent agreement with $|V_{ub}|/|V_{cb}|$ from independent inclusive determinations, given below, but involve nonzero correlations in both the theoretical and experimental uncertainties. We will therefore leave it out of the combination for this edition.

Given the similarities in the theoretical frameworks used for charmed and charmless decays, we choose to also quote separate ratios of $|V_{ub}|/|V_{cb}|$ for inclusive and exclusive B decays, as discussed earlier:

$$|V_{ub}|/|V_{cb}| = 0.097 \pm 0.005 \quad \text{(inclusive)}, \tag{75.52}$$
$$|V_{ub}|/|V_{cb}| = 0.095 \pm 0.005 \quad \text{(exclusive)}. \tag{75.53}$$

The respective determinations of $|V_{ub}|$ and $|V_{cb}|$ are taken to be uncorrelated in the ratio, although there could be some small cancellations of the uncertainties in both the experimental and the theoretical input. We average the B decay values, along with the B_s value weighting by relative errors to find

$$|V_{ub}|/|V_{cb}| = 0.093 \pm 0.003 \quad \text{(average)}, \tag{75.54}$$

where the uncertainty has been scaled by a factor $\sqrt{\chi^2/2} = 1.1$.

75.6 Lepton flavour universality violation

75.6.1 *Semitauonic decays*

Summary: Semileptonic decays to third-generation leptons provide sensitivity to non-Standard Model amplitudes, such as from a charged Higgs boson [266–269] and from leptoquarks [270–276]. The ratios of branching fractions of semileptonic decays involving tau leptons to those involving $\ell = e/\mu$, $R(D^{(*)}) \equiv \mathcal{B}(\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau)/\mathcal{B}(\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell)$, are predicted with good precision and consistency in the Standard Model [7,8,10–12,32,35,38,51,54,277], using a variety of different strategies. Because this ratio is independent of $|V_{cb}|$, it can, in principle, be computed entirely from within the Standard Model, without using experimental decay rate data. Indeed, the lattice-QCD form factor results of Refs. [7–11, 11–13] have been used for just that purpose. Ref. [40] obtains the three-flavor averages

$$R(D)^{\text{LQCD,FLAG2024}} = 0.2938 \pm 0.0054\ ,$$
$$R(D^*)^{\text{LQCD,FLAG2024}} = 0.2582 \pm 0.0051\ . \tag{75.55}$$

and the four-flavor average $R(D^*) = 0.275(15)$. Without constraints from experimental data at large recoil, such SM-theory only evaluations tend to be less precise than those obtained from joint fits that employ experimental data as well as Standard-Model theory inputs (lattice-QCD form factors, HQET constraints, etc.). Here we use the evaluations from Ref. [40], which are based on joint fits to (three-flavor) averages of lattice-QCD form factors and experimental data for $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decays:

$$R(D)^{\text{LQCD+Exp}} = 0.2955 \pm 0.0032\ ,$$
$$R(D^*)^{\text{LQCD+Exp}} = 0.2505 \pm 0.0011\ . \tag{75.56}$$

Measurements [278–287], of these ratios yield higher values; averaging measurements of $R(D)$ and $R(D^*)$ at the $\Upsilon(4S)$ and at LHCb yields [288]

$$R(D)^{\text{meas}} = 0.347 \pm 0.025\ ,$$
$$R(D^*)^{\text{meas}} = 0.288 \pm 0.012\ , \tag{75.57}$$

with a linear correlation of -0.37. These values exceed the Standard Model predictions of Eq. (75.56) by 2.0σ and 2.2σ, respectively. A variety of new physics models have been proposed to explain this excess, see eg. Refs. [266–273] as well as reviews in Refs. [289–291].

75.6.2 *Sensitivity of $\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau$ to additional amplitudes*

In addition to the helicity amplitudes present for decays to $e\bar{\nu}_e$ and $\mu\bar{\nu}_\mu$, decays proceeding through $\tau\bar{\nu}_\tau$ include a scalar amplitude H_s. The differential decay rate is given by [292]

$$\frac{d\Gamma}{dq^2} = \frac{G_F^2\,|V_{cb}|^2\,|\mathbf{p}^*_{D^{(*)}}|q^2}{96\pi^3 m_B^2}\left(1 - \frac{m_\tau^2}{q^2}\right)^2 \left[(|H_+|^2 + |H_-|^2 + |H_0|^2)\left(1 + \frac{m_\tau^2}{2q^2}\right) + \frac{3m_\tau^2}{2q^2}|H_s|^2\right], \tag{75.58}$$

where $|\mathbf{p}^*_{D^{(*)}}|$ is the 3-momentum of the $D^{(*)}$ in the $\bar{B}$ rest frame and the helicity amplitudes H depend on the four-momentum transfer q^2. All four helicity amplitudes contribute to $\bar{B} \to D^*\tau\bar{\nu}_\tau$, while only H_0 and H_s contribute to $\bar{B} \to D\tau\bar{\nu}_\tau$; as a result, new physics contributions can produce larger effects in the latter mode. Semi-leptonic B decays into a τ lepton provide a stringent test of the two-Higgs doublet model of type II (2HDMII), i.e. where the two Higgs doublets couple separately to up- and down-type quarks. The distinct feature of the 2HDMII is that the contributions of the charged scalars scale as $m_\tau^2/m_{H^+}^2$, since the couplings to the charged Higgs particles are proportional to the mass of the lepton. As a consequence, one may expect visible effects in decays into a τ, but only small effects for decays into e and μ. The present data disfavors the 2HDMII, see below.

75.6.3 *Measurement of $R(D^{(*)})$*

$\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau$ decays have been studied at the $\Upsilon(4S)$ resonance and in pp collisions. At the $\Upsilon(4S)$, the majority of experimental measurements are based on signatures that consist of a D or D^* meson, an electron or muon (denoted here by ℓ) from the decay $\tau \to \ell\nu_\tau\bar{\nu}_\ell$, a fully-reconstructed decay of the second B meson in the event, and multiple missing neutrinos. One analysis reconstructs the τ in a hadronic mode. The analyses that use hadronic B tags separate signal decays from $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decays using the lepton momentum and the measured missing mass squared; decays with only a single missing neutrino peak sharply at zero in this variable, while the signal is spread out to positive values. When a semileptonic B tag is used, the discrimination between signal and $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decays comes from the calorimeter energy that is not associated with any particle used in the reconstruction of the B meson candidates, the measured missing mass squared and the cosine of the angle between the $D^*\ell$ system and its parent B meson, which is calculated under the assumption that only one particle (a neutrino) is missing. In both these approaches, background from $\bar{B} \to D^{**}\ell\bar{\nu}_\ell$ decays with one or more unreconstructed particles is challenging to separate from signal, as is background from $\bar{B} \to D^{(*)}H_{\bar{c}}X$ (where $H_{\bar{c}}$ is a hadron containing a $\bar{c}$ quark) decays. The leading sources of systematic uncertainty are due to the limited size of simulation samples used in constructing the PDFs, the composition of the D^{**} states, efficiency corrections, and cross-feed (swapping soft particles between the signal and tag B).

The most precise measurement from Belle [282] uses semileptonic B tags and leptonic τ decays to simultaneously measure $R(D^*)$ and $R(D)$. The measurement combines results from charged and neutral B decays for both $R(D^*)$ and $R(D)$, and is compatible with the Standard Model expectation to approximately 1σ. The first result from Belle II [283] uses a hadronic tag to measure $R(D^*)$ in $\bar{B} \to D^*\tau^-\bar{\nu}_\tau$ decays with a 189 fb^{-1} dataset. The statistical power of the Belle II dataset has been found to outperform that of Belle in this channel. A complementary measurement was recently published by Belle II, using semileptonic B^0 tags and leptonic τ decays [287] with a 365 fb^{-1} dataset. The neutral B tag was studied due to their lower combinatorial background than charged B tag events. A multiclass multivariate approach is used to isolate signal contributions.

In addition to the ratio measurements, the Belle experiment has performed polarization measurements of the τ [281] and D^* [293] respectively. The τ polarization measurement uses hadronic B tags and τ^- decays to $\pi^-\nu_\tau$ or $\rho^-\nu_\tau$. The main discriminant variables are the measured missing mass squared and the unassociated calorimeter energy. This measurement provides the first determination of the τ polarization in the $\bar{B} \to D^*\tau\bar{\nu}_\tau$ decay, $\mathcal{P}_\tau(D^*) = -0.38 \pm 0.51\,^{+0.21}_{-0.16}$, compatible with the Standard Model expectation [35], $\mathcal{P}_\tau(D^*) = -0.476^{+0.037}_{-0.034}$.

Table 75.3: Measurements of $R(D)$ and $R(D^*)$, their correlations, ρ, and the combined averages [288].

		$R(D) \times 10^2$	$R(D^*) \times 10^2$	ρ
BABAR [278,279]	B^0, B^+	$44.0 \pm 5.8 \pm 4.2$	$33.2 \pm 2.4 \pm 1.8$	-0.27
Belle[a] [280]	B^0, B^+	$37.5 \pm 6.4 \pm 2.6$	$29.3 \pm 3.8 \pm 1.5$	-0.49

Belle II[b] [287]	B^0	$41.8 \pm 7.4 \pm 5.1$	$30.6 \pm 3.4 \pm 1.8$	-0.22
Average	B^0, B^+	34.7 ± 2.5	28.8 ± 1.2	-0.39

The main uncertainties on the $R(D^*)$ measurement come from the composition of the hadronic B background and from modeling of semileptonic B decays and mis-reconstructed D^* mesons. The D^* polarization measurement uses an inclusive tag approach based on Refs. [295, 296], and reconstructs the τ decays in $\ell\nu_\tau\bar{\nu}_\ell$ and $\pi^+\bar{\nu}_\tau$ channels. The main discriminant variables are $X_{\rm miss}$, a quantity that approximates missing mass but does not depend on tag B reconstruction, the visible energy of the event, and the beam-energy constrained mass, $M_{\rm bc}$, of the inclusively reconstructed tag side B. This measurement provides the first determination of the D^* longitudinal polarization fraction in the $\bar{B} \to D^*\tau\bar{\nu}_\tau$ decay, $\mathcal{F}_L(D^*) = -0.38 \pm 0.60\,^{+0.08}_{-0.04}$, compatible with the Standard Model expectation [297] within 1.7σ.

The LHCb experiment has performed a simultaneous analysis of $R(D^*)$ and $R(D)$ where $\tau \to \mu\nu_\tau\bar{\nu}_\mu$. The reconstructed decay modes are $\bar{B}^0 \to D^{*+}\tau^-\bar{\nu}_\tau$ with $D^{*+} \to D^0\pi^+$, $B^- \to D^{*0}\tau^-\bar{\nu}_\tau$ with $D^{*0} \to D^0\pi^0$ and $D^{*0} \to D^0\pi^0$, and $B^- \to D^0\tau^-\bar{\nu}_\tau$. Their analysis [285] takes advantage of the measurable flight lengths of b and c hadrons and τ leptons. A multivariate discriminant is used to select decays where no additional charged particles are consistent with coming from the signal decay vertices. The separation between the primary and B decay vertices is used to calculate the momentum of the B decay products transverse to the B flight direction. The longitudinal component of the B momentum can be estimated based on the visible decay products; this allows a determination of the B rest frame, with modest resolution, and enables the calculation of similar discrimination variables to those available at the e^+e^- B factories. The (rest frame) muon energy, missing mass-squared and q^2 are used in a 3-d fit.

A complementary LHCb result [284] on $R(D^*)$ uses three-prong τ decays that take advantage of their excellent vertex resolution to isolate the τ decay from hadronic background. A 3-d fit is performed to determine the signal yield, based on the τ-ν_τ pair q^2, the τ lifetime, as well as a boosted decision tree classifier based on isolation, invariant mass and flight distance information. The leading sources of systematic uncertainty are due to the size of the simulation sample used in constructing the fit templates, uncertainties in modelling the background from hadronic $\bar{B} \to D^{(*)}H_{\bar{c}}X$ decays, as well as reconstruction and trigger effects. The result is normalized to $B^0 \to D^{*-}\pi^+\pi^-\pi^+$ and found to be 1σ from the Standard Model expectation (using the expectation value quoted here). An analogous measurement of $B_c \to J/\psi\tau\bar{\nu}_\tau$ was performed by the LHCb measurement [298], in leptonic τ decays. The result, $R(J/\psi) = 0.71 \pm 0.17 \pm 0.18$, while relatively high is compatible to within 2σ of a recent Standard Model evaluation [299] based on a latttice-QCD calculation [300] of the form factors. Systematic uncertainties are dominated by form factors, as B_c decays are relatively unexplored.

Measurements from BABAR [278, 279], Belle [280–282], Belle II [283, 287] and LHCb [284–286] result in values for $R(D)$ and $R(D^*)$ that exceed Standard Model predictions. Table 75.3 lists these values and their average. Two early untagged Belle measurements [295,296] are subject to larger systematic uncertainties, with a breakdown of the respective contributions that is inconsistent with the more recent determinations, hence they cannot be reliably combined in the average. All three experiments assume the Standard Model kinematic distributions for $\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau$ in their determinations of the branching fraction ratios.

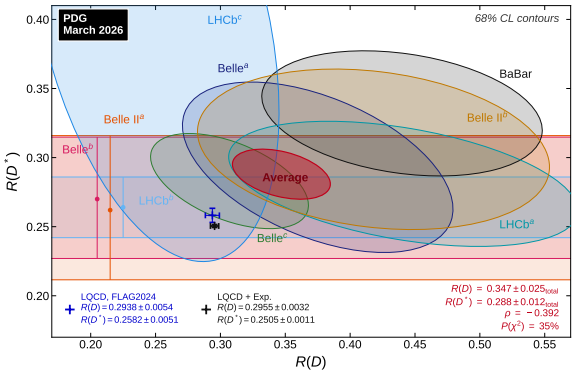

Figure 75.2: Measurements of $R(D)$ and $R(D^*)$ and their two-dimensional average compared with the average predictions for $R(D)$ and $R(D^*)$ given in Eq. 75.56. Contours correspond to 68% CL. The experiment-lattice QCD predictions and the experimental average deviate from each other by 4.4σ.

The measurement combination in the $R(D) - R(D^*)$ plane is shown in Fig. 75.2, compared with the predictions in Eq. (75.55) (LQCD) and Eq. (75.56) (Experiment+LQCD). The measurement combination is based on Ref. [6] with the inclusion of recent results from LHCb and Belle II. The tension between the Standard Model prediction in Eq. (75.56) and the measurements is at the level of 2.0σ ($R(D)$) and 3.1σ ($R(D^*)$); if one considers these deviations together the significance is 4.4σ. However, we note that the LQCD and LQCD+Exp. predictions don't include error estimates due to unknown QED effects, which are significant at this level of uncertainty and would reduce the significances reported above. Still, the observed tensions motivate speculation on possible new physics contributions. The measurements reported in Refs. [283, 284, 294] are all in reasonable agreement with the Standard-Model predictions. There is some tension in the combination coming from the BABAR [278, 279], Belle II [287] and LHCb [285] measurements. The BABAR measurement is the only one to claim a deviation from the Standard Model of more than 3σ, although the $p-$value of the full combination is an acceptable 35%.

The current discussion of $R(D)$ and $R(D^*)$ may be embedded in the theoretical analysis of the other anomalies that have been observed in semileptonic FCNC ($b \to s\ell\ell$) transitions. More sophisticated approaches fit the data to a general effective Hamiltonian. Matching this effective Hamiltonian to simplified models, the current situation of the anomalies seems to be compatible with scenarios with an additional Z' or a leptoquark scenario, see e.g. [270–276].

75.6.4 *Measurements of* $R(X)$

We note that in addition to exclusive modes, inclusive modes also offer an opportunity to test the presence of non-Standard Model contributions, although typically with lower precision. The first measurement of $R(X)$ from a B-factory was recently per-

formed by Belle II [301], $R(X) = 0.228 \pm 0.039$, and found to be compatible with an average of Standard Model predictions $R(X) = 0.223 \pm 0.005$ [302–304]. Prior measurements of the branching fractions of $b \to X\tau\nu$ were performed by LEP experiments and also found to be compatible with Standard Model predictions.

75.6.5 *Ratios of semileptonic decay rates with e to μ final states*

Several tests of lepton flavor universality in semileptonic B decays have recently been undertaken at Belle and Belle II. This includes ratios of rates to electron and muon modes (i.e. $R(e/\mu)$) performed as part of CKM matrix element extraction analyses (Table 75.4), as well as dedicated flavour dependent angular analyses [305]. Refs. [71,73,74,287] provide measurements of LFUV in $\bar{B} \to D^{(*)}\ell\bar{\nu}$ decays at Belle (untagged, and hadron tagged) and Belle II (hadron and semileptonic tagged). The corresponding theoretical predictions are $\mathcal{B}(B \to De\nu)/\mathcal{B}(B \to D\mu\nu) = 1.0028 \pm 0.0001$ and $\mathcal{B}(B \to D^*e\nu)/\mathcal{B}(B \to D^*\mu\nu) = 1.0041 \pm 0.0001$ [38]. Refs. [198, 306] provide measurements of LFUV in $B \to X_c\ell\bar{\nu}$ in hadron tagged events at Belle and Belle II, where the theoretical expectation is $\mathcal{B}(B \to X_c e\nu)/\mathcal{B}(B \to X_c\mu\nu) = 1.006 \pm 0.001$ [303]. Finally, Ref. [195] provides a result for LFUV in $B \to X_u\ell\nu$ decays where the ratio is expected to be close to 1, as in the $B \to X_c\ell\nu$ case. With the exception of the charmless decay measurement, the experimental uncertainties are dominated by lepton identification uncertainties that do not cancel in the ratios. All results are found to be highly compatible with SM expectations.

Table 75.4: Selected measurements of $R(e/\mu) = \mathcal{B}(B \to Xe\nu)/\mathcal{B}(B \to X\mu\nu)$ where the specific decay process is listed.

Ref.	Decay	$R(e/\mu) \times 100$
Belle [73]	$\bar{B} \to D^*\ell\bar{\nu}$	$99.2 \pm 2.3 \pm 2.3$
Belle [71]	$B^0 \to D^{*+}\ell\nu$	$101 \pm 1 \pm 3$
Belle II [74]	$B^0 \to D^{*+}\ell\nu$	$99.8 \pm 0.9 \pm 2.0$
Belle II [287]	$B^0 \to D^+\ell\nu$	$106.8^{+5.0+2.4}_{-4.8-2.3}$
Belle II [306]	$B \to X_c\ell\nu$	$100.7 \pm 0.9 \pm 1.9$
Belle [198]	$B \to X_c\ell\nu$	$100.3 \pm 0.5 \pm 2.4$
Belle [195]	$B \to X_u\ell\nu$	$97 \pm 9 \pm 4$

75.7 Conclusion

The study of semileptonic B meson decays continues to be an active area for both theory and experiment. The application of HQE calculations to inclusive decays is well established, and fits to moments of $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays provide precise values for $|V_{cb}|$ and, in conjunction with input on m_c provide precise and consistent values for m_b. Recent developments will make use of more types of moments and better theoretical inputs to constrain higher order effects. Further into the future, new nonperturbative methods to compute inclusive decay rates, for example, in lattice QCD [124–126], may provide interesting new insights.

The determination of $|V_{ub}|$ from inclusive $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays is based on multiple calculational approaches and independent measurements over a variety of kinematic regions, all of which provide consistent results. Further progress in this area is possible, but will require better theoretical control over higher-order terms, improved experimental knowledge of the $\bar{B} \to X_c\ell\bar{\nu}_\ell$ background and improvements to the modeling of the $\bar{B} \to X_u\ell\bar{\nu}_\ell$ signal distributions.

In both $b \to u$ and $b \to c$ exclusive channels there has been significant recent progress in lattice-QCD calculations, resulting in improved precision on both $|V_{ub}|$ and $|V_{cb}|$, and further progress is expected. These calculations now provide information on the form factors well away from the high q^2 region, allowing better use of experimental data. For $|V_{cb}|$ recent measurements have provided binned data enabling model-independent fits.

While for $|V_{ub}|$ determinations from inclusive and exclusive processes are now compatible, for $|V_{cb}|$ they are only marginally consistent. This is a long-standing puzzle that the recent improvements have, unfortunately, not yet resolved.

Both $|V_{cb}|$ and $|V_{ub}|$ are indispensable inputs into unitarity triangle fits. In particular, knowing $|V_{ub}|$ with good precision allows a test of CKM unitarity in a most direct way, by comparing the length of the $|V_{ub}|$ side of the unitarity triangle with the measurement of $\sin(2\beta)$. This comparison of a "tree" process ($b \to u$) with a "loop-induced" process ($B^0 - \bar{B}^0$ mixing) provides sensitivity to possible contributions from new physics.

The observation of semileptonic decays into τ leptons has opened a new window to the physics of the third generation. The measurements indicate a tension between the data and Standard-Model predictions, which could be a hint for new physics, manifesting itself as a violation of lepton universality beyond the Standard-Model couplings to the Higgs. It should be noted that none of the most recent measurements alone claim discovery of a deviation from the Standard Model. Combining the data of the semitauonic decays with the anomalies observed in the FCNC $b \to s\ell\ell$ transitions allows an interpretation in terms of additional Z' or in terms of additional leptoquarks, but the current data does not allow us to draw a definite conclusion.

76. Determination of CKM angles from B hadrons

Revised July 2025 by T. Gershon (Warwick U.), M. Kenzie (Cambridge U.) and K. Trabelsi (CPPM Marseille).

76.1 Introduction

The Cabibbo–Kobayashi–Maskawa (CKM) description of quark mixing [1, 2] leads to a number of triangle relations between pairs of CKM matrix elements. One of these,

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0 \,, \tag{76.1}$$

is of particular interest since (i) all its terms are of comparable magnitude, and (ii) its properties can be measured through studies of oscillations and decays of B mesons. As the area of this unitary triangle is a measure of the amount of CP violation in the Standard Model [3], it is of particular interest to determine the values of its angles and to test the consistency of the CKM paradigm with the experimental measurements. The angles are defined as

$$\begin{aligned} \alpha &= \arg\left[-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right] \,, \qquad \beta = \arg\left[-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right] \,, \\ \gamma &= \arg\left[-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right] \,, \end{aligned} \tag{76.2}$$

with an alternative notation $(\phi_2, \phi_1, \phi_3) \equiv (\alpha, \beta, \gamma)$ also widely used in the literature.

In this mini-review, the most precise methods to determine the CKM angles are described, with a particular focus on nontrivial aspects of the combination of results. More detailed discussions of these points can be found in Ref. [4]. A similar mini-review on the side of the unitarity triangle adjacent to the angle γ can be found in Ref. [5]. A detailed overview of the CKM quark-mixing matrix is given in Ref. [6] while CP violation in the quark sector is discussed in Ref. [7].

76.2 β

The relative weak (*i.e.* CP-violating) phase between the amplitude for any CKM-favoured B^0 meson decay to a CP eigenstate and that for the decay following B^0–$\overline{B}^0$ oscillation is twice the angle β. The decay-time-dependent CP asymmetry can be expressed as

$$\mathcal{A}_{f_{CP}}(t) \equiv \frac{d\Gamma/dt\left[\overline{B}^0_{\rm phys}(t) \to f_{CP}\right] - d\Gamma/dt\left[B^0_{\rm phys}(t) \to f_{CP}\right]}{d\Gamma/dt\left[\overline{B}^0_{\rm phys}(t) \to f_{CP}\right] + d\Gamma/dt\left[B^0_{\rm phys}(t) \to f_{CP}\right]} \,, \tag{76.3a}$$

$$= S_f \sin(\Delta m t) - C_f \cos(\Delta m t) \,, \tag{76.3b}$$

where the notation $B^0_{\rm phys}(t)$ ($\overline{B}^0_{\rm phys}(t)$) denotes a neutral B meson that decays at time t into the final state f_{CP}, and is known ("tagged") at time $t = 0$ to have flavour content corresponding to B^0 ($\overline{B}^0$). In Eq. (76.3b), Δm denotes the mass difference between the two physical eigenstates of the B^0–$\overline{B}^0$ system, while the corresponding decay-width difference is assumed to be negligible [8]; moreover CPT symmetry and the absence of CP violation in B^0–$\overline{B}^0$ mixing is assumed throughout this mini-review.

In the general case, one can write

$$S_f \equiv \frac{2\,\mathcal{I}m(\lambda_f)}{1 + \left|\lambda_f\right|^2} \qquad \text{and} \qquad C_f \equiv \frac{1 - \left|\lambda_f\right|^2}{1 + \left|\lambda_f\right|^2} \,, \tag{76.4}$$

where the parameter $\lambda_f = \frac{q}{p}\frac{\overline{A}_f}{A_f}$ is defined in terms of p and q, which define the flavour content of the mass eigenstates of the B^0–$\overline{B}^0$ system [8], and the amplitudes $\overline{A}_f$ (A_f) for a $\overline{B}^0$ (B^0) decay to the final state f_{CP}. In the limit that the decay amplitude is dominated by a CKM-favoured transition, as is the case for $B^0 \to J/\psi K^0_{\rm S}$ decays, one obtains simple relations: $S_f = -\eta_{CP}\sin(2\beta)$ and $C_f = 0$, where η_{CP} is the CP eigenvalue of the final state [9,10]. This method has been pursued intensively by experiments. The current world averages, combining results for several charmonium-kaon final states but dominated by results on $B^0 \to J/\psi K^0_{\rm S}$ (CP odd) and $B^0 \to J/\psi K^0_{\rm L}$ (CP even), are [4]

$$-\eta_{CP}S_f = 0.710 \pm 0.011 \,, \qquad C_f = +0.004 \pm 0.010 \,. \tag{76.5}$$

Despite the large number of signal events in the data, the dominant uncertainties are still statistical. One important source of potential systematic correlation between results from different experiments is that due to "tag-side interference" [11], which is common to measurements exploiting production through the $e^+e^- \to \Upsilon(4S) \to B^0\overline{B}^0$ process, including the latest results from BaBar [12], Belle [13] and Belle II [14]. It does not, however, affect the results from LHCb [15] that now have better statistical sensitivity. Another common source of systematic uncertainty is due to knowledge of the value of Δm, but since this quantity has been measured precisely [8] the effect remains small.

The interpretation of the value of $-\eta_{CP}S_f$ from Eq. (76.5) as $\sin(2\beta)$ assumes negligible contributions from subleading amplitudes with a different weak phase to that of the tree diagram (*i.e.* to that of the CKM matrix elements $V_{cb}V_{cs}^*$). This potential additional contribution is often referred to as "penguin pollution". All existing data, including the value of C_f in Eq. (76.5), as well as several explicit calculations [16–19], are consistent with penguin pollution in B^0 meson decays to charmonium-kaon decays being negligible at the current level of precision. Therefore, the value of $-\eta_{CP}S_f$ is generally converted to $\sin(2\beta)$ without any correction or additional uncertainty being assigned due to this assumption. This gives [4]

$$\beta = \left(22.6\,^{+0.5}_{-0.4}\right)^\circ \,, \tag{76.6}$$

where only the solution consistent with the Standard Model is reported (methods to resolve the trigonometric ambiguity in the result are discussed below). It is also possible to use data-driven methods, typically based on flavour symmetries plus some additional assumptions, to constrain the effects of penguin pollution [20–22]. In this case it is necessary to consider each charmonium-kaon final state separately, since the penguin pollution to each may differ. The most common approach [20], which relies on experimental information on $B^0 \to J/\psi\pi^0$ decays, currently gives an additional uncertainty on $\sin(2\beta)$ from $B^0 \to J/\psi K^0_{\rm S}$ of around 0.01.

It is possible to avoid the issue of penguin pollution in the measurement of β by using B^0 meson decays to a charm- and light-meson final state, such as $D_{CP}\pi^0$ (where D_{CP} represents a D^0 meson decaying into a CP eigenstate), instead of the charmonium-kaon final states. These decays do have a CKM-suppressed contribution ($V_{ub}V_{cd}^*$ instead of $V_{cb}V_{ud}^*$), which can in principle bias the determination of $\sin(2\beta)$ from S_f, but this can be calculated and is known to be negligible at current precision. The requirement that the neutral D meson decays to a final state that is common to both D^0 and $\overline{D}^0$, such as the CP-even eigenstate K^+K^-, reduces the sample size that is available for analysis. Consequently, the world average [4], $\sin(2\beta) = 0.71 \pm 0.09$, with these channels is not as precise as that from the charmonium-kaon states.

Converting experimental results on $\sin(2\beta)$ into constraints on β leads to a trigonometric ambiguity in the range $[0°, 180°]$. This can be resolved with experimental measurements of $\cos(2\beta)$, which can be obtained from decay-time-dependent analyses of B^0 meson decays to multibody (non-CP-eigenstate) final states. Among the charmonium-kaon decays, study of $B^0 \to J/\psi K^*(892)^0$ with $K^*(892)^0 \to K^0_{\rm S}\pi^0$ is the most promising approach, but due to the limited sample size that has been analysed to date the precision is not sufficient to resolve the ambiguity conclusively. The charm- and light-meson channels such as $B^0 \to D\pi^0$ with $D \to K^0_{\rm S}\pi^+\pi^-$ have been shown to provide good statistical power for this purpose, with a joint analysis of BaBar and Belle data giving $\cos(2\beta) = 0.91 \pm 0.25$ [23, 24], sufficient to rule out the alternative solution for β.

76.3 α

In the limit that only tree amplitudes contribute to B^0 meson decays to light mesons, such as $B^0 \to \pi^+\pi^-$, then the observables of the decay-time-dependent CP asymmetry of Eq. (76.3) would allow a straight-forward determination of 2α: $S_f = +\eta_{CP}\sin(2\alpha)$

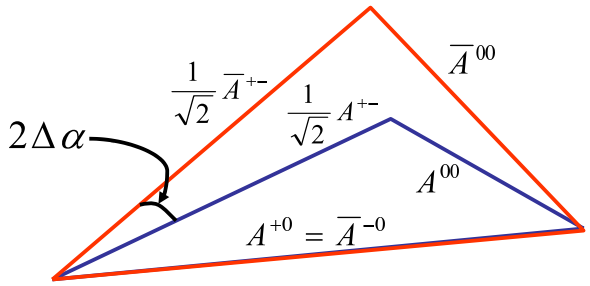

Figure 76.1: Isospin triangles for $B \to \pi\pi$ decays, reproduced from Ref. [25]. Here, the relative phase between A^{+0} and $\overline{A}^{-0}$ has been rotated away to simplify the picture. The total relative phase probed by $S_{\pi^+\pi^-}$ is $\arg\left(\frac{q}{p}\frac{\overline{A}^{+-}}{A^{+-}}\right) = 2\alpha - 2\Delta\alpha$, including contributions from B^0–$\overline{B}^0$ mixing, the tree-level amplitudes and the correction $\Delta\alpha$, and exploiting the unitarity requirement $\alpha + \beta + \gamma = 180°$.

and $C_f = 0$. In general, however, the determination of α is complicated by the presence of contributions from $b \to d(u\bar{u})$ neutral-current penguin transitions, which have a similar level of CKM-suppression as the $b \to u(\bar{u}d)$ charged-current tree amplitudes but have a different weak phase. Consequently, one obtains instead for $B^0 \to \pi^+\pi^-$

$$S_{\pi^+\pi^-} = \sqrt{1 - C^2_{\pi^+\pi^-}}\,\sin(2\alpha - 2\Delta\alpha), \qquad (76.7)$$

where $\Delta\alpha$ is the *a priori* unknown penguin contribution.

This contribution from the penguin amplitude can be accounted for in an analysis relating the amplitudes for isospin partner decays, *e.g.* A^{+-} for $B^0 \to \pi^+\pi^-$, A^{+0} for $B^+ \to \pi^+\pi^0$, A^{00} for $B^0 \to \pi^0\pi^0$ decays and $\left(\overline{A}^{+-}, \overline{A}^{-0}, \overline{A}^{00}\right)$ for their charge conjugates. The isospin analysis relies on the fact that there is no penguin contribution to A^{+0} and $\overline{A}^{-0}$, because $\pi^\pm\pi^0$ is a pure isospin-2 state, and the ($\Delta I = \frac{1}{2}$) QCD-penguin amplitudes only contribute to the isospin-0 final state. One therefore obtains the following isospin triangle relations [26]

$$A^{+0} = \frac{1}{\sqrt{2}}A^{+-} + A^{00} \quad \text{and} \quad \overline{A}^{-0} = \frac{1}{\sqrt{2}}\overline{A}^{+-} + \overline{A}^{00}\,, \quad (76.8)$$

from which it is possible to determine $\Delta\alpha$, as shown in Fig. 76.1.

Since the determination of $\Delta\alpha$ and thus also α requires construction of amplitude-level relations, it is not appropriate to simply average results of α from different experiments. Instead, measurements of each of the observable quantities needed to determine α are input into a combination. For the $B \to \pi\pi$ system, the inputs are the branching fractions of $B^0 \to \pi^+\pi^-$, $B^+ \to \pi^+\pi^0$ and $B^0 \to \pi^0\pi^0$ decays, the lifetimes of the B^+ and B^0 mesons (which are needed to relate the branching fractions to amplitude-level quantities), and the $S_{\pi^+\pi^-}$, $C_{\pi^+\pi^-}$ and $C_{\pi^0\pi^0}$ observables. Potential sources of correlation must be taken into account, but these are predominantly systematic in origin and thus have a small effect on the combination, since the measurements are statistically limited. An exception is that the LHCb measurements of $(S_{\pi^+\pi^-}, C_{\pi^+\pi^-})$ [27,28] have a significant statistical correlation due to the fact that the time variable of Eq. (76.3) is the difference between production and decay, and hence is in the range $[0, \infty]$. This correlation is largely absent for measurements from BaBar [29] and Belle [30], where the difference between the signal and tagging B meson decay times is measured, and hence $t \in [-\infty, \infty]$. The combination itself can be performed with different statistical approaches; the procedure described in detail in Ref. [31], based on a frequentist treatment, is used here. The knowledge of $C_{\pi^0\pi^0}$ [29,32] is currently the limiting factor in the precision on α from the $B \to \pi\pi$ system, and is likely to remain so for some time due to the difficulty to reconstruct this final state.

In general, the isospin triangle construction gives a four-fold ambiguity on $2\Delta\alpha$ (each triangle can face either up or down), leading to an eight-fold ambiguity on α in the range $[0°, 180°]$. This is reduced if either or both of the triangles are flat, or if the two triangles have sides of identical length. The ambiguities can also be reduced if measurement of the $S_{\pi^0\pi^0}$ (or equivalent) observable is available, since this can be combined with the corresponding $\Delta\alpha$ parameter from the right-hand corner of the triangle in Fig. 76.1 to provide an additional constraint. None of these possibilities are realised in the $B \to \pi\pi$ system; in particular a decay-time-dependent analysis of $B^0 \to \pi^0\pi^0$ is extremely challenging experimentally due to the absence of any charged particle originating from the B decay position. Nonetheless, solutions consistent with $\alpha = 0$ can be rejected on physical grounds [25].

The isospin analysis can also be performed with the $B \to \rho\rho$ system, which contains two vector particles in the final state and so does not have a fixed *CP* eigenvalue. In principle the analysis can be performed separately for each $\rho\rho$ polarization state, but in practise it is found that the longitudinal polarization fraction, f_L, is close to unity, and hence the final state is approximately *CP*-even. Compared to $B^0 \to \pi\pi$, the $\rho\rho$ modes benefit experimentally from a higher branching fraction and smaller penguin contributions, so that the isospin triangles are flatter, reducing the ambiguities. (The value of $\Delta\alpha$ in the $B \to \rho\rho$ system, obtained from the isospin analysis, has a single solution in $[0, \pi]$ at $(3 \pm 5)°$, while for $B \to \pi\pi$ there are two solutions at 13° and 27° with $\Delta\alpha \in [7, 33]°$ at 68.3% confidence level (CL). The isospin analysis with either final state has an ambiguity under $\Delta\alpha \Leftrightarrow -\Delta\alpha$.) For the BaBar [33], Belle [34] and Belle II [35] experiments, the high branching fraction and smaller penguin contribution compensate for the increased difficulty to reconstruct the $\rho\rho$ final state relative to $\pi\pi$. Moreover, in contrast to $S_{\pi^0\pi^0}$, measurement of $S_{\rho^0\rho^0}$ is possible due to the four charged pion final state, following $\rho^0 \to \pi^+\pi^-$ decay, as has been demonstrated by BaBar [36].

In the $B \to \rho\pi$ system there are more amplitudes to consider, so that the isospin relation corresponds to a pentagon rather than a triangle and Eq. (76.8) is modified to become

$$\begin{aligned}\sqrt{2}(A^{+0} + A^{0+}) &= A^{+-} + A^{-+} + 2A^{00} \quad \text{and} \\ \sqrt{2}(\overline{A}^{-0} + \overline{A}^{0-}) &= \overline{A}^{+-} + \overline{A}^{-+} + 2\overline{A}^{00}\,.\end{aligned} \qquad (76.9)$$

As in Eq. (76.8), the left-hand sides of these expressions correspond to a pure isospin-2 final state, and therefore the ratio of the right-hand sides gives a pure phase term that, accounting for the B^0–$\overline{B}^0$ mixing phase that also contributes to the measured quantities, is 2α. The relative amplitudes for B^0 and $\overline{B}^0$ decays to $\rho^+\pi^-$, $\rho^-\pi^+$ and $\rho^0\pi^0$ can all be determined from a decay-time-dependent analysis of the $\pi^+\pi^-\pi^0$ Dalitz plot, so that study of this channel alone allows determination of α [37]. This analysis in principle leads to a single solution for α in $[0°, 180°]$, but the precision of current measurements [38–40] is limited.

The isospin analysis used to determine α is believed to be valid to high precision, and theoretical uncertainties in the procedure are usually neglected. Nonetheless, it should be noted that the analysis assumes the absence of electroweak penguin amplitudes, which can contribute to $\Delta I = \frac{3}{2}$ transitions with a different weak phase to that of the tree amplitudes [41,42]. Moreover, isospin-breaking effects such as $\left(\pi^0, \eta, \eta'\right)$ mixing would impact on the relations of Eq. (76.8). A further complication in the $B \to \rho\rho$ system is the effect of the non-zero ρ meson width [43]. Estimates of the size of these effects on the determined value of α are typically at the 1° level or less [31]. By contrast, methods to determine α using SU(3) or other flavour symmetries are generally considered to have larger theoretical uncertainties and are not included here.

The world average obtained for the angle α from isospin analysis of $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ decays is [4]

$$\alpha = (84.1\,^{+3.7}_{-3.0})°\,, \qquad (76.10)$$

where the quoted uncertainty is at the 68.3% CL and does not include effects due to isospin-breaking. This world average, together with results split by decay mode, is shown in Fig. 76.2. The combination has a total of 61 experimental inputs from which 24 parameters are determined, and an overall χ^2 of 28.63, which corresponds to a p-value of 84%. Thus, there is excellent overall consistency between the inputs, despite the tension apparent in

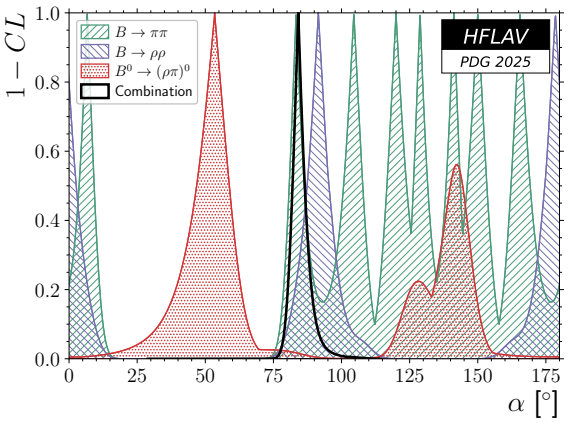

Figure 76.2: World average of α, as well as contributions from individual modes, in terms of 1−CL.

Fig. 76.2 between the results from $B^0 \to (\rho\pi)^0$ and the others. The combination gives a single best-fit for α in $[0°, 180°]$, but an ambiguous solution exists at $\alpha \Leftrightarrow \alpha{+}180°$. A secondary minimum close to zero is disfavoured [31].

76.4 γ

The angle γ is the weak phase between Cabibbo-favoured $b \to c$ and suppressed $b \to u$ quark transitions and can be determined by exploiting interference between them. Explicitly, the ratio of suppressed to favoured amplitudes is parameterized by

$$r_B e^{i(\delta_B \pm \gamma)} = \frac{A_{\rm sup}}{A_{\rm fav}} \,, \tag{76.11}$$

where r_B is the ratio of amplitude magnitudes, δ_B the strong phase difference and the + or − sign depends on whether the transition involves a $\bar{b}$ or b quark, respectively. Measurement of γ in this way has negligible theoretical uncertainty in the Standard Model [44], and therefore this approach provides a benchmark against which determinations from other methods, typically involving loop diagrams, can be compared.

Interference between these amplitudes is realised in $B^+ \to DK^+$ decays, where D represents an admixture of D^0 and $\overline{D}^0$ mesons. The simplest case is that of D decays to CP-eigenstates (GLW method [45, 46]), either CP-even such as K^+K^- ($CP{+}$) or CP-odd such as $K^0_S\pi^0$ ($CP{-}$). The normalized decay rate and CP asymmetry are given by

$$\begin{aligned} R_{CP\pm} &= \frac{\Gamma(B^- \to D_{CP\pm}K^-) + \Gamma(B^+ \to D_{CP\pm}K^+)}{\Gamma(B^- \to D^0K^-) + \Gamma(B^+ \to \overline{D}^0K^+)} \\ &= 1 + r_B^2 \pm 2r_B\cos(\delta_B)\cos(\gamma) \,, \qquad (76.12a) \\ A_{CP\pm} &= \frac{\Gamma(B^- \to D_{CP\pm}K^-) - \Gamma(B^+ \to D_{CP\pm}K^+)}{\Gamma(B^- \to D_{CP\pm}K^-) + \Gamma(B^+ \to D_{CP\pm}K^+)} \\ &= \frac{\pm 2r_B\sin(\delta_B)\sin(\gamma)}{1 + r_B^2 \pm 2r_B\cos(\delta_B)\cos(\gamma)} \,. \qquad (76.12b) \end{aligned}$$

These relations assume the absence of direct CP violation in the charm system; experimentally allowed deviations from this assumption are too small to cause a significant bias on γ [7, 47]. It is convenient to determine the $R_{CP\pm}$ quantities through a double ratio, normalizing to $B^+ \to D\pi^+$ decays involving the same final states, since this cancels potential sources of systematic uncertainty due to the branching fractions of the D decays that are used; small possible effects of CP violation in $B^+ \to D\pi^+$ decays are a source of systematic uncertainty in this procedure. The GLW method can be extended to include final states that are almost CP-eigenstates [48], as is the case in $D \to \pi^+\pi^-\pi^0$ and $D \to K^+K^-\pi^0$ decays, via inclusion of a factor encoding the fraction of CP-even (or CP-odd) content, $F_\pm$, which dilutes the sensitivity to γ by reducing the size of the interference terms (the terms linear with r_B) in Eq. (76.12).

For other D decays, the ratio of amplitudes for the D^0 and $\overline{D}^0$ decays to the final state of interest has to be accounted for in the formalism. The ADS method [49, 50] uses D decays to final states such as $K^\mp\pi^\pm$, which involve interference between Cabibbo-favoured (CF) and doubly-Cabibbo-suppressed (DCS) transitions. The observables in this case are

$$\begin{aligned} A_{\rm ADS} &= \frac{\Gamma(B^- \to [K^+\pi^-]_D K^-) - \Gamma(B^+ \to [K^-\pi^+]_D K^+)}{\Gamma(B^- \to [K^+\pi^-]_D K^-) + \Gamma(B^+ \to [K^-\pi^+]_D K^+)} \\ &= \frac{2r_B r_D \sin(\delta_B + \delta_D)\sin(\gamma)}{r_B^2 + r_D^2 + 2r_B r_D \cos(\delta_B + \delta_D)\cos(\gamma)} \,, \qquad (76.13a) \\ R_{\rm ADS} &= \frac{\Gamma(B^- \to [K^+\pi^-]_D K^-) + \Gamma(B^+ \to [K^-\pi^+]_D K^+)}{\Gamma(B^- \to [K^-\pi^+]_D K^-) + \Gamma(B^+ \to [K^+\pi^-]_D K^+)} \\ &= r_B^2 + r_D^2 + 2r_B r_D \cos(\delta_B + \delta_D)\cos(\gamma) \,, \qquad (76.13b) \end{aligned}$$

where r_D and δ_D are the amplitude magnitude ratio and strong phase difference between the CF and DCS D decay. An alternative pair of observables, (R_-, R_+), is also sometimes used, where R_- (R_+) is the ratio of decay rates between the suppressed and favoured transitions for B^- (B^+) decays. The R_- and R_+ observables are statistically independent, while $A_{\rm ADS}$ and $R_{\rm ADS}$ are not (in particular, the uncertainty on $A_{\rm ADS}$ depends on the central value of $R_{\rm ADS}$). However, the pair (R_-, R_+) has more correlated sources of systematic uncertainty compared to $(A_{\rm ADS}, R_{\rm ADS})$. The observables of Eq. (76.13) are therefore usually preferred once a significant signal is established. The ADS method can also be extended to include decays to multibody final states, such as $D \to K^\pm\pi^\mp\pi^0$ and $D \to K^\pm\pi^\mp\pi^+\pi^-$, by addition of a coherence factor [51] which appears in the interference terms of Eq. (76.13) and accounts for dilution of the sensitivity due to variation of the decay amplitude across the phase space of the final state. A similar method can be used for singly Cabibbo-suppressed D decays to non-CP eigenstates such as K^*K [52].

For D decays to multibody self-conjugate final states (BPGGSZ method [53,54]), such as $D \to K^0_S\pi^+\pi^-$, one can write the partial decay rate as a function of the position in the phase space in terms of the "Cartesian parameters" $x_\pm + iy_\pm = r_B e^{i(\delta_B \pm \gamma)}$:

$$\begin{aligned} d\Gamma(B^\pm \to [K^0_S\pi^+\pi^-]_D K^\pm) &= A^2_{(\mp,\pm)} + r_B^2 A^2_{(\pm,\mp)} \\ &+ 2A_{(\pm,\mp)}A_{(\mp,\pm)}[x_\pm c_{D(\pm,\mp)} + y_\pm s_{D(\pm,\mp)}], \end{aligned} \tag{76.14}$$

where the notation $(+,-)$ is shorthand for the dependence on the Dalitz-plot position — the squared invariant masses of $K^0_S\pi^+$ and $K^0_S\pi^-$ combinations, respectively. The quantities $A_{(+,-)}$ and $A_{(-,+)}$ represent the magnitudes of the D^0 and $\overline{D}^0$ decay amplitudes at the position $(+,-)$ and are interchangable with their CP conjugate amplitudes because CP conservation is assumed in the D decay (*i.e.* $A_{(-,+)} = \overline{A}_{(+,-)}$). The quantities $c_{D(\pm,\mp)}$ and $s_{D(\pm,\mp)}$ are the cosine and sine of the strong phase difference, $\delta_{D(+,-)} = \arg(\overline{A}_{(+,-)}) - \arg(A_{(+,-)})$, between the $\overline{D}^0$ and D^0 amplitudes. These quantities can be determined from an amplitude model, although this leads to a hard-to-quantify systematic uncertainty associated to the composition of the model. An alternative, "model-independent", approach involves dividing the phase space into appropriate bins. In this case, the analysis benefits from external input on the values of c_D and s_D integrated over each bin. Measurements of these external parameters have been performed for the $D \to K^0_S\pi^+\pi^-$ decay by the CLEO-c and BESIII collaborations [55–58]. The use of common input values for these parameters in model-independent determinations of γ with the BPGGSZ method by different experiments is a source of correlation between experiments that is currently negligible but will become more significant as the available B meson data samples increase in size.

The discussion above refers to $B^+ \to DK^+$ decays, but analogous measurements can be made also for additional channels such as $B^+ \to D^*K^+$ (with $D^* \to D\pi^0$, $D\gamma$) and $B^+ \to DK^{*+}$ (with $K^{*+} \to K^0_S\pi^+$, $K^+\pi^0$). In the limit that these can be treated purely as two-body decays, the expressions for $B^+ \to DK^+$ are modified only by ensuring the r_B and δ_B parameters are specific to each B decay. Moreover, for $B^+ \to D^*K^+$ decays an effective

shift of the strong phase by π between $D^* \to D\pi^0$ and $D\gamma$ decays [59] has to be taken into account. In case the finite width of the decaying resonance is non-negligible, as is the case for the $K^*(892)$ state, additional amplitudes can contribute leading to a dilution of the sensitivity, which can be accounted for in the formalism through the introduction of a relevant coherence factor. For the $B^0 \to DK^{*0}$ decay, full amplitude analysis of the $B^0 \to DK^+\pi^-$ Dalitz plot provides additional sensitivity compared to the quasi-two-body approach [60, 61].

It is also possible to measure γ using decay-time-dependent analysis of the B_s^0 meson [62]. The weak phase arising in the interference between direct decay of $B_s^0 \to D_s^\mp K^\pm$ and decay via mixing is $(\gamma - 2\beta_s)$, where β_s is the angle associated with $B_s^0 \to J/\psi\phi$ decays in a similar way to the relation between β and $B^0 \to J/\psi K_S^0$ decays described in Sec. 76.2. Sufficient information can be obtained from the tagged, decay-time-dependent rates of $B_s^0 \to D_s^\mp K^\pm$ decays that this weak phase can be determined, up to an ambiguity, together with the strong phase difference between, and the ratio of the magnitudes of, the suppressed and favoured amplitudes. Since β_s is known to good precision [8], measurements of the decay-time-dependent *CP*-asymmetry observables in $B_s^0 \to D_s^\mp K^\pm$ decays can be used to infer constraints on γ. Alternatively, if effects of penguin pollution in $B_s^0 \to J/\psi\phi$ decays [18, 19] are a concern, as they will become in the future, results from the $B_s^0 \to D_s^\mp K^\pm$ mode can be combined with an independent precise measurement of γ to provide a penguin-free determination of β_s.

The average for γ requires a non-trivial combination due the complicated relations between the observables and the physics parameters of interest, such as in Eqs. (76.12), (76.13) and (76.14). Moreover, hadronic parameters such as r_B and δ_B defined in Eq. (76.11) are common to all different D decay modes (but differ for each B decay mode). Thus, it is not correct to simply average results for γ obtained by different experiments or in different channels. Instead, measurements of rate asymmetries, rate ratios and the Cartesian parameters are taken as inputs to the combination, from which results are obtained not only for γ but also for the hadronic parameters. Independent measurements of auxiliary parameters such as r_D and δ_D are also treated as inputs to the combination. In some cases the B decay data can help to reduce uncertainties on these auxiliary parameters and therefore a simultaneous fit of charm and beauty data can provide stronger constraints [63]; this approach however is not currently used for the world average.

The precision to which γ can be measured with a particular B decay is approximately inversely proportional to the value of r_B. Thus, results from channels with smaller yields but larger values of r_B, such as $B^0 \to DK^{*0}$ and $B_s^0 \to D_s^\mp K^\pm$ ($r_B \approx 0.3$–0.4), can have a significant impact on the world average and are included in the combination. By contrast the $B^+ \to D\pi^+$ mode, for which large samples are available but $r_B \approx 0.005$, has little impact and is also more sensitive to potential systematic biases; hence it is not included. The sensitivity of the world average at present is dominated by results from $B^+ \to DK^+$, where $r_B \approx 0.1$, in particular results with the GLW [64], ADS [64] and BPGGSZ [65] methods.

The world average obtained for the angle γ, obtained by combining results from $B^+ \to DK^+$, D^*K^+, DK^{*+}, $DK^+\pi^+\pi^-$, $B^0 \to DK^+\pi^-$, $B_s^0 \to D_s^\mp K^\pm$ and $B_s^0 \to D_s^\mp K^\pm\pi^+\pi^-$ decays, is

$$\gamma = \left(66.4^{+2.7}_{-2.8}\right)^\circ \ , \qquad (76.15)$$

where the quoted uncertainty is at the 68.3% CL.

Effects related to charm and kaon mixing and *CP* violation are generally negligible at the current level of precision, in particular for modes with $r_B \gtrsim 0.1$. An exception is that a dependence of the selection efficiency on the charm decay time can induce a dependence of the observables on charm mixing parameters [66]. Such effects can be important at hadron collider experiments such as LHCb, but can be and are corrected for. Interactions of neutral kaons with detector material can also cause a bias in determination of γ from modes with low values of r_B [67], such as the BPGGSZ method applied to $B^+ \to D\pi^+$, but are negligible in modes with larger r_B values. A further subtlety is that the identification of the weak phase between suppressed and favoured amplitudes in $B \to DK$ decays with γ, as defined in Eq. (76.2), assumes that the 2×2 submatrix of the CKM matrix is real, *i.e.* that $\arg\left[V_{ud}V_{us}^*/\left(V_{cd}V_{cs}^*\right)\right] = 0$. This is true to an excellent approximation in the Standard Model, and is known experimentally from independent studies of the charm system [47] to contribute negligible bias to current measurements. Nonetheless, in future it will be possible to test directly this assumption by comparing the value of γ obtained from the $B \to DK$ and $B \to D\pi$ systems.

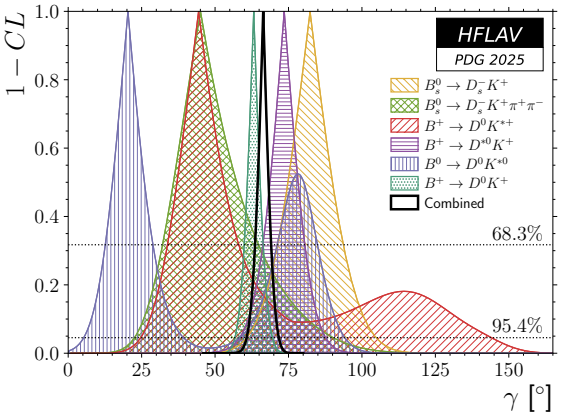

Figure 76.3: World average of $\gamma \equiv \phi_3$, as well as contributions from individual modes, in terms of 1−CL.

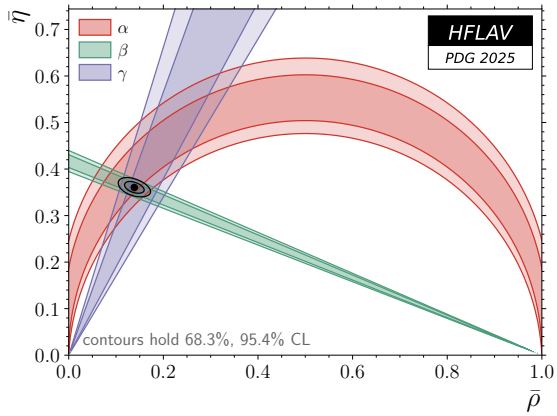

Figure 76.4: Constraints from the measurements of the angles of the CKM unitarity triangle in the $(\overline{\rho}, \overline{\eta})$ plane.

Effects from correlated uncertainties between amplitude models and strong phase differences in charm decays are negligible and are not explicitly accounted for in the combination, nor are effects related to charm and kaon mixing and *CP* violation. This world average, together with results split by decay mode, is shown in Fig. 76.3. The combination has a total of 178 experimental inputs from which 36 parameters are determined, and an overall χ^2 of 159.89, which corresponds to a p-value of 15% indicating reasonable agreement between the inputs. The combination gives a single solution for γ in $[0°, 180°]$, but an ambiguous solution exists at $\gamma \Leftrightarrow \gamma + 180°$.

76.5 Summary

Experimental progress has resulted in all three angles of the CKM unitarity triangle being measured with good accuracy, with β known to subdegree precision and both α and γ known to better than 5°. The constraints from these three measurements in the $(\overline{\rho}, \overline{\eta})$ plane are shown in Fig. 76.4; further discussion and comparison with constraints from independent measurements can be found in Ref. [6]. The determinations of all three angles remain statistically limited, but it will be a challenge for experiments to

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

ensure that this remains the case as the precision improves. Consequently, the correct treatment of sources of correlation between the measurements that go into the world average combinations is becoming increasingly important.

77. Spectroscopy of Mesons Containing Two Heavy Quarks

Revised October 2025 by J.J. Hernández-Rey (IFIC, Valencia), C. Lourenço (CERN), R.E. Mitchell (Indiana U.), S. Navas (Granada U.) and C. Patrignani (Bologna U.).

A golden age for heavy quarkonium physics dawned at the turn of this century, triggered by the confluence of new approaches to non-perturbative quantum chromodynamics (QCD) and a series of experimental results. The subsequent broad spectrum of breakthroughs, surprises, and continuing puzzles had not been anticipated. Indeed, CLEO-c, BESIII, and the B-factories, later joined by ATLAS, CMS and LHCb, have made a series of groundbreaking observations. For an extensive presentation of the status of heavy quarkonium physics, the reader is referred to several reviews [1–10]. This note focuses on experimental developments in heavy quarkonium spectroscopy with very few theoretical comments. Possible theoretical interpretations of the states with properties incompatible with the quark model are presented in the review "Heavy non-$q\bar{q}$ mesons". Note that in this review we follow the new naming scheme for hadrons (see the review "Naming scheme for hadrons" in the current edition of the RPP).

This review covers states discovered since 2003, the year that marked the unexpected discovery of the $X(3872)$ [11]. The $X(3872)$, now called $\chi_{c1}(3872)$, was the first of the mesons containing two heavy quarks that could not be easily accommodated by the $q\bar{q}$ quark model. Its discovery was a watershed event in meson spectroscopy. In earlier versions of this write-up the particles were sorted according to an assumed *conventional* or *unconventional* nature with respect to the quark model. However, since this classification is not always unambiguous, we here follow Ref. [12] and sort the states into three groups, namely states below (*cf.* Table 77.1), above (*cf.* Table 77.2), and near (*cf.* Table 77.3) the lowest open-flavor thresholds. Due to the presence of many open-flavor thresholds, we note that the division of states between "above" and "near" open-flavor thresholds is not absolute.

77.1 States Below Open-Flavor Threshold

Table 77.1 lists properties of recently observed heavy quarkonium states located below the lowest open-flavor thresholds. Those are expected to be (at least prominently) conventional quarkonia. The majority of charmonium ($c\bar{c}$) and bottomonium ($b\bar{b}$) states were established prior to 2003.

77.1.1 *Charmonium*

The $h_c(1P)$ is the 1^1P_1 charmonium state, the singlet partner of the long-known χ_{cJ} triplet 1^3P_J. After being firmly established in 2005 through the process $\psi(2S) \to \pi^0 h_c(1P)$ [13], it has since been studied extensively by BESIII using large samples of $\psi(2S)$ decays. Exclusive hadronic decays of the $h_c(1P)$, strongly suppressed relative to the dominant radiative transition $h_c(1P) \to \gamma\eta_c(1S)$, were first observed in 2019 [14] and additional decays were found in 2020 [15] and 2022 [16].

Belle reported an observation of the $\psi_2(1D)$ decaying to $\gamma\chi_{c1}(1P)$ with J^{PC} presumed to be 2^{--} [17]. This state is listed in Table 77.1 as $\psi_2(3823)$. Its existence was confirmed with high significance by BESIII [18, 19]. While the negative C-parity is indeed established by its observed decay channel, the assignment of $J = 2$ was made by matching to the closest quark model state (1^3D_2) and requires experimental confirmation.

The 1^1D_2 state, or the $\eta_{c2}(1D)$, with a mass expected near 3820 MeV, has not yet been observed. Recently Belle performed a search in $B \to \eta_{c2}(1D)K(\pi)$ decays in the mass range 3795–3845 MeV and found no signal [20]. Thus, the $\eta_{c2}(1D)$ remains the only unobserved conventional charmonium state that does not have open-charm decays.

77.1.2 *Bottomonium*

The ground state of bottomonium, $\eta_b(1S)$, is well established. After the initial reports from BaBar in radiative decays of the $\Upsilon(3S)$ (observation) [21] and $\Upsilon(2S)$ (evidence) [22], Belle confirmed the existence of the $\eta_b(1S)$ with more than 5σ significance in radiative decays of the newly discovered $h_b(1P)$ [23, 24] and $h_b(2P)$ [23] (see next paragraph), as well as in $\Upsilon(2S)$ radiative decays [25]. Belle has also reported strong evidence for the $\eta_b(2S)$ [23], but it still needs confirmation at the 5σ level. Note that there are hints of tension in the $\eta_b(1S)$ mass as measured in radiative M1 and E1 transitions. In the M1 transition $\Upsilon(2S) \to \gamma\eta_b(1S)$ Belle measures a mass of $9394.8^{+2.7+4.5}_{-3.1-2.7}$ MeV [25], while in the E1 transitions $h_b(1P, 2P) \to \gamma\eta_b(1S)$ Belle measures $9402.4 \pm 1.5 \pm 1.8$ MeV [23]. This tension may point to an incomplete understanding of the $\eta_b(1S)$ lineshape in different production mechanisms.

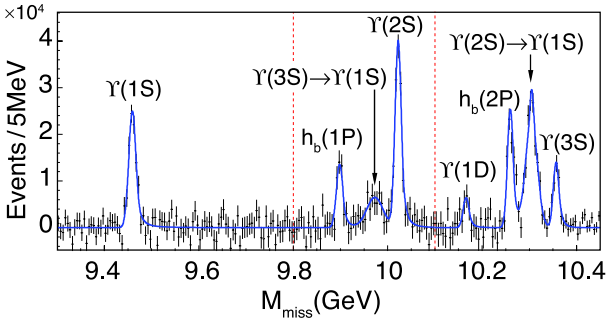

Figure 77.1: From Belle [26], the mass recoiling against $\pi^+\pi^-$ pairs, $M_{\rm miss}$, in e^+e^- collision data taken near the peak of the $\Upsilon(10860)$. The smooth combinatorial and $K^0_S \to \pi^+\pi^-$ background contributions have been subtracted. The fit to the various labeled signal contributions is overlaid (*curve*). The fit is performed separately in three regions with boundaries indicated by the vertical dashed lines.

The $h_b(1P)$, the bottomonium counterpart of the $h_c(1P)$, and the next excited state, the $h_b(2P)$, were simultaneously discovered by Belle using dipion transitions from the $\Upsilon(10860)$ [26] (Fig. 77.1). The same analysis also showed the $\Upsilon_J(1D)$, the lowest-lying D-wave triplet of the $b\bar{b}$ system, but did not resolve the $J = 1, 2, 3$ components. The search for the $h_b(1P)$ was directly inspired by a CLEO result [27], which found a surprisingly copious production of $e^+e^- \to \pi^+\pi^- h_c(1P)$ as well as an indication that $\psi(4230) \to \pi^+\pi^- h_c(1P)$ occurs at a comparable rate with the signature mode $\psi(4230) \to \pi^+\pi^- J/\psi(1S)$. The presence of $\Upsilon(nS)$ peaks in Fig. 77.1 at rates two orders of magnitude larger than expected, along with separate studies with exclusive decays $\Upsilon(nS) \to \mu^+\mu^-$, allow precise calibration of the $\pi^+\pi^-$ recoil mass spectrum and very accurate measurements of the $h_b(1P)$ and $h_b(2P)$ masses. Both corresponding hyperfine splittings are consistent with zero within an uncertainty of about 1.5 MeV (lowered to 1.1 MeV for the $h_b(1P)$ in Ref. [28]). Belle later observed the transition $\Upsilon(4S) \to h_b(1P)\eta$ [24] and the corresponding 1P hyperfine splitting was also found to be compatible with zero at a similar precision level.

Just before Christmas 2011, ATLAS offered the world a beautiful gift, in the form of the discovery of the $\chi_b(3P)$ quarkonium state [29], observed by combining dimuons from $\Upsilon(1S)$ or $\Upsilon(2S)$ decays with photons emitted in the radiative $\chi_b(3P)$ decays (Fig. 77.2, bottom left panel). The new resonance, with a mass of $10\,530 \pm 5(\text{stat}) \pm 9(\text{syst})$ MeV, was soon confirmed by D0 [30]. Also LHCb observed the $\chi_b(3P)$ peak, using the full Run 1 event sample, corresponding to an integrated luminosity of 3 fb^{-1} [31] (Fig. 77.2, middle left panel). Finally, CMS used 80 fb^{-1} of 13 TeV pp collisions, collected in 2016 and 2017, to show two well-resolved $\chi_{b1}(3P)$ and $\chi_{b2}(3P)$ peaks [32], separated by a mass difference of $10.60 \pm 0.64(\text{stat}) \pm 0.17(\text{syst})$ MeV (Fig. 77.2, top left panel). The remarkable precision of the individual mass measurements, with relative uncertainties as small as 50 ppm, shows that the LHC experiments can provide important results in the field of hadron spectroscopy, especially in the case of heavy particles, which require very high collision energies and large event samples.

77.1.3 B_c *System*

The $B_c^\pm$ family is quite special because these (charged) quarkonium states consist of two heavy quarks of different flavor. Among

Table 77.1: New states below the open-flavor thresholds in the $c\bar{c}$, $b\bar{c}$, and $b\bar{b}$ regions, ordered by mass. Masses m and widths Γ represent the PDG25 weighted averages with statistical and systematic uncertainties added in quadrature. In the Production column, the state is always denoted by X. Ellipses (...) indicate inclusively selected event topologies, *i.e.*, additional particles not directly detected by experiment. A question mark (?) indicates an unmeasured value. The Discovery Year column gives the date of the first measurement cited. The Summary Table column indicates whether or not the state appears in the summary tables, usually requiring at least two independent experiments with significance of $>5\sigma$. Refer to the particle listings for references and further information.

*The B_c^+ decays only weakly and has a lifetime of 0.510 ± 0.009 ps ($\Gamma \approx 1.3 \times 10^{-9}$ MeV).

†The observed structure in γB_c^+ is described by two Gaussian functions and is consistent with contributions from $^3P_0$, $^3P_2$, and mixed $^3P_1$ and $^1P_1$ states decaying to both γB_c^+ and γB_c^{*+}.

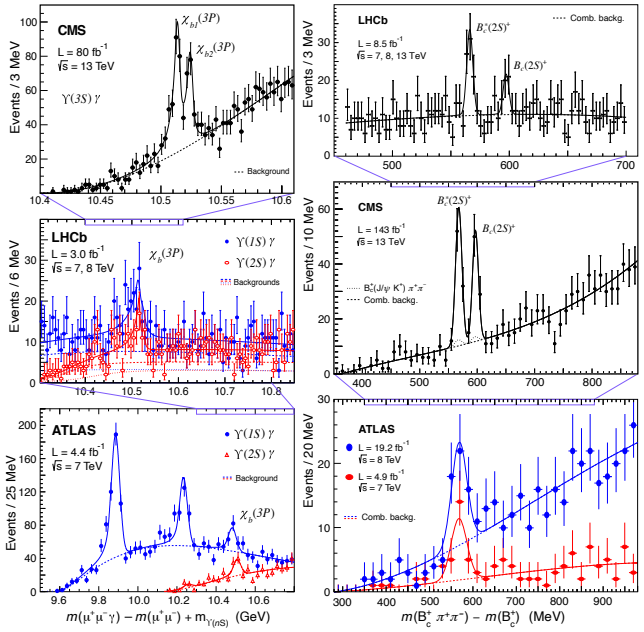

Figure 77.2: (Left Column) Invariant mass distributions measured by the ATLAS [29] (bottom), LHCb [31] (middle) and CMS [32] (top) experiments in their searches for the $\chi_b(3P)$ states through their radiative decays to one of the S-wave bottomonia. (Right Column) Invariant mass distributions measured by the ATLAS [33] (bottom), CMS [34] (middle) and LHCb [35] (top) experiments in their searches for $B_c^\pm$ excited states decaying to the $B_c^\pm$ ground state with the emission of two charged pions.

other interesting properties, this means that they cannot annihilate into gluons, the excited states only decaying to the pseudoscalar ground state, $B_c^\pm$, via electromagnetic and pionic transitions.

On the basis of an event sample collected in the Run 1 of the LHC, corresponding to an integrated luminosity of 24 fb^{-1}, adding the 7 and 8 TeV data, the ATLAS Collaboration observed a resonance in the $B_c^+\pi^+\pi^-$ invariant mass spectrum [33] (Fig. 77.2, bottom right panel). This peak, observed with a significance of 5.2 standard deviations and a mass of $6842 \pm 4(\text{stat}) \pm 5(\text{syst})$ MeV, was immediately recognized as the $B_c(2S)^\pm$ state, the first radial excitation in the $B_c^\pm$ family. Profiting from the much larger Run 2 event sample, corresponding to 143 fb^{-1} of 13 TeV pp collisions, as well as from a measurement resolution of around 6 MeV, the CMS Collaboration could observe *two* well-resolved peaks, separated by $29.1 \pm 1.5(\text{stat}) \pm 0.7(\text{syst})$ MeV [34] (Fig. 77.2, middle right panel). The existence of two peaks, rather than a single one, is established with a significance of 6.5 standard deviations. The "right peak" has a mass of $6871.0 \pm 1.2(\text{stat}) \pm 0.8(\text{syst}) \pm 0.8(B_c^+)$ MeV, where the last term is the uncertainty in the B_c^+ mass, and is identified as the $B_c(2S)^\pm$ state, which decays directly to the $B_c^\pm$, emitting two (easy to detect) pions. The CMS observation, reported a couple of months after the end of the LHC Run 2, was soon followed by the corresponding LHCb result [35] (Fig. 77.2, top right panel), which confirmed the existence of the two states and reported a second measurement of the $B_c(2S)^\pm$ mass, $6872.1 \pm 1.3(\text{stat}) \pm 0.1(\text{syst}) \pm 0.8(B_c^+)$ MeV.

The "left peak" is interpreted as being the $B_c^*(2S)^\pm$ signal. It is observed at a mass lower than the real value because the experiments are unable to detect the low-energy photon emitted in the decay chain, $B_c^*(2S)^\pm \to B_c^{*\pm}\pi^+\pi^-$ followed by $B_c^{*\pm} \to B_c^\pm\gamma$ (Fig. 77.3). Its energy, expected to be in the range 40–80 MeV, leads to a very small probability that the photon converts into an e^+e^- pair and the two electrons are reconstructed. The relative ordering of the two peaks is based

on a generally-agreed assumption: the $M(B_c^{*\pm}) - M(B_c^{\pm})$ mass difference is larger than the $M(B_c^*(2S)^{\pm}) - M(B_c(2S)^{\pm})$ difference. Naturally, these observations provide evidence for the existence of the $B_c^*(1S)^{\pm}$ state. They also provide measurements of two interesting mass differences, between the masses of the pseudoscalar mesons, $M(B_c(2S)^{\pm}) - M(B_c(1S)^{\pm}) = 596.1$ MeV, and of the vector mesons, $M(B_c^*(2S)^{\pm}) - M(B_c^*(1S)^{\pm}) = 567.0$ MeV (Fig. 77.3).

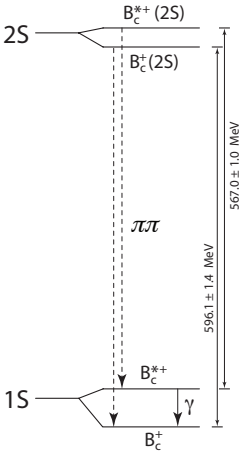

Figure 77.3: Diagram showing the decays mentioned in the text.

77.2 States Above Open-Flavor Threshold

Many states have been discovered both above and near the lowest open-flavor thresholds. They are displayed in Tables 77.2 and 77.3, respectively. With the exception of the $\psi_3(3842)$ and the tensor state located at 3930 MeV (now called $\chi_{c2}(3930)$), which have properties consistent with those expected for the $\psi_3(1^3D_3)$ and $\chi_{c2}(2^3P_2)$, respectively, none of these states can easily be assigned a place in the quark model spectrum of the charmonium or bottomonium families. The theoretical interpretation of these states remains under discussion.

77.2.1 *Charmonium*

Using proton-proton collisions, LHCb observed a narrow state, the $\psi_3(3842)$ resonance, in the decay modes $\psi_3(3842) \to D^0\bar{D}^0$ and D^+D^- [36]. The mass and width of this state are measured to be $3842.71 \pm 0.16 \pm 0.12$ MeV and $2.79 \pm 0.51 \pm 0.35$ MeV, respectively. The observed mass and narrow width are consistent with expectations for the spin-3 $\psi_3(1^3D_3)$ charmonium. Accordingly, the state is given the name $\psi_3(3842)$ in the listings, with the remark that the quantum numbers are fixed from the quark model and need to be confirmed.

The $\chi_{c2}(3930)$, which is a natural candidate for the $\chi_{c2}(2^3P_2)$ quark model state, was originally seen by Belle [37] and later confirmed by BaBar [38] in the $\gamma\gamma$ process $e^+e^- \to e^+e^-D\bar{D}$. This interpretation was strengthened by the more recent LHCb observation of the $\chi_{c2}(3930)$ alongside the $\psi_3(3842)$ in proton-proton collisions [36].

Unlike the $\chi_{c2}(2^3P_2)$, the identification of the $\chi_{c0}(2^3P_0)$ quark model state remains controversial. The original candidate was the $\chi_{c0}(3915)$, discovered by Belle in the $\gamma\gamma$ process $e^+e^- \to e^+e^-\omega J/\psi(1S)$ [39]. In a subsequent measurement by BaBar, its quantum numbers were determined to be $J^{PC} = 0^{++}$ [40]. However, its identification as the $\chi_{c0}(2^3P_0)$ quark model state was soon challenged [41, 42]. In addition, it was pointed out in Ref. [43] that if the assumption of helicity-2 dominance is abandoned and, instead, one allows for a sizeable helicity-0 component, a $J^{PC} = 2^{++}$ assignment is possible. This could imply that it is the same as the $\chi_{c2}(3930)$, but to explain the large helicity-0 component a sizable portion of non-$q\bar{q}$ is necessary [43]. A more recent LHCb amplitude analysis of the process $B^+ \to D^+D^-K^+$ finds distinct 0^{++} and 2^{++} components decaying to D^+D^- [44], which are currently identified in the listings as the $\chi_{c0}(3915)$ and $\chi_{c2}(3930)$, respectively.

An alternative candidate for the $\chi_{c0}(2^3P_0)$ (here referred to as the $\chi_{c0}(3860)$) was reported in Ref. [45] with properties more consistent with expectation: its mass is close to the potential model expectations, it decays to $D\bar{D}$, and the preferred quantum numbers are $J^{PC} = 0^{++}$ (this hypothesis is favored over the 2^{++} one with a 2.5σ significance).

In the excited vector charmonium spectrum, the $\psi(4040)$, $\psi(4160)$, and $\psi(4415)$ are prominent in the inclusive e^+e^- hadronic cross section and are naturally identified as the 3^3S_1, 2^3D_1, and 4^3S_1 $c\bar{c}$ quark model states, respectively. In addition to these long-established states, however, another set of peaks has been found in exclusive e^+e^- cross sections. Unlike conventional vector charmonia, they do not appear in the inclusive hadronic cross section and they apparently do not decay to $D^{(*)}\bar{D}^{(*)}$. The PDG summary table currently lists the $\psi(4230)$, $\psi(4360)$, and $\psi(4660)$ within this category. The first of these to be discovered was originally known as the $Y(4260)$ (now the $\psi(4230)$), seen by BaBar [46] and Belle [47, 48] in $e^+e^- \to \pi^+\pi^- J/\psi(1S)$ using initial state radiation. In a more recent high-statistics scan of $e^+e^- \to \pi^+\pi^- J/\psi(1S)$, BESIII demonstrated that the lineshape in this mass range is highly non-trivial [49]. The latter observation was interpreted by the authors as the presence of two states. This interpretation was supported by the coupled-channel analysis in Ref. [50]. However, this lineshape is also consistent with other possible interpretations, such as one assuming a molecular structure for the $\psi(4230)$ [51,52]. The data of Ref. [49] also called for a significant downward shift of the mass of what was originally called the $Y(4260)$, making it consistent with the masses (but not necessarily the widths) of peaks in other exclusive cross sections, such as $h_c(1P)\pi\pi$ [53]. We thus merged the original $Y(4260)$ (or, more formally, the $\psi(4260)$) with the $\psi(4230)$ in the listings.

BESIII observed the $\chi_{c1}(3872)$, also known as $X(3872)$, in $e^+e^- \to \gamma\chi_{c1}(3872)$ in the $\psi(4230)$ mass range [54], which could allow for additional insight into the structure of both states (see the review "Heavy non-$q\bar{q}$ mesons"). BESIII also performed a recent study of the process $e^+e^- \to \pi^+\pi^-\psi(2S)$ and found evidence for a lower mass state, possibly the $\psi(4230)$, in addition to the more dominant $\psi(4360)$ [55].

Another interesting question is whether a heavier $\pi^+\pi^-\psi(2S)$ state, the $\psi(4660)$, discovered by Belle [56, 57] and confirmed by BaBar [58], is identical to the $\Lambda_c^+\bar{\Lambda}_c^-$ resonance observed by Belle with a nearby mass and width [59]. Most probably it is, the $\Lambda_c^+\bar{\Lambda}_c^-$ being one more decay mode of the $\psi(4660)$ (see the review "Heavy non-$q\bar{q}$ mesons" for more details). Note that this is the interpretation adopted in the particle listings. In addition, Belle reported the first observation of a vector charmonium-like state decaying to $D_s^+D_{s1}(2536)$ with a significance of 5.9σ [60]. Its measured mass and width are $4625.9^{+6.2}_{-6.0} \pm 0.4$ MeV and $49.8^{+13.9}_{-11.5} \pm 4.0$ MeV, respectively, consistent with those of the $\psi(4660)$. Therefore, $D_s^+D_{s1}(2536)$ appears as an additional decay mode of the $\psi(4660)$ in the listings.

A series of isovector states[1] containing $c\bar{c}$ have been found in B decays to $K\pi(c\bar{c})$, where the isovector state decays to $\pi(c\bar{c})$ and $(c\bar{c})$ stands for $J/\psi(1S)$, $\psi(2S)$, or $\chi_{c1}(1P)$. They are manifestly non-$q\bar{q}$. The $T_{c\bar{c}1}(4430)$ (originally called the $Z_c(4430)$), decaying to $\pi\psi(2S)$, is the most well established state in this group. Based on a full amplitude analysis of $B^0 \to K^+\pi^-\psi(2S)$ decays, Belle determined the spin-parity of the $T_{c\bar{c}1}(4430)$ to be $J^P = 1^+$ [61]. From their study of $B^0 \to K^+\pi^- J/\psi(1S)$ decays, Belle also found evidence for the decay mode $T_{c\bar{c}1}(4430) \to \pi J/\psi(1S)$ [62], which has an order of magnitude lower branching fraction than the discovery mode $T_{c\bar{c}1}(4430) \to \pi\psi(2S)$. In the same analysis, Belle reported evidence for one more charged state, dubbed $T_{c\bar{c}1}(4200)$, decaying to $\pi J/\psi(1S)$. The observation of the $T_{c\bar{c}1}(4430)$ in $\pi\psi(2S)$, as well as its quantum number assignments, were confirmed by LHCb [63] with a much larger data sample, leading to improved mass and width values, consistent with earlier measurements; the experiment even reports a resonant behavior of the $T_{c\bar{c}1}(4430)$ amplitude. The $T_{c\bar{c}1}(4430)$ was not confirmed (or excluded) by BaBar [64].

[1] These isovector states were originally called Z_c. They are now referred

*Quantum numbers fixed from the quark model and need confirmation.

Belle also reported an observation of two charged states decaying to $\pi\chi_{c1}(1P)$ in an analysis of $B^0 \to K^+\pi^-\chi_{c1}(1P)$ decays [65]. These were originally called $Z_1(4050)^\pm$ and $Z_2(4250)^\pm$, but are referred to in Table 77.2 as $T_{c\bar{c}}(4050)$ and $T_{c\bar{c}}(4250)$. These states were not confirmed by BaBar [66]. Belle observes signals with 5.0σ significance for both the $T_{c\bar{c}}(4050)$ and $T_{c\bar{c}}(4250)$, whereas BaBar reports 1.1σ and 2.0σ effects, respectively, setting upper limits that are not inconsistent with Belle's measured rates. The situation remains unresolved.

The decay $B^+ \to K^+\phi J/\psi(1S)$ appears to be especially rich in resonant substructure. The $Y(4140)$ (now the $\chi_{c1}(4140)$), decaying to $\phi J/\psi(1S)$, was first observed in 2008 by CDF [67, 68], and confirmed by D0 and CMS [69, 70]. However, a second structure, the $Y(4274)$ (now the $\chi_{c1}(4274)$), could not be established unambiguously. Neither of the two states was seen in B decays at Belle [71], LHCb [72] and BaBar [73], or in $\gamma\gamma$ collisions at Belle [74]. The real breakthrough happened when LHCb performed a full amplitude analysis of $B^+ \to K^+\phi J/\psi(1S)$ with $J/\psi(1S) \to \mu^+\mu^-$, $\phi \to K^+K^-$ decays and showed that the data cannot be described in a model that contains only excited kaon states decaying into $K^+\phi$ [75, 76]. They observe two 1^{++} states with masses close to those originally reported by CDF (the $\chi_{c1}(4140)$ and $\chi_{c1}(4274)$), but the width of the one at 4140 MeV is much larger. In addition, they find two significant 0^{++} structures

to as $T_{c\bar{c}}$. See the "Naming scheme for hadrons" review.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

at 4500 and 4700 MeV (the $\chi_{c0}(4500)$ and $\chi_{c0}(4700)$). The LHCb analysis was extended even further in Ref. [77] with a factor of six increase in statistics: the $\chi_{c1}(4140)$, $\chi_{c1}(4274)$, $\chi_{c0}(4500)$, and $\chi_{c0}(4700)$ were confirmed, and two new states, the $X(4630)$ and $\chi_{c1}(4685)$ were reported, also decaying to $\phi J/\psi(1S)$. Note that the properties (or even the existence) of these states are sensitive to the parameterization of the amplitudes and, in particular, to the treatment of thresholds [78].

77.2.2 *Resonances in the $J/\psi(1S)$-pair mass spectrum*

Based on proton-proton event samples collected at $\sqrt{s} = 7$, 8 and 13 TeV, corresponding to an integrated luminosity of 9 fb^{-1}, the LHCb Collaboration reported the observation of a narrow structure in the invariant mass distribution of $J/\psi(1S)$ pairs [79]. The new resonance, denoted as $T_{cc\bar{c}\bar{c}}(6900)$ (also $X(6900)$), is clearly seen at a mass of 6.9 GeV in the bottom panel of Fig. 77.4, as indicated by the red curve. The ATLAS Collaboration has also

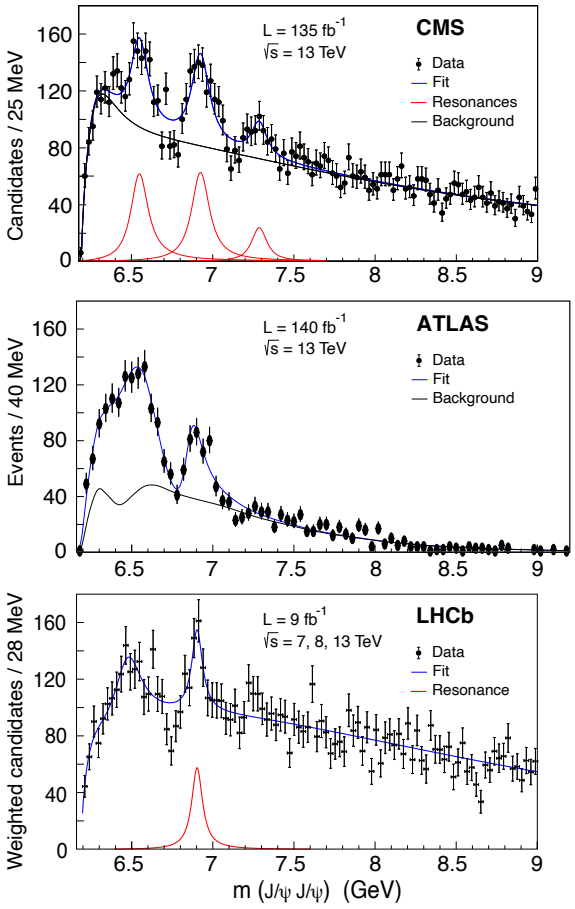

Figure 77.4: $J/\psi(1S)$-pair invariant mass distributions measured by the LHCb [79] (bottom), ATLAS [80] (middle), and CMS [81] (top) experiments.

observed the $T_{cc\bar{c}\bar{c}}(6900)$ resonance in the di-$J/\psi(1S)$ mass spectrum, using 140 fb^{-1} of pp collisions at $\sqrt{s} = 13$ TeV [80], as can be seen in the middle panel of Fig. 77.4. More recently, also the CMS Collaboration reported the observation of the $T_{cc\bar{c}\bar{c}}(6900)$ in the $J/\psi(1S)$-pair mass distribution, using 135 fb^{-1} of 13 TeV pp collisions [81]. Thanks to its good mass resolution and relatively large event yields, CMS determined the mass and width of the $T_{cc\bar{c}\bar{c}}(6900)$ with the best precision among the three measurements. Furthermore, another resonance is seen with a significance exceeding 5 standard deviations, at a mass of 6.55 GeV, as shown in the top panel of Fig. 77.4. The measured values of the masses and widths of the new states depend on whether the model used to fit the distributions includes interference effects between the resonances and the underlying continuum (and also among the resonances). In addition, fits that incorporate the scattering of vector charmonia to explain the structure in the $J/\psi(1S)$-pair mass distribution indicate the possible existence of a state very close to the di-$J/\psi(1S)$ threshold [82–85]. The larger event samples presently being collected by the LHC experiments will surely lead to significantly improved measurements, as well as to complementary results (including determinations of spin-parity quantum numbers), so that one can expect near-future progress in our understanding of the nature of these "narrow structures".

77.2.3 *Bottomonium*

In 2019, Belle reported a measurement of the $e^+e^- \to \Upsilon(nS)\pi^+\pi^-$ ($n = 1, 2, 3$) cross sections at energies from 10.52 to 11.02 GeV [86]. They observed, with a 5.2σ significance, a new structure with a mass near 10753 MeV in the energy dependence of the cross sections. The observation of the $\Upsilon(10753)$ was confirmed by Belle II using a dedicated energy scan with a total integrated luminosity of 19 fb^{-1} [87]. If the combined Belle and Belle II data is described by a Breit–Wigner function, the mass and width of the $\Upsilon(10753)$ are $10756.6 \pm 2.7 \pm 0.9$ MeV and $29.0 \pm 8.8 \pm 1.2$ MeV, respectively. The $\Upsilon(10753)$ was also seen by Belle II in the process $e^+e^- \to \omega\chi_{bJ}(1P)$ using data from the same energy scan [88]. The new structure could have a resonant origin and correspond to the not yet observed $\Upsilon(3D)$ state, provided $S-D$ mixing is enhanced, or an exotic state, e.g., a compact tetraquark or hadrobottomonium. It could also be a non-resonant effect due to rescattering. The $\Upsilon(10753)$ was confirmed in a global K-matrix fit to exclusive and inclusive $e^+e^- \to b\bar{b}$ cross sections in Ref. [89].

We no longer mention a hypothetical $Y_b(10888)$ state since a new analysis of the $\Upsilon(10860)$ energy range does not show evidence for an additional state with a mass different from that of the $\Upsilon(10860)$ [90]. After the mass of the $\eta_b(1S)$ was shifted upwards by about 10 MeV based on the Belle measurements [23,24], all of the bottomonium states mentioned above fit into their respective spectroscopies, roughly where expected. An independent experimental confirmation of the shifted masses came from the Belle observation of $\Upsilon(4S) \to \eta h_b(1P)$ decays [24]. This process turns out to be the strongest observed transition of the $\Upsilon(4S)$ to lower bottomonium states.

77.3 States Near Open-Flavor Threshold

A number of states, listed in Table 77.3, appear near open-flavor thresholds, which is likely an important factor in their theoretical interpretation [91].

77.3.1 *Charmonium*

The $\chi_{c1}(3872)$, also known as $X(3872)$, is widely studied and seen in many transitions — see Table 77.3. Yet its interpretation remains unsettled (see the review "Heavy non-$q\bar{q}$ mesons"). Its unique experimental features include: it has $J^{PC} = 1^{++}$ [92,93], yet it is too light to be the $\chi_{c1}(2^3P_1)$ quark model state; its mass is within 200 keV of the $D^0\bar{D}^{0*}$ threshold; it shows substantial isospin-breaking in its decays to $\rho J/\psi(1S)$ and $\pi^0\chi_{c1}(1P)$; and it is extremely narrow. Using a large sample of inclusively produced $\chi_{c1}(3872)$ decaying to $\pi^+\pi^- J/\psi(1S)$, LHCb recently determined the decay width of the $\chi_{c1}(3872)$ under two different assumptions [94]. Assuming a Flatté-inspired line shape and exploiting the strong coupling of the $\chi_{c1}(3872)$ to $D^0\bar{D}^{*0}$, LHCb performed the first exploration of the pole structure of the $\chi_{c1}(3872)$, finding a FWHM width of $0.22^{+0.06+0.25}_{-0.08-0.17}$ MeV. On the other hand, assuming a Breit–Wigner line shape, its width was found to be $1.39 \pm 0.24 \pm 0.10$ MeV. While the former analysis has a more firm theoretical foundation, the LHCb detector resolution did not allow for a distinction between the different line shapes. More recently, BESIII studied the line shape of the $\chi_{c1}(3872)$ by simultaneously fitting the $e^+e^- \to \gamma\chi_{c1}(3872) \to \gamma\left[D^0\bar{D}^0\pi^0\right]$ and $\gamma\left[J/\psi\pi^+\pi^-\right]$ reactions [95]. Two poles were found on the first and second Riemann sheets corresponding to the $D^{*0}\bar{D}^0$ channel, the most prominent being at $(3871.70 \pm 0.15^{+0.07}_{-0.08}) - i(0.19 \pm 0.08^{+0.14}_{-0.19})$ MeV on the first sheet, confirming the sub-MeV width found by LHCb.

In addition to the $T_{c\bar{c}}$ (also known as Z_c) states found in B decays, discussed above, several isovector states with masses near

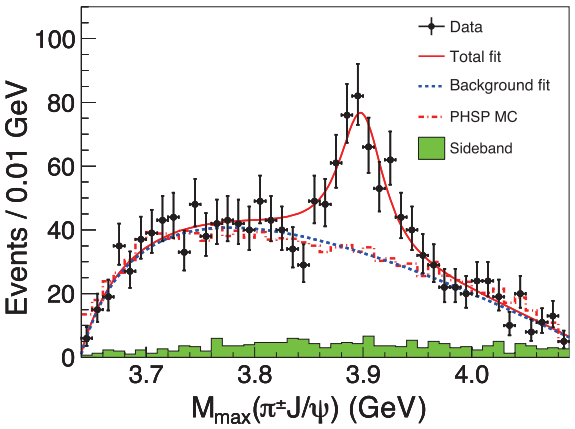

Figure 77.5: The $\pi^\pm J/\psi(1S)$ invariant mass distribution from BESIII [97] e^+e^- collision data taken at a center-of-mass energy near 4260 MeV.

$D\bar{D}^*$ and $D^*\bar{D}^*$ thresholds appear to be unique to e^+e^- annihilation. In 2013, a state named $T_{c\bar{c}1}(3900)$ (originally $Z_c(3900)$) was unearthed in the charmonium region at BESIII [97] and Belle [48] in the process $e^+e^-\to\pi^\mp T_{c\bar{c}1}(3900)^\pm$ with $T_{c\bar{c}1}(3900)^\pm\to\pi^\pm J/\psi(1S)$. The corresponding spectrum from BESIII is shown in Fig. 77.5. An analysis of CLEO data [98] confirmed this finding and also provided evidence for a neutral partner. A nearby signal was also seen in the $D\bar{D}^*$ channel [99] whose quantum numbers were fixed to 1^{+-}. BESIII reported its neutral partner in both $J/\psi(1S)\pi^0$ [100] and $D\bar{D}^*$ [101] decay modes. The masses extracted from these experiments in different decay modes agree within 2σ. However, since the extraction of the mass and width parameters did not allow for an interference with the background and Breit–Wigner line shapes are used, which is not justified near thresholds, there might be some additional systematic uncertainty in the mass values. Therefore, in the RPP listings as well as in Table 77.3 both structures appear under the name $T_{c\bar{c}1}(3900)$. BESIII also reported the observation of another charged state, the $T_{c\bar{c}}(4020)^\pm$ (originally called $Z_c(4020)^\pm$), in two decay modes: $h_c(1P)\pi^\pm$ [102] and $(D^*\bar{D}^*)^\pm$ [103]. The neutral partners have also been observed by BESIII in the $h_c(1P)\pi^0$ [104] and $(D^*\bar{D}^*)^0$ [105] final states. The $T_{c\bar{c}}$ states show some remarkable similarities to the $T_{b\bar{b}}$ states (discussed below), e.g. they decay dominantly to $D^{(*)}\bar{D}^*$ channels. However, current analyses suggest that the mass of the $T_{c\bar{c}1}(3900)$ might be somewhat above the $D\bar{D}^*$ threshold. If confirmed, this feature would challenge a possible $D\bar{D}^*$–molecular interpretation with S-wave interactions only — prominent D-waves can shift molecular poles above threshold (see the discussion in Sec. 77.3.3). Finally, 3.5σ evidence for one more charged charmonium-like state at 4055 MeV decaying into $\psi(2S)\pi^\pm$ was reported by Belle in their analysis of the process $e^+e^-\to\psi(2S)\pi^+\pi^-$ [57]. The same process was studied by BESIII, where there appears to be complications in the Dalitz plot requiring further investigation [55].

An isospin-1/2 state with open strangeness, the $T_{c\bar{c}\bar{s}1}(4000)$, has been reported near D_sD^* threshold by both BESIII [106,107] and LHCb [77]. BESIII observes the charged $T_{c\bar{c}\bar{s}1}(4000)$ in the process $e^+e^-\to K^+(D_s^-D^{*0}+D_s^{*-}D^0)$ [106] and the neutral $T_{c\bar{c}\bar{s}1}(4000)$ in the process $e^+e^-\to K_S(D_s^-D^{*+}+D_s^{*-}D^+)$ [107]. LHCb observes the charged version in $B^+\to\phi(K^+J/\psi(1S))$ [77], although with a much larger decay width. The same LHCb analysis also finds a higher mass $T_{c\bar{c}\bar{s}}$ candidate, the $T_{c\bar{c}\bar{s}1}(4220)$. A search by BESIII for a heavier partner $T'_{c\bar{c}\bar{s}}$ near $D_s^*D^*$ threshold was negative [108].

77.3.2 *Double Charm*

The most striking recent result, however, is due to the observation by LHCb [109, 110] of a doubly charmed state, the $T_{cc}(3875)^+$, in the inclusive cross section of $D^{*+}D^0\to D^0D^0\pi^+$ (see Fig. 77.6). The statistical significance is overwhelming, the minimal quark content is $cc\bar{u}\bar{d}$, and the width is approximately what would be expected for an isoscalar ground state having $J^P=1^+$. The integrated luminosity used in this study was 9 fb^{-1}. The larger integrated luminosity of the event sample to be collected by the end of the LHC Run 3, together with improved analysis techniques, might bring the T_{bc} states within reach.

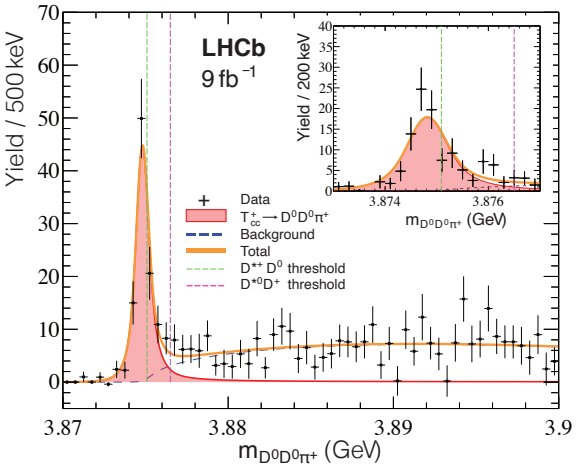

Figure 77.6: The $D^0D^0\pi^+$ invariant mass distribution from LHCb [109, 110].

77.3.3 *Bottomonium*

New results on the η_b, h_b, and $T_{b\bar{b}}$ mostly come from Belle [23,24,26,28,90,111–117], all from analyses of 121.4 fb^{-1} of e^+e^- collision data collected near the peak of the $\Upsilon(10860)$ resonance, as well as from an additional 25 fb^{-1} of data collected during the scans of the c.m. energy range 10.63–11.05 GeV. The η_b, h_b, and $T_{b\bar{b}}$ appear in the decay chains $\Upsilon(10860) \to \pi^- T_{b\bar{b}}^+$, $T_{b\bar{b}}^+ \to \pi^+(b\bar{b})$, and, when the $b\bar{b}$ forms an $h_b(1P)$, frequently decaying as $h_b(1P) \to \gamma\eta_b$.

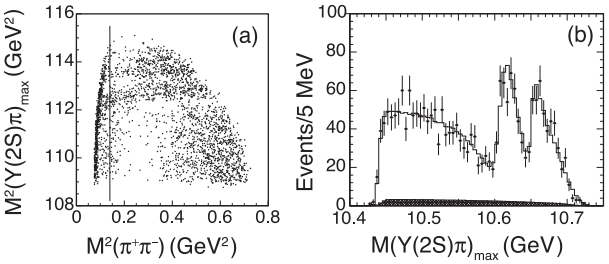

Figure 77.7: From Belle [111] e^+e^- collision data taken near the peak of the $\Upsilon(10860)$ for events with a $\pi^+\pi^-$-missing mass consistent with an $\Upsilon(2S) \to \mu^+\mu^-$, (a) the maximum of the two possible single $\pi^\pm$-missing-mass-squared combinations vs. the $\pi^+\pi^-$-mass-squared; and (b) projection of the maximum of the two possible single $\pi^\pm$-missing-mass combinations overlaid with a fit (*curve*). Events to the left of the vertical line in (a) are excluded from the amplitude analysis. The hatched histogram in (b) corresponds to the combinatorial background. The two horizontal stripes in (a) and two peaks in (b) correspond to the two $T_{b\bar{b}}$ states.

Belle soon noticed that, for events in the peaks of Fig. 77.1 corresponding to the processes $e^+e^- \to \pi^+\pi^-\Upsilon(1S, 2S, 3S)$ and $\pi^+\pi^- h_b(1P, 2P)$, there seemed to be two intermediate charged states in the $\pi^\pm\Upsilon$ and $\pi^\pm h_b$ channels, called the $T_{b\bar{b}}(10610)$ and the $T_{b\bar{b}}(10650)$. For example, Fig. 77.7 shows a Dalitz plot for events restricted to the $\Upsilon(2S)$ region of $\pi^+\pi^-$ recoil mass, with $\Upsilon(2S) \to \mu^+\mu^-$ [111]. The two bands observed in the maximum of the two $M[\pi^\pm\Upsilon(2S)]^2$ values also appear in the $\Upsilon(1S)$, $\Upsilon(3S)$, $h_b(1P)$, and $h_b(2P)$ samples. Belle fits all subsamples to resonant plus non-resonant amplitudes, allowing for interference (notably, between $\pi^- T_{b\bar{b}}^+$ and $\pi^+ T_{b\bar{b}}^-$), and finds consistent pairs of $T_{b\bar{b}}$ masses for all bottomonium transitions, and comparable strengths of the two states. A recent angular analysis assigned $J^P = 1^+$ for both $T_{b\bar{b}}$ states [112], which must also have negative G-parity. Transitions through $T_{b\bar{b}}$ to the $h_b(nP)$ saturate the observed $\pi^+\pi^- h_b(nP)$ cross sections. While the two masses of the $T_{b\bar{b}}$ states as extracted from Breit–Wigner fits for the various channels are just a few MeV above the $B^*\bar{B}$ and $B^*\bar{B}^*$ thresholds, more refined analyses using only S-waves find pole locations right below the corresponding thresholds either on the physical [118] or the unphysical [119] sheet. Once D-waves are included, the pole of the $T_{b\bar{b}}(10650)$ moves above the $B^*\bar{B}^*$ threshold [120]. Regardless of their proximity to the corresponding thresholds, both states predominantly decay into these open-flavor channels [114, 121] with branching fractions that exceed 80% and 70%, respectively, at 90% CL. This feature provides strong evidence for their molecular nature.

77.4 Concluding Remarks

The discovery of the $\chi_{c1}(3872)$ (also known as the $X(3872)$) in 2003 ushered in an era of tremendous progress in experimental heavy quark meson spectroscopy, even though many issues remain unsettled. As shown in Tables 77.1 to 77.3, more than 40 new states have been reported during this period, many of which were unanticipated. While the states below open-flavor thresholds (Table 77.1) appear to be well-explained by the conventional $q\bar{q}$ quark model, a thorough understanding of the suite of states above (Table 77.2) and near (Table 77.3) open-flavor thresholds remains elusive. After nearly two decades, experimental progress remains rapid with the continuation of BESIII, the commencement of the Belle II program, and the imminent accumulation of additional data at the LHC.

78. Heavy Non-$q\bar{q}$ Mesons

Revised October 2025 by T. Gutsche (Tübingen U.), C. Hanhart (FZ Jülich) and R.E. Mitchell (Indiana U.).

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

The constituent quark model describes the observed meson spectrum as bound $q\bar{q}$ states grouped into SU(N) flavor multiplets (see the 'Quark Model' in this issue of the *Review of Particle Physics*). However, the self coupling of gluons in QCD suggests that additional mesons made of bound gluons (glueballs), or $q\bar{q}$-pairs with an excited gluon (hybrids), may exist. Furthermore, multiquark color singlet states such as $qq\bar{q}\bar{q}$ (tetraquarks as compact diquark-antidiquark systems and 'molecular' bound states of two mesons) or $qqq\bar{q}\bar{q}\bar{q}$ (six-quark, 'baryonium' or quasinuclear baryon-antibaryon bound states) have also been predicted—they were actually already mentioned in the pre-QCD works on the quark model in Refs. [1,2] . The focus of this review is on the current understanding of exotic states that apparently do not fit into the most simple realizations of the $q\bar{q}$ constituent quark model and contain at least one heavy quark (charm or bottom — the lifetime of the top quark is too short to provide the formation of hadrons with a sufficiently long life time that allows for spectroscopic investigations). Light non-$q\bar{q}$ candidates (made of u, d and s quarks) are discussed in 'Scalar Mesons below 1 GeV' and 'Spectroscopy of Light Meson Resonances' in this *Review*.

There are candidates for exotic states with both quantum numbers not allowed and quantum numbers allowed for $\bar{q}q$ states. For the latter class it is up to now unclear to what extend a mixing of conventional and unconventional states occurs. While Refs. [3–6] report a significant mixing, Refs. [7, 8] describe a scenario where the mixing especially between molecular structures and $\bar{q}q$ states is suppressed. Ref. [9] finds a mixing that depends strongly on the pole location of the state studied. A promising path to study mixing of different configurations is the use of few-body Bethe-Salpeter equation within the Dyson-Schwinger framework which is outlined in Refs. [10, 11] for open and hidden-flavor doubly heavy states, respectively.

Theoretically heavy non-$q\bar{q}$ mesons are studied using quark models, see, e.g., Refs. [12, 13], diquark-anti-diquark models, where (anti-)diquarks are treated as compact dynamical degrees of freedom within the hadron, see, e.g., Refs. [14–17], meson-exchange models, see, e.g., [18, 19], as well as different variants of effective field theories (EFTs). For mesons made of one heavy quark the proper non-relativistic EFT is called Heavy Quark Effective Theory (HQET), for reviews see [20, 21]. Doubly heavy systems are characterized by various scales. For $m_Q \gg m_Q v \gg m_Q v^2$, non-relativistic QCD (NRQCD) [22–24] can be employed at the scale $m_Q v$, obtained by integrating out QCD modes associated with the heavy scale m_Q, and potential NRQCD (pNRQCD) [25–27] at the scale $m_Q v^2$, obtained additionally integrating out modes associated with the energy scale $m_Q v$. The most modern development in this family of effective field theories is the Born-Oppenheimer EFT (BOEFT) [28–32] that can be applied to quarkonia, and all the exotics states discovered in the last decades that are all composed of two heavy quarks (or antiquarks): hybrids, tetraquarks, pentaquarks and doubly-heavy baryons.

To investigate the energy range around two-hadron thresholds, one can construct an NREFT with these hadrons as the effective degrees of freedom. In particular, in its most simple realisation for S-wave interactions, the LO interaction Lagrangian contains only constant contact terms, while higher-order terms involve derivatives of the hadron fields. The effective parameters that at the same time serve as counter terms in the renormalisation procedure are then adjusted by fits to experimental or lattice data. In this context the role of the one-pion exchange (OPE) is still under debate. There are three different approaches available in the literature, namely pionless EFT [33, 34], EFT with perturbative pions [35–40], and EFT with non-perturbative pions [41–48]. All those find their analogs in studies of the nucleon-nucleon interaction—see, e.g., Refs. [49–51] for reviews. Most of those were used to study the spectrum or line shapes of hadronic molecules [33, 35, 38, 41, 48, 52–56] (for a review, see Ref. [57]). Those are states that owe their existence to the QCD residual force between color–neutral hadrons and not to the gluon exchange between the colored quarks or diquarks. Here chiral symmetry and heavy quark spin symmetry typically guide the construction of the interactions.

QCD sum-rules are also employed to investigate QCD exotics. Here the analyticity of physical amplitudes is used in a dispersion integral to relate the integral over hadronic amplitudes to a sum over various perturbative QCD contributions as well as non-perturbative condensates. The proper choice of interpolating currents allows one to access certain configurations, although the construction is significantly more involved for multi-quark than for quark-antiquark systems [58]. For a recent review on the application of this technique to exotics see Ref. [59].

In recent years lattice QCD also became an important tool to investigate exotics in the light and heavy quark sectors. Lattice QCD, explained in detail in a dedicated section of this *Review*, is a numerical solution of QCD on a discretised space-time lattice, often employing unphysical quark masses, not only for numerical reasons but also to address certain physical phenomena as is detailed below. The applications and challenges of lattice QCD with regard to exotics are discussed in the review [60].

The review is split into 3 parts, discussing separately heavy–light systems, heavy–heavy systems, as well as systems with more than two heavy quarks. For a more detailed discussion of the experimental and/or theoretical status on exotic meson candidates in the doubly heavy meson sector we refer to Refs. [60–66]. Also see the "Spectroscopy of Mesons Containing Two Heavy Quarks" in this *Review*. Reviews with main focus on tetraquarks and molecular states are presented in Ref. [67] and in Ref. [57, 68], respectively. The latest reviews dealing with exotic hadrons are given by Refs. [59, 69, 70].

The naming scheme for hadrons has been updated by the Particle Data Group in 2023, and now covers the heavy "exotic" tetraquark ($qq\bar{q}\bar{q}$) and pentaquark ($qqqq\bar{q}$) candidates recently discovered. We use the new naming scheme in the following. See "Naming Scheme for Hadrons" in this *Review* for details and a table mapping old and new particle names.

78.1 Heavy-light systems

78.1.1 *Positive parity open charm ground states*

Two very narrow states, $D_{s0}^*(2317)^\pm$ and $D_{s1}(2460)^\pm$, were observed at B factories [71, 72]. They lie far below the predicted masses for the two expected broad P-wave $c\bar{s}$ mesons. However, strong cusp effects, due to the nearby DK (DK^*) thresholds, could shift their masses downwards and quench the observed widths, still allowing for a conventional explanation of these states [73]. Such an effect was also claimed for the $a_0(980)$ and $f_0(980)$ mesons, which lie just below the $K\overline{K}$ threshold. In contrast to this picture, many authors favor exotic explanations for these lightest positive parity charmed states, such as compact four-quark states with prominent diquark–anti-diquark structure [74–77] or DK (DK^*) molecules [78–83]. Both states are isoscalars, and thus strong decays are suppressed, since they are possible only to isovector channels $D_s^{(*)\pm}\pi^0$, leading to very small widths. For compact structures the hadronic decay is driven by η–π^0 mixing and one finds widths below 10 keV [73, 84]. In contrast to this, a hadronic width typically larger than 100 keV would be the unequivocal signature for a prominent molecular nature of $D_{s0}^*(2317)^\pm$ [80, 82, 83, 85, 86], since then meson loops generating enhanced isospin violation due to the energy difference between the $D^{(*)0}K^+$ and the $D^{(*)+}K^0$ thresholds would contribute significantly. The most refined analysis in the molecular scenario [85], where the parameters of the formalism are constrained by a large bulk of lattice QCD data on singly charmed systems, reports a prediction for the width in the range (104–116) keV. The currently measured upper bound for the width is 3.8 MeV.

It should be stressed that – akin to $q\bar{q}$ mesons – multiquark states also appear in multiplets. An important probe for the structure of hadrons is therefore the spectra, and in particular the SU(3) flavor multiplets within the different scenarios and associated mass splittings. For example, the tetraquark model advocated in Refs. [77, 87] finds that the $D_{s0}^*(2317)^\pm$ should be de-

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

generate with its non-strange partner state $D_0^*(2300)$ in line with the currently available experimental analyses. However, Ref. [88] showed that the recent LHCb data for $B \to D\pi\pi$ [89, 90] call for a significantly lighter lightest non-strange scalar charmed meson as soon as constraints from the chiral symmetry of QCD are employed in the analysis. This claim is in line with the recent lattice QCD study of Ref. [91]. In fact, experimental as well as lattice data turn out to be consistent with the predictions from unitarised chiral perturbation theory pioneered for these systems in Ref. [79], where the lightest open flavor positive parity states appear as dynamically generated two-hadron states. For more recent calculations see Refs. [85, 92, 93]. Moreover, all the mentioned calculations that are consistent with chiral constraints predict that the interactions in the 15-plet should be repulsive while there should be in addition an about 300 MeV heavier flavor exotic state, formally a member of a flavor sixtet and absent for $c\bar{q}$ states. As shown in Ref. [93] there are indeed indications also for this state in the above mentioned LHCb data—why this state was not reported in the lattice study of Ref. [94] is explained in Ref. [95] by its being located on a hidden Riemann-sheet. The pattern described above—with the interactions in the flavor antitriplet most attractive, in the flavor sixtet attractive and in the 15-plet repulsive—was recently also observed in a lattice QCD analysis for πD scattering based on the Lüscher method at a pion mass of about 700 MeV [96]. Thus, in this picture the structure that appears as $D_0^*(2300)$ in the *Listings* originates from the interplay of two poles, similar to the $\Lambda(1405)$ in the baryon sector, see 'Pole structure of the $\Lambda(1405)$ region' in this *Review*. Two poles in the non-strange scalar sector are also generated in the tetraquark picture of Ref. [77], but in this work the real parts of the poles are located at 2308 MeV and 2666 MeV, in conflict with the data mentioned above. In the refined analysis of Ref. [87] it is shown, however, that the exact pole locations and even the ordering of the higher multiplets depend on the details of the model. In Ref. [97] it was argued that as soon as one restricts the diquark phenomenology to only scalar diquarks, as a consequence of the Pauli principle also the diquark–anti-diquark picture is consistent with a repulsion in the 15-plet. However, axial-vector diquarks, which would be needed for a consistent hadron phenomenology, if diquarks are indeed relevant degrees of freedom, also produce states in the 15-plet. In particular, while in the scalar D-meson sector those should be rather heavy, in the axial-vector spectrum, they should be even lighter than the states in the sixtet [98]. Contrary to this, in the two-hadron picture of unitarised chiral perturbation theory, the scalar and the axial-vector sectors should be equal (up to spin symmetry violations). In this sense the recent lattice study of Ref. [99] is in conflict with the predictions of the diquark-anti-diquark picture, while being consistent with a two-hadron structure for those states.

What is needed in addition to the above quoted strong, mostly theoretical, evidence for the unusual pattern of non-strange D-mesons, is a more direct experimental determination of the pole location of the lightest positive parity D-meson. This could be derived from a high quality measurement of the πD scattering parameters—analogously to the case of the $f_0(500)$, whose pole location was significantly constrained by high quality data on the $\pi\pi$ scattering length. One way to get access to the scattering parameters of unstable particles is to use the femtoscopy technique—here semi-inclusively, the correlations of two (or more) outgoing hadrons produced in a high-energy collision are measured—for reviews see Refs. [100, 101]. Recent studies using this technique find results for the DK and D^*K systems consistent with the above mentioned lattice and chiral effective field theory calculations, however, for $D\pi$ and $D^*\pi$ the extracted scattering parameters are below 0.03 fm and are thus inconsistent with the theoretical investigations [102][1]. It remains to be seen, if these latter values get confirmed by other investigations like in semi-leptonic B decays [104, 105].

Lattice QCD allows for predictions of the flavor partner states in the B-sector. The most recent analysis can be found in Ref. [106]. In this work also a comparison with theoretical predictions can be found. Unfortunately an experimental confirmation for those states is difficult with existing facilities. Radiative decays are predicted to be the most prominent decay channels [86], since the above mentioned isospin violation from meson loops is suppressed in the B sector as a consequence of the tiny $B^\pm - B^0$ mass difference.

78.1.2 *The $T_{cs0}^*(2870)$ and $T_{cs1}^*(2900)$*

Manifestly exotic candidates around 2.9 GeV were reported in Refs. [107–109] by LHCb in the $\bar{D}K$ system. Since the strong interaction preserves the quark flavor and the final state contains an $\bar{s}$ as well as a $\bar{c}$, color neutrality calls for a minimum quark content of $ud\bar{c}\bar{s}$. A resonant structure consistent with the $T_{cs0}^*(2870)$ is also observed in the $D^0K_s^0$ invariant-mass spectrum [110], although with no evidence for the $T_{cs1}^*(2900)$. Charged open-charm tetraquark structures were searched for in $B^0 \to D^+D^-K_s^0$ decays, but without any significant signal [111].

The explanation for those states include compact tetraquarks with a structure dominated by a diquark–anti-diquark pair [112–114], hadronic molecules with a prominent $D^*\bar{K}^*$ component [115–120], or kinematic effects such as cusps or triangle singularities (for an explanation of the latter terms we refer to the section 'Resonances' in this *Review*) without nearby poles [121, 122]. The different pictures are contrasted and observable differences between them are discussed in Ref. [123].

78.1.3 *The $T_{c\bar{s}0}^*(2900)^0$ and $T_{c\bar{s}0}^*(2900)^{++}$*

There is a recent report by LHCb [124] on the observation of a doubly charged open-charm tetraquark candidate together with a neutral partner in the $D_s\pi$ channel, with masses near 2.9 GeV. The results imply two states with $c\bar{s}\bar{u}d$ or $c\bar{s}u\bar{d}$ flavor structures. Although masses and widths are consistent with the T_{cs} states of Refs. [107, 108], the strangeness quantum numbers do not match. The first explanation for those states in coupled-channel studies is based on a kinematic effect such as a cusp [125]. In Ref. [126] a molecular structure with a dominant D^*K^* component is claimed to be excluded. However, since the $T_{c\bar{s}0}^*(2900)$ is situated near this threshold, some works [119, 127–129] argue that this isospin triplet state should be interpreted as a D^*K^* hadronic molecule. Within this picture, in Ref. [129] predictions for states with other quantum numbers are given. A QCD sum rule study based on diquark–anti-diquark interpolating currents is presented in Ref. [130].

Recently LHCb reported an amplitude analysis on a resonant structure in $D_{s1}(2460)^+ \to D_s^+\pi^+\pi^-$ decays [131]. One of the analysis models calls for a new $T_{c\bar{s}}^{++}$ state and its isospin partner $T_{c\bar{s}}^0$ with mass and width of about 2327 MeV and 96 MeV. At first sight these $T_{c\bar{s}}$ states can be interpreted as two members of the isotriplet predicted in Ref. [97], although data could also be explained dynamically [132].

78.2 Heavy-heavy systems

With the discovery of the $\chi_{c1}(3872)$[2] in $B^\pm \to K^\pm X$ ($X \to J/\psi(1S)\,\pi^+\pi^-$) by Belle [133] in 2003, soon confirmed by BaBar [134], many searches for states beyond the standard $q\bar{q}$ quark model were initiated in the charm and bottom sectors. For an updated collection of the currently available experimental information on multiquark states we refer to 'Spectroscopy of mesons containing two heavy quarks' in this *Review*, and in particular to Table 77.2. Moreover, in the decay $\Lambda_b^0 \to J/\psi(1S)\,K^-p$ the LHCb collaboration has recently reported the observation of new baryons decaying into $J/\psi(1S)\,p$, which are candidates for heavy pentaquark states [135, 136]. They are discussed in some depth in 'Pentaquarks' in this *Review*.

In addition to the multiquark scenarios discussed for the heavy-light systems, in double heavy systems two more basic configurations are discussed in the literature. On the one hand there are the hadroquarkonia, which call for a compact quarkonium core surrounded by a light quark cloud [137]. On the other hand there are hybrid mesons, in which an excited gluon field, in combination with the valence quarks, contributes to the overall quantum numbers and properties of the meson.

[1] Ref. [103] shows that there is a systematic uncertainty in the femtoscopy method not yet accounted for.

[2] The $\chi_{c1}(3872)$ is also known as the $X(3872)$. According to the PDG naming scheme, the primary name for a meson expresses its quantum numbers.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

When restricting ourselves to confirmed states we are faced with several states that do not seem to fit into the mass and quantum number schemes of $q\bar{q}$ quark models. This is clear for the five established charged states $(T_{c\bar{c}1}(3900)^{\pm}$, $T_{c\bar{c}}(4020)^{\pm}$ and $T_{c\bar{c}1}(4430)^{\pm}$ in the charmonium sector, and $T_{b\bar{b}1}(10610)^{\pm}$ and $T_{b\bar{b}1}(10650)^{\pm}$ in the bottomonium sector[3]). The neutral states ($\chi_{c1}(3872)$, $\psi(4230)$, $\psi(4360)$, and $\psi(4660)$)[4] also challenge the quark model since their masses and decay properties are in conflict with expectations. Although so far seen just by a single experiment in a single channel [138,139], the $T_{cc}(3875)$ and its proposed heavy partner states are also discussed.

It should be stressed that mass parameters for resonances located not too far with respect to their width from a pertinent threshold extracted with Breit-Wigner methods should be considered with care, since the lineshape can very well be distorted by the threshold. An example for such a case is reported in Ref. [140], where it was demonstrated that the experimental data by Belle are consistent with a $\bar{D}D$ bound state at 3695 MeV in line with lattice QCD simulations for the same system [141], while from experiment a mass as high as 3860 MeV with a width of 200 MeV was extracted [142].

78.2.1 *The* $\chi_{c1}(3872)$

The quantum numbers of the $\chi_{c1}(3872)$ have been determined by LHCb to be $J^{PC} = 1^{++}$, first by assuming zero angular momentum between the $J/\psi(1S)$ and the dipion [143] and then by relaxing this constraint [144]. The $\chi_{c1}(3872)$ cannot be easily identified with the $\chi_{c1}(2^3P_1)$, since the latter is predicted to lie about 100 MeV higher in mass [145]. Instead, the $X(3940)$ reported by Belle in $e^+e^- \to J/\psi(1S)X$, decaying into $D^*\bar{D}$ but not into $D\bar{D}$ [146] could be the $\chi_{c1}(2^3P_1)$. The $\chi_{c2}(3930)$ 2^3P_2 tensor partner was reported by Belle at 3931 MeV in $\gamma\gamma$ interactions [147].

The $\chi_{c1}(3872)$ lies within 200 keV of the $D^0\bar{D}^{*0}$ threshold and its width is very small — recent Breit-Wigner analyses by LHCb [148, 149] result in an average value of $\Gamma = (1.19 \pm 0.21)$ MeV as indicated in the *Listings*. However, since the respective pole is located very close to an S-wave thresholds to which it couples strongly, the Breit-Wigner lineshape should not be used (see section 'Resonances' in this *Review*). Employing the more appropriate Flatté formalism of Ref. [150] under the constraint that the $D^*\bar{D}$ decay channel dominates, results in $\Gamma = 0.22^{+0.18}_{-0.19}$ MeV, where the standard convention is applied to use twice the imaginary part of the pole location as width. A recent determination of the $\chi_{c1}(3872)$ lineshape parameters and the resulting pole location based on BESIII data can be found in Ref. [151]. A combined analysis of the LHCb data and BESIII data is presented in Ref. [152], where the pole location of the $\chi_{c1}(3872)$ was determined with unprecedented accuracy. Moreover, further evidence was presented for the existence of an additional pole in the isovector channel, originally predicted in Ref. [153], which should show up more prominently in e.g. the decay $B^0 \to K^0 J/\psi\pi^+\pi^-$. In the future the mass parameters can be refined more by either a direct measurement of the width that should be possible at the planned PANDA experiment [154, 155] or by exploiting the interplay of a triangle singularity and the $\chi_{c1}(3872)$ pole [156–158].

The most natural explanation for the $\chi_{c1}(3872)$ is a 1^{++} $D\bar{D}^*$ molecule [159]. In this scenario a strong isospin breaking is predicted [159, 160], since the distance of the pole of the $\chi_{c1}(3872)$ to the $D^0\bar{D}^{*0}$ threshold is significantly smaller than to the D^+D^{*-} threshold. Indeed, the comparable rates for $\omega J/\psi(1S)$ and $\rho^0 J/\psi(1S)$ are consistent with an interpretation of $\chi_{c1}(3872)$ as an isoscalar $D\bar{D}^*$ molecule, when the different widths of the ρ and ω are taken into account [161]. A molecular component of above 99% was also found in Refs. [152, 162] in sophisticated analyzes that kept the full three-body dynamics of the intermediate state $D\bar{D}\pi$, first studied in Ref. [41].

A dominant molecular $D^0\bar{D}^{*0}$ structure in the $\chi_{c1}(3872)$ with further subleading more compact hadronic components is used to explain strong and radiative decays involving $J/\psi(1S)$ and $\psi(2S)$ in the final states [163, 164]—it should be mentioned that those rates are also consistent with a $c\bar{q}$ structure [165]. The most recent measurement of the ratio of radiative partial decay widths [166] indicates that the $\psi(2S)\gamma$ mode dominates over $J/\psi\gamma$. This observation is claimed to point to a sizable compact component in the $\chi_{c1}(3872)$ (for a compilation of various structure-dependent predictions see [166]). However, from an effective field theory point of view these radiative transitions are not well suited to quantify the molecular admixture in the $\chi_{c1}(3872)$, since there appears a counter term at leading order, diminishing the sensitivity to the long-ranged molecular component [167].

A diquark–anti-diquark structure $(cq)(\bar{c}\bar{q}')$ is another possible interpretation of the $\chi_{c1}(3872)$ [76]. Contrary to the two hadron structure discussed above, here diquark-anti-diquark substructures are assumed to be bound by QCD flux tubes—for a discussion of possible configurations see Ref. [168]. What speaks against this interpretation is that so far no near mass degenerate charged partner of the $\chi_{c1}(3872)$ has been observed (e.g. not in $B^- \to \bar{K}^0 X^-$ nor in $B^0 \to K^+X^-$, where $X^- \to J/\psi(1S)\,\pi^-\pi^0$ [169])—see [170] for a possible explanation of this non-observation within the tetraquark approach assuming specific diquark correlations and the more recent discussion in Ref. [171]. Note that the isovector partner state of the $\chi_{c1}(3872)$ discussed in [153] is not consistent with the proposed charged compact tetraquark state, since the pole is located on an unphysical sheet, clearly pointing at a molecular nature of the state [172], and its mass is close to the D^+D^{*-} threshold, 8 MeV above the mass of the $\chi_{c1}(3872)$.

The claim that $\chi_{c1}(3872)$ must be a compact (tetraquark) state, since it is also produced at very high p_T in $\bar{p}p$ collisions [173] and in high multiplicity final states [174], was challenged in [175] and [176], respectively, which in particular stress the importance of rescattering, see also Refs. [177, 178].

The high statistics measurement of the $\chi_{c1}(3872)$ lineshape of Ref. [148] also allowed for an extraction of the effective range for the $D^0\bar{D}^{*0}$ interaction. At face value, the values provided in this publication indicate a large and negative effective range [179], which could be interpreted as a signature of a prominent compact component in the $\chi_{c1}(3872)$ wave function — this follows from the famous Weinberg compositeness criterion [180]. The effect of the one-pion exchange on the effective range turns out to be small [40, 41, 181, 182] and should therefore not invalidate the Weinberg-type analysis. However, it was argued in Ref. [183] that once the effect of the large isospin violation as well as the strong correlations between the effective parameters appearing in Ref. [150] are subtracted, the effective range is consistent with a purely molecular $\chi_{c1}(3872)$. There is no consensus yet how to interpret the line shapes of $\chi_{c1}(3872)$.

78.2.2 *The* $\psi(4230)$ *and* $\psi(4360)$

A broad structure, originally called $Y(4260)$, decaying into $J/\psi(1S)\,\pi^+\pi^-$ was reported by BaBar in initial state radiation $e^+e^- \to (\gamma_{\rm ISR})Y(4260)$ [184]. A subsequent measurement with significantly improved precision was reported by BESIII [185], and revealed that the original $Y(4260)$ cannot be described with a simple resonant lineshape. Fitting the BESIII data with two Breit-Wigner distributions leads to a narrower and lighter structure (referred to in the *Listings* as the $\psi(4230)$), but also requires a second state at 4320 MeV. While the $D_1(2420)\bar{D}$ molecular model for the $\psi(4230)$ can describe the same data with just one single exotic pole [186, 187], the coupled channel analysis of Ref. [188] needs an additional exotic state near 4320 MeV. Both, Ref. [187] and Ref. [188] need the interference of the signal of the $\psi(4230)$ with the $\psi(4160)$ to get a good description of the large amount of available data. How many vector states are in the mass range between 4220 MeV and 4400 MeV is not yet settled, but knowing this is crucial to allow for further progress.

There are no charmonium states expected in this mass region with quantum numbers 1^{--} from quark models using the Cornell type of interaction, although this might not be true for some screened versions thereof—for a recent discussion we refer to Ref. [189]. In addition, a charmonium state at this mass is expected to have significant couplings to one or more of the $\bar{D}^{(*)}D^{(*)}$ channels [190, 191], a feature that is not observed for the $\psi(4230)$.

[3] In the literature those states are often labeled as Z_c and Z_b, respectively.

[4] The $\psi(4230)$, $\psi(4360)$, and $\psi(4660)$ are also known as the $Y(4230)$, $Y(4360)$, and $Y(4660)$, respectively. Before improved mass measurements, the $\psi(4230)$ was originally called the $\psi(4260)$ or $Y(4260)$.

This state could be a hybrid charmonium with a spin-1 [28, 192] or a spin-0 [193, 194] $\bar{c}c$ core—for a recent review on this state see Ref. [195]. However, provided that the observation of $\psi(4230)$ decay into $h_c(1P)\pi\pi$ by BESIII [196] is confirmed, the hybrid hypothesis would be under pressure, since the spin of the heavy quarks (coupled to zero in the $h_c(1P)$) should be conserved in leading order in the expansion in $(\Lambda_{\rm QCD}/m_c)$. (The individual conservation of the heavy quark spin and the total angular momentum of the light quark cloud is a consequence of the heavy-quark spin symmetry, see 'Heavy-Quark and Soft-Collinear Effective Theory' in this issue of the *Review*.) The same criticism applies to the hadrocharmonium interpretation of the $\psi(4230)$. To circumvent the spin-symmetry argument, Ref. [197] suggests that $\psi(4230)$ and $\psi(4360)$ could be mixtures of two hadrocharmonia with spin-triplet and spin-singlet heavy quark pairs. The same kind of mixing could also be at work for hybrid structures. Hybrids can also be treated employing the Born-Oppenheimer EFT originally suggested in Ref. [30, 198]. Those studies revealed that while the $\psi(4230)$ is in principle a good candidate for a hybrid state [199], its decays are incompatible with this assignment [200].

A dominant $D_1(2420)\bar{D}$ component in the $\psi(4230)$ [201] explains naturally why the $T_{c\bar{c}1}(3900)^{\pm}$ (interpreted by the authors as a $\bar{D}D^*$ bound state) is seen in $\psi(4230) \to \pi^{\mp}T_{c\bar{c}1}(3900)^{\pm}$. A similar mechanism is also found in Ref. [202] linking in addition the $J/\psi(1S)\pi^+\pi^-$ and $\psi(2S)\pi^+\pi^-$ decays of the $\psi(4230)$. Furthermore, a copious production of $\chi_{c1}(3872)$ in $\psi(4230)$ radiative decays was predicted from the prominent $D_1\bar{D}$ component of the $\psi(4230)$ [203], which was confirmed by BESIII [204]. Possible charmonia components both in $\psi(4230)$ and $\chi_{c1}(3872)$ can influence the radiative transition but they are shown to be of subleading order [205]. It was proposed that $\psi(4360)$ as a $D_1\bar{D}^*$ bound state could be the spin partner of the $\psi(4230)$ [206, 207]. In Ref. [208] a dynamical model is presented that identifies the vector states $\psi(4230)$, $\psi(4360)$ and $\psi(4415)$ as $D\bar{D}_1$, $D^*\bar{D}_1$ and $D^*\bar{D}_2$ molecular states, respectively. Moreover, an exotic 0^{--} state is predicted as $D^*\bar{D}_1$ molecule with a mass of 4366 ± 18 MeV and a width of less than 10 MeV.

The tetraquark picture calls for four ground state vector states — once the parameters of the model are fixed from some candidate states in the negative and positive parity sector, states with other quantum numbers can be predicted. Possible scenarios are for instance discussed in Ref. [209] which builds on a tailor-made spin-spin interaction [16] to describe the $\chi_{c1}(3872)$, both $T_{c\bar{c}1}(3900)^{\pm,0}$ and $T_{c\bar{c}}(4020)^{\pm}$ and even the $T_{c\bar{c}1}(4430)^{\pm}$ confirmed by Belle [210] and LHCb [211]. This model also explains the copious production of $\chi_{c1}(3872)$ in $\psi(4230)$ radiative decays mentioned above [16, 212]. However, tetraquark models (in most cases based on diquark-antidiquark configurations) tend to predict many additional charged and neutral states which have not yet been discovered. In particular, as for the conventional $\bar{q}q$ structures one should expect nearly degenerate isoscalar and isovector states in analogy to the near degeneracy of $\rho(770)$ and $\omega(782)$. The problem and possible explanations are discussed in some detail in Refs. [170, 171].

Ref. [213] found a sizable SU(3) flavor octet contribution when analyzing the $\pi\pi$ final state from $\psi(4230) \to J/\psi(1S)\pi^+\pi^-$, which is consistent with both a molecular and a tetraquark interpretation of $\psi(4230)$, but is at odds with a hybrid or a $\bar{c}c$ interpretation.

78.2.3 *The* $\psi(4660)$

In the mass range above 4600 MeV, the number of poles is also not yet settled. Experimental signals are seen in the $\psi(2S)\pi\pi$, $\Lambda_c^+\bar{\Lambda}_c^-$, $D_s\bar{D}_{s1}$, $D_s\bar{D}_{s2}^*$, and $D^{*0}D^{*-}\pi^+$ final states. In the *Listings* these structures go into one node, $\psi(4660)$, due to their proximity in parameter values. Moreover, various theoretical works describe these states in a combined analysis [214–216]. The signal in the hidden strangeness mode around 4630 MeV still calls for confirmation and might be yet another realization of the same state, but there are already speculations about its nature. Ref. [217] finds a single state in this mass range and identifies it with the $\psi(5S)$. While Ref. [218] argues in favor of a $D_s^{(*)}\bar{D}_{s1}(2536)$ or $D_s^{(*)}\bar{D}_{s2}(2573)$ [219] molecular nature, Ref. [220] does not confirm these claims. Ref. [221] identifies the structure as P-wave $[cs][\bar{c}\bar{s}]$ tetraquark state. Other explanations of the $\psi(4660)$ include a $\psi(2S)f_0(980)$ molecule [222] and a $\Lambda_c^+\bar{\Lambda}_c^-$ baryonium [214]. Also in this mass range studies of the partner states, driven either by spin or flavor symmetry will be very valuable—see e.g. the predictions in Ref. [223].

78.2.4 *The* $T_{c\bar{c}1}(3900)$, $T_{c\bar{c}}(4020)$, $T_{b\bar{b}1}(10610)$, *and* $T_{b\bar{b}1}(10650)$

The isovector states $T_{c\bar{c}1}(3900)$ and $T_{c\bar{c}}(4020)$, first observed by BESIII [224, 225], decay predominantly into $\bar{D}D^*$ and $\bar{D}^*D^*$, respectively, while the $T_{b\bar{b}1}(10610)$ and $T_{b\bar{b}1}(10650)$, first observed by Belle [226, 227], decay predominantly into $\bar{B}B^*$ and $\bar{B}^*B^*$ [228], respectively, although all four were discovered in a decay into a heavy quarkonium plus a pion. This suggests that these states are close relatives and their interactions are connected via heavy quark flavor symmetry[5]. A molecular interpretation for the bottomonium states was proposed shortly after the discovery of the two $T_{b\bar{b}}$ states [230] and also shortly after that of the $T_{c\bar{c}1}(3900)$ [201]—the up-to-now most precise determination of the pole location of the latter state is reported in Ref. [231]. This picture is confirmed within the meson exchange model of Ref. [232]. Decay patterns of $T_{c\bar{c}1}(3900)$ and the two $T_{b\bar{b}}$ were also shown to be consistent with a molecular interpretation [233–235]. However, some of their properties also appear to be consistent with tetraquark structures [236]. If the molecular picture were correct for the $T_{b\bar{b}}$ states, spin symmetry would lead to the existence of spin partner states [37, 237, 238], which are still to be found. In Ref. [47] it was shown that the actual pole locations of these partner states would be good probes of one-pion exchange in the molecular potential, which makes the experimental search for those states even more interesting. A possible interpretation of $T_{c\bar{c}1}(3900)$ and $T_{c\bar{c}}(4020)$ as crossed channel effects is put forward in Ref. [239]. It remains to be seen, however, if this kind of explanation is also capable of explaining the observations of these lowest $T_{c\bar{c}}$ states, also at other total energies. A recent lattice QCD calculation suggests that the $T_{c\bar{c}1}(3900)$ can be reconciled with a two pole structure in the $J/\psi\pi - D\bar{D}^*$ coupled-channel [240]. In this study the coupling between $D\bar{D}^*$ and $J/\psi\pi$ is significant and plays a crucial role.

78.2.5 *The* $T_{c\bar{c}1}(4200)$ *and* $T_{c\bar{c}1}(4430)$

The heaviest confirmed charged state in the charmonium sector is the $T_{c\bar{c}1}(4430)^{\pm}$ observed by Belle [210]. It is interpreted as hadrocharmonium [137], $\bar{D}_1D^*$ molecule [241], as well as diquark–anti-diquark structure [16]. Alternatively, in [242, 243] the $T_{c\bar{c}1}(4430)^{\pm}$ is explained as a cross-channel effect enhanced by a triangle singularity from open charm states. These works were criticized in Ref. [244] where an alternative triangle consisting of a K^*, a π, and the $\psi(4230)$, is proposed to generate the $T_{c\bar{c}1}(4430)$. The Argand diagram shows an anticlockwise circle, in line with the experimental analysis [211], while the one of Ref. [243] shows a clockwise motion. By replacing the $\psi(4230)$ with the $\psi(3770)$, and changing the K^*, one can also interpret the $T_{c\bar{c}1}(4200)$ as a kinematic effect [244].

78.2.6 *The* $T_{c\bar{c}\bar{s}1}(4000)$

There is recent evidence for a charged charmonium-like state with strangeness, $T_{c\bar{c}\bar{s}1}(4000)$, from BESIII [245] and LHCb [246]. The possible existence of a strange partner to the $T_{c\bar{c}}$ near the $D_s\bar{D}^*$ thresholds has been predicted in molecular models [247, 248], for tetraquarks [249, 250], for hadrocharmonium structures [250, 251], and as a coupled-channel effect [252]. Later on this state is interpreted in Refs. [253, 254] as a member of the same multiquark octet and in Refs. [255–257] as a member of the same molecular one as the $T_{c\bar{c}1}(3900)$. Ref. [254] is also able to describe the recent LHCb data in the $J/\psi(1S)K^-$ system [246], although the extracted total width for their lowest $T_{c\bar{c}\bar{s}}$ state is an order of magnitude larger than that found by BESIII. Refs. [258, 259] claim that both the molecular components and the compact tetraquark core are relevant to describe the $T_{c\bar{c}1}(3900)$ and $T_{c\bar{c}\bar{s}1}(4000)$ resonances. Again, in [260] the $T_{c\bar{c}\bar{s}1}(4000)$ can

[5] For a critical examination of this claim from an effective field theory point of view see Ref. [229].

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

be explained as a coupled-channel effect producing the enhancement close to threshold.

Ref. [255] comes to the conclusion that an understanding of the experimental data for the $T_{c\bar{c}\bar{s}1}(4000)$ calls for the inclusion of both triangle diagrams as well as a pole term. The authors conclude from their calculations that $T_{c\bar{c}\bar{s}1}(4000)$ and $T_{c\bar{c}1}(3900)$ are members of the same SU(3) multiplet. This conclusion was confirmed in Ref. [261] and the study extended to higher energies. The fit of the experimental data allowed for two solutions, one where the $T_{c\bar{c}}(4020)$ is a spin partner of the mentioned isovector states and one where it is not. Data e.g. for $e^+e^- \to K^+D^{*-}D^{*0}$ is claimed to be decisive which scenario is indeed realized.

It should be stressed that the various scenarios, while describing much of the available data, also make decisive predictions, *e.g.* for states with yet unobserved quantum numbers [209, 262]. The forthcoming data on heavy meson spectroscopy from various facilities should provide a much deeper understanding of how QCD forms matter out of quarks and gluons.

Note that for various states listed above it is still possible that they reflect the presence of cusps and not states—for recent studies see [263, 264].

78.2.7 *The $T_{cc}(3875)$*

There is a recent report and follow-up by LHCb [138, 139] on the observation of a narrow peak in the $D^0D^0\pi^+$ mass spectrum just below the $D^{*+}D^0$ threshold. The observed state is a candidate for an isoscalar double-charm T_{cc}^+ tetraquark configuration with a quark content of $cc\bar{u}\bar{d}$. Unsuccessful searches in $D^+D^0\pi^+$ and D^+D^+ mass spectra disfavour the isovector assignment. The $D^0\pi^+$ mass distribution indicates that the T_{cc}^+ proceeds through the formation of a D^* in the intermediate state. The additional proximity to the $D^{*+}D^0$ mass threshold favors the $J^P = 1^+$ assignment. The T_{cc}^+ has a remarkable narrow width and lies very close to the $D^{*+}D^0$ threshold [139], comparable to the properties of the $\chi_{c1}(3872)$. Indeed, employing a meson-exchange model [19] or the BOEFT [265] the two states can be described together in the same framework.

Evaluations in the context of QCD sum rules [266,267] result in mass and width values consistent with the assumption of a compact diquark-antidiquark structure of the T_{cc}^+. A pole analysis performed with $D^0D^0\pi^+ - D^{*+}D^0$ coupled-channels [268] suggests that the T_{cc}^+ has its origin in a $D^{*+}D^0$ virtual state resulting from the attraction in this channel and the coupling to $D^0D^0\pi^+$. The interpretation of the observed T_{cc}^+ as a D^*D molecular structure was pursued in [48,56] based on non-relativistic effective field theories without and with pion exchange, respectively, in [269,270] employing a combination of meson exchange and quark-gluon forces, and in [271] employing the Bethe-Salpeter framework. Predictions depend on fine model details and are usually accompanied by additional partner states, like an isovector molecule or higher radial excitations. A fit to the LHCb data on $T_{cc}(3875)$ [272] is also consistent with a molecular D^0D^{*+}, D^+D^{*0} interpretation in the isoscalar channel, while for the isovector case binding is prevented. A coupled-channel analysis of the $D^0D^0\pi^+$ mass spectrum within a meson-exchange model [19] also concludes the nature of T_{cc}^+ as an isoscalar DD^* hadronic molecule. As a consequence a double-charm isoscalar D^*D^* hadronic molecule candidate is predicted.

In analogy to the case of the $\chi_{c1}(3872)$ in Ref. [273] the production of T_{cc}^+ in high-energy proton-proton collisions at the LHC is studied. Effects of a charm-meson triangle singularity on the inclusive production of T_{cc}^+ from the rescattering of DD lead to a narrow peak in the $T_{cc}^+\pi^+$ invariant mass distribution. A spin 2 partner of the T_{cc}^+ is predicted in Refs. [48, 56], whose hadronic decays are studied in Ref. [274].

As for the $\chi_{c1}(3872)$ one can employ the effective range deduced from experiment for the effective range in the DD^*-channel as a measure of the nature of the $T_{cc}(3875)$. Also here isospin violations are significant. It turns out that in a calculation where the one-pion exchange is kept fully non-perturbative, its effect on the effective range is small and positive [48], while it is small and negative when being treated perturbatively [182, 275].

First lattice studies with fully dynamical quarks are also available for the $T_{cc}(3875)$ [276–278], all performed at pion masses slightly larger than physical such that the D^* and with this also the $T_{cc}(3875)$ are stable. They all find that at these pion masses the T_{cc} is a virtual state. In Ref. [279] it was stressed, however, that all those analyses should be redone, since the proximity of a left-hand cut invalidates the method used—analogously also the effective range expansion needs to be changed in the proximity of a left-hand cut [280, 281]. Possible modifications of the Lüscher method are proposed in Refs. [281–284]. Results point towards a resonance interpretation of the $T_{cc}(3875)$. Chiral extrapolations of lattice simulations for the isoscalar DD^* scattering with [285,286] and without left-hand cut [287] to the physical pion mass lead to a T_{cc} bound states with binding energies compatible with experiment, however, significantly different trajectories.

A first coupled channel isospin-0 DD^*, D^*D^* scattering calculation in lattice QCD [288] also indicates a pole below the DD^* threshold, a further pole corresponding to T_{cc}' is also found just below the D^*D^* threshold. A further lattice QCD study [289] in the doubly charm $cc\bar{q}\bar{q}$ isospin-1 channel concludes that no poles are found in the scattering amplitude near the DD^* threshold consistent with the current experimental status.

Not very long after the discovery of the charm quark it was stressed that, if the ratio of heavy (Q) to light quark (q) masses is well beyond 10, binding should occur for states of the kind $QQ\bar{q}\bar{q}$ [290–292]. These studies were performed within constituent quark models. Accordingly the quoted ratio refers to constituent masses, which are of the order of 300 MeV for the light quarks in contradistinction to the current quark masses of the order of a few MeV. Based on those studies one should expect binding for $bc\bar{q}\bar{q}$ systems and even more so for $bb\bar{q}\bar{q}$—the transition from a (predominantly) molecular structure to a diquark–anti-diquark structure as the masses of the heavy quarks are increased is discussed e.g. in the phenomenological models of Ref. [269, 270]. Nowadays many works investigate doubly heavy tetraquarks including phenomenological models [291–298], lattice QCD either employing static potentials [299–302] or NRQCD for the b-quarks [106, 303–307] as well as QCD sum rules [266, 308–310] . All those papers agree that a T_{bb} should be bound for the $I = 0$ and $J^P = 1^+$ channel, but there is no consensus about the binding energy relative to the lowest open bottom threshold (BB^*), which ranges from values near zero to 500 MeV. Since in contrast to the states that contain a heavy quark–anti-quark pair this family of states contains two heavy quarks, no strong decay channels are accessible for the heavier partner states of the $T_{cc}(3875)$ and they could only decay weakly. Accordingly, once found, they would provide an exciting laboratory not only to investigate the strong but also the weak interaction.

78.3 Systems containing four heavy quarks

78.3.1 *The $T_{cc\bar{c}\bar{c}}(6900)$*

LHCb reported the observation of pronounced structures in a double-$J/\psi(1S)$ invariant mass distribution [311] thus pointing at states with $cc\bar{c}\bar{c}$ quarks contents. First results on di-$J/\psi(1S)$ and $J/\psi(1S)\psi(2S)$ invariant mass distributions in proton-proton collision data by the CMS [312] and ATLAS [313] Collaborations confirm and extend the resonance structures seen by LHCb. In Ref. [314] the quantum numbers of the structures were determined to be $J^{PC} = 2^{++}$. Belle reported on a first search for a double-charmonium state with $e^+e^- \to \eta_c J/\psi(1S)$ near threshold via the ISR process. No significant signal of the double charmonium state is found in several bins of the invariant mass of $\eta_c J/\psi(1S)$ [315]. Recently the COMPASS [316] Collaboration also studied double $J/\psi(1S)$ production in pion scattering off nuclear targets. No significant signatures that could be associated with tetraquarks are found in the double $J/\psi(1S)$ mass spectrum in the relatively limited data set.

From quark models the possible existence of bound states like this was discussed already long ago [290]. There are now also many model calculations available in the literature. For discussions of those data from the compact tetraquark perspective see Refs. [317–323]. Most of these quark model calculations assign the reported structure to a $cc\bar{c}\bar{c}$ state in the $2S$ multiplet with near-degenerate $J^P = 0^+$, 1^+ and 2^+ configurations. The dominance of a compact tetraquark component in the apparently ex-

KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

otic structure is also supported by the coupled multichannel study of Ref. [324]. The extended coupled-channel study of Ref. [325], where two-meson states are coupled to a potential derived within a quark model, leads to a very rich spectrum of $c\bar{c}$-$c\bar{c}$ states where parts are candidates for the observed double $J/\psi(1S)$ structures. For direct analyses of the data within the tetraquark approach, see, e.g., Ref. [326]. Also QCD sum rule studies of the system were published, but do not give consistent results: For example Ref. [327] interprets the structure at 6900 MeV as a hybrid state, Ref. [328] as a tetraquark, and Ref. [329] states that both molecular and tetraquark interpretations are possible.

An alternative view on the double-$J/\psi(1S)$ data is provided in Refs. [330–332] where the analyses are performed using coupled channel T-matrices, involving vector-vector channels of quarkonia. In these works the structures in the data emerge from the interplay of thresholds and resonances. While the number of poles that appear above the double J/ψ threshold depends on the number of channels, there is the non-trivial prediction that there should exist, if this dynamical picture were correct, a state located very near the double-$J/\psi(1S)$ threshold. In Ref. [333] it was shown that a $J/\psi(1S)J/\psi(1S)$ scattering potential sufficiently strong to bind is in fact consistent with our current understanding of $\pi J/\psi(1S)$ scattering as well as the strength of the $\pi\pi$ interactions. In Ref. [334] it is shown that the above mentioned data by LHCb, CMS and ATLAS are consistent with the presence of the above mentioned pole, whose pole position could be determined with improved accuracy. In this work it is also stressed that the nature of this $X(6200)$ cannot be determined based on the data currently available.

In contrast, Ref. [335,336] explains the double-$J/\psi(1S)$ data as cusps without nearby poles. This claim can be tested experimentally: if this explanation were correct, there should not be any narrow near threshold structure in the channel that generates the cusp, for that would call for a non-perturbative interaction in that channel, as pointed out in Ref. [337].

79. Baryon Decay Parameters

Revised August 2019 by E.D. Commins (UC Berkeley).

79.1 Baryon semileptonic decays

The typical spin-1/2 baryon semileptonic decay is described by a matrix element, the hadronic part of which may be written as:

$$\overline{B}_f \left[f_1(q^2)\gamma_\lambda + i\, f_2(q^2)\sigma_{\lambda\mu}q^\mu + g_1(q^2)\gamma_\lambda\gamma_5 + g_3(q^2)\gamma_5 q_\lambda \right] B_i \ . \tag{79.1}$$

Here B_i and $\overline{B}_f$ are spinors describing the initial and final baryons, and $q = p_i - p_f$, while the terms in f_1, f_2, g_1, and g_3 account for vector, induced tensor ("weak magnetism"), axial vector, and induced pseudoscalar contributions [1]. Second-class current contributions are ignored here. In the limit of zero momentum transfer, f_1 reduces to the vector coupling constant g_V, and g_1 reduces to the axial-vector coupling constant g_A. The latter coefficients are related by Cabibbo's theory [2], generalized to six quarks (and three mixing angles) by Kobayashi and Maskawa [3]. The g_3 term is negligible for transitions in which an $e^\pm$ is emitted, and gives a very small correction, which can be estimated by PCAC [4], for $\mu^\pm$ modes. Recoil effects include weak magnetism, and are taken into account adequately by considering terms of first order in

$$\delta = \frac{m_i - m_f}{m_i + m_f} \ , \tag{79.2}$$

where m_i and m_f are the masses of the initial and final baryons.

The experimental quantities of interest are the total decay rate, the lepton-neutrino angular correlation, the asymmetry coefficients in the decay of a polarized initial baryon, and the polarization of the decay baryon in its own rest frame for an unpolarized initial baryon. Formulae for these quantities are derived by standard means [5] and are analogous to formulae for nuclear beta decay [6]. We use the notation of Ref. [6] in the Listings for neutron beta decay. For comparison with experiments at higher q^2, it is necessary to modify the form factors at $q^2 = 0$ by a "dipole" q^2 dependence, and for high-precision comparisons to apply appropriate radiative corrections [7].

The ratio g_A/g_V may be written as

$$g_A/g_V = |\, g_A/g_V \,| \, e^{i\phi_{AV}} \ . \tag{79.3}$$

The presence of a "triple correlation" term in the transition probability, proportional to $\mathrm{Im}(g_A/g_V)$ and of the form

$$\boldsymbol{\sigma_i \cdot (p_\ell \times p_\nu)} \tag{79.4}$$

for initial baryon polarization or

$$\boldsymbol{\sigma_f \cdot (p_\ell \times p_\nu)} \tag{79.5}$$

for final baryon polarization, would indicate failure of time-reversal invariance. The phase angle ϕ has been measured precisely only in neutron decay (and in ^{19}Ne nuclear beta decay), and the results are consistent with T invariance.

79.2 Hyperon nonleptonic decays

The amplitude for a spin-1/2 hyperon decaying into a spin-1/2 baryon and a spin-0 meson may be written in the form

$$M = G_F\, m_\pi^2 \cdot \overline{B}_f \,(A - B\gamma_5)\, B_i \ , \tag{79.6}$$

where A and B are constants [1]. The transition rate is proportional to

$$R = 1 + \gamma\, \widehat{\boldsymbol{\omega}}_f \cdot \widehat{\boldsymbol{\omega}}_i + (1-\gamma)(\widehat{\boldsymbol{\omega}}_f \cdot \widehat{\mathbf{n}})(\widehat{\boldsymbol{\omega}}_i \cdot \widehat{\mathbf{n}}) + \alpha(\widehat{\boldsymbol{\omega}}_f \cdot \widehat{\mathbf{n}} + \widehat{\boldsymbol{\omega}}_i \cdot \widehat{\mathbf{n}}) + \beta \widehat{\mathbf{n}} \cdot (\widehat{\boldsymbol{\omega}}_f \times \widehat{\boldsymbol{\omega}}_i) \ , \tag{79.7}$$

where $\widehat{\mathbf{n}}$ is a unit vector in the direction of the final baryon momentum, and $\widehat{\boldsymbol{\omega}}_i$ and $\widehat{\boldsymbol{\omega}}_f$ are unit vectors in the directions of the initial and final baryon spins. (The sign of the last term in the above equation was incorrect in our 1988 and 1990 editions.) The parameters α, β, and γ are defined as

$$\begin{aligned} \alpha &= 2\,\mathrm{Re}(s^* p)/(|\,s\,|^2 + |\,p\,|^2) \ , \\ \beta &= 2\,\mathrm{Im}(s^* p)/(|\,s\,|^2 + |\,p\,|^2) \ , \\ \gamma &= (|\,s\,|^2 - |\,p\,|^2)/(|\,s\,|^2 + |\,p\,|^2) \ , \end{aligned} \tag{79.8}$$

where $s = A$ and $p = |\,\mathbf{p}_f\,| B/(E_f + m_f)$; here E_f and $\mathbf{p}_f$ are the energy and momentum of the final baryon. The parameters α, β, and γ satisfy

$$\alpha^2 + \beta^2 + \gamma^2 = 1 \tag{79.9}$$

If the hyperon polarization is $\mathbf{P}_Y$, the polarization $\mathbf{P}_B$ of the decay baryons is

$$\mathbf{P}_B = \frac{(\alpha + \mathbf{P}_Y \cdot \widehat{\mathbf{n}})\widehat{\mathbf{n}} + \beta(\mathbf{P}_Y \times \widehat{\mathbf{n}}) + \gamma \widehat{\mathbf{n}} \times (\mathbf{P}_Y \times \widehat{\mathbf{n}})}{1 + \alpha \mathbf{P}_Y \cdot \widehat{\mathbf{n}}} \ . \tag{79.10}$$

Here $\mathbf{P}_B$ is defined in the rest system of the baryon, obtained by a Lorentz transformation along $\widehat{\mathbf{n}}$ from the hyperon rest frame, in which $\widehat{\mathbf{n}}$ and $\mathbf{P}_Y$ are defined.

An additional useful parameter ϕ is defined by

$$\beta = (1 - \alpha^2)^{1/2} \sin\!\phi \ . \tag{79.11}$$

In the Listings, we compile α and ϕ for each decay, since these quantities are most closely related to experiment and are essentially uncorrelated. When necessary, we have changed the signs of reported values to agree with our sign conventions. In the Baryon Summary Table, we give α, ϕ, and Δ (defined below) with errors, and also give the value of γ without error.

Time-reversal invariance requires, in the absence of final-state interactions, that s and p be relatively real, and therefore that $\beta = 0$. However, for the decays discussed here, the final-state interaction is strong. Thus

$$s = |\,s\,|\, e^{i\delta_s} \ \text{and} \ p = |\,p\,|\, e^{i\delta_p} \ , \tag{79.12}$$

where δ_s and δ_p are the pion-baryon s- and p-wave strong interaction phase shifts. We then have

$$\beta = \frac{-2\,|\,s\,|\,|\,p\,|}{|\,s\,|^2 + |\,p\,|^2} \sin(\delta_s - \delta_p) \ . \tag{79.13}$$

One also defines $\Delta = -\tan^{-1}(\beta/\alpha)$. If T invariance holds, $\Delta = \delta_s - \delta_p$. For $\Lambda \to p\pi^-$ decay, the value of Δ may be compared with the s- and p-wave phase shifts in low-energy $\pi^- p$ scattering, and the results are consistent with T invariance.

See also the note on "Radiative Hyperon Decays" in this *Review*.

80. N and Δ Resonances

Revised August 2019 by V. Crede (Florida State U.), U. Thoma (Bonn U.), L. Tiator (KPH, JGU Mainz) and R.L. Workman (George Washington U.).

80.1 Introduction

The excited states of the nucleon have been studied in a large number of formation and production experiments. Until recently, the Breit-Wigner masses and widths, the pole positions, and the elasticities of the N and Δ resonances in the Baryon Summary Table came largely from partial-wave analyses of πN total, elastic, and charge-exchange scattering data. The most comprehensive analyses were carried out by the Karlsruhe-Helsinki (KH80) [1], Carnegie Mellon-Berkeley (CMB80) [2], and George Washington U (GWU) [3] groups. Partial-wave analyses have also been performed on much smaller πN reaction data sets to get ηN, $K\Lambda$, and $K\Sigma$ branching fractions (see the Listings for references). Other branching fractions come from analyses of $\pi N \to \pi\pi N$ data.

In recent years, a large amount of data on photoproduction of many final states has been accumulated, and these data are beginning to tell us much about the properties of baryon resonances. A survey of data on photoproduction can be found in the proceedings of recent conferences [4] and workshops [5], and in recent reviews [6, 7].

80.2 Naming scheme for baryon resonances

In the past, when nearly all resonance information came from elastic πN scattering, it was common to label resonances with the incoming partial wave $L_{2I,2J}$, as in $\Delta(1232)P_{33}$ and $N(1680)F_{15}$. However, most recent information has come from γN experiments. Therefore, we have replaced $L_{2I,2J}$ with the spin-parity J^P of the state, as in $\Delta(1232)3/2^+$ and $N(1680)5/2^+$; this name gives intrinsic properties of the resonance that are independent of the specific particles and reactions used to study them. This applies equally to all baryons, including Ξ resonances and charm baryons that are not produced in formation experiments. We do not, however, attach the mass or spin-parity to the names of the ground-state ("stable") baryons $N, \Lambda, \Sigma, \Xi, \Omega$, $\Lambda_c, \cdots$.

80.3 Using the N and Δ listings

Tables 80.1 and 80.2 list all the N and Δ entries in the Baryon Listings and give our evaluation of the overall status and the status channel by channel. Only the established resonances (overall status 3 or 4 stars) are promoted to the Baryon Summary Table. We long ago omitted from the Listings information from old analyses, prior to KH80 and CMB80, which can be found in earlier editions. A rather complete survey of older results was given in our 1982 edition [8].

As a rule, we award an overall status **** or *** only to those resonances which are derived from analyses of data sets that include precision differential cross sections and polarization observables, and are confirmed by independent analyses. All other signals are given ** or * status. New results that are not accompanied by proper error evaluation are less valuable for evaluating star ratings. The following criteria are guidelines for future error analysis.

1. Uncertainties in resonance parameters: The publication should have a detailed discussion on how the uncertainties of parameters were estimated. This requires that the error estimates go beyond the simple fit error as e.g. given by MINUIT, and the robustness of the results should be demonstrated.

2. Fit quality: Concrete measures for the fit quality should be provided. The reduced global χ^2 value of the fit, while useful, is insufficient. Other possibilities include quoting variations of local χ^2 values in kinematic regions where evidence for new resonances, or significantly improved information on resonance parameters, is claimed.

3. Weight factors in observables: Analyses sometimes use weight factors for certain data sets to either increase or reduce their impact on the results. This has been particularly important when polarization observables are involved, which often are sensitive to resonance amplitudes through interferences, but usually have much poorer statistics than differential cross section data. To evaluate sensitivities, the resulting resonance parameters should be checked against variations of the specific weight factors.

Table 80.1: The status of the N resonances and their decays. Sub-threshold decay modes are omitted. Only resonances with an overall status of *** or **** are included in the main Baryon Summary Table.

Claims of evidence for new baryon states must be based on a sufficiently complete set of partial waves in the fit. The robustness of signals must be demonstrated, e.g. by examining the effect of higher partial waves in the fit.

80.4 Properties of resonances

Resonances are defined by poles of the S-matrix, whether in scattering, production or decay matrix elements. These are poles

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com

in the complex plane in s, as discussed in the new review on *Resonances*. As is traditional, we quote here the pole positions in the complex energy $w = \sqrt{s}$ plane. Crucially, the position of the pole of the S-matrix is independent of the process, and the production and decay properties factorize. This is the rationale for listing the pole position first for each resonance. These key properties of the S-matrix pole are in contrast to other quantities related to resonance phenomena, such as Breit-Wigner parameters or any K-matrix pole. Breit-Wigner parameters depend on the formalism used, such as angular-momentum barrier factors, or cut-off parameters, and the assumed or modeled background. However, the accurate determination of pole parameters from the analysis of data on the real energy axis is not necessarily simple, or even straightforward. It requires the implementation of the correct analytic structure of the relevant (often coupled) channels.

In principle, there are two ways to extract pole parameters from experimental data: (i) analytic continuation of theoretical single- or multi-channel models into the complex energy plane or (ii) local expansions of the partial-wave T-matrix amplitudes in the complex energy plane in the vicinity of a pole.

At present, poles are usually extracted using the first method [9–14], but considerable effort has been put into the development of alternate approaches, such as the speed plot [15], time delay [16], N/D method [17], regularization procedure [18], or Padè approximation [19].

Methods of the second type are based on the idea to use first or higher-order derivatives in energy to reduce the importance of, or totally eliminate, the background contribution. One either has to model the background contribution and introduce model dependence, or one is faced with numerical derivatives of single-energy data. In both cases, one reaches almost unsurmountable difficulties.

An alternate way to extract pole parameters from partial waves has been proposed by introducing a Laurent+Pietarinen (L+P) expansion [20–22]

$$T(W) = \sum_{i=1}^{N} \frac{Res_i}{W - W_i} + \sum_{j=1}^{M} \sum_{n=0}^{n_{max}} c_n^j \left(\frac{\alpha_j - \sqrt{x_j - W}}{\alpha_j + \sqrt{x_j - W}}\right)^n , \quad (80.1)$$

where $T(W)$ is a given partial wave amplitude, W_i and Res_i are the N complex pole positions and residues. The background is parameterized with M Pietarinen functions, where α_j are positive range parameters and x_j are real or complex branch points; c_n^j are real expansion coefficients.

The main idea of this procedure is to find the simplest analytic function, with well-defined poles and cuts, regardless of whether they are generated by a theoretical model or some energy-independent procedure. Instead of searching for the function which reproduces the input amplitudes over the complete complex energy plane, on all Riemann sheets, a representation is searched only in a limited complex energy range, near the real axis, which is defined by the radius of convergence of the Laurent decomposition, and which contains the input amplitudes. All details are found in Ref. [21]. Applications of the method can be found in [20–27].

80.5 Photoproduction

A new approach to the nucleon excitation spectrum is provided by dedicated facilities at the Universities of Bonn, Grenoble, and Mainz, and at the national laboratories Jefferson Lab in the US and SPring-8 in Japan. High-precision cross sections and polarization observables for the photoproduction of pseudoscalar mesons provide a data set that is approaching a "complete experiment," one that fully constrains the four complex amplitudes describing the spin-structure of the reaction [28]. A large number of photoproduction reactions has been studied.

In pseudoscalar meson photoproduction, the four independent helicity amplitudes can be expressed in terms of the four CGLN [29] amplitudes allowed by Lorentz and gauge invariance. These amplitudes can be expanded in a series of electric and magnetic multipoles. Except for $J = 1/2$, one electric and one magnetic multipole contributes to each J^P combination.

For a given state, these two amplitudes determine the resonance photo-decay helicity amplitudes $A_{1/2}$ and $A_{3/2}$. As described below, this resonance extraction has been carried out either assuming a Breit-Wigner resonance or at the pole.

If a Breit-Wigner parametrization is used, the $N\gamma$ partial width, Γ_γ, is given in terms of the helicity amplitudes $A_{1/2}$ and $A_{3/2}$ by

$$\Gamma_\gamma = \frac{k_{\rm BW}^2}{\pi} \frac{2m_N}{(2J+1)m_{\rm BW}} \left(|A_{1/2}|^2 + |A_{3/2}|^2 \right) . \quad (80.2)$$

Here m_N and $m_{\rm BW}$ are the nucleon and resonance masses, J is the resonance spin, and $k_{\rm BW}$ is the photon c.m. decay momentum. Most earlier analyses have provided these real quantities $A_{1/2}$ and $A_{3/2}$.

More recent studies have quoted related complex quantities, evaluated at the T-matrix pole. These complex helicity amplitudes, $\tilde{A}_{1/2}$ and $\tilde{A}_{3/2}$, can be cast onto the form

$$\tilde{A}_h = \sqrt{\frac{\pi(2J+1)w_{\rm pole}}{m_N k_{\rm pole}^2}} \frac{Res(T_h(\gamma N \to N\, b))}{\sqrt{Res(T\,(N\, b \to N\, b))}} \quad (80.3)$$

where the residues (Res) are evaluated at the pole position, $w_{\rm pole}$, and $k_{\rm pole}^2 = (w_{\rm pole}^2 - m_N^2)^2/4w_{\rm pole}^2$ [30]. For Breit-Wigner amplitudes, $w_{\rm pole} = m_{\rm BW}$ and $\tilde{A}_h = A_h$. Similar relations for the photo and electro couplings at the pole position can be found in [31,32].

The determination of eight real numbers from four complex amplitudes (with one overall phase undetermined) requires at least seven independent measurements. At least one further measurement is required to resolve discrete ambiguities that result from the fact that data are proportional to squared amplitudes. Photon beams and nucleon targets can be polarized (with linear or circular polarization $P_\perp$, $P_\odot$ and $\vec{T}$, respectively); the recoil polarization of the outgoing baryon $\vec{R}$ can be measured. The experiments can be divided into three classes: (1) the beam and target are polarized (BT); (2) the beam is polarized and the recoil baryon polarization is measured (BR); (3) the target is polarized and the recoil polarization is measured (TR). Different sign conventions are used in the literature, as summarized in [33].

One of the best studied reactions is $\gamma p \to \Lambda K^+$. Published data include differential cross sections, the beam asymmetry Σ, the target asymmetry T, the recoil polarization P, and the BR double-polarization variables $C_{x'}, C_{z'}, O_{x'}$, and $O_{z'}$. For the photoproduction of pions and etas, off proton and neutron targets, differential cross sections, single- and double-polarization asymmetries have been measured, mainly for pions.

80.6 Electroproduction

Electroproduction of mesons provides information on the internal structure of resonances. The helicity amplitudes are functions of the (squared) momentum transfer $Q^2 = -(e-e')^2$, where e and e' are the 4-momenta of the incident and scattered electron, and a third amplitude, $S_{1/2}$, measures the resonance response to the longitudinal component of the virtual photon. Most data stem from the reactions $e^- p \to e^- n\pi^+$ and $e^- p \to e^- p\pi^0$ but also the reactions $e^- p \to e^- p\eta$, $e^- p \to e^- p\pi^+\pi^-$, and $e^- p \to e^- \Lambda(\Sigma^0)K^+$ have been studied. The data and their interpretation are reviewed in Refs. [34,35].

The transition to the $\Delta(1232)3/2^+$ is often quantified in terms of the magnetic dipole transition moment M_{1+} (or the magnetic transition form factor $G^*_{M,Ash}(Q^2)$) [36], and the electric and scalar quadrupole transition moments E_{1+} and S_{1+}. Figure 80.1 shows the strength of the $p \to \Delta^+$ transition plotted versus the photon virtuality Q^2. At $Q^2 = 0$, M_{1+} dominates the resonance transition strength. The two amplitudes E_{1+} and S_{1+} imply a quadrupole deformation of the transition to the lowest excited state. The magnitude of $R_{EM} = E_{1+}/M_{1+}$ remains nearly constant, while the magnitude of $R_{SM} = S_{1+}/M_{1+}$ increases rapidly up to 25% at the highest Q^2 value.

Figure 80.2 shows the transverse and scalar helicity amplitudes for the $N(1440)1/2^+$, $N(1520)3/2^-$, and $N(1535)1/2^-$ resonances from JLab [34]. Similar results have been achieved at

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

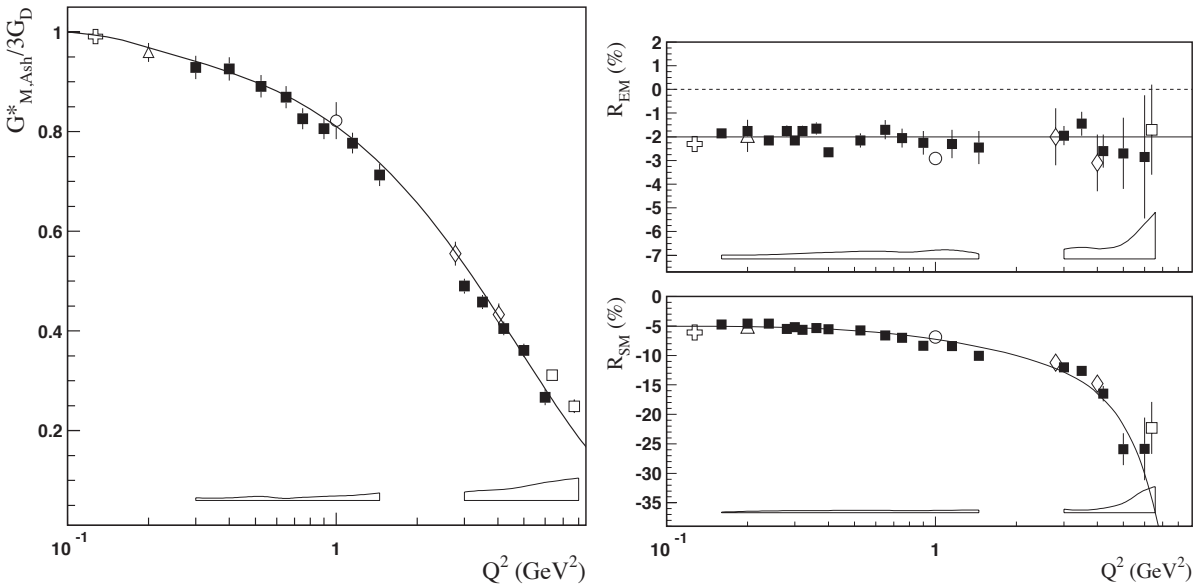

Figure 80.1: Left: The magnetic transition form factor for the $\gamma^* p \to \Delta^+(1232)$ transition versus the photon virtuality Q^2. Right: The electric and scalar quadrupole ratios R_{EM} and R_{SM}. The different symbols are results from different experiments at JLab (squares, diamonds, circle) and MAMI (triangle, cross). The boxes near the horizontal axis indicate model uncertainties of the squares. Curves to guide the eyes.

Mainz [35]. For the states $N(1440)1/2^+$ and $N(1520)3/2^-$, helicity amplitudes and $\pi\Delta$ and ρp decays were determined at JLab in an analysis of $\pi^+\pi^- p$ electroproduction [37]. The data show distinctly different Q^2 dependencies that indicate different internal structures.

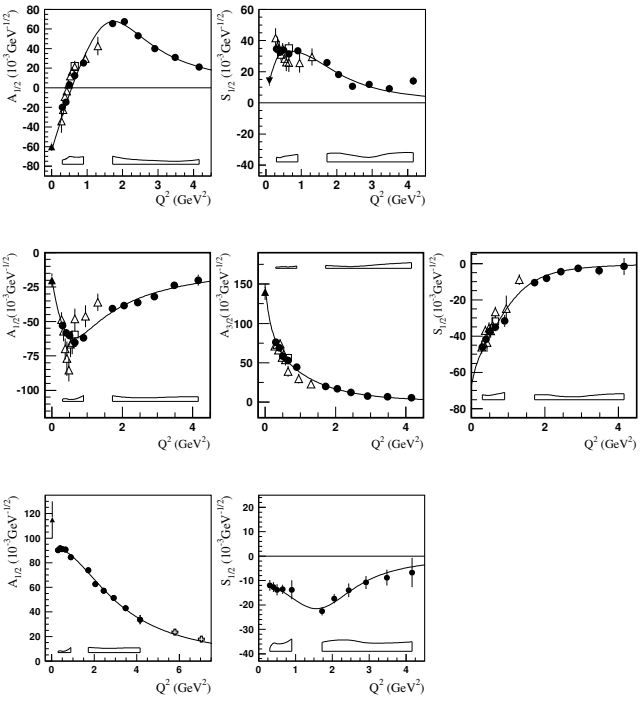

Figure 80.2: Transverse and scalar (longitudinal) helicity amplitudes for $\gamma p \to N(1440)1/2^+$ (top), $\gamma p \to N(1520)3/2^-$ (center), and $\gamma p \to N(1535)1/2^-$ (bottom) as extracted from the JLab/-CLAS data in $n\pi^+$ production (full circles), MAMI/A1 data in $p\pi^0$ production (full down triangle), in $p\pi^+\pi^-$ (open triangles), and combined single and double pion production (open squares). The solid triangle is the PDG 2014 value at $Q^2 = 0$. The open boxes are the model uncertainties of the full circles.

The $N(1520)3/2^-$ helicity amplitudes reveal the dominance of its three-quark nature: the $A_{3/2}$ amplitude is large at the photon point and decreases rapidly $\sim Q^{-5}$ with increasing Q^2; $A_{1/2}$ is small at the photon point, increases rapidly with Q^2 and then falls off with $\sim Q^{-3}$. Quantitative agreement with the data is, however, achieved only when meson cloud effects are included.

At high Q^2, both amplitudes for $N(1440)1/2^+$ are qualitatively described by light front quark models [38]: at short distances the resonance behaves as expected from a radial excitation of the nucleon. On the other hand, $A_{1/2}$ changes sign at about $0.6\,\mathrm{GeV}^2$. This remarkable behavior has not been observed before for any nucleon form factor or transition amplitude. Obviously, an important change in the structure occurs when the resonance is probed as a function of Q^2.

The Q^2 dependence of $A_{1/2}$ of the $N(1535)1/2^-$ resonance exhibits the expected Q^{-3} dependence, except for small Q^2 values where meson cloud effects set in.

Figure 80.3 shows the transverse and scalar amplitudes for three states in the 3rd nucleon resonance region, the $\Delta(1620)1/2^-$, the $N(1675)5/2^-$ and $N(1680)5/2^+$. The latter two states have nearly degenerate masses and are parity partners. In the quark model picture, the transverse amplitudes for $N(1675)5/2^-$ on the proton are suppressed due to the Moorhouse selection rule, allowing for a quantitative evaluation of the meson-baryon contributions. The data show significant meson-baryon strength in the $A_{1/2}$ amplitude even at quite high Q^2, while $A_{3/2}$ drops much faster with Q^2. $N(1680)5/2^+$ shows qualitatively the features predicted in constituent quark models, a dominant $A_{3/2}$ at the real photon point that drops rapidly with increasing Q^2, while $A_{1/2}$ becomes the dominant contribution at high Q^2, indicating a switch of the helicity structure in the resonance transition at short distances.

80.7 Partial wave analyses

Several PWA groups are now actively involved in the analysis of the new data. The GWU group maintains a nearly complete database covering reactions from πN and KN elastic scattering to $\gamma N \to N\pi$, $N\eta$, and $N\eta'$. It is presently the only group determining πN elastic amplitudes from scattering data in sliced energy bins. Given the high-precision of photoproduction data already or soon to be collected, the spectrum of N and Δ resonances will in the near future be better known.

Fits to the data are performed by various groups with the aim

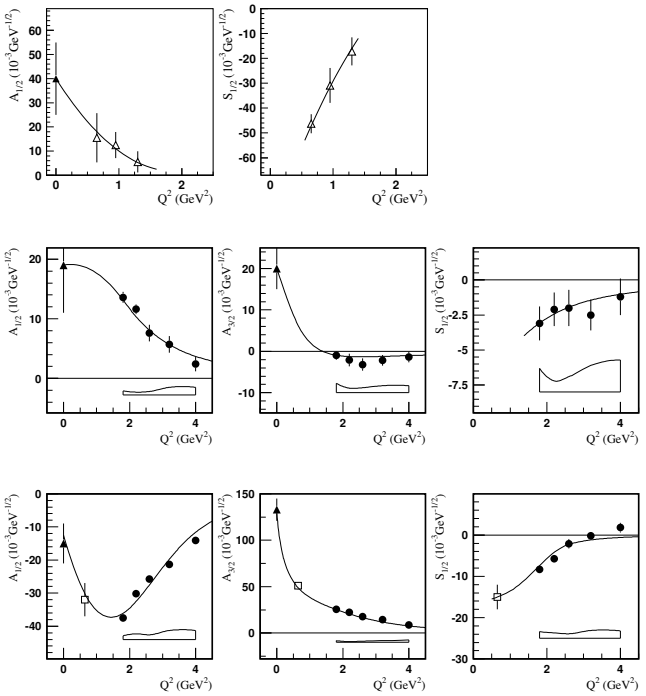

Figure 80.3: Transverse and scalar helicity amplitudes for $\gamma p \to \Delta(1620)1/2^-$ (top), $\gamma p \to N(1675)5/2^-$ (center), and $\gamma p \to N(1680)5/2^+$ (bottom) as extracted from the JLab/CLAS data in $n\pi^+$ production (full circles), $p\pi^+\pi^-$ (open triangles), combined single and double pion production (open square). The solid triangle is the 2014 PDG value at $Q^2 = 0$. The open boxes are the model uncertainties of the full circles. The curves are to guide the eye.

to understand the reaction dynamics and to identify N and Δ resonances. For practical reasons, approximations have to be made. We mention several analyses here: (1) The Mainz unitary isobar model [39] focuses on the correct treatment of the low-energy domain. Resonances are added to the unitary amplitude as a sum of Breit-Wigner amplitudes. This model also obtains resonance transition form factors and helicity amplitudes from electroproduction [35]. (2) For $N\pi$ electroproduction, the Yerevan/JLab group uses both the unitary isobar model and the dispersion relation approach developed in [38]. A phenomenological model was developed to extract resonance couplings and partial decay widths from exclusive $\pi^+\pi^- p$ electroproduction [37]. (3) Multichannel analyses using K-matrix parameterizations derive background terms from a chiral Lagrangian - providing a microscopical description of the background - (Giessen [40, 41]) or from phenomenology (KSU [42, 43], Bonn-Gatchina [44]). (4.) Several groups (EBAC-Jlab [45, 46], ANL-Osaka [47], Dubna-Mainz-Taipeh [48], Bonn-Jülich [49–51], Valencia [52]) use dynamical reaction models, driven by chiral Lagrangians, which take dispersive parts of intermediate states into account. Several other groups have made important contributions. The Giessen group pioneered multichannel analyses of large data sets on pion- and photo-induced reactions [40, 41]. The Bonn-Gatchina group included recent high-statistics data and reported systematic searches for new baryon resonances in all relevant partial waves. A summary of their results can be found in [44].

81. Λ and Σ Resonances

Revised August 2021 by V. Crede (Florida State U.), E. Klempt (Bonn U.), U. Thoma (Bonn U.), L. Tiator (KPH, JGU Mainz) and R.L. Workman (George Washington U.).

81.1 Introduction

For several decades, there has been very little new experimental data bearing on the properties of Λ and Σ resonances. An exception was the study at JLab of the reactions $\gamma p \to K^+\Sigma^\pm\pi^\mp$ and $\gamma p \to K^+\Sigma^0\pi^0$ [1], which established the spin and parity of the $\Lambda(1405)$ [2]. There was also from BNL new data on the very low energy region of K^-p scattering [3–7]. Otherwise, the field is starved for data. Recent analyses (see below) have improved what we know about the *properties* of the known Λ and Σ resonances, but the *established* resonances are the same ones that were listed in our 1984 edition [8] except for the $\Sigma(2250)$ which we consider 2-star only due to its unkown spin-parity. The 1990 Review [9] gave a full report of the status of Lambda and Sigma hyperons, and included Argand plots from the partial-wave analyses. The 2018 Review [10] has a short survey of the $\Sigma(1670)$-region.

In the last few years, four groups have re-analyzed K^-p reactions using more extensive collections of the old data. These analyses justify an update of the status of the Λ and Σ resonances. Although they have not established any new resonances, they have provided at least some evidence for new states and have given a better understanding of the old ones.

Table 81.1: The status of the Λ resonances. Only those with an overall status of *** or **** are included in the main Baryon Summary Table. Decay channels other than $N\overline{K}$ and $\Sigma\pi$ are only given for *** and **** resonances.

		Overall	Status as seen in —		
Particle	J^P	status	$N\overline{K}$	$\Sigma\pi$	Other channels
$\Lambda(1116)$	$1/2^+$	****			$N\pi$ (weak decay)
$\Lambda(1380)$	$1/2^-$	**	**	**	
$\Lambda(1405)$	$1/2^-$	****	****	****	
$\Lambda(1520)$	$3/2^-$	****	****	****	$\Lambda\pi\pi, \Lambda\gamma, \Sigma\pi\pi$
$\Lambda(1600)$	$1/2^+$	****	***	****	$\Lambda\pi\pi, \Sigma(1385)\pi$
$\Lambda(1670)$	$1/2^-$	****	****	****	$\Lambda\eta$

$\Lambda(2350)$	$9/2^+$	***	***	*	
$\Lambda(2585)$		*	*		

Tables 81.1 and 81.2 give our evaluation of the status, both overall and channel by channel, of each Λ and Σ resonance in the Particle Listings. In making these evaluations, we considered, in addition to the four analyses [11–14], the ratings that predated them. The ratings use a 1- to 4-star system. For more details on the evaluation of the overall star ratings, see [15]. The main Summary Table includes only established states with an overall status of 3 or 4 stars; as has already been noted, these are the same fourteen Λ resonances (including $\Lambda(1116)$) and nine Σ resonances instead of the former ten (including $\Sigma(1193)3/2^+$, and $\Sigma(1385)3/2^+$) that had long been in the Table. In addition, there are seven 1-star and two 2-star Λ's, and fourteen 1-star and three 2-star Σ's in the Particle Listings.

Table 81.2: The status of the Σ resonances. Only those with an overall status of *** or **** are included in the main Baryon Summary Table. Decay channels other than $N\overline{K}$, $\Lambda\pi$ and $\Sigma\pi$ are only given for *** and **** resonances.

		Overall	Status as seen in —			
Particle	J^P	status	$N\overline{K}$	$\Lambda\pi$	$\Sigma\pi$	Other channels

81.2 New analyses

The new analysis progress was pioneered by the Kent group which collected a large fraction of the available data and performed a comprehensive partial wave analysis [11,16]. K^-p scattering into a pseudoscalar meson and an octet baryon is governed by two complex amplitudes; hence four quantities need to be measured to fully construct the amplitudes (up to an arbitrary phase per energy and angular bin). Discussions of complete experiments also generally assume perfect data (no experimental uncertainties); realistic uncertainties further complicate the task of amplitude extraction. Here, the available data are limited to the differential cross section and the target or hyperon recoil polarization P; data on the polarization transfer do not exist. The authors of Ref. [16] overcame this difficulty by using start values for the partial wave amplitudes determined in [17] and/or from an energy-dependent fit and by freezing or releasing sets of amplitudes. The resulting amplitudes were fitted with a unitary multichannel parameterization [11].

The JPAC group presented a coupled-channel fit to the $\bar{K}N$ partial waves derived by the Kent group [13]. The JPAC approach was based on the K-matrix formalism. Special attention was paid to the analytical properties of the amplitudes determined by the square-root unitary branch points and the continuation to the complex angular momentum plane. The fit described the Kent partial waves reasonably well. However, when observables were calculated from their partial-wave amplitudes, significant discrepancies became apparent. The results were therefore not included in the RPP.

The ANL-Osaka group derived the energy-dependent amplitudes in fits to a large subset of the data collected in Ref. [16] and

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

further data sets described in Ref. [18]. Their fits were based on a phenomenological SU(3) Lagrangian [18]. The two ANL-Osaka models agree on the leading contributions but differ significantly in cases with weaker candidates [12].

The Bonn-Gatchina (BnGa) group added further (old) data to those analyzed in Ref. [16]. The data set was fitted in a modified K-matrix approach and the resulting amplitudes were compared with those from Refs. [16, 18]. New resonances were found, other states, mostly one and two-star states could not be confirmed; all resonances were tested for their statistical significance. Additional states with any set of quantum numbers were tested and were found to produce only small improvements in the fit [14]. In Ref. [19], properties of the full set of contributing hyperons were reported.

The star ratings of Λ and Σ resonances given in our earlier editions, and the new results from the Kent, ANL-Osaka and BnGa groups were used to update the star rating of the hyperon resonances. In [19], the overall star rating is directly estimated, for [11] we estimate the star rating from the branching-ratio uncertainties. In [12], two solutions are given but no uncertainties for branching ratios. The overall star ratings are based on the evidence for the resonances in the new analyses as well as their consistency including also the results of earlier analyses given in [20]. For further details see also [15].

We decided to remove the three so-called *bumps* $\Sigma(1480)$, $\Sigma(1560)$, $\Sigma(1670)$, and $\Sigma(1690)$ as well as $\Sigma(1620)$ from production experiments. The entries from $\Sigma(1770)1/2^+$ are now listed under $\Sigma(1660)1/2^+$ and $\Sigma(1880)1/2^+$, the entries from $\Sigma(1730)3/2^+$ and $\Sigma(1840)3/2^+$ are now combined to one $\Sigma(1780)3/2^+$. The one-star $\Sigma(2000)1/2^-$ is combined with a new one-star $\Sigma(2160)1/2^-$ to a single one-star $\Sigma(2110)1/2^-$. Apart from $\Lambda(1380)1/2^-$, four further new resonances were included in the Listings: $\Lambda(2070)3/2^+$, $\Lambda(2080)5/2^-$, $\Sigma(2010)3/2^-$, and $\Sigma(2230)3/2^+$, all with one star.

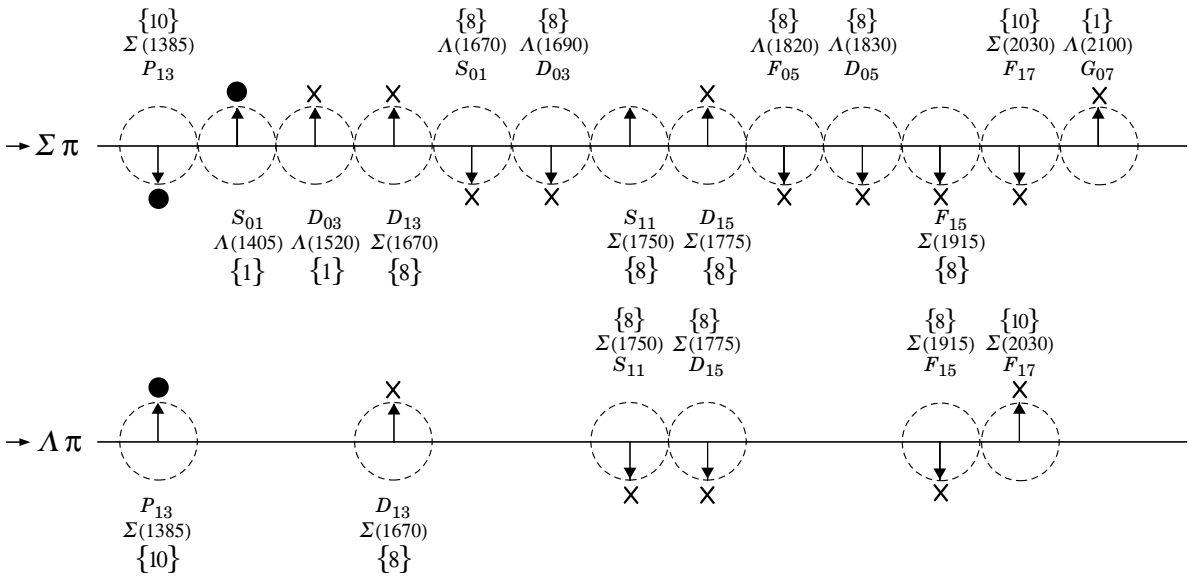

Figure 81.1: The signs of the imaginary parts of resonating amplitudes in the $\overline{K}N \to \Lambda\pi$ and $\Sigma\pi$ channels. The signs of the $\Sigma(1385)$ and $\Lambda(1405)$, marked with a •, are set by convention, and then the others are determined relative to them. The signs required by the SU(3) assignments of the resonances are shown with an arrow, and the experimentally determined signs are shown with an ×.

81.3 Sign conventions for resonance couplings

In terms of the isospin-0 and isospin-1 elastic scattering amplitudes A_0 and A_1, the amplitude for $K^-p \to \overline{K}^0 n$ scattering is $\pm(A_1 - A_0)/2$, where the sign depends on conventions used in conjunction with the Clebsch-Gordan coefficients (such as, is the baryon or the meson the "first" particle). If this reaction is partial-wave analyzed and if the overall phase is chosen so that, say, the $\Sigma(1775)5/2^-(D_{15})$ amplitude at resonance points along the positive imaginary axis (points "up"), then any Σ at resonance will point "up" and any Λ at resonance will point "down" (along the negative imaginary axis). Thus the phase at resonance determines the isospin. The above ignores background amplitudes in the resonating partial waves. That is the basic idea. In a similar but somewhat more complicated way, the phases of the $\overline{K}N \to \Lambda\pi$ and $\overline{K}N \to \Sigma\pi$ amplitudes for a resonating wave help determine the SU(3) multiplet to which the resonance belongs. Again, a convention has to be adopted for some overall arbitrary phases: which way is "up"? Our convention is that of Levi-Setti [21] and is shown in Fig. 81.1, which also compares experimental results with theoretical predictions for the signs of several resonances. In the Listings, a + or − sign in front of a measurement of an inelastic resonance coupling indicates the sign (the *absence* of a sign means that the sign is not determined, *not* that it is positive). Also other decay modes can be used to assign a hyperon to a SU(3) multiplet [22, 23]. Modern analyses determine properties of resonances at the pole position. In these analyses, the + or − sign is replaced by a phase. Background amplitudes can lead to significant phase shifts, and an additional phase shift due to rescattering is admitted in some analyses. In comparison to quark model predictions [19, 24], three Λ spin doublets can be identified as being mainly SU(3) singlets: the well-known ($\Lambda(1405)1/2^-$, $\Lambda(1520)3/2^-$), the ($\Lambda(2080)5/2^-$, $\Lambda(2100)7/2^-$), and ($\Lambda(2070)3/2^+$, $\Lambda(2110)5/2^+$).

81.4 The Λ(1405)

In coupled-channels calculations based on the chiral SU(3) effective field theory, the strongly attractive forces between $N\overline{K}$ and $\Sigma\pi$ generate five poles, one SU(3) singlet pole, two Λ octet poles and two (or one) octet Σ poles (see Section 82). In quark models, these five states are $\Lambda(1405)$, $\Lambda(1670)$, $\Lambda(1800)$, $\Sigma(1620)$, and $\Sigma(1750)$. The octet states are found 100 to 150 MeV above the corresponding nucleon resonances. In chiral SU(3) effective field theories, at least three of these states are seen in the 1300 to 1600 MeV mass range. The appearance of two Λ poles in this mass range, a narrow SU(3) octet at ∼1420 MeV and a wider SU(3) singlet at ∼1380 MeV, was unexpected. This approach has been pursued by a number of groups; for a summary of the results see our Review 82, "Pole Structure of the $\Lambda(1405)$ Region". In the Listings, we have introduced the $\Lambda(1380)$ as a new candidate reso-

nance (with two stars), named in accordance with its approximate pole position. The second SU(3) octet Λ state is the well-known $\Lambda(1670)$. The masses of the two associated Σ states are uncertain so far, and no new entries are introduced in the Listings.

In traditional approaches only one resonance was seen in this mass region, the narrow state at 1405 MeV. It was reported to be the SU(3) singlet state a long time ago in Ref. [25], in agreement with the quark-model expectations but in contrast to the findings based on coupled-channels calculations within chiral SU(3) effective field theories. In the Listings, the $\Lambda(1405)$ has been retained with its traditional name. In quark models, this state is identified with the SU(3) singlet state, the two Λ octet states with $\Lambda(1670)$ and $\Lambda(1800)$, and the two Σ states with $\Sigma(1620)$ and $\Sigma(1750)$.

81.5 Uncertainties on masses and widths

The uncertainties quoted on resonance parameters from partial-wave analyses are often only statistical, and the parameters can change beyond these uncertainties when a different parametrization of the waves is used. Furthermore, the different analyses use more or less the same data, so it is not really appropriate to treat the different determinations of the resonance parameters as independent or to average them. In any case, the spread of the masses, widths, and branching fractions from the different analyses is certainly a better indication of the uncertainties than are the quoted uncertainties. In the Listings, we usually give a range reflecting the spread of the values rather than a particular value with error.

81.6 Production experiments

Partial-wave analyses of course separate partial waves, whereas a peak in a cross section or an invariant mass distribution usually cannot be disentangled from background and analyzed for its quantum numbers; and more than one resonance may be contributing to the peak. The $\Sigma(1385)$ and $\Lambda(1405)$ lie below the $\overline{K}N$ threshold and nearly everything about $\Sigma(1385)$ is learned from production experiments. Our knowledge on $\Lambda(1405)$ benefits greatly from photoproduction of the three $\Sigma\pi$ charge states [1, 2] and from the precise measurement of the energy shift and width of the kaonic hydrogen atom [26].

Production and formation experiments agree quite well in the case of $\Lambda(1520)$ and results have been combined. Above this mass, no new results on peak hunting have been reported for about 40 years. For these early results, we refer the reader to our earlier editions. In photoproduction with energetic photons [27, 28] or at LHCb [29], hyperons are produced abundantly. So far, no attempt has been made to extract hyperon properties from these data. New data on hyperon spectroscopy can be expected from J-PARC [30], JLAB [31], and the forthcoming PANDA experiment [32].

82. Pole Structure of the $\Lambda(1405)$ Region

Revised Feb. 2025 by T. Hyodo (RCNP, Osaka U.; Tokyo Metropolitan U.) and U.-G. Meißner (Bonn U.; FZ Jülich).

The $\Lambda(1405)$ resonance emerges in the meson-baryon scattering amplitude with the strangeness $S = -1$ and isospin $I = 0$. It is the archetype of what is called a dynamically generated resonance, as pioneered by Dalitz and Tuan [1]. The most powerful and systematic approach for the low-energy regime of the strong interactions is chiral perturbation theory (ChPT), see e.g. Ref. [2]. A perturbative calculation is, however, not applicable to this sector because of the existence of the $\Lambda(1405)$ just below the $\bar{K}N$ threshold. In this case, ChPT has to be combined with a non-perturbative resummation technique, just as in the case of the nuclear forces. By solving the Lippmann-Schwinger equation with the interaction kernel determined by ChPT and using a particular regularization, in Ref. [3] a successful description of the low-energy $K^- p$ scattering data as well as the mass distribution of the $\Lambda(1405)$ was achieved (for further developments, see Refs. [4–8] and references therein). As will be discussed below, lattice QCD calculations are also getting close to unraveling the complex structure of the scattering amplitude in this energy region.

The study of the pole structure was initiated by Ref. [9], which finds two poles of the scattering amplitude in the complex energy plane between the $\bar{K}N$ and $\pi\Sigma$ thresholds. The spectrum in experiments exhibits one effective resonance shape, while the existence of two poles results in reaction-dependent lineshapes [10]. The origin of this two-pole structure is attributed to the two attractive channels of the leading order interaction in the SU(3) basis (singlet and octet) [10] and in the isospin basis ($\bar{K}N$ and $\pi\Sigma$) [11]. It is remarkable that the sign and the strength of the leading order interaction is determined by a low-energy theorem of chiral symmetry, i.e. the so-called Weinberg-Tomozawa term. The two-pole nature of the $\Lambda(1405)$ is qualitatively different from the case of the N(1440) resonance. Two poles of the N(1440) appear on different Riemann sheets of the complex energy plane separated by the $\pi\Delta$ branch point. These poles reflect a single state, with a nearby pole and a more distant shadow pole. In contrast, the two poles in the $\Lambda(1405)$ region on the same Riemann sheet (where $\pi\Sigma$ channels are unphysical and all other channels physical, correspondingly to the one, connected to the real axis between the $\pi\Sigma$ and $\bar{K}N$ thresholds) are generated from two attractive forces mentioned above [10, 11].

There have been various experimental results related to the $\Lambda(1405)$ [4]. Among these, the most striking measurement is the precise determination of the energy shift and width of kaonic hydrogen by the SIDDHARTA collaboration [12, 13], which provides a quantitative and stringent constraint on the $K^- p$ amplitude at threshold through the improved Deser formula [14]. Systematic studies with error analyses based on the next-to-leading order ChPT interaction including the SIDDHARTA constraint have been performed by various groups [15–20]. All these studies confirm that the new kaonic hydrogen data are compatible with the scattering data above threshold. Thanks to these developments, starting from the 2020 edition, the name $\Lambda(1405)$ is used to refer to the higher-energy pole, while the lower-energy pole is now called the $\Lambda(1380)$.

The results of the pole positions of the $\Lambda(1405)$ and $\Lambda(1380)$ in the various approaches are summarized in Table 82.1 and Fig. 82.1. We may regard the difference among the calculations as a systematic error, which stems from the various approximations of the Bethe-Salpeter equation, the fitting procedure, and also the inclusion of SU(3) breaking effects such as the choice of the various meson decay constants, and so on. A detailed comparison of the various approaches listed in the table is given in Ref. [21]. An analysis including also the $J^P = 1/2^+$ P-wave contribution (and also an explicit $\Sigma(1385)$ $3/2^+$ state) gives results consistent with the findings reported above, with the pole positions at $(1364 - i43)$ MeV and $(1430 - i15)$ MeV, respectively [22].

The main contribution in this energy region is provided by the $\Lambda(1405)$ pole, whose position converges within a relatively small region near the $\bar{K}N$ threshold. On the other hand, the position of the $\Lambda(1380)$ shows a sizeable scatter. Detailed studies of the $\pi\Sigma$ spectrum in various reaction processes, together with the precise experimental lineshape (see e.g. the recent precise photoproduction data from the LEPS collaboration [24] and from the CLAS collaboration [25, 26], electroproduction data from the CLAS collaboration [27], and proton-proton collision data from COSY [28] and the HADES collaboration [29]), will shed light on the position of the second pole. The $\pi\Sigma$ spectra from the CLAS data are analyzed in Ref. [30] and Ref. [19]. It was shown in Ref. [19] that

Table 82.1: Comparison of the pole positions of $\Lambda(1405)$ and $\Lambda(1380)$ in the complex energy plane from next-to-leading and next-to-next-to-leading order chiral unitary coupled-channel approaches including the SIDDHARTA constraint. The lower two results also include the CLAS photoproduction data.

approach	$\Lambda(1405)$ [MeV]	$\Lambda(1380)$ [MeV]

several solutions, which agree with the scattering data, are ruled out if confronted with the recent CLAS data. The remaining solutions are collected as solution #2 and solution #4 in Table 82.1. The HADES data are analyzed in Ref. [31] and Ref. [32]. Although the result of the pole found in Ref. [31] is not compatible with other results, the authors of Ref. [32] invoke the anomalous triangle singularity mechanism to argue that the invariant mass distribution of the $\pi\Sigma$ system is found at lower masses than in other reactions. It is thus desirable to perform more comprehensive analyses of $\pi\Sigma$ spectra together with the systematic error analysis of the scattering data.

Recently, a next-to-next-to leading order (NNLO) analysis of the meson-baryon scattering was performed [23], by incorporating the constraints from the πN and KN scattering phase shifts, in addition to the $S = -1$ scattering. As tabulated in Table 82.1, the results are qualitatively consistent with the previous studies, reinforcing the existence of the two states, $\Lambda(1405)$ and $\Lambda(1380)$. It is also worth mentioning that the Baryon Scattering collaboration provides the lattice QCD calculation of the meson-baryon coupled-channel scattering [33, 34]. It is found that there appears a virtual state below the $\pi\Sigma$ threshold and a resonance pole just below the $\bar{K}N$ threshold at $M_\pi \approx 200$ MeV. Thus, the existence of $\Lambda(1405)$ and $\Lambda(1380)$ is also indicated by this first principles QCD calculation. These results have been critically assessed in Refs. [35, 36], where it is shown that the nature of the $\Lambda(1380)$ can not yet be definitively determined from these lattice data.

83. Pentaquarks

Revised November 2025 by M. Karliner (Tel Aviv U.) and T. Skwarnicki (Syracuse U.).

Experimental searches for pentaquark hadrons comprised of light flavors have a long and vivid history. No undisputed candidates had been found in 50 years. The first wave of claimed observations of pentaquark candidates containing a strange antiquark occurred in the early seventies, see e.g. a review in the 1976 edition of Particle Data Group listings for $Z_0(1780)$, $Z_0(1865)$ and $Z_1(1900)$ [1]. The last mention of these candidates can be found in the 1992 edition [2] with the perhaps prophetic comment "the results permit no definite conclusion - the same story for 20 years. [...] The skepticism about baryons not made of three quarks, and lack of any experimental activity in this area, make it likely that another 20 years will pass before the issue is decided." A decade later, a second wave of observations occurred, possibly motivated by specific theoretical predictions for their existence [3–5]. The evidence for pentaquarks was based on observations of peaks in the invariant mass distributions of their decay products. More data and subsequent more sensitive experiments did not confirm these claims [6]. In the last mention of the best known candidate from that period, $\Theta(1540)^+$, the 2006 Particle Data Group listing [7] included a statement: "The conclusion that pentaquarks in general, and that Θ^+, in particular, do not exist, appears compelling." which well reflected the prevailing mood in the particle physics community until a study of $\Lambda_b^0 \to J/\psi p K^-$ ($J/\psi \to \mu^+\mu^-$) decays by LHCb [8] (charge conjugate modes are implied). From an analysis of 3 fb^{-1} Run 1 data at 7 and 8 TeV at the LHC, the LHCb collaboration reported a significant $J/\psi p$ structure in $\Lambda_b^0 \to J/\psi p K^-$ decays [8]. The exotic character of this structure, with the minimal quark content of $uudc\bar{c}$, was demonstrated in a nearly model-independent way in Ref. [9], where it was shown that the $J/\psi p$ mass ($m_{J/\psi p}$) peak near 4450 MeV was too narrow to be accounted for by $\Lambda^* \to pK^-$ reflections (Λ^* denotes a generic Λ excitation), reinforcing the results from the earlier model-dependent six-dimensional amplitude analysis of invariant masses and decay angles describing the Λ_b^0 decay in the same data [8]. The LHCb 6 fb^{-1} Run 2 LHC data at 13 TeV, together with the improvements in the data selection for both runs, resulted in a nine-fold increase in the number of reconstructed $\Lambda_b^0 \to J/\psi p K^-$ decays (246,000 events) [10] and observation of new narrow $J/\psi p$ structures which were too faint to had been significant in the Run 1 data analysis. A second horizontal band is observed in the Dalitz plot (Fig. 83.1) near 4312 MeV in the $J/\psi p$ mass.

The 4450 MeV structure also appears to consist of two narrower peaks at 4440 and 4457 MeV. Performing a rigorous six-dimensional amplitude analysis of these faint $J/\psi p$ structures is challenging and has not been accomplished yet. Fortunately, the newly observed peaks are so narrow that it is not necessary to construct an amplitude model to prove that these states are not artifacts of interfering Λ^* resonances, as was previously demonstrated in Ref. [9]. Their masses and widths have been characterized by the LHCb (see Table 83.1) from one-dimensional fits to $J/\psi p$ mass distributions, with different levels of suppression of the Λ^* contributions, which peak at the lower pK^- masses (Fig. 83.1). Such analysis is not sensitive to any broad $J/\psi p$ contributions. The histograms analyzed by the LHCb are available in tabular form at https://www.hepdata.net/record/89271.

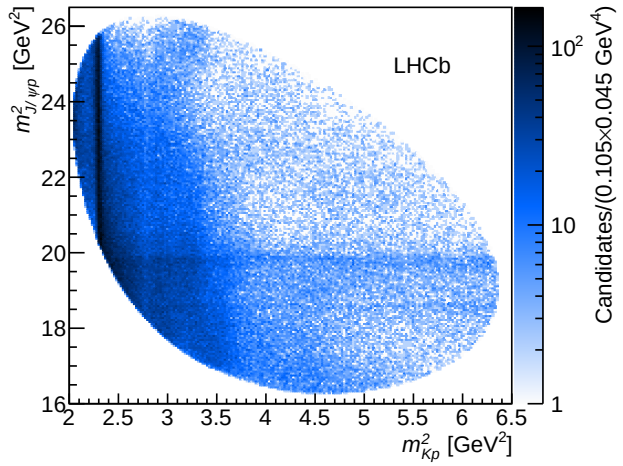

Figure 83.1: Dalitz plot distributions for $\Lambda_b^0 \to J/\psi p K^-$ decays as observed by LHCb.

The fit chosen by the LHCb for the central mass and width values is displayed in Fig. 83.2. The $P_{c\bar{c}}(4312)^+$ state (formerly known as $P_c(4312)^+$) peaks right below the $\Sigma_c^+ \bar{D}^0$ threshold and has statistical significance over 7.6σ. The $P_{c\bar{c}}(4457)^+$ state peaks right below the $\Sigma_c^+ \bar{D}^{*0}$ threshold, while the $P_{c\bar{c}}(4440)^+$ state peaks about 20 MeV below it. The significance of the two-peak versus one-peak hypothesis for the 4450 MeV structure is over 5.4σ, rendering the single peak interpretation of this region obsolete. The six-dimensional amplitude analysis reported in Ref. [8], which in addition to the structure near 4450 MeV, provided also evidence for the broad $P_{c\bar{c}}(4380)^+$ state, is obsolete since it used the single $P_{c\bar{c}}(4450)^+$ state and it lacked the $P_{c\bar{c}}(4312)^+$ state. Furthermore, it used the helicity formalism in which the half-integer spin of the proton was not aligned properly between the different Λ_b^0 decay chains [11, 12]. The newer one-dimensional analysis by LHCb [10] was not sensitive to wide $P_{c\bar{c}}^+$ states. The LHCb result from the six-dimensional amplitude analysis of the Cabibbo suppressed channel $\Lambda_b^0 \to J/\psi p \pi^-$ [13], which contains a statistically marginal evidence for the sum of the $P_{c\bar{c}}^+$ and the $T_{c\bar{c}1}^-$ (formerly known as $Z_c(4200)^-$) contributions, took extensive input from Ref. [8] and, like the $P_{c\bar{c}}(4380)^+$ state, should be treated with caution until the both amplitude analyses are completed on the enlarged data sets with the modified helicity formalism.

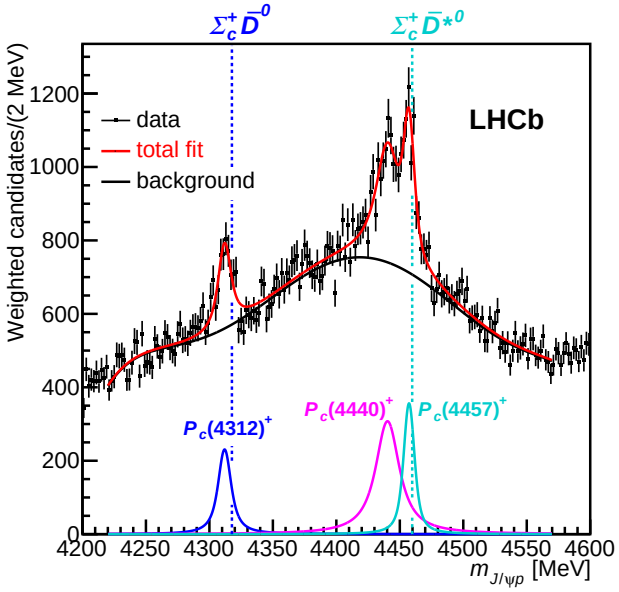

Figure 83.2: Fit to the $J/\psi p$ mass distribution, in which events were weighted to suppress $\Lambda^* \to pK^-$ backgrounds, of three Breit-Wigner functions and a sixth-order polynomial background. This fit was used to determine the central values of the masses and widths of the $P_{c\bar{c}}^+$ states (formerly known as P_c^+) reported by LHCb. The mass thresholds for the $\Sigma_c^+ \bar{D}^0$ and $\Sigma_c^+ \bar{D}^{*0}$ final states are superimposed.

While $\Sigma_c \bar{D}^{(*)}$ states had been predicted [14–17] before the first LHCb results [8], after these results became known, many theoretical groups interpreted the $P_{c\bar{c}}(4450)^+$ and $P_{c\bar{c}}(4380)^+$ states in terms of diquarks and triquarks as building blocks of a compact pentaquark [18–24]. In a different strategy, a tentative attempt has been made to treat the full 5-body dynamics, leading to states below the lowest threshold for spontaneous dissociation [25]. In the first implementation of the former approach [18], the pen-

taquark mass splitting was generated mostly by the change of angular momentum between the sub-components (L) from zero to one, which would also make the heavier state narrower and of opposite parity. Explicit modeling of multiquark systems [26] questions if centrifugal barrier factor provides enough width suppression via spatial separation of c and $\bar{c}$ quarks at these masses, as the phase space for $J/\psi p$ decay is very large (more than 400 MeV). Also, the observed mass splitting was too small to be only due to the mechanism proposed in Ref. [18] and required fine-tuning of such models. A variation of this model, in which the heavy (cu) diquark couples with heavy $\bar{c}$ to form colored triquark attracting the light diquark (ud), has been re-implemented for the narrow $P_{c\bar{c}}^{+}$ states [27]. In this model, the $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ states are accommodated via spin-orbit interactions for the $L = 1$ states, while the $P_{c\bar{c}}(4312)^+$ is one of the $L = 0$ states. However, the mass prediction for the latter is off by (-72 ± 29) MeV [27]. This work was later extended to $SU(3)_F$ [28]. The width dilemma becomes more severe in view of the narrow widths of the newly observed states (Table 83.1), especially for the $L = 0$ $P_{c\bar{c}}(4312)^+$ state, and requires a different origin of potential barrier between c and $\bar{c}$ than angular momentum [27, 29], which remains a subject of theoretical controversy. Measurement of spin-parity of $P_{c\bar{c}}(4312)^+$, $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ will be crucial for testing these and alternative theoretical ideas discussed in the following.

More effective width suppression mechanism is offered by a loosely bound charmed baryon-anticharmed meson molecular model, in which c and $\bar{c}$ can be separated by much larger distances, resulting in a smaller probability of them getting close enough to each other in order to make a J/ψ. Since molecular binding energy cannot be large, such molecules are in S-wave, so it has been realized early on that their masses must be near the sum of the baryon and meson masses and their spin and parity are inherited from their constituent hadrons, see e.g. discussion in [17]. The mass coincidence of the $P_{c\bar{c}}(4312)^+$ and of $P_{c\bar{c}}(4457)^+$ states, with the two related thresholds, $\Sigma_c^+ \bar{D}^0$ and $\Sigma_c^+ \bar{D}^{*0}$, provides very strong experimental evidence in favor of this interpretation. Given how close $P_{c\bar{c}}(4312)^+$ is to the $\Sigma_c^+ \bar{D}^0$ threshold, it might be a virtual rather than a bound state [30]. Since the spins of Σ_c^+ and of $\bar{D}^{*0}$ can be combined in two different ways, the narrow $P_{c\bar{c}}(4440)^+$ peak also finds natural explanation in this physical picture. It cannot be a virtual state since it is sufficiently below the $\Sigma_c^+ \bar{D}^{*0}$ threshold.

It is worth stressing that other baryon-meson combinations, $\Lambda_c^{(*)+} \bar{D}^{(*)0}$ and $\chi_{cJ} p$ are not expected to bind [14, 31]. Before the first pentaquark observation [8] heavy quark symmetry was used to show that, in addition to the three $\Sigma_c \bar{D}^{(*)0}$ states, one expects four $\Sigma_c^* \bar{D}^{(*)0}$ states, for a total of seven [32]. Indeed, additional states at, or below, the $\Sigma_c^{*+} \bar{D}$ and $\Sigma_c^{*+} \bar{D}^*$ thresholds, are expected [33–36]. Since Σ_c^{*+} width is likely around 15 MeV [37], more than the width of either $P_{c\bar{c}}(4312)^+$ or $P_{c\bar{c}}(4457)^+$, it is important to keep in mind that a molecule is typically as broad as the constituents[1] [38–40]. There is no significant evidence for $\Sigma_c^* \bar{D}^{(*)}$ states in the present LHCb data set [10, 41]. Larger data sets are expected from the Upgraded LHCb experiment. For a review on hadronic molecules, and a recent survey in a particular approach, see respectively Refs. [42, 43].

It is useful to consider the $P_{c\bar{c}}(4312)^+$, $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ narrow pentaquarks together with several analogous exotic states with hidden charm and bottom in the meson sector. This provides additional significant motivation for the molecular model. At least five exotic mesons are close to thresholds of two heavy-light mesons: $\chi_{c1}(3872)$ (formerly known as $X(3872)$) [44–47], $T_{b\bar{b}1}(10610)$ and $T_{b\bar{b}1}(10650)$ (formerly $Z_b(10610)$ and $Z_b(10650)$) in the bottomonium sector [48–52] and $T_{c\bar{c}1}(3900)$ (formerly $Z_c(3900)$) [53–57] and $T_{c\bar{c}1}(4020)$ (formerly $Z_c(4020)$) [58–60] in the charmonium sector (see Table II in Ref. [61]; for reviews of experimental information see Ref. [62, 63], as well as *Spectroscopy of Mesons Containing Two Heavy Quarks* and *Heavy Non-$q\bar{q}$ Mesons* in the current Review of Particle Properties. These states share several important features: a) their masses are near thresholds and their spin and parity correspond to S-wave combination of the two mesons; b) they are very narrow, despite very large phase space for decay into quarkonium + pion(s); c) the branching fractions for "fall apart" mode into two mesons are much larger than branching fractions for decay into quarkonium and pion(s). So far, there is no experimental evidence for states at two pseudoscalar thresholds ($D\bar{D}$ and $B\bar{B}$), suggesting that pseudoscalar exchange is essential for binding in meson-meson systems.

The above provide a strong hint that these states are deuteron-like loosely bound states of two heavy mesons [64–72]. It is then natural to conjecture that similar bound states might exist of two heavy baryons [73, 74], or a meson and a baryon or a baryon and an antibaryon, leading to a rather accurate prediction of the $P_{c\bar{c}}(4457)^+$ mass as $3/2^-$ $\Sigma_c \bar{D}^*$ molecule (the mass threshold is 4460 MeV for $\Sigma_c^+ \bar{D}^{*0}$ and 4464 MeV for $\Sigma_c^{++} D^{*-}$) [17, 61], following similar predictions obtained in a wider framework of doubly heavy baryon-meson hadronic molecules, which might include mixtures of various two-hadron states [14–16, 31]. However, single pion exchange is not possible in $\Sigma_c^+ \bar{D}^0$ system. Thus the existence of $P_{c\bar{c}}(4312)^+$ suggests a more general binding mechanism in baryon-meson molecules, e.g. vector or two-pion exchanges, and/or coupled-channel interactions. Two-pion exchange in $D\bar{D}$ system is highly suppressed, because the intermediate state is $D^* \bar{D}^*$, which is 282 MeV heavier than $D\bar{D}$. On the other hand, in the $\Sigma_c \bar{D}$ system the intermediate $\Lambda_c^+ \bar{D}^*$ state is only 25 MeV lighter than $\Sigma_c \bar{D}$, and therefore does not have to suffer significant suppression, providing a possible binding mechanism [75]. In a generic hadronic molecule it is essential that the two hadrons are heavy, in order to minimize the repulsive kinetic energy [73, 74, 76].

Following the initial LHCb discovery [8], several groups carried out a detailed analysis of the $P_{c\bar{c}}^{+}$ states as hadronic molecules [77–86] followed by further analyses [35, 87–111] after the updated LHCb results [10]. Partial widths of all the allowed decay channels for the $P_{c\bar{c}}$ states have been estimated within a specific model in the molecular picture [112]. The most striking suggestion is that $P_{c\bar{c}}(4312)^+$ decays are totally dominated by the $\Lambda_c^+ \bar{D}^{*0}$ channel. This channel is also suggested to be very prominent in decays of $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$. But other scenarios are possible, as shown by a recent theoretical analysis, allowing for the most general scattering potential of the baryon-meson system consistent with QCD symmetries at leading order in a momentum counting [113]. They found that both large and vanishing transitions to $\Lambda_c^+ \bar{D}^{(*)0}$ channels are allowed. Clearly, experimental determination of the branching fraction of these channels is of high priority.

The $P_{c\bar{c}}$ states have also been-interpreted as so called hadrocharmonium [114], a bound state of relatively compact charmonium states with light hadronic matter. It was proposed that $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ are spin-split $\psi(2S)p$ bound states with $J^P = \frac{1}{2}^-$ and $\frac{3}{2}^-$, while $P_{c\bar{c}}(4312)^+$ is a $\chi_{c0} p$ bound state with $J^P = \frac{1}{2}^+$ [115]. While very interesting from the theoretical point of view, it is not at all clear why the binding energies

[1] This feature gets changed if systems are more deeply bound.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

between charmonia and the nucleon should conspire to produce states so close to the $\Sigma_c\bar{D}$ and $\Sigma_c\bar{D}^*$ thresholds. Moreover, the predicted widths of $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ are too big by a factor $\sim$ 2-3. One should also keep in mind that the molecular and hadro-charmonium pictures provide opposite predictions for the parity of $P_{c\bar{c}}(4312)^+$. In principle LHCb can check the spin and parity through partial wave analysis, but at present it is not known if systematic uncertainties can be sufficiently reduced to make such an analysis conclusive.

Shortly after the initial experimental discovery it was conjectured that the $P_{c\bar{c}}(4450)^+$ reflects the presence of a triangle singularity near the $\chi_{c1}p$ threshold [116–119]. These explanations are no longer viable, since the $P_{c\bar{c}}(4440)^+$ mass is not at any threshold and the $P_{c\bar{c}}(4312)^+$ and $P_{c\bar{c}}(4457)^+$ peak slightly below the $\Sigma_c^+\bar{D}^0$ and $\Sigma_c^+\bar{D}^{*0}$ thresholds. The $P_{c\bar{c}}(4457)^+$ mass is exactly at $\Lambda_c^{*+}\bar{D}^0$ threshold, but LHCb has demonstrated that the observed peaking is narrower in the data than expected from the triangle-diagram when a realistic width of the excited D_s^- state exchanged in the triangle is used (Supplemental Material in Ref. [10]).

More extensive pre-2019 reviews of some of the theoretical issues can be found in Refs. [120,121]. Two recent relevant reviews are Refs. [122, 123].

So far the $P_{c\bar{c}}^+$ states have been observed by only one experiment in only one channel. It is essential to explore other possible experimental channels, such as $P_{c\bar{c}}^+ \to \Lambda_c^+\bar{D}^{(*)0}$, $\eta_c p$ [113]. These channels are however much more experimentally challenging than $P_{c\bar{c}}^+ \to J/\psi p$. The decays $\Lambda_b^0 \to \eta_c p K^-$ [124], $\Lambda_b^0 \to \Lambda_c^+\bar{D}^{(*)0}K^-$ [125] and $\Lambda_b^0 \to \Sigma_c^{(*)++}\bar{D}^{(*)-}K^-$ [126] have been observed by the LHCb, but larger data samples are needed to probe for $P_{c\bar{c}}^+$ signals. So far, search for prompt pp production of pentaquarks by the LHCb in charm hadron final states, including $\Lambda_c^+\bar{D}^0$ and $\Lambda_c^+\pi^+\bar{D}^-$, resulted in upper limits only [127]. Search for $P_{c\bar{c}}^+ \to pJ/\psi$ states in inclusive decays of $\Upsilon(1S)$ and $\Upsilon(2S)$ produced in e^+e^- annihilation by the Belle experiment also resulted in upper limits [128].

Proposals have also been made to search for heavy pentaquarks in photo-production [129–136]. Ref. [137] discusses photoproduction within the string-junction physical picture of the pentaquarks. Photoproduction is also related to recent work on $J/\psi(\eta_c)N$ scattering on the lattice [138] and on computation of $J/\psi(\eta_c)N$ and $\Upsilon(\eta_b)N$ cross sections [139]. In addition, pentaquark production has been discussed in the context of antiproton-deuterium collisions [140], of heavy ion collisions at LHC [141], in pA collisions [142] and in pion-induced processes [143–145]. The GlueX Collaboration reported negative search results for the $P_{c\bar{c}}^+$ states in photo-production at JLAB [146, 147], $\gamma p \to (J/\psi \to e^+e^-)p$. Within the large experimental errors and considerable theoretical model dependence these results do not contradict the molecular interpretations of the narrow $P_{c\bar{c}}^+$ states. In particular, vector-meson dominance often assumed in theoretical modelling may not hold for near-threshold J/ψ production, and $\Lambda_c\bar{D}^{(*)0}$ intermediate states may significantly contribute to the $J/\psi p$ production complicating probing for the $P_{c\bar{c}}^+$ states [148, 149].

As noted in e.g. [17], bottom analogues of the $P_{c\bar{c}}^+$ might well exist, but experimental search for such states involves very significant challenges. It is therefore hardly surprising that they have not been observed so far. A detailed discussion is beyond the scope of the current review.

The LHCb collaboration obtained a 3.1σ evidence for a $P_{c\bar{c}}^+ \to J/\psi p$ state in the four-dimensional amplitude analysis of about 800 $B_s^0 \to J/\psi p\bar{p}$ ($J/\psi \to \mu^+\mu^-$) decays [150]. The mass of the state, $4337^{+7}_{-4} \pm 2$ MeV, is not compatible with the the $P_{c\bar{c}}(4312)^+$ state at 3.1 standard deviations. The width is relatively small, $29^{+26}_{-12} \pm 14$ MeV. The present data do not provide sufficient discrimination between various J^P assignments. Its mass is about 19 MeV higher than the $\Sigma_c^+\bar{D}^0$ threshold and about 16 MeV lower than the $\chi_{c0}p$ threshold. At present, no specific explanation for this structure has been proposed, but some intriguing ideas have been raised in Ref. [151]. Since the statistical significance of this evidence is marginal, more data are required before this state is considered experimentally established.

Similarly inconclusive 3.1σ evidence for a $P_{c\bar{c}s}^0 \to J/\psi\Lambda$ structure was observed by the LHCb collaboration in the six-dimensional amplitude analysis of about 1750 $\Xi_b^- \to J/\psi\Lambda K^-$ ($J/\psi \to \mu^+\mu^-$, $\Lambda \to p\pi^-$ decays [12]. The strange counterparts of $P_{c\bar{c}}^+$ states have been predicted in both molecular and compact pentaquark models [15, 99, 101, 152–154]. When interpreted as a single peak, its mass, $4458.8 \pm 2.9^{+4.7}_{-1.1}$ MeV, is 15 MeV above the $\Xi_c'^0\bar{D}^0$ threshold and 18 MeV below the $\Xi_c^0\bar{D}^{*0}$ threshold. Its width, $17.3 \pm 6.5^{+8.0}_{-5.7}$ MeV, is relatively narrow, thus plausibly could be interpreted as a loosely bound $\Xi_c^0\bar{D}^{*0}$ state. However, in the latter model two states are expected with J^P equal to $1/2^-$ and $3/2^-$. In fact, the LHCb data are consistent with such hypothesis, under which 4454.9 ± 2.7 MeV ($\Gamma = 7.5 \pm 9.7$ MeV) and 4467.8 ± 3.7 MeV ($\Gamma = 5.2 \pm 5.3$ MeV) mass (width) estimates are obtained (statistical errors only). It is worth noting, that the $SU(3)$ flavor structure of $\Xi_c^0\bar{D}^{*0}$ states is different from that of $\Sigma_c^+\bar{D}^{*0}$ states, since Ξ_c^0 belongs to the charmed baryon triplet, together with Ξ_c^+ and Λ_c^+, where the two light quarks form a spin-zero diquark, unlike Σ_c^+, which together with $\Xi_c'^0$ and Ω_c^0 belongs to the charmed baryon sextet, where the two light quarks form a spin-1 diquark. More data are required to experimentally establish this structure, clarify its composition, and determine the related quantum numbers.

If the two states at 4455 MeV and 4468 MeV indeed correspond to a $\Xi_c^0\bar{D}^{*0}$ molecule, there perhaps exist two other states, corresponding to $\Xi_c'\bar{D}^*$ [15, 99, 101, 152–154], with a mass shifted upwards by approximately $\Xi_c' - \Xi_c$ mass difference [155,156], i.e. about 108 MeV [37].

More recently, the LHCb experiment observed highly significant ($> 14\sigma$) pentaquark state $P_{c\bar{c}s}(4338)^0 \to J/\psi\Lambda$ (formerly known as $P_{cs}(4338)$) in the six-dimensional amplitude analysis of 4620 ± 70 $B^- \to J/\psi\Lambda\bar{p}$ decays [157]. Its mass $4338.2 \pm 0.7 \pm 0.4$ MeV is right at the $\Xi_c\bar{D}$ threshold (Fig. 83.3), its width is narrow $7.0 \pm 1.2 \pm 1.3$ MeV, and its spin is 1/2, with a preference for negative parity, which all fits the molecular model very well. This makes the $P_{c\bar{c}s}(4338)^0$ state a likely $\Xi_c^0\bar{D}^0$ analog of the $P_{c\bar{c}}(4312)^+$ state in $\Sigma_c^0\bar{D}^0$ system. In addition, as in the $P_{c\bar{c}s}(4459)^0$ case, a $\Xi_c'\bar{D}$ state is expected, for a total of three additional strange pentaquarks [156]. Experimental determination whether yet additional $\Xi_c^{(*,\prime)}\bar{D}^{(*)0}$ states actually exist will provide a useful testing ground for the various theoretical approaches which have been used to predict them.

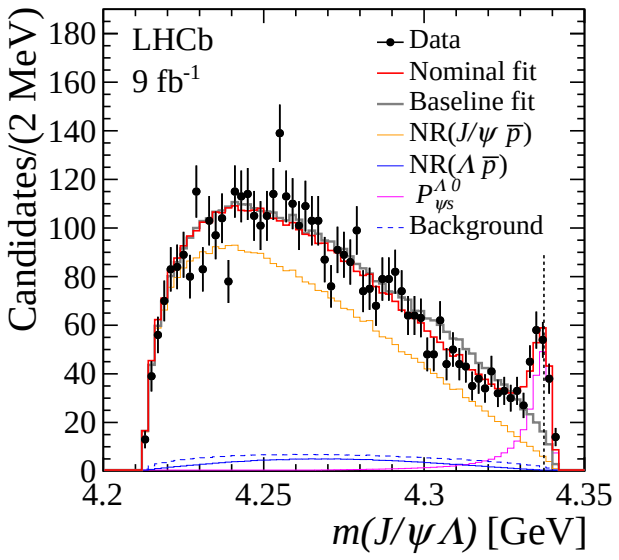

Figure 83.3: Distribution of invariant $J/\psi\Lambda$ mass, with the projection of the amplitude fit model superimposed. The model without the $P_{c\bar{c}s}(4338)^0$ state (labeled as $P_{\psi s}^{\Lambda\,0}$) is also shown in grey. The $\Xi_c^+D^-$ baryon-meson threshold is indicated with a vertical dashed line.

Search for the $P^0_{c\bar{c}s}$ states in decays to $\Lambda_c^+ D_s^-$ have been recently performed by the LHCb using a small sample of $\Lambda_b^0 \to \Lambda_c^+ D_s^- K^+ K^-$ decays [158]. Search by the Belle experiment for $P^+_{c\bar{c}s} \to J/\psi\Lambda$ states in inclusive decays of $\Upsilon(1S)$ and $\Upsilon(2S)$, produced in e^+e^- annihilation, yielded a hint of the $P_{c\bar{c}s}(4459)^0$ state and upper limits on production of the $P_{c\bar{c}s}(4338)^0$ state [159]. When combining the $\Upsilon(1S)$ and $\Upsilon(2S)$ samples together, a peak in $J/\psi\Lambda$ mass is observed at $4471.7 \pm 4.8 \pm 0.6$ MeV with a width of $22 \pm 13 \pm 3$ MeV, which are consistent with the LHCb results at 1.8σ and 0.3σ level, respectively. A local statistical significance of this peak is 3.8σ (not including systematic effects), which is an appropriate figure of merit if the mass and width are considered to be consistent between the LHCb and Belle results. A global signal significance, appropriate measure for stand-alone unbiased search, is 2.8σ (no systematic effects folded in). Imposing Gaussian constraints on the mass and width to the LHCb results, the $P_{c\bar{c}s}(4459)^0$ peak fitted to the Belle data is 3.3σ significant including systematic uncertainties. This result may be affected by the single-peak interpretation of the LHCb data, which has not been established as discussed above. More $\Upsilon(1S)$ and $\Upsilon(2S)$ data are highly desired to verify existence of this mass structure.

In hidden-charm exotics discussed above, the charmed and the anticharmed quarks can form a charmonium and thereby decouple from the light quarks. The molecular model provides an efficient mechanism to suppress such decays, thus making these states narrow. Compact direct color couplings between quarks, in diquark approach, are missing an obvious width suppression mechanism, thus could lead to broader states. In fact, there is plenty of evidence for them in form of broader tetraquark mass structures in $J/\psi\,\phi$ [160–166], $J/\psi\,J/\psi$ [167–169], $T_{c\bar{c}1}(4430)^+ \to \psi(2S)\pi^+$ (formerly $Z_c(4430)^+$) [170–172] and others, although alternative explanations of these structures have been also proposed. Analogous configurations may also exist for pentaquarks, but there is no firm evidence for them yet.

A relatively new theoretical approach to hidden-charm exotics is based on the recognition that heavy quarks move slowly compared to their light quark partners. This is analogous to atomic molecules, which have been successfully described as heavy nuclei vibrating slowly in Born-Oppenheimer (BO) potential, generated by fast-moving electrons. Unlike the hadro-charmonium picture, in which $c\bar{c}$ pair is assumed to be in a polarized color-singlet state, the BO approach assumes that the $c\bar{c}$ pair is in color-octet state [173–176]. Perturbative QCD predicts repulsive $1/r$ potential at short $c\bar{c}$ distances, while LQCD predicts a confining linear potential at large $c\bar{c}$ distances. The transition from octet to singlet charmonium requires hard gluon interaction. This suppresses decays to a charmonium and a light baryon, making the states narrow. To avoid the unobserved rich spectrum of bound states expected in the confining potential, it has been proposed that the potential transitions smoothly to a constant term at large distances, due to light quarks attaching themselves to the heavy quarks as they separate from each other, creating heavy-light charmed baryon – anticharmed meson pair. Thus, the hadronic molecule physical picture naturally emerges as the long-distance limit of the QCD-motivated BO approach. The baryon-meson threshold can be approached from below, creating a shallow potential well with few bound state(s) just below the threshold (e.g. $\Sigma_c^{(*)}\bar{D}^{(*)}$ case); smoothly from above, creating no bound states ($\Lambda_c\bar{D}^{(*)}$ case); or the intermediate potential raising to the confining part can overshoot the threshold somewhat, generating a bound state slightly above the threshold. This mechanism can accommodate the narrow tetraquark states observed just above the $D^*\bar{D}^{(*)}$ and $B^*\bar{B}^{(*)}$ thresholds. The non-relativistic Schrödinger equation can be used to solve the BO potential for bound state energies. The hyperfine structure is created by coupling the total angular momentum of the light quark (diquark) to heavy quark (antiquark) spins. If all combinations of the angular momenta of light quarks are allowed, the number of states and their spin-parity match the predictions of the molecular model [175]. However, in the BO approach the constituents are colored heavy quarks, rather than color-neutral heavy hadrons, providing for a different modelling approach and better prospects for a direct input from QCD via simulations of BO potentials on the lattice. Unlike in the naive molecular model, the short-range structure of the bound states is predictable. The BO approach predicts fewer states, with a different spin-parity pattern if not all values of total the angular momenta of light quarks are assumed to create bound states [176].

The hidden-charm exotic states, should not be confused with exotic hadrons containing two heavy quarks, rather than a heavy quark and a heavy antiquark. Decoupling from the light quarks is impossible in exotics which contain two heavy quarks. This has far-reaching consequences. The first tetraquark of the latter type, i.e. containing two heavy quarks, has been reported by LHCb [177, 178]. A comprehensive discussion of tetraquark candidates can be found in the "Heavy non-$Q\bar{Q}$ Mesons" review.

84. Extra Dimensions

Revised August 2025 by Z. Demiragli (Boston U.) and A. Pomarol (U. Autònoma de Barcelona; IFAE).

84.1 Introduction

Proposals for a spacetime with more than three spatial dimensions date back to the 1920s, mainly through the work of Kaluza and Klein, in an attempt to unify the forces of nature [1]. Although their initial idea failed, the formalism that they and others developed is still useful nowadays. Around 1980, string theory proposed again to enlarge the number of space dimensions, this time as a requirement for describing a consistent theory of quantum gravity. The extra dimensions were supposed to be compactified at a scale close to the Planck scale, and thus not testable experimentally in the near future.

A different approach was given by Arkani-Hamed, Dimopoulos, and Dvali (ADD) in their seminal paper in 1998 [2], where they showed that the weakness of gravity could be explained by postulating two or more flat extra dimensions in which only gravity could propagate. The size of these extra dimensions should range between roughly a millimeter and ∼1/TeV, leading to possible observable consequences in current and future experiments. A year later, Randall and Sundrum (RS) [3] found a new possibility using a warped geometry, postulating a five-dimensional Anti-de Sitter (AdS) spacetime with a compactification scale of order 1/TeV. The origin of the smallness of the electroweak scale versus the Planck scale was explained by the gravitational redshift factor present in the warped AdS metric. As in the ADD model, originally only gravity was assumed to propagate in the extra dimensions, although it was soon clear that this was not necessary in warped extra dimensions and also the SM gauge fields [4, 5] and SM fermions [6, 7] could propagate in the five-dimensional spacetime.

The physics of warped extra-dimensional models has an alternative interpretation by means of the AdS/Conformal Field Theory (CFT) correspondence [8–10]. Models with warped extra dimensions are related to four-dimensional strongly-interacting theories, allowing an understanding of the properties of five-dimensional fields as those of four-dimensional composite states [11]. This approach has opened new directions for tackling outstanding questions in particle physics, such as the flavor problem, grand unification, and the origin of electroweak symmetry breaking or supersymmetry breaking.

84.1.1 *Experimental Constraints*

Constraints on extra-dimensional models arise from astrophysical and cosmological considerations, tabletop experiments exploring gravity at sub-mm distances, and collider experiments. Collider limits on extra-dimensional models are dominated by LHC results, which can be found on the public WWW pages of ATLAS [12] and CMS [13]. This review includes the most recent limits, most of which are published results based on 140 fb^{-1}LHC data collected in 2015-18 at a center-of-mass energy of 13 TeV and legacy results from 20 fb^{-1}of 8 TeV data collected in Run 1. For most of the models, Run 2 results surpass the sensitivity of Run 1.

84.1.2 *Kaluza-Klein Theories*

Field theories with compact extra dimensions can be written as theories in ordinary four dimensions (4D) by performing a Kaluza-Klein (KK) reduction. As an illustration, consider a simple example, namely a field theory of a complex scalar in flat five-dimensional (5D) spacetime. The action will be given by [1]

$$S_5 = -\int d^4x\, dy\, M_5 \left[|\partial_\mu \phi|^2 + |\partial_y \phi|^2 + \lambda_5 |\phi|^4\right] , \qquad (84.1)$$

where y refers to the extra (fifth) dimension. A universal scale M_5 has been extracted in front of the action in order to keep the 5D field with the same mass-dimension as in 4D. This theory is perturbative for energies $E \lesssim \ell_5 M_5/\lambda_5$ where $\ell_5 = 24\pi^3$ [14].

Let us now consider that the fifth dimension is compact with the topology of a circle S^1 of radius R, which corresponds to the identification of y with $y + 2\pi R$. In such a case, the 5D complex scalar field can be expanded in a Fourier series:

$$\phi(x, y) = \frac{1}{\sqrt{2\pi R M_5}} \sum_{n=-\infty}^{\infty} e^{iny/R} \phi^{(n)}(x) , \qquad (84.2)$$

that, inserted in Eq. (84.1) and integrating over y, gives

$$S_5 = S_4^{(0)} + S_4^{(n)} , \qquad (84.3)$$

where

$$S_4^{(0)} = -\int d^4x \left[|\partial_\mu \phi^{(0)}|^2 + \lambda_4 |\phi^{(0)}|^4\right] , \qquad (84.4)$$

and,

$$S_4^{(n)} = -\int d^4x \sum_{n\neq 0} \left[|\partial_\mu \phi^{(n)}|^2 + \left(\frac{n}{R}\right)^2 |\phi^{(n)}|^2\right] + \text{quartic interactions} . \qquad (84.5)$$

The $n = 0$ mode self-coupling is given by

$$\lambda_4 = \frac{\lambda_5}{2\pi R M_5} . \qquad (84.6)$$

The above action corresponds to a 4D theory with a massless scalar $\phi^{(0)}$, referred to as the zero mode, and an infinite tower of massive modes $\phi^{(n)}$ with $n > 0$, known as KK modes. The KK reduction thus allows a treatment of 5D theories as 4D field theories with an infinite number of fields. At energies smaller than $1/R$, the KK modes can be neglected, leaving the zero-mode action of Eq. (84.4). The strength of the interaction of the zero-mode, given by Eq. (84.6), decreases as R increases. Thus, for a large extra dimension $R \gg 1/M_5$, the massless scalar is very weakly coupled.

84.2 Large Extra Dimensions for Gravity

84.2.1 *The ADD Scenario*

The ADD scenario [2, 15] (for a review see, for example, [16]) assumes a $D = 4 + \delta$ dimensional spacetime, with δ compactified spatial dimensions. The apparent weakness of gravity arises since it propagates in the higher-dimensional space. The SM is assumed to be localized in a 4D subspace, a 3-brane, as can be found in certain string theory constructions [17, 18]. Gravity is described by the Einstein-Hilbert action in $D = 4 + \delta$ spacetime dimensions

$$S_D = -\frac{\bar{M}_D^{2+\delta}}{2} \int d^4x d^\delta y \sqrt{-g}\, \mathcal{R} + \int d^4x \sqrt{-g_{\rm ind}}\, \mathcal{L}_{\rm SM} , \qquad (84.7)$$

where x labels the ordinary four coordinates, y the δ extra coordinates, g refers to the determinant of the D-dimensional metric whose Ricci scalar is defined by $\mathcal{R}$, and $\bar{M}_D$ is called the reduced Planck scale of the D-dimensional theory. In the second term of Eq. (84.7), which gives the gravitational interactions of SM fields, the D-dimensional metric reduces to the induced metric on the 3-brane where the SM fields propagate. The extra dimensions are assumed to be flat and compactified in a volume V_δ. As an example, consider a toroidal compactification of equal radii R and volume $V_\delta = (2\pi R)^\delta$. After a KK reduction, one finds that the fields that couple to the SM are the spin-2 gravitational field $G_{\mu\nu}(x, y)$ and a tower of spin-0 KK graviscalars [19]. The graviscalars, however, only couple to SM fields through the trace of the energy-momentum tensor, resulting in weaker couplings to the SM fields. The Fourier expansion of the spin-2 field is given by

$$G_{\mu\nu}(x, y) = G_{\mu\nu}^{(0)}(x) + \frac{1}{\sqrt{V_\delta}} \sum_{\vec{n}\neq 0} e^{i\vec{n}\cdot\vec{y}/R} G_{\mu\nu}^{(\vec{n})}(x) , \qquad (84.8)$$

where $\vec{y} = (y_1, y_2, ..., y_\delta)$ are the extra-dimensional coordinates and $\vec{n} = (n_1, n_2, ..., n_\delta)$. Eq. (84.8) contains a massless state, the 4D graviton $G_{\mu\nu}^{(0)}$, and its KK tower $G_{\mu\nu}^{(\vec{n})}$ with masses $m_{\vec{n}}^2 =$

[1] Our convention for the metric is $\eta_{MN} = \text{Diag}(-1, 1, 1, 1, 1)$.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

$|\vec{n}|^2/R^2$. At energies below $1/R$ the action is that of the zero mode

$$S_4^{(0)} = -\frac{\bar{M}_D^{2+\delta}}{2}\int d^4x\, V_\delta \sqrt{-g^{(0)}}\,\mathcal{R}^{(0)} + \int d^4x \sqrt{-g_{\rm ind}^{(0)}}\,\mathcal{L}_{\rm SM}\,, \tag{84.9}$$

where we can identify the 4D reduced Planck mass, $M_P \equiv 1/\sqrt{8\pi G_N} \simeq 2.4\times 10^{18}$ GeV, as a function of the D-dimensional parameters:

$$M_P^2 = V^\delta \bar{M}_D^{2+\delta} \equiv R^\delta M_D^{2+\delta}\,. \tag{84.10}$$

Fixing M_D at around the electroweak scale $M_D \sim$ TeV to avoid introducing a new mass scale in the model, Eq. (84.10) gives a prediction for R:

$$\delta = 1, 2, ..., 6 \;\rightarrow\; R \sim 10^9 \text{ km}\,, 0.5 \text{ mm}\,, ...\,, 0.1 \text{ MeV}^{-1}\,. \tag{84.11}$$

The option $\delta = 1$ is clearly ruled out, as it leads to modifications of Newton's law at solar system distances. However this is not the case for $\delta \geq 2$, and possible observable consequences can be sought in present and future experiments.

Consistency of the model requires a stabilization mechanism for the radii of the extra dimensions, to the values shown in Eq. (84.11). The fact that we need $R \gg 1/M_D$ leads to a new hierarchy problem, the solution of which might require imposing supersymmetry in the extra-dimensional bulk (for the case of two extra dimensions see for example [20]).

84.2.2 *Tests of the Gravitational Force Law at Sub-mm Distances*

The KK modes of the graviton give rise to deviations from Newton's law of gravitation for distances $\lesssim R$. Such deviations are usually parameterized by a modified Newtonian potential of the form

$$V(r) = -G_N \frac{m_1 m_2}{r}\left[1 + \alpha\, e^{-r/\lambda}\right]\,. \tag{84.12}$$

For a 2-torus compactification, $\alpha = 16/3$ and $\lambda = R$. Searches for deviations from Newton's law of gravitation have been performed in several experiments [21–24]. From Ref. [23] we have the constraint $R < 30\mu$m at 95% CL for $\delta = 2$, corresponding to $M_D > 4.0$ TeV. We see then that bounds from Newton's law deviations are already pushing the scale M_D beyond the TeV for two extra dimensions.

84.2.3 *Astrophysical and Cosmological Constraints*

The light KK gravitons could be copiously produced in stars, carrying away energy. Ensuring that the graviton luminosity is low enough to preserve the agreement of stellar models with observations provides powerful bounds on the scale M_D. The most stringent bound arises from supernova SN1987A, giving $M_D > 27$ (2.4) TeV for $\delta = 2$ (3) [25]. After a supernova explosion, most of the KK gravitons stay gravitationally trapped in the remnant neutron star. The requirement that neutron stars are not excessively heated by KK decays into photons leads to $M_D > 1700$ (76) TeV for $\delta = 2$ (3) [26].

Cosmological constraints are also quite stringent [27]. To avoid overclosure of the Universe by relic gravitons one needs $M_D > 7$ TeV for $\delta = 2$. Relic KK gravitons decaying into photons contribute to the cosmic diffuse gamma radiation, from which one can derive the bound $M_D > 100$ TeV for $\delta = 2$.

We must mention however that bounds coming from the decays of KK gravitons into photons can be reduced if we assume that KK gravitons decay mainly into other non-SM states. This could happen, for example, if there were other 3-branes with hidden sectors residing on them [15].

84.2.4 *Collider Signals*

84.2.4.1 *Graviton and Other Particle Production*

Although each KK graviton has a purely gravitational coupling, suppressed by $1/M_P$, inclusive processes in which one sums over the almost continuous spectrum of available gravitons have cross sections suppressed only by powers of M_D. Processes involving gravitons are therefore detectable in collider experiments if $M_D \sim$ TeV. A number of experimental searches for evidence of large extra dimensions have been performed at colliders, and interpreted in the context of the ADD model.

One signature arises from direct graviton emission. By making a derivative expansion of Einstein gravity, one can construct an effective theory, valid for energies much lower than M_D, and use it to make predictions for graviton-emission processes at colliders [19, 28, 29]. Gravitons produced in the final state would escape detection, giving rise to missing transverse momentum ($p_{\rm T}^{\rm miss}$). The results quoted below are 95% CL lower limits on M_D for a range of values of δ between 2 and 6, with more stringent limits corresponding to lower δ values.

At hadron colliders, experimentally sensitive channels include the jet (j) + $p_{\rm T}^{\rm miss}$ and γ + $p_{\rm T}^{\rm miss}$ final states. ATLAS (CMS) j + $p_{\rm T}^{\rm miss}$ results with 139 (137) fb^{-1} of 13 TeV data provide limits of $M_D > 5.9 - 11.2$ TeV [30] ($M_D > 5.5 - 10.7$ TeV [31]). For these analyses, both experiments are assuming leading order cross sections. Since the effective theory is only valid for energies much less than M_D, the results are quoted for the full space, and include the information that suppressing the graviton cross section by a factor $M_D^4/\hat{s}^2$ for $\sqrt{\hat{s}} > M_D$, where $\sqrt{\hat{s}}$ is the parton-level center-of-mass energy of the hard collision, weakens the limits on M_D by a negligible amount for $\delta = 2$ (∼3% for $\delta = 6$). Less stringent limits are obtained by CMS [32] from analysis of 36 fb^{-1}of 13 TeV data in the γ + $p_{\rm T}^{\rm miss}$ final state ($M_D > 2.85 - 2.90$ TeV for $\delta = 3 - 6$). The analogous ATLAS search [33] uses full Run 2 statistics but does not quote ADD interpretation of the results.

In models in which the ADD scenario is embedded in a string theory at the TeV scale [18], we expect the string scale M_s to be smaller than M_D, and therefore expect production of string resonances at the LHC [34]. A result from CMS analyzing the dijet invariant mass distribution for 137 fb^{-1}of 13 TeV data excludes string resonances that decay predominantly to $q + g$ with masses below 7.9 TeV [35]. ATLAS dijet analysis [36] provides their results in the context of model-independent limits on the cross section times acceptance for generic resonances of a variety of possible widths, from which one can deduce similar lower mass limits ∼ 8 TeV for string resonances decaying to $q + g$.

84.2.4.2 *Virtual graviton effects*

One can also search for virtual graviton effects, the calculation of which however depends on the ultraviolet cut-off of the theory and is therefore very model dependent. In the literature, several different formulations exist [19,29,37] for the dimension-eight operator for gravity exchange at tree level:

$$\mathcal{L}_8 = \pm\frac{4}{M_{TT}^4}\left(T_{\mu\nu}T^{\mu\nu} - \frac{1}{\delta+2}T_\mu^\mu T_\nu^\nu\right), \tag{84.13}$$

where $T_{\mu\nu}$ is the energy-momentum tensor and M_{TT} is related to M_D by some model-dependent coefficient [38]. The relations with the parametrization of Refs. [37] and [19] are, respectively, $M_{TT} = M_S$ and $M_{TT} = (2/\pi)^{1/4}\Lambda_T$. The experimental results below are given as 95% CL lower limits on M_{TT}, including in some cases the possibility of both constructive or destructive interference, depending on the sign chosen in Eq. (9).

The most stringent limits arise from LHC analyses of the dijet angular distribution. Using 35.9 fb^{-1}of 13 TeV data, CMS [39] obtains results that correspond to an approximate limit of $M_{TT} \gtrsim 9$ TeV.

The next most restrictive results come from the analyses of diphoton ($M_{TT} > 6.1$ TeV from ATLAS [40] and $M_{TT} > 8.3$ TeV from CMS [41]) and dilepton ($M_{TT} > 6.5$ TeV from CMS [42]) mass spectra. The complete Run 2 (139 fb^{-1}) analysis of ATLAS di-lepton data [43] does not quote the limits on the ADD model.

At the one-loop level, gravitons can also generate dimension-six operators with coefficients that are also model dependent. Experimental bounds on these operators can also give stringent constraints on M_D [38].

84.2.4.3 *Black Hole Production*

The physics at energies $\sqrt{s} \sim M_D$ is sensitive to the details of the unknown quantum theory of gravity. Nevertheless, in the transplanckian regime, $\sqrt{s} \gg M_D$, one can rely on a semiclassical description of gravity to obtain predictions. An interesting feature of transplanckian physics is the creation of black holes [44,45] (for a review see, for example, [46]). A black hole is expected to be

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

formed in a collision in which the impact parameter is smaller than the Schwarzschild radius [47]:

$$R_S = \frac{1}{M_D}\left[\frac{2^\delta \pi^{(\delta-3)/2}}{\delta+2}\Gamma\left(\frac{\delta+3}{2}\right)\frac{M_{BH}}{M_D}\right]^{1/(\delta+1)}, \quad (84.14)$$

where M_{BH} is the mass of the black hole, which would roughly correspond to the total energy in the collision. The cross section for black hole production can be estimated to be of the same order as the geometric area $\sigma \sim \pi R_S^2$. For $M_D \sim$ TeV, this gives a production of $\sim 10^7$ black holes at the $\sqrt{s} = 14$ TeV LHC with an integrated luminosity of 30 fb^{-1} [44,45]. A black hole would provide a striking experimental signature since it is expected to thermally radiate with a Hawking temperature $T_H = (\delta+1)/(4\pi R_S)$, and therefore would evaporate democratically into all SM states. Nevertheless, given the present constraints on M_D, the LHC will not be able to reach energies much above M_D. This implies that predictions based on the semiclassical approximation could receive sizable modifications from model-dependent quantum-gravity effects.

The most stringent limits on microscopic black holes arise from LHC searches which observed no excesses above the SM background in high-multiplicity final states. The results are usually quoted as model-independent limits on the cross section for new physics in the final state and kinematic region analyzed. These results can then be used to provide constraints of models of low-scale gravity and weakly-coupled string theory. In addition, limits are sometimes quoted on particular implementations of models, which are used as benchmarks to illustrate the sensitivity.

A CMS analysis [48] of multi-object final states using 36 fb^{-1}of 13 TeV data, excludes semiclassical black holes below masses of up to 10.1 TeV for $M_D = 2$ TeV and $\delta = 6$. Analogous Run 2 ATLAS analysis [49], using 3.0 fb^{-1}of 13 TeV data, excludes black hole masses up to $9.0 - 9.7$ TeV, depending on M_D, for $\delta = 6$. Another ATLAS search [50] for an excess of events with multiple high transverse momentum objects, including charged leptons and jets, using 3.2 fb^{-1}of 13 TeV data, excludes semiclassical black holes below masses of ~ 8.7 TeV for $M_D = 2$ TeV and $\delta = 6$.

A complementary approach is to look for jet extinction at high transverse momenta, as we expect hard short distance scattering processes to be highly suppressed at energies above M_D [51]. The CMS analysis [52] of inclusive jet p_T spectrum in 10.7 fb^{-1}of 8 TeV data set a lower limit of 3.3 TeV on the extinction mass scale.

For black hole masses near M_D, the semi-classical approximation is not valid, and one could instead expect quantum black holes (QBH) that decay primarily into two-body final states [53]. In the context of both ADD model with $\delta = 6$ the QBHs have been searched in few final state analysis (based on 2.3 fb^{-1} [54]), dijet [36,39,55], (same and different flavor) dilepton [56–60], photon+jet [61,62] and lepton+jet [63] channels by both ATLAS and CMS experiments. The Run 2 results at 13 TeV provide lower limits on QBH masses of up-to 9.4 TeV in an ADD model with $\delta = 6$. The strongest constraints are from dijet searches.

In weakly-coupled string models the semiclassical description of gravity fails in the energy range between M_s and M_s/g_s^2 where stringy effects are important. In this regime one expects, instead of black holes, the formation of string balls, made of highly excited long strings, that could be copiously produced at the LHC for $M_s \sim$ TeV [64], and would evaporate thermally at the Hagedorn temperature giving rise to high-multiplicity events. The same analyses used to search for black holes can be interpreted in the context of string balls. For example, for the case of $\delta = 6$ with $M_s = M_D/1.26 = 3$ TeV, the ATLAS multiple high transverse momentum object analysis [49] excludes string balls with masses below 6.5 to 9.0 TeV for values of $0.2 < g_s < 0.8$. The CMS multi-object analysis [48] studies string ball production in two scenarios, both assuming $\delta = 6$. For the constant $g_s = 0.2$ and $1 < M_s < 3.5$ TeV the string ball masses below 7.2 to 9.4 TeV are excluded, while at constant $M_s = 3.6$ TeV and $0.2 < g_s < 0.4$ masses below 7.2 to 8.1 TeV are excluded.

84.3 TeV-Scale Extra Dimensions

84.3.1 *Warped Extra Dimensions*

The RS model [3] is the most attractive setup of warped extra dimensions at the TeV scale, since it provides an alternative solution to the hierarchy problem. The RS model is based on a 5D theory with the extra dimension compactified in an orbifold, S^1/Z_2, a circle S^1 with the extra identification of y with $-y$. This corresponds to the segment $y \in [0, \pi R]$, a manifold with boundaries at $y = 0$ and $y = \pi R$. Let us now assume that this 5D theory has a cosmological constant in the bulk Λ, and on the two boundaries Λ_0 and $\Lambda_{\pi R}$. The action is given by

$$S_5 = -\int d^4x\, dy \Big\{ \sqrt{-g}\Big[\frac{1}{2}M_5^3\mathcal{R} + \Lambda\Big] + \sqrt{-g_0}\,\delta(y)\Lambda_0 + \sqrt{-g_{\pi R}}\,\delta(y-\pi R)\Lambda_{\pi R}\Big\}, \quad (84.15)$$

where g_0 and $g_{\pi R}$ are the values of the determinant of the induced metric on the two respective boundaries. Einstein's equations can be solved, giving in this case the metric

$$ds^2 = a(y)^2 dx^\mu dx^\nu \eta_{\mu\nu} + dy^2\,, \quad a(y) = e^{-ky}\,, \quad (84.16)$$

where $k = \sqrt{-\Lambda/6M_5^3}$. Consistency of the solution requires $\Lambda_0 = -\Lambda_{\pi R} = -\Lambda/k$. The metric in Eq. (84.16) corresponds to a 5D AdS space. The factor $a(y)$ is called the "warp" factor and determines how 4D scales change as a function of the position in the extra dimension. In particular, this implies that energy scales for 4D fields localized at the boundary at $y = \pi R$ are redshifted by a factor $e^{-k\pi R}$ with respect to those localized at $y = 0$. For this reason, the boundaries at $y = 0$ and $y = \pi R$ are usually referred to as the ultraviolet (UV) and infrared (IR) boundaries, respectively.

As in the ADD case, we can perform a KK reduction and obtain the low-energy effective theory of the 4D massless graviton. In this case we obtain

$$M_P^2 = \int_0^{\pi R} dy\, e^{-2ky} M_5^3 = \frac{M_5^3}{2k}\left(1 - e^{-2k\pi R}\right). \quad (84.17)$$

Taking $M_5 \sim k \sim M_P$, we can generate an IR-boundary scale of order $ke^{-k\pi R} \sim$ TeV for an extra dimension of radius $R \simeq 11/k$. Mechanisms to stabilize R to this value have been proposed [65,66] that, contrary to the ADD case, do not require introducing any new small or large parameter. Therefore a natural solution to the hierarchy problem can be achieved in this framework if the Higgs field, whose vacuum expectation value (VEV) is responsible for electroweak symmetry breaking, is localized at the IR-boundary where the effective mass scales are of order TeV. The radion field is generically heavy in models with a stabilized R. Nevertheless, it has been recently discussed that under some conditions a naturally light radion can arise [67–70]. In these cases the radion is identified with the dilaton, the Nambu-Goldstone boson associated to the spontaneous breaking of scale invariance, and its mass can be naturally below $ke^{-k\pi R} \sim$ TeV.

In the RS model [3], all the SM fields were assumed to be localized on the IR-boundary. Nevertheless, for the hierarchy problem, only the Higgs field has to be localized there. SM gauge bosons and fermions can propagate in the 5D bulk [4–7] (for a review see, for example, [71, 72]). By performing a KK reduction from the 5D action of a gauge boson, we find [4, 5]

$$\frac{1}{g_4^2} = \int_0^{\pi R} dy\, \frac{1}{g_5^2} = \frac{\pi R}{g_5^2}\,, \quad (84.18)$$

where g_D ($D = 4, 5$) is the gauge coupling in D-dimensions. Therefore the 4D gauge couplings can be of order one, as is the case of the SM, if one demands $g_5^2 \sim \pi R$. Using $kR \sim 10$ and $g_4 \sim 0.5$, one obtains the 5D gauge coupling

$$g_5 \sim 4/\sqrt{k}\,. \quad (84.19)$$

Boundary kinetic terms for the gauge bosons can modify this relation, allowing for larger values of $g_5\sqrt{k}$.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Fermions propagating in a warped extra dimension have 4D massless zero-modes with wavefunctions which vary as $f_0 \sim exp[(1/2-c_f)ky]$, where $c_f k$ is their 5D mass [7,73]. Depending on the free parameter $c_f k$, fermions can be localized either towards the UV-boundary ($c_f > 1/2$) or IR-boundary ($c_f < 1/2$). Since the Higgs boson is localized on the IR-boundary, one can generate exponentially suppressed Yukawa couplings by having the fermion zero-modes localized towards the UV-boundary, generating naturally the light SM fermion spectrum [7]. A large overlap with the wavefunction of the Higgs is needed for the top quark, in order to generate its large mass, thus requiring it to be localized towards the IR-boundary. In conclusion, the large mass hierarchies present in the SM fermion spectrum can be easily obtained in warped models via suitable choices of the order-one parameters c_f [74]. In these scenarios, deviations in flavor physics from the SM predictions are expected to arise from flavor-changing KK gluon couplings [75], putting certain constraints on the parameters of the models and predicting new physics effects to be observed in B-physics processes (see, for example, [76,77]).

The masses of the KK states can also be calculated. One finds [7]

$$m_n \simeq \left(n + \frac{\alpha}{2} - \frac{1}{4}\right) \pi k e^{-\pi k R}\,, \tag{84.20}$$

where $n = 1, 2, ...$ and $\alpha = \{|c_f - 1/2|, 0, 1\}$ for KK fermions, KK gauge bosons and KK gravitons, respectively. Their masses are of order $ke^{-\pi kR} \sim$ TeV (for this reason we refer to these scenarios as TeV-scale extra dimensions). The first KK state of the gauge bosons would be the lightest, while gravitons are expected to be the heaviest.

84.3.1.1 *Models of Electroweak Symmetry Breaking*

Theories in warped extra dimensions can be used to implement symmetry breaking at low energies by boundary conditions (for a review see, for example, [78]). For example, for a $U(1)$ gauge symmetry in the 5D bulk, this can be easily achieved by imposing a Dirichlet boundary condition on the IR-boundary for the gauge-boson field, $A_\mu|_{y=\pi R} = 0$. This makes the zero-mode gauge boson get a mass, given by $m_A = g_4\sqrt{2k/g_5^2}\, e^{-\pi kR}$. A very different situation occurs if the Dirichlet boundary condition is imposed on the UV-boundary, $A_\mu|_{y=0} = 0$. In this case the zero-mode gauge boson disappears from the spectrum. Finally, if a Dirichlet boundary condition is imposed on the two boundaries, one obtains a massless 4D scalar corresponding to the fifth component of the 5D gauge boson, A_5. Thus, different scenarios can be implemented by appropriately choosing the 5D bulk gauge symmetry, $\mathcal{G}_5$, and the symmetries to which it reduces on the UV and IR-boundary, $\mathcal{H}_{UV}$ and $\mathcal{H}_{IR}$, respectively. In all cases the KK spectrum comes in representations of the group $\mathcal{G}_5$.

Among the most interesting scenarios are those called gauge-Higgs unified models, where the Higgs boson appears as the fifth component of a 5D gauge boson, A_5. The Higgs mass is protected by the 5D gauge invariance and can only get a nonzero value from non-local one-loop effects [79]. To guarantee the relation $M_W^2 \simeq M_Z^2 \cos^2\theta_W$, a custodial $SU(2)_V$ symmetry is needed in the bulk and IR-boundary [80]. The simplest realization [81,82] has

$$\begin{aligned} \mathcal{G}_5 &= SU(3)_c \times SO(5) \times U(1)_X, \\ \mathcal{H}_{IR} &= SU(3)_c \times SO(4) \times U(1)_X, \\ \mathcal{H}_{UV} &= G_{SM}. \end{aligned}$$

The Higgs boson gets a potential at the one-loop level that triggers a VEV, breaking the electroweak symmetry. In these models there is a light Higgs boson whose mass can be around 125 GeV, as required by the discovered Higgs boson [83]. This state, as will be explained in Sec. 84.3.2, behaves as a composite pseudo-Nambu-Goldstone boson with couplings that deviate from the SM Higgs [84]. The present experimental determination of the Higgs couplings at the LHC, that agrees with the SM predictions, put important constraints on these scenarios [83]. The lightest KK modes of the model are color fermions with charges $Q = -1/3, 2/3$ and $5/3$ [85].

84.3.1.2 *Constraints from Electroweak Precision Tests*

Models in which the SM gauge bosons propagate in 1/TeV-sized extra dimensions give generically large corrections to electroweak observables. When the SM fermions are confined on a boundary these corrections are universal and can be parameterized by four quantities: $\widehat{S}$, $\widehat{T}$, W and Y, as defined in Ref. [86]. For warped models, where the 5D gauge coupling of Eq. (84.19) is large, the most relevant parameter is $\widehat{T}$, which gives the bound $m_{KK} \gtrsim 10$ TeV [71]. When a custodial symmetry is imposed [80], the main constraint comes from the $\widehat{S}$ parameter, requiring $m_{KK} \gtrsim 3$ TeV, independent of the value of g_5. Corrections to the $Zb_L\bar{b}_L$ coupling can also be important [71], especially in warped models for electroweak symmetry breaking as the ones described above.

84.3.1.3 *Kaluza-Klein Searches*

The main prediction of 1/TeV-sized extra dimensions is the presence of a discretized KK spectrum, with masses around the TeV scale, associated with the SM fields that propagate in the extra dimension.

In the RS model [3], only gravity propagates in the 5D bulk. Experimental searches have been performed for the lightest KK graviton through its decay to a variety of SM particle-antiparticle pairs. The results are usually interpreted in the plane of the dimensionless coupling k/M_P versus m_1, where M_P is the reduced Planck mass defined previously and m_1 is the mass of the lightest KK excitation of the graviton. Since the AdS curvature $\sim k$ cannot exceed the cut-off scale of the model, which is estimated to be $\ell_5^{1/3} M_5$ [38], one must demand $k \ll \sqrt{2\ell_5} M_P \simeq 40 M_P$. The most stringent limits currently arise from LHC searches for resonances in the dilepton and diphoton final states, using 13 TeV collisions. Searches with the $\gamma\gamma$ final state are an especially powerful approach, given that these final states have a branching fraction twice that of any individual lepton flavor. The CMS analysis [41] of 138 fb^{-1}of 13 TeV data excludes KK gravitons below 2.2 to 5.6 TeV, depending on the value of the coupling k/M_P, which is varied between 0.01 and 0.2, while ATLAS [87] using 139 fb^{-1}and provides a lower limit on the KK graviton mass of 4.5 TeV for the coupling parameter 0.1. The CMS [42] dilepton analyses, combining results from the ee and $\mu\mu$ channels, exclude KK gravitons with masses 2.47–4.78 TeV for k/M_P values of 0.01–0.1. The ATLAS [88] analysis of 139 fb^{-1}of Run 2 data does not include a RS KK graviton interpretation of the results. Less stringent limits on the KK graviton mass can be derived from analyses of the dijet [35,36,89,90], HH [91–100], and VV [101–105] final states, where V can represent either a W or Z boson.

In addition, both ATLAS and CMS experiments directly search for heavy radions, with masses above 1 TeV where the dominant decay mode is to pairs of bosons. The main production mechanism is gluon fusion. ATLAS [103] (CMS [106]) excludes radion masses below 3.2 TeV (3.1 TeV) for a radion decaying into WW, ZZ. Radions are also searched in final states with pairs of Higgs bosons HH [91, 94, 96, 97, 99, 107], and dijet final states [108] with additional gluons. Bounds for a light radion (1 keV–10 GeV mass range) can be found in [109].

In warped extra-dimensional models in which the SM fields propagate in the 5D bulk, the couplings of the KK graviton to $ee/\mu\mu/\gamma\gamma$ are suppressed [110], and the above bounds do not apply. Furthermore, the KK graviton is the heaviest KK state (see Eq. (84.20)), and therefore experimental searches for KK gauge bosons and fermions are more appropriate discovery channels in these scenarios. For the scenarios discussed above in which only the Higgs boson and the top quark decays are localized close to the IR-boundary, the KK gauge bosons mainly decay into top quarks, longitudinal W/Z bosons, and Higgs bosons. Couplings to light SM fermions are suppressed by a factor $g/\sqrt{g_5^2 k} \sim 0.2$ [7] for the value of Eq. (84.19) that is considered from now on. Searches have been made for evidence of the lightest KK excitation of the gluon, through its decay to $t\bar{t}$ pairs. The searches take into account the natural KK gluon width, which is typically $\sim 15\%$ of its mass. The decay of a heavy particle to $t\bar{t}$ would tend to produce highly boosted top (anti-)quarks in the final state. Products of the subsequent hadronic top quark decay would therefore tend to be close to each other in the detector. In the case of

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

$t \to Wb \to jjb$ decays, the three jets could overlap with one another and not be individually reconstructed with the standard jet algorithms, while $t \to Wb \to \ell\nu b$ decays could result in the lepton failing standard isolation requirements due to its proximity to the b-jet; in both cases, the efficiency for properly reconstructing the final state would fall as the mass of the original particle increases. To avoid the loss in sensitivity which would result, a number of techniques, known generally as top quark tagging [111,112], have been developed to reconstruct and identify highly boosted top quarks, for example by using a single wide jet to contain all the decay products of a hadronic top decay. The large backgrounds from QCD jets can then be reduced by requiring the jet mass be consistent with that of a top quark, and also by examining the substructure of the wide jet for indication that it resulted from the hadronic decay of a top quark. These techniques are key to extending to very high masses the range of accessible resonances decaying to $t\bar{t}$ pairs. While the ATLAS search in 139 fb^{-1}of Run 2 data [113] does not provide a KK interpretation, dedicated analysis from CMS [114] of 36 fb^{-1} of 13 TeV data combines di-lepton, lepton-plus-jet, and all-hadronic $t\bar{t}$ decays and excludes KK gluons with masses below 4.55 TeV. ATLAS uses all-hadronic [115] and lepton-plus-jet [116] final states to exclude KK gluons up to 3.4 and 3.8 TeV respectively with 36fb^{-1}of 13 TeV data. The results are not directly comparable between the two LHC experiments, since they employ in their respective analyses different implementations of the theoretical model. For masses between 3 and 5 TeV, the cross-section limits are around 20 fb for CMS analysis of 36 fb^{-1}and 30 fb (4 fb) for ATLAS analyses of 36 (139) fb^{-1}.

A gauge boson KK excitation could be also sought through its decay to longitudinal W/Z bosons. Recent analyses from ATLAS [117] (and CMS [118]) with 139 (137) fb^{-1}of 13 TeV data searching for heavy vector resonances decaying to a W or Z boson and a Higgs in the $q\bar{q}b\bar{b}$ final state have set a lower limit on the mass of these KK of 3.2 (3.7) TeV (warped models are equivalent to the Model B considered in the analyses with $g_V \sim g_5\sqrt{k}$). The decay to a pair of intermediate vector bosons has also been exploited to search for KK gravitons in models in which the SM fields propagate in the 5D bulk. The analyses typically reconstruct hadronic W/Z decays using variants of the boosted techniques mentioned previously. An ATLAS analysis [119] combines leptonic and hadronic final states from the KK graviton decay $G^* \to VV$, where V can represent either a W or Z boson, exclude KK gravitons with masses below 2.3 TeV, for a value of $k/M_P = 1$. CMS VV analyses [106,120,121] using 137 fb^{-1}of 13 TeV data also exclude KK gravitons with masses below 1.8 TeV in the context of bulk gravitons for a maximum value of $k/M_P = 0.5$.

Additionally, CMS has searched for the pair production of Standard Model Higgs bosons in the $HH \to b\bar{b}\,b\bar{b}$ final state from the decay of warped extra-dimensional resonances. This has excluded KK gravitons with $m_G < 1.2$ TeV under the narrow-width assumption. Similarly, for a radion, masses below 2.6 TeV (narrow) and 2.9 TeV (10% width) are excluded [122]. More generally the warped extra-dimensional interpretation in the CMS resonant-HH combination [123] sets a lower limit on $\Lambda_R \equiv \sqrt{6}e^{-\pi kR}M_P \approx$ 16 TeV for radion masses near 1.2 TeV, and excludes $k/M_P \gtrsim 0.3$ for KK graviton masses in the range $0.3 < m_G < 1.5$ TeV.

CMS has also probed the topology in which a KK gluon (g_{KK}) decays via an intermediate radion (R) to three gluons (ggg) [124]. The analysis reports upper limits on the model-independent quantity $\sigma \times \mathcal{B}(g_{KK} \to gR \to ggg) \times \mathcal{A}$ as a function of the KK-gluon mass $m_{g_{KK}}$ (and the mass ratio $\rho_m \equiv m_R/m_{g_{KK}}$). A closely related CMS analysis targets the cascade $g_{KK} \to gR \to gW^+W^-$ in the all-hadronic final state, using 138 fb^{-1} [125]. It sets model-independent upper limits on $\sigma \times \mathcal{B}(g_{KK} \to gR \to gWW) \times \mathcal{A}$ as functions of $m_{g_{KK}}$ and m_R; under the benchmark warped extra-dimensional couplings considered, exclusions extend up to $m_{g_{KK}} \sim 3.5$ TeV with $m_R \sim 2.2$ TeV.

The lightest KK states are, in certain models, the partners of the top quark. For example, in 5D composite Higgs models these are colored states with charges $Q = -1/3, 2/3$ and $5/3$ (arising from $SU(2)_L$ doublets with $Y = 7/6, 1/6$), and masses expected to be below the TeV [85]. They can be either singly or pair-produced, and mainly decay into a combination of W/Z with top/bottom quarks [126–129]. An exhaustive review of these searches can be found in Ref. [130]. Of particular note, the $Q = 5/3$ state decays mainly into $W^+t \to W^+W^+b$, giving a very clean signature of a pair of same-sign leptons in the final state. An analysis by ATLAS [131] searching in the lepton-plus-jets final state for evidence of pair production of the $Q = 5/3$ state provides a lower mass limit of 1.25 TeV. A CMS analysis [132] searching for pair production of the $Q = 5/3$ state using both lepton-plus-jets and same sign lepton final states excludes masses below 1.3 TeV. Similarly, searches for single production of the $Q = 5/3$ state [133], also excludes masses up to 0.9 to 1.5 TeV depending on the model parameters. Both LHC experiments have searched for pair production of vector-like quarks T and B of charges $Q = 2/3$ and $-1/3$ respectively, assuming the allowable decays are $T \to Wb/Zt/Ht$ and $B \to Wt/Zb/Hb$. In each case, it is assumed the branching fractions of the three decay modes sum to unity, but the individual branching fractions, which are model-dependent, are allowed to vary within this constraint. Both ATLAS [134–136] and CMS [137,138] obtain lower limits on the mass of the T and B vector-like quarks up to 1.5 TeV and 1.6 TeV respectively. A comprehensive review of such CMS searches can be found in Ref. [139].

Analyses from ATLAS [140–144] and CMS [133, 145–148] also search for a single top partner and single bottom partner production, the cross section for which is model-dependent [149] but does not carry the kinematic penalty for producing two heavy objects.

84.3.2 *Connection with Strongly Coupled Models via the AdS/CFT Correspondence*

The AdS/CFT correspondence [8] provides a connection between warped extra-dimensional models and strongly-coupled theories in ordinary 4D. Although the exact connection is only known for certain cases, the AdS/CFT techniques have been very useful to obtain, at the qualitative level, a 4D holographic description of the various phenomena in warped extra-dimensional models [11, 72].

The connection goes as follows. The physics of the bulk AdS$_5$ models can be interpreted as that of a 4D CFT which is strongly coupled. The extra-dimensional coordinate y plays the role of the renormalization scale μ of the CFT by means of the identification $\mu \equiv ke^{-ky}$. Therefore the UV-boundary corresponds in the CFT to a UV cut-off scale at $\Lambda_{UV} = k \sim M_P$, breaking explicitly conformal invariance, while the IR-boundary can be interpreted as a spontaneous breaking of the conformal symmetry at energies $ke^{-k\pi R} \sim$ TeV. Fields localized on the UV-boundary are elementary fields external to the CFT, while fields localized on the IR-boundary and KK states corresponds to composite resonances of the CFT. Furthermore, local gauge symmetries in the 5D models, $\mathcal{G}_5$, correspond to global symmetries of the CFT, while the UV-boundary symmetry can be interpreted as a gauging of the subgroup $\mathcal{H}_{UV}$ of $\mathcal{G}_5$ in the CFT. Breaking gauge symmetries by IR-boundary conditions corresponds to the spontaneous breaking $\mathcal{G}_5 \to \mathcal{H}_{IR}$ in the CFT at energies $\sim ke^{-k\pi R}$. Using this correspondence one can easily derive the 4D massless spectrum of the compactified AdS$_5$ models. One also has the identification $k^3/M_5^3 \approx 16\pi^2/N^2$ and $g_5^2 k \approx 16\pi^2/N^r$ ($r = 1$ or 2 for CFT fields in the fundamental or adjoint representation of the gauge group), where N plays the role of the number of colors of the CFT. Therefore the weak-coupling limit in AdS$_5$ corresponds to a large-N expansion in the CFT.

Following the above AdS/CFT dictionary one can understand the RS solution to the hierarchy problem from a 4D viewpoint. The equivalent 4D model is a CFT with a TeV mass gap and a Higgs boson emerging as a composite state. In the particular case where the Higgs is the fifth-component of the gauge-boson, A_5 [150], this corresponds to models, similar to those proposed in Ref. [151–154], where the Higgs is a composite pseudo-Nambu-Goldstone boson arising from the spontaneous breaking $\mathcal{G}_5 \to \mathcal{H}_{IR}$ in the CFT. The AdS/CFT dictionary tells us that KK states must behave as composite resonances. For example, if the SM gauge bosons propagate in the 5D bulk, the lowest KK $SU(2)_L$-gauge boson must have properties similar to those of the Technirho ρ_T [130] with a coupling to longitudinal W/Z bosons given by $g_5\sqrt{k} \approx g_{\rho_T}$, while the coupling to elementary fermions is

$g^2/\sqrt{g_5^2 k} \approx g^2 F_{\rho_T}/M_{\rho_T}$.

Fermions in compactified AdS_5 also have a simple 4D holographic interpretation. The 4D massless mode described in Sec. 84.3.1 corresponds to an external fermion ψ_i linearly coupled to a fermionic CFT operator $\mathcal{O}_i$: $\mathcal{L}_{\rm int} = \lambda_i \bar{\psi}_i \mathcal{O}_i + h.c.$. The dimension of the operator $\mathcal{O}_i$ is related to the 5D fermion mass according to $\mathrm{Dim}[\mathcal{O}_i] = |c_f + 1/2| - 1$. Therefore, by varying c_f one varies $\mathrm{Dim}[\mathcal{O}_i]$, making the coupling λ_i irrelevant ($c_f > 1/2$), marginal ($c_f = 1/2$) or relevant ($c_f < 1/2$). When irrelevant, the coupling is exponentially suppressed at low energies, and then the coupling of ψ_i to the CFT (and eventually to the composite Higgs) is very small. When relevant, the coupling grows in the IR and become as large as g_5 (in units of k), meaning that the fermion is as strongly coupled as the CFT states [81]. In this latter case ψ_i behaves as a composite fermion.

84.3.3 *Linear dilaton geometry*

The warp factor $a(y)$ in Eq. (84.16) can be different from the exponential considered above, giving rise to a different KK mass spectrum. A particularly interesting case is the linear dilaton geometry [155] where the KK states become very narrowly-spaced. These scenarios can also be understood in 4D via the clockwork mechanism [156], and for this reason are usually referred to as Clockwork/Linear Dilaton (CW/LD) models. The collider phenomenology becomes different in these models since the decay of the narrowly-spaced KK spectrum appears as a periodic signal in the invariant mass of the decaying products. An excellent detector resolution is needed in order to resolve these KK modes which can be done by looking at 2 electrons or 2 photons in the final state. A search for this type of KK gravitons decaying into ee [157] and $\gamma\gamma$ [41,157,158] put bounds for M_5 in the range of 10 TeV to 1 TeV for values of the lightest KK graviton mass (referred as k in [157,158]) in the range of few TeVs.

84.3.4 *Flat Extra Dimensions*

Models with quantum gravity at the TeV scale, as in the ADD scenario, can have extra (flat) dimensions of 1/TeV size, as happens in string scenarios (see, for example, [159]). All SM fields may propagate in these extra dimensions, leading to the possibility of observing their corresponding KK states.

A simple example is to assume that the SM gauge bosons propagate in a flat five-dimensional orbifold S^1/Z_2 of radius R, with the fermions localized on a 4D boundary. The KK gauge bosons behave as sequential SM gauge bosons with a coupling to fermions enhanced by a factor $\sqrt{2}$ [159]. The experimental limits on such sequential gauge bosons could therefore be recast as limits on KK gauge bosons. Such an interpretation of the ATLAS 7 TeV dilepton analysis [160] yielded the bound $1/R > 4.16$ TeV, while a CMS 8 TeV search with a lepton and missing transverse energy in the final state [161] give $1/R > 3.4$ TeV. Indirect bounds from LEP2 require however $1/R \gtrsim 6$ TeV [86, 162], a bound that can considerably improve in the future by high-energy measurements of the dilepton invariant mass spectrum from Drell-Yan processes at the LHC [163]. More recent LHC limits on leptonically decaying gauge bosons [88, 164–168] are not interpreted as bounds on $1/R$ by the collaborations, but the published results allow for independent derivation of such bounds.

An alternative scenario, known as Universal Extra Dimensions (UED) [169] (for a review see, for example, [170]), assumes that all SM fields propagate universally in a flat orbifold S^1/Z_2 with an extra Z_2 parity, called KK-parity, that interchanges the two boundaries. In this case, the lowest KK state is stable and is a Dark Matter candidate. At colliders, the KK particles would have to be created in pairs, and would then cascade decay to the lightest KK particle, which would be stable and escape detection. The UED mass-spectrum depends not only on the extra-dimensional radius R, but also on the cut-off of the 5D theory Λ, since quantum corrections sensitive to ΛR induce mass-splittings between the KK states. Experimental signatures, such as jets or leptons and $p_{\rm T}^{\rm miss}$, would be similar to those of typical R-parity conserving SUSY searches. An interpretation of the recent LHC experimental SUSY searches for UED models has been presented in Refs. [171,172]. A lower bound $1/R > 1.4 - 1.5$ TeV was derived for ΛR in the range $5 - 35$ [171]. A recent analysis is given in Ref. [173] where it is shown that the minimal UED model is ruled out when LHC data is combined with Dark Matter relic density data. Extensions to the minimal UED model where boundary terms are included can however be compatible with experiments [173].

Finally, realistic models of electroweak symmetry breaking can also be constructed with flat extra spatial dimensions, similarly to those in the warped case, requiring, however, the presence of sizeable boundary kinetic terms [174]. There is also the possibility of breaking supersymmetry by boundary conditions [175]. Models of this type could explain naturally the presence of a Higgs boson lighter than $M_D \sim$ TeV (see, for example, [176–178]).

85. W'-Boson Searches

Revised October 2025 by B.A. Dobrescu (FNAL) and N. Saoulidou (Athens U.).

The W' boson is a massive hypothetical particle of spin 1 and electric charge ±1, which is a color singlet and is predicted in various extensions of the Standard Model (SM).

85.1 W' couplings to quarks and leptons

The Lagrangian terms describing the couplings of a W'^+ boson to fermions are given by

$$\frac{W'^+_\mu}{\sqrt{2}}\left[\overline{u}_i\left(C^R_{q_{ij}}P_R+C^L_{q_{ij}}P_L\right)\gamma^\mu d_j+\overline{\nu}_i\left(C^R_{\ell_{ij}}P_R+C^L_{\ell_{ij}}P_L\right)\gamma^\mu e_j\right]. \tag{85.1}$$

Here, u, d, ν, and e are the SM fermions in the mass eigenstate basis, $i, j = 1, 2, 3$ label the fermion generation, and $P_{R,L} = (1 \pm \gamma_5)/2$. The coefficients $C^L_{q_{ij}}$, $C^R_{q_{ij}}$, $C^L_{\ell_{ij}}$, and $C^R_{\ell_{ij}}$ are complex dimensionless parameters. If $C^R_{\ell_{ij}} \neq 0$, then the ith generation includes a right-handed neutrino. Using this notation, the SM W couplings are $C^L_q = gV_{\rm CKM}$, $C^L_\ell = g \approx 0.63$ and $C^R_q = C^R_\ell = 0$.

Unitarity considerations imply that the W' boson is associated with a spontaneously-broken gauge symmetry. This is true even when it is a composite particle (*e.g.* $\rho^\pm$-like bound states [1]) if its mass is much smaller than the compositeness scale, or a Kaluza-Klein mode in theories where the W boson propagates in extra dimensions [2]. The simplest extension of the electroweak gauge group that includes a W' boson is $SU(2)_1 \times SU(2)_2 \times U(1)$, but larger groups are encountered in some theories. A generic property of these gauge theories is that they also include a Z' boson [3]; the W'-to-Z' mass ratio is often a free parameter.

A tree-level mass mixing may be induced between the electrically-charged gauge bosons. Upon diagonalization of their mass matrix, the W-to-Z mass ratio and the couplings of the observed W boson are shifted from the SM values. Their measurements imply that the mixing angle, θ_+, between the gauge eigenstates must be smaller than about 10^{-2} [4]. In certain theories the mixing is negligible (*e.g.*, due to a new parity [5]), even when the W' mass is near the electroweak scale. Note that $SU(2)$ gauge invariance suppresses the kinetic mixing between the W and W' bosons (in contrast to the case of a Z' boson [3]).

The W' coupling to WZ is fixed by Lorentz and gauge invariances, and to leading order in θ_+ is given by [6]

$$\frac{g\,\theta_+\,i}{\cos\theta_W}\left[W'^+_\mu\left(W^-_\nu Z^{\nu\mu}+Z_\nu W^{-\mu\nu}\right)+Z^\nu W^{-\mu}W'^+_{\nu\mu}\right]+\text{H.c.}, \tag{85.2}$$

where $W^{\mu\nu} \equiv \partial^\mu W^\nu - \partial^\nu W^\mu$, etc. The θ_W dependence shown here corrects the one given in Ref. [7], which has been referred to as the Extended Gauge Model by the experimental collaborations. The W' coupling to Wh^0, where h^0 is the SM Higgs boson, is

$$-\,\xi_h\, g_{W'}\, M_W\; W'^+_\mu\, W^{\mu-} h^0 + \text{H.c.}, \tag{85.3}$$

where $g_{W'}$ is the gauge coupling of the W' boson, and the coefficient ξ_h satisfies $\xi_h \leq 1$ in simple Higgs sectors [6].

In models based on the "left-right symmetric" gauge group [8], $SU(2)_L \times SU(2)_R \times U(1)_{B-L}$, the SM fermions that couple to the W boson transform as doublets under $SU(2)_L$ while the other fermions transform as doublets under $SU(2)_R$. Consequently, the W' boson couples primarily to right-handed fermions; its coupling to left-handed fermions arises due to the θ_+ mixing, so that C^L_q is proportional to the CKM matrix and its elements are much smaller than the diagonal elements of C^R_q. Generically, C^R_q does not need to be proportional to $V_{\rm CKM}$.

There are many other models based on the $SU(2)_1 \times SU(2)_2 \times U(1)$ gauge symmetry. In the "alternate left-right" model [9], all the couplings shown in Eq. (85.1) vanish, but there are some new fermions such that the W' boson couples to pairs involving a SM fermion and a new fermion. In the "ununified SM" [10], the left-handed quarks are doublets under one $SU(2)$, and the left-handed leptons are doublets under a different $SU(2)$, leading to a mostly leptophobic W' boson: $C^L_{\ell_{ij}} \ll C^L_{q_{ij}}$ and $C^R_{\ell_{ij}} = C^R_{q_{ij}} = 0$. Fermions of different generations may also transform as doublets under different $SU(2)$ gauge groups [11]. In particular, the couplings to third generation quarks may be enhanced [12].

It is also possible that the W' couplings to SM fermions are highly suppressed. For example, if the quarks and leptons are singlets under one $SU(2)$ [13], then the couplings are proportional to the tiny mixing angle θ_+. Similar suppressions may arise if some vectorlike fermions mix with the SM fermions [14].

Gauge groups that embed the electroweak symmetry, such as $SU(3)_W \times U(1)$ or $SU(4)_W \times U(1)$, also include one or more W' bosons [15].

85.2 Collider searches

At hadron colliders, W' bosons can be detected through resonant pair production of fermions (f and f') or electroweak bosons with a net electric charge equal to ±1. When W' has a width much smaller than its mass ($\Gamma_{W'}/M_{W'} \lesssim 7\%$), the contribution of the s-channel W' exchange to the total rate for $pp \to f\bar{f}'X$, where X is any final state, may be approximated by the branching fraction $B(W' \to f\bar{f}')$ times the production cross section [16], which may be written as

$$\sigma\left(pp\to W'X\right) \simeq \frac{\pi}{6s}\sum_{i,j}\left[(C^L_{q_{ij}})^2+(C^R_{q_{ij}})^2\right]\, w_{ij}\left(M^2_{W'}/s, M_{W'}\right). \tag{85.4}$$

The functions w_{ij} include the information about proton structure, and are given to leading order in α_s by

$$w_{ij}(z,\mu) = \int_z^1 \frac{dx}{x}\left[u_i(x,\mu)\,\overline{d}_j\left(\frac{z}{x},\mu\right)+\overline{u}_i(x,\mu)\,d_j\left(\frac{z}{x},\mu\right)\right], \tag{85.5}$$

where $u_i(x,\mu)$ and $d_i(x,\mu)$ are the parton distributions inside the proton at the factorization scale μ and parton momentum fraction x for the up- and down-type quarks of the ith generation, respectively. QCD corrections to W' production are sizable (they also include quark-gluon initial states), but preserve the above factorization of couplings at next-to-leading order [17].

The most commonly studied W' signal consists of a high-momentum electron or muon and large missing transverse momentum. The signal transverse mass distribution forms a Jacobian peak with its endpoint at $M_{W'}$ (see Fig. 1 (top) of Ref. [18]). Given that the branching fractions for $W' \to e\nu$ and $W' \to \mu\nu$ could be very different, the results in these channels should be presented separately. Searches in these channels often implicitly assume that the left-handed couplings vanish (no interference between W and W'), and that the right-handed neutrino is light compared to the W' boson and escapes the detector. An example of parameter values that satisfy these assumptions is $C^R_q = gV_{\rm CKM}$, $C^R_\ell = g$, $C^L_q = C^L_\ell = 0$, which define a model that preserves lepton universality and predicts the same total cross section as the Sequential SM used in many W' searches. However, if a W' boson were discovered and the final state fermions have left-handed helicity, then the effects of $W - W'$ interference could be observed [22], providing information about the W' couplings. The effects of the W' width on interference are discussed in Ref. [23].

In the $e\nu$ channel, the ATLAS and CMS collaborations set limits on the W' production cross section times branching fraction $\sigma \times B$ (and thus indirectly on the W' couplings). These limits are set for $M_{W'}$ in the $0.15 - 7$ TeV range and are based on approximately 140 fb^{-1} at $\sqrt{s} = 13$ TeV [18,19], with the most stringent limits reproduced in Fig. 85.1. ATLAS sets the strongest mass limit $M_{W'} > 6.0$ TeV in the Sequential SM (all limits in this mini-review are at the 95% CL). The coupling limits are much weaker for $M_{W'} < 150$ GeV, a range last explored with the Tevatron at $\sqrt{s} = 1.8$ TeV [24].

In the $\mu\nu$ channel, ATLAS and CMS set rate limits for $M_{W'}$ in the $0.15-7$ TeV range [18,19], with the strongest mass lower limit of 5.6 TeV in the Sequential SM set by CMS [19] using 138 fb^{-1} of $\sqrt{s} = 13$ TeV data, as shown in Fig. 85.1. When combined with the $e\nu$ channel assuming lepton universality, the upper limit on the $\sqrt{s} = 13$ TeV cross section times branching fraction to $\ell\nu$ varies between 0.05 and 2.1 fb for $M_{W'}$ values between 1 and 6 TeV [18]. Only weak limits on $W' \to \mu\nu$ exist for $M_{W'} < 150$ GeV [25]. Note that masses of the order of the electroweak

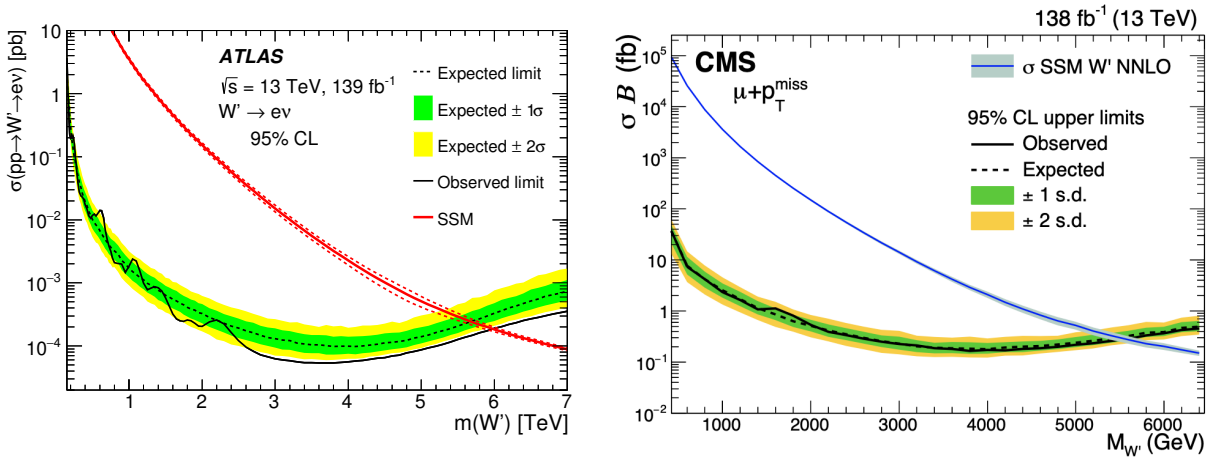

Figure 85.1: Upper limit on $\sigma(pp \to W'X) \times B(W' \to \ell\nu)$ in the $e\nu$ channel from ATLAS [18] (left) and the $\mu\nu$ channel from CMS [19] (right). The red (black) line shows the theoretical prediction in the Sequential SM in the $e\nu$ ($\mu\nu$) channel.

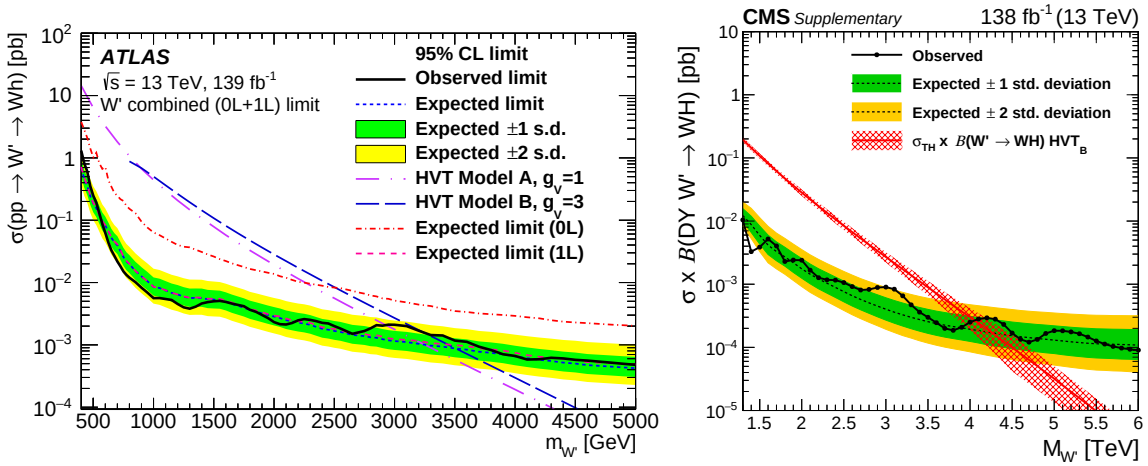

Figure 85.2: Upper limits on W' production cross section times branching fraction into a W and a SM Higgs boson decaying into heavy-flavor quarks, from ATLAS [20] (left) and CMS [21] (right).

scale are interesting from a theoretical point of view, while lepton universality does not necessarily apply to a W' boson.

Searches for $W' \to \tau\nu$ have been performed at 13 TeV by CMS with 138 fb^{-1} [26], and by ATLAS with 139 fb^{-1} [27]. Limits are set on $\sigma \times B$ for $M_{W'}$ between 0.5 and 6 TeV. A mass lower limit of 5.0 TeV is set in the Sequential SM, and the upper limit on the cross section times branching fraction to $\tau\nu$ at 13 TeV varies between 0.4 and 9 fb for $M_{W'}$ values between 1 and 5 TeV [27].

The W' decay into a charged lepton and a right-handed neutrino, ν_R, may also be followed by the ν_R decay through a virtual W' boson into a charged lepton and two quark jets. The CMS [28] and ATLAS [29] searches in the $ee jj$ and $\mu\mu jj$ channels have set limits at $\sqrt{s} = 13$ TeV on the cross section times branching fractions as a function of the ν_R mass and of $M_{W'}$. No requirement is placed on the charge of the lepton pair. A related W' search in the $\tau\tau jj$ channel with hadronic τ decays was also performed by CMS [30].

The $t\bar{b}$ channel is particularly important because a W' boson that couples only to right-handed fermions cannot decay to leptons when the right-handed neutrinos are heavier than $M_{W'}$. Additional motivations are provided by a W' boson with enhanced couplings to the third generation [12], and by a leptophobic W' boson. The usual signature for $W' \to t\bar{b}$ consists of a leptonically-decaying W boson and two b-jets. Recent studies have also incorporated the fully hadronic decay channel for $M_{W'} \gg m_t$ with the use of jet substructure techniques to tag highly boosted top-jets. For a detailed discussion of this channel, see Ref. [31].

Searches for dijet resonances may be used to set limits on $W' \to q\bar{q}'$. ATLAS [32] and CMS [33] provide similar coverage in the $\sim$ 1.5−8 TeV mass range with 139 and 137 fb^{-1} of data, respectively, collected at $\sqrt{s} = 13$ TeV. Interpretation in terms of W' decays with 139 fb^{-1} of 13 TeV data yields a W' mass lower limit of 4.0 TeV in the Sequential SM [32]. For masses in the range $\sim$ $0.5 - 1.5$ TeV, analyses based on jets reconstructed online provide the best sensitivity because they circumvent trigger bandwidth limitations [34, 35]. For W' masses below $\sim$ 0.5 TeV, the best limits are set in novel analyses exploiting boosted technologies and initial state radiation [36–39]. Cross-section limits for W' masses below $\sim$ 1.5 TeV can be derived from the dijet limits on Z' bosons summarized in Ref. [3].

In some theories [5] the W' couplings to SM fermions are suppressed by discrete symmetries. W' production then occurs in pairs, through a photon or Z boson. The decay modes are model-dependent and often involve other new particles. The ensuing collider signals arise from cascade decays and often include missing transverse momentum or boosted multi-jet topologies. Even when single production of W' is large enough, it is possible that its main decay mode is into a new particle and a SM one. An example is a search performed by CMS [40] for W' decays into a vector-like quark and a top or a bottom quark. The final state studied in this analysis involves a boosted SM Higgs or Z boson, as well as a $t\bar{t}$ or $b\bar{b}$ pair, with all heavy particles decaying into jets. Another example is a search performed by ATLAS [41] for W' decays into a W boson and a Z' boson, the latter decaying

into a jet pair.

Searches for WZ resonances at the LHC have focused on the process $pp \to W' \to WZ$ with the production mainly from $u\bar{d} \to W'$, assuming SM-like couplings to quarks. ATLAS and CMS have set upper limits on the $W'WZ$ coupling for $M_{W'}$ in the $0.2 - 5.0$ TeV range with a combination of fully leptonic, semi-leptonic and fully hadronic channels with $\sim 36 - 139$ fb^{-1} at 13 TeV [42,43] (see also Ref. [31]). Constraints in individual channels of the same $pp \to W' \to WZ$ process were obtained based on the full Run 2 data sets by ATLAS [44–46] and CMS [21,47–49]. The strongest lower limit on the W' mass is set by ATLAS [45] in the semi-leptonic channel with a lower limit on $M_{W'}$ of 3.9 TeV [45] in the context of the Heavy Vector Triplet (HVT) weakly-coupled scenario A [50]. A similar result is obtained by CMS in the fully-hadronic channel [21]. A fermiophobic W' boson that couples to WZ may be produced at hadron colliders in association with a Z boson, or via WZ fusion. This would give rise to $(WZ)Z$ and $(WZ)jj$ final states [51]. Results of the search for the latter are reported in Refs. [21,45,47,49,52].

W' bosons have also been searched for in final states with a W boson and a SM Higgs boson in the channels $W \to \ell\nu$ or $W \to q\bar{q}'$ and $h^0 \to b\bar{b}$ by ATLAS [20,53] and CMS [21,49] with 138–139 fb^{-1} at $\sqrt{s} = 13$ TeV. CMS also searched for W' bosons in the $q\bar{q}'\tau\tau$ final state [54]. Cross-section limits are set for W' masses between 0.4 and 6.0 TeV. The most stringent upper limit on the cross section is set by the ATLAS analysis with $W \to \ell\nu$ at low $M_{W'}$ and the CMS analysis with $W \to q\bar{q}'$ at high $M_{W'}$, as shown in Fig. 85.2.

At lepton colliders, W' bosons may be produced in pairs via their photon coupling, which is model independent. At LEP-II, although dedicated searches for W' bosons have not been performed, the large cross section for $e^+e^- \to \gamma^* \to W'^+W'^-$ and small backgrounds suggest that any W' is ruled out up to the kinematic limit, $M_{W'} < \sqrt{s}/2 \approx 105$ GeV, for most decay modes. Sensitivity to $M_{W'}$ above $\sqrt{s}$ could be achieved [55] using the $e^+e^- \to \gamma\nu\bar{\nu}$ process via a t-channel W' exchange, if the W' coupling to $e\nu$ is large enough.

85.3 Low-energy constraints

The properties of W' bosons are also constrained by measurements of processes at energies much below $M_{W'}$. The bounds on $W - W'$ mixing [4] are mostly due to the change in W properties compared to the SM. Limits on deviations in the ZWW couplings provide a leading constraint for fermiophobic W' bosons [14].

Constraints arising from low-energy effects of W' exchange are strongly model-dependent. If the W' couplings to quarks are not suppressed, then box diagrams involving a W and a W' boson contribute to neutral meson-mixing. In the case of W' couplings to right-handed quarks as in the left-right symmetric model, the limit from $K_L - K_S$ mixing is severe: $M_{W'} > 2.9$ TeV for $C_q^R = gV_{\rm CKM}$ [56]. However, if no correlation between the W' and W couplings is assumed, then the limit on $M_{W'}$ may be significantly relaxed [57].

W' exchange also contributes at tree level to various low-energy processes. In particular, it would impact the measurement of the Fermi constant G_F in muon decay, which in turn would change the predictions of many other electroweak processes. A recent test of parity violation in polarized muon decay [58] has set limits of about 600 GeV on $M_{W'}$, assuming W' couplings to right-handed leptons as in left-right symmetric models and a light ν_R. There are also W' contributions to the neutron electric dipole moment, β decays, and other processes [4].

If right-handed neutrinos have Majorana masses, then there are tree-level contributions to neutrinoless double-beta decay, and a limit on $M_{W'}$ versus the ν_R mass may be derived [59]. For ν_R masses below a few GeV, the W' boson contributes to leptonic and semileptonic B meson decays, so that limits may be placed on various combinations of W' parameters [57]. For ν_R masses below $\sim$30 MeV, the most stringent constraints on $M_{W'}$ are due to the limits on ν_R emission from supernovae [60].

86. Z'-Boson Searches

Revised October 2025 by B.A. Dobrescu (FNAL) and N. Saoulidou (Athens U.).

The Z' boson is a massive, electrically-neutral and color-singlet hypothetical particle of spin 1. This particle is predicted in many extensions of the Standard Model (SM) and has been the object of extensive phenomenological studies [1].

86.1 Z' boson couplings

The couplings of a Z' boson to the first-generation fermions are given by

$$Z'_\mu \left(g_u^L\, \overline{u}_L \gamma^\mu u_L + g_d^L\, \overline{d}_L \gamma^\mu d_L + g_u^R\, \overline{u}_R \gamma^\mu u_R + g_d^R\, \overline{d}_R \gamma^\mu d_R + g_\nu^L\, \overline{\nu}_L \gamma^\mu \nu_L + g_e^L\, \overline{e}_L \gamma^\mu e_L + g_e^R\, \overline{e}_R \gamma^\mu e_R \right), \tag{86.1}$$

where u, d, ν, e are the quark and lepton fields in the mass eigenstate basis, and the coefficients g_u^L, g_d^L, g_u^R, g_d^R, g_ν^L, g_e^L, g_e^R are real dimensionless parameters. If the Z' couplings to quarks and leptons are generation-independent, then these seven parameters describe the couplings of the Z' boson to all SM fermions. More generally, however, the Z' couplings to fermions are generation-dependent, in which case Eq. (86.1) may be written with generation indices i, $j = 1$, 2, 3 labeling the quark and lepton fields, and with the seven coefficients promoted to 3×3 Hermitian matrices (*e.g.*, ${g_e^L}_{ij}\, \overline{e}_L^i \gamma^\mu e_L^j$, where e_L^2 is the left-handed muon, etc.).

The parameters describing the Z' boson interactions with quarks and leptons are subject to some theoretical constraints. Quantum field theories that include a heavy spin-1 particle are well behaved at high energies only if that particle is a gauge boson associated with a spontaneously broken gauge symmetry. Quantum effects preserve the gauge symmetry only if the couplings of the gauge boson to fermions satisfy the anomaly equations [2]. Furthermore, the fermion charges under the new gauge symmetry are constrained by the requirement that the quarks and leptons get masses from gauge-invariant interactions with the Higgs fields.

The relation between the couplings displayed in Eq. (86.1) and the gauge charges z_{fi}^L and z_{fi}^R of the fermions $f = u, d, \nu, e$ involves the unitary 3×3 matrices V_f^L and V_f^R that transform the gauge eigenstate fermions f_L^i and f_R^i, respectively, into the mass eigenstates. The Z' couplings also depend on the mixings of the new gauge boson in the gauge eigenstate basis ($\tilde{Z}'_\mu$). The main mixings are a kinetic mixing $(-\chi/2) B^{\mu\nu} \tilde{Z}'_{\mu\nu}$ with the hypercharge gauge boson B^μ (χ is a dimensionless parameter), and a mass mixing $\delta M^2\, \tilde{Z}^\mu \tilde{Z}'_\mu$ with the linear combination ($\tilde{Z}_\mu$) of neutral bosons identified as the SM Z boson [3]. Since both the kinetic and mass mixings shift the mass and couplings of the Z boson, electroweak measurements impose upper limits on χ and $\delta M^2/(M_{Z'}^2 - M_Z^2)$ of the order of 10^{-3} [4]. Keeping only linear terms in these two small quantities, the couplings of the mass-eigenstate Z' boson are given by

$${g_f^L}_{ij} = g_z V_{fii'}^L\, z_{f\,i'}^L \left(V_f^L\right)^\dagger_{i'j} + \frac{e}{c_W} \left(\frac{s_W \chi M_{Z'}^2 + \delta M^2}{2 s_W \left(M_{Z'}^2 - M_Z^2\right)} \sigma_f^3 - \epsilon\, Q_f \right), \tag{86.2}$$

$${g_f^R}_{ij} = g_z V_{fii'}^R\, z_{fi'}^R \left(V_f^R\right)^\dagger_{i'j} - \frac{e}{c_W}\, \epsilon\, Q_f, \tag{86.3}$$

where g_z is the new gauge coupling, Q_f is the electric charge of f, e is the electromagnetic gauge coupling, s_W and c_W are the sine and cosine of the weak mixing angle, $\sigma_f^3 = +1$ for $f = u, \nu$ and $\sigma_f^3 = -1$ for $f = d, e$, and

$$\epsilon = \frac{\chi \left(M_{Z'}^2 - c_W^2 M_Z^2\right) + s_W \delta M^2}{M_{Z'}^2 - M_Z^2}. \tag{86.4}$$

The interaction of the Z' boson with a pair of W bosons has the form

$$\left[i \left(W_\mu^- Z'_\nu - W_\nu^- Z'_\mu \right) \partial^\mu W^{+\nu} + \text{H.c.} \right] + i \left(W_\mu^+ W_\nu^- - W_\nu^+ W_\mu^- \right) \partial^\mu Z'^\nu \tag{86.5}$$

with a coefficient of order $M_W^2/M_{Z'}^2$ [5]. The Z' also couples to one SM Higgs boson and one Z boson, $Z'_\mu Z^\mu\, h^0$, with a coefficient of order M_Z.

86.2 Z' models

A simple origin of a Z' boson is a new $U(1)'$ gauge symmetry. In that case, the matricial equalities $z_u^L = z_d^L$ and $z_\nu^L = z_e^L$ are required by the SM $SU(2)_W$ gauge symmetry. Given that the $U(1)'$ interaction is not asymptotically free, the theory may be well-behaved at high energies (*e.g.*, by embedding $U(1)'$ in a non-Abelian gauge group) only if the charges are commensurate numbers, *i.e.* any ratio of charges is a rational number. Satisfying the anomaly equations [6] with rational numbers is highly nontrivial, and typically new fermions charged under $U(1)'$ are necessary.

If the couplings are generation-independent ($V_f^{L,R}$ are then unit matrices in Eq. (86.2)) and the mixings of $\tilde{Z}'$ are negligible, then there are five commensurate couplings: g_u^R, g_d^R, g_e^R, g_q^L ($q = u$ or d), g_l^L ($l = \nu$ or e). Four sets of charges are displayed in Table 86.1, each of them spanned by a free parameter x [6]. The first set, labeled $B - xL$, has charges proportional to the baryon number minus x times the lepton number. These charges allow all SM Yukawa couplings to the Higgs doublet which is neutral under $U(1)_{B-xL}$, so that there is no tree-level $\tilde{Z} - \tilde{Z}'$ mixing. For $x = 1$ one recovers the $U(1)_{B-L}$ group, which is non-anomalous in the presence of one "right-handed neutrino" (a chiral fermion that is a singlet under the SM gauge group) per generation. For $x \neq 1$, it is necessary to include some fermions that are vectorlike (*i.e.* their mass terms are gauge invariant) with respect to the electroweak gauge group and chiral with respect to $U(1)_{B-xL}$. In the particular cases $x = 0$ or $x \gg 1$, the Z' is leptophobic or quark-phobic, respectively.

The second set, $U(1)_{10+x\bar{5}}$, has charges that commute with the representations of the $SU(5)$ grand unified group. Here x is related to the mixing angle between the two $U(1)$ bosons encountered in the $E_6 \to SU(5) \times U(1) \times U(1)$ symmetry breaking patterns of grand unified theories [1,7]. With these charges, two Higgs doublets are typically required to generate masses for both up- and down- type fermions. This set leads to $\tilde{Z} - \tilde{Z}'$ mass mixing at tree level, such that for a Z' mass close to the electroweak scale, the measurements at the Z-pole require some fine tuning between the charges and VEVs of the two Higgs doublets. Vectorlike quarks charged under the electroweak gauge group are required (except for $x = -3$) to make this set anomaly free. The particular cases $x = -3, 1, -1/2$ are usually labeled $U(1)_\chi$, $U(1)_\psi$, and $U(1)_\eta$, respectively. Under the third set, $U(1)_{d-xu}$, the weak-doublet quarks are neutral, and the ratio of u_R and d_R charges is $-x$. For $x = 1$, this is the "right-handed" group $U(1)_R$. For $x = 0$, the charges are those of the E_6-inspired $U(1)_I$ group, which requires new quarks and leptons. Other generation-independent sets of $U(1)'$ charges are given in Ref. [8].

In the absence of new fermions charged under the SM group, the most general generation-independent charge assignment is $U(1)_{q+xu}$, which is a linear combination of hypercharge and $B-L$. Many other anomaly-free solutions exist if generation-dependent charges are allowed. An example is $B - xL_e - yL_\mu + (y-3)L_\tau$, with x, y free parameters. This allows all fermion masses to be generated by Yukawa couplings to a single Higgs doublet, without inducing tree-level flavor-changing neutral current (FCNC) processes. There are also lepton-flavor dependent charges that allow neutrino masses to arise only from operators of high dimensionality [9].

If the $SU(2)_W$-doublet quarks have generation-dependent $U(1)'$ charges, then the mass eigenstate quarks have flavor off-diagonal couplings to the Z' boson (see Eq. (86.1), and note that $V_u^L \left(V_d^L\right)^\dagger$

Table 86.1: Examples of generation-independent $U(1)'$ charges for quarks and leptons. The parameter x is an arbitrary rational number. Gauge anomaly cancellation requires certain new fermions [6].

fermion	$U(1)_{B-xL}$	$U(1)_{10+x\bar{5}}$	$U(1)_{d-xu}$	$U(1)_{q+xu}$
(u_L, d_L)	1/3	1/3	0	1/3
u_R	1/3	$-1/3$	$-x/3$	$x/3$
d_R	1/3	$-x/3$	1/3	$(2-x)/3$
(ν_L, e_L)	$-x$	$x/3$	$(-1+x)/3$	-1
e_R	$-x$	$-1/3$	$x/3$	$-(2+x)/3$

is the CKM matrix). These are severely constrained by measurements of FCNC processes, which in this case are mediated at tree-level by Z' boson exchange [10]. The constraints are relaxed if the first and second generation charges are the same, although they are increasingly tightened by the measurements of B meson properties [11]. If only the $SU(2)_W$-singlet quarks have generation-dependent $U(1)'$ charges, there is more freedom in adjusting the flavor off-diagonal couplings because the $V^R_{u,d}$ matrices are not observable in the SM.

The anomaly equations for $U(1)'$ could be circumvented only if there is an axion with certain dimension-5 couplings to the gauge bosons. However, such a scenario violates unitarity unless the quantum field theory description breaks down at a scale near $M_{Z'}$ [12]. It is possible, though, that the SM fermions are not charged under the $U(1)'$, but have mass mixing with some vectorlike fermions which are charged under $U(1)'$, implying that the physical fermions have couplings to the Z' [13]. For example, if the only SM quarks that have large mixings with some vectorlike quarks are the b quarks, then the only currently known particles that couple to the Z' would be the physical b quarks.

Z' bosons may also arise from larger gauge groups. These may extend the electroweak group, as in $SU(2)\times SU(2)\times U(1)$, or may embed the electroweak group, as in $SU(3)_W \times U(1)$ [14]. If the larger group is spontaneously broken down to $SU(2)_W \times U(1)_Y \times U(1)'$ at a scale $v_\star \gg M_{Z'}/g_z$, then the above discussion applies up to corrections of order $M^2_{Z'}/(g_z v_\star)^2$. For $v_\star \sim M_{Z'}/g_z$, additional gauge bosons have masses comparable to $M_{Z'}$, including at least a W' boson [14]. If the larger gauge group breaks together with the electroweak symmetry directly to the electromagnetic $U(1)_{\rm em}$, then the left-handed fermion charges are no longer correlated ($z^L_u \neq z^L_d$, $z^L_\nu \neq z^L_e$) and a $Z'W^+W^-$ coupling is induced.

If the electroweak gauge bosons propagate in extra dimensions, then their Kaluza-Klein (KK) excitations include a series of Z' boson pairs. Each of these pairs can be associated with a different $SU(2)\times U(1)$ gauge group in four dimensions. The properties of the KK particles depend strongly on the extra dimensional theory [15]. For example, in universal extra dimensions there is a parity that forces all couplings of Eq. (86.1) to vanish in the case of the lightest KK bosons, while allowing couplings to pairs of fermions involving a SM and a heavy vectorlike fermion. There are also 4-dimensional gauge theories (*e.g.* little Higgs with T parity [16]) with Z' bosons exhibiting similar properties. By contrast, in a warped extra dimension, the couplings of Eq. (86.1) may be sizable even when SM fields propagate along the extra dimension.

Z' bosons may also be composite particles. For example, in confining gauge theories [17], the ρ-like bound state is a spin-1 boson that may be interpreted as arising from a spontaneously broken gauge symmetry [18].

86.3 Non-resonant Z' signatures at colliders

In the presence of the couplings shown in Eq. (86.1), the Z' boson may be produced in the s-channel at colliders, and would decay to pairs of fermions. The decay width into a pair of electrons is given by

$$\Gamma\left(Z' \to e^+e^-\right) \simeq \left[\left(g^L_e\right)^2 + \left(g^R_e\right)^2\right] \frac{M_{Z'}}{24\pi}, \qquad (86.6)$$

where small corrections from electroweak loops are not included. The decay width into $q\bar{q}$ is similar, except for an additional color factor of 3, QCD radiative corrections, and fermion mass corrections. Thus, one may compute the Z' branching fractions in terms of the couplings of Eq. (86.1). However, other decay channels, such as WW or a pair of new particles, could have large widths and need to be added to the total decay width.

As mentioned above, there are theories in which the Z' couplings are controlled by a discrete symmetry that forbids decays into a pair of SM particles. Typically, such theories involve several new particles, which may be produced only in pairs and undergo cascade decays through Z' bosons, leading to signals involving missing transverse momentum. Given that the cascade decays depend on the properties of new particles other than the Z' boson (see, *e.g.* Ref. [19]), this case is not discussed further here.

The Z' contribution to the cross sections for $e^+e^- \to f\bar{f}$ proceeds through an s-channel Z' exchange (when $f = e$, there are also t- and u-channel exchanges). For $M_{Z'} < \sqrt{s}$, the Z' appears as an $f\bar{f}$ resonance in the radiative return process where photon emission tunes the effective center-of-mass energy to $M_{Z'}$. The agreement between the LEP-II measurements and the SM predictions implies that either the Z' couplings are smaller than or of order 10^{-2}, or else $M_{Z'}$ is above 209 GeV, the maximum energy of LEP-II. In the latter case, the Z' exchange may be approximated up to corrections of order $s/M^2_{Z'}$ by the contact interactions

$$\frac{g_z^2}{M^2_{Z'} - s}\left[\bar{e}\gamma_\mu\left(z^L_e P_L + z^R_e P_R\right)e\right]\left[\bar{f}\gamma^\mu\left(z^L_f P_L + z^R_f P_R\right)f\right], \qquad (86.7)$$

where $P_{L,R}$ are chirality projection operators, and the relation between Z' couplings and charges (see Eq. (86.2) in the limit where the mass and kinetic mixings are neglected) is used, assuming generation-independent charges. The four LEP collaborations have set limits on the coefficients of such operators for all possible chiral structures and for various combinations of fermions [20]. Thus, one may derive bounds on $(M_{Z'}/g_z)|z^L_e z^L_f|^{-1/2}$ and the analogous combinations of LR, RL and RR charges, which are typically on the order of a few TeV. LEP-II limits were derived [6] on the four sets of charges shown in Table 86.1.

Somewhat stronger bounds can be set on $M_{Z'}/g_z$ for specific sets of Z' couplings if the effects of several operators (86.7) are combined. Dedicated analyses by the LEP collaborations have set limits on Z' bosons for particular values of the gauge coupling (see section 3.5 of Ref. [20]). For example, $M_{Z_{\rm SSM}} > 1.76$ TeV for a "sequential" Z' of same couplings as the SM Z boson, while $M_{Z_\chi} > 0.785$ TeV for the Z' associated with $U(1)_\chi$ assuming a unification condition for the gauge coupling.

86.4 Searches at hadron colliders

Z' bosons with couplings to quarks (see Eq. (86.1)) may be produced at hadron colliders in the s-channel and would show up as resonances in the invariant mass distribution of the decay products. The cross section for producing a Z' boson at the LHC, which then decays to some $f\bar{f}$ final state, takes the form [23]

$$\sigma\left(pp \to Z'X \to f\bar{f}X\right) \simeq \frac{\pi}{6\,s}\sum_q c^f_q\, w_q\left(s, M^2_{Z'}\right) \qquad (86.8)$$

for flavor-diagonal couplings to quarks. Here, we have neglected the interference with the SM contribution to $f\bar{f}$ production, which is a good approximation for a narrow Z' resonance (deviations from the narrow width approximation are discussed in Ref. [24]). The coefficients

$$c^f_q = \left[\left(g^L_q\right)^2 + \left(g^R_q\right)^2\right] B(Z' \to f\bar{f}) \qquad (86.9)$$

contain all the dependence on the Z' couplings, while the functions w_q include all the information about parton distributions and QCD corrections [6, 8]. This factorization holds exactly at next-to-leading order, and the deviations from it induced at NNLO are very small. Note that the w_u and w_d functions are substantially larger than the w_q functions for the other quarks.

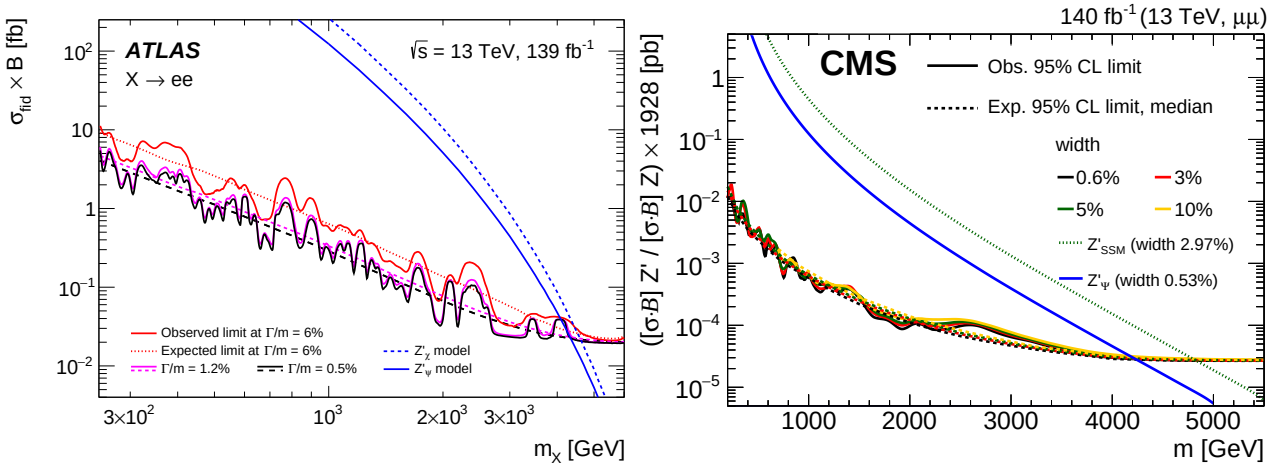

Figure 86.1: Upper limits on the cross section for Z' production times the branching fraction for $Z' \to e^+e^-$ (left panel, set by ATLAS [21]) or $Z' \to \mu^+\mu^-$ (right panel, set by CMS [22]) as a function of $M_{Z'}$. The lines labeled by Z'_ψ and Z'_χ are theoretical predictions for the $U(1)_{10+x\bar{5}}$ models in Table 86.1 with $x = -3$ and $x = +1$, respectively, for g_z fixed by an E_6 unification condition. The $Z'_{\rm SSM}$ line corresponds to Z' couplings equal to those of the Z boson.

Eq. (86.8) also applies to the Tevatron, except for changing the pp initial state to $p\bar{p}$, which implies that the $w_q(s, M^2_{Z'})$ functions are replaced by some other functions $\bar{w}_q((1.96\,\text{TeV})^2, M^2_{Z'})$.

It is common to present results of Z' searches as limits on the cross section versus $M_{Z'}$ (see for example Fig. 86.1). An alternative is to plot exclusion curves for fixed $M_{Z'}$ values in the $c^f_u - c^f_d$ planes, allowing a simple derivation of the mass limit within any Z' model. CMS upper limits in the $c^\ell_u - c^\ell_d$ plane ($\ell = e$ or μ) for different $M_{Z'}$ are shown in Ref. [22] (for Tevatron limits, see Refs. [8, 25]).

The discovery of a dilepton resonance at the LHC would determine the Z' mass and width. A measurement of the total cross section would define a band in the $c^\ell_u - c^\ell_d$ plane. Angular distributions can be used to measure several combinations of Z' parameters (angular distributions were used in Ref. [26] to improve the Tevatron sensitivity). Even though the original quark direction in a pp collider is unknown, the leptonic forward-backward asymmetry $A^\ell_{\rm FB}$ can be extracted from the kinematics of the dilepton system, and is sensitive to parity-violating couplings. A fit to the Z' rapidity distribution can distinguish between the couplings to up and down quarks. These measurements, combined with off-peak observables, have the potential to differentiate among various Z' models [27]. In some cases, $A^\ell_{\rm FB}$ may provide discovery sensitivity that is competitive with the mass distribution [28]. The spin of the Z' boson may be determined from angular distributions [29].

Searches for Z' decays into e^+e^- and $\mu^+\mu^-$ by the ATLAS and CMS collaborations [21,22] have set 95% C.L. upper cross-section limits as low as 0.02 fb (see Fig. 86.1), with the mass lower limits in specific models as high as 4.9 TeV in a single channel. Cross section limits in the dimuon channel for low mass regions, below 200 GeV but not near the Z mass, have been set at the LHC by CMS [30,31] and LHCb [32].

The $Z' \to \tau^+\tau^-$ decay has been searched for by CMS with 140 fb^{-1} of 13 TeV data [33], and a limit $M_{Z'} > 3.5$ TeV has been set in the case of a sequential Z'. Limits on heavy scalars in the $\tau^+\tau^-$ final state, set by ATLAS [34] and CMS [35] with the full Run 2 datasets, can be recast into limits on Z'. New searches of very low mass resonances decaying to $\tau^+\tau^-$ final states, in the ranges of 20 to 60 GeV have been published by the CMS experiment [36]. Limits in the flavor-violating leptonic final states have also been reported by ATLAS [37] and CMS [38, 39] at 13 TeV, for resonances in the $e^\pm\mu^\mp$, $e^\pm\tau^\mp$ and $\mu^\pm\tau^\mp$ channels.

Final states with higher background, jj, $b\bar{b}$ and $t\bar{t}$, are also important as they probe various combinations of Z' couplings to quarks. Besides the improved sensitivity at masses of several TeV, the LHC searches in the dijet channel have been also extended to masses as low as 10 GeV, through the use of new techniques involving boosted topologies and initial state radiation [40]. Such searches, utilizing now the full Run 2 ATLAS [41] and CMS [42] datasets, provide best limits in the low mass regime, below ∼300 GeV. In addition, new limits covering the intermediate mass range of 0.4−1.8 TeV are published by CMS [43] and ATLAS [44], based on the full Run 2 datasets, using trigger-level data.

Given the large number of dijet resonance searches over almost three orders of magnitude in mass, it is convenient to compare all existing limits using a coupling-mass plot for a Z' that has flavor-universal vector couplings to quarks [45]. Limits from Z' searches performed by CMS [46] using hadronic final states are summarized in Fig. 86.2, for $g^L_d = g^R_d = g^L_u = g^R_u = g'_q$ in Eq. (86.1). A similar summary from ATLAS [47] uses axial couplings: $g^L_d = -g^R_d = g^L_u = -g^R_u = g_q$. Constraints from electroweak processes and from Z' mixing with the Υ meson are derived in Ref. [48] for the vector coupling as a function of mass.

Searches for the $Z' \to b\bar{b}$ decay have been performed for two production mechanisms. ATLAS [49] and CMS [50] searched for $b\bar{b}$ resonances using the full Run 2 datasets, setting limits under the assumption that the Z' boson couples to light quarks and thus is produced in the s-channel. The CMS upper limit on the cross-section times the $Z' \to b\bar{b}$ branching fraction decreases from 40 fb at $M_{Z'} = 1.8$ TeV to 0.4 fb at $M_{Z'} = 8$ TeV. The ATLAS search covered the 1.3 TeV – 5 TeV mass range, setting a lower mass limit of 2.7 TeV for the Z'_{SSM}. Independent of any other couplings, if the Z' couples to the b quark, then it can be produced in association with a $b\bar{b}$ pair, and it decays to a second $b\bar{b}$ pair, which forms a resonance. The cross-section limit for that process, set by ATLAS [51] with 103 fb^{-1} of 13 TeV data, is between 0.1 and 0.2 pb for $M_{Z'}$ in the 1.3 – 3 TeV range. For a vector coupling g_b of Z' to b quarks, *i.e*, $g^L_{d\,33} = g^R_{d\,33} = g_b$ using the notation of Eq. (86.1), the limit is $M_{Z'} > 1.45$ TeV when $g_b = 1$. Recently, the ATLAS Collaboration published a b-tagged version of a dijet resonance search [52] utilizing initial state radiation, which probes masses in the 200 − 600 GeV range. Another search that depends on the Z' couplings to the b quark for production (more precisely, for a $b\bar{b}$, $s\bar{b}$ or $b\bar{s}$ initial state) was performed by CMS [53], under the assumption that the Z' boson decays into a muon pair. Searches for the $Z' \to t\bar{t}$ decay are discussed in Ref. [17].

Heavy resonances decaying into Zh^0 with $Z \to \ell^+\ell^-$, $\nu\bar{\nu}$ or $q\bar{q}$ and $h^0 \to b\bar{b}$ have been studied by ATLAS [54,55] and CMS [56,57] using the full 13 TeV dataset. CMS also searched for Z' bosons in the $q\bar{q}\tau\tau$ final state [58]. The most stringent constraint on Z' production in the context of the Heavy Vector Triplet (HVT) model weakly-coupled scenario A [59] is set in the semi-leptonic channel, with a mass lower limit of 3.5 TeV [56].

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

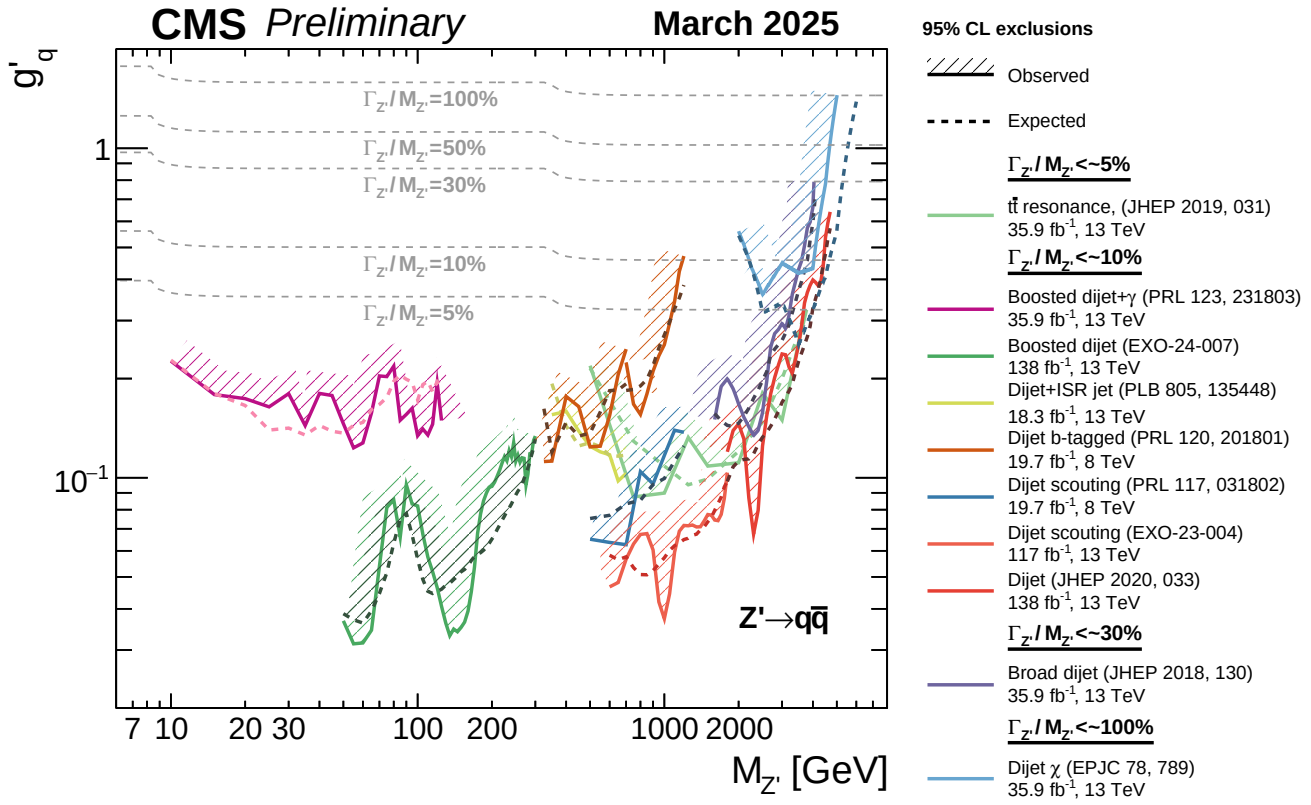

Figure 86.2: Upper limits on the Z' coupling to quarks as a function of $M_{Z'}$ based on various CMS searches [46], for a vector coupling $g_d^L = g_d^R = g_u^L = g_u^R = g'_q$ in Eq. (86.1). Constraints on the coupling due to electroweak and other processes are computed in [48]. Similar ATLAS limits [47] use an axial coupling: $g_d^L = -g_d^R = g_u^L = -g_u^R = g_q$.

Searches for a Z' boson lighter than the SM Z and which couples to leptons have been performed in the 4-lepton final state. ATLAS [60] and CMS [61] focused on the Z decays into a muon pair followed by the radiation of a narrow Z' boson which decays itself into a muon pair. A related CMS search [62] for Z decays into four leptons, but without requiring that a pair of leptons form a narrow resonance, was used to set limits on Z' couplings to electrons or muons as a function of mass, which are relevant for large widths. ATLAS [63] considered the $h^0 \to ZZ'$ and $h^0 \to Z'Z'$ processes followed by the leptonic decays of both spin-1 bosons.

The $pp \to Z'X \to W^+W^-X$ process has also been searched for at the LHC. The channel where the Z' boson is produced through its couplings to quarks, and the W bosons decay hadronically, has been explored using boosted techniques to analyze the 13 TeV data [57, 64–66] with a mass lower limit of 3.5 TeV in the HVT model A [65]. A search in the $e\nu\mu\nu$ final state sets cross-section limits at lower Z' mass [67]. The Z' boson may also be produced through its couplings to W bosons [68], which has been explored with the use of forward jets consistent with a vector boson fusion event topology [57, 65, 66]. The latter process provides a test of fermiophobic Z' models.

At the Tevatron, the CDF and DØ collaborations have searched for Z' bosons in the e^+e^- [69], $\mu^+\mu^-$ [70], $e^\pm\mu^\mp$ [71], $\tau^+\tau^-$ [72], $t\bar{t}$ [73], jj [74] and W^+W^- [75] final states. These limits have been mostly superseded by the LHC results.

86.5 Low-energy constraints

Z' boson properties are also constrained by a variety of low-energy experiments [76]. Polarized electron-nucleon scattering and atomic parity violation are sensitive to electron-quark contact interactions, which get contributions from Z' exchange that can be expressed in terms of the couplings introduced in Eq. (86.1) and M'_Z. Further corrections to the electron-quark contact interactions are induced in the presence of $\tilde{Z}-\tilde{Z}'$ mixing because of the shifts in the Z couplings to quarks and leptons [3]. Deep-inelastic neutrino-nucleon scattering is similarly affected by Z' bosons. Other low-energy observables are discussed in [4]. Viable models with Z' bosons much lighter than the Z boson have been constructed, despite many additional experimental constraints [77]. Limits on the Z' coupling to leptons in the mass range 0.02–10.2 GeV have been set in e^+e^- collisions by BaBar [78], assuming a dark photon, *i.e.*, a Z' boson whose couplings arise only from the kinetic mixing with the hypercharge gauge boson.

In some models, the lower limits on $M_{Z'}$ set by low-energy data are above 1 TeV. For example, $M_{Z_\chi} > 1.1$ TeV and $M_{Z_\eta} > 0.43$ TeV assuming that the Higgs sectors consist of electroweak doublets and singlets only [4], while the gauge coupling is fixed by an $SO(10)$ unification condition for $U(1)_\chi$ and $U(1)_\eta$. For more general models, see Refs. [1, 6, 79]. The mass bounds from direct searches at the LHC [21, 22] exceed the electroweak constraints by a factor of three or more for the models mentioned here. This conclusion could change if the collider bounds are weakened by exotic decay channels [80].

Although the LHC data are most constraining for many Z' models, one should be careful in assessing the relative reach of various experiments given the freedom in Z' couplings. For example, a Z' coupled to $B-yL_\mu+(y-3)L_\tau$ has implications for the muon $g-2$, neutrino oscillations or τ decays, and would be hard to see in processes involving first-generation fermions. Moreover, the combination of LHC searches and low-energy measurements could allow a precise determination of the Z' parameters [81].

87.1 Introduction

Supersymmetry (SUSY) is a generalization of the space-time symmetries of quantum field theory that transforms fermions into bosons and vice versa [1]. The existence of such a non-trivial extension of the Poincaré symmetry of ordinary quantum field theory was initially surprising, and its form is highly constrained by theoretical principles [2]. For example, supersymmetry has been used as a theoretical laboratory for studying nonperturbative aspects of strongly-coupled quantum field theories (e.g., see Refs. [3, 4]).

SUSY also provides a framework for the unification of particle physics and gravity [5–7] at the Planck energy scale, $M_{\rm P} \sim 10^{19}$ GeV, where the gravitational interactions become comparable in strength to the gauge interactions. Moreover, supersymmetry can stabilize the hierarchy between the energy scale that characterizes electroweak symmetry breaking, $M_{\rm EW} \sim$ 100 GeV, and the Planck scale [8–10] against large radiative corrections. The stability of this large gauge hierarchy with respect to radiative quantum corrections is not possible to maintain in the Standard Model (SM) without an unnatural fine-tuning of the parameters of the fundamental theory at the Planck scale. In contrast, in a supersymmetric extension of the SM, it is possible to maintain the gauge hierarchy while providing a natural framework for elementary scalar fields.

If supersymmetry were an exact symmetry of nature, then particles and their superpartners, which differ in spin by half a unit, would be degenerate in mass. Since superpartners have not (yet) been observed, supersymmetry must be a broken symmetry. Nevertheless, the stability of the gauge hierarchy can still be maintained if the SUSY breaking is soft [11,12], and the corresponding SUSY-breaking mass parameters are no larger than a few TeV. Whether this is still plausible in light of recent SUSY searches at the LHC (see Sec. 88) will be discussed in Sec. 87.7.

In particular, soft-SUSY-breaking terms of the Lagrangian involve combinations of fields with total mass dimension of three or less, with some restrictions on the dimension-three terms as elucidated in Ref. [11]. The impact of the soft terms becomes negligible at energy scales much larger than the size of the SUSY-breaking masses. Thus, a theory of weak-scale supersymmetry, where the effective scale of supersymmetry breaking is tied to the scale of electroweak symmetry breaking, provides a natural framework for the origin and stability of the gauge hierarchy [8–10].

At present, there is no unambiguous experimental evidence for the breakdown of the SM at or below the TeV scale. The expectations for new TeV-scale physics beyond the SM are based primarily on three theoretical arguments. First, in a theory with an elementary scalar field of mass m and interaction strength λ (*e.g.*, a quartic scalar self-coupling, the square of a gauge coupling or the square of a Yukawa coupling), the stability with respect to quantum corrections requires the existence of an energy cutoff roughly of order $(16\pi^2/\lambda)^{1/2}m$, beyond which new physics must enter [13]. A significantly larger energy cutoff would require an unnatural fine-tuning of parameters that govern the effective low-energy theory. Applying this argument to the SM leads to an expectation of new physics at the TeV scale [10].

Second, the unification of the three SM gauge couplings at a very high energy close to the Planck scale is possible if new physics beyond the SM (which modifies the running of the gauge couplings above the electroweak scale) is present. The minimal supersymmetric extension of the SM, where superpartner masses lie below a few TeV, provides an example of successful gauge coupling unification [14, 15].

Third, the existence of dark matter, which makes up approximately one quarter of the energy density of the universe, cannot be explained within the SM of particle physics [16]. Remarkably, a stable weakly-interacting massive particle (WIMP) whose mass and interaction rate are governed by new physics associated with the TeV-scale can be consistent with the observed density of dark matter (this is the so-called WIMP miracle, which is reviewed in Ref. [17]). The lightest supersymmetric particle (LSP), if stable, is a promising (although not the unique) candidate for dark matter [18–22]. Further aspects of dark matter can be found in Sec. 27.

87.2 Structure of the MSSM

The minimal supersymmetric extension of the SM (MSSM) consists of the fields of the two-Higgs-doublet extension of the SM and the corresponding superpartner fields [23–27]. A particle and its superpartner together form a supermultiplet. The corresponding field content of the supermultiplets of the MSSM and their gauge quantum numbers are shown in Table 87.1. The electric charge $Q = T_3 + \frac{1}{2}Y$ is determined in terms of the third component of the weak isospin (T_3) and the U(1) weak hypercharge (Y).

The gauge supermultiplets consist of the gluons and their gluino fermionic superpartners and the SU(2)×U(1) gauge bosons and their gaugino fermionic superpartners. The matter supermultiplets consist of three generations of left-handed quarks and leptons and their scalar superpartners (squarks and sleptons, collectively referred to as sfermions), and the corresponding antiparticles. The Higgs supermultiplets consist of two complex Higgs doublets, their higgsino fermionic superpartners, and the corresponding antiparticles. The enlarged Higgs sector of the MSSM constitutes the minimal structure needed to guarantee the cancellation of gauge anomalies [29] generated by the higgsino superpartners that can appear as internal lines in triangle diagrams with three external electroweak gauge bosons. Moreover, without a second Higgs doublet, one cannot generate mass for both "up"-type and "down"-type quarks (and charged leptons) in a way consistent with the underlying SUSY [30–32].

Table 87.1: The fields of the MSSM and their representations under the SU(3)×SU(2)×U(1) gauge group are listed. For simplicity, only one generation of quarks and leptons is exhibited. For a given fermion f, we have defined $f_{L,R} \equiv P_{L,R} f$, where $P_{L,R} = \frac{1}{2}(1 \mp \gamma_5) f$, and the corresponding left-handed charge-conjugated fermion is given by $f_L^c \equiv P_L f^c = [f_R]^c$. For each lepton, quark, and Higgs supermultiplet (each denoted by a hatted upper-case letter), there is a corresponding antiparticle multiplet of charge-conjugated fermions and their associated scalar partners [28].

Field Content of the MSSM						
Super-multiplets	Super-field	Bosonic fields	Fermionic partners	SU(3)	SU(2)	U(1)
gluon/gluino	$\hat{V}_8$	g	$\widetilde{g}$	8	1	0
gauge boson/ gaugino	$\hat{V}$	$W^\pm, W^0$	$\widetilde{W}^\pm, \widetilde{W}^0$	1	3	0
	$\hat{V}'$	B	$\widetilde{B}$	1	1	0
slepton/ lepton	$\hat{L}$	$(\widetilde{\nu}_L, \widetilde{e}_L^-)$	(ν_L, e_L^-)	1	2	-1
	$\hat{E}^c$	$\tilde{e}_R^+$	e_L^c	1	1	2
squark/ quark	$\hat{Q}$	$(\widetilde{u}_L, \widetilde{d}_L)$	(u_L, d_L)	3	2	1/3
	$\hat{U}^c$	$\widetilde{u}_R^*$	u_L^c	$\bar{3}$	1	$-4/3$
	$\hat{D}^c$	$\widetilde{d}_R^*$	d_L^c	$\bar{3}$	1	2/3
Higgs boson/ higgsino	$\hat{H}_d$	(H_d^0, H_d^-)	$(\widetilde{H}_d^0, \widetilde{H}_d^-)$	1	2	-1
	$\hat{H}_u$	(H_u^+, H_u^0)	$(\widetilde{H}_u^+, \widetilde{H}_u^0)$	1	2	1

In the most elegant treatment of SUSY, spacetime is extended to superspace which consists of the spacetime coordinates and new anticommuting fermionic coordinates θ and $\theta^\dagger$ [27, 33, 34]. Each supermultiplet is represented by a superfield that is a function of the superspace coordinates. The fields of a given supermultiplet (which are functions of the spacetime coordinates) are coefficients of the θ and $\theta^\dagger$ expansion of the corresponding superfield.

Vector superfields contain the gauge-boson fields and their gaugino partners. Chiral superfields contain the spin-0 and spin-1/2 fields of the matter or Higgs supermultiplets. A general supersymmetric Lagrangian is determined by three functions of the chiral superfields [6]: the superpotential, the Kähler potential, and the gauge kinetic function (which can be appropriately generalized to accommodate higher derivative terms [35]). Minimal forms for the Kähler potential and gauge kinetic function, which generate canonical kinetic energy terms for all the fields, are required for renormalizable globally supersymmetric theories. A renormalizable superpotential, which is at most cubic in the chiral superfields, yields supersymmetric Yukawa couplings and mass terms. A combination of gauge invariance and SUSY produces couplings of gaugino fields to matter (or Higgs) fields and their corresponding superpartners. The (renormalizable) MSSM Lagrangian is then constructed by including all possible supersymmetric interaction terms (of dimension four or less) that satisfy SU(3)×SU(2)×U(1) gauge invariance and B–L conservation (where B = baryon number and L = lepton number). Finally, the most general soft-supersymmetry-breaking terms consistent with these symmetries are added [11, 12, 36].

Although the MSSM is the focus of much of this review, there is some motivation for considering non-minimal supersymmetric extensions of the SM [37]. For example, extra structure is needed to generate non-zero neutrino masses as discussed in Sec. 87.8. In addition, in order to address some theoretical issues and tensions associated with the MSSM, it has been fruitful to introduce one additional singlet Higgs superfield. The resulting next-to-minimal supersymmetric extension of the Standard Model (NMSSM) [38] is briefly considered in Secs. 87.4–87.7 and 87.9.1. Finally, one is always free to add additional fields to the SM along with the corresponding superpartners, as noted in Sec. 87.9. For example, the motivation for adding a color octet chiral superfield [39, 40] to the MSSM is briefly discussed in Sec. 87.9.2. However, only certain choices for the new superfields (*e.g.*, the addition of complete SU(5) multiplets) will preserve the successful gauge coupling unification of the MSSM.

87.2.1 *R-parity and the lightest supersymmetric particle*

The (renormalizable) SM Lagrangian possesses an accidental global $B-L$ symmetry due to the fact that B and L-violating operators composed of SM fields must have dimension $d = 5$ or larger [41]. Consequently, B and L-violating effects are suppressed by $(M_{\rm EW}/M)^{d-4}$, where M is the characteristic mass scale of the physics that generates the corresponding higher-dimensional operators. Indeed, values of $M \gtrsim 10^{16}$ GeV, corresponding to the grand unification (GUT) scale or larger, may be responsible for the observed (approximate) stability of the proton and suppression of neutrino masses. Unfortunately, these results are not guaranteed in a generic supersymmetric extension of the SM. For example, it is possible to construct gauge-invariant supersymmetric dimension-four B and L-violating operators made up of fields of SM particles and their superpartners. Such operators, if simultaneously present in the theory, would typically yield a proton decay rate many orders of magnitude larger than the current experimental bound. It is for this reason that $B-L$ conservation is *imposed* on the supersymmetric Lagrangian when defining the MSSM, which is sufficient for eliminating all B and L-violating operators of dimension $d \leq 4$.

As a consequence of the $B-L$ symmetry, the MSSM possesses a multiplicative R-parity invariance, where $R = (-1)^{3(B-L)+2S}$ for a particle of spin S [42]. This implies that all the particles of the SM have even R-parity, whereas the corresponding superpartners have odd R-parity. The conservation of R-parity in scattering and decay processes has a critical impact on supersymmetric phenomenology. For example, any initial state in a scattering experiment will involve ordinary (R-even) particles. Consequently, it follows that supersymmetric particles must be produced in pairs. In general, these particles are highly unstable and decay into lighter states. Moreover, R-parity invariance also implies that the LSP is absolutely stable, and must eventually be produced at the end of a decay chain initiated by the decay of a heavy unstable supersymmetric particle. In order to be consistent with cosmological constraints, a stable LSP is almost certainly electrically and color neutral [20]. Consequently, the LSP in an R-parity-conserving theory is weakly interacting with ordinary matter, *i.e.*, it behaves like a stable heavy neutrino and will escape collider detectors without being directly observed. Thus, the canonical signature for conventional R-parity-conserving supersymmetric theories is missing (transverse) momentum, due to the escape of the LSP. Moreover, as noted in Sec. 87.1 and reviewed in Ref. [21, 22], the stability of the LSP in R-parity-conserving SUSY makes it a promising candidate for dark matter.

The possibility of relaxing the R-parity invariance of the MSSM (which would generate new B and/or L-violating interactions) will be addressed in Sec. 87.8.2. However, note that in R-parity violating (RPV) models, the LSP is no longer stable and thus would not be a viable candidate for the dark matter (unless its lifetime was significantly longer than the age of the universe). In such scenarios, one must look elsewhere to explain the origin of

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

dark matter.

87.2.2 *The goldstino and gravitino*

In the MSSM, SUSY breaking is implemented by including the most general renormalizable soft-SUSY-breaking terms consistent with the SU(3)×SU(2)×U(1) gauge symmetry and R-parity invariance. These terms parameterize our ignorance of the fundamental mechanism of supersymmetry breaking. If supersymmetry breaking occurs spontaneously, then a massless Goldstone fermion called the goldstino ($\widetilde{G}_{1/2}$) must exist. The goldstino would then be the LSP, and could play an important role in supersymmetric phenomenology [43].

However, the goldstino degrees of freedom are physical only in models of spontaneously-broken global SUSY. If SUSY is a local symmetry, then the theory must incorporate gravity; the resulting theory is called supergravity [7, 44]. In models of spontaneously-broken supergravity, the goldstino is "absorbed" by the gravitino ($\widetilde{G}$), the spin-3/2 superpartner of the graviton, via the super-Higgs mechanism [45]. Consequently, the goldstino is removed from the physical spectrum and the gravitino acquires a mass (denoted by $m_{3/2}$). If $m_{3/2}$ is smaller than the mass of the lightest superpartner of the SM particles, then the gravitino is the LSP.

In processes with center-of-mass energy $E \gg m_{3/2}$, one can employ the goldstino–gravitino equivalence theorem [46], which implies that the interactions of the helicity $\pm\frac{1}{2}$ gravitino (whose properties approximate those of the goldstino) dominate those of the helicity $\pm\frac{3}{2}$ gravitino. The interactions of gravitinos with other light fields can be described by a low-energy effective Lagrangian that is determined by fundamental principles [47].

87.2.3 *Hidden sectors and the structure of SUSY breaking*

It is very difficult (perhaps impossible) to construct a realistic model of spontaneously-broken weak-scale supersymmetry where the supersymmetry breaking arises solely as a consequence of the interactions of the particles of the MSSM. A more successful scheme posits a theory with at least two distinct sectors: a visible sector consisting of the particles of the MSSM [36] and a sector where SUSY breaking is generated. It is often (but not always) assumed that particles of the hidden sector are neutral with respect to the SM gauge group. The effects of the hidden sector supersymmetry breaking are then transmitted to the MSSM by some mechanism (often involving the mediation by particles that comprise an additional messenger sector). Two theoretical scenarios that exhibit this structure are gravity-mediated and gauge-mediated SUSY breaking.

Supergravity models provide a natural mechanism for transmitting the SUSY breaking of the hidden sector to the particle spectrum of the MSSM. In models of gravity-mediated SUSY breaking, gravity is the messenger of supersymmetry breaking [48–52]. More precisely, supersymmetry breaking is mediated by effects of gravitational strength (*i.e.* suppressed by inverse powers of the Planck mass). The soft-SUSY-breaking parameters with dimensions of mass arise as model-dependent multiples of the gravitino mass $m_{3/2}$. In this scenario, $m_{3/2}$ is of order the electroweak-symmetry-breaking scale, while the gravitino couplings are roughly gravitational in strength [5, 53].[1]

Under certain theoretical assumptions that govern the structure of the Kähler potential (the so-called sequestered form introduced in Ref. [55]), SUSY breaking is due entirely to the super-conformal (super-Weyl) anomaly, which is common to all supergravity models [55]. In particular, gaugino masses are radiatively generated at one-loop, and squark and slepton squared-mass matrices are flavor-diagonal. In sequestered scenarios, sfermion squared-masses arise at two-loops, which implies that gluino and sfermion masses are of the same order of magnitude. This approach is called anomaly-mediated SUSY breaking (AMSB). Indeed, anomaly mediation is more generic than originally conceived, and provides a ubiquitous source of SUSY breaking [56]. However in the simplest formulation of AMSB as applied to the MSSM, the squared-masses of the sleptons are negative (known as the tachyonic slepton problem). It may be possible to cure this otherwise fatal flaw in non-minimal extensions of the MSSM [57]. Alternatively, one can assert that anomaly mediation is not the sole source of SUSY breaking in the sfermion sector. In non-sequestered scenarios, sfermion squared-masses can arise at tree-level, in which case squark masses would be parametrically larger than the loop-suppressed gaugino masses [58].

In gauge-mediated supersymmetry breaking, gauge forces transmit the supersymmetry breaking to the MSSM. A typical structure of such models involves a hidden sector where SUSY is broken, a messenger sector consisting of particles (messengers) with nontrivial SU(3)×SU(2)×U(1) quantum numbers, and the visible sector consisting of the fields of the MSSM [59–62]. The direct coupling of the messengers to the hidden sector generates a supersymmetry-breaking spectrum in the messenger sector. Supersymmetry breaking is then transmitted to the MSSM via the virtual exchange of the messenger fields. In models of direct gauge mediation, there is no separate hidden sector. In particular, the sector in which the SUSY breaking originates includes fields that carry nontrivial SM quantum numbers, which allows for the direct transmission of SUSY breaking to the MSSM [63].

In models of gauge-mediated SUSY breaking with a minimal Kähler potential, the gravitino is the LSP [18], as its mass can range from a few eV (in the case of low SUSY breaking scales) up to a few GeV (in the case of high SUSY breaking scales). In particular, the gravitino is a potential dark matter candidate (for a review and guide to the literature, see Ref. [22]). The couplings of the helicity $\pm\frac{1}{2}$ components of $\widetilde{G}$ to the particles of the MSSM (which approximate those of the goldstino as previously noted in Sec. 87.2.2) are significantly stronger than gravitational strength and amenable to experimental collider analyses.

The mass ranges of the gravitino in either gravity-mediated or gauge-mediated SUSY breaking are further constrained by cosmological considerations [64]. In particular, there is a danger of overabundance of gravitinos as the dark matter or modifications to the successful predictions of light element abundances if $\widetilde{G}$ decays before nucleosynthesis. Avoiding these cosmological gravitino problems imposes strong constraints on gravity-mediated and gauge-mediated SUSY breaking models.

The concept of a hidden sector is more general than SUSY. Hidden valley models [65] posit the existence of a hidden sector of new particles and interactions that are very weakly coupled to particles of the SM. The impact of a hidden valley on supersymmetric phenomenology at colliders can be significant if the LSP lies in the hidden sector [66].

87.2.4 *SUSY and extra dimensions*

Approaches to SUSY breaking have also been developed in the context of theories in which the number of spatial dimensions is greater than three. In particular, a number of SUSY-breaking mechanisms have been proposed that are inherently extra-dimensional [67]. The size of the extra dimensions can be significantly larger than $M_{\rm P}^{-1}$; in some cases of order $(\text{TeV})^{-1}$ or even larger (*e.g.*, see Sec. 84 and Ref. [68]).

For example, in one approach the fields of the MSSM live on some brane (a lower-dimensional manifold embedded in a higher-dimensional spacetime), while the sector of the theory that breaks SUSY lives on a second spatially-separated brane. Two examples of this approach are AMSB [55] and gaugino-mediated SUSY breaking [69]. In both cases, SUSY breaking is transmitted through fields that live in the bulk (the higher-dimensional space between the two branes). This setup has some features in common with both gravity-mediated and gauge-mediated SUSY breaking (*e.g.*, hidden and visible sectors and messengers).

Since a higher dimensional theory must be compactified to four spacetime dimensions, one can also generate a source of SUSY breaking by employing boundary conditions on the compactified space that distinguish between fermions and bosons. This is the so-called Scherk-Schwarz mechanism [70]. The phenomenology of such models can be strikingly different from that of the usual MSSM [71].

87.2.5 *Split-SUSY*

If SUSY is not connected with the origin of the electroweak scale, it may still be possible that some remnant of the superpar-

[1] However, such a gravitino typically plays no direct role in supersymmetric phenomenology at colliders (except perhaps indirectly in the case where the gravitino is the LSP [54]).

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

ticle spectrum survives down to the TeV-scale or below. This is the idea of split-SUSY [72,73], in which scalar superpartners of the quarks and leptons are significantly heavier than 1 TeV, whereas the fermionic superpartners of the gauge and Higgs bosons have masses on the order of 1 TeV or below. With the exception of a single light neutral scalar whose properties are practically indistinguishable from those of the SM Higgs boson, all other Higgs bosons are also assumed to be very heavy. Among the supersymmetric particles, only the fermionic superpartners may be kinematically accessible at the LHC.

In models of split SUSY, the top squark masses cannot be arbitrarily large, as these parameters enter in the radiative corrections to the mass of the observed Higgs boson [74–76]. In the MSSM, a Higgs boson mass of 125 GeV (see Sec. 11) implies an upper bound on the top squark mass scale in the range of 10 to 10^8 TeV [77], depending on the value of the ratio of the two neutral Higgs field vacuum expectation values (VEVs), although this mass range can be somewhat extended by varying other relevant MSSM parameters. In some approaches, gaugino masses are one-loop suppressed relative to the sfermion masses, corresponding to the so-called mini-split SUSY spectrum [75,78]. The higgsino mass scale may or may not be likewise suppressed depending on the details of the model [79].

The SUSY breaking required to produce such a split-SUSY spectrum would destabilize the gauge hierarchy, and thus would not provide an explanation for the scale of electroweak symmetry breaking. Nevertheless, models of split-SUSY can account for the dark matter (which is assumed to be the LSP gaugino or higgsino) and gauge coupling unification, thereby preserving two of the desirable features of weak-scale SUSY. Finally, as a consequence of the very large squark and slepton masses, neutral flavor changing and CP-violating effects, which can be problematic in models with TeV-scale SUSY-breaking masses, are sufficiently reduced to avoid conflict with experimental observations.

87.3 Parameters of the MSSM

The parameters of the MSSM are conveniently described by considering separately the supersymmetry-conserving and the supersymmetry-breaking sectors. A careful discussion of the conventions used here in defining the tree-level MSSM parameters can be found in Refs. [27, 80, 81]. For simplicity, consider first the case of one generation of quarks, leptons, and their scalar superpartners.

87.3.1 *The SUSY-conserving parameters*

The parameters of the supersymmetry-conserving sector consist of: (i) gauge couplings, g_s, g, and g', corresponding to the SM gauge group SU(3)×SU(2)×U(1) respectively; (ii) a supersymmetry-conserving higgsino mass parameter μ; and (iii) Higgs-fermion Yukawa couplings, y_u, y_d, and y_e, of one generation of left- and right-handed quarks and leptons, and their superpartners to the Higgs bosons and higgsinos. Because there is no right-handed neutrino/sneutrino in the MSSM as defined here, a Yukawa coupling y_ν is not included. The complex μ parameter and Yukawa couplings enter via the most general renormalizable R-parity-conserving superpotential,

$$W_{\rm MSSM} = y_d \hat{H}_d \hat{Q} \hat{D}^c - y_u \hat{H}_u \hat{Q} \hat{U}^c + y_e \hat{H}_d \hat{L} \hat{E}^c + \mu \hat{H}_u \hat{H}_d \,, \quad (87.1)$$

where the superfields are defined in Table 1 and the gauge group indices are suppressed. More explicitly, the so-called "μ-term" can be written out as $\mu\epsilon^{mn}(\hat{H}_u)_m(\hat{H}_d)_n$ with an implicit sum over repeated indices, where ϵ^{mn} is used to tie together the SU(2) weak isospin indices $m, n \in \{1, 2\}$ in a gauge-invariant way (where $\epsilon^{12} = -\epsilon^{21} = 1$ and $\epsilon^{11} = \epsilon^{22} = 0$). Likewise, the term $\hat{H}_u\hat{Q}\hat{U}^c$ can be written out as $\epsilon^{mn}(\hat{H}_u)_m\hat{Q}_{in}(\hat{U}^c)^i$, where there is an implicit sum over the SU(3) color index, $i \in \{1, 2, 3\}$. Finally, $\hat{H}_d\hat{Q}\hat{D}^c$ can be written out as $\epsilon^{mn}(\hat{H}_d)_m\hat{Q}_{in}(\hat{D}^c)^i$, with an analogous expression for $\hat{H}_d\hat{L}\hat{E}^c$. One can easily generalize Eq. (87.1) to a three generation model where y_u, y_d, and y_e are 3×3 matrices with the corresponding family indices suppressed.

87.3.2 *The SUSY-breaking parameters*

The supersymmetry-breaking sector contains the following sets of parameters: (i) three complex gaugino Majorana mass parameters, M_3, M_2, and M_1, associated with the SU(3), SU(2), and U(1) subgroups of the SM; (ii) five sfermion squared-mass parameters, $M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, $M^2_{\widetilde{D}}$, $M^2_{\widetilde{L}}$, and $M^2_{\widetilde{E}}$, corresponding to the five electroweak gauge multiplets, *i.e.*, superpartners of the left-handed fields $(u, d)_L$, u^c_L, d^c_L, $(\nu, e^-)_L$, and e^c_L, where the superscript c indicates a charge-conjugated fermion field [28]; and (iii) three Higgs-squark-squark and Higgs-slepton-slepton trilinear interaction terms, with complex coefficients $T_U \equiv y_u A_U$, $T_D \equiv y_d A_D$, and $T_E \equiv y_e A_E$ (which define the "A-parameters"), following the notation employed in Ref. [81]. It is conventional to separate out the factors of the Yukawa couplings in defining the A-parameters [5,27] (originally motivated by a simple class of gravity-mediated SUSY-breaking models [5]). If the A-parameters are parametrically of the same order (or smaller) relative to other SUSY-breaking mass parameters, then in most cases only the third generation A-parameters will be phenomenologically relevant.

Finally, we have (iv) two real squared-mass parameters, $m^2_{H_d}$ and $m^2_{H_u}$ (also called m^2_1 and m^2_2, respectively, in the literature), and one complex squared-mass parameter, $m^2_{12} \equiv \mu B$ (the latter defines the "B-parameter"),[2] which appear in the MSSM tree-level scalar Higgs potential [27, 32],

$$\begin{aligned} V = {} & (m^2_{H_d} + |\mu|^2) H^\dagger_d H_d + (m^2_{H_u} + |\mu|^2) H^\dagger_u H_u \\ & + (m^2_{12} H_u H_d + \text{h.c.}) \\ & + \frac{1}{8}(g^2 + g'^2)(H^\dagger_d H_d - H^\dagger_u H_u)^2 + \frac{1}{2} g^2 |H^\dagger_d H_u|^2 \,, \end{aligned} \quad (87.2)$$

where the SU(2)-invariant combination of the complex doublet scalar fields H_u and H_d that appears in Eq. (87.2) is given by $H_u H_d \equiv \epsilon^{mn}(H_u)_m(H_d)_n = H^+_u H^-_d - H^0_u H^0_d$. Note that the quartic Higgs couplings are related to the gauge couplings g and g' as a consequence of SUSY. The breaking of the SU(2)×U(1) electroweak symmetry group to $\mathrm{U(1)_{EM}}$ is only possible after incorporating the SUSY-breaking Higgs squared-mass parameters $m^2_{H_d}$, $m^2_{H_u}$ (which can be negative) and m^2_{12}. After minimizing the Higgs scalar potential, these three squared-mass parameters can be re-expressed in terms of the two Higgs VEVs, $\langle H^0_d \rangle \equiv v_d/\sqrt{2}$ and $\langle H^0_u \rangle \equiv v_u/\sqrt{2}$, and the CP-odd Higgs mass m_A [cf. Eqs. (87.4) and (87.5) below]. One is always free to rephase the Higgs doublet fields such that v_d and v_u (also called v_1 and v_2, respectively, in the literature) are both real and positive.

The quantity, $v^2 \equiv v^2_d + v^2_u = 4m^2_W/g^2 = (2G^2_F)^{-1/2} \simeq (246\ \text{GeV})^2$, is fixed by the Fermi constant, G_F, whereas the ratio

$$\tan\beta = v_u/v_d \quad (87.3)$$

is a free parameter such that $0 < \beta < \pi/2$. By employing the tree-level conditions resulting from the minimization of the scalar potential, one can eliminate the diagonal and off-diagonal Higgs squared-masses in favor of $m^2_Z = \frac{1}{4}(g^2 + g'^2)v^2$, the CP-odd Higgs mass m_A and the parameter $\tan\beta$,

$$\sin 2\beta = \frac{2m^2_{12}}{m^2_{H_d} + m^2_{H_u} + 2|\mu|^2} = \frac{2m^2_{12}}{m^2_A} \,, \quad (87.4)$$

$$\frac{1}{2}m^2_Z = -|\mu|^2 + \frac{m^2_{H_d} - m^2_{H_u}\tan^2\beta}{\tan^2\beta - 1} \,. \quad (87.5)$$

One must also guard against the existence of charge and/or color breaking global minima due to non-zero VEVs for the squark and charged slepton fields. This possibility can be avoided if the A-parameters are not unduly large [49,82,83]. Additional constraints must also be respected to avoid the possibility of directions in scalar field space in which the full tree-level scalar potential can become unbounded from below [83]. A computer program has been developed to calculate vacuum stability bounds in general

[2] Again, motivated by a simple class of gravity-mediated SUSY-breaking models, it is conventional to separate out the factor of μ in defining the B-parameter [5, 27]. In more general SUSY-breaking scenarios, it is possible to generate $m^2_{12} \neq 0$ even when $\mu = 0$.

models at the one-loop level [84], and has been applied to the MSSM in Ref. [85].

Note that SUSY-breaking mass terms for the fermionic superpartners of the scalar fields and non-holomorphic trilinear scalar interactions (*i.e.*, interactions that mix scalar fields and their complex conjugates) have not been included above in the soft-SUSY-breaking sector. These terms can potentially destabilize the gauge hierarchy [11] in models with a gauge-singlet superfield. The latter is not present in the MSSM; hence as noted in Ref. [12], these so-called non-standard soft-SUSY-breaking terms are benign. The phenomenological impact of non-holomorphic soft SUSY-breaking terms has been reconsidered in Refs. [86–88]. However, in the most common approaches to constructing a fundamental theory of SUSY-breaking, the coefficients of these terms (which have dimensions of mass) are significantly suppressed compared to the TeV-scale [89]. Consequently, we follow the usual approach in the literature and omit these terms from further consideration.

87.3.3 *MSSM-124*

The total number of independent physical parameters that define the MSSM (in its most general form) is quite large, primarily due to the soft-supersymmetry-breaking sector. In particular, in the case of three generations of quarks, leptons, and their superpartners, $M^2_{\underset{\sim}{Q}}$, $M^2_{\underset{\sim}{U}}$, $M^2_{\underset{\sim}{D}}$, $M^2_{\underset{\sim}{L}}$, and $M^2_{\underset{\sim}{E}}$ are hermitian 3×3 matrices, and A_U, A_D, and A_E are complex 3×3 matrices. In addition, M_1, M_2, M_3, B, and μ are in general complex parameters. Finally, as in the SM, the Higgs-fermion Yukawa couplings, y_f ($f=u$, d, and e), are complex 3×3 matrices that are related to the quark and lepton mass matrices via: $M_f = y_f v_f/\sqrt{2}$, where $v_e = v_d$ [with v_u and v_d as defined above Eq. (87.3)].

However, not all these parameters are physical. Some of the MSSM parameters can be eliminated by expressing interaction eigenstates in terms of the mass eigenstates, with an appropriate redefinition of the MSSM fields to remove unphysical degrees of freedom. The analysis of Ref. [90] shows that the MSSM possesses 124 independent real degrees of freedom. Of these, 18 correspond to SM parameters (including the QCD vacuum angle $\theta_{\rm QCD}$), one corresponds to a Higgs sector parameter (the analogue of the SM Higgs mass), and 105 are genuinely new parameters of the model. The latter include: five real parameters and three CP-violating phases in the gaugino/higgsino sector, 21 squark and slepton (sfermion) masses, 36 real mixing angles to define the sfermion mass eigenstates, and 40 CP-violating phases that can appear in sfermion interactions. The most general parameterization of the R-parity-conserving MSSM (without additional theoretical assumptions) will be denoted henceforth as MSSM-124 [91].

87.4 The supersymmetric-particle spectrum

The supersymmetric particles (sparticles) differ in spin by half a unit from their SM partners. The superpartners of the gauge and Higgs bosons are fermions, whose names are obtained by appending "ino" to the end of the corresponding SM particle name. The gluino is the color-octet Majorana fermion partner of the gluon with mass $M_{\underset{\sim}{g}} = |M_3|$. The superpartners of the electroweak gauge and Higgs bosons (the gauginos and higgsinos) can mix due to SU(2)×U(1) breaking effects. As a result, the physical states of definite mass are parameter-dependent linear combinations of the charged or neutral gauginos and higgsinos, called charginos and neutralinos, respectively (sometimes collectively called electroweakinos). The neutralinos are Majorana fermions, which can lead to some distinctive phenomenological signatures [92,93]. The superpartners of the quarks and leptons are spin-zero bosons, with an "s" appended to the beginning of the corresponding SM particle name: the squarks, charged sleptons, and sneutrinos, respectively. A complete set of Feynman rules for the sparticles of the MSSM can be found in Ref. [94]. The MSSM Feynman rules are also implicitly contained in several amplitude generation and Feynman diagram software packages (*e.g.*, see Refs. [95–97]).

It should be noted that all mass formulae quoted below in this Section are tree-level results. Radiative loop corrections will modify these results and must be included in any precision study of supersymmetric phenomenology [98]. Beyond tree level, the definition of the supersymmetric parameters becomes convention-dependent. For example, one can define physical couplings or running couplings, which differ beyond the tree level. This provides a challenge to any effort that attempts to extract supersymmetric parameters from data. The SUSY Les Houches Accord (SLHA) [81,99] has been adopted, which establishes a set of conventions for specifying generic file structures for supersymmetric model specifications and input parameters, supersymmetric mass and coupling spectra, and decay tables. These provide a universal interface between spectrum calculation programs, decay packages, and high energy physics event generators.

87.4.1 *The charginos and neutralinos*

The mixing of the charged gauginos ($\widetilde{W}^\pm$) and charged higgsinos ($\widetilde{H}_u^+$ and $\widetilde{H}_d^-$) is described (at tree-level) by a 2×2 complex mass matrix [100, 101],

$$M_C \equiv \begin{pmatrix} M_2 & \frac{1}{\sqrt{2}} g v_u \\ \frac{1}{\sqrt{2}} g v_d & \mu \end{pmatrix} . \tag{87.6}$$

To determine the physical chargino states and their masses, one must perform a singular value decomposition [102] of the complex matrix M_C [27, 103]:

$$U^* M_C V^{-1} = \mathrm{diag}(M_{\tilde{\chi}_1^+}\,,\, M_{\tilde{\chi}_2^+})\,, \tag{87.7}$$

where U and V are unitary matrices, and the right-hand side of Eq. (87.7) is the diagonal matrix of (real non-negative) chargino masses. Explicit formulae for the singular value decomposition of M_C can be found in Ref. [104]. The physical chargino states are denoted by $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^\pm$. These are linear combinations of the charged gaugino and higgsino states determined by the matrix elements of U and V [100, 101] The chargino masses correspond to the singular values [102] of M_C, *i.e.*, the positive square roots of the eigenvalues of $M_C^\dagger M_C$:

$$M^2_{\tilde{\chi}_1^+,\tilde{\chi}_2^+} = \frac{1}{2}\Big\{ |\mu|^2 + |M_2|^2 + 2m_W^2 \mp \sqrt{\left(|\mu|^2 + |M_2|^2 + 2m_W^2\right)^2 - 4|\mu M_2 - m_W^2 \sin 2\beta|^2}\,\Big\}\,, \tag{87.8}$$

in a convention where v_u and v_d are real and positive, and where the states are ordered such that $M_{\tilde{\chi}_1^+} \le M_{\tilde{\chi}_2^+}$. The relative phase of μ^* and M_2 is physical and potentially observable [105].

The mixing of the neutral gauginos ($\widetilde{B}$ and $\widetilde{W}^0$) and neutral higgsinos ($\widetilde{H}_d^0$ and $\widetilde{H}_u^0$) is described (at tree-level) by a 4×4 complex symmetric mass matrix [100, 101],

$$M_N \equiv \begin{pmatrix} M_1 & 0 & -\frac{1}{2}g' v_d & \frac{1}{2}g' v_u \\ 0 & M_2 & \frac{1}{2} g v_d & -\frac{1}{2} g v_u \\ -\frac{1}{2}g' v_d & \frac{1}{2} g v_d & 0 & -\mu \\ \frac{1}{2}g' v_u & -\frac{1}{2} g v_u & -\mu & 0 \end{pmatrix} . \tag{87.9}$$

To determine the physical neutralino states and their masses, one must perform an Autonne-Takagi factorization [102,106] (also called Takagi diagonalization in Refs. [27,103,107]) of the complex symmetric matrix M_N:

$$W^T M_N W = \mathrm{diag}(M_{\tilde{\chi}_1^0}\,,\, M_{\tilde{\chi}_2^0}\,,\, M_{\tilde{\chi}_3^0}\,,\, M_{\tilde{\chi}_4^0})\,, \tag{87.10}$$

where W is a unitary matrix (which is called N^{-1} in Refs. [23,32]) and the right-hand side of Eq. (87.10) is the diagonal matrix of (real non-negative) neutralino masses. The physical neutralino states are denoted by $\widetilde{\chi}_i^0$ (for $i = 1,\ldots,4$), where the states are ordered such that $M_{\tilde{\chi}_1^0} \le M_{\tilde{\chi}_2^0} \le M_{\tilde{\chi}_3^0} \le M_{\tilde{\chi}_4^0}$. The $\widetilde{\chi}_i^0$ are the linear combinations of the neutral gaugino and higgsino states determined by the matrix elements of W. The neutralino masses correspond to the singular values of M_N, *i.e.*, the positive square roots of the eigenvalues of $M_N^\dagger M_N$. Exact formulae for these

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

masses can be found in Ref. [108]. A numerical algorithm for determining the mixing matrix W has been given in Ref. [109].

If a chargino or neutralino state approximates a particular gaugino or higgsino state, it is convenient to employ the corresponding nomenclature. Specifically, if $|M_1|$ and $|M_2|$ are small compared to m_Z and $|\mu|$, then the lightest neutralino $\widetilde{\chi}_1^0$ would be nearly a pure photino, $\widetilde{\gamma}$, the superpartner of the photon. If $|M_1|$ and m_Z are small compared to $|M_2|$ and $|\mu|$, then the lightest neutralino would be nearly a pure bino, $\widetilde{B}$, the superpartner of the weak hypercharge gauge boson. If $|M_2|$ and m_Z are small compared to $|M_1|$ and $|\mu|$, then the lightest chargino pair and neutralino would constitute a triplet of roughly mass-degenerate pure winos, $\widetilde{W}^{\pm}$, and $\widetilde{W}_3^0$, the superpartners of the weak SU(2) gauge bosons. Finally, if $|\mu|$ and m_Z are small compared to $|M_1|$ and $|M_2|$, then the lightest chargino pair and neutralino would be nearly pure higgsino states, the superpartners of the Higgs bosons. Each of the above cases leads to a strikingly different phenomenology.

In the NMSSM, an additional Higgs singlet superfield is added to the MSSM. This superfield comprises two real Higgs scalar degrees of freedom and an associated neutral higgsino degree of freedom. Consequently, there are five neutralino mass eigenstates that are obtained by a Takagi-diagonalization of the 5×5 neutralino mass matrix. In many cases, the fifth neutralino state is dominated by its SU(2)×U(1) singlet component, and thus is very weakly coupled to the SM particles and their superpartners.

87.4.2 *The squarks and sleptons*

For a given Dirac fermion f, there are two superpartners, $\widetilde{f}_L$ and $\widetilde{f}_R$, where the L and R subscripts simply identify the scalar partners that are related by SUSY to the left-handed and right-handed fermions, $f_{L,R}$, as indicated in Table 87.1. (Since right-handed neutrinos lie outside the SM, there is no corresponding $\widetilde{\nu}_R$ in the MSSM.) However, $\widetilde{f}_L$–$\widetilde{f}_R$ mixing is possible, in which case $\widetilde{f}_L$ and $\widetilde{f}_R$ are not mass eigenstates. For three generations of squarks, one must diagonalize 6×6 matrices corresponding to the basis $(\widetilde{q}_{iL}, \widetilde{q}_{iR})$, where $i = 1, 2, 3$ are the generation labels. For simplicity, only the one-generation case is illustrated in detail below.

Using the notation of the third family, the one-generation tree-level squark squared-mass matrix is given by [27, 110],

$$\mathcal{M}^2 = \begin{pmatrix} M^2_{\widetilde{Q}} + m_q^2 + L_q & m_q X_q^* \\ m_q X_q & M^2_{\widetilde{R}} + m_q^2 + R_q \end{pmatrix} , \tag{87.11}$$

where

$$X_q \equiv A_q - \mu^* (\cot\beta)^{2T_{3q}} , \tag{87.12}$$

and $T_{3q} = \frac{1}{2}$ $[-\frac{1}{2}]$ for $q = t$ $[b]$. The diagonal squared-masses are governed by soft-SUSY-breaking squared-masses $M^2_{\widetilde{Q}}$ and $M^2_{\widetilde{R}} \equiv M^2_{\widetilde{U}}$ $[M^2_{\widetilde{D}}]$ for $q = t$ $[b]$, the corresponding quark masses m_t $[m_b]$ and the electroweak correction terms:

$$\begin{aligned} L_q &\equiv (T_{3q} - e_q \sin^2\theta_W) m_Z^2 \cos 2\beta , \\ R_q &\equiv e_q \sin^2\theta_W \, m_Z^2 \cos 2\beta , \end{aligned} \tag{87.13}$$

where $e_q = \frac{2}{3}$ $[-\frac{1}{3}]$ for $q = t$ $[b]$. The off-diagonal squark squared-masses are proportional to the corresponding quark masses and depend on $\tan\beta$, the soft-SUSY-breaking A-parameters and the higgsino mass parameter μ. Assuming that the A-parameters are parametrically of the same order (or smaller) relative to other SUSY-breaking mass parameters, it then follows that the first and second generation $\widetilde{q}_L$–$\widetilde{q}_R$ mixing is smaller than that of the third generation where mixing can be enhanced by factors of m_t and $m_b \tan\beta$.

In the case of third generation $\widetilde{q}_L$–$\widetilde{q}_R$ mixing ($q = t$ or b), the top squark (also called *stop*) and bottom squark (also called *sbottom*) mass eigenstates, denoted by $\widetilde{q}_1$ and $\widetilde{q}_2$ (with $m_{\widetilde{q}_1} < m_{\widetilde{q}_2}$), are determined by diagonalizing the 2×2 matrix $\mathcal{M}^2$ given by Eq. (87.11). The corresponding squared-masses and mixing angle are given by [110]:

$$\begin{aligned} m^2_{\widetilde{q}_{1,2}} &= \frac{1}{2}\left[\mathrm{Tr}\,\mathcal{M}^2 \mp \sqrt{(\mathrm{Tr}\mathcal{M}^2)^2 - 4\det\mathcal{M}^2} \right] , \\ \sin 2\theta_{\tilde{q}} &= \frac{2 m_q |X_q|}{m^2_{\widetilde{q}_2} - m^2_{\widetilde{q}_1}} . \end{aligned} \tag{87.14}$$

The above results also apply to the charged sleptons, with the obvious substitutions: $q \to \ell$ with $T_{3\ell} = -\frac{1}{2}$ and $e_\ell = -1$, and the replacement of the SUSY-breaking parameters: $M^2_{\widetilde{Q}} \to M^2_{\widetilde{L}}$, $M^2_{\widetilde{D}} \to M^2_{\widetilde{E}}$, and $A_q \to A_\ell$. For the neutral sleptons, $\widetilde{\nu}_R$ does not exist in the MSSM, so $\widetilde{\nu}_L$ is a mass eigenstate.

In the case of three generations, the SUSY-breaking scalar-squared masses $[M^2_{\widetilde{Q}}, M^2_{\widetilde{U}}, M^2_{\widetilde{D}}, M^2_{\widetilde{L}}$, and $M^2_{\widetilde{E}}]$ and the A-parameters $[A_U, A_D$, and $A_E]$ are now 3×3 matrices as noted in Sec. 87.3.3. The diagonalization of the 6×6 squark mass matrices yields $\widetilde{f}_{iL}$–$\widetilde{f}_{jR}$ mixing. In practice, since the $\widetilde{f}_L$–$\widetilde{f}_R$ mixing is appreciable only for the third generation, this additional complication can often be neglected (although see Ref. [111] for examples in which the mixing between the second and third generation squarks is relevant).

87.5 The supersymmetric Higgs sector

Consider first the Higgs sector of the MSSM [31, 32, 112, 113]. Despite the large number of possible CP-violating phases among the MSSM-124 parameters, the tree-level MSSM Higgs potential given by Eq. (87.2) is automatically CP-conserving. This follows from the fact that the only potentially complex parameter (m^2_{12}) of the MSSM Higgs potential can be chosen real and positive by rephasing the Higgs fields, in which case $\tan\beta$ is a real positive parameter. Consequently, in the tree-level approximation the physical neutral Higgs scalars are CP-eigenstates. The MSSM Higgs sector contains five physical spin-zero particles: a charged Higgs boson pair ($H^{\pm}$), two CP-even neutral Higgs bosons (denoted by h and H where $m_h < m_H$), and one CP-odd neutral Higgs boson (denoted by A). In principle, either h or H could be identified with the Higgs boson that was discovered at the LHC [114, 115]. Studies of the MSSM parameter space suggest [116] that it is unlikely that H is the LHC-observed Higgs boson (although this possibility is not yet completely ruled out). Henceforth, we shall identify h with the observed Higgs boson with $m_h \simeq 125$ GeV [117].

In the NMSSM [38], the scalar component of the singlet Higgs superfield adds two additional neutral states to the Higgs sector. In this model, the tree-level Higgs sector can exhibit explicit CP-violation. If CP is conserved, then the two extra neutral scalar states are CP-even and CP-odd, respectively. These states can potentially mix with the neutral Higgs states of the MSSM. If scalar states exist that are dominantly singlet, then they are weakly coupled to SM gauge bosons and fermions through their small mixing with the MSSM Higgs scalars. Consequently, it is possible that one (or both) of the singlet-dominated states is considerably lighter than the Higgs boson that was observed at the LHC.

87.5.1 *The tree-level Higgs sector*

The tree-level properties of the Higgs sector are determined by the Higgs potential given by Eq. (87.2) and the Yukawa Lagrangian discussed below. The quartic interaction terms are manifestly supersymmetric (although these are modified by SUSY-breaking effects at the loop level). In general, the quartic couplings arise from two sources: (i) the supersymmetric generalization of the scalar potential (the so-called "F-terms"), and (ii) interaction terms related by SUSY to the coupling of the scalar fields and the gauge fields, whose coefficients are proportional to the corresponding gauge couplings (the so-called "D-terms").

In the MSSM, F-term contributions to the quartic Higgs self-couplings are absent. As a result, the strengths of the MSSM quartic Higgs interactions are fixed in terms of the gauge couplings, as noted below Eq. (87.2). Consequently, all the tree-level MSSM Higgs-sector parameters depend only on two quantities: $\tan\beta$ [defined in Eq. (87.3)] and one Higgs mass usually taken to be m_A. For example, the tree-level squared mass of the charged

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

Higgs boson is given by

$$m_{H^\pm}^2 = m_A^2 + m_W^2 \,, \tag{87.15}$$

where $m_A^2 = m_{H_d}^2 + m_{H_u}^2 + 2|\mu|^2$ [cf. Eq. (87.4)] and

$$H^\pm = H_d^\pm \sin\beta + H_u^\pm \cos\beta \,,\ A = \sqrt{2}\left(\mathrm{Im}\, H_d^0 \sin\beta + \mathrm{Im}\, H_u^0 \cos\beta\right) . \tag{87.16}$$

The CP-even scalar mass eigenstate fields h and H are identified by diagonalizing the 2×2 squared-mass matrix

$$\mathcal{M}^2 = \begin{pmatrix} m_A^2 \sin^2\beta + m_Z^2 \cos^2\beta & -(m_A^2 + m_Z^2)\sin\beta\cos\beta \\ -(m_A^2 + m_Z^2)\sin\beta\cos\beta & m_A^2\cos^2\beta + m_Z^2 \sin^2\beta \end{pmatrix} . \tag{87.17}$$

In particular,

$$h = -(\sqrt{2}\,\mathrm{Re}\, H_d^0 - v_d)\sin\alpha + (\sqrt{2}\,\mathrm{Re}\, H_u^0 - v_u)\cos\alpha \,, \tag{87.18}$$

$$H = (\sqrt{2}\,\mathrm{Re}\, H_d^0 - v_d)\cos\alpha + (\sqrt{2}\,\mathrm{Re}\, H_u^0 - v_u)\sin\alpha \,, \tag{87.19}$$

with corresponding tree-level squared masses,

$$m_{H,h}^2 = \frac{1}{2}\left(m_A^2 + m_Z^2 \pm \sqrt{(m_A^2 + m_Z^2)^2 - 4 m_Z^2 m_A^2 \cos^2 2\beta}\right) , \tag{87.20}$$

and mixing angle α given by

$$\cos\alpha = \sqrt{\frac{m_A^2 \sin^2\beta + m_Z^2\cos^2\beta - m_h^2}{m_H^2 - m_h^2}} \,, \tag{87.21}$$

in a convention where $|\alpha| \leq \pi/2$, where m_h^2 and m_H^2 are given by Eq. (87.20). However, because the off-diagonal elements of $\mathcal{M}^2$ are negative, it follows that $-\pi/2 \leq \alpha \leq 0$ [104]. In light of Eq. (87.20), the tree-level mass of the lighter CP-even Higgs boson is bounded [31, 32],

$$m_h \leq m_Z |\cos 2\beta| \leq m_Z \,. \tag{87.22}$$

This bound can be significantly modified when radiative corrections are included (see Sec. 87.5.2).

The tree-level Higgs couplings to gauge bosons and the Higgs boson self-couplings are governed by the electroweak gauge couplings and the parameter $\cos(\beta - \alpha)$. Explicitly,

$$\cos(\beta-\alpha) = \frac{m_Z^2 \sin 2\beta \cos 2\beta}{\sqrt{(m_H^2 - m_h^2)(m_H^2 - m_Z^2\cos^2 2\beta)}} \,. \tag{87.23}$$

Note that $\cos(\beta - \alpha) \to 0$ in the limit of $m_H \gg m_h, m_Z$. In this *decoupling limit* [118], the properties of h coincide with those of the SM Higgs boson (see Sec. 87.5.4).

The tree-level Higgs-quark and Higgs-lepton interactions of the MSSM are derived from the superpotential given in Eq. (87.1). The corresponding Higgs-fermion Yukawa couplings can be expressed in terms of the fermion masses and the separate parameters $\cos(\beta - \alpha)$ and $\tan\beta$. In particular, the Higgs sector of the MSSM is a Type-II two-Higgs doublet model [119], in which one Higgs doublet (H_d) couples exclusively to the right-handed down-type quark (or lepton) fields and the second Higgs doublet (H_u) couples exclusively to the right-handed up-type quark fields. For example, the Yukawa Lagrangian that governs the couplings of the Higgs bosons to the third generation of quarks is

$$-\mathcal{L}_Y = \epsilon^{mn}\left[y_b \bar{b}_R (H_d)_m (Q_{L3})_n - y_t \bar{t}_R (H_u)_m (Q_{L3})_n\right] + \text{h.c.}, \tag{87.24}$$

with an implicit sum over the $\mathrm{SU}(2)_L$ indices m and n, where $Q_{L3} \equiv (t_L\,,\, b_L)$, $y_b \equiv (y_d)_{33}$ and $y_t \equiv (y_u)_{33}$. Moreover, after generalizing Eq. (87.24) to three generations of quarks and charged leptons, the diagonalization of the up-type and down-type fermion mass matrices simultaneously diagonalizes the corresponding Yukawa coupling matrices, resulting in flavor-diagonal tree-level couplings of the neutral Higgs bosons h^0, H^0 and A^0 to quark and lepton pairs. As expected, in the decoupling limit where $\cos(\beta - \alpha) \to 0$, the couplings of h reduce to those of the SM.

In the NMSSM, we set $\mu = 0$ in Eq. (87.1) and add two additional terms to the superpotential,

$$W_{\rm NMSSM} \supset \lambda \hat{H}_u \hat{H}_d \hat{S} + \frac{1}{3}\kappa \hat{S}^3 \,, \tag{87.25}$$

where $\hat{S}$ is a singlet Higgs superfield. In the NMSSM as defined here, all terms in $W_{\rm NMSSM}$ are cubic in the superfields due to the presence of a discrete $\mathbb{Z}_3$ symmetry. An effective μ-term is generated, $\mu_{\rm eff} = \lambda\langle S\rangle$, where $\langle S\rangle$ is the VEV of the scalar field component of $\hat{S}$. Moreover, due to the term proportional to λ in Eq. (87.25), there is now an F-term contribution to the quartic Higgs self-couplings. Consequently, the tree-level bound for the mass of the lightest CP-even MSSM Higgs boson is modified [120],

$$m_h^2 \leq m_Z^2 \cos^2 2\beta + \frac{1}{2}\lambda^2 v^2 \sin^2 2\beta \,, \tag{87.26}$$

where $v \equiv (v_u^2 + v_d^2)^{1/2} = 246$ GeV. By requiring that λ remain finite after renormalization-group evolution up to the Planck scale, one finds that λ is constrained to lie below about 0.7–0.8 at the electroweak scale [38] (although larger values of λ have also been considered in Ref. [121]).

87.5.2 *The radiatively-corrected Higgs sector*

When radiative corrections are incorporated, additional parameters of the supersymmetric model enter via virtual supersymmetric particles that appear in loops. The impact of these corrections can be significant [122]. The qualitative behavior of these radiative corrections can be most easily seen in the large top-squark mass limit. In addition, we shall assume that both the splitting of the two diagonal entries and the off-diagonal entries of the top-squark squared-mass matrix [Eq. (87.11)] are small in comparison to the geometric mean of the two top-squark squared-masses, $M_{\rm S}^2 \equiv M_{\widetilde{t}_1} M_{\widetilde{t}_2}$. In this case (assuming $m_A > m_Z$), the predicted upper bound for m_h is approximately given by [123]

$$m_h^2 \lesssim m_Z^2 \cos^2 2\beta + \frac{3g^2 m_t^4}{8\pi^2 m_W^2}\left[\ln\left(\frac{M_{\rm S}^2}{m_t^2}\right) + \frac{X_t^2}{M_{\rm S}^2}\left(1 - \frac{X_t^2}{12 M_{\rm S}^2}\right)\right] , \tag{87.27}$$

where $X_t \equiv A_t - \mu\cot\beta$ [cf. Eq. (87.12)] is proportional to the off-diagonal entry of the top-squark squared-mass matrix (where for simplicity, A_t and μ are taken to be real). The Higgs mass upper limit specified by Eq. (87.27) is saturated when $\tan\beta$ is large (*i.e.*, $\cos^2 2\beta \sim 1$) and $X_t = \sqrt{6}\, M_S$, which defines the so-called maximal mixing scenario.

The set of approximations used to obtain Eq. (87.27) somewhat overestimates the value of m_h. A more complete treatment of the MSSM Higgs mass radiative corrections, which incorporate renormalization group improvement, two-loop and leading three-loop contributions [76, 124, 125], yields a predicted value of m_h shown in Fig. 87.1, as a function of X_t (assumed for simplicity to be real). Higher-order radiative corrections beyond those reviewed in Ref. [76] have recently been obtained in Ref. [126], although their impact on the results shown in Fig. 87.1 is quite small.

The predicted value of m_h can now be used to derive an upper bound for the lightest stop mass in light of the experimentally measured value of m_h. Using the m_h measurement along with the requirement of a valid electroweak minimum of the scalar potential, one obtains a rough upper bound of $m_{\tilde{t}_1} \lesssim 10^{11}$ GeV [127]. In contrast, since m_h receives radiative corrections from many MSSM fields, obtaining a nontrivial lower bound based on any single parameter such as $m_{\tilde{t}_1}$ would typically require additional assumptions regarding the other MSSM parameters.

The radiative corrections to the scalar squared masses discussed above derive from loop corrections to the tree-level neutral CP-even Higgs squared-mass matrix $\mathcal{M}^2$. A complete treatment of Higgs sector radiative corrections must also include radiatively generated vertex corrections to the Higgs-fermion Yukawa couplings. In addition to loop corrections to the Yukawa Lagrangian given in Eq. (87.24), new terms in the Yukawa Lagrangian [the so-called wrong-Higgs Yukawa terms [128],

$$-\Delta\mathcal{L}_Y = (\Delta y_b)\bar{b}_R (H_u^*)_m (Q_{L3})_m + (\Delta y_t)\bar{t}_R (H_d^*)_m (Q_{L3})_m + \text{h.c.}, \tag{87.28}$$

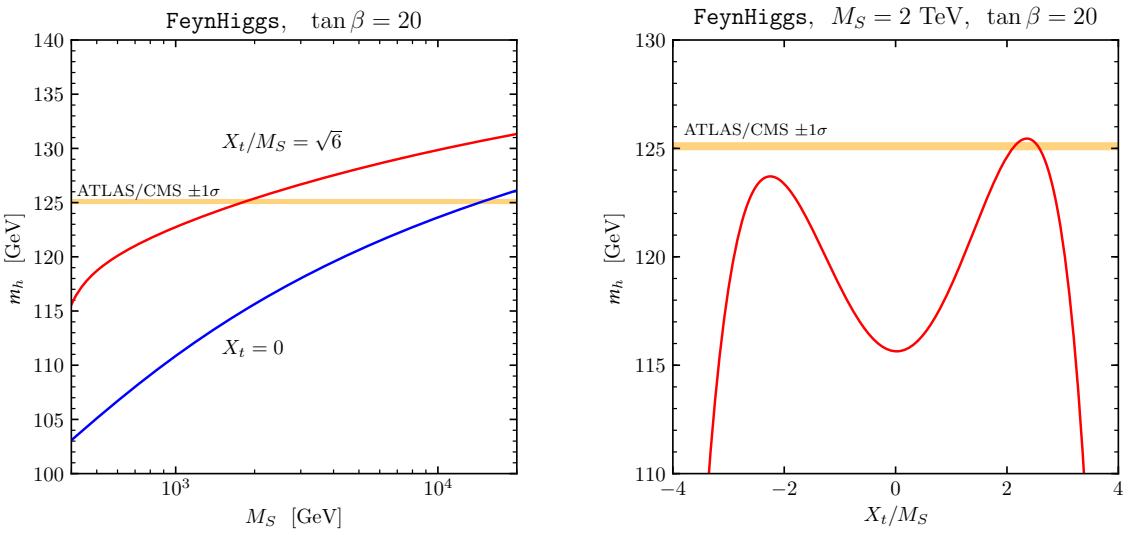

Figure 87.1: The radiatively-corrected value of the MSSM Higgs mass, m_h, as a function of a common SUSY mass parameter M_S and the stop mixing parameter X_t (normalized to M_S), for $\tan\beta = 20$. The value of the observed Higgs mass currently measured by the ATLAS and CMS collaborations [117] at the LHC is also shown. This figure has been adapted from Ref. [76].

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

are generated due to supersymmetry breaking effects. The most significant consequence of the wrong-Higgs Yukawa terms is to shift the relation between the bottom quark mass and its corresponding Yukawa coupling [129]

$$m_b = \frac{y_b v}{\sqrt{2}} \cos\beta(1 + \Delta_b)\,, \tag{87.29}$$

where $\Delta_b \simeq (\Delta y_b/y_b)\tan\beta$. That is, in parameter regimes where $\tan\beta \gg 1$, the impact of the Δ_b correction can be significantly enhanced, thereby modifying the couplings of the neutral Higgs bosons to b-quark pairs [113].

In obtaining Eqs. (87.27) and (87.29), the μ parameter and the potentially complex SUSY-breaking parameters were assumed to be real. In the so-called complex MSSM, where A_t, A_b, μ, and the gaugino mass parameters can be complex, there generically exist unremovable complex phases that provide new sources of CP violation. Thus, the radiatively-corrected Higgs sector, which now depends on these new CP-violating phases, is no longer CP conserving (*e.g.*, the neutral Higgs scalars are no longer CP-eigenstates). Further details on the complex MSSM Higgs sector can be found in Ref. [130].

In the NMSSM with $m_h \simeq 125$ GeV, the dominant radiative correction to Eq. (87.26) is the same as the one given in Eq. (87.27). However, in contrast to the MSSM, one does not need as large a boost from radiative corrections to achieve a Higgs mass of 125 GeV in certain regimes of the NMSSM parameter space (*e.g.*, $\tan\beta \sim 2$ and $\lambda \sim 0.7$ [131]).

87.5.3 *The hMSSM approximation*

As exhibited in Ref. [123], the dominant one-loop radiative correction to the value of m_h^2 in Eq. (87.27) that yields the term proportional to $m_t^4 \ln(M_S^2/m_t^2)$ is due entirely to the radiatively-corrected 22 element of the CP-even Higgs squared-mass matrix $\mathcal{M}_{22}^2$. Thus, the authors of Refs. [132, 133] suggested a simple recipe to account for the leading radiative corrections to the neutral CP-even Higgs sector of the MSSM without explicitly fixing the parameters of the top squark sector. In this recipe, the expressions for $\mathcal{M}_{11}^2$ and $\mathcal{M}_{12}^2$ given in Eq. (87.17) are retained, whereas $\mathcal{M}_{22}^2$ is left unspecified. After diagonalizing the resulting squared-mass matrix, expressions of the form are obtained

$$m_{h,H}^2 = f_\pm(m_A^2, m_Z^2, \tan\beta, \mathcal{M}_{22}^2)\,, \tag{87.30}$$

$$\cos\alpha = g(m_A^2, m_Z^2, \tan\beta, \mathcal{M}_{22}^2)\,, \tag{87.31}$$

where the functions $f_\pm$ and g are the result of the diagonalization procedure described above. One can use Eq. (87.30) to solve for $\mathcal{M}_{22}^2$ in terms of the experimentally measured Higgs mass, $m_h \simeq 125$ GeV. One then uses Eqs. (87.30) and (87.31) to obtain expressions for m_H^2 and $\cos\alpha$ that are functions of the *measured* mass m_h, which replace the tree-level results given in Eqs. (87.20) and (87.21). This framework was dubbed the hMSSM in Ref. [132]. Having fixed $m_h \simeq 125$ GeV, the Higgs phenomenology of the hMSSM is entirely governed by two MSSM input parameters, m_A and $\tan\beta$. For example, one must assume that the radiative corrections to the Yukawa Lagrangian [e.g., the Δ_b correction exhibited in Eq. (87.29)] are negligible.

Although the hMSSM can be readily applied to LHC data to constrain the neutral CP-even Higgs sector of the MSSM, it can lead to results that are not robust in a more general MSSM parameter scan. Indeed, a more complete treatment of the radiative corrections can yield results that cannot be accounted for in the hMSSM framework. Examples of benchmark points in the MSSM parameter space that cannot be reproduced by the hMSSM analysis are examined in Refs. [134–136]. Finally, we note that the hMSSM framework is not relevant for describing the shift in the properties of the charged Higgs boson due to radiative corrections.

87.5.4 *The Higgs alignment limit and SUSY*

In the Higgs alignment limit of an extended Higgs sector [118, 137], the tree-level properties of one of the neutral scalar states match those of the SM Higgs boson. In light of the LHC Higgs data (see Sec. 11), where the Higgs boson is observed to be SM-like [138, 139], any supersymmetric extension of the SM must account for a SM-like Higgs boson.

Starting from Eq. (87.2), we can define two linear combinations of the MSSM Higgs fields H_u and H_d:

$$\mathcal{H}_1 \equiv H_d \cos\beta + H_u \sin\beta\,, \qquad \mathcal{H}_2 \equiv -H_d \sin\beta + H_u \cos\beta\,. \tag{87.32}$$

Note that the corresponding VEVs of these fields are $\langle \mathcal{H}_1^0 \rangle = v/\sqrt{2}$ and $\langle \mathcal{H}_2^0 \rangle = 0$, respectively. If the neutral scalar field defined by $\varphi \equiv \sqrt{2}\,\mathrm{Re}\,\mathcal{H}_1^0 - v$ were an eigenstate of the CP-even neutral scalar squared-mass matrix (corresponding to the alignment in field space of φ with the direction of the VEV), then it would follow that $\cos(\beta-\alpha) = 0$, under the assumption that the observed Higgs boson is the lighter of the two CP-even scalars [114]. One can check that in the alignment limit described above, the tree-level properties of φ coincide with those of the SM Higgs boson.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

To achieve the Higgs alignment limit, one must suppress the mixing of the field φ and the second orthogonal CP-even scalar field. This can be achieved in two different scenarios. In the so-called decoupling limit of the extended Higgs sector, one neutral scalar mass eigenstate is identified with the SM-like Higgs boson, and all other Higgs scalar mass eigenstates are assumed to be much heavier. As previously noted below Eq. (87.23), $m_H \gg m_h$ yields $|\cos(\beta-\alpha)| \ll 1$, which is consistent with current LHC experimental bounds [140]. If the decoupling limit is realized in the MSSM, then H, A and $H^\pm$ must be significantly heavier (most likely with masses of order 500 GeV or larger [140]). Indeed, Higgs alignment via decoupling is generic and can be achieved in many extensions of the SM.

The Higgs alignment limit can also be realized without decoupling if the value of the off-diagonal element of the CP-even squared-mass matrix (expressed with respect to the $\mathcal{H}_1$–$\mathcal{H}_2$ field basis) is much smaller than the corresponding diagonal elements. This cannot be achieved at tree-level in a viable region of the MSSM parameter space (nor in the hMSSM framework discussed in Sec. 87.5.3). However, regions of the MSSM parameter space do exist, albeit quite fine-tuned, in which Higgs alignment without decoupling is achieved once radiative corrections are taken into account [135]. The NMSSM provides a more robust scenario for Higgs alignment without decoupling as shown in Ref. [131], where the discovery of additional Higgs scalar states at future runs at the LHC would be expected.

As recently reiterated in Ref. [141], the precise measurements of the Higgs boson properties, which would be sensitive to small departures from the Higgs alignment limit, offer a valuable and complementary probe of weak-scale SUSY models, due to the radiative effects of superpartners on Higgs couplings, even in scenarios where direct searches for superpartners are not effective.

87.6 Restricting the MSSM parameter freedom

In Sections 87.4 and 87.5, we surveyed the parameters that comprise the MSSM-124. However, the MSSM-124 is not a phenomenologically viable theory over much of its parameter space. In particular, a generic point of the MSSM-124 parameter space exhibits: (i) no conservation of the separate lepton numbers L_e, L_μ, and L_τ; (ii) unsuppressed flavor-changing neutral currents (FCNCs); and (iii) new sources of CP violation [142] that are inconsistent with the experimental bounds.

In addition, one-loop radiative corrections can introduce CP-violating effects in the Higgs sector that depend on some of the CP-violating phases among the MSSM-124 parameters [143]. This phenomenon is most easily understood in a scenario where $m_A \ll M_S$ (i.e., all five physical Higgs states are significantly lighter than the SUSY breaking scale). In this case, one can integrate out the heavy superpartners to obtain a low-energy effective theory with two Higgs doublets. The resulting effective two-Higgs doublet model will now contain all possible Higgs self-interaction terms (both CP-conserving and CP-violating) and Higgs-fermion interactions (beyond those of Type-II) that are consistent with electroweak gauge invariance [128].

As noted above, the MSSM contains new sources of CP violation. Indeed, for TeV-scale sfermion and gaugino masses, some combinations of the complex phases of the gaugino-mass parameters, the A-parameters, and μ must be less than about 10^{-2}–10^{-3} to avoid generating electric dipole moments for the neutron, electron, and atoms [144] in conflict with observed data [145]. The rarity of FCNCs [146, 147] places additional constraints on the off-diagonal matrix elements of the squark and slepton soft-SUSY-breaking squared-masses and A-parameters (see Sec. 87.3.3).

The MSSM-124 is also theoretically incomplete as it provides no explanation for the fundamental origin of the supersymmetry-breaking parameters. The successful unification of the MSSM gauge couplings at the GUT scale, $M_{\rm GUT} \sim 10^{16}$ GeV, close to the Planck scale [15, 73, 148, 149],

$$g_s(M_{\rm GUT}) = g(M_{\rm GUT}) = \sqrt{\frac{5}{3}}\, g'(M_{\rm GUT}), \tag{87.33}$$

suggests that the high-energy structure of the theory may be considerably simpler than its low-energy realization.[3] In a top-down approach, the dynamics that governs the theory at high energies is used to derive the effective broken-supersymmetric theory at the TeV scale.

In this Section, we examine a number of theoretical frameworks that potentially yield phenomenologically viable regions of the MSSM-124 parameter space. The resulting supersymmetric particle spectrum is then a function of a relatively small number of input parameters. This is accomplished by imposing a simple structure on the soft SUSY-breaking parameters at a common high-energy scale M_X (typically chosen to be the Planck scale, M_P, the GUT scale, $M_{\rm GUT}$, or the messenger scale, $M_{\rm mess}$). These serve as initial conditions for the MSSM renormalization group equations (RGEs), which are given in the two-loop approximation in Ref. [150]. An automated program to compute RGEs for the MSSM and other supersymmetric models of new physics has been developed in Ref. [151]. Solving these equations numerically, one can then derive the low-energy MSSM parameters relevant for phenomenology. A number of software packages exist that numerically calculate the spectrum of supersymmetric particles, consistent with theoretical conditions on SUSY breaking at high energies and some experimental data at low energies [76,152].

Examples of viable frameworks are provided by models of gravity-mediated, anomaly-mediated, and gauge-mediated SUSY breaking. In some of these approaches, one of the diagonal Higgs squared-mass parameters is driven negative by renormalization group evolution [153]. In such models, electroweak symmetry breaking is generated radiatively, and the resulting electroweak symmetry-breaking scale is intimately tied to the scale of low-energy SUSY breaking.

87.6.1 *Gaugino mass relations*

One prediction of many supersymmetric grand unified models is the unification of the (tree-level) gaugino mass parameters[4] at some high-energy scale, M_X,

$$M_1(M_X) = M_2(M_X) = M_3(M_X) = m_{1/2}\,. \tag{87.34}$$

Due to renormalization group running, in the one-loop approximation the effective low-energy gaugino mass parameters (at the electroweak scale) are related,

$$M_3 = (g_s^2/g^2)M_2 \simeq 3.5 M_2\ , \qquad M_1 = (5g'^2/3g^2)M_2 \simeq 0.5 M_2. \tag{87.35}$$

Eq. (87.35) can arise more generally in gauge-mediated SUSY-breaking models where the gaugino masses are generated at the messenger scale $M_{\rm mess}$ (which typically lies significantly below the unification scale where the gauge couplings unify). In this case, the gaugino mass parameters are proportional to the corresponding squared gauge couplings at the messenger scale.

When Eq. (87.35) is satisfied, the chargino and neutralino masses and mixing angles depend only on three unknown parameters: the gluino mass, μ, and $\tan\beta$. It then follows that the lightest neutralino must be heavier than 46 GeV due to the non-observation of charginos at LEP [155]. If in addition $|\mu| \gg |M_1| \gtrsim m_Z$, then the lightest neutralino is nearly a pure bino, an assumption often made in supersymmetric particle searches at colliders. Although Eq. (87.35) is often assumed in many phenomenological studies, a truly model-independent approach would take the gaugino mass parameters M_1, M_2, and M_3 to be independent parameters to be determined by experiment. Indeed, an approximately massless neutralino *cannot* be ruled out at present by a model-independent analysis [156].

It is possible that the tree-level masses of the gauginos are zero. In this case, the gaugino mass parameters arise at one-loop and do not satisfy Eq. (87.35). For example, the gaugino masses in

[3] Generically, the normalization of the U(1) hypercharges exhibited in Table 87.1 is a matter of convention. In particular, the U(1) hypercharges can be rescaled by absorbing the scaling factor into a redefinition of the hypercharge gauge coupling g'. However in a grand unified theory (GUT), the embedding of the hypercharge U(1) generator into the Lie algebra of a (unified) simple gauge group fixes the normalization of the U(1) hypercharges and results in the rescaled hypercharge gauge coupling shown in Eq. (87.33).

[4] Non-universal gaugino mass parameters can also be a viable option in grand unified models with non-minimal gauge kinetic functions [154].

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

AMSB models arise entirely from a model-independent contribution derived from the super-conformal anomaly [55, 157]. In this case, Eq. (87.35) is replaced (in the one-loop approximation) by:

$$M_i \simeq \frac{b_i g_i^2}{16\pi^2} m_{3/2}\,, \tag{87.36}$$

where $m_{3/2}$ is the gravitino mass and the b_i are the coefficients of the MSSM gauge beta-functions corresponding to the corresponding U(1), SU(2), and SU(3) gauge groups, $(b_1, b_2, b_3) = (\frac{33}{5}, 1, -3)$. Eq. (87.36) yields $M_1 \simeq 2.8 M_2$ and $M_3 \simeq -8.3 M_2$, which implies that the lightest chargino pair and neutralino comprise a nearly mass-degenerate triplet of winos, $\widetilde{W}^{\pm}$, $\widetilde{W}^0$ (cf. Table 1), over most of the MSSM parameter space. For example, if $|\mu| \gg m_Z, |M_2|$, then Eq. (87.36) implies that $M_{\widetilde{\chi}^{\pm}} \simeq M_{\widetilde{\chi}^0_1} \simeq M_2$ [158]. Alternatively, one can construct an AMSB model where $|\mu|, m_Z \ll M_2$, which yields an LSP that is an approximate higgsino state [159]. In both cases, the corresponding supersymmetric phenomenology differs significantly from the standard phenomenology based on Eq. (87.35) [160, 161].

Finally, it should be noted that the unification of gaugino masses (and scalar masses) can be accidental. In particular, the energy scale where unification takes place may not be directly related to any physical scale. One version of this phenomenon has been called mirage unification and can occur in certain theories of fundamental SUSY breaking [162].

87.6.2 *Constrained versions of the MSSM: mSUGRA, CMSSM, etc.*

In the minimal supergravity (mSUGRA) framework [5–7,27,48–50], the minimal form of the Kähler potential is employed, which yields standard kinetic energy terms for the MSSM fields [52]. As a result, the soft supersymmetry-breaking parameters at the high-energy scale M_X take a particularly simple form in which the scalar squared-masses and the A-parameters are flavor-diagonal and universal [50]:

$$\begin{aligned}
&M^2_{\widetilde{Q}}(M_X) = M^2_{\widetilde{U}}(M_X) = M^2_{\widetilde{D}}(M_X) = m_0^2 \mathbf{1}\,,\\
&M^2_{\widetilde{L}}(M_X) = M^2_{\widetilde{E}}(M_X) = m_0^2 \mathbf{1}\,,\\
&m^2_{H_u}(M_X) = m^2_{H_d}(M_X) = m_0^2\,,\\
&A_U(M_X) = A_D(M_X) = A_E(M_X) = A_0 \mathbf{1}\,,
\end{aligned} \tag{87.37}$$

where $\mathbf{1}$ is a 3×3 identity matrix in generation space. As in the SM, this approach exhibits minimal flavor violation (*e.g.*, see Ref. [163]), whose unique source is the nontrivial flavor structure of the Higgs-fermion Yukawa couplings. The gaugino masses are also unified according to Eq. (87.34).

Renormalization group evolution is then used to derive the values of the supersymmetric parameters at the low-energy (electroweak) scale. For example, to compute squark masses, one should use the low-energy values for $M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, and $M^2_{\widetilde{D}}$ in Eq. (87.11). Through the renormalization group running with boundary conditions specified in Eq. (87.35) and Eq. (87.37), one can show that the low-energy values of $M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, and $M^2_{\widetilde{D}}$ depend primarily on m_0^2 and $m^2_{1/2}$. A number of useful approximate analytic expressions for superpartner masses in terms of the mSUGRA parameters can be found in Ref. [164].

One can count the number of independent parameters in the mSUGRA framework. In addition to 18 SM parameters (excluding the Higgs mass), one must specify m_0, $m_{1/2}$, A_0, the Planck-scale values for μ and B-parameters (denoted by μ_0 and B_0), and the gravitino mass $m_{3/2}$. Without additional model assumptions, $m_{3/2}$ is independent of the parameters that govern the mass spectrum of the superpartners of the SM [50]. In principle, A_0, B_0, μ_0, and $m_{3/2}$ can be complex, although in the mSUGRA approach, these parameters are taken to be real for simplicity.

As previously noted, renormalization group evolution is used to compute the low-energy values of the mSUGRA parameters, which then fixes all the parameters of the low-energy MSSM. In particular, the two Higgs VEVs (or equivalently, m_Z and $\tan\beta$) can be expressed as a function of the Planck-scale supergravity parameters. In light of Eq. (87.4) and Eq. (87.5), a common procedure is to determine μ_0 and B_0 in terms of m_Z and $\tan\beta$ [the sign of μ_0, denoted $\mathrm{sgn}(\mu_0)$ below, is not fixed in this process]. In this case, the MSSM spectrum and its interaction strengths are fixed by five parameters:

$$m_0\,,\ A_0\,,\ m_{1/2}\,,\ \tan\beta\,,\ \text{and}\ \mathrm{sgn}(\mu_0)\,, \tag{87.38}$$

and an independent gravitino mass $m_{3/2}$ (in addition to the 18 parameters of the SM). In Ref. [165], this framework was dubbed the constrained minimal supersymmetric extension of the SM (CMSSM). Additional relations such as $B_0 = A_0 - m_0$ and $m_{3/2} = m_0$ comprise the original mSUGRA proposal [48, 52, 166].

One can also relax the universality of scalar masses by decoupling the squared-masses of the Higgs bosons and the squarks/sleptons. This leads to the non-universal Higgs mass models (NUHMs), thereby adding one or two new parameters to the CMSSM depending on whether the diagonal Higgs scalar squared-mass parameters ($m^2_{H_d}$ and $m^2_{H_u}$) are set equal (NUHM1 [167]) or taken to be independent (NUHM2 [168]) at the high energy scale M_X. Clearly, this modification preserves the minimal flavor violation of the mSUGRA approach. Nevertheless, the mSUGRA approach and its NUHM generalizations are probably too simplistic. Theoretical considerations suggest that the universality of Planck-scale soft SUSY-breaking parameters is not generic [169]. In particular, effective operators at the Planck scale exist that do not respect flavor universality, and it is difficult to find a theoretical principle that would forbid them.

In the framework of supergravity, if anomaly mediation is the sole source of SUSY breaking, then the gaugino mass parameters, diagonal scalar squared-mass parameters, and the SUSY-breaking trilinear scalar interaction terms (proportional to $\lambda_f A_F$) are determined in terms of the beta functions of the gauge and Yukawa couplings and the anomalous dimensions of the squark and slepton fields [55, 157, 161]. As noted in Sec. 87.2.3, this approach yields tachyonic sleptons in the MSSM unless additional sources of SUSY breaking are present. In the minimal AMSB (mAMSB) scenario, a universal squared-mass parameter, m_0^2, is added to the AMSB expressions for the diagonal scalar squared-masses [161]. Thus, the mAMSB spectrum and its interaction strengths are determined by four parameters, m_0^2, $m_{3/2}$, $\tan\beta$ and $\mathrm{sgn}(\mu_0)$.

The mAMSB scenario appears to be ruled out based on the observed value of the Higgs boson mass, assuming an upper limit on M_S of a few TeV, since the mAMSB constraint on A_F implies that the maximal mixing scenario cannot be achieved [cf. Eq. (87.27)]. Indeed, under the stated assumptions, the mAMSB Higgs mass upper bound lies below the observed Higgs mass value [170]. Thus within the mAMSB scenario, either an additional SUSY-breaking contribution to $\lambda_f A_F$, and/or new ingredients beyond the MSSM are required.

87.6.3 *Gauge-mediated SUSY breaking*

In contrast to models of gravity-mediated SUSY breaking, the flavor universality of the fundamental soft SUSY-breaking squark and slepton squared-mass parameters is guaranteed in gauge-mediated supersymmetry breaking (GMSB) because the supersymmetry breaking is communicated to the sector of MSSM fields via gauge interactions [60, 62]. In GMSB models, the mass scale of the messenger sector (or its equivalent) is sufficiently below the Planck scale such that the additional SUSY-breaking effects mediated by supergravity can be neglected.

In the minimal GMSB approach, there is one effective mass scale, Λ, that determines all low-energy scalar and gaugino mass parameters through loop effects, while the resulting A-parameters are suppressed. In addition, the minimal form of the Kähler potential is employed. Assuming that the superpartner masses are no larger than a few TeV, one must take $\Lambda \sim \mathcal{O}(100\ \text{TeV})$. The origin of the μ and B-parameters is model-dependent, and lies somewhat outside the purview of gauge-mediated SUSY breaking [171].

The simplest GMSB models appear to be ruled out based on the observed value of the Higgs boson mass. Due to suppressed A-parameters, it is difficult to boost the contributions of the radiative corrections in Eq. (87.27) to obtain a Higgs mass as large

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

as 125 GeV, under the assumption that M_S is no larger than a few TeV. However, this conflict can be alleviated in more complicated GMSB models [172]. To analyze these generalized GMSB models, it has been especially fruitful to develop model-independent techniques that encompass all known GMSB models [173]. These techniques are well-suited for a comprehensive analysis [174] of the phenomenological profile of gauge-mediated SUSY breaking.

The gravitino is the LSP in minimal GMSB models, as noted in Sec. 87.2.3. As a result, the next-to-lightest supersymmetric particle (NLSP) now plays a crucial role in the phenomenology of supersymmetric particle production and decays. Note that unlike the LSP, the NLSP can be charged. In GMSB models, the most likely candidates for the NLSP are $\tilde{\chi}_1^0$ and $\widetilde{\tau}_R^{\pm}$. The NLSP will decay into its superpartner plus a gravitino (*e.g.*, $\tilde{\chi}_1^0 \to \gamma\widetilde{G}$, $\tilde{\chi}_1^0 \to Z\widetilde{G}$, $\tilde{\chi}_1^0 \to h^0\widetilde{G}$ or $\widetilde{\tau}_1^{\pm} \to \tau^{\pm}\widetilde{G}$), with lifetimes and branching ratios that depend on the model parameters. There are also GMSB scenarios in which there are several nearly degenerate co-NLSPs, any one of which can be produced at the penultimate step of a supersymmetric decay chain [175]. For example, in the slepton co-NLSP case, all three right-handed sleptons are close enough in mass and thus can each play the role of the NLSP.

Different choices for the identity of the NLSP and its decay rate lead to a variety of distinctive supersymmetric phenomenologies [62,176]. For example, a long-lived $\tilde{\chi}_1^0$-NLSP that decays outside collider detectors leads to supersymmetric decay chains with missing energy in association with leptons and/or hadronic jets (this case is indistinguishable from the standard phenomenology of the $\tilde{\chi}_1^0$-LSP). On the other hand, if $\tilde{\chi}_1^0 \to \gamma\widetilde{G}$ is the dominant decay mode, and the decay occurs inside the detector, then nearly *all* supersymmetric particle decay chains would produce a photon. In contrast, in the case of a $\widetilde{\tau}_1^{\pm}$-NLSP, the $\widetilde{\tau}_1^{\pm}$ would either be long-lived or would decay inside the detector into a τ-lepton plus missing energy.

A number of attempts have been made to address the origins of the μ and B-parameters in GMSB models based on the field content of the MSSM (*e.g.*, see Refs. [171, 177]). An alternative approach is to consider GMSB models based on the NMSSM [178]. The VEV of the additional singlet Higgs superfield can be used to generate effective μ and B-parameters [179]. Such models provide an alternative GMSB framework for achieving a Higgs mass of 125 GeV, while still being consistent with LHC bounds on supersymmetric particle masses.

87.6.4 *The phenomenological MSSM*

Any of the theoretical assumptions described in the previous three subsections must be tested experimentally and could turn out to be wrong. To facilitate the exploration of MSSM phenomena in a more model-independent way while respecting the constraints noted at the beginning of Sec. 87.6, the phenomenological MSSM (pMSSM) has been introduced [180].

The pMSSM is governed by 19 independent real supersymmetric parameters: the three gaugino mass parameters M_1, M_2 and M_3, the Higgs sector parameters m_A and $\tan\beta$, the Higgsino mass parameter μ, five sfermion squared-mass parameters for the degenerate first and second generations ($M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, $M^2_{\widetilde{D}}$, $M^2_{\widetilde{L}}$ and $M^2_{\widetilde{E}}$), the five corresponding sfermion squared-mass parameters for the third generation, and three third-generation A-parameters (A_t, A_b and A_τ). The first and second generation A-parameters are typically neglected in pMSSM studies, as their phenomenological consequences are negligible in most applications. One counterexample arises when considering the A_μ dependence of the anomalous magnetic moment of the muon, which can be as significant as other contributions due to superpartner mediated radiative corrections [181]. Consequently, the original pMSSM approach has been extended to include a 20th parameter, A_μ [182]. Other pMSSM extensions that include CP-violating SUSY-breaking parameters have been considered in Ref. [183].

The 19-parameter pMSSM is often further constrained to expedite scans over the parameter space. For example, in Ref. [184], the number of pMSSM parameters is reduced to ten by assuming one common squark squared-mass parameter for the first two generations, a second common squark squared-mass parameter for the third generation, a common (charged) slepton squared-mass parameter and a common third generation Aparameter. In Ref. [185] an eleven parameter pMSSM is defined by allowing for a different stau squared-mass parameter from that of the first two generation charged sleptons. Other applications of the pMSSM approach (with a reduced pMSSM parameter space) to supersymmetric particle searches, and a discussion of the implications for past and future LHC and dark matter studies can be found in Refs. [184, 186].

87.6.5 *Simplified models*

As discussed in Sec. 88, the experimental collaborations present the results of their searches for supersymmetric particles primarily in terms of simplified models. Simplified models for supersymmetric particle searches [187] are defined mostly by the empirical objects and kinematic variables involved in the search. The interpretation of the experimental results usually involves only a small number of supersymmetric particles (often two or three). Other supersymmetric particles are assumed to play no role (this may happen by virtue of them being too heavy to be produced). Experimental bounds from the non-observation of a signal are usually presented in terms of the physical masses of the supersymmetric particles involved. Bounds on the relevant supersymmetric particle masses may be presented assuming values for the branching ratio of certain supersymmetric particle decays, or as an upper bound on the signal production cross section as a function of the relevant supersymmetric particle masses.

For example, consider a search for hadronic jets plus missing transverse momentum. One can match such a search to a simplified model of squark pair production followed by the subsequent decay of each squark into a quark (which appears as a jet) and a neutralino LSP that produces the missing transverse momentum, *i.e.* $\tilde{q}\tilde{q} \to (q\tilde{\chi}_1^0)(q\tilde{\chi}_1^0)$. Excluded cross sections resulting from the non-observation of a signal (which in this case could consist of some specified minimum value of missing transverse momentum and at least two hard jets) may be exhibited in the squark mass versus LSP mass plane.

The large number of free parameters that govern a typical supersymmetric model makes it difficult to present experimentally excluded regions in any generality. This is where simplified models have an apparent advantage in that they depend on far fewer free parameters than more complete supersymmetric models. However, if limits are quoted on supersymmetric particle masses without reference to the signal production cross section from a simplified model analysis, then there are several potential pitfalls. For example, chargino/neutralino mixing affect their production cross sections. Moreover, mass limits can differ from those obtained in full models because there may be contributions to the signal coming from processes involving supersymmetric particles other than those assumed. Indeed, in the $\tilde{q}\tilde{q} \to q\tilde{\chi}_1^0 q\tilde{\chi}_1^0$ process mentioned above, the simplified model analysis does not account for the interference with tree-level t-channel gluino contributions, nor does it account for other decay modes of the $\tilde{q}\tilde{q}$ pair. Nevertheless, simplified model bounds quoted purely in terms of supersymmetric particle masses may still approximately hold over sizable regions of parameter space of more complete models, within which the simplified model is embedded. When simplified model limits are phrased as bounds on signal cross sections, the aforementioned pitfalls are sidestepped.

Simplified models thus remain an efficient tool for organizing and presenting the results of supersymmetric particle searches. A comparison between supersymmetric particle search constraints in the context of simplified models and the corresponding constraints obtained in the more complete pMSSM can be found in Ref. [188].

87.7 Experimental data confronts the MSSM

At present, there is no significant evidence for weak-scale SUSY from the data analyzed by the LHC experiments [189]. Recent LHC data have been employed in ruling out the existence of colored supersymmetric particles (primarily the gluino and the first generation of squarks) with masses below about 2 TeV. Moreover, given that the mass of the observed Higgs boson is 125 GeV, the results exhibited in Fig. 87.1 tend to favor a mass scale of the top squarks somewhat above 2 TeV. However, the precise mass limits

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

are very model dependent. For example, as Fig. 88.13 demonstrates, regions of the pMSSM parameter space can be identified in which lighter squarks and gluinos below 1 TeV cannot be definitively ruled out. Under the assumption of gaugino mass unification [cf. Eq. (87.35)], LHC searches result in a lower bound on neutralino and chargino masses of roughly 200 GeV. It is also difficult to place general bounds on neutralino and chargino masses, since the limits in terms of masses from direct searches tend to be particularly model-dependent. It is therefore premature to rule out the entire framework of weak-scale supersymmetry based on current LHC searches for supersymmetric particles [141]. Nevertheless, one must confront the tension that exists between the theoretical expectations for the magnitude of the SUSY-breaking parameters and the non-observation of supersymmetric phenomena at colliders.

87.7.1 *Naturalness constraints and the little hierarchy*

In Sec. 87.1, weak-scale SUSY was motivated as a natural solution to the hierarchy problem, which could provide an understanding of the origin of the electroweak symmetry-breaking scale without a significant fine-tuning of the fundamental parameters that govern the MSSM. In this context, the weak-scale soft supersymmetry-breaking masses must be generally of the order of 1 TeV or below [190]. This requirement is most easily seen in the determination of m_Z by the scalar potential minimum condition. In light of Eq. (87.5), to avoid the fine-tuning of MSSM parameters, the soft SUSY-breaking squared-masses $m^2_{H_d}$ and $m^2_{H_u}$ and the higgsino squared-mass $|\mu|^2$ should all be roughly of $\mathcal{O}(m_Z^2)$. Many authors have proposed quantitative measures of fine-tuning [190–195]. One of the simplest measures is the one advocated by Barbieri and Giudice [190] (which was also introduced previously in Ref. [191]),

$$\Delta_i \equiv \left| \frac{\partial \ln m_Z^2}{\partial \ln p_i} \right| , \qquad \Delta \equiv \max\, \Delta_i \,, \tag{87.39}$$

where the p_i are the MSSM parameters at the high-energy scale M_X, which are set by the fundamental SUSY-breaking dynamics. The theory is more fine-tuned as Δ becomes larger. However, different measures of fine-tuning yield quantitatively different results [196]; in particular, calculating minimal fine-tuning based on the high-scale parameters [as defined in Eq. (87.39)] yields a difference by a factor of order 10 to fine-tuning based on TeV-scale parameters [197, 198].

One can apply the fine-tuning measure to any explicit model of SUSY breaking. For example, in the approaches discussed in Sec. 87.6, the p_i are parameters of the model at the energy scale M_X where the soft SUSY-breaking operators are generated by the dynamics of SUSY breaking. Renormalization group evolution then determines the values of the parameters appearing in Eq. (87.5) at the electroweak scale. In this way, Δ is sensitive to all the SUSY-breaking parameters of the model (see *e.g.* Ref. [199]). The computation of Δ is often based on Eq. (87.5), which is a tree-level condition. However, the fine-tuning measure obtained at tree level can be somewhat reduced in value when loop corrections are included while remaining consistent with all experimental constraints [88, 200].

One way of taking fine-tuning into account in fits to data using Bayesian statistics is to have a prior probability distribution proportional to $1/\Delta$ [201] so that fine-tuning is balanced against the fit to empirical data. In such a Bayesian approach, it is important to choose the prior probability distribution carefully, since prior probability densities that are flat in one set of variables may not be flat in another, more fundamental set. One can in fact derive a different measure of fine-tuning resulting from a Jacobian factor when transforming to other variables.[5] By comparing the results of several Bayesian fits with different (but reasonable) prior probability distributions, one can assess the robustness of the fit with respect to their variation, mitigating for subjectivity in the interpretation of the fine-tuning measure.

As anticipated, there is a tension between the present experimental lower limits on the masses of colored supersymmetric particles [203] and the expectation that supersymmetry-breaking is associated with the electroweak symmetry-breaking scale. Moreover, in light of the results exhibited in Fig. 87.1, this tension is exacerbated by the observed value of the Higgs mass ($m_h \simeq 125$ GeV), which is suggestive of a value of M_S in the multi-TeV range. Indeed, if M_S characterizes the scale of all supersymmetric particle masses, then one would crudely expect $\Delta \sim M_S^2/m_Z^2$. For example, if $M_S \sim 2$ TeV then one expects a fine-tuning of the MSSM parameters such that $\Delta^{-1} \sim 0.2\%$ to achieve the observed value of m_Z. This separation of the electroweak symmetry-breaking and SUSY-breaking scales is an example of the little hierarchy problem [204].

The fine-tuning parameter Δ can depend quite sensitively on the structure of the SUSY-breaking dynamics, such as the value of M_X and relations among SUSY-breaking parameters in the fundamental high energy theory [205]. For example, in so-called focus point SUSY models [194, 206], all squark masses can be as heavy as 5 TeV *without* significant fine-tuning. This can be attributed to a focusing behavior of the renormalization group evolution when certain relations hold among the high-energy values of the scalar squared-mass SUSY-breaking parameters. Although the focus point region of the CMSSM still yields an uncomfortably high value of Δ due to the observed Higgs mass of 125 GeV, one can achieve moderate values of Δ in models with NUHM2 boundary conditions for the scalar masses [207].

Among the colored superpartners, the third generation squarks typically have the most significant impact on the naturalness constraints [208], while their masses are the least constrained by the LHC data. Hence, in the absence of any relation between third generation squarks and those of the first two generations, the naturalness constraints due to present LHC data can be considerably weaker than those obtained in the CMSSM. Indeed, models with first and second generation squark masses in the multi-TeV range do not necessarily require significant fine tuning. Such models have the added benefit that undesirable FCNCs mediated by squark exchange are naturally suppressed [209]. Other MSSM mass spectra that are compatible with moderate fine tuning have been considered in Refs. [205, 210].

The lower bounds on squark and gluino masses may not be as large as suggested by the experimental analyses based on the CMSSM or simplified models. For example, mass bounds for the gluino and the first and second generation squarks based on the CMSSM can often be evaded in alternative or extended MSSM models, *e.g.*, compressed SUSY [211] and stealth SUSY [212]. Moreover, the experimental lower limits for the third generation squark masses (which have a more direct impact on the fine-tuning measure) are weaker than the corresponding mass limits for other colored supersymmetric states.

Among the uncolored superpartners, the higgsinos are typically the most impacted by the naturalness constraints. Eq. (87.5) suggests that the masses of the two neutral higgsinos and charged higgsino pair (which are governed by $|\mu|$) should not be significantly larger than m_Z to avoid an unnatural fine-tuning of the supersymmetric parameters, which would imply the existence of light higgsinos (whose masses are not well constrained, as they are difficult to detect directly at the LHC due to their soft decay products). However, it may be possible to avoid the conclusion that $\mu \sim \mathcal{O}(m_Z)$ if additional correlations among the SUSY breaking mass parameters and μ are present. Such a scenario can be realized in models in which the boundary conditions for SUSY breaking are generated by approximately conformal strong dynamics. For example, in the so-called scalar-sequestering model of Ref. [213], values of $|\mu| > 1$ TeV can be achieved while naturally maintaining the observed value of m_Z.

Finally, one can also consider extensions of the MSSM in which the degree of fine-tuning is relaxed. For example, it has already been noted in Sec. 87.5 that it is possible to accommodate the observed Higgs mass more easily in the NMSSM due to contributions to m_h^2 proportional to the parameter λ. This means that

[5] For example, one may consider the parameters μ and m_{12}^2 to be more fundamental than $\tan\beta$ and M_Z. In this case, one would choose a flat prior probability distribution in μ and m_{12}^2 rather than in $\tan\beta$ and M_Z [193, 202]. The Jacobian factor is then obtained from Eqs. (87.4) and (87.5).

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

one does not have to rely on a large contribution from radiative corrections to boost the Higgs mass sufficiently above its tree-level bound. This allows for smaller top squark masses, which are more consistent with the demands of naturalness. The reduction of the fine-tuning in various NMSSM models was initially advocated in Ref. [214], and subsequently treated in more detail in Refs. [121, 215]. Naturalness can also be relaxed in extended supersymmetric models with vector-like quarks [216] and in gauge extensions of the MSSM [217].

The experimental absence of any new physics beyond the SM at the LHC suggests that the principle of naturalness is presently under significant stress [218]. Nevertheless, one must be very cautious when drawing conclusions about the viability of weak-scale SUSY to explain the origin of electroweak symmetry breaking, since different measures of fine-tuning noted above can lead to different assessments [196–198]. Moreover, the maximal value of Δ that determines whether weak-scale SUSY is a fine-tuned model (should it be $\Delta \sim 10$? 100? 1000?) is ultimately subjective. Thus, it is premature to conclude that weak-scale SUSY is on the verge of exclusion. It might be possible to sharpen the upper bounds on superpartner masses based on naturalness arguments, which ultimately will either confirm or refute the weak-scale SUSY hypothesis [219]. Of course, if evidence for supersymmetric phenomena in the multi-TeV regime were to be established at a future collider facility (with an energy reach beyond the LHC [220]), it would be viewed as a spectacularly successful explanation of the large gauge hierarchy between the (multi-)TeV scale and Planck scale. In this case, the remaining little hierarchy, characterized by the somewhat large value of the fine-tuning parameter Δ discussed above, would be regarded as a less pressing issue.

87.7.2 *Indirect constraints on supersymmetric models*

While direct empirical searches for supersymmetric particles provide various limits on their properties, indirect constraints can depend more sensitively on details of the whole model. The cold dark matter relic density inferred from cosmological fits to observational data is one such example of an indirect constraint. In supersymmetric models where the LSP is stable (and thus is a dark matter candidate), its thermally-produced relic density depends upon the scattering of various supersymmetric particles into dark matter particles and SM particles. The resulting relic density can depend sensitively on the masses of the non-LSP supersymmetric particles as well as on the mass of the LSP. In a typical model, an appreciable region of the parameter space is ruled out because it yields an overabundance of dark matter (see for example Ref. [221] for a fit to a seven parameter version of the pMSSM). However, subsequent tweaks to the supersymmetric model that yield an unstable LSP, such as the introduction of R-parity violating effects, can mean that the relic density no longer constrains the parameter space.

There are a number of indirect constraints based on low-energy measurements that are sensitive to the effects of new physics via supersymmetric loop effects. For example, the virtual exchange of supersymmetric particles can contribute to the muon anomalous magnetic moment, $a_\mu \equiv \frac{1}{2}(g-2)_\mu$, as reviewed in Ref. [222]. A current SM prediction for a_μ [223] uses conventional perturbative calculations, employing lattice QCD calculations for the hadronic vacuum polarisation contribution as well as dispersive methods *and* lattice QCD estimates of the hadronic light-by-light contribution. The resulting prediction displays no significant tension with the experimentally observed value [224]. This is in contrast to previous estimates that relied on dispersive methods for estimating the hadronic vacuum polarization contribution and found a significant deviation between the measured value and the SM prediction (see *e.g.* Ref. [225]).

The precision of the measured value of a_μ is not sensitive to the experimental error associated with the measured value of the fine structure constant, α. In contrast, the comparison of the SM prediction with the experimental measurement of the anomalous magnetic moment of the electron, a_e, depends critically on the value of α. Using the experimentally determined value of α given in Ref. [226] yields a SM prediction for a_e that is 2.4σ above its measured value [227]. However, this previous determination of α is in tension at the 5σ level with a more recent measurement of the fine structure constant [228]. The latter yields a SM prediction for a_e that is 1.6σ below its measured value [228]. Measurements of the fine structure constant, a_e and a_μ jointly constrain the pMSSM parameter space [229] due to shifts originating from supersymmetric loop effects.

Flavor transitions in radiative, leptonic and semi-leptonic b quark decays [230] provide a fertile ground for physics beyond the SM. For example, the rare inclusive decay $b \to s\gamma$ is a sensitive probe of the virtual effects of new physics beyond the SM. The experimental measurements of $B \to X_s + \gamma$ [231] are in agreement with the theoretical SM predictions of Ref. [232]. Since supersymmetric loop corrections can contribute an observable shift from the SM predictions, the absence of any significant deviation places useful constraints on the MSSM parameter space [233].

The rare decays $B_s \to \mu^+\mu^-$ and $B_d \to \mu^+\mu^-$ are especially sensitive to supersymmetric loop effects, with some loop contributions scaling as $\tan^6\beta$ when $\tan\beta \gg 1$ [234]. Since there are no significant deviations observed between the measurements of these rare decay modes [235] and the predicted SM rates [236], constraints on the parameter space of the MSSM can be derived [234].

Several tensions exist between SM predictions and measurements of some other experimental observables that probe $b \to s\mu^+\mu^-$ transitions, although the level of tension depends upon the theoretical treatment of the SM analysis. In a certain angular distribution parameter (denoted by P_5') extracted from $B^0 \to K^{*0}\mu^+\mu^-$ decays, the tension is around the 4σ level [237]. An even larger discrepancy is observed in a combination of angular distributions and rates derived from $B^\pm \to K^\pm\mu^+\mu^-$ and $B^0 \to K^0\mu^+\mu^-$ [238]. Moreover, there is a 3.6σ deviation in the branching ratio of $B_s \to \phi\mu^+\mu^-$ for di-muon invariant mass squared values between 1.1 GeV^2 and 6.0 GeV^2 [239]. Finally, a recent measurement of $B^+ \to K^+\nu\bar{\nu}$ by the Belle II Collaboration [240] obtained a branching fraction that is roughly four times larger than the SM prediction [241], corresponding to a 2.7σ deviation from the SM expectation. However, it is unlikely that this result can be attributed to new contributions from the MSSM [242], as the latter are expected to be negligible in comparison with the SM.

The decays $B^\pm \to \tau^\pm\nu_\tau$ and $\overline{B} \to D^{(*)}\tau^-\overline{\nu}_\tau$ are noteworthy, since in models with extended Higgs sectors such as the MSSM, these processes possess tree-level charged Higgs exchange contributions that can compete with the dominant W-exchange. As Sec. 71 shows, experimental measurements of $B^\pm \to \tau^\pm\nu_\tau$ are currently consistent with SM expectations [243]. The BaBar Collaboration measured values of the rates for $\overline{B} \to D\tau^-\overline{\nu}_\tau$ and $\overline{B} \to D^*\tau^-\overline{\nu}_\tau$ [244] which exhibited a combined 3.4σ discrepancy from the SM predictions, which was also not compatible with the Type-II Higgs Yukawa couplings employed by the MSSM. Subsequent measurements by the LHCb and Belle Collaborations were compatible with the BaBar measurements although they displayed less deviation from the SM expectations. The combined difference between the measured values of the $\overline{B} \to D\tau^-\overline{\nu}_\tau$ and $\overline{B} \to D^*\tau^-\overline{\nu}_\tau$ decay rates relative to the corresponding SM values has a significance of 3.1σ [245].

In summary, although there are a few hints of possible deviations from the SM in B decays, none of the discrepancies by themselves are significant enough to conclusively imply the existence of new physics beyond the SM. Moreover, the absence of evidence for sizable deviations in other B-physics observables from their SM predictions can place useful constraints on the MSSM parameter space [147, 203, 246].

87.7.3 *Standard Model Effective Field Theory and SUSY*

The SM effective field theory (SMEFT) [247] encodes the effects of fields beyond those of the SM under the assumption that the characteristic mass scale Λ associated with the new fields is much higher than the highest energy scale E of some set of experimentally probed observables. The total Lagrangian density is written

$$\mathcal{L} = \mathcal{L}_4 + \sum_{d=5}^{\infty} \sum_i \frac{C_i}{\Lambda^{d-4}} \mathcal{O}_i^{(d)}, \tag{87.40}$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

where $\mathcal{L}_4$ is the usual renormalizable Lagrangian density of the SM, $\mathcal{O}_i^{(d)}$ is an operator of mass dimension d composed of a product of SM fields (and their spacetime derivatives), and the C_i are dimensionless Wilson coefficients. The index i labels independent operators (for an example of an operator basis up to $d = 6$, see Ref. [248]). The summed term of Eq. (87.40) arises from integrating out fields with masses of order Λ (or larger) from the theory. The effects of successively higher-dimension operators on an observable are suppressed by a factor $(E/\Lambda)^{d-4}$. Thus, in a set of SMEFT operators that contribute to an observable, the dominant effects come from those operators with smallest dimension d. Experimental measurements can then be interpreted as bounds on the C_i, provided that no on-shell beyond-the-SM resonances affect the measurements. After electroweak symmetry breaking, the $d = 5$ operators describe neutrino mass terms and so $d = 6$ SMEFT operators are generically the most relevant for collider physics.

Measurements involving SM particles are often interpreted as constraints on the Wilson coefficients of $d = 6$ operators. The MSSM has been matched to the $d = 6$ SMEFT Lagrangian at the one-loop level in Ref. [249]. In principle, the bounds on the C_i obtained from experimental studies can be translated into constraints on the MSSM parameter space.

87.8 Massive neutrinos in weak-scale SUSY

In the minimal version of the SM and its supersymmetric extension, there are no right-handed neutrinos, and Majorana mass terms for the left-handed neutrinos are absent. However, given the overwhelming evidence for neutrino masses and mixing (see Sec. 14 and Ref. [250]), any viable model of the fundamental particles must provide a mechanism for generating neutrino masses [251]. In extended supersymmetric models, various mechanisms exist for producing massive neutrinos [252]. Although one can devise models for generating massive Dirac neutrinos [253], the most common approaches for incorporating neutrino masses are based on L-violating supersymmetric extensions of the MSSM, which generate massive Majorana neutrinos. Two classes of L-violating supersymmetric models will now be considered.

87.8.1 *The supersymmetric seesaw*

Neutrino masses can be incorporated into the SM by introducing SU(3)×SU(2)×U(1) singlet right-handed neutrinos (ν_R) whose mass parameters are very large, typically near the grand unification scale. In addition, one must also include a standard Yukawa couplings between the lepton doublets, the Higgs doublet, and ν_R. The Higgs VEV then induces an off-diagonal ν_L–ν_R mass on the order of the electroweak scale. Diagonalizing the neutrino mass matrix (in the three-generation model) yields three superheavy neutrino states, and three very light neutrino states that are identified with the light neutrinos observed in nature. This is the seesaw mechanism [254].

It is straightforward to construct a supersymmetric generalization of the seesaw model of neutrino masses [255,256] by promoting the right-handed neutrino field to a superfield $\widehat{N}^c = (\widetilde{\nu}_R\,;\,\nu_R)$. Integrating out the heavy right-handed neutrino supermultiplet yields a new term in the superpotential [cf. Eq. (87.1)] of the form

$$W_{\rm seesaw} = \frac{f}{M_R}(\widehat{H}_U\widehat{L})(\widehat{H}_U\widehat{L})\,, \tag{87.41}$$

where M_R is the mass scale of the right-handed neutrino sector and f is a dimensionless constant. Note that lepton number is broken by two units by Eq. (87.41), which implies that R-parity invariance is preserved. The supersymmetric analogue of the Majorana neutrino mass term in the sneutrino sector leads to sneutrino–antisneutrino mixing phenomena [256, 257]. In addition, new Higgs-slepton interaction terms can probe the structure of the supersymmetric seesaw model [258]. The right-handed sneutrino that resides in $\widehat{N}^c$ also provides an intriguing dark matter candidate [259].

The SUSY Les Houches Accord [81,99], mentioned at the end of the introduction to Sec. 87.4, has been extended to the supersymmetric seesaw (and other extensions of the MSSM) in Ref. [260].

87.8.2 *R-parity-violating SUSY*

It is possible to incorporate massive neutrinos in renormalizable supersymmetric models while retaining the minimal particle content of the MSSM by relaxing the assumption of R-parity invariance. The most general R-parity-violating model involving the MSSM spectrum introduces many new parameters to both the SUSY-conserving and the SUSY-breaking sectors [81, 261]. Each new interaction term violates either B or L conservation. For example, starting from the MSSM superpotential given in Eq. (87.1) [suitably generalized to three generations of quarks, leptons and their superpartners], consider the effect of adding the following new terms:

$$\begin{aligned} W_{\rm RPV} =& (\lambda_L)_{pmn}\widehat{L}_p\widehat{L}_m\widehat{E}^c_n + (\lambda'_L)_{pmn}\widehat{L}_p\widehat{Q}_m\widehat{D}^c_n \\ &+ (\lambda_B)_{pmn}\widehat{U}^c_p\widehat{D}^c_m\widehat{D}^c_n + (\mu_L)_p\widehat{H}_u\widehat{L}_p\,, \end{aligned} \tag{87.42}$$

where p, m, and n are generation indices, and gauge group indices are suppressed. Eq. (87.42) yields new scalar-fermion Yukawa couplings consisting of all possible combinations involving two SM fermions and one scalar superpartner. Note that the term in Eq. (87.42) proportional to λ_B violates B, while the other three terms violate L. The L-violating term in Eq. (87.42) proportional to μ_L is the RPV analog of the $\mu\widehat{H}_u\widehat{H}_d$ term of the MSSM superpotential, in which the $Y = -1$ Higgs/higgsino supermultiplet $\widehat{H}_d$ is replaced by the slepton/lepton supermultiplet $\widehat{L}_p$.

Phenomenological constraints derived from data on various low-energy B- and L-violating processes can be used to establish limits on each of the coefficients $(\lambda_L)_{pmn}$, $(\lambda'_L)_{pmn}$, and $(\lambda_B)_{pmn}$ taken one at a time [261, 262]. If more than one coefficient is simultaneously non-zero, then the limits are in general more complicated [263]. All possible RPV terms cannot be simultaneously present and unsuppressed; otherwise the proton decay rate would be many orders of magnitude larger than the present experimental bound. One way to avoid proton decay is to impose B or L invariance (either one alone would suffice). Otherwise, one must accept the requirement that certain RPV coefficients must be extremely suppressed.

One particularly interesting class of RPV models is one in which B is conserved, but L is violated. It is possible to enforce baryon number conservation (and the stability of the proton), while allowing for lepton-number-violating interactions by imposing a discrete $\mathbb{Z}_3$ baryon triality symmetry on the low-energy theory [264], in place of the standard $\mathbb{Z}_2$ R-parity. Since the distinction between the Higgs and matter supermultiplets is lost in RPV models where L is violated, the mixing of sleptons and Higgs bosons, the mixing of neutrinos and neutralinos, and the mixing of charged leptons and charginos are now possible, leading to more complicated mass matrices and mass eigenstates than in the MSSM. The treatment of neutrino masses and mixing in this framework can be found, *e.g.*, in Ref. [265].

Alternatively, one can consider imposing a lepton parity such that all lepton superfields are odd [264, 266]. In this case, only the B-violating term in Eq. (87.42) survives, and L is conserved. Models of this type have been considered in Ref. [267]. Since L is conserved in these models, the mixing of the lepton and Higgs superfields is forbidden. Moreover, neutrino masses (and mixing) are not generated if lepton parity is an exact symmetry. However, one expects that lepton parity cannot be exact due to quantum gravity effects. Remarkably, the standard $\mathbb{Z}_2$ R-parity and the $\mathbb{Z}_3$ baryon triality are stable with respect to quantum gravity effects, as they can be identified as residual discrete symmetries that arise from spontaneously broken non-anomalous gauge symmetries [264]. The symmetries employed above to either remove or suppress R-parity violating operators were flavor independent. In contrast, there exist a number of motivated scenarios based on flavor symmetries that can also yield the suppression as required by the experimental data (*e.g.*, see Ref. [268]).

The supersymmetric phenomenology of the RPV models exhibits features that are distinct from that of the MSSM [261]. The LSP is no longer stable, which implies that not all supersymmetric decay chains must yield missing-energy events at colliders. A comprehensive examination of the phenomenology of the MSSM extended by a single R-parity violating coupling at the unifica-

tion scale and its implications for LHC searches has been given in Ref. [269]. As an example, the sparticle mass bounds obtained in searches for R-parity-conserving SUSY can be considerably relaxed in certain RPV models due to the absence of large missing transverse momentum signatures [270]. This can alleviate some of the tension with naturalness (discussed in Sec. 87.7.1).

Nevertheless, the loss of the missing-energy signature is often compensated by other striking signals (which depend on which R-parity-violating terms are dominant). For example, supersymmetric particles in RPV models can be singly produced (in contrast to R-parity-conserving models where supersymmetric particles must be produced in pairs). The phenomenology of pair-produced supersymmetric particles is also modified in RPV models due to new decay chains not present in R-parity-conserving SUSY models [261].

In RPV models with lepton number violation (these include weak-scale SUSY models with baryon triality mentioned above), both $\Delta L = 1$ and $\Delta L = 2$ phenomena are allowed, leading to neutrino masses and mixing [271], neutrinoless double-beta decay [272], sneutrino-antisneutrino mixing [273], and resonant s-channel production of sneutrinos in e^+e^- collisions [274] and in charged sleptons in $p\bar{p}$ and pp collisions [275], respectively.

87.9 Extensions beyond the MSSM

In addition to possible extensions of the MSSM to incorporate massive neutrinos discussed in Sec. 87.8, there are numerous reasons for considering more general extensions of the MSSM [37]. Possible extensions include an enlarged electroweak gauge group beyond SU(2)×U(1) [107,276,277], the addition of new Higgs supermultiplets beyond the doublets and singlets of the MSSM/NMSSM [278], and/or the addition of new (possibly exotic) matter supermultiplets [216, 279, 280] such as vector-like fermions and their superpartners or adjoint chiral superfields [281,282].

In this final Section, we shall briefly focus on extensions of the MSSM that have been proposed to solve specific theoretical problems associated with the MSSM.

87.9.1 *The origin of the μ parameter*

In the MSSM, the parameter μ that appears in Eq. (87.1) is a SUSY-*preserving* parameter. However, its magnitude must be of order the effective SUSY-breaking scale of the MSSM to yield a consistent supersymmetric phenomenology [283]. Any natural solution to the so-called μ-problem must incorporate a symmetry that enforces $\mu = 0$ and a small symmetry-breaking parameter that generates a value of μ that is not parametrically larger than the effective SUSY-breaking scale [284]. A number of proposed mechanisms in the literature (*e.g.*, see Ref. [283–285]) provide concrete examples of a natural solution to the μ-problem of the MSSM.

In extensions of the MSSM, other compelling solutions to the μ-problem are possible. For example, one can replace μ by the VEV of a new SU(3)×SU(2)×U(1) singlet scalar field, as noted below Eq. (87.25). This is the NMSSM, which yields phenomena that were briefly discussed in Sections 87.4–87.7. The NMSSM superpotential consists only of trilinear terms whose coefficients are dimensionless. One can also extend the NMSSM further to the so-called USSM [107] by adding a new broken U(1) gauge symmetry [286], under which the singlet field is charged.

Alternatively, one can consider a generalized version of the NMSSM (called the GNMSSM in Ref. [215]), where all possible renormalizable terms in the superpotential are allowed, which yield new supersymmetric mass terms (analogous to the μ term of the MSSM). A discussion of the parameters of the GNMSSM can be found in Ref. [81]. Although the GNMSSM does not solve the μ-problem, it does exhibit regions of parameter space in which the degree of fine-tuning is relaxed, as mentioned in Sec. 87.7.1.

The generation of the μ-term may be connected with the solution to the strong CP problem [287]. Models of this type, which include new gauge singlet fields that are charged under the Peccei-Quinn (PQ) symmetry [288], were first proposed in Ref. [283]. The breaking of the PQ symmetry is thus intimately tied to SUSY breaking, while naturally yielding a value of μ that is of order the electroweak symmetry breaking scale [289].

87.9.2 *Dirac gauginos*

The MSSM and its extensions considered so far in this review contain self-conjugate fermions—the Majorana gluinos and neutralinos. The possibility of Dirac gluinos and neutralinos arises if the R-parity of the supersymmetric model is promoted to a continuous $U(1)_R$ symmetry. In the MSSM, this could be (partially) achieved by setting the supersymmetry-conserving higgsino mass parameter μ and the supersymmetry-breaking gaugino Majorana mass parameters M_i $(i = 1, 2, 3)$ and A-parameters to zero. The resulting spectrum features a massless gluino and a pair of massive Dirac neutralinos whose masses are generated at the tree-level and at the one-loop level, respectively [40].

The mass spectrum of gluinos/neutralinos quoted above is not phenomenologically viable. Nevertheless, one can devise more realistic models by expanding the MSSM to include additional chiral superfields in the adjoint representation (*e.g.*, a color octet chiral superfield), while still respecting the $U(1)_R$ symmetry. The spin-1/2 components of the adjoint chiral superfields can pair up with the gauginos to form Dirac gauginos [39,40,281,282]. Such states appear in models of so-called supersoft SUSY breaking [290] and in some generalized GMSB models [281, 291]. Moreover, by introducing additional Higgs supermultiplets while maintaining the $U(1)_R$ symmetry, the spin-1/2 components of these new superfields can pair up with the neutral higgsino states of the MSSM to form Dirac neutralinos [292]. Various scenarios, often referred to as constrained minimal Dirac gaugino supersymmetric models, have been proposed and analyzed in Refs. [292, 293].

The phenomenology of models with Dirac gauginos can be quite distinct from that of the MSSM, as noted in Ref. [294]. Moreover, such models can lead to significantly relaxed flavor constraints [292]. In particular, the higher mass scale of the gauginos and their Dirac nature lead to suppressed colored sparticle production at the LHC [295]. The implications of models of Dirac gauginos for the properties of the observed Higgs boson and possibilities for improved naturalness are addressed in Ref. [296].

88. Supersymmetry, Part II (Experiment)

Revised August 2025 by M. D'Onofrio (Liverpool U.) and F. Moortgat (CERN; Ghent U.).

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

88.1 Introduction

Supersymmetry (SUSY), a transformation relating fermions to bosons and vice versa [1–9] is one of the most compelling possible extensions of the Standard Model of particle physics (SM).

On theoretical grounds SUSY is motivated as a generalization of space-time symmetries. A low-energy realization of SUSY, *i.e.*, SUSY at the TeV scale, is, however, not a necessary consequence. Instead, low-energy SUSY is motivated by the possible cancellation of quadratic divergences in radiative corrections to the Higgs boson mass [10–15]. Furthermore, it is intriguing that a weakly interacting, (meta)stable supersymmetric particle might make up some or all of the dark matter in the Universe [16–18]. In addition, SUSY GUTs predicts that gauge couplings, as measured experimentally at the electroweak scale, unify at an energy scale $\mathcal{O}(10^{16})$ GeV ("GUT scale") near the Planck scale [19–25].

In the minimal supersymmetric extension to the Standard Model, the so called MSSM [11, 26, 27], a supersymmetry transformation relates every chiral fermion and gauge boson in the SM to a supersymmetric partner with half a unit of spin difference, but otherwise with the same properties (such as mass) and quantum numbers. The MSSM Higgs sector contains two doublets, which give mass to the up-type and down-type quarks, respectively. After electroweak symmetry breaking, five Higgs bosons arise, of which two are charged. The supersymmetric partners of chiral fermions are squarks ($\tilde{q}$) and sleptons ($\tilde{\ell}$, $\tilde{\nu}$), and the "gauginos" for gauge bosons. The supersymmetric partners of the Higgs doublets are known as "higgsinos." The weak gauginos and higgsinos mix, giving rise to charged mass eigenstates called "charginos" ($\tilde{\chi}^{\pm}$), and neutral mass eigenstates called "neutralinos" ($\tilde{\chi}^0$). These are often collectively referred to as electroweakinos (EWkinos). The SUSY partners of the gluons are known as "gluinos" ($\tilde{g}$). The fact that such particles are not yet observed leads to the conclusion that, if supersymmetry is realized, it is a broken symmetry. A description of broken SUSY in the form of an effective Lagrangian with only "soft" SUSY breaking terms maintains the cancellation of quadratic divergences and furthermore if the SUSY particle masses are of order TeV, removes the need for large cancellations in the predicted Higgs vacuum expectation value.

The phenomenology of the MSSM is to a large extent defined by the interactions that bring SUSY breaking from the SUSY breaking sector to the MSSM, as well as the SUSY breaking scale. These determine the SUSY particle masses, the mass hierarchy, the field contents of physical particles, and their decay modes. In addition, phenomenology crucially depends on whether the multiplicative quantum number of R-parity [27], $R = (-1)^{3(B-L)+2S}$, where B and L are baryon and lepton numbers and S is the spin, is conserved or violated. If R-parity is conserved, SUSY particles (sparticles), which have odd R-parity, are produced in pairs and the decays of each SUSY particle must involve an odd number of lighter SUSY particles. The lightest SUSY particle (LSP) is then stable and often assumed to be a weakly interacting massive particle (WIMP). If R-parity is violated, new terms λ_{ijk}, λ'_{ijk} and λ''_{ijk} appear in the superpotential, where ijk are generation indices; λ-type couplings appear between lepton superfields only, λ''-type are between quark superfields only, and λ'-type couplings connect the two. R-parity violation implies lepton and/or baryon number violation. More details of the theoretical framework of SUSY are discussed elsewhere in this volume [28].

The discovery of a Higgs boson with a mass around 125 GeV imposes constraints on SUSY models, which are discussed in Section 87. Low-energy data from flavor physics experiments, high-precision electroweak observables as well as astrophysical data also impose strong constraints on the allowed SUSY parameter space. Recent examples of such data include measurements of the rare B-meson decay $B_s \to \mu^+\mu^-$ [29–31], measurements of the anomalous magnetic moment of the muon [32, 33], and accurate determinations of the cosmological dark matter relic density constraint [34, 35].

Indirect constraints can be more sensitive to higher SUSY mass scales than experiments searching for direct sparticle production at colliders, but the interpretation of these results is often strongly model dependent. In contrast, direct searches for sparticle production at collider experiments, which are the main topic of this review, are less subject to interpretation ambiguities and therefore they play a crucial role in the search for SUSY. Further discussion on indirect constraints can be found in 87.7.2.

88.2 Overview of the experimental search programme

The electron-positron collider LEP was operational at CERN between 1989 and 2000. In the initial phase, center-of-mass energies around the Z-peak were probed, but after 1995 the LEP experiments collected a significant amount of luminosity at higher center-of-mass energies, some 235 pb^{-1} per experiment at $\sqrt{s} \geq 204$ GeV, with a maximum $\sqrt{s}$ of 209 GeV. Searches for new physics at e^+e^- colliders benefit from the clean experimental environment and the fact that the initial state four-momentum is precisely known. This allows momentum balance to be exploited not only in the plane transverse to the beam but also along the beam direction (up to the small effects of beamstrahlung and the beam pipe holes). In contrast, at hadron colliders only the transverse momentum balance can be used, since the longitudinal momentum of the initial partons is not known on an event-by-event basis. Searches at LEP are dominated by the data samples taken at the highest center-of-mass energies.

The CDF and D0 experiments at the Tevatron, a proton-antiproton collider at a center-of-mass energy of up to 1.96 TeV, had an extensive search program for supersymmetric particles. CDF and D0 collected integrated luminosities between 10 and 11 fb^{-1} each up to the end of collider operations in 2011.

The electron-proton collider HERA provided collisions to the H1 and ZEUS experiments between 1992 and 2007, at a center-of-mass energy up to 318 GeV. A total integrated luminosity of approximately 0.5 fb^{-1} was collected by each experiment. At HERA, SUSY searches focused on R-parity violating processes mediated by λ' couplings, which allow resonant production of single squarks in electron–quark interactions.

The Large Hadron Collider (LHC) at CERN started proton-proton operation at a center-of-mass energy of 7 TeV in 2010. By the end of 2011 the ATLAS and CMS experiments had collected about 5 fb^{-1} of integrated luminosity each, and the LHCb experiment had collected approximately 1 fb^{-1}. In 2012, the LHC operated at a center-of-mass energy of 8 TeV, and ATLAS and CMS collected approximately 20 fb^{-1} each, whereas LHCb collected 2 fb^{-1}. In 2015, the LHC started Run 2, with a center-of-mass energy of 13 TeV. At the end of Run 2 in November 2018, ATLAS and CMS had both collected approximately 140 fb^{-1}, and LHCb had collected almost 6 fb^{-1}. The Run 3 of the LHC started in July 2022 with a center-of-mass energy of 13.6 TeV. Almost 240 fb^{-1} of data have been collected by ATLAS and CMS at the time of writing (August 2025), and LHCb collected around 90 fb^{-1}.

At the LHC, cross sections of QCD-mediated processes are the largest achievable at colliders, which is reflected in the higher sensitivity for SUSY particles carrying color charge, squarks and gluinos, with respect to LEP, Tevatron and HERA. In particular, proton-proton collisions at the LHC differ from proton-antiproton collisions at the Tevatron as there are no valence anti-quarks in the proton, and that gluon-initiated processes play a more dominant role. The increased center-of-mass energy of the LHC compared to the Tevatron significantly extends the kinematic reach for SUSY searches. This is reflected foremost in the sensitivity for squarks and gluinos, but also for SUSY particles produced via electroweak processes.

In this review we report results of direct searches for SUSY particles at colliders up to August 2023, mostly covering data analyses at the ATLAS and CMS experiments with reference to results from LEP, HERA and the Tevatron. For more details on LEP and Tevatron constraints, see earlier PDG reviews [36]. Analyses on the Run 3 datasets are still in progress hence the results reported for ATLAS and CMS are moslty based on Run 2 data. Results are categorized depending on the targeted SUSY

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

particles, the nature of their production and decays, and the assumption on R-parity. Brief summaries of search techniques and approaches adopted for interpretation of the results are given in Section 88.3 and 88.4, respectively. Sections 88.5-88.8 focus on results for promptly-decaying gluinos and first and second generation squarks, top and bottom squarks, electroweakinos (charginos, neutralinos) and sleptons. Limits obtained for sparticle masses assuming R-parity violating models are also reported. Results of dedicated searches for long-lived (LL) SUSY particles are reported in Section 88.9. Finally, Section 88.10 provides examples of global reinterpretations of SUSY searches.

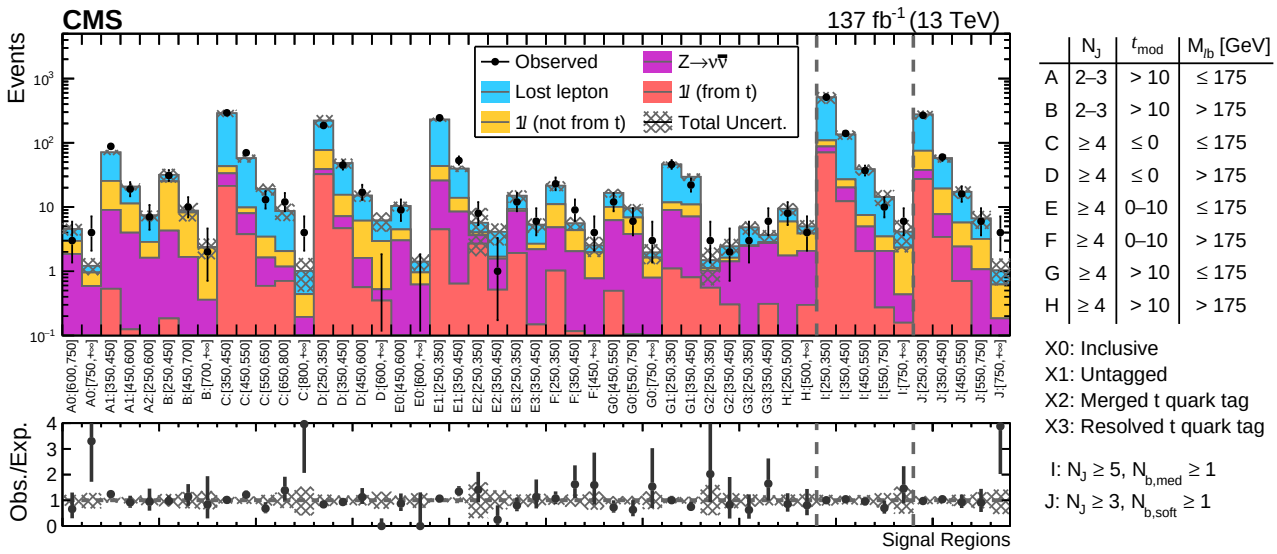
88.3 Experimental search techniques

Large background contributions from Standard Model processes pose challenges to the trigger and analysis. Such backgrounds are dominated by multijet production processes, including, particularly at the LHC, those of top quark production, as well as jet production in association with vector bosons. The proton's momentum is shared between its parton constituents, and in each collision only a fraction of the total center-of-mass energy is available in the hard parton-parton scattering. Since the parton momenta in the longitudinal direction are not known on an event-by-event basis, use of momentum conservation constraints in an analysis is restricted to the transverse plane, leading to the definition of transverse variables, such as the missing transverse momentum, and the transverse mass.

Under the assumption of R-parity conservation (RPC), the typical SUSY search signature for squarks and gluinos at hadron colliders contains high-p_{T} jets, which are produced in the decay chains of heavy squarks and gluinos, and significant missing transverse momentum originating from the two LSPs produced at the end of the decay chains, which escape experimental detection. Electroweakino decays are often characterised by the presence of leptons, for instance from W and Z bosons in the decay chain, plus missing transverse momentum. Standard Model backgrounds with missing transverse momentum include leptonic W/Z-boson decays, associated production of jets and a Z-boson decaying into neutrinos, semi-leptonic heavy-flavor decays to neutrinos, top-quark pair production with one or both W bosons decaying leptonically, and multijet events that may be affected by instrumental effects such as jet mis-measurement.

Selection variables designed to separate the SUSY signal from the Standard Model backgrounds include transverse variables such as H_{T}, $E_{\mathrm{T}}^{\mathrm{miss}}$, and m_{eff}. The quantities H_{T} and $E_{\mathrm{T}}^{\mathrm{miss}}$ refer to the measured transverse energy and the missing transverse momentum in the event, respectively. They are usually defined as the scalar sum of the transverse jet momenta or of the transverse energies of calorimeter clusters measured in the event (H_{T}), or the magnitude ($E_{\mathrm{T}}^{\mathrm{miss}}$) of the negative vector sum of transverse momenta of reconstructed objects like jets and leptons in the event ($\vec{p}_{\mathrm{T}}^{\,\mathrm{miss}}$). The quantity m_{eff} is referred to as the effective mass of the event and is defined as $m_{\mathrm{eff}} = H_{\mathrm{T}} + E_{\mathrm{T}}^{\mathrm{miss}}$. The peak of the m_{eff} distribution for SUSY signal events correlates with the SUSY mass scale, in particular with the produced sparticle masses and the mass difference between the primary produced SUSY particle and the LSP [37], whereas the Standard Model backgrounds dominate at low m_{eff}. An additional reduction of multijet backgrounds can be achieved by demanding isolated leptons or photons in the final states; in such events the lepton or photon transverse momentum may be added to H_{T} or m_{eff} for further signal-background separation. Other kinematic variables and approaches developed to increase the sensitivity to pair production of heavy sparticles with TeV-scale masses focusing on the kinematics of their decays are the α_{T} [38–42], *razor* [43], *stransverse mass* (m_{T2}) [44], and *contransverse mass* (m_{CT}) [45] variables. The *super-razor* [46] and *recursive jigsaw reconstruction* [47] techniques are topological event reconstruction methods also used in searches for sparticles with masses in the TeV-range. In case massive, unstable SM particles such as top quarks, vector bosons or the Higgs boson arise in the decay chain, dedicated procedures are employed for their reconstruction and identification. If these are produced with a significant boost, their decay products will typically overlap and become collimated (boosted) in the direction of the parent particle. Their hadronic decay products can be reconstructed as a single large-radius jet (see studies from ATLAS [48]), and *jet-substructure* [49] techniques can be adopted. Machine-learning (ML) approaches are also used to identify and classify hadronic decays of highly Lorentz-boosted bosons and top quarks, see as example recent studies from CMS [50].

Until recently, analyses used simple combinations of selections on kinematic variables (often referred to as *cut-and-count* analyses) and exploited multiple signal regions defined by categorizing events on the basis of several variables and their correlations. An example is provided in Fig. 88.1 from Ref. [51]: 39 signal regions are set to search for top squarks in events with one lepton, jets and missing transverse momentum. Regions depend on jet multiplicities, reconstructed top-quark candidates and thresholds applied to the most discriminant variables used for optimisation.



At present, shape analyses or analyses using more sophisticated techniques, e.g. machine learning, are being developed more and more often. ML techniques allow analyses to better capture the complexity of the events and achieve improved sensitivity with respect to counting experiments. For example, Boosted Decision Trees (BDTs) allow analyses to exploit simultaneously the discriminating power of multiple variables and that of correlations among objects in the events. Deep Neural Networks (NN) are also employed for object reconstruction and to use directly detector-recorded energies and momenta of produced particles instead of first deriving a restricted set of physical variables. Among others, currently in use are Convolutional NN for image classification techniques, Recurrent NN, parametric NN, Graph NN and Generative Adversarial Networks.

Variables and approaches reported above are also used in searches for R-parity violating (RPV) SUSY models where signal events are often characterised by the presence of multiple leptons and/or jets, and little or no missing transverse momentum. However, if R-parity violating couplings are small, sparticles might be long-lived and may travel macroscopic distances before decaying. Similarly, long lifetimes may be due to small mass splittings, as in the case of pure higgsino/wino scenarios, or to heavy mediators, as in Split SUSY models [52, 53]. The identification of long-lived particles requires dedicated tools and their signatures can be very diverse. At the LHC, customized techniques (also based on NN) have been developed, for example, to reconstruct significantly displaced decay vertices or short track segments, and to identify tracks with atypical properties or unusual ionization, small and localized deposits of energy inside of the calorimeters without associated tracks, or stopped particles that decay out of time with collisions. For an overview, see Ref. [54].

88.4 Interpretation of search results

Since the mechanism by which SUSY is broken is unknown, a general approach to SUSY via the most general soft SUSY breaking Lagrangian adds a significant number of new free parameters. For the minimal supersymmetric standard model, MSSM, *i.e.*, the model with the minimal particle content, these comprise 105 new real degrees of freedom. A phenomenological analysis of SUSY searches leaving all these parameters free is not feasible. For the practical interpretation of SUSY searches at colliders several approaches are taken to reduce the number of free parameters.

One approach is to assume a SUSY breaking mechanism and lower the number of free parameters through the assumption of additional constraints. Before the start of the LHC, interpretations of experimental results were often performed in constrained models of gravity mediated [55, 56], gauge-mediated [57–59], and anomaly mediated [60, 61] SUSY breaking. The most popular model was the constrained MSSM (CMSSM) [55, 62, 63], which in the literature is also referred to as minimal supergravity, or MSUGRA. These constrained SUSY models are theoretically well motivated and provide a rich spectrum of experimental signatures. However, with universality relations imposed on the soft SUSY breaking parameters, they do not cover all possible kinematic signatures and mass relations of SUSY. Furthermore, the Higgs mass measurement from LHC Run 1, together with other collider and non-collider measurements, substantially limits the allowed SUSY parameter space for these models. This indicates that very constrained models like the CMSSM are no longer good benchmark

scenarios to solely characterize the results of SUSY searches at the LHC and efforts have been made to complement them with more flexible approaches.

A broader and more comprehensive subset of the MSSM can be studied via the so-called phenomenological-MSSM, or pMSSM [64–67]. It is derived from the MSSM, using experimental data to eliminate parameters that are free in principle but have already been highly constrained by measurements of *e.g.*, flavor mixing and CP-violation. This effective approach reduces the number of free parameters in the MSSM to typically 19 or even less, making it a practical compromise between the full MSSM and highly constrained models such as the CMSSM.

Even less dependent on fundamental assumptions are interpretations in terms of so-called simplified models [68–71]. Such models assume a limited set of SUSY particle production and decay modes and leave open the possibility to vary masses and other parameters freely. Therefore, simplified models enable comprehensive studies of individual SUSY topologies, and are useful for optimization of the experimental searches over a wide parameter space without limitations on fundamental kinematic properties such as masses and decay modes.

As a consequence, ATLAS and CMS have adopted simplified models as the primary framework to provide interpretations of their searches. In addition to using simplified models that describe prompt decays of SUSY particles, the experiments are now also focusing more on the use of simplified models that allow for decays of long-lived SUSY particles as they can arise in different SUSY scenarios (see Section 88.9 for further discussion). Today, almost every individual search provides interpretations of their results in one or several simplified models that are characteristic of SUSY topologies probed by the analysis.

While simplified models are very convenient for the interpretation of individual SUSY production and decay topologies, care must be taken when applying these limits to more complex SUSY spectra. In particular, the branching ratio of SUSY particles into a specific final state is often assumed to be 100% and in many

of the quoted limits the LSP is assumed to be massless. Therefore, simplified model limits should be seen as an approximation of the constraints that can be placed on sparticle masses in more complex SUSY spectra. Only on a case-by-case basis can it be determined whether the limit of a given simplified model represents a good approximation of the true underlying constraint that can be applied on a sparticle mass in a complex SUSY spectrum. In the following, we will point out explicitly the assumptions that have entered the limits when quoting interpretations from simplified models.

Since none of the searches performed so far have shown significant excess above the SM background prediction, the interpretations of the presented results are exclusion limits on SUSY parameter space. Unless stated differently, all quoted exclusion limits are at the 95% confidence level. Finally, we note that many of the recent publications by ATLAS and CMS also present results in terms of model-independent limits such that their discovery potential is statistically quantified independently on a particular model.

88.5 Exclusion limits on gluino, first and second generation squark masses in RPC scenarios

Colored SUSY particles such as squarks and gluinos are produced via the strong interaction and have the highest cross sections at hadron colliders. Limits on squark masses of the order 100 GeV have been set by the LEP experiments [72], in the decay to quark plus neutralino, and for a mass difference between squark and quark plus neutralino of typically at least a few GeV. However, hadron collider experiments are able to set much more stringent mass limits.

The main production mechanisms at hadron colliders are squark-squark, squark-gluino and gluino-gluino production; when "squark" is used "antisquark" is also implied. Pair production usually involves both the s-channel and t-channel parton-parton interactions. However, since there is a negligible amount of bottom and top quark content in the proton, top and bottom squark production proceeds through s-channel diagrams only. Experimental analyses of squark and/or gluino production typically assume the first and second generation squarks to be approximately degenerate in mass. Cross section calculations at the center-of-mass energy of 13 TeV shown in Fig. 88.2 (from Ref. [73]) assume mass degeneracy of left- and right-handed u, d, s, c squarks. Other sparticle masses are considered decoupled, *i.e.* their masses are assumed to have a very high value (above or of the order of 10 TeV). The LHC experiments also provide simplified model limits on individual first or second generation squarks. Top and bottom squarks have the same production cross section, identical to that of a single light squark.

In this section, we focus on results assuming R-parity conservation. Limits set by the Tevatron experiments on the gluino mass assume the framework of the CMSSM, with $\tan\beta = 5$ (CDF) or $\tan\beta = 3$ (D0). Furthermore, the common trilinear term A_0 is set to 0 and the higgsino mass term μ is assumed to be less than 0. The resulting lower mass limits are about 310 GeV for all squark masses, or 390 GeV for the case $m_{\tilde{q}} = m_{\tilde{g}}$ [74, 75].

ATLAS and CMS limits on the gluino mass have been established in the framework of simplified models. Assuming only gluino pair production, three main primary decay chains of the gluino have been considered by the LHC experiments for interpretations of their search results. The first decay chain, $\tilde{g} \to q\bar{q}\tilde{\chi}_1^0$, assumes gluino mediated production of first and second generation squarks (on-shell or off-shell) which leads to four light flavor quarks in the final state. Therefore, inclusive all-hadronic analyses searching for multijet plus $E_{\mathrm{T}}^{\mathrm{miss}}$ final states are utilized to put limits on this simplified model. These limits are derived as a function of the gluino and neutralino (LSP) mass. As shown in Fig. 88.3 (left)the CMS collaboration [76] excludes in this simplified model gluino masses below approximately 2.1 TeV for a light neutralino mass below about 600 GeV. In scenarios where neutralinos are not very light, the efficiency of the analyses is reduced by the fact that jets are less energetic, and there is less missing transverse momentum in the event. This leads to weaker limits when the mass difference $\Delta m = m_{\tilde{g}} - m_{\tilde{\chi}_1^0}$ is reduced. For example, for neutralino masses above about 1.2 TeV no limit on the gluino mass can be set for this decay chain. Therefore, limits on gluino masses are strongly affected by the assumption of the neutralino mass. Similar results for this simplified model have been obtained by ATLAS [77]. A second simplified model postulates a decay chain where $\tilde{g} \to q\bar{q}W\tilde{\chi}_1^0$, assuming that the intermediate (on-shell or off-shell) squark is left-handed and decays to a chargino and a quark, with the chargino decaying to a W boson and the LSP. This leads to two W bosons and four light flavor quarks plus $E_{\mathrm{T}}^{\mathrm{miss}}$ in the final state. Both leptonic and hadronic decays of the W can be considered. In this scenario, the ATLAS collaboration [78, 79] excludes gluino masses below approximately 2.2 TeV for a sufficiently light neutralino and assuming the chargino mass is halfway between the gluino and neutralino mass, see Fig. 88.3 (right). Again, for neutralino masses above about 1.2 TeV, there exists no limit on the gluino mass for this decay chain. A similar reach has been obtained by the CMS collaboration [80, 80, 81], where the most recent results are obtained using novel algorithms based on deep neutral networks that identify hadronically decaying W bosons.

Gluino decays are not limited to first and second generation squarks: another important decay chain of the gluino considered for interpretation in simplified models is $\tilde{g} \to b\bar{b}\tilde{\chi}_1^0$. In this case the decay is mediated via bottom squarks and thus leads to four jets originating from b-quarks and $E_{\mathrm{T}}^{\mathrm{miss}}$ in the final state. For this topology as well, inclusive all-hadronic searches provide the highest sensitivity. In this case, the use of secondary vertex reconstruction for the identification of jets originating from the b-quarks in the event provides a powerful handle to reject SM background contributions. Therefore, in addition to a multijet plus $E_{\mathrm{T}}^{\mathrm{miss}}$ signature these searches also require between 1 and 4 jets to be tagged as b-jets. As shown in Fig. 88.4 (left), for this simplified model CMS [76] excludes gluino masses below ≈ 2.3 TeV for a sufficiently light neutralino, while for neutralino masses above ≈ 1.5 TeV no limit on the gluino mass can be set. Comparable limits for this simplified model are provided by searches from ATLAS [82, 83], with the most recent results pushing the boundary of gluino masses to 2.44 TeV in the case of a massless neutralino.

If kinematically allowed, decays of gluinos to top squarks via $\tilde{g} \to \tilde{t}t$ are also possible. This defines the next important simplified model characterizing gluino pair production, $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$, which leads to a "four tops" final state, $ttttt\tilde{\chi}_1^0\tilde{\chi}_1^0$. The topology of this decay is very rich in different experimental signatures: as many as four isolated leptons, four b-jets, as many as eight light flavor quark jets, and significant missing transverse momentum from the neutrinos in the W decay and from the two neutralinos. As shown in Fig. 88.4 (right), the ATLAS search [82] rules out gluinos with masses below ≈ 2.4 TeV for light neutralinos in this model. For neutralino masses above ≈ 1.4 TeV, no limit can be placed on the gluino mass. Sensitivity is also achieved in case of gluino pairs with an off-shell top quark in the decay.

The CMS multiple b-jet search [84] and the search in full-hadronic events using identification techniques for boosted top-quarks in the final state [85] result in gluino mass limits of ≈ 2.3 TeV.

Assuming gluinos to be heavier than squarks, squarks will predominantly decay to a quark and a neutralino or chargino, if kinematically allowed. The decay may involve the lightest neutralino (typically the LSP) or chargino, but, depending on the masses and couplings of the gauginos and on the handedness of the squarks, may involve heavier neutralinos or charginos. For pair production of first and second generation squarks, the simplest decay modes involve two jets and missing transverse momentum, with potential extra jets stemming from initial state or final state radiation (ISR/FSR) or from decay modes with longer decay chains (cascades). In cascades, isolated photons or leptons may appear from the decays of sparticles such as neutralinos or charginos.

Limits on first and second generation squark masses set by the Tevatron experiments assume the CMSSM, and amount to lower limits of about 380 GeV for all gluino masses, or 390 GeV for the case $m_{\tilde{q}} = m_{\tilde{g}}$ [74, 75]. At the LHC, limits on squark masses have

been set using up to approximately 140 fb^{-1} of data at 13 TeV. Interpretations in simplified models typically characterize squark pair production considering only one decay chain at the time for the squark, for instance $\tilde{q} \to q\tilde{\chi}_1^0$. It is usually assumed that the left and right-handed $\tilde{u}$, $\tilde{d}$, $\tilde{s}$ and $\tilde{c}$ squarks are degenerate in mass. Furthermore, it is assumed that the mass of the gluino is very high (above or order of 10 TeV) and thus contributions of the corresponding t-channel diagrams to squark pair production are negligible. Therefore, the total production cross section for this simplified model is eight times the production cross section of an individual squark (e.g. $\tilde{u}_L$). Under these assumptions, CMS obtains a lower squark mass limit of ≈ 1.75 TeV for light neutralinos [84], as shown in Fig. 88.5 (left). Only for neutralino masses below ≈ 800 GeV can any squark masses be excluded. Searches for new physics in monojet channels are sensitive to very compressed scenarios, and masses up to 900 GeV are excluded for $\Delta m = m_{\tilde{q}}, m_{\tilde{\chi}_1^0} \approx 5$ GeV [86].

If the assumption of mass degenerate first and second generation squarks is dropped and only the production of a single light squark is assumed, the limits weaken significantly. For example, the CMS limit on degenerate squarks of 1750 GeV for light neutralinos drops to ≈ 1300 GeV for pair production of a single light squark, and for neutralinos heavier than ≈ 600 GeV no squark mass limit can be placed. It should be noted that this limit is not a result of a simple scaling of the above mentioned mass limits assuming eight-fold mass degeneracy but it also takes into account that for an eight times lower production cross section the analyses must probe kinematic regions of phase space that are closer to the ones of SM background production.

A summary of results of the ATLAS searches also targeting more complicated decay chains, where e.g. intermediate bosons are produced as well, can be seen in Fig. 88.5 (right). Depending on the topology, the exclusion limit can reach up to ≈ 2 TeV (this value is only reached in gaugino-mediated simplified models [87]). Recent results include a search in two-opposite-sign, same-flavor dilepton final state events [88] targeting squarks decaying through the next-to-lightest neutralino via a slepton or a Z boson and exclude masses up to ≈ 1550 GeV for a massless

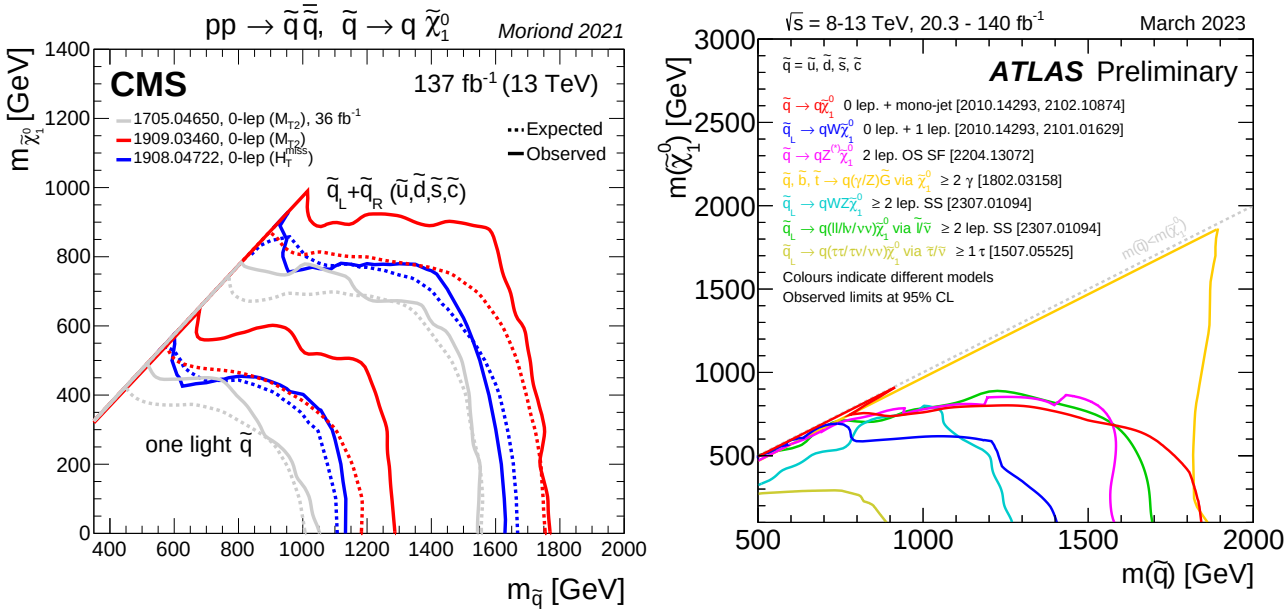

Figure 88.5: Left: 95% C.L. exclusion contours in the framework of simplified models assuming a single decay chain of $\tilde{q} \to q\tilde{\chi}_1^0$, obtained by the CMS collaboration. Right: Assuming more complicated decay chains including W or Z bosons, obtained by the ATLAS collaboration.

neutralino. Squarks decaying via charginos and next-to-lightest neutralinos in long decay chains including W and Z bosons are constrained with searches for same-sign dilepton or three-lepton final state events [89]: in this case, masses up to ≈ 1.7 TeV are excluded.

For single light squarks ATLAS also reports results of a dedicated search for pair production of scalar partners of charm quarks [90, 91]. Assuming that the scalar-charm state exclusively decays into a charm quark and a neutralino, scalar-charm masses up to 900 GeV are excluded for neutralino masses below 260 GeV.

Table 88.1: Summary of squark mass and gluino mass limits using different interpretation approaches assuming R-parity conservation. Masses in this table are provided in GeV. Further details about the assumptions and analyses from which these limits are obtained are discussed in the corresponding sections of the text.

Model	Assumption	$m_{\tilde{q}}$	$m_{\tilde{g}}$
Simplified models $\tilde{g}\tilde{g}$			
$\tilde{g} \to q\bar{q}\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	-	≈ 2300
	$m_{\tilde{\chi}_1^0} > \approx 1200$	-	no limit
$\tilde{g} \to b\bar{b}\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	-	≈ 2440
	$m_{\tilde{\chi}_1^0} > \approx 1600$	-	no limit
$\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	-	≈ 2400
	$m_{\tilde{\chi}_1^0} > \approx 1400$	-	no limit
Simplified models $\tilde{q}\bar{\tilde{q}}$			
$\tilde{q} \to q\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	≈ 1900	-
	$m_{\tilde{\chi}_1^0} > \approx 800$	no limit	-
$\tilde{u}_L \to q\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	≈ 1300	-
	$m_{\tilde{\chi}_1^0} > \approx 600$	no limit	-

A summary of the most important squark and gluino mass limits for different interpretation approaches assuming R-parity conservation is shown in Table 88.1. For gluino masses rather similar limits of about $2.3 - 2.4$ TeV are obtained from different model assumptions, indicating that the LHC is indeed probing direct gluino production at the TeV scale and beyond. However, for neutralino masses above approximately 1.2 to 1.6 TeV, even in the best case scenarios, ATLAS and CMS searches do not place any limits on the gluino mass. Limits on direct squark production, on the other hand, depend strongly on the chosen model. For neutralino masses above ≈ 600 GeV no limits on any direct squark pair production scenario are placed by the LHC.

88.6 Exclusion limits on bottom and top squarks masses in RPC scenarios

Besides placing stringent limits on first and second generation squark masses, the LHC experiments also search for the production of third generation squarks. SUSY at the TeV-scale is often motivated by naturalness arguments, most notably as a solution to cancel quadratic divergences in radiative corrections to the Higgs boson mass. In this context, the most relevant terms for SUSY phenomenology arise from the interplay between the masses of the third generation squarks and the Yukawa coupling of the top quark to the Higgs boson. This motivates a potential constraint on the masses of the top squarks and the left-handed bottom squark. Due to the large top quark mass, significant mixing between $\tilde{t}_L$ and $\tilde{t}_R$ is expected, leading to a lighter mass state $\tilde{t}_1$ and a heavier mass state $\tilde{t}_2$. In the MSSM, the lightest top squark ($\tilde{t}_1$) can be the lightest squark.

Bottom squarks are expected to decay predominantly to $b\tilde{\chi}_1^0$ giving rise to the characteristic multi b-jet and E_T^{miss} signature. Direct production of bottom squark pairs has been searched for at the Tevatron and at the LHC. Limits from the Tevatron are $m_{\tilde{b}} > 247$ GeV for a massless neutralino [92, 93]. ATLAS has set a lower limit of $m_{\tilde{b}} > 1250$ GeV for massless neutralinos in this model [94] exploiting the two b-jets and missing transverse momentum analysis. For $m_{\tilde{\chi}_1^0} \approx 800$ GeV or higher no limit can be placed on direct bottom squark pair production in this simplified model. Limits from CMS are comparable [84]. Reinterpretations of the monojet analysis results can be used to constrain very compressed scenarios, with exclusion of masses up to 550 GeV in case of $\Delta m = m_{\tilde{b}} - m_{\tilde{\chi}_1^0} \approx 5$ GeV [86]. Further bottom squark decay modes have also been searched for by ATLAS [95–97] and CMS [76,98,99], for instance targeting more complex decay chains that include Higgs bosons in the cascade.

The top squark decay modes depend on the SUSY mass spectrum, and on the $\tilde{t}_L$-$\tilde{t}_R$ mixture of the top squark mass eigen-

state. If kinematically allowed, the two-body decays $\tilde{t} \to t\tilde{\chi}_1^0$ (which requires $m_{\tilde{t}} - m_{\tilde{\chi}_1^0} > m_t$) and $\tilde{t} \to b\tilde{\chi}^{\pm}$ (which requires $m_{\tilde{t}} - m_{\tilde{\chi}^{\pm}} > m_b$) are expected to dominate, depending on L-R mixture. If not, the top squark decay may proceed either via the two-body decay $\tilde{t} \to c\tilde{\chi}_1^0$ or through $\tilde{t} \to bf\bar{f}'\tilde{\chi}_1^0$ (where f and $\bar{f}'$ denote a fermion-antifermion pair with appropriate quantum numbers). For $m_{\tilde{t}} - m_{\tilde{\chi}_1^0} > m_b$ the latter decay chain represents a four-body decay with a W boson, charged Higgs $H^{\pm}$, slepton $\tilde{\ell}$, or light flavor squark $\tilde{q}$, exchange. If the exchanged W boson and/or sleptons are kinematically allowed to be on-shell, the three-body decays $\tilde{t} \to Wb\tilde{\chi}_1^0$ and/or $\tilde{t} \to b\nu\tilde{\ell}(\tilde{\nu}\ell)$ will become dominant. For further discussion on top squark decays see for example Ref. [100].

Limits from LEP on the $\tilde{t}_1$ mass are $m_{\tilde{t}} > 96$ GeV in the charm plus neutralino final state, and > 93 GeV in the lepton, b-quark and sneutrino final state [72].

The Tevatron experiments have performed a number of searches for top squarks, often assuming direct pair production. In the $b\ell\tilde{\nu}$ decay channel, and assuming a 100% branching fraction, limits are set as $m_{\tilde{t}} > 210$ GeV for $m_{\tilde{\nu}} < 110$ GeV and $m_{\tilde{t}} - m_{\tilde{\nu}} > 30$ GeV, or $m_{\tilde{t}} > 235$ GeV for $m_{\tilde{\nu}} < 50$ GeV [101, 102]. In the $\tilde{t} \to c\tilde{\chi}_1^0$ decay mode, a top squark with a mass below 180 GeV is excluded for a neutralino lighter than 95 GeV [103, 104]. In both analyses, no limits on the top squark can be set for heavy sneutrinos or neutralinos. In the $\tilde{t} \to b\tilde{\chi}_1^{\pm}$ decay channel, searches for a relatively light top squark have been performed in the dilepton final state [105, 106]. The CDF experiment sets limits in the $\tilde{t} - \tilde{\chi}_1^0$ mass plane for various branching fractions of the chargino decay to leptons and for two values of $m_{\tilde{\chi}_1^{\pm}}$. For $m_{\tilde{\chi}_1^{\pm}} = 105.8$ GeV and $m_{\tilde{\chi}_1^0} = 47.6$ GeV, top squarks between 128 and 135 GeV are excluded for W-like leptonic branching fractions of the chargino.

The LHC experiments have improved these limits substantially and developed dedicated searches for all potential top-squark decay modes. This is well depicted in Fig. 88.6, where a summary of the limits on the top squark mass are reported for the single decay chain of $\tilde{t} \to t\tilde{\chi}_1^0$ as well as for the three-body and four-body decay modes. Interpretations are carried out in simplified models hence care must be taken when interpreting these limits in the context of more complete SUSY models.

The most important searches for the top squark decay topology are dedicated searches requiring zero or one isolated lepton, modest $E_{\mathrm{T}}^{\mathrm{miss}}$, and four or more jets out of which at least one jet must be reconstructed as a b-jet [51, 76, 84, 85, 107–109]. For example, using an all-hadronic analysis, CMS excludes top squarks with masses below about 1300 GeV in this model for light neutralinos, while for $m_{\tilde{\chi}_1^0} > 700$ GeV no limits can be provided [85]. Equivalent constraints are set by the ATLAS all-hadronic search [107]. Analyses targeting final state events characterised by the presence of one lepton (electron or muon) have similar albeit lower sensitivity in the $\tilde{t} \to t\tilde{\chi}_1^0$ decay mode, see for instance the recent ATLAS result [109] using NN methods.

Single and di-lepton analyses are most sensitive to models where the top squark decay exclusively proceeds via the chargino mediated decay chain $\tilde{t} \to b\tilde{\chi}_1^{\pm}$, $\tilde{\chi}_1^{\pm} \to W^{\pm(*)}\tilde{\chi}_1^0$. In this case, top squark mass exclusion limits vary strongly with the assumptions made on the $\tilde{t} - \tilde{\chi}_1^{\pm} - \tilde{\chi}_1^0$ mass hierarchy. For example, for $m_{\tilde{\chi}_1^{\pm}} = (m_{\tilde{t}} + m_{\tilde{\chi}_1^0})/2$, a stop mass below ≈ 1150 GeV for a light $\tilde{\chi}_1^0$ is excluded by CMS, while no limit can be placed for $m_{\tilde{\chi}_1^0} > 550$ GeV [51]. These limits, however, can weaken significantly when other assumptions about the mass hierarchy or the decay of the charginos are imposed [51, 110–112].

Other analyses with zero, one or two leptons target this kinematic region [113–119], also providing sensitivity in the case of alternative decay modes of the top squark, *i.e.* including tau sleptons [112, 120–122] or Higgs and Z bosons in the decay chain [123].

If the decays $\tilde{t} \to t\tilde{\chi}_1^0$ and $\tilde{t} \to b\tilde{\chi}_1^{\pm}$, $\tilde{\chi}_1^{\pm} \to W^{\pm(*)}\tilde{\chi}_1^0$ are kinematically forbidden, the decay chains $\tilde{t} \to Wb\tilde{\chi}_1^0$ and $\tilde{t} \to c\tilde{\chi}_1^0$ can become important. The one-lepton ATLAS search [108] provides for the kinematic region $m_{\tilde{t}} - m_{\tilde{\chi}^{\pm}} > m_b + m_W$ lower limits on the top squark mass of ≈ 700 GeV for a neutralino lighter than ≈ 570 GeV, as also shown in Fig. 88.6. For the kinematic region in which even the production of real W bosons is not allowed, ATLAS and CMS improve the Tevatron limit on $\tilde{t} \to c\tilde{\chi}_1^0$ substantially. Based on a monojet analysis [86] ATLAS excludes top squark masses below $m_{\tilde{\chi}_1^0} \approx 550$ GeV along the kinematic boundary for the $\tilde{t} \to c\tilde{\chi}_1^0$ decay. The ATLAS monojet analysis also places similar boundaries for the other decay chain relevant in this phase region, $\tilde{t} \to bf\bar{f}'\tilde{\chi}_1^0$. Other analyses, such as the search in events with one leptons and jets, are also sensitive to this decay mode: the ATLAS one-lepton analysis excludes up to ≈ 650 GeV for $\Delta m = m_{\tilde{t}}, m_{\tilde{\chi}_1^0} \approx 50$ GeV [108]. A recent dedicated analysis for $\tilde{t} \to c\tilde{\chi}_1^0$ exploiting c-tagging excludes stop masses below about 900 GeV for $m_{\tilde{\chi}_1^0}$ below 420 GeV [91]. Also a topology where one stop decays through $\tilde{t} \to c\tilde{\chi}_1^0$ and the other one through $\tilde{t} \to t\tilde{\chi}_1^0$ has been considered [91, 124] and limits have been placed, in the case of equal branching ratios, 800 GeV for light neutralinos and 600 GeV in the compressed region.

The CMS collaboration uses the hadronic searches [85, 114, 116] to place constraints on stop decay into charm-quark and excludes $m_{\tilde{t}} \approx 630$ GeV for $\Delta m = m_{\tilde{t}}, m_{\tilde{\chi}_1^0} \approx 50$ GeV [85]. Constraints are also set in case of $\tilde{t} \to bf\bar{f}'\tilde{\chi}_1^0$, with CMS excluding masses up to 480 and 700 GeV for $\Delta m = m_{\tilde{t}}, m_{\tilde{\chi}_1^0} \approx 10$ and 80 GeV, respectively [125].

In general, the variety of top squark decay chains in the phase space region where $\tilde{t} \to t\tilde{\chi}_1^0$ is kinematically forbidden represents a challenge for the experimental search program but more data and refined analyses in Run 2 have further improved the sensitivity in this difficult but important region of SUSY parameter space, and more is expected for future Runs of the LHC. Precision SM measurements can also provide important insights to such challenging regions. For instance, analyses of $t\bar{t}$ spin correlations can be used to set constraints on top squark masses close to the top-quark mass. ATLAS [126] excludes the mass region between 150 and 230 GeV for kinematically allowed values of the neutralino mass. CMS [119] results cover a similar mass range.

Table 88.2: Summary of bottom and top squark mass limits using different interpretation approaches assuming R-parity conservation. Masses in this table are provided in GeV. Further details about the assumptions and analyses from which these limits are obtained are discussed in the corresponding sections of the text.

Model	Assumption	$m_{\tilde{q}}$
$\tilde{b} \to b\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	≈ 1250
	$m_{\tilde{\chi}_1^0} > \approx 700$	no limit
$\tilde{t} \to t\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	≈ 1300
	$m_{\tilde{\chi}_1^0} > \approx 600$	no limit
$\tilde{t} \to b\tilde{\chi}_1^{\pm}$	$m_{\tilde{\chi}_1^0} = 0$	≈ 1150
$(m_{\tilde{\chi}_1^{\pm}} = (m_{\tilde{t}} - m_{\tilde{\chi}_1^0})/2)$	$m_{\tilde{\chi}_1^0} > \approx 550$	no limit
$\tilde{t} \to Wb\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} < \approx 570$	≈ 700
$(m_W < m_{\tilde{t}} - m_{\tilde{\chi}^0} < m_t)$		
$\tilde{t} \to c\tilde{\chi}_1^0$	$m_{\tilde{t}} - m_{\tilde{\chi}_1^0} \approx 50$	≈ 900
	$m_{\tilde{t}} \approx m_{\tilde{\chi}_1^0}$	≈ 550
$\tilde{t} \to bff'\tilde{\chi}_1^0$	$m_{\tilde{t}} - m_{\tilde{\chi}_1^0} \approx 50$	≈ 650
$(m_{\tilde{t}} - m_{\tilde{\chi}^0} < m_W)$	$m_{\tilde{t}} \approx m_{\tilde{\chi}_1^0}$	≈ 550

88.7 Exclusion limits on the masses of charginos, neutralinos and sleptons in RPC scenarios

Charginos, neutralinos and sleptons are produced through electroweak interactions and their cross sections depend on the assumptions made for mass and mixing parameters.

Charginos and neutralinos carry no color charge and the mixing of the charged wino and higgsino states (for charginos), and the

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

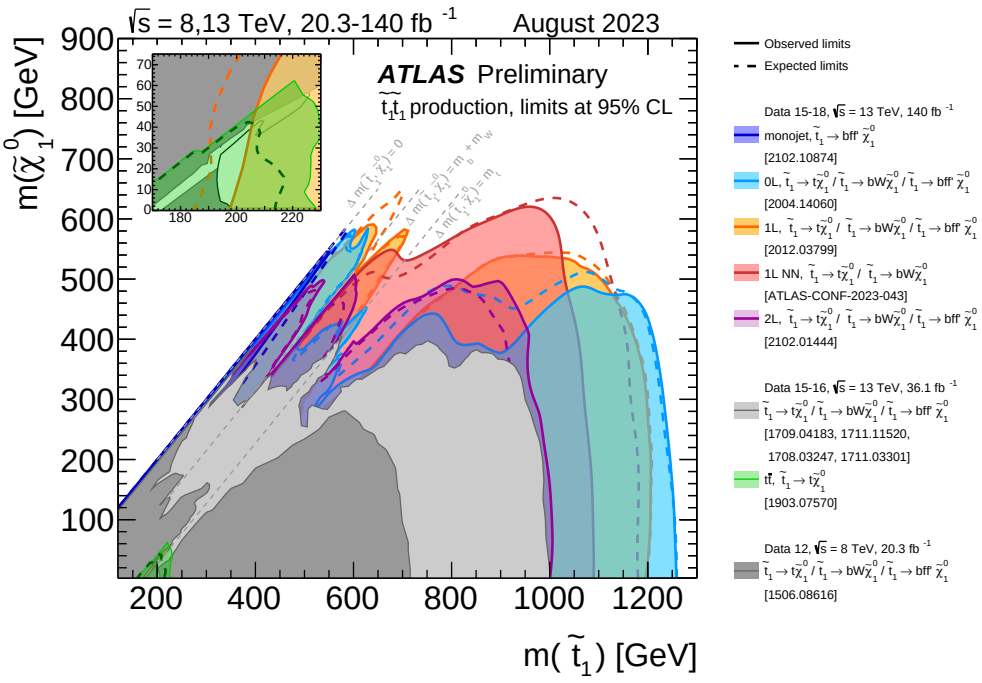

Figure 88.6: A summary of the 95% C.L. exclusion contours in the stop-neutralino mass plane for various possible decay chains, including two-, three- and four-body decays, as obtained in dedicated analyses by ATLAS.

neutral bino, wino and higgsino states (for neutralinos), is determined by a limited number of parameters. For charginos these are the wino mass parameter M_2, the higgsino mass parameter μ, and $\tan\beta$, and for neutralinos these are the same parameters plus the bino mass parameter M_1. If one of the parameters M_1, M_2 or μ is substantially smaller than the others, the chargino/neutralino composition would be dominated by specific states, which are referred to as bino-like ($M_1 \ll M_2, \mu$), wino-like ($M_2 \ll M_1, \mu$), or higgsino-like ($\mu \ll M_1, M_2$). If gaugino mass unification at the GUT scale is assumed, a relation between M_1 and M_2 at the electroweak scale follows: $M_1 = 5/3 \tan^2\theta_W M_2 \approx 0.5 M_2$, with θ_W the weak mixing angle. At hadron colliders the largest production rates arise when the lightest chargino and the next-to-lightest neutralino are wino-like and nearly mass-degenerate, forming an SU(2) triplet. In this case the LSP is typically bino-like. If instead the higgsino mass parameter is much smaller than the gaugino masses, the two lightest neutralinos and the lightest chargino form an approximately mass-degenerate SU(2) doublet; production rates are lower and the mass spectrum is compressed.

In models with slepton and gaugino mass unification at the GUT scale, the superpartner of the right-handed lepton, $\tilde{\ell}_R$, is expected to be lighter than the left-handed one, $\tilde{\ell}_L$. Cross sections depend on the L-R mixing which in turn depends on the mass of the fermion and other parameters. For tau sleptons there may be considerable mixing between the L and R states, leading to a significant mass difference between the lighter $\tilde{\tau}_1$ and the heavier $\tilde{\tau}_2$.

Fig. 88.7 [127, 128] (see also Ref. [73] for further details) shows typical production cross sections at hadron colliders for electroweakinos under various assumptions and considering a center-of-mass energy of 13 TeV. For masses of several hundreds of GeV, they are at least two orders of magnitude smaller than for colored SUSY particles. Thanks to the large data samples collected at the LHC, the sensitivity of LEP and Tevatron searches for direct chargino/neutralino or slepton production has been surpassed in several regions of SUSY parameter space.

88.7.1 *Exclusion limits on chargino masses*

The lightest chargino $\tilde{\chi}_1^\pm$ is searched for either considering pair production, or through associated production of $\tilde{\chi}_1^\pm$ and the next-to-lightest neutralino, $\tilde{\chi}_2^0$, if they are assumed to be degenerate in mass. If kinematically allowed, two body decay modes such as $\tilde{\chi}^\pm \to \tilde{f}\bar{f}'$ (including $\ell\tilde{\nu}$ and $\tilde{\ell}\nu$) are dominant. If not, three-body decays $\tilde{\chi}^\pm \to f\bar{f}'\tilde{\chi}_1^0$, mediated through virtual W bosons or sfermions, become dominant. If sfermions are heavy, the W mediation dominates, and $f\bar{f}'$ are distributed with branching fractions similar to W decay products (barring phase space effects for small mass gaps between $\tilde{\chi}^\pm$ and $\tilde{\chi}^0$). If, on the other hand, sleptons are light enough to play a significant role in the decay, leptonic final states will be enhanced.

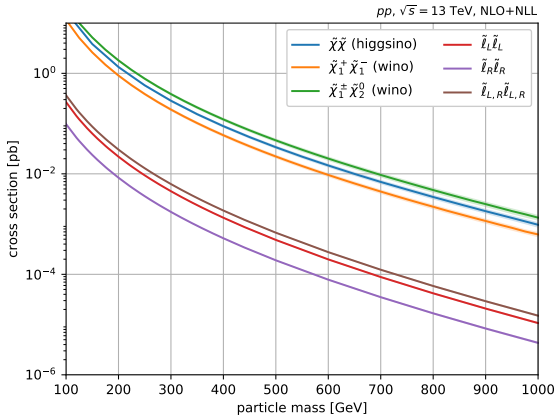

Figure 88.7: Cross sections for pair production of charginos, neutralinos and sleptons calculated for 13 TeV centre-of-mass energy at NLO plus next-to-leading-log (NLL) precision. Wino-like $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ and $\tilde{\chi}_1^+\tilde{\chi}_1^-$ productions are calculated in a limit of mass-degenerate $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$, light bino $\tilde{\chi}_1^0$, and with all the other sparticles assumed to be heavy and decoupled. Higgsino-like cross sections assume mass-degenerate $\tilde{\chi}_1^\pm$, $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^0$. For slepton pair cross sections, left(right)-handed only or 50% mixed states are considered.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

At LEP, $\tilde{\chi}_1^+\tilde{\chi}_1^-$ is the dominant production process. Charginos have been searched for in fully-hadronic, semi-leptonic and fully leptonic decay modes [129, 130]. A general lower limit on the lightest chargino mass of 103.5 GeV is derived, except in corners of phase space with low electron sneutrino mass, where destructive interference in chargino production, or two-body decay modes, play a role. The limit is also affected if the mass difference between $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ is small; dedicated searches for such scenarios set a lower limit of 92 GeV.

At the Tevatron, charginos have been searched for via associated production of $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ [131, 132]. Decay modes involving multilepton final states provide the best discrimination against the large multijet background. Analyses have looked for at least three charged isolated leptons, for two leptons with missing transverse momentum, or for two leptons with the same charge. Depending on the $(\tilde{\chi}_1^\pm - \tilde{\chi}_1^0)$ and/or $(\tilde{\chi}_2^0 - \tilde{\chi}_1^0)$ mass differences, leptons may have soft transverse momentum.

At the LHC, the search strategy is similar to that at the Tevatron but it also exploits the large datasets collected to target missing momentum and fully-hadronic final states and consider $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production only i.e. releasing the assumption of $\tilde{\chi}_1^\pm, \tilde{\chi}_2^0$ mass degeneracy. Furthermore, compressed SUSY spectra are searched for considering low-momentum leptons recoiling against an ISR jet.

Chargino pair production is mainly searched for in the dilepton plus missing momentum final state. In a simplified model interpretation of the results where only the $\tilde{\chi}_1^+\tilde{\chi}_1^-$ process is considered and assuming mediation of the chargino decay by light sleptons ($\tilde{e}$ and $\tilde{\mu}$), ATLAS [133] and CMS [134] set limits on the chargino mass up to 1 TeV for massless LSPs, but no limits on the chargino mass can be set for $\tilde{\chi}_1^0$ heavier than 480 GeV. Limits are fairly robust against variation of the slepton mass, unless the mass gap between sparticles becomes small enough that the charged lepton has a too low-momentum to be reconstructed. For decays mediated through $\tilde{\tau}$ or $\tilde{\nu}_\tau$, recent results reach limits of 970 GeV as set by ATLAS [135] for LSPs not heavier than 440 GeV. The CMS experiment provides limits using Run 2 data [136].

In case slepton masses are higher than the mass of the chargino, searches are performed for charginos decaying via a W boson. Constraints on pair-produced pure-wino charginos using various decay channels have been recently summarized by ATLAS using statistical combinations of Run 2 searches [137]. The combination of the search results closes the gaps left by the individual searches in this simplified model, with chargino masses excluded up to 800 GeV for massless neutralinos. No limits are set for LSP masses above 170 GeV. Individual channels include 2-lepton final state events [133], resulting in masses below 420 GeV being excluded for massless LSPs. In the challenging case where the difference between chargino and LSP masses is close to that of the W boson, dedicated searches have been carried out by ATLAS [138], excluding chargino masses up to 140 GeV. Searches have also been carried out in the single lepton final state. ATLAS excludes chargino masses between 260 and 520 GeV for a massless LSP [139]. Further extension of the sensitivity in the high-mass region is achieved by ATLAS [140] and CMS [141] exploiting the large branching ratio of fully-hadronic final states and the identification of boosted W bosons through large-radius jets and jet substructure information. Considering only wino-like chargino pair production in case of a massless LSP, ATLAS excludes a region between 630 GeV and 760 GeV, while CMS excludes between 290 GeV and 670 GeV. No limits are set for LSP masses above 200 GeV.

Several final states characterized by the presence of missing transverse momentum are studied to set limits on the chargino mass through $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ associated production. Usually, wino-like $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ and bino-like $\tilde{\chi}_1^0$ are assumed with $m_{\tilde{\chi}_1^\pm} = m_{\tilde{\chi}_2^0}$, leaving $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ free. Higgsino models with small mass differences among the electroweakinos are targeted using low-momentum lepton signatures. Again, the branching fraction of leptonic final states is determined by the slepton masses. If the decay is predominantly mediated by a light $\tilde{\ell}_\mathrm{L}$, i.e. $\tilde{\ell}_\mathrm{R}$ is assumed to be heavy, the three charged-lepton flavors will be produced in equal amounts, and a multi-lepton signature is favored. For simplicity, $\tilde{\ell}_\mathrm{L}$ and $\tilde{\nu}$ are taken to be nearly mass-degenerate, and diagrams with sneutrinos are included.

In such a scenario, ATLAS [142] and CMS [143] exclude chargino masses below 1450 GeV for massless LSPs; no limits are set for LSP masses above 1 TeV. If the decay is dominated by a light $\tilde{\ell}_\mathrm{R}$, the chargino cannot be a pure wino but needs to have a large higgsino component, preferring the decays to tau leptons. Limits are set in various scenarios. If, like for $\tilde{\ell}_\mathrm{L}$, a flavor-democratic scenario is assumed (τ-enriched scenario), CMS sets limits of 1150 GeV on the chargino mass for massless LSPs, but under the assumption that both $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ decay leads to tau leptons in the final state (τ-dominated scenario), the chargino mass limit deteriorates to 970 GeV for massless LSPs [143]. ATLAS assumes a simplified model in which staus are significantly lighter than the other sleptons and search for a similar multi-tau final state, setting a lower limit on the chargino mass of 1160 GeV in this model [135].

If sleptons are heavy, the chargino is assumed to decay to a W boson plus LSP, and the $\tilde{\chi}_2^0$ into Z plus LSP (WZ searches) or H plus LSP (WH searches). Searches for the WZ channel exploit events with either two same-sign leptons or three leptons, a single lepton, or with no leptons (all-hadronic). If $\tilde{\chi}_2^0$ decays through a Higgs boson with $m_H = 125$ GeV, search strategies depend on the SM-like Higgs decay modes and branching fractions. Higgs bosons in the final state are identified by either two jets originating from bottom quarks ($h \to b\bar{b}$), two photons ($h \to \gamma\gamma$), or leptons from the WW, ZZ or $\tau\tau$ decay modes. Interpretations are also provided in scenarios where the $\tilde{\chi}_2^0$ does not decay exclusively into a Z or H boson and the LSP.

A combination of the results of several searches for the electroweak production of the supersymmetric partners of standard model bosons has been published by CMS [144]. In the case of wino-like $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production, the combined CMS result gives an observed (expected) limit on the chargino mass of about 875 (950) GeV for the WZ topology. Limits on a higgsino-bino model where charginos decay to a W boson and the LSP up to 800 GeV are set in simplified models where it is degenerate with $\tilde{\chi}_2^0$ and $\tilde{\chi}_3^0$.

The recent ATLAS statistical combinations of Run 2 searches [137] excludes $\tilde{\chi}_1^\pm$ masses up to 1000 GeV, with no mass limits possible for LSP masses above 400 GeV. Searches for $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production in events with three leptons and missing momentum allows to exclude wino-like chargino masses below 640 GeV for massless LSPs [145]. Results have also been reported for searches including same-sign lepton signal regions [146] and single lepton searches [139]. Limits are reduced in case of higgsino-like scenarios, with exclusion down to 210 GeV.

Additional constraints on the chargino mass are placed exploiting all-hadronic analyses. A wino-like (higgsino-like) chargino with mass up to 1060 (900) GeV is excluded by ATLAS [140] when the LSP mass is below 400 (240) GeV and the mass splitting is larger than 400 (450) GeV. This is also included in the Run 2 combination study. CMS [141] excludes wino-like charginos with mass up to 970 GeV for massless LSP.

Searches exploiting the presence of b-jets are most sensitive in the high-mass chargino region if $\tilde{\chi}_2^0$ decays through a Higgs boson, while analyses targeting photon pair or leptonic decays provide the best sensitivity in the region of low masses. CMS [147] sets lower limits on the chargino mass up to 820 GeV for massless LSPs, but vanish for LSP masses above 350 GeV using events with at least one lepton and missing transverse momentum in the final state. In the case of wino-like $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production, the combined CMS result [144] gives an observed (expected) limit on the chargino mass of about 990 (1075) GeV for the WH topology, and 875 (1000) GeV for a mixed topology with WZ. Similar sensitivities are achieved by the ATLAS analyses [148–150], combined in [137].

In both the wino region (a characteristic of anomaly-mediated

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

SUSY breaking models) and the higgsino region of the MSSM, the mass splitting between $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ is small. The chargino decay products are very soft and may escape detection. These compressed spectra are hard to detect, and have triggered dedicated search strategies.

Studies from ATLAS [151] and CMS [152] for charginos and neutralinos in a compressed mass spectrum use initial state radiation and two or three low-momentum (soft) leptons. For wino-like charginos, assuming degenerate $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$, exclusion contours in the chargino-mass versus $\Delta m(\tilde{\chi}_1^\pm - \tilde{\chi}_1^0)$ plane are derived. As an example, such charginos are excluded by CMS (ATLAS) below 280 (240) GeV for $\Delta m(\tilde{\chi}_1^\pm - \tilde{\chi}_1^0) = 10$ GeV. Considering the higgsino model, the masses probed by CMS reach up to 215 GeV for a mass difference of 7.5 GeV and 150 GeV in the highly compressed region with a mass difference of 3 GeV.

Recent ATLAS results [153] using vector boson fusion signatures and missing transverse momentum were interpreted in simplified RPC models in which the LSP is a bino-like neutralino with a mass similar to that of the lightest chargino and second-to-lightest neutralino, both of which are wino-like. Lower limits at 95% confidence level on the masses of NLSPs were established between 117 and 120 GeV when the LSP is within 1 GeV in mass. CMS has also searched for chargino-pair production through vector-boson-fusion [154], also targeting compressed mass spectra. Assuming degenerate $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$, charginos with a mass below 112 GeV are excluded for $\Delta m(\tilde{\chi}_1^\pm - \tilde{\chi}_1^0) = 1$ GeV. CMS has published further searches for such compressed spectra with a soft tau lepton [155]. A combination of several searches for the electroweak production of winos, binos, higgsinos, and sleptons has also been recently been presented by CMS [144].

88.7.2 *Exclusion limits on neutralino masses*

In a considerable part of the MSSM parameter space, and in particular when demanding that the LSP carries no electric or color charge, the lightest neutralino $\tilde{\chi}_1^0$ is the LSP. If R-parity is conserved, such a $\tilde{\chi}_1^0$ is stable. Since it is weakly interacting, it will typically escape detectors unseen. Limits on the invisible width of the Z boson apply to neutralinos with a mass below 45.5 GeV, but depend on the Z-neutralino coupling. Such a coupling could be small or even absent; in such a scenario there is no general lower limit on the mass of the lightest neutralino [156]. In models with gaugino mass unification and sfermion mass unification at the GUT scale, a lower limit on the neutralino mass is derived from limits from direct searches, notably for charginos and sleptons, and amounts to 47 GeV [157]. Assuming a constrained model like the CMSSM, this limit increases to 50 GeV at LEP; however the strong constraints now set by the LHC increase such CMSSM-derived $\tilde{\chi}_1^0$ mass limits to well above a few hundred GeV (the latest reinterpretation only uses Run 1 data and indicates 200 GeV [158–160]).

In gauge-mediated SUSY breaking models (GMSB), the LSP is typically a gravitino, and the phenomenology is determined by the nature of the next-to-lightest supersymmetric particle (NLSP). A NLSP neutralino will decay to a gravitino and a SM particle whose nature is determined by the neutralino composition. Final states with two high p_{T} photons and missing momentum are searched for, and interpreted in gauge mediation models with bino-like neutralinos [161–167].

Assuming the production of at least two neutralinos per event, neutralinos with large non-bino components can also be searched for by their decay in final states with missing momentum plus any two bosons out of the collection γ, Z, H. A number of searches at the LHC have tried to cover the rich phenomenology predicted by the general gauge mediation model (GGM) where $\tilde{\chi}_1^0$ might decay with various BR in the Z and H decay modes [98, 149, 164, 168–178]. As an example, strong constraints for decay modes involving Z and H bosons arise from full-hadronic searches on higgsino-like scenarios: ATLAS [140] excludes higgsino production with decays into a massless gravitino LSP in a mass range between 450 (500) GeV and 940 (850) GeV assuming BR = 1 (0.5) for the Z plus gravitino decay mode. Assuming only H plus gravitino decays, CMS [179] excludes a higgsino mass range between 175 GeV and 1025 GeV. Assuming a mix of γ, Z, H decays, a CMS search [167] in the photonic final state excludes higgsinos up to 1.05 TeV.

Heavier neutralinos, in particular $\tilde{\chi}_2^0$, have been searched for in their decays to the lightest neutralino plus a γ, a Z boson or a Higgs boson. Limits on electroweak production of $\tilde{\chi}_2^0$ plus $\tilde{\chi}_1^\pm$ from all-hadronic, same-sign dilepton and trilepton analyses have been discussed in the section on charginos; the assumption of equal mass of $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^\pm$ make the limits on chargino masses apply to $\tilde{\chi}_2^0$ as well. Multilepton analyses have also been used to set limits on $\tilde{\chi}_2^0\tilde{\chi}_3^0$ production; assuming equal mass and decay through light sleptons, limits are set up to 680 GeV for massless LSPs [180]. Again, compressed spectra with small mass differences between the heavier neutralinos and the LSP form the most challenging region.

Of particular relevance are supersymmetric models characterised by pure wino or pure higgsino states, with small mass splittings between $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$, $\Delta m \sim 160$ MeV for winos and ~ 350 MeV for higgsinos. In this case, the $\tilde{\chi}_1^0$ is a natural candidate for dark matter (thermal relic), with pure winos predicted as $m_\chi \simeq 2.8 - 3.1$ TeV and pure higgsinos with thermal mass near 1.1 TeV. Winos feature a large annihilation cross section and predictions are currently in tension with reinterpretations of gamma-ray bounds. Higgsinos have lower annihilation rates and, under specific assumptions on the dark matter density, are constrained up to 270 GeV [181] (see also the Dark Matter Chapter in this review for references and further details).

In $\tilde{\chi}_2^0$ decays to $\tilde{\chi}_1^0$ and a lepton pair, the lepton pair invariant mass distribution may show a structure that can be used to measure the $\tilde{\chi}_2^0 - \tilde{\chi}_1^0$ mass difference in case of a signal [37]. This structure, however, can also be used in the search strategy itself, as demonstrated by ATLAS [182, 183] and CMS [98, 184].

Fig. 88.8 summarizes some of the most recent results from ATLAS and CMS for chargino pair or chargino and next-to-lightest neutralino pair productions comparing results obtained with various assumptions. The limits on weak gauginos in simplified models are also summarized in Table 88.3. Only results for promptly decaying charginos and neutralinos are included: limits from searches focusing on long-lived particle scenarios are reported in Section 88.9.

Interpretations of the search results outside simplified models, such as in the phenomenological MSSM (see [185–190] and, most recently, [191]), show that the simplified model limits can translate into accurate constraints but must also be interpreted with care. Electroweak gauginos in models that are compatible with the relic density of dark matter in the Universe, for example, have particularly tuned mixing parameters and mass spectra, which are not always captured by the simplified models used.

88.7.3 *Exclusion limits on slepton masses*

The most model-independent searches for selectrons, smuons and staus originate from the LEP experiments [192]. Smuon production only takes place via s-channel γ^*/Z exchange. Search results are often quoted for $\tilde{\mu}_{\mathrm{R}}$, since it is typically lighter than $\tilde{\mu}_{\mathrm{L}}$ and has a weaker coupling to the Z boson; limits are therefore conservative. Decays are expected to be dominated by $\tilde{\mu}_{\mathrm{R}} \to \mu\tilde{\chi}_1^0$, leading to two non-back-to-back muons and missing momentum. Slepton mass limits are calculated in the MSSM under the assumption of gaugino mass unification at the GUT scale, and depend on the mass difference between the smuon and $\tilde{\chi}_1^0$. A $\tilde{\mu}_{\mathrm{R}}$ with a mass below 94 GeV is excluded for $m_{\tilde{\mu}_{\mathrm{R}}} - m_{\tilde{\chi}_1^0} > 10$ GeV. The selectron case is similar to the smuon case, except that an additional production mechanism is provided by t-channel neutralino exchange. The $\tilde{e}_{\mathrm{R}}$ lower mass limit is 100 GeV for $m_{\tilde{\chi}_1^0} < 85$ GeV. Due to the t-channel neutralino exchange, $\tilde{e}_{\mathrm{R}}\tilde{e}_{\mathrm{L}}$ pair production was possible at LEP, and a lower limit of 73 GeV was set on the selectron mass regardless of the neutralino mass by scanning over MSSM parameter space [193]. The potentially large mixing between $\tilde{\tau}_{\mathrm{L}}$ and $\tilde{\tau}_{\mathrm{R}}$ not only makes the $\tilde{\tau}_1$ light, but can also make its coupling to the Z boson small. LEP lower limits on the $\tilde{\tau}$ mass range between 87 and 93 GeV depending on the $\tilde{\chi}_1^0$ mass, for $m_{\tilde{\tau}} - m_{\tilde{\chi}_1^0} > 7$ GeV [192].

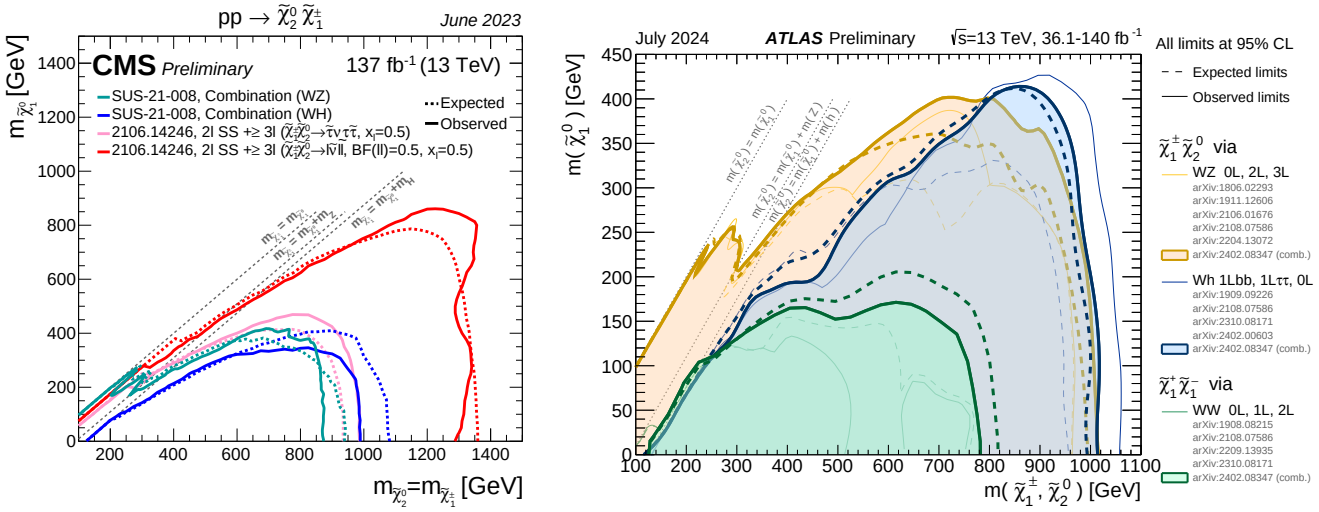

Figure 88.8: LHC exclusion limits on chargino and neutralino masses in a number of simplified models. Left: CMS limits on chargino and neutralino masses for pair production of charginos, pair production of heavier neutralinos, or pair production of chargino and neutralino, under a variety of assumptions including light sleptons mediating the decays. Right: ATLAS limits on chargino and neutralino masses for pair production of chargino and neutralino, under the assumption of decoupled sleptons, and chargino/neutralino decay through on- or off-shell W and Z or H.

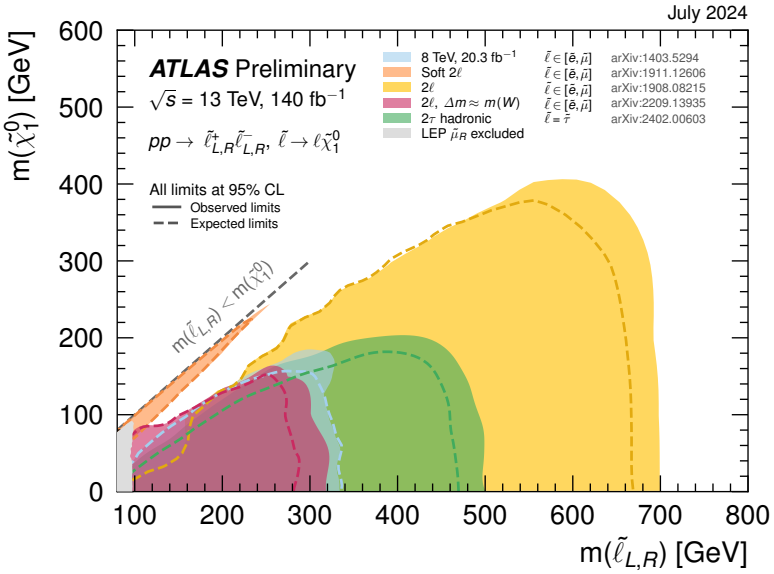

Figure 88.9: LHC exclusion limits on slepton (selectron, smuon and stau) masses, assuming equal masses of selectrons and smuons, degeneracy of $\tilde{\ell}_L$ and $\tilde{\ell}_R$, and a 100% branching fraction for $\tilde{\ell} \to \ell\tilde{\chi}_1^0$.

At the LHC, pair production of sleptons is not only heavily suppressed with respect to pair production of colored SUSY particles but the cross section is also almost two orders of magnitude smaller than the one of pair production of charginos and neutralinos. With the full data sets of Run 1 and Run 2, however, ATLAS and CMS have surpassed the sensitivity of the LEP analyses under certain assumptions.

ATLAS and CMS have searched for direct production of selectron pairs and smuon pairs at the LHC, with each slepton decaying to its corresponding SM partner lepton and the $\tilde{\chi}_1^0$ LSP. In simplified models, ATLAS [133] and CMS [184] set lower mass limits on sleptons of 700 GeV for degenerate $\tilde{\ell}_L$ and $\tilde{\ell}_R$, for a massless $\tilde{\chi}_1^0$ and assuming equal selectron and smuon masses, as shown in Fig. 88.9. The limits deteriorate with increasing $\tilde{\chi}_1^0$ mass due to decreasing missing momentum and lepton momentum. As a consequence, no limits are set for $\tilde{\chi}_1^0$ masses above 400 GeV. Limits are also derived without the assumption of slepton mass degeneracy [133, 194].

A recent combination of the results of several searches for electroweakly produced supersymmetric particles has been published by CMS [144], with improved analysis techniques employed to optimize sensitivity for the compressed spectra in the slepton pair production models, providing constraints up to 210 GeV for mass splitting of 5 GeV between slepton and LSP.

Dedicated searches for sleptons with small mass difference between $\tilde{\ell}$ and $\tilde{\chi}_1^0$ are also performed by ATLAS [151, 195] demanding the presence of ISR jets. The most recent analysis includes an event selection optimization carried out depending on Δm and with ML techniques. Selectrons (smuons) with masses up to 300 (350) GeV are excluded for Δm between 2 GeV and 100 GeV on simplified models of selectron and smuon pair production. A dedicated search [138] in the challenging regime where the mass difference between the slepton and the LSP is close to the W mass results in exclusion of sleptons with masses up to 150 GeV for a

$m_{\tilde{\chi}_1^0} > 300(270)$	indirect detection
	pure-wino(higgsino)

mass-splitting between the sleptons and the LSP of 50 GeV.

ATLAS and CMS have also searched for $\tilde{\tau}$-pair production. In simplified models, ATLAS excludes $\tilde{\tau}$ masses between 90 and 500 GeV assuming light $\tilde{\chi}_1^0$, combining the production of degenerate left- and right-handed $\tilde{\tau}$s [135]. Purely left-handed $\tilde{\tau}$s with masses up to 425 GeV and purely right-handed $\tilde{\tau}$s with masses up to 350 GeV are also excluded. The CMS analysis [196] covers lower masses also closing the mass gap with LEP. In a search for hadronic final states, CMS [197] excludes purely left-handed $\tilde{\tau}$s with masses between 115 and 340 GeV for massless LSP. The ATLAS search [135] for stau pair production in the fully hadronic final state excludes, for a massless LSP, degenerate left- and right-handed $\tilde{\tau}$s with masses up to 480 GeV.

In gauge-mediated SUSY breaking models, sleptons can be (co-)NLSPs, *i.e.*, the next-to-lightest SUSY particles and almost degenerate in mass, decaying to a lepton and a gravitino. This decay can either be prompt, or the slepton can have a non-zero lifetime. Combining several analyses, lower mass limits on $\tilde{\mu}_\mathrm{R}$ of 96.3 GeV and on $\tilde{e}_\mathrm{R}$ of 66 GeV are set for all slepton lifetimes at LEP [198]. In a considerable part of parameter space in these constrained models, the $\tilde{\tau}$ is the NLSP. The LEP experiments have set lower limits on the mass of such a $\tilde{\tau}$ between 87 and 97 GeV, depending on the $\tilde{\tau}$ lifetime. ATLAS and CMS have searched for final states with τs, jets and missing transverse momentum, and have interpreted the results in GMSB models setting limits on the model parameters [199, 200]. CMS has interpreted a multilepton analysis in terms of limits on gauge mediation models with slepton NLSP [201]. CDF has put limits on gauge mediation models at high $\tan\beta$ and slepton NLSP using an analysis searching for like-charge light leptons and taus [202].

The invisible width of the Z boson puts a lower limit on the sneutrino mass of about 45 GeV [203]. Tighter limits are derived from other searches, notably for gauginos and sleptons, under the assumption of gaugino and sfermion mass universality at the GUT scale, and amount to approximately 94 GeV in the MSSM [203].

The limits on sleptons in simplified models are summarized in Table 88.4.

Table 88.4: Summary of slepton mass limits from LEP and LHC, assuming R-parity conservation and 100% branching fraction for $\tilde{\ell} \to \ell\tilde{\chi}_1^0$. Masses in this table are provided in GeV.

Assumption	$m_{\tilde{\ell}}$

$m_{\tilde{\tau}_\mathrm{R}}$, $m_{\tilde{\chi}_1^0} \approx 0$	> 350
$m_{\tilde{\chi}_1^0} >\approx 100$	no LHC limit

88.8 Exclusion limits on promptly decaying sparticle masses in RPV scenarios

The large variety of possible configurations for non-zero λ, λ' and λ'' couplings in RPV SUSY scenarios leads to a huge number of potential signatures to be investigated in the strong and electroweak sectors. The lightest supersymmetric particle can be any particle, although most of the models considered at the LHC assume that to be the lightest neutralino, and can have a prompt or displaced decay. Cascade decays of sparticles down to the LSP can also be prompt or displaced depending on the strength of the couplings involved, although typically such cascades are dominated by gauge couplings which are prompt. In this section, we review dedicated searches for scenarios with small non-zero RPV couplings but still large enough to allow prompt decays of the sparticles involved (see Section 88.9 for examples of dedicated signatures searches for non-prompt decays).

Prompt RPV gluino and squark decays are searched for in final states generally characterised by the presence of multiple leptons or jets and moderate or no missing transverse momentum.

Searches in multilepton final states [89, 169, 204–208] set lower gluino mass limits between 1 and 2.5 TeV for decays mediated by λ and λ' couplings, with strong dependence on the couplings involved, the neutralino mass and the lepton flavor. Multijet final states have been used to search for fully hadronic gluino decays involving λ'' couplings, by CDF [209], ATLAS [96, 210–213] and CMS [214–216]. Lower gluino mass limits range between 600 and 2000 GeV depending on neutralino mass and flavor content of the final state. ATLAS [217] also searched in events characterised by high jet multiplicity, at least one isolated light lepton and either zero or at least three b-tagged jets, reaching as high as 2.4 TeV in gluino mass. If gluinos decay via top squarks into *tbd* final states through a non-zero λ''_{313} coupling, a search for same-sign/three-

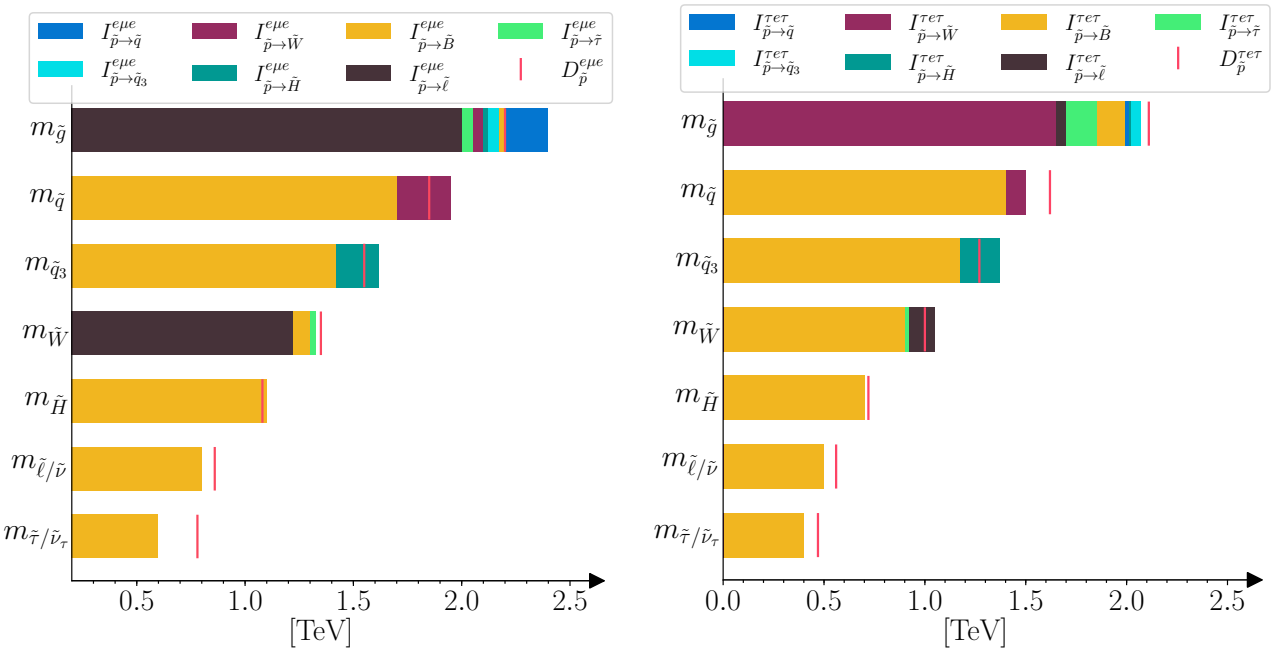

Figure 88.10: Summary of 95% C.L. limits on sparticle masses in RPV models, for λ_{121} (left), and for λ_{313} (right). The vertical red line represents the direct production mass bound when the sparticle under consideration is the LSP.

lepton events can be effective. ATLAS [89] sets a lower limit of 1.65 TeV for a top squark with a mass below 1.45 TeV.

RPV production of single squarks via a λ'-type coupling has been studied at HERA. In such models, a lower limit on the squark mass of the order of 275 GeV has been set for electromagnetic-strength-like couplings $\lambda' = 0.3$ [218]. At the LHC, prompt [205, 208, 219] R-parity violating squark decays have been searched for, with mass limits being very model-dependent.

Dedicated searches for RPV top squarks (at production and/or in decays) have been carried out in the past decades. Production of single top squarks has been searched for at LEP, HERA, and the Tevatron. For example, an analysis from the ZEUS collaboration [220] makes an interpretation of its search result assuming top squarks to be produced via a λ' coupling and decay either to $b\tilde{\chi}_1^{\pm}$ or R-parity-violating to a lepton and a jet. Limits are set on λ'_{131} as a function of the top squark mass in an MSSM framework with gaugino mass unification at the GUT scale. CMS and ATLAS have performed several searches for top squarks using a variety of multilepton and/or multijet final states and Run 2 data. The λ'-mediated top squark decay $\tilde{t} \to b\ell$ has been studied by ATLAS for prompt decays [221,222], and by ATLAS and CMS for non-prompt decays [223–225], setting limits up to $1.4 - 1.9$ TeV in simplified models for this mode. CMS also searched for the λ'-mediated decay $\tilde{t} \to b\ell qq$, setting lower stop mass limits of 890 GeV (e) or 1000 GeV (μ) [226]. The fully hadronic R-parity violating top squark decays $\tilde{t} \to bs$, $\tilde{t} \to ds$, and $\tilde{t} \to bd$, involving λ'', have been searched for by ATLAS [96,205,211,227,228], and CMS [229, 230]. Other recent searches target top squarks decaying through cascades into several $b-$ and light-quarks, for example as in [231]. The most recent results set limits up to 1.35 TeV in top-squark mass [217] if decays include top- and b-quarks [217]. Constraints on masses up to 700 GeV are found if the top squarks decays include top- and light-quarks [232, 233].

Various searches for multi-lepton and lepton plus jets events are interpreted in a model with RPV decays of charginos and neutralinos (including the LSP) involving a non-zero λ [169,204,208] or λ' [205, 213, 234, 235] coupling. Neutralino decays involving non-zero λ'' lead to fully hadronic final states, and searches for multi-jet events and jet-pair resonances are used to set limits, typically on the production of colored particles like top squarks or gluinos, which are assumed to be the primary produced sparticles in these interpretations, as discussed earlier. For instance, the ATLAS search [217] in events with one lepton and high jet multiplicity excludes up to 320 (365) GeV in higgsino (wino) masses. If top quarks arise in the decay of the neutralino, lepton-enriched final state events are also relevant, see for example the results in [146]. The multilepton search in [236] set limits on the production of charginos and neutralinos for a minimal SUSY model with an approximate $B-L$ symmetry. In this case, charginos and neutralinos with masses between 100 GeV and 1.1 TeV are excluded depending on the assumed decay BR into a lepton plus a W, Z or H boson. Finally, recent results from ATLAS [146] set the first experimental constraints on bilinear RPV models (bRPV) with degenerate higgsino masses exploiting same-sign/three-lepton signatures, excluding masses smaller than 440 GeV.

Limits also exist on sleptons in RPV models, both from LEP and the Tevatron experiments. From LEP, lower limits on $\tilde{\mu}_R$ and $\tilde{e}_R$ masses in such models are 97 GeV, and the limits on the stau mass are very close: 96 GeV [237]. CMS has searched for resonant smuon production in a modified CMSSM scenario [238], putting limits on λ'_{211} as a function of $m_0, m_{1/2}$. Production of pairs of sneutrinos in R-parity violating models has been searched for at LEP [237]. Assuming fully leptonic decays via λ-type couplings, lower mass limits between 85 and 100 GeV are set. At the Tevatron [239, 240] and at the LHC [238, 241–243], searches have focused on scenarios with resonant production of a sneutrino decaying to $e\mu$, $\mu\tau$ and $e\tau$ final states. Limits have been set on sneutrino masses as a function of the value of relevant RPV couplings. As an example, the LHC experiments exclude a resonant tau sneutrino with a mass below 3.9 TeV for $\lambda_{312} = \lambda_{321} > 0.07$ and $\lambda'_{311} > 0.11$ [244].

Formulating a general assessment of the existing bounds on RPV SUSY models is becoming increasingly important in order to evaluate loopholes and potential new search directions. A classification of all potential RPV signatures at the LHC for small couplings has been recently published [245] to evaluate the coverage of the most general RPV-MSSM setup, without making any assumptions about the sparticle spectrum details. Small RPV couplings imply that sparticles are pair-produced at the LHC as in the RPC-MSSM case. Figure 88.10 shows a summary of the 95% C.L. limits on sparticle masses in RPV models for two types of λ couplings, compared to the direct production mass bound when the sparticle under consideration is the LSP. This is done to quantify the impact of possible assumptions made on the nature, mass and coupling choices for the LSP which in turn might lead to different leptons, jets and top-quark multiplicities. As under-

lined in [245], changes in exclusion limits on sparticle masses are at most around 20%.

Finally, RPV signatures are often similar to signatures of Stealth SUSY [246–248]. In these scenarios, squarks can decay to a quark and a chargino (neutralino), which can subsequently decay to a singlino $\tilde{S}$ and a $W^{\pm}$ (photon), with the $\tilde{S}$ decaying to two gluons and a soft gravitino $\tilde{G}$. Dedicated CMS searches [249, 250] exclude squark masses up to 1.85 TeV in the photon channel and up to 550 GeV in the charged lepton channel. Gluino masses up to 2.15 TeV are excluded in the di-photon channel [250]. Limits have also been placed on top squarks in stealth SUSY scenarios, where the top squark decays to a top quark, a gluon and a $\tilde{S}$, and the $\tilde{S}$ subsequently decays to a $\tilde{G}$ and two gluons. In such a scenario, top squark masses up to 930 GeV have been excluded by CMS [232, 233].

88.9 Exclusion limits on long-lived sparticles

Long-lived sparticles arise in many different SUSY models. In particular in co-annihilation scenarios, where the NLSP and LSP are nearly mass-degenerate, this is rather common in order to obtain the correct Dark Matter relic density. Prominent examples are scenarios featuring stau co-annihilation, or models of SUSY breaking, e.g. minimal anomaly-mediated SUSY breaking (AMSB), in which the appropriate Dark Matter density is obtained by co-annihilation of the LSP with an almost degenerate long-lived wino. R-parity violating SUSY models might also lead to non-prompt decays. Searches for events with a displaced hadronic vertex, with or without a matched lepton, are for instance interpreted in a model with RPV neutralino decays involving a non-zero λ' coupling [235]. However, in general, other sparticles can also be long-lived and it is desirable to establish a comprehensive search program for these special long-lived cases, which lead to distinct experimental search signatures. Past experiments have performed dedicated searches for long-lived SUSY signatures, but given the absence of any experimental evidence for SUSY so far, more effort and focus has gone into searches for long-lived sparticles at the LHC recently. Signatures interpreted in terms of SUSY models include disappearing tracks, identification of tracks with atypical properties or unusual ionization, small and localized deposits of energy inside of the calorimeters without associated tracks, or stopped particles that decay out of time with collisions. Some examples are reported below with interpretations provided for gluinos, squarks and electroweak SUSY particles in a variety of SUSY models.

If the decay of gluinos is suppressed, for example if squark masses are high, gluinos may live longer than typical hadronization times. It is expected that such gluinos will hadronize to long-living strongly interacting particles known as R-hadrons. In particular, if the suppression of the gluino decay is strong, as in the case that the squark masses are much higher than the TeV scale, these R-hadrons can be (semi-)stable in collider timescales. Searches for such R-hadrons exploit the typical signature of stable charged massive particles in the detector. R-hadrons decaying in the detector are searched for using dE/dx measurements and searches for displaced vertices. As shown in the left plot of Fig. 88.11, the ATLAS experiment excludes semi-stable gluino R-hadrons with masses below $1.9 - 2.3$ TeV for all lifetimes in a simplified model where such gluinos always form R-hadrons, and decay into jets and a light neutralino, by combining a number of analyses [211, 251–254]. A combination of CMS searches for long-lived particles, as shown in Fig. 88.12, reaches similar limits [255–259].

Alternatively, since such R-hadrons are strongly interacting, they may be stopped in the calorimeter or in other material, and decay later into energetic jets. These decays are searched for by identifying the jets [260–262] or muons [262] outside the time window associated with bunch-bunch collisions. As shown in Fig. 88.12, the CMS collaboration sets limits on such stopped R-hadrons over 13 orders of magnitude in gluino lifetime, up to masses of 1390 GeV [262]. Recent results from ATLAS [263] sets constraints on the mass of gluino R-hadrons using large out-of-time energy deposits in the calorimeters. Also in this case, masses of up to 1.4 TeV are excluded for gluino lifetimes of $10^{-5} - 10^{3}$ s.

Top squarks can also be long-lived and hadronize to a R-hadron, for example in the scenario where the top squark is the next-to-lightest SUSY particle, with a small mass difference to the LSP. Searches for massive stable charged particles are sensitive to such top squarks. Tevatron limits are approximately $m_{\tilde{t}} > 300$ GeV [264, 265]. ATLAS sets a limit of 1340 GeV on such top squarks [253], the CMS limits are comparable [257]. Intermediate lifetimes of top squarks decaying through RPV coupling into a quark and a lepton are also targeted by ATLAS and CMS. Limits on top squarks decaying into a quark and a muon are set by ATLAS [266] using events that pass a muon or missing-transverse-momentum trigger and contain a displaced muon track and a displaced vertex. Masses up to 1.7 TeV are excluded for a lifetime of 0.1 ns, and masses below 1.3 TeV are excluded for lifetimes between 0.01 ns and 30 ns. CMS [267] utilizes events with two leptons with transverse impact parameter values between 0.01 and 10 cm not required to form a common vertex to exclude top squarks with masses between 100 and at least 460 GeV for $0.01 < c\tau_0 < 1000$ cm, where $c\tau_0$ is the proper decay length.

In addition to colored sparticles, sparticles like charginos may also be long-lived, especially in scenarios with compressed mass spectra. Charginos decaying in the detectors away from the primary vertex could lead to signatures such as kinked-tracks, or apparently disappearing tracks, since, for example, the pion in $\tilde{\chi}_1^{\pm} \rightarrow \pi^{\pm}\tilde{\chi}_1^0$ might be too soft to be reconstructed. At the LHC, searches have been performed for such disappearing tracks, and interpreted within anomaly-mediated SUSY breaking models [268–271]. The right plot of Fig. 88.11 shows constraints for different ATLAS searches on the chargino mass-vs-lifetime plane for an AMSB model ($\tan\beta = 5$, $\mu > 0$) in which a wino-like $\tilde{\chi}^{\pm}$ decays to a soft pion and an almost mass-degenerated wino-like $\tilde{\chi}_1^0$ [253, 254, 269–272]. The disappearing track search [271] provides constraints also for higgsino-like models. Results from [272] exploiting anomalously large specific ionisation losses dE/dx are extrapolated to the stable regime. For a similar AMSB-like model, CMS excludes $c\tau$ values between 0.15 and 18 m for a chargino mass of 505 GeV [268], see Fig. 88.12. Their most recent results [273] expand and improve the constraints on masses of charginos as well as of colored sparticles (stop, sbottom, gluino) by making use of electron and muon plus disappearing track signatures, measurements of the dE/dx ionization energy loss of candidate tracks, and by re-analyzing the fully hadronic signatures using ML techniques. Bottom (top) squarks decaying to a long-lived chargino which results in a disappearing track signature are excluded below a mass of 900 – 1540 GeV (1100 – 1590 GeV), depending on the LSP mass and the chargino lifetime. Similarly, gluinos decaying to a long-lived chargino are excluded below a mass of 1450 - 2300 GeV, depending on LSP mass and chargino lifetime.

Charginos with a lifetime longer than the time needed to pass through the detector appear as charged stable massive particles. Limits have been derived by the LEP experiments [274], by D0 at the Tevatron [265], and by the LHC experiments [253, 275], and such charginos with mass below 1090 GeV are excluded.

In gauge mediation models, NLSP neutralino decays need not be prompt, and experiments have searched for late decays with photons in the final state. CDF has searched for delayed $\tilde{\chi}_1^0 \rightarrow \gamma\tilde{G}$ decays using the timing of photon signals in the calorimeter [276]. CMS has used the same technique at the LHC [277]. Results are given as exclusion contours in the neutralino mass versus lifetime plane, and for example in a GMSB model with a neutralino mass of 300 GeV, $c\tau$ values between 10 and 2000 cm are excluded [277]. D0 has looked at the direction of showers in the electromagnetic calorimeter with a similar goal [278], and ATLAS has searched for photon candidates that do not point back to the primary vertex, as well as for delayed photons [279].

Charged slepton decays may be kinematically suppressed, for example in the scenario of a NLSP slepton with a very small mass difference to the LSP. Such a slepton may appear to be a stable charged massive particle. Interpretation of searches at LEP for such signatures within GMSB models with a stau NLSP or slepton co-NLSP exclude masses up to 99 GeV [274]. Searches for stable charged particles at the Tevatron [264, 265] and at the LHC [253, 257] are also interpreted in terms of limits on stable

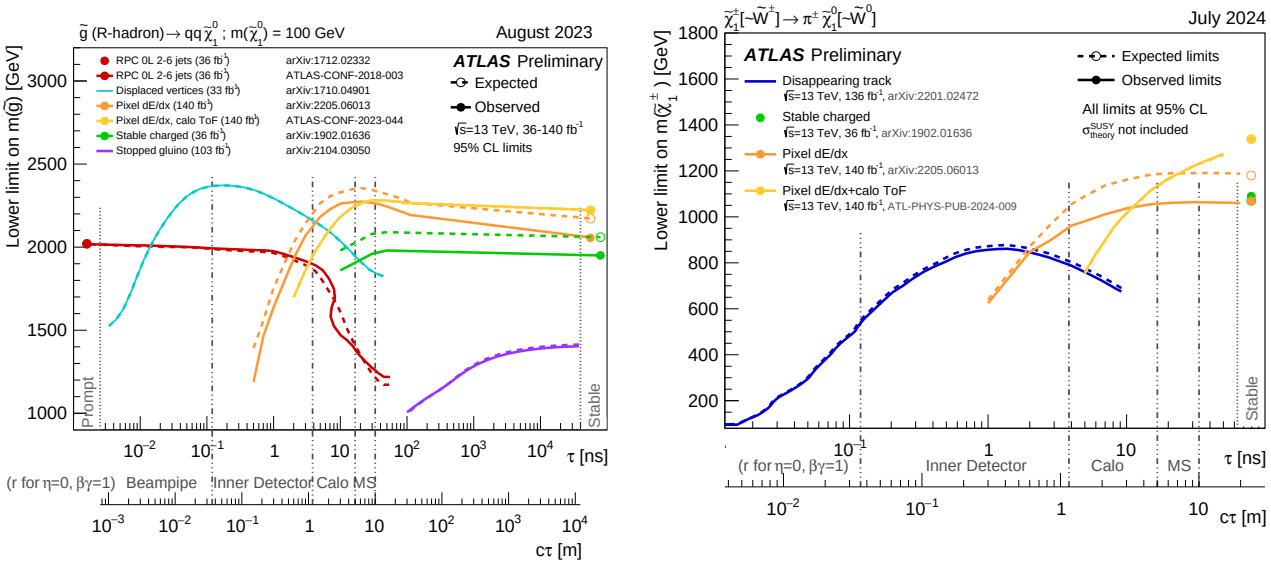

Figure 88.11: Limits at 95% C.L. on the gluino mass in R-hadron models (left), and on the chargino mass in a model where the wino-like chargino is almost degenerate with the LSP (right), as a function of gluino or chargino lifetime, as obtained by ATLAS.

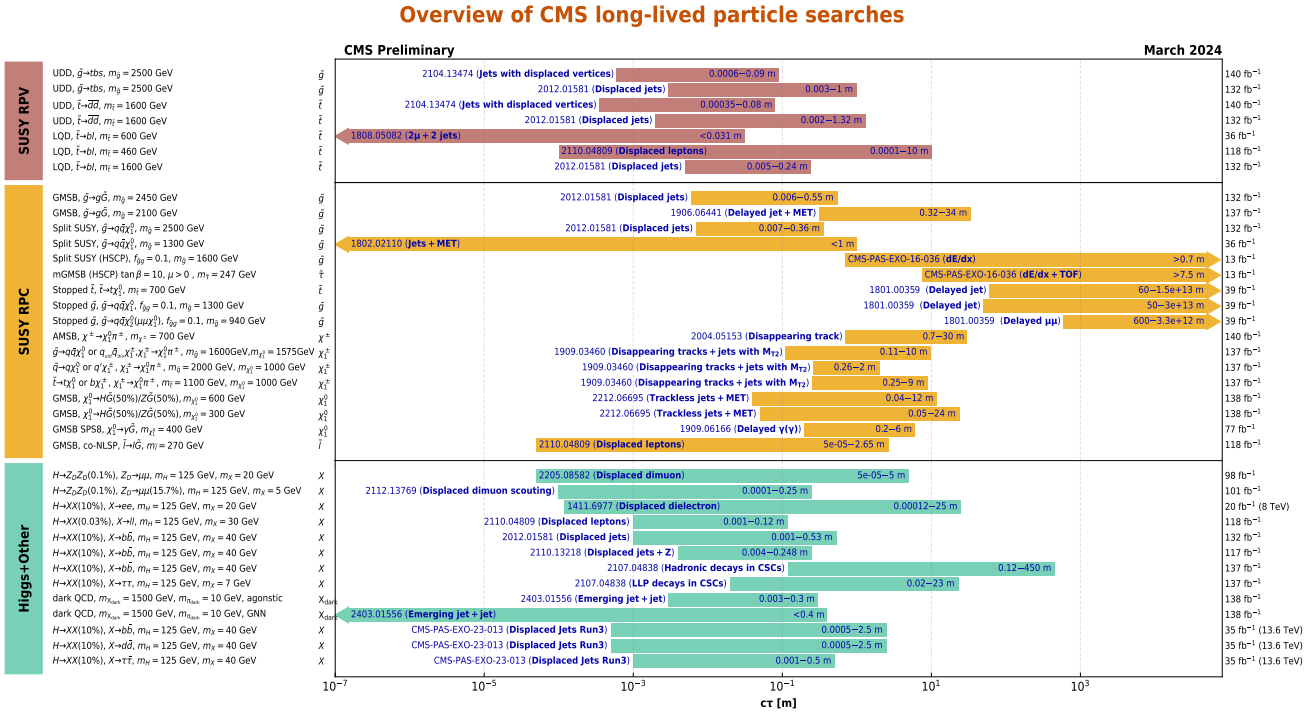

Figure 88.12: Excluded regions, at 95% C.L., in the lifetimes of long-lived particles in several models, as obtained by CMS.

charged sleptons. The limits obtained at the LHC exclude stable staus with masses below 430 GeV when produced directly in pairs, and below 660 GeV when staus are produced both directly and indirectly in the decay of other particles in a GMSB model. Recent results from ATLAS and CMS set constraints on long-lived charged sleptons with intermediate lifetimes. ATLAS searches for charged leptons with large impact parameters and exclude selectron, smuon and stau masses up to 720 GeV, 680 GeV, and 340 GeV, respectively, in case of lifetimes of 0.1 ns. They also exclude smuons with lifetimes down to 1 ps for a smuon mass of 100 GeV, and smuon masses up to 520 GeV are excluded for a proper lifetime of 10 ps [280]. CMS [197] targets long-lived stau with $c\tau$ of about 0.1 mm excluding masses between 115 and 220 GeV for the case that the LSP is nearly massless.

88.10 Global interpretations

Apart from the interpretation of direct searches for sparticle production at colliders in terms of limits on masses of individual SUSY particles, model-dependent interpretations of allowed SUSY parameter space are derived from global SUSY fits. Typically these fits combine the results from collider experiments with indirect constraints on SUSY as obtained from low-energy experiments, flavor physics, high-precision electroweak results, and astrophysical data.

In the pre-LHC era these fits were mainly dominated by indirect constraints. Even for very constrained models like the CMSSM, the allowed parameter space, in terms of squark and

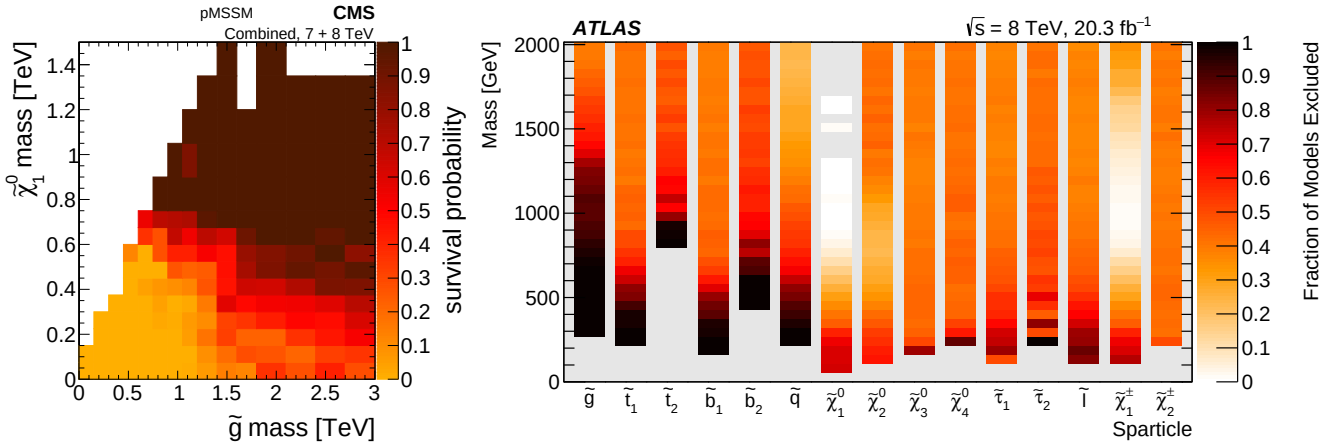

Figure 88.13: The plot on the left shows the survival probability of a pMSSM parameter space model in the gluino-neutralino mass plane after the application of the relevant CMS search results. The plot on the right shows a graphical representation of the ATLAS exclusion power in a pMSSM model. Each vertical bar is a one-dimensional projection of the fraction of models points excluded for each sparticle by ATLAS analyses. The experimental results are obtained from data taken at $\sqrt{s} = 7$ and 8 TeV.

gluino masses, ranged from several hundreds of GeV to a few TeV. Furthermore, these global fits indicated that squarks and gluino masses in the range of 500 to 1000 GeV were the preferred region of parameter space, although values as high as a few TeV were allowed with lower probabilities [281–288].

With ATLAS and CMS now probing mass scales around 1 TeV and beyond, the importance of the direct searches for global analyses of allowed SUSY parameter space has increased. For example, imposing the new experimental limits on constrained supergravity models pushes the most likely values of first generation squark and gluino masses significantly beyond 2 TeV, typically resulting in overall values of fit quality much worse than those in the pre-LHC era [158–160, 188, 289–296]. The measured value of m_h pushes the sparticle masses upwards. Although these constrained models are not yet ruled out, the extended experimental limits impose very tight constraints on the allowed parameter space.

For this reason, the emphasis of global SUSY fits has shifted towards less-constrained SUSY models. Interpretations in the pMSSM [186–190, 275, 289, 297] as well as in simplified models, have been useful to generalize SUSY searches, for example to redesign experimental analyses in order to increase their sensitivity for compressed spectra, where the mass of the LSP is much closer to squark and gluino masses than predicted by the CMSSM. As shown in Table 88.1, for neutralino LSP masses above $0.5-1$ TeV the current set of ATLAS and CMS searches, interpreted in simplified models, cannot exclude the existence of squarks or gluinos with masses only marginally above the neutralino mass. However, as these exclusion limits are defined in the context of simplified models, they are only valid for the assumptions in which these models are defined.

Fig. 88.13 shows graphically the LHC exclusion power in the pMSSM based on searches performed at $\sqrt{s} = 7$ and 8 TeV as reported by ATLAS [186] and CMS [187]. The plot on the left shows the survival probability in the gluino-neutralino mass plane, which is a measure of the parameter space that remains after inclusion of the relevant CMS search results. As can be seen, gluino masses below about 1.2 TeV are almost fully excluded. This result agrees well with the typical exclusion obtained at 8 TeV in simplified models for gluino production. However, as shown in the right plot of Fig. 88.13, when a similar analysis for other sparticles is performed it becomes apparent that exclusions on the pMSSM parameter can be significantly less stringent than simplified model limits might suggest.

More recently, the results of eight searches performed by ATLAS targeting the production of charginos and neutralinos, each using $\sqrt{s} = 13$ TeV data, have been interpreted in the context of the 19-parameter R-parity conserving pMSSM where the LSP is assumed to be the lightest neutralino [191]. Constraints from previous electroweak, flavor and dark matter related measurements are also considered. The results are presented in terms of constraints on supersymmetric particle masses and are compared with limits from simplified models. Example spectra for non-excluded supersymmetric models with light charginos and neutralinos are also reported. This again indicates that care must be taken when interpreting results from the LHC searches and there are still several scenarios where sparticles below the 1 TeV scale are not excluded, even when considering the most recent results at $\sqrt{s} = 13$ TeV.

Further interpretations in the pMSSM of searches performed on the full Run 2 dataset are in preparation and will offer further insights on the validity of constraints obtained with simplified models and, thus, guidance towards the future LHC runs and beyond.

Finally, the discovery of a Higgs boson with a mass around 125 GeV has triggered many studies regarding the compatibility of SUSY parameter space with this new particle (see for example [298, 299]). Much of it is still work in progress and it will be interesting to see how the interplay between the results from direct SUSY searches and more precise measurements of the properties of the Higgs boson will unfold in the future.

88.11 Summary and Outlook

The absence of any observation of new phenomena at the first run of the LHC at $\sqrt{s} = 7/8$ TeV, and after the second run at $\sqrt{s} = 13$ TeV, places significant constraints on SUSY parameter space. An overview of the current landscape of SUSY searches and limits at the LHC is shown in Figure 88.14, where a summary of results from the ATLAS experiment [300] (CMS results are similar [301]), is reported for illustration purposes. Inclusive searches probe production of gluinos at about 2.45 TeV, first and second generation squarks in the range of about 1 to 1.9 TeV, third generation squarks at scales around 600 GeV to 1.2 TeV, electroweak gauginos at scales around $400 - 1100$ GeV, and sleptons around 700 GeV. However, depending on the assumptions made on the underlying SUSY spectrum these limits can also weaken considerably.

With the LHC having reached almost its maximum energy of about $\sqrt{s} = 14$ TeV and analyses explored the full Run 2 dataset, future sensitivity improvements will have to originate from more data, the improvement of experimental analysis techniques and the focus on special signatures like the ones arising in long-lived sparticle decays. Therefore, it is expected that the current landscape of SUSY searches and corresponding exclusion limits at the LHC, especially for strongly produced sparticles in RPC scenarios, will not change as rapidly anymore as it did in the past, when the LHC underwent several successive increases of collision energy.

The interpretation of results at the LHC has moved away from constrained models like the CMSSM towards a large set of simplified models, or the pMSSM. Quoted limits in simplified models

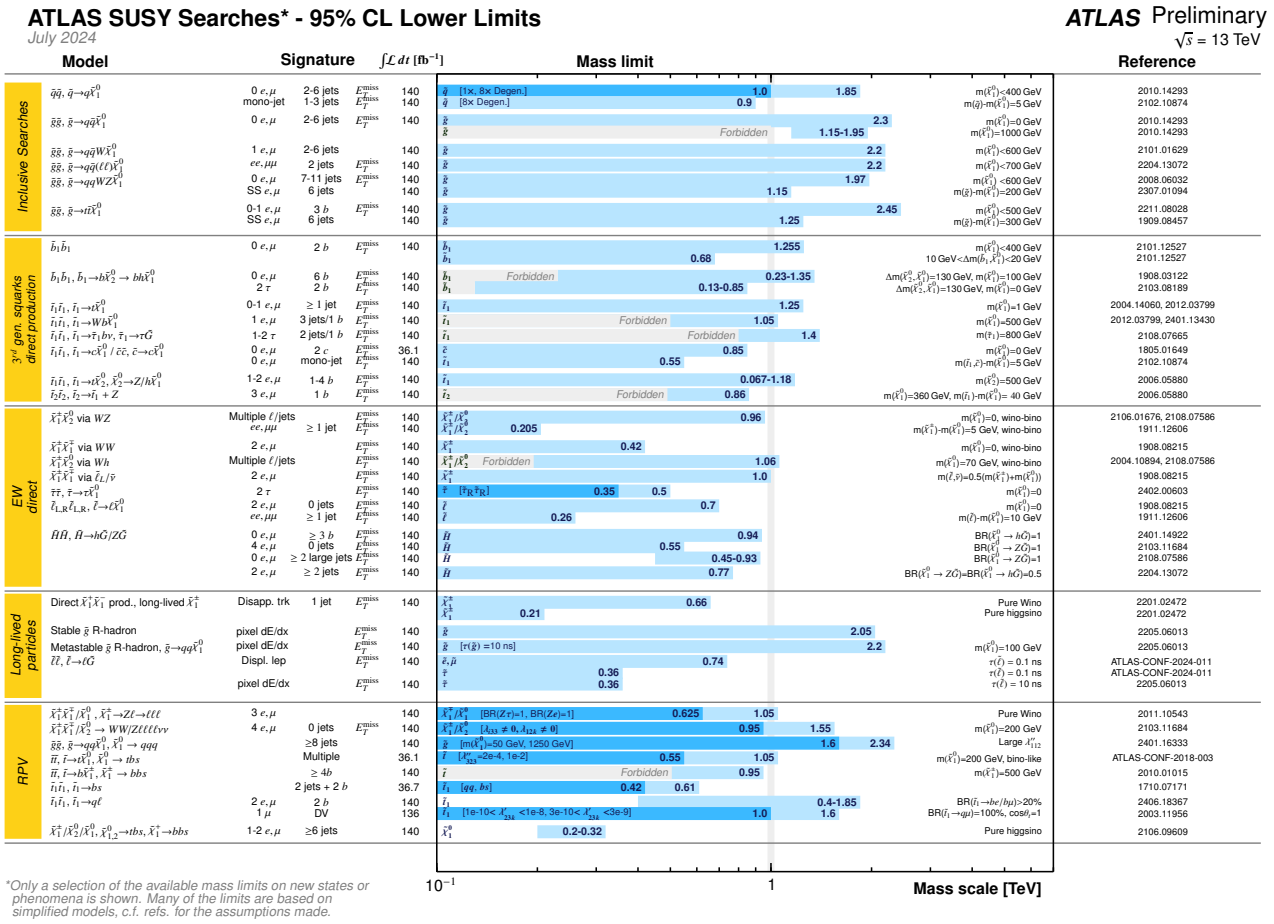

Figure 88.14: Overview of the current landscape of SUSY searches at the LHC (updated on August 2023). The plot shows exclusion mass limits of ATLAS for different searches and interpretation assumptions. The corresponding results of the CMS experiment are similar.

are only valid under the explicit assumptions made in these models. The addition of more comprehensive interpretations in the pMSSM complement those and therefore enable an even more refined understanding of the probed SUSY parameter space.

In this context, the limit range of $1.5 - 2.45$ TeV on generic colored SUSY particles only holds for light neutralinos, in the R-parity conserving MSSM. Limits on third generation squarks and electroweak gauginos also only hold for light neutralinos, and under specific assumptions for decay modes and slepton masses. Constraints in R-parity violating SUSY models strongly depend also on the assumed non-zero couplings.

The next LHC runs, with $\sqrt{s}$ between 13 and 14 TeV and significantly larger integrated luminosities (notably the High-Luminosity LHC), will provide a large data sample for future SUSY searches. As mentioned above, the improvement in sensitivity will largely have to come from a larger data set, and evolution of trigger and analysis techniques, since there will be no significant energy increase at the LHC anymore. Although the sensitivity for colored sparticles will increase somewhat as well, the expanded data set will be particularly beneficial for electroweak gaugino searches, and for the more difficult final states presented by compressed particle spectra, stealth SUSY, long-lived sparticles, or R-parity violating scenarios.

89. Axions and Other Similar Particles

Revised August 2025 by C.A.J. O'Hare (Sydney U.), G. Rybka (U. Washington), B. Safdi (UC Berkeley) and L. Winslow (MIT).

89.1 Introduction

In this section, we list coupling-strength and mass limits for light axion-like particles (ALPs) and QCD axions [1–4]. Such bosons may arise from the spontaneous breaking of a global U(1) Peccei-Quinn (PQ) symmetry, resulting in a massless Nambu-Goldstone (NG) boson. If there is a small explicit symmetry breaking, either already in the Lagrangian or due to quantum effects such as anomalies, the boson acquires a mass and is called a pseudo-NG boson. Axions may also arise in extra dimension constructions as the zero-modes of higher-dimensional gauge fields compactified on internal manifolds; in this case, the absence of a local contribution to the axion mass is due to the higher-dimensional gauge symmetry [5, 6].

A common feature of these light bosons a is that their coupling to Standard-Model particles is suppressed by the energy scale that characterizes the symmetry breaking, *i.e.*, the decay constant f_a. For example, in models where the axion arises as a Goldstone boson, the interaction Lagrangian at energy scales below f_a is

$$\mathcal{L} = f_a^{-1} J^\mu \partial_\mu a \,, \tag{89.1}$$

where J^μ is the Noether current of the spontaneously broken global symmetry. If f_a is very large, these new particles interact very weakly. Detecting them would provide a window to physics far beyond what can be probed at accelerators.

The QCD axions is of particular interest because it provides a compelling scheme to preserve CP-symmetry in QCD. Moreover, the cold dark matter (CDM) of the Universe may well consist of axions and they are searched for in dedicated experiments with a realistic chance of discovery.

Originally it was assumed that the PQ scale f_a was related to the electroweak symmetry-breaking scale $v_{\rm EW} = (\sqrt{2}G_{\rm F})^{-1/2} = 246.22$ GeV. However, the associated "standard" and "variant" axions were quickly excluded—we refer to the Listings for detailed limits. Here we focus on "invisible axions" with $f_a \gg v_{\rm EW}$ as the main possibility.

Axions have a characteristic two-photon vertex, inherited from their mixing with π^0 and η. This coupling allows for the main search strategy based on axion-photon conversion in external magnetic fields [7], an effect that also can be of astrophysical interest. While for axions the product "$a\gamma\gamma$ interaction strength × mass" is essentially fixed by the corresponding π^0 properties, one may consider a more general class of ALPs where the two parameters (coupling and mass) are independent. A number of experiments explore this more general ALP parameter space. ALPs populating the latter are predicted to arise generically, in addition to the axion, in low-energy effective field theories emerging from string theory [5, 6, 8–14].

89.2 Theory

89.2.1 *Peccei-Quinn mechanism and axions*

The QCD Lagrangian includes a CP-violating term $\mathcal{L}_\Theta = -\bar{\Theta}\,(\alpha_s/8\pi)\,G^{\mu\nu a}\tilde{G}^a_{\mu\nu}$, where $-\pi \le \bar{\Theta} \le +\pi$ is the effective Θ parameter after diagonalizing quark masses, $G^a_{\mu\nu}$ is the color field strength tensor, and $\tilde{G}^{a,\mu\nu} \equiv \epsilon^{\mu\nu\lambda\rho}G^a_{\lambda\rho}/2$, with $\varepsilon^{0123} = 1$, its dual. This term induces an electric dipole moment (EDM) of the neutron of strength $d_n = C_{\rm EDM}\, e\,\bar{\Theta}$. The coefficient $C_{\rm EDM}$ is calculated using QCD sum rules as $C_{\rm EDM} = 2.4(1.0) \times 10^{-16}\,{\rm cm}$ [15], while lattice QCD computations find $C_{\rm EDM} = 1.48(14)(31) \times 10^{-16}\,{\rm cm}$ [16] including statistical and systematic uncertainties. Experimental upper bounds on the latter, $|d_n| < 1.8 \times 10^{-26}\, e\,{\rm cm}$ [17, 18], imply $|\bar{\Theta}| \lesssim 10^{-10}$ even though $\bar{\Theta} = \mathcal{O}(1)$ is otherwise completely satisfactory. Note that the proton has a similar EDM as the neutron, but it is less strongly constrained at present; this could change in the future [19]. The proton EDM may be written as $d_p = C^p_{\rm EDM}\, e\,\bar{\Theta}$, with $C^p_{\rm EDM} = -3.8(11)(8)$ [16]. The opposite signs of the neutron and proton EDMs may be understood from the opposite signs of their magnetic moments. The spontaneously broken global PQ symmetry $\mathrm{U}(1)_{\rm PQ}$ was introduced to solve the "strong CP problem" [1, 2] of small Θ , the axion being the pseudo-NG boson of $\mathrm{U}(1)_{\rm PQ}$ [3, 4]. This symmetry is broken due to the axion's anomalous triangle coupling to gluons,

$$\mathcal{L} = \left(\frac{a}{f_a} - \bar{\Theta}\right)\frac{\alpha_s}{8\pi}\,G^{\mu\nu a}\tilde{G}^a_{\mu\nu}\,, \tag{89.2}$$

where a is the axion field and f_a the axion decay constant. Color anomaly factors have been absorbed in the normalization of f_a which is defined by this Lagrangian. Thus normalized, f_a is the quantity that enters all low-energy phenomena [20]. Non-perturbative topological fluctuations of the gluon fields in QCD induce a potential for a whose minimum is at $a = \bar{\Theta}\, f_a$, thereby canceling the $\bar{\Theta}$ term in the QCD Lagrangian and thus restoring CP symmetry.

The resulting axion mass, in units of the PQ scale f_a, is identical to the square root of the topological susceptibility in QCD, $m_a f_a = \sqrt{\chi}$. The latter can be evaluated further [21, 22], exploiting the chiral limit (masses of up and down quarks much smaller than the scale of QCD), yielding $m_a f_a = \sqrt{\chi} \approx f_\pi m_\pi$, where $m_\pi \approx 135$ MeV and $f_\pi \approx 92$ MeV . In more detail one finds, by including $\mathcal{O}(\alpha)$ QED corrections and next-to-next-to-leading order (NNLO) corrections in chiral perturbation theory [23],

$$m_a = 5.691(51)\left(\frac{10^9\ {\rm GeV}}{f_a}\right){\rm meV}\,. \tag{89.3}$$

A direct calculation of the topological susceptibility via QCD lattice simulations finds almost the same central value, albeit with an about five times larger error bar [24].

The QCD axion acquires a variety couplings to low-energy Standard Model observables, as we discuss in detail in this review. The most model-independent couplings are those of the axion to the neutron and proton EDM operators. While the axion removes the static neutron and proton EDMs, displacements of the axion field a from its vacuum expectation value induce field-dependent EDMs, which are characterized through the operator

$$\mathcal{L}_{aN\gamma} = -\frac{i}{2}g_{aN\gamma}\, a\,\overline{\Psi}_N\sigma_{\mu\nu}\gamma_5\Psi_N F^{\mu\nu}\,, \tag{89.4}$$

with $N = n, p$ for neutrons or protons, respectively. The coupling $g_{an\gamma}$ is related to $C_{\rm EDM}$ by $g_{an\gamma} = eC_{\rm EDM}/f_a$ and similarly for $g_{ap\gamma}$. Direct probes of the axion-EDM operators are difficult, though by studying the thermal production of axions in the early universe one can broadly constrain, using Planck and Baryon Acoustic Oscillation (BAO) data, $m_a \lesssim 0.3$ eV [25]. In the presence of an oscillatory relic axion DM field, this operator induces an oscillating neutron EDM; this effect forms the basis of the CASPEr experiment [26, 27] that is discussed more later in this review. Non-linearly realized discrete-symmetries may be used to suppress the QCD axion mass below the prediction in Eq. (89.3), in which case a variety of cosmological and terrestrial constraints on the operator in Eq. (89.4) are also relevant [28–35]

Axions with $f_a \gg v_{\rm EW}$ evade almost all current experimental limits. Given that the axion interacts with ordinary matter through higher-dimensional operators, it requires an ultraviolet (UV) completion at an energy scale of order f_a. Broadly speaking, there are two distinct classes of UV scenarios that give rise to axions in the infrared (IR) low-energy effective field theory (EFT) (see [36] for a review of UV axion models): (i) 4d field theory models that realize the axion as a Goldstone mode of a spontaneously broken but also anomalous abelian $U(1)_{\rm PQ}$ symmetry, (ii) extra-dimensional models where the axion arises as the zero-mode of a higher-dimensional gauge field. Within the first category, one generic class of models is that of "hadronic axions," where new heavy quarks carry $\mathrm{U}(1)_{\rm PQ}$ charges, leaving ordinary quarks and leptons without tree-level axion couplings. The archetype is the KSVZ model [37, 38], where in addition the heavy new quarks are electrically neutral. Another generic class of field theory axion models requires at least two Higgs doublets and ordinary quarks and leptons carry PQ charges, the archetype being the DFSZ model [159, 160]; in this case the quarks and leptons may have

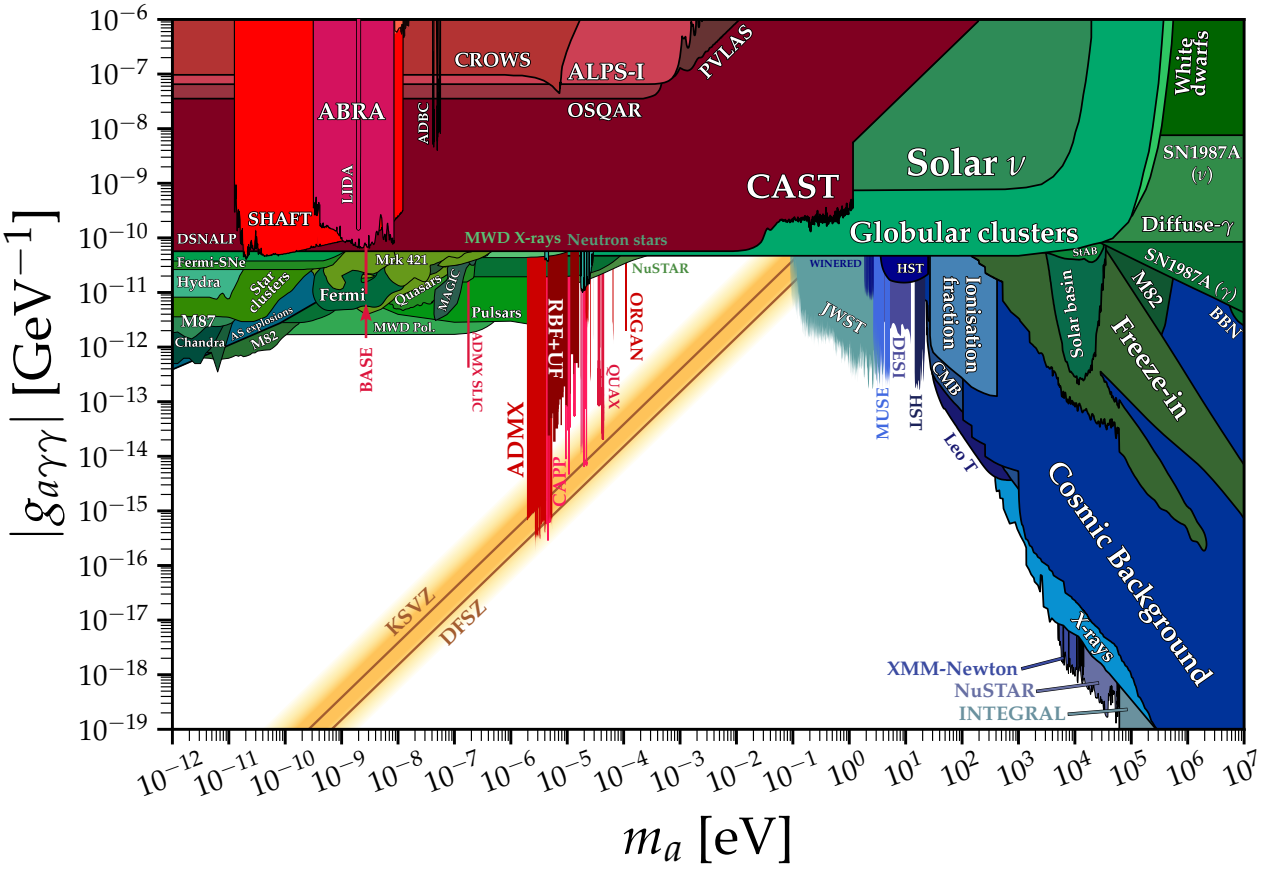

Figure 89.1: Exclusion plot for the ALP-photon coupling. Figure from [39], contains exclusions from refs. [40–158]. Constraints in red are from terrestrial experiments. Haloscope searches assume all local dark matter is axions. Those shown in green are astrophysical but make no assumption about axions being DM. See text for details regarding the diagonal yellow band expectation for the QCD axion and assumptions for blue high mass axion astrophysical limits.

tree-level axion couplings. All of these models contain at least one electroweak singlet scalar that acquires a vacuum expectation value and thereby breaks the PQ symmetry. The KSVZ and DFSZ models are frequently used as benchmark examples, but other field theory models exist where both heavy quarks and Higgs doublets carry PQ charges [36].

The field theory axion constructions, like KSVZ, DFSZ, and related variants, suffer from the so-called PQ quality problem [161–165]. The issue is that global symmetries are not expected to be respected in quantum gravity (see, *e.g.*, [166]); in particular, PQ-violating operators at the Planck scale spoil the quality of the $U(1)_{\rm PQ}$ symmetry, generating a neutron EDM in conflict with the experimental constraints. On the other hand, the axion quality is naturally exponentially better in the second class of UV completions mentioned in the previous paragraph, when the axion arises as the zero mode of an extra dimensional gauge field. In this case, the axion potential is protected by the gauge symmetry of the higher-dimensional theory, instead of a global symmetry. (More technically, the axion quality in extra dimensional constructions is best understood through the language of generalized global symmetries [167–169].) Contributions to the axion potential must be non-local and are thus naturally exponentially suppressed. Extra dimensional axions arise naturally in string theory constructions, as string theory has a plethora of higher-form gauge fields and lives most naturally in 10 or 11 dimensions, which requires some of those dimensions to be compactified. The presence of multiple distinct and non-trivial cycles in the compact manifold and higher-form gauge fields leads to a plethora of axions, which is known as the axiverse [6, 10, 12]—one of these axions can be the QCD axion. While field theory axions can have any $f_a \lesssim M_{\rm pl}$ and thus any mass larger than roughly 10^{-12} eV, axions in string theory most naturally have $m_a \lesssim 10^{-8}$ eV [6, 170], though higher QCD axion masses are also possible in these constructions at the cost of fine tuning [171, 172].

89.2.2 *Model-dependent axion couplings*

Although the generic axion interactions scale approximately with f_π/f_a from the corresponding π^0 couplings, there are non-negligible model-dependent factors and uncertainties. The axion's two-photon interaction plays a key role for many searches,

$$\mathcal{L}_{a\gamma\gamma} = -\frac{g_{a\gamma\gamma}}{4}\, a\, F_{\mu\nu}\tilde{F}^{\mu\nu} = g_{a\gamma\gamma}\, a\, \mathbf{E}\cdot\mathbf{B}\,, \qquad (89.5)$$

where F is the electromagnetic field-strength tensor and $\tilde{F}^{\mu\nu} \equiv \epsilon^{\mu\nu\lambda\rho}F_{\lambda\rho}/2$, with $\varepsilon^{0123} = 1$, its dual. The coupling constant is [173]

$$g_{a\gamma\gamma} = \frac{\alpha}{2\pi f_a}\left(\frac{E}{N} - 1.92(4)\right) = \left(0.203(3)\frac{E}{N} - 0.39(1)\right)\frac{m_a}{\rm GeV^2}\,, \qquad (89.6)$$

where E and N are the electromagnetic and color anomalies of the axial current associated with the axion, and α is the low-energy fine structure constant. In grand unified models, and notably for DFSZ [159, 160], $E/N = 8/3$, whereas for KSVZ [37, 38] $E/N = 0$ if the electric charge of the new heavy quark is taken to vanish. In general, a broad range of E/N values is possible [36, 174–176], as indicated by the diagonal yellow band in Fig. 89.1, whose width is roughly determined by the boundary values $E/N = 44/3$ and $E/N = 5/3$, respectively. However, this band still does not exhaust all the possibilities. In fact, there exist classes of QCD axion models whose photon couplings populate the entire still-allowed region outside the yellow band in Fig. 89.1 [177–182], motivating axion search efforts over a wide range of masses and couplings.

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

The two-photon decay width is

$$\Gamma_{a\to\gamma\gamma} = \frac{g_{a\gamma\gamma}^2 m_a^3}{64\,\pi} \approx 1.1\times10^{-24}\ \mathrm{s}^{-1}\left(\frac{m_a}{\mathrm{eV}}\right)^5 . \tag{89.7}$$

The second expression uses Eq. (89.6) with $E/N = 0$. Axions decay faster than the age of the Universe if $m_a \gtrsim 20$ eV.

The interaction with fermions f has derivative form and is invariant under a shift $a \to a + a_0$ as behooves a NG boson,

$$\mathcal{L}_{aff} = \frac{C_f}{2f_a}\,\partial_\mu a\,\bar\Psi_f\gamma^\mu\gamma_5\Psi_f\ . \tag{89.8}$$

Here, Ψ_f is the fermion field, m_f its mass, and C_f a model-dependent coefficient. The dimensionless combination $g_{aff} \equiv C_f m_f/f_a$ plays the role of a Yukawa coupling and $\alpha_{aff} \equiv g_{aff}^2/4\pi$ of a "fine-structure constant." The often-used pseudoscalar form $\mathcal{L}_{aff} = -\mathrm{i}\,(C_f m_f/f_a)\,a\,\bar\Psi_f\gamma_5\Psi_f$ need not be equivalent to the appropriate derivative structure, for example when two NG bosons are attached to one fermion line as in axion emission by nucleon bremsstrahlung [183–185].

In hadronic axion models, C_e vanishes at tree level, but is then generated radiatively at one loop [186,187],

$$C_e \simeq \frac{3\alpha^2}{4\pi^2}\left[\frac{E}{N}\log\left(\frac{f_a}{m_e}\right) - 1.92\log\left(\frac{\Lambda_\chi}{m_e}\right)\right] , \tag{89.9}$$

where $\Lambda_\chi \simeq 1$ GeV is the chiral symmetry breaking scale. In the DFSZ model [159, 160], the tree-level coupling coefficient to electrons is [186]

$$C_e = \frac{\sin^2\beta}{3}\,, \tag{89.10}$$

where $\tan\beta$ is the ratio of the vacuum expectation values of the two Higgs doublets giving masses to the up- and down-type quarks, respectively: $\tan\beta = v_u/v_d$. As a cautionary note, many of the original axion references, such as [186], defined $\tan\beta = v_d/v_u$, but the choice $\tan\beta = v_u/v_d$ adopted here and in more modern axion works is a reflection of the choice taken in the two-Higgs-doublet literature [188]. The resulting prediction for the axion-electron coupling, as a function of the axion mass, for the KSVZ axion ($E/N = 0$), hadronic axions, with $5/3 \le E/N \le 44/3$, and the DFSZ axion is displayed in Fig. 89.2. For the DFSZ range we have taken into account the constraint $0.28 \lesssim \tan\beta \lesssim 140$ [189] arising from the requirement of perturbative unitarity of the Yukawa couplings of Standard Model fermions.

For nucleons, $C_{p,n}$ have been determined as [173]

$$\begin{aligned} C_p &= -0.47(3) + 0.88(3)C_u - 0.39(2)C_d - 0.038(5)C_s \\ &\quad - 0.012(5)C_c - 0.009(2)C_b - 0.0035(4)C_t\,, \\ C_n &= -0.02(3) + 0.88(3)C_d - 0.39(2)C_u - 0.038(5)C_s \\ &\quad - 0.012(5)C_c - 0.009(2)C_b - 0.0035(4)C_t\,, \end{aligned} \tag{89.11}$$

in terms of the corresponding model-dependent quark couplings C_q, $q = u, d, s, c, b, t$. For hadronic axions, the latter vanish at tree-level, which means that C_n is expected to be much smaller than C_p. In the DFSZ model, $C_u = C_c = C_t = \frac{1}{3}\cos^2\beta$ and $C_d = C_s = C_b = \frac{1}{3}\sin^2\beta$, and C_p and C_n, as functions of β,

$$\begin{aligned} C_p &= -0.435\sin^2\beta + (-0.182 \pm 0.025)\ , \\ C_n &= 0.414\sin^2\beta + (-0.160 \pm 0.025)\ . \end{aligned} \tag{89.12}$$

The resulting prediction for the axion-neutron coupling, as a function of the axion mass, for the KSVZ axion and the DFSZ axion is displayed in Fig. 89.3. Note, however, that these couplings receive in-medium corrections, which may be important when considering compact stars [190].

The axion-pion interaction is given by the Lagrangian [187,191]

$$\mathcal{L}_{a\pi} = \frac{C_{a\pi}}{2f_\pi f_a}\,\partial_\mu a\left(\pi^0\pi^+\partial_\mu\pi^- + \pi^0\pi^-\partial_\mu\pi^+ - 2\pi^+\pi^-\partial_\mu\pi^0\right)\ , \tag{89.13}$$

where $C_{a\pi} = 2(C_p - C_n)/(3g_A)$ and $g_A = 1.2723(23)$ is the nucleon axial charge.

Additionally, there are axion-pion-nucleon interactions of the form

$$\mathcal{L}_{a\pi N} = \frac{C_{a\pi N}}{2f_\pi f_a}\partial_\mu a\left(i\pi^+\bar p\gamma^\mu n - i\pi^-\bar n\gamma^\mu p\right)\ , \tag{89.14}$$

where $C_{a\pi N} = (C_{ap} - C_{an})/(\sqrt{2}g_A)$. Axion-kaon interactions are also present.

89.3 Laboratory Searches

89.3.1 *Light shining through walls*

Searching for "invisible axions" is extremely challenging due to their extraordinarily feeble coupling to normal matter and radiation. Currently, the most promising approaches rely on the axion-two-photon interaction, allowing for axion-photon conversion in external electric or magnetic fields [7]. For the Coulomb field of a charged particle, the conversion can be viewed as a scattering process, $\gamma + Ze \leftrightarrow Ze + a$, called the Primakoff effect [192]. In the other extreme of a macroscopic field, usually a large-scale B-field, the momentum transfer is small, the interaction is coherent over a large distance, and the conversion can be viewed as an axion-photon oscillation phenomenon in analogy to neutrino flavor oscillations [193].

Photons propagating through a transverse magnetic field, with incident $\mathbf{E}_\gamma$ and magnetic field $\mathbf{B}$ parallel, may convert into axions. For $m_a^2 L/2\omega \ll 2\pi$, where L is the length of the B field region and ω the photon energy, the resultant axion beam is coherent with the incident photon beam and the conversion probability is $\Pi \sim (1/4)(g_{a\gamma\gamma}BL)^2$. One such realization uses a laser beam propagating down the bore of a superconducting dipole magnet (like, say, the bending magnets in high-energy accelerators). If another magnet is in line with the first, but shielded by an optical barrier, then photons may be regenerated from the pure axion beam [194, 195]. The overall probability is $P(\gamma \to A \to \gamma) = \Pi^2$.

The first such Light-Shining-through-Walls (LSW) experiment was performed by the BFRT (Brookhaven-Fermilab-Rochester-Trieste) collaboration. It utilized two magnets of length $L = 4.4$ m and $B = 3.7$ T and found $|g_{a\gamma\gamma}| < 6.7\times10^{-7}$ GeV^{-1} at 95% CL for $m_a < 1$ meV [196, 197]. More recently, several such experiments were performed (see Listings) [75, 78, 198–202]. The current best limit, $|g_{a\gamma\gamma}| < 3.5\times10^{-8}$ GeV^{-1} at 95% CL for $m_a \lesssim 0.3$ meV (see Fig. 89.1), has been achieved by the OSQAR (Optical Search for QED Vacuum Birefringence, Axions, and Photon Regeneration) experiment, which exploited two 9 T LHC dipole magnets and an 18.5 W continuous wave laser emitting at the wavelength of 532 nm [78]. The ALPS I (Any Light Particle Search I) experiment achieved a similar sensitivity [75], see Fig. 89.1. Some of these experiments have also reported limits for scalar bosons where the photon $\mathbf{E}_\gamma$ must be chosen perpendicular to the magnetic field $\mathbf{B}$.

The concept of resonantly enhanced photon regeneration may open unexplored regions of coupling strength [203–205]. In this scheme, both the production and detection magnets are within Fabry-Perot optical cavities and actively locked in frequency. The $\gamma \to a \to \gamma$ rate is enhanced by a factor $\mathcal{F}\mathcal{F}'/\pi^2$ relative to a single-pass experiment, where $\mathcal{F}$ and $\mathcal{F}'$ are the finesses of the two cavities. The resonant enhancement could be of order $10^{(10-12)}$, improving the $g_{a\gamma\gamma}$ sensitivity by $10^{(2.5-3)}$. The experiment ALPS II (Any Light Particle Search II) is based on this concept and aims at an improvement of the current laboratory bound on $g_{a\gamma\gamma}$ by a factor $\sim 10^3$ [206]. ALPS II began operations in 2023, the regeneration cavity has been characterized [207], and a result from the first data taking campaign is pending.

Resonantly enhanced photon regeneration has already been exploited in experiments searching for "radiowaves shining through a shielding" [208–211]. For $m_a \lesssim 10^{-5}$ eV, the upper bound on $g_{a\gamma\gamma}$ established by the CROWS (CERN Resonant Weakly Interacting sub-eV Particle Search) experiment [77] is slightly less stringent than the one set by OSQAR, see Fig. 89.1.

89.3.2 *Long-range forces*

New bosons would mediate new long-range forces, which are severely constrained by "fifth force" experiments [212]. Those

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

looking for new mass-spin couplings provide significant constraints on pseudoscalar bosons [213–218], see for example in Fig. 89.3 the limit on the axion-neutron coupling [219] from torsion balance tests of the gravitational inverse square law [220]. Presently, the most restrictive limits are obtained from combining long-range force measurements with stellar cooling arguments [221, 222]. For the moment, any of these limits are far from realistic values expected for the QCD axion. Still, these efforts provide constraints on more general low-mass bosons.

In Ref. [223], a method was proposed that can extend the search for axion-mediated spin-dependent forces by several orders of magnitude. By combining techniques used in nuclear magnetic resonance and short-distance tests of gravity, this method appears to be sensitive to the QCD axion in the μeV – meV mass range, independent of the cosmic axion abundance, if axions have a CP-violating interaction with nuclei as large as the current experimental bound on the electric dipole moment of the neutron allows. (Note that the CP-violation already present in the Standard Model is sufficient for generating an axion-mediated force, though in this case the signal appears too small to be detectable for the QCD axion in the foreseeable future [223].) The ARIADNE (Axion Resonant InterAction DetectioN Experiment) is under development and employs this approach to search for axion-mediated spin-dependent short-range interactions between a hyper-polarized ^{3}He sample and an unpolarized tungsten source mass [224]. The method relies on superconducting magnetic shielding to screen the sample from ordinary magnetic field noise. Experimental tests to demonstrate the requirements of ARIADNE, including characterization of the magnetic field backgrounds, are under way [225, 226].

89.4 Axions from Astrophysical Sources

89.4.1 *Stellar energy-loss limits*

Axions are produced in hot astrophysical plasmas, and can thus transport energy out of stars. The coupling strength of these particles with normal matter and radiation is bounded by the constraint that stellar lifetimes or energy-loss rates are not in conflict with observation [227, 228].

We begin this discussion with our Sun and concentrate first on the axion-photon coupling. In the Sun axions are produced by the Primakoff process $\gamma + Ze \to Ze + a$. Integrating this process over a standard solar model yields the axion luminosity [229]

$$L_a = g_{10}^2 \times 1.85 \times 10^{-3}\, L_\odot\,, \tag{89.15}$$

where $g_{10} = |g_{a\gamma\gamma}| \times 10^{10}$ GeV. The maximum of the spectrum is at 3.0 keV, the average at 4.2 keV, and the number flux at Earth is $g_{10}^2 \times 3.75 \times 10^{11}$ cm^{-2} s^{-1}. The solar photon luminosity is fixed, so energy losses due to the Primakoff process require enhanced nuclear energy production and thus enhanced neutrino fluxes. The all-flavor measurements by SNO (Sudbury Neutrino Observatory), together with a standard solar model, imply $L_a \lesssim 0.10\, L_\odot$, corresponding to $g_{10} \lesssim 7$ [230], mildly superseding a similar limit from helioseismology (sound speed, surface helium and convective radius) [231]. In Ref. [124], this limit was improved to $g_{10} < 4.1$ (at $3\,\sigma$), see Fig. 89.1, exploiting a new statistical analysis that combined helioseismology and solar neutrino observations, including theoretical and observational errors, and accounting for tensions between input parameters of solar models, in particular the solar element abundances. Going beyond the axion-photon coupling, Ref. [230] considered also a non-zero axion-electron coupling and obtained the bound on the latter displayed in Fig. 89.2.

A more restrictive limit derives from globular-cluster (GC) stars that allow for detailed tests of stellar-evolution theory. The stars on the horizontal branch (HB) in the color-magnitude diagram have reached helium burning with a core-averaged energy release of about 80 erg g^{-1} s^{-1}, compared to Primakoff axion losses of $g_{10}^2\, 30$ erg g^{-1} s^{-1}. The accelerated consumption of helium reduces the HB lifetime by about $80/(80 + 30\, g_{10}^2)$. In contrast, the red giant (RG) branch stars are not strongly affected by Primakoff losses, since unlike for the HB stars the plasma frequency in the RG stellar cores is below the temperature. Thus, Primakoff production reduces the R-parameter, which is the number of observed HB branch stars to RG branch stars in a GC. Measurements of

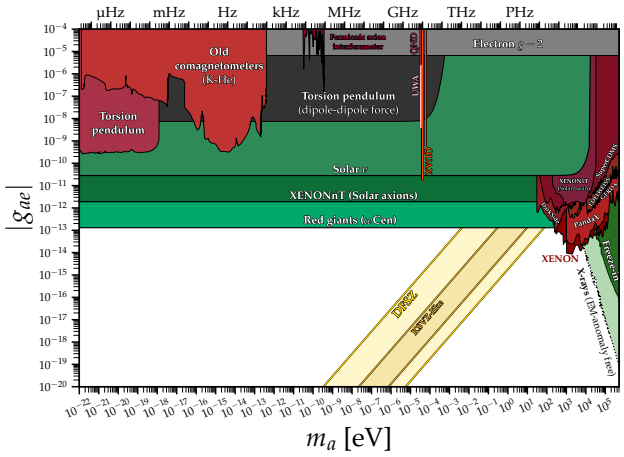

Figure 89.2: Exclusion plot for ALP-electron coupling as described in the text. Figure from [39], contains data from refs. [145, 230, 232–243]. The hadronic QCD axion-electron coupling arises at one loop and is given in Eq. (89.9); varying E/N between 5/3 and 44/3 gives the indicated hadronic axion band. The KSVZ axion has $E/N = 0$, while the DFSZ axion-electron coupling has the tree-level coupling given in Eq. (89.10) that depends on the unknown but bounded value of $\tan\beta$ (see text for details).

the R-parameter in a large sample of 39 Galactic GCs give a weak indication of non-standard losses which may be accounted by Primakoff-like axion emission, if the photon coupling is in the range $|g_{a\gamma\gamma}| = (2.9 \pm 1.8) \times 10^{-11}$ GeV^{-1} [99, 244]. Still, the upper bound found in this analysis,

$$|g_{a\gamma\gamma}| < 6.6 \times 10^{-11}\,\text{GeV}^{-1}\ (95\%\,\text{CL}), \tag{89.16}$$

represents one of the strongest limits on $g_{a\gamma\gamma}$ for a wide mass range. More recently, the R_2-parameter has emerged as a potentially more sensitive probe of axions; the R_2-parameter is defined as the ratio of the asymptotic giant branch (AGB) stars to the HB stars in a GC. AGB stars have more efficient Primakoff production than HB stars, meaning that R_2 is expected to decrease for increasing $|g_{a\gamma\gamma}|$. Ref. [100] used an R_2 measurement based off of 48 GCs as observed by the Hubble Space Telescope [245] to constrain

$$|g_{a\gamma\gamma}| < 4.7 \times 10^{-11}\,\text{GeV}^{-1}\ (95\%\,\text{CL})\,. \tag{89.17}$$

The constraint above on $g_{a\gamma\gamma}$ may be translated to $f_a > 4.8 \times 10^7$ GeV $(m_a < 0.12$ eV) , using $E/N = 0$ as in the KSVZ model, or to $f_a > 1.8 \times 10^7$ GeV $(m_a < 0.32$ eV) , for the DFSZ axion model, with $E/N = 8/3$, see Fig. 89.1.

If axions couple directly to electrons, the dominant emission processes are atomic axio-recombination and axio-deexcitation, axio-bremsstrahlung in electron-ion or electron-electron collisions, and Compton scattering [246]. Stars in the RG branch of the color-magnitude diagram of GCs are particularly sensitive to these processes: they would lead to an extension of the RG branch to larger brightness. In fact, the tip of the RG branch (TRGB) – the brightest point of the RG branch – provides the currently most sensitive method to test the axion coupling to electrons. The strongest bounds on it are derived from analyses of the TRGB in several GCs [247] and in the Galactic GC ω Centauri [239]. The two analyses lead to very similar results,

$$|g_{aee}| < 1.48{\times}10^{-13}\ (95\%\ \text{CL})\ \ \&\ \ |g_{aee}| < 1.3{\times}10^{-13}\ (95\%\ \text{CL}), \tag{89.18}$$

respectively, see Fig. 89.2. Reference [247] finds also a small hint for extra cooling, corresponding to $|g_{aee}| = 0.60^{+0..32}_{-0.58} \times 10^{-13}$, while Ref. [239] does not find any evidence for exotic cooling.

Bremsstrahlung is also efficient in white dwarfs (WDs), where the Primakoff and Compton processes are suppressed by the large plasma frequency. A comparison of the predicted and observed luminosity function of WDs can be used to put limits on $|g_{aee}|$

[248, 249]. An analysis based on detailed WD cooling treatment and data on the WD luminosity function (WDLF) of the Galactic disk found that electron couplings above $|g_{aee}| \gtrsim 3 \times 10^{-13}$ are disfavoured [250]. Lower couplings cannot be discarded from the current knowledge of the WDLF of the Galactic disk [250–252]. These probes may be improved by the Rubin Observatory Large Synoptic Survey Telescope (LSST), which is expected to increase the sample of WDs in the Galactic halo to hundreds of thousands [253]. For pulsationally unstable WDs (ZZ Ceti stars), the period decrease $\dot{P}/P$ is a measure of the cooling speed. The corresponding observations of a handful pulsating WDs imply additional cooling that can be interpreted in terms of axion energy losses [254–258], though with axion-electron coupling values likely incompatible with other constraints [259].

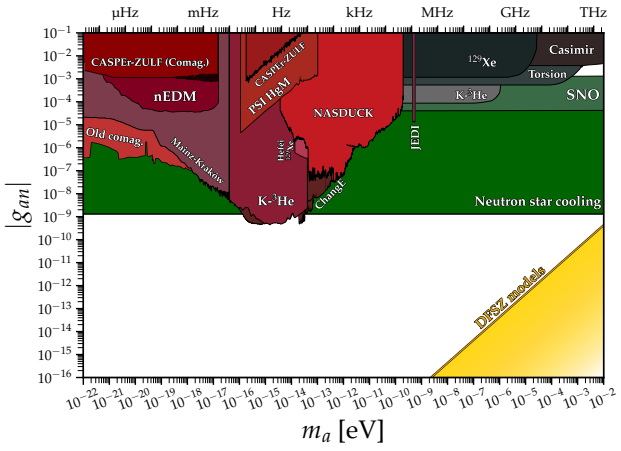

Figure 89.3: Exclusion plot for ALP-neutron coupling as described in the text. Figure from [39], includes data from refs. [31, 33, 219, 260–273]. The hadronic axion model prediction is given in Eq. (89.11) with vanishing quark couplings, while the DFSZ model prediction depends on $\tan\beta$ as is found in Eq. (89.12), giving the shaded yellow region above. Note that for a fine-tuned value of $\tan\beta$ g_{an} can be taken to zero. On the other hand, the neutron star cooling constraints [269] also probe the axion-proton coupling g_{ap} at a comparable level (not shown), and both g_{an} and g_{ap} cannot simultaneously be taken to zero in the DFSZ model.

Analogous constraints derive from neutron star (NS) cooling. Broadly speaking, there are two classes of NS cooling searches for axions. One approach uses the proto-NS formed after SN 1987A to constrain the axion luminosity produced during the first seconds of the proto-NS when the neutrino luminosity is measured with terrestrial experiments. The second class of NS cooling constraints consider older NSs, typically much older than ∼100 yr, and constrains the axion luminosity using the surface temperature as measured with photons versus the age of NS as measured through *e.g.* kinematic considerations. We begin with a discussion of the limits from SN 1987A.

Numerical simulations reveal that the energy-loss rate due to axions in a nuclear medium at the density 3×10^{14} g cm^{-3} and temperature 30 MeV should not exceed about 1×10^{19} erg g^{-1} s^{-1} to be consistent with the neutrino signal observed from SN 1987A [274]. The energy-loss rate from nucleon bremsstrahlung, $N + N \to N + N + a$, is $(C_N/2f_a)^2 (T^4/\pi^2 m_N) F$. Here F is a numerical factor that represents an integral over the dynamical spin-density structure function because axions couple to the nucleon spin. For realistic conditions, even after considerable effort, one is limited to a heuristic estimate leading to $F \approx 1$ [228]. The SN 1987A limits are of particular interest for hadronic axions where the bounds on $|g_{aee}|$ are moot. Using a proton fraction of 0.3, $g_{ann} = 0$, $F = 1$, and $T = 30$ MeV, one finds $f_a > 4 \times 10^8$ GeV and $m_a < 16$ meV [228]. A more detailed numerical calculation [275] with state of the art SN models, again assuming $g_{ann} = 0$, found that a coupling larger than $|g_{app}| \gtrsim 6 \times 10^{-10}$, would shorten significantly the timescale of the neutrino emission. This result is, not surprisingly, rather close to the estimate in Ref. [228]. Improving the calculation of axion emission via nucleon-nucleon bremsstrahlung beyond the basic one-pion exchange approximation appears to loosen the bound [276, 277]. The latter analysis finds a reduction of the axion emissivity by an order of magnitude if one takes into account the non-vanishing mass of the exchanged pion, the contribution from two-pion exchange, effective in-medium nucleon masses and multiple nucleon scattering, leading to the result [277]

$$g_{ann}^2 + 0.61\, g_{app}^2 + 0.53\, g_{ann}\, g_{app} < 8.26 \times 10^{-19}\,, \qquad (89.19)$$

which is consistent with the original estimate in [228]. This analysis, however, still neglects another very efficient mechanism for axion production in a SN: the pion production process, $\pi^- + p \to a + n$, also induced by the axion coupling to nucleons. Pion production was recognized long ago as being competitive with nucleon bremsstrahlung [278–280]. However, only recently it was shown that the pion abundance in the early stages of a SN is much larger than previously expected [281]. It was shown in Ref. [282] that pion induced processes dominate over bremsstrahlung and so strengthen the bound on the axion-nucleon coupling. On the other hand, given the modeling uncertainties and the sparse data from SN 1987A, the constraint on the axion-nucleon couplings from SN 1987A should be considered more as indicative than as a sharp bound [275]. Furthermore, note that if axions interact sufficiently strongly they are trapped. Only about three orders of magnitude in g_{aNN}, where $N = n, p$, or m_a are excluded. For even larger couplings, the axion flux would have been negligible, yet it would have triggered additional events in the detectors, excluding a further range [283].

Further bounds on the axion-nucleon coupling can be derived from observations of the cooling of older NSs. Recently, strong constraints were obtained by modeling the cooling of the "Magnificent Seven" (M7) NSs in the presence of axions [269]. Axion emission would accelerate NS cooling. Thus, if the age and temperature of a NS are independently known, then by modeling axion-induced cooling in conjunction with the standard NS cooling mechanisms, in particular cooling via neutrino emission from the bulk of the NS and thermal emission from the NS surface, one is able to constrain the axion's coupling strength. Ref. [269] used a sample of four of the M7 along with PSR J0659 to constrain $m_a < 16$ meV for the KSVZ QCD axion at 95% CL and $m_a \lesssim 5$ meV ($m_a \lesssim 30$ meV) in the DFSZ scenario for asymptotically large (small) $\tan\beta$. For axions that couple exclusively to neutrons (protons) Ref. [269] constrains $|g_{ann}| < 1.3 \times 10^{-9}$ ($|g_{app}| < 1.5 \times 10^{-9}$), as illustrated in Fig. 89.3. The five NSs used in that work are unique in that their ages, all in the range $0.1 - 1$ Myr, are known by kinematic measurements (*e.g.*, tracing back to the SN remnant), while their surface temperatures are measured in the X-ray band. Beyond statistical uncertainties on these measurements, there are a number of confounding systematic uncertainties that must be accounted for in NS cooling analyses, including uncertainties related to the core-surface temperature relation, which involves the chemical composition of the NS envelope. The NS equation of state and the superfluid critical temperatures of the dense nuclear matter are also sources of uncertainty. Note that axions are predominantly produced by nuclear bremsstrahlung [284, 285] except for temperatures near the superfluid critical temperature, when Cooper pair breaking and formation (PBF) processes may efficiently produce axions [286, 287]. Given the large densities it is crucial to account for medium dependent couplings when computing the axion luminosities [288, 289].

The young NS in the supernova remnant Cassiopeia A (Cas A) was previously thought to strongly constrain axions, at a level similar to the NS cooling bound described above, due to PBF axion production [290]. This is because it was observed that Cas A was cooling rapidly, which may be explained by neutrino cooling with neutron superfluidity and proton superconductivity [291, 292]. However, it is possible that the excessive cooling of Cas A is at least in part instrumental in origin [293]. Fully accounting for uncertainties on both the NS properties and the data, constraints from young NSs such as Cas A and the NS in the supernova remnant HESS J1731-347 [294] appear to be sub-

dominant compared to the limits from SN 1987A and the M7 [269].

Finally, let us note that if $m_a \sim$meV, SNe would lose a large fraction of their energy as axions. This would lead to a diffuse SN axion background in the Universe with an energy density comparable to the extra-galactic background light [295]. However, there is no apparent way of detecting it or the axion burst from the next nearby SN. On the other hand, neutrino detectors such as IceCube, Super-Kamiokande or a future mega-ton water Cherenkov detector will probe exactly the mass region of interest by measuring the neutrino pulse duration of the next Galactic SN [275].

89.4.2 *Searches for solar axions and ALPs*

Instead of using stellar energy losses to derive axion limits, one can also search directly for these fluxes, notably from the Sun. The main focus has been on ALPs with a two-photon vertex. They are produced by the Primakoff process with a flux given by Eq. (89.15) and an average energy of 4.2 keV, and can be detected at Earth with the reverse process in a macroscopic B-field ("axion helioscope") [7]. In order to extend the sensitivity in mass towards larger values, one can endow the photon with an effective mass in a gas, $\omega_{\rm plas}$, and tune the mass to match the axion's dispersion relation ($\omega_{\rm plas} = m_a$) [296].

An early implementation of these ideas used a conventional dipole magnet, with a conversion volume of variable-pressure gas with a xenon proportional chamber as x-ray detector [297]. The conversion magnet was fixed in orientation and collected data for about 1000 s/day. Axions were excluded for $|g_{a\gamma\gamma}| < 3.6 \times 10^{-9}$ GeV^{-1} for $m_a < 0.03$ eV, and $|g_{a\gamma\gamma}| < 7.7 \times 10^{-9}$ GeV^{-1} for $0.03 < m_a < 0.11$ eV at 95% CL.

Later, the Tokyo axion helioscope used a superconducting magnet on a tracking mount, viewing the Sun continuously. They reported $|g_{a\gamma\gamma}| < 6 \times 10^{-10}$ GeV^{-1} for $m_a < 0.3$ eV [298,299]. This experiment was recommissioned and a similar limit for masses around 1 eV was reported [300].

The most recent helioscope CAST (CERN Axion Solar Telescope) uses a decommissioned LHC dipole magnet on a tracking mount. The hardware includes grazing-incidence x-ray optics with solid-state x-ray detectors, as well as x-ray Micromegas position-sensitive gaseous detectors. Exploiting an IAXO (see below) pathfinder system, CAST has established the limit

$$|g_{a\gamma\gamma}| < 5.8 \times 10^{-11}\ \text{GeV}^{-1} \quad (95\%\ \text{CL}), \tag{89.20}$$

for $m_a < 0.02$ eV [76, 158]. To cover larger masses, the magnet bores are filled with a gas at varying pressure. The runs with ^{4}He cover masses up to about 0.4 eV [301], providing the high-mass component of the CAST limits shown in Fig. 89.1. To cover yet larger masses, ^{3}He was used to achieve a larger pressure at cryogenic temperatures. Limits up to 1.17 eV allowed CAST to "cross the axion line" for the KSVZ model [302–304], see Fig. 89.1.

Sensitivity to significantly smaller values of $g_{a\gamma\gamma}$ can be achieved with a next-generation axion helioscope with a much larger magnetic-field cross section. Realistic design options for this "International Axion Observatory" (IAXO) have been studied in some detail [305], as well as its physics potential [306]. Such a next-generation axion helioscope may also push the sensitivity in the product of couplings to photons and to electrons, $g_{a\gamma\gamma}g_{aee}$, into a range beyond stellar energy-loss limits and test the hypothesis that WD, RG, and HB cooling is dominated by axion emission [307, 308]. As a first step towards IAXO, an intermediate experimental stage called BabyIAXO is currently under preparation at DESY [309].

Direct detection experiments searching for dark matter (DM) consisting of weakly interacting massive particles have also the capability to search for solar axions and ALPs. For low masses, $m_a \lesssim 100$ eV, the XENONnT experiment [310] has provided the most stringent bound among those experiments on the axion-electron coupling constant,

$$|g_{aee}| < 1.9 \times 10^{-12} \quad (90\%\ \text{CL}), \tag{89.21}$$

see Fig. 89.2, by exploiting the axio-electric effect in liquid xenon. Limits at approximately the same value have been set by PandaX-4T [311] and LZ [312]. However, this technique has not reached the sensitivity of energy-loss considerations in stars.

89.4.3 *Conversion of astrophysical axion fluxes*

Large-scale B fields exist in astrophysics that can induce axion-photon oscillations. In practical cases, the strength of B is much smaller than in the laboratory, whereas the conversion region L is much larger. Therefore, while the product BL can be large, realistic sensitivities are usually restricted to very low-mass particles, far away from the "QCD axion band" in a plot like Fig. 89.1.

One example of this is SN 1987A, which would have emitted a burst of ALPs due to the Primakoff production in its core. It was pointed out shortly after the SN that the ALPs could have partially converted into γ-rays in the Galactic B-field. The lack of a gamma-ray signal in the GRS instrument of the SMM satellite in coincidence with the observation of the neutrinos emitted from SN 1987A therefore provides a strong bound on their coupling to photons [313, 314]. This bound has been revisited and the underlying physics has been brought to the current state-of-the-art, as far as modeling of the supernova and the Milky-Way along with stellar magnetic field are concerned, resulting in the limit [128,129] $|g_{a\gamma\gamma}| < 5.2 \times 10^{-12}$ GeV^{-1} for $m_a \lesssim 5 \times 10^{-10}$ eV. More recently, it has been understood that the axions could convert to gamma-rays in the stellar magnetic fields of the progenitor star, extending the SN1987A limits to higher masses and potentially allowing gamma-ray observations of future SN to probe the QCD axion [315].

Reference [96] reports no evidence of a γ-ray burst in observations of extragalactic SNe with the Fermi Large Area Telescope (LAT). Under the assumption that at least one SN was contained within the LAT field of view, the authors derive an upper bound on the axion photon coupling which is about a factor of 5 weaker than the one from SN 1987A, see Fig. 89.1.

The cumulative emission of ALPs from all past core-collapse SNe would lead to a diffuse gamma-ray flux peaked at energies $\sim 50 - 100$ MeV which can convert in the Galactic magnetic field into photons. Using Fermi-LAT measurements of the diffuse γ-ray flux, Ref. [316] obtains a conservative bound on the photon coupling, $|g_{a\gamma\gamma}| < 5 \times 10^{-10}$ GeV^{-1}, for $m_a \lesssim 10^{-11}$ eV, see see Fig. 89.1, which can be decreased by nearly three orders of magnitude, if an ALP-nucleon coupling of maximal phenomenologically allowed strength, $|g_{aNN}| \sim 10^{-9}$, is allowed.

Hot, young stars, such as Wolf-Rayet stars, efficiently produce ALPs with energies $\sim 10 - 100$ keV via the Primakoff effect. Large numbers of those stars are hosted by the Galactic Quintuplet and Westerlund 1 super star clusters (SSCs). The non-observation of hard X-rays originating from axion-photon conversion in the Galactic magnetic field in archival NuSTAR (Nuclear Spectroscopic Telescope Array) data from these SSCs leads to a bound on the axion-photon coupling [136], $|g_{a\gamma\gamma}| < 3.6 \times 10^{-12}$ GeV^{-1}, for $m_a \lesssim 5 \times 10^{-11}$ eV, see Fig. 89.1. A somewhat weaker bound in the same mass range was established exploiting NuSTAR data on Betelgeuse [82]. Stronger constraints at low axion masses are found with NuSTAR data by considering axion production and conversion (or decay) in nearby galaxies, such as M82 and M87, accounting for production in all of the stellar members of the galaxies [317–319] (see Fig. 89.1).

A hard X-ray excess in data from the nearby M7 isolated NSs [320] may be explained by ALPs produced in the cores of those stars and converted in the surrounding magnetic fields, with $|g_{aNN}g_{a\gamma\gamma}| \in (2 \times 10^{-21}, 10^{-18})$ GeV^{-1}, for $m_a \lesssim 10^{-5}$ eV [321]. The non-observation of an X-ray excess from the magnetic WD RE J0317-853 [322] by Chandra yields the constraint $|g_{aee}g_{a\gamma\gamma}| \lesssim 1.3 \times 10^{-25}$ GeV^{-1}, for $m_a \ll 10^{-5}$ eV [105], which provides a non-trivial constraint on the ratio g_{aee}/g_{aNN} for axion models explaining the M7 X-ray excess.

In addition to being produced in NS cores, axions may also be produced in NS magnetospheres. In particular, it has recently been shown that axions could be copiously produced in the polar-cap regions of NS magnetospheres due to time-varying, un-screened electric fields [122]. Those axions could then convert to photons in the outer regions of the NS magnetosphere, leading to observable, broadband radio flux. The absence of such radio flux sets competitive constraints on ALPs, as indicated by the "pulsars" constraint in Fig. 89.1.

89.4.4 *Conversion of astrophysical photon fluxes*

Magnetically induced oscillations between photons and ALPs can modify the photon fluxes from distant sources in various ways, featuring (i) frequency-dependent dimming, (ii) modified polarization, and (iii) avoiding absorption by propagation in the form of axions. For example, dimming of SNe Ia could influence the interpretation in terms of cosmic acceleration [323], although it has become clear that photon-ALP conversion could only be a subdominant effect [324].

Polarization measurements are particularly powerful probes of photon-to-axion conversion since only photons polarized parallel to astrophysical magnetic fields may convert into axions, meaning that in the presence of large-scale ordered magnetic fields axions tend to leave distinct polarization signatures in passing radiation. Searches for linear polarization from radio galaxies (see, *e.g.*, Ref. [325]) and quasars [326] may approach in sensitivity $|g_{a\gamma\gamma}| \sim$ few $\times\, 10^{-13}$ GeV^{-1}, albeit with uncertainties related to the underlying modeling assumptions. Recently, robust limits at the level $|g_{a\gamma\gamma}| \leq 1.7 \times 10^{-12}$ GeV^{-1} at 95% CL have been derived from optical polarization measurements of nearby magnetic WDs [106, 327] (see also [328]), see Fig. 89.1. The magnetic fields of magnetic WDs may be well-measured through the Zeeman splitting of bound-bound transitions in the WD atmospheres.

It appears that the Universe could be too transparent to TeV γ-rays that should be absorbed by pair production on the extragalactic background light [86, 329–332]. The situation is not conclusive at present [333–336], but the possibility of axions playing a role has been suggested [337–339]. On the other hand, much of this parameter space is excluded by the previously-discussed WD polarization probes. The region in ALP parameter space, $g_{a\gamma\gamma} \sim 10^{-12} - 10^{-10}$ GeV^{-1} for $m_a \lesssim 10^{-7}$ eV [340], required to explain the anomalous TeV transparency of the Universe, could be conceivably probed by the next generation of laboratory experiments (ALPS II) and helioscopes (IAXO) mentioned above.

This parameter region can also be probed by searching for an irregular behavior of the gamma ray spectrum of distant active galactic nuclei (AGN), expected to arise from photon-ALP mixing in a limited energy range. In these type of studies, the uncertainty in the magnetic field around the source needs to be taken into account. This typically leads to a range of limits on the ALP-photon coupling that depend on the modeling assumptions. The H.E.S.S. collaboration has set a limit of $|g_{a\gamma\gamma}| \lesssim 2.1 \times 10^{-11}$ GeV^{-1}, for 1.5×10^{-8} eV $\lesssim m_a \lesssim 6.0 \times 10^{-8}$ eV, from the non-observation of an irregular behavior of the spectrum of the AGN PKS 2155-304 [341]. The Fermi-LAT collaboration has put an even more stringent limit on the ALP-photon coupling [95] from observations of the gamma ray spectrum of NGC 1275, the central galaxy of the Perseus cluster, see Fig. 89.1. A similar analysis has been carried out in Ref. [342], using Fermi-LAT data of PKS 2155-304, and in Ref. [108], using ARGO-YBJ and Fermi-LAT data of Mrk 421, see Fig. 89.1. However, these constraints were obtained under certain theoretical assumptions about magnetic fields surrounding the sources, not confirmed yet by direct astronomical observations in these particular directions; this introduces large systematic uncertainties in the reported constraints [343].

Evidence for spectral irregularities has been reported in Galactic sources, such as pulsars and supernova remnants, and has been interpreted as hints for ALPs [344, 345] (see also discussion in Ref. [346] and references therein). However, the inferred ALP parameters, $|g_{a\gamma\gamma}| \sim 10^{-10}\,\text{GeV}^{-1}$, $m_a \sim$neV, are in tension with the CAST helioscope bounds. Reference [346] updated the analysis of the pulsar signal region including astrophysical nuisance parameters and correctly deriving confidence intervals on ALP parameters by means of Monte Carlo simulations. The tension with the CAST bounds can be evaded if environmental effects in matter, which would suppress the ALP production in dense astrophysical plasmas like the solar interior, are invoked. If this explanation is correct, the claimed ALP signal would be in reach of the next-generation LSW experiment ALPS II. Other ways to make the CAST bound compatible with photon-ALP conversions in the low-density Galactic medium are invoking photon-ALP-dark photon oscillations [347] or the existence of a number of 'hidden' ALPs [348].

At smaller masses, $m_a \lesssim 10^{-12}$ eV, galaxy clusters become highly efficient at interconverting ALPs and photons at X-ray energies. Constraints on spectral irregularities in the spectra of luminous X-ray sources (Hydra A, M87, NGC 1275, NGC 3862, Seyfert galaxy 2E3140; taken by Chandra and XMM-Newton) located in or behind galaxy clusters then lead to stringent upper limits on the ALP-photon coupling [87–89, 349–351] (for the limits exploiting spectra from Hydra and M87 from Refs. [87] and [88], respectively, see Fig. 89.1). Reference [89] recently performed the most sensitive x-ray searches for ALPs to date by employing Chandra's High-Energy Transmission Gratings that allow for an unsurpassed spectral resolution. New observations of the AGN NGC 1275 then led to the bound $|g_{a\gamma\gamma}| < 8 \times 10^{-13}$ GeV^{-1} at 99.7% C.L. for ultra-light ALPs, as illustrated in Fig. 89.1. On the other hand, magnetic field modeling uncertainties in the clusters may not be fully accounted for in these analyses [343].

89.4.5 *Finite density effects for the QCD axion*

If the QCD axion sector has a discrete, $\mathbb{Z}_{\mathcal{N}}$, shift symmetry, its potential is much shallower, and its mass, in units of its decay constant, $m_a f_a \simeq (3\pi)^{-1/4}\,\mathcal{N}^{3/4}\,2^{-\mathcal{N}/2}\,m_\pi f_\pi$, is smaller than the one of the canonical QCD axion by an exponential factor $\propto 2^{-\mathcal{N}/2}$ [179, 180]. This opens up the parameter space over which one should search for a QCD axion towards the left of the yellow canonical QCD axion band in Fig. 89.1, Fig. 89.2, and Fig. 89.3. Novel bounds apply to this exceptionally light QCD axion due to finite density effects [352–354]. In fact, in dense stellar media, the minimum of the axion potential may be shifted to π. This has a number of phenomenological consequences that span from the modification of nuclear processes in stars due to $\theta = \mathcal{O}(\pi)$ to modifications in the orbital decay of binary systems (and subsequently in the emitted gravitational waves). Recently strong constraints have been set using the modification of the WD mass-radius relation due to such axions [355].

In fact, $\theta \sim 1$ in the solar core would lead to an increased proton-neutron mass difference, which would prohibit the neutrino line corresponding to the ^{7}Be-^{7}Li mass difference observed by Borexino [356].

Moreover, the fact that the position of the minimum of the axion potential depends on the nuclear density of the medium may also source a long-range force between dense stars [352]. This new long-range force sourced by the axion can be constrained by the measurement of the orbital decay of double pulsar or NS-pulsar binaries [352]. The gravitational wave signal of NS-NS mergers or black hole (BH) - NS mergers would also be modified by these axionic long-range forces [352, 353]. There is also a corresponding bound [354] exploiting the gravitational waves observation from the binary NS inspiral GW170817 detected by LIGO (Laser Interferometer Gravitational-Wave Observatory) and Virgo [357].

89.4.6 *Superradiance of black holes*

Light bosonic fields such as axions or ALPs can affect the dynamics and gravitational wave emission of rapidly rotating astrophysical BHs through the superradiance mechanism. When the boson's Compton wavelength is of order of the size of the BH's ergoregion, they form gravitational bound states around the BH. Their occupation number grows exponentially by extracting energy and angular momentum from the black hole, forming a coherent axion or ALP bound state emitting gravitational waves. When accretion cannot replenish the spin of the BH, superradiance dominates the BH spin evolution; this is true for both supermassive and stellar mass BHs. The existence of destabilizing light bosonic fields thus leads to exclusion regions in the mass versus spin plot of rotating BHs. Stellar BH spin measurements exploiting well-studied binaries and two independent techniques exclude a mass range – up to self-interaction caveats discussed below – $6 \times 10^{-13}\,\text{eV} < m_a < 2 \times 10^{-11}$ eV at $2\,\sigma$, which for the axion excludes $3 \times 10^{17}\,\text{GeV} < f_a < 1 \times 10^{19}$ GeV [10, 358, 359], see Fig. 89.4. These bounds apply when gravitational interactions dominate over the axion self-interaction, which is largely true for the QCD axion in this mass range. On the other hand, Refs. [360, 361] considered superradiance bounds for string theory ALPs with a quartic self-coupling (of either sign) given by $\lambda = m_a^2/f_a^2$, using the bosenova model of Ref. [359], and found

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

that for $m_a \sim 10^{-12}$ eV the superradiant cloud, and thus the constraints, are destroyed for $f_a \lesssim 10^{11} - 10^{12}$ GeV, depending precisely on the mass and the source.

Reference [362] used a more advanced model for the effect of self-interactions on superradiant evolution, and a different (frequentist) statistical methodology, leading to more conservative bounds from stellar mass BHs (region near 10^{-12} eV). In particular, Ref. [362] found that QCD axions are only excluded for $m_a \lesssim 6 \times 10^{-12}$ eV instead of the 2×10^{-11} eV, as claimed in [360,361]. Reference [362] also vetoed supermassive BHs (SMBHs) with spins measured at low significance, and thus found no ALP bounds in the SMBH region (near 10^{-18} eV); Ref. [360, 361, 363], in contrast, included SMBHs in a (quasi-)Bayesian analysis with a flat prior on the spin and found non-trivial constraints. In summary, it appears likely that the lower end of the QCD axion mass range is excluded by superradiance, with the requirement $m_a \gtrsim 10^{-11}$ eV, but the exact location of this limit is still debated. It is also too early to claim that ultra-light ALP parameter space is excluded by SMBHs, though this may change with future work.

Long lasting, monochromatic gravitational wave signals, which can be distinguished from ordinary astrophysical sources by their clustering in a narrow frequency range, are expected to be produced by axions or ALPs annihilating to gravitons. Gravitational waves could also be sourced by axions/ALPs transitioning between energy levels of the effective gravitational atom. Accordingly, the gravitational wave detector Advanced LIGO should be sensitive to the axion in the $m_a \lesssim 10^{-10}\,\text{eV}$ region. LIGO measurements of BH spins in binary merger events could also provide statistical evidence for the presence of an axion [364, 365]. Similar signatures could arise for supermassive and intermediate mass BHs for particles with masses $\lesssim 10^{-15}\,\text{eV}$. Gravitational waves from such sources could be detected at lower-frequency observatories such as LISA (Laser Interferometer Space Antenna). First attempts to use LIGO/Virgo data to search for monochromatic signatures of axion superradiance were recently made in [366, 367].

89.5 Cosmic Axions

89.5.1 *Cosmic axion populations*

There are two distinct populations of cosmic relic axion populations: a non-thermal one behaving as CDM, and a thermal one comprising a hot DM (HDM) component, in analogy to massive neutrinos. For $m_a \lesssim 0.01\,\text{eV}$, thermal axions are dominantly produced by processes involving quarks and gluons [368, 369], while, for larger masses, the dominant thermalization process is $\pi + \pi \leftrightarrow \pi + a$ [187,370,371]. A number of evaluations exploiting cosmological precision data have found restrictive constraints on a possible HDM fraction that translate into an upper bound on the axion mass, $m_a \lesssim 1$ eV, if a leading order (LO) axion-pion chiral effective field theory (EFT) analysis of the axion-pion thermalization rate is used [387–390]. Recently, it was found that the next leading order (NLO) contribution exceeds the LO contributions for masses below $m_a \lesssim 1.2\,(0.12/C_{a\pi})\,\text{eV}$ [391]. Therefore, in order to assess the reach in sensitivity of future cosmological data sets, one has to improve the EFT description or to compute axion-pion scattering via lattice QCD techniques. Alternatively, recently Ref. [392] used pion-pion scattering data to overcome the EFT description issues and found the constraint $m_a \lesssim 0.24$ eV, see Fig. 89.4.

For $m_a \gtrsim 10$ eV, axions may decay faster than the age of the Universe (see Eq. (89.7)), depending on the decay constant, which would remove the cosmic axion population while injecting photons. If the axions were in thermal equilibrium in the early Universe, which depends on the inflationary reheat temperature and assumptions about the pre-BBN cosmology [393, 394], this excess radiation provides additional limits on the axion- or ALP-photon coupling up to very large masses [393, 394]. Such photons could contribute to the extragalactic background light (EBL), could ionize primordial hydrogen and thus contribute to the optical depth after recombination, or could spoil the agreement of big bang nucleosynthesis (BBN) with observations. The corresponding up-to-date bounds from Refs. [143, 144] are displayed in Fig. 89.1. It has recently been shown that there is an *irreducible axion background* [145] that arises from axion freeze-in before BBN; decays of that axion population provide strong constraints on axions with masses above roughly 100 eV (see Fig. 89.1). For high enough decay constants, high-mass axions ($m_a \gtrsim 10$ eV) can account for the DM abundance through the misalignment mechanism, described in more detail below, though additional entropy dilution or fine-tuning is needed to avoid overproducing the DM abundance [395] (see also [396] for heavy axion production through lepton-flavor-violating decays). The decay of such high-mass axions to photon pairs could leave narrow spectral features in *e.g.* optical or X-ray backgrounds [103, 115–117, 138, 140, 397, 398] (see Fig. 89.1).

The main cosmological interest in axions at present derives from their possible role as CDM. In addition to thermal processes, axions are abundantly produced by the misalignment (MIS) mechanism [399–401]. The axion DM abundance crucially depends on the cosmological history. Let us first consider the so called *pre-inflationary PQ symmetry breaking scenario*, in which the PQ symmetry is broken before and during inflation and not restored afterwards. This is the cosmological scenario most naturally realized for string theory axions from the open-string sector [167,402]. After the breakdown of the PQ symmetry, the axion field relaxes somewhere in the bottom of the "wine-bottle-bottom" potential. Near the QCD epoch, topological fluctuations of the gluon fields such as instantons explicitly break the PQ symmetry. This tilting of the "wine-bottle-bottom" drives the axion field toward the CP-conserving minimum, thereby exciting coherent oscillations of the axion field that ultimately represent a condensate of CDM. The fractional cosmic mass density in this homogeneous field mode, created by the MIS mechanism, is [24, 403–405],

$$\begin{aligned}\Omega_a^{\rm MIS}h^2 &\approx 0.12\left(\frac{f_a}{9\times10^{11}\ \text{GeV}}\right)^{1.165} F\,\Theta_{\rm i}^2 \\ &\approx 0.12\left(\frac{6\ \mu\text{eV}}{m_a}\right)^{1.165} F\,\Theta_{\rm i}^2\,,\end{aligned} \tag{89.22}$$

where h is the present-day Hubble expansion parameter in units of 100 km s^{-1} Mpc^{-1}, and $-\pi \le \Theta_{\rm i} \le \pi$ is the initial "misalignment angle" relative to the CP-conserving position attained in the causally connected region which evolved into today's observable Universe. $F = F(\Theta_{\rm i}, f_a)$ is a factor accounting for anharmonicities in the axion potential. For $F\Theta_{\rm i}^2 = \mathcal{O}(1)$, m_a should be above $\sim 6\,\mu$eV in order that the cosmic axion density does not exceed the observed CDM density, $\Omega_{\rm CDM}h^2 = 0.12$. However, much smaller axion masses (much higher PQ scales) are still possible if entropy is diluted for example by the late decay of a scalar condensate (see for example [406] and references therein) or the initial value $\Theta_{\rm i}$ just happens to be small enough in today's observable Universe ("anthropic axion window" [407]). In the latter cosmological scenario, however, quantum fluctuations of the axion field during inflation are expected to lead to isocurvature density fluctuations which get imprinted to the temperature fluctuations of the CMB [408,409]. Their non-observation puts severe constraints on the Hubble expansion rate H_I during inflation [410–415], which read, in the simplest cosmological inflationary scenario,

$$H_I \lesssim 5.7\times10^8\ \text{GeV}\left(\frac{5\,\text{neV}}{m_a}\right)^{0.4175}\,, \tag{89.23}$$

if axions represent all of DM. In Ref. [416] an alternative to the MIS mechanism was proposed: the so-called kinetic MIS mechanism. In this case, the axion field is assumed to have an initial velocity which may be generated, e.g., by a hypothesized explicit breaking of the axion shift symmetry in the early universe. The amount of QCD axion dark matter generated by the kinetic MIS mechanism can fit the observed dark matter abundance for any $f_a \lesssim 1.5\times10^{11}$ GeV, down to the minimum value allowed by the SN 1987A constraint.

In the above prediction of the fractional cosmic mass density in axions, the exponent, 1.165, arises from the non-trivial temperature dependence of the topological susceptibility $\chi(T) = m_A^2(T)f_A^2$ at temperatures slighty above the QCD quark-hadron phase transition. Lattice QCD calculations of this exponent [24, 375, 377, 417–419], but also Ref. [376], found it to be close

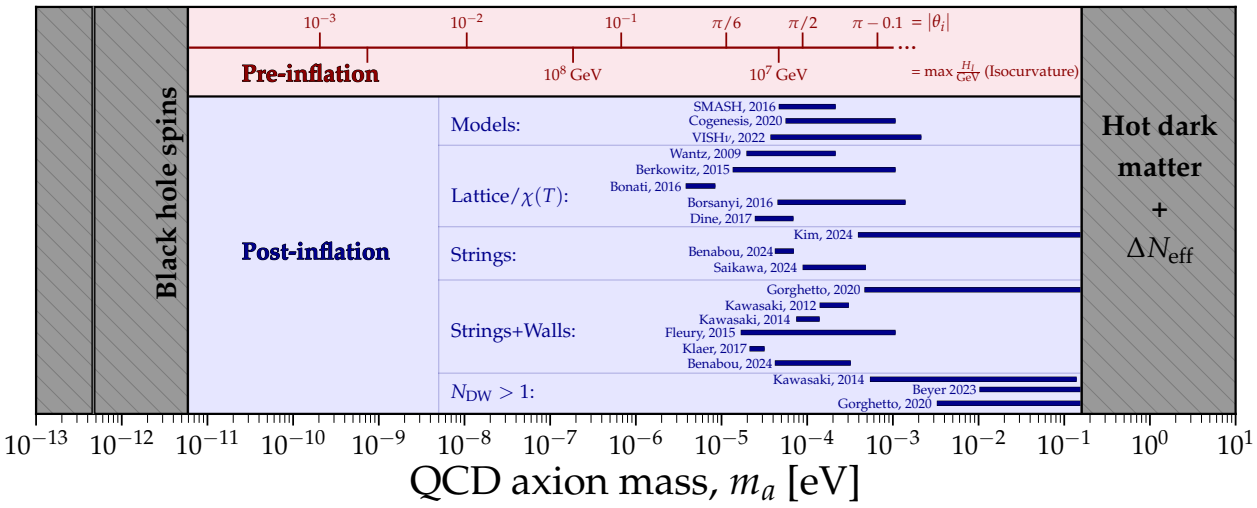

Figure 89.4: QCD axion mass predictions for obtaining the correct DM abundance assuming the PQ symmetry is and is not restored after inflation and, in the case the PQ symmetry is restored after inflation, depending on the domain wall number N. Figure from [39], includes data from refs. [24, 372–386]. The lower-end of the possible mass range is bounded by BH superradiance constraints and the theoretical requirement that f_a be below the Planck scale, while the upper end is bounded by the somewhat model-dependent NS cooling constraints (not shown), which exclude QCD axion masses above roughly ∼15-30 meV, depending on the UV completion. At even higher masses there are strong constraints from the production of DM in the early universe, which behaves as hot DM and contributes to $\Delta N_{\rm eff}$.

to the prediction of the dilute instanton gas approximation [420] which was previously exploited. Therefore, the state-of-the-art prediction of the axion mass relevant for DM for a fixed initial misalignment angle $\Theta_{\rm i}$ differs from the previous prediction by just a factor of order one.

In the *post-inflationary PQ symmetry breaking scenario*, on the other hand, $\Theta_{\rm i}$ will take on different values in different patches of the present Universe. The average contribution is [24, 403–405]

$$\Omega_a^{\rm MIS} h^2 \approx 0.12 \left(\frac{30\ \mu{\rm eV}}{m_a}\right)^{1.165} . \qquad (89.24)$$

The decay of cosmic strings and domain walls gives rise to a further population of CDM axions, whose abundance suffers from significant uncertainties [373, 379–381, 404, 405, 421–432] which arise from the difficulty in understanding the energy loss process of topological defects and the generated axion spectrum in a quantitative way. In fact, in the present state-of-the-art it is still possible that the CDM contribution from the decay of topological defects is subdominant [379] or overwhelmingly large [380] in comparison to the one from the MIS mechanism. Correspondingly, the plausible range of axion masses providing all of CDM in scenarios with postinflationary PQ symmetry breaking is still rather large, namely [379, 380]

$$m_a \approx 26\ \mu{\rm eV} - 0.5\ {\rm meV}, \qquad (89.25)$$

for models with short-lived (requiring unit color anomaly $N = 1$) domain walls, such as the KSVZ model. On the other hand, the most recent adaptive mesh refinement axion string simulations, which are able to evolve over larger dynamic ranges than static lattice simulations, suggest the mass range $m_a \approx 45 - 300\ \mu$eV, with domain wall decay providing the dominant contribution to DM on the upper end of the uncertainty range [432]. For models with long-lived ($N > 1$) domain walls, such as an accidental DFSZ model [433], where the PQ symmetry is broken by higher dimensional Planck suppressed operators, the mass is predicted to be significantly higher [306, 381, 433–435],

$$m_a \approx (0.58 - 130)\,{\rm meV}\,. \qquad (89.26)$$

However, the upper part of the predicted range is in conflict with stellar energy-loss limits on the axion. The pre- and post-inflationary mass predictions are summarized in Fig. 89.4.

In this post-inflationary PQ symmetry breakdown scenario, the spatial axion density variations are large at the QCD transition, and they are not erased by free streaming. Gravitationally bound "axion miniclusters" form before and around matter-radiation equality [436–438]. A significant fraction of CDM axions can reside in these bound objects [426, 439]. The minicluster fraction can be bounded by gravitational lensing [440–442], although more simulations are required to understand whether miniclusters are dense enough and survive in sufficient quantities for lensing bounds to apply.

89.5.1.1 *Ultralight cosmological ALP relics*

The non-thermal production mechanisms attributed to axions are generic to light bosonic weakly interacting particles such as ALPs [384]. The relic abundance is set by the epoch when the axion mass becomes significant, $3H(t) \approx m_a(t)$, and ALP field oscillations begin. For ALPs to contribute to the DM density this epoch must precede that of matter radiation equality. For a temperature independent ALP mass this leads to the bound:

$$m_a \gtrsim 7 \times 10^{-28}\,{\rm eV} \left(\frac{\Omega_m h^2}{0.15}\right)^{1/2} \left(\frac{1+z_{\rm eq}}{3.4\times 10^3}\right)^{3/2} . \qquad (89.27)$$

ALPs lighter than this bound are allowed if their cosmic energy density is small, but they are quite distinct from other forms of DM [443]. Ignoring anharmonicities in the ALP potential, and taking the ALP mass to be temperature independent, the relic density in DM ALPs due to the MIS mechanism is given by

$$\Omega_{\rm ALP}^{\rm MIS} h^2 = 0.12 \left(\frac{m_a}{4.7\times 10^{-19}\,{\rm eV}}\right)^{1/2} \left(\frac{f_a}{10^{16}\,{\rm GeV}}\right)^2 \times \left(\frac{\Omega_m h^2}{0.15}\right)^{3/4} \left(\frac{1+z_{\rm eq}}{3.4\times 10^3}\right)^{-3/4} \Theta_{\rm i}^2\,. \qquad (89.28)$$

An ALP decay constant near the GUT scale gives the correct relic abundance for *ultralight ALPs* (ULAs) with $m_{\rm ULA} \approx 10^{-19}$ eV [444, 445]. ULAs encompass the entire Earth in a single Compton wavelength, and for large occupation numbers are modelled as a coherent classical field. The coherence time is determined by the mass and virial velocity in the Milky Way, $\tau_{\rm coh} \sim 1/m_{\rm ULA} v_{\rm vir}^2$, with the detailed properties described by a stochastic model with an approximately Rayleigh Jeans distribution [446]. Natural models for ULAs can be found in string

and M-theory compactifications [5, 6, 8–13], in field theory with accidental symmetries [447, 448], or new hidden strongly coupled sectors [449, 450].

In addition to the gravitational potential energy, the ULA field also carries gradient energy. On scales where the gradient energy is non-negligible, ULAs acquire an effective pressure and do not behave as CDM. The gradient energy opposes gravitational collapse, leading to a Jeans scale below which perturbations are stable [451]. The Jeans scale suppresses linear cosmological structure formation relative to CDM [452–454]. The Jeans scale at matter-radiation equality in the case that ULAs make up all of CDM is:

$$k_{\rm J,eq} = 8.7\,{\rm Mpc}^{-1}\left(\frac{1+z_{\rm eq}}{3.4\times10^3}\right)^{-1/4}\left(\frac{h^2\Omega_{\rm ALP}^{\rm MIS}}{0.12}\right)^{1/4}\times\left(\frac{m_{\rm ULA}}{10^{-22}\,{\rm eV}}\right)^{1/2}. \quad (89.29)$$

On non-linear scales the gradient energy leads to the existence of a class of pseudo-solitons known as oscillatons, or axion stars [455]. Axion stars are expected to form in all cosmological scenarios, and for all types of ALPs, including the QCD axion [456–458]. Some axion stars may explode into radio photons, heating the interstellar medium [81].

Cosmological and astrophysical observations are consistent with the CDM model, and departures from it are only allowed on the scales of the smallest observed DM structures with $M \sim 10^{6-8} M_\odot$. The CMB power spectrum and galaxy autocorrelation power spectrum limit the ULA mass to $m_{\rm ULA} \gtrsim \mathcal{O}({\rm few}) \times 10^{-24}$ eV from linear theory of structure formation [443, 459]. Analytic models [460] and N-body simulations [461] for non-linear structures show that halo formation is suppressed in ULA models relative to CDM. This leads to constraints on the ULA mass of $m_{\rm ULA} > 10^{-22}$ eV from observations of high-z galaxies [461–463], and $m_{\rm ULA} > 2\times10^{-20}$ eV from the Lyman-alpha forest flux power spectrum [464]. Including the effects of anharmonicities on structure formation with ALPs can weaken these bounds if the misalignment angle $\Theta_{\rm i} \approx \pi$ [465]. A comprehensive study of Milky Way satellites by the DES collaboration resulted in the bound $m_{\rm ULA} > 2.9\times10^{-21}$ eV [466].

Cosmological simulations that treat gradient energy in the ULA field beyond the N-body approximation have just recently become available [456, 467–469], and show, among other things, evidence for the formation of axion stars in the centres of ULA halos (various consequences of axion stars are considered in Refs. [470]). These central axion stars have been conjectured to play a role in the apparently cored density profiles of dwarf spheroidal galaxies, and other central galactic regions [104, 456, 471–475]. However, the relationship between the halo mass and the axion star mass [476] leads to problems with this scenario in some galaxies [477–479]. It should be emphasized that many of the conclusions about the role of ULA axion stars in galactic dynamics are based on use of simulation results that do not contain baryons and feedback could be important [480–482].

Inside DM halos the axion gradient energy causes coherence on the de Broglie wavelength and fluctuations on the coherence time [456, 483]. These fluctuations can be thought of as short-lived quasiparticles and lead to relaxation processes that can be described statistically [445, 484] (this relaxation processes also leads to the gravitational condensation of axion stars [457]). The typical relaxation time is:

$$t \sim 10^{10}\ {\rm years}\left(\frac{m_{\rm ULA}}{10^{-22}\ {\rm eV}}\right)^3\left(\frac{v}{100\ {\rm km\ s}^{-1}}\right)^2\left(\frac{r}{5\ {\rm kpc}}\right)^4, \quad (89.30)$$

where v and r are the velocity and radius of the orbit in the host DM halo.

Relaxation processes such as these are not observed in galaxies, though there are some circumstances where they may be desirable [445]. An absence of observed relaxation can be used to set limits on the ULA mass. An absence of Milky Way disk thickening excludes $m_{\rm ULA} > 0.6\times10^{-22}$ eV [485], while stellar streams give the stronger bound $m_{\rm ULA} > 1.5\times10^{-22}$ eV [486]. The survival of the old star cluster in Eridanus II [487] excludes the range of masses 10^{-21} eV $\lesssim m_{\rm ULA} \lesssim 10^{-19}$ eV [488]. Recently Ref. [489] found that ULA DM is excluded for $m_{\rm ULA} \lesssim 3\times10^{-19}$ eV at 99% CL because such DM would kinematically heat the stars in the Segue I and Segue II ultra-faint dwarf galaxies to a level inconsistent with their observed dynamics.

Finally, one should note that the beyond-CDM physics of ULAs (Jeans scale, relaxation, axion star formation) of course also applies to the QCD axion on smaller length scales. This is of particular interest inside axion miniclusters [436, 437, 457, 458].

89.5.2 *Electron recoil searches*

In a DM direct detection experiment, a DM ALP featuring a coupling to the electron can be absorbed by the target material, leading to a mono-energetic electronic recoil signal peaked at m_a. This mechanism allowed the EDELWEISS [490], PandaX [234], SuperCDMS [235] and XENON1T [491] collaborations to put the bounds on the axion-electron coupling displayed in Fig. 89.2 in the keV mass range. As discussed in the last sub-section, additionally dynamics beyond the standard misalignment mechanism are needed to explain the axion DM abundance for keV-scale axion masses (*e.g.*, [395, 396]). Moreover, such models are subject to stringent constraints from axion decays to photons [395].

89.5.3 *Telescope searches*

The two-photon decay is extremely slow for axions with masses in the CDM regime, but could be detectable for eV masses. The signature would be a quasi-monochromatic emission line from galaxies and galaxy clusters. The expected optical line intensity for DFSZ axions is similar to the continuum night emission. A search for optical line emission in two Abell clusters using spectra from the VIMOS (Visible Multi-Object Spectrograph) integral field unit at the Very Large Telescope (VLT) excludes axions and ALPs with a two photon coupling bigger than $\sim 5\times10^{-12}\,{\rm GeV}^{-1}$ in the mass range between 4.5 and 5.5 eV [140], see Fig. 89.1. Spectral data on the dwarf spheroidal galaxy Leo T from the Multi Unit Spectroscopic Explorer (MUSE) at the VLT improve these constraints by more than an order of magnitude for ALP masses between 2.7 and 5.3 eV [139], see Fig. 89.1. More recently, as shown in Fig. 89.1, James Webb Space Telescope (JWST) data has been used to constrain axion decays in the mass range between roughly 0.1 - 4 eV [492, 493].

Very low-mass axions in halos produce a weak quasi-monochromatic radio line. Virial velocities in undisrupted dwarf galaxies are very low, and the axion decay line would therefore be extremely narrow. A search with the Haystack radio telescope on three nearby dwarf galaxies gave a limit $|g_{a\gamma\gamma}| < 1.0\times10^{-9}\ {\rm GeV}^{-1}$ at 96% CL for $298 < m_a < 363\ \mu$eV [138]. However, this combination of m_a and $g_{a\gamma\gamma}$ does not exclude plausible axion models.

A monochromatic signal is also produced in the conversion of DM axions in the background of slowly varying galactic B-fields [494]. The signal is, however, sensitive to magnetic field power on the scale of the axion mass [495]. Present and future radio telescopes appear to be able to probe ALP DM in the mass range $0.1 - 100\ \mu$eV for couplings $g_{a\gamma\gamma} \gtrsim 10^{-13}\ {\rm GeV}^{-1}$ [495] – several orders of magnitude above the KSVZ benchmark coupling for this mass range.

Resonant conversion of QCD axion or ALP DM in NS magnetospheres may give a detectable signal from individual NSs and populations of NSs for axion masses in the μeV range [496, 497]. Recent analyses of radio data in the frequency range 1-40 GHz from several NSs have found no evidence for a narrow peak predicted from this mechanism and therefore put bounds on the axion-photon coupling around $10^{-11}\,{\rm GeV}^{-2}$ for $m_a \sim 10\ \mu$eV [110–113], see Fig. 89.1. However, these limits may still suffer from uncertainties because the line intensity is difficult to predict in detail in the complicated environments of NSs [112, 498–501]. Still, next-generation radio telescopes such as the Square Kilometer Array (SKA) may reach sensitivity to QCD axion-strength couplings [113]. Stimulated ALP decays in high radiation environments may be detectable, by *e.g.* the future SKA, down to $g_{a\gamma\gamma} \gtrsim 10^{-11}\,{\rm GeV}^{-1}$, for masses between μeV and 0.1 meV [502]. Furthermore, in condensed ALP dark matter structures such as

ALP stars, a parametric instability may lead to an exponential enhancement of the photon flux from ALP-photon conversion by a factor $\sim \exp\left[|g_{a\gamma\gamma}| \int ds \rho_a^{1/2}(s)\right]$, where the integral is along any photon trajectory through the ALP overdensity [503, 504].

Photon propagation on an ULA DM background can induce birefringence that can be compared with upper limits from the CMB [83, 118, 505] and may also be probed with other sources such as pulsars [506].

89.5.4 *Microwave cavity experiments*

Galactic halo axions in the 1-100 μeV mass range may be detected by their resonant conversion into a quasi-monochromatic microwave signal in a high-Q electromagnetic cavity permeated by a strong, static B field [7, 507, 508]. The signal should appear as excess electromagnetic power in the cavity at a frequency of the total axion energy, rest mass plus kinetic energy, $\nu = (m_a/2\pi)\,[1 + \mathcal{O}(10^{-6})]$, with a width representing the axions' virial distribution in the galaxy near Earth (though the frequency spectrum may also contain narrower components from *e.g.* DM streams or other substructure; cavity experiments have enhanced sensitivity to these narrow signals [509]). If the cavity resonant frequency is tuned to the axion frequency then the signal is enhanced by the Q of the cavity. Cavity experiments are thus tuning experiments, typically right circular cylindrical cavities in solenoidal magnets tuned through mechanical motion of conductive or dielectric rods in the hopes of aligning the resonant frequency with the unknown axion mass.

A number of cavity experiments have been executed, and have historically most successful for 1-100 μeV axion masses, where the length scale of the detected photons are at laboratory length scales. At present, the ADMX [45, 46, 510, 511] and CAPP [146,148] cavity experiments have explored CDM axions with sensitivity to the DFSZ benchmark model over much of the 2.7- 4.91 μeV mass range, with the expectation of continuing to scan upwards. A number of other cavity experiments with sensitivity at or near KSVZ coupling have been operated over narrow mass ranges, notably HAYSTAC [151], TASEH [70], QUAX aγ [66], and a higher-order mode of a DMAG (formerly CAPP) cavity [512]. Exclusions are shown in Fig. 89.5.

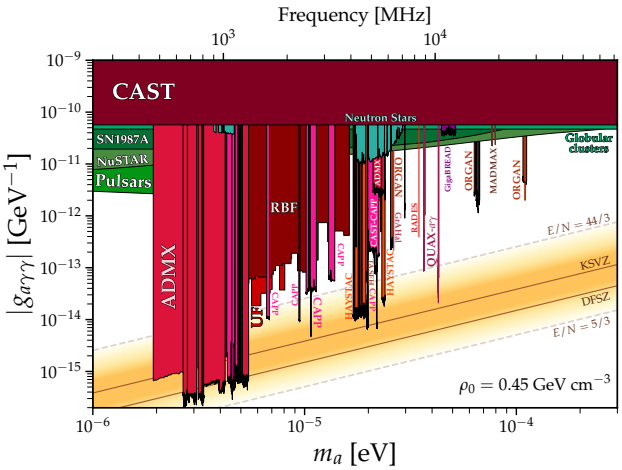

Figure 89.5: Exclusion plot for ALP-photon coupling with closeup on the parameter space of RF cavity experiments as described in the text. This is a zoom-in of Fig. 89.1 that highlights regions probed by axion DM direct detection experiments. In particular, note that all of the terrestrial experiments shaded in red, except that of CAST, assume that the axion is Figure from [39], including data from Refs. [34, 42, 44–46, 55, 58–61, 63, 64, 68, 70, 76, 99, 100, 122, 146, 146–156, 229, 513–518]

89.5.5 *Lower Mass Direct Axion Searches*

The mass range $m_a < 0.1\,\mu eV$ is increasingly of interest because of the strong theoretical motivations to prefer f_a near the GUT scale (see Sec. 89.2.1). As summarized in Fig. 89.1, there are currently no bounds in this region that reach the QCD axion parameter space. Compared to the cavity searches, the wavelength of these axions is much longer than the size of the experiments. When converted to electromagnetic fields in a strong laboratory magnetic field, the resulting signal can be modeled as currents in an equivalent "lumped" element or LC circuit [519–521]. A number of small-scale pathfinder experiments have implemented this approach focusing on the ∼neV region. Some examples are: ABRACADABRA-10cm [40, 41] used a broadband configuration in a toroidal magnet for a broadband search, ADMX-SLIC [48] used a resonant configuration in a solenoid magnet for a narrowband search, BASE [57] used the field of a penning trap for a similar search, and SHAFT [69] used a broadband configuration in a toroidal magnet enhanced with a ferromagnetic core. Future work in this direction is expected to have much more competitive sensitivity [522, 523]. There are several efforts using laser interferometry techniques to access the ∼neV parameter space: LIDA [62] and DANCE [524]. The ADBC experiment uses an optical bow-tie cavity to search for axion-induced birefringence [43].

89.5.6 *Higher Mass Direct Axion Searches*

For axion masses where the Compton wavelength is much smaller than the characteristic laboratory scale, the conversion volume becomes smaller, the characteristic resonator Q decreases, and the standard quantum noise limit increases. Techniques beyond the standard microwave cavity experiments are necessary to probe QCD axion dark matter. No experiment yet has explored a wide range of masses for high masses, beyond ∼25 μeV, at QCD axions couplings, but a number of promising techniques have been proposed and demonstrated. Only a small representative subset of these demonstrations and proposals can be cataloged here.

One path is to build a resonant structure with a characteristic dimension much longer than the converted photon wavelength. This has been proposed with subwavelength metamaterial-like conductive structure such as ALPHA [525], or VERA [526], and demonstrated with periodic dielectrics as in Orpheus [527], LAMPOST [528], and MADMAX [152]. Another option is to forgo resonance entirely and use a single conversion surface that is many wavelengths in dimension. [529] Experiments working on this concept include BRASS [530] and BREAD [150].

Due to the standard quantum limit readout for these higher-mass detectors to transition to quantum sensors and techniques beyond linear amplifiers [526,531]. Benefits of quantum squeezing have been demonstrated in HAYSTAC [60,532], and single photon counters have been shown to be beneficial in QUAX [533] and in dark photon searches using both qubit devices [534] and nanowire detectors [528], among others.

89.5.7 *Non-photon Coupling Axion Searches*

In Fig. 89.2 and Fig. 89.3, the status of the non-photon couplings are discussed in the context of the astrophysical ALP searches. These same non-photon couplings can also be used in direct searches for DM. Much of the recent focus is on the induced oscillating nuclear electric dipole moments (EDMs) [26]. An analysis of the ratio of spin-precession frequencies of stored ultracold neutrons and ^{199}Hg atoms measured by neutron EDM experiments excludes a sizeable region of parameter space in the mass region $10^{-24}\,\text{eV} \leq m_a \leq 10^{-17}\,\text{eV}$ [31], which surpass the limits on anomalous energy loss of SN 1987A by more than seven orders of magnitude and are competitive with the ones from the requirement of successful BBN established in [29].

The oscillating EDMs can also be studied with the precession of nuclear spins in a nucleon spin polarized sample in the presence of an electric field. The resulting transverse magnetization can be searched for by exploiting magnetic-resonance (MR) techniques, which are most sensitive to the low frequencies of the sub-neV axion masses. There are two interactions probed through MR: the electric dipole coupling as searched for by CASPEr-electric (with first result presented in [30]) and an interaction between the axion field gradient and the nuclear spin, which is aimed for by CASPEr-Gradient. The latter has been explored through comagnetometry between a variety of nuclei: H-^{12}C in CASPEr-ZULF [261, 262], Xe-Rb in NASDUCK [535], K-^{3}He [265–267] and K-^{3}He-Rb [273].

The exclusions from these searches are shown in Fig. 89.3.

Sub-μeV ALP masses can also be probed by using the storage ring EDM method proposed in Ref. [536] which exploits a combination of B and E-fields to produce a resonance between the $g-2$ spin precession frequency and the DM ALP field oscillation frequency. This method, however, does not reach the sensitivity to probe the QCD axion prediction for $g_{aN\gamma}$. An non-zero axion electron coupling g_{aee} will lead to an electron spin precession about the axion DM wind [537, 538]. The QUAX a-e experiment exploits MR inside a magnetized material [539]. Because of the higher Larmor frequency of the electron, it is sensitive to masses above 1μeV. Its first run established the bound in the mass range 42.4 to 43.2 μeV [240], slightly better than the solar ν bound, shown in Fig. 89.2. Updated sensitivity projections for MR techniques are detailed in [540], and examples of potential technological improvements in [541, 542].

89.6 Conclusions

There is a strengthening physics case for very weakly coupled light particles beyond the Standard Model. The elegant solution of the strong CP problem proposed by Peccei and Quinn yields a particularly strong motivation for the axion. In many theoretically appealing ultraviolet completions of the Standard Model axions and ALPs occur automatically. Moreover, they are natural CDM candidates. Interestingly, a significant portion of previously unexplored, but phenomenologically interesting and theoretically very well motivated, axion and ALP parameter space can be explored in the foreseeable future by a number of terrestrial experiments and astrophysical observations.

90. Searches for Quark and Lepton Compositeness

Revised August 2025 by K. Hikasa (Tohoku U.), M. Tanabashi (Nagoya U.; KMI, Nagoya U.), K. Terashi (ICEPP, Tokyo U.) and N. Varelas (U. of Illinois at Chicago).

90.1 Limits on contact interactions

If quarks and leptons are made of constituents, then at the scale of constituent binding energies (compositeness scale Λ) there should appear new interactions among them. At energies much below the compositeness scale, these interactions are suppressed by inverse powers of Λ. The dominant effect of the compositeness of fermion ψ should come from the lowest dimensional interactions with four fermions (contact terms), whose most general flavor-diagonal color-singlet chirally invariant form reads [1, 2]

$$\mathcal{L} = \mathcal{L}_{LL} + \mathcal{L}_{RR} + \mathcal{L}_{LR} + \mathcal{L}_{RL},$$

with

$$\mathcal{L}_{LL} = \frac{g^2_{\rm contact}}{2\Lambda^2} \sum_{i,j} \eta^{ij}_{LL} (\bar{\psi}^i_L \gamma_\mu \psi^i_L)(\bar{\psi}^j_L \gamma^\mu \psi^j_L),$$

$$\mathcal{L}_{RR} = \frac{g^2_{\rm contact}}{2\Lambda^2} \sum_{i,j} \eta^{ij}_{RR} (\bar{\psi}^i_R \gamma_\mu \psi^i_R)(\bar{\psi}^j_R \gamma^\mu \psi^j_R),$$

$$\mathcal{L}_{LR} = \frac{g^2_{\rm contact}}{2\Lambda^2} \sum_{i,j} \eta^{ij}_{LR} (\bar{\psi}^i_L \gamma_\mu \psi^i_L)(\bar{\psi}^j_R \gamma^\mu \psi^j_R),$$

$$\mathcal{L}_{RL} = \frac{g^2_{\rm contact}}{2\Lambda^2} \sum_{i,j} \eta^{ij}_{RL} (\bar{\psi}^i_R \gamma_\mu \psi^i_R)(\bar{\psi}^j_L \gamma^\mu \psi^j_L), \qquad (90.1)$$

where i, j are the indices of fermion species. Color and other indices are suppressed in Eq. (90.1). Such interactions can arise by interchanging constituents (when the fermions have common constituents), and/or by exchanging the binding quanta (whenever binding quanta couple to constituents of both particles). Chiral invariance provides a natural explanation why quark and lepton masses are much smaller than their inverse size (inverse radius) Λ. Note $\eta^{ij}_{\alpha\beta} = \eta^{ji}_{\beta\alpha}$, thus $\mathcal{L}_{LR}$ and $\mathcal{L}_{RL}$ are identical. Therefore, in order to specify the contact interaction among the same fermion species $i = j$, it is enough to use η_{LL}, η_{RR} and η_{LR}. We will suppress the indices of fermion species hereafter. We may determine the scale Λ unambiguously by using the above form of the effective interactions; the conventional method [1] is to fix its scale by setting $g^2_{\rm contact}/4\pi = g^2_{\rm contact}(\Lambda)/4\pi = 1$ for the new strong interaction coupling and by setting the largest magnitude of the coefficients $\eta_{\alpha\beta}$ to be unity. In the following, we denote

$$\Lambda = \Lambda^\pm_{LL}\,, \Lambda^\pm_{RR}\,, \Lambda^\pm_{VV}\,, \Lambda^\pm_{AA}\,, \Lambda^\pm_{V-A}\,, \qquad (90.2)$$

for $(\eta_{LL}, \eta_{RR}, \eta_{LR}) = (\pm1, 0, 0)\,, (0, \pm1, 0)\,, (\pm1, \pm1, \pm1)\,, (\pm1, \pm1, \mp1)\,, (0, 0, \pm1)$.

Fermion scattering amplitude induced from the contact interaction in Eq. (90.1) interferes with the Standard Model (SM) amplitude destructively or constructively [2]. The sign of interference depends on the sign of $\eta_{\alpha\beta}$ $(\alpha, \beta = L, R)$. For instance, in the parton level $qq \to qq$ scattering cross section in the $\Lambda^\pm_{LL}$ model, the contact interaction amplitude and the SM gluon exchange amplitude interfere destructively for $\eta_{LL} = +1$, while they interfere constructively for $\eta_{LL} = -1$. In models of quark compositeness, the quark scattering cross sections induced from the contact interactions receive sizable QCD radiative corrections. The exact next-to-leading order (NLO) QCD corrections to the quark scatterings cross sections induced by the contact interactions are given in [3].

Over the last three decades experiments at the CERN Sp$\bar{\rm p}$S [4, 5], the Fermilab Tevatron [6, 7], and the CERN LHC [8–12] have searched for quark contact interactions, characterized by the four-fermion effective Lagrangian in Eq. (90.1), using jet final states. These searches have been performed primarily by studying the angular distribution of the two highest transverse momentum, $p_{\rm T}$, jets (dijets), and the inclusive jet $p_{\rm T}$ spectrum. The variable $\chi = \exp(|(y_1 - y_2)|)$ is used to measure the dijet angular distribution, where y_1 and y_2 are the rapidities of the two jets with the highest transverse momenta. For collinear massless parton scattering, χ is related to the polar scattering angle θ^* in the partonic center-of-mass frame by $\chi = (1+|\cos\theta^*|)/(1-|\cos\theta^*|)$. The choice of χ is motivated by the fact that the angular distribution for Rutherford scattering, which is proportional to $1/(1-\cos\theta^*)^2$, is independent of χ. In perturbative QCD the χ distributions are relatively uniform and only mildly modified by higher-order QCD or electroweak corrections. Signatures of quark contact interactions exhibit more isotropic angular distribution than QCD and can be identified as an excess at low values of χ. In the inclusive jet cross section measurement, quark contact interaction effects are searched for as deviations from the predictions of perturbative QCD in the tails of the high-$p_{\rm T}$ jet spectrum [11].

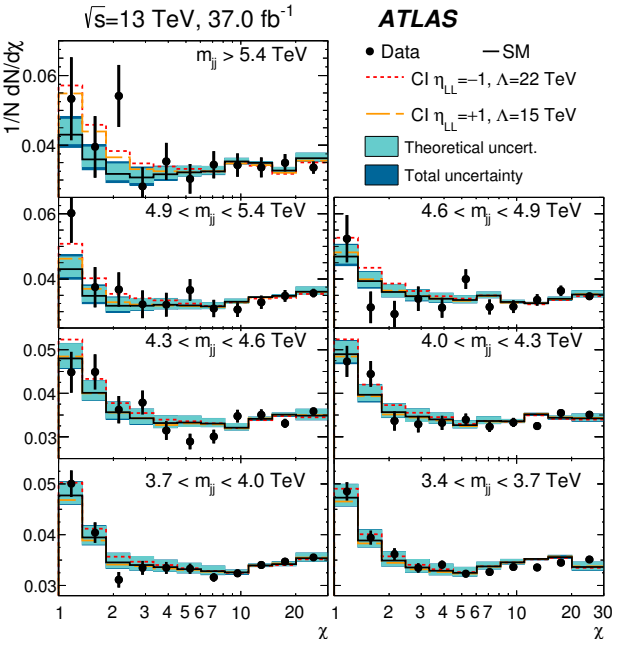

Figure 90.1: Normalized dijet angular distributions in several dijet mass (m_{jj}) ranges. The data distributions are compared to PYTHIA8 predictions with NLO and electroweak corrections applied (solid line) and with the predictions including a contact interaction (CI) term in which only left-handed quarks participate of compositeness scale $\Lambda^+_{LL} = 15$ TeV (dashed line) and $\Lambda^-_{LL} = 22$ TeV (dotted line). The theoretical uncertainties and the total theoretical and experimental uncertainties in the predictions are displayed as shaded bands around the SM prediction. Figure adopted from [9].

Recent results from the LHC, using data collected at proton-proton center-of-mass energy of $\sqrt{s} = 13$ TeV, extend previous limits on quark contact interactions. Figure 90.1 shows the normalized dijet angular distributions for several dijet mass ranges measured in ATLAS [9] at $\sqrt{s} = 13$ TeV. The data distributions are compared with SM predictions, estimated using PYTHIA8 [13] with GEANT4-based [14] ATLAS detector simulation and corrected to NLO QCD calculation provided by NLO Jet++ [15] including electroweak corrections [16]. Predictions including a contact interaction term in which only left-handed quarks participate at compositeness scale $\Lambda^+_{LL} = 15$ TeV ($\Lambda^-_{LL} = 22$ TeV) with destructive (constructive) interference are also shown. Over a wide range of χ and dijet mass the data are well described by the SM predictions. Using the dijet angular distributions measured at high dijet masses and $\sqrt{s} = 13$ TeV, the ATLAS [9] and CMS [12] Collaborations have set 95% confidence level (C.L.) lower limits on the contact interaction scale Λ, ranging from 9.2 to 29.5 TeV for different quark contact interaction models that correspond to various combinations of (η_{LL}, η_{RR}, η_{LR}), as summarized in Figure 90.2. The contact interaction scale limits extracted using the dijet angular distributions include the exact NLO QCD corrections to dijet production induced by contact interactions [3]. In proton-

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

proton collisions, the $\Lambda^{\pm}_{LL}$ and $\Lambda^{\pm}_{RR}$ contact interaction models result in identical tree-level cross sections and NLO QCD corrections and yield the same exclusion limits. For $\Lambda^{\pm}_{VV}$ and $\Lambda^{\pm}_{AA}$, the contact interaction predictions are identical at tree level, but exhibit different NLO QCD corrections and yield different exclusion limits.

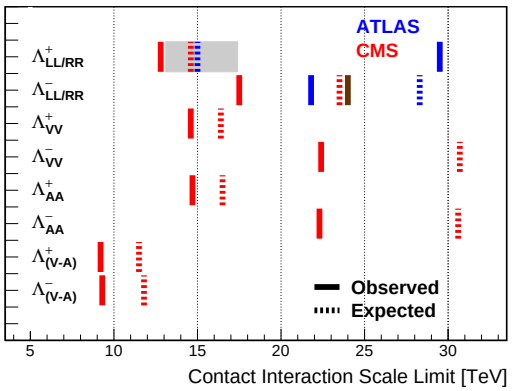

Figure 90.2: Observed (solid lines) and expected (dashed lines) 95% C.L. lower limits on the contact interaction scale Λ for different contact interaction models from ATLAS [9] and CMS [12] using the dijet angular distributions. The contact interaction models used for the dijet angular distributions include the exact NLO QCD corrections to dijet production. The shaded band for the $\Lambda^{+}_{LL/RR}$ model indicates the range of contact interaction scale that was not excluded in ATLAS [9], due to an observed excess in the data that produced a weaker limit. The observed 95% C.L. lower limit on the Λ^{-}_{LL} from CMS [17] is shown as the second solid line in brown.

If leptons (l) and quarks (q) are composite with common constituents, the interaction of these constituents will manifest itself in the form of a $llqq$-type four-fermion contact interaction Lagrangian at energies below the compositeness scale Λ. The $llqq$ terms in the contact interaction Lagrangian can be expressed as

$$\mathcal{L}_{LL} = \frac{g^2_{\text{contact}}}{\Lambda^2} \sum_{i,j} \eta^{ij}_{LL} (\bar{q}^i_L \gamma_\mu q^i_L)(\bar{l}^j_L \gamma^\mu l^j_L),$$

$$\mathcal{L}_{RR} = \frac{g^2_{\text{contact}}}{\Lambda^2} \sum_{i,j} \eta^{ij}_{RR} (\bar{q}^i_R \gamma_\mu q^i_R)(\bar{l}^j_R \gamma^\mu l^j_R),$$

$$\mathcal{L}_{LR} = \frac{g^2_{\text{contact}}}{\Lambda^2} \sum_{i,j} \eta^{ij}_{LR} (\bar{q}^i_L \gamma_\mu q^i_L)(\bar{l}^j_R \gamma^\mu l^j_R),$$

$$\mathcal{L}_{RL} = \frac{g^2_{\text{contact}}}{\Lambda^2} \sum_{i,j} \eta^{ij}_{RL} (\bar{q}^i_R \gamma_\mu q^i_R)(\bar{l}^j_L \gamma^\mu l^j_L). \qquad (90.3)$$

Searches on quark-lepton compositeness have been reported from experiments at LEP [18–21], HERA [22, 23], the Tevatron [24, 25], and recently from the ATLAS [26, 27] and CMS [28, 29] experiments at the LHC. The most stringent searches for $llqq$ contact interactions are performed by the LHC experiments using high-mass oppositely-charged lepton pairs produced through the $q\bar{q} \to l^+l^-$ Drell-Yan process. The contact interaction amplitude of the $u\bar{u} \to l^+l^-$ process ($l = e$ or μ) interferes with the corresponding SM amplitude constructively (destructively) for $\eta^{ul}_{\alpha\beta} = -1$ ($\eta^{ul}_{\alpha\beta} = +1$). The ATLAS Collaboration, using a 139 fb^{-1} dataset at $\sqrt{s} = 13$ TeV, has extracted limits on the $llqq$ contact interaction for the right-right ($\eta_{RR} = \pm 1$, $\eta_{LL} = \eta_{LR} = \eta_{RL} = 0$), left-left ($\eta_{LL} = \pm 1$, $\eta_{RR} = \eta_{LR} = \eta_{RL} = 0$), and left-right ($\eta_{LR} = \eta_{RL} = \pm 1$, $\eta_{RR} = \eta_{LL} = 0$) models. In Ref. [27], ATLAS used a background estimate directly obtained from data. Combining the dielectron and dimuon channels, the 95% C.L. lower limits on the $llqq$ contact interaction scale Λ are 35.5 TeV (26.5 TeV) for the right-right model, 35.8 TeV (26 TeV) for the left-left model, and 32.5 TeV (28.8 TeV) for the left-right model, each with constructive (destructive) interference [27]. The CMS Collaboration, using a 140 fb^{-1} dataset at 13 TeV, has set 95% C.L. exclusion limits on the $llqq$ contact interaction scale that range from $\Lambda_{LL} > 23.9$ TeV for the destructive interference to $\Lambda_{RR} > 36.4$ TeV for the constructive interference, for the left-left and the right-right models, respectively [29].

Note that the contact interactions arising from the compositeness of quarks and leptons in Eq. (90.1) can also be regarded as a part of more general dimension-six operators in the context of low-energy standard-model effective field theory (SMEFT). For a complete list of SM gauge-invariant dimension-six operators, see [30, 31]. A computation of the one-loop anomalous dimension matrix for SMEFT operators are found in Refs. [32–34]. See also Refs. [35–37] for recent reviews. Ref. [17] sets limits on the Wilson coefficients of the contact interaction operators in the SMEFT framework, using the CMS data of the inclusive jet production cross sections together with the deep inelastic scattering data from HERA and the CMS $t\bar{t}$ cross section data. The results are translated into a 95% C.L. exclusion limit on the quark compositeness $\Lambda^{-}_{LL} > 24$ TeV, which is shown as the second solid line in brown in Figure 90.2.

In models where the SM fermions get their masses though the mixing with the composite states, the top-quark is expected to show compositeness properties [38] resulting in the $t\bar{t}t\bar{t}$ contact interaction operators in the SMEFT context. An enhancement of the four-top-quark production cross section is expected at hadron colliders in these models [39]. The ATLAS Collaboration has extracted 95% C.L. observed (expected) limits on the $t\bar{t}t\bar{t}$ contact interaction operator $|C_{4t}|/\Lambda^2 < 1.9$ TeV^{-2} (1.6 TeV^{-2}) using their 36.1 fb^{-1} data at $\sqrt{s} = 13$ TeV [40]. Consistent SMEFT reinterpretations of top-quark data, and high energy non-resonant dijet and dilepton data are provided, e.g., in Refs. [41, 42].

Interactions of hypothetical dark matter candidate particles with SM particles through mediators can also be described as contact interactions at low energy. See *"Searches for WIMPs and Other Particles"* in this volume for limits on the interactions involving dark matter candidate particles.

90.2 Limits on excited fermions

Another typical consequence of compositeness is the appearance of excited leptons and quarks (l^* and q^*). Phenomenologically, an excited lepton is defined to be a heavy lepton which shares a leptonic quantum number with one of the existing leptons (an excited quark is defined similarly). For example, an excited electron e^* is characterized by a nonzero transition-magnetic coupling with electrons. The smallness of the lepton mass and the success of QED prediction for $g-2$ suggest chirality conservation, *i.e.,* an excited lepton should not couple to both left- and right-handed components of the corresponding lepton [43–45].

Excited leptons may be classified by $SU(2) \times U(1)$ quantum numbers. Typical examples are:

1. Sequential type

$$\begin{pmatrix} \nu^* \\ l^* \end{pmatrix}_L, \qquad [\nu^*_R], \qquad l^*_R.$$

   ν^*_R is necessary if we assume ν^* has a Dirac mass.
2. Mirror type

$$[\nu^*_L], \qquad l^*_L, \qquad \begin{pmatrix} \nu^* \\ l^* \end{pmatrix}_R.$$

3. Homodoublet type

$$\begin{pmatrix} \nu^* \\ l^* \end{pmatrix}_L, \qquad \begin{pmatrix} \nu^* \\ l^* \end{pmatrix}_R.$$

Similar classification can be made for excited quarks.

Excited fermions can be pair produced via their minimal gauge couplings. The couplings of excited leptons with Z are given by

$$\frac{e}{2 \sin\theta_W \cos\theta_W} \left[(-1 + 2\sin^2\theta_W) \bar{l^*} \gamma^\mu l^* Z_\mu + \bar{\nu^*} \gamma^\mu \nu^* Z_\mu \right]$$

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

in the homodoublet model. The corresponding couplings of excited quarks can be easily obtained. Although form factor effects can be present for the gauge couplings at $q^2 \neq 0$, they are usually neglected.

Excited fermions may also be produced via the contact interactions with ordinary quarks and leptons [46]

$$\mathcal{L} = \frac{g_{\rm contact}^2}{\Lambda^2}\left[\eta'_{LL}(\bar{\psi}_L\gamma_\mu\psi_L)(\bar{\psi}^*_L\gamma^\mu\psi^*_L) + (\eta''_{LL}(\bar{\psi}_L\gamma_\mu\psi_L)(\bar{\psi}^*_L\gamma^\mu\psi_L) + \text{h.c.}) + \cdots\right]. \quad (90.4)$$

Again, the coefficient is conventionally taken $g^2_{\rm contact} = 4\pi$. It is widely assumed $\eta'_{LL} = \eta''_{LL} = 1$, $\eta'_{LR} = \eta''_{LR} = \eta'_{RL} = \eta''_{RL} = \eta'_{RR} = \eta''_{RR} = 0$ in experimental analyses for simplicity.

In addition, transition-magnetic type couplings with a gauge boson are expected. These couplings can be generally parameterized as follows:

$$\begin{aligned}\mathcal{L} =& \frac{\lambda_\gamma^{(\psi^*)} e}{2m_{\psi^*}}\bar{\psi}^*\sigma^{\mu\nu}(\eta_L\frac{1-\gamma_5}{2} + \eta_R\frac{1+\gamma_5}{2})\psi F_{\mu\nu} \\ &+ \frac{\lambda_Z^{(\psi^*)} e}{2m_{\psi^*}}\bar{\psi}^*\sigma^{\mu\nu}(\eta_L\frac{1-\gamma_5}{2} + \eta_R\frac{1+\gamma_5}{2})\psi Z_{\mu\nu} \\ &+ \frac{\lambda_W^{(l^*)} g}{2m_{l^*}}\bar{l}^*\sigma^{\mu\nu}\frac{1-\gamma_5}{2}\nu W_{\mu\nu} \\ &+ \frac{\lambda_W^{(\nu^*)} g}{2m_{\nu^*}}\bar{\nu}^*\sigma^{\mu\nu}(\eta_L\frac{1-\gamma_5}{2} + \eta_R\frac{1+\gamma_5}{2})l W^\dagger_{\mu\nu} \\ &+ \text{h.c.}, \end{aligned} \quad (90.5)$$

where $g = e/\sin\theta_W$, $\psi = \nu$ or l, $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the photon field strength, $Z_{\mu\nu} = \partial_\mu Z_\nu - \partial_\nu Z_\mu$, *etc.*. The normalization of the coupling is chosen such that

$$\max(|\eta_L|, |\eta_R|) = 1.$$

Chirality conservation requires

$$\eta_L\eta_R = 0. \quad (90.6)$$

These couplings in Eq. (90.5) can arise from $SU(2) \times U(1)$-invariant higher-dimensional interactions. A well-studied model is the interaction of homodoublet type l^* with the Lagrangian (see [47,48])

$$\mathcal{L} = \frac{1}{2\Lambda}\bar{L}^*\sigma^{\mu\nu}(gf\frac{\tau^a}{2}W^a_{\mu\nu} + g'f'YB_{\mu\nu})\frac{1-\gamma_5}{2}L + \text{h.c.}, \quad (90.7)$$

where L denotes the lepton doublet (ν, l), Λ is the compositeness scale, g, g' are $SU(2)$ and $U(1)_Y$ gauge couplings, and $W^a_{\mu\nu}$ and $B_{\mu\nu}$ are the field strengths for $SU(2)$ and $U(1)_Y$ gauge fields. These couplings satisfy the relation

$$\lambda_W = -\sqrt{2}\sin^2\theta_W(\lambda_Z\cot\theta_W + \lambda_\gamma), \quad (90.8)$$

with $\lambda_{W,Z,\gamma}$ being defined in Eq. (90.5) with $\lambda_{W,Z,\gamma} = \lambda^{(\ell^*)}_{W,Z,\gamma}$ or $\lambda_{W,Z,\gamma} = \lambda^{(\nu^*)}_{W,Z,\gamma}$. Here $(\eta_L, \eta_R) = (1, 0)$ is assumed. It should be noted that the electromagnetic radiative decay of l^* (ν^*) is forbidden if $f = -f'$ $(f = f')$.

Additional coupling with gluons is possible for excited quarks:

$$\mathcal{L} = \frac{1}{2\Lambda}\bar{Q}^*\sigma^{\mu\nu}\left(g_s f_s\frac{\lambda^a}{2}G^a_{\mu\nu} + gf\frac{\tau^a}{2}W^a_{\mu\nu} + g'f'YB_{\mu\nu}\right) \times \frac{1-\gamma_5}{2}Q + \text{h.c.}, \quad (90.9)$$

where Q denotes a quark doublet, g_s is the QCD gauge coupling, and $G^a_{\mu\nu}$ the gluon field strength.

If leptons are made of color triplet and antitriplet constituents, we may expect their color-octet partners. Transitions between the octet leptons (l_8) and the ordinary lepton (l) may take place via the dimension-five interactions

$$\mathcal{L} = \frac{1}{2\Lambda}\sum_l\left\{\bar{l}^\alpha_8 g_S F^\alpha_{\mu\nu}\sigma^{\mu\nu}(\eta_L l_L + \eta_R l_R) + \text{h.c.}\right\} \quad (90.10)$$

where the summation is over charged leptons and neutrinos. The leptonic chiral invariance implies $\eta_L\eta_R = 0$ as before.

Searches for the excited quarks and leptons have been performed over the last decades in experiments at the LEP [49–52], HERA [53, 54], Tevatron [55, 56], and LHC [57–91]. Most stringent constraints, which are described below at 95% confidence level, come from the LHC experiments.

The signature of excited quarks q^* at hadron colliders is characterized by a narrow resonant peak in the reconstructed invariant mass distribution of the q^* decay products. The decays via the transition-magnetic type operator in Eq. (90.9) are considered for excited quarks in LHC searches, and the final states to search for are dijet (qg) [57, 58, 70–73] or a jet in association with a photon $(q\gamma)$ [59,60,74,75,89] or a weak gauge boson (qW, qZ) [76,77]. All analyses consider only spin-1/2 excited states of first generation quarks (u^*, d^*) with degenerate masses, expected to be predominantly produced in proton-proton collisions except for the excited b quark searches described below. Only the minimal gauge interactions and the transition-magnetic couplings with the form given in Eq. (90.9) are considered in the production process, and hence the contact interactions in Eq. (90.4) are not considered. The compositeness scale Λ is taken to be the same as the excited quark mass m_{q^*}. The transition-magnetic coupling coefficients f_s, f and f' are assumed to be equal to 1 (denoted by f).

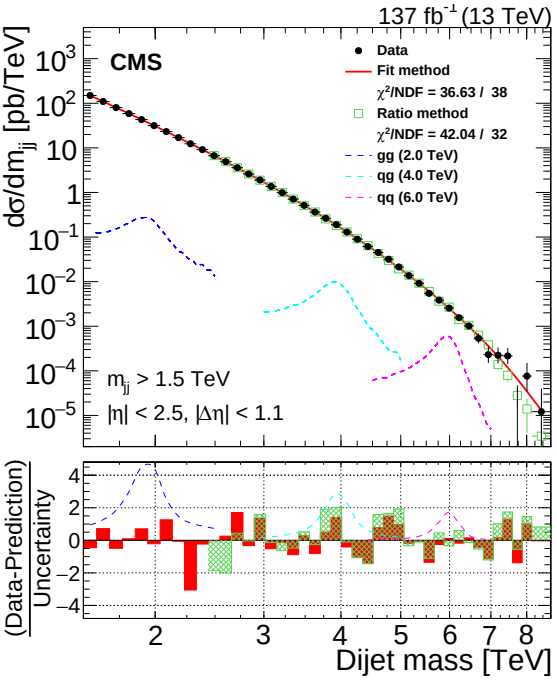

Figure 90.3: Dijet mass distribution measured by CMS using wide jets reconstructed from two highest transverse momentum jets by adding nearby jets within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 1.1$. The data distribution is compared to a fit representing a smooth background spectrum (solid curve) and the background prediction obtained from the $\Delta\eta_{\rm jj}$ control regions (open squares), denoted as Ratio method, at $m_{\rm jj} > 2.4$ TeV. The excited quark signal with mass of 4.0 TeV (labeled as qg) is shown together with other benchmark signals. Shown at the bottom panel is the difference between the data and the fitted parametrization from the fit method or the data and the background prediction from the Ratio method, divided by the statistical uncertainty of the data. Figure adopted from [73].

With proton-proton collision data recorded at $\sqrt{s} = 13$ TeV at the LHC, the excited quark masses are excluded in dijet resonance searches up to 6.7 TeV in ATLAS using 139 fb^{-1} [58] and 6.3 TeV in CMS using 137 fb^{-1} [73]. Figure 90.3 shows the dijet mass ($m_{\rm jj}$) distribution measured in CMS [73] by using the two highest $p_{\rm T}$ jets reconstructed with the anti-$k_{\rm T}$ algorithm [92] of

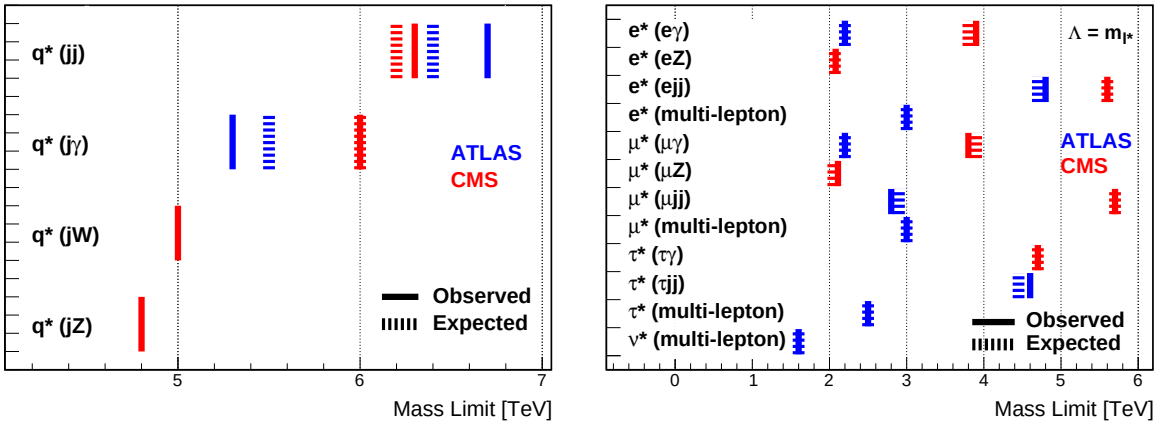

Figure 90.4: 95% C.L. lower mass limits for the excited quarks (left) and excited leptons (right) at ATLAS [58, 60, 66–68, 88] and CMS [73,75,77,80–82,89,90] experiments. Shown are the most stringent limits for each final state (denoted in parentheses) of the excited fermions from both experiments. Only first generation quarks (u, d) with transition-magnetic type interactions with $f_s = f = f' = 1$ are considered for the excited quarks. The excited lepton limits are given for the production via contact interactions with $\Lambda = m_{l^*}$.

a distance parameter of 0.4, and by combining nearby jets within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 1.1$ around the leading two jets. The measured dijet mass spectrum is compared to a fit with smoothly falling background shape (solid curve) at $m_{jj} > 1.5$ TeV and the background prediction obtained from $\Delta\eta_{jj}$ control regions (open squares), denoted as Ratio method, at $m_{jj} > 2.4$ TeV to look for a narrow resonance. Here $\Delta\eta_{jj}$ is the pseudorapidity separation between the two jets. An excited quark signal with mass of 4.0 TeV is shown in the figure (denoted by qg) as one of the benchmark signals considered in the analysis.

The photon + jet resonance searches, targeting excited quarks decaying into a quark and a photon ($q^* \to q + \gamma$), have excluded q^* masses up to 5.3 TeV in ATLAS [60] and 6.0 TeV in CMS [89] using collision data at $\sqrt{s} = 13$ TeV. The W/Z boson + jet final states are examined to look for the $q^* \to q + W$ and $q + Z$ signal in CMS [77], exploiting jet substructure technique designed to provide sensitivity for highly-boosted hadronically decaying W and Z bosons. The lower mass limit of 5.0 (4.8) TeV is obtained from the W + jet (Z + jet) search using dataset recorded at $\sqrt{s} = 13$ TeV.

The excited b quarks (b^*) are also considered in the present searches at the LHC. Assuming the similar production processes to the first-generation excited quarks, the b^* has been searched for in final states containing at least one jet identified as originating from a b quark (b-tagging). The searches using two jets including at least one b-tagged jet have been performed at 8 and 13 TeV [58, 61, 62, 71, 85], resulting in b^* lower mass limits of 3.2 TeV in ATLAS using 139 fb^{-1} at $\sqrt{s} = 13$ TeV [58] and 4.0 TeV in CMS using 138 fb^{-1} at $\sqrt{s} = 13$ TeV [85]. The CMS Collaboration also performed a search for $b^* \to b + \gamma$ in events with a b-tagged jet in association with a photon using data at $\sqrt{s} = 13$ TeV [89], and excluded b^* masses up to 2.2 TeV. The observed lower mass bounds on the excited bottom quarks extends to 3.8 TeV, when the production mode from contact interactions Eq. (90.4) is also considered. Excited b quarks with charged-current decay into a W-boson and a top quark ($b^* \to t + W$) were looked for in both ATLAS and CMS using the full 8 TeV data [63, 78] and in CMS using the full 13 TeV data [86, 87]. For the left(right)-handed couplings, CMS excluded the masses below 2.6(2.8) TeV in the fully hadronic final states [86] and 3.0(3.2) TeV in the lepton+jets final states [87].

The excited top quarks (t^*) have also been searched for at the LHC. The CMS Collaboration performed the search for pair-produced t^* quarks with the assumption of the t^* quark decay into a top quark and a gluon, in events with a charged lepton, missing transverse momentum and multiple jets including b-tagged jets at $\sqrt{s} = 8$ TeV [84] and 13 TeV [83, 91]. With 138 fb^{-1} data at 13 TeV, CMS excluded the t^* masses below 1.7 TeV and 1.05 TeV for spin 3/2 and 1/2 t^* quarks, respectively [91].

Searches for excited leptons l^* are also performed at the LHC using proton-proton collision data recorded at $\sqrt{s} = 7$ and 8 TeV [65–69, 79, 80] as well as at 13 TeV [81, 90]. Considering single l^* production in contact interactions (Eq. (90.4)) and electromagnetic radiative decay to a SM lepton and a photon ($l^* \to l + \gamma$ where $l = e, \mu, \tau$), the excited electron and muon masses are excluded for $\Lambda = m_{l^*}$ up to 3.9 and 3.8 TeV, respectively, using 35.9 fb^{-1} at $\sqrt{s} = 13$ TeV in CMS [81] and 2.2 TeV using 13 fb^{-1} at $\sqrt{s} = 8$ TeV in ATLAS [66]. The CMS Collaboration performed the excited tau lepton search at $\sqrt{s} = 13$ TeV using 138 fb^{-1} [90], and excluded the excited tau lepton mass up to 4.7 TeV for $\Lambda = m_{\tau^*}$.

With the full 20.3 fb^{-1} data at $\sqrt{s} = 8$ TeV, the inclusive search on multi-lepton signatures with 3 or more charged leptons in ATLAS [67] further constrains the excited charged leptons and neutrinos. Considering both the transition-magnetic (Eq. (90.7)) and contact interaction (Eq. (90.4)) processes, the lower mass limits for the e^*, μ^*, τ^* and ν^* (for every excited neutrino flavor) are obtained to be 3.0, 3.0, 2.5 and 1.6 TeV, respectively, for $\Lambda = m_{e^*}$, m_{μ^*}, m_{τ^*} and m_{ν^*}. The rate of pair-produced excited leptons is independent of Λ for the minimal gauge interaction processes, and it allows to improve search sensitivity with multi-lepton signatures at high Λ, especially for excited neutrinos because the predominant $\nu_l^* \to l + W$ decays result in a higher acceptance for ≥ 3 charged lepton final states.

Both ATLAS and CMS Collaborations performed searches for singly produced excited leptons. The single excited leptons, both produced and decaying in contact interaction processes (Eq. (90.4)), were searched for in CMS with 77.4 fb^{-1} at 13 TeV [82] and in ATLAS with 20.3 fb^{-1} at 8 TeV [68] and 139 fb^{-1} at 13 TeV [88] using the final states with two leptons and two jets ($q\bar{q} \to ll^* \to llq\bar{q}$). The CMS search [82] considered both excited electrons and excited muons, using the invariant mass of the combination of the two leptons and two jets as a discriminating variable to separate signal from background. The ATLAS search considered excited muons [68] and excited τ leptons [88]. The single excited electrons, produced in contact interactions and decayed either in contact interaction or charged-current processes, were considered in ATLAS using 36.1 fb^{-1} at 13 TeV [69] in the final states with two electrons and two jets ($q\bar{q} \to ee^* \to eeq\bar{q}$) or an electron, missing transverse momentum and a hadronically decaying W-boson candidate ($q\bar{q} \to ee^* \to e\nu W$). The excited electron (muon) mass was excluded up to 5.6 (5.7) TeV in CMS [82] at $\Lambda = m_{e^*}$ ($\Lambda = m_{\mu^*}$), which is the best limit to date on the excited electrons (muons). The excited τ lepton mass was excluded up to 4.6 TeV in ATLAS [88] at $\Lambda = m_{\tau^*}$.

The CMS Collaboration also performed an excited lepton search

in the final states containing a Z boson [80], probing the excited leptons produced in contact interactions and decayed in neutral-current processes ($l^* \to l + Z$) with $f = f' = 1$ or $f = -f' = 1$. The leptonic and hadronic decays of Z bosons have been considered in the search, and the most stringent limits are obtained from the hadronic Z decay to be 2.08 (2.34) TeV and 2.11 (2.37) TeV for the e^* and μ^*, respectively, with $f = f' = 1$ ($f = -f' = 1$) at $\Lambda = m_{l^*}$.

Figure 90.4 summarizes the most stringent 95% C.L. lower mass limits for excited quarks and leptons obtained from the LHC experiments.

91. Dynamical Electroweak Symmetry Breaking: Implications of the H^0

Revised August 2025 by K.M. Black (Wisconsin U.), G. Cacciapaglia (LPTHE, Paris; CNRS) and A. Lister (U. of British Columbia).

91.1 Introduction and Phenomenology

In theories of dynamical symmetry breaking, the electroweak interactions are broken to electromagnetism by the vacuum expectation value of a composite operator. This is typically a bilinear operator made of fermions charged under a strongly-coupled extension of the standard model. In these theories, the longitudinal components of the massive weak bosons are identified with composite Nambu-Goldstone bosons. They arise from the spontaneous dynamical breaking of a global symmetry that envelops the electroweak gauge one. Viable theories must also explain (or at least accommodate) the presence of a composite scalar state to be identified with the 125 GeV H^0 scalar boson [1, 2] – a state unlike any other observed previously.

Theories of dynamical electroweak symmetry breaking can be classified by the nature of the composite singlet state to be associated with H^0 and the corresponding dimensional scales f, the analog of the pion decay-constant in QCD, and Λ, the scale of the underlying strong dynamics.[1] Of particular importance is the ratio v/f, where $v^2 = 1/(\sqrt{2}G_F) \approx (246\,\text{GeV})^2$, since this ratio measures the expected size of deviations from typical standard model predictions – for instance, in some models, deviations of the composite Higgs couplings to other particles. In all models, new states are predicted below the scale Λ, and we describe the basic possibilities below.

91.1.1 *Technicolor-like models, $v/f \simeq 1$, $\Lambda \simeq 1$ TeV*

Technicolor models [8, 9], based on a scaled-up version of two-flavor QCD, provided the first example of dynamical electroweak symmetry breaking. Models based on different dynamics have been proposed and studied, e.g. [10–14]. Such technicolor-like theories incorporate a new asymptotically free gauge interaction ("hypercolor") and charged massless fermions ("hyperfermions") transforming under a vectorial representation of the gauge group. The ensuing global chiral symmetry is spontaneously broken by the formation of a hyperfermion condensate, just as the approximate chiral symmetry in QCD is broken down to isospin by the formation of a quark condensate. The $\text{SU}(2)_W \times \text{U}(1)_Y$ interactions are embedded in the global hyperfermion chiral symmetries in such a way that the chiral condensate leaves only the electromagnetic $\text{U}(1)_{em}$ unbroken.[2] The theories naturally provide the Nambu-Goldstone bosons "eaten" by the W and Z bosons. There would also typically be additional light states (scalars, analogous to pions) and heavy ones (e.g. vector mesons, analogous to the ρ and ω mesons in QCD) with masses in the TeV range [18, 19]. The original technicolor was Higgsless, hence predicting the WW and ZZ scattering amplitudes to be strong at energies of order 1 TeV [20].

There are various possibilities for the scalar H^0 in technicolor-like models. First, the H^0 could be identified as an accidentally light singlet scalar resonance, analogous to the σ state expected in pion-scattering in QCD [21–23]. Alternatively, the H^0 could be identified as a dilaton, a pseudo-Nambu-Goldstone boson of scale invariance in theories of "walking technicolor" [24–29]. In both cases, the decay constant of the composite scalar requires tuning to obtain viable couplings to other standard model couplings, see e.g. [30].[3] Other possibilities exist, but are less viable in reproducing the standard model [31, 32].

In all of these cases one expects large deviations in the Higgs self-couplings, while the measurements of the H^0 couplings to other particles, which match the standard model predictions at a few percent level [33], impose the most challenging constraints. Technicolor-like models would also predict new states at a few TeV, such as a ρ-like vector resonances below 4 TeV [34], and could accommodate for dark matter [14, 35].

91.1.2 *The Higgs doublet as a pseudo-Nambu-Goldstone Boson, $v/f < 1$, $\Lambda > 1$ TeV*

The challenge with the Higgs couplings can be diminished by use of the vacuum misalignment mechanism [36, 37] in models where the whole scalar quartet in the Higgs doublet arises as a set of (pseudo-)Nambu-Goldstone bosons [38, 39]. Composite Goldstone Higgs models must, therefore, feature a chiral condensate that preserves the embedded electroweak symmetry. Its breaking occurs by misalignment of the vacuum due to external couplings, such as the electroweak gauging, top couplings and hyperfermion masses [40]. Hence, the electroweak scale v emerges as an "angle", $\sin\theta \equiv v/f$.[4] In this case, the underlying dynamics can occur at energies exceeding $f \geq 1$ TeV (hence, $\Lambda \gtrsim 10$ TeV), at the price of some fine-tuning in the Higgs potential [41] – closely related to the "Little Hierarchy Problem" [42]. Furthermore, the couplings of the composite Goldstone H^0 naturally equal those of the standard model Higgs boson, up to corrections of the order of $(v/f)^2$: the ones to weak gauge bosons are in fact universal [43, 44], while the ones to fermions strongly depend on the fermion mass origin [45]. Hence, these theories feature a decoupling limit when $v/f \to 0$ at constant v, while also featuring a technicolor-like limit when $v/f \to 1$ [40].[5]

As the misalignment is due to gauge and top couplings, some model building efforts have been directed towards mitigating the fine tuning issue. For instance, "Little Higgs" theories [48–51] can be seen as realizations of a composite Goldstone Higgs, where misalignment occurs at higher loop order thanks to collective symmetry breaking. Another avenue involves the enlargement of the global symmetry, as in the case of "Maximal Symmetric Models" [52–54].

Composite Goldstone Higgs models typically require a larger global symmetry of the underlying theory than technicolor-like ones. Hence, additional relatively light (compared to Λ) scalar particles are present [55–57], some of which could play the role of dark matter [58–60]. In addition to these states, one would expect the underlying dynamics to yield additional scalar and vector resonances with masses of order Λ. Lighter resonances, with masses of order f, may play an important role in mitigating the little hierarchy problem in the Higgs potential [61], particularly spin-1 resonances of the weak gauge bosons [62] and fermionic top partners [63, 64]. The presence of a custodial symmetry [65, 66] constrains the couplings and quantum numbers of these light resonances, for instance requiring top partners of exotic charge $+5/3$ [66] or a charged vector resonance with similar branching ratios to WZ and WH. Colored top partners also provide additional contributions to Higgs production via gluon fusion [67] and to Higgs pair production [68, 69]. A precise measurement of the Higgs properties at the LHC and future colliders, therefore, provides strong constraints on this class of models, together with electroweak precision (which currently yields the strongest bounds, $f \gtrsim 1$ TeV) and direct searches for light resonances.

The larger symmetry of the underlying composite Higgs theory also allows for more exotic states to appear (e.g. [70–72]), including colorless top partners in composite twin Higgs models [73, 74]. The phenomenology of the additional scalar and fermionic states is rather different. Lacking color, the production of these particles at the LHC will be suppressed and their decays may lead to long-lived signatures.

91.1.3 *Top-Condensate, Top-Color, Top-Seesaw and related theories, $v/f < 1$, $\Lambda > 1$ TeV*

A third alternative is offered by strongly interacting theories where a fine-tuning in the coupling strength allows a hierarchy

[1] In a strongly interacting theory "Naive Dimensional Analysis" [3, 4] implies that, in the absence of fine-tuning, $\Lambda \simeq g^* f$ where $g^* \lesssim 4\pi$ is the typical size of a strong coupling in the low-energy theory [5, 6]. This estimate is modified in the presence of multiple flavors or colors [7] .

[2] For a review of technicolor models, see [15–17].

[3] For the dilaton, this would require that chiral and scale symmetries are broken by the same condensate.

[4] Equivalently, misalignment can be described as a vacuum expectation value of the pseudo-Nambu-Goldstone Higgs, whose potential is dynamically generated by loops of top quarks and weak gauge bosons, as well as the hyperfermion mass terms.

[5] For a review of composite Goldstone Higgs models, see [46, 47].

between the dynamical scale and the electroweak scale. This scenario is only possible if the electroweak (quantum) phase transition is continuous (second order) in the strength of the strong dynamics [75]. Similarly to the Goldstone Higgs scenario, the tuned underlying strong interactions generate a light composite Higgs bound state, whose couplings match those of the standard model Higgs boson up to corrections of order $(1\ \text{TeV}/\Lambda)^2$. Hence, a precise measurement of the H^0 couplings gives rise to lower bounds on the scale Λ. By construction, the theory has a decoupling limit $\Lambda \to \infty$, at the price of arbitrary fine adjustment of the interaction strength.

Concrete realizations often posit the top-quark itself as strongly interacting at high energies [76, 77], potentially through an extended color gauge sector [78–80]. In these theories, top-quark condensation (or the condensation of an admixture of the top with additional vector-like quarks) is responsible for electroweak symmetry breaking, and the H^0 is identified with a bound state involving the third generation of quarks. The mechanism of top condensation has also been combined to technicolor like theories to explain the large top mass [81]. Theories of top condensation typically include an extra set of massive color-octet vector bosons (top-gluons), and an extra $U(1)$ interaction (giving rise to a top-color Z′) which couple preferentially to the third generation and whose masses define the scale Λ of the underlying physics.

91.1.4 *Extra-dimensions, CFTs and holography*

Theories with compact extra-dimensions [82] lead to low energy effective theories of "resonances", which are hard to distinguish from composite states. In these scenarios, the electroweak gauge symmetry can be broken by boundary conditions, leading to both technicolor-like scenarios [83, 84] and Goldstone Higgs ones [85, 86]. A dictionary between extra dimensions and composite models can be established for both the gauge [85] and fermion [87, 88] sector, motivated by the AdS/CFT correspondence [89] (dubbed holography).

A more formal application of holography would require the composite sector to behave as a strongly coupled conformal theory, where the gravity dual can be used as an analog computer to predict low energy properties of the composite resonances. This technique has been applied to technicolor-like models [34, 90, 91], composite Goldstone Higgs scenarios with top partners [92] and top-color models [90].

91.1.5 *Flavor*

In addition to the electroweak symmetry breaking dynamics described above, which gives rise to the masses of the W and Z bosons, additional interactions must be introduced to generate the masses of the standard model fermions. As they are typically induced by higher order terms (such as four-fermion interactions), small fermion masses are natural while a challenge is posed by the top mass, the only one which is close to the electroweak scale. Two broad classes have been suggested for these new interactions.

In "extended technicolor" (ETC) theories [93,94], the gauge interactions in the underlying strongly interacting theory are extended to incorporate flavor. This extended gauge symmetry is broken down (possibly sequentially, at several different mass scales) to the residual hypercolor responsible for electroweak symmetry breaking. The massive gauge-bosons corresponding to the broken symmetries mediate interactions between mass operators for the quarks/leptons and the corresponding bilinears of hyperfermions, giving rise to the masses of the ordinary fermions via the electroweak symmetry breaking condensate.

In the "partial compositeness" class [95], the additional flavor-dependent interactions arise from mixing between the ordinary elementary quarks and leptons and (massive) composite operators in the strongly-interacting underlying theory. At low energies, fermionic resonances that couple largely to heavy fermions appear, with masses in the multi-TeV range. The main advantage of partial compositeness is that the coupling of the composite operators may be enhanced at low energy by large anomalous dimensions.[6]

Since the flavor interactions must give rise to quark and lepton mixing, a generic composite theory would give rise to large flavor-changing neutral-currents [94]. In ETC theories, these constraints are typically somewhat relaxed if the theory incorporates approximate generational flavor symmetries [97], the theory has a slowly running coupling constant or "walks" [24–28], or if $\Lambda > 1$ TeV [98]. In theories of partial compositeness, the masses of the ordinary fermions depend on the scaling-dimension of the operators corresponding to the composite fermions with which they mix. This leads to a new mechanism for generating the mass-hierarchy of the observed quarks and leptons that, potentially, ameliorates flavor-changing neutral current problems [99–103]. Alternatively, one can assume that the underlying flavor dynamics respect flavor symmetries ("minimal" [104, 105] or "next-to-minimal" [106] flavor violation) that suppress flavor-changing neutral currents in the two light generations [107]. Additional considerations apply when extending these arguments to potential explanation of neutrino masses (see, for example, [108]).

While most analyses of composite flavor rely on low energy effective theories, generating the necessary interactions in a complete model remains a challenge, often requiring multiple mechanisms at once (typically partial compositeness for the top, and bilinear ETC-like interactions for the light fermions). Theories of top partial compositeness have been defined in terms of hyperfermions [109], leading to possible ultra-violet completion which involve partial unification of the hypercolor interactions [110–112]. An alternative idea consists in adding Yukawa-like interactions with strongly interacting scalars, leading to "fundamental partial compositeness" for all fermions [113, 114]. Finally, one could assume that the theory flows to a conformal field theory above Λ, however no concrete and fully self-consistent model of this kind has been constructed yet.

91.1.6 *Theoretical Considerations*

Since the underlying low-energy dynamics in these theories is strongly coupled, there are no straightforward calculation techniques that can be applied to analyze their properties. Instead, most phenomenological studies depend on the construction of a "low-energy" effective theory describing additional scalar, fermion, or vector boson degrees of freedom, which incorporates the relevant symmetries and, when available, dynamical principles. In some cases, motivated by the AdS/CFT correspondence [89], the strongly-interacting theories described above have been investigated by analyzing a dual compactified five-dimensional gauge theory.

More recently, progress has been made in investigating strongly-coupled models using lattice gauge theory (see e.g. [115–120]). These calculations offer the prospect of establishing which strongly coupled theories of electroweak symmetry breaking have a particle with properties consistent with those observed for the H^0 – and for establishing concrete predictions for these theories at the LHC [121].

91.1.7 *Summary*

The theoretical ideas and models reviewed here motivate searches for a wide variety of new states. Heavy vector bound states decaying to dibosons and additional scalar states appear naturally in both technicolor-like (91.1.1) and Goldstone Higgs models (91.1.2). Light W' and Z' states are typically required in models featuring collective symmetry breaking, together with vector-like fermions that couple strongly to the top quark. The latter are also required by partial compositeness to generate a large mass for the top and address the flavor problem (91.1.5). Top-condensate and related models (91.1.3) predict the existence of colorons which preferentially couple to third-generation quarks. In all cases, realistic models that have a well-defined underlying model often predict the existence of more exotic states, such as exotic-color fermions and vectors, and colorless top partners. Finally, the new states discussed here also occur in extra-dimensional models (91.1.4)), which is understandable given that many strongly-coupled theories can be viewed as compactified five-dimensional gauge theories via duality. We turn now to a review the status of experimental searches related to dynamical electroweak symmetry breaking.

[6] For a review, see [47, 96].

91.2 Experimental Searches

As discussed above, the extent to which the couplings of the H^0 conform to the expectations for a standard model Higgs boson constrains the viability of each of these models. Measurements of the H^0 couplings, and their interpretation in terms of effective field theory, are summarized in the H^0 review in this volume. In what follows, we will focus on searches for the additional particles that might be expected to accompany the singlet scalar: extra scalars, fermions, and vector bosons. In some cases, detailed model-specific searches have been made for the particles described above (though generally not yet taking account of the demonstrated existence of the H^0 boson).

In most cases, however, generic searches (e.g. for extra W' or Z' particles, extra scalars in the context of multi-Higgs models, or for fourth-generation quarks) are quoted that can be used – when appropriately translated – to derive bounds on a specific model of interest.

The mass scale of the new particles implied by the interpretations of the low mass of H^0 discussed above, and existing studies from the Tevatron and lower-energy colliders, suggests that only the Large Hadron Collider has any real sensitivity. A number of analyses already carried out by ATLAS and CMS use relevant final states and might have been expected to observe a deviation from standard model expectations – in no case so far has any such deviation been reported. The detailed implications of these searches in various model frameworks are described below.

Except where otherwise noted, all limits in this section are quoted at a confidence level of 95%. The searches at $\sqrt{s} = 8$ TeV (Run 1) are based on 20.3 fb^{-1} of data recorded by ATLAS, and an integrated luminosity of 19.7 fb^{-1} analyzed by CMS. The datasets collected at $\sqrt{s} = 13$ TeV during Run 2 of the LHC since 2015 are based on analyses with varied integrated luminosities ranging from ∼2-140 fb^{-1}.

91.2.1 *Searches for Z' or W' Bosons*

Massive vector bosons or particles with similar decay channels would be expected to arise in Little Higgs theories, in theories of Technicolor, or models involving a dilaton, adjusted to produce a light Higgs boson, consistent with the observed H^0. These particles would be expected to decay to pairs of vector bosons, or to third generation quarks, or to leptons. The generic searches for W' and Z' vector bosons listed below can, therefore, be used to constrain models incorporating a composite Higgs-like boson.

A general review of searches for Z' and W' bosons is also included in this volume [122, 123]. In the context of the dynamical electroweak symmetry breaking models, we emphasize their decays to third generation fermions by including a detailed overview, while also briefly summarizing the other searches.

$Z' \to \ell\ell$:

ATLAS [124] and CMS [125] have both searched for Z' production with $Z' \to ee$ or $\mu\mu$. No deviation from the standard model prediction was seen in the dielectron and dimuon invariant mass spectra, by either the ATLAS or the CMS analysis, and lower limits on possible Z' boson masses were set. A $Z'_{\rm SSM}$ with couplings equal to the standard model Z' (a "sequential standard model" Z') and a mass below 5.1 TeV was excluded by ATLAS, while CMS set a lower mass limit of 5.15 TeV. The experiments also place limits on the parameters of extra dimension models and in the case of ATLAS on the parameters of a minimal walking technicolor model [24–28], consistent with a 125 GeV Higgs boson [126]. For a general review of searches in these channels see the PDG review of Z prime in this volume [122].

In addition, both experiments have also searched for Z' decaying to a ditau final state [127,128]. An excess in $\tau^+\tau^-$ could have interesting implications for models in which lepton universality is not a requirement and enhanced couplings to the third generation are allowed. This analysis led to lower limits on the mass of a $Z'_{\rm SSM}$ of 2.4 and 2.1 TeV from ATLAS and CMS respectively.

$Z' \to q\bar{q}$:

The ability to relatively cleanly select $t\bar{t}$ pairs at the LHC together with the existence of enhanced couplings to the third generation in many models makes it worthwhile to search for new particles decaying in this channel. Both ATLAS [129] and CMS [130] have carried out searches for new particles decaying into $t\bar{t}$.

Both ATLAS and CMS searched for $t\bar{t}$ in the all hadronic mode [131] [132] in both the resolved and boosted regions. No evidence of resonance production were seen and limits were produced for various models including the Z' boson in topcolor-assisted technicolor which excludes masses less than 3.1 to 3.6 TeV (ATLAS) depending on the details of the model and 3.3, 5.25, and 6.65 TeV for widths of 1, 10 and 30 percent relative to the mass of the resonance .

ATLAS also presented results on the lepton plus jets final state, where the top quark pair decays as $t\bar{t} \to WbWb$ with one W boson decaying leptonically and the other hadronically; CMS used final states where both, one or neither W decays leptonically and then combined the results. The $t\bar{t}$ invariant mass spectrum was analyzed for any excess, and no evidence for any resonance was seen. ATLAS excluded a narrow ($\Gamma/m = 1.2\%$) leptophobic topcolor Z' boson with masses between 0.7 and 2.1 TeV and with $\Gamma/m = 3\%$ between 0.7 and 3.2 TeV. CMS set limits on leptophobic Z' bosons for three different assumed widths $\Gamma/m = 1.0\%$, $\Gamma/m = 10.0\%$, and $\Gamma/m = 30.0\%$ of 3.9 TeV to 4.0 TeV and exclude RS KK gluons up to 3.3 TeV.

Both ATLAS [133] and CMS [134] have also searched for resonances decaying into $q\bar{q}$, qg or gg using the dijet invariant mass spectrum. Excited quarks are excluded up to masses of 6.7 TeV and model-independent upper limits on cross sections with a Gaussian signal shape were set. CMS excluded string resonances with masses below 7.9 TeV, scalar diquarks below 7.5 TeV, axigluons and colorons below 6.6 TeV, excited quarks below 6.3 TeV, color-octet scalars below 3.7 TeV, W' bosons below 3.6 TeV, Z' bosons with SM-like couplings below 2.9 TeV and between 3.1 TeV and 3.3 TeV, Randall–Sundrum Gravitons below 2.6 TeV.

$W' \to \ell\nu$:

Both LHC experiments have also searched for massive charged vector bosons. In this section we include a summary of the results, with emphasis on final states with third generation fermions, while the details on other decays are discussed in the mini-review of W' [123]. ATLAS searched for a heavy W' decaying to $e\nu$ or $\mu\nu$ and found no excess over the standard model expectation. A sequential standard model (SSM) W' boson (assuming zero branching ratio to WZ) with mass less than 7 TeV was excluded [135] using the 139 fb^{-1} dataset at $\sqrt{s} = 13$ TeV. Model independent cross-section limits as a function of mass were also set. Based on a similar dataset, the CMS experiment excluded a SSM W' boson with mass up to 5.7 TeV [136] and presented upper limits on the production of generic W' bosons decaying into this final state using a model-independent approach.

CMS [137] has carried out a complementary search in the $\tau\nu$ final state. As noted above, such searches place limits on models with enhanced couplings to the third generation. No excess was observed and limits between 2.0 and 2.7 TeV were set on the mass of a W' decaying preferentially to the third generation; a W' with universal fermion couplings was also excluded for masses less than 2.7 TeV.

$W' \to t\bar{b}$:

Heavy new gauge bosons can couple to left-handed fermions like the SM W boson or to right-handed fermions. W' bosons that couple only to right-handed fermions (W'_R) may not have leptonic decay modes, depending on the mass of the right-handed neutrino. For these W' bosons, the tb ($t\bar{b} + \bar{t}b$) decay mode is especially important because in many models the W' boson is expected to have enhanced couplings to the third generation of quarks relative to those in the first and second generations. It is also the hadronic decay mode with the best signal-to-background. ATLAS and CMS have performed searches for W' bosons via the $W' \to tb$ decay channel in the lepton+jets and all-hadronic final state.

The CMS lepton+jets search [138–141], $W' \to tb \to Wbb \to \ell\nu bb$, proceeded via selecting events with an isolated lepton (electron or muon), and at least two jets, one of which is identified to originate from a b-quark. The mass of the W' boson (M_{tb}) was reconstructed using the four-momentum vectors of the final state objects ($bb\ell\nu$). The distribution of M_{tb} is used as the search dis-

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

criminant. A search [141] using 35.9 fb^{-1} of data, collected at $\sqrt{s}$ = 13 TeV, led to an exclusion of W'_R bosons with masses below 3.4 TeV (3.6 TeV) if $M_{W'_R} >> M_{\nu_R}$ ($M_{W'_R} < M_{\nu_R}$), where M_{ν_R} is the mass of the right-handed neutrino.

The CMS search for $W' \to tb$ decays using the all-hadronic final state focused on W' masses above 1 TeV [140, 142]. In this region, the top quark gets a large Lorentz boost and hence the three hadronic products from its decay merge into a single large-radius jet. Deep neural network(DNN) algorithms are used to identify the jet initiated by the bottom quark. Techniques including DNN, which rely on substructure information of the jets [143] are employed to identify boosted all hadronic W boson and top quark [142] decays. The W' candidate mass was computed from back-to-back boosted top-tagged jet and a low mass b-tagged jet. From this all-hadronic search, W' bosons were excluded for masses up to 3.4 TeV [142].

ATLAS has searched for W'_R bosons in the $t\bar{b}$ final state both for lepton+jets [144] and all-hadronic [145] decays of the top. No significant deviations from the standard model were seen in either analysis and limits were set on the $W' \to t\bar{b}$ cross section times branching ratio and W' bosons with with both purely right and purely left-handed coupling and limits are set between 0.5 and 6 TeV for different values of the coupling strength.

In addition, the above studies also provided upper limits on the W' effective couplings to right- and left-handed fermions. In Fig. 91.1 (bottom) the upper limits on W' couplings normalized to the SM W boson couplings derived by ATLAS [145] are shown. The top panel of Fig. 91.1 shows the upper limits for arbitrary combinations of left- and right-handed couplings of the W' boson to fermions set using a model independent approach by CMS [141].

91.2.2 *Searches for Resonances decaying to Vector Bosons and/or Higgs Bosons*

Both ATLAS and CMS have used the data collected at $\sqrt{s}$ = 13 TeV to search for resonances decaying to pairs of bosons. Overall no significant excesses were seen in the full datasets that were analyzed and the results are interpreted in models with heavy vector triplets (HVT) [147], models with strong gravity and extra spatial dimensions, and model independent limits as a function of mass are set. For a full review of models including extra spatial dimensions and the interpretation of many of these results in that context please see the review of extra dimensions in this volume [82].

Utilizing data collected at $\sqrt{s}$ = 13 TeV, ATLAS [148] and CMS [149], have both looked for a resonant state decaying into VV (with $V = W$ or Z) , VH (with H representing the SM Higgs boson), and HH. ATLAS has searched in the $qqqq$, $\nu\nu qq$, $l\nu qq$, $llqq$, $l\nu l\nu$, $ll\nu\nu$, $l\nu ll$, $llll$, $qqbb$ $\nu\nu bb$, $l\nu bb$, and $llbb$ final states and combined the results . While CMS analyzed the $qqqq$, $\nu\nu qq$, $l\nu qq$, $llqq$, $ll\nu\nu$, $\nu\nu bb$, $l\nu bb$, $llbb$, $bbbb$, $\tau\tau bb$, and $qq\tau\tau$ final states.

The combined limits are expressed both as limits on the cross-section as a function resonance mass as well as constraints on the coupling of the heavy boson triplet to quarks, leptons, and the Higgs boson.

$X \to WZ$:

ATLAS searched for new heavy resonances decaying into WZ in the channels $WZ \to qqqq$ [150] , $l\nu qq$ [151], and $l\nu ll$ [152]. In the fully leptonic channel , the invariant mass of the W Z pair is obtained by considering all possible four lepton permutations in each event. The dominant background is Standard Model continuum WZ production, ZZ production where one lepton is not identified or falls outside the detector acceptance, and top quark plus vector boson production. No resonant production is seen in data and lower limits on the mass of a HVT decaying into WZ are set at 2260 (2460) GeV assuming a coupling constant of $g_V = 1$ ($g_V = 3$). In the $WZ \to l\nu qq$ mode, ATLAS searches in both the cases that the quarks are observed as individual jets (resolved) and where they merge into one jet in the detector (boosted) which probe the low and high p_T regime of the Z boson. No significant excess is seen in either channel and combined lower mass limits are placed at 2900 (3000) GeV for $g_V = 1$ ($g_V = 3$) in the HVT model. In the all hadronic decay mode, ATLAS searched for two high p_T hadronically decaying vector bosons looking for a resonant structure. No excess is seen and limits are placed exclude 1200-3000 (1200-3300) GeV for $g_V = 1$ ($g_V = 3$) in the HVT model.

CMS searched for new heavy resonances in the ZV final state using the semi-leptonic decay channels excluding W' masses up to 1800 GEV in HVT two models with $g_V = 1$ and 3 and in the ZZ channel excludes gravitons up to 1200 GeV. The CMS collaboration searched for $VV \to qqqq$ [153] in the large R dijet search. The W and Z boson are identified through the mass of the large R jet and substructure variables. No excess is seen and limits are set for charged HVT bosons with masses lower than 3200 (3800) GeV for $g_V = 1$ ($g_V = 3$). Cross-section limits as function of mass are reported for the charged spin-1 resonance interpretation and are placed at 44.4 fb at 1.4 TeV to 0.7 pb at 4 TeV. In the $\nu\nu qq$ final state [154], the CMS collaboration searched for a charged spin 1 resonance decaying into a VZ final state with a Z boson decaying into a pair of neutrinos and the other boson decaying into two collimated quarks reconstructed as a large R-jet. The transverse mass of the VZ candidate is reconstructed and utilized to search for evidence of resonant VZ production. No excess is seen and lower mass limits are placed on the charged resonance at 3100 (3400) GeV for $g_V = 1$ ($g_V = 3$) . In the $2l2q$ final state, the CMS collaboration searched for a heavy resonance decaying into ZV [155] looking for events with one large R-jet consistent with the hadronic decay of a vector boson and a Z boson reconstructed in the charged lepton decay channel (e or μ). Limits are set for a HVT W' with a lower mass of 2270 (2330) for $g_V = 1$ ($g_V = 3$) .

$X \to WW$:

ATLAS searched for a new heavy resonance decaying into WW in the channels $WW \to qqqq$ [150] , $l\nu qq$ [151], and $l\nu\nu$ [156]. In the case where both Ws decay leptonically, ATLAS utilized the transverse mass of the two lepton and two neutrino final state and searched for an excess in this distribution between 200 GeV and 5 TeV. No excess is seen and a HVT is excluded for masses below 1300 GeV. Vector boson fusion is also considered and cross-section limits as a function of mass are placed ranging from 1.3 pb to 0.006 pb at 200 GeV to 3 TeV, respectively. In the $l\nu qq$ mode , ATLAS completed a companion analysis to the $WZ \to$ analysis discussed above and places lower mass limits of 2850 (3150) GeV for $g_V = 1$ ($g_V = 3$) in the HVT model. ATLAS also interprets the all hadronic mode analysis in the hypothesis that $WW \to qqqq$ and places limits on a HVT boson decaying into WW in the all hadronic mode between 1200 and 2200 (1200 and 2800) GeV for $g_V = 1$ ($g_V = 3$).

The CMS collaboration searched for $VV \to qqqq$ [153] in the large R dijet search. The W and Z boson are identified through the mass of the large R jet and substructure variables. No excess is seen and limits are set for charged HVT bosons with masses lower than 2700 (2800) GeV for $g_V = 1$ ($g_V = 3$). Cross-section limits as function of mass are reported for the uncharged spin-1 resonance interpretation and are placed at 41.6 fb at 1.4 TeV to 0.6 pb at 4 TeV.

$X \to VH$:

ATLAS searched for a new heavy resonance decaying into WH and ZH in the $qqbb$ (WH and ZH) [157], $l\nu bb$ (WH), $\nu\nu bb$ (ZH), $llbb$(ZH) [158] modes. In the all hadronic mode, ATLAS searched for boosted VH production looking for two large R jets where the larger invariant mass large R jet is interpreted as the Higgs boson decay products while the lesser invariant mass jet is taken to be the hadronically decaying vector boson requiring b-tagging on the Higgs boson subjets. The invariant mass is reconstructed and a search is performed for resonant production of ZH. None is found and limits from 1100 to 2500 (1300 to 3800 GeV) are placed for $g_V = 1$ ($g_V = 3$). ATLAS also searched for XH where the W or Z boson decays into $\nu\nu$, $l\nu$, and ll . The analysis searched for both resolved and merged (boosted) b-jets from the decay of the Higgs boson and defines the signal regions based on the number of reconstructed charged leptons (0,1,or 2). In the dilepton channel the invariant mass is explicitly reconstructed of the entire diboson

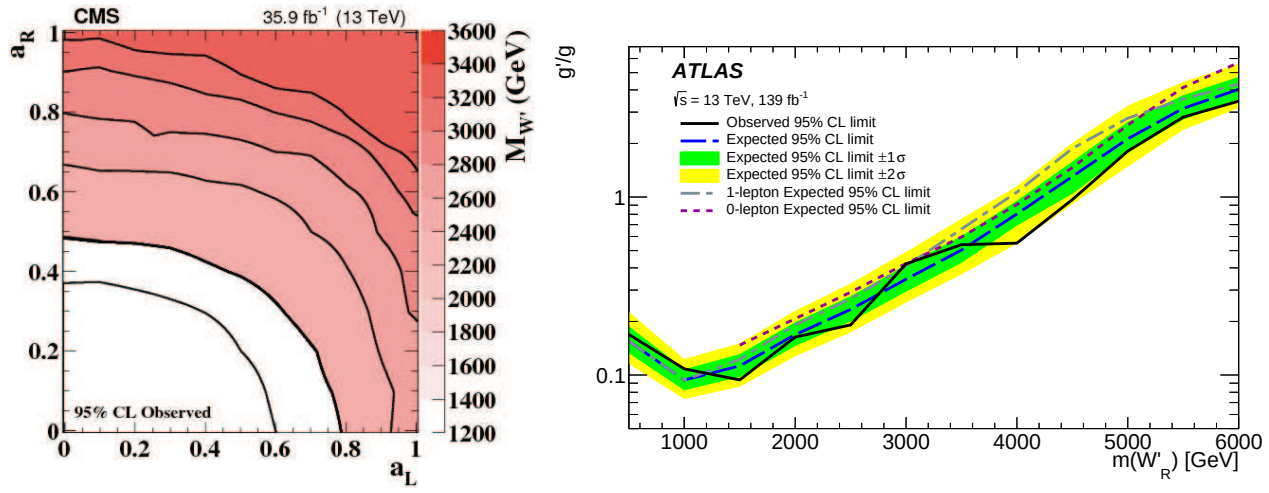

Figure 91.1: Left panel: Observed limits on the W' boson mass as function of the left-handed ($a_{\rm L}$) and right-handed ($a_{\rm R}$) couplings. Black lines represent contours of equal W' boson mass [141]. Right panel: Observed and expected regions, on the g′/g vs mass of the W' boson plane, that are excluded at 95% CL, for right-handed W' bosons [146] showing the exclusion of the values of a hypothetical right-handed coupling of a heavy W particle.

system, the single lepton channel reconstructs the diboson final state constraining the lepton and missing transverse momentum utilizing the known W boson mass, while the 0 charged lepton channel reconstructs the transverse mass of the diboson system. No excess is seen in any channel and limits on the production of a HVT are placed at 2800 GeV (2930) GeV for $g_V = 1$ ($g_V = 3$).

The CMS Collaboration searched for a heavy resonance decaying into VH [159] searching for a resonances decaying into a Higgs boson and a hadronically decaying W or Z boson. The search identifies events with two large-R jets using substructure variables and requires one large-R jets is tagged with a pair of b-hadrons clustered in a single jet. The invariant mass of the VH bosons is reconstructed and evidence for resonance production is sought. No excess is seen and limits are placed. With $g_V = 1$ (3) a narrow W' resonance with $m_{W'} < 2470(3150)$ GeV and $m_{Z'} < 1150(1190)$.

The CMS collaboration searched for a heavy resonance decaying into a pair of boosted Higgs boson with $HH \to b\bar{b}WW^*$ in the single and dilepton channel [160]. Events are categorized according to lepton flavor and multiplicity, along with discriminators that characterize the compatibility with having jets arising from the decay of boosted Higgs and W bosons. The reconstructed Higgs and diHiggs mass distributions are fit and used as the final discriminators. No significant deviations in the 12 sub-categories are seen and 95% confidence limits on spin-0 bosons are set from 24.5 fb at 0.8 TeV to 0.78 fb at 4.5 TeV and spin-2 bosons from 16.7 fb at 0.8 TeV to 0.67 fb at 4.5 TeV. A similar search in the four b-quark final state is used to set limits range 9.74 to 0.29 fb and 4.94 to 0.19 fb in the spin-0 bosons and spin-2 gravitons (respectively) interpretation with masses of 1-3 TeV [161].

$X \to H\gamma$ or $V\gamma$:

Both CMS and ATLAS search for heavy resonances decaying into either a vector boson and a photon or a Higgs boson or a photon. These searched are motivated generically by the fact that new heavy gauge bosons are generically predicted to decay to either a Higgs boson or a vector boson and a photon by one loop decays [162]. ATLAS searched for for a heavy resonances decaying into a Higgs boson and a photon and sets limits from 0.7 to 4 TeV from 11.6 fb to 0.11 fb [163]. ATLAS searched for a heavy resonance decaying into XH where $XH \to qqbb$ [164] and sets limits from 1 to 4 TeV. CMS searched for a heavy resonance decaying into a W boson and a photon [165] setting limits for narrow resonances range between 0.17 fb at 6.0 TeV and 55 fb at 0.7 TeV.

Summary of Searches with Diboson Final States:

Both ATLAS [148] and CMS [149] provide plots summarizing the various searched results and limits combining. The results are shown in the context of HVT models and models of strong gravity with extra spatial dimensions. No excess is seen in any search and limits on the 4.3 (4.5) TeV (ATLAS) and (CMS). Inclusion of decays directly to fermions increase these limits to 5.3 (5.5) TeV and 5.0 (5.2) TeV from the ATLAS and CMS combinations, respectively. Both collaborations also place varying limits on the coupling strength as a function of HVT boson mass as well.

Searches for Triboson Resonances:

The CMS collaboration presents the first search for massive triboson resonances in both the semi-leptonic [166] and fully hadronic final state [167]. Three boson final states can be produced via the decay of Kaluza-Klein (KK) states decaying via $W_{KK} \to WR$ with $R \to WW$ where R is a scalar radion. The search utilizes novel deep neural networks to perform optimal separation between signal and background and searched for evidence of resonance structure in the triboson invariant mass-spectrum. No excesses above SM backgrounds are seen and W_{KK} and radion masses are excluded up to $M_{W_{KK}} = 3.4$ TeV and $M_R = 1$ TeV and up to $M_{W_{KK}} = 3.6$ TeV and $M_R = 0.35$ TeV . $M_{W_{KK}}$ below 3 TeV are excluded for $0.6 < \frac{M_R}{M_{W_{KK}}} < 0.7$ in the semi-leptonic final state and up to $M_{W_{KK}} = 3.0$ TeV and $M_R = 200$ GeV and up to $M_{W_{KK}} = 1.5$ TeV and $M_R = 1.5$ TeV in the fully hadronic final state.

91.2.3 *Vector-like third generation quarks*

Vector-like quarks (VLQ) have non-chiral couplings to W bosons, i.e. their left- and right-handed components couple in the same way. They therefore have vectorial couplings to W bosons. Vector-like quarks arise in Little Higgs theories, top-coloron-models, and theories of a composite Higgs boson with partial compositeness. In the following, the notation T quark refers to a vector-like quark with charge 2/3 and the notation B quark refers to a vector-like quark with charge $-1/3$, the same charges as the SM top and b quarks respectively. The exotic vector-like quarks $X_{5/3}$ and $Y_{-4/3}$ have charges 5/3, and $-4/3$ respectively. Vector-like quarks couple with SM quarks with Yukawa interactions and may exist as SU(2) singlets (T, and B), doublets $[(X_{5/3}, T),(T, B),(B, Y_{-4/3})]$, or triplets $[(X_{5/3}, T, B),(T, B, Y_{-4/3})]$. At the LHC, VLQs can be pair produced via the dominant gluon-gluon fusion process. VLQs can also be produced singly by their electroweak effective couplings to a weak boson and a standard model quark. The single production rate is expected to dominate over the rate of pair production at large VLQ masses. T quarks can decay to bW, tZ, or tH^0. Weak isospin singlets are expected to decay to all three final states with (asymptotic) branching fractions of 50%, 25%, 25%, respectively. Weak isospin doublets are expected to decay exclusively to tZ and to tH^0 [168]

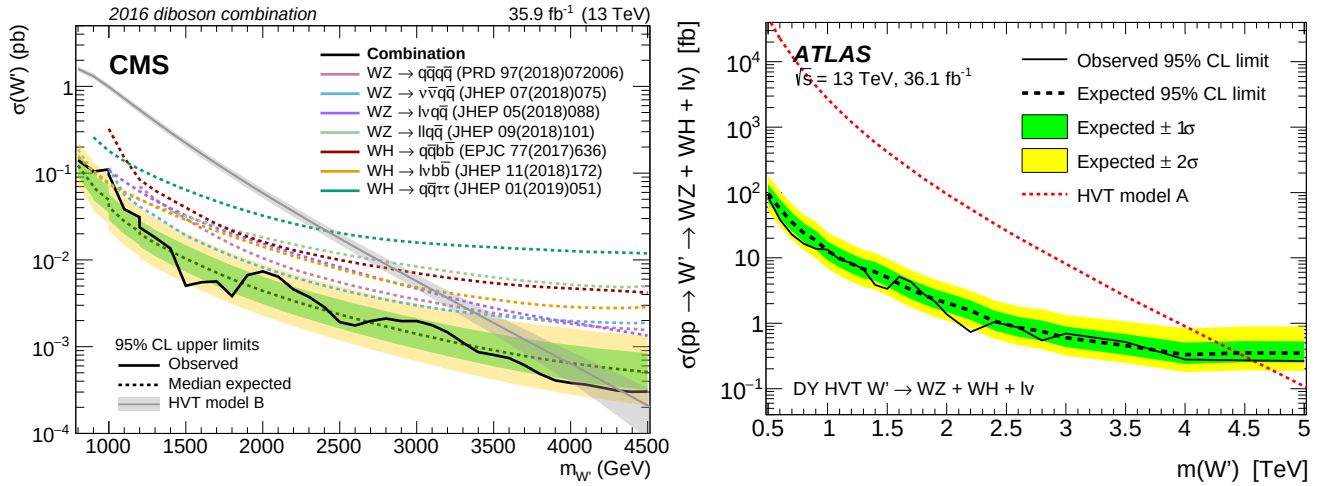

Figure 91.2: Left panel:Observed limits from W' to diboson from CMS [149]. Right panel: Observed limits from W' to diboson decays from ATLAS [148].

with equal branching ratios. Analogously, B quarks can decay to tW, bZ, or bH^0. The $Y_{-4/3}$ and $X_{5/3}$ quarks decay exclusively to bW and to tW. While these are taken as the benchmark scenarios, other representations and decays to exotic new particles are possible [169–171], and hence the final results are interpreted for many allowed branching fraction combinations.

Given the multiple decay modes of the VLQs, the final state signatures of both pair produced and the singly produced VLQs are fairly rich with leptons, jets, b-jets, and missing energy. Depending on the mass of the VLQ, the top quarks and $W/Z/H^0$ bosons may be Lorentz boosted and identified using jet substructure techniques. Thus the searches are performed using lepton+jets signatures, multi-lepton and all-hadronic decays. In addition, T or B quarks with their antiparticles can result in events with same-sign leptons, for example if the decay $T \to tH \to bWW^+W^-$ is present, followed by leptonic decays of two same-sign W bosons. In the following subsections, while we describe the searches for each of the decay modes of the VLQs, the same analysis can be re-interpreted to obtain the sensitivity to a combination with varied branching fractions to the different decay modes.

In the following sections, the results obtained for T (B) quarks assuming 100% branching ratio to Wb (Wt) are also applicable to heavy vector-like $Y_{-4/3}$ ($X_{5/3}$) with charge 4/3 (5/3).

91.2.3.1 *Searches for* $\boldsymbol{T}$ *quarks that decay to* $\boldsymbol{W}$, $\boldsymbol{Z}$ *and* $\boldsymbol{H^0}$ *bosons*

$T/Y \to qW$:

ATLAS has searched for pair production of heavy T quarks that decay to a W boson and a light quark q [172]. The search focuses on the channel where one W decays to a lepton (electron or muon) , and one W decays hadronically leading to a large R jet. Thus the final state is a charged lepton, missing transverse energy, a large radius jet, and multiple small radius jets. The analysis uses the scalar sum of all the final state objects S_T to discriminate against background and searches in hypothetical reconstructed heavy quark mass. The analysis excludes T masses below 1530 GeV.

$T/Y \to bW$:

CMS has searched for pair production of heavy T quarks that decay exclusively to bW [173–175]. The analysis selected events with exactly one charged lepton, assuming that the W boson from the second T quark decays hadronically. Under this hypothesis, a 2-constraint kinematic fit can be performed to reconstruct the mass of the T quark as a narrow mass peak with a mass resolution of around 7%. In Refs. [174] and [175], the two-dimensional distribution of reconstructed mass vs S_T was used to test for the signal, where S_T is the scalar sum of the missing p_T and the transverse momenta of the lepton and the leading four jets. This analysis, when combined with the search in the fully hadronic final state [176] excluded new quarks that decay 100% to bW for masses below 0.89 TeV [175]. At times the hadronically-decaying W boson is produced with a large Lorentz boost, leading to the W decay products merged into a large-radius jet. Algorithms such as jet pruning [177] were used to remove contributions from soft, wide angle radiation, from large-radius jets, leading to better discrimination between jets from multijet events and those arising from decays of the heavy particles. If the mass of the boosted jet was compatible with the W boson mass, then the W boson candidate jet and its subjets were used in the kinematic reconstruction of the T quark. No excess over standard model backgrounds was observed. Upper limits on the production cross section as a function of the mass of T quarks were measured. By comparing them with the predicted cross section for vector like quark pair production, the strong pair production of T quarks was excluded for masses below 1.30 TeV (1.28 TeV expected) [173].

Another "cut-based" search for pair produced T quarks in the all-hadronic final state targeting the Wb decay mode [178], relies on mass reconstruction of two highest p_T Wb combinations using boosted W boson candidates with $p_T > 200$ GeV and b-tagged jets. H_T is used as the signal discriminator, with selected events divided into nine categories based on the multiplicity of W and b-jets in the event. From this search T quarks with pure Wb decays are excluded for masses below 1.04 TeV (1.07 TeV expected).

An analogous search has been carried out by ATLAS [179,180] for the pair production of heavy T quarks. It used the lepton+jets final state with an isolated electron or muon and at least four jets, including a b-jet, and required reconstruction of the T quark mass. Given that the mass range for the T quark being explored was from a 0.4 TeV to a couple of TeV, the W boson from the T quark may fall in two categories: those with a high boost leading to merged decay products, and others where the two jets from the W boson were resolved. In addition, the selection was optimized to require large angular separation between the high p_T W bosons and the b-jets.

The $T \to Wb$ candidates were constructed from both the leptonically and hadronically decaying W bosons by pairing them with the two highest p_T b-tagged jets in the event. The pairing of b-jets with W bosons which minimizes the difference between the masses of leptonically decaying T ($m_{lep}(T)$) and the hadronic T ($m_{had}(T)$) was chosen. Finally, $m_{lep}(T)$ was used as the discriminating variable in a signal region defined by high S'_T (here S'_T is defined as the scalar sum of the missing p_T, the p_T of the lepton and jets), and the opening angle between the lepton and the neutrino ($\Delta R(e,\nu)$). With the 36.1 fb^{-1} data collected during Run 2 at $\sqrt{s} = 13$ TeV, assuming 100% branching ratio to the Wb decay, the observed lower limit on the T mass was 1.35 TeV, and in the SU(2) singlet scenario, the lower mass limit was obtained to be 1.17 TeV [179].

A targeted search for a T quark, produced singly in association with a light flavor quark and a b quark and decaying into

bW, was carried out by CMS at $\sqrt{s}$=13 TeV and a dataset corresponding to 2.3 fb^{-1} [181]. The analysis used lepton+jets events, with at least one b-tagged jet with large transverse momentum, and a jet in the forward η region. Selected events were required to have $S_T'' > 500$ GeV, where S_T'' is defined as the scalar sum of the transverse momenta of the lepton, the leading central jet, and the missing transverse momentum. The invariant mass of the T candidate was used as the discriminating variable and was reconstructed using the four-vectors of the leptonically decaying W boson and the leading central jet. No excess over the standard model prediction was observed. As the VLQ width is proportional to the square of the coupling, upper limits were set on the production cross section assuming a narrow width VLQ with coupling greater than 0.5. For Y/T quarks with a coupling of 0.5 and a 100% branching fraction for the decay to bW the excluded masses were in the range from 0.85 to 1.40 TeV [181]. A similar search [182, 183] was performed by ATLAS for a singly produced T or $Y_{-4/3}$ quark decaying to Wb using a dataset corresponding to 36.1 fb^{-1}. The search was performed using lepton+jets events with a high p_T b-tagged jet, and at least one forward jet. The reconstructed mass of the $T/Y_{-4/3}$ quark, was used as the discriminating variable and showed no excess above the expectation from SM. Interference effects with the SM background are included in the study. This search led to 95% CL upper limits on the mixing angle $|sin(\theta_L)|$ (C_L^{Wb}) in the range of 0.18–0.35 (0.25–0.49) for singlet T quark mass between 0.8–1.2 TeV. This search also provided limits as a function of the $Y_{-4/3}$ quark mass, on the coupling of the $Y_{-4/3}$ quark to bW, and the mixing parameter $|sin\theta_R|$ (C_R^{Wb}) for a (B,$Y_{-4/3}$) doublet model [182]. For VLQ masses between 0.08–1.8 TeV, the limits on $|sin(\theta_R)|$ (C_R^{Wb}) are in the range 0.17–0.55 (0.24–0.77), and for for $Y_{-4/3}$ quark mass between 0.9–1.25 TeV, the limits on $|sin\theta_R|$ are around 0.18–0.19 and below the constraints from electroweak precision observables. For $Y_{-4/3}$ quark in the triplets (T,B,$Y_{-4/3}$), limits on $|sin(\theta_L)|$ (C_L^{Wb}) are between 0.16–0.39 (0.31–0.78) for masses between 0.8 GeV–1.6 TeV [182].

$T \to tH^0$:

ATLAS has performed a search for $T\overline{T}$ production with $T \to tH^0$ [180, 184]. Given the dominant decay mode $H^0 \to b\bar{b}$, these events are characterized by a large number of jets, many of which are b-jets. Thus the event selection required one isolated electron or muon and high jet multiplicity (including b-tagged jets). The sample is categorized by the jet multiplicity (5 and $\geq$6 jets in the 1-lepton channel; 6 and $\geq$7 jets in the 0-lepton channel), b tag multiplicity (2, 3 and $\geq$4) and mass-tagged jet multiplicity (0, 1 and $\geq$2). The distributions of $m_{\rm eff}$, defined as the scalar sum of the lepton and jet p_T and the missing p_T, for each category were used as the discriminant for the final signal and background separation. No excess of events was found. Weak isospin doublet T quarks were excluded below 1.16 TeV.

A search by ATLAS for pair produced VLQs with an all-hadronic final state signature yields an exclusion of pure decays $T \to tH^0$ upto a T quark mass of 2.3 TeV [185].

The CMS search for $T\overline{T}$ production, with $T \to tH^0$ decays has been performed in lepton+jets, multilepton and all-hadronic final states. The lepton+jets analysis [186] emphasizes the presence of a large number of b-tagged jets, and combines it with other kinematic variables in a Boosted Decision Tree (BDT) to enhance signal to background discrimination. The multilepton analysis [186] was optimized for the presence of b-jets and the large hadronic activity. For $\mathcal{B}(T \to tH^0) = 1$, the combined lepton+jets and multilepton analyses led to a lower limit on T quark masses of 0.71 TeV. A search for $T \to tH^0$ in all-hadronic decays [187], optimized for a high mass T quark, and based on identifying boosted top quark jets has been carried out by CMS. This search aimed to resolve subjets within the jets arising from boosted top quark decays, including b tagging of the subjets. A likelihood discriminator was defined based on the distributions of H_T and the invariant mass of the two b-jets in the events for signal and background. No excess above background expectations was observed. Assuming 100% branching ratio for $T \to tH^0$, this analysis led to a lower limit of 0.75 TeV on the mass of the T quark.

Searches for T quarks at $\sqrt{s}$=13 TeV, based on a 2.6 fb^{-1} dataset [188] have been performed by CMS using the lepton+jets final state. This search has been optimized for high mass T quarks by exploiting techniques to identify W or Higgs bosons decaying hadronically with large transverse momenta. The boosted W channel excluded T quarks decaying only to bW with masses below 0.91 TeV, and the boosted tH channel excluded T quarks decaying only to tH for masses below 0.89 TeV.

A CMS search for $T \to tH^0$ with $H^0 \to \gamma\gamma$ decays has been performed [189] in pair production of T quarks. To identify the Higgs boson produced in the decay of the heavy T quark, and the subsequent $H^0 \to \gamma\gamma$ decay, the analysis focused on identification of two photons in events with one or more high p_T lepton+jets or events with no leptons and large hadronic activity. A search for a resonance in the invariant mass distribution of the two photons in events with large hadronic activity defined by the H_T variable showed no excess above the prediction from standard model processes. The analysis resulted in exclusion of T quark masses below 0.54 TeV. CMS also searches for a single vector like T decaying to either Z boson or a Higgs boson and a T quark [190] placing a limit of up to 1.4 TeV.

A search for single production of a vector-like quark either a singlet T with charge $\frac{2}{3}$ or a Y from a triplet (T,B,Y) with charge $-\frac{4}{3}$ decaying into W (l ν) and b-quark was performed by the ATLAS collaboration [191]. Limit on the coupling strength , κ ranges between 0.22 and 0.52 for masses from 1150 to 2300 GeV for the singlet interpretation while with the triplet assumption the limits on vary from 0.14 to 0.46 for masses from 1150 to 2600 GeV. A companion analysis [192] searches in the all hadronic final state for the same single production of a vector-like quark The observed lower limits on the masses of Y quarks with κ of 0.5 and κ of 0.7 and are 2.0 TeV and 2.4 TeV, respectively. For T quarks, the observed mass limits are 1.4 TeV for and 1.9 TeV for κ of 0.5 and κ of 0.7. The combination of these two analysis [193] results in a combined limit of κ 0.5 and m_T excluded for masses above 2.1 TeV, the most restrictive to date. ATLAS also searches for a a T quark decaying into Z t with the Z boson decaying leptonically into electron or muon pairs and the top quark resulting in a large-R top quark jet [194] which produces limits and excludes this decay up to 1.8 TeV.

A search for electroweak single production of T quarks decaying to tH^0 using boosted topologies in fully hadronic [195] and lepton+jets [196] in the final states has been performed by CMS. The electroweak couplings of the T quarks to the SM third generation quarks are highly model dependent, and hence these couplings determine the rates of the single T quark production. In both analyses, T quark invariant mass was reconstructed using the boosted Higgs boson jet and the top quark. Higgs boson jets were identified using jet substructure techniques and subjet b tagging. For the lepton+jets analysis, the top quark was reconstructed from the leptonically decaying W and the b jet, while in the all-hadronic analysis the top quark jet was tagged using substructure analysis. There was no excess of events observed above background. Exclusion limits on the product of the production cross section and the branching fraction $(\sigma(pp \to Tqt/b) \times \mathcal{B}(T \to tH^0)$ were derived for the T quark masses in the range 0.70-1.8 TeV. From the lepton+jets analysis, for a mass of 1.0 TeV, values of $(\sigma(pp \to Tqt/b) \times \mathcal{B}(T \to tH^0)$ greater than 0.8 and 0.7 pb were excluded assuming left- and right-handed coupling of the T quark to standard model fermions, respectively [196]. For the all-hadronic analysis, upper limits between 0.31 and 0.93 pb were obtained on $(\sigma(pp \to Tqt/b) \times \mathcal{B}(T \to tH^0)$ for T quark masses in the range 1.0-1.8 TeV [195]. ATLAS performs a similar search [197] for single production of vector-like T quarks decaying into a Higgs Boson and a top quark and places limits between 1 and 1.7 TeV depending on the coupling

$T \to tZ$:

Both ATLAS and CMS search for T quarks that decay exclusively into tZ in pp collisions at $\sqrt{s} = 13$ TeV. No excesses were found in either search.

ATLAS performs a search [198] optimized for pair production of vector-like top quarks decaying into tZ where the Z boson subse-

by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

quently decays into neutrino pairs, utilizing 139 fb^{-1} of data. The search selected events with one lepton, multiple jets, and significant missing transverse momentum. No significant excesses were found and lower limits on the mass of a vector like top quark were placed, excluding masses below 1.59 TeV (weak-isospin doublet) and 1.47 TeV (pure tZ mode).

Another search by ATLAS for pair produced T decaying to tZ has been carried out by reconstructing the high transverse momentum Z boson from a pair of opposite-sign same-flavor leptons, using events with two or three charged leptons [199]. The final analysis is based on three final state signatures. In the trilepton events, at least one b-tagged jet is required and H_T, formed from all hadronic jets and charged leptons, is used as the discriminating variable. In events with two leptons, at least 2 b-jets are requested and events with zero or one high p_T top-tagged jet, use H_T as the discriminator. The second dilepton analysis with two top-tagged high p_T jets focuses on hadronically decaying heavy resonances and the invariant mass of the Z boson and the highest p_T b-tagged jet is found to be a good discriminating variable. No excess was observed over the background expectations. Limits were placed at a heavy vector like top of 1.6 TeV.

ATLAS has subsequently carried out a search [200] for singly produced T quarks decaying to tZ where the Z boson decays into neutrino pairs. The search is carried out using 36.1 fb^{-1} of data in events with two different final state signatures: one with jets and significant missing p_T (0L) and the other with a single lepton, jets and missing p_T (1L). Events are divided into signal and dedicated W+jets and $t\bar{t}$ background control regions. The sensitivity to the T quark signal is extracted using distributions of missing p_T for the 1L and the distribution of T quark transverse mass constructed from missing p_T and the high p_T large-radius top-tagged jet, for 0L analysis. There is no excess found over the expected background and lower limits on the production of T singlets are obtained as a function of the left- and right-handed couplings $c_{L,W}$ and $c_{R,W}$ to top quarks and W bosons, where c_W above 0.7 is excluded for T quark mass of 1.4 TeV. The limits on c_W are also recasted into expected and observed 95% CL upper limits for the mixing angle (θ_L) of a singlet T with the top quark.

CMS searched [201] for single production of T quarks decaying into tZ with the Z boson decaying to pairs of charged leptons (electrons and muons) and the top quark decaying hadronically using 35.9 fb^{-1} of data. Limits were placed on T quarks with masses between 0.7 and 1.7 TeV excluding the product of cross section and branching fraction above values of 0.27 to 0.04 pb. Additionally, limits on the product of cross section and branching fractions for a Z' boson decaying into tZ were set between 0.13 and 0.06 pb for Z' boson masses in the range from 1.5 to 2.5 TeV.

Similar searches by ATLAS for singly produced T decaying to Zt have been performed in final state signatures with two or three charged leptons [202]. The analysis relies on tagging b-jets and high p_T large-radius jets originating from top-quarks. Additional selections are devised to reduce the contributions from pair production of T quarks. For events with dilepton analysis, the discriminating variable is the mass of the T quark formed using the invariant mass of the Z boson candidate and the highest p_T top-tagged jet, while for the trilepton analysis, the variable S_T is used to search for an excess of data over the expected SM background. No excess above the SM expectations is observed. The two final states (dilepton and trileptons) are combined to obtain the final results. For the coupling parameter κ_T between 0.1–1.6, the 95% CL upper limits on the production cross section times branching fraction into Zt is between 0.16–0.18 (0.03–0.05) pb at T quark mass of 0.7 (2) TeV.

The search by the ATLAS experiment for VLQ pair production optimized to search for $T \to tZ$ decays [203] in a dataset with 139 fb^{-1} of luminosity has been performed in final states with either two leptons or three or more leptons. A multi-class boosted object tagger based on DNN techniques for large-radius jets is used to categorize events according to the number of high p_T boosted H^0, Z/W, and top quark jets. The discriminant in the signal to evaluate the sensitivity depends on the number of leptons in the event. For the two lepton analysis, the discriminant is the mass of the T quark which is constructed from b and Z candidates, while for the three or more lepton analysis, H_T computed using the p_T of the jets and leptons is used as the discriminant. This analysis excludes T quark masses up to 1.27 GeV (1.46 GeV), for the singlet (doublet) configuration [203].

Combination of $T \to tZ/tH^0$:

The search performed by the ATLAS experiment for electroweak single production of T quark decaying to tH^0 and tZ uses a dataset corresponding to 139 fb^{-1} of integrated luminosity, and events with a single lepton with multiple jets and b-jets in the final state [204]. The single production channel for VLQs probes κ, the universal coupling constant, which also controls the production cross section and the resonance width of the VLQ. The analysis uses techniques to tag boosted jets, and categorizes events by numbers of jets and b-jets. The event discriminant is the "effective mass" (meff) observable, defined as the scalar sum of the p_T of all central jets, p_T of leptons and the missing p_T in the event. No significant excess is observed. Limits on the mass of T quark and universal coupling strength (κ) are obtained. For singlet T quarks, values of κ above 0.5 are excluded for all masses below 1.8 TeV. For T quark mass of 1.6 TeV, κ above 0.41 is excluded [204].

A CMS search published in 2020 concentrates on the electroweak production of the T quark with $T \to tH^0$, and $T \to tZ$ decays, where subsequently both H^0 and Z Bosons decay hadronically, leading to fully hadronic final states [205]. The search focuses on evidence of T quarks produced in association with a b quark ($qg \to T\bar{b}q'$) or a top quark ($qg \to T\bar{t}q$). The production cross sections are model dependent, as the electroweak production depends on the strength of the T quark coupling, TbW (TtZ), for the charged-current (neutral-current) process, at the production vertex. The searches are split into two domains depending on the mass of the T quark and consider a wide range of widths of the T quark from a few percent to about 30% of the T quark mass. The event selection relies primarily on the large number of jets and on efficient identification of jets from b-quarks, in addition to double-b jet decays of the H^0 and Z bosons. The final sensitivity is derived by the search for a resonant peak in the tH^0/Z invariant mass spectrum. For low mass T quark searches, three independent regions based on the b-tagged jet requirements are examined. For T quark masses above 1 TeV, which result in highly Lorentz-boosted top quarks and H^0 or Z boson, large-area jets are used to form the T quark. This search reports upper limits at 95% confidence level on $\sigma B(T \to tH)$ and $\sigma B(T \to tZ)$ between 2 pb and 20 fb for T masses between 0.6 to 2.6 TeV in the Tbq and Ttq production channels. The analysis also reports combined results for $T \to tH$ and $T \to tZ$ associated production with a bottom quark and provides constraints on T quarks in the T singlet model for masses below 1.00 TeV. For an expected fractional width of 30%, the expected sensitivity extends to 1.28 TeV, comparable to the most stringent results.

Another inclusive search for pair produced T in the all-hadronic final state [178] has been performed by CMS using the boosted event shape tagger (BEST NN) neural network technique to classify jets in six categories W, Z, H^0, t, b, and light. This search does not focus on a given VLQ mode, but on various combinations of the boson and quark jets in the final state. Anti-k_T jets with a distance parameter of 0.8 are used. The BEST NN algorithm simultaneously classifies jets according to heavy object type. For each of the six particle hypotheses, it boosts each jet constituent into corresponding frame along the jet momentum direction, and calculates event shape and angular variables in the boosted frame, with the expectation that when boosting to the correct rest frame, jet constituents will be isotropic and show the expected N-prong structure of the decaying object in its rest frame. A neural network is trained using the event shape and angular variables in the boosted frame to classify jets according to one of those six possibilities (W, Z, H, t, b, or light). The analysis bins the events into 126 categories depending on the number of W, Z, H, t, b, or light jets in the final state with a maximum of four such objects. For each category H_T^{AK8}, the scalar sum of p_T of all AK8 jets, is used as the signal discriminator. A scan over a combination of various branching fractions is also performed. This search excludes T quark masses in the range 0.74–1.37 TeV for the tH decay mode

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

in the NN analysis.

An inclusive search for VLQs has been carried out by CMS targeted at heavy T quarks decaying to any combination of bW, tZ, or tH^0 as described in [186]. Selected events have at least one isolated charged lepton. Events were categorized according to number and flavor of the leptons, the number of jets, and the presence of hadronic vector boson and top quark decays that are merged into a single jet. The use of jet substructure to identify hadronic decays significantly increases the acceptance for high T quark masses. No excess above standard model backgrounds was observed. Limits on the pair production cross section of the new quarks are set, combining all event categories, for all combinations of branching fractions into the three final states. For T quarks that exclusively decay to $bW/tZ/tH^0$, masses below 0.70/0.78/0.71 TeV are excluded.

91.2.3.2 *Searches for* $\boldsymbol{B}$ *quarks that decay to* $\boldsymbol{W}$, $\boldsymbol{Z}$ *and* $\boldsymbol{H^0}$ *bosons*

ATLAS and CMS have performed searches for pair production of heavy B quarks which subsequently decay to Wt, bZ or bH^0. The searches have been carried out in final states with single leptons, dileptons (with same charge or opposite charge), multileptons, as well as in fully hadronic final states.

$B \to bH^0$:

A search for B pair-produced events has been performed by the CMS experiment [179] using 137 fb^{-1} of data where the B decays into a $b/\bar{b}$ quark and either a H^0 or a Z boson. This search concentrates on final states with fully hadronic signatures, and utilizes different jet multiplicity categories to account for two resolved jets or merged single jets from H^0 or Z boson to $b\bar{b}$ decays, depending on the p_T of the H^0 or Z bosons. Nine final state categories are used, depending on the number of observed jets and the reconstructed event mode. No significant excess over expected background is observed. For the case $\mathcal{B}(B \to bH) = 100\%(50\%)$, VLQs with masses below 1.57 (1.45) TeV are ruled out.

Using 36.1 fb^{-1} of data, ATLAS has performed a search for pair produced VLQs with all-hadronic final state signature [206]. While this analysis provides exclusion limits for all third generation VLQs, it provides the strongest results for the $B \to bH^0$ decay mode and excludes decays with $\mathcal{B}(\mathcal{B} \to \lfloor\mathcal{H}') = \infty$.ı scenario for B masses upto 1.01 TeV. The limits are also cast in a two-dimensional plane of branching ratio values of $B \to bH^0$ vs. $B \to Wb$. This analysis required the presence of high p_T jets and multiple b tags. It used a multi-class DNN to classify jets arising from W, Z, H^0 bosons and top-quarks. In addition, the matrix element method was used to compute the likelihood for the event to arise from a particular VLQ final state and to construct the final discriminator. To increase the sensitivity of the analysis, processes with the same number of top quarks, W/Z bosons, and H^0 Higgs bosons are combined into a single hypothesis.

ATLAS has performed a search for single production of a vector-like B quark decaying to a b-quark and a H^0 boson, with $H^0 \to b\bar{b}$ decay, using a dataset corresponding to an integrated luminosity of 139 fb^{-1} [207]. The all hadronic final state signature relies on identification of at least 3 b-jets, with an additional soft forward jet from the spectator quark. Large area jets are used to identify boosted H^0 decays. This analysis results in excluding the single production of a VLQ (B, Y) doublet with relative width larger than 5% between masses of 1.0 TeV and 2.0 TeV [208]. The CMS experiment has searched for a single vector-like quark decaying into tH or tZ in the all hadronic final state with 138 fb^{-1} of data in the all hadronic channel reconstructing both the boson invariant mass and the tH or tZ invariant mass and searching for a resonance. No significant excess is found and cross-section limits are placed between 600 GeV and 1200 GeV between 600 and 68 fb [209].

$B \to Wt$:

A search for $B \to tW$ in B pair produced events has been performed by ATLAS [179] using lepton+jets events with one hadronically decaying W and one leptonically decaying W utilizing 36.1 fb^{-1} of data at $\sqrt{s} = 13$ TeV. The search was optimized for T production decaying into Wb. Since the analysis was optimized for $T \to Wb$ rather than Wt decays the analysis does not reconstruct the full B mass. As discussed earlier, the hadronically and leptonically decaying heavy quarks were required to have similar reconstructed masses (within 300 GeV). The interpretation of the $T \to Wb$ in the context of $B \to tW$ production led to the exclusion of heavy B like VLQs for masses less than 1.25 TeV and 1.08 TeV, assuming a 100% branching fraction to tW or SU(2) singlet B scenario, respectively.

A similar search by CMS [210], using 19.8 fb^{-1} of $\sqrt{s} = 8$ TeV data, selected events with one lepton and four or more jets, with at least one b-tagged jet, significant missing p_T, and further categorized them based on the number of jets tagged as arising from the decay of boosted W, Z or H^0 bosons. The S_T distributions of the events in different categories showed no excess of events above the expected background and yielded a lower limit on the B quark mass of 0.73 TeV for $BR(B \to Wt) = 1$.

CMS [188] also searched for pair production of both TT and BB with collisions from 2.5 fb^{-1} of $\sqrt{s} = 13$ TeV data. The analysis searched for events with one high p_T lepton , multiple jets, and highly boosted W or Higgs bosons decaying hadronically. The analysis focused on pair production and selects events with either a boosted W or Higgs candidate and then proceeds to search for anomalous production in excess of standard model production. Seeing no significant excesses CMS then proceeded to set limits in many different interpretations. The strongest was from the $B \to Wt$ interpretation leading to excluding heavy vector-like B quarks with mass less than 0.73 TeV.

The all-hadronic inclusive analysis [178] performed by CMS using the BEST NN technique to classify $W/Z/H^0/t/b$/light jets also gives exclusion limits on B quark production for various combinations of branching fractions for decays to tW, bZ, bH^0. By considering categories based on various combinations of the boson and quark jets in the final state it excludes B quarks with masses up to 1230 GeV, for B decays to tW with a 100% branching fraction.

Electroweak production of single heavy B+b production has been studied by CMS in the decay to tW with the lepton+jets final state [211]. Single lepton events with hadronic jets, including a forward jet, and missing p_T are selected and divided into 10 different categories based on lepton flavor (e/μ), top-tagged, W-tagged, and 0/1/2 b-tagged jets. The B quark mass m_{reco} is fully reconstructed from lepton, jets, and missing p_T, where the neutrino four-momentum is computed using the missing p_T and the W mass constraint. For events within the top-tagged category, the high p_T top-tagged hadronic jet and the leptonically decaying W boson are used to compute m_{reco}. The m_{reco} distribution are used as the signal discriminator. In the absence of an excess over the expected SM background, the exclusion limits on the production cross section for B quark masses between 0.7-2 TeV varies between 0.3 to 0.03 pb. In addition, B quarks with left-handed couplings and a relative width of 10, 20, and 30% are excluded for masses below 1.49, 1.59, and 1.66 TeV respectively.

$B \to bZ$:

As mentioned above, a search for B pair produced events, with final states with fully hadronic signature, using 137 fb^{-1} of data, has been performed by the CMS experiment [179]. In this search, the B decays into a $b/\bar{b}$ quark and either a H^0 or a Z boson. For the case $\mathcal{B}(B \to bZ) = 100\%(50\%)$, VLQs with masses below 1.39 (1.45) TeV are ruled out by this analysis.

A search by CMS [212] for the pair-production of a heavy B quark and its antiparticle has been performed, where one of the heavy B quark decays to bZ. Events with a Z boson decaying to e^+e^- or $\mu^+\mu^-$ and at least one b jet are selected. The signal from $B \to bZ$ decays is expected to appear as a local enhancement in the bZ mass distribution. No such enhancement was found and B quarks that decay 100% into bZ are excluded below 0.70 TeV. This analysis also set upper limits on the branching fraction for $B \to bZ$ decays of 30-100% in the B quark mass range 0.45-0.70 TeV. A complementary search has been carried out by ATLAS for new heavy quarks decaying into a Z boson and a b-quark [213]. Selected dilepton events contain a high transverse momentum Z boson that decays leptonically, together with two b-jets. If the dilepton events have an extra lepton in addition to

Int. J. Mod. Phys. A 2026.41. Downloaded from www.worldscientific.com
by KARLSRUHE INSTITUTE OF TECHNOLOGY on 10/26/26. Re-use and distribution is strictly not permitted, except for Open Access articles.

those from the Z boson, then only one b-jet is required. No significant excess of events above the standard model expectation was observed, and mass limits were set depending on the assumed branching ratios. In a weak-isospin singlet scenario, a B quark with mass lower than 0.65 TeV was excluded, while for a particular weak-isospin doublet scenario, a B quark with mass lower than 0.73 TeV was ruled out.

The search by ATLAS for $B \to bZ$ decays [203] in final states with either two leptons or three or more leptons using a multi-class boosted object tagger to categorize events according to the number of high p_T boosted H^0, Z/W, and top quark jets excludes B quark masses up to 1.20 GeV (1.32 GeV), for the singlet (doublet) configuration [203].

In addition to pair production, ATLAS has also searched for the electroweak production of single B quarks, which is accompanied by a b-jet and a light jet [213]. The dilepton selection for double B production was modified for the single B production study by requiring the presence of an additional energetic jet in the forward region. An upper limit of 200 fb was obtained for the process $\sigma(pp \to B\bar{b}q) \times B(B \to Zb)$ with a heavy B quark mass at 0.70 TeV. This search indicated that the electroweak mixing parameter X_{Bb} below 0.5 is neither expected nor observed to be excluded for any values of B quark mass.

91.2.3.3 *Searches for top-partner quark* $\boldsymbol{X_{5/3}}$

Searches for a heavy top vector-like quark $X_{5/3}$, with exotic charge $\pm 5/3$, such as that proposed in Refs. [215, 216], have been performed by both ATLAS and CMS [179, 217].

The analyses assumed pair-production or single production of $X_{5/3}$ with $X_{5/3}$ decaying with 100% branching fraction to tW. Searches for $X_{5/3}$ have been performed using two final state signatures: same-sign leptons and lepton+jets.

The analysis based on searching for same-sign leptons, from the two W bosons from one of the $X_{5/3}$, has smaller backgrounds compared to the lepton+jets signature. Requiring same-sign leptons eliminates most of the standard model background processes, leaving those with smaller cross sections: $t\bar{t}W$, $t\bar{t}Z$, WWW, and same-sign WW. In addition, backgrounds from instrumental effects due to charge misidentification were considered. Assuming pair production of $X_{5/3}$, the analysis by CMS using H_T as the discriminating variable restrict the $X_{5/3}$ mass to be higher than 1.16 (1.10) TeV for a right (left) handed chirality particle [217–219]. The limits obtained by ATLAS, by classifying the signal region by number of b-jets, H_T, and missing p_T in the event, led to a lower mass limit on $X_{5/3}$ of 1.19 TeV [220, 221].

Searches for $X_{5/3}$ using leptons+jets final state signatures are based on either full or partial reconstruction of the T mass from the lepton, jets (including b-jets) and missing p_T. The CMS search [217, 222] also utilized jet substructure techniques to identify boosted $X_{5/3}$ topologies. The discriminating variable used was the mass constructed from the lepton and b-tagged jet, $M_{(\ell,b)}$, which corresponds to the visible mass of the leptonically decaying top quark. To optimize the search sensitivity, the events were further separated into categories based on lepton flavor (e, μ), the number of b-tagged jets, the number of W-tagged jets, and the number of t-tagged jets. In the absence of a signal, the CMS analysis excluded $X_{5/3}$ quark masses with right-handed (left-handed) couplings below 1.32 (1.30) TeV [222]. Combining the lepton+jets with the same-sign leptons analyses leads to a slight improvement and excludes $X_{5/3}$ quark masses with right-handed (left-handed) couplings below 1.33 (1.30) TeV.

The ATLAS lepton+jets search for $X_{5/3}$ utilized events with high p_T W bosons and b-jets. The search described earlier for T pair production, with $T \to Wb$ decays, can be reinterpreted as a search for $X \to tW$. This analysis excluded $X_{5/3}$ with masses below 1.25 TeV [179].

The single $X_{5/3}$ production cross section depends on the coupling constant λ of the tWX vertex. ATLAS has performed an analysis of same-sign dileptons which includes both the single and pair production. This analysis led to a lower limit on the mass of the $X_{5/3}$ of 0.75 TeV for both values of $\lambda = 0.5$ and 1.0 [223].

Single heavy $X_{5/3}$+t production has been studied by CMS in the decay to tW with the lepton+jets final state [211]. The description of the analysis is provided earlier in the discussion of $B \to WtX$ decays, where the reconstructed mass of $X_{5/3}$, m_{reco} distribution is used as the signal discriminator. In the absence of an excess over the expected SM background, the exclusion limits on the production cross section for $X_{5/3}$ quark masses between 0.7–2 TeV varies between 0.3 to 0.03 pb, depending on the width of $X_{5/3}$ between 1–10%. In addition, $X_{5/3}$ quarks with left-handed couplings and a relative width of 10, 20, and 30% are excluded for masses below 0.92, 1.3, and 1.45 TeV respectively.

91.2.4 *Heavy resonances decaying to VLQ*

CMS has performed search for VLQ production in the decay of massive resonances such as Z' and W' bosons.

$\underline{Z' \to tT}$: Specifically searches are presented by CMS in Refs. [224] and [225] for massive spin-1 Z' resonances decaying to a top quark and a heavy VLQ top quark partner T. The results of this search for a heavy spin-1 resonance are interpreted in the context of two different models. In the $G^\star$ model which predicts ten VLQs (T, $B, \tilde{T}, \tilde{B}, T_{5/3}, T_{2/3}, T', B', B_{-1/3}, B_{-4/3}$) with the mass relationship $M(T_{5/3}) = M(T_{2/3}) = M(T)\cos(\phi_L)$. For the benchmark scenario [226], $\cos(\phi_L)$=0.84 and the branching fractions $T \to tH^0, tZ, Wb$ are 0.25, 0.25 and 0.5 respectively. The ρ^0 model predicts a multiplet of four new VLQs $T, B, X_{2/3}, X_{5/3}$, and in the benchmark scenario [227], the branching fractions $T \to tH^0, tZ, Wb$ are 0.5, 0.5 and 0 respectively.

Two of the three decays of the $Z' \to tT$ with $T \to tH^0, tZ, Wb$ are characterized by the presence of two top quark decays and a boson (H^0/Z). A search [225] by CMS, optimized for $T \to tH/Zt$ decays was carried out in the lepton+jets final state using a dataset corresponding to an integrated luminosity of 35.9 fb^{-1}. Jet substructure techniques are used to identify (or tag) the high p_T large-radius jets originating from H^0, Z bosons and merged top quarks. The mass of the Z' boson is used as the signal discriminator and constructed using H^0 or Z-tagged dijet, the hadronic and leptonic top quark four vectors. For the leptonic top quark reconstruction ($t \to b\ell\nu_\ell$), the neutrino four vector is obtained from the event missing p_T using the W boson mass constraint. While the high p_T hadronic top quark jets from decays of massive Z' bosons are mostly merged and identified by top tagging techniques, those from T decays maybe resolved. The reconstructed Z' candidate events are classified into six different categories requiring the presence of either a H^0-tagged jet with 2 b-tagged subjets or one b-tagged subjet or a Z-tagged boson, each with either zero or one top-tagged jet. This search does not observe any significant deviation in data over the expectation from standard model backgrounds. Within the context of the $G^\star$ model, for a T mass of 1.2 (1.5) TeV, this search excludes $G^\star$ [226] resonances with masses between 1.5–2.3 (2.0–2.4) TeV.

The search in the all-hadronic final state is based on a 2.6 fb^{-1} dataset [224], and optimized for $T \to Wb$ decays. Jet substructure techniques are deployed for tagging jets from high p_T W boson and top quarks. Events are categorized into two groups based on the presence of b-tagged subjets in the top-tagged jet. The multijet background estimation is challenging and determined using side-bands defined by inverting the b-tagging requirement. Upper limits on the cross section for $Z' \to tT$ are obtained in the range of 0.13–10 pb.
